Paper Electrophoresis. This was carried out under the following conditions: paper, Toyo Roshi No. 51A chromatography paper; solvent, pyridine–acetic acid–water (10 : 0.4 : 90, v/v) (pH 6.4); voltage gradient, 15 V/cm; charge period, 2.5 h. Electrophoretic mobilities were recorded as R_{Arg}, the ratio of the distance the compounds moved to that which a standard arginine spot moved on the same electrophoreogram. The compounds (**1**, **2**, and **3**) migrated toward the cathode and revealed a single spot by spraying Sakaguchi reagent; ninhydrin gave the same result. The R_{Arg} value of each compound was 0.72.

CD Measurements. This was performed with a JASCO J-20 A. A cell of path length 0.2 mm was used. Patterns in water are shown in Fig. 2.

Sensory Test. Taste of the peptides was organoleptically determined by panel evaluation employing four people. A series of solutions of decreasing concentration, each half as strong as the proceeding one, were prepared. Before tasting the sample, the mouth was thoroughly rinsed with deionized water. The sample solution was held in the mouth for *ca.* 10 s and then spit out and the threshold value was determined. The results are listed in the Table.

The authors wish to express their thanks to Associate Professor Michio Kondo of Saga University for the CD measurements. Thanks are also due to Dr. Shinji Okumura of Ajinomoto Co., Inc., for supplying some amino acids.

Reaction of Secondary Aromatic Amines with Manganese(III) Acetate

Hiroshi Nishino* and Kazu Kurosawa
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
(Received November 18, 1982)

The reaction of 2-(methylamino)benzophenone with manganese(III) acetate afforded 5-[(*o*-benzoylanilino)-methyl]-2-(methylamino)benzophenone, 2-aminobenzophenone, 5-formyl-2-(methylamino)benzophenone, 2-amino-5-[(*o*-benzoylanilino)methyl]benzophenone, 2-formamidobenzophenone, 2-amino-5-formylbenzophenone, and 2-(*N*-methylformamido)benzophenone. It was found that the reaction did not cause oxidative cyclization, but dimerization and conversion of *N*-methyl into *N*-formyl groups. Characterization of the products, the detailed oxidation mechanism, and the effects of the additives are discussed.

It is well known that oxidation of amino compounds with metal salts such as Hg(II), Cu(II), Co(III), Pb(IV), Ce(IV), *etc.* causes metal complex formation, *N*-acylation, *N*-dealkylation, *N,N*-coupling, and cyclization reactions. However, reaction of these compounds with manganese(III) acetate has been scarcely investigated except for the oxidation of *N,N*-dialkylarylamines.[1-3] In connection with our studies on the reaction of manganese(III) acetate with various organic substrates, we decided to investigate in detail the reaction of amino compounds, especially primary and secondary amines, with manganese(III) acetate in acetic acid.

We have previously reported that reaction of some phenolic compounds having an unsaturated side chain or aroyl group with manganese(III) acetate gave cyclic ethers in moderate yields.[4-9] We were interested in the reaction of analogous amines which may give cyclic amines because amino groups have reactivities similar to those of hydroxyl groups. We employed 2-(methylamino)benzophenone (**1**) as an amino compound whose amino group was located in a position suitable for forming a nitrogen containing six membered ring. As the result it was observed that this compound did not undergo the intramolecular oxidative cyclization, but was oxidized to give formamides in higher oxidant/substrate ratio, and dimeric compounds in lower oxidant/substrate ratio which were readily hydrolyzed to yield benzaldehydes and amines. We will describe in the present paper the detailed oxidation mechanism for the secondary amine (**1**), the effect of additives, and the synthetic application of the conversion of *N*-methyl into *N*-formyl group.

Results and Discussion

The 2-(methylamino)benzophenone (**1**) was oxidized with from one-half to eight molar equivalents of manganese(III) acetate in acetic acid at 100 °C or reflux temperature and the products were separated by TLC. The reaction conditions and the yields are summarized in Table 1.

Oxidation of **1** with one-half or one molar equivalent of manganese(III) acetate gave 5-[(*o*-benzoylanilino)-methyl]-2-(methylamino)benzophenone (**2**), 2-aminobenzophenone (**3**), and 5-formyl-2-(methylamino)benzophenone (**4**) (Table 1, Entries 1 and 2). The mass spectrum of **2** showed a parent ion peak at *m/e* 420, indicating that this product was a dimeric compound. Its NMR spectrum revealed two doublets at δ=2.88 (3H, J=4.8 Hz) and 4.26 (2H, J=4.8 Hz) for a methyl and a methylene group both coupled with an amino hydrogen, a multiplet at δ=6.34—7.66 for seventeen aromatic protons, and a broad quartet and

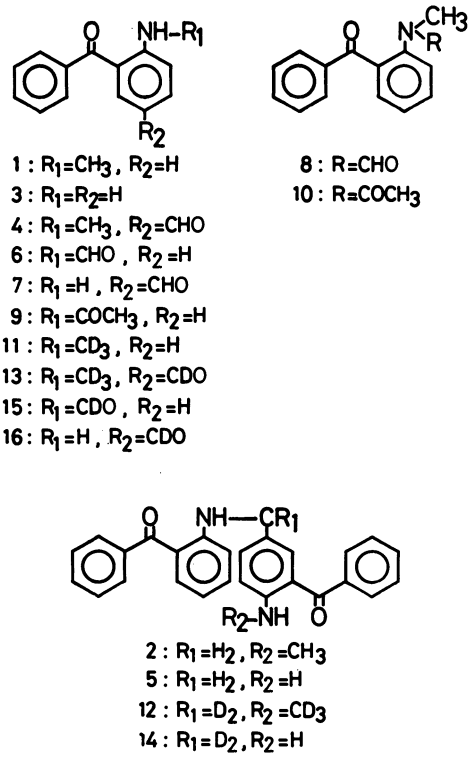

Fig. 1. 2-(Methylamino)benzophenones (**1** and **11**) and the oxidation products (**2**—**10** and **12**—**16**).

triplet at δ=8.43 (1H, J=4.8 Hz) and 8.74 (1H, J=4.8 Hz) for amino groups. The IR spectrum indicated a strong carbonyl absorption band at 1625 cm^{-1} and a broad weak absorption band at 3200—3400 cm^{-1} due to amino groups. Therefore, this spectroscopic evidence supported the structure of 5-[(*o*-benzoylanilino)methyl]-2-(methylamino)benzophenone. The product **3** was identical with an authentic sample. The NMR spectrum of **4** showed the presence of a formyl group at δ=9.61 (1H, s), and an ABX pattern of the aromatic protons at δ=6.82 (1H, d, J=9.0 Hz), 7.88 (1H, dd, J=9.0 and 1.8 Hz), and 7.94 (1H, d, J=1.8 Hz), besides a methylamino group and a phenyl group. The IR spectrum of **4** showed absorption bands at 1615, 1695, and 3300—3500 cm^{-1} due to two carbonyls, and an amino group. Accordingly, the structure of **4** was considered to be 5-formyl-2-(methylamino)benzophenone.

The compound **1** was oxidized with two molar equivalents of manganese(III) acetate to yield **2**, **3**, **4**, 2-amino-5-[(*o*-benzoylanilino)methyl]benzophenone (**5**), 2-formamidobenzophenone (**6**), and 2-amino-5-formylbenzophenone (**7**) (Table 1, Entry 3). The NMR spectrum of **5** was similar to that of **2** except for the absence of a methyl group and the appearance of a primary amino group instead of a secondary amino group. Since the molecular ion peak showed at m/e 406 in its mass spectrum, this product was deduced to be 2-amino-5-[(*o*-benzoylanilino)methyl]benzophenone which was formed by the *N*-demethylation of **2**. In the IR spectrum of **6** two carbonyls and a broad amino absorption appeared at 1640, 1710, and 3100—3600 cm^{-1}. The NMR spectrum of **6** revealed the presence of a formamido group at δ=8.40 (1H, br. s, CHO) and 10.60 (1H, br. s, –NH–). In addition, **6** was hydrolyzed with dil H_2SO_4 at reflux temperature to afford **3** (89%). Therefore, the structure of **6** was confirmed to be 2-formamidobenzophenone. The NMR spectrum of **7** which was an isomer of **6** was analogous to that of **4**, although an amino group was present instead of a methylamino group. Accordingly the structure of **7** was considered to be 2-amino-5-formylbenzophenone which is compatible both with the IR and mass spectra.

Using from four to eight molar equivalents of manganese(III) acetate, four products were obtained; these were determined to be **3**, **6**, **7**, and 2-(*N*-methylformamido)benzophenone (**8**) (Table 1, Entries 5, 7, and 8). The product (**8**) was obtained as pale yellow crystals, mp 96 °C. It showed a parent ion peak at m/e 239 in the mass spectrum, and a strong IR absorption band at 1695 cm^{-1} in chloroform. The NMR spectrum showed the presence of a methyl group (δ=3.00) and a formyl group (δ=8.10). However, the IR and NMR spectra revealed the absence of an amino hydrogen. Accordingly, this evidence suggested that the structure was 2-(*N*-methylformamido)benzophenone.

When **1** was oxidized using six molar equivalents of manganese(III) acetate at reflux temperature, **6** was obtained in the highest yield (65%) for this oxidation reaction. Since in higher oxidant/substrate ratio other products were formed only in small amounts, this reaction may be a useful method for the conversion of *N*-methyl into *N*-formyl compounds.

We then investigated how additions of formaldehyde,[1] acetic anhydride,[10] and/or water[11] influence the product distribution. Addition of formaldehyde to the reaction mixture increased the yield of the *N*-methylformamide (**8**) five times, while the yield of the formamide **6** was not changed (Table 1, Entry 9). When four molar equivalents of acetic anhydride were added, formation of the formamide (**6**) was completely inhibited and acetamides (**9** and **10**) were newly produced; these were identical with compounds obtained by an alternative synthesis (Table 1, Entry 10). The formation of **9** was explained in terms of oxidative *N*-demethylation of tertiary aromatic amines.[2,3,12,13] The product yields

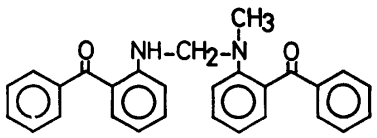
were not appreciably changed by addition of water (3 equiv.) except for **3** (Table 1, Entry 11).

In order to elucidate the reaction mechanism, we prepared and oxidized deuterated 2-(methyl-d_3-amino)-benzophenone (**11**). The reaction conditions and the yields are shown in Table 2.

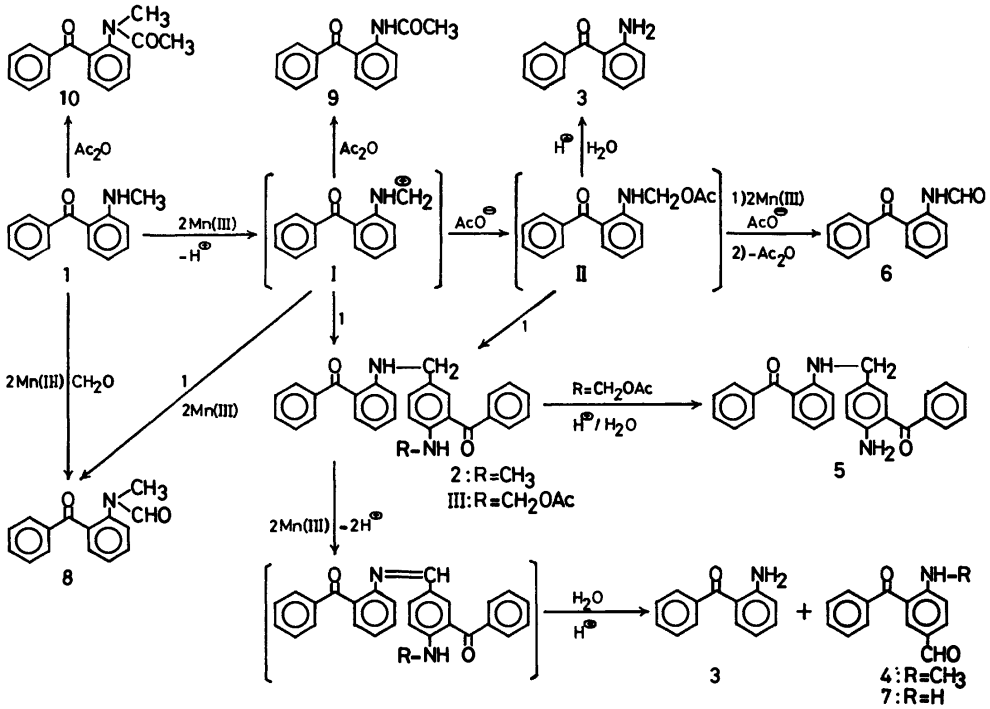
When **11** was oxidized with two molar equivalents of manganese(III) acetate in acetic acid at 100 °C, **3**, 5-[(*o*-benzoylanilino)methyl-d_2]-2-(methyl-d_3-amino)-benzophenone (**12**), 5-(formyl-*d*)-2-(methyl-d_3-amino)-benzophenone (**13**), 2-amino-5-[(*o*-benzoylanilino)methyl-d_2]benzophenone (**14**), 2-(formyl-*d*-amino)benzophenone (**14**), 2-(formyl-*d*-amino)benzophenone (**15**), and 2-amino-5-(formyl-*d*)benzophenone (**16**) were obtained. This experiment proved that the formyl group of the products, **13** and **16**, must come from the *N*-methyl group. Therefore, it suggests that the precursors of the benzaldehydes **4** or **7** must be the dimeric compound **2** or **5**, respectively. Manganese(III) acetate oxidation was then carried out for **2** and **5**, to confirm the above facts. These oxidations gave the corresponding benzaldehydes (**4** and **7**) and amine (**3**) in good yields as expected (Table 3, Entries 1, 2, and 9). The product (**4**) was also oxidized by manganese(III) acetate to **7** by the oxidative *N*-demethylation (Table 3, Entries 5 and 6).

It was thought that the dimeric compound (**5**) might



IV

Fig. 2. Dimeric intermediate (**IV**).



Scheme 1. Oxidation mechanism of 2-(methylamino)benzophenone (**1**) by manganese(III) acetate.

be formed by reaction between the intermediate carbenium cation (**I**) (formed by the oxidation of **1** with manganese(III) acetate) and the amine (**3**), presumably generated by the oxidative *N*-demethylation of **1**. However, oxidation of a 1 : 1 mixture of **1** and **3** under the above conditions gave **5** (Table 3, Entries 3 and 4) in a yield similar to that in the reaction of **1** alone (Table 1, Entry 3). This suggests that primary amines did not exist in the reaction mixture, but were formed during the work-up. We suggest that 2-(acetoxymethylamino)benzophenone (**II**) was produced from the carbenium ion (**I**) by the attack of an acetate ion. It reacted with **I** to give the dimeric compound (**III**), which was hydrolyzed to yield **5** and/or further oxidized to afford **3** and **7** during the work-up.

Reaction of the primary amine (**3**) with manganese(III) acetate gave 2-acetamidobenzophenone (**9**) as the only isolable reaction product (Table 3, Entries 7 and 8).

The mechanism for the formation of the formamide (**6**) can be explained by assuming that the intermediate (**II**) was further oxidized to **6**, since the deuterated isomer (**15**) was obtained from the oxidation of **11** and the yield of **6** was scarcely changed on oxidation of **1** under nitrogen atmosphere (Table 1, Entries 4 and 6). Formation of *N*-methylformamide (**8**), however, might be due to the reaction of **1** with formaldehyde which was produced in the reaction (**II**→**6**), since the yield of **8** was increased by the addition of formaldehyde to the reaction mixture. Alternatively, the intermediate carbenium cation (**I**) might react with the amino group of **1** to give **8** *via* an analogous dimeric intermediate (**IV**). In either event these alternative pathways could not be distinguished. The above reaction mechanism is outlined in Scheme 1.

It is characteristic of this reaction that the use of lower oxidant/substrate ratio induces dimerization, leading to aldehydes and amines. On the other hand, conversion of *N*-methyl into *N*-formyl compounds occurs preferentially at higher oxidant/substrate ratios. By contrast, however, it was found that oxidation of aromatic secondary amines with lead(IV) acetate in chloroform caused *N*-dealkylation and nuclear acetoxylation.[14] The conversion of *N*-methyl into *N*-formyl group by means of manganese(III) acetate can be useful in organic synthesis.

Experimental

Measurements. The IR spectra were measured on a JASCO IRA-1 grating spectrometer. The ^{1}H-NMR spectra were recorded on a Hitachi Perkin-Elmer R-24 spectrometer (60 MHz) with tetramethylsilane as an internal standard; the chemical shifts are reported in δ values. The mass spectra were obtained with a JEOL JMS-DX300 mass spectrometer. The HPLC analyses were performed on an ALTEX model 330/110A/153 isocratic liquid chromatograph equipped with a HY-ODS-5U column, eluting with methanol or 70% aqueous methanol. The melting points were taken on a Yanagimoto micromelting point apparatus and are uncorrected.

Preparation of the Materials. 2-(Methylamino)benzophenone (**1**) was synthesized by the methylation of 2-aminobenzophenone which was obtained from the commercial sample of Wako Pure Chemical Industries, Ltd. The 2-aminobenzophenone (10 mmol) was heated under reflux for 12 h with dimethyl sulfate (15 mmol) in dry acetone (50 ml) containing anhydrous potassium carbonate (2 g). The solvent was removed *in vacuo* and the residue was triturated with water. The aqueous reaction mixture was extracted with chloroform, followed by column chromatography on silica gel (Wakogel C-100) using chloroform as eluent to give **1** (55%); yellow needles (from hexane), mp 68.5 °C (lit,[15] mp 69 °C); IR ($CHCl_3$) 1620 (C=O) and 3250—3400 cm^{-1} (NH); NMR ($CDCl_3$) δ=2.91 (3H, s, CH_3), 6.34—7.69 (9H, m, aromatic), 8.47 (1H, br. s, NH). Found: C, 79.41; H, 6.18; N, 6.41%. Calcd for $C_{14}H_{13}ON$: C, 79.59; H, 6.20; N, 6.63%.

2-(Methyl-d_3-amino)benzophenone (**11**) was also obtained from the same methylation of the 2-aminobenzophenone with dimethyl-d_6 sulfate which was available from E. Merck AG.; 43%; yellow needles (from hexane), mp 69.0—69.5 °C; IR ($CHCl_3$) 1620 (C=O) and 3250—3600 cm^{-1} (NH); NMR ($CDCl_3$) δ=6.32—7.72 (9H, m, aromatic), and 8.48 (1H, br. s, NH). Found: C, 78.46; H+D/2, 6.19; N, 6.51%. Calcd for $C_{14}H_{10}D_3ON$: C, 78.47; H+D/2, 6.11; N, 6.54%.

*Oxidation of **1** and **11**.* The compound **1** (1 mmol) was dissolved in acetic acid (25 ml) and suitable amounts of manganese(III) acetate dihydrate[16] were added. The mixture was heated on a water bath until the brown color of Mn(III) ion disappeared (see Table 1). The solvent was removed *in vacuo* and the residue was triturated with 2 M (1 M = 1 mol dm^{-3}) hydrochloric acid (25 ml), followed by extraction with chloroform. The products were separated on TLC (Wakogel B-10) with chloroform as the developing solvent, and simultaneously tested by HPLC. The deuterated compound **11** (1 mmol) was also oxidized by the procedure described above. It was found that substantial quantities of unidentified tarry materials were formed in both reaction mixture besides the isolated products.

*Oxidation Products of **1**.* *5-[(o-Benzoylanilino)methyl]-2-(methylamino)benzophenone (**2**)*: Yellow liquid; IR ($CHCl_3$) 1625 (C=O) and 3200—3400 cm^{-1} (NH); NMR ($CDCl_3$) δ=2.88 (3H, d, J=4.8 Hz, CH_3), 4.26 (2H, d, J=4.8 Hz, $-CH_2-$), 6.34—7.66 (17H, m, aromatic), 8.43 (1H, q, J=4.8 Hz, –NH–), and 8.74 (1H, t, J=4.8 Hz, –NH–); MS *m/e* (rel intensity), 420 (M^+, 22), 405 (4), 239 (3), 224 (100), 196 (6), 180 (2), 146 (5), 132 (2), 118 (3), 105 (10), 91 (9), and 77 (23). Oxidation Products of 11. *5-[(o-Benzoylanilino)methyl-d_2]-2-(Methyl-d_3-amino)benzophenone (12)*: Yellow liquid; IR ($CHCl_3$) 1625 (C=O) and 3200—3600 cm^{-1} (NH); NMR ($CDCl_3$) δ=6.36—7.61 (17H, m, aromatic), 8.41 (1H, br. s, –NH–), and 8.74 (1H, br. s, –NH–); MS *m/e* (rel intensity), 425 (M^+, 20), 229 (100), 151 (20), 105 (22), and 77 (45).

5-(Formyl-d)-2-(methyl-d_3-amino)benzophenone (13): Yellow needles (from hexane), mp 136 °C; IR ($CHCl_3$) 1610 and 1675 (C=O), and 3150—3600 cm^{-1} (NH); NMR ($CDCl_3$) δ=6.83 (1H, d, J=9.0 Hz, $H_{(3)}$), 7.25—7.68 (5H, m, aromatic), 7.88 (1H, dd, J=9.0 and 1.8 Hz, $H_{(4)}$), 7.94 (1H, d, J=1.8 Hz, $H_{(6)}$), and 9.18 (1H, br. s, –NH–); MS *m/e* (rel intensity), 243, (M^+, 100), 197 (20), 166 (26), 105 (27), and 77 (90).

2-Amino-5-[(o-benzoylanilino)methyl-d_2]benzophenone (14): Yellow liquid; IR ($CHCl_3$) 1625 (C=O) and 3340—3500 cm^{-1} (NH); NMR ($CDCl_3$) δ=6.05 (2H, br. s, NH_2), 6.41—7.69 (17H, m, aromatic), and 8.79 (1H, br. s, –NH–); MS *m/e* (rel intensity), 408 (M^+, 12), 212 (36), 167 (10), 105 (43), and 77 (100).

2-(Formyl-d-amino)benzophenone (15): Pale yellow liquid; IR ($CHCl_3$) 1645 and 1680 (C=O), and 3100—3650 cm^{-1} (NH); NMR ($CDCl_3$) δ=6.93—8.71 (9H, m, aromatic), and 10.61 (1H, br. s, –NH–); MS *m/e* (rel intensity), 226 (M^+, 20), 197 (100), 167 (10), 121 (27), and 77 (78).

2-Amino-5-(formyl-d)benzophenone (16): Pale yellow needles (from benzene/hexane), mp 132—133 °C; IR ($CHCl_3$) 1610 and 1690 (C=O), and 3320—3490 cm^{-1} (NH); NMR ($CDCl_3$) δ=6.77 (1H, d, J=9.0 Hz, $H_{(3)}$), 6.95 (2H, br. s, NH_2), 7.22—7.69 (5H, m, aromatic), 7.78 (1H, dd, J=9.0 and 1.8 Hz, $H_{(4)}$), and 7.94 (1H, d, J=1.8 Hz, $H_{(6)}$); MS *m/e* (rel intensity), 226 (M^+, 25), 149 (15), 105 (30), and 77 (100).

Oxidation of a Mixture of 1 and Formaldehyde. The compound **1** (1 mmol) was dissolved in acetic acid (25 ml), and aqueous formaldehyde (37%, 1 mmol) and manganese(III) acetate (2 mmol) were added to it. The mixture was heated at 100 °C for 6 min, followed by treatment in a manner similar to that described above, which gave **2** (2%), **3** (8%), **4** (6%), **5** (2%), **6** (4%), **7** (2%), and **8** (24%).

Oxidation of 1 in Acetic Acid Containing Acetic Anhydride. A mixture of **1** (1 mmol), acetic anhydride (4 mmol), and manganese(III) acetate (2 mmol) were heated at 100 °C for 7 min in acetic acid (25 ml). This oxidation gave **2** (1%), **3** (5%), **4** (6%), **8** (5%), **9** (52%), and **10** (6%).

2-Acetamidobenzophenone (9): Colorless crystals (from hexane), mp 88.0—88.5 °C (lit,[18] mp 88 °C); IR ($CHCl_3$) 1640 and 1710 (C=O), and 3100—3650 cm^{-1} (NH); NMR ($CDCl_3$) δ=2.17 (3H, s, $COCH_3$), 6.88—8.67 (9H, m, aromatic), and 10.74 (1H, br. s, –NH–); MS *m/e* (rel intensity), 239 (M^+, 30), 196 (100), 134 (13), 120 (28), 105 (15), 92 (24), and 77 (55).

2-(N-Methylacetamido)benzophenone (10): Colorless needles (from hexane), mp 80—81 °C; IR ($CHCl_3$) 1650 and 1680 cm^{-1} (C=O); NMR ($CDCl_3$) δ=1.84 (3H, s, $COCH_3$), 3.04 (3H, s, CH_3), and 7.20—7.84 (9H, m, aromatic); MS *m/e* (rel intensity), 253 (M^+, 10), 210 (86), 194 (48), 148 (100), 105 (8), and 77 (20). Found: *m/e* 253.10693. Calcd for $C_{16}H_{15}O_2N$: M, 253.11028.

Acetylation of 1 and 3: The compound **1** (33.3 mg) and acetic anhydride (0.1 ml) were heated at 100 °C for 6 h in pyridine (5 ml) to yield **10** (39.9 mg, 99%). The product **3** (1 mmol) was treated with acetic anhydride (1.5 mmol) in pyridine (5 ml) overnight to give **9** (99%).

Oxidation of a Mixture of 1, Formaldehyde, and Acetic Anhydride. A mixture of **1** (1 mmol), aqueous formaldehyde (37%, 1 mmol), acetic anhydride (3 mmol), and manganese(III) acetate (2 mmol) were heated on a water bath for 6 min in acetic acid (25 ml) to afford **2** (trace), **3** (8%), **4** (6%), **8** (25%), **9** (25%), and **10** (8%).

Oixdation of a Mixture of 1 and Water. The compound **1** (1 mmol), water (3 mmol), and manganese (III) acetate (2 mmol) were heated in acetic acid (25 ml) at 100 °C for 7 min to give **2** (1%), **3** (24%), **4** (5%), **6** (6%), **7** (3%), and **8** (5%).

Oxidation of 2. The product **2** (54.7 mg) was heated at 100 °C for 4 min with manganese(III) acetate (36.5 mg) in acetic acid (5 ml) to yield **3** (15.1 mg, 59%), **4** (16.1 mg, 52%), and **7** (1.7 mg, 6%) which was determined by HPLC.

Oxidation of 3. A mixture of **3** (1 mmol) and manganese(III) acetate (2 mmol) was heated in acetic acid (25 ml) at 100 °C for 15 min. The reaction mixture was treated in a manner similar to that described above to give intractable tarry materials and **9** (5%) as the only isolable reaction product.

Oxidation of 4. A mixture of **4** (31.3 mg) and manganese(III) acetate (76.7 mg) was heated in acetic acid (5 ml) at 100 °C for 6 min to yield **7** (10.2 mg, 35%) and unidentified products (10.2 mg).

Oxidation of 5. A mixture of **5** (32.9 mg) and manganese(III) acetate (45.0 mg) was heated in acetic acid (5 ml) at 100 °C for 5 min to give **3** (12.3 mg, 77%) and **7** (15.3 mg, 84%).

Oxidation of a Mixture of 1 and 3. A mixture of **1** (0.5 mmol) and **3** (0.5 mmol) was dissolved in acetic acid (25 ml) and the mixture was oxidized with manganese(III) acetate (1 mmol) to give **2** (9%), **4** (1%), **5** (7%), and **7** (8%).

Hydrolysis of 6. The product **6** (17.5 mg) was heated under reflux for 1 h in dil H_2SO_4 (5 ml), which was extracted with chloroform, followed by recrystallization from hexane to give **3** (13.7 mg, 89%).

The authors wish to thank Mr. Masanori Tsumura of the Ichikawa Chemical Co. Ltd., Higashi Osaka, for his measurements of the MS spectra, and also wish to thank Dr. John F. W. McOmie of Bristol University, England, for his helpful discussion and for reading the manuscript.

(Received December 4, 1982)

Reactions of 2-methylene-3-phenacylbenzothiazoline and 3-benzyl-2-methylenebenzothiazoline, generated *in situ* from the corresponding 2-methylbenzothiazolium bromide and triethylamine, with methylenecyclopropenes gave a variety of products, cross-conjugated systems, spiro-cyclopentafurans and/or cyclopentabenzothiazines, depending on the nature of substituents of the methylenecyclopropenes. The reaction pathways for the formation of products are also described.

It is known that dehydrohalogenation of 3-phenacylthiazolium halide systems generates the corresponding thiazolium *N*-phenacylides whose synthetic utility as 1,3-dipoles has been established in a few recent reports.[1-6] On the treatment with triethylamine (NEt_3), however, 2-methyl-3-phenacylbenzothiazolium bromide does not yield the *N*-phenacylide but generates 2-methylene-3-phenacylbenzothiazoline which was first confirmed by the formation of Michael adducts to electron-deficient olefins and acetylenes.[7] The methylenebenzothiazoline has an electron-rich exocyclic C=C bond and is classified as a cyclic ketene acetal.

Although the reactions between enamines and methylenecyclopropenes have been extensively investigated[8] and known to give different types of products depending on the nature of substituents at the 4-position of methylenecyclopropenes,[9] few examples for the reaction of a ketene acetal, which is expected to show reaction patterns similar to those of enamines, with methylenecyclopropenes have been reported up to date.[10,11]

This paper describes the reactions of 2-methylene-3-phenacyl- (**3**) and 3-benzyl-2-methylenebenzothiazoline (**4**),[12] generated in situ from 2-methyl-3-phenacyl- (**1**) and 3-benzyl-2-methylbenzothiazolium bromide (**2**), and NEt_3 at 0 °C respectively, with methylenecyclopropenes having electron-withdrawing substituents at the 4-position: Different types of products were found to be formed depending on the nature of the substituents of methylenecyclopropenes.

Results and Discussion

Reactions with 2-(2,3-Diphenyl-2-cyclopropenylidene)propanedinitrile (5) and Ethyl 2-Cyano-2-(2,3-diphenyl-2-cyclopropenylidene)acetate (6). The reaction of 2-methylenebenzothiazoline **3** with the methylenecyclopropene **5** in dry chloroform at room temperature for 3 h gave a deeply colored 1 : 1 adduct **7** in 95% yield.[13] On the basis of spectral data (Table 1), the 1 : 1 adduct **7** was identified as a cross-conjugated system, 2-(2-dicyanomethylene-1,3-diphenyl-3-butenylidene)-3-phenacylbenzothiazoline. In the ^1H NMR spectrum terminal olefinic protons (2H) are observed, and the ^{13}C NMR spectrum exhibits no sp^3-carbon except for that in the phenacyl group but signals assinable to the olefinic carbons, $=\mathbf{C}(CN)_2$ and $=\mathbf{C}H_2$. The absorption maximum at a long wave region in the electronic spectrum indicates the presence of relatively long conjugation.

Similarly, 2-methylene benzothiazoline **4** reacted with **5** to afford the corresponding cross-conjugated system **8**, whose structure was identified on the basis of spectral data, in an excellent yield. Thus, it can be thought that the behaviour of the methylenebenzothiazolines **3** and **4** toward the methylenecyclopropene **5** is similar to that of enamines.[14]

Scheme 1.

Few examples for the reaction of an enamine with the methylenecyclopropene **6** have been reported.[15] 2-Methylenebenzothiazolines **3** and **4** reacted with **6** in dry THF at room temperature for 1 h to give corresponding cross-conjugated systems **9** and **10** in good yields (Scheme 1). Structural elucidation of **9** and **10** was again accomplished on the basis of spectral data.

The yields, physical and spectral data of cross-conjugated system **7**—**10** are listed in Table 1.

Reactions with 2-Benzoyl-2-(2,3-diphenyl-2-cyclopropenylidene)-2,4-pentanedione (12). It has been well established that enamines react with methylenecyclopropenes having an acyl group at the 4-position to produce the corresponding 6,6a-dihydro-5*H*-cyclopenta[*b*]furans.[16] In order to compare with the reaction of enamines, the reactions of 2-methylenebenzothiazolines, **3** and **4**, with methylenecyclopropenes, **11** and **12**, having an acyl group at the 4-position were investigated.

The benzoyl-substituted methylenecyclopropene **11** was found to be less reactive than the above methylenecyclopropenes **5** and **6**, being recovered in the reaction with **3** and **4** at room temperature. When the reaction of **3** and **4** with **11** was performed in dry THF under reflux, however, the corresponding 1 : 1 adducts **13** and **14** were obtained in 36 and 46% yields, respectively.

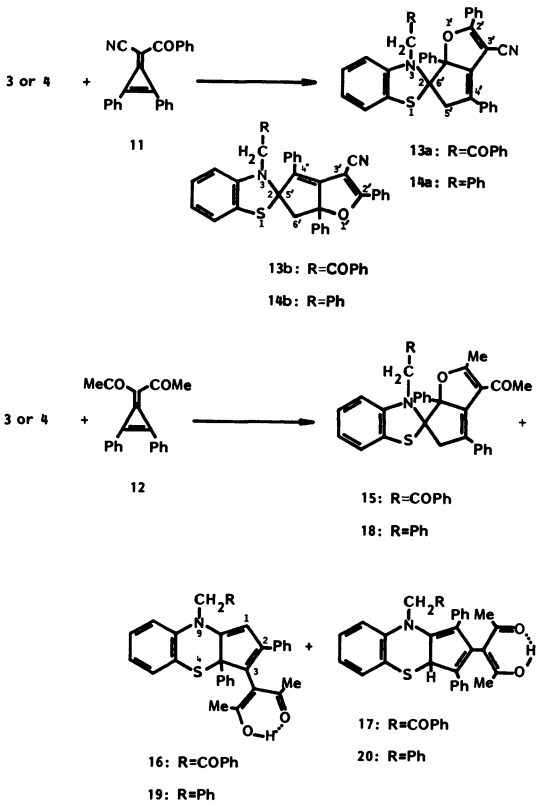
20	207—208	1610 1540 1470	1.70, 1.90 (each 3H, s), 4.26 (1H, s, >**C**H), 4.60, 4.85 (each 1H, d, N**C**H$_2$, J=18.0 Hz), 6.80—7.65 (19H, m), 16.32 (1H, s, **O**H)	23.51, 23.63 (each q, **C**H$_3$), 43.67 (d, 3a-**C**), 52.08 (t, N**C**H$_2$), 108.43, 117.01, 120.85 (each s, 1-**C**, **C**=C(OH)Me), 190.05, 191.75 (each s, **C**=O)

The compounds, **13**, **14**, **17**, **18**, and **20** are all yellow needles. **13**: UV $\lambda_{max}^{CHCl_3}$/nm (log ε) 270 (4.28), 325 (4.21), 360 (4.27). **14**: UV $\lambda_{max}^{CHCl_3}$/nm (log ε) 265 (4.35), 330 (4.29), 360 (4.34). The ^{1}H NMR spectral data of **15**, **16**, and **19** are given as follows: **15**: δ 1.86, 2.15 (each 3H, s), 3.30, 3.43 (each 1H, d, **C**H$_2$, J=13.0 Hz), 4.20 (2H, s, N**C**H$_2$). **16**: δ 0.73, 2.36 (each 3H, s), 5.06, 5.36 (each 1H, d, N**C**H$_2$, J=18.0 Hz), 5.56 (1H, s, =**C**H), 17.10 (1H, s, **O**H). **19**: δ 0.76, 2.28 (each 3H, s), 5.02, 5.20(each 1H, d, N**C**H$_2$, J=18.0 Hz), 5.78 (1H, s, =**C**H), 16.93 (1H, s, **O**H).

The IR spectra of **13** and **14** showed no carbonyl absorptions came from the benzoyl group in **11**, and two singlets assignable to quaternary carbons appeared in the ^{13}C NMR spectra. Thus, **13** and **14** can be assumed as spiro-cyclopenta[*b*]furans **13a**, **14a** or **13b**, **14b** derived from the participation of the benzoyl group in a cyclization. In the ^{1}H NMR spectra, however, both **13** and **14** showed doublets assignable to allylic methlenes at δ 3.06, 3.46 and 3.26, 3.33, respectively.[17] It is thus reasonable to conclude that 1 : 1 adducts **13** and

14 are spiro[benzothiazole-2(3*H*),6′-cyclopenta[*b*]furan]s **13a**, **14a** rather than isomeric spiro[benzothiazole-2(3*H*),5′-cyclopenta[b]furan]s **13b**, **14b** (Scheme 2).



Scheme 2.

In contrast to the above reaction which exhibited a reaction pattern similar to enamines, the methylenebenzothiazolines **3** and **4** reacted with the diacetyl-substituted methylenecyclopropene **12** to give novel rearranged products.

The reaction of **3** with **12** in dry THF at room temperature for 0.5 h afforded a mixture of three isomeric 1 : 1 adducts **15**, **16**, and **17**, from which only the major product **17** was isolated in 87% yield. The yields of **15** and **16** were so poor that their isolation was unsuccessful, but their formation was shown by inspection of the ^{1}H NMR spectrum of reaction mixture. Under the same conditions, **4** reacted with **12** to give three 1 : 1 adducts **18**, **19**, and **20** in 21, 10 and 57% yields, respectively. In the same reaction for a long time (15 h), a yield of the major product **20** increased up to 84% with decreased yields of **18** (10%) and **19** (trace). Although the products **18** and **20** were isolated in pure forms, **19** was too unstable to be isolated. Actually, **19** gradually changed into **20** even at room temperature in solution.

The spectral data of products **15**—**20** are summarized in Table 2. It is quite certain that the minor products **15** and **18** have the same ring structure to the spiro-cyclopenta[*b*]furans, **13a** and **14a**, by comparison of the spectral data.

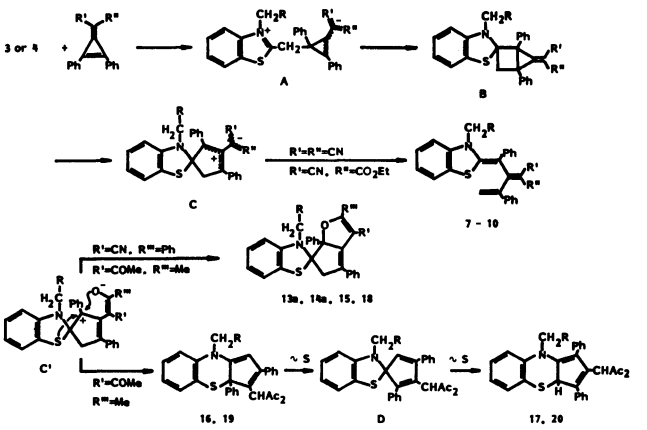
Structural elucidation of the major products, 2-(1-acetylacetonyl)-9-phenacyl-(**17**) and 2-(1-acetylacetonyl)-9-benzyl-1,3-diphenyl-3a,9-dihydrocyclopenta[*b*]-[1,4]benzothiazine (**20**), was accomplished on the basis of the spectral data. The ^{1}H NMR spectrum showed the signals of a methine and an enolic proton at δ 4.41 and 16.35 for **17** or at δ 4.26 and 16.32 for **20**, respectively, and the ^{13}C NMR spectra indicated the presence of a tertiary carbon in both **17** and **20**. In analogy with cross-conjugated systems, **7**—**10**, methylene protons and carbon in the phenacyl group in **17** or in the benzyl group in **20** are observed at considerably lower fields than those of the spiro-cyclopentafuran **13a** or **14a** respectively, meaning that the phenacyl or benzyl group should be located on an enamino nitrogen atom.[18] The above facts strongly support the assigned benzothiazine structures, **17** and **20**, arisen from a rearrangement of benzothiazoline ring.[19]

As mentioned above, the minor product **19**, whose spectral data are similar to those of **16**, changed into the major product **20**. Thus, **16** and **19** can be regarded as the precursors for **17** and **20**, respectively.

In the ^{1}H NMR spectrum of **16** or **19**, an enolic proton is also observed, but an olefinic proton appears instead of the methine one in **17** or **20**.[19] The phenacyl or benzyl group is under circumstance similar to that in **17** or **20**. Thus, it was deduced that the precursors are 3-(1-acetylacetonyl)-9-phenacyl-(**16**) and 3-(1-acetylacetonyl)-9-benzyl-2,3a-diphenyl-3a,9-dihydrocyclopenta[*b*][1,4]benzothiazine (**19**). In these cases, both the methyl groups are magnetically quite different (δ 0.73, 2.36 for **16** and δ 0.76, 2.28 for **19**) since one of them is forced to face the plane of the phenyl group at the 3a-position. The thermal isomerization of **16** into **17** or **19** into **20** might be driven by release from the steric hindrance around 3a-position.

Reaction Pathways. Although the mechanistic aspects concerning the reactions of enamines with methylenecyclopropenes have not been fully established,[8] the reaction of a cyclic enamine with methylenecyclopropenes leading to pentalene derivatives[20] and cross-conjugated systems[21] has been interpreted as *via* an intermediary [2+2] cycloadduct. The reaction pathways in this paper can be again explained as *via* an intermediary [2+2] cycloadduct (Scheme 3).

The electron-deficient endocyclic C=C bond of methylenecyclopropenes, **5**, **6**, **11**, and **12**, interacts



Scheme 3.

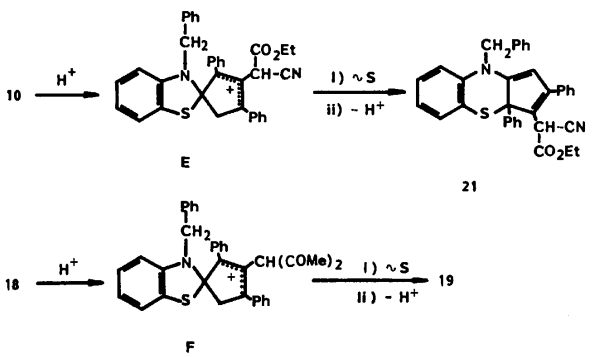
with the electron-rich exocyclic one of methylenebenzothiazolines, **3** and **4**, forming an intermediary [2+2] cycloadduct **B**, probably *via* a zwitterion **A**. The intermediate **B** undergoes a ring opening of the fused cyclopropane moiety to yield a new zwitterion **C** that is stabilized by the electron-withdrawing substituents (R′ and R″).

The five-membered ring of cyclopentadienyl cation in **C** opens in a conrotatory manner[21] to give the cross-conjugated systems, **7**—**10**, when the substituents have a relatively weak stabilization effect on the zwitterion **C** (R′ is cyano and R″ is cyano or ethoxycarbonyl).[22] On the other hand, when the substituents strongly stabilize **C** (R′=CN, R″=COPh; R′=R″=COMe)[22] and have at least one acyl moiety, the zwitterion **C** (=**C**′, R″=Ph, Me) takes an opportunity for the cyclization of the acyl group to give the spiro-cyclopentafurans, **13a**, **14a**, **15**, and **18**.

Another novel rearrangement also occurs in the case of **C** having two acetyl groups. The rearrangement of sulfur atom in **C**′ onto the cationic center followed by concurrent proton transfer gives the unstable cyclopenta[*b*][1,4]benzothiazines, **16** and **19**. Their lability might be due to steric hindrance between the phenyl group at the 3a-position and the 1-acetylacetonyl group. Release from the steric hindrance may cause the 1,5-sigmatropic rearrangement of sulfur atom to give a spiro intermediate **D**. A further rearrangement gives rise to the less hindered cyclopenta[*b*][1,4]benzothiazines, **17** and **20**. The reason why only the sulfur atom migrates in the rearrangements would be that the nitrogen migration does not reduce the steric hindrance around the position to which the nitrogen atom migrates.

The reaction pathways depicted in Scheme 3 are supported by the following facts. The cross-conjugated compound **10** canged into the cyclopenta[*b*][1,4]-benzothiazine **21**, whose structure was identified on the basis of the spectral data, when treated with a catalytic amount of hydrochloric acid at room temperature. Contrary to thermal instability of the previous cyclopenta[*b*][1,4]benzothiazines, **16** and **19**, the compound **21** is much more stable on heating. This stability may be due to the less steric hindrance of the cyano(ethoxycarbonyl)methyl substituent. On the treatment with hydrochloric acid, the spiro-cyclopenta[*b*]furan **18** quantitatively isomerized into **19** which further thermally changed into **20** (Scheme 4).

The above isomerizations seem to be explained as follows: Protonation onto the carbon possessing two electron-withdrawing substituents of **10** and a conrotatory cyclization of the resulting pentadienyl cation lead to an intermediate **E** that corresponds to a protonated **C** in Scheme 3. The similar rearrangement of sulfur atom with concurrent deprotonation gives **21**. Similarly, the oxygen atom of furan ring in **18** is protonated and the furan ring opens to form the similar intermediate **F** that gives **19** in the same manner.



Scheme 4.

As shown in Scheme 3, it is reasonable to say that the degree of stabilization of **C** by the electron-withdrawing substituents (R′ and R″)[22] primarily controls the reaction pathways.

Experimental

All melting points were determined on a Yanagimoto micro melting point apparatus and were uncorrected. The IR spectra were taken with a JASCO IRA-1 or a JASCO A-102 spectrometer. The ^{1}H NMR spectra were recorded on a Hitachi R-40 or a JEOL FX-100 instrument and ^{13}C NMR spectra were obtained on a JEOL FX-100 spectrometer at 25.05 MHz. Chemical shifts are expressed in parts per million downfield from tetramethylsilane. The UV spectra were recorded on a Shimadzu UV-240 spectrometer, and mass spectra were measured with a JEOL JMS-01SG-2 spectrometer at 75 eV of ionization energy. Elemental analyses were performed on a Hitachi 026 CHN analyzer. Thin-layer chromatography was accomplished on 0.2-mm precoated plates of silica gel 60 F-254 (Merck) or on 0.2-mm precoated plates of aluminum oxide 60 F-254 type E (Merck). Visualization was with ultraviolet light (254 and 365 nm) and iodine. Preparatory column chromatography was performed on silica gel Wako C-300 (Wako) or on neutral aluminum oxide Woelm type N (Woelm).

The reactions were performed under nitrogen atmosphere, and solvents were evaporated with a Tokyo Rikakikai rotary vacuum evaporator type V at 50 °C.

Materials. 2-Methyl-3-phenacylbenzothiazolium bromide (**1**)[23] was prepared according to the reported method. 3-Benzyl-2-methylbenzothiazolium bromide (**2**), mp 255—256 °C, was similarly prepared by refluxing equimolar amounts of 2-methylbenzothiazole and benzyl bromide in dry acetone for 7 h: Yield 31%; colorless prisms; IR 1570, 1450, 1430 cm^{-1}. 2-(2,3-Diphenyl-2-cyclopropenylidene)propanedinitrile (**5**),[24] ethyl 2-cyano-2-(2,3-diphenyl-2-cyclopropenylidene)acetate (**6**),[25] 2-benzoyl-2-(2,3-diphenyl-2-cyclopropenylidene)acetonitrile (**11**),[16] and 3-(2,3-diphenyl-2-cyclopropenylidene)-2,4-pentanedione (**12**)[26] were synthesized by the reaction of 1-ethoxy-2,3-diphenylcyclopropenium tetrafluoroborate with the corresponding active methylene compounds, respectively.

Reactions with 2-(2,3-Diphenyl-2-cyclopropenylidene)propanedinitrile (5). A solution of NEt_3 (0.12 g, 1.2 mmol) in dry chloroform (5 mL) was added dropwise, at 0 °C, to a stirred suspension of the benzothiazolium bromide **1** (0.41 g, 1.2 mmol) and **5** (0.3 g, 1.2 mmol) in dry chloroform (40 mL). After 3 h at room temperature, the reaction mixture was poured into water (200 mL) and extracted with chloroform (130 mL). The extract was dried over $MgSO_4$, and evaporated to give a red residue. The residue was chromatographed on silica gel using chloroform as an eluent to give 583 mg (95%) of the cross-conjugated system **7** which was recrystallized from benzene afforded reddish violet prisms. Found: C, 80.01; H, 4.93; N, 6.87%. Calcd for $C_{34}H_{23}N_3OS \cdot C_6H_6$: C, 80.07; H, 4.87; N, 7.00%. MS *m/e* 521 (M^+).

A similar reaction of the benzothiazolium bromide **2** (0.38 g, 1.2 mmol) with **5** (0.3 g, 1.2 mmol) in the presence of NEt_3 (0.12 g, 1.2 mmol) gave 545 mg (99%) of the cross-conjugated system **8** which was purified by recrystallization from benzene to give reddish violet prisms. Found: C, 81.87; H, 5.12; N, 7.50%. Calcd for $C_{33}H_{23}N_3S \cdot C_6H_6$: C, 81.90; H, 5.07; N, 7.35%. MS *m/e* 493 (M^+).

The spectral data of **7** and **8** are shown in Table 1.

