
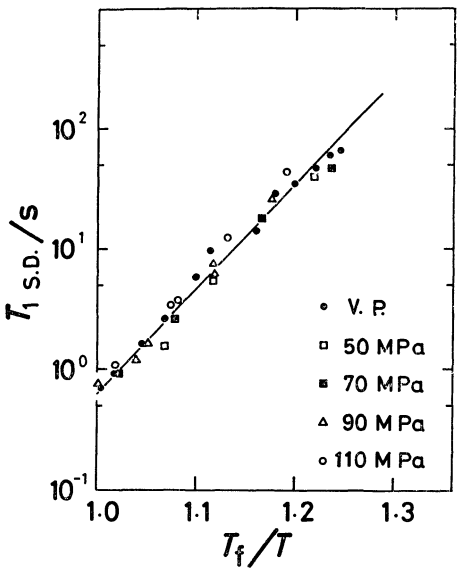

Fig. 4. Spin-lattice relaxation time due to self-diffusion ($T_{1\,SD}$) is plotted against the reduced temperature T_f/T, where T_f is the melting temperature at each pressure. V.P. means the vapor pressure of the sample itself.

pirically given by

$$\tau_{SD} = \tau^0_{SD}\exp\{b(T_f/T)\}, \tag{9}$$

where b is 20.2±2.6 for neopentane. If one substitutes Eq. 9 to Eqs. 3 and 4, b is shown to be related to the enthalpy and volume of activation for self-diffusion through the formulas

$$\Delta H^* = bRT_f \tag{10}$$

and

$$\Delta V^* = bR(dT_f/dP). \tag{11}$$

By substituting Eqs. 10 and 11 into the Clapeyron-Clausius equation (Eq. 7), we obtain

$$\Delta V^*/\Delta H^* = \Delta V_f/\Delta H_f. \tag{12}$$

If we use the values observed in the present experiment, *i.e.* $\Delta V^* = 133\pm17$ cm^3 mol^{-1} and $\Delta H^* = 43.5\pm8.4$ kJ mol^{-1}, we obtain $\Delta V^*/\Delta H^* = 3.3\pm1.1$ cm^3 (kJ)$^{-1}$ which is in reasonable agreement with the value $\Delta V_f/\Delta H_f = 2.3$ cm^3 (kJ)$^{-1}$ where $\Delta V_f = 7$ cm^3 mol^{-1} [24] and $\Delta H_f = 3.093\pm0.001$ kJ mol^{-1}.[5] Equation 12 which is an almost exact consequence of the relation (9) shows that the activation process for diffusion is in a way related to the melting process.

The activation energy ΔE^* of diffusion is the sum of the energy of formation (E_f) of a vacancy and its migration (E_m). Cauchman and Reynolds[29] derived a relation between the energy of migration of a vacancy (E_m) and the melting temperature (T_f),

$$E_m = \frac{K_1}{D}\left(\frac{k}{\hbar}\right)^2 T_f, \tag{13}$$

where K_1 and D are constants determined primarily by geometry of the lattice. By combining Eq. 13 with the formula for E_f due to Glyde,[30] we obtain a relation between ΔE^* and T_f similar to Eq. 13,

$$\begin{aligned}\Delta E^* &= E_m + E_f \\ &= \left(\frac{k}{\hbar}\right)^2\left(\frac{K_1+K_2}{D}\right)T_f \\ &= CT_f,\end{aligned} \tag{14}$$

where K_2 is also a constant. Because the contribution of the $P\Delta V^*$ term to the activation enthalpy, $\Delta H^* = \Delta E^* + P\Delta V^*$, is small (less than 1%), the comparison between Eq. 10 and Eq. 14 is possible. The constant b in Eq. 9 must therefore depend on the properties of the lattice in which diffusion takes place. In many plastic crystals, the value of b ($=C/R$) in Eq. 9 is also about 20[31] and similar values of C/R were also found for many metals. This fact is very suggestive but the theory is only of qualitative nature and does not warrant any quantitative calculation.

Finally, it is perhaps significant to note that the straight line of Fig. 4 covers both situations of melting of Phase I and Phase I'. This is related to the fact that we failed to detect any change in T_1 on going from Phase I to Phase I'. Probably, Phase I' is also a plastic crystal which has a similar property to that of Phase I (f.c.c.).

The authors would like to express their gratitude to Dr. Akifumi Onodera for help provided in the calibration of the pressure gage (manganin gage).

Oxygen Evolution Reaction on Composite Cobalt Borides

Tetsuya Osaka,* Yoshio Iwase, Hiroshi Kitayama, and Toshihiro Ichino

Department of Applied Chemistry, School of Science and Engineering, Waseda University, Okubo, Shinjuku-ku, Tokyo 160

(Received December 4, 1982)

The Oxygen evolution reaction on cobalt borides and composite cobalt borides was investigated in a 6 M KOH solution (1 M = 1 mol dm^{-3}) using the factor of the magnetic properties. In the system of cobalt borides (Co:B = 3:1) prepared at various sintering temperatures, the boride having a higher saturation magnetization revealed a higher activity of the oxygen evolution reaction. In the system of composite cobalt borides which have various magnetic moments, μ_B, a clear correlation between the activity of the oxygen evolution reaction and the saturation magnetization (or magnetic moment, μ_B) was observed for several composite cobalt boride species (*i.e.*, Co-Fe-B, Co-Ni-B, Co-Mn-B, and Co-B). Among the composite cobalt boride species, the cobalt iron boride (Co:Fe:B = 1:2:1) sintered at 450 °C showed the highest activity of oxygen evolution reaction in a 6 M KOH solution. The conditions of oxide formation on Co-Fe-B(1:2:1) and on Co-B(3:1) in a 6 M KOH solution were compared with those on cobalt by means of voltammetry and chronopotentiometry. It was concluded that the ease and stability of oxide films in higher oxidation states are strongly correlated to the activity of the oxygen evolution reaction which occurs on more highly oxidized oxide films.

Oxygen evolution reaction on non-noble metals or alloys is attractive in the field of oxygen electrode catalysts because of the demand for low-cost electrocatalyst materials for water electrolyzers. The transition metal borides have been reported to have a high activity for an oxygen evolution reaction in an alkaline solution.[1] In the present paper, we will focus on the cobalt boride and investigate the activity of the oxygen evolution reaction on composite cobalt borides in terms of the factor of magnetic properties.

Experimental

The composite cobalt borides were prepared by mixing the powders of cobalt, the other transition metal (Fe, Ni, or Mn), and amorphous boron in a proper atomic ratio. The mixed powders, whose particle sizes were adjusted by means of 200 mesh sieve, were pressed with 10 t cm^{-2} into a cylinder shape (0.7 cm in diameter). The cylindrical samples were sintered for 4 h in an Ar gas atmosphere at several temperatures. The identification and characterization of the composite cobalt borides were performed by means of an X-ray diffractometer, a differential thermal analyzer, an X-ray photoelectron spectroscopy, and a magnetic-property analyzer (sensitive vibrating sample magnetometer). The surface conditions and roughness of the electrodes were examined by means of a scanning electron microscope and a stylus technique (Talystep). The mean surface roughness† of the boride electrodes became lower with the increase in the sintering temperature, reaching a constant value of 0.6 μm at a sintering temperature of more than 400 °C. The SEM observation showed that the surface of borides sintered at more than 300 °C for 4 h is non-porous.†† The current *vs.* potential curves with IR correction for oxygen evolution reaction on the composite cobalt borides were measured potentiostatically in a 6 M KOH solution at 25 °C under an N_2 atmosphere. After having been covered by epoxy resin, the working electrode was carefully polished with emery paper, and then it was washed with ethanol and water. The boride electrode was used after pretreatment consisting of anodic oxidation for 1 h at 0.80 V (Hg-HgO) in the case of the oxygen evolution reaction in order to obtain stable oxidized surface condition. The activation energy of the oxygen evolution reaction was evaluated by means of the apparent activation energy at 0.60 V (Hg-HgO) (or at proper potential) and it was determined in the temperature range between 0 °C and 50 °C with the temperature correction. The electrochemical investigation of electrode surface oxides was done in a 6 M KOH solution by means of linear potential sweep voltammetry and chronopotentiometry. A mercury-mercury(II) oxide electrode in the same solution was used as the reference electrode, and all the potential was referred to the Hg-HgO electrode. The stability of the borides was evaluated by means of the amount of boron dissolved after 24 h electrolysis at 0.70 V in the 6 M KOH solution. The amount of boron dissolved in the solution was examined by means of photospectroscopy using the Methylene Blue method. A small amount of boron dissolved was detected as having values between 2 and 4 mg after 24 h electrolysis for the three cases of Co-B(3 : 1), Fe-B(3 : 1), and Co-Fe-B(1 : 2 : 1), which were sintered at 400 or 450 °C.

† The mean surface roughness is evaluated by averaging 10 point data of ΔR_{max} (difference between top and bottom positions as measured by Talystep).

Results and Discussion

Oxygen Evolution Reaction on Cobalt Borides. It was found that the cobalt boride at proper conditions has a higher activity for oxygen evolution reaction than does nickel or cobalt in an alkaline solution.[1] The activity of the oxygen evolution reaction depends

†† The double layer capacities of Co, Co-B(3 : 1) sintered at 400 °C, and Co-Fe-B(1 : 2 : 1) sintered at 450 °C, measured at −1.0 V and at 1 kHz in 6 M KOH, were observed as the reasonable values of 110, 60, and 110 μF cm^{-2} respectively. The current-potential curve on the Co electrode, which was prepared by the same method as the borides, was observed to show the same behavior as on an usual Co electrode. These two facts also strongly support the theory that these borides can be used as non-porous states.

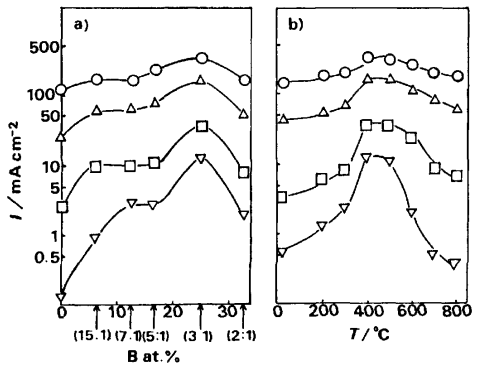

Fig. 1. Effects of sintering temperature and boron content of cobalt borides on oxygen evolution current in 6 M KOH at 25 °C.
a) Oxygen evolution current *vs.* boron content curves on Co-B sintered at 400 °C for 4 h. b) Oxygen evolution current *vs.* sintering temperature curves on Co-B(3 : 1), ○: at 0.80 V, △: at 0.70 V, □: at 0.60 V, ▽: at 0.50 V.

largely on the composition ratio of Co:B and the sintering temperature. The effects of the boron content and the sintering temperature on the activity of the oxygen evolution reaction (*i.e.*, current values at several constant potentials) are demonstrated in Fig. 1. The best conditions for a high activity of oxygen evolution were obviously observed to be at the composition ratio of Co:B=3:1 and at the sintering temperature=400—500 °C, as may be seen in Fig. 1. The apparent activation energy, ΔH, at 0.60 V, of the oxygen evolution reaction on cobalt boride sintered at 400—500 °C, gave the lowest value of 8.6 kcal mol^{-1}.††† As has already been pointed out in Ref. 1, the cobalt boride sintered at 400 °C is considered to be amorphous or in a transition state, judging from the combined results of X-ray diffraction analysis, differential thermal analysis, and magnetic property measurement. The magnetic properties which are sensitive to the structure change in materials were measured and discussed in Ref. 1 in connection with the function of the sintering temperature. A rapid decrease in coercivity, Hc, was observed in the range of sintering temperature between 350 and 400 °C. The saturation magnetization, σ_s, also started to change from the sintering temperature of 300 °C and showed its maximum in the sintering temperature region between 350 and 500 °C. In the region of sintering temperatures, higher than 500 °C, the value of σ_s abruptly decreased. The change in magnetic properties from the lower sintering temperature, at which the peaks of X-ray diffraction analysis and DTA caused by the formation of compounds are not recognized (*cf.* Ref. 1), may indicate that the amorphous or transition state compounds are formed in the range between 400 and 500 °C.**

††† 1 kcal mol^{-1}=4.184 J mol^{-1}.

** The X-ray diffraction peak of CoB was partially observed at 400 °C, while the peaks of Co_3B were detected from 600 °C.

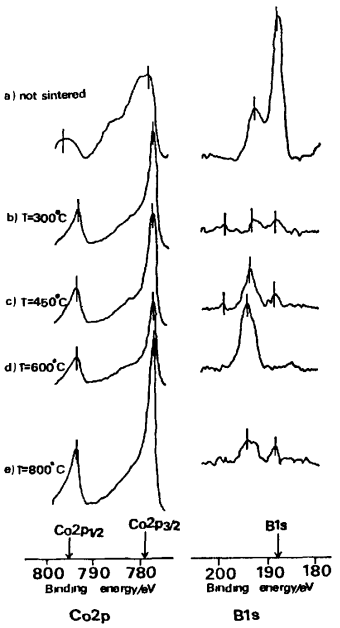

Fig. 2. Photoelectron spectra of Co 2p levels and B 1s level for Co-B(3 : 1) at various sintering temperatures.

Since X-ray photoelectron spectroscopy (XPS) is a powerful technique for the investigation of bonding in transition metal compounds, the XPS measurements were performed in order to confirm the formation of compounds. The XPS spectra of the Co 2p and B 1s levels are shown in Fig. 2 as a function of the sintering temperature. The spectra were measured after pretreatment of 5 min Ar^+ sputtering. The peak values of the metal states, which are given by arrows in the figure, have been reported to be 794.0 and 779.0 eV for Co $2p_{1/2}$ and $2p_{3/2}$ respectively and 188.1 eV for the B 1s state.[2,3] The chemical shifts for the Co $2p_{3/2}$ and $2p_{1/2}$ were observed to become the lower energy level at a sintering temperature of more than 300 °C. The chemical shifts for the Co $2p_{3/2}$ level reach a constant value of 1.0 eV from the sintering temperature of 300 °C. In the case of the Co $2p_{1/2}$ level, the shifts give 0.7 eV at 300 °C and close to the final value of 1.0 eV at 800 °C with the increase in the sintering temperature. In the spectra of the B 1s level, there appear two peaks, at 188.9 eV and in the range between 193 and 194 eV. In the range of sintering temperatures between 300 and 450 °C, where the oxygen evolution reaction on cobalt borides shows the highest activity, the spectra show unclearly three small peaks (the peak at 199.5 eV was newly observed), which might be satellite peaks caused by the exchange splitting of the B 1s level with the unpaired valence electrons under amorphous conditions. It can be also confirmed from the above results, shown in Fig. 2, that the compounds of cobalt borides showing amorphous or transition state conditions are formed in the range of sintering temperatures between 300 °C and 500 °C.

The magnetic properties of 3d transition-metal alloys are strongly connected to the electron numbers of 3d

plus 4s, and they are usually discussed with the magnetic moment, μ_B, expressed by Bohr magnetons. The magnetic moment, μ_B, can be calculated from σ_s by using the following equation:

$$\mu_B = M/\beta = A \cdot \sigma_s/(N \cdot \beta), \quad (1)$$

where M, A, N, and β are magnetic moment per atom, the atomic mass, the Avogadro constant, and the unit of the Bohr magneton respectively. Since the saturation magnetization of cobalt borides reaches a maximum in the range where the activity of oxygen evolution reaction becomes the highest, the saturation magnetization, σ_s, or the magnetic moment, μ_B, may be one of the most important factors which are correlated to the activity. Therefore, we tried to form the composite cobalt borides by referring to the Slater-Pauling curves,[5] which demonstrate the relationship between μ_B and the electron number of the outer-most orbitals (3d+4s) in the case of 3d transition-metal alloys. In the Slater-Pauling curves, the 30% Co-Fe alloy has the maximum value of μ_B=2.5.

Oxygen Evolution Reaction on Composite Cobalt Borides. The current *vs.* potential curves for oxygen evolution reactions with IR correction on several composite cobalt borides and cobalt in a 6 M KOH solution are demonstrated in Fig. 3. Among the composite cobalt borides, the cobalt boride containing iron (Co-Fe-B), which has a higher saturation magnetization value than that of the cobalt boride species, gives the highest activity of oxygen evolution reaction, as may be seen in Fig. 3. The activity order of composite cobalt borides is as follows:

Co-Fe-B(1:2:1) > Co-Fe-B(3:3:2) > Co-B(3:1) > Co-Ni-B(3:3:2) > Co-Mn-B(3:3:2) > Co,

where the almost composite cobalt borides were sintered at 400 or 450 °C for 4 h. The effect of the iron composition ratio of composite cobalt borides (Co-Fe-B) was evaluated by means of the apparent activation energy at 0.60, 0.65, and 0.70 V as is shown in Fig. 4, where the sintering temperature was fixed at 450 °C, at which temperature the Co-Fe-B species usually gives the highest activity of the oxygen evolution reaction. In Fig. 4, the cobalt iron boride with Co:Fe:B=1:2:1 shows the lowest apparent activation energy, namely, the highest activity of the oxygen evolution reaction (*e.g.*, ΔH at 0.60 V=5.2 kcal

mol^{-1}). The results correspond well to the information from the Slater-Pauling curves, where the 30% Co–Fe alloy has the maximum μ_B value of 2.5.

The relationship between the activity of the oxygen evolution reaction and the magnetic moment, μ_B, is demonstrated in Fig. 5, where the activity is expressed as the potential at a constant oxygen evolution current, 0.10 A cm^{-2}. As has previously been supposed, the above relation has a clear linear correlation, the composite cobalt boride with the higher μ_B gives the higher activity of the oxygen evoulution reaction. Since the magnetic moment, μ_B, is correlated to the numbers of unpaired electrons in the 3d transition metal alloys, the number of unpaired electrons is considered to be the most important factor in determining the activity of the oxygen evolution reaction in the composite cobalt boride species. The oxygen evolution reaction, however, occurs not on bare boride, but on oxidized boride. Therefore, the magnetic moment or the number of unpaired electrons may be connected with the ease of surface oxide film formation, which frequently affects the oxygen evolution reaction because the oxygen evolution reaction occurs in many cases on oxide films. Since the formation and conditions of oxide films can be strongly correlated to the activity of the oxygen evolution reaction on composite cobalt borides, the conditions of oxide films on Co–Fe–B and on Co–B with the higher activity will, in the next section, be investigated by means of linear potential sweep voltammetry and chronopotentiometry by comparing the oxide conditions of cobalt in a 6 M KOH solution.

Electrochemical Investigation of Surface Oxide on Cobalt, Cobalt Boride, and Cobalt Iron Boride in a 6 M KOH Solution. A Typical linear potential sweep voltammogram and a chronopotentiogram on cobalt in a 6 M KOH solution are shown in Fig. 6. The behavior of the linear potential sweep voltammogram is almost the same as that in 0.2—8 M KOH solutions reported by Behl and Toni.[6] They discussed the five peaks and concluded that the following reaction scheme holds for the electrooxidation of cobalt in a KOH solution:

$$Co + 2OH^- \rightarrow Co(OH)_2 + 2e \quad \text{Peak 1 and 2} \quad (2)$$

$$Co + 2OH^- \rightarrow CoO + H_2O + 2e \quad \text{Peak 2} \quad (3)$$

$$3Co(OH)_2 + 2OH^- \rightarrow Co_3O_4 + 4H_2O + 2e \quad \text{Peak 3} \quad (4)$$

$$Co(OH)_2 + OH^- \rightarrow CoOOH + H_2O + e \quad \text{Peak 4} \quad (5)$$

$$CoOOH + OH^- \rightarrow CoO_2 + H_2O + e \quad \text{Peak 5} \quad (6)$$

In Fig. 6, the Peak 3 is not clear in the voltammogram, but it is detectable at an enlarged scale. It is likely that the first film formed on cobalt is cobalt(II) hydroxide and that the cobalt(II) oxide films are formed after hydroxide formation. Finally, the more highly oxidized oxide films, such as Co_3O_4, CoOOH, and CoO_2, begin to form at the more anodic oxidation. The same conclusion can be drawn from our results for linear potential sweep voltammogram judging from the similar behavior in Fig. 6(a). The behavior of the chronopotentiogram shown in Fig. 6(b) is similar to that of the linear potential sweep voltammogram, but only three waves are observed. The first large wave corresponds to the hydroxide film formation, while the small second and third waves are connected with the more highly oxidized oxide film formation.

The linear potential sweep voltammograms and

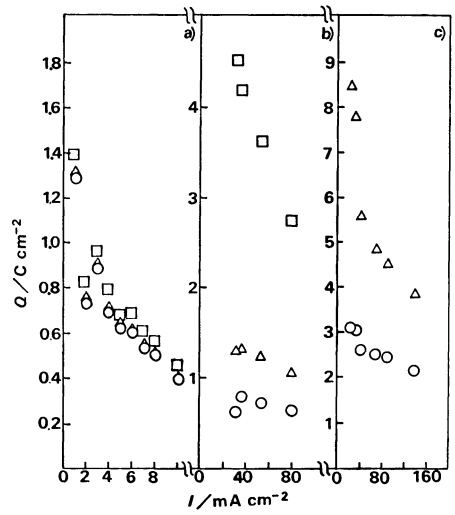

Fig. 9. Relation between amount of charge and current density at chronopotentiometry. a) Co, b) Co-B(3 : 1) sintered at 400 °C, c) Co-Fe-B(1 : 2 : 1) sintered at 450 °C. ○: 1st wave, △: 2nd wave, □: 3rd wave, where the charges for the 2nd and the 3rd waves are, for convenience, calculated from the initial potential of the 1st wave.

chronopotentiograms on the most active cobalt boride and cobalt iron boride are shown in Figs. 7 and 8. The behavior of the voltammogram and chronopotentiogram on cobalt boride (3:1) shown in Fig. 7 is similar to that on cobalt; however, the current peaks in the voltammogram due to the formation of hydroxide, shown as 1, or oxides, shown as 2 and 3, in Fig. 7, become larger (*i.e.*, the unit of the current axis in the voltammogram for Co–B is five times that for Co), and the initial potential at which the hydroxide film starts to form shifts to the more cathodic side. In the case of Co–Fe–B(1:2:1) the linear potential sweep voltammogram and chronopotentiogram are also very similar to those for Co–B(3:1), and the anodic peaks due to hydroxide (shown as 1) and oxide (shown as 2 in Fig. 8) formations become very large (*i.e.*, the unit of the current axis in the voltammogram for Co–Fe–B is twenty times that for Co). The order of the potential at which the hydroxide film starts to form is as follows:

$$\text{Co-Fe-B}(1:2:1) = -1.00\,\text{V},\ \text{Co-B}(3:1) = -0.93\,\text{V},$$
$$\text{Co} = -0.83\,\text{V}.$$

The order of the amount of charge due to hydroxide and oxide films can easily be determined by means of chronopotentiometry. Figure 9 represents the amount of charge due to the waves in the chronopotentiograms. The total charges due to hydroxide and oxide film formations on the borides are much larger than on cobalt. Moreover, the charge due to oxide formation in the case of cobalt is much smaller than that due to hydroxide formation (*cf.* Fig. 9(a)), while in the case of borides, the charge due to the oxide formation is much larger than that of hydroxide film formation. Therefore on the borides, the hydroxide film may change completely to oxide films on the anodic side and the thicker oxide films in higher oxidation states are easily formed on the surface. It may be concluded from the above results that the composite cobalt boride and the cobalt boride with the higher activity of the oxygen evolution reaction form the thicker and more stable oxide films in higher oxidation states in which the oxygen evolution reaction occurs. The very thick oxide layer in higher oxidation states might act as an intermediate in accelerating the oxygen evolution reaction on the borides. The above conclusion corresponds fairly well with the information, deduced from the relation between the magnetic moment, μ_B, and its activity, seen in Fig. 5, considering that the formation of oxide films becomes easier with the increase in the number of unpaired valence electrons.

Therefore, the oxide films on composite cobalt borides are considered to play an important role in the oxygen evolution reaction, and it may be concluded that the ease and stability of more highly oxidized oxide film formation are strongly connected with the activity of the oxygen evolution reaction.

The authors would like to thank Mr. Haruo Sekiguchi, Analytical Centre, Shimadzu Corporation, for his experimental support of the XPS measurements.

(Received January 21, 1983)

The structure of the novel sugar, methyl D-tetronitroside [methyl 2,3,4,6-tetradeoxy-4-(methoxycarbonylamino)-3-*C*-methyl-3-nitro-D-*xylo*-hexopyranoside], was determined by X-ray analysis. This compound is a structural component of the antitumor antibiotics, tetrocarcins. The space group is $P2_1$ with $a=11.782(3)$, $b=10.271(2)$, $c=11.636(3)$ Å, $\beta=105.12(4)°$, and $Z=4$. The structure was solved by direct methods, and least-squares refinement using 2503 reflexions gave the final R value of 0.079. Both the two independent molecules take a $^4C_1$ chair conformation and they are connected together through two hydrogen bonds. Although the average C-C distance in the rings is 1.527 Å, the C(2)-C(3) distance is significantly long (average 1.546 Å) due to the steric hindrance by the nitro groups.

D-Teronitrose is a structually important component of antitumor antibiotics, tetrocarcins,[1] and is the third naturally occuring nitro sugar discovered in antibiotics. The nitro sugar is so rare in nature that its detailed molecular structure has not yet been reported. Only the structure of the tetronitrose was spectroscopically and chemically elucidated but the molecular configuration was not confirmed because of having the asymmetric carbon atom with the nitro group as a side chain. In this paper we will report the X-ray analysis of methyl D-teronitroside in order to describe the stereochemical features of the nitro sugar. Recently a nitro sugar with the same composition as D-tetronitrose has been isolated from kijanimicins.[2]

Experimental and Structure Determination

The crystals of methyl D-teronitroside prepared by methanolysis of tetrocarcin A[1] were obtained by evaporation from a hexane-dichloromethane solution. A crystal, $0.4\times0.3\times0.3$ mm^3 in size, was used for data collection on a Rigaku four-circle automated diffractometer with graphite monochromated Mo $K\alpha$ radiation ($\lambda=0.71069$ Å). Preliminary unit cell dimensions and space group were obtained from photographs. Accurate cell dimensions were determined by least-squares calculations with the 2θ values of 15 high-angle reflexions measured on the diffractometer. Crystal data are as follows: $C_{10}H_{18}N_2O_6$; $M.W.=262.26$; $P2_1$; $Z=4$; $a=11.782(3)$, $b=10.271(2)$, $c=11.636(3)$ Å, $\beta=105.12(4)°$; $D_x=1.282$ g cm^{-3}; μ(Mo $K\alpha$) $=1.141$ cm^{-1}. All independent reflexions within the range $2\theta\leqq55°$ were collected by use of the ω-2θ scan mode with a scanning rate of $4°(2\theta)$ min^{-1}. Stationary background counts were accumulated for 10 s before and after each scan. Periodic check of the intensities of three standard reflexions showed no significant X-ray damage or decay. Correction for absorption or extinction was not applied. A total of 3308 independent reflexions were obtained, of which 2503 ($|F_o|>3.0\sigma(|F_o|)$) were considered as observed.

The structure was solved by direct methods using MULTAN.[3] The structural parameters were refined by block-diagonal least-squares methods with a modified HBLS program.[4] All the hydrogen atoms were found on a difference Fourier map and included in further refinement with isotropic thermal parameters. The final R value was 0.079 for 2503 observed reflexions. The weighting scheme used in the final stage was $w=(\sigma(F_o)^2+(0.015F_o)^2)^{-1}$. Atomic scattering factors were taken from Ref. 5. The final positional and thermal parameters are given in Table 1.**

Results and Discussion

The stereoscopic drawing of the two independent molecules are shown in Fig. 1, together with the atom numbering system. The absolute configuration of the tetronitrose, D-configuration, has been determined by applying Hudson's rules of isorotation to its α- and

β-glycosides; $[M]_{D\alpha}-[M]_{D\beta}=363.5°-66.4°=297.1°$. Very recently α-D-tetronitroside has been synthesized from D-mannose by Yoshii, and its D-absolute configuration was confirmed.[6]

Bond Lengths and Angles. The bond lengths and angles are shown in Table 2. Although most of the corresponding bond lengths in molecules A and B agree within the experimental error, the differences between them by greater than 3σ are observed in the amide bond. The average C–C distance of 1.527 Å in the rings agree with those observed in usual monosaccharides,[7] but the C(2)–C(3) distance (average 1.546 Å) is significantly longer than the other C–C distance in the rings and its reason will be discussed later. The two C–C bonds in the ring are almost equal to the average of 1.435 Å. The average distance of N(2)–C(3) bond (1.548 Å) is in good agreement with the corresponding N–C bond (1.541(3) Å) in *c*-5-methyl-*t*-5-nitro-1,3,2-dioxathian *r*-2-oxide.[8] The C(1)–O(6) bond (average 1.391 Å) is significantly shorter than the O(6)–C(7) bond (average 1.417 Å), which indicates large anomeric effect.

The differences between the corresponding bond angles in the two molecules are rather large compared to those of bond lengths. The average bond angles in the pyranose ring are 110.8 and 110.6° for molecules A and B, respectively, which are in agreement with

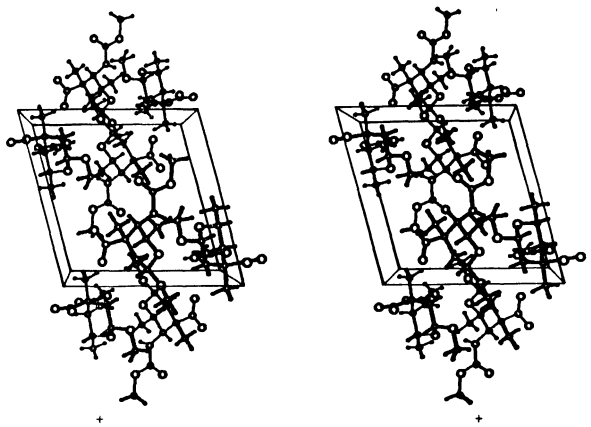

Fig. 2. Stereoscopic drawing of the crystal structure viewed along the b axis. The vertical and the holizontal axes are a and c, respectively. This figure and Fig. 1 were drawn by TSD : XTAL, a program for NOVA 3 computer.[9]

those found in pyranoses.[7]

Conformation. Both of the two independent molecules take a $^4C_1$ chair conformation. Selected torsion angles are tabulated in Table 3. The average torsion angles in the ring, 54.9 and 56.4° in A and B, respectively, are within the range observed for monosaccharides.[7] The *d* values (the deviation of the two atoms from the least-squares plane of the other four atoms forming the seat of a chair)[9] of the ring atoms in two molecules are averaged as follows; O(1) 0.706, C(1) 0.657, C(2) 0.569, C(3) 0.574, C(4) 0.651, C(5) 0.717 Å. The O(1) and C(5) atoms are most puckered, while the C(3) and C(2) atoms are less puckered. The O(4) atom is nearly eclipsed to the C(2) atom (O(4)–N(2)–C(3)–C(2) torsion angle is 6.2° for A and −13.9° for B). Therefore, the O(4) has short contact with C(2); the O(4)···C(2) nonbonded distance is 2.693(8) in A and 2.685(8) Å in B. The less puckering of C(3) and C(2) and the lengthening of C(2)–C(3) bond may cause the relief of steric hindrance, and it eventually causes the large puckering of the O(1) and C(5) atoms.

Crystal Structure. Crystal structure viewed along the b axis is shown in Fig. 2. The two independent molecules make pairs through the two NH···O hydrogen bonds with following geometry: N(1A)···O(1B) =3.157(6), N(1B)···O(1A)=3.147(6) Å, ∠N(1A)–H···O(1B)=170.1(5), ∠N(1B)–H···O(1A)=157.8(5)°. The paired molecules are packed together with usual van der Waals contacts.

(Received February 7, 1983)

The molecular and liquid structures of formamide have been studied by means of X-ray diffraction. Relative stabilities of aggregates of formamide molecules have been calculated by using the *ab initio* LCGO-MO-SCF procedure and minimal basis sets. The atomic distances within a formamide molecule and the intermolecular N···O distance between the hydrogen-bonded molecules are determined by the X-ray diffraction experiment as follows: C=O: 1.24(1) Å, C–N: 1.33(1) Å, N···O (intramolecular): 2.25(2) Å, and N···O (intermolecular): 3.05(5) Å. The intermolecular -HNH···O=C< bond angle (θ) is about 120°. It is concluded from the X-ray diffraction experiment that liquid formamide mainly consists of the chain-like hydrogen-bonded structure of formamide molecules by combining through $-NH_2\cdots O=CH-$ interactions. The conclusion is supported by the *ab initio* calculations. Formation of ring-dimers in the liquid formamide has not been confirmed by the X-ray diffraction study, although a possibility of the formation of the ring-dimer structure as another constituent of liquid formamide is suggested from the *ab initio* calculations.

Formamide ($HCONH_2$) has a relatively large dielectric constant ($\varepsilon/\varepsilon_0=107$ at 25 °C, where ε and ε_0 represent the dielectric constants of formamide and vacuum, respectively), and thus can dissolve many electrolytes. Since the oxygen and nitrogen atoms within a formamide molecule are negatively charged and the carbon and hydrogen atoms have partially positive charges, a formamide molecule has a dipole moment of about 12.4×10^{-30} C m *in vacuo*. The donor number of formamide ($DN=24$) is larger than that of water ($DN=18.0$), although the acceptor number of the former ($AN=39.8$) is smaller than that of the latter ($AN=54.8$). Therefore, rather strong interactions between formamide molecules can be expected in the condensed phase.

Molecular and crystal structures of formamide have been determined by X-ray and electron diffraction methods,[1,2] and it has been found that all atoms within one molecule lay on a plane. A similar structure is kept even in the gas phase.[3] Therefore, we can expect that molecules of formamide in the liquid state have the planar structure similar to that observed in the gas and solid phases.[1–3] In crystal, formamide molecules form ring dimers which construct a large ring structure through hydrogen bonds (see Fig. 1).[1,2] However, the stable ring structure exisiting in the solid state may be rather unfavorable to give the high dielectric constant of formamide and high solubilities of electrolytes in it in the liquid phase.

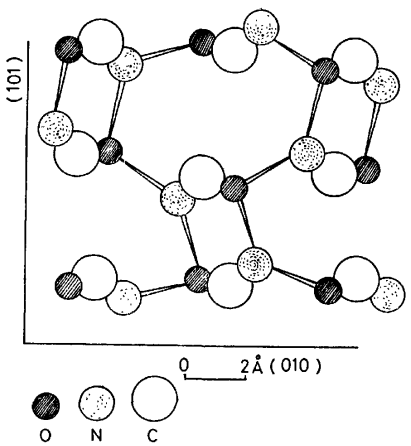

Fig. 1. Structure of formamide in the solid state,[1]

The aim of the present study is to determine the molecular arrangement, as well as the molecular structure of formamide in the liquid phase, in order to compare the structures with those in the gas and solid phases. The liquid structure of formamide estimated by the X-ray diffraction method will be compared with structural models of various aggregates examined by the *ab initio* LCGO-MO-SCF calculations.

Experimental

Preparation of Sample Solution. Formamide of reagent grade, purchased from Wako Pure Chemicals Co., Tokyo, was distilled twice under a reduced pressure. The water content of the formamide was determined by means of the Karl-Fischer titration. Since the amount of water (about 0.02% w/w) was very small, it was neglected in the course of the data analysis of X-ray diffraction.

Method of Measurement and Treatment of X-Ray Scattering Data. The X-ray diffractometer, JEOL DX-GO-Y (θ-θ type), was employed in combination with Philips 2255/20 Mo $K\alpha$ X-ray tube ($\lambda=0.7107$ Å) and an NaI-Tl scintillation counter. Scattered X-rays were monochromatized by a Johansson-type LiF monochromator and a pulse-height analyzer. The scattering angle (2θ) measured was in the range of 2° to 140°, and the data were recorded twice over the whole angle range. Corrections and analysis of the scattering data were performed by the same ways as those described elsewhere.[4] The scattering and correction factors of atoms in the system were taken from the literature.[5]

The reduced intensities $i(s)$ were obtained by the following equation:

$$i(s) = KI_{\mathrm{corr}}(s) - \sum_i n_i[\{f_i(s)+\Delta f_i'\}^2+(\Delta f_i'')^2], \qquad (1)$$

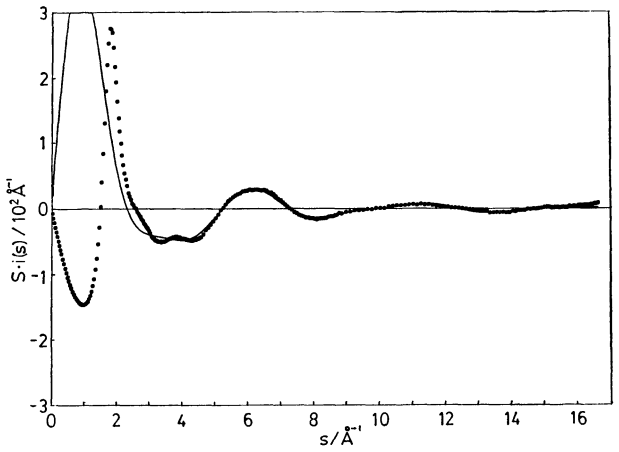

Fig. 2. Reduced intensities, $s \cdot i(s)$, experimentally obtained (circles) and calculated values ($s \cdot i_{\text{calcd}}^{\text{intra}}(s)$, solid line) by taking into account only intramolecular interactions.

where K denotes a factor for transforming measured intensities $I_{\text{corr}}(s)$, which had been corrected for absorption, polarization and multiple scatterings of X-rays by the usual methods,[4] to the absolute ones. The factor had been obtained by the high-angle method[6] and the method by Krogh-Moe[7] and Norman.[8] The K values obtained by the two methods agreed with each other within 1%. $\Delta f_i'$ and $\Delta f_i''$ in Eq. 1 represent the real and imaginary parts of the anomalous dispersion of atom i, respectively.

The reduced intensities multiplied by s ($=4\pi\lambda^{-1}\sin\theta$) of the test solution are shown in Fig. 2.

The radial distribution function $D(r)$ was calculated by the Fourier transform of the reduced intensities according to Eq. 2.

$$D(r) = 4\pi r^2\rho_0 + \frac{2r}{\pi}\int_0^{s_{\max}} s \cdot i(s) \cdot M(s) \cdot \sin(sr)\mathrm{d}s, \qquad (2)$$

where ρ_0 is the average scattering density in the stoichiometric volume V of the test solution, and $s_{\max}$ denotes the maximum s-value attained in the measurement ($s_{\max}=16.6$ Å^{-1}). $M(s)$ represents the modification function

$$M(s) = \frac{[\sum_i n_i f_i(0)^2]}{[\sum_i n_i f_i(s)^2]} \cdot \exp(-ks^2), \qquad (3)$$

where n_i denotes the number of atom i in the stoichiometric volume. $f_i(0)$ and $f_i(s)$ stand for the scattering factors of atom i at $s=0$ and s, respectively. The damping factor k was chosen as 0.01 Å^2 in the present experiment.

Calculations for data treatments were carried out by using the KURVLR program developed by Johansson and Sandström.[9]

Raman spectra of the test solution were measured before and after X-ray radiation, and it was confirmed that formamide was not decomposed by the X-ray radiation.

Computations for treating the X-ray data were performed at the Tokyo Intitute of Technology at Nagatsuta by using HITAC M-170.

Theoretical Treatment

In order to investigate the relative stabilities of various possible aggregates of formamide molecules in the condensed phase, varying structural models were examined by means of *ab initio* LCGO-MO-SCF calculations with a minimal basis set (2s/1p),[10] which has been successfully employed in other cases.[11–13] The molecular geometry of formamide was kept constant at the experimental values obtained by the present work, except for the C–H and N–H bond lengths which were taken from the literature,[2] throughout the calculations. The dimer models which were investigated by the *ab initio* calculations were selected on the basis of knowledges obtained by the present X-ray diffraction experiment. Some possible structural models were also examined in order to compare their relative stabilities with those of the selected geometries. The computations were carried out by using computers at the University of Innsbruck and partly at the Interuniversity Computer Center of the Technical University of Vienna.

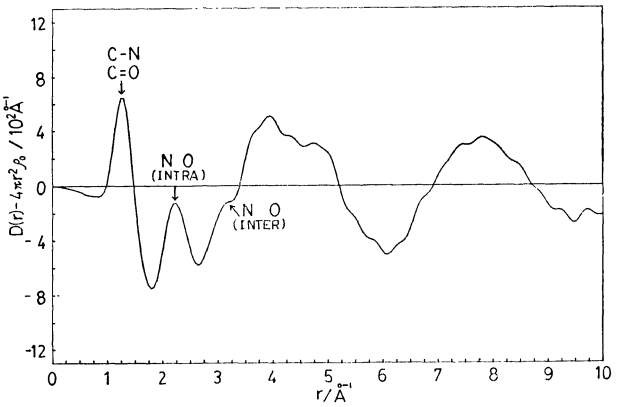

Fig. 3. Differential radial distribution curve of liquid formamide.

Results and Discussion

X-Ray Diffraction. The differential radial distribution curve, $D(r)-4\pi r^2\rho_0$, of formamide is shown in Fig. 3. The first peak appearing at about 1.2 Å is ascribed to the C–N and C=O bonds within a formamide molecule, and the second peak at 2.3 Å is attributed to the intramolecular N···O distance. A shoulder is observed at about 3 Å, which may be due to the intermolecular N···O distance according to the data by X-ray crystallography of formamide.[1,2] The reduced intensity curve calculated by using the intramolecular bond distances found from the differential radial distribution curve well reproduced the experimental curve in the range $s>5$ Å^{-1} (see Fig. 2). At the lower s range the two curves are remarkably discrepant, the discrepancy being due to intermolecular interactions between formamide molecules which have not been taken into account at the present stage of the X-ray data analysis.

The intramolecular distances thus roughly estimated from the differential radial distribution curve were further refined by applying the least-squares method to the reduced intensities $s \cdot i(s)$ over various s ranges, where $s_{\max}$ was fixed at 16.6 Å^{-1} and $s_{\min}$ was varied from 4 Å^{-1} to 6 Å^{-1}. The least-squares refinement was carried out by using the following equation:

$$U = \sum_{s_{min}}^{s_{max}} s^2\{i(s) - i_{calcd}^{intra}(s)\}^2, \quad (4)$$

where $i_{calcd}^{intra}(s)$ denotes the calculated $i(s)$ values by taking into account the intramolecular interactions only.

The results obtained for the intramolecular distances within a formamide molecules, as well as the temperature factors of each atom pair, in the liquid state are summarized and compared with those found in the gas and solid states in Table 1. No significant difference was noticed in the bond distances within a formamide molecule in the different phases.

At the second stage of the analysis of the X-ray scattering data, intermolecular interactions between formamide molecules in the liquid state were estimated from intensities due to the intermolecular interactions only which were obtained by subtracting the intensities due to the intramolecular interactions thus evaluated from the experimental values:

$$i^{inter}(s) = i(s) - i_{calcd}^{intra}(s). \quad (5)$$

Intensities $s \cdot i^{inter}(s)$ due to the intermolecular interactions thus estimated are shown in Fig. 4.

In order to interprete the $s \cdot i^{inter}(s)$ data, various dimer models were examined. In Fig. 5 the models examined are summarized. In each model the C–N and N–H bonds were rotated in order to compare the theoretical scattering intensities calculated from the models having various configurations with the experimentally obtained $s \cdot i(s)$ values. However, those except two models did not give theoretical intensities which satisfactorily fitted the experimental curves. The two models were the extremes of model (3) in Fig. 5. One was a linear dimer bonded through the N–H···O hydrogen bond with $\Theta=0°$ (two molecules were in the same plane) and $\Theta'=0°$ (Fig. 6A) and the other was a ring dimer ($\Theta=0°$ and $\Theta'=180°$) (Fig. 6B). A model at an intermediate configuration ($\Theta=0°$ and $0°<\Theta'<180°$) gave a theoretical intensity curve between those of the two extremes. In the course of the calculations of the theoretical intensity curve $s \cdot i_{calcd}^{inter}(s)$, the N···O distance was fixed at 3.05 Å in each model, which was experimentally determined by the present X-ray diffraction work. Theoretical intensities calculated on the basis of the two models were compared with the experimental ones in Fig. 4. The theoretical $s \cdot i_{calcd}^{inter}(s)$ curve drawn by using

TABLE 1. INTRA- AND INTERMOLECULAR DISTANCES OF FORMAMIDE. r AND b DENOTE THE BOND DISTANCE AND TEMPERATURE FACTOR, RESPECTIVELY[a)]

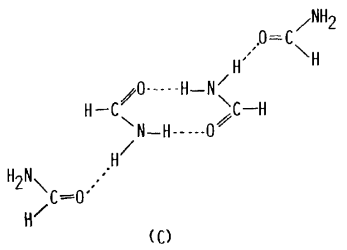

Fig. 7. A structural model consisting of linear and cyclic constituents.

the linear dimer model shown in Fig. 6A gave a better agreement with the experimental values than that calculated from the ring dimer model (Fig. 6B) in the range 3.5 Å^{-1}<s<5.5 Å^{-1}, and moreover, the hump appearing around $s\simeq2.8$ Å^{-1} was better reproduced by the former model than the latter.

A possibility of formation of a mixture of the two models were also examined at various mole ratios. However, an increase in the content of the ring dimers in the mixture enhanced the discrepancy between the theoretical and experimental intensity curves in the range 2.5 Å^{-1}<s<3.5 Å^{-1}, and therefore, the mixture model could not give a satisfactory interpretation for the $s\cdot i^{\text{inter}}(s)$ curve.

A chain-like structure consisting of the linear and the ring dimer units was taken into consideration in order to interprete the experimental $s\cdot i^{\text{inter}}(s)$ curve. The model employed is shown in Fig. 7 (model C). However, no noticeable improvement could be achieved in the interpretation of the experimentally obtained $s\cdot i^{\text{inter}}(s)$ curve by the introduction of the mixture model.

The intra- and intermolecular distances thus determined on the basis of the linear dimer model are summarized in Table 1. Disagreement between the experimental and theoretical $s\cdot i(s)$ curves observed at s<3.5 Å^{-1} is due to a disregard of longer range intermolecular and inter-chain interactions.

Although the linear model gave a better interpretation than the ring model for the experimental X-ray scattering data, the difference between the $s\cdot i(s)$ curve calculated by using the two models was so small that the existence of the ring dimers in the liquid formamide could not be completely excluded by the X-ray diffraction method examined in the present study. Therefore, we examined *ab initio* calculations for estimating energies of intermolecular interactions between formamide molecules in order to compare relative stabilities of the linear and ring dimer structures.

Ab Initio *LCGO-MO-SCF Calculations.* Relative stabilities of intermolecular interactions of dimeric, trimeric and even tetrameric polymers of formamide were calculated by the *ab initio* LCGO-MO-SCF procedure with a minimal basis set, which had been employed for calculations in other systems.[10-13] The geometry of the formamide molecules was kept constant at the experimental values given in Table 1 which were obtained by the present work, except for the C–H and N–H distances which were taken from the literature,[1] throughout the calculations, and the intermolecular –NH_2···O=CH– distances were allowed to change in order to search the energy minimum of the interaction at a given aggregate model.

Table 2. Energies at optimized C-H···O and N-H···O hydrogen bond distances (R) and energies per hydrogen bond (E_h) within formamide dimers[a]

Model	R/Å	E_h/kJ mol^{-1}
(a) 	3.27	−8.4
(b) 	2.75	−43.9
(c) 	2.80	−45.2
(d) 	2.80	−67.8
(e) 	2.80	−63.2

a) The total energy of monomer is −143.34210 hartrees. 1 hartree=2625.34 kJ mol^{-1}.

For dimers, five different models as shown in the first column of Table 2 were examined as selected ones on the basis of considerations described in the previous section for the X-ray diffraction experiment. In models (a), (b), (d), and (e) we assumed that the two molecules were situated in the same plane. In model (c), on the other hand, the planes containing each molecule differed by 90°.

The optimized distance (R) of the intermolecular hydrogen bonds and energies for each hydrogen bonding (E_h) are listed in Table 2. In agreement with previous results,[14,15] model (d) gave the largest stabilization energy for the hydrogen bonding among the chain-like structures examined here. The stabilization energy for the formation of the dimers becomes largest in model (e), because the dimer has two hydrogen bonds within the unit structure (*i.e.*, −63.2 kJ per hydrogen bond×2=−126.4 kJ per dimer). Thus we can say that the cyclic structure is most stable in the formation of dimeric formamide. Nevertheless, as we will discuss in later sections, the structure shown in the linear model (d) can be more favorable than the cyclic dimer model (e) at a high degree of polymerization of the molecules in the condensed phase in which a large number of formamide molecules interact each other.

In model (d) the change in the relative stability of the linear dimer with changing angle of rotation (Θ in Fig. 6A) of the second molecule around the axis of the hydrogen bond was examined. The changes in the total energy (ΔE_{tot}) by the rotation are tabulated in Table 3. A shallow minimum appeared at

Table 3. The energy change (ΔE_{tot}) of the linear dimer model (d) at various rotation angles (Θ)

Θ/°	ΔE_{tot}/kJ mol^{-1}
0	—
30	6.7
60	9.7
90	7.5
120	9.5
150	11.6
180	11.6

$\Theta=90°$, which suggested that the rotated structure of model (d) could have some contribution to the liquid structure of formamide, although the minimum was very shallow and the basis set employed in the present calculations was not highly sophisticated.

The hydrogen-bond distance between two formamide molecules through either C–H···O or N–H···O interaction was calculated by optimizing the distance at the lowest energy of interactions of a given configuration of the formamide dimers by the *ab initio* method (Table 2). Except for model (a) which had a longer hydrogen bond than the experimental value (3.05 Å), the distance found in models (b) to (e) was in the range 2.75—2.80 Å independent of the configurations. The result suggested that the intermolecular hydrogen-bonded distance of formamide molecules is rather insensitive to the molecular arrangement.

The distances of the hydrogen bond in models (b) to (e) were all slightly shorter than the observed value. The shortening of the calculated distance of the hydrogen bond may mainly be due to a more or less simplified basis set used in the present calculations, although the minimal basis set employed in the present calculations can give rather reasonable distances for hydrogen bonds between molecules compared with other minimal basis sets used so far.[16]

Stabilization energies of formation of trimers were estimated by the same procedure for five kinds of trimeric aggregates, four of them being shown in Fig. 8. The other one is the trimeric moiety of the chain-like structure of the mixed linear-and-ring structure shown in Fig. 7 (structure C). The energy of the hydrogen bonds within the last trimer model was a simple sum of the energies of the linear dimer (d in Table 2) and the ring dimer (e), *i.e.* $(-67.8+(2\times -63.2))$ kJ per trimer. The stabilization energies of the other trimers shown in Fig. 8 are summarized in Table 4. Structure (II), which is an extension of the linear dimer (d) (or model A in Fig. 5), has the largest energy per hydrogen bond among the five models. However, the total energy of stabilization of the trimers is largest in the mixed linear-and-ring model. Therefore, this type of the chain-like structure may contribute to some extent to the construction of liquid formamide, although the existence of the ring-dimer structure was not well accepted as the model explainable for the X-ray diffraction data.

It should be noted that the energy of hydrogen bonding in the formation of trimer (II) was the same as that in dimer (d). This result suggests that the

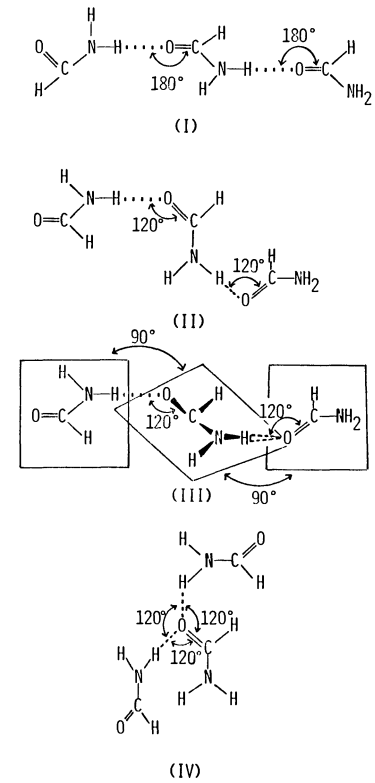

Fig. 8. Structural models of trimers.

Table 4. Stabilization energies for trimeric structures due to hydrogen bonding (E_h)

Model	E_h/kJ mol^{-1}
(I)	−48.5
(II)	−67.8
(III)	−60.2
(IV)	−44.4

energy of hydrogen-bonding of this type seems to be additive. On the other hand, trimer model (I), which is an extension of dimer (b), had an increased energy of the hydrogen bond by polymerization, although the stabilization energy of the formation of trimer (I) was still smaller than that of trimer (II). A relatively large stabilization energy of the hydrogen bond in trimer (III) suggested that rotation of molecules in trimer (II) might be easy. Trimer (IV) seems to be rather unstable compared with trimers (II) and (III) and has almost the same stability as trimer (I).

Stabilization energies for the formation of some tetramers were also calculated. For a tetramer similar to trimer (I) (*i.e.*, a linear polymer with the N–H···O angle of 180°), a slight increase by 1.3 kJ mol^{-1} (the total energy of the hydrogen bond was −49.8 kJ mol^{-1}) was observed in the stabilization energy of the aggregate, which was much less than the increment in the formation of trimer (I) from dimer (b) (4.6 kJ mol^{-1}). This suggests that the stabilization energy due to hydrogen bonding of this type may reach a constant value of about −50 kJ mol^{-1} at a pentamer or a hexamer of formamide. Since the stabilization energy of the formation of hydrogen bonds of this type is much

less compared with that of the type of dimer (d) or trimer (II) (67.8 kJ mol^{-1}), the chain-like structure of the trimer (I)-type may be less important in liquid formamide. The stabilization energy per hydrogen bond of the trimer (II)-type (or the dimer (d)-type) within a linear tetramer was essentially the same as that of the corresponding trimer and dimer, which indicated that the additivity of the stabilization of the aggregates was held in this configuration, and the chain structure of this type thus becomes the most stable one in liquid formamide.

Although the ring dimer has a larger stabilization energy due to the formation of two hydrogen bonds within it than any of the open-chain structures examined, the open structure consisting of dimer (d)-units becomes more stable than the ring structure, if the chains is formed with more than 16 molecules. Entropy effects due to easier bond rupture between molecules in the chain structure than in the ring structure and due to rotation of molecules in the chain will probably make the chain structure more favorable than the ring structure, so that the number of molecules for polymerization necessary to form stable chains might be much less than 16. Thus it can be concluded from the results of the MO-calculations that the open structures consisting of the trimer (II)-units and, to some extent the trimer (III)-units, should be dominant in liquid formamide. The ring-dimer structure may contribute to some extent to the chain structure as a link between the linear chain structures, as indicated in structure C, although the contribution was not detectable by the X-ray diffraction experiments.

A long chain structure and a mixed linear-and-ring structure did not give improved interpretations to the X-ray diffraction data, because interactions between the chain structures could hardly be estimated in the interpretation of the intensities of scattered X-rays.

The work has been partially supported by the Grant-in-Aid for Special Project Research (No. 510806) from the Ministry of Education, Science and Culture of Japan, and by the International Research Cooperation Project (Erl. zl. 18 889/25-10/79) from the Austrian Federal Ministry.

16) Minimal basis sets such as the STO-3G basis set sometimes give a very short distance for a hydrogen-bond compared with hydrogen-bond distances calculated by extended basis sets. The basis set employed here has a much small effect for the shortening of the calculated distances of hydrogen-bonds. An example may be given for an O···N distance in an NH_3-H_2O system, in which the O···N distance has been estimated to be 3.000 Å by using the present (2s/1p) basis set (B. M. Rode and K. Sagarik, *Chem. Phys. Lett.* **88**, 337 (1982)) and 3.075 Å by a more extended basis set (8s/4p/1d).

Electrochemical Kinetic Parameters of Geometric Isomers of Singly Charged Cobalt(III) Complexes

Akifumi YAMADA* and Tadatsugu YOSHIKUNI†

Department of Materials Science and Technology, Technological University of Nagaoka, Kamitomioka, Nagaoka 949-54

†*Research Laboratory of Otsuka Chemical Co., Ltd., Kagasuno 463, Kawauchi, Tokushima 771-01*

(Received Decembar 3, 1982)

The kinetic parameters of electrode reactions of several geometric isomers of singly charged cobalt(III) complexes have been determined by means of Tast polarography. The complexes studied are *trans*-$[Co(NCS)(NO_2)(en)_2]Cl\cdot H_2O$, *cis*-$[Co(NCS)(NO_2)(en)_2]Cl\cdot 2H_2O$, *trans*-$[Co(NO_2)_2(en)_2]NO_3$, *cis*-$[Co(NO_2)_2(en)_2]NO_3$, *trans*-$[Co(NO_2)_2(NH_3)_4]NO_3\cdot 0.5H_2O$, *cis*-$[Co(NO_2)_2(NH_3)_4]NO_3$, *trans*-$[CoCl(NO_2)(en)_2]NO_3$, and *cis*-$[CoCl(NO_2)(en)_2]NO_3$. These complexes showed two irreversible reduction waves; the first corresponds to $Co^{III}\rightarrow Co^{II}$, and the second, to $Co^{II}\rightarrow Co^0$. The electrochemical kinetic parameters for the one-electron reduction wave were obtained in 0.1 and 1.0 M acetate buffer solutions. The half-wave potentials for the first wave of the complexes were more positive for the *cis* isomers than for the corresponding *trans* isomers. The cathodic rate constants at $E=0$ for the *cis* isomers were also larger than those for the corresponding *trans* isomers. A slight increase in the rate constant with the decrease in ionic strength was observed.

A number of electrochemical studies of cobalt(III) complexes[1] have been carried out. Among these studies, the polarography of geometric isomers of cobalt(III) complexes has been discussed by Holtzclaw and Sheetz,[2] Holtzclaw,[3] Inoue and Imai,[4] and Vlček.[5] However, no systematic work on geometric isomers under the same conditions has yet been done. In this paper, the electrochemical kinetic parameters of geometric isomers of singly charged cobalt(III) complex ions are determined, and the differences in kinetic parameters between isomeric pairs are discussed.

Experimental

Materials. The complexes, *trans*-$[Co(NCS)(NO_2)(en)_2]Cl\cdot H_2O$,[6] *cis*-$[Co(NCS)(NO_2)(en)_2]Cl\cdot 2H_2O$,[7] *trans*-$[Co(NO_2)_2(en)_2]NO_3$,[8] *cis*-$[Co(NO_2)_2(en)_2]NO_3$,[9] *trans*-$[Co(NO_2)_2(NH_3)_4]NO_3\cdot 0.5H_2O$,[10] *cis*-$[Co(NO_2)_2(NH_3)_4]NO_3$,[11] *trans*-$[CoCl(NO_2)(en)_2]NO_3$,[12] and *cis*-$[CoCl(NO_2)(en)_2]NO_3$,[7] were prepared by the literature methods. The ionic strength of the solution was adjusted with a sodium acetate buffer(pH=5.0). A portion of 0.005% gelatin was used as the maximum suppressor. All the other chemicals used were of a guaranteed reagent grade.

Electrochemical Measurements. A three-electrode cell[13] equipped with a saturated calomel electrode (Yanagimoto MR-P2-05-1) and a platinum-wire electrode was employed. A dropping mercury electrode (flow rate, 1.17 mg s^{-1} and drop time, 3.97 s in 0.1 M (1 M=1 mol dm^{-3}) acetate buffer solutions) served as a working electrode. The kinetic parameters of the electrode reactions were determined by means of Tast polarography. The Tast polarograms were recorded by means of a Fuso Model 312 polarograph with a Watanabe Model WX441 X-Y recorder. A Takeda Riken digital multimeter, Model TR-6355, was used, the current and the potential were thus measured precisely. Dissolved oxygen was removed by bubbling purified nitrogen gas through the solution. All the measurements were made at 25 °C.

Results and Discussion

In every complex studied, two polarographic waves were obtained. The height of the second step was about twice that of the first, which suggests that a one-electron reduction is followed by a two-electron reduction. Both steps were found to be proportional to the bulk concentration of the complex and to be diffusion-controlled. The present investigation is concerned only with the reduction of Co^{III} to Co^{II}. Slopes of the log-plots for the Tast polarogram indicate an irreversible reduction throughout. Figure 1 shows a Tast polarogram of the first waves of the *cis* and *trans* isomers obtained in 0.1 M acetate buffer solutions.

The Tast polarograms were analyzed by applying the following relations for a totally irreversible electrode process:[14]

$$(\boldsymbol{RT}/\alpha n\boldsymbol{F})\ln[2x(3-x)/5(1-x)] = E_{1/2}-E, \quad (1)$$

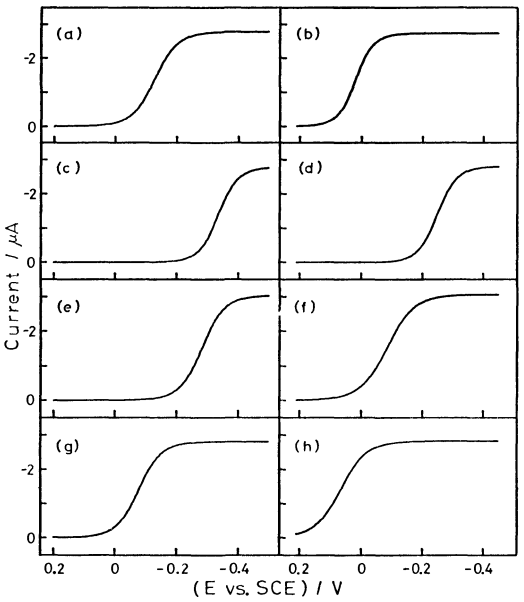

Fig. 1. Tast polarograms for the first wave of several isomeric cobalt(III) complex ions obtained in 0.1 M acetate buffer and 0.005% gelatin at 25 °C.
(a) *trans*-$[Co(NCS)(NO_2)(en)_2]^+$, (b) *cis*-$[Co(NCS)(NO_2)(en)_2]^+$, (c) *trans*-$[Co(NO_2)_2(en)_2]^+$, (d) *cis*-$[Co(NO_2)_2(en)_2]^+$, (e) *trans*-$[Co(NO_2)_2(NH_3)_4]^+$, (f) *cis*-$[Co(NO_2)_2(NH_3)_4]^+$, (g) *trans*-$[CoCl(NO_2)(en)_2]^+$, (h) *cis*-$[CoCl(NO_2)(en)_2]^+$.

with

$$x = I/I_d, \quad (2)$$

and

$$E_{1/2} = (\boldsymbol{R}T/\alpha n\boldsymbol{F})\ln[1.35k_c^\circ(t_d/D)^{1/2}], \quad (3)$$

where I is the current at the potential, E; I_d, the diffusion-controlled current; D, the diffusion coefficient; t_d, the drop time; α, the transfer coefficient; k_c°, the cathodic rate constant at $E=0$; n, the number of electrons; $\boldsymbol{R}$, the gas constant; $\boldsymbol{F}$, the Faraday constant, and T, the absolute temperature. According to Eq. 1, a plot of $\ln[2x(3-x)/5(1-x)]$ *vs.* E should be a straight line. The transfer coefficient, α, can be obtained from the slope, and the half-wave potential, $E_{1/2}$, from the intersection. The rate constant, k_c°, can be obtained from $E_{1/2}$ by applying Eq. 3.

The kinetic parameters of the electrode reactions thus obtained in 0.1 M acetate buffer solutions are given in Table 1. The kinetic parameters thus obtained were checked by calculating the current according to this relation:

$$2x(3-x)/5(1-x) = 1.35k_c^\circ(t_d/D)^{1/2}\exp(-\alpha n\boldsymbol{F}E/\boldsymbol{R}T). \quad (4)$$

The calculated currents were in good agreement with the observed ones.

The diffusion coefficient of the cobalt complexes was measured by means of a method previously reported[15] by using $[Co(NH_3)_6]^{3+}$ as the reference substance; the results are also given in Table 1. The magnitude of the diffusion coefficients of these isomers decreased in this order; *cis*- and *trans*-$[Co(NO_2)_2(NH_3)_4]^+$ > *cis*- and *trans*-$[CoCl(NO_2)(en)_2]^+$ > *cis*- and *trans*-$[Co(NO_2)_2(en)_2]^+$ > *cis*- and *trans*-$[Co(NCS)(NO_2)(en)_2]^+$. According to the Stokes-Einstein equation, a diffusion coefficient increases with a decrease in the ion size. Since the size of the complex depends on that of the ligand, the magnitude of the diffusion coefficient reflects the bulkiness of the ligand.

An examination of Table 1 shows that the half-wave potentials for the first wave of the complex containing negative groups in two of the coordination positions and neutral groups in the other four are more positive for the *cis* isomer than for the corresponding *trans* isomer. This tendency is in good agreement with the earlier polarographic observation which dealt with *cis* and *trans* isomers of cobalt(III).[2] The order of the half-wave potential in the series of isomers is: *cis*- and *trans*-$[CoCl(NO_2)(en)_2]^+$ > *cis*- and *trans*-$[Co(NCS)(NO_2)(en)_2]^+$ > *cis*- and *trans*-$[Co(NO_2)_2(NH_3)_4]^+$ > *cis*- and *trans*-$[Co(NO_2)_2(en)_2]^+$. This may be attributed to the electronegativity of the ligand.

The specific rate constant, k_c°, of the *cis* complex which contains two negative groups and four neutral groups was found to be larger than that of the symmetrical *trans* isomer. In this type of complex, a dipole exists within the coordination sphere of the *cis* form, but not in that of the symmetrical *trans* isomer. Because of the mutual electrostatic repulsion of these adjacent centers of electronegativity, the *cis* complex may be less stable than the symmetrical *trans* isomers. This may be expected to lead to faster specific rate constants for the *cis* isomer, indicating an easier reduction. The transfer coefficients of the *cis* complex in Table 1 tend to be slightly smaller than those of the corresponding *trans* isomers except for the *cis*- and *trans*-isothiocyanatonitrobis(ethylenediamine)cobalt-

Table 1. Kinetic parameters of one-electron reduction of several isomeric cobalt(III) complex ions obtained in 0.1 M acetate buffer (pH=5.0) at 25 °C

Complex ion	α	$E_{1/2}$ *vs.* SCE / V	k_c° / cm s^{-1}	D / 10^{-6} cm^2 s^{-1}
trans-$[Co(NCS)(NO_2)(en)_2]^+$	0.61	−0.129	4.86×10^{-5}	7.96

cis-$[CoCl(NO_2)(en)_2]^+$	0.52	+0.046	2.72×10^{-3}	8.21

Table 2. Kinetic parameters of one-electron reduction of several isomeric cobalt(III) complex ions obtained in 1.0 M acetate buffer (pH=5.0) at 25 °C

Complex ion	α	$E_{1/2}$ *vs.* SCE / V	k_c° / cm s^{-1}
trans-$[Co(NCS)(NO_2)(en)_2]^+$	0.65	−0.143	2.82×10^{-5}
cis-$[Co(NCS)(NO_2)(en)_2]^+$	0.72	−0.014	7.03×10^{-4}
trans-$[Co(NO_2)_2(en)_2]^+$	0.72	−0.346	6.46×10^{-8}
cis-$[Co(NO_2)_2(en)_2]^+$	0.69	−0.317	2.12×10^{-7}
trans-$[Co(NO_2)_2(NH_3)_4]^+$	0.62	−0.293	9.73×10^{-7}
cis-$[Co(NO_2)_2(NH_3)_4]^+$	0.49	−0.123	1.10×10^{-4}
trans-$[CoCl(NO_2)(en)_2]^+$	0.61	−0.085	1.40×10^{-4}
cis-$[CoCl(NO_2)(en)_2]^+$	0.53	+0.038	2.32×10^{-3}

(III) complexes. Since the thiocyanate ion is strongly adsorbed on mercury, the transfer coefficient of *cis*-$[Co(NCS)(NO_2)(en)_2]^+$ is probably larger than that of the corresponding *trans* isomer.

The effect of the ionic strength on the kinetic parameters of the electrode reaction was tested in solutions of a 1 M acetate buffer. The results are shown in Table 2. With the increase in the ionic strength, the half-wave potential shifted toward negative potentials. This would be expected for the reduction of the positive-charge complex ions in this potential region. The specific rate constant decreased slightly with the increase in the ionic strength. The effect of the ionic strength on the rate constant may be estimated by means of Frumkin's equation as a first approximation:[16]

$$k_c^\circ = (k_c^\circ)_t \exp[(\alpha n - z)\boldsymbol{F}\phi/\boldsymbol{R}T], \quad (5)$$

where $(k_c^\circ)_t$ is a true cathodic rate constant at $E=0$; z, the ionic charge of the reactant, and ϕ, the double-layer potential. In this work, the value of $(\alpha n - z)$ is negative, as may be seen from Table 1. The double-layer potential of acetate salt has a small negative value in this potential region and decreases with the decrease in the ionic strength;[17] this may cause the slight increase in the rate constant with the decrease in the ionic strength.

It is difficult to compare the electrochemical kinetic parameters obtained in this work with those reported in the literature since the experimental conditions are quite different and only few data have been reported. Inoue and Imai[4] have determined the kinetic parameters for the reduction of *trans*- and *cis*-$[Co(NO_2)_2(NH_3)_4]^+$ at the DME in 1 M $NaNO_2$: the values are $k_c^\circ = 2.9\times10^{-3}$ cm s^{-1}; $\alpha=0.65$ for *trans*-$[Co(NO_2)_2(NH_3)_4]^+$ and $k_c^\circ = 7.1\times10^{-2}$ cm s^{-1}; $\alpha=0.58$ for *cis*-$[Co(NO_2)_2(NH_3)_4]^+$ at 25 °C. Vlček[5] has also reported the kinetic parameters of the same complex in 0.14 M $HClO_4$+1.26 M $NaClO_4$: $k_c^\circ/\sqrt{D} = 1.9\times10^{-4}$ s$^{-1/2}$; $\alpha=0.6$ for *trans*-$[Co(NO_2)_2(NH_3)_4]^+$ and $k_c^\circ/\sqrt{D} = 2.3\times10^{-2}$ s$^{-1/2}$; $\alpha=0.54$ for *cis*-$[Co(NO_2)_2(NH_3)_4]^+$.

The authors wish to express their deep thanks to Prof. Yu Yokoyama of the Technological University of Nagaoka and also to Prof. Nobuyuki Tanaka and to Dr. Yoshikiyo Kato of Tohoku University for their encouragement. This work was supported by Grant-in-Aid for Scientific Research No. 364205 from the Ministry of Education, Science and Culture.

Structure and Properties of Dichloro(L-proline)cadmium(II) Hydrate

Yasuhiko YUKAWA,* Yoshie INOMATA, and Toshio TAKEUCHI

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho, Chiyoda-ku, Tokyo 102

(Received December 8, 1982)

An X-ray diffraction study of the title complex has been carried out. The crystal is orthorhombic, with the space group $P2_12_12_1$; $Z=4$, $a=10.021(3)$, $b=13.562(4)$, $c=7.298(3)$ Å. Block-diagonal least-squares refinements have led to the final R value of 0.035. The structure is very similar to that of dichloro(4-hydroxy-L-proline)cadmium(II), which has a one-dimensional polymer bridged by chlorine atoms and a carboxyl group like an infinite folding screen. The thermal behavior is, however, different from that of dichloro(4-hydroxy-L-proline)cadmium(II). The difference is likely to be due to a difference of the crystal structure, whether it contains intermolecular hydrogen bonds or not.

Amino acids such as 4-hydroxy-L-proline (Hhpro) and proline (Hpro), which have a pyrrolidine ring, are important to biochemists who investigate the constitution and configuration of proteins. There are few studies, however, about metal complexes with Hhpro and Hpro. The crystal and molecular structure of $CdCl_2$(Hhpro) was previously determined in order to investigate how Hhpro coordinates to the metal.[1]

In this work, the complex with Hpro was prepared and characterized, including the determination of its structure. These results were compared with those from $CdCl_2$(Hhpro).

Experimental

Preparation of Dichloro(L-proline)cadmium(II) Hydrate; *$CdCl_2$-(Hpro)·H_2O.* The complex was prepared in almost the same way as used for $CdCl_2$(Hhpro);[1] equimolar amounts of $CdCl_2\cdot 2.5H_2O$ and Hpro were mixed in aqueous solution, and the solution was adjusted to pH 4 with *ca.* 2 mol dm^{-3} HCl. All chemicals used were reagent grade. The obtained colorless prisms were air-dried.

Found: C, 18.91; H, 3.01; N, 4.58; Cl, 22.45; Cd, 35.4%. Calcd for $CdCl_2(C_5H_9NO_2)\cdot H_2O$: C, 18.98; H, 3.50; N, 4.43; Cl, 22.41; Cd, 35.52%.

X-Ray Measurements. The crystal data are given in Table 1.

The crystal for data collection was shaped into a sphere ($\phi=0.34$ mm) and covered by cyanoacrylate resin to prevent the loss of H_2O from the crystal. The reflections were collected by the ω-2θ scan technique ($2\theta<65°$) on a Philips PW 1100 automated four-circle diffractometer, using Mo $K\alpha$ radiation (0.7107 Å). The 1464 independent reflections with $|F_o|>3\sigma(|F_o|)$ were used for the structure refinement. The intensities were corrected for Lorentz and polarization factors, but no correction was made for the absorption because of the low magnitude of μr ($=0.45$). All the calculations were carried out on a HITAC M-200H computer at the Computer Center of the University of Tokyo, using the local version of UNICS.[2] The atomic scattering factors were taken from tables.[3]

Table 1. Crystal data

$CdCl_2(C_5H_9NO_2)\cdot H_2O$	F.W. = 316.45
Orthorhombic	Space group $P2_12_12_1$
$a=10.021(3)$ Å	
$b=13.562(4)$ Å	
$c=7.298(3)$ Å	
$Z=4$	$U=991.8(6)$ Å^3
$D_m=2.13$ g cm^{-3}	$D_x=2.12$ g cm^{-3}
μ(Mo $K\alpha$) = 26.7 cm^{-1}	

Structure Determination. The structure was solved by a heavy-atom method. The positions of the cadmium atom and chlorine atoms were obtained from a three-dimensional Patterson function, while the positions of all the other non-hydrogen atoms were successively located by Fourier syntheses. Since the positions of only a few hydrogen atoms were obtained by a difference-Fourier syntheses, all of the positions were calculated and fixed. Their isotropic temperature factors were all assumed to be 5.0 Å^2. Since the absolute configuration of Hpro was known, the structure analysis was based on this configuration.

All other positions and thermal parameters were refined by a repeated block-diagonal least-squares method. The weighting scheme was $W=1/[\{\sigma(|F_o|)\}^2+(0.04\times|F_o|)^2]$. In the last cycle of the refinement with anisotropic temperature factors for all non-hydrogen atoms, all the parameter shifts were less than one-third of the corresponding standard deviations. The final R value ($R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$) was 0.035.

The Other Measurements. The simultaneous thermogravimetric (TG) and differential thermal (DTA) analyses were carried out with a Rigaku Denki "Thermoflex" M-8075 using a sample weighing about 10 mg in each operation; the heating rate was 5 °C min^{-1} in air and α-alumina was used as the reference.

The infrared spectra of the samples were obtained by means of a Hitachi EPI-G2 infrared spectrophotometer, using Nujol and hexachloro-1,3-butadiene mull, and KBr disks.

Results and Discussion

The final atomic parameters are listed in Table 2,[4] the interatomic distances in Table 3, and the bond angles in Table 4. The perspective drawing of the complex and the numbering scheme of the atoms are shown in Fig. 1.

The complex has a very similar structure to that of $CdCl_2$(Hhpro); it consists of a one-dimensional polymer bridged by chlorine atoms and carboxyl oxygen atoms. The four chlorine atoms which coordinate to a cadmium atom are almost on a plane; the deviations of these atoms from the calculated best plane are shown in Table 5. The planes extended zigzag in the direction of the c axis like an infinite folding screen, sharing opposite edges. The dihedral angle between adjacent planes is 146°. From the trough positions in the zigzag folding structure, the two carboxyl oxygen atoms of Hpro coordinate to the two cadmium atoms. All the angles around the cadmium

TABLE 2. FINAL POSITIONAL PARAMETERS ($\times 10^4$ FOR NON-HYDROGEN ATOMS; $\times 10^3$ FOR HYDROGEN ATOMS) AND EQUIVALENT ISOTROPIC TEMPERATURE FACTORS (B_{eq}/Å^2),[a] WITH THE ESTIMATED STANDARD DEVIATIONS

a) The equivalent isotropic temperature factors for non-hydrogen atoms were computed using the following expression: $B_{eq}=4/3(B_{11}a^2+B_{22}b^2+B_{33}c^2+B_{12}ab\cos\gamma+B_{13}ac\cos\beta+B_{23}bc\cos\alpha)$. The B_{ij}'s are defined by: $\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2klB_{23}+2hlB_{13}+2hkB_{12})]$. b) The numbering scheme of hydrogen atoms is based on the number of the atom attached to the hydrogen atom.

TABLE 3. INTERATOMIC DISTANCES WITH THE ESTIMATED STANDARD DEVIATIONS IN PARENTHESES

Interatomic distance	l/Å	Interatomic distance	l/Å
Cd-Cd^{I}	3.650(3)	C(1)-C(2)	1.528(10)
		C(2)-N	1.477(11)

Key to symmetry operations in this table and subsequent tables: I. $0.5-x$, $-y$, $0.5+z$; II. $0.5-x$, $-y$, $-0.5+z$; III. x, y, $-1.0+z$.

atom with four chlorine atoms and two carboxyl oxygen atoms are approximately 90°. The average bond distance of Cd–Cl is 2.61 Å, and that of Cd–O is 2.32 Å. Thus the cadmium atom has octahedral coordination. The bond distance of Cd–Cl and the angle of Cd–Cl–Cd (=88°) are comparable with those of $CdCl_2(biuret)_2$, which consists of an infinite linear ribbon of $CdCl_2$: Cd–Cl, 2.55(1), 2.62(1) Å; Cd–Cl–Cd, 91.5(3)°.[5] The ligand is a zwitter ion in the complex.

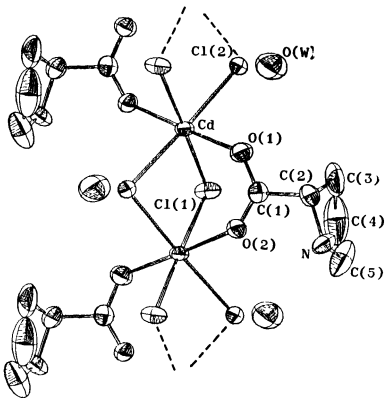

Fig. 1. The perspective drawing of $CdCl_2(Hpro)\cdot H_2O$ and the numbering scheme of non-hydrogen atoms.

In $CdCl_2(Hhpro)$, there are intermolecular hydrogen bonds between the nitrogen atom in the pyrrolidine ring and the hydroxyl oxygen atom. In contrast, $CdCl_2(Hpro)\cdot H_2O$ does not contain any intermolecular hydrogen bonds. Thus the pyrrolidine ring is not fixed and the positions far from the coordination atoms in Hpro have rather large temperature factors. Therefore, the calculated bond lengths of C(3)–C(4) (1.479(20) Å) and C(4)–C(5) (1.468(19) Å) are slightly shorter than the normal C–C bond length. A water molecule is connected to the nitrogen atom in the pyrrolidine ring by hydrogen bonding, instead of by intermolecular hydrogen bonds.

On coordination, the pyrrolidine ring in Hpro is bent on the line from N to C(3), and C(4) and C(5) atoms deviate from the best-plane of the pyrrolidine ring. The intramolecular hydrogen bond exists between N and O(2).

The projections of $CdCl_2(Hpro)\cdot H_2O$ along the c axis and of $CdCl_2(Hhpro)$ along the b axis are given in Fig. 2. In both cases, the zigzag folding screen is parallel to 2_1 axis. In $CdCl_2(Hhpro)$ it is connected with the neighboring one by hydrogen bonds between the nitrogen atom in the pyrrolidine ring and the hydroxyl oxygen atom; a sheet forms parallel to the (101) plane. In $CdCl_2(Hpro)\cdot H_2O$, there are no such hydrogen bonds and individual zigzag folding

X, Y, and Z are coordinates expressed by the following equation:

$$\begin{pmatrix} X \\ Y \\ Z \end{pmatrix} = \begin{pmatrix} a & b\cos\gamma & c\cos\beta \\ 0 & b\sin\gamma & -c\cos\alpha^* \sin\beta \\ 0 & 0 & c\sin\alpha^* \sin\beta \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix}.$$

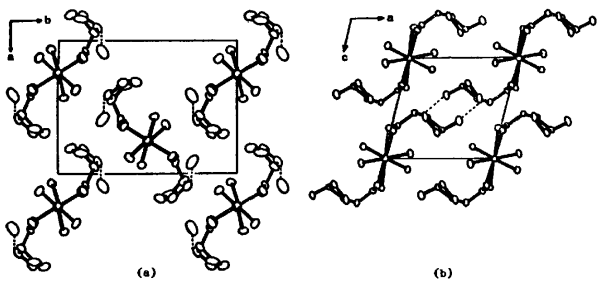

Fig. 2. The projection of (a) $CdCl_2(Hpro)\cdot H_2O$ along the c axis and (b) $CdCl_2(Hhpro)$ along the b axis. (----: Hydrogen bonding)

screens are bundled only by van der Waals' contacts.

The infrared spectra of the free ligand, the deuterated ligand, $CdCl_2(Hpro)\cdot H_2O$, and the deuterated complex are shown in Fig. 3. The deuterated compounds were obtained by recrystallization from 99.75% D_2O. It was already confirmed that the free ligand is a zwitter ion.[6] According to Herlinger and Long,[7] the peaks at 3050 and 1555 cm^{-1} are assigned to NH stretching vibration and NH_2^+ scissors vibration, respectively. The antisymmetric and symmetric stretching vibrations of COO^- are observed at 1619 and 1402 cm^{-1}, respectively. In $CdCl_2(Hpro)\cdot H_2O$, the peak at 3550 cm^{-1} is assigned to the OH stretching vibration of H_2O. Although there is a peak at 3180 cm^{-1} corresponding to the NH stretching vibration, the peak of NH_2^+ scissors vibration can not be assigned because it overlaps with the peaks of H_2O bending and COO^- antisymmetric stretching vibrations. To discuss the carboxyl stretching vibrations, the deuteration of NH_2^+ and H_2O is required since the peak near 1600 cm^{-1} (COO^- antisymmetric stretching) is probably coupled to NH_2^+ modes in Hpro;[7] there are also overlapping NH_2^+ bending and H_2O scissors vibrations[8,9] in $CdCl_2(Hpro)\cdot H_2O$, as mentioned above.

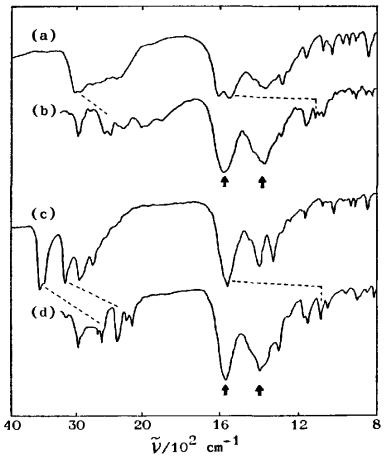

Fig. 3. Infrared spectra of (a) Hpro, (b) the deuterated ligand, (c) $CdCl_2(Hpro)\cdot H_2O$, and (d) the deuterated complex. The shifts of the peaks by deuteration are indicated by the dotted lines. The arrows indicate the peaks of COO^- antisymmetric (left) and symmetric (right) stretching vibrations.

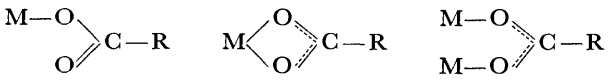
The carboxylate ion may coordinate to a metal in one of the following modes:



(I) (II) (III)

In the unidentate complex (structure (I)), the separation between COO^- anti- and symmetric stretching vibrations is much larger than that of the free ion, while it is smaller than that of the free ion in structure (II). In the bridging complex (structure (III)), however, two COO^- stretching vibrations are close to the free ion values.[10] In the present case, this separation evaluated from the deuteration spectrum is 180 cm^{-1}, and the separation for the free ligand is 185 cm^{-1}. This accords with the trend in the structure (III). The trend is also observed in $CdCl_2(Hhpro)$. Thus the trends in the carboxylate ion are likely to be observed in the amino acids which have a pyrrolidine ring.

The results of the simultaneous TG and DTA of $CdCl_2(Hpro)\cdot H_2O$ and of $CdCl_2(Hhpro)$ are shown in Fig. 4. In the former, an endothermic peak on the DTA with a mass loss corresponding to one water molecule is observed at about 80 °C. At about 180 and 210 °C, endothermic peaks on the DTA without mass loss are observed. The complex seems to become an amorphous state; this was confirmed from the X-ray powder pattern. It then melts at 210 °C. At about 230 °C the ligand is thought to decompose and the complex changes into cadmium chloride. About 35% mass loss occurs in the region 230—300 °C. Moreover, from 410 °C about 60% mass loss begins and becomes constant at about 800 °C, where no residue is obtained. Therefore in the region cadmium chloride changes into cadmium oxide and then it is sublimed.[11] The observation of an endothermic peak at 560 °C may indicate that cadmium chloride melts.[12]

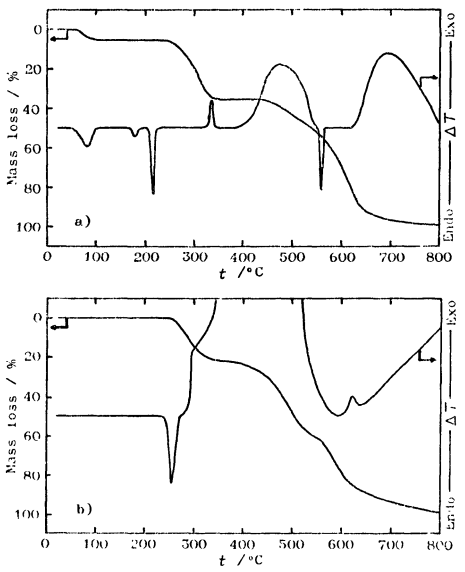


Fig. 4. Thermogravimetric and differential thermal analysis curves of a) $CdCl_2(Hpro)\cdot H_2O$ and b) $CdCl_2$-(Hhpro).

This thermal behavior is not observed in $CdCl_2$-(Hhpro); the DTA curve shows only an endothermic peak at about 210 °C and the complex burns with a gradual mass loss. This difference of the behavior between $CdCl_2(Hhpro)$ and $CdCl_2(Hpro)\cdot H_2O$ is thought to be due to the difference of the crystal structure, whether it contains intermolecular hydrogen bonds which connect with the neighboring zigzag folding screen or not.

The authors wish to express their thanks to Professor Yoichi Iitaka for the X-ray diffractometer measurements, and to Dr. Shoichi Sato and Dr. Shin-ichi Nishikiori, The University of Tokyo, for helpful discussions. They would also like to thank Dr. F. S. Howell of Sophia University for correcting this manuscript. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 57430011 from the Ministry of Education, Science and Culture.

Complex Formation between Molybdate and Alizarin Red S

Takanori KATO and Teisuke MURAYAMA*

Department of Industrial Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu 432

(Received December 24, 1982)

The complex formation between molybdate and Alizarin Red S (ARS) has been studied by spectrophotometry and pH titration. Results by the former method confirm that the composition of the complexes formed corresponds to a ratio of 1:1 for molybdate to ARS and that the complexes are stable between pH 2 to 6. Those by the latter are summarized by the following stability constants at 25 °C and an ionic strength of 0.1: $MoO_4^{2-} + ars^{3-} + 2H^+ = MoO_3ars^{3-} + H_2O$, $\log(\beta_1/mol^{-3}\,L^3) = 20.18 \pm 0.01$; $MoO_4^{2-} + ars^{3-} + 3H^+ = MoO_3(Hars)^{2-} + H_2O$, $\log(\beta_2/mol^{-4}\,L^4) = 24.93 \pm 0.04$ (the completely deprotonated species of ARS is denoted by ars^{3-}, and the concentration of H_2O is not included in the definition of stability constants). Protonation constants of MoO_4^{2-} and ars^{3-} were also determined under the same conditions.

Nearly three decades ago, Nazarchuk[1] observed the formation of a complex between molybdate and Alizarin Red S (9,10-dihydro-3,4-dihydroxy-9,10-dioxo-2-anthracenesulfonic acid monosodium salt, abbreviated to ARS) at pH 2—5, and used for colorimetric determinations of molybdenum. He considered that the composition of the complex was 1:1. However, Dey *et al.*,[2] Ishibashi *et al.*,[3] and Csanyi[4] reported it as 1:2. Krizan and Nozaki[5] wrote it as 1:1. Although these authors all have used spectrophotometry and conditions employed for the measurements are not so different each other (except Krizan and Nozaki who used 1:1 ethanol–water mixture as solvent), their conclusions are not in harmony. The present investigation aimed at determining the composition of the complex and its stability constant. We have used pH titration in conjunction with a spectrophotometric method, and found the formation of, instead of one, two complexes, one protonated and another unprotonated both with the composition corresponding to a ratio of 1:1 for molybdate to ARS.

Experimental

All chemicals used were of guaranteed reagent grade. Solutions were prepared with usual precautions, and the ionic strength was controlled to 0.1 with sodium nitrate. Sodium molybdate was used as a source of the molybdate ion.

Absorption spectra were recorded with a HITACHI UV-VIS spectrophotometer Model 200-10 and 10-mm quartz cells. A glass electrode (TOA HGS-2005) and a reference electrode (TOA HS-205S) were used with a TOA pH-meter Model HM-20E for pH titrations, and nitrogen was bubbled through the solution to exclude carbon dioxide. All measurements were made at 25.0 °C.

The refinement of equilibrium constants was carried out by a SHARP personal computer PC-3200.

Results and Discussion

Determination of the Composition of the Complex by Spectrophotometry. Figure 1 shows absorption spectra of ARS and its mixture with sodium molybdate at pH 4.00. An absorption maximum of ARS at 420 nm shifts to longer wavelengths on the complex formation with molybdate which is transparent in the visible region. A continuous variation curve at this pH and 475 nm indicates that the composition of the complex or complexes formed was 1:1, though it has

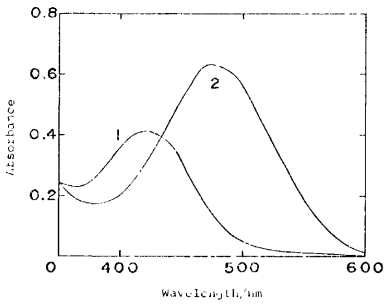

Fig. 1. Absorption spectra of ARS in the absence and presence of sodium molybdate. Concentration of ARS, 8.0×10^{-5} mol/L; pH 4.00. Concentration of sodium molybdate: curve 1, 0 mol/L; curve 2, 17.6×10^{-5} mol/L.

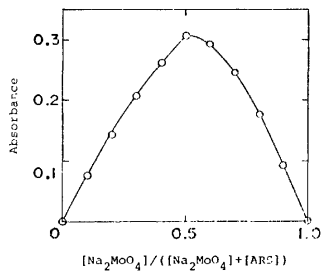

Fig. 2. Continuous variation curve for sodium molybdate and ARS mixture at 475 nm. Total concentration, 1.00×10^{-4} mol/L; pH 4.00.

a slight distortion (Fig. 2). The same conclusion was drawn from measurements at other pH's. The pH dependence of the ordinate of the continuous variation curve at the 1:1 composition is given by curve 1 in Fig. 3. The curve illustrates that the complex or complexes formed in a range of pH 2—6, and that they became unstable at outside of these limits. These facts are in accord with results reported by previous authors.[1-5]

Determination of Protonation Constants of MoO_4^{2-} by pH Titration. Measurements were carried out by titrating dilute mixtures of sodium molybdate and nitric acid with a sodium hydroxide solution. The protonation of MoO_4^{2-} proceeds through following two steps:

$$H^+ + MoO_4^{2-} = HMoO_4^- \quad K_1^M = \frac{[HMoO_4^-]}{[H^+][MoO_4^{2-}]}, \quad (1)$$

TABLE 1. PROTONATION CONSTANTS OF MoO_4^{2-} AND ars^{3-}, AND STABILITY CONSTANTS OF THEIR COMPLEXES IN 0.1 mol L^{-1} $NaNO_3$ SOLUTION AT 25 °C

Protonation constant

$\log \frac{K_1^M}{mol^{-1}\,L}$ 3.77±0.02	$\log \frac{K_2^M}{mol^{-1}\,L}$ 2.35±0.16	$\log \frac{K_{78}^M}{mol^{-14}\,L^{14}}$ 53.00±0.05
$\log \frac{K_1^L}{mol^{-1}\,L}$ 10.34±0.02	$\log \frac{K_2^L}{mol^{-1}\,L}$ 5.66±0.01	$\log \frac{K_3^L}{mol^{-1}\,L}$ 2.12±0.07

Stability constant

$\log \frac{\beta_1}{mol^{-3}\,L^3}$ 20.18±0.01	$\log \frac{\beta_2}{mol^{-4}\,L^4}$ 24.93±0.04

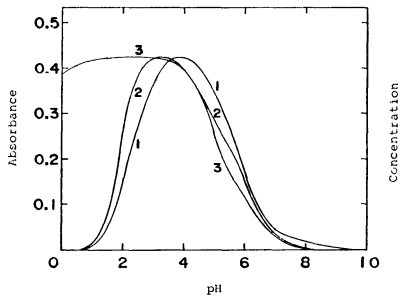

Fig. 3. pH dependence of the absorbance of the continuous variation curve for sodium molybdate and ARS mixture at the 1 : 1 composition. Wavelength, 475 nm; concentration of sodium molybdate, 8.0×10^{-5} mol/L; concentration of ARS, 8.0×10^{-5} mol/L. Curve 1, observed pH dependence of the absorbance; curve 2, $[MoO_3ars^{3-}]+[MoO_3(Hars)^{2-}]$; curve 3, $[MoO_3ars^{3-}]+[MoO_2ars^-]$. The concentration curves were drawn on arbitrary scales to make their highest points on equal level with the highest point of the absorbance curve.

and

$$H^+ + HMoO_4^- = H_2MoO_4 \qquad K_2^M = \frac{[H_2MoO_4]}{[H^+][HMoO_4^-]}, \tag{2}$$

where [X] is the concentration of species X in mol/L. Besides, molybdate ion in acidified solutions is known to produce many kinds of isopolyanions.[6] Under the experimental conditions adopted in this study, an assumption of the formation of heptamolybdate ion, $Mo_7O_{24}^{6-}$, is sufficient to explain titration curves.

$$8H^+ + 7MoO_4^{2-} = Mo_7O_{24}^{6-} + 4H_2O$$

$$K_{78}^M = \frac{[Mo_7O_{24}^{6-}]}{[H^+]^8[MoO_4^{2-}]^7}. \tag{3}$$

Protonation constants were calculated by the method for two-pK systems by Briggs and Stuehr[7] with some modifications for the formation of heptamolybdate ion. Instead of Eq. 9 in their paper, the computation was carried out by using the equation

$$\frac{(1+K_1^M[H^+]+7K_{78}^M[H^+]^8[MoO_4^{2-}]^6)(V+R-\Delta V)}{2+K_1^M[H^+]+6K_{78}^M[H^+]^8[MoO_4^{2-}]^6} = -\frac{K_1^M[H^+]^2(V+R-\Delta V)}{2+K_1^M[H^+]+6K_{78}^M[H^+]^8[MoO_4^{2-}]^6}K_2^M + V_e, \tag{4}$$

where

$$R = ([H^+]-[OH^-])V_t/C_B, \tag{5}$$

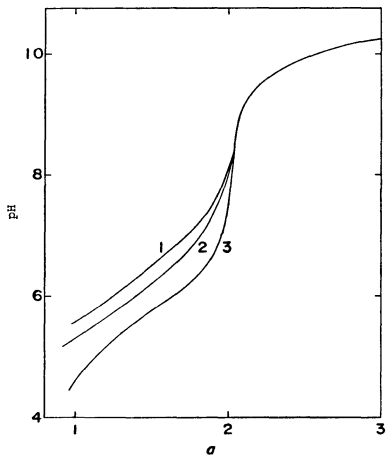

Fig. 4. Titration curves of ARS in the absence and presence of sodium molybdate. Concentration of ARS, 4.90×10^{-4} mol/L. Concentration of sodium molybdate: curve 1, 5.33×10^{-4} mol/L; curve 2, 2.67×10^{-4} mol/L; curve 3, 0 mol/L. The abscissa *a* is the ratio of the volume of sodium hydroxide solution added to the theoretical volume of the base per proton required to neutralize the acid H_3ars.

and C_B is the concentration of sodium hydroxide in the titrating solution, V is the volume of the base added, V_t is the total volume of the solution titrated, V_e is the theoretical volume of the base per proton required to neutralize the acid H_2MoO_4, and ΔV is the volume of the base neutralized by any strong acid present in the solution at the beginning of the titration. Protonation constants obtained are given in Table 1.

Determination of Protonation Constants of ARS by pH Titration. Curve 3 in Fig. 4 is a titration curve of ARS in the absence of the molybdate. The protonation of ARS consists of following three steps:

$$H^+ + ars^{3-} = Hars^{2-} \qquad K_1^L = \frac{[Hars^{2-}]}{[H^+][ars^{3-}]}, \tag{6}$$

$$H^+ + Hars^{2-} = H_2ars^- \qquad K_2^L = \frac{[H_2ars^-]}{[H^+][Hars^{2-}]}, \tag{7}$$

and

$$H^+ + H_2ars^- = H_3ars \qquad K_3^L = \frac{[H_3ars]}{[H^+][H_2ars^-]}. \tag{8}$$

In the above, ars^{3-} represents the completely deprotonated species of ARS with three negative charges.

Protonation constants were calculated by the method for three-pK systems.[7] The constants obtained are

shown in Table 1.

Identification of the Complex Species Formed and Determination of Their Stability Constants by pH Titration. Figure 4 shows titration curves of ARS in the presence and absence of the molybdate. Titration curves in the presence of the molybdate lie above the curve in the absence of the molybdate in the lower pH range and coincide with it in the upper range. Titration curves of this kind represent the formation of the ester between participating species, *i.e.* molybdate and ARS. The corresponding formation reaction of the complex consumes protons and thereby increases pH of the solution.

Conditions of the 1:1 composition and of the instability in acid solutions limit possible complex species to ones whose formation reactions are given by

$$MoO_4^{2-} + ars^{3-} + mH^+ = MoO_{4-n}(H_{m-2n}ars)^{(5-m)-} + nH_2O, \quad (9)$$

where $5>m\geqslant 2n>0$. This restriction leaves only three candidate complexes to be considered: MoO_3ars^{3-}, $MoO_3(Hars)^{2-}$, and MoO_2ars^-. Formation reactions of these complexes are

$$MoO_4^{2-} + ars^{3-} + 2H^+ = MoO_3ars^{3-} + H_2O, \quad (10)$$

$$MoO_4^{2-} + ars^{3-} + 3H^+ = MoO_3(Hars)^{2-} + H_2O, \quad (11)$$

and

$$MoO_4^{2-} + ars^{3-} + 4H^+ = MoO_2ars^- + 2H_2O. \quad (12)$$

Stability constants are defined as follows:

$$\beta_1 = \frac{[MoO_3ars^{3-}]}{[MoO_4^{2-}][ars^{3-}][H^+]^2}, \quad (13)$$

$$\beta_2 = \frac{[MoO_3(Hars)^{2-}]}{[MoO_4^{2-}][ars^{3-}][H^+]^3}, \quad (14)$$

and

$$\beta_3 = \frac{[MoO_2ars^-]}{[MoO_4^{2-}][ars^{3-}][H^+]^4}. \quad (15)$$

As shown in Fig. 4, the titration of ARS in the presence of the molybdate was carried out at above pH 5, where the atomic ratio of molybdenum of the heptamolybdate to the total molybdenum was below 10^{-5}. Hence the concentration of heptamolybdate ions is ignored in the following derivation of equations.

Total concentrations of the molybdate, ARS, and dissociable hydrogen ions are respectively given as follows:

$$M_t = [MoO_4^{2-}] + [HMoO_4^-] + [H_2MoO_4] + [MoO_3ars^{3-}] + [MoO_3(Hars)^{2-}] + [MoO_2ars^-], \quad (16)$$

$$L_t = [ars^{3-}] + [Hars^{2-}] + [H_2ars^-] + [H_3ars] + [MoO_3ars^{3-}] + [MoO_3(Hars)^{2-}] + [MoO_2ars^-], \quad (17)$$

and

$$H_t = [H^+] - [OH^-] + [HMoO_4^-] + 2[H_2MoO_4] + [Hars^{2-}] + 2[H_2ars^-] + 3[H_3ars] + 2[MoO_3ars^{3-}] + 3[MoO_3(Hars)^{2-}] + 4[MoO_2ars^-]. \quad (18)$$

Combination of these equations and equilibrium constants results Eqs. 19 and 20:

$$f_1f_5[MoO_4^{2-}]^2 + (f_2f_3-f_1f_4-f_5f_6)[MoO_4^{2-}] + (f_4f_6-f_3f_7) = 0, \quad (19)$$

and

$$(L_t-F[MoO_4^{2-}])\beta_3[H^+]^4 + \{(L_t-F[MoO_4^{2-}])\beta_2-K_1^LK_2^LK_3^LF\}[H^+]^3 + \{(L_t-F[MoO_4^{2-}])\beta_1-K_1^LK_2^LF\}[H^+]^2 - K_1^LF[H^+] - F = 0, \quad (20)$$

where

$$f_1 = 1 + K_1^M[H^+] + K_1^MK_2^M[H^+]^2, \quad (21)$$

$$f_2 = 4 + 3K_1^M[H^+] + 2K_1^MK_2^M[H^+]^2, \quad (22)$$

$$f_3 = 1 + K_1^L[H^+] + K_1^LK_2^L[H^+]^2 + K_1^LK_2^LK_3^L[H^+]^3, \quad (23)$$

$$f_4 = K_1^L[H^+] + 2K_1^LK_2^L[H^+]^2 + 3K_1^LK_2^LK_3^L[H^+]^3, \quad (24)$$

$$f_5 = 2\beta_1[H^+]^2 + \beta_2[H^+]^3, \quad (25)$$

$$f_6 = M_t - L_t, \quad (26)$$

$$f_7 = 4M_t - H_t + [H^+] - [OH^-], \quad (27)$$

and

$$F = M_t/[MoO_4^{2-}] - f_1. \quad (28)$$

The procedure for obtaining a set of the best values of stability constants involves the following steps:

(1) Estimate β_1, β_2, and β_3.
(2) Calculate f_i's for data points in the appropriate pH region using the estimates of stability constants and the values of other equilibrium constants.
(3) Solve Eq. 19 for $[MoO_4^{2-}]$, and calculate F.
(4) Solve Eq. 20 for $[H^+]$.
(5) Convert $[H^+]$ to pH, and find the standard error of estimate from the experimental and calculated pH values.
(6) Vary β_3 by small amounts, and repeat steps 4—5 until a minimum in the standard error of estimate is obtained.
(7) Repeat steps 2—6 using new estimates of β_2 until the smallest standard error of estimate is found.
(8) Repeat steps 2—7 using new estimates of β_1 until the lowest standard error of estimate of pH is gotten. A set of values of β_1, β_2, and β_3 which yields the lowest standard error of estimate is chosen as the most probable set of values.

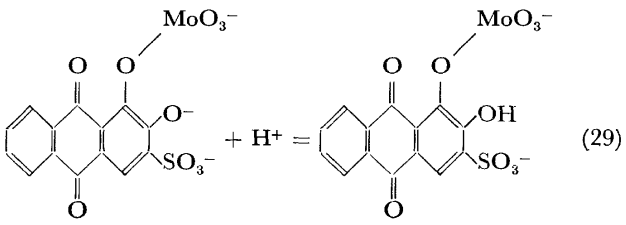
Although it is possible to compute the three stability constants with the above method by adopting the three-complex-species (*i.e.* MoO_3ars^{3-}–$MoO_3(Hars)^{2-}$–MoO_2ars^-) model, this is not the best way to explain titration curves. This unnecessarily increases the number of new species, which must be a minimum indispensable.

Three one-complex-species models were tried at first. However they failed to reproduce titration curves. Two of two-complex-species models were equally successful to reproduce the curves. These are the MoO_3ars^{3-}–$MoO_3(Hars)^{2-}$ and MoO_3ars^{3-}–MoO_2ars^- models. The concentrations of respective complex species were calculated as functions of pH by using resulted values of stability constants, and examined whether they were in accord with observed results illustrated by curve 1 in Fig. 3 or not. Curves 2 and 3 in this figure are, respectively, the sum of concentrations of MoO_3ars^{3-} and $MoO_3(Hars)^{2-}$, and the sum of con-

centrations of MoO_3ars^{3-} and MoO_2ars^-. If the difference of molar absorption coefficient between different species is taken into account, the discrepancy between curve 1 (absorbance) and curve 2 (sum of the concentrations) is explicable, but the one between curve 1 and curve 3 (sum of the concentrations) is not. Hence, the MoO_3ars^{3-}–$MoO_3(Hars)^{2-}$ model is acceptable, but the MoO_3ars^{3-}–MoO_2ars^- model is not.

Values of stability constants of MoO_3ars^{3-} and $MoO_3(Hars)^{2-}$ in Table 1 are ones based on the MoO_3ars^{3-}–$MoO_3(Hars)^{2-}$ model. Dey *et al.* reported two values of 9.5[2b] and 9.2[2c] for logarithm of the stability constant of the 1:2 complex at pH 3.5. Csanyi gave a value of 7.7 for the same constant at pH 3.8.[4] Krizan and Nozaki reported a value of 5.4 for the logarithmic constant of the 1:1 complex at pH 5.[5] These are all apparent constants, however. Hence it is not profitable to compare these with the values in Table 1.

It seems natural that the ester formation takes place at a site where the protonation occurs most easily in free ars^{3-}. Yampol'skii *et al.*[8] stated that the protonation in ars^{3-} occurs at the anionic 1-O at first. Therefore the MoO_3 group is concented to ARS through the 1-O in MoO_3ars^{3-}. The protonation of this complex is given by



(29)

and the protonation constant was calculated to be $10^{4.75}$ mol^{-1} L from values shown in Table 1. This value is about an eighth of K_2^L, the corresponding protonation constant of uncomplexes $Hars^{2-}$. The decrease of the protonation constant is a reflection of the difficulty of proton's arriving at the anionic 2-O due to the overcrowding around the O-atom by complexation with the MoO_3 group at the 1-O.

Determination of Diffusion Coefficients of Metals Dissolved in Mercury by Double Potential Step Chronoamperometry at Hanging Mercury Drop Electrodes

Sang Yun PARK,† Koichi AOKI, Koichi TOKUDA, and Hiroaki MATSUDA*

Department of Electronic Chemistry, Graduate School at Nagatsuta, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokahama 227

(Received January 31, 1983)

Double potential step chronoamperometry at the hanging mercury drop electrode is proposed for determination of diffusion coefficients of metals dissolved in mercury. The expression for chronoamperometric curves is obtained, from which the algorithm is derived for evaluating diffusion coefficients of metals. The diffusion coefficients of lead, zinc, and cadmium in mercury at 25 °C were determined by the present technique.

Symbols

- c_O^s Concentration of substance O at the electrode surface.
- c_R^s Concentration of substance R at the electrode surface.
- c_O^* Bulk concentration of substance O.
- D_O Diffusion coefficient of substance O.
- D_R Diffusion coefficient of substance R.

- τ Duration of the first potential step.
- γ Ratio of square root of D_R to that of D_O, defined by Eq. 9.
- ϕ Dimensionless anodic current, defined by Eq. 10.
- θ Dimensionless duration of the first potential step, defined by Eq. 8.
- ξ Dimensionless electrolysis time during the second potential step, defined by Eq. 7.

Electrochemical methods have often been applied to a study on determination of the solubility of metals and the diffusion coefficients of metal atoms in mercury.[1] A classical electrochemical method for determination of the diffusion coefficients of metals in mercury is amalgam polarography developed extensively by Furman and Cooper,[2] Stromberg,[3] and Stackelberg and Toome.[4] This method has difficulties in determining accurately the concentration of dissolved metal, especially when the amalgam is unstable. The other method is linear sweep voltammetry at a hanging mercury drop electrode (HMDE) which was proposed by Stromberg and Zakharova[5] and Baransky[6] and later investigated quantitatively by Tokuda *et al.*[7] This can be undertaken with a simple electrochemical instrument in relatively short time but this method is often subjected to complexity when the charge transfer is slow. A new technique leading to more accurate determination was introduced by Stevens and Shain,[8] which is chronoamperometry following the amalgam formation by a pre-electrolysis at the HMDE. In this method, amalgam is prepared by the long-term electroreduction of the metal ion in solution such that the concentration of metal may be uniform over the whole mercury drop. Stevens and Shain took advantages of characteristics of the spherical diffusion at the HMDE and proposed the method of plotting $It^{1/2}$ against $t^{1/2}$ so that the plots fall into a straight line, where I is the anodic current at electrolysis time, t. Fitak determined the diffusion coefficients of many metals in mercury by this method.[9] However, this method is not necessarily an extensively applicable technique because, during the pre-electrolysis, unstable amalgam may be altered in properties and further the HMDE may be influenced by unexpected fluctuations of temperature and undesirable mechanical vibrations. Therefore it is required to develop a method with a short time window.

We present here a technique of double potential step chronoamperometry at the HMDE, of which conditions are as follows: (a) The HMDE does not contain initially any foreign metal while metal ions are in the solution phase. (b) The potential of the HMDE is initially set at E_i, which is positive enough for no faradaic process to occur. (c) The potential is stepped to a sufficiently negative region corresponding to the limiting diffusion-controlled current for the reduction of the metal ions in the solution, and then switched back to E_i. (d) The duration of the cathodic electrolysis is ranged from a few seconds to some ten seconds and the subsequent anodic current is measured within one second. The equations for the double potential step chronoamperometric curves are derived and the procedures of evaluating the diffusion coefficients of metals in mercury are presented. Furthermore this method is applied to the determination of the diffusion coefficients of lead, zinc and cadmium in mercury.

Theoretical

We consider a simple electrode reaction, $O+ne \rightleftarrows R$, without any chemical complication. We assume that the limiting currents are governed by the spherical diffusion of substance O in the solution and of sub-

† Present address: The Korea Meritime University, 1, Dongsam-Dong, Yongdo-ku, Busan, Korea.

stance R in the mercury drop. This means that the shielding effect of capillary tip and the deviation of the shape of the drop from a perfect sphere are neglected. Further it is assumed that the solution initially contains only the spicies O and supporting electrolytes.

The diffusion equation within the finite spherical region has been solved and the concentrations of O and R at the electrode surface have been expressed as functions of the current density and the electrolysis time.[7]

[*A*] *First Potential Step.* Concentrations of the ion and the metal at the surface of the HMDE are given by[7]

$$c_O^s = c_O^* - (\pi D_O)^{-1/2}\int_0^t (j/nF)(t-x)^{-1/2}dx + (1/r)\int_0^t G(D_O(t-x)/r^2)(j/nF)dx, \quad (1)$$

$$c_R^s = (1/r)\int_0^t H(D_R(t-x)/r^2)(j/nF)dx, \quad (2)$$

with

$$G(x) = \exp(x)\,\mathrm{erfc}\sqrt{x} \quad (3)$$

$$H(x) = 1/\sqrt{\pi x} + \exp(x)(1+\mathrm{erf}\sqrt{x}) \quad \text{for } 0<x<0.06, \quad (4)$$

where the function $H(x)$ is the inverse Laplace transform of the asymptotic expansion for $1/(\sqrt{s}\coth\sqrt{s}-1)$. Taking c_O^s to be zero yields the well-known expression for the limiting current density controlled by spherical diffusion,[10]

$$j_c = nFc_O^*\sqrt{D_O}(1/\sqrt{\pi t}+\sqrt{D_O}/r). \quad (5)$$

This equation has been applied to determination of diffusion coefficients of several metal ions with high accuracy in the elaborate operation of the HMDE.[12,13]

[*B*] *Second Potential Step.* After the first potential step, of which duration is described as τ, the electrode potential is stepped back to E_i to make the concentration of species R effectively zero at the electrode surface, *i.e.*,

$$c_R^s = 0 \quad \text{for } t>\tau. \quad (6)$$

Substituting condition (6) into Eq. 2 and introducing the dimensionless variable, parameters and function as follows:

$$\xi = D_O(t-\tau)/r^2, \quad (7)$$

$$\theta = D_O\tau/r^2, \quad (8)$$

$$\gamma = (D_R/D_O)^{1/2}, \quad (9)$$

$$\phi(\xi) = -(j_a/nF)[\sqrt{\pi}\,r/c_O^*D_O], \quad (10)$$

then we have

$$\int_0^\xi H[\gamma^2(\xi-x)]\phi(x)dx = \int_0^\theta H[\gamma^2(\xi+\theta-x)](1/\sqrt{x}+\sqrt{\pi})dx, \quad (11)$$

where j_a is the anodic current density and $\phi(\xi)$ the dimensionless anodic current. Since it is somewhat complicated to solve the above integral equation, details of the derivation are given in Appendix. Then $\phi(\xi)$ is expressed as

$$\phi(\xi) = (1+\gamma)[2\exp(\gamma^2\theta)-G(\gamma^2\theta)][1/\gamma\sqrt{\xi}-\sqrt{\pi}\,G(\gamma^2\xi)] + (2/\sqrt{\pi})[\gamma^2(\xi+\theta)+1]\arctan\sqrt{\xi/\theta} + 2\gamma(\gamma+1)\sqrt{\theta}\,G(\gamma^2\xi) - 2\gamma(\gamma+1)\sqrt{\xi+\theta} + (2/\sqrt{\pi})\gamma^2(\gamma+1)\sqrt{\xi\theta} - 1/\sqrt{\xi+\theta} - 1/\gamma\sqrt{\xi} - 2(1+\gamma)\gamma^3\int_0^\xi(\xi+\theta-x)^{1/2}G(\gamma^2x)dx. \quad (12)$$

Equation 12 represents the current-time curve for the second potential step, with the parameters of ξ and θ given by Eqs. 7 and 8, respectively.

In Fig. 1, numerically calculated values of $\phi(\xi)\sqrt{\xi}$, which corresponds to $j_a(t-\tau)^{1/2}$, are plotted against $\sqrt{\xi}$ for $\theta=0.06$ and various values of γ. The integral involved in Eq. 12 was evaluated by Simpson's 1/3 rule. The figure shows that a difference between any two curves increases with a decrease in ξ and that every curve becomes almost a straight line as $\sqrt{\xi}$ tends to zero. Therefore extrapolation of $\phi(\xi)\sqrt{\xi}$ to $\sqrt{\xi}\to 0$ is a useful procedure for determinating D_R. The function, $\phi(\xi)\sqrt{\xi}$, can be expanded about $\sqrt{\xi}=0$, as follows:

$$\phi(\xi)\sqrt{\xi} = p + q\sqrt{\xi} + \cdots, \quad (13)$$

with

$$p = [(1+\gamma)\exp(\gamma^2\theta)(1+\mathrm{erf}(\gamma\sqrt{\theta}))-1]/\gamma, \quad (14)$$

$$q = (4/\sqrt{\pi}-2)\sqrt{\theta}\,\gamma(1+\gamma)-1/\sqrt{\theta}-2(1+\gamma) \times\exp(\gamma^2\theta)[1+\mathrm{erf}(\gamma\sqrt{\theta})]. \quad (15)$$

The parameter p is a main factor for evaluating D_R. If the value of D_O is determined from the cathodic current-time curves during the first potential step by plotting j_c against $t^{-1/2}$ and applying Eq. 5, p and q become experimentally accessible quantities. Since the radius of the HMDE, r, can readily be evaluated, θ becomes a known value. Hence it is possible to obtain γ, that is, D_R, from Eq. 14 in principle. In Fig. 2 theoretical values of p calculated from Eq. 14 are plotted against γ for several values of θ, demonstrating that the slopes of the curves increase with an increase in θ. This indicates that making longer the duration of the first potential step and/or using the HMDE with a smaller radius leads to more accurate determination of the diffusion coefficients.

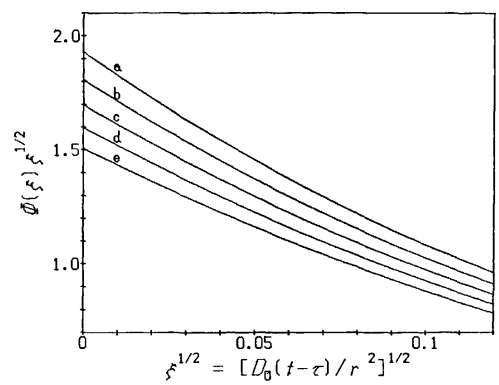

Fig. 1. Variations of $\phi(\xi)\sqrt{\xi}$ with $\sqrt{\xi}$ for $\theta=0.06$ and γ=(a) : 1.4, (b): 1.2, (c): 1.0, (d): 0.8, (e): 0.6,

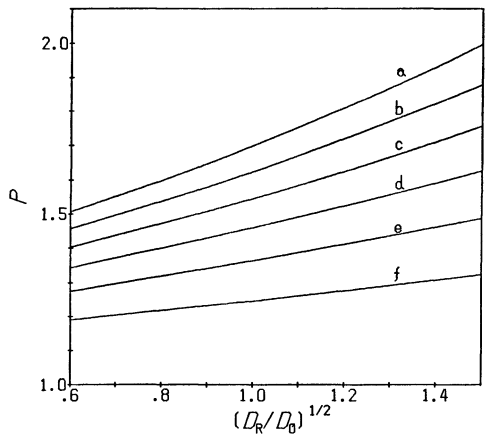

Fig. 2. Dependence of extrapolated values of $\phi(\xi)\sqrt{\xi}$ upon γ for $\theta=$(a): 0.06, (b): 0.05, (c): 0.04, (d): 0.03, (e): 0.02, (f): 0.01.

Since the curves in Fig. 1 have concave forms, extrapolating the curves from the region corresponding to large values of $\sqrt{\xi}$ may yield smaller values of γ than the true ones. We examined the extrapolation procedure of a number of theoretical curves and found that the values of γ can be obtained within 2.5% errors if values of $\sqrt{\xi}$ less than 0.03 are used for extrapolation.

It is not so convenient or elegant to use the working curves in Fig. 2 for evaluating γ from chronoamperometric data. It might be more desirable to utilize the explicit form of γ than to use Fig. 2. Unfortunately, we could not find the inverse function for p. Instead we propose the algorithm for evaluating γ with reasonably high accuracy by Newton-Raphson's method as follows:

$$\gamma_{k+1} = \gamma_k - \frac{[(1+\gamma_k)h_k - 1 - \gamma_k p]\gamma_k}{\left[\begin{array}{l}\{2\gamma_k{}^2\theta(1+\gamma_k)-1\}h_k \\ \quad +2\sqrt{\theta/\pi}(1+\gamma_k)\gamma_k \exp(-\gamma_k{}^2\theta)+1\end{array}\right]}, \quad (16)$$

$$h_k = \exp(\gamma_k{}^2\theta)[1+\mathrm{erf}(\gamma_k\sqrt{\theta})],$$

$$(k=0,\ 1,\ 2,\ \cdots).$$

The initial value of γ,γ_0, is usually taken to be unity. Substituting γ_0 and measured value of p into Eq. 16 gives a new value of γ_1, which is again inserted into Eq. 16 to yield γ_2. We confirmed that accuracy with four digits is ensured after two or three iterations.

The values of γ thus evaluated should be consistent with those calculated from slopes of the straight lines by the use of Eq. 15. Since the slope, q, is a secondary term, it is desirable to make use of the slopes for a criterion of the value obtained from p by means of extrapolation. In other words, inserting a value of γ calculated from p into Eq. 15 yields q, which should be the same as that obtained experimentally. If one fails to reach the consistency, the data may be invalid or one can try again to determine γ by varying the slope slightly.

Experimental

Apparatus and Chemicals. A micrometer-type HMDE assembly MCI AS01 (Mitsubishi Chemical Industries, Ltd.) was employed. In order to avoid the shielding of the diffusion space by the capillary wall and to ensure the spherical diffusion as completely as possible, the capillary end was drawn to give a tip of *ca.* 0.2 mm in outer diameter as has been done by Ikeuchi *et al.*[13] Five capillaries were prepared but two of them had good performance in the relation of the size of a mercury sphere to the reading of the micrometer. We paid special attention to the temperature of the cell and mechanical vibrations, to both of which the characteristics of the HMDE are quite sensitive. The H-typed cell with the capillary was dipped into a thermostat at (25± 0.1) °C, which was supported by four semiinflated balls.

All the solutions were made up using Analar grade chemicals and twice-distilled water. Solutions of 3 mmol dm^{-3} of Pb(II) and Cd(II) were prepared by dissolving known amounts of lead oxide and cadmium oxide into solutions of nitric acid, respectively. A supporting electrolyte was sodium sulfate (1.0 mol dm^{-3}).

The electrode potential was controlled with the aid of a home-made potentiostat equipped with a current limiter and a signal generator for clock-controlled potential-time sequences. Transition of the currents was measured with a 12-bit digital oscilloscope (Nicolet 1090A explorer digital oscilloscope).

Procedures. Five glass cups in one centimeter height were placed on the bottom of the cell before passing nitrogen gas through a solution. They function as a vessel for collecting a mercury drop after each experimental run. The initial and the first-step potentials were selected to be about 200 mV more positive and more negative than the half-wave potential, respectively. Durations of the first step used were 3, 7, and 12 s and the current responses were sampled after a 30 ms lapse. Currents during the second potential step were measured in the range from 50 ms to 1 s. Five different radii of the HMDE's were examined. After an experimental run, the HMDE was dropped into one of the glass cups, which was taken out from the cell when five cups were occupied with mercury drops. The mercury drop was rinsed with water, ethanol and acetone in turn and dried. It was weighed immediately after most of acetone was evapolated, because evapolation of mercury causes serious error in determining the radius of a drop. The radius and the area of the HMDE were evaluated from the weight of the drop. Radii of the HMDE were varied from 0.36 mm to 0.55 mm.

Results and Discussion

Plots of the cathodic currents for lead against the reciprocal of the square root of time are shown in Fig. 3. As expected from Eq. 3, the plots fall into a straight line, of which slope gives $nFc_0{}^*D_0{}^{1/2}$. The values of D_0 for Pb(II),Cd(II), and Zn(II) ions thus calculated from slopes and Eq. 3 are summarized in Table 1. They were constant regardless of the variations in radii of the HMDE and are quite reasonable values. Unfortunately, we could not find the literature values of D_0 under the same conditions as in this experiment. If we take into account the fact that accuracy of the balance was 0.1 mg, *i.e.*, 4% of relative errors, it turns out that the errors involved in D_0 values can be attributed mainly to errors of weighing mercury drops.

The plots in Fig. 3 deviate upward from the straight line when t ($t<\tau$) is less than 60 ms. Since we confirmed that the residual cathodic current decays almost

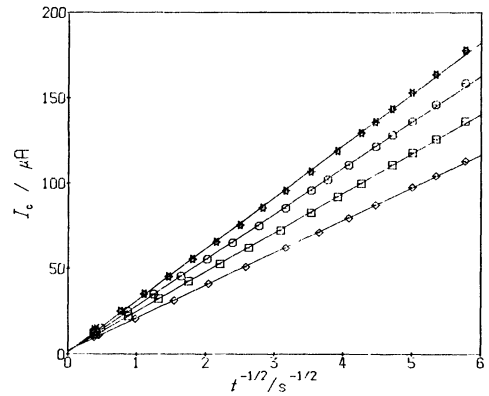

Fig. 3. Plots of cathodic currents *vs.* inverse square roots of time at the HMDE with radii of (★): 0.545, (○): 0.475, (□): 0.445, and (◇): 0.410 mm. The solution was 3 mmol dm^{-3} of Pb^{2+} in 1.0 mol dm^{-3} Na_2SO_4 at 25 °C.

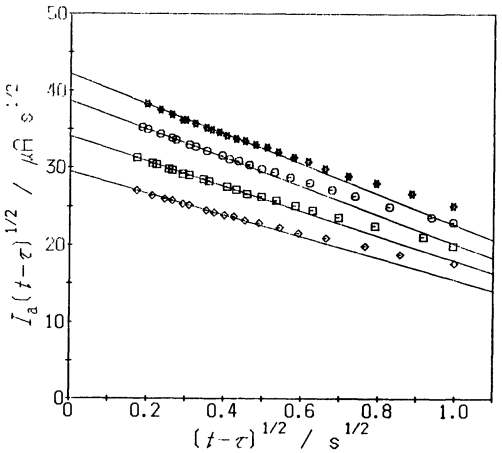

Fig. 4. Plots of products of anodic currents by square roots of time against square roots of time at the HMDE with radii of (★): 0.545, (○): 0.475, (□): 0.445, and (◇): 0.410 mm. The solution was 3 mmol dm^{-3} of Pb^{2+} in 1.0 mol dm^{-3} Na_2SO_4 at 25 °C.

to zero at 4 ms, the deviation cannot be attributed to the charging current. One of the causes of the enhancement of the currents may be the saturation of the potentiostat due to extremely high currents at short times although a current limiter was employed.[13]

The plots of $I_a(t-\tau)^{1/2}$ *vs.* $(t-\tau)^{1/2}$ corresponding to the curves given in Fig. 3 are presented in Fig. 4. The curves in Fig. 4 are quite similar in shape to those of Fig. 1. Since an extrapolated value is required for determination of D_R, it is desirable to measure currents at short electrolysis times. As described above, however, currents obtained at the times less than 60 ms may involve some extraneous components. Plots at the times $(t-\tau)$ more than 0.35 s, which correnspond to $\sqrt{\xi}>0.03$, are ineffective for the extrapolation because of the nature of the concave curves, as predicted from the theoretical curves in Fig. 1. Hence a straight line was drawn for the extrapolation so as to fit the plots in the restricted region (60—350 ms). The procedure for evaluation of D_R is illustrated below by taking the third plot in Fig. 4 as an example. The extrapolated value is 34.0 μA s$^{1/2}$. Substituting this value and the corresponding D_O value ($=7.71\times10^{-10}$ m^2 s^{-1}) into the following equation:

$$p = \lim_{t\to\tau} j_a[\pi(t-\tau)]^{1/2}/nFc_O^*D_O^{1/2}, \quad (17)$$

we obtain $p=1.48$. Since $\tau=7.0$ s, θ is equal to 0.027. Inserting the values of p and θ into Eq. 16, we obtained the recurrent values of γ such as 1.348, 1.326, 1.327, and 1.326, indicating that the convergent value is 1.326. Hence it follows that $D_R=1.02\times10^{-10}$ m^2 s^{-1}. The value of q calculated from Eq. 15 with the values of θ and γ was −12.0, which is in good agreement with the dimensionless slope, −11.6, of the third straight line.

The diffusion coefficients of lead, zinc and cadmium in mercury were determined in this way for some different values of the cathodic pre-electrolysis time, τ, (3—12 s) and the radius of the HMDE, r, (0.36—0.55 mm). The values of D_R obtained are given in Table 1, together with the values suggested by Galus in the light of his present knowledge.[1] These values were constant regardless of variations not only in τ but also in r. We did not observe any dependence of diffusion coefficient of zinc on r although Dowgird and Galus did.[14]

The precision of the values of D_R is twice as poor as that of D_O. The errors may partly result from the extrapolation shown in Fig. 4 and partly be attributed to the double potential perturbation.

Conclusion

The expression for the double potential step chronoamperometric curve has been derived and the procedure for determining the diffusion coefficient of metal in mercury has been developed on the basis of examination of the theoretical curves. The procedure is as follows: (1) D_O is evaluated from the slope of the plots of cathodic currents against $t^{-1/2}$ $(t<\tau)$. (2) Anodic currents multiplied by $(t-\tau)^{1/2}$ are plotted against $(t-\tau)^{1/2}$. (3) A part of the straight line of the plots is extrapolated up to $(t-\tau)^{1/2}\to 0$. (4) This extrapolated value and the values of D_O determined in process (1) are inserted into Eq. 16, and the ratio of D_R to D_O is obtained by iterative computation. (5) The slope of the straight line is used for checking whether the extrapolation is reasonable or not.

The measurements for lead, zinc, and cadmium in mercury gave the diffusion coefficients in agreement with literature values. This method is suitable for short time measurement of diffusion coefficients of unstable metals in mercury regardless of the degree of reversibility.

Appendix

The appendix describes details of the derivation of $\phi(\xi)$ from integral equation 11. Applying Laplace transformation with respect to ξ to Eq. 11 yields

$$\begin{aligned}\mathrm{L}[\phi(\xi)]/\gamma(\sqrt{s}-\gamma) &= (s-\gamma^2)^{-1}\\ &\times\int_0^\theta[(\sqrt{s}/\gamma)\exp[s(\theta-x)]\mathrm{erfc}\sqrt{s(\theta-x)}\\ &+\exp[\gamma^2(\theta-x)](1+\mathrm{erf}\sqrt{\gamma^2(\theta-x)})]\\ &\times(1/\sqrt{x}+\sqrt{\pi})\mathrm{d}x, \qquad \text{(A-1)}\end{aligned}$$

where L denotes the operator of the Laplace transformation. The left-hand side has been obtained with the aid of the convolution theorem, whereas the right-hand side has been derived by the direct Laplace integration. Since the integral in Eq. A-1 is of the form of convolution with respect to θ, it is convenient to evaluate the integrals using the convolution theorem for the Laplace transformation. One of the examples is given below.

$$\begin{aligned}&\int_0^\theta\exp[s(\theta-x)]\mathrm{erfc}\sqrt{s(\theta-x)}x^{-1/2}\mathrm{d}x\\ &=\mathrm{L}_\theta^{-1}[\mathrm{L}(1/\sqrt{\theta})\mathrm{L}_\theta(\exp(s\theta)\mathrm{erfc}\sqrt{s\theta})]\\ &=\mathrm{L}_\theta^{-1}[\sqrt{\pi}/u(\sqrt{u}+\sqrt{s})]\\ &=\sqrt{\pi/s}[1-\exp(s\theta)\mathrm{erfc}\sqrt{s\theta}],\end{aligned}$$

where L_θ denotes the Laplace transformation operator with respect to θ and u the Laplace transformed variable of θ. Then the Laplace transformed function of $\phi(\xi)$ becomes

$$\begin{aligned}\mathrm{L}[\phi(\xi)] &= \sqrt{\pi}(1+\gamma)[2\exp(\gamma^2\theta)-G(\gamma^2\theta)]/\gamma(\sqrt{s}+\gamma)\\ &-\sqrt{\pi/s}/\gamma+\sqrt{\pi}G(\theta s)/\gamma\sqrt{s}\\ &-\sqrt{\pi}(1+\gamma)G(\theta s)/\gamma(\sqrt{s}+\gamma). \qquad \text{(A-2)}\end{aligned}$$

Carrying out the inverse Laplace transformation of Eq. A-2 with the help of a table of the transformation[11] yields Eq. 12.

Thermal Properties and Raman Spectra of Crystalline and Vitreous $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$

Yoji KAWAMOTO* and Fumiko SAKAGUCHI

Department of Chemistry, Faculty of Science, Kobe University, Rokkodai, Nada-ku, Kobe 657

(Received February 3, 1983)

Differential thermal analysis and Raman spectroscopic studies have been performed of crystalline and vitreous $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$ compounds in order to examine the thermal properties and the F coordination of Zr. The differential thermal analyses clarified the definite phase transformation characteristics of crystalline $BaZrF_6$, and $SrZrF_6$ and also suggested that the low- and high-temperature modifications are present in $PbZrF_6$ as well as in $BaZrF_6$ and $SrZrF_6$. The Raman spectra of crystalline $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$ were discussed in relation to the F coordination of Zr in fluorozirconate compounds. The crystallization behaviors and Raman spectra of vitreous $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$ revealed that Zr in the vitreous compounds is eight-coordinated by F although small amounts of seven-coordinated Zr may exist in vitreous $BaZrF_6$.

Zirconiumtetrafluoride-based glasses recently developed[1] are a new family of glasses and are noted in properties of high F ion conductivity and mid infrared transparency.[2] Currently various properties of the glasses are being examined to evaluate the possibility of the potential applications.[2] However, the structural studies are a few[3–5] so that the glass structures are not thoroughly understood yet.

The binary systems BaF_2–, PbF_2–, and SrF_2–ZrF_4 yield vitreous materials in given composition ranges[6] and besides the combination of the binaries and other fluorides gives a number of polynary fluorozirconate glasses.[2] Accordingly the binary systems can be regarded as mother systems for fluorozirconate glasses. Thus, elucidating the structures of the binary glasses is indispensable for the structural understanding of ZrF_4-based fluoride glasses. As the first step of the structural studies of the BaF_2–, PbF_2–, and SrF_2–ZrF_4 glasses, the present authors dealt with Ba, Pb, and Sr metafluorozirconate glasses, that is, vitreous $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$.

The objective of this work is to elucidate the short-range structure, mainly the F coordination environment of Zr, of the vitreous $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$. Differential thermal analysis and Raman spectroscopy were employed for the investigation. A method frequently employed for inferring the structure of a glass is to compare the various spectra of the glass with those of the related crystalline compounds. In the present study the thermal properties and Raman spectra of crystalline $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$ that were not reported were first studied. Then the thermal behaviors and Raman spectra of vitreous $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$ were examined and compared with those of the crystalline compounds.

Experimental

Materials. Raw materials employed for the preparation of crystalline and vitreous $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$ were ZrF_4 (Morita Chemicals, 99.9% purity), BaF_2(Merck, suprapur), PbF_2 (Merck, suprapur), and SrF_2(Merck, suprapur). About 5 g stoichiometric mixtures of the raw materials with addition of small amounts of NH_4HF_2 were melted in platinum crucibles in an N_2 gas atmosphere using a simple SiC resistance furnace and the melts were kept at about 850 °C for 10 min. The low-temperature modifications(α) of $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$ were obtained by cooling the melts slowly to room temperature in the furnace. On the other hand, the high-temperature forms(β) of $BaZrF_6$ and $SrZrF_6$ were prepared by crystallizing the melts at temperatures a few degrees below their melting points and then quenching them by liquid nitrogen. Vitreous $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$ were prepared by quenching the melts rapidly using a twin roller. The synthesized crystalline compounds were polycrystalline and were identified by X-ray powder diffraction to be the respective single phases. In the identification the reference X-ray powder patterns were computed from the available crystal structure data. The prepared vitreous compounds were thin films of about 20 μm thickness and amorphous in X-ray diffraction.

Differential Thermal Analyses. Differential thermal analyses were undertaken to examine the phase transformation (T_t) and melting (T_m) temperatures of crystalline $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$ compounds and the glass transition(T_g) and crystallization (T_c) temperatures of the vitreous compounds. The measurements were made in an Ar gas stream with a heating or cooling rate of 5 °C min^{-1}.

Raman Spectra. Raman scattering of crystalline and vitreous $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$ were measured with a Spex 14018 double monochromator in the 90° scattering configuration using the Ar^+ 488.0 nm laser line at ambient temperature. In the measurements the slits were opened to 400 μm and the pressed-disc samples were used. No sample deterioration was observed under irradiation with an about 150 mW beam.

Results and Discussion

Differential Thermal Analyses. So far the followings have been reported on the modifications and crystal structures of $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$: Both $BaZrF_6$ and $SrZrF_6$ have the low- and high-temperature modifications but $PbZrF_6$ is present only in a single modification.[7] The structures of β-$BaZrF_6$, $PbZrF_6$, and α-$SrZrF_6$ are crystallographically isomorphous and are composed of $(ZrF_8)^{4-}$ dodecahedra connected by two edges to form chain linked by Ba^{2+}, Pb^{2+}, and Sr^{2+} ions.[7] The structure of α-$BaZrF_6$ is built up of $(Zr_2F_{12})^{4-}$ complex anions linked by Ba^{2+} cations, where a Zr atom is coordinated by seven F atoms.[8]

Although the presence of α- and β-modifications in $BaZrF_6$ and $SrZrF_6$ is confirmed in crystal structure studies the α-β phase transformation temperatures are

not well-defined. Furthermore, even the melting temperatures of $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$ are not reported. In the present work, therefore, thermal studies were first made of crystalline $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$ compounds with differential thermal analysis. In the analyses the products at endotherm or exotherm peaks were identified by X-ray diffraction measurements of the quenched samples. The results of α- and β-$BaZrF_6$, $PbZrF_6$, and α- and β-$SrZrF_6$ are shown in Figs. 1(a, b), 2(a), and 3(a, b), respectively, where

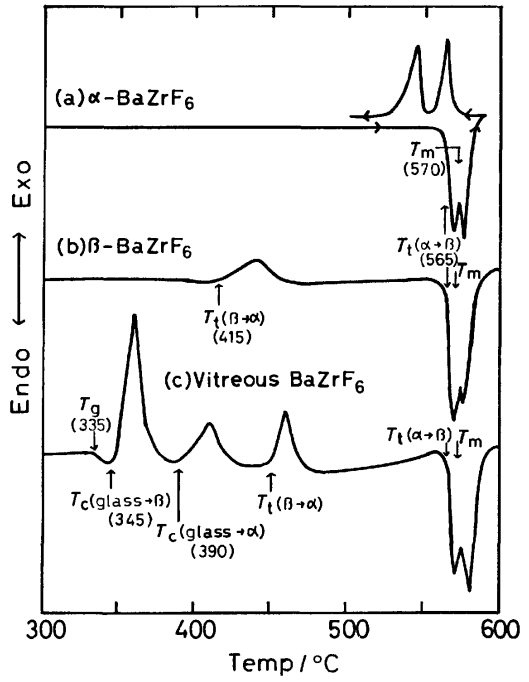

Fig. 1. Differential thermal analysis curves of α- and β-$BaZrF_6$ and vitreous $BaZrF_6$. Numerals in parentheses are temperatures in °C.

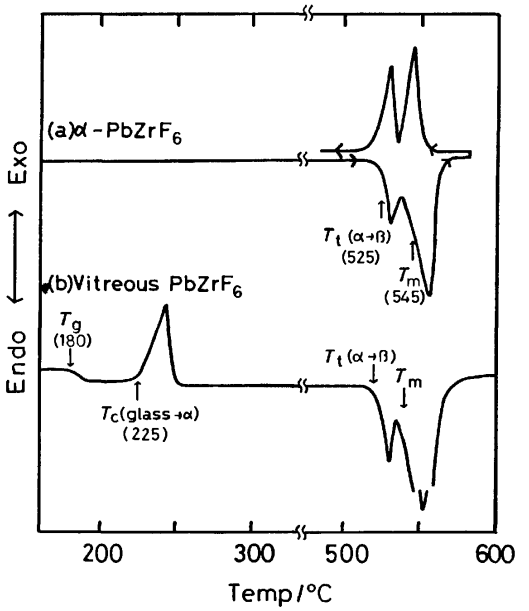

Fig. 2. Differential thermal analysis curves of crystalline and vitreous $PbZrF_6$. Numerals in parentheses are temperatures in °C.

the subscripts (α→β) and (β→α) of T_t refer to transformation from α-form to β-form and from β-form to α-form, respectively. As shown in Figs. 1(a, b) and 3(a, b), the phase transformation characteristics of $BaZrF_6$ and $SrZrF_6$ were clearly defined. As can be seen from Fig. 2(a), on the other hand, $PbZrF_6$ showed a differential thermal analysis curve very similar to those of α-$BaZrF_6$ and α-$SrZrF_6$. This indicates that $PbZrF_6$ also may exhibit the α-β phase transformation and that crystalline $PbZrF_6$ already known may be the α-modification. The attempt of preparing β-$PbZrF_6$ according to the method described in Experimental was unfortunately unsuccessful. So the presence of α- and β-modifications in $PbZrF_6$ could not be firmly established in this work.

The differential thermal analysis curves of vitreous $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$ compounds are shown in Figs. 1(c), 2(b), and 3(c), respectively, where the subscripts (glass→α) and (glass→β) of T_c indicate that α- and β-form compounds crystallized from glasses, respectively. The crystallization behaviors show that the crystallized products of vitreous $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$ were β-$BaZrF_6$ and small amounts of α-$BaZrF_6$, α-$PbZrF_6$, and α-$SrZrF_6$, respectively.

Raman Spectra. The Raman spectra observed for crystalline $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$ compounds are shown in Figs. 4—6. In the figures the Raman peaks with asterisks may be bands assigned to symmetric stretching vibration (ν_s).

Here the Raman spectra of crystalline fluorozirconates are discussed in relation to the F coordination of Zr. It is known that, in crystalline fluorozirconates, Zr atoms exhibit three kinds of F coordination numbers (six, seven, and eight) to form fluorozirconate complex anions. Toth *et al.* measured the Raman spectra of

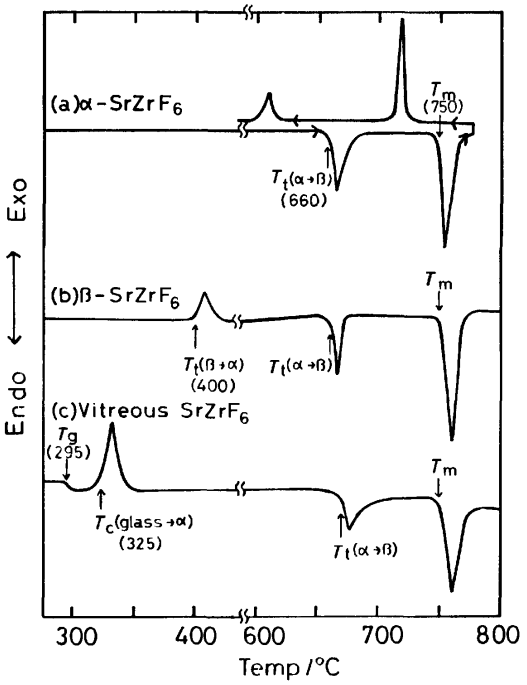

Fig. 3. Differential thermal analysis curves of α- and β-$SrZrF_6$ and vitreous $SrZrF_6$. Numerals in parentheses are temperatures in °C.

several alkali fluorozirconate compounds with known crystal structures and discussed the correlation between the ν_s and the F coordination number of Zr.[9] They mentioned that, only in the absence of bridging between F complex ions of Zr, an inverse correlation between the ν_s and the coordination number holds.

The ν_s frequencies observed for the present compounds and alkali fluorozirconate compounds are classified according to the F coordination number of Zr and tabulated in Table 1. In the table the average Zr–F bond lengths and structural characteristics in the respective compounds are also given. In the series of alkali fluorozirconates an inverse correlation is found between the ν_s and the F coordination number, but throughout alkali and alkaline earth fluorozirconates such a correlation does not hold at all. In particular the Zr atoms in β-$BaZrF_6$, α-$PbZrF_6$, and α-$SrZrF_6$ have the same F coordination number(eight) and the same dodecahedral coordination.[7] Nevertheless the ν_s frequencies in the three compounds are significantly different from each other, though the ν_s frequency differences might be probably attributed to the Badger rule, *i.e.*, an inverse correlation between ν_s and Zr–F bond length.[15] The same situation can be seen in a set of Li_2ZrF_6 and Cs_2ZrF_6. Thus no consistent correlation can be deduced between the ν_s and the F coordination number of Zr in fluorozirconate compounds. The following reasons for this may be supposed: Even if the F coordination number is identical the coordination environment may be highly different, especially in large coordination numbers. Moreover, when bridging takes place between the F complex ions it should give many complicated effects on the ν_s vibrations. The bridging manner also may be different in the respective compounds. The above concludes that the Raman ν_s frequency can not be utilized as a reliable guide for identifying the F coordination number of Zr in a fluorozirconate complex with unknown structure.

F Coordination Numbers of Zr in Vitreous $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$. The Raman spectra of vitreous $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$ are shown in Figs. 4, 5, and 6, respectively, together with those of the corresponding crystalline compounds to facilitate the comparison between both the spectra. In the vitreous Raman spectra only the polarized bands were strong and prominent, and all other bands were very weak and broad. In a comparison of vitreous spectra and crystalline spectra, very close resemblance in spectral features can be seen between vitreous $BaZrF_6$ and β-$BaZrF_6$, between vitreous $PbZrF_6$ and α-$PbZrF_6$, and between vitreous $SrZrF_6$ and α-$SrZrF_6$. As already described, on the other hand, the crystallization products of vitreous $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$ compounds were predominantly β-$BaZrF_6$, only α-$PbZrF_6$, and only α-$SrZrF_6$, respectively. In general it is antic-

TABLE 1. F COORDINATION NUMBERS OF Zr AND RAMAN ν_S FREQUENCIES IN VARIOUS FLUOROZIRCONATE COMPOUNDS

ipated that compounds which crystallize from a glass are crystals with the structures closer to the glass structures. Therefore the crystallization behaviors and Raman spectra of vitreous $BaZrF_6$, $PbZrF_6$, and $SrZrF_6$ conclude that the Zr atoms in the vitreous compounds are eight-coordinated by the F atoms like the Zr atoms in crystalline β-$BaZrF_6$, α-$PbZrF_6$, and α-$SrZrF_6$. Furthermore it may be proposed that the basic structures of the vitreous compounds consist of chains of ZrF_8 dodecahedra. Radial distribution analyses of the vitreous $BaZrF_6$ and $PbZrF_6$ compounds are now in progress to verify the present proposal.[16] Here it is a wonder that vitreous $BaZrF_6$ has a β-$BaZrF_6$-like structure and, on the contrary, vitreous $PbZrF_6$ and $SrZrF_6$ possess the α-form crystal-like structures. Elucidating the crystal structures of β-$PbZrF_6$ and β-$SrZrF_6$ should answer to this question.

Almeida and Mackenzie have inferred that the Ba metafluorozirconate glass is composed of six- and seven-coordinated Zr atoms.[3] In their study, however, they have compared the Raman spectra of fluorozirconate glasses with those of alkali fluorozirconate compounds. This comparison is not proper, as described in the preceding section. In addition it is questioned that the crystallized product of the glass has been reported to be α-$BaZrF_6$. Probably the product identified by Almeida and Mackenzie would be the phase-transformed product of β-$BaZrF_6$ that crystallized initially from the glass.

This work was supported in part by Grant-in-Aid for Special Research, Project "New Investigation of Functional Ceramics" from Ministry of Education, Science and Culture and also in part by Hyogo Prefecture Foundation for Promotion of Science and Technology.

Synthesis and Characterization of Imidazolate-bridged Copper(II) Complexes of Triangular Skeleton

Hisashi Ōkawa,* Masahiro Mikuriya, and Sigeo Kida

Department of Chemistry, Faculty of Science, Kyushu University 33, Higashi-ku, Fukuoka 812

(Received February 16, 1983)

New polynuclear copper(II) complexes of the composition [CuL(im)]X (L=*N,N,N',N'*-tetramethylethylenediamine (tmen), bip, phen; X=ClO_4, PF_6, BF_4; im=imidazolate ion) have been prepared. Cryomagnetic measurements have indicated that the complexes involve a trianglar-trinuclear skeleton and an antiferromagnetic spin-exchange interaction operates between copper(II) ions; exchange integrals being evaluated at -37—-45 cm^{-1}. Based on the Dreiding model consideration of the complexes and the crystal structure of $[Cu(tmen)(imH)_2](ClO_4)_2$, a trinuclear structure of the triangular skeleton with imidazolate bridges, Cu-Im-Cu-Im-Cu-Im-┐, was supposed for the complexes.

Bovine erythrocyte superoxide dismutase (BESOD) is known to involve an imidazolate-bridged copper(II)–zinc(II) unit at the active site.[1] Cryomagnetic investigation of the copper-substituted enzyme Cu_4-BESOD revealed that an antiferromagnetic spin-exchange interaction operates within each Cu^{2+}–Im–Cu^{2+} unit, the exchange integral being evaluated at -26 cm^{-1}.[2] Therefore, imidazolate-bridged polynuclear copper(II) complexes are of current interest.

So far binuclear and tetranuclear copper(II) complexes with imidazolate bridge have been prepared and characterized. Syntheses of the complexes were achieved (1) by the use of polynucleating ligands containing imidazolate group,[3-6] (2) by the use of biimidazolate or bibenzimidazolate as bridging group,[7] (3) by the reaction of a tridentate or tetradentate ligand, copper(II) ion and imidazole (or 2-methylimidazole) in the 2:2:1 mole ratio,[4,6,8-11] and (4) by the reaction of a binucleating macrocycle, copper(II) ion and imidazole in the 1:2:1 mole ratio.[12,13] Haddad and Hendrickson also prepared and characterized the imidazolate-bridged complexes $[Cu_2(bip)_4(im)](PF_6)_3$ and $[Cu_2(phen)_4(im)](ClO_4)_3$.[7]

In this study we have synthesized new imidazolate-bridged trinuclear copper(II) complexes of the composition CuL(im)X (L=*N,N,N',N'*-tetramethylethylenediamine (tmen), bip, phen; X=ClO_4, PF_6, BF_4; im=imidazolate ion). The triangular structure has been characterized on the basis of cryomagnetic properties, Dreiding model consideration, and the crystal structure of $[Cu(tmen)(imH)_2](ClO_4)_2$.

Experimental

Syntheses. *[CuL(im)]X (L=tmen, bip, phen; X=ClO_4, PF_6, BF_4)*: The synthetic methods for the complexes are nearly the same and exemplified by $[Cu(tmen)(im)]ClO_4$. Copper(II) acetate monohydrate (2.0 g) and tmen (1.2 g) were dissolved in a methanol–water mixture (1:1, 100 cm^3) and warmed at 60 °C. To this was added an aqueous solution of NaOH (0.4 g) and $NaClO_4$ (1.4 g) with stirring to give a di-μ-hydroxo complex $[Cu_2(tmen)_2(OH)_2](ClO_4)_2$. Imidazole was added to this mixture with stirring and warming. When the most part of the di-μ-hydroxo complex was dissolved, the reaction mixture was quickly filtered to separate insoluble materials and the filtrate was allowed to stand overnight. The crystals thus obtained were filtered, washed with methanol and dried *in vacuo*.

$[Cu(phen)(im)]ClO_4$ was practically insoluble in water and in methanol. In order to avoid the contamination of $[Cu_2(phen)_2(OH)_2](ClO_4)_2$, it was prepared by adding a small excess of imidazole to the di-μ-hydroxo complex and the product was throughly washed with hot water.

$[Cu(tmen)(imH)_2](ClO_4)_2$. Copper(II) perchlorate hexahydrate (3.7 g), tmen (1.2 g), and imidazole (1.5 g) were dissolved in hot water (30 cm^3), and the resulting purple solution was filtered and left stand overnight to give bluish purple crystals.

Elemental analyses of the complexes are given in Table 1.

Measurements. Electronic spectra were recorded on a Shimadzu Multipurpose Spectrophotometer model MSP-1000 by reflection on powder samples. Magnetic susceptibilities were measured by the Faraday method, the apparatus being calibrated by the use of $[Ni(en)_3]S_2O_3$.

X-Ray Crystal Structure Analysis of $[Cu(tmen)(imH)_2](ClO_4)_2$. A crystal with dimensions of 0.02 mm×0.17 mm×0.45 mm

was used for the X-ray analysis. The unit-cell parameters and intensities were measured on a Rigaku AFC-5 automated four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation (λ=0.71069 Å) at 20±1 °C. The unit-cell parameters were determined by the least-squares refinement based on the 25 reflections in the range of $17<2\theta<29°$.

Crystal Data: $C_{12}H_{24}Cl_2CuN_6O_8$, F.W.=514.81; monoclinic; $P2_1/n$; a=12.920(5), b=16.171(9), and c=10.084(4) Å; β=97.15(3)°; D_m=1.62; D_c=1.64 g cm^{-3}; Z=4.

The intensity data were collected by the 2θ-ω scan technique with a scan rate of 4° min^{-1}. Three standard reflections were monitored every 100 reflections, and their intensities showed a good stability. A total of 4030 reflections with $2\theta<50°$ were collected. The intensity data were corrected for the Lorentz and the polarization effects, but not for absorption. Independent 1838 reflections with $|F_o|>3\sigma(|F_o|)$ were considered as "observed" and were used for the structure analysis.

The structure was solved by the heavy-atom method and refined by the block-diagonal least-squares method. To identify the nitrogen atoms of the imidazole rings which are not coordinated to the copper atom, the two possible atoms of each ring were both labelled nitrogen. Then the atoms with the lower temperature factors were distinctly labelled nitrogen. Hydrogen atoms were located from the difference Fourier map and included in the refinement. In the least-squares refinement the weighting scheme,[14] $w=(15.56+|F_o|+0.0078|F_o|^2)^{-1}$, was employed. The final R values were R=0.097 and R_w=0.126.

The atomic scattering factors and the anomalous dispersion corrections were taken from the International Tables for X-ray Crystallography.[15] All the calculations were carried out on the FACOM M-200 computer in the Computer Center of Kyushu University by the use of a local version[16] of the UNICS-III[17] and the ORTEP[18] programs. The final positional and thermal parameters with their estimated standard deviations are given in Table 2. The anisotropic thermal parameters of the nonhydrogen atoms, the coordinates and isotropic temperature factors of hydrogen atoms, and the F_o-F_c tables have been deposited as a Document No. 8330 at the Office of the Editor.

Results and Discussion

All the complexes except for [Cu(phen)(im)]BF_4 were isolated as anhydrous purple crystals, while [Cu(phen)(im)]BF_4 crystallized as blue-colored monohydrate. Deprotonation of imidazole nitrogen in these complexes was evidenced by no N–H stretching mode in the region 3200—3500 cm^{-1}.

Reflectance spectra of the complexes show a d-d band at about 17,000 cm^{-1}. Judging from the fact that the d-d frequency of [Cu(tmen)(im)]ClO_4 (17,300 cm^{-1}) is nearly the same as that (17,500 cm^{-1}) of [Cu(tmen)(imH)$_2$]$(ClO_4)_2$ which possesses a nearly coplanar [CuN_4] chromophore as will be shown later, all the complexes (except for [Cu(phen)(im)]$BF_4\cdot H_2O$ are assumed to have a planar configuration with four nitrogen donor atoms. This suggests that the complexes contain imidazolate group acting as a bridge.

Magnetic moments of the complexes fall in the range 1.59—1.65 BM lower than the spin-only value 1.73 BM. This again implies that the complexes are of polynuclear structure bridged by imidazolate group. In order to obtain further informations on the structure of the complexes, magnetic susceptibilities were measured in the temperature range from liquid nitrogen temperature to room temperature. Magnetic susceptibility of each complex (except for [Cu(phen)(im)]-$BF_4\cdot H_2O$) increases with lowering of temperature, while magnetic moment decreases with lowering of temperature and reaches to 1.2—1.3 BM near liquid nitrogen temperature. This behavior suggests that the complexes involve odd, probably three, copper(II) ions within each molecule.

Since a cyclic-polynuclear structure is more likely than a linear-chain structure for the present complexes, it was attempted to explain the magnetism in terms of the susceptibility equation for triangular-trinuclear copper(II) system. Based on the Heisenberg model, magnetic susceptibility expression for the triangular copper(II) system (Fig. 1) is given by

$$\chi_A=\frac{Ng^2\beta^2}{12kT}\frac{5+\exp(-3J/kT)}{1+\exp(-3J/kT)}+N\alpha,$$

on the assumption of equal exchange integrals ($J_{12}=J_{23}=J_{31}=J$). Each symbol in the equation has its conventional meaning. Magnetic susceptibilities of the complexes except for [Cu(phen)(im)]$BF_4\cdot H_2O$ were satisfactorily explained by the use of the equation as is exemplified by [Cu(tmen)(im)]PF_6 in Fig. 2. Mag-

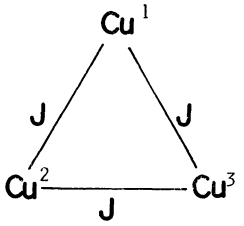

Fig. 1.

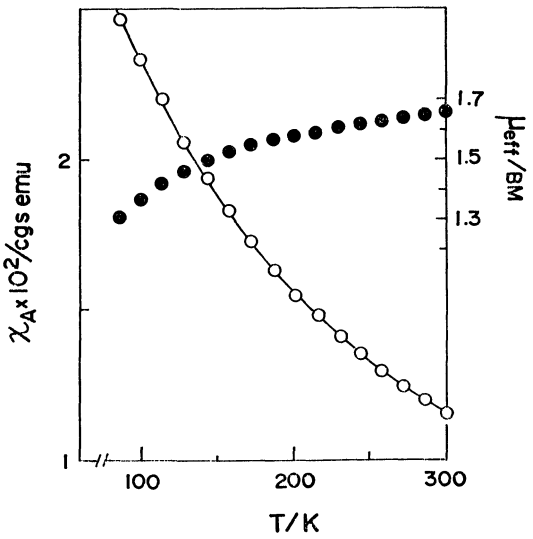

Fig. 2. Temperature variations of magnetic susceptibility and magnetic moment of $[Cu(tmen)(im)]PF_6$.

Table 3. Magnetic parameters, $-J$, g and $N\alpha$, of complexes

Complex	$-J$/cm^{-1}	g	$N\alpha\times10^6$ / cgs mol^{-1}
$[Cu(tmen)(im)]PF_6$	37	2.08	40
$[Cu(tmen)(im)]ClO_4$	45	2.08	60
$[Cu(tmen)(im)]BF_4$	43	2.08	50
$[Cu(bip)(im)]PF_6$	40	2.07	45
$[Cu(bip)(im)]ClO_4$	44	2.08	60
$[Cu(bip)(im)]BF_4$	45	2.08	50
$[Cu(phen)(im)]PF_6$	38	2.07	45
$[Cu(phen)(im)]ClO_4$	37	2.08	60

netic parameters, J, g, and $N\alpha$, obtained by the best fit technique are given in Table 3. The exchange integrals are in the range -37——-45 cm^{-1}, which are moderate or a little larger in absolute value compared with the exchange integrals of the imidazolate-bridged binuclear and tetranuclear copper(II) complexes so far studied.

Magnetic susceptibility of $[Cu(phen)(im)]BF_4\cdot H_2O$ is also subnormal but does not obey the above equation. Judging from its magnetic behavior, this complex is presumed to be composed of even copper(II) ions. However, its structure was not further investigated in this study.

The structure of the present complexes was considered by means of the Dreiding model. The projec-

tion of the model for $[Cu(tmen)(im)]^+$ is shown as an example in Fig. 3. Two coordination sites around planar copper(II) ion are occupied by tmen and remaining sites by imidazolate nitrogens. Triangular-trinuclear skeleton is built up of three copper atoms at the apices and three imidazolate groups combining these copper atoms. The plane of each imidazolate group is nearly perpendicular (*ca.* 70—80°) to the plane described by the donor atoms and are arranged "*cis*" to each other with respect to nitrogen atoms (see Fig. 3). The alternative configuration in which one of the imidazolate groups is placed "*trans*" to the remaining two is also possible, but this configuration seems unfavorable to that in Fig. 3. This trinuclear skeleton is quite rigid, but this is reasonably constructed without changing bond distances and distorting bond angles from the usual ones. ESR spectra of the complexes in *N,N*-dimethylformamide showed a very broad signal both at room temperature and near liquid nitrogen temperature. This implies that the polynuclear structure of the complexes is considerably stable and is maintained even in *N,N*-dimethylformamide solution. Since such a rigid skeleton can not be formed in the cases of cyclic polynuclear structure larger than triangular structure, the stability of the complexes in *N,N*-dimethylformamide seems to be associated with the triangular-trinuclear skeleton shown in Fig. 3.

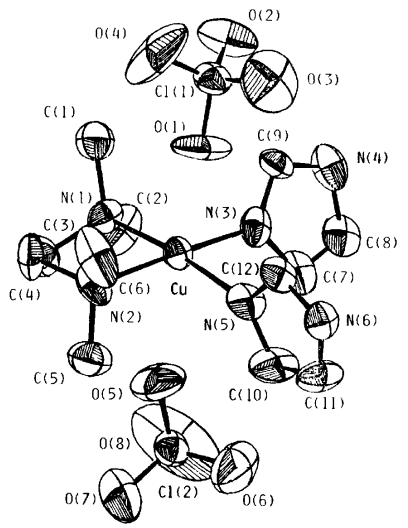

Fig. 4. Crystal structure of $[Cu(tmen)(imH)_2](ClO_4)_2$.

So far all efforts to obtain a single crystal suitable for X-ray analysis have been in vain. In order to obtain an additional support for the triangular-trinuclear structure with the imidazolate bridges for [CuL(im)]X, we have examined the crystal structure of $[Cu(tmen)(imH)_2](ClO_4)_2$ which contains the $[CuN_4]$-chromophore relevant to [Cu(tmen)(im)]X. A perspective drawing of the complex and the numbering system are illustrated in Fig. 4. Bond lengths and angles are listed in Table 4.

The copper atom is coordinated by two amino nitrogen atoms of tmen, N(1) and N(2), and two imidazole nitrogen atoms, N(3) and N(5), at distances 2.037(11), 2.093(13), 2.003(12), and 2.013(13) Å, respectively. These in-plane atoms form an approximate square plane (Table 5). The copper atom is further coordinated by the oxygen atoms of the perchlorate ions, O(1) and O(5), at the distances of 2.487(12) and 3.058(15) Å, respectively. Thus, the coordination geometry may be described as an elongated octahedron. The copper atom lies above the equatorial plane toward the oxygen atom O(1) by 0.09 Å. The tmen moiety forms a five-membered chelate ring with the copper atom. The Cu–N(1)–C(3)–C(4)–N(2) chelate rings has a gauche conformation, C(3) and C(4) being located 0.538 Å below and 0.144 Å above the plane defined by Cu, N(1), and N(2), respectively.

The most striking characteristic in the structure of $[Cu(tmen)(imH)_2](ClO_4)_2$ is that two imidazole rings are nearly perpendicular to the equatorial plane (the rings being inclined by 66.0 and 85.3° to the plane, respectively) and are arranged "*cis*" to each other with respect to the non-coordinating nitrogen atom. It should be noted that the local coordination environment of [CuL(im)]X considered on the basis of the Dreiding model (Fig. 3) is substantially the same as that of $[Cu(tmen)(imH)_2](ClO_4)_2$. Although this is

a) The equation of the plane is expressed as $LX+MY+NZ=D$, where X, Y, and Z are in Å units referred to the crystallographic axes. b) Deviations (l/Å) of atoms from the planes are listed in square brackets.

not a direct evidence, it may afford a support for the structure of [CuL(im)]X with "*cis*"-arranged imidazolate bridges.

Based on these facts we may conclude that the [CuL(im)]X complexes are imidazolate-bridged trinuclear complexes with a triangular skeleton.

Reactions of Dialkylnickel(II) Complexes NiR_2L_2 with Alkyl (or Aryl) Halides, R'COY (Y=Cl, Br, OPh, OCOPh), and CS_2

Takakazu YAMAMOTO,* Teiji KOHARA, Kohtaro OSAKADA, and Akio YAMAMOTO

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227

(Received February 24, 1983)

Reactions of $Ni(CH_3)_2(bpy)$ (**1**), $Ni(C_2H_5)_2(bpy)$ (**2**) (bpy=2,2'-bipyridine), *trans*-$Ni(CH_3)_2(triethylphosphine)_2$ (**3**), $Ni(CH_3)_2$(1,2-bis(diphenylphosphino)ethane) (**4**), and $Ni(CH_3)_2$(1,3-bis(diphenylphosphino)propane) (**5**) with alkyl or aryl halides, R'COY (Y=Cl, Br, OC_6H_5, $OCOC_6H_5$), and CS_2 have been investigated. The reactions of NiR_2L_2 with alkyl or aryl halides are classified into three types of reactions by their reactirn products: Type A: $NiR_2L_2+R'X\rightarrow NiX(R')L_2+R\text{-}R$, Type B: $NiR_2L_2+R'X\rightarrow$alkane (RH)+olefin (R'(-H)), and Type C: $NiR_2L_2+R'X\rightarrow NiR(X)L_2+R\text{-}R'$. Complexes **1** and **2** undergo mainly Type A reaction. Complex **3** gives Type A reaction product on treatment with C_6H_5Br, but it gives Type B reaction product on treatment with C_2H_5Br. On the other hand, **4** undergoes Type C reaction on interaction with C_6H_5Cl. The reactions with R'COY (Y=Cl, Br, OPh, OCOPh) are classiffed into two types of reactions by their reaction products: Type D: $NiR_2L_2+R'COY\rightarrow NiY(R)L_2+RCOR'$ and Type E: $NiR_2L_2+R'COY\rightarrow NiY(R')L_2+RCOR$. Complexes **1**—**3** undergo mainly Type D reaction, whereas complexes **4** and **5** mainly Type E reaction. The difference in the reaction route is discussed on the basis of presence or absence of vacant coordination site for attack by R'COY. The reaction of **4** with CS_2 affords $Ni(CS_2)$(1,2-bis(diphenylphosphino)ethane) with evolution of a reductive elimination product, ethane, whereas the reaction of **3** with CS_2 gives a 1:1 adduct of **3** and CS_2.

Although chemistry of organonickel complexes has been developed in the past two decades,[1] examples of isolated dialkylnickel(II) complexes[2-7] are still limited and chemical reactivities of the dialkylnickel complexes have been poorly understood in comparison with the chemical reactivities of much more stable dialkylplatinum(II) complexes. Our research group has been dealing with the dialkylnickel(II) complexes and has reported isolation and chemical reactivities of the dialkylnickel(II) complexes.[2,7-9] As an extension of the study on the dialkylnickel(II) complexes, we have examined chemical reactivities of the following dialkylnickel(II) complexes, NiR_2L_2, with organic halides and their analogues (R'X and R'COY) and CS_2. We now report the results of the reactions.

$NiMe_2(bpy)$ (**1**), $NiEt_2(bpy)$ (**2**), *trans*-$NiMe_2(PEt_3)_2$ (**3**), $NiMe_2(dpe)$ (**4**), $NiMe_2(dpp)$ (**5**). Me=CH_3, Et=C_2H_5. bpy=2,2'-Bipyridine. PEt_3=triethylphosphine. dpe=1,2-Bis(diphenylphosphino)ethane. dpp=1,3-Bis(diphenylphosphino)propane.

To clarify the process of the reaction of NiR_2L_2 with R'X is particularly important, since it often induces C–C coupling between R and R or R and R' which is considered to be a crucial elemental step of Ni-catalyzed C–C coupling reactions between metal alkyls (*e.g.*, RMgX) and organic halides.[10]

Results and Discussion

Reactions with R'X. Table 1 shows results of the reactions of complexes **1**—**4** with R'X. It includes results of a previously reported reaction of **2** with C_6H_5Cl.[11] The reactions listed in Table 1 can be classified into the following three types of reactions according to their products,

Type A: Formation of the reductive elimination product, R–R, and $NiX(R')L_2$.
$NiR_2L_2+R'X\rightarrow NiX(R')L_2+R\text{-}R$.

Type B: Hydrogen migration from R' to R to release alkane, RH, and olefin, R'(–H).
$NiR_2L_2+R'X\rightarrow RH+R'(-H)$.

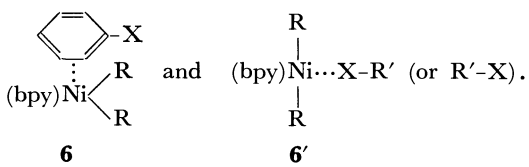
Type C: Cross coupling of R and R' to form R–R' and $NiR(X)L_2$.
$NiR_2L_2+R'X\rightarrow NiR(X)L_2+R\text{-}R'$.

Each type of reaction is discussed below.

Type A: The reaction of **1**, a homologue of **2**, with 2-chlorotoluene leads to the evolution of the reductive elimination product, ethane, which is accompanied by formation of NiCl(2-tolyl)(bpy), similarly to the reaction of **2** with chlorobenzene.[11] The results indicate that the Ni–R bonds in $NiR_2(bpy)$ is activated by interaction with haloarene to induce the reductive elimination of R–R,

$$NiR_2(bpy) + \text{chloroarene} \longrightarrow NiCl(aryl)(bpy) + R\text{-}R. \quad (1)$$

Since it is known that electron transfer from Ni in $NiR_2(bpy)$ to an electron accepting ligand causes activation or weakening of the Ni–R bonds,[2d,12] we assume that the elimination of R–R is promoted by the electron transfer from nickel to the coordinating chloroarene in reaction intermediates such as



6 **6'**

In the intermediate **6**, the haloarene coordinates with nickel through the aromatic ring and an electron migration from Ni to π^* orbital(s) of chloroarene is assumed. On the other hand, in the intermediate **6'**, chloroarene (R'X) approaches to Ni through the electron-withdrawing halogen atom or positively charged R' carbon bonded to X. When the reductive elimination takes place, the reaction is considered to be followed by a rapid oxidative addition of chloroarene

to Ni^0 species.

An alternative reaction mechanism involving oxidative addition of chloroarene to $NiR_2(bpy)$ to form a quadrivalent $Ni(R)_2(aryl)(Cl)(bpy)$ species and elimination of R–R from the intermediate is also conceivable. However, this mechanism is less plausible as judged from selective formation of R–R and no liberation of the cross coupling product, R–aryl, although formation of such a four valent nickel species as a reaction intermediate is assumed as for the Types B and C reactions (*vide infra*).

The reaction of **1** with 2-chlorotoluene requires a somewhat higher temperature than for a similar reaction of **2**,[11] reflecting stronger Ni–R bonds in **1** than in **2**.[2d]

When an alkyl halide, *t*-butyl chloride, was employed in the reaction with **2**, the reaction also led to liberation of R–R, butane, with formation of a reddish brown complex, which may be assignable to NiCl(*t*-butyl)(bpy). Attempts to isolate this complex failed due to its instabilities, and prolonged reaction caused formation of light green $NiCl_2(bpy)$ (proved by IR) and evolution of isobutene and a small amount of isobutane which are considered to be formed through the thermal decomposition of the *t*-butyl–Ni complex. When poly(vinyl chloride) is employed in the reaction with **2**, the chloro(alkyl)nickel complex produced, $\{CH_2\text{-}CH(NiCl(bpy))\}_n$ (see experimental), has some stabilities and can be used for further reaction with CO to afford an acylnickel group pending in poly(vinyl chloride),

$$\mathbf{2} + \{CH_2\text{-}CHCl\}_n \longrightarrow \{CH_2\text{-}CH(NiCl(bpy))\}_n + R\text{-}R \quad (2)$$

$$\{CH_2\text{-}CH(NiCl(bpy))\}_n + CO \longrightarrow \{CH_2\text{-}CH(CONiCl(bpy))\}_n. \quad (3)$$

In the case of the activation of the Ni–Et bonds in **2** by the alkyl halides, formation of the intermediate complex of type **6** is not possible and the reaction is considered to proceed through formation of the intermediate of type **6'**.

Similar reductive elimination of R–R in the PEt_3-coordinated dimethylnickel complex **3** is also induced by the interaction with an haloarene, bromobenzene. The reductive elimination is again accompanied by the formation of an oxidative addition product, *trans*-

$$\mathbf{3} + PhBr \xrightarrow[\text{2) oxidative addition}]{\text{1) reductive elimination}} Me\text{-}Me + NiBr(Ph)(PEt_3)_2 \quad (4)$$

$NiBr(Ph)(PEt_3)_2$, which was prepared by Morrell and Kochi[13] through a different reaction pathway. The formation of a small amount of toluene in the reaction of **3** with PhBr suggests that the following cross coupling reaction (Type C reaction) partially occurs,

$$\mathbf{3} + PhBr \longrightarrow \left[\begin{array}{c} Ph \\ \vdots \\ Br \cdots Me \\ \vdots \\ L_2Ni \\ Me \end{array} \right] \text{or} \left[\begin{array}{c} Me \\ | \\ L_2Ni\text{—}Ph \\ | \\ Me \end{array} \begin{array}{l} \\ \\ \\ \\ Br \end{array} \right]$$

7a **8a**

$$\longrightarrow (NiBr(Me)(PEt_3)_2) + CH_3C_6H_5. \quad (5)$$

9a

In the above reaction, formation of a bromo(methyl)-nickel complex **9a** is assumed. However, detection of **9a** was not feasible.

Type B: When propyl bromide is employed in the reaction with **3**, a similar inductive effect of the alkyl bromide on the reductive elimination of R–R, ethane, was observed. However, in this case, methane and propylene became the major gaseous products, suggesting that occurrence of hydrogen migration from the propyl group to the methyl group on a Ni^{IV} species formed by oxidative addition of propyl bromide to **3**.

$$\mathbf{3} + C_3H_7Br \longrightarrow \left[\begin{array}{c} Me \\ | \\ (PEt_3)_2Ni\text{—}C_3H_7 \\ | \\ Me \end{array} \begin{array}{l} \\ \\ \\ \\ Br \end{array} \right] \longrightarrow$$

8b

$$\left[(PEt_3)_2Ni \begin{array}{l} Br \\ Me \end{array} \right] + CH_4 + C_3H_6$$

9b

$\downarrow C_3H_7Br$

$$\left[\begin{array}{c} Br \\ | \\ (PEt_3)_2Ni\text{—}Br \\ | \\ Me \end{array} \begin{array}{l} \\ \\ \\ \\ C_3H_7 \end{array} \right]$$

10b

$$CH_4 + C_3H_6 + NiBr_2(PEt_3)_2$$

Scheme 1.

The formation of C_3H_8 in this reaction indicates that certain hydrogen abstraction reaction by the C_3H_7 group in the intermediate species takes place. Although the number of isolated Ni^{IV} complexes is not large,[14] various Pt^{IV} complexes including alkylplatinum(IV) complexes are known[15] and the results of the reaction of **3** with propyl bromide is most straightforwardly explained by assuming the Ni^{IV} intermediate as shown in Scheme 1. The agreement of the amount of CH_4 evolved with that of C_3H_6 supports the mechanism shown above.

Type C: In the case of the reaction of **4** with PhCl, a cross coupling reaction such as expressed by Eq. 5 constitutes the main reaction route, and a complex of type **9**, NiCl(Me)(dpe) (**9c**), is formed as the main nickel product.

$$\mathbf{4} + PhCl \longrightarrow \left[\begin{array}{c} Ph \\ \vdots \\ Cl \cdots Me \\ \vdots \\ (dpe)Ni \\ Me \end{array} \text{or} \begin{array}{c} Me \\ | \\ (dpe)Ni\text{—}Ph \\ | \\ Cl \end{array} \right]$$

7c **8c**

$$\longrightarrow NiCl(Me)(dpe) + CH_3C_6H_5 \quad (6)$$

The partial formation of ethane and NiPh(Cl)(dpe) (proved by acidolysis) indicates that the reductive

elimination of Me–Me in **8c** or the reductive elimination induced by PhCl as discussed for the reactions of **1** and **2** with aryl halides also takes place (see Experimental),

$$\mathbf{4} + \mathrm{PhCl} \xrightarrow{\text{minor route}} [\mathbf{6}, \mathbf{6}', \text{or } \mathbf{8c}] \longrightarrow \mathrm{Me\text{-}Me} + \mathrm{NiCl(Ph)(dpe)}. \quad (7)$$

In contrast to the reaction of **4** with PhCl, that with an alkyl halide, ethyl bromide (No. 9), affords the cross coupling product, propane, in only a small yield, and the reaction causes evolution of other gaseous products which are produced through the Type A (ethane) and Type B (methane and ethylene) reaction routes.

The results shown above indicate that subtle differences in the structures of the dialkylnickel complex and R'X cause a considerable change in the reaction route. It may be noted that the intermediate formed in the reaction of a diphosphine-coordinated dialkylnickel complex with alkyl halide having β-hydrogen has a trend to undergo the hydrogen shift reaction (or β-elimination reaction) from R' to R, and this may be related to the fact that the C–C coupling catalyzed by nickel–phosphine complexes does not give good results when alkyl halides are used as the reactants.[10]

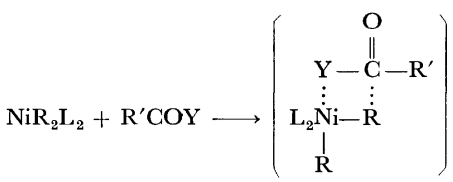
Reactions with R'COY. Table 2 shows results of the reactions of the dialkylnickel(II) complexes with acyl halides and their analogues, R'COY. It includes some previously reported results[8b] of the reactions of NiR_2L_2 with R'COY. The reaction listed in Table 2 can be classified into the following two types of reactions according to the product distribution:

Type D: Formation of asymmetric ketone, RCOR', and $NiX(R)L_2$.
$NiR_2L_2 + R'COY \rightarrow NiY(R)L_2 + RCOR'$

Type E: Formation of symmetric ketone RCOR, accompanied by formation of $NiX(R')L_2$.
$NiR_2L_2 + R'COY \rightarrow NiY(R')L_2 + RCOR$.

Each type of the reaction is discussed below.

Type D: Complexes **1**—**3** undergo Type D reaction on treatment with R'COY or its analog (Nos. 1—9 in Table 2). The formation of these products is explained by assuming the following four-center mechanism.

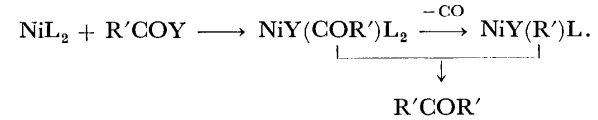


$$\longrightarrow NiY(R)L_2 + RCOR' \quad (8)$$

Scheme 2.

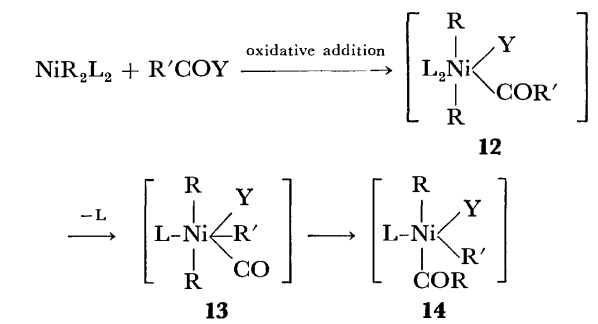
The isolation of NiY(Et)(bpy) in Nos. 2 and 3 indicates that NiY(Et)(bpy) is less reactive toward R'COY than **2**. The isolation of $NiMe(OCOPh)(PEt_3)_2$ in No. 8 also indicates the isolated complex is not reactive toward $(C_6H_5CO)_2O$. When an excess of C_2H_5COCl is added, complex **3** is transformed to *trans*-$NiCl_2(PEt_3)_2$, suggesting that $NiCl(Me)(PEt_3)_2$ initially formed reacts further with C_2H_5COCl.

In most cases, the formation of RCOR' and $NiY(R)L_2$ is accompanied by evolution of alkanes (RH and R–R) and alkene (ethylene from **2**), indicating that activation of the Ni–R bond on interaction with R'COY takes place. The formation of RCOR in Nos. 1 and 9 suggests that Type E reaction occurs partly. R'COR' obtained in Nos. 5—7 seems to be formed through oxidative addition of R'COY to Ni^0 complex(es) which is formed in the reaction system, *e.g.*,

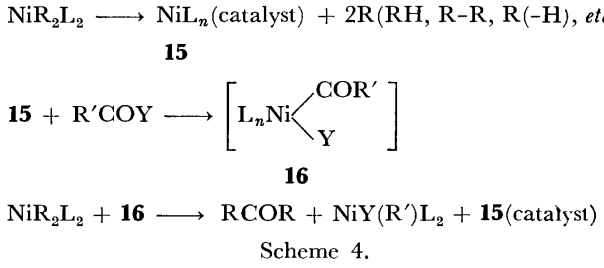


Type E: The diphosphine-coordinated dialkylnickel(II) complexes, **4** and **5**, undergo Type E reaction to afford RCOR. In the case of the reaction of **4** with PhCOCl (No. 10), the complex of the type $NiY(R')L_2$ is isolable. $NiCl_2(dpe)$ obtained in No. 11 is considered to be formed by a reaction of initially formed NiCl(Et)(dpe) with C_2H_5COCl.

The formation of RCOR clearly indicates migration of CO from R'COCl to NiR_2L_2. As for the process to produce RCOR, we consider the following two mechanisms.



Scheme 3.



Scheme 4.

Scheme 3 involves oxidative addition of R'COX to NiR_2L_2 to form a Ni^{IV} species **12**, decarbonylation from the R'CO– ligand in **12**, insertion of the CO ligand into the Ni–R bond, and reductive elimination of RCOR from the four-valent nickel intermediate. Ruddick and Shaw showed that pyrolysis of $PtCl(Me)_2(COMe)(PMe_2Ph)_2$ gave acetone and *trans*-$PtCl(Me)(PMe_2Ph)_2$ as the sole products.[16a]

In Scheme 4, we assume initial formation of Ni^0 complex, NiL_n, by thermal decomposition of NiR_2L_2. The Ni^0 species thus formed is assumed to react with

R'COY to give the oxidative addition product **16**, which further reacts with NiR_2L_2 to yield RCOR with resumption of NiL_n, which thus serves as a catalyst to carry the decarbonylative CO transfer agent. Oxidative addition of RCOX to Ni^0 complexes is well known,[17] and we previously reported[18] formation of RCOR and the $NiY(R')L_2$ type complex by reactions of an acylnickel(II) complex, *trans*-Ni(COMe)(phthalimido)$(PEt_3)_2$ (Y=phthalimido), with NiR_2(bpy) (R=Me, Et).

$$Ni(COMe)Y(PEt_3)_2 + NiR_2(bpy) \longrightarrow RCOR + NiMeY(PEt_3)_2$$

Y=phthalimido

At the moment, we have no strong evidence to prove or disprove the mechanisms. However, the decarbonylation reaction from the coordinatively saturated **12** to **13** seems to require partial or full dissociation of the bidentate diphosphine ligand. Therefore, if we take into account the previously observed fact[9] that the diphosphine ligands have much higher coordinating abilities toward nickel complexes than PEt_3 and bpy, the present observation that Type E reaction does not proceed with the dialkylnickel(II) complexes having the weakly coordinating PEt_3 or bpy ligand but with the complexes having the strongly coordinating dpe or dpp ligand seems not compatible with the mechanism shown in Scheme 3. Moreover, if the reaction proceeds by Scheme 3, the reaction would give RCOR' besides RCOR.

If we assume Schemes 2 and 4, the variation of the products depending on the nature of the dialkylnickel(II) may be explained by the presence or absence of an open coordination site in the dialkylnickel complexes for interaction with R'COY to form the active intermediate **11**. Complexes **1** and **2** having the flat bpy ligand possess an open vacant site for R'COX at their apical positions as can be seen on the CPK molecular model, and **3** has a trend to liberate the PEt_3 ligand as shown by variable temperature NMR spectroscopy[7] which shows a rapid exchange between the coordinating PEt_3 ligand and free PEt_3 in solutions even at low temperatures (*e.g.*, −60 °C). Under these circumstances, R'COY has an access to coordinate to Ni in **1**—**3**, and thus can undergo Type D reaction. On the other hand, the bulky and strongly coordinating diphosphine ligands in **4** and **5** block the coordination site in the nickel dialkyls. Therefore, the production of the unsymmetrical ketone RCOR' in the reactions of **4** and **5** with R'COY is hindered, and complexes **4** and **5** take a different reaction course as shown in Scheme 4.

Reaction with CS_2. The reductive elimination of R–R from **4** is induced by interaction with CS_2, and the Ni(0) complex thus formed takes up one molecular of CS_2 per the nickel complex,

$$\underset{}{\mathbf{4}} + CS_2 \longrightarrow \underset{69\%}{Me\text{-}Me} + \underset{\mathbf{17}(84\%)}{Ni(CS_2)(dpe)}. \quad (9)$$

Baird and Wilkinson reported formation of a similar CS_2 adduct of $Ni(PPh_3)_2$ by a reaction of $Ni(PPh_3)_4$ with CS_2.[19] An absorption band at 1190 cm^{-1} in an IR spectrum (KBr) of **17** is comparable with reported ν(C=S) vibrations of $Ni(CS_2)(PPh_3)_2$ (1196, 1117 cm^{-1} in CS_2),[19] $Pd(CS_2)(PPh_3)_2$ (1193 cm^{-1} in CS_2),[19] and $Pd(CS_2)$(dpe) (1178, 1167, 1152 cm^{-1}).[20] The CS_2 in **17** is strongly coordinated with Ni, and it is not replaced even by CO at 1 atm. The reaction of **3** with CS_2, on the contrary, does not lead to the reductive elimination of R–R, but it gives a 1:1 adduct of **3** and CS_2 as shown by elemental analysis of the adduct. IR spectrum of the adduct shows new bands at 1430, 1270, and 605 cm^{-1}, suggesting a different mode of the coordination of CS_2 to Ni from that in **17**.

Experimental

Manipulation, Material, and Analysis. Manipulation of complexes and reactions were carried out under atmosphere of N_2 or Ar or under vacuum. Complexes **1**—**5** were prepared according to literature.[2,7] Solvents were dried over Na, distilled under N_2, and stored under N_2. Microanalysis of C, H, N, and S was performed by Mr. T. Saito of our research laboratory. The amount of gas produced was measured with a Toepler pump and the gas collected was analyzed by GLC using a Shimadzu GC-3BT gas chromatograph. IR and NMR spectra were recorded on a Hitachi Model 295 infrared spectrometer and a JEOL JNM-PS-100 spectrometer, respectively.

*Reaction with R'X (*cf. *Table 1).* *No. 1*: 2-Chlorotoluene (3 cm^3) was added to a tube containing 360 mg (1.5 mmol) of deep green **1** at −78 °C. After the tube was evacuated, the mixture was warmed to 50 °C and stirred for 3 h at the temperature. Evolution of 1.23 mmol of C_2H_6 (84% per **1**) and a small amount of CH_4 was observed. The reddish brown precipitate formed was filtered off and crystallized from acetone (yield=250 mg, 73%). The reddish brown complex was characterized as NiCl(2-tolyl)(bpy) by comparing its IR spectrum with that of an authentic sample prepared according to literature.[11b]

No. 3: $(CH_3)_3CCl$ (3 cm^3) was added by trap-to-trap distillation to a tube containing 176 mg (0.64 mmol) of deep green **2** by using a vacuum line. When the green solution was stirred at room temperature, a smooth reaction proceeded to give a brown solution and a precipitate. At this point, evolution of butane was checked by GLC. Further stirring of the reaction mixture at room temperature for 3 d gave a greenish gray precipitate. Analysis of the gas phase showed evolution of gases shown in Table 1. The gaseous and liquid materials in the reaction system was removed by evaporation under vacuum and the gray precipitate was identified as $NiCl_2$ (bpy) from its IR spectrum.[2d]

No. 4:[21] When **2** (230 mg, 0.86 mmol) was added into a THF solution (20 cm^3) of poly(vinyl chloride) (M.W.=103000, 1.0 g, 16 mmol), the deep green homogeneous solution initially obtained rapidly changed to a deep red color with evolution of butane (0.60 mmol). The nickelated poly(vinyl chloride) was recovered by adding hexane, washed with hexane repeatedly, and dried under vacuum. The visible spectrum of the nickelated poly(vinyl chloride) showed a strong band assignable to a CT band at 535 nm ($\varepsilon=2\times10^3$), the λ_{max} and ε values being the same as that of a low molecular weight analogue of the polymer–nickel adduct, NiEt(Cl)(bpy)[8b] ($\lambda_{max}=533$ nm, $\varepsilon=2\times10^3$). The reaction of the nickelated poly(vinyl chloride) with carbon monoxide was carried out as follows. Carbon monoxide (atmospheric pressure) was introduced into a vessel containing a THF solution of the nickelated poly(vinyl chloride). After stirring

the solution for 20 min, the polymer was recovered by adding hexane to the THF solution and dried under vacuum. The infrared spectrum of the product of the reaction with carbon monoxide showed a ν(C=O) band at 1640 cm^{-1}. The infrared spectrum of a low molecular weight analogue of $\{CH_2-CH(CONiCl(bpy))\}_n$, Ni(COEt)Cl(bpy),[18] shows the ν(C=O) band at 1660 cm^{-1}. The carbonylated complex, $\{CH_2-CH(CONiCl(bpy))\}_n$ reacts with methanol to give a $\{CH_2-CHCOOCH_3\}_n$ monomer unit introduced into poly (vinyl chloride) as proved by IR (ν(C=O)=1730 cm^{-1}). This also supports the formation of $\{CH_2-CH(CONiCl(bpy))\}_n$.

No. 5: Bromobenzene (82×10^{-3} cm^3, 0.78 mmol) was added into a diethyl ether (2 cm^3) solution of **3** (120 mg, 0.36 mmol) at −50 °C. After evacuation of the reaction vessel, the reaction mixture was stirred at room temperature for 1 d. GLC analysis showed formation of gaseous and liquid products shown in Table 1. A yellow precipitate obtained by adding hexane to the reaction mixture was collected by filtration and dried under vacuum to yield 57 mg (36%) of a yellow solid, which was characterized as *trans*-$NiBr(Ph)(PEt_3)_2$ by comparing its IR and NMR spectra with those of an authentic sample prepared according to literature.[13]

No. 6: Propyl bromide (0.10 cm^3, 1.1 mmol) was added into a toluene (1 cm^3) solution of **3** (120 mg, 0.37 mmol). The reaction mixture was stirred at room temperature for 12 h. GLC analysis showed the formation of the gaseous and liquid products shown in Table 1. After removing toluene under vacuum, the complex formed was crystallized from a mixture of diethyl ether and hexane to yield reddish purple crystals (120 mg, 0.26 mmol, 71%), which were characterized as *trans*-$NiBr_2(PEt_3)_2$ from its IR spectrum and elemental analysis. The reactions of **3** and **4** with EtBr (Nos. 7 and 9) were carried out analogously.

No. 8: A mixture of **4** (380 mg, 0.79 mmol) and chlorobenzene (6 cm^3) was stirred at room temperature for 5 d. Analysis of the gaseous and liquid products by GLC showed evolution of 0.90 mmol of CH_4, 0.11 mmol of C_2H_6, and 0.39 mmol of toluene. Addition of hexane to the reaction mixture gave a brownish yellow precipitate. The precipitate was dissolved in THF and a yellow solid (260 mg) was recovered by addition of hexane to the THF solution. ^1H and $^{31}P\{^1H\}$-NMR spectra showed that it contained NiMe(Cl)dpe as a chief component and $NiCl_2$(dpe) and NiPh(Cl)dpe (*cf.* No. 10 in Table 2, *vide infra*) as minor. The ratios between these three complexes were determined as 79:7:14 from the area ratios of their peaks in $^{31}P\{^1H\}$-NMR spectrum. Attempts to separate these compounds have not been successful. Acidolysis of 46 mg of this yellow solid gave 0.08 mmol of CH_4 and 0.01 mmol of C_6H_6 in accord with its $^{31}P\{^1H\}$-NMR data. An authentic sample of NiMe(Cl)dpe was prepared separately from a 1:1 reaction of **4** with HCl according to the procedure shown below.

To a THF (25 cm^3) solution of **4** (500 mg, 1.0 mmol), a THF (5 cm^3) solution of dry HCl (0.95 mmol) was added dropwise at −50 °C. After stirring for 30 min at this temperature, the solvent was reduced to 10 cm^3 by evaporation. The yellow solid thus obtained was filtered, washed with hexane, and dried under vacuum. Recrystallization from THF–diethyl ether (1:1) gave orange yellow crystals of NiMe(Cl)dpe (160 mg). Found: C, 64.2; H, 5.3; Cl, 7.5%. Calcd for $C_{27}H_{27}ClNiP_2$: C, 63.9; H, 5.4; Cl, 7.0%. ^1H-NMR(*N*,*N*-dimethylformamide-d_7): δ=0.1 (3H, multiplet, CH_3–Ni), 1.9—2.8 (4H, multiplet, CH_2–P), and 7.3—8.1 (20H, multiplet, C_6H_5–P). $^{31}P\{^1H\}$-NMR(CH_2Cl_2): 67.7 (d, J_{P-P}=8 Hz) and 43.7 (d, J=8 Hz) ppm from external PPh_3.

*Reaction with R'COY (*cf. *Table 2). No. 1*: When a mixture of **1** (110 mg, 0.42 mmol) and PhCOCl (0.16 cm^3, 1.4 mmol) in THF (1.5 cm^3) was stirred at room temperature, the color of the solution changed instantly from deep green to purple. The color of the solution, then, turned to brown gradually with formation of a brown precipitate. The GLC analysis after 1 d showed formation of ketones and other products shown in Table 2. Reactions Nos. 2 and 3 were carried out analogously as reported in our previous paper.[8b] Reactions Nos. 4—9 were also carried out analogously. The nickel complexes obtained in Nos. 5 and 8 were characterized by comparing their IR spectra with authentic samples.[8b]

No. 10: Toluene (5 cm^3) and PhCOCl (0.15 cm^3) were added into a reaction vessel containing 0.30 g of **4** at −196 °C. After evacuation of the vessel, the reaction mixture was stirred at room temperature for 1 d. GLC analysis of the gas and liquid phase indicated the formation of the gaseous and liquid products shown in Table 2. The yellow precipitate formed during the reaction was collected by filtration and crystallized from a mixture of THF and diethyl ether. The nickel complex thus isolated was identified as NiCl(Ph)dpe from its elemental analysis and IR and NMR spectra. The same complex was prepared by a ligand exchange reaction of known $NiCl(Ph)(PPh_3)_2$[22] with dpe. Found: C, 67.2; H, 5.1; Cl, 6.2. Calcd for $C_{32}H_{29}ClNiP_2$: C, 67.5; H, 5.1; Cl, 6.2. IR(KBr, cm^{-1}): 1560s, 1460vs, 320 m. ^1H NMR: δ=1.6—2.8 (4H, multiplet, CH_2–P), 6.6 (3H, *o*, *m*- or *m*, *p*-H of Ni–C_6H_5), 6.9—8.2 (22H, multiplet, C_6H_5–P and *o*- or *m*-H of Ni–C_6H_5). $^{31}P\{^1H\}$-NMR-(CH_2Cl_2): 60.3 (d, J_{P-P}=20 Hz) and 43.4 (d, J=20 Hz) ppm from external PPh_3. Reactions Nos. 11—14 were carried out analogously. $NiCl_2$(dpe) obtained in No. 11 was characterized by comparing its IR spectrum with that of an authentic sample.[23]

Reaction with CS_2. Toluene (6 cm^3) and CS_2 (0.10 cm^3, 1.7 mmol) were added into a vessel containing **4** (0.28 g, 0.58 mmol) at −196 °C. After evacuation of the vessel, the reaction mixture was stirred at room temperature. After 1 h, formation of a green precipitate was observed. Analysis of the gas phase by gas chromatography indicated formation of 0.40 mmol (69%) of ethane and a small amount of CH_4. The green precipitate was collected by filtration, washed repeatedly with diethyl ether, and dried under vacuum to yield 260 mg of Ni(CS_2)(dpe). Found: C, 61.6; H, 4.7; S, 12.2. Calcd: C, 60.8; H, 4.5; S, 12.0. The complex was soluble in CH_2Cl_2, but it decomposes in the solvent as judged from IR spectra of a solid recovered from the CH_2Cl_2 solution. Ni(CS_2)(dpe) was sparingly soluble in other solvents, and recrystallization has not been succesful.

The reaction of **3** with CS_2 was carried out analogously by using 0.19 g (0.60 mmol) of **3** and 0.078 cm^3 (1.30 mmol) of CS_2 at −25 °C for 2 d (solvent=2 cm^3 of diethyl ether). The pale brown precipitate was collected by filtration at −30 °C, washed with diethyl ether at −30 °C, and dried under vacuum to yield 220 mg (85%) of a nickel complex having an approximate composition of $NiMe_2(PEt_3)_2(CS_2)$. Found: C, 43.9; H, 9.4; S, 16.2%. Calcd: C, 44.9; H, 9.0; S, 16.0%. Acidolysis of $NiMe_2(PEt_3)_2(CS_2)$ gave methane quantitatively.

Metal Complexes in Organic Synthesis. VIII.[1,2] Allylic Alcohols as Starting Materials in Palladium-catalyzed Wittig-type Olefinizations

Marcial MORENO-MAÑAS* and Antonio TRIUS

Departamento de Química Orgánica, Universidad Autónoma de Barcelona, Bellaterra, Barcelona, Spain

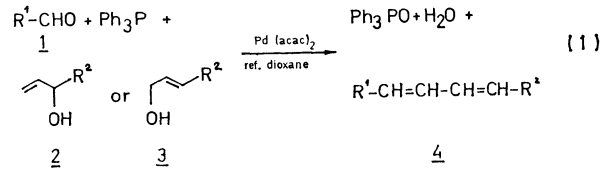
(Received July 28, 1982)

Allylic alcohols, aldehydes, and triphenylphosphine participate in a one-pot process catalyzed by palladium, which is formally equivalent to the Wittig olefinization. It can be applied to both aliphatic and aromatic aldehydes. The resulting olefins which appear as mixtures of stereoisomers were fully hydrogenated. Two different mechanisms can account for the observed results.

Palladium catalyzed and promoted reactions have attracted the interest of the chemical community since this transition metal provides us with the possibility of performing several interesting transformations.[3]

In the course of our study on the alkylation of 2,4-pentanedione with allylic and related alcohols under palladium catalysis,[4] we observed the formation of *ca.* 0.7% of (*Z*)- and (*E*)-stilbene in the reaction of sodium 2,4-pentanedionate with benzyl alcohol in the presence of catalytic amounts of bis(2,4-pentanedionato)palladium ($Pd(acac)_2$), and triphenylphosphine. Since benzaldehyde is formed together with toluene by disproportionation of benzyl alcohol, we first reasoned that the phosphine present in the reaction media could somehow react with the alcohol to yield benzyltriphenylphosphonium hydroxide, which should be the precursor of the Wittig reagent. The ylide could finally react with benzaldehyde in a conventional way.

We then started a study on the reaction of several different aldehydes with allylic alcohols and triphenylphosphine under palladium catalysis, the metal being always added in the form of $Pd(acac)_2$. The general reaction can be formulated as indicated in Eq. 1, and the results of the most significant experiments are collected in Table 1.



1 2 3 4 (1)

Some experimentation was performed before appropriate experimental conditions could be found. Dioxane was shown to be superior as solvent to THF, DME, diglyme, and toluene. The refluxing dioxane was passed through a molecular sieve pad before returning to the reaction flask. This shortened the required reaction times although the yields were not affected. Triphenylphosphine was the most suitable phosphorus compound for this reaction since tributylphosphine, tri-*o*-tolylphosphine, tris(*o*-methoxyphenyl)-phosphine, triethyl phosphite and bis(1,2-diphenylphosphino)ethane gave clearly lower yields of condensation products.

The olefinization method has been extended to aliphatic aldehydes, both saturated and α,β-unsaturated, as well as to aromatic aldehydes with different

a) One equivalent of PPh_3 and a 5% molar of Pd were used unless otherwise stated. b) 1-Octen-3-ol (**2**), (*E*)-2-buten-1-ol (**3a**), (*E*)-2-hexen-1-ol (**3b**). c) 1,3-Octadienes were also detected. d) 10% molar of Pd was used. e) 3-((*E*)-2-Octenyl)-2,4-pentanedione and 3,3-bis((*E*)-2-octenyl)-2,4-pentanedione could also be isolated.[4] f) For **4f**. See text for **4g**. g) See text for **5g**. h) Two equivalents of PPh_3 were used. i) Two drops of hydrazine were added to reduce the Pd(II). j) 2-Pentyltoluene was also detected. k) 1-Pentyl-2-propylbenzene was also detected.

substituents at the ring. 4-Chlorobenzaldehyde (**1a**), 4-nitrobenzaldehyde (**1b**), 4-methoxybenzaldehyde (**1c**), terephthalaldehyde (**1d**), phthalaldehyde (**1e**), hexanal (**1f**), (*E*)-2-butenal (**1g**), and (*E*)-2-hexenal (**1h**), were shown to react with triphenylphosphine and one or more of the following allylic alcohols: 1-octen-3-ol (**2**), its acetate (**2**-OAc), (*E*)-2-buten-1-ol (**3a**) and (*E*)-2-hexen-1-ol (**3b**). However, a simple ketone, 6-methyl-2-heptanone was recovered after refluxing in dioxane for seven days with **2**, triphenylphosphine and 5% molar $Pd(acac)_2$.

Irrespective of primary or secondary nature of the allylic alcohols, products **4** were always formed by reaction at the terminal end of the allylic system (see ops. 4 and 6 in Table 1). The regioselectivity of the reaction is always higher than 99% as shown by GLC analysis of the hydrogenated products **5** (see below).

The olefins **4** were formed as mixtures of stereoisomers. We did not study the stereochemical outcome of our reactions. However, ratios of isomers as determined by GLC are indicated in the experimental part.

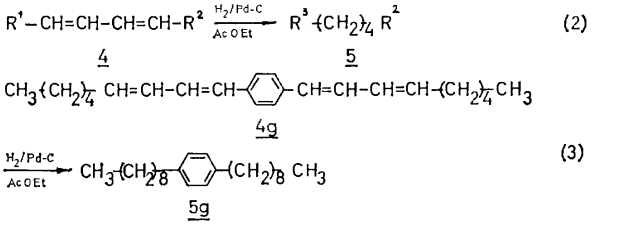
When the unsaturated aldehydes **1g** and **1h** were used as starting materials, only reaction at the carbonyl group was observed, products arising from attack at the electrophilic β position not being detected.

Terephthalaldehyde (**1d**) reacted with one equivalent of **2** to yield mainly the product of monocondensation, 1-(4-formylphenyl)-1,3-nonadiene (**4f**) (51%), and only minor amounts of the corresponding product of dicondensation, 1,4-bis(1,3-nonadienyl)benzene (**4g**) (4%) (see op. 8). Even working with a large excess of alcohol, **4f** was formed as the major product (op. 9). A similar selectivity in the reactions of the aldehyde **1d** in Wittig olefinizations has been described.[5]

In our first experiments aimed at preparing 1-(4-chlorophenyl)-1,3-nonadiene (**4a**), we realized that the reaction stopped when both the aldehyde **1a** and triphenylphosphine, but not the alcohol **2**, were still present in the reaction media. Elimination of water or acetic acid from allylic alcohols and acetates through the intermediacy of π-allylpalladium complexes is well documented[4,6] and we could demonstrate that dehydration of **2** was indeed a side reaction. In op. 2 a ratio **1a**/**2** of 1.0/2.2 was adopted, the yield of **4a** being raised to 68%. Also, the solvent, which was carefully recovered after the reaction and analyzed by GLC, showed two additional peaks. Hydrogenation under 10% Pd–C catalysis led to a dioxane containing octane as the only accompanying product, thus allowing us to assign the (*Z*)- and (*E*)-1,3-octadiene structures to the products present in the dioxane before hydrogenation.

The reactions were quite clean except when the nitroaldehyde **1b** was used. In such cases (ops. 5 and 6) no triphenylphosphine was recovered, a complicated array of products without nitro group being also formed. The reduction of nitro groups by trivalent phosphorus compounds is a well known fact[7] which can account for the observations made.

Since the olefins **4** were formed as mixtures of stereoisomers, we hydrogenated them under 10% Pd–C

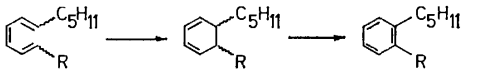


(2)

(3)

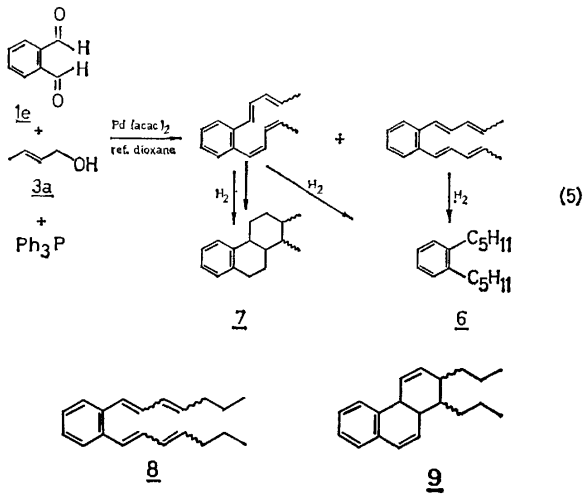
catalysis to the corresponding saturated compounds **5** as indicated in Eqs. 2 and 3. The results are collected in Table 1. Products **5** were homogeneous in GLC to an extent higher than 99%. They were fully characterized by elemental analysis and the usual spectroscopic techniques, or by comparison (GLC) with authentic specimens.

When trienes **4i** and **4j** were hydrogenated, the corresponding paraffins, dodecane (**5i**) and tetradecane (**5h**), were contaminated with *ca.* 6% of another components which presented a molecular ion in mass spectrometry at *m/e* eight units lower than the corresponding **5**, and aromatic absorptions in the ^{1}H-NMR spectrum. On these grounds the structures of 2-pentyltoluene and 1-pentyl-2-propylbenzene can be attributed to the contaminant products. They can arise from electrocyclic ring closures on the pertinent isomers of constitutions **4i** and **4j** followed by oxidative aromatization (Eq. 4).



(4)

We turned next to **1e** as starting aldehyde. Its reactions were much more complicated than those previously described. When **1e** was treated with a tenfold excess of **3a** and two equivalents of triphenylphosphine under palladium catalysis, a 17% of a complex mixture of products without carbonyl group was isolated. Also triphenylphosphine was recovered, but no **1e** could be detected in the mixture. This was hydrogenated to only two products formed in a ratio of *ca.* 2/1. Mass spectrometric analysis coupled with GLC allowed us to assign the structure of 1,2-dipentylbenzene (**6**), and the constitution of 1,2-dimethyl-1,2,3,4,4a,9,10,10a-octahydrophenanthrene (**7**) to the products (Eq. 5).



(5)

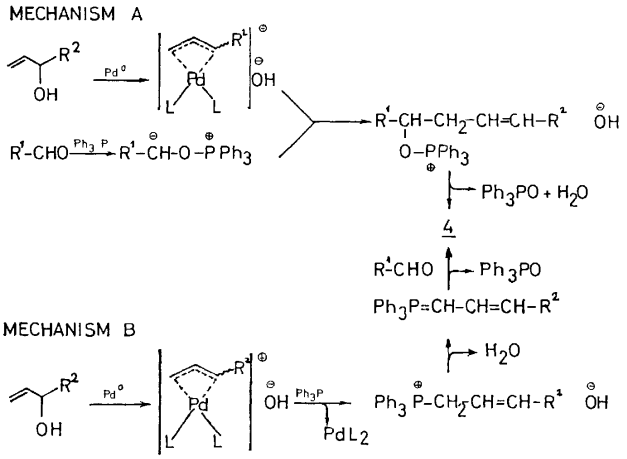


Fig. 1. Possible mechanisms accounting for the observed olefinizations.

Similar experiments were performed with **3b** as starting alcohol. In this case a 48% of diolefinization products could be isolated as a mixture of no less than eight components with the constitutions of 1,2-bis(1,3-heptadienyl)benzene (**8**), and probably 1,2-dipropyl-1,2,4a,10a-tetrahydrophenanthrene (**9**). A sample of **8** was isolated by column chromatography and inequivocally characterized by ^{1}H-NMR spectroscopy and mass spectrometry.

Two different mechanisms can account for the observed olefinizations. They are indicated in Fig. 1. Both mechanisms involve the intermediacy of π-allyl complexes formed by reaction of allylic alcohols with palladium(0) species. It should be recalled that allylic alcohols can indeed act as precursors for such complexes,[4] palladium(0) being formed by *in situ* reduction of the bivalent palladium compound really added to the reaction mixture. The inversion of reactivity at the carbonyl group needed for mechanism A to be operative has been previously postulated.[8] However, the reaction between phosphines and π-allylnickel[9] and palladium[10] complexes as exemplified by mechanism B has been described. At this point we can not decide through which mechanism the reactions proceed.

Experimental

Infrared and ^{1}H-NMR spectra were respectively recorded with a Perkin-Elmer Infracord 720 and a Perkin-Elmer R-12 models. Mass spectra were run with a Hewlett-Packard 5930 spectrometer. Only peaks with a *m/e* value above 20 are indicated unless they correspond to the molecular ion. GLC determinations were carried out in the Hewlett-Packard 5831A and Perkin-Elmer Sigma 1 models, both provided with flame ionization detection and UCW columns (0.5 m) unless otherwise stated.

Reaction between ***1a***, ***2***, *and Triphenylphosphine (op. 2); Preparation of 1-(4-Chlorophenyl)-1,3-nonadiene (****4a****).* The aldehyde **1a** (1.405 g, 10.0 mmol), alcohol **2** (2.816 g, 22.0 mmol), triphenylphosphine (2.751 g, 10.5 mmol) and Pd(acac)$_2$ (0.153 g, 0.5 mmol) were refluxed in dioxane (8 ml) for 70 h under magnetic stirring and dry nitrogen. The refluxing solvent was passed through a molecular sieve (4 Å) pad. The solvent was distilled off and the residue was chromatographed through a silica-gel column to afford **4a** (eluted with hexane), triphenylphosphine, **1a**, and triphenylphosphine oxide (eluted respectively with hexane(85)–dichloromethane(15), dichloromethane and chloroform).

4a: 1.591 g (68%). Ratio of isomer peaks in GLC: 38/15/13/34. IR (film): 1640, 1600, 980, 840, 790 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.75—1.10 (broad t, 3H), 1.10—1.75 (m, 6H), 1.9—2.4 (m, 2H), 5.50—6.95 (m, 4H), 7.25 (s, 4H). MS: *m/e* 236(7), mol wt 234(M$^+$, 30), 177(46), 163(49), 142(80), 129(100), 115(38), 96(34), 67(28), 41(44).

The distilled dioxane was analyzed by GLC showing two additional peaks in a 44/56 ratio. The mixture was treated with hydrogen at atmospheric pressure under 10% Pd–C (0.035 g) catalysis. When the uptake of hydrogen was over the catalyst was filtered off and the filtrate was analyzed by GLC. Only one additional peak was observed which was shown to correspond to octane by comparison with an authentic specimen.

The following products were prepared in a similar manner (see Table 1):

*1-(4-Chlorophenyl)-1,3-pentadiene (****4b****)*: Ratio of isomer peaks in GLC: 25/35/40. IR (film): 1640, 1590, 980, 940, 920, 840, 810, 790, 720 cm^{-1}. ^{1}H-NMR (CCl_4): δ 1.80 (d, J=6 Hz, 3H), 5.50—6.77 (m, 4H), 7.28 (broad s, 4H). MS: *m/e* 180(4), mol wt 178(M$^+$, 17), 143(67), 128(100), 115(46), 89(21), 75(25), 53(26).

*1-(4-Nitrophenyl)-1,3-nonadiene (****4c****)*: Ratio of isomer peaks in GLC: 9 (including a shoulder)/11/80. IR (film): 1630, 1590, 1510, 1330, 980 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.7—1.1 (m, 3H), 1.15—1.80 (m, 6H), 1.85—2.50 (m, 2H), 5.7—7.3 (m, 4H), 7.45, 7.60, 8.15, 8.30 (4H). MS: *m/e* mol wt 245(M$^+$, 6), 158(26), 142(50), 141(54), 137(26), 128(100), 119(48), 117(44), 115(58), 102(32), 96(40), 91(64), 83(38), 77(34), 67(36), 65(32), 63(26), 57(26), 44(76).

*1-(4-Nitrophenyl)-1,3-heptadiene (****4d****)*: Ratio of isomer peaks in GLC: 28.5/4.5/11.5/55.5. IR (film): 1640, 1580, 1510, 1340, 990, 950, 860, 740 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.92 (t, J=7 Hz, 3H), 1.15—1.80 (m, 2H), 2.15 (q, J=7 Hz, 2H), 5.5—7.2 (m, 4H), 7.30, 7.45, 8.00, 8.15 (4H). MS: *m/e* mol wt 217(M$^+$, 43), 188(36), 174(21), 143(83), 142(69), 129(50), 128(100), 115(58), 83(40), 77(23), 55(73), 41(77), 39(69).

*1-(4-Methoxyphenyl)-1,3-nonadiene (****4e****)*: Ratio of isomer peaks in GLC: 40.5/11.5/10.5/37.5. IR(film): 1610, 990, 820 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.75—1.10 (broad t, 3H), 1.1—1.8 (m, 6H), 1.85—2.65 (m, 2H), 3.78 (s, 3H), 5.45—6.83 (m, 4H), AA'BB' system centered at 7.17 (4H). MS: *m/e* mol wt 230(M$^+$, 25), 204(21), 202(32), 187(21), 173(28), 168(21), 159(32), 134(100), 121(57), 119(46), 91(34), 89(25).

*1-(4-Formylphenyl)-1,3-nonadiene (****4f****) and 1,4-Bis(1,3-nonadienyl)benzene (****4g****).* ***4f***: Ratio of isomer peaks in GLC: 42/10/13/35. IR (film): 2890, 2750, 1690, 1600, 990, 950, 860, 840, 820, 800 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.7—1.1 (broad t, 3H), 1.1—1.7 (m, 6H), 1.90—2.05 (m, 2H), 5.25—7.20 (m, 4H), 7.30, 7.45, 7.65, 7.80 (4H), 9.90 (broad s, 1H). MS: *m/e* mol wt 228(M$^+$, 12), 157(21), 143(20), 129 (100), 115(28), 91(28), 67(23), 41(20).

4g: Ratio of isomer peaks in GLC: 13/10/12/29/11/11/14. IR (film): 1640, 980, 940, 860 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.70—1.80 (m, 18H), 1.90—2.60 (m, 4H), 5.40—7.15 (m, 8H), 7.22 (s, 4H). MS: *m/e* mol wt 322(M$^+$, 7), 181(35), 167(82), 155(80), 141(100), 129(51), 128(48), 115(36), 91(20), 67(27), 55(23), 41(28).

*6,8-Tetradecadiene (****4h****)*: Ratio of isomer peaks in GLC (Carbowax 20 M column, 2 m): 71/29. IR (film): 990, 950 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.75—1.15 (m, 6H), 1.15—1.85 (m, 12H), 1.85—2.45 (m, 4H), 5.15—6.65 (m, 4H).

MS: *m/e* mol wt 194(M^+, 46), 124(25), 110(50), 109(36), 96(92), 95(78), 82(72), 81(96), 67(100), 55(21), 54(20), 41 (32).

*2,4,6-Dodecatriene (**4i**)*: Ratio of peaks in GLC: 3/6.5 (this belongs to *2-pentyltoluene*)/90.5. IR (film): 1640, 990, 940, 920 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.90 (t, J=6 Hz, 3H), 1.10—1.70 (m, 6H), 1.78 (d, J=6 Hz, 3H), 1.95—2.45 (m, 2H), 5.30—6.85 (m, 6H). *4,6,8-Tetradecatriene (**4j**)*: Ratio of peaks in GLC: 23/11/7.5 (this belongs to *1-pentyl-2-propylbenzene*)/58. IR (film): 990, 960 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.7—1.2 (m, 6H), 1.20—1.75 (m, 8H), 1.8—2.6 (m, 4H), 5.2—6.6 (m, 6H). MS: *m/e* mol wt 192(M^+, 17), 121(25), 105(27), 93(42), 92(35), 91(87) 79(100), 77(50), 71(46), 67(33), 65(25), 55(21), 53 (20), 43(79).

*Hydrogenation of **4a**; Preparation of 1-Chloro-4-nonylbenzene (**5a**).* The diene **4a** (0.850 g, 3.6 mmol) in ethyl acetate (25 ml) was hydrogenated at atmospheric pressure for 20 min in the presence of 10% Pd–C (0.050 g). The catalyst was filtered off and the solvent was evaporated to yield 0.848 g (98%) of **5a**, bp 127 °C (oven temp)/0.5 mmHg (1 mmHg= 133.322 Pa), which was homogeneous in GLC. ^{1}H-NMR (CCl_4): δ 0.7—1.1 (m, 3H), 1.1—2.0 (broad s, 14H), 2.6 (t, J=7 Hz, 2H), 7.2 (m, 4H). MS: *m/e* 240(7), 239(7), mol wt 238(M^+, 20), 125(100), 91(40), 57(30), 44(47). Found: C, 75.40; H, 9.84; Cl, 15.20%. Calcd for $C_{15}H_{23}Cl$: C, 75.44; H, 9.71; Cl, 14.85%.

The following products were prepared in a similar manner (see Table 1):

*1-Chloro-4-pentylbenzene (**5b**)*: Bp 112 °C (oven temp)/0.9 mmHg, 98% yield, homogeneous to an extent of more than 99% in GLC. ^{1}H-NMR (CCl_4): δ 0.65—1.95 (m, 9H), 2.50 (t, J=8 Hz, 2H), 7.0, 7.15, 7.20, 7.35 (4H). MS: *m/e* 184(3), mol wt 182(M^+, 7), 127(29), 125(100), 91(64), 89(36), 77(22), 63(34), 51(32), 41(91). Found: C, 71.98; H, 8.29; Cl, 19.74%. Calcd for $C_{11}H_{15}Cl$: C, 72.32; H, 8.27; Cl, 19.41%.

*1-Amino-4-nonylbenzene (**5c**)*: Bp 158 °C (oven temp)/1 mmHg, homogeneous in GLC. IR (film): 3500, 3400 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.9 (t, J=5 Hz, 3H), 1.25 (broad s, 14H), 2.45 (t, J=7 Hz, 2H), 3.35 (s, 2H), 6.35, 6.50, 6.80, 6.95 (4H). MS: *m/e* mol wt 219(M^+, 13), 106(100). Found: C, 81.94; H, 11.70; N, 6.45%. Calcd for $C_{15}H_{25}N$: C, 82.13; H, 11.49; N, 6.38%.

*1-Amino-4-heptylbenzene (**5d**)*: Bp 135 °C (oven temp)/1 mmHg, homogeneous to an extent of more than 99% in GLC. IR (film): 3450, 3380 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.60—1.05 (m, 3H), 1.10—1.75 (broad s, 10H), 2.45 (t, J= 8 Hz, 2H), 3.75 (s, 2H), 6.30, 6.45, 6.70, 6.85 (4H). MS: *m/e* mol wt 191(M^+, 12), 106(100). Found: C, 81.31; H, 11.17; N, 7.41%. Calcd for $C_{13}H_{21}N$: C, 81.62; H, 11.06; N, 7.32%.

*1-Methoxy-4-nonylbenzene (**5e**)*: Bp 140 °C (oven temp)/0.5 mmHg, homogeneous to an extent of more than 99% in GLC. ^{1}H-NMR (CCl_4): δ 0.55—1.05 (m, 3H), 1.05—1.95 (broad s, 14H), 2.53 (t, J=7 Hz, 2H), 3.70 (s, 3H), AA′BB′ system centered at 6.85 (4H). MS: *m/e* mol wt 234(M^+, 5), 121(100). Found: C, 81.95; H, 11.37%. Calcd for $C_{16}H_{26}O$: C, 81.99; H, 11.18%.

*4-Nonyltoluene (**5f**)*: Bp 120 °C (oven temp)/0.6 mmHg, homogeneous to an extent of more than 99% in GLC. ^{1}H-NMR (CCl_4): δ 0.90 (t, J=5 Hz, 3H), 1.25 (broad s, 14H), 2.25 (s, 3H), 2.50 (t, J=7 Hz, 2H), 6.87 (s, 4H). MS: *m/e* mol wt 218(M^+, 0.5), 105(100), 41(51). Found: C, 87.92; H, 12.14%. Calcd for $C_{16}H_{26}$: C, 88.00; H, 12.00%.

*1,4-Dinonylbenzene (**5g**)*: Bp 205 °C (oven temp)/0.5 mmHg, homogeneous to an extent of more than 99% in GLC. ^{1}H-NMR (CCl_4): δ 0.90 (t, J=7 Hz, 6H), 1.27 (broad s, 28H), 2.52 (t, J=7 Hz, 4H), 6.95 (s, 4H). MS: *m/e* mol wt 330(M^+, 0.3), 105(100), 92(60), 91(63), 77(21). Found: C, 87.29; H, 12.90%. Calcd for $C_{24}H_{42}$: C, 87.19; H, 12.81%.

*Tetradecane (**5h**)*: It was compared with an authentic specimen and homogeneous to an extent of more than 99% in GLC when it was produced from **4h**. However, **5h** originated from **4j** was contaminated with an 8% of *1-pentyl-2-propylbenzene* which gave peaks in MS at *m/e* 190, 91, and 77.

*Dodecane (**5i**)*: It was compared with an authentic specimen. An analysis by GLC coupled with mass spectrometry revealed that it was contaminated with a 7% of *2-pentyltoluene* which gave peaks in MS at *m/e* 162(M^+, 2), 105(77), 92(24), 91(45), 79(30), 77(35), 65(28), 55(20), 53(24), 51(30), 43(54), 41(100).

*Reaction of **1e**, **3a**, and Triphenylphosphine.* The aldehyde **1e** (1.340 g, 10.0 mmol), the alcohol **3a** (7.200 g, 0.1 mol), triphenylphosphine (5.502 g, 21.0 mmol) and $Pd(acac)_2$ (0.152 g, 0.5 mmol) were refluxed in dioxane (10 ml) for 72 h under magnetic stirring and dry nitrogen. The refluxing solvent was passed through a molecular sieve (4 Å) pad. The solvent was distilled off and the residue was extracted with hexane leaving insoluble triphenylphosphine oxide. The hexane was evaporated and the new residue was chromatographed through a silica-gel column giving 0.460 g (17%) of a hydrocarbon mixture eluted with hexane and 2.089 g of the starting phosphine eluted with hexane(4)–dichloromethane(1). All the other eluted fractions were complex mixtures of unidentified products. The hydrocarbon mixture (0.402 g, 1.9 mmol) was hydrogenated at atmospheric pressure in ethyl acetate (10 ml) in the presence of 10% Pd–C (0.040 g). The catalyst was filtered off and the solvent evaporated to afford a colourless liquid (0.409 g) which analyzed by GLC gave two peaks in a ratio 66.5/33.5. An analysis by GLC coupled to mass spectrometry was consistent with, respectively, the structure of *1,2-dipentylbenzene* (**6**) and the constitution of *1,2-dimethyl-1,2,3,4,4a,9,10,10a-octahydrophenanthrene* (**7**).

6: MS: *m/e* mol wt 218(M^+, 12), 105(100), 91(26).

7: MS: *m/e* mol wt 214(M^+, 2), 129(100), 115(21).

*Reaction of **1e**, **3b**, and Triphenylphosphine.* The aldehyde **1e** (1.340 g, 10 mmol), the alcohol **3b** (4.000 g, 40 mmol) triphenylphosphine (5.502 g, 21 mmol), and $Pd(acac)_2$ (0.152 g, 0.5 mmol) were refluxed in dioxane (10 ml) for 64 h under magnetic stirring and dry nitrogen and the refluxing solvent being passed through a molecular sieve (4 Å) pad. The solvent was evaporated and the residue was chromatographed through a silica-gel column. A mixture (1.845 g) of hydrocarbons and triphenylphosphine was eluted with hexane. Further elutions gave triphenylphosphine (0.761 g), a mixture (0.267 g) of triphenylphosphine, **3b** and unidentified products (all eluted with hexane(4)–dichloromethane(1)), **3b** (0.247 g) (eluted with hexane(7)–dichloromethane(3)), and triphenylphosphine oxide (eluted with chloroform). The mixture of hydrocarbons and triphenylphosphine was treated in benzene (25 ml) with methyl iodide (1.5 g) at room temperature for 2 h. The precipitate of methyltriphenylphosphonium iodide formed was filtered off and the remaining solution evaporated to afford 1.284 g (48%) of a mixture of *1,2-bis(1,3-heptadienyl)benzene* (**8**) and probably *1,2-dipropyl-1,2,4a,10a-tetrahydrophenanthrene* (**9**), which presented eight peaks in GLC with relative areas 10/33/13.5/5/12/9.3/6.8/10.4. A further chromatography through

a silica-gel column gave 0.052 g of pure **8**.

8: ^{1}H-NMR (CCl_4): δ 0.95 (t, J=7 Hz, 6H), 1.10—1.80 (m, 4H), 2.15 (dt, J *ca.* 6 and 6 Hz, 4H), 5.40—6.90 (m, 8H), 6.95—7.60 (m, 4H). MS: *m/e* mol wt 266(M^+, 12), 183(34), 181(37), 167(100), 166(27), 165(47), 155(28), 153 (34), 152(32), 141(97), 128(53), 115(37), 91(26), 79(25), 77(20), 67(25), 55(31).

The authors express their gratitude to the "Comisión Asesora de Investigación Científica y Tecnica" and to "INAPE" (Ministerio de Educación y Ciencia of Spain) for financial support and for a grant (to A. T.). The authors are also indebted to Dr. P. de March and A. Virgili for kindly registering the mass spectra.

Nb_2O_5 Supported on TiO_2. Catalytic Activity for Reduction of NO with NH_3

Susumu Okazaki* and Tetsuhiro Okuyama

Department of Industrial Chemistry, Faculty of Engineering, Ibaraki University, Nakanarusawa-cho Hitachi 316

(Received May 26, 1982)

Synopsis. Niobium(V) oxide supported on TiO_2 showed a high catalytic activity for the reduction of NO with NH_3 at temperatures higher than 450 °C. The presence of SO_4^{2-} in Nb_2O_5 or in Nb_2O_5 supported on TiO_2 brought about an increase in the catalytic activity.

Vanadium(V) oxide[1] supported on TiO_2 is commonly used for the reduction of NO with NH_3. Other metal oxides such as MoO_x[2] and FeO_x[3] supported on TiO_2 also show considerable catalytic activity for this reaction. Although Nb is a neighbor of Mo or V in the periodic table, the catalytic activity of Nb_2O_5 for denitration has not been well-studied; this topic is presented here. In particular, the effect of SO_4^{2-} on the catalytic activity was carefully studied, since in industrial denitration processes small amounts of SO_2 included in the reacting gas combine with O_2 to form SO_4^{2-}, which may be adsorbed and further combined with the catalysts.

Most catalyst samples were prepared by a coprecipitation method in which a mixture of niobium(V) oxide hydrate and titanium tetraisopropoxide was neutralized with 28% aqueous ammonia, followed by washing and drying. The niobium(V) oxide hydrate, supplied by the CBMM Company, contained about 55 wt% of Nb and no detectable amounts of alkali components such as Na and K, which would decrease the catalytic activity for denitration. For comparison of the activities as catalyst carriers, Al_2O_3, ZrO_2, and SiO_2 were prepared from $Al(NO_3)_3$, $Zr(OH)_4$, and colloidal silica respectively.

To elucidate the effect of the preparation method on the catalytic activity, some catalyst samples were prepared by impregnating TiO_2 with niobium(V) oxide hydrate dissolved in a 20 wt% aqueous solution of oxalic acid. Other niobium(V) oxide catalysts supported on Al_2O_3, ZrO_2, and SiO_2 were prepared by impregnation similarly to the TiO_2 supported niobium(V) oxide.

The samples containing definite amounts of SO_4^{2-} were prepared by adding ammonium sulfate to a solution containing the catalyst components.

All the catalyst samples were heat-treated at 500 °C for 3 h immediately before use as catalysts in the same reactor used for the denitration.

The specific surface area was determined by applying the BET equation to the adsorption of N_2 at −196 °C. The solid acidity was measured by NH_3 adsorptions at 250 and 450 °C. The acidity was further examined by the catalytic activity for isomerization of cyclopropane to propene which is promoted only by Brönsted acid sites.[4]

The reaction of NO with NH_3 was carried out at 200—500 °C by using a conventional flow reactor. The mixture of NO and NH_3, which was diluted with air so that the concentrations of both gases were 500 ppm, was passed through 2 g of catalyst, the flow rate and space velocity being 35 ml min^{-1} and 50000 h^{-1}, respectively. After the reaction, the amount of unreacted NO was measured by a NO_x meter(Kyoto Denki Kogyo, NX 22 or Takeda Kikai, KN 400 type).

The catalytic activity of Nb_2O_5 supported on TiO_2 for the reduction of NO with NH_3 in the presence of air was much higher than those of Nb_2O_5 supported on other oxides(Fig. 1). As is shown in Fig. 2, the activities of Nb_2O_5–TiO_2 were also higher than those of the component oxides. The catalytic activity for the mixed oxides prepared by coprecipitation had a maximum at the atomic ratio(Nb/Ti) of 1/1.

Figure 3 shows that the specific surface area of the mixed oxide is maximum at the atomic ratio of, not 1/1, but 1/9. Further, the specific activity(conversion/surface area) is especially high at the ratio(1/1). So, the higher activity is not merely due to the high dispersibility of the Nb component on TiO_2. It has been observed that the solid acidity is closely related to

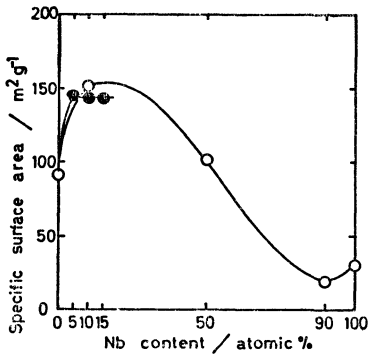

Fig. 3. Effect on specific surface area of Nb_2O_5 content on Nd_2O_5-TiO_2 prepared by coprecipitation and impregnation. ○: Coprecipitation, ●: impregnation. All the samples were heat-treated at 500 °C for 3 h immediately before determinations.

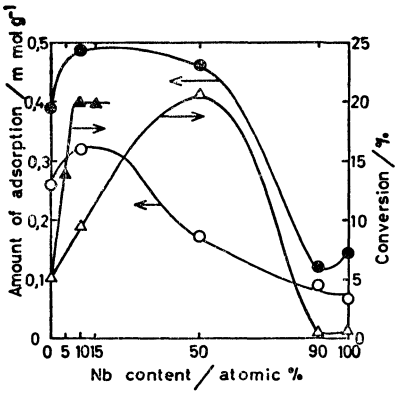

Fig. 4. Effects on adsorptive activity for NH_3 and catalytic activity for cyclopropane isomerization of Nb_2O_5 content.
○: NH_3 adsorption at 450 °C, ●: NH_3 adsorption at 250 °C, △: cyclopropane isomerization over mixed oxides prepared by coprecipitation, ▲: cyclopropane isomerization over mixed oxides prepared by impregnation. The condition of cyclopropane isomerization are as following; pulse method; pulse size: 1.09 ml, catalyst weight: 50 mg, reaction temperature: 250 °C, carrier gas: He, 40 ml/min.

the catalytic activity for the denitration of MoO_x-TiO_2.[5] However, as Fig. 4 shows, the total acidity measured by NH_3 adsorptions at 250 and 450 °C, was maximum at the atomic ratio of 1/9; thus this observation is unable to explain the catalytic activity of Nb_2O_5-TiO_2 prepared by coprecipitation. The catalytic activity is more adequately explicable by the Brönsted acidity determined by the catalytic activity for the isomerization of cyclopropane. Also, the fact that the activity of the mixed oxide of low Nb/Ti atomic ratio prepared by impregnation is higher than that prepared by coprecipitation may be due to the high Brönsted acidity of the sample prepared by impregnation. In the reduction of NO with NH_3, the NH_3 molecules are considered to be adsorbed on Brönsted acid sites as NH_4^+.[6] Thus, the Brönsted acid sites formed on the mixed oxides may contribute to activation of NH_3.

The catalytic activities of the oxides containing SO_4^{2-} shown in Figure 5 are considerably higher than those

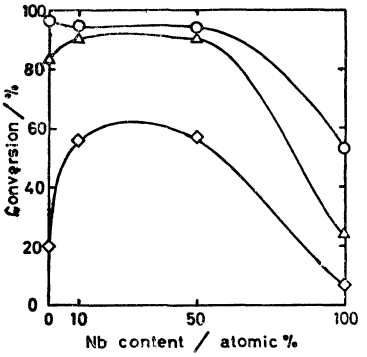

Fig. 5. Effect on catalytic activity of Nb_2O_5 content in Nb_2O_5-TiO_2 containing SO_4^{2-}.
Reaction temperature; ○: 450 °C, △: 400 °C, ◇: 350 °C. Mixed oxides were prepared by coprecipitation. The atomic ratio of S to the sum of Nb and Ti, S/(Nb+Ti) was kept constant at 5/95.

of oxides free from SO_4^{2-} (shown in Fig. 2). The effect of SO_4^{2-} addition is especially remarkable for the activities of TiO_2 and mixed oxides of high Ti content. Since it is already known that an addition of small amount of SO_4^{2-} greatly increases the solid acidity of TiO_2,[7] the enhancement in catalytic activity may also be due to the increase in Brönsted acidity. The addition of SO_4^{2-} to an extent that an atomic ratio of S to the sum of Nb and Ti, (S/(Nb+Ti)) equaled 5/95 appeared to be enough for the enhancement of the catalytic activity of Nb_2O_5-TiO_2 prepared by coprecipitation.

Compared to the catalytic activities of V_2O_5-TiO_2 and MoO_3-TiO_2,[5] that of Nb_2O_5-TiO_2 was still lower, especially at temperatures lower than 300 °C. Unlike V_2O_5 and MoO_3, Nb_2O_5 is not readily reduced, as is shown by the fact that NbO_2 is formed with difficulty by treating Nb_2O_5 with H_2 at temperatures as high as 1000—1200 °C.[8] Hence, the redox activity of Nb component may be not so large as V and Mo components. This seems to be the reason why Nb_2O_5-TiO_2 shows only relatively low catalytic activity, even though it has a considerable amount of Brönsted acid sites.

The authors wish to express their thanks to the CBMM Company for their financial support of this study.

Rapid Diffusion of Oxygen Ions in Indium Oxide during Reduction-oxidation

Kiyoshi Otsuka,* Takao Yasui, and Akira Morikawa

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received January 12, 1983)

Synopsis. Rapid diffusion of oxygen ions in indium oxide particles has been suggested by measuring the distribution of ^{18}O ions after oxidation of reduced-indium oxide by $^{18}O_2$ (gas). This result explains the observation that the reduced-indium oxide is one of the most efficient compounds among the reduced metal oxides for reduction of H_2O, CO_2, or NO.

In the previous works we have demonstrated that In_2O_3 is one of the most effective metal oxides to the two step hydrogen production from water which applies reduction (Step 1) and oxidation (Step 2) cycles of the oxide.[1,2] If the Step 1 is operated by using hydrogen for simplicity, the Steps 1 and 2 can be expressed by the following forward and reverse reactions, respectively:[1,3]

$$In_2O_3 + 3H_2 \rightleftharpoons 2In + 3H_2O. \quad (1)$$

When CO_2, NO, or O_2 instead of H_2O was used in Step 2, the following reactions proceeded smoothly at 673 K:[3]

$$2In + 3CO_2 \longrightarrow In_2O_3 + 3CO \quad (2)$$

$$2In + 3NO \longrightarrow In_2O_3 + 3/2\,N_2 \quad (3)$$

$$2In + 3/2O_2 \longrightarrow In_2O_3. \quad (4)$$

In the previous studies we have proposed a mechanism of reduction of In_2O_3 and that of reoxidation of the reduced oxide which assume a rapid diffusion of oxygen ions from the reaction interface at the surface of indium oxide particles into the bulk or vice versa, respectively (homogeneous model).[4] This model inevitably requires an apparent homogeneous distribution of the oxygen ions and indium metals throughout a oxide particle. With regard to this requirement, we intend to describe in this note an experimental proof that the oxygen ions in indium oxide particles distribute homogeneously during their redox cycles.

Experimental

The In_2O_3 used was a reagent-grade powder (purity>99.9 %) obtained from Wako Pure Chemical Co. The BET surface area of the oxide was 13.9 $m^2\,g^{-1}$. The apparatus employed was a conventional mercury-free, greese-free, static gas-circulation system of *ca.* 320 cm^3 volume. The water vapor evolved during the reduction of In_2O_3 by hydrogen was always condensed in a trap which had been placed in the gas-circulation line and cooled at 77 K. Contents of oxygen isotopes in oxygen or water were determined by mass-spectroscopic analysis.

Results and Discussion

After the reduction of In_2O_3 by hydrogen to the degree of reduction of 19.7%, which was estimated from the quantity of oxygen removed from the oxide, the reoxidation by $^{18}O_2$ (98.5% ^{18}O content) was carried out at 673 K. The oxygen ions of the sample thus oxidized by $^{18}O_2$ were stripped by reduction with hydrogen at 623—673 K. The contents of $H_2{}^{18}O$ in the produced water at certain range of reduction levels were measured by mass spectrometer. The change in contents of ^{18}O ions thus determined is demonstrated in Fig. 1 as a function of the degree of reduction of In_2O_3 (solid lines). The hight of bars in the figure indicates the average percentage of ^{18}O ions observed between the each two levels of reduction of the sample oxide.

Let us consider first the distribution of ^{18}O ions in a indium oxide particle. If the reduction of In_2O_3 proceeds from the surface of In_2O_3 particle into the bulk, leaving indium metal layer covering the particle (Fig. 2, model A), we expect the distribution of ^{18}O ions after reoxidation by $^{18}O_2$ as indicated by the chain line (— — —) in Fig. 1. On the other hand, if the oxide ions diffuse rapidly into or from the bulk, resulting in seemingly homogeneous distribution of ^{18}O ions (Fig. 2, model B), the distribution of ^{18}O ions in a particle should be the one indicated by the broken line (– – – –). The experimental results (bars) suggest that the distribution of ^{18}O ions is roughly homogeneous, supporting the propriety of the latter model.

The formation of In_2O by the reduction of In_2O_3 was assumed by several workers.[5-7] However, there are no evidence suggesting the existence of crystalline In_2O.[8-10] Our X-ray spectroscopic studies of the partially reduced In_2O_3 could establish only the existence of In_2O_3 and indium metal. Brewer[8] concluded in

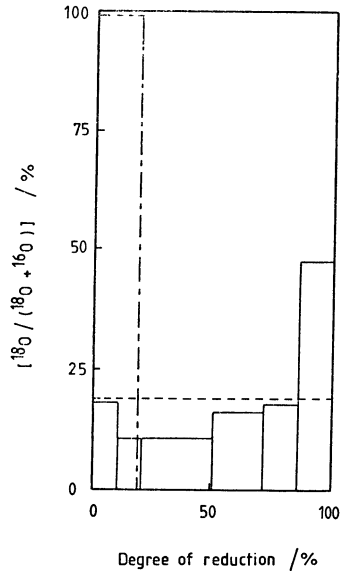

Fig. 1. ^{18}O ions distribution in a particle of the reoxidized indium oxide by $^{18}O_2$(gas). (——); Experimental observation, (— — —); idealized distribution according to the model A, (- - - -); idealized distribution according to the model B or C.