Reactions with Ethyl 2-Cyano-2-(2,3-diphenyl-2-cyclopropenylidene)acetate (6). A solution of NEt_3 (0.1 g, 1 mmol) in dry THF (5 mL) was added dropwise, at 0 °C, to a stirred suspension of the benzothiazolium bromide **1** (0.35 g, 1 mmol) and **6** (0.3 g, 1 mmol) in dry THF (40 mL). After 1 h at room temperature, the precipitated triethylammonium bromide was filtered off and the filtrate was evaporated. The residue was chromatographed over neutral alumina using chloroform as an eluent affording 550 mg (80%) of the cross-conjugated system **9** which was purified by recrystallization from benzene to give violet prisms. Found: C, 76.22; H, 5.12; N, 4.95%. Calcd for $C_{36}H_{28}N_2O_3S$: C, 76.06; H, 4.93; N, 4.93%. MS *m/e* 568 (M^+).

A similar reaction of the benzothiazolium bromide **2** (0.32 g. 1 mmol) with **6** (0.3 g, 1 mmol) in the presence of NEt_3 (0.1 g, 1 mmol) yielded 510 mg (94%) of the cross-conjugated system **10** as reddish violet prisms. Found: C, 77.65; H, 5.19; N, 5.20%. Calcd for $C_{35}H_{28}N_2O_2S$: C, 77.76; H, 5.22; N, 5.18%. MS *m/e* 540 (M^+).

The spectral data of **9** and **10** are shown in Table 1.

Reactions with 2-Benzoyl-2-(2,3-diphenyl-2-cyclopropenylidene)-acetonitrile (11). A mixture of the benzothiazolium bromide **1** (0.35 g, 1 mmol), **11** (0.34 g, 1.1 mmol), and NEt_3 (0.1 g, 1 mmol) in dry THF (40 mL) was refluxed for 1 h. The precipitated triethylammonium bromide was filtered off and the filtrate was evaporated to give a colored residue. The residue was chromatographed over silica gel using benzene as an eluent to afford 215 mg (36%) of the spiro-cyclopenta[*b*]-furan **13a** which was purified by recrystallization from benzene–hexane. Found: C, 79.82; H, 4.95; N, 4.36%. Calcd for $C_{40}H_{28}N_2O_2S$: C, 79.98; H, 4.70; N, 4.66%. MS *m/e* 600 (M^+), 105.

Similarly, the benzothiazolium bromide **2** (0.32 g, 1 mmol) reacted with **11** (0.34 g, 1.1 mmol) in the presence of NEt_3 (0.1 g, 1 mmol) to give 264 mg (46%) of the spiro-cyclopenta-[*b*]furan **14a**. Found: C, 81.74; H, 4.90; N, 4.70%. Calcd for $C_{39}H_{28}N_2OS$: C, 81.80; H, 4.93; N, 4.89%. MS *m/e* 572 (M^+), 481, 105.

Reactions with 3-(2,3-Diphenyl-2-cyclopropenylidene)-2,4-pentanedione (12). A solution of NEt_3 (0.3 g, 3 mmol) in dry THF (5 mL) was added dropwise, at 0 °C, to a suspension of the benzothiazolium bromide **1** (1.04 g, 3 mmol) and **12** (0.86 g, 3 mmol) in dry THF (60 mL). After 0.5 h at room temperature, the precipitated triethylammonium bromide was filtered off and the filtrate was evaporated. The residue was dissolved in benzene and the benzene solution was passed through a short column packed with neutral alumina to afford a mixture of **15**, **16**, and **17** (1.48 g, 90%). The formation of the spiro-cyclopentafuran **15** and benzothiazine **16** was indicated by inspection of the ^1H NMR spectrum of the above mixture. Evaporation of the benzene gave yellow pasty material that solidified on trituration with hexane to give 1.45 g (87%) of the benzothiazine **17** which was purified by recrystallization from benzene–hexane.

The same reaction in dry acetonitrile (30 mL) gave **17** in 73% yield. The benzothiazine **17**. Found: C, 78.08; H, 5.49; N, 2.70%. Calcd for $C_{36}H_{29}NO_3S$: C, 77.84; H, 5.23; N, 2.52%. MS *m/e* 555 (M^+), 450, 435, 105.

A similar reaction of the benzothiazolium bromide **2** (0.96 g, 3 mmol) with **12** (0.86 g, 3 mmol) in THF (60 mL) in the presence of NEt_3 (0.3 g, 3 mmol) yielded a mixture of **18**, **19**, and **20** (1.39 g, 88%) whose relative yields were determined on the basis of the ^1H NMR spectrum (**18**: 21%; **19**: 10%; **20**: 57%). The mixture was carefully chromatographed over neutral alumina. The first benzene–hexane eluent afforded almost pure **20** and the next benzene eluent gave **18** which was contaminated with **20**. Both the spiro-cyclopentafuran **18** and benzothiazine **20** were purified by recrystallization from benzene–hexane.

The spirocyclopentafuran **18**. Found: C, 79.96; H, 5.61; N, 2.89%. Calcd for $C_{35}H_{29}NO_2S$: C, 79.67; H, 5.54; N, 2.66%. MS *m/e* 527 (M^+), 436, 91. The benzothiazine **20**. Found: C, 79.97; H, 5.59; N, 2.52%. Calcd for $C_{35}H_{29}NO_2S$: C, 79.67; H, 5.54; N, 2.66%. MS *m/e* 527 (M^+), 436, 394, 350, 91.

The spectral data of **15**—**20** are listed in Table 2.

Acid-catalyzed Isomerization of the Cross-conjugated System 10. An ethanol solution (15 mL) of **10** (0.27 g, 0.5 mmol) containing a catalytic amount of hydrochloric acid was stirred at room temperature for 24 h and evaporated to give a residue. The residue was treated with 10% aqueous potassium carbonate and extracted with chloroform. The chloroform extract was dried over $MgSO_4$ and evaporated. Column chromatography of the residue over neutral alumina using benzene as an eluent afforded the benzothiazine **21** (0.057 g, 31%) which on recrystallization from benzene gave yellow prisms, mp 154—155 °C. IR (KBr) 2230 (C≡N), 1730 (C=O), 1590, 1540, 1440 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.03 (3H, t), 3.60 (2H, q), 4.56 (1H, s, -CH), 4.90, 5.10 (each 1H, d, NCH_2, J=18.0 Hz), 5.55 (1H, s, =CH), 6.60—7.60 (19H, m); ^{13}C NMR ($CDCl_3$) δ=13.55 (q, CH_3), 35.38 (d, CH), 53.36 (t, NCH_2), 59.01 (s, 3a-C), 62.67 (t, CH_2Me), 103.02 (d, 1-C), 164.17 (s, C–O); MS *m/e* 540 (M^+), 449, 403, 375, 91. Found: C, 77.70; H, 5.33; N, 5.10%. Calcd for $C_{35}H_{28}N_2O_2S$: C, 77.76; H, 5.22; N, 5.18%.

Acid-catalyzed Isomerization of the Spiro-cyclopenta[b]*furan 18.* A drop of hydrochloric acid was added to a solution of **18** in deuteriochloroform and the ^1H NMR spectrum was started to measure at room temperature. The signals for **18** gradually disappeared with the appearance of those for the dihydrocyclopenta[*b*][1,4]benzothiazine **19**. In 0.5 h the change was completed and then **19** was observed to isomerize into **20**. After 15 h, the solvent was evaporated to give **20** in a quantitative yield.

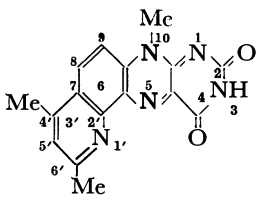
Coenzyme Models. 34. Synthesis and Oxidation Ability of a Metal-coordinative Flavin

Seiji SHINKAI,* Yuichi ISHIKAWA, and Osamu MANABE
Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852
(Received December 2, 1982)

A new metal-coordinative flavin(2,4,7-trimethylquino[8,7-*g*]pteridine-9,11(7*H*,10*H*)-dione: (**1**)) which has a phenanthroline-like skeleton within the molecular structure was synthesized. Being different from conventinal flavins, the new flavin showed a significant affinity toward metal ions and the absorption spectra were sensitively affected by added metal ions. The spectral patterns were classified into three types, which were assigned respectively to the different coordination structures. It was demonstrated through oxidation of dihydropyridine derivatives, phenylhydrazine, and L-ascorbic acid that complexed metal ions are able to "activate" **1** as oxidizing agent. The complexes with Zr^{4+} and Fe^{3+} even oxidized alcohols at ambient temperature. Unexpectedly, it was found that tetrahedral coordination metals such as Cd^{2+}, Zn^{2+}, and Co^{2+} frequently give the stable semiquinone radical of **1**. The remarkable stabilization effect of these metals was attributed to a bent, butterflywing structure of the semiquinone radical. These findings suggest that the **1**–metal complexes are useful not only as a model system of metalloflavoproteins but also as an *in vitro* oxidation catalyst.

Flavin coenzymes are versatile redox catalysts in many biological systems and it is now known that more than 100 proteins require flavin coenzymes.[1-3] In contrast to the ability of flavin coenzymes to oxidize a variety of substrates *in vivo*, however, flavin molecules *in vitro* exhibit a rather weak oxidation ability. We have been aiming at "activating" flavin molecules in nonenzymatic systems with the intention of utilizing flavins as an organic turnover oxidation catalyst. There are now recognized two main methods to facilitate flavin-mediated oxidation reactions: That is, (i) to convert substrates into more "specific" ones with the aid of second cofactors or environmental effects and (ii) to shift the redox potential of flavins to more positive values. Method (i) has been achieved by employing cyanide ion,[4-7] thiazolium ions,[8-13] and thiols[14,15] as second cofactors or by conducting flavin-mediated reactions in aqueous micelles and water-soluble polymers.[16-22] Method (ii) is precedented by Cl-, CN-, pyridino-, and nitro-substituted flavins.[19,23-27] To the best of our knowledge, however, no precedent for the metal-activation of flavin catalyses exists, which would be classified as an example of method (ii). The difficulty of the method is solely ascribable to the lack of the metal affinity of flavins, except a few metal ions such as Ag^{+} and Ru^{2+}.[28,29]

It thus occurred to us that it would be of value to synthesize a new flavin which has a metal-coordinative function. With the object in view, we synthesized 2,4,7-trimethylquino[8,7-*g*]pteridine-9,11(7*H*,10*H*)-dione (**1**)† which has a phenanthroline-like skeleton in the molecular structure and examined the influence of complexed metal ions on the oxidation ability of **1**. As control experiments, we used 10-ethylisoalloxazine (**7**). Since flavin coenzymes mediate electron transfers to and from ion-sulfur, molybdenum, and heme in proteins, the investigation would be also of value as a model study of metalloflavoproteins to gain an insight into metal–flavin interactions.



† When the isoalloxazine ring is taken as a basic skeleton, **1** may be named 4′,6′,10-trimethyl-6,7-(2′,3′-pyrido)-isoalloxazine. For the sake of the analogy to conventional isoalloxazines, we will use this naming when we point to the atoms in **1**.

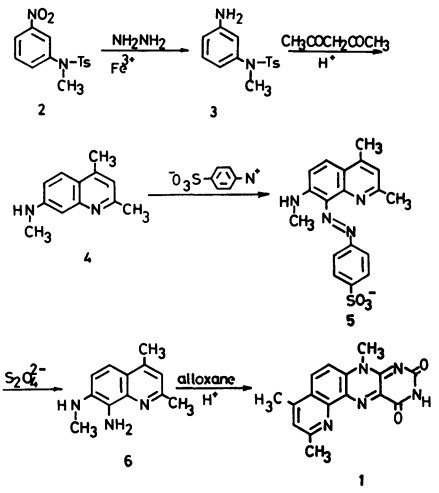
Experimental

Materials. Compound **1** was synthesized according to a following reaction sequence (Ts=tosylate).



2 **3** **4** **5** **6** **1**

m-*Nitro*-N-*methyl*-N-*tosylaniline* (**2**). *m*-Nitro-*N*-tosylaniline (100 g; 0.34 mol) was dissolved in 800 ml of 1 M NaOH (1 M=1 mol dm^{-3}) aqueous solution and dimethyl

sulfate (45.5 g; 0.34 mol) was added dropwise with stirring at room temperature. After 1 h, 50 ml of 1 M NaOH aqueous solution was added and then dimethyl sulfate (10 g; 0.075 mol) was added dropwise again. The same operation was repeated two more times. The white precipitate was collected by suction, washed with aqueous NaOH, dilute HCl, and water, and then dried *in vacuo*; mp 109.5—110.5 °C, yield 95%. The row product was used for the following synthesis without further purification.

N-Methyl-N-tosyl-m-phenylenediamine (3). The nitro group was reduced by Fe^{3+}–hydrazine.[30] **2** (100 g; 0.33 mol) was dissolved in 100 ml of methanol containing 10 g of active carbon and 1.5 g (5.5×10^{-3} mol) of $FeCl_3\cdot6H_2O$, and the solution was refluxed for 15 min. Hydrazine hydrate (90%) (35 g; 0.495 mol) was added dropwise and then the reaction mixture was heated under reflux for 2.5 h. We here confirmed that the spot of **2** in TLC had disappered. The solution was filtered while it was hot, the solvent being evaporated *in vacuo*. The residue (mp 100—102 °C, yield 94%) was subjected to the following analyses. Found: C, 60.76; H, 5.84; N, 10.17%. Calcd for $C_{14}H_{16}N_2O_2S$: C, 60.85; H, 5.84; N, 10.14%. NMR($CDCl_3$): Ar–CH_3, 2.39 ppm, 3H; *N*-CH_3, 3.09 ppm, 3H; NH_2, 3.69 ppm, 2H; aromatic protons, 6.34 ppm (1H), 6.52 ppm (2H), 7.01 ppm (1H), 7.22 ppm (2H), 7.48 ppm (2H).

2,4-Dimethyl-7-(methylamino)quinoline (4). In 120 ml of acetic acid containing 20 ml of concd sulfuric acid were added **3** (80 g; 0.29 mol) and acetylacetone (34 g; 0.319 mol), and the reaction mixture was refluxed. The progress of the reaction was followed by the TLC method (silica gel–methanol). In order to accelerate the reaction, 3.4 g (0.032 mol) of acetylacetone was added several times so that the total amount of added acetylacetone became 0.49 mol. After 3 d, the solution was concentrated *in vacuo* to one-third and poured into 200 ml of water. The precipitate was collected by suction and washed with hot water. The solid was once dissolved in hot NaOH solution. On cooling, the yellow precipitate was formed, which was recovered by filtration and washed with water: mp 140.0—140.5 °C, yield 28.7%. Found: C, 76.79; H, 7.52; N, 14.91%. Calcd for $C_{12}H_{14}N_2$: C, 77.38; H, 7.58; N, 15.04%. IR(KBr): ν_{NH} 3220 cm^{-1}, ν_{Ar-H} 842, 830, 801 cm^{-1}. NMR ($CDCl_3$): 4-CH_3, 2.56 ppm, 3H; 2-CH_3, 2.64 ppm 3H; *N*-CH_3, 2.94 ppm, 3H; NH, 4.16 ppm 1H; 6-H, 6.82 ppm, 1H(quartet); 3-H, 6.84 ppm, 1H(singlet); 8-H, 7.02 ppm, 1H(doublet); 5-H, 7.88 ppm, 1H(doublet). IR and NMR spectral data support that the product is 2,4-dimethyl-7-(methylamino)quinoline (**4**) but not 2,4-dimethyl-5-(methylamino)quinoline.

4-(2,4-Dimethyl-7-methylamino-8-quinolylazo) benzenesulfonate (5). Compound **4** (11.2 g; 0.06 mol) was dissolved in 60 ml of hot 3.5% HCl solution, and after cooling, the solution was poured into 500 ml of aqueous solution containing the diazonium salt of sulfanilic acid (10.4 g; 0.06 mol). 120 g of urea was added in order to accelerate the coupling reaction. The solution was adjusted to pH 4.5 ± 0.5 with sodium acetate and the reaction was continued for 90 h at 0—10 °C. The precipitate was recovered by filtration. The product solid was once dissolved in aqueous NaOH solution and reprecipitated by adding NaCl. The precipitate was then dissolved in aqueous solution and reprecipitated again by adding concd HCl solution; mp 271—273 °C (red powder), yield 82.4%. IR(KBr): ν_{NH} 3400 cm^{-1}, $\nu_{quinoline\ ring}$ 1620 cm^{-1}, SO_3H, 1219 and 1025 cm^{-1}. Found: C, 55.70; H, 4.80; N, 14.25%. Calcd for $C_{18}H_{18}N_4O_3S$: C, 58.30; H, 4.90; N, 15.13%.

2,4-Dimethyl-7-methylamino-8-quinolinamine (6). Compound **5** (0.5 g; 1.4 mmol) was dissolved in 40 ml of 3% NaOH aqueous solution. 0.7 g (4.0 mmol) of sodium dithionite (practical grade) was added, and the reaction mixture was refluxed for 1 h. The product was extracted with 1-butanol (100 ml×2). Since the product **6** was relatively sensitive to air oxidation, the 1-butanol extract was immediated used for the following reaction. Meanwhile, the aliquot was withdrawn from the solution and cooled in a nitrogen atmosphere. The precipitate was recovered by filtration and subjected to the NMR measurement. NMR($CDCl_3$): 4-CH_3, 2.55 ppm, 3H; 2-CH_3, 2.60 ppm, 3H; *N*-CH_3, 2.96 ppm 3H; 7-NH and 8-NH_2, 3.98 ppm, 3H; 3-H, 6.84 ppm 1H(singlet); 6-H, 7.02 ppm, 1H(doublet); 5-H, 7.37 ppm, 1H(doublet). The NMR spectral data show that diazocoupling occurs at 8-position of **4**.

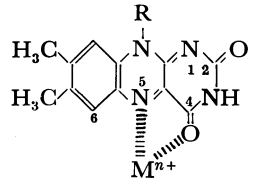
To the 1-butanol solution containing **6** were added 0.21 g (1.4 mmol) of alloxane and 0.24 g (1.4 mmol) of *p*-toluenesulfonic acid, and the reaction mixture was refluxed for 6 h. The precipitate formed on the addition of several drops of pyridine was collected by suction and washed with water. The product solid **1** was recrystallized from acetic acid with active carbon: mp>293 °C, yield from **5**, 40%. Mass spectrum: M^+ 307. Found: C, 58.39; H, 4.61; N, 20.95%. Calcd for $C_{16}H_{13}N_5O_2\cdot H_2O$: C, 59.07; H, 4.65; N, 21.53%.

Preparations of 10-ethylisoalloxazine (**7**) and 1-benzyl-3-carbamoyl-1,4-dihydroquinoline (BCQH) were described previously.[31,32]

Kinetics. The kinetic measurements of the flavin oxidation of phenylhydrazine, L-ascorbic acid, and alcohols were carried out at 30 °C under anaerobic conditions. The rates were determined by following each absorption maximum of the **1**–metal complexes. The reactions with the dihydro compounds were carried out at 30 °C aerobically under the recycle conditions.[17] The rates were determined by following each absorption maximum of BCQH (340 nm) and 10-methyl-9,10-dihydroacridine (284 nm). The further detailed reaction conditions are recorded in footnotes to each table.

Results and Discussion

Influence of Metal Ions on the Absorption Spectrum of 1. Early spectral studies of model flavin–metal interactions reveal that oxidized flavins exhibit no singificant affinity for most metals, whereas Ag(I), Cu(I), Mo(V), Ru(II), and Fe(II) were found to complex oxidized flavins probably owing to a metal–flavin charge transfer stabilization.[28,29,33-35] The spectral studies suggested that the metal binds to *O*(4) or *N*(5), or both as **8**.[28,29,35] Crystallographic studies of Ag(I) complexes later verified *O*(4)–*N*(5) coordination and in addition revealed second chelate site consisting of *N*(1)–*O*(2).[33,34]



8

We measured absorption spectra of **1** and **7** in methanol at 30 °C. The absorption spectrum of **1**, which features the shift of the S2 band (317 nm) to shorter wavelength and the weakened S1 band (437 nm) relative to the S2 band, is closely akin to that of some 6-substituted flavins[36] rather than to that of conven-

a) [**1**]$=2.00\times10^{-5}$ M. In the spectral measurements, the sample cell contains **1** and metal salt while the reference cell contains metal salt only.

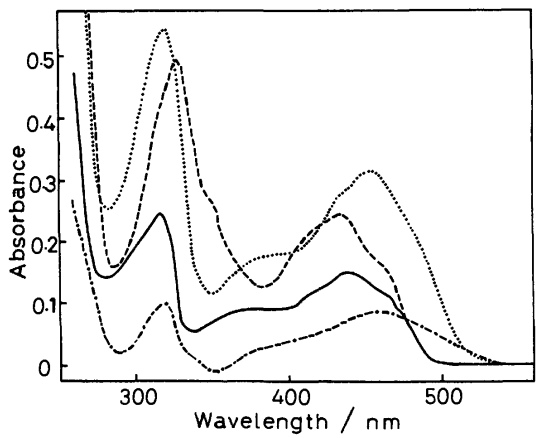

Fig. 1. Influence of added metal ions on the difference absorption spectra of **1** (1.72×10^{-5} M) in methanol at 30 °C. The reference cell contains metal ion equal to that in the sample cell. ——, No metal ion; ------, [Zr^{4+}] $=3.30\times10^{-5}$ M (type A); ·····, [Hg^{2+}]$=3.30\times10^{-4}$ M (type B); ·–·–·, [Ag^+]$=3.30\times10^{-4}$ M (type C).

tional flavins. As reported previously,[28,35] no significant spectral change of **7** occurred on the addition of metals listed in Table 1 (expect Ag(I)). On the other hand, the absorption spectrum of **1** was sensitively affected by various kinds of metal ions (Table 1 and Fig. 1). The influence of metal ions on the absorption spectra would be classified into three types (Table 2). In type A, the absorption bands are enhanced in whole wavelength region of **1**. In type B, a new absorption band spreading to longer wavelength region appears in addition to type A. Type C features the reduction of the flavin bands and the enhancement of the longer wavelength band. On the other hand, the absorption spectrum changed only slightly on the addition of Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, Ni^{2+}, and Mn^{2+}.

Two facts established in the early spectral studies[28,29,35] are very helpful to speculate the coordination structure: That is, (i) conventional flavins do not form complexes with most metals, indicating that the complexation with **1**, when it occurs, must involve the coordination of $N(1')$-position to metal and (ii) the interaction of metal with $O(4)$ is the origin of the longer-wavelength absorption band. Metal ions of type A have not the longer-wavelength absorption band. Thus, the coordination structure possibly involves the interaction at $N(5)$ and $N(1')$ but not at $O(4)$.

TABLE 2. CLASSIFICATION OF METAL IONS FROM SPECTRAL PATTERNS

Type	ε_{max} at 317 nm	ε_{max} at 437 nm	Longer wavelength	Metal
A	Increase	Increase	No	Zr^{4+}, Sb^{3+}, Fe^{3+}, Mo^{5+}
B	Increase	Increase	Increase	Hg^{2+}, Cd^{2+}, Zn^{2+},Co^{2+}
C	Decrease	Decrease	Increase	Cu^{2+}, Ag^+

Type C metals are Cu^{2+} and Ag^+. As described above, Ag^+ is capable of forming the stable complex with conventional flavins through the $O(4)$–$N(5)$ coordination. Also in the present system, Ag^+ would form the complex through the interaction with $O(4)$ and $N(5)$ and would not interact with $N(1')$, because the three-point $O(4)$–$N(5)$–$N(1')$ coordination requires a planar structure while the typical coordination structure of Ag^+ is tetrahedral. In contrast, Cu^{2+} would reasonably interact with **1** at $O(4)$, $N(5)$, and $N(1')$, because it usually adopts a planar coordination structure.

To rationalize the coordination structure of type B metals is very difficult. Since these metal ions do not form the complex with conventional flavins, one must take the interaction with $N(1')$ into account. Since the absorption band at longer wavelength region exists, one must also take the intraction with $O(4)$ into account. Thus, the three-point coordination at $O(4)$–$N(5)$–$N(1')$ becomes a candidate, but this is basically incompatible with the fact that these metal ions favorably adopt a tetrahedral coordination structure. Another reasonable candidate that satisfies the above requirements is the $O(4)$–$N(1')$ coordination. In fact, the basicity of $N(5)$ is very low($pK_a=0$).[37] It is more unlikely, however, that the complex is formed by the $O(4)$–$N(1')$ coordination because the metal complex has an eight-membered ring. It thus seems too complicated to elucidate the coordination structure of type B metals only from the absorption spectroscopy. As a separate attempt, we inquired whether the spectral classification is associated with the ion radius of metal ions but could not find a good correlation between them.

Oxidation of Dihydrophyridine Derivatives. It is interesting to know the co-catalytic effect of complexed metals on the oxidation ability of **1**. The determination of the redox potential of metal–**1** complexes without isolation may be difficult, but one may easily evaluate it through the reaction with NADH model compounds. The reaction is a typical inter-coenzyme reaction and the logarithm of the rate constants is linearly correlated with polarographic half-wave potentials.[38] We first used 1-benzyl-1,4-dihydronicotinamide as a NADH model compound. We found, however, that most of

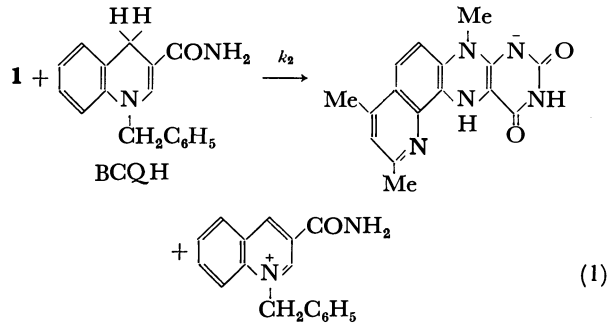
a) 30 °C, methanol, O_2, [dihydro compound] = 5.00×10^{-5} M, [**1**] = $(2.5—3.3) \times 10^{-5}$ M. b) 2,6-Lutidine was added: [2,6-lutidine]/[metal] = 5.0. c) $k_2 = (k'_{metal+1} - k'_{metal})/[\mathbf{1}]$.

metal ions are capable of oxidizing (or decomposing) the dihydronicotinamide at ambient conditions in methanol. We thus employed more "deactivated" and "acid-resistant" NADH model compounds, 1-benzyl-3-carbamoyl-1,4-dihydroquinoline (BCQH)[32] (Eq. 1) and 10-methyl-9,10-dihydroacridine. The kinetic results are summarized in Table 3.



(1)

The reaction rates were monitored spectrophotometrically by following the disappearance of the absorption band of BCQH. The examination of Table 3 reveals that (i) the reaction does not occur in methanol in the absence of metal, (ii) Hg^{2+} ad Sb^{3+}, which do not or scarcely oxidize the dihydro compounds by themselves, serve as efficient co-catalysts for the oxidation by **1**, and (iii) Cu^{2+} is able to oxidize the dihydro compounds by itself but the Cu^{2+}–**1** complex exhibits a markedly higher oxidation ability. As the addition of NaCl provides no catalytic effect on the reaction rate, the co-catalytic behavior of the heavy metals cannot be attributed to a simple salt effect. Strangely, the rate for Fe^{3+} was rather suppressed by the addition of **1**. Compound **1** may weaken the oxidation power of Fe^{3+} through the complex formation. On the other hand, the reaction with **7** which was carried out as a control experiment was not facilitated at all by metal ions listed in Table 3.

Oxidation of Phenylhydrazine. It is known that conventional flavins oxidize phenylhydrazine in the presence of a strong base such as 1,8-diazabicyclo[5.4.0]-undec-7-ene, the product from phenylhydrazine being benzene.[39] The reaction takes place, although slowly, even in the presence of a basic component. The second-order rate constants (k_2) in the absence of metal (Table 4) show that **1** is 18.9 times more reactive than **7**. We found that the oxidation of phenylhydrazine by **1** in ethanol is strongly catalyzed by Cu^{2+} and Fe^{3+}. The examination of Table 4 manifests, however, that the oxidation by **7** is also catalyzed by Co^{2+}, Mg^{2+}, and Fe^{3+}. Hence, the metal catalysis may not be rationalized in terms of the preequilibrium complexation between **1** and metals but rather in terms of the stabilization of the transition state by metal ions.

More interesting is the finding that in the oxidation of

Table 4. Effect of added metal ions on the oxidation of phenylhydrazine[a]

a) 30 °C, ethanol, N_2. [**1** or **7**] = 1.50×10^{-5} M, [phenylhydrazine] = 0.510 M, [metal ion (as chloride salt)] = 2.25×10^{-4}M. b) $k_2 = k_1'$ (pseudo-first-order rate constant)/[phenylhydrazine]. c) The increase in the absorption band continued and the absorbance did not satisfy the first-order equation. d) $Mg(ClO_4)_2$.

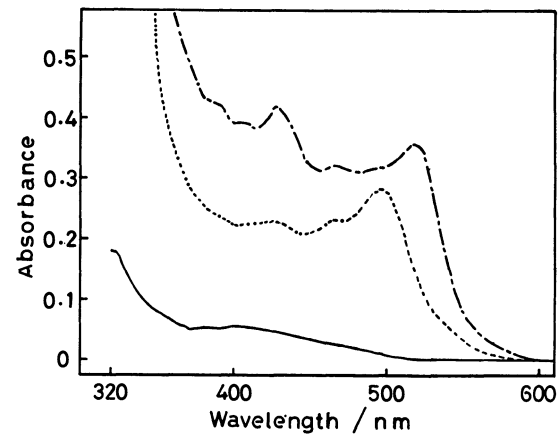

Fig. 2. Absorption spectra of reduced and semiquinone species. ——, Reduced by EDTA and light; ·—·—, semiquinone in phenylhydrazine + Cd^{2+}; ------, semiquinone in phenylhydrazine + Zn^{2+}. 30 °C, [**1**] = 2.80×10^{-5} M, [metal chloride] = 4.20×10^{-4} M, [phenylhydrazine] = 9.67×10^{-1} M, ethanol containing 0.8 vol% *N*,*N*-dimethylformamide.

phenylhydrazine by **1** a new absorption maximum assignable to the semiquinone radical species[28,40] appears at around 510 nm in the presence of Co^{2+}, Cd^{2+}, Zn^{2+}, and Fe^{3+} (Fig. 2). The absorption band immediately disappeared when oxygen was introduced, and the oxidized **1** was regenerated quantitatively. In other cases, the spectrum of oxidized **1** changed to that of reduced **1** without accumulation of any intermediary absorption spectrum. The authentic spectrum of reduced **1** was obtained by photoreduction with disodium salt of ethylenediaminetetraacetic acid([EDTA]/[**1**]=60). It warrants considerable attention that these metal ions (except Fe^{3+}) are classified as type B in Table 1 and usually adopt tetrahedral coordination. It is now unequivocally established that the steric shape of reduced flavins is folded along the $N(5)$–$N(10)$ axis like a butterfly wing.[41,42] It is very conceivable that the semiquinone radical species have a similar bent structure. If so, the tetrahedral coordination metals would be able to specifically stabilize the semiquinone radical species of **1** through a three-point coordination (Scheme 1). Probably, the tetrahedral metals of type B interact with semiquinone **1** at $O(4)$–N(5)–$N(1')$.

a) 30 °C, 95% ethanol, N_2. [**1** or **7**]$=1.40\times10^{-5}$ M, [DBU] = 0.14 M, [ascorbic acid] $=1.43\times10^{-2}$ M, [metal ion (as chloride salt)]$=2.15\times10^{-4}$M. b) Rate constant for the first-order decrease in the absence of ascorbic acid. c) Rate constant for the first-order decrease in the presence of ascorbic acid. d) The increase in the absorption band continued and the absorbance did not satisfy the first-order equation. e) $Mg(ClO_4)_2$.

Oxidation of L-*Ascorbic Acid.* The oxidation of L-ascorbic acid to dehydroascorbic acid is another diagnostic reaction to estimate the oxidation ability of flavins. In the absence of base the reaction did not occur in 95% ethanol, so that we used excess DBU. The addition of DBU caused not only the oxidation (k_1') but the decomposition (probably hydrolytic) of the isoalloxazines (k_{decomp}) which was observed in the absence of L-ascorbic acid. In particular, Cd^{2+} and Co^{2+} (type B metals) caused a remarkably fast decomposition of **1**. It is known that the base-mediated decomposition of isoalloxazines is usually facilitated by electron-withdrawing substituents.[24] Therefore, the k_{decomp} values in Table 5 suggest that the metal ions complexed with **1** make the isoalloxazine ring more electron-deficient. However, the fact that type B metals efficiently catalyze the (hydrolytic) decomposition may imply that these metals have some specific catalytic mechanism (*e.g.*, nucleophilic attack of metal-coordinated hydroxide). On the other hand, Mg^{2+}, Ca^{2+}, and Zr^{4+} are good catalyst for the oxidation of ascorbic acid by **1**, but other metals play no or little cocatalytic role. We have found that the **1**–Zr^{4+} complex acts as a strong oxidizing agent.[47] On the other hand, Mg^{2+} and Ca^{2+} would stabilize the transition state through the interaction with ascorbate anion. Interestingly, the complex with Zn^{2+} and Cd^{2+}, which are tetrahedral coordination metals, gave a radical peak at around 510 nm. The finding supports again that the type B metals are able to stabilize the semiquinone radical of **1**.

Oxidation of Alcohols. It is known that many electron-deficient organic molecules (*e.g.*, azodicarboxylic diesters, 5-deazaisoalloxazines, 2,3-dichloro-5,6-dicyanobenzene, *etc.*) serve as oxidizing reagents for alcohols.[43–46] However, few of them are able to catalyze the oxidation in a recycle manner because of the insensitivity of the reduced forms to molecular oxygen. If the **1**–metal complexes are able to oxidize alcohols, a new possibility arises that alcohols are oxidized by molecular oxygen with the aid of the ping-pong-type

TABLE 6. EFFECT OF ADDED METAL IONS ON THE OXIDATION OF ALCOHOLS AND HYDROQUINONE[a]

a) 30 °C, acetonitrile, N_2. [**1**]$=1.50\times10^{-5}$ M, [metal ion (as chloride salt)]$=2.30\times10^{-4}$ M. b) k_2(apparent second-order rate constant)$=v_{initial}/$[**1**][alcohol]. c) Acetonitrile containing 0.8 vol% *N*,*N*-dimethylformamide.

flavin catalysis. We tested the oxidation of several alcohols by the **1**–metal complexes in various solvents and found out that in acetonitrile the alcohols are in fact oxidized to corresponding aldehydes and ketone (Table 6).[47] The effective metal ions are Zr^{4+} and Fe^{3+}. The result indicates that the complexes with these metal cations are so electron-deficient as to abstract electron(s) from alcohols. The finding suggests that the present **1**–metal complexes are useful not only as a model system of metalloflavoproteins but also as an oxidation catalyst for alcohols and others.

We thank Professor Y. Murakami and Dr. Y. Fuchida for helpful discussions. This work is partly supported by a grant from Toyo Soda Kogyo Co. Ltd.

(Received December 6, 1982)

Cylindrical and phane crown ethers with azobenzene segments as a light-switch functional group were synthesized. Cylindrical ionophores in which two diazacrown ethers are linked by two photoresponsive azobenzene pillars change their binding ability for polymethylenediammonium salts in response to photoirradiation. Thus, the distance between the two crown rings can be photocontrolled. A phane-type ionophore in which 1,23-bis(*p*-aminophenoxy)-3,6,9,12,15,18,21-heptaoxatricosane is linked by a *trans*-4,4′-azobenzenedicarbonyl segment exhibits no affinity with all alkali metal cations but significantly binds Rb^+ and Cs^+ under UV-light irradiation. This is the example of the "all-or-nothing" control of the ion-binding ability and implies that a crown-like loop emerges only when the azobenzene segment is photoisomerized to the *cis*-configuration. These ionophores are categorized to novel photoresponsive crown ethers.

The importance of macrocyclic ligands has been recognized not only in organic chemistry but also in relation to biological chemistry. One of the recent exploration is associated with the combination of a photoresponsive function with macrocyclic ligands, which leads to photocontrol of chemical and physical functions of a crown ether family by an on-off light switch.[2-7)] For example, we and others have reported that a photoresponsive crown ether that combines within a molecule both a crown ether and a photoresponsible chromophore changes its conformation in response to the photoinduced configurational change in the chromophore,[2-7)] resulting in a change in the complexation ability. The finding has been applied to the novel photocontrol of solvent extraction and ion transport across membranes.[8-10)]

We here wish to address two new classes of photoresponsive crown ethers, cylindrical and phane ionophores. A cylindrical ionophore, in which two macrocyclic ligands are linked by two (or more than two) pillars, is an interesting receptor molecule which is able to bind diammonium ions and plural metal ions.[11-14)] Since the metal affinity of cylindrical ionophores is crucially governed by the pillar length, one may expect that the binding ability and the binding selectivity would be readily controlled by changing the length of the two pillars. Thus, cylindrical ionophores with azobenzene pillars would act as "elastic" ionophores in response to photoinduced *trans-cis* isomerization of the azobenzene pillars. Meanwhile, a phane ionophore, in which a poly(oxyethylene) chain is linked by 4,4′-azobenzene, may exhibit the photoresponsive "all-or-noting" change in the ion-binding ability.[15)] Since the distance between the 4- and 4′-positions of *trans*-azobenzene is 9.0 Å while that of *cis*-azobenzene is 5.5 Å, one may visualize that an ionophoric polyoxyethylene loop would appear in *cis*-isomers and disappear in *trans*-isomers reversibly in response to photoirradiation. With these objects in view we synthesized cylindrical and phane ionophores (**1** and **2**, respectively) and evaluated their photoresponsive behaviors in comparison with their model compounds **3**.

Experimental

Materials. Compound **1**(X=CO) was synthesized in benzene from equimolar amounts of 1,10-diaza-4,7,13,16-tetraoxa-18-crown-6 and 4,4′-bis(chloroformyl)azobenzene[4)] according to the high-dilution method. In a 1-l three-necked flask with a reflux condenser were placed 200 ml of benzene and 5 ml of triethylamine, and 2.10 g (8.0 mmol) of 1,10-diaza-4,7,13,16-tetraoxa-18-crown-6 in 100 ml of benzene from one dropping funnel and 2.46 g (8.0 mmol) of 4,4′-bis(chloroformyl)azobenzene in 100 ml of benzene from another dropping funnel were added simultaneously. The reaction mixture was stirred vigorously at room temperature. It took about 1 h to complete the addition of two reactants, and the reaction

was continued for 1 h. The precipitate was removed by filtration, the filtrate being washed with water. The benzene was evaporated to dryness *in vacuo*. When the residual red solid was redissolved in 50 ml of benzene, insoluble, viscous material(polymer?) was removed. The benzene solution was concentrated again, and the residue was recrystallized three times from xylene; mp 224—226 °C, yield 21%, hygroscopic. IR(KBr): $\nu_{C=O}$ 1635 cm^{-1}. NMR(Me_2SO-d_6, 80 °C): crown protons, 3.5—3.8 ppm, 48H; 2′-H of azobenzene, 7.56 ppm, 8H; 3′-H of azobenzene, 7.88 ppm, 8H. Mass spectrum: M^+ (*m/e*) 992. Found: C, 62.36; H, 6.64: N, 11.01%. Calcd for $C_{52}H_{64}N_8O_{12}$: C, 62.89; H, 6.50; N, 11.28%. Gel permeation chromatography gave a single peak at 1000±40.

Compound **1**(X=OCH_2CO) was similarly synthesized by the high-dilution method from equimolar amounts of 1,10-diaza-4,7,13,16-tetraoxa-18-crown-6 and 4,4′-bis(chloroformylmethoxy)azobenzene. 4,4′-Bis(carboxymethoxy)azobenzene was prepared from 4,4′-dihydroxyazobenzene and chloroacetic acid in aqueous solution containing NaOH: mp 250 °C, yield 73%. 4,4′-Bis(chloroformylmethoxy)azobenzene was obtained by treating this compound with thionyl chloride: mp 140—145 °C, yield 69%. The condensation to synthesize **1**(X=OCH_2CO) was carried out in benzene in the presence of triethylamine. The raw product was purified by the TLC method(silica gel, chloroform–methanol (8 : 2 v/v)) and finally recrystallized from chlorobenzene: mp 219—221 °C yield 37%. IR(KBr): $\nu_{C=O}$ 1660 cm^{-1}, ν_{C-O-C} 1060—1160 cm^{-1}. NMR($CDCl_3$): crown protons, 3.4—3.8 ppm, 48H; OCH_2, 4.80 ppm, 8H; 3′-H of azobenzene, 6.92 ppm, 8H; 2′-H of azobenzene, 7.72 ppm, 8H. Found: C, 60.47; H, 6.59; N, 9.73%. Calcd for $C_{56}H_{72}O_{16}N_8$: C, 60.42; H, 6.52; N, 10.07%. Gel permeation chromatography gave a single peak at 1000±50.

Compound **2**(*n*=9) was synthesized according to the high-dilution method from equimolar amounts of 1,23-bis(*p*-aminophenoxy)-3,6,9,12,15,18,21-heptaoxatricosane[16] and 4,4′-bis(chloroformyl)azobenzene[4] in benzene in the presence of triethylamine. The precipitate was a mixture of triethylamine hydrochloride and orange solid. The colored solid(polymer?) was insoluble in usual organic solvents. The filtrate was washed with water and concentrated to dryness *in vacuo*. The residue was recrystallized from benzene: mp 179—183 °C, yield 8.4%. IR(KBr): ν_{NH} 3450 cm^{-1}, $\nu_{C=O}$ 1670 cm^{-1}, ν_{C-O-C} 1120—1126 cm^{-1}. NMR(Me_2SO-d_6, 70 °C): central methylene protons at 8, 10, 11, 13, 14, and 16 positions, 3.21 ppm, 12H; 5, 7, 17, and 19 methylene protons, 3.46 ppm, 8H; 4 and 20 methylene protons, 3.57 ppm 4H; 2 and 22 methylene protons, 3.79 ppm, 4H; 1 and 23 methylene protons, 4.22 ppm, 4H; aromatic protons of the aminophenol moiety, 7.02 ppm (4H), 7.40 ppm (4H); aromatic protons of the azobenzene moiety, 7.88 ppm (4H), 8.00 ppm (4H); NH, 10.04 ppm, 2H. Mass spectrum: M^+ (*m/e*) 786. Found: C, 63.57: H, 6.38; N, 7.11%. Calcd for $C_{42}H_{50}O_{11}N_4$: C, 64.11; H, 6.40; N, 7.12%. Gel permeation chromatography gave a single peak at 770±50.

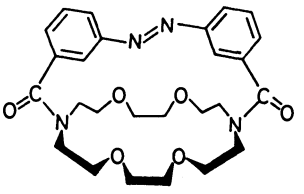
Compound **3**(Y=An) and **3**(Y=EtAn) were prepared by the reaction of 4,4′-bis(chloroformyl)azobenzene[4] with aniline and *N*-ethylaniline, respectively, in benzene in the presence of triethylamine. **3**(Y=An): mp>260 °C. Found: C, 74.37; H, 4.66; N, 13.47%. Calcd for $C_{26}H_{20}N_4O_2$: C, 74.27; H, 4.79; N, 13.32%. **3**(Y=EtAn): mp 135—140 °C. Found: C, 70.23; H, 6.19; N, 10.98%. Calcd for $C_{30}H_{28}N_4O_2 \cdot 2H_2O$: C, 70.29; H, 6.29; N, 10.93%. The preparation of **3**(Y-Morph) was described previously.[4]

Miscellaneous. The method of solvent extraction was described priviously.[4,8] The deteils of the work-up conditions are recorded in footnotes to Table 2. A 500-W high-pressure Hg-lamp with a color glass filter (330 nm<λ<380 nm) was used for the *trans*-to-*cis* photoisomerization unless otherwise stated. The ionophore concentration for the solvent extraction was usually higher than that for the kinetic measurements. In case the concentration was extremely high, the *trans*-to-*cis* photoisomerization was slow and the *cis*-percentage at the photostationary state was not sufficiently high. We thus prepared a thin solution layer between two glass plates and photoirradiated the solution. This method enabled a satisfactory photoconversion to the *cis*-isomers. The *cis*% at the photostationary state was estimated from the decrease in the absorption maximum of the *trans*-isomers, assuming that the absorbance of the *cis*-isomers at the wavelength is neglible in comparison to that of the *trans*-isomers. In all cases, the *cis-trans* isomerism was reversible within the experimental error.

The method of kinetic measurements was also described in the previous papers.[4,8] After a cuvette containing an ionophore solution was photoirradiated, the cuvette was transferred to a thermostated cell-holder (30 °C) in a spectrophotometer. The reaction was monitored by following the appearance of the absorption maximum of the *trans*-isomers.

Results and Discussion

Syntheses, Spectroscopic Properties, and Photoresponsiveness. We previously synthesized an azobenzene-capped azacrown ether **4** (*i.e.*, 1 : 1 adducts) from 1,10-diaza-4,7,13,16-tetraoxa-18-crown-6 and 3,3′-bis(chloroformyl)azobenzene in 23% yield.[4] On the other hand, the reaction between the azacrown ether and 4,4′-bis(chloroformyl)azobenzene mainly gave the polymer.[4] The difference was rationalized in terms of the steric factor that the distance between 1-*N* and 10-*N* of the azacrown ether is almost equal to that between two carbonyl groups of the 3,3′-isomer but significantly shorter than that between two carbonyl groups of the 4,4′-isomer. The present result indicates that when the distances between two reaction centers do not fit each other, the 2 : 2-adduct such as **1** (X=CO) and (**1** X=OCH_2CO) results under high-dilution conditions



4

An azobenzenophane **2** (*n*=9) was also synthesized according to the high-dilution method. The CPK model of **2** (*n*=9) suggests that the poly(oxyethylene) clain is almost linearly extended when the azobenzene segment adopts the *trans*-configuration. We attempted the synthesis of the homologues with the smaller ring-size (*e.g.*, **2** (*n*=7 and 8)), but we could not isolate any cyclic compound by the TLC method. The result suggests that eight oxyethylene units are the shortest chain to form the cyclic adduct.

In the NMR measurements, the crown protons of **1** (X=CO) and **1** (X=OCH_2CO) appeared at 3.5—3.8 ppm and 3.4—3.8 ppm, respectively, as a broad single

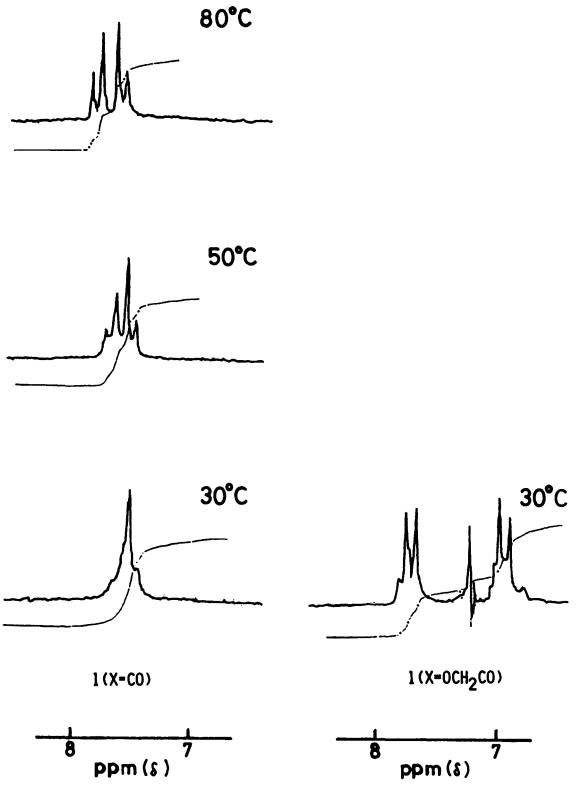

Fig. 1. Temperature dependence of the NMR spectra of **1** (X=CO) (in Me_2SO-d_6) and **1** (X=OCH_2CO) (in $CDCl_3$).

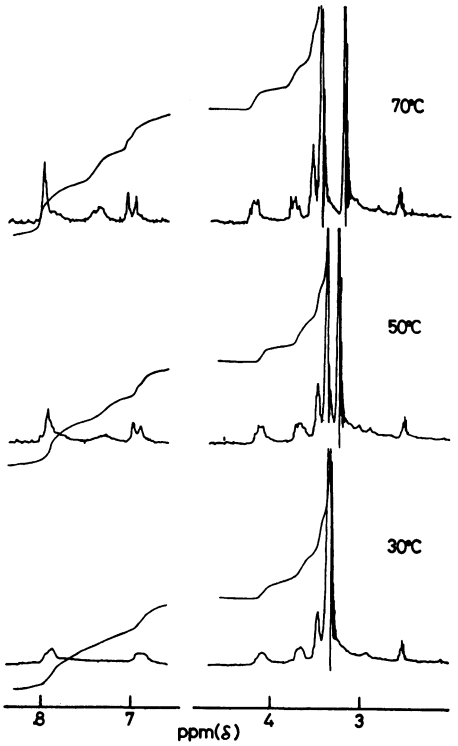

Fig. 2. Temperature dependence of the NMR spectra of **2** (n=9) (in Me_2SO-d_6).

peak. On the other hand, the NMR spectrum of **4** gave two resolved peaks at 3.6—3.9 ppm (8H) and 4.1—4.8 ppm (16H), which were attributed to *N*-CH_2 and *O*-CH_2 of the crown ring, respectively.[4] The comparison of these data suggests that the *O*-methylene protons of **4** are somewhat deshielded by the ring current of the azobenzene moiety. The finding is in line with our previous prediction that the azobenzene moiety of *trans*-**4** stands vertically over the crown ether plane.[4]

Another interesting finding in the NMR measurements is the fact that the NMR peaks of **1** (X=CO) and **2** (n=9) are significantly broad at 30 °C, whereas those of **1** (X=OCH_2CO) are not subject to such a broadening effect (Figs. 1 and 2). The peaks are sharpened with increasing temperature. Conceivably, the broadening effect is induced by the steric rigidity of these molecules and in fact, the CPK models of **1** (X=CO) and **2** (n=9) are more rigid than that of **1** (X=OCH_2CO). It is interesting to know whether the steric rigidity is reflected by photoresponsive behaviors of these molecules. As shown is Table 1, we have found that it takes a long time for **1** (X=CO) and **2** (n=9) to reach the photostationary states as compared with the time required for **1** (X=OCH_2CO) and model compounds such as **3** (Y=An), **3** (Y=EtAn), and **3** (Y=Morph). In contrast, the significant difference was not found for the rate of the thermal *cis*-to-*trans* isomerization: the rate constants ($k_{cis\rightarrow trans}$) for **1** (X=CO) and **2** (n=9) are comparable with those for the model compounds. These results may mean that the transition state of **1** (X=CO) and **2** (n=9) in the photoisomerization process is more destabilized than that of **1** (X=OCH_2CO) and model compounds. Previously, Shiga *et al.*[3] synthesized phane-type crown ether in which a poly(oxyethylene) chain is linked directly by 2,2′-azobenzene. It was found, however, that the photoisomerization of this compound is extremely slow and sometimes accompanied by photodecomposition. This would be also due to the sterically-destabilized transition state. Fortunately, the *trans*-isomers used in the present

study were photochemically converted to the *cis*-isomers and the *cis*-isomers were thermally converted back to the *trans*-isomers: the *cis-trans* isomerism was reversible within the allowable experimental error. Meanwhile, we consider that the enhanced rate constant ($k_{cis \rightarrow trans}$) observed for **1** (X=$OCH_2CO$) is attributable to the electronic effect but not to the steric effect.

Along the isomerization process of the photoresponsive cylindrical ionophores there exist three different isomers: *trans-trans*, *trans-cis*, and *cis-cis*. The thermal isomerization of these cylindrical ionophores satisfied the first-order rate equation for up to four half-lives and the UV-visible spectra of the thermal isomerization showed sharp isosbestic points. The results support that no intermediate is accumulated along the isomerization pathway. One may suppose, therefore, that 65% *cis*-**1** (X=CO) means, for example, 65% *cis-cis*-**1** (X=CO) and 35% *trans-trans*-**1** (X=CO).

Solvent Extraction of Alkali Metal Cations. Solvent extraction of alkali picrates with cylindrical and phane ionophores is summarized in Table 2. Ex% denotes the partition of picrate to organic phase. At the start of this experiment, we expected that *trans-trans*-**1** (X=CO) would form a 1 : 1 crown/metal (*i.e.*, 1 : 2 **1** (X=CO)/metal) complex, whereas *cis-cis*-**1** (X=CO) would form a 2 : 1 crown/metal (*i.e.*, 1 : 1 **1** (X=CO)/metal) sandwich-type complex with large alkali metal cations. The Ex% of picrate salts in Table 2 reveals, however, that the formation of the sandwich-type complex is rather unlikely: *cis-cis*-**1** (X=CO) generally exhibits a metal affinity greater than *trans-trans*-**1** (X=CO), but the enhancement in the Ex% is not limited to large alkali metal cations. We consider at present that the steric rigidity of the crown rings is somewhat relaxed through the photoisomerization of the azobenzene pillars, resulting in the improved affinity toward all alkali metal cations. Similarly, *cis-cis*-**1** (X=OCH_2CO) has the larger Ex% than *trans-trans*-**1** (X=OCH_2CO) and exhibits the selectivity for small alkali metal cations.

It is speculated on the basis of the CPK model building that the poly(oxyethylene) chain of *trans*-**2** (n=9) is almost linearly extended while that of *cis*-**2** (n=9) may form a crown-like loop. The examination of Table 2 reveals that *trans*-**2** (n=9) completely lacks the affinity with metal ions, whereas photoisomerized *cis*-**2** (n=9) is capable of extracting large alkali metal cations such as Rb^+ and Cs^+ in the significant Ex%. Thus, an ionophoric, crown-like loop appears and disappears in response to photoirradiation and the loop size is roughly comparable with that of 21-crown-7.

Solvent Extraction of Polymethylenediammonium Salts. One of the most interesting characteristics of photoresponsive cylindrical ionophores would be the possibility that the distance between two crown rings changes reversibly by an on-off light-switch. The possibility was tested by the solvent extraction of polymethylenediammonium salts as a molecular measure. The inspection of CPK models suggests that, assuming that the polymethylene chain adopts an extended conformation, the distances between the two crown rings of *trans-trans*-**1** (X=CO) and *cis-cis*-**1** (X=CO) are almost equal to those between the two terminal ammonium groups of decamethylenediamine and hexamethylenediamine, respectively.

Table 3. Extraction of polymethylenediammonium salts with cylindrical crown ethers (30 °C)

Crown	Ex(%) of $H_3N^+(CH_2)_nNH_3^+\cdot(picrate)_2$				
	n=4	6	8	10	12
1 (X=CO)[a], dark	0.5	3.0		20.0	27.2
light(*cis* 22%)	0.8	8.9		12.3	22.0
light(*cis* 38%)	2.4	12.6		9.3	18.9
light(*cis* 54%)	3.0	19.0		6.7	13.1
1 (X=OCH_2CO)[b], dark		0	0	3.0	7.6
light(*cis* 67%)		0	0	0.4	4.2

a) Aqueous phase: [picric acid]=4.00×10^{-4} M, [HCl]=5.96×10^{-2} M, [$H_2N(CH_2)_nNH_2$]=3.00×10^{-2} M. Organic phase: [**1** (X=CO)]=3.00×10^{-3} M, *o*-dichlorobenzene: butyl alcohol=9 : 1 by volume. b) Aqueous phase:[picric acid]=4.00×10^{-4} M, [HCl]=5.96×10^{-2} M, [$H_2N(CH_2)NH_2$]=2.99×10^{-2} M. Organic phase: [**1** (X=OCH_2CO)]=2.98×10^{-3} M in chloroform.

The Ex% was evaluated on the basis of the partition equilibrium of picrate ion added as counter-anion between an organic phase and an aqueous phase (see footnote b) in Table 3). The results in Table 3 substantiates several important points: (i) *trans-trans*-**1** (X=CO) extracts decamethylane and dodecamethylenediammonium salts efficiently but hardly extracts tetramethylene and hexamethylenediammonium salts, (ii) hexamethylenediammonium salt gives the greatest Ex% value under UV-light irradiation, and (iii) with increase in the concentration of *cis-cis*-**1** (X=CO), Ex% of tetramethylene and hexamethylenediammonium salts increases while Ex% of decamethylene and dodecamethylenediammonium salts decreases. The findings are basically compatible with the prediction from CPK model building. Similarly, *trans-trans*-**1** (X=OCH_2CO)

is capable of extracting diammonium salts with long methylene units but scarcely extracts those with short methylene units. As expected, the Ex% of decamethylene and dodecamethylenediammonium salts is suppressed by UV irradiation.

Conclusion

The present paper represents two novel findings. One is the fact that in the photoresponsive cylindrical ionophores, the distance between two crown rings is readily convertible by photoinduced *cis-trans* isomerism of the azobenzene pillars. The other is the all-or-noting change in the metal affinity observed for the azobenzenophane-type ionophore. These novel photoresponsive behaviors would be applicable to the photocontrol of solvent extraction, membrane transport, spatial distance between two metal ions, *etc.*

Photoaddition Reaction of 1,4-Dibromo-2,5-piperazinedione with Cyclohexene

Kuniaki Itoh

Department of Science of Material Reactions, Division of Science of Materials, Graduate School of Science and Technology, Kobe University, Kobe 657

(Received December 27, 1982)

The photo-induced addition reaction of 1,4-dibromo-2,5-piperazinedione (1) with cyclohexene in acetonitrile gave 1 : 1-adducts[1-(2-bromocyclohexyl)-2,5-piperazinediones] and 1 : 2-adducts[1,4-bis(2-bromocyclohexyl)-2,5-piperazinediones] besides 3-bromocyclohexene, 1,2-dibromocyclohexane, and a solvent-incorporated product, *trans*-2-acetylamino-2-bromocyclohexane. Stereochemistry of the adducts was elucidated and mechanism of the addition reaction was discussed.

The characteristic feature of the reactions of *N*-halo imides and amides is their use in well-known allylic halogenation of olefins.[1,2] However, in some instances, the *N*-centered free radicals produced from *N*-halo imides or amides underwent addition to the olefinic double bonds to give addition products.[3-6] The two processes proceed competitively, but the one process can predominate over the other according to the subtle change in the reaction conditions. Thus, Skell and his co-workers[3,7] demonstrated that the photoreaction of *N*-chlorosuccinimide with cyclohexene gave *N*-(2-chlorocyclohexyl)succinimide, 3-chlorocyclohexene, and 4-chlorocyclohexene: the addition and the substitution being closely competitive processes. Chow and his co-workers[4] also showed that the substitution/addition ratio of the photoreaction of *N*-bromosuccinimide (NBS) with cyclohexene was dependent on temperature, solvents, added ethylene oxide (a hydrogen bromide trap), and molar ratio of reactants. The solubility of NBS in organic solvents changed noticeably the reaction pattern (hydrogen abstraction *vs.* addition to double bond) of NBS. Recently, we reported that irradiation of 1,4-dibromo-2,5-piperazinedione (**1**) with cyclohexene in the presence of alcohols efficiently induced alkoxy-bromination of cyclohexene in dichloromethane.[8] A free radical scavenger was employed to avoid possible free radical reactions. However, with less reactive alcohols, especially with *t*-butyl alcohol, the reaction gave an addition product, 1,4-dibromo-2,5-piperazinedione-cyclohexene 1 : 2-adduct, in addition to the expected alkoxybrominated product. Because the *N*-bromo compound (**1**) is almost insoluble in dichloromethane, the photoreaction had been carried out under heterogeneous conditions. The present investigation concerns the photoaddition reaction of **1** with cyclohexene in acetonitrile or halogenated hydrocarbon solvents. Acetonitrile is a poor solvent for **1**, but better than carbon tetrachloride. Structure of the adducts and the stereochemical course of the reaction are discussed.

Results and Discussion

The photoreaction of 1,4-dibromo-2,5-piperazinedione (**1**) was carried out with cyclohexene in a 1 : 10 mole ratio for 3 h at 20 °C in acetonitrile. The reaction mixture was vigorously stirred during the irradiation. After usual work-up, products were separated by silica gel chromatography. The results are given in Table 1.

The photoreaction of NBS with cyclohexene in carbon tetrachloride (heterogeneous conditions) gave no NBS-olefin adduct. In contrast, that in acetonitrile (homogeneous conditions) was reported to yield *N*-(2-bromocyclohexyl)succinimide.[2,4] With 1,4-dibromo-2,5-piperazinedione (**1**), predominant formation of 3-bromo-

a) Irradiation of a mixture of **1** (20 mmol) and cyclohexene (200 mmol) in 100 ml of a solvent at 20 °C for 3 h. Isolated yields are given based on **1** employed. b) The yields are determined by GLC. c) Unchangel **1** was recovered in a 25% yield. d) Hydroquinone (0.1 molar equivalent to **1**) was added. e) The molar ratio of **1** to cyclohexene was 1/5.

cyclohexene (**5**) in a carbon tetrachloride solution (heterogeneous conditions) was observed. This implied the intervention of hydrogen abstraction at the allylic position of cyclohexene by means of the Goldfinger mechanism proposed originally for the reaction of NBS with olefins in carbon tetrachloride.[1] However, in better solvents for *N*-bromo imides and amides[9] (*e.g.* acetonitrile and dichloromethane; though the reaction conditions are still not completely homogeneous, they are somewhat more homogeneous than in the carbon tetrachloride solution) the addition of 2,5-dioxo-1-piperazinyl radical to the cyclohexene double bond proceeded rather smoothly to yield the adducts **2** and **3**. The 1,2-adducts, [1,4-bis(2-bromocyclohexyl)-2,5-piperazinedione, **2**], were separated by a silica-gel column to give four stereoisomers (**2a, b, c, d**) in a ratio given in Table 1. In addition, small amounts of the 1 : 1-adducts, [1-(2-bromocyclohexyl)-2,5-piperazinedione(**3**)], were isolated besides *trans*-1,2-dibromocyclohexane (**4**) and 3-bromocyclohexene (**5**). The 1 : 1-adducts were also separated to give a pair of stereoisomers (**3a, b**). Interestingly a small amount of a solvent-incorporated product, *trans*-2-acetylamino-2-bromocyclohexane (**6**), was obtained in case where acetonitrile was employed as the solvent. Other solvents gave no solvent-incorporated products. In all cases, 2,5-piperazinedione (**7**) was obtained in variable amounts.

Stereochemistry of the Adducts. The structures of all the products were determined by means of spectroscopic data and elemental analyses. The 1 : 1-adducts (**3a, b**) and 1 : 2-adducts (**2a—d**) showed characteristic infrared absorptions of the 2,5-piperazinedione moiety. The infrared absorption of these compounds (Table 2) allowed us to assign the adduct structures. Klaeboe, Lothe and Lunde[10] reported that, of the two C–Br stretching frequencies of bromocyclohexanes, the 685 cm^{-1} band should be assigned to the equatorial C–Br bond and the 658 cm^{-1} (lower frequency) band to the axial C–Br bond. In addition, *trans*-*N*-(2-chlorocyclohexyl)piperazine was reported to show its equatorial C–Cl stretching frequency at 730 cm^{-1}. The absorption of the axial C–Cl bond of the corresponding *cis* isomer was observed at 680 cm^{-1} (lower frequency).[5] The structures of the 1 : 1-adducts (**3a, b**) were confirmed to be 1-(2-bromocyclohexyl)-2,5-piperazinedione by means of preliminary spectroscopic analysis. In addition, from Table 2, it was deduced that **3a** has an equatorial bromine atom and **3b** has an axial bromine atom. Thus, **3a** and **3b** are possibly diastereoisomeric to each other. This assignment was reinforced by inspection of their NMR spectra. The axial –CHBr– protons of bromocyclohexane is known to appear at 3.82 ppm whereas the equatorial counterpart does at a lower field, 4.60 ppm. The half-height width of the former signal is wider than that of the latter. For example, Driguez and Lessard[5] reported that in *trans*-*N*-(2-chlorocyclohexyl)piperazine the axial proton on C_2 appeared at 3.72 ppm with a half-height width of 25 Hz, while in the *cis* isomer the equatorial proton on C_2 did at 4.43 ppm with a half-height width of 6.5 Hz. Chemical shifts and half-height widths given in Table 2 clearly

indicated the structure of **3a** as *trans*-1-(2-bromocyclohexyl)-2,5-piperazinedione, and that of **3b** as the corresponding *cis* isomer having an axial bromine substituent.

Structural elucidation of the 1 : 2-adducts (**2a**—**d**) was achieved taking the following consideration into account. The infrared absorptions of the 1 : 2-adducts showed that **2a** and **2b** have two equatorial bromine atoms, while **2c** has an axial and an equatorial bromine atoms. Interestingly, the presence of two axial bromine atoms in **2d** was indicated by its strong infrared absorption at 660 cm^{-1}. Each 1 : 2-adduct was reduced by tributyltin hydride to give identical 1,4-dicyclohexyl-2,5-piperazinedione. Accordingly these four 1 : 2-adducts were determined to be stereoisomeric to each other at the carbon atoms bound to bromine atoms. The chemical shifts and half-height widths of **2a** and **2b** (Table 2) indicated the presence of the *trans*-diaxial orientation of the vicinal protons (H_1/H_2, H_{11}/H_{12}, or H_{11}/H_{16}), which gave large half-height width absorptions, respectively. The 2,5-piperazinedione ring protons (H_8 and H_{10}) appeared as a singlet, indicating that they experienced an equivalent magnetic environment. A definitive structure assignment for **2a** was made by X-ray crystallography. A suitable single crystal of **2a** was obtained by careful recrystallization from acetone. The unit cell was found to be monoclinic, space group $P2_1/C$, with lattice parameters $a=13.37(1)$ Å, $b=11.59(1)$ Å, $c=11.93(1)$ Å, $\beta=98.55(7)°$, and $Z=4$. Of 4192 independent reflections obtained by using monochromated Mo *Ka* radiation, 1946 reflections with $|F_0|\geq 3\sigma(|F_0|)$ were considered to be observed.[11] The molecular structure of **2a** shown in Fig. 1 reveals that the C–Br bonds and the C=O groups are forced to located at an opposite direction by their dipole-dipole repulsion. The structure of **2b** was similarly determined as a diastereoisomer of **2a** as shown in Scheme 2 by its spectral characteristics.

The other 1 : 2-adducts, **2c** was found to possess an axial and an equatorial bromine substituents. The narrow half-height width observed for one of –CHBr– protons (an axial proton) supported this assignment. A crystal of **2c** obtained from methanol was monoclinic, space group C2/C, with lattice parameters $a=27.043$ (6) Å, $b=12.543(3)$ Å, $c=11.251(3)$ Å, $\beta=109.23(2)°$, and $Z=8$. The molecular structure of **2c** was determined by X-ray analysis, and shown by the ORTEP drawing in Fig. 1.[11] Crystallographic analysis gave the torsional angle of about 90° between the left-hand cyclohexane ring and the central 2,5-piperazinedione ring, and that of about 60° between the right-hand cyclohexane ring and the 2,5-piperazinedione ring. The central 2,5-piperazinedione ring was determined to exist in a flattened boat conformation. This molecular geometry resulted in characteristic NMR signals of **2c**. The structure of **2c** (Fig. 1 [C]) reveals that one of the protons on C_8 is placed close to the axial C_{16}–Br bond of the right-hand cyclohexane ring so that the C_8 methylene protons become magnetic nonequivalent to each other to give an AB quartet centered at 4.17 ppm. The other methylene proton on C_{10} appear at 3.92 ppm (singlet) as the corresponding C_8 and C_{10} protons of **2a** and **2b** do. The other chemical shift data and half hight widths are consistent with those expected from the depicted structure.

The structure of **2d**, which had two axial bromine atoms, was elucidated as shown in Scheme 2 taking the following spectral data into consideration; low field shift and narrow $\Delta\nu_{1/2}$ observed for both H_2 and H_{16}, and AB splitting of H_8 and H_{10} protons.

Course and Stereochemistry of Addition Reaction. The reaction did not occur in the dark. 1,4-Dibromo-2,5-piperazinedione (**1**) was hardly soluble in carbon tetrachloride, and the reaction gave no adducts, but the dominant allylic bromination was observed. The other chlorinated hydrocarbons showed a slightly enhanced solubility for **1**. The photoreaction of **1**

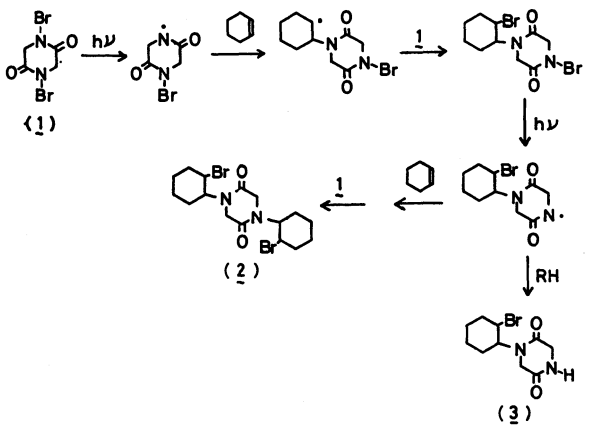
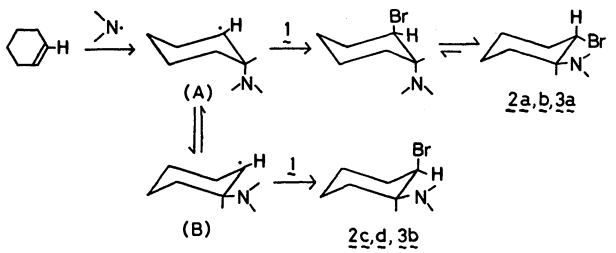


Scheme 3.

with cyclohexene in these solvents gave the adducts **2** and **3**. Acetonitrile was found to be the most convenient solvent for the photoreaction of **1**, although the solubility of **1** was not satisfactory. In acetonitrile the photoreaction of **1** with cyclohexene gave the adducts in considerable amounts. In the presence of hydroquinone, the yield of the adducts (**2** and **3**) decreases down to 7% from 52%. From this observation and the absence of rearranged products in the photoreaction of **1** with 3,3-dimethyl-1-butene,[12] an ionic reaction mechanism was ruled out. Thus the adducts were thought to be produced through a radical process involving the 2,5-dioxo-1-piperazinyl radical as the chain transfer species (Scheme 3).

In acetonitrile, a small amount of *trans*-2-acetylamino-2-bromocyclohexane (**6**) was produced. The yield of **6** was increased with an increased mole ratio of cyclohexene to **1**. The formation mechanism of **6** is to be noted. Photodecompotion of **2** in acetonitrile did not give rise to **6**. This suggests that **2** is not an intermediate to give **6**. Instead, the photoreaction of **1** with cyclohexene in acetonitrile-d_3 gave Me-d_3-**6**, indicating the intervention of a Ritter type reaction.[13] A concomitant reaction which is often encountered in NBS reactions is the ring opening to produce the isomeric 3-bromopropionyl isocyanate.[2] The reaction is reported to be enhanced in the presence of olefins.[14,15] However, in the present investigation, we could not detect any ring opening product.

It is reasonable to expect that the 2,5-dioxo-1-piperazinyl radical attacks the double bond of cyclohexene at the least hindered site, which corresponds to an axial direction in the resulting cyclohexyl radical (Scheme 4, A). The bromine atom is then transferred from **1** to this radical (*trans* addition), and following ring inversion give the adducts with equatorial bromine substituents (**2a, b**, and **3a**). The intermediate radical (A) can invert to give rise to the conformationally more favorable radical (B) having the equatorial 2,5-piperazinedione moiety. Inspection of the stereomodel of B indicates a sterically favored axial bromine attack which gives the adducts **2c, d**, and **3b**. Diastereomers **2a, b** having all substituents at the equatorial position of cyclohexane rings are undoubtedly most stable products, so that the yield of (**2a**+**2b**) is always exceeded that of (**2c**+**2d**). The conformationally unfavored adduct **2d** with two axial bromine substituents was produced in a lowest yield. In addition, it seems that highly symmetrical molecular geometry of **2a** (a center of symmetry, see Fig. 1) is responsible for its predominant formation over **2b**.



Scheme 4.

The regioselectivity of the addition of **1** to 1-methylcyclohexene and 3,3-dimethyl-1-butene provides a straightforward evidence for the 2,5-dioxo-1-piperazinyl radical as the initial attacking entity to the double bonds (Scheme 2).[12] As pointed out by Skell and Day[15] the radical generated by the processes like **1** + R·→2,5-dioxo-1-piperazinyl radical + R–Br has overwhelmingly σ_N–character (the first exited state). Recent ab initio[16] as well as INDO[17] calculations for the succinimido radical suggested that the ground state (π-radical) is 83 kJ mol^{-1} more stable than the first exited state (σ_N-radical). This energy difference nicely explains the selectivity differences observed for the hydrogen abstraction reactions by **1**, and the enhanced reactivity of the NBS σ_N-radical for aromatics.[2] For other cyclic imido and amido radicals, Apeloig and Schreiber[16] pointed out that the energy differences between the ground state π- and the first exited state σ_N-radical is expected to be greater than 83 kJ mol^{-1}. This difference may be responsible for the enhanced addition reactivity of the radical. However, absence of the radical isomerization and failure of the reaction of **1** with aromatics[12] indicate complex nature of 2,5-dioxo-1-piperazinyl radical.

Experimental

Cyclohexene was dried over Molecular Sieves 4A and distilled over copper(I) chloride prior to use. Acetonitrile was dried over calcium hydride and distilled. 1,4-Dibromo-2,5-piperazinedione (**1**) was prepared according to the procedure reported ealier.[8] IR spectra were recorded as KBr disk with JASCO IR-A-1 and IR-A-3 spectrometers. NMR spectra were measured on JEOL JNM-PMX-60 and JNM-PS-100 spectrometers using tetramethylsilane as the internal standard. Mass spectra were obtained by a Hitachi RMU-6MG spectrometer. GLC anaysis was carried out by a Yanagimoto Model G 1800-F. Irradiation was carried out using a Halos EHB-WU high pressure mercurry arc lamp (100 W).

Reaction of 1,4-dibromo-2,5-piperazinedione (1) with cyclohexene. A typical experimetal procedure is described. Irradiation of a mixture containing 5.44 g (20 mmol) of **1** and 16.43 g (200 mmol) of cyclohexene in acetonitrile (100 ml) was carried out under stirring for 3 h. The mixture was filtered to give 2,5-piperazinedione (**7**) in a 36% yield. A part of the filtrate was directly injected into a GLC column to determine the amounts of low boiling products: *trans*-1,2-dibromocyclohexane (**4**) and 3-bromocyclohexene (**5**) were produced in 17% and 24% yields, respectively. The rest of the filtrate was evaporated up to a syrup, which was separated by a column packed with silica gel using benzene–acetone (4 : 1) as a eluant. Yields are given in Table 1 on the basis of **1** employed. Physical constants of the isolated products are shown below. For characteristic IR absorptions and NMR chemical shifts, see Table 2.

Found; C, 44.28, H, 5.80%; Calcd;

see above. **2d**: Mp 212—213 °C; IR, 1650, 1470, 1175 cm^{-1}, NMR($CDCl_3$), δ=1.1—2.6 (16H, m); MS (*m/e*), the same as that of **2a**. Found; C, 44.36, H, 5.71%; Calcd see above.

1-(2-Bromocyclohexyl)-2,5-piperazinedione (3a): Mp 165.5—166.5 °C; IR, 3300, 1680, 1470, 1190 cm^{-1}; NMR($CDCl_3$) δ=1.1—2.6 (8H, m), 7.10 (1H, s); MS (*m/e*), 274, 272 (M^+), 194, 115, 81. Found; C, 43.53, H, 5.94%; Calcd for $C_{10}H_{15}BrN_2O_2$; C, 43.65, H, 5.49%. **3b**: Mp 165—166 °C; IR, 3480, 1680, 1630, 1470, 1170 cm^{-1}; NMR($CDCl_3$), δ=1.1—2.5 (8H, m), 6.90 (1H, s); MS (*m/e*), the same as that of **3a**. Found; C, 43.29 H, 5.61%; Calcd see above.

trans-2-acetylamino-2-bromocyclohexane (6): Mp 116.5—117.5 °C (lit,[16] 109—110 °C). IR, 3300, 1620, 690 cm^{-1}; NMR($CDCl_3$), δ=1.1—2.6 (8H, m), 2.00 (3H, s), 3.8—4.1 (2H, m), 5.6—6.0 (1H, m); MS (*m/e*), 221, 219 (M^+), 140, 98, 81. Found; C, 43.62, H, 6.32%; Calcd for $C_8H_{14}BrNO$; C, 43.65, H, 6.41%.

Reduction of 1,4-Bis(2-bromocyclohexyl)-2,5-piperazinedione (2) with Tributyltin Hydride. Compound **2a** (73.5 mg, 0.17 mmol), tributyltin hydride (117 mg, 0.4 mmol), and AIBN (8 mg) were dissolved in 5 ml of benzene, and the mixture was kept in an atmosphere of nitrogen at 80 °C for 3 h. The solvent was evaporated off and the residure was chromatographed through a silica gel column using benzene–acetone (4 : 1) to give 1,4-dicyclohexyl-2,5-piperazinedione in a 85% yield; mp 230.5—232.0 °C; IR, 1650, 1480, 1180 cm^{-1}; NMR ($CDCl_3$), δ=0.9—2.2 (20H, m), 3.93 (4H, s), 3.9—4.6 (2H, m). Found; C, 68.80, H, 9.40%; Calcd for $C_{16}H_{26}N_2O_2$; C, 69.03, H, 9.41%. All the other isomer, **2b—d**, were reduced similarly, and the same 1,4-dicyclohexyl-2,5-piperazinedione was obtained in all cases.

The author is grateful to Professor Akira Sera, Faculty of Science, Kobe University for his comments and suggestions for improvement of the manuscript, and wishes to thank Professor Kazumi Nakatsu and Mr. Kohmei Kafuku, Faculty of Science, Kwansei Gakuin University, for X-ray crystallographic analysis.

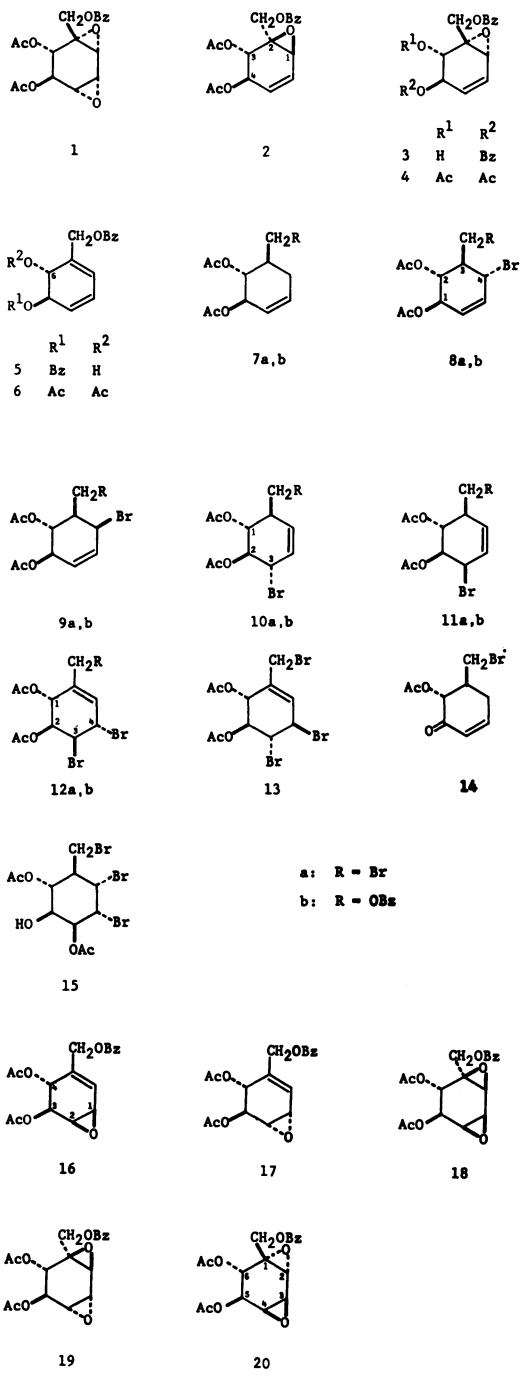
(Received January 14, 1983)

The title substituted 1,3-cyclohexadiene was prepared in three steps from the readily available DL-1,2-di-*O*-acetyl-(1,3/2)-3-bromomethyl-5-cyclohexene-1,2-diol. Epoxidation of it with *m*-chloroperoxybenzoic acid in 1,2-dichloroethane afforded several stereoisomers of the biologically interesting highly oxygenated cyclohexane derivatives.

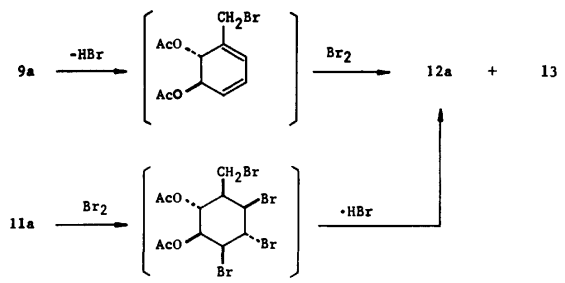
Crotepoxide (**1**),[2] senepoxide (**2**),[3] and pipoxide (**3**)[4] belong to a family of highly oxygenated cyclohexane derivatives which exhibit tumor-inhibitory, antileukemic, or antibiotic activity. Very recently, 1,6-desoxypipoxide (**5**), a key intermediary metabolite of **3**, has been isolated from *Uvaria purpurea*.[5] As a part of a synthetic study of mono- and diepoxycyclohexane compounds of biological interest,[6] several stereoisomeric compounds of this class were synthesized by epoxidation of properly functionalized 1,3-cyclohexadiene **6**.

Synthesis of the Substituted 1,3-Cyclohexadiene. Allylic bromination of DL-1,2-di-*O*-acetyl-(1,3/2)-3-bromomethyl-5-cyclohexene-1,2-diol (**7a**)[7] with molar equiv. of *N*-bromosuccinimide (NBS) in carbon tetrachloride in the presence of α,α'-azobisisobutyronitrile (AIBN) was carried out at 80 °C under nitrogen atmosphere for 0.5 h to give, after crystallization followed by fractionation on a silica-gel column, two dibromides **8a** (23%) and **10a** (7%), and one tribromide **12a** (9%), together with a small proportion of an α,β-unsaturated ketone **14** (3.7%).[8] When the same reaction was quenched after heating for 5 min, the new dibromide **11a** could be isolated in 2.6%, together with **8a** (16%). Under these reaction conditions, four dibromides **8a**—**11a** were expected to be obtainable and to be interconvertible by way of an allylic rearrangement. The results indicated that **8a** and **10a** were comparatively stable among them. When excess NBS (3 molar equiv.) was used in the reaction, **12a** was obtained in a quantitative yield. A small proportion of the isomeric tribromide **13** was shown to be present in a crude **12a** by ^{1}H NMR spectroscopy. Formation of **12a** would be rationalized by a readily dehydrobromination of an unstable dibromide **9a** followed by an addition of bromine generated *in situ* by hydrobromic acid and NBS or an addition of bromine to **9a** and/or **11a** followed by dehydrobromination (Scheme 2).

The structures of the dibromides and tribromide were elucidated on the basis of their ^{1}H NMR spectra. Thus, the spectrum of **8a** showed the coupled signals for H-3 and H-4 as a doublet of doublets of triplets (δ 2.59, J= 3, 3, 9, and 12 Hz) and a doublet of quartets (δ 4.90, J=2.5, 2.5, 2.5, and 9 Hz), indicating the axial–pseudoaxial conformations for H-3 and H-4. In the spectrum of **10a**, two protons attached to the carbon atoms bearing the acetoxyl groups appeared as coupled two doublets of doublets (J=8 and 10 Hz) at δ 5.10 and 5.50, being in accord with the assigned structure.



Scheme 1.



Scheme 2.

In the spectrum of **11a**, one-proton doublet of doublets of doublets (δ 6.10, J=3, 5, and 11 Hz) could be attributed to the C-4 olefinic proton adjacent to the bromo group oriented pseudoaxial conformation. In the spectrum of **12a**, the signals for H-1, H-2, H-3, and H-4 appeared as a doublet (δ 6.04, J=7.5 Hz), a doublet of doublets (δ 5.51, J=3.5 and 7.5 Hz), a triplet (δ 4.63, J=3.5 Hz), and a doublet of doublets (δ 4.96, J=3.5 and 4.5 Hz), respectively, indicating pseudoaxial–axial–equatorial–pseudoequatorial conformations for H-1, H-2, H-3, and H-4. In addition, two doublets of doublets (J=7 and 10 Hz) of small intensity were observed at δ 4.39 and 5.31, which were probably due to C-3 and C-2 protons, respectively, of the isomer **13** contained in crude **12a**.

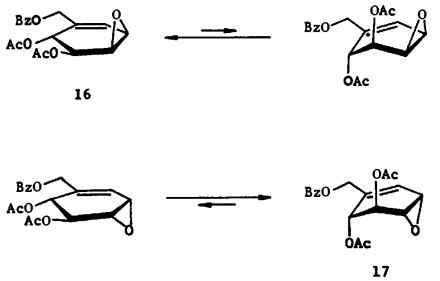
Compound **8a** was converted into the tribromide **15** by treatment with NBS in aqueous acetic acid. The structure of **15** was fully proved by the ^{1}H NMR spectrum, which further confirmed the assigned structure of **8a**.

A similar bromination of the benzoyloxy derivative **7b**[7] with NBS (1.5 molar equiv.) in carbon tetrachloride yielded a mixture of products, from which two monobromides **8b** (20%) and **11b** (10%), and one dibromide **12b** (18%) were isolated. The structures were correlated with those of the corresponding bromo compounds by ^{1}H NMR spectroscopy. In this case, a use of excess NBS did not increase the yield of **12b**. Compounds **8b** and **11b** seemed to be stable under the reaction conditions, probably due to an inductive effect of the benzoyloxyl function. The desired **12b** was conveniently prepared in 42% overall yield from **7a** by direct treatment of crude **12a** with sodium benzoate in 90% aqueous *N*,*N*-dimethylformamide (DMF) at room temperature for 4 h.

Synthetically useful 1,3-cyclohexadiene **6** was prepared by treatment of **12b** with zinc dust in ethanol at 70 °C for 0.5 h. The product was purified by chromatography on silica gel to give **6** as an oil in 62% yield. The structure of **6** was established by the ^{1}H NMR spectrum, which showed a doublet of doublets (δ 5.25, J=4 and 5 Hz) and a doublet (δ 5.53, J=5 Hz) attributable to two olefinic protons H-3 and H-4, respectively. These data were in good accord with those of the corresponding 1-benzyloxyl derivative reported by White *et al.*[9]

Epoxidation of **6**. Compound **6** was treated with *m*-chloroperoxybenzoic acid (*m*CPBA) in 1,2-dichloroethane at room temperature or at reflux temperature with a radical inhibitor.[10] When an equimolar *m*CPBA was used at room temperature, **6** was consumed within 15 h and three monoepoxides were formed. They were fractionated by use of a silica-gel column to give **4** (14%), **16** (8.4%), and **17** (13%). The structure of **4** was deduced by comparison of the ^{1}H NMR spectrum with those of **2** and **3**. Thus, the signals due to H-3 and H-4 appeared as a two-proton narrow multiplet at δ 5.53 in contrast with those of **2** [H-3 (δ 5.57) and H-4 (δ 5.17)].[3] The C-4 proton of **4** was apparently deshielded by the proximate 1,2-epoxide ring in the half-chair conformation with two acetoxyl groups being diequatorially situated. It was further supported by the spectrum of **3** which revealed the C-4 proton attached to the carbon atom bearing the benzoyloxyl group at δ 5.68.[4b]

The ^{1}H NMR spectra of **16** and **17** showed two epoxide and one olefinic protons, respectively, indicating that they were an epimeric pair of the 3,4-epoxide of **6**. In the spectrum of **16**, the signals due to H-3 and H-4 appeared as a doublet (J=8.2 Hz) at δ 5.28 and 5.79, respectively, being in consistent with the proposed structure in which two acetoxyl groups were oriented diequatorially and the C-4 proton was deshielded by the epoxide group. Whereas, in the spectrum of **17**, two narrow triplets (J=2 Hz) appeared δ 5.30 and 5.46, which could be attributed to H-3 and H-4, respectively, in the preferred conformation with two acetoxyl groups in diaxial disposition.[11] The above data suggested that the conformational preference of these compounds might be due to the configurational relationship between trans-vicinal substituents and epoxide group independent of the steric and polar effect of benzoyloxymethyl group.[12]



Scheme 3.

When the similar reaction was carried out under forcing conditions[10] (2,6-di-*t*-butyl-*p*-cresol, reflux, 1.5 h), a sole crystalline diepoxide **20** was isolated, after chromatography on silica gel, in 12% yield, along with **4** (3.5%), **16** (1.3%), and **17** (2.6%). The ^{1}H NMR spectrum of **20** showed two coupled sharp doublets (J=8 Hz) at δ 5.28 and 5.65, attributable to H-5 and H-6, respectively. The spectral data were in accord with the proposed structure where the C-5 and C-6 protons adopted the diaxial conformation and the former was deshielded by the proximate 1,2-epoxide group.[13]

The structure was further confirmed by epoxidation of the monoepoxides obtained. Epoxidation of **16** with *m*CPBA occurred smoothly to give **20** selectively. While, **4** did not react with *m*CPBA at room temperature, however, under forcing conditions, formation of **20** was detected by TLC. On the other hand, although **17** was expected to give **1** and/or **19**, it was not oxidized,

but underwent decomposition on prolonged reaction time. The reactivity of **17** may be explained by the steric and electronic effects exerted by diaxial arrangement of two acetoxyl groups.

Accordingly, it was noted that the 1,2-double bond of **6** was deactivated by the inductive effect of the C-1 benzoyloxymethyl group, comparing with that of the corresponding diene with the C-1 benzyloxymethyl group.[9] Stereospecificity of the epoxidation of *trans*-5,6-diacetoxy-1,3-cyclohexadienyl system seems to depend rather on an interaction of the neighboring group than on the spacial steric effect,[14] *e.g.* a conformational requirement of the molecule in the transition state of epoxidation, leading predominantly to the epoxide with two acetoxyl groups in equatorial orientation.

Experimental

Unless otherwise noted, melting points were determined on a Mitamura Riken micro hot stage and are uncorrected. ^{1}H NMR spectra were taken on a Varian EM-360 (60 MHz), EM-390 (90 MHz), or HA-100D (100 MHz) spectrometer in chloroform-*d* ($CDCl_3$) with reference to tetramethylsilane as an internal standard. The peak positions are given in terms of δ-values and values given for coupling constants are of first-order. Mass spectrum was recorded on a Hitachi M-80 mass spectrometer at 70 eV. TLC was performed on silica gel (Wakogel B-10, Wako Pure Chemical Ind., Ltd.). The silica gel used for a column chromatography was Wakogel C-300. Organic solutions were dried over anhydrous sodium sulfate and concentrated below 50 °C under reduced pressure.

Bromination of DL-*1,2-Di*-O-*acetyl-(1,3/2)-3-bromomethyl-5-cyclohexene-1,2-diol (7a) with NBS in Carbon Tetrachloride.* *a)*: To a solution of **7a**[7] (1.46 g) in carbon tetrachloride (15 ml) was added NBS (0.89 g, molar equiv.) and AIBN (10 mg), and the mixture was stirred at 80 °C under nitrogen stream for 0.5 h. After the reaction mixture was cooled to room temperature, succinimide formed was removed by filtration and washed with carbon tetrachloride. The filtrate and washings were combined and concentrated. The oily residue was crystallized from ethanol to give 0.34 g (20%) of DL-1,2-di-*O*-acetyl-(1,3/2,4)-4-bromo-3-bromomethyl-5-cyclohexene-1,2-diol (**8a**) as needles: mp 103—105 °C; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=2.03 (3H, s) and 2.08 (3H, s) (OAc), 2.59 (1H, tdd, $J_{2,3}$=12 Hz, $J_{3,4}$=9 Hz, $J_{3,7}$=$J_{3,7'}$=3 Hz, H-3), 3.73 (1H, dd) and 3.90 (1H, dd) (J_{gem}=12 Hz, H-7 and H-7'), 4.90 (1H, dq, $J_{1,4}$=$J_{4,5}$=$J_{4,6}$=2.5 Hz, H-4), 5.19 (1H, dd, $J_{1,2}$=9 Hz, H-2), 5.42—5.71 (2H, H-1 and H-5) and 6.05 (1H, dt, $J_{5,6}$=10.5 Hz, $J_{1,6}$=2.5 Hz, H-6).

Found: C, 35.43; H, 3.83; Br, 42.96%. Calcd for $C_{11}H_{14}Br_2O_4$: C, 35.70; H, 3.81; Br, 43.19%.

The mother liquor of **8a** was concentrated and the residue was chromatographed on a silica-gel column (65 g) with 2-butanone–toluene (1 : 20) as an eluent. The first fraction [R_f 0.71, 2-butanone–toluene (1 : 8)] gave 0.20 g (9%) of DL-1,2-di-*O*-acetyl-(1,4/2,3)-3,4-dibromo-6-bromomethyl-5-cyclohexene-1,2-diol (**12a**) as an oil: ^{1}H NMR ($CDCl_3$, 100 MHz) δ=2.10 (6H, s, OAc), 3.93 (2H, AB q, J=12 Hz, C$\underline{H}_2$Br), 4.63 (1H, t, $J_{2,3}$=$J_{3,4}$=3.5 Hz, H-3), 4.96 (1H, dd, $J_{4,5}$=4.5 Hz, H-4), 5.51 (1H, dd, $J_{1,2}$=7.5 Hz, H-2), 6.04 (1H, d, H-1) and 6.16 (1H, br d, H-5). Traces of the ^{1}H NMR signals due to the isomer **13** were observed: δ=4.39 (1H, dd, $J_{2,3}$=10 Hz, $J_{3,4}$=7.5 Hz, H-3), 5.31 (1H, dd, $J_{1,2}$=7 Hz, H-2), 5.84 (1H, br d, H-1).

Found: C, 29.82; H, 3.07%. Calcd for $C_{11}H_{13}Br_3O_4$: C, 29.42; H, 2.92%.

The second fraction (R_f 0.58) gave an another crop (90 mg) of **8a** and the combined yield was 23%.

The third fraction (R_f 0.49) gave 0.13 g (7%) of DL-1,2-di-*O*-acetyl-(1,3/2,6)-3-bromo-6-bromomethyl-4-cyclohexene-1,2-diol (**10a**) as prisms: mp 126—128 °C; ^{1}H NMR ($CDCl_3$, 60 MHz) δ=2.06 (3H, s) and 2.09 (3H, s) (OAc), 2.75—3.10 (1H, m, H-6), 4.62 (1H. br d, $J_{2,3}$=8 Hz, H-3), 5.10 (1H, dd, $J_{1,2}$=10 Hz, $J_{1,6}$=8 Hz, H-1), 5.50 (1H, dd, H-2), 5.62 (1H, dt, $J_{3,5}$=$J_{5,6}$=2 Hz, $J_{4,5}$=10 Hz, H-5) and 5.99 (1H, dt, $J_{3,4}$=$J_{4,6}$=2.5 Hz, H-4).

Found: C, 35.87; H, 3.81; Br, 43.05%. Calcd for $C_{11}H_{14}Br_2O_4$: C, 35.70; H, 3.81; Br, 43.19%.

The fourth fraction (R_f 0.42) gave 45 mg (3.7%) of DL-*trans*-6-acetoxy-5-bromomethyl-2-cyclohexen-1-one (**14**) as a glass: ^{1}H NMR ($CDCl_3$, 60 MHz) δ=2.21 (3H, s, OAc), 2.60 (2H, m, H-4 and H-4'), 3.52 (2H, d, $J_{3,5}$=3.5 Hz, C$\underline{H}_2$Br), 5.32 (1H, d, $J_{5,6}$=12 Hz, H-6), 6.03 (1H, dt, $J_{2,3}$=10 Hz, $J_{2,4}$=$J_{2,4'}$=1.5 Hz, H-2) and 6.95 (1H, dt, $J_{3,4}$=$J_{3,4'}$=3.5 Hz, H-3).

Found: C, 43.77; H, 4.44; Br, 32.26%. Calcd for $C_9H_{10}BrO_3$: C, 43.93; H, 4.10; Br, 32.47%.

b): The similar reaction of **7a** (1.46 g) with NBS (0.89 g) was quenched after heating at 80 °C for 5 min, and the reaction mixture was processed similarly as described in a. The product was fractionally crystallized from ethanol to give 0.30 g (16%) of **8a** and 49 mg (2.6%) of DL-1,2-di-*O*-acetyl-(1/2,3,-6)-3-bromo-6-bromomethyl-4-cyclohexene-1,2-diol (**11a**) as cubic crystals: mp 105—108 °C; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=2.08 (3H, s) and 2.10 (3H, s) (OAc), 2.78—3.13 (1H, m, H-6), 3.33 (1H, dd, $J_{6,7}$=6.5 Hz, J_{gem}=10 Hz, H-7), 3.51 (1H, dd, $J_{6,7'}$=4.5 Hz, H-7'), 4.75—4.98 (2H, m, H-2 and H-3), 5.49 (1H, dd, $J_{1,2}$=10.5 Hz, $J_{1,6}$=9 Hz, H-1), 5.56 (1H, dd, $J_{4,5}$=11 Hz, $J_{5,6}$=3 Hz, H-5) and 6.01 (1H, ddd, $J_{3,4}$=5 Hz, $J_{4,6}$=3 Hz, H-4).