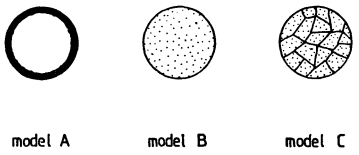

Fig. 2. Schematic model of the distribution of indium metal in the bulk of a particle (sectional views of a particle). Black part or spots are indium metal layer or nuclei. The lines in model C are grain boundaries.

his review that the supporsedly crystalline In_2O is a stoichiometric mixture of indium and In_2O_3 or is a metastable homogeneous phase. Wit *et al.*[10] commented that an indium(I) oxide like In_2O exists only as a parasitic phase, in combination with the contacting indium metal and In_2O_3, and is highly nonstoichiometric. We consider that the model B in Fig. 2 corresponds to the homogeneous mixture of indium metal and In_2O_3 as described above.

The mean dimension of the In_2O_3 crystallites estimated from the half width of X-ray diffraction peaks using the Scherrer's equation[11] was 23 nm. The SEM picture of the sample indicated that the sizes of the particles are in the range of 100—1000 nm. Therefore, the netwarks of the grain boundaries can be assumed to spread over in a particle. The rapid transport of oxygen ions in a particle may be enabled by the short circuit diffusion through these grain boundaries (model C in Fig. 2).

The exchange of $^{18}O_2$ in gas phase with ^{16}O ions of fresh In_2O_3 occurred at temperatures higher than 673 K. The sample of In_2O_3, whose oxygen ions had been exchanged by $^{18}O_2$ at 773 K to the extent of 7.3 atomic percentage of the total oxygen ions of the oxide, was reduced by hydrogen at 623 K stepwise to the degree of reduction of 62% and at 673 K to 90%. The analysis of the produced water indicated the distribution of ^{18}O in the oxide as demonstrated in Fig. 3. The broken line indicates the ideal homogeneous distribution of ^{18}O ions in a In_2O_3 particle or grain. The observed distribution demonstrated by the bar graph in Fig. 3 suggests that the ^{18}O ions have penetrated deep into a In_2O_3 particle or crystal grain, supporting the easy diffusion of oxygen ions from the surface or grain boundaries into the bulk. The high content of ^{18}O at the lowest range of reduction level (0—10%) may be ascribed either to adsorbed

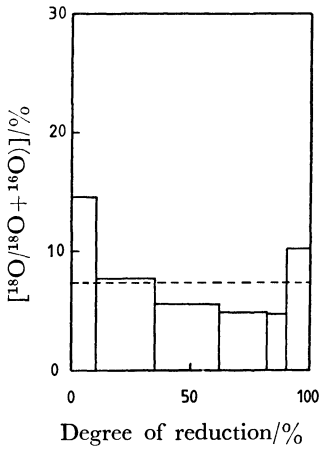

Fig. 3. ^{18}O ions distribution in a particle of In_2O_3 which had been exchanged by $^{18}O_2$(gas). (——); Experimental observation, (----); idealized distribution according to the model B or C.

oxygen atoms on the surface or to the oxygen atoms at grain boundaries which were equilibrated with $^{18}O_2$ in gas phase during the exchange pretreatment. The rather high concentration of ^{18}O ions at the highest reduction levels indicated both in Figs. 1 and 3 cannot be explained at the moment. They might be the one trapped in dislocations or defects of crystals, resulting in their total stabilization.

Mechanochemical Decomposition of Dipotassium Peroxodisulfate by Dry Grinding

Itaru MOTOOKA,* Hiroyuki NARIAI, and Mitsutomo TSUHAKO†

(Received August 2, 1982)

Synopsis. The mechanochemical decomposition of dipotassium peroxodisulfate by dry grinding was investigated by X-ray diffractometry, infrared spectrophotometry, electron spin resonance (ESR) spectrometry, and thermal and volumetric analyses. When dipotassium peroxodisulfate ($K_2S_2O_8$) was ground, type I of $K_2S_2O_8$ was transformed into type II and then into type III. With prolonged grinding, the O–O linkage in $K_2S_2O_8$ was severed to produce $KSO_4\cdot$ radicals, which reacted with a little moisture to give $KHSO_4$.

Mechanochemical phenomena have recently been noted in the wide field of scientific and technical investigations because mechanical treatment influences structures, physical and chemical properties, and reactivity of solids. Although effects of pressure and heat on the mechanochemical phenomena were observed,[1] mechanical force, particularly shear stress, has an important influence on the scission of chemical bonds.[2]

The chemical bonds in solid substances are reported to be severed by mechanical treatment[3] as in the case of grinding sodium pyrophosphate which gives orthophosphates by severing the P–O–P linkage.[4]

Peroxide is liable to decompose and produce radicals since the O–O bond energy is relatively small. Dipotassium peroxodisulfate gives $SO_4^{-}\cdot$ radicals by heating or exposing to ultraviolet light.[5,6] Therefore, it is used as an initiator for radical polymerization. If treated mechanically, the O–O bonds in peroxodisulfate are expected to be severed easily to produce radicals such as $SO_4^{-}\cdot$.

In the present paper, the mechanochemical decomposition of dipotassium peroxodisulfate by dry grinding is investigated.

Experimental

Reagent grade dipotassium peroxodisulfate was used without further purification. All other reagents used were of analytical grade.

The X-ray diffraction patterns were obtained with a Rigaku Geigerflex diffractometer using nickel-filtered Cu $K\alpha$ radiation. Infrared spectra were recorded on a JASCO IR-E spectrophotometer equipped with gratings. Thermal analyses (DTA and TG) were carried out by a Rigaku 8002 SD thermal analyzer. The ESR spectra were recorded on a JEOL JES-3BX electron spin resonance spectrometer equipped with an X-band microwave units and 100 kHz field modulation.

The grinding apparatus was an Ishikawa's grinder equipped with an agate mortar and installed in a steel box. Five grams of crystalline dipotassium peroxodisulfate was ground for the specified lengths of time with the relative humidity of 30—40% at room temperature because the mechanochemical effects are affected by the atomosphere, particularly moisture.

The amount of peroxodisulfate ($S_2O_8^{2-}$) was determined volumetrically by adding excess Mohr's salt to a solution of the ground sample and titrating excess iron(II) ion with a standard solution of potassium permanganate. The amount of sulfate (SO_4^{2-}) was determined as follows. Potassium ions in the solution of the ground sample were exchanged for hydrogen ions using a cation-exchange resin. The resulting peroxodisulfuric acid was thoroughly hydrolyzed to sulfuric acid (total sulfate) by heating for 20 min in boiling water, which was titrated with a standard solution of sodium hydroxide. The amount of sulfate in the ground sample was calculated by subtracting the amount of peroxodisulfate from total sulfate.

Results and Discussion

Figure 1 shows X-ray diffraction patterns of $K_2S_2O_8$ at various stages of grinding. The intensity of each diffraction line decreased, the line-width broadened for all the diffraction lines, and the different diffraction lines appeared. That is, with the distortion in crystal lattice, type I of $K_2S_2O_8$ was transformed into type II after a grinding period of 6 h and into type III after 168 h. With further grinding (250 h), the diffraction lines of $KHSO_4$ appeared and became stronger after 430 h. Type I of $K_2S_2O_8$ is apparently converted to $KHSO_4$ through types II and III. The infrared spectra of the samples ground for more than 250 h also indicated the presence of $KHSO_4$.[7]

Figure 2 shows the DTA and TG diagrams of the ground samples. The DTA and TG curves for 6 and 168 h were essentially the same as those of the original sample. In Fig. 2 an exothermic peak in the 200 °C region with a weight loss is due to the decomposition of $K_2S_2O_8$ with the evolution of oxygen, and the two endothermic peaks at about 330 and 370 °C are due to the order-disorder transformation and melting of $K_2S_2O_7$, respectively.[8] The melting point lowered with an increase in the grinding time because the particle size became smaller by grinding, and then it coincided in position with the transformation point. The samples ground for 250 h and 430 h also had an endothermic peak at about 200 °C. This peak may be attributed to the pyrolysis of $KHSO_4$ produced by

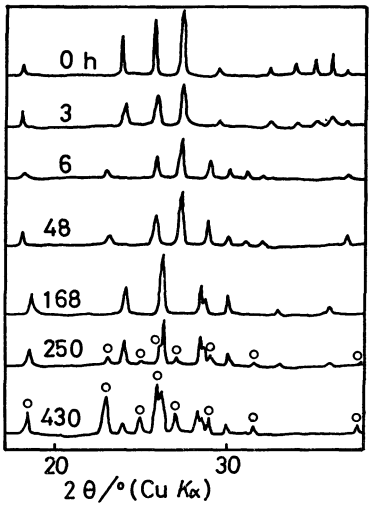

Fig. 1. X-Ray diffraction diagrams of ground samples.
○: $KHSO_4$.

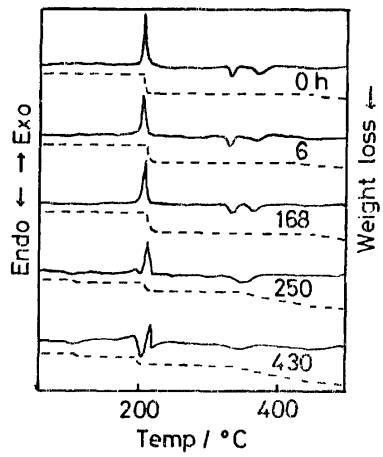

Fig. 2. DTA-TG curves of ground samples.
Solid line: DTA, dotted line: TG.

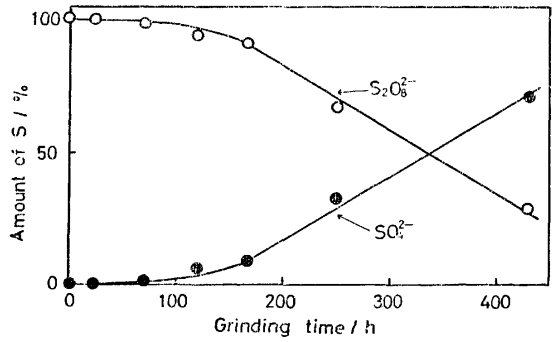

Fig. 3. Changes of distribution of sulfur in ground samples upon grinding.

the grinding of $K_2S_2O_8$. The intensity of this peak increased with an increase in the grinding time, while the weight loss in the 200 °C region decreased. This finding indicates that $K_2S_2O_8$ changes to $KHSO_4$ by grinding. This fact is compatible with the results of X-ray diffractometry and infrared spectrophotometry.

Figure 3 shows the distribution of sulfur in the ground samples. In the first stage of grinding (less than 72 h), sulfate was produced to a small extent and increased with decreasing amount of peroxodisulfate after grinding for more than 120 h.

The absence of peroxomonosulfate (SO_5^{2-}) in the ground samples was confirmed by paper chromatography.[9]

Above findings indicate that $K_2S_2O_8$ decomposes to $KHSO_4$ by prolonged grinding.

Figure 4 shows ESR spectra of the ground $K_2S_2O_8$. A singlet signal with two g values, $g_1=2.011$ and $g_2=2.007$, indicates the presence of radicals, probably $KSO_4\cdot$.[6] In the first stage of grinding, this signal was very weak, reached a maximum in 168 h, and decreased gradually with grinding time. This fact indicates the presence of radicals which are larger in the beginning of the severing of O–O linkages than after grinding for more than 250 h. Thus, it is considered that the radicals produced in the beginning are relatively stable, but that those produced by prolonged grinding react immediately with the moisture adsorbed on the powder surface which is very active due to prolonged grinding.

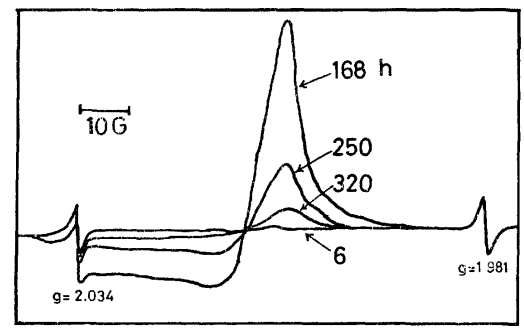

Fig. 4. ESR spectra of ground samples.

It is concluded that the following changes take place when $K_2S_2O_8$ is ground.

$$K_2S_2O_8(\text{type I}) \xrightarrow{\text{Grinding}} K_2S_2O_8(\text{type II}) \xrightarrow{\text{Grinding}} K_2S_2O_8(\text{type III}) \xrightarrow{\text{Grinding}} 2KSO_4\cdot \xrightarrow{+H_2O} 2KHSO_4 + 1/2\,O_2$$

After conversion I→II→III, the O–O linkages in $K_2S_2O_8$ are severed to produce the $KSO_4\cdot$ radicals which react with a little moisture adsorbed on the powder surface and are stabilized as $KHSO_4$ accompanied by oxygen evolution. The reaction of the $KSO_4\cdot$ radical with H_2O seems to take place by the following mechanism proposed by Kolthoff and Miller.[10]

$$2KSO_4\cdot + H_2O \longrightarrow 2KHSO_4 + 2\cdot OH$$
$$2\cdot OH \longrightarrow H_2O + 1/2\,O_2$$

The authors wish to thank Professor Yukio Kanaji, Faculty of Engineering, Kobe University, for his advice in making the ESR measurements.

Polarography of Pb(II) Complexes with *N,N'*-Bis(2-hydroxyethyl)-ethylenediamine-*N,N'*-diacetic Acid

Tsutomu MATSUO,* Yoshitaka MASUDA,† and Eiichi SEKIDO†

Kobe Technical College, Tarumi-ku, Kobe 655

†*Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe 657*

(Received August, 1982)

Synopsis. The electrochemical behaviour of the Pb(II)–*N,N'*-Bis(2-hydroxyethyl)ethylenediamine-*N,N'*-diacetic acid(H_2bhedda=H_2L) system has been examined by means of d.c. polarography. Two well-defined polarographic reduction waves were observed. The mechanisms of the electrode reaction for the two waves were elucidated. The kinetic parameters of the irreversible reduction of the complexes have been evaluated; $k_{f1}=3.80\times10^{-5}$ cm/s and $k_{f2}=5.25\times10^{-16}$ cm/s. The stability constant of the $PbHL^+$ species is calculated to be $10^{1.45}$.

Many workers[1,2] have reported on the electrochemical behaviour of H_4edta derivative complexes with several kinds of metals. We ourselves have previously studied the mechanisms of the electrode reactions of Pb(II)–H_6ttha(triethylenetetramine-*N,N,N',N'',N''',N'''*-hexaacetic acid) and Cd(II)–H_2bhedda(*N,N'*-bis(2-hydroxyethyl)ethylenediamine-*N,N'*-diacetic acid) complexes.[3-5] Little is known, however, concerning the properties of the H_2bhedda ligand and its metal complexes, except for the acid-dissociation constants.[6] In this report, the mechanisms and parameters of the electrode reactions for Pb(II)–H_2bhedda complexes are investigated. The influence of the hydroxymethyl groups on the stability constant and the rate constant of the reduction is also discussed.

Experimental

A Pb(II) solution(Pb(II) aquo ion) was prepared by dissolving reagent-grade lead nitrate. The ligand, H_2bhedda (Clewat OH-300, Tcikoku Chemical Co.) was twice recrystallized from hot water, and 0.01 mol dm^{-3} solution was prepared. The acetate buffer solutions were used to adjust the pH values of the test solutions. A sodium perchlorate solution (1.0 mol dm^{-3}) was added to keep the ionic strength constant (μ=0.4).

Results and Discussion

Polarograms of Pb(II)–H_2bhedda System. The polarogram of the Pb(II)–H_2bhedda system exhibited a maximum(−0.84 V *vs.* SCE). Triton X-100 (up to 1.7×10^{-4}%) was added to suppress the maximum. In an excess of the metal ion to the ligand, the polarograms gave two well-defined reduction waves(Fig. 1). The two waves are referred to as Wave A (first wave) and Wave B(second wave). In an excess of the ligand, the limiting current for Wave A was independent of the mercury-head height below pH 4.0. The temperature coefficient of the limiting current for Wave A was 3.5% (pH=3.28, M:L=1:5). From the analysis of *i-t*(*i*:current, *t*:time) curves for Wave A, the value of γ in the equation, $i=kt^{\gamma}$, was calculated to be 0.67(pH=3.28, 1:5, −0.7 V *vs.* SCE). The limiting current for Wave A involves a kinetic characteristic below pH 4.0 in an excess of the ligand.

As the limiting current for Wave B was proportional to the square root of the mercury-head height at any pH, and the temperature coefficient of the limiting current for Wave B was 1.5%(1:5, pH=4.9), the limiting current for Wave B can safely be said to be diffusion-controlled. The average value of the reciprocal slope of the conventional log-plot for Wave B was 47.1 mV, and so Wave B is considered to be an irreversible two-electron reduction wave.

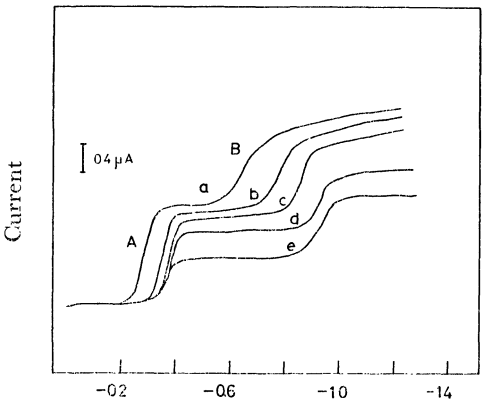

Fig. 1. Polarograms of Pb(II)–H_2bhedda system varying with pH.
$[Pb]_t=5.0\times10^{-4}$ mol dm^{-3}, $[H_2bhedda]_t=2.5\times10^{-4}$ mol dm^{-3}, μ=0.4($NaClO_4$), acetate buffer, pH —— (a) 3.05, (b) 3.53, (c) 4.08, (d) 5.19, (e) 7.72. A: Wave A, B: Wave B.

Test of Kinetic Current Theory for Wave A. The rate-determining step of the kinetic process for Wave A in an acetate buffer is expressed as follows;

$$PbHL^+ + qH^+ \xrightarrow{k_d} Pb^{2+} + H_{q+1}L, \quad (1)$$

$$Pb^{2+} + jOAc^- \rightleftharpoons Pb(OAc)_j^{2-j}. \quad (2)$$

The following relationship, derived by Koryta,[7] is applicable to such a kinetic current;

$$\left(\frac{(i_k)_a}{(i_d)_a-(i_k)_a}\right)\left(1+\frac{(i_k)_a}{(i_d)_a}\cdot\frac{C_M}{C_L}\cdot\frac{K_{PbHL}\cdot\delta_{HL}/\sum_{p=0}^{1}K_{PbHL_p}\cdot\delta_{H_pL}}{\delta_{H_{(q+1)}L}}\right)^{1/2}$$

$$=0.886[H^+]^q\sqrt{\frac{k_d\cdot t_d\sum_{j=0}^{p}(K_0'\cdots K_j'[OAc]^j)}{K_{eq}\cdot C_L\cdot\delta_{H_{(q+1)}L}}}, \quad (3)$$

where C_M is the total concentration of Pb(II); δ_{H_pL}, the molar distribution ratio of H_pL species; q, the number of the proton participating in reaction (1); k_d, the dissociation rate constant of the complex; t_d, the dropping time; [OAc], the concentration of the acetate ion, and $K_{eq}=[PbHL][H^+]^q/[Pb^{2+}][H_{(q+1)}L]$. The effect of the acetate buffer solution on the kinetic current $(i_k)_a$ was also considered. The value of $\Sigma(K_0'\cdots K_j'[OAc]^j)$ was obtained from the shift of the half-wave potential. The plot of

$$F_1=\log\frac{(i_k)_a}{(i_d)_a-(i_k)_a}+\frac{1}{2}\log\left(1+\frac{(i_k)_a}{(i_d)_a}\cdot\frac{C_M}{C_L}\cdot\frac{K_{PbHL}\cdot\delta_{HL}/\sum_{p=0}^{1}K_{PbH_pL}\cdot\delta_{H_pL}}{\delta_{H_{(q+1)}L}}\right)vs.$$

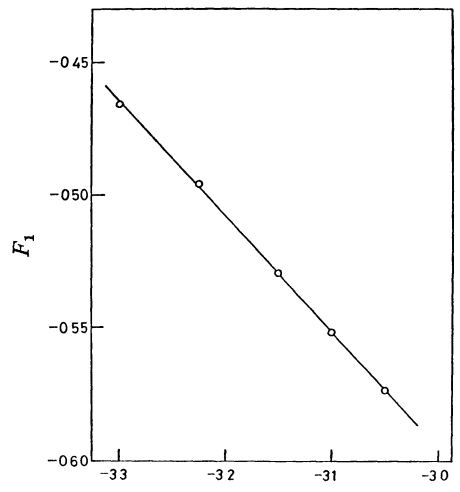

Fig. 2. Test of kinetic current theory for Wave A (Plot of F_1 *vs.* $\log C_L \cdot \delta_{H_2L}$)

$$\left(F_1 = \log\frac{(i_k)_a}{(i_d)_a-(i_k)_a} + \frac{1}{2} \times \log\left(1 + \frac{(i_k)_a}{(i_d)_a} \cdot \frac{C_M}{C_L} \cdot \frac{K_{PbHL} \cdot \delta_{HL} / \sum_{p=0}^{1} K_{PbH_pL} \cdot \delta_{H_pL}}{\delta_{H_{(q+1)}L}}\right)\right)$$

$[Pb]_t = 5.0 \times 10^{-4}$ mol dm^{-3}, $[H_2bhedda]_t = 5.0 \times 10^{-4}$, -9.0×10^{-4} mol dm^{-3}, $\mu = 0.4(NaClO_4)$, acetate buffer

$\log C_L \cdot \delta_{H_2L}$ is shown in Fig. 2. The slope of the straight line (−0.43) is consistent with the theoretical value of Eq. 3 (−0.5). Thus, the number of the proton participating in the above reaction mechanism could be obtained by plotting F_1 *vs.* pH ($q=1$). The average dissociation rate constant(k_d) of the complex was also calculated($k_d = 1.49 \pm 0.43$ s^{-1}, pH=2.95—3.53).

Electrode Reaction for Wave B. The dependence of the half-wave potential $(E^{irr}_{1/2})_b$ on the pH was remarkably changed from −92 mV/pH to −4.0 mV/pH at pH 5.4. In order to analyze the irreversible reduction mechanisms for Wave B, a theoretical equation proposed by Vlček,[3] could be used. By assuming that the complex species, PbL, participates in the reaction in the pH range from 4.0 to 5.4, the number of the proton is found to be 2. The electrode reaction mechanism is expressed as follows:

$$PbL + 2H^+ + 2e + Hg \xrightarrow[k_{j_1}]{} Pb(Hg) + H_2L. \quad (4)$$

The electrode reaction rate constant, k_{j_1}, was calculated ($k_{j_1} = 3.80 \times 10^{-5}$ cm/s at $E^{irr}_{1/2} = -0.888$ V *vs.* SCE). Above pH 5.4, the mechanism of the electrode reaction can also be expressed as follows:

$$PbL + 2e + Hg \xrightarrow[k_{j_2}]{} Pb(Hg) + L^{2-}, \quad (5)$$

where k_{j_2} was calculated to be 5.25×10^{-16} cm/s($E^{irr}_{1/2} = -0.947$ V *vs.* SCE).

The stability constants[7,8] of the Pb(II)–H_2bhedda and Pb(II) complexes with the analogous H_2bhedda ligands are shown in Table 1. Both of the stability constants, K_{PbL} and K_{PbHL}, become smaller in the order of the ligands: H_4edta > H_3hedta > H_2bhedda. This results from the drop in the coordinating ability of the ligand due to the substitution of the hydroxymethyl group for the carboxyl group in the ligand. The small value of k_{j_2} (pH>5.4) for H_2bhedda results from the increase on the transfer coefficient, the negative shift of the half-wave potential, and the steric hindrance caused by uncoordinated hydoxymethyl groups in H_2bhedda.

The Determination of 5-Iodouracil Using the *o*-Hydroxyhydroquinonephthalein–Palladium(II) Complex†

Yoshikazu FUJITA, Itsuo MORI,* and Shoko KITANO
Osaka College of Pharmacy, 2-10-65, Kawai, Matsubara, Osaka 580
(Received November 11, 1982)

Synopsis. A simple and sensitive spectrophotometric procedure was studied for the determination of 5-iodouracil (IU) using the *o*-hydroxyhydroquinonephthalein(Qn.Ph.)–palladium(II) complex and avoiding any effect of iodide ions. This method could be used in the concentration range of 0—15 μg/10 ml of IU, where the Sandell sensitivity was 0.0020 μg/cm² for at 630 nm; the coexistence of the iodide ion did not interfere with the determination of IU, even when it was present in a 500-fold excess.

The determination of organic iodine compounds involves, in general, a preliminary ashing step to release iodide ions.[1,2] Moreover, organic iodine compounds tend to decompose upon exposure to ambient light and so liberate iodide ions. Therefore, it is important that organic iodine compounds be determined without any interference by iodide ions.

We have already reported simple and sensitive spectrophotometries[3–5] for the determination of cephalexin, ampicillin, *etc.* based on the decrease in the absorbance of the *o*-hydroxyhydroquinonephthalein(Qn.Ph.)–palladium(II) complex solution.

This paper will describe a procedure for the determination of 5-iodouracil(IU) using the Qn.Ph.–palladium(II) complex without any effect of the coexistence of iodide ions.

Experimental

Apparatus. The absorption spectra and absorbance were measured with a Shimadzu Model 240 recording spectrophotometer using matched 1.0-cm quartz cells. A Hitachi-Horiba Model F-7 AD glass electrode pH meter was used for the pH measurements.

Reagents. A stock solution(1.0×10^{-3} M, 1 M=1 mol dm^{-3}) of IU(Tokyo Kasei Kogyo Co., Ltd., Tokyo) was prepared by dissolving IU in a 20% methanol solution, while the working solution was made by the suitable dilution of this stock solution as required. A 5.0×10^{-4} M aqueous solution of palladium(II) and a 5.0×10^{-4} M methanol solution of Qn.Ph. were prepared according to the method of a previous report.[3] A 1.0×10^{-2} M solution of hexadecyltrimethylammonium chloride(HTAC) was prepared by dissolving the respective compound in water. A 0.1 M sodium carbonate–0.1 M sodium hydrogencarbonate buffer solution[6] was used for the pH adjustment. All the other reagents were of an analytical grade.

Standard Procedure. 0.5 ml of the 5.0×10^{-4} M palladium(II) solution, 2.0 ml of the 1.0×10^{-2} M HTAC solution, 2.0 ml of the buffer solution(pH 9.8), 0.75 ml of the 5.0×10^{-4} M Qn.Ph. solution, and a solution containing up to 15 μg of IU were placed in a 10-ml calibrated flask. The mixture was diluted to 10 ml with water, kept at 60 °C for 15 min, and then cooled 5 min in water. The difference in absorbance [ΔA] between the Qn.Ph.–palladium(II)–IU and the Qn.Ph.–palladium(II) solutions was measured at 630 nm against water.

Results and Discussion

Absorption Spectra. The absorption spectra of Qn.Ph.–palladium(II) in the presence of IU at pH 9.8 are shown in Fig. 1. On the addition of IU to the Qn.Ph.–palladium(II) solution, the decrease in the absorbance of the Qn.Ph.–palladium(II) complex at 630 nm was proportional to the concentration of IU.

Effect of pH and Surfactants. The effects of the pH and the surfactants were examined. The maximum and constant ΔA value was obtained in the pH range from 9.3 to 10.5 with a 0.1 M sodium carbonate–0.1 M sodium hydrogencarbonate buffer solution. Subsequent measurements were carried out by the addition of 2.0 ml of the pH buffer solution(pH 9.8). Compared with nonionic surfactants, such as poly(vinyl alcohol) and poly(*N*-vinylpyrrolidone), or an anionic surfactant such as sodium dodecyl sulfate, the ΔA value in the presence of a cationic surfactant was more than 30 times as large. HTAC was superior to the other cationic surfactants examined in terms of sensitivity; the maximum and constant ΔA value could be obtained over the range of 1.5—2.5 ml of the 1.0×10^{-2} M HTAC solution in the final 10 ml.

Effects of Palladium(II) and Qn.Ph. Concentration. The effect of the amount of Qn.Ph. on ΔA was examined by varying the molar ratio of Qn.Ph. to palladium(II), the amounts of palladium(II) and IU

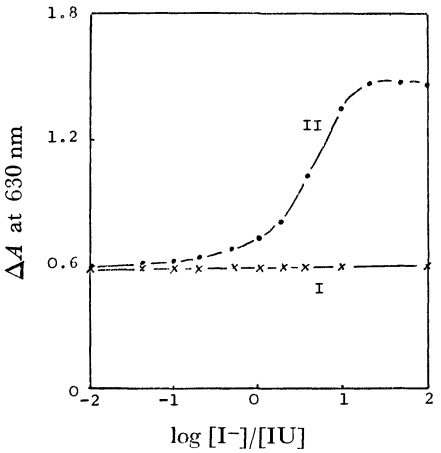

Fig. 2. Effect on ΔA with sequence of addition of iodide ion.
IU: 5.0×10^{-6} M; Pd(II): 2.5×10^{-5} M; Qn.Ph.: 3.75×10^{-5} M; HTAC: 2.0×10^{-3} M; pH: 9.8; Reference: water; sequence of addition of reagents, curve I, Pd(II)→HTAC→Buffer→Qn.Ph.→IU, iodide ion; curve II, IU, iodide ion→Pd(II)→HTAC→Buffer →Qn.Ph.

being kept constant. The molar ratio of palladium(II) 2:Qn.Ph. 3 was most effective. Further, the molar ratio of palladium(II) to Qn.Ph. was found to be 2:3 by using the molar ratio method. Accordingly, all further work was carried out with 2.5×10^{-5} M palladium(II) and 3.75×10^{-5} M Qn.Ph. solutions in the final 10 ml.

Sequence of Addition. The identical ΔA value was obtained in the determination of IU even when the order of the addition of the reagents was varied. However, the influence of iodide ions could be completely eliminated when a solution containing iodide ions was added to the solution obtained after the color reaction between palladium(II) and Qn.Ph. The effect on ΔA of the sequence of addition is shown in Fig. 2.

Stability and Calibration Curve. The maximum ΔA value at 630 nm was given by heating at 60 °C for 15 min. The ΔA value was constant for at least 90 min. The calibration curve for the determination of IU was prepared according to the standard procedure. It obeyed Beer's law over the range of 0—15 μg of IU in the final 10 ml. The Sandell sensitivity was estimated to be 0.0020 μg/cm² IU at 630 nm, and the effective "desorptivity" was 1.15×10^5 l mol^{-1} cm^{-1}. When 5 solutions containing 11.3 μg/10 ml were determined by the standard procedure, the coefficient of variation was 0.95%.

Effects of Foreign Substances. The interfering effects of various substances were examined under the standard conditions. The results are summarized in Table 1. Various metal ions, such as iron(III), copper(II), zinc(II), and cobalt(II) reacted with Qn.Ph. to form a colored complex, thus interfering with the determination of IU. Large amounts of chloride, nitrate, sulfate, organic acids ions, *etc.* did not interfere, while small amounts of cyanide, thiosulfate and thiocyanate ions did so. Uracil, thiourea, purine, orotic acid, amino acids, *etc.* in small amounts affected the determination of IU. Large amounts of salicylic acid, glucose, phenol, urea, *etc.* did not, however, interfere. Uracil present up to 4 times the amount of IU could be permitted by determining the IU according to the standard addition method. As has been described above, iodide ions did not interfere, even in a 500-fold excess. Therefore, the present method could be used to determine IU in the presence of large amounts of iodide ions without a preliminary ashing step to release the iodide ions.

Table 1. Effects of foreign substances

Foreign substances	Added as	Added (μg/10 ml)	ΔA at 630 nm
—	—	—	0.576

(Received December 18, 1982)

Synopsis. By injecting an isotope pulse into the eluent of liquid chromatography, it has been shown that the eluent flow does not go into the stationary phase, while each of the molecules in the eluent is replaced by an equivalent molecule originally contained in the stationary phase. Meanwhile, an appropriate method for determining the t_0 value is given.

Liquid chromatography is useful, not only for the preparation and/or analysis of chemical substances, but also for deriving some thermodynamic functions of intermolecular interactions. For this purpose, it is convenient to regard a chromatogram as free-energy spectrum and to assign to each molecule in question a proper, standard free energy on the basis of the observed chromatogram.[1,2] It is essential in this procedure to determine the t_0 value, which is the time required for the eluent to go through the column, in other words, t_0 is the retention time of a hypothetical molecule which is kept always in the mobile phase and which never goes into the stationary phase.[2] In the present note, our examination of how to determine t_0 will be briefly discussed.

An example of our present experimental results is shown in Fig. 1. Here is a series of chromatograms in which the eluent is always CH_3CN (50%)+H_2O (50%). In every case, a small amount of a sample solvent was injected at zero time. Whenever its composition was different from that of the eluent (chromatograms b,c,d,e,f, and j), a peak (or a negative peak) appeared 6.7 min after the injection. The peak height depends upon the composition of the sample solvent, but its position (6.7 min) is independent of it. This position is considered to correspond to the total volume of the mobile phase of the particular column now in question. In other words, 6.7 min must be the time required for the sample solvent (having a different index of refraction from that of the eluent) to go through the mobile phase of the column. This is taken as the above-defined t_0 for this particular column system.

Next, in order to confirm the above determination of the t_0 value, the microscopic behavior of the eluent in this system is examined. Whenever an isotopic acetonitrile CD_3CN is involved in a sample solvent, another negative peak appears at a definite position: t_c=7.9 min after the injection, *i.e.*, at a somewhat retarded time (see chromatograms c,g,i, and j). This means that CD_3CN in the present column system, with the CH_3CN (50%)+H_2O (50%) eluent, has a relative retention time (t_c-t_0) of 7.9—6.7=1.2 min. Figure 1 indicates also that, after the injection of isotopic water D_2O, a negative peak appears at t_w=10.5 min (chromatograms e,h,i,j) and that the relative retention time (t_w-t_0) is 10.5—6.7=3.8 min.

In order to determine whether the relative retention times (1.2 min or 3.8 min) come from the microscopic behavior of the individual solvent molecule (acetonitrile or water) in the eluent or from simple isotope effects (CH_3CN–CD_3CN or H_2O–D_2O), radioisotopic water T_2O was examined in this system. When a small amount of T_2O is added to the D_2O injected, a radioactivity peak of T_2O is found to be superimposed on the refractive index peak of D_2O (Fig. 1,f). We could not find any difference among T_2O, D_2O, THO, TDO, and HDO in their retention time t_w, nor could we detect any isotopic effect.

Therefore, it is evident that H_2O has the same retention time t_w as those mentioned above. It is also evident that CH_3CN has the same retention time t_c as that of CD_3CN.

It can now be stated that the molecules constituting the solvent are retained to a proper extent in the stationary phase, while the solvent sample as a mac-

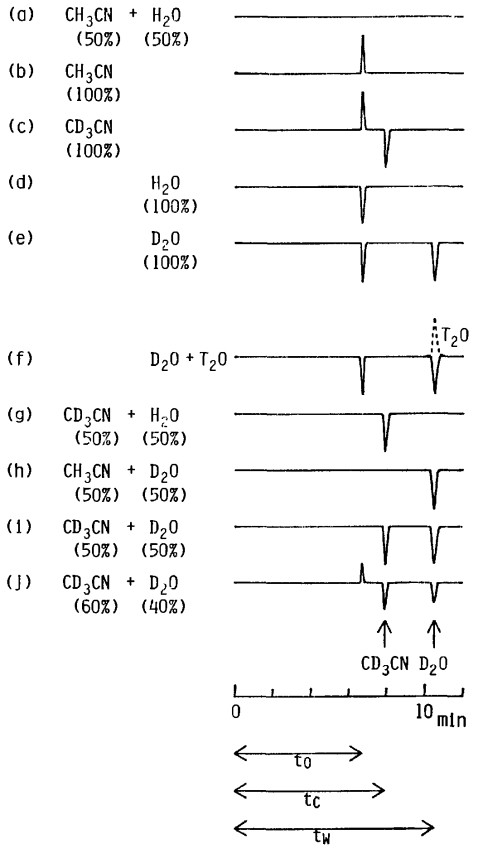

Fig. 1. A series of chromatograms for the determination of t_0, t_c, and t_w values.
Column, Hitachi #3013-N (8ϕ×500 mm); eluent, CH_3CN: H_2O: 1 M phosphate buffer (pH 7)=50 : 49 : 1 (v/v); flow rate, 2 ml/min; temperature, 50 °C; detection, refractive index.

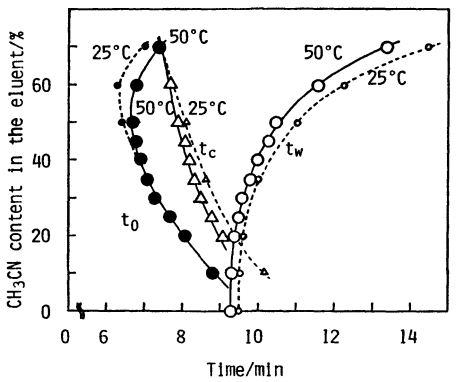

Fig. 2. The values of t_0, t_c, and t_w in a chromatograph system (Hitachi #3013-N with CH_3CN+H_2O as eluent), as functions of the CH_3CN content in the eluent.
Here t_0 is the time required for the solvent to go through the mobile phase (—●—, at 50 °C; --●--, at 25 °C); t_c is the time required for the CD_3CN molecule to come out from the column after its injection (—△—, at 50 °C; --△--, at 25 °C); and t_w is the time required for the D_2O (or HOD or T_2O) molecule to come out from the column after its injection (—○—, at 50 °C; --○--, at 25 °C).

roscopic mass goes through the mobile phase without any retention. In other words, the sample solvent does go down through the mobile phase without changing its composition, but a certain amount of microscopic exchange of the solvent molecules is considered to take place between the mobile phase and the stationary phase. Without an isotopic injection, we cannot detect such a retention of the solvent or eluent molecule (Fig. 1,a), but it is evident that a similar microscopic molecular exchange takes place in every eluent used.

As for how to determine t_0, we have now found an answer: we should inject a solvent pulse with a slightly different composition from that of the eluent. Quite often one does this without intention, for the solvent of a sample solution is actually often slightly different in its composition from that of the eluent, and this causes a small peak in chromatogram which corresponds to t_0. One might think that an isotopic solvent should directly indicate t_0, but actually this does not work, as has been shown here.

We have made similar series of experiments, with different eluents, to see how the t_0, t_c, and t_w values depend upon the eluent composition. These results are given in Fig. 2. As may be seen in the figure, the effective volume of the mobile phase gives a minimum at about 50% of CH_3CN. The retention time (t_w) of D_2O increases, while that (t_c) of CD_3CN decreases, with the increase in the CH_3CN content in the eluent. There is a small temperature effect for each of the t_0, t_c, and t_w values.

Nitration of Aromatic Heterocycles with Palladium(II) Acetate and Sodium Nitrite

Toshio ITAHARA,* Reiko EBIHARA, and Kazukuni KAWASAKI
Institute of Chemistry, College of Liberal Arts, Kagoshima University, Kagoshima 890
(Received August 9, 1982)

Synopsis. Treatments of 1,3-dimethyluracil, 1-methyl-2-pyridone, and thiophene with palladium(II) acetate and sodium nitrite gave the corresponding nitro-substituted products.

The treatment of benzene with palladium(II) salts and sodium nitrite in acetic acid was reported to give nitrobenzene.[1] We have studied the oxidation of aromatic heterocycles with palladium(II) acetate.[2] In the course of the studies, we have found that the treatments of 1,3-dimethyluracil (**1a**), 1-methyl-2-pyridone (**2a**), and thiophene (**4a**) with palladium acetate and sodium nitrite gave the corresponding nitro-substituted products in good yields.

The treatment of **1a** with palladium acetate and sodium nitrite in acetic acid at the reflux temperature gave 1,3-dimethyl-5-nitrouracil (**1b**) in a good yield. In the absence of palladium acetate, the treatment of **1a** with sodium nitrite gave only a small amount of **1b**, although it was reported that the reaction of **1a** with nitronium tetrafluoroborate gave **1b**.[3] These results are summarized in Table 1. Previously it was reported that the oxidation of **1a** with palladium acetate in acetonitrile gave a mixture of dimeric compounds.[4] However, under the present conditions no dimeric compounds were obtained. The attempted nitration of **1a** with other metal acetates and sodium nitrite were unsuccessful, as listed in Table 1.

The treatments of 1-methyl-2-pyridone (**2a**) and of thiophene (**4a**) with palladium acetate and sodium nitrite also resulted in the nitration, although it is known that the treatment of **2a** with nitric acid gives 1-methyl-3-nitro-2-pyridone, 1-methyl-5-nitro-2-pyridone (**2b**), and 3,5-dinitro-1-methyl-2-pyridone (**3b**),[5] and a similar treatment of **4a** gives 2-nitrothiophene, 2,5-dinitrothiophene, and 2,4-dinitrothiophene (**4b**).[6] When **2a** was treated with palladium acetate and sodium nitrite, **3b** was obtained in the yield of 49% together with a small amount of **2b**. The treatment of **4a** under similar conditions also gave **4b**, but no mononitrothiophenes were obtained. It was previously reported that the nitration of 3-nitrothiophene gave

4a (20 ml)		20	10		**4b** (trace)[d,f]

a) The reactions were carried out in acetic acid (30 ml) at the reflux temperature under nitrogen unless otherwise noted. b) Yields based on the substrate **1a** or **2a** consumed. c) Yields (mol/mol%) based on $Pd(OAc)_2$ used. d) The amount of **4a** recovered was not determined. e) The reaction was carried out at 80 °C. f) The reactions were carried out in AcOH (40 ml) at 80 °C in air.

only **4b**, while 2-nitrothiophene gave a mixture of 2,5-dinitrothiophene and **4b**,[6] suggesting that the formation of **4b** from **4a** proceeded *via* 3-nitrothiophene. The attempted nitration reactions of pyrroles such as 1-methyl-, 1-acetyl-, and 1-benzoylpyrroles, 1-acetylindole, and furan with palladium acetate and sodium nitrite in acetic acid were unsuccessful.

Experimental

*1,3-Dimethyl-5-nitrouracil (**1b**).* A solution of 1,3-dimethyluracil **1a** (1 mmol), $Pd(OAc)_2$ (1 mmol), and $NaNO_2$ (2 mmol) in acetic acid (30 ml) was heated at the reflux temperature under nitrogen for 18 h. The reaction mixture was evaporated to give a brown residue which was then chromatographed on a silica-gel plate with ethyl acetate as the developer to give **1a** (0.18 mmol), and **1b** (0.61 mmol), the latter being identical with the sample prepared by the method of Huang and Torrence.[3]

*1-Methyl-5-nitro-2-pyridone (**2b**) and 1-Methyl-3,5-dinitro-2-pyridone (**3b**).* A solution of 1-methyl-2-pyridone (**2a**) (1 mmol), $Pd(OAc)_2$ (1 mmol), and $NaNO_2$ (3 mmol) in acetic acid (30 ml) was heated at the reflux temperature under nitrogen for 7 h. The reaction mixture was evaporated and chromatographed on a silica-gel plate with ethyl acetate as the developer to give **2a** (0.45 mmol), **2b** (0.04 mmol; mp 173—174 °C, lit,[7] 173—174 °C), and **3b** (0.27 mmol) which was identical with the sample prepared by the method of Matsumura *et al.*[5] The structure of **2b** was further confirmed by comparing its ^{1}H-NMR spectrum with that of the compound reported by Mohrle and Weber.[7]

*2,4-Dinitrothiophene (**4b**).* A solution of $Pd(OAc)_2$ (1 mmol) and $NaNO_2$ (10 mmol) in a mixture of thiophene **4a** (20 ml) and acetic acid (40 ml) was heated at 80 °C in air for 10 h. The reaction mixture was evaporated and chromatographed on a silica-gel plate with benzene as the developer to give **4b** (0.66 mmol); mp 54—56 °C (lit,[6] 56 °C); IR (Nujol) 1540, 1510, 1340 cm^{-1}; NMR ($CDCl_3$) δ=8.43—8.66(m); Mass: *m/e* (relative intensity) 174 (M^+, 100), 144(12), 82(49), 81(36), 70(22), 69(44).

The authors wish to thank Professor Tsunao Hase and Professor Tsutomu Sakakibara of Kagoshima University for their encouragement throughout the study.

Aromatic Nucleophilic Substitution. XVII.[1] Formation and Decomposition of Anionic σ Complexes in Reactions of 2-Acetylaminoethyl 2,6-Dinitrophenyl Ether and *N*-Acetyl-*N*-(2-hydroxyethyl)-2,6-dinitroaniline with Potassium *t*-Butoxide

Shizen SEKIGUCHI,* Ohtomo HOSHINO, Motohiko HIRAI, Keiji OKADA, and Noboru TOMOTO
Department of Synthetic Chemistry, Gunma Uuiversity, Kiryu, Gunma 376

(Received September 1, 1982)

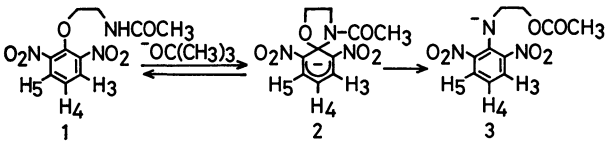
Synopsis. Reactions of 2-acetylaminoethyl 2,6-dinitrophenyl ether and *N*-acetyl-*N*-(2-hydroxyethyl)-2,6-dinitroaniline with *t*-butyl alcoholic $KOC(CH_3)_3$ in DMSO were followed by UV-VIS and NMR spectroscopies. In both reactions the same spiro anionic σ complex was formed.

Previously we reported the kinetics of the base-catalyzed Smiles rearrangement of 2-acetylaminoethyl 2-X-4-nitrophenyl ether (X: NO_2, Br, and CN) giving *N*-(2-acetoxyethyl)-2-X-4-nitroaniline in aqueous DMSO.[2] We have been successful in preparing 2-acetylaminoethyl 2,6-dinitrophenyl ether (**1**) and *N*-acetyl-*N*-(2-hydroxyethyl)-2,6-dinitroaniline (**8**).

This paper reports the formation and decomposition of the same anionic σ complexes in the reactions of **1** and **8** with $KOC(CH_3)_3$ in DMSO–*t*-BuOH mixtures by UV-VIS and NMR spectroscopies.

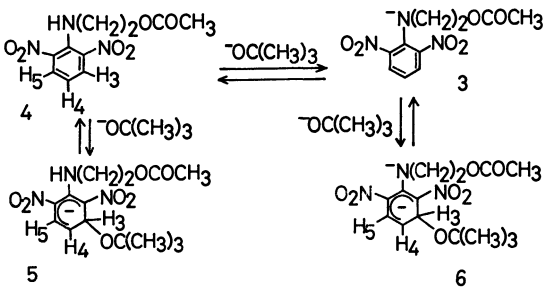
Results and Discussion

*Absorption Spectra. Reaction of 2-Acetylaminoethyl 2,6-Dinitrophenyl Ether (**1**) with $KOC(CH_3)_3$*: Upon addition of *t*-butyl alcoholic $KOC(CH_3)_3$ [1.10×10^{-2} M (1 M=1 mol dm^{-3})] to **1** (2.68×10^{-5} M) in DMSO, the solution was colored purple instantly [λ_{max} 340 (m) and 585 nm (s)], which could be attributed to the formation of **2** (Scheme 1),[3] and then the color slowly faded away. The absorption spectrum after 4 h [λ_{max} 368 nm (m)] could be attributed to the anionic species **5** (Scheme 2).[4] These results show that the respective O→N and N→O migrations of 2,6-dinitrophenyl and acetyl groups take place concurrently, and would be compatible with Scheme 1.



Scheme 1.

Reaction of N-*(2-Acetoxyethyl)-2,6-dinitroaniline (**4**) with $KOC(CH_3)_3$*: In order to elucidate further the final species in the reaction of **1** with $KOC(CH_3)_3$, the reaction of **4** with $KOC(CH_3)_3$ was carried out. Upon addition of *t*-butyl alcoholic $KOC(CH_3)_3$ (1.10×10^{-2} M) to **4** (4.71×10^{-5} M) in DMSO, the solution was colored purple instantly [λ_{max} 320 (m), 368 (m), and 585 nm (w)], and then the color slowly faded away. From a consideration of the results of Crampton *et al.*[3,4] Pollitt and Saunders,[3] and ours[2] together with the NMR spectral evidence, these bands could be attributed to a mixture of **3** (585 nm), **5** (368 nm), and **6** (320 nm). After 2 h the absorption peak at 368 nm (**5**) increased at the expense of that at 320 nm (**6**). Therefore Scheme 2 would be compatible with the results.



Scheme 2.

Reaction of N-*Acetyl*-N-*(2-hydroxyethyl)-2,6-dinitroaniline (**8**) with $KOC(CH_3)_3$*: In order to elucidate the processes described above in detail the reaction of **8** with $KOC(CH_3)_3$ was carried out.

Upon addition of *t*-butyl alcoholic $KOC(CH_3)_3$, almost similar absorption spectra to that obtained at the initial stage in the reaction of **1** with $KOC(CH_3)_3$ appeared [λ_{max} 340 (m) and 585 nm (s)] indicating the presence of the complex **2**. In course of time the absorption peak at 368 nm increased at the expense of the peak at 585 nm, indicating that after the complex **2** had been formed, the anionic species **5** was produced *via* **3** (Scheme 2).

*NMR Spectra. Reaction of 2-Acetylaminoethyl 2,6-Dinitrophenyl Ether (**1**) with $KOC(CH_3)_3$*: Upon addition of 1 equiv. of *t*-butyl alcoholic $KOC(CH_3)_3$ amide proton signal (δ=8.00) of **1** disappeared instantly, and $H_{3,5}$ and H_4 signals shifted upfield respectively (δ=8.33→7.77; 7.57→5.15) (Fig. 1). Such shifts are quite the same as the results observed in the reaction of 2-acetylaminoethyl 2,4-dinitrophenyl ether with $NaOCH_3$ in DMSO,[5] indicating the proton abstraction by $^-OC(CH_3)_3$ followed by the intramolecular nucleophilic attack of amide ion on C-1 position (Scheme 3).

Reaction of N-*(2-Acetoxyethyl)-2,6-dinitroaniline (**4**) with $KOC(CH_3)_3$*: Upon addition of 1 equiv. of *t*-butyl alcoholic $KOC(CH_3)_3$ amide proton signal (δ=8.10) of **4** disappeared instantly, and $H_{3,5}$ and H_4 signals shifted upfield instantly (δ=8.27→8.00; 6.93→6.43), which are due to the formation of **3** (Fig. 2b). After 2 h, collapsed doublets appeared at δ=*ca.* 7.87 and 5.30, attributed to H_5 and H_3 protons of **6**, respectively (Fig. 2c). Further, $H_{3,5}$ doublet (δ=8.27) of **4** reappeared, indicating the reversion of **6**⇄**3**⇄**4** (Scheme 2). This is also strongly evidenced by the presence of amino proton signal at δ=*ca.* 8.10, although it partly overlapped $H_{3,5}$ doublet (δ=8.27) of **4** (Fig. 2c). Collapsed triplet at δ=6.93 could be attributed to H_4 proton of **4**. The weak signals at δ=*ca.* 5.45 would be a part of the doublet due to H_3 proton of **5**. H_3 doublet (δ=*ca.* 5.20) of **5** partly overlapped collapsed H_3 doublet (δ=*ca.* 5.40) of **6**.

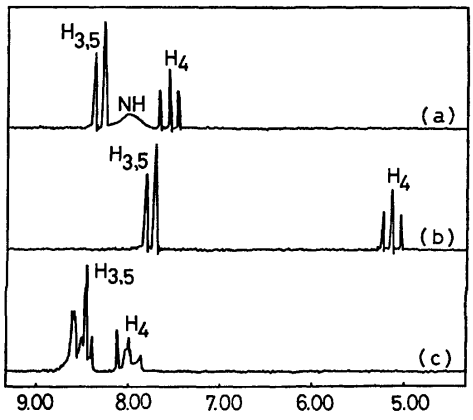


Fig. 1. NMR spectral change relevant to the reactions of 2-acetylaminoethyl 2,6-dinitrophenyl ether (**1**) and *N*-acetyl-*N*-(2-hydroxyethyl)-2,6-dinitroaniline (**8**) with $KOC(CH_3)_3$ in DMSO. a: **1**, b: just after addition of 1 equiv. of *t*-butyl alcoholic $KOC(CH_3)_3$, c: **8**.

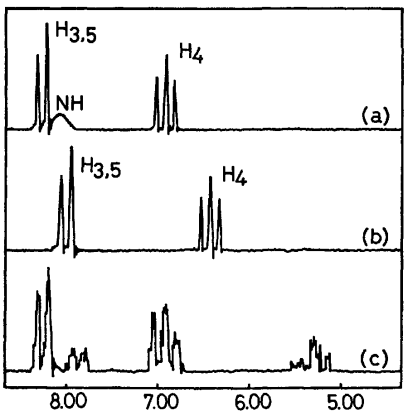

Fig. 2. NMR spectral change relevant to the reaction of *N*-(2-acetoxyethyl)-2,6-dinitroaniline (**4**) with $KOC(CH_3)_3$ in DMSO. a: **4**, b: just after addition of 1 equiv. of *t*-butyl alcoholic $KOC(CH_3)_3$, c: 6 h after addition.

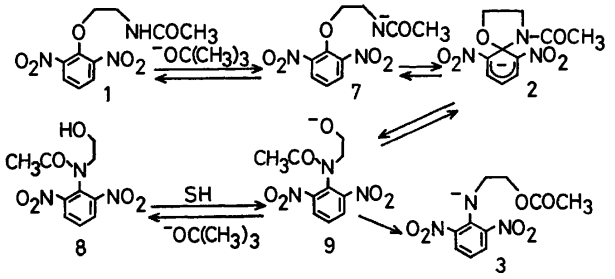

Scheme 3.

These results show that just after addition of $KOC(CH_3)_3$ **4** is transformed to **3**, which partly reverts to **4**, producing **5**, and partly changes into **6** (Scheme 2).

Reaction of N-*Acetyl*-N-*2-(hydroxyethyl)-2,6-dinitroaniline (8) with* $KOC(CH_3)_3$: Upon addition of 1 equiv. of *t*-butyl alcoholic $KOC(CH_3)_3$ to **8** in DMSO (Fig. 1c), the same signal pattern as Fig. 1b appeared, indicating the formation of the complex **2**. Complicated $H_{3,5}$ and H_4 signals (Fig. 1c) are considered to be due to the coexistence of (*E*) and (*Z*) isomers of **8**.

In conclusion, it is confirmed that **1** undergoes the base-catalyzed Smiles rearrangement, producing **4** *via* the spiro anionic σ complex **2**, producing **4** *via* **9** and **3**, and that **8** is base-catalyzed to at first produce **2**, which reverts to **9**, producing **4** *via* **3**.[2]

Experimental

Mps were uncorrected. Compounds **1**, **4**, and **8** were identified by NMR, IR, and MS. Their results of the elementary analysis were in good agreement with those calculated ones within the experimental errors.

2-Acetylaminoethyl 2,6-Dinitrophenyl Ether (1). According to the method described in the literature[6] was prepared 2,6-dinitroaniline (DNA) from chlorobenzene (yield 20%), and 2,6-dinitrochlorobenzene (DNC) prepared from DNA (yield 69%).

After a nitrobenzene (10 g) solution of KF (6 g, 0.103 mol) and DNC (14 g, 0.0069 mol) was stirred at 190 °C for 5 h and, then, the nitrobenzene distilled off under reduced pressure, the residue was further distilled at 145—150 °C/6 mmHg to produce 8.4 g of 2,6-dinitrofluorobenzene (DNF) (yield 61%), mp 60—62 °C (lit, 60—63 °C).[10]

From DNF and 2-acetylaminoethanol was prepared **1** according to the method described previously.[5] Recrystallization from ligroin gave pure **1** crystals (yield 13%); mp 92—93 °C; UV_{max} (DMSO) 305 nm (ε=1970).

N-(2-Acetoxyethyl)-2,6-dinitroaniline (4). A 30 ml DMSO solution of 2.4 g (0.0039 mol) of 2-aminoethanol was added dropwise to a 60 ml DMSO stirred solution of 4 g (0.020 mol) of DNC for 3 h at room temperature, and then the mixture poured into an ice-water. The precipitate formed was filtered and recrystallization from ethanol gave 2 g of pure *N*-(2-hydroxyethyl)-2,6-dinitroaniline (HDNA) (yield 44.5%). After a 100 ml dioxane solution of 2 g (0.0088 mol) of HDNA and 1.4 g (0.018 mol) of acetyl chloride was stirred at 80 °C for 1 h, the mixture was poured into an ice-water and extracted with benzene. The benzene layer was dried over anhydrous Na_2SO_4 overnight, filtered and evaporated. The residue was chromatographed over silica gel (benzene) and recrystallized from methanol to give 1.7 g of **4** (yield 75.5%); mp 55—56 °C; UV_{max} (DMSO): 428 nm ($\varepsilon=6.05\times10^3$).

N-Acetyl-N-(2-hydroxyethyl)-2,6-dinitroaniline (8). A 50 ml dioxane solution of 5.5 g (0.053 mol) of 2-acetylaminoethanol, and 1.0 g (0.027 g-atom) of potassium was refluxed until potassium was dissolved. To this solution was rapidly added a 50 ml dioxane solution of 5.0 g (0.027 mol) of DNF, and the mixture swirled for *ca.* 3 min (short reaction time should be necessary). Then, the mixture was poured into an ice-water, neutralized with dilute HCl (10%), and extracted with chloroform. The chloroform layer was dried over anhydrous Na_2SO_4 overnight, filtered, evaporated, and chromatographed over silica gel (benzene:acetone 5:1 v/v), and recrystallized from ligroin to give 0.09 g (yield 1.3%) of **1** and 0.32 g (yield 4.4%) of **8**; mp 118—119 °C; UV_{max} (DMSO) 320 nm ($\varepsilon=4.13\times10^3$).

Reinvestigation of the Synthetic Reaction of Dimethylamino-1,3-indandione

Masaaki Ito*, Kazuo Abe, Teruji Sasaki, and Kenzo Misono†

Chemistry Laboratory, Department of General Education, Higashi-Nippon-Gakuen University, Onbetsu, Hokkaido 088-01

†*Hokkaido-Togyo Co., Ltd., 1, 2-Kandajinbocho, Chiyoda-ku, Tokyo 101*

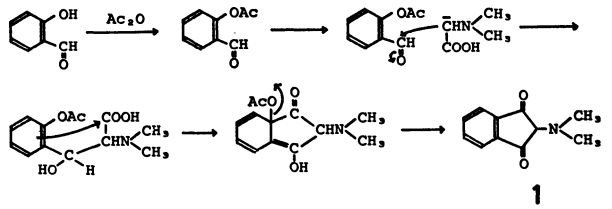
(Received October 9, 1982)

Synopsis. One step preparation of dimethylamino-1,3-indandione (**1**) from salicylaldehyde with glycine betaine was reinvestigated. Reaction conditions to give the best yield of **1**, characterization of a minor product (2-acetoxybenzylidene diacetate), and reaction pathway were described.

The reaction of salicylaldehyde with (carboxymethyl)trimethylammonium hydroxide inner salt (glycine betaine) in acetic anhydride provides a convenient procedure for the preparation of dimethylamino-1,3-indandione (**1**).[1,2]

The pathway of the reaction is proposed as depicted in Scheme 1. The reaction is based on an acetylation of the hydroxyl group of salicylaldehyde, a nucleophilic attack of α-carboxy(dimethylamino)methanide ion which is formed from the glycine betaine, and an acetylation of the benzene ring accompanied by elimination of the acetoxyl group.

The reaction mixture containing salicylaldehyde and the glycine betaine in acetic anhydride was refluxed at 150 °C for 7 h. After removal of the volatile matters, the resulting residue was recrystallized from benzene to give pale yellow crystals of **1**. The optimum reaction conditions for this reaction were investigated on several ratios of acetic anhydride and the glycine betaine *versus* the salicylaldehyde, and on the reaction time as shown in Tables 1 and 2. To obtain optimum



Scheme 1.

Table 1. Yields of the 1,3-indandione **1** and by-product **2**[a]

Run	Molar ratio of glycine betaine : salicylaldehyde : Ac_2O	Yield[b]/% **1**	Yield[b]/% **2**
1	1 : 1 : 1	42.6	none
2	1 : 1 : 2	53.5	10.2
3	1 : 1 : 5	52.5	21.0
4	1.5 : 1 : 2	69.3	5.4
5	2 : 1 : 2	78.7	2.4
6	2.5 : 1 : 2	80.1	1.6
7	3 : 1 : 2	77.8	trace
8	1 : 2 : 2	61.1	trace

a) The reaction was carried out at 150 °C for 7 h. b) Yields are based on salicylaldehyde used. Determined by GLC.

Table 2. Effect on reaction time for yields

Run	Reaction time/min	Yield/% **1**	Yield/% **2**
9	15	55.1	4.9
10	30	61.5	3.6
11	60	68.4	4.5
12	180	72.6	3.6

Reaction conditions: Molar ratio of the glycine betaine : salicylaldehyde : acetic anhydride = 2 : 1 : 2, temp: 150 °C. Yields are based on salicylaldehyde used. Determined by GLC.

yield of **1**, the reaction must be conducted at 150 °C for 7 h using 2—2.5 mol of the glycine betaine and 2 mol of acetic anhydride *versus* one mol of salicylaldehyde.

It is found that this reaction is accompanied by formation of 2-acetoxybenzylidene diacetate (**2**) as a minor product. By-product **2** will be formed by acetalyzing and acetylation of salicylaldehyde with acetic anhydride. The formation of **2** increases in yield when acetic anhydride is used in large quantities. The structure of **2** was confirmed by the analytical and spectral data, and by the fact that compound **2** is hydrolyzed to salicylaldehyde.

The similar reaction using hydroxybenzoic acids, methyl salicylate in place of salicylaldehyde did not give the product **1**, and in the case of methyl salicylate it gave only methyl 2-acetoxybenzoate.

Experimental

All melting points were uncorrected. The IR, ^{1}H NMR, UV, and Mass spectra were recorded on a Shimadzu IR-400, a JEOL JNM-PMX-60 using TMS as internal standard, a Shimadzu MPS-5000, and a Shimadzu LKB-9000 spectrometer, respectively. The analytical GLC were performed on a Shimadzu GC-4B apparatus equipped with a data processor, Chromatopac C-R1B, and with a 1.5 m glass column packed 10% Silicone OV-17 at 210 °C. Acetic anhydride was purified by refluxing with CaC_2 and by distillation before use.

*Preparation of Dimethylamino-1,3-indandione (**1**).* A mixture of the glycine betaine (29.3 g, 0.25 mol) and salicylaldehyde (12.2 g, 0.1 mol) in acetic anhydride (20.4 g, 0.2 mol) was refluxed at 150 °C for 7 h. After sufficient water was added to decompose the excess acetic anhydride, the mixture was extracted with benzene, washed with water, dried over sodium sulfate, and evaporated to leave a crude product 15.2 g of the 1,3-indandione **1** in 80.1% yield (based on salicylaldehyde, obtained on GLC datum). An analytical sample was recrystallized from benzene, a pale yellow crystal: mp 85—86 °C; UV_{max} (EtOH) 245 (ε 8100) and 340 nm (ε 14400); ^{1}H NMR ($CDCl_3$): δ=2.98 (6H, s), 6.69 (1H,

s), 7.27 (4H, s); IR (KBr): 1705 (C=O) cm^{-1}; MS (*m/e*) 189 (M^+); Found: C, 69.56; H, 5.77; N, 7.40%. Calcd for $C_{11}H_{11}NO_2$: C, 69.82; H, 5.86; N, 7.40%.

The reactions shown in Tables 1 and 2 were carried out under the full range of the reaction conditions noted above.

*2-Acetoxybenzylidene Diacetate (**2**). Isolation of **2***: A mixture of the glycine betaine (5.9 g, 0.05 mol), salicylaldehyde (6.1 g, 0.05 mol) in acetic anhydride (25.5 g, 0.25 mol) was refluxed at 150 °C for 7 h. After the usual work-up, the residue was chromatographed on silica-gel column. From a benzene elute, 2.4 g, (18.0%) of **2** was obtained. Colorless crystals; mp 102.7—103.4 °C; ^1H NMR ($CDCl_3$): δ=2.12 (6H, s), 2.34 (3H, s), 7.06—7.73 (4H, m), 7.91 (1H, s); IR (KBr): 1755—1745 (C=O) cm^{-1}; Found: C, 58.57; H, 5.33%. Calcd for $C_{13}H_{14}O_6$: C, 58.64; H, 5.30%. Mol wt (Rast, benzene) 267. Calcd 266.24. E.V. 48.24. Calcd 48.51. The saponification value was determined by hydrolysis with a 0.5 M ethanolic KOH solution for 1 h.

*Preparation of **2***: A mixture of salicylaldehyde (12.2 g, 0.1 mol) in acetic anhydride (25.5 g, 0.25 mol) was refluxed at 150 °C for 2 h. After cooling, a crystalline product was filtered and recrystallized from benzene to give **2** (19.3 g, 72.5%). The product was identified by means of gas chromatography in comparison with the isolated product described above.

*Reaction of 2-Acetoxybenzylidene Diacetate (**2**) with the Glycine betaine and Acetic Anhydride.* A mixture of 2.7 g (0.01 mol) of **2** and 2.3 g (0.02 mol) of the glycine betaine in 3 g (0.03 mol) of acetic anhydride was refluxed at 150 °C for 4.5 h. After the usual work-up, 0.19 g (47.6% based on **2** used) of the 1,3-indandione (**1**) was obtained on GLC. Its IR and ^1H NMR spectra data agreed with those of **1** obtained as noted above.

The authors wish to express their thanks to Hokkaido-Togyo Co., Ltd. for its finacial support, to Dr. Hajime Takahashi of Department of General Education, Higashi-Nippon-Gakuen University for his helpfull discussion, and to Mr. Akiyo Sakushima of Faculty of Pharmaceutical Sciences, Higashi-Nippon-Gakuen University for Mass spectra measurement.

Preparation and Properties of Polymers Anchoring Biphenyl-2-ol

Tomomichi ISHIKAWA* and Satoshi ASAI

Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158

(Received December 18, 1982)

Synopsis. The monomer, 2-biphenylyl acrylate (BPA), was prepared and was polymerized and copolymerized with vinyl acetate (VAc), styrene and *N*-vinylpyrrolidone. The reactivity ratios of BPA(M_1) with VAc were evaluated as $r_1=4.6+0.4$ and $r_2=0.37+0.08$. The polymers were hydrolyzed in methanol–phosphate buffer solution(pH 6 and 8), and the release rate of biphenyl-2-ol from the polymer was investigated.

Recently, there has been a great deal of interest in drugs,[1–3] agricultural medicines[4,5] and coatings[6,7] with long-lasting biological activity. Polymers of which fungicidal biphenyl-2-ol(*o*-phenylphenol, abbreviated to OPP) is anchored *via* hydrolyzable ester link to the main chain may be available to control the release of the fungicide over an extended period. Preparation of the polymers is accomplished by polymerization and copolymerization of 2-biphenylyl acrylate (BPA). In this work we describe the synthesis of both the monomer and polymer, and a study of the hydrolytic release of OPP from the polymer.

Experimental

Materials. Vinyl acetate(VAc), *N*-vinylpyrrolidone (NVP), styrene(St), and acryloyl chloride were distilled under reduced pressure prior to use. OPP and α,α′-azobisisobutyronitrile (AIBN) were purified by recrystallization. Benzene used as reaction media was dried and purified by distillation.

Synthesis of BPA. Previously dried benzene(100 cm³), OPP(34.0 g, 0.2 mol) and triethylamine(22 g, 0.22 mol) were placed in a 200 cm³ four necked round-bottom flask equipped with a stirrer, condenser and dropping funnel with a nitrogen inlet tube. The mixture was then maintained at 20—25 °C while acryloyl chloride(20.0 g, 0.22 mol) was added through the dropping funnel. Stirring was continued for additional 4 h. After the precipitate was filtered, the benzene solution was washed with 5% aqueous $NaHCO_3$ solution and twice with water. The benzene layer was dried over Na_2SO_4, and then the benzene was removed by vacuum evaporation. The pale yellow solution which remained was distilled under reduced pressure in the presence of 4-*t*-butylcatechol to yield 31.0 g (64.0%) BPA: bp 120—122 °C(200 Pa); IR (liquid) 1740(C=O), 1630(C=C), 1190, 1145(C–O–C) cm^{-1}; ^{1}H-NMR ($CDCl_3$) $\delta=5.60$, 6.25 (3H, m, CH_2=CH) and 7.30 (9H, m, aromatic proton). Found: C, 83.43; H, 6.29%. Calcd for $C_{15}H_{12}O_2$: C, 83.36; H, 6.18%.

General Procedure for Polymerization. All the polymerization experiments were carried out using a bulk technique at 60 °C in the presence of 0.5 wt% AIBN. The polymers obtained were purified by repeated precipitation from a solvent system into a non-solvent system. The purified polymers were dried at 60 °C under vacuum to constant weight and submitted to elemental analysis.

General Procedure for Hydrolysis. The polymer (converted into 0.5—0.6 mmol OPP) and the phosphate buffered methanol–water solution (pH 6 or 8; 200 cm³) were placed in 300 cm³ Erlenmeyer flask, and then maintained at 30 °C with a regulated water bath. The mixture was shaken often, and a part of this mixture (1 cm³) was taken out periodically. The polymers was removed by filtration. The filtrate was diluted with the buffer solution (4 cm³). The solution was put into a cubic quartz cell (1 cm) and detection of OPP was performed by UV at 244.0 nm.

Synthesis of 2-Biphenylyl Propionate (BPP). BPP was prepared from OPP with propionyl chloride by a similar procedure to that of BPA-synthesis: yield 54.0%; bp 156—158 °C (1333 Pa); IR (liquid) 1760(C=O), 1180 and 1140 (C–O–C) cm^{-1}; ^{1}H-NMR ($CDCl_3$) $\delta=1.00$ (3H, t, CH_3), 2.30 (2H, m, CH_2) and 7.30 (9H, m, aromatic proton). Found: C, 79.46; H, 6.44%. Calcd for $C_{15}H_{14}O_2$: C, 79.62; H, 6.24%.

Results and Discussion

Polymerization and Copolymerization of BPA. The BPA obtained was a colorless viscous liquid. The

homopolymer was purified by reprecipitation from dichloromethane and methanol. Purification of the copolymers with NVP were by repeated precipitation from benzene and hexane. The copolymers with VAc or St were redissolved in dichloromethane and reprecipitated in methanol. Results are shown in Table 1. These polymers are colorless powders, soluble in organic solvents such as acetone, benzene, tetrahydrofuran and dichloromethane.

For BPA(M_1) with VAc, the reactivity ratios were determined by the integral form of the general copolymerization equation from the results for Runs 1—3 in Table 1. The r_1 and r_2 values obtained were $r_1=4.6\pm0.4$ and $r_2=0.37\pm0.08$. The conversion was calculated using Spinner and co-worker's equation[8] from these r_1 and r_2 values were fairly consistent with the results for Runs 4—6.

Release of OPP from Polymer. The polymers were hydrolyzed at pH 6 and 8. OPP released during the hydrolysis was dissolved in methanol–phosphate buffer solution(1/1 volume ratio) because of their lower solubility in water. The amount of OPP released was determined by measuring its absorbance at 244.0 nm. Table 2 shows the results after one and two weeks. It appears that the release rate of OPP are faster at pH 8 than at pH 6. After one week at pH 8, BPA–NVP copolymer was hydrolyzed faster than the other two copolymers, but much slower than the BPA homopolymer. In the period between one and two weeks, however, BPA–VAc copolymer was more susceptible to hydrolysis than the others. In this copolymer also, it was observed that the time-conversion plots are nearly linear and release the incorporated OPP by zero-order kinetics for at least two weeks.

As Table 2 shows, when the OPP content becomes higher, the conversion increases. But the BPA homopolymer was hydrolyzed very slowly and even after two weeks, about 70% of OPP unit remained on the polymer chain. In order to compare with the hydrolysis rate of the BPA homopolymer, a model compound, BPP, was hydrolyzed. The results were shown in Fig. 1. From these results, it seems that the polymers were resistant to hydrolysis and released OPP gradually. When the polymers are used as coating films, the above results suggest that the polymers will lose few OPP under a natural environment such as in the rain.

Synthesis of 4*H*-Cyclopenta[*def*]phenanthrene from Fluorene Skeleton

Masaaki Yoshida*, Masahiro Minabe, and Kazuo Suzuki†

Department of Industrial Chemistry, Faculty of Engineering, Utsunomiya University, Ishiicho, Utsunomiya 321

†*Akita Technical College, Iijima-bunkyocho, Akita 011*

(Received January 10, 1983)

Synopsis. 4-Fluoreneacetic acid was prepared and its chloride was cyclized with $AlCl_3$ to give 4*H*-cyclopenta-[*def*]phenanthren-8-ol accompanied by the 8,9-dione. These were both reduced to 4*H*-cyclopenta[*def*]phenanthrene: the overall yield was 40—50% from diphenic acid. The phenol was converted to acetoxy and amino substrates.

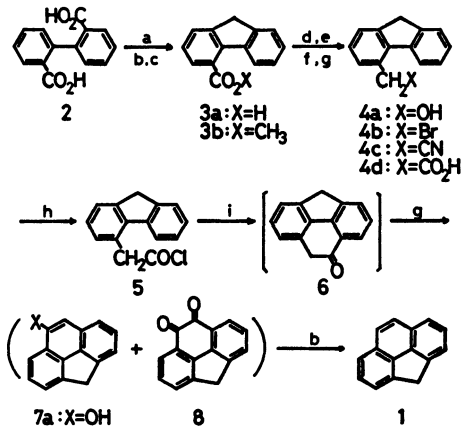
Hydrocarbon 4*H*-cyclopenta[*def*]phenanthrene (**1**) involves an active methylene, a located C_8–C_9 double bond, and strained aromatic rings, and is of interest for carcinogenic screening tests. The characterized aromatic **1** possesses features of naphthalene, fluorene, and phenanthrene, thus **1** is one of the key compounds for studying arenes[1] and annulenes.[2] Reported synthetic pathways of **1** could be classified in three types, according to the ring which is built up at the last step from the component skeleton: (a) formation of the five-membered ring from phenanthrene derivatives;[3] (b) formation of the side six-membered ring from acenaphthene derivatives;[4] (c) formation of the center six-membered ring from fluorene derivatives. The first two methods require many steps, resulting in very low yields, and the third type has not yet succeeded.[5,6]

We wish to report here a convenient preparation of **1** from diphenic acid (**2**) *via* fluorene derivative (Scheme 1). The preparation of 4-fluorenecarboxylic acid (**3a**) in a good yield was reported by one of us.[7] Extension of the carbon chain of **3a** to **4d** has been carried out by means of the Arndt-Eistert reaction;[5] however, no diazomethane is available for mass production. The synthesis of **4d** from **3a** proceeded by the following stepwise sequence: esterification to **3b**, reduction to **4a**, bromination to **4b**, substitution to **4c**, and hydrolysis to **4d**. All these reactions gave very high yields and required only easy treatment.

Ring closures of 4-fluoreneacetic acid (**4d**) and 9-oxo-4-fluoreneacetic acid to the **1** derivatives were attempted unsuccessfully under the conditions which has sufficed to convert biphenyl-2-acetic acid to phenanthrene derivative.[5,8] This may be due to an increase of the distance between C_4 and C_5 of **4d**. This experiment shows that only 4-fluoreneacetyl chloride (**5**) was cyclized under the Friedel-Crafts conditions to 4*H*-cyclopenta[*def*]phenanthren-8-ol (**7a**) accompanied by 4*H*-cyclopenta[*def*]phenanthrene-8,9-dione (**8**). Both **7a** and **8** were reduced to the hydrocarbon **1** with hydriodic acid and red phosphorus[9] in good yields. Also, from the crude products of the ring closure reaction, the hydrocarbon was obtained in a 66% overall yield from **5**.

The phenol **7a** is a tautomer with 4*H*-cyclopenta-[*def*]phenanthren-8(9*H*)-one (**6**), which failed to separate for **6**, probably forming a complex with aluminium, but was confirmed as an intermediate by the NMR spectrum of the reaction mixture in $CDCl_3$ (Fig. 1). The singlets of 4.73 and 4.18 ppm were assigned to the methylene protons of 9- and 4-position of **6**, respectively, by comparison with the spectrum of 9,9-dimethyl-4*H*-cyclopenta[*def*]phenanthren-8(9*H*)-one.[10] Owing to the tautomer with **6**, **7a** may be readily oxidized to dione **8** on exposure to air. So, for storage during a long period, the hydroxyl group of **7a** was protected as the acetate (**7b**: X=OAc) which was hydrolyzed quantitatively to **7a**.

Consequently, this procedure appears more simple and easier than the methods hitherto available. One of the merits of this facile method is a moderate yield of **1** (40—50% based on **2**). The second is a ready transformation to the 8-derivatives which are difficult to obtain by electrophilic substitution of **1**.[11] **7a** was



a: H_2SO_4. b: HI, P. c: MeOH, H_2SO_4 d: $LiAlH_4$. e: HBr. f: KCN. g: $H_3{}^+O$. h: $SOCl_2$. i: $AlCl_3$

Scheme 1.

derived to 4*H*-cyclopenta[*def*]phenanthren-8-amine (**7c**: X=NH_2)[12] which was converted easily into many 8-substituted 4*H*-cyclopenta[*def*]phenanthrenes.

Experimental

All the melting points are uncorrected. The following spectrometers were used: ^1H NMR, JEOL C-60-HL (downfield from internal Me_4Si); IR, JASCO IR-G (KBr pellets); mass spectra, Hitachi RMU-6E or M-80 (direct inlet system). Elemental analyses were determined on a Yanagimoto CHN-corder.

4-(Bromomethyl)fluorene (4b). Dicarboxylic acid **2** was treated with concentrated sulfuric acid at 130—140 °C for 15 min to afford 9-oxo-4-fluorenecarboxylic acid (yield 97%). The keto acid was reduced with hydriodic acid and red phosphorus in acetic acid under refluxing for 20 h to give **3a** (yield 95%).[7] 4-Fluorenemethanol (**4a**) was obtained from methyl 4-fluorenecarboxylate (**3b**) with lithium aluminium hydride in a 99% yield.[13] A solution of **4a** (11.8 g, 60 mmol) in acetic acid (150 ml) was saturated with hydrogen bromide, followed by standing overnight at room temperature. The resulting mixture was extracted with benzene (60 ml) and the extract was washed with water to neutrality. The organic layer was dried and recrystallized from cyclohexane to give **4b** (14.4 g, 93%): mp 126—127 °C (lit,[13] mp 115—118 °C); NMR (CCl_4) δ=3.80 (s, 2H), 4.77 (s, 2H), and 7.02—8.01 (m, 7H). Found: C, 65.19; H, 4.07%.

4-Fluoreneacetonitrile (4c). To a solution of **4b** (4.50 g, 17.3 mmol) in *N,N*-dimethylformamide (100 ml) was added aqueous potassium cyanide (3 normal, 10 ml) and the mixture was refluxed for 4 h. The resulting mixture was poured into water (300 ml) and the precipitate was recrystallized from cyclohexane to give **4c** (3.05 g, 86%): mp 101—102 °C; IR 2270 cm^{-1}; NMR ($CDCl_3$) δ=3.87 (s, 2H), 4.10 (s, 2H), and 7.12—7.76 (m, 7H); MS *m/e* 205 (M^+), 178, and 165. Found: C, 87.94; H, 5.39; N, 6.62%. Calcd for $C_{15}H_{11}N$: C, 87.77; H, 5.40; N, 6.82%.

4-Fluoreneacetyl Chloride (5). Nitrile **4c** was hydrolyzed with dilute sulfuric acid in acetic acid to give carboxylic acid **4d** in a 96% yield; mp 178—179 °C (lit,[5] mp 178.5—179.0 °C). A mixture of **4d** (2.1 g, 9.4 mmol) in thionyl chloride (10 ml) was gently refluxed for 0.5 h and was dried *in vacuo*. The residue was recrystallized from hexane to afford **5** (2.13 g, 94%): mp 98.0—98.5 °C; IR 1786 cm^{-1}; NMR ($CDCl_3$) δ=3.92 (s, 2H), 4.60 (s, 2H), and 7.11—7.81 (m, 7H); MS *m/e* 244 and 242 (M^+), 206, and 165. Found: C, 74.31; H, 4.51%. Calcd for $C_{15}H_{11}OCl$: C, 74.20; H, 4.57%.

Ring Closure of 5. To a suspension of anhydrous aluminium chloride (0.53 g, 4 mmol) in 1,2-dichloroethane (30 ml), a solution of **5** (485 mg, 2 mmol) in 1,2-dichloroethane (5 ml) was added slowly at 20 °C and stirring was continued for 2 h. The mixture was hydrolyzed with dilute hydrochloric acid and extracted with benzene. The extract was submitted to silica-gel column chromatography to afford **7a** from the first eluate (269 mg, 65%): mp 167—168 °C decomp; IR 3330 and 1126 cm^{-1}; NMR ($CDCl_3$) δ=4.32 (s, 2H), 5.55 (s, 1H, OH), 7.04 (s, 1H), and 7.32—8.00 (m, 6H); MS *m/e* 206 (M^+) and 178. Found: C, 87.21; H, 5.05%. Calcd for $C_{15}H_{10}O$: C, 87.35; H, 4.89%.

The second eluate of the column gave **8** (44 mg, 10%): mp 254—256 °C decomp (lit,[10] mp 256 °C decomp).

4H-Cyclopenta[def]*phenanthrene (1).* Upon the intramolecular Friedel-Crafts reaction of **5** (242 mg, 1 mmol), the mixture containing **7a** and **8** was treated with hydriodic acid (57%, 10 ml) and red phosphorus (1.0 g) in acetic acid (50 ml) to reflux under nitrogen for 90 h. The resulting mixture was poured into aqueous sodium hydrogensulfite (1%, 100 ml) and was extracted with benzene. The organic layer was chromatographed on a silica gel to give **1** from the colorless eluate (126 mg, 66% from **5**): mp 113—114 °C (lit,[14] mp 116 °C).

The reductions of **7a** and **8** were carried out: **1** was obtained in yields of 27, 53, 88, and 78% from **7a** during the reaction times of 16, 24, 48, and 90 h, respectively, by a method similar to that described above. Also, **1** was afforded from **8** in yields of 26, 37, 58, and 80%, respectively.

8-Acetoxy-4H-cyclopenta[def]*phenanthrene (7b).* The mixture of **7a** (721 mg, 3.5 mmol) and acetic anhydride (100 ml) was refluxed for 1 h and was then quenched with cold water. The precipitate was recrystallized from ethanol, affording **7b** (780 mg, 90%): mp 97—98 °C; IR 1758 and 1199 cm^{-1}; NMR ($CDCl_3$) δ=2.48 (s, 3H), 4.31 (s, 2H), 7.50 (s, 1H), and 7.28—7.87 (m, 6H); MS *m/e* 248 (M^+) and 206. Found: C, 82.50; H, 4.96%. Calcd for $C_{17}H_{12}O_2$: C, 82.24; H, 4.87%.

Hydrolysis of **7b** (248 mg, 1 mmol) was carried out in aqueous ethanol (30%, 15 ml) with potassium hydroxide (1.0 g) at 60 °C for 10 min to give 200 mg (97%) of **7a**.

4H-Cyclopenta[def]*phenanthren-8-amine (7c).* A mixture of **7a** (103 mg, 0.5 mmol), sulfur dioxide (3 g), and aqueous ammonia (28%, 40 ml) was heated in an autoclave (50 ml volume) at 150—160 °C at 8.5 kg/cm^2 for 10 h. The resulting product was purified by silica-gel column chromatography to yield **7c** (52 mg, 56%): mp 139.5—140.0 °C decomp (lit,[12] mp 136—138 °C).

The Stereochemistry of Cross-coupling Adducts of Norbornenes with Butadiene Catalyzed by Ni Complex

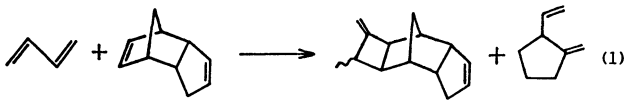
Yasutaka Ishii,* Masakazu Kawahara, Toshimitsu Noda, Hiroyuki Ishigaki, and Masaya Ogawa*

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita Osaka 564

(Received January 31, 1983)

Synopsis. The stereochemistry of cross-coupling adducts of norbornenes with butadiene catalyzed by Ni complex generated in situ by $NiBr_2(Ph_3P)_2$ and $NaBH_4$ in ethanol was investigated. The configuration of four-member cross-coupling products could be confirmed by means of independent synthesis.

The Ni catalyzed cross-coupling reaction of butadiene (**1**) with strained olefins, such as *endo*-tricyclo[5.2.1.$0^{2,6}$]-deca-3,8-diene (**2**), gives the four-member cross-coupling product (**3**) together with a small amount of 1-methylene-2-vinylcyclopentane (**4**) (Eq. 1).[1,2]

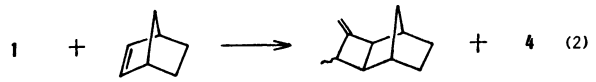


(1)

1 **2** **3** **4**

Unfortunately, the stereochemistry on coupling reactions has not been established because of the difficulty in determining the configuration of the coupling products. However, this unusual coupling reaction is of interest from the synthetic and mechanistic aspects. Thus, the coupling reactions of **1** with some strained olefins having a bicyclo[2.2.1]heptene skeleton catalyzed by $NiBr_2(Ph_3P)_2$ and $NaBH_4$ were studied to confirm the stereochemistry of cross-coupling products; the stereochemical course of coupling reactions is briefly discussed here.

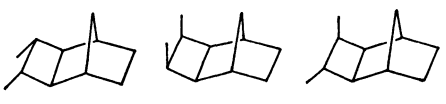
In order to obtain the most simple cross-coupling product, **1** was allowed to react with bicyclo[2.2.1]-heptene (**5**), in the presence of $NiBr_2(Ph_3P)_2$ and $NaBH_4$ in ethanol (Eq. 2).



(2)

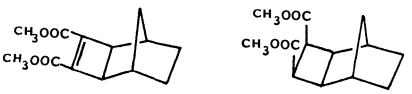
5 **6**

The four-member coupling product (**6**) was obtained in 60% yields together with **4** (12%). The exo-configuration of adduct **6** was readily assigned from the characteristic ^{13}C NMR chemical shift of the bridge carbon (C-9).[3] The hydrogenation of **6** on Pd/C suggested the formation of **7** or **8**, but not **9**, because the ^{13}C NMR spectrum of the hydrogenation product consisted of six carbon signals. The determination of configuration, either **7** or **8**, could be achieved by the independent synthesis of **8**.

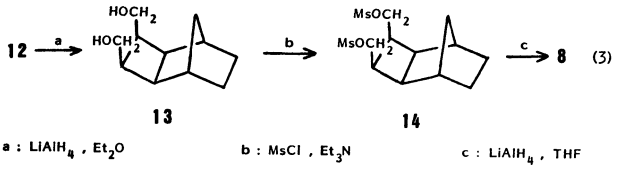


7 **8** **9**

Under the influence of $RuH_2(Ph_3P)_4$ catalyst, **5** reacts with dimethyl acetylenedicarboxylate (**10**) to give [2+2] cross-adduct (**11**) which on subsequent hydrogenation on Pd/C is converted into a saturated compound (**12**), whereupon both methoxycarbonyl groups are oriented in the syn-direction.[4]



11 **12**



(3)

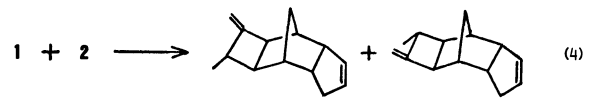
13 **14**

a : $LiAlH_4$, Et_2O b : MsCl, Et_3N c : $LiAlH_4$, THF

Since the subsequent interconversion of **12** to **8** proceeds with complete retention of the stereochemistry, **12** was converted into *syn,syn*-3,4-dimethyl-*exo*-tricyclo[4.2.1.$0^{2,5}$]nonane (**8**) (Eq. 3). From the comparison of spectral data of **8** with those of the compound obtained by the hydrogenation of **6** derived from Ni catalyzed reaction, it was identified as *anti,anti*-3,4-dimethyl-*exo*-tricyclo[4.2.1.$0^{2,5}$]nonane (**7**). Thus the configuration of **6** could be assigned to *anti*-3-methyl-4-methylene-*exo*-tricyclo[4.2.1.$0^{2,5}$]nonane.

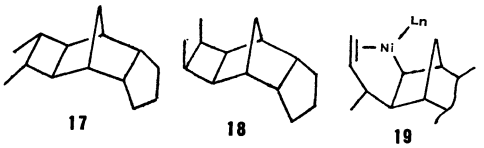
On the other hand, the reaction of **1** with **2** catalyzed by Ni-complex gave cross-coupling products which consisted of two components[5] with approximately 1:1 ratio, whose NMR spectral patterns were very similar. The hydrogenation of coupling products led to the same saturated compound, which was identified to *anti,anti*-9,10-dimethyl-2-*endo*-8-*exo*-tetracyclo[5.4.2.1.$0^{2,6}$.$0^{8,11}$]dodecane (**17**), since the Ru-catalyzed reaction of **2** with **10** followed by the interconversion of functional groups afforded the corresponding *syn,syn*-dimethyl compound (**18**).

Thus the configuration of cross-coupling products of **1** with **2** was established as *anti*-9-methyl-10-meth-



(4)

15 **16**



17 **18** **19**

ylene-2-*endo*-8-*exo*-tetracyclo[5.4.1.$0^{2,6}$.$0^{8,11}$]dodec-3-ene (**15**) and its regioisomer (**16**).

Kiji[2] suggested that the active species of coupling reaction of **1** with **2** catalyzed by $NiCl_2(n\text{-}Bu_3P)_2$ and $NaBH_4$ is a nickel hydride such as $HNiBr(n\text{-}Bu_3P)_2$,[6] and that the reaction proceeds through a π-crotyl nickel intermediate. Consequently, π-crotyl nickel thus generated couples with a strained olefin coordinated to nickel to form an intermediate such as **19** which subsequently undergoes β-elimination after coupling to give the four-member cross-coupling adduct. This reaction path explains satisfactorily the formation of regioisomers of **15** and **16** for the coupling reaction of **1** with **2**.

Experimental

The ^{1}H NMR and ^{13}C NMR spectra were recorded with a JEOL PMX-60 and a JNM-PS-100 FT-NMR spectrometer, respectively. The IR spectra were taken with a JASCO-A202 spectrometer. The GLC analyses were carried out on a Yanagimoto G1800 apparatus. The melting and boiling points are uncorrected.

Materials. Unless otherwise noted, the materials were obtained from commercial suppliers and used without further purification, except for solvents. *endo*-Tricyclo[5.2.1.$0^{2,6}$]-deca-3,8-diene (**2**) was prepared from the dimerization of cyclopentadiene obtained by the destructive distillation of commercially available **2**. Solvents were purified by the conventional methods.

*Coupling Reactions of **1** with **2** and **5** Catalyzed by $NiBr_2(Ph_3P)_2$–$NaBH_4$.* A solution of $NiBr_2(Ph_3P)_2$[7] (4 mmol) and $NaBH_4$ (4 mmol) in ethanol (30 cm^3) was placed in an autoclave and then **1** (72 mmol) and **5** (60 mmol) was added to this solution at −78 °C under nitrogen stream. The mixture was allowed to react under stirring at 80 °C for 24 h, and the reaction mixture was extracted with hexane (50 cm^3×4). After evaporation of solvents, the residue was distilled under reduced pressure to give (**6**) (60%), bp 118—120 °C/3300 Pa; IR(neat) 3050, 2940, 1680, 1450, 880 cm^{-1}; ^{13}C NMR($CDCl_3$) δ=158.2(s), 105.2(t), 49.1(d), 46.6(d), 40.8(d), 39.4(d), 39.3(d), 32.9(t), 28.4(t), 27.4(t), 20.1(q). Found: C, 89.10; H, 10.85%. Calcd for $C_{11}H_{16}$: C, 89.12; H, 10.88%.

The hydrogenation of **6** (1 mmol) in hexane (10 cm^3) on 5% Pd/C (30 mg) under 50 kg/cm^2 H_2 gave a saturated compound **7** (95%), bp 119—123 °C/3300 Pa; IR(neat) 2930, 2850, 1450, 1210, 750 cm^{-1}; ^{13}C NMR($CDCl_3$) δ= 48.1(d), 38.5(d), 33.2(t), 33.0(d), 27.8(t), 15.6(q).

The coupling reaction of **1** with **2** was carried out in a similar manner to that above to give a regioisomeric mixture of **15** and **16** in 70% yields; this was hydrogenated to give **17** (95%), bp 124—126 °C/2660 Pa; IR(neat) 2940, 1470, 1450, 1060, 890 cm^{-1}; ^{13}C NMR($CDCl_3$) δ=44.7(d), 43.7 (d), 41.7(d), 37.7(t), 32.9(d), 29.2(t), 15.8(q). Found: C, 88.38; H, 11.60%. Calcd for $C_{14}H_{22}$: C, 88.35; H, 11.65%.

*Preparation of **8** and **18**.* To a solution of $LiAlH_4$ (18 mmol) in ether (70 cm^3) was added dropwise an etheral solution of **12** (15 mmol) prepared according to the literature procedure,[4] and then the mixture was refluxed for 5 h. After decomposition of unreacted $LiAlH_4$ with ethyl acetate, followed by H_2O, the reaction mixture was extracted with ether. Removal of solvents yielded **13** (85%); the immediate mesylation of **13** according to the method of Jung[8] gave dimesylate (**14**) (42%). The treatment of **14** (4.5 mmol) with $LiAlH_4$ (10.8 mmol) in THF (20 cm^3) by the method of Mitsudo[9] afforded hydrocarbon **8** (44%), which was separated by MPLC on silica gel (elution with 10% ether in hexane); IR(neat) 2920, 2850, 1450, 1090, 660 cm^{-1}; ^{13}C NMR($CDCl_3$) δ=44.7(d), 36.7(t), 35.5(d), 31.9(d), 29.3 (t), 9.2(q). Found: C, 87.85; H, 12.10%. Calcd for $C_{11}H_{18}$: C, 87.93; H, 12.07%.

Compound **18** was prepared by the same method as above; IR (neat) 2940, 1470, 1440, 1050, 760 cm^{-1}; ^{13}C NMR ($CDCl_3$) δ=46.2(d), 41.1(t), 40.4(d), 37.8(d), 31.5(d), 29.1 (t), 26.9(t), 9.1(q). Found: C, 88.30; H, 11.70%. Calcd for $C_{14}H_{22}$: C, 88.35, H, 11.65%.

Synthesis of Lepiochlorin, a Chlorinated Antibiotic, by Use of Electrochemical Haloalkoxylation

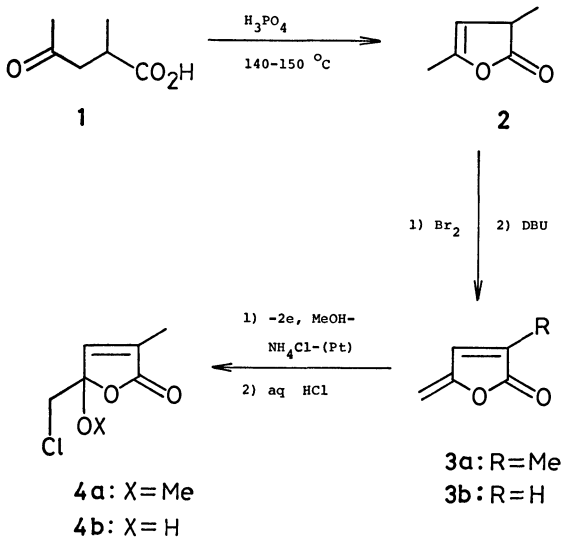
Sigeru Torii,* Tsutomu Inokuchi, and Kazumi Kondo
Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700
(Received February 4, 1983)

Synopsis. The fungal metabolite lepiochlorin was synthesized from 2-methyl-4-oxopentanoic acid by the electrochemical chloromethoxylation of 2-methyl-2,4-pentadien-4-olide in MeOH–NH_4Cl–(Pt–Pt) system followed by hydrolysis in a mixed solution of dioxane–H_2O–concd HCl (25/10/1 V/V/V) in 38% overall yield.

γ-Oxygenated butenolides appeared in naturally occurring products exhibit interesting biological activities.[1] Synthetic methodology for the butenolide has been well documented in a recent review.[2] As a new antibiotic butenolide, lepiochlorin (**4b**), a chlorinated metabolite of a fungus (a *Lepiota* species) cultivated by a leaf-cutting ants, has been isolated.[3] In the previous study,[4] we reported a convenient haloalkoxylation of enol ethers by the electrolysis in ROH–NH_4X (X=Cl, Br, I)–(Pt–Pt) system. This procedure is expected to be potentially useful for the preparation of chlorohydrin moiety of **4b**. We describe here a short-step synthesis of the butenolide **4b** by introducing the electrochemical chloromethoxylation of γ-methylenebutenolide **3a**.

The target molecule **4b** has been synthesized recently by McMorris *et al.* in 18—20% overall yields in a laborious seven-step synthesis from α-phenylthiopropionic acid and allyl methoxyethoxymethyl ether.[5] In our route to **4b** we started with 2-methyl-3-penten-4-olide **2** which can be obtained from commercially available 2-methyl-4-oxopentanoic acid (**1**)[6] by the procedure of Helberger *et al.*[7] (Scheme 1).

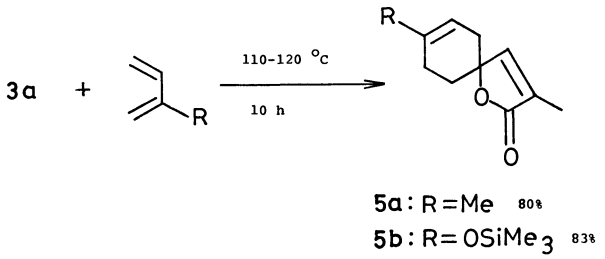
Bromination of **2**, obtained by dehydration of **1** with phosphoric acid, with one equivalent of bromine and subsequent treatment with 1,8-diazabicyclo[5.4.0]-undec-7-ene (DBU) at −20 to 10 °C in benzene provided the key intermediate, γ-methylenebutenolide **3a**,



Scheme 1.

in 51% yield (from **1**).[8]

It is interesting to note that the butenolide **3a** is stable to heat in contrast to unstable protoanemonine (**3b**) which lacks methyl group at C-2 position of **3a** and dimerizes spontaneously at room temperature.[7b,9] For example, Diels-Alder reaction of **3a** with 1,3-dienes, *i.e.*, isoprene and 2-trimethylsiloxy-1,3-butadiene, took place on heating at 110—120 °C for 10 h in toluene to give the corresponding diene adducts **5** in 80—83% yields (Scheme 2). In addition, the reaction of **3a** with appropriate nucleophiles has been explored to give the corresponding 1,6-adducts.[10]



Scheme 2.

Electrochemical halogenation of **3a** in a MeOH–NH_4Cl (1.5 equiv.)–(Pt–Pt) system was carried out under a current of 3.5—6.7 mA/cm² (applied voltage: 2.0 V, cell voltage: 0.8—1.0 V *vs.* Ag wire) in a beaker type undivided cell. The passage of 3.0 F/mol of electricity (10 h) at room temperature afforded the chlorinated acetal **4a** in 88% yield. On the other hand, attempts at the direct electrochemical chlorohydroxylation of **3a** employing a MeCN–H_2O (3/1 V/V)–NH_4Cl–(Pt–Pt) system resulted in the low yield of **4b** (10—20% yields). Hydrolysis of acetal group of **4a** by heating to reflux in a mixed solvent of dioxane–H_2O–concd HCl (25/10/1 V/V/V) afforded the desired **4b** in 86% yield.[11]

Experimental

Melting point is uncorrected and boiling points are indicated by an air-bath temperature without correction. IR spectra were determined with a JASCO IRA-1 grating spectrometer. NMR spectra were obtained with a Hitachi R-24 (60 MHz for proton) and/or a JEOL FX-100 (100 MHz for proton and 25.05 MHz for carbon-13) spectrometers. Samples were dissolved in $CDCl_3$ and the chemical shift values (δ) are expressed in parts per million downfield from an internal Me_4Si. Elemental analyses were performed in our laboratory.

2-Methyl-3-penten-4-olide (2). According to the procedure reported in the literature,[7b] **1** (5.0 g, 38.4 mmol) was heated with H_3PO_4 (0.25 g) at 140—150 °C for 4 h. The mixture was distilled at 140—150 °C/20 Torr and the distillate was chromatographed (SiO_2, hexane–AcOEt 8:1) to give 2.6 g of **2** (89% yield based on 1.06 g of unchanged

1). **2**: bp 77—78 °C/41 Torr (lit,[12] 53 °C/6 Torr).

*2-Methyl-2,4-pentadien-4-olide (**3a**).* To a solution of **2** (107.3 mg, 0.97 mmol) in CS_2 (2 ml) was added dropwise Br_2 (155 mg, 0.97 mmol) at −20 °C. After the solution had become colorless, the CS_2 was removed *in vacuo* with cooling in a water bath. The residue was dissolved in benzene (5 ml) containing a catalytic amount of 2,5-di-*t*-butylhydroquinone, and to this solution was added DBU (433 mg, 2.91 mmol) with immediate cooling to about −20 °C. The mixture was stirred for 30 min and warmed gradually to room temperature over about 5 h. Concentration and chromatography (SiO_2,[13] hexane–Et_2O 3:1) gave 62 mg (58%) of **3a**: bp 52—53 °C/2 Torr (lit,[14] 25 °C/0.05 Torr); MS, *m/e* (rel int.) 111 (M^++1, 8.2), 110 (M^+, 100), 82 (29.0), 68 (27.1), 54 (25.4). Spectroscopic properties were identical with those reported previously.[14]

*5-Chloro-4-methoxy-2-methyl-2-penten-4-olide (**4a**).* The electrochemical halogenation was carried out in an undivided cell fitted with two platinum foil (2.0×1.5 cm^2) electrodes.[4] A solution of **2a** (15 mg, 0.14 mmol) and NH_4Cl (11.3 mg, 0.21 mmol) in MeOH (4 ml) was electrolyzed under a constant applied voltage of 2.0 V (3.5—6.7 mA/cm^2). After 3.0 F/mol of electricity has been passed, the mixture was concentrated and the residue was taken up in ether. The extract was washed with brine and dried (Na_2SO_4). Evaporation of the solvent followed by chromatography (SiO_2, hexane–AcOEt 3:1) gave 21.2 mg (88%) of **4a**: bp 88—89 °C/1.0 Torr; IR (neat) 3040, 1775 (lactone C=O), 1665 cm^{-1} (C=C); ^1H NMR (100 MHz) δ 1.99 (d, J=1.5 Hz, 3H, CH_3), 3.26 (s, 3H, OCH_3), 3.61 (d, J=12 Hz, 1H, CHCl), 3.85 (d, J=12 Hz, 1H, CHCl), 6.82 (q, J=1.5 Hz, 1H, HC=C); ^{13}C NMR δ 10.7 (q, C-2 Me), 48.5 (t, C-5), 51.7 (q, OMe), 106.7 (s, C-4), 135.8 (s, C-2), 143.5 (d, C-3), 170.4 (s, C-1); MS, *m/e* (rel int.) 179 (M^++2, 0.34), 177 (M^+, 0.94), 159 (0.51), 147 (6.9), 145 (21.6), 127 (100), 99 (35.3), 97 (18.3), 79 (17.0), 77 (48.4). Found: C, 47.56; H, 5.20. Calcd for $C_7H_9ClO_3$: C, 47.61; H, 5.13.

*5-Chloro-4-hydroxy-2-methyl-2-penten-4-olide (Lepiochlorin, **4b**).* A solution of **4a** (29 mg, 0.16 mmol) in a mixed solution of dioxane–H_2O–concd HCl (25/10/1 V/V/V, 2 ml) was heated to reflux for 6 h. The mixture was extracted with benzene–ether (1:1). The usual workup and chromatography (SiO_2,[13] hexane–AcOEt 3:1) gave 20 mg (86%) of **4b**: mp 69—70 °C (from petroleum ether) (lit,[3] 68—70 °C,[5] 74—74.5 °C); ^{13}C NMR δ 10.4 (q, C-2 Me), 46.7 (t, C-5), 103.8 (s, C-4), 134.1 (s, C-2), 145.0 (d, C-3), 172.0 (s, C-1). IR and ^1H NMR spectra were identical with those reported.[3]

The present work was partially supported by a Grant-in-Aid for the Special Project Research No. 57118002 (Innovative Studies on Highly Selective Synthesis) from the Ministry of Education, Science and Culture.

A Convenient Synthesis of C(2)-Substituted Cephalosporins

Sigeru Torii,* Hideo Tanaka, Norio Saitoh, Takashi Siroi,
Michio Sasaoka, Nobuhito Tada, and Junzo Nokami
Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700
(Received March 3, 1983)

Synopsis. Replacement of the C(2)-substituents of 2-acetoxy- or 2-methoxycephalosporin with nucleophiles was performed efficiently in dichloromethane in the presence of acid-catalysts, affording cephalosporins bearing heteroaromatic moieties, sulfenyl, and alkoxyl groups at the C(2)-position.

Chemical modification of natural penicillins and cephalosporins has been intensively investigated in order to obtain new clinically significant drugs with greater antibacterial activity.[1] In this connection, much attention has been paid to introduction of a desired functional group to the C(2)-position of cephalosporins.[2] However, the C(2)-substituents so far introduced are only known of alkyl,[3] alkylidene,[4] and/or a few simple functional groups, *e.g.*, acetoxyl,[5] methoxyl,[6] and methylthio groups.[7]

The development of synthesis procedures of C(2)-acetoxy- and methoxycephalosporins[5,6] prompted us to investigate the replacement of the acetoxyl and methoxyl groups of **2** with more complex substituents. We now found that the replacement of the C(2)-substituents of **2** can be successfully performed by treatment with various nucleophiles in dichloromethane in the presence of an acid catalyst.

Table 1. C(2)-Substitution of 2-acetoxy- or 2-methoxycephalosporin with nucleophiles[a]

Entry	Compound 2 R	Nu-H	Acid	Temp °C	Time h	Product 4	Yield[b] %
1	CH_3CO		$TiCl_4$	-25	4	4a	87
2	CH_3CO		$AlCl_3$	3	1.5	4a	84
3	CH_3CO		p-TsOH	5	8	4a	78
4	CH_3		$AlCl_3$	25	0.6	4a	67
5	CH_3		p-TsOH	25	3	4a	67
6	CH_3		p-TsOH	25	3	4b	55
7	CH_3CO		$TiCl_4$	-30	0.2	4c	96
8	CH_3CO		$AlCl_3$	-30	1.6	4d	91
9	CH_3CO	C_4H_9S–H [c]	$TiCl_4$	-30	0.6	4e	64
10	CH_3CO	$HOCOC_2H_4S$–H [c]	$TiCl_4$	-40	3	4f	59
11	CH_3CO	[c]	$AlCl_3$	-30	1.1	4g	90
12	CH_3CO	[c]	$AlCl_3$	-30	2	4h	81
13	CH_3CO	[c]	$AlCl_3$	-20	2	4i	74
14	CH_3CO	CH_2=$CHCH_2O$–H [c]	$TiCl_4$	3	3	4j	83

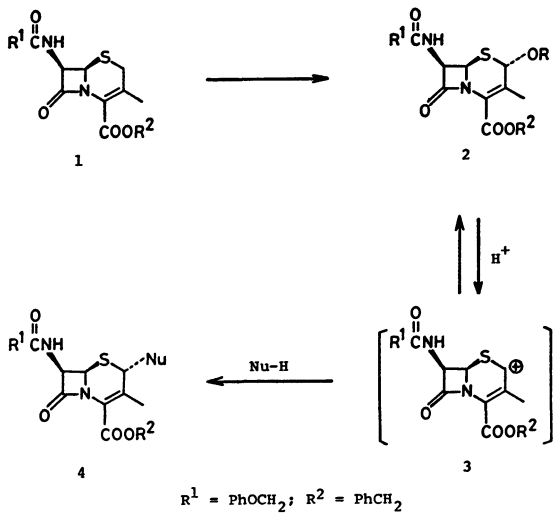
a) Unless otherwise noted, reaction was carried out according to the general procedure described in the experimental. b) Isolated yield after column chromatography (SiO_2, benzene–AcOEt). c) 1.2—1.5 molar equiv of nucleophiles were used.

The reaction conditions along with the yield of the desired products **4** are summarized in Table 1. Treatment of **2a** (R=CH_3CO) with 2-methylfuran in dichloromethane in the presence of titanium(IV) chloride at −25 °C for 25 min afforded 2-(5-methyl-2-furyl)cephalosporin **4a** in 87% yield (entry 1). Aluminum (III) chloride and *p*-toluenesulfonic acid were also effective catalysts for this transformation (entries 2 and 3). Reaction of **2b** (R=CH_3) with 2-methylfuran in the same media afforded same product **4a** (entries 4 and 5). In a similar manner, the reaction of **2a** with furan, 2-methylthiophene, and *N*-methylpyrrole afforded the corresponding C(2)-substituted cephalosporins **4b—d**. Replacement of the acetoxyl group of **2a** with sulfenyl and allyloxyl groups was performed by treatment with various thiols and allyl alcohol in dichloromethane in the presence of titanium (IV) chloride and/or aluminum (III) chloride (entries 9—14).

In the present acid-catalyzed substitution reaction, no detectable amounts of by-products resulting from the C(2)-carbon-sulfur bond fission were isolated. This suggests that in the initial stage of the reaction, selective attack of Lewis acids or proton on the acetoxyl and methoxyl groups of **2** generates cation **3**, which, in turn, reacts with the nucleophiles to give **4** (Scheme 1).

Experimental

All melting points are uncorrected. IR spectra were determined with a JASCO IRA-I infrared spectrometer. ^1H NMR spectra were obtained at 60 MHz with a Hitachi R-24 spectrometer and/or at 100 MHz with a JEOL FX-100 spectrometer. Elemental analyses were performed in our



R^1 = $PhOCH_2$; R^2 = $PhCH_2$

Scheme 1.

laboratory.

Benzyl 2-acetoxy-3-methyl-7-phenoxyacetoamido-Δ^3-cephem-4-carboxylate (**2a**) was prepared from benzyl 3-methyl-7-phenoxyacetoamido-Δ^3-cephem-4-carboxylate (**1**) as previously described:[2] mp 63—65 °C (from ether); IR ($CHCl_3$) 3450, 1790, 1745, 1730, and 1690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.98 (3H, s), 2.00 (3H, s), 4.40 (2H, s), 5.00 (1H, d, J=5 Hz), 5.16 (2H, s), 5.76 (1H, dd, J=5 and 9 Hz), 6.17 (1H, s), and 6.6—7.4 (11H, m).

Found: C, 60.43; H, 5.15%. Calcd for $C_{25}H_{24}N_2O_7S$: C, 60.47; H, 4.87%.

Benzyl 2-methoxy-3-methyl-7-phenoxyacetoamido-Δ^3-cephem-4-carboxylate (**2b**) was prepared from **1** in accordance with the reported procedure:[3] mp 121—122 °C (from ether); IR ($CHCl_3$) 3250, 1775, 1730, and 1675 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.14 (3H, s), 3.38 (3H, s), 4.49 (2H, s), 4.70 (1H, s), 4.96 (1H, d, J=5 Hz), 5.20 (2H, s), 5.80 (1H, dd, J=5 and 9 Hz), 6.7—7.4 (10H, m), and 7.45 (1H, d, J=9 Hz).

Found: C, 61.66; H, 5.23%. Calcd for $C_{24}H_{24}N_2O_6S$: C, 61.53; H, 5.16%.

Replacement of the C(2)-Substituents of 2-Acetoxy- or 2-Methoxycephalosporin with Nucleophiles. The reaction conditions and results are summarized in Table 1. The general procedure is exemplified by the preparation of **4a** (Nu=5-methyl-2-furyl) (entry 1 in Table 1). To a stirred solution of **2a** (34.2 mg, 0.069 mmol) and 2-methylfuran (0.5 mL, 5 mmol) in CH_2Cl_2 (0.5 mL) was added $TiCl_4$ (0.8 μL, 0.007 mmol) at −25 °C. After being stirred at −25 °C for 4 h, the reaction was quenched with two drops of an aqueous $NaHCO_3$. The mixture was diluted with CH_2Cl_2, dried over Na_2SO_4, and filtered. The filtrates were concentrated and chromatographed (SiO_2, benzene–AcOEt=20:1) to give **4a** (31.3 mg, 87%) as a colorless foam: IR ($CHCl_3$) 1782, 1724, and 1698 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.12 (3H, s), 2.28 (3H, s), 4.57 (2H, s), 4.61 (1H, s), 5.10 (1H, d, J=5 Hz), 5.35 (2H, s), 5.96 (1H, dd, J=5 and 8.4 Hz), 5.98 (2H, s), and 6.9—7.7 (11H, m).

Found: C, 64.99; H, 5.32%. Calcd for $C_{28}H_{26}N_2O_6S$: C, 64.85; H, 5.05%.

Compound **4b** (Nu=2-furyl): IR ($CHCl_3$) 1787, 1730, and 1697 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.08 (3H, s), 4.49 (2H, s), 4.58 (1H, s), 5.01 (1H, d, J=5 Hz), 5.28 (2H, s), 5.88 (1H, dd, J=5 and 9 Hz), 5.95—6.40 (2H, m), and 6.7—7.6 (12H, m).

Found: C, 64.13; H, 4.85%. Calcd for $C_{27}H_{24}N_2O_6S$: C, 64.27; H, 4.79%.

Compound **4c** (Nu=5-methyl-2-thienyl): IR ($CHCl_3$) 1783, 1725, and 1693 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.14 (3H, s), 2.44 (3H, s), 4.54 (2H, s), 4.26 (1H, s), 4.95 (1H, d, J=5.2 Hz), 5.32 (2H, s), 5.94 (1H, dd, J=5.2 and 8 Hz), 6.55 (2H, s), and 6.78—7.26 (11H, m).

Found: C, 63.14; H, 4.98%. Calcd for $C_{28}H_{26}N_2O_5S_2$: C, 62.90; H, 4.90%.

Compound **4d** (Nu=1-methyl-2-pyrrolyl): IR ($CHCl_3$) 1784, 1725, and 1698 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.07 (3H, s), 3.60 (3H, s), 4.50 (2H, s), 4.54 (1H, s), 4.80 (1H, d, J=5 Hz), 5.29 (2H, s), 5.6—6.05 (3H, m), and 6.5—7.6 (13H, m).

Found: C, 65.02; H, 5.25%. Calcd for $C_{28}H_{27}N_3O_5S$: C, 64.97; H, 5.26%.

Compound **4e** (Nu=butylthio): IR ($CHCl_3$) 1780, 1720, and 1695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 (3H, m), 1.55 (4H, m), 2.22 (3H, s), 2.74 (2H, m), 4.45 (1H, s), 4.49 (2H, s), 5.30 (2H, s), 5.39 (1H, d, J=5 Hz), 6.00 (1H, dd, J=5 and 10 Hz), and 6.8—7.6 (11H, m).

Found: C, 61.65; H, 5.46%. Calcd for $C_{27}H_{30}N_2O_5S_2$: C, 61.57; H, 5.74%.

Compound **4f** (Nu=2-carboxylethylthio): IR ($CHCl_3$) 1780, 1710, and 1690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.18 (3H, s), 2.5—3.1 (4H, m), 4.54 (3H, s), 5.25 (2H, s), 5.32 (1H, d, J=5 Hz), 5.95 (1H, dd, J=5 and 9 Hz), and 6.7—8.6 (12H, m).

Found: C, 57.62; H, 5.13%. Calcd for $C_{26}H_{26}N_2O_7S_2$: C, 57.55; H, 4.83%.

Compound **4g** (Nu=1-phenyl-1,2,3,4-tetrazol-5-ylthio): IR ($CHCl_3$) 1795, 1735, and 1700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.22 (3H, s), 4.51 (2H, s), 5.06 (1H, d, J=4.2 Hz), 5.24 (2H, s), 5.87 (1H, s), 5.87 (1H, dd, J=4.2 and 8.8 Hz), and 6.7—7.7 (16H, m).

Found: C, 58.66; H, 4.40%. Calcd for $C_{30}H_{26}N_6O_5S_2$: C, 58.62; H, 4.26%.

Compound **4h** (Nu=1-methyl-1,2,3,4-tetrazol-5-ylthio): IR ($CHCl_3$) 1785, 1723, and 1692 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.26 (3H, s), 3.90 (3H, s), 4.48 (2H, s), 5.23 (1H, d, J=5 Hz), 5.27 (2H, s), 5.71 (1H, s), 5.93 (1H, dd, J=5 and 8 Hz), and 6.7—7.5 (11H, m).

Found: C, 54.57; H, 4.56%. Calcd for $C_{25}H_{24}N_6O_5S_2$: C, 54.33; H, 4.38%.

Compound **4i** (Nu=5-methyl-1,3,4-thiadiazol-2-ylthio): IR ($CHCl_3$) 1790, 1730, and 1698 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.30 (3H, s), 2.78 (3H, s), 4.58 (2H, s), 5.34 (1H, d, J=4.4 Hz), 5.35 (2H, s), 5.81 (1H, s), 6.05 (1H, dd, J=4.4 and 9.6 Hz), and 6.7—7.6 (11H, m).

Found: C, 55.11; H, 4.38%. Calcd for $C_{26}H_{24}N_4O_5S_3$: C, 54.91; H, 4.25%.

Compound **4j** (Nu=allyloxy): IR ($CHCl_3$) 1782, 1722, and 1690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.15 (3H, s), 4.15 (2H, m), 4.54 (2H, s), 4.92 (1H, s), 5.10 (1H, d, J=4.4 Hz), 5.28 (2H, s), 5.0—5.5 (3H, m), 5.94 (1H, dd, J=4.4 and 8.8 Hz), and 6.8—7.5 (11H, m).

Found: C, 63.23; H, 5.28%. Calcd for $C_{26}H_{26}N_2O_6S$: C, 63.14; H, 5.30%.

Conversion of Lupeol into Dammarane Derivatives

Shinya OHTA, Motoo TORI, Takahiko TSUYUKI, and Takeyoshi TAKAHASHI*

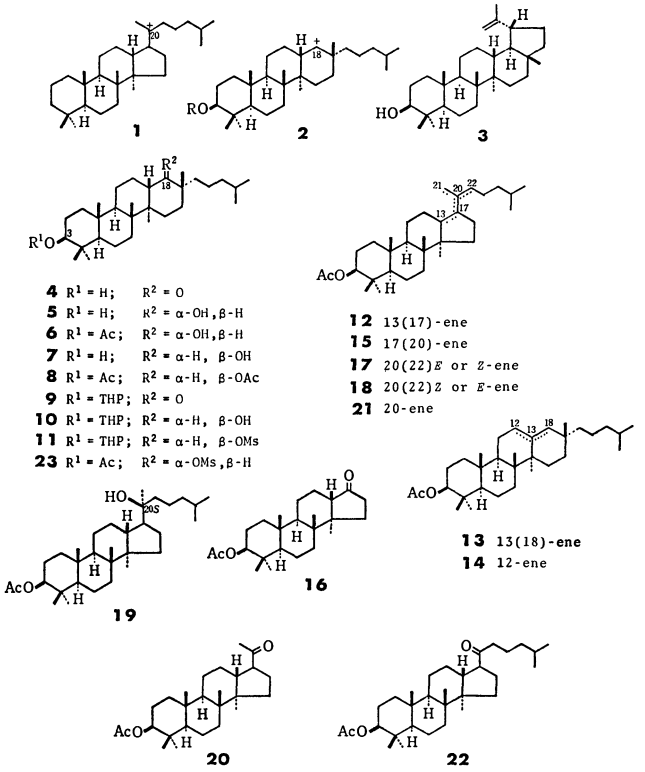
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received February 5, 1983)

Synopsis. On treatment with potassium carbonate in aqueous dioxane, 3β-tetrahydropyranyloxybaccharan-18β-yl mesylate, prepared from lupeol, underwent D-ring contraction. The solvolytic products were hydrolyzed and acetylated to give Δ^{20}-, $\Delta^{20(22)}$-, $\Delta^{17(20)}$-, and $\Delta^{13(17)}$-dammaren-3β-yl acetates and (20*S*)-20-hydroxydammaran-3β-yl acetate together with bacchar-13(18)- and -12-en-3β-yl acetates.

It has been proposed that dammarane derivatives undergo D-ring enlargement to afford baccharane derivatives, which yield lupane derivatives by E-ring formation in succession in the biogenesis of triterpenes. In connection with a study on the behavior of C-20 cation on dammarane derivatives, such as **1**,[1] we examined reactivities of C-18[2] cation on baccharane derivatives (**2**). In this paper, a conversion of baccharane derivatives into dammarane derivatives is described. Baccharane derivatives being prepared from lupeol (**3**), this conversion constitutes a reverse transformation[3] from the biogenetic pathway described above.

3β-Hydroxybaccharan-18-one (**4**) was prepared from **3** by a known procedure.[4] Reduction of **4** with lithium aluminium hydride gave a 3β,18α-dihydroxy derivative (**5**) exclusively, which on partial acetylation afforded a 3β-monoacetate (**6**). On the other hand, Birch reduction of **4** afforded a 3β,18β-dihydroxy derivative (**7**). Although selective acetylation of the 3β-hydroxyl group of **7** was attempted under various conditions, a satisfactory selectivity was not attained; a diacetate (**8**) appeared at the early reaction stage. Protection of the 3β-hydroxyl group of **4** by tetrahydropyranylation gave a tetrahydropyranyloxy ketone (**9**), which was subjected to Birch reduction to afford a 3β-tetrahydropyranyloxy-18β-hydroxy derivative (**10**).



The mesylate (**11**; *ca.* 50 mg), prepared from **10**, was treated with potassium carbonate in boiling aqueous dioxane for 4 h and the products were treated with 10% hydrochloric acid to give a mixture of alcohols, which was acetylated. The acetylation product was separated by column chromatography into three fractions, A, B, and C. The fraction A, a mixture of unsaturated acetates, was further separated by column chromatography of silica gel impregnated with silver nitrate into five components. The first (the least polar) component was found to be a mixture of dammar-13(17)-en-3β-yl acetate (**12**) and bacchar-13(18)- and bacchar-12-en-3β-yl acetates (**13** and **14**) by comparison of their retention times with those of authentic samples[5,6] in GLC examination. The second component was shown to be a tetrasubstituted olefinic acetate by ^{1}H NMR and high resolution mass spectrum. This compound, on oxidation with ruthenium tetraoxide, afforded an octanor keto acetate (**16**),[7] showing a molecular ion at *m/e* 374. Therefore, the original acetate (**15**) is inferred to be dammar-17(20)-en-3β-yl acetate.

The third component showed an olefinic proton at δ 5.14 (1H, m), IR 1730 cm^{-1}, and a molecular ion at *m/e* 470.4221. The fourth component gave almost the same fragmentation pattern as that of the third one in the mass spectrum and showed an olefinic proton at δ 5.08 (1H, m) and a molecular ion at *m/e* 470.4106. These two compounds were found to be identical with an *E,Z*-isomeric pair of dammar-20(22)-en-3β-yl acetates (**17** and **18**), prepared from dammaranediol II monoacetate (**19**).[6] On oxidation with ruthenium tetraoxide, **17** and **18** gave the same product, hexanordammaran-20-one (**20**).[6,7]

The most polar component showed the presence of an *exo*-methylene moiety by ^{1}H NMR, IR, and a molecular ion. Spectral comparison showed that the compound was identical with dammar-20-en-3β-yl acetate (**21**),[6] prepared from **19**. Oxidation of the acetate (**21**) with ruthenium tetraoxide gave 22-nor-20-oxodammaran-3β-yl acetate (**22**).[6,7]

The fraction B was identical with baccharane-3β,18β-diyl diacetate (**8**). The fraction C was shown to be dammaranediol II monoacetate (=(20*S*)-20-hydroxydammaran-3β-yl acetate) (**19**).[6] A 20*R*-epimer was not detected in the solvolytic product.

3β-Acetoxy-18α-hydroxy derivative (**6**) was treated with mesyl chloride in a mixture of triethylamine and dichloromethane to give a mesylate (**23**), which was subjected to solvolysis under the same conditions as before. The product was found to be a mixture of bacchar-13(18)- and bacchar-12-en-3β-yl acetates (**13** and **14**)[5] by ^{1}H NMR and GLC examination.

Experimental[8]

Baccharane-3β,18α-diol (5) and 18α-Hydroxybaccharan-3β-yl Acetate (6). 3β-Hydroxybaccharan-18-one (**4**; 27 mg)[4]

was treated with $LiAlH_4$ (*ca.* 5 mg) in THF and the reaction product was worked up as usual to afford **5** as white crystals, NMR δ 3.20 (1H, m) and 3.25 (1H, br s); MS *m/e* 446 (M^+), 428, and 410. The diol (**5**) was acetylated with Ac_2O (0.1 ml) in pyridine (0.1 ml) at room temperature overnight. Usual work-up and crystallization from $CHCl_3$–MeOH gave **6** (26 mg) as white needles, mp 199—202 °C; IR (Nujol) 3560, 1720, and 1260 cm^{-1}; NMR δ 0.80—1.10 (24H), 2.03 (3H, s), 3.23 (1H, br s), and 4.47 (1H, dd-like); MS *m/e* 488 (M^+), 470, 455, 428, 413, 410, 385, 344, 189, 135 (base peak); Found: *m/e* 488.4220. Calcd for $C_{32}H_{56}O_3$: M 488.4229.

Baccharane-3β,18β-diol (7) and Baccharane-3β,18β-diyl Diacetate (8). A solution of **4** (40 mg) in THF (1 ml) and MeOH (0.1 ml) was added to Li (*ca.* 30 mg) in liquid NH_3 (3 ml) at −78 °C with stirring and the reaction mixture was kept at −33 °C for 15 min. An aqueous NH_4Cl solution was added and the solution was warmed to remove NH_3 and extracted with Et_2O. The ethereal layer was worked up to give **7** in a quantitative yield, NMR δ 0.77—1.02 (24H), 3.16 (1H, d, J=10 Hz), and 3.18 (1H, dd-like); MS *m/e* 446 (M^+), 428, 220, 207, 189, and 95 (base peak).

A solution of diol (**7**; *ca.* 40 mg) in Ac_2O (0.1 ml) and pyridine (0.1 ml) was allowed to stand overnight at room temperature. The reaction was stopped by addition of MeOH and the usual work-up was followed to give **8** (*ca.* 45 mg); mp 183—184 °C ($CHCl_3$–MeOH); IR (film) 1740 and 1245 cm^{-1}; NMR δ 0.82—1.03 (24H), 2.06 (6H, s), 4.48 (1H, dd-like), and 4.76 (1H, d, J=11 Hz); MS *m/e* 530 (M^+), 470 (base peak), 455, 410, 249, 220, 207, 202, and 189; Found: C, 76.75; H, 10.84%. Calcd for $C_{34}H_{58}O_4$: C, 76.93; H, 11.01%.

3β-Tetrahydropyranyloxybaccharan-18β-ol (10). A solution of **4** (46 mg) and 3,4-dihydro-2*H*-pyran (0.1 ml) in $CHCl_3$ (2 ml) was kept with a catalytic amount of TsOH for 1 h. After addition of an aqueous $NaHCO_3$ solution, organic layer was worked up to give a residue, which was purified by silica gel column chromatography. Elution with 5—10% EtOAc in hexane afforded **9** (50 mg), mp 183—185 °C ($CHCl_3$–MeOH); IR (KBr) 1695 cm^{-1}; MS *m/e* 528 (M^+), 444, 427, 426, 411, 388, 383, 360 (base peak), 342, 237, 223, 207, 196, and 189; Found: *m/e* 528.4530. Calcd for $C_{35}H_{60}O_3$: M 528.4540.

The ketone (**9**; 50 mg), dissolved in a mixture of THF (2 ml) and MeOH (0.1 ml), was added to Li (40 mg) in liquid NH_3 (3 ml) kept at −78 °C, and the reaction mixture was subjected to the same treatment as in the case of **7** to afford **10** (49 mg), NMR δ 0.80—1.01 (24H) and 3.07 (1H, d, J=11 Hz); MS *m/e* 530 (M^+), 446, 429, 428, 410, 395, 344, 220, 207, 189, and 85 (base peak).

Solvolysis of 3β-Tetrahydropyranyloxybaccharan-18β-yl Mesylate (11). Mesyl chloride (0.1 ml) was added to a solution of **10** (50 mg) in Et_3N (0.2 ml) and CH_2Cl_2 (1 ml) and the mixture was allowed to stand for 1 h. The usual work-up afforded a mesylate (**11**), which, without further purification, was subjected to solvolysis. The mesylate (**11**) was dissolved in a solution of K_2CO_3 in H_2O (2 ml) and dioxane (2 ml), and refluxed for 4 h. The reaction mixture was slightly acidified with 10% HCl and warmed for 10 min to complete the deprotection at C-3. The usual work-up afforded a residue, which was acetylated with Ac_2O (0.1 ml) and pyridine (0.1 ml). The reaction product was separated by silica gel (2.5 g) column chromatography into three fractions A, B, and C.

Fraction A (32 mg), eluted with 5—10% EtOAc in hexane, was further subjected to separation by column chromatography of silica gel (3 g) impregnated with $AgNO_3$ (0.5 g). Elution with 10% $CHCl_3$ in hexane gave two components. One component (*ca.* 1.2 mg) gave three peaks at t_R 18.3, 20.3, and 21.4 min in GLC analysis. These retention times were identical with those of **12**, **13**, and **14**, respectively. The other component (**15**; 1.2 mg) showed ^1H NMR δ 2.05 (3H, s) and 4.48 (1H, m); MS *m/e* 470 (M^+), 410, 357, 249, 205, 190, and 69 (base peak); Found: *m/e* 470.4077. Calcd for $C_{32}H_{54}O_2$: M 470.4121. On oxidation with RuO_4 in CCl_4, **15** affoded 17-oxooctanordammaran-3β-yl acetate (**16**); IR (KBr) 1738 cm^{-1}; MS *m/e* 374 (M^+), 314, 299, 271, 191, 190, and 189.

Elution with 33% $CHCl_3$ in hexane afforded a geometrical pair of dammar-20(22)-en-3β-yl acetates (**17** and **18**); the isomer (**17**; 3.7 mg) with a large R_f value: mp 143—144 °C, IR (KBr) 1730 and 1250 cm^{-1}; NMR δ 0.82—0.97 (24H), 2.03 (3H, s), 4.46 (1H, m), and 5.14 (1H, m); MS *m/e* 470 (M^+), 410, 344, 289, 249, 229, 220, 189, and 69 (base peak); Found: *m/e* 470.4221. Calcd for $C_{32}H_{54}O_2$: M 470.4121. The other isomer (**18**) with a small R_f value: mp 159.5—161 °C; IR (KBr) 1730 and 1250 cm^{-1}; NMR δ 0.80—0.96 (24H), 2.03 (3H, s), 4.46 (1H, m), and 5.08 (1H, m); MS *m/e* 470 (M^+), 410, 395, 344, 289, 249, 229, 220, 189, and 95 (base peak); Found: *m/e* 470.4106. Calcd for $C_{32}H_{54}O_2$: M 470.4121. Oxidation of **17** and **18** with RuO_4 in CCl_4 afforded hexanordammaran-20-one (**20**), mp 202.5—204 °C; IR (KBr) 1730, 1710, and 1250 cm^{-1}; NMR δ 0.83—0.90 (12H), 0.97 (3H, s), 2.03 and 2.11 (each 3H, s), and 4.47 (1H, dd-like); MS *m/e* 402 (M^+), 359, 342, 327, 299 (base peak), 229, 204, 191, and 189; Found: *m/e* 402.3108. Calcd for $C_{26}H_{42}O_3$: M 402.3133.

The most polar component (**21**; 9 mg) was eluted with 50% $CHCl_3$ in hexane, mp 142.5—144 °C (MeOH); IR (KBr) 1730, 1260, and 885 cm^{-1}; NMR δ 0.83—0.97 (21H), 2.03 (3H, s), 4.46 (1H, m), and 4.68 (2H, br s); MS *m/e* 470 (M^+), 410, 395, 344, 289, 249, 229, 220, 189, and 95 (base peak); Found: *m/e* 470.4055. Calcd for $C_{32}H_{54}O_2$: M 470.4121. Oxidation of **21** with RuO_4 gave 22-nor-20-oxodammaran-3β-yl acetate (**22**), IR 1740 (sh) and 1730 cm^{-1}; NMR δ 0.82—0.91 (18H), 0.98 (3H, s), 2.03 (3H, s), 2.25—2.55 (2H, m), and 4.48 (1H, m).

Solvolysis of 3β-Acetoxybaccharan-18α-yl Mesylate (23). 3β-Acetoxybaccharan-18α-ol (**6**; *ca.* 10 mg) was dissolved in Et_3N (0.1 ml) and CH_2Cl_2 (0.3 ml). The solution was treated with mesyl chloride (1 drop) and worked up to give **23**, which was subjected to solvolysis as before. The solvolytic product was a mixture of **13** (t_R=20.3 min) and **14** (t_R=21.4 min) by GLC examination.

Branched-chain Sugars. XXXIV. Synthesis of Methyl Dihydroeurekanate[1]

Juji YOSHIMURA,* Kazutoshi HARA, and Masafumi MATSUZAWA†

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received February 9, 1983)

Synopsis. Methyl dihydroeurekanate; methyl 6-deoxy-4-*C*-[(*S*)-1-hydroxyethyl]-2,3-*O*-methylene-D-galactonate was synthesized from benzyl 6-deoxy-4-*C*-[(*S*)-1-hydroxyethyl]-2,3-*O*-methylene-D-galactopyranoside.

Up to the present, three branched-chain aldonolactones have been found in oligosaccharide antibiotics of orthothomycin family,[2] and they were characterized as their methyl aldonate. The structure of the first one in everninomicins[3] was determined to be 4-*C*-[(*S*)-1-methoxyethyl]-2,3-*O*-methylene-L-arabinono-1,5-lactone by X-ray analysis,[4] and the corresponding aldonate, methyl 6-deoxy-4-*C*-hydroxymethyl-5-*O*-methyl-2,3-*O*-methylene-L-idonate[5] was synthesized from L-arabinose *via* the introduction of equatorial 4-*C*-vinyl group by us.[6] The structure of methyl eurekanate obtained from flambamycin[2] and avilamycin A[7] was determined to be methyl 4-*C*-acetyl-6-deoxy-2,3-*O*-methylene-D-galactonate by a similar synthesis[8] and X-ray analysis.[7] D-*galacto* configuration of the remaining methyl dihydroeurekanate (**1**) from avialamycin C was proved by the fact that one of the epimers obtained by reduction of the 4-*C*-acetyl group of methyl eurekanate was identical with **1**,[9] but, the chirality of its 1-hydroxyethyl group was unknown. As was commonly observed in naturally occuring branched-chain sugars such as L-*γ*-octose[10] and D-aldgalose,[11] the chirality of 1-hydroxyethyl group of **1** was deduced to be (*S*), and in fact, it was recently proved by X-ray analysis.[12] This paper describes a simple preparation of **1** from benzyl 6-deoxy-4-*C*-[(*S*)-1-hydroxyethyl]-2,3-*O*-methylene-α-D-galactopyranoside [(1′*S*)-**2**].[13]

Results and Discussion

In our previous report,[13] (1′*R*)-**2** and (1′*S*)-**2** obtained by reduction of (1′*R*)- and (1′*S*)-mixture of the corresponding 4-*C*-(oxiranyl) derivative were directly separated by silica-gel column chromatography, but, the separation proceeded more smoothly after the usual acetylation into (1′*R*)-**3** and (1′*S*)-**3**. The both epimers were thoroughly characterized by ^{1}H- and ^{13}C-NMR. However, the hydrogenolysis of (1′*S*)-**3** into **4** gave an unstable complex mixture which showed two acetyl signals in the ratio of 3:1 and aldehydic proton at *δ* 9.73 in ^{1}H-NMR spectrum. This fact indicates the presence of acyclic species and/or the occurrence of acetyl migration. Oxidation of crude **4** into **5** with bromine–water gave again a mixture which showed two acetyl signals. Therefore, crude **5** was converted into the corresponding methyl aldonate by treatment with diazomethane in methanol. ^{1}H-NMR spectrum of the product indicated the presence of two monoacetate (**6** and **7**) in the ratio of 1.5:1, indicating the acetyl migration during these conversions. Usual acetylation of the mixture gave diacetate (**8**) in fairly good yield. The ^{1}H NMR spectrum and the specific rotation of **8** shown in Table 1 revealed its structure. Deacetylation of **8** in methanol with catalytic amount of sodium methoxide gave **1** in 76% yield. ^{1}H-NMR and ^{13}C-NMR spectra shown in Table 2 together with that of **8** proved that **1** was identical with that obtained from avilamycin C.

Experimental

Specific rotations were measured with JASCO DIP-4 polarimeter in chloroform. ^{1}H- and ^{13}C-NMR were recorded in chloroform-*d* with JEOL PS-100 and JEOL FX-100 spectrometers, respectively. Chemical shifts and Coupling constants were recorded in *δ* (ppm) and Hz units, respectively.

*Isolation of (1′*R*)-3 and (1′*S*)-3.* The mixture of (1′*R*)-**1** and (1′*S*)-**1** (3.2 g, 10.3 mmol) in pyridine (25 ml) was acetylated in the usual procedure to give a syrupy product which was separated on a silica-gel (WAKO C-200) column (1:2 ethyl acetate–hexane). (1′*R*)-**3** (R_f 0.28) and (1′*S*)-**3** (R_f 0.41) were obtained in 49% (1.79 g) and 34% (1.23 g) yields, respectively.

(1′*R*)-**3**: $[\alpha]_D$ +167° (*c* 1.0), ^{1}H-NMR (*δ*): 7.41 (s, 5H, Ph), 5.36 (d, $J_{1,2}$ 3.0, H-1), 5.14 and 5.24 (ABq, 2H, *J* 1.4, OCH_2O), 5.00 (q, $J_{1',2'}$ 6.8, H-1′), 4.79 (s, 2H, CH_2Ph), 4.03 (d, $J_{2,3}$ 9.8, H-3), 3.92 (dd, H-2), 3.70 (q, $J_{5,6}$ 6.8, H-5), 2.85 (bs, OH), 2.14 (s, 3H, OAc), 1.28 (d, 3H, H-2′), 1.19 (d, 3H, H-6); ^{13}C-NMR (ppm): 13.4 and 15.7 (each q, C-6,2′), 21.3 (q, CH_3CO), 68.1, 73.2, 73.3 and 73.6 (each d, C-2,3,5,1′), 70.1 (t, CH_2Ph), 76.6 (s, C-4), 96.4 (t, OCH_2O), 96.7 (d, C-1), 127.9 and 128.5 (each d, Ph), 137.3 (s, Ph), 171.2 (s, C=O).

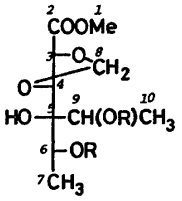
a) The numbering of carbon atoms is shown below.
b) **8** showed additional signals of acetyl carbons: 21.2 (q, 2×C), 170.0 and 174.8 (each s, 2×C=O) ppm.
c) Each pairs of marked assignments may be reversed although those given here are preferred.



(1′*S*)-**3**: $[\alpha]_D$ +116° (*c* 0.64); ^{1}H-NMR (δ): 7.42 (s, 5H, Ph), 5.36 (d, $J_{1,2}$ 3.6, H-1), 5.15 and 5.24 (ABq, 2H, *J* 1.0, OCH_2O), 5.07 (q, $J_{1',2'}$ 6.6, H-1′), 4.78 (s, 2H, CH_2Ph), 4.17 (d, $J_{2,3}$ 10.0, H-3), 3.85 (dd, H-2), 3.78 (q, $J_{5,6}$ 6.6, H-5), 2.36 (bs, OH), 2.04 (s, 3H, OAc), 1.38 (d, 3H, H-2′), 1.16 (d, 3H, H-6); ^{13}C-NMR (ppm): 13.4 and 15.7 (each q, C-6,2′), 21.3 (q, CH_3CO), 68.1, 73.2, 73.3 and 73.6 (each d, C-2,3,5,1′), 70.1 (t, CH_2Ph), 76.6 (s, C-4), 96.4 (t, OCH_2O), 96.7 (d, C-1), 127.9 and 128.5 (each d, Ph), 137.3 (s, Ph), 171.2 (s, CO). Found for (1′*R*)-**3**: C, 60.97; H, 6.79 and for (1′*S*)-**3**: C, 60.96; H, 6.88%. Calcd for $C_{18}H_{24}O_7$: C, 61.35; H, 6.86%.

Conversion of (1′S)-3 into 6 and 7. A suspension of (1′*S*)-**3** (540 mg, 1.46 mmol) and palladium–carbon (10%, 500 mg) in ethanol (100 ml) containing 1 M HCl (2 ml) was hydrogenolyzed in an autoclave under hydrogen atmosphere (60 kg/cm^2) for 7 h at room temperature. The usual work-up of the reaction mixture gave crude **4** in 76% (292 mg) yield. To a suspension of the above **4** (241 mg, 0.92 mmol) and trilead (II) dicarbonate dihydroxide (2.84 g) in water (5 ml) was added bromine (94.9 μl) and the mixture was shaken in dark for 12 h at room temperature. After aeration the mixture was filtered, and the filtrate was passed through IR 120 (H^+) column and then evaporated to give a syrupy **5** in 95% (194 mg) yield. This syrup was esterified with diazomethane in the usual manner gave a mixture of **6** and **7**. The predominant product showed the following ^{1}H-NMR data: 5.40 (q, $J_{1',2'}$ 7.0, H-1′), 5.20 (q, $J_{5,6}$ 6.4, H-5), 5.19 and 5.00 (each s, 2H, OCH_2O), 4.88 (d, $J_{2,3}$ 4.4, H-3), 4.72 (d, H-2), 3.83 (s, 3H, MeO), 2.14 (s, 3H, OAc), 1.51 (d, 3H, H-2′), 1.32 (d, 3H, H-6).

Methyl Dihydroeurekanate Diacetate (8). The mixture of **6** and **7** (58 mg, 0.199 mmol) in pyridine (0.5 ml) was acetylated by the usual manner to give syrupy **8** in 66% (42 mg) yield, which was purified by a preparative TLC (2:3 acetone–hexane). Found: C, 50.01; H, 6.72%. Calcd for $C_{14}H_{22}O_9$: C, 50.29; H, 6.63%.

Methyl Dihydroeurekanate (1). A solution of **8** (23 mg, 0.1 mmol) in methanol (1 ml) containing catalytic amount of sodium methoxide was kept at room temperature for 6 h, passed through a IR 120 (H^+) column, evaporated, to give a sirup which was purified on a preparative TLC (1:1 acetone–hexane). Yield, 76% (15 mg).

Hydrolysis of *p*-Nitrophenyl Esters by Hydrophobic Linear Molecule Containing Two Histidine Residues

Masato KODAKA

National Chemical Laboratory for Industry, Tsukuba 305

(Received March 1, 1983)

Synopsis. A new type of linear nucleophile, CH_3O–His–CO–$(CH_2)_8$–CO–His–OCH_3(HisC$_8$His), was designed, and its catalytic behavior for the hydrolysis of *p*-nitrophenyl acetate, hexanoate and laurate was investigated. It was shown that HisC$_8$His enhanced the hydrolysis of *p*-nitrophenyl laurate and hexanoate as compared with imidazole both in the absence and presence of methyltrioctylammonium chloride.

Hydrophobic interaction has proved to be very significant for the enzyme activity by the use of simple model compounds, such as functional polymers,[1,2] peptides,[3–5] cyclodextrins,[6,7] micelles[8–13] or other hydrophobic aggregates.[14,15] In the present paper, the author wishes to describe the catalytic behavior of a new type of simple-structure nucleophile which is composed of a long alkyl chain and two histidine residues placed on both sides of the long alkyl chain. The linear molecule with such a structure will have enough hydrophobicity but simultaneously have enough solubility in water. Furthermore, in the present study the effect of the hydrophobic quaternary ammonium salt, methyltrioctylammonium chloride (MTAC), was investigated, since there is a possibility that the hydrolysis might be considerably activated due to the formation of hydrophobic ion pairs between imidazolate anion and ammonium cation.[14,15] In relation to this, the author tried to combine MTAC with histidine residue covalently.

Experimental

CH_3O–His–CO–$(CH_2)_8$–CO–His–OCH_3(HisC$_8$His) or $CH_3(CH_2)_4$CO–His–OCH_3(C$_5$His) was synthesized from L-histidine methyl ester and sebacoyl chloride or hexanoyl chloride. $Br(CH_2)_5$CO–His–OCH_3 was prepared from L-histidine methyl ester and 6-bromohexanoyl chloride, and then it was converted to $Br^-[CH_3(CH_2)_7]_3N^+(CH_2)_5$CO–His–$OCH_3$(N$^+C_5$His) by the reaction with trioctylamine. Imidazole, *N*-*t*-butoxycarbonyl-L-histidine methyl ester (Boc–His–OCH_3), methyltrioctylammonium chloride (MTAC), and *p*-nitrophenyl esters were commercially available.

The hydrolysis was carried out in 10 v/v% ethanol–water at 25 °C, μ=0.5(KCl), buffered with 1/10 mol dm^{-3} potassium dihydrogenphosphate–1/20 mol dm^{-3} sodium borate for pH 7—9, 1/20 mol dm^{-3} sodium borate–1/20 mol dm^{-3} sodium carbonate for above pH 9. The reaction rate was determined by using the absorbance of *p*-nitrophenolate at 400 nm with a Hitachi Model 100-10 spectrophotometer. Pseudo-first-order rate constant (k_1) was estimated by correcting the total rate constant (k_{total}) for the spontaneous hydrolysis as follows:

$$k_1 = k_{total} - k_{spont}.$$

In the presence of MTAC, k_{spont} means the rate constant for the hydrolysis only by MTAC. Second-order rate constant (k_2) was obtained by dividing k_1 by the total catalyst concentration per histidine residue.

Results and Discussion

Second-order rate constants (k_2) for the hydrolysis of *p*-nitrophenyl esters are summarized in Table 1. It should be noted that HisC$_8$His showed much higher activity than imidazole, Boc–His–OCH_3 and C$_5$His for the hydrolysis of *p*-nitrophenyl laurate (PNPL). For *p*-nitrophenyl hexanoate (PNPH), HisC$_8$His showed a little higher activity than imidazole and 2—4 times higher activity than Boc–His–OCH_3 and C$_5$His. HisC$_8$His gave a little greater activity for *p*-nitrophenyl acetate (PNPA) than Boc–His–OCH_3 and C$_5$His but smaller activity than imidazole. These results suggest that the rate enhancement for PNPL and PNPH was primarily ascribed to the hydrophobic interaction between the long alkyl chain of HisC$_8$His and those of the substrates. The significance of the hydrophobic interaction is also indicated by the following results. When 3 mol dm^{-3} urea was added the hydrolytic rate of PNPL by HisC$_8$His was decreased by *ca.* 80%, while that of PNPA only by *ca.* 20%. It is generally known that urea denaturates enzymes partly owing to the inhibition of hydrophobic interaction.[16] The analogous linear molecules which have a long alkyl chain but only one histidine residue, $CH_3(CH_2)_6$CO–His–OCH_3(C$_7$His) and $CH_3(CH_2)_{14}$CO–His–OCH_3(C$_{15}$His), also seem to be hydrophobic but they are poorly soluble in water, and therefore these catalysts could not be investigated in the present study. In this respect, the bi-histidine catalyst like HisC$_8$His designed in the present study is superior to the mono-histidine catalysts like C$_7$His and C$_{15}$His.

As reported by Kunitake *et al.*, hydrophobic nucleophiles having imidazoles gave enormously large rate enhancement in the hydrolysis of *p*-nitrophenyl ester in the presence of MTAC, due to the increase in the fraction of imidazolate anion facilitated by the formation of hydrophobic ion pairs between imidazolate anion and quaternary ammonium cation.[14,15] In the present study, therefore, the author has attempted the hydrolysis in the presence of both HisC$_8$His and MTAC in order to increase the catalytic ability of HisC$_8$His. The kinetic data are summarized in Table 2. Also in this case, HisC$_8$His gave considerably high catalytic activity for PNPL and PNPH as compared with the other nucleophiles, while it gave virtually no enhancement for PNPA. The hydrolysis of PNPL by HisC$_8$His was enhanced by *ca.* 20 times in the presence of MTAC. Figure 1 shows the relation between the pseudo-first-order rate constant (k_1) and the concentration of HisC$_8$His in the presence of MTAC. The k_1 values increase almost linearly with the HisC$_8$His concentration for both PNPH and PNPL. In Fig. 2 are shown the pH profiles of k_2 for PNPH and PNPL in the presence of HisC$_8$His and MTAC, where k_2 begins to increase exceedingly above pH 8.5—9.0. This suggests that the imidazolate anion is the catalytic nucleophile mainly contributing to the hydrolysis.[11,14,15] Since HisC$_8$His showed considerably higher catalytic activity on addition of MTAC, the author attempted then to design the catalyst, N$^+$C$_5$His, which has both MTAC

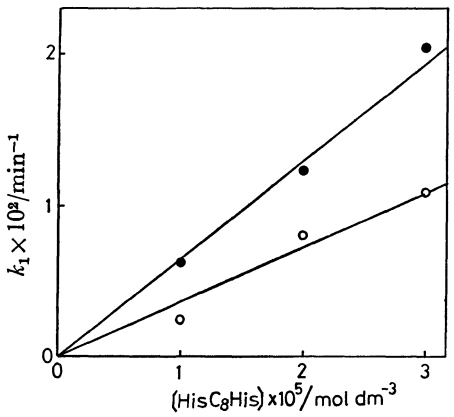

Fig. 1. Dependence of the pseudo-first-order rate constant (k_1) on the HisC$_8$His concentration in the presence of MTAC: (●) PNPL, (○) PNPH; 25 °C, pH 8.0, μ=0.5(KCl), 1/10 mol dm^{-3} KH_2PO_4-1/20 mol dm^{-3} $Na_2B_4O_7$ buffer, [PNPL]=[PNPH]=2.0×10^{-5} mol dm^{-3}, [MTAC] = 2.0 × 10^{-5} mol dm^{-3}. 10 v/v% EtOH was contained.

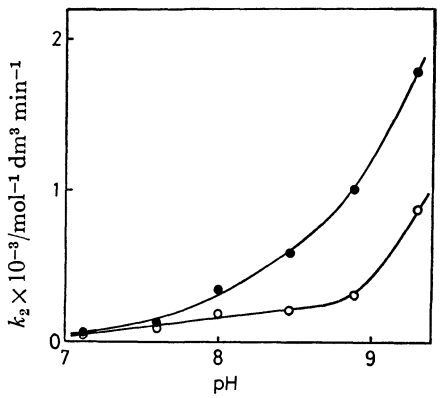

Fig. 2. pH-rate profiles for the hydrolysis of *p*-nitrophenyl esters in the presence of HisC$_8$His and MTAC: (●) PNPL, (○) PNPH; 25 °C, μ=0.5(KCl), 1/10 mol dm^{-3} KH_2PO_4-1/20 mol dm^{-3} $Na_2B_4O_7$ buffer(pH 7—9), 1/20 mol dm^{-3} $Na_2B_4O_7$-1/20 mol dm^{-3} Na_2CO_3 buffer(pH>9), [PNPL] = [PNPH] = 2.0 × 10^{-5} mol dm^{-3}, [HisC$_8$His] = 3.0 × 10^{-5} mol dm^{-3}, [MTAC] = 2.0 × 10^{-5} mol dm^{-3}. 10 v/v% EtOH was contained.

Table 1. Second-order rate constants (k_2) for the hydrolysis of *p*-nitrophenyl esters[a]

Catalyst	k_2 / mol^{-1} dm^3 min^{-1}		
	PNPA	PNPH	PNPL
Imidazole	20	15	0.3
Boc-His-OCH$_3$	6.7	5.7	0.5
C$_5$His	7.0	7.9	1.7
HisC$_8$His[b]	9.0	20	15
N$^+$C$_5$His	9.7	8.1	2.2

a) 25 °C, pH 8.0, μ=0.5(KCl), 1/10 mol dm^{-3} KH_2PO_4-1/20 mol dm^{-3} $Na_2B_4O_7$ buffer, [PNPA]=[PNPH]=[PNPL]=2.0×10^{-5} mol dm^{-3}, [catalyst]=1.0×10^{-3} mol dm^{-3} except for HisC$_8$His, [HisC$_8$His]=5.0×10^{-4} mol dm^{-3}. 10 v/v% EtOH was contained. b) The values of k_2 were estimated per histidine residue.

Table 2. Second-order rate constants (k_2) for the hydrolysis of *p*-nitrophenyl esters in the presence of methyltrioctylammonium chloride(MTAC)[a]

Catalyst	$k_2 \times 10^{-1}$ / mol^{-1} dm^3 min^{-1}		
	PNPA	PNPH	PNPL
Imidazole	<0.05	2.1	0.4
Boc-His-OCH$_3$	<0.05	0.8	2.0
C$_5$His	<0.05	0.3	1.9
HisC$_8$His[b]	<0.05	18	34
N$^+$C$_5$His	<0.05	0.8	1.8

a) 25 °C, pH 8.0, μ=0.5(KCl), 1/10 mol dm^{-3} KH_2PO_4-1/20 mol dm^{-3} $Na_2B_4O_7$ buffer, [PNPA]=[PNPH]=[PNPL]=2.0×10^{-5} mol dm^{-3}, [catalyst]=3.0×10^{-5} mol dm^{-3}, [MTAC] = 2.0 × 10^{-5} mol dm^{-3}. 10 v/v% EtOH was contained. b) The values of k_2 were estimated per histidine residue.

and histidine parts intramolecularly. The kinetic data for N$^+$C$_5$His are also shown in Table 1. As a whole, N$^+$C$_5$His does not have so large activity, although it gives a little enhancement for PNPA. As shown in Table 2, N$^+$C$_5$His does not give so large enhancement even in the presence of MTAC, too. N$^+$C$_5$His studied in the present report might not be able to form hydrophobic aggregates like MTAC in itself and not be able to be incorporated into MTAC aggregates, although there is still great room for improvement in this catalyst.

Lattice Dynamical Analysis of MgO

Akiko KIDA,*,† Mitiko MIURA, and Hiromu MURATA
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730
†*Hiroshima Prefectural Research Center for Environmental Science, Minami-machi, Hiroshima 734*
(Received December 4, 1981)

The lattice dynamical properties of MgO are studied using a model based on the Birman method, which is different from the conventional point-like atom model. The model includes three kinds of forces: the short-range, the long-range Coulomb, and the long-range polarization interactions. The long-range interactions are dependent on the magnitude of the expansion of the electron distribution. The degrees of the expansion for Mg and O (w_{Mg} and w_O) are estimated from the X-ray data. The calculated phonon dispersion curves agree with the observed curves in the case of $w_{Mg}=0.35$ Å and $w_O=0.73$ Å, which are nearly equal to the estimated values, 0.35 and 0.65 Å.

Many theoretical treatments have been accumulated in order to interpret and describe the dielectric and dynamical behavior of lattices observed by means of inelastic neutron scattering in ionic crystals. In these attempts, two processes of the theoretical treatments have been developed: (1) from the rigid-ion model (RIM) through the rigid-shell model to the three-body-force shell model;[1-7] (2) from the RIM through the polarizable-ion model (PIM) to the modified PIM.[8,9]

In the previous paper,[10] the lattice dynamics of wurzite has been studied on the basis of the PIM, which is a point-like atom model like the RIM. Later this model was modified by taking the expansion of the electron distribution (electron expansion or expansion of electrons) on the basis of the Birman method;[11,12] this new model was called the modified PIM,[9] where attention was paid only to the influence of the electron expansion on the macroscopic quantities.

Then this method was applied to CaO[13] in order to see the relation between the expansion estimated by the modified PIM method and that obtained by the X-ray analysis; discrepancy was found between them because only the electron expansion of one side of an ion pair in CaO was taken into account.

This paper, therefore, will be concerned with the lattice dynamics of MgO using further modified treatment regarding the electron expansion of both the Mg and O ions. On this occasion, since the Birman method includes many hard problems when it is applied explicitly to lattice dynamics, some assumptions are introduced into the practical treatment in order to simplify the procedure. The last section shows the relation between the further modified PIM treatment and the shell-model treatment, which has been the most frequently used one and which has achieved a close reproduction of the observed data.

Theoretical Treatment

The Modified PIM. In the conventional method of calculating the electrostatic lattice potential, called the Ewald method,[14] the contribution of any ion to the potential at a point in a crystal consists of the sum of two terms including a Gaussian function with a width parameter w for a rapid convergence on the evaluation of the crystal potential. These two terms we previously symbolized as Φ_r and Φ_t.[12] The potential $\Phi(=\Phi_r+\Phi_t)$ based on the Ewald method is independent of w after summation. Birman[11] noticed the physical meaning of the two terms and the Gaussian function: Φ_t represents the potential due to a neutral configuration (core plus compensating Gaussian), and Φ_r, the potential due to the unbalanced Gaussian charge, while a half-width parameter w of a Gaussian indicates the degree of electron expansion of an atom. Under the Birman method, two potentials are differently weighted with the ion and the core (nucleus and inner electrons) charge, z and q^c, and total:

$$\begin{aligned}\phi(w) &= z\Phi_r(w) + q^c\Phi_t(w), \text{ or}\\ &= q^v\Phi_r(w) + q^c\Phi,\end{aligned} \tag{1}$$

where q^v represents the valence-electron charge ($q^v=z-q^c$). The electron-charge distribution is assumed to be described by a single normalized Gaussian:

$$\rho(\mathbf{x}) = \exp[-\mathbf{x}^2/w^2]/w^3\pi^{3/2}. \tag{2}$$

The interaction energy between the kth and k'th ions is represented as the sum of the products of the charge and the potential, and expressed by:

$$\begin{aligned}\phi(kk') &= q_k^c\{z_{k'}\Phi_r(w_{k'},\mathbf{x}_{k'}) + q_{k'}^c\Phi_t(w_{k'},\mathbf{x}_{k'})\}\\ &+ q_k^v\int\{z_{k'}\Phi_r(w_{k'},\mathbf{x}_{k'}-\mathbf{x}') + q_{k'}^c\Phi_t(w_{k'},\mathbf{x}_{k'}-\mathbf{x})\}\\ &\times \rho_k^v(\mathbf{x}_k-\mathbf{x}')d\mathbf{x}',\end{aligned} \tag{3}$$

where $\rho_k^v(\mathbf{x}_k-\mathbf{x}')$ denotes the valence-electron charge-density distribution of the kth ion, the center of which resides at the position $\mathbf{x}_k(=0)$.[11,13]

The dynamical matrix for the PIM is written by its constituents as:[8]

$$\boldsymbol{D}(\boldsymbol{y},kk') = \boldsymbol{D}^N(\boldsymbol{y},kk') + \boldsymbol{D}^C(\boldsymbol{y},kk') + \boldsymbol{D}^P(\boldsymbol{y},kk'), \tag{4}$$

where $\boldsymbol{y}$ is the wave vector. Three interaction terms, $\boldsymbol{D}^N$, $\boldsymbol{D}^C$, and $\boldsymbol{D}^P$, are concerned with the short-range force, the long-range Coulomb force, and the long-range polarization force respectively. In the MPIM, long-range interactions are dependent upon the degree of the width parameter w in a Gaussian related to the electron expansion. The model parameters are the effective ionic charge z, the polarizabilities α_+ and α_-, four short-range force coefficients, A, A', B, and B', and the width parameter w. The formulas for the calculation of macroscopic quantities, such as the wavenumbers and elastic constants in the MPIM, have been shown in previous papers.[9,10,13]

Electron Expansion of Both Side Ions. In a previous paper,[13] we assumed $\rho(\mathbf{x}_k-\mathbf{x}')=\delta(\mathbf{x}_k-\mathbf{x}')$ in Eq. 3, that is, in the interaction between k and k', one side of

an ion pair is always assumed to be a point charge. This approximation is called the first approximation. Though the expansion of both ions is taken into account in the treatment, the overlap between two expanded ions is not considered. The present treatment is a PIM further modified by taking into consideration the overlap effect due to both sides of the Mg and O ions. This approximation is called the second approximation.

When $\phi^{(1)}$ denotes the first term of Eq. 3 with respect to the charge, it can be represented as:

$$\phi^{(1)} = q_k^c q_{k'}^v \times \text{Gaussian}(w_{k'}) + q_k^c q_{k'}^c \times \text{Dot(Point)}, \quad (5)$$

where the first Gaussian term represents the interaction between the dotty (point-like) core of k and the Gaussian valence electron of the k' ion, and the second, the Dot term between the dotty core of k and that of k'. The remaining interactions of $q_k^v q_k^c \times$ Gaussian and $q_k^v q_{k'}^v \times$ Gaussian are included in the second term of Eq. 3, $\phi^{(2)}$. This term is rewritten by means of the constitutive charge-density distributions as:

$$\phi^{(2)} = q_k^v \iint \sum_l \{[q_k^v q_{k'}^v(\mathbf{x}''-\mathbf{x}_{lk'}) + q_k^c q_{k'}^c(\mathbf{x}''-\mathbf{x}_{lk'})] / |\mathbf{x}''-\mathbf{x}'|\} d\mathbf{x}'' \rho_k(\mathbf{x}_{lk}-\mathbf{x}')d\mathbf{x}', \quad (6)$$

and hence:

$$\phi^{(2)} = q_k^v \sum_l \iint \{q_k^v q_{k'}^v(\mathbf{x}''-\mathbf{x}_{lk'})/|\mathbf{x}''-\mathbf{x}'|\} d\mathbf{x}'' \rho_k(\mathbf{x}')d\mathbf{x}' + q_k^v q_{k'}^c \sum_l \int \rho_k\{(\mathbf{x}_k-\mathbf{x}')/(\mathbf{x}_{lk}-\mathbf{x}')\} d\mathbf{x}', \quad (7)$$

where l indicates the cell index. The second term in this equation represents the contribution to the potential field at $\mathbf{x}_{lk}$ due to the Gaussian charge distribution, the center of which resides at $\mathbf{x}_k$ and the sum of which as regards l is represented by means of Φ_r.

The double integrals appearing in the first term in Eq. 7 are troublesome or scarcely calculable. A practical treatment is, therefore, carried out as follows. The overlap integral of the charge distributions $\rho(\mathbf{x})$ between the ions is given as:

$$\int \{\exp[-(\mathbf{x}_k-\mathbf{x}')^2/w_k^2]/w_k^2\pi^{3/2} \times \{\exp[-(\mathbf{x}_{k'}-\mathbf{x}')^2/w_{k'}^2]/w_{k'}^3\pi^{3/2}\} d\mathbf{x}' = \exp[-(\mathbf{x}_k-\mathbf{x}_{k'})^2/(w_k^2+w_{k'}^2)]/[(w_k^2+w_{k'}^2)\pi]^{3/2}. \quad (8)$$

This result can be considered to represent the charge density at the point $\mathbf{x}_k$ due to the Gaussian residing at $\mathbf{x}_{k'}$ and with the width parameter of $(w_k^2+w_{k'}^2)^{1/2}$. Accordingly, the double integral term is approximately represented by means of Φ_r with the with the width parameter of $(w_k^2+w_{k'}^2)^{1/2}$. Though this approximation is mathematically not valid, this simplifies Eq. 3 to:

$$\begin{aligned}\phi(kk') &= q_k^c[z_{k'}\Phi_r(w_{k'},\mathbf{X}) + q_{k'}^c\Phi_t(w_{k'},\mathbf{X})] \\ &+ q_k^v q_{k'}^c\Phi_r(w_k,\mathbf{X}) + q_k^v q_{k'}^v\Phi_t(\sqrt{w_k^2+w_{k'}^2},\mathbf{X}) \\ &= (z_k z_{k'} - q_k^v q_{k'}^c - q_k^c q_{k'}^v)\Phi_r(w_{k'},\mathbf{X}) \\ &+ q_k^c q_{k'}^c\Phi_t(w_{k'},\mathbf{X}) + q_k^v q_{k'}^c\Phi_r(w_k,\mathbf{X}) \\ &+ q_k^v q_{k'}^v\Phi_t(\sqrt{w_k^2+w_{k'}^2},\mathbf{X}), \end{aligned} \quad (9)$$

where $\mathbf{X}=\mathbf{x}_k-\mathbf{x}_{k'}$. The signs of the terms with regard to the interaction between the valence charges of different kinds of ions have to be inverted. Though a physical reason for this inversion can not yet be given explicitly, it seems that the interaction between the valence charges of different kinds of ions makes a different contribution in comparison with that of the same kind.

The phonon dispersion is calculated by means of Eq. 9, where the calculation is performed by assuming $\phi(kk')=\phi(k'k)$.

Calculation and Results

Determination of w and q^c. In the Birman method, the electrons of an ion are divided into two parts, the "inner" (tightly bound) and the "valence" (loosely bound) parts.[11] The inner-core part is built of the nucleus and the inner electrons, while the electron expansion is formed of the outer, valence electrons. The division of electrons into the valence and the core may be unequivocal. In this paper the electrons are divided in accordance with the experimental charge-density distribution, though in the case of CaO[13] the division was based on the atomic arrangement of the neighbors.

Vidal-Valat *et al.*[16] have determined the atomic charge-density distribution for MgO by means of X-ray analysis, as is shown in Fig. 1. The dense inner distributions are assigned to the core electrons, shown by the shadow in the figure. The partitions of the electrons are illustrated in Fig. 2, together with their charges. The integration of these distributions leads to the findings that the total charge of the inner electrons of Mg is nearly equal to $4e$ and that of O to $2e$. Accordingly, the core charges, q^c, become $8|e|$ and $6|e|$ for Mg and O respectively. The dense outer distributions are assigned to the valence electrons. The width parameter w of the normalized Gaussian function for each ion is determined so as to reproduce the corresponding dense outer distributions. The results are that the w for Mg

α_+ is fixed as 0.12 Å^3.

(w_{Mg}) is equal to 0.35 Å, while the w for O (w_O) is 0.65 Å. The effective ionic charge determined roughly by the use of this experimental charge distribution is nearly equal to the formal charge. The manner in which the experimental charge distribution is reconstructed with the Gaussian having these w values is shown in Fig. 1 by broken curves. Though the charge distribution constructed of the Gaussian in this way does not closely reproduce the observations up to the inner part, this is not important, for the interaction due to the electronic overlap occurs mostly in the outer part.

The accuracy of these evaluated w values is governed by the experimental error allowed for the X-ray measurements. By taking into account the experimental error and assuming that the charge distribution is represented by the Gaussian with only one parameter, the error of these w values was estimated at about ± 0.1 Å.

Reproduction of Macroscopic Quantities. The macroscopic quantities are tabulated in Table 1. The effective ionic charge, $z(=q^c+q^v)$, and the electronic polarizability, a, are determined respectively from the observed *TO-LO* splitting and high-frequency dielectric constants.[10] The Coulomb and the polarization force terms in the dynamical matrix in Eq. 4 are estimated from z and a. The short-range force coefficients are adjusted towards agreement between the calculated and observed Γ-point optical mode wavenumbers and the elastic constants by successive approximations.

To make it clear that the second approximation is reasonable, the result calculated by means of the first approximation is given. Table 2 summarizes reasonable parameter sets producing observed macroscopic quantities against several different values of w_O, fixing $w_{Mg}=$ 0.35 Å. In order to examine the reasonableness of the parameters determined, the phonon dispersions are calculated by the use of these parameters, where $w_{Mg}=$ 0.35 Å and $w_O=0.65$ Å, both determined by the X-ray analysis, are adopted. However, certain marked discrepancies in the acoustic-branch mode towards higher wave vectors along the [y00] and [yy0] directions are seen (dotted curves in Fig. 3) and are improved by taking into account the further electron expansion, that is, when the w_O is expanded so far as to 1.1 Å (full curves in Fig. 3).

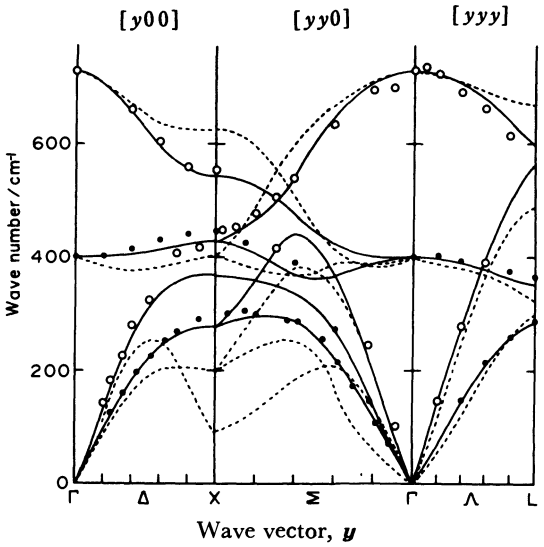

Fig. 3. The dispersion curves of MgO along three symmetry directions using the modified PIM on the assumption $\rho(\mathbf{x}_k-\mathbf{x}')=\delta(\mathbf{x}_o-\mathbf{x}')$. ------ Calculated results for $w_{Mg}=0.35$ Å and $w_O=0.65$ Å; —— those for $w_{Mg}=0.35$ Å and $w_O=1.1$ Å. Observation; ○ transverse branches; ● longitudinal branches.

Under the second approximation, where the overlap effect is due to both side ions, Mg and O, a closer reproduction of the phonon dispersion is given, as can be seen in Fig. 4, when the w_{Mg} and w_O are equal to 0.35 Å and 0.73 Å respectively, which are nearly equal to the values determined by the X-ray analysis. Even if the w_O changes from 0.65 Å to 0.73 Å, the total density is not far different from the observation. The model parameters for the further modified PIM are as follows: z/e, 1.97; a_-/Å^3, 1.82; A, A', B, and B'/mdyn Å^{-1}, 0.76, −0.14, −0.012, and 0.0025. Table 3 gives the calculated macroscopic quantities and the contributions of each kind of force to them. The value of the effective ionic charge, z, increases toward the formal charge with an increase in the value of w_O (see Table 2). The increase in the z value may be interpreted as indicating that all the electrons, spreading in accordance with the width parameter, can be explicitly assigned to each domain of

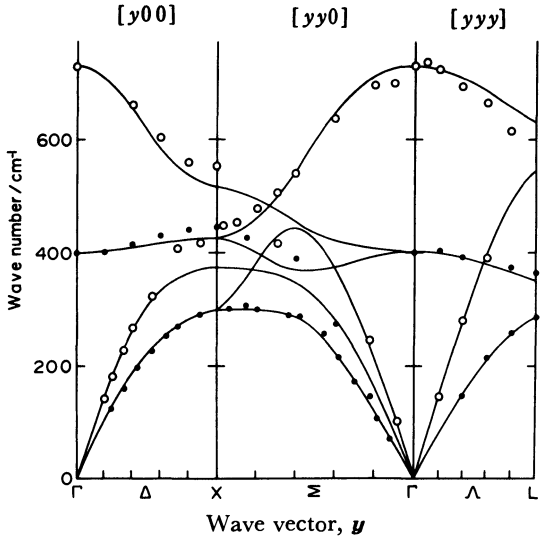

Fig. 4. The dispersion curves of MgO for $w_{Mg}=0.35$ and $w_o=0.73$ Å using the further modified PIM taking account of valence electron expansion of both the side ions.

TABLE 3. CALCULATED MACROSCOPIC QUANTITIES AND CONTRIBUTION OF EACH KIND OF FORCE TO THEM UNDER THE SECOND APPROXIMATION

	Calcd	Contribution (%)		
		D^N	D^C	D^P
ν	400.4	105	−5	−0
c_{11}	282	125	−25	
c_{12}	98	56	44	
c_{44}	163	−42	142	

an expanded ion. Usually the z value is smaller than the formal charge because of the neglect of the overlap or because of the interaction between the valence electrons. In the present treatment, as can be seen, by taking the electron expansion explicitly into account the z is estimated as the formal charge.

Thus, we have improved the previous finding that the electron expansion determined on the basis of the assumption that one side of an ion pair is a point charge is larger than that expected from the experimental data, and the w values determined from the phonon dispersion agree with those determined by means of the X-ray data.

Discussion

The origin of the polarization has been assumed to be the effective field at the lattice sites, which is composed of the externally applied field and the field due to the point dipoles of the crystal.[8] Woods *et al.*[12] have given an extended treatment so as to consider the short-range interaction causing the polarization—a treatment which has been termed the shell-model method. In this model, the polarizability is made finite by an arbitrary short-range harmonic restoring force with a spring constant k that acts between the core and the shell of an ion, while the relative displacement between the shell and the core produces a dipole moment at the ion site. The calculated phonon dispersions given by Sangster *et al.* on the basis of the shell model have reproduced the observed values very closely.[3b]

The value of k represents the strength of the bond between the core and the shell. If $k\to\infty$, the shell shrinks down to the core and the ion, therefore, becomes rigid. This rigid-shell model corresponds to the PIM. This feature of k is just the same as that of the width parameter w in the modified PIM, which can be determined by the X-ray data. As has been mentioned previously in the study on CaO[13] the shell charge, the core-shell coupling parameters, *etc.*, are the adjustable parameters in the shell model, whereas in the modified PIM treatment the only adjustable parameters are four short-range force coefficients. The other parameters, w, z, and α, can be determined independently from the results of the electron-charge distribution by means of the X-ray analysis, the *TO-LO* splitting phenomenon, and the dielectric property respectively. In conclusion, the further modified PIM treatment deserves well of the examination of lattice dynamics as well as the shell model because the parameter w reproducing the observed phonon dispersion curve agrees with the one estimated from the electron-density distribution. This treatment has, moreover, two advantages; the ease of handling because of the less adjustable parameters and the electronic overlap effect obtained by describing the valence-electron expansion by the Gaussian function.

The author wish to express their thanks to Professor Yosio Sakamoto and Mr. Hitoshi Arimori, Hiroshima University, for their indespensable help in the preparation of this paper.

An NMR Study on Molecular Interactions in 3-Methylsydnone and Its Aqueous Mixtures

Shoji TANAKA† and Masatoki YOKOI*
Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390
(Received August 16, 1982)

Molecular motion in neat 3-methylsydnone and molecular interaction in 3-methylsydnone–water mixtures were studied by the multinuclear FT-NMR method. The estimated rotational correlation times of the methine carbon and the carbonyl oxygen atom in neat sydnone are 8.6 and 8.1 ps at 40 °C, respectively. According to shift variations of the ^{13}C, ^{14}N, and ^{17}O nuclei of the sydnone molecule in sydnone–water mixtures, the sydnone forms a hydrogen bond with water at the carbonyl oxygen and not at the ring oxygen site. The effect of dissolved paramagnetic ions was investigated on the ^{13}C spin-lattice relaxation time of the carbon atoms of sydnone, and a discussion was made on the possible relative configuration of cation and anion to the solvent sydnone molecule.

The group of sydnones is a prototype for the general class of mesoionic compounds which cannot satisfactory be represented by Lewis forms involving no charge separation. The structure and reactions of sydnones were studied extensively.[1-3] Recently Lemire and Sears[4] measured bulk physical properties of 3-methylsydnone (Fig. 1), pointing out that it would be a

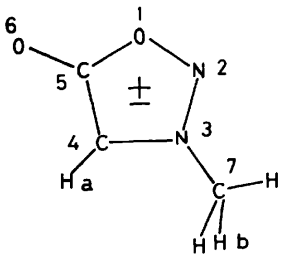

Fig. 1. Structure and numbering of the atoms of 3-methylsydnone.[5]

promising nonaqueous solvent; its dipole moment is 7.3 D (1 D$=3.3356\times10^{-30}$ cm) and its relative permittivity for the liquid phase is 144.0 (40 °C). In their subsequent work,[5] interaction of 3-methylsydnone with water and solvation of ions dissolved in the sydnone were studied by determining bulk properties of sydnone–water mixtures and conductivities of ions in the sydnone, respectively. In the present study, we examined four aspects of solvent properties of 3-methylsydnone by the multinuclear FT-NMR method: First, to investigate the self-association of the sydnone, we measured the ^{13}C spin-lattice relaxation time of the methine carbon C(4) and the ^{17}O spin-spin relaxation time of the carbonyl oxygen O(6), and discussed on the molecular motion in neat 3-methylsydnone. Second, to investigate the electron accepting ability of the sydnone, pyridine was used as a probe; we measured the ^{13}C spin-lattice relaxation time of the pyridine carbon atoms in an equimolecular mixture with the sydnone to detect any association of pyridine with the sydnone at the pyridine nitrogen atom. Third, to identify proton-accepting sites in 3-methylsydnone, measurements were made of chemical shift variations of the ^{1}H, ^{13}C, ^{14}N, and ^{17}O nuclei of the sydnone with dilution of the sydnone with D_2O. On the basis of these data we attempted to determine the site at which the sydnone is hydrogen-bonded to water. Fourth, to investigate solvation of ions in 3-methylsydnone paramagnetic ions were used; we measured the ^{13}C spin-lattice relaxation time of the sydnone carbon atoms before and after addition of a paramagnetic cation or anion, and then attempted to determine the relative configuration of the ion to the sydnone molecule.

† Prestnt address: Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980.

Experimental

3-Methylsydnone was synthesized from *N*-methylglycine by the method of Vasil'eva and Yashunskii,[6] and purified by the zone melting method. The final freezing point of the purified sydnone was 36 °C. Pyridine, paramagnetic reagents, and deuterium oxide were commercially available and used without further purification. 3-Methylsydnone–D_2O and –pyridine mixtures were prepared on the weight basis. NMR sample tubes for relaxation time measurement were degassed on a vacuum line by at least three freeze-pump-thaw cycles and sealed before use. All NMR experiments were performed on naturally abundant materials.

NMR measurements were carried out on a JEOL FX-90Q spectrometer operating in the Fourier transform mode. A JEOL Temperature-controller (NM-VTS) with a thermocouple external to the sample was used to monitor the probe temperature within 1 K. The ^{13}C spin-lattice relaxation time was obtained from satandard inversion-recovery FT-NMR experiments. The ^{14}N spectrometer frequency was 6.42 MHz and 8192 data points were used for a 4 kHz spectral width. Pulses with 8 μs width and 1.0 s interval were used for each scan. Averaging 1000 scans were sufficient to get a reasonable S/N ratio for the signal of the N(3) atom of sydnone. The experimental error for the reported ^{14}N chemical shifts is within ±0.1 ppm. The ^{17}O spectral parameters were as follows: spectrometer frequency, 12.10 MHz; spectral width, 10 kHz; pulse interval, 40 ms; pulse width, 10 μs: 512 data points were used. Normally, 10^6 scans were adequate for obtaining a well resolved ^{17}O NMR signal. The ^{17}O spin-spin relaxation time was calculated from $T_2=(\pi\Delta\nu_{1/2})^{-1}$, where $\Delta\nu_{1/2}$ is the full width at the half height of absorption signal in Hz. The accuracies for the reported T_2 and chemical shifts were estimated as ±10% and ±10 ppm, respectively. The temperature was 40±1 °C except for the shift measurement for the O(1) atom in 3-methylsydnone. Since the absorption signal of O(1) was too broad at 40 °C, we could obtain no precise shift values. The shift variation was measured at 100 °C.

Table 1. Chemical shifts of atoms in neat 3-methylsydnone

Atom	Chemical shift/ppm	Reference[a)]
O(1)	389	External D_2O
N(2)	Very broad	—

H(b)	4.307	Internal DSS

a) The relative shift based on the external referencing was corrected for the difference in bulk susceptibility between the sample and the reference compound.

Results and Discussion

Assignment of NMR Signals. Table 1 presents the chemical shifts of the ^1H, ^{13}C, ^{14}N, and ^{17}O atoms of neat 3-methylsydnone. The assignment of the NMR signals, except for the ^{17}O atoms, is based on shift data reported in the literature.[7-11] The assignment of the two ^{17}O NMR signals is based on the assumption that the NMR signal of the ^{17}O atom with higher local electron density appears at higher field.[12] Eckert-Maksić and Maksić[13] estimated the local electron density of the atoms in 3-methylsydnone by means of MO calculation (MNDO). We utilized their results on the assignment of the ^{17}O signals.

Molecular Motion and Self-association in Neat 3-Methylsydnone. Table 2 presents the ^{13}C spin-lattice relaxation time of the methine carbon C(4) and the ^{17}O spin-spin relaxation time of the carbonyl oxygen O(6) together with the estimated values for the rotational correlation time τ_c. The estimation of τ_c's is based on the assumption that the ^{13}C atom relaxes primarily through dipolar interaction with the directly bonded proton, whereas the ^{17}O atom does through quadrupole interaction with the filed gradient tensor of the molecule. The dipolar relaxation expression is given by

$$\frac{1}{T_1^{DD}} = \frac{n_H \gamma_C \gamma_H \hbar^2}{r_{C-H}^6} \tau_c, \quad (1)$$

where n_H is the number of protons directly attached to the carbon of interest. The quadrupole relaxation expression is given by the following equation within the limits of extreme narrowing condition:[14]

$$\frac{1}{T_1^Q} = \frac{1}{T_2^Q} = \frac{3(2I+3)}{40I^2(2I-1)}\left(1+\frac{\eta^2}{3}\right)\left(\frac{e^2qQ}{\hbar}\right)^2 \tau_c, \quad (2)$$

where I is the spin quantum number, η is the asymmetric parameter, and e^2qQ/h is the quadrupole coupling constant (NQCC). The calculation of τ_c for the ^{13}C atom requires the value of carbon-hydrogen bond distance. We employed a C–H distance of 1.09 Å which is reasonable for the sp^2 carbon. The calculation of τ_c for the ^{17}O atom requires the value of NQCC and asymmetry parameter. There have been reported only a few ^{17}O NQR studies, and therefore we employed a NQCC of 10.2 MHz, which is the value for urea, and an asymmetric parameter $\eta=0.45$, which is the nominal value for the carbonyl oxygen.[15] Since the NQCC is included squared in the relaxation equation, the molecular correlation time as calculated from nuclear quadrupolar relaxation data is dependent highly on the NQCC value. The coupling constant for urea is in good agreement with the 10.6—10.9 MHz range of constants obtained for substituted benzaldehydes.[16]

Table 2. ^{13}C spin-lattice and ^{17}O spin-spin relaxation times and rotational correlation times of C(4) and O(6) atoms of 3-methylsydnone at 40 °C

Atom	T_1, T_2	τ_c /ps
$^{13}C(4)$	5.4 s	8.6
$^{17}O(6)$	1.1_8 ms	8.1

The estimated rotational correlation times for the methine carbon C(4) and carbonyl oxygen O(6) are nearly equal to each other. Since 3-methylsydnone is not a spherical top, it is possible that there will be a preferred axis of molecular rotation. Both Eqs. 1 and 2 essentially correspond to the isotropic molecular reorientation. The carbon $\tau_c(^{13}C)$, however, reflects the motions effective for reorienting each C–H vector, and the oxygen τ_c (^{17}O) reflects the motion most effective for reorienting the electric field gradients at the ^{17}O atom. Therefore, it can be inferred that the estimated correlation time for the methine carbon $\tau_c(^{13}C)$ corresponds to that for the reorientation of the C(4)–H vector and that the correlation time for the carbonyl oxygen $\tau_c(^{17}O)$ corresponds to that for the reorientation of the C(5)–O(6) vector. These two vectors are not parallel to each other. Thus the agreement between $\tau_c(^{13}C)$ and $\tau_c(^{17}O)$ leads us to a conclusion that the molecular reorientation of 3-methylsydnone is fairly isotropic.

If chain-like association as found in some amide systems[17] takes place in neat sydnone, the reorientation of aggregates is expected to be highly anisotropic. Thus, from the above discussion it may be concluded that such "anisotropic" association does not take place in neat 3-methylsydnone. We have estimated the radius of the molecule from the average correlation time for C(4) and O(6) by the Debye relation

$$\tau_c = \frac{4\pi r^3 \eta}{3kT}, \quad (3)$$

where r is the molecular radius, η is the macroscopic shear viscosity, k is the Boltzmann constant, and T is the absolute temperature. The estimated molecular

radius is 1.2 Å. This result suggests that 3-methylsydnone does not form large aggregates. The intermolecular interactions in neat 3-methylsydnone seem weak and nonspecific. It is important, however, that the above discussion do not disprove the formation of aggregates which are small and rotating isotropically.

The Electron-accepting Ability of 3-Methylsydnone. Campbell *et al.*[18] proposed that pyridine is a useful probe for studying association of molecules when the interaction is weak and the life time of the complex is short. Pyridine has a basic lone electron pair at its nitrogen. The reorientation of pyridine, when the lone pair is free, is effectively isotropic and thus pyridine has nearly equal ^{13}C spin-lattice relaxation times for C(2), C(3), and C(4). When pyridine associates with a molecule on the lone pair site, the reorientation of the molecule becomes anisotropic. The formation of such complexes slows down the tumbling about the axis perpendicular to the C(4)–N(1) axis, and a change in rotational diffusion tensor can be detected by measuring the spin-lattice relaxation times for C(2), C(3), and C(4). They introduced a parameter R, defined as the ratio of the mean of the relaxation times of C(2) and C(3) to that of C(4), *i.e.*

$$R = \frac{T_1(C2) + T_1(C3)}{2T_1(C4)}. \quad (4)$$

Table 3 presents the relaxation times of C(2), C(3), and C(4) of pyridine in the neat liquid and in an equimolar mixture with 3-methylsydnone, together with the estimated values of R. The addition of 3-methylsydnone does not change the R value. This result indicates that any charge-transfer complexes between pyridine and the sydnone do not form, and that 3-methylsydnone has no site on which the sydnone interacts with a basic lone pair.

Identification of the Proton-aceepting Site in 3-Methylsydnone. Chemical shifts of all the atoms except N(2) in 3-methylsydnone were measured in sydnone–D_2O mixtures at 40 °C. Figures 2 and 3 present chemical shift differences relative to the neat sydnone as a function of mole fraction of D_2O. 3-Methylsydnone has four lone-pair sites where the sydnone can be expected to form hydrogen bonds to water. As shown in Fig. 2,

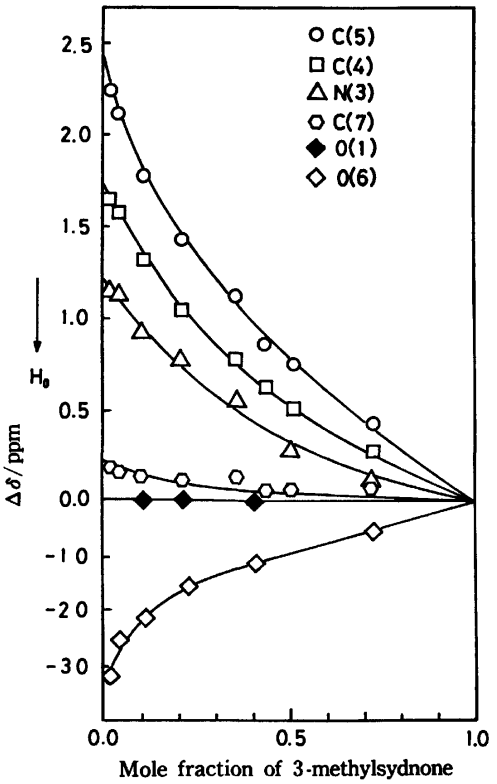

Fig. 2. The shift variations of ^{13}C, ^{14}N, and ^{17}O atoms in 3-methylsydnone–D_2O system.

when 3-methylsydnone is diluted with D_2O, the carbonyl oxygen O(6) show a very large up-field shift, up to about 34 ppm at infinite dilution. It has been reported that the hydrated carbonyl oxygens of acetone, *N*-substituted formamides, and *N*-substituted acetamides show a large up-fieled shift (20—50 ppm).[12,19] As a significant aspect the experimental results show that the shift variation of the other atoms C(5), C(4), N(3), and C(7) decreases in this order; this indicates that an electron transfer from the ring to carbonyl oxygen takes place. These results lead us to the conclusion that 3-methylsydnone forms a hydrogen bond with water at the carbonyl oxygen site. The chemical shift of the ring oxygen O(1) is almost unchanged. Though the shifts were measured at 100 °C, we may conclude that no hydrogen bond is formed on this site of the sydnone. The NMR signal of the N(2) atom is too broad to be observed. We can, however, rule out the possibility that hydrogen bond will be formed only on this site: First, on the basis of MO calculation results,[13] protonation at the N(2) atom decreases the local electron density at the O(6) atom and thus if a hydrogen bond is to be formed at the N(2) atom, the carbonyl oxygen O(6) should show a down-field shift. This is against the experimental results. Second, formation of hydrogen bond at the N(2) atom will change electronic states of the atom adjacent to N(2) most effectively. Nevertheless, the shift variations of the O(1) and N(3) atoms are smaller than those of the other atoms of the ring. The above discussions are based on the assumption that the chemical shifts of ^{13}C, ^{14}N, and ^{17}O atoms are dependent predominantly on the paramagnetic nuclear screening

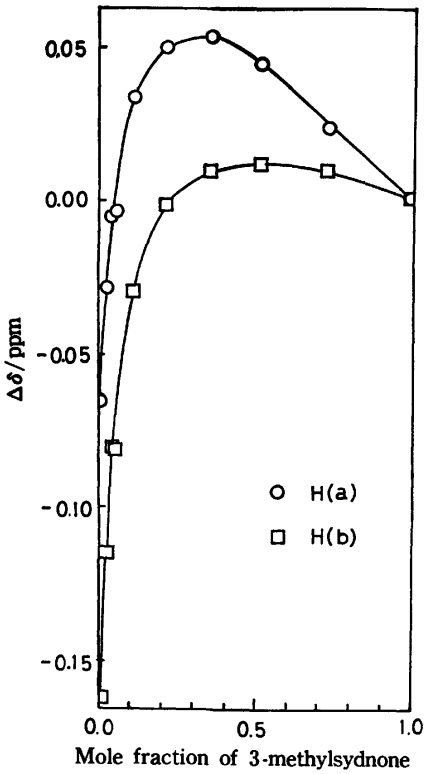

Fig. 3. The shift variations of the ^1H atoms of 3-methylsydnone in the sydnone–D_2O system.

constant σ_P so that the changes in chemical shift are due primarily to alternation in the local electron density at the atom.[12]

As shown in Fig. 3, as 3-methylsydnone is diluted with D_2O, the protons of the sydnone show a down-field shift at low dilution and an up-field shift at high dilution. The down-field shift variation can be explained in terms of the hydrogen bonding effect. The hydrogen bonds between the sydnone and water decrease the electron density of the sydnone ring so as to give rise to down-field shift of the proton. To interpret the up-field shift change, we assume that part of the sydnone molecules associate to form aggregates, whose protons are capable of resonance at lower fields than those of the monomer, possibly by the ring current effect. Thus, in sufficiently diluted solution, aggregates break out until the up-field shift effect has outweighed the hydrogen bonding effect.

The Solvation of Ions in 3-Methylsydnone. Table 4 presents the spin-lattice relaxation rates $1/T_1$ of the ^{13}C atoms in 3-methyl sydnone before and after addition of paramagnetic ions. From these results the relative configuration of ions to the sydnone molecule is to be considered. Paramagnetic relaxation reagents can interact with organic compounds to form collision type or electron-transfer type complexes and to change T_1's of the atoms in the molecule according to the electron-nuclear dipole-dipole relaxation mechanism. This relaxation mechanism has a reciprocal sixth-power distance dependence and no angle dependence. Atoms close to the site of complexation will have shortest T_1 values. We have estimated the electron-nuclear d-d relaxation time of the atoms in the molecule. The effect of a paramagnetic reagent on T_1 is given by

$$\frac{1}{T_{1\,ob}} = \frac{1}{T_{1\,dia}} + \frac{1}{T_1^e}, \tag{5}$$

where $1/T_{1\,op}$ is the observed relaxation rate, $1/T_{1\,dia}$ is the sum of all diamagnetic relaxation rates, and $1/T_1^e$ is the relaxation rate according to the electron-spin d-d relaxation mechanism. Levy and Komoroski[20] pointed out that the atoms in a given molecule may be under a considerable effect from relaxation reagent ions that are not complexed, being led to formulate

$$\frac{1}{T_1^e} = \frac{X_f}{T_{1f}^e} + \frac{X_c}{T_{1c}^e}, \tag{6}$$

where $1/T_1^e$ is the total relaxation rate for the electron-nuclear dipolar interaction, $1/T_{1f}^e$ and $1/T_{1c}^e$ are the rates when the molecule is free and complexed, respectively, and X_f and X_c are the respective molar fractions. Since X_f, X_c, and T_{1f}^e are common for given atoms in a molecule, T_{1c} may be taken to be proportional to the reciprocal sixth power of distance R from the atom of interest to the relaxation reagent. Thus we have

$$\frac{1}{T_1^e} = \alpha\frac{1}{R^6} + \beta, \tag{7}$$

where α and β are positive constants. By positioning systematically the paramagnetic ion relative to the 3-methylsydnone molecule, we have calculated the distances from the carbon atoms to the ion. The bond lengths and angles for the sydnone used in the calculation are based on the X-ray analysis on 4,4'-dichloro-3,3'-ethylenebissydnone by Thiessen and Hope.[21] From these distances and the experimental relaxation rates, parameters α and β were calculated by the least-square procedure, and then the variances was estimated by

$$\text{Variance} = \log\left(\sum\left\{\frac{1}{T_{1\,ob}^e} - \frac{1}{T_{1\,cal}^e}\right\}\right), \tag{8}$$

where $1/T_{1\,ob}^e$ and $1/T_{1\,cal}^e$ are the observed and calculated relaxation rates, respectively. If the variance is less than -4 and both α and β are positive for a given position, the ion can be taken to exist at the position.

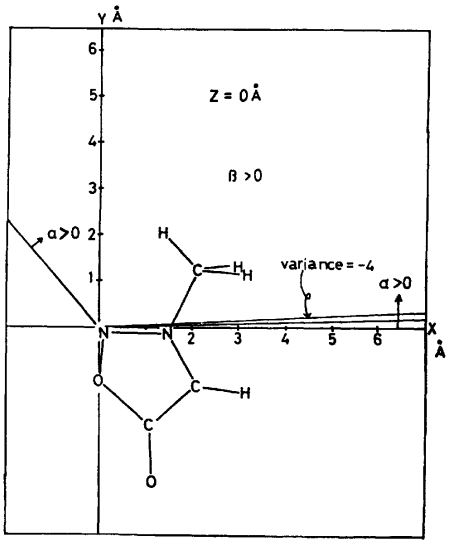

Fig. 4. Parameter diagram of $Cr(C_2O_4)_3^{3-}$–sydnone system.

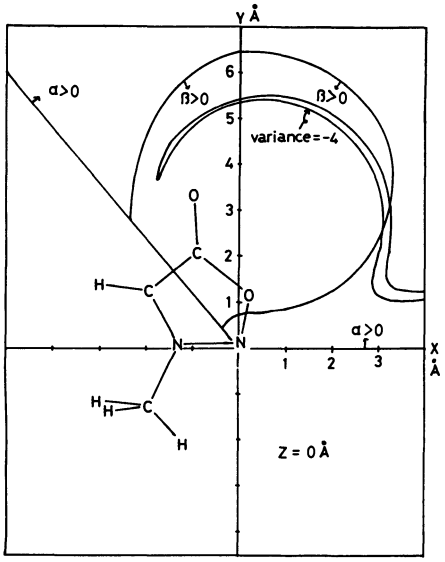

Fig. 5. Parameters diagram of Mn^{2+}–sydnone system.

This threshold value of −4 has been determined from the experimental error for the T_1 measurement of ±5%. Figures 4 and 5 illustrate contour diagrams of the variance for anion and cation, respectively. Since we have not a fitting point but a fitting surface as shown in these figures, we cannot quantitatively specify the relative positions of the ions. We can, however, obtain information on the site of ion solvation in 3-methylsydnone from these results. The methine proton and methyl group with large positive formal charge[13] are closest to the anion. For the cation, on the other hand, the carbonyl oxygen and ring oxygen with large negative formal charge and lone pairs of electron are closest to the ion. The NMR signal of the carbonyl carbon is broadened by addition of Mn^{2+} ion. The broadening can be explained in terms of contact interaction of the unpaired electron of the ion with the carbon.

The authors are particularly indebted to Professor Hiroshi Kato of the Shinshu University for many useful suggestions on the preparation and purification of 3-methylsydnone.

Catalysis by "Copper Chromite". I. The Effect of Hydrogen Reduction on the Composition, Structure, and Catalytic Activity for Methanol Decomposition

Akira IIMURA,* Yasunobu INOUE,† and Iwao YASUMORI

Department of Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

†*Analytical Center, Nagaoka Technological University, Kamitomioka, Nagamine, Nagaoka, Niigata 949-54*

(Received November 27, 1982)

The effect of hydrogen reduction on the composition, structure, and catalytic activity of dichromium(III) copper(II) tetraoxide (copper chromite), $CuCr_2O_4$, was investigated. In this oxide, the surface and the bulk Cu^{II} was reduced into Cu^{I} and further to Cu^{0} by heating in hydrogen. The methanol decomposition on fresh copper chromite proceeded in a manner similar to that on metallic copper formed as the result of strong reduction and dispersed on chromium(III) oxide. The contribution of Cu^{II}, Cu^{I}, and Cu^{0} species to catalytic activity was examined and the similarity in the character of reaction on these two samples with different surface states was discussed. The role of Cr_2O_3 interacting with zerovalent copper was postulated.

Dichromium(III) copper(II) tetraoxide (copper chromite), $CuCr_2O_4$, having the spinel structure has been used as a catalyst for the hydrogenation[1-3] of carbonyl compounds or olefins and for the decomposition of alcohols.[4] The durability of $CuCr_2O_4$ to heat and inhibitor seems to be superior to that of metallic copper. The catalytic activities of this oxide, however, often vary with the method of preparation and the conditions of pretreatment.[5] Especially, under reductive conditions, surface or bulk reduction may occur, and the catalytic activity would be influenced by these processes. Accordingly, the study on the structural and activity changes, occurring in reduction treatment is considered to be important. Furthermore the study provides useful information on the structure of the active sites available for catalytic reactions.

Stroupe[6] found that Adkins' catalyst,[1,2] which is composed mainly of $CuO \cdot CuCr_2O_4$ and is active for the hydrogenolysis of esters, was reduced to Cu and $Cu_2Cr_2O_4$ during the course of reaction. Although there are several reports[6,7] on the reduction of the CuO/Cr_2O_3 system, few investigations about the changes of the surface structure of copper chromite by reducing treatments have been made.

Recently, Capece *et al.* reported that the structure of "copper chromite" was elucidated by means of X-ray photoelectron spectroscopy.[8] However, the changes in the surface structure of spinels by reduction have not been clearly discussed because the samples measured by them are commercial "copper chromite" catalysts which contain CuO as well as $CuCr_2O_4$. Thus, in the present study, the copper chromite catalyst was treated in various reducing conditions and the changes of the composition and the structure of the bulk and the surface of the catalyst were investigated. The difference of the catalytic activities between fresh and reduced catalysts was also examined by using the decomposition of methanol as a test reaction. The effect of reducing treatments on the composition and the structure of the simple oxides, CuO and Cr_2O_3 was also studied in comparison with that on $CuCr_2O_4$.

Experimental

Catalysts. $CuCr_2O_4$ was prepared by co-precipitation with aqueous ammonia from an aqueous solution of chromium(III) nitrate and an excess of copper(II) nitrate in relation to the stoichiometric amount of copper, followed by calcination in air at 600—650 °C for 6 h. The crude product was washed with 3 M HNO_3 (1 M = 1 mol dm^{-3}) until there was no detectable Cu^{II} species in the filtrate, and then heated in air at 400 °C for 4 h. This sample will be designated F catalyst in this paper.

The F catalyst was heated under an initial pressure of hydrogen of 50 Torr (1 Torr = 133.322 Pa) in a circulating system for 2 h at various temperatures. Then, the system was evacuated for a few minutes. After evacuation, the catalyst was heated to 500 °C in a closed system, and the water produced was collected in a trap cooled with liquid nitrogen. Finally, the sample catalyst was evacuated at 500 °C for 1 h. The temperatures chosen for the heating in hydrogen were 100, 200, 300, and 400 °C, and the catalysts obtained by these treatments were designated R100, R200, R300, and R400, respectively.

In order to obtain a strongly reduced copper chromite, the F catalyst was placed in a circulating reactor with a liquid nitrogen trap and heated in hydrogen at 500 °C until the rate of water formation became lower than 10 μmol/h g catalyst. Then the catalyst was evacuated for 1 h at the same temperature and was designated SR catalyst.

Commercial CuO(elemental analysis grade) was used for the experiment after pulverization. Chromium(III) oxide was prepared by decomposition of ammonium dichromate, followed by heating in air at 600—650 °C for 6 h.

Characterization of the Catalysts. The X-ray powder diffraction of the prepared catalysts was measured using the Cu $K\alpha_1$ line as an X-ray source.

XP spectra of these catalysts were recorded with a Hewlett-Packard 5950A ESCA Spectrometer. The monochromatized Al $K\alpha$ line (1486.6 eV) was used as an X-ray source. The F catalyst sample was used for the measurement both without treatment and after evacuation at 500 °C in the XPS apparatus for 45 min. R200 and R400 catalyst sample were prepared by heating F catalyst at 200 and 400 °C, respectively in the preparation chamber of the spectrometer under 4 Torr of hydrogen followed by evacuation at 500 °C for 45 min. The SR catalyst was also used for the measurement after evacuation at 500 °C for 45 min in the XPS apparatus. The binding energy values of emitted electrons were corrected by using the carbon Cls value, 285 eV, as an internal standard.

BET surface areas of the catalysts were measured by the use of krypton at liquid nitrogen temperature.

Catalytic Activities. Catalytic activities were examined

for the decomposition of methanol and the initial reaction rates were measured in a circulating system of 470 ml in volume. The reaction was followed by analyzing the products with a gas chromatograph. A good reproducibility of catalytic activity was obtained by evacuation at the reaction temperature for one hour.

For purposes of comparison, the rates of propene hydrogenation on these catalysts were measured using the circulating system described above. To obtain reproducibility of rate measurement, the catalysts were evacuated at 500 °C for one hour before each experimental run of the hydrogenation.

Results

Reduction Behavior. In Fig. 1, the X-ray powder diffraction patterns of F, R100-R400, and SR catalysts are shown and the percentage fractions of reduction are summerized in the column 2 of Table 1. The latter values were estimated from the partial pressure of water formed, by assuming that the reduction was completed when all $CuCr_2O_4$ was turned into Cu and Cr_2O_3.

As shown in the figure, the diffraction lines assigned to $Cu_2Cr_2O_4$, which would be produced by the partial reduction of $CuCr_2O_4$, appeared in the pattern of R200, and the lines became more distinct on the patterns of R300 and R400. In the pattern of SR catalyst, however, the lines corresponding to $Cu_2Cr_2O_4$ completely disappeared and, on the contrary, only the lines assigned to copper metal and Cr_2O_3 appeared. As the (311) diffraction was most intense in all the diffractions of $CuCr_2O_4$, the values of full width at half maximum (FWHM) of this line and the crystallite sizes[9] calculated from these FWHM values are listed in column 3 and 4 of Table 1, respectively. The table shows that the decrease in the crystallite size takes place by reduction at temperatures between 200 and 300 °C. The degree of reduction of R300 is also largely different from that of R200.

It was found that simple oxides of copper, CuO and Cu_2O, were easily reduced into metallic copper by heating at 50 Torr of hydrogen at 300 °C, while the X-ray diffraction patterns of Cr_2O_3 were almost the same before and after heating in hydrogen at 500 °C.

In Fig. 2, $Cu2p_{3/2}$ X-ray photoelectron spectra for F, R200, R400, and SR catalysts are shown. In the spectrum of F catalyst, there are two peaks at about 936 and 940—945 eV which are characteristic of the Cu^{II} species and are assigned to a main peak and its shake-up satellite peak, respectively.[10] A peak which was assigned to photoelectrons from Cu^{I} or Cu^{0} species was also

TABLE 1. REDUCTION PERCENTAGE, FWHM OF 311 LINE, CRYSTALLITE SIZE, AND SURFACE AREA OF F, R100—R400, SR, AND REOXIDIZED R400 CATALYSTS

Sample	Reduction/%	FWHM/°	D_{311}/Å	Specific surface area/$m^2\ g^{-1}$
F	0	0.24	347	5.7
R100	2	0.24	347	5.6
R200	4	0.24	347	5.9
R300	11	0.30	278	8.4
R400	20	0.42	199	9.9
SR	73	—	—	16.3
Reox.	—	0.42	199	6.4

observed at about 932 eV in all the spectra in the figure. For F, R400, and SR catalysts, peaks were observed at about 917.6, 916.8, and 919.1 eV of kinetic energies, respectively, and assigned to the $L_3M_{4,5}M_{4,5}$ Auger electrons from Cu^{II}, Cu^{I}, and Cu^{0}, respectively.[11] The intensity ratio was estimated at 2 : 1 : 5.

From the spectrum **a** in Fig. 2, the $Cu^{I}/(Cu^{I}+Cu^{II})$ intensity ratio was determined as about 0.15. By assuming that the cross sections of photoionization for Cu^{I} and Cu^{II} species were equal, it was estimated that 15% of the Cu species existed as Cu^{I} in the surface layer of the F catalyst.

Since photoelectrons from Cu^{II} species are scarcely observed in the spectrum of R200, the amount of Cu^{II} species existing in the surface layer of R200 is negligible.

In order to see the changes in the ratio of copper to chromium atoms existing in the surface layer, the intensity ratio of $Cu2p_{3/2}$ to $Cr2p_{3/2}$ in the XP spectra were determined. The results are shown in Table 2; the Cu/Cr ratios of R200 and R400 were significantly lower than that of F catalyst. This indicated that the Cr^{III} species was exposed preferentially to the surface of the catalyst when F was reduced into R200 or R400. The Cu/Cr ratio of SR was the highest all over the catalysts, so that it is concluded that the metallic copper produced by strong reduction is enriched in the surface layer. Therefore, it seems that the SR catalyst has the structure of dispersed metallic copper on Cr_2O_3.

In the bottom of the figure, the spectrum of an R400 sample heated at 400 °C in 4 Torr of oxygen for a further 45 min is shown. The observed main peak at about 936 eV and the satellites at 940—945 eV indicate clearly that the sample surface was partly reoxidized.

Table 2. XPS Intensity ratio of $Cu(2p_{3/2})$ to $Cr(2p_{3/2})$

Sample	$Cu(2p_{3/2})/Cr(2p_{3/2})$
F	1.6
R200	0.2
R400	0.2
SR	1.7

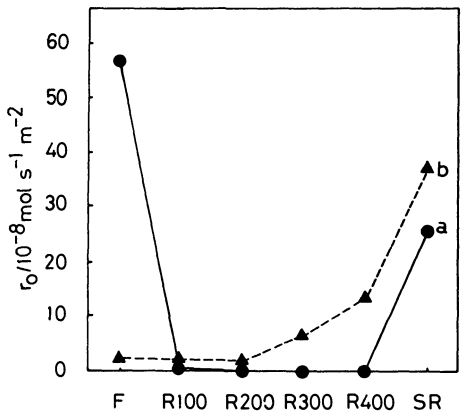

Fig. 3. Relationship between reduction conditions and initial rates of the reactions.
a: Decomposition of methanol at 200 °C, $p_0(CH_3OH) \simeq$ 20 Torr. b: Hydrogenation of propene at 0 °C, $p_0(C_3H_6) \simeq p_0(H_2) \simeq 17$ Torr.

In the spectrum of copper(II) oxide, CuO, no characteristic peaks of the Cu^{I} species were observed.

Catalytic Activities. In Fig. 3, the initial rates of methanol decomposition and propene hydrogenation on F, R100—R400, and SR catalysts are shown. In the case of methanol decomposition, the initial pressure of methanol and reaction temperature were fixed at 20 Torr and 200 °C, respectively. The rates were evaluated from the initial decreases in the partial pressure of methanol. As shown in the plot **a** of the figure, the catalytic activity decreased abruptly on increasing the degree of reduction to 2% (F→R100), and the decomposition did not occur on R200, R300, and R400 catalysts. However, on SR catalyst which was the highest in the extent of reduction, the catalytic activity was observed. The hydrogenation of propene was examined at 0 °C using a equimolar mixture of H_2 and C_3H_6, 35 Torr in total pressure. The product of the hydrogenation was found to be propane only. The reaction rate was evaluated by the initial decrease in the total pressure of the reactant. The plot **b** of the figure shows that the rates of propene hydrogenation were relatively low on F, R100, and R200, whereas the rate became higher on R300 and attained the highest point on the SR catalyst.

Typical runs of methanol decomposition on F and SR catalysts are shown in Fig. 4. The reaction products consisted of methyl formate, hydrogen, and carbon monoxide and there was no obvious difference between the courses of reaction on these catalysts. The changes in the composition of the gaseous product during the course of reaction on F and SR catalysts are appreciably different from that for the reaction on copper wire reported by Miyazaki and Yasumori;[12] the decay of methyl formate as the intermediate was faster than that in the reaction on copper wire.

The initial rates, r_0, of the decomposition on these catalysts were both expressed in the form as

$$r_0 = kKp/(1+Kp),$$

where p is the partial pressure of methanol, k and K are the rate constant and the adsorption constant, respectively: the linear relationships between $1/r_0$ and $1/p$ hold as shown in Fig. 5. From the dependence of ln k against $1/T$, the true activation energies of the reactions on F and SR were evaluated as 62 ± 5 and 60 ± 4 kJ mol^{-1},

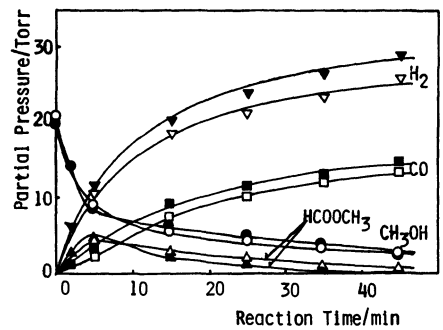

Fig. 4. Courses of methanol decomposition on F and SR catalyst.

respectively.

The reactions of methanol on CuO and Cu_2O were examined at 200 °C. In these cases, the formation of CO_2, H_2O, and H_2 was observed in the initial stage of the reaction and methyl formate was produced later. This result shows that the reduction of the oxides proceeded simultaneously with the methanol decomposition, and, the reaction became similar to that on copper wire after the completion of reduction.

The decomposition of methanol on Cr_2O_3 was not observed up to 250 °C.

Discussion

Reduction-Reoxidation Behavior. The present work revealed the details of the effect of reduction conditions upon the composition and structure of copper chromite, $CuCr_2O_4$. Namely;

i) When the catalyst was heated in hydrogen below 200 °C, the bulk composition remained unchanged (Fig. 1 and Table 1), while Cu^{II} ions in surface layer were reduced to the state of Cu^{I} as revealed by the XPS data.

ii) The data shown in Table 1 indicated that the effects of hydrogen reduction began to penetrate deeper at about 300 °C. Under such conditions, the reaction,

$$2CuCr_2O_4 \xrightarrow{H_2} Cu_2Cr_2O_4 + Cr_2O_3 + H_2O, \quad (1)$$

was considered to occur even in the bulk, and the crystallites of starting material, $CuCr_2O_4$, would became smaller. Absence of the Cr_2O_3 lines on the X-ray diffraction chart indicated that the Cr_2O_3 produced by Reaction 1 did not crystallize.

iii) On heating at 500 °C, the catalyst was further reduced to Cu and Cr_2O_3. This suggested that $Cu_2Cr_2O_4$ produced in the Reaction 1 was converted to metallic copper and Cr_2O_3,

$$Cu_2Cr_2O_4 \xrightarrow{H_2} 2Cu + Cr_2O_3 + H_2O. \quad (2)$$

The X-ray data showed that Cr_2O_3 began to crystallize under this condition. On SR catalyst, therefore, the fine crystals of metallic copper were considered to be dispersed over Cr_2O_3.

The reoxidation of the reduced sample provides us with additional information about the structure of the catalyst. When R400 was heated in 25 Torr of oxygen at 400 °C for 1 h, the bluish green sample changed to black in color. The X-ray diffraction pattern of this reoxidized sample was similar to the pattern of R400; the positions, the widths, and the intensity ratios of the diffraction lines of the former sample were almost identical with the corresponding values of the latter sample. This result suggests that reoxidation scarcely occurred in the bulk of R400 under the conditions described above. However, as shown in Fig. 2, reoxidation occurred in the sample surface even under milder conditions. In addition, Table 1 shows that the surface area of the R400 sample decreased appreciably on heating at 400 °C in oxygen. On the basis of these findings, the reduction-reoxidation processes of the present copper chromite catalyst are indicated as follows;

i) The starting material F: The catalyst is the aggregates of polycrystalline particles of $CuCr_2O_4$. Since a small amount of Cu^{I} species is contained in the surface layer of the particles, $Cu_2Cr_2O_4$ and amorphous Cr_2O_3 coexists with $CuCr_2O_4$.

ii) Reduction to R100-R200: Oxygen atoms are removed from the catalyst surface by reduction with hydrogen and Cu^{II} ions are converted into Cu^{I} ions on the surface. The Cr_2O_3 produced covers most of the catalyst surface.

iii) Reduction to R300-R400: Oxygen atoms at the grain boundaries in the polycrystalline particles are also removed; the surface area of the catalyst increases since the original polycrystalline particles are divided into smaller ones.

iv) Reoxidation: When the reduced catalyst to the stage (iii) is heated in oxygen, Cu^{I} ions are oxidized to Cu^{II} ions in the surface layer, and the polycrystalline particles are sintered, so that the surface area of the catalyst decreases again. The crystallite size of $CuCr_2O_4$ in the catalyst particle which is covered with $Cu_2Cr_2O_4$ does not change because the reoxidation occurs only in a few layers of $Cu_2Cr_2O_4$ near the surface. These processes are illustrated by Fig. 6.

As described in the preceding section, the simple oxides of copper, CuO and Cu_2O, were more sensitive to hydrogen treatments than F catalyst, and metallic copper readily formed by heating in hydrogen at 200 °C. Thus it is possible to consider than Cu^{II} ions are somewhat stabilized in the bulk of the spinel structure of $CuCr_2O_4$. The Cu^{I} ions in $Cu_2Cr_2O_4$ are also stable up to 400 °C in 50 Torr of hydrogen, whereas Cu_2O

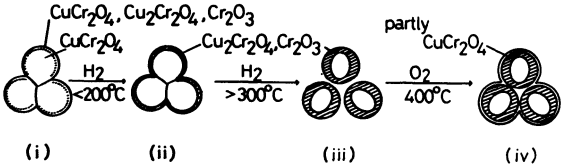

Fig. 6. Reduction-reoxidation process of $CuCr_2O_4$.

is reduced into metallic copper at 200 °C in the same pressure of hydrogen.

Cr_2O_3 formed on the catalyst surface was stable against reduction in the hydrogen treatment under conditions of the present study.

Catalytic Activities. For the decomposition of methanol, high activities were observed only on F and SR catalysts. Cu^{II} species exists only on the F catalyst. On R200—R400, the surface concentration of Cu^{I} species became quite small and methanol decomposition did not occur. These results indicate that Cu^{I} and/or Cu^{II} species are responsible for the methanol decomposition on F catalyst.

From the data of XPS intensity in Table 2, it is considered that the surfaces of R200—R400 catalysts are almost covered with amorphous Cr_2O_3. Therefore, their poor activities may be attributed to the low degree of exposure of Cu^{I} species or the absence of Cu^{II} species.

In SR catalyst, the main surface component is metallic copper; the Auger spectrum of SR catalyst indicates that the Cu^{I} species were rarely exposed on the surface. It is well known[12] that metallic copper has an activity for methanol decomposition, so it is possible to consider that metallic copper is the active component in the SR catalyst.

It has been reported by several authors that olefin hydrogenation proceeds on dehydrated chromium oxide gel,[13] and metallic copper:[14] The high activity of SR catalyst for propene hydrogenation reflects the formation of the dehydrated Cr_2O_3 and Cu^0 species on the surface.

The rate equation applied to the decomposition on these catalysts indicates that the rate determining step of the reaction is a unimolecular process on the catalyst surface. Wachs and Madix[15] reported that, in the reaction of methanol over oxygen preadsorbed Cu(110), a stable surface intermediate, CH_3O, existed on the catalyst below room temperature. By taking their results into consideration, it can be suggested that the O–H bond in methanol adsorbed on F and SR catalysts is weakened to some extent. Accordingly, the sequence of reaction on these catalysts can be represented as follows:

$$CH_3OH(g) \rightleftarrows CH_3O\cdots H(a),$$
$$CH_3O\cdots H(a) \nrightarrow H_2CO(a) + 2H(a),$$
$$2H_2CO(a) \rightleftarrows HCOOCH_3(g),$$
$$2H(a) \rightleftarrows H_2(g).$$

The results obtained for methanol decomposition show that the characteristics of the reaction on F and SR catalysts are very similar to each other, although the surface compositions and the valence states of copper are greatly different between these catalysts. The view that chromium ions act as the main active sites is excluded since the reaction was not observed on Cr_2O_3. Thus these similarities in the catalytic activities have to be attributed to the similarity in the nature of Cu^0 on Cr_2O_3 and that of Cu^{I} or Cu^{II} in F catalyst. Although the characteristics of methanol decomposition of F and SR catalysts (the rate equation and the value of real activation energy) are similar to those for the reactions on copper wire reported by Miyazaki and Yasumori,[12] the changes in the composition of the gas phase product during the course of the reaction are appreciably different. Wachs and Madix[15] reported that the ability of the copper surface to chemisorb methanol was greatly enhanced by surface oxygen. It is expected that Cu^0 on SR catalyst shows characteristics similar to that of Cu^{I} or Cu^{II} species if the oxygen atoms of Cr_2O_3 interact strongly with metallic copper under the present reaction conditions.

In order to reveal clearly the reason for the poor activities of R100-R400 as well as the mechanisms of catalyses by F and SR, it is necessary to analyze precisely the adsorbed state of reactant molecule and its behavior on the catalyst surfaces.

This study was supported by Grant-in-Aid for Special Project Research No. 56119004 from the Ministry of Education, Science and Culture.

NMR Study of Protonated Halothiophenes. I. ^{1}H NMR Study of Chlorothiophenium Ions[1)]

Yukihiro YOKOYAMA, Yukihide YAMASHITA, Kensuke TAKAHASHI,* and Tyo SONE†
Department of Industrial Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466

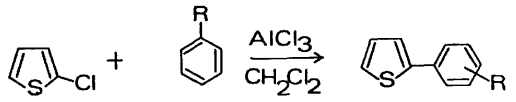
(Received November 30, 1982)

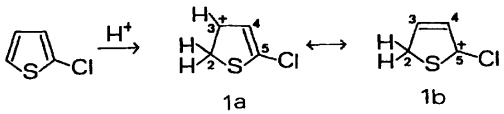
Well-resolved ^{1}H NMR signals of the cations formed from chlorothiophenes were observed in the HSO_3F or $AlCl_3$–HCl–CH_2Cl_2 system. Chlorothiophenes are protonated exclusively at the position adjacent to sulfur, either with or without substituents. The protonation of 2-chloro-5-methylthiophene occurs at the 5-position, and, in the HSO_3F system, the cation 5*H*-2-chloro-5-methylthiophenium ion thus formed undergoes an irreversible 2,5-hydrogen shift.

It was recently reported that 2-chlorothiophene reacted with active benzene derivatives such as aromatic ethers in the presence of aluminum chloride to give 2-arylthiophenes.[2)] In this reaction, the existence of a



Scheme 1.

protonated intermediate (**1**) was assumed because a proton was presumably derived from the contact of aluminum chloride with water in the moist air.



1a 1b

Scheme 2.

Studies of various kinds of arenium ions in the super acids have been energetically performed by many researchers.[3)] These studies are important and interesting in connection with the direct observation of the protonation of aromatic rings and the kinetics of arenium-ion rearrangement. However, the cations in the super acids are not necessarily the same as the species produced in ordinary cationic reaction processes, *e.g.*, in the $AlCl_3$–HCl–solvent system. In general, it is difficult to observe such species directly during the reaction process.

This study was undertaken to get proof of the formation of chlorothiophenium ions involving **1** in the $AlCl_3$–HCl–CH_2Cl_2 system as well as in the HSO_3F system, and, in addition, to obtain information about the structures of the chlorothiophenium ions. A few works have been carried out so far by Okami *et al.*[4)] and Belen'kii *et al.*[5)] aimed at the direct NMR spectroscopic observation of some protonated benzenes and thiophenes in the $AlCl_3$–HCl–solvent system, but they were concerned with compounds having active substituents such as alkyl groups. There has not yet been reported any work concerning thiophenes having inactive substituents such as halogens. Our preliminary results have previously been reported.[6)]

Experimental

All the compounds studied were synthesized by one of the present authors (T.S.). The reagents used were commercial ones and were used without further purification.

The ^{1}H NMR measurements were carried out by means of a Hitachi R-20B spectrometer at 60 MHz with a variable-temperature controller (R-202-VTC). The ^{1}H chemical shifts are referred to the signal of tetramethylsilane in a sealed Pyrex capillary inserted into each sample tube.

The cations studied were prepared by the following general procedures.

Preparation of the Cations in HCl–$AlCl_3$–Solvent Systems. In the reaction of 2-chlorothiophene with active benzene derivatives, once a small amount of the products has been formed, it can provide HCl, which in turn can prompt a further reaction. However, for the ^{1}H NMR measurements of the cation, the second material (benzene derivative) is not brought into the system; therefore, the addition of HCl gas is necessary.

A hand-made Pyrex container (*ca.* 10 ml) is filled with *ca.* 1 g of $AlCl_3$ powder. The container has an inlet for HCl gas, and the gas is blown into the container from a HCl-generator for about 5 min. The container is then immersed in a low-temperature bath (methanol–Dry Ice), which is kept at about −40 °C, and *ca.* 5 ml of solvent is introduced. Further HCl gas is then blown into the container for about 90 min or more. The solvent in the container is thus thoroughly saturated with HCl and $AlCl_3$. A small reactor, connected to an NMR sample tube, is first filled with $AlCl_3$ in an amount corresponding to the 1 : 1 mole ratio of the sample (chlorothiophene) used, and then kept at −40 °C. About 1 ml of the previously prepared solvent is then added into the reactor, and the mixture is stirred by means of a magnetic stirrer. The starting material, chlorothiophene, is then added into the reactor. A suitable reaction time is about 2—6 min depending upon the reactivity of the material. When enough time has passed, the material seems to be polymerized. When the amount of the material is in excess of that of HCl or $AlCl_3$ in the solvent, a polymerization of the material occurs. The NMR spectra of the polymerized products give broad signals. When the protonation is considered to have progressed to a desired extent, the mixture is transferred into the connected NMR tube and kept at −40 °C in the bath. Then the NMR tube is moved into another Dry Ice–methanol bath at *ca.* −80 °C, cut off from the reactor, and sealed by means of a Teflon cap. The sample is then used for the NMR measurements. When it is kept at −80 °C, the reaction seems to be frozed, showing no progress for several hours.

Preparation of the Cations in Fluorosulfonic Acid or in the Magic Acid. The magic acid used in this study contains 7.7 mol/l of SbF_5 in HSO_3F, which has been prepared by mixing the two reagents in a stream of nitrogen in a dry box. The acid is kept in several sealed Pyrex glass tubes until it is used. The

NMR samples of the cations are prepared by the following procedure. An ordinary NMR sample tube is filled with about 0.5 g of the magic acid or HSO_3F, and then kept in a Dry Ice–methanol bath at −80 °C. The starting material (*ca.* 0.05—0.10 g) is then added to the tube. The material ordinarily keeps in the solid state on the wall of the tube and does not react with the acid under these conditions. The tube is then pulled out from the bath, shaken in the air for a few seconds, and again put into the bath. The shaking is repeated several times until the solution in the tube shows a homogeneous coloration. In this instance, when the shaking in the air has continued long enough, the reaction products are too complex to be analyzed by means of the ^1H NMR. However, when the shaking time is too short, the reaction will not start at all. The coloration of the solution is a most suitable indication of the reaction progress. When the sample exhibits a suitable and characteristic coloration, it is kept in the bath at −80 °C until it is used for the NMR measurements.

Results and Discussion

The ^1H NMR data of the eight cations produced are given in Table 1. The site of the protonation is taken to be the 2-position to make clear the comparison of the species.[7]

A typical ^1H NMR spectrum of protonated 2-chlorothiophene (**1**) in HSO_3F and an $AlCl_3$–HCl–solvent system is given in Figs. 1a and 1b respectively. It is shown that the two cations produced under the two different circumstances are of the same kind, although the chemical shifts of the signals of the cation (**1**) are

a) As stated in the text, the site of the protonation is taken to be the 2-position. b) ^1H chemical shifts are referred to an external neat TMS contained in a capillary. c) Abbreviations: A, HSO_3F; B, HSO_3F–SbF_5; C, $AlCl_3$–HCl–dichloromethane; D, $AlCl_3$–HCl–1,2-dichloroethane. d) The values in parentheses are the coupling constants between protons in Hz; they are given only for the first example of each starting material. e) Not available because of the large solvent peaks.

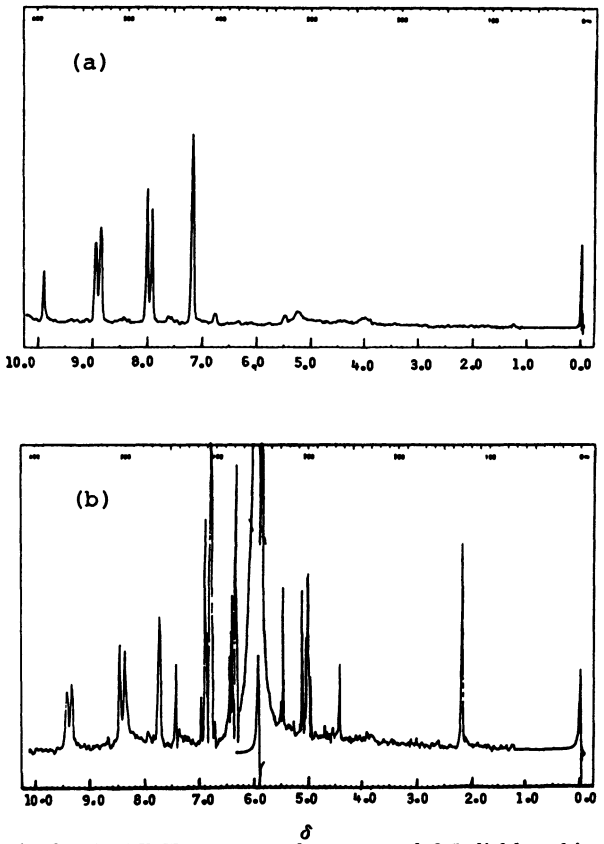

Fig. 2. ^{1}H NMR spectra of protonated 2,5-dichlorothiophene (**6**) at 60 MHz. (a) In the magic acid (see text) at −50 °C and the signal at near 10.0 ppm is due to the sideband of the acid proton, (b) in $AlCl_3$–HCl–dichloromethane at −50 °C and a signal at 2.17 ppm is unknown.

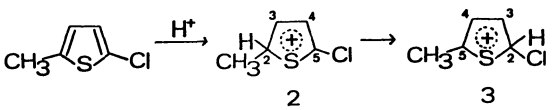
larger by about 0.5 ppm in the latter than those in the former system. The chemical shifts are quite apart from each other, so the signals can easily be assigned. The intensity ratio of the three peaks is 1 : 1 : 2 from low to high field in Fig. 1a, as would be expected for the cation (**1**). The protonation of 2-chlorothiophene at the 5-position is consistent with the ordinary concept of thiophene chemistry. The protonation of 2,3-dichlorothiophene also occurs at the 5-positioned carbon atom not carrying the substituent.

In the cases where the two α-positions have already been substituted, the protonations still occur at the α-position. Thus, the protonation of 2,5-dichlorothiophene has occurred at the chlorine-bearing α-position and produced the cation (**6**), as is shown in Fig. 2, in sharp contrast to those of chlorobenzenes, which occur at the unsubstituted ring position,[8] although Olah *et al.* have reported that the protonation of the halogen-bearing carbon can be assumed in explaining a Friedel-Crafts-type isomerization.[9]

The protonation of 2-chloro-5-methylthiophene has



Scheme 3.

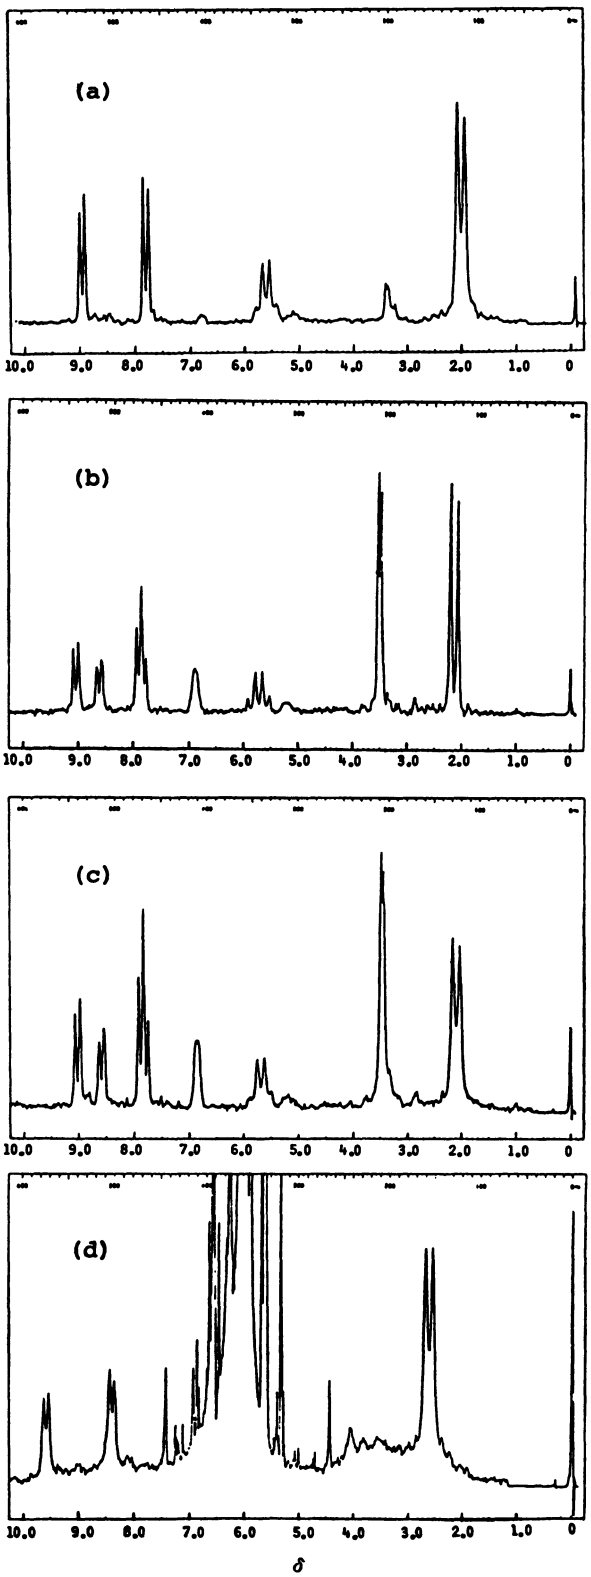


Fig. 3. ^{1}H NMR spectra of protonated 2-chloro-5-methylthiophene (**2** and **3**) at 60 MHz. (a) In HSO_3F at −70 °C, (b) at −30 °C, (c) again at −70 °C after observing the spectrum b, (d) in $AlCl_3$–HCl–dichloromethane at −70 °C.

produced two cations, (**2**) and (**3**), in HSO_3F in ratios from 3 : 1 to 10 : 1, depending on the shaking time described in the Experimental part. The signals of **2**

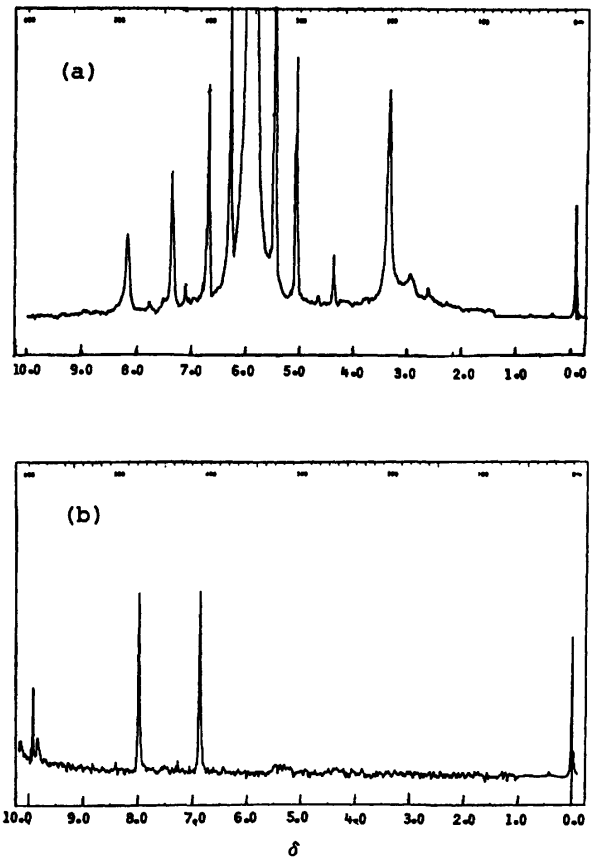

Fig. 4. ^1H NMR spectra of (a) protonated 2,5-dichloro-3-methylthiophene (**7**) in $AlCl_3$–HCl–dichloromethane at −70 °C, (b) protonated 2,3,5-trichlorothiophene (**8**) in the magic acid at −30 °C.

are considerably stronger than those of **3** at low temperatures, as is shown in Fig. 3a. When the temperature is carefully raised from −70 °C to −30 °C, the signals of **3** increase in intensity to the same extent as those of **2** (Fig. 3b). When the temperature is again lowered, the signals of **3** do not show any decrease (Fig. 3c). The conversion from **2** to **3** is not reversible. These results clearly indicate that the protonation occurs at the 5-position to give the cation (**2**), which later rearranges to the thermodynamically stable cation (**3**).[10] In the $AlCl_3$–HCl–CH_2Cl_2 system, the cation (**2**) is produced exclusively, as is shown in Fig. 3d.

The protonation of the compounds having one β- and two α-substituents occurred at the α-position neighbouring the β-substituent. This was the case with the cations (**7** and **8**), whose spectra are given in Fig. 4. In such cases, the electron-donating ability of the β-substituent seems to play a role.

The cations produced in this study are stable until the temperature reaches about −30 °C. Above −30 °C, the spectra gradually become complex, probably because of the rearrangement and/or polymerization of the molecule.

The data given in Table 1 are those obtained at the lower temperature rather than at the higher, because the proton-exchange effects are then suppressed and so are small. However, the resolution of the absorption lines is ordinarily better at a higher temperature than at a lower one.

A characteristic point of the couplings in thiophenium ions appears in the values of J_{23} and J_{34}. The J_{34} values of the thiophenium ions are larger than those of thiophenes. The J_{23} and the J_{34} of **1** are 1.3 and 5.5 Hz, while the corresponding values of 2-chlorothiophene are 6.1 and 4.0 Hz respectively. The change in these coupling constants shows the change in the system caused by protonation. It means that the distance between C_2 and C_3 increases, while that between C_3 and C_4 decreases, upon the protonation at the 2-position. The structural change in the system is clearly expressed by the change in the interproton couplings. The J_{24} of **1** is about 0.5 Hz, as estimated from the line broadening of the H_4 signal. The same is true for that of **6**. This may be compared with the J_{35} of 2-chlorothiophene (1.1 Hz).

The chemical shifts of the H_3 are always larger than those of the H_4 in thiophenium ions. Two limiting resonance structures of the ions are shown in Scheme 2. The positive charge is localized at C_3, but not at C_4, in the Scheme. This fact is consistent with the chemical-shift difference between H_3 and H_4 in Table 1.

This study provides a proof of the formation of the 2-chlorothiophenium ion (**1**) as a key intermediate in the reaction shown in Scheme 1. The cations observed here become reaction intermediates in similar acid-catalyzed reactions, one example of which is given in the case of 2,5-dichlorothiophene.[11] The study is now being extended to other halothiophenes; the synthetic use of halothiophenium ions is also under investigation.

The Ultraviolet Photoelectron Spectroscopy of Aliphatic Hydrocarbons and Tetramethylsilane in the Solid State

Kazuhiko Seki* and Hiroo Inokuchi
Institute for Molecular Science, Myodaiji, Okazaki 444
(Received January 5, 1983)

He I, Ne I, and Ar I ultraviolet photoelectron spectra were measured for solid hexane, 3-methylpentane, 2,2-dimethylbutane, neopentane, tetramethylsilane, cyclohexane, and 1-hexene deposited on a substrate at the temperature of liquid nitrogen. The spectra of all the compounds except hexane showed valence-band features. The threshold ionization potential was 7.6—8.9 eV, with a lowering of the threshold from the gas to the solid phase (polarization energy P_S) of 1.2—1.8 eV. These P_S values are in reasonable agreement with theoretical model calculations. To clarify the effect of intra- and intermolecular factors on P_S, the observed P_S values were compared with those of liquid-phase and solid-aromatic hydrocarbons. For compounds in which the bottom of the conduction band lies above the vacuum level, the polarization energy data showed that electrons with energies between these states are also emitted, possibly without any excitation of electrons to the conduction band in the bulk of the solid.