Found: C, 35.53; H, 3.88; Br, 43.27%. Calcd for $C_{11}H_{14}Br_2O_4$: C, 35.70; H, 3.81; Br, 43.19%.

c): A mixture of **7a** (2.0 g), NBS (2.45 g, 2 molar equiv.), and AIBN (5 mg) in carbon tetrachloride (20 ml) was heated at reflux under nitrogen atmosphere for 2 h. Succinimide formed was removed by filtration and the filtrate was concentrated to give 3.1 g (100%) of **12a** as an oil.

DL-*1,3-Di*-O-*acetyl-(1,2,4/3,5,6)-5,6-dibromo-4-bromomethyl-1,-2,3-cyclohexanetriol (15).* To a mixture of **8a** (90 mg) in 50% aqueous acetic acid (12 ml) was added NBS (43 mg, molar equiv.) and the reaction mixture was allowed to stand at room temperature for 2 d. Precipitates were collected to give 17 mg (11%) of **15**: mp 198—200 °C; ^{1}H NMR (dimethyl-d_6 sulfoxide, 60 MHz) δ=2.09 (6H, s, OAc), 3.68 (2H, d, J=2 Hz, C$\underline{H}_2$Br), 4.31 (1H, dd, $J_{4,5}$=3.5 Hz, $J_{5,6}$=10 Hz, H-5), 4.71 (1H, t, $J_{3,4}$=3.5 Hz, H-4), 5.07 (1H, t, $J_{1,2}$=$J_{1,6}$=10.5 Hz, H-1) and 5.22 (1H, t, $J_{2,3}$=3.5 Hz, H-3).

Found: C, 28.44; H, 3.24; Br, 51.25%. Calcd for $C_{11}H_{15}Br_3O_5$: C, 28.29; H, 3.24; Br, 51.34%.

Bromination of DL-*1,2-Di*-O-*acetyl-(1,3/2)-3-benzoyloxymethyl-5-cyclohexene-1,2-diol (7b) with NBS in Carbon Tetrachloride.* To a solution of **7b**[7] (0.664 g) in carbon tetrachloride (20 ml) was added NBS (0.356 g, molar equiv.) and AIBN (10 mg), and the mixture was heated at reflux under nitrogen stream for 1 h. An additional amount of NBS (0.18 g) and AIBN (5 mg) was added and heating was continued for 1 h. At this time, **7b** was almost consumed and the formation of four components were detected by TLC [R_f 0.67, 0.60, 0.49, and 0.42 in 2-butanone–toluene (1 : 9)]. An insoluble material was removed by filtration and the filtrate was concentrated to an oil (0.60 g), which was chromatographed on a silica-gel column (30 g) with 2-butanone–toluene (1 : 20) as an eluent. The

first fraction (R_f 0.67) gave, after recrystallization from ethanol, 0.172 g (17.6%) of DL-1,2-di-*O*-acetyl-(1,6/2,5)-3-benzoyloxymethyl-5,6-dibromo-3-cyclohexene-1,2-diol (**12b**) as prisms: mp 132—134 °C; ^{1}H NMR ($CDCl_3$, 90 MHz) δ= 2.03 (3H, s) and 2.07 (3H, s) (OAc), 4.63 (1H, t, $J_{5,6}=J_{1,6}=$ 3 Hz, H-6), 4.78 (2H, br s, C$\underline{H}_2$OBz), 4.93 (1H, br dd, $J_{4,5}=$ 4.5 Hz, H-5), 5.49 (1H, dd, $J_{1,2}=7.3$ Hz, H-1), 6.01 (1H, br d, H-2), 6.11 (1H, br d, H-4), and 7.29—7.68 (3H, m) and 7.91—8.10 (2H, m) (phenyl).

Found: C, 44.29; H, 3.87; Br, 32.85%. Calcd for $C_{18}H_{18}Br_2O_6$: C, 44.12; H, 3.71; Br, 32.60%.

The second fraction (R_f 0.60) gave 0.163 g (20%) of DL-1,2-di-*O*-acetyl-(1,3/2,4)-3-benzoyloxymethyl-4-bromo-5-cyclohexene-1,2-diol (**8b**) as an oil: ^{1}H NMR ($CDCl_3$, 60 MHz) δ= 2.03 (3H, s) and 2.07 (3H, s) (OAc), 2.50—3.20 (1H, m, H-6), 4.30—4.72 (2H, m, C$\underline{H}_2$OBz), 4.91 (1H, ddd, $J_{4,5}=J_{4,6}=2.8$ Hz, $J_{3,4}=9$ Hz, H-4), 5.33 (1H, dd, $J_{1,2}=9.7$ Hz, $J_{2,3}=11.3$ Hz, H-2), 5.59 (1H, ddd, $J_{1,5}=J_{1,6}=2.7$ Hz, H-1), 5.69 (1H, ddd, $J_{5,6}=10.3$ Hz, H-6), 6.09 (1H, ddd, H-5), and 7.30—7.70 (3H, m) and 7.90—8.20 (2H, m) (phenyl).

Compound **8b** was not stable enough to give a satisfactory analytical data.

The third fraction (R_f 0.49) gave 82 mg (10%) of DL-1,2-di-*O*-acetyl-(1,3/2,6)-3-benzoyloxymethyl-6-bromo-4-cyclohexene-1,2-diol (**11b**) as crystals: mp 90—92 °C; ^{1}H NMR ($CDCl_3$, 60 MHz) δ=2.06 (3H, s) and 2.14 (3H, s) (OAc), 2.79—3.22 (1H, m, H-3), 4.22 (1H, dd, $J_{3,7}=5$ Hz, $J_{gem}=11$ Hz, H-7), 4.50 (1H, dd, $J_{3,7'}=4.5$ Hz, H-7'), 4.73—5.03 (2H, m, H-1 and H-6), 5.66 (1H, dd, $J_{3,4}=2$ Hz, $J_{4,5}=10.5$ Hz, H-4), 6.00 (1H, ddd, $J_{3,5}=2.5$ Hz, $J_{5,6}=5$ Hz, H-5), and 7.30—7.60 (3H, m) and 7.90—8.20 (2H, m) (phenyl).

Found: C, 52.72; H, 4.70; Br, 19.43%. Calcd for $C_{18}H_{19}BrO_6$: C, 52.56; H, 4.62; Br, 19.43%.

Practical Synthesis of ***12b***. A mixture of crude **12a** (1.13 g), sodium benzoate (0.40 g), and 90% aqueous DMF (20 ml) was stirred at room temperature for 1 d. TLC indicated the formation of one major (R_f 0.64) and one minor components (R_f 0.35) in 2-butanone–toluene (1 : 8). The reaction mixture was partitioned between ethyl acetate (30 ml) and water (20 ml). The organic layer was washed with water thoroughly, dried, and concentrated. The residue was crystallized from ethanol to give 0.58 g (47% based on **7a** used) of **12b**: mp 129—130 °C.

DL-trans-*5,6-Diacetoxy-1-benzoyloxymethyl-1,3-cyclohexadiene (****6****).* To a stirred solution of **12b** (2.0 g) in ethanol (45 ml) was added zinc dust (1.06 g, 4 atomic equiv.) in portions at 70 °C. The suspension was stirred vigorously at this temperature for 20 min. At this time, **12b** disappeared and one main component (R_f 0.51) and two minor components (R_f 0.16 and 0.12) were formed [TLC: 2-butanone–toluene (1 : 15)]. An insoluble material was removed by filtration and the filtrate was concentrated to give a pale yellow oil (1.2 g), which was chromatographed on a silica-gel column (30 g) with 2-butanone–toluene (1 : 15) as an eluent. The major fraction gave 0.83 g (62%) of **6** as a homogeneous oil: ^{1}H NMR ($CDCl_3$, 60 MHz) δ=1.98 (3H, s) and 2.00 (3H, s) (OAc), 4.74 (2H, s, C$\underline{H}_2$OBz), 5.25 (1H, dd, $J_{4,5}=4$ Hz, $J_{5,6}=5$ Hz, H-5), 5.53 (1H, d, H-6), 5.61—6.20 (3H, br m, H-2, H-3, and H-4) and 6.71—7.92 (5H, m, phenyl).

Found: *m/e* 330.1097. Calcd for $C_{18}H_{18}O_6$: M, 330.1102.[15]

Epoxidation of ***6****. a)*: To a solution of **6** (0.83 g) in 1,2-dichloroethane (20 ml) was added dropwise a solution of *m*CPBA (0.62 g, one molar equiv., purity 70%) in 1,2-dichloroethane (8 ml) at room temperature for 10 min. The reaction mixture was stirred at room temperature for 15 h. At this time, disappearance of **6** and formation of three major components were shown by TLC [R_f 0.51, 0.39, and 0.35 2-butanone–toluene (1 : 8)]. Then the mixture was washed successively with 10% aqueous sodium sulfite, saturated aqueous sodium hydrogencarbonate, and water, and dried. Evaporation of the solvent gave a clear oil which was chromatographed on a silica-gel column (50 g) with 2-butanone–toluene (1 : 15) as an eluent. The first fraction gave an oil which crystallized on standing to give 81 mg (14%) of DL-3,4-di-*O*-acetyl-1,2-anhydro-(1,2,3/4)-2-*C*-benzoyloxymethyl-5-cyclohexene-1,2,3,4-tetrol (**4**) as prisms: mp 112—113 °C; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=2.02 (3H, s) and 2.10 (3H, s) (OAc), 3.51 (1H, dd, $J_{1,5}=1.5$ Hz, $J_{1,6}=3.8$ Hz, H-1), 4.26 (1H, d) and 4.56 (1H, d) ($J_{gem}=12.5$ Hz, C$\underline{H}_2$OBz), 5.53 (2H, m, H-3 and H-4), 5.71 (1H, dt, $J_{4,5}=1.5$ Hz, $J_{5,6}=9.5$ Hz, H-5), 6.00 (1H, ddd, $J_{4,6}=1.5$ Hz, H-6), and 7.47—7.99 (5H, m, phenyl).

The second fraction gave 50 mg (8.4%) of DL-3,4-di-*O*-acetyl-1,2-anhydro-(1,2,3/4)-5-benzoyloxymethyl-5-cyclohexene-1,2,3,4-tetrol (**16**) as a homogeneous oil: ^{1}H NMR ($CDCl_3$, 90 MHz) δ=2.00 (3H, s) and 2.10 (3H, s) (OAc), 3.44 (1H, t, $J_{1,2}=J_{1,6}=4$ Hz, H-1), 3.58 (1H, dd, $J_{2,3}=1.3$ Hz, H-2), 4.73 (2H, s, C$\underline{H}_2$OBz), 5.28 (1H, dd, $J_{3,4}=8.2$ Hz, H-3), 5.79 (1H, br d, H-4), 6.16 (1H, br s, H-6), and 7.43—7.96 (5H, m, phenyl).

The third fraction gave 76 mg (13%) of DL-3,4-di-*O*-acetyl-1,2-anhydro-(1,2,4/3)-5-benzoyloxymethyl-5-cyclohexene-1,2,-3,4-tetrol (**17**) as prisms: mp 116—117.5 °C; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=2.00 (3H, s) and 2.03 (3H, s) (OAc), 3.38 (1H, t, $J_{1,2}=J_{1,6}=4$ Hz, H-1), 3.55 (1H, m, H-2), 4.74 (2H, s, C$\underline{H}_2$OBz), 5.30 (1H, t, $J_{2,3}=J_{3,4}=2$ Hz, H-3), 5.46 (1H, t, $J_{4,6}=2$ Hz, H-4), 6.43 (1H, br d, H-6), and 7.41—7.98 (5H, m, phenyl).

Found for **4**: C, 62.24; H, 5.33%, for **16**: C, 62.17; H, 5.32%, and for **17**: C, 62.50; H, 5.27%. Calcd for $C_{18}H_{18}O_7$: C, 62.42; H, 5.24%.

b): When the similar reaction was carried out in dichloromethane in the presence of phosphate buffer solution (pH 8) under vigorous stirring, **4** (11%); **16** (14%), and **17** (13%) were isolated by chromatography.

c): To a solution of crude **6** prepared from **12b** (0.30 g) were added *m*CPBA (0.20 g, 1.2 molar equiv.) and 2,6-di-*t*-butyl-*p*-cresol (3 mg), and the mixture was refluxed for 90 min. After having been cooled, the reaction mixture was filtered to remove *m*-chlorobenzoic acid and the filtrate was processed similarly as described in a. The mixture of products was chromatographed on silica gel (30 g) with 2-butanone–toluene (1 : 15) as an eluent. The first fraction [R_f 0.51, 2-butanone–toluene (1 : 8)] gave 8 mg (3.5%) of **4** as an oil.

The second fraction (R_f 0.38) gave an oil which crystallized on standing to give 30 mg (12%) of DL-5,6-di-*O*-acetyl-1,2 : 3,4-dianhydro-(1,2,6/3,4,5)-1-*C*-benzoyloxymethyl-1,2,3,4,5,6-cyclohexanehexol (**20**): mp 128—129 °C; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=2.06 (6H, s, OAc), 3.35 (1H, d, $J_{3,4}=4.5$ Hz, $J_{4,5}=1.2$ Hz, H-4), 3.56 (1H, dd, $J_{2,3}=2.5$ Hz, H-3), 3.69 (1H, d, H-2), 4.13 (1H, d) and 4.42 (1H, d) ($J_{gem}=12$ Hz, C$\underline{H}_2$OBz), 5.28 (1H, dd, $J_{5,6}=8$ Hz, H-5), 5.65 (1H, d, H-6), and 7.36—7.98 (5H, m, phenyl).

Found: C, 59.81; H, 5.11%. Calcd for $C_{18}H_{18}O_8$: C, 59.67; H, 5.11%.

The third fraction (R_f 0.37) gave 3 mg (1.3%) of **16**.

The fourth fraction (R_f 0.35) gave 6 mg (2.6%) of **17**.

d): When **6** was treated with excess *m*CPBA (3 molar equiv.) similarly as described in c, **20** was obtained in 20% yield after chromatography, along with a trace of monoepoxides.

Epoxidation of ***4****.* A solution of **4** (0.14 g) and *m*CPBA (0.19 g, 2 molar equiv.) in 1,2-dichloroethane (3.5 ml) was allowed to stand at room temperature for 2 d. At this time,

TLC indicated that **4** remained almost unchanged.

Treatment of **4** (58 mg) with *m*CPBA (42 mg, equimolar) in 1,2-dichloroethane in the presence of 2,6-di-*t*-butyl-*p*-cresol (3 mg) at reflux temperature for 7 h, followed by the conventional acetylation, gave many products, one of which was identified with **20** by TLC. There was no product present, which was identical with **1**.[16]

*Epoxidation of **16**.* Compound **16** (5 mg) was treated with *m*CPBA (7 mg, 2 molar equiv.) in 1,2-dichloroethane (0.6 ml) at room temperature for 3 d. About half of **16** was found to be converted into **20** by TLC.

*Epoxidation of **17**.* Compound **17** (20 mg) was recovered unchanged, after having been treated with *m*CPBA (28 mg, 2 molar equiv.) in 1,2-dichloroethane (2 ml) at room temperature for 2 d. Under the forcing conditions,[10] **17** (62 mg) gave several products, but there was no product identical with **1**. Furthermore, the ^{1}H NMR spectrum of the mixture of products did not show any signals due to epoxide protons.

The authors express their sincere thanks to Mr. Saburo Nakada for the elementary analyses, and to Mr. Isamu Kasahara and Mr. Kenji Kato for assistance in the preparative experiments.

The Interaction of a Neutral Polymer with Small Ions in Solution. III. Ionic Association on a Poly(oxyethylene) Chain

Hiroshi Awano, Katsumichi Ono,* and Kenkichi Murakami
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai 980
(Received August 21, 1982)

Conductivities of NaSCN and KSCN solutions have been measured in ethanol and nitromethane in the presence of poly(oxyethylene). For poly(oxyethylene)-KSCN solutions in ethanol and nitromethane, a distinct minimum appears in conductivity *vs.* polymer concentration curves. In addition, for a poly(oxyethylene)-NaSCN solution in nitromethane, the conductivity curve rises steeply after passing through the minimum. These anomalies cannot be explained by the cation binding to the polymer alone, and the ionic association on the polymer chain should be taken into account at the same time. In order to analyze the results, a theory based on the duplicate ion binding on a one-dimensional lattice has been developed. The theory not only predicts the appearance of the conductivity minima, but also makes it possible to estimate the ionic association constants.

The authors have investigated by conductometry the the binding of alkali metal ions to poly(oxyethylene) (POE) in various solvents.[1-3] It has been found that the equivalent conductivities of the alkali metal salts, Λ, decrease monotonically with an increase in the concentration of POE (monomer base mole), C_p. For solutions of potassium thiocyanate in methanol, acetonitrile, propylene carbonate, and sulfolane, the amount of potassium ion bound to a POE chain has been evaluated from the decrement of Λ. In these cases, it is not necessary to take into account the contribution of the anion to the decrement of Λ, since the specific interaction between the cation and the anion is virtually negligible. A binding constant, K_0, which does not include the contribution of the interaction between the cation bound to a POE chain, has been obtained on the basis of a one-dimensional lattice model.[2] It has been shown that, over a variety of solvents, a linear correlation exists between the logarithmic binding constant, log K_0, and the standard chemical potential of the cation, $\mu^{\ominus}$.[3]

Thus, it can be expected that the binding of potassium ions to POE occurs extensively in ethanol, nitromethane, or the like, in which $\mu^{\ominus}$ is much larger than in methanol, acetonitrile, *etc.* Similarly to the polyelectrolyte systems, in which counter ions are bound to the polyion, it is expected that anions would be bound to the POE–cation complexes and make no contribution to the conductivity, when the charge density of the cation on the chain is enhanced. In addition, ionic association or ion-pair formation also occurs to a large extent even in the polymer free solutions of some alkali metal thiocyanates in ethanol and nitromethane.

In this paper, we assume that the following three equilibria exist in these systems:

1) binding of the cation to a POE chain; 2) ionic association on a POE chain; 3) ionic association in the bulk solvent.

It is necessary to treat the equilibria 1 and 2 on the basis of the one-dimensional lattice model, because both equilibria might be influenced by the interference between the positive charges bound on the chain. In our treatment, an extended one-dimensional lattice model is proposed to interpret the Λ *vs.* C_p curves in such complicated cases. The outline of the treatment has already been published in our preliminary report.[4]

Theory

An Extension of the One-dimensional Lattice Model. When we extend the one-dimensional lattice model to the case of the duplicate ion binding to POE, the following two basic assumptions are made.

In the first place, we must specify the binding state of a site. Three kinds of binding states were assumed for each site according to their energies. The energy of the site was assumed to be 0 if nothing is bound (state $\underline{0}$), E_c if a cation is bound (state $\underline{1}$), and E_c+E_a if not only a cation but also an anion is bound (state $\underline{2}$).

In the second place, we must specify the interaction energy between the sites. When either or both of the i-th and j-th sites are the state $\underline{0}$ or state $\underline{2}$, then the interaction energy J_{ij} between i-th and j-th sites is represented as:

$$J_{ij} = 0. \tag{1}$$

This means that the site specified as state $\underline{2}$ has no effective charges and does not exert electrostatic potential at the other sites. On the other hand, if both of the i-th and j-th sites are in the state $\underline{1}$, J_{ij} is assumed to be represented as:

$$J_{ij} = \begin{cases} J_m, & m \equiv j - i < k \\ 0, & j - i > k, \end{cases} \tag{2}$$

and k is the range of the number of sites, beyond which the interaction is truncated, and J_m is the Debye-Hückel potential. This has the following form:

$$J_m = \frac{e^2 \exp(-\kappa_D r_m)}{4\pi\varepsilon r_m}, \quad \kappa_D^2 = \frac{2N_A e^2 I}{\varepsilon k_B T}, \tag{3}$$

where e is the elementary electronic charge, κ_D the Debye's shielding parameter, r_m the intersite distance, ε the dielectric constant of the solvent, N_A the Avogadro constant, I the ionic strength, k_B the Boltzmann constant, and T the absolute temperature. A statistical weight factor A_m is defined by:

$$A_m \equiv \exp(-J_m/RT). \tag{4}$$

If we denote the chemical potentials of the cation and the anion as μ_c and μ_a, respectively, then the normalized activities of these ions are defined as follows:[2]

$$\xi \equiv \exp[(\mu_c - E_c)/RT] \tag{5}$$

$$\eta \equiv \exp[(\mu_a - E_a)/RT]. \quad (6)$$

The grand partition function of this system may be conveniently described in terms of the following matrix product:

$$\Xi = \boldsymbol{e}\, \boldsymbol{U}_k^N \boldsymbol{e}' \quad (7)$$

where $\boldsymbol{e}$ and $\boldsymbol{e}'$ are row and column vectors such as:

$$\boldsymbol{e} = (1,1,1,\cdots\cdots,1) \qquad \boldsymbol{e}' = \begin{pmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{pmatrix}. \quad (8)$$

In Eq. 7, N is the number of a lattice point on a chain, and $\boldsymbol{U}_k$ is a statistical weight matrix whose order is 3^k. A few examples of the matrix are shown below:

for $k = 1$,

$$\mathrm{U} = \begin{array}{c|ccc} i+1 & \underline{0} & \underline{1} & \underline{2} \\ i & & & \\ \hline \underline{0} & 1 & 1 & 1 \\ \underline{1} & \xi & \xi A_1 & \xi \\ \underline{2} & \xi\eta & \xi\eta & \xi\eta \end{array} \quad (9)$$

for $k = 2$,

$$\boldsymbol{U} = \begin{array}{cc|ccccccccc} i+2 & & \underline{0} & \underline{1} & \underline{2} & \underline{0} & \underline{1} & \underline{2} & \underline{0} & \underline{1} & \underline{2} \\ i & i+1 & \underline{0} & \underline{0} & \underline{0} & \underline{1} & \underline{1} & \underline{1} & \underline{2} & \underline{2} & \underline{2} \\ \hline \underline{0} & \underline{0} & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ \underline{0} & \underline{1} & 0 & 0 & 0 & 1 & 1 & 1 & 0 & 0 & 0 \\ \underline{0} & \underline{2} & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 \\ \underline{1} & \underline{0} & \xi & \xi A_2 & \xi & 0 & 0 & 0 & 0 & 0 & 0 \\ \underline{1} & \underline{1} & 0 & 0 & 0 & \xi A_1 & \xi A_1 \xi A_2 & \xi A_1 & 0 & 0 & 0 \\ \underline{1} & \underline{2} & 0 & 0 & 0 & 0 & 0 & 0 & \xi & \xi A_2 & \xi \\ \underline{2} & \underline{0} & \xi\eta & \xi\eta & \xi\eta & 0 & 0 & 0 & 0 & 0 & 0 \\ \underline{2} & \underline{1} & 0 & 0 & 0 & \xi\eta & \xi\eta & \xi\eta & 0 & 0 & 0 \\ \underline{2} & \underline{2} & 0 & 0 & 0 & 0 & 0 & 0 & \xi\eta & \xi\eta & \xi\eta \end{array} \quad (10)$$

Extrapolation to $k \to \infty$ can be carried out in a similar manner as was shown in our previous paper of this series.[2]

It is convenient to define the degree of binding in terms of the probability that a site is occupied by the cation or the anion, respectively. This probability is *formally* represented for the cation and the anion by;[5]

$$\theta_c = \left(\frac{1}{N}\frac{\partial \ln \Xi}{\partial \ln \xi}\right)_\eta, \quad (11)$$

$$\theta_a = \left(\frac{1}{N}\frac{\partial \ln \Xi}{\partial \ln \eta}\right)_\xi. \quad (12)$$

The binding constants for the cation and the anion are defined as:

$$K_0^c \equiv \exp[(\mu_c^\ominus - E_c)/RT] \quad (13)$$

$$K_0^a \equiv \exp[(\mu_a^\ominus - E_a)/RT], \quad (14)$$

where $\mu_c^\ominus$ and $\mu_a^\ominus$ are the standard chemical potentials of cation and the anion, respectively.

Reproduction of Conductivity Curves. From Eqs. 5, 6, 13, 14, the concentration of the free cation, C_c, and that of the free anion, C_a, are given by:

$$C_c = (\xi/K_0^c y_\pm)C^\ominus, \quad (15)$$

$$C_a = (\eta/K_0^a y_\pm)C^\ominus, \quad (16)$$

where $y_\pm$ is the mean activity coefficient on the molar concentration basis. This is approximately estimated by the Debye-Hückel limiting law, and $C^\ominus$ is the standard value of molar concentration, being equal to 1 mol dm^{-3}. According to the principle of electron-neutrality, C_c and C_a are related to one another, and the following relationship holds:

$$C_c + (\theta_c - \theta_a)C_p/4 = C_a. \quad (17)$$

The second term of the lefthand side of Eq. 17 corresponds to the concentration at the site where only a cation is bound (state $\underline{1}$), and the denominator of this term is introduced on the assumption that a site is compcsed of four oxyethylene units.[1] Substituting Eqs. 15 and 16 into Eq. 17, we obtain:

$$C_p = \frac{4(\eta/K_0^a - \xi/K_0^c)C^\ominus}{y_\pm(\theta_c - \theta_a)}. \quad (18)$$

Next we introduce an ionic association constant K_A.

$$K_\mathrm{A} \equiv \frac{C_{assoc}/C^\ominus}{(C_c y_\pm/C^\ominus)(C_a y_\pm/C^\ominus)}. \quad (19)$$

Where C_{assoc} is the concentration of the ion-pair, the activity coefficient being assumed to be 1. C_{assoc} is obtained by subtracting the concentration of the free anion and that of the bound anion from the total anion concentration, C_s, as follows:

$$C_{assoc} = C_s - C_a - \theta_a C_p/4. \quad (20)$$

Substituting Eq. 20 into Eq. 19, and combining with Eqs. 15 and 16 we finally obtain:

$$\eta = K_0^a y_\pm \frac{(C_s - \theta_a C_p/4)/C^\ominus}{1 + K_\mathrm{A} y_\pm \xi/K_0^c}. \quad (21)$$

For a fixed value of ξ, the set of Eqs. 11, 12, 18, and 21 are simultaneous equations with respect to η, θ_c, θ_a, and C_p. Athough the equations cannot be solved analytically, we can obtain a solution by an iterative method. Then C_c and C_a are calculated from Eqs. 15 and 16.

Molar conductivity is estimated by the following equation,

$$\Lambda = (C_c\lambda_c + C_a\lambda_a)/C_s, \quad (22)$$

where λ_c and λ_a are the molar conductivities of the cation and anion, respectively, in the absence of ionic association. These values are calculated in terms of the Onsager's limiting law.[6]

$$\lambda = \lambda^\infty - (\alpha\lambda^\infty + \beta)\sqrt{I}, \quad (23)$$

where λ^∞, the limiting molar conductivity of the ion, can be found in the literature, α and β are the Onsager parameters, and for a uni-univalent electrolyte;

$$\alpha = \frac{e^2}{3k_\mathrm{B}\varepsilon T}\frac{q}{1+\sqrt{q}}\frac{\kappa_\mathrm{D}}{\sqrt{I}}, \quad q = \frac{1}{2}$$

$$\beta = \frac{Fe}{6\pi\eta_v}\frac{\kappa_\mathrm{D}}{\sqrt{I}}, \quad (24)$$

where η_v is the viscosity of the solvent and F is the Faraday constant. In this way, we can calculate the relationship between Λ *vs.* C_p for a POE–alkali metal salt–solvent system.

Experimental

Poly(oxyethylene) samples, with a nominal molecular weight range from 200 to 5×10^6 (Wako pure chemicals and Union Carbide Co.) were used. Except where indicated, measurements were performed for a sample with molecular weight 2×10^4 (viscosity average MW, 2.47×10^4). Reagent grade potassium and sodium thiocyanates were dried under vacuum before use. Ethanol was stirred with molecular sieve 4A, and distilled. $\kappa=3\times10^{-7}$ S cm^{-1}. Reagent grade nitromethane was used without further purification. $\kappa=2\times10^{-6}$ S cm^{-1}. The measurement of the conductivity was carried out in the manner previously reported.

Results and Discussion

The conductivity curves for the KSCN–EtOH systems are shown in Fig. 1. It may be seen that with increasing C_p conductivity first decreases, passes through a minimum, and then increases gradually at higher C_p. Such a minimum was not observed in the solvent systems studied previously.[3] The minimum becomes more pronounced as C_p becomes greater.

In Fig. 2, the conductivity curve for 5 mmol dm^{-3} NaSCN–EtOH is compared with that of KSCN solution. The minimum is not observed in this case, and the conductivity decreases continually.

The conductivity curves for KSCN–nitromethane systems are shown in Fig. 3. The minimum in the conductivity is also observed. As is different from that observed in the KSCN–EtOH systems, the intrinsic

value of the conductivity value of the conductivity in the large C_p increases with increasing C_s.

In contrast to the above systems, the behavior in the NaSCN–nitromethane solutions is anomalous. After the conductivity passes through a small minimum, Λ increases tremendously as can be seen in Fig. 4. The degree of the increase in the conductivity is dependent on C_s (Fig. 5). The effect of the molecular weight is shown in Fig. 6. The curves are almost independent of the molecular weight above 2×10^4. This means that the effect of the bulk viscosity of the solution is virtually negligible. In addition, it can be deduced that the electric mobility of the bound ions may be neglected as compared with that of the free ions, if the molecular weight of POE is above 2×10^4. As the molecular weight of POE decreases, the minimum of the curve becomes less prominent and finally diminishes. This is probably due to the increasing contribution of the bound ion to the conductivity.

Similar minima in the conductance plots were also observed by Smid and his coworkers, for the mixture of poly(vinylbenzo crown ether)s and potassium tetraphenylborate in methyl ethyl ketone.[7] The main reason for the appearance of the minima was ascribed to the reduction of viscosity in the higher C_p, where the charge density of the bound cation is relatively low. In view of our results, this is not likely because the conductivity does not depend on molecular weight above 2×10^4, so that the viscosity effect is negligible. We propose alternatively that the ion association on a polymer chain is the main cause of the occurence of the minima.

Before considering the systems quantitatively we should evaluate the ionic association constants in the absence of POE. These constants are calculated by the Fuoss-Kraus method[8] using molar conductivity data

Table 1. Ionic association constants in polymer free solutions calculated by the Fuoss-Kraus method[8]

Solvent	KSCN	NaSCN
EtOH[a]	47.53	32.32
Nitromethane[b]	109.3	1591

a) Ref. 9, b) Ref. 10.

cited in the literatures[9,10] (Table 1). It should be noted that the ionic association constant of NaSCN in nitromethane is extremely large.

To calculate the Λ *vs.* C_p relationships in terms of the extended one-dimensional model, we must know the values for K_A, K_0^c, K_0^a, λ_c^∞, and λ_a^∞. The data in Table 1 can be used for the values for the K_A, and λ_c^∞ and λ_a^∞ values are cited in literatures.

In our previous paper, we have shown that a linear relationship exists between the binding constant and the standard chemical potential of the cation.[3] Using the relative values of the standard chemical potential of potassium ion to that of a reference solvent, reported by Owensby and his coworkers,[11] K_0^c for potassium ion is estimated as 4270 in ethanol and 23400 in nitromethane, respectively. For sodium ion in nitromethane, no reliable estimations of K_0^c are possible, but we tentatively use the same K_0^c value for the potassium ion.

The calculated curves are shown in Figs. 7 through 9, together with the observed values. It is necessary to take into account the ion association on a POE chain in reproducing the conductance minimum. As shown in the figures, the conductance minimum becomes sharper with increasing K_0^a. An optimum fitting is obtained by assuming that $K_0^a \simeq 50$ for KSCN–eth anol, $\simeq 20$ for KSCN–nitromethane, and $\simeq 10$ for NaSCN–nitromethane. Thus, it appears that the ion association occurs to a considerable extent along POE chains.

In Fig. 10, the dependence of the calculated conductivity curves on C_s is shown for KSCN–EtOH solutions. From this figure and Fig. 1, it is noted that the calculated curves well reproduce the qualitative aspect of the C_s dependence of the observed curve as well as that of the conductivity minimum, thereby giving further support on the present model.

The quantitative agreement, however, is rather poor,

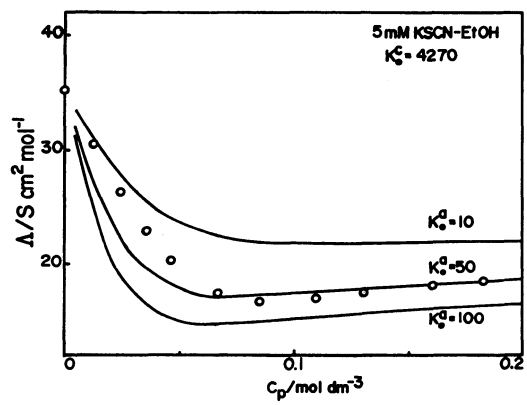

Fig. 7. Calculated Λ *vs.* C_p curves for 5 mmol dm^{-3} KSCN–EtOH solution, together with the observed plots.

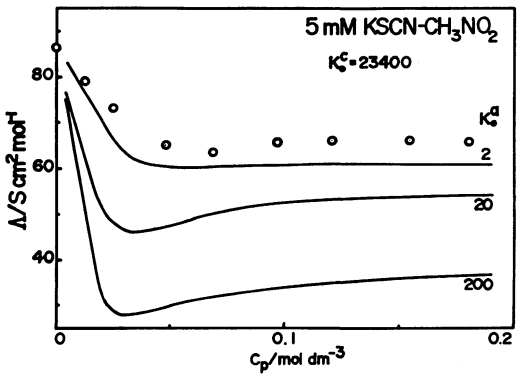

Fig. 8. Calculated Λ *vs.* C_p curves for 5 mmol dm^{-3} KSCN–nitromethane solution, together with the observed plots.

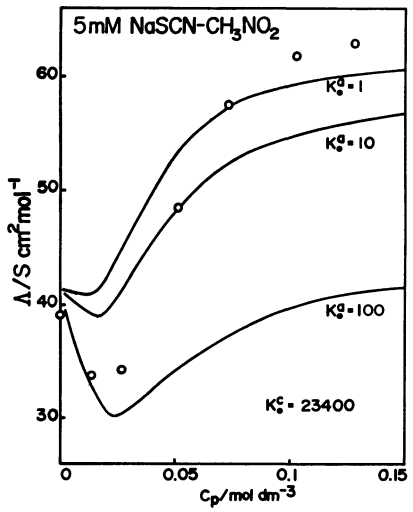

Fig. 9. Calculated Λ *vs.* C_p curves for 5 mmol dm^{-3} NaSCN–nitromethane solution, together with the observed plots.

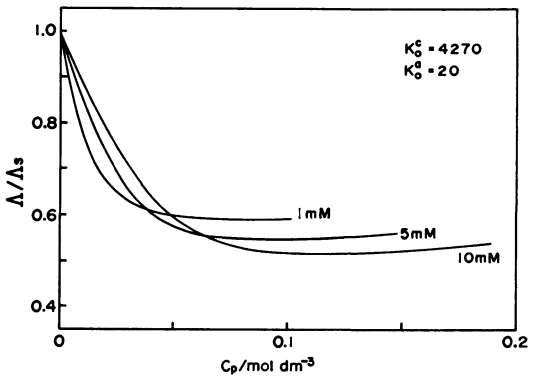

Fig. 10. Dependence of calculated Λ *vs.* C_p curves on total KSCN concentration for KSCN–EtOH solutions.

especially for NaSCN–nitromethane. The theoretical curve can not reproduce the steep rise in conductivity with C_p. One of the causes for the disagreement is the uncertainty in the determination of λ^∞. The precise determination of λ^∞ is difficult in a solvent where the ionic association constant is very large. Another possible cause is the inadequacy of the model where the charge density of the bound cation is high. In the present model, the statistical weight factor of the i-th site being in state $\underline{2}$ is assumed to be $\xi\eta$ irrespective of the binding state of the neighboring sites. In practice, however, this factor may be related to whether $(i+1)$-th site is occupied or not.

It is worth noting that K_0^a values for NaSCN solutions are comparable in ethanol and in nitromethane, despite of the great difference in the ionic association constant, K_A, in the polymer free solution. This result is qualitatively explained by the solvation effects on the sodium ion.[12] In the acidic solvents, such as nitromethane, the solvating power for a cation is very low. On the other hand, basic POE strongly coordinates to sodium ion, which results in the reduction of ionic association if the charge density of the cation on the POE chain is low. This is the reason why the conductance increases in the high C_p for the nitromethane solution.

On the contrary, the hydrogen-bonding solvents, such as ethanol, have well-defined basic sites for the solvation to cation.[12] Consequently, the degree of association is small both in POE free solution and in solutions at high POE concentration. The association is only appreciable in the intermediate regions, where the charge density of the bound cation is high.

We observed a great difference in the behavior of NaSCN and KSCN solutions in nitromethane. As has been stated above, the ionic association constant for sodium ion is much larger than that for potassium ion in the absence of polymer. In the presence of excess POE, almost all the cations are bound to the POE chain. As the effective ion sizes of complexed sodium and potassium ions seem to be identical, the degree of the ionic association of these ions would be similar in magnitude. Consequently, the degree of ionic association for the sodium ion is greatly reduced by the addition of POE, while the reduction is less for the potassium ion.

Finally, we should briefly discuss the correlation with the Manning theory of polyelectrolyte solutions.[13] In his elegant theory, Manning stated that the so-called ion condensation of counter ions is uniquely determined by the charge density parameter ξ_M of the polyion, which is defined by;

$$\xi_M = \frac{e^2}{\varepsilon k_B T b}, \tag{25}$$

where b is the average distance between charges on the polyelectrolyte. According to the theory, for $\xi_M > 1$ the system becomes unstable and the counter ions condense on the polymer chain to achieve the ξ_M value of unity. While the Manning model explains the equilibrium properties of polyelectrolytes in aqueous solutions, the applications to the organic solvent systems are few in the literature.

According to the original theory, the Manning model assumes that the unbound free ions may be treated in the Debye-Hückel approximation. Therefore, the application of the model to the POE–NaSCN–nitromethane system is inadequate, since extensive ionic association occurs even in the POE free solution. We have examined the applicability of the Manning model

to 5 mM KSCN–ethanol and –nitromethane systems, because the ionic association of KSCN is less in these solvents.

It follows from the above that the increase of the conductivity at higher C_p is due to the decrease of ionic association on a POE chain. Thus the POE concentration at the onset of ionic association may be estimated from the point that the increase of the conductivity is no longer detectable in Λ *vs.* C_p curves. From Figs. 1 and 3, for POE–5 mM KSCN–ethanol and –nitromethane systems, this point corresponds to $C_p \simeq 0.2$ and 0.13 M, respectively. Using the intersite distances calculated by a stiff-chain model,[2] ξ_M is estimated to be about 0.4 in both cases. This value is far lower than the limit of the ion condensation predicted from the Manning theory.

It should be noted that the Manning theory is based on the Bjerrum theory[14] of the ionic association between low-molecular weight ions. In the Bjerrum theory, the ionic association is a function only of the dielectric constant of the solvent and the inter-ionic distance. Recent investigations of the solvent effect of ionic association, however, have revealed that this is not true for the ionic association in organic solvents and that it also depends on a specific interaction between the ion and the solvent molecules.[12] This is also the case for the present systems, since the anion binding to the POE chain is related not only to the interaction between the POE–cation complex and the anion but also to that between the cation and the anion in the bulk solvent. As the result, the application of the Manning model to the present systems is inappropriate.

In conclusion, the anomalous conductivity curves for POE-alkali metal ions in ethanol and nitromethane are well explained by a duplicate ion binding model based on the one-dimensional lattice. An improvement of the model would be necessary to achieve a more sufficient agreement between the theoretical and the experimental conductivity curves.

Received August 6, 1982)

Ab initio LCAO-SCF-MO calculations of a model oxyheme were carried out on several singlet, triplet and quintet states arising from the three types of configurations, $(d_\epsilon)^6(\pi_g^a)^2$, $(d_\epsilon)^5(d_\gamma)^1(\pi_g^a)^1(\pi_g^b)^1$, and $(d_\epsilon)^5(\pi_g^a)^2(\pi_g^b)^1$. The lowest states in the SCF energy are of the configuration $(d_\epsilon)^5(\pi_g^a)^2(\pi_g^b)^1$ whose electronic structures can be also expressed as Fe(III)–O_2^- from the results of Mulliken's population analysis. Calculated Mössbauer parameters of those states are in good agreement with experiments for oxyhemoglobin, oxymyoglobin and model oxyheme, while those of the closed-shell singlet state $(d_\epsilon)^6(\pi_g^a)^2$ are inconsistent with experiments. The Fe–O_1 overlap populations indicate a bonding nature for the former states and a non-bonding nature for the latter state. These results all predict singlet states of Fe(III)–O_2^- structure as the main configuration of the ground state in the model oxyheme.

The nature of the iron-oxygen bond in oxyhemoglobin and oxymyoglobin is a controversial problem. Although X-ray data from a model oxyheme[1] and oxymyoglobin[2] support the bent Fe–O_1–O_2 geometry proposed by Pauling,[3] questions concerned with the details of the bondings and the charge on the oxygen molecule have not yet been resolved.

Mössbauer resonance of the proteins[4-6] and of the model compound[7] has been used to probe the electron distribution around the iron nucleus. Electronic transitions spectra,[8,9] magnetic circular dichroism spectra,[9,10] infrared stretching frequencies,[11-14] resonance Raman frequencies,[15,16] magnetic susceptibility,[17-22] and the Fe $K\alpha$ fluorescence emission spectrum of oxyhemoglobin[23] have been measured in order to elucidate the bonding of dioxygen to iron porphyrins.

The large quadrupole splitting observed in Mössbauer resonance of the oxyhemoglobin[5,6] and of the model oxyheme compound,[7] would imply the presence of large asymmetric 3d electron distribution caused by covalent bondings if the oxyhemoglobin were to be considered as low-spin iron(II). However the observed negative electric field gradient would be compatible with the loss of electron charge from a $d\pi$ orbital, which may imply an Fe(III)–O_2^- structure.

The oxygen-oxygen stretching frequencies observed in myoglobin (1103 cm^{-1}),[11] in hemoglobin (1107 cm^{-1}),[12] and in the model compounds (1160 cm^{-1})[13] were cited as evidence for the Fe(III)–O_2^- structure, since they fall in the range found for superoxide complexes (KO_2, 1100—1150 cm^{-1}), while the stretching frequencies for the O_2 molecule are 1556 cm^{-1} for the $^3\Sigma_g^-$ state and 1484 cm^{-1} for the $^1\Delta_g$ state. However the force constant of the O–O bond in ozone (6.16 mdyn/Å) displayed a similar value to that for the O_2^- complex (5.7—6.2 mdyn/Å). This suggests that a neutral O_2 unit in heme complexes can have the observed frequencies mentioned above (1 mdyn/Å$=1\times10^{-7}$ N nm^{-1}).

Thus no definite conclusion can be drawn from experimental measurements. Many theoretical calculations[24-35] have been made to try to resolve these uncertainties and to account for the observed properties of oxyhemoglobin.

Recent semi-empirical INDO-SCF-CI calculations on a model oxyheme complex were reported to yield a singlet diamagnetic ground state with a very low-lying paramagnetic triplet state.[31] The diamagnetic ground state has considerable Fe(III)(d^5)–O_2^- character due to extensive charge-transfer but is not described by a single open-shell configuration of the Fe(III)(d^5)–O_2^- type. The calculations gave a quadrupole splitting and an electric field gradient in agreement with experiments, using delicate sets of semi-empirical parameters.

Ab initio LCAO-SCF-MO calculations for the model oxyheme were made by Dedieu *et al.*[33-35] Both minimal and valence-double basis set calculations yielded the lowest energy for a triplet state $^3A'$ with the formal configuration $(d_{x^2-y^2})^2(d_{xz})^2(d_{yz})^1(\pi_g^a)^2(\pi_g^b)^1$. However they assigned the ground state to the closed-shell state ($^1A'$), $(d_{x^2-y^2})^2(d_{xz})^2(d_{yz})^2(\pi_g^a)^2$, which lies at 0.036 a.u. (in the minimal basis) and 0.051 a.u. (in the valence-double basis set calculation) higher than the triplet state, since they estimated the correlation energy to be larger than 0.051 a.u. (1 a.u.$=4.35968\times10^{-18}$ J). This ground state wavefunction could not reproduce experimental Mössbauer parameters.[27,28,34] These calculations of Dedieu *et al.*[33,34] employed a split basis for the iron 3d orbitals consisting of optimized atomic 3d orbitals and additional Gaussian functions with a small exponent of 0.20. In our previous *ab initio* LCAO-SCF-MO calculations on cobalt porphine with a triple zeta 3d set,[36] the Gaussian 3d functions with an exponent of 0.18 were found to be negligible, while those with an exponent of 0.555999 were found to be critical in the description of the electronic structures of high oxidation states (see Discussion). Similarly in the present study we have found that Dediue's description of 3d orbitals is not flexible enough accurately to compare energies between Fe(III)- and Fe(II)-complexes.

In the present investigation we have examined *ab initio* LCAO-SCF-MO calculations using a basis set different from Dedieu's sets with a hope to predict correct energy levels and Mössbauer parameters. In the following sections we give details of the calculation

methods, then present the results, and discuss the total energies, Mössbauer parameters, charge distributions, and bonding natures for the oxyheme model.

Method

The geometry of the iron-porphine core, with the iron atom in the assumed porphine plane, was taken as the experimental geometry of the ($\alpha,\beta,\gamma,\delta$-tetraphenylporphinato)iron(II)(py)(CO)[37] (somewhat idealized) and is shown in Fig. 1a. For the Fe–O_1–O_2 moiety we have used an Fe–O_1 bond length of 1.75 Å, and an O_1–O_2 bond length of 1.24 Å and a Fe–O_1–O_2 angle of 136° corresponding to the experimental values for the dioxygen complex of the picket fence porphyrin.[7] We have used the experimental geometries of the ammonia ligand with an Fe–N bond length of 2.12 Å (Fig. 1b).[38] Our choice of axis is shown in Fig. 1b with the porphine plane being the xy plane. The four nitrogen atoms of the pyrrole rings are along the bisector of the axes x and y. The Fe–O_1 axis is the z axis and the O_1–O_2 axis projects along the axis x. The model system is assumed to have C_s symmetry.

The *ab initio* LCAO-SCF-MO calculations including all electrons have been carried out on the oxyheme model described above with a primitive Gaussian basis set (11s, 7p, 4d/7s, 3p/3s)[39,40] contracted to [4s, 3p, 2d/2s, 1p/1s] which is a minimal set except for the 3d functions with a split basis. The basis sets are shown in Table 1. For H, the (3s) set was contracted to the minimal set. The (7s, 3p) set was contracted to the minimal bases for C, O, and N. The (11s, 7p, 4d) basis set for the Fe atom is constructed from a (12s, 6p, 4d) basis optimized for Fe,[39] where two diffuse s functions were replaced by one s function of exponent 0.26; a set of p functions with an exponent of 0.28 was incremented. A comparison between ours and Dedieu's 3d orbitals is shown in Table 2. To improve the quality of the bases for light atoms, scale factors were used for the valence orbitals. Scale factors are 1.283, 1.098, 1.102, 1.102, 0.966, 1.019, 1.073, 1.073, 0.981, and 0.950 for H(1s), C(2s), C($2p_x$), C($2p_y$), C($2p_z$), N(2s), N($2p_x$) N($2p_y$), N($2p_z$), and O(2s), respectively. The calculations were carried out using the JAMOL 3 program package with a Roothaan's open shell formulation. We adopted a modified scheme of integral approximation[42] based on semi-orthogonalized orbitals.[43–45] The values 3.0×10^{-3} and 1.0×10^{-5} a.u. were taken as the threshold ones, respectively, for the overlap and exchange integrals from the results of the previous studies.[42–45] The calculation of molecular integrals and supermatrices took about 5 h of CPU time on a HITAC M-180 computer at the Computer Center of the Institute for Molecular Science. The HITAC M-180 is faster in speed by a factor of 1.5 as compared with that of an IBM 370-168. Each iteration in the SCF procedure took about 2 min. Iterations were performed to obtain SCF convergence, the criterion of which was less than 1.0×10^{-6} a.u. and 5.0×10^{-4} in the maximum differente between input and output values of the total energy

and density matric elements, respectively.

Results

The $3d_{z^2}$, $3d_{xz}$, $3d_{yz}$ orbitals of iron and $1\pi_g$ antibonding orbitals of dioxygen play important roles in the iron-oxygen bond. The π_g orbitals which are degenerate in the oxygen molecule are no longer equivalent in the complex with a bent structure. They are separated into two distinguished orbitals which are labeled as π_g^a and π_g^b in the following. The orbital π_g^a is made of $2p_x$ and $2p_z$ orbitals of the oxygen atoms and is symmetric with respect to the Fe–O_1–O_2 plane which is a plane of symmetry, while π_g^b is made of $2p_y$ orbitals and is antisymmetric with respect to the Fe–O_1–O_2 plane. The π_g^a orbital is stabilized relatively to the π_g^b orbital by the bonding interaction with the iron.