Ultraviolet photoelectron spectroscopy (UPS) is a powerful tool for studying the electronic structure and electron-transport properties of solids, including organic compounds.[1] Although extensive studies have been carried out on aromatics,[2-4] however, few results have been reported for aliphatics. We have already reported UPS studies of long-chain alkanes (n-$C_{28}H_{58}$, n-$C_{36}H_{74}$, and polyethylene),[5-9] whilst others[10] have concentrated more on small compounds containing one or two carbon atoms. We wish here to report a UPS study of aliphatic hydrocarbons containing five to seven carbon atoms, and of tetramethylsilane.

This work has two aims. One is to study the energetics of the ionized states of these solids. An important quantity obtained by UPS is the threshold ionization potential of a solid, which gives the location of the top of the occupied valence band. Together with the reported energy of the bottom of the conduction band, V_0 (relative to the vacuum level),[11,12] it gives a basic picture of the electronic structure of these solids. Further, a comparison of the threshold with that in the gas phase gives the interaction energy between the ionized molecule and the surroundings. This is mainly to be ascribed to the electric polarization of the surroundings and is called the polarization energy.[13,14] It is a fundamental quantity in discussing the ionized state of molecular solides.[14] However, the values of the polarization energies of aliphatic solids have not been experimentally determined except in a few small-molecule compounds. The experimental values observed here are discussed in comparison with theoretical-model calculations, the polarization energies in liquid phase,[15,16] or aromatic hydrocarbon solids.[3]

The second aim of this study is to obtain information as to the photoemission mechanism from aliphatic solids. In most of the solids studied here, the bottom of conduction band has been reported to lie above the vacuum level ($V_0>0$), with no bulk electronic state in-between.[11,12] Some compounds have V_0's as high as $\approx$1 eV (1 eV=0.1602 aJ). It is of interest to determine whether or not electrons which do have energies between these two levels are emitted. This problem could be elucidated by the measured photoemission threshold and the polarization energies.

There is also a question about the origin of features in the photoelectron spectra. In our previous studies of long-chain alkane solids,[6,7] the UPS spectra for 11 eV $\leq h\nu \leq$ 21 eV were dominated by conduction-band features, unlike those of most other organic solids, dominated by valence-band features.[1-4] The present study will elucidate if similar behavior is also exhibited by smaller aliphatic compounds.

Since the electronic properties of aliphatic compounds in the condensed phase are known to depend significantly on the molecular structure,[11,12,17,18] we chose to study the following species: hexane, 3-methylpentane, 2,2-dimethylbutane, neopentane, tetramethylsilane, cyclohexane, methylcyclohexane, and 1-hexene.

Experimental

The samples were commercially obtained, of the purity indicated: Hexane (99.8%, gas chromatographic standard), cyclohexane (99.7%), and tetramethylsilane (99.7%, NMR standard) from Merck; 3-methylpentane (99%), 2,2-dimethylbutane (99.8%), and methylcyclohexane (99.9%) from Tokyo Kagaku Seiki; neopentane (96.3%) and 1-hexene (99%) from Tokyo Kasei. All were further purified by vacuum distillation and the freeze-and-thaw technique in a system with a base pressure of 5×10^{-6} Pa.

The photoelectron spectra were recorded on a retarding-potential-type photoelectron spectrometer. The base pressure of the vacuum chamber was 2×10^{-8} Pa. A copper substrate 12 mm in diameter was located at the center of a nearly spherical collector coated inside with gold. The sample vapor was deposited through a variable-leak valve onto a substrate cooled to about 80 K by means of liquid nitrogen. The light source was a dc discharge lamp capable of He I (21.22 eV), Ne I (16.67 and 16.85 eV), and Ar I (11.62 and 11.83 eV) emission. For Ne I and Ar I, the mean values, 16.8 and 11.7 eV, were taken to be the incident energies respectively. As an exception, the higher energy components were used to calculate the photoemission thresholds. The energy analysis was performed by means of the ac-modulated retarding-potential technique reported previously,[2a] with a 0.2 V peak-to-peak modulation of 4 Hz. The energy resolution was 0.2—0.3 eV, determined by the Fermi edge of gold.

Although the film thickness was not measured, it was increased step-by-step until no essential change in the spectra could be observed on further deposition. Figure 1 shows such

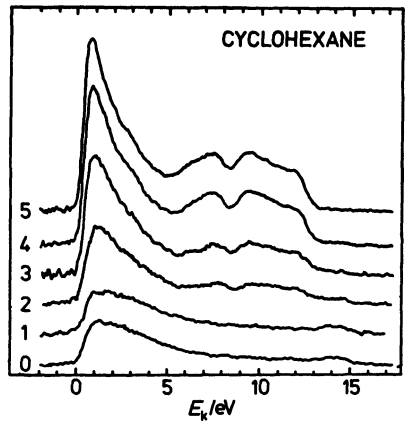

Fig. 1. He I photoelectron spectra of condensed cyclohexane against kinetic energy of electron E_k with a different degree of sample deposition. 0, copper substrate; 1 to 5, spectra showing the larger amount of condensation of cyclohexane.

a series for the He I photoelectron spectra of cyclohexane, plotted against the kinetic energy of photoelectrons E_k. The spectral profile appears to become settled at Curve 5, apart from the increasing secondary electron peak at $E_k \approx 0$ eV. A further increase in thickness resulted in the charging of the deposited sample, which could be detected as the tailing at the left-hand cutoff of the spectrum. Since 3-methylpentane, methylcyclohexane, and 1-hexene are known to form glass on rapid cooling, with their glass-transition temperatures above the temperature of liquid nitrogen,[19] they should form such glasses under the present experimental conditions. For the other compounds, it is not clear whether they form crystalline films or become amorphous.

Results and Discussion

General Aspects of the Photoelectron Spectra. Figures 2—9 (a) show the solid UPS spectra of the aliphatic

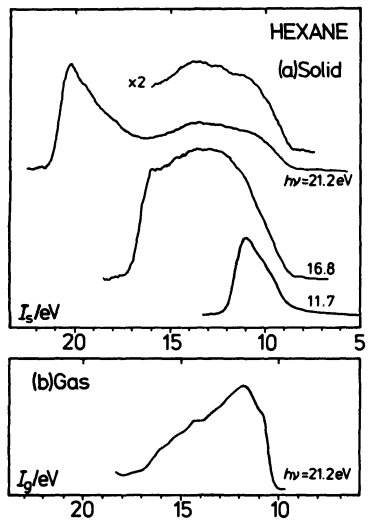

Fig. 2. Photoelectron spectra of hexane in solid (a) and gas (b) phases. Energy scales are shifted by 0.6 eV. The correspondence between the spectra of the two phases is dubious for this compound. The units of the ordinate are arbitrary and not common to the different curves (the same also in Figs. 5(a)—9(a)).

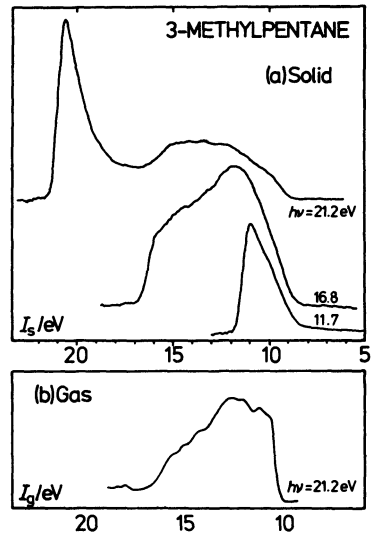

Fig. 3. Photoelectron spectra of 3-methylpentane in solid (a) and gas (b) phases. Energy scales are shifted by 0.8 eV for a good peak correspondence between the two phases.

compounds studied here. The abscissa is the solid ionization potential, I_s, relative to the vacuum level of the sample, converted from E_k as:

$$I_s = h\nu - E_k. \quad (1)$$

For all the compounds some features in the low I_s region correspond to constant values of I_s, independent of $h\nu$. which indicates that they originate from valence bands. In particular, the right-hand edge of the spectrum corresponds to the top of the valence bands, and its I_s gives the threshold ionization potential of the solid. For the sake of comparison, the gas-phase photoelectron spectra reported by other workers[20] are shown in Figs. 2—9 (b). The valence-band features of a solid corre-

spond well with the gas-spectrum features, when we make a shift between I_s and the gas-phase ionization potential I_g, as is indicated in each figure caption. Such a good correspondence shows that the photoemission from an organic solid may be regarded as the ionization of a molecule in the solid.[2,3]

If the conduction band gives rise to a band in the photoelectron spectrum its value of E_k should be independent of $h\nu$.[6,21] No such features are seen except for the secondary-electron peak at $E_k \approx 0$ eV. The features in the spectra of 1-hexene and hexane at $I_s \approx 9$ eV cannot be ascibed unambiguously to either the valence- or the conduction-band. These results show that the dominance of conduction-band features observed in the spectra of long-chain alkanes for $h\nu \leq 21.2$ eV[6,7] is not common to aliphatic compounds. Rather, they suggest that linear-chain aliphatics, maybe including hexane and 1-hexene, form a special group in terms of the photoemission from organics. Naturally, the cause of such variation in valence- or conduction-band dominance is of great interest, but here we will not discuss this point in detail, leaving it to a later publication.

The relative intensity of the secondary-electron peak at $E_k \approx 0$ eV is much larger in the He I spectrum than in the Ne I spectrum. This intensity difference can be ascribed to inelastic electron-electron (e-e) scattering, which can occur only when the photon energy exceeds the threshold energy E_1 given by:[21,22]

$$E_1 = E_g + E_x, \tag{2}$$

where E_g and E_x are the band gap and the energy of the lowest electronic excitation in the solid respectively. The values of E_1 in condensed aliphatic compounds are

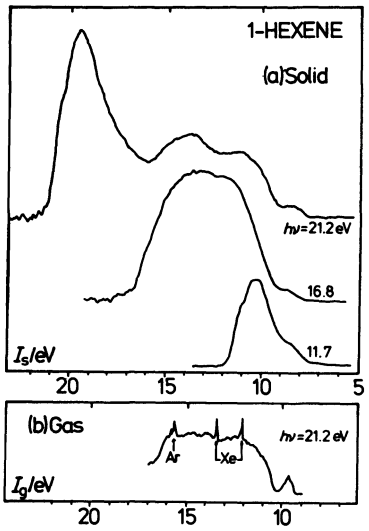

Fig. 9. Photoelectron spectra of 1-hexene in solid (a) and gas (b) phases. Energy scales are shifted by 1.0 eV for a good correspondence of the lowest ionization potential peaks between the two phases. The correspondence is dubious for the region of $I_s > 9$ eV.

estimated to be ≈16 eV (*e.g.*, for liquid hexane, E_g= 8.7 eV[16] and E_x=7.4 eV).[23] In the Ne I ($h\nu$=16.8 eV) spectra, $h\nu$ is comparable with E_1, and most of the photoexcited electrons cannot undergo e-e scattering. In the He I spectra, $h\nu$ is sufficiently large to cause appreciable e-e scattering, and hence secondary-electrons. In contrast to the present results, the smaller E_1 values of 4—8 eV in aromatics result in strong secondary-electron bands, even in the Ne I spectra.[2b]

Photoemission Threshold and Polarization Energy. Table 1 lists the values of the threshold ionization energy I_s^{th} determined as the intercept of the low I_s linear extrapolation of the spectrum with the energy axis. The values obtained from the spectra for three photon energies agreed within ±0.1 eV, including a reproducibility for several samples.

There is a problem in the determination of the I_s^{th} of amorphous solids, for the ionization potential of a molecule in the solid may depend on the arrangement of the surrounding molecules. However, the onsets in the lowest I_s region of the observed spectra are fairly distinct, which suggests that the fluctuation of this kind is minimal.

Using these values and the reported values of V_0,[11,12] which are also listed in Table 1, we can construct basic energy diagrams for these compounds. The band gap between the valence and conduction bands is 8—9 eV, which is consistent with the onset energies of the electronic absorption[23] and the photoconduction[16,24] of these compounds in the condensed phase.

The ionization potential of a molecule in the bulk of a solid is determined as the gas-phase ionization potential lowered by the polarization energy, P_s of the surroundings.[13,14] We can determine P_s from a comparison of the gas and solid-state photoelectron spectra. According to an analysis of the contribution of molecules in the bulk and at the surface, we have already noted[3] that we should compare the thresholds of these spectra, rather than the peak energies, to obtain the bulk polarization energy. That is, P_s should be determined as:

$$P_s = I_g^a - I_s^{th}, \quad (3)$$

where I_g^a is the threshold (adiabatic) ionization potential

in the gas phase. The values of I_g^a reported by other workers and the P_s values calculated by means of Eq. 3 are listed in Table 1. The maximum error in P_s is estimated to be ± 0.2 eV from those (± 0.1 eV) for both I_g^a and I_s^{th}. As has already been noted, the shift between I_s and I_s to give the best peak correspondence (relaxation shift) is shown in each caption of Figs. 2—9, which may be convenient in comparing our results with those of other workers.

Recently Hiraoka[12] estimated the P's for several of the compounds studied here. He estimated I_s^{th}, from the values of E_g and V_0 measured by an electron-transmission experiment, as:

$$I_s^{th} = E_g - V_o, \tag{4}$$

and used Eq. 3. His values are also listed in Table 1. They are, on the average, 0.4 eV larger than the present directly measured ones, but the latter are within the estimated error of his values, ± 0.4 eV for E_g and $^{+0.2}_{-0.3}$ eV for V_0.

We will discuss the observed values of the polarization energy P_s in some detail, for it is an important quantity in the energestics of the ionized state of a molecular solid.

Comparison with Theoretical Models. Two models have been reported for the theoretical estimation of the polarization energy. In the first model, by Lyons and his-coworkers,[13,25,26] the polarization energy is calculated as the sum of the interaction energy between the cation and the multipoles induced on surrounding molecules. Lyons and Mackie[25] reported $P_s = 1.7$ eV for hexane, which is in good agreement with the present experimental result. Unfortunately, no calculations are reported for the other compounds studied here.

In the second model, by Born,[27] the ion is treated as a point charge at the center of a spherical cavity, while the surrounding molecules are regarded as a continuous medium. The polarization energy is given by:

$$P_s = (e^2/2\rho)(1 - 1/\varepsilon), \tag{5}$$

where e is the electronic charge: ρ, the effective radius of the ionic cavity, and ε the optical permittivity of the medium. This model can be applied not only to crystals but also to liquids[15-17] and amorphous solids.[11,12]

In order to calculate P_s by means of this model, the values of ρ and ε are needed. We estimated ε (solid) at the temperature of liquid nitrogen in two ways (A and B), as will be described in the Appendix. For compounds whose state of aggregation is not clear, ε was evaluated for both crystalline and glassy states. The effective radius was calculated as $v^{1/3}/2$, where, $v = 1/N$ and where N is the number density of molecules, as evaluated from the density; this gave a reasonable agreement with the experimental values in the case of aromatic hydrocarbons.[3] The values of these parameters and of P_s as calculated by means of Eq. 5 are listed in Table 2.

The agreement between the experimental and calculated values is reasonable, considering the estimated error of ± 0.2 eV in the observed values. The state of aggregation or the method of estimation of ε do not affect the calculated P_s so much. Calculations using two other kinds of effective radius: (1) the van der Waals radius used in the hard-core model of the critical volume[28] and (2) the electron-molecule hard-core radius,[16,27] gave larger P_s values, with poorer agreement with the experimental values. We note that the above trends are common in molecules from spherical to linear, which have varying degrees of matching to the assumption of spherical cavity. This suggests that the anisotropy in the molecular shape of these compounds is not yet so large as to break the validity of this model.

The reasonable success of the present way of evaluating ρ tempts us to calculat the ρ of TMPD (N,N,N',N'-tetramethyl-p-phenylenediamine), which has been frequently used as a photoionizing dopant in these compounds. The crystal structure[30] gives 316 pm, which is comparable with one of the previous estimates, 324 pm,[31a] but which shows a discrepancy from the 249 and 193 pm in Refs. 31b and 11c.

In conclusion, theoretical calculations, both the Lyons model and Born's, predict reasonably accurate values for P_s. However, a very detailed discussion of the correlation between the calculated and observed values does not appear feasible at this time.

Comparison with Aromatic Hydrocarbons. Aromatic hydrocarbons form another representative group of organic compounds. The P_s values of aliphatics range from 1.2 to 1.8 eV, which is, on the average, a little smaller than the almost constant value of ≈1.7 eV for condensed aromatic hydrocarbons with planar structures.[3]

We can analyze these values in terms of molecular polarizability and molecular packing.[3] In aliphatics, ε is much smaller than those in aromatics (ε=4.8—5.9 from naphthalene to coronene). As may be seen in Eq. 5, this will make the P_s values of aliphatics smaller. However, ρ is also smaller in aliphatics than in aromatics (ρ=280—360 pm for the aromatics described above). This tends to increase the P_s. The observed P_s values should be the result of the balance between these two factors.

Such a difference in P_s preserves or even enlarges the difference between the I_g^a's of aliphatics and aromatics in going to the solid phase. Thus, the I_s^{th} values of saturated compounds exceed 8 eV and are higher than those of aromatics (*e.g.*, 7.1 eV for benzene[32]). A similar preservation also exists between saturated and unsaturated (*e.g.*, 7.1 eV for 1-hexene) aliphatic hydrocarbons.

Comparison with Polarization Energies of Liquid Phase. Recently, data have accumulated on the polarization energies of pure liquid P_l. Schmid *et al.*[15] and Casanovas *et al.*[16] measured the band gap of tetramethylsilane and some alkanes as the photoconduction thresholds. The polarization energies were calculated by means of Eqs. 4 and 3 using reported values of I_g^a and V_0. Their results are listed in Table 3, together with the $\Delta P_{sl}=P_s-P_l$ calculated with P_s in Table 1. For most compounds, P_s and P_l are rather similar, indicating that the polarization energy and the ionization threshold do not change very much in these condensed states. The small positive values of ΔP_{sl} (except for 2,2-dimethylbutane) may be understood as being due to the decrease in density, and thus in ε, at the transition from the solid to the liquid phase. The calculation of ΔP_{sl} by means of Eq. 5, using the ρ and ε of these two states, gives an almost common value of 0.2—0.3 eV. Considering the possible errors in P_l and P_s, however, it is difficult to discuss these values further.

Interpretation of the Observed Photoemission Threshold Energies. Most of the compounds studied here have been reported to have fairly large positive V_0 values (Table 1). This means that the lower boundary of the conduction band (CB) lies above the vacuum level (VL) (Fig. 10), with no bulk electronic states in between. This raises a question as to whether photoelectrons with energies between CB and VL may be emitted by direct photoemission from the valence band into the vacuum (Case I), or whether the electron must first be excited to the conduction band in the bulk of the solid, and hence may not possess an energy between the two levels

Table 3. Polarizatuion energies of liquid phase and their differences from solid phase

Compound	P_l[a] / eV	ΔP_{sl}[b] / eV
Hexane	1.61[c]	0.1
2,2-Demethylbutane	1.46[c]	−0.1

a) Polarization energy of the liquid phase. b) $\Delta P_{sl}\equiv P_s-P_l$. c) Ref. 16. The values are slightly different from theoriginal values due to the use of the I_g's in Table 1 instead of tho se used in Ref. 16. d) Ref. 15.

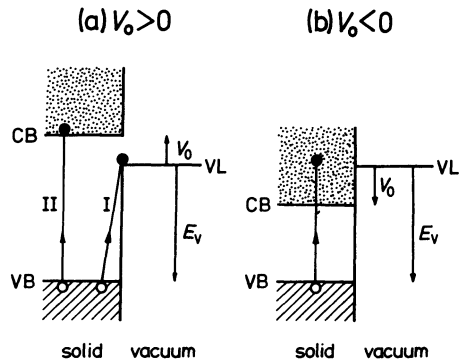

Fig. 10. Schematic energy diagram of photoemission process. VB, top, of the valence band; CB, bottom of the conduction band; VL, vacuum level; V_0, the energy of CB relative to VL; E_v, the energy differnce between VL and VB. (a) The case of $V_0>0$. I denotes the direct photoemission into vacuum and II denotes the photoexcitation process in the rigorous three-step model. (b) The case of $V_0<0$.

(Case II). The latter case was favored by Delahay[33] and by Less and Wilson[24] on the basis of a three-step photoemission model (photoexcitation in the bulk/electron transport/escape into the vacuum).[21]

An examination of the photoemission thresholds and polarization energies enables us to determine which model is most probably correct. In Case I, the experimentally observed threshold I_s^{th} corresponds to the excitation energy from the top of the valence band to the vacuum E_v (VB→VL in Fig. 10(a)), as in the case of $V_0<0$ (Fig. 10(b)). This was our assumption in the preceding part of this paper. In Case II, I_s^{th} gives the band gap $E_g=E_v+V_0$ (VB→CB in Fig. 10(a)). Since the polarization energy is defined as $I_g^a-E_v$, the "true" polarization energy in Case II, P_s^*, is:

$$P_s^* = I_g^a - (I_s^{th}-V_0), \quad (6)$$

instead of $I_g^a-I_s^{th}$ (Eq. 3). The values of P_s^* calculated using the reported V_0's are listed in Table 1.

The theoretical results of Lyons and Mackie[25] give the polarization energies for hexane and anthracene as 1.7 and 2.1 eV respectively. This indicates that the polarization energy of hexane is unlikely to exceed that of anthracene. For anthracene, the negative value of V_0[14] assures that Eq. 3 gives the polarization energy. The observed P_s=1.7 eV for anthracene[3] shows that

the idea that $P_s^* = 2.3_2$ to 2.6_8 eV for hexane is very improbable, while $P_s = 1.7$ eV in Table 1 is reasonable. Therefore, Case I applies, and I_s^{th} corresponds to the VB→VL excitation. Thus, the discussion in the preceding part of this paper is substantiated. To support this, Koch *et al.*[34] showed that $E_g > I_s^{th}$ for solid Ne and Ar, from independent measurements of E_g and I_s^{th} by means of optical spectra and photoemission respectively. This gives another example where Case I applies.

It was shown that the photoemission experiment can provide the energy of electrons relative to the vacuum level, even for organic solids with positive V_0 values. Considering that an advantage of UPS is that one can get the absolute energy of electrons relative to the vacuum level, this is an important conclusion. Furthermore, the above discussion suggests that the photoemission in aliphatic solids most probably cannot be rigorously divided into three steps (only because at present we cannot exclude the possibility of the existence of defect states between CB and VL, which may allow optical excitation and the transport of electrons in this energy range[12]).

Concluding Remarks

The ultraviolet photoelectron spectra of seven aliphatic hydrocarbons and tetramethylsilane were measured in an attempt to elucidate the energetics of the ionized state and the photoemission mechanism. Most of the spectra revealed valence-band features, but linear compounds (hexane and 1-hexene) showed some spectral features which may be due to conduction-band structures. Together with the dominance of the conduction band observed in longer-chain normal alkanes, this suggests that long linear aliphatics may form a special group in terms of photoemission from organics.

Although it has been reported that the conduction bands lie above the vacuum level, with no bulk electronic states in between, electrons with energies between the two levels are emitted. That is, we can determine the location of the valence-band features relative to the vacuum level. This ensures the usefulness of UPS as a tool for probing the electronic structures of organic solids with positive V_0 values. By virtue of this fact, the experimental values of the photoemission thresholds and the polarization energies could be obtained directly from the observed spectra.

The reasonable agreement of the observed polarization energies with the model calculations confirmed the validity of these models, and also indicated that both aliphatics and aromatics can be treated in a common theoretical frame. Further studies of other aliphatics are desired in order to confirm this point.

Although the present study gave these important pieces of general information on the electronic structure and photoemission mechanism of aliphatic solids, more studies are required in order to clarify such problems as the peculiarity of long-chain molecules and the difference between solid and liquid states. The accumulation of data on other compounds is required for the former, while the continuous examination of the solid and liquid states, using the same photoelectron spectrometer, will be useful for the latter. We have already started these kinds of studies.

The authors are grateful to Professors Edgar Heilbronner and R. A. Burgess for providing some of the gas-phase photoelectron spectra, to Professor Yoshihiko Hatano and his collaborators for the data on the density of solid tetramethylsilane, to Dr. J. Casanovas for sending preprints, to Dr. Nobuo Ueno and Professor Kenzo Hiraoka for useful information and comments, and to Dr. Naoki Sato and Professor Kosuke Shobatake for their critical reading of the manuscript.

This work was partly supported by a Grant-in-Aid for Scientific Research (No. 474210) from the Ministry of Education, Science and Culture.

Appendix

Here we will describe the two methods[11] of evaluating the optical permittivity ε of aliphatic solids at the temperature of liquid nitrogen, methods which were used for the calculation of P_s by means of Eq. 5.

One of them (Method A) applies the Clausius–Mosotti relation $(\varepsilon-1)/(\varepsilon+2)(M/d) = N_A\alpha/3$, where M is the molecular weight; d, the density; N_A, the Avogadro constant, and α, the molecular polarizability. Assuming that α is independent of the temperature, we first calculated its value using ε and d[35] for the liquid at room temperature. The value of ε was taken as the square of the refractive index n for the Na D emission lines.[35] The procedure was then reversed to obtain ε at low temperatures from the solid density.

In the other method (Method B), the value of n at a low temperture was estimated by the extrapolation of n using dn/dT (liquid), and ε was taken as equal to n^2.

Method A is applicable for both crystalline and glassy states, while B may be used only for the glassy state because of the discrete change in n at the liquid-crystal transition. For compounds whose state of aggregation was not clear, ε was evaluated for both states. The low-temperature values of d for crystalline states were calculated for the nearest temperature phase whose crystal structure data are available.[36] For tetramethylsilane, a directly measured value for d is available.[37] For glasses, d and dn/dT are available for several compounds.[19,36] For compounds with no observed data, dn/dT of similar compounds were used. The various values of ε thus obtained are listed in Table 2.

One-electron Oxidation Potentials of an NADH Model Compound and a Dimeric Rhodium(I) Complex in Irreversible Systems. A Convenient Determination from the Fluorescence Quenching by Electron Acceptors

Shunichi Fukuzumi, Katsuhiko Hironaka, Nobuaki Nishizawa, and Toshio Tanaka*
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565
(Received February 19, 1983)

A new methodology for experimental determinations of redox potentials of oxidants or reductants in both reversible and irreversible systems is presented. The Rehm-Weller free energy relationship between the activation free energy $\Delta G^{\ddagger}$ and the free energy change ΔG for the electron transfer quenching of the excited states of oxidants or reductants by a series of reductants or oxidants is converted to a linear correlation between $\Delta G^{\ddagger}-\Delta G$ and $(\Delta G^{\ddagger})^{-1}$, which can be utilized in convenient determinations of redox potentials of oxidants or reductants. This methodology is established in various reversible systems where the redox potentials of oxidants or reductants determined based on the Rehm-Weller free energy relationship agree well with those determined independently by electrochemical methods. By using this method, one-electron oxidation potentials of two quite different compounds, one is an NADH model compound, 1-benzyl-1,4-dihydronicotinamide (BNAH), and the other $[Rh_2(dicp)_4]^{2+}$ (dicp=1,3-diisocyanopropane), in MeCN have been determined as 0.60 ± 0.10 and 0.38 ± 0.10 V *vs.* SCE, respectively. The relation between the oxidation potential and the oxidation peak potential of BNAH measured by the cyclic voltammetry is discussed in the context of free energy relationships.

Electron transfer processes are receiving increased attention in oxidation-reduction reactions especially in those related to biological redox systems which play a dominant role in energy conversion and substrate metabolism in living systems.[1] Electrons are transferred in the direction of increasing redox potentials. Therefore, redox potentials of oxidants and reductants are of great importance for an understanding of electron transfer processes from reductants to oxidants. Redox potentials of a number of oxidants or reductants, however, have not been determined precisely by electrochemical methods because of the irreversible nature of these one-electron oxidation or reduction on the time scale of electrochemical measurements. In such irreversible systems, there have been no established methodology for experimental determinations of redox potentials of oxidants or reductants. In principle, however, redox potentials of oxidants or reductants in irreversible systems as well as reversible systems can be determined from the activation free energy $\Delta G^{\ddagger}$ for one-electron transfer reactions between oxidants and reductants, since $\Delta G^{\ddagger}$ is known to be expressed as a monotonous function of the redox potentials of the oxidants and reductants.[2-5] Thus, if the other parameters in the relation between $\Delta G^{\ddagger}$ and the redox potential of an oxidant (or a reductant) are somehow obtained, the redox potential can be determined from $\Delta G^{\ddagger}$. When the excited states of oxidants (or reductants) show the emissions, the $\Delta G^{\ddagger}$ values for electron transfer reactions of the excited states of the oxidants (or reductants) are readily determined experimentally from the electron transfer quenching of the excited states by a series of appropriate reductants (or oxidants).[3,6-9]

In the present study, we wish to show how free energy relationships between $\Delta G^{\ddagger}$ and ΔG obtained from the emission quenching by electron transfer reactions can be utilized in convenient determinations of redox potentials of oxidants or reductants in both reversible and irreversible systems. First, the methodology of experimental determinations of redox potentials will be established in various reversible systems reported in the literatures,[3,6-9] where the redox potentials of oxidants or reductants determined by the method based on the free energy relationships for electron transfer quenching of the excited states are compared with those obtained independently by conventional electrochemical methods. Next, the methodology thus established is applied to irreversible systems of current interest to determine one-electron oxidation potentials of 1-benzyl-1,4-dihydronicotinamide (BNAH), a model compound of NADH, which is one of the principal coenzymes for biochemical oxidation-reduction reactions[10] and also of a dimeric rhodium(I) complex $[Rh_2(dicp)_4]^{2+}$ (dicp=1,3-diisocyanopropane) which has recently merited a special attention as offering a possibility for photochemical energy storage.[11,12] The one-electron oxidation potential of BNAH in the irreversible system will be compared with the oxidation peak potential measured by the cyclic voltammetry in the context of free energy relationships for electron transfer reactions.

Experimental

Materials. 1-Benzyl-1,4-dihydronicotinamide (BNAH) and the 4-deuterio compound (BNAH-4-d_1) were prepared according to the literature,[13] and purified by recrystallization from ethanol. Preparation of $[Rh_2(dicp)_4]^{2+}$ was described previously.[14] Electron acceptors used in this study are commercially available and were purified by the standard methods.[15] Acetonitrile was purified and dehydrated with calcium hydride by the standard procedure.[15]

Fluorescence Quenching Experiments. Fluorescence measurements were performed using a Hitachi 650-10S fluorescence spectrophotometer. The excitation wavelengths of BNAH, BNAH-4-d_1, and $[Rh_2(dicp)_4]^{2+}$ were chosen so that the absorption by quenchers may be neglected (normally 360 nm for BNAH and BNAH-4-d_1 but 400 nm when acetophenone derivatives are used as quenchers, and 553 nm for $[Rh_2(dicp)_4]^{2+}$). The monitoring wavelengths were those corresponding to the maxima of the respective emission bands (BNAH and BNAH-4-d_1, 443 nm; $[Rh_2(dicp)_4]^{2+}$, 656 nm). Relative fluorescence

intensities were measured for an MeCN solution of BNAH, BNAH-4-d_1, or $[Rh_2(dicp)_4]^{2+}$ with a quencher at various concentrations. There has been no change in the shape but intensity of the fluorescence spectrum by the addition of a quencher. The Stern-Volmer relationship (Eq. 1) was obtained

$$I_f^0/I_f = 1 + K_{sv}[Q] \quad (1)$$

between the ratio of the fluorescence intensities in the absence and presence of a quencher I_f^0/I_f and the quencher concentration [Q]. The quenching rate constant k_q was determined from the Stern-Volmer constant K_{sv} and the fluorescence lifetime τ (BNAH, 0.76 ns;[16] $[Rh_2(dicp)_4]^{2+}$, 1.3 ns[17]) by using

$$k_q = K_{sv}\tau^{-1} \quad (2)$$

Eq. 2. Degassing of an MeCN solution of BNAH, BNAH-4-d_1, or $[Rh_2(dicp)_4]^{2+}$ with a quencher has been found to cause no effect on the fluorescence intensity in accordance with the quenching of the singlet excited state.

Cyclic Voltammetry. Reduction potentials of some electron acceptors were determined by the cyclic voltammetry (CV) measurements which were performed on a Hokuto Denko Model HA-301 potentiostat/galvanostat at 298 K in MeCN containing 0.1 mol dm^{-3} n-Bu_4NClO_4 as a supporting electrolyte, using a standard NaCl calomel reference electrode (SCE) or a Ag/Ag^+ reference electrode ($Ag/AgNO_3$ 0.1 mol dm^{-3}); the reduction potential *vs.* Ag/Ag^+ is 0.34 V lower than that *vs.* SCE.[18] The oxidation peak potentials of BNAH and BNAH-4-d_1 were measured by changing the sweep rate in the range 10—1000 mV s^{-1}.

Results and Discussion

Determination of Redox Potentials of Oxidants or Reductants from the Electron Transfer Quenching of the Excited States. The increase of the donor or acceptor abilities of electron donors or acceptors by the electronic excitation often results in electron transfer quenching of the excited states by the ground states of acceptors or donors.[3,6-9] Rehm and Weller[3] have formulated the following reaction scheme for the fluorescence quenching by electron transfer reactions in polar solvents such as MeCN,

$$D^* + A \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} (D^*\,A) \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} (D^+\,A^-) \xrightarrow{k_{30}} D + A, \quad (3)$$

where asterisk stands for the excited state which can be either the donor (D*) or the acceptor (A*) molecule, k_{12} and k_{21} are the diffusion and the dissociation rate constants, k_{23} and k_{32} are the rate constants of forward electron transfer for the actual electron transfer process and the back electron transfer to the excited state, respectively, and k_{30} is the rate constant of back electron transfer to the ground state. The over-all rate constant k_q of fluorescence quenching is given by Eq. 4,

$$k_q = \frac{k_{12}k_{23}}{k_{23}+k_{21}(1+k_{32}/k_{30})}, \quad (4)$$

which is reduced to Eq. 5 under the condition that the

$$k_q = \frac{k_{12}k_{23}}{k_{23}+k_{21}} \quad (5)$$

back electron transfer to the ground state is much faster than that to the excited state, *i.e.*, $k_{30} \gg k_{32}$. Then, the activation free energy ΔG^* for the actual electron transfer process k_{23}, encounter complex (D* A)→ion pair ($D^+\,A^-$), is obtained from the quenching rate constant k_q by using Eq. 6 derived from Eq. 5,

$$\Delta G^* = \frac{RT}{F}\ln\left[Z\left(\frac{1}{k_q}-\frac{1}{k_{12}}\right)\right], \quad (6)$$

where ΔG^* is given in the unit of V, Z is the collision frequency which is generally taken as 1×10^{11} mol^{-1} dm^3 s^{-1},[1,2,16] F is the Faraday constant, the k_{12} value has been reported as 2×10^{10} mol^{-1} dm^3 s^{-1} for neutral organic molecules,[3,8,9,16] and the other notations are conventional. The Rehm-Weller free energy relationship for the quenching of excited states of oxidants or reductants by electron transfer reactions (Eq. 3) has well been established as represented by Eq. 7,[3,6-9]

$$\Delta G^* = \frac{\Delta G}{2} + \left[\left(\frac{\Delta G}{2}\right)^2 + (\Delta G_0^*)^2\right]^{1/2}, \quad (7)$$

where ΔG_0^* is the intrinsic barrier representing the activation free energy for electron transfer when the driving force is zero, *i.e.*, $\Delta G^* = \Delta G_0^*$ at $\Delta G = 0$. According to the thermochemical cycle in Scheme 1, the free energy change ΔG of the actual electron transfer process, (D* A)→(D^+ A^-), is expressed in terms of the redox potentials of electron donors (E_{ox}^0) and acceptors (E_{red}^0) as shown in Eq. 8,

$$\begin{array}{ccc} & D^* + A \xrightarrow{w_r} (D^*\,A) & \\ E_{ox}^0 - E_{red}^0 - \Delta E_{0,0} \downarrow & & \downarrow \Delta G \\ & D^+ + A^- \xrightarrow{w_p} (D^+\,A^-) & \end{array}$$

Scheme 1.

$$\Delta G = E_{ox}^0 - E_{red}^0 + w_p - \Delta E_{0,0}, \quad (8)$$

where w_p is the work term required to bring the products D^+ and A^- together, w_r which is the corresponding term for the reactants has been neglected in Eq. 8,[19] and $\Delta E_{0,0}$ is the zero-zero transition energy which is obtained from the frequencies of the absorption (ν) and fluorescence (ν_f) maxima by using Eq. 9.[3,20]

$$\Delta E_{0,0} = (h\nu + h\nu_f)/2 \quad (9)$$

A simple mathematical consideration of Eq. 7 yields a linear formulation between $\Delta G^* - \Delta G$ and $(\Delta G^*)^{-1}$ (Eq. 10),

$$\Delta G^* - \Delta G = (\Delta G_0^*)^2/\Delta G^*, \quad (10)$$

which is rewritten by Eq. 11, using Eq. 8. Thus, the $E_{red}^0 - w_p$ value of the acceptor can be evaluated from

$$\Delta G^* - E_{ox}^0 + \Delta E_{0,0} = \frac{(\Delta G_0^*)^2}{\Delta G^*} - (E_{red}^0 - w_p) \quad (11)$$

the intercept of the linear correlation between $\Delta G^* - E_{ox}^0 + \Delta E_{0,0}$ and $(\Delta G^*)^{-1}$ based on Eq. 11. This methodology for determining reduction potentials of electron acceptors (oxidants) is tested for reductive quenching of fluorescent aromatic hydrocarbons Ar* (acceptors) by a series of electron donors (amines and methoxybenzenes) having various known oxidation potentials (Eq. 12).[3]

$$Ar^* + D \xrightarrow{k_q} Ar^- + D^+ \quad (12)$$

a) Used in reactions (Eq. 12) taken from Ref. 3. b) Used in reactions (Eq. 13) taken from Ref. 7. c) Used in reactions (Eqs. 15—17) taken from Refs. 8,9,6. d) This value corresponds to $E^0_{ox} + w_p - w_r$ (Ref. 25). e) N. E. Tokel-Takvoryan, R. E. Hemingway, and A. J. Bard, *J. Am. Chem. Soc.*, **95**, 6582 (1973). f) This value corresponds to $w_p - w_r$.

fluorescence quenching of some aromatic acceptors (benz[*a*]anthracene, 4-pyrenecarboxylic acid, benz[*c*]-acridine, and 3-pyrenecarboxylic acid) by a series of electron donors in MeCN are shown in Fig. 1.[21] The $E^0_{red} - w_p$ values for the acceptors obtained from the intercepts in Fig. 1 by the least squares analysis are listed in Table 1 together with the E^0_{red} values determined independently by electrochemical methods.[3] Although the linear correlations in Fig. 1 are not very impressive,[22] the $E^0_{red} - w_p$ values obtained from the intercepts in Fig. 1 agree well with the electrochemical values of E^0_{red} (Table 1) by taking into account the work terms w_p which are considered as being small negative values for the product ions of opposite charge in outer-sphere electron transfer reactions.[23]

Transition metal complexes containing bpy (2,2'-bipyridine) or phen (1,10-phenanthroline) as ligands have recently been shown to act excellent donors or acceptors in the excited state electron transfer reactions and thus the rate data for both reductive[7] and oxidative[6,8,9] quenching of excited states by electron transfer reactions are now available. The linear plots of Eq. 11 for the reductive quenching of excited states of transition metal complexes M^{n+} ($[Ru(bpy)_3]^{2+}$, $[Ir(Me_2phen)_2Cl_2]^+$, and $[Cr(bpy)_3]^{3+}$) by a series of electron donors D (aromatic amines and methoxybenzenes) in MeCN (Eq. 13)[7] are shown in Fig. 2. The $E^0_{red} - w_p$ values of

$$M^{n+*} + D \longrightarrow M^{(n-1)+} + D^+ \qquad (13)$$

M^{n+} determined from the intercepts in Fig. 2 are slightly more negative than the corresponding electrochemical values of E^0_{red} (Table 1). Therefore, the work terms w_p obtained by subtracting $E^0_{red} - w_p$ from E^0_{red} are small positive values, which agree with those expected for the product ions of the same charge type (Eq. 13)[24] in contrast with those of opposite charge (Eq. 12).

The oxidation potentials of electron donors (reductants) can also be determined from oxidative quenching of excited donors by appropriate electron acceptors (oxidants) having various reduction potentials, based on the plots of Eq. 14 ($\Delta G^* + E^0_{red} + \Delta E_{0,0}$ *vs.* $(\Delta G^*)^{-1}$) which is obtained by rearranging Eq. 11. Figure 3 depicts the plots of $\Delta G^* + E^0_{red} + \Delta E_{0,0}$ *vs.*

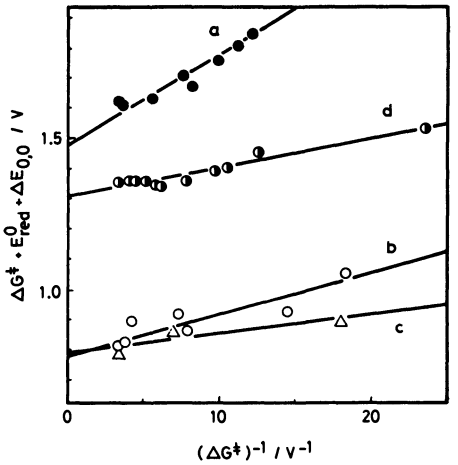

Fig. 3. Plots of Eq. 14 ($\Delta G^* + E^0_{red} + \Delta E_{0,0}$ *vs.* $(\Delta G^*)^{-1}$) for the oxidative quenching of the excited stated of electron donors ((a) $[Ru(bpy)_3]^{2+}$, (b) $[Ru(phen)_2(CN)]$, and (c) $[Ru(bpy)_2(CN)]$) by pyridinium ions (Eqs. 15 and 16; the data were taken from Refs. 8 and 9 and of (d) $[Ru(bpy)_3]^{2+}$ by nitrobenzene derivatives (Eq. 17); the data were taken from Ref. 6. Note that the intercepts correspond to the $E^0_{ox}+w_p$ values of the donors, see Eq. 14 in text.

$$\Delta G^* + E^0_{red} + \Delta E_{0,0} = \frac{(\Delta G^*_0)^2}{\Delta G^*} + E^0_{ox} + w_p, \quad (14)$$

$(\Delta G^*)^{-1}$ for the oxidative quenching of $[Ru(bpy)_3]^{2+*}$ by bipyridinium ions BP^{2+} as electron acceptors (Eq. 15),[8] that of $[RuL_2(CN)]^*$ (L=bpy and phen) by pyridinium ions P^+ (Eq. 16)[9] and also that of $[Ru(bpy)_3]^{2+*}$ by nitrobenzene derivatives (Eq. 17).[6]

$$[Ru(bpy)_3]^{2+*} + BP^{2+} \longrightarrow [Ru(bpy)_3]^{3+} + BP^+ \quad (15)$$

$$[RuL_2(CN)]^* + P^+ \longrightarrow [RuL_2(CN)]^+ + P^0 \quad (16)$$

$$[Ru(bpy)_3]^{2+*} + Ar\text{–}NO_2 \longrightarrow [Ru(bpy)_3]^{3+} + Ar\text{–}NO_2^{\cdot -} \quad (17)$$

The $E^0_{ox}+w_p-w_r$ value of $[Ru(bpy)_3]^{2+}$, the E^0_{ox} values of $[RuL_2(CN)]$, and the $E^0_{ox}+w_p$ value of $[Ru(bpy)_3]^{2+}$ determined from the respective intercepts in Fig. 3 by using Eq. 14[25] show reasonable agreement with the corresponding E^0_{ox} values determined electrochemically by taking into account the small work terms.[23]

Thus, the methodology of experimental determinations of both reduction and oxidation potentials based on the Rehm-Weller free energy relationship (Eqs. 11 and 14) for electron transfer quenching of excited states of oxidants and reductants, respectively, has well been established. The experimental errors in the determinations of redox potentials by this method are considered to be comparable with those by electrochemical methods.[26] Of course, as far as the determinations of the redox potentials in reversible systems are concerned, electrochemical methods are more suitable and convenient than the present method. It should be emphasized, however, that the method based on Eq. 11 or 14 does not depend on the systems whether oxidation of reductants (or reduction of oxidants) is reversible or irreversible, since with regard to reductants or oxidants of interest, only the kinetic data (k_q or ΔG^*) are required in Eq. 11 or 14.

A Comparison between the Rehm-Weller and the Marcus Free Energy Relationships. The Marcus free energy relationship (Eq. 18) also has frequently been used for electron transfer reactions.[2,5,8] From Eqs. 8 and 18 is obtained Eq. 19. According to Eq. 19, the intercept

$$\Delta G^* = \Delta G^*_0 \left(1+\frac{\Delta G}{4\Delta G^*_0}\right)^2 \quad (18)$$

$$(\Delta G^*)^{1/2} = (\Delta G^*_0)^{1/2} + (16\Delta G^*_0)^{-1/2}(E^0_{ox} - E^0_{red} + w_p - \Delta E_{0,0}) \quad (19)$$

to the abscissa of the linear plot between $(\Delta G^*)^{1/2}$ and E^0_{ox} or $-E^0_{red}$ gives the relation of Eq. 20. Then, the

$$E^0_{ox} - E^0_{red} + w_p - \Delta E_{0,0} + 4\Delta G^*_0 = 0 \quad (20)$$

$E^0_{red}-w_p$ or $E^0_{ox}+w_p$ value can be evaluated from Eq. 20 by using the ΔG^* value obtained from the slope $(16\Delta G^*)^{-1/2}$ of the plot between $(\Delta G^*)^{1/2}$ and E^0_{ox} or $-E^0_{red}$ (Eq. 19).

As pointed out by Indelli and Scandola,[27] however, the Marcus equation (Eq. 18) cannot be applied to electron transfer quenching of excited states because of the serious disagreement with experimental results especially in the largely exothermic region (Eq. 18 predicts the increase of ΔG^* as ΔG decreases in the region $\Delta G < -4\Delta G^*_0$, although most experimental results have shown that $\Delta G^* \to 0$ in the largely exothermic region).[6-9] Thus, the application of the Marcus equation is restricted to the region $\Delta G > -4\Delta G^*_0$.[28] In order to compare the Marcus free energy relationship (Eq. 18 or 19) with the Rehm-Weller's (Eq. 7 or 11), the data for the fluorescence quenching of 1,2-benzanthracene by electron donors (Fig. 1a) are replotted according to Eq. 19, *i.e.*, $(\Delta G^*)^{1/2}$ *vs.* E^0_{ox}, as shown by open circles in Fig. 4, where the solid line represents the plot corresponding to the Rehm-Weller equation (Eq. 7). A significant deviation from the linear relation between $(\Delta G^*)^{1/2}$ and E^0_{ox} is observed in the region $E^0_{ox} < 1.3$ V. However, the extrapolation of the linear

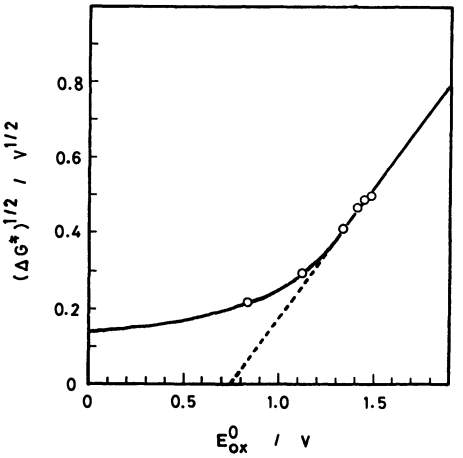

Fig. 4. A plot of $(\Delta G^*)^{1/2}$ *vs.* E^0_{ox} (Eq. 19) for the reductive quenching of 1,2-benzanthracene by electron donors; the solid line represents the plot corresponding to the Rehm-Weller equation (Eq. 7 or 11) for the data shown in Fig. 1a. For the deviation of the solid line from the linear correlation between $(\Delta G^*)^{1/2}$ and E^0_{ox} in the region $E^0_{ox} < 1.3$ V, see the discussion in text.

a) Relative to a standard NaCl calomel reference electrode (SCE), measured by cyclic voltammetry. b) Determined from k_q^h and k_q^d by using Eq. 21. c) Similar values are reported in Ref. 16.

part in the region $E^0_{ox}>1.3$ V to the abscissa gives the intercept value $E^0_{ox}=0.74$ V with the slope of 0.69, which yields essentially the same $E^0_{red}-w_p$ value (−1.92 V) of benz[*a*]anthracene using Eq. 20 as the value (−1.90 V in Table 1) obtained from the intercept to the ordinate in the plot of Eq. 11 (Fig. 1a).

In conclusion, from a purely empirical point of view, the use of the Rehm-Weller free energy relationship (Eq. 11 or 14) is preferable to that of the Marcus free energy relationship (Eq. 19), since the method based on the plot of Eq. 11 or 14 directly gives the $E^0_{red}-w_p$ or $E^0_{ox}+w_p$ value from the intercept, respectively, while that of Eq. 19 is restricted to the region $\Delta G>-4\Delta G_0^*$ (Fig. 4) and also requires both the slope and intercept in determining the $E^0_{red}-w_p$ or $E^0_{ox}+w_p$ value.

One-electron Oxidation Potentials of an NADH Model Compound and $[Rh_2(dicp)_4]^{2+}$ in Irreversible Systems. The excitation of the absorption band (350 nm) of an MeCN solution of BNAH or the 4-deuterio compound BNAH-4-d_1 results in fluorescence ($\lambda_{max}=443$ nm, $h\nu_f=2.80$ eV, and $\tau=0.76$ ns).[16] The BNAH or BNAH-4-d_1 fluorescence was quenched by electron acceptors which have various reduction potentials. The quenching rate constants k_q determined by the Stern-Volmer plots (see Experimental, Eq. 1) are listed in Table 2 together with the reduction potentials of the acceptors. The kinetic isotope effect k_H/k_D has also been determined from the ratio of the quenching rate constants of BNAH (k_q^h) and BNAH-4-d_1 (k_q^d) by using Eq. 21.[29] No isotope

$$k_H/k_D = (2k_q^d/k_q^h-1)^{-1} \quad (21)$$

effect for the fluorescence quenching of BNAH by the electron acceptors is observed (Table 2), indicating that the quenching process is one-electron transfer from BNAH* to an acceptor (Eq. 22). One-electron transfer from BNAH is known to be irreversible since $BNAH^+$

$$BNAH^* + A \xrightarrow{k_q} BNAH^+ + A^- \quad (22)$$

formed by the electron transfer reaction (Eq. 22) is unstable to undergo the disproportionation reaction (Eq. 23).[30] The ΔG^* values for the actual electron

$$2BNAH^+ \longrightarrow BNA^+ + (BNAH)H^+ \quad (23)$$

transfer process k_{23} (Eq. 3) are obtained from the k_q values in Table 2 by using Eq. 6. The zero-zero transition energy $\Delta E_{0,0}$ of BNAH and BNAH-4-d_1 is obtained as 3.17 eV from the $h\nu$ and $h\nu_f$ values (3.54 and 2.80 eV, respectively) by using Eq. 9. In order to determine the one-electron oxidation potential E^0_{ox} of BNAH and BNAH-4-d_1, the values of $\Delta G^*+E^0_{red}+\Delta E_{0,0}$ are plotted against the $(\Delta G^*)^{-1}$ values in Fig. 5a which shows the same linear correlation for BNAH and BNAH-4-d_1. Thus, the intercept in Fig. 5a gives the $E^0_{ox}+w_p$ value of BNAH and BNAH-4-d_1 as 0.50 V.

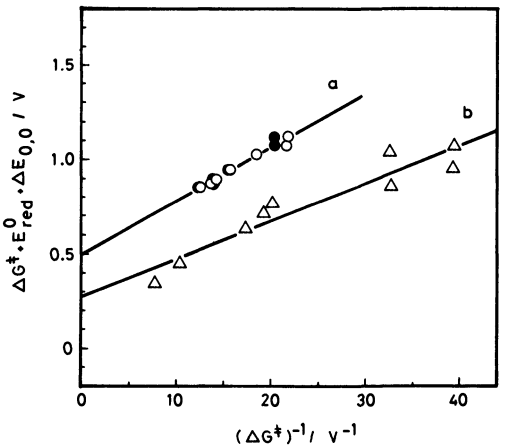

Fig. 5. Plots of $\Delta G^*+E^0_{red}+\Delta E_{0,0}$ *vs.* $(\Delta G^*)^{-1}$ (Eq. 14) for the fluorescence quenching of (a) ○ BNAH and ● BNAH-4-d_1 by the electron acceptors in Table 2 (Eq. 22) and that of (b) ◑ $[Rh_2(dicp)_4]^{2+}$ by the acceptors in Table 3 (Eq. 24). The intercepts 0.50 and 0.28 V give the $E^0_{ox}+w_p$ values of BNAH (or BNAH-4-d_1) and $[Rh_2(dicp)_4]^{2+}$, respectively, according to Eq. 14.

Similarly, the one-electron oxidation potential of $[Rh_2(dicp)_4]^{2+}$ whose one-electron oxidation also is irreversible[14] has been determined from the fluorescence quenching of $[Rh_2(dicp)_4]^{2+}$ by a series of electron acceptors A (Eq. 24). The k_q values of $[Rh_2(dicp)_4]^{2+*}$

$$[Rh_2(dicp)_4]^{2+*} + A \xrightarrow{k_q} [Rh_2(dicp)_4]^{3+} + A^- \quad (24)$$

as well as the reduction potentials of the acceptors are listed in Table 3. The $E^0_{ox}+w_p$ value of $[Rh_2(dicp)_4]^{2+}$ is obtained as 0.28 V from the intercept of the linear plot between $\Delta G^*+E^0_{red}+\Delta E_{0,0}$[31] and $(\Delta G^*)^{-1}$, as shown in Fig. 5b. Thus, the one-electron oxidation

potentials E^0_{ox} of BNAH (or BNAH-4-d_1) and $[Rh_2(dicp)_4]^{2+}$ are determined as 0.60 ± 0.1 and 0.38 ± 0.1 V, respectively, by taking into account the value −0.1 V as the work term w_p.[32)]

Thus, the oxidation potentials in irreversible systems can be determined based on the Rehm-Weller free energy relationship (Eq. 14) for the electron transfer quenching of the excited states of reductants by a series of oxidants. Although this method requires the knowledge of the emission lifetime τ of the excited states to determine the electron transfer rate constants k_q from the quenching constants K_{sv} (Eq. 2), the k_q values can be estimated from the K_{sv} values without the direct measurement of τ by assuming that the K_{sv} value which reaches a constant value with increasing E^0_{red} of oxidants is equivalent to the diffusion rate constant k_{12}.

A Comparison between the Oxidation Potential E^0_{ox} and the Oxidation Peak Potential E^p_{ox} in an Irreversible System.

In the foregoing sections, we have shown that how free energy relationships between ΔG^* and ΔG obtained from the electron transfer quenching of the excited states of oxidants or reductants can be successfully used in determining the redox potentials of the oxidants or reductants in irreversible systems as well as reversible systems. In this section, such free energy relationships are shown to be utilized also for the irreversible electrochemical oxidation of BNAH to determine the oxidation potential E^0_{ox} of BNAH from the cyclic voltammetry (CV) measurements, which is compared with the E^0_{ox} value determined from the electron transfer quenching study of the BNAH fluorescence.

The cyclic voltammogram of BNAH is illustrated in Fig. 6, which shows an anodic wave with a current maximum but no cathodic wave on the reverse scan as confirmed by changing the sweep rates in the range 10 to 1000 mV s^{-1}. The anodic oxidation of BNAH is thus irreversible, indicating that the follow-up chemical reaction (Eq. 23)[30)] is fast on the time scale of the CV measurements. The width of the anodic wave $E^p_{ox}-E^{p/2}_{ox}$ in such an irreversible system has been shown

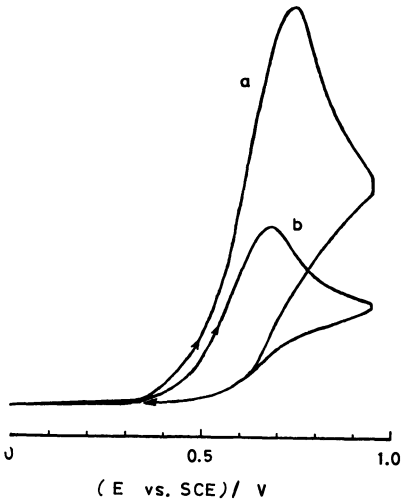

Fig. 6. Cyclic voltammograms of BNAH in MeCN containing 0.1 mol dm^{-3} n-Bu_4NClO_4 at the sweep rates of (a) 0.5 V s^{-1} and (b) 0.1 V s^{-1}.

to depend only on the transfer coefficient β according to Eq. 25.[33,34)] Then, the transfer coefficient β defined by

$$E^p_{ox} - E^{p/2}_{ox} = 1.857\,(RT/\beta F) \tag{25}$$

the tangent of the free energy relationship $\partial\Delta G^*/\partial\Delta G$ at the oxidation peak potential E^p_{ox} is obtained from the width of the anodic wave $E^p_{ox}-E^{p/2}_{ox}$ by using Eq. 26,

$$\beta = \frac{1.857\,RT}{F(E^p_{ox}-E^{p/2}_{ox})}, \tag{26}$$

which is derived from Eq. 25. The β value can be determined also from the dependence of the oxidation peak potential E^p_{ox} on the sweep rate v (V s^{-1}) by using Eq. 27,[33,34)]

$$E^p_{ox} = \frac{2.3\,RT}{2\beta F}\log v + \text{Const}, \tag{27}$$

in which the constant is given by Eq. 28,

$$\text{Const} = E^0_{ox} + \frac{2.3\,RT}{\beta F}\log\frac{2.18\,D\beta F}{k(E^0_{ox})RT}, \tag{28}$$

where $k(E^0_{ox})$ (cm s^{-1}) is the electron transfer rate constant at the oxidation potential E^0_{ox}. On the other hand, the transfer coefficient β is expressed as a function of $\Delta G(=E^0_{ox}-E)$ (Eq. 29) by differentiating the Rehm-

$$\beta = \frac{1}{2} + \frac{\Delta G}{4[(\Delta G/2)^2+(\Delta G^*_0)^2]^{1/2}} \tag{29}$$

Weller free energy relationship (Eq. 7) with respect to ΔG. From Eq. 29 is derived a relation between the oxidation potential E^0_{ox} and the oxidation peak potential E^p_{ox} (Eq. 30) when $\Delta G=E^0_{ox}-E^p_{ox}$. According to Eq. 30,

$$E^p_{ox}=E^0_{ox} + \frac{(1-2\beta)}{[\beta(1-\beta)]^{1/2}}\Delta G^*_0 \tag{30}$$

the oxidation potential E^0_{ox} can be evaluated from the intercept of the linear plot between E^p_{ox} and $(1-2\beta)/[\beta(1-\beta)]^{1/2}$. The E^p_{ox} values of BNAH obtained from the cyclic voltammograms of BNAH measured at various sweep rates are plotted against the corresponding values of $(1-2\beta)/[\beta(1-\beta)]^{1/2}$ in which β is determined by Eq. 26, as shown in Fig. 7a. The intercept of the linear correlation in Fig. 7a gives the E^0_{ox} value of BNAH as 0.57 V which agrees well with the E^0_{ox} value $0.60\pm$

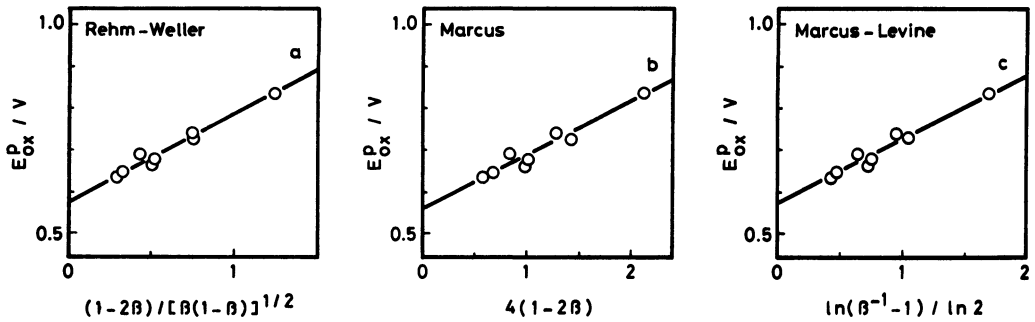

Fig. 7. The oxidation peak potential E^p_{ox} of BNAH plotted as a function of the transfer coefficient β based on (a) the Rehm-Weller (Eq. 7), (b) the Marcus (Eq. 18), and (c) the Marcus-Levine (Eq. 30) free energy relationships. See Eqs. 28, 29, and 31 in text, respectively. Note that the intercept corresponds to the E^0_{ox} value of BNAH.

0.10 V determined by the fluorescence quenching study described above. The same E^0_{ox} value of BNAH-4-d_1 was obtained from the cyclic voltammograms of BNAH-4-d_1 at various sweep rates by the plot of Eq. 30.

The other free energy relationships which are currently used also are applied to the determination of the E^0_{ox} value of BNAH from the CV measurements. One is the Marcus free energy relationship being already given by Eq. 18, from which Eq. 31 is derived. The other is

$$E^p_{ox} = E^0_{ox} + 4(1-2\beta)\Delta G_0^{\ddagger} \quad (31)$$

the Levine free energy relationship (Eq. 32)[4] which has the equivalent formulation to that derived by

$$\Delta G^{\ddagger} = \Delta G + \frac{\Delta G_0^{\ddagger}}{\ln 2} \ln\left[1+\exp\left(-\frac{\Delta G \ln 2}{\Delta G_0^{\ddagger}}\right)\right] \quad (32)$$

Marcus.[35] From Eq. 32 is derived a relation between E^p_{ox} and E^0_{ox} as well (Eq. 33). The plots according to Eqs. 31 and 33 are shown in Figs. 7b and 7c, respectively. The intercept values in Figs. 7a—c are essentially the

$$E^p_{ox} = E^0_{ox} + \frac{\Delta G_0^{\ddagger}}{\ln 2} \ln(\beta^{-1}-1) \quad (33)$$

same, and thereby the same E^0_{ox} value of BNAH is obtained irrespective of the use of different free energy relationships for electron transfer reactions (Eqs. 7, 18, and 32).

In conclusion, reliable values of redox potentials of oxidants or reductants in irreversible systems can be determined based on the free energy relationships for the electron transfer quenching of the excited states of oxidants or reductants (Eq. 11 or 14) as well as for the electrochemical electron transfer measured by cyclic voltammetry (Eqs. 30, 31, and 33).

18) C. K. Mann, *Electroanal. Chem.*, **4**, 57 (1969).

19) The work term w_r for the neutral reactants is known to be negligible (see Ref. 3).

20) The energy difference $\Delta E_{0,0}$ between the thermally equilibrated excited and ground states of the donor D or the

acceptor A is larger than the energy corresponding to the emission maximum $h\nu_f$ and smaller than the energy corresponding to the absorption maximum $h\nu$ since the absorption and emission are vertical processes.

21) The ΔG^{*} values are evaluated for the quenching rate constant k_q smaller than 1.3×10^{10} mol^{-1} dm^3 s^{-1} since the experimental errors in determining ΔG^{*} by using Eq. 6 become large when the k_q values are close to the diffusion rate constant $k_{12}=2\times10^{10}$ mol^{-1} dm^3 s^{-1}.

22) The correlation coefficients ρ of the plots in Fig. 1 are 0.995 for benz[*a*]anthracene, 0.97 for 4-pyrenecarboxylic acid, 0.87 for benz[*c*]acridine, and 0.90 for 3-pyrenecarboxylic acid.

23) The work term w_r or w_p can be estimated from Debye-Hückell theory by using the equation w (in V)$=(0.395z_Az_B/d)/(1+0.48d\mu^{1/2})$, in which z_A and z_B are the ion charges, μ is the ionic strength, and d is the distance (in Å) between the ion centers (Ref. 8). The w_p values of the product ions of opposite charge have been evaluated as -0.01——-0.08 V depending on the systems (Refs. 3, 6—8), which are the same order of magnitude as those in Table 1.

24) In the case of $[Ir(Me_2phen)_2Cl_2]^+$, however, the work term w_p is expected to be negligiblly small since the product $[Ir(Me_2phen)_2Cl_2]$ is an uncharged species.

25) In the case of the oxidative quenching of $[Ru(bpy)_3]^{2+*}$ by BP^{2+} (Eq. 15), the intercept corresponds to $E^0_{ox}+w_p-w_r$, since the work term w_r of the reactants which are charged species cannot be neglected. The work terms w_r and w_p for the reactions of $[RuL_2(CN)]^*$ (Eq. 16) may be negligibly small since both reactants and products contain uncharged species.

26) The experimental errors in the $E^0_{red}-w_p$ or $E^0_{ox}+w_p$ values determined by the present method (Table 1) are considered to be less than ±0.1 V by taking into account the small w_p values (Ref. 23).

27) M. T. Indelli and F. Scandola, *J. Am. Chem. Soc.*, **100**, 7733 (1978).

28) In the endothermic region, the application of the Marcus equation is resticted also to the region $\Delta G<4\Delta G^{*}_0$, since $\Delta G^{*}\rightarrow\Delta G$ for $\Delta G\gg4\Delta G^{*}_0$.

Electronic Relaxation Processes from Single Vibronic Levels in the $S_1(n, \pi^*)$ State of Pyridine Vapor

Kazuyoshi SUSHIDA, Masahisa FUJITA, Iwao YAMAZAKI,† and Hiroaki BABA*
Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo 060
†*Institute for Molecular Science, Myodaiji, Okazaki 444*
(Received February 24, 1983)

The rate constants of radiative decay (k_F), internal conversion (k_{IC}), and intersystem crossing (k_{ISC}) for single vibronic levels in the $S_1(n, \pi^*)$ state of pyridine-d_0 and -d_5 vapors have been determined from measured fluorescence quantum yields (Φ_F), intersystem crossing quantum yields (Φ_{ISC}), and picosecond fluorescence lifetimes. The Φ_{ISC} values are fairly constant in the region of lower excess vibrational energy (<1000 cm^{-1}), while the Φ_F values are particularly large for vibronic levels involving non-totally symmetric vibrations, ν_{16b} and ν_{10a}. The latter observation is attributed to both an increase of k_F and a decrease of k_{IC} and k_{ISC} (relative to the zero-point level) for the ν_{16b} levels ($16b^2$ and $16b^26a^1$), and to an increase of k_F for the ν_{10a} levels. The relative values of k_F are discussed using the Herzberg-Teller theory of vibronic coupling. The values of k_F for $16b^1$ and $16b^2$ are significantly larger than that for the zero-point level, though no absorption band corresponding to $16b_0^1$ can be observed. In both pyridine-d_0 and -d_5, the value of k_{IC} is as large as 1.7×10^{10} s^{-1} even for the zero-point level, which is more than twice the k_{ISC} value for the same level.

In previous papers,[1] we reported the results of experimental studies on the excitation-energy dependence of nonradiative electronic relaxation in pyridine vapor. It was shown that the fluorescence quantum yield of pyridine is almost constant in the neighborhood of the zero-point vibrational level of the $S_1(n, \pi^*)$ state and decreases rapidly as the vibrational energy in excess of the zero-point energy, ΔE, becomes higher than 800 cm^{-1}. This observation was interpreted as due to an increase in rate of the internal conversion $S_1 \rightsquigarrow S_0$. In these studies, however, on account of the extreme weakness of the fluorescence of pyridine, the bandwidth of the exciting light employed was so great (>100 cm^{-1}) that the individual vibronic bands could hardly be resolved.

In the present study, we have re-examined the fluorescence and intersystem-crossing quantum yields of pyridine-d_0 and -d_5 with a small excitation bandwidth of ≈1 cm^{-1}, using a high-resolution laser spectrophotometric system. The resulting data, along with the picosecond fluorescence lifetimes obtained using a mode-locked dye laser, have made it possible to determine precisely the rate constants for the radiative and nonradiative processes that start from single vibronic levels in the S_1 state of pyridine-d_0 and -d_5. In the absorption spectrum of pyridine, the long-wavelength tail of the $S_2 \leftarrow S_0$ absorption has a significant intensity in the $S_1 \leftarrow S_0$ absorption region. The present paper is concerned with a region of ΔE lower than 1600 cm^{-1} where the contribution of $S_2 \leftarrow S_0$ absorption is relatively small.

The vibrational analyses of the $S_1 \leftarrow S_0$ absorption spectra of pyridine-d_0 and -d_5 were made, respectively, by Sponer and Stücklen[2] and Shukla *et al.*[3] More recently, Mochizuki *et al.*[4] analyzed vibronic bands of the pyridines, and showed that the $\nu_{10a}(a_2)$ vibration induces a vibronic interaction between $S_1(^1B_1)$ and $S_2(^1B_2)$ states. The band at $\nu_{0-0}+139$ cm^{-1} of pyridine-d_0 was assigned by Jesson *et al.*[5] to an overtone of the $16b(b_1)$ mode with two quanta, *i.e.* $16b_0^2$. (Jesson *et al.* adopted a wavenumber of 138 cm^{-1} instead of 139 cm^{-1}). Mochizuki *et al.*[6] had a doubt about this assignment, because they could not observe any progression involving the ν_{16b} vibration in their single vibronic level (SVL) fluorescence spectrum from the $16b^2$ level. In the present study, attention was directed to the role of these non-totally symmetric vibrations in the electronic relaxation processes in pyridine.

Experimental

Pyridine-d_0 (Merck, Uvasol) was allowed to stand over potassium hydroxide for a few days, and was fractionally distilled under a stream of nitrogen. Pyridine-d_5 (Aldrich, Spectrograde) and biacetyl (Nakarai Chemicals, G. R.) were purified by repeated distillation under reduced pressure. Sulfur hexafluoride (SF_6, Seitetsu Chemicals, 99.65%) was used as an inert foreign gas without further purification.

Absorption spectra and excitation spectra of fluorescence or sensitized phosphorescence were measured simultaneously at room temperature with a high-resolution laser spectrophotometric system, the details of which were described in previous papers.[7] In this system, a pulsed dye laser (Molectron DL14) pumped by a nitrogen laser (Molectron UV22) is used as a light source. The dye laser is operated by the use of a mixture of Coumarin 495 and Rhodamine 6G, and the frequency is doubled by a KDP crystal to generate UV laser pulses with a repetition rate of 20 pulses/s, a spectral bandwidth of about 0.5 cm^{-1}, and a pulse duration of 3 ns. A somewhat wide spacing was taken between the successive wavelengths of the laser light, so that the overall resolution was about 1 cm^{-1} for both absorption and excitation spectra. All the emission measurements were made by the use of 35 mm square quartz cells.

For obtaining the fluorescence quantum yield (Φ_F), the fluorescence spectrum was measured and corrected for the spectral sensitivity of the emission monochromator-photomultiplier system. The absolute Φ_F value of pyridine-d_0 or -d_5 was determined for excitation at the 0–0 band of the $S_1 \leftarrow S_0$ absorption by comparing the corrected fluorescence spectrum of the pyridine with that of quinine sulfate in (1/2) M sulfuric acid (1 M = 1 mol dm^{-3}), which has a Φ_F value of 0.51.[8]

The intersystem-crossing quantum yields (Φ_{ISC}) of the pyridines were determined by means of the sensitized-biacetyl-phosphorescence method based on T–T energy transfer.[9] To a mixture of 0.5 Torr (1 Torr = 133 Pa) of pyridine-d_0 or -d_5 (donor) with 0.5 Torr of biacetyl (acceptor) was added 160

Torr of SF_6. Under such high pressure conditions, the energy transfer takes place from the thermally equilibrated T_1 levels of the donor to the isoenergetic triplet levels of the acceptor, irrespective of the initially excited singlet level of the donor. The energy transfer is followed by rapid vibrational relaxation into the thermally equilibrated triplet of biacetyl, from which the biacetyl phosphorescence is emitted. The intensity of the sensitized biacetyl phosphorescence (I_p) was measured following excitation of the donor at 0–0 band of its $S_1 \leftarrow S_0$ absorption. On the other hand, for a mixture composed of 0.5 Torr of biacetyl and 160 Torr of SF_6, the intensity of biacetyl phosphorescence (I_p^0) was measured by exciting biacetyl at 453 nm, *i.e.*, at the 0–0 band of its $S_1 \leftarrow S_0$ absorption. The Φ_{ISC} value of biacetyl is known to be unity when excitation is made at long wavelengths including 453 nm.[10] The Φ_{ISC} value of the donor can then be obtained by comparing I_p with I_p^0 after the usual corrections are made.

The pressure of the pyridines was determined from the absorption intensity, while that of biacetyl was determined by measuring the intensity of its phosphorescence excited at 453 nm; biacetyl vapor is known to give a definite phosphorescence quantum yield when it is excited at this wavelength and at a pressure higher than 1 Torr.[10]

For measuring the excitation spectra, the fluorescence was monitored through filters, UV-D35 (Toshiba) and 2,6-lutidine (25% by volume) in hexane, and the sensitized phosphorescence was monitored through a cut filter, VY-45 (Toshiba). The excitation spectra were corrected for the spectral intensity distribution of the exciting laser light and for the inner filter effect. Relative values of Φ_F and Φ_{ISC} at various excitation positions were obtained by taking the ratios of the intensities of the corrected excitation spectra to the intensities of the corresponding absorption spectra. By combining the resulting relative yields with the absolute quantum yield which had been determined, as mentioned earlier, at a particular excitation position for the fluorescence or sensitized phosphorescence, the absolute values of Φ_F and Φ_{ISC} were obtained as a function of excitation energy for pyridine-d_0 and -d_5.

The fluorescence lifetimes (τ_F) of pyridine-d_0 and -d_5 were obtained by using a synchronously-pumped, mode-locked dye laser[11] as an exciting light source. The details of the experiments have been reported elsewhere.[12]

Results

Figures 1(a) and 2(a) show, respectively, the $S_1 \leftarrow S_0$ absorption spectra of pyridine-d_0 and -d_5 in the vapor phase. Band assignments are given in the figures and also in Table 1, where FR means Fermi resonance. These assignments are the ones made by Mochizuki *et al.*[4] except for the bands involving the ν_{16b} vibration, the assignments of which are taken from a paper by Jesson *et al.*[5]

The spectrum of pyridine-d_0 consists mainly of bands that correspond to fundamentals, overtones, or combinations of two totally symmetric vibrations $\nu_{6a}(a_1)$ and $\nu_{12}(a_1)$, which in the excited state S_1 have frequencies of 542 cm^{-1} (ν_{6a}') and 995 cm^{-1} (ν_{12}'). The progression $6a_0^n$, starting with the 0–0 band ($n=0$), is seen to be most prominent. Note that the 0–0 band is located at 34769 cm^{-1}. Some other bands are observed which

a) See Figs. 1 and 2 for the absorption transitions which lead to the vibronic levels in this column. The 0–0 band for pyridine-d_0 is located at 34769 cm^{-1} and that for pyridine-d_5 at 34950 cm^{-1}. b) From Ref. 4 except for c). c) From Ref. 5.

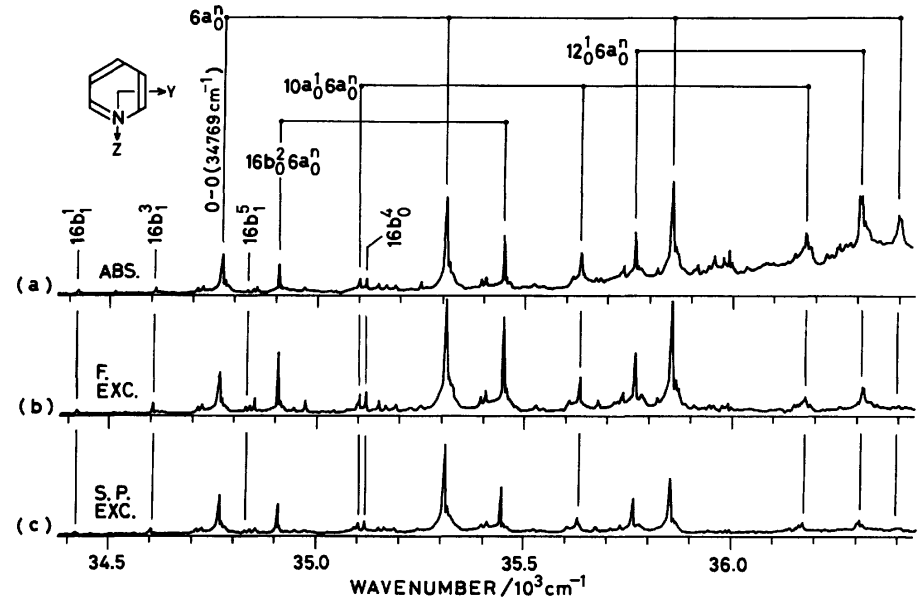

Fig. 1. (a) Absorption spectrum, (b) fluorescence excitation spectrum, and (c) sensitized biacetyl phosphorescence excitation spectrum for pyridine-d_0 vapor. The pressures of pyridine-d_0: (a) 5.4, (b) 0.5, and (c) 1.0 Torr. In the case of (c), 0.8 Torr of biacetyl and 160 Torr of SF_6 are added to the pyridine-d_0 vapor. In the notation of vibronic transitions, the superscript and subscript denote the vibrational quantum numbers in the S_1 and S_0 states, respectively.

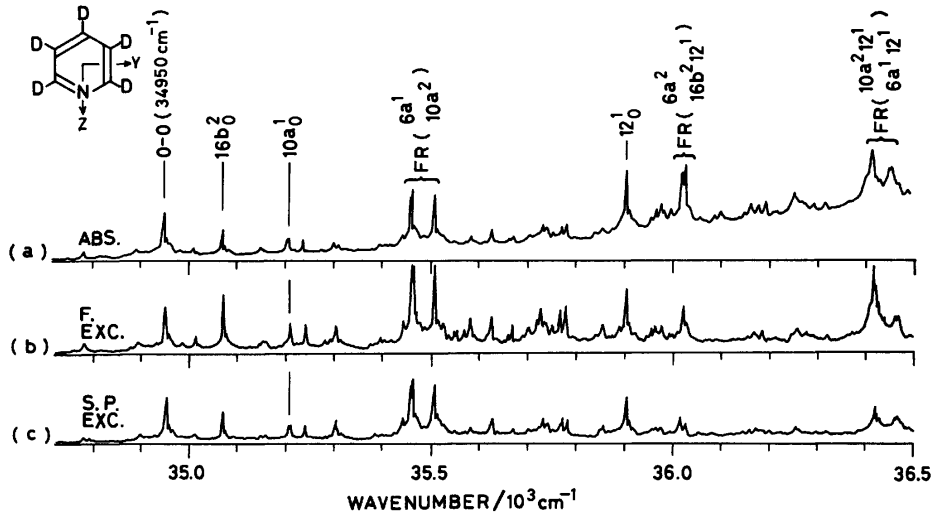

Fig. 2. (a) Absorption spectrum, (b) fluorescence excitation spectrum, and (c) sensitized biacetyl phosphorescence excitation spectrum for pyridine-d_5 vapor. The pressures of pyridine-d_5: (a) 7.6, (b) 1.8, and (c) 0.8 Torr. In the case of (c), 1.1 Torr of biacetyl and 160 Torr of SF_6 are added to the pyridine-d_5 vapor. In the notation of vibronic transitions, the superscript and subscript denote the vibrational quantum numbers in the S_1 and S_0 states, respectively.

involve non-totally symmetric vibrations, $\nu_{16b}(b_1)$ and $\nu_{10a}(a_2)$. Thus the bands at $\nu_{0-0}+139$ cm^{-1} and $\nu_{0-0}+331$ cm^{-1} can be assigned to $16b_0^2$ and $10a_0^1$, respectively. The combination band $16b_0^2 6a_0^1$ and weak hot bands $16b_1^n$ ($n=1, 3, 5$) also appear in the spectrum. A progression in ν_{6a}', denoted by $10a_0^1 6a_0^n$ in the figure, starts with the $10a_0^1$ band. On the other hand, the absorption spectrum of pyridine-d_5 does not show any regular progressions of bands. This is due mainly to the occurrence of Fermi resonance, as is seen in Fig. 2(a). The 0-0 band is located at 34950 cm^{-1} in this case.

Figures 1(b) and 1(c) show the excitation spectra of the fluorescence and sensitized biacetyl phosphorescence for pyridine-d_0, and Figs. 2(b) and 2(c) the same spectra for pyridine-d_5. Band positions in these excitation spectra agree very well with those in the corresponding absorption spectra, indicating that the observed fluorescence and sensitized phosphorescence originate from pyridine-d_0 or -d_5 itself. It was confirmed that no change in shape of the fluorescence excitation spectra occurs

upon adding the foreign gas, SF_6, up to 160 Torr. In Figs. 1 and 2, it can be seen at a glance that, so far as the lower excitation energy region is concerned, the sensitized phosphorescence excitation spectrum is similar to the absorption spectrum, but that the fluorescence excitation spectrum is substantially different from the absorption spectrum in intensity distribution. In fact, in the fluorescence excitation spectra of pyridine-d_0 and -d_5, some bands which involve the ν_{16b} mode have particularly high intensities.

The values of fluorescence quantum yields (Φ_F) and of the intersystem-crossing quantum yields (Φ_{ISC}) from various vibronic levels are shown in Table 1, and the excess vibrational energy (ΔE) dependence of Φ_F and Φ_{ISC} is illustrated in Figs. 3 and 4. These yield values were determined according to the method described in the preceding section. As is seen in Figs. 1 and 2, each of the bands is characterized by a peak. However, the peak is accompanied by a background which is due to superposition of the rotational contours of neighboring bands and, at higher frequencies, also to overlap of the tail of the $S_2 \leftarrow S_0$ absorption. In the evaluation of Φ_F and Φ_{ISC}, therefore, care was taken to eliminate the contribution of the background to the spectral intensity.[13] It is seen from Figs. 1—4 that the values of Φ_F are significantly large for levels involving the ν_{16b} mode, *i.e.*, $16b^2$ and $16b^26a^1$ of pyridine-d_0 and $16b^2$ of pyridine-d_5. The value of Φ_F for the $10a^1$ level is about 1.4 times that for the zero-point level in both molecules. In pyridine-d_0, Φ_F rapidly decreases as ΔE exceeds about 1100 cm^{-1}. In pyridine-d_5, the values of Φ_F for the Fermi resonance levels are larger than that for the zero-point level except for the level at 1082 cm^{-1}. On the other hand, the values of Φ_{ISC} for both pyridine-d_0 and -d_5 are fairly constant regardless of the nature of the vibronic level in the lower ΔE region ($<$1000 cm^{-1}). In the case of pyridine-d_0, Φ_{ISC} is found to decrease rapidly in the higher ΔE region.

The observed fluorescence lifetimes (τ_F) of pyridine-d_0 and -d_5 are summarized in Table 1. When ΔE increases, τ_F does not decrease monotonously, but varies in a characteristic way. The lifetimes for $16b^2$ and $16b^26a^1$ levels are seen to be notably long.

Discussion

Since pyridine is considered to belong to the statistical limit rather than to the intermediate case,[1,12] the experimental results described in the preceding section can be analyzed on the basis of a simple kinetic scheme. Suppose that the pyridine molecule is excited into a vibronic level v in the S_1 state. The molecule will then relax through radiative and nonradiative decay processes. The rate constant for the radiative fluorescence decay is denoted by k_F^v, and those for the $S_1 \rightsquigarrow S_0$ internal conversion and the $S_1 \rightsquigarrow T$ intersystem crossing are denoted by k_{IC}^v and k_{ISC}^v, respectively. So far as lower excitation energies are concerned, nonradiative processes other than the latter two processes may safely be neglected in the case of pyridine, because the quantum yield of the photochemical reaction in pyridine vapor is known to be negligibly low, as was described in a previous paper.[1] The quantum yield of the fluorescence (Φ_F^v) and that of the intersystem crossing (Φ_{ISC}^v) from a vibronic level v can thus be expressed as $\Phi_F^v = k_F^v/(k_F^v+k_{IC}^v+k_{ISC}^v)$ and $\Phi_{ISC}^v = k_{ISC}^v/(k_F^v+k_{IC}^v+k_{ISC}^v)$. The radiative rate constant k_F^v is given by

$$k_F^v = \Phi_F^v/\tau_F^v, \tag{1}$$

where τ_F^v represents the lifetime of the fluorescence from v. The nonradiative rate constants can be written as

$$k_{IC}^v = k_F^v(1-\Phi_F^v-\Phi_{ISC}^v)/\Phi_F^v, \tag{2}$$

$$k_{ISC}^v = k_F^v\Phi_{ISC}^v/\Phi_F^v. \tag{3}$$

On the basis of Eqs. 1—3, the rate constants k_F^v, k_{IC}^v, and k_{ISC}^v were determined from the experimental values of τ_F^v, Φ_F^v, and Φ_{ISC}^v, with the results summarized in Table 1. The relative values of the rate constants, k_F^v/k_F^0, k_{IC}^v/k_{IC}^0, and k_{ISC}^v/k_{ISC}^0, are shown in Figs. 5 and 6, the values for the zero-point level (v=0) being normalized to unity.

An increase of the quantum yield of fluorescence from an excited vibronic level will result, in general, from an increase of the radiative rate and/or a decrease of the nonradiative rate. We first consider pyridine-d_0. For

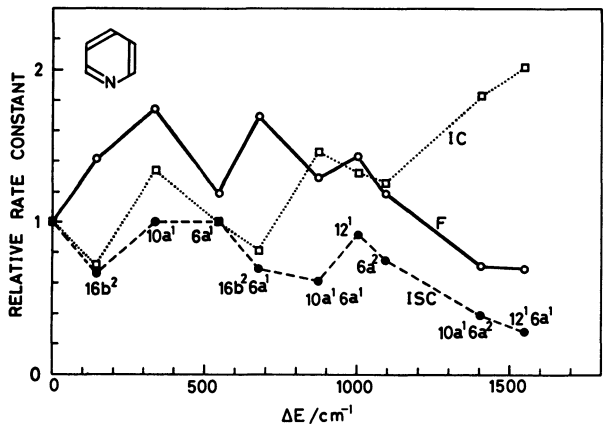

Fig. 5. Relative rate constants plotted against ΔE for pyridine-d_0: ——, k_F^v/k_F^0; ·····, k_{IC}^v/k_{IC}^0; ------, k_{ISC}^v/k_{ISC}^0.

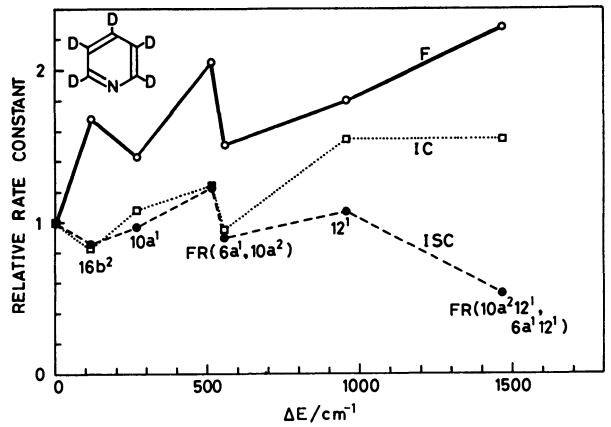

Fig. 6. Relative rate constants plotted against ΔE for pyridine-d_5: ——, k_F^v/k_F^0; ·····, k_{IC}^v/k_{IC}^0; ------, k_{ISC}^v/k_{ISC}^0.

its $16b^2$ level, k_F^v is 1.41 times as large as k_F^0, while the values of k_{IC}^v and k_{ISC}^v are about 70% of the values of k_{IC}^0 and k_{ISC}^0. These relations existing among the rate constants account for the finding that Φ_F^v is particularly large for the $16b^2$ level ($\Phi_F^v/\Phi_F^0=2.02$). The $16b^26a^1$ level is in a similar situation, as is seen from Table 1 and Fig. 5. For the $10a^1$ level, Φ_F^v is significantly larger than Φ_F^0, *i.e.*, $\Phi_F^v/\Phi_F^0=1.41$. This observation is interpreted as due solely to the fact k_F^v/k_F^0 is as large as 1.74. Note that in this case k_{IC}^v/k_{IC}^0 and k_{ISC}^v/k_{ISC}^0 are greater than or equal to unity. Inspection of the kinetic data given in Table 1 will reveal that the relatively high values of Φ_F for the $16b^2$ and $10a^1$ levels of pyridine-d_5 be explained in essentially the same manner as the corresponding values of pyridine-d_0.

Since the $S_1(^1B_1)$ state of the pyridine molecule is of an (n, π^*) type, the rate of the radiative decay from S_1 may be noticeably enhanced by the vibronic interaction. Let us first discuss vibronic levels involving the ν_{10a} vibration after the method adopted by Yamazaki, Fujita, and Baba[14] in their discussion about the radiative rate constant of the fluorescence of pyrazine. According to these authors, the ratio of the radiative rate constant for the $10a^j$ level to that for the zero-point level, *i.e.*, $k_F(10a^j)/k_F^0$ is given by

$$\frac{k_F(10a^j)}{k_F^0}=\frac{1+(\zeta/u)(2j+1)}{1+\zeta/u}, \tag{4}$$

where ζ is the ratio of the intensity of the $10a_0^1$ absorption band to that of the 0–0 absorption, and u is a numerical factor introduced to allow for the difference between $\nu_{10a'}$ and $\nu_{10a''}$, which denote the frequencies of ν_{10a} in S_1 and S_0, respectively. Equation 4 is based on the Herzberg-Teller theory of vibronic coupling. From the integrated intensities for the rotational contours of the $10a_0^1$ and 0–0 absorption bands, ζ is determined to be 0.28 for pyridine-d_0 and 0.24 for pyridine-d_5. There is a great difference between $\nu_{10a'}$ and $\nu_{10a''}$. In fact, $\nu_{10a'}=331\ cm^{-1}$ and $\nu_{10a''}=886\ cm^{-1}$ for pyridine-d_0, while $\nu_{10a'}=253\ cm^{-1}$ and $\nu_{10a''}=690\ cm^{-1}$ for pyridine-d_5. By the use of these frequency values, the numerical factor u is calculated to be 0.30 for pyridine-d_0 and 0.29 for pyridine-d_5. These data lead to the results that $k_F(10a^1)/k_F^0=1.97$ and 1.91 for pyridine-d_0 and -d_5, respectively. The corresponding experimental values are 1.74 and 1.43, so that in either case the calculated value is higher than the experimental. However, in view of the fact that no allowance has been made for the mixing of vibrational modes due to the Duschinskii effect, which is likely to occur between ν_{10a} and ν_{16a} in pyridine,[6] as well as for the anharmonicity of the ν_{10a} vibration,[4] it may be said that the theoretical results obtained from Eq. 4 account, to a good extent, for the experimental data on the radiative rate constants.

As is seen in Table 1, the ν_{16b} vibration, the out-of-plane "boat" vibration, seems to have an effect on k_F which is similar to the one observed for the ν_{10a} vibration. In the case of ν_{16b}, however, if an equation analogous to Eq. 4 is used, $k_F(16b^j)/k_F^0$ is estimated to be unity regardless of j. The reason for this is that the ratio ζ between the intensities of $16b_0^1$ and 0–0 absorption bands is zero, because no absorption band can be observed which is to be assigned to $16b_0^1$. In contrast to the above theoretical estimation, the experimental values of k_F for both $16b^1$ and $16b^2$ levels are significantly larger than k_F^0, as is seen from Table 1.

Mochizuki *et al.*[6] recently reported that the SVL fluorescence spectrum from "the $16b^2$ level" of pyridine-d_0 or -d_5 is essentially the same as the corresponding fluorescence spectrum from the zero-point level except for a relative shift by $139\ cm^{-1}$ in pyridine-d_0 and by $118\ cm^{-1}$ in pyridine-d_5, and that no fluorescence band is observed which is to be related to the ν_{16b} vibration. Accordingly, they pointed out that one cannot decide whether the absorption band at $\nu_{0-0}+139\ cm^{-1}$ (or $\nu_{0-0}+118\ cm^{-1}$) should be assigned as a cold band like $16b_0^2$ or as a hot band of an unknown vibration. In a later report, on the basis of the absorption spectrum measured in a supersonic cold beam, these authors showed that the band in question must be regarded as a cold one.[15] To sum up it may be said that the assignments involving the ν_{16b} vibration, given by Jesson *et al.*[5] for some absorption bands at lower frequencies of pyridine-d_0 and -d_5, are considered to be reasonable, but that the spectral or kinetic properties associated with these bands appear to be unusual.

Another point to be noted is that the values of k_F for some vibronic levels involving totally symmetric vibra-

tions 6a and 12 are observed to be larger than k_F^0. At present, we are not in a position to give an adequate explanation for the above observation. It is possible, however, that a higher energy singlet state having the same symmetry as S_1 may be vibronically coupled to S_1 through mode 6a or 12 to enhance the rate of the radiative decay from the vibronic levels in question.

The Φ_{ISC} value of pyridine vapor is obviously smaller than unity even for the zero-point level and decreases with increasing ΔE, in marked contrast to pyrazine and pyrimidine vapors whose Φ_{ISC} values are known to be close to unity over a wide range of ΔE.[14] This is due to the fact that in pyridine k_{IC} is more than twice as large as k_{ISC} even at the zero-point level, whereas in pyrazine and pyrimidine k_{IC} is much smaller than k_{ISC}. The anomalously large k_{IC} value in pyridine, which is responsible for the extreme weakness of its fluorescence, suggests that there should be a strong vibronic coupling between $S_1(n, \pi^*)$ and S_0. The detailed mechanism of such a coupling, however, remains to be elucidated.

Crystal Structure of Adenine-1-(2-Carboxyethyl)uracil (1 : 1) Complex. A Model for Interactions of Amino Acid Side Chains with Nucleic Acid Base Pair

Shigeo FUJITA, Akio TAKENAKA, and Yoshio SASADA*

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received March 15, 1983)

As a model for protein-nucleic acid interactions, crystals of the title complex were prepared from a water-ethanol (1 : 1) solution containing equimolar amounts of adenine and 1-(2-carboxyethyl)uracil. The space group is $P2_1/c$ with the unit cell dimensions of $a=12.567(1)$, $b=13.358(1)$, $c=8.032(1)$ Å and $\beta=93.28(1)°$. The crystal structure was determined by X-ray analysis. The final R value was 0.053. The adenine and uracil moieties form a reversed Hoogsteen base pair in which N(7) and N(6) of adenine are hydrogen-bonded with N(3) and O(2) of uracil, respectively. The carboxyl group is dissociated and hydrogen-bonded to the protonated N(1) of adenine in the adjacent base pair at a distance of 2.542(3) Å. It is suggested that the protonation of adenine–uracil reversed Hoogsteen base pair could occur to make the base pair more stable, and the dissociated carboxyl group may be hydrogen-bonded to it in the protein–nucleic acid interactions.

Protein–nucleic acid interactions are essential for gene expression and its regulation.[1] Recently, the three-dimensional structures of cro repressor,[2] λ repressor[3] and catabolite gene activator protein[4] were determined by the X-ray method, and a binding model of cro repressor to its operator site on DNA was constructed by adjusting the structure so as to make hydrogen bonds, assuming the two-fold symmetry.[5] This model suggests that the hydrogen bonds between the nucleotide bases and the amino acid side chains must be the leading part of the specific protein–nucleic acid interactions. For understanding of the molecular basis of recognition between the two kinds of macromolecules, it is important to know the hydrogen bonds between their components. There should be some elementary patterns of hydrogen bonding with different degree of preference or stability, and their suitable combination would give a specificity of the interactions.

Protein crystallography has shown that the atoms located at the protein–protein or protein–substrate interface are packed as close as those in crystals of small molecules.[6] It may be expected that the recognition between different biomolecules are performed in a circumstance similar to crystalline field and the suitable model crystals give us information at atomic level for interpreting the specificity. By X-ray analyses of model crystals in which both the components coexist, we have been studying the elementary binding patterns between nucleotide bases and amino acid side chains.[7–14] We have found the three different binding patterns between adenine and carboxyl group: a carboxyl group is (i) hydrogen-bonded to N(3),[10] (ii) doubly hydrogen-bonded to N(6) and N(7),[15] and (iii) dissociated and doubly hydrogen-bonded to N(6) and protonated N(1).[11] In combination with uracil, a carboxyl group is hydrogen-bonded to O(2)[12] or doubly hydrogen-bonded to N(3) and O(4).[16] Thus, a carboxyl group interacts with both adenine and uracil in the binary model systems. What preference is displayed by a carboxyl group if both adenine and uracil bases are present? We have prepared model crystals that contain these components and revealed the binding geometry by the X-ray method.

Experimental and Structure Determination

1-(2-Carboxyethyl)uracil was prepared from uracil and β-propiolactone, according to Kondo *et al.*[17] The titration curve of 1-(2-carboxyethyl)uracil (0.01 mol dm^{-3}) with NaOH (0.008 mol dm^{-3}) was recorded using Toshiba-Beckman pH meter, and the value of pK_a was evaluated to be 4.1 from the curve. Colorless plate crystals were obtained by slow evaporation of a water–ethanol (1 : 1) solution containing equimolar amounts of adenine and 1-(2-carboxyethyl)uracil. The syste-

TABLE 1. FRACTIONAL COORDINATES AND ISOTROPIC TEMPERATURE FACTORS

The B values accompanied with < > are the equivalent isotropic temperature factors calculated from anisotropic thermal parameters using the equation $B=8\pi^2(U_1+U_2+U_3)/3$, where U_1, U_2, and U_3 are principal components of mean square displacement matrix U. Values in < > are anisotropicity defined by $(\sum(B-8\pi^2U_i)^2/3)^{1/2}$ and those in ( ) are e.s.d.'s; they refer to last decimal places.

matic absence of reflections showed the space group to be $P2_1/c$. The density was measured by the flotation method in hexane and carbon tetrachloride mixture.

A crystal, $0.5\times0.4\times0.1$ mm^3 in size, was used for data collection on a Rigaku four-circle diffractometer with Ni-filtered Cu $K\alpha$ radiation ($\lambda=1.5418$ Å). Accurate unit cell dimensions were derived from 2θ values of 80 high-angle reflections. The crystal data are as follows: $C_5H_5N_5\cdot C_7H_8N_2O_4$ F.W. 319.3, monoclinic, space group $P2_1/c$, $a=12.567(1)$, $b=13.358(1)$, $c=8.032(1)$ Å, $\beta=93.28(1)°$, $Z=4$, $D_m=1.57$ g cm^{-3}, and $D_c=1.575$ g cm^{-3}.

Intensities were measured in the $\omega/2\theta$ scan mode with a scan width of $2.6°(2\theta)$ plus α_1—α_2 divergence and a scan speed of $4°(2\theta)$ min^{-1}. Five reference reflections monitored showed no significant intensity deterioration. Correction was not made for absorption effect. Of 2087 independent reflections within the range $2°<2\theta<125°$, 154 weak reflections below background were considered zero-reflections. The structure was solved by the direct method and its parameters were refined by the full-matrix least-squares method. The weighting scheme and the treatment of the zero-reflections were the same as those in Ref. 11. The value of q and $F_{\rm lim}$ were taken as 2.99×10^{-5} and 1.108, respectively. All the hydrogen atoms were found on a difference map and included in the refinement. The R value was 0.053 for 1914 reflections with $F_o>3\sigma$; the maximum shift in atomic parameters was 0.3σ in the last cycle. The final atomic parameters are listed in Table 1.[18] The atomic scattering factors were taken from Ref. 19.

Results and Discussion

Molecular Structure. The carboxyl group in 1-(2-carboxyethyl)uracil is dissociated and a proton acceptor is N(1′) of adenine, as confirmed by the difference synthesis.

Bond lengths and angles are shown in Fig. 1. The dimensions of the carboxyl group are typical of carboxylate ion. The pyrimidine ring is planar within 0.015 Å. The bond lengths and angles are similar to those found in 1-(2-carboxyethyl)uracil.[12] Closer examination shows, however, that the C(2)–N(3) bond is slightly shortened and the C(2)–O(2) bond is lengthened. These changes indicate the increase of the contribution from the quinonoidal form, accompanied by the polarization at H(3)–N(3)–C(2)–O(2). The polarization must be induced by the hydrogen bonds with the adenine monocation. The methylene chain is extended, contrary to the folded form found in 1-(2-carboxyethyl)uracil.[12]

As compared with the neutral adenine, the N(1′)–C(6′) bond is lengthened, the C(6′)–N(1′)–C(2′) bond angle is expanded and the C(5′)–C(6′)–N(1′) and N(1′)–C(2′)–N(3′) bond angles are contracted. Such changes are typical of adenine monocation protonated at N(1′).[20–24] The six-membered ring is ruffled, as usually observed in the purine ring.[25]

Hydrogen Bond in Crystal. As shown in Figs. 2 and 3, the uracil moiety and the adeninium cation form a reversed Hoogsteen base pair[26] through the two hydrogen bonds N(3)–H···N(7′) (2.842(3) Å for N···N) and N(6′)–H···O(2) (2.951(3) Å for N···O). The geometries of both the hydrogen bonds are similar to those of the reversed Hoogsteen base pair without protonation, found in the complexes of 9-ethyladenine: 1-methyl-5-bromouracil[27] and adenosine: 5-bromouridine.[28] The

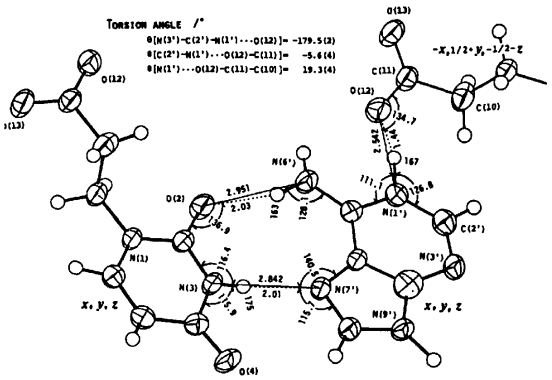

Fig. 2. A projective view of binding mode of the carboxyl group to the adenine–uracil base pair with hydrogen bond distances (l/Å) and angles (ϕ/°). E.s.d.'s are 0.003 Å and 0.2°, respectively, for distances and angles involving nonhydrogen atoms. The corresponding values involving hydrogen atoms are 0.03 Å and 2°, respectively.

two ring systems are nearly coplanar with a dihedral angle of 5.0(1)° between their respective least-squares planes; similar values are reported for the other reversed Hoogsteen base pairs.[27–28]

The carboxyl group interacts with the protonated N(1′) of adenine through the strong N(1′)–H···O(12) hydrogen bond; the N···O distance is 2.542(3) Å and the torsion angles, θ[N(3′)–C(2′)–N(1′)···O(12)], θ[C(2′)–N(1′)···O(12)–C(11)], and θ[N(1′)···O(12)–C(11)

a) The other hydrogen bonds found in the present crystal are shown in Fig.2. b) Symmetry codes: (i) $-x$, $1/2+y$, $-1/2-z$; (ii) x, $1+y$, z.

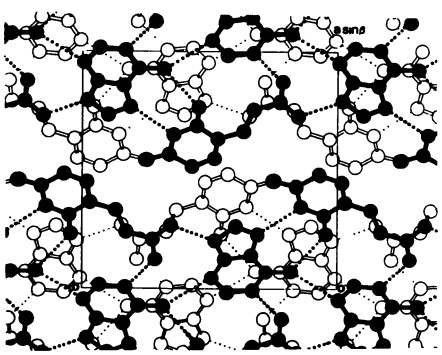

Fig. 3. Crystal structure of adenine: 1-(2-carboxyethyl)-uracil (1 : 1) complex, projected along the c axis. The broken lines indicate the hydrogen bonds.

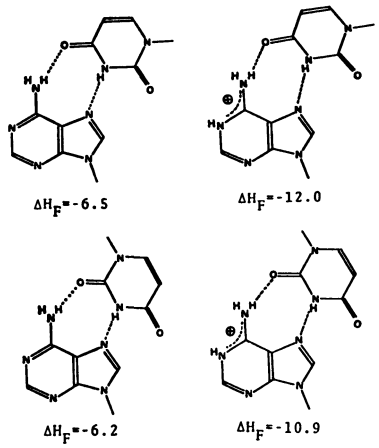

Fig. 4. Formation energies (ΔH_F/kcal mol^{-1}) of four types of adenine–uracil base pairs calculated with the CNDO/2 method.

C(10)] are −179.5(2), −5.6(4), and 19.3(4)°, respectively. The other oxygen atom O(13) is hydrogen-bonded to N(9′) at a distance of 2.646(3) Å. These two hydrogen bonds are very short compared with normal N–H···O hydrogen bonds. Between adeninium cations related by 2_1 screw, the N(6′)–H···N(3′) hydrogen bond is formed; the distance of 2.972(4) Å is normal, but this hydrogen bond deviates to some extent from linearity, the N(6′)–H···N(3′) being 145(3)°. The O(4) atom of uracil moiety does not participate in hydrogen bonding and surrounded by the hydrophobic groups. The O(4) atom points to the hydrogen atom of C(6) at $1-x$, $1/2+y$, $1/2-z$ at a distance of 3.357(3) Å for O···C. The base pairs related by 2_1 screw around $x=0$ and $z=1/4$ form a ribbon along the b axis. The detailed hydrogen bond distances and angles are given in Fig. 2 or Table 2.

Hydrogen Bonding between Carboxyl Group and Adenine–Uracil Base Pair. The present crystal structure suggests that the proton transfer from the carboxyl group to N(1) of adenine, accompanied by hydrogen bonding between them, makes the reversed Hoogsteen base pair more stable. This is confirmed by a CNDO/2 calculation[29)] of the formation energies; it is obvious from Fig. 4 that the protonation at N(1) stabilizes by about 5 kcal mol^{-1} both the reversed and normal Hoogsteen base pair.** It is plausible that the base pair to which a suitable proton donor is close may be protonated in a hydrophobic conditions. But such stabilization may be unlikely for the Watson-Crick base pair because of the small pK_a value for N(7) or N(3) of adenine (pK_a<1). If the protonation is compelled, it would occur at N(1) of adenine (pK_a=4.25) to lead a break-down of Watson-Crick base pair.[30)]

The dissociation constant, as an indication, of 1-(2-carboxyethyl)uracil (pK_a=4.1) is comparable to those of the acidic side chains of amino-acid derivatives and peptides,[31)] which shows that the chemical behavior of the carboxyl group of model compound is similar to that of the acidic side chains of protein. Therefore, one could expect that the interaction between the carboxylate ion and the charged reversed Hoogsteen base pair found in the present model crystal is also realized in a living system and takes some part in recognition of the special type of base pair by protein side chains.

As mentioned in the previous section, the specificity in protein–nucleic acid interactions would arise from the suitable combinations of preferred hydrogen bonds between their components which are supported by the three-dimensional structure of macromolecule. It is important to examine if the hydrogen bonding found in the present model crystal could be applied to the binding of the amino acid side chain with bases in a particular secondary or tertiary structure of nucleic acid.

The Hoogsteen base pair commonly exists between U8 and A14 residues in t-RNA for which, it is known,

** 1 cal=4.186 J.

aminoacylsynthetase,[32] elongation factor Tu,[33] ethidium bromide[34] and Mg^{2+} ion[35] can be accessible. Based on the geometry of the present hydrogen bond, model fitting of the dissociated carboxyl group into the t-RNA^{phe} molecule[36] was tried by interactive computer graphics. The carboxyl group is close to the G20 residue which does not form a pair with other bases. X-Ray studies have shown that this residue, located at the surface of the molecule, is mobile even in crystalline state.[37] If the guanine moiety of G20 is rotated by 60° around its glycosidic bond (the resulting χ^{CN} of 51.2° is within the range reported for purine nucleosides and nucleotides[38]), there is no abnormal contacts between atoms. Therefore, the present binding could be justified as one of possibilities of the extention from the model crystal structure to the protein-nucleic acid interactions.

Recently, it has been reported that the carbamoyl group is also hydrogen-bonded to N(1) of adenine in the normal Hoogsteen base pair between adenine and thymine in the crystalline complex of 9-(2-carbamoylethyl)adenine:1-methylthymine.[14] So, N(1) of adenine may be a preferential binding site in the normal and reversed Hoogsteen pairs.

The present work was supported in part by a Grant-in-Aid for Scientific Research No. 57380026 from the Ministry of Education, Science and Culture, and Kawakami Foundation, to which the authors' thanks are due. A part of calculation was carried out on a HITAC M200 at the Computer Center of the Institute for Molecular Science.

Pressure-Volume-Temperature Relations and Isotropic-nematic Phase Transitions for 4-(*trans*-4-Pentylcyclohexyl)benzonitrile

Hajime Ichimura, Toshiaki Shirakawa,* Taneki Tokuda, and Tsutomu Seimiya
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158
(Received April 7, 1983)

Pressure-volume isotherms of 4-(*trans*-4-pentylcyclohexyl)benzonitrile were directly measured by means of piston-cylinder method at various temperatures. From the relation of the molar volume and the transition temperature which was determined by its clearing point, the parameter $\partial \ln T_c/\partial \ln V_c$, was found to assume a value of -5.24, which should be closely related with the intermolecular potential energy. The value of this parameter increased correlatively with the alkyl chain length in the homologous series of 4-(*trans*-4-alkylcyclohexyl)benzonitriles.

The liquid crystal molecules generally have a long and thin rod-like structure. The straight-chain hydrocarbon molecule also has a similar linear structure, however, it never shows liquid crystalline behavior. The characteristic difference between them lies in the flexibility of the linear structure. The flexibility of the straight-chain hydrocarbon molecule is dustributed uniformly over an entire molecule, while an ordinary liquid crystal molecule is roughly regarded to consist of two characteristic parts. One is a flexible part such as chain structure and the other is a rigid core part such as aromatic ring group. Such morphological classification of liquid crystal molecule is well known in the practical application field, whereas it has still been unsuccessful in phase transition theory to take the characteristic chemical structure into account.

Several phase transition theories have hitherto been proposed to explicate the nematic-isotropic phase transition. The intermolecular potential function assumed in those theories is roughly divided into the contributions of two parts, one is the orientation dependent part and the other is the volume dependent part. The volume dependent part determines the type of interaction which is dominant in the nematic-isotropic phase transition. From the intermolecular potential function thus derived, the clearing temperature is expressed as a function of the volume at clearing point:

$$T_c \propto V_c^{-\gamma}. \quad (1)$$

The exponent γ in Eq. 1 differs by the type of interaction assumed in the theory. Equation 1 may be transformed into the following expression:

$$\gamma = -\frac{\partial \ln T_c}{\partial \ln V_c}. \quad (2)$$

In Maier-Saupe theory,[1] dispersion force is assumed as the intermolecular force, in which the value γ is calculated to be 2, while in Pople-Karasz theory,[2] γ become 4 where they assumed repulsive force. It is clear in Eq. 2 that the value γ can be determined from a series of *P-V-T* measurements for liquid crystalline substances from which the actual interaction operating among the liquid crystal molecules may be analyzed.

In this study, *P-V-T* relations were measured for 4-(*trans*-4-pentylcyclohexyl)benzonitrile, hereafter refered as 5PCH. The volume dependent part of the intermolecular potential energy was also discussed.

Experimental

5PCH of 99% purity (Merck and Co., Inc.) was used as obtained without further purification. Density of this sample was measured by Lipkin-Devison type pycnometer. *P-V-T* relations were measured by using a piston-cylinder apparatus shown in Fig. 1. Variation of the pressure was detected by a manganin pressure gauge mounted in the cylinder. The degree of compression of the sample was estimated by a differential transformer attached to one end of a piston. Both the analog output of the differential transformer and that of the manganin pressure gage were acquisited to a microcomputer after the proper amplification and digital conversion. The microcomputer also served to control an oil pressurizing pump to compress the sample at a predetermined sequence by monitoring these signals. The volume of the cylinder was about 10 cm^3. The details of the present computer-controlled apparatus for *P-V-T* measurement will appear elsewhere.[3] The error of measurements of pressures and volumes were with ± 0.03 MPa and $\pm 0.002\%$, respectively. The piston-cylinder apparatus was kept in air bath which was thermocontrolled within ± 0.01 K.

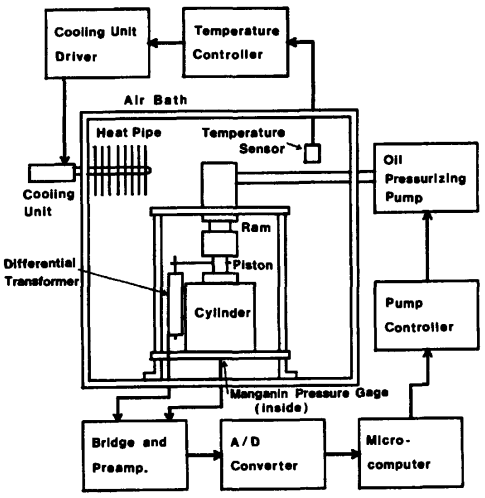

Fig. 1. The schematic diagram for the *P-V-T* measurement apparatus.

Results and Discussion

In Fig. 2, the density of 5PCH at atmospheric pressure is plotted as a function of temperature. The clearing temperature is read to be 327.59 ± 0.08 K from the

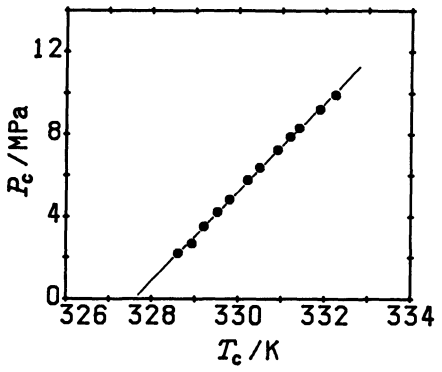

Fig. 4. The transition pressure *vs.* temperature for 5PCH.

figure. Transition occurs sharply within the temperature range of about 0.2 K. Figure 3 shows the series of pressure-volume isotherms for 5PCH in the vicinity of a clearing point at various temperatures. The plots are approximately linear in the isotropic side, and slightly curved in the nematic side. Drastic volume change at the transition is clearly observed. The molar volume at a clearing point decreased as temperature increased. From these isotherms, the pressure at a clearing point is obtained and plotted in Fig. 4 as a function of temperature. The plots show almost linear relation with a slope of 2.09 ± 0.02 MPa/K. The clearing temperature at atmospheric pressure is estimated by extrapolation to be 327.55 ± 0.03 K. This value agrees well with that obtained by the density measurement shown in Fig. 2. Figure 5 shows a full logarithmic plot of the temperature and the molar volume relation at a clearing point. The slope of this curve, $\partial \ln T_c/\partial \ln V_c$, is estimated to be -5.24 ± 0.09.

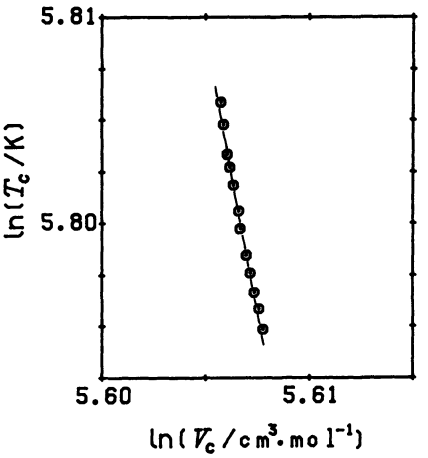

Fig. 5. The transition temperature *vs.* molar volume for 5PCH.

According to Maier-Saupe theory,[1] the intermolecular potential energy is expressed as follows:

$$U = -\frac{A}{2V^2}\cdot S\cdot(3\cos^2\theta - 1), \tag{3}$$

where V is the molar volume, A is the constant which is independent of pressure, volume and temperature, θ is the angle the long axis of molecule forms with the uniaxial direction of medium, and S is an order parameter. At the transition point, following well-known equation is obtained:

$$T_c = \frac{A}{4.541\, kV_c^2}. \tag{4}$$

Equation 4 indicates that the transition temperature is inversely proportional to the square of molar volume at the transition point. The value of γ as calculated from Eqs. 2 and 4 is found to be 2. This value does not agree with our experimentally observed value.

Pople and Karasz have also proposed a theory[2] which is an extension of Lennard-Jones and Devonshire model of melting. They assumed the anisotropic intermolecular potential energy to be expressed by

$$W = W_0\left(\frac{V_0}{V}\right)^4, \tag{5}$$

where W_0 and V_0 are constants. The transition temperature is expressed in their theory as follows:

$$T_c = \frac{zW(2S-1)}{2k\ln\dfrac{S}{1-S}}, \tag{6}$$

where z is the coordination number of a given molecule and S is the order parameter at the transition. The substitution of Eq. 5 in Eq. 6 leads to the relation in

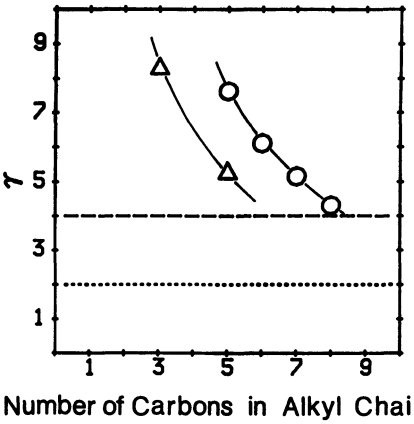

Fig. 6. The value γ *vs.* carbon number in alkyl chain. —○—: Data for CB series, —△—: data for PCH series, ·····: Maier-Saupe model, ------: Pople-Karasz model.

which the transition temperature is inversely proportional to the fourth power of the molar volume at the transition point, which means that γ assumes the value 4. This value is much closer to ours than that calculated after Maier-Saupe theory. Hence, our observation seems to indicate that the repulsive interaction should have a dominant contribution to the nematic-isotropic transition. Some liquid crystals, however, show rather big γ value,[5,6] which do not agree with Pople-Karasz theory.

It was also found in the recent study[5] that the value γ decreases with increasing alkyl chain length for homologous series of 4′-alkyl-4-cyanobiphenyls (abbreviated as CB series). The value γ is plotted against the carbon number of alkyl chain for CB series and PCH series in Fig. 6,[4-6] and compared to above-mentioned values theoretically predicted. The dotted and the dashed horizontal lines each represents the expected relation by the Maier-Saupe and the Pople-Karasz theories, respectively. These lines show constant γ values which are independent of carbon number. The value γ for PCH series varies in a similar manner as that for CB series.

There have been several attempts in the theories to take into account the molecular shape factor to interpret the properties of the nematic-isotropic phase transition. The typical one may be represented by scaled particle theory.[7] Savithramma and Madhusudana have extended the Andrews method of deriving thermodynamic properties of an assembled particles, and compared their results with those obtained on the basis of scaled particle theory.[8] The common feature of both theories is the assumption that molecules are good regarded as rigid spherocylinders. Their calculations showed that the value γ assumes the value close to 4 for a spherocylinders having particular length to breadth ratio. This value seems to be in reasonably good agreement with the experimental data for 4,4′-azoxydianisole.[9] Their results, however, contrary to ours show that the value γ becomes exceedingly greater as the length to breadth ratio of molecule increases. Our experimental data indicates that the value γ becomes smaller as the molecule lengthens. They assumed the shape of molecule to be the spherocylinder. This is the obvious reason why their theoretical calculation showed inverse tendency against the experimental data, because it will not be favorable to assume rigid rod for the actual liquid crystal molecule.

As mentioned earlier, a liquid crystal molecule generally considered to be made up of a core part and a chain part. In homologous series of a compound PCH we have chosen, the core part of molecule is the same: For example, each molecule has a cyclohexylbenzonitrile core shown below. For the core parts are the same, the

variation of γ in a homologous series may be attributed to the difference in the alkyl chain parts. An alkyl chain has a conformational freedom, because it is made of linear framework of C–C single bonds. As the length of a chain increases, the conformational freedom increases. Therefore, decrease of γ in Fig. 6 may be caused by the increased flexibility of alkyl chain part. It should be noted next that the difference in the values γ between 5CB and 5PCH may be rendered to the structural difference of their core parts. The core part of CB series is made of a biphenyl structure. The core part of PCH series includes cyclohexane ring. The conformational freedom for the core of CB series should be lower than that of PCH. The value γ for 5CB is 7.62,[5] while that for 5PCH is 5.24, the difference is comparable to that between 5CB and 6CB, and is attributed to the change of flexibility between benzene ring and cyclohexane ring. Perrin and Bergès reported lately that the flexibility of the core is comparable to that of the alkyl chain.[10]

Though the evaluation of the effect of flexibility on liquid crystal formation still needs further analysis, it is clear that the value γ is closely related to the conformational character of liquid crystal molecule: Especially, the flexibility of alkyl chain part and that of core part where it plays an important role in the nematic-isotropic phase transition.

(Received October 30, 1982)

The crystal and molecular structure of tetrakis{(isopropylthio)acetato}bis(quinoline)dicopper(II) (**1**), bis(dibenzylamine)bis{(ethylthio)acetato}copper(II) (**2**), and bis{(isopropylthio)acetato}tris(isoquinoline)copper(II) (**3**) were determined by the X-ray diffraction method. The final R values obtained are 0.041, 0.055, and 0.078 for **1**, **2**, and **3** respectively. **1** is green in color and is orthorhombic with the space group Pcab. It has a dimer structure similar to that of the copper(II) acetate hydrate, where four (alkylthio)acetate liagnds bridge both copper(II) atoms. **2** is violet in color and is monoclinic with the space group A2/a. It has a square-palnar geometry, and no atoms are coordinated to the copper(II) atom from the axial direction, probably because of the steric effect of the large dibenzylamine molecules. **3** is blue in color and is triclinic with the space group P$\bar{1}$. It has potentially a hepta-coordinate geometry, where one nitrogen atom and two oxygen atoms ligate from the axial direction of the CuN_2O_2 plane.

(Alkylthio)acetic acids are interesting ligands, as they have a carboxyl group as well as a sulfide sulfur atom which can be coordinated to a metal atom. In the cases of cobalt(II) or copper(II) (alkylthio)acetate dihydrates, the ligand is bidentate, forming a five-membered chelate ring by the coordination of its oxygen and sulfur atoms.[2-4)] On the other hand, in the anhydrous cobalt(II) (propylthio)acetate hexamer, it was found that the ligands bridge the metal atoms; half of them bridge two cobalt atoms by both of the carboxyl oxygen atoms, while the other half bridge three cobalt atoms with both of carboxyl oxygen and the sulfide sulfur atoms.[5)]

This time, the authors planned the synthesis of the anhydrous copper(II) (alkylthio)acetate. However, the dehydration of the hydrated copper(II) (alkylthio)acetates by the azeotropic method, *i.e.*, evaporating the benzene–alcohol solution to dryness as in the cases of cobalt(II) or nickel(II) salts, was not successful; the copper(II) salts were destroyed during the process. On the other hand, when quinoline or some such kind of amine was added to the solution before the evaporation process, the water in the complex was completely replaced by the amine, and their mono-, bis-, and tris-(amine) adducts were obtained without decomposing the (alkylthio)acetate ligand. They are easily soluble in nonpolar solvents such as benzene, and they are stable in air. Each of them has a characteristic color; *i.e.*, the mono(amine) adducts are green; the bis(amine) adducts, violet, and the tris(amine) adducts, blue. The absorption coefficients of their benzene solution (containing excess of amine) are rather high (about 150—200 $cm^{-1}\,mol^{-1}\,dm^3$) compared with those of the common copper(II) salts. Therefore, it seems that it would be interesting to clarify their geometries around the copper(II) atom, and so we began to study their structures by means of the X-ray diffraction technique.

Experimental

Synthesis of Tetrakis{(isopropylthio)acetato}bis(quinoline)dicopper(II) (1) and the Related Mono(amine) Adduct Dimers. The ligand, (isopropylthio)acetic acid, was obtained by a condensation reaction between 2-bromopropane and mercaptoacetic acid (Larsson's method).[6)] The copper(II) (isopropylthio)acetate dihydrate was obtained according to the method described in early papers.[7)] (The other ligands and the starting copper(II) salts were obtained similarly.) The hydrated copper(II) salt (violet isomer) (0.55 g, 1.5 mmol) and quinoline (0.40 g, 3.1 mmol) were boiled with about 10 cm^3 of benzene for several minutes, and then cooled. Then the supernatant fluid was separated into another open vessel; the water in the hydrate remained on the wall of the original vessel. About 10 cm^3 of petroleum benzine was then added, and the mixture was left standing for several hours. The deposited crystals were filtered off, washed with a small portion of benzene–petroleum ether mixture (1 : 1=v/v), and dried in a vacuum desiccator (yield, 0.47 g, 68%). They were purified by reprecipitation: the product was dissolved into benzene containing an excess of quinoline, and the solution in an open vessel was left standing in petroleum benzine vapor (in a desiccator) for several days to obtain the crystals.

The other mono(amine) adduct dimers with the formula of $[Cu_2(RSCH_2CO_2)_4(amine)_2]$ (where R=CH_3, C_2H_5, or $(CH_3)_2CH$, and amine=quinoline, isoquinoline, or pyridine) were obtained similarly; their yields were comparable to that of **1**.

Synthesis of Bis(dibenzylamine)bis{(ethylthio)acetato}copper(II) (2). Diaquabis{(ethylthio)acetato}copper(II) (0.50 g, 1.5 mmol) and dibenzylamine (1.2 g, 6.0 mmol) were boiled in 5 cm^3 of benzene, and they dissolved. The supernatant fluid was mixed with 5 cm^3 of petroleum benzine in a beaker, after which the mixture was left standing overnight in petroleum benzine vapor (in a desiccator). A deep violet product was thus precipitated (yield, 0.73 g, 70%). It was purified by the reprecipitation process (see the process for **1**). The same type of adducts were similarly obtained using (methylthio)- or (isopropylthio)acetate of copper(II) in place of the (ethylthio)-acetate mentioned above.

Synthesis of Bis{(isopropylthio)acetato}bis(isoquinoline)copper(II). Bis{(isopropylthio)acetato}copper(II) dihydrate (violet isomer) (0.55 g, 1.5 mmol) and isoquinoline (0.40 g, 3.1 mmol), were dissolved into about 5 cm^3 of a benzene–ligroine mixture (1 : 1=v/v) by heating them. To the supernatant fluid, about 15 cm^3 of ligroine was then added. After the mixture had been left standing for several hours, a violet precipitate was deposited; the precipitate was filtered off and washed with

a) 1 BM$=9.274078(36)\times10^{-24}$ J T^{-1}.
** Mono (amine) adducts are shown by the experimental formula.

ligroine (yield 0.50 g, 57%). When isoquinoline is present in a large excess, and when the volume ratio of benzene to ligroine of the mixed solvent is high, only the blue tris(isoquinoline) adduct was obtained. On the other hand, when the amount of added isoquinoline was less than twice that of the starting copper(II) salt in mol/mol, only the green mono(isoquinoline) adduct was obtained. No bis(amine) adduct was obtained by using quinoline in place of isoquinoline.

Synthesis of Bis{(isopropylthio)acetato}tris(isoquinoline)copper(II) (3). Bis{(isopropylthio)acetato}copper(II) (violet isomer) (0.55 g, 1.5 mmol) and isoquinoline (1.0 g, 7.8 mmol) were boiled with 5 cm^3 of benzene, and they dissolved. The supernatant fluid was mixed with 8 cm^3 of ligroine, after which the mixture was left standing for several hours until blue crystals were precipitated (yield, 0.7 g, 65%). The crude product was recrystallized from toluene–ligroine (1 : 1.5=v/v) containing about 2 mol dm^{-3} of isoquinoline.

The same type of complexes were also obtained using (methylthio)- or (ethylthio)acetato of copper(II) and/or pyridine in place of the starting materials mentioned above, but the pyridine adducts were unstable and they lost pyridine even when they were washed with petroleum benzine, changing into green mono(amine) adduct dimers. Even when the blue pyridine adduct crystals obtained without washing were kept in a bottle at room temperature, they decomposed within several days. The same type of adducts were not obtained using quinoline.

Their analyses and the magnetic moments as measured by means of Gouy balance at room temperature (15—20 °C), are shown in Table 1. The yields of the complexes were between 55 and 68%.

Single-crystal X-Ray Analyses. The crystals used were in the shape of parallelepipeds (**1**, $0.3\times0.3\times0.2$ mm^3; **2**, $0.3\times0.3\times0.3$ mm^3; and **3**, $0.3\times0.3\times0.4$ mm^3). All their edges were ground off, though they were not shaped into perfect spheres. The reflections within the range of $2\theta<55°$ were collected on a Philips PW 1100 automated four-circle diffractometer with graphite monochromated Mo $K\alpha$ radiation (0.7107 Å), the θ-2θ scan technique being employed (scan speed 4° min^{-1}; scan width, $1.0+0.3\tan\theta$°). The intensities were corrected for Lorentz and polarization factors, but no correction was made for absorption and extinction. As a representative bis(amine) adduct, bis(dibenzylamine)bis{(isopropylthio)acetato}copper(II) had been studied first, because **1** and **3** are the adducts of (isopropylthio)acetates and it was thought to be convenient to compare its data with those of the other types of adducts. However, the attempt was not successful, because the complex was decomposed under the X-ray radiation within several hours. On the other hand, the crystals of **2** did not decompose even under X-ray radiation for several weeks.

The crystallographic and X-ray measurement data of **1**, **2**, and **3** are as follows:

1. $Cu_2C_{38}H_{50}S_4O_8N_2$, F.W.=918.17; orthorhombic; space group Pcab (The systematic absences of the reflections were

those of $kk0(k=\text{odd})$, $0kl(l=\text{odd})$, and $h0l(h=\text{odd})$; $a=17.525(6)$, $b=28.068(18)$, $c=8.870(4)$ Å, $Z=4$,[8] $D_m=1.40(3)$, $D_x=1.38$ g cm^{-3}, μ(Mo $K\alpha$)$=1.24$ mm^{-1}. In total, 2323 independent reflections with $|F_o|>3\sigma(|F_o|)$ among the 2485 measured ones were used for the structure refinement.

2. $CuC_{36}H_{44}S_2O_4N_2$, F.W.$=696.43$; monoclinic; space group A2/a (the systematic absences of the reflections were $hkl(k+l=\text{odd})$ and $h0l(h=\text{odd})$; $a=19.235(8)$, $b=11.944(2)$, $c=17.137(5)$ Å, $\beta=111.13(3)°$, $Z=4$, $D_m=1.26(2)$, $D_x=1.25$ g cm^{-3}, μ(Mo $K\alpha$)$=0.592$ mm^{-1}. In total, 2090 independent reflections with $|F_o|>3\sigma(|F_o|)$ among the 2188 measured ones were used for the structure determination.

3. $CuC_{37}H_{39}S_2O_4N_2$, F.W.$=717.41$; triclinic; space group P$\bar{1}$; $a=11.550(10)$, $b=16.912(6)$, $c=9.792$ Å, $\alpha=100.32(5)$, $\beta=109.96(13)$, $\gamma=79.50(5)°$, $Z=2$, $D_m=1.36(2)$, $D_x=1.34$ g cm^{-3}, μ(Mo $K\alpha$)$=0.553$ mm^{-1}. In total, 3404 independent reflections with $|F_o|>3\sigma(|F_o|)$ among the 3832 measured ones were used for the structure refinement.

The Structure Determination. The calculations were carried out on a HITAC M200H computer at the Computer Center of The University of Tokyo, using the local version of the UNICS program.[9]

The atomic scattering factors were taken from the tables.[10] The structure was solved by the heavy-atom method. The positional and thermal parameters were refined by the block-diagonal least-squares method. The positions of several hydrogen atoms were obtained from a difference Fourier synthesis, and some others, by calculation on the assumption of C–H$=1.0$ Å; they were also refined assuming $B_{iso}=8.0$. In the last cycle of the refinement, all the parameter shifts were less than $\sigma/3$'s. The final R values[11] were 0.041, 0.055, and 0.078 for **1**,**2**, and **3** respectively.

The Spectroscopic Measurements. The infrared absorption spectra of the samples were obtained by means of a JASCO 403G infrared spectrophotometer, using nujol and hexachloro-1,3-butadiene mull.

The visible absorption spectra in a benzene solution, and the reflectance spectra of their solids, were measured by means of a Hitachi 124 spectrophotometer.

Results and Discussion

The final atomic parameters of non-hydrogen atoms are listed in Table 2, while their interactomic distances and bond angles are tabulated in Table 3.[12] A perspective drawing of each complex and the numbering scheme are shown in Figs. 1, 2, and 3.

No abnormal intermolecular contact is found in the crystal structures of **1**—**3**.

As is shown in Fig. 1, the **1** complex has a dimer structure, in which four (isopropylthio)acetate ions bridge two copper atoms. The complex has a center of symmetry at the middle point of the Cu–Cu bond (2.676(4) Å).

All of the Cu–O bond lengths are normal (1.964(5)—1.981(5) Å).[13] The average plane of the CuO_4 is shown by this equation:

$$-0.651x - 0.729y - 0.211z + 1.164 = 0$$

(where x, y, z, are taken in the a-, b-, and c-axis directions respectively and are shown in Å units), and the distances from the average plane are: Cu, −0.174; O(12), 0.051; O(22), 0.052; O(11^I), 0.050; and O(21^I), 0.052 Å. Thus, the Cu atom deviates a little to the N(31) side from the plane. The ∠Cu^I–Cu–N(31) is about 8° less than 180°, and ∠O–Cu–N(31) are in the 90.84(12)—102.18(13)° range. The Cu–N(31) (2.222(6) Å) is a little longer than the common Cu–N bond (2.00 Å).[13] The dihedral angle between the CuO_4 plane and the quinoline one is 81.5°. Both of the carboxyl groups of the carboxylate ligands are almost symmetric. Neither of the sulfur atoms, S(1) and S(2), is coordinated. Thus, the structure is similar to that of tetrakis(acetato)-diaquadicopper(II) or some such bis(amine)tetrakis-(carboxylato)copper(II) dimers;[14] and the bond lengths and bond angles of **1** are comparable to those of the dimers.

The complexes with the same chemical formula, $[Cu(RSCH_2CO_2)_4(amine)_2]$, where amine=isoquinoline or pyridine, are expected to have similar structures, though those of some aromatic amines are expected to have different structures, as has been shown for bis-(propionato)-*p*-toluidinecopper(II).[15]

c) The equivalent isotropic temperature factors for non-hydrogen atoms were computed using the following expression: $B_{eq}=4/3\,(B_{11}a^2+B_{22}b^2+B_{33}c^2+B_{12}ab\cos\gamma+B_{13}ac\cos\beta+B_{23}bc\cos\alpha)$. The B_{ij}'s are defined by: $\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2klB_{23}+2hlB_{13}+2hkB_{12})]$.

As is shown in Fig. 2, the copper atom of **2** lies at the center of symmetry, forming a N_2O_2 tetra-coordinate square-planar complex. Both the Cu–O and Cu–N bond lengths are normal,[13] but the ∠O–Cu–N angle is 4.6° more than the right angle. Although the axially elongated octahedral geometry is the most common coordination site around a copper(II) ion, there are not many complexes with the pure square-planar configuration. In the case of bis(oxalato)copper(II), two oxygen atoms of other chelates are coordinated weakly from both the axial directions,[16] while in the cases of β-diketonates,[17–21] which are typical square-planar complexes, weak Cu–C bondings between the copper(II) and the γ-carbon atoms of other chelates were found. Recently, a long-distance interaction of the type was also reported in copper(II) metalaacetylacetonate.[22]

Especially in crystaline state, copper(II) complexes coordinated to four unidentate ligands arer are, although $Na_4[Cu^{II}(NH_3)_4][Cu^{I}(S_2O_3)_2]_2$,[23] $Cu(C_5H_5NO)_4X_2$ (where $X=BF_4$ or ClO_4),[24] and $Cu(diazepam)_2Cl_2\cdot 2H_2O\cdot 1/3\,CHCl_3$ (where diazepam=7-chloro-1,3-dihydro-1-methyl-5-phenyl-3*H*-1,4-benzodiazepin-2-one)[25] have been reported.

In the case of **2**, the phenyl rings of the ligand effectively block the axial coordination site, as in the case of the diazepam complex.[25] In **2**, all distances between any carbon atoms of a phenyl ring and any one of the other phenyl rings of the same dibenzylamine ligand are over 4.0 Å. From the molecular-structure-model study of the **2** complex, using the HGS model and assuming that

each bond length is kept to the value shown by the X-ray analysis and that all sigle-bonded atoms can rotate freely around the axis, it was found that the phenyl

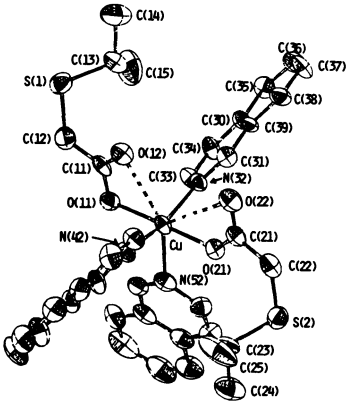

Fig. 3. A perspective drawing of bis{(isopropylthio)-acetato}tris(isoquinoline)copper(II) (**3**), and the numbering scheme of atoms.

groups of the amine ligand must approach each other when one more oxygen or sulfur atom of an (alkylthio)-acetate ligand bonds to the copper(II) atom. In the real structure, the intra-molecular interaction between phenyl groups of the amine is likely to be dominant, because the phenyl groups spread to prevent the bonding of the additional ligand atoms like a "*picket fence*."[12]

As is shown in Fig. 3, the copper atom of **3** is coordinated to two oxygen and two nitrogen atoms in a O_2N_2 square planar geometry. These Cu–O as well as Cu–N bond lengths are normal compared with those of common copper(II) complexes.[13] The average plane of the CuO_2N_2 is shown by this equation:

$$-0.773x + 0.057y - 0.631z + 6.591 = 0$$

and the shifts from the plane are: Cu, −0.105; N(32), 0.201; N(42), 0.170; O(11), −0.135; and O(21), −0.117 Å. The ∠(Nor O)–Cu–N(or O) angles between side-by-side atoms in the plane are 88.0(3)—92.1(3)°.

The copper(II) atom is surrounded by seven atoms. Among them, the O(11), O(21), N(32), N(42), and N(52) atoms are situated in the axially elongated octahedral geometry, where one axially ligating atom is absent. While ∠O(11)–Cu–O(12) is 55.1°, and Cu–

O(12) is 2.642(10) Å, the deviation of the O(12) position from the octahedral environment is rather extreme compared with the positions of other five atoms mentioned above. Moreover, as ∠O(21)–Cu–O(22) is 41.4(2)° and Cu–O(22) is 3.282(10) Å, Cu–O(22) should not be considered as the common coordination bond. However, the three axial atoms, N(52), O(12), and O(22), together with the Cu, O(11), and O(21) atoms, are almost all on one plane, shown by the following plane equation:

$$0.552\,x + 0.631\,y - 0.545\,z + 3.301 = 0.$$

The shifts of the atoms are: Cu, 0.026; O(11), 0.001; O(12) −0.002; O(21), 0.047; O(22), −0.032; and N(52), −0.037 Å. An abnormally long-distance Cu–O bonding has already been reported in copper(II) oxalate[16] or in the nitrate.[26] In some carboxylate complexes of large metal ions, two oxygen atoms of a carboxylate ion are coordinated to the same metal ion.[27] Consequently, although both Cu–O(12) and Cu–O(22) are too long, and the bonds can be expected to be weak, it seems that both O(12) and O(22) atoms are coordinated to the copper atom, cooperating with each other. Therefore, the configuration of **3** is, tentatively, named the "*potentially hepta-coordinated configuration.*"

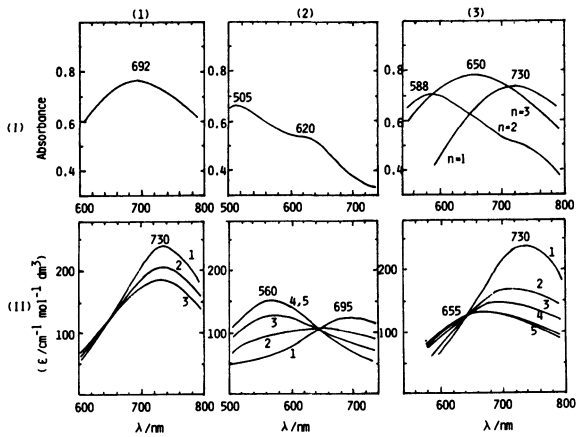

Fig. 4. Reflectance and absorption spectra of the complexes. (The wavelengths of absorption maxima are shown in figures.) (I): Diffuse reflectance spectra (upper figures). (II): Absorption spectra in benzene solution (lower figures). The concentration of Cu(II) in the solution: (1) 4.54×10^{-3}; (2) 4.72×10^{-3}, (3) 4.42×10^{-3} mol dm^{-3}.
(1) (Left figs.) : tetrakis{(isopropylthio)acetato}bis(quinoline)dicopper(II). Amine: Cu(II) in the solution: 1, 6; 2, 175; 3, 406 (mol/mol). (2) (Middle figs.): bis (dibenzylamine)bis{(ethylthio)acetato}copper(II). Amine: Cu(II) in the solution: 1, 5; 2, 7; 3, 12; 4, 53; 5, 214 (mol/mol). (3) (Right figs.): $n=1$, tetrakis-{(isopropylthio) acetato}bis (isoquinoline) dicopper (II) ; $n=2$, bis{(isopropylthio)acetato}bis(isoquinoline)copper-(II); $n=3$, bis{(isopropylthio)acetato}tris(isoquinoline)-copper(II). Amine: Cu(II) in the solution: 1, 6; 2, 45; 3, 80; 4, 150; 5, 400 (mol/mol). (For the absorption spectra in benzene solution, the same result was obtained when the mol ratio of Cu(II): amine in the solution is the same, when the $n=1$, $n=2$, or $n=3$ complex was used.)

A similar type of structure was found in tris(pyridine)-copper(II) nitrate,[28] where two oxygen atoms of each nitrate ion are coordinated to the copper(II) atom, and where the geometry of the CuO_4N_3 configuration closely resembles that of **3**.

The diffuse reflectance spectra of the solid, and the absorption spectra in a benzene solution of **1**, **2**, and **3**, as well as those of mono- and bis(isoquinoline) adducts of copper (isopropylthio)acetate, are shown in Fig. 4. The reflectance spectra of **1** are characteristic of a copper(II) carboxylate dimer,[14,29,30] as the d-d band maximum appears at about 690—730 nm. Its benzene solution shows an absorption maximum of almost the same wavelength as that of the reflectance spectra of its solid. Consequently, their dimer structure is likely kept, even in the benzene solution.

When an excess of quinoline is added to the benzene solution of **1**, the absorption maximum does not move. On the other hand, when as excess of isoquinoline or pyridine is added to a solution of their adduct of the respective Type-**1** complex, the formation of Type-**3** complex is found by the change in color and in spectra. For example, as is shown in Fig. 4, in the case of the solution of Type-**1** isoquinoline adduct, the wavelength of the absorption maximum decreased from 730 to 655 nm depending on the increase in the isoquinoline concentration in the solution. The final wavelength, 655 nm, is almost the same as that of the maximum of the reflectance spectra of the solid **3**. During the process, as the minimum wavelength of the absorption maximum observed was 655 nm, its bis(amine) adduct is probably not the dominant species under these conditions, because the reflectance spectra of the solid bis(amine) adduct of the Type-**2**, bis{(isopropylthio)acetato}bis-(isoquinoline)copper(II), has an absorption maximum at 588 nm. As has been shown in the experimental part, the solid Type-**2** adducts were obtained from a benzene–ligroine mixture solution containing both the starting copper(II) complex and the amine in higher concentrations.

The reflectance spectra of **2** shows an absorption maximum at about 505 nm, which is shorter than that of common copper complexes.[31] Such a short wavelength maximum is found only in D_{4h}-type complexes, where the axial atoms are bonded very weakly or where no axially ligating atoms exist.[32] (An additional shoulder appears at about 620 nm).

For example, bis{(isopropylthio)acetato}copper(II) dihydrate (violet isomer) shows a similar absorption maximum at 566 nm in its reflectance spectra of the solid, which has an axially elongated D_{4h} geometry.[2]

When a benzene solution of **2** is diluted, the change in the spectra and in the color of the solution shows the formation of the Type-**1** dimer complex. Therefore, in the solution, the amine ligand of **2** is in dissociation equilibrium, and a part of it is dissociated. Even when a large excess of dibenzylamine (about amine : Cu= 200, in mol/mol) is added to the solution, the absorption maximum shifts at most to 560 nm, not to 505 nm.

The reflectance spectra of **3** has an absorption maximum at about 650 nm, which is intermediate

a) The $n=1$ complexes are shown by the experimental formula.

between those of **1** and **2**, probably because its axial atom bondings are of medium strength.

The wave numbers of the $\nu_{as}(COO)$ and $\nu_s(COO)$ of the adducts are shown in Table 4. As each of these complexes has Type-**1**, **-2**, or **-3** structure, the maximum wave numbers should also be classified into three groups.

In **1**, the carboxyl group of the ligand bridges the copper atoms with both of its oxygen atoms, and the group is almost completely symmetric. The $\nu_{as}(COO)$ of Type-**1** adducts is about 1600—1630 cm^{-1}, which is typical of the bridging carboxylate group of the copper-(II) carboxylate dimer.[33,34]

In **2**, the carboxyl group bonds with the metal ion by only one oxygen atom, and the group is rather asymmetric. However, the $\nu_{as}(COO)$ of **2** appears in a relatively low wave number region, *i.e.*, at about 1590 cm^{-1}.

In **3**, as Cu–O(12) and Cu–O(22) are different in their bond lengths, the grades of asymmetry of the two carboxyl groups can be expected to be different, too. Therefore, two types of $\nu_{as}(COO)$ as well as $\nu_s(COO)$ bands overlap in its spectra.

The authors wish to thank Professor Yoichi Iitaka, The Faculty of Pharmaceutical Sciences, The University of Tokyo, for the collection of the intensity data. The present work was partially supported by a Grant-in-Aid for Scientific Research (No. 57430011) from the Ministry of Education, Science and Culture.

A Calorimetric Study on the Relative Thermal Stability of Some Bis(diamine)cobalt(III) Complexes in a Solid Phase

Ryokichi Tsuchiya,* Akira Uehara, Toshio Wazumi, and Yoshinori Muramatsu
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received November 18, 1982)

The enthalpy changes (ΔH) in the reaction of *trans*-$[CoX_2(AA)_2]X\cdot mHX\cdot nH_2O$-type complexes with an alkaline sodium sulfide solution were calorimetrically measured at 25 °C, where AA is diamine and X is Cl^-, Br^-, or ClO_4^-; $m=0$ or 1, and $n=0$, 0.5, 1, or 2. The thermal stabilities were found to decrease in the following orders for both dichloro and dibromo complexes: 1,2-ethanediamine>*l*- or *d*-1,2-propanediamine>racemic 1,2-propanediamine, *d,l*-2,3-butanediamine>meso-2,3-butanediamine>2-methyl-1,2-propanediamine, 1,2-ethanediamine>1,3-propanediamine, and *meso*-2,4-pentanediamine>*d,l*-2,4-pentanediamine. The complexes containing six-membered diamine chelate rings were less stable than those containing five-membered diamine chelate rings. The dibromo complex bromides were less stable than the corresponding dichloro complex chlorides.

Neither trans-to-cis nor cis-to-trans isomerization has so far been found in the solid $[CoX_2en_2]X$-type complexes (X: Cl^- or Br^-). Our previous paper, however, calorimetrically predicted that the above complexes undergo cis-to-trans isomerization in a solid phase, and the prediction was actually verified.[1] The enthalpy change was predominant relative to the entropy change in the free energy change of the above isomerization. The relative thermal stability among the trans-complexes in a solid phase is, therefore, considered to depend principally upon the difference in enthalpy changes of complex formation from each component in a gaseous state. On the basis of such idea, the strain energy calculation by conformational analysis has been carried out by many workers[2] for mono-, bis- and tris-diamine Co(III), Mo(0), Cr(III), Cr(0), Pt(II), and Pd(II) complexes. On the other hand, the relative strain enthalpies have been obtained calorimetrically by Woldbye *et al.*[3] for some tris(diamine)cobalt(III) complexes in an aqueous solution. The strain enthalpies by conformational analysis and by calorimetry have never been obtained for these diamine complexes in a solid phase. In the present study, the thermal stability of $[CoX_2(AA)_2]X\cdot mHX\cdot nH_2O$-type complexes in a solid phase was discussed on the basis of lattice energies evaluated from the enthalpy changes for the reaction with an alkaline sodium sulfide solution, where AA is a diamine, m is 0 or 2, and n is 0, 0.5, 1, or 2.

Experimental

Preparation of Diamines. 1,2-Ethanediamine (en), 1,2-propanediamine (pn), and 1,3-propanediamine (tn) were commercially available. 2,3-Butanediamines (*dl*-bn and *m*-bn)[4] and 2,4-pentanediamines (*dl*-ptn and *m*-ptn)[5] were prepared by the literature methods and characterized by NMR spectra.[6,7] 2-Methyl-1,2-propanediamine (*i*-bn) was supplied by Aldrich Chemical Co. Inc.

Preparation of Complexes. The following complexs were prepared by the literature methods slightly modified: *trans*-$[CoCl_2en_2]Cl\cdot HCl\cdot 2H_2O$, *trans*-$[CoCl_2en_2]Cl$,[8] *trans*-$[CoCl_2pn_2]Cl\cdot HCl\cdot 2H_2O$, *trans*-$[CoCl_2pn_2]Cl\cdot H_2O$, *trans*-$[CoCl_2(l\text{-pn})_2]Cl\cdot H_2O$,[9] *trans*-$[CoCl_2(dl\text{-bn})_2]ClO_4$, *trans*-$[CoCl_2(m\text{-bn})_2]ClO_4$, *trans*-$[CoCl_2(i\text{-bn}_2)]ClO_4$,[5] *trans*-$[CoCl_2tn_2]Cl$,[10] *trans*-$[CoCl_2(dl\text{-ptn})_2]Cl\cdot 0.5H_2O$, *trans*-$[CoCl_2(m\text{-ptn})_2]Cl\cdot 0.5H_2O$,[11] *trans*-$[CoBr_2en_2]Br\cdot HBr\cdot 2H_2O$, *trans*-$[CoBr_2en_2]Br$,[12] *trans*-$[CoBr_2pn_2]Br\cdot HBr\cdot 2H_2O$, *trans*-$[CoBr_2pn_2]Br\cdot H_2O$, *trans*-$[CoBr_2(d\text{-pn})_2]Br\cdot H_2O$,[9] *trans*-$[CoBr_2(dl\text{-bn})_2]ClO_4$, *trans*-$[CoBr_2(m\text{-bn})_2]ClO_4$, *trans*-$[CoBr_2(i\text{-bn})_2]ClO_4$,[5] *trans*-$[CoBr_2tn_2]Br$,[10] *trans*-$[CoBr_2(dl\text{-ptn})_2]Br\cdot 0.5H_2O$, and *trans*-$[CoBr_2(m\text{-ptn})_2]Br\cdot 0.5H_2O$.[11]

Calorimetric Measurements. The enthalpy changes in the reaction of the complexes in the powder state with an alkaline sodium sulfide solution were measured with a Tokyo-Riko twin isoperibol calorimeter TIC-2S at 25 °C. In each run, the diamine complexes were accurately weighed and the reacting solution was 100 cm^3 of a mixture containing 2×10^{-2} mol dm^{-3} Na_2S and 1 mol dm^{-3} NaOH.

Results and Discussion

Thermal Stability of $[CoX_2(AA)_2]X\cdot mHX\cdot nH_2O$-type Complexes with Various Diamines. The enthalpy changes measured for the reaction of these complexes with an alkaline sodium sulfide solution are summarized in Table 1. The enthalpy changes for *trans*-$[CoCl_2en_2]Cl\cdot HCl\cdot 2H_2O$l and *trans*-$[CoCl_2pn_2]Cl\cdot HCl\cdot 2H_2O$, are given as below,

$$\text{trans-}[CoCl_2en_2]Cl\cdot HCl\cdot 2H_2O(s)+3/2\ S^{2-}(aq)+OH^-(aq) = 1/2\ Co_2S_3(s)+4Cl^-(aq)+2en(aq)+3H_2O(l)\qquad \Delta H=-117.4\ \text{kJ mol}^{-1},\quad (1)$$

$$\text{trans-}[CoCl_2pn_2]Cl\cdot HCl\cdot 2H_2O(s)+3/2\ S^{2-}(aq)+OH^-(aq) = 1/2\ Co_2S_3(s)+4Cl^-(aq)+2pn(aq)+3H_2O(l)\qquad \Delta H=-136.7\ \text{kJ mol}^{-1}.\quad (2)$$

On the other hand, the heats of dissolution of diamines into an alkaline sodium sulfide solution in the same concentration as above were also measured with the calorimeter, and their heats of vaporization were calculated from the boiling points and Trouton's constants. The values for en and pn are as follows:

$$\left.\begin{array}{ll} en(l) = en(aq) & \Delta H=-30.4\ \text{kJ mol}^{-1} \\ en(l) = en(g) & \Delta H=34.3\ \text{kJ mol}^{-1} \end{array}\right\},\quad (3)$$

$$\left.\begin{array}{ll} pn(l) = pn(aq) & \Delta H=-33.4\ \text{kJ mol}^{-1} \\ pn(l) = pn(g) & \Delta H=34.5\ \text{kJ mol}^{-1} \end{array}\right\}.\quad (4)$$

Combining these values with those of Eqs. 1 and 2, the enthalpy change for the reaction,

$$\text{trans-}[CoCl_2en_2]Cl\cdot HCl\cdot 2H_2O(s)+2pn(g) = \text{trans-}[CoCl_2pn_2]Cl\cdot HCl\cdot 2H_2O(s)+2en(g),$$

Table 1. Enthalpy changes, ΔH, for the reaction of cobalt(III) complexes with sodium sulfide solution

Complex	X=Cl⁻ ΔH/kJ mol⁻¹	X=Br⁻ ΔH/kJ mol⁻¹

Table 2. Enthalpy changes, ΔH, for the substitution reaction of diamine

Substitution reaction	X=Cl⁻ ΔH/kJ mol⁻¹	X=Br⁻ ΔH/kJ mol⁻¹
trans-$[CoX_2en_2]X\cdot HX\cdot 2H_2O\rightarrow pn_2$ [a]	12.9	11.5
trans-$[CoX_2en_2]X\rightarrow tn_2$	17.9	5.8
trans-$[CoX_2(l\text{-pn or }d\text{-pn})_2]X\cdot H_2O\rightarrow pn_2$	5.0	5.2
trans-$[CoX_2(dl\text{-bn})_2]ClO_4\rightarrow(m\text{-bn})_2$	9.6	5.7
trans-$[CoX_2(dl\text{-bn})_2]ClO_4\rightarrow(i\text{-bn})_2$	14.2	12.4
trans-$[CoX_2(m\text{-ptn})_2X\cdot 0.5H_2O\rightarrow(dl\text{-ptn})_2$	20.5	8.8

a) Represents the substitution reaction, *trans*-$[CoX_2en_2]X\cdot HX\cdot 2H_2O(s)+2pn(g) =$ *trans*-$[CoX_2pn_2]X\cdot HX\cdot 2H_2O(s)+2en(g)$. Such expressions are similarly used for the respective reactions.

was calculated as $\Delta H=12.9$ kJ mol^{-1}. The enthalpy change in substituting pn for en in the corresponding bromide was obtained as $\Delta H=11.5$ kJ mol^{-1} in the same way. These values should correspond to the difference in lattice energies between the bis(en) and bis(pn) complexes in chlorides and bromides. Thus, the bis(pn) complexes are thermally less stable than the corresponding bis(en) complexes (Table 2).

In order to compare the thermal stability between the complexes containing racemic pn and optically active *l*-pn or *d*-pn, the enthalpy changes for the following reactions were calculated by using the data in Table 1 and those in Eq. 4:

trans-$[CoCl_2pn_2]Cl\cdot H_2O(s) + 2(l\text{-pn})(g)$
$= $ *trans*-$[CoCl_2(l\text{-pn})_2]Cl\cdot H_2O(s) + 2pn(g)$
$\Delta H = -5.0$ kJ mol^{-1},

trans-$[CoBr_2pn_2]Br\cdot H_2O(s) + 2(d\text{-pn})(g)$
$= $ *trans*-$[CoBr_2(d\text{-pn})_2]Br\cdot H_2O(s) + 2pn(g)$
$\Delta H = -5.2$ kJ mol^{-1}.

These data suggest that the complexes containing optically active pn are thermally more stable than those containing racemic pn in both the chloride and the bromide.

By similar calculations, the enthalpy changes for the following reactions substituting tn for en were obtained:

trans-$[CoCl_2en_2]Cl(s) + 2tn(g)$
$= $ *trans*-$[CoCl_2tn_2]Cl(s) + 2en(g)$
$\Delta H = 17.9$ kJ mol^{-1},

trans-$[CoBr_2en_2]Br(s) + 2tn(g)$
$= $ *trans*-$[CoBr_2tn_2]Br(s) + 2en(g)$
$\Delta H = 5.8$ kJ mol^{-1}.

Here, the following data,

tn(l) = tn(aq) $\Delta H = -34.4$ kJ mol^{-1},
tn(l) = tn(g) $\Delta H = 35.9$ kJ mol^{-1},

were used. These data show that the bis(tn)cobalt(III) complexes with six-membered chelate rings are thermally less stable than the corresponding bis(en)cobalt(III) complexes with five-membered chelate rings in a solid phase.

By using the following data,

dl-bn(l) = *dl*-bn(aq) $\Delta H = -35.9$ kJ mol^{-1},
dl-bn(l) = *dl*-bn(g) $\Delta H = 35.9$ kJ mol^{-1},
m-bn(l) = *m*-bn(aq) $\Delta H = -37.1$ kJ mol^{-1},
m-bn(l) = *m*-bn(g) $\Delta H = 35.6$ kJ mol^{-1},
i-bn(l) = *i*-bn(aq) $\Delta H = -36.2$ kJ mol^{-1},
i-bn(l) = *i*-bn(g) $\Delta H = 35.6$ kJ mol^{-1},

the enthalpy changes for the following reactions were calculated:

trans-$[CoX_2(dl\text{-bn})_2]ClO_4(s) + 2m\text{-bn}(g)$
$= $ *trans*-$[CoX_2(m\text{-bn})_2]ClO_4(s) + 2dl\text{-bn}(g)$,
for X = Cl⁻ $\Delta H = 9.6$ kJ mol^{-1},
for X = Br⁻ $\Delta H = 5.7$ kJ mol^{-1},

trans-$[CoX_2(dl\text{-bn})_2]ClO_4(s) + 2i\text{-bn}(g)$
$= $ *trans*-$[CoX_2(i\text{-bn})_2]ClO_4(s) + 2dl\text{-bn}(g)$,
for X=Cl⁻ $\Delta H = 14.2$ kJ mol^{-1},
for X=Br⁻ $\Delta H = 12.4$ kJ mol^{-1}.

In these three dichloro and three dibromo complexes, the thermal stabilities decrease in the following orders,

trans-$[CoCl_2(dl\text{-bn})_2]ClO_4 >$ *trans*-$[CoCl_2(m\text{-bn})_2]ClO_4$
$>$ *trans*-$[CoCl_2(i\text{-bn})_2]ClO_4$,
trans-$[CoBr_2(dl\text{-bn})_2]ClO_4 >$ *trans*-$[CoBr_2(m\text{-bn})_2]ClO_4$
$>$ *trans*-$[CoBr_2(i\text{-bn})_2]ClO_4$.

These orders coincide with those of the stability of tris(*l*-bn), tris(*m*-bn), and tris(*i*-bn) complexes in solution calculated from strain enthalpy.[3] The difference in the stabilities between bis(*dl*-bn) and bis(*m*-bn) or bis(*i*-bn) complexes can be understood from the fact that two methyl groups in the coordinated *dl*-bn (*S*, *S*-δ or *R*, *R*-λ) are equatorial,[2c] whereas one of two methyl groups in the *m*-bn (*R*, *S*-δ or *R*, *S*-λ) and *i*-bn (δ or λ) are in the axial position.

By using the following data,

dl-ptn(l) = *dl*-ptn(aq) $\Delta H = -39.0$ kJ mol^{-1},
dl-ptn(l) = *dl*-ptn(g) $\Delta H = 37.0$ kJ mol^{-1},
m-ptn(l) = *m*-ptn(aq) $\Delta H = -39.6$ kJ mol^{-1},
m-ptn(l) = *m*-ptn(g) $\Delta H = 37.1$ kJ mol^{-1},

the enthalpy changes for the following reactions are calculated:

$$trans\text{-}[CoX_2(dl\text{-ptn})_2]X\cdot 0.5H_2O(s) + 2m\text{-ptn}(g) = trans\text{-}[CoX_2(m\text{-ptn})_2]X\cdot 0.5H_2O(s) + 2dl\text{-ptn}(g),$$

for $X = Cl^-$ $\Delta H = -20.5$ kJ mol^{-1},

for $X = Br^-$ $\Delta H = -8.8$ kJ mol^{-1}.

In these cases, the complexes containing the meso-form of ptn are thermally more stable than those containing the racemic form in contrast to the bis(bn) complexes. Such a difference will be ascribed to the difference in the conformation of the chelates, although the orientation of methyl groups is all equatorial in both complexes.[13]

The enthalpy changes for the substitution reaction of diamines are listed in Table 2.

Thermal Stability Differences between Dichloro Complex Chlorides and the Corresponding Dibromo Complex Bromides. Considering the following data,

$Cl^-(aq) = Cl^-(g)$ $\Delta H = -76.5$ kJ mol^{-1},[14]

$Br^-(aq) = Br^-(g)$ $\Delta H = -110.5$ kJ mol^{-1},[14]

the enthalpy changes for the following reactions,

$$trans\text{-}[CoCl_2(AA)_2]Cl\cdot m HCl\cdot nH_2O(s) + (3+m)Br^-(g) = trans\text{-}[CoBr_2(AA)_2]Br\cdot m HBr\cdot nH_2O(s) + (3+m)Cl^-(g),$$

were calculated, which are summarized in Table 3.

These values correspond to the decrement of lattice energies of the solid complexes when chloride ions coordinated and/or those present as counter ions are replaced by bromide ions. It is shown that the dibromobis(diamine)cobalt(III) bromides are thermally less stable than the corresponding dichloro chlorides by about 35—70 kJ mol.$^{-1}$ Especially, a tendency seems to exist that, in the complexes containing 1,2-ethanediamine or the diamines with two methyl groups attached to the distant carbon atoms like ptn, the enthalpy increments in the replacement of Cl^- by Br^- are about 40 kJ mol.$^{-1}$ On the other hand, for the other complexes containing the diamines with two methyl groups at the adjacent carbon atoms like bn, the enthalpy increments are about 60 kJ mol.$^{-1}$

Thermal Stability Diagram of the Bis(en), Bis(pn) and Bis(tn) Complexes. The enthalpy change for the reaction of *trans*-$[CoCl_2en_2]Cl$ with an alkaline sodium sulfide solution is, as Table 1 shows, given as,

$$trans\text{-}[CoCl_2en_2]Cl(s) + 3/2\ S^{2-}(aq) = 1/2\ Co_2S_3(s) + 3Cl^-(aq) + 2en(aq)$$

$$\Delta H = -60.5 \text{ kJ mol}^{-1}. \quad (5)$$

Combining the value of Eq. 5 with that of Eq. 1 and the values[14] shown below,

$HCl(g) = H^+(aq) + Cl^-(aq)$ $\Delta H = -75.2$ kJ mol^{-1},

$H_2O(l) = H^+(aq) + OH^-(aq)$ $\Delta H = 55.9$ kJ mol^{-1},

$H_2O(l) = H_2O(g)$ $\Delta H = 44.0$ kJ mol^{-1},

the enthalpy change for the reaction,

$$trans\text{-}[CoCl_2en_2]Cl\cdot HCl\cdot 2H_2O(s) = trans\text{-}[CoCl_2en_2]Cl(s) + HCl(g) + 2H_2O(g),$$

was calculated as $\Delta H = 162.2$ kJ mol^{-1}. Using this value, and taking account of the other data concerned, the enthalpy levels of some bis(en) and bis(pn) complexes are obtained, which are diagramatically shown in Fig. 1.

Table 3. Enthalpy changes, ΔH, for the reaction substituting Br^- for Cl^- in cobalt (III) complexes

Complex	ΔH/kJ mol^{-1}
trans-$[CoX_2en_2]X\cdot HX\cdot 2H_2O$	40.4
trans-$[CoX_2en_2]X$	48.0
trans-$[CoX_2pn_2]X\cdot HX\cdot 2H_2O$	39.0
trans-$[CoX_2\ pn_2]X\cdot H_2O$	62.2
trans-$[CoX_2(l\text{-pn or } d\text{-pn})_2]X\cdot H_2O$	62.0
trans-$[CoX_2(dl\text{-bn})_2]ClO_4$	71.2
trans-$[CoX_2(m\text{-bn})_2]ClO_4$	67.3
trans-$[CoX_2(i\text{-bn})_2]ClO_4$	69.4
trans-$[CoX_2tn_2]X$	35.9
trans-$[CoX_2(dl\text{-ptn})_2]X\cdot 0.5H_2O$	34.9
trans-$[CoX_2(m\text{-ptn})_2]X\cdot 0.5H_2O$	46.6

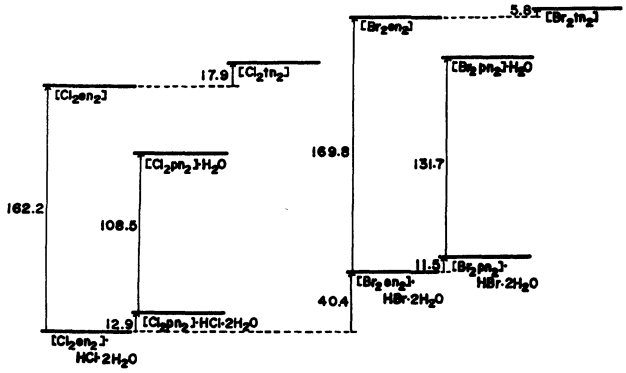

Fig. 1. Enthalpy level diagram for bis(en), bis(pn), and bis(tn) complexes. $[Cl_2en_2]\cdot HCl\cdot 2H_2O$ and $[Cl_2en_2]$ are abbreviations of *trans*-$[CoCl_2en_2]Cl\cdot HCl\cdot 2H_2O$ and *trans*-$[CoCl_2en_2]Cl$, respectively. Other abbreviations are similarly used. The numerals are expressed by the unit of kJ mol^{-1}.

Comparing the data in Table 2 with those in Table 3, the enthalpy changes for the substitution reaction of halide ions are considerably larger than those for the diamines. Such a tendency is obviously illustrated in Fig. 1 for each of the bis(en), bis(pn), and bis(tn) complexes. In summary, the thermal stability based on the lattice energy difference was found to be largely affected by the kind of halide ions rather than that of diamines.

Simultaneous Determination of Trace Amounts of Carbazole and Anthracene in Dibenzofuran by Synchronous Fluorescence Spectrometry after Zone-melting Separation

Masaki TACHIBANA* and Motohisa FURUSAWA
Faculty of Engineering, Yamanashi University, Takeda, Kofu 400
(Received December 4, 1982)

Trace amounts of carbazole and anthracene in dibenzofuran can be simultaneously determined by measuring the synchronous fluorescence intensities at 336 and 381 nm respectively. The determination limit is 2 ppm. For the application of this method to the practical samples containing interfering impurities, a zone-melting technique was applied successfully to remove the impurities prior to the determination. The recoveries of carbazole and anthracene were 99 and 92% respectively.

Synchronous fluorescence spectrometry was introduced by Lloyd[1] and has been further developed as a technique for the multicomponent analysis of polynuclear aromatic compounds.[2-5] In this spectrometry, a fluorescence signal is recorded while both excitation and emission wavelengths are scanned simultaneously with a fixed wavelength interval between them. Consequently, this method offers several advantages compared with conventional fluorimetry, an enhancement in selectivity by a narrowing of the spectral band, and a decrease of spectral interference from other luminescent species.

The determination of small amounts of carbazole and anthracene by ultraviolet spectrophotometry[6] has been developed. The determination limit is approximately 0.01% and it is difficult to apply to samples containing colored substances. Other spectrophotometric methods[7-8] have been also developed for the determination of carbazole. The determination limits are more than 0.004%.

In the present paper, simultaneous determination of trace amounts of carbazole and anthracene by synchronous fluorescence spectrometry is described. The determination limit is 2 ppm. Carbazole and anthracene in dibenzofuran can be selectively separated from the impurities by the zone-melting technique because each distribution coefficient is greater than unity. The proposed method, therefore, has a wide applicability to the determination of trace amounts of carbazole and anthracene in the practical samples containing interfering impurities. Due to the zone-melting separation, however, this method requires a relatively large amount of the sample and is time-consuming.

Experimental

Reagents. Commercially available dibenzofuran was dissolved in warm acetic acid and the solution was stirred for a while after the addition of a small amount of chromium trioxide. The crystals precipitated by the addition of water were collected, washed with water, dried, and dissolved in benzene. The benzene solution was shaken 4 times with 85% sulfuric acid, washed with water, dried over anhydrous calcium chloride, and passed through an alumina column, and then the benzene was evaporated off. The dibenzofuran thus obtained was further purified by zone refining. The content of carbazole and anthracene was less than 0.1 ppm. Cyclohexane and xylene were of guaranteed reagent grade and used without further purification.

Apparatus. All the measurements of synchronous fluorescence spectra were made on a Hitachi 650-40 fluorescence spectrophotometer equipped with a Hitachi 056 recorder. The spectral bandpass was set at 2 nm. A 150-W xenon lamp was used as the exciting source. A $10\times10\times45$ mm^3 quartz cell was used.

For zone melting a Shibayama SS-950 high-speed zone refiner was used. In this apparatus six zones are produced by six ring heaters placed at equal spacings on the charge, and each zone is set to travel by moving the heater along the charge.

Procedure. In a glass tube with an i.d. of 4 mm, 4.0 g of the sample was charged to a length of about 26 cm, and then the zone-pass was repeated 20 times. The molten zones about 30 mm long were set to travel at the speed of 100 mm/h. During the travels, the zones were stirred by spinning the tube at 1200 min^{-1} with reversal of the rotation direction at intervals of 1.0 s. Exactly 2.0 g of the zone-molten sample was cut out from the beginning part of the ingot and dissolved in 50 ml of xylene. Then 2 ml of the solution was transferred into a 20-ml volumetric flask and diluted to the mark with cyclohexane. The synchronous fluorescence intensity of the solution was measured at 336 nm for carbazole and at 381 nm for anthracene with the wavelength interval of 5 nm. As the standard, the synchronous fluorescence intensity of a dibenzofuran solution (0.1 μg/ml) in cyclohexane was used, which was measured at 303 nm with a wavelength interval of 6 nm. The calibration curves for carbazole and anthracene were prepared by using their solutions (0—0.2 μg/ml) containing dibenzofuran (4 mg/ml). Carbazole was almost recovered quantitatively, but the recovery of anthracene was 92%. The incomplete recovery of anthracene was corrected for by using the reciprocal of 0.92 as the correction factor.

Results and Discussion

Synchronous Fluorescence Spectra. A wavelength interval is one of the important factors in the measurement of synchronous fluorescence spectrum. For the determination of carbazole and anthracene, the wavelength interval of 3 nm is suitable under ordinary conditions.[5] For the determination of more minute amounts of these compounds, however, a larger wavelength interval is necessary for enhancement of the signal-to-noise ratio, and a wavelength interval of 5 nm was effective. The synchronous fluorescence spectrum of a mixed solution containing carbazole (0.2 μg/ml), anthracene (0.2 μg/ml) and dibenzofuran (4 mg/ml) is shown in Fig. 1(1). For comparison, the spectrum of

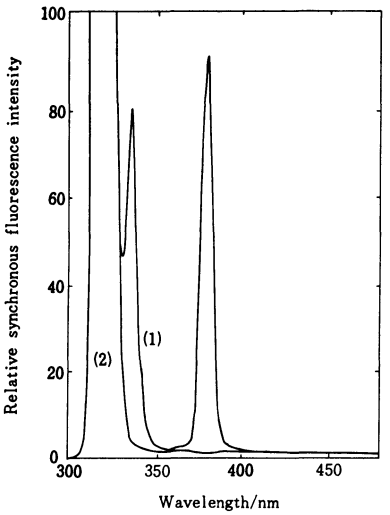

Fig. 1. Synchronous fluorescence spectra of carbazole, anthracene, and dibenzofuran.
Wavelength interval ($\Delta\lambda$): 5 nm; solvent: cyclohexane–xylene mixture (9 : 1); standard: synchronous fluorescence intensity of a dibenzofuran solution (0.100 μg/ml) in cyclohexane measured at 303 nm ($\Delta\lambda$=6 nm) was taken as 70 div.; (1): dibenzofuran (4.0 mg/ml) containing both carbazole (0.20 μg/ml) and anthracene (0.20 μg/ml); (2): dibenzofuran (4.0 mg/ml).

dibenzofuran solution (4 mg/ml) measured under identical experimental conditions is shown in Fig. 1(2). In Fig. 1 the spectral bands of these compounds are well-resolved, and the peaks at 336 and 381 nm are due to carbazole and anthracene, respectively.

Calibration Curves. For the determination of minute amounts of carbazole and anthracene in dibenzofuran, it is desirable to use a concentrated solution of the sample for the measurement of synchronous fluorescence spectrum. On the other hand, the concentrated solution shows the interferences due to both absorption and fluorescence of dibenzofuran at the characteristic wavelength of carbazole. From the result of experiments the concentration of 4 mg/ml was found suitable. In this concentration, the interference seems to be correctable by using a calibration curve, which is prepared under the presence of dibenzofuran. The calibration curves of carbazole and anthracene were prepared by using their solutions (0—0.2 μg/ml) containing dibenzofuran (4 mg/ml). The synchronous fluorescence intensities of carbazole and anthracene were measured at 336 and 381 nm respectively. As the standard, the synchronous fluorescence intensity of a dibenzofuran solution (0.1 μg/ml) in cyclohexane was used, which was measured at 303 nm with a wavelength interval of 6 nm. The calibration curves thus obtained were linear. However, the curve for carbazole did not pass the origin, and the gradient showed a slight decrease compared with the corresponding curve of carbazole alone.

Separation by Zone-melting Technique. To remove the impurities contained in the practical samples, a zone-melting method was applied. The dibenzofuran sample containing both carbazole (66 ppm) and anthracene (65 ppm) was charged in the tube for the zone melting. The zone-molten ingot obtained was divided into 15 portions. The concentrations of the carbazole and the anthracene were simultaneously measured by the synchronous fluorescence method, and then each relative concentration, C/C_0, was calculated, where C_0 and C were initial and final concentrations, respectively. Their concentration profiles in dibenzofuran are shown in Figs. 2(1) and (2), which indicate that both compounds are concentrated toward the beginning of the zone-molten ingot. The profile for acenaphthene which interferes the determination of carbazole is shown in Fig. 2(3). The initial content of acenaphthene was 0.24%. Acenaphthene was evaluated by ultraviolet spectrophotometry. Figure 2(3) shows that acenaphthene is removed from the beginning of the ingot. Some practical samples of dibenzofuran contain colored substances which show the interference due to absorption, and they were found to be accumulated in the end of the ingot. By these experiments carbazole and anthracene in dibenzofuran were found to be effectively separated from the interfering impurities.

Recoveries of Carbazole and Anthracene. After the zone melting had been performed on the dibenzofuran sample containing carbazole (66 ppm) and anthracene (65 ppm), the zone-molten ingot was divided into 13 portions. The quantities of both compounds in each portion were determined, and the relations between the amounts of the dibenzofuran cut out from the beginning of the ingot and the recoveries of both compounds were calculated. The results illustrated in Fig. 3 indicate that the use of 2.0 g of the zone-molten ingot was preferable for the determination judging from the recoveries of both compounds and the removal of the interfering impurities. Approximately 100% of carbazole and 92% of anthracene are recovered. To measure the recoveries more precisely, the zone melting was

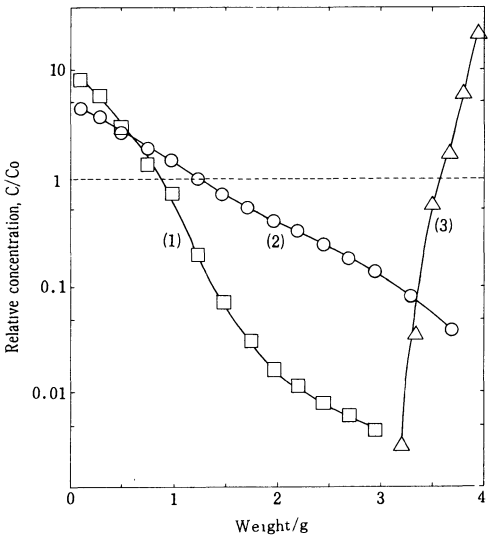

Fig. 2. Concentration profiles for carbazole, anthracene, and acenaphthene in dibenzofuran.
C_0 and C are initial and final contents of the solute; (1): carbazole, C_0=66 ppm; (2): anthracene, C_0=65 ppm; (3): acenaphthene, C_0=0.24%.

TABLE 1. RECOVERIES OF CARBAZOLE AND ANTHRACENE

Added (μg)		Found (μg)		Recovery %					
Carbazole	Anthracene	Carbazole	Anthracene	Carbazole			Anthracene		
265	282	265	261	$100._0$			$92._6$		
265	282	263	260	$99._2$			$92._2$

a) Synchronous fluorescence intensity of the dibenzofuran solution (0.100 μg/ml) in cyclohexane measured at 303 nm (wavelength interval=6 nm) was taken as 70 div. b) 2 mg/ml solution of the mixture was used for the measurement.

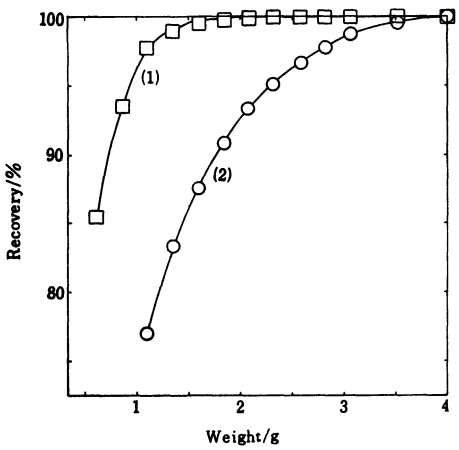

Fig. 3. Recovery profiles for carbazole and anthracene. (1): Carbazole, C_0=66 ppm; (2): anthracene, C_0=65 ppm.

carried out by the use of the dibenzofuran samples containing various amounts of both compounds. The quantities of both compounds in a 2.0 g portion of the zone-molten ingot are shown in Table 1. The recoveries of carbazole and anthracene are 99% with a coefficient of variation of 1.2%, and 92% with that of 1.0%, respectively. Carbazole can be almost quantitatively recovered, but anthracene cannot. The incomplete recovery of anthracene, however, can be corrected for by use of the reciprocal of 0.92 as the correction factor because a reproducible value is obtained.

Determination of Carbazole and Anthracene in Synthetic Mixtures. The analytical results for carbazole and anthracene in synthetic mixtures of dibenzofuran are shown in Table 2. Each mixture contains 0.3% of biphenyl, naphthalene, acenaphthene, fluorene, and phenanthrene, and 0.02% of pyrene, fluoranthene, 9-fluorenone, 1,4-naphthoquinone, and 9,10-phenanthrenequinone. Table 2 indicates that the analytical results agree closely with the individual contents of carbazole and anthracene in the synthetic mixtures. Therefore, trace amounts of carbazole and anthracene in dibenzofuran containing impurities can be simultaneously determined by the present method.

Determination of Carbazole and Anthracene in Practical Samples. Carbazole and anthracene in three different commercial dibenzofuran samples were determined by the present method. The analytical results for carbazole were 61, 41, and 12 ppm, and those for anthracene, 65, 41, and 24 ppm, respectively. The shapes of the synchronous fluorescence spectra, one of which is shown in Fig. 4(1), agree closely with that of the spectrum shown in Fig. 1(1). The solutions used for the determination did not show the absorption based on interfering impurities. The synchronous fluorescence spectra of the remaining parts of the zone-molten ingot of the practical samples were also measured by the same procedure. From these spectra, one of which is shown in Fig. 4(2), the interfering impurities in dibenzofuran are found to be accumulated toward the end of the zone-molten ingot. As the results of the above experi-

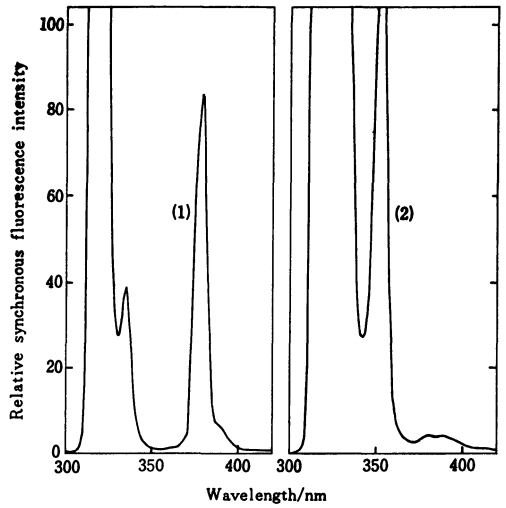

Fig. 4. Synchronous fluorescence spectra of zone-molten commercial dibenzofuran.
$\Delta\lambda$: 5 nm; solvent: cyclohexane–xylene mixture (9 : 1); standard: synchronous fluorescence intensity of a dibenzofuran solution (0.100 μg/ml) in cyclohexane measured at 303 nm ($\Delta\lambda$=6 nm) was taken as 70 div.; (1): solution used for the determination, 4.0 mg/ml; (2): solution prepared by dissolving the opposite end of the same ingot, 4.0 mg/ml.

ments, the method proposed in the present paper can be applied to the practical samples of dibenzofuran.

The authors are indebted to Miss Sumiko Yamada and Mr. Tadayuki Yano for their technical assistance. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

The Affinity for Carbon Monoxide, Electrochemical and Spectral Properties of Binuclear Copper(I) Complexes

Susumu KITAGAWA, Megumu MUNAKATA,* and Noboru MIYAJI
Department of Chemistry, Faculty of Science and Technology, Kinki University, Kowakae, Higashi-Osaka, Osaka 577
(Received December 15, 1982)

Binuclear copper(I) complexes $[CuXL]_2$(X=Cl^- and I^-; L=2,2′-bipyridine, 1,10-phenanthroline, and their derivatives) have been synthesized in acetone, which react with CO reversibly to give crystalline carbonyl adducts $[Cu_2X_2L_2(CO)]$. The cyclic voltammograms of $[CuXL]_2$ and $[Cu_2X_2L_2(CO)]$ show two couples of copper-centered oxidation-reduction waves, indicative of binuclear structure. One couple of waves in $[Cu_2X_2L_2(CO)]$ alone shifts to the anodic region, exhibiting the formation of monocarbonylated complexes. All the half-wave potentials are primarily governed by the basicity of a ligand L, and the contribution of a coordinated CO to the stabilization of Cu^I state by π back-bonding is found. The equilibrium constants of the reaction, $[CuXL]_2+CO\overset{K_{CO}}{\rightleftharpoons}[Cu_2X_2L_2(CO)]$, are lowered with the decrease in the transition energy of the ligand←metal charge transfer of $[CuXL]_2$. On this basis, it is concluded that CO competes with L concerning π back-bonding with copper(I). The ν_{CO} values of the coordinated CO exhibit apparent L-dependence, which is accounted for by the competition between Cu–L and Cu–CO π-bonding, and hence, ν_{CO} values are useful probe to inquire into the nature of Cu–CO bonding among these copper(I) complexes.

A greater knowledge of coordination chemistry of copper(I) particularly of binuclear structure, is important in view of current interest in understanding the structure-function relationship of the "type 3" copper proteins. We have recently reported novel binuclear copper(I) complexes,[1] which have two bridging halogen atoms. It has been demonstrated that the binuclear complexes reversibly react with carbon monoxide (CO) to form a monocarbonylated complex which have the stoichiometry of 1CO/2Cu, corresponding to that of hemocyanin,[2,3] and their affinity for CO is remarkably influenced by the bridging halogens and solvent.

To gain further insight into the nature of copper(I)-ligand binding, we present here a systematic electrochemical properties of binuclear copper(I) complexes containing several 2,2′-bipyridine (bpy) and 1,10-phenanthroline (phen) derivatives (Figs. 1; **1a—f**, **2a**, and **2b**), and their carbonyl adducts. Furthermore, the relationship between the affinity for CO and the bonding nature of Cu^I–L or Cu^I–CO is examined on the basis of visible absorption and infrared spectra.

Experimental

Materials. The reagent grade copper(I) chloride was purified according to literature.[4] Reagent grade copper(I) iodide was used without further purification. They were all dried *in vacuo* (75—100 °C). 2,2′-Bipyridine (bpy), 4,4′-dimethyl-2,2′-bipyridine (4,4′-dmbp), 1,10-phenanthroline (phen), 5-chloro-1,10-phenanthroline (5-Cl-phen), 5-bromo-1,10-phenanthroline (5-Br-phen), 5-methyl-1,10-phenanthroline (5-mp), 4,7-dimethyl-1,10-phenanthroline (4,7-dmp), 4,7-diphenyl-1,10-phenanthroline (4,7-dpp), and 2,9-dimethyl-1,10-phenthroline (2,9-dmp) were commercially available (Wako Pure Chemical Ltd). 6,6′-Dimethyl-2,2′-bipyridine (6,6′-dmbp) was prepared according to literature.[5] They were recrystallized several times from acetone, and dried *in vacuo* before use.

Acetone was dried over anhydrous potassium carbonate, and distilled from 4 Å molecular sieves before use. Tetrabutylammonium perchlorate (TBAP) was prepared by the usual method.

Cyclic Voltammograms. Cyclic voltammetric (CV) measurement were made with a Hokuto model HA104 potentiostat/galvanostat driven by a Hokuto model HB107A function generator. Scans were recorded with a Rika Denki X-Y recorder. A conventional three-electrode system was utilized. A Pt wire served as the working electrode, and a Pt coil was used as the counter electrode. A commercial saturated calomel electrode (SCE) was utilized as the reference electrode. Current-voltage curves were measured at 0.05—0.5 V/s. The SCE was separated from the bulk of the solution with a fritted-glass bridge filled with solvent and supporting electrolyte. All potentials are reported in volts *vs.* SCE.

A solution of phen (1.0×10^{-4} mol) and anhydrous CuCl (1.0×10^{-4} mol) in 50 cm^3 of acetone was stirred under argon at 25 °C for 4 h. Complete complex formation was checked by monitoring the band at 440 nm (peak maxima). This solution was transferred anerobically into the electrolytic cell containing TBAP (5.0×10^{-3} mol), and maintained at constant temperature. Temperature was set at 5 and 25 °C. During measurments, argon atmosphere was kept over the solution in the electrolytic cell. The carbonyl adduct was prepared by directly passing CO gas into the stock solution prepared in a similar way. It was then transferred into the electrolytic cell in which CO atmosphere (1 atm) was maintained during measurements. The partial pressure of CO in the gas bubbled through the stock solution and the electrolytic cell was adjusted by mixing pure argon with pure CO, using two Kusano KG-1 rotameters and two precission needle valves. Partial pressure effect was examined only for $[CuCl(bpy)]_2$. The cyclic voltammograms of the copper(I) complexes containing the other phen or bpy derivatives were measured in similar ways.

Solution Equilibria. Visible spectra were recorded on Hitachi 200-10 spectrophotometer. The cell used for the

determination of CO equilibria consisted of 1.0-cm quartz cuvette with gas inlet and outlet tubes, by means of which N_2 gas containing varying partial pressure of CO can be bubbled through the copper(I) complex solution. The change in absorbance maxima was measured as a function of the partial pressure of CO. The equilibrium constants given by Eqs. 1 and 2 were obtained.

$$[CuClL]_2 + CO \overset{K_{co}}{\rightleftharpoons} [Cu_2Cl_2L_2(CO)] \quad (1)$$

$$K_{co} = [Cu_2Cl_2L_2(CO)]/[[CuClL]_2](P_{co}) \quad (2)$$

The detailed procedure to obtain the equilibrium constants has been described elsewhere.[1]

Measurements of Infrared Spectra. Infrared spectra were recorded on Hitachi 260-10 spectrophotometer. The spectra of saturated solutions of $[Cu_2Cl_2L_2(CO)]$ were measured in 0.05-cm cavity KCl cells, with polystyrene film as calibration standard. KBr disk pellet was prepared as follows. A solution of $L(1.0\times10^{-3}$ mol) and $CuCl(1.0\times10^{3}$ mol) in 50 cm^3 acetone was stirred under argon for 4 h. A suspended brown solution was obtained. Carbon monoxide was then added to this solution; the initially brown color turned pale yellow and the precipitate dissolved into acetone. When the solution was cooled at −70 °C, a pale yellow crystals were obtained. This was stable at low temperature. The quick preparation of KBr disk pellets provided IR spectra of $[Cu_2Cl_2L_2(CO)]$. The carbonyl adduct in KBr disk was stable for many hours.

Results and Discussion

Electrode Reactions. Figure 2 illustrates a typical cyclic voltammogram of $[CuCl(phen)]_2$ (**1c**) in acetone/0.1 M TBAP (1 M=1 mol dm^{-3}). The oxidation-reduction reactions noted here correspond to the metal-centered reactions, Cu^I/Cu^{II} at 0.3—0.7 V *vs.* SCE, because the ligand phen encounters no reaction in this region. The cyclic voltammogram of **1c** (Fig. 2) shows two oxidation processes. The ^1H NMR spectrum of **1c** in acetone showed the signals attributed to only a single species indicative of no dissociation of **1c**. The first two peaks(1) in cyclic voltammogram at 0.22 and 0.44 V in Fig. 2 are coupled to the initial oxidation-reduction process of the other copper of **1c**. These are chemically reversible and non-Nernstian at a platinum electrode ($E_{p,a}-E_{p,c}$=0.1—0.2 V). These electrode reactions are represented by Eqs. 3 and 4.

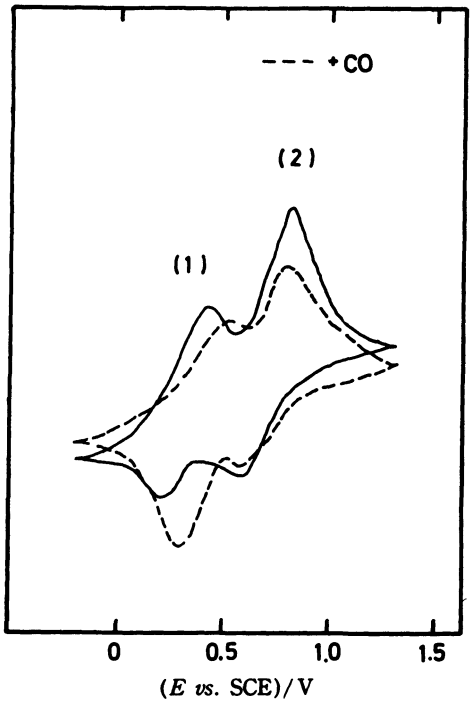

Fig. 2. Cyclic voltammograms of $[CuCl(phen)]_2$(solid line) and $[Cu_2Cl_2(phen)_2(CO)]$(dotted line) in acetone.

$$(phen)Cu^ICl_2Cu^I(phen) \overset{-e}{\rightleftharpoons} (phen)Cu^{II}Cl_2Cu^I(phen) \quad (3)$$

$$(phen)Cu^{II}Cl_2Cu^I(phen) \overset{-e}{\rightleftharpoons} (phen)Cu^{II}Cl_2Cu^{II}(phen) \quad (4)$$

On the other hand, copper(I) complex containing 2,9-dmp or 6,6′-dmbp showed a single oxidation process; this indicates that the dominant species is a mononuclear form. Appearance of the two oxidation peaks[6] at this region is a good measure of the binuclear structure of the copper(I) complex in question. The other binuclear copper(I) complexes, **1a**, **1b**—**f**, **2a**, and **2b**, also have similar anodic properties. If differences in diffusion coefficients between the oxidation and reduction halves of redox couples are ignored, value of $E_{1/2}$ obtained in the above electrochemical experiments can be used. These formal half-wave potentials ($E_{1/2}$s) are listed in Table 1. Knowledge of these formal potentials enables one to quantify some interesting properties of the system.

Electrode Reactions under CO Atmosphere. In this electrode reaction, both two sets of coupled peaks should shift anodically if a dicarbonyl adduct is formed. The ^1H NMR and visible spectra have demonstrated that $[CuCl(phen)]_2$ binds to CO at room temperature to give a monocarbonyl adduct $[(phen)CuCl_2Cu(CO)(phen)]$.[1] It is worth noting in Fig. 2 that the couple(1) alone moves anodically and the other couple(2) remains. This also support the formation of monocarbonyl adduct. In order to firmly assign this cyclic voltammogram, the partial pressure of CO is varied. When the partial pressure increases, the peak current of the couple(1) of $[CuCl(phen)]_2$ decreases and a new couple(1) (a dashed curve in Fig. 2) appears.[7] The high pressure of CO causes the increase in the peak current of the new couple(1) but it does not influence the redox potential. This fact exhibits that the monocarbonylated complex

a) [Complex]=2.0×10^{-3} M and [TBAP]=0.1 M in acetone at 25°C.

forms with the increase of the CO pressure. Hence, the new couple(1) is attributable to the copper coordinated with CO. The selective anodic shift of the copper coordinated by CO has also been found in $Cu^{I}Cu^{I}L'(CO)$,[6] in which the stabilization of the copper(I)(Cu–CO) is attributable to the π back-bonding interaction between CO and Cu. It is interesting to compare the relative stability of two copper(I) ions in the binuclear monocarbonyl complex. In the case of $[Cu_2Cl_2L_2(CO)]$ studied here, the first oxidation occurs at $Cu^{I}(CO)$, while it occurs at the Cu^{I} without coordinated CO in the case of $[Cu^{I}Cu^{I}(CO)L']$. It should be remembered that copper(I) prefers the tetrahedral geometry while copper(I) favors the square-planar one. $[Cu_2Cl_2L_2(CO)]$ has a flexible structure[1] and the geometry around each copper atom is different and may not be simply square-planar; one is distorted square-pyramidal (CO-coordinated) and the other is tetrahedral.[8] On this basis, the five-coordinate copper(I) is less stable than the tetrahedral one in spite of the coordination of CO. On the other hand, [CuCu(CO)L'][6] has square-planar and square-pyramidal geometry around each copper atom. The square-planar copper is less stable than the square-pyramidal copper because the latter is stabilized by π back-bonding interaction with CO. Consequently, the contribution of geometry around the copper atom may predominate over the effect of stabilization of CO as the fifth ligand in the carbonyl copper(I) complexes studied here.

Relationship between $E_{1/2}$ and pK_a of Ligands. Figure 3 shows that the $E_{1/2}$ values for copper(I) complexes containing phen derivatives are plotted against the pK_a values of phens. The straight lines exhibit a good relationship between $E_{1/2}$ and pK_a: the negative slope reveals that the ligand having the higher pK_a destabilizes the copper(I) complexes. Similar results have been found in copper(I) complex in aqueous solution.[9] This is accounted for by the following two reasons. Firstly, when the coordinated ligand gives a more negative charges to the copper(I) ion, this ion will be more unstable. In fact, the aliphatic amines having the greater basicity (pK_a=10—11) form very unstable complexes with copper(I) ion, which are readily oxidized to copper(II) complexes. On the other hand, copper(II) ion favors the ligand having the greater basicity and forms the stable complex.[10] Hence, the ligand having the greater basicity contributes to the stabilization of its copper(II) complexes more effectively than that of copper(I) complex. Secondly, the π conjugated structure of the ligand can accept electronic

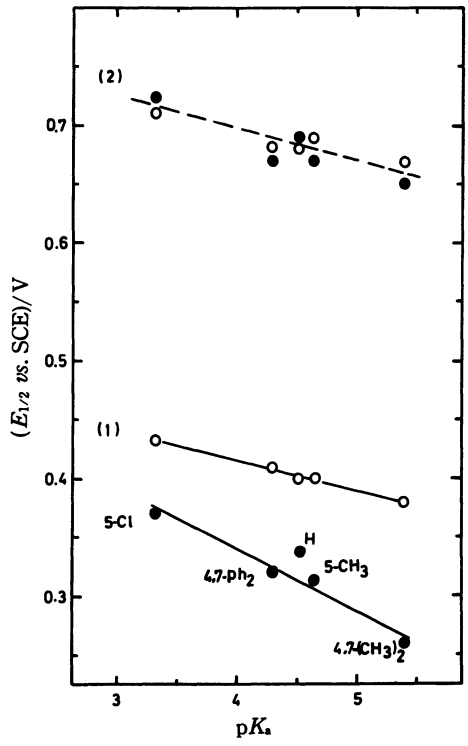

Fig. 3. Plots of half-wave potentials ($E_1/_2$) of $[CuClL]_2$ (●) and $[Cu_2Cl_2L_2(CO)]$ (○) *vs.* pK_a of the ligand (L; phen derivatives).

charge from copper(I) ion through π back-bonding. The substituent which enhances the donor ability of the nitrogen of the ligand tends to destabilize the lowest vacant (LV) π^* orbital[11,12] of the ligand which is significantly associated with the π back-bonding. This effect has been demonstrated in the case of 4-substituted pyridines.[13] On this basis, the ligand with the greater basicity is disadvantageous for π back-bonding interaction with copper(I) ion, and it lowers the redox potential of the resultant copper(I) complex. Consequently, in a series of bidentate ligands possessing donor atoms which have both σ and π bonding natures, their copper(I) complexes are destabilized with an increase in their pK_a values.

It is worth noting in Fig. 3 that the gradient of the straight line(1) of the CO adducts is smaller than that of the precursor complex, indicative of the contribution of a coordinated CO to the stabilization of copper(I) ion: even if phen derivatives with the higher basicity destabilizes Cu^I state in a moiety ($LCu(CO)<^{x}_{x}$) of a CO adduct, coordinated CO stabilizes Cu^I state through π back-bonding. On the other hand, the copper(I) ion in the residual moiety ($^{x}_{x}>CuL$) shows a pK_a-dependence of $E_{1/2}$ similar to that of the precursor one. In this sense, CO is a good π acceptor. This nature of CO leads to the expectation that CO competes with L for π back-bonding. In fact, the intense MLCT band between L and copper(I) ion in the visible region disappears[1] when CO binds [$LCuCl_2CuL$]. This indicates that CO is significantly associated with π back-bonding and subsequently, it enhances the stabilization of copper(I) state, competing with a bidentate ligand L.

Relationship between K_{CO} and λ_{MLCT}. The stability of the CO adduct is examined with the aid of the equilibrium constants. The K_{CO} values obtained for the binuclear complexes (Eqs. 1 and 2) are listed in Table 2, together with the peak maxima of the metal-to-ligand charge transfer (MLCT) band of $[CuClL]_2$, λ_{MLCT}. This K_{CO} exhibits the affinity for CO of copper(I) ion. K_{CO} reflects the competition of L with CO concerning the metal-ligand binding. A good measure to depict the Cu–L π back-bonding is λ_{MLCT}, whose greater value indicates the significant association of π back-bonding in Cu–L bond. In order to examine the relationship between stability of CO adducts and their π back-bonding nature of Cu–CO bonding, K_{CO} is plotted against λ_{MLCT} (Fig. 4). Figure 4 shows the good correlation between K_{CO} and λ_{MLCT}, indicative of considerable contribution of π back-bonding to the stabilization of CO adducts. The stronger Cu–L π back-bonding (the greater λ_{max}) results in the weaker CO-affinity (the smaller K_{CO}). It is concluded that L controls the affinity for CO of copper(I) through π-bonding although overall stability of the CO adduct, of course, results from the delicate balance between bondings of Cu–CO and Cu–L and the resultant geometry.

Coordinated Carbonyl Stretching Frequencies. To gain further insight into the nature of the Cu–CO bonding, CO-stretching frequencies of the copper(I) complexes have been measured. These ν_{CO} values are presented in Table 3. Inspection of Table 3 reveals that they fall within the range 2063—2088 cm^{-1}. It is well known that π back-bonding plays an important role in the metal–CO bond. This π back-bonding brings about a shift of ν_{CO} toward the lower frequency region.[14] On this basis, the smaller value of ν_{CO} indicates the stronger π back-bonding in the Cu–CO bond. Floriani *et al.*[15-18] have synthesized several four-coordinate carbonyl copper(I) complexes containing aliphatic amines such as ethylenediamine and their derivatives. These ν_{CO} values fall within 2055—2080 cm^{-1}, and the bond distances of Cu–CO(r_{Cu-CO}) and C–O(r_{C-O}) are 1.73—1.80 Å, and 1.11—1.17 Å, respectively. They, however, could not find the evident relationship between the ν_{CO} and r_{Cu-CO} or r_{C-O} in their four-coordinate copper(I) complexes containing the terminal CO. A five-coordinate carbonyl, copper(I) complex has been synthesized by Gagne *et al.*[19,20] This gave ν_{CO}=2068 cm^{-1}. Five coordinate [$Cu_2X_2L_2(CO)$] studied here also encounters ν_{CO} values of 2063—2088 cm^{-1}. These terminal CO provides no ν_{CO} values characteristic of the five-coordinate form. The stretching frequencies of CO coordinated to Cu^I seem to have no evident correlation with a coordination number and geometry around copper, such as tetrahedral or square-pyramidal. Then, a question arises. What does the ν_{CO} inform us about carbonyl copper(I) complexes? It is worth noting that most of carbonyl copper(I) complexes are ternary ones containing Cu, CO, and L. On the basis of the discussion in the previous section, we are now in a position to focus on the ν_{CO} in relation to the Cu–CO bonding influenced by L through the Cu–L bonding. This effect of the coordinated ligand should be examined by use of a series of structural analogs of carbonyl copper(I) complexes in order to exclude the contribution of other structural factors. We have explored the Cu–CO bonding of [$Cu_2X_2L_2(CO)$] with the aid of the formation constants of carbonyl copper(I) complexes,[1] which depend on the coordinated ligands and halide ions. We now refer to monocarbonyl copper(I) complexes studied here. These are relevant to inquire into the nature of Cu–CO bonding as a function of L and X^-. Table 3 shows that the ligand L influences the ν_{CO} values appreciably: the CO adduct of **1a** (or **1b**) has a greater ν_{CO} value than that of **1c** while the affinity for CO of these complexes is cataloged with the increasing order **1a**<**1c** (Table 2). This is accounted for by the π-acceptor capability of phen derivatives. As is discussed in the previous section, 5-Cl-phen π encounters stronger π back-bonding from copper(I) ion than non-substituted phen,

Table 3. CO-stretching frequencies of carbonyl adducts

Precursor complex	ν_{CO}/cm^{-1}	
	In the solid state[a]	In solution[b]
1a	2088	2085
1b	2082	—
1c	2063	2076
1d	2068	—
2a	2066	2075
$[CuI(bpy)]_2$	2064	—

a) KBr disk. Error limit, ± 1 cm^{-1}. b) In acetone. Error limit, ± 2 cm^{-1}.

and it should weaken the π back-bonding between copper(I) and CO, leading to the decrease in CO-affinity of the precursor complex. The similar trend in ν_{CO} is also obtained from $[Cu_2X_2L_2(CO)]$ in solution, as shown in Table 3. As is expected from the affinity for CO in Table 2, ν_{CO} obtained for **1d** is similar to that for **1c**. Hence, the effect of the methyl group at 5-position of phen is smaller than that of the halogeno groups.

The ν_{CO} of **2a** containing bpy is close to that of **1c**, both in solution and in solid states. Substitution of I^- for Cl^- in **2a** causes ν_{CO} signal to shift slightly to the lower frequency region. Similar phenomena are also found in $[Cu_2(tmen)_2(CO)_2X]$ ($X=Cl^-$, Br^-, and I^-).[17] This trend in ν_{CO} is reasonable in the light of the fact that $[CuI(bpy)]_2$ has stronger affinity for CO than $[CuCl(bpy)]_2$ (Table 3 in the Ref. 1). This slight change in ν_{CO} upon substitution of halide ion indicates that L is more effective for carbonyl stretching frequencies than halide ions, and this is in good contrast to the fact that a halide ion exerts its drastic effect upon the affinity for CO of the precursor complex. In conclusion, ν_{CO} values are available to investigate the bonding nature of Cu–CO among the structural analogs of carbonyl copper(I) complexes. The ν_{CO} values as well as K_{CO} reflect the competition of CO with L concerning the π-bonding.

We appreciate the assistance of Mr. Yonezawa. This work was supported in part by a Grant-in-Aid Scientific Research No. 57740326 from the Ministry of Education, Science and Culture.

A Kinetic Study of a Zn^{2+}-catalyzed Transamination Reaction between Pyridoxamine Analogs with a Pyridinophane Structure and α-Keto Acids

Yoji TACHIBANA,† Makoto ANDO, and Hiroyoshi KUZUHARA*
The Institute of Physical and Chemical Research, Wako, Saitama 351
(Received January 6, 1983)

The kinetics of the nonenzymatic transamination reaction from pyridoxamine analogs with a pyridinophane structure to α-keto acids catalyzed by Zn^{2+} were investigated by monitoring the changes in the absorption spectra in methanol. It was found that these reactions obeyed first-order kinetics for the formation of the Zn^{2+} chelate of an aldimine. No appreciable change in the reaction rate was observed when the concentration of the α-keto acid was increased, indicating that the isomerization of the ketimine chelate to the aldimine chelate is the rate-determining step. There was a considerable enhancement of the reaction rate when the molar ratio of the zinc ion to the pyridoxamine analogs was reduced from 1/1 to 0.5/1. The reaction rates corresponding to the various α-keto acids employed in the presence of an amount of Zn^{2+} equimolar to the pyridoxamine analog decreased in this order; phenylpyruvic acid>pyruvic acid≈4-methyl-2-oxopentanoic acid>3-methyl-2-oxobutanoic acid, whereas those in the presence of half-molar equivalents of Zn^{2+} to the pyridoxamine analog decreased in this order; pyruvic acid>phenylpyruvic acid ≈4-methyl-2-oxopentanoic acid>3-methyl-2-oxobutanoic acid. Furthermore, the use of the pyridoxamine analog with a linear "ansa" bridge resulted in a larger reaction rate than the use of the one with a branched "ansa" bridge. The solvent isotope effect is also described.

In a series of studies of the vitamin B_6-dependent enzyme mimics, we have succeeded in the asymmetric synthesis of various α-amino acids by employing the chiral pyridoxamine analogs with an "ansa" bridge between the 2- and the 5-positions of the pyridine ring as the donor of an amino group to the corresponding α-keto acids.[1,2] This stereoselective nonenzymatic transamination reaction was catalyzed by Zn^{2+}, like the usual transamination model reactions.[3] The mechanism of the transamination reaction involves the formation of the zinc chelate complex of the ketimine Schiff base (**4**) and the subsequent isomerization to the aldimine Sciff base (**6**) within the complex.[4] In order to obtain further information about the mechanism of this system, we investigated the kinetics of this nonenzymatic transamination reaction.

All the reactions examined here with the racemates of the pyridoxamine analogs proceeded quite smoothly at room temperature, and all could be followed by means of the spectral change in a methanol solution. This paper will describe the influence of the molar ratio of Zn^{2+} to the pyridoxamine analogs, and also that of the bulkiness of the "ansa" bridge in the pyridoxamine analog molecules, on the reaction rates of the nonenzymatic transamination reaction; our results indicate some different aspects from those reported for the reactions using pyridoxamine itself.[3,5]

Experimental

The pyridoxamine analogs, 15-aminomethyl-14-hydroxy-5,5-dimethyl-2,8-dithia[9](2,5)pyridinophane (**1**)[6] and 15-aminomethyl-14-hydroxy-2,8-dithia[9](2,5)pyridinophane (**2**),[1] and pyridoxal analogs, 15-formyl-14-hydroxy-5,5-dimethyl-2,8-dithia[9](2,5)pyridinophane (**7**)[6] and 15-formyl-14-hydroxy-2,8-dithia[9](2,5)pyridinophane (**8**),[7] were prepared as has been reported previously. The other materials were obtained from commercial sources. The UV spectra were recorded with a Hitachi 124 spectrometer.

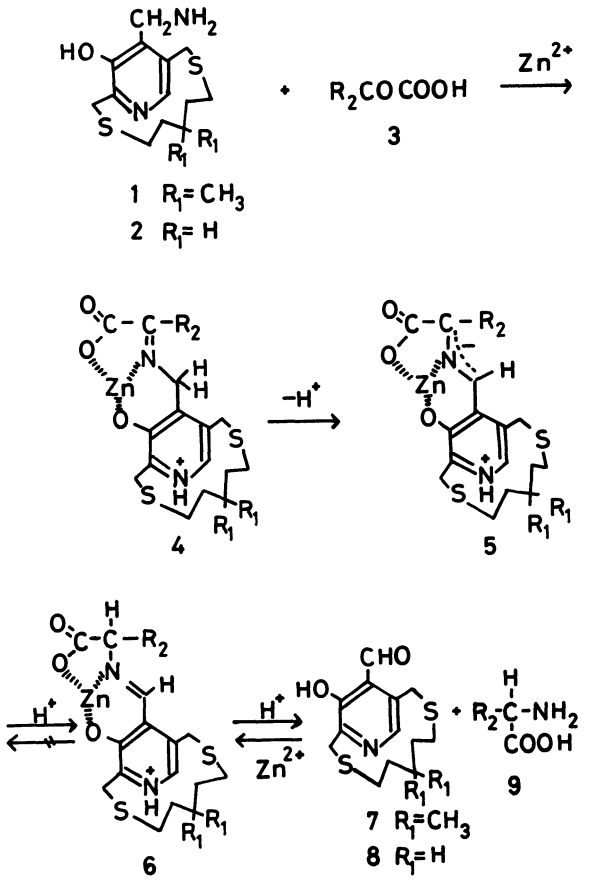

Fig. 1. Nonenzymatic transamination reaction between pyridoxamine analogs and α-keto acid.

Theree methanolic solutions (100 ml each) of a pyridoxamine analog (0.1 mmol), of α-keto acid (0.2—1.6 mmol), and of $Zn(ClO_4)_2 \cdot 6H_2O$ (0.025—0.3 mmol) were prepared. To the pyridoxamine analog solution (10 ml) we added an α-keto acid solution (10 ml) and a zinc perchlorate solution (10 ml) successively; we then immediately diluted them with methanol until the total volume of the solution was 100 ml. The solution was stirred at 23 °C, and aliquots of the solution were taken at

regular time intervals for recording the electronic-absorption spectrum.

Results and Discussion

Spectral Changes. The rates of the changes in the absorption spectra that occur when the pyridoxamine analog (**1**), sodium pyruvate, and zinc perchlorate solutions are mixed simultaneously in the molar ratios of 1 : 4 : 0.5 and 1 : 4 : 1 are shown in Figs. 2 and 3 respectively. When the molar ratio of Zn^{2+} to the pyridoxamine analog (**1**) was 0.5/1, only one peak at 305 nm was formed initially. As the intensity of the 305 nm peak decreased with time, a newly formed peak at 395 nm increased, accompanied by the formation of a couple of isosbestic points at 290 and 340 nm (Fig. 2).

When the molar ratio of Zn^{2+} to the pyridoxamine analog (**1**) was 1/1, the initial spectrum in the reaction had an absorption maximum at 305 nm and a shoulder at 320 nm. As the peak at 305 nm disappeared, the absorption at 320 nm became a single absorption maximum within 3 h. With the gradual decrease in the peak at 320 nm with time, the band at 395 nm is strengthened, with its isosbestic points at 290 and 350 nm (Fig. 3). Although the final spectra were quite similar in both cases, the rate of the absorption spectral change was much smaller in the latter case (Zn^{2+}/**1**=1/1) than in the former case (Zn^{2+}/**1**=0.5/1). The final absorption spectra in both cases were the same as those of the Zn^{2+}–aldimine chelates (**6**) prepared from the pyridoxal analog (**7**), sodium salt of alanine, and zinc perchlorate in the molar ratios of 1 : 4 : 0.5 and 1 : 4 : 1 respectively. These facts suggest that the transformation of the ketimine (**4**) to the aldimine (**6**) was completed within the chelated complex, in each cases including a different amount of Zn^{2+}; the mode of the chelation also seemed to be different.

Matsushima and Martell have reported kinetic studies of the reaction between pyridoxamine, potassium 3-methyl-2-oxobutanoic acid, and zinc acetate to produce Zn^{2+} chelate of pyridoxylidenevaline.[3] They used the absorption band of the Zn^{2+} chelate of pyridoxylidenevaline at 385 nm for these kinetic studies because of its large molecular extinction coefficient, and also because the pyridoxylidenevaline chelate is the only substance that might be present which absorbs at that wavelength. In the same manner, we employed for the present kinetic studies the 395 nm band, which should be assigned to the Zn^{2+}–aldimine chelate (**6**). The plot of $\ln A_\infty/(A_\infty - A_t)$ against the time t (where A_∞ and A_t indicate the optical densities at 395 nm at the completion of the reaction and the time t respectively) gave straight lines. This indicates that these reactions obeyed first-order kinetics for the formation of the Zn^{2+}–aldimine chelate. The first-order rate constant, k_{opsd}, was obtained for the slopes of the straight lines.

Influence of the Concentration of Keto Acid. The results of kinetic runs in which the concentration of the pyridoxamine analog (**1**) was kept at 1.0×10^{-4} M (1 M=1 mol dm^{-3}), while those of the α-keto acids and zinc perchlorate were varied, are shown in Table 1. When the molar ratio of Zn^{2+} to the pyridoxamine

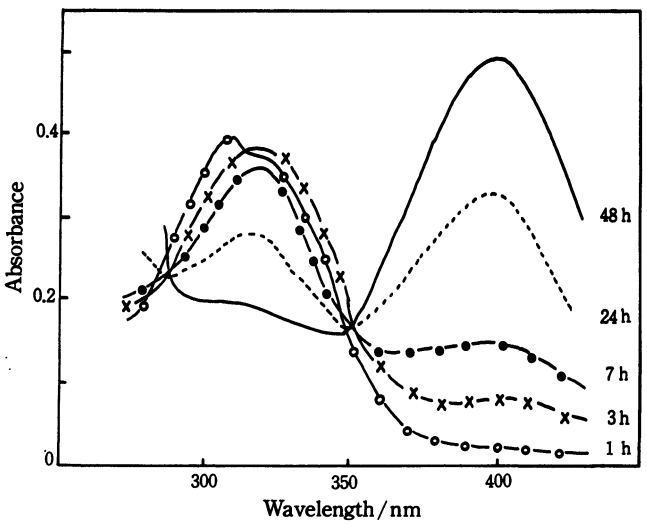

Fig. 3. Changes of electronic absorption spectra with time for a methanolic solution of pyridoxamine analog (**1**) (1.0×10^{-4} M), zinc perchlorate (1.0×10^{-4} M), and sodium pyruvate (4.0×10^{-4} M).

analog (**1**) was 0.5/1, the rate constants increased very slightly with the increase in the α-keto acid concentration from 2.0×10^{-4} M up to 6.0×10^{-4} M, while they were almost constant at higher α-keto acid concentrations ($\approx8.0\times10^{-4}$ M). When the molar ratio of Zn^{2+}/**1** was 1/1, the rate constants were little influenced by the concentration of the α-keto acids. Such an essential independence of the rate constants from the concentration of the α-keto acids indicates that the rate-determining step in the nonenzymatic transamination reaction is not the formation of the Zn^{2+}–ketimine chelates (**4**), but its isomerization to the Zn^{2+}–aldimine chelates (**6**), which is comprised of two reaction stages: the deprotonation of **4** and the protonation of the resulting **5**. The electronic absorption ascribable to **5** has not been observed,[8] suggesting that the protonation of **5** takes

place rapidly to give **6**. The observation that the employment of a large excess of α-keto acid reduced the rate constant might be explained by the chelation with the α-keto acid that lowers the concentration of the utilizable Zn^{2+}.

Influence of the Kind of Keto Acid. The rate constants decreased in this order; phenylpyruvic acid> pyruvic acid ≈4-methyl-2-oxopentanoic acid>3-methyl-2-oxobutanoic acid when Zn^{2+} and the pyridoxamine analog (**1**) were used in a molar ratio of 1/1. The largest rate constant of phenylpyruvic acid might be explained by assuming that the electron-withdrawing ability of the phenyl group stabilizes the carbanion intermediates (**5**).[9,10] On the other hand, the employment of half-molar equivalents of Zn^{2+} to **1** resulted in this order; puruvic acid>phenylpyruvic acid≈4-methyl-2-oxopentanoic acid>3-methyl-2-oxobutanoic acid. Since the amount of Zn^{2+} is restricted under these

a) **2**: 1.0×10^{-4} M.

conditions, a rigid octahedral Zn^{2+} intermediate coordinated with 2 mol of the ketimine ligands is formed.[11,12] The reaction rate is influenced more by the steric factor than by the electronic factor in this situation.[13,14] This is the reason why the order of the rate constants between pyruvic acid and phenylpyruvic acid was reversed when Zn^{2+}/**1** ratio was changed from 1/1 to 0.5/1.

Influence of the Bulkiness of the "Ansa" Bridge in the Pyridoxamine Analogs. A comparison of Table 2 with Table 1 shows that the rate constants of the transamination reaction using **2** was larger than those using **1**. The branched-bridge chain in **1** seems to affect the reaction rate more negatively than the linear one in **2**.

Influence of the Molar Ratio of Zn^{2+} to Pyridoxamine Analogs. According to Matsushima and Martell,[3] the rate constants for the formation of the Zn^{2+} chelate of pyridoxylidenevaline decreased with the decrease in the Zn^{2+} concentration in the range from 2.0×10^{-4} M to 0.5×10^{-4} M (pyridoxamine: 1.0×10^{-4} M and potassium 3-methyl-2-oxobutanoate: 1.0×10^{-3} M). In contrast to their results, the rate constants of our nonenzymatic transamination reaction using the pyridoxamine analogs with a pyridinophane structure such as **1** increased almost linearly as the Zn^{2+} concentration was decreased from 1.0×10^{-4} M to 0.5×10^{-4} M; they then decreased at lower concentrations of Zn^{2+} ($\approx0.25\times10^{-4}$ M). When the concentration of Zn^{2+} was above 1.0×10^{-4} M, the rate constants were constant. The results are illustrated in Fig. 4. The mechanism of such interesting changes in the reaction rates is obscure at this stage. However, they remind us of a similar correlation between the ratio of Zn^{2+}/**1** and the enantiomeric excesses of the α-amino acids that was obtained through the same transamination reaction using chiral **1**[2]; *i.e.*, an enhancement of the enantiomeric excesses was observed with a lowering of the ratio of Zn^{2+}/chiral **1** from 1/1 to 0.5/1, like the enhancement of the reaction rates with the racemate in this paper. The figures in

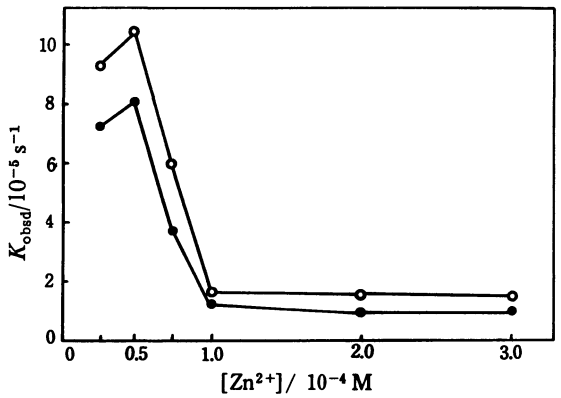

Fig. 4. Variation of k_{obsd} as a function of zinc perchlorate concentration; solutions contained 1.0×10^{-4} M pyridoxamine analog (**1**) with 6.0×10^{-4} M sodium pyruvate (○) and with 6.0×10^{-4} M sodium 4-methyl-2-oxopentanoate (●).

parentheses in Table 1 indicate that there was little difference in the reaction rates between the racemic pyridoxamine analog and the chiral one. This means all discussions of the reaction rates concerning the racemate in this paper are also applicable to the reactions with the chiral one. Consequently, it may be concluded in the chiral system that the enhancement of both the reaction rate and stereoselectivity at the same time can be attained by lowering the ratio of Zn^{2+}/**1**. These interesting phenomena are suggestive of some role of the "ansa" bridge present in the pyridoxamine analog in determining the reaction rate, as this seemed to dominate the enantiomeric excesses of the products in the chiral system.[4]

Solvent Isotope Effect. We have also reported that the α-proton of an amino acid produced through the nonenzymatic transamination reaction was deuteriated when methanol-*d* (MeOD) was used as the solvent.[4] This indicates that the deuterium atom comes directly from the solvent. Furthermore, the pyridoxal analog recovered after the reaction contained no deuterium atom. These results and the aforementioned fact that there was no observable electronic absorption ascribable to **5** strongly support the idea that the rate-determining step of this transamination reaction is the deprotonation of **4** (Fig. 1). In order to measure the solvent isotope effect, the reaction in MeOD was examined. The rate constant was found to be about three times smaller in MeOD than in MeOH. The obtained hydrogen isotope effects, k^H/k^D, were 3.5 for **1** and 2.9 for **2** (1.0×10^{-4} M pyridoxamine analogs, 0.5×10^{-4} M Zn^{2+}, and 6.0×10^{-4} M sodium pyruvate).

Immunoassay Using a Metal-complex Compound as a Chemiluminescent Catalyst. I. Iron(III)phthalocyanine as a Labeling Reagent

Tadashi Hara,* Motohiro Toriyama, and Kazuhiko Tsukagoshi
Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602
(Received January 10, 1983)

A synthesized metal-complex compound with catalytic activity for a chemiluminescence reaction has been used for the first time as a labeling reagent for immunoassay. Several complex compounds of iron(III) and cobalt(II) were synthesized, and their catalytic activities for the chemiluminescence reaction between 5-amino-2,3-dihydro-1,4-phthalazinedione (luminol) and hydrogen peroxide (H_2O_2) were examined. Iron(III) 4,11,18,25-tetracarboxyphthalocyanine (TCP-Fe(III)) showed the highest catalytic activity. The immunoassay of free albumin was carried out by a competitive method using albumin labeled with TCP-Fe(III) by means of the carbodiimide method; free albumin in the range of 2 to 1000 μg/tube could be determined with a coefficient of variation of from 6 to 16% in 5 analyses.

In order to determine a trace amount of component in a biological sample, various immunoassays, including radioimmunoassay (RIA), enzyme immunoassay (EIA), fluoroimmunoassay, spin immunoassay, and metalloimmunoassay, have been reported. EIA is an excellent method for the determination of a trace amount of a component in a biological sample, but it has the following defects: 1) an inhomogeneous antigen-antibody reaction caused by the steric hindrance of a large enzyme molecule as a labeling reagent, 2) the additional time necessary for the enzyme reaction, and 3) the instability of the enzyme.

Chemiluminescence immunoassay (CLIA) has also become a method of interest since the defects in EIA can be more or less overcome. Moreover, CLIA has the following characteristics: 1) high sensitivity, 2) rapid analysis after the separation of bound and free antigens, and 3) a simple and inexpensive apparatus. Various natural substances,[1-3] such as hemin, cytochrome c, vitamin B_{12}, ferritin, catalase, hemoglobin, and peroxidase, have been used as a labeling agent for CLIA. These labeling agents are limited by the kind and number of functional groups available for labeling, and by their instability and purity.

The use of a synthesized metal-complex compound instead of the above-mentioned natural substances as a catalyst in CLIA is supposed to make CLIA sensitive, inexpensive, and reproducible, and also to make labeling easy. No immunoassay has, however, been reported in which a synthesized metal-complex catalyst is used as a labeling reagent. In this connection, several metal-complex catalysts were synthesized by the authors, and their catalytic activities were examined, TCP-Fe(III) being found to be most promising. In the present study, albumin was selected as a model compound for the analysis of a protein. It was determined by CLIA using a metal-complex catalyst as follows: the free albumin as an analyte and labeled albumin with TCP-Fe(III) as a competitor were made to react competitively with an antibody immobilized on glass beads, and the TCP-Fe(III) on the bound fraction after the separation of the bound and free fractions was determined by measuring the chemiluminescence intensity between luminol and H_2O_2.

Experimental

Preparation of Labeled Albumin. TCP-Fe(III) as a labeling reagent was synthesized by the method of Shirai *et al.*[4,5] The human serum albumin (HSA) with TCP-Fe(III) was labeled by the carbodiimide method as follows. Five milligrams of TCP-Fe(III) was dissolved in 10 cm^3 of a potassium dihydrogenphosphate–disodium hydrogenphosphate buffer solution (pH 7.0)(Buffer Soln (A)); 20 mg of *N*-cyclohexyl-*N'*-(2-morpholinoethyl)carbodiimide - methyl *p*-toluenesulfonate (Fluka) was then added to the solution, and it was mixed for 20 min. Thirty milligrams of HSA (Sigma, Fraction V) was added to the above mixture, and the resulting mixture was incubated for 48 h at 4 °C. After the reaction, the mixture was centrifuged at 15000 *g*, and the precipitate was removed. To the supernatants we added 10 cm^3 of a saturated ammonium sulfate solution, after which the mixed solution was kept at 4 °C overnight. The supernatants was removed by centrifugation, and the precipitate thus obtained was dissolved in 2 cm^3 of Buffer Soln (A), after which the solution was dialyzed against Buffer Soln (A) to remove the ammonium sulfate. After dialysis, the solution was submitted to gel chromatography on a TOYOPEARL HW-50 (TOYO SODA) column (150 cm^3) by the use of Buffer Soln (A) as an eluent; a 30-cm^3 portion of an albumin fraction containing albumin labeled with TCP-Fe(III) was thus obtained.

Preparation of Glass Beads Immobilized Antibodies. One cubic centimeter of a saturated ammonium sulfate solution was added to 1 cm^3 of rabbit anti-HSA serum (Medical and Biological Laboratories), after which the mixture was kept at room temperature for 1 h. The precipitate was collected by centrifuging it at 10000 *g* for 10 min and was then dissolved in 2 cm^3 of a 0.005 mol dm^{-3} phosphate buffer solution (Buffer Soln (B), pH 7.2) consisting of sodium dihydrogenphosphate and disodium hydrogenphosphate, the resulting solution being dialysed overnight against Buffer Soln (B). The precipitate thus produced was centrifuged, and an immunoglobulin G fraction was obtained by purifying the supernatants on a DEAE-cellulose column equilibrated with a Buffer Soln (B).

On the other hand, the glass-bead surface was activated by holding 100 g of glass beads (4 mm diam.) at 100 °C for 6 h in 100 cm^3 of a 50 wt% sodium hydroxide solution. The glass beads were washed and dried; alkylamino-bonded glass beads were then prepared by holding the glass beads for 6 h under refluxing in 300 cm^3 of a 2% (3-aminopropyl)triethoxysilane toluene solution. The immobilization of antibodies onto alkylamino-bonded glass beads was done by the glu-

taraldehyde method as follows. Thirty grams of the glass beads were dipped in 50 cm^3 of 5% glutaraldehyde/Buffer Soln (B) (0.01 mol dm^{-3}), and the mixture was made to react for 24 h at room temperature. After washing with Buffer Soln (B), the activated glass beads were dipped in 50 cm^3 of Buffer Soln (B) containing one-third of the antibodies which were taken out of 1 cm^3 of the antiserum; the mixture was then held at 4 °C for 48 h. The glass beads thus immobilized with antibodies were preserved at 4 °C in a Buffer Soln (B) containing 0.1% sodium azide and 0.1% bovine serum albumin.

Antigen-antibody Reaction. Twenty-five cubic millimeters of labeled albumin (containing about 0.6 μg of conjugated TCP-Fe(III)) were added to 1 cm^3 of Buffer Soln (B) containing a definite amount of albumin as an analyte, while one glass bead immobilized with an antibody was soaked in its solution. Thus the labeled albumin and the free albumin as an analyte were made to react competitively at 4 °C overnight with an antibody immobilized on the glass bead (competitive immunoassay).

Measurement of Chemiluminescence Intensity. The apparatus used for the measurement of the chemiluminescence intensity is shown in Fig. 1. One cubic centimeter of a 1.0×10^{-3} mol dm^{-3} luminol solution (pH 10.2, boric acid–potassium hydroxide buffer) and 1 cm^3 of a 2.5×10^{-3} mol dm^{-3} H_2O_2 solution were mixed in a 90×10 mm diam. test tube. The test tube was placed in front of the photomultiplier (Hamamaust TV, R464) equipped with a shutter (Copal No. 3), after which it was allowed to stand for 30 min before measurement in order to stabilize the chemiluminescence background.

After the antigen-antibody reaction, the glass beads immobilized with antibodies were washed twice with Buffer Soln (B) and then put into the above mixed solution. The shutter of the photomultiplier was immediately opened, and the chemiluminescence intensity was measured by means of a photon counter (Hamamatsu TV, C1230), the output being recorded by a Matsushita Communication Industrial apparatus (VP-6521A). Since the chemiluminescence intensity showed a maximal value about 3 min after the glass beads were put in, the maximal value was taken as the chemiluminescence intensity of a sample.

The procedure for immunoassay is shown schematically in Fig. 2.

Results and Discussion

Selection of a Labeling Reagent. The requirements for the catalyst as a labeling reagent in CLIA may be summarized as follows: 1) the catalytic activity for a chemiluminescence reaction is large enough for the sensitive detection of an analyte; 2) it has a functional group available for labeling; 3) a labeling reaction is feasible under mild conditions, 4) it is a stable compound, and 5) it can easily be prepared. Though metal ions such as cobalt(II), iron(III), copper(II), and osmium(VIII) show high catalytic activity for chemiluminescence reactions between luminol and H_2O_2, these metal ions can not satisfy all the requirements.

On the other hand, it is well known that chelate compounds, such as peroxidase, microperoxidase, hemin, hematin, and (*N,N'*-disalicylideneethylenediaminato)-cobalt(II),[6] strongly catalyze the chemiluminescence reaction between luminol and H_2O_2. Therefore, some kinds of chelate compounds may be supposed to be useful as labeling reagents. The common structure in the above-mentioned chelate compounds has the following characteristics: 1) the center of a molecule is occupied by iron(III) or cobalt(II), whose coordination number is six, 2) four coordination sites in a planar square are strongly linked with four donor atoms in a quadridentate ligand, and 3) two axial sites are weakly linked with donor atoms.

Cobalt(II) and iron(III) complex compounds were

	Cobalt(II)	7600	9.0
Hematin[b]		300000	360

a) An alkylamino-bonded glass disk was soaked in 20 cm^3 of a 1.0×10^{-3} mol dm^{-3} aqueous complex catalyst solution, and to it a 84.7-mg portion of *N*-cyclohexyl-*N'*-(2-morpholinoethyl)carbodiimide-methyl *p*-toluenesulfonate was added, the mixture then being allowed to react at room temperature for 24 h. b) Hematin was made to react with dicyclohexylcarbodiimide.

prepared by the use of the following quadridentate ligands, each of which has four donor atoms besides the carboxyl group used for the labeling reaction: 5,10,15,20-tetrakis(4-carboxyphenyl)porphine,[7,8] 4,11,18,25-tetracarboxyphthalocyanine, 3,4-bis(salicylideneamino)benzoic acid, *N,N'*-bis[2-(*o*-hydroxyphenylacetic acid)]ethylenediamine (Dojin Laboratories, EDDHA), and *N,N'*-bis(4-carboxysalicylidene)ethylenediamine[9] (Fig. 3). Their catalytic activities for the chemiluminescence reaction between luminol and H_2O_2 were measured by means of the flow-injection analysis system[10,11] and compared with each other. The flow diagram of the flow-injection analysis system and its experimental conditions are shown in Fig. 4, while the results obtained are shown in Fig. 5.

To examine the catalytic activity of a labeled complex compound, an experiment was carried out as follows: the surface of a 12-mm-diam. alkylamino-bonded glass disk was immobilized with a complex catalyst by means of the carboidimide method, and then the glass disk was placed in a stream of a mixed solution (pH 10.2, flow rate 1.96 cm^3 min^{-1}) of luminol (5.0×10^{-4} mol dm^{-3}) and H_2O_2 (1.25×10^{-3} mol dm^{-3}); after the chemiluminescence intensity was then measured with the apparatus[12] shown in Fig. 6. The results are shown in Table 1.

Figure 5 and Table 1 confirm that iron complexes generally show a higher catalytic activity and that their activities remain even after the bond formation of a carboxyl group. Especially, the catalytic activity of TCP–Fe(III) was higher than that of hematin,[13] which had been reported to be one of the most sensitive catalysts for chemiluminescence reactions. Hemin[2] has to be labeled in dimethyl sulfoxide, while TCP–Fe(III) can be labeled easily in water. Judging from these results, TCP–Fe(III) is superior to hemin.

Labeling of Albumin with TCP–Fe(III). The labeling in the immunoassay has to be carried out under mild conditions, since the analyte to be labeled is

chemically unstable. Antigen as an analyte can be easily labeled with TCP-Fe(III) under mild conditions by the use of a water-soluble carbodiimide reagent, because water-soluble TCP-Fe(III) has carboxyl groups which are used for the formation of an amide linkage between TCP-Fe(III) and an analyte. The absorption spectrum of free TCP-Fe(III) in Buffer Soln(A) gave two peaks at 637 and 325 nm, while conjugated TCP-Fe(III) showed a peak at 630 nm and two shoulders at 576 and 338 nm. The retention volume of albumin labeled with TCP-Fe(III) in gel chromatography was slightly smaller than that of albumin alone. Judging from these results, it was concluded that albumin can be certainly labeled with TCP-Fe(III).

In addition, the precipitin arc of labeled HSA with TCP-Fe(III) in an immunodiffusion technique using rabbit anti-HSA serum was the same as that of HSA. This means that the activity of albumin for antigen-antibody reactions is not lost by its labeling.

The catalytic activities of conjugated TCP-Fe(III) and free TCP-Fe(III) for chemiluminescence reactions were also examined (Fig. 7). The concentration of conjugated TCP-Fe(III) in a labeled albumin solution was estimated from the absorption of the solution at 325 nm. As can be seen from Fig. 7, there was no marked difference between the catalytic activities of conjugated TCP-Fe(III) and free TCP-Fe(III). Thus, TCP-Fe(III) was shown to be useful as a labeling reagent for immunoassay.

Immunoassay. The relationship between the time consumed for an antigen-antibody reaction and the chemiluminescence intensity is shown in Fig. 8. The chemiluminescence intensity of a bound fraction for a certain time consumed for an antigen-antibody reaction is shown in Fig. 8 on the basis of the chemiluminescence intensity of the bound fraction which was made to react with albumin labeled with TCP-Fe(III) for 42 h. As can be seen from Fig. 8, the chemiluminescence intensity of a bound fraction was almost constant after 8 h. In all the following experiments, the antigen-antibody reaction was done overnight at 4 °C.

Figure 9 shows a calibration curve obtained by the competitive method. According to this calibration curve, albumin in the range of from 2 to 1000 μg/tube can be determined with a coefficient of variation of from 6 to 16% for 5 analyses. This calibration curve was linear, but not sigmoidal as is seen in a usual immunoas-

I, I_0: Chemiluminescence intensity of the sample in the presence or absence of HSA.

say. This may be supposed to be due to the competitive reaction under unfavorable conditions,[14] *e.g.*, the ues of heterogeneous labeled albumin.

The present method is superior to the conventional methods of immunoassay, such as RIA and EIA, in the following points: 1) no counterplan is necessary for hazards of radioactivity in RIA; 2) the time necessary for measurement is short in comparison with EIA because the measurement is based on the chemiluminescence reaction, and 3) an analytical value is not so much influenced by contaminants[3] because the bound and free fractions are easily separated by the use of glass beads immobilized with antibodies.

It is concluded from the above-mentioned results that a synthesized metal-complex compound which works as a catalyst for a chemiluminescence reaction is useful and promising for immunoassay. Though the sensitivity and precision in the present work were not always satisfactory, they are now being improved by investigating the conditions for antigen-antibody reactions, chemiluminescence reactions, and instrumental measurements. Additional results will be reported in the near future.

An Improved Preparation and Characterization of Tetrahedral Co^{II} and Co^{III} Complexes with Dodecatungstate as the Tetrahedral Ligand

Kenji Nomiya, Ryoichi Kobayashi, and Makoto Miwa*
Department of Industrial Chemistry, Faculty of Engineering, Seikei University, Musashino, Tokyo 180
(Received January 28, 1983)

Tetrabutylammonium salt of the 12-tungstoheteropolyanion with central Co^{II} as the heteroatom in a tetrahedral oxygen environment, $[Co^{II}W_{12}O_{40}]^{6-}$, has been prepared by an improved manner. This manner remarkably shortens the total time needed for preparation, especially the time for purification, and gives a compound of a high purity. The corresponding Co^{III} compound has been obtained by oxidation with potassium peroxodisulfate from the potassium salt of the Co^{II} compound; its spectroscopic data (IR, near-infrared, UV-vis, and MCD) are presented.

Recently we have reported on the syntheses and the spectroscopic properties of tetrahedral transition-metal complexes of the $[MW_{12}O_{40}]$ type ($M=Cu^{II}$, Fe^{III}, Co^{II}), with dodecatungstate as the tetrahedral ligand.[1] In this paper, we wish to report on an improved method for the preparation of the cobaltate(II) ion and its subsequent conversion to the cobaltate(III) ion. The purities and absorption coefficients of the compounds obtained here were superior to those previously reported.[1-3] The cobaltate(III) ion is a d^6 high-spin complex in a tetrahedral field of the $W_{12}O_{40}$ ligand and is one of the spectrophotometrically interesting compounds. From the point of view of a reaction, the Co^{III} compound has been known to promote the oxidation of alkyl-substituted aromatic hydrocarbons[4] and to exchange an electron with the parent Co^{II} compound *via* an outer-sphere mechanism.[5] In this paper, we wish also to report the spectroscopic data (IR spectra both on a solid and in a solution and the near-infrared and UV-vis spectra and the MCD spectra in the UV-vis region) of the tetrabutylammonium cobaltate(III).

Experimental

The near-infrared and vis-UV absorption spectra were measured by means of a Hitachi 340-spectrophotometer with a computer keyboard attached. The intensity is expressed in terms of the molar absorptivity, ε, which has units of mol^{-1} dm^3 cm^{-1}. The MCD spectra were recorded by means of a JASCO J-40AS spectropolarimeter with a 10.0-kG† electromagnet mounted on it. The MCD intensity is expressed in terms of $\Delta\varepsilon=\varepsilon_l-\varepsilon_r$, which has units of mol^{-1} dm^3 m^{-1} G^{-1}. Measurements were made at room temperature. The IR spectra in acetonitrile were measured by using a KBr cell with a 0.1-mm optical path.

Preparation. $K_6[Co^{II}W_{12}O_{40}]\cdot nH_2O$: The pH of a sodium tungstate solution ($Na_2WO_4\cdot 2H_2O$ 79.2 g (0.24 mol) in 160 cm^3 water) was adjusted within 6.5—7.0 by the use of glacial acetic acid. The solution was then boiled over an open flame. $Co(CH_3COO)_2\cdot 4H_2O$ 10.0 g (0.04 mol) was dissolved in 50 cm^3 hot water, whereinto some drops of glacial acetic acid were added. This solution was then added, with continuous stirring, into a boiling sodium tungstate solution. After this addition, the solution was boiled further for about 10 min. The hot solution was then filtered, and a hot, aqueous solution saturated with KCl (52 g) was added to the boiling filtrate. The dark green solution thus obtained was allowed to stand overnight at room temperature. The green crystals of the dicobalt species, $K_8[CoCoW_{11}O_{40}H_2]$, obtained were recrystallized twice from an acid solution with the ratio of 2 cm^3 of glacial acetic acid to 400 cm^3 of water. The green compound obtained in this step was not yet pure. The crude sample was dissolved in about 150 cm^3 of water, whereinto ether was added. Into this solution, 400 cm^3 of 6 M-sulfuric acid (1 M=1 mol dm^{-3}) was continuously stirred, drop by drop. The system separated into three layers; the highest was an ether, and the second was an aqueous layer, while the lowest layer contained the ether adduct of 12-tungstocobaltic acid and metatungstic acid as impurities. The lowest layer was collected, diluted with a small amount of water, and evaporated to dryness on a steam-bath. During the process, metatungstic acid (white) was decomposed to tungsten oxide (yellow), which was insoluble in water. The residue was extracted with water and again heated on a steam-bath. This procedure was repeated until no yellow compound was formed. During the ether-extraction and the purification, the intermediate dicobalt species was changed to the monocobalt species. Free acid, $H_6[Co^{II}W_{12}O_{40}]$, obtained as blue-green crystals, was converted to the potassium salt from a concentrated aqueous solution of potassium chloride. The potassium salt was coarsely ground and thoroughly dried at 110 °C; in this procedure, the hydrogen chloride as an adduct was lost. When the compound was analyzed, it was found to be potassium tetrabutylammonium salt. Found: C, 19.91; H, 3.79; N, 1.66%. Calcd for $K_2[(C_4H_9)_4N]_4[Co^{II}W_{12}O_{40}]$: C, 19.84; H, 3.72; N, 1.75%.

$K[(C_4H_9)_4N]_4[Co^{III}W_{12}O_{40}]$: Using the potassium salt of the Co^{II} compound, the potassium salt of the Co^{III} compound was prepared by oxidation with potassium peroxodisulfate according to the method of Baker and his co-workers.[2,3] It should be noted that the free acid of the Co^{II} compound could not be directly converted into that of the Co^{III} compound because of the decomposition of the peroxodisulfate by the very strong acidity of the cobaltate(II) and/or cobaltate(III). The aqueous solution, acidified with nitric acid, with an excess of tetrabutylammonium bromide was added to the aqueous solution of potassium cobaltate(III). The precipitate thus formed was filtered, washed thoroughly with water, dried *in vacuo*, and recrystallized from acetonitrile (yield, 7.2%; golden yellow). Found: C, 19.64; H, 3.71; N, 1.43%. Calcd for $K[(C_4H_9)_4N]_4[Co^{III}W_{12}O_{40}]$: C, 19.53; H, 3.74; N, 1.48%.

Results and Discussion

The cobalt(II) compound has been obtained as potassium salt by the acid-decomposition of the intermediate dicobalt species, $K_8[Co^{II}Co^{II}W_{11}O_{40}H_2]$, which is itself formed by adding a sodium tungstate solution

to an acidic solution of cobalt(II) acetate at 80 °C.[2] The dicobalt compound has been purified by repeated recrystallizations from an acidic aqueous solution. This process takes more than one month, however, we tried the extraction with ether and 6 M-sulfuric acid for the purification of the dicobalt compound, for such extraction has been a traditional work-up for the preparation of many other analogous tetrahedral complexes $[MW_{12}O_{40}]$ ($M=Cu^{II}$, Fe^{III}, Al^{III}, Zn^{II}, and so on), as has been described by Brown and Mair.[6-8] In this manner, free acid of the monocobalt compound, $H_6[Co^{II}W_{12}O_{40}]$, could be obtained without the procedure of acid-decomposition, although metatungstic acid is present as an impurity. The cobaltate(II) acid can be easily separated by repeatedly heating the mixture on a steam-bath, followed by extraction with water, because the metatungstic acid (white) is readily decomposed to tungsten oxide (yellow), which is insoluble in water. After the isolated free acid is converted into the potassium salt, the potassium salt of the cobalt(III) compound, $K_5[Co^{III}W_{12}O_{40}]$, is obtained by oxidation with potassium peroxodisulfate. By the use of this modified manner, the total time for preparation is shortened to within two weeks.

The analytical values of two tetrabutylammonium compounds, $K_2[(C_4H_9)_4N]_4[Co^{II}W_{12}O_{40}]$, which have been obtained with both the previous recrystallization method[1] and the present ether-extraction method agree within the allowed range (0.3%). However, the intensities of the absorption bands in the near-infrared and visible regions of the previous compound are about 10% smaller than those of the present compound, whereas the intensity in the UV region is about 10% larger. Since metatungstate has only an absorption band in the UV region, it seems that the previous compound contains metatungstate as an impurity. This cannot be completely removed only by recrystallization. A contaminating metatungstate of about 10% may not influence the analytical value because of the relatively large molecular weight of the cobalt(II) compound. This shows the essential disadvantage of the recrystallization method, for such contamination significantly influences the purity of the final product, the cobalt(III) compound. The absorption maxima and molar absorptivities of the cobalt(II) compounds obtained by two methods are presented in Table 1.

IR Spectra. The frequencies of the cobalt(III) anion in the metal-oxygen vibrational region, recorded in a KBr disk, are presented in Table 2, together with the data on the parent cobalt(II) anion. The listed bands correspond to the Keggin-structure with a $W_{12}O_{40}$ skeleton and a central tetrahedral CoO_4 moiety, as has been previously in the case of the $[MW_{12}O_{40}]$ anions ($M=Cu^{II}$, Fe^{III}, Si, P).[1,9] In the undistorted tetrahedron (T_d symmetry) of an MO_4^{n-}-type ion, there are two IR active F_2 modes: $\nu_3(F_2)$ and $\nu_4(F_2)$, both triply degenerated. The former is the mode by the M–O stretching motion, and the latter, the deformation mode by the O–M–O angle bending motion. The spectral envelopes of these bands are diagnostic, whether the central-site symmetry is a regular tetrahedron or distorted, if the effects of the crystal packing and/or the environment upon these bands are eliminated. Since the ν_3 band is overlapped with the W–O–W octahedral

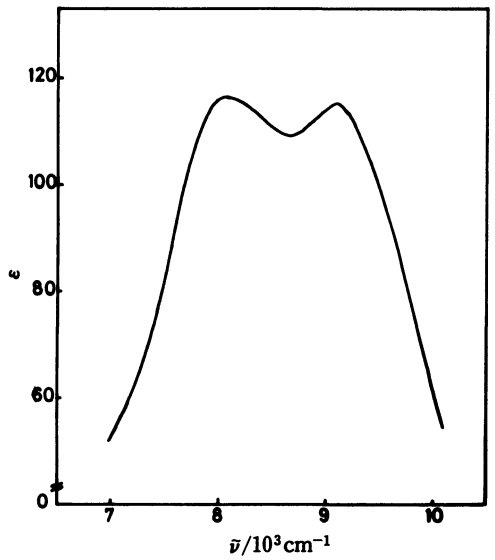

Fig. 1. Near-infrared spectrum of tetrabutylammonium salt of $[Co^{III}W_{12}O_{40}]^{5-}$ in acetonitrile solution.

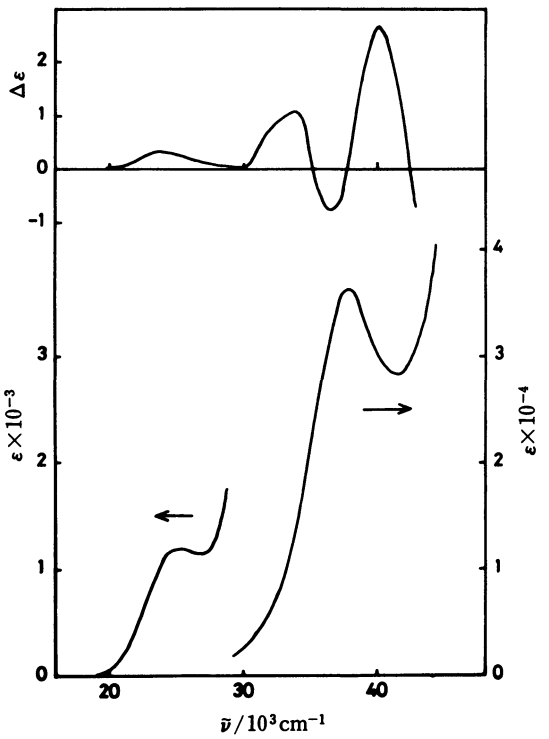

Fig. 2. Absorption and MCD spectra in UV-vis region of tetrabutylammonium salt of $[Co^{III}W_{12}O_{40}]^{5-}$ in acetonitrile solution.

corner-sharing band at *ca.* 780 cm^{-1}, the variations in the frequency and the half-width about the ν_4 band were examined in the acetonitrile solution. No splitting of the ν_4 band has been observed; a relatively symmetrical and sharp band appeared at 440 cm^{-1}, with a half-width of 25 ± 0 cm^{-1}. This fact suggests that this compound may retain an excellent T_d symmetry in the ground state, like the parent cobalt(II) compound. This is in good agreement with the crystallographical feature of $K_5[Co^{III}W_{12}O_{40}]\cdot 20H_2O$ found by Baker and his co-workers.[10]

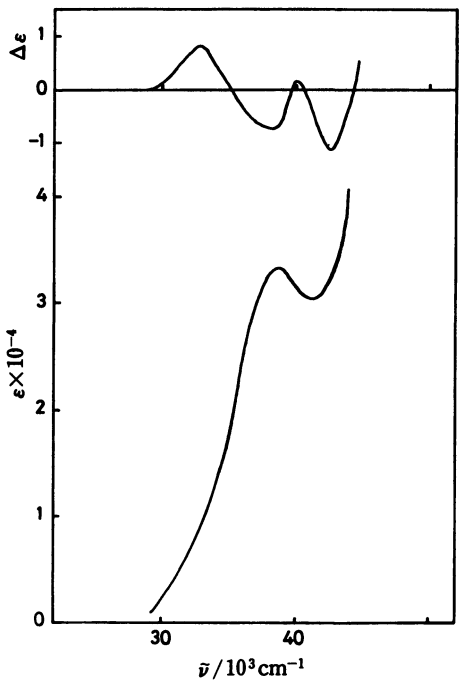

Fig. 3. UV and MCD spectra of tetrabutylammonium salt of $[Co^{II}W_{12}O_{40}]^{6-}$ in acetonitrile solution.

Absorption and MCD Spectra. The electronic spectra of the cobalt(III) compound, the absorption in the near-infrared region and the absorption and MCD in the UV-vis region, are shown in Figs. 1 and 2, respectively. The absorption in the near-infrared region with a double structure (8.06×10^3 and 9.09×10^3 cm^{-1}; ε 116 and 115 respectively; a splitting of 1.03×10^3 cm^{-1}) is due to the d-d transition. The compound is a d^6 high-spin system in a tetrahedral field. Thus, only one absorption band due to the excitation of the d shell electrons ($^5T_2\leftarrow{}^5E$) is to be expected if no account is taken of (1) the spin-orbit coupling, (2) the static and permanent distortion of the tetrahedron in the ground state, and (3) the Jahn-Teller effect in the electronically excited state.[11] In this system, the spin-orbit coupling may be discounted, for the observed splitting is 10 times the magnitude of the spin-orbit coupling constant for cobalt(III) ion. Furthermore, IR studies have inuicated that there is little distortion around the CoO_4 moiety in the ground state. It must, then, be concluded that the Jahn-Teller effect in th lectronically excited state may occur.

The large band at 37.9×10^3 cm^{-1} (ε 3.62×10^4) is due to the charge-transfer transition within the dodecatungstate lattice, such as is commonly observed in the spectra of other dodecatungstates of both central nonmetals and transition metals, and even of metatungstate. The MCD spectrum in the region clearly shows two positive and one negative components; the negative one appears near the position of the absorption maximum and exists between the two positive ones. This is characteristic of the compounds with a $W_{12}O_{40}$ skeleton, but not of the compounds with a $Mo_{12}O_{40}$ skeleton; the intensity of each component changes with the central transition metal. In Fig. 3, the absorption and MCD

in the UV region of the parent cobalt(II) compound are shown. Thus, the W–O charge-transfer band, observed as one absorption, has been found to be composed of several transitions and to be strongly influenced by the central metal.

The broad maximum at 25.4×10^3 cm^{-1} (ε 1.18×10^3) is a band unique to the cobalt(III) compound, having been first observed by Shimura and Tsuchida.[12] The MCD spectrum shows a comparably small and broad band with a positive sign. The absorption has been previously attributed to a charge transfer of the O atom, which occupies the corner of the central tetrahedral cavity, to the central Co^{III} ion.[13]

Circular Dichroism Spectra and Stereochemistry of Dicyanotetrakis-(diamine)-tetra-μ-hydroxo-tricobalt(III)(3+) Complexes

Satoshi KAKI,* Kazuaki YAMANARI, and Yoichi SHIMURA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received February 3, 1983)

The chiral tetra-μ-hydroxo-trinuclear complexes, *cis*-$[Co(CN)_2\{(OH)_2Co(NH_3)_4\}_2]^{3+}$ and *cis*-$[Co(CN)_2\{(OH)_2Co(diamine)_2\}_2]^{3+}$ have been prepared and separated into their optical isomers and/or diastereomers by column chromatography (diamine: ethylenediamine, (*R*)-1,2-propanediamine, and (*S,S*)-1,2-cyclohexanediamine). The absolute configurations of isomers have been assigned on the basis of their CD and ^{13}C NMR spectra and the characterization of mononuclear complex produced by decomposition of the trinuclear isomers of ethylenediamine ligands. It has been proved that the main CD contributions due to the two chiral $Co(OH)_4(CN)_2$ and $Co(N)_4(OH)_2$ centers are additive for the present systems.

Octaamminedicyano-tetra-μ-hydroxo-tricobalt (III) complex salts have been prepared from the reaction of "hexol" complex[1,2] $[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$ with excess cyanide by Siebert and Schiedermaier,[3] the composition of the trinuclear(3+) ion being comfirmed by X-ray crystal structure analysis.[4] The complex ion has a chiral structure with two cyano ligands in *cis* positions. Thus the *cis*-$[Co(CN)_2\{(OH)_2Co(NH_3)_4\}_2]^{3+}$ ion should be optically resolved. However, no attempt has been reported to resolve this complex.

The present paper deals with the optical resolution of the *cis*-$[Co(CN)_2\{(OH)_2Co(NH_3)_4\}_2]^{3+}$ complex, and the preparation and the separation of isomers of the corresponding diamine complexes, *cis*-$[Co(CN)_2\{(OH)_2Co(diamine)_2\}_2]^{3+}$, where diamine stands for en (ethylenediamine), *R*-pn ((*R*)-1,2-propanediamine), or *S,S*-chxn ((*S,S*)-1,2-cyclohexanediamine). The isomers were characterized from UV-VIS absorption, circular dichroism (CD), and ^{13}C NMR spectra and from the identification of the decomposition products. The trinuclear isomers are composed of two kinds of chromophore, a *cis*-$Co(OH)_4(CN)_2$ and two *cis*-$Co(N)_4(OH)_2$, as shown in Fig. 1. The central $Co(OH)_4(CN)_2$ chromophore has a configurational chirality, Δ or Λ, due to the skew arrangement of two $Co(OH)_2Co$ four-membered rings. In the cases of the diamine complexes, each $Co(N)_4(OH)_2$ chromophore also has a configurational chirality, Δ or Λ, due to the tris-chelate type arrangement of two diamine and a $Co(OH)_2Co$ rings. Thus six optically active isomers are possible for the diamine complexes in total: $\Delta(\Delta\Delta)$, $\Delta(\Delta\Lambda)$, $\Delta(\Lambda\Lambda)$, $\Lambda(\Delta\Delta)$, $\Lambda(\Delta\Lambda)$, and $\Lambda(\Lambda\Lambda)$, where the chirality symbols in parentheses denote the configurations of the peripheral

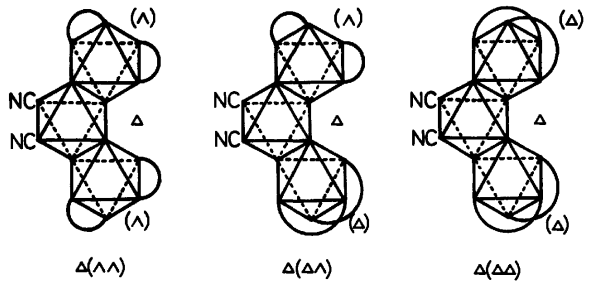

Fig. 1. Three geometrical isomers of the Δ configuration of $Co(OH)_4(CN)_2$ chromophore.

$Co(N)_4(OH)_2$ chromophores. The six optical isomers of en analogue can be classified into three geometrical isomers, since each of them finds its enantiomer in themselves. Two of these geometrical isomers, $\Delta(\Delta\Delta)$ or $\Lambda(\Lambda\Lambda)$, and $\Delta(\Lambda\Lambda)$ or $\Lambda(\Delta\Delta)$, possess a C_2 axis, whereas another one geometrical isomer $\Delta(\Delta\Lambda)$ or $\Lambda(\Delta\Lambda)$ possesses no symmetry element other than C_1 axis.

Experimental

Preparation and Optical Resolution of cis-$[Co(CN)_2\{(OH)_2Co(NH_3)_4\}_2]^{3+}$. The racemic sulfate salt was prepared by a modification of the procedure of Siebert and Schiedermaier.[3] To 5 g of "hexol" sulfate[5] $[Co\{(OH)_2Co(NH_3)_4\}_3](SO_4)_3\cdot 4H_2O$ suspended in 30 cm^3 of water was added 1.5 g of sodium cyanide dissolved in 15 cm^3 of water with stirring. A red precipitate was obtained immediately. After continued stirring for a few hours, the precipitate was filtered off and washed with water, ethanol, and ether.

Four-tenths grams of $Ba(CH_3CO_2)_2$ was added to 0.6 g of the red racemic sulfate salt suspended in 20 cm^3 of water and, after stirring for a few hours, the precipitated $BaSO_4$ was removed by filtration. To the filtrate was added 0.36 g of $Na_2(d\text{-}C_4H_4O_6)\cdot 2H_2O$. A pale-red precipitate appeared as the less-soluble diastereomer, which was filtered and purified by washing with water until the washings showed a constant CD value at *ca.* 500 nm. The less-soluble diastereomer was added to an aqueous solution containing ion exchanger resin QAE-Sephadex A-25 ($CH_3CO_2^-$ form, *ca.* 10 times excess) and stirred for a few hours. The resin was removed by filtration and $(NH_4)_2SO_4$ was added to the filtrate to give the optically active salt (Δ isomer), which was washed with water, ethanol, and ether, and dried in air. Found: C, 4.28; H, 4.92; N, 23.81%. Calcd for $[Co(CN)_2\{(OH)_2Co(NH_3)_4\}_2](SO_4)_{3/2}$: C, 4.16; H, 4.89; N, 24.27%.

Preparation and Separation of Isomers of cis-$[Co(CN)_2\{(OH)_2Co(diamine)_2\}_2]^{3+}$. *1)* cis-$[Co(CN)_2\{(OH)_2Co(en)_2\}_2]^{3+}$: A solution of the "en hexol" complex $[Co\{(OH)_2Co(en)_2\}_3]^{6+}$ prepared in the one-tenth scale of the Ref. 6 was poured onto a short column of SP-Sephadex C-25 (Na^+ form) and eluted with a NaCl solution. To the collected brown eluate of the en hexol (3.76×10^{-3} mol) was added 1.1 g of NaCN (*ca.* 6 times excess). The solution became red within a few hours. After the precipitated solid had been filtered off, the filtrate was poured onto a column (5×60 cm) of SP-Sephadex C-25 (Na^+ form). The adsorbed band was eluted with a 0.2 mol dm^{-3} $Na_2(d\text{-}C_4H_4O_6)$ solution. Succeeding a broad pink band (chemically unidentified) two red ones were eluted. The earlier- and later-eluted portions of each band showed the

opposite CD signs; that is, each band consists of a couple of enantiomers. Each of the enantiomers was named E1(−), E1(+), E2(+), or E2(−) after its sign of the CD extremum at *ca.* 500 nm. Each combined eluate E1 or E2 was diluted to about 5 times the volume with water, poured onto a short column of SP-Sephadex C-25 (Na^+ form), and eluted with a NaCl aqueous solution. The eluate was evaporated to a small volume at a temperature below 30 °C. After repeated removal of NaCl, the resulting solution was treated with an adequate amount of ethanol and kept standing in a refrigerator. Red crystals (the chloride salt) deposited in a few days were collected with suction, recrystallized from a water–ethanol solution, washed with ethanol and ether, and dried in air. The perchlorate salt was obtained in a similar way. Found for the racemic chloride of E1: C, 16.60; H, 6.06; N, 19.49%. Calcd for $[Co(CN)_2\{(OH)_2Co(en)_2\}_2]Cl_3\cdot 4.5H_2O$: C, 16.57; H, 6.26; N, 19.33%. Found for the racemic perchlorate salt of E1: C, 14.33; H, 4.40; N, 16.74%. Calcd for $[Co(CN)_2\{(OH)_2Co(en)_2\}_2](ClO_4)_3$: C, 14.37; H, 4.34; N, 16.76%. Found for the racemic chloride salt of E2: C, 16.18, H, 6.33; N, 18.88%. Calcd for $[Co(CN)_2\{(OH)_2Co(en)_2\}_2]Cl_3\cdot 5.5H_2O$: C, 16.17; H, 6.38; N, 18.86%. Found for the racemic perchlorate salt of E2: C, 13.48; H, 4.76; N, 15.77%. Calcd for $[Co(CN)_2\{(OH)_2Co(en)_2\}_2](ClO_4)_3\cdot 3H_2O$: C, 13.50; H, 4.76; N, 15.74%.

In cases in which the optically active $\Lambda(\Delta\Delta\Delta)$ isomer[6] of hexol complex $[Co\{(OH)_2Co(en)_2\}_3]^{6+}$ was used as starting material, also two red bands were characterized on the chromatographic column. The CD measurements indicated that the band eluted firstly was E1(−) and that the one eluted afterward a new isomer, which was denoted as E3(+). Each eluate was reloaded on a short column of SP-Sephadex C-25 (Na^+ form) to remove the *d*-$C_4H_4O_6^{2-}$ ion, and eluted with a NaCl aqueous solution. After repeated removal of NaCl, the E1(−) solution was poured onto a short column of QAE-Sephadex A-25 (Br^- form) and eluted with water, and the eluate was evaporated to a small volume. The resulting solution was treated with an adequate amount of ethanol and kept standing in a refrigerator. Red crystals of E1(−) deposited in a few days were collected with suction, washed with ethanol and ether, and dried in air. E3(+) isomer was obtained in a similar manner using acetone in place of ethanol. Found for E1(−): C, 14.35; H, 5.15; N, 16.40%. Calcd for $[Co(CN)_2\{(OH)_2Co(en)_2\}_2]Br_3\cdot 4H_2O$: C, 14.15; H, 5.22; N, 16.50%. Found for E3(+): C, 14.00; H, 5.06; N, 16.04%. Calcd for $[Co(CN)_2\{(OH)_2Co(en)_2\}_2]Br_3\cdot 3.5H_2O\cdot 1/5\ NaBr$: C, 13.96; H, 5.15; N, 16.28%.

The isomer E2(−) was separated as follows. The eluate E2 was diluted with water and reloaded on a column of SP-Sephadex C-25 (Na^+ form). The adsorbed band was eluted with 0.2 mol dm^{-3} Na_2(*d*-$C_4H_4O_6$) and some later fractions which showed the same CD spectrum of (−) sign at *ca.* 500 nm were collected together. This procedure was repeated until the CD values became constant and then the solution was stored for CD measurements after the chromatographic removal of *d*-$C_4H_4O_6^{2-}$ ion.

2) cis-$[Co(CN)_2\{(OH)_2Co($S,S-*chxn*$)_2\}_2]^{3+}$: The isomers were prepared and separated by the same procedure as in *1)* except for the use of *S,S*-chxn instead of en. Four red bands were observed on the chromatographic column. The CD measurements showed that the second and the third bands were each composed of two isomers. The separation of these two isomers was accomplished by the way described for E2(−). The resulting six bands were denoted as C1, C2, C3, C4, C5, and C6 in the elution order. The isolation as solid crystalline salts was successful only for the C4 and C6 eluate. Found for C4: C, 29.83; H, 6.21; N, 13.27%. Calcd for $[Co(CN)_2\{(OH)_2Co(S,S\text{-chxn})_2\}_2]Br_3\cdot 3H_2O$: C, 29.82; H, 6.35; N 13.37%. Found for C6: C, 33.51; H, 7.24; N, 14.89%. Calcd for $[Co(CN)_2\{(OH)_2Co(S,S\text{-chxn})_2\}_2]Cl_3\cdot 4H_2O$: C, 33.50; H, 7.35; N, 15.03%. The eluates C1, C2, C3, and C5 were stored for CD measurements.

3) cis-$[Co(CN)_2\{(OH)_2Co($R-*pn*$)_2\}_2]^{3+}$: The isomers were prepared and separated by the same procedure as in *1)* except for the use of *R*-pn instead of en. Three red bands were observed on the column. From the measurements of CD spectra, it turned out that the third band was composed of four isomers. Their separation was carried out by a similar procedure as described for E2(−). The resulting six bands were denoted as P1, P2, P3, P4, P5, and P6 in the elution order. No crystalline salt was isolated in this system as yet. Each eluate was stored for CD measurements after chromatographic removal of *d*-$C_4H_4O_6^{2-}$ ion.

Measurements: The visible and ultraviolet absorption spectra were measured on a Hitachi 330 spectrophotometer and CD spectra recorded on a JASCO MOE-1 spectropolarimeter. The absorption and CD measurements were made in aqueous solutions at room temperature. The ^{13}C NMR spectra were measured with a JEOL FX-90Q NMR spectrometer in D_2O containing dioxane as an internal standard.

Results and Discussion

Preparation and Characterization of Isomers. In the preparation of trinuclear complexes with diamine ligands, the purity of the starting "hexol" complex was of primary importance and therefore its separation was carried out cautiously. An unidentified brown band was observed just before the desired hexol band on the chromatographic column. If the starting hexol solution includes this unknown brown species, the reaction with NaCN gave an insoluble pale-brown precipitate as a main product. Infrared spectra of the precipitate showed two sharp bands at 2160 and 2240 cm^{-1} in the region of the CN stretching vibration mode, which indicated the coodination of CN^-. The N/C ratio was 1 for the en system and 0.8 for the *R*-pn system. These data suggest that the precipitate is a di- or polynuclear complex $Co_2(CN)_4(\mu\text{-}OH)_2(diamine)_2$, which was insoluble in most solvents.

The yields of isomers were in the order of E2>E1 for en series, P2>P4≃P6>P5>P3>P1 for the *R*-pn series, and C1≃C3≃C4≃C6>C2≃C5 for the *S,S*-chxn series. The isomers P5 and P6 underwent mutarotation during the separation by the column chromatography. In the course of attempted crystallization of C1 isomer, it was C6 isomer that appeared as crystals.

The first spin-allowed d-d absorption band of *cis*-$[Co(CN)_2\{(OH)_2Co(NH_3)_4\}_2]^{3+}$ appears at 19420 cm^{-1} and seems to be composed of those of *cis*-$CoN_4(OH)_2$ and *cis*-$Co(OH)_4(CN)_2$ chromophores, since the first absorption band of $[Co(CO_3)(NH_3)_4]^+$ appears[7] at 19100 cm^{-1} and the two components[8] of first absorption band of *cis*-$[Co(CO_3)_2(CN)_2]^{3-}$ at 18300 and 22500 cm^{-1}. In the corresponding region of CD curve there are two extrema at 16860 and 19380 cm^{-1} (Fig. 2). The absorption shoulder at 23500 cm^{-1} may be assigned to the higher wavenumber component of the split first band of $Co(OH)_4(CN)_2$ moiety. Since the second d-d transition bands of both the chromophores are expected to have about the same energies, the absorption shoulder

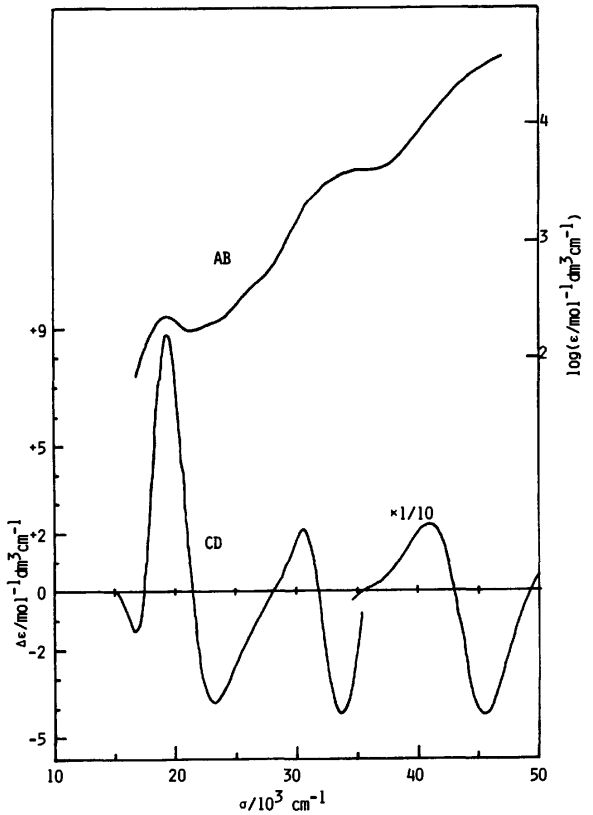

Fig. 2. The absorption (AB) and CD curves of *cis*-$[Co(CN)_2\{(OH)_2Co(NH_3)_4\}_2]^{3+}$.

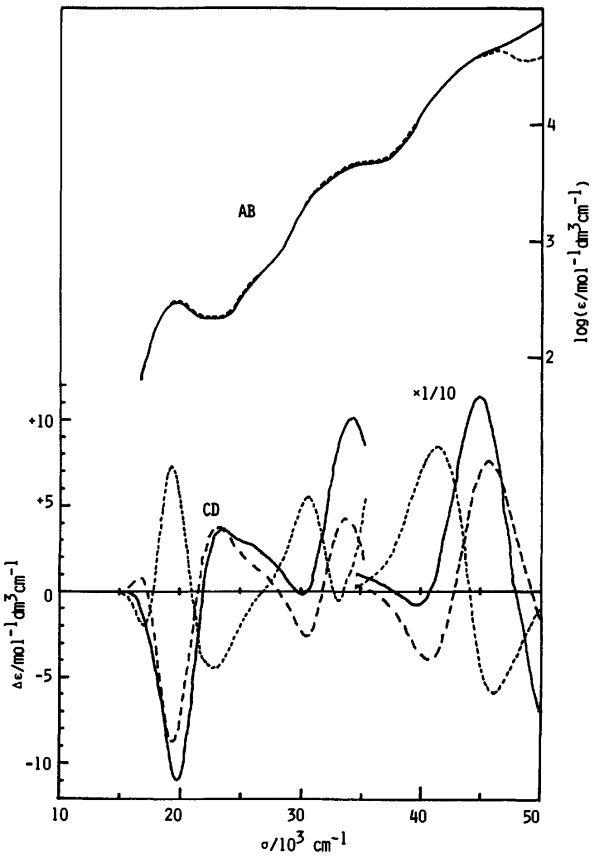

Fig. 3. The absorption (AB) and CD curves of *cis*-$[Co(CN)_2\{(OH)_2Co(en)_2\}_2]^{3+}$ isomers: E1(−) (——) and E2 (------) (AB); E1(−) (——), E2(−) (---), and E3(+) (------) (CD).

at 26700 cm^{-1} is assigned to their overlap. The intense band at 35700 cm^{-1} can be assigned to the charge-transfer transition from the OH bridging group to the central metal, $e_g(Co) \leftarrow p_\pi(O)$. The CD pattern is very similar to that of the parent "hexol" $[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$ in the regions of around 20000 and 35000—50000 cm^{-1} (Fig. 2), and the CD intensity being about two-thirds of the "hexol."[2] Therefore, the absolute configuration of the present trinuclear complex is assigned on the basis of the CD signs in these regions: *Λ* configuration for (+) CD around 20000 cm^{-1} and for (+) and (−) bands from the lower energy side in the region of 35000—50000 cm^{-1}. Thus the isomer obtained from the less-soluble diastereomer of *d*-tartrate salt has the *Λ* absolute configuration.

All complexes containing diamine ligands showed similar absorption spectra to one another (Table 1). The first d-d absorption maxima become more intense and shift to the higher wave number than that of the corresponding ammine complex. Therefore, the CD

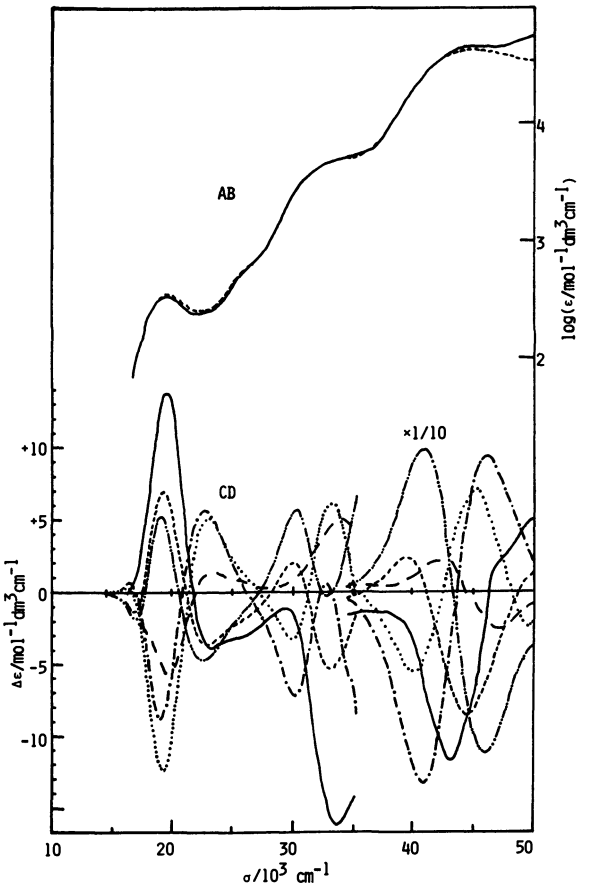

Fig. 4. The absorption (AB) and CD curves of *cis*-[Co(CN)$_2${(OH)$_2$Co(*S*,*S*-chxn)$_2$}$_2$]$^{3+}$ isomers: C4 (——) and C6 (------) (AB); C1 (——), C2 (– – –), C3 (------), C4 (·····), C5 (–·–), and C6 (—·—) (CD).

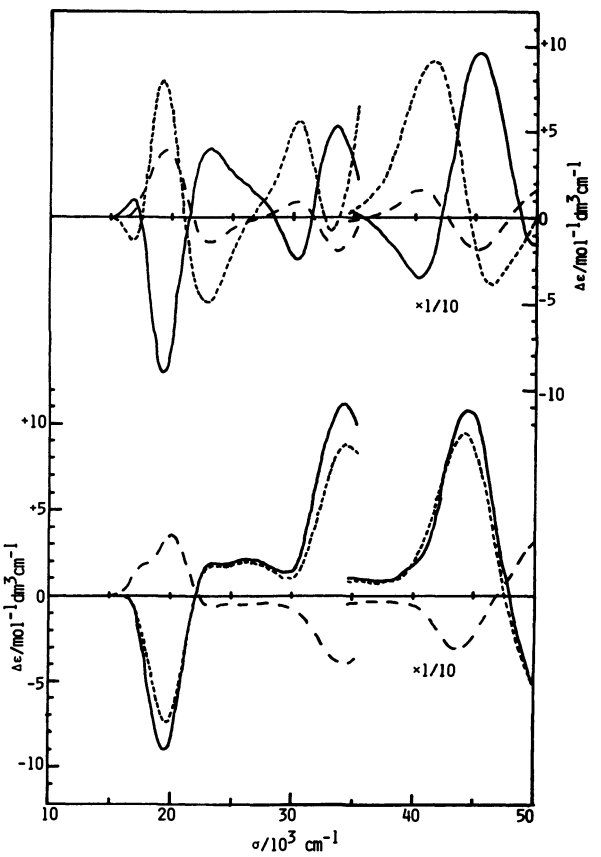

Fig. 5. The CD curves of *cis*-[Co(CN)$_2${(OH)$_2$Co(*R*-pn)$_2$}$_2$]$^{3+}$ isomers: P1 (——), P2 (------), and P3 (– – –) (lower curves); P4 (——), P5 (— —), and P6 (------) (upper curves).

intensities of the isomers which were not obtained as solid salt, were calculated on the basis of the assumption that E2(−) and all *R*-pn isomers have the molar absorption coefficient log (ε/mol^{-1} dm^3 cm^{-1})=2.50 at 19800 cm^{-1} and C1, C2, C3, and C5 isomers 2.55 at 19610 cm^{-1}. The $|\Delta\varepsilon|$ values at *ca.* 20000 cm^{-1} are in the range of 7—12 (Figs. 3, 4, and 5), being comparable with that for the ammine complex. The absolute configuration of Co(OH)$_4$(CN)$_2$ moiety can be assigned by the sign of this band; that is, *Λ* configuration for negative sign and *Δ* for positive. The CD pattern in the region of 35000—50000 cm^{-1} are also similar to that of the ammine analogue, though their intensities about 2—3 times stronger (Table 2). The intensity and sign of the CD band at *ca.* 45000 cm^{-1} of the diamine complex are comparable with those of the hexol complex of corresponding diamine.[9] The absolute configuration of Co(OH)$_4$(CN)$_2$ moiety can be assigned also on the basis of the sign of this band as was done for the Co(OH)$_6$ moiety of hexol: *Δ* configuration for a negative sign and *Λ* for positive. The assignments are in good agreement to those from the CD sign of the first d-d absorption band.

Configuration of cis-[*Co(CN)$_2${(OH)$_2$Co(en)$_2$}$_2$*]$^{3+}$. ^{13}C NMR spectra showed four signals (45.89, 45.19, 44.97, and 43.29 ppm) for E3(+), also four (46.16, 45.02, 44.64, and 43.89 ppm) for E1(rac), and six (46.27, 46.05, 45.08, 44.64, 44.00, and 42.86 ppm) for E2(rac) in the methylene region of en. This result confirms that the isomer E2(rac) has no symmetry and that the configuration of its two Co(N)$_4$(OH)$_2$ moieties are (*ΔΔ*).

Acid hydrolysis of one mole of *cis*-[Co(CN)$_2${(OH)$_2$Co(en)$_2$}$_2$]$^{3+}$ ion is expected to produce one mole of [Co(CN)$_2$(H$_2$O)$_4$]$^+$ and two moles of *cis*-[Co(en)$_2$(H$_2$O)$_2$]$^{3+}$. Since the former tetraaqua ion has no chirality, only latter bis(ethylenediamine) complex will contribute to the CD spectrum. The isomer *Δ*(*ΔΔ*) or *Λ*(*ΔΔ*) will produce two *Δ*-[Co(en)$_2$(H$_2$O)$_2$]$^{3+}$ ions, and *Δ*(*ΛΛ*) or *Λ*(*ΛΛ*) two *Λ*-[Co(en)$_2$(H$_2$O)$_2$]$^{3+}$ ions, whereas *Δ*(*ΔΔ*) or *Λ*(*ΔΔ*) will produce an equal amount of *Δ*- and *Λ*-[Co(en)$_2$(H$_2$O)$_2$]$^{3+}$, namely rac-[Co(en)$_2$(H$_2$O)$_2$]$^{3+}$. The isomer E1(−) was decomposed by adding a 6.0 mol dm^{-3} HCl solution to give a negative CD band at 483 nm ($\Delta\varepsilon$=−0.81), which corresponds to that of *Δ*-[Co(en)$_2$(H$_2$O)$_2$]$^{3+}$ ($\Delta\varepsilon_{485}$=−1.05).[10] Similarly, the isomer E3(+) also showed a negative CD band ($\Delta\varepsilon$=−0.56). These results indicate that the isomers E1(−) and E3(+) prepared from *Λ*(*ΔΔΔ*)-hexol have the *Λ*(*ΔΔ*) and *Δ*(*ΔΔ*) configurations, respectively.

Thus, from the CD and ^{13}C NMR spectra and the acid decomposition experiment it is concluded that the absolute configurations of E1(−), E1(+), E2(−), E2(+), and E3(+) isomers are *Λ*(*ΔΔ*), *Δ*(*ΛΛ*), *Λ*(*ΔΛ*),

TABLE 3. THE FORMATION RATIOS OF OPTICAL ISOMERS OF *cis*-$[Co(CN)_2\{(OH)_2Co(en)_2\}_2]^{3+}$ IN THE REACTION OF THE OPTICALLY ACTIVE HEXOL ISOMERS WITH EXCESS CYANIDE

(The ratio was determined from the absorbance at 505 nm.)

Absolute configuration of the starting hexol isomer[4]	Formation ratios of derivatives				
Λ(*ΔΔΔ*)	Calcd	*Λ*(*ΔΔ*) only			
	Obsd	*Λ*(*ΔΔ*)	3	*Δ*(*ΔΔ*)	1
Λ(*ΔΔΛ*)	Calcd	*Λ*(*ΔΔ*)	1	*Λ*(*ΔΛ*)	2
	Obsd	*Λ*(*ΔΔ*)	1	E2*	5

* E2: *Λ*(*ΔΛ*)+*Δ*(*ΔΔ*).

Λ(*ΔΛ*), and *Δ*(*ΔΔ*), respectively.

The preparation of en trinuclear complexes was achieved from the two optical isomers of en "hexol" instead of a mixture of several isomers. If the trinuclear complex is formed without racemization nor isomerization, that is, each of the $Co(en)_2(OH)_2$ moiety in the starting complex is replaced statistically by two cyano ligands, it is possible to predict the yields and the absolute configurations of the derivatives. However, the observed ratios are somewhat different from the estimated ones (Table 3), which are related with the partial racemization and/or isomerization.

Characterization of cis-$[Co(CN)_2\{(OH)_2Co(R\text{-}pn)_2\}_2]^{3+}$ *and* cis-$[Co(CN)_2\{(OH)_2Co(S,S\text{-}chxn)_2\}_2]^{3+}$ *Complexes.* The trinuclear complex of optically active diamine has six diastereomers. In the *R*-pn series, six isomers were found in the chromatographic separation. The isomers P1 and P2, however, showed almost the same CD spectra in all of the region measured. It appears that these isomers correspond to the geometrical ones due to the different spacial arrangements of the asymmetric carbons of four *R*-pn ligands. A similar kind of isomerism was observed for the hexol complex.[9] The six isomers of *R*-pn series are assigned in comparison of the CD spectra (Table 2) with those of the en series as follows: *Λ*(*ΔΔ*) for P1 and P2, *Δ*(*ΔΛ*) for P3, *Λ*(*ΔΔ*) for P4, *Δ*(*ΔΔ*) for P5, and *Δ*(*ΔΔ*) for P6 (Table 4).

For the *S,S*-chxn series, all the six diastereomers were completely identified. Since an *S,S*-chxn chelate ring take a *δ* conformation, the *ob* or *lel* orientation[11] should be fixed for *Δ*- or *Λ*-configuration of the $Co(N)_4(OH)_2$ moiety, respectively. It is generally accepted that the *lel* orientation is more stable than the *ob* one. The isomers C2 and C5 were less stable than the others in addition to their low yield. Therefore, their configurations of $Co(N)_4(OH)_2$ moiety are expected to be (*ΔΔ*), that is they have ob_4 form. Taking this expectationinto account, the absolute configurations of all the isomers are estimated on the CD spectra (Table 2) as follows:

TABLE 4. ABSOLUTE CONFIGURATIONS OF *cis*-$[Co(CN)_2\{(OH)_2Co(diamine)_2\}_2]^{3+}$ ISOMERS

Absolute configuration	en series	Absolute configuration	*R*-pn series	Absolute configuration	*S,S*-chxn series
$\Lambda(\Delta\Delta)$	E1(−)	$\Lambda(\Delta lel_2\cdot\Delta lel_2)$	P1, P2	$\Lambda(\Delta ob_2\cdot\Delta ob_2)$	C2
$\Delta(\Lambda\Lambda)$	E1(+)	$\Delta(\Lambda ob_2\cdot\Lambda ob_2)$	P3	$\Delta(\Lambda lel_2\cdot\Lambda lel_2)$	C1
$\Delta(\Delta\Lambda)$	E2(+)	$\Delta(\Delta lel_2\cdot\Lambda ob_2)$	P5	$\Delta(\Delta ob_2\cdot\Lambda lel_2)$	C3
$\Lambda(\Delta\Lambda)$	E2(−)	$\Lambda(\Delta lel_2\cdot\Lambda ob_2)$	P4	$\Lambda(\Delta ob_2\cdot\Lambda lel_2)$	C4
$\Delta(\Delta\Delta)$	E3(+)	$\Delta(\Delta lel_2\cdot\Delta lel_2)$	P6	$\Delta(\Delta ob_2\cdot\Delta ob_2)$	C5
$\Lambda(\Lambda\Lambda)$	—	$\Lambda(\Lambda ob_2\cdot\Lambda ob_2)$	—	$\Lambda(\Lambda lel_2\cdot\Lambda lel_2)$	C6

$\Lambda=\{E1(-)-E3(+)\}/2$ (——), $\Lambda=\Lambda(\Delta\Delta)=E2(-)$ (------), and Λ configuration of ammine series (— —).

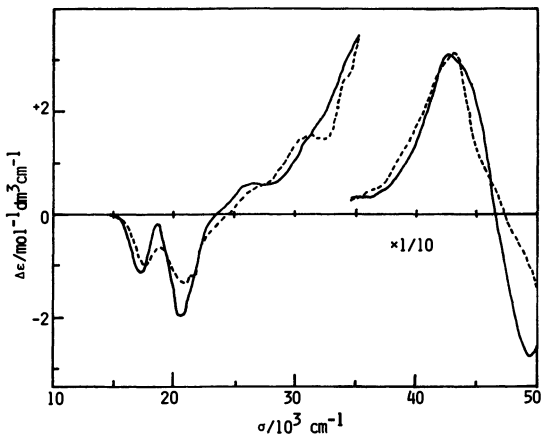

Fig. 7. Configurational CD curves of $Co(N)_4(OH)_2$ chromophore for en.
$(\Delta)=\{E1(-)-E2(-)\}/2$ (——) and $\{E2(-)+E3-(+)\}/2$ (---).

$\Delta(\Lambda\Lambda)$ for C1, $\Lambda(\Delta\Delta)$ for C2, $\Delta(\Delta\Lambda)$ for C3, $\Lambda(\Delta\Lambda)$ for C4, $\Delta(\Delta\Delta)$ for C5, and $\Lambda(\Lambda\Lambda)$ for C6. The estimation are completely confirmed by the CD curve analysis discussed below and summarized in Table 4.

Additivity of CD Contributions. If the observed CD curves of *cis*-$[Co(CN)_2\{(OH)_2Co(en)_2\}_2]^{3+}$ can be simply divided into each contribution due to $Co(OH)_4(CN)_2$ and $Co(N)_4(OH)_2$ chiralities as has been established for configurational and vicinal chiralities of many mononuclear cobalt(III) complexes,[12] the following relations are expected to hold for the observed CD curves $\Lambda(\Lambda\Lambda)$, $\Lambda(\Delta\Lambda)$, or $\Lambda(\Delta\Delta)$:

$$\Lambda(\Lambda\Lambda) = \Lambda + 2(\Lambda),$$
$$\Lambda(\Delta\Lambda) = \Lambda + (\Lambda) + (\Delta) = \Lambda,$$
$$\Lambda(\Delta\Delta) = \Lambda + 2(\Delta),$$

where Λ and Δ, and (Λ) and (Δ) are CD contributions due to the central $Co(OH)_4(CN)_2$ and the peripheral $Co(N)_4(OH)_2$ chiralities, respectively. Then the individual Λ and (Λ) contributions can be derived from the observed CD curves by the following relations:

$$\Lambda = [\Lambda(\Delta\Delta)-\Delta(\Delta\Delta)]/2,$$
$$(\Delta) = [\Lambda(\Delta\Delta)-\Lambda(\Delta\Lambda)]/2,$$
$$(\Lambda) = [\Lambda(\Delta\Lambda)+\Delta(\Delta\Delta)]/2.$$

Figure 6 shows the calculated CD contribution Λ due to the $Co(OH)_4(CN)_2$ moiety. This is quite similar to the observed CD curve $\Lambda(\Delta\Lambda)=\Lambda$ of the E2(−) isomer and also in good agreement with that of the Λ isomer of ammine series. The calculated Δ CD curves due to

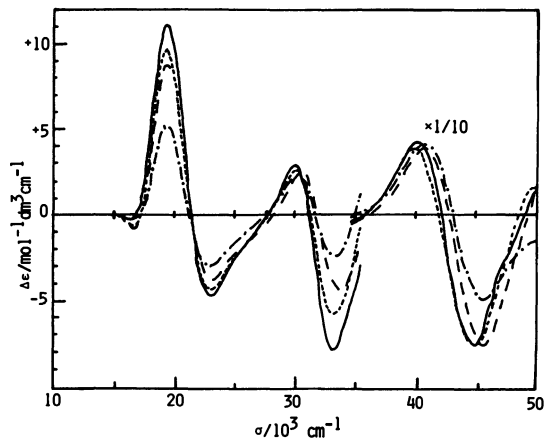

Fig. 8. Configurational CD curves of $Co(OH)_4(CN)_2$ chromophore for *S,S*-chxn. $\Delta=(C1-C6)/2$ (——), $(C5-C2)/2$ (—·—), and $(C3-C4)/2$ (------), and E2(+) (— —) for comparison.

the $Co(N)_4(OH)_2$ moiety are also similar to one another (Fig. 7) and the CD sign at *ca.* 20000 cm^{-1} is compatible with that of the main component in the region of the first d-d transition of the $[Co(en)_2(O-O)]$ complexes having the same configuration.[10] These facts mean that the simple additivity rule assumed above is adequate for the present system. It is recognized evidently that the chirality of the central $Co(OH)_4(CN)_2$ moiety induces the dominant CD contribution. In the case of the en hexol isomers, this kind of additivity of CD spectra was unsatisfactory.[6]

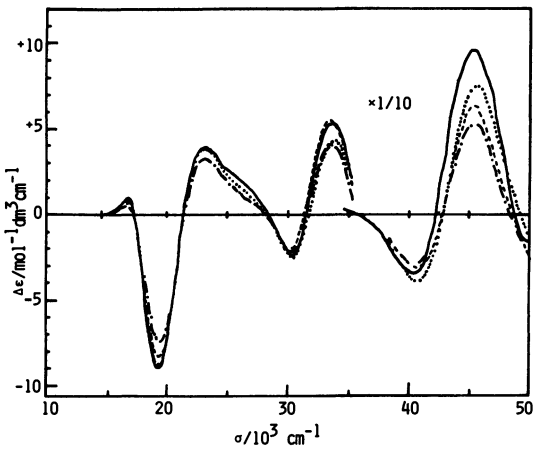

Fig. 9. Configurational CD curves of $Co(OH)_2(CN)_2$ chromophore for *R*-pn. Λ=P4 (——), (P1—P6)/2 (------), and (P2—P6)/2 (—·—), and E2(—)(·····) for comparison.

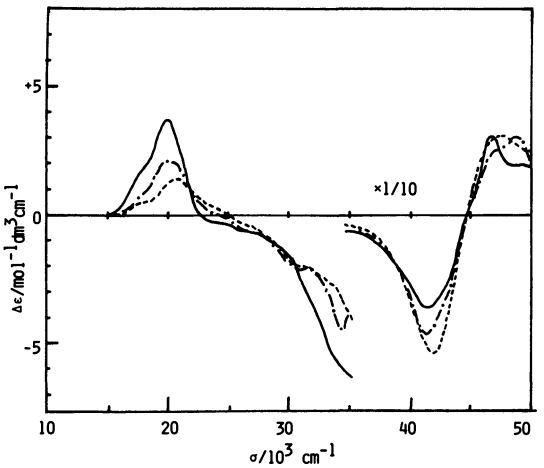

Fig. 10. Configurational CD curves of $Co(N)_4(OH)_2$ chromophore for *S,S*-chxn. (Λ)=(C1—C3)/2 (——), (C3—C5)/2 (------), and (C6—C4)/2 (—·—).

As for the *R*-pn series, we get the following relations:

$$\Delta(\Delta R_2\cdot\Delta R_2) = \Delta + 2(\Delta) + 4(R),$$

$$\Delta(\Delta R_2\cdot\Lambda R_2) = \Delta + (\Delta) + (\Lambda) + 4(R) = \Delta + 4(R),$$

$$\Lambda(\Lambda R_2\cdot\Lambda R_2) = \Lambda + 2(\Lambda) + 4(R),$$

where (R) is the vicinal contribution of an *R*-pn ligand. The individual Δ (or Λ) and (Λ) (or (Δ)) can be derived from the observed CD curves from the following relations:

$$\begin{aligned}\Delta &= [\Delta(\Lambda R_2\cdot\Lambda R_2) - \Lambda(\Lambda R_2\cdot\Lambda R_2)]/2\\ &= [\Delta(\Delta R_2\cdot\Delta R_2) - \Lambda(\Delta R_2\cdot\Delta R_2)]/2\\ &= [\Delta(\Delta R_2\cdot\Lambda R_2) - \Lambda(\Delta R_2\cdot\Lambda R_2)]/2,\\ (\Lambda) &= [\Delta(\Lambda R_2\cdot\Lambda R_2) - \Delta(\Delta R_2\cdot\Lambda R_2)]/2\\ &= [\Delta(\Delta R_2\cdot\Lambda R_2) - \Delta(\Delta R_2\cdot\Delta R_2)]/2\\ &= [\Lambda(\Lambda R_2\cdot\Lambda R_2) - \Lambda(\Delta R_2\cdot\Lambda R_2)]/2.\end{aligned}$$

Figures 8 and 9 show the calculated CD curves due to the central $Co(OH)_4(CN)_2$ moiety in the *S,S*-chxn(Δ) and *R*-pn(Λ) trinuclear complexes, respectively, as well as the observed Δ or Λ CD curves of the en isomer E2(+) or E2(—) for comparison. The vicinal contribution of *R*-pn ligands is neglected in the calculation for *R*-pn series. However, the curves are in fair agreement with one another except for that obtained from the unstable C2 and C5 isomers. Figures 10 and 11 show the calculated (Λ) and (Δ) CD curves due to the peripheral $Co(N)_4(OH)_2$ moiety. The curves are relatively in good agreement with one another. The vicinal CD contributions due to the coodinated optically active diamine (R) and (S) can not be calculated clearly because they are negligibly small compared with the CD contributions Δ, Λ, (Λ), or (Δ).

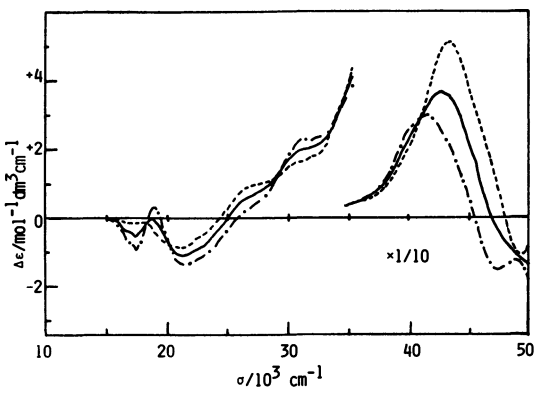

Fig. 11. Configurational CD curves of $Co(N)_4(OH)_2$ chromophore for *R*-pn. (Δ)=(P1+P6)/4 (——), (P4+P6)/2 (------), and (P1—P4)/2 (—·—).

Stereoselective Formation of Rotaxanes Composed of Polymethylene-bridged Dinuclear Cobalt(III) Complexes and α- or β-Cyclodextrin

Kazuaki YAMANARI* and Yoichi SHIMURA
Department of Chemistry, Faculty of Science, Osaka University Toyonaka, Osaka 560
(Received February 5, 1983)

[2]-[[$(en)_2Co\{NH_2(CH_2)_2S(CH_2)_nS(CH_2)_2NH_2\}Co(en)_2]Cl_6$]-[α- or β-CDX]-rotaxanes were prepared with partial stereoselectivity and characterized from their absorption and ^{13}C NMR spectra, molar conductance, and elemental analysis (CDX=cyclodextrin; $n=8$, 10, and 12). The rotaxanes always showed apparently *ΔΔ*-rich CD spectra, the highest selectivity (16% *ΔΔ*-rich) being found in the case of $n=10$ and α-CDX. The results are related to the direct preparation of [2]-[*ΔΔ*-[$(en)_2Co\{NH_2(CH_2)_2S(CH_2)_nS(CH_2)_2NH_2\}Co(en)_2]Cl_6$]-[α-CDX]-rotaxanes ($n=8$, 10, and 12) in relatively higher yields than the corresponding *ΛΛ* rotaxanes: 3.5% for $n=8$, 21% for $n=10$, and 28% for $n=12$. Inclusion complexes of a new type $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_nBr\}]Cl_3\cdot 2$(α-CDX) were also isolated ($n=10$ and 12).

Cyclodextrin (CDX)[1] forms a large number of inclusion complexes with such organic compounds as benzene derivatives, carboxylic acids, alcohols, and alkane derivatives.[2] The inclusion-complex-forming property of CDX was recently applied to the synthesis of novel rotaxanes consisting of a dinuclear cobalt(III) complex $[(en)_2ClCo\{NH_2(CH_2)_{12}NH_2\}CoCl(en)_2]^{4+}$ and α- or β-CDX.[3] We have recently prepared another kind of polymethylene-bridged dinuclear complexes $[(en)_2Co\{NH_2(CH_2)_2S(CH_2)_nS(CH_2)_2NH_2\}Co(en)_2]^{6+}$ from the reaction of $[Co(aet)(en)_2]^{2+}$ with α,ω-dibromoalkane $Br(CH_2)_nBr$,[4] the complexes also being expected to form rotaxanes (aet=2-aminoethanethiolato, $NH_2CH_2CH_2S^-$).

Here we report the preparation of a series of [2]-[[$(en)_2Co\{NH_2(CH_2)_2S(CH_2)_nS(CH_2)_2NH_2\}Co(en)_2$]-$Cl_6$]-[α- or β-CDX]-rotaxanes[5] by two methods. The bridging tetradentate ligands are abbreviated to dtdd for $n=8$: 3,12-dithiatetradecane-1,14-diamine, dhdd for $n=10$: 3,14-dithiahexadecane-1,16-diamine, and dodd for $n=12$: 3,16-dithiaoctadecane-1,18-diamine. In these rotaxanes, four diastereomers are possible because of the inequality of both openings of CDX as shown in Fig. 1 (neglecting the *R* and *S* chiralities of the donor sulfur atoms). The cobalt(III) rotaxanes isolated were characterized from their elemental analyses, absorption, circular dichroism (CD) and ^{13}C NMR spectra, and molar conductance measurements. The optically active rotaxanes, [*ΔΔ*]-[α-CDX] and [*ΛΛ*]-[α-CDX], were also prepared starting from the resolved mononuclear complexes and characterized. A preliminary report has been presented.[6]

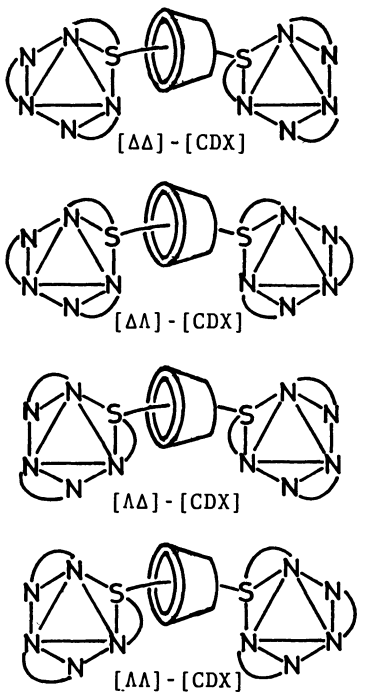

Fig. 1. Four possible diastereomers of [2]-[[$(en)_2$-$Co\{NH_2(CH_2)_2S(CH_2)_nS(CH_2)_2NH_2\}Co(en)_2]Cl_6$]-[CDX]-rotaxane.

Experimental

Preparation and Separation. *$[Co(aet)(en)_2](ClO_4)_2$*: The complex was prepared according to the literature,[7] and used as a starting material. It was found that the racemic perchlorate salt crystallizes as a conglomerate, our racemate being incidentally *Λ*-rich (*ca.* 1.5%) even when a portion of *ca.* 60 g was recrystallized in a lot. Therefore, a sample of the pure racemate was prepared by addition of an appropriate amount of *Λ*-form ($\Delta\varepsilon_{522}=-1.32$ mol^{-1} dm^3 cm^{-1}), which was obtained from optical resolution of the racemic chloride salt.[8]

To confirm the spontaneous resolution, we determined the solubilities in binary and ternary systems containing *rac*- and/or *Λ*-$[Co(aet)(en)_2](ClO_4)_2$ in water. Solubility (g/100 g H_2O): 5.39 (5 °C), 6.88 (10 °C), 8.61 (15 °C), 11.1 (20 °C), 14.0 (25 °C), 18.1 (30 °C), 23.0 (35 °C), 30.7 (40 °C), and 39.0 (45 °C) for racemic perchlorate; 3.85 (5 °C), 4.71 (10 °C), 5.98 (15 °C), 7.28 (20 °C), 9.04 (25 °C), 13.7 (35 °C), 17.0 (40 °C), and 19.0 (45 °C) for *Λ*-complex perchlorate. Solubility (mol fraction $\chi\times10^3$) in the ternary system, H_2O-*Λ*-$[Co(aet)(en)_2](ClO_4)_2$-*Δ*-$[Co(aet)(en)_2](ClO_4)_2$ at 30 °C, (χ_Λ, χ_Δ): (4.34, 0), (4.07, 1.04), (4.00, 1.20), (3.99, 1.30), (3.94, 1.61), (3.69, 2.89), (3.64, 3.29), (3.67, 3.54), and (3.65, 3.65). The solubility ratio of racemate/*Λ*-complex is 1.40 at 5 °C, 1.55 at 25 °C, and 2.05 at 45 °C. Since the ratio is larger than $2^{1/3}=1.26$ the perchlorate salt is spontaneously resolvable.[9] The ternary solubility isotherm at 30 °C showed the only one invariant point. The results confirm that the two enantiomers form a racemic mixture in the solid state.

$[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_nBr\}](ClO_4)_3$ ($n=8$, 10, and 12): These complexes were also used as a starting material. Only the perchlorate salts are highly soluble in dimethyl sulfoxide (DMSO), which turned out to be the most favorable

solvent for the preparation of rotaxanes.

The chloride salts were isolated previously as a by-product in the column chromatography of the bridged complexes, $[(en)_2Co\{NH_2(CH_2)_2S(CH_2)_nS(CH_2)_2NH_2\}Co(en)_2]^{6+}$ ($n=8$ and 10).[4] They were prepared more effectively in the following way. To a 20 cm³ of DMSO solution containing $[Co(aet)(en)_2](ClO_4)_2$ (0.004 mol) was added 0.01 mol of relevant α,ω-dibromoalkane $Br(CH_2)_nBr$, and then the mixture was kept at 30 °C for 2 d. The unreactive dibromoalkane was extracted into diethyl ether for several times. The resulting dark red oil was diluted by *ca.* 20 cm³ of water, and 10 cm³ of a saturated aqueous solution of NaCl was added to it . An oily product appeared immediately and was kept standing for 2 h to give a powder precipitate of the chloride salt. The corresponding bromide (or iodide) salt could be obtained by the same procedure except for the use of NaBr (or KI) instead of NaCl. The halide salts were converted into the perchlorate salt by using QAE-Sephadex A-25 (ClO_4^- form). The eluate was concentrated on a rotary evaporator to dryness, the residue being used for the preparation of rotaxane without further purification.

[2]-[[(en)₂Co(dodd)Co(en)₂]Cl₆]-[α-CDX]-rotaxane (1). *Method [A]*: 2.2 mmol of *rac*-$[Co(aet)(en)_2](ClO_4)_2$ and 1.3 mmol of 1,12-dibromododecane (20% excess) were dissolved in 6 cm³ of DMSO containing 2.5 g of α-CDX. The mixture was kept at 30 °C for 10 d, leading to deep red solution. During this period, white crystals appeared gradually at the bottom of a reaction vessel, which were identified as the inclusion compound of $Br(CH_2)_{12}Br$ and α-CDX. The unreactive dibromoalkane was extracted into diethyl ether. The resulting dark red oil was dissolved in water, adsorbed on a cation exchange column (SP-Sephadex C-25, Na^+ form), and eluted with a 0.8 mol dm^{-3} NaCl solution. Six colored bands, f1—f6, were eluted in this order. The species, f2 (dark brown), f3 (orange), f5 (orange), and f6 (orange), were identical to the products formed by the "blank reaction" without CDX and therefore corresponded to $[Co(aet)(en)_2]^{2+}$, $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_{12}OH\}]^{3+}$, $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_{12}Br\}]^{3+}$, and the bridged complex $[(en)_2Co(dodd)Co(en)_2]^{6+}$, respectively.[4] The species isolated from the f1 eluate agreed with the composition of $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_{12}Br\}]Cl_3\cdot 2(\alpha\text{-CDX})\cdot 18H_2O$. The eluate from the orange band f4 was evaporated to a small volume and, after repeated removal of NaCl deposited out, the solution was treated with a large amount of ethanol (or acetone) to give an orange precipitate of the desired rotaxane. Analytical data are shown in Table 2. The yields based on the starting mononuclear complex *rac*-$[Co(aet)(en)_2](ClO_4)_2$ were 5±1% for f1, 4±1% for f3, 16±2% for f4, 6±1% for f5, and 34±3% for f6 (The mean for 4 preparations).

In the above preparation, pronounced stereoselectivity was observed. All eluates of each band were collected together and its optical purity was checked by CD measurements.[10] Each band showed the CD spectrum. The species f4 always showed apparently *ΔΔ*-rich CD spectra (*ca.* 8%) and f6 *ΛΛ*-rich (*ca.* 3%). The selectivities for f1, f3, and f5 species were not definitive because of their low CD values, which were also varied depending upon the preparative method ([A] or [B]) and conditions such as the molar ratio and concentrations of *rac*-$[Co(aet)(en)_2]^{2+}$ and CDX.

Method [B]: The complex $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_{12}Br\}](ClO_4)_3$ was used as a starting material. This complex (0.6 mmol), $[Co(aet)(en)_2](ClO_4)_2$ (0.72 mmol, 20% excess), and α-CDX (1.5 g) were allowed to react in 5 cm³ of DMSO and the reaction mixture was separated in a similar manner described above. The yields based on $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_{12}Br\}](ClO_4)_3$ were 1.5±0.5% for f1, 5±1% for f3, 26±1% for f4, 4±1% for f5, and 46±2% for f6 (2 preparations). The apparent selectivity was *ca.* 8% *ΔΔ*-rich for f4 and *ca.* 4% *ΛΛ*-rich for f6.

[2]-[[(en)₂Co(dhdd)Co(en)₂]Cl₆]-[α-CDX]-rotaxane (2): The complex was prepared and chromatographed by the same manner as **1** except for the use of 1,10-dibromodecane instead of 1,12-dibromododecane. In this separation, the orange band f1 was small in amount, becoming very broad during the chromatography, finally obscuring. This species is inferred as an inclusion compound of $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_{10}Br\}]Cl_3$ and α-CDX from the analogy with $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_{12}Br\}]Cl_3\cdot 2(\alpha\text{-CDX})$ described above. The yields were 5±1% for f3, 6±1% for f4, 6±1% for f5, and 54±4% for f6 (3 preparations) in method [A] and 5±1% for f3, 9±1% for f4, 3.5±1% for f5, and 63±4% for f6 (2 preparations) in method [B]. The apparent selectivity was higher in method [A] than [B]: the band f4 was *ca.* 16% *ΔΔ*-rich and f6 *ca.* 2.5% *ΛΛ*-rich in method [A], but f4 was *ca.* 8% *ΔΔ*-rich and f6 *ca.* 0.7% *ΛΛ*-rich in method [B].

[2]-[[(en)₂Co(dtdd)Co(en)₂]Cl₆]-[α-CDX]-rotaxane (3): The complex was not detectable in method [A] but prepared in a 4±1% yield (3 preparations) in method [B]. In the separation, the inclusion compound between $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_8Br\}]^{3+}$ and α-CDX, which corresponds to the f1 band in the case of **1**, was almost undetectable and five bands corresponding to f2—f6 appeared. The rotaxane was eluted as the fourth band (*ca.* 5% *ΔΔ*-rich) just before the fifth band of the bridged 6+ complex. The isolation of the rotaxane, however, was incomplete: the analytical C/N ratio (51.2/10) was low as compared with the ideal value 5.80. Satisfactory analytical data were obtained for the corresponding optically active rotaxane described below.

[2]-[ΔΔ-[(en)₂Co(dodd)Co(en)₂]Cl₆]-[α-CDX]-rotaxane (4) *and [2]-[ΛΛ-[(en)₂Co(dodd)Co(en)₂]Cl₆]-[α-CDX]-rotaxane (5)*: The rotaxane [*ΔΔ*]-[α-CDX] or [*ΛΛ*]-[α-CDX] was prepared and chromatographed in the same manner as for **1** by the use of *Δ*- or *Λ*-$[Co(aet)(en)_2](ClO_4)_2$ as a starting material, respectively. Six bands were characterized, being corresponded to the species in the separation of **1** in both cases. The yields were 2±1% for f1, 6±1% for f3, 28±1% for f4, 4±1% for f5, and 44±2% for f6 (2 preparations) in the *Δ*-system, and 0.8% for f1, 6% for f3, 14% for f5, and 49% for f6 (1 preparation) in the *Λ*-system.

[2]-[ΔΔ-[(en)₂Co(dhdd)Co(en)₂]Cl₆]-[α-CDX]-rotaxane (6): The complex was prepared by the method [A] as for **2** except for the use of *Δ*-$[Co(aet)(en)_2](ClO_4)_2$ instead of the racemate. The yields were 10±1% for f3, 22±1% for f4, 0% for f5, and 49±2% for f6 (2 preparations). It is noteworthy that the yield of rotaxane **6** (f4 band) is considerably higher than that of **2**. An attempt to prepare the corresponding [*ΛΛ*]-[α–CDX] isomer was made in the same way by using *Λ*-$[Co(aet)(en)_2](ClO_4)_2$. The yield of [*ΛΛ*]-[α-CDX], which is not isolated in solid as yet, was below 7%.

[2]-[ΔΔ-[(en)₂Co(dtdd)Co(en)₂]Cl₆]-[α-CDX]-rotaxane (7): The complex was prepared and chromatographed in the same manner as for **3** by the use of *Δ*-$[Co(aet)(en)_2](ClO_4)_2$ as a starting material. Five bands appeared and the fourth band was the desired rotaxane with a 3.5±0.5% yield, which showed the satisfactory analytical data as seen in Table 2.

[2]-[[(en)₂Co(dodd)Co(en)₂]Cl₆]-[β-CDX]-rotaxane (8): The complex was prepared by the method [A] except for the use of β-CDX instead of α-CDX. In the separation five bands f1′—f5′ were eluted in this order, though f2′ and f3′ were partly overlapped each other. The species, f1′(dark brown), f2′(orange), f3′(orange), f4′(orange), and f5′(orange), were characterized as $[Co(aet)(en)_2]^{2+}$, $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_{12}OH\}]^{3+}$, the desired rotaxane, $[Co(en)_2\{NH_2(CH_2)_2$-

$S(CH_2)_{12}Br\}]^{3+}$, and $[(en)_2Co(dodd)Co(en)_2]^{6+}$, respectively. Each band also showed a CD spectrum but the apparent selectivity was much lower than that in the corresponding system containing α-CDX: *ca.* 2% *ΔΔ*-ric for f3′ and *ca.* 0.3% *ΔΔ*-rich for f5′. The yield of f3′ rotaxane was 5±1% (3 preparations).

[2]-[[(en)$_2$Co(dhdd)Co(en)$_2$]Cl$_6$]-[β-CDX]-rotaxane (9): The complex was obtained in a 2±0.5% yield (3 preparations) by the same procedure as for **8**. The f3′ rotaxane indicated *ca.* 1% *ΔΔ*-rich CD. No β-CDX rotaxane was detectable for the corresponding dtdd case.

Measurements. The visible and ultraviolet absorption spectra were measured on a Hitachi 330 spectrophotometer and CD spectra with a JASCO MOE-1 spectropolarimeter in aqueous solutions. The ^{13}C NMR spectra were recorded with a JEOL FX-90Q NMR spectrometer in D_2O containing dioxane as an internal standard. The conductance measurements were made in water on a TOA CM-30ET conductivity apparatus. The values at room temperature were converted automatically to those at 25 °C based on the assumption that the conductance changes by 2% per one degree. The solubility in water was determined in the same way as previously reported.[9]

Results and Discussion

Preparation and Characterization. The yields of rotaxanes are collected in Table 1. The two kinds of method were used for the preparation of rotaxane. The yield was usually higher in the method [B] because the formation of inclusion compounds $Br(CH_2)_nBr\cdot m$(CDX) in DMSO lowered the yield in the method [A]. The yield of the rotaxane was higher for α-CDX than for β-CDX. This means that the annular structure of α-CDX is more suitable in size for the formation of rotaxane of the present complexes than that of β-CDX. The number of bridging methylene groups, *n*, also affected the yield in the decreasing order 12>10>8.

Table 2 shows the analytical data of the complexes containing CDX. The ratio C/N was most indicative of rotaxane formation, but somewhat higher than the ideal value (for example C/N=60/10=6.00 for the dodd rotaxane without organic solvent) because a large amount of ethanol or acetone was used for the isolation of rotaxane having high solubility. The experimental value of C/N ratio well agreed with the composition with a few molecules of the organic solvent (Table 2). In the preparation using 1,12-dibromododecane and α-CDX, the species f1 isolated from chromatography showed the C/N ratio about 18, which corresponded to $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_{12}Br\}]Cl_3\cdot 2$(α-CDX). A similar inclusion complex could be prepared directly from an aqueous solution of $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_nBr\}]Cl_3$ (*n*=10 or 12) and α-CDX (molar ratio 1 : 1). These inclusion complexes as well as the other compounds formed between $Br(CH_2)_nBr$ and α-CDX in the method [A] are considered as precursors of the rotaxanes. The direct isolation of such precursors gives strong support for the formation of rotaxanes in the reaction mixtures.

The first spin-allowed d-d absorption bands of the cobalt(III) rotaxanes locate at 20440 cm^{-1} (Fig. 2), which are characteristic of the $[Co(N)_5(S)]$ chromophore containing a thioether donor atom.[4] The absorption

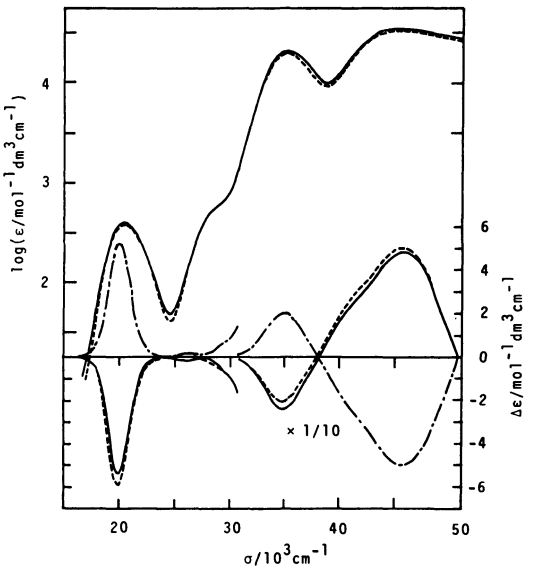

Fig. 2. Absorption and CD spectra of [2]-[$\Delta\Delta$-[(en)$_2$Co(dodd)Co(en)$_2$]Cl$_6$]-[α-CDX]-rotaxane(——), [2]-[$\Lambda\Lambda$-[(en)$_2$Co(dodd)Co(en)$_2$]Cl$_6$]-[α-CDX]-rotaxane (-----), and $\Delta\Delta$-[(en)$_2$Co(dodd)Co(en)$_2$]Cl$_6$ (------).

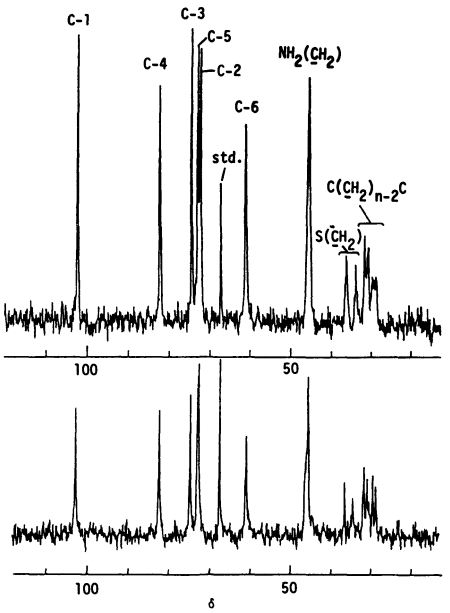

Fig. 3. ^{13}C NMR spectra of [2]-[[(en)$_2$Co(dhdd)Co(en)$_2$]Cl$_6$]-[α-CDX]-rotaxane (**2**) (upper) and [2]-[[(en)$_2$Co(dodd)Co(en)$_2$]Cl$_6$]-[α-CDX]-rotaxane (**1**) (lower). 1,4-Dioxane (δ 67.4 *vs.* Me$_4$Si) was used as the internal reference. The signals of α-CDX (C1—C6) were assigned after Ref. 12.

spectra of rotaxanes are very similar to one another irrespective of the kind of CDX (Table 3). Molar absorption coefficients of the rotaxanes are slightly higher in the thioether charge transfer (CT) band region around *ca.* 35000 cm^{-1} than those of the corresponding bridged complexes. A similar increase of CD intensity is observed in the CT band region (Fig. 2). The ratio of $\Delta\varepsilon_{287}/\Delta\ \varepsilon_{502}$is rather higher in the rotaxanes (4.48 and 3.86 for [$\Delta\Delta$]-[α-CDX] and [$\Lambda\Lambda$]-[α-CDX], respectively) than the bridged $\Delta\Delta$-complex (3.43). Interestingly, the ratio in the [$\Delta\Delta$]-[α-CDX] series increased regularly with the decrease of the methylene chain length: 4.48, 4.91, and 5.82 for the dodd-, dhdd-, and dtdd-rotaxanes, respectively. On the other hand, all the corresponding bridged complexes of $\Delta\Delta$-form showed the identical ratio *ca.* 3.5. This fact clearly shows that the steric repulsion between the cobalt(III) moiety and α-CDX becomes larger with the shortening of the methylene chain. The CD spectra of both $\Delta\Delta$ and $\Lambda\Lambda$ dodd-rotaxanes are not completely enantiomeric to each other. The deviation is eminent in the CT band region. The CD intensity ratio of $\Delta\varepsilon_{219}/\Delta\varepsilon_{287}$ is 1.97 for [$\Delta\Delta$]-[α-CDX] and 2.46 for [$\Lambda\Lambda$]-[α-CDX].

^{13}C NMR spectra offered the direct evidence of the frotaxane formation (Fig. 3). The rotaxanes **1** and **2** gave strong six signals in a lower magnetic field (60—110

ppm), which were assigned to α-CDX moiety.[11,12] Similarly, the rotaxanes of β-CDX **8** and **9** showed five signals in this region. The spectral patterns and chemical shifts of α- and β-CDX moieties are similar to those of free α- and β-CDX, respectively. The other signals in a higher field (0—60 ppm) were assigned to methylene carbons of $NH_2(CH_2)$–, –$S(CH_2)$–, and –$C(CH_2)_{n-2}C$– regions from the lower magnetic field side. These spectral patterns, however, were complicated since the present rotaxanes are a mixture consisted of four diastereomers. Figures 4 and 5 show the ^{13}C NMR spectra of the optically active rotaxanes **4**, **5**, **6**, and **7**, which are composed of a single diastereomer without symmetry element. In the –$C(CH_2)_{n-2}C$– region, the rotaxanes **4** (or **5**), **6**, and **7** showed seven (three strong and four weak), seven (one strong and six weak), and five (one strong and four weak) methylene resonances, respectively. Since it can be assumed that each of the strong signals corresponds to two methylene carbons, the total number of the methylene resonances becomes ten for **4** (or **5**), eight for **6**, and six for **7**. The results gave the direct evidence of the rotaxane formation with C_1 symmetry. Both the dodd rotaxanes, [*ΔΔ*]-[α-CDX] and [*ΛΛ*]-[α-CDX], showed seven signals in the –$C(CH_2)_{10}C$– region but the spectral patterns are obviously different from each other as expected from the fact that they are diastereomeric.

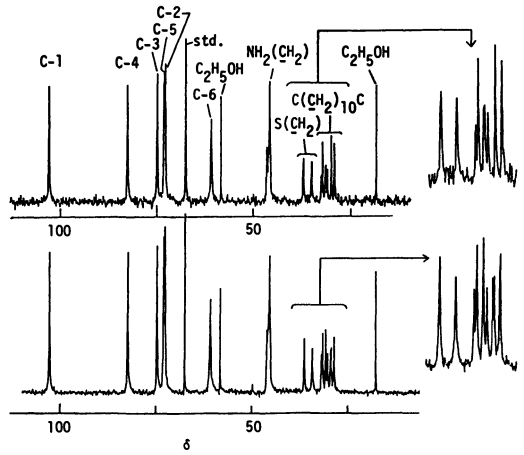

Fig. 4. ^{13}C NMR spectra of [2]-[*ΔΛ*-[$(en)_2$Co(dodd)Co-$(en)_2$]Cl_6]-[α-CDX]-rotaxane (**5**) (upper) and [2]-[*ΔΔ*-[$(en)_2$Co(dodd)Co$(en)_2$]Cl_6]-[α-CDX]-rotaxane (**4**) (lower).

The chemical shifts due to CDX in the rotaxanes were summarized in Table 4. The signals of β-CDX were assigned in the same manner by Usui *et al.*[11] and Colson *et al.*[12] but the assignment of α-CDX became reverse at C2 and C5 resonances, our assignment being after

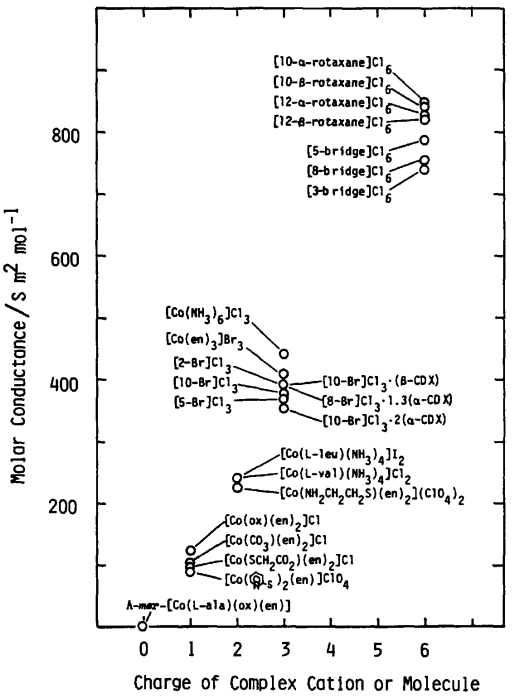

Fig. 6. Molar conductivity of the rotaxanes and other cobalt(III) complexes in water at 25 °C. Abbreviation, complex: [*n*-α-rotaxane]Cl_6=[2]-[[(en)$_2$Co{NH_2-$(CH_2)_2$S$(CH_2)_n$S$(CH_2)_2NH_2$}Co(en)$_2$]Cl_6]-[α-CDX]-rotaxane, [*n*-bridge]Cl_6=[(en)$_2$Co{$NH_2(CH_2)_2$S-$(CH_2)_n$S$(CH_2)_2NH_2$}Co(en)$_2$]Cl_6, and [*n*-Br]Cl_3=[Co(en)$_2$\{$NH_2(CH_2)_2$S$(CH_2)_n$Br\}]Cl_3; ligand: L-ala=L-alaninato, L-leu=L-leucinato, L-val=L-valinato, and ox=oxalato.

Colson *et al.*[12] The values of the dodd rotaxanes containing α-CDX are very similar to one another irrespective of the absolute configurations of the cobalt(III) moieties. The change of the bridging length affects the chemical shift. Three resonances of C4, C5, and C6 were shifted regularly to the down field with the decrease of the methylene chain length, whereas the chemical shifts of C1, C2, and C3 were hardly affected. It is well known that the intra hydrogen bonding between adjacent glucose units in α- or β-CDX is found as a stabilization factor of the cyclic structure in DMSO solution[13] as well as in solid.[14] Since the hydroxyl groups at C2 and C3 are relevant to this hydrogen bonding network, the chemical shifts of C1, C2, and C3 are almost insensitive to the change of the bridging length. On the other hand, the hydroxyl group at C6 can rotate freely and is sensitive to the steric change. Such a steric change at C6 also influences the chemical shifts of C4 and C5. Thus, our results support the assignment of the C2 and C5 resonances for α-CDX by Colson *et al.*[12] but not Usui *et al.*[11]

Chromatography and Molar Conductance. The rotaxane complex cations should have a 6+ charge, but eluted before the 3+ cations [Co(en)$_2$\{$NH_2(CH_2)_2$S-$(CH_2)_n$Br\}]$^{3+}$ (n=10 and 12). The species f1 containing α-CDX (3+) also eluted before [Co(aet)(en)$_2$]$^{2+}$. Such anomalous chromatographic behaviors as well as a similar observation reported in a similar system[3] can be ascribed to the property of SP-Sephadex ion exchangers, which have a kind of non-ionic effect in addition to the dominant ionic one. The former effect, as seen in gel filtration by Sephadex G-type, is based on the molecular size. The bulky complexes such as the rotaxanes are expected to be more rapidly eluted than the corresponding bridged complexes. The rotaxanes **3** and **7**, however, showed a normal elution order as expected from the complex charge. This fact means that the rotaxanes **3** and **7** with n=8 are relatively small in size than the other **1**, **2**, **4**, **5**, **6**, **8**, and **9** with n=10 and 12.

Molar conductances of the rotaxanes and the related complexes at 25 °C are plotted in Fig. 6. The plots for the complexes of each the same charge are distributed in a narrow range, and well separated on the other hand from those of other complexes with the different charges. The rotaxanes have slightly higher values than the corresponding bridged 6+ complexes. Mononuclear inclusion complexes with the charge 3+ showed almost the same values as the corresponding complexes [Co(en)$_2$\{$NH_2(CH_2)_2$S$(CH_2)_n$Br\}]$^{3+}$. Thus, molar conductance was not affected by the presence of CDX. The anomalous column behavior is relevant to the interaction between the SP-Sephadex resin and bulky CDX.

Stereoselectivity. The rotaxanes prepared from *rac*-[Co(aet)(en)$_2$]$^{2+}$ are each the mixture of four diastereomers, *ΔΔ*-, *ΛΛ*-, and two *ΔΛ*-forms (pseudo-*meso*) with respect to the bridged cobalt(III) moieties. Though the two pseudo-*meso* rotaxanes have no CD contribution due to the skew pairs of chelate rings around the central cobalt(III) ion, they will show the induced CD spectra owing to the chiral α- or β-CDX. This contribution is, however, considered to be relatively low and therefore the chiralities of the former two diastereomers contribute mainly to the CD spectra of the product, if an unequal distribution of them takes place. In fact, a very weak positive CD band ($\Delta\varepsilon_{545}$=+0.04) was reported as such induced CD of [2]-[[(en)$_2$ClCo {$NH_2(CH_2)_{12}NH_2$} CoCl(en)$_2$] $(ClO_4)_4$]-[β-CDX]-rotaxane.[3] In the present dodd system, the CD contribution due to α-CDX, which could be evaluated from the mean of the CD spectra of [*ΔΔ*]-[α-CDX] and [*ΛΛ*]-[α-CDX] in Fig. 2, was proved to be small. Therefore, it is reasonable that the two pseudo-*meso* type rotaxanes have a small CD contribution. The rotaxane **2** prepared by the method [A] showed a negative CD spectrum ($\Delta\varepsilon_{502}$=−0.80) in the first d-d absorption band region, which corresponded to a *ca.* 16% optical purity of *ΔΔ*-form (the highest selectivity observed). Thus the unequal distribution of [*ΔΔ*]-[α-CDX] and [*ΛΛ*]-[α-CDX] diastereomers is confirmed. This is also supported by the fact that the bridged complex formed concomitantly indicated the CD band of opposite sign ($\Delta\varepsilon_{502}$=+0.13). In general, the rotaxanes of β-CDX were less stereoselective, though they showed a positive CD band in the first d-d absorption band region. Because of the narrow cavity, α-CDX behaves more effectively to the stereoselectivity as well as to the formation of rotaxane than β-CDX. The bridging methylene chain length also influences the effectiveness of the selectivity: the order is 10>12>8 for the rotaxanes containing α-CDX.

The optically active [*ΔΔ*]-[α-CDX] rotaxane, **4** or **6**, was prepared by the method [A] in a considerably higher yield than the corresponding mixture **1** or **2**, respectively. The dtdd rotaxane with $n=8$ was not detectable in the method [A] starting from *rac*-$[Co(aet)(en)_2]^{2+}$ but could be prepared in a 3.5% yield even by the same method using *Δ*-$[Co(aet)(en)_2]^{2+}$. The stereoselectivity will be more clear by comparison between the pure *Δ*- and *Λ*-systems. In the dodd system, the yield of [*ΔΔ*]-[α-CDX] isomer is 28%, whereas that of [*ΛΛ*]-[α-CDX] one only *ca.* 14%. Similarly in the dhdd system, the yield of [*ΔΔ*]-[α-CDX] is 21% but that of [*ΛΛ*]-[α-CDX] below 7%. These results are consistent with the stereoselective formation of rotaxanes, that is, *ΔΔ*-complex being included preferentially into α-CDX.

The formation reaction of rotaxane is stepwise one as shown schematically by Ogino.[3] In the course of bridge formation process, there is the step forming an intermediate inclusion complex of $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_nBr\}]^{3+}$ and CDX. This stage is expected to be the most important for the present stereoselectivity. The expectation is confirmed by the partial optical resolution of $[Co(en)_2(NH_2CH_2CH_2SR)]^{3+}$ with a long alkyl or bromoalkyl chain ($R=(CH_2)_nBr$ and $(CH_2)_nCH_3$).[15] Interestingly, the best resolution was achieved in the case of $R=(CH_2)_{10}Br$ and α-CDX, corresponding to 61% optical purity of *Δ*-complex. The results are in fair agreement with the present selectivities.[16]

16) β-CDX preferentially included *Λ*-complexes in the optical resolution contrary to the present system. The difference may result from the properties of used solvents: water for the former and DMSO for the latter.

Hydration of Iodide Ions in Nitrobenzene from Charge-transfer-to-solvent Spectra and ^{1}H NMR

Kazuaki Ito, Etsuro Iwamoto, and Yuroku Yamamoto*
Department of Chemistry, Faculty of Science, Hiroshima University, Naka-ku, Hiroshima 730
(Received February 7, 1983)

The charge-transfer-to-solvent (c.t.t.s.) spectrum of the iodide ion in nitrobenzene was observed in the visible region, the intensity of the spectrum being lowered by addition of a small amount of water to the solution. From the spectral changes, the first, second, and third hydration constants, $K_1=3.5$, $K_2=2.6$, and $K_3=1.4$ (mol^{-1} dm^3) were determined. On the basis of ^{1}H NMR of water in nitrobenzene solutions in conjunction with the hydration constants obtained from the spectra, it was suggested that a fraction of the water molecules bound to the iodide ion is hydrogen bonded to each other.

The solvation of anions by a small amount of protic solvents such as water and methanol in aprotic solvents plays an important role in ionic reactions such as ligand substitution[1] and ion pair extraction,[2] and has been studied by UV,[3] NMR,[4-6] IR,[7,8] solubility,[6,9] conductance,[10,11] extraction,[12,13] and isopiestic method.[14,15] Addition of protic solvents to solutions of iodides in acetonitrile resulted in loss of a c.t.t.s. band at 40.7×10^3 cm^{-1} and growth of new bands at higher energy which were assigned to the iodide ion hydrogen bonded to a single hydroxyl proton.[3] For ethyleneglycol chelation to the iodide ion was suggested.[3]

Although nitrobenzene, dipolar aprotic and poorly basic, can not be used as a medium transparent in the ultraviolet region, it has widely been used as a useful solvent for ion pair extraction[16] and conductance studies[17] due to its solubilizing power for salts. The amount of coextracted water with anions into nitrobenzene decreases with increasing anionic radius.[12,13,15] From isopiestic measurements, hydration constants of the perchlorate ion in nitrobenzene were estimated for five hydration models.[14]

In connection with our study on solvent extraction of ion pair with tetraalkylammonium iodides (R_4NI)[2,16] it was found that when tetraalkylammonium iodides are dissolved in nitrobenzene the colour results in deep yellow from yellow and the intensity decreases as a small amount of water is added to the solution. This spectrum change which is reversible with regard to water concentrations is attributed to the formation and rupture of a charge transfer complex. On the basis of the water concentration dependence of the visible spectrum and the chemical shift of water proton, we discuss the interaction among the iodide anion, nitrobenzene and water, and the structure of hydrated species.

Experimental

Tetrapropylammonium iodide (Pr_4NI) and tetraphenylphosphonium chloride (Ph_4PCl), of the reagent grade available, were further purified by several recrystallizations from ethanol–ether (peroxide free) mixtures. Nitrobenzene was purified as previously described.[16]

Visible spectra were recorded with a Hitachi model 210-10 spectrometer, using 10 mm quartz cells at 25 °C. The absorbance for a nitrobenzene solution containing a certain concentration of $Pr_4NI$was measured as a function of water content. Nitrobenzene containing water was used as reference. ^{1}H NMR spectra were measured with a Hitachi model R-20 NMR spectrometer (60 MHz) at 25 °C, relative to tetramethylsilane in nitrobenzene as external reference. Water concentrations in nitrobenzene were determined coulometrically with a Hiranuma AQ-3 aquacounter.

Results and Discussion

(a) C.t.t.s. Spectra. Tetrapropylammonium iodide is easily dissolved in nitrobenzene and its solution gives slightly deeper yellow than that of nitrobenzene. The conductance experiment showed that no conductance change was observed in a solution at 10^{-4} mol dm^{-3} levels over the period of 1 h, suggesting that the species in nitrobenzene are stable.

The absorption spectrum of Pr_4NI (1.275×10^{-3} mol dm^{-3}) in nitrobenzene and its water concentration dependence over the range 400 to 500 nm are shown in Fig. 1 where the reference is nitrobenzene containing water of the same concentration as that in the sample cell; therefore the strong absorption due to nitrobenzene itself results in the rapid drop in absorbance below 430 nm. The addition of a small amount of water leads to a decrease in the intensity of absorption. Table 1 gives the absorbances at various concentrtions of water at 440

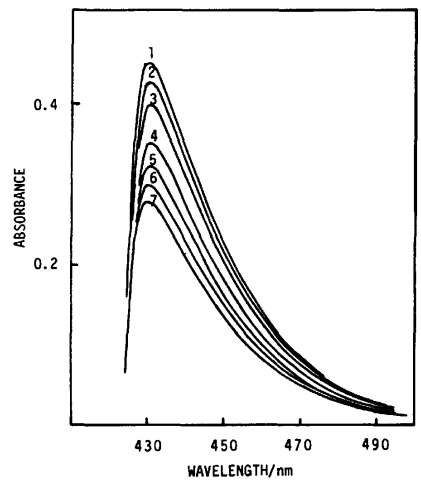

Fig. 1. Spectra of Pr_4NI (1.275×10^{-3} mol dm^{-3}) in nitrobenzene solutions using 10 mm cells as a function of water concentration in mol dm^{-3}; 1, 0.005; 2, 0.0213; 3, 0.0376; 4, 0.0702; 5, 0.103; 6, 0.135; 7, 0.168.

Table 1. Absorbances of Pr_4NI(1.275×10^{-3} mol dm^{-3}) in nitrobenzene at 440 nm as a function of water concentration at 25 °C

$[H_2O]$/mol dm^{-3}	Absorbance	$\frac{\varepsilon_{obsd}}{10\ mm^{-1}\ mol^{-1}\ dm^3}$
0.0050	0.346	271
0.0132	0.333	261
0.0213	0.325	255
0.0376	0.309	242
0.0702	0.280	220
0.103	0.255	200
0.135	0.232	182
0.152	0.221	173
0.160	0.219	172
0.168	0.215	169

nm where Lambert's law was confirmed to hold for the intensity over the range of light pass 1 to 10 mm. This water concentration dependence of the absorbance is reversible: The drying of wet nitrobenzene solutions by calcium chloride increases the absorbance again. The results mentioned above indicate that the shoulder of spectra observed above 430 nm are due to the formation of a charge transfer complex between the iodide ion and nitrobenzene or c.t.t.s. spectra. Such c.t.t.s. spectrum in the visible region is not observed for chloride, bromide, and perchlorate, which being expected on the basis of the ionization potentials of the halide ions.[18,19] The decrease in the intensity with increasing water concentration can be assigned to the hydration of the iodide ion, the iodide–nitrobenzene interaction being weakened. A similar effect of addition of a protic solvent on c.t.t.s. spectra in a aprotic solvent was also observed; addition of methanol and water results in loss of the c.t.t.s. band with a maximum at 40.7×10^3 cm^{-1} for iodide in acetonitrile and in growth of a new band at 41.8×10^3 cm^{-1} due to the iodide ion hydrogen bonded to the protic solvents.[3]

Since the ionic association constant, 33,[16] for Pr_4NI in nitrobenzene at 25 °C gives a degree of dissociation of 0.97 at 1.275×10^{-3} mol dm^{-3}, the effect of ion pairing is negligible for the following calculation. The hydration of the iodide ion is represented as

$$I^-\cdot(n-1)H_2O + H_2O \rightleftharpoons I^-\cdot nH_2O$$

with the corresponding formation constants,

$$K_n = [I^-\cdot nH_2O]/[I^-\cdot(n-1)H_2O][H_2O]. \quad (1)$$

The apparent molar extinction coefficient (ε_{app}) is written as

$$\varepsilon_{app} = [I^-](\varepsilon_0 + \varepsilon_1K_1[H_2O] + \varepsilon_2K_1K_2[H_2O]^2 + \varepsilon_3K_1K_2K_3[H_2O]^3 + \cdots)/[I^-]_{total}, \quad (2)$$

where $[I^-]_{total}$ is the total concentration of iodide ions and ε_0, ε_1, ε_2, and ε_3 the apparent absorptivity of non-hydrated, 1 : 1, 1 : 2, 1 : 3 hydrated iodide ions, respectively. Assuming $n=1$, 2, and 3, the hydration constants were calculated by use of the dependence of the absorbance at 440 nm on the water concentration (Table 1) and the monomer-dimer equilibrium constant $K_s(=[(H_2O)_2]/[H_2O]^2)$, 1.054 mol^{-1} dm^3, for water in nitrobenzene at 25 °C:[20] First, the concentrations of monomer water and nonhydrated iodide ions were obtained from the K_s value and an initial value of K_n, and then an iterative calculation was carried out to minimize the standard deviation, $[\sum(\varepsilon_{calcd}-\varepsilon_{obsd})^2/(N-1)]^{1/2}$, with a given value of ε_0 where ε_{calcd} and ε_{obsd} are apparent molar extinction coefficient calculated and observed, respectively, and N is the number of data. The best fitting values for each case are given in Table 2. For both $n=1$ and 2, ε_1 and ε_2 are nearly zero, showing that the hydration of iodide ions almost disrupts the charge-transfer transition. For $n=3$ the hydration constants were calculated, by assuming that ε_1, ε_2, and ε_3 are zero. The K_1 value, 3.5, for iodide ions is comparable to 2.4 for perchlorate ions in nitrobenzene obtained by the isopiestic method.[14]

Table 2. Hydration constants of iodide ions in nitrobenzene at 25 °C

n	1	2	3
ε_0	281	277	274
ε_1	0.0	0.4	0
ε_2		0.0	0
ε_3			0
K_1	5.0	3.9	3.5
K_2		2.1	2.6
K_3			1.4
σ[a]	3.6	1.7	1.1

a) $\sigma=\{\sum(\varepsilon_{calcd}-\varepsilon_{obsd})^2/(N-1)\}^{1/2}$, where ε_{calcd}, ε_{obsd} are apparent molar extinction coefficient calculated and observed, respectively, and N is the number of data.

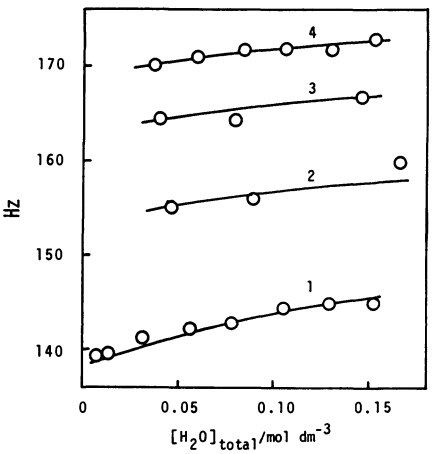

Fig. 2. Chemical shifts of water protons in the presence of Pr_4NI in nitrobenzene. Solid lines show the calculated values. Concentration of Pr_4NI in mol dm^{-3}; 1, 0.0; 2, 0.05; 3, 0.100; 4, 0.143.

(b) ^1H NMR Spectra of Water. A single resonance line for water protons in nitrobenzene was obtained irrespective of the presence of Pr_4NI and Ph_4PCl. Figures 2 and 3 show the chemical shifts of water protons as a function of water and salt concentrations. Hydrogen bonding usually leads to a down-field shift.[4,6] In Fig. 2 the increased down field shift with water concentration irrespective of the presence of salts is ascribed to the increased dimerization of water and hydration of ions, respectively.

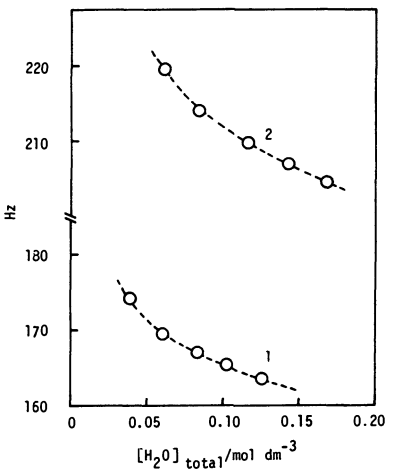

Fig. 3. Chemical shifts of water protons in the presence of Ph_4PCl in nitrobenzene. Concentration of Ph_4PCl in mol dm^{-3}; 1, 0.0109; 2, 0.0471.

In a way similar to the case for c.t.t.s. spectra, the observed chemical shift (δ_{obsd}) of water protons is represented as, in the absence of salts,

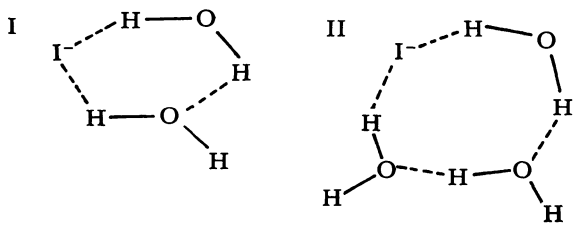
$$\delta_{obsd} = (\delta_0[H_2O]+2\delta_s K_s[H_2O]^2)/[H_2O]_{total}, \quad (3)$$

in the presence of salts,

$$\delta_{obsd} = (\delta_0[H_2O] + 2\delta_s K_s[H_2O]^2 + \delta_1 K_1[I^-][H_2O] + 2\delta_2 K_1 K_2[I^-][H_2O]^2 + 3\delta_3 K_1 K_2 K_3[I^-][H_2O]^3)/[H_2O]_{total}, \quad (4)$$

where δ_0, δ_s, δ_1, δ_2, and δ_3 are chemical shifts for non-bonded monomeric and dimeric water, 1 : 1, 1 : 2, and 1 : 3 hydrates, respectively. Although in the salt concentration range used in the NMR study the degree of ionic association for Pr_4NI is marked (0.14 for 0.01 mol dm^{-3} and 0.44 for 0.15 mol dm^{-3}), the hydration of iodide ions is not affected significantly by the association.[2,12-15] Thus, the association effect was disregarded. The chemical shifts, δ_0(138) and δ_s(175) from Eq. 3 and δ_1(232), δ_2(245), and δ_3(265) from Eq. 4 were estimated from K_s and K_1, K_2, and K_3 obtained from the c.t.t.s. spectra. It is noteworthy that the chemical shift increases stepwise with increasing degree of hydration of iodide, $\delta_1<\delta_2<\delta_3$, contrary to the behaviour for lithium ions in propylene carbonate.[4] Furthermore, the chemical shift for iodide increases with increasing the water concentration, while that for chloride decreases (Fig. 3). The increased down-field shift for iodide would be explained in terms of chelation of water molecules bound to iodide ions; models I for $n=2$ and II for $n=3$.

The chemical shift for chloride ions is much larger than that for iodide ions, showing the stronger hydration of chloride ions. It is likely that the orientation of water molecules towards chloride ions through hydrogen bonding is too strong to make a chelate ring such as the one observed for iodide ions.



This work was supported in part by a Grant-in-Aid for Scientific Research Nos. 443013 and 454183 from the Ministry of Education, Science and Culture.

Fractional Spectrophotometric Determination of Ethylenediaminetetraacetate and nitrilotriacetate as Their Iron(III) Complexes by Use of H- and Na-form Ion Exchange Resin Columns

Akihiro YAMAGUCHI, Kunio OHZEKI,* and Tomihito KAMBARA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received February 21, 1983)

The fractional determination of ethylenediaminetetraacetate(EDTA) and nitrilotriacetate(NTA) was carried out by use of hydrogen- and sodium-form ion exchange resin columns. After the conversion of free and complexed EDTA and NTA to the corresponding iron(III) complexes, two aliquots of the sample solution were separately passed through the columns. The iron(III)–EDTA complex was stable in both columns but iron(III)–NTA complex was completely decomposed in the hydrogen-form resin column, therefore, both of iron(III)–EDTA and –NTA were found in the effluent of sodium form resin column but only iron(III)–EDTA was found in the effluent of hydrogen-form resin column. The complexes in the respective effluents were determined spectrophotometrically at 255 nm. The recovery tests of EDTA and NTA from the synthetic sample solutions containing various metal ions were examined and the results observed were satisfactory.

The determination of chelating agents has recently been required for the estimation of the complexing capacity and for the speciation of trace metals in water. The general method was based on the conversion of chelating agents to the corresponding copper(II) complexes with the addition of excess copper(II) ion. After the removal of excess copper(II) by means of the chelating resin column,[1] or as copper(II) oxide,[3,4] the resulting copper(II) complexes were determined by atomic absorption spectrometry[1-3] or spectrophotometry.[4] A CuO-loaded ion exchange resin column was used to determine EDTA as the copper(II) complex.[5] Chelating agents were also determined as iron(III) complexes.[6,7] The fractional determinations of chelating agents were carried out with various methods, *i.e.*, gas chromatography as methyl esters,[8] liquid chromatography as copper(II) complexes,[9] and polarography as cadmium(II) complexes.[10]

In the present paper a simple spectrophotometric method of fractional determination of EDTA and NTA is described.

Experimental

Reagents. All chemicals used were of analytical reagent grade. The stock solutions of EDTA and NTA were prepared from the Dotite reagents (Dojindo Lab.). A 10^{-2} M (1 M=1 mol dm^{-3}) EDTA solution was made by dissolving dried disodium dihydrate salt (80 °C, 2 h) in deionized water. A 10^{-2} M NTA solution was prepared by dissolving dried acid (110 °C, 2 h) in a sodium hydroxide solution, the pH of final solution being around 8. Ammonium iron(III) sulfate dodecahydrate was dissolved into acidified water (pH 1) to give a 2×10^{-2} M solution. Other metal ion solutions were made from the nitrate or chloride salts.

Ion Exchange Resin. Dowex 50W-X8 (100—200 mesh) was used in H- and Na-forms, respectively. Hydrogen-form resin was packed in a column (23 cm long, 1 cm i.d.) to make a 2-cm resin bed, and it was washed with 0.025 M sulfuric acid. Sodium-form resin was packed in another column of the same size to give a 1-cm resin height, and the column was washed with a buffer solution (pH 3.1) composed of 0.05 M formic acid and 0.01 M sodium formate.

Apparatus. A Shimadzu spectrophotometer, UV-240, was used with 1-cm quartz cells.

General Procedure. The sample solution containing EDTA and NTA was divided in two equal aliquots and placed in 50-ml volumetric flasks.

A) Procedure by the H-form Resin Column. To one of the sample aliquot were added 2.5 ml of 0.5 M sulfuric acid and 0.5 ml of 0.02 M iron(III) solution. The mixture was filled up to the mark with deionized water, the pH of final solution being 1.4. The solution was then passed through the hydrogen-form resin column at a flow rate of 2—3 ml min^{-1}. The first 10-ml portion of effluent was discarded and the next 5-ml portion was collected. The absorbance of iron(III)–EDTA complex in the effluent was measured at 255 nm against deionized water. The blank value was also determined without addition of chelating agents.

B) Procedure by the Na-form Resin Column. To another aliquot of sample solution were added 2.5 ml of 0.5 M sulfuric acid, 0.5 ml of 0.02 M iron(III) solution, and finally 3 ml of 1 M sodium formate solution. The mixture was filled up to the mark, the pH of final solution being 3.1. This solution was passed through the sodium-form resin column and the effluent was collected as described in the above procedure. The absorbance corresponding to the sum of EDTA and NTA was also determined at 255 nm.

Results and Discussion

Absorption Spectrum. Absorption spectra of iron(III)–EDTA and –NTA complexes were shown in Figs. 1 and 2. The iron(III)–NTA complex in the formate buffer solution differed from that in dilute sulfuric acid, the adduct formation of the complex with formate being suggested. The absorbance due to the excess iron(III) was successfully removed by use of the cation exchange resin column. While the photosensitivity of iron(III)–EDTA complex is known,[11,12] the complex was found to be stable at least for 3 h, when the solution was protected from the direct sunlight.

Stability of Iron(III)–NTA Complex in H- and Na-form Resin Columns. The iron(III)–NTA complex was completely dissociated during the passage of the 2-cm column packed with hydrogen-form resin, being not found in the effluent (Fig. 3). By use of a 1-cm column, however, a part of iron(III)–NTA was eluted from the column indicating that the degree of decomposition depends on the column length. On the other hand, iron(III)–NTA complex in the formate buffer solution passed safely through the sodium-form resin column.

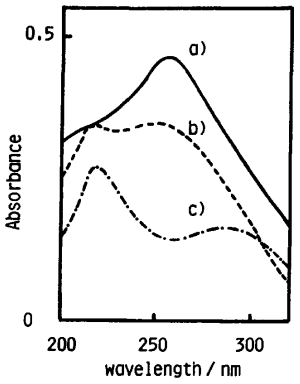

Fig. 1. Absorption spectra of iron(III) complexes in formate buffer solution (0.05 M HCOOH—0.01 M HCOONa, pH 3.1). a) 50.0 μM iron(III)–EDTA, b) 50.0 μM iron(III)–NTA, c) 50.0 μM iron(III), reference: reagent blank.

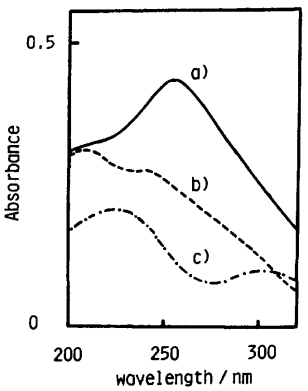

Fig. 2. Absorption spectra of iron(III) complexes in 0.025 M sulfuric acid solution (pH 1.4). The symbols have the same meanings as in Fig. 1.

The absorbance of iron(III)–NTA complex in the effluent increased with increasing pH, probably due to the adduct formation of the complex with formate.

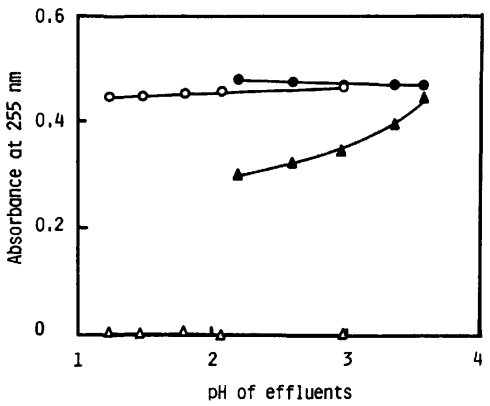

Fig. 3. Effects of pH on the stability of iron(III) complexes after passing the H- and Na-form resin columns. Iron(III)–EDTA: 51.3 μM, (○) H-form, (●) Na-form. Iron(III)–NTA: 51.0 μM, (△) H-form, (▲) Na-form.

Stability of Iron(III)–EDTA Complex in H- and Na-form Resin Column. Iron(III)–EDTA complex was stable in both columns (Fig. 3).

Calibration Curves. The calibration curves of EDTA and NTA were linear over the concentration range 20—100 μM; the regression equations were shown by

$$A_{H}^{EDTA} = 8762[EDTA] - 0.003, \quad (1)$$

$$A_{Na}^{EDTA} = 9185[EDTA] - 0.001, \quad (2)$$

$$A_{Na}^{NTA} = 6664[NTA] - 0.002, \quad (3)$$

where A denotes the absorbance and the suffixes H and Na indicate the signal obtained with the hydrogen- or sodium-form resin column. The relative standard deviations for 5.13×10^{-5} M EDTA were 0.3% (n=5) in the procedure A and 0.2% in the procedure B, respectively, and the value for 5.10×10^{-5} M NTA was 0.6% in the procedure B.

	25	51.2	100	51.3	100

EDTA taken: 51.3 μM. a) Mean of three determinations.

Effect of Diverse Ions. By the addition of excess iron(III), both the free and complexed NTA's were quantitatively converted to the iron(III)–NTA complex at room temperature. In the case of EDTA, however, the conversion of copper(II) and nickel(II) complexes to the iron(III) complex was first achieved by heating the acidified reaction mixture (pH 1.4) for 10 min on a water bath (Table 1).

Fractional Determination of EDTA and NTA. The determination was carried out as follows. The concentration of EDTA in the sample solution was determined by the procedure A; namely, from Eq. 1, one has

$$[\text{EDTA}] = 1.141(A_{\text{H}}^{\text{EDTA}} + 0.003) \times 10^{-4}\ \text{M}. \quad (4)$$

On the other hand, the absorbance corresponding to the sum of EDTA and NTA was determined by the procedure B; namely,

$$A_{\text{Na}} = A_{\text{Na}}^{\text{EDTA}} + A_{\text{Na}}^{\text{NTA}}. \quad (5)$$

By introducing Eqs. 2, 3, and 4 into Eq. 5, the following relationship was obtained.

$$[\text{NTA}] = [1.501(A_{\text{Na}} + 0.003) - 1.573(A_{\text{H}}^{\text{EDTA}} + 0.003)] \times 10^{-4}\ \text{M} \quad (6)$$

The results show the good accuracy, as shown in Table 2.

Recovery of EDTA from River Water Samples. The water samples were filtered through membrane filters (0.45 μm) and the various amounts of EDTA were added. After the addition of excess iron(III), the samples were heated for 10 min on a water bath and subjected to the determination according to the procedures A and B and Eqs. 1 and 2, NTA being assumed to be absent in the original sample solutions. The complete recovery of EDTA was observed in the both procedures (Table 3), which indicated that no appreciable amount of EDTA and NTA was contained in the original sample waters.

(Received February 25, 1983)

Photochemical reactions of $RMn(CO)_3L_2$ (R=H and CH_3; L=$P(OC_6H_5)_3$) and $CH_3Mn(CO)_4L$ in benzene gave several kinds of orthometalated products, $(PhO)_2\overline{P(OC_6H_4)}Mn(CO)_{4-x}L_x$ (x=0, 1, and 2). The reactions have been shown to proceed *via* ligand dissociation, CO and/or L, from the parent compounds and the resulting 16-electron intermediates activate a C–H bond of phenyl groups in triphenyl phosphite intramolecularly to yield orthometalated products. The results of photochemical reactions for $MeMn(CO)_3L_2$ and $MeMn(CO)_4L$ are compared with those of thermal reactions for these compounds. $HMn(CO)_4L$ was left intact by photochemical and thermal reactions.

Photochemical reactions of manganese or rhenium carbonyls with phosphines or phosphites have been a subject of recent intensive scrutiny.[1-8] The reactions have been shown to proceed *via* metal centered radicals and to terminate in intermolecular reactions by abstracting X from RX such as CCl_4 and/or by coupling of two 17-electron metal carbonyl radicals, but the importance of intramolecular reaction pathway of metal carbonyl radicals or unstable intermediates with phosphines or phosphites has not yet been well explored to our knowledge. In the previous paper, we have demonstrated that manganese carbonyl radicals with triphenyl phosphite(s) which were produced by photochemical degradation of Me_3Sn–$Mn(CO)_3L_2$ (**1**) (hereafter L denotes triphenyl phosphite) underwent intramolecular reactions by abstracting hydrogen from a benzene ring in the triphenyl phosphite moieties to afford orthometalated products[9] and the key role of 15-electron manganese carbonyl radicals with triphenyl phosphite ligand(s) was suggested to attain orthometalation. In this regard, $MeMn(CO)_3L_2$ (**2**) and $HMn(CO)_3L_2$ (**3**), which are isostructural and isoelectronic about the manganese atom with that of **1**, are attractive compounds to deepen our understanding on the intramolecular reactivity and/or orthometalation reaction mechanisms of unstable manganese carbonyl triphenyl phosphite intermediates which may be produced by photochemical excitation of these compounds. This paper reports isolation of orthometalated products from photochemical reactions of **2**, **3**, and $MeMn(CO)_4L$ (**4**) and some suggestions on the photochemically induced orthometalation mechanisms of these compounds.

Experimental

$CH_3Mn(CO)_3L_2$ (**2**),[10] $HMn(CO)_3L_2$ (**3**),[10] and $CH_3Mn(CO)_4L$ (**4**),[11] and $HMn(CO)_4L$ (**5**)[12] were prepared via reported methods under a nitrogen atmosphere. The photolysis was carried out under an argon atmosphere with a Riko 100 W high-pressure Hg lamp which was inserted in a 300 cm^3 Pyrex reaction vessel. IR spectra were obtained on a JASCO-701G infrared spectrometer with 0.1 mm NaCl windowed liquid cells or for Nujol mulls. Molecular weight was determined by a Corona 114 molecular weight apparatus with a vapor pressure osmometry; benzene was employed as a solvent.

Photolysis of 2. A 0.9 g sample of **2** was dissolved in 50 cm^3 of benzene and the solution was irradiated for 5 h. The solvent was vacuum-stripped to leave a pale yellow oil. The oil was dissolved in a minimum amount of benzene and was loaded on a Florisil column (60—100 mesh). The products were eluted with petroleum ether, cyclohexane, benzene, and chloroform successively. A colorless oil (**6**) (175 mg), three kinds of colorless crystals (**7**) (25 mg), (**8**) (50 mg), (**9**) (25 mg), and yellow crystals (**10a**) (15 mg) were obtained by carefully repeated recrystallizations of each fraction from benzene–cyclohexane. These products were characterized by IR, elemental analyses on C, H, and P, molecular weight determination and/or X-ray diffraction methods; the products **6**—**9** exhibited three IR bands (Nujol mulls) with mediumintensities at around 1100, 950, and 800 cm^{-1} which are characteristic of an orthometalated triphenyl phosphite ligand.[9] The IR spectra in ν(CO) region of **6**, **7**, and **9** are consistent with those of authentic $(PhO)_2\overline{P(OC_6H_4)}Mn(CO)_4$ (**6**), *fac-cis*-$(PhO)_2\overline{P(OC_6H_4)}Mn(CO)_3L$ (**7**), and $(PhO)_2\overline{P(OC_6H_4)}Mn(CO)_2L_2$ (**9**).[9] C, H, and P analyses on **8** suggested that this crystal has the same composition as that of **7** and molecular weight measurenents indicated a monomeric property; elemental analyses of **8**. Found C, 61.86; H, 3.79; P, 8.02%. Calcd for $C_{39}H_{29}MnO_9P_2$: C, 61.75; H, 3.85; P, 8.17%. Molecular weight: Found 787. Calcd 759. The crystal of **8** showed two ν(CO) peaks at 2055 (m) and 1975 (vs) cm^{-1}, while the isomer **7** showed three ν(CO) peaks at 2030 (vs), 1965 (s), and 1941 (vs) cm^{-1} in benzene. This result indicates that **8** has a higher symmetry than that of **7** around the manganese atom and thus a mer-trans structure is assigned to **8** (Fig. 1). The yellow crystals of **10a** are the same product as that obtained by the photolysis of **1** from all respects. The final characterization of this yellow crystal is described below.

Photolysis of 3. A 0.9 g sample of **3** was dissolved in 50 cm^3 of benzene and the solution was irradiated for 5 h. After similar work up as the case of **2**, the product were separated by column chromatography over Florisil. The first fraction was eluted with petroleum ether to afford 300 mg of the starting material after recrystallization from benzene–petroleum ether. The second fraction was eluted with cyclohexane and the third fraction was eluted with benzene. By recrystallization from benzene–petroleum ether, 60 mg of 9 and 10 mg of **7** were obtained. The final fraction was eluted with chloroform to afford 15 mg of yellow crystals **10a**.

Photolysis of 4. A 0.8 g sample of **4** was dissolved in 50 cm^3 of benzene and the solution was irradiated for 8 h. Similar work up and purification as above gave 360 mg of **6**, 40 mg of

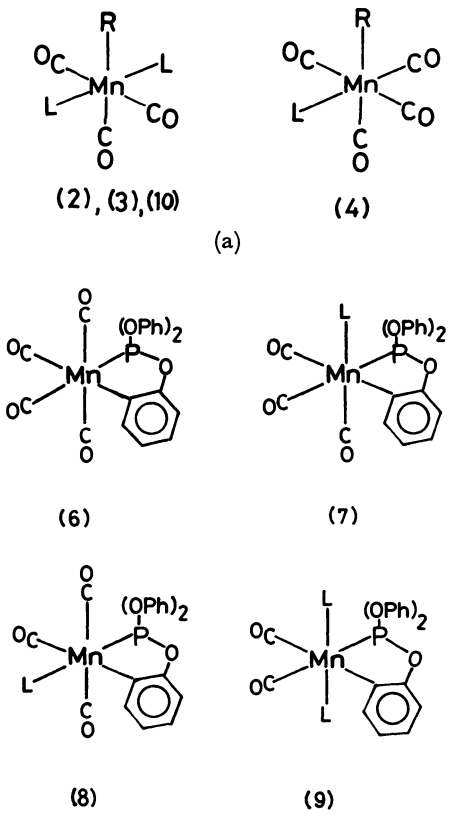

Fig. 1. Schematic pictures of starting materials (1(a)) and photochemical reaction products (1(b)).

7, 10 mg of **8**, 5 mg of **9**, and 15 mg of **10a**.

Photolysis of 5. A 0.9 g sample of **5** was dissolved in 50 cm^3 of benzene and the solution was photolyzed for 8.5 h. However, IR monitoring of the solution did not show any significant sign of reaction except slight decomposition.

Photolysis of 2 with P(OPh)$_3$. To a benzene solution (50 cm^3) containing 0.77 g (1 mmol) of **2**, 310 mg of $P(OPh)_3$ (1 mmol) was added and the solution was photolyzed for 5 h. After similar procedure of purification as above gave 20 mg of **7**, 20 mg of **8**, and 270 mg of **9**.

Photolysis of 4 with P(OPh)$_3$. A 0.88 g (1.8 mmol) of **4** and 0.83 g (2.7 mmol) of $P(OPh)_3$ were dissolved in 50 cm^3 of benzene and the mixture was photolyzed for 8 h. Through similar method of purification as above, 30 mg of **6**, 280 mg of **7**, 190 mg of **8**, 510 mg of **9**, and 15 mg of **10a** were obtained.

Photolysis of 2 in CCl_4. A carbon tetrachloride solution (40 cm^3) which contained 0.63 g of **2** was photolyzed for 1 h. With similar procedure of purification, about 200 mg of *mer-trans*-$ClMn(CO)_3L_2$ (**10**) was isolated.

Photolysis of 3 in CCl_4. A 1.0 g sample of **3** was dissolved in 50 cm^3 of carbon tetrachloride and the solution was irradiated for 1.5 h. The reaction mixture was similarly treated as above to give 200 mg of **10** and small amounts of unidentified products.

Photolysis of 4 in CCl_4. A 1.1 g sample of **4** was dissolved in 50 cm^3 of CCl_4 and the mixture was photolyzed for 3 h. Similar work up as above gave 20 mg of **2**, 50 mg of **6**, 100 mg of **7**, and 90 mg of **10**.

Thermolysis of 2 in Toluene. A 1.0 g sample of **2** was dissolved in 50 cm^3 of toluene and the mixture was refluxed for 3.5 h. The solvent was distilled off under a reduced pressure and the resulting pale brown oil was subjected to column chromatography over Florisil. By similar procedure of purification as the case of photolysis, trace amount of **6**, 280 mg of **7**, 140 mg of **8**, and 35 mg of **9** were obtained.

Table 1. Photochemical and thermal reaction products of **2**, **3**, and **4** and their proportions

Reactant	Products (Molar ratio)
Photolysis	
$CH_3Mn(CO)_3L_2$ (**2**)	**6** : **7** : **8** : **9**=10 : 1 : 2 : 1
$HMn(CO)_3L_2$ (**3**)	**7**: **9**=1 : 5
$CH_3Mn(CO)_4L$ (**4**)	**6** : **7** : **8** : **9**=160 : 10 : 4 : 1
Thermolysis	
$CH_3Mn(CO)_3L_2$ (**2**)	**6** : **7** : **8** : **9**=≈0 : 10 : 5 : 1
$CH_3Mn(CO)_4L$ (**4**)	**6** : **7**=16 : 1

Thermolysis of 3 in Toluene. A 0.4 g sample of **3** was dissolved in 30 cm^3 of toluene and the solution was refluxed for 5 h. However, no detectable change was observed by IR except decomposition.

Thermolysis of 4 in Toluene. A toluene solution (50 cm^3) which contained 0.8 g of **4** was refluxed for 3 h. Similar work up as the thermolysis of **2** afforded 400 mg of **6** and 40 mg of **7**.[13]

Thermolysis of 5. A *p*-xylene solution which contained 0.71 g of **5** was refluxed for 1 h. However, no appreciable change was observed by IR except decomposition.

The yields were averaged for several runs and molar ratios of the products are collected in Table 1.

Characterization of Yellow Crystals 10a. Attempts for characterizing this yellow crystalline compound, **10a**, was not rewarded in the previous study.[9] After publication of the paper, various experiments were added to the previous efforts; fluorescent X-ray analysis[14] revealed that chlorine atom was contained as a main component in these crystals and FD mass indicated the parent peak at m/e=795 ($ClMn(CO)_3L_2$=795). These evidences established that the crystalline compound is $ClMn(CO)_3L_2$, **10**. Next experiment was performed to clarify the origin of the chlorine atom; photolysis of relevant compounds in spectral grade benzene (Dojin Chemistry Co.) did not yield yellow crystals, **10a**. Therefore, the chlorine atom should come from HCl contained as a trace amount of impurity[15] in the benzene used as a solvent for photolysis.

Results and Discussion

As was described in the Experimental section, several kinds of orthometalated products were obtained from photodegradation of mononuclear manganese carbonyl triphenyl phosphite derivatives. Among the data on photochemically induced orthometalation reactions including those of the previous paper,[9] a few points merit description; first, the absorption spectra for **2**—**5** are essentially identical with that of **1** in the region of 230—700 nm. However, the yields of the orthometalated products and molar ratios among the products depend not only on the number of triphenyl phosphite groups of the starting materials, but also on the kind of the sixth ligand, L′, of the manganese atom for $L'Mn(CO)_xL_y$. Therefore, a comparison of the results for a series of isoelectronic and isostructural compounds, Me_3Sn–$Mn(CO)_3L_2$ (**1**), $MeMn(CO)_3L_2$ (**2**), and $HMn(CO)_3L_2$ (**3**) is interesting; **1** and **3** give the products of the same components, **7** and **9**, with somewhat different molar ratio, but **2** affords two extra products, that is **6** and a new compound **8**, in addition to **7** and **9**. In this regard,

2 is rather close to **4** which has one triphenyl phosphite group if the components of the products alone are considered. In order to get a clue on the photochemical reaction pathways of this series of compounds, following types of experiments were performed; (i) photolysis in CCl_4, (ii) photolysis with $C_6H_5CH_2Cl$ in C_6H_6, (iii) photolysis in C_6H_6 which was saturated with air, (iv) photolysis in C_6H_6 with the presence of triphenyl phosphite, and (v) photolysis in C_6H_6 with constant bubbling of argon to purge out evolved gaseous products, especially CO. The first three experiments (i), (ii), and (iii) were made to check whether a radical process, that is, homolytic cleavage of the L'–Mn bond, is a main route or not. For **2**, we obtained following results; *mer-trans*-$ClMn(CO)_3L_2$, **10** and *fac-cis*-$ClMn(CO)_3L_2$, **10'** were yielded from the experiment (i). However, bibenzyl which should be produced if the initial step is a radical process, could not be detected from the experiment (ii). The products **6**—**9** were harvested with similar total amounts, but with somewhat different molar ratios from those of the normal photolysis in the experiment (iii). For experiment (iv), **6** which contains only one triphenyl phosphite group was not isolated, instead the yield of **9** which contains three triphenyl phosphite groups was about tenfolded. For experiment (v), the yield of **9** was considerably increased, but **6** eluded isolation. The result of the second and third experiment (ii) and (iii) indicated that the radical process of homolytic cleavage of the CH_3–Mn bond is not a main process, although the result of experiment (i) suggested some contribution of the radical process (this issue will be discussed later based on the results for **4**). The experiment (iv) and (v) provided evidence that the ligand dissociation L and/or CO was photochemically induced to afford 16-electron intermediates and the dissociated ligand(s) was incorporated again into the 16-electron intermediates or orthometalated 16-electron intermediates. Before we advance our discussion on **2**, it seems appropriate to assess some results on **4** which behaved similarly to **2** in the normal photolysis; photolysis of **4** in CCl_4 produced $CH_3Mn(CO)_3L_2$ (**2**), two kinds of orthometalated products, **6** and **7**, and $ClMn(CO)_3L_2$ (**10**). As the photolysis of **10** in benzene did not yield any kind of orthometalated products, isolation of **6** and **7** indicates that these products are obtained from **4** and especially isolation of **2** is a clear evidence that the ligand dissociation is an important photochemical process for **4**. Another evidence to support this contention comes from the comparison of the result with that of $Me_2Sn[Mn(CO)_4L]_2$; according to the previous paper,[9] irradiation of this compound in benzene brought homolytic cleavage of the Sn–Mn bond to afford $\cdot Mn(CO)_4L$ radical and from this radical only one kind of orthometalated product **6** was isolated with low yield. From these observations, we are tempted to the assertion that the preponderant process of photoexcitation of **4** is ligand dissociation L or CO from the manganese atom to leave coordinatively unsaturated metal site, that is, 16-electron intermediates and these 16-electron intermediates activate a C–H bond in the phenyl groups of triphenyl phosphite(s) intramolecularly to yield orthometalated products, although some contribution of radical process to the orthometalation should not be overlooked as was described in the previous study.[9] (Schemes 1 and 2)

$$(PhO)_2\overbrace{P(OC_6H_4)}Mn(CO)_3 + CO \overset{h\nu}{\rightleftharpoons} (PhO)_2\overbrace{P(OC_6H_4)}Mn(CO)_4 \quad (15)$$

Scheme 2.

Scheme 2 is devoid of the mechanism for the formation of **9**. However, we would like to suggest that **9** is produced by secondary photochemical degradation of **7** and/or **8** as was clarified in the previous study[9] and the reason for low yield of **9** from **4** is also accounted for by this mechanism. $CH_3Mn(CO)_5$ eluded isolation.

For **3**, the experiment (i) afforded **10** and a few kinds of unidentified products in low yields. Although these results suggested that radical process was predominant, we could not isolate bibenzyl in the experiment (ii) and the yields of **7** and **9** were not suppressed in the

experiment (iii). In the experiment (v), the yield of **7** was suppressed, but the yield of **9** was doubled. The result of the experiment (v) indicates that the process of carbonyl dissociation and its uptake is also included in the mechanisms of the formations of **7** and **9**. Although general patterns of the photochemical reactions of **3** are quite close to those of **1**, it may be appropriate to postpone our conclusion on the orthometalation reaction mechanisms for **3** until we can get affirmative evidence in the future experiment.

Kaesz *et al.* isolated two kinds of orthometalated products, **6** and **7** by thermal reaction of $CH_3Mn(CO)_4L$ (**4**).[13] However, photochemical reaction of **4** in the present study afforded four kinds of orthometalated products instead. The ramification appeared to suggest that the intermediates produced thermally from **4** are not the same as those produced photochemically. This idea prompted us to investigate thermal reaction of **2**. As was described 'n the Experimental section, thermolysis of **2** in toluene yielded the same products as in the case of photolysis. However, the molar ratios of the orthometalated products were significantly different from those of photolysis and especially the yield of **6** was quite low. In the thermolysis, the solvent was refluxed and gaseous products such as CO should be purged out easily with this reflux. Thus, the situation is quite similar to the photolysis of **2** with constant bubbling of argon (experiment (v)); in experiment (v) of **2**, **6** was not isolated. Therefore, quite low yield of **6** in thermolysis of **2** may not be considered to imply that the intermediates produced from **2** by thermal reaction is different from those produced photochemically.

Photochemical reaction of **4** yielded extra two orthometalated products in addition to two compounds **6** and **7** which are obtained by thermolysis. The low yield of **9** in photolysis suggests that this product is generated by secondary photodegradation of orthometalated products **7** and **8**. Indeed, it was clarified in the previous study that photolysis of **7** gave **8** and **9**[9] and further, thermolysis of **7** did not yield **8** and **9**; IR monitoring of thermal reaction of **7** in refluxed toluene for 3.5 h did not exhibit significant spectral change in carbonyl stretching region. Therefore, we can suggest at present that the intermediates from **4** by thermal reaction are not essentially different from those by photochemical reaction.

(Received April 19, 1983)

Stereochemistry of enzymatic oxygenations of various diaryl, dialkyl and aryl alkyl sulfides to the corresponding sulfoxides with hepatic microsomes obtained from phenobarbital pretreated rabbit was investigated in comparison with those of nonenzymatic oxidations. Relative reactivity of the sulfides in the enzymatic oxygenation, based on the yields of the sulfoxides and the amount of oxygen absorption, depends upon the steric demand of the substituent in the oxygenation of 2-substituted thiochroman derivatives. However, such a trend was not observed in the enzymatic oxygenations of various acyclic sulfides. A substantial asymmetric induction on the sulfur atom was always observed (*e.g.*, 54% *e.e.* for benzyl *t*-butyl sulfide). Formation of the sulfoxide with *R*-configuration predominated over that with *S*-configuration. The enzymatic oxygenation of all the unsymmetrical sulfides examined proceeded *via* the same steric course. Diastereomeric ratios of the sulfoxides formed in the enzymatic oxygenations of various racemic sulfides bearing alkyl substituents at α-position are markedly favoured more for the trans isomers than for the cis ones, while the ratio was nearly fifty-fifty in the nonenzymatic oxidations with both MCPBA and $NaIO_4$. These results suggest that the enzymatic oxygenation takes place at the less hindered side of the sulfide. Both enzymatic and nonenzymatic oxidations of rigid six-membered cyclic sulfides, *trans*-thiadecalins and 4-(*p*-chlorophenyl)thiane, similarly occurred at the less hindered side to give mainly equatorial sulfoxides. The yields of the four stereoisomeric sulfoxides were nicely determined in the enzymatic oxygenation of racemic 2-methyl-2,3-dihydrobenzothiophene to elucidate the steric course of the oxygenation. Dependency of this microsomal oxygenation upon cytochrome P-450 enzyme was proved by several inhibition experiments and also by the identical stereochemical results of the oxygenation of a few selected sulfides to those with a reconstituted system with purified cytochrome P-450 and co-factors.

Cytochrome P-450, a monooxygenase, is known to be present in multiple forms in mammalian tissues.[2)] Some cytochrome P-450s in adrenal grand, cytochrome $P\text{-}450_{11\beta}$ and cytochrome $P\text{-}450_{17\alpha}$, participate in the regiospecific and stereospecific hydroxylations of the steroids while cytochrome P-450s in plants carry out specific biosyntheses of biologically important substances.[2)] One major role of cytochrome P-450 in mammalian liver is known to be the oxygenation of various kinds of lipophilic xenobiotics, such as drugs, insecticides, food additives, *etc.*, to the more hydrophilic metabolites in order for these xenobiotic substances to be excreted.[2)] In such metabolic oxygenations in liver, stereospecificity may not be neccesary because the main function of the oxygenation is to convert the foreign substances to other more hydrophilic products which

$$[S] + NADPH + O_2 + H^+ \xrightarrow{\text{Cytochrome P-450}} [S\text{-}O] + NADP^+ + H_2O \quad (1)$$

can be excreted readily out of living bodies. Since the cytochrome P-450 is demonstrated to play such a role, the oxygenation with this enzyme would be less substrate selective and less stereospecific as compared to most other enzymes. However, practically no stereochemical study has appeared in the oxygenation of xenobiotic compounds by hepatic microsomal cytochrome P-450.

Meanwhile, organic sulfides are good substrates for studying the stereochemistry of the oxygenation with cytochrome P-450,[3)] since chemical and biomimetic oxidations of sulfides to the sulfoxides and their stereochemistry have been extensively studied in our laboratory,[3-5)] and hence stereochemical results obtained in the enzymatic oxygenation can be readily compared with our accumulated data.[3-5)] Thus, we have investigated the stereochemistry of the oxygenation of various sulfides to the corresponding sulfoxides with rabbit liver microsomal cytochrome P-450 in both microsomal level and reconstituted system with purified liver microsomal cytochrome P-450[1)] obtained from rabbit pretreated with phenobarbital for 5 d to induce the enzyme.

Experimental

General. Melting points and infrared spectra were taken on a Yanaco instrument and a Hitachi 215 spectrometer, respectively, and uncorrected. NMR spectra were recorded on a Hitachi Perkin-Elmer R-20 spectrometer. FT-NMR spectra were obtained by a JEOL FX-90Q spectrometer at the chemical analysis center of this university. Mass spectra were taken with a Hitachi RMU-6MG mass spectrometer. A Shimadzu GC-6A instrument was used for gas chromatography using N_2 gas as a carrier gas. Specific rotations were calculated from the values of optical rotations which were measured by a JASCO DIP-140 polarimeter using a 5 cm (length) quartz cell. CD spectra were recorded on a JASCO J-20 spectrometer. Elemental analyses were carried out by the chemical analysis center of this university.

Materials. Liver microsomes were obtained from phenobarbital pretreated (5 d) male rabbits according to the reported method.[3b,6)] Purified cytochrome P-450 was obtained from the same liver microsomes by Imai's method.[7)] NADPH-cytochrome P-450 reductase was purified by the

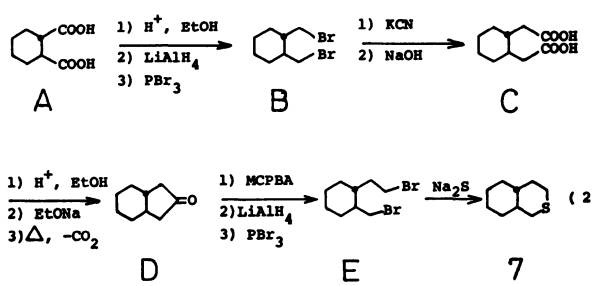
method of Iyanagi *et al.* with some modification.[8] NADP+, D-glucose 6-phosphate (G-6-P), and G-6-P dehydrogenase (G-6-PDH) were obtained from Oriental Yeast Co. NMR shift reagents, $Eu(dpm)_3$ and $Eu(hfc)_3$ were of Dojin Chemical Co. and Aldrich Chemical Co., respectively. SKF 525-A ((2-*N*,*N*-diethylamino)ethyl 2,2-diphenylpentanoate) was given from Tanabe Seiyaku Co.

Sulfide and Sulfoxide. Physical and spectral data, and elemental analyses data of various sulfides and sulfoxides used here are listed in Table 1.

Most of the sulfides were either commercially available or prepared by known method described below, and some were new compounds.

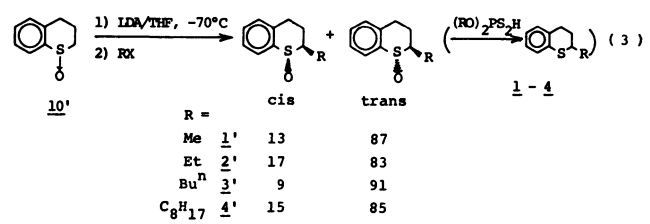
Common dialkyl and aryl alkyl sulfides (**9**, **12**—**19**) were prepared by the usual method, *i.e.* the reaction of the corresponding thiols and alkyl halides in the presence of a base,[9] while *t*-butyl *p*-tolyl sulfide (**17**) was obtained by treating *p*-toluenethiol with gaseous isobutylene.[10] The genuinely pure **17** was obtained by the oxidation of the crude sulfide with H_2O_2 in AcOH followed by reduction with *O*,*O*'-diethyl hydrogenphosphodithioate[11] after purification of the sulfoxide by column chromatography (eluent: hexane and then chloroform, on silica gel). Di-*t*-butyl sulfide (**21**) and thiane (**22**) were commercially available from Tokyo Kasei Kogyo Co. and Aldrich Chemical Co., respectively. *o*-Methoxyphenyl phenyl sulfide (**20**) was prepared by the reaction of *o*-methoxybenzenediazonium salt and thiophenol as reported previously.[12] *trans*-1-Thiadecalin (**6**) was also synthesized from 1,2-epithiocyclohexane *via* several reaction steps as reported.[13] 2,3-Dihydrobenzothiophene (**11**) was obtained by the reduction of benzothiophene with metallic sodium in ethanol[14] and purified by distillation using Kugelrohr.

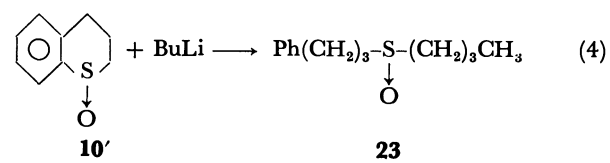
trans-*2-Thiadecalin* (**7**): The title sulfide, a new compound, was prepared from *trans*-1,2-cyclohexanedicarboxylic acid (**A**) through several steps as shown in Eq. 2.[15] Namely, esterification of the starting material **A**, reduction of the diester with $LiAlH_4$ and bromination of the diol with PBr_3 gave dibromide **B**. Substitution of **B** with CN^- and alkaline hydrolysis of the dicyanide thus formed afforded dicarboxylic acid **C**, which was then subjected to the Dieckmann condensation after esterification to give the cyclic keto ester that was then decarboxylated to afford ketone **D**. The Baeyer-Villiger oxidation of **D**, reduction of the lactone with $LiAlH_4$ to the diol, and bromination of the diol, yielded dibromide **E** which was then converted to desired *trans*-2-thiadecalin (**7**) by treatment with Na_2S (total yield 5%).[15]



2-Methyl-2,3-dihydrobenzothiophene (5) and 1-Thiochroman (10): Cyclic sulfides **5** and **10** were obtained as an isomeric mixture in the thermal cyclization of allyl phenyl sulfide in quinoline, as reported by Anderson *et al.*[16] The mixture of **5** and **10** was separated by careful distillation, affording **10** and impure **5** containing **10**. The impure **5** was purified by oxidation with H_2O_2 in AcOH to the corresponding sulfone, followed by reduction with $LiAlH_4$, as reported.[10]

2-Alkyl Thiochroman 1-Oxides (1'—4') (Eq. 3): To a cooled solution (−70 °C) of **10'** (10 mmol) in dry THF (50—100 ml), diisopropylamine (12 mmol) and then BuLi (10% hexane solution, 10 mmol) were added under argon atmosphere. The clean colorless solution immediately turned to reddish black due to the formation of the anion of **10'**. After warming the solution up to −30 °C for several minutes the solution was cooled again to −70 °C. A dry alkyl halide (10 mmol, MeI, EtBr, *n*-BuBr, or *n*-$C_8H_{17}Br$) was added to the solution at −70 °C. The reaction mixture was gradually warmed up to 0 °C. The black color of the solution gradually faded out as the reaction proceeded, to give eventually a colorless solution. The reaction mixture was poured into cold dilute hydrochloric acid and extracted three times with chloroform. The combined organic layer was dried over anhydrous $MgSO_4$ and evaporated. The residue was subjected to column chromatography on silica gel (eluent: hexane–ethyl acetate–chloroform=4 : 1 : 1). The first fraction was a by-product. The second gave the desired alkylated product in 65—85% yield and the last fraction gave the starting material recovered. The by-product was then identified by NMR and MS spectra and elemental analysis to be butyl 3-phenylpropyl sulfoxide (**23**) which was a product by a direct reaction of **10'** with BuLi (Eq. 4).





Note the predominant formation of trans 2-substituted thiochromen 1-oxides over their cis isomers in the alkylations of **10'** (Eq. 3). The cis/trans ratio was determined from the NMR spectrum using $Eu(dpm)_3$, as mentioned later. This stereochemical result can be best explained in terms of the findings[28] that the alkylation of α-sulfinyl carbanion takes place from the opposite side of the chelated ring involving Li^+ and sulfinyl oxygen to give predominantly the trans isomer, as shown in Fig. 1.

Butyl 3-Phenylpropyl Sulfoxide (23): Mp 44—47.5 °C from hexane; NMR (δ, $CDCl_3$), 0.91 (t, 3H, CH_3, J=6.8 Hz),

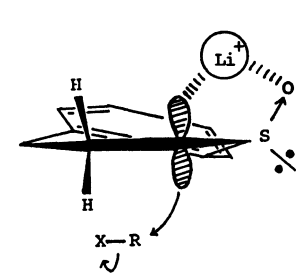


Fig. 1. Direction of alkylation of **10'** with LDA and RX (see Eq. 3). Stereospecific alkylation forms *trans*-sulfoxide predominantly.

*2-Alkyl Thiochromans (**1**—**4**) from Sulfoxides (**1′**—**4′**)*: The sulfoxide (**1′**, **2′**, **3′**, or **4′**, 1 mmol) obtained above, and *O,O′*-diethyl hydrogenphosphodithioate (7—9 mmol)[11] were mixed at room temperature. After keeping the mixture standing till the sulfoxide disappeared (TLC), the mixture was subjected directly to column chromatography on silica gel using hexane as an eluent. Yields were nearly quantitative in all cases.

Authentic Sulfoxides. Authentic sulfoxides were prepared by treating the corresponding sulfides with one of the following oxidation systems, *i.e.* H_2O_2/AcOH, H_2O_2/H_2SO_4/MeOH, and *m*-chloroperbenzoic acid (MCPBA)/CH_2Cl_2. Physical and spectral data, and elemental analysis data of all the sulfoxides are shown in Table 1.

Oxygenation of Sulfide with Microsomes. A mixture of hepatic microsomes (190 mg protein), 250 μmol of G-6-P and 25 μmol of $NADP^+$ in phosphate buffer (0.2 M, pH 7.4) (final volume: 17 ml) was incubated with stirring with a magnetic stirrer at 37 °C for *ca.* 10 min. The substrate. sulfide (*ca.* 0.5 mmol) and then G-6-PDH (20 units) were added to the mixture and the resulting reaction mixture was incubated at 37 °C under air or pure oxygen atmosphere. After the incubation for 1.5 h, the reaction was stopped by adding 15—20 ml of acetone and 0.5 M trichloroacetic acid (to make the solution pH *ca.* 2.0) into the reaction mixture. The resulting mixture was left in a refrigerator (at *ca.* 4 °C) for 10 min to precipitate the protein, prior to centrifugation of the mixture (3000 min^{-1} for 20 min). The supernatant collected was extracted three times with $CHCl_3$. The combined organic layer was washed with 2 M KOH and water, dried over anhydrous $MgSO_4$, and concentrated under reduced pressure. GLPC analysis of the residue showed the presence of the recovered sulfide, the product sulfoxide and some impurities derived from the protein. The sulfoxide was purified by TLC fractionation (on alumina, eluent: benzene–ethyl acetate (2 : 1)), and identified by comparison with the authentic sample. Yields and other data are listed in Tables 3 and 4.

The purified sulfoxide was subjected to the measurements of NMR, CD and optical rotation. The cis/trans ratio of the sulfoxide was determined by measuring the NMR spectrum of the mixture of the isomeric sulfoxides and a shift reagent Eu $(dpm)_3$ (0.2—0.4 equiv). The results are shown in Table 3.

Enantiomeric excess was calculated from the integration ratio in NMR spectrum of the mixture of the enantiomeric sulfoxide and an optically active shift reagent Eu $(hfc)_3$ (0.4—0.6 equiv), and/or from the value of specific rotation and reported maximum rotation of the sulfoxide (Table 4).

CD spectra were measured for **5a′**, **5b′**, **10′**, and **11′** in ethanol, though the concentrations of the compounds were not measured (Fig. 5).

Oxygen Consumption. The oxygen consumption in the oxygenation with microsomes was measured with a gas bullet attached to the two-necked reactor in a constant temperature room (24 °C). The reaction conditions were same as that in the section of "*Oxygenation of Sulfides with Microsomes.*" The measurement of the oxygen consumption was started as soon as the reaction was initiated by the addition of the substrate and G-6-PDH through a serum cap into the reactor, which contained other co-factors and was thermally pre-equilibriated. The results are shown in Fig. 2.

Control Experiments. Relative reactivities were determined by following the yields of the sulfoxides formed in a given time. As for CO inhibition test, an atmospheric mixture of CO and O_2 gas (*ca.* 1 : 1) was used as a reaction atomsphere instead of pure oxygen or air. SKF 525-A (11.3 mg, 32 μmol), 1,4-diazabicyclo[2.2.2]octane (DABCO, 120 mg, 0.61 mmol) and catalase (134 nmol) were further added to the complete system which is described in "*Oxygenation of Sulfides with Microsomes,*" at the beginning of the reaction. Boiled microsomes prepared by heating for 10 min in boiled water, was used instead of microsomes. Results obtained according to the procedure described in "*Oxygenation of Sulfides with Microsomes,*" are shown in Table 2.

*Oxidation of Racemic Sulfides (**1**—**5** and **9**) to Mixture of Diastereomeric Sulfoxides with MCPBA and $NaIO_4$.* MCPBA (1.1 mmol) was slowly added to a solution of the sulfide (1 mmol) in 5—10 ml of CH_2Cl_2 and the mixture was stirred under cooling with an ice-water bath until the spot of the sulfide disappeared (TLC). The usual work-up afforded crude diastereomeric sulfoxides which then were purified by column chromatography on silica gel using an appropriate eluent.

Oxidation with $NaIO_4$ was carried out by adding slowly an aqueous solution (5—10 ml) of $NaIO_4$ (1.1 mmol) into an acetone or methanol solution (20—25 ml) of sulfide (1 mmol) under cooling with an ice-water bath. The mixture was warmed up to room temperature and kept stirring till the sulfide was completely consumed. The usual work-up and the subsequent column chromatography (on silica gel) of the crude products gave a mixture of two pure diastereomeric sulfoxides.

In both cases, the yields of the pure sulfoxides were ranging from 70 to 85%. The mixture of diastereomeric sulfoxides thus obtained were mixed with 0.1—0.4 equiv of $Eu(dpm)_3$ in order to determine the diastereomeric ratio by NMR spectrum in which protons at peri-position (7- or 8- position of **1′**—**5′**) appeared separately in a region between 8 and 12 ppm.

Although two separable protons due to diastereomers in NMR spectrum of **9'** using $Eu(dpm)_3$ (0.4 equiv) were confirmed it was not certain which one is threo or erythro.

Both **6'** and **7'** were also prepared by the method mentioned above, and two isomeric sulfoxides (axial and equatrial) could be separated two repeated careful column chromatography in which axial one was eluted faster than the equatorial one.

Oxygenation with Reconstituted System Containing Purified Cytochrome P-450. A phosphate buffer (7 ml; 0.2 M; pH 7.7) containing 60 nmol of cytochrome P-450 and 80 nmol of cytochrome P-450 reductase was incubated for 5 min at room temperature and combined with a solution of NADPH generating system (G-6-P: 250 μmol; $NADP^+$: 25 μmol and G-6-P-DH: 36 units) containing substrate (**5** or **10**) which was finely suspended into a phosphate buffer (30 ml: 0.2 M; pH 7.7) by ultrasonic vibrator. The reaction mixture was incubated understirring with a magnetic stirrer at 37 °C for 1.5 h and subjected to the same work-up procedure described in "*Oxygenation of Sulfides with Microsomes.*" Yields of **5'** and **10'** were 5.5 and 9.0 mg, respectively. The diastereomeric ratio of **5a'** and **5b'** was similarly determined to be *ca.* 25 : 75 by measuring the FT-NMR spectrum of the mixture of **5'** and $Eu(dpm)_3$ (*ca.* 0.3 equiv) in $CDCl_3$, while *e.e.* value of **10'** was *ca.* 7.5% from the integration ratio of the FT-NMR spectrum of the mixture of **10'** and $Eu(hfc)_3$ (0.5 equiv) in $CDCl_3$.

Results and Discussion

The oxygenation of sulfides with microsomal cytochrome P-450 was carried out according to the method mentioned in Experimental section. In order to clarify co-factor requirements typical for the enzymatic oxygenation of sulfides to sulfoxides, at first control experiments were carried out.

Control Experiments. In order to examine whether or not the oxygenation of sulfides to sulfoxides with liver microsomes depends only on cytochrome P-450 enzyme, the following control experiments were carried out with thiochroman **10**. Carbon monooxide ($CO : O_2 = 1 : 1$ (v/v)) inhibited partially the oxygenation to the same extent as was found in our early study,[3b] while the reaction was not inhibited by SKF-525-A which is known to be a good inhibitor for a certain kind of dealkylation but does not inhibit the oxygenation of sulfur compounds.[27] DABCO (0.61 mmol), a singlet oxygen quencher, did not affect the oxygenation of **10**, which was either not affected by the addition of catalase (134 nmol) that catalyzes decomposition of hydrogen peroxide. Oxygenation either with boiled microsomes instead of microsomes or without NADPH generating system did not proceed, as was expected. Dependency of the oxygenation of sulfides with microsomes upon cytochrome P-450 enzyme, observed in these reactions, was also proved by the oxygenation with the reconstituted system with purified cytochrome P-450, as described later in this paper. Thus, the oxygenations of the various sulfides with liver microsomes obtained from phenobarbital pretreated rabbits are clearly due to the cytochrome P-450 enzyme.

Oxygenation of Sulfide and Oxygen Consumption. Various dialkyl, aryl alkyl, and diaryl sulfides were found to be oxygenated with the microsomal cytochrome P-450, as shown in Tables 3 and 4. However, benzothiophene was not oxygenated to the sulfoxide under the same conditions, but was recovered. Chloropromazine which is a well-known drug containing sulfur and is the first compound subjected to the oxygenation to the corresponding sulfoxide with microsomes,[3a] was also oxygenated but the yield of the sulfoxide was determined by high pressure liquid chromatography to be very small.

Table 2. Control Experiments. Relative reactivity was determined from the yield of the sulfoxide of **10** under various conditions

−Ms. +Boiled Ms. (100 °C, 10 min)	0.00

* The oxygenation was carried out at 37 °C for 1.5 h.
a) Ms. : Microsomes.

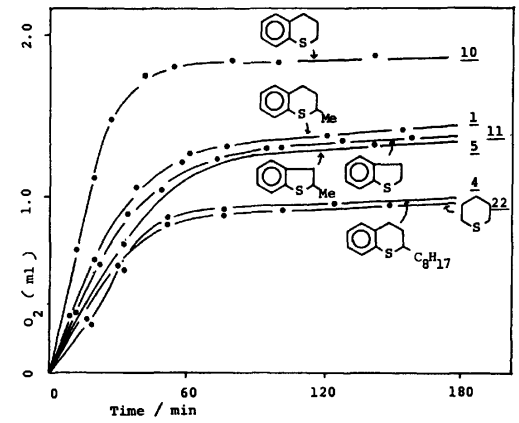

Fig. 2. Oxygen consumption in Enzymatic oxygenation of sulfides with microsomal cytochrome P-450 at 37 °C for 1.5 h was measured at a constant temperature room (24 °C).

Sulfoxides were the only products in the oxygenation. Activity of the enzyme toward various sulfides is expressed in terms of moles of product per 1.5 h per moles of cytochrome P-450, while as shown in Fig. 2, most enzymes died out after the incubation for 1 h. Since most sulfides are insoluble in water, the extent of the dispersion of the substrate into the reaction system may affect the yield of the sulfoxide. However, the yield of the sulfoxide did not change at all upon sufficient mixing of the sulfide with the buffer solution by ultrasonic vibration before the start of the oxygenation. This fact may indicate that the oxygenation takes place in a hydrophobic enzyme region.

Oxygen consumption during the reaction was measured for the compounds, **1**, **4**, **5**, **10**, **11**, and **22** at a constant temperature room (Fig. 1), and was found to follow a typical mode till 90% completion in *ca.*

45—60 min in all cases. This observation indicates that the lifetime of the enzyme is independent on the structure of the sulfide used. However, the amount and the rate of the oxygen consumption differed for each substrate but were parallel to the yields of the sulfoxides as shown in Tables 3 and 4. Since the rate of oxygen

Table 5. Relative reactivity of sulfides. Total turnover (product mol/cytochrome P-450 mol) and efficiency of oxygen used during the oxygenation (product mol/O_2 absorbed mol), in the oxygenation with microsomal cytochrome P-450 at 37 °C for 1.5 h

	**10**	145	35
	**1**	128	—[b]
	**2**	102	—[b]
	**3**	35	—[b]
	**4**	7	0
	**11**	120	48
	**5**	72	36

a) Product is sulfoxide. b) Not determined.

absorption into the reaction solution is sufficiently fast, the rate of oxygen consumption (initial slope) should be comparable to that of the oxygenation of each sulfide.

Meanwhile dependency of the yield of the sulfoxide on the substrate structure was confirmed with both thiochroman and 2,3-dihydrobenzothiophene derivatives. Relative reactivities of these sulfides toward cytochrome P-450 decrease with the increase of the bulkiness of the alkyl substituent (Table 5). Thus, in the oxygenations of these cyclic sulfides with microsomal cytochrome P-450, the reactivities of the sulfides seem not to depend on the hydrophobicity of the substituent but to depend largely on the steric hindrance of the substituent.

On the other hand, in the oxygenation of acyclic sulfides such clear structure-reactivity relationship was observed. Even bulky *t*-butyl group on the sulfur atom did not hinder the formation of the sulfoxide, *i.e.* *t*-butyl *p*-tolyl sulfide (**17**), di-*t*-butyl sulfide (**21**), and *t*-butyl octyl sulfide (**19**) were equally well oxygenated to the corresponding sulfoxides, although the oxygenation of 2-octylthiochroman (**4**) hardly proceeded. No good correlation between the yields of the sulfoxides and the structures of the sulfides, has also been reported for the *in vivo* oxygenations of the similar sulfides with *Aspergillus niger*.[23] This is comparable with the results obtained with *in vitro* oxygenation with microsomal cytochrome P-450 in this study. Therefore, based only on the yields of the sulfoxides in the oxygenations of both cyclic and acyclic sulfides, the steric hindrance by bulky substituents on sulfur atom may not always be crucial in the enzymatic oxygenation.

Diastereotopic Differentiating Reactions. There is always a possibility that two diastereomers are obtained in the oxidation of racemic sulfide which has an asymmetric center: for example, 2-substituted thiochromans and 2-substituted 2,3-dihydrobenzothiophene would give both cis and trans sulfoxides, while thiadecalins may give both axial and equatorial sulfoxides. In order to examine how much the diastereotopic differentiation would take place, these sulfides were oxidized enzymatically and nonenzymatically to the sulfoxides. In many cases, two diastereomeric sulfoxides were separated in pure forms, while in the others such a separation of two diastereomers was unsuccessful, and hence the ratio o the diastereomers was determined by NMR spectroscopy using an NMR shift reagent. NMR signals of the aromatic ring protons at 7-position of both cis and trans 2-methyl-2,3-dihydrobenzothiophene 1-oxides (**5a'** and **5b'**), appear in the same region. However, upon addition of an NMR shift reagent ($Eu(dpm)_3$) to the sulfoxide mixture, these signals of the cis and trans isomers shifted to down fields in different extents. Using pure authentic samples of *cis*-**5'** and *trans*-**5'** whose structures were determined by Anderson *et al.*[16] the 7-H signal of the trans isomer was found to appear at an extremely down field as compared to that of the cis isomer, so that the two signals of 7-H's of *cis*-**5'** and *trans*-**5'** can be seen separately on the NMR spectrum. Similarly, the cis/trans ratios of **1'**—**4'** obtained by both enzymatic and nonenzymatic oxidations of the corresponding sulfides were successfully determined by the relative intensities of the two NMR signals due to the protons at 8-position of the products in the presence of $Eu(dpm)_3$. The larger down field shift of the proton of the trans isomer of **1'**—**5'** than that of the cis one is presumably due to the distance between the hydrogen at 8-(or 7-) position and the europium complex bound to the oxygen of the sulfoxide. Actually, an examination with a CPK model reveals that the distance between the hydrogen of the trans sulfoxide and the shift reagent is shorter than that of the cis one. In Table 3, are summarized the results which reveal that the formation of the trans sulfoxide exceeds that of the cis isomer in the enzymatic oxygenation of the cyclic sulfides each bearing an alkyl group at α-position. However, the nonenzymatic oxidation with MCPBA and $NaIO_4$ gave nearly equal amounts of both isomers. Both *trans*-thiadecalins (**6** and **7**) gave the equatorial sulfoxides predominantly in the enzymatic and the nonenzymatic oxidations. Probably the enzyme, which has a very bulky porphyrinoxenoid at the active site,[2] would interact with the sulfide in a certain geometry, prior to the oxygenation in the enzym pocket. NMR spectroscopic analysis using the shift reagent ($Eu(dpm)_3$) of both the enzymatic and the nonenzymatic oxidations of racemic benzyl *s*-butyl sulfide (**9**), revealed that two diastereomeric sulfoxides, *threo*- and *erythro*-**9'** were formed in the both oxidations. The diastereomeric ratio of **9'** obtained by the enzymatic oxygenation was found to be considerably different from that of the MCPBA oxidation product (Table 3). Unfortunately, it could not be assigned which diastereomer was threo or erythro, since no authentic sample of the pure diastereomer was available.

Enantiotopic Differentiating Reactions. The extent of asymmetric induction in the enzymatic oxygenation of prochiral sulfides was determined, and the absolute configurations of the sulfoxides formed were also examined. The values of enantiomeric excess (*e.e.*) of the sulfoxides obtained by the enzymatic oxygenations were determined by measuring their specific rotations in comparison with the reported maximum optical rotations and/or the NMR spectroscopies using an optically active shift reagent, $Eu(hfc)_3$. Although the *e.e.* values of some of the linear acyclic sulfoxides were difficult to be determined even with the use of the shift reagent, cyclic sulfoxides such as **10'** and **11'** were easily determined by the NMR spectroscopy. For example, the doublet signals due to the aromatic proton at 8-position of **10'** of *R*-configuration appeared in the down field than that of **10'** of *S*-configuration separately in the presence of the shift reagent. The results are listed in Table 4. Inspection of the data in Table 4 reveals clearly that the asymmetric induction took place in the enzymatic oxygenation of all the sulfides. The maximum *e.e.* value of the sulfoxide obtained was 53.8% (Entry No. 3) which is unexpectedly large despite the role of the enzyme to oxidize indiscriminatingly any xenobiotic substances only to be excreted. The small *e.e.* values in the oxygenations of cyclic sulfides (**10** and **11**) may be due to the difficulty in recognition of the prochiral sulfides by the enzyme, because of the structural similarity of these prochiral sulfides, *i.e.* the two substituents attached to sulfur atom. The *e.e.* values in Table 4 should indicate that the extent of the enantiotopic differentiation in the enzymatic oxygenation of sulfides increases with the increase of the bulkiness of the substituents bound to the sulfur atom. A similar trend also has been observed in the *in vivo* oxygenations of sulfides with *Aspergillus niger*.[21]

R-Configuration was assigned to the major enantiomer of **10'** (Table 4, No. 1) obtained by the enzymatic oxygenation based on the same signs of both its specific rotation and CD spectrum (Fig. 3) as those of *R*-2,3-dihydrobenzothiophene 1-oxide (*R*-**11'**) of which the absolute configuration was already known,[20] since there is no serious structural difference between *R*-**10'** and *R*-**11'**. As for sulfoxides whose absolute configurations are not yet known (Entry Nos. 4, 6, and 10), all their configurations are considered to be of *R*-form since the configurations of most of dextro-rotatory acyclic sulfoxides of similar structures are known to be of *R*-form.[23] Thus, in the oxygenation of sulfides, **1**—**11** with cytochrome P-450 enzyme the formation of sulfoxides of *R*-configuration is prefered. When the stereospecific oxygenations of sulfides (**12**, **14**, **16**, **17**, and **18**) are compared with those of *in vivo* oxygenations with *Aspergillus niger* (for 3, 5, 7, 8, and 9 of entry in Table 4),[23] signs of the absolute configurations of these sulfoxides except for **18** are opposite (for 3, 5, 7, and 8 of entry).

Figure 4 illustrates the two directions of the oxygenations on the sulfur atom of the prochiral sulfide (R_S–*S*–R_L), when a more bulky group (R_L) is placed in a rear side, regardless of the sequence rule. Actually, the order of the bulkinesses of the substituents is not always

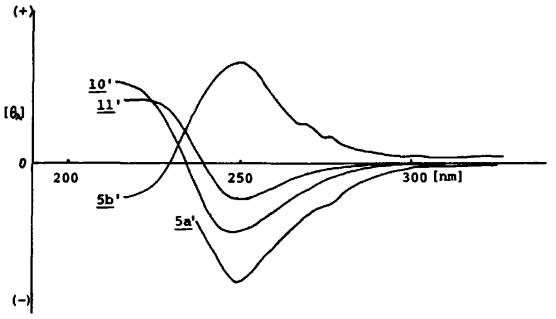

Fig. 3. CD spectra of sulfoxides obtained in the enzymatic oxygenation with microsomal cytochrome P-450 at 37 °C for 1.5 h. The spectra were recorded using EtOH as a solvent, though the concentration of the sulfoxide was not determined.

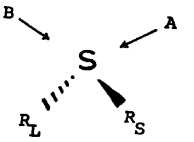

Fig. 4. Direction of the oxygenation of prochiral sulfide. More bulky substituent of the sulfide (R_L) was placed in rear side.

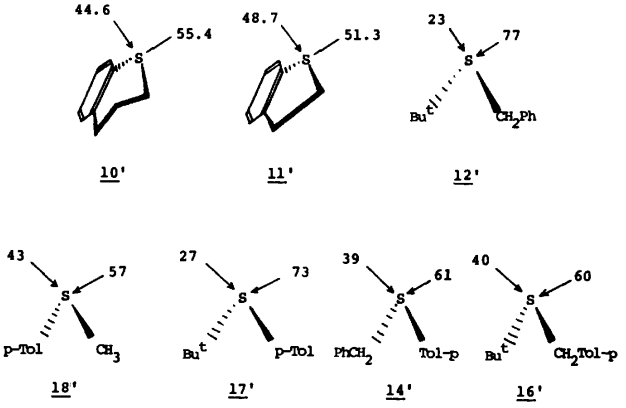

Fig. 5. Direction of the oxygenation of various prochiral sulfides with liver microsomes at 37 °C for 1.5 h. Numerical values indicate the ratios of the oxygenation at sulfur atom to produce *R* or *S*-sulfoxides.

consistent with that of the sequence rule in the *R*,*S*-nomenclature. Figure. 5 shows the actual directions of the oxygenations of various sulfides used in this study and indicates that "the direction A predominates over the direction B" in all cases (with only one exception, *i.e.* diaryl sulfide **21**), where the bulkiness is assumed to decrease in the following order: *t*-Bu>*p*-TolCH_2> $PhCH_2$>*p*-Tol>Ph>Me.

Although the enzymatic action of the hepatic cytochrome P-450 induced by phenobarbital should be sterically insensitive because of its indiscriminative nature of the metabolism of various xenobiotics, the enzyme-catalyzed reaction prefers to take the same steric course "Direction A" and this enantiotopic differentiation becomes greater as the difference of the bulkiness between the two substituents (R_S and R_L)

Table 6. Optical activity of separated diastereomers in the oxygenation with microsomal cytochrome P-450 at 37 °C for 1.5 h

bound to sulfur atom becomes larger.

Concurrent Diastereotopic and Enantiomer Differentiating Reaction. The earlier section dealt only with the ratios of the diastereomers in the enzymatic oxygenations of the racemic sulfides (**1**—**7** and **9**), despite that the mixtures of the cis and trans sulfoxides formed in this oxygenation were shown to be chiral and have some specific rotation values (Table 3). Table 6 shows the optical activities of the two separable diastereomers in the oxygenation with microsomal cytochrome P-450.

Determination of the absolute yields of the four stereoisomers was attempted in the enzymatic oxygenation of a racemic sulfide **5**. Two diastereomers of 2-methyl-2,3-dihydrobenzothiophene 1-oxides (*cis*-**5′** and *trans*-**5′**) were easily separated by TLC on alumina but diastereomeric mixtures of the other sulfoxides such as 2-substituted thiochroman 1-oxide derivatives were not separated. The values of *e.e.* of the two diastereomers were obtained from the FT-NMR spectra using $Eu(hfc)_3$. The optical activity of the *cis*-**5′** (40% *e.e.*) was relatively higher than that of the *trans*-**5′** (12% *e.e.*) (Table 6). From the CD spectra (Fig. 3) of the two diastereomers, the absolute configurations of the sulfur atoms of the enantiomerically excess sulfoxides of *cis*-**5′** and *trans*-**5′** are presumed to be of *R* for the cis form and of *S* for the trans form, respectively, on the basis of the comparison of the signs of the CD spectra with those of the other sulfoxides as shown in Fig. 3. Signs of the specific rotations also support the assignments. Thus, the extent of relative contributions of four possible steric courses in the oxygenation of racemic **5** can be shown in Fig. 6. The results shown in Fig. 6 reveal the following two features:

1) Enantiomer differentiation of racemic **5** is quite small; *i.e.* the enzymatic oxygenation of R_c-**5** is only 1.4 times greater than that of S_c-**5** (rate ratio, S_c-**5** : R_c-**5**=41 : 59 in Fig. 6).

2) In the enzymatic oxygenation of S_c-**5**, the formation of the *trans*-R_sS_c-**5**, predominates over that of the cis isomer by 6.2 folds (Course A : Course B=6.2 : 1, in Fig. 4). The formation of the *trans*-S_sR_c-**5′** predominates over that of cis isomer, however, only 3.4 folds (Course A: Course B=1 : 3.4 in Fig. 4) in the oxygenation of R_c-**5**. Apparently, the diastereotopic differentiation is more important than the enantiomer differentiation to determine the steric course in the enzymatic oxygenation of racemic **5**. Thus, the stereospecific enzymatic oxygenation of racemic **5** may be summarized at the following rules.

1) The oxidant approaches preferentially from the less hindered side, anti to α-methyl group.

2) When the sulfide **5** is placed in a manner as shown in Fig. 6, the oxygenation *via* the Course A is more favored than that *via* the Course B.

3) The rule 1 is more important than the rule 2.

As for *trans*-1- and 2-thiadecalin 1-oxides **6′** and **7′**, two diastereomers, *i.e.* axial and equatorial forms, were readily separated. All these diastereomers isolated were found to have some specific rotations (Table 6). However, unfortunately, neither the absolute configurations nor *e.e.* values of these optically active sulfoxides could be determined, because there were no authentic samples of the optically active sulfoxides.

Oxygenation with Reconstituted System with Purified Cytochrome P-450 and Co-factors.[32] In order to prove that the microsomal oxygenations depend upon the catalysis of cytochrome P-450 enzyme but not any other concomitant in the microsomes, the oxygenations of **5** and **10** with the reconstituted enzyme system containing co-factors, were carried out. The standard oxygenating system is made up with purified cytochrome P-450 (30 nmol), cytochrome reductase (80 nmol), G-6-P (250 μmol), $NADP^+$ (20 μmol), G-6-PDH (36 units), and 0.2 M phosphate buffer (pH 7.7, 30 ml) in a total volume of 37.5 ml. The oxygenation of racemic **5** with this system afforded a mixture of two diastereomeric sulfoxides (**5′**) with the ratio of cis/trans of 25/75 which is practically identical to that in the oxygenation with the microsomes (Table 7). The enantiomeric excess of the sulfoxide in the oxygenation of **10** with the reconstituted system with purified cytochrome P-450 was also identical to that with the microsomal oxygenation, and the sulfoxide of the *R*-form was produced preferentially over the *S*-form, as in the oxygenation with the microsomes (Tables 4 and 7).

Ratio of the yield of **5′** to that of **10′** (or total turnover ratio) in the oxygenation with the reconstituted system was nearly consistent with that in the microsomal oxygenation. Thus, it is concluded that cytochrome P-450 enzyme is responsible for the oxygenation of sulfide in the microsomal oxygenation in this work. Surprizing is the difference of the total turn-over

Table 7. Oxygenation of racemic **5** and **10** with reconsituted system with purified cytochrome P-450, at 37 °C for 1.5 h (see Experimental section)

Substrate	Product (sulfoxide)	Turnover[a] (min^{-1})	Total[b] turnover (−)	Total[c] turn-over with Ms. (−)
 **5**	*cis*-**5′** (25%)[d] / *trans*-**5′** (75%)[d]	12	1104	72
 **10**	**10′**	(*R*)[e] *e.e.* 7.5%	20	1807	145

a) Product (mol)/cytochrome P-450 (mol)/min. b) Product (mol)/cytochrome P-450 (mol) with reconstituted system with purified cytochrome P-450. c) Product (mol)/cytochrome P-450 (mol) in the oxygenation with microsomes (see Tables 3 and 4). d) Ratio of *cis*-**5′** and *trans*-**5′**. e) Estimated absolute configuration.

number between the oxygenations with microsomes and with the purified cytochrome P-450. In the oxygenations with the reconstituted systems the total turn-over numbers are more than 10 times of those in the microsomal oxygenations (Tables 3, 4, and 7).

Conclusion

Various dialkyl, aryl alkyl, and diaryl sulfides were oxygenated readily with the cytochrome P-450 enzyme to the corresponding sulfoxides while the sulfone or hydroxylated product was not obtained (or too small to be detected).[33] The amount of oxygen consumed in a set period was parallel to the reactivity of the sulfide or the yield of the sulfoxide. The yield of the sulfoxide depends on the structure of the sulfide in 2-substituted thiochroman derivatives, and the bulky substituent on the thiochroman markedly decreased the reactivity. Hydrophobicity appears not to be an important factor for the reactivity of sulfides, since it has no relation with the yields of the acyclic sulfoxides, as shown in Table 4. Based on the various inhibition experiments and the stereochemical results obtained by the liver microsomal oxygenation of sulfide consistent with those obtained by the reconstituted system with the purified liver microsomal cytochrome P-450, the oxygenation of sulfides with rabbit liver microsomes is concluded to be catalyzed undoubtedly by the cytochrome P-450 enzyme. Relatively large asymmetric inductions were obtained in the oxygenations of various sulfides. Assuming the following order of the bulkiness, *t*-Bu>*p*-TolCH_2>PhCH_2>*p*-Tol>Ph>Me, the oxygenation *via* the Course A (Fig. 4) predominates significantly over that *via* the Course B. The extent of this enantiotopic differentiation in the enzymatic oxygenation of the prochiral sulfide increases with the increase of the difference of the bulkiness between the two substituents on the sulfur atom. In the enzymatic oxygenation of racemic α-substituted cyclic sulfides, the diastereotopic differentiation is more important than the enantiomer differentiation in the stereochemical course of the oxygenation. Thus, the following stereoselectivity rule may be derived.

1) The enzymatic oxygenation of the cyclic sulfide takes place predominantly at the opposite side of the alkyl substituent at α-position, to form mainly the trans sulfoxide rather than the cis one.

2) When the sulfide is represented as shown in Fig. 4, the Course A is more preferable than the Course B.

3) The rule 1 is more important than the rule 2. Thus, the stereospecificity in the oxygenation of sulfides with the aid of cytochrome P-450 clearly reveals that although the enzymatic oxygenation of xenobiotic compounds in living boides may not require any stereospecificity because the metabolic oxygenation is supposed to increase only the hydrophobicity of the oxygenated compounds, the enzyme is assymetric and hence the enzymatic oxygenation of sulfides results in the partial asymmetric induction.

Synthesis of 2-(4-Azulenyl)ethanamine Derivatives as a Nonbenzenoid Analog of Biogenic Amine

Shinji KUROKAWA

Department of Chemistry, Faculty of Education, Saga University, Honjo-machi, Saga 840

(Received October 6, 1982)

2-(4-Azulenyl)ethanamine derivatives, nonbenzenoid analogs of the biologically active amine, were synthesized by the action of methyleneammonium salts on sodium 4-methylazulenide, sodium 4,6,8-trimethylazulenide, and sodium guaiazulenide. These compounds, as well as their hydrochlorides, were characterized by UV, IR, ^{1}H NMR, ^{13}C NMR, and MS data. The reaction of sodium guaiazulenide and *N*-ethylidenemethylamine also yielded the corresponding 2-(4-azulenyl)ethanamine derivatives, but the low yield of the product showed that the electrophilicity of azomethine carbon atom to 4-methylene carbanion was insufficient. The enzyme activity for some of those products was investigated. Negligible effect was found on prostaglandin 15-hydroxydehydrogenase, and considerable inhibition to cyclic AMP-phosphodiesterase, *in vitro*.

2-Phenylethanamine derivatives, together with their indole analogs, constitute an important class of biological active compounds related to biogenic amines.[1] In studying azulene analogs of biological active amines, we previously reported the synthesis of some acyl and alkyl derivatives of 2-(1-azulenyl)ethanamine by aminoethylation of azulene or guaiazulene with *N*-acylaziridines or with aziridinium salts, as well as the effect of those compounds on enzyme activity.[2]

Our study on azulene derivatives aminoethylated in the 5-membered ring of the azulene nucleus continued with those having aminoethyl side chains in the 7-membered ring. For this type of compounds we preliminarily reported the synthesis of 2-(4-azulenyl)ethanamine derivatives by the reaction of sodium guaiazulenide and methyleneammonium salts;[3] more details are given in this paper.

The present paper also deals with the synthesis of 2-(4-azulenyl)ethanamine derivatives by the action of *N*-methylenedimethylammonium iodide on sodium 4-methylazulenide or on sodium 4,6,8-trimethylazulenide.

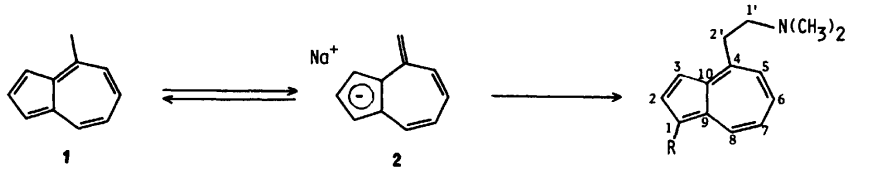
Results and Discussion

Sodium *N*-methylanilinide, used as the reagent, was conveniently prepared from sodium hydride and *N*-methylaniline in THF according to our modification.[4] This reagent reacted smoothly with 4-methylazulene (**1**) to form a reddish-orange solution of sodium 4-methylazulenide (**2**).[5] Next **2** was mixed with *N*-methylenedimethylammonium iodide[6] at *ca.* −80 °C, and left for 5 h to rise to room temperature.

From the hydrochloric acid extract of the reaction mixture, the intended *N*,*N*-dimethyl-2-(4-azulenyl)-ethanamine, a major product, was isolated as its hydrochloride (**7**) (44%); this was easily converted to free amine (**3**) (90%) by the usual treatment with alkali. Both compounds (**3** and **7**) were characterized by spectral data.

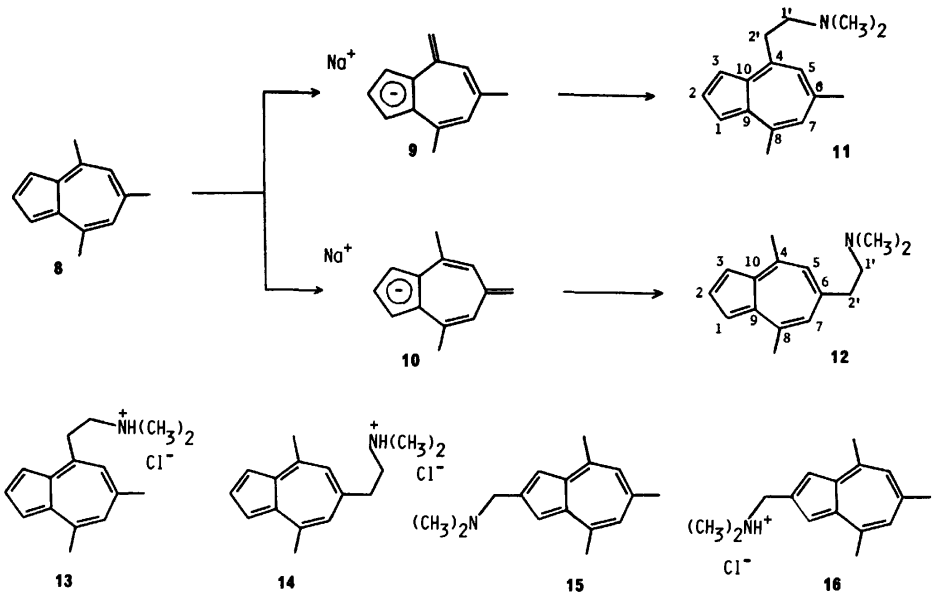
In this reaction, three by-products: **4** (7%), **5** (2%), and **6** (2%), were also obtained. **5** and **6** are already known to occur in the aminomethylation of **1** with *N*,*N*,*N*′,*N*′-tetramethylmethanediamine.[7] The attempted aminomethylation of **1** with *N*-methylenedimethylammonium iodide was also found to yield **5** (7%) and **6** (13%). Consequently, the formation of **5** and **6** as by-products may be reasonably explained by aminomethylation of **1**, which coexists in the solution of **2** at equilibrium and increases in its ratio after the addition of an excess of methyleneammonium salt. Quaternary salt of *N*-methylaniline might act as a proton source.

The assigned position of the dimethylaminomethyl group of the other product, **4**, was indicated by low-field shift of 8-proton (0.15 ppm) of **4** relative to **3** in ^{1}H NMR. This conclusion is consistent with the observation that a dimethylaminomethyl group gives



1 **2** **3** : R=H **4** : R=$CH_2N(CH_3)_2$

5 : R_1=H, R_2=$CH_2N(CH_3)_2$ **6** : R_1=R_2=$CH_2N(CH_3)_2$ **7**



rise a considerable low-field shift at *peri*-position, as is shown in 8-proton of **5** relative to **1** (0.31 ppm) and in 2'-methylene protons of **22** relative to **21** (0.38 ppm).

Moreover, the structure of **4** was established by the action of sodium *N*-methylanilinide on **5** leading to sodium 1-dimethylaminomethyl-4-methylazulenide, followed by the reaction of it with *N*-methylenedimethylammonium iodide to yield **4** (6%). This process, even if possible, could not be a major course of formation of **4** in the reaction of **2** and methyleneammonium salt, judging from the low yields of **5** from **2** and of **4** from **5**. Thus most of **4** may be formed from the main product **3** by successive aminomethylation after aminoethylation of **2**.

Reaction of 4,6,8-trimethylazulene and sodium *N*-methylanilinide at −15 °C is known to give rise to **9** selectively, though proton abstraction from both 4(8)- and 6-methyl group is possible for this compound at higher temperatures.[5] Sodium 4,6,8-trimethylazulenide was thus prepared at −15 °C and reacted with *N*-methylenedimethylammonium iodide, at first at *ca.* −80 °C, followed by gradual completion at room temperature.

Hydrochloric acid treatment of the reaction products afforded **13** (13%), **14** (15%), and **16** (7%), all of which regenerated the corresponding 2-aminoethyl (**11** and **12**) and aminomethyl derivatives (**15**) almost quantitatively when treated with alkali.

Formation of **12** in this reaction is inconsistent with the observation in Ref. 5, but the same type of product from **10** is also noted in sodium 4,6,8-trimethylazulenide, prepared in THF at −15 °C, when it was successively treated with carbon dioxide at −10 °C.[8] The present reaction, in which the sodium 4,6,8-trimethylazulenide formed is used continuously for the next step, is thought to involve equilibrated species **8**, **9**, and **10** in the reaction mixtures, since *N*-methylaniline coexists also. Thus, **9** formed at first at −15 °C may change into **10** *via* **8** in the following reaction with *N*-methylenedimethylammonium iodide to yield **12**. Another pathway of direct conversion from **9** to **10** would require an ionic-attack of the nucleophile on anion **9** and seems improbable.[8]

The yield ratio of **11** and **12** (46 : 54) is very close to that (45 : 55) of carbonation products at 4- and 6-methylene positions in sodium 4,6,8-trimethylazulenide prepared at ordinary temperature,[8] indicating that the equilibrium between **9** and **10** is faster than the reaction of those with methyleneammonium salt.

On the other hand, product **15** cannot be formed from **8**, because the electrophilic substitution of azulene is well known to occur at 1(3)-position,[9] and in fact, aminomethylation of **8** was found to yield 1-substituted and 1,3-disubstituted products.[10] Since the substitution at 2-position, along with that at 1(3)-position, is known in carbonation of azulenide anion of Meisenheimer type,[8] this product is though to be formed from **9** and/or **10** by aminomethylation in a similar manner. So far as we know, it is the first case in methyleneazulenide-type anion that the electrophilic substitution was observed in the 5-membered ring of azulenide anion. Moreover, this fact also suggests that **5** and **6** may arise, at least in part, from **2** in the former reaction of **2** and methyleneammonium salt.

Similarly to the cases of **1** and **8**, **18** was prepared from **17** and allowed to react with some methyleneammonium salts.[3] The reaction of **18** and *N*-methylenedimethylammonium iodide was carried out as described above for **2** to give **21** (50%), **22** (7%), **19** (1%), and **20** (14%). By-products **20** and **22** may be produced by aminomethylation of **17** and/or **18**, or of **21**, as already discussed in cases of **1** and **8**. **19** is thought to be formed by nucleophilic attack of anilinide anion on the 3-methylene position of conjugate acid of **20** ($-CH_2-\overset{+}{N}H(CH_3)_2$), as described before.[3]

By virtually the same procedure as described above, the reaction of **18** with *N*-isopropylidenedimethylammonium perchlorate, *N*-isopropylidenepyrrolidinium perchlorate, or with *N*-(α-methylbenzylidene)pyrrolidinium perchlorate[11] at −20 °C or at room temperature yielded

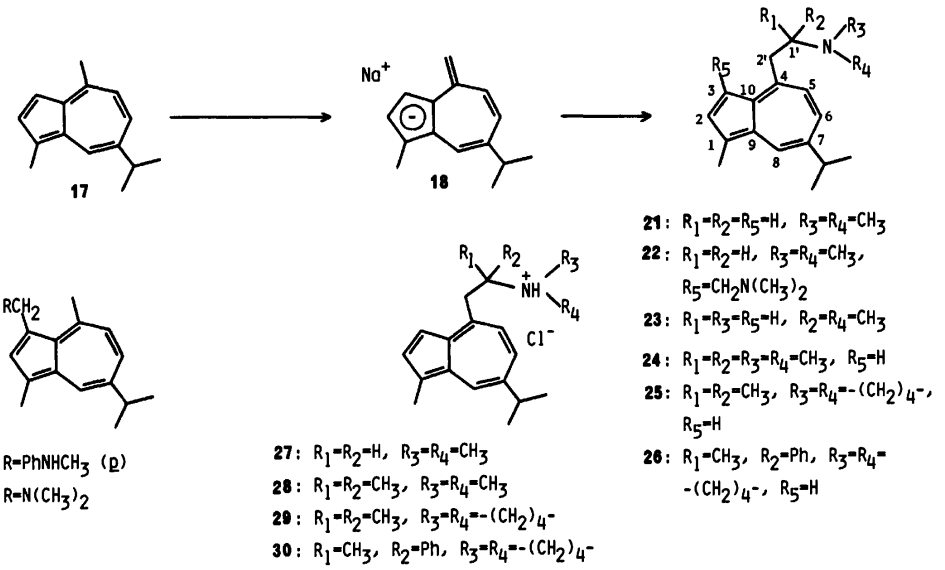


Table 1. Inhibition of cyclic AMP-phosphodiesterase (a) and prostaglandin 15-hydroxydehydrogenase (b) by 2-(4-azulenyl)ethanamine derivatives (addition of 20 μg cm^{-3} in each)

Compound	Inhibition/%	
	a	b
21	31.7	0
22	39.7	0
24	49.2	4.1
25	45.3	9.2
26	26.4	10.3

the corresponding 2-(4-azulenyl)ethanamine derivatives **24** (64%), **25** (62%), and **26** (54%). No appreciable amount of by-product was found in these cases. Of these 2-aminoethyl derivatives, **21** and **24**—**26** were converted to crystalline hydrochlorides **27** (50%), **28** (65%), **29** (51%), and **30** (28%), respectively. Both free amines and hydrochlorides were characterized by spectral data.

To clarify the reactivity of **18** further, the reaction of **18** and *N*-ethylidenemethylamine[12] was also tried and found to yield the corresponding amine, **23** (8%). However, the low yield of **23** is though to show that the electrophilicity of azomethine carbon atom is rather insufficient to allow a smooth reaction of it with the methylene carbanion of **18**.

An additional investigation was undertaken on the effect of 2-(4-azulenyl)ethanamine derivatives (**21**—**26**) for enzyme activity, *in vitro*.[13] As is observed in Table 1, considerable activities are found in inhibitions of cyclic AMP-phosphodiesterase in all compounds and especially in **24** and **25**, though less active than *N*-butyryl-2-(5-isopropyl-3,8-dimethyl-1-azulenyl)ethanamine (69.9%).[2]

Different from the amide or primary amine derivatives of 2-(1-azulenyl)ethanamine previously reported,[2] these tertiary amine derivatives (**21**—**26**) had almost a negligible effect on prostaglandin 15-hydroxydehydrogenase. This observation well accords with that about tertiary amine derivatives of 2-(1-azulenyl)ethanamine, in which no appreciable effect was found on the inhibition by prostaglandin I_2 of ADP-induced aggregation of blood platelets.[14]

Experimental

All the melting points are uncorrected. Spectral data were recorded on the following instruments: UV, Hitachi 624 digital spectrometer with a Hitachi 056 recorder; IR, Hitachi 260-10 spectrometer; ^{1}H NMR, JEOL MH-100; ^{13}C NMR, JNM-FX 100; MS, JEOL-D300 at 70 eV.

Reaction of Sodium 4-Methylazulenide (2) and N-Methylenedimethylammonium Iodide. Under dry nitrogen, a stirred solution of sodium *N*-methylanilinide, prepared from 200 mg (5.1 mmol) of 61% sodium hydride and 1.81 g (16.9 mmol) of *N*-methylaniline in 20 cm^3 of THF according to our modified procedure,[4] was mixed with another solution of 710 mg (4.99 mmol) of 4-methylazulene (**1**)[15] in 5 cm^3 of THF over a period of 15 min, and stirring was continued for 30 min more (violet color changed to reddish orange). To the stirred solution of **3** thus obtained was added, under Dry Ice–acetone cooling, 2.00 g (10.8 mmol) of *N*-methylenedimethylammonium iodide over a period of 20 min (washed in with 5 cm^3 of THF); sitrring was continued for 1 h with Dry Ice –acetone cooling and then for 5 h more, during which period the reaction mixture was gradually brought to room temperature. A facile color change from reddish orange to violet was observed at *ca.* −20 °C. The reaction mixture was taken up into 200 cm^3 of benzene, washed with 50% potassium carbonate solution (100 cm^3×2), dried on sodium sulfate, and concentrated (reduced pressure) to give a violet oil. Successive alumina chromatography (elution with 9 : 1 benzene–ethyl acetate) of the oil gave 2.15 mg (0.3%) of unchanged 4-methylazulene and 637 mg of violet oil, which was again dissolved in 200 cm^3 of benzene, extracted with 1 mol dm^{-3} hydrochloric acid (100 cm^3×3), and the hydrochloric acid solution extracted with chloroform (100 cm^3×10). The chloroform solution was dried (sodium sulfate), concentrated (reduced pressure), and chromatographed on a silica-gel column (elution with 8 : 2 chloroform–methanol) to give 521 mg (44%) of **7** as violet crystals, mp 228—230 °C: UV (C_2H_5OH) 240 (log ε 4.41), 270 (sh, 4.55), 275 (sh, 4.66), 278 (4.68), 283 (4.67), 298 (3.78), 318 (sh, 3.48), 329 (3.62), 342 (3.72), 354 (3.24), 531 (sh, 2.51), 553 (sh, 2.59), 571 (2.65), 588 (sh, 2.61), 617 (2.57), 644 (sh, 2.33), and 677 nm (2.14); IR ($CHCl_3$) 2545, 2510,

2400, 2310 (NH^+), and 1192 cm^{-1} (C–N); ^1H NMR ($CDCl_3$) δ=2.44 (6H, s, $N(CH_3)_2$), 2.90 (2H, m, 1'-H_2), 3.48 (2H, m, 2'-H_2), 6.96—7.58 (3H, m, 5-, 6-, and 7-H), 7.36 (1H, d, J=4 Hz, 1-H), 7.50 (1H, d, J=4 Hz, 3-H), 7.82 (1H, t, J=4 Hz, 2-H), and 8.28 (1H, d, J=9 Hz, 8-H).

The hydrochloric acid solution, after completion of chloroform extraction, was made alkaline by addition of ice-cooled 50% potassium carbonate solution, and extracted with benzene to give 449 mg of violet oil after removal of the solvent. Alumina chromatography of this oil with THF gave 19.6 mg (2%) of **5**, 29.7 mg (2%) of **6**, and 92.0 mg (7%) of **4** as violet oils in each case. **5** and **6** were identical with those in Ref. 7, as well as with authentic specimen obtained by the reaction of **1** and *N*-methylenedimethylammonium iodide, in UV, IR, and ^1H NMR. These compounds were also characterized with MS data. **5**: MS *m/e* (rel intensity) 199 (M^+; 18) and 155 ($M^+ - N(CH_3)_2$; 100). **6**: MS *m/e* (rel intensity) 256 (M^+; 17), 212 ($M^+ - N(CH_3)_2$; 23), and 167 ($M^+ - 2N(CH_3)_2 - H$; 100).

Product **4** was characterized as follows: UV (C_2H_5OH) 242 (log ε 4.28), 278 (sh, 4.49), 282 (4.54), 286 (4.53), 290 (sh, 4.49), 300 (sh, 3.98), 336 (3.55), 345 (3.64), 359 (3.38), 543 (sh, 2.48), 575 (2.76), 617 (2.51), and 677 nm (sh, 2.09); IR (CCl_4) 2870, 2775, 2720 ($N(CH_3)_2$), 2980, 2950, 2860, 1468, 1456, 1440, 1430, 1374 (CH_3 and CH_2), and 1040 cm^{-1} (C–N); ^1H NMR ($CDCl_3$) δ=2.25 (6H, s, $N(CH_3)_2$), 2.35 (6H, s, $N(CH_3)_2$), 2.77 (2H, m, 1'-H_2), 3.39 (2H, m, 2'-H_2), 3.86 (2H, s, 1-CH_2), 7.04 (1H, t, J=10 Hz, 7-H), 7.18 (1H, d, J=10 Hz, 5-H), 7.43 (1H, d, J=4 Hz, 3-H), 7.47 (1H, m, 6-H), 7.78 (1H, d, J=4 Hz, 2-H), and 8.47 (1H, d, J=9.5 Hz, 8-H); MS *m/e* (rel intensity) 256 (M^+; 37), 212 ($M^+ - N(CH_3)_2$; 7), 198 ($M^+ - CH_2N(CH_3)_2$; 3), 154 ($M^+ - CH_2N(CH_3)_2 - N(CH_3)_2$; 20), and 58 ($(CH_3)_2NCH_2^+$; 100).

Found: C, 79.80; H, 9.35; N, 10.46%. Calcd for $C_{17}H_{24}N_2$: C, 79.64; H, 9.44; N, 10.93%.

In order to obtain **3** from **7**, **7** was dissolved in a mixed solvent of benzene–water (100 cm^3 each) and slowly treated with 200 cm^3 of 50% potassium carbonate solution under ice-cooling and stirring. The benzene layer was separated, the aqueous layer was extracted with benzene (30 $cm^3 \times 2$), and the combined benzene extract, after being dried (sodium sulfate) and concentrated (reduced pressure), was chromatographed over alumina (elution with 98 : 2 benzene–methanol) to give 126 mg (90%) of **3** as a violet oil: UV (C_2H_5OH) 240 (log ε 4.36), 265 (sh, 4.35), 270 (sh, 4.49), 275 (sh, 4.60), 278 (4.62), 283 (4.61), 298 (3.70), 317 (sh, 3.34), 328 (3.51), 342 (3.64), 354 (3.05), 530 (sh, 2.48), 550 (sh, 2.56), 568 (2.61), 587 (sh, 2.58), 615 (2.55), 642 (sh, 2.29), and 675 nm (2.12); IR (CCl_4) 2820, 2770, 2720 (NCH_3), 2980, 2945, 2860, 1456, 1440, 1362 (CH_3 and CH_2), 1045, and 1037 cm^{-1} (C–N); ^1H NMR ($CDCl_3$) δ=2.35 (6H, s, $N(CH_3)_2$), 2.77 (2H, m, 1'-H_2), 3.40 (2H, m, 2'-H_2), 7.06 (1H, t, J=10.5 Hz, 7-H), 7.15 (1H, d, J=10.5 Hz, 5-H), 7.43 (1H, d, J=4 Hz, 1-H), 7.52 (1H, m, 6-H), 7.58 (1H, d, J=4 Hz, 3-H), 7.91 (1H, t, J=4 Hz, 2-H), and 8.33 (1H, d, J=9.5 Hz, 8-H); ^{13}C NMR ($CDCl_3$) δ=36.5 (t, 2'-C), 45.1 (q, $N(CH_3)_2$), 60.6 (t, 1'-C), 115.1 (d, 3-C), 118.8 (d, 1-C), 121.5 (d, 7-C), 125.8 (d, 5-C), 135.3 (d, 2-C), 136.3 (d, 6-C), 136.7 (d, 8-C), 137.4 (s, 10-C), 139.9 (s, 9-C), and 148.8 (s, 4-C) [*cf.* 4-methylazulene in Ref. 16][16]; MS *m/e* (rel intensity) 199 (M^+; 20), 141 ($M^+ - (CH_3)_2NCH_2$; 3), and 58 ($(CH_3)_2NCH_2^+$; 100).

Found: C, 84.34; H, 8.51; N, 7.07%. Calcd for $C_{14}H_{17}N$: C, 84.37; H, 8.60; N, 7.03%.

*Reaction of 4-Methylazulene (**1**) and N-Methylenedimethylammonium Iodide.* To a stirred solution of 300 mg (2.11 mmol) of 4-methylazulene in 5 cm^3 of dry dichloromethane was added 600 mg (3.24 mmol) of *N*-methylenedimethylammonium iodide, and the suspension was stirred for 43 h. The reaction mixture was diluted with 100 cm^3 of water, made alkaline by addition of 50% potassium carbonate solution, and extracted with chloroform (60 $cm^3 \times 3$). The chloroform extract was dried (sodium sulfate), concentrated (reduced pressure), and taken up into 100 cm^3 of benzene. This benzene solution was extracted with 1 mol dm^{-3} hydrochloric acid (35 $cm^3 \times 3$), and the hydrochloric acid solution was extracted with chloroform (50 $cm^3 \times 4$). The chloroform extract, after being dried (sodium sulfate) and concentrated (reduced pressure), was chromatographed over silica gel (elution with 8 : 2 chloroform–methanol) to give 37.0 mg (7%) of hydrochloride of **5** as dark violet crystals, mp 177—179 °C: UV (C_2H_5OH) 241 (log ε 4.42), 271 (sh, 4.47), 277 (sh, 4.62) 281 (4.67), 286 (4.66), 290 (sh, 4.57), 301 (3.98), 318 (sh, 3.45), 332 (3.60), 341 (3.68), 353 (3.40), 550 (2.70), 584 (sh, 2.66), 617 (sh, 2.45), 643 (2.28), and 680 nm (1.72); IR ($CHCl_3$) 2650, 2550, 2500, 2400, 2325 (NH^+), and 1195 cm^{-1} (C–N); ^1H NMR ($CDCl_3$) δ=2.74 (6H, s, $N(CH_3)_2$), 3.02 (3H, s, 4-CH_3), 4.70 (2H, s, CH_2), 6.54 (1H, broad s, NH), 7.48 (1H, t, J=10 Hz, 7-H), 7.53 (1H, d, J=10 Hz, 5-H), 7.68 (1H, d, J=4 Hz, 3-H), 7.92 (1H, t, J=10 Hz, 6-H), 8.34 (1H, d, J=4 Hz, 2-H), and 8.90 (1H, d, J=10 Hz, 8-H).

The hydrochloric acid layer, after completion of chloroform extraction, was made alkaline by addition of 200 cm^3 of 50% potassium carbonate solution, and extracted with benzene (50 $cm^3 \times 3$). Benzene extract, after removal of the solvent (reduced pressure), was submitted to alumina chromatography (elution with 3 : 1 benzene–THF) to afford 68.0 mg (13%) of **6**, identical with that of Ref. 7 and the authentic specimen (described above) in its UV, IR, and ^1H NMR spectra.

In order to obtain **5**, its hydrochloride was suspended in 80 cm^3 of benzene and slowly mixed with 200 cm^3 of ice-cooled 50% potassium carbonate solution. This mixture was worked up as described for **3** from **7** to give, without chromatographic separation, 17.9 mg (90%) of **5**, identical with that of Ref. 7 and the authentic specimen (described above) in its UV, IR, and ^1H NMR spectra.

Reaction of Sodium 1-Dimethylaminomethyl-4-methylazulenide and N-Methylenedimethylammonium Iodide. To a stirred solution of 0.114 mmol of sodium *N*-methylanilinide in 4 cm^3 of THF was added, under dry nitrogen, another solution of 21.8 mg (0.110 mmol) of **5** in 1 cm^3 of THF during a period of 15 min, and then, under Dry Ice–acetone cooling, 30 mg (0.162 mmol) of *N*-methylenedimethylammonium iodide (washed in with 1 cm^3 of THF). Stirring was continued at *ca.* −80 °C for 1 h and then 5 h; after the first hour the reaction mixture was gradually brought to room temperature. The reaction mixture was taken up into 20 cm^3 of benzene and extracted with 1 mol dm^{-3} hydrochloric acid (20 $cm^3 \times 3$). The hydrochloric acid extract was washed with benzene (20 $cm^3 \times 3$), made alkaline by addition of 100 cm^3 of ice-cooled 50% potassium carbonate solution, and extracted with benzene (20 $cm^3 \times 3$) to give 19.6 mg of brown oil after removal of the solvent (reduced pressure). Preparative TLC on an alumina sheet (3 : 1 benzene–THF) of the oil afforded 0.56 mg (3%) of unchanged **5** and 1.76 mg (6%) of **4**, identical with authentic specimen in TLC, UV, and IR results.

Reaction of Sodium 4,6,8-Trimethylazulenide and N-Methylenedimethylammonium Iodide. Under dry nitrogen, a stirred solution of 5.1 mmol of sodium *N*-methylanilinide in 20 cm^3 of THF was mixed at −15 °C with another solution of 850 mg (4.99 mmol) of **8** in 5 cm^3 of THF (violet color changed to orange), and then, under Dry Ice–acetone cooling, with 2.00 g (10.8 mmol) of *N*-methylenedimethylammonium iodide (washed in with 5 cm^3 of THF). The suspension was stirred for 1 h at *ca.* −80 °C and for 5 h more with a gradual rising

of the temperature. The reaction mixture was worked up as described in **2** to give a violet oil, which was taken up into 200 cm^3 of benzene, extracted with 1 mol dm^{-3} hydrochloric acid (100 $cm^3 \times 3$); the hydrochloric acid layer was extracted with chloroform (100 $cm^3 \times 6$). The benzene solution, after being dried (sodium sulfate) and concentrated (reduced pressure), was chromatographed on a silica-gel column with hexane to afford 220 mg (26%) of unchanged **8**. The chloroform extract was also dried (sodium sulfate), concentrated (reduced pressure), and submitted to silica gel chromatography (elution with 8 : 2 chloroform–methanol) to allow separation into three fractions.

From the first eluate, 174 mg (13%) of **13** was obtained as a violet oil; UV (C_2H_5OH) 244 (log ε 4.48), 270 (sh, 4.32), 275 (sh, 4.50), 281 (sh, 4.67), 285 (4.73), 294 (sh, 6.67), 305 (sh, 4.00), 328 (sh, 3.62), 334 (3.70), 343 (3.74), 348 (3.80), 359 (sh, 2.73), 547 (2.78), 565 (sh, 2.76), 580 (sh, 2.73), and 635 nm (sh, 2.31); IR ($CHCl_3$) 2500, 2400, 2360, 2325 (NH^+), and 1195 cm^{-1} (C–N); ^1H NMR ($CDCl_3$) δ=2.40 (6H, s, $N(CH_3)_2$), 2.63 (3H, s, 6-CH_3), 2.84 (2H, m, 1′-H_2), 2.86 (3H, s, 8-CH_3), 3.42 (2H, m, 2′-H_2), 7.13 (1H, s, 7-H), 7.16 (1H, s, 5-H), 7.48 (1H, q, J=4 and 1.8 Hz, 1-H), 7.58 (1H, q, J=4 and 1.8 Hz, 3-H), and 7.80 (1H, t, J=4 Hz, 2-H).

From the second eluate, 201 mg (15%) of **14** was obtained as violet crystals; these showed no certain melting point but decomposed above 200 °C: UV (C_2H_5OH) 245 (log ε 4.43), 270 (sh, 4.26), 275 (sh, 4.46), 281 (sh, 4.63), 285 (4.69), 294 (sh, 4.61), 306 (sh, 3.90), 327 (sh, 3.69), 333 (3.75), 342 (sh, 3.78), 348 (3.84), 520 (sh, 2.53), 555 (2.64), 575 (sh, 2.61), 592 (sh, 2.56), and 650 nm (sh, 2.09); IR ($CHCl_3$) 2550, 2510, 2450, 2390, 2355, 2330, 2280 (NH^+), and 1195 cm^{-1} (C–N); ^1H NMR (CD_3OD) δ=2.88 (6H, s, $N(CH_3)_2$), 2.90 (6H, s, 4- and 8-CH_3), 3.33 (4H, m, 1′- and 2′-H_2), 7.13 (2H, s, 5- and 7-H), 7.36 (2H, d, J=4 Hz, 1- and 3-H), and 7.66 (1H, t, J=4 Hz, 2-H).

From the last fraction, 85.4 mg (7%) of **16** was obtained as violet crystals, mp 41—45 °C: UV (C_2H_5OH) 246 (log ε 4.53), 287 (4.79), 293 (4.79), 335 (4.00), 351 (4.04), 536 (2.72), 560 (sh, 2.70), 615 (sh, 2.33), and 624 nm (sh, 2.27); IR ($CHCl_3$) 2500, 2400, 2350, 2330 (NH^+), and 1190 cm^{-1} (C–N); ^1H NMR ($CDCl_3$) δ=2.17 (6H, s, $N(CH_3)_2$), 2.61 (3H, s, 6-CH_3), 2.86 (6H, s, 4- and 8-CH_3), 3.83 (2H, s, CH_2), 4.48 (1H, broad s, NH^+), 7.08 (2H, s, 5- and 7-H), and 7.33 (2H, s, 1- and 3-H).

In order to obtain **11** from **13**, a solution of 51.6 mg (0.196 mmol) of **13** in 70 cm^3 of benzene–methanol (98 : 2) was mixed dropwise with 200 cm^3 of ice-cooled 50% potassium carbonate solution. After the mixture was worked up in the usual manner as described before, 44.5 mg (100%) of **11** was obtained as a violet oil: UV (C_2H_5OH) 244 (log ε 4.43), 271 (sh, 4.31), 275 (sh, 4.45), 281 (sh, 4.61), 285 (4.67), 290 (4.67), 294 (sh, 4.61), 305 (sh, 3.93), 322 (sh, 3.45), 328 (sh, 3.51), 334 (3.59), 344 (sh, 3.64), 349 (3.71), 359 (sh, 3.06), 547 (2.71), 564 (sh, 2.69), 581 (sh, 2.65), and 637 nm (sh, 2.20); IR (CCl_4) 2825, 2775, 2725 ($N(CH_3)_2$), 2980, 2950, 2860, 1467, 1458, 1438, 1372 (CH_3 and CH_2), 1045, and 1040 cm^{-1} (C–N); ^1H NMR ($CDCl_3$) δ=2.37 (6H, s, $N(CH_3)_2$), 2.60 (3H, s, 6-CH_3), 2.78 (2H, m, 1′-H_2), 2.84 (3H, s, 8-CH_3), 3.38 (2H, m, 2′-H_2), 7.06 (1H, s, 7-H), 7.09 (1H, s, 5-H), 7.40 (1H, q, J=4 and 1.5 Hz, 1-H), 7.50 (1H, q, J=4 and 1.5 Hz, 3-H), and 7.73 (1H, t, J=4 Hz, 2-H); ^{13}C NMR ($CDCl_3$) δ=25.0 (q, 8-CH_3), 28.7 (q, 6-CH_3), 37.3 (t, 2′-C), 45.2 (q, $N(CH_3)_2$), 61.1 (t, 1′-C), 115.5 (d, 3-C), 116.2 (d, 1-C), 126.7 (d, 5-C), 127.0 (d, 7-C), 132.6 (d, 2-C), 136.0 (s, 9- and 10-C), 145.4 (s, 8-C), 146.3 (s, 6-C), and 147.8 (s, 4-C) [*cf.* 4,6,8-trimethylazulene in Ref. 16][16]; MS *m/e* (rel intensity) 227 (M^+; 12), 169 ($M^+ - (CH_3)_2NCH_2$; 3), and 58 ($(CH_3)_2NCH_2^+$; 100).

*Reaction of Sodium Guaiazulenide (**18**) with Methyleneammonium Salts or with N-Ethylidenemethylamine. A) With N-Methylenedimethylammonium Iodide*: To a stirred solution of 10 mmol of sodium guaiazulenide (**18**) in 30 cm^3 of THF [from 440 mg (10.2 mmol) of sodium hydride, 3.62 g (33.8 mmol) of *N*-methylaniline, and 1.99 g (10.0 mmol) of guaiazulene, as described in the preparation of **2**], under dry nitrogen and with Dry Ice–acetone cooling, was added 3.70 g (20 mmol) of *N*-methylenedimethylammonium iodide over a period of 20 min (washed with 5 cm^3 of THF), and the suspension was stirred for 1 h at *ca.* −80 °C and for an additional 5 h with a gradual elevation of the temperature. The reaction mixture, after being worked up as described above for **2**, was chromatographed over alumina (elution with 9 : 1 hexane–ethyl acetate) and separated into four fractions. Further elution with ethanol afforded one more fraction.

Rechromatography of the first fraction on a silica-gel column with hexane gave 30.2 mg (2%) of unchanged guaiazulene. Successively the solvent was changed into benzene to give 32.2 mg (1%) of **19** as a blue oil: UV (C_2H_5OH) 248 (log ε 4.44), 283 (sh, 4.54), 290 (4.60), 307 (4.22), 341 (sh, 3.58), 354(3.73), 371 (3.63), 584 (sh, 2.49), 625 (2.58), 676 (sh, 2.49), and 748 (sh, 2.05); IR (CCl_4) 3440 (NH), 1375 and 1360 cm^{-1} (CH_3); ^1H NMR ($CDCl_3$)[18] δ=1.32 (6H, d, J=7 Hz, $CH(C\underline{H}_3)_2$), 2.60 (3H, s, 1-CH_3), 2.70 (3H, s, NCH_3), 2.84 (3H, s, 4-CH_3), 2.98 (1H, m, J=7 Hz, $C\underline{H}(CH_3)_2$), 3.34 (1H, broad s, NH), 4.48 (2H, s, CH_2), 6.48 (2H, d, J=8 Hz, 3″- and 5″-H), 6.76 (1H, d, J=10 Hz, 5-H), 6.88 (2H, d, J=8 Hz, 2″- and 6″-H), 7.22 (1H, q, J=10 and 2 Hz, 6-H), 7.40 (1H, s, 2-H), and 8.08 (1H, d, J=2 Hz, 8-H); MS *m/e* (rel intensity) 317 (M^+; 100), 302 ($M^+ - CH_3$; 57), and 120 ($CH_3NHC_6H_4CH_2^+$; 29).

E) With N-Ethylidenemethylamine: Reaction of 10 mmol of **18** and 3.0 cm³ (40 mmol) of *N*-ethylidenemethylamine was carried out as described in *B*. Chromatography of the reaction mixture on an alumina column (elution with 8 : 2 benzene–methanol) yielded 4.08 g of blue oil, which on rechromatography (hexane–silica gel) afforded 1.74 g (88%) of unchanged **17**. The second blue eluate was rechromatographed on an alumina column (elution with 8 : 2 benzene–methanol) to afford 210 mg (8%) of **23** as a blue oil: UV (C_2H_5OH) 219 (log ε 4.02), 246 (4.36), 285 (4.58), 289 (4.58), 303 (3.99), 349 (3.62), 367 (3.49), 565 (sh, 2.55), 607 (2.66), 656 (2.59), and 725 nm (sh, 2.15); IR (CCl_4) 3330 (NH), 2790 (NCH_3), 2960, 2925, 2870, 1470, 1460, 1445, 1438, 1420, 1390, and 1370 cm⁻¹ (CH_3 and CH_2); ¹H NMR ($CDCl_3$) δ=1.12 (3H, d, J=6.3 Hz, 1′-$C(CH_3)$), 1.35 (6H, d, J=6.9 Hz, $CH(C\underline{H}_3)_2$), 1.71 (1H, broad s, NH), 2.39 (3H, s, NCH_3), 2.64 (3H, s, 1-CH_3), 2.88—3.40 (4H, m; 1′-H, 2′-H_2, and $C\underline{H}(CH_3)_2$), 6.96 (1H, d, J=10.3 Hz, 5-H), 7.28 (1H, d, J=3.4 Hz, 3-H), 7.36 (1H, q, J=10.3 and 1.7 Hz, 6-H), 7.59 (1H, d, J=3.4 Hz, 2-H), and 8.14 (1H, d, J=1.7 Hz, 8-H;) MS *m/e* (rel intensity) 255 (M^+; 7), 198 ($M^+-C_3H_7N$; 32), and 58 ($C_3H_8N^+$; 100).

Found: C, 84.70; H, 9.56; N, 5.62%. Calcd for $C_{18}H_{25}N$: C, 84.65; H, 9.87; N, 5.48%.

Preparation of Hydrochlorides from 2-(7-Isopropyl-1-methyl-4-azulenyl)ethanamine Derivatives. A) From 21: A solution of 209 mg (0.818 mmol) of **21** in 100 cm³ of benzene was extracted with 1 mol dm⁻³ hydrochloric acid (50 cm³×3); the hydrochloric acid layer was then extracted with chloroform (50 cm³×3). The chloroform solution was dried (sodium sulfate) and concentrated (reduced pressure) to leave a blue crystalline mass, which was washed with hexane (20 cm³×5) and chromatographed on a silica-gel column (elution with 9 : 1 chloroform–methanol) to give 120 mg (50%) of **27** as blue crystals, mp 200—204 °C: UV (C_2H_5OH) 218 (sh, log ε 4.05), 245 (4.29), 280 (sh, 4.46), 285 (4.52), 289 (4.51), 303 (3.95), 350 (3.58), 367 (3.41), 565 (sh, 2.51), 588 (sh, 2.57), 605 (2.61), 633 (sh, 2.56), 658 (2.53), and 730 nm (2.09); IR ($CHCl_3$) 2500, 2400, 2350, 2328 (NH^+), and 1097 cm⁻¹ (C–N); ¹H NMR ($CDCl_3$) δ=1.28 (6H, d, J=7 Hz, $CH(C\underline{H}_3)_2$), 2.32 (6H, s, $N(CH_3)_2$), 2.61 (3H, s, 1-CH_3), 2.74 (2H, m, 1′-H_2), 3.02 (1H, m, J=7 Hz, $C\underline{H}(CH_3)_2$), 3.31 (2H, m, 2′-H_2), 7.00 (1H, d, J=11 Hz, 5-H), 7.32 (1H, d, J=4 Hz, 3-H), 7.38 (1H, q, J=11 and 2 Hz, 6-H), 7.64 (1H, d, J=4 Hz, 2-H), and 8.18 (1H, d, J=2 Hz, 8-H).

B) From 24: By treating 210 mg (0.741 mmol) of **24** as described above in *A*, 153 mg (65%) of **28** was obtained as blue crystals, mp 200—204 °C: UV (C_2H_5OH) 215 (log ε 4.64), 246 (5.00), 285 (5.28), 290 (5.27), 303 (sh, 4.65), 330 (sh, 2.52), 351 (3.19), 368 (2.90), 440 (sh, 2.43), 565 (sh, 2.35), 614 (2.45), 666 (2.36), and 740 nm (1.89); IR ($CHCl_3$) 2615, 2540, 2510, 2440, 2350, 2340 (NH^+), and 1144 cm⁻¹ (C–N); ¹H NMR ($CDCl_3$) δ=1.34 (6H, s, 1′-$C(CH_3)_2$), 1.40 (6H, d, J=7 Hz, $CH(C\underline{H}_3)_2$), 2.72 (3H, s, 1-CH_3), 2.82 (6H, s, $N(CH_3)_2^+$), 3.16 (1H, m, J=7.0 Hz, $C\underline{H}(CH_3)_2$), 3.68 (2H, s, 2′-H_2), 7.12 (1H, d, J=11 Hz, 5-H), 7.54 (1H, q, J=11 and 4 Hz, 6-H), 7.60 (1H, d, J=4 Hz, 3-H), 7.84 (1H, d, J=4 Hz, 2-H), and 8.38 (1H, d, J=2 Hz, 8-H).

C) From 25: By treating 321 mg (1.04 mmol) of **25** as described in *A*, except that 6 mol dm⁻³ hydrochloric acid and a mixed solvent of chloroform–methanol (7 : 3) were used for extraction and for chromatographic separation respectively, 183 mg (51%) of **29** was obtained as blue crystals, mp 82—84 °C: UV (C_2H_5OH) 216 (log ε 3.21), 245 (3.69), 284 (4.03), 290 (4.02), 304 (sh, 2.54), 338 (sh, 3.38), 352 (3.46), 368 (3.38), 608 (2.59), 660 (2.49), and 730 nm (2.02); IR ($CHCl_3$) 2690, 2645, 2560, 2500—2400, 2360, 2340 (NH^+), and 1194 cm⁻¹ (C–N); ¹H NMR ($CDCl_3$)[18] δ=1.32 (6H, s, $C(CH_3)_2$), 1.43 (6H, d, J=7 Hz, $CH(C\underline{H}_3)_2$), 2.08 (4H, m, β- and γ-H_2), 2.24 (1H, s, NH^+), 2.76 (3H, s, 1-CH_3), 3.18 (1H, m, J=7 Hz, $C\underline{H}(CH_3)_2$), 3.32 (4H, t, J=6 Hz, α- and δ-H_2), 3.68 (2H, s, 2′-H_2), 7.19 (1H, d, J=11 Hz, 5-H), 7.58 (1H, q, J=11 and 2 Hz, 6-H), 7.64 (1H, d, J=4 Hz, 3-H), 7.84 (1H, d, J=4 Hz, 2-H), and 8.36 (1H, d, J=2 Hz, 8-H).

D) From 26: By treating 415 mg (1.12 mmol) of **26** as described in *C*, 128 mg (28%) of **30** was obtained as blue crystals, mp 80—85 °C: UV (C_2H_5OH) 246 (log ε 4.03), 286 (4.34), 291 (4.31), 303 (3.52), 329 (sh, 3.46), 335 (sh, 3.54), 351 (3.66), 368 (3.54), 416 (2.90), 436 (2.89), 560 (sh, 2.50), 602 (sh, 2.59), 611 (2.60), 660 (2.52), and 730 nm (2.08); IR ($CHCl_3$) 2670, 2560, 2490—2430, 2400, 2360, 2340 (NH^+), and 1192 cm⁻¹ (C–N); ¹H NMR ($CDCl_3$)[18] δ=1.23 (3H, s, 1′-$C(CH_3)$), 1.32 (6H, d, J=7 Hz, $CH(C\underline{H}_3)_2$), 1.88 (4H, m, β- and γ-H_2), 2.64 (3H, s, 1-CH_3), 3.02 (4H, m, α- and δ-H_2), 3.70 (1H, d, J=12.5 Hz, 2′-H), 4.15 (1H, d, J=12.5 Hz, 2′-H), 6.10 (1H, d, J=11 Hz, 5-H), 6.96 (1H, q, J=11 and 2 Hz, 6-H), 7.30 (3H, m, 3″-, 4″-, and 5″-H), 7.34 (1H, d, J=4 Hz, 3-H), 7.64 (2H, m, 2″- and 6″-H), 7.62 (1H, d, J=4 Hz, 2-H), and 8.16 (1H, d, J=2 Hz, 8-H).

We wish to thank Professor Hitoshi Takeshita of Kyushu University, for his kind measurements of ¹³C NMR, and Konan-kako Co. Ltd., for generously giving us the sample of 4,6,8-trimethylazulene.

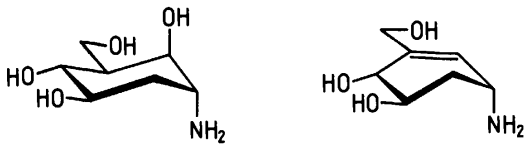
Synthetic Studies on the Validamycins. VII. Synthesis of DL-2-Deoxyhydroxyvalidamine and DL-2-Deoxyvalienamine[1,2]

Seiichiro OGAWA, Hiroyuki ITO, Takao OGAWA, Shinichi IWASAKI, and Tetsuo SUAMI*
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223
(Received October 16, 1982)

Synthesis of the 2-deoxy analogs of DL-hydroxyvalidamine and DL-valienamine starting from DL-1,2-di-*O*-acetyl-(1,3,5/2)-5-bromo-3-bromomethyl-1,2-cyclohexanediol is described.

In connection with the previous paper,[3] DL-2-deoxyhydroxyvalidamine (**1**), DL-2-deoxyvalienamine (**2**), and the related cyclitol derivatives were synthesized starting from the readily available DL-1,2-di-*O*-acetyl-(1,3,5/2)-5-bromo-3-bromomethyl-1,2-cyclohexanediol (**3**),[4] following mainly the sequence previously employed for the synthesis of DL-hydroxyvalidamine.[3]



1 **2**

Scheme 1.

Treatment of **3** with 2 molar equiv. of sodium benzoate in 90% aqueous *N,N*-dimethylformamide (DMF) at 75 °C gave the monobenzoate **4** in 52% yield. When **4** reacted with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in toluene at reflux temperature, two olefins **7** and **8** were obtained, after chromatography on silica gel, in 48 and 25% yields, respectively. On the other hand, treatment of **3** with 3 molar equiv. of sodium benzoate and a molar equiv. of lithium bromide in DMF at 120 °C for 1 h gave, after chromatography, **7** (36%), **8** (26%), dibenzoate **9** (8%), and diolefin **10** (19%). Compound **7** was identified with an authentic sample.[5] The ^{1}H NMR spectrum of **8** showed the signals of H-1 and H-2 as a triplet of doublets (δ=5.10, J=6, 11, and 11 Hz) and a triplet (δ=5.28, J=11 Hz), supporting the structural assignment. Compound **4** was first converted, by attack of a bromide ion, into its C-5 epimer, which would readily undergo elimination to give **7** and **8**. This assumption may be supported by the formation of **9**. The ^{1}H NMR spectrum of **10** revealed the signals of H-2, H-4, and H-5 as a broad doublet (δ=6.13, J= 10 Hz), a doublet (δ=5.60, J=9 Hz) and a triplet of doublets (δ=5.53, J=3.6, 9, and 9 Hz), respectively, indicating the assigned structure. Compound **10** was characterized by conversion into the crystalline bis(*p*-nitrobenzoate).

In order to obtain desired **8** selectively, **3** was transformed into the 1,2-*O*-isopropylidene derivative **6**. Since introduction of the 1,2-*O*-isopropylidene-fused ring into the cyclohexane ring gave appreciable strain in it, the elimination reaction was expected to proceed regioselectively to give rise to either one of the two isomeric olefins.

O-Deacetylation of **3** was carried out with hydrobromic acid in aqueous ethanol at reflux temperature

Scheme 2.

to give the dihydroxy compound **5** in 95% yield. Treatment of **5** with 2,2-dimethoxypropane in DMF in the presence of *p*-toluenesulfonic acid at 70 °C gave **6** in 97% yield. Similar treatment of **6** with sodium benzoate and lithium bromide in DMF produced a single olefin **11** in 60% yield,[6] together with the substitution products **12** (12%) and **13** (5%). The structure of

11 was confirmed by converting it into **8**. The structures of **12** and **13** were tentatively assigned by ^{1}H NMR spectroscopy. Thus, the spectra of **12** and **13** showed the signals of H-5 as a wide triplet of triplets (δ=5.20, J= 5, 5, 11, and 11 Hz) and a narrow quitet (δ=5.58, J= 3 Hz), respectively. Formation of **12** and **13** indicated that the ring bromine atom of **6** was first displaced by bromide ion as well as benzoate ion. The intermediate C-5 epimer of **6** would be converted into **11** *via* regioselective elimination and a small proportion of **12** *via* displacement reaction.

In order to see reactivity of **8** and to provide ^{1}H NMR spectral data of related cyclitol derivatives, synthesis of (hydroxymethyl)cyclohexanetetrol was carried out by oxidation with osmium tetraoxide in 2-propanol containing 5% hydrogen peroxide at room temperature. The products were subsequently acetylated with acetic anhydride in pyridine at room temperature and fractionated by silica-gel chromatography to give pentol peracylate **14** and α,β-unsaturated ketone **15** in 38 and 5.2% yields, respectively.[7] The ^{1}H NMR spectrum of **14** showed a quartet (J=3 Hz) at δ=5.40, which was attributed to the proton attached to the carbon atom bearing an axial acetoxyl group. The spectrum of **15** was interpreted assuming the first-order splitting. Formation of **15** involved facile β-elimination of the acetoxyl group at C-1.

Epoxidation of **8** with *m*-chloroperoxybenzoic acid (*m*CPBA) and sodium hydrogencarbonate in 1,2-dichloroethane at room temperature yielded almost exclusively the epoxide **16** in 80% yield, together with an isomeric epoxide (<7%). Treatment of **16** with sodium azide and ammonium chloride in aqueous 2-methoxyethanol at 75 °C gave the single azido compound **18** in 76% yield through *trans*-diaxial opening of the epoxide ring. The ^{1}H NMR spectrum of **18** exhibited a quartet (J=2.5 Hz) at δ=3.83, which was ascribed to the axial proton on the carbon atom bonding to the azido function. Treatment of **16** with sodium acetate and ammonium chloride followed by acetylation gave the chloride **17** in 58% yield. The structure of **17** was shown to correspond with that of **18** by comparison of their ^{1}H NMR spectra. Accordingly, the structure of **16** was established as shown in Scheme 2 on the basis of the above results and the ^{1}H NMR spectral data. It was thought that the peroxy acid may attack **8** from less hindered side, since there is no polar substituent on the α-carbon atom that would influence the direction of the attack of the peroxy acid.

Compound **18** was converted into the triacetate **19** or the mesylate **20** in good yield. Hydrogenation of **19** with Raney nickel in ethanol followed by the conventional acetylation afforded the peracyl derivative **21** of **1** in 60% yield. Alternatively, ammonolysis of **16** with methanolic ammonia in a sealed tube at 90 °C for 15 h followed by acetylation gave, after chromatography, three amides **21** (17%), **22** (31%), and **24** (19%). The structure of **22** was determined by comparison of the ^{1}H NMR spectrum with that of **21**. The ^{1}H NMR spectrum of **24** was in accord with that of the product derived by *trans*-diequatorial opening of the epoxide.

On the other hand, **20** was treated with DBU in toluene at reflux temperature for 6 h gave the olefin **28** in 76% yield. The ^{1}H NMR spectrum of **28** showed a broad doublet (δ=6.12, J=3 Hz) and a narrow multiplet (δ=4.10), which were assigned to H-4 and H-5, respectively. Reduction of the azido group was effected by hydrogen sulfide in aqueous pyridine at room temperature,[8] and, after acetylation, the amide **29** was obtained in 65% yield. In the ^{1}H NMR spectrum of **29**, the olefinic proton appeared as a broad doublet (J=3.5 Hz) at δ=6.03. This is indicative of the pseudo-axial conformation of the acetamido group.[9] Compound **29** was a 2-deoxy analog of valienamine.

The 5-epimer of **2** and related cyclitols were prepared according to the following sequence. Compound **8** reacted with bromine in carbon tetrachloride at room temperature to give dibromide **23** in 47% yield as the only product. The ^{1}H NMR spectrum of **23** showed the signal of C-1 proton as a triplet of doublets (J=6, 9.5, and 9.5 Hz) at δ=5.38 somewhat lower-field as compared with that (δ=4.85) of **4**. It may be attributable to the presence of the bromine atom in a 1,3-diaxial position. Treatment of **23** with sodium azide in DMF at 120 °C gave azide **30** in 91% yield as the sole product.

Scheme 4.

The structure was assigned by comparison of its ^{1}H NMR spectrum with that of **28**. In contrast, the signal of C-4 olefinic proton appeared as a broad singlet (δ=5.99) in the case of **30**. Upon similar reduction followed by acetylation, **30** was converted into amide **31** in 58% yield. Reaction of **23** with benzoate ion in DMF similarly gave dibenzoate **34** in 62% yield. The reactions of **23** seemed to involve first the ready elimination of hydrobromic acid between C-3 and C-4. The intermediate allyl bromide was then substituted by the nucleophile *via* direct S_N2 reaction.

In addition, alternative synthetic route for deoxyvalienamine derivatives was studied starting from **10**, which could readily be prepared by treatment of **3** with DBU in toluene at reflux temperature. Reaction of **10** with bromine in carbon tetrachloride at 0 °C yielded a stereoisomeric mixture of 1,4-addition products **26** and **27** in 54% yield, together with a small amount of crystalline tetrabromide. Without further separation, the mixture of **26** and **27** was treated with an excess of sodium benzoate in 90% aqueous DMF at room temperature to give the dibenzoate **34** in 30% yield. The epimer of **34** was not isolated in pure form because of their similar mobility on TLC. Compound **34** was converted into the corresponding tetraacetate **35**. When the mixture was treated with potassium phthalimide in DMF at room temperature, a single bis(phthalimide) **36** was obtained in 58% yield selectively. Treatment of **36** with butylamine in methanol, followed by acetylation gave the bis(acetamide) **37** in 98% yield. The ^{1}H NMR spectrum was consistent with the assigned structure.

On the other hand, epoxidation of **10** with *m*CPBA in dichloromethane and phosphate buffer solution (pH 8) afforded mainly crystalline spiro epoxide **25** in 50% yield.[10] Azidolysis of **25** with sodium azide and ammonium chloride in DMF at 60 °C resulted in preferential attack at C-7 by azide ion to give only azide **38** in 92% yield. The structure of **38** was supported by ^{1}H NMR signal of the branched-chain methylene protons which appear at somewhat higher-field (AB-quartet, δ=3.60 and 3.83) than those (δ=4.15 and 4.51) of the related 1-*C*-acetoxymethyl compound.[11] Reduction of **38** with hydrogen sulfide followed by acetylation gave the amide **39** in quantitative yield. However, treatment of **25** with sodium azide and sulfuric acid in aqueous acetone at room temperature yielded, after acetylation, mainly the azide **32** in 48% yield. Similar reduction followed by acetylation gave the amide **33**, whose ^{1}H NMR spectrum showed the olefinic proton as a broad singlet (δ=4.70) and was comparable with **31** in the vicinity of the signals due to ring protons.

The branched-chain aminocyclitols and cyclitols described in this paper are not only biologically interesting compounds, but also useful model substances for structural elucidation of pseudonitrogen disaccharides reported in the accompanying paper.[12]

Experimental

Unless otherwise noted, melting points were determined on a Mitamura Riken micro hot stage apparatus and are uncorrected. ^{1}H NMR spectra were taken on a Varian EM-360 (60 MHz) or a Varian EM-390 (90 MHz) in chloroform-*d* ($CDCl_3$) with reference to tetramethylsilane as an internal standard. The peak positions are given in terms of δ-values. Values given for coupling constants are of first-order. TLC was performed on precoated silica gel 60 F-254 plates (Merck, Darmstadt; 0.25 mm thickness). The silica gel for a column chromatography was Wakogel C-300 (Wako Pure Chemical Industries, Ltd.). Organic solutions were dried over anhydrous sodium sulfate. Solutions were concentrated below 50 °C under reduced pressure.

DL-1,2-Di-O-acetyl-(1,3,5/2)-3-benzoyloxymethyl-5-bromo-1,2-cyclohexanediol (4). A mixture of DL-1,2-di-*O*-acetyl-(1,3,-5/2)-5-bromo-3-bromomethyl-1,2-cyclohexanediol (**3**)[4] (2.0 g), sodium benzoate (1.56 g, 2 molar equiv.), and 90% aqueous DMF was stirred at 75 °C for 10 h, and then concentrated. The residue was extracted with ethyl acetate and the extracts were filtered through a short column of alumina. The filtrate was concentrated and the residue was crystallized from ethanol to give 1.15 g (52%) of **4**: mp 121—123 °C.** ^{1}H NMR (90 MHz) δ=2.03 (6H, s, OAc), 4.00 (1H, tt, $J_{4eq,5}=J_{5,6eq}=4$ Hz, $J_{4ax,5}=J_{5,6ax}=12$ Hz, H-5), 4.18 (1H, dd, $J_{3,7}=5$ Hz, $J_{gem}=11.5$ Hz, H-7), 4.35 (1H, dd, $J_{3,7'}=3$ Hz, H-7′), 4.85 (1H, ddd, $J_{1,2}=9.5$ Hz, $J_{1,6eq}=4.5$ Hz, $J_{1,6ax}=11$ Hz, H-1), 5.10 (1H, t, $J_{2,3}=9.5$ Hz, H-2), 7.34—7.74 (3H, m) and 8.01—8.17 (3H, m) (phenyl).

Found: C, 52.13; H, 5.22; Br, 19.64%. Calcd for $C_{18}H_{21}BrO_6$: C, 52.31; H, 5.21; Br, 19.33%.

Reaction of 4 with DBU. A mixture of **4** (0.20 g), DBU (0.36 ml), and toluene (6 ml) was refluxed for 14 h. The reaction mixture was diluted with toluene (20 ml) and the solution was washed with 1 M hydrochloric acid (1 M=1 mol dm^{-3}), saturated sodium hydrogencarbonate, and water, and dried. Evaporation of the solvent gave an oil (0.17 g) which was chromatographed on a silica gel with ethyl acetate–hexane (1 : 5) as an eluent. The first fraction gave crystals which were recrystallized from ethanol to give 96 mg (48%) of DL-1,2-di-*O*-acetyl-(1,3/2)-3-benzoyloxymethyl-5-cyclohexene-1,2-diol (**7**) as prisms: mp 75.5—76 °C,** identical with an authentic sample (mp 75—76.5 °C).

The second fraction gave crystals which were recrystallized from ethanol to give 50 mg (25%) of DL-1,2-di-*O*-acetyl-(1,3/2)-3-benzoyloxymethyl-4-cyclohexene-1,2-diol (**8**) as prisms: mp 76—78 °C.** ^{1}H NMR (90 MHz) δ=2.03 (6H, s, OAc), 4.20 (1H, dd, $J_{3,7}=5.5$ Hz, $J_{gem}=10.5$ Hz, H-7), 4.43 (1H, dd, $J_{3,7'}=5$ Hz, H-7′), 5.10 (1H, td, $J_{1,2}=J_{1,6ax}=11$ Hz, $J_{1,6eq}=6$ Hz, H-1), 5.28 (1H, t, $J_{2,3}=11$ Hz, H-2), 5.50—5.79 (2H, m, H-4 and H-5), 7.28—7.66 (3H, m) and 7.95—8.11 (2H, m) (phenyl).