We have studied three groups of configurations $(d_\epsilon)^6(\pi_g^a)^2$, $(d_\epsilon)^5(d_\gamma)^1(\pi_g^a)^1(\pi_g^b)^1$, and$(d_\epsilon)^5(\pi_g^a)^2(\pi_g^b)^1$, where d_ϵ stands for $d_{x^2-y^2}$, d_{yz}, d_{xy} and d_γ represents d_{z^2} or d_{xy}. The closed-shell singlet state $(d_\epsilon)^6(\pi_g^a)^2$ with the $^1A'$ symmetry corresponds to an Fe(II)–O_2 formal configuration. An open-shell singlet state with the configuration $(d_\epsilon)^5(d_\gamma)^1(\pi_g^a)^1(\pi_g^b)^1$ was predicted as the main configuration in the ground state of oxyheme from the *ab initio* GVB-CI calculations on the model oxyheme system composed of O_2–Fe$(NH_2)_4$–NH_3.[29,30] The configuration $(d_\epsilon)^5(\pi_g^a)^2(\pi_g^b)^1$ corresponds to the formal Fe(III)–O_2^- configuration.

The calculated results, summarized in Table 3, indicate that the lowest energies for the oxyheme model were obtained for a group of states having a $(d_\epsilon)^5(\pi_g^a)^2(\pi_g^b)^1$ configuration. The open-shell singlet $^1A''$ (see the footnote (c) in Table 3) with the same formal configuration to that of $^3A''$ is calculated to be only 0.001 a.u. (0.03 eV) above the triplet state. One finds the quintet open-shell states, $^5A''$, and $^5A'$ at 0.032 and 0.047 a.u. (0.87 and 1.3 eV) above the lowest triplet states, respectively. Further above 0.043 a.u. (1.2 eV) from $^5A'$, there exists the closed-shell singlet $^1A'$ which corresponds to the Pauling model. These energy levels are illustrated in Fig. 2c.

The quadrupole splitting ΔE_Q of the present oxyheme model was calculated and is listed in Table 3 with the observed values in Mössbauer spectra. The ΔE_Q was determined as follows. The nine components V_{ij} of the electric field gradient tensor were calculated and the 3×3 tensor was then diagonalized. The principal values were ordered as $|V_{zz}|>|V_{xx}|>|V_{yy}|$. These values were then used in the expression:

$$\Delta E_Q = (1/2)(1/-R)eQq[1+\eta^2/3]^{1/2},$$

where $q=V_{zz}$, $\eta=|(V_{xx}-V_{yy})/V_{zz}|$ $(0<\eta<1)$, R is Sternheimer shielding constant, and Q is nuclear quadrupole moment. The sign of ΔE_Q is the sign of the largest component V_{zz} and $(1-R)eQ$ was taken as an empirical parameter determined to be 2.07 from our previous paper.[48] The calculated values of ΔE_Q, η, and the direction of the largest component of the electric field gradient tensor are listed in Table 3. These

results indicate that only the open-shell states with the configurations $(d_{x^2-y^2})^2(d_{xz})^2(d_{yz})^1(\pi_g^a)^2(\pi_g^b)^1$ and $(d_{x^2-y^2})^2(d_{xz})^1(d_{yz})^2(\pi_g^a)^2(\pi_g^b)^1$ can give ΔE_Q, and the sign and direction of the principal axis (V_{zz}) in agreement with the experimental low-temperature values ($\Delta E_Q=-2.10$ mm s^{-1}, V_{zz} in plane).[5,6]

Table 4 demonstrates the gross atomic populations and net atomic charges for the iron, oxygen and nitrogen atoms for the $^1A''$ and $^1A'$ states. As seen in Table 4, the net charges on the iron and oxygen atoms for $^1A''$ correspond well to an Fe(III)(d^5)–$O_2^-(\pi_g^3)$ configuration while those for $^1A'$ correspond to an Fe(II)(d^6)–$O_2(\pi_g^2)$ with reduced positive charge on the iron and nearly neutral oxygen atoms.

Table 5 displays the bond overlap populations of the open-shell singlet ($^1A''$) and the closed-shell singlet ($^1A'$) states calculated by Mulliken's population analysis. The

difference (0.15) in the total overlap population of the O_1–O_2 bond between the two states is related mainly to the p orbitals. This indicates that the O_1–O_2 bond of the $^1A''$ state is weakened by the excess electron population in the anti-bonding π_g^b orbital. Another important difference exists in the Fe–O_1 bond, which is non-bonding for the $^1A'$ state but bonding for the $^1A''$ state. Therefore, the Fe–O_1 bond in $^1A''$ state is more stabilized than that in the $^1A'$ state by both covalent and ionic interactions. There exist no significant differences in the overlap populations of the Fe–$N_{pyrrole}$ and the Fe–N_{axial} bonds between the two states.

Discussion

As shown in Fig. 2, the energy gap between $^1A'$ and $^3A'$, $^1A''$ or $^3A''$ in the present SCF calculation is substantially different from those obtained by Dedieu *et al.*[33–35] in the similar *ab initio* SCF-MO calculations with both a minimal set (except for 3d functions) (Basis Set I) and a valence-double basis set (Basis Set II). This difference gives contrary conclusions in the assignment of the ground state of oxyheme model. The total energy of the d^6 closed-shell configuration would be relatively more stabilized than those of the d^5 and d^6 open-shell configurations by the effect of the electron correlation. We have previously estimated that the correlation energy differences of the closed-shell configuration $(d_\epsilon)^6(\pi_g^a)^2$ from the open-shell configurations $(d_\epsilon)^5(\pi_g^a)^2(\pi_g^b)^1$, and $(d_\epsilon)^5(d_\gamma)^1(\pi_g^a)^1(\pi_g^b)^1$ would be ≈2.0 eV[49] and ≈1.2 eV,[50] respectively. Figure 2d illustrates the effect of the electron correlation on the open-shell configurations relative to the closed-shell one. As seen from Fig. 2d, the lowest state is one with the open-shell configuration $Fe(III)(d_\epsilon^5)$–$O_2^-(\pi_g^3)$, even after consideration for the correlation energy. The open-shell state $^3A''$ with the configuration $Fe(II)(d_\epsilon^5 d_\gamma^1)$–$O_2(\pi_g^2)$ stays just above those with the $(d_\epsilon)^5(\pi_g)^3$ configurations, and another open-shell quintet state $^5A'$ lies close to the closed-shell $^1A'$ state in Fig. 2d.

In the calculations with basis set I and II by Dedieu *et al.*[33–35] the energies of the closed-shell state ($^1A'$) are only 0.036 a.u. (0.98 eV) and 0.051 a.u. (1.39 eV), respectively above those of the open-shell state ($^3A'$). They concluded that the closed-shell state ($^1A'$) is the ground state because the SCF energy gap of the two states is smaller than the difference in the correlation energy.

The reason why the SCF energy gap is larger in the present calculation than in their calculations comes from the contents of the basis functions, since the present calculation employed the same oxyheme model as that of Dedieu *et al.*[33–35] Between the present basis set and Dedieu's basis set I, there is no fundamental difference except for the 3d functions. They do differ significantly in the split between ours and those of Dedieu *et al.* as listed in Table 2. Dedieu *et al.* incremented primitive Gaussian functions with an exponent of 0.20 to the atomic 3d orbitals optimized for the iron atom, while we divided the original atomic 3d orbitals into two components (d_1 and d_2) composed of 3 and 1 primitive Gaussian functions, the latter of which has a exponent of 0.505755. Our choice is based on the following argument. In our calculation on cobalt porphine with a triple zeta basis for 3d orbitals[36] the most diffuse d function with an exponent of 0.18 was not effective, while the d function with an exponent of 0.555999 was very important in the proper description of the molecular orbitals. The present form of the split could take account of the effect of the contraction of the 3d orbitals in the change from iron(II) (in $^1A'$) to iron(III) (in $^1A''$). In Table 6, the ratio of coefficients of the two 3d functions (d_1/d_2) is shown for each molecular orbital. The ratios for the iron(II) state are not very different from the ratio of 1.67 for the atomic orbital of the neutral iron. This means that the 3d components in the iron(II) state are as well described as in the iron atom. The large values of the ratio in the iron(III) state indicate the contraction of the 3d components. Therefore the form of the split by Dedieu *et al.*[33–35] is not adequate to describe the iron(III) states, even if it is acceptable for a description of the iron(II) states.

From the observed predominant diamagnetism of oxyhemoglobin and of the dioxygen complex of the picket fence porphyrin, the ground state is assigned to the open-shell singlet $^1A''$ in the present SCF calculation. A strong support for this assignment of the ground state comes from the calculation of the Mössbauer parameters. As shown in Table 3, the open-shell singlet state $^1A''$ yields a large negative electric field gradient whose direction is in the heme plane. These calculated results are in good agreement with low temperature measurements of the single crystal Mössbauer resonance of oxyhemoglobin.[5,6] On the contrary, the closed-shell singlet state $^1A''$, which was assigned as the ground state of the oxyheme by Dedieu *et al.*, can not yield correct Mössbauer parameters, as is seen in Table 3, and as was also shown previously.[27] It should be added that the quintet states do not yield Mössbauer parameters consistent with the low temperature experimental values (Table 3).

The $^1A''$ state can be regarded as a $d\pi$-π_g charge-transfer state of $^1A'$ and has the iron(III) superoxide character as shown in Table 4. This arises from an appreciable amount of charge-transfer from the iron atom to the dioxygen ligand. One electron is transferred from the iron d_{xz} orbital to the oxygen anti-bonding

TABLE 6. COMPARISON OF THE COEFFICIENTS OF THE MOLECULAR ORBITALS WITH PREDOMINANT 3d CHARACTER AND THE RATIOS OFTHOSE FOR $^1A'$ WITH THOSE FOR $^1A''$

	(1.55)				

orbital. The ligands donate approximately one electron (0.77) to the formally empty d_{z^2} and d_{xy} orbitals (Table 4). Furthermore the iron 4s and 4p orbitals receive approximately one electron (0.85) from the ligands. This results in atomic charges of 1.50 on the iron atom and −0.65 on the dioxygen ligand in the $^1A''$ state (Table 4).

The following conclusions were obtained from the present *ab initio* LCAO-SCF-MO calculations of the oxyheme model on several singlet, triplet, and quintet states, which arise from the three types of configurations, $(d_\epsilon)^6(\pi_g^a)^2$, $(d_\epsilon)^5(d_\gamma)^1(\pi_g^a)^1(\pi_g^b)^1$, and $(d_\epsilon)^5(\pi_g^a)^2(\pi_g^b)^1$. The lowest states in the SCF energy have the configuration $(d_\epsilon)^5(\pi_g^a)^2(\pi_g^b)^1$ whose electronic structure can be expressed as Fe(III)–O_2^- from the results of Mulliken's population analysis. This configuration remains as the lowest energy states even after consideration of the correlation energy. Calculated Mössbauer parameters of these states are in good agreement with experiments for oxyhemoglobin, oxymyoglobin and oxyheme model, while those of the closed-shell singlet state $(d_\epsilon)^6(\pi_g^a)^2$ are inconsistent with experiment. The Fe–O_1 overlap populations indicate a bonding nature for the $(d_\epsilon)^5(\pi_g^a)^2(\pi_g^b)^1$ states and a non-bonding nature for the $(d_\epsilon)^6(\pi_g^a)^2$ state. From the above discussion, the open-shell singlet state $^1A''$, $(d_\epsilon)^5(\pi_g^a)^2(\pi_g^b)^1$, is the most promising candidate for the ground state of the oxyheme model in the framework of the present Hartree-Fock level calculation. However the ground state and low-lying states would need to be described as a more complex wavefunction than a sigle configuration function if we consider the configuration interaction, the spin-orbit interaction, and the lack of C_s symmetry. Our results indicate singlet configurations $(d_\epsilon)^5(\pi_g)^3$ with the Fe(III)–O_2^- structure as the most important configurations of the ground state in the oxyheme model.

The authors wish to thank Professor Kimio Ohno (Hokkaido University) for his earnest encouragement throughout this study. They also thank Professor Fukashi Sasaki and Dr. Toshikazu Takada (Hokkaido University) for their helpful advices on the program package (JAMOL 3). The author (M. H.) acknowledges the support of a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

The calculations reported in this paper were carried out on the HITAC M-180 and M-200H computers at the Computer Center of the institute for Molecular Science. This research was supported by the Joint Studies Program (1979—1980) of the Institute for Molecular Science.

48) S. Obara and H. Kashiwagi, *J. Chem. Phys.*, **77**, 3155 (1982).
49) The correlation energy was estimated from the differences between calculated and experimental transition energies. The well characterized charge-transfer transition for metmyoglobin cyanide at 6.4×10^3 cm^{-1} (0.79 eV)[51] was utilized for this purpose. Our *ab initio* calculation with a partial-double basis on (porphinato)iron(III)(py)(CN^-) yielded the excited state $^2A_1$ $((d_{x^2-y^2})^2(d_{xz})^2(d_{yz})^2(a_{1u})^2(a_{2u})^1)$ (a d^6 state) at 2.80 eV above the ground state $^2B_2$ $((d_{x^2-y^2})^2(d_{xz})^2(d_{yz})^1(a_{1u})^2(a_{2u})^2$ (a d^5 state) (unpublished results). The difference (2.01 eV) between the calculated transition energy (2.80 eV) and the experimental one (0.79 eV) should be the correlation bias between d^5 states and d^6 states which is the predominant correlation energy difference between $^3A'$, $^3A''$ or $^1A''$, and $^1A'$.
50) The correlation energy between the $^5A'$ or $^5A''$ and $^1A'$ was estimated from the difference between the *ab initio* SCF energies calculated for (porphinato)iron(II)(py) with a partial-double basis[48] and the energy diagram determined by Eicher and Trautwein for deoxyhemoglobin.[52]

(Received September 18, 1982)

The Zeeman effect on ^{81}Br NQR in a single crystal of $PBr_3 \cdot BBr_3$ was studied at room temperature. The crystal has an orthorhombic symmetry. The bond angles have been f und to be $111.2 \pm 0.1°$ and $111.5 \pm 0.1°$ for Br–B–Br, and $107.0 \pm 0.1°$ and $109.1 \pm 0.3°$ for Br–P–Br. The Br atoms of BBr_3 group have relatively large values of η, 0.151 ± 0.004 and 0.120 ± 0.007, while the Br atoms of PBr_3 group have small values, 0.025 ± 0.005 and 0.020 ± 0.004. The large η values of Br atoms of BBr_3 group are ascribed to the π bonding existing in the B–Br bonds.

It is of interest to investigate the halogen nuclear quadrupole resonance (NQR) of Lewis acid-base complexes $PX_3 \cdot BY_3$ (X, Y=Cl, Br, or I), because both donors PX_3 and acceptors BY_3 contain halogen atoms. Furthermore, the strong interaction between the donors and the acceptors may shift the resonance frequency more than that expected from the crystalline field effects. The previous paper has reported the ^{79}Br and ^{127}I NQR frequencies of $PBr_3 \cdot BBr_3$, $PBr_3 \cdot BI_3$, and $PI_3 \cdot BBr_3$ at 77 K.[1] For these complex-formations, the resonance frequencies (or quadrupole coupling constants) of the donors increased significantly compared to those of the parent molecules, while those of the acceptors also increased by a small extent. The frequency increase in the donors shows that the electric charge on X atoms of PX_3 decreases through p_σ bonds on complexation. In contrast, the charge on Y atoms of BY_3 may increase through both p_σ and p_π bonds. The small increase in frequency in acceptors may be net results of the two opposite effects: frequency lowering and raising due to the increase of the number of p_σ and p_π electrons of the Y atoms, respectively.

The ground state wave function Ψ_N of the complex $PX_3 \cdot BY_3$ may be approximately expressed according to Mulliken[2] by

$$\Psi_N = a\Psi_0(PX_3, BY_3) + b\Psi_1(X_3P^+ - B^-Y_3), \quad (1)$$

where Ψ_0 represents a no-bond structure and Ψ_1 a dative structure. (Chemical experience shows $b^2 > a^2$ in Eq. 1.) This equation shows that a decrease in B–Y π bonding will occur upon progressive increase of the dative structure. On the one hand, the asymmetry parameter η is a measure of the π character of chemical bond when only one of the p_π lone-pair orbitals of halogen atoms can interact to form a π bond.[3] Relatively large values of η, 0.104 and 0.173, were found for $-BI_3$ of $PBr_3 \cdot BI_3$.[1] Another contributions to η arise from the intermolecular bonding in which the relevant atoms participate and the asymmetric distributions of electric charges around the bonds. It is, therefore, desirable to estimate such contributions in order to discuss the bond nature. The η values of X atoms in PX_3 group will offer a clue for this. The η of I atoms in $PI_3 \cdot BBr_3$ have, however, not been obtained owing to the failure to detect these ($m = \pm 3/2 \leftrightarrow \pm 5/2$) transitions. Nor have structural studies of the $PX_3 \cdot BY_3$ been carried out. We examined the Zeeman effect on ^{81}Br NQR for $PBr_3 \cdot BBr_3$ (which is stable on melting, unlike the other complexes stated above) in order to obtain precise NQR parameters as well as information about crystal and molecular structure.

Experimental

The complex was prepared as described previously[1] using Shlenk type glasswares[4] and glove bags; the product was once purified by sublimation at *ca.* 38 °C in a closed Shlenk flask. A single crystal was obtained by the Bridgman method in the sealed glass ampoule of 15 mm diameter.

NQR signals were displayed on an oscilloscope using two superregenerative oscillators: One is a usual LC-oscillator for lower frequency resonances and the other is a Lecher-line oscillator for higher ones. The Zeeman effect was measured by means of a goniometer newly constructed by us. The polar angle Θ is defined by the rotation of the magnetic field which is generated by means of a Helmholtz coil. A field of 7.5×10^{-3} T is generated with a current of 1 A in the Helmholtz coil which has a diameter of 38 cm and a separation of 10 cm between a pair of coils. The azimuthal angle Φ is defined by the rotation of the Φ disk which is attached to a cylinder inserted in the Helmholtz coil. The single crystal is held in the Φ disk. All frames of the goniometer are made of brass. To attain smooth rotation, the heavy Helmholtz coil is supported on 72 pieces of 8 mm diameter brass balls in a circular groove. The scales of Θ and Φ are engraved with marking at 1° intervals. The orthogonality between the rotation axes of Θ and Φ was checked according to the method described by Dean.[5] In the preliminary investigation with a single crystal of $NaClO_3$, the accuracy of the measurement is estimated within ± 0.01 in η and $\pm 0.2°$ in the angle.[6] Zerosplitting cones were obtained using the magnetic field of *ca.* 2×10^{-2} T at room temperature (17—21 °C). The analysis of the data of the Zeeman effect measurement was performed by using a electronic computer HITAC M-180 from Hiroshima University. The resonance signals for $-BBr_3$ of the complex have doublet structures.[1] The measurements were done for the stronger signals of the doublets.

Results and Discussion

Figure 1 shows ^{81}Br NQR spectra of $PBr_3 \cdot BBr_3$ with those of the parent compounds at 77 K. The four resonance lines (labeled ν_1, ν_2, ν_3, and ν_4) are divided into two sets spaced widely in frequency having the signal intensity ratios $I(\nu_1) : I(\nu_2) = I(\nu_4) : I(\nu_3) \approx 1 : 2$. The sets of ν_1 and ν_2, and of ν_3 and ν_4 are ascribed to the bromine atoms of fragments BBr_3 and PBr_3 of the complex, respectively. Thus, the resonance frequencies increase significantly in the donor (*ca.* 30 MHz) but to a small extent for the acceptor (*ca.* 0.5 MHz) on

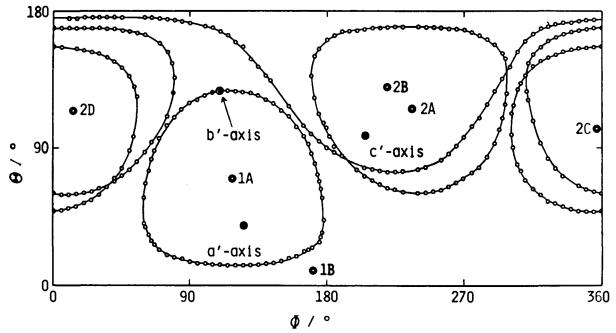

Fig. 2. Zero-splitting patterns of ^{81}Br NQR lines for $-BBr_3$ of $PBr_3 \cdot BBr_3$. 1A, 1B, *etc.*, denote the EFG z-axes of Br_{1A}, Br_{1B}, *etc.*, respectively. The zerosplitting pattern of 1B was not obtained owing to its unfavorable orientation. The direction of 1B was deduced from 1A and the crystal axes.

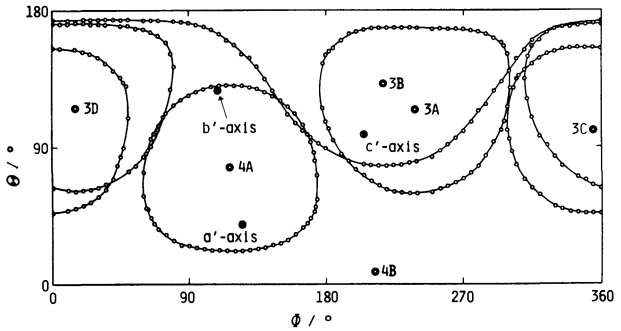

Fig. 3. Zero-splitting patterns of ^{81}Br NQR lines for $-PBr_3$ of $PBr_3 \cdot BBr_3$. 3A, 3B, *etc.*, denote the EFG z-axes of Br_{3A}, Br_{3B}, *etc.*, respectively. The zerosplitting pattern of 4B was not obtained owing to its unfavorable orientation. The direction of 4B was deduced from 4A and the crystal axes.

complexation.

The zero-splitting patterns obtained from the Zeeman effect of the resonance lines for $-BBr_3$ and $-PBr_3$ of the complex are shown in Figs. 2 and 3. The existence of four loci for ν_2 and ν_3, and of two loci for ν_1 and ν_4 was confirmed, but one of the two loci for each of ν_1 and ν_4 could not be determined owing to its unfavorable orientation. The number of the loci shows that the crystal belongs to orthorhombic symmetry. The directions of z-axes of electric field gradients (EFG) obtained from the zero-splitting loci and the crystal axes (tentatively named a', b', and c') which are found from the symmetrical distributions of the z-axes are shown in Figs. 2 and 3. The z-axes of the missing loci 1B and 4B are also shown.

The angles between the z-axes of EFG tensors are listed in Table 1. The bond angle Br–P–Br in gaseous PBr_3 has been found to be 101.0°.[7] In a recent X-ray analysis of solid PBr_3 at 193 K, Enjalbert and Galy[8] have found the bond angles of 101.3° and 99.0°. On the other hand, all the Br–B–Br angles in the few know complexes of the present type $(CH_3)_3N \cdot BX_3$,[9,10] $(CH_3)_3P \cdot BX_3$,[11,12] and $CH_3CN \cdot BX_3$[13] are close to 111° in both gaseous and crystalline states. Taking these angles into consideration and assuming that the z-axes are parallel to the directions of bond axes, the angles Br–M–Br (M=P and B) can be deduced from the angles in Table 1 (and their supplementary angles). These values are listed in Table 2. Further, assuming that the complex molecule has a staggered conformation, (Br_{1A}, Br_{2B}, Br_{2D}, Br_{3B}, Br_{3D}, and Br_{4A}) and (Br_{1B}, Br_{2A}, Br_{2C}, Br_{3A}, Br_{3C}, and Br_{4B}) belong to each molecule which orients in two different directions. The angles Br–B–Br and Br–P–Br in $PBr_3 \cdot BBr_3$ are a little larger than the Br–B–Br and C–M–C (M=P, N) in solid $(CH_3)_3P \cdot BBr_3$[12] and solid $(CH_3)_3N \cdot BBr_3$,[10] respectively. On complexing, the Br–B–Br angles decrease by 7% from the value of a free molecule of BBr_3[14] (Br–B–Br=120°), while the Br–P–Br angles increase by 7% from the value of a free molecule of PBr_3[7] (Br–P–Br=101.0°).

The angles between EFG axes and the crystal axes are listed in Table 3. The B–Br_1 and P–Br_4 bonds exist in the a'b'-plane within experimental errors. For further investigation, the direction of the vector P–Br(G_P) which is directed to the center of mass of three Br atoms in $-PBr_3$, and that of the corresponding vector B–Br(G_B) in $-BBr_3$ were obtained on the assumption that all P–Br or B–Br bonds had equal bond lengths. The angle between the P–Br(G_P) and the B–Br(G_B) in one molecule is $1.4 \pm 0.1°$. The small angle indicates that the molecule

	ν_4	213.22	426.41	0.020±0.004		
BBr_3[b]		146.41	283.80	0.45	0.12	

a) At 293 K. b) Ref. 18; at 77 K.

has effective $3m$ symmetry. The angle between the respective P–Br(G_p) (or B–Br(G_B)) vectors of the two molecules in different orientations is 30.4±1.4°, which is considered as almost coinciding with the angles between the P–B bonds in different orientations.

The asymmetry parameter can be deduced by transforming the zero-splitting locus in the EFG principal axis system,[15] in which the locus is expressed for $I=3/2$ as follows:[16]

$$\sin^2\theta = 2/(3 - \eta\cos 2\phi), \quad (2)$$

where θ and ϕ are polar and azimuthal angles, respectively. Thus, the quadrupole coupling constant $e^2q_{zz}Q/h$ is obtained using the resonance frequency ν and η according to the following equation:

$$\nu = (1/2)(e^2q_{zz}Q/h)[1+(1/3)\eta^2]^{1/2}. \quad (3)$$

The $e^2q_{zz}Q/h$ and η at room temperature are listed in Table 4. It is noted that η values are relatively large for the Br atoms of $-BBr_3$ but very small for the Br atoms of $-PBr_3$ in the complex. This finding may show that the intermolecular contributions to η are very small in the crystal and that the large η of the Br atoms of $-BBr_3$ originate mostly in the π-bonding existing in the B–Br bonds. Neglecting the intermolecular contributions to η, we can estimate the π bonding character of B–Br bonds of $PBr_3 \cdot BBr_3$ according to the following equation:[2]

$$f = (2/3)\eta(e^2q_{zz}Q/h)/(e^2q_{at}Q/h), \quad (4)$$

where f denotes the degree of π character and $e^2q_{at}Q/h$ denotes the atomic quadrupole coupling constant, which is 643.03 MHz for ^{81}Br atom.[17] The values of f are listed in Table 4. On complex-formation, the π character of B–Br bonds reduces from *ca.* 12% to 5%. It is found from Table 3 that the x-axis of the Br_1 atom exists in the mirror plane in which the B–Br_1 bond lies. Furthermore the x-axis of the Br_2 atom makes only a small angle, 5.3±0.3°, with the plane which contains the B–Br_2 bond and the B–Br(G_B) vector in a molecule. This is consistent with the existence of the π bonding in the B–Br bonds of the complex.

The authors express their sincere thanks to Mr. Tokuji Hirakawa of Tokushima University for the construction of the goniometer.

(Received October 7, 1982)

The crystal structure of heptakis(2,3,6-tri-*O*-methyl)-β-cyclodextrin–*p*-iodophenol (1 : 1) tetrahydrate, $C_{63}H_{112}O_{35}\cdot C_6H_5OI\cdot 4H_2O$, was determined by the X-ray method. The crystal is orthorhombic with the space group $P2_12_12_1$, $Z=4$, $a=14.997(2)$, $b=21.368(2)$, and $c=28.205(3)$ Å. The structure was solved by the heavy atom method combined with the rigid-body least-squares technique and refined by the block-diagonal least-squares method to the final *R*-value of 0.094 for 3268 reflections ($\sin\theta/\lambda<0.49$). Heptakis(2,3,6-tri-*O*-methyl)-β-cyclodextrin is in the shape of a truncated elliptical cone. The macrocyclic ring is remarkably distorted from a regular heptagonal structure. The iodophenyl group of the guest is inserted into the host cavity. The phenolic hydroxyl group protrudes from the cavity, forming hydrogen bonds with two water molecules. The iodine atom is located at the center of the macrocyclic ring, while the benzene ring occupies its position at the base side of the cone. The crystal is built up of columns which are formed by the stack of host molecules in a head-to-tail mode along the two-fold screw axis which is parallel to the crystallographic b axis. Four water molecules fill intermolecular spaces in the crystal.

Recently, extensive attention has focused on the chemical modification of cyclodextrins.[1,2] Many substituted cyclodextrins have been studied to improve complexing and catalytic abilities of these macrocyclic oligosaccharides. Methylated cyclodextrins are quite interesting compounds to investigate the effect of substituents on the macrocyclic conformation and host-guest interaction. Previously, we have determined crystal structures of some permethylated α-cyclodextrin complexes.[3-5] In those structures, the macrocyclic ring is distorted by the steric hindrance which is caused by the methyl groups introduced to secondary hydroxyl groups. Permethylated α-cyclodextrin forms inclusion complexes with benzene derivatives, but their host-guest geometry is quite different from the corresponding α-cyclodextrin complexes. On the other hand, Stezowski and his co-workers have reported the structure of heptakis(2,6-di-*O*-methyl)-β-cyclodextrin-adamantanol complex,[6] and shown that the host macrocyclic ring is almost round just like as β-cyclodextrin.[7-11] In this paper, we present the crystal structure of the heptakis-(2,3,6-tri-*O*-methyl)-β-cyclodextrin–*p*-iodophenol (abbreviated to methyl-β-CDx–*p*-IPH) complex. This is the first structural determination of permethylated β-cyclodextrin.

Experimental

Methyl-β-CDx was dissolved in a *p*-IPH saturated aqueous solution. The solution was allowed to stand at 40 °C, then colorless prismatic crystals were obtained. Lattice parameters and reflection intensities were measured on a Nicolet P3/F diffractometer with graphite-monochromated Cu *Kα* radiation. By using θ-2θ scan mode, 3286 independent reflections with $|F_o|\geqq 3\sigma(F)$ were obtained up to 90° in 2θ. No corrections were made for absorption and extinction effects.

Crystal Data: $C_{63}H_{112}O_{35}\cdot C_6H_5OI\cdot 4H_2O$, *F.W.*=1721.6, orthorhombic, space group $P2_12_12_1$, $Z=4$, $a=14.977(2)$, $b=21.368(2)$, $c=28.205(3)$ Å, $V=9026(2)$ Å^3, $D_x=1.267$, $D_m=1.25$ g cm^{-3}.

Determination and Refinement of the Structure

The structure was solved by the heavy atom method. The electron-density map, which was calculated with iodine phases, revealed the outline of methyl-β-CDx. Owing to the low resolution of the map, however, it was quite difficult to estimate coordinates of light atoms. A trial structure of methyl-β-CDx was set up so as to fit the electron-density map, then the orientational and rotational parameters of each 2,3,6-tri-*O*-methylglucose residue were corrected by the rigid-body least-squares technique. After the refinement of the methyl-β-CDx structure by the block-diagonal least-squares method, the light atoms of *p*-IPH and water molecules were found on a difference-Fourier map. Successive refinements of the structure by the block-diagonal least-squares method achieved the *R*-value of 0.094. The quantity minimized was $\sum w(|F_o|-|F_c|)^2$ with $w=1.0$ for all the reflections. The atomic scattering factors were taken from the "International Tables for X-ray Crystallography."[12] The atomic parameters are given in Table 1. Tables of observed and calculated structure factors, anisotropic temperature factors, and bond distances, angles, and conformation angles of methyl-β-CDx are kept at The Chemical Society of Japan (Document No. 8324). The computation was carried out on a FACOM M-200 computer at the RIPS Center, Tsukuba.

Description and Discussion of the Structure

Outline of the Structure. The structure and numbering scheme of the complex are shown in Figs. 1 and 2. Methyl-β-CDx is in the shape of an elliptically-distorted and truncated cone. The guest *p*-IPH molecule is inserted into the methyl-β-CDx ring. The iodine atom is located at the center of the host cavity, while

a) $B_{eq}=8\pi^2(u_1^2+u_2^2+u_3^2)/3$, where u_i is the root-mean-square deviation in the i-th principal axis of the thermal ellipsoid.

the benzene ring occupies its position at the O(2), O(3) side. The phenolic hydroxyl group protrudes from the O(2), O(3) side and forms hydrogen bonds with two water molecules. Methyl-β-CDx molecules are stacked along the two-fold screw axis parallel to the b axis to form a head-to-tail channel-type structure.

Conformation of Methyl-β-CDx. Average bond distances and angles over seven 2,3,6-tri-*O*-methylglucose residues are shown in Fig. 3. Geometrical data for the methyl-β-CDx ring are given in Tables 2—4. No significant differences in the bond distances and angles are found between methyl-β-CDx and β-cyclodextrin.[8–11] The C(6)–O(6) bonds in the G2 and G4 residues are in a *gauche-trans* conformation, while the other C(6)–O(6) bonds have a *gauche-gauche* conformation. Six of seven C(9)–O(6) bonds are *trans* to the corresponding C(5)–C(6) bonds. The C(9)–O(6) bond in the G6 residue shows a somewhat different orientation; the conformation angle of C(5)–C(6)–O(6)–C(9) is 89°. All the C(7)–O(2) bonds are oriented outside the methyl-β-CDx ring, and give average conformation angles of 96° for C(7)–O(2)–C(2)–C(1) and −147° for C(7)–O(2)–C(2)–C(3). On the other hand, the C(8)–O(3) bonds are extended along the molecular axis of methyl-β-CDx, which is defined as the axis perpendicular to the least-squares plane of seven O(4) atoms. The average conformation angles of C(8)–O(3)–C(3)–C(2) and C(8)–O(3)–C(3)–C(4) are −117° and 127°, respectively. These conformations of the C(7)–O(2) and C(8)–O(3) bonds are quite similar to those of methyl-α-CDx,[3–5] and the orientation of these bonds is scarcely affected by the ring size of macrocycles.

TABLE 2. GEOMETRICAL DATA FOR METHYL-β-CDx

The estimated standard deviations are in the ranges 0.04—0.05 Å for O···O distances and 0.05—0.07 Å for C···O distances.

I. Radius of the O(4) hexagon

Residue	Radius l/Å	Residue	Radius l/Å
G1	4.92	G5	5.27
G2	5.35	G6	5.18
G3	4.99	G7	4.63
G4	4.57	Average	4.99

II. O(4)···O(4) distances between adjacent residues

Distance	l/Å	Distance	l/Å
O(4,G1)···O(4,G2)	4.42	O(4,G4)···O(4,G5)	4.20
O(4,G1)···O(4,G7)	4.41	O(4,G5)···O(4,G6)	4.45
O(4,G2)···O(4,G3)	4.24	O(4,G6)···O(4,G7)	4.29
O(4,G3)···O(4,G4)	4.32	Average	4.33

III. O(2)···O (3) distances between adjacent residues

Average	3.36	Average	3.46

TABLE 3. TORSION-ANGLE INDICES AND TILT-ANGLES

I. Torsion-angle index[a)]

Residue	Index ϕ/°	Residue	Index ϕ/°
G1	126	G5	122
G2	126	G6	115
G3	100	G7	130
G4	143	Average	123

a) The torsion-angle index is defined as follows: $\phi = |\phi(C(1)-C(2))| + |\phi(C(2)-C(3))| + |\phi(C(5)-O(5))| + |\phi(O(5)-C(1))| - |\phi(C(3)-C(4))| - |\phi(C(4)-C(5))|$, where $\phi(C(1)-C(2))$ is the conformation angle of O(5)-C(1)-C(2)-C(3).

II. Tilt-angle[b)]

Residue	Angle ϕ/°	Residue	Angle ϕ/°
G1	30.4	G5	34.9
G2	16.7	G6	−16.3
G3	−12.7	G7	42.6
G4	43.0	Average	19.8

b) The tilt-angle is defined as the angle made by the plane through seven O(4) atoms and the plane through C(1), C(4), O(4), and O(4′).

Seven glycosidic oxygen atoms (O(4)) form an elliptically distorted heptagon. The radius of the heptagon, which is measured from the center of gravity of seven O(4) atoms to each O(4) atom, is in the range 4.57—5.35 Å (Table 2). The O(4,G2) atom is at the longest distance from the center of gravity, the O(4,G4) atom being nearest to the center. Although the average value of 4.99 Å is in good agreement with the value (5.02 Å) found in the β-cyclodextrin complex with 1,4-diazabicyclo[2.2.2]octane,[11] the distortion of the O(4) heptagon is more remarkable in methyl-β-CDx. In spite of such distortion, the O(4)···O(4) distances between adjacent residues (4.20—4.45 Å) and the torsion-angle indices (100—143°) are similar to those of β-cyclodextrin. This indicates that, unlike methyl-α-CDx, the conformation of the pyranose ring of methyl-β-CDx is less affected by permethylation. The least-

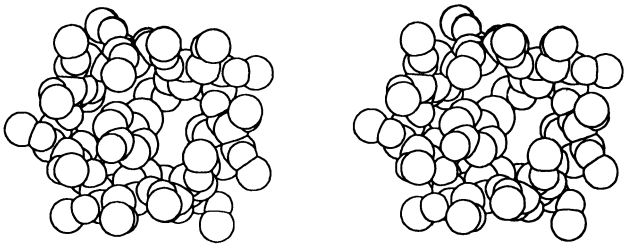

Fig. 2. A stereo-drawing of the structure of the methyl-β-CDx–p-IPH complex. Circles are drawn with three-fourths of van der Waals radii.

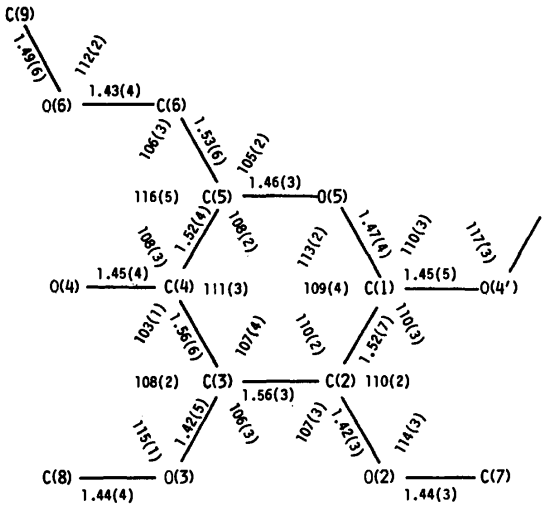

Fig. 3. Average bond distances and angles over seven 2,3,6-tri-*O*-methylglucose residues. Standard deviations in parentheses were estimated according to the equation: $\sigma=[\sum_{i=1}^{7}(x_i-\bar{x})^2/6]^{1/2}$, where x_i refers to the bond distance or angle of the i-th residue and $\bar{x}$ is the average value.

squares plane through seven O(4) atoms and deviation of atoms from the plane are given in Table 4. The maximum deviation of 0.65 Å is remarkably larger than that of β-cyclodextrin.

Compared with β-cyclodextrin, another remarkable difference is found in the tilt-angles of the 2,3,6-tri-*O*-methylglucose residues. The tilt-angles are in the range from −16.3° to 43.0°. The average value of 19.8° is similar to those (16.7—18.8°) found in the methyl-α-CDx complexes,[3-5] but the maximum value of 43.0° is larger than that of 28.1° in methyl-α-CDx.[5] The residues, G1, G2, G4, G5, and G7, incline with their O(6) side nearer to the molecular axis of methyl-β-CDx, while the G3 and G6 residues incline so that their O(2), O(3) sides are nearer to each other. The G6 residue is tilted in a direction opposite to that of the G7 residue. Therefore, the plane through C(1), C(4), O(4), and O(4') of the G6 residue makes a quite large angle, 54.5°, with the corresponding plane of the G7 residue. A similar relationship is found between the G3 and G4 residues, giving an angle of 46.4°. Such a conformational feature of methyl-β-CDx is not observed in β-cyclodextrin. In spite of the inclusion of a variety of guest molecules, the β-cyclodextrin ring is almost round, and the tilt-angle is restricted to a relatively narrow region (from −5° to 23°).[10,11] The C(8)H_3 methyl group is situated between the two O(2) atoms. The average C(8)···O(2) distances are 3.36 and 3.46 Å, which are somewhat larger than the values of 3.20 and 3.35 Å in the methyl-α-CDx–*p*-iodoaniline complex.[3] The O(2)···O(3) distances between adjacent residues are in the range 3.23—3.71 Å, and the average value of 3.46 Å is also larger than the corresponding value (3.28 Å) of the methyl-α-CDx–*p*-iodoaniline complex. These differences in the O(2)···O(3) and C(8)···O(2) distances and the tilt-angles suggest that the 2,3,6-tri-*O*-methylglucose residue of methyl-β-CDx has more flexibility around the glycosidic linkage than that of methyl-α-CDx. The large tilt-angles of the 2,3,6-tri-*O*-methylglucose residues may be ascribed to the inability of methyl-β-CDx for forming intramolecular O(2)···O(3) hydrogen bonds and the steric hindrance between the C(8)H_3 methyl group and O(2) atoms. In unsubstituted cyclodextrins, the adjacent glucose residues are mostly linked by O(2)–H···O(3) or O(3)–H···O(2) hydrogen bonds, and the macrocyclic conformation is held by such intramolecular hydrogen bonds. In the permethylated cyclodextrins, however, the methyl groups require to enlarge the O(2)···O(3) distance to avoid unfavorable interatomic repulsion between the O(2) atoms and C(8)H_3 methyl groups.

Table 5. Intermolecular distances between methyl-β-CDx and *p*-IPH less than 4.0 Å[a]

Distance	*l*/Å	Distance	*l*/Å
O(IP)–C(8,G1)	3.76	C(3,IP)–C(3,G2)	3.97

C(1,IP)–C(8,G1)	3.79	C(5,IP)–C(5,G7)	3.80
C(2,IP)–C(8,G3)	3.74	C(6,IP)–O(4,G7)	3.66
C(3,IP)–C(8,G3)	3.63	C(6,IP)–O(2,G6)	3.69
C(3,IP)–O(4,G2)	3.87		

a) Estimated standard deviations are in the range 0.04—0.08 Å.

Host-Guest Interaction. Intermolecular distances between *p*-IPH and methyl-β-CDx are given in Table 5. The iodophenyl group is inserted into the methyl-β-CDx cavity, while the phenolic hydroxyl group protrudes from the O(2), O(3) side of the cavity. The *p*-IPH molecule is included not parallel to the molecular axis of methyl-β-CDx but tilting with the benzene ring nearer to the G1 residue; the benzene plane makes an angle of 57.5° with the O(4) plane. The iodine atom is located at the center of the methyl-β-CDx ring. The O(6) atom of the G4 residue is at the nearest distance (3.50 Å) from the iodine atom, but there are no other contacts less than 4.0 Å between the iodine atom and methyl-β-CDx. The benzene ring is located at the O(2), O(3) side of the cavity. The shortest intermolecular distance between the benzene ring and methyl-β-CDx is 3.63 Å, which is found between C(3,IP) and C(8,G3). Therefore, the *p*-IPH molecule seems to be in weak van der Waals contact with methyl-β-CDx.

The inclusion geometry of the present complex is quite different from that found in the β-cyclodextrin–*p*-IPH complex,[7] in which three *p*-IPH molecules are located in the cylindrical cavity formed by two β-cyclodextrin molecules in a head-to-head dimer-type arrangement. The iodine atom is located at a similar position which is found in the methyl-β-CDx complex, but the benzene ring is located at the O(6) side. On the other hand, in the methyl-β-CDx complex, the large tilt of 2,3,6-tri-*O*-methylglucose residues makes the O(6) side narrower. As a result, the benzene ring is more suitably accommodated to the wider O(2), O(3) side of the cavity. A similar situation has been observed in the methyl-α-CDx–*p*-iodoaniline complex, although the *p*-iodoaniline molecule is included parallel to the molecular axis of methyl-α-CDx. These indicate that the methylation affects not only the macrocyclic

TABLE 6. INTERMOLECULAR DISTANCES LESS THAN 3.5 Å

conformation of the host molecule but also the geormety of the host-guest interaction.

Molecular Packing. Methyl-β-CDx molecules are stacked to form a channel-type structure in a head-to-tail mode along the two-fold screw axis which is parallel to the b axis. The methyl-β-CDx molecule is nearly parallel to the ac plane; the O(4) plane is tilted by an angle of 4.1° with respect to the ac plane. Two adjacent methyl-β-CDx molecules, which are related by the two-fold screw axis parallel to the b axis, are laterally shifted to each other. As a result, the channel runs not straight but zigzag. This packing feature differs from that of the typical channel-type structure, in which the guest molecule is enclosed within the column formed by the stack of host molecules. The zigzag packing of the methyl-β-CDx molecules enables the *p*-IPH molecule to have contacts with the water molecules, which are located outside the methyl-β-CDx ring as shown in Fig. 4. The phenolic hydroxyl group forms hydrogen bonds with two water molecules, W2 and W4. Intermolecular distances less than 3.5 Å are given in Table 6. There are no significantly short intermolecular contacts. The crystal is built up of columns of methyl-β-CDx. The water molecules are located outside the column. They fill intermolecular spaces between columns, and are linked one another by the W1···W2···W3···W4 hydrogen bonds. These water molecules are also hydrogen-bonded to the oxygen atoms of methyl-β-CDx: O(W1)··· O(5,G3), O(W1)···O(6,G7), and O(W3)···O (3,G2).

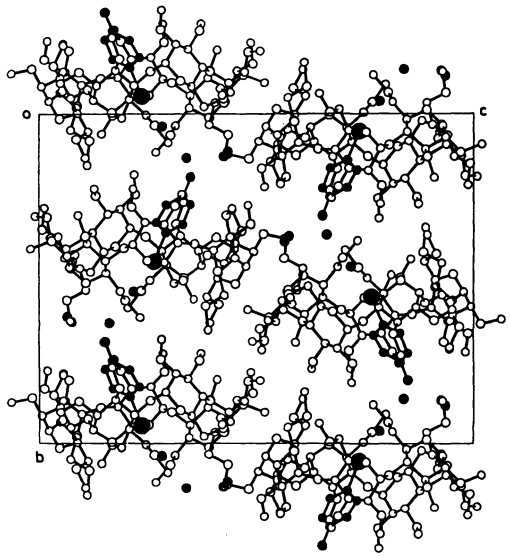

Fig. 4. The crystal structure viewed down along the a axis. Atoms in *p*-IPH and water molecules are denoted by black dots.

Anomalous Near Infrared Emission Observed in High Energy Electron Excited Xe and Xe-Ar

Masako TANAKA,* Susumu SASAKI, and Meiseki KATAYAMA
Department of Atomic Science and Nuclear Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060
(Received October 30, 1982)

The near infrared emission spectra of Xe and Xe-Ar which were excited by the pulsed irradiation of electrons by using a 45 MeV linear accelerator were investigated. A new broad band, probably due to the transition between the upper molecular states, was observed at 1200 to 1400 nm. The effects of O_2 and SF_6 on this band were studied.

The emission spectra of excited rare gas atoms and excimers have been studied theoretically and experimentally in the vacuum ultraviolet region with respect to the development of bound-free lasers.[1-3] Recent studies are concentrated on the properties of the lowest excited states, 0_u^+ and 1_u, of the Xe excimer, which can be selectively excited by means of synchrotron radiation.[4-8] However, spectroscopic information on the upper molecular states has not been studied well because of the lack of experimental approaches. It is expected from theoretical estimations that the absorption of photons or emission related to the molecular transition should appear in the near infrared region.[9] Arai *et al.* have found the near infrared absorption bands which were assigned to the molecular transition from the first excimer states, $^{1,3}\Sigma_u^+$, for Ne to Xe, which were excited by electron beam pulses.[10] Distefano *et al.* observed the near infrared fluorescence due to the atomic transition from 6p to 6s configuration for vacuum ultraviolet irradiated Xe.[11]

We have investigated the near infrared emission spectra of Xe gas which had been excited by the pulsed irradiation of a high energy electron beam, and have found a new broad band; this is probably due to the transition of the upper to the lower molecular states where the excitation seems to be a nonionic process.