Found: C, 65.15; H, 6.07%. Calcd for $C_{18}H_{20}O_6$: C, 65.05; H, 6.07%.

Reaction of 3 with Sodium Benzoate in DMF. A mixture of **3** (0.30 g), sodium benzoate (0.35 g), lithium bromide (0.17 g), and dry DMF (10 ml) was stirred at 120—130 °C for 1 h, and then concentrated. The residue was extracted with ethyl acetate and the extracts was passed through a short column of alumina. The filtrate was concentrated to give an oil (0.27 g), which was chromatographed on a silica-gel column (15 g) with ethyl acetate–hexane (1 : 4) as an eluent. The first fraction gave 32 mg (19%) of DL-*trans*-4,5-diacetoxy-3-methylene-1-cyclohexene (**10**) as an oil. ^{1}H NMR (90 MHz) δ=2.00 (3H, s) and 2.08 (3H, s) (OAc), 2.63 (1H, br dt, $J_{1,6eq}=J_{5,6eq}=5$ Hz, $J_{gem}=16.5$ Hz, H-6eq), 4.90—5.12 (3H, m, H-5 and exocyclic methylene), 5.35—5.73 (2H, m, H-4 and H-5), 6.13

** Determined on a Büchi 510 capillary melting point apparatus.

(1H, br d, $J_{1,2}=10$ Hz, H-2). This compound was identical with a sample later derived by an unequivocal route.

The second fraction gave 97 mg (36%) of **7**. The third fraction gave 70 mg (26%) of **8**. The fourth fraction gave crystals which were recrystallized from ethanol to give 28 mg (8%) of DL-1,2-di-*O*-acetyl-5-*O*-benzoyl-(1,3,5/2)-3-benzoyloxymethyl-1,2,5-cyclohexanetriol (**9**) as needles: mp 126—128 °C. ^{1}H NMR (90 MHz) $\delta=2.02$ (3H, s) and 2.04 (3H, s) (OAc), 4.23 (1H, dd, $J_{3,7}=4.5$ Hz, $J_{gem}=11$ Hz, H-7), 4.40 (1H, dd, $J_{3,7'}=4$ Hz, H-7'), 4.86—5.30 (3H, m, H-1, H-2, and H-5), 7.32—8.18 (10H, m, phenyl).

Found: C, 66.28; H, 5.89%. Calcd for $C_{25}H_{26}O_8$: C, 66.07; H, 5.77%.

DL-(1,3,5/2)-5-Bromo-3-bromomethyl-1,2-cyclohexanediol (5). A mixture of **3** (15.0 g) and ethanol (300 ml) containing 47% hydrobromic acid (30 ml) was heated at reflux for 6 h. The reaction mixture was neutralized with 2 M sodium hydroxide (120 ml) and concentrated until precipitates appeared. The solution was extracted with chloroform (100 ml), and the extracts were washed with water thoroughly and dried. Evaporation of the solvent gave crystals which were recrystallized from chloroform to give 11.0 g (95%) of **5** as needles: mp 108—110 °C.

Found: C, 29.37; H, 4.05; Br, 55.71%. Calcd for $C_7H_{12}Br_2O_2$: C, 29.20; H, 4.20; Br, 55.49%.

DL-1,2-O-Isopropylidene-(1,3,5/2)-5-bromo-3-bromomethyl-1,2-cyclohexanediol (6). To a solution of **5** (7.0 g) in dry DMF (80 ml) was added 2,2-dimethoxypropane (30 ml) and a catalytic amount of *p*-toluenesulfonic acid, and the mixture was heated at 70—80 °C for 2 h. The reaction mixture was concentrated with a small amount of sodium hydrogencarbonate to give an oil which was dissolved in chloroform and passed through a short column of alumina. The filtrate was concentrated and the residue was crystallized from ethanol to give 7.7 g (97%) of **6** prisms: mp 59—60.5 °C.

Found: C, 36.88; H, 4.90; Br, 48.89%. Calcd for $C_{10}H_{16}Br_2O_2$: C, 36.61; H, 4.92; Br, 48.72%.

Reaction of 6 with Sodium Benzoate in DMF. A mixture of **6** (0.50 g), sodium benzoate (0.55 g), lithium bromide (0.16 g), and dry DMF (10 ml) was stirred at 105—110 °C for 2 h. The reaction mixture was processed similarly as described in the reaction of **3** and the products were fractionated by chromatography on silica gel with 2-butanone–toluene (1 : 30) as an eluent.

The first fraction gave 0.26 g (60%) of DL-1,2-*O*-isopropylidene-(1,3/2)-3-benzoyloxymethyl-4-cyclohexene-1,2-diol (**11**) as an oil. ^{1}H NMR (90 MHz) $\delta=1.44$ (6H, s, isopropylidene), 3.47 (1H, t, $J_{1,2}=J_{2,3}=9$ Hz, H-2), 3.72 (1H, td, $J_{1,6eq}=5$ Hz, $J_{1,6ax}=9$ Hz, H-1), 4.28 (1H, dd, $J_{3,7}=7$ Hz, $J_{gem}=11$ Hz, H-7), 4.57 (1H, dd, $J_{3,7'}=5$ Hz, H-7'), 5.51—5.56 (2H, m, H-4 and H-5), 7.28—7.73 (3H, m) and 8.00—8.26 (2H, m) (phenyl). Compound **11** did not give a satisfactory analytical data, and the mass spectrum was measured:[13] Found: *m/e* 194.1295. Calcd for $C_{17}H_{20}O_4$: M$^+$ 194.1307.

Compound **11** (4.6 g) was treated with 50% aqueous acetic acid (50 ml) at room temperature for 30 min. and then mixture was concentrated. The residue was treated with acetic anhydride (20 ml) and pyridine (30 ml) at room temperature overnight. The reaction mixture was concentrated and the product was recrystallized from ethanol to give 5.1 g (96%) of **8**, identical with the compound obtained before.

The second fraction gave 72 mg (12%) of DL-5-*O*-benzoyl-1,2-*O*-isopropylidene-(1,3,5/2)-3-benzoyloxymethyl-1,2,5-cyclohexanetriol (**12**) as an oil. ^{1}H NMR (90 MHz) $\delta=1.44$ (6H, s, isopropylidene), 3.32 (1H, t, $J_{1,2}=J_{2,3}=9$ Hz, H-2), 3.52 (1H, td, $J_{1,6eq}=3$ Hz, $J_{1,6ax}=9$ Hz, H-1), 4.22 (1H, dd $J_{3,7}=6.5$ Hz, $J_{gem}=11$ Hz) and 4.49 (1H, dd, $J_{3,7'}=3.5$ Hz) (C$\underline{H}_2$OBz), 5.20 (1H, tt, $J_{4eq,5}=J_{5,6eq}=5$ Hz, $J_{4ax,5}=J_{5,6ax}=11$ Hz H-5).

The third fraction gave 31 mg (6%) of DL-5-*O*-benzoyl-1,2-*O*-isopropylidene-(1,3/2,5)-3-benzoyloxymethyl-1,2,5-cyclohexanetriol (**13**) as an oil. ^{1}H NMR (90 MHz) $\delta=1.47$, (6H, s, isopropylidene), 3.35 (1H, dd, $J_{1,2}=9$ Hz, $J_{2,3}=10.5$, Hz, H-2), 3.88 (1H, ddd, $J_{1,6eq}=4$ Hz, $J_{1,6ax}=11$ Hz, H-1) 4.33 (1H, dd, $J_{3,7}=6$ Hz, $J_{gem}=11$ Hz) and 4.56 (1H, dd, $J_{3,7'}=5$ Hz) (C$\underline{H}_2$OBz), 5.58 (1H, quintet, $J=3$ Hz, H-5).

Found for **12**: *m/e* 395.1523, and for **13**: *m/e* 410.1754, 395.1475. Calcd for $C_{24}H_{26}O_6$: M$^+$, 410.1728, M$^+-15$, 395.1493.

Oxidation of 8 with Osmium Tetraoxide. To a solution of **8** (0.10 g) in *t*-butyl alcohol (2.2 ml) containing 6% hydrogen peroxide was added a solution of osmium tetraoxide (0.65 ml, 0.013 mmol), and the mixture was stirred at room temperature for 20 h. The reaction mixture was diluted with water (2 ml) and sodium sulfite was added until the peroxide was consumed. The mixture was concentrated and the residue was acetylated in the usual way. The product was chromatographed on a silica-gel column with 2-butanone–toluene (1 : 12) as an eluent. The first fraction gave crystals which were recrystallized from ethanol to give 42 mg (38%) of DL-1,2,4,5-tetra-*O*-acetyl-(1,2,4/3,5)-3-benzoyloxymethyl-1,2,4,5-cyclohexanetetrol (**14**) as prisms: mp 145—146 °C. ^{1}H NMR (90 MHz) $\delta=1.98$ (3H, s), 1.99 (3H, s), 2.02 (3H, s), and 2.10 (3H, s) (OAc), 4.28 (2H, m, C$\underline{H}_2$OBz), 4.90 (1H, dd, $J_{1,2}=3$ Hz, $J_{2,3}=11$ Hz, H-2), 5.03—5.30 (2H, m, H-4 and H-5), 5.40 (1H, q, $J=3$ Hz, H-5), 7.11—7.99 (5H, m, phenyl).

Found: C, 58.69; H, 5.89%. Calcd for $C_{22}H_{26}O_{10}$: C, 58.66; H, 5.82%.

The second fraction gave crystals which were recrystallized from ethanol to give 5.4 mg (5.2%) of DL-*r*-4,*c*-6-diacetoxy-*t*-5-benzoyloxymethyl-2-cyclohexanone (**15**) as prisms: mp 109—110 °C. ^{1}H NMR (90 MHz) $\delta=2.10$ (3H, s) and 2.15 (3H, s) (OAc), 2.75 (1H, ddd, $J_{4,5}=10$ Hz, $J_{5,6}=13$ Hz, $J_{5,7}=3$ Hz, H-5), 4.39 (2H, d, $J=3$ Hz, C$\underline{H}_2$OBz), 5.45 (1H, d, H-6), 5.77 (1H, ddd, $J_{2,4}=2$ Hz, $J_{3,4}=2.5$ Hz, H-4), 6.10 (1H, dd, $J_{2,3}=10.5$ Hz, H-3), 6.77 (1H, dd, H-2).

Found: C, 62.17; H, 5.36%. Calcd for $C_{18}H_{18}O_7$: C, 62.42; H, 5.24%.

DL-4,5-Di-O-acetyl-1,2-anhydro-(1,2,3,5/4)-3-benzoyloxymethyl-1,2,4,5-cyclohexanetetrol (16). A suspension of **8** (1.0 g), *m*CPBA (1.06 g, *ca.* 1.5 molar equiv), and sodium hydrogencarbonate (0.72 g) in 1,2-dichloroethane (20 ml) was vigorously stirred at room temperature for 18 h. The reaction mixture was diluted with water (20 ml) and sodium sulfite was added to destroy the peracid. The organic layer was washed with water thoroughly and dried. Evaporation of the solvent gave crystals which were recrystallized from ethanol to give 0.84 g (80%) of **16** as needles: mp 96—99 °C. ^{1}H NMR (90 MHz) $\delta=2.01$ (6H, s, OAc), 3.18 (1H, t, $J_{1,2}=J_{2,3}=4.5$ Hz, H-2), 3.40 (1H, ddd, $J_{1,6eq}=3.5$ Hz, $J_{1,6ax}=6.5$ Hz, H-1), 4.37 (1H, dd, $J_{3,7}=7$ Hz, $J_{gem}=11$ Hz, H-7), 4.56 (1H, dd, $J_{3,7'}=5$ Hz, H-7'), 4.82 (1H, td, $J_{4,5}=J_{5,6ax}=9.5$ Hz, $J_{5,6eq}=7.5$ Hz, H-5), 5.11 (1H, t, $J_{3,4}=9.5$ Hz H-4), 7.30—7.58 (3H, m) and 7.96—8.12 (3H, m) (phenyl).

Found: C, 61.92; H, 5.81%. Calcd for $C_{18}H_{20}O_7$: C, 62.06; H, 5.79%.

A trace of a stereoisomeric epoxide (8 mg, 7%) was obtained as an oil. ^{1}H NMR (90 MHz) $\delta=2.02$ (3H, s) and 2.07 (3H, s) (OAc), 3.07 (1H, d, $J_{1,2}=3.5$ Hz, H-2), 3.30 (1H, m, H-1), 4.35 (1H, dd, $J_{3,7}=3$ Hz, $J_{gem}=10$ Hz, H-7), 4.72 (1H, dd, $J_{3,7'}=4$ Hz, H-7'), 4.78—5.16 (2H, m, H-4 and H-5), 7.32—7.60 (3H, m) and 7.98—8.14 (2H, m) (phenyl).

DL-1,2-Di-O-acetyl-(1,3,4/2,5)-3-benzoyloxymethyl-5-chloro-1,2-

4-cyclohexanetriol (17). A mixture of **16** (0.10 g), sodium acetate (47 mg), and ammonium chloride (46 mg) in 90% aqueous 2-methoxyethanol (5 ml) was heated at 80 °C for 5 h, and then concentrated. The residue was treated with acetic anhydride and pyridine in the usual way. The product was purified by a silica-gel column with 2-butanone–toluene (1 : 10) as an eluent. The main fraction gave crystals which were recrystallized from ethanol to give 54 mg (44%) of **17**: mp 96—97 °C. ^{1}H NMR (90 MHz) δ=2.07 (3H, s) and 2.10 (6H, s) (OAc), 2.80—3.20 (1H, m, H-3), 4.25—4.70 (3H, m, H-5 and C$\underline{H}_2$OBz), 5.30—5.65 (2H, m, H-1 and H-2).

Found: C, 56.55; H, 5.40; Cl, 8.55%. Calcd for $C_{20}H_{23}ClO_8$: C, 56.28; H, 5.43; Cl, 8.31%.

DL-*1,2-Di*-O-*acetyl-(1,3,4/2,5)-5-azido-3-benzoyloxymethyl-1,2,4-cyclohexanetriol (18).* A mixture of **16** (0.20 g), sodium azide (0.11 g), ammonium chloride (0.11 g), and 90% aqueous 2-methoxyethanol (10 ml) was stirred at 75 °C for 3 h, and then concentrated. The residue was taken up in chloroform (20 ml) and the solution was filtered through a short column of alumina. The filtrate was concentrated and the residue was chromatographed on a silica-gel column (10 g) with 2-butanone–toluene (1 : 10) as an eluent. The main fraction gave crystals which were recrystallized from ethanol to give 0.17 g (76%) of **18** as needles: mp 107—109 °C. ^{1}H NMR (90 MHz) δ=2.00 (3H, s) and 2.03 (3H, s) (OAc), 3.35 (1H, d, J=4.5 Hz, OH), 3.83 (1H, q, J=2.5 Hz, H-5), 3.95 (1H, t, J=2.5 Hz, H-4), 4.20 (1H, dd, $J_{3,7}$=4.5 Hz, J_{gem}=11.5 Hz, H-7), 4.65 (1H, dd, $J_{3,7'}$=9 Hz, H-7'), 5.09 (1H, td, $J_{1,2}$=$J_{1,6ax}$=9 Hz, $J_{1,6eq}$=7.5 Hz, H-1), 5.29 (1H, t, $J_{2,3}$=9 Hz, H-2), 7.33—7.74 (3H, m) and 7.98—8.17 (2H, m) (phenyl).

Found: C, 54.97; H, 5.41; N, 10.45%. Calcd for $C_{18}H_{21}N_3O_7$: C, 55.24; H, 5.41; N, 10.74%.

DL-*1,2,4-Tri*-O-*acetyl-(1,3,4/2,5)-5-azido-3-benzoyloxymethyl-1,2,4-cyclohexanetriol (19).* Compound **18** (49 mg) was treated with acetic anhydride and pyridine in the usual way. The product was purified by passage through a short column of alumina with chloroform, giving 55 mg (100%) of **19** as an oil. ^{1}H NMR (90 MHz) δ=2.02 (3H, s) and 2.04 (6H, s) (OAc), 3.94 (1H, q, J=3.5 Hz, H-5), 4.10—4.50 (2H, m, C$\underline{H}_2$OBz), 7.36—7.73 (3H, m) and 7.98—8.17 (phenyl).

Found: C, 55.55; H, 5.43; N, 9.46%. Calcd for $C_{20}H_{23}N_3O_8$: C, 55.42; J, 5.35; N, 9.70%.

DL-*1,2-Di*-O-*acetyl-4*-O-*methylsulfonyl-(1,3,4/2,5)-5-azido-3-benzoyloxymethyl-1,2,4-cyclohexanetriol (20).* To a solution of **18** (0.17 g) in pyridine (3 ml) was added methanesulfonyl chloride (0.067 ml) dropwise under ice cooling, and then the mixture was stirred at room temperature for 16 h. Ethyl acetate (6 ml) was added to the mixture and it was washed thoroughly with saturated sodium hydrogencarbonate and water and dried. Removal of the solvent gave a crude product which was chromatographed on a silica-gel column with 2-butanone–toluene. The main fraction gave 177 mg (87%) of **21** as an oil. ^{1}H NMR (90 MHz) δ=2.03 (3H, s) and 2.06 (3H, s) (OAc), 3.07 (3H, s, OMe), 4.94 (1H, dd, $J_{3,4}$=3 Hz, $J_{4,5}$=3.5 Hz, H-4).

Found: C, 48.77; 5.05; N, 8.69; S, 6.63%. Calcd for $C_{19}H_{23}N_3O_9S$: C, 48.61; H, 4.94; N, 8.95; S, 6.83%.

DL-*1,2,4-Tri*-O-*acetyl-(1,3,4/2,5)-5-acetamido-3-benzoyloxymethyl-1,2,4-cyclohexanetriol (21).* A solution of **19** (55 mg) in ethanol (6 ml) in the presence of Raney nickel T-4[14] was hydrogenated in Parr shaker type apparatus in the initial hydrogen pressure of 3.4 kg/cm^2 at room temperature for 32 h. The product was acetylated in the usual way and purified by chromatography on silica gel with ethanol–toluene (1 : 10). The main fraction gave 35 mg (60%) of **21** as an oil. ^{1}H NMR (90 MHz) δ=1.97 (3H, s), 2.03 (6H, s), and 2.04 (3H, s) (NAc and OAc), 6.05 (1H, br d, J=7.5 Hz, NH).

Found: C, 58.50; H, 6.25; N, 2.97%. Calcd for $C_{22}H_{27}NO_9$: C, 58.79; H, 6.06; N, 3.12%.

Ammonolysis of 16. A mixture of **16** (0.10 g) and ethanol (10 ml) saturated with ammonia at 5 °C was heated in a sealed tube at 90 °C for 15 h. The reaction mixture was concentrated and the residue was treated with acetic anhydride and pyridine in the usual way. Excess reagent was removed by evaporation and the products (0.17 g) were fractionated by chromatography on silica gel (8 g) with ethanol–toluene (1 : 12) as an eluent.

The first fraction gave 25 mg (19%) of DL-1,2,5-tri-*O*-acetyl-(1,3,5/2,4)-4-acetamido-3-benzoyloxymethyl-1,2,5-cyclohexanetriol (**24**) as crystals: mp 136—140 °C. ^{1}H NMR (90 MHz) δ=2.03 (3H, s), 2.06 (6H, s), and 2.09 (3H, s) (NAc and OAc), 4.14 (1H, dd, $J_{3,7}$=6.5 Hz, J_{gem}=11 Hz, H-7), 4.32 (1H, dd, $J_{3,7'}$=7 Hz, H-7'), 4.46 (1H, 0.3 ppm width m, H-4), 4.90—5.45 (3H, m, H-1, H-2, and H-5), 6.44 (1H, br d, J=7.5 Hz, NH), 7.39—7.57 (3H, m) and 7.70—7.90 (2H, m) (phenyl).

Found: C, 58.50; H, 6.25; N, 2.97%. Calcd for $C_{22}H_{27}NO_9$: C, 58.79; H, 6.06; N, 3.12%.

The second fraction gave 22 mg (17%) of **21** as an oil, identical with the compound obtained before.

The third fraction gave 41 mg (31%) of DL-1,2,4,7-tetra-*O*-acetyl-(1,3,4/2,5)-5-acetamido-3-hydroxymethyl-1,2,4-cyclohexanetriol (**22**) as an oil. ^{1}H NMR (90 MHz) δ=2.00 (3H, s), 2.04 (9H, s), and 2.10 (3H, s) (NAc and OAc), 4.04 (1H, dd, $J_{3,7}$=6 Hz, J_{gem}=11 Hz, H-7), 4.23 (1H, dd, $J_{3,7'}$=7 Hz, H-7'), 4.02—4.31 (1H, m, H-5), 4.88—5.34 (3H, m, H-1, H-2, and H-4), 6.10 (1H, m, NH).

Found: C, 52.76; H, 6.56; N, 3.45%. Calcd for $C_{17}H_{25}NO_9$: C, 52.71; H, 6.51; N, 3.62%.

DL-*1,2-Di*-O-*acetyl-(1/2,5)-5-azido-3-benzoyloxymethyl-3-cyclohexene-1,2-diol (28).* A mixture of **20** (157 mg), DBU (0.15 ml), and toluene (9 ml) was refluxed for 6 h. The reaction mixture was washed successively with 1 M hydrochloric acid, saturated sodium hydrogencarbonate, and water, and dried. The solvent was removed and the crude product was chromatographed on a silica-gel column with 2-butanone–toluene (1 : 10) to give 95 mg (76%) as an oil. ^{1}H NMR (90 MHz) δ=2.00 (3H, s) and 2.03 (3H, s) (OAc), 4.10 (1H, m, H-5), 4.76 (2H, br s, C$\underline{H}_2$OBz), 5.12 (1H, ddd, $J_{1,2}$=5 Hz, $J_{1,6eq}$=3.5 Hz, $J_{1,6ax}$=7 Hz, H-1), 5.45 (1H, br d, H-2), 6.12 (1H, br d, $J_{4,5}$=3 Hz, H-4).

Found: C, 57.71; H, 5.18; N, 11.03%. Calcd for $C_{18}H_{19}N_3O_6$: C, 57.90; H, 5.13; N, 11.25%.

DL-*1,2-Di*-O-*acetyl-(1,2/5)-5-acetamido-3-benzoyloxymethyl-3-cyclohexene-1,2-diol (29).* To a solution of **28** (62 mg) in pyridine (1.5 ml) and water (1.5 ml) was bubbled with hydrogen sulfide for 2 h. Nitrogen was introduced to remove an excess of hydrogen sulfide for 30 min, and the mixture was concentrated. The residue was acetylated in the usual way and purified by chromatography on silica gel with ethanol–toluene (1 : 10). The main fraction gave crystals which were recrystallized from ethanol to give 43 mg (65%) of **24** as crystals: mp 135—136 °C. ^{1}H NMR (90 MHz) δ=1.96 (6H, s) and 2.00 (3H, s) (NAc and OAc), 4.72 (2H, br s, C$\underline{H}_2$OBz), 5.09 (1H, ddd, $J_{4,5}$=5 Hz, $J_{5,6eq}$=3.5 Hz, $J_{5,6ax}$=8 Hz, H-5), 5.41 (1H, br d, H-4), 6.00 (1H, d, NH), 6.03 (1H, br d, $J_{1,2}$=3.5 Hz, H-2).

Found: C, 61.87; H, 6.07; N, 3.52%. Calcd for $C_{20}H_{23}NO_7$: C, 61.69; H, 5.95; N, 3.60%.

DL-*1,2-Di*-O-*acetyl-(1,3,4/2,5)-3-benzoyloxymethyl-4,5-dibromo-1,2-cyclohexanediol (23).* To a solution of **8** (0.10 g) in carbon tetrachloride (2 ml) was added bromine (0.1 ml) in carbon tetrachloride (2 ml) and the mixture was stirred at room temperature for 2 h. The reaction mixture was treated with Amberlite IRA-400 (OH^-) (3 ml) and then concentrated

to give a crude oil which was crystallized from ethanol to give 70 mg (47%) of **23** as crystals: mp 109—110 °C. ^{1}H NMR (90 MHz) δ=2.00 (3H, s) and 2.03 (3H, s) (OAc), 4.23 (1H, dd, $J_{3,7}$=8 Hz, J_{gem}=11 Hz, H-7), 4.47 (1H, dd, $J_{3,7'}$=5.5 Hz, H-7'), 4.56—4.76 (2H, m, H-4 and H-5), 5.18—5.60 (2H, m, H-1 and H-2), 7.12—8.03 (5H, m, phenyl).

Found: C, 43.79; H, 4.09; Br, 32.15%. Calcd for $C_{18}H_{20}Br_2O_6$: C, 43.93; H, 4.10; Br, 32.47%.

DL-*1,2-Di-O-acetyl-(1,5/2)-5-azido-3-benzoyloxymethyl-3-cyclohexene-1,2-diol (30).* A mixture of **23** (0.28 g), sodium azide (91 mg), and DMF (10 ml) was stirred at 120 °C for 30 min. The reaction mixture was concentrated to give a solid residue which was suspended with chloroform and passed through a short column of silica gel. The filtrate was concentrated to give 0.19 g (91%) of **30** as an oil. ^{1}H NMR (90 MHz) δ=2.00 (3H, s) and 2.04 (3H, s) (OAc), 3.94—4.23 (1H, m, H-5), 4.75 (2H, s, C<u>H</u>$_2$OBz), 5.00 (1H, ddd, $J_{1,2}$=7 Hz, $J_{1,6eq}$=3 Hz, $J_{1,6ax}$=9.5 Hz, H-1), 5.62 (1H, br d, H-2), 5.99 (1H, br s, H-4), 7.13—8.04 (5H, m, phenyl).

Found: C, 58.03; H, 5.28; N, 11.31%. Calcd for $C_{19}H_{19}N_3O_6$: C, 57.91; H, 5.13; N, 11.25%.

DL-*1,2-Di-O-acetyl-(1,5/2)-5-acetamido-3-benzoyloxymethyl-3-cyclohexene-1,2-diol (21).* Compound **30** (0.13 g) was reduced similarly as described in the preparation of **29**. The crude amine was acetylated in the usual way and the product was purified by chromatography on silica gel with chloroform and then with ethanol–toluene (1 : 5) as an eluent . The main fraction gave crystals which were recrystallized from ethanol to give 80 mg (58%) of **31** as crystals: mp 162—163 °C. ^{1}H NMR (90 MHz) δ=1.93 (3H, s), 1.99 (3H, s), and 2.00 (3H, s) (NAc and OAc), 4.69 (2H, s, C<u>H</u>$_2$OBz), 5.50—5.76 (2H, m, H-1 and H-2), 5.90 (1H, br s, H-4), 7.11—8.01 (5H, m, phenyl).

Found: C, 61.59; H, 6.01; N, 3.80%. Calcd for $C_{20}H_{23}NO_7$: C, 61.69; H, 5.96; N, 3.60%.

DL-*1,2-Di-O-acetyl-5-O-benzoyl-(1,5/2)-3-benzoyloxymethyl-3-cyclohexene-1,2,5-triol (34).* A mixture of **23** (0.10 g), sodium benzoate (44 mg), and DMF (5 ml) was stirred at 120 °C for 30 min, and then concentrated. The residue was suspended in ethyl acetate and the mixture was passed through a short column of silica gel. The filtrate was concentrated and the residue was recrystallized from ethanol to give 57 mg (62%) of **34** as crystals: mp 107—108.5 °C. ^{1}H NMR (90 MHz) δ=2.04 (6H, s, OAc), 4.82 (2H, s, C<u>H</u>$_2$OBz), 5.15 (1H, ddd, $J_{1,2}$=6.5 Hz, $J_{1,6eq}$=3.5 Hz, $J_{1,6ax}$=9 Hz, H-1), 5.55—5.90 (2H, m, H-2 and H-5), 6.18 (1H, br s, H-4), 7.22—8.10 (10H, m, phenyl).

Found: C, 66.41; H, 5.38%. Calcd for $C_{25}H_{24}O_8$: C, 66.36; H, 5.35%.

Compound **34** was *O*-deacylated by treatment with methanolic sodium methoxide in methanol and then acetylated in the usual way to give the tetraacetate **35** as an oil. ^{1}H NMR (60 MHz) δ=1.96 (3H, s) and 1.99 (9H, s) (OAc), 4.29 (1H, d) and 4.61 (1H, d) (J_{gem}=12 Hz, C<u>H</u>$_2$OAc), 4.97 (1H, ddd, $J_{1,2}$=6 Hz, $J_{1,6eq}$=4 Hz, $J_{1,6ax}$=10 Hz, H-1), 5.53 (1H, br d, H-2), 5.20—5.50 (1H, m, H-5), 5.85 (1H, br s, H-4).

Found: C, 54.45; H, 5.95%. Calcd for $C_{15}H_{20}O_8$: C, 54.87; H, 6.14%.

*Alternative Preparation of **10** from **3**.* A mixture of **3** (3.0 g), DBU (6 ml), and toluene (6 ml) was refluxed for 90 min, and then allowed to stand in a refrigerator overnight. Precipitates were removed by filtration and the filtrate was washed successively with 1 M hydrochloric acid, saturated sodium hydrogencarbonate, and water, and dried. Evaporation of the solvent gave 1.28 g (76%) of **10** as an oil, identical with the sample obtained before by the different reaction conditions.

Compound **10** (0.80 g) was *O*-deacylated by treatment with methanolic sodium methoxide to give the dihydroxy compound: ^{1}H NMR (90 MHz, CD_3OD) δ=2.13 (1H, br dd, $J_{5,6ax}$=18 Hz, H-6ax), 2.51 (1H, dt, $J_{1,6eq}$=$J_{5,6eq}$=5.5 Hz, H-6eq), 3.60 (1H, ddd, $J_{4,5}$=9 Hz, H-5), 4.00 (1H, dt, $J_{4,7}$=$J_{4,7'}$=2.5 Hz, H-4), 4.98 (1H, br s) and 5.25 (1H, br s) (exocyclic methylene), 5.63 (1H, m, H-1), 6.12 (1H, br d, $J_{1,2}$=*ca.* 10 Hz, H-2). It was then treated with *p*-nitrobenzoyl chloride in pyridine in the usual way to give, after recrystallization from ethanol, 0.75 g of the bis(*p*-nitrobenzoate): mp 187—188 °C.

Found: C, 59.16; H, 3.95; N, 6.36%. Calcd for $C_{21}H_{16}N_2O_8$: C, 59.44; H, 3.80; N, 6.60%.

*Reaction of **10** with Bromine in Carbon Tetrachloride.* To a cooled solution of **10** (1.99 g) in carbon tetrachloride (25 ml) was added a solution (2 ml) of bromine–carbon tetrachloride (1 : 3, v/v), and the mixture was stirred at −8 °C for 30 min. The mixture was concentrated and the products were roughly fractionated by a silica-gel column with 2-butanone–toluene (1 : 6) as an eluent. The main fraction gave 1.8 g (54%) of a mixture of DL-1,2-di-*O*-acetyl-(1/2,5)- (**26**) and (1,5/2)-5-bromo-3-bromomethyl-3-cyclohexene-1,2-diol (**27**): ^{1}H NMR (90 MHz) δ=2.03 (3H, s) and 2.10 (3H, s) (OAc), 2.36 (2H, br t, $J_{1,6}$=9 Hz, $J_{5,6}$=8 Hz, H-6 and H-6'), 3.91 (2H, br s, C<u>H</u>$_2$Br), 4.75 (1H, br q, J=8 Hz, H-5), 5.23 (1H, q, J=9 Hz, H-1), 5.71 (1H, d, $J_{1,2}$=9 Hz, H-2), 6.19 (1H, d, $J_{4,5}$=8 Hz, H-4). The spectrum showed that **26** was the major product. Attempts to prepare a pure sample by chromatography failed, because of the high lability. Therefore, a crude mixture was directly used in the following experiments.

A trace of a tetrabromide was obtained: mp 158—160 °C; ^{1}H NMR (60 MHz) δ=2.05 (3H, s) and 2.15 (3H, s) (OAc), 3.65 (1H, d) and 4.15 (1H, d) (J=12 Hz, C<u>H</u>$_2$Br).

Found: C, 25.08; H, 2.70; Br, 60.49%. Calcd for $C_{11}H_{14}Br_4O_4$: C, 24.94; H, 2.66; Br, 60.32%.

*Reaction of **26** and **27** with Sodium Benzoate.* A mixture of **26** and **27** (1.29 g), sodium benzoate (2.0 g), and 90% aqueous DMF (9 ml) was stirred at room temperature overnight. Water was added and the mixture was extracted with ethyl acetate (30 ml). The extracts were dried and concentrated to give crystals which were recrystallized from ethanol to give 0.30 g (30%) of **34**: mp 100—101 °C, identical with a sample derived from **23**.

*Reaction of **26** and **27** with Potassium Phthalimide.* A mixture of **26** and **27** (0.53 g), potassium phthalimide (1.06 g), and DMF (15 ml) was stirred at room temperature overnight. The reaction mixture was diluted with ethyl acetate and washed with water thoroughly. The organic layer was dried and concentrated to give crystals. Recrystallization from ethyl acetate gave 0.42 g (58%) of DL-1,2-di-*O*-acetyl-(1,5/2)-5-phthalimido-3-phthalimidomethyl-3-cyclohexene-1,2-diol (**36**) as crystals: mp 206—207 °C. ^{1}H NMR (60 MHz) δ=1.97 (3H, s) and 2.10 (3H, s) (OAc), 4.06 (1H, d) and 4.50 (1H, d) (J=15 Hz, C<u>H</u>$_2$N), 7.76 (8H, m, phenyl).

Found: C, 64.31; H, 4.59; N, 5.65%. Calcd for $C_{27}H_{22}N_2O_8$: C, 64.55; H, 4.41; N, 5.57%.

DL-*1,2-Di-O-acetyl-(1,5/2)-5-acetamido-3-acetamidomethyl-3-cyclohexene-1,2-diol (37).* A mixture of **36** (0.50 g), butylamine (10 ml), and methanol (20 ml) was refluxed for 60 h, and then concentrated. The residue was acetylated in the usual way to give, after crystallization from ethanol, 0.32 g (98%) of **37** as crystals: mp 193—194 °C. ^{1}H NMR (60 MHz) δ=1.98 (6H, s), 2.03 (3H, s), and 2.08 (3H, s) (NAc and OAc), 3.76 (2H, d, $J_{7,NH}$=9 Hz, C<u>H</u>$_2$NHAc), 5.05 (1H, ddd, $J_{1,2}$=7 Hz, $J_{1,6eq}$=4 Hz, $J_{1,6ax}$=9.5 Hz, H-1), 5.49 (1H, d, H-2), 5.71 (1H, br s, H-4), 6.10—6.50 (2H, m, N<u>H</u>Ac).

Found: C, 54.95; H, 6.64; N, 8.37%. Calcd for $C_{15}H_{22}N_2O_6$: C, 55.20; H, 6.80; N, 8.58%.

DL-*2,3-Di-O-acetyl-1,7-anhydro-(1,2/3)-1-C-hydroxymethyl-5-cyclohexene-1,2,3-triol (25)*. A mixture of **10** (2.0 g), *m*CPBA (3.2 g), dichloromethane (60 ml), and phosphate buffer solution[15] (pH 8) (150 ml) was stirred vigorously at room temperature for 2 h. The organic layer was washed successively with aqueous sodium sulfite, sodium hydrogencarbonate, and water, and dried. The solution was concentrated to give crystals which were recrystallized from ethanol–ether to give 1.0 g (47%) of **25** as crystals: mp 91—92 °C. ^{1}H NMR (90 MHz) δ=2.01 (3H, s) and 2.09 (3H, s) (OAc), 2.37 (1H, m, H-4), 2.60 (1H, m, H-4'), 2.82 and 2.91 (AB-quartet, J=4.5 Hz, C$\underline{H}_2$O), 5.10—5.40 (3H, m, H-2, H-3, and H-6), 5.92 (1H, dt, $J_{4,5}=J_{4',5}$=3.5 Hz, $J_{5,6}$=10.5 Hz, H-5).

Found: C, 58.13; H, 6.27%. Calcd for $C_{11}H_{14}O_5$: C, 58.40; H, 6.24%.

DL-*1,2,3-Tri-O-acetyl-(1,2/3)-1-C-azidomethyl-5-cyclohexene-1,2,3-triol (38)*. A mixture of **25** (0.25 g), sodium azide (0.23 g), ammonium chloride (0.23 g), and DMF (10 ml) was stirred at 60 °C for 2 h, and then concentrated, The residual product was acetylated in the usual way in the presence of 4-diethylaminopyridine (0.20 g). An oily product was purified by chromatography on silica gel to give 0.40 g (92%) of **38** as an oil. ^{1}H NMR δ=2.00 (3H, s), 2.03 (3H, s), and 2.10 (3H, s) (OAc), 3.60 (1H, d) and 3.83 (1H, d) (J=12 Hz, C$\underline{H}_2N_3$), 5.25 (2H, br s, H-2 and H-3), 5.81 (1H, ddd, $J_{4,5}$= 3.5 Hz, $J_{4',5}$=4.5 Hz, $J_{5,6}$=10.5 Hz, H-5), 6.05 (1H, dt, $J_{4,6}$=2 Hz, H-6).

Found: C, 50.00; H, 5.47; N, 13.24%. Calcd for $C_{13}H_{17}N_3O_6$: C, 50.15; H, 5.51; N, 13.50%.

DL-*2,3-Di-O-acetyl-(1,2/3)-1-C-acetamidomethyl-5-cyclohexene-1,2,3-triol (39)*. Compound **38** (0.55 g) was reduced similarly as described in the preparation of **31**, and the product was acetylated in the usual way. The oily product was purified by a silica-gel column with 2-butanone–toluene (2 : 1) as an eluent to give 0.51 g (100%) of **39** as an oil. ^{1}H NMR (90 MHz) δ=1.93 (3H, s), 1.97 (3H, s), and 2.08 (3H, s) (NAc and OAc), 2.69 (1H, ddd, $J_{3,4}$=6 Hz, $J_{4,5}$=3 Hz, J_{gem}=18 Hz, H-4), 3.01 (1H, d) and 3.47 (1H, d) (J=13 Hz, C$\underline{H}_2$NHAc), 4.91 (1H, d, $J_{2,3}$=10.5 Hz, H-2), 5.25 (1H, td, $J_{3,4'}$=9 Hz, H-3), 5.63 (2H, br s, H-5 and H-6).

Found: C, 54.72; H, 6.32; N, 4.25%. Calcd for $C_{13}H_{19}NO_6$: C, 54.73; H, 6.71; N, 4.91%.

DL-*1,2-Di-O-acetyl-(1,5/2)-5-azido-3-acetoxymethyl-3-cyclohexene-1,2-diol (32)*. A mixture of **25** (0.46 g), sodium azide (0.9 g), acetone (20 ml), and water (12 ml) was added concd sulfuric acid (1 g), and the mixture was stirred at room temperature for 5 d. The reaction mixture was concentrated and the residue was treated with acetic anhydride and pyridine. The product was extracted with chloroform, and the extracts were washed with water, dried, and concentrated. The product was purified by chromatography on silica gel to give 0.28 g (48%) of **32** as an oil as a main product: ^{1}H NMR (90 MHz) δ=2.03 (9H, s, OAc), 4.07 (1H, m, H-5), 4.35 (1H, d) and 4.61 (1H, d) (J=13.5 Hz, C$\underline{H}_2$OAc), 4.98 (1H, ddd, $J_{1,2}$=7 Hz, $J_{1,6eq}$=4 Hz, $J_{1,6ax}$=10.5 Hz, H-1), and 5.53 (1H, d, H-2).

Found: C, 50.31; H, 5.51; N, 13.25%. Calcd for $C_{13}H_{17}N_3O_6$: C, 50.15; H, 5.51; N, 13.50%.

DL-*1,2-Di-O-acetyl-(1,5/2)-5-acetamido-3-acetoxymethyl-3-cyclohexene-1,2-diol (33)*. Compound **32** (0.42 g) was reduced with hydrogen sulfide similarly as described in the preparation of **29** and the product was acetylated in the usual way. The crude product was recrystallized from ethanol–ether to give 0.40 g (92%) of **33**: mp 148—149 °C; ^{1}H NMR (90 MHz) δ= 1.93 (3H, s) and 2.02 (9H, s) (NAc and OAc), 4.28 (1H, d) and 4.59 (1H, d) (J=13 Hz, C$\underline{H}_2$OAc), 4.70 (1H, br s, H-5), 5.00 (1H, ddd, $J_{1,2}$=7 Hz, $J_{1,6eq}$=4 Hz, $J_{1,6ax}$=10 Hz, H-1), 5.45 (1H, d, H-2), and 5.80 (2H, m, H-4 and NH).

Found: C, 54.80; H, 6.30; N, 4.42%. Calcd for $C_{15}H_{21}NO_7$: C, 55.04; H, 6.47; N, 4.28%.

The authors express their sincere thanks to Mr. Saburo Nakada for the elementary analyses. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 56550617 from the Ministry of Education, Science and Culture.

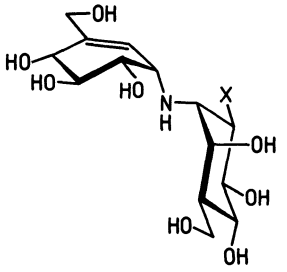
Synthetic Studies on the Validamycins. VIII. Synthesis of DL-2-Deoxyvalidoxylamine B and Related Compound[1,2]

Seiichiro OGAWA, Hiroyuki ITO, and Tetsuo SUAMI*
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223

(Received October 16, 1982)

DL-2-Deoxyvalidoxylamine B and its diastereomer have been synthesized by the reaction of the protected DL-valienamine and the anhydro derivative of (hydroxymethyl)cyclohexanetetrol followed by removal of the protecting groups.

In connection with the previous paper,[3] the synthesis of the 2-deoxy analog (**2**) of validoxylamine B (**1**) and its related compounds is described. In the present study, a nucleophilic substitution reaction of the protected DL-valienamine and the anhydro derivative of (hydroxymethyl)cyclohexanetetrol was undertaken to build up a pseudo-disaccharide structure.

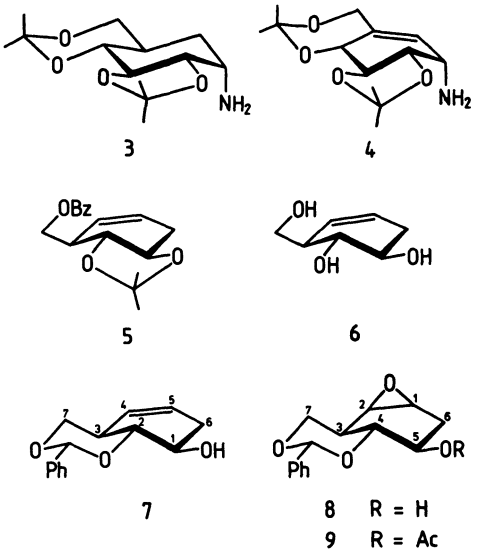


Validoxylamine B (1): X = OH
2-Deoxyvalidoxylamine B (2): X = H

Scheme 1.

DL-1,2-Anhydro-4,7-*O*-benzylidene-(1,2,3,5/4)-3-hydroxymethyl-1,2,4,5-cyclohexanetetrol (**8**) was prepared from DL-1,2-*O*-isopropylidene-(1,3/2)-3-benzoyloxymethyl-4-cyclohexene-1,2-diol (**5**)[1b] by the following sequence. *O*-Deacylation of **5** with methanolic sodium methoxide, followed by treatment with Amberlite IR-120B (H^+), gave the triol **6** in 76% yield. Treatment of **6** with α,α-dimethoxytoluene in *N*,*N*-dimethylformamide (DMF) in the presence of *p*-toluenesulfonic acid gave the benzylidene derivative **7** in 62% yield. Compound **7** was oxidized with *m*-chloroperoxybenzoic acid (*m*CPBA) to give almost specifically the β-epoxide **8** in 77% yield, together with a small proportion of the α-epoxide (9%). The mixture of the epoxides was directly treated with acetic anhydride in pyridine and the products were separated to give the acetate **9** of **8** in 88% yield. The structure of **8** was determined by the ^{1}H NMR spectrum, in which the C-4 proton resonated slightly lower field (δ 3.62) compared with that of the α-epoxide (δ 3.30), indicating that the C-4 proton which was situated close to the oxygen atom of the epoxide ring was deshielded by this moiety. The epoxidation seemed to be controlled by steric hindrance.

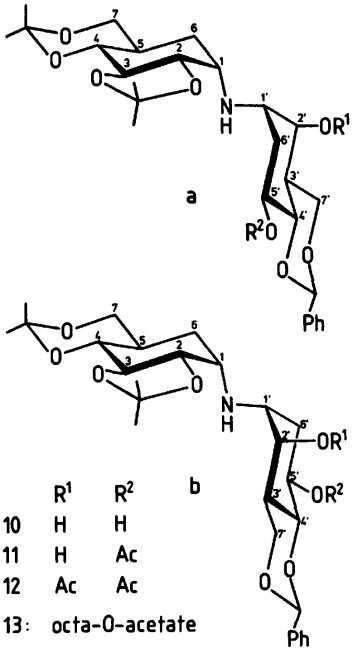
Reaction of an equimolar amount of the di-*O*-isopropylidene derivative (**3**)[4] of DL-validamine and **8** was carried out in 2-propanol in a sealed tube at



Scheme 2.

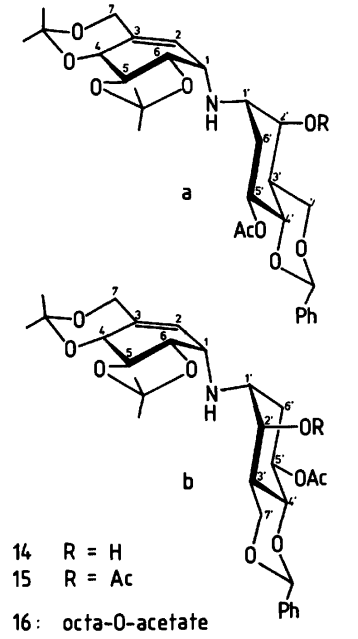
120 °C. After 44 h, the starting materials were almost consumed and the formation of two new components was observed by TLC. The products were fractionated by chromatography on silica gel with 2-butanone–toluene (1 : 30) as an eluent to give the diastereoisomeric secondary amines **10a** (42%) and **10b** (44%) as an oil. Their structures were supported by analytical data and ^{1}H NMR spectroscopy. The NMR spectral pattern was nearly identical with each other except for a small difference of the chemical shifts of the signals due to the C-1′ protons. Therefore, it was impossible to assign the exact structures to each diastereomers in this stage.

Next, the similar reaction of **3** and **9** was carried out to give an inseparable mixture of secondary amines **11a** and **11b** in 83% yield. Treatment of the mixture with acetic anhydride in pyridine gave the di-*O*-acetyl derivatives, which could clearly be separated by a silica gel column to give **12a** (31%) and **12b** (64%). The latter compound was shown to be identical with the bis(acetate) derived from **10b**. The structures of **12a** and **12b** were postulated on the basis of ^{1}H NMR spectroscopy, taking account of the data which had been observed to differentiate the diastereomers of validoxylamine A or B.[5,6] The ^{1}H NMR spectra of **12a** and **12b** revealed the signals for H-1′ as a quartet (J=3 Hz) at δ 2.94 and 3.07, and those for H-2′ as a doublet of doublets (J=2.5 and 3 Hz) at δ 4.72 and 4.93, respectively. The slight deshielding of the signals



Scheme 3.

observed for **12b** might be explained by a proximity of C-2′ proton to the oxygen atoms of the 2,3-*O*-isopropylidene group. Therefore, the structures of **12a** and **12b** were tentatively assigned as shown in Scheme 3. Deprotection of **12a** and **12b** by treatment with 1 M hydrochloric acid (1 M=1 mol dm^{-3}) at reflux temperature, followed by acetylation, gave the corresponding octa-*O*-acetyl derivatives **13a** (82%) and **13b** (82%), respectively.



Scheme 4.

Finally, the reaction of the di-*O*-isopropylidene derivative **4**[5] of DL-valienamine and **9** was carried out by the similar way. The reaction was completed within 26 h to give 82% yield of a mixture of secondary amines **14a** and **14b** as a homogeneous oil. They were converted into the di-*O*-acetyl derivatives and separated by chromatography on silica gel to give **15a** (46%) and **15b** (54%). The ^{1}H NMR spectra of **15a** and **15b** showed the signals for H-2′ at δ 4.85 and 4.93, and those for H-3′ at δ 2.66 and 2.86, respectively. Studies of their Dreiding models indicated that the 5,6-*O*-isopropylidene group was situated close to C-2′ and C-3′ protons enough to affect, if any difference, the chemical shifts of their signals in the one diastereomer. Therefore, on the basis of the down-field shifts of H-2′ and H-3′ signals of **15b**, the relative configurations of **15a** and **15b** were tentatively assigned as shown in Scheme 4.[7] The protecting groups of **15a** and **15b** were removed to give the free bases, which were characterized by converting into the corresponding octa-*O*-acetyl derivatives **16a** (73%) and **16b** (87%), respectively.

Experimental

General Methods. The same method was used as described in the preceding paper.[1b]

DL-*(1,3/2)-3-Hydroxymethyl-4-cyclohexene-1,2-diol (6).* A mixture of DL-1,2-*O*-isopropylidene-(1,3/2)-3-benzoyloxymethyl-4-cyclohexene-1,2-diol (**5**)[1b] (2.8 g) and 1 M methanolic sodium methoxide (4 ml) in methanol (20 ml) was stirred at room temperature for 30 min. The reaction mixture was treated with Amberlite IR-120B (H$^+$) (4 ml) at room temperature for 2 h and then concentrated. The residue was crystallized from ethanol to give 1.1 g (76%) of **6**: mp 100—101 °C.

Found: C, 58.10; H, 8.17%. Calcd for $C_7H_{12}O_3$: C, 58.32; H, 8.39%.

DL-*2,7-O-Benzylidene-(1,3/2)-3-hydroxymethyl-4-cyclohexene-1,2-diol (7).* To a solution of **6** (1.08 g) in dry DMF (10 ml) was added α,α-dimethoxytoluene (1.36 ml) and a trace of *p*-toluenesulfonic acid, and the mixture was stirred at 60 °C under reduced pressure for 2 h. The reaction mixture was treated with sodium hydrogencarbonate and diluted with ethyl acetate (20 ml). The solution was washed thoroughly with water, dried, and concentrated. The residue was crystallized from ethanol to give 1.07 g (62%) of **7** as needles: mp 120—122 °C. ^{1}H NMR ($CDCl_3$) δ=3.45 (1H, dd, $J_{3.7ax}$=5 Hz, J_{gem}=10.5 Hz, H-7ax), 3.65 (1H, $J_{1.2}=J_{2.3}$=8 Hz, H-2), 4.00 (1H, td, $J_{1.6ax}$=8 Hz, $J_{1.6eq}$=6.5 Hz, H-1), 4.22 (1H, dd, $J_{3.7eq}$=4.5 Hz, H-7eq), 5.22 (1H, br d, $J_{4,5}$=*ca.* 9 Hz, H-4), 5.52—5.86 (1H, m, H-5), 5.60 (1H, s, benzylic), 7.32—7.75 (5H, m, phenyl).

Found: C, 72.39; H, 6.87%. Calcd for $C_{14}H_{16}O_3$: C, 72.39; H, 6.94%.

DL-*1,2-Anhydro-4,7-O-benzylidene-(1,2,3,5/4)-3-hydroxymethyl-1,2,4,5-cyclohexanetetrol (8).* To a solution of **7** (0.10 g) in 1,2-dichloroethane (2 ml) was added *m*CPBA (0.21 g, *ca.* 2 molar equiv.) and sodium hydrogencarbonate (0.21 g), and the mixture was vigorously stirred at room temperature for 1 h. Excess of the peroxy acid was destroyed by washing with a solution of sodium thiosulfate (0.16 g) in water (5 ml), and the organic layer was washed with water and dried. Evaporation of the solvent gave an oil (0.11 g) that was chromatographed on a silica-gel column (5 g) with 2-butanone–toluene (1 : 5) as an eluent. The major fraction (R_f 0.22) gave a crystalline product which was recrystallized from ethanol to give 82 mg (77%) of **8**: mp 111.5—112.5 °C. ^{1}H NMR ($CDCl_3$) δ=2.97 (1H, br d, J=4.5 Hz) and 3.05 (1H, br t, J=4.5 Hz) (H-1, H-2), 3.50—3.82 (2H, m, H-4, H-5), 3.95 (1H, t, $J_{3.7ax}$=10.5

Hz, J_{gem}=10.5 Hz, H-7ax), 4.30 (1H, dd, $J_{3,7eq}$=4 Hz, H-7eq), 5.52 (1H, s, benzylic), 7.30—7.65 (5H, m, phenyl).

Found: C, 67.48; H, 6.44%. Calcd for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50%.

The minor fraction (R_f 0.18) gave an oily product (10 mg, 9%), which was considered by ^{1}H NMR spectrum to be a stereoisomer of **8**, but further characterization was not attempted. ^{1}H NMR ($CDCl_3$) δ=2.56—2.82 (1H, m, H-2), 2.96—3.23 (1H, m, H-1), 3.30 (1H, t, $J_{3,4}=J_{4,5}$=10 Hz, H-4), 4.34 (1H, dd, $J_{3,7eq}$=5 Hz, J_{gem}=10.5 Hz, H-7eq), 5.53 (1H, s,benzylic), 7.31—7.60 (5H, m, phenyl).

DL-*5-O-Acetyl-1, 2-anhydro-4, 7-O-benzylidene-(1,2,3,5/4)-3-hydroxymethyl-1,2,4,5-cyclohexanetetrol (9)*. Compound **7** (0.33 g) was treated with acetic anhydride (5 ml) in pyridine (5 ml) at room temperature overnight. The reaction mixture was concentrated to give the acetate as an oil. Without further purification, it was treated with *m*CPBA similarly as described in the preparation of **8**. The crude product was purified by chromatography on silica gel (25 g) with 2-butanone–toluene (1 : 20) as an eluent. The major fraction [R_f 0.45, 2-butanone–toluene (1 : 5)] gave crystals which were recrystallized from ethanol to give 0.37 g (88%) of **9** as needles: mp 126—130 °C. ^{1}H NMR ($CDCl_3$) δ=2.03 (3H, s, OAc), 2.31 (1H, td, $J_{3,4}=J_{3,7ax}$=11.5 Hz, $J_{3,7eq}$=5 Hz, H-3), 2.68 (1H, ddd, $J_{1,6eq}$=4.5 Hz, $J_{5,6eq}$=8 Hz, J_{gem}16 Hz, H-6eq), 3.04 (1H, d, J=4.5 Hz) and 3.14 (1H, t, J=4.5 Hz) (H-1, H-2), 3.95 (1H, dd, $J_{4,5}$=10 Hz, H-4), 4.02 (1H, t, J_{gem}=11.5 Hz, H-7ax), 4.38 (1H, dd, H-7eq), 4.98 (1H, br td, $J_{5,6ax}$=8 Hz, H-5), 5.56 (1H, s, benzylic), 7.30—7.59 (5H, m, phenyl).

Found: C, 66.22; H, 6.35%. Calcd for $C_{16}H_{18}O_5$: C, 66.19; H, 6.25%.

This compound was identical with a sample obtained by acetylation of **8**.

The minor fraction (R_f 0.42) gave an oily product (25 mg, 6%), whose ^{1}H NMR spectrum was in accord with that expected for a stereoisomer of **9**, but further characterization was not attempted. ^{1}H NMR ($CDCl_3$) δ=2.01 (3H, s, OAc), 2.68 (1H, d, $J_{1,2}$=4.5 Hz, H-2), 2.95—3.23 (1H, m, H-1), 3.49 (1H, t, $J_{3,7ax}$=11 Hz, J_{gem}=11 Hz, H-7ax), 3.75 (1H, dd, $J_{3,4}$=11 Hz, $J_{4,5}$=10 Hz, H-4), 4.35 (1H, dd, $J_{3,7eq}$=5 Hz, H-7eq), 4.97 (1H, td, $J_{5,6eq}$=10 Hz, $J_{5,6eq}$=6.5 Hz, H-5), 5.51 (1H, s, benzylic), 7.30—7.59 (5H, m, phenyl).

Reaction of DL-*2,3 : 4,7-Di-O-isopropylidene-(1,2,4/3,5)-2,3,4-trihydroxy-5-(hydroxymethyl)cyclohexylamine (3) and 8*. A mixture of **3**[4] (64 mg, 0.24 mmol) and **8** (59 mg, 0.24 mmol) in 2-propanol (0.5 ml) was heated in a sealed tube at 120 °C for 44 h. Formation of two components was detected by TLC [R_f 0.44 and 0.40, ethanol–toluene (1 : 5)]. The reaction mixture was concentrated and the residue was chromatographed on a silica-gel column (7 g) with ethanol–toluene (1 : 30) as an eluent. The first fraction was fractionated again by a silica-gel column (3.5 g) with 2-butanone–toluene (1 : 3) to give **3** (10 mg) and 52 mg (42%) of DL-*N*-[4,7-*O*-benzylidene-(1,4/2,3,5)-2,4,5-trihydroxy-3-(hydroxymethyl)-cyclohexyl]-2,3 : 4,7-di-*O*-isopropylidene-(1,2,4/3,5)-2,3,4-tri-hydroxy-5-(hydroxymethyl)cyclohexylamine (**10a**) as an oil. The second fraction gave 54 mg (44%) of the diastereomer **10b** as an oil. ^{1}H NMR ($CDCl_3$) for **10a**, δ=1.44 (9H, s) and 1.50 (3H, s) (isopropylidene), 2.85 (1H, q, J=3 Hz, H-1′), 5.58 (1H, s, benzylic), 7.32—7.62 (5H, m, phenyl), and for **10b**, δ=1.44 (9H, s) and 1.50 (3H, s) (isopropylidene), 2.91 (1H, q, J=3 Hz, H-1′), 5.57 (1H, s, benzylic), 7.30—7.62 (5H, m, phenyl).

Found for **10a**: C, 64.20; H, 7.73; N, 2.56%, and for **10b**, C, 64.41; H, 7.57; N, 2.75%. Calcd for $C_{27}H_{39}NO_8$: C, 64.14; H, 7.78; N, 2.77%.

Reaction of 3 and 9. A mixture of **3** (93 mg, 0.37 mmol) and **9** (100 mg, 0.34 mmol) in 2-propanol (0.7 ml) was heated in a sealed tube at 120 °C for 26 h. The reaction mixture was concentrated and the residue was chromatographed on a silica-gel column [7 g, 2-butanone–toluene (1 : 3)]. The major fraction [R_f 0.29, ethanol–toluene (1 : 8)] gave crystals which were recrystallized from ethanol to give 157 mg (83%) of a mixture of the diastereomers of DL-*N*-[5-*O*-acetyl-4,7-*O*-benzylidene-(1,4/2,3,5)-2,4,5-trihydroxy-3-(hydroxymethyl)-cyclohexyl]-2,3 : 4,7-di-*O*-isopropylidene-(1,2,4/3,5)-2,3,4-tri-hydroxy-5-(hydroxymethyl)cyclohexylamine (**11a** and **11b**) as homogeneous crystals: mp 117—119 °C. ^{1}H NMR ($CDCl_3$) δ=1.44 (9H, s) and 1.50 (3H, s) (isopropylidene), 2.03 (3H, s, OAc), 2.94 (0.5H, q) and 2.97 (0.5H, q) (J=3 Hz, H-1′), 4.96—5.30 (1H, m, H-5), 5.56 (1H, s, benzylic), 7.29—7.60 (5H, m, phenyl).

Found: C, 63.40; H, 7.43; N, 2.44%. Calcd for $C_{29}H_{41}NO_9$: C, 63.60; H, 7.55; N, 2.56%.

Diastereomers 12a and 12b of DL-N-[*2,5-Di-O-acetyl-4,7-O-benzylidene-(1,4/2,3,5)-2,4,5-trihydroxy-3-(hydroxymethyl)cyclohexyl]-2,3 : 4,7-di-O-isopropylidene-(1,2,4/3,5)-2,3,4-trihydroxy-5-(hydroxymethyl)cyclohexylamine*. A mixture of **11a** and **11b** (90 mg) was treated with acetic anhydride (1 ml) and pyridine (1 ml) at room temperature overnight. Formation of two components was detected by TLC [R_f 0.47 and 0.44, ethanol–toluene (1 : 8)]. The products were fractionated by chromatography on a silica-gel column (5 g) with 2-butanone–toluene (1 : 10) as an eluent to give in turn 30 mg (31%) of **12a** and 62 mg (64%) of **12b** as a homogeneous oil. ^{1}H NMR ($CDCl_3$) for **12a**, δ=1.45 (9H, s) and 1.50 (3H, s) (isopropylidene), 2.05 (3H, s) and 2.11 (3H, s) (OAc), 2.57 (1H, tdd, $J_{2',3'}$=2.5 Hz, $J_{3',7'eq}$=4.5 Hz, $J_{3',4'}=J_{3',7'ax}$=11 Hz, H-3′), 4.72 (1H, dd, H-2′), 5.17 (1H, ddd, $J_{4',5'}$=10 Hz, $J_{5',6'eq}$=5 Hz, $J_{5',6'ax}$=11.5 Hz, H-5′), 5.56 (1H, s, benzylic), 7.29—7.59 (5H, m, phenyl), and for **12b**, δ=1.45 (6H, s), 1.48 (3H, s), and 1.50 (3H, s) (isopropylidene), 2.04 (3H, s) and 2.10 (3H, s) (OAc), 2.57 (1H, tdd, $J_{2',3'}$=2.5 Hz, $J_{3',7'eq}$=5 Hz, $J_{3',4'}=J_{3',7'ax}$=11.5 Hz, H-3′), 3.07 (1H, q, $J_{1',2'}=J_{1',6'eq}=J_{1',6'ax}$=3 Hz, H-1′), 4.93 (1H, dd, H-2′), 5.17 (1H, ddd, $J_{4',5'}$=10 Hz, $J_{5',6'eq}$=5 Hz, $J_{5',6'ax}$=11.5 Hz, H-5′), 5.54 (1H, s, benzylic), 7.28—7.62 (5H, m, phenyl).

Found for **12a**: C, 63.12; H, 7.19; N, 2.48%, and for **12b**: C, 63.24; H, 7.36; N, 2.29%. Calcd for $C_{31}H_{43}NO_{10}$: C, 63.14; H, 7.35; H, 2.38%.

Compounds **10a** and **10b** could be correlated to **12a** and **12b**, respectively, by acetylation in the usual way.

N-[*(1SR)-(1,4/2,3,5)-2,4,5-Trihydroxy-3-(hydroxymethyl)cyclohexyl*]-*(1SR)-(1,2,4/3,5)-2,3,4-trihydroxy-5-(hydroxymethyl)cyclohexylamine Octaacetate (13a)*. A mixture of **12a** (30 mg) and 1 M hydrochloric acid (2 ml) was heated at reflux for 1 h. The reaction mixture was concentrated and the residue was acetylated in the usual way to give 28 mg (82%) of **13a** as an oil: R_f 0.21, 2-butanone–toluene (1 : 3). ^{1}H NMR ($CDCl_3$) δ=1.61 (1H, m, NH, disappears on deuteration), 1.98 (3H, s), 1.99 (3H, s), 2.02 (3H, s), 2.03 (9H, s), 2.07 (3H, s), and 2.11 (3H, s) (OAc), 2.82 (1H, q, J=3 Hz, H-1′), 3.27 (1H, q, J=3 Hz, H-1). The free base showed a single spot on TLC [R_f 0.24, chloroform–methanol (3 : 1)].

Found: C, 53.62; H, 6.50; N, 2.17%. Calcd for $C_{30}H_{43}NO_{16}$: C, 53.49; H, 6.43; N, 2.08%.

N-[*(1SR)-(1,4/2,3,5)-2,4,5-Trihydroxy-3-hydroxymethyl)cyclohexyl*]-*(1RS)-(1,2,4/3,5)-2,3,4-trihydroxy-5-(hydroxymethyl)cyclohexylamine Octaacetate (13b)*. Compound **12b** (62 mg) was deprotected and then acetylated similarly as described in the preparation of **13a** to give 58 mg (82%) of **13b** as an oil: R_f 0.23, 2-butanone–toluene (1 : 3). ^{1}H NMR ($CDCl_3$) δ=1.61 (1H, m, NH, disappears on deuteration), 1.97 (3H, s),

1.975 (3H, s), 1.99 (3H, s), 2.01 (3H, s), 2.03 (3H, s), 2.035 (3H, s), 2.06 (3H, s), 2.065 (3H, s) (OAc), 2.91 (1H, q, J=3 Hz, H-1′), 3.28 (1H, q, H-1). The free base showed a single spot on TLC [R_f 0.18, chloroform–methanol (3 : 1)].

Found: C, 53.55; H, 6.52; N, 2.19%. Calcd for $C_{30}H_{43}NO_{16}$: C, 53.49; H, 6.43; N, 2.08%.

Reaction of DL-*4,7 : 5,6-Di-*O*-isopropylidene-(1,4,6/5)-4,5,6-trihydroxy-3-hydroxymethyl-2-cyclohexylamine (**4**) with **9***. A mixture of **4**[6] (109 mg, 0.43 mmol) and **9** (124 mg, 0.43 mmol) in 2-propanol (1 ml) was heated in a sealed tube at 120 °C for 26 h. The reaction mixture was concentrated and the residue was chromatographed on a silica-gel column (13 g) with 2-butanone–toluene (1 : 6) as an eluent to give 191 mg (82%) of a mixture of the diastereomers of DL-*N*-[5-*O*-acetyl-4,7-*O*-benzylidene-(1,4/2,3,5)-2,4,5-trihydroxy-3-(hydroxymethyl)-cyclohexyl]-4, 7 : 5, 6-di-*O*-isopropylidene-(1,4,6/5)-4, 5, 6-trihydroxy-3-hydroxymethyl-2-cyclohexenylamine (**14a** and **14b**) as a homogeneous oil: R_f 0.48, ethanol–toluene (1 : 8). ^{1}H NMR ($CDCl_3$) δ=1.44 (6H, s), 1.47 (3H, s), and 1.54 (3H, s) (isopropylidene), 2.04 (3H, s, OAc), 2.45 (1H, m, H-3′), 3.17 (0.5H, q) and 3.30 (0.5H, q) (J=3 Hz, H-1′), 4.98—5.34 (1H, m, H-5′), 5.44 (0.5H, br d) and 5.61 (0.5H, br d) (J=*ca.* 4.5 Hz, H-2), 5.55 (1H, s, benzylic), 7.28—7.60 (5H, m, phenyl).

Found: C, 64.00; H, 7.25; N, 2.53%. Calcd for $C_{29}H_{39}NO_9$: C, 63.84; H, 7.20; N, 2.57%.

*Diastereomers **15a** and **15b** of* DL-N-[*2,5-Di-*O*-acetyl-4,7-O-benzylidene-(1,4/2,3,5)-2,4,5-trihydroxy-3-(hydroxymethyl)cyclohexyl]-4,7:5,6-di-*O*-isopropylidene-(1,4,6/5)-4,5,6-trihydroxy-3-hydroxymethyl-2-cyclohexenylamine*. A mixture of **14a** and **14b** (77 mg) was treated with acetic anhydride (1 ml) and pyridine (1 ml) at room temperature overnight. Formation of two components was detected by TLC [R_f 0.50 and 0.47, ethanol–toluene (1 : 8)]. The reaction mixture was concentrated and the residual products were fractionated by a silica-gel column (4.5 g) with 2-butanone–toluene (1 : 5). The first fraction (R_f 0.50) gave 38 mg (46%) of **15a** as a glass. The second fraction (R_f 0.47) gave 45 mg (54%) of **15b** as a glass. ^{1}H NMR ($CDCl_3$) for **15a**, δ=1.43 (3H, s), 1.47 (6H, s), and 1.54 (3H, s) (isopropylidene), 2.04 (3H, s) and 2.11 (3H, s) (OAc), 2.66 (1H, tdd, $J_{2',3'}$=3 Hz, $J_{3',7'eq}$=5 Hz, $J_{3',4'}=J_{3',7'ax}$=10.5 Hz, H-3′), 3.19 (1H, q, J=3 Hz, H-1′), 4.85 (1H, t, J=3 Hz, H-2′), 5.20 (1H, ddd, $J_{5',6'eq}$=6 Hz, $J_{4',5'}$=9.5 Hz, $J_{5',6'ax}$=11.5 Hz, H-5′), 5.54 (1H, s, benzylic), 5.54 (1H, br d, H-2), 7.28—7.58 (5H, m, phenyl), and for **15b**, δ=1.44 (6H, s) and 1.53 (6H, s) (isopropylidene), 2.03 (3H, s) and 2.10 (3H, s) (OAc), 2.86 (1H, tdd, $J_{2',3'}$=3 Hz, $J_{3',7'eq}$=5 Hz, $J_{3',4'}=J_{3',7'ax}$=11 Hz, H-3′), 3.21 (1H, q, J=3 Hz, H-1′), 4.93 (1H, t, J=3 Hz, H-2′), 5.19 (1H, ddd, $J_{5',6'eq}$=5.5 Hz, $J_{4',5'}$=9.5 Hz, $J_{5',6'ax}$=11 Hz, H-5′), 5.53 (1H, s, benzylic), 5.60 (1H, br d, $J_{1,2}$=5 Hz, H-2), 7.28—7.57 (5H, m, phenyl).

Found for **15a**: C, 62.52; H, 7.06; N, 2.54%, and for **15b**: C, 63.24; H, 6.94; N, 2.28%. Calcd for $C_{31}H_{41}NO_{10}$: C, 63.36; H, 7.03; N, 2.38%.

N-[(*1*SR)-(*1,4/2,3,5*)-*2,4,5-Trihydroxy-3-(hydroxymethyl)-cyclohexyl*]-(*1*SR)-(*1,4,6/5*)-*4,5,6-trihydroxy-3-hydroxymethyl-2-cyclohexenylamine Octaacetate (**16a**)*. A mixture of **15a** (24 mg) and 1 M hydrochloric acid (5 ml) was heated at reflux for 2 h. The reaction mixture was concentrated and the residue was treated with acetic anhydride and pyridine in the usual way. The product was purified by passage through a short column of active alumina with chloroform. The eluate was concentrated to give 20 mg (73%) of **16a** as a glass: R_f 0.21, 2-butanone–toluene (1 : 3). ^{1}H NMR ($CDCl_3$) δ=1.99 (3H, s), 2.03 (3H, s), 2.04 (6H, s), 2.06 (3H, s), 2.07 (6H, s), and 2.08 (3H, s) (OAc), 2.52—2.86 (1H, m, H-3′), 3.09 (1H, q, J=3 Hz, H-1′), 3.70 (1H, t, J=4 Hz, H-1), 3.96 (1H, dd, $J_{3',7'}$=5 Hz, J_{gem}=11.5 Hz) and 4.19 (1H, dd, $J_{3',7''}$=8 Hz) ($C\underline{H}_2OAc$), 4.41 (1H, d) and 4.69 (1H, d) (J_{gem}=13 Hz, C=CH_2OAc), 5.97 (1H, br d, $J_{1,2}$=4 Hz, H-2).

Found: C, 53.82; H, 6.25; N, 2.24%. Calcd for $C_{30}H_{41}NO_{16}$: C, 53.64; H, 6.15; N, 2.09%.

The free base showed a single spot on TLC [R_f 0.44, chloroform–methanol (3 : 1)].

N-[(*1*SR)-(*1,4/2,3,5*)-*2,4,5-Trihydroxy-3-(hydroxymethyl)-cyclohexyl*]-(*1*RS)-(*1,4,6/5*)-*4,5,6-trihydroxy-3-hydroxymethyl-2-cyclohexenylamine Octaacetate (**16b**)*. Compound **15b** (15 mg) was converted into **16a** similarly as described for the preparation of **16a**: yield 15 mg (87%), R_f 0.19, 2-butanone–toluene (1 : 3). ^{1}H NMR ($CDCl_3$) δ=2.00 (3H, s), 2.03 (3H, s), 2.05 (15H, s), and 2.10 (3H, s) (OAc), 2.59 (1H, m, H-3′), 3.05 (1H, q, J=3 Hz, H-1′), 3.68 (1H, m, H-1), 3.95 (1H, dd, $J_{3',7'}$=4.5 Hz, J_{gem}=11.5 Hz) and 4.20 (1H, dd, $J_{3',7''}$=9 Hz) ($C\underline{H}_2OAc$), 4.39 (1H, d) and 4.69 (J_{gem}=13 Hz, C=CCH_2OAc), 6.06 (1H, br d, $J_{1,2}$=5 Hz, H-2).

Found: C, 53.87; H, 6.28; N, 2.30%. Calcd for $C_{30}H_{41}NO_{16}$: C, 53.64; H, 6.15; N, 2.09%.

The free base showed a single spot on TLC [R_f 0.44, chloroform–methanol (3 : 1)].

The authors express their sincere thanks to Mr. Saburo Nakada for the elementary analyses. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 56550617 from the Ministry of Education, Science and Culture.

A Basic Study of the Amino Acid Residue in Protein. The Molecular Interaction Responsible for the Differentiation of Hydrocarbon Residues

Yuji Hiraki, Toshihiko Oda, and Akira Tai*
Institute for Protein Research, Osaka University, Yamada-oka, Suita, Osaka, 565
(Received October 26, 1982)

A pair of primary amines was competitively acylated with acid anhydride in water–dioxane mixed solvents. Based on the product distribution, the mode of differentiation of hydrocarbon residues in the competing substrates with a reagent was studied. In solvents with a low water content, where both reactants and products were completely soluble, no appreciable differentiation of the alkyl-chain length of alkylamines occurred. On the other hand, the differentiation of a phenyl group from an alkyl group occurred. From the dependency of the product distribution on the water content in reaction media, an attractive interaction induced by water was postulated between alkyl and phenyl groups, but no such interaction was observed between alkyl and alkyl groups. The differences in functions of the phenyl and alkyl groups in the differentiation process are discussed. In solvents with a very high water content, the acylation proceeded under heterogeneous conditions, since acid anhydrides became insoluble and provided an organic phase in the reaction mixture. In this case, the differentiation was controlled by the hydrophobicity of hydrocarbon residues of amines indexed by the partition coefficients of amines between the aqueous phase and the organic phase.

Among the various molecular interactions affecting the molecular recognition,[1–5] the interaction between hydrocarbon residues of reactant molecules is one of the essential factors in understanding the various phenomena found in the biological and organic reactions in either an aqueous or nonaqueous environment.

A systematic investigation of the competitive acylation of primary amines with an acid anhydride (Eq. 1) was carried out in order to characterize the interactions between such medium-size hydrocarbon residues as found in common amino acids in proteins.

As was briefly reported in a previous communication,[6] this reaction system had the following advantages: 1) the reaction readily proceeded in a quantitative manner in kinds of reaction media, including an aqueous one, and gave kinetically controlled products; 2) the reaction products were stable and could readily be analyzed by means of quantitative gas chromatography and; 3) the substrates and reagents substituted with many different hydrocarbon groups were readily available.

The contributions of the hydrocarbon residues to the molecular recognition in the course of the reaction (the differentiation process) were evaluated by the use of logarithmic molar ratio of products (Eq. 2):

$$\left.\begin{matrix} R^1\text{–}NH_2 \\ R_2\text{–}NH_2 \end{matrix}\right\} + (R^0\text{–}CO)_2O \longrightarrow \begin{cases} R^1\text{–}NHCO\text{–}R^0 \\ R^2\text{–}NHCO\text{–}R^0 \end{cases} \quad (1)$$

$$\ln r = \ln(R^1\text{–}NHCO\text{–}R^0/R^2\text{–}NHCO\text{–}R^0), \quad (2)$$

where R^1, R^2–, and R^0– are the hydrocarbon residues.

Experimental

Instruments. The ^{1}H-NMR and IR spectra were taken with a JEOL FX-100 spectrometer and a Shimadzu IR 27 G spectrometer respectively. The analytical GLC was carried out with a Shimadzu GC 6A gas chromatograph equipped with a Shimadzu Chromatopack C-RIA, using a 3 m-5 mm o.d. glass column packed with 2% Silicon OV-17 on Chromosorb W (OV-17) at the stated temperature. The preparative GLC was carried out with a Shimadzu 3 A instrument, using a 3 m-6 mm o.d. stainless column packed with OV-17.

Materials. All the chemical except those noted below were obtained from commercial sources and were used without further purification. The phenylacetic anhydride was prepared from the corresponding acid chloride and sodium salt of the acid by the conventional method. The needle crystals were obtained by recrystallization from ether–hexane (mp 71 °C, lit, 72 °C). The 2-phenylbutyric anhydride was prepared from the corresponding acid by refluxing with a large excess of acetic anhydride, followed by the removal of the acetic acid released by distillation. The *N*-acetyl-L-isoleucine *N*-hydroxysuccinimide ester was prepared from *N*-acetyl-L-isoleucine and *N*-hydroxysuccinimide by treatment with dicyclohexylcarbodiimide according to a conventional method; it was then purified by recrystallization from isopropyl alcohol. The authentic samples for the identification of reaction products were prepared from appropriate acid chlorides and amines by a conventional method, and were purified by preparative GLC. The NMR and IR spectra and the elemental analyses of the samples were consistent with the desired structures of the samples.

Reaction Procedure of Competitive Acylation. When the concentration of an acylating reagent was 50 mM (1 mM= 10^{-3} mol dm^{-3}), the competitive acylation was carried out by the following procedure. In a flask, a 50-μl portion of a stock solution of each amine (2 M dioxane solution) was dissolved in 0.8 ml of the solvent. A 100-μl portion of a solution of anhydride (0.5 M dioxane solution) was then added, all at once, with vigorous stirring at room temperature, after which the mixture was allowed to stand for 1 h. After a 100-μl portion of a stock solution of an internal standard (0.25 M dioxane solution), which will be described is detail, in the following section, had been added for GLC analysis, the volume of the reaction mixture was made up to 5 ml with dioxane. GLC was used for the quantitative analysis of the products of the reaction solution. When the concentration of the acylating reagent was 6.25 mM, 25-μl of each amine solution, 50-μl of the acid anhydride solution, 3.9 ml of the solvent, and 50-μl of the internal standard solution were employed instead.

Quantitative Analysis of Reaction Products. The reaction mixture prepared as has been described in the previous section was subjected to GLC analysis. The amount of the product was determined by the internal standard method. The analyses of the 2-phenylbutyramides and phenylacetamides were carried out in a column with a temperature elevated from 150 °C to 250 °C by 10 °C/min; methyl stearate was used as the internal standard. The 4-methylpentanamides were

analyzed under such GLC conditions that the column temperature was elevated from 100 °C to 260 °C by 10 °C/min, with methyl palmitate as the internal standard. The *N*-acetyl-L-isoleucinamides, isobutyramides, and isovaleramides were analyzed under such GLC conditions that the column temperature was elevated from 100 °C to 250 °C by 10 °C/min, with acetanilide as the internal standard.

Solubility of Acid Anhydrides in Aqueous Media. The solubility of an acylating reagent in water–dioxane mixed solvents was determined as follows. A 100-μl portion of a acylating reagent (0.5 M dioxane solution) was vigorously stirred into a water–dioxane mixture (0.9 ml). The resultant mixture was centrifuged at 2000 min^{-1} for 20 min to separate any undissolved acylating reagent from the solvent phase. A 50-μl portion of butylamine (2 M dioxane solution) was added to the 100-μl portion of supernatant obtained under vigorous stirring, and the mixture was allowed to stand for 1 h to complete the reaction. The quantitative GLC analysis of the *N*-butyl amides was carried out by following the procedure described in the above section.

Results

The Competitive Reaction Conditions. The competitive acylation was carried out at room temperature by using an equimolar mixture of two primary amines as substrates. The ln *r* value depends not only on the interactions between substrates and the reagent in the differentiation process, but also on the changes in the relative concentrations of the two substrates during the reaction. Thus, the reaction should be carried out in the presence of so large an excess of the substrates relative to the reagent as to eliminate the effects of the concentration changes in the substrates. To establish the appropriate reaction conditions, the ln *r* values were determined under a variety of molar ratios of substrates relative to reagent ($[R^1\text{–}NH_2+R^2\text{–}NH_2]/[(R^0\text{–}CO)_2O]$, as is shown in Fig. 1. The ln *r* value became constant when the relative molar ratio of substrates to a reagent was over four. Therefore, four molar equivalents of substrates were treated with one molar equivalent of a reagent in the following experiments. With this ratio

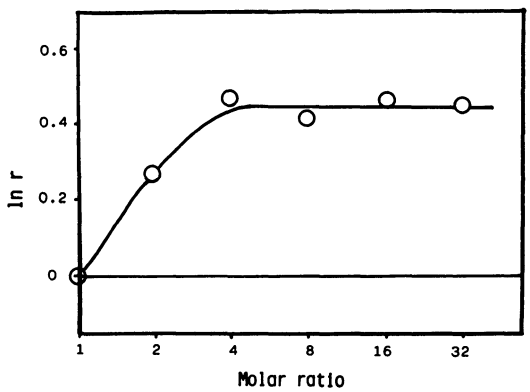

Fig. 1. The dependence of the ln *r* value on the molar ratio of substrates to a reagent ($[R^1\text{–}NH_2+R^2\text{–}NH_2]/[(R^0\text{–}CO)_2O]$).
Isovaleric anhydride, hexylamine, and propylamine were employed as $(R^0\text{–}CO)_2O$, $R^1\text{–}NH_2$, and $R^2\text{–}NH_2$, respectively. The reaction was carried out in water–dioxane mixtures of $\chi_{H_2O}=0.88$. The concentration of isovaleric anhydride was 6.25 mM.

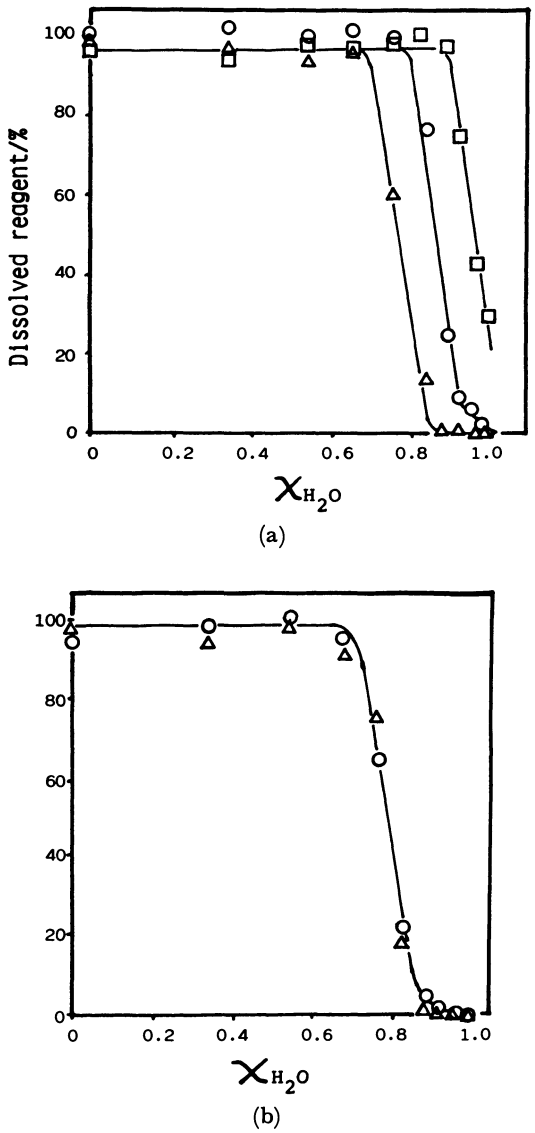

Fig. 2. The dependence of the amount of dissolved reagent (% of applied reagent) on the mole fraction of water (χ_{H_2O}) in water–dioxane mixtures.
In (a), 4-methylpentanoic anhydride (△), isovaleric anhydride (○), and isobutyric anhydride (□) were employed. Their concentration was 50 mM if all dissolved. In(b), 2-phenylbutyric anhydride (○) and phenylacetic anhydride (△) were employed. Their concentration was 12.5 mM if all dissolved.

of substrates to a reagent, it was also confirmed that the ln *r* value was not affected by the carboxylic acids liberated during the reaction: the same ln *r* values were obtained in the presence and in the absence of triethyl amine, an acid quencher.

Benzene, dioxane, and water–dioxane mixtures were employed as solvents. Figure 2 shows the relationship between the solubility of a reagent and the mole fraction of water (χ_{H_2O}) in the water–dioxane mixture. As may be found in the figure, the solubility of an acid anhydride suddenly decreased above a certain value of χ_{H_2O}. When an acid anhydride was added to a solution with a value above this critical χ_{H_2O}, the formation of a distinct organic phase was observed.

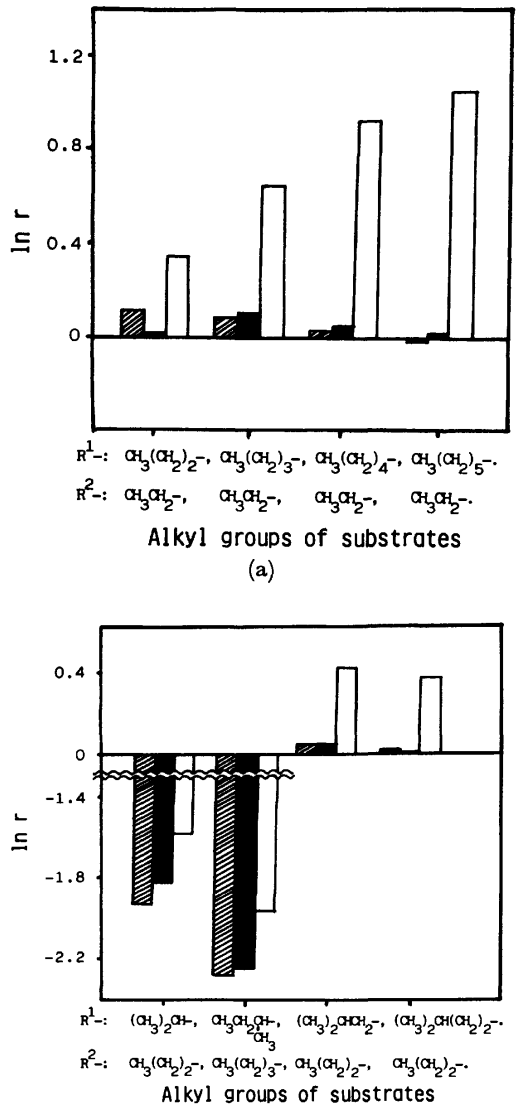

Fig. 3. (a) and (b). The competitive acylation of a pair of alkylamine with isovaleric anhydride.
The reaction was carried out in benzene (▨), dioxane (■), or water–dioxane mixtures at $\chi_{H_2O}=0.88$ (□). The concentration of a reagent was 50 mM.

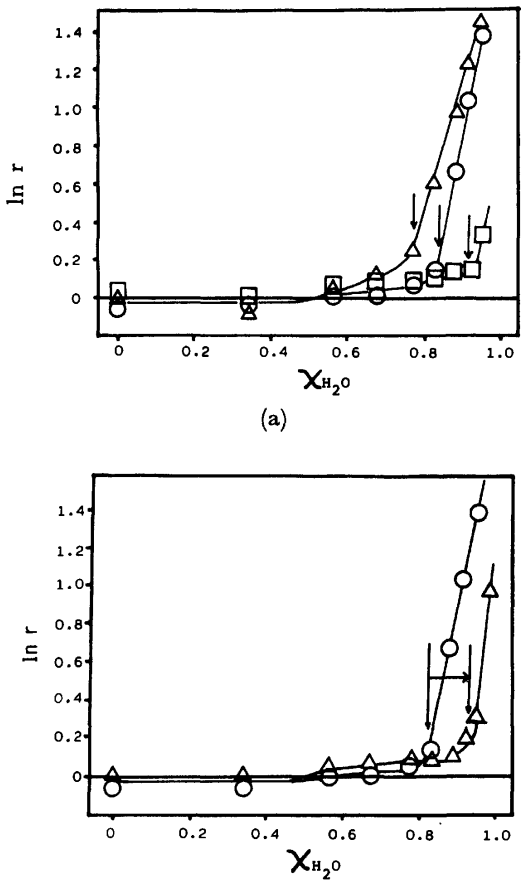

Fig. 4. The relationship between the mole fraction of water in water–dioxane mixtures (χ_{H_2O}) and the ln r value of the competitive acylation of hexylamine (R^1–NH_2) and propylamine (R^2–NH_2).
In (a), 4-methylpentanoic anhydride (△), isovaleric anhydride (○), and isobutyric anhydride (□) were employed. Their concentration was 50 mM. In (b), isovaleric anhydride was employed. Its concentration was 50 mM (○) or 6.25 mM (△).

The Competition of Alkylamines with Different Chain Lengths. A pair of alkylamine were competitively acylated with isovaleric anhydride in benzene, dioxane, or water–dioxane mixtures ($\chi_{H_2O}=0.88$). The results are shown in Fig. 3.

In dioxane or benzene, the ln r values were found to be substantially zero in every competition between unbranched alkylamines (Fig. 3(a)), and in the competition of a β- or γ-branched amine with an unbranched one (Fig. 3(b)). In the competition of an α-branched alkylamine, such as isopropylamine and *s*-butylamine, with the unbranched amines, large negative ln r values were obtained in every solvent; the formation of amides from α-branched amines was significantly suppressed, as is shown in Fig. 3(b).

In aqueous media (water–dioxane), positive ln r values were obtained except in the competition of an α-branched amine with an unbranched one (Fig. 3(a) and (b)). The ln r values obtained in the competitions of unbranched amines in water–dioxane mixtures are shown in Table 1. Thus, the reagent distinguished the longer alkylamine from the shorter one and preferentially gave the amide with the longer alkylamine.

In order to ascertain the mode of the differentiation in an aqueous solvent, the competition of hexylamine with propylamine was carried out in water–dioxane mixtures with a variety of χ_{H_2O} values. The profile of the resulting plots was apparently composed of two regions: Phase I and Phase II. For example, the plot (○) in Fig. 4(a) was composed of Phase I ($\chi_{H_2O}<0.83$) and Phase II ($\chi_{H_2O}>0.83$). In Phase I, no effective differentiation of the alkyl-chain length was observed, while considerable differentiation was observed in Phase II, and ln r remarkably increased with the increase in χ_{H_2O}.

In the acylation carried out in solvents with $\chi_{H_2O}>0.9$, it was observed that the reaction mixture became slightly turbid just after the addition of a reagent and that the turbidity disappeared instantaneously. The same ln r values were obtained in the competitive acyla-

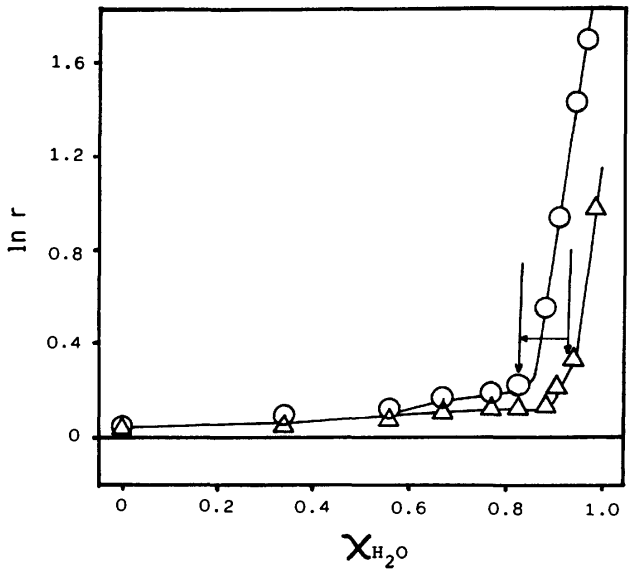

Fig. 5. The relationship between the mole fraction of water in water–dioxane mixtures (χ_{H_2O}) and the ln r value of the competitive acylation in the presence (○) or the absence (△) of CTAB.
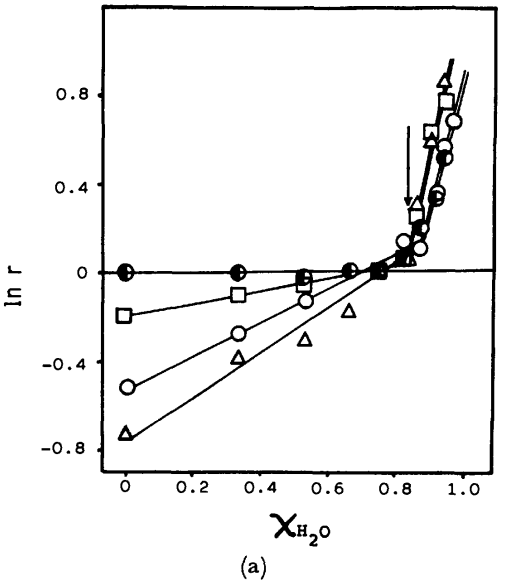
Isovaleric anhydride, hexylamine, and propylamine were employed as $(R^0\text{–}CO)_2O$, $R^1\text{–}NH_2$, and $R^2\text{–}NH_2$, respectively. The concentration of a reagent was 6.25 mM.

tion carried out in two different manners: one was the reaction carried out by the addition of an acid anhydride to amine mixtures homogeneously dissolved in solvents the standard procedure is described in the experimental section, while the other is the reaction carried out by the addition of amine mixtures to suspensions of reagents previously prepared in solvents with large χ_{H_2O} values. These facts strongly suggested that the occurrence of two regions in the plots of ln r *vs.* χ_{H_2O} is related to the solubility of acid anhydrides in water–dioxane mixed solvents. A comparison of Figs. 4(a) and 2(a) clearly shows that the reaction took place under homogeneous conditions in Phase I, while in Phase II it took place under heterogeneous conditions. Accordingly, it can well be understood that the boundary between Phase I and Phase II shifted to a larger χ_{H_2O} value, from 0.82 to 0.9, in the eight-fold dilution of the reagent (Fig. 4(b)).

When cetyl trimethylammonium bromide (CTAB) was added to the reaction system, no apparent phase separation of the reagent occurred. However, Phase II appeared even in the presence of CTAB, as is shown in Fig. 5. The boundary between Phases I and II shifted to a smaller χ_{H_2O} value. Thus, the reagent incorporated into micelles provided by CTAB functioned much like the organic phases produced only by the aggregation of reagents.

When a water-soluble reagent such as the *N*-acetyl-L-isoleucine *N*-hydroxysuccinimide ester was used, Phase II did not appear. In this case, no effective differentiation of alkyl-chain length was observed, not even in solvents with a high χ_{H_2O} value as is shown in Table 1.



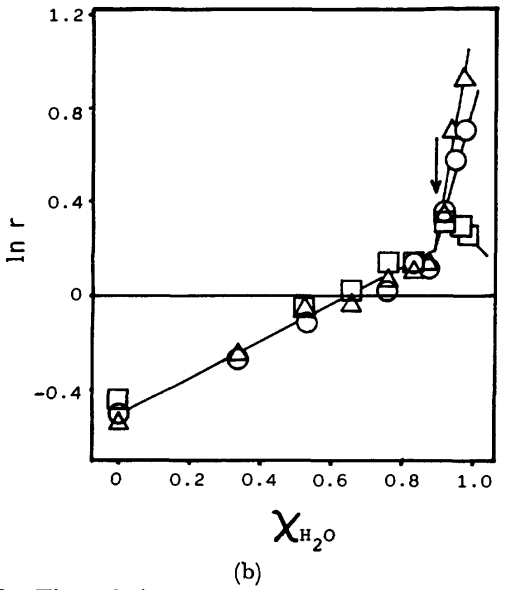


Fig. 6. The relationship between the mole fraction of water in water–dioxane mixtures (χ_{H_2O}) and the ln r value of the competitive acylation with isovaleric anhydride. In (a), benzylamine (△), phenethylamine (△), 3-phenylpropylamine (○), and pentylamine (◐) were employed as $R^1\text{–}NH_2$. Butylamine was employed as $R^2\text{–}NH_2$ in every case. The concentration of a reagent was 50 mM. In (b), phenethylamine was employed as $R^1\text{–}NH_2$. As $R^2\text{–}NH_2$, propylamine (△), butylamine (○), and hexylamine (□) were employed. The concentration of a reagent was 50 mM.

The Competition of an Alkylamine and a Phenylalkylamine. Figure 6(a) shows the results of the competitive acylation between a phenylalkylamine and an unbranched alkylamine with isovaleric acid anhydride (R^0=–$CH_2CH(CH_3)_2$). Benzylamine, phenethylamine, or 3-phenylpropylamine was employed as $R^1\text{–}NH_2$, and butylamine was employed as $R^2\text{–}NH_2$. The profile of the plots is composed of two phases: Phase I ($\chi_{H_2O}<0.83$) and Phase II ($\chi_{H_2O}>0.83$). In Phase II, the ln r values increased remarkably with the increase in χ_{H_2O}. In Phase I, the ln r value increased from negative to

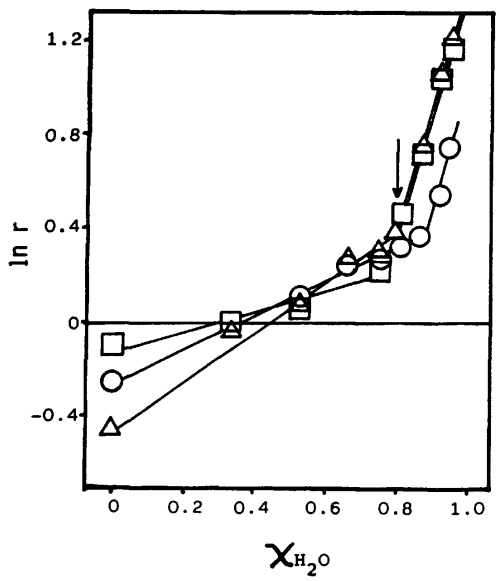

Fig. 7. The relationship between the mole fraction of water in water–dioxane mixtures (χ_{H_2O}) and the ln r value of the competitive acylation with isovaleric anhydride. Phenethylamine and butylamine were employed as R^1–NH_2 and R^2–NH_2, respectively. As a reagent, butyric anhydride (○), 2-phenylbutyric anhydride (△), and phenylacetic anhydride (□) were employed. The concentration of a reagent was 50 mM.

positive with the increase in χ_{H_2O}. This increase in ln r was more pronounced when the phenyl group was substituted near the amino group.

Figure 6(b) shows the ln r *vs.* χ_{H_2O} plots obtained by the competition of phenethylamine with propylamine, butylamine, or hexylamine. In Phase I, all the plots overlapped, even though the chain lengths of the alkylamines were different from one another. In Phase II, the slope of each plot was different. In the case of hexylamine, the ln r value decreased with the increase in χ_{H_2O} ((□) plot).

Figure 7 shows the results of the competitive acylation between phenethylamine and butylamine with several different types of reagents. In this case, the slopes of the plots in Phase I changed significantly with the change in the hydrocarbon residues of the reagents, whereas those of Phase II were similar to one another.

Figure 8 shows the results of the competitive acylation between amines with different pK_a's. The ln r value changed with χ_{H_2O} in Phase I only when benzylamine competed with others (the (○) and (□) plots). No change in the ln r value with a change in χ_{H_2O} was observed in any other combinations of amines (the (□) and (◧) plot). Thus, the changes in the ln r value with χ_{H_2O} in Phase I in the competition of phenylalkylamines with alkylamines are caused not by the difference in the pK_a's of the amines, but by the phenyl groups in the reactants.

Figure 9 shows the results of the competitive acylation in methanol–dioxane or acetonitrile–dioxane mixed solvents. At any composition of these solvents, the reaction proceeded under homogeneous conditions which corresponded to Phase I in water–dioxane solvents. As is shown by the (○) and (△) plots, the changes of

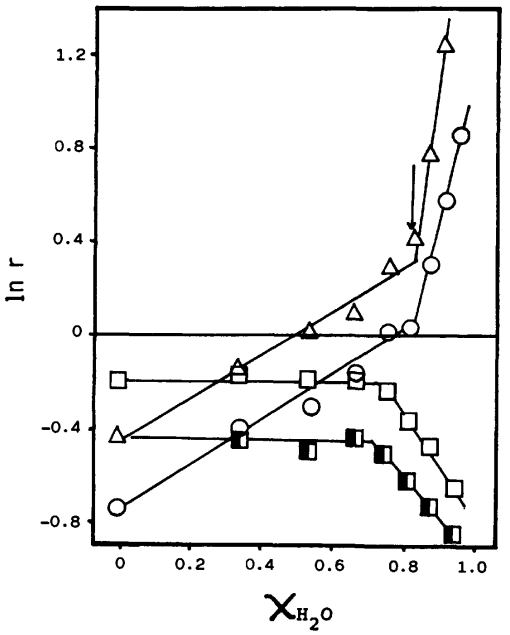

Fig. 8. The relationship between the mole fraction of water in water–dioxane mixtures (χ_{H_2O}) and the ln r value of the competitive acylation with isovaleric anhydride. The following combinations of R^1–NH_2 and R^2–NH_2 were examined: benzylamine and butyl-2-amine (○), benzylamine and 2-methoxyethylamine (△), 2-methoxyethylamine and butylamine (□), and 2-aminoethanol and butylamine (◧). The pK_a values of butylamine, benzylamine, 2-methoxyethylamine, and 2-aminoethanol were 10.64, 9.35, 9.28, and 9.5, respectively. The concentration of a reagent was 50 mM.

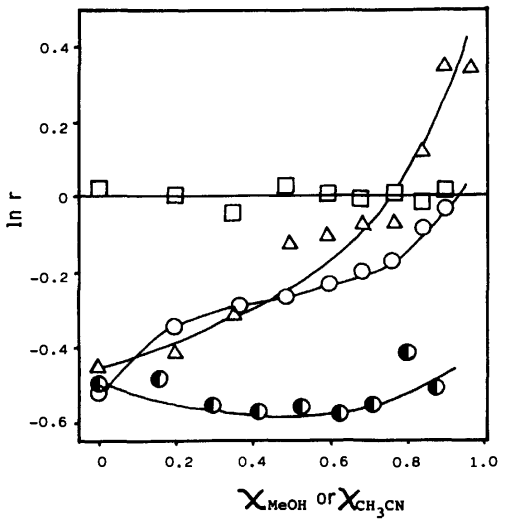

Fig. 9. The relationship between the mole fraction of methanol or acetonitrile in methanol–dioxane or acetonitrile–dioxane mixtures (χ_{MeOH} or χ_{CH_3CN}) and the ln r value.
The following combination of R^1–NH_2, R^2–NH_2, and $(R^0$–$CO)_2O$ were examined: phenethylamine, butylamine, and isovaleric anhydride in methanol–dioxane (○) and in acetonitrile–dioxane (◐), phenethylamine, butylamine, and 2-phenylbutyric anhydride in methanol–dioxane (△), hexylamine, butylamine, and isovaleric anhydride in methanol–dioxane (□). The concentration of a reagent was 50 mM.

the ln r value in Phase I were induced by either water or methanol, but no appreciable change in the ln r value was observed in acetonitrile–dioxane mixed solvents.

Discussion

In the acylation of a primary amine with an acid anhydride or an active ester, the rate-determining step is the nucleophilic attack by an amino group on a carbonyl carbon of the reagent.[7] When an excess amount of an amine ($pK_a>9$) is acylated by a reagent carrying a good leaving group such as an acid anhydride, the rate of acylation becomes insensitive to a small change in the nucleophilicity of an amino group, indexed by its pK_a value.[8] From the examination of competing reaction conditions, it was shown that the ln r value was not affected by the relative ratio of competing substrates during the reaction if the initial molar ratio of substrates to a reagent, *i.e.*, $[R^1\text{–}NH_2+R^2\text{–}NH_2]/[(R^0\text{–}CO)_2O]$, was over four (Fig. 1). Under the experimental conditions employed in the study, the ln r value is expected to represent the degree of the differentiation of substrate molecules by a reagent.

In aprotic solvents, such as dioxane and benzene, the reagent molecule could distinguish only an α-branched substrate from an unbranched one, while it could distinguish neither the difference in the alkyl-chain length of unbranched substrates nor the β- and γ-branched substrates from an unbranched one (Fig. 3). These facts show that the differentiation in a nonaqueous system was controlled by the bulkiness of the alkyl groups near the reaction center.[4]

In Phase I of water–dioxane mixed solvents, the reaction proceeded under homogeneous conditions, where the differentiation of the substrates by the reagent must be controlled by molecular interactions. As may be found in Fig. 4(a) and (b), no effective differentiation of the chain length of alkyl groups took place, even in solvents with high χ_{H_2O} value, as long as the reaction took place in Phase I. Thus, it was shown that there is no characteristic interaction contributing to the differentiation of the chain length of alkyl groups in Phase I. The absence of interaction between alkyl groups in the reagent and substrate is also supported by the fact that the slope of plots in phase I in Fig. 6(b) were not affected by the alkyl-chain length of $R^2\text{–}NH_2$.

However, the ln r value increased with the increase in χ_{H_2O} from a negative value to a positive one in the competition of a phenylalkylamine with an alkylamine in Phase I. As may be found in Fig. 6(a), the slopes of the plots depended on the structural features of the phenylalkylamines. As may be found in Fig. 6(b), the slope of the plot was determined by the sort of phenylalkylamine and was not changed by the change in the chain length of alkylamines. The results shown in Fig. 8 exculde the possibility that the slope of a plot depends on the difference in the pK_a's of the competing amines. These facts can be explained in terms of an attractive interaction between the phenyl group of a substrate and the alkyl group of a reagent (an alkyl-phenyl interaction) that was induced by the addition of water to the reaction media. Since this sort of alkyl-phenyl interaction is a molecular interaction functioning under homogeneous conditions, it can participate in the differentiation of chirality, as was reported in the previous communication.[6]

When phenylacetic anhydride is used in the competitive acylation between phenethylamine and butylamine, the slope of the ln r *vs.* χ_{H_2O} plot in Phase I will represent the difference between a phenyl-phenyl interaction (an interaction between phenyl groups of a substrate and a reagent) and an alkylphenyl interaction. The slope of the (□) plot in Fig. 7 showed a more gentle gradient than that of the (○) plot in Fig. 7 or than those of the plots in Fig. 6(b). The results show that a phenyl-phenyl interaction was induced as well as an alkyl-phenyl interaction by the addition of water to solvents. The former was a little stronger than, or comparable to, the latter.

Since the alkyl-phenyl interaction occurred not only in water, but also in methanol, which has strong intermolecular hydrogen bonds, the interaction must be solvophobic in character. No alkyl-phenyl interaction occurred in dioxane or acetonitrile ($\varepsilon=37.5$)[11] whose dielectric constant is comparable to that of methanol ($\varepsilon=32.6$)[11] (Fig. 9).

The alkyl chains of substrates were remarkably differentiated in Phase II (Fig. 4 and Table 1). These results are in clear contrast to the results in Phase I. In Phase II, the added reagents separated from the solvent phase to make fine oily droplets prior to the reaction with amines. Therefore, almost all of the reaction must proceed inside the hydrophobic domain constituted by acid anhydride. Moreover, the ln r value must be determined by the relative concentration of substrates transferred from an aqueous phase by partition. The results shown in Figs. 4 and 5 suggest that the formation of a hydrophobic domain in the aqueous phase is indispensable for the effective distinction of

Table 1. The ln r values obtained in the competitive acylation of unbranched alkylamine with isovaleric anhydride in water–dioxane mixtures ($\chi_{H_2O}=0.88$)[a]

a) The concentration of a regent was 50 mM. The results of the competitions where the *N*-acetyl-L-isoleuine *N*-hydroxysuccinimide ester was used as a regent are given in parentheses.

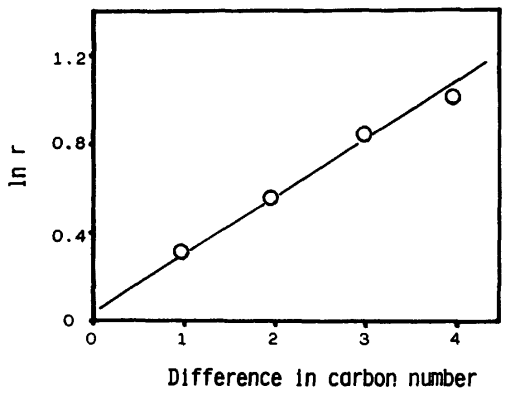

Fig. 10. The relationship between ln r and the difference in carbon number of alkyl chain of substrates in the competition of unbranched alkylamine and ethylamine.

alkyl-chain length.

In general, the hydrophobicity of a compound is evaluated from its partition constant between water and a certain organic solvent (*i.e.*, the π value).[12] Figure 10 shows the relationship between the ln r value and the difference in carbon number between alkyl groups in the competition with ethylamine. The ln r value has been linearly correlated with the difference in the carbon numbers of the hydrocarbon residues.[5a] Thus, the ln r values in Phase II can be well explained by the hydrophobicity of hydrocarbon groups.

In the competition of phenethylamine with hexylamine, the slope of the plot in Phase II showed a negative gradient, while in the competition with other, shorter alkylamines, the slopes of plots were positive (Fig. 6(b)). This result can be explained by the published finding that the phenylethyl group is more hydrophobic than the butyl group and less hydrophobic than the hexyl group.[5a]

In the results shown in Fig. 6(b), it is also worthy of note that the slopes of the plots in Phase I are all positive, regardless of their variation from positive to negative in Phase II. These results indicate that the alkyl-phenyl interaction resulting in the differentiation in Phase I has a different character from a conventionally stated hydrophobicity contributing to the differentiation in Phase II.[3,5]

In this study, we have shown that there are two different modes of the differentiation of hydrocarbon groups in the reaction in aqueous media. One is the differentiations is based on the partition of substrates between an aqueous solvent and the hydrophobic aggregates of reagents. The other is the differentiation based on characteristic molecular interactions between homogeneously dissolved substrates and reagents, such as the phenyl-phenyl and alkyl-phenyl interactions. In contrast, the molecular interaction between alkyl groups (an alkyl-alkyl interaction) is not so large as to contribute to this mode of differentiation.

The formation of a hydrophobic domain by the assembly of certain amounts of reagents is necessary for the differentiation of substrates carrying relatively short alkyl chains, since the alkyl-alkyl interaction is weak. This is an important part of understanding the role of the hydrophobic domain in macromolecules such as protein in the differentiation of the molecules carrying small-size alkyl groups. It has been reported that the rate of acylation was remarkably enhanced in an aqueous solvent when both a reagent and a substrate carried a long alkyl group.[9] This phenomenon was interpreted in terms of the "proximity effect" caused by hydrophobic bonding between hydrocarbon residues in aqueous media. However, further, critical reexaminations should be made to prove this proximity effect, as has been pointed out by Guthrie.[10] At least, the results of the present study indicate that the proximity effect is not generally applicable. Especially its contribution to the differentiation of short and medium-size alkyl groups must be negligible.

The differentiation of a phenyl group from an alkyl one could take place to a certain extent by means of a soluble reagent under homogeneous conditions. The present results suggest that aromatic hydrocarbon residues in protein not only provide a hydrophobic domain, but also have some additional functions in the differentiation of hydrocarbon residues. Several facts in the biochemical field support our results. For example, the importance of Trp or Tyr residues in the interfacial recognition site of phospholipase A_2 is well documented.[13] It has also been shown that many aromatic amino acids are neatly located along the antigen binding site of the Bence Jones protein Mcg.[14]

We wish to thank Professor Yoshiharu Izumi, Dr. Hiroshi Ozaki, and Dr. Tadao Harada of Osaka Universoty for their helpful suggestions. Thanks are also due to Mrs. Mihoko Yamamoto, Miss Masako Yamashita, and Mr. Yoichi Kuroda for their valuable assistance.

Reaction of 1,8-Naphthalenediamine with Dimethyl and Diethyl Acetylenedicarboxylates

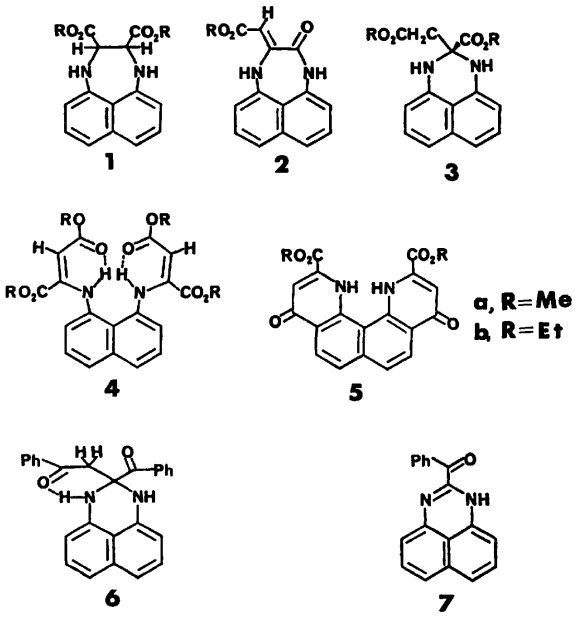
Koichi HONDA,* Hiroshi NAKANISHI, and Akira YABE
National Chemical Laboratory for Industry, Tsukuba, Yatabe, Ibaraki 305

(Received November 12, 1982)

1,8-Naphthalenediamine reacted with dimethyl and diethyl acetylenedicarboxylates, giving rise to tetrahydronaphtho[1,8-*ef*]diazepinones (**2**), dihydroperimidines (**3**) and bis(enamino)fumarates (**4**). The relative yields of **3** and **4** depended on the reaction conditions, while products **2** were always very minor. Products **4**, the yields of which increased considerably in the presence of a large excess of the acetylenes, underwent cyclization at 230 °C leading to quinolinoquinolinediones.

The reaction of amines with acetylenic esters has been investigated in detail.[1] In general, primary monoamines react with acetylenedicarboxylates, giving rise chiefly to the enaminofumarates. In the reaction of aromatic diamines such as *m*-, *p*-phenylenediamines, and 2,2'-biphenyldiamine with dimethyl acetylenedicarboxylate (DMAD), the corresponding bisenamines are formed. Aromatic *vicinal* diamines such as *o*-phenylenediamine and 2,3-naphthalenediamine, however, react with DMAD to give tetrahydroquinoxaline derivatives. On the other hand, in the reaction of 1,8-naphthalenediamine (NDA) with diethyl acetylenedicarboxylate (DEAD), it has been reported that a unique 1 : 1 adduct, 2,3-bis(ethoxycarbonyl)-1,2,3,4-tetrahydronaphtho[1,8-*ef*][1,4]diazepine (**1b**) is formed as a main product, in addition to 3-ethoxycarbonylmethylene-1,2,3,4-tetrahydronaphtho [1,8-*ef*] [1,4] diazepin-2-one (**2b**) which is a product analogous to those from the reactions of *vicinal* diamines.[2]

In connection with the study on the reaction of *peri*-substituted naphthalenes, bis(methoxycarbonyl)tetrahydronaphtho[1,8-*ef*]diazepine (**1a**) was required. Then, the synthesis of **1a** by the reaction of NDA with DMAD was attempted according to the reported method.[2] However, there was found no **1a** in the products, and **2a** was only very minor. The reaction of NDA with DEAD instead of DMAD was also attempted, but the results were similar to those for DMAD, and no **1b** was obtained. We, therefore, have studied the reactions of NAD with DMAD and DEAD in detail.



Results and Discussion

There were found two products besides **2** in the reactions. The products were identified by spectroscopic and elementary analyses as a 1 : 1 adduct, 2-methoxycarbonyl-2-methoxycarbonylmethyl-1,2,3-dihydro-1*H*-perimidine (**3a**) and a 1 : 2 adduct, 2,2'-(1,8-naphthylenediimino)difumarate (**4a**) for the reaction with DMAD, and their ethoxycarbonyl derivatives (**3b**) and (**4b**) for the reaction with DEAD. The spectroscopic data of **2a**, **3a**, and **4a** are summarized in Table 1. Identity of the IR spectrum of **3b** with that of **1b** shown in Ref. 2 indicates that **3b** was erroneously assigned as **1b**, one of the structural isomers of **3b**.

In order to elucidate the pathway of the reaction, the equimolar ethanol solutions of NDA and DMAD or DEAD were mixed under several reaction conditions. As shown in Table 2, products **2** were very minor under all the reaction conditions adopted here, while the yields of **3** and **4** depended appreciably on the conditions. Main process of the reaction is the formation of 1 : 1 adducts **3**, but the formation of 1 : 2 adducts **4** becomes efficient in the presence of a large excess of the acetylenes (Conditions **A**). The reactions probably proceed through intermediate monoenamines, although they could not be isolated under our experimental conditions. The results indicate that the intermediates undergo cyclization to **3** in preference to **2** in contrast to the analogous intermediates from *vicinal* diamines which cyclize almost exclusively to the corresponding amides like **2**.[1] At room temperature, the intramolecular cyclization of the intermediates was slow enough to compete with the formation of **4** by the reaction with the second acetylene molecule, but it became a sole process at the refluxing temperature of ethanol (Conditions **D**).

The enamine adducts formed in the reaction of primary aromatic amines with acetylenic esters were usually fumarates and underwent cyclization leading to quinolone derivatives.[1] The IR spectrum of **4a** showed two distinctive absorption bands at 1740 and 1680 cm^{-1}, corresponding to a free and a chelated ester group respectively, and a broad band at 3280 cm^{-1} due to hydrogen-bonded N–H. The IR spectrum of **4b** also showed similar bands. These bands indicate that

TABLE 2. RELATIVE YIELDS OF THE PRODUCTS IN THE REACTIONS OF NDA WITH AN EQUIMOLAR AMOUNT OF DMAD OR DEAD IN ETHANOL

Acetylenic diester	Reaction conditions[a]	Product (Relative yield/%)[b]		
DMAD	Conditions **A**	**2a** (1)	**3a** (39)	**4a** (60)
DMAD	Conditions **B**	**2a** (1)	**3a** (70)	**4a** (29)
DMAD	Conditions **C**	**2a** (3)	**3a** (86)	**4a** (11)
DMAD	Conditions **D**	**2a** (0)	**3a** (100)	**4a** (0)
DMAD	Conditions **A**	**2b** (1)	**3b** (78)	**4b** (21)
DMAD	Conditions **C**	**2b** (3)	**3b** (94)	**4b** (3)

a) The reaction conditions are as follows: Conditions **A**, dropwise addition of NDA to the acetylene over 1 h at room temperature; Conditions **B**, similar to Conditions **A** but quick addition; Conditions **C**, dropwise addition of the acetylene to NDA over 1 h at room temperature; Conditions **D**, similar to Conditions **C** but at refuxing temperature of ethanol. b) Based on the molar ratio of the isolated products.

compounds **4** have bis(enamino)fumarate structures with two intramolecular chelates between the N–H and C=O groups. The cyclization of **4a** was attempted by refluxing it in diphenyl ether, and a single product which is slightly soluble in organic solvents was isolated The structure of this product was assigned as 2,11-bis-(methoxycarbonyl) quinolino [7,8-*h*] quinoline - 4,9(1*H*,-12*H*)-dione (**5a**), on the basis of elemental analysis and spectral evidences. Therefore, it was confirmed that **4a** affords a quinolone like other bis(enamino)fumarates. The same is expected to hold for **4b**, although the cyclization was not attempted.

The reaction of NDA with acetylenic esters was found to be quite similar to that with dibenzoylacetylene (DBA). The reaction of NDA with DBA is reported to give a mixture of products consisting of 2-benzoyl-2-phenacyl-2,3-dihydro-1*H*-perimidine (**6**) (9%) and 2-benzoyl-1*H*-perimidine (**7**) (89%).[3] The formation of **7** can be rationalized in terms of loss of one acetophenone molecule from **6**. However, the corresponding perimidines were not formed from **3** under our experimental conditions. It has been reported that two methylene protons of **6** are nonequivalent because of the restricted rotation of the phenacyl group due to the hydrogen-bonding between the N–H and C=O groups.[3] On the other hand, for **3**, the singlet signal for the methylene at around 3 ppm in the ^{1}H NMR spectrum and the strong IR band of the N–H groups at around 3350 cm^{-1} indicated the free rotation of the alkoxycarbonylmethyl group without such chelation. The structural difference between **3** and **6** is very interesting in view of their facility of cyclization, and the chelation in **6** seems to play an important role for its easy conversion to **7**.

Experimental

All melting points were determined on a Mettler FP61 instrument and were uncorrected. ^{1}H NMR and ^{13}C NMR spectra were recorded on a JEOL FX-400 (400.05 MHz for ^{1}H nuclei) and a JEOL FX-90Q (22.50 MHz for ^{13}C nuclei) spectrometer respectively using TMS as an internal standard. Mass, IR and UV spectra were measured with a YHP 595A, a Hitachi 260-30 and a Shimadzu UV-300 apparatus respectively.

Materials. Commercially available NDA was purified by repeated recrystallizations from aqueous ethanol and used immediately after the purification. DMAD and DEAD were purified by distillation under reduced pressure.

Reaction of NDA with DMAD. Ethanol solutions of NDA (1.1 g, 7.0 mmol, 10 ml) and DMAD (1.0 g, 7.0 mmol, 10 ml) were mixed under stirring by the several ways described in Table 2. The mixture was left in a refrigerator (*ca.* −10 °C) overnight, from which **2a** and **4a** precipitated. On treatment of the precipitate with $CHCl_3$ at room temperature, **2a** and **4a** were separated as an undissolved product and a dissolved one respectively. Recrystallization of the undissolved product from ethanol gave pure **2a** as silky red needles; mp>300 °C. Found: C, 67.00; H, 4.55; N, 10.26%. Calcd for $C_{15}H_{12}O_3N_2$: C, 67.16; H, 4.51; N, 10.44%. Recrystallization of the dissolved product from ethanol gave pure **4a** as yellow-brown needles; mp 146 °C. Found: C, 59.66; H, 5.10; N, 6.12%. Calcd for $C_{22}H_{22}O_8N_2$: C, 59.73; H, 5.01; N, 6.33%.

From the concentrated mother liquor kept in a refrigerator for a week, **3a** was obtained as a massive precipitate. Recrystallization of the precipitate from ethanol gave pure **3a** as white needles; mp 99 °C. Found: C, 63.79; H, 5.43; N, 9.09%. Calcd for $C_{16}H_{16}O_4N_2$: C, 63.99; H, 5.37; N, 9.33%.

The spectroscopic data of **2a**, **3a**, and **4a** are shown in Table 1. The yields of **2a**, **3a**, and **4a** were as follows respectively: Conditions **A**, 0.01 g (0.53%), 0.39 g (18.6%), and 0.90 g (29.1%); Conditions **B**, 0.01 g (0.53%), 0.81 g (38.5%), and 0.51 g (16.5%); Conditions **C**, 0.05 g (2.7%), 1.35 g (64.2%), and 0.25 g (8.1%); Conditions **D**, 0 g (0%), 1.70 g (80.9%), and 0 g (0%).

Reaction of NDA with DEAD. The reaction was carried out in the same manner as that with DMAD by using 1.1 g (7.0 mmol) of NDA and 1.2 g (7.0 mmol) of DEAD. Sparingly soluble **2b** precipitated from the reaction mixture. Recrystallization of the precipitate from ethanol gave pure **2b** as red silky needles; mp>300 °C. Found: C, 67.24; H, 5.07; N, 9.59%. Calcd for $C_{16}H_{14}O_3N_2$: C, 68.08; H, 5.00; N, 9.92%. ^{13}C NMR (DMSO-d_6) 14.16 (CH_3), 59.82 (OCH_2), 94.51 (=CH), 114.14, 114.65, 122.67, 123.69, 126.77(doubled) (aromatic CH), 115.15, 133.46, 136.30, 136.34 (aromatic *q*.C), 146.89 (=CNH), 159.93 (CONH), 169.46 (CO_2Et). ^{1}H NMR (DMSO-d_6) δ 1.299 (t, J=7.0 Hz, 3H, CH_3), 4.243 (q, J=7.0 Hz, 2H, OCH_2), 6.009 (s, 1H, =CH), 6.963 (d, J=7.3 Hz, 1H), 7.239 (d, J=7.3 Hz, 1H), 7.387 (dd, J=7.8, 8.1 Hz, 1H), 7.392 (dd, J=7.3, 8.1 Hz, 1H) 7.494 (d, J=8.1 Hz, 1H), 7.546 (d, J=7.8 Hz, 1H) (aromatic protons), 10.841 (s, 1H, NH), 11.038 (s, 1H, NH).

The concentrated mother liquor left in a refrigerator for a week gave a massive precipitate of **3b**. On recrystallization from ethanol, pure **3b** was obtained as white needles; mp 80 °C. Found: C, 65.73; H, 6.11; N, 8.46%. Calcd for $C_{18}H_{20}O_4N_2$: C, 65.84; H, 6.14; N, 8.53%. ^{13}C NMR (acetone-d_6) δ 30.26 ($2CH_3$), 60.11 (CH_2CO), 77.37, 77.83 (OCH_2), 85.74 (HNCNH), 122.15, 133.58, 143.58 (aromatic CH), 129.19, 151.13, 156.58 (aromatic *q*.C), 186.24, 188.19 (C=O). ^{1}H NMR (acetone-d_6) δ 1.039 (t, J=7.1 Hz, 3H, CH_3), 1.254 (t, J=7.1 Hz, 3H, CH_3), 3.079 (s, 2H, CH_2), 4.015 (q, J=7.1 Hz, 2H, OCH_2), 4.168 (q, J=7.1 Hz, 2H, OCH_2), 6.179 (s, 2H, NH), 6.621 (d, J=7.4 Hz, 2H), 7.083 (d, J=8.3 Hz, 2H), 7.188 (dd, J=7.4, 8.3 Hz, 2H) (aromatic protons).

Removal of the solvent from the residual ethanol solution gave a mass which was chromatographed over silica gel. Elution of the column with a mixture (9 : 1) of petroleum ether (boiling range, 30—70 °C) and ether gave **4b** and **2b** as the first and the second eluted compounds respectively. Pure **4b** was obtained by recrystallization from ethanol as yellow needles; mp 92 °C. Found: C, 62.49; H, 6.03; N, 5.58%. Calcd for $C_{26}H_{30}O_8N_2$: C, 62.64; H, 6.07; N, 5.62%. ^{13}C NMR (acetone-d_6) δ 29.93, 30.80 (CH_3), 76.31, 78.37 (OCH_2), 110.28 (=CH), 138.92, 142.85, 143.33 (aromatic CH), 140.60, 153.16, 154.12 (aromatic *q*.C), 165.63 (=CNH), 180.75, 185.89 (C=O). ^{1}H NMR (acetone-d_6) δ 0.879 (t, J=7.1 Hz, 6H, $2CH_3$), 1.232 (t, J=7.1 Hz, 6H, $2CH_3$), 4.041 (q, J=7.1 Hz, 4H, $2OCH_2$), 4.111 (q, J=7.1 Hz, 4H, $2OCH_2$), 5.385 (s, 2H, 2=CH), 6.955 (d, J=6.8 Hz, 2H), 7.432 (dd, J=6.8, 8.4 Hz, 2H), 7.763 (d, J=8.4 Hz, 2H) (aromatic protons), 10.239 (s, broad, 2H, 2NH).

UV, IR, and mass spectra of **2b**, **3b**, and **4b** are similar to those of **2a**, **3a**, and **4a** respectively. The yields of **2b**, **3b**, and **4b** were as follows respectively: Conditions **A**, 0.01 g (0.51%), 0.81 g (35.2%), and 0.41 g (11.7%); Conditions **C**, 0.04 g (2.0%), 1.60 g (69.6%), and 0.08 g (2.3%).

Preparation of 5a. A mixture of **4a** (0.3 g, 0.7 mmol) and diphenyl ether (5 ml) was heated at 230 °C for 30 min. The precipitated product was filtered and treated with ether to give **5a** (0.15 g, 58% yield) as pale yellow foils, which is sparingly soluble in usual organic solvents; mp>300 °C. Found: C, 62.65; H, 3.73; N, 7.16%. Calcd for $C_{20}H_{14}O_6N_2$: C, 63.50; H, 3.73; N, 7.40%. ^{1}H NMR (DMSO-d_6) δ 4.066 (s, 6H, $2OCH_3$), 6.278 (s, broad, 2H, NH), 7.290 (s, 2H, 2=CH), 7.801 (d, J=8.2 Hz, 2H), 8.140 (d, J=8.2 Hz, 2H) (aromatic protons). IR (KBr) ν_{max} 1735 (ester C=O), 1610 (ring C=O), 1540, 1515 (C=C), 1440, 1350 (CH_3), 1215 (C–O–C) cm^{-1}. UV (methanol) λ_{max} (ε_{max}) 393 (13300), 374 (10700), 330 (sh), 322 (12700), 307 (sh), 278 (sh), 271 (sh), 249 (19700), 235 (20600), 221 (sh), 216 (37300) nm.

Ionic Composition of Micelles and the Dissolved State of the Mixed Surfactant Solutions of Calcium and Sodium Decyl Sulfates

Masakatsu KOSHINUMA

Laboratory of Chemistry, Faculty of Education, Chiba University, Chiba 280

(Received February 20, 1982)

Single activities of the decyl sulfate (DeS^-), the calcium (Ca^{2+}), and the sodium (Na^+) ions in mixed surfactant solutions of varying mole ratios (R_m=$Ca(DeS)_2$/NaDeS) were obtained at 30±1 °C by means of three kinds of EMF cells with ion-exchange membranes or Na^+-selective electrode. The results showed that with increasing concentrations above the cmc, the activity of the DeS^- decreases gradually, while that of the Na^+ increased linearly; the activity of the Ca^{2+} remained nearly constant in the solution of $R_m=2$, but it showed a minimum in the solutions of $R_m=1$, 0.5 and 0.2. From these activities, the counterion attachments of the Ca^{2+}(r_{Ca}) and the Na^+(r_{Na}) and the degree of micellar charge ($1-2r_{Ca}-r_{Na}$) were obtained. With increasing concentration, r_{Ca} diminished gradually and approached a constant value, while r_{Na} and $1-2r_{Ca}-r_{Na}$ changed reversely except in the solution of $R_m=2$ where they were nearly constant. The Ca^{2+} was bound preferentially to the micelle surface. The Na^+, which almost diffused away for the solution of $R_m=2$, bound increasingly to lessen the electrical potential of the micelle as R_m decreased. The specific adsorption potentials and the electrical free energies of transfer of Ca^{2+} and Na^+ from solution to micelle were calculated as 1.7 and −18.4 kJ mol^{-1}, and 1.1 and −14.3 kJ mol^{-1} respectively at their cmcs. It was showed clearly that little dehydration from the counterion occured and the coulombic interaction played an important role in the counterion binding.

It is well known that valences of counterions of ionic surfactants and of added electrolytes influence markedly both the micellization and the micellar properties of surfactant solutions. A number of authors have shown that the electrical potential at the micelle surface played an important role in the formation of micelles.[1] For solutions of mixed surfactants, it has been shown that the cmc value, the ionic composition and the dissociation of micelles changed greatly depending on the valence and the concentrations of each counterion.[2,3] In explanation of the changes in the cmc, Shinoda formulated some theoretical equations,[1,4] further, Lange[5] and Moroi *et al.*[6] have independently proposed the theoretical relations.

On the other hand, the dissolved state of micellar solution containing counterions with different valences can not be clarified unless the behavior of each ion in the mixed solution is investigated separately. Recently the behavior and activities of single ions have been studied by means of the electromotive force measurements using ion-selective electrodes[7-9] or ion-exchange membranes[10-12] in the single surfactant solutions and in the solutions of the added electrolyte.[13] In the present paper, the degrees of dissociation of micelles and the ionic composition of the counterion in the micelles are studied in solutions of mixed surfactants of different valences on the basis of the single ionic activities. Furthermore, the standard free energies and the coulombic interaction energies of counterions transferring from solution to micelle surface will be calculated and discussed.

Experimental

Materials. The surfactants, calcium ($Ca(DeS)_2$) and sodium (NaDeS) decyl sulfates, were synthesized and purified in the normal way.

Electromotive Force Measurements. In order to investigate the single ionic behavior of the decyl sulfate ion (DeS^-), the calcium ion (Ca^{2+}), and the sodium ion (Na^+) in the mixed surfactant solution, three kinds of cell systems were used for the measurement of the electromotive force. For the DeS^-, a concentration cell was constructed as follows.

Saturated Ag–AgCl electrode	2 mol dm^{-3}-NH_4NO_3, 2%-Agar bridge	Sample solution $Ca(DeS)_2$+NaDeS	Anion-exchange membrane AV-4T
Standard solution NaDeS	2 mol dm^{-3}-NH_4NO_3, 2%-Agar bridge	Saturated Ag–AgCl electrode.	

The solutions of 10.0 and 2.0 mmol dm^{-3} of NaDeS were used as standards for the sample solutions having the concentrations above and below 2.0 mmol dm^{-3} of the DeS^-. The electrical potential developing across the membrane is termed E_{DeS}. For the Ca^{2+}, the multi-ionic potential was measured and the following cell was used:

Saturated Ag–AgCl electrode	2 mol dm^{-3}-NH_4NO_3, 2%-Agar bridge	Sample solution $Ca(DeS)_2$+NaDeS	Cation-exchange membrane Cl-25T
Standard solution NaDeS	2 mol dm^{-3}-NH_4NO_3, 2%-Agar bridge	Saturated Ag–AgCl electrode,	

where the solution of 10.0 mmol dm^{-3} of NaDeS was also used as the standard solution. The potential generated on the membrane is denoted as E_{Ca}. The potentials of E_{DeS} and E_{Ca} were measured at 30±1 °C by means of an electrometer (Keithly, model 610C), and were recorded as functions of time. Other experimental conditions and procedures were the same as in a previous paper.[14]

For the Na^+, the following cell was also set up:

Saturated Ag–AgCl electrode	2 mol dm^{-3}-NH_4NO_3, 2%-Agar bridge	Sample solution $Ca(DeS)_2$+NaDeS	Na^+-selective electrode

The potential, E_{Na}, of sodium-ion selective electrode (Horiba mfg. Co., model pNa-A) was measured with a pH meter (Hitachi-Horiba, model F-5) and recorded as a function of time.

Results and Discussion

Calculation of Single Ionic Activities. The observed values of E_{DeS}, E_{Ca}, and E_{Na} in the mixed surfactant solutions of R_m=2 and 0.5 (R_m: mole ratio of Ca(DeS)$_2$ to NaDeS) are plotted against the logarithmic concentration of NaDeS in Figs. 1a and b. From these EMF, the single ionic activities, though they are conventionally defined, can be calculated in terms of the following equations. According to the Nernst equation,

$$E_{DeS} = (2.303\,RT/F)\log(a_{DeS}/a_{ODeS}), \quad (1)$$

where R, T, and F denote the gas constant, the absolute temperature, and the Faraday constant. The activities of the DeS$^-$ in the sample and in the standard solutions are represented as a_{DeS} and a_{ODeS}, respectively. Since a_{ODeS} is obtained by the same procedure as in a previous paper,[14] the values of a_{DeS} can be calculated.

The multi-ionic potential is given by[15]

$$E_{Ca} = (2.303\,RT/F)[(a_{Na}+Ua_{Ca}-a_{ONa})/(a_{Na}+2U\,a_{Ca}-a_{ONa})]\log[a_{ONa}/(a_{Na}+2Ua_{Ca})], \quad (2)$$

where U is the ratio of the mobility of Ca^{2+} to that of Na^+ in the membrane, a_{ONa}, a_{Na}, and a_{Ca} denote the activities of the Na^+ in the standard solution, of the Na^+ and of the Ca^{2+} in the sample solution, respectively. Since a_{ONa} has been obtained as 9.16 mmol dm^{-3} in the solution of 10.0 mmol dm^{-3} of single NaDeS in the previous study,[14] the value of a_{Ca} can be calculated if those of U and a_{Na} are known exactly.

For Na^+, E_{Na} is also expressed;

$$E_{Na} = (2.303\,RT/F)\log(a_{Na}+K_{NaCa}a_{Ca}^{1/2}), \quad (3)$$

where K_{NaCa} is a selective factor of the Na^+ to the Ca^{2+}. The values of U and K_{NaCa} are functions of a_{Ca} and a_{Na} and must be known in the mixed surfactant solution prior to calculation. Unfortunately we can find neither U, K_{NaCa} nor a_{Ca} and a_{Na} in the literature. Therefore we measured the values of U and K_{NaCa} by use of mixed solutions of $CaCl_2$–NaCl at various mole ratios. From these, the single ionic activities of the Ca^{2+} and the Na^+ can be calculated with the assumption of pH convention.[16] Namely, the activity coefficient of

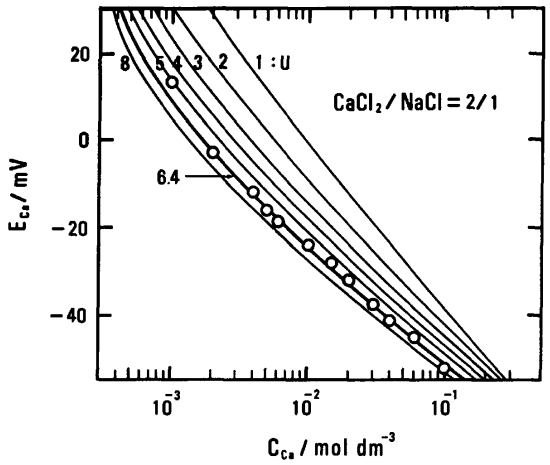

Fig. 2. Comparison of the observed E_{Ca} with the calculated E_{Ca} by use of the pH convention.
——: The calculated value. ○: the observed value.

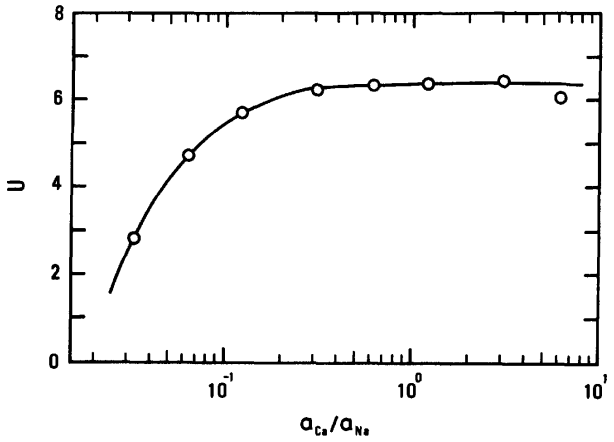

Fig. 3. The relationship between U and a_{Ca}/a_{Na}.
The activity ratio was determined at about 25 mmol dm^{-3} of total Cl^- concentration in the mixed solution.

chloride ion(f_{Cl}) is assumed,

$$\log f_{Cl} = -(0.516 \cdot I^{1/2})/(1+1.552 \cdot I^{1/2}), \quad (4)$$

where I is the total ionic strength in the solution. According to the Debye-Hückel theory, the mean activity coefficients of $CaCl_2$(f_{CaCl_2}) and of NaCl(f_{NaCl}) are given as follows;

$$\log f_{CaCl_2} = -(1.032 \cdot I^{1/2})/(1+1.552 \cdot I^{1/2}), \quad (5)$$

and

$$\log f_{NaCl} = -(0.516 \cdot I^{1/2})/(1+1.320 \cdot I^{1/2}), \quad (6)$$

where the mean radii of hydrated ions in $CaCl_2$ and NaCl are assumed as 4.7 and 4.0 Å, respectively. From the definition of the mean activity coefficient, we also have

$$3\log f_{CaCl_2} = 2\log f_{Cl} + \log f_{Ca}, \quad (7)$$

and

$$2\log f_{NaCl} = \log f_{Cl} + \log f_{Na}, \quad (8)$$

where f_{Ca} and f_{Na} denote the activity coefficients of the Ca^{2+} and the Na^+, respectively. In the mixed solution, a_{Ca} can be calculated from Eqs. 4, 5, and 7, and a_{Na} also from Eqs. 4, 6, and 8. By use of a_{Ca} and a_{Na} values obtained, U and K_{NaCa} can be determined from Eqs. 2 and 3. For example, Fig. 2 shows the curves of E_{Ca} calculated as a function of C_{Ca} with varying U and the observed values of E_{Ca}. In this calculation, the most suitable value of U was chosen as that for which the calculated E_{Ca} coincided with the experimental values. When 6.4 was adopted as U, they agreed fairly with each other except at low concentration. Figure 3 shows the U values determined in the various mixed solutions. The K_{NaCa} values, which were also determined from a_{Ca}, a_{Na}, and E_{Na} in the various mixed solutions by Srinivasan's method,[17] are shown in Fig. 4.

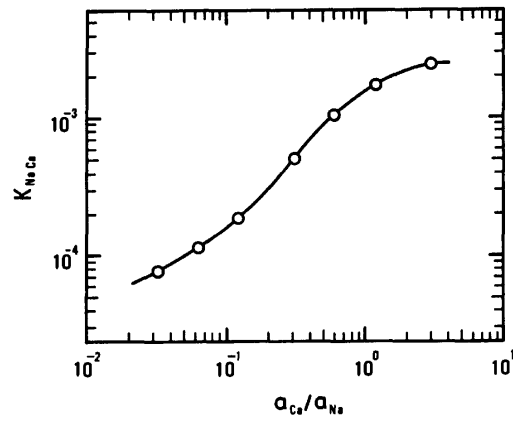

Fig. 4. The relationship between K_{NaCa} and a_{Ca}/a_{Na}.

When the values of U and K_{NaCa} are used, a_{Ca} and a_{Na} in the mixed surfactant solutions can be computed from E_{Ca} and E_{Na} through the following successive calculations. First, a_{Na} was calculated from E_{Na} by Eq. 3, where K_{NaCa} was assumed to be zero because of its small value, and then a_{Ca} could be also obtained from the value of a_{Na} calculated above and E_{Ca} by Eq. 2, where the U value was determined with the assumption that a_{Ca}/a_{Na} was equal to C_{Ca}/C_{Na} in Fig. 3. Secondly, the K_{NaCa} value was also determined from a_{Ca}/a_{Na} in Fig. 4 by use of the values of a_{Ca} and a_{Na} obtained, and then a_{Na} was recalculated by Eq. 3. Moreover, a_{Ca} could be calculated again by Eq. 2 when the values of a_{Na} obtained above and of U determined from a_{Ca}/a_{Na} in Fig. 3 were used. This successive calculation having been performed, the activities were finally obtained as the converged values.

Figures 5a and b show a_{Ca} and a_{Na} together with a_{DeS} in the mixed surfactant solutions of $R_m=2$ and 0.5. The activities of all the ions increase linearly with the surfactant concentration up to the cmc. With an increase in the concentration above the cmc, a_{DeS} decreases. This shows that the smaller the R_m value becomes, a_{DeS} decreases slightly more steeply. Contrarily, a_{Na} increases linearly giving a break point in the curve of a_{Na} against the concentration of NaDeS; the slope of the curve above the CMC reduces as the R_m value decreases. Moreover, a_{Ca} in the solution of $R_m=2$ remains almost constant, but those of $R_m=1$, 0.5 and 0.2 show minima; the sum of the activities of the three kinds of ions in the mixed solution increases gradually with the the concentration in the same manner as in the solution of each single surfactant. From the fact that a_{Na} increases linearly with the concentration without a change in the slope of the curve of a_{Na} against concentration at the

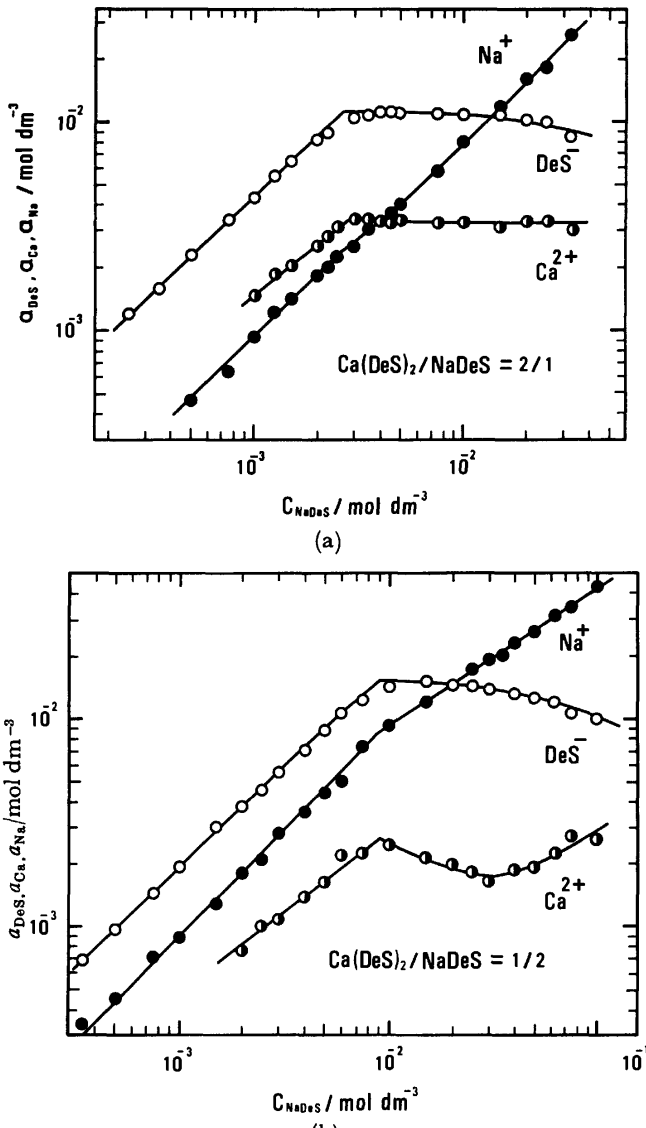

Fig. 5. The single ionic activities against the concentration of NaDeS in the mixed surfactant solutions of varying mole ratios.

TABLE 1. THE VALUES OF CMC IN THE TOTAL CONCENTRATION OF THE DeS^- AND OF K AND L IN EQ.10 IN THE MIXED SURFACTANT SOLUTIONS OF VARYING MOLE RATIO

R_m=Ca(DeS)$_2$/NaDeS	1/0	2/1	1/1	1/2	1/5	0/1
cmc / mmol dm^{-3}	12.8	13.5	14.4	18.4	22.4	32.8

L		0.186	0.181	0.147	0.153	

cmc, it is suggested that most of the Na^+ in the solution of R_m=2 remains in the intermicellar solution. Further, from the decrease in the slope above the cmc with the decrease in R_m, the Na^+ may be considered to bind gradually on the micelle surface. These results can be explained by a change in the ionic composition which depends on the coulombic interaction of counterion with negatively charged micelles. Thus, the ionic composition of micelle will be determined and discussed later.

The cmcs in the mixed solutions are shown in Table 1 where these values were determined as the averages of the breaking points in the curves of activity *vs.* surfactant concentration.

Dissociation and Ionic Composition of Micelle. The valence effects of counterions on the dissociation of the micelle and on the mechanism of micelle formation have been studied in a previous paper.[14] In the mixed micellar solution of ionic surfactants, having counterions of uni and bivalence, it has been suggested that the binding of bivalent counterion occurred on the micelle surface in preference to the univalent one.[2,3] Thus the ionic composition of the micelles and the degree of micellar charge need to be investigated.

If a micelle is composed of p DeS^-, q Na^+, and s Ca^{2+} ions in equilibrium, the micelle formation is expressed by

$$p\,DeS^- + q\,Na^+ + s\,Ca^{2+} \rightleftharpoons M'$$

$$M: [D_pS_pNa_qCa_s]^{-(p-q-2s)}$$

and $$a_M/(a_{DeS}{}^p \cdot a_{Na}{}^q \cdot a_{Ca}{}^s) = K'_M,$$

where a_M is the activity of micelle and K'_M, a constant. This equation is rewritten;

$$\log a_{DeS} + r_{Na}\log a_{Na} + r_{Ca}\log a_{Ca} = (1/p)\log(a_M/K'_M) = K_M, \quad (9)$$

here, $r_{Na}(=q/p)$ and $r_{Ca}(=s/p)$ denote the counterion attachments of the Na^+ and of the Ca^{2+}, respectively. If p, q, s, a_M, and K_M are constant and independent of the surfactant concentration the phase separation theory,[18] which has described satisfactorily the formation of micelles in solutions of single NaDeS and Ca(DeS)$_2$,[14] is applicable. The solution of R_m=2 is this special cases so r_{Ca} and r_{Na} can be obtained by Eq. 9 because of the constants of a_{Ca} and K_M. But if p, q, and s change with the concentration, r_{Ca} and r_{Na}, in general, can not be calculated unless the value of K_M is given: K'_M and K_M also change.

On the other hand, we can compute r_{Ca} and r_{Na} from the intermicellar concentrations of the $DeS^-(C_{DeS})$, the $Ca^{2+}(C_{Ca})$ and the $Na^+(C_{Na})$ in the solution having the concentrations of C_{CaDeS} of Ca(DeS)$_2$ and C_{NaDeS} of NaDeS: $r_{Ca} = (C_{CaDeS} - C_{Ca})/(2C_{CaDeS} + C_{NaDeS} - C_{DeS})$ and $r_{Na} = (C_{NaDeS} - C_{Na})/(2C_{CaDeS} + C_{NaDeS} - C_{DeS})$. The values of C_{DeS}, C_{Ca}, and C_{Na} are given through the arrows illustrated schematically in Fig. 6; presence of micelle is assumed to give no effect on each activity coefficient of singly dispersed ions. Thus, C_{DeS} and C_{Ca} can be obtained provided the activity coefficient corresponding to the activity above the cmc is taken to be equal to that corresponding to the same activity below the cmc. C_{Na} is obtained with an aid of the dashed line. This is determined from the activity coefficient(f^s_{Na}) calculated with the assumption that the linear relation which holds between its activity coefficient and concentration below the cmc is also applicable to that of the Na^+ in the intermicellar solution above the cmc. Below the cmc, f^s_{Na} was successfully expressed by

$$\log f^s_{Na} = -(K\log C_{NaDeS} + L), \quad (10)$$

where K and L are the constant values which are sum-

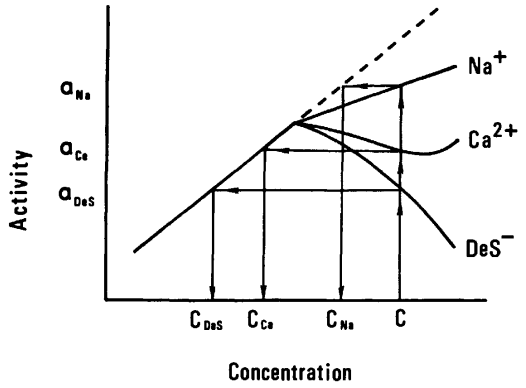

Fig. 6. Schematic description of determination of the intermicellar concentrations; C_{DeS}, C_{Ca}, and C_{Na} in the surfactant concentration of C are given through arrows. The dashed line is calculated with the assumption that the activity coefficient is given by the equation: $\log f_{Na} = -(K \log C_{NaDeS} + L)$.

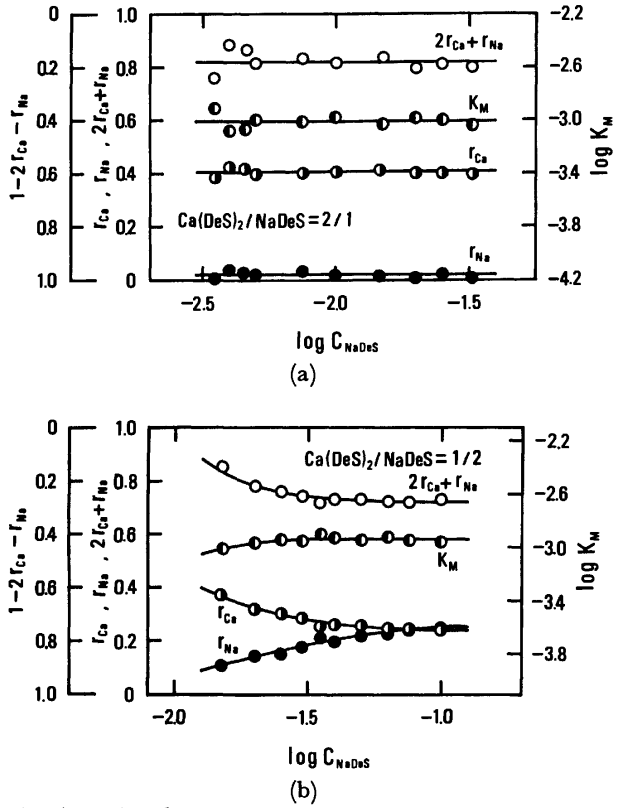

Fig. 7. The degrees of counterion attachment of the Ca^{2+} (r_{Ca}), of the Na^+ (r_{Na}), of dissociation of micelle ($1-2r_{Ca}-r_{Na}$) and the value of log K_M against the concentration of NaDeS.

marized in Table 1 for the solution of varying R_m.

Figure 7a expresses r_{Ca} and r_{Na} together with the degree of micelle charge ($1-2r_{Ca}-r_{Na}$) in the solution of $R_m=2$ showing that they are nearly constant and independent of the concentration within an experimental error. As R_m becomes smaller, r_{Ca} decreases more steeply with the concentration, and it approaches asymptopically to a constant at high concentration as shown in Fig. 7b; r_{Na} and $1-2r_{Ca}-r_{Na}$ change reversely. The assumption of Eq. 10 may be applicable just above the cmc, but it

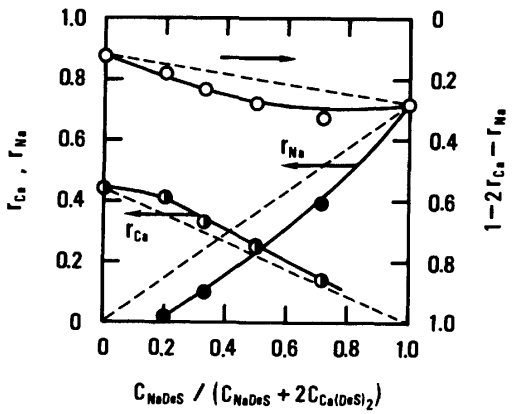

Fig. 8. The ionic composition of micelle and the degree of dissociation of micelle against the composition of the mixed surfactants.

should be tested at higher concentrations. If the assumption of Eq. 10 as well as the phase separation theory are set up, the value of K_M in Eq. 9 must be constant at the higher concentrations where r_{Ca} and r_{Na} are constant. The calculated values of K_M are shown in Figs. 7a and b, indicating that they do become constant at the high concentrations of various R_m and particularly K_M for the solution of $R_m=2$ is independent of the concentration. Therefore, the micelle formation in the mixed surfactant solution can be described by the phase separation theory at least in the solution of $R_m=2$ and in the high concentrations. The values obtained for r_{Ca}, r_{Na}, and $1-2r_{Ca}-r_{Na}$ suggest the following interpretation. Just above the cmc, the Ca^{2+} is bound on the micelle surface by the strong coulombic interaction in preference to the Na^+ from the intermicellar solution. The remaining $Na^+(C_{Na})$ increases with an increase in the surfactant concentration; the ratio of a_{Na}/a_{Ca} increases rapidly, therefore, r_{Na} increases and r_{Ca} reduces gradually. An increase in the total intermicellar concentration due to that in C_{Na} shields mainly the electrical potential at the micelle surface and consequently increases $1-2r_{Ca}-r_{Na}$.

The converged values of r_{Ca}, r_{Na}, and $1-2r_{Ca}-r_{Na}$ are plotted against the composition of mixed surfactant in Fig. 8, and these make the ionic composition of the micelle clearer. The dashed line indicates each calculated value from the assumption that r_{Ca} and r_{Na} vary proportionally to the fraction of each surfactant in the solution. The Ca^{2+} are bound preferentially on the micelle while the Na^+, which remains in the intermicellar solution of $R_m=2$, binds progressively to lessen the electical potential as R_m decreases; $1-2r_{Ca}-r_{Na}$ becomes larger mainly because of the shielding effect due to the increase in C_{Na} with the increasing content of NaDeS.

Specific Adsorption Potentials of the Ca^{2+} and the Na^+ Ions. With regard to the preferential binding of the Ca^{2+} on the micelle surface, free energies of transfer of counterions from solution to micelle surface, which have been referred to as specific adsorption potentials[19] and calculated,[3,19,20] are determined in the solution of two single surfactants for simplicity in calculation. In a solution of $Ca(DeS)_2$, we assume that a micelle consists of p DeS^- ions and $p \cdot r_{Ca} (=q)$ Ca^{2+} ions bound on the micelle surface and has $p(1-2r_{Ca})\varepsilon$ charges.

Equilibrium of the Ca^{2+} between the bulk phase and the micelle surface region is described by an equality of each electrochemical potential, $\bar{\mu}_{bCa}=\bar{\mu}_{mCa}$, in the two phases;

$$\bar{\mu}_{bCa} = \mu^{\circ}_{bCa} + kT\ln a_{Ca}, \quad (11)$$

$$\bar{\mu}_{mCa} = \mu^{\circ}_{mCa} + kT\ln C_{mCa} + \int_0^{2\varepsilon}\phi_{mCa}dQ + W_{mCa}. \quad (12)$$

Here, $\bar{\mu}_{bCa}$, $\bar{\mu}^{\circ}_{bCa}$, $\bar{\mu}_{mCa}$, and $\bar{\mu}^{\circ}_{mCa}$ are the electrochemical and the standard chemical potentials in the bulk phase and in the micelle surface region, respectively; C_{mCa} the concentration of the Ca^{2+} bound in the micellar surface region of volume V_{Ca} and W_{mCa}, a free energy related to hydration of the ion. Further, it is assumed that the electrical free energy may be given by the electrical work done, $\int_0^{2\varepsilon}\phi_{mCa}\,dQ$, when the Ca^{2+} having charge Q are brought about up to the micelle surface. The electrical potential, ϕ_{mCa}, at the micelle surface is given by[4]

$$\phi_{mCa} = -(kT/2\varepsilon)[\ln(2000\pi\cdot\sigma^2/DNkT) - \ln C_{Ca}]. \quad (13)$$

Here, D and N denote the dielectric constant of water and the Avogadro number, respectively; C_{Ca}, the intermicellar concentration of the Ca^{2+} which has been calculated theoretically in a previous paper.[14] The surface charge density of the micelle, σ, is expressed as follows;

$$\sigma = -(\varepsilon - r_{Ca}Q)/A_{CaD}, \quad (14)$$

where A_{CaD} is the molecular area occupied by the DeS^- at the surface of $Ca(DeS)_2$ micelle.

The concentration of the Ca^{2+} in the micelle surface region can be written as

$$C_{mCa} = 1000p\cdot r_{Ca}/NV_{Ca}. \quad (15)$$

If the thickness of the Stern layer can be assumed to be equal to the diameter, h_{Ca}, of the hydrated Ca^{2+}

$$V_{Ca} = pA_{CaD}h_{Ca} \quad (16)$$

is set up. From Eq. 11 to Eq. 16, we obtain the following relation,

$$\ln a_{Ca} = \Delta\mu^{\circ}_{tNa}/kT + \ln[DkTr_{Ca}A_{CaD}C_{Ca}/2\pi h_{Ca}\varepsilon^2(1-2r_{Ca})^2] + (1/r_{Ca})\ln(1-2r_{Ca}) + 2 + \Delta W_{tCa}, \quad (17)$$

where $\Delta\mu^{\circ}_{tCa}=\mu^{\circ}_{mCa}-\mu^{\circ}_{bCa}$ is a standard free energy of transfer of the Ca^{2+} from solution to micelle; similarly, ΔW_{tCa}, a hydration free energy of transfer due to changes in the state of hydration.

Similarly, in a solution of NaDeS,[3]

$$\ln a_{Na} = \Delta\mu^{\circ}_{tNa}/kT + \ln[DkTr_{Na}A_{NaD}C_{Na}/2\pi h_{Na}\varepsilon^2(1-r_{Na})^2] + 2[(1/r_{Na})\ln(1-r_{Na}) + 1] + \Delta W_{tNa} \quad (18)$$

is given, where $\Delta\mu^{\circ}_{tNa}=\mu^{\circ}_{mNa}-\mu^{\circ}_{bNa}$, A_{NaD}, h_{Na}, and ΔW_{tNa} correspond to those for the Ca^{2+}, respectively.

The specific adsorption potentials, $\Delta\mu^{\circ}_{s}+\Delta W_t$, can be calculated by Eqs. 17 and 18 if, A_{CaD}, h_{Ca}, A_{NaD}, and h_{Na} are given, because D, k, T, and ε are constant values, while a_{Ca}, a_{Na}, C_{Ca}, C_{Na}, $r_{Ca}(=0.44)$, and $r_{Na}(=0.72)$ have been obtained and reported in a previous paper.[14] Values of 4.6[3] and 6.2 Å, calculated by Stokes law based on the limiting mobility, are used for h_{Na} and h_{Ca} respectively. For A_{NaD} and A_{CaD}, values of 53.6 and 43.7 $Å^2$ molecule^{-1} have been calculated from the saturated amount of adsorption at the air/solution interfaces.[21,22] These values are employed respectively instead of those at the micelle surface. At the cmc, $\Delta\mu^{\circ}_{tNa}+\Delta W_{tNa}$ is computed as 1.1 kJ mol^{-1}, which fairly agrees with 1.3 kJ mol^{-1} expected theoretically,[19] when $a_{Ca}=25.1$ mmol dm^{-3} and $C_{Na}=32.8$ mmol dm^{-3}; $\Delta\mu^{\circ}_{tCa}+\Delta W_{tCa}$ is 1.7 kJ mol^{-1} when $a_{Ca}=3.71$ mmol dm^{-3} and $C_{Ca}=6.40$ mmol dm^{-3}, but no value to be compared has been reported for calcium alkyl sulfate. In cationic surfactant solutions, investigations have shown that for various counterions the specific adsorption potentials became progressively larger as the valence of the counterion increased.[20] This tendency is also observed in this experiment. These calculated values must be correlated to changes in the hydration of the counterions bound on the micelles on the basis not only of free energy but also of enthalpy and entropy to transfer the counterions from solution to the micelle surface, although the latter two were not determined in this experiment. However the changes may be roughly estimated, if the specific adsorption potentials can be attributed only to dehydration in binding the counterions on the micelles.

The enthalpy and the entropy of hydration[23] and the number of primary hydrated water molecule (a hydrated water molecule being adjacent to an ion)[24] of the Ca^{2+} have been reported at 25 °C as -1669 kJ mol^{-1}, -254 J deg^{-1} mol^{-1}, and 10, respectively and those of the Na^+ also as -443.9 kJ mol^{-1}, -110 J deg^{-1} mol^{-1} and 5. The value of $\Delta\mu^{\circ}_{tNa}+\Delta W_{tCa}$ corresponds to dehydration of 1.1×10^{-2} water molecule per the Ca^{2+} from the primary hydrated water and that of $\Delta\mu^{\circ}_{tNa}+\Delta W_{tNa}$ also to dehydration of 1.3×10^{-2} water molecule. From these small values, therefore, it may be considered that dehydration by counterions scarcely occurs in the binding. And if dehydration takes place, water molecules hydrated in the secondary, tertiary and outer layers, which weakly bind to the counterion, are perphaps dehydrated rather than those in the primary layer. The relation between the specific adsorption potential and the hydration entropy has been hitherto reported,[20] and importance of entropy change in the formation of ionic pair, such as the Ca^{2+} and the SO_4^{2-}, has been also studied.[25] Accordingly it would seem to be worthwhile to pay attention to such entropy changes in this study. However from the present results, it can not be clearly said what change in the hydration of the counterion is intimately correlated to the specific adsorption potential. Experimental and detailed studies are desirable on the state of the counterion near the micelle surface.

The electrical free energies, $\int\phi_m dQ$, of the Ca^{2+} and the Na^+ at the cmc were calculated as -18.4 and -14.3 kJ mol^{-1}, respectively. It is indicated that the electrical free energy dominates in the specific adsorption potential in the counterion binding. Further, the value of $\int_0^{2\varepsilon}\phi_{mCa}\,dQ$ is larger than that of $\int_0^{\varepsilon}\phi_{mNa}dQ$, then the Ca^{2+} comes to bind preferentially even in low concentrations of surfactant.

Finally, we must say that the problem of the influence of micelles on the activities of single ions remains

unconfirmed, although it has been reported that the surface tensions calculated above the cmc by use of the activities agreed satisfactorily with those observed.[11]

Reactions of NH Radicals. I. Photolysis of HN_3 Vapor at 313 nm

Sukeya KODAMA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591

(Received September 13, 1982)

Photolysis of HN_3 vapor was studied at 313 nm as a function of HN_3 and Xe pressures, light intensity, and temperature. The photolysis of hydrazoic acid labeled with ^{15}N was also studied. The quantum yields of N_2, H_2, and NH_4N_3 as a product were 4.85, 0.494, and 0.842 at 30 °C and 6.7 kPa of HN_3, respectively. The mechanism for the main reactions was postulated as follows: $HN_3+h\nu(313\text{ nm})\rightarrow N_2+NH(a^1\Delta)$; $NH(a^1\Delta)+HN_3\rightarrow 2N_2+2H$ (2); $NH(a^1\Delta)+HN_3\rightarrow N_3+NH_2$ (3); $NH(a^1\Delta)+HN_3\rightarrow N_2+N_2H_2{}^*$ (4). The rate constant ratios of $k_3/k_2=0.746$ and $k_4/k_2=1.23$ were obtained at 30°C. $(k_3+k_4)/k_2$ decrease drastically with rising temperature. Xe is effective for the collisional deactivation, $NH(a^1\Delta)+Xe\rightarrow NH(X^3\Sigma^-)+Xe$ (15), and $k_{15}/(k_2+k_3+k_4)=0.187$ was obtained at 30 °C.

In order to study the reactions of various reactants with $NH(X^3\Sigma^-$ and $a^1\Delta)$ radicals that are in the same isoelectronic state as carbon, oxygen, and sulfur atoms and CH_2, SiH_2, and PH radicals, hydrazoic acid was chosen as a photochemical radical source.

The photolysis of HN_3 vapor at about 190 nm[1] and the mercury-photosensitized decomposition[2] were first investigated by Beckman and his co-workers. On the basis that the products are N_2, H_2, and NH_4N_3, and the quantum yield for the disappearance of HN_3 is about 3.6 in both cases, they have presented the following mechanism:

$$HN_3 + h\nu(\text{or Hg}^*) \longrightarrow NH + N_2$$
$$NH + HN_3 \longrightarrow H_2 + 2N_2 \quad (18\%)$$
$$NH + HN_3 \longrightarrow N_2H_2 + N_2 \quad (82\%)$$
$$N_2H_2 + HN_3 \longrightarrow NH_3 + 2N_2$$
$$NH_3 + HN_3 \longrightarrow NH_4N_3.$$

Thrush[3] has proposed the following mechanism from the identifications of NH, NH_2, and N_3 radicals in flash photolysis:

$$HN_3 + h\nu \longrightarrow NH + N_2$$
$$NH + HN_3 \longrightarrow NH_2 + N_3$$
$$NH_2 + HN_3 \longrightarrow NH_3 + N_3$$
$$N_3 + N_3 \longrightarrow 3N_2.$$

On the photolysis of HN_3 vapor in the vacuum-ultraviolet, Welge[4] has observed that $NH(c^1\Pi)$ and $NH(A^3\Pi_i)$ are produced below 160 nm. Okabe[5] has shown that the yield of the $NH(c^1\Pi)$ production is at most 2%, and $NH(A^3\Pi_i)$ may be formed largely by the reaction of electronically excited N_2, most probably $N_2(B^3\Pi_g)$, with HN_3.

Konar, Matsumoto, and Darwent[6] have investigated the photochemical decomposition of HN_3 at 214 nm, and reported that the primary processes are

$$HN_3 + h\nu(214\text{ nm}) \longrightarrow {}^1NH' + N_2' \quad (95—97\%)$$
$$\longrightarrow H + N_3 \quad (3—5\%)$$

and the vibrationally excited $^1NH'$ and N'_2 are capable of causig further decomposition of HN_3.

Paur and Bair[7,8] have studied the flash photolysis of HN_3 by coordinated time-resolved spectroscopic measurements of HN_3, $NH(a^1\Delta)$, $NH(X^3\Sigma^-)$, $NH(c^1\Pi)$, $NH(A^3\Pi)$, NH_2, and N_3. They have reported that the major reactive product is $NH(a^1\Delta)$ or states which quickly decay to $NH(a^1\Delta)$ above 200 nm. Disappearance of $NH(a^1\Delta)$ occurs predominantly by the process

$$NH(a^1\Delta) + HN_3 \longrightarrow NH_2 + N_3$$

with a rate constant of 9.3×10^{-11} cm^3 molecule^{-1} s^{-1}.[8]

Recently, Piper *et al.*[9] have studied the UV photolysis of HN_3 by observing the time dependent decay in the number density of the $NH(a^1\Delta)$ product following photolysis at about 290 nm. They have obtained 18×10^{-11} cm^3 molecule^{-1} s^{-1} as a rate constant for the reaction

$$NH(a^1\Delta) + HN_3 \longrightarrow NH_2(\tilde{A}^2A_1) + N_3.$$

They also obtained 9.3×10^{-11} cm^3 molecule^{-1} s^{-1} as a specific rate for the reaction of $NH_2(\tilde{A}^2A_1)$ with HN_3.

Although the photolysis of HN_3 has been investigated intensively, as cited above, the quantitative mechanism is not clear. Notably, the reaction mechanisms at short wavelengths are more complex than those at long wavelengths because of the appearance of highly excited species. On the other hand, an absorption edge on the longest absorption band of HN_3 is located at about 310 nm,[10] and the formation of the first excited singlet $NH(a^1\Delta)$ can be expected at this wavelength. Thus, the photolysis of HN_3 vapor at 313 nm had been carried out in this work, before the studies of reactions of $NH(a^1\Delta$ and $X^3\Sigma^-)$ with various reactants.

Experimental

Materials. Hydrazoic acid was prepared from the reaction of NaN_3 with sulfuric acid (H_2SO_4: H_2O=1 : 2 in volume ratio) at room temperature, dried by passing through columns packed with $CaCl_2$ and P_2O_5, and stored below a half atm in a reservoir protected from light to avoid explosion.

The UV absorption of HN_3 of 14.3 kPa at 25.7 °C was observed at wavelengths longer than 220 nm. The molecular extinction coefficients calculated from $\log_{10}(I/I_0)=-ecl$ are illustrated in Fig. 1, and are slightly higher than those measured by McDonald and co-workers.[10] In the infrared region, two absorption peaks appear at 1.54 (ε_{max}=1.79) and 2.36 μm (ε_{max}=1.34 dm^3 mol^{-1} cm^{-1}). The former peak has been found in the spectrum of frozen HN_3.[11]

To elucidate the mechanism the photolysis was also carried out with hydrazoic acid labeled with nitrogen-15. For this purpose, potassium azide labeled with ^{15}N at the third nitrogen atom to the extent of 97% was obtained from Isomet Co. The hydrazoic acid was prepared from the azide in the same way

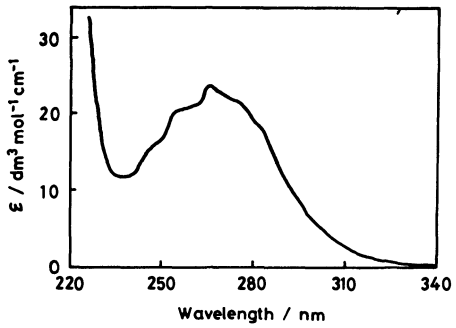

Fig. 1. UV absorption spectrum of HN_3 vapor.

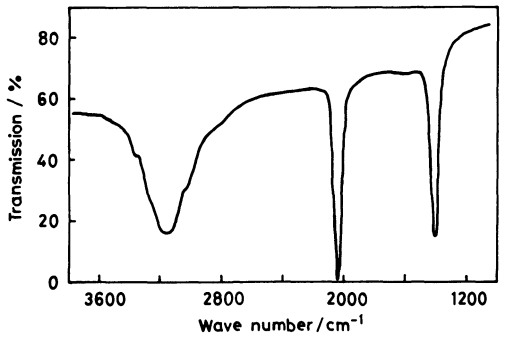

Fig. 2. Infrared spectrum of the white volatile powder condensed at the Dry Ice–acetone temperature.

as described above. It was presumably labeled at the first and third nitrogen atoms with the same probability, since the formation was due to the ionic processes:[12] $KNN^{15}N \xrightarrow{(H_2O)} K^+ + {}^{15}NNN^-$; $H^{15}NNN \longleftarrow H^+ + {}^{15}NNN^- \longrightarrow HNN^{15}N$.

Xe was obtained from Takachiho Chemical Co., and purified by vacuum distillation at liquid nitrogen temperature.

Apparatus. The photolysis was carried out at 313 nm obtained from a high pressure mercury lamp (Toshiba, SHL-100UV) of 100 W. As a filter for 313 nm, UV-D2 (Toshiba) was used. The light intensity was controlled by inserting screens between the light source and the reaction cell. The reaction cell was a quartz cylinder of 5.0 cm inner diameter and 10 cm length, with a volume of 196 cm^3. It was inserted in an electric furnace to maintain a fixed temperature.

Procedure. Hydrazoic acid was purified each time before use by condensation and evacuation at −120 °C and at Dry Ice–acetone temperature, introduced into the reaction cell, and exposed to the light. The irradiation time was usually 20 min. The degree of conversion of HN_3, calculated from the relation[13] $(2[N_2]+4[NH_4N_3])/3[HN_3]_0$, was less than 7% for all runs except 12.8% at the lowest pressure (0.787 kPa).

The reaction products were only N_2, H_2, and NH_4N_3. The formation of NH_4N_3 was first reported by Beckman and Dickenson,[1] and was further confirmed by infrared spectroscopy in this work. The spectrum observed by the KBr method for the white volatile powder condensed at Dry Ice–acetone temperature is shown in Fig. 2, and is in accord with the main three peaks in the spectrum of solid NH_4N_3 at 90 K.[14] The formation of hydrazinium azide ($N_2H_5N_3$) is ruled out judging from the infrared spectrum of hydrazine vapor.[15]

Noncondensable gases (N_2 and H_2) at the liquid nitrogen temperature were introduced into a column of silica gel[16] (for gas chromatography) at −196 °C. Hydrogen was passing through the column and collected in a Toepler gauge, and its amount was determined. Nitrogen, trapped on silica gel at −196 °C, was collected in the gauge by warming the column, and its amount was also determined.

The following method was used for the quantitative analysis of NH_4N_3: Unconverted HN_3 was removed by evacuating at Dry Ice–acetone temperature. Ammonium azide, trapped at −78 °C, was warmed, introduced into a CuO column and burnt at about 550 °C. N_2, NO, N_2O, and H_2O were separated as combustion products[17] at −210, −196, and −110 °C, respectively. The amounts of N_2, NO, and N_2O were in turn determined by the Toepler gauge. The amount of NH_4N_3 was calculated from the equation, $NH_4N_3=(N_2+N_2O)/2+NO/4$. The expectation amount of NH_4N_3 can be estimated by the equation[18] $NH_4N_3=N_2/4-3H_2/4$, and agreement between the experimental and expected amounts was very good.

The photolysis of HN_3 in the presence of Xe was also carried out by the same procedure.

Determination of Quantum Yield. Acetone was used as an actinometer, since the quantum yield of CO in photolysis of acetone at 313 nm is almost unity above 100 °C.[19] The quantum yield of nitrogen formation was 4.85 as an average value of three experiments at 30 °C, 313 nm, and 6.7 kPa of HN_3. The other quantum yields were calculated on the basis of the value for N_2.

Determination of Isotopic Composition. The isotopic composition of nitrogen formed in the photolysis of hydrazoic acid labeled by ^{15}N was analyzed by a mass spectrometer (Hitachi, RUM-5). The content of ^{15}N in NH_4N_3 was also determined by the mass spectrometric analysis of isotopic N_2, NO, and N_2O produced by the combustion.

Results

The results for photolysis of HN_3 of 6.7 kPa, measured as a function of the absorbed light intensity at 313 nm and 30 °C are shown in Fig. 3. It is found in Fig. 3 that the quantum yields, ϕ_{N_2}, ϕ_{H_2}, and $\phi_{NH_4N_3}$, are independent of the light intensity. The average values of ϕ_{N_2}, ϕ_{H_2}, and $\phi_{NH_4N_3}$ were 4.85, 0.494, and 0.842, respectively.

Figure 4 shows the results of photolysis, measured as a function of HN_3 pressure at 313 nm, 30 °C, and the incident light intensity of 2.0×10^{16} quanta s^{-1}. It is

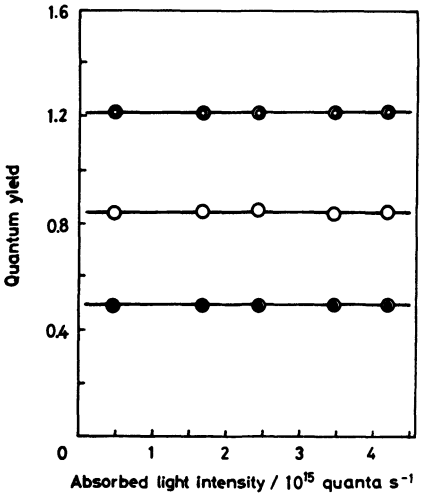

Fig. 3. Results of the photolysis of HN_3 of 6.7 kPa, measured as a function of the absorbed light intensity at 313 nm and 30 °C. ◎, $\phi_{N_2}/4$; ○, $\phi_{NH_4N_3}$; ⊙, ϕ_{H_2}.

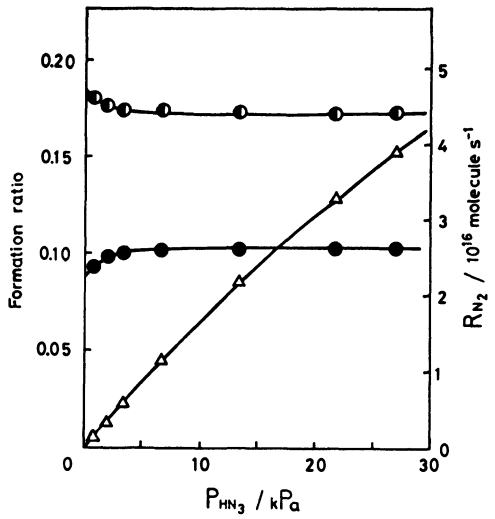

Fig. 4. Results of the photolysis, measured as a function of HN_3 pressure at 30 °C, 313 nm, and the incident light intensity of 2.0×10^{16} quanta s^{-1}. ◐, NH_4N_3/N_2; ●, H_2/N_2; △, R_{N_2}.

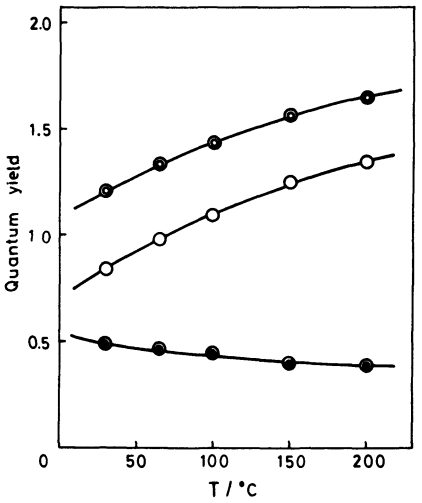

Fig. 5. Temperature dependence on the photolysis of HN_3 of 2.64 mmol dm^{-3} at 313 nm and the incident light intensity of 2.0×10^{16} quanta s^{-1}. ◎, $\phi_{N_2}/4$; ○, $\phi_{NH_4N_3}$; ⊙, ϕ_{H_2}.

seen in Fig. 4 that the relation of R_{N_2}, formation rate of N_2, *versus* P_{HN_3} changes slightly as is anticipated from Berr's law, H_2/N_2 decreases with lowering of the pressure, and NH_4N_3/N_2 increases in contrast with H_2/N_2.

The thermal decomposition of HN_3 has been studied at about 380[20] and 1000 °C,[21,22] but no decomposition was detected at least up to 200 °C in our system. Figure 5 shows the temperature dependence on the photolysis of HN_3 of 2.64×10^{-3} mol dm^{-3} (6.7 kPa at 30 °C) at 313 nm and the incident light intensity of 2.0×10^{16} quanta s^{-1}, where the quantum yields were estimated by assuming that the molecular extinction coefficient of HN_3 is independent of temperature. It is seen in Fig. 5 that ϕ_{N_2} and $\phi_{NH_4N_3}$ increase, but ϕ_{H_2} decreases with increase in temperature.

The results for the photolysis of HN_3 of 6.7 kPa,

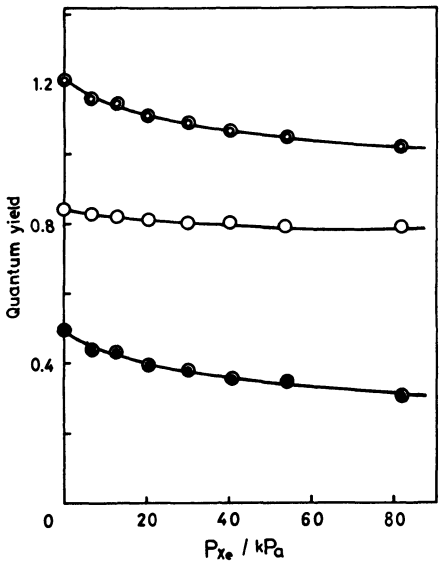

Fig. 6. Results of the photolysis of HN_3 of 6.7 kPa, measured as a function of Xe pressure at 313 nm, 30 °C, and the absorbed light intensity of 3.2×10^{15} quanta s^{-1}. ◎, $\phi_{N_2}/4$; ○, $\phi_{NH_4N_3}$; ⊙ ϕ_{H_2}.

measured as a function of Xe pressure at 313 nm, 30 °C, and an absorbed light intensity of 3.2×10^{15} quanta s^{-1}, are shown in Fig. 6. It is shown in Fig. 6 that all quantum yields decrease with an increase of Xe pressure.

On the photolysis of the labeled hydrazoic acid of 6.7 kPa at 313 nm and 30 °C, $^{14}N^{14}N/N_2$, $^{14}N^{15}N/N_2$, and $^{15}N^{15}N/N_2$ which mean the fractions of isotopic nitrogen molecules to total nitrogen molecules(N_2) were 44.5, 48.7, and 6.8%, respectively. The fraction of ^{15}N atoms to total N atoms in NH_4N_3 was 36.2%.

Discussion

Reaction Mechanism. It is difficult to determine the reaction scheme in this system, because only three kinds of products were obtained. However, we suggest the following reaction mechanism on the basis of the present results, our results in the photolysis of HN_3 in the presence of C_2H_6[23] and C_2H_4,[24] and the results obtained by previous investigators:

$$HN_3 + h\nu(313\text{ nm}) \longrightarrow N_2 + NH(a^1\Delta) \quad (1)$$

$$NH(a^1\Delta) + HN_3 \longrightarrow 2N_2 + 2H \quad (2)$$

$$NH(a^1\Delta) + HN_3 \longrightarrow N_3 + NH_2 \quad (3)$$

$$NH(a^1\Delta) + HN_3 \longrightarrow N_2 + N_2H_2^* \quad (4)$$

$$H + HN_3 \longrightarrow H_2 + N_3 \quad (5)$$

$$H + HN_3 \longrightarrow NH_2 + N_2 \quad (6)$$

$$N_2H_2^* \longrightarrow N_2H_2^{**} \quad (7)$$

$$N_2H_2^* + HN_3 \longrightarrow N_2 + H_2 + HN_3 \quad (8)$$

$$N_2H_2^* + HN_3 \longrightarrow NH_3 + 2N_2 \quad (9)$$

$$N_2H_2^{**} + HN_3 \longrightarrow NH_3 + 2N_2 \quad (10)$$

$$NH_2 + HN_3 \longrightarrow NH_3 + N_3 \quad (11)$$

$$NH_3 + HN_3 \longrightarrow NH_4N_3 \quad (12)$$

$$N_3 + HN_3 \longrightarrow HN_3\cdot N_3 \quad (13)$$

$$2HN_3\cdot N_3 \longrightarrow 3N_2 + 2HN_3. \quad (14)$$

In the photolysis of HN_3 in the presence of Xe, the following reactions were added to those listed above:

$$NH(a^1\Delta) + Xe \longrightarrow NH(X^3\Sigma^-) + Xe \quad (15)$$

$$NH(X^3\Sigma^-) + HN_3 \longrightarrow H_2 + 2N_2 \quad (16)$$

$$NH(X^3\Sigma^-) + HN_3 \longrightarrow NH_2 + N_3. \quad (17)$$

Thermochemical considerations were taken into account using the standard heats of formation listed in Table 1.

For HN_3 excited by absorbing light of 313 nm, the photo-decomposition processes

$$\begin{aligned} HN_3 + h\nu(313\text{ nm}) &\longrightarrow H(^2S) + N_3(X^2\Pi) \\ &\longrightarrow N_2(X^1\Sigma_g^+) + N(^4S) + H(^2S) \\ &\longrightarrow N_2(X^1\Sigma_g^+) + N(^2D) + H(^2S) \\ &\longrightarrow HN_2 + N(^2D) \end{aligned}$$

to give H and N atoms are not possible energetically.[5,25] Reaction 1 is the only photochemical process which is energetically possible and spin allowed, except the process

$$HN_3 + h\nu(313\text{ nm}) \longrightarrow N_2(X^1\Sigma_g^+) + NH(b^1\Sigma^+)$$

However, the formation of $NH(b^1\Sigma^+)$ was not detected although $NH(a^1\Delta)$ was observed as a predominant primary product.[7-9] It seems that $NH(b^1\Sigma^+)$ decays quickly to $NH(a^1\Delta)$, even if $NH(b^1\Sigma^+)$ was formed. Therefore, reactions yielding $NH(b^1\Sigma^+)$ were excluded from the reaction mechanism.

The formation of $NH(X^3\Sigma^-)$ by the collisional spin relaxation process

$$NH(a^1\Delta) + HN_3 \longrightarrow NH(X^3\Sigma^-) + HN_3$$

is negative judging from the facts that McDonald *et al.*[26] were not able to observe any triplet NH formation when helium was introduced even at pressures as high as 12 kPa, and the relation of $[NH(X^3\Sigma^-)] \ll [NH(a^1\Delta)]$ was found by Piper *et al.*[9] While, $NH(X^3\Sigma^-)$ has been observed in flash photolysis.[3,7,8,27] It seems that the formation of $NH(X^3\Sigma^-)$ is due to an emission process, $NH(A^3\Pi) \rightarrow NH(X^3\Sigma^-) + h\nu$, and the collisional quenching of $NH(a^1\Delta)$ by diluent gases such as Reaction 15.

Reactions 2, 3 and 4 are highly exothermic and their enthalpy changes are −370, −166, and −631 kJ mol^{-1}, respectively. The formation of H atoms has been found in the flash photolysis[28] and the photolysis of HN_3 in inert and reactive matrices.[29,30] Reaction 2 is also supported by the fact that the reaction, $H + C_2H_4 \rightarrow C_2H_5$, occurs during the photolysis of HN_3 with C_2H_4.[24] NH_2 radicals have been observed in the flash photolysis of HN_3 vapor.[3,7-9]

The formation of N_2H_2 has been detected in the photolysis of HN_3 in frozen matrices.[12,29,31] Reaction 4 is also supported by the facts that the similar reaction, $CH_3N + CH_3N_3 \rightarrow CH_3N_2CH_3 + N_2$, was found in the photolysis of CH_3N_3 vapor[32] and the rapid hydrogenation reaction,[33] $N_2H_2 + C_2H_4 \rightarrow C_2H_6 + N_2$, takes place in the photolysis of HN_3 with C_2H_4.[24]

On the reaction to give nitrogen atoms,

$$NH(a^1\Delta) + HN_3 \longrightarrow N(^4S \text{ or } ^2D) + N_3H_2$$

the reaction to form $N(^4S)$ is rejected because of the spin forbidden reaction. The reaction to give $N(^2D)$ may also be excluded because the heat of formation of N_3H_2 seems to be higher than 102.7 kJ mol^{-1} judging from the heat of formation of NH_2–N=NH and the bond dissociation energies of NH_2NN–H and H–NHNNH. The reaction to give H_2 molecules,

$$NH(a^1\Delta) + HN_3 \longrightarrow H_2 + 2N_2$$

is excluded because the H_2 formation decreases drastically on adding C_2H_4 in small amount.[24] Baird[25] has predicted a value of 255 kJ mol^{-1} for the heat of formation of HN_2 radicals. Therefore, the reaction

$$NH(a^1\Delta) + HN_3 \longrightarrow 2HN_2$$

is energetically possible. However, the HN_2 will decompose immediately with large excess energy even if HN_2 were formed, and it results in Reaction 2.

On the reactions of H atoms with HN_3 molecules, only Reactions 5 and 6 are energetically possible processes. The reactions

$$\begin{aligned} H + HN_3 &\longrightarrow N(^4S \text{ or } ^2D) + N_2H_2 \\ &\longrightarrow NH(X^3\Sigma^- \text{ or } a^1\Delta) + HN_2 \end{aligned}$$

are excluded energetically. Reaction 5 is the hydrogen abstraction reaction from HN_3 by H, and is supported because HN_3 is a good hydrogen donor.[34] Reaction 6 is 337 kJ mol^{-1} exothermic, and the formations of N_3 and NH_2 radicals were confirmed in the flash photolysis.[3,7,8,35] Combourieu *et al.*[36] have obtained $k = 2.54 \times 10^{-11} \exp(-2300/T)$ cm^3 molecule^{-1} s^{-1} as a rate constant of the reaction

$$H + HN_3 \longrightarrow \text{Products}.$$

Reactions 7 to 10 were introduced in order to explain the facts that NH_4N_3/N_2 increases and H_2/N_2 decreases with decrease of the HN_3 pressure, although the detail of these reactions are not clear. $N_2H_2^*$ formed by Reaction 4 is probably in an electronically excited state,[37] because Reaction 4 is very exothermic with 631 kJ mol^{-1}. If $N_2H_2^*$ is in an excited state, it may be possible that $N_2H_2^*$ transfers to a lower electronic state ($N_2H_2^{**}$) by internal conversion or intersystem crossing as Reaction 7, and $N_2H_2^{**}$ reacts to give NH_3 by Reaction 10. $N_2H_2^*$ may also possibly react with HN_3 by Reactions 8 and 9.

The bimolecular reactions as to N_2H_2,[38,39] $2N_2H_2 \rightarrow N_2H_4+N_2$ and $2N_2H_2 \rightarrow N_2+H_2+N_2H_2$, are ruled out in our system, because the formation of N_2H_4 was not observed, and the quantum yields of N_2 and H_2 were independent of the light intensity. It means that the concentration of N_2H_2 in our system is much lower than those described in Refs. 38 and 39.

Reaction 11 is the hydrogen abstraction reaction by NH_2 from HN_3 which is a good hydrogen donor.[34] Piper *et al.*[9] have presented the mechanism

$$NH(a^1\Delta) + HN_3 \longrightarrow NH_2(\tilde{A}^2A_1) + N_3$$
$$NH_2(\tilde{A}^2A_1) \longrightarrow NH_2(X^2B_1) + h\nu$$
(α bands of ammonia[40])
$$NH_2(\tilde{A}^2A_1) + HN_3 \longrightarrow NH_2(X^2B_1) + HN_3$$
$$\longrightarrow NH_3 + N_3$$

to explain the formation and disappearance of NH_2 ($\tilde{A}^2A_1$), and obtained 9.3×10^{-11} cm^3 $molecule^{-1}$ s^{-1} as a rate constant for the disappearance of $NH_2(\tilde{A}^2A_1)$ by HN_3. However, the HN_3 pressure dependence of NH_4N_3/N_2 in Fig. 4 can not be explained by their mechanism, provided that all $NH_2(X^2B_1)$ radicals disappear to give NH_3 as Reaction 11.

On the other hand, Kajimoto *et al.*[41] have observed the fluorescence from $NH_2(\tilde{A}^2A_1)$ formed by the reaction, $H+HN_3 \rightarrow N_2+NH_2(\tilde{A}^2A_1)$. Thus, Reactions 2, 3, and 6 are supported in terms of both observations for the fluorescence from $NH_2(\tilde{A}^2A_1)$. Judging from the enthalpy changes of Reactions 3 and 6, it is surmised that the emission from $NH_2(\tilde{A}^2A_1)$ formed by Reaction 6 appears at shorter wavelength than that from NH_2 ($\tilde{A}^2A_1$) formed by Reaction 3.[41]

Basic NH_3 reacts rapidly in the vapor phase with acidic HN_3 to give NH_4N_3 as a white volatile powder[42] by Reaction 12.

Paur and Bair[7,8] have observed that the disappearance rate of N_3 radicals is faster than expected for reaction with other radicals at concentrations present in their system, and concluded that this rate most likely represents reaction with HN_3. Therefore, it seems that N_3 radicals disappear to give N_2 *via* an addition intermediate ($HN_3 \cdot N_3$) as Reactions 13 and 14. Addition intermediates of N_3 with C_2H_4 and *cis*-C_4H_8 having π bond are also found in the photolysis of HN_3 with C_2H_4[24] and *cis*-C_4H_8.

Finally, all of the Reactions 1 to 14 in the photolysis of HN_3 vapor are energetically possible and spin allowed. The reaction mechanism satisfy the experimental requirements that the quantum yields of N_2, H_2, and NH_4N_3 are independent of the light intensity, and NH_4N_3/N_2 increases but H_2/N_2 decreases with lowering of HN_3 pressure. Reactions 1 to 14 are also found as a common reaction pattern in the photolysis of HN_3 in the presence of C_2H_6[23] and C_2H_4.[24]

On the photolysis of HN_3 in the presence of Xe, Reaction 15 seems to be the only process for the reaction of $NH(a^1\Delta)$ with Xe as an inert gas. For reactions of $NH(X^3\Sigma^-)$, we do not have enough experimental evidence. In any case, $NH(X^3\Sigma^-)$ will disappear to give H_2 and NH_3 by reactions with HN_3 such as Reactions 16 and 17.[43]

Recently, Kajimoto *et al.*[22] have estimated $3.0\times10^{11}\exp(-805/T)$ cm^3 mol^{-1} s^{-1} as k_{17} and 2.5×10^{13} cm^3 mol^{-1} s^{-1} as a rate constant of the reaction, $2NH(X^3\Sigma^-) \rightarrow N_2+2H$, in the thermal decomposition of HN_3 in shock waves. However, the possibility of the reaction, $2NH(X^3\Sigma^-) \rightarrow$ Products, will be negligible, because the $NH(X^3\Sigma^-)$ concentration is low in our system.

Reaction Kinetics. On the basis of the mechanism of Reactions 1 to 17, the equation

$$\frac{1}{\phi_{H_2}+\phi_{NH_4N_3}-1} = \frac{k_2+k_3+k_4}{k_2} + \frac{k_{15}[Xe]}{k_2[HN_3]}, \quad (I)$$

can be derived for the formations of H_2 and NH_4N_3. From the intercept and slope in Fig. 7 and from $k_4/k_2=1.23$ obtained in the photolysis of HN_3 with C_2H_4,[24] $k_3/k_2=0.746$, $k_{15}/k_2=0.557$ and $k_{15}/(k_2+k_3+k_4)=0.187$ are obtained.

Equation II can be derived for the formations of H_2 and N_2 in the absence of Xe.

$$\frac{1}{4/(1+R_{N_2}/R_{H_2})-\alpha} = \frac{2k_2+k_3+k_4}{k_4}\left(1+\frac{k_9}{k_8}+\frac{k_7}{k_8[HN_3]}\right), \quad (II)$$

where

$$\alpha = \frac{k_2}{2k_2+k_3+k_4}\frac{2k_5}{k_5+k_6}.$$

When α is 0.234, the best straight line is obtained as is seen in Fig. 8. From the intercept, the slope and $\alpha=0.234$, $k_6/k_5=1.15$, $k_9/k_8=1.19$, and $k_7/k_8=2.27\times10^{-7}$ mol cm^{-3} are obtained.

On the formations of H_2 and N_2 in the presence of Xe, Equation III can be derived.

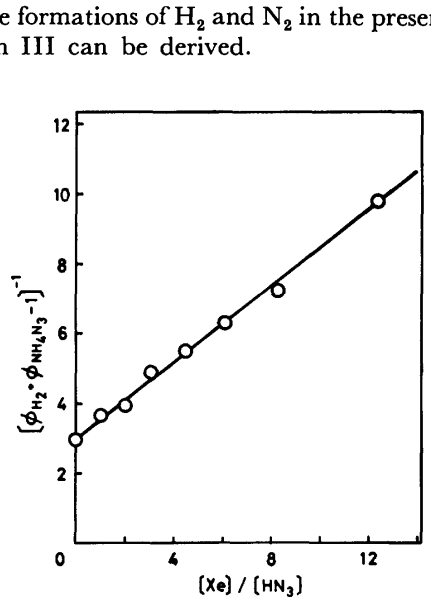

Fig. 7. Plot of $1/(\phi_{H_2}+\phi_{NH_4N_3}-1)$ *versus* $[Xe]/[HN_3]$.

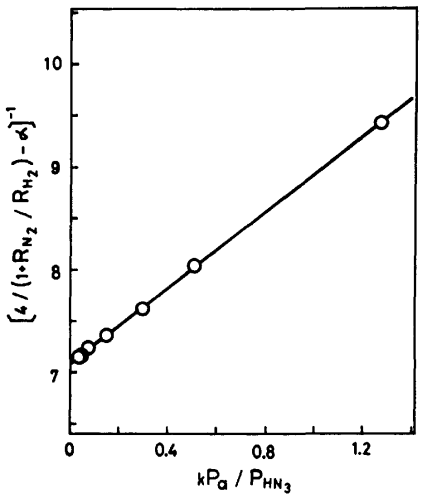

Fig. 8. Plot of $1/[4/(1+R_{N_2}/R_{H_2})-\alpha]$ against $1/P_{HN_3}$.

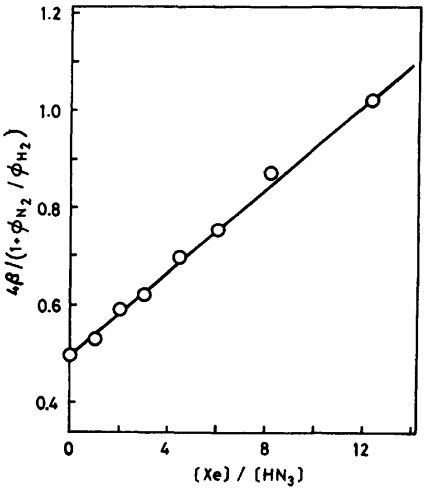

Fig. 9. Plot of $4\beta/(1+\phi_{N_2}/\phi_{H_2})$ *versus* $[Xe]/[HN_3]$.

$$\frac{4\beta}{1+\phi_{N_2}/\phi_{H_2}} = \alpha + \frac{k_4}{k_2+k_3+k_4}\frac{k_8[HN_3]}{k_7+(k_8+k_9)[HN_3]} + \frac{k_{15}}{k_2+k_3+k_4}\frac{k_{16}}{k_{16}+k_{17}}\frac{[Xe]}{[HN_3]}, \quad \text{(III)}$$

where

$$\beta = 1 + \frac{k_2}{k_2+k_3+k_4}\left(1+\frac{k_{15}}{k_2}\frac{[Xe]}{[HN_3]}\right) = 1.336 + 0.187[Xe]/[HN_3].$$

The plot of $4\beta/(1+\phi_{N_2}/\phi_{H_2})$ *versus* $[Xe]/[HN_3]$ at 6.7 kPa of HN_3 is shown in Fig. 9, and $k_{17}/k_{16}=3.22$ is obtained from the slope.

Equation I can be rewritten as

$$\frac{1}{\phi_{H_2}+\phi_{NH_4N_3}-1} - 1 = \frac{k_3+k_4}{k_2}, \quad \text{(IV)}$$

in the absence of Xe. The temperature dependence is shown in Fig. 10. It is found in Fig. 10 that $(k_3+k_4)/k_2$ decreases drastically from 1.976 at 30 °C with increasing temperature.

Isotopic Considerations. In order to confirm the reaction mechanism obtained above, the experimental values of $^{14}N^{14}N/N_2$, $^{14}N^{15}N/N_2$, $^{15}N^{15}N/N_2$, and $^{15}N/NH_4N_3$ in the absence of Xe were compared with the

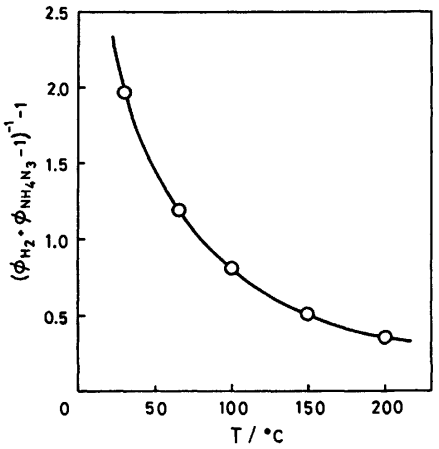

Fig. 10. Temperature dependence of $(k_3+k_4)/k_2$.

values calculated by using Eqs. V to VIII.

$$^{14}N^{14}N/N_2 = \sum_i S_i\alpha_i\phi_i/\phi_{N_2} \quad \text{(V)}$$

$$^{14}N^{15}N/N_2 = \sum_i S_i\beta_i\phi_i/\phi_{N_2} \quad \text{(VI)}$$

$$^{15}N^{15}N/N_2 = \sum_i S_i\gamma_i\phi_i/\phi_{N_2} \quad \text{(VII)}$$

$$^{15}N/NH_4N_3 = 1.5/4 \quad \text{(VIII)}$$

Here, ϕ_i is the quantum yield of i-th reaction, and can be calculated using the rate constant ratios obtained above. S_i is the stoichiometry of N_2 formed in i-th reaction. α_i, β_i and γ_i mean the fractions of $^{14}N^{14}N$, $^{14}N^{15}N$, and $^{15}N^{15}N$ including in total N_2 formed by i-th reaction, respectively. The values needed for the calculations of Eqs. V to VII are listed in Table 2, where S_i values in Reactions 3, 5, 6, and 7 include additional N_2 formations by subsequent Reactions 10, 11, 13, and 14.

The calculated values of $^{14}N^{14}N/N_2$, $^{14}N^{15}N/N_2$, $^{15}N^{15}N/N_2$, and $^{15}N/NH_4N_3$ are 43.1, 50.0, 6.89, and 37.5%, respectively. These values are consistent with the experimental values of 44.5, 48.7, 6.8, and 36.2%. Slight discrepancies may be due to incomplete isotopic enrichment (97%) of ^{15}N in the labeled hydrazoic acid. The recovery of ^{15}N calculated from the equation $3[\phi_{^{14}N^{15}N}+2\phi_{^{15}N^{15}N}+4(^{15}N/NH_4N_3)\phi_{NH_4N_3}]/(2\phi_{N_2}+4\phi_{NH_4N_3})$ is 0.974, and in accord with the original (0.97).

On the other hand, if Beckman's[1,2] and Thrush's[3] mechanisms are applied to Eq. VII, the values of $^{15}N^{15}N/N_2$ become 6.55 and 8.33%, respectively. Papazian[44] has postulated the following mechanism in outline on the photolysis of HN_3 in frozen state: $HN_3+h\nu \rightarrow NH + N_2$; $NH+HN_3 \rightarrow HN{=}N{-}N{=}NH \rightarrow 2HN_2$; $NH+HN_2+HN_3 \rightarrow H_2N{-}N{=}NH + 3/2\ N_2$; $H_2N{-}N{=}NH \rightarrow NH_3+N_2$; and $NH_3+HN_3 \rightarrow NH_4N_3$. From the mechanism, we obtain $^{15}N^{15}N/N_2=7.30\%$. The value of $^{15}N^{15}N/N_2$ calculated from the reaction scheme proposed by Konar *et al.*[6] was 2.65% in the absence of forein gases. Of the various possible mechanisms, our mechanism of Reactions 1 to 14 gives the best agreement with the isotopic measurements.

I would like to thank Emeritus Professor Osamu Toyama and Professor Shigeru Yamashita of University of Osaka Prefecture for their helpful discussions. I would also like to thank Dr. Sotaro Esho and Mr.

TABLE 2. VALUES USED TO CALCULATE THE ISOTOPIC COMPOSITIONS OF NITROGEN

Reaction No.	Quantum yield of i-th reaction	Stoichiometry of N_2 formation	Probability[a]		
			$^{14}N^{14}N$	$^{14}N^{15}N$	$^{15}N^{15}N$
i	ϕ_i	S_i	α_i	β_i	γ_i
1	1	1	1/2	1/2	0
2	0.3360	2	3/8	1/2	1/8
3	0.2505	3	5/12	1/2	1/12
4	0.4135	1	1/2	1/2	0
5	0.3128	3/2	5/12	1/2	1/12
6	0.3592	5/2	9/20	1/2	1/20
7	0.0156[b]	2	3/8	1/2	1/8
8	0.1817[b]	1	1/4	1/2	1/4
9	0.2163[b]	2	3/8	1/2	1/8

a) The probabilities (α_i, β_i, and γ_i) were estimated assuming that the enrichment of ^{15}N in the labeled hydrazoic acid is 1.00. b) Values at 6.7 kPa of HN_3.

Hidetoshi Hori for support of this work.

Reactions of NH Radicals. II. Photolysis of HN_3 in the Presence of C_2H_6 at 313 nm

Sukeya KODAMA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591

(Received September 13, 1982)

Photolysis of HN_3 vapor with C_2H_6 was studied at 313 nm and 30 °C. The products are N_2, H_2, CH_4, NH_4N_3, $CH_3NH_2 \cdot HN_3$, $C_2H_5NH_2 \cdot HN_3$, CH_3N_3, and CH_3CN. The quantum yields of these products were measured as a function of pressures of HN_3 and C_2H_6, and the light intensity. The following mechanism for the main reactions was proposed: $HN_3+h\nu(313\text{ nm}) \rightarrow N_2+NH(a^1\Delta)$; $NH(a^1\Delta)+HN_3 \rightarrow 2N_2+2H$ (2a); $NH(a^1\Delta)+HN_3 \rightarrow NH_2+N_3$ (2b); $NH(a^1\Delta)+HN_3 \rightarrow N_2+N_2H_2^*$ (2c); $NH(a^1\Delta)+C_2H_6 \rightarrow C_2H_5NH_2^*$ (3); $NH(a^1\Delta)+C_2H_6 \rightarrow NH(X^3\Sigma^-)+C_2H_6$ (4); $C_2H_5NH_2^* \rightarrow CH_3+CH_2NH_2$ (5); $C_2H_5NH_2^* \rightarrow CH_3CN+2H_2$ (6); $C_2H_5NH_2^*+M \rightarrow C_2H_5NH_2+M$ (7). The rate constant ratios at 30 °C are: $k_3/k_2=0.334$; $k_4/k_2=0.217$; $k_6/k_5=0.038$. The values of k_7/k_5 for C_2H_6, HN_3, CO_2, and Xe are 36.5, 30.3, 29.0, and 14.5 $dm^3\ mol^{-1}$, respectively. The values of $k_5=9.8\times10^9\ s^{-1}$, $k_6=3.7\times10^8\ s^{-1}$, τ (half life of $C_2H_5NH_2^*$)$=6.8\times10^{-11}$ s, η (collisional deactivation efficiency of $C_2H_5NH_2^*$)$=1$ for C_2H_6, HN_3, and CO_2, and $\eta=0.60$ for Xe were obtained by using the collision theory.

In the previous work,[1] on the photolysis of HN_3 vapor at 313 nm, it was found that hydrazoic acid is a good radical source for the first excited singlet $NH(a^1\Delta)$. Therefore, the formation of amines by insertion of the singlet NH into the C–H bond is expected in the photolysis of HN_3 with hydrocarbons, because the insertion is a characteristic reaction of the excited singlet species as were found in the reactions of $O(^1D)$,[2] $S(^1D)$,[3] and $CH_2(^1A_1)$[4] with hydrocarbons.

Miller[5] has demonstrated the formation of amines in the photolysis of HN_3 with propane, butane, isobutane, and neopentane. Cornell *et al.*[6] have studied the flash and steady photolyses of HN_3 (DN_3) with hydrocarbons including methane and ethane. They have found that the principal nitrogen-containing products are HCN and alkanenitriles in the steady photolysis. Brash and Back[7] have investigated the photolysis of HNCO in the presence of ethane, propane, neopentane, *etc.* but no amines could be detected. Recently, Tsunashima *et al.*[8] have studied the photolysis of HN_3 in liquid ethane, propane, and isobutane at the Dry Ice–methanol temperature, and observed the formation of ethylamine from ethane, propyl- and isopropylamine from propane, and isobutyl- and *t*-butylamine from isobutane.

In the work, C_2H_6 was chosen as a reactant by the following reasons: (a) the formation of ethylamine by collisional stabilization of chemically excited $C_2H_5NH_2^*$ produced by the insertion may be expected in the vapor phase photolysis, although CH_3NH_2 could not be detected in the case of CH_4,[5] because $C_2H_5NH_2$ has more degrees of internal freedom than CH_3NH_2; and (b) the identification and the quantitative analysis of amines are easy, because C_2H_6 has only primary hydrogen as compared with higher hydrocarbons that have secondary and tertiary hydrogens. Thus, the photolysis of HN_3 with C_2H_6 in the gas phase at 313 nm and 30 °C has been carried out in the present work to obtain quantitative results.

Experimental

Reaction Procedure. Ethane obtained from Takachiho Chemical Co. was 99.8% pure. It was purified each time before use by condensation and evacuation at −160 °C and liquid nitrogen temperature. Preparation and purification of HN_3, and the reaction apparatus were the same as described previously.[1] All runs in this work were carried out at 313 nm and 30 °C. The light intensity was controlled by screens, and the irradiation time was 20 to 390 min. The degree of conversion of HN_3 was only a few per cent for all runs. The reaction products were N_2, H_2, CH_4, NH_4N_3, $CH_3NH_2 \cdot HN_3$, $C_2H_5NH_2 \cdot HN_3$, CH_3N_3, and CH_3CN. On the other side, the formation of HCN was found in addition to above products at high light intensities.

Identifications of $CH_3NH_2 \cdot HN_3$ and $C_2H_5NH_2 \cdot HN_3$. An NMR spectrum of a D_2O solution of the white volatile products, condensed at the Dry Ice–acetone temperature, was

Fig. 1. NMR spectrum of a D_2O solution of the white volatile products trapped at the Dry Ice–acetone temperature.

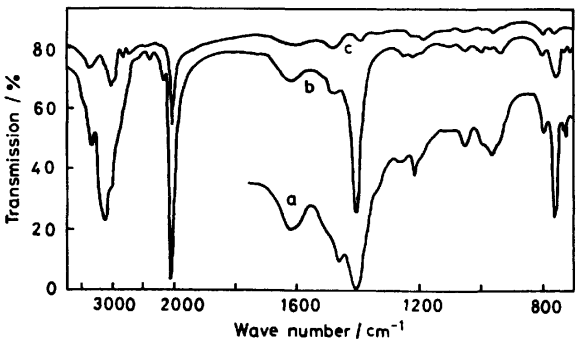

Fig. 2. IR spectra of the white volatile products (a and b) and $C_2H_5NH_2 \cdot HN_3$ sample (c).

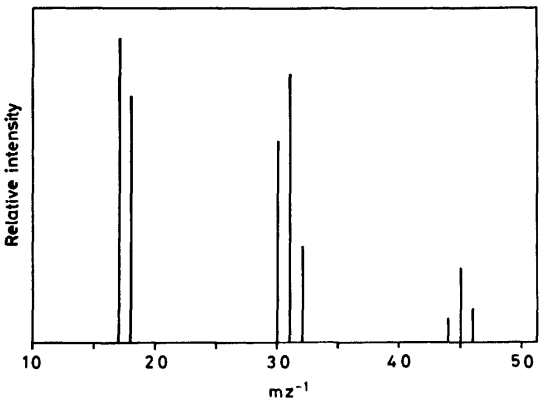

Fig. 3. Mass spectrum of the substances removed HN_3 from the white volatile products. The ionizing voltage is 15 eV.

obtained with a JNM 3H-60 (Japan Electron Optics) spectrometer, and is shown in Fig. 1. Chemical shifts are given in parts per million from $(CH_3)_4Si$. NMR spectra of known samples[9] of $CH_3NH_2 \cdot HN_3$, $C_2H_5NH_2 \cdot HN_3$, and $(CH_3)_2NH \cdot HN_3$ were also observed under the same conditions as above. From comparisons of the spectrum in Fig. 1 with the spectra of known samples, it was found that three peaks at 1.61, 1.73, and 1.85, a peak at 3.08, four peaks at 3.36, 3.48, 3.60, and 3.72, and a peak at 5.32 ppm correspond to the CH_3 group of ethylamine, CH_3 group of methylamine, CH_2 group of ethylamine, and NH_2 group of methyl- and ethylamine, respectively. Since a small peak at 3.20 ppm in Fig. 1 is in agreement with a peak of CH_3 group of $(CH_3)_2NH \cdot HN_3$ sample, the insertion of NH ($a^1\Delta$) into the C–C bond may be possible.

Infrared spectra of the white volatile products by the KBr disk method are shown in Fig. 2 together with a spectrum of a sample of $C_2H_5NH_2 \cdot HN_3$.[9] The main three peaks (1404, 2040, and 3150 cm^{-1}) in the spectra of the products are due to NH_4N_3,[1] and all peaks in the spectrum of the $C_2H_5NH_2 \cdot HN_3$ sample are found in the spectra of products as peaks or shoulders. The formation of $CH_3NH_2 \cdot HN_3$ could not be verified from the infrared spectra, because the spectrum of $CH_3NH_2 \cdot HN_3$ overlaps with the spectrum of $C_2H_5NH_2 \cdot HN_3$.

The white volatile products were introduced into a column of solid sodium hydroxide, then HN_3 molecules in the products ($RNH_2 \cdot HN_3$) were removed by the reaction,[8] $RNH_2 \cdot HN_3 + NaOH \longrightarrow RNH_2 + NaN_3 + H_2O$. A mass spectrum of the HN_3-removed products at the ionizing voltage of 15 eV is shown in Fig. 3. The existence of CH_3NH_2 and $C_2H_5NH_2$ together with NH_3 were verified from the masses of 17 (NH_3^+), 18 (NH_4^+), 30 (CH_3NH^+ or $CH_2NH_2^+$), 31 ($CH_3NH_2^+$), 32 ($CH_3NH_3^+$), 44 ($C_2H_5NH^+$ or $C_2H_4NH_2^+$), 45 ($C_2H_5NH_2^+$), and 46 ($C_2H_5NH_3^+$).

Quantitative Analysis of the Products. Noncondensable gases (N_2, H_2, and CH_4) at −210 °C were introduced into a column of silica gel (for gas chromatography) at −196 °C. Hydrogen, not trapped in the column, was collected in a Toepler gauge, and its amount determined. Nitrogen and methane, trapped on silica gel at −196 °C, were collected in the gauge by warming the column, and the total amount was also determined. The separation of N_2 and CH_4 was carried out by gas chromatography using a 5A molecular sieve column.

In the quantitative determinations of NH_4N_3, $CH_3NH_2 \cdot HN_3$, and $C_2H_5NH_2 \cdot HN_3$, the white volatile products condensed at the Dry Ice–acetone temperature were introduced on to a CuO column at about 550 °C. The combustion products were N_2, NO, CO_2, N_2O, and H_2O. The amounts of N_2 passing through a trap at −210 °C, NO trapped at −210 °C, and CO_2 and N_2O condensed at −196 °C were in turn determined by the Toepler gauge. H_2O was eliminated by trapping at −110 °C. The separation of CO_2 and N_2O was performed using a soda-lime column. The amount of CO_2 was determined by substracting the amount of N_2O from the total amount of CO_2 and N_2O.

From the stoichiometry for the combustion reactions, the relation, $[CO_2] = [CH_3NH_2 \cdot HN_3] + 2[C_2H_5NH_2 \cdot HN_3]$, is obtained for the CO_2 formation. On the other hand, the amount of $CH_3NH_2 \cdot HN_3$ can be estimated from the relation, $[CH_3NH_2 \cdot HN_3] = 0.540\ [CH_4]$, for all runs at low light intensities as discussed later. Therefore, the amount of $C_2H_5NH_2 \cdot HN_3$ can be calculated from the relation, $[C_2H_5NH_2 \cdot HN_3] = ([CO_2] - 0.540[CH_4])/2$. From the material balance of the nitrogen atoms, the amount of NH_4N_3 can be estimated by the equation, $[NH_4N_3] = (2[N_2] + 2[N_2O] + [NO])/4 - ([CO_2] + 0.540 \times [CH_4])/2$.

The quantum yields of products were measured by using HN_3 as an actinometer.[1]

Results

The results for the photolysis of HN_3 of 6.7 kPa, measured as a function of the absorbed light intensity at 313 nm, 30 °C, and 26.7 kPa of C_2H_6, are shown in Fig. 4. It is found in Fig. 4 that ϕ_{N_2}, ϕ_{CH_4}, $\phi_{CH_3NH_2 \cdot NH_3}$, and $\phi_{(CO_2)}(\phi_{CH_3NH_2 \cdot HN_3} + 2\phi_{C_2H_5NH_2 \cdot HN_3})$ decrease with an increase of the light intensity. The decrease of quantum yields seems due to radical-radical reactions, and the quantum yields converge to constant values at low light intensities. $\phi_{NH_4N_3}$, ϕ_{H_2}, and $\phi_{C_2H_5NH_2 \cdot HN_3}$ are independent of the light intensity.

Figure 5 shows the results of the photolysis measured as a function of C_2H_6 pressure at 6.7 kPa of HN_3 and low absorbed light intensity of 4.6×10^{14} quanta s^{-1} to eliminate radical-radical reactions. It is seen in Fig. 5 that ϕ_{N_2}, $\phi_{NH_4N_3}$, and ϕ_{H_2} decrease, and $\phi_{C_2H_5NH_2 \cdot HN_3}$ and $\phi_{(CO_2)}$ increase with an increase of C_2H_6 pressure, but ϕ_{CH_4} and $\phi_{CH_3NH_2 \cdot HN_3}$ decrease *via* each maximum value

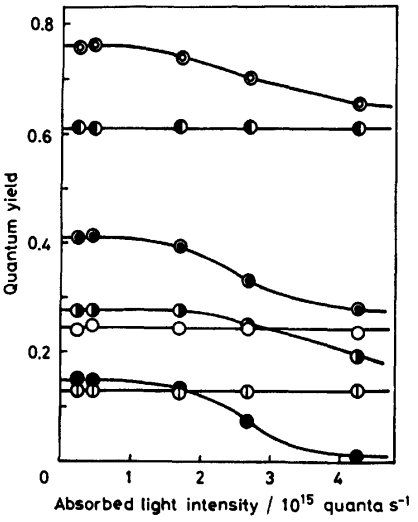

Fig. 4. Results for the photolysis of HN_3 of 6.7 kPa, measured as a function of the absorbed light intensity at 313 nm, 26.7 kPa of C_2H_6, and 30 °C. ◎, $\phi_{N_2}/5$; ◐, $\phi_{NH_4N_3}$, ⊙, $\phi_{(CO_2)}$; ◑, ϕ_{CH_4}; ○, ϕ_{H_2}; ◔, $\phi_{C_2H_5NH_2 \cdot HN_3}$; ●, $\phi_{CH_3NH_2 \cdot HN_3}$.

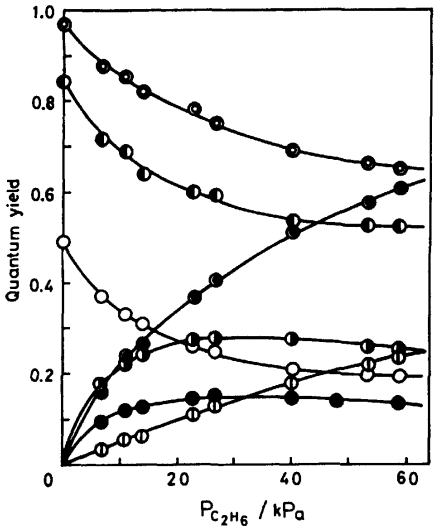

Fig. 5. Results of the photolysis of HN_3 of 6.7 kPa, measured as a function of C_2H_6 pressure at 313 nm, 30 °C, and low absorbed light intensity of 4.6×10^{14} quanta s^{-1}. The marks are the same as those in Fig. 4.

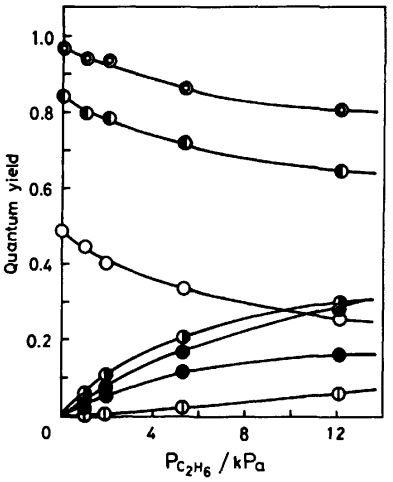

Fig. 6. Pressure dependence of C_2H_6 on the photolysis of HN_3 of 4.1 kPa at 313 nm, 30 °C, and low absorbed light intensity of 2.4×10^{14} quanta s^{-1}. The marks are the same as those in Fig. 4.

at about 27 kPa of C_2H_6.

The results for the photolysis of HN_3 at 4.1 kPa, measured as a function of C_2H_6 pressure, at low absorbed light intensity of 2.4×10^{14} quanta s^{-1} are shown in Fig. 6. In comparison with Fig. 5, it is seen from Fig. 6 that ϕ_{N_2} and ϕ_{H_2} decrease more rapidly, and ϕ_{CH_4} $\phi_{(CO_2)}$, and $\phi_{CH_3NH_2\cdot HN_3}$ increase more quickly as the C_2H_6 pressure increases.

Figure 7 shows the results of the photolysis, measured as a function of C_2H_6 pressure, at 6.7 kPa of HN_3 and high absorbed light intensity of 4.2×10^{15} quanta s^{-1}. It is seen in Fig. 7 that $\phi_{NH_4N_3}$ and ϕ_{H_2} are almost the same, but ϕ_{N_2}, $\phi_{(CO_2)}$, and ϕ_{CH_4} are lower as compared with those in Fig. 5.

Discussion

Reaction Mechanism. On the basis of the experimental results obtained above, the following reaction mechanism is postulated for the photolysis of HN_3 in the presence of C_2H_6 at low light intensities, where A, E, and M denote HN_3, C_2H_6, and deactivator molecules, respectively:

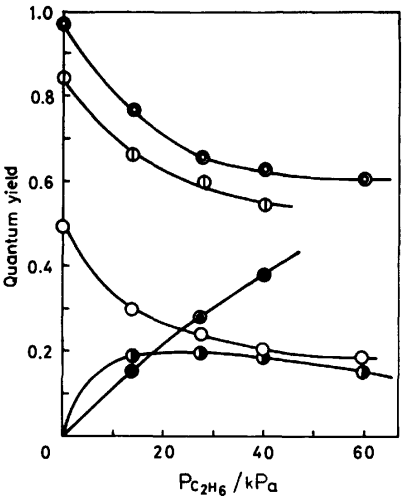

Fig. 7. Results of the photolysis of HN_3 of 6.7 kPa, measured as a function of C_2H_6 pressure at 313 nm, 30 °C, and high absorbed light intensity of 4.2×10^{15} quanta s^{-1}. The marks are the same as those in Fig. 4.

$$A + h\nu(313\text{ nm}) \longrightarrow N_2 + NH(a^1\Delta) \quad (1)$$

$$NH(a^1\Delta) + A \longrightarrow 2N_2 + 2H \quad (2a)$$

$$NH(a^1\Delta) + A \longrightarrow NH_2 + N_3 \quad (2b)$$

$$NH(a^1\Delta) + A \longrightarrow N_2 + N_2H_2^* \quad (2c)$$

$$NH(a^1\Delta) + E \longrightarrow C_2H_5NH_2^* \quad (3)$$

$$NH(a^1\Delta) + E \longrightarrow NH(X^3\Sigma^-) + E \quad (4)$$

$$C_2H_5NH_2^* \longrightarrow CH_3 + CH_2NH_2 \quad (5)$$

$$C_2H_5NH_2^* \longrightarrow 2H_2 + CH_3CN \quad (6)$$

$$C_2H_5NH_2^* + M \longrightarrow C_2H_5NH_2 + M \quad (7)$$

$$CH_2NH_2 + A \longrightarrow CH_3NH_2 + N_3 \quad (8)$$

$$CH_2NH_2 + A \longrightarrow CH_3N_3 + NH_2 \quad (9)$$

$$NH(X^3\Sigma^-) + A \longrightarrow H_2 + 2N_2 \quad (10)$$

$$NH(X^3\Sigma^-) + A \longrightarrow NH_2 + N_3 \quad (11)$$

$$H + A \longrightarrow H_2 + N_3 \quad (12)$$

$$H + A \longrightarrow NH_2 + N_2 \quad (13)$$

$$N_2H_2^* \longrightarrow N_2H_2^{**} \quad (14)$$

$$N_2H_2^* + A \longrightarrow N_2 + H_2 + A \quad (15)$$

$$N_2H_2^* + A \longrightarrow NH_3 + 2N_2 \quad (16)$$

$$N_2H_2^{**} + A \longrightarrow NH_3 + 2N_2 \quad (17)$$

$$CH_3 + A \longrightarrow CH_4 + N_3 \quad (18)$$

$$NH_2 + A \longrightarrow NH_3 + N_3 \quad (19)$$

$$N_3 + A \longrightarrow A\cdot N_3 \quad (20)$$

$$2A\cdot N_3 \longrightarrow 3N_2 + 2A \quad (21)$$

$$RNH_2(R=H,\ CH_3,\text{ and } C_2H_5) + A \longrightarrow RNH_2\cdot HN_3. \quad (22)$$

Thermochemical considerations were taken into account using the standard heats of formation listed in Table 1.

Since the formation of ethylamine has been established by the NMR, IR, and MS measurements, it is clear that the first excited singlet $NH(a^1\Delta)$ formed by the photolysis of HN_3 at 313 nm[1] reacts to give ethylamine by the insertion into a C–H bond of C_2H_6. The formation of ethylamine has also been found in the photolysis of HN_3 in liquid ethane.[8] Reaction 4 is a collisional spin relaxation process of $NH(a^1\Delta)$ by C_2H_6 as was found for Xe.[1] Similar collisional quenching processes have also been found for the other excited singlet species.[10]

Since the $C_2H_5NH_2$* formed by Reaction 3 possesses excess energy in excess of 470 kJ mol^{-1}, Reactions 5 and 6 are energetically possible. The unimolecular decomposition of $C_2H_5NH_2$* to give $C_2H_4+NH_3$, $C_2H_2+NH_3+H_2$, and $CH_4+HCN+H_2$ is possible, but these reactions are excluded, because C_2H_4, C_2H_2, and HCN were not detected in the products. The decompositions of $C_2H_5NH_2$* to give $H_2+C_2H_5N$, $C_2H_5+NH_2$, $H+C_2H_6N$, and CH_4+CH_2=NH are also possible energetically. However, the possibilities of these reactions could not be established in the reaction kinetics, although the kinetics for the formations of H_2, CH_4, and NH_4N_3 were treated with scrupulous care as mentioned later.

On the other hand, Lovas *et al.*[11] have reported that ethylamine decomposes thermally to give $NH_3+C_2H_4$, CH_2=NH+CH_4, CH_2=$CHNH_2+H_2$, and CH_3CH=NH+H_2 at about 900 °C. The difference in reaction mechanism seems to be due to the reaction conditions, that is, the thermal decomposition at high temperatures and the unimolecular decomposition of the chemically activated $C_2H_5NH_2$* at room temperature.

Reaction 7 is a collisional deactivation process of the vibrationally excited $C_2H_5NH_2$* by a third body(M). Similar collisional deactivation processes have also been found in the $O(^1D)$[2] and $CH_2(^1A_1)$[4] systems.

The CH_2NH_2 radicals formed by Reaction 5 disappear to give CH_3NH_2 and N_3 by a hydrogen abstraction reaction from HN_3, and to give CH_3N_3 and NH_2 *via* addition to a π bond of HN_3 in Reactions 8 and 9. Both reactions are supported by the formations of CH_3NH_2 and CH_3N_3. Reaction 18 is a hydrogen abstraction reaction by CH_3 from HN_3 as a strong hydrogen donor. Konar *et al.*[12] have obtained $k_{18}=8.9\times10^7$ cm^3 mol^{-1} s^{-1} in the photolysis of azomethane in the presence of HN_3 at 25 °C.

Reaction 22 was proved by the experimental fact[9] that basic ammonia and amines of CH_3NH_2 and C_2H_5-NH_2, (RNH_2), react with acidic HN_3 in the vapor phase to give the azide salts ($RNH_2\cdot HN_3$) as a white volatile powder.

In the presence of HN_3, the reactions of $NH(X^3\Sigma^-)+C_2H_6\rightarrow NH_2+C_2H_5$ and $H+C_2H_6\rightarrow H_2+C_2H_5$ could not be found in the reaction kinetics for the formations of H_2 and NH_4N_3. Reactions other than those mentioned above were discussed previously,[1] and are omitted here.

At high light intensities, the formation of HCN is observed. Moreover, as seen in Fig. 4, $\phi_{NH_4N_3}$ increases, but ϕ_{N_2}, ϕ_{CH_4}, and $\phi_{CH_3NH_2}$ decrease with an increase of the light intensity. It is clear that these facts are due to some radical-radical reactions at high light intesities. The most abundant radical in this system will be $A\cdot N_3$, because the other radicals disappear and are converted into N_3 radicals by reactions with HN_3 as Reactions 8, 11, 12, 18, and 19. The N_3 radicals then rapidly become $A\cdot N_3$, most probably by addition as Reaction

20, with HN_3.[13] Thus, the following reactions

$$CH_3 + A\cdot N_3 \longrightarrow CH_3N_3 + A, \quad (23)$$

$$CH_2NH_2 + A\cdot N_3 \longrightarrow (N_3CH_2NH_2) + A, \quad (24)$$

were added at high light intensities. By the inclusion of the above reactions, we can explain not only the formation of HCN, but also the trends shown in Fig. 4. These are also useful to ascertain the existences of CH_3, CH_2NH_2, and $A\cdot N_3(N_3)$ radicals.

Reaction Kinetics. The following reaction kinetics were formulated to confirm the mechanism of Reactions 1 to 22 and to obtain the rate constant ratios at low light intensities.

As to the formations of CH_4, $CH_3NH_2\cdot HN_3$, and $C_2H_5NH_2\cdot HN_3$, the equation

$$\frac{\phi_{(CO_2)}}{\phi_{CH_4}} = \frac{k_8}{k_8+k_9} + \frac{2k_7(HN_3)[HN_3]}{k_5} + \frac{2k_7(C_2H_6)[C_2H_6]}{k_5}, \quad (I)$$

can be derived, where $\phi_{(CO_2)}$ denotes the total formation rate of CO_2 formed by the combustions of amine salts.

$$\phi_{(CO_2)} = \phi_{CH_3NH_2\cdot HN_3} + 2\,\phi_{C_2H_5NH_2\cdot HN_3}$$

plots of $\phi_{(CH_2)}/\phi_{CO_4}$ measured as a function of C_2H_6 pressure at 4.1 and 6.7 kPa of HN_3 are shown in Fig. 8, and the values of $k_9/k_8=0.852$, $k_7(HN_3)/k_5=3.03\times10^4$ $cm^3\,mol^{-1}$, and $k_7(C_2H_6)/k_5=3.65\times10^4$ $cm^3\,mol^{-1}$ are obtained from the intercepts and the slopes. Accordingly, the quantum yield of $CH_3NH_2.HN_3$ is given by the equation, $\phi_{CH_3NH_2\cdot HN_3}=[k_8/(k_8+k_9)]\phi_{CH_4}=0.540\ \phi_{CH_4}$.

In order to obtain the collisional deactivation efficiencies of $C_2H_5NH_2$* by Xe and CO_2, the photolysis of HN_3 in the presence of C_2H_6 and Xe or CO_2 was also carried out by the same method as mentioned above. Plots of $\phi_{(CO_2)}/\phi_{CH_4}$ measured as a function of Xe or CO_2 pressure at 6.7 kPa of HN_3 and 21.6 kPa of C_2H_6 are also shown in Fig. 8. The values of $k_7(Xe)/k_5=1.45\times10^4$ and $k_7(CO_2)/k_5=2.90\times10^4$ $cm^3\,mol^{-1}$ were obtained from the relation

$$\frac{\phi_{(CO_2)}}{\phi_{CH_4}} = \left(\frac{k_8}{k_8+k_9} + \frac{2k_7(HN_3)[HN_3]+2k_7(C_2H_6)[C_2H_6]}{k_5} + \frac{2k_7(Xe)[Xe]+2k_7(CO_2)[CO_2]}{k_5}\right), \quad (II)$$

and the slopes in Fig. 8.

On the formations of H_2, CH_4, NH_4N_3, $CH_3NH_2\cdot HN_3$, and $C_2H_5NH_2\cdot HN_3$, the equation

$$\left(\frac{\phi_{(N/4)}+\phi_{H_2}}{\phi_{CH_4}} - \frac{k_6}{k_5}\right)\frac{1}{\alpha} = 1 + \frac{k_4}{k_3} + \frac{k_2+k_{2a}}{k_3}\frac{[HN_3]}{[C_2H_6]}, \quad (III)$$

can be derived, where

$$\alpha = 1 + \frac{k_6}{k_5} + \frac{k_7(HN_3)[HN_3]+k_7(C_2H_6)[C_2H_6]}{k_5},$$

and

$$k_2 = k_{2a} + k_{2b} + k_{2c},$$

and $(N/4)$ means one-quater of total nitrogen atoms found in the combustions of azide salts.

$$\phi_{(N/4)} = \phi_{NH_4N_3} + \phi_{CH_3NH_2\cdot HN_3} + \phi_{C_2H_5NH_2\cdot HN_3}$$

Equation IV can be derived as to the formations of N_2, H_2, and CH_4.

$$\left(\frac{\phi_{N_2}+\phi_{H_2}}{\phi_{CH_4}} - \frac{3k_5+2k_6}{k_5}\right)\frac{1}{\alpha} = 1 + \frac{4k_4}{k_3} + 4\left(\frac{k_2+k_{2a}}{k_3}\right)\frac{[HN_3]}{[C_2H_6]} \quad (IV)$$

By combining Eqs. III and IV, the equation

$$\frac{4\phi_{(N/4)}+3\phi_{H_2}-\phi_{N_2}}{\phi_{CH_4}} - 3\left(\frac{k_7(HN_3)[HN_3]+k_7(C_2H_6)[C_2H_6]}{k_5}\right) = \frac{5k_6}{k_5}, \quad (V)$$

can be derived. By using the experimental values of $\phi_{(N/4)}$, ϕ_{N_2}, ϕ_{H_2}, and ϕ_{CH_4}, and the values of $k_7(HN_3)/k_5$ and $k_7(C_2H_6)/k_5$ obtained above, $k_6/k_5=0.038$ was obtained as a mean value.

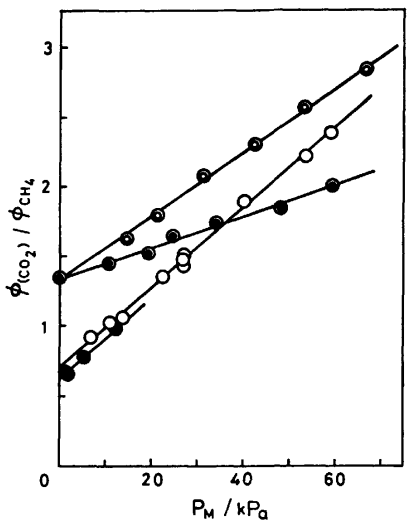

Fig. 8. Pressure dependence of $\phi_{(CO_2)}/\phi_{CH_4}$ at 313 nm and 30 °C. ◎, Measured as a function of CO_2 pressure at 6.7 kPa of HN_3 and 21.6 kPa of C_2H_6; ⊙, measured as a function of Xe pressure at 6.7 kPa of HN_3 and 21.6 kPa of C_2H_6; ○, measured as a function of C_2H_6 pressure at 6.7 kPa of HN_3; ●, measured as a function of C_2H_6 pressure at 4.1 kPa of HN_3.

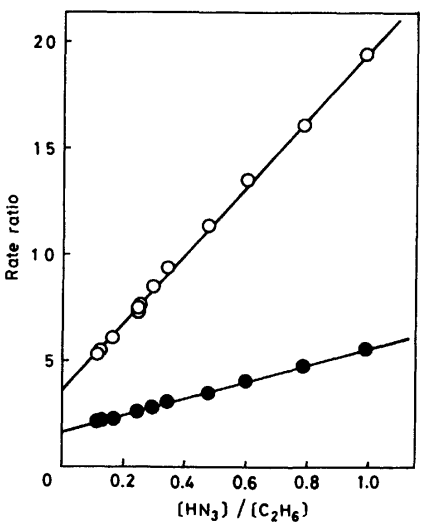

Fig. 9. Plots for Eqs. III and IV. ○, $[(\phi_{N_2}+\phi_{H_2})/\phi_{CH_4}-(3+2k_6/k_5)]/\alpha$; ●, $[(\phi_{(N/4)}+\phi_{H_2})/\phi_{CH_4}-k_6/k_5]/\alpha$. $k_6/k_5=0.038$.

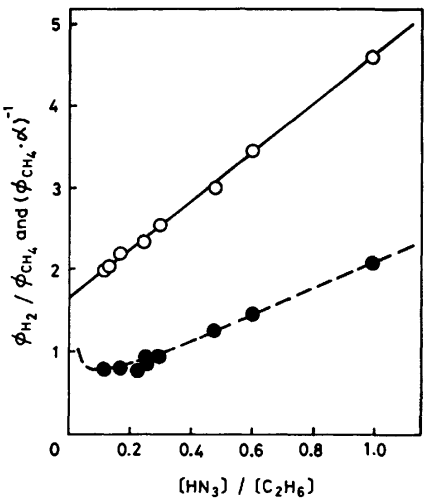

Fig. 10. Plots of $(\phi_{CH_4}\cdot\alpha)^{-1}$ and ϕ_{H_2}/ϕ_{CH_4} *versus* $[HN_3]/[C_2H_6]$. ○, $(\phi_{CH_4}\alpha)^{-1}$; ●, experimental value of ϕ_{H_2}/ϕ_{CH_4} at 6.7 kPa of HN_3; ---, calculated value of ϕ_{H_2}/ϕ_{CH_4} by Eq. VII.