Experimental

The electon beam pulses were generated by a 45 MeV linear accelerator installed at Hokkaido University. The duration of the pulses was 3 μs. The charge provided in one pulse was 5×10^{-6} C. The dose was estimated to be approximately 10 krad per pulse at 700 Torr (1 Torr=133.32 Pa) of N_2O by means of its decomposition.[12]

A block diagram of the experimental system is shown in Fig. 1. A stainless steel cell of 60 mm in diam. by 350 mm long was used. The electron beam entered the cell at one end. The emissions from irradiated sample gases were reflected by a thin mirror which was fixed in the cell just behind the incident window at 45° to the electron beam axis, and directed to the NaCl window, which was attached at a right angle to the beam direction. Thus the emission from the samples was observed in the reverse direction to the electron beam so that interference by the intense Cerenko light in the Xe gas upon irradiation could be avoided in the infrared observation. The detection system for the emission consists of a Bausch and Lomb high-intensity grating monochromator and a PbSe detector (Hamamatsu TV, p 791) with a response time of 2.5 μs. The signals from the detector were amplified 10 fold by an ac amplifier (Keithlel 105) and were followed on a transient

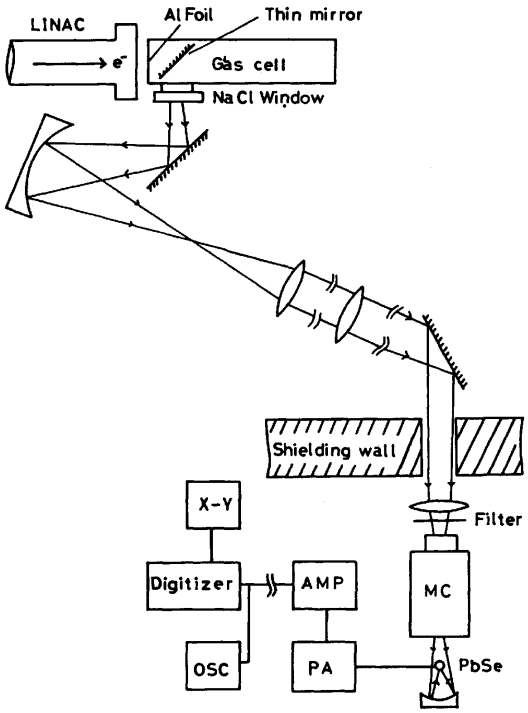

Fig. 1. Block diagram of experimental system.

digitizer (Iwatsu DM901). All the data were recorded on an X-Y recorder. Typical signal traces are shown in the inserts in Fig. 2. Since the response time of the detector was much too long relative to the life time of this kind of emission, the spectra were obtained by plotting the peak intensity of the signal trace against the wavelength. The sensitivity of the detector is known to increase linearly from 1000 to 1600 nm but no correction for this was made. A filter for the cut-off at 650 nm was used to avoid the contribution of higher components.

Research grade Xe (99.995% pure from Nihon Sanso) and ultrahigh pure Ar (99.999% pure from Nihon Sanso) were used. The gases were introduced into the cell through a molecular sieve 5A trap. When necessary, a column of Ba getter at 190 °C was used before the trap to remove any O_2 contained as impurity.

Results

Emission Spectra in Xe. The emission spectrum in the irradiated Xe of 400 Torr is shown in Fig. 2(a). The well known emission lines due to the 6p-6s transitions were observed at 830, 890, and 990 nm, where each band is unresolved but consists of more than one line.

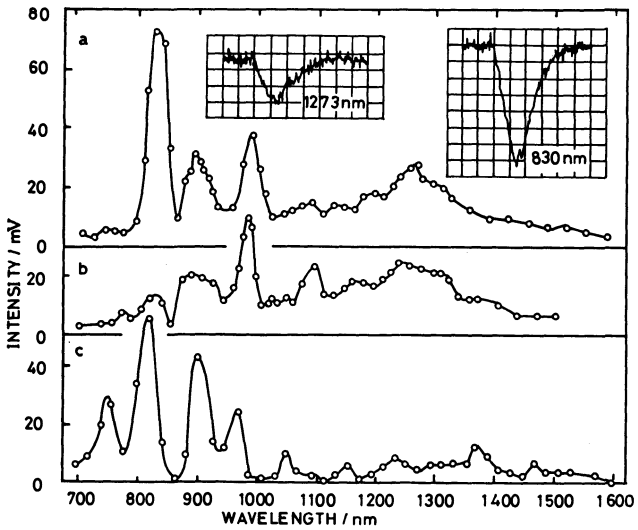

Fig. 2. Emission spectra of irradiated Xe, Xe–Ar and Ar. (a) 400 Torr Xe, inserts: 4 mV/div and 2.5 μs/div, (b) 400 Torr Ar+200 Torr Xe, (c) 500 Torr Ar.

In addition to these lines, a broad band was observed in the region of 1200 to 1400 nm with the maximum at 1270 nm; this has not been reported previously. Since this anomalous emission might originate from the window material having been excited by the Cerenkov light or the second continuum of Xe, the experiment was repeated with a quartz window instead of the NaCl window, and it was confirmed that the intensity of this emission band was not changed. Thus it was concluded that the origin of this band was the irradiated Xe gas.

Emission Spectrum in Xe–Ar. The mixtures of Ar and Xe at various compositions were irradiated. The total pressure of the mixtures was 600 Torr. Figure 2(b) shows the emission spectrum of the irradiated mixture of 200 Torr Xe and 400 Torr Ar. The atomic line at 830 nm, which was the most intense in pure Xe, disappeared, and the intense lines at 990 and 1080 nm were enhanced strongly as the Xe concentration decreased. The emission band similar to that obtained for pure Xe was also observed at around 1270 nm. Assuming that the ionization cross section of Xe is approximately twice that of Ar,[13] the absorption energy for this mixture was calculated to be approximately equal to that of 400 Torr Xe in Fig. 2(a). It is obvious from comparison between Fig. 2(a) and (b) that the equal intensity was obtained for the 1270 nm band under the equal absorption energy. Contrary to the intensity at 990 and 1080 nm lines, the intensity of this band decreased with the decrease of the Xe concentration.

In pure Ar this kind of broad band was not detected between 700 and 1600 nm, as shown in Fig. 2(c).

Effect of O_2. When the 0.01 Torr of O_2 was added to 430 Torr of Xe, the intensity of the broad band at 1270 nm decreased to one-half relative to that in pure Xe, whereas the intensity of the atomic lines was not influenced by the addition of such trace amounts of O_2. The 1270 nm band was quenched completely by 1 Torr of O_2.

Effect of SF_6. Figures 3 and 4 exhibit the effect of a trace amount of SF_6, which was added as a

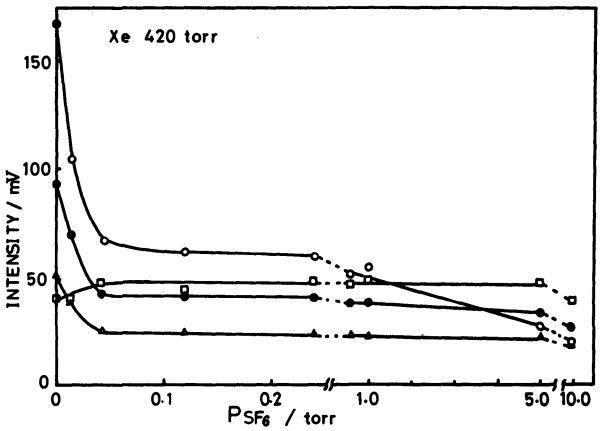

Fig. 3. Effect of SF_6 on the intensities of emission bands in Xe. ○: 830 nm. ●: 990 nm, △: 890 nm, □: 1270 nm.

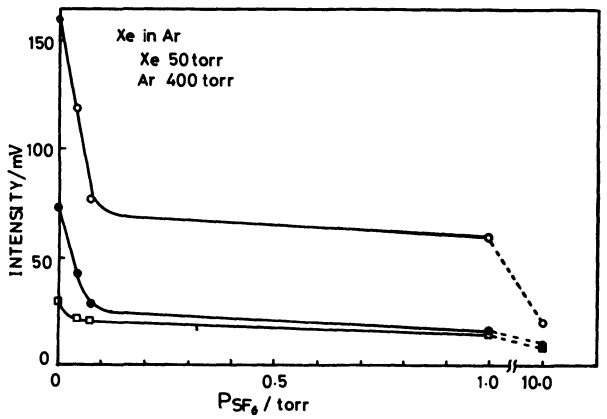

Fig. 4. Effect of SF_6 on the intensity of emission bands in Xe–Ar. ○: 990 nm, ●: 1080 nm, □: 1270 nm.

scanvenger of thermal electrons in Xe and in Xe–Ar respectively. In Xe, as shown in Fig. 3, the intensities of the three atomic lines decreased markedly on the addition of less than 0.05 Torr of SF_6, whereas the intensity of the 1270 nm band was unchanged except for a small increase at the same range of the concentration for which the significant decrease in the intensities of atomic lines occurred. The effect of SF_6 on the emission spectrum in Xe–Ar was essentially the same as in Xe. As shown in Fig. 4, the intensities of the two atomic lines at 990 and 1080 nm decreased to half on adding less than 0.1 Torr of SF_6, while the intensity of the 1270 nm band was almost unchanged except for the small decrease at less than 0.1 Torr of SF_6.

Discussion

A new emission band was observed at around 1270 nm in Xe gas on the bombardment of high energy electrons. Since O_2 is known to be the effective lasing component in the mixture with Xe, the possibility that this new emission band might be caused by contamination with air had to be considered. The result of the experiment on the addition of O_2 indicated that the origin of this emission band was not an impurity but the

excited Xe itself. The large width of this band must be attributed to certain molecular transitions in excited Xe. The recent report by Keto *et al.* about the similar O_2 effect on the intensity of the second continuum in electron excited Ar[14] also supports the above assignment.

As shown in previous publications,[1-3] excited rare gas atoms are produced mainly from the dissociative recombination of Xe_2^+ with the secondary electron; they subsequently form the bound excimer, $^{1,3}\Sigma_u^+$, by three-body collision with atoms in the ground state. Accordingly, these excimer bands should be affected by the addition of SF_6. However, the result shown in Figs. 3 and 4 indicated that the 1270 nm band was not quenched by SF_6. This means that the precursor responsible for the 1270 nm band was not the excited atom. The excimer states observed in this experiment should thus be formed by some direct excitation not *via* the above mentioned ionic process. The small increase in the intensity at 1270 nm on the addition of SF_6 shown in Fig. 3 suggests that the small fraction of the excimer states observed here can be produced directly by the ion recombination of Xe_2^+ and SF_6^-. One of the possible paths of direct excitation under irradiation by high energy electrons is the excitation of the van der Waals (vdW) molecule, Xe_2, to vibrationally excited levels of the upper molecular states by inelastic collision with the secondary electrons, which have kinetic energy higher than thermal electrons. The emission band presented here might be attributed to the transition from the upper molecular states with the shallow minimums of the potential curves, which are located in the vicinity of the vdW distance. Since at least two shoulders were observed at both sides of the 1270 nm peak, several transitions could be associated. The radiative transitions from the 1_u of $7s[3/2]_1$ to the bound states of $6s'[1/2]_1$ or from the 0_u^+ of $6s'[1/2]_1$ to the bound states of $6s[3/2]_1$ were expected to give the emission band at 1200 to 1400 nm. According to Castex, the concentration of vdW bound and quasibound molecules is 0.6% at 760 Torr and at room temperature.[15] In the case of photon excitation, there has been some evidence for the excitation of vdW molecules to upper states both in absorption spectra[16] and in excitation spectra.[4,5,7,8,15,17,18] The vibrational progression was observed in the two-photon excitation spectra of high pressure Xe in the energy range of 6p and 5d configurations by Gornik *et al.*[18] They assigned the molecular bands to the transition from the bound vdW dimers. Recently work on this kind of excitation using monochromatic synchrotron radiation indicated that the red wing in the vicinity of $6s'[1/2]_1$ and $6s[3/2]_1$ excitation band,[4,5,7,8,17] was due to the transition of the vdW dimers to the vibrationally excited molecular states. Analogous with these results for photon excitation, then, the direct excitation of vdW molecules can occur in the high energy and high intensity electron excitation.

In the case of the Xe–Ar system, the disappearance of the emission line at 830 nm due to Xe $6p[1/2]_0$ and the enhancement of the 990 and 1080 nm lines due to Xe $6p[1/2]_1$, which were observed in Fig. 2(b), suggest that the dominant energy transfer occurs from the Ar excimer, $^{1,3}\Sigma_u^+$, to Xe atoms. However, concerning the 1270 nm band in Xe–Ar, the excitation process seems to be completely different, as indicated in Fig. 4, where similar mechanism to that considered in pure Xe can be applicable. The small decrease of the 1270 nm band shown in Fig. 4 can be interpreted to mean that in Xe–Ar the energy transfer from the Ar excimer to the vdW dimers of Xe occurs to a small extent.

The authors would like to thank Professor Yoshihiko Hatano of Tokyo Institute of Technology for his helpful discussions at the early stage of the present investigation. The authors are also indebted to Professor Takeaki Enoto, Messrs. Hiroaki Tanida, and Koichi Sato for the operation of the accelerator.

Raman Spectra of Compounds under Inversion Motions. III. *N*-Methylpyrrolidine

Kunio FUKUSHIMA* and Hisayo SASAKI†
Department of Chemistry, Faculty of Science, Shizuoka University 836, Oya, Shizuoka 422
(Received November 8, 1982)

Raman spectra of *N*-methylpyrrolidine were measured in various states and a normal vibration calculation was carried out on its conformers. Results of the measurement and calculation indicate that the Raman band of the inversion vibrational mode is caused to shift remarkably by the formation of hydrogen bond to the nitrogen atom. This phenomenon, along with the enthalpy of hydrogen bond formation obtained from measurements at various temperatures, suggests that the conformer predominant in pure liquid corresponds to one minimum in the potential for the inversion motion, which has a low potential barrier and high anharmonicity.

Some Raman bands of 1,4-dimethylpiperazine and 1-methylpiperazine are caused to shift remarkably by formation of hydrogen bonds to their nitrogen atoms, and this phenomenon has been interpreted as being due to a suppression of the motion of inversion at the nitrogen by the hydrogen bonding.[1,2] The present study is concerned with a five-membered heterocyclic compound, *N*-methylpyrrolidine. Existence of an inversion motion at the nitrogen in this compound was concluded by NMR studies,[3-5] and a value of 33.5 kJ/mol was obtained for the free energy of activation.[5] In addition, dipole moment studies also suggested the existence of the motion.[6,7] An effect of a hydrogen bonding between this compound and chloroform was found in NMR spectral measurements, and a report[8] was made on shifts of its Raman bands of CH stretching vibrations caused by dissolution in water. In the present study, Raman spectra of *N*-methylpyrrolidine in various states were measured, and band shifts found in association with hydrogen bonding are discussed from many points of view.

recorded on a Model R-800T Raman spe trometer (Japan Spectroscopic Co.) with an excitation effected by use of a Spectra Physics argon ion laser (Model 165) at 514.5 nm (300 mW). Depolarization ratio was measured with a system consisting of a half-wave plate, a lens, and a polarizer. Liquid samples at room temperatures were measured with 0.3 ml Raman cells, while crystals, solutions, and pure liquids at lower temperatures were measured with an Oxford-type cryostat and liquid nitrogen. Experimental results are shown in Table 1 and 2 and Figs. 1, 2, and 3.

Normal Vibration Calculation

Normal vibration calculations on conformers of *N*-methylpyrrolidine (the axial and equatorial conformers and other molecular models) were carried out according to Wilson's GF matrix method[9)] by use of the Computation Center, University of Tokyo and library programs BGLZ and LSMB. The molecular parameters used are: bond lengths, $r(N\text{-}CH_3)=1.49$ Å, $r(NCH_2\text{-}CH_2)=1.53$ Å, $r(CH_2\text{-}CH_2)=1.54$ Å, and $r(C\text{-}H)=1.09$ Å; bond angles, $\alpha(N\text{-}CH_2\text{-}CH_2)=105°$, $\alpha(CH_2\text{-}CH_2\text{-}CH_2)=104°$, and $\alpha(H\text{-}C\text{-}H)(CH_2$ group$)=$bond abgles of CH_3 group$=$bond angles around nitrogen atoms$=$tetrahedral angle. For the molecular models, an envelope structure for the five-membered ring was used on the basis of the existence of depolarized bands in the observed Raman spectra of *N*-methylpyrrolidine in the liquid state. Force constants and results of calculation are shown in Table 3 and Fig. 4, respectively.

Results and Discussion

Spectral Change with State Change from Liquid to Solid. As shown in Table 1, no bands are caused to disappear by the state change from liquid to solid. Therefore, it may reasonably be concluded that one conformer prevails in the pure liquid and that this persists in the solid state. The intensity change of the bands at 1238, 873 and 348 cm^{-1} may be due to a change in their associated polarizabilities.

dissolution in water was reported by Hirokawa *et al.*[8] in a spectal region above 2600 cm^{-1}. In a region below 2600 cm^{-1}, a change has been found, as shown in Table 1, that the band at 375 cm^{-1} (pure liquid) remarkably shifts to higher frequencies in aqueous solutions. Relative intensity changes in this band and its shifted band are shown in Fig. 1. With increasing mol fraction of water, the band at 375 cm^{-1} decreases its intensity, while a band appears in the higher frequency side of the band with increasing intensity. In the case of the lowest concentration in the figure, the former disappears and only the latter remains at 424 cm^{-1}. The frequency increase 375 $cm^{-1} \rightarrow 424$ cm^{-1} is a remarkably large one. No other bands in the region below 2600 cm^{-1} show such a remarkable change, although some of them experience smaller frequency change. The valence state of the nitrogen atom of *N*-methylpyrrolidine is expected to resemble an sp^3 state when it is hydrogen-bonded. The observed frequencies for hydrogen-bonded species in Table 1 correspond well to the frequencies calculated for the equatorial conformer by using the first-guess force constants, but not satisfactorily to the axial conformer. The calculated frequencies for the equatorial conformer were made to fit to the observed frequencies so as to give the final force constant set by the method of least squares.[10] The set is shown in Table 3. The calculated frequencies for the skeletal vibrations of the axial conformer for the set of force constants are shown in Fig. 4. They are very different from those of the equatorial conformer included in the figure, which agree well with the observed frequencies. Therefore, it is reasonable to consider that most of hydrogen-bonded species assume equatorial conformations.

Spectral Change with Temperature Change. As discussed in the preceding section, two bands (one at 375 cm^{-1} and the other at the higher frequency side) appear

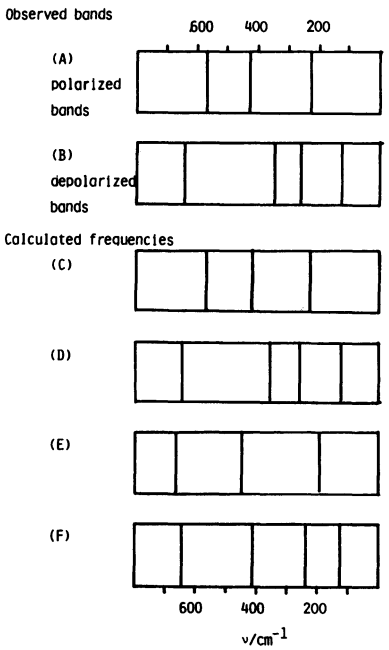

Fig. 4. Observed frequencies of liquid *N*-methylpyrrolidine ((A) and (B)) compared with the calculated frequencies ((C): equatorial form, A′ species, (D): quatorial form, A species, (E): axial form, A′ species, (F): axial form, A″ species).

in the spectra of *N*-methylpyrrolidine solutions in hydrogen-bonding solvents, suggesting two conformers (a hydrogen-bonded equatorial conformer and a conformer having a different conformation) to exist in the solutions. In order to evaluate the energy difference between these two conformers, spectra of a methanol solution were measured at various temperatures between 298 and 110 K. At equilibrium, *N*-methylpyrrolidine ($b-a$ mol)$+CH_3OH$($a-a$ mol)$\rightleftarrows$ hydrogen-bonded complex (a mol), hence the equilibrium constant $K=a/(b-a)(a-a)$, where a and b are the initial quantities in mol of CH_3OH and *N*-methylpyrrolidine, respectively. On the assumption that $b-a$ and a are proportional to the band intensities of the band at 375 cm^{-1} and the one in the higher frequency side, respectively, K was obtained at various temperatures. Plots of ln K *vs.* $1/T$ are shown in Fig. 3. From the figure and the equation $\ln K=-\Delta H/(RT)+$ const, the enthalpy difference for the above reaction is estimated as $\Delta H=-1.3\pm0.2$ kJ/mol.

Spectra of N-*Methylpyrrolidine in Non-hydrogen-bonding Solvents.* Benzene (nonpolar), dioxane (polar), and acetone (polar) were used. They give spectra almost the same as the spectrum of pure liquid. This indicates that the shift of Raman band mentioned above under the second heading is due to hydrogen bonding to the nitrogen atom of the compound.

Spectra of N-*Methylpyrrolidine in Carboxylic Acids and Aqueous Hydrochloric Acid Solutions.* A band corresponding to the band of liquid *N*-methylpyrrolidine at 375 cm^{-1} is observed for each of the solutions shown in Table 2 (HCOOH soln, 450 cm^{-1}; CH_3COOH, 430 cm^{-1}; aqueous hydrochloric acid solution, 455 cm^{-1}). For *N*-methylpyrrolidine in a deuterium chloride–heavy water mixture, the corresponding band appears at 443 cm^{-1}, close to 455 cm^{-1} for the band of aqueous hydrochloric acid solution, indicating that this band is not due to the NH deformation mode but to the skeletal deformation mode. Between these frequency values and 375

cm^{-1} (*N*-methylpyrrolidine, liquid) there lie frequency values for bands of the inversion mode of *N*-methylpyrrolidine in hydrogen-bonding solvents, in agreement with the change in valence state of the nitrogen atom to the sp^3 type with hydrogen bonding.

Concluding Remarks. In liquid *N*-methylpyrrolidine, almost all the molecules are in one conformation different from that for the hydrogen-bonded equatorial conformer.

These two conformers give rise to bands at different frequencies 375 and 424 cm^{-1} for the vibrational mode of inversion at the nitrogen. This may be explained as follows. The hydrogen bonding to the nitrogen atom increases the potential barrier for the inversion motion at the nitrogen and changes the shape of potential for the motion. As a result, for the inversion mode the energy level separation between the ground state ($v=0$) and the first excited state ($v=1$) increases, and the $0\rightarrow1$ transition frequency increases to give the above-mentioned shift of band. On the other hand, the observed enthalpy difference, -1.3 kJ mol, between the hydrogen-bonded equatorial conformer and the abundant conformer in the pure liquid is very small compared with ordinary hydrogen-bond energy values. Therefore, the instability of the non-hydrogen-bonded equatorial form having a nitrogen atom in the sp^3 state may be considered to be compensated by the stabilization energy due to hydrogen bonding. Thus, the potential for the inversion vibrational mode of the conformer in the pure liquid is a low barrier potential with high anharmonicity, one of whose potential minima corresponds to the abundant conformer in the pure liquid. The conformer is stabler than the non-hydrogen-bonded equatorial conformer having a nitrogen atom in the sp^3 state, and the structure around the nitrogen atom is intermediate between the planar and tetrahedral structures.

Crystal Structures of Mixed Ligand Copper(II) Complexes Containing L-Amino Acids. III. Aqua(L-histidinato)(L-serinato)copper(II) Trihydrate

Yoshio SASADA,* Akio TAKENAKA, and Toshio FURUYA†

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received November 19, 1982)

The copper(II) complex containing L-histidine and L-serine crystallizes from an aqueous solution. Crystals of aqua(L-histidinato)(L-serinato)copper(II) trihydrate are monoclinic, space group $P2_1$, $a=11.046(2)$, $b=7.315(1)$, $c=9.737(1)$ Å, $\beta=101.34(2)°$ and $Z=2$. A square-planar coordination around copper consists of α-amino nitrogen and δ-nitrogen atoms in histidine and α-amino nitrogen and α-carboxyl oxygen atoms in serine, the two amino groups being in *cis* position. The fifth coordination site is occupied by a water molecule, and the carboxyl oxygen atom of serine in the adjacent complex makes a weak bond with copper to complete a distorted octahedron. The chelating scheme and overall crystal structure are the same as those of (L-alaninato)aqua(L-histidinato)copper(II) trihydrate (**1**). Crystallization water molecules are situated on the fixed positions in the void space surrounded by the columns of the complexes, but the hydroxyl group of serine takes two sites randomly. The common chelating scheme in the present crystal and **1** is in correspondence with the observation that serine and alanine are of moderate cooperativity with histidine in forming the ternary complexes.

Although most of the copper ions in human serum are bound unexchangeably to ceruloplasmin, the remaining copper ions (10^{-6} mol dm^{-3}) form complexes with albumine, some amino acids and others in complicated equilibria. Binary and ternary complexes, such as L-glutaminatocopper(II) and (L-histidinato)(L-threoninato)copper(II), can be separated by chromatography, and are supposed to be mediators in copper transport between blood and tissues.[1] Neumann and Sass-Kortsak[2] suggested that asparagine, glutamine, and threonine exhibit significant cooperativity with histidine in forming ternary complexes, while alanine, valine, serine, and glutamic acid have weaker effects. Computer simulation also indicated that the content of copper complexes containing histidine is relatively high, although some details are controversial.[3,4] In order to establish the structural basis of these observations, several attempts to synthesize ternary complexes and to determine their geometry have been made, but only a few has been successful.[5]

We have previously reported the structures of (L-asparaginato)(L-histidinato)copper(II) and its hydrate[6] and also (L-alaninato)aqua(L-histidinato)copper(II) trihydrate,[7] (hereafter these complexes are abbreviated as, *e.g.*, Cu(asn his) by using the three-letter code of amino acids). In the former complex, histidine behaves as a terdentate ligand, while in the latter it is a bidentate ligand. It seems that the second amino acid has an effect on the character of the histidine ligand. As found by Freeman *et al.*,[5] Cu(his thr) has the same structure as Cu(asn his). It is interesting to examine whether histidine is a terdentate or bidentate ligand when the second amino acid is serine, which is an amino acid closely related to threonine. We have succeeded in growing suitable crystals of aqua(L-histidinato)(L-serinato)copper(II) trihydrate and have determined its crystal structure by X-ray analysis. The present paper deals with the structure of this complex and discusses the three-dimensional architectures of such ternary complexes.

† On leave from Product Development Laboratories, Yamanouchi Pharmaceutical Co., Ltd., 1-1-8, Azusawa, Itabashi-ku, Tokyo 174

Experimental

Suitable blue single crystals were obtained from aqueous solution placed under an atmosphere of acetone vapour. Preliminary Weissenberg photographs indicated a monoclinic space group $P2_1$ or $P2_1/m$. Since this complex was optically active, the former space group was chosen. Accurate unit cell dimensions were determined by least-squares fits from 2θ values of 20 reflexions measured on a Rigaku four-circle diffractometer. Crystal data are as follows: $C_9H_{16}O_6N_4Cu\cdot 3H_2O$, $P2_1$, $a=11.046(2)$, $b=7.315(1)$, $c=9.737(1)$ Å, $\beta=101.34(2)°$, $Z=2$, $D_m=1.67$, $D_x=1.67$ g cm^{-3}.

Since the crystals gradually deteriorated in air, they were sealed in Lindemann-glass capillaries. Intensity measurements were carried out on a Rigaku four-circle diffractometer, graphite-monochromated Mo $K\alpha$ radiation ($\lambda=0.71073$ Å) being used. Intensities of independent reflexions were collected within the range of $2°<2\theta<55°$. An ω-2θ scan mode was applied with scanning rate of 4° (2θ) min^{-1}. The crystal used had dimensions of $0.6\times0.4\times0.5$ mm^3. Five standard reflexions monitored showed no significant change in intensity. Out of 1917 reflexions measured, 123 reflexions had zero intensity ($I<0$). The observational threshold value, $F_{\rm llm}$, was 1.65. The standard deviations were estimated by the equation, $\sigma^2(F_o)=\sigma_p^2(F_o)+q|F_o|^2$, where $\sigma_p(F_o)$ was evaluated by counting statistics and q (1.22×10^{-5}) was derived from the variations of the monitored reflexions. No correction for absorption was made.

Structure Determination

Although it was expected from the similarity of the unit cell dimensions that the crystal structure of the present complex is close to that of Cu(ala his), the structure determination was made by the straightforward application of the heavy atom method. The first Fourier synthesis based on phases of the copper atom revealed the positions of the three nitrogen and one oxygen atoms that were directly coordinated to copper. Successive Fourier and difference syntheses followed by least-squares refinement led to the location of the other non-hydrogen atoms and to the disordering of the hydroxyl oxygen atom of serine into two sites. these two sites were estimated to be 0.6 and 0.4, respectively, from a difference map constructed at a later stage. Structural parameters were refined by the block-diagonal least-squares method: the quantity minimized was $\sum w(|F_o|-|F_c|)^2$ with $w=1/\sigma^2(F_o)$. Zero reflexions were taken in the least-squares by assuming $F_o=F_{lim}$ and $w=w(F_{lim})$. Hydrogen atoms found on a difference map were included in the calculation. Atomic scattering factors were taken from Ref. 8. The R value dropped to 0.057 for 1767 reflexions with $|F_o|>3\sigma(F_o)$. The final atomic coordinates and equivalent temperature factors are listed in Table 1.[9]

Results and Discussion

Molecular Structure. The geometry of the molecule and the numbering system are presented in Fig. 1, where the bond lengths and angles are also shown.

A square-planar coordination around copper is formed by the chelation of histidine and serine; α-amino nitrogen and imidazole δ-nitrogen atoms in the former and α-amino nitrogen and α-carboxyl oxygen atoms in the latter participate in coordination. Two α-amino nitrogen atoms are in a *cis* position, as found in the mixed ligand copper complexes already reported.[5-7] An apical coordination site is occupied by the water molecule, and the carboxyl oxygen atom in the adjacent complex makes a weak bond to copper from the direction opposite to the water ligand, to complete a distorted octahedron. This coordination scheme is the same as that found in (L-alaninato)aqua(L-histidinato)copper-(II) trihydrate;[7] histidine behaves as a bidentate ligand. Since the value of pK_a of serine is 2.20,[10] slightly smaller than that of alanine, the explanation for modifying the ligating nature of histidine, proposed in the previous paper,[7] could be applied to the present complex.

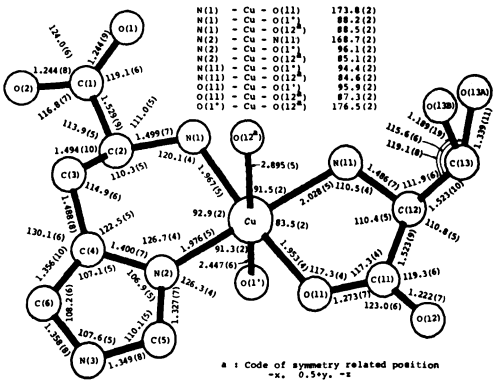

Fig. 1. Bond lengths (l/Å) and angles (ϕ/°) in aqua(L-histidinato)(L-serinato)copper(II). Estimated standard deviations in the last digits are in parentheses.

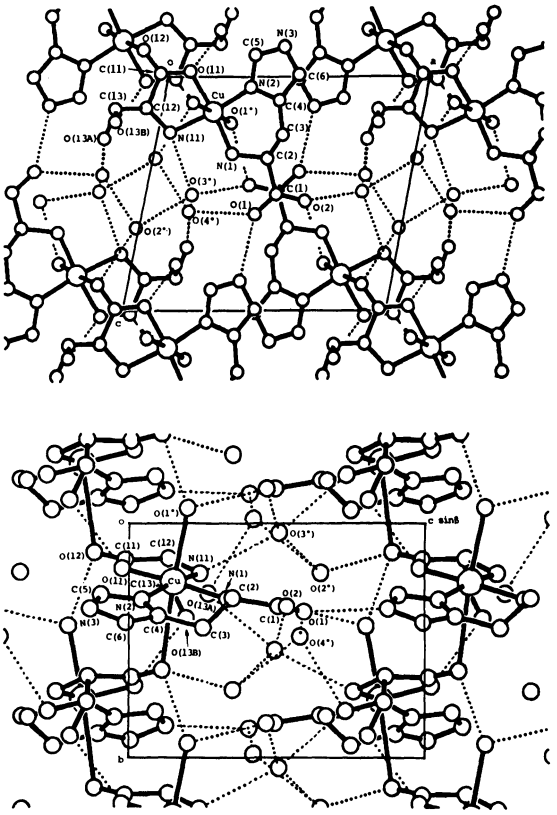

Fig. 2. Crystal structure of aqua(L-histidinato)(L-serinato)copper(II) trihydrate projected along **b** (upper) and **a** (lower).

According to Neumann and Sass-Kortsak,[2] alanine and serine belong to the class of moderate cooperativity with histidine in forming the mixed ligand copper complexes, while asparagine and threonine belong to a class of significant cooperativity. The present serial studies, in addition to the result by Freeman *et al.*,[5] have established that two different chelation modes correspond to the cooperativity classes. These observations reinforce the idea that one of the structural bases for the cooperativity is the chelating mode of histidine.

Coordination distances Cu–N(1), Cu–N(2), Cu–N(11), and Cu–O(11) are 1.967(5), 1.976(5), 2.028(6), and 1.953(4) Å, respectively. The former two Cu–N

Table 2. Hydrogen bond geometry

Donor (D)	Acceptor (A)	Site of A[a)]	l(D···A) Å	ϕ(D–H···A) °

O(13B)	O(11)	a	2.97(1)	113.0(9)[b)]
O(1′)	O(12)	b	2.913(7)	163(6)
O(1′)	O(2)	c	2.726(7)	169(6)
O(2′)	O(12)	e	2.85(1)	166(8)
O(2′)	O(3′)	o	2.97(2)	118(8)[c)]
O(2′)	O(4′)	d	3.07(2)	122(8)[c)]
O(3′)	O(2)	c	2.81(1)	157(10)
O(3′)	O(13A)	d	2.79(1)	147(8)
O(4′)	O(1)	o	2.89(1)	140(9)

a) Site is expressed by symmetry code. o: x, y, z; a: $-x$, $1/2+y$, $-z$; b: $-x$, $-1/2+y$, $-z$; c: $1-x$, $-1/2+y$, $1-z$; d: $-x$, $-1/2+y$, $1-z$; e: $x, y, -1+z$; f: $x, y, -1+z$. Donor atom at o. b) Since the position of hydrogen atom attached to O(13B) is not certain, this is an angle of C(13)-O(13B)···O(11). c) Probably bifurcated hydrogen bond.

distances are slightly shorter than the values (1.98···2.04 Å) reported for rectangular coordination complexes.[11] But these distances, except for Cu–N(1), and two apical coordination distances for Cu–O(12[a]) and Cu–O(1′) seem to be within the fluctuation range found in the related mixed ligand copper complexes.[6,7]

The copper atom is shifted from the mean basal coordination plane toward the apical O(1′) by 0.118(7) Å. The dihedral angle between the planes, N(1)–Cu–N(2) and N(11)–Cu–O(11), is 10.9(2)° (Λ configuration).

The imidazole ring is approximately planar, with maximum deviations of −0.016(6) for C(4) and +0.015(7) Å for C(5). Its mean plane makes a dihedral angle of 2.4(3)° with the plane of N(1)–Cu–N(2).

Crystal Structure. Crystal structures projected along the b and a axes are shown in Fig. 2. As expected from the similarity of the unit cell dimensions, the principal frame of the crystal structure is the same as that of Cu(ala his). The carboxyl oxygen atom, O(12), is weakly coordinated to copper in the complex at $(-x, -1/2+y, -z)$, so that a column extending along the b axis is constructed. ε-Nitrogen atom of the imidazole ring is hydrogen-bonded to the carboxyl oxygen, O(1), in the complex at $(x, y, -1+z)$. These hydrogen bonds connect together the columns above-mentioned, so that a void space extending along the b axis is left, in which three crystallization water molecules and serine side chain are occluded.

While three water molecules are distributed among seven sites randomly in the void space of Cu(ala his), those in the present crystal occupy fixed positions. The serine hydroxyl oxygen atom makes two kinds of hydrogen bonds, by taking two different sites: O(13A) at one site with occupancy of 0.6 links to the water molecule, O(4′), and O(13B) at another site with occupancy of 0.4 is connected to the carboxyl oxygen atom, O(11) in the complex at $(-x, 1/2+y, -z)$.

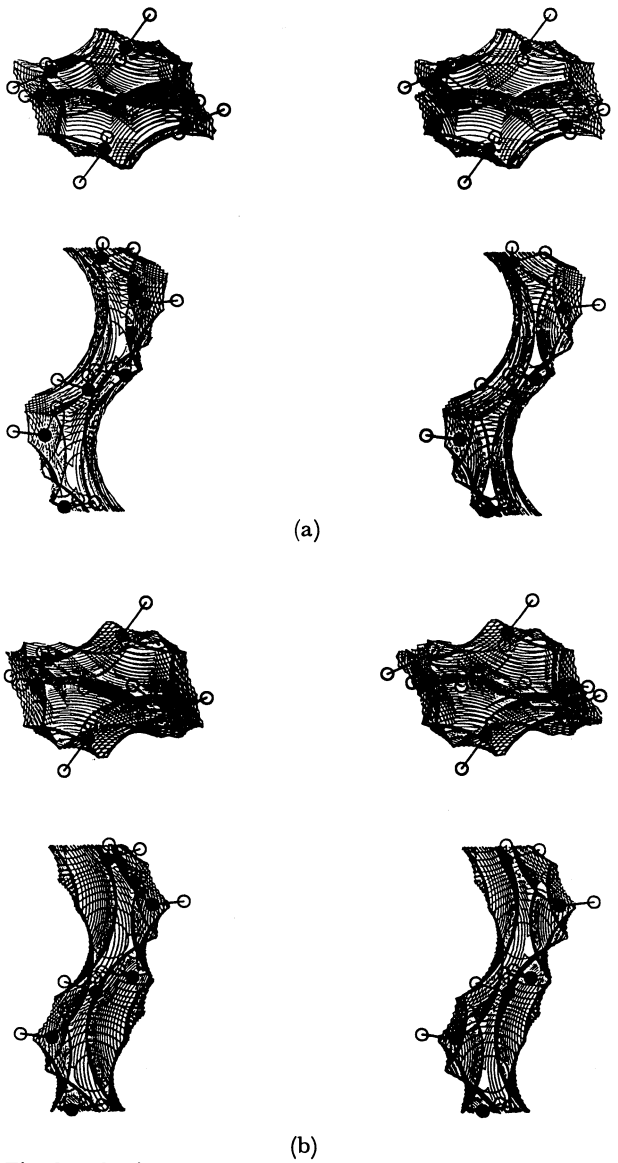

Fig. 3. Cavity for three water molecules viewed along **b** (upper) and **a** (lower), a) when the hydroxyl group of serine takes the site A, b) when the hydroxyl group of serine takes the site B.

Details of these hydrogen bonds are listed in Table 2.

In order to clarify the feature of arrangement of three water molecules, we have drawn the "cavity" for waters, which is defined as a closed space in which the atomic centres of the occluded molecules can be situated (for details of the cavity, see Ref. 12). Taking into account the hydrogen bond formation between water and its surrounding molecules, the radii allotted for hydrogen bond donor and acceptor atoms, O and N, were assumed to be 2.70 and 2.85 Å, respectively (hydrogen atoms attached to these atoms are neglected). Figure 3 shows the cavity viewed along the a and b axes, where the positions of the three water molecules are indicated. As seen from Fig. 3a, the oxygen atoms of water, consisting a triangle, fit very well with the cavity. Hydrogen atoms of water may protrude from the cavity, because the radii of O and N are taken as hydrogen bond distances. Figure 3b indicates the cavity for the case in which the

serine hydroxyl group takes a site with low occupancy. The fit of the water triangle into the cavity is also good. Disordering of serine O(13) gives rise to a slight change for the shape of the cavity, but this does not affect the position and orientation of the triangle. The cavity in the crystal of Cu(ala his) was also drawn, and the shape is nearly the same as that in the present case.

The volumes of the cavities were calculated in the way proposed in the previous paper[12] to be 12.94 Å^3 for the present complex and 17.22 Å^3 for Cu(ala his). The larger cavity of the latter allows the disordering of three water molecules, as discussed in Ref. 7.

Since the side chain of alanine is hydrophobic, while that of seine is hydrophilic, one might expect different crystal structures for Cu(ala his) and Cu(his ser). It is interesting that completely the same building principle applies to those two ternary complexes, perhaps owing to the common chelating mode of the mixed amino acids.

The authors are grateful to Professor Akitsugu Nakahara, Osaka University, for a gift of the sample, to Mr. Taizo Ono in our laboratory for the successful growth of the present crystal, and to Mr. Akira Uchida in our laboratory for drawing the cavities.

The Osmotic and Activity Coefficients of Quaternary Phosphonium Halides in Aqueous Solutions at Freezing Point

Toshiki WAKABAYASHI* and Katsuko TAKAIZUMI
The College of General Education, Tohoku University, Kawauchi, Sendai 980
(Received December 2, 1982)

The osmotic and activity coefficients have been obtained cryoscopically for $(n\text{-Bu})_{4-n}\text{Ph}_n\text{PX}$($n$=0—4, X=Cl, Br) in aqueous solutions at freezing point. The $\gamma_\pm$ decreases with increasing n, for both the chloride and the bromide salts. With the chloride salts, $\gamma_\pm$'s for the salts of n from 0 to 2 show positive deviation from the Debye-Hückel limiting law as concentration increases, whereas $\gamma_\pm$'s for others show negative deviation. Replacement of the anion from Cl^- to Br^- results in lower $\gamma_\pm$'s for the salts of n from 0 to 2, but this elevates the other $\gamma_\pm$'s. These results were interpreted qualit tively in terms of the cosphere overlap model by Desnoyers *et al.*, by assuming a hydrophilic character of the present phenyl group. An attempt was made to evaluate the pairwise interaction coefficients(B^*) and to estimate the contributions to B^* from the interactions, butyl-Cl^- and phenyl-Cl^-.

This paper is part of a continuing study of the thermodynamic properties of aqueous solutions of the quaternary phosphonium halides, $(n\text{-Bu})_{4-n}\text{Ph}_n\text{PX}$($n$=0—4). Since their molal volumes are nearly the same[1,2] we can expect that the size effect of the cations on the solvent water would be commom and the changes with n in their partial molal thermodynamic quantities would reflect directly the effects arising from the systematic variation in the state of cosphere water around the cation.

The activity coefficients of $(C_6H_5)_4MX$ (M=P, As, and Sb) in water at 37 °C were reported by Kalfoglou and Bowen,[3] these values are much lower than those of the usual 1 : 1 electrolytes. The authors attributed the low $\gamma_\pm$'s to the structure-breaking effects of the phenyl groups on the water structures. On the other hand the activity coefficients of tetraalkylammonium chlorides and bromides,[4,5] the higher members of which are known as typical structure-makers, are higher than that given by the Debye-Hückel limiting law. Thus, it is of interest to examine the variation of the osmotic(ϕ) and activity($\gamma_\pm$) coefficients of the present phosphonium halides with successive replacement of the butyl groups of the $n\text{-Bu}_4\text{P}^+$ ion by phenyl groups, this procedure provides an opportunity to test the group contribution to ϕ and $\gamma_\pm$. Also, the concentration dependences of ϕ's and $\gamma_\pm$'s will offer information about the pairwise interactions between each hydrocarbon cosphere and anions as well as those between the hydrocarbon cospheres.

Here, the cryoscopic method is employed to obtain the osmotic and activity coefficients.

Experimental

The phosphonium halides used for the freezing point measurements, $(n\text{-Bu})_{4-n}\text{Ph}_n\text{PX}$($n$=0—4, X=Cl, Br), were synthesized from the phosphines, except for the Ph_4PCl, which was a commercial product (DOTITE). The methods for synthesizing and purifying the salts were almost the same as those reported previously.[1] The sodium chloride delivered from Merck (Suprapur) was used for calibration of a thermistor, after drying. Solutions were prepared with conductivity-grade water by weight and buoyancy corrections were applied.

Cooling curves were obtained on a thermistor-differential amplifier-recorder system, which is essentially the same as that devised by Takahashi *et al.*[6] A sample solution was cooled at a rate of about 0.1 K min^{-1} or less; it was stirred constantly by a magnetic stirrer (1500 min^{-1}) in a Dewar-type cell of about 10 cm^3 inner-capacity, equipped with a rodtype thermistor. The cell was immersed in a cooling bath, the temperature of which was maintained lower by about 10K than the freezing point of the solution. Freezing was initiated by mechanical vibration of the cell assembly if super-cooling of the solution continued even at a temperature lower than the freezing point by 1 K or more. The freezing point was determined, as usual, by extrapolation of the linear part of the cooling curve to the point where the freezing would begin without the supercooling. The electric resistance of the thermistor was about 34 kΩ at 0 °C and the d.c. current which passed was regulated to be about 10 μA. Thus, the Joule's heat evolved is about 0.34 μJ s^{-1} which would hardly affect the temperature measurement under the experimental conditions. The thermistor was standardized against the freezing points of a series of aqueous solutions of sodium chloride, twelve solutions over a concentration range of 0.005 to 1.1 mol kg^{-1}, for which accurate data have been reported by Scatchard and Prentiss.[7]

The thermistor resistance was fitted to this equation as a function of T:

$$\log R = \log R^\circ + b(1/T - 1/T^\circ) + c(1/T - 1/T^\circ)^2,$$

where T° is 273.15 K and R° is the resistance at T°; the parameters b and c were determined by the least-squares method to fit the observed resistances to the freezing points of the aq eous sodium chloride solutions, with a standard deviation, 3×10^{-5}, in log R. The temperature coefficient of the thermistor was about -1.3 kΩ K^{-1}, which enabled us to attain a resolution of 1×10^{-4} K by amplifying. The reproducibility of the freezing point measurements for conductivity-grade water and dilute solutions was within 3×10^{-4} K provided that the stirring was steady and that the reference (R_{ref}) and standard (R_{st}) resistors, decade-types of six figures, were set in a thermostat bath (35±.2 °C), as was the case of the present measurement. Each cooling curve was always preceded and followed by the measurements for the couple, R_{st}-R_{ref}, to compare with the couple, $R_{thermistor}$-R_{ref}. This procedure enables us to eliminate any drift in the recorder or in the amplifier. No aging effect of the thermistor was found, within experimental reproducibility, as confirmed by occasional measurements for the freezing point of pure water.

Results and Discussion

The Lewis-Randall function, j, was obtained from the freezing point depression, θ, by the equation:[8]

a) The standard deviation between the observed and reproduced j-values. b) The coefficient given by Eq. 7 multiplied by 0.4343.

$$j = 1 - \theta/(\lambda\nu m), \tag{1}$$

where λ is the molal lowering of the freezing point of water, 1.860 K mol^{-1} kg, and ν the number of moles of ions formed from 1 mol of electrolyte (*i.e.*, 2 for the present case). The error in j comes mostly from the error in θ and becomes increasingly large as concentration decreases; it amounts to 0.016 due to an error in θ, 3×10^{-4} K, for solution of 5×10^{-3} mol kg^{-1} which was the lowest concentration in the present measurements. The values of j listed in Table 1 are the average values from several measurements for each solution of low concentrations (below 0.1 mol kg^{-1}) and from triple measurements for solutions of higher concentrations.

An empirical form for the j-function was assumed:

$$j = \frac{Am^{1/2}}{1+a_0m^{1/2}} + a_1m + a_2m^2, \tag{2}$$

where A is the Debye-Hückel limiting slope, 0.377 $mol^{-1/2}$ $kg^{1/2}$, and other parameters, a_i, were adjusted to fit the observed j values by the least-squares method. The parameters determined for the n-$Bu_{4-n}Ph_nPX$ salts are summarized in Table 2, where the standard deviations between the observed and reproduced j values are also listed.

The activity coefficients were calculated by the equation:

$$\ln\gamma_\pm = -j - \int_0^m j\,d\ln m + \xi\int_0^\theta \frac{\theta}{\nu m}d\theta, \tag{3}$$

where the last term including $\xi(0.00054)$[8] contributes hardly at all to $\ln\gamma_\pm$, *i.e.*, only a few units in the fourth decimal of $\ln\gamma_\pm$, and was neglected here. Placing Eq. 2 into Eq. 3 and integrating, we obtain the relation:

Table 3. Osmotic coefficients and activity coefficients of n-$Bu_{4-n}Ph_nPX$ in aqueous solutions at freezing point

$$-\ln\gamma_\pm = \frac{Am^{1/2}}{1+a_0m^{1/2}} + \frac{2A}{a_0}\ln(1+a_0m^{1/2}) + 2a_1m + \frac{3}{2}a_2m^2. \quad (4)$$

In Table 3, the osmotic coefficients ϕ and the activity coefficients $\log\gamma_\pm$ are listed. The present results are, as a whole, accompanied by errors of a few units in the third decimal place of j and are considered to be preliminary ones, especially with the bromide salts, mainly because the measurements for them were confined to low concentration ranges owing to their limited solubilities.

The mean chemical potential for an electrolyte may be described by:[9]

$$\mu_\pm = \mu_\pm^\circ + RT\ln c + Sc^{1/2} + RT[B_2(\kappa)c + B_3(\kappa)c^2 + \cdots], \quad (5)$$

where the coefficient S is given by the Debye-Hückel limiting law. According to Friedman and Krishnan,[9] $B_2(\kappa)$ reflects mainly the effects arising from the pairwise interactions between ions due to the short-range focres, though it depends also on the ionic strength through the Debye κ, and is decomposed into three contributions

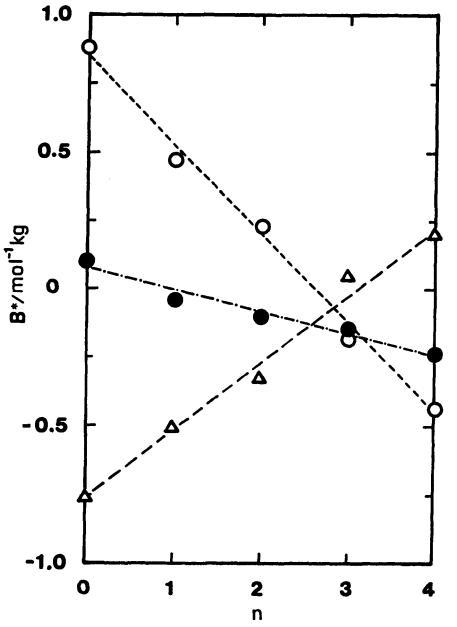

Fig. 1. The B^* coefficient and the difference between the bromide salts and the chloride salts, ΔB^*, as functions of the number of phenyl groups on the cation, n.
---○---, B^*(chloride); -·-●-·-, B^*(bromide); --△--, ΔB^*.

from the pairwise ionic interactions, ++, +−, and −−. For a 1 : 1 electrolyte it can be expressed as

$$B_2(\kappa) = \frac{1}{4}[B_{++}(\kappa) + 2B_{+-}(\kappa) + B_{--}(\kappa)]. \quad (6)$$

Expanding Eq. 4 into polynomial of $m^{1/2}$, we obtain the equation,

$$\ln\gamma_\pm = -Am^{1/2} + Bm + Cm^{3/2} + \cdots,$$

where the first term of the right hand side is the Debye-Hückel limiting term and the coefficient B is given by,

$$B = 2(Aa_0 - a_1). \quad (7)$$

In the last column of Table 2, the values for B^* which is the B coefficient for $\log\gamma_\pm$, *i.e.*, 0.4343 B, are listed. The B^* coefficients may be assumed, as a first approximation, to be proportional to $B_2(\kappa)$, since in dilute solutions the excess part of $\ln\gamma^\pm$ from the Debye-Hückel limiting law would mainly originate from pairwise interactions between ions due to short-range forces and the difference between the two concentration scales is negligible.

The B^*'s for the salts and the differences in B^* between the bromide and chloride salts, ΔB^*, are shown as functions of n in Fig. 1. Some features are to be noted: 1 the B^*, and hence $\log\gamma_\pm$, decreases successively with increasing n for both the chloride and bromide salts, 2) the n dependence of B^* is marked with the chloride salts, while it is not marked with the bromide salts, and 3) the ΔB^* is negative for Bu_4PX, while it is positive for Ph_4PX; those for the intermediate salts appear to distribute between these two ΔB^*'s. Qualitatively, these features are explicable by the structural

hydration interaction model proposed by Desnoyers *et al.*,[10] if the phenyl groups in the present cations are assumed to be hydrophilic rather than hydrophobic, as suggested by Kalfoglou and Bowen[3] and from the volumetric studies.[2,11] In their model, the interactions between ions are classified into four types based on a qualitative consideration about the states of water in the cosphere overlap region: hydrophobic-hydrophobic-(I), hydrophobic-hydrophilic(II), hydrophilic-hydrophilic (ions with opposite charge (III), and hydrophilic-hydrophilic (ions with the same charge) (IV). The contributions to the excess partial molal Gibbs free energy $\bar{G}^{ex}$, and hence also to B_2, are negative for the interactions I and III and positive for those II and IV. This leads to the sign assignment for B_{ij}: for Bu_4PX, $B_{++}<0$ and $B_{+-}>0$, and for Ph_4PX, $B_{++}>0$ and $B_{+-}<0$. Since for each of the two salts the sign of B^* is the same as that of B_{+-}, it comes to be that the cation-anion interactions are dominant for both the cations among the ion-ion interactions $++$, $+-$, and $--$. The chloride ion may be more hydrophilic than the bromide ion in the sense that the former ion is more effective in electrostrictive hydration and B_{+-} for Bu_4PCl would be more positive than that for Bu_4PBr, while the reverse would be true for the Ph_4P^+ ion, *i.e.*, B_{+-} for Ph_4PCl would be more negative than that for Ph_4PBr. The hydrophilic character assumed for the present phenyl groups would be caused by a rather large polarizability due to the π electrons and delocalized charges on them induced by the large electronegativity of $P(V)^+$, as revealed by an NMR study.[12]

With the intermediate cations ($n=1$—3), the opposite effects due to the interactions, butyl-X^- and phenyl-X^-, appear to successively cancel each other, suggesting that the cosphere around each group is affected only weakly by the nearest groups on the same cation. A similar result has been obtained from the volume studies.[2,11]

As examined in the volume studies, the B^* would also be expressed as a quadratic equation of n, if the contribution from the cation-cation interactions are of considerable importance. Although the present results are not accurate enough to discuss the B^*_{++} values the B^* for the chloride salts seems to be a linear function of n. If this is the case, this means that the B^* coefficients are nearly equal to $(1/2)B^*_{+-}$'s (Eq. 6) and hence we can split the contributions, butyl-Cl^- and phenyl-Cl^-. Roughly, they may be given from the B^*'s for Bu_4PCl and Ph_4PCl by dividing $2B^*$ by four, and neglecting B^*_{++} and B^*_{--}, that is, about 0.4 and -0.1 mol^{-1} kg, respectively.

In conclusion, two points are to be noted: First, the present and previous[2,11] results seem to support a simple assumption that the state of cosphere water around any group on the present cations is independent of the nearest groups on the same cation and each of group cospheres(i) interacts with another cosphere(j) around a simple anion or group on another cation with a relative probability proportional to the concentration product, c_ic_j, in dilute solutions. A similar assumption has been used by Wood *et al.*[13,14] for predicting pairwise interaction enthalpies and free energies of nonelectrolytes in dilute aqueous solutions. Applying the Wood method, Visser *et al.*[15] have estimated the enthalpy parameter for the pairwise interaction between the methylene group on tetraalkylammonium ions and the bromide ion. Second, the cosphere overlap model by Desnoyers *et al.*, which is somewhat different from that used by Friedman and his coworkers[16,17] and Streng and Wen,[18] seems to be reasonable and useful to interpret qualitatively ion-ion interactions in aqueous solutions, though the model would be limited to qualitative use until our knowledge on the structures around various ions as well as those of pure water would become more profound.

Structure of the Electrical Double Layer at the Interface between Nitrobenzene Solution of Tetrabutylammonium Tetraphenylborate and Aqueous Solution of Lithium Chloride

Takashi KAKIUCHI and Mitsugi SENDA*

Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606

(Received December 22, 1982)

Electrocapillary curves at the polarized interface between a nitrobenzene solution of tetrabutylammonium tetraphenylborate (TBATPB) and an aqueous solution of lithium chloride at various concentrations of TBATPB and LiCl have been measured by the drop time method using a dropping electrolyte solution electrode at 25 °C. The relative surface excesses of tetrabutylammonium and tetraphenylborate ions in the nitrobenzene phase and of lithium and chloride ions in the aqueous phase were well described by the Gouy-Chapman theory of diffuse layers for both sides of the interface. A model of the electrical double layer for the nitrobenzene–water interface is presented, in which an ion-free inner layer consisting of laminated monolayers of water and nitrobenzene is sandwiched by the two diffuse layers on each side of the interface. The potential difference across the inner layer, which was estimated to be *ca.* 20 mV at the potential of zero charge, was found to be dependent on the surface charge density and to be nearly independent of the electrolyte concentration.

In a previous paper[1] we have reported the experimental conditions under which the interface between a nitrobenzene solution of tetrabutylammonium tetraphenylborate (TBATPB) and an aqueous solution of lithium chloride behaves as a polarized interface. Such an interface is amenable to a study of its double structure based on the thermodynamics of an ideal polarized interface between two immiscible electrolyte solutions. Watanabe *et al.*[2] first applied the concept of ideal polarizability to the oil–water interfaces in order to analyze their double layer structure. At such interfaces, however, there always existed a significant amount of ion transfer current through the interface, so that the precise control of the electrical potential difference across the interface was not achieved. Gavach *et al.*[3,4] have studied the double layer structure of the non-polarized nitrobenzene–water interfaces by surface tension measurements. They have shown that the Gouy-Chapman theory of diffuse double layers well describes their experimental results when no specific adsorption of ions at the interface was assumed. In a non-polarized interface, however, the specific adsorption of ions cannot be detected from the electrocapillary measurements, since the surface charge density and surface excesses of ions cannot be independently determined.

In this paper, we describe the results of the experimental study of the double layer structure at the polarized interface between a nitrobenzene solution of TBATPB and an aqueous solution of LiCl on the basis of the electrocapillary measurements and we present an electrical double layer model of the interface. Electrocapillary curves of a polarized interface, in conjunction with the thermodynamics of ideal polarized interface between two immiscible electrolyte solutions[5] and with the Gouy-Chapman theory of electrical double layer, provide us an unequivocal way to examine the adsorption of ions at the interface by determining the surface charge density and surface excesses of individual ionic species.

Experimental

The interfacial tension at the polarized interface between the nitrobenzene solution of TBATPB and the aqueous solution of LiCl was measured with the drop time method using a dropping electrolyte solution electrode.[1] The aqueous lithium chloride solution was dropped upward into the nitrobenzene solution from the tip of a poly(tetrafluoroethylene) capillary of 0.5 mm inner diameter. The flow rate of the aqueous solution and the drop time were typically 0.00036 ml s^{-1} and 50 s. The potential drop across the interface was controlled using a four-electrode potentiostat with a positive feedback device for IR compensation.[6] Details of the measurements and the calculation of the surface tension from the drop time have been reported elsewhere.[1] All the measurements were made at 25.00±0.05 °C in the dark.

TBATPB, tetrabutylammonium chloride (TBACl) and nitrobenzene were purified as described elsewhere.[1] Lithium chloride(spurapur grade, E. Merck) was dissolved into twice distilled water to prepare the stock solution. The concentration of LiCl was determined potentiometrically using a standard silver nitrate solution. Aqueous LiCl solutions of desired concentrations were prepared by serial dilution of the stock solution. Nitrobenzene solutions of TBATPB were prepared in the dark immediately before use.

Results

The electrochemical cell employed in this study is represented by

I	II	III	IV	V
Ag	AgCl	a mol dm^{-3} TBACl	b mol dm^{-3} TBATPB	c mol dm^{-3} LiCl
		(water)	(nitrobenzene)	(water)

VI	VII
AgCl	Ag.

(I)

The interface between phases IV and V is the polarized nitrobenzene–water interface which we are concerned with. The nitrobenzene–water interface between phases III and IV is a non-polarized interface where the potential drop across the interface is determined by the activities of TBA^+ ions in the phases III and IV.[7-9] The electrocapillary equation for the present system at constant temperature and pressure takes the form[5]

$$-d\gamma = q^{W}dE^{W}_{0^+} + \Gamma_{Li/W}d\mu_{LiCl} + \Gamma_{TPB/NB}d\mu_{TBATPB}, \quad (1)$$

where $\Gamma_{Li/W}$ and $\Gamma_{TPB/NB}$ are the relative surface concentrations (the relative surface excesses) of Li^+ and TPB^- ions defined by

$$\Gamma_{Li/W} = \Gamma_{Li} - \frac{x_{NB}^{NB}\Gamma_W - x_W^{NB}\Gamma_{NB}}{x_W^W x_{NB}^{NB} - x_W^{NB} x_{NB}^W} x_{LiCl}^W, \quad (2)$$

and

$$\Gamma_{TPB/NB} = \Gamma_{TPB} - \frac{x_W^W\Gamma_{NB} - x_{NB}^W\Gamma_W}{x_W^W x_{NB}^{NB} - x_W^{NB} x_{NB}^W} x_{TBATPB}^{NB}. \quad (3)$$

Here, γ is the interfacial tension, q^W the surface charge density in aqueous phase defined by $q^W = F(\Gamma_{Li} - \Gamma_{Cl})$, F being the Faraday. x_i^α, μ_i^α, and Γ_i denote the mole fraction, the chemical potential and the surface concentration (the amount of matter in unit area of the interphase),[10] respectively, of i component in α phase (α= NB : nitrobenzene or W : aqueous phase). E_{O+}^{W-} is the potential of the right hand side terminal of the cell (I) with respect to the left, and the subscript O+ and superscript W− on E indicate that the reference electrodes in the nitrobenzene and aqueos phases are reversible to a cation (TBA^+) and an anion (Cl^-), respectively. Since x_W^{NB} and x_{NB}^W are 0.0175 and 0.000295, respectively, for water and nitrobenzene in the absence of an electrolyte at 25 °C,[11] Eqs. 2 and 3 can be approximated by[12]

$$\Gamma_{Li/W} = \Gamma_{Li} - \frac{x_{LiCl}^W}{x_W^W}\Gamma_W, \quad (4)$$

and

$$\Gamma_{TPB/NB} = \Gamma_{TPB} - \frac{x_{TBATPB}^{NB}}{x_{NB}^{NB}}\Gamma_{NB}. \quad (5)$$

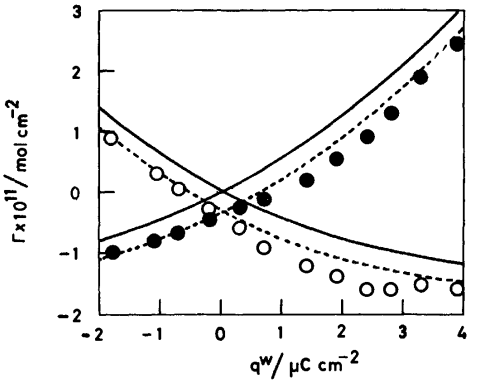

Fig. 2. Relative surface excesses of lithium ion (●) and chloride ion (○) in the aqueous phase as a function of the surface charge density in aqueous phase at 0.1 mol dm^{-3} lithium chloride. The solid lines are the theoretical curves based on Gouy-Chapman theory. Dashed lines are the curves corrected for the exclusion of lithium and chloride ions from the inner layer.

Aqueous Phase. Electrocapillary curves were measured for seven different concentrations of LiCl, c=0.01 to 1.00 mol dm^{-3}, at a=0.1 mol dm^{-3} and b= 0.1 mol dm^{-3} in the cell (I). Some of the results are shown in Fig. 1. The coordinates of the electrocapillary maximum are given in Table 1. The potential of zero charge, E_{pzc}, and the interfacial tension at the potential of zero charge, γ_{pzc}, were determined by a least square fit of an electrocapillary curve around the maximum to a third order polynomial. The mean molar ionic activity of LiCl, $a_{LiCl}^{\pm,W}$, in Table 1 was calculated from Davies' extended equation[13] of the Debye-Hückel theory for the concentrations below 0.1 mol dm^{-3} and was taken from the literature data[14] for the concentrations above 0.1 mol dm^{-3}.

Using Eq. 1, we obtained q^W by numerical differentiation of the electrocapillary curves with respect to E_{O+}^{W-}. $\Gamma_{Li/W}$ was calculated from numerical differentiation of γ *vs.* log $a_{LiCl}^{\pm,W}$ curves with respect to log $a_{LiCl}^{\pm,W}$. The relative surface excess of Cl^- ion, $\Gamma_{Cl/W}$, was evaluated by $q^W = F(\Gamma_{Li} - \Gamma_{Cl}) = F(\Gamma_{Li/W} - \Gamma_{Cl/W})$. Figure 2 shows $\Gamma_{Li/W}$ and $\Gamma_{Cl/W}$ for 0.1 mol dm^{-3} LiCl as a function of q^W.

Nitrobenzene Phase. Electrocapillary curves were measured for seven different concentrations of TBATPB

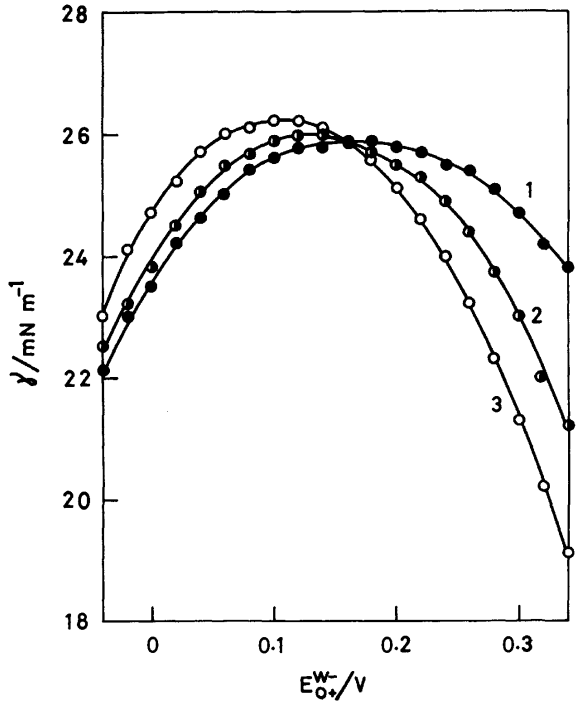

Fig. 3. Electrocapillary curves for the interface between aqueous solution of 0.1 mol dm^{-3} lithium chloride and nitrobenzene solution of (1): 0.02, (2): 0.05, and (3): 0.17 mol dm^{-3} tetrabutylammonium tetraphenylborate at 25 °C.

Table 2. Coordinates of electrocapillary maximum for the interface between aqueous solution of 0.1 mol dm^{-3} lithium chloride and nitrobenzene solution of 0.01 to 0.17 mol dm^{-3} tetrabutylammonium tetraphenylborate at 25 °C

0.17	0.099	26.3	0.108

in the nitrobenzene phase, b=0.01 to 0.17 mol dm^{-3}, at a=0.005 mol dm^{-3} and c=0.1 mol dm^{-3} in the cell (I). Some of the results are shown in Fig. 3. The concentration of TBACl in phase III in the cell (I) was kept at such a low value to ensure that the potential across the interface between the phases III and IV would show a Nernstian response for the activity of TBA$^+$ ion in the nitrobenzene phase[9] in the concentration range of TBATPB. Separate measurements showed that the potential of this reference electrode was 0.145 V more negative than that of the reference electrode with 0.1 mol dm^{-3} TBACl used in the measurements of ion adsorption in the aqueous phase.

The coordinates of the electrocapillary maximum are given in Table II. To check the degree of the association

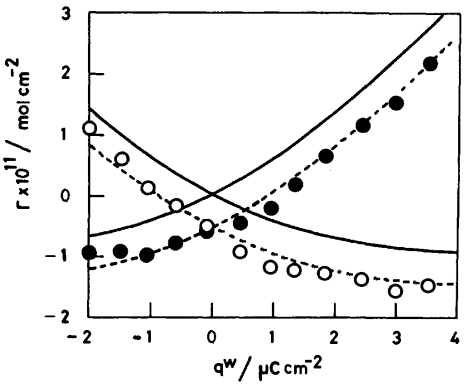

Fig. 4. Relative surface excesses of tetrabutylammonium (○) and tetraphenylborate (●) ions in the nitrobenzene phase as a function of the surface charge density in the aqueous phase at 0.1 mol dm^{-3} tetrabutylammonium tetraphenylborate.

of TBA$^+$ and TPB$^-$ ions in water-saturated nitrobenzene, the conductance of a series of the TBATPB solutions was measured. No indication of the association of the ions was observed in the concentration range used in the electrocapillary measurements. The mean molar ionic activity of TBATPB in the nitrobenzene phase was calculated using the Debye-Hückel theory allowing for a finite size of the ions;[14] here an apparent diameter, 10 Å, was assumed for TBA$^+$ and TPB$^-$ ions.[15] The surface charge density and relative surface excesses of TBA$^+$ and TPB$^-$ ions ($\Gamma_{TBA/NB}$ and $\Gamma_{TPB/NB}$) were calculated similarly. $\Gamma_{TBA/NB}$ and $\Gamma_{TPB/NB}$ at 0.1 mol dm^{-3} TBATPB are plotted against q_W in Fig. 4.

Discussion

We consider that the nitrobenzene–water interface consists of an inner layer which is sandwiched by the two diffuse double layers in the nitrobenzene and the aqueous solution sides.

Ion Adsorption in Aqueous Solution Side. The relative surface excess of Li$^+$ ions defined by Eq. 4 may be divided formally into two parts, that is, the relative surface excess in the inner layer, ${}^{i}\Gamma_{Li/W}$, and that in the diffuse layer, ${}^{d}\Gamma_{Li/W}$;

$$\Gamma_{Li/W} = {}^{i}\Gamma_{Li/W} + {}^{d}\Gamma_{Li/W}, \quad (6)$$

with

$${}^{i}\Gamma_{Li/W} = {}^{i}\Gamma_{Li} - \frac{x^{W}_{LiCl}}{x^{W}_{W}} {}^{i}\Gamma_{W}, \quad (7)$$

and

$${}^{d}\Gamma_{Li/W} = {}^{d}\Gamma_{Li} - \frac{x^{W}_{LiCl}}{x^{W}_{W}} {}^{d}\Gamma_{W}, \quad (8)$$

where ${}^{i}\Gamma_j$ and ${}^{d}\Gamma_j$ (j=Li for lithium ion and W for water) are the surface amounts of j in the inner layer and diffuse layer, respectively, per unit surface area. If we assume that the number of moles of water molecules per unit volume in the diffuse layer, ${}^{d}n^{W}_{W}$, is constant and equal to that in the bulk of the solution, ${}^{b}n^{W}_{W}$, we may write

$${}^{d}\Gamma_{Li/W} = \int_{x=x_2}^{x=\delta} ({}^{d}n^{W}_{Li} - {}^{b}n^{W}_{Li})dx, \quad (9)$$

where ${}^{d}n_{Li}^{W}$ and ${}^{b}n_{Li}^{W}$ are the number of moles of Li^+ ion per unit volume in the diffuse layer and that in the bulk of the solution, respectively, and the integration extends from the outer Helmholtz plane ($x=x_2$) to the boundary plane of the interphase ($x=\delta$) where the composition is identical with that of the bulk of the solution. Similarly, for a Cl^- ion we may write

$$\Gamma_{Cl/W} = {}^{i}\Gamma_{Cl/W} + {}^{d}\Gamma_{Cl/W}, \tag{10}$$

with

$${}^{i}\Gamma_{Ci/W} = {}^{i}\Gamma_{Ci} - \frac{x_{LiCi}^{W}}{x_{W}^{W}} {}^{i}\Gamma_{W}, \tag{11}$$

and

$${}^{d}\Gamma_{Ci/W} = {}^{d}\Gamma_{Ci} - \frac{x_{LiCl}^{W}}{x_{W}^{W}} {}^{d}\Gamma_{W}, \tag{12}$$

and also

$${}^{d}\Gamma_{Cl/W} = \int_{x=x_2}^{x=\delta} ({}^{d}n_{Ci}^{W} - {}^{b}n_{Ci}^{W})dx. \tag{13}$$

The relative surface excesses of Li^+ and Cl^- ions in the diffuse layer defined by Eqs. 8 and 12 can be calculated from the Gouy-Chapman theory and are given, respectively, by ${}^{d}\Gamma_{+}^{W}$ and ${}^{d}\Gamma_{-}^{W}$ as follows:

$${}^{d}\Gamma_{\pm}^{W} = \frac{A^W}{F}\left(\pm\frac{q^W - {}^{i}q^W}{2A^W} + \sqrt{\left(\frac{q^W - {}^{i}q^W}{2A^W}\right)^2 + 1} - 1\right). \tag{14}$$

Here, ${}^{i}q^W$ is the charge density in the inner layer of the aqueous solution side and $A^W=(2RT\varepsilon^W c_{LiCl}^{W})^{1/2}$, where ε^W is the permittivity of water and c_{LiCl}^{W} is the concentration of LiCl. When all the ions are excluded from the inner layer, *i.e.*, in the case of an ion-free inner layer or of no specific adsorption of ions, ${}^{i}\Gamma_{Li}$, ${}^{i}\Gamma_{Cl}$, and ${}^{i}q^W$ reduce to zero. The calculated ${}^{d}\Gamma_{\pm}^{W}$ *vs.* q^W curves when ${}^{i}q^W=0$, $c_{LiCl}^{W}=0.1$ mol dm^{-3} and $\varepsilon^W=6.5\times10^{-10}$ F m^{-1} are shown by solid lines in Fig. 2. We estimated ${}^{i}\Gamma_W$ to be 1.73×10^{-9} mol cm^{-2}, assuming that the density of water in the inner layer is equal to that in the bulk of water and that the inner layer has the thickness of a monomolecular layer of water. Thus, ${}^{i}\Gamma_{Li/W}={}^{i}\Gamma_{Cl/W}=-(x_{LiCl}^{W}/x_{W}^{W}){}^{i}\Gamma_W=-3.1\times10^{-12}$ mol cm^{-2} when $c_{LiCl}^{W}=0.1$ mol dm^{-3}. The dashed lines in Fig. 2 are the calculated curves of the relative surface excess of Li^+ and Cl^- ions obtained by shifting the solid lines by this amount of $-(x_{LiCl}^{W}/x_{W}^{W}){}^{i}\Gamma_W$. The experimental relative surface excesses agree fairly well with the calculated curves for both Li^+ and Cl^- ions. Thus, the results in Fig. 2 can reasonably be explained by assuming the existence of an ion free inner layer, *i.e.*, the absence of specific adsorption of ions, in the aqueous solution side of the interface.

The variation of γ_{pzc} with $\ln(a_{LiCl}^{\pm W})$ can be calculated from the integral form of Eq. 1:

$$\gamma_{pzc} = (\gamma_{pzc})_{c_{LiCl}^{W}=0.1} + 2RT\int_{\ln(0.079)}^{\ln(a_{LiCl}^{\pm W})} -(x_{LiCl}^{W}/x_{W}^{W}){}^{i}\Gamma_W d\ln(a_{LiCl}^{\pm W}), \tag{15}$$

when ${}^{i}\Gamma_{Li}={}^{i}\Gamma_{Ci}=0$ at the pzc. In Eq. 15 R and T have the usual meanings. The lower limit of the integration corresponds to $\ln(a_{LiCl}^{\pm W})$ at $c_{LiCl}^{W}=0.1$ mol dm^{-3}. The observed increase of γ_{pzc} with the increase in $\ln(a_{LiCl}^{\pm W})$ is well reproduced by Eq. 15, as shown in Fig. 5.

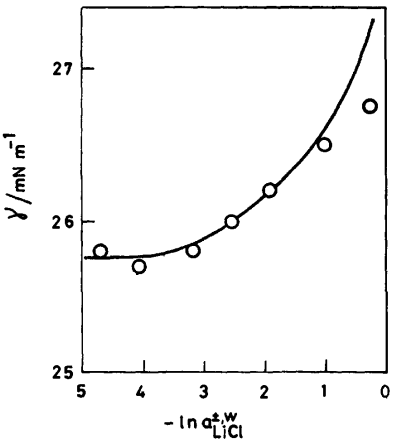

Fig. 5. Variation of interfacial tension at the potential of zero charge with the change of the activity of lithium chloride. Solid line is the calculated curve assuming the exclusion of lithium and chloride ions from the inner layer.

Figure 6 shows E_{0+}^{W-} values plotted against $\ln(a_{LiCl}^{\pm W})$ at several different q^W values. The slope of these plots, analogous to the Esin-Markov coefficient at the mercury-solution interface,[16] is given by

$$\left(\frac{\partial E_{0+}^{W-}}{\partial \ln(a_{LiCl}^{\pm W})}\right)_{q^W,\mu_{J\neq LiCi}} = -2RT \times\left[\left(\frac{\partial {}^{d}\Gamma_{Li/W}}{\partial q^W}\right)_{\mu_J} + \left(\frac{\partial {}^{i}\Gamma_{Li}}{\partial q^W}\right)_{\mu_J} - \frac{x_{LiCl}^{W}}{x_{W}^{W}}\left(\frac{\partial {}^{i}\Gamma_W}{\partial q^W}\right)_{\mu_J}\right]. \tag{16}$$

When both the presence of the ions in the inner layer and the dependence of ${}^{i}\Gamma_W$ on q^W are negligible, the coefficient is given by the first term of the right hand side of Eq. 16, which can be calculated from the Gouy-Chapman theory; from Eq. 14 we have

$$\left(\frac{\partial {}^{d}\Gamma_{Li/W}}{\partial q^W}\right)_{\mu_J} = \frac{1}{F}\left(1+\frac{q^W/2}{[(q^W/2)^2+(A^W)^2]^{1/2}}\right). \tag{17}$$

Therefore, in the case of the absence of specific absorption of ions, the coefficient is expected to become $-2RT/F$, $-RT/F$ and 0 when $q^W\gg0$, $q^W=0$, and $q^W\ll0$, respectively. The experimental plot at the pzc in Fig. 6 is a straight line with the slope of -23 mV which is close to $-RT/F=-25.6$ mV at 25 °C. The small difference might be attributable to a slight dependence of ${}^{i}\Gamma_W$ on q^W and/or a weak specific adsorption of ions in the inner layer. Figure 6 shows that the slope becomes larger with the positive increase of q^W, which is consistent with the prediction of Eq. 15.

We calculated the potential at the outer Helmholtz plane in the aqueous solution side (OHP(W)), ϕ_2^W, referred to the inner potential of the bulk of the aqueous solution, ϕ^W, by using the Gouy-Chapman theory:

$$\phi^W - \phi_2^W = \frac{2RT}{F}\sinh^{-1}[q^W/(2A^W)]. \tag{18}$$

In Fig. 7 $\phi^W-\phi_2^W$ is plotted against the rational potential,[17] $E_{0+}^{W-}-E_{pzc}$, at three different concentrations of LiCl. The variation of $\phi^W-\phi_2^W$ with $E_{0+}^{W-}-E_{pzc}$ is much smaller than those usually observed at the mercury-

aqueous solution interface in the absence of specific adsorption of ions.[18]

Ion Adsorption in Nitrobenzene Solution Side. The relative surface excesses of TBA^+ and TPB^- ions in the diffuse layer in the nitrobenzene solution side were calculated under the assumption of the ion-free inner layer from the Gouy-Chapman theory:

$$ {}^{d}\Gamma^{o}_{\pm} = \frac{A^{NB}}{F}\left[\mp\frac{q^{W}-{}^{i}q^{W}}{2A^{NB}}\sqrt{\left(\frac{q^{W}-{}^{i}q^{W}}{2A^{NB}}\right)^{2}+1}-1\right]. \quad (19) $$

In Eq. 19 ${}^{d}\Gamma^{o}_{+}$ and ${}^{d}\Gamma^{o}_{-}$ are the surface excesses of TBA^+ and TPB^- ions, respectively, in the diffuse layer,

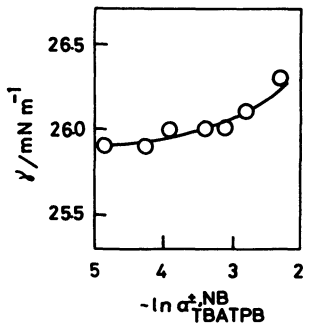

Fig. 8. Variation of interfacial tension at the potential of zero charge with the change of the activity of tetrabutylammonium tetraphenylborate. Solid line is the calculated curve assuming the exclusion of tetrabutylammonium and tetraphenylborate ions from the inner layer.

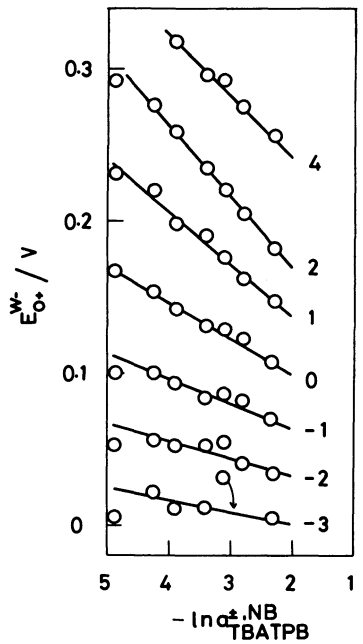

Fig. 9. Esin-Markov plots for nitrobenzene solution phase in contact with aqueous solution of 0.1 mol dm^{-3} lithium chloride. The surface charge density in aqueous phase is indicated by each line in μC cm^{-2}.

and $A^{NB}=(2RT\varepsilon^{NB}c^{NB}_{TBATPB})^{1/2}$ where ε^{NB} and c^{NB}_{TBATPB} are the permittivity of nitrobenzene and the concentration of TBATPB in the nitrobenzene phase. The solid lines in Fig. 4 are the curves calculated according to Eq. 19, when ε^{NB} and c^{NB}_{TBATPB} are 3.08×10^{-9} F m^{-1} and 0.1 mol dm^{-3}, respectively. The number of moles of nitrobenzene molecules in the inner layer per unit surface area was estimated to be 5.40×10^{-10} mol cm^{-2}. The dashed lines in Fig. 4 are the calculated curves corrected for the exclusion of ions from the inner layer. The curves well represent the experimental points, indicating that there exists a certain ion-free inner layer in the nitrobenzene solution side of the interface.

The change of γ_{pzc} with $\ln(a^{\pm,NB}_{TBATPB})$ was calculated from

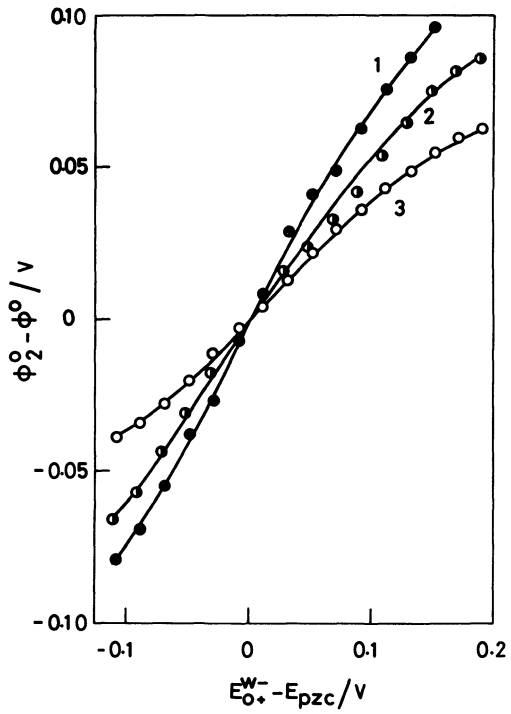

Fig. 10. Potential at outer Helmholtz plane in nitrobenzene solution side of the interface as a function of rational potential difference at (1): 0.02, (2): 0.05, and (3): 0.17 mol dm^{-3} tetrabutylammonium tetraphenylborate.

$$\gamma_{pzc} = (\gamma_{pzc})_{c_{TBATPB}^{NB}=0.1} + 2RT\int_{\ln(0.61)}^{\ln(a_{TBATPB}^{\pm,NB})} -(x_{TBATPB}^{NB}/x_{NB}^{NB})^{i}\Gamma_{NB}\,d\ln(a_{TBATPB}^{\pm,NB}). \quad (20)$$

The lower limit of the integration corresponds to $\ln(a_{TBATPB}^{\pm,NB})$ when $c_{TBATPB}^{NB}=0.1$ mol dm^{-3}. The calculated curve well reproduces the experimental data, as shown in Fig. 8.

The Esin-Markov plots at several constant q^W values for the nitrobenzene phase are shown in Fig. 9. The coefficient of the plot when ${}^{i}\Gamma_{TPB}=0$ (or $\partial^{i}\Gamma_{TPB}/\partial q^W=0$) and $\partial^{i}\Gamma_{NB}/\partial q^W=0$ is given, analogously to the case of the aqueous phase, by

$$\left(\frac{\partial E_{O+}^{W-}}{\partial \ln(a_{TBATPB}^{\pm,NB})}\right)_{q^W,\mu_{j\neq TBATPB}} = -2RT\left(\frac{\partial^{d}\Gamma_{TPB}}{\partial q^W}\right)_{\mu_j} = -\frac{RT}{F}\left(1+\frac{q^W/2}{[(q^W/2)^2+(A^{NB})^2]^{1/2}}\right). \quad (21)$$

Accordingly, the coefficient should reduce to $-2RT/F$, $-RT/F$, and 0 when $q^W \gg 0$, $q^W=0$, and $q^W \ll 0$, respectively. At the pzc, the experimental plot in Fig. 9 has the slope of -24 mV, which is close to $-RT/F=-25.6$ mV. The slope of the plots in Fig. 9 increases with the increase of q^W, which is consistent with the prediction of Eq. 21.

We calculated the potential at the outer Helmholtz plane in the nitrobenzene side (OHP(NB)), ϕ_2^0, referred to the inner potential in the bulk of the nitrobenzene phase, ϕ^0, by using the Gouy-Chapman theory:

$$\phi_2^0 - \phi^0 = \frac{2RT}{F}\sinh^{-1}[q^W/(2A^{NB})]. \quad (22)$$

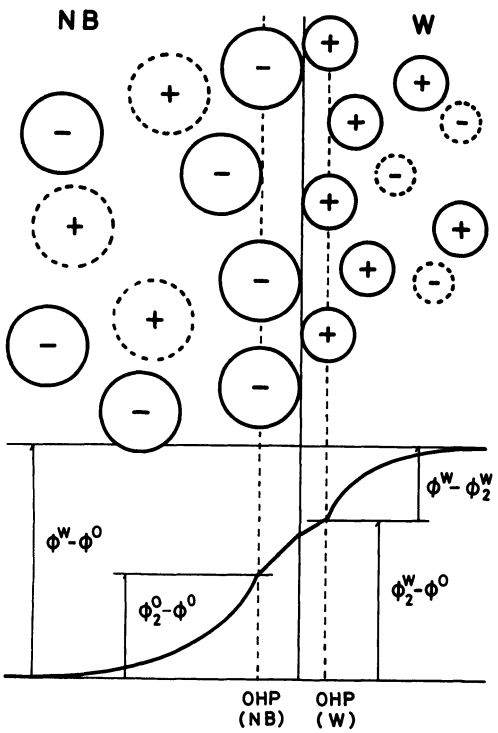

Fig. 11. Schematic representation of the double layer structure and potential profile of the interface between aqueous solution of lithium chloride and nitrobenzene solution of tetrabutylammonium tetraphenylborate.

The calculated values at three concentrations of TBATPB are plotted in Fig. 10.

Electrical Double Layer at Nitrobenzene–Water Interface. The above discussion shows that in the concentration range and the potential range studied, the adsorption of all the ions at the nitrobenzene–water interface primarily occurs in the diffuse parts of the double layer in both sides of the interface and that there exists an ion-free inner layer between the two diffuse layers. The double layer structure of the interface may then be schematically represented by Fig. 11.

The potential drop across the two inner layers, $\Delta\phi_{O2}^{W2}=\phi_2^W-\phi_2^{NB}$, can be expressed by

$$\Delta\phi_{O2}^{W2} = E_{O+}^{W-} - E_{pzc} - (\phi_2^0-\phi^0) - (\phi^W-\phi_2^W) + \Delta\phi_{O,pzc}^{W}, \quad (23)$$

where $\Delta\phi_{O,pzc}^{W}$ is the inner potential difference between the two phases, *i.e.*, $\Delta\phi_O^W=\phi^W-\phi^O$ at the pzc. The value of $\Delta\phi_{O2}^{W2}-\Delta\phi_{O,pzc}^{W}$ at various concentrations of LiCl and TBATPB are plotted in Fig. 12 as a function of q^W. The experimental points in the positive q^W region are scattered on a single curve with only small deviations. This indicates the virtual invariance of the structure of the inner layer with the change of the concentration of the electrolytes at a given value of q^W and is consistent with the previous conclusion of the absence of ions in the inner layers. The slope of the curve at $q^W=2$ μC cm^{-2} gives the inner layer capacity of 90 μF cm^{-2}, which is in agreement with the value of 83 μF cm^{-2} estimated from the differential capacity measurement of the interface.[19] These values are much higher than the inner layer capacity at the interface between mercury and aqueous solution.[17] Figure 12 also shows that

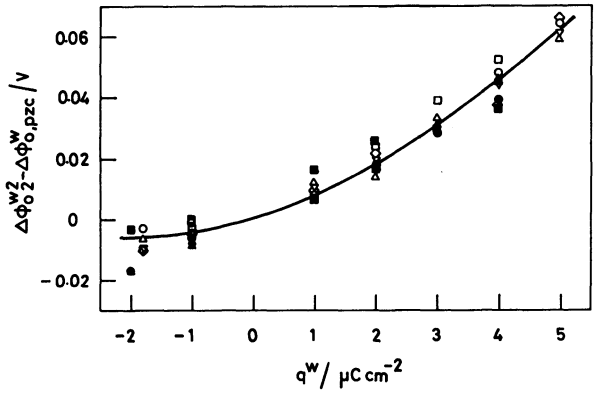

Fig. 12. Change of the inner layer potential difference across the two outer Helmholtz planes $\Delta\phi_{02}^{w2}$ with the change of the surface charge density in aqueous phase at various solution compositions. The concentration of lithium chloride is 0.05 (□), 0.1 (△), 0.2 (◇), 0.5 (▽) and 1.0 (○) mol dm^{-3} when the concentration of tetrabutylammonium tetraphenylborate is 0.1 mol dm^{-3} and the concentration of tetrabutylammonium tetraphenylborate is 0.05 (■), 0.1 (●), and 0.17 (▲) mol dm^{-3} when the concentration of lithium chloride is 0.1 mol dm^{-3}.

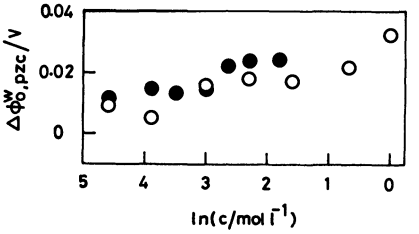

Fig. 13. Potential drop across the two outer Helmholtz planes as a function of the concentrations of tetrabutylammonium tetraphenylborate (●) and of lithium chloride (○).

$\Delta\phi_{02}^{w2}$ increases with the increase of q^w. The slope also becomes larger with increasing q^w, which indicates the decrease of the inner layer capacity with increasing q^w.

The absolute magnitude of $\Delta\phi_{02}^{w2}$ can be evaluated if the value of $\Delta\phi_{0,pzc}^{w}$ is known. In the cell (I) the sum of the potential drops across the phases I and III, and V and VII, $\Delta\phi_{I}^{III}+\Delta\phi_{V}^{VII}$, was calculated from the relation: $\Delta\phi_{I}^{III}+\Delta\phi_{V}^{VII}=(RT/F)\ln(a_{LiCl}^{\pm,w}/a_{TBACl}^{\pm,w})$. The potential drop across the phase III and IV, $\Delta\phi_{III}^{IV}$, was calculated by the theory of the mixed ion transfer potential[9] to be 247.1 mV when $a=b=0.1$ mol dm^{-3} in the cell (I). In the calculation, simultaneous ion transfer of a primary ion (TBA^+) and its co-ion (Cl^-) in the absence of supporting electrolyte was taken into account and the values of the standard ion transfer potentials of ions from water to nitrobenzene were taken as −0.248 and −0.324 V for TBA^+ and Cl^- ions, respectively.[20] Thus, $\Delta\phi_{0,pzc}^{w}$ was estimated by $\Delta\phi_{0,pzc}^{w}=E_{pzc}-(\Delta\phi_{I}^{III}+\Delta\phi_{III}^{IV}+\Delta\phi_{V}^{VII})$. The result is shown in Fig. 13 as a function of the logarithm of the concentrations of TBATPB and LiCl. The $\Delta\phi_{0,pzc}^{w}$ value was always positive and nearly constant at 20 mV when the electrolyte concentration in the two phases was changed. This value is less than one third of the surface potential at the mercury–water interface at the pzc.[21] Such a small surface potential may imply the compensation of the surface potential due to the water dipoles with that of oppositely oriented nitrobenzene dipoles in the inner layer and/or the less oriented structure of the inner layer compared with that at the mercury–water interface.

While this paper was under preparation, Samec *et al.*'s paper[22] on the study of the double structure at the nitrobenzene–water interface appeared. These authors have measured the differential capacity at the interface and analyzed their results with the assumption that the potential at the minimum in the capacity *vs.* potential curve corresponds to the potential of zero charge. However, the capacity minimum occurs at 0.303 V[19] in our system, when $a=b=c=0.1$ mol dm^{-3} in the cell (I), which is 38 mV more positive than the pzc. Also, these authors have estimated $\Delta\phi_{0,pzc}^{w}$ to be 42 mV irrespective of the concentration of LiCl and suggested that the variation of $\Delta\phi_{02}^{w2}$ with q^w is negligible, which is at variance with the present results (see Fig. 12). Gross *et al.*[4] have reported on the basis of the electrocapillary measurements of the non-polarized nitrobenzene–water interface that $\Delta\phi_{0,pzc}^{w}=1$ mV. In their estimation, however, they assumed that the electrocapillary maximum of the non-polarized nitrobenzene–water interface gives the potential of zero charge. This assumption is not generally valid in non-polarized interfaces.[5]

Electrochemical Oxidation and Reduction of Flavin-Adenine Dinucleotide Adsorbed on a Mercury Electrode Surface

Tadaaki KAKUTANI, Isao KATASHO, and Mitsugi SENDA
Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606
(Received December 23, 1982)

The electrochemical redox reaction of flavin-adenine dinucleotide (FAD) adsorbed on a hanging mercury drop electrode was studied in a pH 6.9 phosphate buffer by means of cyclic d.c. and a.c. voltammetry. Both the oxidized and reduced forms of FAD were strongly adsorbed on the mercury electrode surface. At the surface concentrations of FAD, Γ, lower than 5.0×10^{-11} mol cm^{-2}, the cyclic d.c. and a.c. voltammetric behavior of adsorbed FAD was explained by the theory for a two-step one-electron surface redox reaction. The formal redox potential, semiquinone formation constant, and charge transfer rate constant for the surface redox reaction of FAD and the interaction parameter of adsorbed FAD species were determined. Cyclic d.c. voltammetry and differential capacity measurement showed that, as Γ exceeded 5×10^{-11} mol cm^{-2}, the reorientation of adsorbed FAD molecules occurred. At $\Gamma>5.8\times10^{-11}$ mol cm^{-2}, the semiquinone formation constant was very small and the behavior was interpreted by the theory of a single-step two-electron surface redox reaction. The electrochemical surface redox properties of FAD adsorbed on a mercury electrode surface appear to depend on the orientation mode of adsorbed FAD molecules.

In a previous paper[1] we have shown that a stable adsorption monolayer of flavin mononucleotide (FMN) is formed on a mercury electrode surface and that the electrochemical redox reaction of the adsorbed FMN is well explained by the theory of a two-step one-electron surface redox reaction. The apparent charge transfer rate constants, redox potentials, and semiquinone formation constants of the surface redox reaction have been determined at pH 6.9 and 4.9 using cyclic d.c. and a.c. voltammetry. Recently the electrochemical behavior of flavin-adenine dinucleotide (FAD) irreversibly adsorbed on graphite and glassy carbon electrode has been studied by Gorton and Johansson[2] and Huck[3,4] using cyclic d.c. voltammetry. The (apparent) charge transfer rate constant of *ca.* 1 s^{-1} for FAD adsorbed on graphite electrode at pH 1.05[2] and the semiquinone formation constant of 2.6 for FAD adsorbed on glassy carbon electrode at pH 7[3] are reported. The charge transfer rate constant obtained by the former authors is considerably smaller compared with that for FMN adsorbed on a mercury electrode,[1] though the isoalloxazine moiety is oxidized or reduced in both the redox reactions of the adsorbed FMN and FAD. It seems interesting to determine the charge transfer rate constant of FAD adsorbed on a mercury electrode and to compare the results with those obtained with FAD adsorbed on a carbon electrode and to elucidate whether the difference, if any, should be ascribed to the difference in the electrode material.

In this work the electrochemical redox reaction of FAD adsorbed on a hanging mercury drop electrode has been studied in a pH 6.9 phosphate buffer by means of cyclic d.c. and a.c. voltammetry. We have determined the kinetic and equilibrium parameters of the surface redox reaction of FAD at the various surface concentrations and found that the charge transfer rate constant and the semiquinone formation constant depend on the orientation mode of the adsorbed FAD molecules. The results and discussion are presented here.

Experimental

Flavin-adenine dinucleotide (FAD) and other chemicals were commercially-available reagent grade materials and were used as received.