The values of $[(\phi_{N_2}+\phi_{H_2})/\phi_{CH_4}-(3+2k_6/k_5)]/\alpha$ in Eq. IV were calculated using the experimental values and the rate constant ratios obtained above, and were plotted against $[HN_3]/[C_2H_6]$ as shown in Fig. 9. From the intercept and the slope, and from $k_{2b}/k_{2a}=0.746$ and $k_{2c}/k_{2a}=1.23$ obtained previously,[1] $k_3/k_2=0.334$ and $k_4/k_2=0.217$ were obtained. The relation of $[(\phi_{(N/4)}+\phi_{H_2})/\phi_{CH_4}-k_6/k_5]/\alpha$ *versus* $[HN_3]/[C_2H_6]$ in Eq. III was also plotted in Fig. 9, and the values of k_3/k_2 and k_4/k_2 obtained from the intercept and the slope were identical as those obtained from the plot for Eq. IV.

The values of k_3/k_2 and k_4/k_2 can also be obtained from the relation

$$\frac{1}{\phi_{CH_4}\alpha}=1+\frac{k_4}{k_3}+\frac{k_2}{k_3}\frac{[HN_3]}{[C_2H_6]}. \qquad \text{(VI)}$$

The values of k_3/k_2 and k_4/k_2 obtained from the straight line relation in Fig. 10 are consistent with those obtained from Eqs. III and IV.

To confirm the mechanism of succeeding reactions, the equation

$$\frac{\phi_{H_2}}{\phi_{CH_4}}=\frac{2k_6}{k_5}+\frac{k_4}{k_3}\frac{k_{10}\alpha}{k_{10}+k_{11}}+\frac{k_{2a}\alpha}{k_3}\left(\frac{2k_{12}}{k_{12}+k_{13}}+\frac{k_{2c}}{k_{2a}}\frac{k_{15}[HN_3]}{k_{14}+(k_{15}+k_{16})[HN_3]}\right)\frac{[HN_3]}{[C_2H_6]}, \qquad \text{(VII)}$$

was derived as to the formations of H_2 and CH_4. A plot of ϕ_{H_2}/ϕ_{CH_4} *versus* $[HN_3]/[C_2H_6]$ is shown in Fig. 10. The experimental values for ϕ_{H_2}/ϕ_{CH_4} are in good accord with the values calculated using the values of k_3/k_2, k_4/k_2, k_6/k_5, k_7/k_5, k_{2b}/k_{2a}, and k_{2c}/k_{2a} mentioned above, and of $k_{11}/k_{10}=3.22$, $k_{13}/k_{12}=1.15$, $k_{14}/k_{15}=2.27\times10^{-7}$ mol cm^{-3}, and $k_{16}/k_{15}=1.19$ obtained previously.[1] This means that the reaction mechanism and the rate constant ratios proposed previously[1] are also useful in the present system.

At high light intensities, the equation

$$\frac{\phi^*_{(CO_2)}-\beta\phi^\circ_{CH_4}}{\phi^*_{CH_4}}=\frac{k_8}{k_{18}}\frac{k_{23}}{k_{24}}+\left(1-\frac{k_8+k_9}{k_{18}}\frac{k_{23}}{k_{24}}\right)\left(\frac{\phi^*_{(CO_2)}}{\phi^\circ_{CH_4}}-\beta\right) \qquad \text{(VIII)}$$

can be derived for the formations of CH_4 and CO_2 by combustion, where

$$\beta=2(k_7(HN_3)[HN_3]+k_7(C_2H_6)[C_2H_6])/k_5$$

$\phi^*_{CH_4}$ and $\phi^*_{(CO_2)}$ denote the quantum yields of CH_4 and CO_2 at high light intensities. $\phi^\circ_{CH_4}$ is the estimated quantum yield of CH_4 at low light intensity, but the other experimental conditions are the same as those for $\phi^*_{CH_4}$ and $\phi^\circ_{CH_4}$. A plot of $(\phi^*_{(CO_2)}-\beta\phi^\circ_{CH_4})/\phi^*_{CH_4}$ *versus* $\phi^*_{(CO_2)}/\phi^\circ_{CH_4}-\beta$ is shown in Fig. 11. The values of $k_8k_{23}/k_{18}k_{24}=0.030$ from the intercept and $(k_8+k_9)k_{23}/k_{18}k_{24}=0.056$ from the slope were obtained. If we assumed that k_{23} is nearly equal to k_{24} because both reactions are the radical-radical combination,[14] $k_{18}/k_8=33.3$ and $k_{18}/(k_8+k_9)=18.0$ are obtained. These values imply that the reactivity of CH_2NH_2 for reaction with HN_3 is much lower than that of CH_3. It may be because CH_2NH_2 is stabilized by the interaction of an unpaired electron in CH_2 group with nonbonding electrons in NH_2 group.[15]

Comparisons of Rate Constants. The rate constant ratios for the reactions of $NH(a^1\Delta)$ are shown in Table 2, together with the values obtained by Tsunashima *et al.*[8] on the photolysis of HN_3 in liquid ethane at the Dry Ice–methanol temperature and 250 to 330 nm. The value of $k_3/(k_3+k_4)$ obtained by them is slightly higher than the value in the present work. The discrepancy may be due to the difference of the experimental conditions of phase, temperature, wavelength, *etc.*

On the other hand, their value for k_2/k_3 is extremely high as compared with our value. The most significant differences between the mechanisms are as follows: Reactions 2a, 2c, 10, and 13 were not taken into account in their mechanism; the reaction, $2NH_2\rightarrow N_2H_4$, was considered in their mechanism, although they failed to detect hydrazine.

The slope for Eq. III in Fig. 9 is steeper than the slope for Eq. VI in Fig. 10. This implies that k_{2a} is not zero.

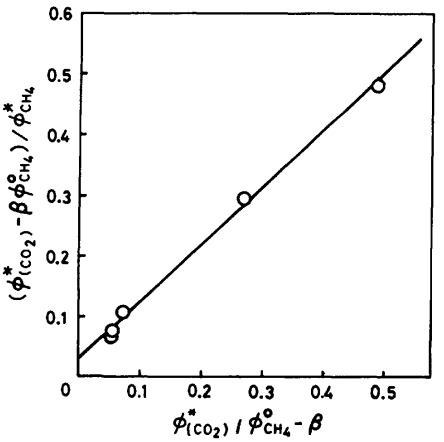

Fig. 11. Plot of $(\phi^*_{(CO_2)}-\beta\phi^\circ_{CH_4})/\phi^*_{CH_4}$ *versus* $\phi^*_{(CO_2)}/\phi^\circ_{CH_4}-\beta$.

TABLE 2. RATE CONSTANT RATIOS FOR THE REACTIONS OF $NH(a^1\Delta)$

$k_3/(k_3+k_4)$	k_2/k_3	
0.86 ± 0.04	125 ± 21	Ref. 8
0.606	2.99	This work

Moreover, if k_{2a} and k_{10} are zero, ϕ_{H_2}/ϕ_{CH_4} in Eq. VII should be reduced to 0.076 independently of $[HN_3]/[C_2H_6]$. This assumption is inconsistent with the experimental results of ϕ_{H_2}/ϕ_{CH_4} in Fig. 10. However, the large discrepancy for k_2/k_3 can not be explained by the existence of Reactions 2a, 10, and others, because the influence to k_2/k_3 on the succeeding reactions is not very large.

It seems that the reaction rate of NH($a^1\Delta$) with C_2H_6 is not very slow, judging from the specific rates of reactions of the first excited singlet species, $C(2^1D_2)$,[16] $O(2^1D_2)$,[17] and $S(3^1D_2)$,[18] with CH_4, C_2H_6, C_3H_8, and others. The main reason for the large discrepancy of k_2/k_3 seems to be due to the difference of the liquid and vapor phases.

If we assume that the arrangement of molecules in the liquid is closest-packed hexagonal, and both C_2H_6 and HN_3 molecules have the same size and a spherical shape, HN_3 molecules are mutually separated by five molecular distances at the concentration ratio of $[HN_3]/[C_2H_6]=0.0034$. When a HN_3 molecule was converted into NH($a^1\Delta$) and N_2 by the photochemical decomposition, all of 322 molecules in four molecular layers from the central NH($a^1\Delta$) are ethane. Although twelve molecules of HN_3 exist at the fifth layer, the NH($a^1\Delta$) will be lost by an insertion or quenching reaction with C_2H_6 before the NH($a^1\Delta$) encounters a HN_3 molecule, because the set-collision with C_2H_6 as a solvent molecule takes place during the diffusion process.

Since the five molecule separation was merely taken as an average value, and the mutual diffusion between NH($a^1\Delta$) and HN_3 occurs during the reaction period, the situation is not quite so simple. However, the probability that the excited singlet NH($a^1\Delta$) encounters a HN_3 molecule will be much less than that expected from the concentration. This prediction drastically reduces the appearent k_2/k_3 value. Therefore, the high value for k_2/k_3 may be due to a contribution from succeeding reactions for NH($X^3\Sigma^-$).

The high value of k_2/k_3 is also explainable if dimers and clusters of HN_3 are formed in liquid ethane at Dry Ice–methanol temperature. However, it is uncertain at present if dimers and clusters are in fact formed hydrogen bonding and molecular association.

The specific rate of Reaction 7 can be estimated from the equation

$$k_7 = \eta k_z, \qquad \text{(IX)}$$

where, k_z is the collision number of $C_2H_5NH_2$* per second, and η is the collisional stabilization efficiency. The value of k_z can be calculated from the Lennard-Jones collision frequency.[19]

$$k_z = N_A\sigma^2_{B-M}(8\pi kT/\mu_{B-M})^{1/2}\Omega^{(2,2)*}_{B-M} \qquad \text{(X)}$$

Here, N_A is Av σ_{B-M} ogadro's number,and k is Boltzmann's constant. σ_{B-M}, μ_{B-M}, and $\Omega^{(2,2)*}_{B-M}$ mean the collision diameter, the reduced mass, and the reduced collision integral for B(ethylamine) and M molecules, respectively. The values of $\Omega^{(2,2)*}_{B-M}$ are conveniently tabulated[20] as a function of kT/ε_{B-M} with the Lennard-Jones well depth $\varepsilon_{B-M}=(\varepsilon_{B-B}\cdot\varepsilon_{M-M})^{1/2}$. The σ_{B-M} is given by $\sigma_{M-B}=(\sigma_B+\sigma_M)/2$. For ethylamine, $\sigma_B=4.80$ Å and $\varepsilon_{B-B}/k=320$ K were estimated from those for C_2H_5OH,[21] C_3H_6,[22] and C_3H_8[23] molecules. The values of k_z calculated using Eq. X are shown in Table 3.

The absolute value of k_5 can be estimated from the relation

$$k_5 = \eta k_z/(k_7/k_5)_{obsd}. \qquad \text{(XI)}$$

The values of k_5 calculated by assuming $\eta=1$ are shown in Table 3, and it is found that the values for C_2H_6, HN_3, and CO_2 are almost the same. This result means that the $C_2H_5NH_2$* is deactivated with every collision in the collisions with polyatomic molecules such as C_2H_6, HN_3, and CO_2.

The value of k_5 calculated with $\eta=1$ for Xe is higher than the values for the polyatomic molecules. Therefore the collisional deactivation efficiency of Xe is less than unity, and should be reduced to 0.60 to adjust to the same value as k_5 for polyatomic molecules. The result is supported by the fact that the collisional energy transfer efficiencies by monatomic molecules are much less than those by polyatomic molecules.[24]

As a specific rate of the unimolecular decomposition of $C_2H_5NH_2$* to give CH_3 and CH_2NH_2, $k_5=9.8\times10^9$ s^{-1} is obtained by averaging the three values for polyatomic molecules. From the rate constant ratio of $k_6/k_5=0.038$, $k_6=3.7\times10^8$ s^{-1} is obtained for the unimolecular decomposition of $C_2H_5NH_2$* to give CH_3-CN and $2H_2$. By using the relation $\tau=\ln 2/(k_5+k_6)$, $\tau=6.8\times10^{-11}$ s is obtained as a half life of $C_2H_5NH_2$*.

The author is gratefully indebted to Emeritus Professor Osamu Toyama of University of Osaka Prefecture for his helpful advice and to Dr. Sotaro Esho for his cooperation.

Reactions of NH Radicals. III. Photolysis of HN_3 in the Presence of C_2H_4 at 313 nm

Sukeya KODAMA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591

(Received September 13, 1982)

Photolysis of HN_3 vapor in the presence of C_2H_4 was studied at 313 nm and 30 °C. The main products were N_2, H_2, CH_4, C_2H_6, NH_4N_3, $C_2H_5N \cdot HN_3$ (salt of C_2H_5N (azomethines) with HN_3), HCN, CH_3CN, CH_3N_3, and $C_2H_5N_3$. The quantum yields of these products were measured as a function of the light intensity and pressures of HN_3 and C_2H_4. The following mechanism for the main reactions was infered: $HN_3+h\nu(313\text{ nm})\rightarrow NH(a^1\Delta)+N_2$; $NH(a^1\Delta)+HN_3\rightarrow 2N_2+2H$ (2a); $NH(a^1\Delta)+HN_3\rightarrow NH_2+N_3$(2b); $NH(a^1\Delta)+HN_3\rightarrow N_2+N_2H_2{}^*$ (2c); $NH(a^1\Delta)+C_2H_4\rightarrow C_2H_5N^*$ (aziridine and vinylamine) (3); $C_2H_5N^*\rightarrow CH_3+CH_2N$ (4); $C_2H_5N^*\rightarrow H_2+CH_3CN$ (5); $C_2H_5N^*\rightarrow H+C_2H_4N$ (6); $C_2H_5N^*\rightarrow C_2H_3+NH_2$ (7). The rate constant ratios at 30 °C are: $k_3/k_2=1.64$; $k_5/k_4=0.102$; $k_6/k_4=0.564$; $k_7/k_4=0.734$. The collisional deactivation from $NH(a^1\Delta)$ to $NH(X^3\sum^-)$ by C_2H_4 was not found. The lifetime of $C_2H_5N^*$ is much shorter than 6.8×10^{-11} s for $C_2H_5NH_2{}^*(\leftarrow NH(a^1\Delta)+C_2H_6)$. The relative and absolute rates for the reactions of $NH(a^1\Delta)$ with HN_3, Xe, C_2H_6, and C_2H_4 are discussed.

The photolysis of HN_3 in the presence of Xe[1] and C_2H_6[2] at 313 nm has been studied previously, and it was found that HN_3 is a useful source for the first excited singlet $NH(a^1\Delta)$; ethylamine is produced by insertion of $NH(a^1\Delta)$ into a C–H bond of C_2H_6.

On the other hand, an addition reaction to a π bond as well as the insertion reaction is to be expected in the reactions of $NH(a^1\Delta)$ with unsaturated hydrocarbons, as were found in the reactions of unsaturated hydrocarbons with the isoelectronic species such as $O(^1D)$,[3] $S(^1D)$,[4] and $CH_2(^1A_1)$.[5] Therefore, it is of interest that the reactions of $NH(a^1\Delta)$ with C_2H_4 having π bond are compared with those for C_2H_6 having σ bond only.

On the photolysis of HN_3 with C_2H_4 in the vapor phase, Miller[6] has found that the reaction products are N_2, H_2, CH_4, C_2H_6, HCN, CH_3CN, NH_4N_3, and a yellowish film of polymeric material. Cornell, Berry, and Lwowski[7] have found the products of H_2, CH_4, HCN, CH_3CN, and an amorphous solid in the flash and steady photolyses. Back and his co-workers[8] have studied the reactions of C_2H_4 with NH formed by the photolysis of HNCO, and reported that no aziridine, vinylamine, nor other nitrogen-bearing products could be detected. Tidemann and Schiendler[9] have obtained $\phi_{C_2H_6}=0.56$ and $\phi_{n\text{-}C_4H_{10}}=0.03$ in the photolysis of HN_3 vapor with C_2H_4.

Jacox and Milligan[10] have observed the formation of aziridine in the photolysis of HN_3 with C_2H_4 in an argon matrix at 4 K. Recently, Kitamura, Tsunashima, and Sato[11] have found N_2, NH_3, and aziridine in the photolysis of HN_3 in liquid ethylene at the Dry Ice–methanol temperature, and obtained the relative yields of $NH_3/N_2=0.16$ and aziridine/$N_2=0.18$, independently of $[HN_3]/[C_2H_4]$.

Many results have been obtained for the reactions of NH with C_2H_4, however, they are insufficient to explain in detail the reaction mechanism and the reaction rates. Therefore, the photolysis of HN_3 vapor with C_2H_4 was reinvestigated in the present work.

Experimental

Ethylene obtained from Takachiho Chemical Co. was 99.9% in purity, and was purified each time before use by condensation and evacuation at −160 and −196 °C. Preparation and purification of HN_3, and the apparatus and procedure for reaction were the same as described previously.[1,2] All runs in this work were carried out at 313 nm at 30 °C. The light intensity was controlled with screens, and the irradiation time was varied from 10 to 120 min. The degree of conversion of HN_3 was below a few per cent for all runs.

The main reaction products were N_2, H_2, CH_4, C_2H_6, NH_4N_3, $C_2H_5N \cdot HN_3$ (salt by HN_3 with C_2H_5N(azomethines)), HCN, CH_3CN, CH_3N_3, $C_2H_5N_3$, and polymers. C_2H_2, C_3H_8, C_4H_8, and n-C_4H_{10} are also found as small amount.

For the identification of azides, CH_3N_3,[12] $C_2H_5N_3$,[13] n-$C_3H_7N_3$,[14] n-$C_4H_9N_3$,[15] and $N_3CH_2CH_2N_3$[16] were prepared as reference samples, $N_3(CH_2)_4N_3$ was prepared by heating for about 12 hours in a water bath a mixture of NaN_3 (35 g), $Br(CH_2)_4Br$ (46 g), C_2H_5OH (40 cm³), and water (100 cm³). The retention times of these azides were measured by gas chromatography using a silicone oil column (1 m) at 35 °C. The relative retention times, zero for CH_4 and unity for benzene, are shown in Table 1 together with $N_3CH_2CH_2Cl$ and $N_3(CH_2)_4Br$ formed as monosubstituted azides of $ClCH_2$-CH_2Cl and $Br(CH_2)_4Br$. The formations of CH_3N_3 and $C_2H_5N_3$ were ascertained using the data in Table 1. While, n-$C_3H_7N_3$, n-$C_4H_9N_3$, $N_3CH_2CH_2N_3$, and $N_3(CH_2)_4N_3$ could not be detected as a product.

The formation of HCN was verified by the pyridine–pyrazolone method.[17] The formation of CH_3CN was confirmed by gas chromatography using a squalene column (2 m) at 40 °C and a silicone oil column (1 m) at 35 °C.

The basic products(B) such as NH_3 and amines react with acidic HN_3 to give salts ($B \cdot HN_3$) as white volatile powders.[2] Therefore, the white volatile products trapped at the Dry Ice–acetone temperature were introduced into a solid sodium

Table 1. Relative retention times of azides by a silicone oil column (1 m) at 35 °C[a]

Azide	Relative retention time	Azide	Relative retention time
HN_3	0.187	$N_3(CH_2)_2Cl$	2.25
CH_3N_3	0.194	$N_3(CH_2)_2N_3$	5.08
$C_2H_5N_3$	0.382	$N_3(CH_2)_4Br$	22.9
n-$C_3H_7N_3$	0.846	$N_3(CH_2)_4N_3$	27.2
n-$C_4H_9N_3$	2.03		

a) The relative retention time was measured on the basis of zero for methane and unity for benzene.

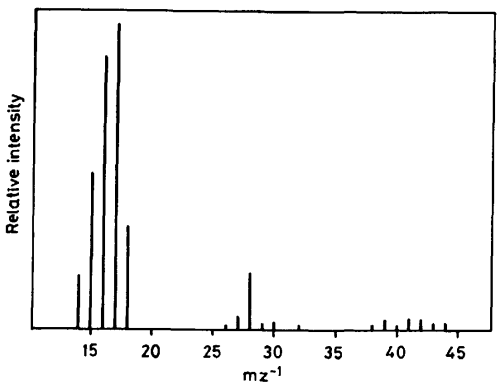

Fig. 1. Mass spectrum of a substance removed HN_3 from the white volatile products trapped at the Dry Ice–acetone temperature. The ionizing voltage is 15 eV.

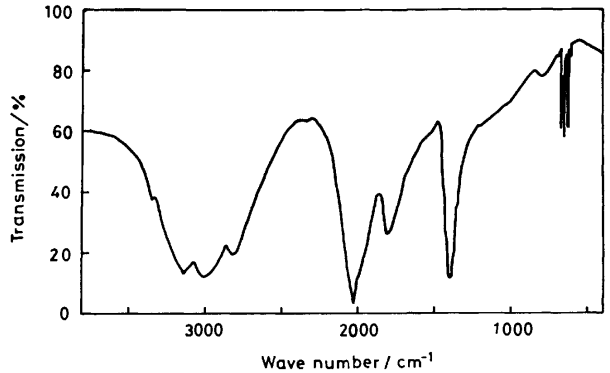

Fig. 2. Infrared spectrum of the white volatile products.

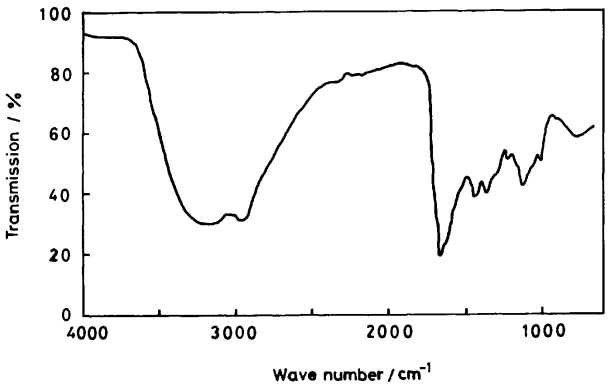

Fig. 3. Infrared spectrum of a substance prepared by removing ethanol from an ethanol solution of the yellowish polymeric material formed on the inside of the reaction cell.

hydroxide column to remove HN_3 from $B \cdot HN_3$ by the reaction $B \cdot HN_3 + NaOH \longrightarrow B + NaN_3 + H_2O$. A mass spectrum of the HN_3-free products at the ionizing voltage of 15 eV is shown in Fig. 1.

The spectrum is more complicated than the spectrum of the mixture of NH_3, CH_3NH_2, and $C_2H_5NH_2$ formed in the photolysis of HN_3 with C_2H_6.[2] It seems that $m/z=16$. 17, and 18 correspond to NH_2^+, NH_3^+, NH_4^+,[2] and the other peaks are due to $C_2H_5N^+$ ($m/z=43$) and its fragments. The large fragment peaks of $m/z=15$ and 28 may be due to the cracking reactions of $C_2H_5N \xrightarrow{e^-} CH_3^+ + CH_2{=}N$ (or $CH{=}NH$), $CH_3 + CH_2{=}N^+$ (or $CH{=}NH^+$), $C_2H_4^+ + NH$, and $C_2H_4 + NH^+$. However, the later two may be minor, because both need fission of two single bonds for aziridine and vinylamine and a double bond for CH_3–$CH{=}NH$. A mass spectrum of the HN_3-free products at the ionizing voltage of 75 V is inconsistent with that of aziridine measured at 70 V.[18] Vinylamine is not stable in the normal state. Judging from these reasons, the C_2H_5N may be CH_3–$N{=}CH_2$ or CH_3–$CH{=}NH$.

An infrared spectrum of the white volatile products trapped at Dry Ice–acetone temperature was observed by the KBr disk method, and is shown in Fig. 2. Since the spectrum is almost the same as the spectrum of solid NH_4N_3 at 90 K,[19] it was not possible to identify the structure of C_2H_5N from the spectrum in Fig. 2.

A yellowish film of polymeric material was formed on the inside of the reaction cell. The yellowish material is nonvolatile, very highly viscous, and soluble in ethanol. An infrared spectrum by the KBr disk method of a substance prepared by removing ethanol from an ethanol solution of the yellowish material is shown in Fig. 3. It is found from the spectrum that the substance includes the functional groups of NH (3200 and 1620), CH_3 (2960, 2870, 1450, 1380, and 1125), CH_2 (2950, 2850, 1450, and 1300), C=N (1670), and C–N (1230, 1175, and 1040 cm^{-1}).

A yellowish oily liquid[6] is formed by mixing aziridine and HN_3 at room temperature and the vapor phase. However, an infrared spectrum of the oily liquid is different from the spectrum in Fig. 3. Accordingly, it seems that the yellowish film of polymeric material does not result from aziridine.

N_2, H_2, CH_4, C_2H_6, NH_4N_3, and $C_2H_5N \cdot HN_3$ of the reaction products were determined quantitatively. First, these products were separated at solid nitrogen temperature (−210 °C), −160 °C, and Dry Ice–acetone temperature. Quantitative analyses of N_2, H_2, and CH_4, noncondensable gases at −210 °C, were carried out by the procedures described previously.[2] The total amount of C_2H_6 and unconverted C_2H_4, passing through a trap at −160 °C, was determined by a Toepler gauge. C_2H_6 and C_2H_4 were separated by the gas chromatography using a silica gel column (2 m) at 80 °C.

NH_4N_3 and $C_2H_5N \cdot HN_3$ condensed at Dry Ice–acetone temperature were introduced into a CuO column at about 550 °C. The amounts of N_2, NO, N_2O, and CO_2 as combustion products were determined by the method described previously.[2] The amounts of $C_2H_5N \cdot HN_3$ and NH_4N_3 can be calculated from the equations of $[C_2H_5N \cdot HN_3] = [CO_2]/2$ and $[NH_4N_3] = ([N_2] + [N_2O] - [CO_2])/2 + [NO]/4$.

The quantum yields of products were determined using HN_3 as an actinometer.[1]

Results

Results for the photolysis of HN_3 of 6.7 kPa, measured as a function of C_2H_4 pressure at 313 nm, 30 °C, and the absorbed light intensity of 2.2×10^{15} quanta s^{-1} are shown in Fig. 4. It is seen in Fig. 4 that ϕ_{H_2} and $\phi_{NH_4N_3}$ decrease drastically by adding C_2H_4 in small amount.

Figure 5 shows the results of the photolysis measured as a function of HN_3 pressure at 4.0 kPa of C_2H_4, 30 °C, 313 nm, and the incident light intensity of 1.9×10^{16} quanta s^{-1}. In Fig. 5, it is found that ϕ_{N_2} and $\phi_{C_2H_6}$ increase, but ϕ_{CH_4} decreases with an increase of HN_3 pressure. It is also found that the formation rate of N_2, R_{N_2}, increases rectilinearly as the HN_3 pressure increases.

Figure 6 shows the results of the photolysis measured as a function of the absorbed light intensity at 6.7 kPa of

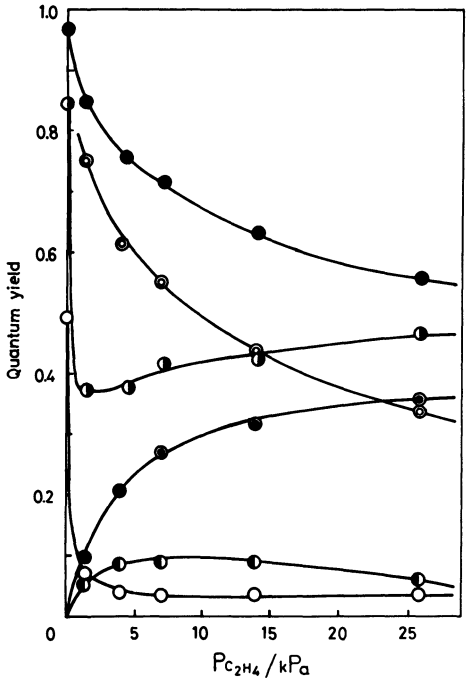

Fig. 4. Results of the photolysis of HN_3 of 6.7 kPa, measured as a function of C_2H_4 pressure at 313 nm, 30 °C, and the absorbed light intensity of 2.2×10^{15} quanta s^{-1}. ●, $\phi_{N_2}/5$; ◎, $\phi_{C_2H_6}$; ◑, $\phi_{NH_4N_3}$; ⊙, ϕ_{CH_4}; ◐, $\phi_{C_2H_5N\cdot HN_3}$; ○, ϕ_{H_2}.

HN_3, 4.0 kPa of C_2H_4, 30 °C, and 313 nm. It is shown in Fig. 6 that all quantum yields are independent of the light intensity.

Discussion

Reaction Mechanism. On the basis of the experimental results in this work and in the light of the results

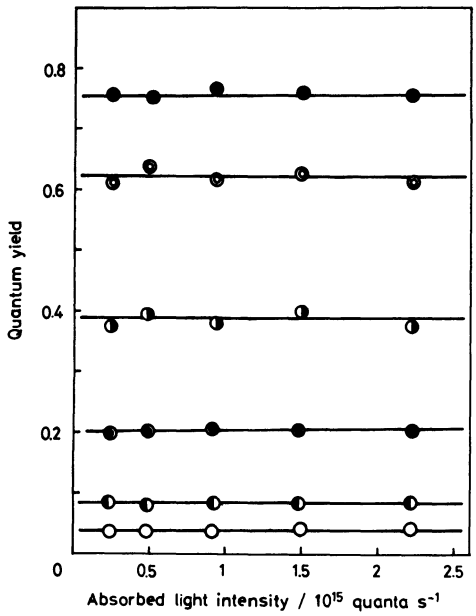

Fig. 6. Results of the photolysis measured as a function of the absorbed light intensity at 6.7 kPa of HN_3, 4.0 kPa of C_2H_4, 30 °C, and 313 nm. The marks are the same as those in Fig. 4.

achieved by previous investigators, we have postulated the following mechanism for the photolysis of HN_3 vapor in the presence of C_2H_4, where A and E mean HN_3 and C_2H_4 molecules, respectively:

$$A + h\nu(313\text{ nm}) \longrightarrow N_2 + NH(a^1\Delta) \quad (1)$$

$$NH(a^1\Delta) + A \longrightarrow 2N_2 + 2H \quad (2a)$$

$$NH(a^1\Delta) + A \longrightarrow NH_2 + N_3 \quad (2b)$$

$$NH(a^1\Delta) + A \longrightarrow N_2 + N_2H_2^* \quad (2c)$$

$$NH(a^1\Delta) + E \longrightarrow C_2H_5N^* \quad (3)$$

$$C_2H_5N^* \longrightarrow CH_3 + CH_2N \quad (4)$$

$$C_2H_5N^* \longrightarrow H_2 + CH_3CN \quad (5)$$

$$C_2H_5N^* \longrightarrow H + C_2H_4N \quad (6)$$

$$C_2H_5N^* \longrightarrow C_2H_3 + NH_2 \quad (7)$$

$$C_2H_4N + A \longrightarrow C_2H_5N + N_3 \quad (8)$$

$$C_2H_4N + E \longrightarrow C_4H_8N \quad (9)$$

$$H + A \longrightarrow H_2 + N_3 \quad (10)$$

$$H + A \longrightarrow NH_2 + N_2 \quad (11)$$

$$H + E \longrightarrow C_2H_5 \quad (12)$$

$$CH_2N + A \longrightarrow N_2 + HCN + NH_2 \quad (13)$$

$$N_2H_2^* + E \longrightarrow N_2 + C_2H_6 \quad (14)$$

$$R(CH_3, C_2H_3, C_2H_5, \text{and } NH_2) + A \longrightarrow RH + N_3 \quad (15)$$

$$NH_3 + A \longrightarrow NH_4N_3 \quad (16)$$

$$C_2H_5N + A \longrightarrow C_2H_5N\cdot HN_3 \quad (17)$$

$$C_4H_8N + E \longrightarrow \text{Polymers} \quad (18)$$

$$N_3 + A \longrightarrow A\cdot N_3 \quad (19)$$

$$N_3 + E \longrightarrow E\cdot N_3 \quad (20)$$

$$A\cdot N_3 + A\cdot N_3 \longrightarrow 2A + 3N_2 \quad (21)$$

$$A\cdot N_3 + E\cdot N_3 \longrightarrow A + CH_3N_3 + HCN + N_2 \quad (22)$$

$$E\cdot N_3 + E\cdot N_3 \longrightarrow C_2H_5N_3 + CH_3CN + N_2 \quad (23)$$

Thermochemical considerations were taken into account by using the standard heats of formation listed previously.[1,2]

Of the reactions of the first excited singlet $NH(a^1\Delta)$ with C_2H_4, the insertion reaction into the C–H bond and the addition reaction to the π bond are to be expected. Therefore, the $C_2H_5N^*$ formed by Reaction 3 are vibrationally excited vinylamine and aziridine molecules.

If the collisional spin relaxation process

$$NH(a^1\Delta) + E \longrightarrow NH(X^3\Sigma^-) + E$$

takes place, the formations of aziridine and $C_2H_5NH_2$ are expected according to the reactions

$$NH(X^3\Sigma^-) \xrightarrow{E} C_2H_5N(\text{Triplet}) \begin{cases} \nearrow \text{aziridine} \\ \xrightarrow{A} C_2H_6N(\text{doublet}) \xrightarrow{A} C_2H_5NH_2. \end{cases}$$

However, the possibility of the relaxation process seems to be negligible because neither of the products were found.

Reactions 4 to 7 are unimolecular decomposition processes of vibrationally excited $C_2H_5N^*$, and these are possible energetically. An other energetically possible reaction is

$$NH(a^1\Delta) + C_2H_4 \longrightarrow C_2H_2 + NH_3,$$

which is exothermic with 378 kJ mol^{-1}. The trace formation of C_2H_2 is probably due to this reaction. The reaction

$$NH(a^1\Delta) + C_2H_4 \longrightarrow CH_4 + HCN$$

is also exothermic with 503 kJ mol^{-1}, but the reaction to give CH_4 and HCN by this molecular mechanism could not be formulated in the reaction kinetics discussed later. Since the weakest bond in the $C_2H_3NH_2$ molecule is C–N bond,[20] the precursor for C_2H_3 and NH_2 radicals in Reaction 7 seems to be vibrationally excited vinylamine. The C_2H_4N radicals formed by Reaction 6 will be removed by hydrogen abstraction from HN_3 and addition to the π bond of C_2H_4 by such reactions as 8 and 9.

Reaction 12 is well known and very efficient.[21] Reaction 13 may proceed *via* an intramolecular hydrogen abstraction in the addition intermediate H–Ṅ–N=N–N=CH_2. Reaction 14 is the hydrogenation reaction of C_2H_4 by $N_2H_2^*$ which is an effective hydrogenation reagent.[22] The previously discussed reactions,[1,2] $N_2H_2^* \rightarrow N_2H_2^{**}$, $N_2H_2^* + HN_3 \rightarrow N_2 + H_2 + HN_3$, and $N_2H_2^* + HN_3 \rightarrow 2N_2 + NH_3$, were omitted by assuming that Reaction 14 is very fast. Reaction 15 is the hydrogen abstraction reaction by CH_3, C_2H_3, C_2H_5, or NH_2 radicals from HN_3 as a good hydrogen donor.[23] The reactions, $NH_2 + C_2H_4 \rightarrow C_2H_4NH_2$ and $C_2H_4NH_2 + HN_3 \rightarrow C_2H_5NH_2 + N_3$, are excluded because the $m/z=45$ peak ($C_2H_5NH_2^+$) was not found in the mass spectrum.

The trace formations of C_3H_8, 1-C_4H_8, and n-C_4H_{10}[9] are probably due to the reactions

$$R(CH_3, C_2H_3, C_2H_5) + C_2H_4 \longrightarrow R\text{–}C_2H_4$$
$$R\text{–}C_2H_4 + HN_3 \longrightarrow R\text{–}C_2H_5 + N_3.$$

The rate constant at 25 °C is 8.9×10^7 cm^3 mol^{-1} s^{-1} for the hydrogen abstraction from HN_3 by CH_3 radicals[23] and is about 1.2×10^6 cm^3 mol^{-1} s^{-1} for the addition of CH_3 radicals to C_2H_4.[24] The trace formation of C_3H_8 is explainable by comparing both rate constants. The same reason can also be applied for the trace formations of 1-C_4H_8 and n-C_4H_{10}. Reactions 4, 7, and 12 are supported by the existences of CH_3, C_2H_3, and C_2H_5 radicals.

The basic C_2H_5N (azomethines) formed by Reaction 8 may react to form the azide salt ($C_2H_5N \cdot HN_3$) of the white volatile powder by reaction with acidic HN_3 as Reaction 17 as well as the case of amines.[2] The C_4H_8N formed by Reaction 9 may react to produce the yellowish polymers *via* addition to C_2H_4 as Reaction 18.

Reactions 19 to 23 were introduced to explain the disappearance of N_3 radicals and the formations of HCN, CH_3CN, CH_3N_3, and $C_2H_5N_3$. It has been found in the flash photolysis of HN_3 that N_3 radicals disappear very rapidly in the presence of HN_3.[25,26] This seems due to the formation of an addition intermediate ($A \cdot N_3$), Similarly intermediate ($E \cdot N_3$) can be expected, because the addition of N_3 radicals to π bond of C_2H_4 is possible. Reactions 22 and 23 are supported by the facts that CH_3N_3 was found as a product, and $C_2H_5N_3$ of almost the same amount as CH_3CN is formed. The reactions

$$N_3 \cdot A + E \cdot N_3 \longrightarrow N_3(CH_2)_2N_3 + A$$
$$2E \cdot N_3 \longrightarrow N_3(CH_2)_4N_3$$

are excluded because $N_3(CH_2)_2N_3$ and $N_3(CH_2)_4N_3$ were not found as a product.

Reactions other than those mentioned above have been discussed previously,[1,2] and are omitted here.

Reaction Kinetics. The reaction kinetics were carried out to confirm the mechanism of Reactions 1 to 23 and to obtain the rate constant ratios.

On the quantum yield of CH_4, the equation

$$\phi_{CH_4}^{-1} = \frac{k_4 + k_5 + k_6 + k_7}{k_4}\left(1 + \frac{k_2}{k_3}\frac{[HN_3]}{[C_2H_4]}\right) \qquad \text{(I)}$$

can be derived, where

$$k_2 = k_{2a} + k_{2b} + k_{2c}.$$

The plot of $1/\phi_{CH_4}$ *versus* $[HN_3]/[C_2H_4]$ is shown in Fig. 7.

On the formations of CH_4 and $C_2H_5N \cdot HN_3$, the equation

$$\frac{\phi_{CH_4}}{\phi_{C_2H_5N \cdot HN_3}} = \frac{k_4}{k_6}\left(1 + \frac{k_9}{k_8}\frac{[C_2H_4]}{[HN_3]}\right) \qquad \text{(II)}$$

is obtained, and the linear relation is shown in Fig. 8.

Equation III was derived for the formations of CH_4, C_2H_6, H_2, and NH_4N_3, and its relation is plotted in Fig. 9.

$$\frac{\phi_{C_2H_6} + \phi_{H_2} + \phi_{NH_4N_3}}{\phi_{CH_4}} = \frac{k_4 + k_5 + k_7}{k_4} + \frac{k_2 + k_{2a}}{k_3}\frac{k_4 + k_5 + k_6 + k_7}{k_4}\frac{[HN_3]}{[C_2H_4]} \qquad \text{(III)}$$

As to the formations of H_2, CH_4, and C_2H_6, the equation

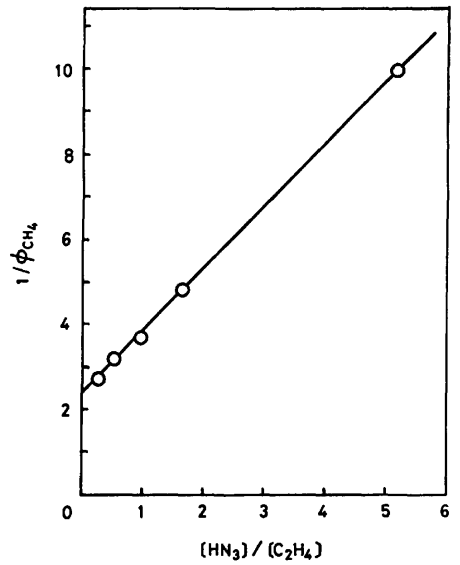

Fig. 7. Plot of $1/\phi_{CH_4}$ *versus* $[HN_3]/[C_2H_4]$.

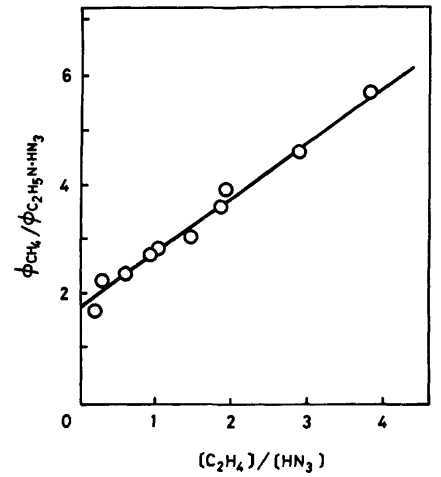

Fig. 8. Plot of $\phi_{CH_4}/\phi_{C_2H_5N\cdot HN_3}$ *versus* $[C_2H_4]/[HN_3]$.

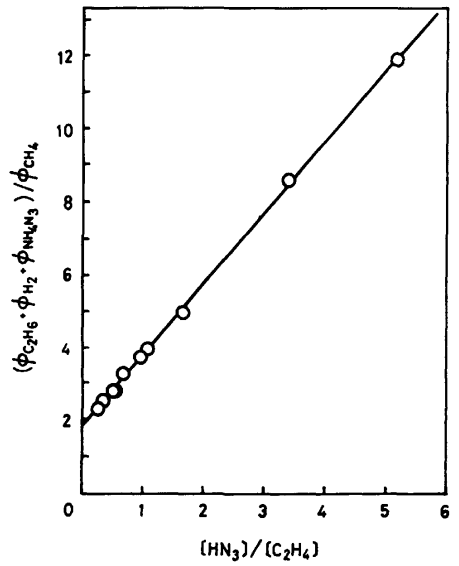

Fig. 9. Plot of $(\phi_{C_2H_6}+\phi_{H_2}+\phi_{NH_4N_3})/\phi_{CH_4}$ against $[HN_3]/[C_2H_4]$.

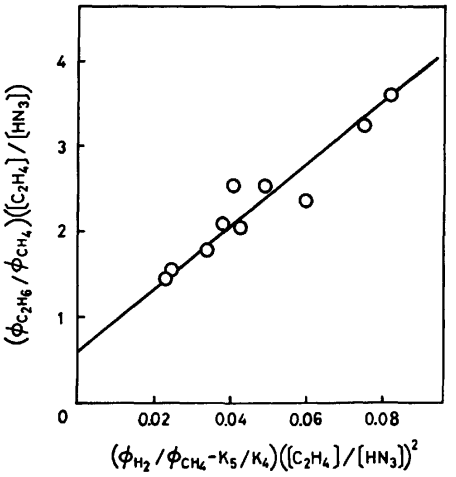

Fig. 10. Plot for Eq. IV.

$$\frac{\phi_{C_2H_6}}{\phi_{CH_4}}\frac{[C_2H_4]}{[HN_3]} = \frac{k_{2a}}{k_3}\frac{k_4+k_5+k_6+k_7}{k_4} + \frac{k_{12}}{k_{10}}\left(\frac{\phi_{H_2}}{\phi_{CH_4}}-\frac{k_5}{k_4}\right)\frac{[C_2H_4]^2}{[HN_3]^2} \quad \text{(IV)}$$

can be deerivd. Plot of $\phi_{C_2H_6}[C_2H_4]/\phi_{CH_4}[HN_3]$ *versus* $(\phi_{H_2}/\phi_{CH_4}-k_5/k_4)([C_2H_4]/[HN_3])^2$ is shown in Fig. 10, where the value of 0.102 for k_5/k_4 was selected to obtain the best straight line.

From the intercepts and the slopes in Figs. 7 to 10, and by using $k_{2b}/k_{2a}=0.746$ and $k_{11}/k_{10}=1.15$ obtained previously,[1] we obtain $k_3/k_2=1.64$, $k_5/k_4=0.102$, $k_6/k_4=0.564$, $k_7/k_4=0.734$, $k_9/k_8=0.560$, $k_{2c}/k_{2a}=1.23$, and $k_{12}/k_{10}=36.4$.

On the formations of N_2 and CH_4, the equation

$$\frac{\phi_{N_2}}{\phi_{CH_4}} = \frac{2k_4+k_5+k_6+k_7}{k_4} + \frac{(k_4+k_6+k_7)\alpha}{k_4} + \frac{k_4+k_5+k_6+k_7}{k_4}\left(\frac{k_2}{k_3}+\frac{2(k_{2a}+k_{2c})+(k_{2a}+k_{2b})\alpha}{k_3}\right)\times\frac{[HN_3]}{[C_2H_4]} + \left(\frac{k_6}{k_4}+\frac{2k_{2a}}{k_3}\frac{k_4+k_5+k_6+k_7}{k_4}\frac{[HN_3]}{[C_2H_4]}\right)\Big/\left(1+\frac{k_{10}}{k_{11}}+\frac{k_{12}}{k_{11}}\frac{[C_2H_4]}{[HN_3]}\right) \quad \text{(V)}$$

can be derived, where

$$\alpha = 1 + 2\left(1+\frac{k_{20}}{k_{19}}\frac{[C_2H_4]}{[HN_3]}\right)^{-2}.$$

Here, α was derived by assuming $k_{21}=k_{23}$ and $k_{22}=2k_{21}$, because Reactions 21 to 23 are radical-radical reactions. If $A\cdot N_3$ is non-existent ($k_{19}=0$), the stoichiometry of N_2 forming from two moles of N_3 becomes 1 by Reactions 22 and 23. The stoichiometry in the absence of $E\cdot N_3$ ($k_{20}=0$) becomes 3 by Reaction 21. Thus, α depends on the ratios of k_{20}/k_{19} and $[C_2H_4]/[HN_3]$.

The experimental values of ϕ_N/ϕ_{CH_4} *versus* $[HN_3]/[C_2H_4]$ were plotted in Fig. 11 together with the values calculated from Eq. V for two cases of $\alpha=1$ and $\alpha=3$ using the rate constant ratios obtained above. It is clear that the appropriate value for α is between 1 and 3. The values of ϕ_{N_2}/ϕ_{CH_4} calculated using $k_{19}/k_{20}=2.70$ are shown by the doted line in Fig. 11, and are in good accord with the experimental values.

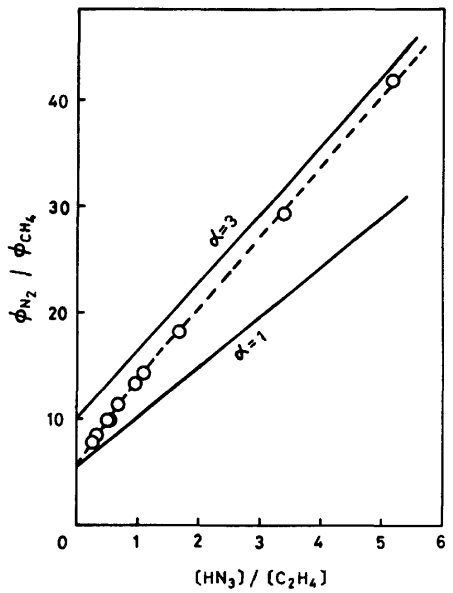

Fig. 11. Plots of ϕ_{N_2}/ϕ_{CH_4} *versus* $[HN_3]/[C_2H_4]$. ○, experimental value of ϕ_{N_2}/ϕ_{CH_4}; ---, calculated value of ϕ_{N_2}/ϕ_{CH_4} by Eq. V with $k_{19}/k_{20}=2.70$. The upper and under solid lines denote the calculated values of ϕ_{N_2}/ϕ_{CH_4} by Eq. V with $\alpha=3$ and $\alpha=1$, respectively.

Comparisons of the Rate Constants. Bras *et al.*[27] have reported that the rate constant for the reactions of hydrogen atoms with HN_3 is $2.54\times10^{-11}\exp(-4600/RT)$ cm^3 molecule^{-1} s^{-1} in the temperature range from 293 to 462 K. On the other hand, Sugawara *et al.*[21] have found that the specific rate for the addition of hydrogen atoms to C_2H_4 is $4.70\times10^{-11}\exp(-2178/RT)$ cm^3 molecule^{-1} s^{-1} in the temperature range from 206 to 461 K. From both results, it is found that the addition to C_2H_4 is 103 times faster than the reactions with HN_3 at 30 °C. In the present system, the rate constant ratio $k_{12}/(k_{10}+k_{11})$, is 17.0. The discrepancy seems to be due to "hot" hydrogen atoms because Reaction 2a is highly exothermic with 370 kJ mol^{-1}, and the hot atom effect is rather effective for reaction with high activation energy. If the value of k_{12} obtained by Sugawara *et al.*[21] is used as a basis, the absolute values of $k_{10}=2.09\times10^{10}$ and $k_{11}=2.40\times10^{10}$ cm^3 mol^{-1} s^{-1} in the present reaction conditions can be obtained from the rate constant ratios of k_{11}/k_{10} evaluated previously[1] and k_{12}/k_{10} obtained above.

Since the $C_2H_5N^*$ ($C_2H_3NH_2^*$ and aziridine*) decomposes before it is stabilized by collision with a third body M, the lifetime of $C_2H_5N^*$ is much shorter than the lifetime ($\tau=6.8\times10^{-11}$ s) of $C_2H_5NH_2^*$ formed by the insertion of $NH(a^1\Delta)$ into C–H bond of C_2H_6.[2] On the thermodynamic considerations of the reactions,

$$NH(a^1\Delta) + C_2H_4 \longrightarrow \underset{\diagdown\,N\,\diagup}{CH_2\text{–}CH_2}{}^* \quad (3a)$$
$$\qquad\qquad\qquad\quad H$$

$$NH(a^1\Delta) + C_2H_4 \longrightarrow C_2H_3NH_2^* \quad (3b)$$

$$NH(a^1\Delta) + C_2H_6 \longrightarrow C_2H_5NH_2^* \quad (3e)$$

ΔH_{3a} is almost the same as ΔH_{3e}, although Reaction 3b is 40 kJ mol^{-1} more exothermic than Reaction 3e. Therefore, the main reason for the short lifetime may be because the internal degrees of freedom of $C_2H_5N^*$ are six less than those of $C_2H_5NH_2^*$.

If we assume that all $C_2H_3NH_2^*$ molecules decompose to give C_2H_3 and NH_2 radicals as Reaction 7, and all molecules of aziridine formed by Reaction 3a decompose by Reactions 4 to 6, the reaction yield ratio of the addition to the π bond to the insertion into the C–H bond, k_{3a}/k_{3b}, is given by

$$k_{3a}/k_{3b} = (k_4+k_5+k_6)/k_7 = 2.27.$$

This ratio is similar to the result that the ratio of the addition to the insertion is 2.75 for the reactions of $NH(a^1\Delta)$ with C_3H_6 in the liquid phase.[11]

If all $C_2H_3NH_2^*$ molecules decompose to give C_2H_3 and NH_2 as assumed above, the reactivity ratio of the insertion of $NH(a^1\Delta)$ into a C–H bond of C_2H_4 to that of C_2H_6, k_{3b}/k_{3e}, is given by

$$\frac{k_{3b}}{k_{3e}} = \left(\frac{k_3}{k_2}\frac{k_7}{k_4+k_5+k_6+k_7}\right)\Big/\left(\frac{k_{3e}}{k_2}\right).$$

By using $k_{3e}/k_2=0.334$ obtained previously,[2] $k_{3b}/k_{3e}=1.50$ is obtained. The ratio per C–H bond is given by $6k_{3b}/4k_{3e}=2.25$. This means that the insertion of $NH(a^1\Delta)$ into a C–H bond which consists of a sp^2 hybrid orbital is more efficient than for the sp^3 hybrid orbital. For the photolysis of COS in the presence of both C_2H_4 and C_2H_6,[28] it has been found that the insertion rate of $S(3^1D_2)$ per C–H bond of C_2H_4 is 1.15 times faster than that of C_2H_6. This result has the same tendency as for $NH(a^1\Delta)$.

Kitamura *et al.*[11] have studied the photolysis of HN_3 in a binary solution of C_2H_6 and C_2H_4 at Dry Ice–methanol temperature, and found that the formation ratio of $C_2H_5NH_2/N_2$ decreases with an increase of the mole fraction of C_2H_4. Provided that in their experimental conditions N_2 is formed only by Reaction 1 except the high mole fraction range of C_2H_6, and that all the molecules of $C_2H_5NH_2^*$ formed by Reaction 3e are stabilized by collisions with solvent molecules, then $k_3/k_{3e}=4.4$ is obtained from the plot of $N_2/C_2H_5NH_2$ *versus* $[C_2H_4]/[C_2H_6]$. Our value for k_3/k_{3e} is $4.9((k_3/k_2)/(k_{3e}/k_2))$. The slight discrepancy seems to be due to the differences of the experimental conditions of wavelength, temperature, phase, *etc.*

When the reactions of $NH(a^1\Delta)$ with reactant (X) are presented by the general expressions,

$$NH(a^1\Delta) + X \longrightarrow \text{Products} \qquad k_r$$
$$NH(a^1\Delta) + X \longrightarrow NH(X^3\Sigma^-) + X \qquad k_d$$

the values of k_r/k_2 and k_d/k_2 for HN_3,[1] Xe,[1] C_2H_6,[2] and C_2H_4 are shown in Table 2. The following tendencies are shown in Table 2: k_r/k_2 for C_2H_6 consisting of σ bonds only is very low as compared with those for HN_3 and C_2H_4 having π bond; Xe and C_2H_6 have some

Table 2. Relative reactivity of $NH(a^1\Delta)$ with X

Phys.*, **66**, 4776 (1977). c) P. Sliwinski, *Z. Phys. Chem. (Frankfurt am Main)*, **63**, 263 (1969). d) N. J. Bridge and A. D. Buckingham, *Proc. R. Soc. London, Ser. A*, **295**, 334 (1966).

ability to induce collisional spin relaxation; the relaxation efficiencies by HN_3 and C_2H_4 having π bond are negligible. The relaxation efficiency by Xe, which is a monatomic molecule, is comparable to that of C_2H_6 consisting of eight atoms. It is probably due to a heavy atom effect.[29]

The absolute rate constant for the disappearance of NH($a^1\Delta$) by HN_3 was reported to be 5.6×10^{13} cm^3 mol^{-1} s^{-1} by Paur and Bair,[26] and 10.84×10^{13} cm^3 mol^{-1} s^{-1} by Piper, Krech, and Taylor.[30] If the rate constant obtained by Piper *et al.*, k_2(PKT), is used as a basis, the absolute rate constant for the quenching of NH($a^1\Delta$) by X, k_q(X), can be calculated by the equation

$$k_q(X) = \frac{(k_r+k_d)_x}{k_2}k_2(PKT).$$

The calculated values of k_q(X) are shown in Table 3.

On the other hand, the maximum rate constant of the bimolecular reaction in the gas phase, k_b, can be calculated by the equation[31]

$$k_b = \frac{2\Gamma(1-2/s)N_A}{\sigma}\left(\frac{2\pi kT}{\mu}\right)^{1/2}\left[\frac{(s-2)A}{2kT}\right]^{2/s},$$

when the intermolecular attractive potential, u, is expressed by $u=-A/r^s$. Here, A, r, Γ, N_A, σ, k, and μ mean the attractive potential constant, the intermolecular distance, the gamma function, Avogadro's number, the symmetry number, Boltzmann's constant, and the reduced mass, respectively. The attractive potential is given by

$$A = A_{dis} + \alpha_{NH}\mu_D(X)^2 + \alpha_x\mu_D(NH)^2 + 2\mu_D(NH)^2\mu_D(X)^2/3kT,$$

where α is the polarizability, and μ_D the dipole moment. The dispersion effect term of A, A_{dis}, is given by Slater and Kirkwood[32] as

$$A_{dis} = \frac{3\,h\,e\,\alpha_{NH}\alpha_X}{4\,\pi m_e^{1/2}[(\alpha/N_e)_{NH}^{1/2} + (\alpha/N_e)_X^{1/2}]}.$$

Here, h, N_e, and e and m_e are Planck's constant, the number of outer-shell electrons, and the charge and mass of an electron, respectively.

The values of k_b calculated using $s=6$ and $\sigma=1$ are shown in Table 3 together with α and N_e for X. The values of $\alpha=1.38\times10^{-24}$ cm^3,[33] $N_e=6$, and $\mu_D=1.627$ debye[34] for NH, and $\mu_D=0.847$ debye[35] for HN_3 were used for the calculation. It is shown in Table 3 that the reactivity of the first excited singlet NH($a^1\Delta$) is, in general, very high, especially $k_q(C_2H_4)$ which is close to one-half of its maximum rate constant.

The absolute and relative quenching rates of

C(2^1D_2),[36,37] O(2^1D_2),[38-41] and S(3^1D_2)[42,43] by Xe, C_2H_6, C_2H_4, and others have been observed widely. These over-all quenching rate constants are shown in Table 4 together with those for NH($a^1\Delta$). It is found in Table 4 that the trend on the collisional quenching of NH($a^1\Delta$) is very similar to those of the first excited singlet atoms.

The author is gratefully indebted to Emeritus Professor Osamu Toyama of University of Osaka Prefecture for his helpful discussion. I would also like to thank Dr. Hideo Tabata, Mr. Akio Tomiyasu, and Katsuichi Ohta for their asistances.

Nonequilibrium Thermodynamics of the Ion and Solvent Transports through Ion-exchange Membrane

Hideo KIMIZUKA,* Yoshihiko NAGATA, and Kozue KAIBARA
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received November 12, 1982)

A theory for the ion and solvent transports through membrane has been developed on the basis of nonequilibrium thermodynamics. The fluxes were represented as linear functions of the effective driving potentials. The theory is reduced to that of Katchalsky when the concentration ratio of two aqueous solutions is near unity and the solutions are dilute. The effect of solvent flow on the interionic correlations was discussed. It was pointed out that Despić and Hills' theory of the electroosmotic effect on the membrane conductance is not valid with respect to both theoretical and experimental aspects. The comparison of the present theory with the previous one[1] was also made. The six independent phenomenological coefficients (elements of the conductance matrix) were experimentally determined as a function of concentration with the concentration cell consisting of the amphoteric ion-exchange membrane and aqueous calcium chloride solutions. The membrane properties were discussed in terms of the conductance matrix. The diffusional ion conductance was much greater than the electrical ion conductance, as an indication of the failure of the Nernst-Einstein relation. The cation-anion coupling coefficient was close to unity whereas the ion-water coupling coefficients were less than 0.1. The solvent effects on the interionic conductance elements were found to be small in spite of the fact that the water permeability was extremely high. The distinction between the cationic and amphoteric ion-exchange membranes was explored in terms of the elements of the conductance matrix.

A variety of transport phenomena is known to take place when a membrane system is subject to various driving forces such as the gradients of electric potential, concentration, and hydrostatic pressure. This paper is concerned with an analysis of the transport properties of an isothermal system consisting of an amphoteric ion-exchange membrane, water, and a single salt dissociating into two kinds of ions on the basis of nonequilibrium thermodynamics. Even in this simple case, there are six independent phenomenological coefficients, and hence six independent experiments are required to elucidate the transport properties.

Many papers have appeared on the application of nonequilibrium thermodynamics to the transport phenomena across the membrane, where the fundamental treatments are to determine the coefficients in the phenomenological equations. However, it is usual to make some nonthermodynamic assumptions for studying the membrane phenomena, since it is laborious to perform the detailed study for determining the six phenomenological coefficients. Nevertheless, it is important to complete the detailed study not only for elucidating the transport properties, but also for examining whether the nonthermodynamic assumptions are valid or not.

So far, only a few papers[2-4] have been published on the detailed study of the transport phenomena with the cation exchange membrane–aqueous single electrolyte system. In the preceding paper,[2] the transport phenomena with the cation-exchange membrane–aqueous barium chloride system were studied for determining the six phenomenological coefficients and the transport properties were discussed. However, the preceding theories[2-4] were essentially for the systems with the same concentrations of two external solutions and can not be suitably applied to the concentration cell. Thus a theory for the ion and solvent transports has been developed by extending the previous theory,[1] so that the solvent transport is included.

For estimating the phenomenological coefficients, the ion and solvent transports in the presence and absence of the electric current and the pressure difference should be measured in addition to the membrane potential and membrane conductance. Among these, the accurate determination of the ion transports is especially important in order to estimate the phenomenological coefficients exactly, because the transport number of an ion plays a decisive role in calculating the coefficients from the observed data. Since an accurate determination of the transport number for the co-ion is difficult with the cation- and anion-exchange membranes due to their high selectivity to the counter ions, the amphoteric ion-exchange membrane was used in the present study for the exact determination of the transport number.

In the present paper, the measurements were performed with the concentration cell consisting of the amphoteric ion-exchange membrane and the aqueous calcium chloride solutions. The six independent phenomenological coefficients (elements of a conductance matrix) were estimated from the observed data according to our theory and the membrane properties were discussed in terms of the conductance matrix.

Theory

1. Phenomenological Equation. In the previous paper,[1] the steady ion currents through the membrane have been expressed by linear functions of the effective driving potentials under the assumption of no solvent flow. Even without the assumption, it is easily seen that the flux equations including solvent flux may be written in the similar forms to those in the previous paper.[1] Thus, for the case in which the permeating species are cation α, anion β, and water w, the phenomenological equation can be written as

$$\begin{bmatrix} i_\alpha \\ i_\beta \\ Fj_w \end{bmatrix} = - \begin{bmatrix} g_{\alpha\alpha} & g_{\alpha\beta} & g_{\alpha w} \\ g_{\beta\alpha} & g_{\beta\beta} & g_{\beta w} \\ g_{w\alpha} & g_{w\beta} & g_{ww} \end{bmatrix} \begin{bmatrix} V-V_\alpha \\ V-V_\beta \\ -V_w \end{bmatrix}, \quad (1)$$

where the subscripts, α, β, and w refer to cation, anion, and water, respectively; i denotes an ion current; j_w, water flux; $g_{\gamma\delta}$ ($\gamma,\delta=\alpha,\beta$) and g_{kw} (k=α,β,w), the elements of the conductance matrix; V, the transmembrane potential; V_γ($\gamma=\alpha,\beta$), the pseudo equilibrium potential; V_w, the effective driving potential for water. V_w, V_γ, $g_{\gamma\delta}$, and g_{kw} are given by

$$FV_w = RT \ln a_w^I/a_w^{II} - \bar{v}_w \Delta P = \bar{v}_w(\Delta\pi - \Delta P) \quad (2)$$

$$Z_\gamma F V_\gamma = RT \ln a_\gamma^I/a_\gamma^{II} - \bar{v}_\gamma \Delta P \quad (3)$$

$$g_{\gamma\delta} = Z_\gamma Z_\delta F^2 |R|_{\gamma\delta}/|R| \quad (4)$$

$$g_{\gamma w} = Z_\gamma F^2 |R|_{\gamma w}/|R|, \quad (5)$$

and

$$g_{ww} = F^2 |R|_{ww}/|R|, \quad (6)$$

respectively, where the superscripts I and II refer to phases I and II separated by a membrane, respectively; R, F, and T have usual meanings; Z denotes the charge, a, the activity; v_k, the partial molar volume of a species k; $\Delta\pi$, the osmotic pressure difference; $\Delta P(=P^{II}-P^I)$, the external pressure difference; $|R|$, the determinant having R_{kl}(k,l=α,β,w) as the kl element of the generalized friction intergrated over the membrane phase, and $|R|_{kl}$, the cofactor of R_{kl}.[1] In Eq. 2, a constant molar volume is assumed for the two aqueous phases I and II. The expression such as Eq. 1 is advantageous for treating the electrical properties of the membrane.

The equation for the membrane current, I, is obtained from Eq. 1 as follows:

$$I = i_\alpha + i_\beta = - g_\alpha(V-V_\alpha) - g_\beta(V-V_\beta) + g_w V_w \quad (7)$$

$$= - G_m(V-V_0), \quad (8)$$

where g_α, g_β, and g_w denote the conductances for permeating species α, β, and w, respectively,

$$g_k = g_{k\alpha} + g_{k\beta}, \quad (9)$$

G_m, the membrane conductance

$$G_m = g_\alpha + g_\beta, \quad (10)$$

and V_0, the membrane potential at zero membrane current

$$V_0 = t_\alpha V_\alpha + t_\beta V_\beta + t_w V_w \quad (11)$$

$$t_k = g_k/G_m, \quad (12)$$

t_k, the transport number of a species k.

When the membrane current is absent, the equation for the ion current, i_γ^0, under this restriction can be written as

$$i_\gamma^0 = - g_k^0(V_0 - V_\gamma) + g_{\gamma w}^0 V_w, \quad (13)$$

where the superscript 0 refers to the absence of membrane current,

$$\frac{g_k^0}{g_k} = 1 - g_{\alpha\beta}\left(\frac{1}{g_\alpha} + \frac{1}{g_\beta}\right), \quad (14)$$

and

$$g_w^0 = g_{\alpha w}^0 + g_{\beta w}^0. \quad (15)$$

Thus, Eq. 11 is seen to be consistent with Eqs. 13—15.

2. Determination of Phenomenological Coefficient. Let us consider the way for determining the elements of the conductance matrix.

When the ion and solvent fluxes in the presence and absence of the membrane current are measured, we have from Eqs. 1, 8, and 12

$$i_\gamma - i_\gamma^0 = - g_\gamma(V-V_0) = t_\gamma I$$

$$F(j_w - j_w^0) = - g_w(V-V_0) = t_w I. \quad (16)$$

Thus, the measurements of the fluxes as a function of the potential enable to estimate g_k's and t_k's (k=α,β,w) according to Eq. 16.

When the membrane current is absent, we have from Eq. 1

$$\begin{bmatrix} i_\alpha^0 \\ Fj_w^0 \end{bmatrix} = - \begin{bmatrix} g_{\alpha\alpha} - G_m t_\alpha^2 & g_{\alpha w} - G_m t_\alpha t_w \\ g_{\alpha w} - G_m t_\alpha t_w & g_{ww} - G_m t_w^2 \end{bmatrix} \begin{bmatrix} V_\beta - V_\alpha \\ -V_w \end{bmatrix}. \quad (17)$$

Now it is assumed that the addition of nonpermeant neutral substance, *e.g.*, such as sucrose, causes no appreciable change in the phenomenological coefficients as well as the activity coefficients of salt and ions provided the salt concentrations are unaltered.[2] Then we have from Eq. 17

$$\Delta i_\alpha^0 = (g_{\alpha w} - G_m t_\alpha t_w)\Delta V_w, \quad (18)$$

$$F\Delta j_w^0 = (g_{ww} - G_m t_w^2)\Delta V_w, \quad (19)$$

where Δi_α^0 and Δj_w^0 means the changes in fluxes and ΔV_w, the change in the water potential due to the addition of sucrose. Since ΔV_w can be evaluated from the concentration of nonpermeant neutral solute, the measurements of the changes in the salt and solvent fluxes enable us to determine the coefficients $(g_{\alpha w} - G_m t_\alpha t_w)$ and $(g_{ww} - G_m t_w^2)$ according to Eqs. 18 and 19, respectively. Thus $g_{\alpha w}$ and g_{ww} can be estimated when g_k's are known. The value of $g_{\beta w}$ can be estimated according to Eq. 9 provided $g_{\alpha w}$ is known. Furthermore, $(g_{\alpha\alpha} - G_m t_\alpha^2)$ can be determined from the i_α^0 data according to Eq. 17, provided $(g_{\alpha w} - G_m t_\alpha t_w)$, V_w, and $(V_\beta - V_\alpha)$ are known. Then we can estimate $g_{\alpha\alpha}$ which serves to obtain the values of $g_{\alpha\beta}$ and $g_{\beta\beta}$ successively according to Eq. 9. Thus, the six independent phenomenological coefficients, $g_{\alpha\alpha}$, $g_{\alpha\beta}$, $g_{\beta\beta}$, $g_{\alpha w}$, $g_{\beta w}$, and g_{ww} can be determined according to the procedures mentioned above.

3. Transformation of Phenomenological Equation. Equation 1 can be rewritten as follows

$$\begin{bmatrix} i_\alpha \\ I \\ Fj_w \end{bmatrix} = - \begin{bmatrix} g_{\alpha\alpha} & g_\alpha & g_{\alpha w} \\ g_\alpha & G_m & g_w \\ g_{w\alpha} & g_w & g_{ww} \end{bmatrix} \begin{bmatrix} V_\beta - V_\alpha \\ E \\ -V_w \end{bmatrix}, \quad (20)$$

where

$$E = V - V_\beta. \quad (21)$$

Here, we introduce the osmoequilibrium potential for an ion defined as

$$Z_\gamma F V_\gamma^* = RT \ln a_\gamma^I/a_\gamma^{II} - \bar{v}_\gamma \Delta\pi$$

$$= Z_\gamma F V_\gamma - \bar{v}_\gamma(\Delta\pi - \Delta P), \quad (22)$$

then $(V_\beta - V_\alpha)$ may be expressed as

$$V_\beta - V_\alpha = V_\beta^* - V_\alpha^* - \bar{v}_s V_w/Z_\alpha \nu_\alpha \bar{v}_w, \quad (23)$$

where $\bar{v}_s$ and ν_α are the partial molar volume of the salt and the stoichiometric coefficient of cation, respectively.

Introducing the volume flow as a new flux

$$FJ_v/\bar{v}_w = Fj_w + \bar{v}_s i_\alpha/Z_\alpha\nu_\alpha\bar{v}_w, \tag{24}$$

and $(V_\beta^*-V_\alpha^*)$ as a new force, Eq. 20 can be rearranged as

$$\begin{bmatrix} i_\alpha \\ I \\ FJ_v/\bar{v}_w \end{bmatrix} = -\begin{bmatrix} g_{\alpha\alpha} & g_\alpha & g_{\alpha v} \\ g_\alpha & G_m & g_v \\ g_{v\alpha} & g_v & g_p \end{bmatrix}\begin{bmatrix} V_\beta^*-V_\alpha^* \\ E \\ -V_w \end{bmatrix}, \tag{25}$$

where

$$\begin{aligned} g_{\alpha v} &= g_{\alpha w} + g_{\alpha\alpha}\bar{v}_s/Z_\alpha\nu_\alpha\bar{v}_w \\ g_v &= g_w + g_\alpha\bar{v}_s/Z_\alpha\nu_\alpha\bar{v}_w \\ g_p &= g_{ww} + (g_{\alpha w}+g_{\alpha v})\bar{v}_s/Z_\alpha\nu_\alpha\bar{v}_w. \end{aligned} \tag{26}$$

We have from Eq. 25

$$I = -G_m(E-E_0) \tag{27}$$

$$E_0 = t_\alpha(V_\alpha^*-V_\beta^*) + t_v V_w, \tag{28}$$

where

$$t_v = g_v/G_m. \tag{28}$$

The term t_vV_w is the streaming potential referred to the anion reversible electrode, and g_v and t_v may be regarded as the conductance and transport number of volume flow, respectively.

Equation 25 can be rewritten as

$$\begin{bmatrix} J_s \\ I \\ J_v \end{bmatrix} = -\begin{bmatrix} L_{11} & L_{12} & L_{13} \\ L_{21} & L_{22} & L_{23} \\ L_{31} & L_{32} & L_{33} \end{bmatrix}\begin{bmatrix} \Delta\mu_S^* \\ E \\ \Delta P-\Delta\pi \end{bmatrix}, \tag{30}$$

where

$$\Delta\mu_s^* = Z_\alpha\nu_\alpha F(V_\beta^*-V_\alpha^*) = \bar{v}_s(\Delta\pi-\Delta\pi_s), \tag{31}$$

$$\bar{v}_s\Delta\pi_s = -(\nu_\alpha+\nu_\beta)RT\ln a_\pm^{II}/a_\pm^{I}, \tag{32}$$

$$J_s = i_\alpha/Z_\alpha\nu_\alpha F, \tag{33}$$

$$\begin{aligned} &L_{11} = g_{\alpha\alpha}/(Z_\alpha\nu_\alpha F)^2,\ L_{12} = g_\alpha/Z_\alpha\nu_\alpha F, \\ &L_{13} = \bar{v}_w g_{\alpha v}/Z_\alpha\nu_\alpha F^2, \\ &L_{22} = G_m,\ L_{23} = \bar{v}_w g_v/F,\ L_{33} = (\bar{v}_w/F)^2 g_p. \end{aligned} \tag{34}$$

When the external aqueous solutions are dilute and their concentration ratio is close to unity, the approximation given by Kachalsky[5] may be applied and $\Delta\mu_s^*$ is reduced to

$$\Delta\mu_s^* = \Delta\pi/C_s, \tag{35}$$

where C_s is the mean of the concentrations of external solutions. Thus, Eq. 30 is reduced to the phenomenological equation given by Katchalsky only when the approximation given by Eq. 35 is permitted. Krämer and Meares[6] found a new force equivalent to Eq. 23, but unfortunately they adopted this approximation to obtain the phenomenological equation equivalent to that of Katchalsky and discussed the transport phenomena. Practically, the most solvent permeation experiments were performed under the condition that Eq. 35 may not be permitted. Equation 30 should be applied in this case.

When the membrane current is absent, we have from Eq. 25

$$\begin{bmatrix} i_\alpha^0 \\ FJ_v^0/\bar{v}_w \end{bmatrix} = -\begin{bmatrix} g_{\alpha\alpha}-G_m t_\alpha^2 & g_{\alpha v}-G_m t_\alpha t_v \\ g_{\alpha v}-G_m t_\alpha t_v & g_p-G_m t_v^2 \end{bmatrix}\begin{bmatrix} V_\beta^*-V_\alpha^* \\ -V_w \end{bmatrix}, \tag{36}$$

which can be rewritten as

$$\begin{bmatrix} \bar{v}_s J_s^0 \\ J_v^0 \end{bmatrix} = -\begin{bmatrix} L_s & L_{sp} \\ L_{ps} & L_p \end{bmatrix}\begin{bmatrix} \Delta\pi-\Delta\pi_s \\ \Delta P-\Delta\pi \end{bmatrix}, \tag{37}$$

where L_s, L_{sp}, and L_p denote the thermodynamic solute permeability, the mechanical filtration coefficient, and the hydrodynamic permeability, respectively,

$$L_s = \bar{v}_s^2(g_{\alpha\alpha}-G_m t_\alpha^2)/(Z_\alpha\nu_\alpha F)^2 = -[\bar{v}_s J_s^0/(\Delta\pi-\Delta\pi_s)]_{\Delta P=\Delta\pi} \tag{38a}$$

$$\begin{aligned} L_{sp} = L_{ps} &= \bar{v}_s\bar{v}_w(g_{\alpha v}-G_m t_\alpha t_v)/Z_\alpha\nu_\alpha F^2 \\ &= -[J_v^0/(\Delta\pi-\Delta\pi_s)]_{\Delta P=\Delta\pi} \\ &= -[\bar{v}_s J_s^0/(\Delta P-\Delta\pi)]_{\Delta\pi=\Delta\pi_s}, \end{aligned} \tag{38b}$$

and

$$L_p = (\bar{v}_w/F)^2(g_p-G_m t_v^2) = -[J_v^0/(\Delta P-\Delta\pi)]_{\Delta\pi=\Delta\pi_s}. \tag{38c}$$

Eliminating $(\Delta P-\Delta\pi)$ from Eq. 37, we have

$$J_s^0 = -\omega_s(\Delta\pi-\Delta\pi_s) + (1-\sigma)J_v^0/\bar{v}_s, \tag{39}$$

where ω_s is the solute permeability coefficient

$$\omega_s = (L_s-L_{sp}^2/L_p)/\bar{v}_s = [J_s^0/(\Delta\pi-\Delta\pi_s)]_{J_v^0=0}, \tag{40}$$

and σ, the reflection coefficient

$$1-\sigma = L_{sp}/L_p = (\bar{v}_s J_s^0/J_v^0)_{\Delta\pi=\Delta\pi_s}. \tag{41}$$

According to Eq. 37, the equilibrium is established at the condition

$$\Delta P = \Delta\pi_s = \Delta\pi. \tag{42}$$

There are two cases which satisfy this condition. The one is that the two external solutions possess the same compositions and hence $\Delta P=\Delta\pi_s=\Delta\pi=0$ and the other, that a nonpermeable polyelectrolyte is present at one side and the osmotic eqilibrium such as the Donnan membrane equilibrium is established, where $\Delta P=\Delta\pi_s=\Delta\pi\neq 0$. Taking the approximation given by Eq. 35, Eqs. 37—41 are reduced to those obtained by Katchalsky.[5]

4. Electrokinetic Phenomena. It is important to examine how the electroosmosis is involved in the electrical properties of the membrane. Eliminating V_w in Eq. 25, we obtain

$$\begin{bmatrix} i_\alpha - g_{\alpha v}FJ_v/g_p\bar{v}_w \\ I - g_v FJ_v/g_p\bar{v}_w \end{bmatrix} = -\begin{bmatrix} g_{\alpha\alpha}-g_{\alpha v}^2/g_p & g_\alpha-g_{\alpha v}g_v/g_p \\ g_\alpha-g_{\alpha v}g_v/g_p & G_m-g_v^2/g_p \end{bmatrix} \times\begin{bmatrix} V_\beta^*-V_\alpha^* \\ E \end{bmatrix}, \tag{43}$$

we have from Eq. 43

$$I - g_v F(J_v-J_v^0)/g_p\bar{v}_w = -(G_m-g_v^2/g_p)(E-E_0), \tag{44}$$

which leads to

$$G_m' = -(I)_{J_v=J_v^0}/(E-E_0) = G_m - g_v^2/g_p, \tag{45}$$

where G_m' denotes the membrane conductance without volume flow. On the other hand we have from Eqs. 25 and 27

$$F(J_v-J_v^0)/\bar{v}_w = -g_v(E-E_0) = FD_e I/\bar{v}_w, \tag{46}$$

where D_e denotes the electroosmotic permeability. Since G_m' is the membrane conductance without volume flow, the L.H.S. of Eq. 44 gives the membrane current without electroomsotic current. Thus, the second term of the L.H.S. of Eq. 44 may be considered as the electroosmotic current I_v accompanied by the volume flow.

Comparing this second term with Eq. 46, we have

$$I_v = g_v F(J_v - J_v^0)/g_p \bar{v}_w = -g_v^2(E-E_0)/g_p. \quad (47)$$

Let X be the charge concentration per unit volume of pore liquid within the membrane, the elctroosmotic current I_v may be given by the relation

$$I_v = F(J_v - J_v^0)X. \quad (48)$$

Comparing Eq. 48 with Eq. 47, we find

$$X = g_v/\bar{v}_w g_p. \quad (49)$$

Combining Eq. 45 with Eqs. 38c and 49, we derive the equation for the part of the membrane conductance due to the electroosmosis as follows:

$$G_m - G'_m = g_v^2/g_p = (FX)^2 L_p + G_m(\bar{v}_w t_v X)^2. \quad (50)$$

Taking the capillary model and assuming the membrane controlling process, L_p is expressed by[5]

$$L_p = \phi_w r^2\theta/8\eta\Delta x, \quad (51)$$

where ϕ_w represents the membrane area available for permeation; r, the capillary radius; θ, the tortuosity factor; η, the viscosity of pore liquid; Δx, the membrane thickness. Substituting Eq. 51 into Eq. 50 and multiplying $\Delta x/\bar{X}$ where $\bar{X}$ is the equivalent concentration of salt per unit volume within the membrane, we have

$$\lambda - \lambda' = (FXr)^2\phi_w\theta/8\eta\bar{X} + \lambda(\bar{v}_w t_v X)^2, \quad (52)$$

where λ and λ' represent the equivalent conductances of electrolyte with and without the electroosmosis, respectively. For the cation- or anion-exchange membranes, λ and λ' respresent the equivalent conductances of counter ions with and without the electroosmosis, respectively, provided the co-ion concentration may be ignored as compared with the counter ion concentration in the membrane.

Despić and Hills[7] expressed the equation for the electroomsotic effect on the equivalent conductance of counter ions based on the kinetic approach as follows:

$$\lambda - \lambda' = (Fr)^2\bar{X}/8\eta, \quad (53)$$

which differs from Eq. 52. Ignoring the second term of the R.H.S. of Eq. 52 and putting $\phi_w\theta = 1$ and $X = \bar{X}$, Eq. 52 is reduced to Eq. 53. The replacement of X by $\bar{X}$ can not be allowed, since X is the charge concentration at the slipping plane of the pore liquid and differs from the counter ion concentration $\bar{X}$. This is experimentally recognized with the polyelectrolyte solution[8] as well as the charged membrane.[9] Furthermore, it is well known that the electroosmosis decreases with the increase in the exterior salt concentration. This implies the decrease in X of the pore liquid due to the increase in the ionic strength of the pore solution as is expected from the theory of the electrical diffuse double layer. Despić and Hills[7] also applied the Nernst-Einstein relation for evaluating λ' from the self-diffusion coefficient of the counter ion. It has been shown[10,11] that the Nernst-Einstein relation is valid only at the infinite dilution of salt solution and should not be applied to the salt solution of higher concentration[11] as well as the ion-exchange membrane.[10] Thus Despić and Hills' theory is seen to be theoretically invalid based on the above arguments. Nevertheless, several authors[12] performed the experimental studies of Eq. 53 according to Despić and Hills' treatment.[7] It is unfortunate that their studies have nothing to do with Eq. 53 because of the estimation of λ' from the self-diffusion coefficient of counter ion according to the Nernst-Einstein relation. Such experimental studies should be consulted with Eq. 14 as reported in the preceeding paper.[10]

5. Solvent Effect on the Apparent Conductance Matrix. In the preceeding paper,[10] the conductance matrix was determined from the membrane conductance, the transport number and the salt flux data according to the previous theory[1] developed by assuming no solvent flow. Thus it is of interest to examine, on the basis of the present theory, the effect of solvent flow on the apparent values of the elements of the conductance matrix estimated according to the previous theory.[1]

It is seen by comparing the present theory with the previous one[1] that the current-potential relation are the same, although the ion flux-potential relations at non membrane current are different from each other. This implies that the diffusional ion conductance estimated according to the previous theory is the apparent one, although the membrane conductance is identical. We obtain from Eq. 13

$$(g_\tau^0)_{app} = -i_\tau^0/(V_0 - V_\tau) = g_\tau^0(1+f_\tau), \quad (54)$$

where $(g_\tau^0)_{app}$ denotes the apparent diffusional conductance and f_τ, the solvent effect given by

$$f_\tau = -g_{\tau w}^0 V_w/g_\tau^0(V_0 - V_\tau)$$
$$= -[g_{\tau w} - g_{\alpha\beta}t_w/(1-t_\tau)]V_w/g_\tau^0((V_0 - V_\tau). \quad (55)$$

The expression for E_0 is obtained from Eq. 54 as follows

$$E_0 = V_0 - V_\beta = (t_\alpha)_{app}(V_\alpha - V_\beta)$$
$$= [(\nu_\alpha+\nu_\beta)(t_\alpha)_{app}RT/Z_\alpha\nu_\alpha F]\ln a_\pm^{I}/a_\pm^{II}, \quad (56)$$

and

$$(t_\tau)_{app} = (g_\tau^0)_{app}/(g_\alpha^0+g_\beta^0)_{app} = t_\tau(1+f_\tau)/(1+t_\alpha f_\alpha + t_\beta f_\beta), \quad (57)$$

provided the external pressure difference is absent. It is seen in Eq. 56 that the transport number determined from the membrane potential *vs.* salt activity relation is also the apparent one.

Thus an element of the conductance matrix estimated by the previous treatment[1] is an apparent one, too. The interionic correlation term is expressed by the relation

$$(g_{\alpha\beta})_{app} = (t_\alpha)_{app}[g_\beta - g_\beta^0]_{app}, \quad (58)$$

where $(g_\beta)_{app}$ is given by $G_m(t_\beta)_{app}$. Equation 58 has the same form as the equation for $g_{\alpha\beta}$ obtained by rewriting Eq. 14. Combining Eq. 58 with Eqs. 14, 54, and 57, we derive

$$(g_{\alpha\beta})_{app} = \frac{(1+f_\alpha)(1+f_\beta)}{1+t_\alpha f_\alpha + t_\beta f_\beta}\left\{g_{\alpha\beta} - \frac{t_\alpha t_\beta(t_\alpha f_\beta + t_\beta f_\beta)}{1+t_\alpha f_\alpha + t_\beta f_\beta}G_m\right\}, \quad (59)$$

which satisfies the reciprocal relation, accordingly we have

$$(g_{\tau\tau})_{app} = (g_\tau)_{app} - (g_{\alpha\beta})_{app}$$
$$= \frac{(1+f_\alpha)(1+f_\beta)}{1+t_\alpha f_\alpha + t_\beta f_\beta}\left\{\frac{g_{\tau\tau} - f_\tau g_{\alpha\beta}}{1+f_\tau} + \frac{t_\alpha t_\beta(t_\alpha f_\alpha + t_\beta f_\beta)}{1+t_\alpha f_\alpha + t_\beta f_\beta}G_m\right\}. \quad (60)$$

It is seen in Eqs. 57, 59, and 60 that the deviations of the apparent values from the true ones can not be evaluated unless all the matrix elements are determined. However, it will be shown later that the apparent values are close to the true ones, as an indication of small f_r's in the present experimental conditions.

It is noted here that the present theory can be applied to both the solid and liquid membranes, since the formulation is unaltered whether the membrane is solid or liquid.

Experimental

Materials. The amphoteric ion exchange membrane used in the present study is a thin crosslinked polystyrene layer with homogeneously dispersed sulfonate and quaternary ammonium groups and is tight contact with a porous support of polyvinyl chloride sheet with *ca.* 0.1 mm in thickness. The ion exchange capacity was 1 mequiv. (g-wt membrane)$^{-1}$ and the cationic/anionic capacity ratio was ranged 1.0 ± 0.2. The membrane is coded as a "1.0-PA-29" which was developed by Central Research Laboratory of Kanegafuchi Chemical Industry Co., Ltd. and kindly supplied for the present study. The details for the preparation of the membrane were described elsewhere.[13] Pure specimen of calcium chloride as well as sucrose and twice redistilled water were used for preparing salt and sucrose solutions. As to aqueous phases separated by a membrane, the salt concentration of phase II was kept at 10^{-2} mol dm^{-3} and that of phase I was varied from 10^{-3} to 10^{-1} mol dm^{-3}. The sucrose concentrations used for the osmotic flux measurement were 0.02 to 0.12 mol dm^{-3}.

Procedures of Experiments. The procedures of experiments were essentially the same as those described in the preceding paper.[2] The experiments were carried out under the regulated room temperature at 25.0 ± 1.0 °C.

The solvent flow j_w was estimated according to the relation

$$j_w = (J_v - \bar{v}_s J_s)/\bar{v}_w. \quad (61)$$

Results and Discussion

Figure 1 shows the membrane potential, E_0, at zero electric current and the membrane conductance, G_m, as a function of the logarithm of the mean electrolyte activity, $a_\pm^I$, in phase I. The apparent transport number

$(t_+)_{app}$ estimated according to Eq. 56 is also shown in this figure. Figure 1 indicates that the membrane is rather selective to anion than cation. Further, G_m increases with the increase in the external salt concentration. This may indicate the increase in the concentrations of cations and anions in the membrane with the increasing external salt concentration.

Figure 2 shows the changes in i_a and Fj_w as functions of the applied potential V. All the fluxes were shown to be linear against V in this figure as an indication of the constancy of the conductances under the present experimental condition.

The values of g_{Ca} and g_w can be estimated according to Eq. 16 and hence g_{Cl} can be calculated according Eq. 10. These are plotted as functions of $a^I_\pm$ in Fig. 3 together with g^0_γ calculated according to Eq. 14.

The deviation of the apparent transport number $(t_+)_{app}$ from the true one $t_{Ca}(=g_{Ca}/G_m)$ was found to be very small less than one percent and within the experimental error. This indicates that the solvent effect on the membrane potential at no membrane current, E_0, may be ignored under the present experimental conditions. This can be confirmed also by comparing E_0 with the calculated value of $t_w V_w$.

Figure 4 indicates the effect of the osmotic pressure difference ΔV_w caused by the addition of sucrose on the salt and water fluxes. The fluxes were linear against ΔV_w as shown in this figure. It is found in this figure that the slope of the i^0_a *vs.* ΔV_w relation agrees well with the intercept of the Fj^0_w *vs.* ΔV_w relation. This indicates the validity of the reciprocal relation assumed in the present theory. The membrane potential changed little by the addition of sucrose, and the change was within experimental error, probably due to the small solvent effect on the membrane potential. The phenomenological coefficients can be estimated stepwise as described in the theoretical section from the data shown in Figs. 1, 3, and 4. The estimated elements of the conductance matrix are shown in Fig. 5 as functions of the mean activity of salt in phase I.

This figure indicates that $g_{CaCa} \approx g_{ClCl} > -g_{CaCl}$ and all these coefficients are the same order of magnitude in contrast to the result in the cation-exchange membrane,[10] $g_{CaCa} \gg g_{CaCl} > g_{ClCl}$. In the preceding paper,[2] the l_{kl}(k,l=α,β,w) coefficients were determined with the cation-exchange membrane-barium chloride system. The $g_{\gamma\delta}(\gamma,\delta=\alpha,\beta)$ may be calculated according to the relation, $g_{\gamma\delta}=Z_\gamma Z_\delta F^2 l_{\gamma\delta}\Delta x$, where Δx is the membrane thickness. The order of $g_{\alpha\beta}$ is found to be $g_{BaBa} \gg g_{BaCl} > g_{ClCl}$ at the external salt concentrations less than 0.1 mol dm^{-3}. On the other hand, g_{BaCl} becomes negative at the concentrations more than 0.4 mol dm^{-3} and the order of $g_{\gamma\delta}$ is found to be $g_{BaBa} \simeq g_{ClCl} > -g_{BaCl}$ as a similar result to the amphoteric membrane. An appreciable amount of the Donnan salt may migrate in the cation-exchange membrane when the external salt concentration becomes comparable with the fixed ion concentration. Thus, the negative cross coefficients in the cation and amphoteric ion exchange-membranes may correspond to the positive $l_{\alpha\beta}(\alpha \neq \beta)$ coefficient in the salt solution.[11]

Figure 5 also indicates the positive g_{Caw} and the negative g_{Clw}. A similar result, the positive g_{Baw} and the negative g_{Clw}, may be deduced from the $l_{\gamma w}$ data observed with the cation-exchange membrane[2] at the external salt concentrations more than 0.2 mol dm^{-3}. On the other hand, both g_{Baw} and g_{Clw} are postive at the concentrations less than 0.2 mol dm^{-3}. Similar to $g_{\gamma\delta}$, the concentration dependence of $g_{\gamma w}$ in the cation-exchange membrane may be ascribed to the increase of the Donnan salt within the membrane with increasing salt concentration. Thus it may be concluded that the behaviors of the cation and amphoteric ion exchange-membranes are quite different each other at the concentrations of external salt solutions less than 0.1 mol dm^{-3} where the major migrating ionic species in the former is cations and in the latter, both cations and anions. This reflects to the relation between the diffusional and conductive membrane conductances, *i.e.*, $g_\gamma \gg g^0_\gamma$ in the cation-exchange membrane[10] and this order is reversed in the amphoteric membrane as shown in Fig. 3. The values of g_γ and g^0_γ are estimated from $g_{\gamma\delta}$'s according to Eqs. 9 and 14, and related to the electrical absolute mobility $\bar{U}_\gamma$ and the diffusion coefficient $\bar{D}_\gamma$ within the membrane, respectively, as follows:[14]

$$g_\gamma = (Z_\gamma F)^2 \bar{U}_\gamma \bar{C}_\gamma / \Delta x$$
$$g^0_\gamma = (Z_\gamma F^2) \bar{D}_\gamma \bar{C}_\gamma / RT\Delta x, \qquad (62)$$

where $\bar{U}_\gamma$ and $\bar{D}_\gamma$ denotes the mean electrical absolute

mobility and the mean diffusion coefficient of ion γ within the membrane, respectively, and $\bar{C}_\gamma$ the mean concentration of ion γ within the membrane. Comparing Eq. 14 with Eq. 62, we have

$$\lambda_\gamma - \lambda_\gamma^0 = (g_\gamma - g_\gamma^0)\Delta x/\bar{C}_\gamma = (Z_\gamma F)^2(\bar{U}_\gamma - \bar{D}_\gamma/RT) \quad (63)$$

$$= g_{\alpha\beta}\Delta x/\bar{C}_\gamma(1-t_\gamma), \quad (64)$$

where λ_γ and λ_γ^0 are the equivalent electrical and diffusional ion conductances, respectively. Despić and Hills evaluated the electroosmotic effect according to Eq. 63, although they derived Eq. 53.[7] It is evident that Despić and Hills' treatment has no relation to their theoretical expression, Eq. 53. The disagreement between g_γ and g_γ^0 implies the failure of the Nernst-Einstein relation. The order, $g_\gamma^0 \gg g_\gamma$, in the amphoteric membrane indicates that the usual dialysis is energetically more effective than the electrodialysis for removing the salt through the amphoteric membrane.

It is seen in Eq. 25 that this phenomenological equation involves $g_{\alpha v}$, g_v, and g_p as new conductance elements. These coefficients can be evaluated from the original set of conducatnce matrix elements according to Eq. 26. The deviation of the new elements from the corresponding original elements are found to be small as shown in Fig. 6. L_s, L_{sp}, L_p, and ω_s calculated according to Eqs. 38a, b, c, and 40, are plotted against $a_\pm^1$ as shown in Fig. 7. Since the value of σ calculated by Eq. 41 is almost unity over the range of concentrations studied in the present paper, it is not plotted in Fig. 7. In the phenomenological equation, a flux is given by a linear combination of forces with phenomenological coefficients and *vice versa*. This implies that the processes are more or less coupled and the coupling phenomena can be discussed in terms of the phenomenological coefficients.[5] In this respect, it is interesting to consider the phenomena in terms of the degree of coupling.[15,16] The degree of coupling can be expressed by the coupling coefficient which is an important parameter for treating the energy conversion.[15,16]

For the phenomena dealing with the two and three processes, *e.g.*, those expressed by Eqs. 37 and 1, respectively, the coupling coefficients are given by

$$q = L_{sp}/(L_s L_p)^{1/2}, \quad (65)$$

and

$$q_{kl} = -|g|_{kl}/(|g|_{kk}|g|_{ll})^{1/2}, \quad (66)$$

respectively, where $|g|_{kl}$ is the cofactor of an element g_{kl} in the conductance matrix. The coupling coefficient q_{kl} can be regarded as the extent to which the k-th flow is dragged by the l-th flow when no other flow is present and the force conjugate to the k-th flow is zero. The absolute values of q, $q_{\alpha\beta}$, $q_{\alpha w}$ and $q_{\beta w}$ calculated according to Eqs. 65 and 66, respectively are shown in Fig. 8 as functions of $a_\pm^1$. It is shown in this figure that q_{CaCl} is close to unity, although q_{Caw} and q_{Clw} are less than 0.1. This indicates that the interionic processes are strongly coupled, although the coupling between the water and ionic fluxes is weak. This might be reflected to the small solvent effects on the interionic conductance elements. Actually, deviations of the apparent interionic conductance elements, $(g_{\gamma\delta})_{app}$, estimated according to the previous treatment[10] from the true ones is within the experimental error as shown in Fig. 9. Thus it is seen that the coupling coefficient plays an important role

in the cross phenomena. The small V_w due to the small concentration difference in the concentration cell will be also responsible to little solvent effect as deduced from Eq. 55.

The electroosmosis is an example of the coupling phenomena. The electroosmotic contribution to the membrane conductance is given by g_v^2/g_pG_m as shown by Eq. 45. The factor g_v^2/g_pG_m corresponds to the square of the coupling coefficient for the membrane current-volume flow coupling in the case of no concentration difference between the two external solutions. The contribution is found to be a negligible order of 10^{-3} and the same order as that for the cation-exchange membrane.[10] This may be attributed to the low charge concentration of the flowing pore liquid X which is evaluated according to Eq. 49. In the present study, X is found to be an order of 10^{-4} mol dm^{-3} over the concentration range studied. Even for the cation-exchange membrane with the fixed ion concentration of *ca.* 2 mol dm^{-3}, the value of X evaluated from the observed phenomenological coefficient[2] is an order of 10^{-2} mol dm^{-3} and much less than the counter ion concentration within the membrane, $\bar{X}$. The strong interaction of the counter ions with the fixed charges may be the cause of the lower charge concentrations of flowing pore liquid. It is seen in Eqs. 48 and 50 that the small electroosmotic current with an appreciable volume flow may be ascribed to the low X. It is seen in the foregoing discussion that there is no appreciable contribution of the solvent effect on the interionic conductance elements, $g_{\gamma\delta}$'s, for the amphoteric and cation-exchange membranes as far as the concentrations of the external salt solutions are dilute as compared with the fixed ion concentrations. This also verifies the previous treatment[10] for estimating the $g_{\gamma\delta}$'s in the cation-exchange membrane-aqueous calcium chloride system.

It should be pointed out here that the small coupling coefficient for the coupling between solvent and ion flows is responsible to these results. It is shown in Fig. 5 that g_{ww} is extremely high and much greater than $g_{\gamma\delta}$'s by a factor of 10^5. A similar result has been observed with the cation-exchange membrane.[2] Thus, the fact that $g_{ww} \gg g_{\gamma\delta}$ suggests the small coupling coefficient. On the other hand, this fact also invalidates the assumption of no solvent flow in the previous theory.[1] The assumption should be revised as the assumption of little solvent effect on the ion transports. The small coupling coefficients may, in turn, imply no appreciable salt effect on the solvent flow.

Comparing Eq. 41 with Eq. 62, we have

$$\sigma = 1 - q(L_s/L_p)^{1/2} \tag{67}$$

which implies that the small coupling coefficient and and $L_p \gg L_s$ are the recommended conditions for the reverse osmosis.

When the external salt concentration becomes higher, the deviation of $(g_{\gamma\delta})_{app}$ from $g_{\delta\gamma}$ will be greater as can be deduced from Eq. 55. This tendency may already be seen even in Fig. 9 and in fact, a remarkable deviation occurs in the cation-exchange membrane-barium chloride system at higher salt concentrations more than 0.1 mol dm^{-3}.[2] This may be related to the increasing coupling coefficient with salt concentration.[2]

For the membrane with higher water content and lower fixed charges, the ions move as fast as the solvent molecule and hence the coupling coefficient $q_{\gamma w}$ will be greater. This may be the cause of an anormalous osmosis.[17]

Whether the water content and fixed ion concentration of a membrane is high or not, the detailed study for determining all the phenomenological coefficients should be required for describing the membrane properties precisely.

It has been shown in the present paper that the cross coefficients play an important role for elucidating the membrane properties. Thus the nonthermodynamic assumption such as ignoring the cross term should be avoided unless it is verified experimentally.

Behavior of Trajectory with Stable and Unstable Limit Cycles in the Oregonator Model for the Belousov-Zhabotinskii Reaction

Shinji SAKANOUE,* Chiaki MURASE,† and Mitsuo ENDO

Department of Chemistry, Faculty of General Education, Tokyo University of Agriculture and Technology, Saiwaicho, Fuchu, Tokyo 183

†*Department of Physics, Faculty of General Education, Tokyo University of Agriculture and Technology, Saiwaicho, Fuchu, Tokyo 183*

(Received December 6, 1982)

Computer simulations and a theoretical analysis of the Oregonator model of the Belousov-Zhabotinskii reaction are made based on Tyson's equation. The behavior of the amplitudes of the unstable limit cycle near the transition point, p_c, can be explained theoretically fairly well by the Landau theory. The global behavior of one stable limit cycle and one unstable limit cycle is examined by means of simulations. The existence of a triple point at which three different global states coexist has been suggested.

Field and Noyes[1] have proposed a simple model (Oregonator model) for the kinetics of the Belousov-Zhabotinskii (B-Z) reaction. Tyson[2] presented this model as follows,

$$\varepsilon \frac{dx}{dt} = x + y - qx^2 - xy,$$
$$\frac{dy}{dt} = -y + fz - xy, \qquad (1)$$
$$p \frac{dz}{dt} = x - z,$$

where t, x, y, and z are the dimensionless variables corresponding to the time and the three concentrations $[HBrO_2]$, $[Br^-]$, and $[Ce^{4+}]$ respectively, and where ε, f, p, and q are the dimensionless parameters to be decided from the rate constants of the elementary reactions, the concentration of $BrCH(COOH)_2$, *etc.* The stiffly coupled approximation $dx/dt=0$ has been introduced into Eq. 1.[1,2] The meaning of this approximation has been discussed in detail by Field and Noyes[1] and by Tyson.[2] Simply speaking, this approximation is obtained by postulating that bromous acid is always present in a steady state concentration as determined by the concentration of bromide ions. Under the stiffly coupled approximation, we get:

$$\dot{\bar{y}} = -\delta\bar{y} + f\bar{z} - (\gamma+\bar{y})X(\bar{y}),$$
$$\dot{\bar{z}} = r\{X(\bar{y})-\bar{z}\}, \quad r = \frac{1}{p}, \qquad (2)$$

where $\bar{y}$ and $\bar{z}$ are the deviations of y and z from the steady state values y_0 and z_0, respectively; where the dot shows the time differentiation, and where

$$X(\bar{y}) = \{-(\alpha+\bar{y})+\sqrt{(\alpha+\bar{y})^2-4q\beta\bar{y}}\}(2q)^{-1}.$$

The detailed derivation of Eq. 2 and the definition of the constants, α, β, γ, and δ, may be seen in Ref. 3. For the sake of simplicity, we call this model (Eq. 2) the simple Oregonator model.

In a previous paper[3] we made computer simulations of Eq. 2. These simulations confirmed the coexistence of an unstable limit cycle and a stable limit cycle. Figure 1 shows a typical example of the coexistence state of the two limit cycles around a stable steady state. In the figure, the dot-dash-line denotes the trajectory. The solid line shows the stable limit cycle, and the dotted line, the unstable limit cycle, as estimated from the simulations. The steady state (y_0, z_0) is represented by the symbol "a." In order to analyze the behavior of the simple Oregonator model theoretically, we must define two quantities: the amplitude, A, of a trajectory and the amplitude-expansion rate, F. The amplitude, A, of a trajectory is defined by the distance between the steady state, "a," and the point at which the trajectory intersects the $z=z_0$ line. The amplitude-expansion rate, F, is defined by the time differentiation of the square of the amplitude, A:

$$\frac{dA^2}{dt} = F.$$

In numerical simulations, the dA^2/dt quantity is determined by $\Delta A^2/\Delta t$, where ΔA^2 and Δt are, respectively, the differences in the squares of the amplitude, A^2, and the time, t, over one turn of a trajectory. The points at which an unstable limit cycle and a stable one intersect the $z=z_0$ line are denoted by the symbols "b"

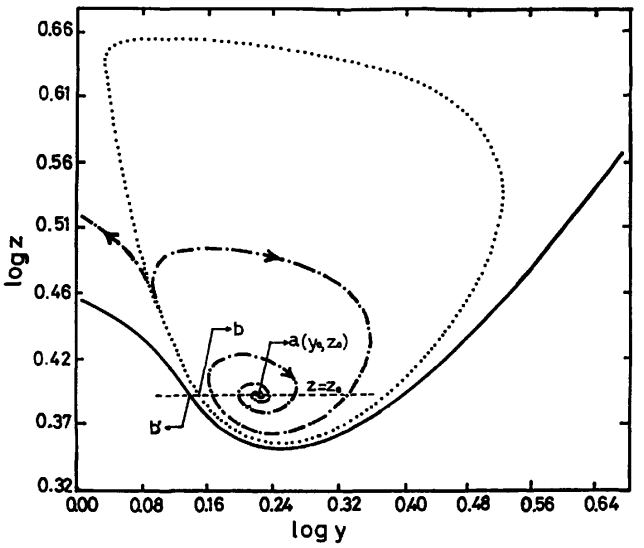

Fig. 1. Phase plane plot of $\log z$ *vs.* $\log y$ obtained numerical integrations of Eq. 1 under $dx/dt=0$ for $q=0.006$, $f=2.350$, and $p=2.0$ ($p_c=90.24$).

and "b'" respectively, as is shown in Fig. 1. We define the A_u and A_s amplitudes (the amplitudes of an unstable limit cycle and a stable-limit one) by the ab and ab' distances, respectively.

In this paper the behavior of the trajectory and the amplitudes of two kinds of limit cycles are examined for various values of the p and f parameters by means of computer simulations. The changes in the amplitudes of the two kinds of limit cycles are obtained numerically. A quantitative explanation of these changes is made by the use of the Landau theory.[4]

Behavior of an Unstable Limit Cycle near p_c and a Perturbational Approach

Figure 2 shows the log-log plots of the amplitude, A_u, of the unstable limit cycle against (p_c-p). The solid lines represent the results from computer simulations. We will examine, on the basis of the Landau theory, how the behavior of A_u can be explained theoretically. The Landau theory elucidates the transition from a laminar flow to a turbulent one and may be represented as follows:[4]

$$\frac{dA^2}{dt} = F = \gamma_2 A^2 + \gamma_4 A^4 + \cdots. \tag{3}$$

This approach (Landau theory) is a kind of perturbation method. We will show that the behavior of the unstable limit cycle near the transition point p_c can be explained fairly well by means of Landau's equation (Eq. 3).

We determine two coefficients, γ_2 and γ_4, in Eq. 3 by the use of perturbation method. In deriving the nonlinear terms in Eq. 2, which we represent as N_y and N_z, we use the approximation $q=0$, because the q parameter is very small in a real system, of the order of 10^{-6}, as estimated by Field and Noyes.[1] Then, Eq. 2 can be presented as follows:

$$\begin{aligned} \dot{\bar{y}} &= r_c\bar{y} + f\bar{z} + N_y, \\ \dot{\bar{z}} &= ra_1\bar{y} - r\bar{z} + N_z, \end{aligned} \tag{4}$$

where the nonlinear terms, N_y and N_z, are given by:

$$\begin{aligned} N_y &= -(b_1\bar{y}^2 + b_2\bar{y}^3 + \cdots), \\ N_z &= r(a_2\bar{y}^2 + a_3\bar{y}^3 + \cdots), \end{aligned} \tag{5}$$

$$a_n = \frac{\beta}{(-\alpha)^n},\quad b_n = -\frac{2+r_c}{(-\alpha)^n}\quad (n=1,2,\cdots),$$

and where the constant, r_c, is the boundary value defined by:

$$r_c = \frac{1}{p_c} = \frac{\beta\gamma}{\alpha} - \delta.^{2,3)}$$

The linear approximation ($N_y=0$, $N_z=0$) of Eq. 4 gives two solutions, y_l and z_l (complexes), of these forms:

$$y_l = A_y \exp(\lambda t),\ z_l = A_z \exp(\lambda t), \tag{6}$$

where the eigenvalue, λ, is:

$$\begin{aligned} \lambda &= \lambda_0 + i\omega, \\ \lambda_0 &= -\frac{1}{2}(r-r_c), \\ \omega &\simeq -r\sqrt{(r_c+a_1 f)},\ (r \simeq r_c). \end{aligned} \tag{7}$$

We seek this solution:

$$\bar{y} = \mathrm{Re}(y_l+y_n),\ \bar{z} = \mathrm{Re}(z_l+z_n), \tag{8}$$

where Re denotes the real part. The contributions to y_n and z_n from nonlinear terms are determined to be of these forms:

$$\begin{aligned} y_n &= B_y \exp(2i\,\omega_c t) + C_y, \\ z_n &= B_z \exp(2i\,\omega_c t) + C_z, \end{aligned} \tag{9}$$

where ω_c is ω at $p=p_c$. The constants, B_y and C_y, are

determined to be exact up to the A_y^2 order, whereas B_z and C_z are exact to the A_z^2 order. Putting Eq. 8 into Eq. 4, we get:

$$B_y = -\frac{1}{6}cA_y^2, \quad C_y = \frac{1}{2}c|A_y|^2, \tag{10}$$

where:

$$c = \frac{b_1 - a_2 f}{r_c + a_1 f}.$$

The amplitude, A, is given by:

$$A = y_l + y_n \simeq y_l = |A_y|. \tag{11}$$

Since $\langle \bar{y}^2 \rangle \simeq (1/2)|y_l|^2 = (1/2)A^2$, the amplitude-expansion rate, F, is calculated from:

$$F = 2\frac{\mathrm{d}}{\mathrm{d}t}\langle \bar{y}^2 \rangle, \tag{12}$$

where $\langle \ldots . \rangle$ denotes the time average over one period. Using Eqs. 8 and 12, the coefficients, γ_2 and γ_4, are obtained from:

$$\gamma_2 = 4\langle \mathrm{Re}\, y_l \, \mathrm{Re}\, \dot{y}_l \rangle A^{-2},$$
$$\gamma_4 = \gamma_{41} + \gamma_{42}, \tag{13}$$

where:

$$\gamma_{41} = -4b_2\langle \mathrm{Re}\, y_l (\mathrm{Re}\, y_l)^3 \rangle A^{-4},$$
$$\gamma_{42} = -8b_1\langle \mathrm{Re}\, y_l (\mathrm{Re}\, y_l \, \mathrm{Re}\, y_n) \rangle A^{-4}.$$

Putting Eqs. 6, 9, and 10 into Eq. 13, we get:

$$\gamma_2 = -(r - r_c),$$
$$\gamma_{41} = -\frac{3}{2}b_2, \quad \gamma_{42} = -\frac{5}{3}cb_1. \tag{14}$$

For $p = p_c$ (or $r = r_c$), we can get:

$$\gamma_4 = \frac{1}{3\alpha\beta f}\left(20 - \frac{\beta}{\alpha}f\right). \tag{15}$$

Now we have determined two coefficients, γ_2 and γ_4, in Laudau's equation (Eq. 3). The properties of the two coefficients, γ_2 and γ_4, for p near p_c can easily be seen from Eqs. 14 and 15. These satisfy:

$$\gamma_2 \propto -(p_c - p) < 0, \text{ for } p < p_c,$$
$$\gamma_4 = \text{a constant independent of } p. \tag{16}$$

Figure 3 shows the plot of the amplitude-expansion rate, F, against A for $q = 0.006$, $f = 2.350$, and $p = 58.00$ ($p_c = 90.24$). The broken line shows the theoretical curve calculated from Eq. 3 using the coefficients, γ_2 and γ_4, in Eqs. 14 and 15. For the above values of q, f, and p, we get: $\gamma_2 = -0.616 \times 10^{-2}$ and $\gamma_4 = 2.132$. The solid line shows the plots of the data from the computer simulations. When p is not so far from p_c, the theoretical curve is in fairly good agreement with the results of the computer simulations. The amplitude, A_u, of the unstable limit cycle can be obtained theoretically from $F = 0$ thus:

$$\gamma_2 A_u^2 + \gamma_4 A_u^4 = 0. \tag{17}$$

For $A < A_u$, the amplitude-expansion rate, F, becomes negative and the trajectory shrinks towards $A = 0$ (steady state), whereas for $A > A_u$ the amplitude-expansion rate becomes positive and the trajectory expands. Therefore, the trajectory with A near A_u grows apart from A_u as time goes on (unstable limit cycle). From Eq. 17, the amplitude, A_u, of the unstable limit cycle becomes:

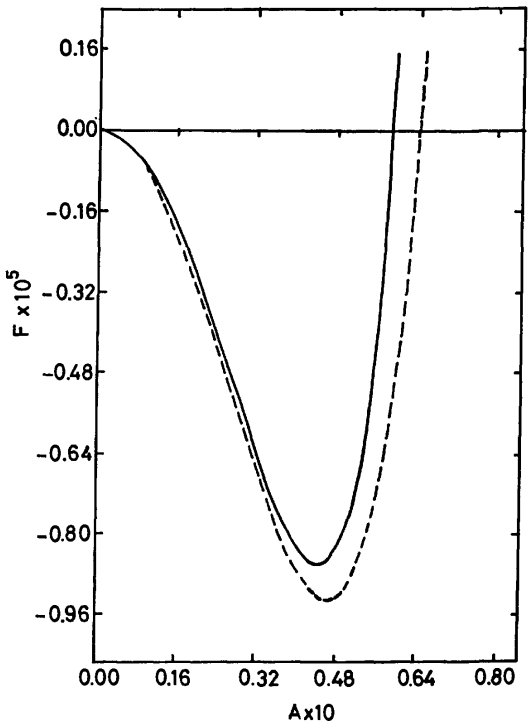

Fig. 3. Variation of amplitude expansion rate F with amplitude A of trajectory.
——: Plots of data from computer simulations, ------: theoretical curve by Landau's equation (Eq. 3) on using values of $\gamma_2 = -0.616 \times 10^{-2}$ and $\gamma_4 = 2.132$ from Eqs. 14 and 15.

$$A_u = \sqrt{-\frac{\gamma_2}{\gamma_4}}. \tag{18}$$

For $p \simeq p_c$,

$$\log A_u = \frac{1}{2}\log(p_c - p) + C, \tag{19}$$

where C is a constant independent of p. In Fig. 2 the broken line represents a theoretical curve derived from Eq. 18. For $p \simeq p_c$, the gradient of the plotted line is 1/2, which agrees well with Eq. 19. For $p \ll p_c$, however, the agreement becomes less good. The reason for this discrepancy comes from the roughness of our approximations in the perturbation method.

It has been confirmed that our perturbation method (Landau theory) can explain the behavior of the unstable limit cycle near p_c fairly well. It is insufficient, however, to explain the global behavior of the limit cycles.

Global Behavior

The global behavior of the simple Oregonator model is different from the local behavior around the steady state. The estimation of the global behavior is difficult on the basis only of the theoretical analysis (linear approximation) of the local behavior. In order to examine the global behavior of the simple Oregonator model, we have made computer simulations for various values of f and p under a fixed q (=0.05). The q parameter depends on the constants determined by the elementary reactions in the FKN model.[1] These are

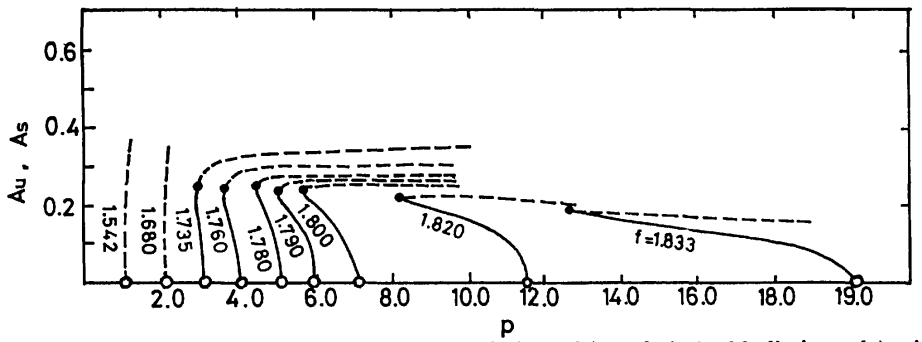

Fig. 4. Variations of amplitudes A_u (unstable limit cycle) and A_s (stable limit cycle) with parameters p and f for fixed $q=0.05$ ($f_{c_1}=0.714$, $f_{c_2}=1.850$, $f_T=1.688$).
——: Amplitude of unstable limit cycle, ------: amplitude of stable limit cycle, ○: p_c, ●: p_d.

$k_1=k_1'[H^+]^2$, $k_2=k_2'[H^+]$, $k_3=k_3'[H^+]$ and $k_4=k_4'$. The q parameter becomes:

$$q=\frac{2k_1k_4}{k_2k_3}=\frac{2k_1'k_4'}{k_2'k_3'},$$

where k_1', k_2', k_3', and k_4' are, respectively, the rate constants of the following elementary reactions in the B-Z reaction:

$$Br^- + BrO_3^- + 2H^+ \xrightarrow{k_1'} HBrO_2 + HOBr,$$

$$Br^- + HBrO_2 + H^+ \xrightarrow{k_2'} 2HOBr,$$

$$BrO_3^- + HBrO_2 + H^+ \xrightarrow{k_3'} 2BrO_2\cdot + H_2O$$

$$2HBrO_2 \xrightarrow{k_4'} HOBr + BrO_3^- + H^+.$$

As q depends only on the rate constants of the elementary reactions described above, its value can be varied by changing the temperature. Field *et al.* have determined by using known rate constants, that at 25 °C $q=8.375\times10^{-6}$. However, the dependency of every rate constant on the temperature has not been confirmed. Hence, a further examination is necessary to see whether the state of $q=0.05$ can be realized experimentally or not by changing the temperature.

We have selected such a relatively high value of q for two reasons. One is a technical reason with regard to computer simulations. In order to get the numerical value of the amplitude-expansion rate, F, continuously, we need to set q at such a high value. For a small q, for example $q=0.006$ (Fig. 1), the amplitude-expansion rate, F, becomes discontinuous near $A=A_s$. This is because the entrainment into the stable limit cycle is too strong and the trajectory does not take even one turn around the steady state. The other reason is involved with our concerns as to the qualitative property of the global behavior. As we shall see later, the global behavior of the simple Oregonator model shows a kind of phase transition as the r parameter changes.† For this purpose, the absolute value of q is not absolutely essential.

Figure 4 shows the variations in the amplitudes of the two kinds of limit cycles against p for fixed f and q values. The solid lines show the amplitudes, A_u, of the unstable limit cycles, while the broken lines show the amplitudes, A_s, of the stable limit cycles. The p_c point is the point from which a limit cycle appears. As is shown in the figure, no unstable limit cycle exists for $p>p_c$. The other transition point, p_d, is the lowest boundary value of p for the coexistence of an unstable limit cycle and a stable limit cycle. Hence, only for $p_d<p<p_c$ can two limit cycles coexist (coexistence state). Figure 5 shows the various boundary parameters on which the global behavior of the trajectory changes topologically. The f_{c_1} and f_{c_2} points are a pair of the boundary values of f inside which the steady state can be unstable; numerically, $f_{c_1}=0.714$ and $f_{c_2}=1.850$ for $q=0.05$. The T point in Fig. 5 shows the point at which three different global states coexist, where $p_d=p_c(f=f_T)$ or $r_d=r_c(f=f_T)$. We call this point, T, "a triple point"

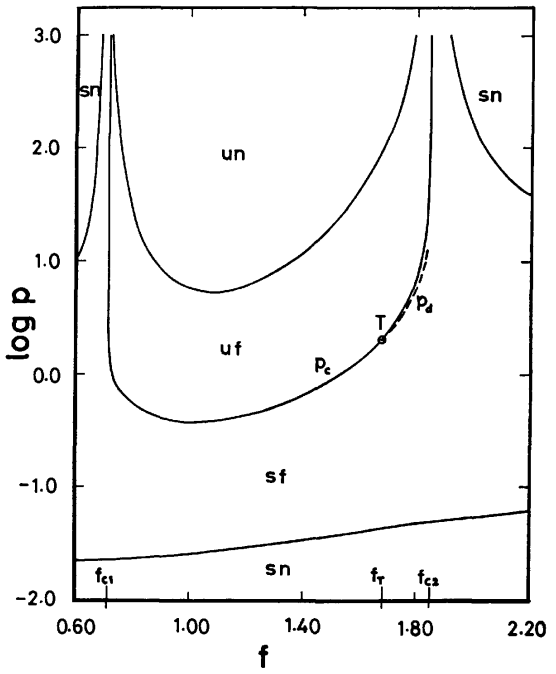

Fig. 5. Boundary parameters map for different kinds of global behavior of trajectory under $q=0.05$.

TABLE 1. VALUES OF BOUNDARY PARAMETERS FOR COEXISTENCE OF TWO KINDS OF LIMIT CYCLES (q=0.05)

f	r_c	r_d
1.8339	0.0500	0.0787
1.8200	0.0860	0.1215
1.8000	0.1399	0.1754
1.7900	0.1675	0.1994
1.7795	0.1969	0.2245
1.7603	0.2518	0.2793
1.7347	0.3275	0.3484
1.688 (f_T)	0.473 (r_T)	0.473 (r_T)

for the sake of simplicity. Figure 6 shows the variations in r_c and r_d near the triple point. The Arabic figures written in Fig. 6 represent the total number of limit cycles. The area specified by the Arabic figure 2 is the coexistence state (the coexistence of two kinds of limit cycles). The areas specified by the two figures 0 and 1 correspond to the states of a no-limit cycle and a one-limit cycle respectively. The solid line shows r_c. The black circles represent the points of r_d as obtained from computer simulations. The detailed values of r_c and r_d are shown in Table 1. The broken line has been obtained by the method of the least squares. The intersection of two lines, r_c and r_d, gives the triple point, T. The values of p_T, r_T, and f_T, which are defined by the values of p, r, and f respectively at the triple point, T, are obtained for q=0.05 as:

$$p_T = 2.11,\ r_T = r_c(f = f_T) = r_d(f = f_T) = 0.473,$$
$$f_T = 1.688.$$

Next we will examine the global behavior of the amplitude-expansion rate, F, under a fixed f value. The global behavior can be classified into two types: that with the coexistence state and that with no coexistence state. Our numerical simulations show that the former type can be seen for $f > f_T$, whereas the latter type can be seen for $f < f_T$. Figure 7 shows a typical example of

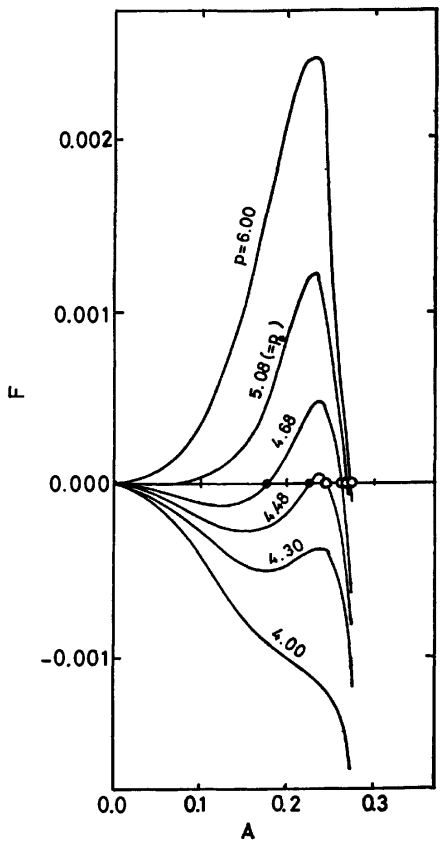

Fig. 7. Variations of amplitude expansion rate F with amplitude A of trajectory for q=0.05 and f=1.7795. (p_c=5.080, p_d=4,454, f_{c_2}=1.850, f_T=1.688) ●: Amplitude of unstable limit cycle, ○: amplitude of stable limit cycle.

the former type: f=1.7795 ($> f_T$=1.688) for q=0.05. Figure 8 shows one of the latter type: f=1.100 ($< f_T$). Here the problem arises of whether or not the coexistence

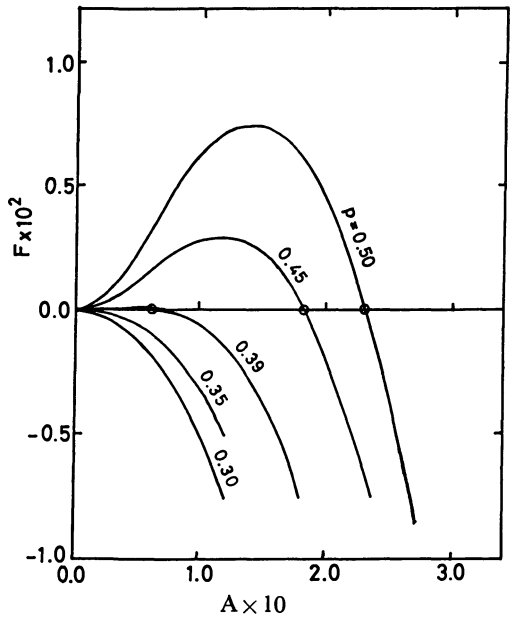

Fig. 8. Variation of amplitude expansion rate F with amplitude A of trajectory for $q=0.05$ and $f=1.100$. ($p_c=0.383$, $f_{c_1}=0.714$, $f_T=1.688$) ○: Amplitude of stable limit cycle.

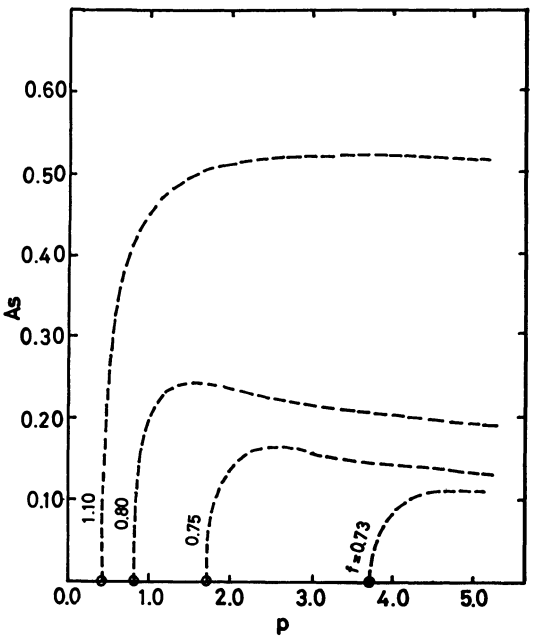

Fig. 9. Variations of amplitudes A_s (stable limit cycle) with parameters p and f for fixed $q=0.05$ ($f<1.100$, $f_T=1.688, f_{c_1}=0.714$).
------: Amplitude of stable limit cycle, ○: p_c.

state can exist for f near f_{c_1} in the range from f_{c_2} to f_{c_1} (the low-f side of the $f_{c_1}<f<f_{c_2}$ region). We conclude that there is no coexistence state on the low-f side of the region where case $q=0.05$. There are two reasons for deriving this conclusion. The first is the confirmation of the absence of an unstable limit cycle on the low-f side of the region, within the limits of accuracy of our numerical calculation by means of computer simulations. The second is the mode of the dependence of the amplitude, A_s, on p. Figures 8 and 9 show F and A_s in a no-coexistence state. In this case, the stable limit cycle (the broken line in Fig. 9) appears immediately above p_c. This kind of behavior of the amplitudes can be seen for all cases of $f<f_T$ and is quite different from the coexistence state ($f>f_T$). In the coexistence state, the unstable limit cycle (solid line) appears from p_c, and a stable limit cycle can also exist for p below p_c, as is shown in Fig. 4.

Janz *et al.*[5] have studied the steady state stability property in an attempt to investigate a coexistence state in a simple Oregonator. By simulations for $q=8.375\times 10^{-6}$, they have found two regions of the coexistence state: the low-f side and the high-f side of the region ($f_{c_1}<f<f_{c_2}$). The coexistence state investigated by us corresponds to the one on the high-f side of the region (the region of f near and below f_{c_2}). In fact, Janz *et al.* have found that the area of the coexistence state goes to zero as r exceeds a certain value††. This property is qualitatively the same as those which we have found. In our case, the boundary value of r is r_T. For $r>r_T$, the coexistence state disappears. We can not, however, find the coexistence state on the low-f side of the region for a high q ($q=5\times 10^{-2}$). The most reasonable explanation for these two inconsistent results is that the coexistence state on the low-f side disappears as q exceeds a certain value. Janz *et al.* have pointed out that the area of the coexistence state on the low-f side is about 1/10 times narrower than that on the high-f side. For example, the maximum value of Δf (the width of f for which the coexistence state has been observed) is only $\Delta f=0.038$ ($\Delta f/f_{c_1}=0.08$), whereas the maximum value of Δf on the high-f side is $\Delta f=0.38$ ($\Delta f/f_{c_2}=0.28$). This means that the area of the coexistence state on the low-f side is very small, even for a small q value ($q=8\times 10^{-6}$). This also suggests the disappearance of the coexistence state for a high q, and so the above explanation is reasonable.

Now we will show the qualitative change in the global behavior of the simple Oregonator model as determined by means of computer simulations. The global behavior can simply be expressed by the term "phase transition." The r_c (or p_c) and r_d (or p_d) quantities give the phase boundary, and the r_T point, the triple point. The phase corresponds to the number of limit cycles. The state with no limit cycle and one limit cycle is a single-phase state. The state with two limit cycles is the coexistence state of the two phases. This global behavior of the simple Oregonator model shows the type of statistical dynamic property. This property offers an important point of view from which to investigate the relations between the Oregonator model and other nonlinear, nonequilibrium systems.

Kinetics of Gas Phase Addition Reactions of Trichlorosilyl Radicals. VIII. Reinvestigation of Addition to Ethylene

Takaaki DOHMARU* and Yoshio NAGATA
Radiation Center of Osaka Prefecture, Shinke-cho, Sakai, Osaka 593
(Received January 5, 1983)

The addition of $\cdot SiCl_3$ radicals to ethylene has been reinvestigated using a large conversion method. The amended values are $\log(k_3/k_5) = -0.17\pm0.05-(0.80\pm0.10)$ kcal mol^{-1}/2.303 RT and $\log\{k_{-5}/k_6$ (mol cm^{-3})$\} = 3.4\pm0.3-(22.5\pm0.7)$ kcal mol^{-1}/2.303 RT where the reactions involved are $\cdot SiCl_3 + CH_3COCH_3 \xrightarrow{3} (CH_3)_2\dot{C}OSiCl_3$, $\cdot SiCl_3 + C_2H_4 \underset{-5}{\overset{5}{\rightleftarrows}} \cdot CH_2CH_2SiCl_3$ and $\cdot CH_2CH_2SiCl_3 + HSiCl_3 \xrightarrow{6} C_2H_5SiCl_3 + \cdot SiCl_3$.

Silyl radical chemistry is now in the stage where any kinetic data leading to precise rate constants involving silyl radicals or silicon-containing compounds are in urgent need.

In the course of our kinetic study of addition of $\cdot SiCl_3$ radicals to olefins we found[1] that the A-factor of reaction (−5) for ethylene (see synopsis, $\log(A_{-5}/s^{-1}) = 12.8$) was too small compared with the ones for other 1-alkenes ($\log(A_{-5}/s^{-1}) = 14.8$—$16.3$. There is no convincing elucidation that the transition state of decomposition of the adduct radical for ethylene should be so tight while those for the other 1-alkenes are very loose. Further, transition state theory requires that $\log(A_{-5}/s^{-1}) \geq 13.4$.

In view of these facts we attempted to reinvestigate the addition to ethylene using a large conversion method (*vide infra*). In the previous study[2] there was a very small amount of impurity (possibly $(CH_3)_2CHOSiCl_2H$ by GC–MS analysis) which could not be separated completely from $C_2H_5SiCl_3$ by GLC analysis and which arised only when CH_3COCH_3 and $HSiCl_3$ were mixed. We purified CH_3COCH_3 but failed to reduce the amount of the impurity. Although we ascertained that the impurity itself did not participate in the reaction, it may have caused some systematic errors during the analytic process.

In this study we allowed the reaction to proceed to the extent that the yield of $C_2H_5SiCl_3$ is 10 times larger than the amount of the impurity.

Experimental

Materials and procedures are essentially similar to those described earlier.[2] Mixtures of CH_3COCH_3, C_2H_4, and $HSiCl_3$ were introduced into a cylindrical Pyrex cell of 137 cm^3 which was heated in an electric oven. The light source was a 50 W medium pressure mercury arc. After photolyzed, the reaction mixture was passed to a gas sampling loop and was immediately analyzed by GLC on a 2m SE 30 column.

Kinetic Equation. Photolysis of acetone in the presence of $HSiCl_3$ and C_2H_4 can be interpreted by the following chain reaction;[2] Eqs. 1 and 2, Eqs. 3 to 6, and Eqs. 7 to 9 are initiation, propagation and termination steps, respectively.

$$CH_3COCH_3(Ac) \xrightarrow{h\nu} 2\cdot CH_3 + CO \quad (1)$$

$$\cdot CH_3 + HSiCl_3(TCS) \longrightarrow CH_4 + \cdot SiCl_3 \quad (2)$$

$$\cdot SiCl_3 + CH_3COCH_3 \longrightarrow (CH_3)_2\dot{C}OSiCl_3 \quad (3)$$

$$(CH_3)_2\dot{C}OSiCl_3 + HSiCl_3 \longrightarrow (CH_3)_2CHOSiCl_3(A) + \cdot SiCl_3 \quad (4)$$

$$\cdot SiCl_3 + C_2H_4(Et) \rightleftarrows \cdot CH_2CH_2SiCl_3 \quad (5)$$

$$\cdot CH_2CH_2SiCl_3 + HSiCl_3 \longrightarrow C_2H_5SiCl_3(E) + \cdot SiCl_3 \quad (6)$$

$$2(CH_3)_2\dot{C}OSiCl_3 \longrightarrow \text{Products} \quad (7)$$

$$2\cdot CH_2CH_2SiCl_3 \longrightarrow \text{Producrs} \quad (8)$$

$$(CH_3)_2\dot{C}OSiCl_3 + \cdot CH_2CH_2SiCl_3 \longrightarrow \text{Products} \quad (9)$$

Assuming long reaction chains,[3] we obtain the following rate equation by the conventional steady state treatment of the scheme.

$$(R_A/R_E)([Et]/[Ac]) = (k_3/k_5)\{1 + (k_{-5}/k_6)[TCS]^{-1}\}, \quad (10)$$

where R, k, and [ ] have usual meanings of rate, rate constant, and concentration, respectively.

In a study where the conversion of the reactants can be kept small, we may make an approximation:

$$R_A/R_E = [A]/[E]. \quad (11)$$

Previously,[2] we used Eqs. 10 and 11 to obtain k_3/k_5 and k_{-5}/k_6.

When the conversion of the reactants can not be assumed small, however, we must find out an alternative to Eq. 11. Equation 10 itself applies at any time during the course of reaction, so the simplest solution to this problem is to obtain the initial rate ratio, *i.e.* $(R_A/R_E)_0$.

First-order approximation can be made to R_A and R_E, when reactant conversions are not very large.

Then, $$R_A/[Ac] = a_0 + a_1 t, \quad (12)$$

and $$R_E/[Et] = b_0 + b_1 t. \quad (13)$$

Here the problem is to evaluate a_0 and b_0. Integration of Eq. 12 gives

$$\ln([Ac]_0/[Ac]) = a_0 t + a_1 t^2/2. \quad (14)$$

From the mechanism we obtain

$$[\cdot SiCl_3] = (k_1/k_7)^{1/2}(k_4/k_3)[Ac]^{1/2}[TCS] \times \{[Ac]+[Et](\lambda_4/\lambda_6 p)\}^{-1}, \quad (15)$$

where λ is a kinetic chain length and p stands for $(R_A/R_E)([Et]/[Ac])$. On the other hand, $R_A/[Ac] = k_3[\cdot SiCl_3]$, so that

$$a_0 = k_4(k_1/k_7)^{1/2}[Ac]_0^{1/2}[TCS]_0 \times \{[Ac]_0 + [Et]_0(\lambda_4/\lambda_6 p)\}^{-1}, \quad (16)$$

and

$$a_1/a_0 = 1/t\left\{\frac{[Ac]^{1/2}[TCS]\{[Ac]_0+[Et]_0(\lambda_4/\lambda_6 p)\}}{[Ac]_0^{1/2}[TCS]_0\{[Ac]+[Et](\lambda_4/\lambda_6 p)\}} - 1\right\}. \quad (17)$$

Substitution of Eqs. 16 and 17 into Eq. 14 gives

$$a_0 = \frac{2}{t}\left\{\frac{[Ac]^{1/2}[TCS]\{[Ac]_0+[Et]_0(\lambda_4/\lambda_6 p)\}}{[Ac]_0^{1/2}[TCS]_0\{[Ac]+[Et](\lambda_4/\lambda_6 p)\}} + 1\right\}^{-1} \times \ln\frac{[Ac]_0}{[Ac]}. \quad (18)$$

An approximate value of p can be obtained using Eq. 11 and λ_4/λ_6 is easily calculated since $\lambda_4/\lambda_6=(k_4/k_6)(k_8/k_7)^{1/2}$, where log $(k_4/k_6)=-1.2$ kcal mol^{-1}/2.3 RT[1] and $(k_8/k_7)^{1/2}=1.04$ (calculated based upon the mass difference between the terminating radicals). Also a concentration of each reactant obeys the stoichiometric Eq. 19.

$$[\mathrm{Ac}]=[\mathrm{Ac}]_0-[\mathrm{A}]$$
$$[\mathrm{Et}]=[\mathrm{Et}]_0-[\mathrm{E}]$$
$$[\mathrm{TCS}]=[\mathrm{TCS}]_0-[\mathrm{A}]-[\mathrm{E}] \quad (19)$$

In the similar way b_0 can be derived using Eqs. 10, 12, and 13.

$$b_0=\frac{2}{t}\left[\frac{(a_0+a_1t)\{1+(k_{-5}/k_6)[\mathrm{TCS}]_0^{-1}\}}{a_0\{1+(k_{-5}/k_6)[\mathrm{TCS}]^{-1}\}}+1\right]^{-1}\ln\frac{[\mathrm{Et}]_0}{[\mathrm{Et}]} \quad (20)$$

An approximate value of k_{-5}/k_6 can be obtained from the plot of ([A]/[E])([Et]/[Ac]) *vs.* $[\mathrm{TCS}]^{-1}$. Thus we obtain a_0 and b_0. At the initial stage of reaction, Eq. 10 is expressed as

$$(R_\mathrm{A}/R_\mathrm{E})_0([\mathrm{Et}]_0/[\mathrm{Ac}]_0)=(k_3/k_5)\{1+(k_{-5}/k_6)[\mathrm{TCS}]_0^{-1}\}, \quad (21)$$

where $(R_\mathrm{A}/R_\mathrm{E})_0([\mathrm{Et}]_0/[\mathrm{Ac}]_0)=a_0/b_0$.
In this study we employed Eq. 21 to obtain k_3/k_5 and k_{-5}/k_6.

Results and Discussion

Mixtures of CH_3COCH_3, C_2H_4 and varying amounts of $HSiCl_3$ were photolyzed in the gas phase between 150 and 275 °C. Reaction conversions of C_2H_4 were *ca.* 10%. The results are shown in Table 1.

a) The volume of the cell was 137 cm^3 and the rate of absorption of light by 3 μmol cm^{-3} of acetone was *ca.* 7×10^{-12} einstein cm^{-3} min^{-1}.

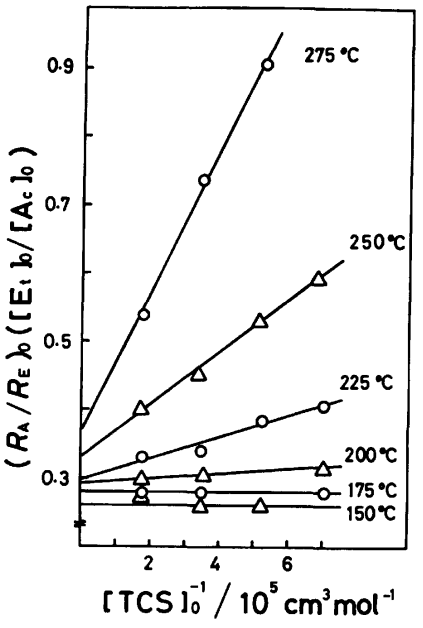

Fig. 1. Plot of Eq. 21.

The data in Table 1 were used to calculate $(R_\mathrm{A}/R_\mathrm{E})_0$, which are then plotted according to Eq. 21 (Fig. 1). The linearity of the plot at each temperature is excellent. Eq. 21 shows that the intercept of each line gives k_3/k_5 and its slope divided by the intercept value gives k_{-5}/k_6.

The least-mean-squares treatment of the Arrhenius plots of these rate constant ratios provides the Arrhenius parameters, which are shown in Table 2.

In Table 2 are compared the Arrhenius parameters obtained in this work with the previous values for 1-alkenes. The values of k_5/k_3 and k_{-5}/k_6 at 200 °C (middle temperature) in this work (3.5, 1.0×10^{-7} mol cm^{-3}) are in good agreement with those (3.2, 0.96×10^{-7} mol cm^{-3}) of the previous work.[2] Comparison of the values of log (A_{-5}/A_6) shows that the present value seems more reasonable, since there is no convincing

Table 2. Comparison of Arrhenius parameters with the previous values

	log (A_5/A_3)	$\frac{E_5-E_3}{\text{kcal mol}^{-1}}$	$\log\frac{A_{-5}/A_6}{\text{mol cm}^{-3}}$	$\frac{E_{-5}-E_6}{\text{kcal mol}^{-1}}$

Electric Field Orientation of Poly(*p*-styrenesulfonate) and Its 9-Aminoacridinium Complex as Studied by Square-pulse Transient Electric Birefringence

Kiwamu YAMAOKA* and Kazuyoshi UEDA

Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

(Received January 20, 1983)

Electric birefringence was measured at 20 °C and at 535 nm for sodium poly(*p*-styrenesulfonate) (NaPSS), with and without added sodium chloride, and the 9-aminoacridinium (AA) complex in aqueous solutions. The field strength dependence of both the steady-state EB ($\Delta n(\infty)$) and the field-free decay time ($\langle\tau\rangle_{EB}$) was examined. Charge suppression by added Na^+ ions or neutralization by strongly bound AA decreased both $\Delta n(\infty)$ and $\langle\tau\rangle_{EB}$ considerably, altering not only the optical factor Δg and electric moments, but also the backbone chain length. The weight-average values of chain length (l_w), pseudopermanent dipole moment (μ_w), counterion-induced electric polarizability anisotropy ($\Delta\alpha_w$), and the length-independent values of Δg were estimated by analyzing the experimental data on the basis of the "classical" orientation function which takes into account the continuous distribution of chain length for the polydisperse NaPSS sample. The electric field orientation of NaPSS and the AA-complex could be described by the interaction between an applied field and the electric moment which transforms from counterion-induced type in the extremely low field region (<1.5 kV/cm) to saturated induced permanent type at higher fields.

Among synthetic vinyl polymers, poly(*p*-styrenesulfonate) (NaPSS) has been employed as a model polyelectrolyte in many physicochemical studies.[1-12] These studies indicate that the PSS chain is stiff and may be represented by a rodlike model. A recent electric dichroism study showed that the ionized NaPSS can be oriented by an external electric field, exhibiting a negative dichroism of considerable magnitude, and that the *p*-sulfonatophenyl chromophores are arranged nearly at 60° relative to the PSS backbone chain.[10] Earlier, Yoshioka and his coworkers[2,3,7] extensively studied the electric birefringence of the potassium salt of PSS (KPSS) in aqueous solutions with various additives; they found that the field orientation of KPSS may be described as being due to the permanent dipole moment. Very recently, Tricot and Houssier[11] reported a careful work on the electric birefringence of some NaPSS fractions, finding that the birefringence (Δn) curve fits a pure induced dipole orientation. These two groups are mostly concerned with the field strength dependence of the steady-state data. We believe that the solution property of PSS polyions should also be deduced from the result obtained by transient electrooptical techniques.

The objectives of this work are (1) to show that the field orientation mechanism of the chain of NaPSS in salt-free solution can be described in terms of a transformation of the electric polarizability to a permanent-like moment, by analyzing the field strength dependence of the steady-state Δn; (2) to exemplify that the weight-average chain length (hence, the overall shape) may be estimated from the field strength dependence of the field-free relaxation times with a reasonable model by taking into account the polydispersity of the sample; (3) to demonstrate that the PSS backbone chain can be contracted significantly due to partial neutralization or suppression of the negative charge on the sulfonato group by monovalent cationic additives; (4) to simulate the rise and decay portions of a transient signal in the Kerr-law region, in order to support the notion that the field orientation is due to fast counterion-induced dipole moment.[8,12] These objectives were successfully achieved by the method of fast square-pulse transient electric birefringence.

Experimental

Materials. Sodium poly(*p*-styrenesulfonate) (NaPSS) is the same sample that was used in previous studies.[8,10,13] The original sample (KPSS) was a generous gift of Professor Koshiro Yoshioka of the University of Tokyo. The degree of polymerization was estimated to be 1360.[10] 9-Aminoacridinium chloride (denoted simply as AA), a strongly binding monocationic dye, was described elsewhere.[10,13]

Preparation of Sample Solutions. The salt-free NaPSS solution was prepared by dissolving an anhydrous sample in twice-distilled water. The NaCl-added NaPSS solution was prepared by adding an appropriate amount of NaCl to the stock NaPSS solution, the ratio of the total Na^+ ions to the counterion Na^+ being 6.00. The AA-added NaPSS solution was prepared in a similar manner. The ratio of the polymer residue to AA finally present in the mixture (denoted as P/D)[10,13] is 6.14. The concentration of NaPSS in the monomer unit is 0.66 mM (1 mM = 1×10^{-3} mol dm^{-3}) in all cases.

Measurements. Square-pulse electric birefringence was measured on an apparatus built in this Laboratory.[10,14] The pulse width was continuously variable up to 5 ms and the pulse amplitude was varied up to 11.3 kV/cm. A 1-cm long H-shaped Kerr cell made of Kel-F was used, the electrode gap being 0.207 cm. Instrumental time constants were less than 0.5 μs for the transient rise and decay signals. The phase retardation, δ, in degrees was measured at 535 nm and at 20 °C, the sign being determined with a quarter-wave plate.

Analysis of Data. The steady-state birefringence Δn and the specific Kerr constant, B/c, are defined as[14]

$$\frac{B}{c}=\lim_{E^2\to0}\frac{\Delta n}{\lambda c}\left(\frac{1}{E^2}\right)=\lim_{E^2\to0}\frac{\delta}{2\pi dc}\left(\frac{1}{E^2}\right), \quad (1)$$

where λ is the wavelength *in vacuo*, c is the mass concentration in g/cm^3, and d is the optical path length (= 1 cm). Since the theoretical treatments of the field orientation of polyelectrolytes are under development, no complete expression for the transient electric birefringence is available as yet. Under these circumstances, the "classical" theory for nonconducting rodlike macromolecules of axial symmetry should be utilized.[15] This theory is nevertheless known to be an adequate approximation for NaPSS in aqueous solutions.[2,3,7,10,11] For a polydisperse

polymer sample, the steady-state birefringence, $\Delta n(\infty)$, at an arbitrary electric field strength E is given as[16-18]

$$\Delta n(\infty) = \frac{2\pi \bar{C}_v}{n}(g_3 - g_1)\langle \Phi(\beta(l), \gamma(l))\rangle_w, \quad (2)$$

where n is the refractive index of the solution, $\bar{C}_v$ is the volume fraction of the solute, (g_3-g_1) is the optical anisotropy factor, $\langle \Phi(\beta,\gamma)\rangle_w$ is the weight-average orientation function, $\beta(l)=\mu(l)E/kT$, and $\gamma(l)=\Delta\alpha(l)E^2/2kT$. In the low electric field region where the Kerr law holds, the rise portion of the normalized transient signal is expressed by

$$\frac{\Delta n(t)}{\Delta n(\infty)} = 1 - \frac{\int_0^\infty \Delta n(\infty, l)\left\{\frac{3\beta(l)^2 e^{-2\theta_{11}(l)t} - [\beta(l)^2 - 4\gamma(l)]e^{-6\theta_{11}(l)t}}{2[\beta(l)^2+2\gamma(l)]}\right\} dl}{\int_0^\infty \Delta n(\infty, l) dl}, \quad (3)$$

where θ_{11} is the rotary diffusion coefficient of the undeformable molecule around the transverse axis, $\Delta n(\infty,l)=(2\pi\bar{C}_v/15n)(g_3-g_1)\times\phi(l)[\beta(l)^2+2\gamma(l)]$, $\phi(l)$ is the fraction of solute molecules with the length l, and $\Delta n(0)=\Delta n(\infty)$. The decay portion is expressed by

$$\frac{\Delta n(t)}{\Delta n(0)} = \frac{\int_0^\infty \Delta n(0, l)e^{-6\theta_{11}(l)t} dl}{\int_0^\infty \Delta n(0, l) dl}. \quad (4)$$

Results and Discussion

Dependence of Steady-state Birefringence on Electric Field. Figure 1 shows the dependence of phase retardation, δ, on electric field strength for NaPSS solutions with and without additives. The charge suppression of the ionized sulfonato group by added Na^+ decreases the magnitude of δ. More remarkably, the charge neutralization of the same group (one out of six) by bound AA cations diminishes the values of δ nearly tenfold. In order to ascertain if these decreases in δ are due solely to the change in the optical anisotropy factor in Eq. 2, the δ *vs.* E^2 curves of the NaPSS–AA and NaPSS–NaCl systems were multiplied by factors at an arbitrarily selected field strength ($E^2=10$ (kV/cm)^2). As indicated in Fig. 1, the NaPSS–AA and NaPSS–NaCl curves cross at this point, but otherwise they do not coincide with the salt-free NaPSS curve. This behavior suggests that the electric part in Eq. 2 is also affected; hence, the electric moment of the salt-free NaPSS chain should also be decreased by the addition of NaCl or AA.

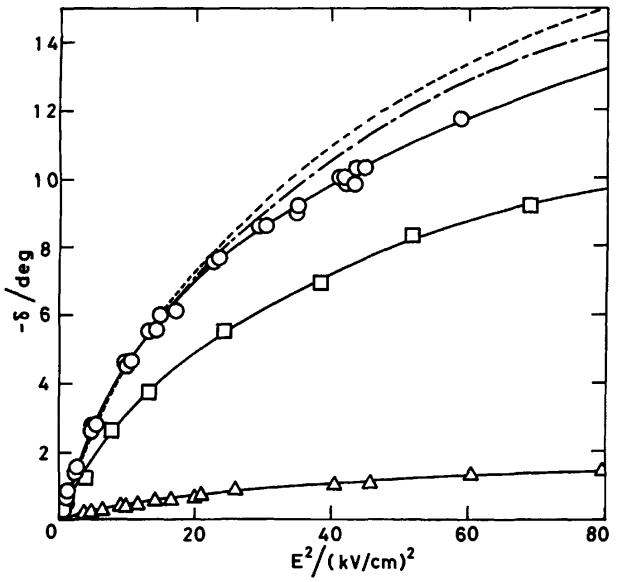

Fig. 1. The dependence of steady-state birefringence, δ, on the square of electric field strength, E^2, for the salt-free NaPSS (○), the NaPSS–NaCl (□), and the NaPSS–AA (△) solutions. The residue concentration of NaPSS is 0.66 mM in these cases. The dashed (– – –) line represents the NaPSS–AA curve which is multiplied by a factor of 10.3 at a field strength ($E^2=10$ (kV/cm)^2), while the dash-dot-dashed (—·—) line is the NaPSS–NaCl curve multiplied by 1.47.

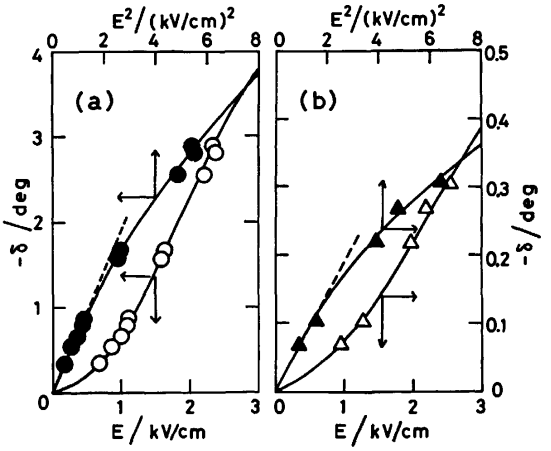

Fig. 2. The linear and quadratic dependence of δ on field strength in the low field region. (○, ●) for NaPSS and (△, ▲) for NaPSS–AA. The dashed lines indicate a linear dependence of δ on E^2 at limiting low fields.

Low Electric Field Behavior and the Kerr Constant. Figure 2 shows the values of δ in the low electric field region for the NaPSS and NaPSS–AA solutions. They

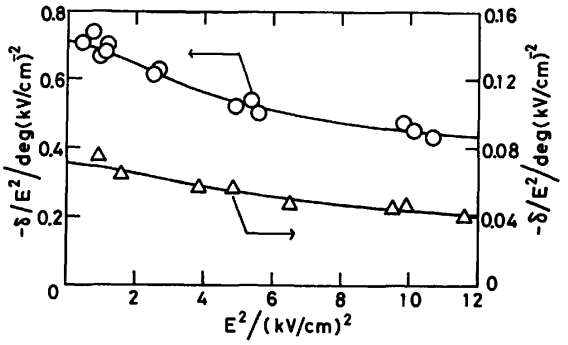

Fig. 3. Plots of the phase retardation per square of field strength, δ/E^2, against the square of field strength for NaPSS (○) and NaPSS–AA (△). The values extrapolated to zero field strength, $(-\delta/E^2)_{E\to 0}$, are 0.701 deg(cm/kV)^2 for NaPSS and 0.071 deg(cm/kV)^2 for NaPSS–AA.

TABLE 1. ELECTROOPTICAL AND HYDRODYNAMIC PROPERTIES OF NaPSS WITH AND WITHOUT IONIC ADDITIVES

Samples	B/c 10^{-6} cm^4 V^{-2} g^{-1}	$\langle\tau\rangle_w$ μs	l_w Å	μ_w 10^3 D[b]	$\Delta\alpha_w$ 10^{-15} cm^3 [c]	(g_3-g_1)[a] $\times 10^2$
NaPSS	14.2	35	1210	6.48	1.32	−1.2
NaPSS–NaCl	—	20	980	5.65	—	−0.98
NaPSS–AA	1.44	10	760	5.12	0.99	−0.16

a) A value of 0.565 was used for the partial specific volume of NaPSS in water.[11] b) 1 D$=3.336\times10^{-30}$ C m.
c) 1 cm$^3=1.113\times10^{-16}$ F m^2.

are plotted against E and also against E^2. The linear dependence of δ on the second power of the field strength is clear. It is thus evident that the Kerr law holds for the 0.66 mM NaPSS solutions with and without ionic additives.

Figure 3 shows the procedure for determining the Kerr constant. The observed values of δ/E^2 are plotted against E^2. The values extrapolated to zero field strength yield the Kerr constant B. The specific Kerr constant is given in Table 1. It should be noted that the extrapolation is inevitably associated with a small uncertainty, since the curvature of the δ/E^2 *vs.* E^2 curve depends on the electric property of a particular polymer system (*cf.* Fig. 7).[15]

Dependence of Decay Process on Electric Field. Since the field-free decay curves of the 0.66 mM NaPSS solution indicate that the sample is polydisperse,[12] the relaxation time must be the birefringence-average quantity obtained by area method[19] (*e.g.*, Eq. 6 in Ref. 17), $\langle\tau\rangle_{EB}$, which depends on the field strength of a pulse applied to orient the solute prior to the start of the decay process.[16,19] Figure 4 shows a large field dependence of $\langle\tau\rangle_{EB}$ for the salt-free NaPSS system; a clear indication of the polydispersity of molecular length.[10,16] It should be noted that the addition of NaCl or AA decreases the relaxation time considerably; unfortunately, the values of $\langle\tau\rangle_{EB}$ are scattered or undetermined at low electric fields due to low signal-to-noise ratios. The $\langle\tau\rangle_{EB}$ value at infinitely high electric field reduces to the weight-average relaxation time $\langle\tau\rangle_w$

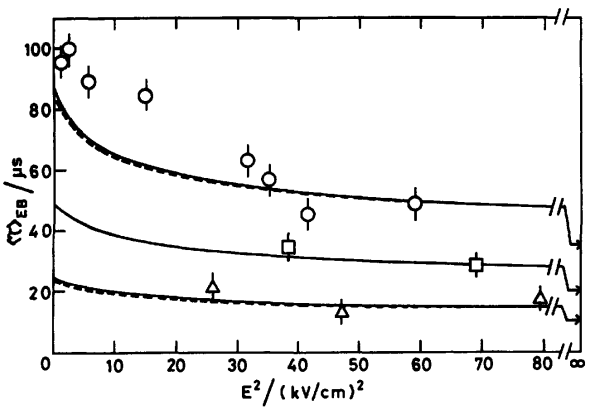

Fig. 4. The dependence of field-free relaxation time, $\langle\tau\rangle_{EB}$, on electric field strength applied prior to the start of decay process. (○) for NaPSS, (□) for NaPSS–NaCl, and (△) for NaPSS–AA. Horizontal arrows indicate the values extrapolated to infinite field strength. Points are experimental and smooth curves are theoretical.

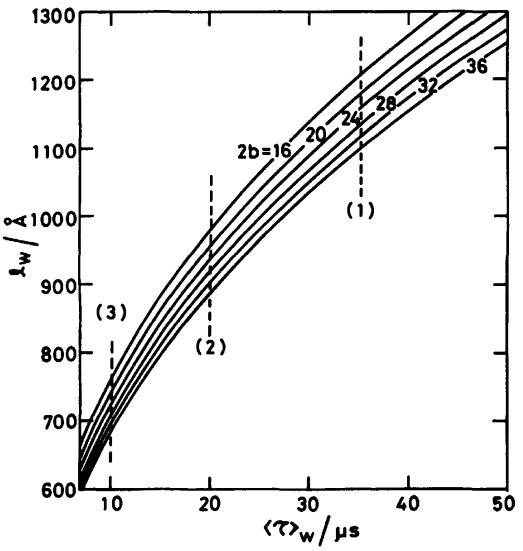

Fig. 5. Relationship between the weight-average length, l_w, and the weight-average relaxation time, $\langle\tau\rangle_w$, calculated for a polydisperse sample. The Schulz-Zimm distribution function was used to describe the polydispersity ($l_w/l_n=1.3$). The diameter of a molecule with length l was changed from 16 Å to 36 Å to calculate the value of $\langle\tau\rangle_w$ by using the Broersma equation. Vertical lines indicate the experimentally obtained values of $\langle\tau\rangle_w$ for salt-free NaPSS (1), NaCl-added NaPSS (2), and AA-added NaPSS (3).

(Eq. 9 in Ref. 17), which is independent of the electric parameters of the molecules, since the orientation function $\langle\Phi\rangle_w$ approaches unity. The values of $\langle\tau\rangle_w$ for the NaPSS, NaPSS–NaCl, and NaPSS–AA systems are given in Table 1.

Weight-average Relaxation Time and Chain Length. The overall shape of the PSS backbone chain may be assumed to be an undeformable cylinder in the sense that an applied electric field does not alter the molecular conformation. This is a reasonable approximation, when the field strength is less than 19 kV/cm for NaPSS and NaPSS–AA.[10,20] The rotational relaxation time $\tau(l)$ is related to the length l with the aid of the Broersma equation for a cylindrical model[21] (*e.g.*, Eq. 8 in Ref. 17). The diameter of the cylinder, $2b$, is not known for the present NaPSS system; therefore, it must be varied parametrically. The axial translation per residue of the most elongated PSS backbone is *ca.* 2.5 Å. It shortens to about 2.0 Å without changing the diameter appreciably; hence, the elongated chain length is in the range of 3400—2700 Å. The diameter of this rather stretched backbone is estimated to be at least 16 Å with CPK atomic models, if the *p*-sulfonatophenyl groups

wind around the backbone. If a folding of hair-pin type occurs in the backbone chain, the diameter may be widened, from 16 Å to 24 Å (radius times three) and further to 32 Å (radius times four). By varying the diameter $2b$ from 16 Å to 36 Å at intervals of 4 Å, the weight-average length l_w was calculated as a function of $\langle\tau\rangle_w$. The results are shown in Fig. 5, where the vertical dashed lines indicate the experimental values of $\langle\tau\rangle_w$ for the salt-free NaPSS (1), NaPSS–NaCl (2), and NaPSS–AA (3) solutions. The length l_w of the salt-free NaPSS ranges from 1200 Å ($2b$=16 Å) to 1100 Å ($2b$=36 Å), being affected only slightly by these diameters. These lengths are far shorter than the most extended chain length (3400 Å); hence, the folding-back of the vinyl backbone is evident. If a value of 16 Å is assumed for $2b$, the chain length l_w is 1210 Å for the salt-free NaPSS, 980 Å for the NaPSS–NaCl, and 760 Å for the NaPSS–AA. Thus, the binding of AA probably reduces the overall chain length appreciably.

An entirely different approach to the interpretation of the rotary diffusion coefficient $\theta_{11}(=(6\tau)^{-1})$ is possible. By adopting a flexible wormlike model, the persistence length of a polymer chain could be estimated from Hearst's[22] expression, which, however, introduces an additional parameter. This in turn means that to avoid ambiguities the polymer sample should be nearly monodisperse as regards the molecular weight. Thus, the flexibility of the polymer chain is an interesting subject for future studies.

Orientation Mechanism and Electric Moments. The orientation mechanism of the NaPSS in aqueous solution may be deduced from the electric field dependence of steady-state Δn (*cf.* Fig. 1). Yoshioka and his coworkers showed that the dependence can be best fitted by the permanent dipole orientation over a limited range of field strength.[2,3,7] Recently, Tricot and Houssier also studied the field dependence for NaPSS, confirming this permanent dipole orientation.[11] In addition, they believe that the induced dipole moment may also be adequate to describe the field dependence. In an electric dichroism study of NaPSS, Matsuda and Yamaoka have shown that, by taking into account a polydispersity in chain length, the field dependence can be best fitted by a mixed dipole orientation with the ratio $(\beta_w)^2/2\gamma_w$ of 8 over a very wide field strength range.[10] They also pointed out that, if the polydispersity is ignored, the dependence can be described equally well by the permanent dipole (*i.e.*, β-term only) orientation. In either case, Matsuda and Yamaoka have indicated that the fitting between the theoretical orientation function $\Phi(\beta)$ or $\langle\Phi(\beta)\rangle_w$ and the experimental points is poor in the very low field region.

With the above background, we can now analyze the field dependence of Δn. It is unrealistic to consider that the ionized PSS backbone bears a true permanent dipole moment of large magnitude. By now, ample evidence from reversing-pulse electric birefringence (PREB) indicates that the field orientation of NaPSS is not due to the permanent dipole but due to the counterion-induced dipole moment.[8,12] The redistribution of the counterions (Na^+) responsible for the induced dipole moment is faster than 10^{-6} s. We now demonstrate that the orientation of NaPSS results from the interaction between an external electric field and the ionic polarizability of the polyion in a limited, very low field region, in analogy to the pure electronic polarizability orientation for a nonconducting polymer, and that the interaction transforms gradually to a type between the field and an apparent permanent dipole moment. Theoretical treatments on this concept of induced dipole-permanent dipole transformation have lately appeared,[23,24] but further refinements are needed to fit experimental data over an entire field range.[10]

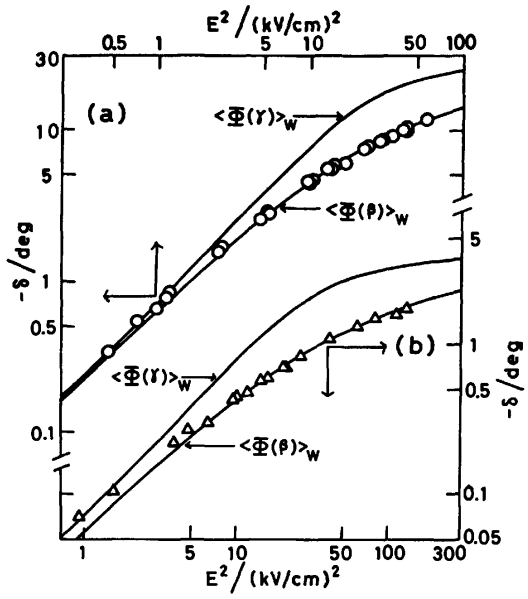

Fig. 6. Double logarithmic plots of the steady-state phase retardation *vs.* electric field strength and the theoretical orientation function, $\langle\Phi\rangle_w$. (a) Salt-free NaPSS (○) for which δ is $-29°$ at limiting high field, $\Delta a_w = 1.32\times 10^{-15}$ cm³, and μ_w=6480 D. (b) AA-added NaPSS (△) for which δ is $-3.9°$ at limiting high field, $\Delta a_w = 0.99\times 10^{-15}$ cm³, and μ_w=5120 D. $2b$=16 Å.

Experimental values of δ for NaPSS and NaPSS–AA in Fig. 1 have been replotted against E^2 on a double logarithmic scale in Fig. 6. With the parameters l_w, obtained in the preceding section, $l_w/l_n(=1.3)$, and the Schulz-Zimm distribution function[25,26] (*e.g.*, Eq. 3 in Ref. 17), the orientation functions for pure polarizability anisotropy $\langle\Phi(\gamma)\rangle_w$ and for pure permanent dipole moment $\langle\Phi(\beta)\rangle_w$ were calculated. The observed points were fitted to these functions under the assumption that the orientation mechanism transforms from the pure polarizability anisotropy γ_w in the extremely low electric field region to the pure permanent dipole moment β_w over a wide medium-to-high field range. The best-fitted orientation functions are shown with solid-lined curves in Fig. 6. In this matching procedure, both functions are adjusted to yield the same optical anisotropy factor, since this is considered to be independent of field strength.[10,18,27] The values of μ_w, Δa_w, and (g_3-g_1), all obtained from the fitting, are given in Table 1.

The pure γ_w-orientation is considered to be equivalent to the counterion-induced or ionic polarizability, while the pure β_w-orientation is equivalent to the saturated

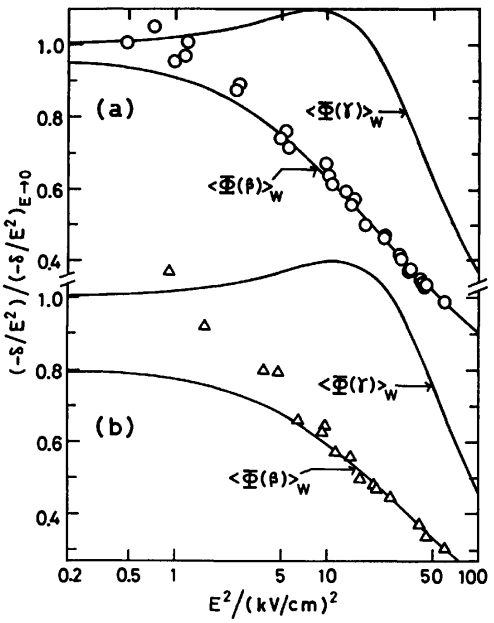

Fig. 7. Semilogarithmic plots of $(-\delta/E^2)/(-\delta/E^2)_{E\to 0}$ *vs.* E^2. Experimental values are given by circles for salt-free NaPSS (a) and by triangles for AA-added NaPSS (b), and theoretical curves by solid lines. Notations, parameters, and other conditions are all the same as those in Fig. 6.

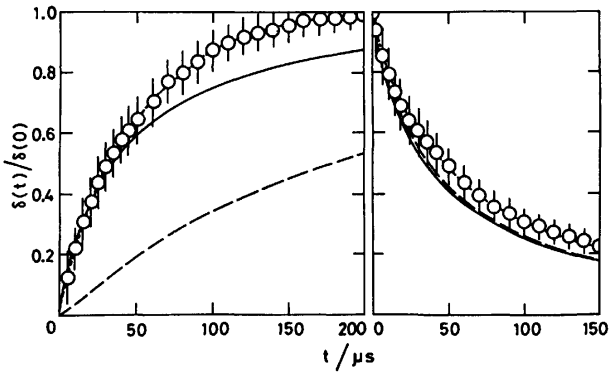

Fig. 8. Comparison of an experimental rise-and-decay signal for salt-free NaPSS with theoretically calculated transient curves. Experimental points are read from an oscillogram taken at a field strength of 1.01 kV/cm. The solid-lined curve is the theoretical one calculated on the basis of the orientation function for pure polarizability with a set of parameters ($l_w/l_n=1.3$, $l_w=1480$ Å, $2b=16$ Å) which yields the z-average relaxation time, $\langle\tau\rangle_z$, of 100 μs. The dash-lined curve is the theoretical one for pure permanent dipole orientation calculated with a set of parameters ($l_w/l_n=1.3$, $l_w=1270$ Å, $2b=16$ Å) which yields the $(z+1)$-average relaxation time, $\langle\tau\rangle_{z+1}$, of 100 μs.

induced-dipole moment. In conformity with classical theory, both the ionic polarizability and the saturated dipole moment are assumed to be proportional to the first power of the length. The dependence of these moments on the chain length remains to be explored more thoroughly in the future. In any case, it is clear that deviation from the pure γ_w-orientation appears at extremely low fields ($E<1.5$ kV/cm) for NaPSS and NaPSS–AA. This explains the previous observations that the pure permanent dipole orientation is the most appropriate one for the ionized NaPSS solution.[7,10,11]

Theoretical calculations have shown that a maximum appears in the birefringence per field strength ($\Delta n/E^2$) *vs.* E^2 curve, if the pure γ_w-orientation is the case.[15] In Fig. 7, the theoretical orientation functions, $\langle\Phi(\beta)\rangle_w$ and $\langle\Phi(\gamma)\rangle_w$, per (field strength)^2 are plotted by solid-lined curves. The observed points definitely deviate from the pure γ_w-curve, transforming to the pure β_w-curve already in the extremely low field strength region, before they reach the maximum position of the theoretical curve for the pure γ_w-orientation.

Once the values of μ_w and $\Delta\alpha_w$ are obtained from the above matching, the field strength dependence of $\langle\tau\rangle_{EB}$ shown in Fig. 4 may be examined theoretically. In this Figure are shown the theoretical curves which were calculated by assuming the pure permanent dipole moment orientation and the Schulz-Zimm distribution function. The parameters ($2b$, l_w, μ_w) are as follows: (16 Å, 1210 Å, 6480 D (1 D$=3.336\times10^{-30}$ C m)) for solid line and (32 Å, 1120 Å, 6480 D) for dashed line in the case of the salt-free NaPSS, (16 Å, 980 Å, 5650 D) for the NaCl-added NaPSS, (16 Å, 760 Å, 5120 D) for solid line and (32 Å, 700 Å, 5120 D) for dashed line in the case of the AA-added NaPSS; the viscosity of solvent is 1.009×10^{-3} Pa s. These theoretical curves are in fair agreement with experimental points, particularly, in the medium-to-high field region.

Simulation of the Rise and Decay Processes. In order to confirm the notion that the counterion-induced electric moment is fast as compared with the overall molecular rotation and that this moment can be approximated by the electronic polarizability, two theoretical transient curves for the rise and decay signal are calculated from Eqs. 3 and 4 in Fig. 8: one for the pure γ_w-orientation (solid line) and the other for the pure β_w-orientation (dashed line). In the Figure, the experimental points represent a signal of an NaPSS solution, taken at a low field strength for which the Kerr law holds. The points fit the γ_w-orientation curve better than the β_w-curve in the whole rise and decay process. This may be taken as a strong support for the notion that the orientation of NaPSS results from the fast counterion-induced dipole moment, whose induction is much faster than the overall molecular orientation. At the same time, the result in Fig. 8 indicates the limitation of the use of the classical orientation function derived for nonconducting rodlike macromolecules to an ionized polyion like NaPSS. It is clear from the present work that a further study is desirable to obtain more realistic orientation functions which can describe the electric field orientation of ionized polyelectrolytes.

Conclusion

Although the present NaPSS sample is polydisperse as regards the molecular weight, we could present a unified quantitative treatment of the ionized polyion, which possesses no permanent dipole moment, on the

framework of the classical theory for nonconducting polymers. The electric field orientation of NaPSS is due to the ionic polarization which results from the redistribution of counterions on the PSS chain surface. This counterion-induced electric moment saturates at very low electric fields and then behaves as if it was a permanent dipole moment. In conjunction with our previous work on electric dichroism[10] and reversing-pulse electric birefringence,[8,12] we believe that the solution conformation of the NaPSS and NaPSS–AA systems are now established fairly well, and that the dynamic electrooptical techniques are of great assistance in interpreting the electric properties and solution conformation of field-orientable macromolecules.

Effects of Pressure on Dielectric Relaxation in Supercooled Triphenylchloromethane-*o*-Terphenyl Solution

Motosuke NAOKI* and Manabu MATSUSHITA
Department of Textiles and Polymers, Faculty of Technology, Gunma University, Kiryu, Gunma 376
(Received February 2, 1983)

Dielectric measurements have been made as a function of frequency, temperature, and pressure on a binary mixture of triphenylchloromethane and *o*-terphenyl in its supercooled liquid region. Since the distribution of relaxation time is independent of temperature and pressure in the present experimental range, the time-temperature-pressure superposition is accurately applied. The activation parameters such as the activation enthalpy at constant pressure, H^*_P, the activation enthalpy at constant volume, H^*_V, and the activation volume V^* are obtained as a function of temperature and pressure. H^*_V is only half H^*_P unlike polymer liquids and associated liquids such as alcohols. V^* as well as the pressure coefficient of temperature at constant relaxation time τ, $(\partial T/\partial P)_\tau$, is similar in magnitude to that of polymer liquids and larger than that of associated liquids. These facts have revealed the contributions of inter- and intramolecular interactions to the molecular mobility in the supercooled liquid. $(\partial T/\partial P)_\tau$ coincides with the pressure coefficient of the glass transition temperature, dT_g/dP. This gives a statement that the glass transition temperature in simple normal liquids, as well as in polymer liquids, is an isorelaxation-time state.

The molecular mobility associated with the Brownian motion in simple liquids or with the micro-Brownian motion in polymer liquids is observed as a relaxation process at the audio- and radio-frequency range in the supercooled liquid region. The molecular mobility in the supercooled liquids is closely related to the glass transition[1,2] and the glassy state,[3-5] and the study of the relaxation process may make an important contribution to our understanding of the liquid state.

The secondary relaxation process pertaining to the local mode of motions governed by the localized energy field exists in the liquid state as well as in the glassy state,[6,7] and it merges the primary process pertaining to the Brownian motion at high frequency in elevated temperature region.[8,9] In the supercooled liquid region, however, the two processes are well separated from each other and their relaxation spectra can readily be obtainable.[6]

The introduction of pressure as a variable to the study in the molecular mobility makes primarily the role of volume in the relaxation process clear.[10] Analyses of the pressure effects on the dielectric relaxation have been reported in large numbers for associated liquids such as alcohols[11] and polymer liquids,[12-15] but a few for simple normal liquids such as short alkanes and benzene derivatives.[16] From the analysis of the viscosity of many liquids under elevated pressures above the melting temperature, MacKenzie has obtained that the activation enthalpy at constant volume, H^*_V, is only a small fraction of the activation enthalpy at constant pressure, H^*_P, in simple normal liquids, but H^*_V is almost equivalent to H^*_P in associated liquids.[17] H^*_P is given by

$$H^*_P = R\left[\frac{\partial \ln \tau}{\partial (1/T)}\right]_P, \quad (1)$$

as far as the empirical activation equation:

$$\tau = A \exp\left(\frac{G^*}{RT}\right), \quad (2)$$

is obeyed, and H^*_V is defined by

$$H^*_V = R\left[\frac{\partial \ln \tau}{\partial (1/T)}\right]_V, \quad (3)$$

Here, τ is the relaxation time, G^*, the activation Gibbs energy, R, the gas constant, and A, a constant independent of temperature T and pressure P. The ratio H^*_V/H^*_P prepresents the direct contribution of temperature to the temperature dependence of the relaxation time and gives a rough estimation of the magnitudes of the energetic or entropic contribution to the relaxation process. It may be very interesting to know H^*_V/H^*_P for simple normal liquids in the supercooled liquid region.

Many dielectric studies on the *o*-terphenyl solutions have been presented,[18,19] since *o*-terphenyl and its solutions can easily be vitrified at a relatively high temperature.[20-22] We now wish to clarify the effects of pressure on the dielectric relaxation process in the supercooled triphenylchloromethane/*o*-terphenyl solution as an example of simple normal liquids and to elucidate some intrinsic contributions to the molecular mobility in the supercooled liquid state.

Experimental

Sample. Triphenylchloromethane (TPCM) and *o*-terphenyl (oTP) were purchased from Tokyo Chemical Industry Co. and were used without further purification. In order to perform dielectric measurements without any apprehension of crystallization during the experimental period (about 3 d), crystallizability of the mixture of TPCM/oTP was preliminary tested. TPCM and oTP in various concentrations were mixed in test tubes at 130 °C. Then the mixtures were slowly cooled down to room temperature and were stored in a desiccator. Samples containing TPCM more than 50 wt% crystallized within 5 h. In samples containing TPCM less than 10 wt%, a slight crystallization peak was detected by a differential scanning calorimeter, Model DSC-1B (Perkin-Elmer Corporation) after 3 d. Any crystallization was not observed in samples containing 20—40 wt% of TPCM for one month, and we used the mixture TPCM/oTP in weight ratio of 25/75 in dielectric measurements.

Equipment. A General Radio 1620-A Capacitance Measuring Assembly, in conjunction with a General Radio 1310-B Oscillator employed to make small changes in frequency near dielectric loss peaks, was used for dielectric

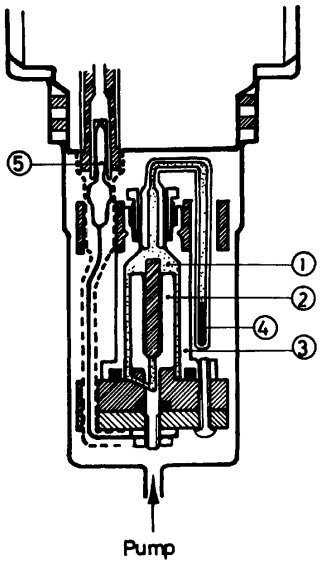

Fig. 1. Diagram of dielectric cell.
1: Sample, 2: main electrode, 3: sub electrode, 4: mercury seal, 5: electric terminal.

measurements in a frequency range of 0.03—100 kHz. The cell shown in Fig. 1 has a nominal geometric capacitance of about 15 pF with a small stray capacitance. Corrections for the stray capacitance and the change in the geometric capacitance with temperature and pressure were made by measuring the capacitance of the cell with air and with benzene (uvasol grade, Merck) in each measurement. The dielectric data of benzene were taken from those of Vij and Scaife.[23] Silicone oil (KF-94, Shin-Etsu Chemical Co.) was used to transmit the hydrostatic pressure. The pressure was measured by a Nikkiso bourdon gauge calibrated by a Heise bourdon gauge. The temperature was measured by a calibrated alumel-chromel thermocouple inserted near the sub electrode.

Experimental Procedure. The mixture (TPCM/oTP, 25/75) was prepared at 130 °C and was applied into the electrode at 70 °C. The dielectric cell was set in the pressure vessel heated previously up to 70 °C. After the pressure being increased to a desired value P_1, the temperature was lowered to the glass transition temperature T_g at P_1, $T_g(P_1)$. The dielectric measurements at P_1 were isobarically carried out at about 2 K intervals with increasing temperature to a temperature at which the frequency of dielectric loss maximum exceeded 100 kHz. This experimental operation (from the sample set to the isobaric measurements) was repeated for each pressure, *i.e.*, 1, 200, 400, 600, and 800 kg cm^{-2}. (1 kg cm^{-2}= 0.09807 MPa). The operation recurred twice for 1, 600, and 800 kg cm^{-2}.

Crystallization of the sample during the experimental period could easily be detected as a precipitous decrease in the capacitance and loss. We have excluded all the dielectric data of the experimental opetation in which the indication of the crystallization was recognized at any temperature.

Results

Some examples of the dielectric dispersion are shown in Fig. 2. The shapes of the loss curves at every temperature and pressure are all similar, being asymmetric to the high frequency side of the dispersion. The limiting low- and high-frequency dielectric constants, *i.e.*, ε_0 and ε_∞, respectively, were determined by extrapolation of

the Cole-Cole plots. The plots appear to be well represented by the Davidson-Cole equation of a skewed-arc behavior,[24] but we do not discuss the parameter in the Davidson-Cole equation. It should be noted, however, that its asymmetric factor is independent over the present experimental range.

Values of ε_0 and ε_∞ interpolated to log $\tau=-4$ are listed in Table 1. Influences of pressure on ε_0, ε_∞, and the relaxation intensity represented by $\varepsilon_0-\varepsilon_\infty$ are very little. ε_0 is almost independent of pressure in the experimental errors, when ε_0 is plotted against $T-T_g$. ε_∞ increases with pressure in correspondence with the increase in density. Consequently, $\varepsilon_0-\varepsilon_\infty$ decreases slightly with pressure. The rather large experimental errors in ε_0 and ε_∞ values may be due to the experimental procedure that the electrode cell was reassembled for each pressure. These errors, however, exert no influence upon the following analysis, in which only the shape of the dispersion curve, the maximum loss, ε''_{max}, and the frequency of the maximum loss, f_{max}, are significant.

Figure 3 shows a master curve obtained by superposition of reduced dielectric loss, $\varepsilon''/\varepsilon''_{max}$, at every temperature and pressure to the reference one at 286.74 K and 600 kg cm^{-2}. The relaxation spectrum of the α relaxa-

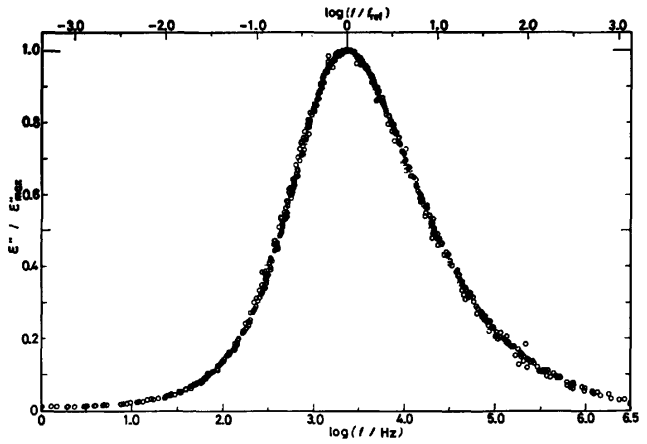

Fig. 3. Master curve of reduced dielectric loss. The reference temperature and pressure are 286.74 K and 600 kg cm^{-2}, respectively.

tion process in TPCM/oTP is typical in shape as Williams *et al.* demonstrated for oTP solutions and many polymers.[25] The value of the half width of the master curve of TPCM/oTP is 1.67 decade in frequency. This value is equal to that of anthrone/oTP solutions[18a] and smaller than those of other oTP solutions[18b] and decalin solutions.[6c]

The susperposition gives the shift factor $a_{T,P}$ at any temperature and pressure:

$$a_{T,P} = \frac{\tau}{\tau(T_r,P_r)}, \tag{4}$$

where τ is the characteristic relaxation time at T and P and $\tau(T_r,P_r)$, that at the reference temperature and pressure. The value of $\tau(T_r,P_r)$ was obtained from f_{max} at 286.74 K and 600 kg cm^{-2} by using

$$\tau(T_r,P_r) = \frac{1}{2\pi f_{max}(T_r,P_r)}, \tag{5}$$

Variations of log $a_{T,P}$ or log τ with reciprocal temperature, *i.e.*, the Arrhenius plots, are shown in Fig. 4.

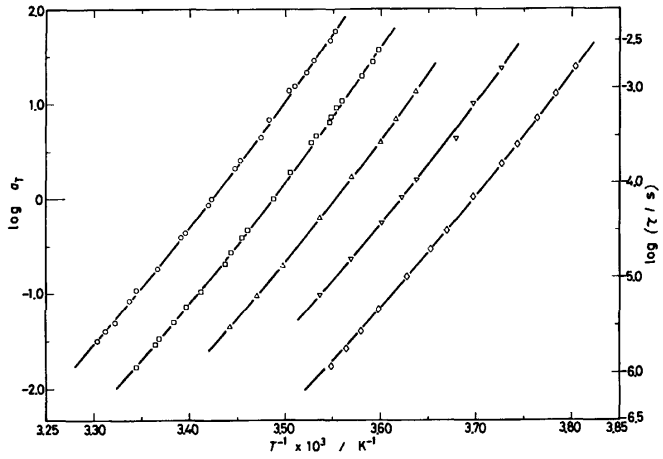

Fig. 4. Arrhenius plots of logarithmic shift factor and characteristic relaxation time. Lines: VFTH equation, Eq. 6.
◇: 1 kg cm^{-2}, ▽: 200 kg cm^{-2}, △: 400 kg cm^{-2}, □: 600 kg cm^{-2}, ○: 800 kg cm^{-2}.

The log τ isobars are well represented by the Vogel-Fulcher-Tammann-Hesse (VFTH) equation:[26]

$$\log \tau = -A + \frac{B}{T-T_0}, \tag{6}$$

which is transformable into the WLF equation for polymer liquids.[27] Values of the VFTH parameters A, B, and T_0 obtained to minimize the standard deviation σ by the least-squares regression are listed in Table 2. Since the experimental frequency range is limited, the temperature range where the dielectric loss reaches maximum is rather narrow. Consequently, long extrapolation of Eq. 6 may lead to a large uncertainty and there is no point in discussing about physical significance of B and T_0. The VFTH equation is utilized only for precise interpolation of τ to every temperature.

The T—P relations at constant τ calculated from Eq. 6 are shown in Fig. 5, in which values of the glass transition temperature T_g obtained by isobaric cooling experiments[28] are also plotted. The slope of the isochronal T—P relation is very similar to that of T_g—P relation shown in the same figure. The isothermal

dependences of τ on pressure are also shown in Fig. 5. Pressure effects on the slope of log τ—P relation are scarcely observed due to the narrowness of the experimental frequency range.

Discussion

Activation Parameters. The activation enthalpy at constant pressure, H^*_P, given by Eq. 1 was obtained by differentiating the VFTH equation, Eq. 6:

$$\frac{\partial \ln \tau}{\partial(1/T)} = \frac{BT^2}{(T-T_0)^2}, \tag{7}$$

Values of H^*_P are plotted as a function of $T-T_g$, in Fig. 6 where the value of T_g was calculated from the least-squares quadratic equation for the pressure dependence of T_g.[28] H^*_P depends on temperature and pressure. The pressure effects on H^*_P cannot be reduced by an exchange of the temperature scale from T to $T-T_g$ only. This situation remains unchanged when $T-T_g$ is replaced by T/T_g. This may be evidence for the fact that the glass transition temperature is not the corresponding point for the molecular mobility in the supercooled liquid.

The activation volume V^* given by

$$V^* = RT\left[\frac{\partial \ln \tau}{\partial P}\right]_T, \tag{8}$$

is shown in Fig. 6. The pressure effects on V^* seem to be almost reduced in the experimental errors when V^* is plotted as a function of $T-T_g$ instead of T. V^* of TPCM/oTP is equal in magnitude to that of chlorinated diphenyl,[16] similar to that of polymer liquids which ranges from 50 to 400 cm^3 mol^{-1},[14a,15] and larger than that of associated liquids.[11]

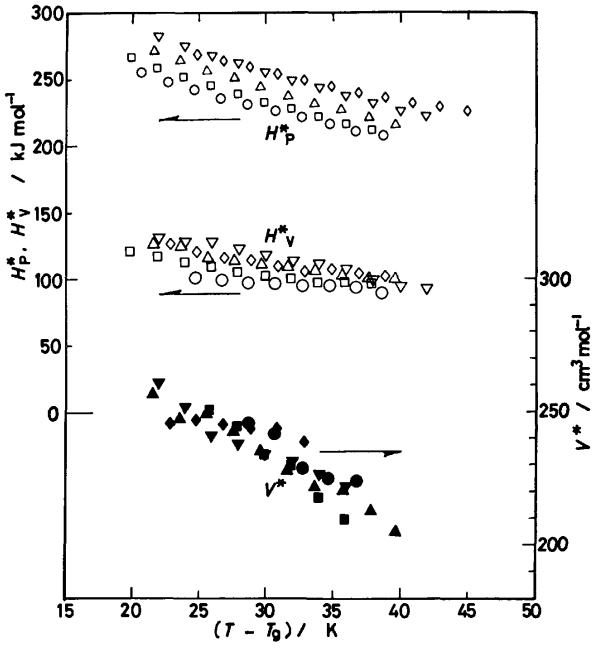

Fig. 6. Activation enthalpies at constant pressure and volume (open symbols) and activation volume (closed symbols) as a function of $T-T_g$.

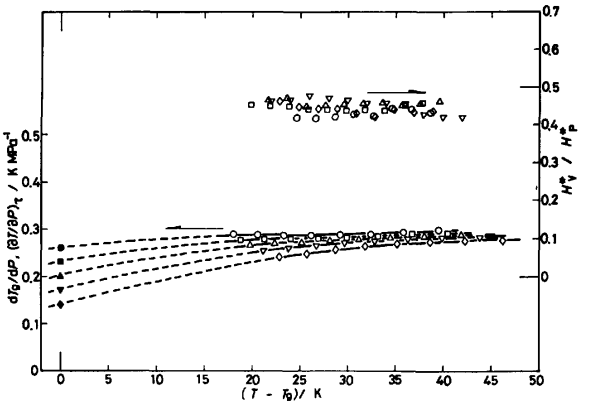

Fig. 7. Variations of H^*_V/H^*_P, $(\partial T/\partial P)_\tau$, and dT_g/dP with $T-T_g$. Symbols are the same as those in Fig. 6.

The activation enthalpy at constant volume, H^*_V, defined by Eq. 3 can be obtained from Eqs. 1 and 8 as

$$H^*_V = H^*_P - T\gamma V^*, \tag{9}$$

where γ is the thermal-pressure coefficient, $(\partial P/\partial T)_V$. From dilatometric measurements, γ of TPCM/oTP is obtained as a function of the specific volume v:[28]

$$\gamma = 11.1587 - 10.3500\,v \quad (\mathrm{K^{-1}\,MPa}). \tag{10}$$

H^*_V, which is often called as the *true* energy of activation,[29] calculated from Eqs. 9 and 10 is plotted as a function of $T-T_g$. The pressure effects on H^*_V seem not to be well-reduced by the $T-T_g$ scale. The second term in Eq. 9 is comparatively large as H^*_V and H^*_V is much smaller than H^*_P.

In Fig. 7, the ratio H^*_V/H^*_P is shown as a function of $T-T_g$. The ratio has a value of about 0.45 and is almost independent of temperature and pressure. This value is equal to those of simple normal liquids near their melting temperatures obtained by viscosity measurements,[17] and is much smaller than those of polymer liquids[30,31] and associated liquids.[17]

Pressure Coefficient of Temperature at Constant Relaxation Time. The tangent of the T—P relation at constant τ, $(\partial T/\partial P)_\tau$, is expressed by

$$\left(\frac{\partial T}{\partial P}\right)_\tau = -\left(\frac{\partial \ln \tau}{\partial P}\right)_T \Big/ \left(\frac{\partial \ln \tau}{\partial T}\right)_P. \tag{11}$$

Values of $(\partial T/\partial P)_\tau$ calculated from this equation are plotted in Fig. 7. Effects of pressure on $(\partial T/\partial P)_\tau$ diminish as the temperature increases. At lower temperature, $(\partial T/\partial P)_\tau$ approaches the pressure coefficient of the glass transition temperature, dT_g/dP, shown in the same figure, *i.e.*,

$$\left(\frac{\partial T}{\partial P}\right)_\tau \simeq \frac{dT_g}{dP}. \tag{12}$$

This supports the argument that the glass transition temperature is an isorelaxation-time state or an isoviscose state.[3-5] The argument has been proposed[32,33] and been supported[34] by the time-temperature-pressure superposition for polymer liquids. It may be stated that, irrespective of molecular weight, the T_g trace in the PVT space is identical with the isorelaxation-time trace.

$(\partial T/\partial P)_\tau$ of TPCM/oTP is equal in magnitude to

TABLE 3. REPRESENTATIVE VALUES OF H^*_V/H^*_P, $(\partial T/\partial P)_\tau$, AND dT_g/dP

Substance	H^*_V/H^*_P	$(\partial T/\partial P)_\tau$ / K MPa^{-1}	dT_g/dP / K MPa^{-1}

Associated liquids			
1-Propanol	0.86[a]	—	0.07[f]
Glycerol	0.95[g], 0.86[a]	0.029[g]	0.04[f]

a) Values near the melting temperature (Ref. 17). b) Ref. 35. c) Ref. 32. d) Ref. 4. e) Ref. 34. f) Ref. 36. g) Ref. 11d.

dT_g/dP of oTP,[35] almost the same as $(\partial T/\partial P)_\tau$ of polymer liquids,[15,30,32,36] much larger than dT_g/dP of associated liquids.[35,36] In terms of V^*, $(\partial T/\partial P)_\tau$ can be expressed as

$$\left(\frac{\partial T}{\partial P}\right)_\tau = T\frac{V^*}{H^*_P}. \tag{13}$$

The small value of associated liquids is due to the smallness of V^*. In the molecular mobilities in such liquids, the arrangements of the free space or the free volume, *i.e.*, the formation of holes, are scarcely of importance, and the rearrangements of the number of the hydrogen bonds only are significant.

It is very interesting to compare the results above on $(\partial T/\partial P)_\tau$ with that on the ratio H^*_V/H^*_P. Representative values of H^*_V/H^*_P, $(\partial T/\partial P)_\tau$, and dT_g/dP are listed in Table 3. With respect to the magnitude of H^*_V/H^*_P, liquids can be classified into two categories: the one (polymer liquids and associated liquids) whose H^*_V/H^*_P is larger than 0.7 and the other (simple normal liquids) whose H^*_V/H^*_P is smaller than 0.5. Whereas, with respect to the magnitudes of $(\partial T/\partial P)_\tau$ and dT_g/dP, the another classification applies: the one (simple normal liquids and polymer liquids) whose $(\partial T/\partial P)_\tau$ or dT_g/dP is larger than 0.15 K MPa^{-1} and the other (associated liquids) whose $(\partial T/\partial P)_\tau$ or dT_g/dP is smaller than 0.10 K MPa^{-1}.

$(\partial T/\partial P)_\tau$ is related to H^*_V/H^*_P through the following equation.

$$\frac{H^*_V}{H^*_P} = 1 - \gamma\left(\frac{\partial T}{\partial P}\right)_\tau \tag{14}$$

If one disregards differences in magnitude of γ, one finds from Eq. 14 that large(small) $(\partial T/\partial P)_\tau$ corresponds to the small(large) H^*_V/H^*_P. This is the case for simple normal liquids and associated liquids.

In polymer liquids, the contribution of the intramolecular conformational entropy is very large to the liquid entropy.[37] From the thermodynamic Maxwell relation

$$\gamma = \left(\frac{\partial P}{\partial T}\right)_V = \left(\frac{\partial S}{\partial V}\right)_T, \tag{15}$$

i.e., the thermal pressure coefficient is related to the dependence of the entropy S on volume. The intramolecular conformational entropy is regarded to be independent of volume.[37] Therefore, the magnitude of γ in polymer liquids is usually smaller than that of simple normal liquids. This is the reason for the large values of H^*_V/H^*_P in polymer liquids.

Conclusion

From the analysis on the isochronic pressure coefficient of temperature, $(\partial T/\partial P)_\tau$, we have found the fact that the glass transition temperature can be regarded as an isorelaxation-time state in the simple normal liquid as well as in polymer liquids. Therefore, the correspondence of the α relaxation process to the glass transition temperature is independent of the length of the molecules, *i.e.*, the molecular weight. The molecular mobility represented by the characteristic relaxation time, however, is significantly influenced by the molecular types such as simple normal liquids, polymer liquids, and associated liquids. The length of the molecules, regardless whether the bonds between molecules are covalent or hydrogen bonds, affects the magnitude of the ratio H^*_V/H^*_P, but not that of $(\partial T/\partial P)_\tau$. On the other hand, the kind of the intermolecular interactions such as the short range one (London potential) and long range one (coulomb potential) affects the magnitude of $(\partial T/\partial P)_\tau$ and dT_g/dP, but not that of H^*_V/H^*_P. These properties of the molecular mobilities obtained by the time-temperature-pressure superpositions of the dielectric α relaxation process are very similar to the properties of the viscosity above the melting temperature.[17] A more detailed investigation of the molecular mobility in the supercooled liquid state will be given in a succeeded paper.

Effect of Pressure on the Adsorption of 1-Octadecanol at Oil/Water Interfaces

Hidemi IYOTA,* Makoto ARATONO, Michio YAMANAKA, Kinsi MOTOMURA, and Ryohei MATUURA
Department of Chemistry, Faculty of Science, Kyushu University 33, Fukuoka 812

(Received February 4, 1983)

In order to investigate the effect of pressure on the adsorption at interfaces, the interfacial tension was measured as a function of pressure and composition for the systems of water and dilute solutions of 1-octadecanol in cyclohexane, benzene, and their equimolar mixture. The interfacial density of 1-octadecanol and the volume of interface formation were evaluated from the experimental data. Under atmospheric pressure, cyclohexane exhibits a significant adsorption of 1-octadecanol and a rapid decrease in the volume of interface formation, giving rise to the phase transition from the expanded to the condensed state in the adsorbed film, while benzene and equimolar mixture display only a small decrease in the thermodynamic quantities on the 1-octadecanol adsorption. Under high pressure, however, all the systems studied cause the phase transition. The effects of pressure and solvent on the phase transition of the adsorbed film were revealed on the basis of the thermodynamic quantities.

The adsorption of long-chain fatty alcohols at interfaces has been studied by many workers.[1-7] However, the pressure effect on the adsorption has hardly been investigated.[8-10] In the previous paper,[10] we clarified that the phase transition of the adsorbed film of 1-octadecanol takes place from an expanded to a condensed state at hexane/water interface and its interfacial tension is altered remarkably by pressure. Further, it was found that the adsorption of 1-octadecanol decreases with an increase in the affinity of oil to water.[7,11]

The object of this paper is to make clear the effect of pressure and solvent on the adsorption of 1-octadecanol, especially on the phase transition of the adsorbed film, at the organic solvent/water interface.

Experimental

Octadecanol was recrystallized five times from hexane after distillation under reduced pressure. Its purity was indicated to be better than 99.5% according to a gas-liquid chromatography test. Cyclohexane and benzene (Nakarai Chemicals Guaranteed Reagent) were refluxed with metallic sodium for 15 h and passed through a column of activated alumina(Woelm neutral activity grade I), and then distilled. Water was triply distilled, the second and third steps being done from dilute alkaline permanganate solution. Purities of organic liquid and water were checked by the equilibrium value of interfacial tension between them. Organic solvent and water were mutually saturated before measurements.

The pendant drop technique described previously[9,12] was used for the determination of interfacial tension. The pendant drops were allowed for about 45 min to attain the thermodynamic equilibrium. Densities of organic liquids, equimolar mixture of them, and water taken from literature[13-15] were used instead of those of mutually saturated oil and water because of so small solubilities. The interfacial tension was measured at 298.15 K with an accuracy of 0.05 mN m^{-1} as functions of pressure up to 150 MPa and mole fraction of 1-octadecanol. Temperature was controlled within 0.05 K at 298.15 K over the whole range of the experiments and pressure was regulated with a precision of 0.25 MPa.

Results and Discussion

The interfacial tension γ of the cyclohexane solution of 1-octadecanol against water was measured as a function of pressure p at a given mole fraction of 1-octadecanol x_1^0 in the cyclohexane solution. The γ *vs.* p curves at various concentrations are drawn in Fig. 1. In the lower concentration region, γ increases linearly with increasing p and the positive slope of γ *vs.* p curve becomes gradually smaller as the concentration increases. In the higher concentration region, on the other hand, the slope has a large negative value. It is noteworthy that a break point is observed on the γ *vs.* p curve at an intermediate concentration. This behavior resembles that of the system of hexane solution and water.[10] Therefore, we may conclude that the phase transition of the adsorbed film occurs from an expanded to a condensed state at the break point. Figure 2 shows the γ *vs.* p curves at various concentrations for the system of benzene solution and water. It is seen from this figure that the phase transition of the adsorbed film of 1-octadecanol at the benzene/water interface takes place

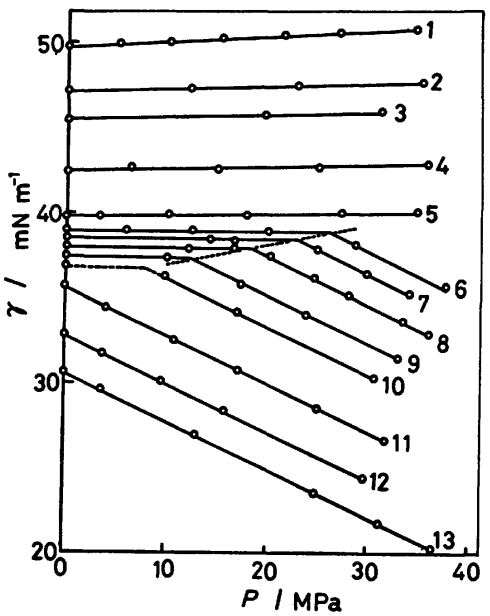

Fig. 1. Interfacial tension *vs.* pressure curves of 1-octadecanol at the cyclohexane/water interface at 298.15 K and constant mole fraction: $10^3 x_1^0 =$ (1) 0; (2) 0.199; (3) 0.404; (4) 0.910; (5) 1.543; (6) 1.881; (7) 2.030; (8) 2.189; (9) 2.499; (10) 2.729; (11) 3.354; (12) 3.965; (13) 4.560.

only at very high pressure and concentration.

Now it is of great interest to investigate the adsorption of 1-octadecanol from the equimolar mixture of cyclohexane and benzene. Given in Fig. 3 is the γ *vs.* p curve at X_b^0=0.503, where X_b^0 is the composition of mixed solvent defined by

$$X_b^0 = x_b^0/(x_c^0 + x_b^0), \quad (1)$$

x_c^0 and x_b^0 being the mole fraction of cyclohexane and benzene, respectively. The behavior of 1-octadecanol in this interface seems to be akin to that in the benzene/water interface rather than in the cyclohexane/water interface, although the γ *vs.* p curve is slightly convex upward at higher concentrations. From Figs. 1 to 3, it is evident that higher pressure makes smaller the concentration of 1-octadecanol at which the phase transition takes place.

The adsorption behavior of 1-octadecanol is compared among the systems of cyclohexane, benzene, and their mixture in Figs. 4a and 4b where the value of interfacial tension taken up from Figs. 1 to 3 is plotted against the concentration at 0.1 and 80 MPa; the γ *vs.* x_1^0 curve at 80 MPa is not drawn for the system of cyclohexane because the cyclohexane solution freezes above about

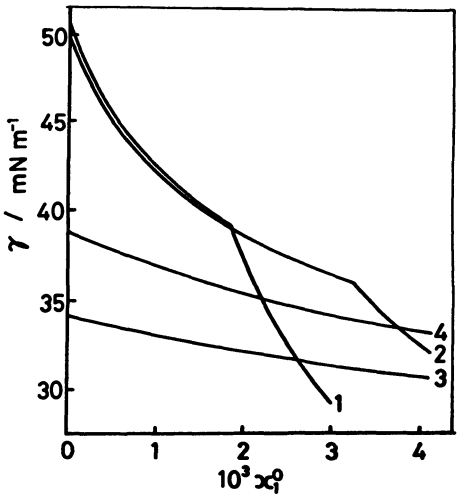

Fig. 4a. Interfaciale tension *vs.* mole fraction curves of 1-octadecanol at 298.15 K and 0.1 MPa: (1) hexane; (2) cyclohexane; (3) benzene; (4) X_b^0=0.503.

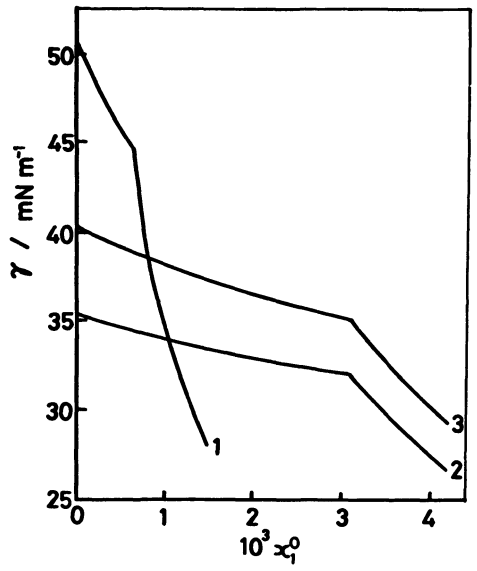

Fig. 4b. Interfacial tension *vs.* mole fraction curves of 1-octadecanol at 298.15 K and 80 MPa: (1) hexane; (2) benzene; (3) X_b^0=0.503.

40 MPa. The results for the hexane system[10] are also shown for comparison. It may be supposed from Fig. 4a that the 1-octadecanol molecule is adsorbed remarkably at the cyclohexane/water interface as at the hexane/water interface whereas it is not done so much at the benzene/water interface, and its adsorption from the mixed solvent is intermediate between the adsorptions from the pure solvents. At 80 MPa, on the other hand, the γ *vs.* x_1^0 curves are characterized by the break point.

It is now appropriate to estimate the interfacial density of 1-octadecanol Γ_1^H and the volume of interface formation Δv defined on the basis of the Hansen convention. Since the system under consideration satisfies the conditions that the two phases are actually immiscible and that the surfactant is soluble only in one of the phases, we have the following equations:[16,17]

$$\Gamma_1^H = -(x_1^0/RT)(\partial\gamma/\partial x_1^0)_{T,p} \quad (2)$$

and

$$\Delta v = (\partial\gamma/\partial p)_{T,x_1^0}, \quad (3)$$

where the ideality of the alcohol solution is assumed.

For the system in which the solvent of the oil phase is a mixture, Eqs. 2 and 3 are replaced by the equations[18]

$$\Gamma_1^H = -(x_1^0/RT)(\partial\gamma/\partial x_1^0)_{T,p,X_b^0}, \quad (4)$$

and

$$\Delta v = (\partial\gamma/\partial p)_{T,x_1^0,X_b^0}, \quad (5)$$

where the two dividing planes are chosen so as to satisfy the relations

$$\Gamma_w^H = 0, \quad (6)$$

and

$$\Gamma_b^H + \Gamma_c^H = 0. \quad (7)$$

The value of Γ_b^H is estimated by

$$\Gamma_b^H = -X_b^0 X_c^0 (\partial\gamma/\partial X_b^0)_{T,p,x_1^0} / RT[1+(\partial \ln f_b^0/\partial \ln X_b^0)_{T,p,x_1^0}], \quad (8)$$

where f_b^0 is the activity coefficient of solvent b in the oil phase.

Applying Eqs. 2 and 4 to the γ *vs.* x_1^0 curves in Figs. 4a and 4b, the value of Γ_1^H was evaluated at 0.1 and 80 MPa as a function of x_1^0. The results are illustrated in Figs. 5a and 5b, respectively. It is seen at 0.1 MPa that the Γ_1^H value of the cyclohexane system, like that of the hexane system changes discontinuously at the point of phase transition from a relatively small value of the expanded film to a very large one of the condensed film. For the benzene system, the adsorbed film remains in an expanded state of which the Γ_1^H value is significantly small. The value of the $X_b^0=0.503$ system seems to be close to that of the benzene system. On the other hand, it is found at 80 MPa that the phase transition takes place for the benzene and $X_b^0=0.503$ systems and the Γ_1^H values of condensed films are about the same irrespective of the solvent. Therefore, it may be said that the affinity of benzene molecules to water molecules affects the adsorption of 1-octadecanol in the expanded state but not in the condensed state. This can be ascribed to the intermolecular interaction between octadecanol molecules in the condensed film which is strong enough to disregard a difference in that between octadecanol and organic solvent and between organic solvent and water.

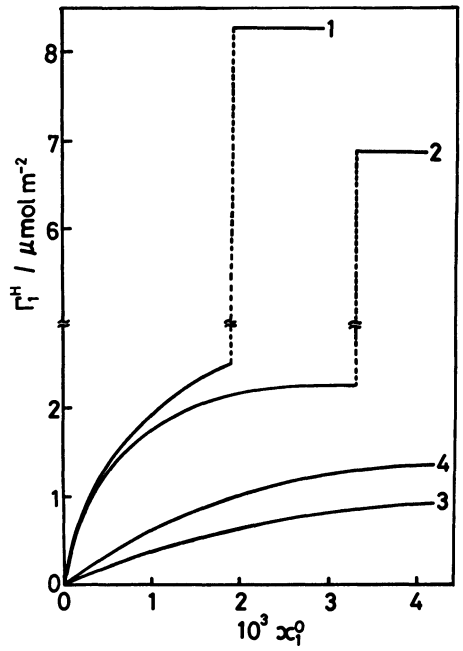

Fig. 5a. Interfacial density *vs.* mole fraction curves of 1-octadecanol at 298.15 K and 0.1 MPa: (1) hexane; (2) cyclohexane; (3) benzene; (4) $X_b^0=0.503$.

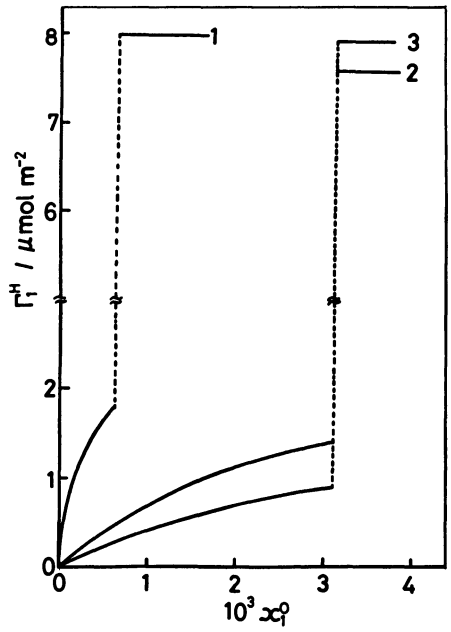

Fig. 5b. Interfacial density *vs.* mole fraction curves of 1-octadecanol at 298.15 K and 80 MPa: (1) hexane; (2) benzene; (3) $X_b^0=0.503$.

The application of Eqs. 3 and 5 to the γ *vs.* p curves in Figs. 1 to 3 enables us to calculate the value of Δv. The variation in Δv with x_1^0 at 0.1 and 80 MPa is shown in Figs. 6a and 6b. Under atmospheric pressure the Δv value for the cyclohexane system decreases rapidly with an increase in x_1^0 from the positive value of the pure

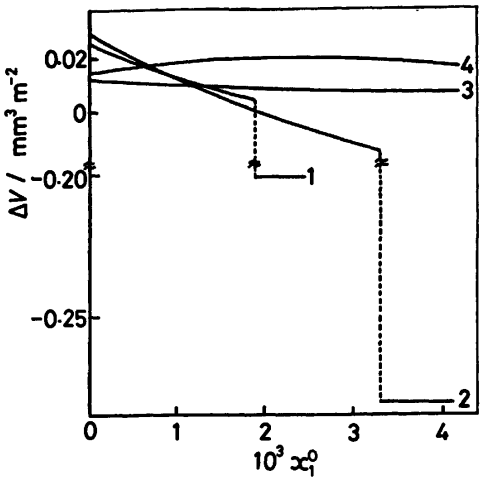

Fig. 6a. Volume change *vs.* mole fraction curves of 1-octadecanol at 298.15 K and 0.1 MPa: (1) hexane; (2) cyclohexane; (3) benzene; (4) $X_b^0=0.503$.

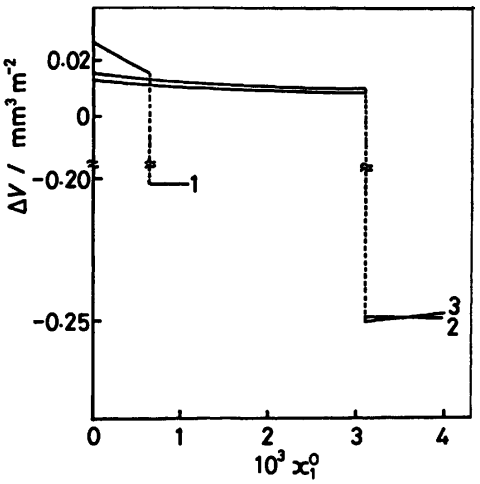

Fig. 6b. Volume change *vs.* mole fraction curves of 1-octadecanol at 298.15 K and 80 MPa: (1) hexane; (2) benzene; (3) $X_b^0=0.503$.

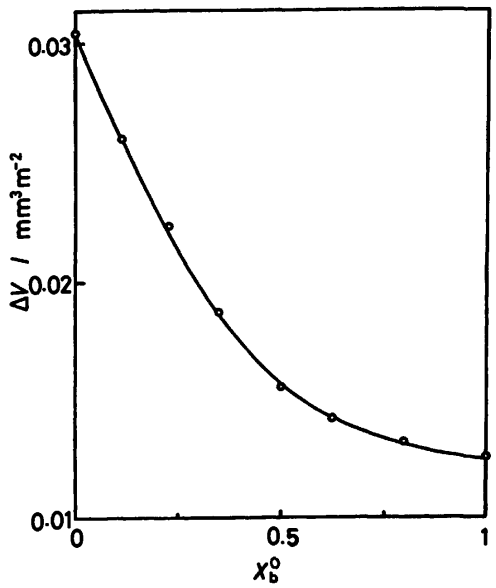

Fig. 7. Volume change *vs.* composition curve for $x_1^0=0$ at 298.15 K and 0.1 MPa.

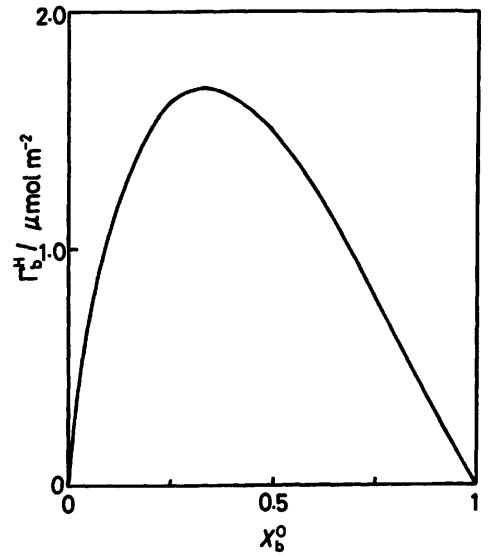

Fig. 8. Interfacial density *vs.* composition curve for $x_1^0=0$ at 298.15 K and 0.1 MPa.

interface to a large negative value of the condensed film, while the Δv values for benzene and $X_b^0=0.503$ systems vary slightly. At 80 MPa, the Δv *vs.* x_1^0 curves of the benzene and $X_b^0=0.503$ systems are quite similar in shape. It is observed that Δv has a large negative value for all the condensed films. This can be accounted for by a negative value of the partial molar volume change associated with the transfer of octadecanol molecules from the solution to the interface.[9,10] The similarity between the adsorption of 1-octadecanol from the mixture and that from benzene is presumed to be accounted for by a large concentration of benzene in the interfacial region. In Figs. 7 and 8, the values of Δv and Γ_b^H evaluated for $x_1^0=0$ are plotted against X_b^0 at 298.15 K and 0.1 MPa.[19] It is seen from Fig. 7 that the Δv *vs.* X_b^0 curve deviates greatly from the straight line connecting the values of the pure cyclohexane and benzene systems and the value of Δv at $X_b^0=0.503$ is not so different from that at $X_b^0=1$. Further, Fig. 8 shows that the value of Γ_b^H is remarkably large at the maximum. These results support the above presumption.

In order to visualize the effect of pressure on the adsorbed film of 1-octadecanol at the oil/water interfaces, let us draw its surface pressure *vs.* area curves. Since the interfacial pressure and the area per 1-octadecanol molecule are defined, respectively, by

$$\pi = \gamma^0 - \gamma, \tag{9}$$

and

$$A = 1/N_A\Gamma_1^H, \tag{10}$$

where γ^0 is the interfacial tension of pure interface and N_A is Avogadro number, the curves are obtained by making use of Figs. 4 and 5. The results are depicted in Figs. 9a and 9b. It is seen that the pressure makes the adsorbed film of 1-octadecanol condensed while the affinity of oil to water does it expanded. It should be

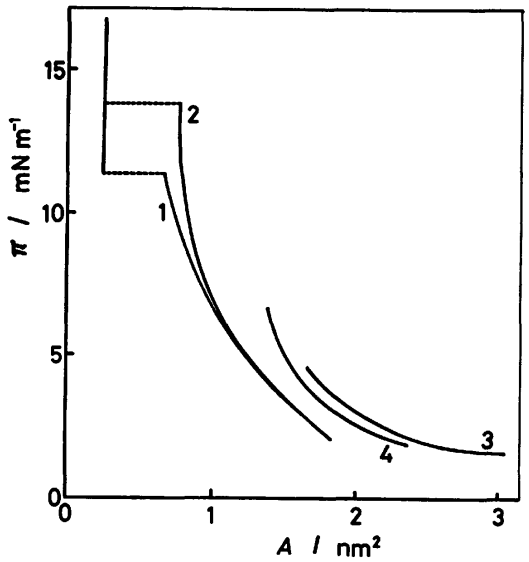

Fig. 9a. Interfacial pressure *vs.* area curves of 1-octadecanol at 298.15 K and 0.1 MPa: (1) hexane; (2) cyclohexane; (3) benzene; (4) $X_b^g=0.503$.

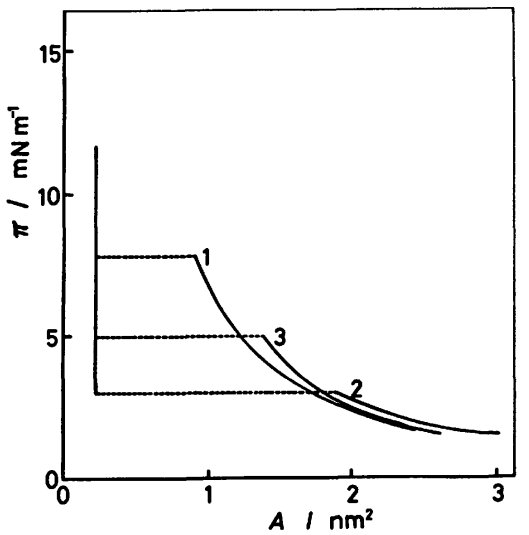

Fig. 9b. Interfacial pressure *vs.* area curves of 1-octadecanol at 298.15 K and 80 MPa: (1) hexane; (2) benzene; (3) $X_b^g=0.503$.

noted that the adsorption behavior of 1-octadecanol at the oil mixture/water interface is affected similarly by pressure.

In conclusion, we can say that the pressure has a significant effect on the phase transition of the adsorbed film to transform the expanded state produced by the affinity of benzene molecules to water molecules into the condensed one.

Acid-Base and Catalytic Properties of ZrO_2–SnO_2

Gong-Wei WANG, Hideshi HATTORI, and Kozo TANABE*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received February 18, 1983)

The acid-base properties of ZrO_2–SnO_2 with different compositions have been measured by the indicator method and the adsorption with NH_3 and CO_2 and the catalytic activities studied. The ZrO_2–SnO_2 (atomic ratio=9 : 1) catalyst which was found to have the highest acid strength and the maximum acid amount exhibited the highest activities for the isomerization of cyclopropane and the dehydration of 2-butanol. The activities of the catalysts with different compositions for the two reactions correlated with the acidic properties. On the other hand, the activities for the isomerization of 1-butene and the decomposition of diacetone alcohol (4-hydroxyl-4-methyl-2-pentanone) correlated with the basic properties. The activity for the dehydrogenation of 2-butanol was found to increase with an increase of the SnO_2 content. The active sites on the ZrO_2–SnO_2 catalysts are discussed.

Recently, many kinds of mixed oxides were reported to show acidic property on the surfaces.[1] Among them, the binary oxides consisting of the oxides of the fourth group metals in the periodic table are interesting from the view-point of the acid-base property. Namely, the acid strengths of SiO_2–TiO_2[2] and SiO_2–ZrO_2[3] are very strong and that of TiO_2–SnO_2[4] is moderate, while TiO_2–ZrO_2 has not only strong acidic property,[5] but also distinct basic property.[6] These catalysts showed interesting activities for particular reactions, respectively. However, no study has been made on the acid-base and catalytic property of ZrO_2–SnO_2, another type of the binary oxides consisting of the fourth group metal oxides. Therefore, various kinds of ZrO_2–SnO_2 with different compositions calcined at different temperatures have been prepared and the acid-base property has been characterized in the present work. The catalytic activity and selectivity for the isomerizations of cyclopropane and 1-butene, and the decompositions of 2-butanol and diacetone alcohol are also studied.

Experimental

Catalysts and Reagents. Zirconium(IV) hydroxide and tin(IV) hydroxide were prepared by adding 28% aqueous ammonia to aqueous solutions of zirconium(IV) dichloride oxide ($ZrOCl_2 \cdot 8H_2O$) and anhydrous tin(IV) chloride ($SnCl_4$), respectively. The precipitates were aged at 100 °C over a water bath for 1 h, washed with deionized water until no chloride ions were detected with a silver nitrate test solution and dried at 100 °C for 24 h. The mixtures of zirconium(IV) and tin(IV) hydroxides with different atomic ratios of Zr to Sn were prepared by coprecipitation of mixed solutions of $ZrOCl_2 \cdot 8H_2O$ and $SnCl_4$ with 28% aqueous ammonia, followed by aging, washing and drying similarly as in the cases of zirconium and tin hydroxides. Zirconium oxide, tin oxide and the binary oxides with different atomic ratios of Zr to Sn were obtained by calcining the respective hydroxides at various temperatures in air for 2 h.

1-Butene and cyclopropane were purified by passage through 4A Molecular Sieves kept at Dry Ice temperature and distilled before use. 2-Butanol and diacetone alcohol were obtained from Wako Pure Chemical Industries Ltd., the latter being purified by vacuum distillation.

Measurement of Physico-chemical Properties. Specific surface areas of the samples calcined in air at various temperatures were obtained by applying the BET equation to the adsorption isotherm of nitrogen at −196 °C. Differential thermal analysis (DTA) and thermal gravimetry (TG) were carried out simultaneously with a heating rate of 10 °C/min. X-Ray diffraction patterns were measured over the range of $2\theta=20$—60 ° for the powdered samples which had been calcined in air at 500 °C for 2 h.

Acidic and basic properties of the samples calcined in the air at 500 °C for 3 h were measured by titrating with butylamine and benzoic acid in benzene, respectively, the indicators of different pK_a values being used.[7] Adsorbed amounts of CO_2 and NH_3 were measured by use of Cahn 200 electrobalance. The sample was outgassed at 500 °C for 2 h. After cooling to room temperature, it was exposed to about 10 Torr (1 Torr≈133.322 Pa) of CO_2 or NH_3 for 30 min, followed by outgassing at room temperature for 20 min.

Reaction Procedure. The isomerizations of 1-butene and cyclopropane were carried out in a closed recirculation reactor having a volume of about 789 ml. Prior to reaction, catalysts were outgassed at 500 °C for 2 h. A 100 Torr of 1-butene or cyclopropane was allowed to react at 100 °C for 1-butene or 300 °C for cyclopropane. The catalyst weights were 200 mg for the isomerization of 1-butene and 400 mg for the isomerization of cyclopropane. The reaction mixture was periodically withdrawn and analyzed by gas chromatography; VZ-7 was used for a 6 m chromatographic column of 4 mm o.d. copper tubing. For the dehydration of 2-butanol, a microcatalytic pulse reactor was employed. One μl of 2-butanol was passed over a 100 mg catalyst at 200 °C in a helium carrier whose flow rate was 20 ml/min. Products were first trapped in a liquid nitrogen trap and flash evaporated into a first gas chromatographic column in which PEG 20M was packed. Olefins which flowed out of the first column were trapped again and flash evaporated into a second gas chromatographic column in which VZ-7 was packed.

The decomposition of diacetone alcohol was carried out at 30±0.5 °C in a reactor of liquid phase suspension. Thirty ml of diacetone alcohol was allowed to react over a powdered catalyst calcined at various temperatures. The sample was taken out from the reactor at 10 min interval and analyzed by gas chromatography.

Activities for all reactions were expressed as initial mole conversion to the product per unit time per unit surface area or unit weight of catalyst.

Results and Discussion

Surface areas of ZrO_2, SnO_2, and the binary oxides with different compositions calcined in the air at different temperatures are given in Table 1. For all samples, the surface areas decreased monotonously with a rise

TABLE 1. SPECIFIC SURFACE AREAS /$m^2\ g^{-1}$

Catalyst composition	Pretreatment temperature/°C				
	500	650	750	850	1000
ZrO_2	47.8	22.8	16.7	6.35	3.06
ZrO_2–SnO_2 (9 : 1)	80.3	37.4	26.6	16.9	8.73
ZrO_2–SnO_2 (7 : 3)	72.6	—	—	—	—
ZrO_2–SnO_2 (1 : 1)	52.2	31.4	27.6	21.4	9.11
ZrO_2–SnO_2 (3 : 7)	59.9	—	—	—	—
ZrO_2–SnO_2 (1 : 9)	57.6	35.8	28.8	27.4	9.94
SnO_2	37.6	—	14.5	8.68	4.85

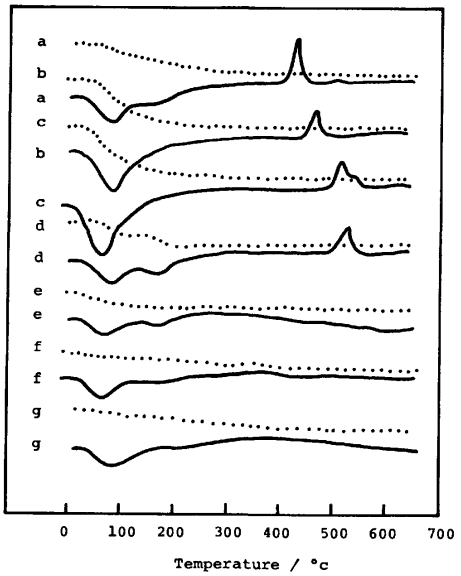

Fig. 1. DTA (——) and TG (·····) diagrams of ZrO_2, SnO_2, and the binary oxides.
a: ZrO_2, b: ZrO_2–SnO_2 (9 : 1), c: ZrO_2–SnO_2 (7 : 3), d: ZrO_2–SnO_2 (1 : 1), e: ZrO_2–SnO_2 (3 : 7), f: ZrO_2–SnO_2 (1 : 9), g: SnO_2.

of the calcination temperature. The binary oxides had larger surface areas than the single component oxides when compared at the same calcination temperature. The DTA and TG curves are shown in Fig. 1. The exothermic peak for ZrO_2 was observed at about 424 °C. The exothermic peaks for the ZrO_2–SnO_2 samples with atomic ratios (Zr/Sn) of 9 : 1, 7 : 3, and 1 : 1 shifted to 459, 508, and 516 °C, respectively. However, no exothermic peaks were observed for SnO_2 and ZrO_2–SnO_2 containing more than 50% of SnO_2. X-Ray diffraction patterns of ZrO_2–SnO_2 (9 : 1) and (7 : 3) were similar to those of monoclinic ZrO_2, while those of ZrO_2–SnO_2 (3 : 7) and (1 : 9) were similar to those of tetragonal SnO_2, though the peaks for the binary oxides were broad as compared with the single component oxides. However, ZrO_2–SnO_2 (1 : 1) showed a distinct but unidentified X-ray peak at $2\theta=29.6°$ in addition to the patterns for ZrO_2 and SnO_2. The acidity and basicity distributions of the catalysts calcined at 500 °C are summarized in Table 2. The acid sites on ZrO_2 and SnO_2 are weak; $H_0=+4.0$ and $+4.8$, respectively. Among the binary oxides, ZrO_2–SnO_2 (9 : 1) showed the highest acid strength whose H_0 value was -3. The other binary oxides were weakly acidic. The strengths were in the range of $H_0=+3.3$—$+4.0$. The amount of basic sites equal to or stronger than $H_-=9.1$ decreased with an increase in SnO_2 content. In the case of ZrO_2–SnO_2 (9 : 1), the amount of basic sites is almost comparable with the amount of acid sites having $H_0 \leqq +6.8$.

The amounts of NH_3 and CO_2 adsorbed on the catalysts outgassed at 500 °C for 2 h are shown in Fig. 2. The adsorbed amount of NH_3 was maximum on ZrO_2–SnO_2 (9 : 1) which showed the highest acid strength. The amount of CO_2 adsorbed decreased with an

increase in SnO_2 content except ZrO_2–SnO_2 (9 : 1). The basic sites on all samples were as weak as $H_- = -9.1$.

The activities of the catalysts calcined at 500 °C for the isomerization of cyclopropane are plotted against the catalyst composition in Fig. 3. The activity change roughly correlates with the change of the acid amount measured by NH_3 adsorption shown in Fig. 2. The highest activity was observed over the ZrO_2–SnO_2 (9 : 1) catalyst which showed the maximum acid amount and the highest acid strength (*cf.* Table 2).

Table 3. Distribution of products in isomerization of 1-butene in 60 min

Catalyst composition	Products distribution/%			*cis*-/*trans*-
	cis-2-Butene	*trans*-2-Butene	1-Butene	
ZrO_2	56.2	31.6	12.2	1.78
ZrO_2–SnO_2 (9 : 1)	0	0	100	—
ZrO_2–SnO_2 (7 : 3)	43.0	14.0	43.0	3.05
ZrO_2–SnO_2 (1 ; 1)	5.74	1.25	93.0	4.59
ZrO_2–SnO_2 (3 : 7)	0.52	0	99.5	
ZrO_2–SnO_2 (1 : 9)	0.93	0	99.1	
SnO_2	1.37	0	98.6	

The variations in the activities for the isomerization of 1-butene as a function of SnO_2 content are shown in Fig. 4 for the catalysts calcined at different temperatures. For all catalysts, the activities increased with an increase in the calcination temperature and reached maxima when calcined at 850 °C. Further increase in the calcination temperature to 1000 °C resulted in a decrease in the activities. It is interesting to note that the ZrO_2–SnO_2 (9 : 1) catalyst showed no activity in spite of its acid sites being stronger than those of the other catalysts. The products distributions in the isomerization of 1-butene are summarized in Table 3. With all catalysts, *cis*-2-butene was predominantly formed. The predominant formation of *cis*-2-butene is generally observed in the base-catalyzed isomerization of 1-butene[8–11] in contrast with the formation of about equal amounts of *cis*-2-butene and *trans*-2-butene in the acid-catalyzed reaction.[8,12] Therefore, the isomerization is suggested to proceed by a carbanion mechanism over the all catalysts. Hence, no activity of the ZrO_2–SnO_2 (9 : 1) catalyst seems to be partly due to the small amount of basic sites as seen in Fig. 2, and partly due to the basic strength being weakened by the electron shift to the neighboring strong acid sites.

The results of the decomposition of 2-butanol are summarized in Table 4. As the content of SnO_2 increased, the dehydration to 1-butene decreased, whereas the dehydrogenation to ethyl methyl ketone increased. The highest activity for the formation of butenes was

Table 4. Catalytic activity and distribution of products in decomposition of 2-butanol

$1\text{-}C_4'$: 1-Butene: $2\text{-}C_4'$: 2-butenes.

observed over ZrO_2–SnO_2 (9 : 1) which possessed the highest acidity. The dehydration activity correlates with the catalyst acidity. The butenes produced over ZrO_2, ZrO_2–SnO_2 (7 : 3) and (1 : 1) consisted exclusively of 1-butene. In the case of the ZrO_2–SnO_2 (9 : 1) catalyst, however, the formation of 2-butenes exceeded that of 1-butene. This was generally observed in the dehydrations catalyzed by strong acids.[13] It is suggested that the relatively strong acid sites which are generated on the surface of ZrO_2–SnO_2 (9 : 1) (*cf.* Table 2) are the active sites for the dehydration.

The decrease of the dehydrogenation activity with the increase of ZrO_2 content might be attributed to the decrease in the reducing property of SnO_2 on mixing of ZrO_2, since the reducing property of SnO_2 is reported to decrease on mixing of the other oxide, TiO_2.[4]

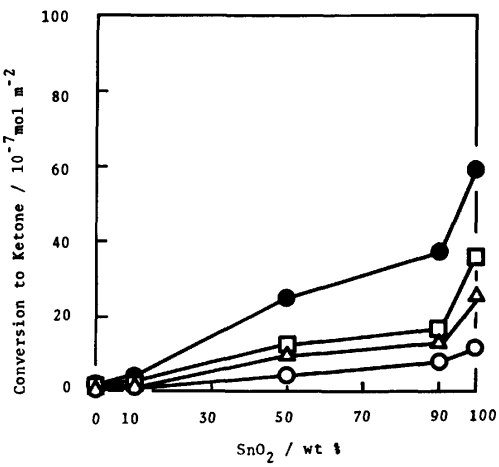

Fig. 5. Change of conversion to ketone from 2-butanol with change of pretreatment temperature of catalysts.
○: 500 °C, △: 750 °C, □: 850 °C, ●: 1000°C.

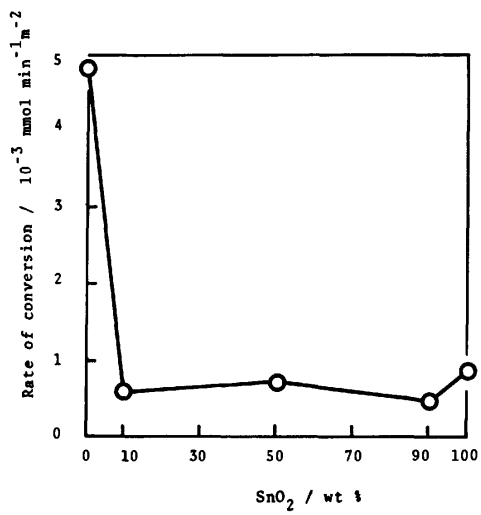

Fig. 6. Change in catalytic activity for decomposition of diacetone alcohol with catalyst compositions.

The conversion of 2-butanol to ethyl methyl ketone in the decomposition of 2-butanol over the catalysts calcined at different temperatures are plotted against the catalyst composition in Fig. 5. The formation of ethyl methyl ketone increased with a rise of the calcination temperature for all catalysts.

The activities for the decomposition of diacetone alcohol are shown in Fig. 6. The activities decreased as the content of SnO_2 increased. The activity change is roughly similar to the basicity change in Fig. 2. The little ambiguity is probably due to the difference in basic strength, though it could not be differentiated by the indicator method. Thus, the decomposition of diacetone alcohol is concluded to be controlled by both the amount and strength of the basic sites on the catalyst.

In summary, the ZrO_2–SnO_2 (9 : 1) catalyst can be classified as a solid acid catalyst having a moderate acid strength ($H_0 \leqq -3$). The acid strength is lower than that of SiO_2–TiO_2, SiO_2–ZrO_2, or TiO_2–ZrO_2 and almost equal to that of TiO_2–SnO_2. The difference in acid-base property of ZrO_2–SnO_2 from TiO_2–SnO_2 is that the ZrO_2–SnO_2 catalysts with different compositions have a definite basic property and only the ZrO_2–SnO_2 (9 : 1) showed the acid strength of $H_0 \leqq -3$. These acid-base properties reflected on the catalytic behavior.

(Received March 9, 1983)

Crystals of *t*-BuMgCl–(−)-sparteine (**1**) belongs to orthorhombic system; $P2_12_12_1$, $a=25.689(6)$, $b=10.030(2)$, $c=7.942(2)$ Å, and $Z=4$; $MgCl_2$–(−)-sparteine (**2**) also crystallizes in orthorhombic system; $P2_12_12_1$, $a=11.180(4)$, $b=11.957(4)$, $c=12.573(5)$ Å, and $Z=4$. Both structures were solved by the heavy atom method, and refined by the block-diagonal least-squares procedure; (**1**) $R=0.098$ for 1199 non-zero reflections and (**2**) $R=0.091$ for 1347 observed reflections. The Mg atom in each complex has a distorted tetrahedral geometry: (**1**) Mg–N= 2.17(2) and 2.18(2), Mg–C=2.19(2), and Mg–Cl=2.332(7) Å and N–Mg–N=83.9(5)°; (**2**) Mg–N=2.150(9) and 2.160(9), and Mg–Cl=2.269(5) and 2.279(6) Å, and N–Mg–N=85.0(4)°.

The kinetics[1] and the structure and reactivity of a series of Grignard reagent–(−)-sparteine (or its derivative) complexes in the asymmetric selective polymerization of α-methylbenzyl methacrylate have been studied. The molecular structure of EtMgBr–(−)-sparteine,[2] which chooses the (*S*)-monomer out of the racemic mixture of α-methylbenzyl methacrylate (or other methacrylates) and initiates the asymmetric selective polymerization, has been determined by means of X-ray diffraction. Molecular structures of the inactive EtMgBr–(−)-α-isosparteine[3] and *t*-BuMgCl–(−)-sparteine also have been determined. This paper deals with the crystal structure determination of inactive *t*-BuMgCl–(−)-sparteine (**1**) and of related complex $MgCl_2$–(−)-sparteine (**2**).

Experimental

Many trials to prepare the complex between *t*-BuMgBr and (−)-sparteine have been unsuccessful. The *t*-BuMgCl–(−)-sparteine was then prepared by mixing a toluene solution of (−)-sparteine and an ether solution of *t*-BuMgCl under nitrogen atmosphere. Crystals obtained were recrystallized from toluene, which were used for X-ray study. All of the crystals examined did not give any sharp diffraction profiles. The other crystals, obtained from the mother liquor at room temperature, were also recrystallized from toluene, which were first considered as *t*-BuMgCl–(−)-sparteine and were later found as $MgCl_2$–(−)-sparteine. *t*-BuMgCl–(−)-sparteine was then prepared again and recrystallized from toluene. The crystals were found useful for X-ray diffraction data collection.

As both crystals were sensitive to moisture in the air, they were sealed in thin-walled glass capillary tubes, which were mounted on a Rigaku automated, four-circle diffractometer. Graphite monochromatized Mo *Kα* radiation ($\lambda=0.71069$ Å) was used. Unit-cell dimensions were determined by the least-squares fit using 2θ values of 25 strong reflections. A prismatic crystal of *t*-BuMgCl–(−)-sparteine with approximate dimensions of $0.4\times0.20\times0.18$ mm³ was used for the X-ray experiment. The $MgCl_2$–(−)-sparteine crystal used had dimensions of $0.20\times0.18\times0.50$ mm³.

Crystal Data. *t*-BuMgCl–(−)-sparteine (**1**): $C_{19}H_{35}N_2$-MgCl, M 351.3, orthorhombic, space group $P2_12_12_1$, $a=25.689(6)$, $b=10.030(2)$, $c=7.942(2)$ Å, $V=2046.3(7)$ Å³, $D_c=1.140$ g cm⁻³ for $Z=4$, μ(Mo *Kα*)=2.22 cm⁻¹. $MgCl_2$–(−)-sparteine (**2**): $C_{15}H_{26}N_2MgCl$, M 329.6, orthorhombic, space group $P2_12_12_1$, $a=11.180(4)$, $b=11.957(4)$, $c=12.573(5)$ Å, $V=1680.7(10)$ Å³, $D_c=1.303$ g cm⁻³ for $Z=4$, μ(Mo *Kα*)= 4.18 cm⁻¹.

Integrated intensities for both crystals were measured by the θ-2θ scan technique (**1**) $2\theta\leqq46.0°$; (**2**) $2\theta\leqq50.5°$: the 2θ scan rate was 4° min⁻¹ and the scan width $\Delta2\theta=(2.4+0.7\ \tan\theta)°$. The background scattering was counted for 7.5 s at both ends of a scan. Four standard reflections measured after every 60 reflections were used in order to check the crystal orientation and X-ray damage. They showed less than 5% fluctuation throughout the data collection of *t*-BuMgCl–(−)-sparteine. For $MgCl_2$–(−)-sparteine, the intensities of the four standard reflections decreased; as they did so uniformly with time, the observed intensities were corrected linearly. Usual corrections for Lorentz and polarization effects were applied but those for absorption and extinction corrections were ignored. Totals of 1678 (1199 non-zero) and 1763 (1451 non-zero) reflections were collected for *t*-BuMgCl–(−)-sparteine and $MgCl_2$–(−)-sparteine, respectively.

Structure Solution and Refinement

Both structures were solved by the heavy atom method, and refined anisotropically for non-hydrogen atoms by the block-diagonal least-squares procedure (*HBLS* V).[4] The function minimized was $\sum w(\Delta F)^2$. The H atoms were located and fixed at the calculated positions with equal isotropic thermal parameters ($B=3.3$ Å²). At the final stage of the refinement the anomalous dispersion of all the non-hydrogen atoms were considered.

t-BuMgCl–(−)-sparteine. (1) Initial positional parameters of the Cl and Mg atoms were determined by a three-dimensional Patterson function with the aid of the direct method (*MULTAN* 78).[5] The N and C atoms were located on a subsequent Fourier map. The structure was then refined. The final R factor was 0.098 for non-zero (0.206 for all) reflections and R_w was 0.124. The weighting schemes used at the final stage were

† Abbreviated as *t*-BuMgCl–(−)-sparteine.
†† Abbreviated as $MgCl_2$–(−)-sparteine.

a) After Hamilton.[6)]

$w=\{\sigma_{cs}^2(F_o)+0.03251|F_o|+0.00231|F_o|^2\}^{-1}$ for $|F_o|>0$ and $w=0.02855$ for $|F_o|=0$.

The final atomic positional and equivalent thermal parameters[6)] are listed in Table 1.††††

$MgCl_2$-(−)-sparteine (**2**). The crystals were expected to contain *t*-BuMgCl-(−)-sparteine, but the three-dimensional Patterson function could not be interpreted satisfactorily. The *E*-map calculated by using the *MULTAN* 78 program showed a good coincidence with the interpretation of the Patterson map for $MgCl_2$-(−)-sparteine instead of *t*-BuMgCl-(−)-sparteine. The Fourier synthesis based on the phases of the Mg and two Cl atoms revealed the remaining N and C atoms of the $MgCl_2$-(−)-sparteine. The anisotropic refinement gave the final *R* as 0.091 for 1347 observed ($|F_o|\leqq 3\sigma(F_o)$) reflections ($R_w=0.104$). At the final stage the weighting scheme used was $w=\{\sigma^2(F_o)+0.10124|F_o|\}^{-1}$. The final atomic positional and equivalent thermal parameters are listed in Table 2.††††

Atomic scattering factors[7)] and anomalous dispersion coefficient[8)] used in the refinement were taken from the International Tables for X-Ray Crystallography. All the computations were done on an ACOS 700S computer at the Crystallographic Research Center, Institute for Protein Research, Osaka University.

†††† Tables of observed and calculated structure factors and anisotropic thermal parameters and calculated hydrogen positions of *t*-BuMgCl-(−)-sparteine and $MgCl_2$-(−)-sparteine are kept at the Chemical Society of Japan, Document No. 8335.

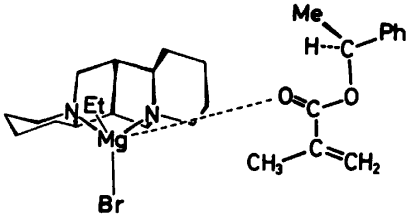
a) After Hamilton.[6)]

Results and Discussion

Molecular Structure. Perspective views (*ORTEP* II)[9)] of *t*-BuMgCl-(−)-sparteine and $MgCl_2$-(−)-sparteine molecules with the numbering scheme of atoms are drawn in Figs. 1 and 2, respectively. Bond lengths and bond angles in the two complexes are given in Figs. 3 and 4, respectively.

t-*BuMgCl-(−)-sparteine* (**1**). The coordination geometry around the Mg atom is distorted tetrahedral: two N atoms of the sparteine skeleton, the C atom of the *t*-Bu group and the Cl bond to the Mg atom. Two Mg–N bond lengths are equal [2.171(12) and 2.175(12) Å] and the N(1)–Mg–N(2) angle is 83.9(5)°. The Mg–C(1) bond length of 2.19(2) Å is comparable with that in EtMgBr-(−)-sparteine [2.24(3) Å].[3)] The Mg–Cl bond length is 2.332(7) Å. The Cl–Mg–N(2) angle [117.4(4)°] is much larger than the Cl–Mg–N(1) angle [100.8(4)°]. The (−)-sparteine skeleton has a similar structure to that in EtMgBr-(−)-sparteine (an all-chair conformation). The remarkable feature of the structure is that the geometrical relation of the alkyl and halogen ligands to the (−)-sparteine skeleton in the present complex is reverse to that in EtMgBr-(−)-sparteine. The initial stage of the asymmetric selective polymerization of racemic methacrylate is considered to be coordination of the carbonyl oxygen of a substrate to the Mg atom of a Grignard reagent-(−)-sparteine complex.[1)]



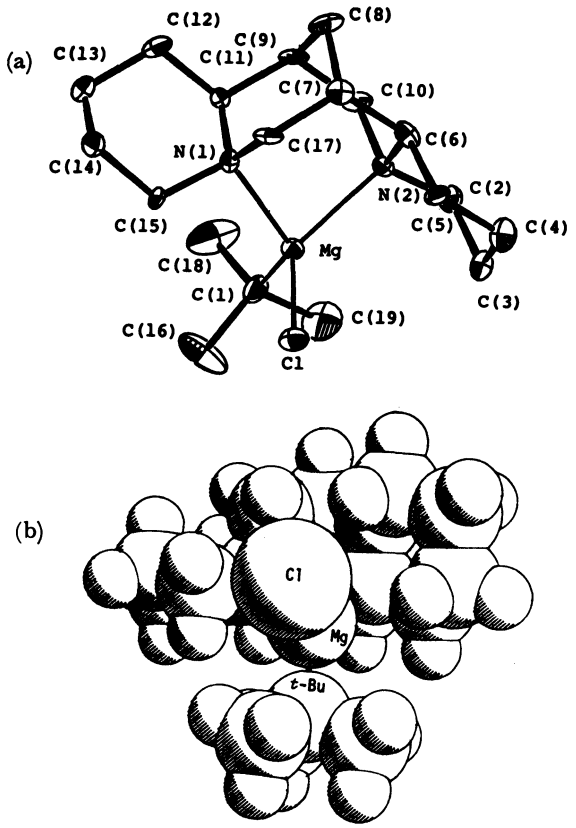


Fig. 1. (a): A perspective view[9] of the *t*-BuMgCl–(−)-sparteine molecule with the numbering scheme of atoms. Non-hydrogen atoms are drawn as thermal ellipsoids with 20% probability level. (b): A space-filling model[10] of the *t*-BuMgCl–(−)-sparteine molecule.

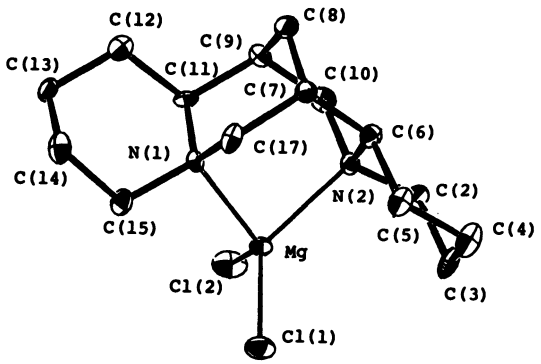

Fig. 2. A perspective view[9] of the $MgCl_2$–(−)-sparteine molecule with the numbering scheme of atoms. Non-hydrogen atoms are drawn as thermal ellipsoids with 20% probability level.

In the latter complex, the Et ligand is not so large and the Mg atom has a sufficient room to access the substrate in its neighborhood. In the former, however, the bulky *t*-Bu group blocks the central Mg atom from the substrate together with the Cl atom. This fact may explain the inactivity of the *t*-BuMgCl–(−)-sparteine on the asymmetric selective polymerization of methyl methacrylate.

$MgCl_2$–(−)-sparteine (2). As is seen in Fig. 2, the central Mg atom is tetrahedrally coordinated by

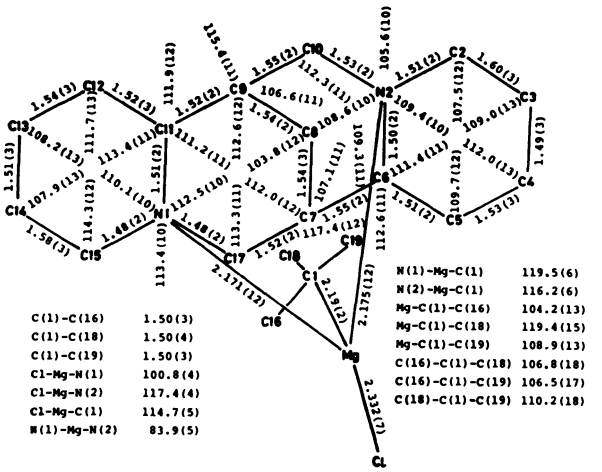

Fig. 3. Selected bond lengths [*l*/Å] and bond angles [ϕ/°] in the *t*-BuMgCl–(−)-sparteine molecule.

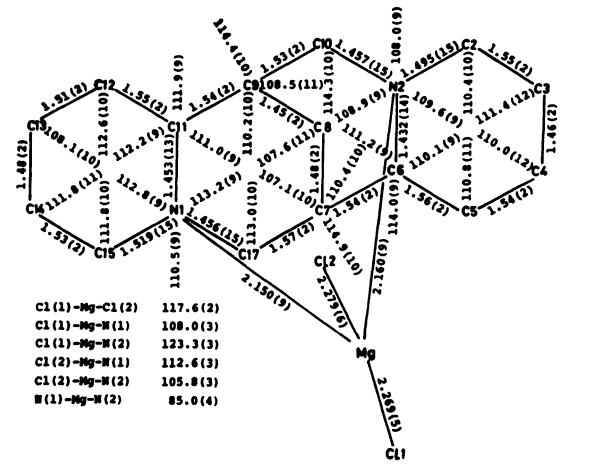

Fig. 4. Selected bond lengths [*l*/Å] and bond angles [ϕ/°] in the $MgCl_2$–(−)-sparteine molecule.

two N atoms of (−)-sparteine and two Cl ligands. Two Mg–N bond lengths [2.150(9) and 2.160(9) Å] are equal, and they are also equal to those in EtMgBr–(−)-sparteine [2.14(2) and 2.16(3) Å][2] and in *t*-BuMgCl–(−)-sparteine mentioned above. The N(1)–Mg–N(2) angle [85.0(4)°] is also equal to those in EtMgBr–(−)-sparteine [84.0(8)°] and *t*-BuMgCl–(−)-sparteine. Two Mg–Cl bonds are equal in length [2.269(5) and 2.279(6) Å], but they are significantly shorter than that in *t*-BuMgCl–(−)-sparteine. The Cl(1)–Mg–N(2) angle [123.3(3)°] is larger than the Cl(1)–Mg–N(1) [108.0(3)°] whereas the Cl(2)–Mg–N(2) [105.8(3)°] is smaller than Cl(2)–Mg–N(1) [112.6(3)°]. The (−)-sparteine skeleton in the present complex has nearly the same structure as those in EtMgBr–(−)-sparteine and *t*-BuMgCl–(−)-sparteine.

Crystal Structure. The crystal structures of *t*-BuMgCl–(−)-sparteine and $MgCl_2$–(−)-sparteine are depicted in Figs. 5 and 6, respectively. The closest intermolecular atomic contact in *t*-BuMgCl–(−)-sparteine is 3.73(3) Å (C(14) (x, y, z)···C(12) $(1/2-x, 1-y, -1/2+z)$). Molecular contacts in the crystal are rather loose, which may explain poor quality of the

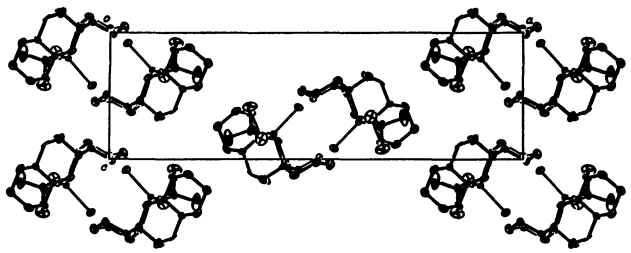

Fig. 5. The crystal structure of *t*-BuMgCl–(−)-sparteine.[9]

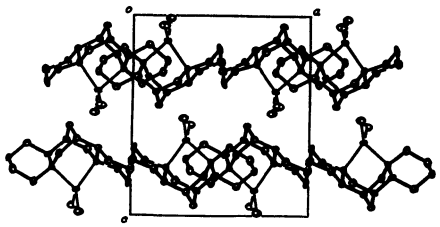

Fig. 6. The crystal structure of $MgCl_2$–(−)-sparteine.[9]

crystal. The shortest interatomic distance between molecules in contact in $MgCl_2$–(−)-sparteine is 3.64(2) Å (C(10) $(x, y, z)\cdots$C(12) $(1/2-x, 1-y, 1/2+z)$).

A part of the cost of this study was defrayed by the Grant-in-Aid for Scientific Research (No. 56470069) from the Ministry of Education, Science and Culture.

Mass-spectrometric Measurements of Thermodynamic Properties of the Molten KCl-$MnCl_2$ System

Tadashi Sasamoto,* Mitsuru Itoh,†,†† and Toshiyuki Sata†,†††
Tokyo National Technical College, 1220-2 Kunugida, Hachioji, Tokyo 193
†*Research Laboratory of Engineering Materials, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227*
(Received September 27, 1982)

Activities and heats of mixing for the molten KCl-$MnCl_2$ system were determined mass-spectrometrically by the ion-current ratio method. Activities of components KCl and $MnCl_2$ show large negative deviations from Raoult's law, indicating a very strong interaction between KCl and $MnCl_2$. Entropies of mixing calculated from measured activities and heats of mixing have minimum values in the vicinity of 33% $MnCl_2$, and have been compared with those calculated on the basis of some molten structure models to infer possible chemical species in the molten salt.

Thermodynamic measurements on molten salts have so far been made mainly by the calorimetric or the emf method. In our previous investigation[1] we measured mass-spectrometrically activities in both solid and liquid solutions of the KCl-NaCl system, and showed that mass spectrometry had a wide range of application in the measurement of thermodynamic properties in multicomponent salt systems.

The aim of the present study is to measure activities, heats of mixing, and entropies of mixing for the KCl-$MnCl_2$ system by mass spectrometry and to discuss the relation between thermodynamic properties and molten salt structures in such binary charge-unsymmetrical molten salt mixtures as an alkali-metal halide–transition metal halide system.

There have been many reports on physical properties of the molten KCl-$MnCl_2$ system: density,[2,3] molar refractivity,[4] electrical conductivity,[2,3] magnetism,[5] liquid structure according to the X-ray diffraction analysis,[6] Raman spectra,[7] and absorption spectra.[8] Papatheodorou and Kleppa[9] and Kleppa and McCarty[10] measured enthalpies of mixing for alkali-metal chloride-MCl_2 systems (M=Mn, Co, Ni, and Mg) by using calorimeters. They found that exothermic enthalpies of mixing, ΔH^M, increase sharply with increasing ionic radius of alkali-metals and that the interaction parameter, $\lambda^M=\Delta H^M/X_1X_2$ (X_1 and X_2 are mole fractions of MCl_2 and ACl, respectively), has a minimum near $X_{MnCl_2}=1/3$ only, indicating an appreciable formation of tetrahedral complex MCl_4^{2-} in the mixture. On the other hand, the emf method also has been applied to the charge-unsymmetrical alkali-metal chloride-MCl_2 molten salts: M=Mn,[11,12] Co,[13] Ni,[14] Zn,[15] Mg,[16] Ca, Sr, and Ba.[17] These reports showed that each heat of mixing agreed roughly with each of those obtained by the variation of mixing entropy with composition was characterized by an S-shaped curve in the vicinity of $X_{MnCl_2}=0.33$. The S-shaped behavior of entropy has been explained by a few investigators[11,16,18] in terms of the partial dissociation of ionic complex species through the reaction

$$[MCl_4]^{2-} \rightleftharpoons M^{2+} + 4Cl^-, \quad (1)$$

whereas Kucharski and Flengas[12] adopted configurational terms of MCl_4^{2-}, A^+, M^{2+}, and Cl^- ions. It has been found by Φstvold and Kleppa[19] that the PbO-SiO_2 system also shows an S-shaped behavior which they attributed to formation of orthosilicate anion, $[SiO_4]^{4-}$.

Experimental

Instrument. The instrument used was a JEOL JMS-01BK doubly-focused mass spectrometer with a Knudsen cell source. As the details of the instrument were described elsewhere,[1,20] we would mention here only on the Knudsen cell which differed from the one used in our previous experiment.[1] The nickel Knudsen cell (Ni metal over 99.9% in purity) had a conical orifice, 0.005—0.006 cm in diameter, bored by electric discharge processing. In order to prevent the clogging of the cell orifice caused by wetting and crawling-up of molten salt, a fence made of thin Ni-foil was fixed in the upper part of the inside cell wall.

Sample. Vacuum-dried $MnCl_2$ and KCl powders were used as starting materials. Anhydrous $MnCl_2$ powder was obtained from $MnCl_2 \cdot 2H_2O$ by dehydration at 200 °C. Solid solution samples for the KCl-$MnCl_2$ system were prepared by the following processes: (1) preparing a mixture of KCl and $MnCl_2$ powders by weighing in dry Ar, (2) fusing the mixture in a stream of HCl gas in quartz tube to remove impurities such as alkali-metal oxides and water, and (3) replacing the HCl gas by Ar to remove the HCl dissolved in the molten salt and then cooling down the mass to room temperature. The product was pulverized just before measurement, and a sample of approximately 1 g for each run was charged in the cell in a dry box.

Calibration of Cell Temperature. As the cell temperature was measured with a W-5%Re/W-26%Re thermocouple positioned under the outside bottom of the cell, the temperature difference between the sample in the cell and the outside in contact with the thermocouple was determined by measuring some of the melting points of LiCl (883 K), $MnCl_2$ (923 K), KCl (1044 K), and NaCl (1074 K). The temperature difference was about 25 K, increasing slightly with a rise in cell temperature.

Procedure of Mass-spectrometric Measurement. Ion identification and intensity measurement for derived species were

†† Present address: Department of Metallurgy, Faculty of Engineering, Osaka University, 2-1 Yamadaoka, Suita, Osaka 565.

††† Present address: Department of Industrial Chemistry, Kumamoto Institute of Technology, 4-22-1 Ikeda, Kumamoto 860.

made by the usual mass spectrometric technique in the temperature range from melting temperature to several hundreds degrees above the melting point. Prior to starting an ion intensity measurement the constant ion intensity was examined.

The ionic species detected were K^+, KCl^+, K_2Cl^+, Cl^+, Mn^+, $MnCl^+$, and $MnCl_2^+$. Their appearance potentials, relative to H_2O^+, were 11.0, 10.5, 10.8, 15.5, 13.0, 8.5, and 7.5 eV, respectively. No other ions such as $Mn_2Cl_3^+$ (dimer ion), $KMnCl_3^+$ (mixed dimer ion), and $NiCl_n^+$ ($n=1, 2$) were detected. Both by considering appearance potentials and by using an analogy with other chlorides,[1,21-23] the molecular ions formed by simple ionization were estimated to be KCl^+, K_2Cl^+, and $MnCl_2^+$. In view of the apparent potentials for all the ions, an ionization potential of 17.5 eV was used.

Activity coefficient, γ, and heat of mixing, ΔH^M, were calculated from ion-current ratios of related ionic species by the previously outlined procedure.[1] According to Belton and Fruehan,[24] for example, the activity coefficient, γ_{MnCl_2}, and heat of mixing, $\Delta H^M_{MnCl_2}$, for the $MnCl_2$ component are given by

$$\ln \gamma_{MnCl_2} = \int_{X_{MnCl_2}=1}^{X_{MnCl_2}} \frac{X_{KCl}}{1+X_{MnCl_2}} \times d\left[\ln \frac{I_{K_2Cl^+}}{I_{MnCl_2^+}} - \ln \frac{X^2_{KCl}}{X_{MnCl_2}}\right], \quad (2)$$

$$\Delta H^M_{MnCl_2} = -R \int_{X_{MnCl_2}=1}^{X_{MnCl_2}} \frac{X_{KCl}}{1+X_{MnCl_2}} \times d\left\{\frac{d[\ln(I_{K_2Cl^+}/I_{MnCl_2^+}) - \ln(X^2_{KCl}/X_{MnCl_2})]}{d(1/T)}\right\}, \quad (3)$$

where X is mole fraction, I_i^+ the ion intensity of ion i^+, and R the gas constant.

Results and Discussion

Activity. Figure 1 shows the ion-current ratio as a function of temperature. The relationship between the ion-current ratio and the reciprocal of absolute temperature was determined by the regression analysis. In Table 1 the regression coefficients and standard deviations of error were summarized. The ion-current ratio values for the 10 mol% KCl–90 mol% $MnCl_2$ system at temperatures above 1083 K are not included in the regression analysis, since they deviated greatly from the regression line. This was probably because $MnCl_2$ gas molecules did not satisfy the Knudsen

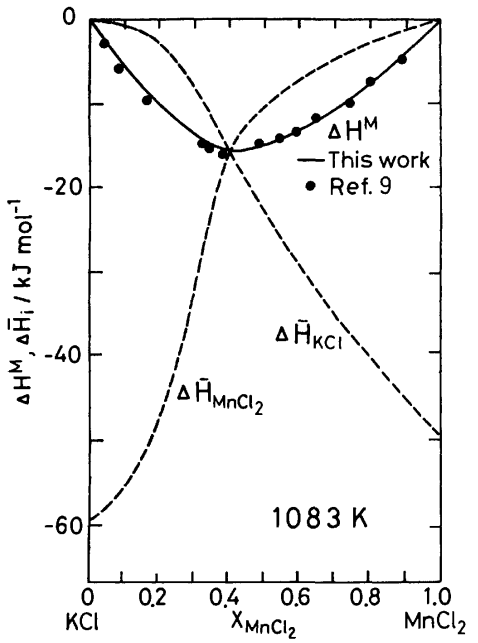

Fig. 6. Enthalpy of mixing in the molten KCl-$MnCl_2$ system.

molecular flow condition when allowed to effuse out from the orifice. In order to integrate Eq. 2 graphically and to obtain the activity coefficient, the term $[\ln(I_{K_2Cl^+}/I_{MnCl_2^+})-\ln(X/X_{KCl}^2X_{MnCl_2})]$ was plotted against the composition, X, as illustrated in Fig. 2. The solid line in Fig. 2 was given by the regression analysis. The relationships of composition *vs.* logarithmic activity coefficient and composition *vs.* activity are shown in Figs. 3 and 4. Braunstein[25] proposed a method to obtain the equilibrium constant for Reaction 1 by extrapolating the log γ *vs.* X line to $X=0$, as applicable when the excess Gibbs energy, ΔG_{XS}, is attributable to the excess entropy. His method, however, was not adopted in this case since ΔG_{XS} depends mainly on the large heat of mixing, as will be described later. It is seen from Fig. 3 that $\ln\gamma$ has an inflection point at the concentration of 30—40 mol% $MnCl_2$, which suggests a structural change in the molten salt. As shown in Fig. 4, the activity shows a great deviation from Raoult's law, suggesting a presence of strong interaction between KCl and $MnCl_2$.

Heat of Mixing and Entropy of Mixing. Figure 5 shows a preliminary curve for obtaining the heat of mixing, ΔH^M, from both Eq. 2 and the data in Table 1. An integration along the curve in Fig. 5 gives the ΔH's in Fig. 6. This result is in good agreement with the values determined by Papatheodorou and Kleppa[9] and hence the interaction parameter λ^M also agrees with them. Although the heats of mixing obtained here are considered to be average values for a wide range of temperature, they are in close agreement with those determined calorimetrically at a constant temperature. This fact suggest that the liquid structure of the KCl-$MnCl_2$ molten salt is independent of temperature, in accord with the fact that the intensity of Raman spectra in this system is independent of temperature.[7]

The partial molar entropy, $\Delta\bar{S}_i$, and the integral entropy of mixing, ΔS^M, for the molten salt were calculated from the well-known thermodynamic relations

$$\Delta\bar{G}_i = \Delta\bar{H}_i - T\Delta\bar{S}_i, \quad (4)$$

$$\Delta S^M = \sum_i X_i\Delta\bar{S}_i, \quad (5)$$

the results obtained being shown in Fig. 7.

Estimation of Chemical Species in Molten Mixture. The integrated and partial molar entropies of mixing, as shown in Fig. 7, from an S-shaped curve in the vicinity of $X_{MnCl_2}=0.33$, which suggests that some marked structural change occurs in this composition range. If anions and cations in the system behave as those in an ideal solution, the entropy of mixing should be in agreement with the values calculated from the equation $\Delta S^M_{ideal}=-R\sum X_i\ln X_i$. Obviously, this is not the case, as seen from Fig. 7. Kucharski and Flengas[12] explained the deviation from ideal entropy on the basis of possible ionic species: (1) Mn^{2+} and Cl^- ions in the pure molten $MnCl_2$; (2) A^+ (alkali-metal ion), Cl^-, and $[MnCl_4]^{2-}$ ions in the composition region of $0<X_{MnCl_2}<0.33$; (3) only $[MnCl_4]^{2-}$ and A^+ ions at $X_{MnCl_2}=0.33$; (4) A^+, Mn^{2+}, Cl^-, and $[MnCl_4]^{2-}$ ions in the region $X_{MnCl_2}>0.33$. On the basis of this model the theoretical entropy of mixing was calculated from the equations

$$\Delta S^M = -R[\sum n(i^+)\ln N(i^+) + \sum n(j^-)\ln N(j^-)]$$
$$= -R[n(K^+)\ln N(K^+) + n(Mn^{2+})\ln N(Mn^{2+})$$
$$+ n(Cl^-)\ln N(Cl^-) + n(MnCl_4^{2-})\ln N(MnCl_4^{2-})], \quad (6)$$

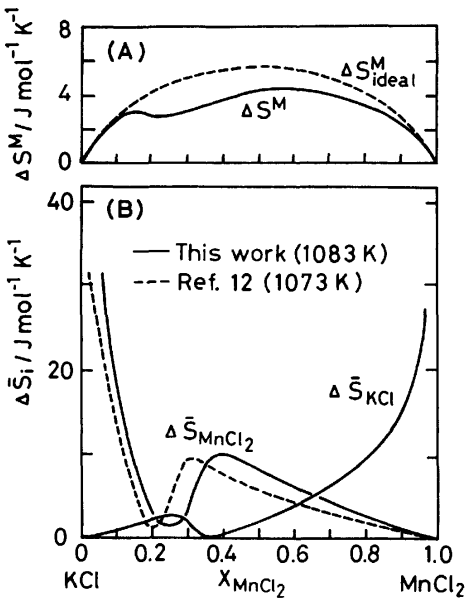

Fig. 7. Partial moral entropy of mixing and integral entropy in the molten KCl–$MnCl_2$ system.

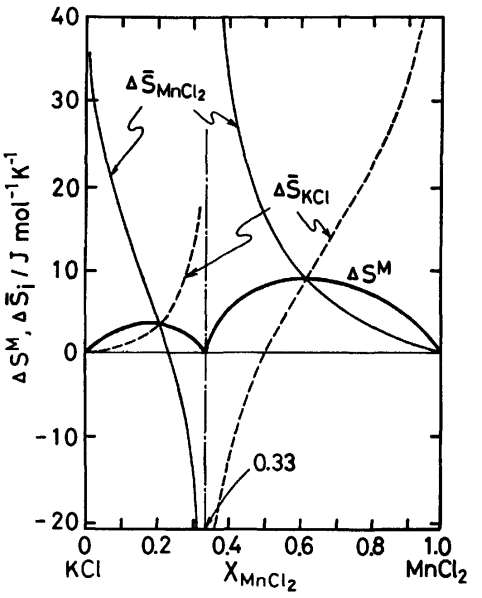

Fig. 8. Entropy of mixing in the KCl–$MnCl_2$ system calculated on the basis of Kucharski and Flengas' model.[12]

where $n(i^+ \text{ or } j^-)$ and $N(i^+ \text{ or } j^-)$ denote the mole number and ionic fraction of i^+ or j^- ion, respectively, and

$$\Delta\bar{S}_{KCl} = -\frac{R}{2}\ln\frac{X_{KCl}^3(4X_{MnCl_2}-X_{KCl})}{(1+X_{KCl})(2X_{MnCl_2}-X_{KCl})^3} \quad (7)$$

in the composition region of $X_{MnCl_2}>1/3$. Equation 6 was derived simply on statistical thermodynamics by assuming that the cations and anions will distribute randomly and that the contribution of a vibration of molecule to the entropy can be neglected. Figure 8 shows the entropies calculated from Eqs. 6 and 7. As for a comparison of Figs. 7 and 8, the model described above can explain the decrease in entropy in the vicinity of $X_{MnCl_2}=0.33$, but can not explain the value of ΔS^M at $X_{MnCl_2}=0.33$ since the ΔS^M should be 0 at $X_{MnCl_2}=0.33$ if the model is correct. Furthermore, the observed values of ΔS^M and $\Delta\bar{S}_{KCl}$ are smaller than the calculated. Therefore, we must further modify Kucharski and Flengas' model.

Takagi *et al.*[2] have concluded from electrical conductivity measurements for the KCl–$MnCl_2$ system that free Mn^{2+} ions exist in the molten salt at $X_{MnCl_2}=0.33$. Considering this fact and the proposals of Φstvold,[11] Ikeuchi and Krohn,[16] and Pelton and Thompson,[18] we take into account the following chemical equilibrium in calculating the entropy

$$[MnCl_4]^{2-} \rightleftharpoons Mn^{2+} + 4Cl^- . \quad (8)$$

Figure 9 shows the result computed for $\alpha=0.15$ and 0.50, where α is the degree of dissociation of $[MnCl_4]^{2-}$ into Mn^{2+} and Cl^- on the assumption that the dissociation constant for Eq. 8 is independent of the composition. As can be seen from Fig. 9, the disagreement near $X_{MnCl_2}=0.33$ may be solved by considering Dissociation Reaction 8. The disagreement in the high $MnCl_2$ composition side, however, remains still unsettled.

Takagi *et al.*[6] proposed the following model from an X-ray structure analysis: clusters or polymer ions (made up of $[MnCl_4]^{2-}$ exist even in the pure molten $MnCl_2$,

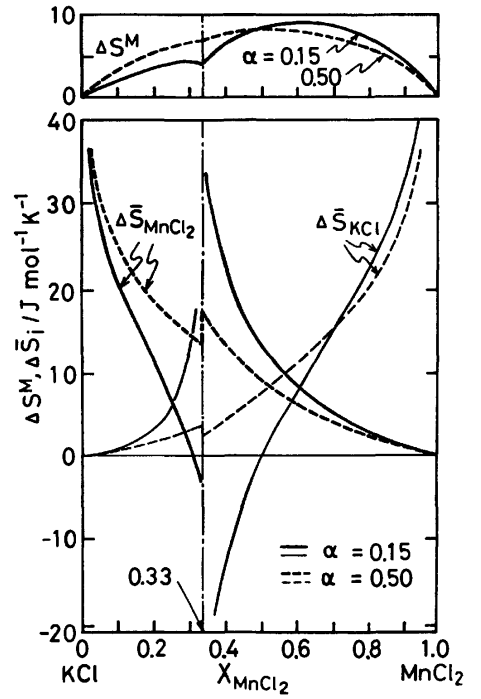

Fig. 9. Entropy of mixing in the KCl–$MnCl_2$ system calculated on the basis of the dissociation model.

and addition of component KCl will cause the polymeric ions to decompose to $[MnCl_4]^{2-}$ monomer ion through the intermediate cluster ions Mn_5Cl_{10}, $[Mn_4Cl_{10}]^{2-}$, $[Mn_3Cl_9]^{3-}$, and $[Mn_2Cl_7]^{3-}$ at compositions $X_{MnCl_2}=$ 1.0, 0.666, 0.5, and 0.4, respectively. Based on the model by Takagi *et al.*[6] we attempted again to calculate the entropy of mixing by using Eq. 6. However, we have failed in obtaining consistent results. This is probably attributable to the assumption that (1) such large cluster ions as $[Mn_3Cl_9]^{3-}$ and $[Mn_4Cl_{10}]^{2-}$ are almost negligible and the mixing of each ion is ideal,

that (2) the degree of dissociation of the complex species is independent of composition, and that (3) vibrational entropy can be neglected. A new model for the structure of a molten mixture containing polymer complex species is needed to provide an explanation for the entropy in the $MnCl_2$-rich side.

Conclusion

(1) Activities of components KCl and $MnCl_2$ in their molten mixtures show large negative deviations from Raoult's law. This suggests a very strong interaction between KCl and $MnCl_2$.

(2) The entropy of mixing has a minimum in the vicinity of $X_{MnCl_2}=1/3$ only, and the minimum has been explained in terms of the formation of complex species $[MnCl_4]^{2-}$.

The authors wish to thank Professor Tetsuro Nakamura of the Tokyo Institute of Technology for his discussion.

Circular Dichroism Spectra and Absolute Configurations of *fac*(NH_3)-[Co(a)(gly)(NH_3)$_3$]$^{n+}$-type Complexes

Shuhei Fujinami,* Akihiko Hattori, and Muraji Shibata
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920
(Received December 9, 1982)

Four complexes [Co(a)(gly)(NH_3)$_3$]$^+$ (a=CN^-, NO_2^-, NCS^-, and N_3^-) and a related [Co(NO_2)(β-ala)(NH_3)$_3$]$^+$ complex have been prepared; they were characterized by the absorption spectra in the ultraviolet region. The *fac*(NH_3) isomers of these complexes have been optically resolved by column chromatography. The CD spectra of *fac*(NH_3)-[Co(H_2O)(gly)(NH_3)$_3$]$^{2+}$ and *fac*(NH_3)-[Co(H_2O)(β-ala)(NH_3)$_3$]$^{2+}$ have also been measured. The absolute configurations of the *fac*(NH_3) isomers have been determined by referring to the CD spectrum of *fac*(NH_3)-(−)$_{589}$[Co(NO_2)(gly)(NH_3)$_3$]ClO_4 which had been subjected to an X-ray analysis. Each isomer has exhibited a dominant Cotton peak at *ca.* 20000 cm^{-1} in the first absorption band region. The peak has been assigned to the electronic transition component which arises in the plane containing the glycinate chelate. The CD spectra of *fac*(NH_3)-[Co(a)(gly)(NH_3)$_3$]$^+$ have been compared with those of the corresponding [Co(a)(gly)(1,4,7-triazacyclononane)]$^+$ complexes, and the sources of the optical activities in these complexes have been investigated.

We are interested in the optically active complexes whose chiralities are due to the arrangements of donor atoms around a central metal ion. In the previous papers,[1,2] the circular dichroism (CD) spectra of *fac*(*D*)-[Co(a)(BC)(DDD)]$^{n+}$ complexes have been reported. Here a represents several kinds of unidentate ligands; DDD represents a cyclic terdentate ligand: 1,4,7-triazacyclononane(=tacn), (2*R*)-2-methyl-1,4,7-triazacyclononane (Me-tacn), or 1,5,9-triazacyclododecane(=tacdd); BC denotes an amino carboxylate ion; glycinate, β-alaninate, or L-valinate. Though two helical ring-pairs exist in the complexes, the optical activities of the complexes have been mainly attributed to a chiral arrangement of four kinds of donor atoms around the central metal ion.

The *fac*(NH_3)-(−)$_{589}$[Co(NO_2)(gly)(NH_3)$_3$]$^+$ complex[3] has a chiral arrangement of donor atoms similar to the [Co(NO_2)(gly)(tacn)]$^+$ and no ring-pair is contained in the complex. The absolute configuration of the complex has been determined by X-ray analysis.[4] This paper will deal with further syntheses and optical resolutions of the *fac*(NH_3)-[Co(a)(gly)(NH_3)$_3$]$^{n+}$ (a=CN^-, NO_2^-, NCS^-, N_3^-, or H_2O) and *fac*(NH_3)-[Co(b)(β-ala)(NH_3)$_3$]$^{n+}$ (b=NO_2^- or H_2O) complexes. The CD spectra of the *fac*(NH_3) complexes will be compared with those of the corresponding tacn complexes, and the contribution of the chelate ring to the optical activities will be reported.

Experimental

Synthesis and Optical Resolution. *1)* fac(NH_3)-*Triammineglycinatonitrocobalt(III) Chloride*, fac(NH_3)-[*Co*(*NO*$_2$)(*gly*)(*NH*$_3$)$_3$]*Cl*: This complex was prepared from [Co(NO_2)(NH_3)$_5$]$^{2+}$, and optically resolved according to the literature.[3]

2) fac(NH_3)-*Triammineglycinatoisothiocyanatocobalt(III) Bromide 0.5-Hydrate*, fac(NH_3)-[*Co*(*NCS*)(*gly*)(*NH*$_3$)$_3$]*Br*·*0.5H*$_2$*O*: To an aqueous solution of [Co(NCS)(NH_3)$_5$]SO_4 (15 g in 150 cm^3 H_2O) were added glycine (3.3 g), Na_2CO_3 (2.0 g) and activated charcoal (1.0 g), and the solution was stirred for a day at room temperature. After filtering off the activated charcoal, the filtrate was adjusted to pH 7 with perchloric acid and diluted to 3 dm^3 with water. The solution was poured onto a column of Dowex 50W-X8 (Na^+ form, 100—200 mesh, ϕ4.0 cm × 40 cm). By elution with a 0.1 mol/dm^3 NaCl solution, four bands of univalent cations were discharged; they were labelled A1, A2, A3, and A4 in the order of elution. The labels are also used to designate the complex species in each band. The A3 fraction was rechromatographed with a short column of the same resin (ϕ2 cm × 10 cm) in order to convert the counter ion to bromide. The adsorbed band was eluted with 0.1 mol/dm^3 NaBr, and collected in a fraction (A3′). Each fraction was concentrated by means of a rotary evaporator with simultaneous removal of precipitated eluent. To a final filtrate was added a small amount of ethanol, and the whole was kept in a refrigerator. The crude product which precipitated was recrystallized from a minimum amount of warm water. A2 and A4 were identified to be the isomers of a known complex, [Co(gly)$_2$(NH_3)$_2$]$^+$.[5] From elemental analyses, absorption and IR spectra, A1 and A3′ were assigned to the isomers of the [Co(NCS)(gly)(NH_3)$_3$]$^+$ complex. The yields of A1 and A3′ were 0.3 g and 0.2 g respectively. Found for A1: C, 13.00; H, 4.76; N, 25.22%. Calcd for [Co(NCS)(gly)(NH_3)$_3$]Cl: C, 12.98; H, 4.72; N, 25.23%. Found for A3′: C, 11.17; H, 3.90; N, 21.02%. Calcd for [Co(NCS)(gly)(NH_3)$_3$]Br·0.5H_2O: C, 10.88; H, 4.22; N, 21.15%.

The A3′ isomer was resolved into optical antipodes by using a column of Dowex 50W-X8 (Na^+ form, 200—400 mesh, ϕ2.5 cm × 70 cm) and 0.05 mol/dm^3 Na_2[Sb_2(*d*-tart)$_2$] as eluent. This fact indicates that A3′ is a *fac*(NH_3) isomer and A1 is a *mer*(NH_3) one. When the adsorbed band descended in the neighborhood of the outlet of the column, the band was washed sufficiently with water, and collected in several fractions by eluting with 0.1 mol/dm^3 NaCl. Each fraction was concentrated and submitted to the measurement of CD spectrum, while the concentration of the complex species was evaluated from the absorption spectral data.

3) fac(NH_3)-*Triammineazidoglycinatocobalt(III) Chloride*, fac(NH_3)-[*Co*(*N*$_3$)(*gly*)(*NH*$_3$)$_3$]*Cl*: The complex was prepared in the same manner as the isothiocyanato complex, except for the use of [Co(N_3)(NH_3)$_5$]Cl_2 (13 g, 0.05 mol, in 150 cm^3 H_2O) in place of [Co(NCS)(NH_3)$_5$]SO_4. By elution with a 0.1 mol/dm^3 NaCl solution, four bands of univalent cations were discharged; they were labelled B1, B2, B3, and B4 in the order of elution. B2 and B4 were identified to be the isomers of [Co(gly)$_2$(NH_3)$_2$]$^+$.[5] B1 and B3 were assigned to the isomers of [Co(N_3)(gly)(NH_3)$_3$]$^+$. The yields of B1 and B3 were *ca.* 0.3 g. Found for B1: C, 9.48; H, 4.87; N, 37.73%. Found for B3: C, 9.41; H, 5.24; N, 37.57%. Calcd for [Co(N_3)(gly)(NH_3)$_3$]Cl: C, 9.18; H, 5.01; N, 37.49%.

The B3 isomer was optically resolved by a method similar to that described in 2). Therefore, B3 was assigned to a *fac*(NH_3)

isomer, and B1 was a *mer*(NH_3) one.

4) fac(NH_3)-*Triamminecyanoglycinatocobalt(III) Chloride 0.75-*fac(NH_3)-[*Co(CN)(gly)(NH_3)$_3$]Cl·0.75H_2O*: To a cold green solution of tricarbonatocobaltate(III) (0.042 mol scale),[6] potassium cyanide (4.1 g, 0.063 mol) was added by portions, and the mixture was stirred vigorously at room temperature for 20 min. A deep red solution was obtained. After addition of glycine (3.75 g, 0.05 mol), the solution was carefully adjusted to pH 8 with 30% perchloric acid, and stirred at room temperature for two days. The resulting red-violet solution was adjusted to pH 3 with 60% perchloric acid under an iced conditions, and stirred for 30 min. Concentrated aqueous ammonia (20 cm^3, 0.28 mol) and activated charcoal (1 g) were added to the solution and the whole was stirred at room temperature for two days. After filtration, the filtrate was neutralized with 30% perchloric acid under an iced conditions, and the precipitate was filtered out. The filtrate was diluted to 3 dm^3 with water and charged on a column of Dowex 50W-X8 (Na^+ form, 200—400 mesh, ϕ4 cm × 30 cm). By elution with a 0.1 mol/dm^3 NaCl solution, five bands of univalent cations were discharged; they were labelled C1, C2, C3, C4, and C5 in the order of elution. Each fraction was concentrated to a small volume by a rotary evaporator, with simultaneous removal of deposited NaCl. A small amount of ethanol was added to the concentrate, and the whole was kept in a refrigerator. C1 was identified to be $[Co(CN)_2(NH_3)_4]^+$,[7] and C5, to be the isomers of $[Co(gly)_2(NH_3)_2]^+$.[5] The yellow crystals obtained from C2 and the orange crystals from C3 were assigned to isomers of $[Co(CN)(gly)(NH_3)_3]^+$. Each yield was *ca.* 0.3 g. Found for C2: C, 13.04; H, 5.86; N, 25.68%. Calcd for $[Co(CN)(gly)(NH_3)_3]Cl\cdot 1.5H_2O$: C, 13.22; H, 5.92; N, 25.69%. Found for C3: C, 13.66; H, 5.76; N, 27.29%. Calcd for $[Co(CN)(gly)(NH_3)_3]Cl\cdot 0.75H_2O$: C, 13.91; H, 5.64; N, 27.03%.

The C3 isomer was optically resolved by column chromatography in the same manner as in 2). Therefore, C3 was assigned to a *fac*(NH_3) isomer and C2 to a *mer*(NH_3) one.

5) fac(NH_3)-*Triammineaquaglycinatocobalt(III) Cation,* fac-(NH_3)-[*Co(H_2O)(gly)(NH_3)$_3$*]$^{2+}$: This complex was prepared by acid-hydrolysis of the *fac*(NH_3)-[$Co(NO_2)$(gly)-(NH_3)$_3$]$^+$ complex. The nitro complex (1.0 g) was dissolved in hydrobromic acid (47%, 20 cm^3). The solution was stirred at 50—60 °C for 90 min, whereupon the corresponding aqua complex was formed. The solution was diluted to 3 dm^3 with water, and poured onto a column of SP-Sephadex C-25 (Na^+ form, ϕ4.0 cm × 30 cm). The adsorbed red band was eluted with 0.1 mol/dm^3 $HClO_4$, and collected in a fraction. The eluate was concentrated to a small volume by a rotary evaporator, and its absorption spectrum was measured. The metal concentration was evaluated from the data of the atomic absorption spectrum. This complex was unable to be crystallized because of the great solubility of the complex species in water. The chromatographic behavior of the species indicates that the species is a bivalent cation. This complex was resolved into enantiomers by using a column of SP-Sephadex C-25 (Na^+ form, ϕ2.5 cm × 140 cm) and a 0.05 mol/dm^3 $Na_2[Sb_2(d\text{-tart})_2]$ solution as eluent.

1) fac(NH_3)-*(β-Alaninato)triamminenitrocobalt(III) Chloride Monohydrate,* fac(NH_3)-[*Co(NO_2)(β-ala)(NH_3)$_3$*]Cl·H_2O: This complex was prepared in the same manner as the *fac*(NH_3)-[$Co(NO_2)$(gly)(NH_3)$_3$]Cl, except for the use of β-alanine in place of glycine. The yield was *ca.* 0.3 g. Found: C, 12.24; H, 5.69; N, 23.37%. Calcd for $[Co(NO_2)(\beta\text{-ala})(NH_3)_3]Cl\cdot H_2O$: C, 12.11; H, 5.76; N, 23.53%.

The complex was also resolved into the optical antipodes in the same manner as in 2).

7) fac(NH_3)-*(β-Alaninato)triammineaquacobalt(III) Cation,* fac(NH_3)-[*Co(H_2O)(β-ala)(NH_3)$_3$*]$^{2+}$: This complex was prepared from *fac*(NH_3)-[$Co(NO_2)$(β-ala)(NH_3)$_3$]Cl and optically resolved by the method described in 5). The values of ε and $\Delta\varepsilon$ were evaluated from the data of atomic absorption spectra. The complex species could not be isolated because of its great solubility in water.

Derivations from Optically Active Complexes. The optically active complex, *fac*(NH_3)-$(+)_{589}$[Co(NCS)(gly)(NH_3)$_3$]$^+$, was derived from the *fac*(NH_3)-$(+)_{589}$[$Co(H_2O)$(gly)(NH_3)$_3$]$^{2+}$ complex by the following procedure. To a solution of the aqua complex was added an excess amount of NaSCN, and the mixture was adjusted to pH 4 with $HClO_4$. The solution was stirred at 50—60 °C for 1 h, and then subjected to Sephadex column chromatography in a similar way to that described in 5). The eluate obtained by elution with 0.05 mol/dm^3 NaCl was concentrated by means of a rotary evaporator, and a small amount of ethanol was added to the concentrate. When the whole kept in a refrigerator, red crystals deposited.

The *fac*(NH_3)-$(-)_{589}$[$Co(N_3)$(gly)(NH_3)$_3$]$^+$ and *fac*(NH_3)-$(-)_{589}$[$Co(NO_2)$(β-ala)(NH_3)$_3$]$^+$ were also derived from *fac*-(NH_3)-$(+)_{589}$[$Co(H_2O)$(gly)(NH_3)$_3$]$^{2+}$ and *fac*(NH_3)-$(+)_{589}$-[$Co(H_2O)$(β-ala)(NH_3)$_3$]$^{2+}$ respectively, by a similar procedure to that described above. The optically active complex *fac*-,(NH_3)-$(-)_{589}$ [$Co(NO_2)$(gly)(NH_3)$_3$]$^+$, was directly converted to the optically active aqua complex, *fac*(NH_3)-$(+)_{589}$ [Co-(H_2O)(gly)(NH_3)$_3$]$^{2+}$, according to the method described in 5). When the *fac*(NH_3)-$(+)_{589}$[Co(NCS)(gly)(NH_3)$_3$]$^+$ complex was treated with aqueous H_2O_2 at *ca.* pH 3 in a similar manner to that described in the previous paper,[1] *fac*(NH_3)-$(-)_{589}$[Co(CN)(gly)(NH_3)$_3$]$^+$, *fac*(NH_3)-$(+)_{589}$[$Co(H_2O)$-(gly)(NH_3)$_3$]$^{2+}$, and optically inactive $[Co(gly)(NH_3)_4]^{2+}$ [8] were obtained by means of chromatography.

Measurements. The absorption spectra in aqueous solution were recorded with a Hitachi 323 recording spectrophotometer. The CD spectra were measured with a JASCO J-40C automatic recording spectropolarimeter equipped with a JASCO Model J-DPZ data processor for CD. For the measurements of the optical rotation, a JASCO Model DIPSL automatic polarimeter was used. In order to evaluate the metal concentrations from the data of atomic absorption spectra, a Hitachi 170-50 atomic absorption spectrophotometer was used.

Results and Discussion

Preparation and Characterization. Three *fac*(NH_3)-[Co(a)(gly)(NH_3)$_3$]$^+$ (a=NO_2^-, NCS^-, and N_3^-) complexes and the *fac*(NH_3)-[$Co(NO_2)$(β-ala)(NH_3)$_3$]$^+$ complex were derived from the corresponding pentaammineanionocobalt(III) complexes. However, the *fac*(NH_3)-[Co(CN)(gly)(NH_3)$_3$]$^+$ complex could not be derived from a $[Co(CN)(NH_3)_5]^{2+}$ complex because of the small solubility of the pentaammine complex in water. The desired cyano complex was obtained by substitution reactions starting from $[Co(CO_3)_3]^{3-}$. The aqua complexes were also not obtained from $[Co(H_2O)(NH_3)_5]^{3+}$.

There are three possible geometrical isomers in the [Co(a)(amino acidato)(NH_3)$_3$]$^{n+}$ complex: *mer*(NH_3)-*trans*(*a*,*O*), *mer*(NH_3)-*trans*(*a*,*N*), and *fac*(NH_3), where O and N represent donors of the amino acidato ligand.[3] Two *mer*(NH_3) isomers are achiral, while the *fac*(NH_3) isomer is chiral and resolvable into the optical antipodes. Except for *fac*(NH_3)-[$Co(H_2O)$(β-ala)(NH_3)$_3$]$^{2+}$, all the

fac(NH_3) isomers were separated completely into the enantiomers on columns of 200—400 mesh cation exchanger. These isomers were only partially resolved on columns of 100—200 mesh exchanger.

Absorption spectra of *fac*(NH_3)-[Co(a)(gly)$(NH_3)_3$]$^{n+}$ complexes are shown in Figs. 1—5 (a=CN^-, NO_2^-, NCS^-, N_3^-, and H_2O), along with those of the related [Co(a)(gly)(tacn)]$^{n+}$ complexes. The numerical data are summarized in Table 1. The absorption maxima of the first absorption bands of the *fac*(NH_3) complexes appear at somewhat lower frequencies than those of the corresponding tacn complexes, and the intensities of the bands of the former are weaker than those of the latter.

Two *mer*(NH_3) isomers were isolated for the [Co(NO_2)(gly)(NH_3)$_3$]$^+$ complex, and assigned on the basis of absorption spectra in the ultraviolet region.[3] However only one of two *mer*(NH_3) isomers was obtained for each of the [Co(CN)(gly)(NH_3)$_3$]$^+$, [Co(NCS)(gly)(NH_3)$_3$]$^+$, and [Co(N_3)(gly)(NH_3)$_3$]$^+$ complexes. As to the isothiocyanato complex, the absorption band at *ca.* 32000 cm^{-1} can be assigned to 2π(NCS)→d(z^2).[9] Since the band in the *mer*(NH_3) isomer is observed at a lower frequency than that in the corresponding *fac*(NH_3) isomer, the *mer*(NH_3)-*trans*(*NCS,O*) configuration is assignable for the *mer*(NH_3) complex in the same manner as described in the nitro complex.[3]

The absorption band at *ca.* 47000 cm^{-1} in the cyano complex can be assigned to dπ→π(CN).[9] The bands observed at *ca.* 30000 cm^{-1} in the nitro complex are assignable to dπ→π(NO_2), and the maximum of the *mer*(NH_3)-*trans*(NO_2,*O*) isomer is observed at a lower frequency than those of the *mer*(NH_3)-*trans*(NO_2,*N*) and *fac*(NH_3) isomers. Since the maximum of the *mer*(NH_3)-cyano isomer is observed at a lower frequency than that of the *fac*(NH_3) isomer, the isomer is considered to have the *mer*(NH_3)-*trans*(*CN,O*) configuration.

CD Spectra and Absolute Configurations. CD spectra of *fac*(NH_3)-[Co(a)(gly)(NH_3)$_3$]$^{n+}$ isomers, all of which were slow-moving isomers in column chromatography, are shown in Figs. 1—5, together with those of the fast-moving isomers of the corresponding tacn complexes. The (+)$_{589}$[Co(H_2O)(gly)(NH_3)$_3$]$^{2+}$ complex exhibits a single Cotton peak in the first absorption band region, and (−)$_{589}$[Co(NO_2)(gly)(NH_3)$_3$]$^+$ two peaks in this region, the CD spectra of these complexes being different from those of the corresponding tacn complexes. However, the CD spectra of (−)$_{589}$[Co(CN)(gly)-(NH_3)$_3$]$^+$, (+)$_{589}$[Co(NCS)(gly)(NH_3)$_3$]$^+$, and (−)$_{589}$-[Co(N_3)(gly)(NH_3)$_3$]$^+$ resemble those of the corresponding tacn complexes.

The *fac*(NH_3)-(+)$_{589}$[Co(H_2O)(gly)(NH_3)$_3$]$^{2+}$ complex could be converted to *fac*(NH_3)-(−)$_{589}$[Co(NO_2)-(gly)(NH_3)$_3$]$^+$, *fac*(NH_3)-(+)$_{589}$[Co(NCS)(gly)(NH_3)$_3$]$^+$, and *fac*(NH_3)-(−)$_{589}$[Co(N_3)(gly)(NH_3)$_3$]$^+$ complexes. Furthermore, the *fac*(NH_3)-(+)$_{589}$[Co(NCS)(gly)-(NH_3)$_3$]$^+$ complex was converted to *fac*(NH_3)-(+)$_{589}$-[Co(H_2O)(gly)(NH_3)$_3$]$^{2+}$ and *fac*(NH_3)-(−)$_{589}$[Co(CN)-(gly)(NH_3)$_3$]$^+$ by treatment with H_2O_2. Therefore, it is concluded that the isomers, *fac*(NH_3)-[Co(a)(gly)(NH_3)$_3$]$^{n+}$ (a=CN^-, NO_2^-, NCS^-, H_2O, or N_3^-), given in Figs. 1—5 have the same absolute configuration. The absolute configurations of the fast-moving isomers of the tacn complexes have been determined as shown in Fig. 6(a).[1,4] Since the CD spectra of (−)$_{589}$[Co(CN)-(gly)(NH_3)$_3$]$^+$, (+)$_{589}$[Co(NCS)(gly)(NH_3)$_3$]$^+$, and (−)$_{589}$[Co(N_3)(gly)(NH_3)$_3$]$^+$ resemble those of the corresponding tacn complexes, all the slow-moving isomers of the triammine complexes are predicted to have the absolute configuration illustrated in Fig. 6(b).

In order to confirm the above prediction, an X-ray analysis of *fac*(NH_3)-(−)$_{589}$[Co(NO_2)(gly)(NH_3)$_3$]ClO_4 was attempted.[4] The results of the analysis support the prediction. Since the glycinate ligand forms a chelate ring much less puckered than the 1,2-diamine chelate ring, the optical activity of *fac*(NH_3)-[Co(a)(gly)-(NH_3)$_3$]$^{n+}$ is considered to be mainly derived from a chiral arrangement of donor atoms.

Though the aqua complex exhibits a single Cotton peak in the first absorption band region, the remaining complexes exhibit two or three extrema in this region. The dominant peaks are observed at the lower frequency side of this region for the cyano and nitro complexes, and at the higher frequency side of this region for the isothiocyanato and azido complexes. However, the dominant Cotton peak is observed at *ca.* 20000 cm^{-1} in each complex.

Every complex has a rhombic ligand field in which the A_{1g}→T_{1g} transition component in octahedral parentage splits into three transition components: (xy)→(x^2—y^2), (yz)→(y^2—z^2), and (zx)→(z^2—x^2). An angular overlap model[10] predicts that the electronic transition at *ca.* 20000 cm^{-1} should be assigned to the transition component which arises in the plane containing the glycinato and two ammine ligands.[11] Therefore, it is suggested that a single chelate ring increases somewhat the rotatory strength of the Cotton peak associated with the electronic transition which arises in the plane containing a chelate ring. This finding is incompatible with the results obtained in the tris or bis(diamine) complexes such as [Co(en)(tn)(tmd)]$^{3+}$ [12] and *cis*-[Co(NH_3)$_2$(tn)$_2$]$^{3+}$.[13] In these complexes, the number of asymmetric pairs of

chelate rings is more important in determining the CD intensity than the number of chelate rings.

The [Co(a)(gly)(tacn)]$^{n+}$ complexes have the same chromophore as the present complexes.[1] An intense Cotton peak was characteristically observed at the highest frequency side of the first absorption band region in the tacn complexes. Such an intense peak is not always observed in the present complexes. It is noticeable that when the unidentate ligand a in [Co(a)-(gly)(NH_3)$_3$]$^{n+}$ is planar, the CD spectrum of the complex is somewhat different from that of the corresponding [Co(a)(gly)(tacn)]$^{n+}$ complex. On the other hand, when the unidentate is a linear ligator, the CD spectrum of the complex is similar to that of the tacn complex. Since the CD spectral patterns of the [Co(a)-(gly)(NH_3)$_3$]$^{n+}$ complexes, on the whole, resemble those of the corresponding [Co(a)(gly)(tacn)]$^{n+}$ complexes, it is concluded that the chiral arrangement of donor atoms is the main source of the optical activity in [Co(a)(gly)(tacn)]$^{n+}$. This is supported by the fact that the [Co(a)(gly)(tacn)]$^{n+}$ complexes give CD spectra similar to [Co(a)(NH_3)(H_2O)(tacn)]$^{(n+1)+}$ complexes (a=CN^-, NO_2^-, NCS^-, N_3^-, and Cl^-).[14]

The *fac*(NH_3)-(−)$_{589}$[Co(NO_2)(β-ala)(NH_3)$_3$]$^+$ complex exhibits a CD spectrum similar to that of the *fac*(NH_3)-(−)$_{589}$[Co(NO_2)(gly)(NH_3)$_3$]$^+$ complex, namely, a negative dominant peak is observed at *ca.* 20000 cm^{-1} and a positive minor peak at *ca.* 24000 cm^{-1}. The CD spectrum of *fac*(NH_3)-(+)$_{589}$[Co(H_2O)(β-ala)-(NH_3)$_3$]$^{2+}$ also resembles that of *fac*(NH_3)-(+)$_{589}$[Co-(H_2O)(gly)(NH_3)$_3$]$^{2+}$, a positive extremum being observed in the complexes. Therefore, each pair of the glycinato and β-alaninato complexes is considered to have the same absolute configuration, and the change

from the five-membered chelate ring to the six-membered one has little effect on the optical activity in the complexes. A similar situation is encountered in the $(-)_{589}$[Co(NO_2)(gly)(tacn)]$^+$ and $(-)_{589}$[Co(NO_2)(β-ala)(tacn)]$^+$ complexes, the same absolute configuration being assigned to these complexes.[2)]

Potentiometric and Calorimetric Studies on the Formation of Ethylenediamine Complexes of Nickel(II) Ion in Water and Dioxane-Water Mixtures

Shin-ichi Ishiguro, Yoshihiro Oka, and Hitoshi Ohtaki*
Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, 4259 Nagatsuta-cho, Midori-ku, Yokohama 227
(Received December 27, 1982)

Equilibria between ethylenediamine and protons or nickel(II) ions have been investigated at 25 °C by means of potentiometric and calorimetric titrations in water and in dioxane–water mixtures (the dioxane contents are 0.1 and 0.2 mole fractions, which correspond to 35.2 and 55.0%w/w, respectively) containing 3 mol dm^{-3} $LiClO_4$ as a constant ionic medium. Thermodynamic parameters ($\Delta G°$, $\Delta H°$, and $\Delta S°$) referring to the formation of the species HL^+, H_2L^{2+}, NiL^{2+}, NiL_2^{2+}, and NiL_3^{2+} (L denotes ethylenediamine) have been determined in the solutions. All the formation constants of the nickel(II)–ethylenediamine complexes increased with increasing dioxane content in the solvent mixtures, although the formation constants of the ethylenediammonium ions remained practically unchanged. On the other hand, enthalpies referring to the formation of the nickel(II)–ethylenediamine complexes became less negative, and thus entropies for the corresponding reactions increased remarkably with increasing dioxane content in the mixtures. The solvent effects on the thermodynamic parameters of the complex formation of nickel(II) ions with ethylenediamine are discussed in terms of enhancement of solvation of the complexes due to weakening of the hydrogen-bonded structure of the bulk water by the addition of dioxane.

We have reported solvent effects on hydrolytic reactions of metal ions in water and in dioxane–water mixtures.[1-3] The thermodynamic quantities of transfer of the hydrolyzed species from water to aqueous dioxane solutions have been discussed in terms of the change in the structures of the bulk solvent and in the second coordination sphere of metal ions of the aqua and hydroxo complexes. The Gibbs energy difference divided by P (*i.e.*, $\Delta G^t_{pq}/p$) for the reaction $qM^{2+} + pOH^- = M_q(OH)_p^{(2q-p)+}$ between the aqueous solution and an aqueous dioxane mixture was approximately independent of the composition (p,q) of the complex and the kind of the metal ion, where $\Delta G^t_{pq} = \Delta G°_{pq}(\text{mix}) - \Delta G°_{pq}(\text{aq}) = -RT \ln \{\beta_{pq}(\text{mix})/\beta_{pq}(\text{aq})\}$ and β_{pq} denotes the overall formation constant of the $M_q(OH)_p^{(2q-p)+}$ complex.

On the other hand, values of $\Delta H^t_{pq}/p$ for the enthalpy difference of the reaction between in water and in dioxane–water mixtures largely depended on the species, and thus the contribution of the enthalpy term to the formation of the hydroxo complexes was practically compensated for that of the $T\Delta S^t_{pq}/p$ term.

The results are summarized in the following ways:[1-3] The hydration of the hydroxo complexes is weak relative to that of the aqua complex and depends on the fractional charge on the metal ions within the complexes. The molar enthalpy of transfer of a hydroxo complex becomes less negative compared with that of the hydrated metal ion, the fractional charge of the metal ion being lower within the former complex than within the latter.

Having a much lower donor property than water, dioxane may hardly solvate primarily to metal ions in such dioxane–water mixtures as employed here (dioxane contents are 0.1 and 0.2 mole fractions, which correspond to 35.2 and 55.0%w/w, respectively), while it may destroy the hydrogen-bonded structure of the bulk water.[4] The formation of a strong solvation shell around a metal ion stabilizes the ion in water,[5] and the weakened hydrogen-bonded structure of the bulk water might cause the hydration of metal ions more favorable.[6]

The results obtained in the determination of the partial molar enthalpies of transfer of the hydroxo complexes of metal ions in the previous investigations[1-3] suggest that a complex with a larger fractional charge on the metal ion within the complex has a stronger hydration sphere than a complex in which the metal ion has a smaller fractional charge.

It is expected that the enthalpy of transfer of a complex is closely related to the solvation structure in the second coordination sphere of the complex, if the structure of the first coordination shell of the complex remains unchanged in the course of the transfer of the complex from water to a mixed solvent.

Considering that the charge of the complexes affects significantly the structure of the second solvation sphere, we employ ethylenediamine complexes of divalent metal ions keeping the total charge at +2, and the Gibbs energies and enthalpies of transfer of the complexes with different ligand numbers are compared. In the present investigation, the ethylenediamine complexes of nickel(II) ions were chosen on considering that the structures of some of the complexes were determined by means of X-ray diffraction in aqueous solutions.[7]

Experimental

Reagents. *Lithium perchlorate*, *lithium hydroxide*, and *perchloric acid* were prepared as described previously.[8] *Dioxane* was purified by an ordinary method.[8] *Ethylenediamine* of reagent grade was first dried by adding sodium hydroxide, and then further dried by using metallic sodium with refluxing overnight under a nitrogen atmosphere, and finally distilled. *Nickel(II) perchlorate* was prepared from nickel(II) oxide and perchloric acid, and the nickel(II) oxide had been prepared by decomposition of nickel(II) nitrate under an infrared lamp, followed by heating in an electric oven at 500 °C for 12 h. The nickel(II) nitrate was of reagent grade and recrystallyzed twice from water. The nickel(II) perchlorate thus prepared

was filtered through a G4 glass filter and then recrystallyzed twice from water. In order to prevent hydrolysis of nickel(II) ions, a small amount of perchloric acid was added to the stock solution and pH of the solution was adjusted to be about 3. The concentration of the free acid in the stock solution was determined coulometrically. The concentration of nickel(II) ions was determined gravimetrically by using dimethylglyoxime.

Measurements. All potentiometric and calorimetric titrations were performed in a room thermostated at (25.0± 0.5) °C. Throughout the measurements, $LiClO_4$ of 3 mol dm^{-3} was employed as a constant ionic medium.

Potentiometric Measurement. Potentiometric measurements were performed in a liquid paraffin bath controlled at (25.00± 0.02) °C, and pH of a test solution was determined by using a glass electrode in combination with an Ag–AgCl electrode as a reference. The measurements were carried out under an atmosphere of nitrogen gas which was equilibrated with solvent vapor. In each series of titrations the constant appearing in the Nernst equation, E_0, was first determined by means of Gran plots[9] by titrating 10 cm^3 of a perchloric acid solution of a known concentration with a lithium hydroxide solution in the constant ionic medium, the concentration of the lithium hydroxide solution being also known. Then, 10 cm^3 of a solution containing metal and hydrogen ions and ethylenediamine of known concentrations was added to the solution and titrations were continued with the same lithium hydroxide solution as used for the Gran-plot procedure until pH of the test solution reached about 10. Potentials at each point of measurements were related to the concentration of free hydrogen ions, h, by the Nernst equation, $E=E_0+59.15 \log h$, in the pH region where the liquid junction potential was negligible ($3 \leq pH \leq 10$). Concentrations of nickel(II) ions and ethylenediamine in the test solutions at the initial stage of titration ranged from 8—46 mmol dm^{-3} and 32—111 mmol dm^{-3}, respectively.

Calorimetric Measurement. In the course of calorimetric measurements, a test solution of 150 cm^3 was placed in a Dewar vessel immersed in a water bath thermostated at (25.000± 0.007) °C. Initial test solutions contained nickel(II) ions and ethylenediamine, the concentration of the latter being slightly larger than three times the concentration of the former. The concentration of hydrogen ions in the solutions was kept so low that the predominant complex species in the solutions was NiL_3^{2+} at the initial stage of the titration. Then a perchloric acid solution of *ca.* 0.4 mol dm^{-3} was used for the calorimetric titrations. At each step of the calorimetric titrations was added the perchloric acid solution of 0.6—1.6 cm^3 with the certainty of ±0.001 cm^3 to the test solution by using an automatic piston buret (Dosimat E535, Metrohm, Switzerland) The on-line calorimetric system fully automatically controlled by an electronic computer JEC-6 (JEOL, Tokyo) was employed throughout the titrations, details of the procedure having been described in previous papers.[2,3]

Analysis of Potentiometric and Calorimetric Data. At each point of titrations the total concentrations of nickel(II) (C_M) and hydrogen ions (C_H) and ethylenediamine (C_L) are related to concentrations of respective free species, m, h, and l, on the basis of the mass-balance and the mass action law:

$$C_M = \sum_p \sum_q \sum_r p\beta_{pqr} m^p h^q l^r, \quad (1)$$

$$C_H = \sum_p \sum_q \sum_r q\beta_{pqr} m^p h^q l^r - K_w h^{-1}, \quad (2)$$

$$C_L = \sum_p \sum_q \sum_r r\beta_{pqr} m^p h^q l^r, \quad (3)$$

where β_{pqr} and K_w stand for the overall formation constant of the complex $M_pH_qL_r^{(2p+q)+}$ and the autoprotolysis constant of the solvent, respectively (β_{000}, β_{100}, β_{010}, and β_{001} are defined to be unity). The formation constants were determined by the least-squares method, where the error square sum, $U=\sum\{(C_M-C_{M,calcd})^2+(C_H-C_{H,calcd})^2+(C_L-C_{L,calcd})^2\}$ was minimized by using the MINIQUAD program.[10] The protonation constants of ethylenediamine had been determined in advance of the equilibrium measurements of the complexes by separate experiments, and they were kept constant in the course of the least-squares refinement of the formation constants of the nickel(II)–ethylenediamine complexes.

On the basis of the formation constants of the complexes thus obtained, the calorimetric data were analyzed by using the program KALORI.[11] Concentrations of all species involved at each point of calorimetric titrations were calculated by using the formation constants determined. The total heat accompanying the formation of species involved in a solution of the volume V is given as follows:

$$Q = -V(\sum_p \sum_q \sum_r \beta_{pqr} \Delta H^\circ_{\beta pqr} m^p h^q l^r - K_w \Delta H^\circ_{Kw} h^{-1}), \quad (4)$$

where $\Delta H^\circ_{\beta pqr}$ and ΔH°_{Kw} denote the enthalpies pertaining to the reactions, $pNi^{2+}+qH^++rL=Ni_pH_qL_r^{(2p+q)+}$ and $H^++OH^-=H_2O$, respectively. The values of K_w and ΔH°_{Kw} had been determined in the solvent mixtures in the previous works.[1,2] Heat evolved (q) at the i-th titration point was compared with the calculated one, $q_{i,calcd}=Q_{i,calcd}-Q_{i-1,calcd}$, by taking into account suitable values of $\Delta H^\circ_{\beta pqr}$ for each species. The enthalpies were optimized by minimizing the error square sum, $U=\sum(q_i-q_{i,calcd})^2$. Enthalpies for the protonation reactions of ethylenediamine were determined in advance by separate experiments.

All calculations were carried out by using an M-180 computer at the Tokyo Institute of Technology.

Results and Discussion

In all the solvents employed potentiometric titration curves for the nickel(II)–ethylenediamine system were well explained by assuming the formation of three mononuclear complexes NiL^{2+}, NiL_2^{2+}, and NiL_3^{2+}, and no protonated nickel(II)–ethylenediamine complex was detected in the present experiment. Typical titration curves obtained in the aqueous solution are shown in Fig. 1, where pH values measured are plotted against X, the degree of neutralization of ethylenediammonium ions in the solution.

All the experimental points fell on the lines calculated (X_{calcd}) by Eq. 5 over the whole range of pH examined.

$$X_{calcd} = (2C_L + K_w h^{-1} - h - \sum_p \sum_q \sum_r q\beta_{pqr} m^p h^q l^r)/C_L \quad (5)$$

The formation constants of the complexes NiL_r^{2+} ($r=1$, 2, and 3) thus obtained are listed in Table 1, together with those of the protonated ethylenediamine species H_qL^{q+} ($q=1$ and 2).

In Fig. 2, typical results for the calorimetric titrations of the nickel(II)–ethylenediamine system in the aqueous solution are depicted, where the heat evolved q_i at the addition of the i-th portion of the titrant was plotted against the average ligand number n of the nickel(II)–ethylenediamine complexes in the solution. The solid lines are drawn by using the enthalpies of formation of each species finally obtained. The values of $\Delta H^\circ_{\beta pqr}$ thus evaluated are summarized in Table 2. At each

point of the titrations, heat of 9—22 J was evolved, and the calculated heat $q_{i,\,calcd}$ agreed with the experimental one q_i within 0.3 J.

Thermodynamic parameters for the successive reactions are defined as follows:

$$H^+ + H_{q-1}L^{(q-1)+} = H_qL^+;\ \Delta G^\circ_{0q1},\ \Delta H^\circ_{0q1},\ \text{and}\ \Delta S^\circ_{0q1}, \quad (6)$$

$$NiL_{r-1}^{2+} + L = NiL_r^{2+};\qquad \Delta G^\circ_{10r},\ \Delta H^\circ_{10r},\ \text{and}\ \Delta S^\circ_{10r}. \quad (7)$$

These quantities are tabulated in Table 3.

Solvent Effects on the Formation Constants. The formation constants of the nickel(II)–ethylenediamine complexes slightly increased with the dioxane content in the solvents, although the β_{0q1} values of ethylenediammonium ions were practically independent of the solvent composition (Table 1). The stepwise formation constants or the stepwise Gibbs energies of formation of each complex ($-\Delta G^\circ_{10r}$) linearly increased with the mole fraction of dioxane in the solvent and the increment of the $-\Delta G^\circ_{10r}$ values was practically independent of the number of ethylenediamine molecules within the complexes (see Table 3). As we will discuss in later sections, the increase in $-\Delta G^\circ_{10r}$ with the dioxane content in the solvents was attributed to the contribution of the entropy term, and the enthalpy for the complex formation played a role unfavorable for stabilizing the complexes in the mixed solvents.

The $-\Delta G^\circ_{102}$ value was smaller than $-\Delta G^\circ_{101}$ by about 6.9 kJ mol^{-1} in all the solvents examined here, and $-\Delta G^\circ_{103}$ was still smaller than $-\Delta G^\circ_{102}$ by *ca.* 11.4

kJ mol^{-1}. The differences between $-\Delta G^{\circ}_{101}$ and $-\Delta G^{\circ}_{102}$ and between $-\Delta G^{\circ}_{102}$ and $-\Delta G^{\circ}_{103}$ were independent of the composition of the solvents. This fact indicated that replacement of two water molecules with one ethylenediamine within the coordination sphere of nickel(II) ion became more and more difficult with successive steps, although the replacement became more and more exothermic as will be described later.

Solvent Effects on the Enthalpies. According to the X-ray diffraction measurements of the hexaaquanickel(II) ions[12] and the nickel(II)–ethylenediamine complexes[7] in aqueous solutions, the Ni–O bond length increased from 2.04 Å within the $[Ni(H_2O)_6]^{2+}$ ion to 2.10 Å within the $[Ni(H_2O)_2L_2]^{2+}$ complex with the increase in the number of ethylenediamine molecules coordinated. The lengthening of the Ni–O bond indicated weakening of the bond due, perhaps, to the electron donation from the nitrogen atoms within the ethylenediamine molecules to the central metal ion by which the fractional charge on the nickel(II) atom might decrease. Although no structural data have been reported for the $Ni(H_2O)_4L^{2+}$ complex, we can expect such an elongation of the Ni–O bond within the Ni-$(H_2O)_4L^{2+}$ complex when an ethylenediamine molecule coordinates to an aquanickel(II) ion. Therefore, the replacement of water molecules within the $[Ni(H_2O)_{6-2r}L_r]^{2+}$ complex ($0\leq r\leq 3$) needs less and less energies with the increase in the number of ethylenediamine molecules r within the complex.

The Ni–N bond lengths are 2.10 Å and 2.20 Å within the $[Ni(H_2O)_2L_2]^{2+}$ and $[NiL_3]^{2+}$ complexes, respectively,[7] and therefore, the Ni–N bond may be weaker in the latter than in the former. Thus, we can expect that both Ni–O and Ni–N bonds more and more weaken with the introduction of ethylenediamine molecules to the coordination sphere of nickel(II) ion.

In spite of the weakening of the Ni–N bond in the $[Ni(H_2O)_{6-2r}L_r]^{2+}$ complex with increasing r, ΔH°_{10r} in the aqueous solution became more negative. This suggests that the decrease of the Ni–O bond energy within the $[Ni(H_2O)_{6-2r}L_r]^{2+}$ complex may be more enhanced than that of the Ni–N bond by the ligand substitution of two moles of H_2O with one mole of ethylenediamine.

From the enthalpic point of view, the formation of nickel(II)–ethylenediamine complexes became less favorable in a dioxane–water mixture than in water, although the decrease in the Gibbs energies at each successive complexation reaction was more pronounced in mixed solvents than in water.

We can assume that the bond lengths within the complexes are not appreciably changed when the complexes are transferred from water to a dioxane–water mixture, because no change has been observed in the UV and visible absorption spectra of the complexes in solutions with different dioxane contents. Invariable $\Delta\Delta G^{\circ}_{10r}$ and $\Delta\Delta H^{\circ}_{10r}$ values between the successive stages of formation of a given pair of complexes in two different solutions may give an indirect support for the invariable structures of the complexes concerned. Therefore, the changes in the enthalpy of the complex formation reactions in different solvents, as well as entropy changes, should be attributed to the structural changes in the second coordination sphere of the complexes, in which solvent molecules interact with the ligand molecules coordinated to the central nickel(II) ion.

It is well accepted that water molecules interact each other through hydrogen bonds in the bulk water and that the hydrogen-bonded water structure is broken by the addition of dioxane. In the ionic medium

employed here, many water molecules are hydrated to the medium salt, but still there are some water molecules having a bulk-like structure in the solution.

When nickel(II) ions are brought into the aqueous solution, the nickel(II) ions form the hexaaquanickel(II) complex which can still be solvated with water molecules in their second coordination sphere. Nickel(II)–ethylenediamine complexes, the first coordination shell of which are filled with ethylenediamine and water molecules (except for the NiL_3^{2+} complex), can be also solvated with water molecules in the aqueous solution. The second-sphere hydration of the complexes may be weak and not highly ordered, and therefore, the interaction between the ligand molecules in the first coordination sphere and water molecules in the second solvation shell may be affected rather sensitively by the change in the hydrogen-bonded structure of the bulk water. The more the hydrogen-bonded structure of the bulk water is broken by the addition of dioxane, the easier the construction of the second hydration shell is, and thus, the more negative the enthalpy of hydration in the second sphere of the complex should be, provided that the structure of the first coordination shell of the complex is not practically affected by the change in the bulk structure of water.

The enthalpies of each successive formation of the complexes became less negative with increasing dioxane content in the solvent (see Table 3). This fact suggests that the enthalpy difference of a complex $[Ni(H_2O)_{6-2r}L_r]^{2+}$ in two different solvents is larger than that of a complex $[Ni(H_2O)_{6-2(r+1)}L_{r+1}]^{2+}$.

In order to discuss the enthalpy changes of the complex formation reactions in different solvents, we estimated enthalpies of transfer of each complex ion from water to the dioxane–water mixtures employed in the present work.

Underdown *et al.*[13] have reported that the enthalpy of transfer of nickel(II) ion from water to a dioxane–water mixture was positive (endothermic) when the dioxane content in the mixture was lower than 0.04 mole fraction, but decreased to tend to be negative (exothermic) with an increase in the dioxane concentration. In an aqueous mixture with the dioxane content larger than 0.06 mole fraction, the enthalpy of transfer of nickel(II) ion from water to the mixture became negative. This fact indicates that the solvation of nickel(II) ion is enhanced in the aqueous dioxane mixtures with the dioxane content higher than 0.06 mole fraction.

The solvation of ethylenediamine does not seem to change significantly when dioxane is added to water. The heats of solution of ethylenediamine in water and in a dioxane–water mixture containing 0.2 mole fraction dioxane, both solutions having 3 mol dm^{-3} $LiClO_4$, were 34.5 kJ mol^{-1} and 34.8 kJ mol^{-1}, respectively.[14] Therefore, the enthalpy of transfer of ethylenediamine from water to the dioxane–water mixture was practically zero.

The difference $\Delta H^\circ_{\beta 10r}(\text{mix}) - \Delta H^\circ_{\beta 10r}(\text{aq})$ can be separated into contributions of each species concerned as follows:

$$\begin{aligned}
&\Delta H^\circ_{\beta 10r}(\text{mix}) - \Delta H^\circ_{\beta 10r}(\text{aq}) \\
&= \{\Delta H^\circ_{\text{sv.mix}}(NiL_r^{2+}) - \Delta H^\circ_{\text{sv.aq}}(NiL_r^{2+})\} \\
&\quad - \{\Delta H^\circ_{\text{sv.mix}}(Ni^{2+}) - \Delta H^\circ_{\text{sv.aq}}(Ni^{2+})\} \\
&\quad - r\{\Delta H^\circ_{\text{sv.mix}}(L) - \Delta H^\circ_{\text{sv.aq}}(L)\} \\
&= \Delta H^\circ_{\text{tr}}(NiL_r^{2+}) - \Delta H^\circ_{\text{tr}}(Ni^{2+}) - r\Delta H^\circ_{\text{tr}}(L), \qquad (8)
\end{aligned}$$

where $\Delta H^\circ_{\text{sv}}(j)$ and $\Delta H^\circ_{\text{tr}}(j)$ stand for the enthalpies of solvation and of transfer of species j, respectively. Here we can reasonably assume that $\Delta H^\circ_{\text{tr}}(L)$ is zero. $\Delta H^\circ_{\text{tr}}(Ni^{2+})$ can be estimated by inter- and extrapolating the values reported by Underdown *et al.*[13] to 0.1 and 0.2 mole fraction dioxane–water mixtures, respectively. Therefore, by using experimental values given in Table 2 for $\Delta H^\circ_{\beta 10r}$ of each complex formation reaction, we can evaluate the values of $\Delta H^\circ_{\text{tr}}(NiL_r^{2+})$ for the various complexes. The values thus estimated are tabulated in Table 4. The enthalpies of transfer of all the species from water to the aqueous dioxane mixtures are negative, and the values are more negative in the mixtures with the higher dioxane content. The result implies that the second-sphere solvation of the nickel(II)–ethylenediamine complexes, as well as the aquanickel(II) ion, is enhanced in the dioxane–water mixtures, but the degree of the enhancement of the second-sphere solvation is less in the complexes than in the aquanickel(II) ion.

This result indicates that the enhancement of the second-sphere solvation of the complexes and the aquanickel(II) ion may be due to a less energy needed for breaking the water structure to produce non-hydrogen-bonded water molecules which solvate the complexes, and the hydrogen-bonding of water molecules in the second-coordination sphere may be stronger in the hexaaquanickel(II) ion than in the nickel(II)–ethylenediamine complexes.

The enthalpies for the formation of ethylenediammonium ions (HL^+ and H_2L^{2+}) slightly increased with an increase in the dioxane content of the solvents, and the increment of the ΔH°_{0q1} values was practically compensated for an increase in the ΔS°_{0q1} values, which led to the ΔG°_{0q1} values practically independent of the solvent composition (see Table 3).

Solvent Effects on the Entropies. Entropies of the reaction, $[Ni(H_2O)_{6-2r}L_r]^{2+} + L = [Ni(H_2O)_{6-2(r+1)}L_{r+1}]^{2+} + 2H_2O$, decreased with an increase in the number of ethylenediamine molecules r within the complex, as reported previously by many authors. On the other hand, in the formation of a given complex, the entropies increased remarkably with increasing dioxane content

TABLE 4. ENTHALPIES OF TRANSFER, $\Delta H^\circ_{\text{tr}}$/kJ mol^{-1}, OF THE AQUANICKEL(II) ION AND NICKEL(II) –ETHYLENEDIAMINE COMPLEXES FROM WATER TO DIOXANE–WATER MIXTURES[a]

Dioxane content mole fraction	$-\Delta H^\circ_{\text{tr}}$			
	Ni^{2+}	NiL^{2+}	NiL_2^{2+}	NiL_3^{2+}
0.1	8.0[b]	7.0	4.4	1.0
0.2	24.0[c]	21.5	17.5	12.3

a) Values for NiL_r^{2+} complexes were calculated by assuming $\Delta H^\circ_{\text{tr}}(L) = 0$. b) Interporated from the values in Ref. 13. c) Extraporated from the values in Ref. 13.

in the solutions (Table 3). The increase in the entropies for the stepwise complex formations with an increase in the dioxane content in the solution is most remarkable in the formation of the highest complex NiL_3^{2+}.

The formation of the $[Ni(H_2O)_{6-2(r+1)}L_{r+1}]^{2+}$ complex is accompanied by the dehydration of two moles of water in the first coodination sphere of the $[Ni(H_2O)_{6-2r}L_r]^{2+}$ complex. The number of water molecules expelled from the whole coordination shell of the complex at the introduction of one ethylenediamine molecule may be larger than 2, because dehydration of the ethylenediamine molecule and from the second coordination sphere of the complex may also be expected in the complex formation reaction. The dehydration will cause the increase in entropy, although a part of the entropy increase in the dehydration process may be cancelled out by a decrease in entropy due to combination of an ethylenediamine molecule with the metal ion.

As we have discussed in the previous section, the hydrogen-bonded structure of water is broken by the addition of dioxane, and therefore, in the dioxane–water mixture water molecules can behave more freely compared with those in the aqueous solution.

When water molecules are liberated from the coordination sphere of a nickel(II) ion by the chelate formation with ethylenediamine molecules, the water molecules can behave more freely in the bulk phase of a dioxane–water mixed solvent than in an aqueous solution. Therefore, in the dehydration process accompanying the chelate formation with ethylenediamine, the entropy of the reaction becomes more positive in a dioxane–water mixture than in water.

The entropies for the protonation of ethylenediamine increased with increasing dioxane content in the mixture, although the increase was not remarkable compared with that for the formation of any of the nickel(II)–ethylenediamine complexes in the same solvents. In the course of the protonation reaction of ethylenediamine, $L+qH_3O^+=LH_q^{q+}+qH_2O$, the liberated water molecules might solvate the protons at the amino groups within the ethylenediammonium ion formed, so that the entropy gain by the liberation of water molecules from H_3O^+ may be cancelled out by the combination of the water molecules with the NH_3^+ groups formed.

The work has partially been supported by the Grant-in-Aid for Scientific Research No. 57470054 from the Ministry of Education, Science and Culture and by the Asahi Glass Foundation for Industrial Technology.

Reactivity of Aromatic *o*-Hydroxy Oximes. I. Synthesis and Aminolysis of Acylglycine Esters of Aromatic *o*-Hydroxy Oximes

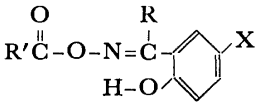
Ikuo HAYASHI,* Keizo OGIHARA, and Kiyoshi SHIMIZU
Research and Development Laboratory of Nitto Boseki Co., Ltd., Fukuyama, Koriyama, Fukushima 963
(Received July 3, 1982)

Active esters (**1**) of glycine with *o*-hydroxybenzaldehyde oxime, *o*-hydroxyacetophenone oxime, *o*-hydroxybenzophenone oxime, and their 5-Cl and 5-NO_2 derivatives were prepared by several methods. For aminolysis with benzylamine, esters **1** show higher reactivity than similar esters containing no hydroxyl group in the ortho position. It is suggested that esters **1** forms an intramolecular hydrogen bond between the hydrogen of the hydroxyl group at the ortho position and the hydroxyimino nitrogen so as to have its carbonyl group activated for the aminolysis; this mechanism of activation seems to be a sort of "intramolecular acid-catalysis." Among the series of esters **1**, esters of *o*-hydroxybenzaldehyde oxime and its 5-Cl and 5-NO_2 derivatives are most reactive in the aminolysis. The reactivity of esters **1** is also discussed in relation to pK_a values of aromatic *o*-hydroxy oximes.

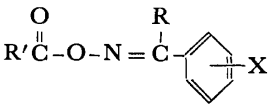
In the coupling reaction of acylamino acid with amino acid alkyl esters, various oximes are used as their alcoholic components.[1-7] As compared with esters of *p*-nitrophenol, pentachlorophenol, and *N*-hydroxysuccinimide, even the most active esters of these oximes show rather a low reactivity for the condensation with amino component.

Losse *et al.*[2] reported that esters of *m*-nitroacetophenone oxime react faster with amino acid alkyl esters than those of acetophenone oxime. But the reactivity of the former is still lower than that of *p*-nitrophenol ester for the aminolysis. Itoh[4] showed that oximes of type $HO\text{-}N{=}C\langle^{CN}_{COR}$ (R=OEt, NH_2) are effective in peptide synthesis.

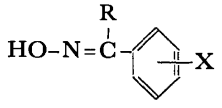
A general consideration drawn from all the above cases is that an ester is activated by introduction of an electron-withdrawing substituent to its alcoholic component. According to this general consideration, it should be expected that introduction of electron-withdrawing substituent X such as NO_2 or CN to an alcoholic component (oximes **3**) is to increase the reactivity, whereas X=OH or OR is to have a deactivating effect.



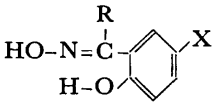
1



2

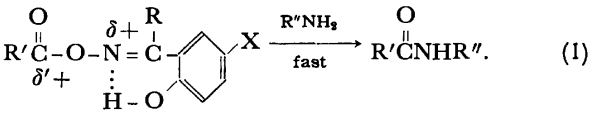


3



4

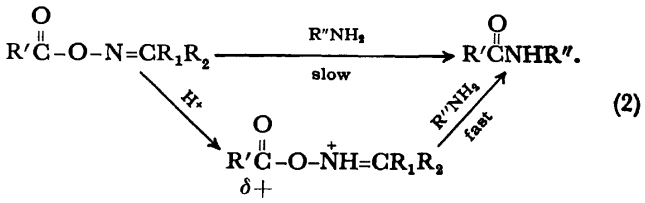
When oximes containing hydroxyl group at the ortho position in a benzene nucleus were used as active esters, we found that reactions with benzylamine were accelerated greatly. This unexpected result let us to conclude that the activation of **1** was a consequence of hydrogen bond formation between the phenolic hydrogen atom and the spacially adjacent unshared electron pair of the nitrogen atom in the hydroxyimino group. Such interaction induces the electron density at the nitrogen atom to decrease so that esters **1** may show a high reactivity:



(1)

1

It is known that addition[5-8] of a weak acid (acetic or formic acid) as catalyst to oxime esters will cause rapid and smooth condensation:



(2)

The mechanism of activation for our system corresponds to the presence of weak acids.

From the consideration descrived above, we prepared esters **1** from *N*-(benzyloxycarbonyl)glycine (Z–Gly) and various oximes of *o*-hydroxybenzaldehyde, *o*-hydroxyacetophenone, *o*-hydroxybenzophenone, and their 5-Cl and 5-NO_2 derivatives, and measured rates of aminolysis with benzylamine in order to compare reactivities of esters **1** and **2**.

We also discuss the reactivity of aminolysis of **1** in connection with pK_a values of aromatic *o*-hydroxy oximes **4**.

Results and Discussion

All aromatic *o*-hydroxy oximes **4** were of (*E*) configuration and are summarized in Table 1 together with oximes **3**.

Acylated Position of Aromatic o-*Hydroxy Oximes* **4**.
There are many papers on the aminolysis of oxime esters of acylamino acid. But there is no study on the reaction of esters of oxime **4** except for a report of Przybylski and Miecznikowska[19] on a coupling method using dicyclohexylcarbodiimide (DCC) and *o*-hydroxybenzladehyde oxime as an "Eintopf" procedure. It is of interest which position is esterified by acylamino acid, phenolic hydroxyl, or hydroxyimino group in the case of **4** with a bifunctional nature. There have been many reports[9,10,13,20-24] on the acetylation of these oximes.

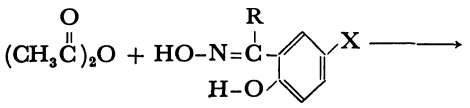
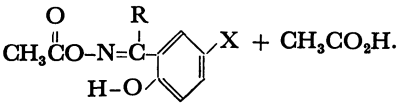
In the reaction of aromatic o-hydroxy oximes **4** with acetic anhydride under mild conditions, compounds **5** are usually obtained:



4



5

We tried to condense oximes **4** with acetic acid by a direct condensation using DCC and obtained the same products as in the reaction with acetic anhydride.

Esters **1** and **2** of Z-Gly with oximes **4** and **3** have been prepared (A) by direct condensation using DCC, (B) with carbonic carboxylic anhydride, or (C) with acid chloride. Representatives of them are summarized in Table 2.

Rate of Aminolysis. Effect on o-*Hydroxyl Group*: To compare reactivities of esters **1** and **2**, we measured their rates of aminolysis with benzylamine in THF at 30 °C. The results are shown in Fig. 1.

All aromatic o-hydroxy oxime esters **1** have a higher reactivity than oxime esters **2** containing no o-hydroxyl group. It is demonstrated that the existence of o-hydroxyl group greatly accelerates the rate of aminolysis.

We concluded that the activation of **1** is caused by hydrogen bond formation[9—13,25)] between the phenolic hydrogen atom and the spacially adjacent lone-pair electrons of the nitrogen atom in hydroxyimino group, and that the electron-withdrawing nature of aromatic

proximity, in which **1** assumes an (*E*) configuration. Therefore, the aminolysis of **1** proceeds faster than those of **2**.

Although a considerable number of acylamino acid active esters have been prepared since the first application of *p*-nitrophenyl ester to peptide synthesis, the new method of activation adopted in this study has not so far been presented. Typical active esters comprise electron-withdrawing groups. The reason for the high reactivity of esters **1** in spite of the existence of the electron-donating hydroxyl group, is that the particular configuration of oximes **4** favors hydrogen bond formation so as to activate **1** *via* the mechanism of "intramolecular acid-catalysis."

As shown in Fig. 1, the reactivity of oxime esters having different substituents R decreases in the order;

$$H > C_6H_5 > CH_3. \quad (3)$$

The effect of phenyl group on the reactivity is less than that of hydrogen. Both the phenyl groups in this molecule can not be coplanar owing to the bulkiness of substituent $R=C_6H_5$. This noncoplanarity[10,12] of aromatic rings for HOHBP and its 5-Cl and 5-NO_2 derivatives (all abbreviations shown in Table 1) results in two "mutually independent" conjugate systems, with reduction in the electron-withdrawing effect of the phenyl substituent.

Comparison between the Effects of o*-Hydroxyl Group and of Electron-withdrawing Substituents X for Oximes 3*: Amino-

lysis rates for various substituents (X=Cl and NO_2) are shown in Fig. 2.

Z-Gly-OHBA and Z-Gly-OHAP have higher reactivity than the series of oxime esters **2**:

$$\text{Z-Gly-OHBA} > \text{Z-Gly-OBA-}m\text{NO}_2 > \text{Z-Gly-OBA-}p\text{Cl}, \quad (4)$$

$$\text{Z-Gly-OHAP} > \text{Z-Gly-OAP-}m\text{NO}_2 > \text{Z-Gly-OAP-}p\text{Cl}. \quad (5)$$

It is found that the introduction of hydroxyl group to the ortho position of aromatic oximes is superior in activating effect to the substitution of NO_2, and much more to that of Cl. It is worthwhile to point out that the activation of nonbonding interaction owing to hydrogen bonding (and thus "intramolecular acid-catalysis") is more effective than the activation through a conjugate system provided by the electron-withdrawing group such as NO_2.

Effect of Substituent X in Aromatic o-Hydroxy Oximes **4**: The effect of substituent X on the aminolysis rate is illustrated in Fig. 3, including Z-Gly-ONp for comparison. The reactivities of the active esters from HOHBA-5NO_2, HOHBA-5Cl, or HOHBP-5NO_2 are nearly equal to that of *p*-nitrophenol.

The order of reactivity is

$$NO_2 > Cl > H. \quad (6)$$

Typical examples may be provided with esters of HOHBA and its 5-NO_2 and 5-Cl derivatives. Although no series of HOHAP and HOHBP are shown in Fig. 3, the same tendency can be found to exist from a comparison with Fig. 1. This result may be understood in terms of the inductive effect that the substitution of NO_2 or Cl at the 5-position to the hydroxyimino group in an aromatic nucleus will reduce strongly the electron density on the phenolic oxygen in combination with the hydrogen bond favorable to the *o*-hydroxyl group. Therefore, the ease of the protonation of the hydroxyl group to the nitrogen atom of the hydroxyimino group increases extremely.

Relation between pK_a *values of Oximes* **3** *and* **4** *and the Reactivity for the Aminolysis of Their Active Esters.* The pK_a values of the oximes prepared are listed in Table 3.

Aromatic *o*-hydroxy oximes **4** exhibit stronger acidity than the corresponding oximes **3** containing no *o*-hydroxyl groups. Regardless of the character of R, the order of pK_a values with respect to X in **4** is

$$NO_2 < Cl < H. \quad (7)$$

The order of pK_a values with respect to R is

$$H < C_6H_5 < CH_3. \quad (8)$$

It is demonstrated that the reactivity order for the aminolysis of esters **1** is parallel to the order of pK_a values of corresponding oximes **4**.

It is well known that only the phenolic proton in **4** dissociates.[9,11,12] Therefore, the proton transfer to the hydroxyimino nitrogen has enhanced the acidity as a result of an intramolecular hydrogen bond formation between the phenolic proton and the hydroxyimino nitrogen.

When pK_a values are subject to a detailed check, no good relations are always found for **4** having X=Cl or H between the order of rate of aminolysis and that of pK_a values given by relation 8.

Patel and Patel[11] reported that the electronegative substituent Cl will reduce the electron density of HOHBP-5Cl and thus facilitate the dissociation of phenolic proton. But they[11] also postulated that the Cl would act also as a p-π donor. The irregularity found in pK_a values may be explained on their conclusion and postulate.

Experimental

All melting points were uncorrected. IR spectra were recorded on a JASCO A-102 spectrophotometer. The homogeneity of substances and the purity of isomers were checked by TLC using silica gel (Kiesel Gel 60 F254, Merck) and various developing solvent systems: R_{f2}, $CHCl_3$–MeOH–AcOH (95 : 5 : 3); R_{f4}, $CHCl_3$–MeOH–benzene (95 : 5 : 3); R_{f5}, $CHCl_3$–MeOH–ethyl acetate (95 : 5 : 3); R_{f6}, $CHCl_3$–MeOH–petroleum ether (95 : 5 : 3); R_{f8}, $CHCl_3$–MeOH–petroleum ether (95 : 3 : 3); R_{f9}, $CHCl_3$–MeOH–AcOH (95 : 2 : 3); R_{f13}, $CHCl_3$–MeOH (100 : 1). R_f spots were made visible with iodine vapor or UV light for all oximes and demonstrated by the combination of hydrobromic acid and 0.2% ninhydrin in acetone for Z-Gly derivatives.

Starting Materials. HOBA,[16] HOAP,[16] HOBP,[16] HOAP-*p*Cl,[16] HOBA-*p*Cl,[16] HOBA-*m*NO_2,[16] and HOHBA[16] were prepared in aqueous EtOH by the reaction of corresponding aldehydes or ketones with hydroxylamine hydrochloride and sodium carbonate (or sodium acetate) according to the usual method.[14] Aromatic *o*-hydroxy ketones, *o*-hydroxyacetophenone,[26] 5-chloro-2-hydroxyacetophenone,[26] *o*-hydroxybenzophenone,[27] and 5-chloro-2-hydroxybenzophenone[28] were prepared by Fries rearrangement of the corresponding phenyl esters in the presence of anhydrous aluminium chloride

Table 3. pK_a values of oximes **3** and **4**

HONp[a]					

a) HONp : *p*-Nitrophenol.

and then their oximes were prepared according to the usual method,[14] except for HOHBP and its derivatives which were prepared as described below. 2-Hydroxy-5-nitrobenzaldehyde[29] and 2-hydroxy-5-nitroacetophenone[30] were prepared by nitration from corresponding parent compounds and their oximes were obtained according to the usual method.[14]

HOHBP: Both isomers were prepared by the method of Kohler and Bruce.[15] We obtained products of mp 139—140 °C for (*E*) and 132—133 °C for (*Z*) isomer. The mp values of the (*E*) and (*Z*) isomers of HOHBP prepared here did not agree with those given by Kohler and Bruce,[15] who reported 142—143 °C for the (*E*) and 141—142 °C for the (*Z*) isomer. We separated a mixture of (*E*) and (*Z*) isomers prepared by the usual method.[14] TLC values were as follows: $R_{f13}=0.54$ for the (*E*), 0.22 for the (*Z*), and 0.54+0.22 for the mixture. These values are identical with those obtained by the method of Kohler and Bruce. The magnitude of R_f values for the (*E*) isomer was greater than that of the (*Z*) isomer. The same tendency was also observed by Ashbrook.[32] We used the (*E*) isomer in this study.

HOHBP-5Cl: This compound was also prepared essentially as described above: mp 139—141 °C (Lit,[18] 144—144.5 °C).

HOHBP-5NO$_2$: To a suspension of 2-chloro-5-nitrobenzoic acid (50.0 g, 0.248 mol) in benzene (250 ml), phosphorus pentachloride (51.6 g, 0.248 mol) was added at room temperature with stirring. The mixture was then refluxed for 3 h. After the evolution of HCl had ceased, the excess of solvent was evaporated, leaving a viscous oil. 2-Chloro-5-nitrobenzoyl chloride was obtained from the oil: 154—155 °C (7.5 mmHg) 50.8 g (93.1%).

The acid chloride (52.9 g, 0.24 mol) was dissolved in dry benzene (300 ml) and then anhydrous aluminium chloride (48.1 g, 0.36 mol) was added. After refluxing for 1 h the mixture was cooled and poured into a mixture of cracked ice (500 ml) and concd HCl (180 ml), then the benzene layer was separated and the aqueous layer was extracted twice with benzene (200 ml). The benzene solution was washed twice with 2 mol dm^{-3} NaOH and water, and dried over magnesium sulfate. The solvent was removed by distillation, and a recrystallization of the resulting solid from EtOH gave 2-chloro-5-nitrobenzophenone: 53.7 g (85.4%), mp 83—85 °C.

Found: C, 59.70; H, 3.07; N, 5.38%. Calcd for $C_{13}H_8NO_3Cl$: C, 59.67; H, 3.08; N, 5.35%.

A mixture of 2-chloro-5-nitrobenzophenone (30.0 g, 0.115 mol), water (300 ml), and KOH (9.70 g, 0.128 mol) was charged in an autoclave. After heating at 150—160 °C with stirring for 5 h, the clear solution was cooled and then strongly acidified by adding concd HCl. The resulting solid was filtered off and washed with water. A recrystallization of the solid from EtOH gave 2-hydroxy-5-nitrobenzophenone: 15.7 g (56.1%), mp 122—123 °C (lit,[31] 124—124.5 °C).

HOHBP-5NO$_2$ was prepared essentially as described by Kohler and Bruce[15] (and, in part, Blatt and Russell[9]) for HOHBP. 2-Hydroxy-5-nitrozophenone (25.0 g, 0.103 mol) was added to 40% KOH (150 ml). To this mixture was added hydroxylamine hydrochloride (50.0 g, 0.72 mol) at room temperature with stirring. After 5 h the solution was acidified with concd HCl and the precipitated pale yellow solid was collected and washed successively with water and with a small amount of 50% MeOH. Recrystallization of the solid from benzene and a small amount of petroleum ether gave the product: 17.1 g (64.4%), mp 193—196 °C, $R_{f8}=0.78$.

Found: C, 60.38; H, 3.85; N, 10.76%. Calcd for $C_{13}H_{10}N_2O_4$: C, 60.47; H, 3.90; N, 10.85%.

Preparation of Active Esters 1 and 2. Typical example are as follows.

Method (A) Z-Gly-OHAP-5NO$_2$: Z-Gly (9.40 g, 44.9 mmol) and HOHAP-5NO$_2$ (8.80 g, 44.9 mmol) were dissolved in DMF (100 ml) and DCC (9.70 g, 47.1 mmol) was added to the solution below 0 °C with stirring. After a night the *N,N'*-dicyclohexylurea was filtered off and ethyl acetate and water were added to the filtrate. The organic layer was separated, washed with water, and dried. Evaporation of the dried solution gave a solid. This material was recrystallized from ethyl acetate–petroleum ether to give 15.1 g (87.0%), mp 125—128 °C, $R_{f6}=0.87$.

Found: C, 56.15; H, 4.56: N, 10.87%. Calcd for $C_{18}H_{17}N_3O_7$: C, 55.82; H, 4.42: N, 10.85%.

Method (B) Z-Gly-OHAP: To a solution of Z-Gly (4.18 g, 20 mmol) and triethylamine (2.8 ml, 20 mmol) in dioxane (50 ml) below −10 °C was added dropwise (over a period of 1 min) isobutyl chloroformate (2.73 g, 20 mmol) with stirring. After 5 min, HOHAP (3.02 g, 20 mmol) in dioxane (20 ml) was added. After 1 h the mixture was brought to room temperature and stirred overnight. Ethyl acetate (200 ml) and water (200 ml) was added to the mixture. The organic layer was separated, and the solution was washed with 1 mol dm^{-3} NaHCO$_3$ and water, and dried. The solvent was evaporated and the crude solid was recrystallized from ethyl acetate–petroleum ether: 3.75 g (55.0%); mp 109—110 °C; $R_{f9}=0.70$.

Found: C, 62.05; H, 5.02; N, 8.53%. Calcd for $C_{17}H_{16}N_2O_5$: C, 62.19; H, 4.91; N, 8.53%. The same material was also prepared from (Z-Gly)$_2$O and HOHAP.

Method (C) Z-Gly-OBA: To a solution of Z-Gly-Cl[33] (11.38 g, 50 mmol) in THF (120 ml) below −10 °C was added dropwise over a period of 10 min a solution of HOBA (6.06g, 50 mmol) in THF (50 ml) and triethylamine (7.0 ml, 50 mmol) with stirring. After being kept for 10 min below −10 °C, the mixture was allowed to stand overnight and then was worked up as in Method (B): 15.6 g (36.0%); mp 100—102 °C; $R_{f5}=0.76$.

Found: C, 65.04; H, 5.19: N, 9.09%. Calcd for $C_{17}H_{16}N_2O_4$: C, 65.38; H, 5.16; N, 8.97%.

Determination of the Rate of Aminolysis. In to a 50 ml volumetric flask was put a solution containing 2.0 mmol of an appropriate derivative in distilled THF. To the solution having been heated and thermostated (20±0.1 °C) was added a thermostated solution of 4.0 mmol of benzylamine in distilled THF (50 ml). At predetermined time intervals, a 10 ml aliquot of the solution was withdrawn and diluted with 40 ml of distilled water. The excess of benzylamine was back-titrated with 0.1 mol dm^{-3} HCl with Bromocresol Green solution as the indicator.[1] Blank tests showed that any presence of free oxime did not influence the accuracy of titration. Each point in Figs. 1—3 represents a mean of three to six values.

The Acetyl Derivative of HOHBA. This compound was obtained by treating the oxime with (a) an excess of acetic anhydride (Ac$_2$O) or (b) DCC. *(a)*: Ac$_2$O (75 ml) was added to the oxime. The mixture was warmed for 30 min. The solid acetyl derivative formed by stirring with an excess of cold water was collected and washed with water. Pale pink crystals (10.25 g, 57.2%) were obtained by crystallization from benzene–petroleum ether: mp 69—71 °C (lit,[20] 69 °C).

Found: C, 60.33; H, 5.11; N, 7.94%. Calcd for $C_9H_9NO_3$: C, 60.33; H, 5.06; N, 7.82%.

(b): AcOH (6.01 g, 100 mmol) and HOHBA (6.86 g, 50 mmol) were dissolved in THF (80 ml) and DCC (11.3 g, 55 mmol) was added to the solution below 0 °C with stirring. The mixture was stirred for 24 h. *N,N'*-Dicyclohexylurea was filtered off and the filtrate was diluted with ethyl acetate (200 ml) and water (200 ml). The organic layer was separated and treated as in Method (B). Recrystallization of the

residue from benzene–petroleum ether gave the acetyl ester: 5.06 g (53.8%); mp 69 °C.

Found: C, 60.38; H, 5.18; N, 7.88%. Calcd for $C_9H_9NO_3$: C, 60.33; H, 5.06; N, 7.82%.

The authors are indebted to Mr. Toshiyuki Takabayashi of our laboratory for elemental analysis. We are also grateful to the Head of our laboratory, Dr. Susumu Harada, for his helpful discussion and encouragement to this work.

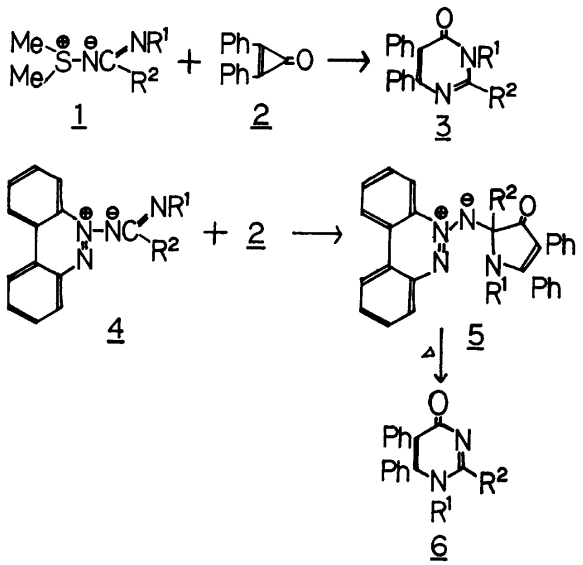
The Cycloaddition Reaction of *N*-Imidoyl Sulfoximides with Diphenylcyclopropenone to Yield Pyrimidinone or Pyrrolinone Derivatives

Hiroshi YOSHIDA,* Shingo SOGAME, Yasunori TAKISHITA, and Tsuyoshi OGATA
Department of Applied Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu 432
(Received September 29, 1982)

N-Imidoyl sulfoximide (**7**) reacted with diphenylcyclopropenone (**2**) at 130 °C to yield a mixture of 1,2-disubstituted 5,6-diphenyl-4(1*H*)-pyrimidinone (**6**) and *N*-(4-oxo-2-pyrrolin-5-yl)sulfoximide (**10**), which might be formed by [3+3] and [2+3] cycloaddition reactions between **2** and **7**. The yields of **6** and **10** depended on the electronic and steric effects of the substituents of **7**.

Diphenylcyclopropenone (**2**) and its analogs react with a variety of ylides and imides to give heterocycles.[1] *N*-Imidoyl sulfimides (**1**)[2] reacts with **2** to yield pyrimidine (**3**). In contrast, the reaction of benzo[*c*]cinnolium imide (**4**) with **2** gives the adduct (**5**),[3] which on pyrolysis yields the isomeric pyrimidine (**6**) (Scheme 1).

In a continuation of our earlier works of the chemical and physical properties of *N*-, *P*-, and *S*-ylides and imides substituted with C=S or C=N groups,[4] we have found an easy route for the preparation of the new *N*-imidoyl sulfoximide (**7**). In this paper, the reaction of **7** with **2** was carried out in order to compare it with those of **1** and **4**.



Scheme 1.

Results and Discussion

The reaction of acid chloride with unsubstituted sulfoximide (**8**) to give *N*-acylsulfoximide has been well known.[5] On the similar treatment of **8** with imidoyl chloride (**9**) in the presence of triethylamine, the sulfoximides **7** were prepared in moderate yields. The imides **7** were fairly stable at room temperature; their physical properties are collected in Table 1.

It has been reported that propenone **2** decomposes over 140 °C.[6] Thus, an equimolar mixture of **2** and **7d** in xylene was heated at 130 °C. The disappearance of **2** was checked by TLC at suitable time intervals. The subsequent purification of the product by chromatography over silica gel yielded two products: the colorless 4(1*H*)-pyrimidinone (**6d**) and the yellow sulfoximide (**10d**). The structure assignment is based on the following evidence.

The former product had the same physical properties as the previously reported compound,[3] but quite different from those of the **3a** isomer (R^1=4-MeC_6H_4, R^2=Ph) obtained from the reaction of **1a** (R^1=4-MeC_6H_4, R^2=Ph) with **2**.[2,7] The mass spectroscopic studies of **3a** and **6d** clarified the ambiguity of the structure elucidation. The **6d** isomer showed a characteristic peak corresponding to MeC_6H_4N–C(Ph)=CPh; in contrast, **3a** showed no such peak.

The latter product, **10d**, gave satisfactory elemental analysis, ^{1}H-NMR, MS, and chemical transformation. Upon treatment with ethanol in the presence of trifluoroacetic acid, **10d** yielded the pyrrolinone derivative **11b** in quantitative yield. The hydrolysis of **11b** in a mixture of aqueous sulfuric and acetic acids yielded the known furanone **12**,[8] not the isomeric acid **13**.[9]

The reaction of other sulfoximides with **2** yielded two kinds of products, corresponding to **6** and **10**. The product ratios **10**/**6** and physical properties of **6** and **10**

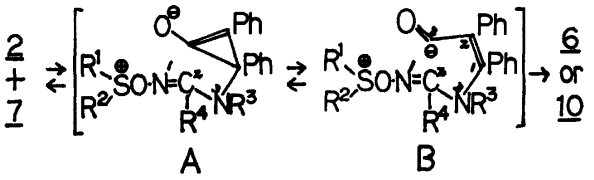
7m	4	**6d**	22	**10m**	63	2.9
7n	20	**6d**	1	**10n**	37	37

a) None of the products corresponding to **6** or **10** were found.

are shown in Tables 2 and 3. Since **2** decomposed slowly at the reaction temperature,[6] half a molar excess **2** was added in the course of the reaction for the cases of imides of a low reactivity: **7c**, **7f**, **7g**, and **7j**. From the reaction mixtures of such imides, none of the expected products **6** and **10** was isolated, or they were isolated only in low yields, together with an unidentifiable tarry mass. *N*-Alkylbenzimidoyl sulfoximides, **7a** and **7b**, gave **10a** and **10b** in an overwhelming majority. In contrast, the *N*-arylbenzimidoyl sulfoximides **7d**, **7e**, **7g**—**i**, and **7k**—**m** yielded the corresponding **6** and **10** in nearly similar ratios, although much rate retardation was observed for the imides substituted with the electron-withdrawing groups: **7k** and **7g**.



Scheme 2.

Upon heating at 140 °C for 12 h, the isolated **10b** or **10d** did not yield **6b** or **6d**, and long-time heating of the reaction mixtures of **7b** or **7d** with **2** did not improve the yields of **6b**/**10b** or **6d**/**10d**. These observations seem to indicate that **10** was not the precursor or intermediate of the production of **6**.

The ^{1}H-NMR spectroscopic studies for the sulfoximides **7** and **10** were interesting. The signal of the *S*-methyl groups of **7** appeared as a singlet at around δ 3.3, while those of the pyrrolinone-substituted sulfoximide **10** appear as two singlets at around δ 2.9 and 3.2 (Tables 1 and 3). The resolution of the two methyl groups for the *N*-alkyl substituted imides **10a** and **10b** was small. These observations seem to indicate that the free rotation around the S–N bond of **10** might be highly hindered by the bulky aryl substituents on the pyrrolinone ring.

Aldimine, ketimine, and amidine, which have C=N bonds, react with **2** to give 2-pyrrolin-4-one derivatives[8,10] *via* a [2+3] cycloaddition reaction. Considering the results obtained, the most plausible mechanism is that shown in Scheme 2. The nucleophilic attack of he terminal nitrogen (N^3) on the cyclopropenone **2**

a) The reported[5] mp for the **3b** isomer (R^1=Et, R^2=Ph) was 175 °C. b) The reported[2] mp for **6d** was 204—205 °C. The isomer **3d** (R^1=MeC_6H_4, R^2=Ph) had 262—265 °C. c) Phenyl-ring protons were observed at δ 6.4—8.3.

yields the intermediate **A**, followed by the ring-opening of the cyclopropenone and the nucleophilic attack of the carbonyl carbon (C^3) on the imino nitrogen (N^1) or the imino carbon (C^2) to yield either **6** or **10** *via* [3+3] or [2+3] cycloaddition. The pyrrolinone **10** is not an intermediate for the formation of **6**.

Table 2 indicates that bulkiness and electronic nature of the substituents R^1—R^4 on **7** controlled the reactivity of **7**. The nucleophilicity of the terminal nitrogen N^3 decreased with the electron-attracting substituents on N^3 (*i.e.*, R^3) and C^2 (*i.e.*, R^4) through the C=N bond. Bulky substituents lowered the reactivity of **7** (**7c**, **7f**, and **7j**), indicating that steric hindrance might contribute not only to the initial nucleophilic attack, but also to the ring-forming step to yield **6** or **10**.

The product ratios **10**/**6** also seem greatly affected by the bulkiness of the substituents R^1—R^4. Two phenyl groups of **7n** and alkyl groups for R^3 (**7a** and **7b**) increased the product ratios. These results seem to indicate that the ring formation of **10** would be easier than the formation of **6** due to the steric crowding between the substituents.

Barr *et al.* have indicated that the nature of the cationic center of the imide can profoundly affect the character of an ambident anionic portion.[3] This finding agrees well with our present results. The free *S*,*S*-dimethylsulfimide and *S*,*S*-dimethylsulfoximide (**8a**) have pK_a values of 7.28 and 3.24 respectively.[11,12] This big difference seems to affect the imino nitrogens of **1** and **7** (N^1 in Scheme 2). The imide **1** reacts with **2** at imino nitrogen (N^1); in contrast, the sulfoximide **7** reacts with **2** at the terminal nitrogen (N^3).

Experimental

General. The melting points were not corrected. ^{1}H-NMR spectra were recorded on a Hitachi-Perkin-Elmer R-20(60 MHz) spectrometer, using TMS as the internal standard; the IR spectra, on a Japan Spectroscopic Co. Ltd., A-3 infrared spectrophotometer, and the mass spectra, on a Hitachi RMU-7M mass spectrometer.

*Preparation of Unsubstituted Sulfoximides (**8a**—**c**).* *S*,*S*-Dimethyl-, *S*-methyl-*S*-phenyl-, and *S*,*S*-diphenylsulfoximides (**8a**—**c**) were prepared according to the literature.[13-15]

*Preparation of N-Imidoyl Sulfoximides (**7**).* A solution of

unsubstituted sulfoximide **8** (10 mmol) in benzene (30 cm³) and triethylamine (11 mmol) was dried over sodium carbonate (1 g). To the stirred mixture we then added, drop by drop, imidoyl chloride **9** (10 mmol) in benzene (10—20 cm³) over a 2-h period, the temperature being kept at around 15 °C. After the reaction, the precipitate was separated by filtration and the benzene solution was washed with water, dried over sodium carbonate, and evaporated *in vacuo* to yield the crude sulfoximide **7**, which was then recrystallized from benzene–petroleum ether. The physical properties of the products **7** are shown in Table 1.

The Reaction of ***7*** *with* ***2***. An equimolar mixture of **2** and **7** (1 mmol) in a minimum amount of xylene (*ca.* 3 cm³) was heated at 130 °C. The reaction was checked by means of TLC (silica gel, ethyl acetate–petroleum ether 2 : 1) at suitable time intervals. After the reaction, the cooled mixture was chromatographed over silica gel. Elution with a mixture of chloroform and ethyl acetate (5 : 1) gave **6** and **10**. The physical properties of the products are collected in Table 3.

The Reaction of ***10a*** *and* ***10d*** *with Ethanol*. To a solution of **10a** (0.1 mmol) in dry ethanol (10 cm³) we added 3 drops of trifluoroacetic acid at room temperature. One hour later, the reaction mixture was quenched with water and extracted with chloroform. The chloroform extract was dried under reduced pressure to yield a crystalline mass, which was then recrystallized from ethanol to give **11a** in a 90% yield. **11a** (R^3=Me, R^4=Ph): mp 157—158 °C; NMR ($CDCl_3$) δ=1.37 (3H, t, J=7 Hz, $C\underline{H}_3CH_2$), 2.80 (3H, s, MeN), 3.59 (2H, q, CH_2), and 6.8—7.8 (15H, m, Ph). Found: C, 81.51; H, 6.18; N, 3.83%; M^+ 369. Calcd for $C_{25}H_{23}NO_2$: C, 81.27; H, 6.27; N, 3.79%; M 369.

When **10d** was treated similarly **11d** (R^3=4-MeC_6H_4, R^4=Ph) was obtained in a 94% yield. **11d**: mp 178—180 °C; NMR ($CDCl_3$) δ=1.27 (3H, t, J=7 Hz, $C\underline{H}_3CH_2$), 2.16 (3H, s, $\underline{Me}C_6H_4$), 3.86 (2H, q, CH_2), and 6.6—7.8 (19H, m, Ar). Found: C, 83.29; H, 6.22; H, 3.21%; M^+ 445. Calcd for $C_{31}H_{27}NO_2$: C, 83.57; H, 6.11; N, 3.14%; M 445.

Hydrolysis of ***11a*** *and* ***11d***. A solution of **11a** or **11d** (0.2 mmol) in a mixture of acetic acid, sulfuric acid, and water (50 : 2 : 25 v/v) (10 cm³) was refluxed for 24 h. The cooled mixture was quenched with water and extracted with chloroform. The extract was dried under reduced pressure to yield a colorless mass, which, on crystallization, from benzene–petroleum ether gave needles of **12**; mp 190 °C (lit,[8] mp 191 °C).

Preparation of ***3a*** *(R^1=4-MeC_6H_4, R^2=Ph)*. A solution of **1a** (R^1=4-MeC_6H_4, R^2=Ph) and **2** in benzene was refluxed for 24 h. Layer chromatography (silica gel, chloroform–ethyl acetate 1 : 1 v/v) and crystallization from ethyl acetate–petroleum ether afforded **3a** in a 21% yield. **3a**: mp 262—264 °C; NMR ($CDCl_3$) δ=2.19 (3H, s, Me) and 6.8—7.8 (19H, m, Ar). Found: C, 83.96; H, 5.64; N, 6.88%; M^+ 414. Calcd for $C_{29}H_{22}N_2O$: C, 84.03; H, 5.35; N, 6.76%; M 414.

The Electrolytic Behavior of Tetrasubstituted Iminium Salt in Acetonitrile

Atsutaka KUNAI,* Junji HARADA, Masayasu NISHIHARA, Yasuo YANAGI, and Kazuo SASAKI
Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Saijo, Higashi-Hiroshima, 724
(Received October 12, 1982)

Cathodic behavior of *N*-cyclohexylidenepyrrolidinium salt (**1**) and *N*-cyclohexylideneaniline (**2**) in acetonitrile has been studied by means of dc polarography, cyclic voltammetry and preparative electrolysis under controlled potential conditions. The compound **1** exhibits a reduction wave at about −1.8 V, which is accompanied by formation of a surface compound. The products obtained from the preparative electrolysis were neither saturated amines nor dimeric compounds but were mostly polymeric materials. However, when electrophilic olefins, such as acrylonitrile or methyl acrylate, were present in the solution, coupling products were produced. The compound **2**, which cannot be reduced by itself below −2.7 V, is reduced at about −1.8 V when benzoic acid is in the solution. The reduction product in this case was *N*-cyclohexylaniline, which was replaced by a coupling product when acrylonitrile was present in the reaction system. The formation of the coupling products is considered to occur by a radical mechanism in both cases.

The formation of C–C bonds by addition of strong nucleophilic carbanion to the carbonyl carbon atom is widely used in organic synthesis. Similar addition reaction to the imino group or particularly to the iminium group, which is the *N*-analogue of carbonyl group, is frequently utilized in alkaloid synthesis.[1] Since the carbon atom at the iminium group is strongly positively polarized, the electrolytic reduction is easier than for the corresponding carbonyl group.[2] It is considered that the product is generally a monomeric amine in protic solvents while dimeric compounds are favored in aprotic solvents.[2-4] Accordingly, it is expected that the intermediate derived from the reduction of an iminium salt will add to certain kinds of electrophiles. In fact, the electrolytic reductive coupling of some aromatic iminium salt with various benzyl bromides has been reported.[5] Except for the heterocyclic iminium salt,[3,4] however, the electrode reduction of iminium salt has not hitherto been studied extensively.[2]

In the present paper, we study the reaction of *N*-cyclohexylidenepyrrolidinium perchlorate (**1**) as a representative of an iminium salt of simple aliphatic ketones. The crossed coupling with electrophilic olefins is the main subject of our interest.[6] In addition, a similar reaction of *N*-cyclohexylideneaniline (**2**) is also studied. Polarographic studies of related compounds are available in the literature.[7] The solvent used was acetonitrile in all cases, and acrylonitrile and methyl acrylate were used as the electrophilic olefins. In some cases, methyl 3-bromopropionate was also used as the electrophile.

Experimental

General. D.c. polarography using a dropping mercury electrode and linear potential sweep experiments using a platinum, gold and hanging mercury drop electrodes were utilized for studying electrochemical properties. All measurements were made in acetonitrile solutions containing 0.1 M tetraethylammonium perchlorate (1 M = 1 mol dm^{-3}). The solution were degassed with nitrogen.

Preparative electrolyses were carried out in a divided cell with a mercury pool cathode at a constant potential.

Electrodes. The height of the dropping mercury electrode s was kept at 50 cm. The capillary constant was 578 mmHg s mg^{-1}.** Platinum and gold wires of 1 mm in dia meter and 5 mm in length were used for cyclic voltammetry. All the potential values cited are those referred to a saturated calomel electrode using acetonitrile as the solvent.[8]

Reagents. Reagent grade acetonitrile was distilled over phosphorus pentaoxide and the distillate was refluxed over calcium hydride. This was freshly distilled before use. *N*-cyclohexylidenepyrrolidinium perchrorate (**1**) was prepared by the condensation of cyclohexanone with pyrrolidinium perchlorate.[9] Similarly, *N*-cyclohexylideneaniline (**2**) was prepared from cyclohexanone and aniline, bp 87 °C/133 Pa.

Controlled Potential Electrolysis. *(a)* N-*Cyclohexylideneaniline (2)*: The base solution was acetonitrile containing 0.1 M. tetraethylammonium perchlorate. A solution (100 cm^3) containing 1 mmol of **2** and 2 mmol of benzoic acid was electrolyzed at −1.9 V under a nitrogen atmosphere. The telectrolysis was continued until the current fell to the background level. The electrolyzed solution was evaporated to remove the solvent and the residue was extracted with ether by use of a Soxhlet extractor. The extract was again concentrated and subjected to TLC separation. The amount of the starting material remaining was determined by means of the formation of cyclohexanone 2,4-dinitrophenylhydrazone. The conversion of **2** was 80% and the yield of *N*-cyclohexylaniline (**3**) was 66% on the base of the reacted imine.

(b) 2 in the Presence of Acrylonitrile: A similar procedure was applied as used in the above. The amount of acrylonitrile added was 2 millimoles. The products, **3** (R_f 0.85) and 1-anilino-1-(2-cyanoethyl)cyclohexane (**4**) (R_f 0.70), were isolated by using silica gel TLC plates (5% EtOAc in benzene). Results are shown in Table 1.

(c) N-*Cyclohexylidenepyrrolidinium Perchlorate (1) in the Presence of Acrylonitrile*: Solutions of 1 mmol of **1** and 3 mmol of acrylonitrile were electrolyzed at −1.80 V. Others were the same as *(a)*. The product, 1-(2-cyanoethyl)-1-(1-pyrrolidinyl)-cyclohexane (**6**), was isolated by preparative GLC (5% OV-17, 2 m, 215 °C). Results are shown in Table 2.

(d) 1 in the Presence of Methyl Acrylate: A mixed solvent of 10% MeOH and 90% CH_3CN was used in this case, which contained **1** (1 mmol) and methyl acrylate (3 mmol). Products obtained were 1-[2-(methoxycarbonyl)ethyl]-1-(1-pyrrolidinyl)cyclohexane (**7**) (34%) and 1,2-bis[2-(methoxycarbonyl)-ethyl]-1-(1-pyrrolidinyl)cyclohexane (**8**) (30%).

(e) 1 in the Presence of Methyl 3-Bromopropionate: Procedure

** 1 mmHg≈133.322 Pa.

was the same as (*d*). Three millimoles of 3-bromopropionate was used. Products were **7** (3%) and **8** (3%).

Product Analyses. **4**: IR (neat) 3420 (-NH-), 2950 ($-CH_2-$), 2250 (CN), 750 and 690 cm^{-1} (Ph); NMR ($CDCl_3$) δ=1.17—1.75 (10H, m), 1.75—2.60 (4H, A_2B_2), 3.37 (1H, broad), 6.53—6.95 (3H, m), and 7.00—7.30 (2H, m); MS (70 eV), *m/e* (I_{rel}), 228 (M^+, 30), 185 ($M^+-C_3H_7$, 50), 174 ($M^+-CH_2CH_2CN$, 100), and 93 ($PhNH_2$, 79). Found: C, 79.06; H, 8.82; N, 12.13%. Calcd for $C_{15}H_{20}N_2$: C, 78.90; H, 8.83; N, 12.27%.

6: IR (neat) 2950 ($-CH_2-$), 2250 (CN), and 1450 cm^{-1} ($-CH_2-$); NMR ($CDCl_3$) δ=0.83—2.10 (16H, m) and 2.10—2.70 (6H, m); MS (70 eV), *m/e* (I_{rel}), 206 (M^+, 6), 163 ($M^+-C_3H_7$, 4), and 152 ($M^+-CH_2CH_2CN$, 100). Found: C, 75.90; H, 10.70; N, 13.40%. Calcd for $C_{13}H_{22}N_2$: C, 75.68; H, 10.75; N, 13.58%.

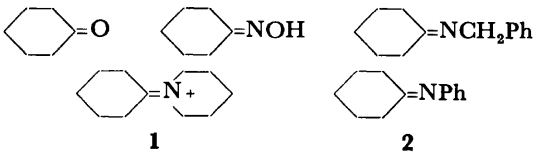
7: IR (neat) 2940 ($-CH_2-$), 1745 and 1190 cm^{-1} ($COOCH_3$); NMR ($CDCl_3$) δ=1.22—2.05 (16H, m), 2.22—2.88 (6H, m), and 3.65 (3H, s); MS (70 eV), *m/e* (I_{rel}), 239 (M^+, 3), 208 (M^+-OCH_3, 6), 196 ($M^+-C_3H_7$, 26), and 152 ($M^+-CH_2CH_2COOCH_3$, 100). Found: C, 70.50; H, 10.56; N, 6.16%. Calcd for $C_{14}H_{25}O_2N$: C, 70.25; H, 10.53; N, 5.85%.

8: IR (neat) 2950 ($-CH_2-$) and 1745 cm^{-1} ($COOCH_3$); MS (70 eV), *m/e* (I_{rel}), 325 (M^+ for $C_{18}H_{31}O_4N$, 5), 294 (M^+-OCH_3, 8), 282 ($M^+-C_3H_7$, 18), and 238 ($M^+-CH_2-CH_2COOCH_3$, 100).

Other compounds were identified by comparison with authentic samples.

Results and Discussion

Polarography. The parent compound, cyclohexanone, does not show any reduction wave below the limit of solvent decomposition in acetonitrile (Fig. 1). Neither cyclohexanone oxime nor *N*-cyclohexylidenebenzylamine exhibits a reduction wave. *N*-cyclohexylideneaniline **2**, however, gives rise to a reduction wave with a half-wave potential at −2.8 V. The iminium salt **1** shows a wave with a characteristic maximum at about −1.8 V. On the other hand, all of electrophilic reagents such as acrylonitrile or methyl acrylate have their half-wave potentials at more negative than −2.2 V, indicating the possibility of selective reduction of the iminium salt **1**. *N*-Cyclohexylideneaniline (**2**) is also



1 **2**

selectively reduced when benzoic acid is deliberately added. This is shown in Fig. 2, where the effect of benzoic acid on the polarogram of the imine **2** is studied. It is clearly evident that a marked shift of reduction wave occurs upon addition of benzoic acid. Denoting the waves of $E_{1/2}$=−1.8, −2.3, and −2.8 V as the waves I, II, and III, respectively, we analyzed the height of each wave. This is shown in Fig. 3, where

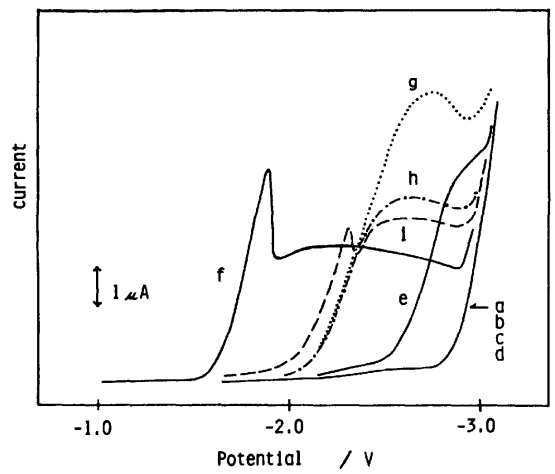


Fig. 1. Polarograms of the substrates in acetonitrile solution (1 mmol dm^{-3}).
The solution contains: a) none; b) cyclohexanone; c) cyclohexanone oxime; d) *N*-cyclohexylidenebenzylamine; e) *N*-cyclohexylideneaniline; f) *N*-cyclohexylidenepyrrolidinium perchlorate; g) acrylonitrile; h) methyl acrylate; and i) methyl 3-bromopropionate.

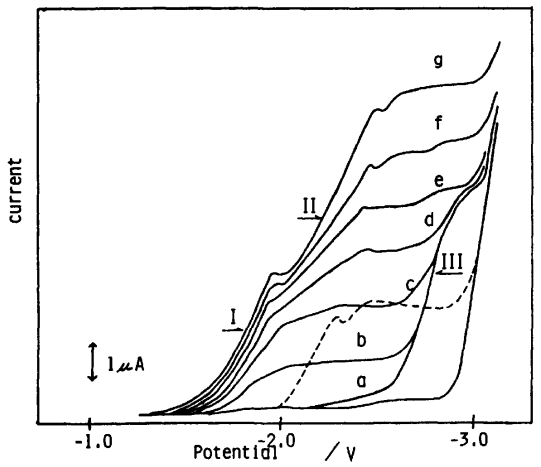

Fig. 2. Effect of benzoic acid on the polarogram of *N*-cyclohexylideneaniline (1 mmol dm^{-3}).
The concentration of benzoic acid is: a) 0; b) 0.5; c) 1; d) 1.5; e) 2; f) 2.5; and g) 3 mmol dm^{-3}. Dotted line shows the polarogram of 1 mmol dm^{-3} of benzoic acid.

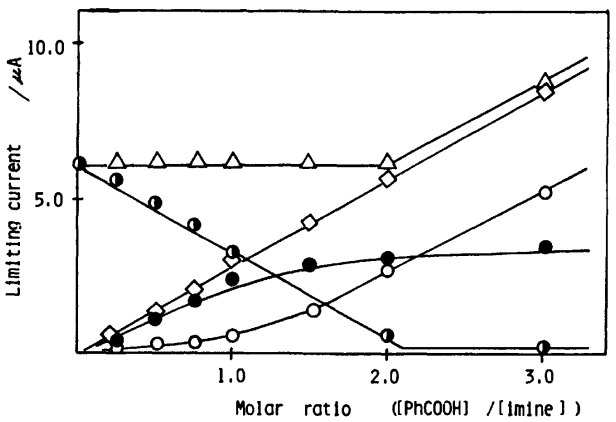

Fig. 3. Relation of the waves I through III appearing in Fig. 2.
Ordinate stands for the limiting current of: (●) wave I; (○) wave II; (◑) wave III; (◇) waves I and II; and (△) waves I, II, and III. Abscissa stands for molar ratio of benzoic acid against 1 mmol of the imine.

the scale of the abscissa indicates the molar ratio of benzoic acid to imine; R=[benzoic acid]/[imine].

The wave I increases monotonously until R becomes equal to 1 and then stops increasing. The final height is roughly one half of the original wave of the imine. Although the second wave (wave II) coincides with the wave of benzoic acid itself, a hasty interpretation seems to be misleading.

It should be noted that the second wave starts to grow appreciably after exceeding R=1 and the sum of the waves, I and II, increases exactly linearly. Moreover, the total height of waves I, II, and III remains constant until R reaches 2. In accord with the above facts, the following sequences of the reaction can be assumed, where A stands for **2** and HB is benzoic acid (Eqs. 1 through 5).

$$A + HB \rightleftharpoons AH^+ + B^- \quad (1)$$

$$AH^+ + e + \overset{\text{wave I}}{\rightleftharpoons} AH\cdot \quad (2)$$

$$2\,AH\cdot \longrightarrow AH_2 + A \quad (3)$$

$$AH\cdot + H^+ + e \overset{\text{wave II}}{\longrightarrow} AH_2 \quad (4)$$

$$A + 2e \overset{\text{wave III}}{\longrightarrow} A^= \quad (5)$$

That the final height of the wave I is one half of the original wave height of imine suggests the process occurring in the wave I to be one-electron transfer. The follow-up chemical step (3) should occur sufficiently fast to provide wave III, where free imine is reduced by two-electron transfer. At the second wave, the primary electrode product, AH·, is further reduced as far as proton is donated from benzoic acid. The reaction of wave III is undoubtedly the reduction of free imine itself, and the wave diminishes when sufficient amount of benzoic acid is present in the solution. This mechanism agrees with the result of preparative electrolysis made at a potential of wave I. As Table 1 indicates, *N*-cyclohexylaniline (**3**) is dominated in the reaction products.

Cyclic Voltammetry of ***1***. The polarogram of **1** exhibited a wave with strong maximum (see Fig. 1). It was impossible to displace this maximum by any means. Therefore we attempted to study the effect of the electrode material on the reaction of **1**. Platinum, gold and hanging mercury electrodes were chosen and cyclic voltammetry was employed. Figure 4 indicates the results. In the case of the platinum electrode (Fig. 4a), the first cathodic wave appeared at about −0.95 V, which is very positive compared with the peaks observed with gold or mercury electrodes. Because of this, we estimate the reaction at the platinum electrode to be different from that at the mercury electrode. With platinum, the peak current showed a linear dependence on the square root of the potential sweep rate. The reaction, which is consistent with the result of preparative electrolysis is as follows (Eq. 6).

$$\mathbf{1} + e \longrightarrow \mathbf{5} + 1/2\,H_2 \quad (6)$$

It should be noted that only when a platinum cathode was used hydrogen evolved appreciably. This must be related to the special affinity of hydrogen on the platinum surface.

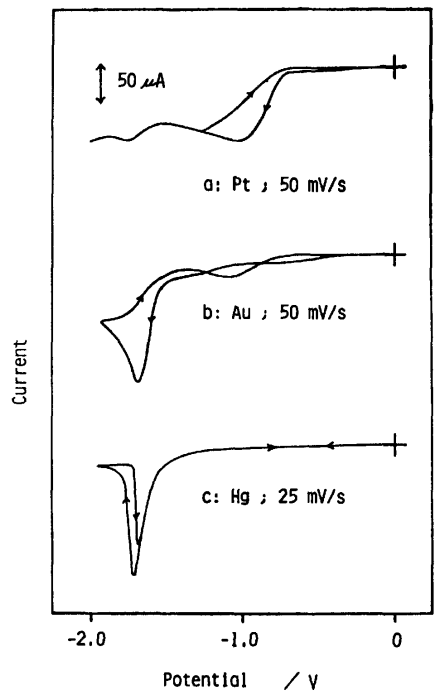

Fig. 4. Cyclic voltammograms of *N*-cyclohexylidenepyrrolidinium perchlorate in acetonitrile solution (5 mmol dm^{-3}).
Electrode is: a) platinum; b) gold; and c) hanging mercury. Sweep started from 0 V towards negative direction.

With the gold electrode (Fig. 4b), the current peak appeared at about −1.7 V. The peak current was also linear against the square root of the rate of potential sweep but did not cross the origin of the coordinate showing the contribution of some kinetic complication. The reaction at this electrode was not studied further.

At the hanging mercury drop electrode (Fig. 4c), a sharp current peak appeared at −1.72 V. The peak current, however, did not change systematically with the change of the rate of potential sweep while the peak potential value was unchanged. In addition, the current diminished rapidly after passing the peak potential, −1.72 V. When the direction of the potential sweep was reversed, the peak reappeared at a potential slightly positive to the forward sweep.

These findings lead us to assume that a surface compound was formed on the mercury surface. The surface compound would be an insulating material and the current fell steeply after it covered the mercury surface fully. A quantitative analysis of the peak current, however, failed because of the difficulty of reproducing the experiments, which was mainly caused by the poor reproducibility of the size of the hanging mercury drop.

Controlled Potential Electrolysis. *N-Cyclohexylideneaniline (**2**)*: This compound has been electrolyzed in the presence of acrylonitrile at −1.9 V, in the region of wave I, with a mercury pool electrode. In order to do this, the addition of benzoic acid was necessary as was described in the previous section. The products obtained are listed in Table 1 as a function of the molar ratio of

Table 1. Electrolysis of *N*-cyclohexylideneaniline (2)

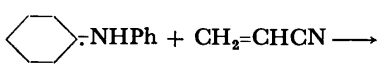
a) The elcctrolyses were made for the solution (100 cm^3) containing 1 mmol of **2** at −1.90 V. b) The yields were based on **2** unrecovered.

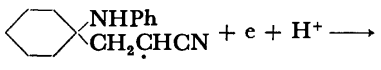
benzoic acid to the imine. In every case, the main product was the adduct **4** of acrylonitrile to the imine and the by-product was *N*-cyclohexylaniline (**3**). No dimeric product was observed. When the electrolysis was done in the absence of acrylonitrile but in the presence of 2 mmol of benzoic acid, the main product was *N*-cyclohexylaniline (**3**) (66%), which showed the sequence of Eqs. 2 and 3 is operating.

Isolation of both **3** and **4** was performed by the use of silica-gel TLC. The amount of unreacted imine was analyzed as its 2,4-dinitrophenylhydrazone. It is worth noting that the increasing amount of benzoic acid added improves the percentage conversion of imine to the adduct.

The reaction occurring in this system can be expressed by the following equations.



(7)



(8)

4

N-*Cyclohexylidenepyrrolidinium Perchlorate* (*1*). Referring the result of cyclic voltammetry, we electrolyzed **1** at −1.80 V in the presence of acrylonitrile with a mercury pool electrode. The results obtained are listed in Table 2. In all cases, the current reached the background level after passing about 1 F† per mole of electricity. The highest yield of the adduct **6** was 37%. No starting material remained in the electrolyzed solution. No diamine, the formation of which was suggested by Andrieux,[2] was detected. For producing **6**, an addition of methanol or 2-propanol seems to be effective.

When platinum was used as the electrode material, hydrogen evolved vigorously during the course of electrolysis. Both the GC and TLC analyses indicated that a number of compounds are produced in this case. Among these, three dominant compounds were characterized to be adiponitrile, enamine **5** (21%), and 2-(2-cyanoethyl)cyclohexanone, by comparing with the authentic samples, respectively. The amount of the adduct **6** was only 5%. These findings indicate that

† 1 F≈96480 C.

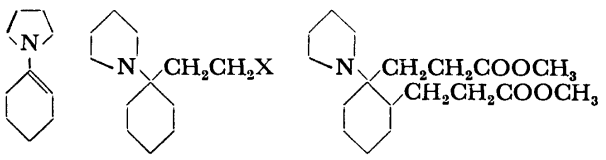
Table 2. Electrolysis of *N*-cyclohexylidene-pyrrolidinium perchlorate **1** in the presence of acrylonitrile

Run[a]	Base solution	Coulometric *n* value	Yield[b]/% of **6**
1	MeCN	0.96	26
2	MeCN–MeOH(1%)	0.98	32
3	MeCN–MeOH(5%)	0.97	33
4	MeCN–MeOH(10%)	1.11	37
5	MeCN–MeOH(10%)[c]	1.04	31
6	MeCN–*i*-PrOH(1%)	1.09	29
7	MeCN–*i*-PrOH(5%)	1.04	31
8	MeCN–*i*-PrOH(10%)	1.04	31

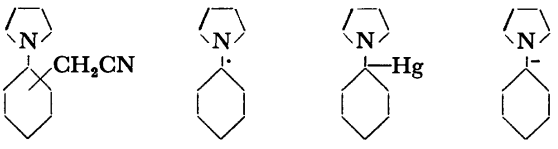
a) The electrolyses were made for the solution (100 cm^3) containing 1 mmol of **1** and 3 mmol of acryronitrile at −1.80 V. b) The yields were based on the amount of **1** used. c) Ten millimoles of acrylonitrile was used in this case.

the primary step occurring at the platinum electrode is the reductive decomposition (Eq. 6). The enamine **5** thus produced will further undergo the follow-up chemical reaction to give a complex mixture of the products. The cyanoethylation seems to be a suitable follow-up reaction in this case.[10]

In contrast to the platinum electrode, mercury pool electrode seems to be favored for producing **6**. This may be correlated to the difference in the primary intermediates between the two electrode systems. The formation of organomercury compounds seems plausible but their detection failed.

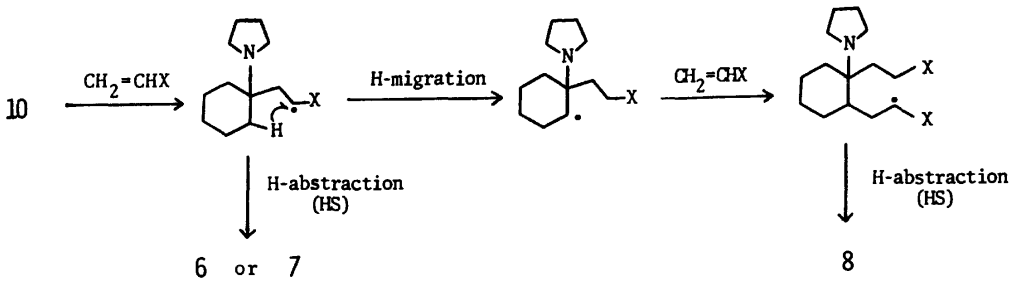


5 **6** X = CN, **7** X = $COOCH_3$ **8**



9 **10** **11** **12**

When the electrolysis was carried out in the absence of acrylonitrile, the product was mostly a polymeric substance together with a small amount of **9**, which



(X= -CN or $-COOCH_3$, HS= solvent)

Scheme 1.

might be derived from **10** by a radical mechanism.

When methyl acrylate was used in place of acrylonitrile, **8** was produced in 30% yield in addition to **7** (34%).

In order to account for the formation of **6** through **9**, it seems reasonable to assume the formation of the neutral radical **10** as the primary intermediate on the mercury surface. The possibility of forming either organomercury compound **11** or carbanion **12** seems unlikely in the following reasons. 1) When methyl 3-bromopropionate was used in place of methyl acrylate, the yield of **7** and **8** was less than 3%. This means that the primary species has a poor SN_2-displacement ability. 2) No organomercury compound was detected in the electrolyzed solution.

The radical **10** will react with olefins, such as acrylonitrile or methyl acrylate to form **7**, **8** or **9** as is expressed in Scheme 1. The presence of certain co-solvents such as alcohols inhibits undesirable radical polymerization.

Conclusion

The tetrasubstituted iminium salt **1** is reduced more easily than corresponding carbonyl compounds. It forms a neutral radical when it is reduced cathodically at a mercury surface. The radical thus formed is favored to polymerize rather than to dimerize. The presence of electrophilic olefins such as acrylonitrile gives rise to the formation of radical adduct as the intermediate, which gives the final products of **6** through **8**. The latter reaction is not highly selective and the polymerization always accompanies. The addition of a hydrogen donor such as methanol is effective in inhibiting the polymerization and increasing the yield of adducts.

The compound **2** is easily reduced electrolytically when it is protonated. When acrylonitrile is present in the solution, the adduct **4** is formed in more than 70% yield.

(Received November 18, 1982)

Photochemical dechlorinations and debrominations of $C_6H_nX_{6-n}$ (X=Cl, Br) isomers were carried out in hexane. The products and residual reactant were determined quantitatively by means of gas chromatography. From these experiments, the relative rates of dehalogenation were obtained. The different rates among unequivalent sites in a molecule were interpreted by the effect of steric acceleration by the neighboring halogen atom(s). The reactivity of the halogen atom in polyhalobenzene towards photochemical elimination reaction is dependent both on its position in the molecule when compared among isomers and on the number of halogen atoms in a molecule when compared among polyhalobenzenes of various degrees of substitution. The latter effect is more predominant in the series of polybromobenzenes.

Physical properties of polyhalogenated aromatic compounds have been investigated rather extensively, since they were widely used as insulator, thermally stable heat-transfer medium and lubricant, and other purposes. On the other hand, reactions of these polyhaloaromatics were not known thoroughly because of their inertness towards most chemicals. Environmental contamination caused by polychlorinated biphenyls also attracted the attention to the chemical reactions of other polyhalogenated aromatics.[2)] Considerably large number of investigations concerning their metabolism, toxicity, and abundance in environment were reported[3)] together with the investigations on polychlorinated biphenyls. However, reactions of polyhalobenzenes have not been studied so extensively. In connection with the detoxication of polyhalogenated aromatic compounds, several photochemical dehalogenation procedures were reported in this decade.[4,5)] Thus some polychlorinated biphenyls were successfully dechlorinated by irradiation of ultraviolet light in aqueous alkaline media.[6)]

Pinhey and Rigby,[7)] and Ichimura and Mori[8)] have studied the mechanism of dehalogenations of several rather simple haloarenes, showing that the photochemical process is the initial absorption of light causing $^1(\pi,\pi^*)$ excitation and subsequent intersystem crossing to $^3(\sigma,\sigma^*)$ state localized on a carbon-halogen bond, which induces the fission of the bond.

$$\text{Ar–X} \xrightarrow{h\nu} \text{(Ar–X)}^* \qquad \text{X = Cl, Br}$$
$$\text{(Ar–X)}^* \longrightarrow \text{Ar}\cdot + \text{X}\cdot$$
$$\text{Ar}\cdot + \text{RH} \longrightarrow \text{Ar–H} + \text{R}\cdot$$

The abstraction of hydrogen from solvent (RH) is a thermal reaction of aryl free radical. Another explanation assuming the π-chlorobenzene intermediate, or transition state, was also proposed by Lemal[9)] and have been contradicted by Arnold.[10)]

In our previous report,[11)] relative migrating ability of halogen atom of polyhalobenzenes in the Jacobsen type rearrangement was determined and the mechanism was discussed. In this connection, the photochemical dehalogenations were carried out on all possible polychloro- and polybromobenzene isomers, as well as some polybromopolychlorobenzenes, in hexane in order to compare the reactivities of halogen (Cl or Br) atoms occupying different positions in a polyhalogenated benzene molecule. The products were analyzed quantitatively by gas chromatography, and the relative rate of dehalogenation of each dissimilar halogen atom was evaluated.

Experimental

Materials. Several tri-, tetra-, and pentabromobenzenes were prepared by the method previously reported by Furuyama *et al.*[12)] Some of other polybromo-, polychloro-, and polybromopolychlorobenzenes were prepared by combination of direct halogenation and nitration followed by reduction and Sandmeyer reaction (replacement by halogen) of appropriately halogenated benzenes and anilines. Commercially available materials were used after purification by distillation or by chromatography. All of polyhalobenzenes were identified by their melting and/or boiling points and by spectral properties.

Reactions. Photo-reactions were carried out using a 30 W low pressure Hg lamp placed at the center of concentrically surrounded quartz vessel containing the solution of reactant. In some runs, a 100 W high pressure Hg lamp was also employed. The temperature of the solution was kept at 25 °C by external cooling, though the reaction is not dependent on the temperature of the solution. The solution was sampled at an interval of definite time (usually every two hours when the reaction is not very fast) and analyzed by gas chromatography.

Spectral and Chromatographic Measurements. GC/MS measurements were carried out on a Hitachi-6L or a Shimadzu LKB-9000B mass spectrometer. Routine gas chromatographic analyses of the products were carried out on a Shimadzu GC-6A apparatus or a GC-4B-PTF apparatus equipped with a polyethylene glycol 20M, a Silicone SE 30, or an Apiezon L column (3 mm×2 m). UV/VS spectra and NMR spectra were recorded on a Shimadzu UV 365 and a JEOL FX 90Q spectrometers, respectively.

Results and Discussion

The photochemical reactions were pursued by quantitative GC analysis of the products and the starting

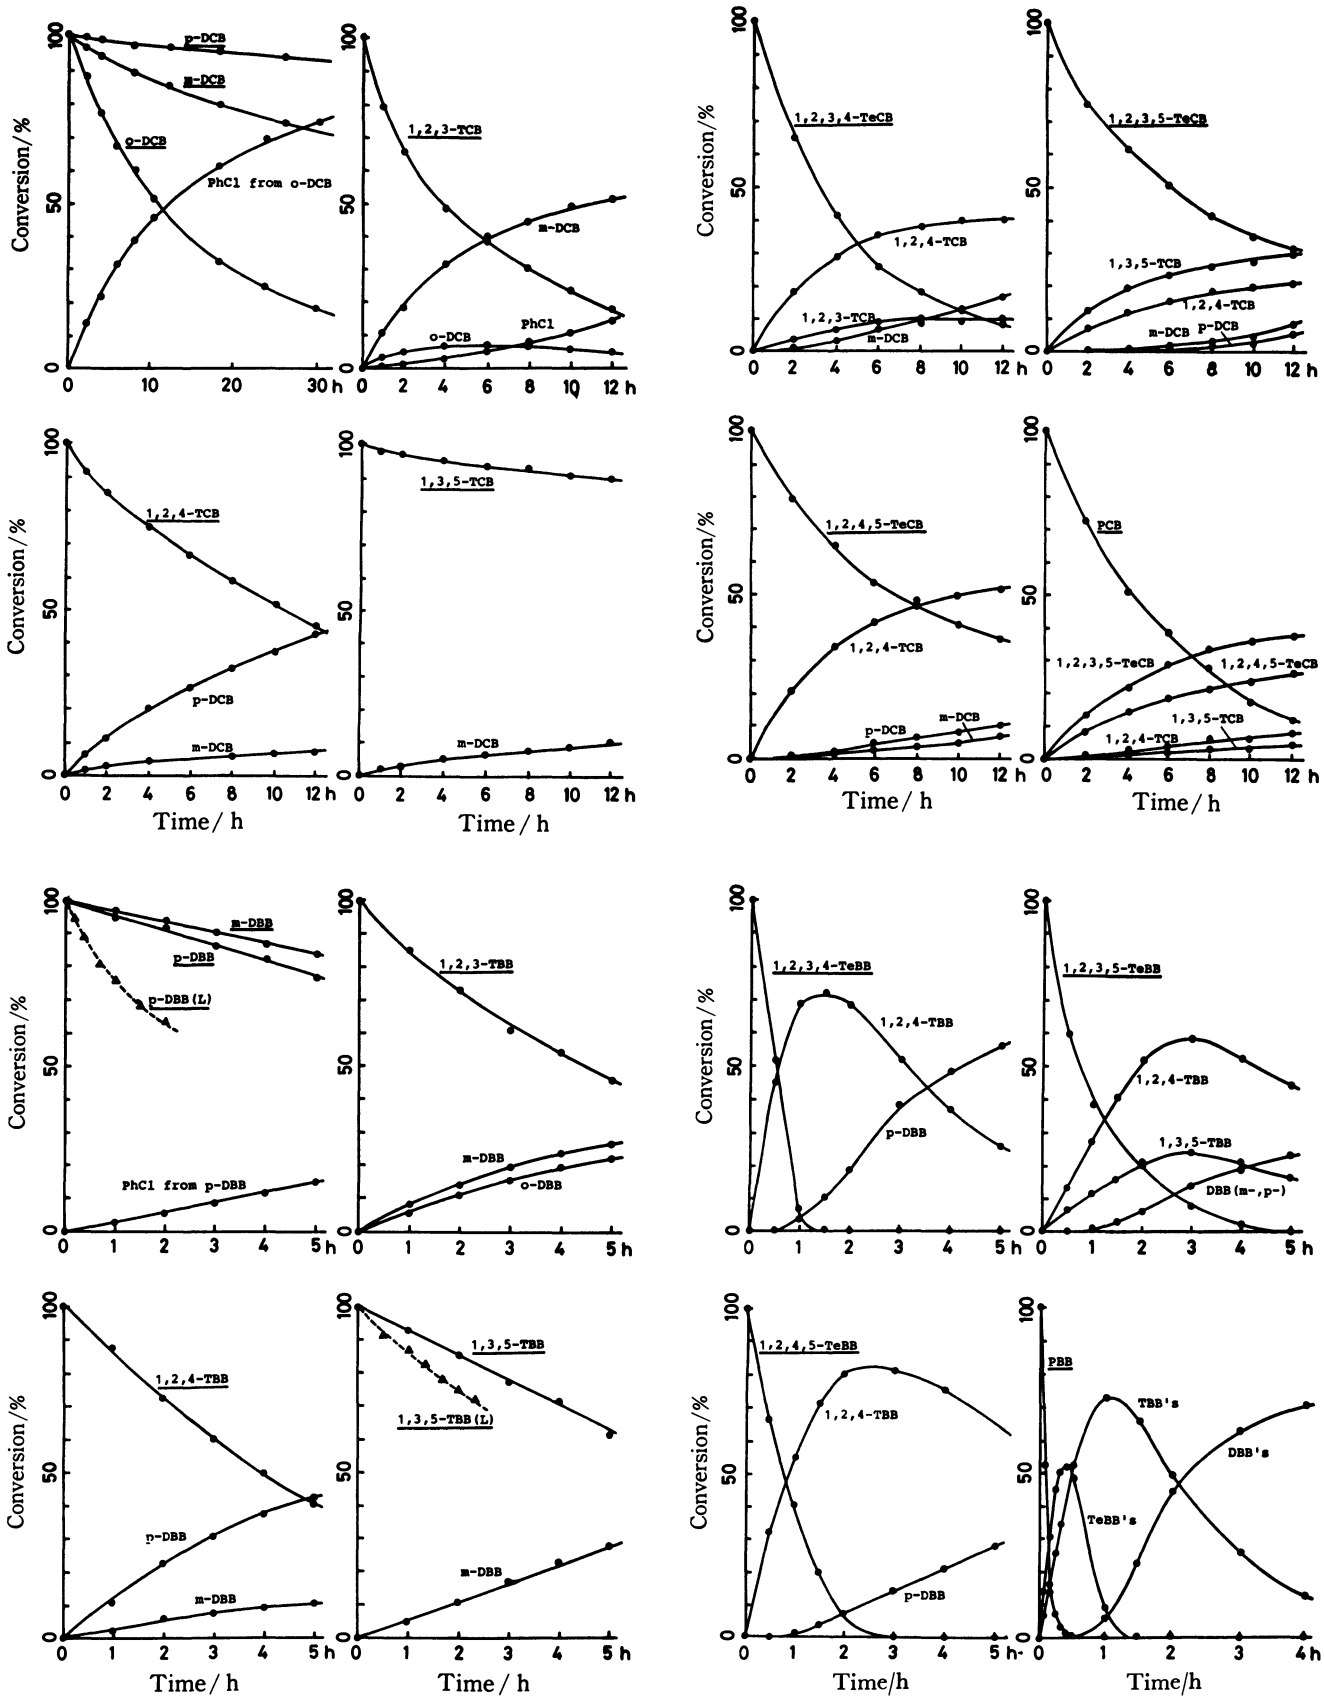

Fig. 1. Time-conversion curves for the photochemical dehalogenation of polyhalobenzenes. Experimental conditions are given in Table 1. In this figure, abbreviations such as following are used in order to name the starting materials and the products: *o*-DCB=*o*-dichlorobenzene, 1,2,3-TBB=1,2,3-tribromobenzene, 1,2,3,4-TeCB=1,2,3,4-tetrachlorobenzene, and so on. The starting material for each run is designated by underline in each diagram.

a) The amounts of consumed starting polyhalobenzenes after 4 h are given, since the time-conversion curves are not shown in Fig. 1.

material. Since no quantitative consideration was taken on the intensity of the light for irradiation, only the relative reactivity will be discussed here. The time-conversion curves are given in Fig. 1.

In hexane solution, dehydrogenation reaction proceeds almost exclusively. In polyhaloarenes, elimination of halogen atom from different sites proceeds competitively as initial reactions from the excited state. The relative rates of C–X (X=Cl, Br) bond fission, or the relative partial rate factors, are given in Table 1.

When the intramolecular reactivity of similar halogen atom is compared, the halogen atom flanked by two halogen atoms (at 2- and 6-positions) is the most reactive, and the one having an ortho halogen atom is the next most reactive. For example, the 2-halogen atom is the most reactive in the dehalogenations of all

1,2,3-trihalogenated benzenes investigated (**5a**, **5b**, **8a**, **8b**, **9a**, and **9b**). This might be due to the steric and electrostatic repulsion caused by the neighboring halogen atoms. Elimination of halogen atom to give the corresponding aryl free radical reduces the steric hindrance of the molecule remarkably. Electronic effect caused by non-neighbor halogen atoms are rather complicated and cannot be related quantitatively to the electron densities and bond orders from molecular orbital calculations.[14] Empirically, the halogen substituent meta to the site of reaction accelerates the dehalogenation reaction more predominantly than the para substituent when other circumstances are similar. For example, the 2-halogen atom (having one ortho and one meta halogen) of 1,2,4-trihalobenzenes (**6a** and **6b**) are more reactive than the 1-halogen atom (having one ortho- and one para-halogen). When compared intermolecularly, the 2-halogen atom of 1,2,3,4-tetrahalobenzene (having two ortho and one meta halogen) are again more reactive than the 2-halogen atom of 1,2,3,5-tetrahalobenzene (having two ortho- and one para-halogen). The same is true also for the 1-bromine atom of 1-bromo-2,3,4-trichlorobenzene and 1-bromo-2,3,5-trichlorobenzene, and other cases investigated. Since the Hammett σ-constants for *m*-chloro (+0.373) and *m*-bromo (+0.391) substituents are more positive than the corresponding constants for para substituents (*p*-Cl, +0.226; *p*-Br, +0.232), implying that meta substituents are more electron-withdrawing than the para substituents, the destabilization can be expected by the second substitution by electronegative halogen atom. This can contribute to facilitate the release of the halogeno substituent even in the homolytic fission of carbon-halogen bond.

Differences in reactivity among the positional isomers are mainly determined by the positions of halogen atoms in the molecule. In general, 1,2,3-trihalobenzene reacts most promptly and 1,3,5-trihalobenzene most slowly among isomeric trihalobenzenes. Dehalogenation of 1,2,3,4-tetrahalobenzene is the fastest among the isomeric tetrahalobenzenes.

The effect of the number and the positions of halogen substitution is considerably different when compared quantitatively between the series of polychlorobenzenes and polybromobenzenes. In the series of polybromobenzenes, the reactivity tends to increase in the following order : monobromo $<$ *o*-dibromo $<$ *m*-dibromo $<$ *p*-dibromo $<$ 1, 3, 5-tribromo $<$ 1, 2, 4-tribromo $<$ 1, 2, 3-tribromo $<$ 1,2,4,5-tetrabromo $<$ 1,2,3,5-tetrabromo $<$ 1,2,3,4-tetrabromo $<$ pentabromo $<$ hexabromo derivative. The rate of dehalogenation increases remarkably as the increase in the number of substituent halogen atoms even when statistic factor is taken into account (when the overall rate is divided by the number of halogen atoms on the benzene ring).[15] The photodehalogenation in this series of compounds were carried out using high pressure mercury arc (100 W). Two runs (with *p*-dibromo- and 1,3,5-tribromobenzenes) were carried out using low pressure mercury arc (30 W) which were used in the series of polychlorobenzenes. The overall patterns of time-conversion curves are very similar to each other.

In contrast to the reactions with polybromobenzenes, the reactivity of polychlorobenzene is very sensitive to the number of neighbor halogen atoms. As can be seen with *m*-dichloro-, *p*-dichloro-, and 1,3,5-trichlorobenzenes in Fig. 1, the rates of dechlorination of isolated chloro substituents (without ortho halogen substitution) are very low when compared with those carrying ortho halogen substituent(s). On the other hand, the rate of debromination is not so dependent on the neighboring halogen atoms. The total number of chloro-substituents on the benzene nucleus is less important than in the case of polybromobenzenes. Thus, the dehalogenations of 1,2,4-trichloro- and 1,3,5-trichlorobenzenes proceed approximately as fast as those of *o*-dichloro- and *m*-dichlorobenzenes, respectively. Increasing number of halogen substitution accelerates the reactions beyond the experimental error in polychlorobenzenes of higher degree of substitution, however.

As a consequence of the bond energy (C–Cl, 360 kJ/mol and C–Br, 297 kJ/mol) difference, the bond fission to produce the corresponding free radical proceeds more predominantly with C–Br bond than with C–Cl bond in the same molecule. Thus the debrominations take place almost exclusively in all dibromodichlorobenzenes investigated, giving corresponding bromodichlorobenzenes as primary products. No dibromochlorobenzenes were formed in detectable amounts in any runs, even if chlorobenzene (as a secondary product) was detected in some runs. In the reactions of several bromotrichlorobenzenes, dechlorination proceeds competitively with debromination. 1-Bromo-2,3,4-trichlorobenzene produces 1,2,3-trichloro- and 1-bromo-3,4-dichlorobenzenes in a 10 : 1 ratio after irradiation of 2 h. Similarly 1-bromo-2,3,5-trichlorobenzene gives 1,2,4-trichloro- and 1-bromo-3,5-dichlorobenzenes in a 12 : 1 ratio. In all cases debromination proceeds by far more promptly than dechlorination when both chloro and bromo substituents are located in the same molecule.

In order to confirm the difference in reactivity observed between polychloro- and polybromobenzenes more confidently, the photodehalogenations of some polyhalobenzenes were carried out in methanol. Methanol is another hydrogen-donating solvent from which the photochemically produced aryl free radical can abstract hydrogen atom, forming the dehalogenated product. Relative rates of dehalogenation in methanol are given in Table 2, reproducing the relative rates in hexane.

The effect of the nature of halogen (Cl or Br) on the

Table 2. Rates of dehalogenation of dihalobenzenes C_6H_4XY relative to the rate of *o*-C_6HCl_2 in methanol (0.10 mol/l)

X	Y	*o*-C_6H_4XY	*m*-C_6H_4XY	*p*-C_6H_4XY	Product
Cl	Cl	1,00	0.25	0.04	C_6H_5Cl
Cl	Br	0.73 (1.00)[a]	0.67 (0.91)	0.66 (0.89)	C_6H_5Cl
Br	Br	0.94 (1.00)	0.87 (0.92)	0.81 (0.86)	C_6H_5Br

a) Rates relative to the ortho-isomer of each series are given in parentheses.

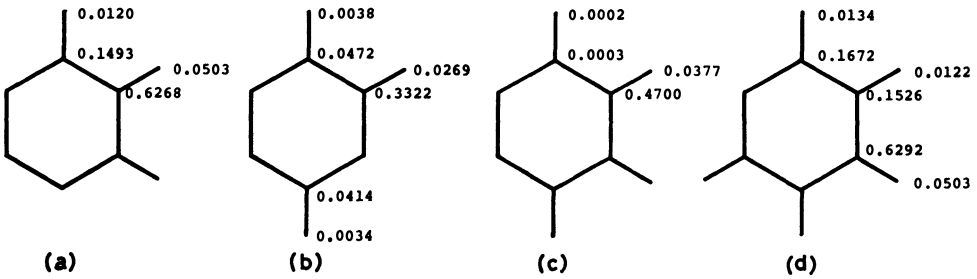

Fig. 2. π-LUMO densities of some polychlorobenzenes. (a) 1,2,3-Trichlorobenzene, (b) 1,2,4-trichlorobenzene, (c) 1,2,3,4-tetrachlorobenzene, and (d) pentachlorobenzene.

reactivity can be interpreted in the following way. In hexane, initial photolysis reaction of halobenzene to generate the corresponding aryl free radical might proceed similarly to the photolysis in gas phase. Thus the excited state leading to the photolytic cleavage of (carbon-halogen bond is expected to be the $^3(\sigma,\sigma^*)$ state localized on the breaking bond. Then the rates of dehalogenation should be determined by the probability of intersystem crossing from $^1(\pi,\pi^*)$ to $^3(\sigma,\sigma^*)$,[8] which is a function of both the energy difference of these two states and the LUMO(π^*) density on the breaking bond[14] if the wavelength and the intensity of incident light is invariable. The halogen substituent(s) ortho to the reaction site might weaken the carbon-halogen bond and lower the $^3(\sigma,\sigma^*)$ state due to the steric and electrostatic repulsive interaction. Since the energy difference between the $^1(\pi,\pi^*)$ and the $^3(\sigma,\sigma^*)$ states is supposed to be small in the case of chlorinated benzenes, the neighboring halogen effect lowering the $^3(\sigma,\sigma^*)$ state may favor the release of chlorine atom drastically under certain conditions sufficing the energetic requirement for the conversions involved. In contrast, the energy of the $^3(\sigma,\sigma^*)$ state localized on the breaking C–Br bond is considerably lower than the $^1(\pi,\pi^*)$ state in participation, and the assistance by the repulsive force does not affect their reactivities seriously. Effect of the number of substituent halogen atoms is far more predominant in the series of polybromobenzenes. This cannot be attributed to the simple steric effect due to the buttressing by the second neighbor halogen atoms. In this case, participation of direct $^3(\sigma,\sigma^*)$ or $^3(n,\sigma^*)$ excitation by irradiation is suspected owing to the contribution of heavy atom effect by bromine.[16]

The authors are grateful to Mr. Akio Kanno, former Director of Yokohama Research Institute for Environmental Protection, for his advice and support to this investigation.

13) During the preparation of our manuscript, dehalogenation of isomeric tetrachlorobenzenes in 2-propanol was reported (M. Usui, T. Nishiwaki, K. Anda, and M. Hida, *Nippon Kagaku Kaishi*, **1982**, 638). Their results are in line with those in this Table.

14) The densities of LUMO(π^*) by simple LCAO-MO calculation could be correlated with the reactivity of polychlorobenzenes (and polybromobenzenes), however. Except the case of 1,2,3,5-tetrachlorobenzene whose LUMO has a node along the most reactive C–Cl bond because of its symmetrical property, all trichloro-, tetrachloro-, and pentachlorobenzenes have the largest LUMO density on the most reactive C–Cl bond (that is to say, the largest LUMO density of all carbon atoms and the largest LUMO density among chlorine atoms in the molecule) as given in Fig. 2. The large LUMO density will favor the intersystem crossing on the $^1(\pi, \pi^*)$ state to the $^3(\sigma, \sigma^*)$ state localized on the respective C–Cl bond.

15) Our experiment shows that the rates of conversion were related very close to the inverse of concentration, showing that the rate is controlled by the intensity of irradiated light. Substantial retarding effect by the increase of concentration was observed towards the end of reaction, which might be due to the deposit of solid or resinous secondary products on the surface of reaction vessel and also due to the coloration of the reaction mixture.

16) Possibility of the participation of direct S-T absorption has been pointed out by Soumillon and the co-worker in the photo-dechlorination of 2,4-dichloroanisole (J. Ph. Soumillon and J. Vermeulen, *Bull. Soc. Chim. Belg.*, **91**, 474 (1982).). Thus the participation of direct S-T excitation is very probable in the photo-reactions of polybromo aromatic compounds.

The Ruthenium Complex Catalyzed *N*-Heterocyclization of Aminoarenes to Quinoline Derivatives Using Allylic Alcohols and Aliphatic Aldehydes[1)]

Yoshihisa WATANABE,* Yasushi TSUJI, Yukihiro OHSUGI, and Jun SHIDA

(Received December 13, 1982)

Aminoarenes reacted with 2-propen-1-ol and 2-buten-1-ol at 180 °C to give quinoline derivatives in fairly good yields in the presence of a catalytic amount of a ruthenium complex. Dichlorotris(triphenylphosphine)-ruthenium was the most effective catalyst. The aminoarenes with electron-releasing groups favored the formation of the quinolines. The *N*-heterocyclization also proceeded when aliphatic aldehydes were used in place of the allylic alcohols. The employment of allylic alcohols gave, however, higher yields in several cases. The reaction involves the isomerization of the allylic alcohols to the corresponding aldehydes. The aldehydes reacted with aminoarenes to give Schiff-base dimers which were then cyclized in the presence of the ruthenium complex to the quinolines. As a key intermediate in the reaction, the ortho-metallated species has been proposed.

Several methods have been reported using transition-metal complex catalysts for the formation of nitrogen heterocycles, such as pyrrole,[2)] indole,[3,4)] and quinoline[5,6)] derivatives. These procedures have been used to develop novel synthetic methods under non-acidic conditions.

In previous papers, we have demonstrated that rhodium, ruthenium, and palladium complexes were effective catalysts for the preparation of quinoline derivatives from aminoarenes and nitroarenes.[7-9a)] Aminoarenes were converted into quinoline derivatives in the presence of μ,μ'-dichlorobis(norbornadiene)-dirhodium(I) ($[RhCl(nbd)]_2$) by the reaction with aliphatic aldehydes.[7)] Nitroarenes were reductively converted into quinolines and (dialkylamino)arenes using aliphatic aldehydes in the presence of a rhodium–palladium binary catalyst system under carbon monoxide pressure.[8)] The quinoline derivatives were also obtained by the reductive transformation of nitroarenes using aliphatic alcohols in the presence of dichlorotris-(triphenylphosphine)ruthenium ($RuCl_2(PPh_3)_3$).[9a)] Recently, this nitroarene–aliphatic alcohol system was also adopted for the synthesis of the quinoline derivatives using a rhodium–molybdenum binary catalyst in a much larger amount (total 20 mol%).[9b)] These procedures provide a variety of synthetic methods for building up a quinoline nucleus.

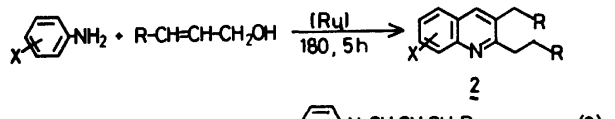
(2)



(3)

Recently, we have revealed that aniline was effectively *N*-alkylated with a primary alcohol in the presence of a ruthenium catalyst (Eq. 1).[1)] When allylic alcohols were employed in place of the primary alcohol, we first expected that *N*-alkenylated products would be obtained in the same manner as when the saturated alcohols were employed (Eq. 2). However, that was not the case. Instead, quinoline derivatives and *N*-(alkylamino)-arenes were obtained as products, and no *N*-alkenylated products were formed.

This paper deals with the ruthenium-catalyzed synthesis of the quinoline derivatives by the *N*-heterocyclization of aminoarenes using allylic alcohols. The *N*-heterocyclization also proceeds with aliphatic aldehydes in place of allylic alcohols. The results with aliphatic aldehydes are also described.

Results and Discussion

Aminoarenes reacted with allylic alcohols, such as 2-propen-1-ol and 2-buten-1-ol, at 180 °C in the presence of a catalytic amount of ruthenium and rhodium complexes to give 2,3-dialkylquinolines and *N*-alkyl-aminoarenes in good yields (Eq. 3, Table 1).

When 2-buten-1-ol was employed (Runs 1—8), the yield of 3-ethyl-2-propylquinoline depended greatly on the catalyst used. The highest yield was achieved with $RuCl_2(PPh_3)_3$ (Run 1). Ruthenium trichloride was also active, but the quinoline was obtained in a lower yield (Run 2). However, ruthenium complexes, such as $RuH_2(PPh_3)_4$, $RuHCl(PPh_3)_3$, $RuHCl(CO)(PPh_3)_3$, and $Ru(CO)_3(PPh_3)_2$, had almost no catalytic activity for the *N*-heterocyclization (Runs 3—6). On the other hand, $[RhCl(nbd)]_2$, which was the most effective catalyst for the *N*-heterocyclization of aminoarenes with *aldehydes*,[7)] showed only a low catalytic activity for this reaction (Run 7). The *N*-heterocyclization did not proceed at all without the catalyst (Run 8).

A similar trend was observed when 2-propen-1-ol was employed (Runs 9—12), although the best yield of 2-ethyl-3-methylquinoline was realized with ruthenium trichloride as a catalyst (Run 10). $RuHCl(CO)(PPh_3)_3$ had some activity (Run 11). $[RhCl(nbd)]_2$ showed also a low activity for the *N*-heterocyclization (Run 12).

The effects of other reaction variables were also

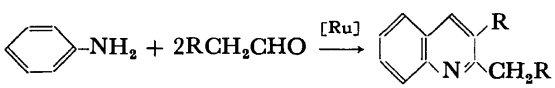
a) A mixture of aniline (20 mmol), aldehyde (10 ml; 94—138 mmol), $RuCl_2(PPh_3)_3$(0.2 mmol), and nitrobenzene (20 mmol) was stirred at 180 °C for 5 h. b) Based on aniline charged by GLC. c) See Eq. 3. d) Isolated yield. e) A mixture of aniline (20 mmol), aldehyde (44 mmol; 1.6—2.3 ml), benzene (10 ml), $RuCl_2(PPh_3)_3$ (0.2 mmol), and nitrobenzene (22 mmol) was stirred at 180 °C for 5 h.

examined; the results are shown in Table 2. A lower reaction temperature (150 °C) and a smaller amount of the catalyst (0.5 mol%) resulted in decreases in the conversion of aniline and in the yield of the quinoline (Runs 13 and 14). However, the yield was not improved by increasing the amount of the catalyst to 2.0 mol% (Run 15). These results indicate that an elevated temperature (180 °C) is required and that a 1.0 mol% catalyst is sufficient for a moderate yield of the quinoline. The yields of the quinolines decreased in the absence of nitrobenzene, which is considered to operate as an oxidant in the dehydrogenation step from hydroquinoline to the quinoline derivative (*vide infra*) (Runs 16 and 18). The dilution of the reaction system with benzene improved the yield of the quinoline derivatives (Runs 17 and 19).



(4)

The allylic alcohols can be replaced by aliphatic aldehydes (Eq. 4). The results are listed in Table 3. Employing pentanal in excess, 2-butyl-3-propylquinoline was obtained in a 33% isolated yield (Run 20). Butanal and propanal also gave the corresponding quinolines (Runs 21 and 23). On the other hand, in the rhodium-catalyzed preparation of quinolines using aldehydes,[8]

a) A mixture of aminoarene (20 mmol), nitroarene (22 mmol), allylic alcohol or aldehyde (10 ml), benzene (10 ml), and $RuCl_2(PPh_3)_3$ (0.2 mmol) was stirred at 180 °C for 5 h. b) Determined by GLC based on aminoarene charged. c) Reaction time was 7.5 h. d) The reaction was carried out without nitroarene.

an excess of aliphatic aldehyde interfered with the formation of the quinolines because of side reactions, *e.g.*, aldol condensation. In the present reaction, the employment of 2.2 equivalents of aldehyde did not affect the yield essentially (Runs 22 and 24). The present results indicate that the ruthenium catalyst can be used in the preparation of the quinolines from aniline and aliphatic aldehydes, though its catalytic activity is lower than that of the rhodium catalyst described in a previous paper.[7] However, the rhodium catalyst was revealed to be less effective for the preparation of quinolines with allylic alcohols, as has been mentioned above.

This procedure is applicable to a variety of aminoarenes for the preparation of various substituted quinolines. The results for para- and ortho-substituted anilines with methyl, methoxyl, and chloro substituents are summarized in Table 4. 3-Ethyl-6-methoxy-2-propylquinoline was produced in an 81% yield by the reaction of *p*-anisidine with 2-buten-1-ol (Run 25). Prolonging the reaction time slightly improved the yield (Run 26), while the absence of the nitroarene (*p*-nitroanisole) reduced the yield (Run 27). The use of butanal in place of 2-buten-1-ol resulted in a decrease in the yield of the substituted quinoline (Run 28). *p*-Toluidine and 2-buten-1-ol gave 3-ethyl-6-methyl-2-propylquinoline in an 82% yield (Run 29). Prolonging the reaction time appreciably improved the yield to 97% (Run 30). On the other hand, the absence of nitroarene (*p*-nitrotoluene) and the use of butanal in place of 2-buten-1-ol gave poorer yields of the substituted quinoline (Runs 31 and 32). 6-Chloro-3-ethyl-2-propylquinoline was also obtained, but in a poor yield (17%), when *p*-chloroaniline was employed as an aminoarene (Run 33).

The results obtained with *p*-substituted anilines clearly indicate that aminoarenes with electron-releasing groups, *i.e.*, aminoarenes with high pK_a values, favor the *N*-heterocyclization to quinoline derivatives. Furthermore, the employment of 2-buten-1-ol in place of butanal is more favorable to the *N*-heterocyclization.

2-Propen-1-ol reacted in a similar manner with *p*-anisidine and *p*-toluidine to give 2-ethyl-6-methoxy-3-methylquinoline and 2-ethyl-3,5-dimethylquinoline in moderate yields (Runs 34 and 35).

In contrast, ortho-substituted aminoarenes gave 8-substituted quinoline derivatives only in low yields (Runs 36—38). This is presumably the result of a steric effect of the ortho-substituting groups, which interfere with the coordination of the amino group to the ruthenium catalyst.

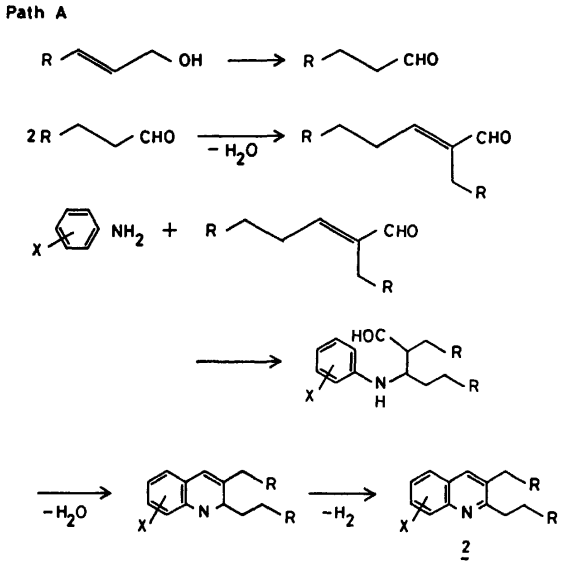
There have been several studies concerning the ruthenium- or rhodium-catalyzed isomerization of allylic alcohols to ketones and aldehydes.[10,11] The present reaction is believed to include the isomerization of the allylic alcohols to the corresponding aldehydes. Indeed, 2-buten-1-ol and 2-propen-1-ol were isomerized to butanal and propanal in 59 and 29% yields respectively in the presence of $RuCl_2(PPh_3)_3$ under conditions similar to those for the *N*-heterocyclization (Eq. 5; see Experimental section). In the present *N*-heterocyclization, the aldehydes produced are considered to react with

$$RCH{=}CHCH_2OH \xrightarrow[180\,^\circ C,\ 5\,h]{RuCl_2(PPh_3)_3} RCH_2CH_2CHO \qquad (5)$$

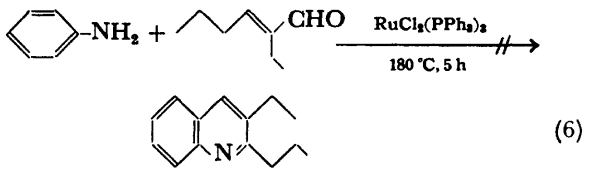
	Yield/%
$R=CH_3$	59
R=H	29

aminoarenes to give the quinoline derivatives.

In this reaction *N*-alkylaminoarenes as well as the quinoline derivatives were formed. Saturated alcohols were obtained in the isomerization reaction of the allylic alcohols (see Experimental section). Therefore, we can safely say that the saturated alcohols functioned as *N*-alkylating reagents in the reaction, as has previously been reported (Eq. 1).[1] The saturated alcohols can be produced by the hydrogenation of the allylic alcohols, since $RuCl_2(PPh_3)_3$ is known to be an effective catalyst for the hydrogen-transfer reaction from alcohols.[12]

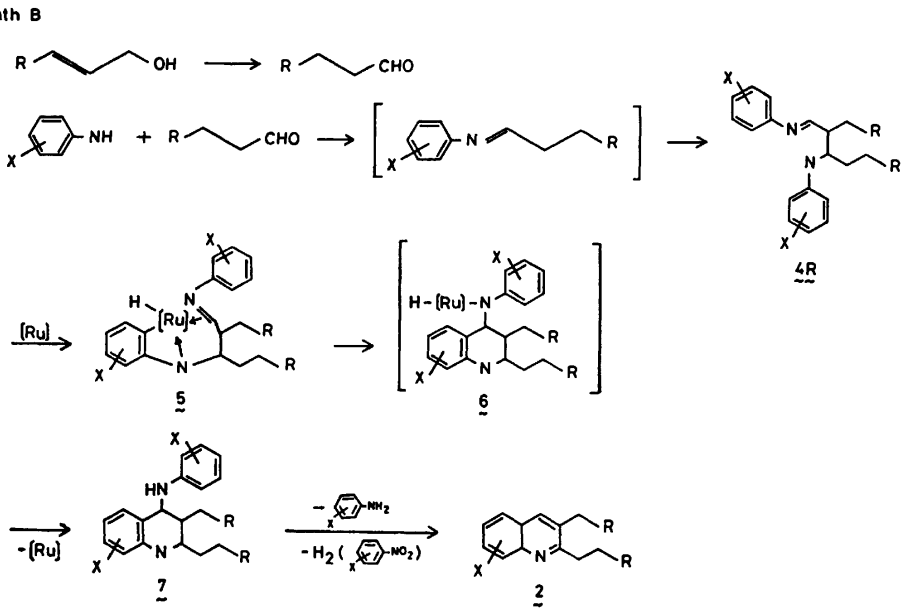


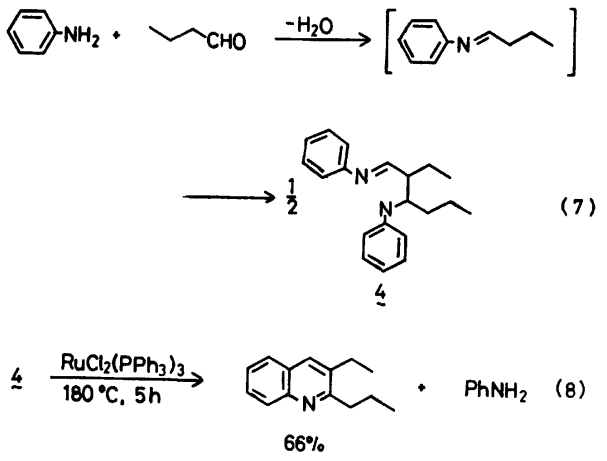
Some further studies on the mechanism of the *N*-heterocyclization to the quinolines have been carried out. Two reaction pathways are considered for the reaction. One is the path *via* aldol condensation, followed by the Michael-type addition of aminoarene (Path A). Transition metal-catalyzed aldol condensation reactions have been reported by several authors.[13] In order to examine the possibility of Path A, aniline was reacted with 2-ethyl-2-hexenal, which is an aldol condensate of butanal obtained by the method of the literature.[14] However, the corresponding quinoline, 3-ethyl-2-propylquinoline, was not obtained at all by the reaction (Eq. 6). Therefore, Path A seems not to be probable.



(6)

Aniline is known to react with an aldehyde to give a Schiff-base dimer.[15] The second pathway to the quinolines is one *via* the Schiff-base dimer (Path B). An equimolar mixture of aniline and butanal readily gave a Schiff-base dimer (**4**) at room temperature as white crystals (60% yield, lit, 78% yield[15b]) (Eq. 7). This Schiff-base dimer (**4**) was effectively converted to 3-ethyl-2-propylquinoline in the presence of $RuCl_2(PPh_3)_3$ (Eq. 8). Without the ruthenium complex or with 1 mol% (based on **4**) $ZnCl_2$, the corresponding quinoline was not obtained under the same reaction conditions. These results strongly suggest that the *N*-heterocyclization proceeds *via* the Schiff-base dimer and that the ruthenium catalyst operates in the cyclization stage. In Path B, the Schiff-base dimer, **4R**, forms presumably without the assistance of the ruthenium catalyst. Several transition metals have been reported to activate the aromatic *ortho*-C–H bond by oxidative addition to that bond, that is, by so-called orthometallation.[16] The ligands containing nitrogen are good ligands for maintaining such ortho-metallated species.[17] Furthermore, ruthenium is one of the most active central transition metals generating the ortho-metallated species.[18] Therefore, as one of the most plausible mechanisms of the cyclization stage, we propose the





one *via* ortho-metallated species, such as **5**. This reaction is considered to proceed from **5** to **6** by an insertion of the C=N bond into the Ru–C bond.[19] The following reductive elimination of active ruthenium species will generate **7**. Finally, the quinoline is obtained by the elimination of aniline and hydrogen from **7**. The elimination of hydrogen is favored by the presence of nitroarene.

In this study, aminoarene with an electron-releasing group favored the formation of the quinoline derivatives. This might be because the more basic aminoarene facilitates a nucleophilic attack on the carbonyl carbon of the aldehyde, and so favors the formation of the Schiff-base dimer.

Experimental

Materials and Catalysts. The alcohols, aldehydes, aminoarenes, and nitroarenes were commercial products and were purified by distillation or crystallization before use. The $RuCl_3 \cdot nH_2O$ (mainly trihydrate) was purchased from Wako Chemicals and was used without further purification. The $RuCl_2(PPh_3)_3$,[21] $RuH_2(PPh_3)_4$,[22] $RuHCl(PPh_3)_3$,[23] $RuHCl(CO)(PPh_3)_3$,[24] $Ru(CO)_3(PPh_3)_2$,[25] and $[RhCl(nbd)]_2$[25] were prepared according to the methods in the literatures.

Reaction Procedure and Identification of the Products. A mixture of aminoarene (20 mmol), allylic alcohol or aliphatic aldehyde (10 ml), a ruthenium catalyst (0.20 mmol, 1.0 mol% based on aminoarene charged), nitroarene (22 mmol), and benzene (10 ml), if required, was placed in a glass liner. The glass liner was set in a 50 ml stainless steel autoclave (Taiatsu Kogyo) and the mixture was stirred with a magnetic stirrer at 180 °C for 5 h under an argon atmosphere. The GLC analysis of the reaction mixture was performed with 5% Apiezon Grease L supported on Neopak 1A 60—80 mesh (0.3 cmϕ × 3 m) by the internal-standard method. The product was isolated by fractional distillation or by medium-pressure column chromatography (silica gel, Merck No. 9385, as the absorbent and hexane–ethyl acetate as the eluent) and identified by means of ^{1}H-, ^{13}C-NMR, IR, mass spectra, and elemental analysis.

Identification of the Products. The ^{1}H-NMR spectra were obtained with a Varian HR-220(220 MHz) or JEOL JNM FX100 (100 MHz) spectrometer. The ^{13}C NMR spectra were recorded at 25.05 MHz on a JEOL JNM FX100 spectrometer. The IR spectra were measured on a Hitachi model 215 grating spectrometer, and the mass spectra were recorded on a JMS 01SG mass spectrometer. Elemental analysis was performed at the Microanalytical Center of Kyoto University.

N-*Butyl*-p-*toluidine.* ^{1}H-NMR ($CDCl_3$) δ=0.94 (t, 3H), 1.48 (m, 4H), 2.21 (s, 3H), 3.02 (t, 2H), 3.35 (s, 1H), 6.47—7.04 (m, 4H); ^{13}C-NMR ($CDCl_3$) δ=13.9(s), 20.4(s), 20.4(s), 31.8(s), 44.1(s), 112.9(s), 126.1(s), 129.6(s), 146.3(s); IR 3400 cm^{-1} (ν NH).

N-*Butyl*-p-*anisidine.* ^{1}H-NMR ($CDCl_3$) δ=0.92 (t, 3H), 1.36 (m, 2H), 1.51 (m, 2H), 2.98 (t, 2H), 3.27 (s, 1H), 3.66 (s, 3H), 6.47—6.77 (m, 4H); ^{13}C-NMR ($CDCl_3$) δ= 14.0(s), 20.4(s), 31.8(s), 44.6(s), 55.7(s), 113.9(s), 114.9(s), 142.9(s), 151.8(s); IR 3400 cm^{-1} (ν NH). The spectral data of the other products which appeared in this study were all consistent with those reported in the previous paper.[7]

Isomerization of Allylic Alcohols. In a glass liner, 2-propen-1-ol (5.0 ml, 74.6 mmol) and $RuCl_2(PPh_3)_3$ (95.9 mg, 0.10 mmol) were placed. The glass liner was then set in the autoclave, and the mixture was stirred with magnetic stirrer at 180 °C for 5 h under an argon atmosphere. The subsequent GLC analysis of the reaction mixture showed that 96% of the 2-propen-1-ol was converted and that 22 mmol (29% based on the 2-propen-1-ol used) of propanal and 7.5 mmol (10%) of propanol were obtained.

The isomerization of 2-buten-1-ol (5.0 ml, 60.5 mmol) with $RuCl_2(PPh_3)_3$ (95.9 mg, 0.10 mmol) was carried out in a similar manner. The conversion of 2-buten-1-ol was almost 100%, and 36 mmol (59% based on 2-buten-1-ol used) of butanal and 9.7 mmol (16%) of butanol) were formed.

Reaction of Aniline with 2-Ethyl-2-hexenal. A mixture of aniline (11 mmol), 2-ethyl-2-hexenal (15 mmol), nitrobenzene (12 mmol), benzene (5.0 ml), and $RuCl_2(PPh_3)_3$ (0.10 mmol) was stirred at 180 °C for 5 h under an argon atmosphere. The GLC analysis of the reaction mixture showed that no 3-ethyl-2-propylquinoline was obtained, although considerably aniline was converted.

Transformation of **4** *into 3-Ethyl-2-propylquinoline.* A solution of **4** (2.94 g, 10 mmol) in benzene (20 ml) was stirred in the presence of nitrobenzene (20 mmol) and $RuCl_2(PPh_3)_3$ (0.20 mmol) at 180 °C for 5 h. After the reaction mixture had cooled, 6.6 mmol (66% yield based on **4**) of 3-ethyl-2-propylquinoline was found by GLC analysis. When the reaction was carried out in the absence of nitrobenzene, the yield of the quinoline decreased to 3.4 mmol (34% yield).

The Reaction of Olefins with a Mixture of Iodine and Mercury(II) Thiocyanate. Predominant Formation of *vic*-Iodo(isothiocyanato)alkanes

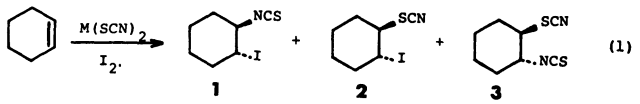
Nanao WATANABE,† Sakae UEMURA, and Masaya OKANO*
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
†*Koei Chemical Co. Ltd., Joto-ku, Osaka 536*
(Received December 27, 1982)

Treatment of olefins with a mixture of iodine and mercury(II) thiocyanate in benzene or diethyl ether gives *vic*-iodo(isothiocyanato)alkanes and *vic*-iodo(thiocyanato)alkanes in a high yield, the former being predominant. Similar results were obtained by using silver(I) and thallium(I) thiocyanates, though both the yield and the selectivity are slightly lower. By use of potassium thiocyanate and copper(I) isothiocyanate in place of mercury(II) thiocyanate, β-iodo thiocyanates were mainly formed. A reaction scheme involving initial formation of an iodonium ion from olefin and ISCN (formed *in situ*) and a subsequent attack of complex anion $I(SCN)_2^-$ has been proposed to account for this predominant formation of β-iodo isothiocyanates.

We reported previously that $Hg(SCN)_2$ reacts with alkyl halides in solvents of low polarity to afford alkyl isothiocyanates (RNCS) and alkyl thiocyanates (RSCN), with the former being predominant.[1] The preponderant isothiocyanate formation was explained by assuming the reaction of $XHg(SCN)_2^-$ with the alkyl cation. When a mixture of olefin and halogen is used in place of alkyl halides, selective formation of *vic*-iodo(isothiocyanato)-alkanes might be expected in a similar manner. We report here our new findings on this subject. Cambie *et al.* have recently reported that a mixture of I_2 and TlSCN reacts with cyclohexene to give the expected β-iodo isothiocyanate and β-iodo thiocyanate as the main products.[2] They have observed an unusual solvent dependence of the isothiocyanate/thiocyanate ratio: In solvents of sulfolane, dichloromethane, or diethyl ether, the ratios were around 1.5 regardless of their polarity, whereas in a suitable mixed solvent ($CHCl_3$ and sulfolane or DMSO with 1 : 1) the ratios were higher (*ca.* 3.0—4.0). Such a trend was not observed in the reaction of alkyl halides with $Hg(SCN)_2$.

Results and Discussion

First of all, we examined the reaction of cyclohexene with a mixture of I_2 and various metal thiocyanates, $M(SCN)_2$, to study the effect of metal salts on the isomer distribution in the expected products. Dry benzene was chosen as a solvent, since we previously observed the favorable formation of isothiocyanates from alkyl halides in less polar solvents. Although I_2 is soluble in benzene, all metal salts examined are only slightly soluble and thus the reaction mixture is heterogeneous in all cases. The reaction was generally carried out in the dark by adding cyclohexene to a pre-stirred (0.5 h) mixture of I_2 and $M(SCN)_2$ in benzene and by stirring the resulting mixture for 18—24 h at room temperature. The products were *trans*-1-iodo-2-isothiocyanatocyclohexane (**1**), *trans*-1-iodo-2-thiocyanatocyclohexane (**2**), and a very small amount of *trans*-1-isothiocyanato-2-thiocyanatocyclohexane (**3**) (Eq. 1). The results are shown in Table 1. $Hg(SCN)_2$ showed the



1 2 3 (1)

best results for both the total yield of **1** and **2** and the selectivity for the *N*-alkylation product **1**. Among other metal salts examined, AgSCN and TlSCN were found to be fairly effective for the formation of **1**, while almost no reaction occurred using $Ni(NCS)_2$ and $Pb(SCN)_2$, probably due to their poor reactivities toward I_2 (see below). On the contrary, the *S*-alkylation product **2** was mainly formed when KSCN (in ether), CuNCS and $Cu(NCS)_2$ were used. Cambie *et al.* also reported

Table 1. Reaction of cyclohexene with various metal thiocyanates and iodine[a]

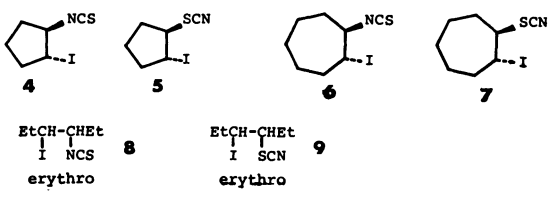
a) I_2 (10 mmol) was used in all cases. Benzene (25 ml) was used as solvent for $Hg(SCN)_2$ and diethyl ether (25 ml) for KSCN. b) Isolated yield.

a predominant formation of β-iodo thiocyanates from some olefins in sulfolane and/or chloroform as a solvent.[2,3]

Next, the effects of the solvent and the reaction temperature and the time upon the isomer ratio in the products were studied in the reaction using $Hg(SCN)_2$. Table 2 shows that the reaction proceeds smoothly even at shorter reaction times and at a lower temperature in benzene or diethyl ether as solvent, in spite of the heterogeneous reaction system, and that the ratio of **1**/**2** is nearly constant by changing the reaction time. These results suggest that no isomerization between the two isomers occurs under these conditions.[4] As to the selectivity for the formation of **1**, diethyl ether is superior to benzene as solvent and the reaction at a lower temperature seems to be favorable. The reaction proceeded homogeneously in tetrahydrofuran, but both the product yield and the selectivity for **1** were somewhat lower. No reaction occurred in hexane as solvent.

Extension of the reaction using $Hg(SCN)_2$ to other olefins such as cyclopentene, cycloheptene, and *trans*-3-hexene resulted also in the formation of the expected β-iodo isothiocyanates (**4**, **6**, **8**) and β-iodo thiocyanates (**5**, **7**, **9**), the former being predominant in all cases as in the case of cyclohexene. Similarly, the reaction using KSCN afforded the latter highly selectively. Typical results are summarized in Table 3 together with the data of cyclohexene.



Though it is known that $Pb(SCN)_2$ effectively reacts with Br_2 to give thiocyanogen $[(SCN)_2]$[5,6] and with excess Cl_2 to afford thiocyanogen chloride (ClSCN), few similar reactions with I_2 have been reported, except for the case of the Ag salt.[7,8] Cambie *et al.*[2] recently stated that, in the reaction of 2-phenylpropene with I_2 and TlSCN in chloroform–sulfolane solvent, the total yield of the β-isothiocyanato thiocyanate and the dithiocyanate predominated over the yield of the β-iodo isothiocyanate, but no evidence was given for the generation of $(SCN)_2$ species from a mixture of I_2 and TlSCN.

We have obtained some information regarding the formation of some active species including $(SCN)_2$ from I_2 and metal thiocyanates as shown below. When an equimolar quantity of I_2 was added gradually to a stirred suspension of $Hg(SCN)_2$ in benzene and then the stirring was continued for a further 0.5 h at 25 °C, the red color of I_2 in solution almost disappeared and a red solid separated. Treatment of the filtrate, after the removal of the solid, with cyclohexene (1 equiv) for 17 h at 16—19 °C under stirring afforded **3** (19%) along with **1** (12%) and **2** (2%). In contrast to this, the use of 2 mol of I_2 in the above experiment resulted in a different product distribution: *i.e.*, **1** (57%), **2** (16%), and **3** (1%). The total yield of **1** and **2** is somewhat lower than that in the reaction without filtration of the red solid, but the ratio of **1**/**2** is nearly the same in both cases. Quite similar results were obtained in the I_2–TlSCN system as well. These observations clearly indicate that the generation of $(SCN)_2$ from an equiva-

lent mixture of I_2 and $Hg(SCN)_2$ or TlSCN (possibly the Ag(I) salt as well) is fairly rapid in spite of a heterogeneous reaction, and that under the presence of excess I_2 the *vic*-iodothiocyanation and *vic*-iodoisothiocyanation occur substantially with only a little or without any formation of the olefin–$(SCN)_2$ and olefin–I_2 adducts. Thus the most probable species for addition to olefin would be the ISCN species, which is formed by the following scheme (Eqs. 2 and 3). Here, the equilibrium shown in Eq. 3 is already known.[8]

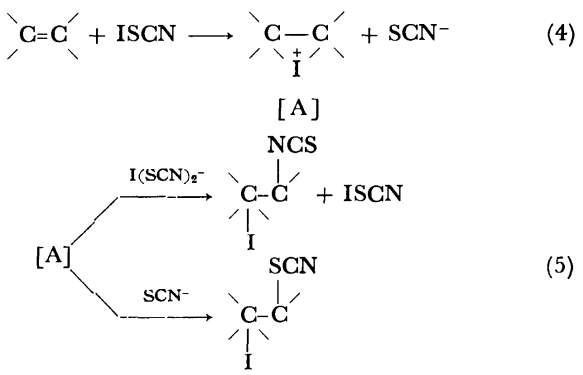
$$Hg(SCN)_2 + I_2 \longrightarrow (SCN)_2 + HgI_2\downarrow$$

$$2TlSCN + I_2 \longrightarrow (SCN)_2 + 2TlI\downarrow \quad (2)$$

$$(SCN)_2 + I_2 \rightleftarrows 2\,ISCN \quad (3)$$

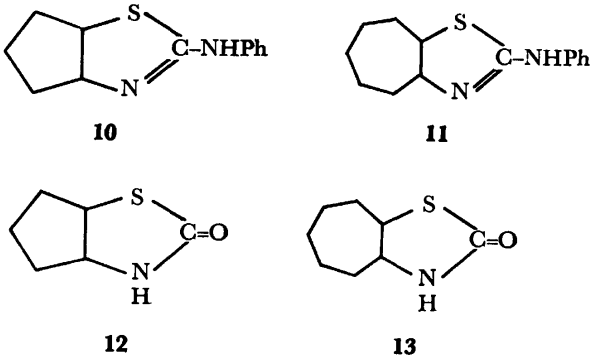
However, in the cases of $Pb(SCN)_2$ and $Ni(SCN)_2$ the generation of $(SCN)_2$ by Eq. 2 seemed to be difficult, since no appreciable decolorization of the reaction mixture was observed and no principal products other than *vic*-diiodide were found (see Table 1).

As to the product-determining step, Cambie *et al.* suggested a probable pathway for the reaction with a mixture of I_2 and $(SCN)_2$. This pathway involves the initial formation of a bridged iodonium ion, and a subsequent attack by SCN^- leading to *β*-iodo thiocyanate and the attack by ISCN or $(SCN)_2$ to *β*-iodo isothiocyanate.[3] However, we believe that a nucleophile $I(SCN)_2^-$, which is in equilibrium with SCN^- and ISCN,[9] is a more conceivable species for the latter attack. If this complex ion serves as a source of SCN^-, the reaction with cationic species would occur mainly at either of the two terminal N atoms, which are the sterically favorable and more electronegative sites (Eqs. 4 and 5). Further, when a large excess of I_2 was used in the reaction of cyclohexene, a further increase in the *N*-selectivity was observed (see Table 1). This might be attributed to the concentration of another active species $I_2(SCN)^-$, but the phenomenon was not so general for other olefins.



For comparison with the data using the I_2–$Hg(SCN)_2$ system, we also examined the reaction using an equimolar mixture of I_2 and $(SCN)_2$ (prepared by a known method[5] separately). The reaction in benzene at 17—24 °C for 20 h afforded the products **1** (53%), **2** (16%), and **3** (1%). A slight excess in the total yield of **1** and **2** and in the *N*-selectivity in the I_2–$Hg(SCN)_2$ cases compared to this case can be explained by assuming the competitive thiocyanation with a complex anion of $Hg(SCN)_2$ such as $IHg(SCN)_2^-$ or $Hg(SCN)_3^-$, though no direct evidence of this is available.

It is known that *vic*-iodo(isothiocyanato)alkanes react with aniline and methanol to afford 2-anilino-2-thiazoline and 2-thiazolidinone respectively.[10] By the reported methods we could prepare the corresponding new compounds such as **10** and **12** from **4** and **11** and **13** from **6** respectively.



Experimental

All organic substances were distilled immediately before use. Diethyl ether and tetrahydrofuran were dried over sodium and then distilled. Commercial metal thiocyanates and isothiocyanates, HgI_2, and bromine were used without further purification.

The ^1H NMR spectra were recorded with JEOL JNM FX-100 (100 MHz) instruments on solutions in $CDCl_3$ with Me_4Si as internal standard. The ^{13}C NMR spectra were taken at 25.1 MHz with a JEOLCO ^{13}C Fourier transform NMR system and were recorded on solutions in $CDCl_3$, after 250—1000 pulses with intervals of 2.7—2.8 s. The GLC analyses were carried out with a Yanagimoto G-2800 apparatus using SE-30 (1 m) and EGSS-X (1 m) columns (H_2 as carrier gas), benzyl isothiocyanate ($PhCH_2NCS$) being used as an internal standard. The IR spectra were recorded with a Hitachi SPI-G3 spectrometer. The liquid chromatographic analyses were carried out with a Waters HPLC system equipped with a 6000A solvent delivery system and a Model 440 absorbance detector (at 254 nm) with a μ-Porasil (3.9 mm × 0.3 m) column [hexane–chloroform (3 : 1) as eluent]. The mass spectra were measured on a JEOL JMS-D300 mass spectrometer, the ionization voltage being 10 and 70 eV.

The yield of *vic*-iodo(isothiocyanato)alkanes was determined by GLC, while *vic*-iodo(thiocyanato)alkanes were decomposed at the GLC conditions. Therefore, the yield of the iodothiocyanates was evaluated by HPLC using a calibration curve between the two isomers which are stable enough for HPLC determination. The isolation of products was carried out by column chromatography using silica gel (Wakogel C-200; benzene as eluent), the isothiocyanates being eluted first.

Typical experimental procedures and analytical data of new compounds are given below.

a) The Reaction of $Hg(SCN)_2$ and I_2 with Cyclopentene in Benzene. To a suspension of $Hg(SCN)_2$ (1.58 g, 5 mmol) and benzene (5 ml) was slowly added a benzene (20 ml) solution of I_2 (2.53 g, 10 mmol) under stirring at room temperature. After 30 min, cyclopentene (0.68 g, 10 mmol) was added to the mixture by keeping the temperature within the range of 18—22 °C (a slight heat evolution was observed during the addition) and the resulting mixture was stirred for 18 h at that temperature. All operations described above were carried out in the dark by wrapping the flask with aluminium foil.

The precipitated red solid (mainly HgI_2) was filtered and the filtrate was washed with aqueous KI, aqueous $Na_2S_2O_3$, and brine successively, and then dried over $MgSO_4$. Evaporation of the solvent from the filtrate left a yellow oil, an aliquot of it being analyzed by GLC and HPLC; *trans*-1-iodo-2-isothiocyanatocyclopentane (**4**) (7.29 mmol, 73% yield) and *trans*-1-iodo-2-thiocyanatocyclopentane (**5**) (2.13 mmol, 21%). These were isolated respectively by column chromatography: **4** (1.75 g, 6.91 mmol, 69%) and **5** (0.49 g, 1.95 mmol, 20%). **4**; A colorless oil, IR 2050 (ν_{-NCS}, br) cm^{-1}. ^1H NMR δ= 1.6—2.7 (m, 6H), 4.1—4.5 (m, 2H). ^{13}C NMR δ=22.2 (t), 27.8 (d, >CHI), 31.3 (t), 36.3 (t), 66.8 (d, >CHNCS), 134.4 (s, -NCS). Mass (*m/e*) 253 (M^+), 195 (M^+—NCS), 126 (M^+—I). Found: C, 28.49; H, 3.27; N, 5.71%. Calcd for C_6H_8INS: C, 28.47; H, 3.19; N, 5.53%. **5**; A colorless oil, IR 2150 (ν_{-SCN}) cm^{-1}. ^1H NMR δ=1.6—2.7 (m, 6H), 3.93 (td. 1H, J=4.5 and 7.2 Hz, >CHSCN), 4.40 (td. 1H, J=4.5 and 6.0 Hz, >CHI). ^{13}C NMR δ=22.9 (t), 29.0 (d, >CHI), 30.6 (t), 37.0 (t), 57.1 (d, >CHSCN), 110.4 (s, -SCN). Mass (*m/e*) 254 (M^++1), 195 (M^+—SCN), 126 (M^+—I). Found: C, 28.33; H, 3.16; N, 5.84%.

The analytical data of *trans*-1-iodo-2-isothiocyanatocycloheptane (**6**) and *trans*-1-iodo-2-thiocyanatocyloheptane (**7**) are as follows. **1**, **2**, **8**, and **9** are known compounds[2,3] and the spectral and analytical data are completely the same as those of each authentic sample.

6; A colorless oil, IR 2050 (ν_{-NCS}, br) cm^{-1}. ^1H NMR δ=1.64 (br s, 6H), 1.8—2.3 (m, 4H), 4.20 (ddd 1H, J=7.5, 7.0, and 3.2 Hz, >CHNCS), 4.46 (td 1H, J=7.5 and 4.0 Hz, >CHI). ^{13}C NMR δ=22.3 (t), 26.3(t), 26.6 (t), 32.6 (t), 35.7 (d, >CHI), 36.3 (t), 67.1 (d, >CHNCS), 133.1 (-NCS). Mass (*m/e*) 281 (M^+), 233 (M^+—NCS), 154 (M^+—I). Found: C, 34.24; H, 4.49; N, 5.20%. Calcd for $C_8H_{12}INS$: C, 34.18; H, 4.30; N, 4.98%.

7; A Colorless oil, IR 2150 (ν_{-SCN}) cm^{-1}. ^1H NMR δ= 1.4—2.0 (m, 6H), 2.0—2.5 (m, 4H), 3.89 (ddd, 1H, J=7.3, 7.1, and 3.3 Hz, >CHSCN), 4.63 (dt, 1H, J=7.1 and 5.0 Hz, >CHI). ^{13}C NMR δ=24.2 (t), 25.7 (t), 26.7 (t), 32.2 (t), 36.5 (d, >CHI), 36.7 (t), 60.0 (d, >CHSCN), 110.9 (s, -SCN). Mass (*m/e*) 281 (M^+), 223 (M^+—SCN), 154 (M^+—I). Found: C, 34.14; H, 4.42; N, 5.06%.

b) The Reaction of KSCN and I_2 with Cyclopentene in Diethyl Ether. The reaction was carried out in a similar manner to that given above, using dry KSCN (0.98 g, 10 mmol), I_2 (2.53 g, 10 mmol), and cyclopentene (0.68 g, 10 mmol) in diethyl ether (25 ml) as solvent at 20—26 °C for 20 h. The products were **4** and **5**; the isolated yields of **4** and **5** were 0.04 g (0.17 mmol, 2%) and 1.91 g (7.56 mmol, 76%), respectively.

c) The Reaction of a Mixture of I_2 and Thiocyanogen with Cyclohexene. The solution of thiocyanogen (10 mmol) in benzene (20 ml) was prepared by the reported method[5] using $Pb(SCN)_2$ (3.60 g, 11 mmol) and Br_2 (1.60 g, 10 mmol). To this solution was added a benzene (20 ml) solution of I_2 (2.53 g, 10 mmol) at 10—17 °C under stirring. After 30 min, cyclohexene (0.82 g, 10 mmol) was added and the resulting mixture was stirred for 20 h at 17—24 °C in the dark and then worked up as in the case of a). The GLC and HPLC analysis revealed the presence of 1-iodo-2-isothiocyanatocyclohexane (**1**) (5.30 mmol, 53%), 1-iodo-2-thiocyanatocyclohexane (**2**) (1.90 mmol, 19%), and 1-isothiocyanato-2-thiocyanatocyclohexane (**3**) (0.10 mmol, 1%) as products. Each product was isolated by column chromatography. **3**; A colorless semisolid (lit,[11] a colorless solid), IR 2130 (ν_{-SCN}) and 2050 (ν_{-NCS}) cm^{-1}. ^1H NMR δ=1.1—2.0 (m, 6H), 2.1—2.6 (m, 2H), 3.10 (ddd, 1H, J=4.0, 10.5, and 11.5 Hz, >CHSCN), 3.76 (td, 1H, J= 10.5 and 4.0 Hz, >CHNCS). ^{13}C NMR δ=23.5 (t), 25.2 (t), 32.5 (t), 34.2 (t), 52.3 (d, >CHSCN), 59.9 (d, >CHNCS), 109.5 (>SCN), 135.5 (-NCS). Found: C, 48.24; H, 5.09; N, 14.24%. Calcd for $C_8H_{10}N_2S_2$: C, 48.46; H, 5.08; N, 14.13%.

d) The Reaction of trans*-1-Iodo-2-isothiocyanatocyclopentane (**4**) with Aniline. Preparation of* **10**: Aniline (0.76 g, 8 mmol) and (**4**) (1.02 g, 4 mmol) were dissolved in diethyl ether (25 ml) and the resulting solution was kept for 3 d at room temperature in the dark, during which period a yellow semisolid appeared at the bottom of the flask.[10] The whole mixture was washed with aqueous K_2CO_3 (in order to liberate the product from its HI salt) and brine, and then dried over $MgSO_4$. Evaporation of the solvent left a white solid of *cis*-2-anilino-4,5-trimethylenethiazoline (**10**) which was recrystallized from benzene–hexane: yield; 0.665 g, 3.05 mmol (76%). Mp 117—118 °C, IR (KBr disk) 3420 (ν_{N-H}), 1620 $\nu_{(C=N)}$ cm^{-1}. ^1H NMR δ=1.3—2.2 (m, 6H), 3.9—4.2 (m, 1H), 4.4—4.7 (m, 1H), 6.2 (br s, 1H), 6.9—7.4 (m, 5H). ^{13}C NMR δ=23.5 (t), 34.6 (t), 36.1 (t), 49.7 (d, >CH-S), 68.2 (d, >CH-N), 121.5 (d), 122.9 (d), 128.8 (d), 147.6 (s), 160.9 (s, -N=C-S). Mass (*m/e*) 218 (M^+). Found: C, 66.01; H, 6.44; N, 13.25%. Calcd for $C_{12}H_{14}N_2S$: C, 66.02; H, 6.46; N, 12.83%.

By similar treatment of **6** with aniline, *cis*-2-anilino-4,5-pentamethylenethiazoline (**11**) was obtained in an isolated yield of 84%. A colorless solid from diethyl ether–hexane (1 : 2). Mp 124.5—125.5 °C, IR (KBr disk) 3420 (ν_{NH}), 1630 ($\nu_{C=N}$) cm^{-1}. ^1H NMR δ=1.0—1.5 (m, 3H), 1.5—2.0 (m, 7H), 3.7—4.2 (m, 2H), 5.55 (br s, 1H), 6.9—7.4 (m, 5H). Mass (*m/e*) 247 (M^++1). Found: C, 68.15; H, 7.41; N, 11.68%. Calcd for $C_{14}H_{18}N_2S$: C, 68.25; H, 7.36; N, 11.37%.

*e) The Reaction of **4** with Methanol. Preparation of **12**:* The mixture of **4** (1.56 g, 6.2 mmol), methanol (10 ml), and tetrachloroethylene (20 ml) was refluxed for 3 d in the dark.[10] Evaporation of the solvent left a yellow oil which was subjected to column chromatography [silica gel, $CHCl_3$ as eluent] to give a pure *cis*-4,5-trimethylene-2-thiazolidinone (**12**) as a pale yellow oil: yield, 0.47 g, 3.3 mmol (53%). IR (neat) 3221 (ν_{NH}, br), 1660 ($\nu_{C=O}$, br) cm^{-1}. ^1H NMR δ=1.5—2.3 (m, 6H), 4.0—4.3 (m, 2H), 7.26 (br s, NH). ^{13}C NMR δ= 23.1 (t), 34.5 (t), 36.2 (t), 47.5 (d, >CH-S), 60.0 (d, >CH-N), 175.4 (>C=O). Mass (*m/e*) 143 (M^+). Found: C, 49.93; H, 6.60; N, 10.10%. Calcd for C_6H_9NOS: C, 50.32; H, 6.34; N, 9.78%.

By similar treatment of **6** with methanol, *cis*-4,5-pentamethylene-2-thiazolidinone (**13**) was obtained in an isolated yield of 42% by column chromatography as above. Mp 94—95 °C, IR (KBr disk) 3200 (ν_{NH} br), 1660 ($\nu_{C=O}$, br) cm^{-1}. ^1H NMR δ=1.0—2.1 (m, 10H), 3.9—4.1 (m, 2H), 7.18 (br s, 1H). ^{13}C NMR δ=24.8 (t), 27.3 (t), 30.4 (t), 31.2 (t), 32.5 (t), 49.5 (d, >CH-S), 59.3 (d, >CH-N), 174.5 (>C=O). Mass (*m/e*) 171 (M^+). Found: C, 56.82; H, 7.94; N, 8.29%. Calcd for $C_8H_{13}NOS$: C, 56.11; H, 7.65; N, 8.18%.

The Substituent Effects in Thiophene Compounds. I. ^{1}H NMR and IR Studies in Methyl (Substituted 2-Thiophenecarboxylate)s

Hajime SATONAKA

Industrial Research Institute of Kanagawa Prefecture, 3173, Showa-machi, Kanazawa-ku, Yokohama 236

(Received January 11, 1983)

The ^{1}H NMR spectra and the IR carbonyl stretching frequencies of methyl (3-, 4-, and 5-substituted 2-thiophenecarboxylate)s have been reported. Good linear correlations between the chemical shifts of the ring protons in methyl (4- and 5-substituted 2-thiophenecarboxylate)s and those of the corresponding protons in substituted thiophenes were observed. The coupling constants in methyl (substituted 2-thiophenecarboxylate)s gave good correlations against the corresponding ones in substituted thiophenes. The IR carbonyl stretching frequencies in methyl (5-substituted 2-thiophenecarboxylate)s were correlated reasonably well with the chemical shifts of 5-protons in 2-substituted thiophenes. The coupling constants in methyl 2-thiophenecarboxylate series were found to vary linearly with the electronegativities of the substituents.

The ^{1}H NMR spectra have been obtained for 2- and 3-substituted thiophene,[1-3] and disubstituted thiophenes,[1,4] and the effects of the substituents have been discussed.

The present study was undertaken to examine the substituent effects in methyl (3-, 4-, and 5-substituted 2-thiophenecarboxylate)s in comparison with those of 2- and 3-substituted thiophenes. The correlations of the chemical shifts and of the coupling constants between methyl (substituted 2-thiophenecarboxylate)s and substituted thiophenes have been discussed in this paper. Attempts have also been made to compare the IR carbonyl stretching frequencies in methyl (substituted 2-thiophenecarboxylate)s with the chemical shifts in substituted thiophenes, and the coupling constants in methyl (substituted 2-thiophenecarboxylate)s with the electronegativities of the substituents.

Results and Discussion

The ^{1}H NMR spectra of 2- and 3-substituted thiophenes (**1** and **2**), and methyl (3-, 4-, and 5-substituted 2-thiophenecarboxylate)s (**3**—**5**) were measured in deuteriochloroform at 25 °C. The assignments of the signals were made tentatively on the basis of the chemical shifts and the coupling constants. The refined chemical

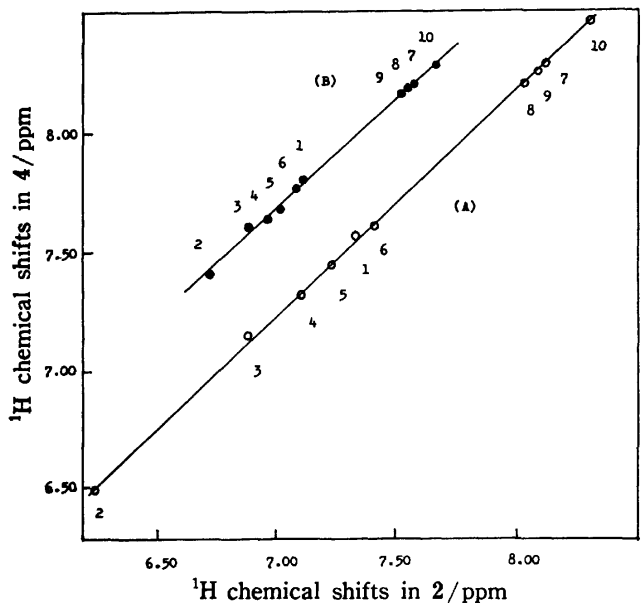

Fig. 1. Correlation between ^{1}H chemical shifts in **4** and **2**; numbering as in Table 2. A, δ_5(**4**) *vs.* δ_2(**2**); B, δ_3(**4**) *vs.* δ_4(**2**).

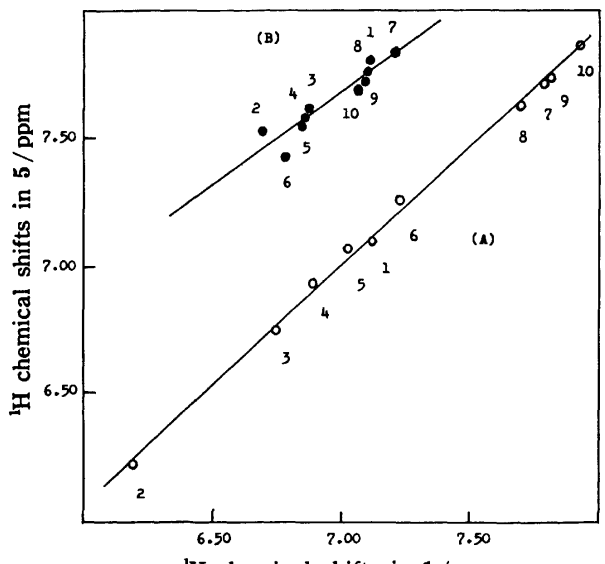

Fig. 2. Correlation between ^{1}H chemical shifts in **5** and **1**; numbering as in Table 1. A, δ_4(**5**) *vs.* δ_3(**1**). B, δ_3(**5**) *vs.* δ_4(**1**).

shifts and coupling constants were obtained iteratively using LAOCN 3.[5] The results are given in Tables 1—5. For convenience, the author uses, hereafter, the notation H_r(**N**) for the *r*-th(position)-proton on the thiophene ring of the series of compounds **N**, δ_r(**N**) for its chemical shift, and *cc*, *p*, *i*, and *s* for the correlation coefficient, slope, intercept, and standard deviation in the least-squares analysis.

The δ_5(**4**) *vs.* δ_2(**2**) (A, *cc* 1.000, *p* 0.938, *i* 0.658, *s* 0.006) and the δ_3(**4**) *vs.* δ_4(**2**) (B, *cc* 0.999, *p* 0.907, *i* 1.323, *s* 0.013) plots gave excellent correlations, as shown in Fig. 1. Line A runs almost parallel with B. The correlation coefficient between δ_3(**4**) and δ_5(**4**) is

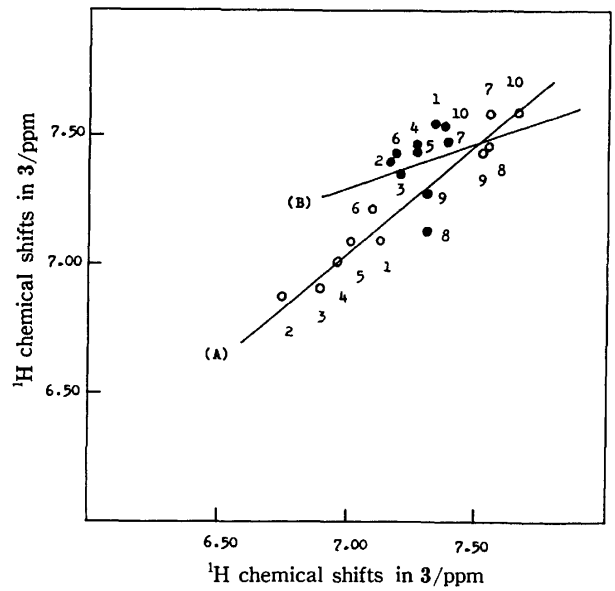

Fig. 3. Correlation between ^{1}H chemical shifts in **3** and **2**; numbering as in Table 2. A, δ_4(**3**) *vs.* δ_4(**2**); B, δ_5(**3**) *vs.* δ_5(**2**).

0.980, and this value is in accord with that between δ_2(**2**) and δ_4(**2**). These data show that the introduction of a methoxycarbonyl group into position 5 of 3-substituted thiophene is confined to the parallel transfer of the substituent effects on H_2(**2**) and H_4(**2**).

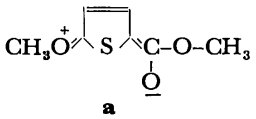
As seen in Fig. 2, good correlations were obtained with the δ_4(**5**) *vs.* δ_3(**1**) (A, *cc* 1.000, *p* 0.935, *i* 0.455, *s* 0.018) and δ_3(**5**) *vs.* δ_4(**1**) (B, *cc* 0.939, *p* 0.717, *i* 2.651, *s* 0.044) plots. The ratio of the slope of A against that of B is 0.768. Moreover, the slope of A is comparable with that of A in Fig. 1. The correlation coefficient and slope of the δ_4(**5**) *vs.* δ_5(**4**) plot are in good agreement with those between δ_3(**1**) *vs.* δ_2(**2**). These facts indicate that the methoxycarbonyl group in **5** reduces the substituent effect on the δ_3(**5**), whereas it has no effect on the δ_4(**5**).

Figure 3 shows good linearity (A, *cc* 0.982, *p* 0.835, *i* 1.207, *s* 0.051) between the effects of the substituents on δ_4(**3**) and those on δ_4(**2**), and no correlation (B, *cc* 0.215, *p* 0.357, *i* 4.806, s 0.115) between those on δ_5(**3**) and δ_5(**2**). The relationship between δ_4(**3**) and δ_3(**4**) was obtained as a linear response with a good correlation coefficient and unit slope. The correlation between δ_4(**3**) and δ_5(**4**) is almost equal to that between δ_4(**2**) and δ_2(**2**). However, apparently there is no correlation between δ_5(**3**) and δ_3(**5**), contrary to the situation between δ_5(**2**) and δ_4(**1**). Consequently, it seems that the chemical shift for the H_5 adjacent to the methoxycarbonyl group, which has a substituent on the *ortho* position, is affected considerably.

Methyl proton chemical shifts of methyl (substituted 2-thiophenecarboxylate)s, which are much less affected by the substituents on the ring, were found to have rather good correlations between proton chemical shifts of corresponding substituted thiophenes.

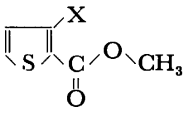
The chemical shifts of the ring protons of methyl (3-, 4-, and 5-substituted 2-thiophenecarboxylate)s were calculated by making use of the chemical shifts of the

protons of 2- and 3-substituted thiophenes. The calculated chemical shifts are in good agreement with the observed ones, within 0.1 ppm in the series of compounds **4** and **5** (excluding δH_4 of methoxyl derivative). For example, the calculated ring proton chemical shifts were 7.64 and 7.31 ppm for methyl 4-chloro-2-thiophenecarboxylate (**4**, X=Cl) and 7.71 and 7.91 ppm for methyl 5-nitro-2-thiophenecarboxylate (**5**, $X=NO_2$). These calculated values were in good accord with the observed ones. In methyl 5-methoxy-2-thiophenecarboxylate, the contribution of the canonical structure **a** can be presumed to become larger. Therefore, δH_3 in the compound may be shifted to lower field.

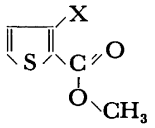


a

On the other hand, in the series of compounds **3**, there occur large deviations of the methoxyl, iodo, formyl, acetyl, and methoxycarbonyl derivatives. The two C=O stretching bands are observed in methyl 3-halo-2-thiophenecarboxylates (Table 6). These bands are considered to arise from the *syn-s-trans* and *anti-s-trans* forms as in *t*-butyl 3,4-dimethyl-2-thiophenecarboxylate.[6] Only one C=O band is observed and this is considered to be due to **b**-type isomer in methyl 2-thiophenecarboxylate. The field and magnetic



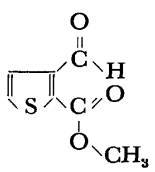
b



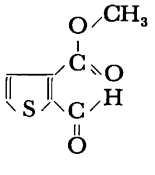
c

anisotropy effects of the C=O function may be changed by the contribution of the **c**-type isomer. The field and magnetic effects of a halogen may be also affected by the repulsion of the lone pair electrons and the steric hindrance between the halogen and the methoxycarbonyl group. The δH_4 of methyl 3-iodo-2-thiophenecarboxylate, which is greatly influenced by the effects mentioned above, thus shifts to a lower field than that calculated by the contribution of this conformational change.

The ^{1}H NMR spectrum of methyl 3-formyl-2-thiophenecarboxylate was studied by Gronowitz and coworkers.[7,8] They have reported that aldehydic hydrogen resonance in this compound occurred at a field 0.54—0.65 ppm (depending on the solvents) lower than that of the unsubstituted 2-thiophenecarbaldehyde, but that the contribution to the chemical shift of intramolecular hydrogen bonding is small. However, judging from the following experimental results, it is considered that the contribution of the rotational isomer **d**, which is capable of forming intramolecular hydrogen bonding, is a better explanation of the results



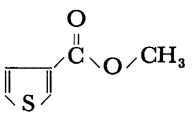
d



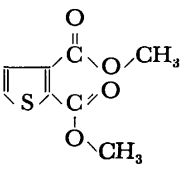
e

in methyl 3-formyl-2-thiophenecarboxylate. The resonance line of H_4 was found at 7.60 ppm, and that of H_5 at 7.48 ppm. The δH_4 was shifted towards a lower field than the values calculated, and the δH_5 towards a higher field. The chemical shift of the aldehydic hydrogen in 3-formyl derivative was 10.65 ppm, and shifted about 0.7 ppm lower than those in 4-, and 5-formyl derivatives. The chemical shift for methyl protons of methoxycarbonyl group is shifted lower than that of other compounds. The low field shift cannot be ascribed only to the effects of thiophene ring current and the substituent. The unusually low chemical shift of formyl proton might be due to the anisotropy effect of the ester carbonyl group located very close to it. If a weak hydrogen bond is persistent between the carbonyl oxygen and the formyl proton, the electric field effect lowers the chemical shift of formyl proton further. The strong ester carbonyl band in IR spectrum occurred at 1725 cm^{-1}, and could be assigned to *anti-s-trans* form **c**. The same consideration can be applied to methyl 2-formyl-3-thiophenecarboxylate. Its ^{1}H NMR spectrum exhibits the signals due to H_4 at 7.58 ppm, H_5 at 7.64 ppm, and the aldehydic proton at 10.62 ppm, indicating the presence of the preferred conformation **e**.

The chemical shifts for H_4 and H_5 in dimethyl 2,3-thiophenedicarboxylate are identical (7.51 ppm) in the calculations, but the two doublets occur at 7.45 and 7.28 ppm. Four planar conformations are considered in this ester. In methyl 3-thiophenecarboxylate, whose conformation study has not yet been reported, only one C=O stretching band is observed at 1726 cm^{-1}. It is considered that this compound exists in *syn-s-trans* form **f**, judging from the conformation of 3-thiophenecarbaldehyde.[9] From this consideration and a comparison with the chemical shifts of two ring protons in methyl 3-formyl-2-thiophenecarboxylate (conformation **d**) and methyl 2-formyl-3-thiophenecarboxylate (conformation **e**), the signal at higher field in dimethyl 2,3-thiophenedicarboxylate will be assigned to H_5, and that at lower field to H_4; the predominant conformation of this ester will lead to **g**. However, since the IR C=O stretching band occurs as a broad peak centered at 1734 cm^{-1}, other conformations are presumed to be present besides the **g** form.



f



g

The correlations between the C=O stretching frequencies (*syn-s-trans* form) of methyl (substituted 2-thiophenecarboxylate)s and the proton chemical shifts of the corresponding substituted thiophenes were examined. The correlation coefficients between $\nu_{C=O}$(**4**)[10] and δ_5(**2**), between $\nu_{C=O}$(**5**) and δ_5(**1**), and between $\nu_{C=O}$(**3**) and δ_2(**2**) gave high values. As shown in Table 6, $\nu_{C=O}$(**3**), $\nu_{C=O}$(**4**), and $\nu_{C=O}$(**5**) depend strongly on the nature of the substituent. It is considered that in the series of **5** the substituent effect is mainly transmitted by the

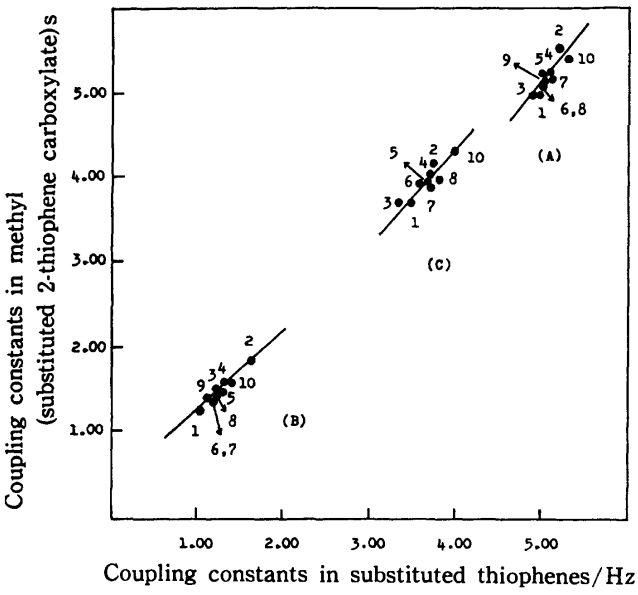


Fig. 4. Correlation between coupling constants in methyl (substituted 2-thiophenecarboxylate)s and substituted thiophenes, numbering as in Table 1. A, $J_{45}(\mathbf{3})$ *vs.* $J_{45}(\mathbf{2})$; B, $J_{35}(\mathbf{4})$ *vs.* $J_{24}(\mathbf{2})$; C, $J_{34}(\mathbf{5})$ *vs.* $J_{34}(\mathbf{1})$.

contribution of the canonical structure such as **a**, but in the series of **4** this occurs by the inductive effect. However, the correlation between $\nu_{C=O}(\mathbf{4})$ and $\nu_{C=O}(\mathbf{5})$ (*cc* 0.981, *p* 0.891) shows that the substituent effects on both frequencies have almost the same trend. It is interesting that the substituent effects in the series of **2** are almost insensitive to δH_5 but those in the series of **4** are transmitted strongly to the C=O stretching frequencies of the methoxycarbonyl groups. The slope between $\nu_{C=O}(\mathbf{4})$ and $\delta_5(\mathbf{2})$ is fivefold as steep to that between $\nu_{C=O}(\mathbf{5})$ and $\delta_5(\mathbf{1})$. The substituent effects on the C=O stretching frequencies in the series of **3**, which belong to *ortho* derivatives, are considered to become complicated due to the steric effect, in addition to the mesomeric and inductive effects, but show rather good correlations between $\delta_2(\mathbf{2})$.

The plots between the proton-proton coupling constants in methyl (substituted 2-thiophenecarboxylate)s and those in substituted thiophenes gave good correlations, as shown in Fig. 4. It is interesting that $J_{45}(\mathbf{3})$[11] gives a good correlation coefficient with $J_{45}(\mathbf{2})$ because $\delta_5(\mathbf{3})$ does not one with $\delta_5(\mathbf{2})$, in contrast to the good $\delta_4(\mathbf{3})$ *vs.* $\delta_4(\mathbf{2})$ correlation coefficient. The slopes of $J_{35}(\mathbf{4})$ *vs.* $J_{24}(\mathbf{2})$ and $J_{34}(\mathbf{5})$ *vs.* $J_{34}(\mathbf{1})$ plots are 1.00 and 0.97, respectively. This fact shows that the substituent effect is transferred equally, even though a methoxycarbonyl group is introduced into position 5 of **1** or **2**. However, the slope of $J_{45}(\mathbf{3})$ *vs.* $J_{45}(\mathbf{2})$ is 1.26, and the reason why the introduction of $COOCH_3$ into position 2 of **2** makes the substituent effect somewhat larger is not clear.

Studies on the relationships between the substituent electronegativity and the coupling constants in thiophene compounds have carried out by Bulman[12] and Galasso.[13] Bulman reported that the substituent electronegativity gave a good correlation with the sum of the coupling constants, but a rather more scattered one with the individual coupling constants in the series of compounds **1**. The relationship of the coupling constants in the series of compounds **3**, **4**, and **5** with the sum of the electronegativities of all substituents including methoxycarbonyl group was examined. Good correlations were found in all three cases. It is interesting that the three slopes are almost the same, even though the inductive and mesomeric effects of substituents on the spin-spin coupling are quite different in the three series.