All voltammetric measurements were performed in a dark box at 25 °C under potentiostatic conditions with a three-electrode system consisting of a hanging mercury drop working electrode, a coiled platinum counter electrode, and a saturated calomel reference electrode (SCE). The hanging mercury drop electrode (HMDE) was a Metrohm drop electrode E410, the surface area being 0.0187 ± 0.0003 cm^2. Buffer solution containing 0.2 mol dm^{-3} sodium dihydrogenphosphate-disodium hydrogenphosphate of pH 6.9 was used as the base solution. The ionic strength was adjusted to 0.5 mol dm^{-3} with potassium nitrate. D.c. and a.c. voltammograms were recorded after a fresh mercury drop from the HMDE had been exposed to a test solution for a given period of time, referred to in the following as the exposure time, t_{exp}, at a constant d.c. potential, E_i. All potentials were measured against a saturated calomel electrode (SCE). The d.c. voltage scan was started from E_i with the scan rates, v, of 98 mV s^{-1} for cyclic d.c. voltammetry and of 18 mV s^{-1} for a.c. voltammetry unless otherwise stated. Other details concerning the apparatus and methods of electrochemical measurements have been described elsewhere[1]

Results

Electrochemical measurements were performed at concentrations of FAD, C_{FAD}, lower than 3.6×10^{-6} mol dm^{-3}, at which the current due to the redox reaction of diffusing, unadsorbed FAD will be negligibly small compared with the current due to the surface redox reaction of FAD confined to the electrode surface by adsorption. The exposure time, t_{exp}, was varied from 0.5 to 5 min. In cyclic d.c. voltammetry FAD gave a pair of peak-shaped cathodic and anodic waves characteristic of the surface redox reaction at -0.40 V, which is attributable to the redox reaction of the isoalloxazine moiety.[1] The waves appeared in various shapes, depending on the exposure time and bulk concentration of FAD (Fig. 1), *i.e.*, on the surface concentration of FAD accumulated on the electrode surface during the exposure time. Figure 1 shows cyclic d.c. voltammograms of 2.7×10^{-6} mol dm^{-3} FAD, recorded after three different exposure times; the voltammograms A, B, and C were recorded at $t_{exp}=70$, 90, and 120 s, respec-

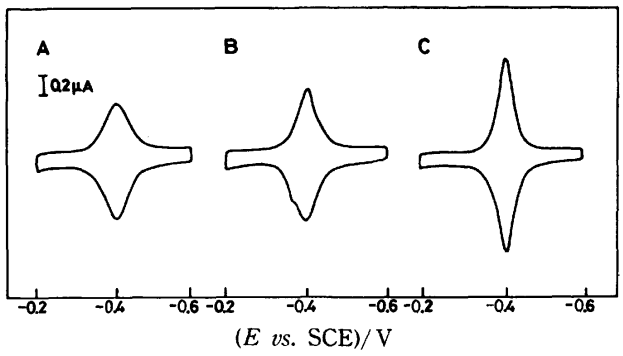

Fig. 1. Cyclic d.c. voltammograms of 2.7×10^{-6} mol dm^{-3} FAD recorded in a pH 6.9 phosphate buffer after three different t_{exp}'s at $E_i=-0.20$ V *vs.* SCE. t_{exp}: (A) 70 s, (B) 90 s, (C) 120 s.

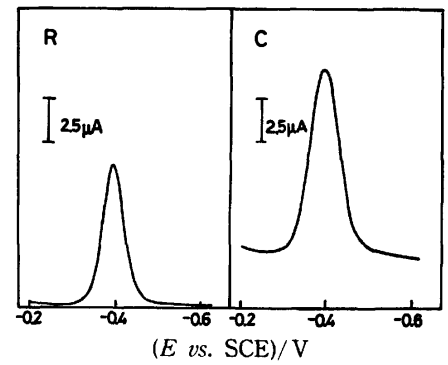

Fig. 2. A.c. voltammograms of 8.1×10^{-7} mol dm^{-3} FAD in a pH 6.9 phosphate buffer at 500 Hz. D.c. voltage scan was started from $E_i=-0.20$ V *vs.* SCE after $t_{exp}=$ 5 min. R Real component, C: imaginary component.

tively, at $E_i=-0.20$ V. In this study the surface concentrations of FAD, Γ, were estimated from the area under the cyclic d.c. wave (corrected for the base current) by assuming that the number of electron transferred for each molecule of FAD is equal to 2 and that $m_1/n_1=m_2/n_2=1$[5] or $m/n=1$.[6] When the surface concentration of FAD was lower than 5.0×10^{-11} mol cm^{-2}, the shapes of the cyclic d.c. waves were broadened and flattened as seen by voltammogram A in Fig. 1, of which Γ was estimated at 4.9×10^{-11} mol cm^{-2}. When Γ exceeded 5.0×10^{-11} mol cm^{-2} and approached 5.8×10^{-11} mol cm^{-2}, the waves became narrower and sharper (see voltammogram C in Fig. 1). In the intermediate surface concentrations of FAD, *i.e.*, 5.0×10^{-11} mol cm^{-2} $<\Gamma<5.8\times10^{-11}$ mol cm^{-2}, the wave shape was asymmetrical and deformed (see voltammogram B in Fig. 1) and changed sensitively with Γ. Quite interestingly the electrochemical behavior of the adsorbed FAD at $\Gamma<5.0\times10^{-11}$ mol cm^{-2} was different from that at $\Gamma>5.8\times10^{-11}$ mol cm^{-2}. In the following the surface concentration of FAD lower than 5.0×10^{-11} mol cm^{-2} will be referred to as the low surface concentration, whereas the surface concentration higher than 5.8×10^{-11} mol cm^{-2} will be referred to as the high surface concentration.

Cyclic d.c. and a.c. Voltammetric Behavior at the Low Surface Concentration. When $\Gamma<5.0\times10^{-11}$ mol cm^{-2}, *i.e.*, at the low surface concentration, the electrochemical behavior of FAD adsorbed on the HMDE was essentially the same[8] as that of FMN adsorbed on the HMDE.[1] In cyclic d.c. voltammetry, the peak heights of the cathodic and anodic waves, I_{pc} and I_{pa}, after correction for the base currents, were proportional to the potential scan rate, v, between 32 and 192 mV s^{-1}, and also to Γ at $\Gamma<5.0\times10^{-11}$ mol cm^{-2} (Fig. 3). The peak height ratio I_{pa}/I_{pc} was unity in the above-stated ranges of v and Γ when corrected for the difference between the amounts of the adsorbed FAD at the cathodic and anodic peak potentials due to the difference in t_{exp}. The peak potentials of the cathodic and anodic waves, E_{Pc}^{DC} and E_{Pa}^{DC}, coincided with each other and were independent of both v and Γ; $E_{Pc}^{DC}=E_{Pa}^{DC}=-0.40$ V. The half-peak widths of the cathodic and anodic waves, $\Delta E_{p/2.c}^{DC}$ and $\Delta E_{p/2.a}^{DC}$, were also independent within experimental errors of both v and Γ; $\Delta E_{p/2.c}^{DC}=\Delta E_{p/2.a}^{DC}=$ 70 ± 3 mV.

Figure 2 shows representative real and imaginary components of a.c. voltammograms of adsorbed FAD at $\Gamma<5.0\times10^{-11}$ mol cm^{-2}; the voltammograms were recorded after the electrode had been exposed to the electrolysis solution containing 8.1×10^{-7} mol dm^{-3} FAD for $t_{exp}=5$ min at $E_i=-0.20$ V, where $\Gamma$was estimated at 3.0×10^{-11} mol cm^{-2} from the cyclic d.c. wave measured under the same conditions. The peak potentials of the real and imaginary components, E_p^{real} and E_p^{imag}, were independent of the ac frequency in the range between 100 and 500 Hz, and also of Γ less than 5.0×10^{-11} mol cm^{-2}. They agreed with each other and with the peak potentials of the cyclic d.c. waves; $E_p^{real}=E_p^{imag}(=E_p^{AC})=-0.40$ V. The ratio of the peak height of the real component ($\delta_1 I_p^{real}$) to that of the imaginary component ($\delta_1 I_p^{imag}$), $(\delta_1 I_p^{real}/\delta_1 I_p^{imag})_{E=E_p^{AC}}$, was proportional to the a.c. frequency between 100 and 500 Hz.

Cyclic d.c. and a.c. Voltammetric Behavior at the High Surface Concentration. When Γ exceeded 5.8×10^{-11} mol cm^{-2}, *i.e.*, at the high surface concentration, the shape of the cyclic d.c. waves became narrower and sharper compared with those observed at the low surface concentration (see Fig. 1). Table 1 shows the scan rate dependence of the peak heights, peak potentials, and half-peak widths of the cyclic d.c. voltammograms. The voltammograms were recorded with various scan rates after the electrode had been exposed to 3.6×10^{-6} mol dm^{-3} FAD solution for $t_{exp}=2$ min at $E_i=-0.20$ V, when the surface concentration of FAD was estimated at 6.7×10^{-11} mol cm^{-2}. E_{Pc}^{DC} and E_{Pa}^{DC} agreed with each other and were independent of both v and Γ; $E_{Pc}^{DC}=E_{Pa}^{DC}(=E_P^{DC})=-0.40$ V. $\Delta E_{p/2.c}^{DC}$ and $\Delta E_{p/2.a}^{DC}$ were practically invariant with both v and Γ; $\Delta E_{p/2.c}^{DC}=\Delta E_{p/2.a}^{DC}=43\pm0.7$ mV. Both I_{pc} and I_{pa} were proportional to v (Table 1) and increased linearly with Γ at $\Gamma>5.8\times10^{-11}$ mol cm^{-2} as shown in Fig. 3. The peak height ratio I_{pa}/I_{pc} was unity independently of v and Γ.

The a.c. voltammetric behavior of adsorbed FAD at the high surface concentration was different from that at the low surface concentration described above. Figure 4 shows a.c. voltammograms of 3.6×10^{-6} mol dm^{-3} FAD at two a.c. frequencies, 100 and 500 Hz;

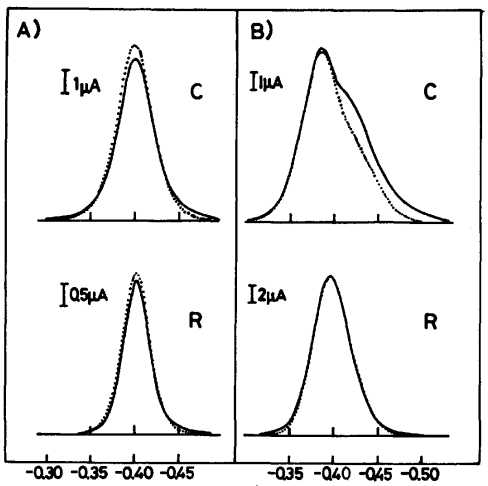

Fig. 4. A.c.voltammograms of 3.6×10^{-6} mol dm^{-3} FAD recorded after $t_{exp}=2$ min at $E_i=-0.20$ V *vs.* SCE at (A) 100 Hz and (B) 500 Hz. R: Real component, C: imaginary component. Dotted lines represent theoretical voltammograms calculated by Eqs. 5 and 6 using $E'_0=-0.400$ V *vs.* SCE, $k_{sap}=5.12\times10^2$ s^{-1}, $J=1.5$, $G=0.13$, $\theta_t=0.957$ and $\Gamma^{max}=7.0\times10^{-11}$ mol cm^{-2}.

the voltammograms were recorded after $t_{exp}=2$ min at $E_i=-0.20$ V, when Γ was estimated at 6.7×10^{-11} mol cm^{-2} from the corresponding cyclic d.c. wave. The peak potentials of the real and imaginary components shifted to a more positive potential with an increase in the a.c. frequency as shown in Table 2. In addition, the wave shapes, in particular, of the imaginary components changed from a nearly symmetrical to an asymmetrical one with a shoulder with increasing a.c. frequency. However, the current ratio of the real component to the imaginary one measured at $E=E_P^{pc}$, $(\delta_1 I_F^{real}/\delta_1 I_F^{imag})_{E=E_P^{pc}}$, was proportional to a.c. frequency as shown in Fig. 5.

Discussion

Adsorption of FAD on Mercury Electrode Surface. The cyclic d.c. voltammetric data given above indicate that both the oxidized and reduced forms of FAD are strongly adsorbed on the HMDE surface. Figure 6 shows the dependence of the cathodic peak height, I_{pc}, on t_{exp} at various concentrations of FAD. In this figure the points below the broken line correspond to the cyclic d.c. voltammograms at the low surface concentration, *i.e.*, at $\Gamma<5.0\times10^{-11}$ mol cm^{-2} (see Fig. 1A), whereas the points above the line correspond to the voltammograms at the high surface concentration, *i.e.*, at $\Gamma>5.8\times10^{-11}$ mol cm^{-2} (see Fig. 1C), and the points in parentheses correspond to the intermediate surface concentration between 5.0×10^{-11} and 5.8×10^{-11} mol cm^{-2}. At $C_{FAD}\leq1.08\times10^{-6}$ mol dm^{-3}, the peak height I_{pc} (and also I_{pa}) increased linearly with the

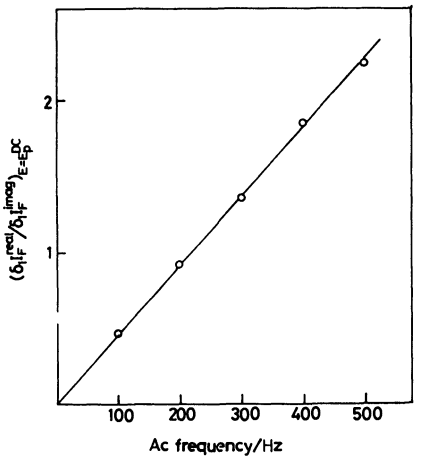

Fig. 5. Frequency dependence of the ac current ratio at $E=E_p^{dc}$, $(\delta_1 I_p^{real}/\delta_1 I_p^{imag})_{E=E_p^{dc}}$. A.c. voltammograms were recorded after the electrode had been exposed to 3.6×10^{-6} mol dm^{-3} FAD solution for $t_{exp}=2$ min at $E_i=-0.20$ V *vs.* SCE.

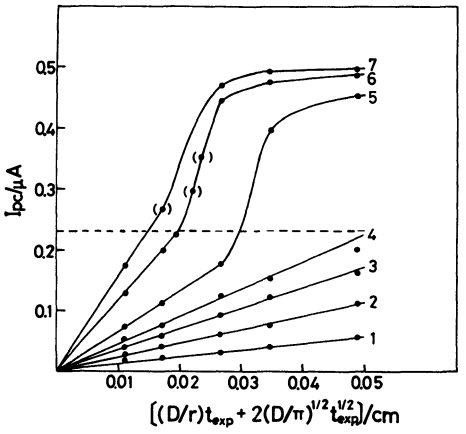

Fig. 6. Plot of I_{pc} against $[(D/r)t_{exp}+2(D/\pi)^{1/2}t_{exp}^{1/2}]$ at pH 6.9. Bulk concentrations of FAD in mol dm^{-3} are: (1) 2.7×10^{-7}; (2) 5.4×10^{-7}; (3) 8.1×10^{-7}; (4) 1.08×10^{-6}; (5) 1.62×10^{-6}; (6) 2.7×10^{-6}; (7) 3.6×10^{-6}.

$[(D/r)t_{exp}+2(D/\pi)^{1/2}t_{exp}^{1/2}]$ function, where D is the diffusion coefficient of FAD, which was estimated to be 2.4×10^{-6} cm^2 s^{-1} from the d.c. polarographic data, using the Ilkovič equation, and r is the radius of the HMDE, which was estimated to be 0.038 cm. In addition, the slopes of the linear plots were proportional to C_{FAD}. These results indicate the diffusion-controlled adsorption of FAD at the mercury electrode surface.[1,9] On the other hand, at $C_{FAD}\geq1.62\times10^{-6}$ mol dm^{-3}, as t_{exp} increased the wave shapes changed from a broad (see Fig. 1A) to a sharp one (see Fig. 1C) and the peak height I_{pc} increased and attained a maximum value, when Γ reached a maximum value, Γ^{max}. The Γ^{max} value was estimated to be 7.0×10^{-11} mol cm^{-2} from the cyclic d.c. voltammogram. If we assume that an FAD molecule is adsorbed on the electrode surface with its isoalloxazine ring plane parallel but its adenine ring plane vertical to the electrode surface, a CPK molecular model gives $\Gamma^{max}=7.5\times10^{-11}$ mol cm^{-2}. On the other hand, when both the ring planes are oriented parallel

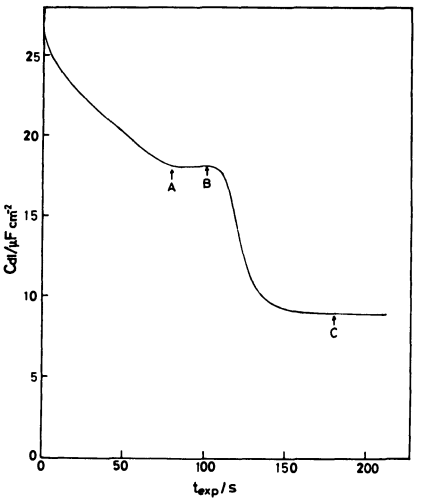

Fig. 7. t_{exp}-dependence of C_{dl} measured in 2.7×10^{-6} mol dm^{-3} FAD solution at -0.20 V *vs.* SCE at pH 6.9.

to the electrode surface, it gives $\Gamma^{max}=5.2\times10^{-11}$ mol cm^{-2}. These results suggest that at the low surface concentrations, *i.e.*, at $\Gamma<5.0\times10^{-11}$ mol cm^{-2} FAD molecule is adsorbed probably with both isoalloxazine and adenine ring planes oriented parallel to the electrode surface, and that, as the surface concentration of FAD exceeds 5.0×10^{-11} mol cm^{-2}, reorientation of the adsorbed FAD molecule occurs, resulting in an adsorbed FAD molecule probably with the isoalloxazine ring plane oriented parallel and the adenine ring plane oriented vertical to the electrode surface. This reorientation of the adsorbed FAD molecule should cause the observed transition in the voltammetric behavior of FAD at the HMDE.

The reorientation of the adsorbed FAD molecules was further indicated by the differential capacity measurement. Figure 7 shows the t_{exp}-dependence of the differential capacity, C_{dl}, at -0.20 V, where no faradaic current takes place, in 2.7×10^{-6} mol dm^{-3} FAD solution. Under these experimental conditions the surface concentrations of FAD at various t_{exp}'s were estimated from the corresponding cyclic d.c. voltammograms as: $\Gamma=5.0$, 5.8, and 6.9×10^{-11} mol cm^{-2} at $t_{exp}=$ 80, 100, and 180 s, respectively (marked by arrows A, B, and C, respectively, in Fig. 7). If the orientation mode of the adsorbed molecules remains unchanged in spite of an increase in Γ and if the relative decrease of the double layer capacitance is proportional to the surface concentration of the adsorbed molecules, then the double layer capacitance can be written as

$$C_{dl} = C_{dl}^{\circ} + (C_{dl}^{max}-C_{dl}^{\circ})(\Gamma/\Gamma^{max}), \quad (1)$$

where C_{dl}° and C_{dl}^{max} are the double layer capacitances in the absence of adsorbed FAD and at the maximum adsorption of FAD, respectively. That is, the double layer capacitance should decrease monotonically with the increase of Γ. Actually, for $t_{exp}<70$ s the decrease in the double layer capacitance, $\Delta C_{dl}=C_{dl}^{\circ}-C_{dl}$, was proportional to the $[(D/r)t_{exp}+2(D/\pi)^{1/2}t_{exp}^{1/2}]$ function as shown in Fig. 8, indicating the diffusion-controlled adsorption of FAD for $t_{exp}<70$ s. Substituting $\Gamma=[(D/r)t_{exp}+2(D/\pi)^{1/2}t_{exp}^{1/2}]C_{FAD}$ into Eq. 1, the slope of

the ΔC_{dl} *vs.* $[(D/r)t_{exp}+2(D/\pi)^{1/2}t_{exp}^{1/2}]$ plot can be given by $[(C_{dl}^{\circ}-C_{dl}^{max})\times C_{FAD}/\Gamma^{max}]$. If we assume that $C_{dl}^{max}=C_{dl}$ at $t_{exq}=80$ s and $\Gamma^{max}=5.0\times10^{-11}$ mol cm^{-2}, the slope can be calculated to be 4.6×10^{2} μF cm^{-3}, which agreed reasonablly well with the experimental value of 4.2×10^{2} μF cm^{-3} obtained from the plot in Fig. 8. These results show that the decrease of C_{dl} with t_{exp} at $t_{exp}<70$ s can be explained by the diffusion-controlled monolayer adsorption of FAD, approaching monotonically to the maximum adsorption near at $t_{exp}=80$ s or $\Gamma=5.0\times10^{-11}$ mol cm^{-2}, which is the maximum adsorption at the low surface concentration. At $t_{exp}>100$ s or $\Gamma>5.8\times10^{-11}$ mol cm^{-2}, C_{dl} decreased abruptly and approached a small value, approximately one half of the value at $\Gamma=5.0\times10^{-11}$ mol cm^{-2}, near at $t_{exp}=180$ s or $\Gamma=7.0\times10^{-11}$ mol cm^{-2}, which is the maximum adsorption at the high surface concentration. The decrease in the capacitance implies an increase in the effective thickness of the adsorbed FAD layer. This interpretation agrees with the above-stated reorientation mechanism of adsorbed FAD molecules when the surface concentration exceeds 5.8×10^{-11} mol cm^{-2}.

Surface Redox Reaction of FAD Adsorbed on the HMDE. A) Surface Redox Reaction at the Low Surface Concentration: As described above the cyclic d.c. and a.c. voltammetric behavior of the adsorbed FAD at the low surface concentration was essentially the same as that of the adsorbed FMN on the mercury electrode surface.[1] The behavior was explained also by the simplified equations[1,5] of the cyclic d.c. and a.c. voltammetry for a two-step surface redox reaction;

$$O_{ad} + e = S_{ad}$$
$$S_{ad} + e = R_{ad}. \quad (I)$$

The semiquinone formation constant, $K=[S_{ad}]^2/[O_{ad}][R_{ad}]$, was determined from the cyclic d.c. voltammograms as $K=1.5$ from $\Delta E_{p/2.c}^{DC}$ or $\Delta E_{p/2.a}^{DC}$ using Eq. 5 in Ref. 1 and $K=1.5$ from the slope of the I_{pc} *vs.* Γ plot (Fig. 3) using Eq. 6 in Ref. 1. The apparent (average) rate constants of the charge transfer, k_{sap}, were determined at several surface concentrations using Eq. 7 in Ref. 1. A linear dependence of ln k_{sap} on the surface coverage θ_t with a slope, a, of 1.0 was obtained, where $\theta_t\equiv\Gamma/\Gamma^{max}$ was estimated by taking $\Gamma^{max}=5.0\times10^{-11}$ mol cm^{-2}. The apparent rate constant at $\theta_t=0$, $k_{sap}(\theta_t\to0)$, was determined by the extrapolation of the ln k_{sap} *vs.* θ_t plot to $\theta_t=0$. Table 3 summarizes the values of the formal redox potential of the adsorbed redox couple O_{ad}/R_{ad}, E_o', as well as K, $k_{sap}(\theta_t\to0)$, Γ^{max}, and a. For reference the values of the electrochemical redox reaction parameters for the surface redox reactions of FMN[1] and riboflavin (RF)[8] at mercury electrode are also given in Table 3.

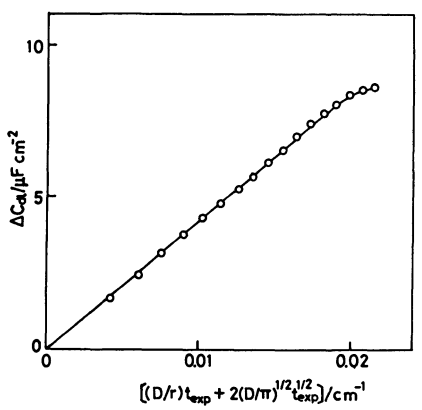

Fig. 8. Plot of ΔC_{dl} against $[(D/r)t_{exp}+2(D/\pi)^{1/2}t_{exp}^{1/2}]$ at pH 6.9. Data were taken from the results presented in Fig. 7.

Table 3. Electroche mical redox properties of flavins adsorbed on mercury electrode at pH 6.9

	RF[8]	FMN[1]	FAD[a]
$(E_o'$ *vs.*SCE)/V	−0.40	−0.41	−0.40
K	1.2	1.1	1.5
$k_{sap}(\theta_t\to0)/10^3$ s^{-1}	9.9	9.5	7.2
$\Gamma^{max}/10^{-11}$ mol cm^{-2}	8.9	8.0	5.0
a	2.0	1.3	1.0

a) Data obtained in this study at the low surface concentration (see text). Previous, less accurate data[8] on FAD were corrected as given here.

B) Surface Redox Reaction at the High Surface Concentration: As described above, at the high surface concentration, *i.e.*, 5.8×10^{-11} mol cm^{-2} $<\Gamma<7.0\times10^{-11}$ mol cm^{-2}, the half-peak widths of the cyclic d.c. waves were 43 mV, which suggest that the semiquinone formation constant K is very small. Therefore, the cyclic d.c. and a.c. voltammetric behavior of adsorbed FAD at the high surface concentration was interpreted in terms of a single-step two-electron surface redox reaction rather than a two-step one-electron surface redox reaction. According to the theory of cyclic d.c.[6,7] and a.c.[6] voltammetry for a single-step n-electron surface redox reaction,

$$O_{ad} + ne = R_{ad}, \quad (II)$$

in which the interactions between the adsorbed reactants are taken into account, the peak heights, I_{pc} and I_{pa}, the peak potentials, E_{Pc}^{DC} and E_{Pa}^{DC}, and the half-peak widths, $\Delta E_{p/2.c}^{DC}$ and $\Delta E_{p/2.a}^{DC}$, of the reversible cyclic d.c. voltammogram, and the real and imaginary components of the a.c. current, $\delta_1 I_F^{real}$ and $\delta_1 I_F^{imag}$, of d.c. reversible surface redox process can be written, for $\alpha=\beta=0.5$ and $n=m=2$ (see Ref. 6 for the details), as:

$$-I_{pc} = I_{pa} = (4F^2/RT)vA\Gamma_t(4-G\theta_t)^{-1} \quad (2)$$

$$E_{pc}^{DC} = E_{pa}^{DC} = E_o' = E_o + (RT/2F) \times[\ln(B_R/B_O) - (H\theta_t/2)] \quad (3)$$

$$\Delta E_{p/2.c}^{DC} = \Delta E_{p/2.a}^{DC} = (RT/F)|\ln(1+\gamma)/(1-\gamma) - (G\theta_t/2)| \quad (4)$$

$$\delta_1 I_F^{real} = 4(F^2/RT)\omega\Gamma_t A\delta_1 E \times \frac{\lambda\exp[-(G-J)\bar{f}\theta_t/2](1-\bar{f})^{3/2}\bar{f}^{3/2}}{\exp[-(G-J)\bar{f}\theta_t][1-G\theta_t(1-\bar{f})\bar{f}]^2+\lambda^2(1-\bar{f})\bar{f}} \quad (5)$$

$$\delta_1 I_F^{imag} = 4(F^2/RT)\omega\Gamma_t A\delta_1 E \times \frac{\exp[-(G-J)\bar{f}\theta_t][1-G\theta_t(1-\bar{f})\bar{f}]\bar{f}(1-\bar{f})}{\exp[-(G-J)\bar{f}\theta_t][1-G\theta_t(1-\bar{f})\bar{f}]^2+\lambda^2(1-\bar{f})\bar{f}}, \quad (6)$$

with

$$G = a_{OO} + a_{RR} - a_{OR} - a_{RO} \quad (7a)$$

$$H = a_{OO} - a_{RR} + a_{OR} - a_{RO} \quad (7b)$$

$$\gamma = [(4-G\theta_t)/(8-G\theta_t)]^{1/2} \quad (7c)$$

$$J = 2(a_{RR}-a_{RO}) \quad (7d)$$

$$\lambda = \omega/k_{sap} \quad (7e)$$

$$k_{sap} = k_s(B_O B_R)^{-1/2}\exp[-(a_{RR}+a_{OR})\theta_t/2], \quad (7f)$$

where B_i is the constant representing the adsorption energy of species i(i=O,R), a_{ij}(i,j=O,R) Frumkin's a-parameter of the interaction between the adsorbed species i and j, E_o^* and E_o are the formal potentials of the adsorbed redox couple O_{ad}/R_{ad} and of the redox couple O/R in the bulk of solution, respectively, ω and $\delta_1 E$ are the angular frequency and amplitude of the applied a.c. voltage, respectively, $\bar{f}$ is the mean ("d.c.") ffraction of the surface coverage defined by $\bar{f}=\bar{\Gamma}_O/\Gamma_t(\Gamma_t=\bar{\Gamma}_O+\bar{\Gamma}_R)$, $\bar{\Gamma}_i$ being the mean ("d.c.") value of the surface concentration of species i, θ_t the total surface coverage defined by $\theta_t=\Gamma_t/\Gamma^{max}$, and A the surface area of the electrode. $\bar{f}$ is related to the d.c. potential, $E_{d.c.}$ by

$$E_{d.c.} = E_o' + (RT/2F)[\ln(\bar{f}/(1-\bar{f})) + (1-2\bar{f})G\theta_t/2]. \quad (8)$$

The interaction parameter G can be determined from the half-peak widths of the cyclic d.c. voltammograms (Eq. 4). Application of Eq. 4 to the experimental results gave the average value of G as 0.13 ± 0.02 in the range of Γ between 5.8×10^{-11} and 7.0×10^{-11} mol cm^{-2}, *i.e.*, $0.83\leq\theta_t\leq1.0$. This G value leads us to the normalized peak heights of the d.c. waves, $\Phi=-I_{pc}/4(F^2/RT)v\Gamma_t A = I_{pa}/4(F^2/RT)v\Gamma_t A$, of 0.257 at $\theta_t=0.83$ and of 0.258 at $\theta_t=1.0$, which means that the peak heights are practically proportional to Γ_t, *i.e.*,

$$-I_{pc} = I_{pa} \cong 0.257(4F^2/RT)v\Gamma_t A. \quad (2')$$

Thus the (theoretical) slope of the I_{pc} *vs.* Γ_t plot can be calculated using Eq. 2′ to be 7.1×10^3 A cm^2 mol^{-1}, which agreed well with the experimental value of 7.0×10^3 A cm^2 mol^{-1}. Equation 3 predicts a linear dependence of E_{Pc}^{pc} or E_{Pa}^{pc} on θ_t for $H\neq0$. However, since θ_t varied between 0.83 and 1.0, the dependence of E_{Pc}^{pc} or E_{Pa}^{pc} on θ_t would not be experimentally detectable when $|H|$ is not so large. For example, the difference in E_{Pc}^{pc}'s between at $\theta_t=0.83$ and 1.0 is calculated to be 2.2 mV for $H=2$, which is well below the magnitude of experimental errors of the present determination. Thus we may conclude that the value of $|H|$ is not so large and should not exceed 2, which is a reasonable conclusion in view of Eq. 7.

Equations 5 and 6 predict that both the real and imaginary components are not symmetrical with respect to the E_o'-axis for $G\neq J$, that their peak potentials, E_p^{real} and E_p^{imag}, should shift positively for $G<J$ or negatively for $G>J$ with increasing a.c. frequency, and that the current ratio $(\delta_1 I_F^{real}/\delta_1 I_F^{imag})_{E_{d.c.}=E_o^*}$ should be proportional to a.c. frequency:

$$(\delta_1 I_F^{real}/\delta_1 I_F^{imag})_{E_{d.c.}=E_o'} = \omega/2k_{sap}\exp[-(G-J)\theta_t/4](1-G\theta_t/4). \quad (9)$$

The linear dependence of current ratio on the a.c. frequency was experimentally found, as shown in Fig. 5. Table 2 gives the experimental and calculated values of E_p^{real}, E_p^{imag}, $\Delta E_{p/2}^{real}$, and $\Delta E_{p/2}^{imag}$ of the surface redox reaction of adsorbed FAD at the high surface concentration, where the calculated values were obtained using the following values of the parameters: $E_o'=-0.400$ V, $k_{sap}=5.12\times10^2$ s^{-1}, $J=1.5$ and $G=0.13$. The a.c. peak currents are plotted against the a.c. frequency in Fig. 9, in which the solid lines are drawn by Eqs. 5 and 6 using the same values of the parameters as above. In Fig. 4 the dotted curves represent the theoretical a.c. voltammograms calculated by using the same values of the parameters as above, which are compared with the experimental voltammograms shown as solid lines. The agreement between the theory and experimental results seems reasonably good, except for curves C in Fig. 4B, in which the experimental asymmetric wave form is reproduced only semi-quantitatively by the present theory. These results indicate that the essential features of the cyclic d.c. and a.c. voltammetric behavior of adsorbed FAD at the high surface concentration can be reproduced by the theory of a single-step surface redox reaction in which the interaction between the adsorbed molecules are taken into account. It is interesting that the orientation mode of the adsorbed FAD molecules has a significant influence on the electrochemical properties of the surface redox reaction of FAD, such as the semiquinone formation constant and the charge transfer rate constant.

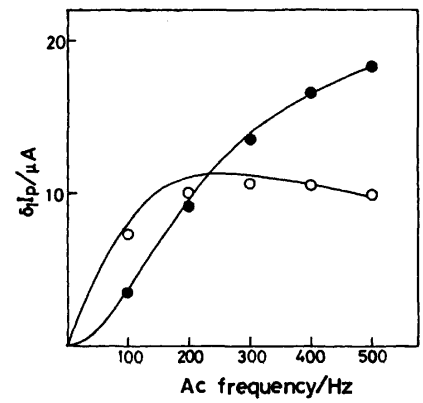

Fig. 9. Dependence of the a.c. peak heights of 3.6×10^{-6} mol dm^{-3} FAD on a.c. frequency at pH 6.9. A.c. voltammograms were recorded after $t_{exp}=2$ min at $E_i=-0.20$ V *vs.* SCE. ●: Real component, ○: imaginary component. Solid lines represent theoretical curves calculated by Eqs. 5 and 6 using the same values of the parameters as used in Fig. 4.

A Photoelectron Spectroscopic Estimation of the Concentrations of Simple Hydrogen-bonded Dimers Produced in the Temperature-controlled Supersonic Nozzle Beam

Shinji Tomoda and Katsumi Kimura*
Institute for Molecular Science, Myodaiji, Okazaki 444
(Received January 24, 1983)

A photoelectron spectroscopic method is proposed to estimate the ratio of number densities between the monomer and the dimer produced in the supersonic jet. Approximate monomer-dimer ratios have been estimated for water, methanol and formic acid by assuming that the photoionization cross sections of the monomer and dimer are equal to each other. The results show reasonable agreement under similar conditions to those available from mass spectrometric analyses of fragmentation patterns. A simple temperature-controlled supersonic nozzle beam source is described here, which enables us to produce hydrogen-bonded dimers in measurable amounts.

Supersonic nozzle beam technique has recently been drawing a considerable attention not only in the field of molecular beam scattering study but also in various kinds of molecular spectroscopic studies. This seems to be due to the advantageous characters of supersonic nozzle beams which produce molecular clusters (van der Waals molecules, hydrogen-bonded species, *etc.*) with relatively high concentrations and realize low temperature states for internal degrees of molecular freedoms.

Dehmer and Dehmer[1] have first demonstrated the potentiality of this technique in the field of photoelectron spectroscopic studies using inert gas dimers. However, no extensive application of this technique to various chemical species has been published, probably because of the difficulty in controlling the production of their dimers and clusters as well as in analyzing their concentrations quantitatively.

From the chemical points of view, it is important to investigate various kinds of molecular dimers and clusters by photoelectron spectroscopy as well as other molecular spectroscopy. However, in order to apply a supersonic nozzle beam technique to various chemical species which exist in the liquid phase under the normal condition, we have to overcome the following problems. The general criterion to use a supersonic nozzle beam system is to achieve sufficient supersonic expansion under proper stagnation and pumping conditions. For chemical species such as water and many other fundamental chemical compounds, it is essentially important to control the temperature of the whole nozzle beam system both for regulating the vapor pressure stable and for preventing the nozzle from clogging. An electric heating system for the nozzle is not suitable for photoelectron measurements, because of its disturbing electromagnetic field.

In this report we first describe the temperature-controlled supersonic nozzle beam source in detail, which has recently been constructed to measure HeI photoelectron spectra of the water dimer,[2] the methanol dimer,[3] and the formic acid dimer.[4] Secondly, we propose an approximate method to estimate the relative dimer concentration with respect to the monomer concentration from the subtraction procedure between photoelectron spectra of the monomer (reference) and the monomer-dimer mixture. This approach depending on the assumptions is still crude, but it offers a more straightforward interpretation for the dimer concentration than other methods such as mass spectrometry, at least for hydrogen bonded clusters. In the mass analysis of the hydrogen-bonded clusters, it is reported that the fragmentation pattern of these species are rather complicated for the quantitative analysis of neutral concentrations because of a serious protonation in ionization.

Experimental

Design of the temperature-controlled nozzle beam source used in photoelectron measurements is illustrated in Fig. 1. The design and performance of the photoelectron spectrometer combined with this nozzle beam system has been given elsewhere.[4] In the measurements discussed in this paper, a disk with a pinhole of 0.1 mm in diameter and 0.5 mm in thickness has been used in the nozzle.

In the present temperature-controlling system, a copper block ($34\times34\times28$ mm^3) is used as a heat bath for the nozzle, through which a temperature-regulated fluid is circulated. The stainless-steel tubing (8 mm in diameter) is thermally contacted with the heat bath by fastening with screws. The temperature of the top of the nozzle is measured by a copper-constantan thermocouple. A hole of 6 mm in diameter is drilled in the copper block, perpendicular to two parallel holes (6 mm in diameter). The open end of the drilled hole is plugged with a cylindrical block to form a U-shaped tunnel through which the fluid is circulated. The both ends of the U-shaped tunnel are connected with stainless steel bellows (CAJON 1/4″ flexible tubings). The other ends of the bellows are connected to the circulator through the vacuum flange by tubings. All the junctions were carefully brazed to be vacuum tight.

The temperature of the top of the nozzle is controlled by circulating an appropriate fluid from a temperature-regulated bath circulator (NESLAB EX-300). By using water as a circulating fluid, the nozzle temperature is controlled within ±0.3 K between 290 and 370 K. It is possible to raise the nozzle temperature up to about 500 K by using an appropriate circulating fluid and also to lower down to about 250 K by employing a refrigerated circulating bath (NESLAB EN-850). Flowing a cold nitrogen gas, we were able to lower the nozzle temperature down to 175 K in 40 min.

During photoelectron measurements, the vapor pressure of the sample is kept constant by heating a sample container made of stainless steel. Both the container and the pipeline which connects the nozzle to the container can separately be

heated by a mantle-shaped heater and a tape heater, respectively. When a 'seeding method' was employed,[4] a carrier gas such as helium or argon was bubbled through a liquid sample in the container. Three pairs of Helmholtz coils are used to compensate the earth's magnetic field, because of the difficulty in covering the ionization and electron energy analyzing regions by μ-metal plates completely.

Results and Discussion

The approximate dimer concentration with respect to the monomer concentration can be estimated from HeI photoelectron spectra by the following way. In the present analysis we consider some two-component (monomer-dimer) systems for which the resulting monomer-dimer ratio seems to be consistent with those of mass spectrometry under similar conditions.[5,6]

The Method of Analysis. Let us consider a series of photoelectron spectra which consist of (a) a normalized spectrum of a monomer-dimer mixture, (b) a normalized spectrum of the pure monomer (reference), and (c) the stripped spectrum, as illustrated schematically in Fig. 2. The first two spectra (a) and (b) in Fig. 2 are obtained directly from the photoelectron measurements followed by intensity normalization at the maxima. In the mixture spectrum (a), the ratio of the band area (S_d/S_m) between the first bands of the dimer and the monomer, for instance, should reflect the ratio of the concentrations between the dimer and the monomer in the supersonic jet. The stripped spectrum (c) is obtained in such a way that the intense monomer band in the mixture spectrum (a) should be reasonably cancelled by subtraction of the reference spectrum (b) with a proper ractor α. In other words, the following relationship holds for the photoelectron intensity curves which are given as a function of the photoelectron kinetic energy (E).

$$I_s(E) = I_m(E) - \alpha I_r(E), \quad (1)$$

where $I_m(E)$, $I_r(E)$, and $I_s(E)$ are the photoelectron intensities of the mixture spectrum, the reference spectrum and the stripped spectrum, respectively.

The number densities of the monomer (N_m) and the dimer (N_d) in the beam should be proportional to the band areas S_m and S_d, respectively, as can be expressed by the following equations.

$$S_m = \alpha \int_{band} I_r(E)dE = \alpha k_m \sigma_m N_m, \quad (2a)$$

and

$$S_d = \int_{band} I_s(E)dE = k_d \sigma_d N_d, \quad (2b)$$

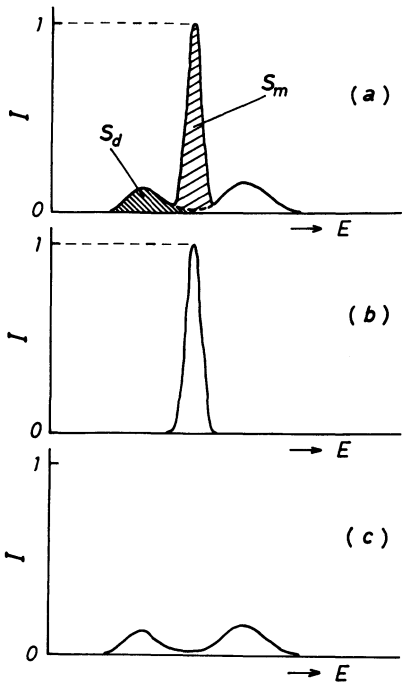

Fig. 2. An illustrative representation of the relation among (a) a normalized photoelectron spectrum of the monomer-dimer mixture ($I_m(E)$), (b) a normalized reference (monomer) spectrum ($I_r(E)$), and (c) the stripped spectrum: $I_s(E)=I_m(E)-\alpha I_r(E)$. Photoelectron intensity in each spectrum is a function of the kinetic energy (E). The monomer and dimer contributions (the shaded areas in spectrum (a)) are indicated by S_m and S_d, respectively.

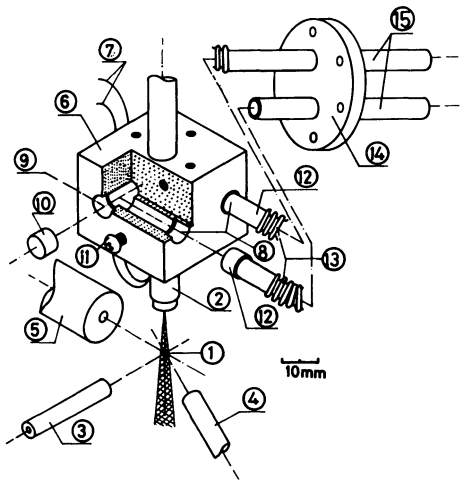

Fig. 1. A schematic drawing of the construction of the temperature-controlled supersonic nozzle beam source: (1) ionization region, (2) nozzle pipe, (3) glass capillary for the light beam, (4) copper tubing for the effusive source, (5) the first piece of an electrostatic lens system, (6) copper block heat bath, (7) copper-constantan thermocouple, (8) two parallel holes, (9) hole connecting the two parallel holes, (10) plug, (11) screw to fasten the nozzle pipe with the heat bath, (12) braze adopters, (13) bellows, (14) vacuum flange, and (15) tubings connected with the fluid circulator.

Table 1. Approximate dimer concentrations estimated from the photoelectron measurements

	Estimated dimer/monomer ratio[a]	Stagnation condition[b] T/K	P/Torr	Ref.
Water	0.06	335	390	2
Methanol	0.2	295—320	100—260	3
Formic acid	3	298	20+130(He)	4

a) Probable errors depend on the validity of the assumptions (see text). b) An aperture of 0.1 mm in diameter is used for the nozzle.

where σ_m and σ_d are the total photoionization cross sections of the monomer and the dimer, respectively. The constants k_m and k_d represent the difference in the angular distribution of photoelectrons, since the photoelectron transmission efficiencies at the same kinetic energy for the monomer and the dimer are equal to each other. It is easily noted from consideration of the differential photoionization cross section[7] that the ratio k_d/k_m would never exceed a factor of two even in the extreme case, when photoelectrons are measured at 90° with respect to the photon beam as in the present case.** Provided that the difference in the angular distribution is negligibly small, the monomer-dimer number density ratio is simply given by

$$N_d/N_m = \alpha(S_d\sigma_m/\sigma_d S_m). \quad (3)$$

Since we have no established knowledge on the ratio of σ_m and σ_d, let us assume $\sigma_d=\sigma_m$ to the crudest approximation. The resulting equation can give the order of the magnitude of the monomer-dimer number density ratio in the sample jet,

$$N_d/N_m \approx \alpha(S_d/S_m). \quad (4)$$

Results of Estimation. The relative dimer concentrations for water, methanol, and formic acid estimated from the previous measurements with a nozzle pinhole of 0.1 mm in diameter are summarized in Table 1, along with the stagnation conditions.

Before making a quantitative comparison between our photoelectron spectroscopic estimation and the available mass spectrometric analysis, we should note the following points.

(1) Production of the dimeric and polymeric species depends on the stagnation conditions and the nozzle characteristics (the shape and the size of the aperture and the depth of the throat), which are different in various studies. Therefore, in order to make proper comparisons of the results, the following experimental conditions should be specified: (a) the diameter and the depth of the aperture of the nozzle (the latter is sometimes not indicated in literatures) and (b) the stagnation pressure and temperature and also the composition of gases if the seeding method is applied.

(2) Fragmentation patterns of the hydrogen-bonded clusters in mass spectrometry seem to be rather complicated, depending on the ionizing projectile (electrons or photons) and its impact energy. No quantitative method to identify the original components from the relative abundance of the ions has been established yet. Under the condition where concentrations of higher polymers are negligible, however, the intensity ratio of the protonated ions (MH^+) or the sum of the protonated ion (MH^+) and the parent ion (M_2^+) with respect to the parent monomer ion (M^+) can be regarded as reflecting the neutral monomer-dimer ratio as a crudest approximation, since hydrogen-bonded dimers yield protonated monomer ions (MH^+) predominantly.[5,6,8-11]

Our monomer-dimer ratio for the water (6%) is in good agreement with the result of the ion intensity ratio ($H_3O^+/H_2O^+\approx 10\%$) reported by Dyke *et al.*[5] under the similar condition. For the methanol dimer, Odutola *et al.*[6] obtained a value of 8% for $(CH_3OH)H^+$ and 4% for $(CH_3OH)_2^+$ with respect to $(CH_3OH)^+$ under the stagnation condition of 317 K and 100 Torr (1 Torr=133.322 Pa). This result also shows a reasonable agreement with our present estimation. Cook *et al.*[8] have recently suggested larger relative concentrations of the dimer to higher polymers for methanol. However, their results cannot be compared directly with our present estimation, because their nozzle (conical, 0.33 mm in diameter) quite differs from ours both in the shape and size of the aperture.[9]

Our estimation of the dimer concentration for the formic acid gives a quite large value which means about three times more dimers than the monomer in the supersonic jet. There seems no available data on the mass analysis of the formic acid dimer for direct comparison. Recently, the temperature dependence of cluster formation for some carboxylic acids in the supersonic jet has been studied by Cook *et al.*[10] and by Mori *et al.*[11] by means of mass spectrometry. These studies have indicated that the dimer formation is extremely dominant for these cyclic dimers and it behaves as a monomer-dimer equilibrium mixture even in the supersonic jet. Therefore, it may be reasonable to understand the high dimer concentration of the present estimation for the formic acid as a "quasi-equilibrium" at a reduced pressure,[4] since about ten times higher dimer concentration (monomer : dimer =10% : 90%) is expected for the saturated formic acid vapor (about 40 Torr at 298 K) from the equilibrium constant by Coolidge.[13]

Conclusion

(1) By using the approximate method described above, the monomer-dimer number density ratio in the supersonic jet has been deduced from careful examinations of the stripping procedure involved in the photoelectron data analysis. The estimated values show reasonable agreements with the available results of mass spectrometric analysis.

(2) The deduction of HeI photoelectron spectra for some hydrogen-bonded dimers has clearly demonstrated the importance and the potentiality of the temperature-controlled nozzle beam source. The present nozzle system is especially suitable for electron spectroscopic measurements, because it is free from electromagnetic fields around the ionization region.

(3) A variety of its applications to molecular beam experiments may be expected not only for electron spectroscopic studies but also for other spectroscopic studies, especially because of its simple structure.

The authors are grateful to Mr. Toshio Horigome of the Institute for Molecular Science for his skilful and thorough work in constructing the present temperature-controlled supersonic nozzle beam source.

** The angular distribution of photoelectrons is given by the following equation,

$$d\sigma(\theta)/d\Omega = (\sigma_{tot}/4)[1-(\beta/4)(3\cos^2\theta-1)],$$

where σ_{tot} is the total photoionization cross section and β is the asymmetry parameter which ranges from -1 to 2.

Ylide-Metal Complexes. VII.[1] The Preparation and Properties of IIA Group Metal(