Experimental

The ^1H NMR spectra of the compounds were obtained at 100 MHz on a JEOL PS-100 spectrometer. The chemical shifts were determined with an accuracy of ± 0.005 ppm relative to TMS as an internal standard and the coupling constants were determined with an accuracy of ± 0.02 Hz. The concentrations of solutions were adjusted approximately at 0.3 mol dm^{-3} with respect to substrates. The IR spectra were recorded on a Perkin–Elmer model 257 infrared spectrophotometer.

Most of materials used in this investigation were synthesized according to the methods reported,[14-25] or obtained by purification of commercially available materials.

Methyl 3-Chloro-2-thiophenecarboxylate. This material was prepared by the refluxing 3-chloro-2-thiophenecarboxylic acid[26] with methanol and H_2SO_4 for 4.5 h, mp 36 °C. Found: C, 40.92; H, 2.91; Cl, 20.07; S, 18.01%. Calcd for $C_6H_5ClO_2S$: C, 40.80; H, 2.85; Cl, 20.07; S, 18.15%. IR (KBr, cm^{-1}): 3110 (=C–H), 1719 (C=O), 1516, 1438, 1414, 730 (thiophene ring).

Methyl 3-Acetyl-2-thiophenecarboxylate. This material was prepared by the esterification of 3-acetyl-2-thiophenecarboxylic acid,[27] bp 103—105 °C/2.5 mmHg (1 mmHg≈ 133.322 Pa). Found: C, 52.02; H, 4.58; S, 17.67%. Calcd for $C_8H_8O_3S$: C, 52.16; H, 4.38; S, 17.41%. IR (neat, cm^{-1}): 3100 (=C–H); 1715, 1685 (C=O); 1510, 1438, 778 (thiophene ring).

Methyl 4-Chloro-2-thiophenecarboxylate. This material was prepared by the esterification of 4-chloro-2-thiophenecarboxylic acid,[28] bp 115—117 °C/21 mmHg. Found: C, 40.85; H, 2.78; Cl, 19.85; S, 18.28%. Calcd for $C_6H_5ClO_2S$: C, 40.80; H, 2.85; Cl, 20.07; S, 18.15%. IR (neat, cm^{-1}): 3130 (=C–H); 1718 (C=O); 1528, 1428, 1411, 749 (thiophene ring).

Methyl 4-Formyl-2-thiophenecarboxylate. This material was prepared by the esterification of 4-formyl-2-thiophenecarboxylic acid,[8] mp 63 °C. Found: C, 49.28; H, 3.63; S, 18.98%. Calcd for $C_7H_6O_3S$: C, 49.40; H, 3.55; S, 18.84%. IR (KBr, cm^{-1}): 3110, 3080 (=C–H); 1719, 1673 (C=O); 1535, 1454, 750 (thiophene ring).

Methyl 5-Methoxy-2-thiophenecarboxylate. This material was prepared by the esterification of 5-methoxy-2-thiophenecarboxylic acid,[14] mp 46 °C. Found: C, 48.98; H, 4.60; S, 18.76%. Calcd for $C_7H_8O_3S$: C, 48.82; H, 4.68; S, 18.62%. IR (KBr, cm^{-1}): 3080 (=C–H); 1699 (C=O); 1544, 1439, 1415, 748 (thiophene ring).

Methyl 4-Acetyl-2-thiophenecarboxylate. A solution of 4-acetyl-2-thiophenecarbaldehyde[29] (3.9 g, 0.025 mol) in ethanol (50 ml) was added to a shaken suspension of silver oxide, produced by adding NaOH (3.5 g) to $AgNO_3$ (9.0 g) in water (200 ml), and the mixture was shaken for 1 h. The free silver was removed by filtering, washed with water, and the filtrate was acidified with HCl. The white precipitate was recrystallized from water to give 4-acetyl-2-thiophenecarboxylic acid (3.2 g, 75%), mp 165 °C. The acid was esterified by refluxing with methanol and H_2SO_4 for 4.5 h to give methyl

4-acetyl-2-thiophenecarboxylate, mp 99—100 °C. Found: C, 52.37; H, 4.20; S, 17.51%. Calcd for $C_8H_8O_3S$: C, 52.16; H, 4.38; S, 17.41%. IR (KBr, cm^{-1}): 3110 (=C–H); 1709 (C=O); 1538, 1433, 751 (thiophene ring).

The author wishes to thank to Professor Minoru Hirota of Yokohama National University for his kind suggestions and encouragement, to Dr. Hiroshi Ozawa of Tokyo University for his permission to use the Computation Program LAOCN 3, and to Mr. Takayoshi Ozawa for the elemental analyses.

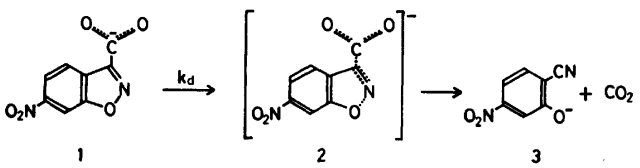
Effect of Multiple Field Assistance with Reversed Micelles on the Decarboxylation of 6-Nitro-1,2-benzisoxazole-3-carboxylate

Junzo SUNAMOTO,* Kiyoshi IWAMOTO, Shinichi NAGAMATSU, and Hiroki KONDO
Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852
(Received January 22, 1983)

Decarboxylation reaction of 6-nitro-1,2-benzisoxazole-3-carboxylate (**1**) in cationic and anionic reversed micelles has been investigated with particular attention to the microenvironmental effect, such as microviscosity, micropolarity, and microactivity, in the specific and restricted reaction field as provided by reversed micelles. In 0.20 M CTAC/0.32 M $H_2O/CHCl_3$ reversed micelles, the reaction was accelerated about 1300-fold compared with that in bulk aqueous solution. Of various surfactant aggregate systems such as aqueous micelle, bilayer, and reversed micelle, the cationic reversed micelle could provide the most effective reaction field for the present decarboxylation reaction. This reaction is never accelerated in an anionic aqueous micelle. However, in the anionic AOT reversed micelle, the reaction was apparently accelerated by both lowering the micropolarity and increasing the microviscosity around the substrate. The unique rate enhancement for the decarboxylation reaction of **1** provided by reversed micelles was interpreted in terms of the "multiple field assistance."

The specific reaction field of the enzyme active site provides multiply and simultaneously different effects such as a proximity, an electronic or a structural strain, an orbital steering, an anchoring effect, and so forth. Hence, enzymes can specifically control chemical equilibria and reaction pathways or rates by *simultaneously* adjusting pH, polarity, viscosity, and activity in the microenvironment. This specific effect has been called "multiple field assistance."[1] We ourselves have presented many examples so far that reversed micelles can mimic the enzyme active site and provide a specific reaction field to afford the "multiple field assistance" for various organic[2-5] and inorganic reactions.[6-9] Because, the state and nature of water in the interior core of micelles are known to be less polar,[10,11] highly viscous,[5,10,12-14] and more active,[2,7,15-18] largely different from those of bulk water.

In the present study, as an extension of a series of our studies, the effect of the specific microenvironment, the multiple field assistance, of the water pool provided by several ionic reversed micelles on the unimolecular decarboxylation of 6-nitro-1,2-benzisoxazole-3-carboxylate (**1**) was investigated. Unimolecular reaction seems most convenient to inspect the microenvironmental effect, especially the effect of restricting the mobility of substrates on the reaction rate or path.[5,19] In addition, the decarboxylation of **1** is very insensitive to an acid-base catalysis, while extremely sensitive to solvent polarity.[20-23]



1 2 3

Scheme 1.

Experimental

Materials. 6-Nitro-1,2-benzisoxazole-3-carboxylic acid was prepared according to the method described previously.[24,25] The white and needle crystals, after drying *in vacuo* over P_2O_5 at 110 °C, showed mp 167—169 °C [lit,[25] 167—169 (monohydrate)]. Preparations and purifications of hexadecyltrimethylammonium bromide (CTAB),[9] hexadecyltrimethylammonium chloride (CTAC),[9] and sodium 1,2-bis(2-ethylhexyloxycarbonyl)ethanesulfonate (AOT)[3] were described elsewhere. Solvents employed were carefully purified, dried, and stored under prevention against moisture over molecular sieves Linde 4A.

Miscellaneous Measurements. When the *R*-value (= $[H_2O]$/[surfactant]) was changed, the water content in reversed micelles was carefully determined on a Karl-Fischer moisture automatic titration apparatus, Kyoto Electronics MFG, Model MK-AIII.

In order to examine the microscopic polarity and viscosity in the core of micelles, fluorescence spectra and steady-state fluorescence polarizations of trisodium 8-methoxy-1,3,6-pyrenetrisulfonate (Py-OMe)[10] cosolubilized in micelles were measured on a Hitachi 650-10S fluorospectrophotometer and a Union Giken FS-501S fluorescence polarization spectrophotometer using a sharp cut-off filter Y-46 (Hoya Glass Works, Tokyo).

An aqueous stock solution of the substrate **1** was freshly prepared just before the use. Reaction rates were followed by monitoring an increase in the absorbance at around 415 nm based on the release of 2-cyano-5-nitrophenolate (**3**) using a Hitachi Model 200-10 spectrophotometer equipped with a thermoregulated cell compartment. The first-order rate constants, k_d, for the decarboxylation were obtained by the Guggenheim treatment[26,27] and the correlation coefficients were always larger than 0.999. Chloroform was used as the bulk organic solvent for CTAB and CTAC micelles, while heptane was employed for AOT micelles. Surfactant concentrations were kept at 0.20 M through all the runs, while the substrate concentration was 7.2×10^{-5} M (M = mol dm^{-3}) unless otherwise stated. The reaction was initiated by injecting an aliquot (15 μl) from the stock solution of **1** into the cell containing a given amount of micellar solution (3.0 ml) with an appropriate amount of aqueous sodium hydroxide solution.

Results and Discussion

Rate constants of the decarboxylation of **1** at 30 °C in reversed micelles are summarized in Table 1 along with those in pure solvents and in a surfactant bilayer system. Clearly from Table 1, of the surfactant-aggregate systems the CTAC reversed micelle provided the most effective reaction field for the decarboxylation of **1** to be accelerated. For the decarboxylation of **1**, the dehydration

(desolvation) of the substrate is one of essential factors for the rate enhancement.[20–23] In fact, a linear relationship between log k_d and the wave number of the absorption maximum of Methyl Orange has been previously presented by Kunitake and his coworkers for the polysoap-catalyzed decarboxylation of **1**.[27] First of all, hence, we must consider the effect of micropolarity (desolvation) around the substrate on the large rate acceleration in cationic reversed micelles. Even in the reversed micellar system, the decarboxylation of **1** must proceed in an aqueous environment. Nevertheless, the decarboxylation rate in the cationic CTAC micelle was enhanced about 1300-fold compared with that in bulk water (Table 1). However, this rate enhancement seems to involve the effect of the lowered micropolarity in the reversed micellar core. Table 1 gives also the fluorescence maxima of Py–OMe to assess the micropolarity of the reaction field.[10] Py–OMe is definitely localized only in the water pool of reversed micelles owing to its highly ionic character and is considered to be a convenient probe to know the microenvironment around a water soluble substrate.[10] Results of Table 1 suggest that the micropolarity of the cationic aqueous and reversed micelles as the reaction field is almost comparable to that of methanol. Nevertheless, the reaction rate in the CTAC reversed micelle is still 40-times higher than that in methanol. As is already known, the decarboxylation of **1** is effectively accelerated by cationic aqueous micelles,[28–30] cationic polymers with a hydrophobic side chain (polysoap),[27,31,32] polymeric crown ethers complexable with cations, K^+ or Na^+,[33,34] and synthetic bilayer membranes with a positive surface charge.[35] These catalytic effects are ascribed to the stabilization of the anionic transition state (**2**) with an electrostatic assistance by the positive surface charge of these molecular assemblies. Certainly, the anionic SDS aqueous micelle can not promote this reaction.[28,29] Also in the interior core of the cationic reversed micelles, hence, the additional rate acceleration may be ascribed to the electrostatic assistance by lowering the transition state energy upon interaction of the activated complex with the cationic surface in the micellar core.

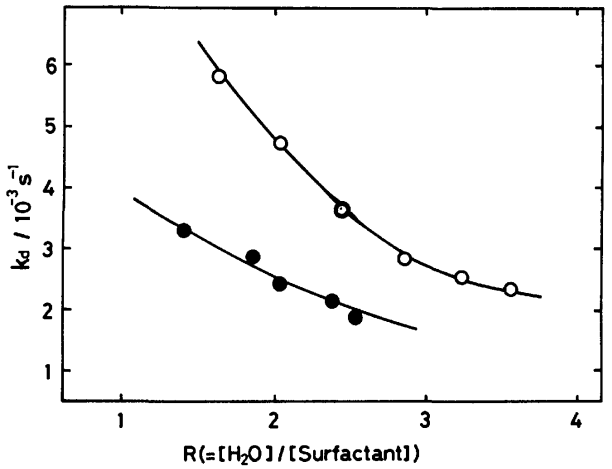

Fig. 1. The decarboxylation rates, k_d, as a function of R-value in 0.20 M CTAC/7.4×10^{-5} M aq NaOH/$CHCl_3$ (—○—) and 0.20 M CTAB/7.4×10^{-5} M aq NaOH/$CHCl_3$ (—●—) reversed micelles containing 7.2×10^{-5} M substrate **1** at 25.0 °C.

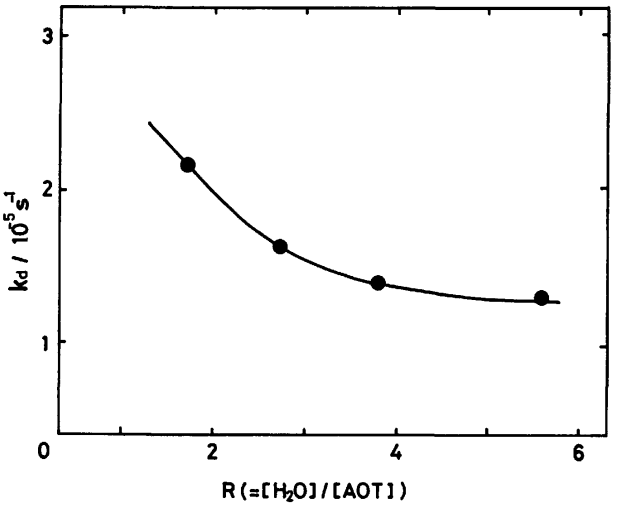

Fig. 2. The decarboxylation rate of **1** (7.2×10^{-5} M) in 0.20 M AOT/7.4×10^{-5} M aq NaOH/heptane reversed micelle as a function of R-value at 25.0 °C.

a) From Ref. 22. b) 1 cal=4.184 J.

The CTAB reversed micelle showed lower catalytic efficiency than the CTAC one (Table 1 and Fig. 1). One reason is the slightly higher microscopic polarity in the interior core of the CTAB micelle compared with the case of CTAC micelle as suggested by the fluorescence maximum of Py-OMe (Table 1). As is well known, the hydration number for bromide ion is smaller than that for chloride ion. This means that more free water may exist in the interior core of the CTAB micelle than in the CTAC one when compared at an identical R-value, thus the former providing a more polar microenvironment. Another reason is the difference in the aggregation number between both surfactants. It has been found that for cationic reversed micelles the aggregation number decreases with an increase in the radius of the counter anion of the surfactant.[36] Assuming that one molecule of the substrate is encapsulated in a micelle, the larger aggregates (the higher aggregation number) will provide the more effective electrostatic assistance, leading to a larger rate enhancement.

Nevertheless an anionic aqueous micelle cannot accelerate this reaction,[28,29] the anionic reversed micelle shows a small, but discernible catalytic activity for the reaction. In the interior core of the AOT reversed micelle, the micropolarity is just middle between water and methanol, while the microviscosity is higher than that of the cationic reversed micelle (Table 1). Most probably, opening the benzisoxazole ring will relax the intramolecular strain upon the decarboxylation, of which effect will be more amplified in a highly viscous environment. Therefore, it appears that the release of the internal strain as well as the decreased micropolarity counteract the large destabilization of the anionic transition state with the negative surface charge of the micellar core.

Figures 1 and 2 show the rate deceleration with an increase in the R-value, or the water content, of the cationic and anionic reversed micelles, respectively. In reversed micellar systems the effect of water content on the reaction was drastic, though the rate is hardly affected by a minute amount of water in a simple organic solvent.[27] In general, an increase in the R-value leads to an increase in the micropolarity and a decrease in the microviscosity of the water pool.[11,14,18] We also observed similar phenomena for the present system employing the fluorescent probe, Py-OMe.[10] This means that in reversed micelles one can control the polarity, viscosity, and activity of the reaction field and consequently the reaction rate by changing the water content of micelles. In any event, both an increase in the micropolarity and a decrease in the microviscosity act as negative effect on the present decaboxylation (Figs. 1 and 2).

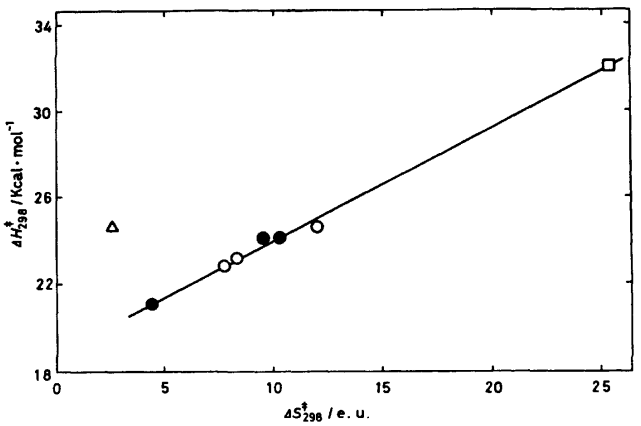

Fig. 3. Isokinetic relationship for the decarboxylation of 1 in various microenvironments, water (□), CTAC reversed micelles (○), CTAB reversed micelles (●), and AOT reversed micelle (△).

In Table 2, thermodynamic parameters of activation for the decarboxylation of 1 in reversed micelles are listed along with those in bulk aqueous solution previously reported by Kemp and Paul.[22] Its isokinetic relationship is given in Fig. 3. Except for the AOT reversed micelle, a good linear relation was obtained with the isokinetic temperature β=517 K. This means that under the reaction conditions adopted (at 298 K) the reaction is controlled enthalpically. Figure 3 supports the above argument that the low catalytic efficiency of the AOT reversed micelle in this reaction may be derived from the destabilization of the anionic transition state with the electrostatic repulsion brought about by the negative surface charge of the micellar core (ΔH^*-control). This negative effect might exceed the rate acceleration effects by the decreased polarity (ΔH^*-control) and the increased internal strain of the substrate molecule in the highly restricted reaction field (ΔS^*-

control). In any event, it is clear that in the specific and restricted reaction field as provided by reversed micelles the reaction rate is controlled simultaneously by plural factors.

Authors are grateful to Professors Toyoki Kunitake (Kyushu University) and Seiji Shinkai (Nagasaki University) for their fruitful discussion. We also thank Mr. Ichiro Miwa for his measurement of the fluorescence depolarization. This work was supported by Grants-in-Aid (No. 447068 and 56550594) for Scientific Research from the Ministry of Education, Science and Culture.

A Facile One-pot Synthesis of Hydroxy-substituted Crown Ethers

Isao IKEDA, Tetsuya KATAYAMA, Kikuo TSUCHIYA, and Mitsuo OKAHARA*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka 2-1, Suita, Osaka 565

(Received February 7, 1983)

Hydroxy-substituted crown ethers were prepared in one-pot synthesis by treatment of oligoethylene glycols with epichlorohydrin in the presence of alkali metals, alkali metal hydride or alkali metal hydroxides. The stability constants of complexes with sodium and potassium cations in methanol were determined.

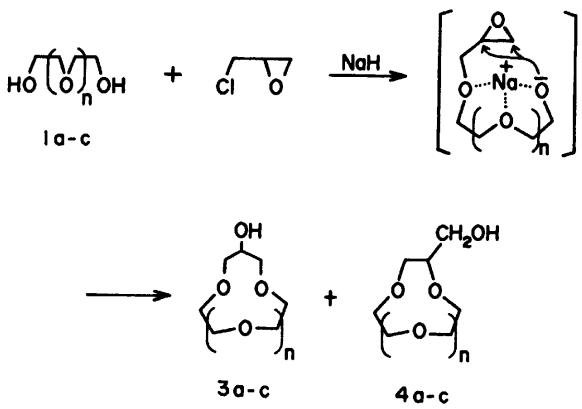
Crown compounds having a functional group are useful for designing phase transfer catalysts, ion-selective electrodes, ion carriers or polymer supported crown compounds. Hydroxy-functionalized derivatives have recently attracted attention as one of the most promising intermediates for these purposes, and various syntheses[1-9] and applications[10-14] have been reported.

We now describe a facile one-pot synthesis of hydroxy-substituted 13-, 16-, and 19-crown ethers using epichlorohydrin and oligoethylene glycols, which are industrially available inexpensive raw materials. Although one of these crown ethers has already been prepared by Tomoi *et al.*[4] *via* several steps starting from 3-chloro-2-chloromethyl-1-propene, the improvement in preparation procedure should enhance the usefulness of these unique functional compounds. Furthermore, some trials to synthesize hydroxy crown ethers using epichlorohydrin were reported,[1,2,8] but in these cases this material was restrictively used as a coupling agent for two phenolic hydroxyl groups in a multi-step synthesis.

Results and Discussion

The reaction of oligoethylene glycols (**1**) with epichlorohydrin in the presence of base may afford oligoethylene glycol monoglycidyl ethers (**2**), which may successively cyclize to the hydroxy-substituted crown ethers (**3**) and/or (**4**) by the intramolecular attack of the alkoxide anion to the epoxy ring, as shown in the Scheme.

In practice, the reaction product showed only one peak in the expected region of the gas chromatogram. In order to confirm their formation, the possible compounds **3** and **4** were synthesized by alternative methods. The authentic compound **3b** were prepared by the coupling reaction of 2-benzyloxy-1,3-propanediol[15] and tetraethylene glycol ditosylate, and **4a**—**c** by the reported method,[7] followed by debenzylation.



a, $n=2$ *b*, $n=3$ *c*, $n=4$

Scheme. Probable pathway of the reaction.

From GLC analysis, only **3b** was confirmed to be formed and **4b** could not be detected in the reaction product (Shimadzu GC-4CPT, Silicone OV-1 on Uniport KS 60—80 mesh, 1 m, started from 100 °C, 20 °C/min, retention time; **3b**, 4.5 min; **4b**, 4.8 min). The isolated product was characterized by spectral and elemental analyses. For the purpose of further confir-

	K	0.0021	0.002	0.002	60	20	42[e,f]

a) Bp: **3a**; 115—120 °C/0.05 Torr, **3b**; 128—135 °C/0.02 Torr, 150 °C/0.05 Torr (Kugelrohr distillation), **3c**; 185 °C/0.04 Torr (Kugelrohr distillation). b) Epichlorohydrin. c) Dioxane was used as the solvent. d) Calculated by GLC. e) Isolated. f) KBF_4 (0.002 mol) was added in the reaction system.

mation, the product was acetylated by treatment with acetic anhydride in pyridine.

From the reactions between epichlorohydrin and tri- and pentaethylene glycol, hydroxy-13-crown-4 (**3a**, $n=2$), and hydroxy-19-crown-6 (**3c**, $n=4$) were obtained. No detectable amount of **4a** nor **4c** could be observed in any run by GLC (the same conditions as for **3b**, retention time; **3a**, 3.0 min; **4a**, 3.3 min; **3c**, 5.8 min; **4c**, 6.1 min). Spectral data of the products and their acetates are summarized in Table 1.

In the case of the reaction of tetraethylene glycol and epichlorohydrin, sodium hydroxide and metallic sodium also worked well to give the objective crown ether (**3b**), but metallic potassium gave it in a poorer yield. To obtain **3a** and **3c**, metallic lithium and potassium or their hydroxides were used and showed good yields. The reaction conditions and the yields are listed in Table 2.

The fractional distillation afforded the oligoethylene glycol-free **3**, but it is usually difficult to remove a small amount of contaminates, mainly oligoethylene glycols, from the objective compounds by Kugelrohr distillation, which is convenient in a small scale preparation. The compounds **3**, however, could be freed of the last traces of oligoethylene glycols by either of following methods: a) passing through an ion-exchange resin (metal form) column, or b) extracting from the aqueous solution with chloroform. In the case of hydroxy-16-crown-5 (**3b**), the pyrolysis of $MgBr_2$·complex also afforded the purified compound.

In order to verify the complexing property of **3**, the stability constants of the complexes with sodium and potassium cations in methanol were measured,[16] and are summarized in Table 3. The complexing ability of **3a** with both cations was too low to give reliable stability constant values. Compounds **3b** and **3c**, however, showed the good and rather selective complexing ability toward sodium and potassium cations.

TABLE 3. STABILITY CONSTANTS OF **3b** AND **3c** COMPLEXES

Crown ether	log K'[a]	
	Sodium cation	Potassium cation
3b	3.03 ± 0.01	2.53 ± 0.005
3c	2.62 ± 0.03	4.03 ± 0.03

a) Crown ether + $M^+ \overset{K'_1}{\rightleftarrows}$ (Crown ether·M)$^+$ In methanol, 25 °C. Values with the standard deviation at the 95% confidence level.

Experimental

The ^{1}H-NMR spectra were taken at 100 MHz on a JEOL JNM-PS-100 spectrometer using the tetramethylsilane internal standard. The infrared spectra were obtained on a Hitachi-260-10 spectrometer. The mass spectra were taken at an ionization potential of 70 eV on a Hitachi RMU-6E mass spectrometer.

Preparation of Hydroxy-16-crown-5 (3b). As a typical procedure for the preparation of **3**: tetraethylene glycol (**1b**, $n=3$, 3.9 g, 0.002 mol) was added dropwise to a suspension of sodium hydride (50% oil suspension, 2.0 g, 0.004 mol, washed with dioxane by decantation) in dioxane (50 ml). After the evolution of hydrogen gas had ceased, epichlorohydrin (1.9 g, 0.002 mol) was added in one quantity and the mixture was stirred for 1 h during which time the temperature was carefully regulated not to exceed 40 °C. Then the mixture was heated to 60 °C and was stirred for an additional 3 h at this temperature. The reaction mixture was neutralized with hydrochloric acid (1 : 1 ethanol), filtered and washed with dichloromethane. The solvent was removed from the filtrate combined with washings and the resultant viscous material was washed with hexane to give 4.5 g of the crude product. The hydroxy-substituted crown ether (**3b**) was obtained as a pale yellow oil by distilling a portion of the crude product (2.72 g) on a Kugelrohr distillation apparatus. Yield, 0.95 g (31%, 55% by GLC analysis).

Purification of 3b by an Ion-exchange Resin Column. Amberlite CG-120 (Type 1, Na form, 30 g) was washed 3 times with a plenty of water, and then 3 times with acetone. A little contaminated distillate (0.5 g) of **3b** dissolved in acetone was charged into the column packed with this washed resin, and eluted with 200 ml of acetone. Evaporation of the solvent afforded 0.38 g of oligoethylene glycol-free **3b**, checked by GLC.

Preparation and Pyrolysis of $MgBr_2$·Complex of 3b. The acetone solution of **3b** contaminated with a small amount of **2b** was added to acetone saturated with $MgBr_2 \cdot 6H_2O$ under stirring. White precipitates which appeared immediately were collected by filtration, washed with acetone repeatedly, and dried under reduced pressure. The white solid was heated to 200 °C in a Kugelrohr distillation apparatus at

0.015 Torr (1 Torr=133.322 Pa) to release purified **3b**, which was checked to be free of **2b** by GLC.

Synthesis of Authentic 3b. Although the synthesis of **3b** was reported,[6] from the point of availability of the starting material, an alternative method was employed to obtain the authentic compound. The starting material 2-benzyloxy-1,3-propanediol (137—140 °C/0.004 Torr, Kugelrohr distillation) was obtained by hydrolysis of *cis*-5-benzyloxy-2-phenyl-1,3-dioxane (mp 79.0—80.0 °C), which was prepared by benzylation of *cis*-2-phenyl-1,3-dioxan-5-ol (mp 84.5—85.5 °C).[15] 2-Benzyloxy-1,3-propanediol (1.8 g, 0.01 mol) was added to *t*-butyl alcohol (30 ml) containing 0.02 mol of *t*-BuONa at 60 °C under stirring. To the resulting solution was added dropwise a solution of tetraethylene glycol ditosylate (5.0 g, 0.01 mol)[17] in *t*-butyl alcohol (20 ml), and the mixture was stirred for 2 h at 60 °C. After the removal of solid salt by filtration, the *t*-butyl alcohol was evaporated off under reduced pressure to leave a viscous oil (3.5 g). An aliquot of the oil (1.6 g) was fractionated by Kugelrohr distillation. The distillate of 150 °C/0.05 Torr (0.48 g, 31%) was hydrogenated with hydrogen gas in the presence of Pd/C and *p*-toluenesulfonic acid.[7] After the work-up, the viscous oil was fractionated by Kugelrohr distillation to give a pale yellow oil (0.23 g, bp 150 °C/0.1 Torr, Kugelrohr distillation). This fraction showed the same GLC retention time and spectral data as those of **3b** shown in Table 1.

Studies on the β-Turn of Peptides. IV.[1] Effect of the Chain Length on the CD Spectra of *N*-(2,4-Dinitrophenyl)-(Gly)$_n$-D-Ala-L-Pro-(Gly)$_n$ *p*-Nitroanilides (n=1—3)

Kazuki SATO,* Noriko TAKI, Ukon NAGAI, and Tsutomu HIGASHIJIMA†

Mitsubishi-Kasei Institute of Life Sciences, Minamiooya, Machida, Tokyo 194

†*Department of Biophysics and Biochemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113*

(Received March 25, 1983)

N-(2,4-Dinitrophenyl)-(Gly)$_n$-D-Ala-L-Pro-(Gly)$_n$ *p*-nitroanilides (**7b**, n=2; **7c**, n=3) were synthesized in order to study the effect of chain length on their conformations. The CD spectra of both **7b** and **7c** showed similar patterns to that of **7a** (n=1), but their Cotton effects were much weaker. Therefore, both compounds seem still to have some populations of folded conformers because their Cotton effects near 350 nm were significantly larger than those of the tetrapeptide derivatives in random conformation. However, the population of the folded conformers must be quite small.

In the previous paper, we gave an outline of a new method to study the β-turn conformation of linear tetrapeptides.[2] *N*-(2,4-Dinitrophenyl)tetrapeptide *p*-nitroanilides (Dnp-tetrapeptide-pNA's)[3] exhibit characteristic CD spectra above 250 nm when they take β-turn conformations. The Cotton effects are considered to be due to exciton coupling of the transition moments in the two terminal chromophores. The magnitudes of the Cotton effects near 350 nm and 310 nm were shown to reflect well the β-turn preference of the tetrapeptides.

In this paper, we attempted to apply the method to larger peptides than tetrapeptides. CD spectrum of Dnp-Gly-D-Ala-L-Pro-Gly-pNA (**7a**) is known to show large Cotton effects at 350 nm and 310 nm, indicating that it takes β-turn conformation to a high extent.[2] So, in this work, two compounds with a general structure Dnp-(Gly)$_n$-D-Ala-L-Pro-(Gly)$_n$-pNA (**7b**, n=2; **7c**, n=3) were synthesized to study the effect of chain length on the CD spectra. If **7b** and **7c** also have high population of folded conformers with a β-turn at the D-Ala-L-Pro sequence, large Cotton effects are expected to be observed due to the approach of the Dnp and pNA chromophores (Fig. 1).

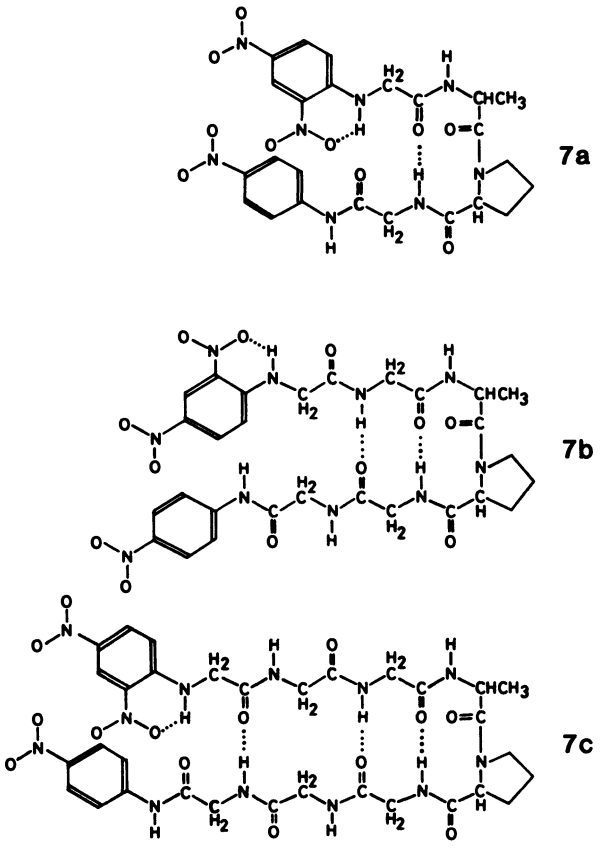

Fig. 1. Models of folded (β-sheet) conformers with a β turn at D-Ala-L-Pro sequence of Dnp-(Gly)-D-Ala-L-Pro-(Gly)$_n$-pNA (**7a**—**c**).

Results and Discussion

Syntheses of Peptides. Compounds **7b** and **7c** were synthesized by a similar manner to that described previously for **7a** (Fig. 2).[4] Boc-D-Ala-L-Pro-OH[5] and H-(Gly)$_2$-pNA·HCl (**2b**·HCl)[1] were coupled by EDC method to afford Boc-D-Ala-L-Pro-(Gly)$_2$-pNA (**3b**), which was treated with hydrogen chloride in formic acid. H-D-Ala-L-Pro-(Gly)$_2$-pNA·HCl (**4b**·HCl) obtained was coupled with Boc-(Gly)$_2$-OH[6] to afford Boc-(Gly)$_2$-D-Ala-L-Pro-(Gly)$_2$-pNA (**5b**), which was converted to the Dnp derivative, Dnp-(Gly)$_2$-D-Ala-L-Pro-(Gly)$_2$-pNA (**7b**), by deprotection and subsequent treatment with 1-fluoro-2,4-dinitrobenzene. Synthesis of **7c** was carried out similarly. Homogeneities of the peptides synthesized were confirmed by thin-layer chromatography and elemental analyses.

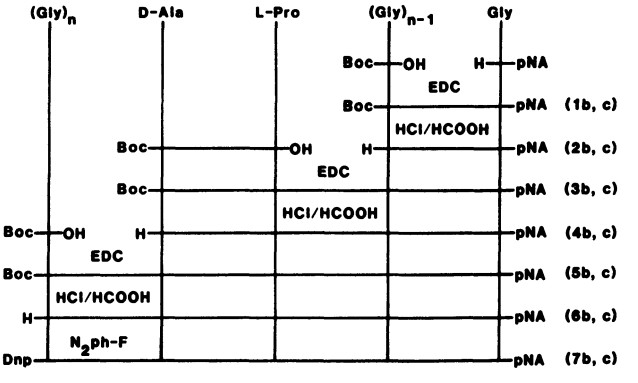

Fig. 2. Syntheses of Dnp-(Gly)$_n$-D-Ala-L-Pro-(Gly)$_n$-pNA (n=2, 3).

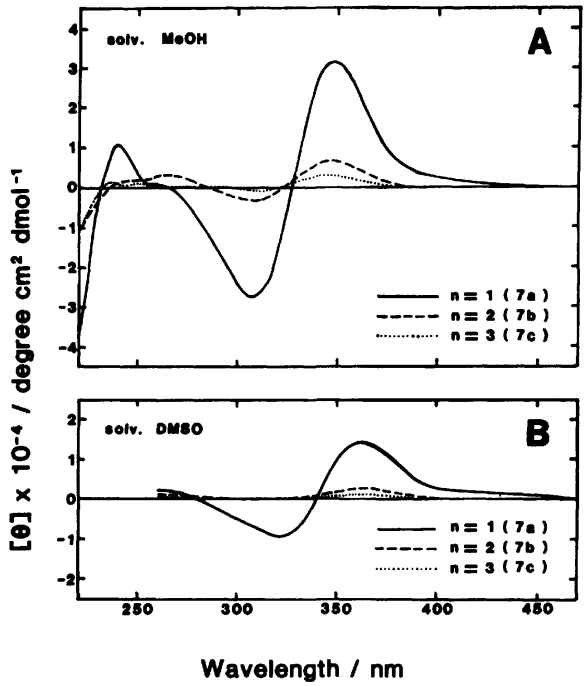

Fig. 3. CD spectra of Dnp–$(Gly)_n$–D-Ala–L-Pro–$(Gly)_n$–pNA (n=1—3).

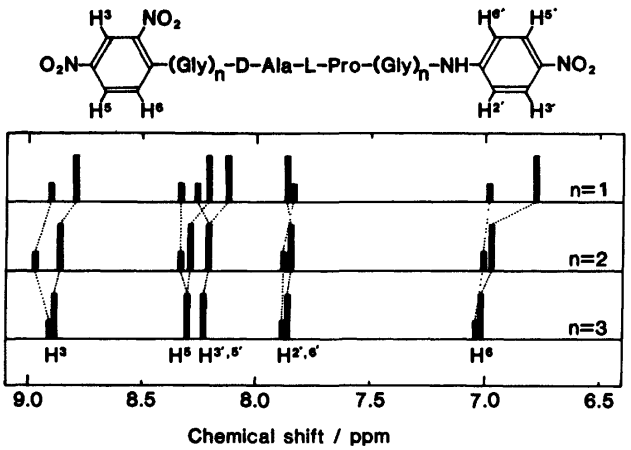

Fig. 4. Chemical shifts of aromatic protons of Dnp–$(Gly)_n$–D-Ala–L-Pro–$(Gly)_n$–pNA (n=1—3) in DMSO-d_6 at 23 °C. The large and the small bars show the major and the minor conformers with *trans* and *cis* D-Ala–L-Pro bonds, respectively.

CD Spectra Due to the Interaction between Dnp and pNA Chromophores. CD spectra of **7b** and **7c** measured in MeOH solution are represented in Fig. 3A together with that of **7a**. Both showed a similar pattern to that of **7a**, but the magnitudes were much smaller than that of **7a**. Between the two, **7b** showed a little larger Cotton effects than **7c**. Figure 3B represents the spectra measured in DMSO solution, and both showed similar spectra but of weaker strength than those in MeOH. Decrease of Cotton effects was observed also in **7a**, but the relative strengths of Cotton effects of **7b** and **7c** to those of **7a** were not so much affected by the change of solvents. Such decrease of Cotton effects as mentioned above suggested that the populations of β-turn conformer of **7a**—**c** decreased in DMSO solution as compared with those in MeOH solution, since it had been ascertained that the solvent dependence of Cotton effects were in good accordance with that of the populations of β-turn conformers using a model peptide (Dnp–L-Leu–D-Ala–L-Pro–L-Val–pNA) related to the β-turn part of gramicidin S,[2] which showed larger Cotton effects in MeOH solution than in DMSO solution as well as **7a**—**c**. MeOH is considered to be suitable for β-turn conformation of hexa- or octapeptides as well as for those of tetrapeptides. UV absorption spectra of **7a**—**c** showed maxima at 326 nm in MeOH solution and at 343 nm in DMSO solution as well as those of other peptides reported previously.[2,4] This red-shift of UV maxima corresponded well to that of CD maxima as expected from the fact that the CD spectra of Dnp–peptide–pNA's were considered to be due to the exciton coupling of the transition moments in two terminal chromophores. These results indicated that there was still a little interaction between the two terminal chromophores of **7b** and **7c**, and that they contained some populations of folded conformers, because, in the case of Dnp–L-Leu–L-Ala–L-Pro–L-Val–pNA and other tetrapeptide derivatives which take random conformation, no CD bands are observed near 350 nm. From comparison of the CD spectra, **7b** is considered to have a little higher population of β-turn conformers than **7c**, and the population was higher in MeOH solution than in DMSO.

Higher-field Shifts of Aromatic Proton Chemical Shifts Due to the Ring-current Effects. ^{1}H NMR spectra of **7a**—**c** were measured in DMSO-d_6 solution. All the spectra showed two sets of resonances for most of the protons due to *cis-trans* isomerism for the D-Ala–L-Pro bonds. In all the peptides, the populations of *trans* isomers were estimated to about 70% according to the relative peak area of the same proton. Figure 4 shows that aromatic protons of the *trans* isomer in **7a** were shifted apparently to higher field than those of the *cis* isomer because of ring-current effects, indicating the proximity of the two terminal chromophores. The *trans* isomers of **7b** and **7c** also showed similar higher-field shifts, but the shifts were much smaller than that of **7a**. Between the two, **7b** showed a little higher shift than **7c**. The *cis* isomers of **7a**—**c** are considered to take unordered conformations and consequently to have little contribution to the CD spectra of **7a**—**c**, since they showed similar chemical shifts of aromatic and some other protons for the three compounds irrespective of the chain length. In contrast, the *trans* conformers of **7a**—**c** showed large chain-length dependences of chemical shifts for many of the protons, indicating that their *trans* conformations depended on chain length. The *trans* isomers of **7b** and **7c** are considered still to have a little population of folded conformers which cause proximities of the two terminal chromophores. Between the two, **7b** is considered to have a little higher population of folded conformers than **7c**.

Intramolecular Hydrogen Bondings and β-Turn Conformations. Temperature dependences of chemical shifts of amide proton resonances are useful for distinguishing between "exposed" and "intramolecularly hydrogen-

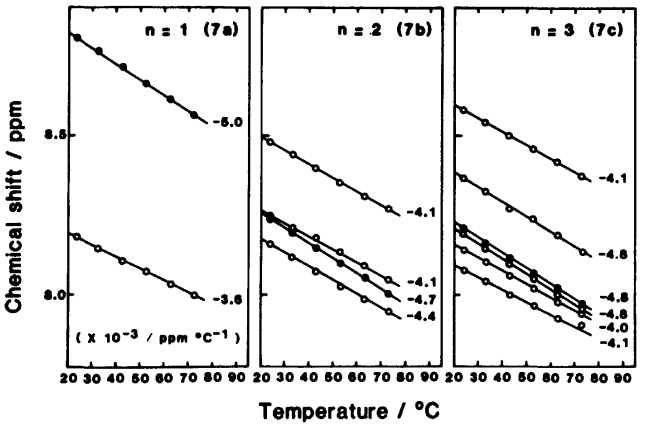

Fig. 5. Temperature dependences of chemical shifts of N^aH protons in major conformer of Dnp-$(Gly)_n$-D-Ala-L-Pro-$(Gly)_n$-pNA (n=1—3) in DMSO-d_6. The Gly^1-NH protons are omitted. ●: D-Ala-NH, ○: Gly-NH.

bonded" amide proton;[7] exposed protons exhibited larger temperature dependences than hydrogen-bonded amide protons. The temperature dependences of the chemical shifts of NH protons of **7a**—**c** were studied in DMSO-d_6 solution. Figure 5 shows the results for NH protons of the *trans* isomers in **7a**—**c**, where Gly^1-NH protons were omitted because they were not amide protons and also exhibited constantly small temperature dependence due to hydrogen bonding with the *o*-nitro group in the Dnp chromophore. The Gly^4-NH proton in **7a** showed smaller temperature dependences than the D-Ala^2-NH proton, indicating the presence of β-turn conformer with 4→1 hydrogen bond concerned by the Gly^4-NH proton as shown in Fig. 1. In the case of **7b** and **7c**, the differences in temperature dependences of Gly-NH protons and D-Ala-NH proton were quite small, but still a little differences were observed; the D-Ala-NH proton always showed the largest temperature dependence of all the NH protons, and the numbers of the Gly-NH protons with smaller dependences (-4.0——-4.1×10^{-3} ppm $°C^{-1}$) were in good accordance with the numbers of the Gly-NH protons involved in hydrogen bonding in the models of folded conformers of **7b** and **7c** shown in Fig. 1. These results suggested that both **7b** and **7c** had a little population of folded conformers, though they were quite lower levels as compared with that of **7a**. The Gly^4-NH proton of *cis* isomer in **7a**, which separated well from other resonances, showed large temperature dependence (-5.2×10^{-3} ppm $°C^{-1}$) as well as that of the D-Ala^2-NH proton (-5.3×10^{-3} ppm $°C^{-1}$), indicating that the *cis* isomer of **7a** took unordered conformation as described in the preceding section. In the case of **7b** and **7c**, the NMR spectra were too complex to study the temperature dependences of all the NH protons of minor (*cis*) isomers. Most of the protons other than amide ones of **7a**—**c** showed little temperature dependences, suggesting that the conformations of **7a**—**c** did not change significantly in the temperature range of these experiments.

Correlation between CD Spectra and β-Turn Conformations. The characteristic CD spectra of Dnp-peptide-pNA's are considered to be due to the exciton coupling of the transition moments in the two terminal chromophores. The relative strength of Cotton effects of **7a**—**c** shown in Fig. 3 were in good accordance with the populations of β-turn conformers in **7a**—**c** estimated from NMR measurements. All of the results with both CD and NMR spectra indicate that the interaction between the two chromophores decreases rapidly as length of the peptide chain increases, however, some populations of β-turn conformers are considered still to be present in both compounds (**7b** and **7c**) examined. Between the two, **7b** is considered to have a little higher population of β-turn conformers than **7c**.

Experimental

Syntheses of Peptides. All the melting points were measured on a Yanagimoto micro melting point apparatus and were uncorrected. TLC's were carried out on Merck silica gel 60 F_{254} plates with the following solvent systems: R_f^1, $CHCl_3$-MeOH (5 : 1, v/v); R_f^2, $CHCl_3$-MeOH-AcOH (95 : 5 : 1, v/v); R_f^3, *n*-BuOH-AcOH-pyridine-H_2O (4 : 1 : 1 : 2, v/v). Optical rotations were measured on an Union automatic polarimeter PM-201.

Boc-(Gly_3)-pNA (1c). To a chilled solution of Boc-$(Gly)_2$-OH[6] (465 mg, 2 mmol) and H-Gly-pNA (390 mg, 2 mmol) in DMF (8 ml) was added EDC·HCl (383 mg, 2 mmol). The mixture was stirred at 0 °C for 1 h and at room temperature overnight and evaporated *in vacuo*. Addition of water to the residue gave a solid, which was collected by filtration and washed successively with 10% citric acid, 4% $NaHCO_3$, and water. After being dried *in vacuo* over P_2O_5, the product was recrystallized from DMF-ether; yield, 562 mg (69%), mp 235—237 °C; R_f^1 0.44, R_f^2 0.10, R_f^3 0.75.

Found: C, 49.93; H, 5.71; N, 17.11%. Calcd for $C_{17}H_{23}O_7N_5$: C, 49.87; H, 5.66; N, 17.11%.

H-$(Gly)_3$-pNA·HCl (2c·HCl). Compound **1c** (491 mg, 1.2 mmol) was dissolved in 0.1 M (1 M=1 mol dm^{-3}) hydrogen chloride in formic acid (18 ml). The solution was allowed to stand at room temperature for 30 min and evaporated to leave an oil, which was crystallized by addition of ether; yield, 426 mg (100%); mp 238—240 °C; R_f^3 0.51.

Found: C, 41.47; H, 4.74; N, 20.17%. Calcd for $C_{12}H_{16}O_5N_5Cl$: C, 41.68; H, 4.66; N, 20.26%.

Boc-D-Ala-L-Pro-$(Gly)_2$-pNA (3b). To a chilled solution of Boc-D-Ala-L-Pro-OH[5] (287 mg, 1 mmol), H-$(Gly)_2$-pNA·HCl[1] (289 mg, 1 mmol), and TEA (0.14 ml, 1 mmol) in DMF (6 ml) was added EDC·HCl (192 mg, 1 mmol), and the mixture was stirred at 0 °C for 1 h and at room temperature overnight and evaporated. The residue was dissolved in EtOAc, and the solution was washed successively with 10% citric acid, 4% $NaHCO_3$, and water, dried (Na_2SO_4), and evaporated. The residue was solidified by addition of ether. The crude product dissolved in MeOH (2 ml) was applied to a column (3×170 cm) of Sephadex LH-20 and eluted with MeOH. The fractions containing the desired product detected with UV absorption and TLC were collected and evaporated, and the residue was solidified by addition of ether and recrystallized from EtOH-ether; yield, 215 mg (42%); mp 197—200 °C; $[\alpha]_D^{22}$ −2.1° (*c* 1, MeOH); R_f^1 0.77, R_f^2 0.28, R_f^3 0.75.

Found: C, 52.96; H, 5.88; N, 16.39%. Calcd for $C_{23}H_{32}O_8N_6$: C, 53.07; H, 6.20; N, 16.15%.

Boc-D-Ala-L-Pro-$(Gly)_3$-pNA (3c). This compound

was prepared from Boc-D-Ala-L-Pro-OH[5] (287 mg, 1 mmol) and **1c**·HCl (346 mg, 1 mmol) as described for **3b**; yield, 284 mg (48%); mp 112—115 °C; $[\alpha]_D^{22}$ +5.8° (*c* 1, MeOH); R_f^1 0.63, R_f^2 0.12, R_f^3 0.74.

Found: C, 51.62; H, 6.14; N, 16.77%. Calcd for $C_{25}H_{35}O_9N_7$: C, 51.98; H, 6.11; N, 16.98%.

H-D-Ala-L-Pro-(Gly)$_2$-pNA·HCl (4b·HCl). Compound **3b** (182 mg, 0.35 mmol) was dissolved in 0.1 M hydrogen chloride in formic acid (4.2 ml). The solution was allowed to stand at room temperature for 30 min and evaporated to leave an oil. The product was used for the next reaction without further treatment; the yield was quantitative; R_f^3 0.61.

H-D-Ala-L-Pro-(Gly)$_3$-pNA·HCl (4c·HCl). Compound **3c** (104 mg, 0.18 mmol) was treated with 0.1 M hydrogen chloride in formic acid (2.7 ml) as described for **4b**·HCl. The product was used for the next reaction without further treatment; the yield was quantitative; R_f^3 0.42.

Boc-(Gly)$_2$-D-Ala-L-Pro-(Gly)$_2$-pNA (5b). This compound was prepared from Boc-(Gly)$_2$-OH[6] (81 mg, 0.35 mmol) and **4b**·HCl (134 mg, 0.35 mmol) as described for **3b** except that the column chromatography with Sephadex LH-20 was not used. The crude product was recrystallized from MeOH–ether; yield, 66 mg (30%); mp 133—136 °C; $[\alpha]_D^{22}$ +0.4° (*c* 1, MeOH); R_f^1 0.52, R_f^2 0.03, R_f^3 0.73.

Found: C, 50.13; H, 5.99; N, 17.32%. Calcd for $C_{27}H_{38}O_{10}N_8 \cdot 1/2\ H_2O$: C, 50.38; H, 6.11; N, 17.41%.

Boc-(Gly)$_3$-D-Ala-L-Pro-(Gly)$_2$-pNA (5c). To a chilled solution of Boc-(Gly)$_3$-OH[8] (52 mg, 0.18 mmol), **4c**·HCl (93 mg, 0.18 mmol), and TEA (0.025 ml, 0.18 mmol) in DMF (2 ml) were added DCC (37 mg, 0.18 mmol) and HOBt (49 mg, 0.36 mmol), and the reaction mixture was stirred at 0 °C for 1 h and at room temperature overnight. Insoluble materials were removed by filtration, and the filtrate was evaporated. The residue was dissolved in MeOH (3 ml), applied to a column (3×170 cm) of Sephadex LH-20, and eluted with MeOH. The fractions containing the desired product were collected and evaporated, and the residue was crystallized from EtOH–ether, and collected by filtration. The product dissolved in a mixture (3 ml) of $CHCl_3$–MeOH (5 : 1) was applied to a column (2.5×20 cm) of silica gel 60 (Merck) and eluted with the same solvent. The fractions with the desired product were collected and evaporated, and the residue was crystallized from MeOH–ether; yield, 82 mg (61%); mp 141—143 °C; $[\alpha]_D^{22}$ +11.8° (*c* 1, MeOH); R_f^1 0.17, R_f^3 0.64.

Found: C, 48.71; H, 5.80; N, 18.44%. Calcd for $C_{13}H_{44}O_{12}N_{10} \cdot H_2O$: C, 48.56; H, 6.04; N, 18.27%.

H-(Gly)$_2$-D-Ala-L-Pro-(Gly)$_2$-pNA·HCl (6b·HCl). Compound **5b** (19 mg, 0.03 mmol) was treated with 0.1 M hydrogen chloride in formic acid (0.6 ml) as described for **4b**·HCl. The product was used for the next reaction without further treatment; the yield was quantitative; R_f^3 0.39.

H-(Gly)$_3$-D-Ala-L-Pro-(Gly)$_3$-pNA·HCl (6c·HCl). Compound **5c** (52 mg, 0.07 mmol) was treated with 0.1 M hydrogen chloride in formic acid (0.9 ml) as described for **4b**·HCl. The product was used for the next reaction without further treatment; the yield was quantitative; R_f^3 0.36.

Dnp-(Gly)$_2$-D-Ala-L-Pro-(Gly)$_2$-pNA (7b). To a solution of **6b**·HCl (17 mg, 0.03 mmol) and TEA (0.013 ml, 0.09 mmol) in DMF (1 ml) was added N_2ph–F (11 mg, 0.06 mmol), and the reaction mixture was stirred at room temperature for 3 h and evaporated. The residue dissolved in $CHCl_3$ (5 ml) was applied to a column (1.8×20 cm) of silica gel 60 (Merck), and the column was washed with $CHCl_3$. The product was eluted with the mixture of $CHCl_3$–MeOH (5 : 1, v/v). The fractions containing the desired product were evaporated to leave crystals, which were recrystallized from DMF–ether; yield, 18 mg (86%); mp 145—148 °C; $[\alpha]_D^{22}$ −15.0° (*c* 0.5, DMF); R_f^1 0.46, R_f^2 0.03, R_f^3 0.63.

Found: C, 47.48; H, 4.79; N, 19.46%. Calcd for $C_{28}H_{32}O_{12}N_{10} \cdot 1/2\ H_2O$: C, 47.39; H, 4.69; N, 19.74%.

Dnp-(Gly)$_3$-D-Ala-L-Pro-(Gly)$_3$-pNA (7c). Compound **6c**·HCl (48 mg, 0.07 mmol) was treated with N_2ph–F (26 mg, 0.14 mmol) as described for **7b**; yield, 46 mg (81%); mp 176—178 °C; $[\alpha]_D^{22}$ −1.6° (*c* 0.5, DMF); R_f^1 0.15, R_f^3 0.63.

Found: C, 44.94; H, 4.59; N, 19.72%. Calcd for $C_{32}H_{38}O_{14}N_{12} \cdot 2H_2O$: C, 45.17; H, 4.97; N, 19.76%.

CD Measurements. CD spectra were recorded on a JASCO spectropolarimeter model J-20 or J-40 in a 0.1 mM solution at room temperature (23±2 °C).

^{1}H NMR Measurements. ^{1}H NMR spectra were recorded on a Bruker WH-270 spectrometer equipped with a Nicolet-1180 computer and with a Bruker B-ST-100/700 temperature control unit. The spectra were measured at 23±0.5 °C if not mentioned otherwise. Chemical shifts were measured from the internal standard of DSS.[3] The spectra were assigned by spin-decoupling, H–D exchange, and saturation transfer methods.

The authors wish to express their thanks to Professor Tatsuo Miyazawa of The University of Tokyo for helpful discussion. Thanks are also due to the members of Analytical Department of System Engineering Laboratory, Mitsubishi-Kasei Industries Ltd., for elemental analyses.

Free Radical Chain Reaction of Allylic Tin Compounds with Organic Halides Involving S_H' Process

Toshihiko MIGITA,* Kazukiyo NAGAI, and Masanori KOSUGI
Department of Chemistry, Faculty of Technology, Gunma University, Kiryu, Gunma 376
(Received March 28, 1983)

Negatively substituted halomethanes were allylated easily by allyltin compounds *via* radical chain reaction involving S_H' process. Aryl, aralkyl, and alkyl halides underwent similar chain reactions only when the tin compound was charged in excessive amounts.

Since stannyl radical has been known to add to a double bond reversibly[1] and to abstract halogen atoms from organic halides,[2] the following radical chain reaction involving S_H' process is expected to proceed.

$$\rangle Sn\cdot + R\text{-}X \longrightarrow \rangle Sn\text{-}X + R\cdot$$

$$R\cdot + CH_2{=}CHCH_2Sn\langle \longrightarrow R\text{-}CH_2CH{=}CH_2 + \rangle Sn\cdot$$

Since the first examples of the chain reaction have been presented in 1973,[3] several applications were carried out with various organic halides.[4,5] In those reports, however, experimental details are frequently not provided. In this study, in order to survey scope and limitation of the chain reaction, various organic halides were subjected to the reaction of allylic tin compounds under ordinary reaction conditions where the radical chain carrier could be produced. As a result, negatively substituted aliphatic halides such as polyhaloalkanes, α-halo esters, and α-halo nitrile were found to be good substrates, whereas aryl, benzyl, and alkyl halides were shown to be poor substrates.

Results and Discussion

Reaction of Radical Generators with Allyltin Compounds. Table 1 shows the products detected in the reaction mixtures which were obtained by decomposing the common radical generators in benzene containing allyltin compounds. With α,α'-azobisisobutyronitrile (AIBN), about 75% of 1-cyano-1-propyl radical can be explained by the products: 50% were captured by allyltin compounds giving 2,2-dimethyl-4-pentenenitrile, and 25% dimerized under these conditions. Although the fate of the stannyl groups is uncertain, the fact suggests capability of AIBN as an initiator of the reaction of the tin compounds with organic halides.

Phenyl radical derived from phenylazotriphenylmethane (PAT) was also found to react with allyltin compounds, giving allylbenzene in 50%. Formation of biphenyl indicates that some of phenyl radical (*ca.* 10%) are consumed by phenylation of the solvent benzene. The product which is expected for S_H' process between triphenylmethyl radical and allyltin compounds was not detected.

Benzoyl peroxide (BPO) reacts with allyltin compounds, giving allyl benzoate and organotin benzoate in good yield. However, these products are explained most reasonably in terms of bimolecular mechanism between BPO and allyltin, instead of S_H' involving benzoxyl radical.[6] The detailed chemistry of the reaction will be shown elsewhere.

Reaction of Allylic Tin Compounds with Negatively Substituted Halomethanes. Reaction of halides such as polyhalomethanes, α-halo carboxylic esters, α-halo ketones, and α-halo nitriles with allyltributyltin was initiated by AIBN and gave the results as shown in in Table 2. Halogen atoms in the organic halides were displaced by an allyl group in moderate yield. In all cases, tributyltin halides were produced in almost quantitatively. In the absence of AIBN the reaction occurred hardly, and the reactants were almost remained unchanged at these temperature, although at much higher temperature considerable conversion was reported to be observed.[4] The presence of galvinoxyl (10 mol%) inhibited the AIBN (3 mol%) induced reaction completely. These facts indicate that the reaction proceeds by a radical chain mechanism.

Table 3 shows the results of the reaction of these halides with crotyltributyltin under similar conditions. Halogen atoms in the substrates were displaced by 1-methyl-2-propenyl group, but not by 2-butenyl group. The observed yields were lower than those in the reaction of allyltin compound. These findings support that the radical derived by abstraction of a halogen atom reacts with allylic tin compounds by a S_H' manner.

a) Allylic tin compound 1 mmol, solvent: PhH 1 ml, at 21—22 °C, irradiated by high pressure Hg lamp.

$$R\cdot + CH_3CH = CHCH_2Sn\langle \longrightarrow$$
$$R\text{-}CH(CH_3)CH = CH_2 + \rangle Sn\cdot$$

Lower yields in the reactions of crotyltin may be due to crowdiness at the position being attacked by R·.

Quite similar reactions between these halides and allyl- or crotyltin compounds proceeded under irradiation by a high pressure mercury lamp. As shown in Table 4, tendencies in dependence of yield on the structure of halide are quite resembling to those in the AIBN induced reaction. This implies the nature of radical chain mechanism of the photoreactions.

Reaction of Aryl, Aralkyl, and Alkyl Halide with Allyltributyltin. Under conditions similar to those for the above reactions, AIBN- as well as photoinduced reactions of aryl, benzyl, and alkyl halides with allyltin compound were quite sluggish. Thus, as shown in Tables 5 and 6, with equimolar reactants only few % of conversion were observed, and with large excess of halide reactions did not take place almost at all. In these cases, the reactants were recovered almost quantitatively. This inactiveness of aryl halide might be surprising at a glance, since both halogen abstraction from aryl halide by stannyl radical[2)] and S_H' process involving phenyl radical have been well known.[7)]

Table 7 shows the effect of additives on the yield of

benzene produced by reduction of iodobenzene by organotin hydride for which Kuivila proposed the radical chain mechanism involving halogen abstraction by stannyl radical.[2] Even without any additive,

$$R_3SnH + PhX \longrightarrow R_3SnX + PhH$$

benzene was formed in *ca.* 30% yield by heating a mixture of iodobenzene and tributyltin hydride at 80 °C for 24 h. The yield did not diminish in the presence of radical scavengers such as galvinoxyl and *p*-benzoquinone, indicating that the reduction occurring under the conditions is not a radical chain process. However, in the presence of AIBN yield of benzene was increased up to 80%, which again fell to *ca.* 40% by the addition of a radical scavenger. This fact means that AIBN assisted reaction was suppressed almost completely by a radical scavenger. This suggests that Kuivila's chain mechanism is sound at least for the AIBN assisted reaction, and stannyl radical once formed in a medium containing iodobenzene abstracts an iodine atom quite effectively.

TABLE 7. REACTION OF IODOBENZENE BY TRIBUTYLTIN HYDRIDE[a]

AIBN 0.04,	*p*-Benzoquinone 0.1	42

a) PhI 10 mmol, Bu_3SnH 1 mmol, 80 °C, 24 h. b) Based on Bu_3SnH.

On the other hand, the fact that biphenyl was formed in a considerable amount by decomposing PAT in benzene containing allyltributyltin (Table 1) suggests that S_H' reaction of phenyl radical with allyltin compound is not enough fast to construct an effective chain process. Some of phenyl radical may be consumed by non-chain by-pass such as phenylation of aryl halide

or the solvent benzene.

Employing more inert solvents, then, might be one of possible ways to enhance the efficiency of the chain reaction. However, since among the usual solvents,[8] benzene has been known to be relatively unreactive toward phenyl radical, and phenyl radical has been known to undergo S_H' with allyl sulfides 15—20 times faster than it adds to benzene,[8] increasing the relative concentration of allyltin is expected to give better results. Actually, when large excess of allyltin was employed, iodo- and bromobenzene were converted into allylbenzene in good yield, in either AIBN- or photo-induced reaction (Tables 5 and 6). However, even under these conditions, considerable amount of AIBN or prolonged irradiation is necessary to realize satisfactory yield, indicating very small kinetic chain length.

Chlorobenzene which is reduced by organotin hydride only in poor yield,[2] did not react even in the presence of large excess of allyltin, perhaps due to difficulty in chlorine abstraction by stannyl radical.

Benzyl and alkyl bromide also react under similar conditions, giving the corresponding displacement products. During the course of the study, we met the communication that the AIBN initiated reaction of cyclohexyl bromide with allyltributyltin gave allylcyclohexane in 88% yield, when 2 equiv. of tin compound was employed.[5]

Conclusion

Efficiency of free radical chain reaction between allylic tin compounds and organic halide depends on the nature of the halide, and is affected by easiness of halogen abstraction by stannyl radical and more subtly by efficiency of S_H' process. Negatively substituted halomethanes which are classified as acceptor subtrates in Huyser's sense[9] produce electron seeking radicals which will easily attack the π-bond of allyltin compound, giving S_H' product. Aralkyl and alkyl radicals, donor radicals, are less reactive toward the π-bond of allyltin. As a result, the expected chain reaction proceeds smoothly only when an excess amount of allyltin is employed. And at least concerning with the present reaction aryl radicals fall into the latter category.

Experimental

Materials. Allyltributyltin[10] was prepared by treating allylmagnesium chloride in ether. Bp 106—107 °C/1.6 mmHg (1 mmHg=133.322 Pa). Crotyltributyltin[4] was prepared by similar method or by the reaction of tributyltin-lithium with *trans*-crotyl chloride: In a three-necked flask (300 ml), tributyltin chloride (32.5 g) was placed and 7 g of metal lithium. The mixture was stirred for about 2 h. under argon atmosphere. To the mixture cooled by ice-water, was added dropwise tetrahydrofuran (100 ml) during 4 h. After the mixture turned to deep green, the mixture was stirred for one night at room temperature. After removal of unchanged lithium, a solution of *trans*-crotyl chloride (9.5 g) in tetrahydrofuran (50 ml) was added to the mixture cooled at −20 °C by means of ice–salt, during 1 h. The reaction mixture was stirred at the temperature for a half day, and for further one night, cooling by water. The mixture was treated with a saturated solution of ammonium chloride, then the product was extracted by ether. After the ethereal solution was dried over magnesium sulfate, removal of the ether and distillation under reduced pressure gave 20.9 g of the product (61%), bp 115—118 °C/2.0 mmHg. Tributyltin hydride[11] was prepared by reducing tributyltin chloride with $LiAlH_4$. Commercial organic halides were used as substrates after distillation.

Reaction Procedure. A solution containing reactants and solvent of amounts noted in the Tables is placed in a Pyrex tube and degassed. The tube was sealed and immersed in a bath kept at designated temperature for the thermal reactions. For photoinduced reaction, the tube was immersed in running water and irradiated with a high pressure mercury lamp (200 W). The products were collected by GLPC and identified NMR and IR spectroscopically. Amounts of products were determined by also GLPC.

Products. Except the well known compounds, the structures of the products were deduced based on the analytical and spectroscopic data recorded here.

4,4,4-Trichloro-1-butene: IR (neat) 1865 (C–H, out of plane), 1640 (C=C), and 645 cm^{-1} (C–Cl): ^1H NMR (CCl_4) δ=3.40 (2H, d, J=6.6 Hz) and 5.80 (3H, m). Found: C, 30.38; H, 3.08; Cl, 66.30%. Calcd for $C_4H_5Cl_3$: C, 30.13; H, 3.16; Cl, 66.71%.

4,4-Dichloro-1-butene: IR (neat) 1860 (C–H, out of plane), 1640 (C=C), 670 and 610 cm^{-1} (C–Cl): ^1H NMR (CCl_4) δ=2.87 (2H, t, J=6.4 Hz) and 5.60 (4H, m). Found: C, 38.81; H, 4.60; Cl, 56.38%. Calcd for $C_4H_6Cl_2$: C, 38.44; H, 4.84; Cl, 56.72%.

4,4-Dichloro-1-pentene: IR (neat) 1860 (C–H, out of plane), 1640 (C=C), 1380 (C–H, in plane), and 673 cm^{-1} (C–Cl): ^1H NMR (CCl_4) δ=2.17 (3H, s), 3.05 (2H, d, J=6.0 Hz), and 5.65 (3H, m). Found: C, 43.67; H, 5.45; Cl, 50.68%. Calcd for $C_5H_8Cl_2$: C, 43.20; H, 5.80; Cl, 51.00%.

4,4,4-Trichloro-3-methyl-1-butene: IR (neat) 1860 (C–H, out of plane), 1640 (C=C), and 575 cm^{-1} (C–Cl): ^1H NMR (CCl_4) δ=1.47 (3H, d, J=6.8 Hz), 3.20 (1H, m), and 5.60 (3H, m). Found: C, 34.91; H, 4.11; Cl, 61.03%. Calcd for $C_5H_7Cl_3$: C, 34.60; H, 4.02; Cl, 61.38%.

4,4-Dichloro-3-methyl-1-butene: IR (neat) 1643 (C=C) and 680 cm^{-1} (C–Cl): ^1H NMR (CCl_4) δ=1.28 (3H, d, J=7.2 Hz), 2.80 (1H, m), and 5.65 (4H, m). Found: C, 43.01; H, 5.52; Cl, 50.70%. Calcd for $C_5H_8Cl_2$: C, 43.20; H, 5.80; Cl, 51.00%.

3-Methyl-4-pentenenitrile: IR (neat) 2240 (C≡N) and 1640 cm^{-1} (C=C): ^1H NMR (CCl_4) δ=1.18 (3H, d, J=6.2 Hz), 2.49 (3H, m), and 5.60 (3H, m). Found: C, 75.49; H, 9.29; N, 15.01%. Calcd for C_6H_9N: C, 75.74; H, 9.54; N, 14.72%.

Methyl 3-Methyl-4-pentenoate: IR (neat) 1740 (C=O ester) and 1640 cm^{-1} (C=C): ^1H NMR (CCl_4) δ=1.11 (3H, d, J=6.2 Hz), 2.50 (3H, m), 3.70 (3H, s), and 5.55 (3H, m). Found: C, 65.35; H, 9.20%. Calcd for $C_7H_{12}O_2$: C, 65.60; H, 9.43%.

N,N'-Carbonyldi[1,2-benzisoxazol-3(2*H*)-one]: New, Reactive Condensing Agent

Mitsuru UEDA,* Hideaki OIKAWA, Naomi KAWAHARASAKI, and Yoshio IMAI†

Department of Polymer Chemistry, Faculty of Engineering, Yamagata University, Yonezawa, Yamagata 992

†*Department of Textile and Polymeric Materials, Tokyo Institute of Technology, Meguro-ku, Tokyo 152*

(Received April 7, 1983)

A new condensing agent, *N,N'*-carbonyldi[1,2-benzisoxazol-3(2*H*)-one] (**6**), was readily prepared by the reaction of 1,2-benzisoxazol-3-ol and trichloromethyl chloroformate in toluene. The condensing agent **6** was shown to be very useful for the preparation of amides, esters, and dipeptides under mild conditions. A successful polyamide synthesis by one-pot polycondensation of isophthalic acid with diamines using **6** was also described.

Condensations among the most important and fundamental reactions in organic synthesis and many reagents for promoting condensations by one-pot procedures have been reported.[1-4] In particular, their full potential has been realized in conversions of carboxylic acids into amides and esters. Most such condensing agents first react with the carboxylic acids to give the intermediates, active esters or amides, which undergo subsequent nucleophilic attack by the amino or hydroxyl group. Therefore, a primary factor in determining whether or not the condensing agents are effective is their ability to activate carboxylic acids.

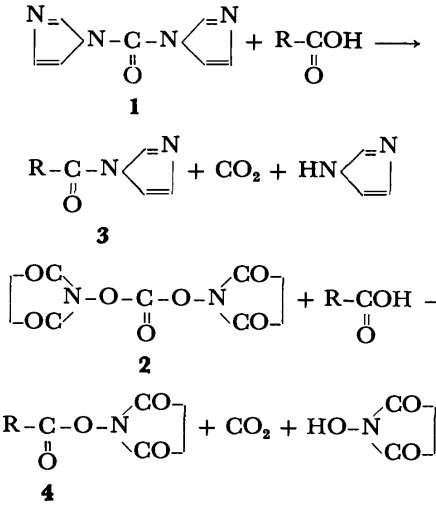
It is well recognized that increased reactivity of carboxylic acid derivatives toward nucleophiles may be roughly correlated with greater stability of the leaving group anions, that is, pK_a of the leaving groups. From this point of view, we previously exploited a series of good leaving groups in the syntheses of active esters and amides, demonstrating that the active ester and amide methods are useful in the preparation of high molecular weight polyamides under mild conditions.[5]

Based on the success of those studies, we continued to investigate new active condensing agents for the synthesis of amides, esters and polyamides. One requirement for improved condensing agents is that the conversion of carboxylic acids to the active intermediates should occur readily under mild conditions. In the preceding paper, we showed that 3-(2-benzothiazolythio)-1,2-benzisothiazole 1,1-dioxide and 3-(2-benzoxazolylthio)-1,2-benzisothiazole 1,1-dioxide were new reactive condensing agents for the synthesis of amides and esters.[6]

We now report that amides, esters, peptides, and polyamides can be easily obtained from carboxylic acids and nucleophiles by a one-pot procedure using the new condensing agent, *N,N'*-carbonyldi[1,2-benzisoxazol-3(2*H*)-one] (**6**).

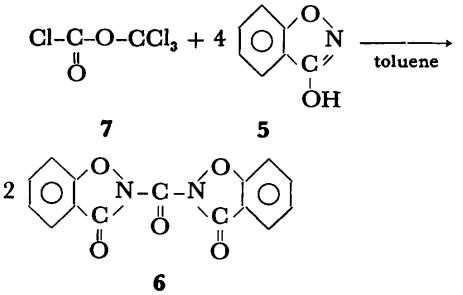
Results and Discussion

Synthesis of N,N'-*Carbonyldi[1,2-benzisoxazol-3*(2H)*-one]* (*6*). The widely used condensing agents derived from phosgene, such as *N,N'*-carbonyldiimidazole (**1**) and *N,N'*-(carbonyldioxy)disuccinimide (**2**) have been reviewed.[7,8] The reaction of carboxylic acids with **1** and **2** lead to the intermediate imidazolides (**3**) and *N*-hydroxysuccinimide ester (**4**) respectively, both of which have been characterized by their very high reactivity in nucleophilic reactions.

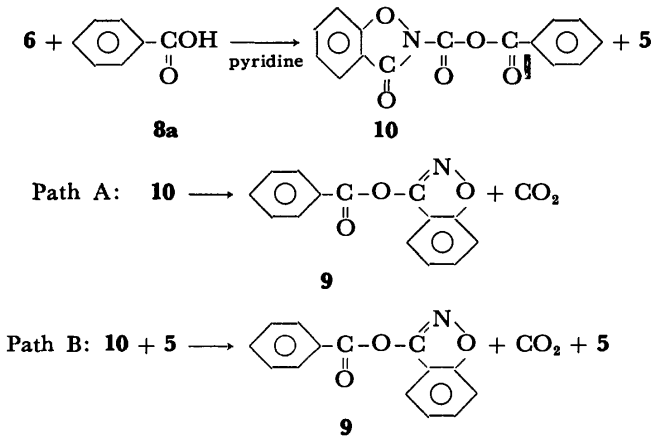


Recently, we found that the *N*- or *O*-acyl products from the acylation of 1,2-benzisoxazol-3-ol (**5**) were susceptible to aminolysis under mild conditions and the corresponding amides were produced in quantitative yields.[5i] This finding led to the synthesis of *N,N'*-carbonyldi[1,2-benzisoxazol-3(2*H*)-one] (**6**) which was expected to serve as new condensing agent with a wide range of preparative applications.

The condensing agent **6** was readily prepared in high yield by reacting **5** with trichloromethyl chloroformate (**7**) in a 4 : 1 molar ratio in toluene (Scheme 1). Recrystallization from toluene gave white needles melting point at 205—206 °C. Acylation of **5** may involve reaction at either oxygen or nitrogen. Acylations reported earlier gave *N*- or *O*-acyl products, depending on the reaction conditions employed and acylating agent used.[9] The reaction of **5** with **7** in toluene under reflux conditions gave preferentially the more thermo-



Scheme 1.



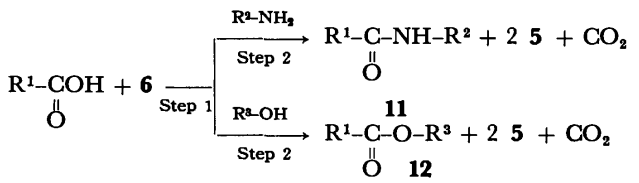
Scheme 2.

dynamically stable *N*-acyl product **6**. The structure of **6** was characterized by elemental analysis and IR spectroscopy. The IR spectrum showed carbonyl absorption bands at 1780, 1765, and 1750 cm^{-1}.

Reaction of ***6*** *with Benzoic Acid* (***8a***). To get a better picture of the course of the reaction, **6** was treated with benzoic acid (**8a**) in *N*-methyl-2-pyrrolidone (NMP) at 50 °C for 1 h in the presence of pyridine. The condensing agent **6** reacted rapidly with **8a** with liberation of CO_2, to give 3-benzoyloxy-1,2-benzisoxazole (**9**). The formation of benzoic anhydride was not observed. The intermediate **9** has been characterized by its high reactivity toward aminolysis.[5i] Consequently, the reaction pathway suggested for the formation of **9** is shown in Scheme 2.

Initially, the attack of the benzoate anion at the carbonyl carbon of **6** gives the mixed anhydride (**10**). Two pathway are possible for the further reaction of **10**. The mixed anhydride (**10**) loses CO_2 to form the intermediate **9** (Path A). Alternatively, **5** liberated in the first step of the reaction attacks the carbonyl carbon of **10**, giving the intermediate **9** (Path B). A similar mechanism has been proposed to account for the formation of imidazolide (**3**) by the reaction of **1** with carboxylic acids.[10]

Synthesis of Amides (***11***) *and Esters* (***12***). The syntheses of amides (**11**) and esters (**12**), using our new activating reagent **6**, were carried out by a one-pot procedure. This efficient procedure consists essentially of two reactions: formation of the active ester (**9**) from carboxylic acids as described above, and subsequent aminolysis or alcoholysis of the active ester (**9**) as shown in Scheme 3. The aminolysis and alcoholysis of the active ester (**9**) proceeded smoothly at room temperature to give the corresponding amides (**11**) and esters (**12**). The alcoholysis required an equimolar amount of triethylamine (TEA).



Scheme 3.

Next, the selective *N*-acylation and the *N,O*-diacylation of *p*-aminophenol (**13**) were performed in either the absence or the presence of TEA, respectively. The corresponding amide (**14**) or amide ester (**15**) were obtained in good yields (Scheme 4). These results are summarized in Table 1.

Synthesis of Dipeptides (***18***). In order to further demonstrate the preparative utility of our method, it was applied to the synthesis of dipeptides. Thus the reaction of an *N*-protected amino acid (**16**) with an amino acid ester hydrochloride (**17**) was carried out in the presence of pyridine. The *N*-protected amino acid (**16**) was reacted with equimolar amount of **6** in dichloromethane in the presence of pyridine at room temperature. After several hours, the amino acid ester hydrochloride (**17**) and TEA as an acid acceptor were added. The dipeptide product **18** was isolated in the normal manner. *N*-Protected dipeptide ester (**18**) were prepared in good yields virtually without racemization (Table 2), (Scheme 5).

Synthesis of Polyamides (***19***). Our method can be extended to the synthesis of polyamides (**19**) and it provides a novel approach to direct polycondensation. The one-pot polycondensation of isophthalic acid was carried out in solution at low temperature using three diamines (**20**): 4,4′-oxydianiline, 4,4′-methylenedianiline, and 1,6-hexanediamine. The polar aprotic solvents, NMP, hexamethylphosphoric triamide

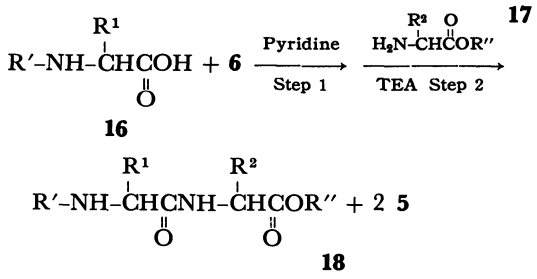
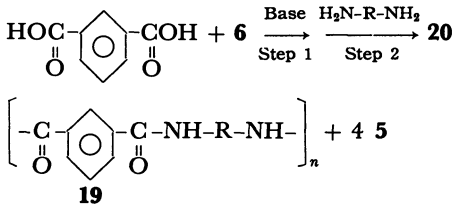
a) Polymerzation was carried out with 1 mmol of the monomers using the condensing agent **6** (2 mmol) in the solvent.
b) Measured at a concentration of 0.5 g/dl in concentrated sulfuric acid at 30 °C.

(HMPA), and *N*,*N*′-dimethylacetamide (DMAc) were used as polymerization media (Scheme 6). Polycondensations in the NMP and DMAc proceeded heterogeneously which impeded the increase in molecular weight. Various tertiary amines with different base strength were also tested in these polymerizations in order to elucidate the influence of bases. TEA, with its high basicity, was found to be good base. The results are summarized in Table 3. The polyamides were produced in quantitative yields with inherent viscosities of 0.1 to 0.25 dl·g^{-1}. The polymers were identified as polyamides by comparison of their IR spectra with those of the authentic polyamides. Although this one-pot syntheses of polyamides was successful, the viscosities of polyamides were relatively low. Thus, studies of the polycondensation conditions must be continued.

In summary, our studies indicate that **6** is a very useful reagent for the formation of amides, esters and



Scheme 5.



Scheme 6.

peptides. The new condensing agent **6** is a crystalline solid having excellent hydrolytic stability and therefore it is handled more easily than conventional agents. Furthermore, 1,2-benzisoxazol-3-ol (**5**), a reaction byproduct, is readily removed from the reaction products by washing the reaction mixture with 1% aqueous sodium hydrogencarbonate.

Experimental

Melting points were uncorrected. Infrared spectra were obtained using potassium bromide pellets with a JASCO IRA-1 spectrophotometer. 4,4'-Oxydianiline, and 4,4'-methylenedianiline were recrystallized from tetrahydrofuran and benzene respectively. *N*-methyl-2-pyrrolidone (supplied by Mitsubishi Chemical Industries Ltd.), hexamethylphosphoric triamide and *N,N*-dimethylacetamide were purified by vacuum distillation and stored over 4-Å Molecular Sieves. *N*-Protected amino acids and amino acid ester hydrochlorides were prepared by usual procedures. The other reagents were used without further purification.

1,2-Benzisoxazol-3-ol (5). This compound was prepared by the modified method reported by Böshangen.[11] To a ice-cold suspention of salcilohydroxamic acid (15.3 g 0.1 mol) in tetrahydrofuran (45 ml), thionyl chloride (10 ml) was added dropwise over 1 h. Then excess thionyl chloride and the solvent were removed *in vacuo* to give a white paste, which was dissolved in dioxane (10 ml). This solution was added dropwise over 1 h to a solution of triethylamine (42 ml) in dioxane (35 ml). The temperature was kept below 10 °C. The yellow mixture was poured into water (300 ml) and then was acidified with 10% HCl. The solution was allowed to crystallize overnight at 0—10 °C. The product was collected by filtration, washed with water, and dried to give 9 g of **5**. Recrystallization from 25% aqueous ethanol solution produced faint yellow needles. Mp 145—146 °C (lit,[11] 144 °C).

N,N'-*Carbonyldi*[*1,2-benzisoxazol-3(2H)-one*] (*6*). A mixture of (**5**) (4.3 g, 0.032 mol) and trichloromethyl chloroformate (0.96 ml, 0.008 mol) in toluene (30 ml) was refluxed with stirring for 1 d, then cooled. The precipitate was isolated by filtration and washed with toluene, and dried. Yield was 3.5 g (73%). Purification by recrystallization from toluene to give a white needles. Mp 205—206 °C; IR (KBr), 1780, 1765, and 1750 cm^{-1}.

Found: C, 60.8; H, 2.9; N, 9.3%. Calcd for $C_{15}H_8N_2O_5$: C, 60.82; H, 2.72; N, 9.46%.

3-Benzoyloxy-1,2-benzisoxazole (9). To a stirred solution of benzoic acid (0.244 g, 2.0 mmol), pyridine (0.16 ml, 2.0 mmol) in NMP (4 ml) was added **6** (0.592 g, 2.0 mmol), followed by stirring at 50 °C for 1 h. The reaction mixture was poured into water (100 ml). The precipitate formed was collected filtration, washed with water and dried *in vacuo*. Yield: 0.400 g (98%). Recrystallization from hexane produced white needles, mp 65—66 °C (lit,[9] 64 °C).

Amide (11). General Procedure: The condensing agent **6** (0.592 g, 2 mmol) was added to a stirred solution of the carboxylic acid (2 mmol) and pyridine (2 mmol) in NMP (4 ml) at 50 °C. After 1 h, the amine (2 mmol) was added. Stirring was continued for several hours. The mixture was poured into 1% aqueous sodium hydrogencarbonate. The precipitate was filtered and washed with water and dried.

Ester (12). General Procedure: A mixture of **6** (2 mmol), benzoic acid (2 mmol) and pyridine (2 mmol) in NMP (4 ml) was stirred at 50 °C for 1 h. To this mixture the alcohol (2 mmol) and triethylamine (2 mmol) were added. Stirring was continued for several hours. The reaction mixture was worked up as described above.

Amide Esrer (15). The condensing agent **6** (2 mmol) was added with stirring to a solution of benzoic acid (2 mmol) and pyridine (2 mmol) in NMP (4 ml) at 50 °C. After 1 h, *p*-aminophenol (**13**) (1 mmol) was added to this mixture. After stirring 1 d, triethylamine (2 mmol) was added, the mixture was stirred for 2 d and worked up as described. The compound **14** was obtained when triethylamine was omitted.

Protected Dipeptide Ester (18). General Procedure: To a solution of the *N*-protected α-amino acid (1 mmol) and pyridine (1 mmol) in dichloromethane (5 ml), **6** (1 mmol) was added under nitrogen. The solution was stirred for several hours at room temperature, then the α-amino acid ester hydrochloride (1 mmol) was added. The solution was stirred for 1 d at room temperature. After removal of the solvent *in vacuo*, the residue was dissolved in ethyl acetate, and the organic solution was washed successively with 5% aqueous sodium hydrogencarbonate, 1 M hydrochloric acid and saturated brine, and then dried ($MgSO_4$). After evaporation of ethyl acetate, the dipeptide ester was purified by crystallization.

Polyamide (19). General Procedure: The condensing agent **6** was added to a stirred solution of isophthalic acid (1 mmol) and pyridine (2 mmol) in NMP (2 ml). The mixture was stirred for a defined time, then diamine (1 mmol) was added at room temperature. Stirring was continued for 2 d. The resulting solution was poured into 1% aqueous sodium hydrogencarbonate (200 ml) and the precipitated polymer was collected and dried *in vacuo* at 60 °C for 2 d. Inherent viscosity was measured at a concentration of 0.5 $g \cdot dl^{-1}$ in concentrated sulfuric acid at 30 °C.

We are indebted to Mr. Sadao Kato for the performance of the elemental analyses.

The Recovery of Lithium from Geothermal Water in the Hatchobaru Area of Kyushu, Japan

Kenjiro YANAGASE, Tetsutaro YOSHINAGA,* Kentaro KAWANO, and Toshikazu MATSUOKA†

Department of Environmental Science, Faculty of Engineering, Kyushu Institute of Technology, Tobata-ku, Kitakyushu, Fukuoka, 804

(Received May 28, 1982)

The recovery of lithium from geothermal water at Hatchobaru in Kyushu, Japan, was investigated. A coprecipitation method using aluminium salts was employed. The lithium concentration in the geothermal water used in the present study was about 10 ppm. To make our experimental results more applicable for geothermal water, a reference lithium solution (10 ppm) was also studied as a control solution. A perfect recovery of lithium was obtained for the reference lithium solution by choosing appropriate conditions. For geothermal water, the yield of Li was not so good as in the control solution. However, an almost complete recovery of lithium was attained for geothermal water by the removal of calcium ions and polymerized silica. The mechanism of Li recovery was also considered.

The lithium industry was a minor one before World War II. In recent years, however, commercial uses of lithium and its compounds have increased in many fields, such as ceramics, glass, batteries, and metallurgy. In addition to these commercial uses, it is also anticipated that lithium can be used as blanket material in fusion reactors.[1] Still more, from the point of view of the energy problem,[2] the most important solution in the next coming century will definitely be the more basic use of lithium in the fusion energy process. A basic deuterium–tritium (D–T) reaction will release a neutron, an alpha particle, and an energy of 17.6 MeV carried by the neutron and alpha particle. Deuterium is available in seawater, but natural tritium is scarce. Bombarded by a neutron, lithium can be used as a breeder for tritium in the fusion reactor. The energy value of one gram of lithium can be increased by adding to the breeding ratio (tritons produced/tritons consumed) or by increasing the amount of energy per fusion. Lee estimated that the effective energy content of natural Li ranges from about 8.5×10^3 kW h (normal) per gram to 2.7×10^4 kW h (thermal) per gram of natural lithium.[3]

In Japan, there are practically no lithium resources. Although the concentration is very dilute (=0.18 ppm), there is a vast supply of lithium in seawater (estimated to be 2.5×10^{14} kg), probably the most reliable energy resource in the near future. At the present stage, however, the recovery of lithium from seawater in a commercially practical way is very difficult. Possible substitute for petroleum have been investigated recently in Japan. One of them is a geothermal energy. Water from the Hatchobaru power plant (50 MW), for example, gives Li values of about 140 (kg/d), (5.3×10^4 kg/Year) provided that the Li content is 10 ppm, and the fluid velocity of geothermal water, 600 t/h. Though the Li content thus obtained is small, it is equal to about one hundred million private persons' electric demand (as 1 kW·Year/Man·Year). Incidentally, the Li production in the world is about 9000 t (metric)/Year (1977), and most of lithium in the world is produced in the U.S.A. (*ca.* 70%), U.S.S.R(15—20%), Africa and china.[4] The possible lithium recovery from Hatchobaru geothermal water will contribute only 0.6% to the total world production at present. Within the next 10 years however, the ratio of geothermal energy to the total energy in Japan will become 1%. According to our calculation, lithium products in Japan in the near future will become about 50 times as large as at present. The Li concentration in seawater is about 0.2 ppm, as has been stated above, while the concentration in geothermal water from the Hatchobaru bore is about 10 ppm. Thus, the recovery from geothermal water seems relatively easy and practicable compared with that from seawater. In the present work, the recovery of lithium from geothermal water is aimed at. As techniques to recover lithium from a lithium containing solution, there have been used the inorganic ion-exchange method, the adsorption method using many adsorbents, the solvent-extraction method, the coprecipitation method, and so on. The coprecipitation method seemed to be the simplest among these and so was employed in the present study. Although the lithium recovery from low-concentration solutions has been extensively investigated,[1,5-24] the details of the mechanism for Li recovery seem not yet to have been clarified. Since the many factors concerning Li recovery are very complicated, the reported results are sometimes in conflict with each other. Thus, in the present work, a basic investigation will be made at first, then it will be applied to geothermal water.

Experimental

Geothermal Water. The geothermal water used in the present study was sampled out from bores at the Hatchobaru Power Station in Kyushu, Japan. The sampling of geothermal water was done from May 10, 1980, to January 22, 1981. Some typical constituents of geothermal water are shown in Table 1.

Reagents. *a) Precipitating Agents*: The $AlCl_3\cdot6H_2O$, $NaAlO_2$, $FeSO_4\cdot7H_2O$, $FeCl_3\cdot6H_2O$, $MgSO_4\cdot7H_2O$, $Ti(SO_4)_2$, and H_fO_2 were commercially obtained from Wako Pure Chemical Industries, Ltd.; the $ZrO\cdot nH_2O$ was from the Shinnippon Kinzoku Kagaku Co. Ltd.; the Ta_2O_5 was from Johnson, Mathey and Co., Ltd., and the $(NH_4)_6Mo_7O_{24}\cdot4H_2O$, from the Ishizu Pharmaceutical Co., Ltd.

† Present address: The Industrial Waste Guidance Division Bureau in Kitakyushu, Kokurakita-ku, Kitakyushu, Fukuoka 803.

Table 1. Typical compositions (and pHs) of geothermal waters from bores in Ohtake and Hatchobaru areas (in ppm)

Constituents	Ohtake Well Nos.		Hatchobaru Well Nos.	
	No. 9	No. 10	No. 4	No. 7
Na	1050	1030	2250	2140
K	132	124	277	266

As	2.0	2.1	3.2	3.6
pH	8.57	8.44	6.99	7.04

b) Other Reagents: The LiCl, Na_2CO_3, $(NH_4)_2CO_3$, $CaCl_2 \cdot 2H_2O$, EDTA ($C_{10}H_{14}N_2O_8Na_2 \cdot 2H_2O$), $CaCO_3$, NH_4Cl, E.B.T (indicator), and NN (indicator) were obtained from Wako Pure Chemical Industries, Ltd. All the reagents used were guaranteed reagents.

Instruments. A Toyo Kagaku Sangyo pH meter, Model Pt-3D, and Denki Kagaku Keiki pH meter, MG-7, were used with a combination electrode, HCE 101C-1T, for the measurement of the (apparent) pH's of the reference lithium solutions (abbreviated as ref. Li solutions hereafter) and geothermal water. A Nippon Jarrell-Ash AA-8200 atomic absorption spectrophotometer and flame emission were used to determine the lithium content in the sample solutions. The X-Ray diffraction patterns were measured with a Rigaku Rotor Flex RU-200 diffractometer. The DTA and TG curves were measured with a Rigaku Denki thermal analysis instrument, No. 802981.

Procedure. To examine the performance of precipitating agents, the procedure shown in Fig. 1 was employed.

Results and Discussion

No precipitating agents employed in this study, except for aluminium salts, exhibited any pronounced effect on lithium recovery. Aluminium salts have previously been employed as reagents for Li extraction,[5] and the efficiencies of Al salts were confirmed in the present investigation. Hereafter, the results will be shown and discussed only for the aluminium salts. The recovery of lithium from geothermal water is the main purpose of the present work. However, the compositions of geothermal water are different from place to place. A ref. Li solution with the same lithium concentration as in geothermal water from Hatchobaru was prepared as a control solution to make the experimental results

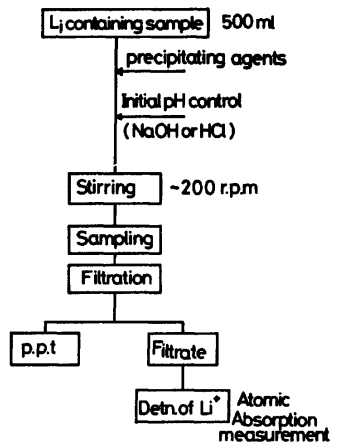

Fig. 1. Flow chart of procedure for the estimation of lithium recorvery.

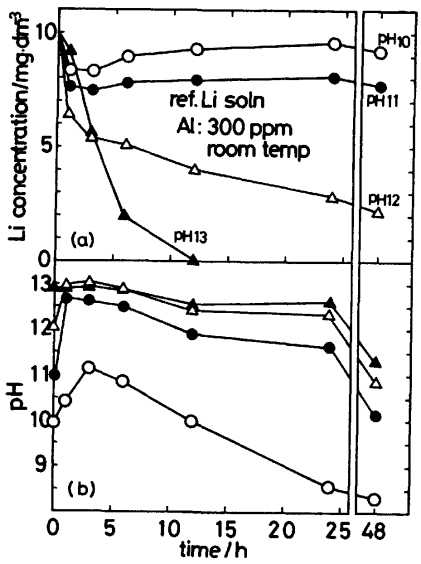

Fig. 2. The plots of residual Li concentration *vs.* time and pH *vs.* time for reference Li solution with various kinds of pH at room temperature.
Initial Li concentration: 10.0 ppm; Al concentration: 300 ppm ($AlCl_3$). (Apparent) initial pH: —○— 10.0; —●— 11.0; —△— 12.0; —▲— 13.0.

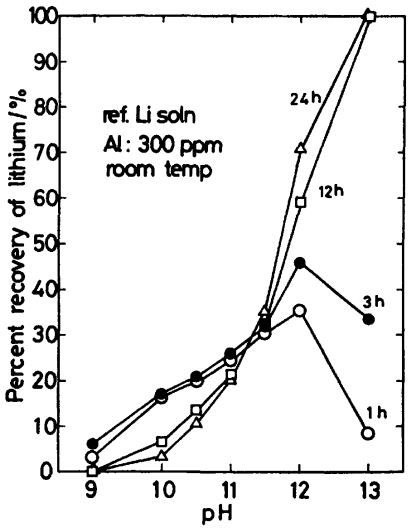

Fig. 3. The relation between percent recovery of lithium and initial pH for reference Li solution at room temperature. Initial Li concentration: 10.0 ppm; Al concentration: 300 ppm ($AlCl_3$), Stirring time: —○— 1 h; —●— 3 h; —□— 12 h; —△— 24 h.

widely applicable. In this study, LiCl was added to distilled water so that the Li concentration became 10 ppm, to be referred to hereafter as the "reference Li solution." Extensive investigations of lithium recovery have been made by many researchers. However, the conditions of Li extraction from a low-Li-content solution are influenced by many factors, such as the Li concentration, the salt constituents and their concentrations in the solution, the concentrations of the precipitating agents, the pH, the temperature, and the stirring time. Thus, the optimum conditions reported cover wide range, depending on the characteristics of the solutions, and are sometimes in conflict with each other. First, the results for the ref. Li solution will be shown. Figure 2 shows the plots of the residual Li consentration *vs.* the time, and the (apparent)pH *vs.* the time for the ref. Li solution at room temperature. The figure shows that the influence of the initial (apparent)pH is great. In this case, the experiment at an initial pH value of 12 gives the best results within about an hour. However, Fig. 2 also shows that, after 24 h, the higher the pH, the better the yield recovered. From this result, the plot of the Li recovery *vs.* pH was made, and it is shown in Fig. 3. The plot of the time dependence of pH shows a tendency, from the beginning to 1—3 h, for the values of the pH's to increase and then to decrease gradually. These changes in the pH and Li recovery with the passage of time seem to be an important key to the mechanism of Li recovery. As long as aluminium salts were used, a high Li recovery was obtained at relatively higher pH regions in this experimental study. This suggests that the use of sodium aluminate needs only a small amount of pH-control agents (acid or base) for the recovery of lithium. In Fig. 4, a pH titration curve for Al salt in an acidic solution is shown. The equilibria of Al^{3+}, $Al(OH)_3$, and AlO_2^-(or $Al(OH)_4^-$) are:

$$Al^{3+} \underset{H^+}{\overset{OH^-}{\rightleftharpoons}} Al(OH)_3 \underset{H^+}{\overset{OH^-}{\rightleftharpoons}} Al(OH)_4^-.$$

With this equilibria relation and calibration curve, the Al content in the (Li containing) solution was also determined. That is, the central region of the titration curve was used; it corresponds to the total content of the aluminium in solution. The coexistence of the Li ion did not disturb the Al analysis. At an initial pH of the 13, the Li recovery *vs.* the time, the (apparent)pH *vs.* the time, and the Li recovery *vs.* the Al concentration were examined with various kinds of Al concentrations. The results are shown in Figs. 5 and 6. Except for the Al concentrations of 50 and 1000 ppm, the percentage of the recovery of Li was about 100% after stirring for a long time. There is also a tendency that the higher the Al concentration, the quicker the recovery. For an Al concentration of 50 ppm, almost no effective recovery was observed, and for 1000 ppm, a percentage of the recovery of only 50—60% was obtained, not in accord with our expectation. This might be explained

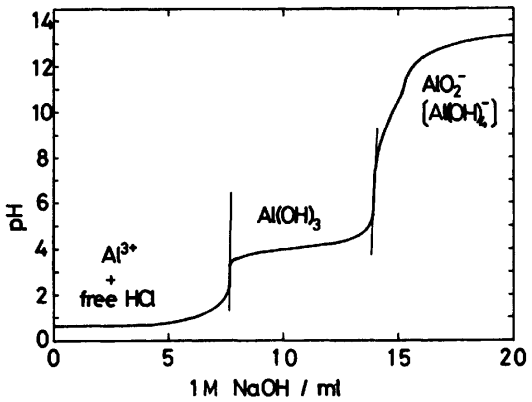

Fig. 4. pH change of aluminium salt solution during alkaline titration. [Al concentration of lithium aluminate is also determined using this potentiometric technique].

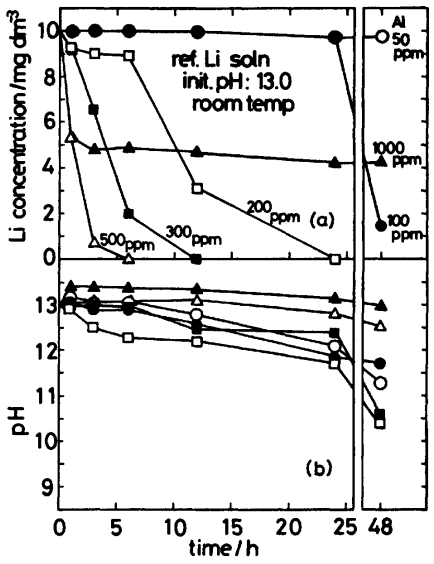

Fig. 5. The plots of residual Li concentration *vs.* time and pH *vs.* time for reference Li solution with various kinds of aluminium concentration at room temperature. Initial Li concentration: 10.0 ppm; initial pH: 13.0; Al concentrations: —○— 50 ppm; —●— 100 ppm; —□— 200 ppm; —■— 300 ppm; —△— 500 ppm; —▲— 1000 ppm.

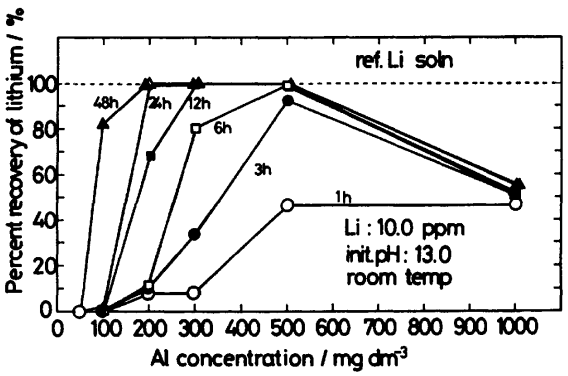

Fig. 6. The relation of percent recovery of lithium and Al concentrations for reference Li solution at room temperature.

(Apparent) initially set pH: 13.0. Al salt: $AlCl_3$.

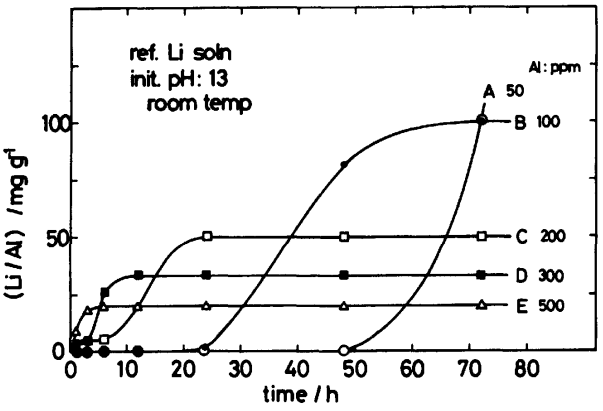

Fig. 7. The relation of (lithium/alminium) and stirring time for reference Li solution at room temperature. Al concentrations and percent recoveries of Li (in parentheses): A —○— 50 ppm (50%); B —●— 100 ppm (100%); C —□— 200 ppm (100%); D —■— 300 ppm (100%); E —△— 500 ppm (100%); [Theoretical maximum = 257 mg (Li)/g (Al), as $LiAlO_2$] (Apparent) initially set pH: 13.0.

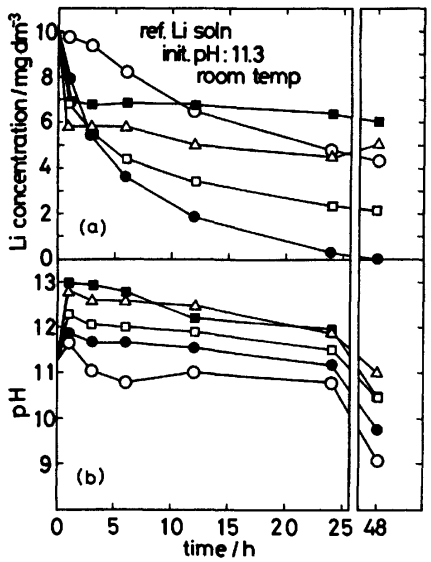

Fig. 8. The plots of residual Li concentration *vs.* time and pH *vs.* time for reference Li solution with various kinds of Al concentrations at room temperature.
Al concentrations: —○— 50 ppm; —●— 100 ppm; —□— 200 ppm; —■— 300 ppm; —▲— 500 ppm; initially set (apparent) pH: 11.3.

by the partial crystallization of the aluminium hydroxide coprecipitated. The relation of (Li(mg)/Al(g)) and the time course is shown in Fig. 7. The figure shows that, although a 100% recovery of Li for an Al concentration of 100—500 ppm is achieved after 72 h stirring, the Li yield for 1 g of aluminium decreases with the increase in the Al concentration. However, as the relation between the stirring time and the Al concentration shows, there are several cases of Li recovery [see Fig. 7]. Therefore, the stirring time is also an important factor for Li recovery from the economical point of view. Figure 8 shows the plot of the Li recovery *vs.* time for the respective Al concentration at an initial pH of 11.3.

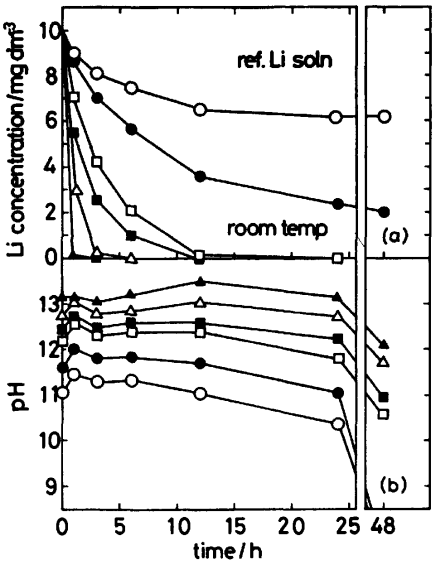

Fig. 9. The plots of residual Li concentration *vs.* time and pH *vs.* time for reference Li solution with various kinds of Al concentrations at room temperature. [Without initial pH controls]
Al concentrations ($NaAlO_2$): —○— 50 ppm; —●— 100 ppm; —□— 200 ppm; —■— 300 ppm; —△— 500 ppm; —▲— 1000 ppm.

The effects of Al concentration differ much from the results for the initial pH of 13 and a higher Li recovery is obtained in the region of relatively low Al concentrations. As has been stated above, in this experimental research, the recovery of lithium was achieved in a relatively higher pH region. This result differs considerably from the results of Goodenough *et al.*[5] In a high pH region, Al salt will exist in the state of the aluminate ion ($Al(OH)_4^-$), and the use of water-soluble aluminate might be preferable, as has been mentioned already. In Fig. 9, the results for sodium aluminate instead of aluminium chloride are shown without any pH control. This experimental result could not be compared with those for $AlCl_3$ since the initial pH control was not made. However, from the values of initial pH, the experimental results for the Al concentration of 1000 ppm by the use of $AlCl_3$ at pH 13 and the results for the Al concentration of 50 ppm at pH 11.3 can be compared with those of the corresponding Al concentration by the use of $NaAlO_2$. As far as these high and low Al concentrations are concerned, the use of sodium aluminate seems to be superior to that of aluminium chloride (see Figs. 5, 8, and 9). The difference should be small in principle, but the real difference observed cannot be explained properly at present.

On the Mechanism of Li Recovery. On the Li recovery by the coprecipitation method, two explanations are considered; one is the recovery by adsorption,[17] and the other, that by precipitation by the formation of a water-insoluble aluminate complex.[5-8] However, no satisfactory explanation has yet been given. Therefore, in the present work, attempts will be made to clarify the effects of both adsorption and precipitation by

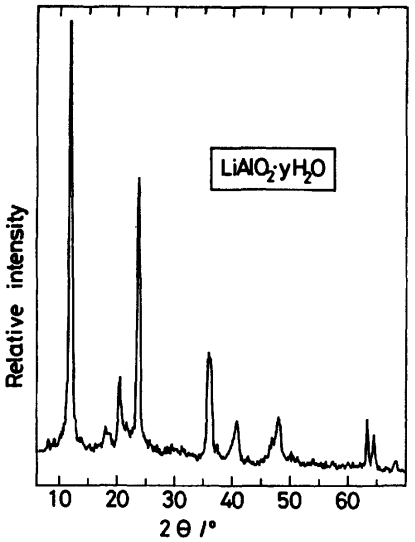

Fig. 10. X-Ray diffraction pattern of lithium alminate, $LiAlO_2 \cdot yH_2O$ (Cu $K\alpha$).

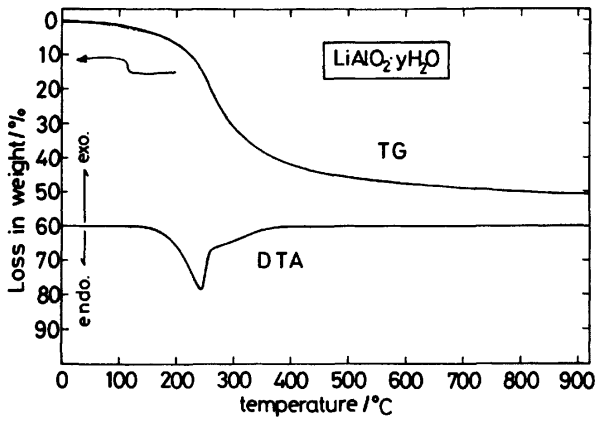

Fig. 11. Thermal analysis of lithium alminate ($LiAlO_2 \cdot yH_2O$).

means of complex formation.

(1) Formation of an Insoluble Aluminate Complex. A mixture of a $NaAlO_2$ solution and a LiCl solution causes precipitation. The precipitate is a white powder. Many kinds of precipitates were produced by the use of different mixing ratios at room temperature. After a certain time of stirring, the precipitates were filtrated with a glass filter (G-4) and then washed with water and acetone until the chloride ion was no longer detectable. Parts of the precipitates were dried in two ways: (A) by vacuum drying at room temperature, and (B) by 105 °C drying. The X-ray diffraction patterns and DTA and TG curves were measured for the A and B samples. A and B gave nearly the same patterns. In Figs. 10 and 11, the pattern and the DTA and TG curves for B (prepared under a Li-rich condition; $(Li/Al)_{mol}=5$) are shown. The X-ray diffraction patterns obtained for B were consistent with the lattice constants of lithium aluminate ($LiAlO_2 \cdot yH_2O$) listed on the ASTM card (20-618). The diffraction patterns for these compounds agreed very closely with each other, irrespective of the mixing ratio of Li to Al, although the relative intensities sometimes differed. It might be noted here that if a

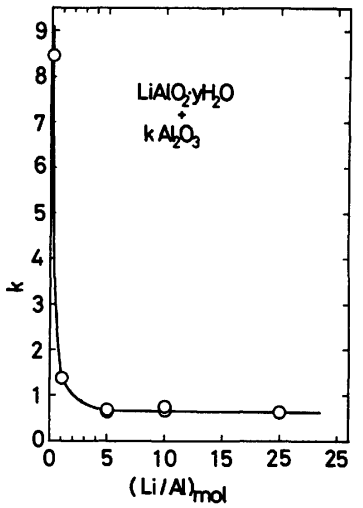

Fig. 12. Relation of $(Li/Al)_{mol}$ *vs.* k, where k represents the amount of additionally produced aluminium hydroxide.

stoichiometrically excess amount of aluminium salt for lithium was used, additional peaks of aluminium hydroxide were found. The composition of the lithium aluminate complex has been reported to be $Li_2O \cdot 2Al_2O_3$ or $Li_2O \cdot 2.5Al_2O_3$ or around $Li_2O \cdot 4.7Al_2O_3$;[5,20] this seemed somewhat in conflict with our present results obtained by means of X-ray diffraction analysis. If the aluminium complex is $LiAlO_2 \cdot yH_2O$, the ratio of Li_2O to Al_2O_3 is unity. Therefore, the precipitates obtained in our study were dissolved by hot hydrochloric acid to determine the accurate ratio of aluminium to lithium. For the analysis of aluminium, the titration method was employed (see Fig. 4). The results show that, in the synthesis of the lithium aluminate complex, the reduction of the molar ratio of LiCl to $NaAlO_2$ increases the aluminium content in the lithium aluminate complex. The DTA and TG curves for lithium aluminate complex exhibit simple patterns, as is shown in Fig. 11. However, the increase in the aluminium content in the lithium aluminate complex gives an additional endothermic DTA peak about 230 °C. The TG curve for the lithium aluminate complex (Sample B) in Fig. 11 shows a rapid decrease in weight in the range of about 200 and 300 °C; this might correspond to the dehydration of hydrated water in the lithium aluminate complex. A consideration of several data on the lithium aluminate complex leads to the following formula:

Lithium aluminate complex precipitated in the solution $\equiv LiAlO_2 \cdot yH_2O$(crystal) $+ k\, Al_2O_3 \cdot zH_2O$(amorphous).

It seems that, theoretically, in the very high pH region (about pH 13), only the lithium aluminate exsists. However, the real lithium aluminate complex precipitated contains relatively much aluminium. Aluminium hydroxide seems to be very easily formed. Figure 12 shows the relation of the k value and the lithium to aluminium ratio, $R[=(Li/Al)_{mol}]$. k decreases with an increase in R. Even if the R goes beyond 5, however, the k value does not decrease below about

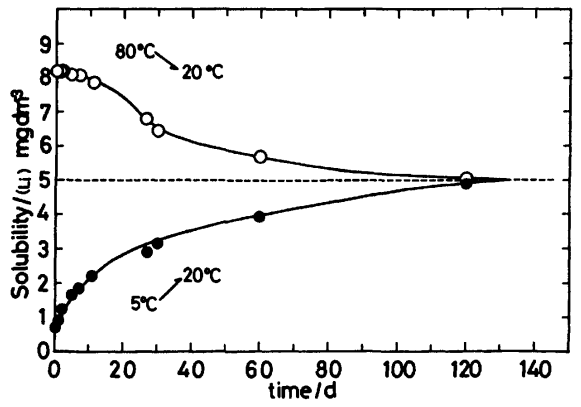

Fig. 13. Solubility of lithium alminate, $LiAlO_2 \cdot yH_2O$, represented by Li concentration (mg dm^{-3}) at 20 °C. —●—: Heated to 80 °C (1 d) and set to 20 °C. —○—: Cooled to 5 °C (1 d) and set to 20 °C.

0.6. From this value, the ratio of $(Li : Al)_{mol} = 1 : 2.2$ is obtained; this value is intermediate between 2.0 and 2.5. To diminish the k values, various conditions were introduced, such as a high pH, a high temperature (90 °C) and low temperature (5 °C) of the solutions, and high and low concentrations of LiCl and Al salts, but the results were all unsatisfactory. The use of solvents such as methanol, ethanol, acetone, and their mixture with water sometimes lowered the k values, but it was difficult to decrease the k to less than the 0.38 in the present work. [By the way, the $LiAlO_2$ listed in the ASTM card on the X-ray diffraction pattern was prepared at room temperature by the hydrolysis of γ-$LiAlO_2$ which is synthesized at a high temperature.[25]]

(2) Adsorption. A $NaAlO_2$ (500—1000 ppm as Al) solution was hydrolyzed to aluminium hydroxide by blowing CO_2 through the solution. Immediately after the $Al(OH)_3$ had been prepared, the Li ion was adsorbed, but the amount of the lithium adsorbed on hydroxide was very small. According to an experimental study by Kitamura *et al.*,[17] the value of 0.36 mg (Li)/g (adsorbent) is obtained under the best conditions. The reason for the difference between their results and ours is not clear, but, as a result of the substle difference in preparation conditions, a partial crystallization of aluminium hydroxide might have occurred in the present work. Kitamura *et al.* reported that amorphous aluminium hydroxide adsorbs much lithium, while crystallized aluminium hydroxides (beyerite, pseud böhmite *etc.*) do not adsorb lithium.

These results show that the success with lithium recovery using the coprecipitation method can not be explained by the adsorp tion only, but can be explained by the formation of a ithium aluminate complex slightly soluble in water. The formation of the lithium aluminate compound was also found in geothermal water after the removal of polymerized silica using much iron(III) hydroxide. That is, after the removal of the silica, Al salt (50—100 ppm as Al) was added to the geothermal water and the compound precipitated was measured by means of an X-ray diffractometer. In the lithium recovery using Al salt, the formation of the lithium aluminate complex is dominant. Therefore, the solubility of the lithium aluminate will be very important. The solubility of the lithium aluminate ($LiAlO_2 + (0.38Al_2O_3)$) obtained in the present study was measured by determining the Li concentration; it is shown in Fig. 13. The figure shows that the solubility of lithium aluminate is 5.0 ppm (as Li) at 20 °C.

Provided the solubility equilibrium of lithium aluminate

$$LiAlO_2 \rightleftarrows Li^+ + AlO_2^-$$

the solubility product is:

$$K_{sp} = [Li^+][AlO_2^-] = 5.2 \times 10^{-7} \text{ (at 20 °C)}.$$

If the detection limit of Li^+ by the atomic-absorption flame method is 0.02—0.05 ppm, the concentration of aluminate ions of 0.072—0.180 M; in other words, an aluminium concentration of 2000—5000 ppm is required to recover the lithium essentially to completion. The same calculation tells us that an Al concentration of about 200 ppm is required to reduce the lithium concentration to 0.5 ppm. However, when a pure LiCl solution ($[Li^+] = 10$ ppm) was used, the Al concentration of 200 ppm was enough to recover the Li completely with the optimum pH and temperature. On the basis of the above results, the following mechanism may be suggested. First, stoichiometrically excess amount of aluminium salt causes the reaction of Li^+ and the aluminate ion (AlO_2^-) to form the lithium aluminate complex, ($LiAlO_2 \cdot yH_2O$). Then, successively or simultaneously the residual Li^+ will be adsorbed by the aluminium hydroxide which is formed by the extra amount of Al salt, although the $Al(OH)_3$ is easily formed even if a stoichiometrical amount of Al salt is used. This simplified two-step mechanism can explain the major part of the lithium recovery by the coprecipitation method. The solubility of $LiAlO_2$ will depend upon the pH, the temperature, and the various kinds of polynuclear aluminium complexes and other kind of salts in solution. Thus, the values cited above may be first approximations.

Influence of Temperature on Li Recovery. It is clear that, when the Li concentration of 10 ppm is used, the formation of the lithium aluminate complex is essential and the solubility may largely depend upon the solution temperature. Geothermal water in the Hatchobaru area has a relatively high temperature (80—90 °C) at the outlet. In view of the effective utilization of the geothermal water, operations at a high temperature will be required. The experimental results on Li recovery at 80 °C are shown in Fig. 14. The figure depicts behavior fairly different from that at room temperature. That is, for all the ref. Li solutions with variously set pH's, minima are found. Within 1 to 6 h, the plot of the residual Li concentration *vs.* the time shows minima, and then shows a linear rise to the Li concentration of 9—10 ppm with the time. This phenomenon might be interpreted as follows. In the first stage, the lithium aluminate complex and aluminium hydroxide which adsorbed Li^+ are precipitated rapidly; then the aluminate dissolves linearly according to the solubility equilibrium and $Al(OH)_3$ releases the

Li^+ ions. Also, in this case, a high temperature seems to accelerate the precipitating speed, as is shown in Fig. 14. When the Li recovery is made at a high temperature, the pH control must be made accurately and a short recovery time is desirable.

Li Recovery Using Geothermal Water. The basic study of Li recovery has revealed several important facts, and now Li can be recovered from geothermal water.

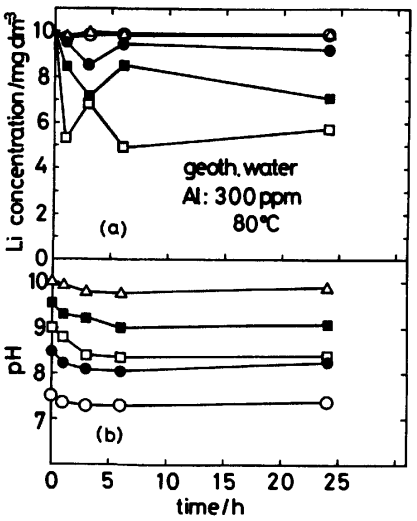

Fig. 16. The plots of residual Li concentration *vs.* time and pH *vs.* time for geothermal water with various kinds of pHs at 80 °C. Al concentration: 300 ppm ($AlCl_3$).

Figure 15 shows the results obtained at room temperature. For geothermal water, even under the best conditions, only a recovery of 80 to 85% was attained; the optimum pH was in the range of 10—10.5. For the ref. Li solution, the percentage of recovery was 100% at the optimum pH (about 13). A relatively large difference in the behavior of Li extraction was found between the ref. Li solution and geothermal water. That is, for geothermal water, the pH dependence on the Li recovery was not large as in the case of the ref. Li solution. Geothermal water seems to have a kind of buffering action. The use of an Al concentration of 500 ppm increased the Li recovery, and the optimum pH region became wider (pH 10—11). Figure 16 shows the experimental results at 80 °C using an Al concentration of 300 ppm. The extent of Li recovery is very low, as had been expected, and the optimum pH is around 9, which is lower than that for geothermal water at room temperature. A comparison of Fig. 16 with Fig. 14 shows that, for the ref. Li solution, a high Li recovery is possible within a few hours. For geothermal water, however, no such rapid recovery of lithium is observed. In the case of the ref. Li solution, the yield of Li becomes small (within 10%) after 24 h. For geothermal water, however, the change in the Li recovery with the time is relatively small. From this fact, it can also be recognized that geothermal water has a buffering action even if the temperature rises. Next, the dependence of the Al concentration by the use of $NaAlO_2$ on the Li recovery was studied; it is shown in Figs. 17 and 18 at room temperature and at 80 °C respectively. The addition of $NaAlO_2$ to geothermal water without pH control was done just as in the case of the ref. Li solution. The yield of Li in this case was not so good as in the case of the ref. Li solution using the Al concentration of 100 ppm. In the case of geothermal water, the recovery of lithium was naught

using the same concentration of aluminium salt. Even if the Al concentrations of 500 and 1000 ppm are used, a complete recovery is not accomplished. Strangely, the residual lithium concentration changed in a zig-zag fashion with the passage of time for the Al concentration of 1000 ppm. The results at 80 °C for Al concentrations of 300, 500, and 1000 ppm are similar to those at room temperature, although for Al concentrations of 100, or 200 ppm, practically no Li is recovered. The reasons for this are not clear. One reason may be that geothermal water contains various kinds of salts. The most probable constituents which function negatively are high-concentration sodium chloride, polymeric silicic acid, and calcium ions. The addition of much NaCl (10^4—3×10^4 ppm) to a ref. Li solution did not change the effect on the Li recovery. The polymerization of silicic acid and silicate in geothermal water is accelerated by the addition of alkali, and the particle sizes of the colloidal silica are increased. Colloidal and suspended silica in geothermal water was examined by

the molybdenum yellow method in connection with the percentage of the recovery of silica *vs.* the pH. The results are shown in Fig. 19. As is shown in this figure, a greater part of the silica in geothermal water is recovered at pH 10 or above. A perfect recovery of silica from geothermal water is accomplished by the addition of $FeCl_3$ ($[Fe^{3+}]=1000$ ppm), with the pH controlled at 10.5. The influence of silica in geothermal water was examined at room temperature and at 80 °C; the results are shown in Fig. 20. The results show that polymeric silica affects the Li recovery, but to a small extent. The influence of the calcium ions was then examined. The calcium ions (about 20 ppm) in the geothermal were eliminated in the form of calcium oxalate. The results are shown in Fig. 21. A comparison of Fig. 21 with Fig. 15 (with Ca^{2+}) shows that the Li recovery rises remarkably and that the short-time percent-recovery is relatively high in the case of calcium-free geothermal water. Experiments were also made for ref. Li solutions to which calcium chloride had been added so that the Ca concentrations were 70 and 400 ppm respectively. The effects of calcium ions are prominent, as is shown in Fig. 22.

It may be concluded, from the results obtained, that geothermal water has a kind of buffering action and that the buffer capacity may be attributed mainly to the polymeric silicic acid and/or silicate ions. The existence of polymeric silica and calcium ions leads to remarkably negative effects on the recovery of lithium from geothermal water at the Hatchobaru bores. The mechanism of lithium recovery by the coprecipitation method can be explained by the formation of lithium aluminate complex, followed by the adsorption of residual lithium by the aluminium hydroxide (amorphous) coprecipitated.

Glass-like Carbon Made from Epoxy Resin Cured with 2,4,6-Trinitrophenol

Kazuro KAWAMURA* and Shiushichi KIMURA†

Department of Chemistry, National Defense Academy, 1-10-20, Hashirimizu, Yokosuka 239

†*Research Laboratory of Engineering Materials, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 237*

(Received July 24, 1982)

It has been found that a glass-like carbon can be produced by the slow and carefully controlled pyrolysis of the epoxy resin (Epikote 828) cured with 2,4,6-trinitrophenol (TNP) with a weight of 10—15%. The most characteristic property of the glass-like carbon was seen in its change in density with the heat-treatment temperature. Under heat treatment at temperatures up to 1000 °C, a dense glass-like carbon of which density was 1.65—1.70 g/cm^3 was formed. The density of the glass-like carbon decreased, however, at heat-treatment temperatures above 1000 °C. Upon heat treatment at the temperature of 3000 °C, the density dropped to a low value of 1.04—1.11 g/cm^3. The former increase in density is connected with the large-scale dehydration reaction which may proceed between nitro groups and hydrocarbon chains in the cure resin. The latter decrease in density is caused by the progress of the graphitic orientation of carbon-layer planes in the cross-linked structure of the highest degree. If carbon fibers were present in this glass-like carbon, the graphitization of the glass-like carbon in the composite proceeded more easily than that of the glass-like carbon alone.

In general, there is a 40—50% loss in weight when carbon-rich materials are carbonized under atmospheric pressure, for pores or cracks then develop in the carbonized product as a result of the release of volatile matter and the shrinkage in volume. It is well known that some thermosetting polymer resins are converted into carbonized products resembling glass in appearance and in fractural property. The glass-like carbon is characterized by a low density, a very low gas permeability, and an isotropic disordered structure.[1-6] Phenol–formaldehyde resin and furfuryl alcohol resin are suitable as starting materials to obtain glass-like carbon in a good yield.

We have previously reported that 2,4,6-trinitrophenol (TNP) can be used as the curing agent of the liquid expoxy resin, Epikote 828. Moreover, the explanation of the curing mechanism and some applications of this cure system have been attempted.[7,8] It is a good example of the applications that the pre-heated cure resin at 150 °C turned to the glass-like carbon upon slow and carefully controlled pyrolysis. If the common curing agents such as aliphatic polyamines were used instead of TNP for the epoxy resin, the cure resin could not maintain its original shape during carbonization. In this glass-like carbon there can be seen some characteristic behavior in the process of carbonization and graphitization. In the present paper this behavior is examined by means of thermogravimetric analysis, the measurement of the density, a microindentation hardness test, an X-ray diffraction study, and optical observation, and the behavior is compared with that of the usual glass-like carbons made from phenol-formaldehyde resin and furfuryl alcohol resin. Moreover, the graphitization of the glass-like carbon containing carbon fibers is examined.

Experimental

The epoxy resin was Epikote 828 (Shell Chemical Co., diglycidyl ether of bisphenol A). The TNP used here was of a commercially guaranteed reagent grade and was dried after grinding. As furfuryl alcohol resins, Hitafuran 302 (Hitachi Kasei Co.) and its curing agent, A_3 (the same company) were used. The phenol–formaldehyde resin was of a resol type, which scarcely needed the curing agent. The carbon fibers of PAN-based Torayca T300 were chosen.

A sample containing carbon fibers was prepared in the following manner: the carbon fibers aligned in the same direction were stacked in the vessel, and then the resin was poured upon them and cured at 130 °C in air. After curing, the composite was cut in small pieces (about $10\times10\times20$ mm) by means of a diamond cutter. On the basis of a photographical survey, the carbon-fiber content in the composite was found to be in the range of 30—42% in volume.

The heat treatment was accomplished at a rate of 30 °C/h up to 500 °C, and thereafter at a rate of 120 °C/h to 1000 °C in a stream of argon. The heat treatment at temperatures from 1500 to 3000 °C was carried out in a graphite-resistance furnace in a stream of argon. Each heat treatment was achieved at a rate of 256 °C/h, after which the maximum temperature was held for 30 min.

The thermogravimetric analysis of the samples (a 100-mg portion of each sample was placed in a platinum cup) was run by heating at a rate of 2 °C/min in an argon atmosphere by using the electronbalance (Cahn 1000).

To obtain a clear indent with the Vickers hardness tester (Shimadzu Seisakusho Ltd.), the surfaces of the carbonized samples were polished as plane mirrors. The indents were marked by means of a Vickers diamond for 30 s under a load of 1000 g.

The X-ray diffraction profile of (002) line on the powdered sample was obtained with Ni-filtered Cu *Ka* radiation. The interlayer spacing, d_{002}, and the crystallite thickness, L_c, were estimated from profiles in which the corrections of the Lorentz-polarization, atomic-scattering, and absorption factors were made in a usual way.[9] The profile of the composite made from cure resin containing carbon fibers was separated into the component profiles of the matrix carbon and the fiber carbon. The separation was made as follows: the profile of fiber carbon was obtained at an individual temperature. We assumed that the profile of fiber carbon agreed with the fiber-carbon component in the composite profile at the individual temperature. The composite profile could be separated into its component profiles based on the fiber-carbon component.

Results

Carbonization. It is most proper to use 10—15%

a) Carbonized to 1000 °C. b) Densities of finely ground samples were measured by the immersion method in 1-butanol using a pycnometer at 20 °C.

of TNP as a curing agent for the epoxy resin. The polymerization reaction of the system was dependent on the curing temperature, as has been reported previously.[7] Under the curing condition at 130 °C in air, at first a linear structure was formed, and then it was converted into a cross-linked one. The system containing 10% TNP was converted from the linear structure into the cross-linked one at 130 °C after 24 h. The converting time for the system containing 15% TNP became short (about 3 h). When carbonized at a heating rate of 30 °C/h in a stream of argon, the resin cured at 130 °C was burned with smoke by means of the rapid exothermic pyrolysis of nitro groups in the cure resin, and a porous carbonized product was formed. When the resin cured at 130 °C for 48 h in air was carefully heated at 150 °C in steps and then maintained at this temperature for about 48 h, its colour changed from yellow-orange to brown-black. When the cure resin preheated at 150 °C was heated at a rate of 30 °C/h in a stream of argon, it was gradually pyrolyzed, while keeping its shape, and was converted into a nonporous carbonized product considered to a glass-like carbon. This appearance is shown in Fig. 1. There are some cracks in the glass-like carbon, as denoted by the arrow.

The curing condition of the resins used and some properties of the glass-like carbons obtained from the cure resins heat-treated at 1000 °C are given in Table 1.

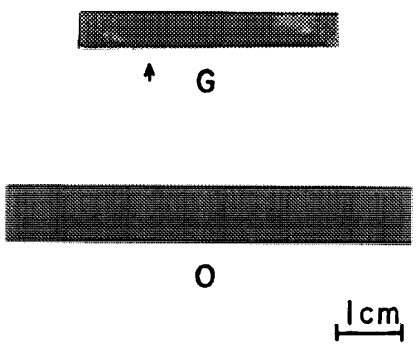

Fig. 1. Appearance of glass-like carbon made from epoxy resin cured with 10% of TNP.
O: Original resin heat-treated at 150 °C. G: Glass-like carbon obtained by heat treatment at 1000 °C.

It is worth noting that the density and the hardness of the glass-like carbon made from the epoxy resin cured with TNP are high, though its yield is low and the shrinkage in volume is larger than those of phenol–formaldehyde resin and furfuryl alcohol resin.

The pyrolysis of the epoxy resin cured with TNP was compared with that of samples heat-treated at 130 and 150 °C. The weight loss with the temperature is shown in Fig. 2. On the sample treated at 130 °C (Fig. 2, Curve 3) a rapid loss appeared at 215 °C, while on the other one, no corresponding loss could be seen (Fig. 2, Curve 4). This fact showed the difference in the appearance of the carbonized products; the former product was porous, and the latter, glass-like.

Change in Density with Heat-treatment Temperature. The changes in density on the glass-like carbons heat-treated at various temperatures up to 3000 °C are shown in Fig. 3. The density of the glass-like carbon made from the epoxy resin cured with TNP decreases as the heat-treatment temperature rises (Fig. 3, Curves 1 and 2). Although the decrease in density introduced by heat-treating glass-like carbons has previously been reported by Honda *et al.*[10] and Bose *et al.*,[11] no such large

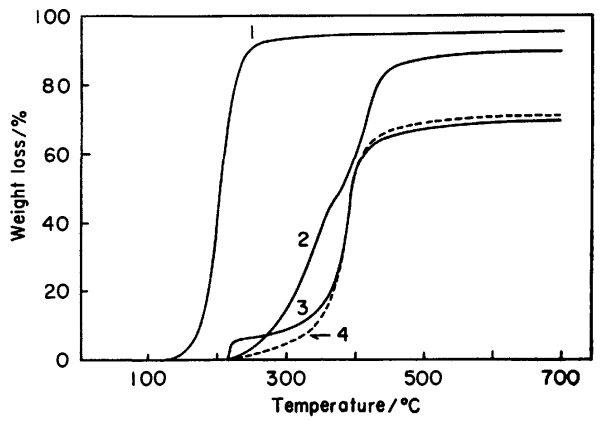

Fig. 2. Thermogravimetric analyses of TNP, epoxy resin and epoxy resin cured with 10% of TNP.

decrease in density as that here obtained has been known. When the glass-like carbon was made from the epoxy resin cured with 10% TNP in the heat-treatment temperature range from 1000 to 3000 °C, its density dropped from 1.65 g/cm³ to 1.11 g/cm³. On the other hand, when the glass-like carbon made from the epoxy resin was cured with 15% TNP, the density fell from 1.70 to 1.04 g/cm³. The differences in the densities of these samples are equivalent to 34 and 70% increases in the volume respectively. The change in volume is calculated by this equation; $(V_1-V_2)/V_1\times 100$, where V_1 and V_2 show the volume of the glass-like carbons heat-treated at 1000 and 3000 °C. No remarkable decrease in the density with an increase in the heat-treatment temperature can be seen on the glass-like carbons from phenol–formaldehyde resin and furfuryl alcohol resin (Fig. 3, Curves 3 and 4). They are almost constant with the heat-treatment

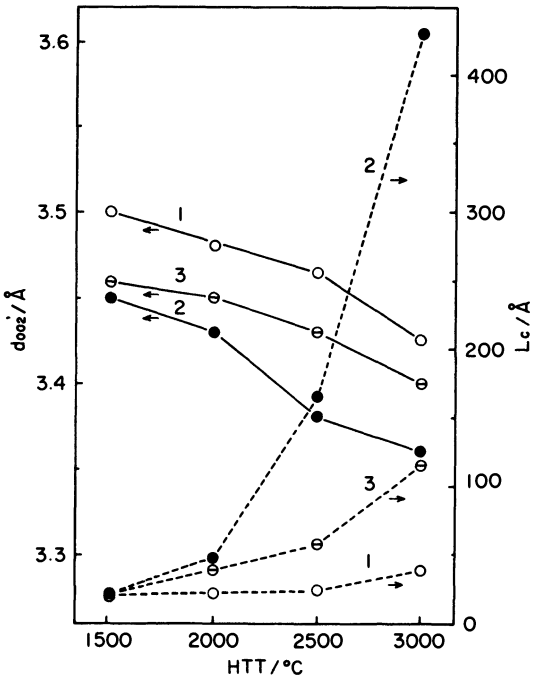

Fig. 5. Changes of interlayer spacing d_{002} and crystallite size L_c with heat-treatment temperature (HTT).

temperature. The change in the density of Curve 2 is larger than that of Curve 1. This shows that the large decreases in density is caused by the TNP which is used as the curing agent of the original resin.

Microindentation Hardness. Figures 4(a) and (b) show the imprints of the glass-like carbon heat-treated at 1000 and 3000 °C respectively. These photographs indicate that the imprint changes from a diagonal to a concave pattern as the heat-treatment temperature increases. This change can also be seen in the glass-like carbons made from phenol-formaldehyde resin and furfuryl alcohol resin in spite of the small change in the density, as is shown in Fig. 3, Curves 3 and 4. The concave imprint may show that the hardness of the glass-like carbon is remarkably lowered.

X-Ray Diffraction. The volume of the epoxy resin cured with TNP decreased extremely in the process of carbonization and increased largely on heat-treating above 1000 °C. If carbon fibers are contained in this cure resin, the graphitization of the matrix carbon of the composite may be influenced. This phenomenon is of interest in connection with the stress graphitization of glass-like carbon,[12-17] because the effect of a large change in the volume of the matrix carbon on the process of carbonization and graphitization has not yet been examined.

Figure 5 shows the changes in the values of d_{002} and L_c on the glass-like carbon made from the epoxy resin cured with TNP (Fig. 5, Curve 1), on the matrix carbon in the composite (Fig. 5, Curve 2), and on the fiber carbon (Fig. 5, Curve 3) heat-treated at 1500—3000 °C. Above 2000 °C, the glass-like carbon is more difficult

to graphitize than the carbon fibers. The graphitization of the matrix carbon in the composite proceeded greatly in comparison with that of the glass-like carbon only, regardless of the large increase in volume above 1000 °C.

Microscopic Observations. Micrographs of the composite made from the carbon fibers and the epoxy resin–TNP mixture are shown in Fig. 6. The matrix precursor before being carbonized had an isotropic structure (Fig. 6(a)). After heat-treatment at 1000 °C, anisotropic areas appeared in the matrix carbon around the carbon fibers and then spread out in the matrix (Fig. 6(b)). The area decreased somewhat after heat treatment at 2500 °C (Fig. 6(c)). This phenomenon is caused by the increase in the volume of the matrix carbon, which takes place upon heat treatment above 1000 °C. However, the development of a graphite-like structure was clearly recognized in the anisotropic region in the matrix, as is denoted by arrows. The carbon fibers were extremely deformed after heat treatment at 3000 °C (Figs. 6(d) and 7(b)-B). When the carbon fiber separates from the matrix carbon on heating, the shape of the carbon fiber is deformed a little (Fig. 7(b)-A). The micrograph of the cross-section parallel to the fiber axis in the composite heat-treated at 3000 °C (Fig. 7(a)) shows that the graphite-like layers are not simply aligned parallel to the fiber axis, but are zigzagged.

Discussion

Generally polynitro compounds are easily decomposed by heating, so it is difficult to keep the pyrolysis under control. This property does not change if they are present in cure resins.[18,19] The epoxy resin cured with 10—15% of TNP also has the property of rapidly decomposing upon heating. When the cure resin was preheated at 150 °C in air, however, the pyrolysis went on gently. It is considered that this gentle pyrolysis is brought about by the building of a highly cross-linked structure in company with the structural change in the nitro groups in the cure resin. The improvement of cross-linking formed by preheat treatment at 150 °C is proved by the insolubility in acetone. The resin cured with 10% of TNP and heat-treated at 130 °C for 48 h contained an insoluble part amounting to 70—80%. After heat treatment at 150 °C, the insoluble part increased to above 99% by weight.

Yamada, from the analytical results on gases evolved by the pyrolysis of a mixture of pitch and a nitro compound, found that the gases volatilized up to 500 °C were almost entirely occupied by water.[20] The formation of water in the present sample was suggested by the fact that the quartz window of the furnace used for carbonization was clouded by water drops at an early stage of the pyrolysis. A large-scale dehydration reaction during carbonization may lead to the formation of the highest degree of cross-linking in the structure.

The decrease in density above the heat-treatment temperature of 1000 °C can be interpreted in terms of the development of micropores and/or spaces caused by thermal swelling and structural change in the glass-like carbon. The thermal swelling may be brought by a relaxation of the rigid structure formed through the carbonization. It may be instructive to consider that nitro groups in the cured resin play an important role in pulling the carbon networks through the dehydration reaction. As a result, a rigid structure is established after carbonization. When the glass-like carbon in this state is heated at a temperature above 1000 °C, a partial bond-breaking may take place at the unstable positions of carbon networks in the glass-like carbon. The bond-breaking results in an expansion in volume. On the other hand, the structural change arises from the graphitic orientation of the carbon-layer planes in the glass-like carbon, as is shown in Fig. 5. When the values of density are plotted against those of the interlayer spacing, d_{002} (Figs. 3 and 5), along with the heat-treatment temperatures, a linear relationship is seen, as is indicated in Fig. 8. This relationship suggests that the spread of micropores and/or spaces originate in a narrowing of the interlayer spacing. This suggestion would mean that small-waved and entangled carbon-layer planes in the glass-like carbon are oriented straightly, accompanied by a combination of the carbon-

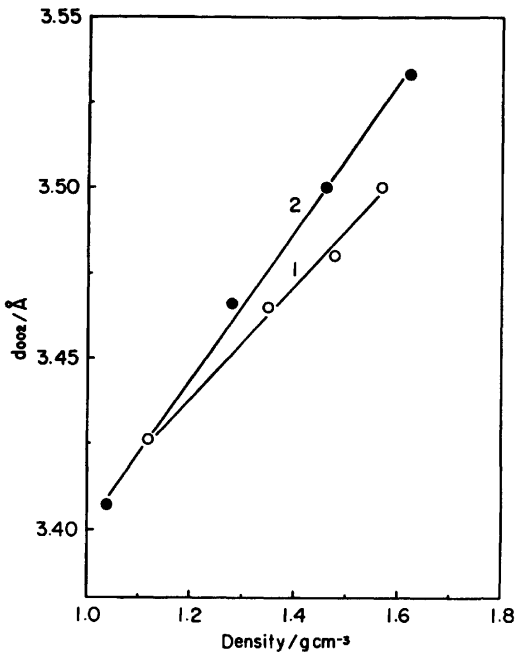

Fig. 8. Relation between interlayer spacing d_{002} and density.
1. Glass-like carbon made from epoxy resin cured with 10% of TNP. 2. Glass-like carbon made from epoxy resin cured with 15% of TNP.

layer planes, and that they jostle each other as the graphitization proceeds. The combination of carbon-layer planes and the complicated jostling may bring about the expansion in the volume of the glass-like carbon following the spread of micropores and/or spaces.

If the carbon fibers are contained in the glass-like carbon, its volumetric change will be suppressed to some degree by the stiffness of the carbon fibers. The carbon fibers in the matrix did not appear to be deformed during the carbonization (Fig. 6(b)). The expansion in volume of the matrix carbon which was caused by the high heat-treatment brought about the deformation of the carbon fibers (Figs. 6(d) and 7(b)-B). From the point of view of the stress graphitization of the matrix carbon in the carbon fiber–glassy carbon composite, the orientation of molecules (carbon-layer planes) of the matrix carbon formed in the process of carbonization is little influenced, even if a large volumetric expansion takes place in the matrix carbon of the composite after carbonization. Inagaki *et al.* have proved that the stress accumulation caused by shrinkage in the process of carbonization plays a significant role in the graphitization of matrix carbon in the carbon fiber-glassy carbon composite.[17] Our results also support their finding.

Decomposition of Hydrogen Bromide or Iodide by Gas Phase Electrolysis

Wakichi KONDO,* Susumu MIZUTA, Yoshinao OOSAWA, Toshiya KUMAGAI, and Kinjiro FUJII
Energy Chemistry Division, National Chemical Laboratory for Industry, Tsukuba Research Center, Yatabe, Ibaraki, 305
(Received December 10, 1982)

Gas phase electrolysis of HBr or HI was studied by using a fuel-cell-type electrolyzer provided with graphite gas diffusion electrodes and liquid film electrolyte of H_3PO_4. Current efficiency 100% may be achieved at decomposition voltages of 0.73 V (at 100 mA cm^{-2} and 150 °C) for HBr and 0.28 V (at 100 mA cm^{-2} and 145 °C) for HI. Both bromine and iodine produced may smoothly be evolved out of the anode in the gas or liquid form without being dissolved into the electrolyte H_3PO_4, causing no trouble on the separation of products. This electrolytic method may be incorporated in the bromine or iodine cycles for thermochemical hydrogen production to constitute an effective hybrid system.

The hydrogen production by a thermochemical cycle was extensively studied in 1970's. On the other hand, the hybrid system consisting of thermochemical and electrochemical processes began to be investigated when the pure thermochemical system was concluded to be extremely difficult. For the bromine and the iodine cycles,[1-6] much effort has been concentrated on the electrochemical decomposition of hydrogen bromide and iodide[4-12] since the decomposition of hydrogen halides was found to play a vital role in the cycle.

Below are listed some thermochemical values[13] associated with the decomposition of HBr and HI:

$$2HBr(g) \longrightarrow H_2(g) + Br_2(g) \quad (1)$$
$$\Delta H^\circ_{298} = 24.8 \text{ kcal mol}^{-1} \text{ (1 cal} = 4.184 \text{ J)}$$
$$\Delta S^\circ_{298} = -5.2 \text{ cal mol}^{-1} \text{ K}^{-1}$$
$$\Delta G^\circ_{298} = 26.2 \text{ kcal mol}^{-1}$$
$$\Delta G^\circ_{700} = 28.0 \text{ kcal mol}^{-1},$$
$$2HI(g) \longrightarrow H_2(g) + I_2(g) \quad (2)$$
$$\Delta H^\circ_{298} = 2.3 \text{ kcal mol}^{-1}$$
$$\Delta S^\circ_{298} = -5.3 \text{ cal mol}^{-1} \text{ K}^{-1}$$
$$\Delta G^\circ_{298} = 3.9 \text{ kcal mol}^{-1}$$
$$\Delta G^\circ_{700} = 5.6 \text{ kcal mol}^{-1}.$$

From these values one can easily understand that the thermochemical decomposition of HBr is fairly difficult[6,14,15] because of its too high a ΔG° (over 25 kcal mol^{-1}). The electrochemical decomposition of HBr in the aqueous state has extensively been studied by several investigators; according to Schuetz,[5] an HBr electrolysis, using graphite electrodes, at a cell voltage of 0.75—0.8 V and a current density of 200 mA cm^{-2} proceeds with a highly concentrated (47 wt%) HBr aqueous solution at 353—373 K and atmospheric pressure.

On the other hand, the decomposition of HI seems at first sight much easier because of its low ΔG° (5.6 kcal mol^{-1} at 700 K), but has been found more troublesome than expected since the mixed gas (H_2, I_2, HI, and H_2O) formed by direct pyrolysis requires a severe separation processing; some separation processes have been proposed[16-20] but their improvement is still required. As for the HI electrolysis no reports with detailed experimental descriptions have been published to the best of the present authors' knowledge.

The present authors have noted that the gas phase electrolysis is superior to the aqueous electrolysis in the following three respects:

1) As shown in Table 1, the theoretical decomposition voltages for the HX gases (0.58 V for HBr and 0.065 V for HI) are by far lower than those (1.08 and 0.54 V, respectively) for the aqueous HX. This is because the HX molecule in the gas phase is at a higher energy level than the one in the aqueous state ($a=1$) by the amount of free energy of hydration. For aqueous electrolyses at sufficiently low cell voltages (*e.g.*, 0.6—0.8 V for HBr) are to be achieved, an extremely concentrated HX solution is required as previously reported.[8,9,12]

2) In the case of aqueous electrolysis, it is necessary to separate product X_2 from HX solution because Br_2 or I_2 immediately dissolves into aqueous HBr or HI solution by forming polyions such as Br_3^-, Br_5^-, I_3^-, and I_5^-. Such a separation process for the aqueous products is regarded as a great burden on the whole cycle from both the viewpoints of the circulation of materials along the cycle and the suppression of excessive overvoltage. On the other hand, the gas phase electrolysis has a possibility to be provided with some proper electrolyte in which Br_2 or I_2 is insoluble.

3) In the case of actual thermochemical cycles where HBr or HI is produced mostly in the gas phase, the direct participation of HX in electrolysis with no condensation

TABLE 1. FREE ENERGY CHANGES AND THEORETICAL DECOMPOSITION VOLTAGES FOR THE DECOMPOSITION OF HBr AND HI

Reaction	Temp / K	ΔG° / kcal mol^{-1}	E° / V
$2HBr(aq\ a=1) \longrightarrow H_2(g)+Br_2(l)$	298	49.7	1.08
$2HBr(g) \longrightarrow H_2(g)+Br_2(g)$	400	26.8	0.58
$2HI(aq\ a=1) \longrightarrow H_2(g)+I_2(c)$	298	24.7	0.54
$2HI(g) \longrightarrow H_2(g)+I_2(l)$	400	3.0	0.065

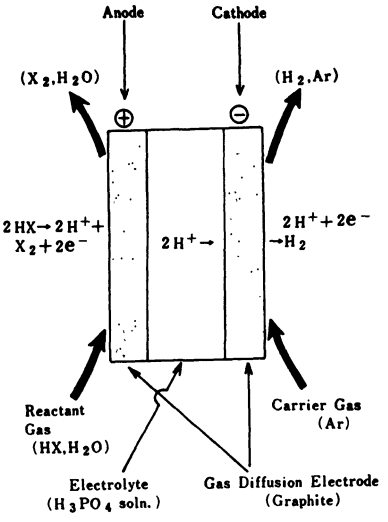

Fig. 1. Principle of the gas phase electrolysis for HX.

process is efficient and favorable.

In view of the above advantages a new process of gas phase electrolysis for hydrogen bromide or iodide has been devised and experimentally studied which makes use of a fuel-cell-type electrolyzer with electrolyte H_3PO_4 and graphite gas-diffusion electrodes.

Principle

The principle of this method is illustrated in Fig. 1. When reactant gas HX (=HBr or HI) containing some amount of water vapor is supplied into the gas diffusion type anode, the following electrochemical reaction takes place at contact points among the three phases of gas, electrolyte, and electrode:

$$2HX \longrightarrow 2H^+ + X_2 + 2e^-. \quad (3)$$

Product X_2 (=Br_2 or I_2) hardly dissolves into the electrolyte H_3PO_4 because of its intrinsic, extremely low solubility and is released from the anode in the gas or liquid form, whereas the H^+ migrates through the electrolyte to be reduced at the cathode according to the following reaction and removed by a carrier gas of Ar:

$$2H^+ + 2e^- \longrightarrow H_2. \quad (4)$$

These electrochemical processes require no cation exchanger membranes since the dissolution of HBr or HI gas into H_3PO_4 and their subsequent diffusion toward the cathode are negligible; the electrolyte H_3PO_4 is taken to serve as an ion separator.

The water vapor contained in the reactant gas does not interfere with the electrochemical reactions but has a favorable effect for the suppression of water evaporation from the electrolyte H_3PO_4.

Experimental

The fuel-cell-type electrolyzer used is illustrated in Fig. 2. The cell consists of the following parts: two stainless steel flanges of 140×120×5 t mm; two graphite holders of 95×110×22 t mm, each of which is provided with 26 ditches of 2×50×1 d mm to allow the reaction gas to pass from the inlet to outlet and with a lead terminal made of tantalum;

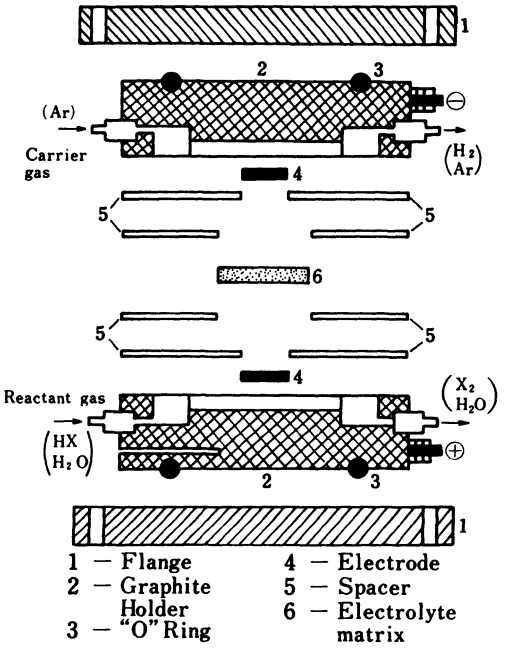

Fig. 2. Fuel-cell-type electrolyzer for HX gas.

two gas-diffusion-type graphite-cloth electrodes of 18×45×0.5 t mm, on both of which platinum was loaded by impregnation of hexachloroplatinic(IV) acid followed by H_2 reduction; four PTFE spacers 0.3—0.5 mm thick; an electrolyte-bearing matrix of 35×55×0.5 t mm, made of tantalum(V) oxide cloth with a porosity of *ca.* 90%. No trouble was experienced throughout the experiment up to temperatures as high as 170 °C. The electric resistance of the cell was about 0.12± 0.02 Ω for 85% H_3PO_4 electrolyte.

A reactant gas, prepared by mixing a commercially available anhydrous cylinder HBr or HI gas (Matheson, purity >99%) and a vaporized hydrobromic acid (aqueous HBr, 47.5 wt%) or hydriodic acid (aqueous HI, 57 wt%), respectively, was introduced into the anode side at a rate of 250 cm^3 min^{-1}. An argon carrier gas was supplied into the cathode side at a rate of about 80 cm^3 min^{-1}. The current efficiency was calculated on the basis of the hydrogen concentration in the argon as determined by gas chromatography.

To examine qualitatively the dissolution of bromine or iodine into phosphoric acid, a mixture of bromine or iodine with 85 wt% H_3PO_4 solution was heated to 150 °C, and subjected to a visual check for coloration; such a slight color change was observed that we might regard the dissolution as negligible.

Results and Discussion

Gas Phase Electrolysis for Hydrogen Bromide. The following four findings have been derived from the current-voltage results in Fig. 3 and the current efficiency results in Table 2.

(i) Current efficiency 100% is always obtained at electrolysis temperatures above 150 °C, in contrast to 75—95% at 118 °C (see Table 2). This low current efficiency at a lower temperature is possibly due to dissolution of bromine into the electrolyte H_3PO_4 followed by diffusion to the cathode. It is evident that there is no problem with respect to current efficiency above 150 °C (compare runs 1, 3, 7, and 8 with runs

a) Extrapolated.

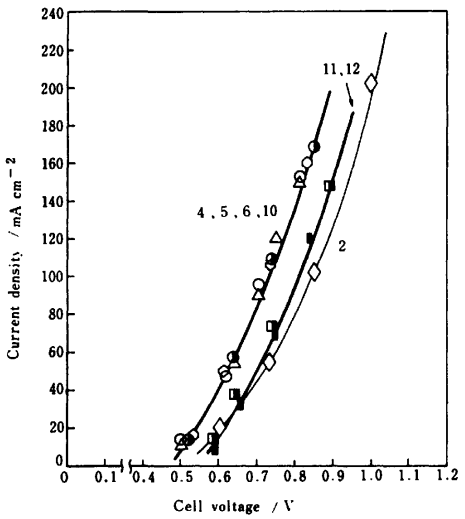

Fig. 3. Current-voltage Curves for HBr gas electrolysis.

5, 6, 10, 11, and 12).

(ii) When the reactant gas composition and the electrolysis temperature are kept $HBr/H_2O/Br_2/N_2$= 0.45/0.45/0/0.1 and 135 °C, respectively, the decomposition voltage at a current density of 100 mA cm^{-2} lowers (0.84→0.73 V) with increasing amount of the Pt catalyst loaded on the graphite electrodes (0.75→5.3 mg-Pt cm^{-2}) (compare run 2 with run 4).

Decomposition voltage 0.73 V obtained in runs 4, 5, and 6 may be considered to be low enough to be comparable with the values 0.75—0.8 V (at 200 mA cm^{-2} and 80—100 °C with 47.5 wt% HBr soln.) reported by Schuetz.[5]

(iii) When the amount of catalyst and the electrolysis temperature are kept 5.3 mg-Pt cm^{-2} and 150 °C, the decomposition voltage rises (0.73→0.80 V) with decrease in the HBr partial pressure P_{HBr} (0.78→0.2 atm) (see runs 5, 10, and 11).

(iv) Inclusion of bromine in the reactant gas decreases the current efficiency at 118 and 135 °C (runs 7, 8, and 9), and at 150 °C it causes no change in current efficiency from 100% and increases the decomposition voltage a little (0.80→0.81 V) (runs 11 and 12).

Gas Phase Electrolysis for Hydrogen Iodide. The following four findings have been derived similarly to the case of hydrogen bromide, from the current-voltage results in Figs. 4 and 5 and the current efficiency results in Table 3.

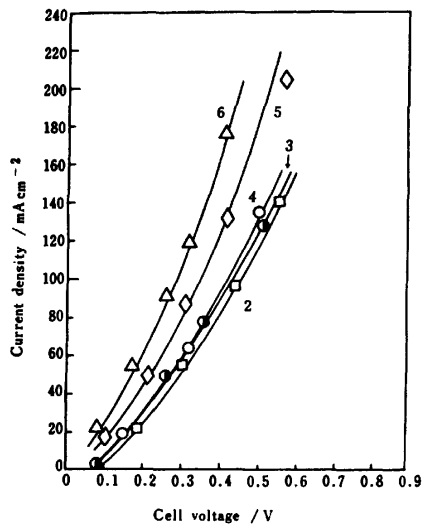

Fig. 4. Current-voltage curves for HI gas electrolysis with reactant gas constituent ($HI/H_2O/I_2/N_2$=0.45/0.45/0/0.10).

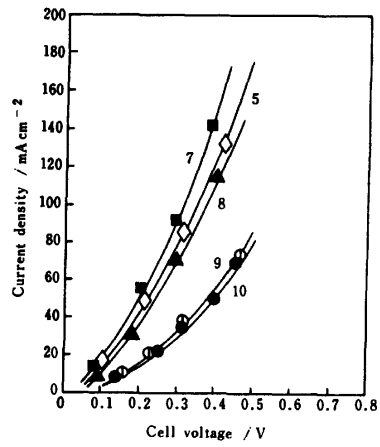

Fig. 5. Current-voltage curves for HI gas electrolysis with amount of catalyst 3.5 mg Pt/cm².

(i) Current efficiency 100% is successfully obtainable except at 118 °C (Table 3). The current efficiency drop at 118 °C is attributable to the dissolution of iodine into the electrolyte H_3PO_4 followed by the diffusion to the cathode. Above 135 °C, however, there is no trouble with the magnitude of current efficiency (compare run 1 with runs 2, 3, and 4).

(ii) When the reactant gas composition and the electrolysis temperature are kept $HI/H_2O/I_2/N_2$= 0.45/0.45/0/0.10 and 145 °C, respectively, the decomposition voltage at a current density of 100 mA cm^{-2} lowers (0.43→0.35→0.28 V) with increasing amount of the Pt catalyst loaded on the graphite electrodes (0.75→3.5→5.3 mg cm^{-2}) (see runs 3, 5, and 6).

Decomposition voltage 0.28 V obtained in run 6 may be regarded practically as sufficiently low.

(iii) When the amount of catalyst and the electrolysis temperature are fixed at 3.5 mg-Pt cm^{-2} and 145 °C, respectively, the decomposition voltage lowers (0.35→ 0.315 V) with increasing HI partial pressure P_{HI} (0.45→0.66 atm) (see runs 5 and 7). A similar lowering occurs at 155 °C (see runs 4 and 9). However, in the case of extremely low H_2O partial pressures (P_{H_2O}) such as 0.06 atm as in run 8, the decomposition voltage even rises up to 0.37 V in spite of the high P_{HI} (0.86 atm). Thus, some amount of P_{H_2O}, together with high P_{HI}, is supposed to be important for the electrochemical reaction at the anode.

(iv) Inclusion of I_2 in the reactant gas does not interfere with the electrolysis or the separation of products, although it causes the decomposition voltage to increase a little (0.54→0.57 V) (see runs 9 and 10).

No change in H_3PO_4 concentration was observed throughout the experiments and a negligible evaporation of water was observed from the cathode. No adhesion of liquid I_2 onto the anode causing an increase in overvoltage was found.

Summary. The findings described above lead us to conclude that the present gas phase electrolysis can be operated with 100% in current efficiency at a favorable decomposition voltage as low as that in the conventional electrolyses, if the electrolysis temperature, electrode catalyst, P_{HX}, and P_{H_2O} are suitably selected; for example, operating voltages available are 0.73 V at 100 mA cm^{-2}, 150 °C, 5.3 mg-Pt cm^{-2}, and 0.45 atm for HBr and 0.28 V at 100 mA cm^{-2}, 145 °C, 5.3 mg-Pt cm^{-2}, and 0.45 atm for HI.

An important advantage of the present method is the immediate separation of products Br_2 and I_2 from the electrolyte, which enables a long-term operation to run with a steady condition.

The authors would like to express their gratitude to Messrs. Kyo Fuchida, Chiaki Kawamura, and Hiroshi Yufu of Yuasa Battery Co., Ltd. for their cooperation in making the fuel-cell-type electrolyzer.

Thermal Studies of Nickel(II) Hydrazine Complexes in Solid State†

Bijoy BANERJEE, Prasanta Kumar BISWAS, and Nirmalendu RAY CHAUDHURI*
Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta 700032, India
(Received July 13, 1982)

Two bis(hydrazine)nickel(II) fluoro complexes of the type $[NiL_2F_2]\cdot H_2O$, where $L=NH_2NH_2$ have been synthesized. Besides these, $[NiL_{2.5}(H_2O)_2]F_2\cdot 0.5H_2O$ and $[NiL_{2.5}F_2]\cdot 2H_2O$ have also been synthesized. Thermal investigations of these complexes have been carried out. Four tris(hydrazine)nickel(II) chloride and four tris-(hydrazine)nickel(II) bromide complexes have been prepared and their thermal investigations have been done. Two bis(hydrazine) thiocyanato complexes have also been prepared and their thermal studies have also been carried out. These nickel(II) hydrazine complexes have been found to decompose through several complex species as intermediates. All these intermediates as well as the parent complexes have been characterized by elemental analyses, color, magnetic moment, electronic spectra (mull), and IR spectra. X-Ray powder diffraction pattern of two tris(hydrazine)nickel(II) bromide complexes have been obtained. The probable mechanistic paths for each step of decomposition have been proposed.

The formation of many inorganic compounds is generally dependent upon the conditions employed. Slight alteration in a described procedure sometimes results in an apparently identical but rather different compounds. This type of difference exhibited in the apparently similar compounds is very difficult to detect unless we characterize the compounds with X-ray crystal structure determinations. On the other hand, identification by thermal techniques may differentiate the compounds qualitatively. With this idea we have synthesized several hydrazine complexes of NiX_2, where $X=F^-$, Cl^-, Br^-, or SCN^-, considering the versatile character of hydrazine as complexing ligand[1-4] and tried to utilize the thermal techniques in differentiating apparently similar type of compounds. We wish to report the thermal investigation of hydrazine complexes of nickel(II) salts.

Experimental

Preparation of Nickel(II) Hydrazine Complexes. $[NiL_2F_2]\cdot H_2O$ $(L=NH_2NH_2)$ ***(1)***: 2 mmol†† of hydrazine hydrate (80%) was added to the 1 mmol of green hydrated nickel(II) fluoride crystals. While stirring the green crystals turned bluish pink crystals **1**. The crystals were filtered, washed thoroughly with ethanol–water mixture (1 : 1) and finally with dry ethanol.

$[NiL_2F_2]\cdot H_2O$ ***(2)***: Hydrazine hydrate (2 mmol) was added dropwise with constant stirring to the concentrated ammoniacal solution of nickel(II) fluoride crystals. Fine bluish pink shining crystals **2** separated out slowly from the solution. These shining crystals were collected and washed as mentioned in the preparation of complex **1**.

$[NiL_{2.5}(H_2O)_2]F_2\cdot 0.5H_2O$ ***(3)***: This compound was synthesized following the method adopted for the preparation of complex **1**. Here aqueous solution of nickel(II) fluoride was used instead of crystals.

$[NiL_{2.5}F_2]\cdot 2H_2O$ ***(4)***: Aqueous solution of nickel(II) fluoride afforded this compound following the method described for the preparation of complex **2**.

$[NiL_3]Cl_2$ ***(5)***: This was prepared following the method described for complex **1**.

$[NiL_3]Cl_2$ ***(6)***: This was prepared following the method described for complex **2**.

$[NiLCl_2]$ ***(7)***: This was prepared by pyrolysis of $[NiL_3]Cl_2$ (**5**) at ≈176 °C.

$[NiLCl_2]$ ***(8)***: This was synthesized by pyrolysis of $[NiL_3]Cl_2$ (**6**) at ≈170 °C.

$[NiL_3]Cl_2\cdot H_2O$ ***(9)***: This was synthesized by addition of hydrazine hydrate to the $[NiLCl_2]$ (**7**).

$[NiL_3]Cl_2\cdot H_2O$ ***(10)***: This was prepared by addition of hydrazine hydrate to the $[NiLCl_2]$ (**8**).

$[NiL_3]Br_2$ ***(11)***: This was synthesized by the corresponding procedure to the preparation of complex **1**.

$[NiL_3]Br_2$ ***(12)***: This was prepared by the corresponding procedure to the preparation of complex **2**.

$[NiL_2Br_2]$ ***(13)***: This was obtained on keeping the complex **11** in vacuum at ambient temperature. This was also prepared similarly from the complex **12**. The preparation from complex **11** required comparatively high vacuum relative to that from complex **12**.

$[NiL_2Br_2]$ ***(14)***: This was obtained from complex **11** by pyrolytic technique at ≈176 °C in nitrogen atmosphere.

$[NiL_3]Br_2$ ***(15)***: This was prepared by treatment of hydrazine hydrate on complex **13**.

$[NiL_3]Br_2$ ***(16)***: This was synthesized by treating complex **14** with hydrazine hydrate.

$[NiL_2(SCN)_2]$ ***(17)***: This was prepared by treating hydrazine hydrate (2—3 mmol) with ethanolic solution of nickel(II) thiocyanate (1 mmol).

$[NiL_2(SCN)_2]$ ***(18)***: This was prepared by the treatment of hydrazine hydrate (2—3 mmol) with ethanolic ammoniacal nickel(II) thiocyanate solution.

Thermal Measurements. The thermal analysis was carried out using a thermal analyzer (Shimadzu, Model DT-30, Japan). A constant flow of dry nitrogen (30 ml min^{-1}) was maintained. Platinum crucibles were used. Heating rate was maintained 5 °C min^{-1}. The particle size of the samples was within 150—200 mesh. Aluminium oxide was used as reference.

Elemental Analyses. Elemental analyses were carried out in the microanalytical section of the Australian Mineral Development Laboratories as well as in the microanalytical laboratory of our institute.

Spectral Measurements. Infrared spectra (KBr disk, 4000—400 cm^{-1}) and electronic spectra in mull (28570—11111 cm^{-1}) were recorded using a Beckman IR spectrophotometer, Model IR-20A and a Pye Unicam spectrophotometer, model SP8-150, respectively. Cary 17D was also used for mull

† Part of the work was presented at the third national symposium of Indian Thermal Analysis Society held at VSSC, Trivandrum, India.

†† Similar experiment was performed by using 3 mmol of hydrazine hydrate but we obtained complex $[NiL_2F_2]\cdot H_2O$.

spectra in some cases.

Magnetic Measurement. Magnetic moments of the compounds were evaluated from the magnetic susceptibilities of the samples at room temperature, corrected by applying Pascal's constants of the elements involved, using the Gouy technique where $Hg[Co(SCN)_4]$ was taken as standard.

X-Ray Powder Diffraction. X-Ray powder diffraction patterns of the compounds were obtained on a Philips powder diagram camera, using Cu *Kα* radiation.

Results

The thermal curves of two bis(hydrazine)nickel(II) fluoro complexes **1** and **2** are shown in Fig. 1. Both the species become anhydrous first and then lose hydrazine on heating. But the thermal profiles of them are distinctly different from each other.

$[NiL_{2.5}(H_2O)_2]F_2 \cdot 0.5H_2O$ (**3**) loses first its lattice water and then two molecules of coordinated water. The derived $NiL_{2.5}F_2$ is very much unstable and loses immediately hydrazine molecules in two steps as observed in TG curve (Fig. 2). The first step corresponds roughly to elimination of 0.5 molecule of hydrazine and the second corresponds to that of two molecules. But its DTA curve indicates that the elimination of hydrazine occurs in more than two steps. On the other hand, thermal curve of $[NiL_{2.5}F_2] \cdot 2H_2O$ (**4**) shown in Fig. 2 indicates that hydrazine elimination occurs here also in two steps. The first step corresponds to the elimination of one hydrazine and the second corresponds to that of the rest of hydrazine.

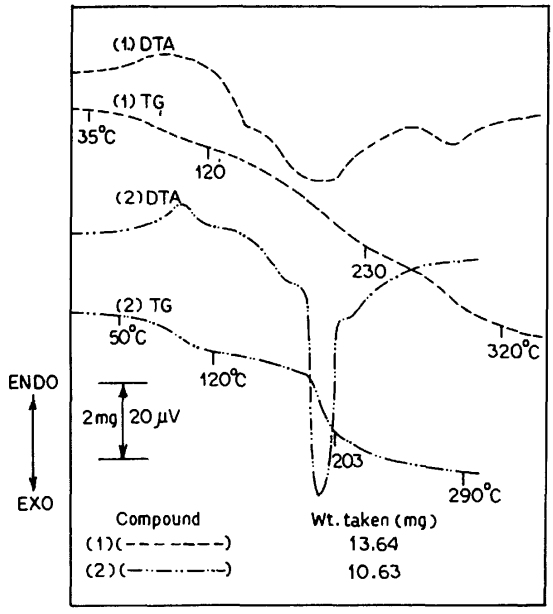

Fig. 1. Thermal curves of $[NiL_2F_2] \cdot H_2O$ (**1**) and $[NiL_2F_2] \cdot H_2O$ (**2**).

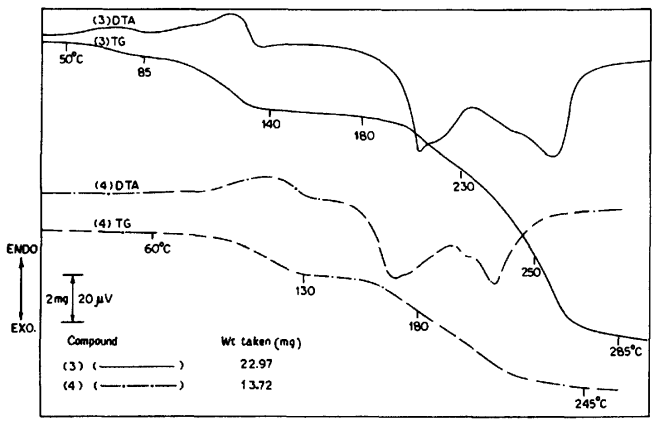

Fig. 2. Thermal curves of $[NiL_{2.5}(H_2O)_2]F_2 \cdot 0.5H_2O$ (**3**) and $[NiL_{2.5}F_2] \cdot 2H_2O$ (**4**).

Thermal curve of tris(hydrazine)nickel(II) chloride (**6**) is shown in Fig. 3. It transforms straightly to $NiLCl_2$ on heating and then to nickel(II) chloride *via* an unstable intermediate compound $NiL_{0.5}Cl_2$. Thermal curve of tris(hydrazine)nickel(II) chloride (**5**) is almost identical to that of complex **6**. Here the TG curve does not support the formation of hemi(hydrazine) species (Fig. 3).

The TG curve of $[NiL_3]Cl_2 \cdot H_2O$ (**9**) (Fig. 3) shows that it decomposes stepwise with the formation of bis as well as unis(hydrazine) chloro complex on heating. Its DTA curve hints the formation of another intermediate species in between $NiLCl_2$ and $NiCl_2$. The thermal profile of $[NiL_3]Cl_2 \cdot H_2O$ (**10**) does not differ much from that of complex **9**. In complex **10** formation of hemi(hydrazine) species, though not isolable, is evident from the TG and DTA profile (Fig. 3).

The TG curve of tris(hydrazine)nickel(II) bromide (**11**) (Fig. 4) shows that it transforms to NiL_2Br_2 in single step. But its DTA curve shows an exotherm followed by a prominent hump which indicates that the formation of isolable NiL_2Br_2 takes place *via* an unstable intermediate $[NiL_{2.5}Br]Br$. The TG curve of derived bis species shows elimination of two hydrazine molecules taking place in one step, but its DTA curve indicates the elimination taking place *via* an another unstable intermediate complex. On the other hand, tris(hydrazine)nickel(II) bromide (**12**) transforms straightly to $NiLBr_2$ in a single step as evident from its thermal curves (Fig. 4). This uni species is not isolable in pure form even by arresting temperature rising. $NiLBr_2$ on further heating transforms to $NiBr_2$ *via* probably an unstable hemi(hydrazine) complex $NiL_{0.5}Br_2$.

The TG curve of $[NiL_2Br_2]$ (**13**) (Fig. 5) shows elimination of two hydrazine molecules taking place in a single step but its DTA profile hints the elimination in two steps probably through a uni (hydrazine)species. The thermal behavior of $[NiL_2Br_2]$ (**14**) is almost identical to that of **13**.

$[NiL_3]Br_2$ (**15**) transforms straightly to $NiBr_2$ in a single step as evident from its sharp TG and DTA curves, but $[NiL_3]Br_2$ (**16**) transforms to $NiLBr_2$ in a single step (Fig. 5). The unis(hydrazine) species derived from complex **16** is not isolable in pure state even by temperature arrest technique, but transforms to $NiBr_2$ in a single step (Fig. 5).

$[NiL_2(SCN)_2]$ (**17**) begins to lose hydrazine at ≈160 °C and becomes $Ni(SCN)_2$ at ≈225 °C in a single step observed from its TG curve (Fig. 6). But the presence of two peaks overlapping with each other in the corresponding DTA curve indicates elimination of hydrazine taking place in two steps. The metal thiocyanate is not

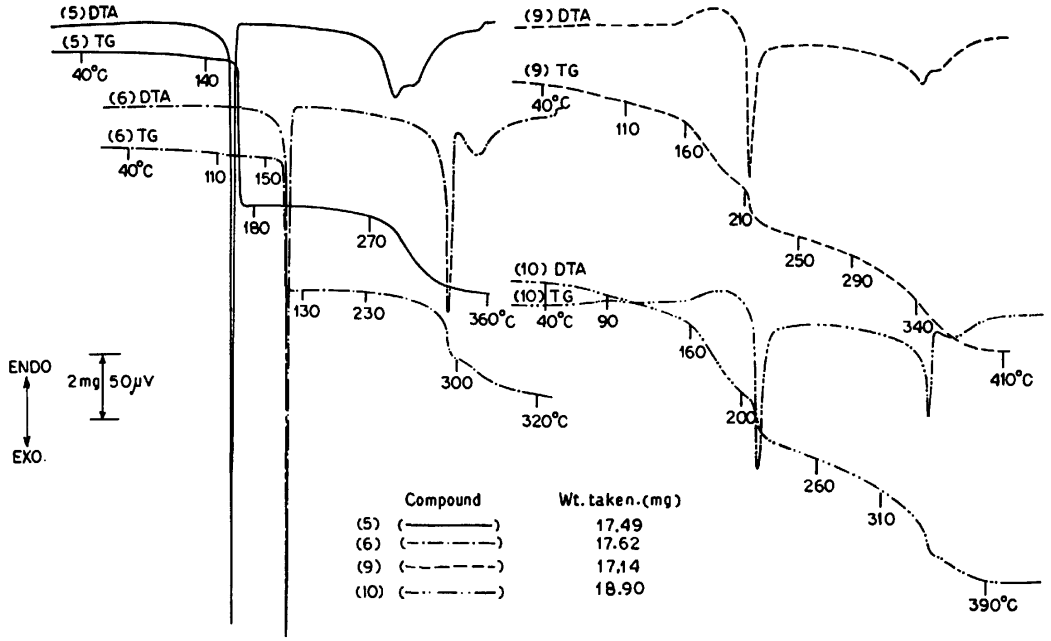

Fig. 3. Thermal curves of $[NiL_3]Cl_2$ (**5**), $[NiL_3]Cl_2$ (**6**), $[NiL_3]Cl_2 \cdot H_2O$ (**9**), and $[NiL_3]Cl_2 \cdot H_2O$ (**10**).

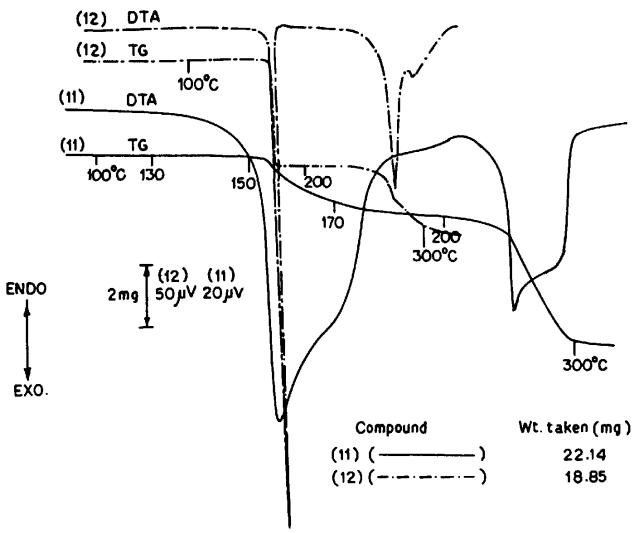

Fig. 4. Thermal curves of $[NiL_3]Br_2$ (**11**) and $[NiL_3]Br_2$ (**12**).

isolable. It immediately decomposes to metal sulfide and sulfur in two steps. On the other hand, in case of $[NiL_2(SCN)_2]$ (**18**) elimination of hydrazine and decomposition of metal thiocyanate occur simultaneously (Fig. 6).

Table 1 shows the thermal decomposition reaction in details along with temperature range and DTA peak temperature for each step of decomposition. Table 2 shows the analytical data of the hydrazine complexes and intermediate hydrazine complex species isolated by temperature arrest technique along with the color and magnetic data. IR spectra of all the hydrazine complexes are taken. Electronic mull spectra of the complexes are taken and corresponding data are shown in Table 3. X-Ray data of two complexes are shown in Table 4.

Discussion

The Complexes Derived from NiF_2 and Hydrazine Hydrate. $NiL_xF_y \cdot zH_2O$ ($x=2$, 2.5, $y=2$, $z=1$, 2, 2.5): Treatment of NiF_2 crystal with hydrazine hydrate afforded bluish pink $[NiL_2F_2] \cdot H_2O$ (**1**), whilst the samely formulated complex **2** was synthesized by reaction of hydrazine hydrate with NiF_2 crystals in concentrated ammoniacal solution. Electronic spectra (Table 3) in mull of both **1** and **2** complexes suggest O_h symmetry[5] existing in the system which is also supported by the magnetic moment (Table 2). The thermal profile for the water elimination shows existence of water molecule[6,7] as noncoordinated in both the cases. IR data also collaborate with the inference[8] drawn from thermal profile regarding the play of water molecule (Fig. 7). The medium broad band at $\approx 580\ cm^{-1}$ in IR is expected to be assigned to ν(Ni–F).[8] The bridging character of NH_2NH_2 exists in both species as ν(N–N)[9,10] appearing at $\approx 980\ cm^{-1}$. The weak intensity of this band seems to be due to the fact that the vibrational mode of N–N stretching frequency tends to be IR inactive for the strong hydrogen bonding between F and hydrogen of NH_2 group. On the other hand, the thermal decomposition patterns of both species are different which implies that they are structurally somewhat different. It is rather difficult to comment on the mechanism of decomposition pattern as no intermediate species are isolable. However, for **1** the decomposition probably follows O_h $Ni^{II} \rightarrow T_d$ Ni^{II} which ultimately affords NiF_2.

It is interesting to note that the treatment of hydrazine hydrate with concentrated solution of NiF_2 yields $[NiL_{2.5}(H_2O)_2]F_2 \cdot 0.5H_2O$ (**3**). The electronic spectrum in mull as well as magnetic moment suggests it to exist as O_h symmetry. As water molecules evolve in two steps, it seems that two types of water *i.e.* lattice water

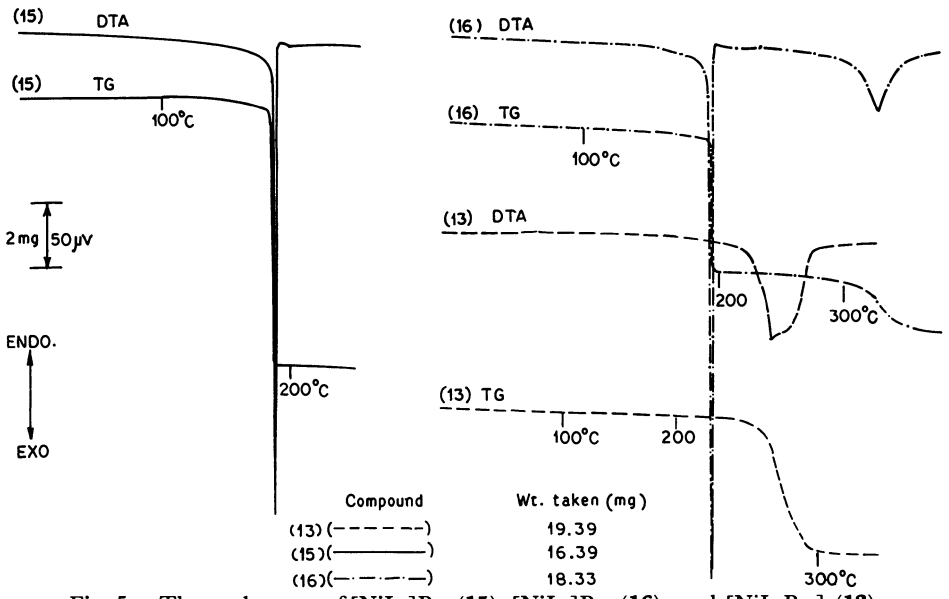

Fig. 5. Thermal curves of $[NiL_3]Br_2$ (**15**), $[NiL_3]Br_2$ (**16**), and $[NiL_2Br_2]$ (**13**).

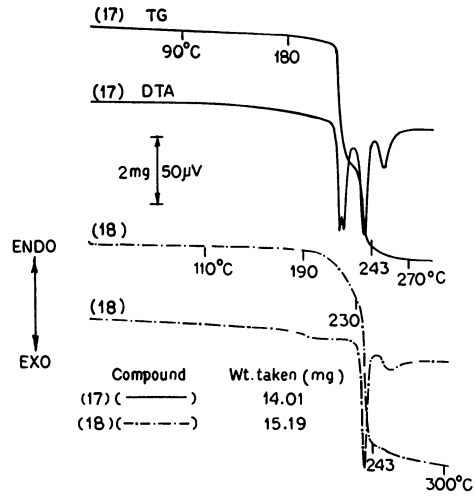

Fig. 6. Thermal curves of $[NiL_2(SCN)_2]$ (**17**) and $[NiL_2(SCN)_2]$ (**18**).

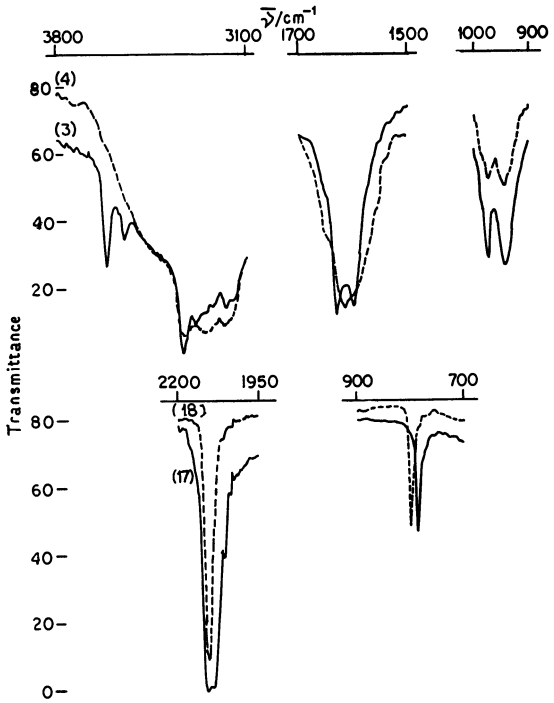

Fig. 7. IR spectra (3800—3100, 1700—1500, and 1000—900 cm^{-1}) of $[NiL_{2.5}(H_2O)_2]F_2 \cdot 0.5H_2O$ (**3**)and $[NiL_{2.5}F_2] \cdot 2H_2O$ (**4**); IR spectra (2200—1950, 900—700cm^{-1}) of $[NiL_2(SCN)_2]$ (**17**) and $[NiL_2(SCN)_2]$ (**18**).

and coordinated water exist in the system. However, the IR spectrum suggests that the two molecules of water are coordinated[11,12] to Ni^{II} as evident from the sharp bands at $\approx$3500 cm^{-1} [ν(OH)] (Fig. 7) and δ(HOH) at $\approx$1630 cm^{-1}, ρw(HOH) at 625 cm^{-1}, and [ν(MO)] at $\approx$465 cm^{-1}. The coordination of F^- to Ni^{II} is nullified by the absence of ν(MF) at $\approx$590 cm^{-1} as observed in the case of complexes **1** and **2**. Hydrazine molecules are existing in the system as both unidentate and bidentate as evident[2,4] from the presence of ν(N–N) vibrations at $\approx$935 and $\approx$975 cm^{-1} respectively (Fig. 7). The tentative structure of complex **3** is shown in Fig. 8. The elimination of water and hydrazine is complicated as the decomposition follows a number of intermediates as evident from DTA profile (Fig. 2). On the other hand, the treatment of hydrazine hydrate with concentrated solution of NiF_2 in ammoniacal medium yields $[NiL_{2.5}F_2] \cdot 2H_2O$ (**4**). O_h symmetry also exists here and the existence of hydrazine in the species is similar to complex **3**. Moreover, Ni–F bonding is also suggested by the presence of ν(MF) at $\approx$590 cm^{-1} as observed in complexes **1** and **2**. Water molecules in the complex **4** exist outside the coordination sphere as evident from its IR spectrum (Fig. 7) though temperature range for the elimination of water shown in Table 1 differs from that of complex **3**. The tentative structure of complex **4** is shown in Fig. 8. The decomposition of complex **4** appears also complicated (Fig. 2).

The Complexes Derived from $NiCl_2$ and Hydrazine Hydrate. Treatment of hydrazine hydrate with $NiCl_2$ affords

TABLE 1. THERMAL PARAMETERS OF THE NICKEL(II) COMPLEXES OF HYDRAZINE

Decomposition reactions	Temp range °C	DTA peak temp/°C
$[NiL_2F_2]\cdot H_2O$ (**1**)$\rightarrow NiL_2F_2$	40—140	85

$[NiL_3]Cl_2$(**5**)$\rightarrow NiLCl_2$	120—176	160
$NiLCl_2\rightarrow NiCl_2$	240—350	290, 305
$[NiL_3]Cl_2$(**6**)$\rightarrow NiLCl_2$	115—170	158
$NiLCl_2\rightarrow NiL_{0.5}Cl_2$	220—295	285
$NiL_{0.5}Cl_2\rightarrow NiCl_2$	295—360	305
$[NiL_3]Cl_2\cdot H_2O$(**9**)$\rightarrow NiL_2Cl_2$	40—215	158
$NiL_2Cl_2\rightarrow NiLCl_2$	215—320	220
$NiLCl_2\rightarrow NiCl_2$	320—400	340, 360
$[NiL_3]Cl_2\cdot H_2O$(**10**)$\rightarrow NiL_2Cl_2$	40—218	180
$NiL_2Cl_2\rightarrow NiLCl_2$	218—295	220
$NiLCl_2\rightarrow NiL_{0.5}Cl_2$	295—345	342
$NiL_{0.5}Cl_2\rightarrow NiCl_2$	345—410	364
$[NiL_3]Br_2$(**11**)$\rightarrow NiL_2Br_2$	140—176	155, 170
$NiL_2Br_2\rightarrow NiBr_2$	195—280	250, 270
$[NiL_3]Br_2$(**12**)$\rightarrow NiLBr_2$	170—180	172
$NiLBr_2\rightarrow NiL_{0.5}Br_2$	185—280	257
$NiL_{0.5}Br_2\rightarrow NiBr_2$	280—320	300
$[NiL_2Br_2]$(**13**)$\rightarrow NiBr_2$	200—310	250, 270
$[NiL_3]Br_2$(**15**)$\rightarrow NiBr_2$	130—190	175
$[NiL_3]Br_2$(**16**)$\rightarrow NiLBr_2$	160—200	185
$NiLBr_2\rightarrow NiBr_2$	205—350	320
$[NiL_2(SCN)_2]$(**17**)$\rightarrow Ni(SCN)_2$	160—225	210, 215
$Ni(SCN)_2\rightarrow NiS+S$	225—255	235, 250
$[NiL_2(SCN)_2]$(**18**)$\rightarrow NiS+S$	190—290	235, 268

$[NiL_3]Cl_2$ (**5**), while with ammoniacal medium another $[NiL_3]Cl_2$ (**6**) is formed. These two show similarity in color, magnetic moment as well as in other physical properties *e.g.*, IR and electronic spectra (mull). The spectral behavior suggests them to exist as O_h symmetry with the bridging characteristic of hydrazine. Thermal curves suggest that unis(hydrazine)nickel(II) chloride complexes $[NiLCl_2]$ (**7** and **8**), derived from the complexes **5** and **6** are slightly structurally different.

Treatment of hydrazine with complex **7** results in $[NiL_3]Cl_2\cdot H_2O$ (**9**). Similar treatment with complex **8** results in $[NiL_3]Cl_2\cdot H_2O$ (**10**). These two tris-(hydrazine) species also show similarity in color, magnetic moment and other physical properties. We expected that these two hydrated tris species, on heating, will generate anhydrous tris species, identical to complexes **5** and **6**, but the thermal behaviors of complexes **9** and **10** show that synthesis of anhydrous tris species is not feasible by pyrolytic treatment. This hints the presence of water within the coordination sphere, but both IR and electronic (mull) spectra indicate noncoordination of water molecule. No significant DTA curve is obtained (Fig. 3) at the time of evolution of first hydrazine molecule, which probably due to the simultaneous elimination of H_2O and NH_2NH_2. The exotherm for NH_2NH_2 evolution and the endotherm of H_2O probably nullify the energy with each other. This also suggests that tris species **9** and **10** are quite different

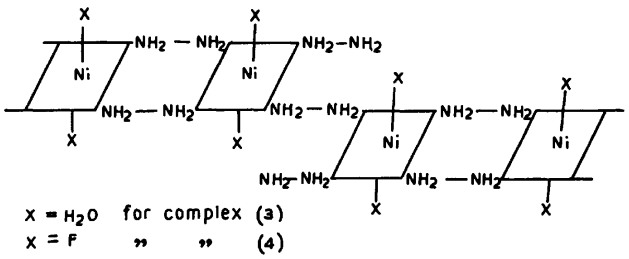

Fig. 8. Structures of $[NiL_{2.5}(H_2O)_2]F_2\cdot 0.5H_2O$ (**3**) and $[NiL_{2.5}F_2]\cdot 2H_2O$ (**4**).

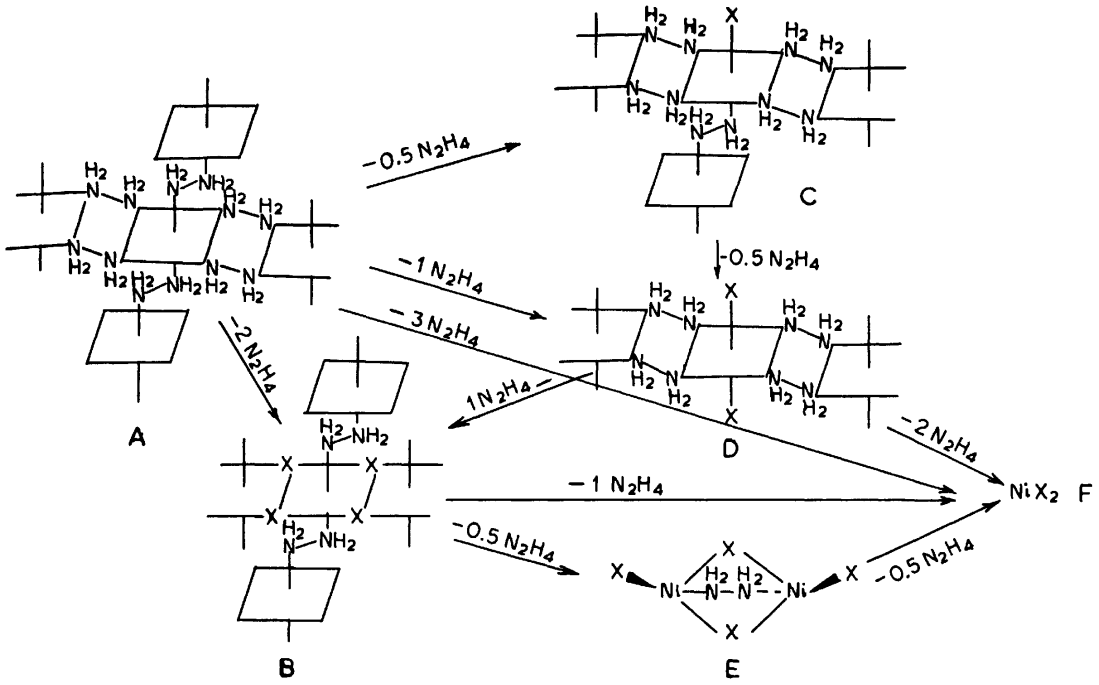
from **5** and **6** complex species. It is observed that unis(hydrazine) complex could not be isolated from complexes **9** and **10** but it is true that the structure of unis(hydrazine) complexes **7** and **8** remains intact on hydrazine treatment as evident from the comparison of the nature of decomposition of either complexes **5** and **9** or **6** and **10**. Color, magnetic moment, IR and electronic (mull) spectra of complexes **9** and **10** apparently show no difference between them, suggesting O_h symmetry and bridging characteristic of hydrazine as observed in complexes **5** and **6**.

Tsuchiya *et al.*[2] investigated the thermal behaviors of $[Ni(NH_2NH_2)_6]X_2$. They noticed that hexakis(hydrazine) species becomes nickel(II) chloride *via* tris, bis and unis(hydrazine) complexes. It seems that much differences existing between the decomposition pattern of the complexes being to be reported by us and of the species reported by Tsuchiya *et al.*[2] will be due to the basic differences playing in the preparative procedures. The tentative decomposition mode of complexes **5** and **6** is probably A→B→E→F (Scheme 1), whilst the complexes **9** and **10** form $NiCl_2$ through A→D→B→E→F (Scheme 1).

The unis(hydrazine)nickel(II) chloro complexes **7** and **8** are characterized. The magnetic moments appear to be higher than those of the tris complexes (Table 2). The mull spectra suggest its O_h symmetry but the shift



(X=Cl/Br)

Scheme 1.

of the bands (Table 3) towards lower energy region is probably due to the displacement of hydrazine molecules by chloride ions as evident from the fact that halide ions are in the lower position of the spectrochemical series. The color change, pink (tris) to sky blue (unis), also supports the halide substitution.[2,13] Moreover, this unis(hydrazine) complex further decomposes to nickel(II) chloride through unstable hemi(hydrazine) complex as evident from DTA and TG profiles (Fig. 3).

The Complexes Derived from $NiBr_2$ and Hydrazine Hydrate. Treatment of nickel(II) bromide with hydrazine hydrate yields $[NiL_3]Br_2$ (**11**) while with ammoniacal medium another tris species **12** is generated. Both of the species show no difference in color, magnetic moment and IR spectra. Electronic spectra in mull suggest O_h symmetry in them. IR spectra suggest bridging characteristics of hydrazine. But the thermal characteristics of these two species (Fig. 4, Table 1) are distinctly different from each other. It is interesting to note that both the tris species, **11** and **12** yield $[NiL_2Br_2]$ (**13**) while keeping in vacuum though the preparation from the species **11** requires high vacuum in comparison with that from the species **12**. On the contrary, complex **13** is not obtained (Table 1) as an intermediate product upon heating the complex **12**.

Treatment of hydrazine with bis(hydrazine) bromo complex **13** yields tris species **15**. Bis species **14** also yields another tris species **16** with hydrazine hydrate. These two tris species **15** and **16** possess the same color as those of complexes **11** and **12**. IR and electronic mull spectra of these two species imply here also the O_h symmetry as well as bridging characteristic of hydrazine like those of complexes **11** and **12**. But thermal profile of complex **16** is distinctly different from that of complex **15** (Fig. 5, Table 1). These observations indicate that bis species **13** is structurally different from the bis species **14** although the thermal behaviors of these two bis species **13** and **14** apparently show no difference amongst them. Moreover, these two bis complexes **13** and **14** are identical in color, magnetic moments, electronic (mull) and IR spectra suggesting here also O_h symmetry and bridging characteristic of hydrazine. DTA profile of thermal curves of complex **11** exhibits that the stable (D*** of Scheme 1) bis(hydrazine) bromo complex is formed *via* an intermediate $[NiL_{2.5}Br]Br$ (C of Scheme 1). This bis(hydrazine) bromo complex again passes through a nonisolable$[NiLBr_2]$ (B** of Scheme 1) which ultimately transforms straightly to nickel(II) bromide unlike complexes **5**, **6**, **9**, and **10**. On the other hand, the thermal curves of complex **12** suggest the decomposition to follow A→B→E→F in which B is not well characterized like complexes **5** and **6**. Moreover, the thermal curves of complex **16** suggest its decomposition pattern to follow A→B→F where B is not isolable in pure form. However, it is interesting to note that thermal curves distinctly suggest the structural differences existing in complexes **12** and **16** as an intermediate species (E) found in complex **12** is not observed in complex **16**.

The Complexes Derived from $Ni(SCN)_2$ and Hydrazine Hydrate. Treatment of nickel(II) thiocyanate in ethanol with hydrazine hydrate yields $[NiL_2(SCN)_2]$ (**17**). On the other hand, hydrazine hydrate treatment with ammoniacal nickel(II) thiocyanate in ethanolic

** B form in the general scheme is well characterized for **5** and **6**. This form is also expected for **12** as Cl/Br belongs to halide group.

*** D form is well characterissed by **11**. This suggests to follow the general scheme for the other complexes such as **9** and **10**.

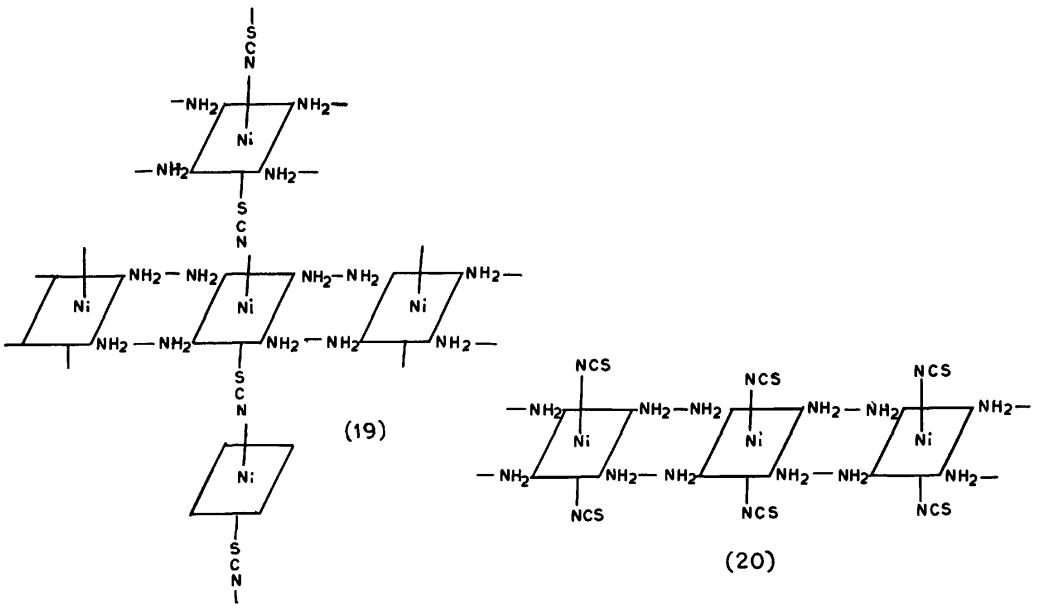


Fig. 9. Structures of $[NiL_2(SCN)_2]$ (**17**) and $[NiL_2(SCN)_2]$ (**18**).

medium yields $[NiL_2(SCN)_2]$ (**18**) which is similar in color to the species (**17**). Electronic mull spectra and magnetic data of these two thiocyanato complexes having identical chemical composition show O_h symmetry in each case. IR spectra indicate the bridging character of the hydrazine. But the thermal behaviors of these two species **17** and **18** are distinctly different from each other, indicating some structural differences. Their structural differences are evident from IR spectra of complexes **17** and **18**. The sharp band at 2085 cm^{-1} [ν(CN)] corresponds to Ni–N bonding[8] which is further supported by the sharp medium band at 800 cm^{-1} ν(CS), whilst the splitting of ν(CN) at 2085 cm^{-1} in complex **17** (Fig. 7) collaborates the bridging of SCN group.[14,15] Moreover, the negative shift of ν(CS) to 785 cm^{-1} [17] (Fig. 7) for complex **17** indicates also Ni–S bonding. The structure for compound **17** should be either $Ni(N_5S)$ or $[Ni(N_4S_2)+Ni(N_6)]$ type. However, the present limited data cannot exclusively comment on the exact chromophores of the system. Thermal data support the higher stability of compound **18** than the compound **17** as compound **18** possesses more symmetric system *i.e.*, NiN_6 chromophores whilst complex **17** possesses less symmetric system as shown in Fig. 9. Nature of the DTA curve of compound **17** suggests that the hydrazine molecules evolve successively through an unstable hydrazine complex as intermediate. On the other hand, the DTA profile for thiocyanate decomposition displays two exotherms suggesting a complicated pattern shown below:

$$Ni(SCN)_2 \longrightarrow Ni^{2+} + 2(SCN)^-$$
$$2(SCN)^- \longrightarrow S^{2-} + 1/2(CN)_2 + 1/2(SCN)_2$$

responsible for 1st DTA peak

$$Ni^{2+} + S^{2-} \longrightarrow NiS$$
$$1/2(SCN)_2 \longrightarrow S + 1/2(CN)_2$$

responsible for 2nd DTA peak

On continuation of heating it is evident that sulfur is evolved first as SO_2 followed by the decomposition of NiS which ultimately transforms to NiO.

Conclusion

In the foregoing discussion, it was observed that the presence of ammonia during the preparation of complexes **2**, **4**, **6**, **12**, and **18** probably plays an important role to form the apparently identical but structurally different complexes as explored by thermal techniques. The structural differences existing in the apparently identical compounds do not involve the change of microsymmetry (O_h) as evident from their absorption spectra taken in mull. However, this is not true for the apparently identical compounds **11** and **12** in which the spectra (Fig. 10) appearing at 540 nm as a maximum in complex **12** is split to 560 and 600 nm in complex **11**.

The X-ray diffraction patterns (Table 4) of complexes **11** and **12** are absolutely different from each other which would indicate the difference in crystal symmetry implying the bond distances being different from each

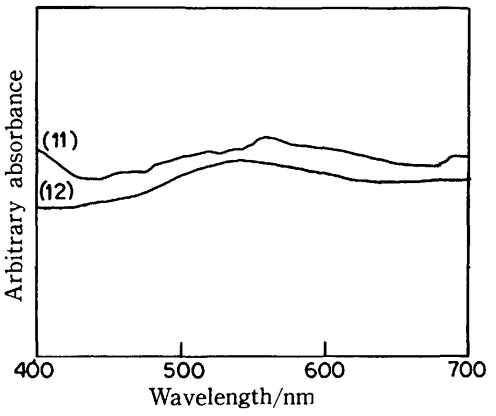

Fig. 10. Electronic spectra of $[NiL_3]Br$(**11**) and $[NiL_3]Br_2$(**12**) in mull.

other. Such concept about the structures of complexes **11** and **12** also supports the differences exhibited (high vacuum for **11** and low vacuum for **12**) in vacuum treatment. In the case of chloride, the vacuum treatment does not alter the tris variety. Since the Br^- is more labile than Cl^- in the complexes, however, the different varieties of Br^- complexes are obtained by the change of the physical and chemical environments. On the other hand, nickel fluoro complexes of hydrazine take up water molecule as F^- and H_2O possess almost similar coordinating ability.[19] Among the tested halide ions (F^-, Cl^-, Br^-)Cl^- is the most preferable one for bridging between two metal ions provided the condition for the bridging should be filled in. Br^- behaves as both bridging and unidentate ligand since the coordinating as well as briding capacity of Br^- and hydrazine may be the same. Therefore, the degree of variation in the case of bromo complexes is more than that of chloro complexes.

Emission Spectra of Toluidines by Controlled Electron Impact

Teiichiro OGAWA,* Takayuki OOMORI,† and Hirofumi KAWAZUMI
Department of Molecular Science and Technology, Kyushu University, Kasuga, Fukuoka 816
(Received March 11, 1983)

Synopsis. The spectra of *o*-, *m*-, and *p*-toluidines show an intense band of the S_1-S_0 transition of the parent molecule, and lines and bands of fragment species such as H, CH, C_2, CN, and NH.

Electron impact excitation of molecules is a revised form of the traditional electric discharge method. The aromatic molecules show intense photoemission of the parent molecules in the ultraviolet region.[1,2] These bands are similar with the fluorescence spectra and they have been assigned to the S_1-S_0 transition of the parent molecule. In the present note, the emission spectra of three isomers of toluidines have been measured and their excitation processes have been discussed.

The apparatus consists of a collision chamber, a SPEX 1269 monochromator and a photon counting system; they have been described previously.[2]

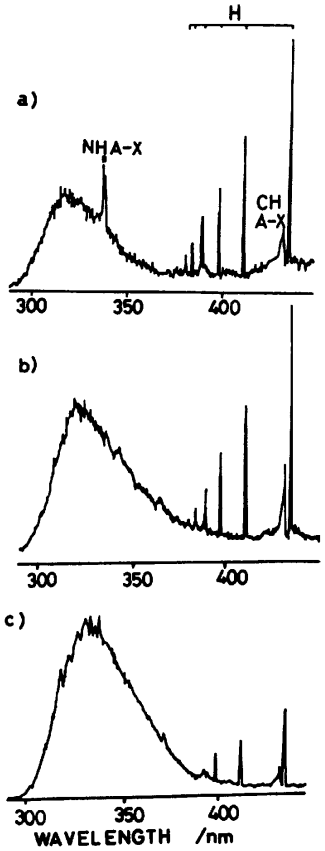

Fig. 1. Emission spectra of (a) *o*-toluidine (100 eV, 500 μA), (b) *m*-toluidine (100 eV, 100 μA), and (c) *p*-toluidine (100 eV, 70 μA) by controlled electron impact.

Typical emission spectra of toluidines by controlled electron impact are shown in Fig. 1. The intense bands observed in the 300—400 nm region are similar to those of aniline[3] and xylenes.[4] The fluorescence spectra of these molecules were measured in ethanol; they have a similar band in the identical region. Therefore, these bands have been assigned to the S_1-S_0 transition of the parent molecules.

There are also many lines and bands of fragment species. They are the Balmer series of the excited hydrogen atom, the 4300 Å system of CH (A-X), the 3360 Å system of NH (A-X) and the Swan system of C_2 (d-a). Their assignments are shown in Fig. 1.

The emission intensities of the parent molecules and such fragments as H* and CH* are proportional to the electron-beam current up to at least 600 μA; this finding indicates that these excited species are produced through a single collision between an electron and a molecule.

The S_1-S_0 band is relatively more intense at lower electron energies than lines and bands of fragments.[2] This is partly due to need of larger excitation energies for the formation of the excited fragments, as is common to most aromatic molecules.[2]

The relative intensity of this band for three toluidines can be estimated from the intensity relative to those of fragments, since the intensity of fragments is expected to be approximately independent of the molecular structure. At an identical electron energy, the band of *p*-toluidine is the most intense, as in the case of xylenes.[4] Furthermore, the band of *p*-toluidine has more vibrational structures. This is due to the higher symmetry of this molecule and, as a result, a higher quantum yield of emission.

Usually a molecule consisted of four atoms or more does not show a band of the parent molecule, unless it is fluorescent. The emission spectra of toluidines have been related with their fluorescence, as have been shown for several aromatic molecules.[1,2]

Carbon Monoxide Absorption by Solutions of Aluminium Copper(I) Chloride in Various Aromatic Solvents

Hidefumi HIRAI,* Masahiro NAKAMURA, and Makoto KOMIYAMA
Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received December 10, 1982)

Synopsis. Carbon monoxide absorbents composed of aluminium copper(I) chloride and various aromatic solvents are prepared, and their absorbing capacities are determined. The plot of the equilibrium molar ratio of the absorbed carbon monoxide to $AlCuCl_4$ *vs.* the ionization potential of the aromatic solvent indicates that both electronic and steric factors are important in the molecular complex formation between $AlCuCl_4$ and aromatic solvent molecules.

Carbon monoxide, a valuable starting material in industry, is generally separated from gas mixtures of carbon monoxide, hydrogen, carbon dioxide, methane, nitrogen, and others.[1]

One of the recently developed carbon monoxide-separation methods takes advantage of the molecular complex formation of aluminium copper(I) chloride ($AlCuCl_4$) with carbon monoxide in a toluene solution.[2] On contact with gas mixtures, toluene interacting with aluminium copper(I) chloride is replaced by carbon monoxide. This absorbent is readily deactivated with water in the feed gas. The present authors have now exploited a water-resistant carbon monoxide absorbent by protecting aluminium copper(I) chloride with polystyrene.[3,4] Here, the water resistance has been attributed to the interactions of $AlCuCl_4$ with adjacent aromatic rings of polystyrene.

This paper will describe the preparation of carbon monoxide absorbents composed of aluminium copper(I) chloride and various aromatic solvents. The dependence of their absorbing capacities on the electronic and steric properties of the aromatic solvents will be shown.

Experimental

The aluminium chloride (guaranteed grade, Kishida Chemical Co.) was purified by sublimation. The copper(I) chloride (guaranteed grade, Koso Chemical Co.) was used without further purification. All the aromatic solvents were dried with calcium hydride immediately before use. The triethylbenzene, obtained from the Nakarai Chemical Co., was a mixture of the 1,3,5- and 1,2,4-isomers in a molar ratio of about 2 : 1. The carbon monoxide gas and nitrogen gas, which had purities of 99.95 and 99.999% respectively, were passed through the columns of a 3A molecular sieve.

The carbon monoxide absorbents were prepared by heating 35 mmol of copper(I) chloride and 35 mmol of aluminium chloride in 20 ml of an aromatic solvent in a 100 ml flask for 5 h at 100 °C (for 1,2,3,4-tetrahydronaphthalene, triethylbenzene, and triisopropylbenzene) or 40 °C (for others).

The carbon monoxide–nitrogen mixture, which had an initial volume of 1400 ml and an initial molar ratio of 0.84 : 0.16, was placed in contact with the absorbents, and then the mixture was continuously stirred with a magnetic stirrer (at 20 °C; 1 atm). The absorptions of carbon monoxide were followed by reading the uptake of carbon monoxide with a gas burette. During the first 10 min, the carbon monoxide–nitrogen mixture was made to flow over the absorbent at rate of 30 ml/s by the use of a gas pump.

Results and Discussion

Homogeneous solutions of aluminium copper(I) chloride were prepared for all the aromatic solvents investigated, *i.e.*, benzene, toluene, *o*-xylene, *m*-xylene, *p*-xylene, 1,2,3,4-tetrahydronaphthalene, mesitylene, triethylbenzene, and 1,3,5-triisopropylbenzene.

On contact with carbon monoxide-nitrogen mixtures at 20 °C, all of these solutions exhibited a rapid absorption of carbon monoxide. The molar ratios of the carbon monoxide absorbed to $AlCuCl_4$ attained equilibrium values within 1 h. By raising the temperature from 20 °C to 90 °C, almost all of the absorbed carbon monoxide was rapidly released.

Table 1 lists the equilibrium molar ratios of the absorbed carbon monoxide to $AlCuCl_4$ for all the absorbents. The molar ratio varies considerably with the aromatic solvent used; this fact seems to indicate the significant roles played by the aromatic solvents in these absorbents.

Figure 1 depicts the plot of the molar ratio *vs.* the ionization potential of the aromatic solvent.[5,6] The molar ratio decreases almost linearly with the decrease in the ionization potential from benzene to 1,2,3,4-tetrahydronaphthalene. This is attributable to the fact that the charge-transfer complex between $AlCuCl_4$ and the aromatic-solvent molecule becomes more stable with the decrease in the ionization potential. The absorption of carbon monoxide by the absorbent should be more favorable for the aromatic solvent forming the less stable molecular complex with aluminium copper(I) chloride, since it involves the substitution of the ligand on aluminium copper(I) chloride from the aromatic-solvent molecule to carbon monoxide.

As may clearly be seen from Fig. 1, the molar ratio

Table 1. Equilibrium molar ratios of the absorbed carbon monoxide to $AlCuCl_4$ in various aromatic solvents[a]

Aromatic solvent	Equilibrium molar ratio
Benzene	0.87
Toluene	0.81
o-Xylene	0.70
m-Xylene	0.74
p-Xylene	0.72
1,2,3,4-Tetrahydronaphthalene	0.63
Mesitylene	0.87
Triethylbenzene	0.85
1,3,5-Triisopropylbenzene	0.91

a) At 20 °C: total pressure, 1 atm; initial partial pressures of carbon monoxide and nitrogen, 0.84 and 0.16 atm respectively.

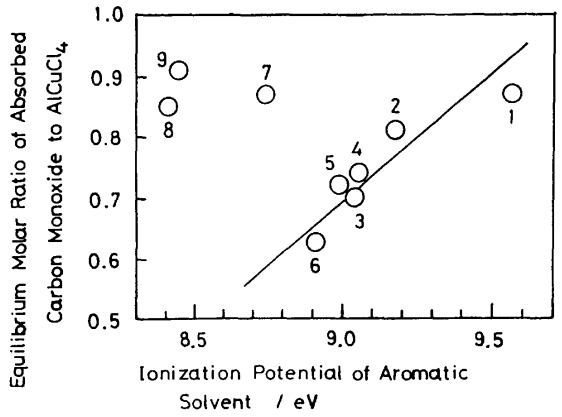

Fig. 1. Plot of equilibrium molar ratio of the absorbed carbon monoxide to $AlCuCl_4$ *vs.* ionization potential of aromatic solvent: benzene(1), toluene(2), *o*-xylene(3), *m*-xylene(4), *p*-xylene(5), 1,2,3,4-tetrahydronaphthalene (6), mesitylene (7), triethylbenzene(8), and 1,3,5-triisopropylbenzene(9).

for mesitylene, triethylbenzene, or triisopropylbenzene is much higher than the value estimated from the ionization potential alone. The molecular complex formation of these trisubstituted benzenes with aluminium copper(I) chloride in the absorbents is largely suppressed by steric hindrance, resulting in feasible ligand substitutions from the aromatic solvents to carbon monoxide. Thus, both electronic and steric factors are important in molecular-complex formation in the absorbents.

In the molecular complexes, the copper atoms, the electron-accepting centers in aluminium copper(I) chloride, are probably located on one of the six C–C bonds of the aromatic rings of the solvents. Under these circumstances, alkyl substitution at an aromatic carbon atom of the solvent molecule should hinder to a large extent the interactions of aluminium copper(I) chloride with aromatic rings at the two C–C bonds involving the substituted carbon. This is in accord with Fig. 1, which shows that the contributions of steric factors in the molecular-complex formation of trisubstituted benzenes with aluminium copper(I) chloride are larger than those for the benzenes with two, one, or no substituents. If the copper were located near the center of the aromatic ring, such large contributions of steric factors should not be observed. The proposed conformations of the molecular complexes in solutions are consistent with that of the $AlCuCl_4$–benzene complex in a solid.[7]

The above arguments are supported by the fact[8] that the equilibrium constants for the formation of molecular complexes of the silver ions with aromatic compounds, which involved silver ions located on one of the six C–C bonds of the aromatic rings,[9] were in the following order: xylenes>benzene≫mesitylene.

In conclusion, the capacities of the carbon-monoxide absorbents composed of aluminium copper(I) chloride and aromatic solvents are governed by both electronic and steric factors in the molecular-complex formation between aluminium copper(I) chloride and the aromatic compounds.

The Heats of Solution of Optically Active Amino Acids, the Corresponding Racemic Amino Acids, and Their Derivatives in Water

Masayuki MATSUMOTO† and Kazuo AMAYA*

National Chemical Laboratory for Industry, 1-1, Azuma, Yatabe-machi, Tsukuba, Ibaraki 305

(Received January 7, 1983)

Synopsis. The heats of solution of normal and branched α-amino acids and of their derivatives in water were measured at 298.15 K. The experimental results show that the racemates are more stable than optically active compounds, except for glycylleucine, and that the differences in the heat of solution between the two species for branched compounds are nearly constant, about 2 kJ mol^{-1}, while those for the normal compounds are dependent on the number of carbon atoms in the alkyl chains.

In the previous papers,[1,2] measurements of the heat of solution of optically active α-amino acids and their corresponding racemic compounds in water were made at 298.15 K, and that the differences in the heat of solution between the two species were appreciably larger than the heats of mixing of concentrated aqueous solutions of *d*- and *l*-isomers.

In the present work, in order to obtain further information on the difference in crystal-lattice energy between optically active amino acid and the corresponding racemic amino acid, and on that between amino acid derivatives, solution calorimetry was undertaken.

Experimental

The apparatus and procedure were the same as have been described in a previous work.[2] The alanylalanine, norvaline, and norleucine were purchased from the Sigma Chemical Company. The glycylleucine, α-amino butyric acid (ABA), *N*-formylvaline, *N*-acetylvaline, and *N*-acetylleucine were purchased from the Tokyo Kasei Company, and the other, reagents were purchased from the Takara Kohsan Company. All the samples used were the purest reagents commercially. available. The purities of the amino acid crystals were certified by the above makers and were guaranteed to be more than 98%.

The acylamino acids and dipeptides were kept in a freezer before use. The other materials were also dried as previously has been described, and then used without further purification.

Results and Discussion

At first, the measurements of the heat of solution were made at various concentrations in order to confirm the concentration dependence. No concentration dependence of the molar enthalpy of solution was found within the limits of error of measurement in the range from 10^{-3} to 10^{-2} mol kg^{-1}.

The results obtained are given in Tables 1 and 2, and they are plotted in Fig. 1 alone with two data of the previous paper.[2] The values obtained are the means of three determinations. The ΔH_s values of L-leucine and glycyl-L-leucine are in approximate agreement with those of Kresheck and Benjamin.[3] Also, the ΔH_s value of the A-form in DL-α-amino butyric acid is in good agreement with that of Abraham *et al.*[4] The difference in the ΔH_s of alanylalanine is about 1.5 times that of Alanine.

The experimental results show that the differences in ΔH_s between the two species for branched α-amino

acids are nearly constant, about 2 kJ mol.$^{-1}$ In addition by replacing the hydrogen atom of the amino group in amino acids with an acyl group, the differences in ΔH_s for the series of acylamino acids become small.

On the other hand, the differences in ΔH_s for the normal compounds are dependent on the number of carbon atoms, n, in the alkyl chains, and they increase with the n value as is shown in Fig. 1.

It seems that, for the normal alkyl chain amino acids, the contribution of the intramolecular configuration is included in the heat of solution, whereas such contribution for the branched compounds is not included. It is known that rotational isomers exist for DL-α-amino butyric acid and DL-norleucine.[5-9] Therefore, the contribution of the intramolecular configuration is assumed to be proportional to the number of carbon-carbon bonds. Accordingly, the dependency of $\Delta\Delta H_s$ on the carbon number in the alkyl chains can reasonably be explained.

Finally, a further thermodynamic study of polymorphic forms in DL-α-amino butyric acid and DL-norleucine is now in progress.

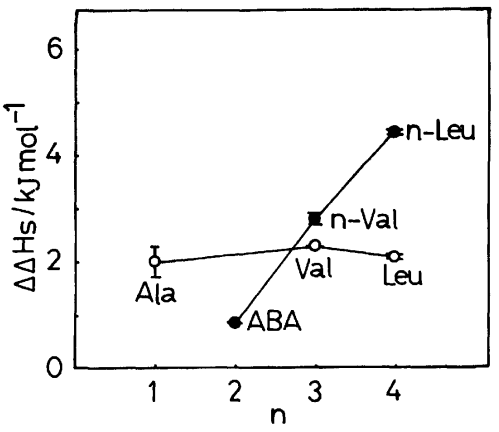

Fig. 1. The plots of the differences in the heat of solution against number of carbon atoms, n, in the alkyl chains of α-amino acids.

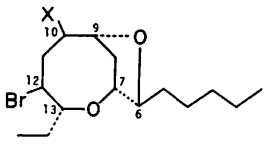
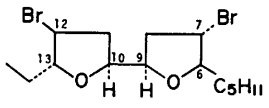
Synopsis. The main product of the bromination of hexahydrolaurefucin with sulfinyl bromide has been established as (10*R*)-10-bromo-10-deoxyhexahydrolaurefucin by X-ray crystal structure analysis.

In a previous paper, we reported that, when treated with silica gel, the dibromo compound **1** derived from hexahydrolaurefucin (**2**) was transformed into an isomerization product **3**.[1] Although the structure of **3** was recently elucidated,[2] that of **1** remained uncertain. Therefore, in order to confirm that no skeletal change occurred during the bromination of **2** and to establish the configuration of the bromine atom at the 10-position, we have now undertaken an X-ray crystal structure analysis of **1**.





1 : X=Br 2 : X=OH 3

Experimental

A colorless, single crystal with dimensions of about 0.3×0.4×0.4 mm³ was used for the X-ray measurement. The crystal data are as follows: $C_{15}H_{26}O_2Br_2$, mp 36—37 °C, mol wt 398.18, orthorhombic, space group $P2_12_12_1$, a=10.924(4), b=17.642(7), c=9.143(3) Å, Z=4, D_c=1.501 g cm^{-3}, μ(Cu $K\alpha$)=58.6 cm^{-1}. The cell dimensions and diffraction intensities were measured on a Rigaku four-circle diffractometer at the High Energy X-Ray Diffraction Laboratory of Hokkaido University, using graphite-monochromated Cu $K\alpha$ radiation (λ=1.54178 Å). The θ-2θ scan technique was applied at a θ scan rate of 4° min^{-1}; the background was measured for 5 s at each end of the scan range. Three standard reflections, measured at intervals or every 50 reflections, showed a gradual decrease in intensity with the course of data collection; the final-intensity/initial-intensity ratios were about 0.72—0.74. The intensities were corrected for this damage of the sample as well as for the Lorentz and polarization factors, but not for the absorption or the extinction effect. In the range of 2θ values up to 120°, 1354 independent structure factors above the $3\sigma(F)$ level were selected for the structure determination.

Structure Determination

The structure was solved by the Monte Carlo direct method,[3] using the 20 reflections with the greatest $|E|$ values as the starting set. The ninth-generated random phase set led to the correct solution; an E-map based on 459 phases revealed the locations of all the non-hydrogen atoms. After the structure had been well refined by the block-diagonal least-squares method with anisotropic temperature factors, the absolute configuration was determined by taking account of the anomalous dispersion of the bromine atoms for Cu $K\alpha$ radiation. The R ratio for the two enantiomeric structures, 1.022, rejected one of them at the 99.5% confidence level.[4] Since a difference Fourier map afforded the 10 hydrogen atoms attached to the rings, further least-squares refinements were carried out including the hydrogen atoms. For these refinements, the following weighting scheme was used:

$$w = 1/\{\sigma(F)^2 \exp(AX^2+BY^2+CXY+DX+EY)\},$$

where $X=|F_o|$ and $Y=\sin\theta/\lambda$. The A, B, C, D, and E coefficients were evaluated from the $(\Delta F)^2$ distribution; $A=-0.107\times10^{-5}$, $B=-4.06$, $C=-0.757\times10^{-2}$, $D=-0.488\times10^{-3}$, and $E=1.75$. The final R value was 0.069. The final atomic parameters are listed in Table 1.[5]

The calculations were performed on a HITAC M-200H computer at the Hokkaido University Computing Center, using our own programs. The atomic scattering factors were taken from the International Tables.[6]

Results and Discussion

The molecular structure of **1** including the absolute configuration is shown in Fig. 1. This absolute configuration (6*R*, 7*R*, 9*R*, 10*R*, 12*S*, 13*R*) corresponds to that which has been already assigned to laurefucin by X-ray

a) $B_{eq}=8\pi^2(u_1^2+u_2^2+u_3^2)/3$, where u_i is the root-mean-square deviation in the ith principal axis of the thermal ellipsoid.

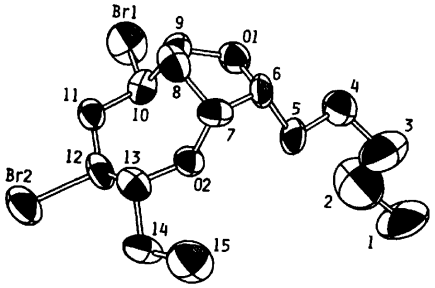

Fig. 1. A perspective view of the **1** molecule. Each non-hydrogen atom is represented as a thermal ellipsoid enclosing a 50% probability. The symbol C for carbon atoms is omitted.

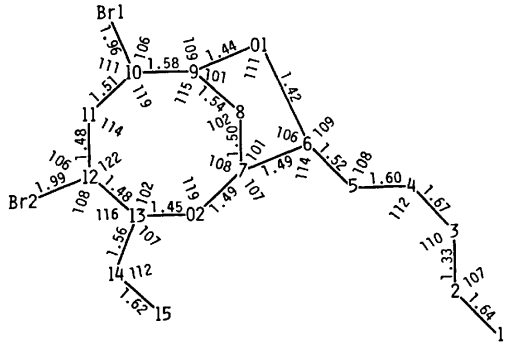

Fig. 2. The bond distances (l/Å) and angles (θ/°). The e.s.d.'s are 0.01—0.02 Å and 0.6—1.3° respectively.

methods.[1] Figure 1 demonstrates that **1** has the same skeleton as **2**, and that the Br(1) and Br(2) atoms are *cis* to each other. Thus, it has been confirmed that **2** undergoes no skeleton rearrangement during its bromination with sulfinyl bromide. It has also been revealed that this bromination proceeds with retention of the original configuration at the C(10) atom.

The bond distances and angles and the torsion angles are given in Figs. 2 and 3 respectively. If the standard deviations are considered, all the bond distances, except the C(1)–C(2), C(2)–C(3), and C(3)–C(4) distances, are normal. Of these three bond distances, the second is much shorter than the standard C–C single-bond distance, while the remaining two are considerably longer. Since the spectroscopic data show the absence of a C=C double bond in **1**, these abnormal bond distances may be due to a special and vigorous thermal

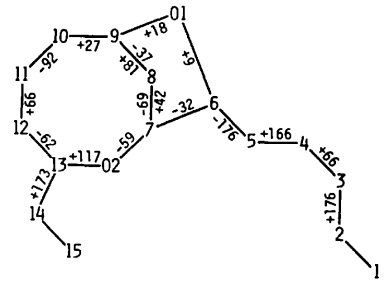

Fig. 3. The torsion angles (ϕ/°). The torsion angles relevant to atoms which form the same ring are given in the ring. The values given near the C(5)–C(6) and C(13)–C(14) bonds show the C(4)–C(5)–C(6)–C(7) and C(12)–C(13)–C(14)–C(15) torsion angles respectively.

motion or a disordering of the pentyl group. The eight-membered ether ring takes on a boat-chair conformation with an approximate mirror plane through the C(8) and C(12) atoms; the Br(1) and Br(2) atoms and the C(14)H_2–C(15)H_3 ethyl group are equatorially oriented, while the O(1) and C(6) atoms are axially placed. The five-membered ether ring adopts a conformation intermediate between the envelope form with an approximate mirror plane through the C(8) atom and the half-chair form with an approximate two-fold rotation axis through the O(1) atom. This deformation from the envelope form somewhat relieves the severe steric repulsion between the O(2) atom and the C(5)H_2 group; the O(2)···C(5) distance is 2.70(1) Å.

The molecules are held together mainly by the van der Waals interactions; there are no unusual intermolecular distances.

A New Apparatus for Surface Pressure Measurements

(Received March 23, 1983)

Synopsis. A new type of horizontal film balance is described. The principal features of the balance are the use of lightly paraffined silk threads without the conventional floating barrier of the Langmuir surface balance and of a strain gauge as the surface pressure detector.

For the measurement of surface pressures of insoluble monolayers at the air/water interface the Wilhelmy plate and the Langmuir float methods are generally used.[1] The Wilhelmy method has the advantage that no threads are required to close off the gaps at the end of the float used in the Langmuir method, but it has the drawback that contact angle changes can occur, particularly at high surface pressures. Our experience with the Wilhelmy method will be reported elsewhere, but we note here that it is particularly sensitive to inadequate control of temperature and relative humidity. Under appropriate conditions it may be used for micromanometry or higher pressure measurements, but cross-checking with the Langmuir method is generally required to rule out contact angle changes at the plate. Although the Langmuir float method does not suffer from the contact angle problem it requires considerable care. In particular, each of the threads between the float and the sides of the trough must be set up as an arc of a circle with the points of attachment to the float and side of the trough in a line at right angles to the side.[2] If the threads are mounted in other geometries spurious results are obtained.

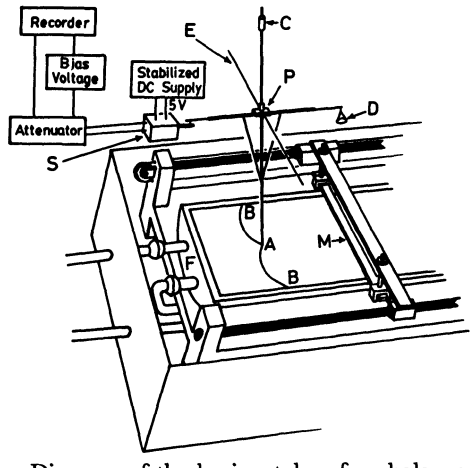

Fig. 1. Diagram of the horizontal surface balance. A is the end of the vertical arm of the frame; B, the edges of the trough; C, a counter weight; D, the calibrating pan; E, a torsion wire; P, a pivot; S, the strain gauge. The trough (F), is fitted with a glass tube for thermostatted water circulation and a driving system for the movable barrier (M) and is placed in a thermostatted box made of glass and aluminium plates. The ceiling of box is a glass plate which has a small hole for the vertical arm of the balance. The box and the balance are together installed in another thermostatted box.

The present paper describes a new apparatus adopting a strain gauge as a detector for the surface pressure and which replaces the conventional float and thread system to separate monolayer and clean surface with a simple arrangement of threads.

Figure 1 shows a schematic drawing of the surface balance. A frame made of thin stainless steel tubes (diameters 0.75 to 1.66 mm) is attached to a tungsten torsion wire (diameter 0.33 mm) with a pivot block made of aluminium. The tubes and the pivot are fixed together by spot welding. The total weight of the frame and the pivot is 4.6 g. The strain gauge (type UL-2-240, Shinko Communication Industry Co. Ltd., Zushi, Japan) is connected to the end of the horizontal arm of the frame *via* thin tungsten wire. The effect of temperature on the strain gauge output is within $\pm 0.1\%/°C$, and the total temperature effect on the calibration is *ca.* $0.2\%/°C$. The sensitivity of the strain gauge is such that surface pressures were measured down to 0.05 mN m^{-1}. This is an excellent value, though can not be compared with a sensitivity limit of 50 nN m^{-1} obtainable with the photoelectric detector described recently.[2]

The monolayer is confined between a movable hydrophobic barrier (M) and silk threads across the trough in place of the conventional float arrangement. The threads are 160 μm in diameter. A pair is knotted together, cut off in equal lengths and immersed briefly in a solution of purified paraffin[3] in distilled hexane. The threads are mounted to form to equal arcs with the vertical arm (A) in the knot and the two ends attached to the sides of the trough with paraffin wax such that the ends and knot are in a straight line at right angles to the sides of the dish. Depending on the studies intended, the dish may be of silica or Pyrex glass hydrophobed with dimethyldichlorosilane.[4] With a little experience, the hydrophobing of the thread can be judged to give excellent resistance to monolayer leakage while remaining soft and flexible to allow the threads to adopt a circular profile when a surface pressure is applied.

The use of threads without a float to confine a monolayer has been reported previously, notably by Guastalla[5] and Kim and Cannell.[6] These workers used unequal arcs of thread so arranged that the restraining arm experienced a force in a direction across the trough which was read on a torsion wire mounted in a direction along the trough. This force can be amplified by making one (short) thread in the form of a semi-circle and the other (long) in the form of a shallow arc. The geometry of the arrangement must be measured exactly to

†† Present address: Pulp and Paper Research Institute of Canada, Pointe Claire, Montreol, Quebec, Canada.

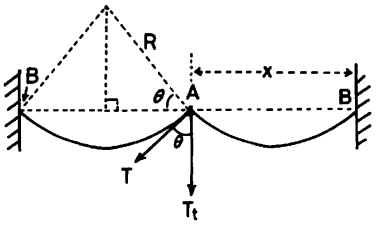

Fig. 2. Schematic drawing of the arc-shaped threads. A is the end of the arm of the frame; B, the edges of the trough; R, the radius of curvature of the threads; x, the distance A to B; T, the tension on the thread; T_t, the force on A along the direction of the trough and transverse to the torsion wire; θ, the angle between the direction of T and T_t.

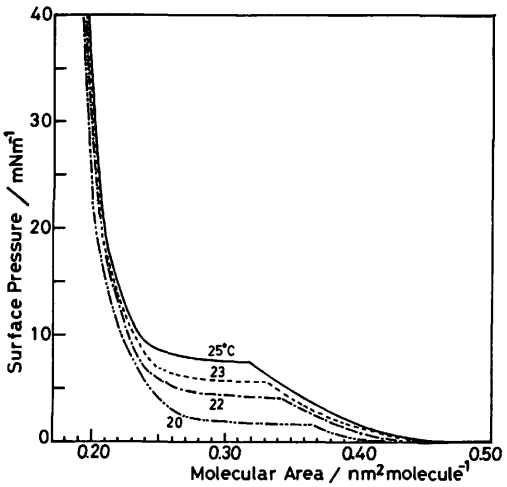

Fig. 3. Π-A diagrams for pentadecanoic acid on 0.01 mol dm^{-3} HCl at various temperatures.

convert the measured force to the surface pressure. With sensitive detectors, the use of these awkward geometried to obtain force amplification is unnecessary. The force may be read in the direction of the length of the trough and the geometry of the two equal threads used in our apparatus need not be known provided they adopt circular arc shapes with the length of each (l) conveniently in the middle of the range $\pi x > 2l > 2x$, where x is the half width of the trough and π is 3.14.

The force balance is shown in Fig. 2. For a given surface pressure Π, the tension in a flexible thread of radius of curvature R is given by the one-dimensional Laplace relation $T = \Pi R$. If each thread makes an angle θ to the direction along the trough, the force contribution in that direction (T_t) as read on the torsion balance is given by

$$T_t = 2T\cos\theta \quad (1)$$

and since $$x = 2R\cos\theta \quad (2)$$

we have $$\Pi = T_t/x. \quad (3)$$

The force read on the balance thus converts directly to surface pressure for all thread lengths in the required range. It will be obvious that if the threads are of unequal length, Eq. 3 may still be used provided that the ends and the arm (A) are again in a line at right angles to the sides of the trough. For lower pressures we have found that a single thread without a knot is convenient. The application of a surface pressure pushes the thread onto the arm, and it is sufficient to arrange the two sides approximately equal.

The surface balance was calibrated by suspending known weights from the horizontal arm of the system and measuring the voltage output of the strain gauge. The voltage output was found to be linear with applied force. Our experimental value for the surface pressure of an oleic acid (purity>99%) drop on the surface of 0.01 mol dm^{-3} HCl was good compared with that of Langmuir and Schaeffer.[7] Figure 3 shows typical Π-A diagrams for pentadecanoic acid on 0.01 mol dm^{-3} HCl; The diagrams are in agreement with reported[1] and our unpublished results which were obtained by using a conventional film balance with a float. The response of the new apparatus for a surface pressure change was superior to that of the float type film balance.

The observation of the time dependence of the surface pressure for pentadecancoic acid crystals sprinkled on the surface of 0.01 mol dm^{-3} HCl showed that the thread was resistant to film leakage at surface pressures up to 25 mN m^{-1} over a period of several days.

The authors wish to express their thanks to Miss Nobuko Maehara and Mr. Yoshihide Kaneko for their experimental assistances. The work was partially supported by a Grant-in-Aid from the National Science Foundation.

Synopsis. The IR spectra of nitrosyl(protoporphyrin IX dimethyl ester)iron(II) [Fe(ppdme)(NO)] complexes with various nitrogenous bases (B), such as imidazoles, pyridines, cyclic secondary amines, and aliphatic amines, were measured in benzene and 1,2-dichloroethane. The NO stretching frequencies (ν_{NO}) of these complexes and the equilibrium constants in equilibrium, [Fe(ppdme)(NO)]+B⇌[Fe(ppdme)-(NO)B], decreased and increased respectively with an increase in the basicity, $pK_a(BH^+)$, of the bases. These results are discussed in relation to the σ- and π-bonding abilities of the bases.

The investigation of (nitrosyl)(porphyrinato)iron(II) complexes as model systems for nitrosylhemoproteins have played an important role in the identification of an axial ligand *trans* to the nitrosyl group of various nitrosylhemoproteins and the elucidation of the stereochemistry of the heme environment.[1-7]

During the course of this investigation of the model complexes,[1] it has been found that the EPR and IR parameters of the (nitrosyl)(porphyrinato)iron(II) complexes are very sensitive to changes in the *trans* axial base and the solvent. The present work will report on an IR study of the system with [Fe(ppdme)-(NO)] and nitrogenous bases, such as imidazoles, pyridines, cyclic secondary amines, and aliphatic amines, in benzene and 1,2-dichloroethane.

A five-coordinate [Fe(ppdme)(NO)] reacts with a base in a solution to form a six-coordinate [Fe(ppdme)-(NO)B] according to Eq. 1:

$$[\mathrm{Fe(ppdme)(NO)}] + \mathrm{B} \overset{K}{\rightleftharpoons} [\mathrm{Fe(ppdme)(NO)B}], \quad (1)$$

Therefore, in the IR spectra of the solution, two NO bands of five- and six-coordinate species are revealed at different frequencies. It has been demonstrated that the ν_{NO} values and the equilibrium constant of Eq. 1 are markedly sensitive to the polarity and the hydrogen-bonding ability of the solvent.[1f] Accordingly, the essential differences in the *trans* effect of an axial base can be detected only in IR spectral results in the same solvent.
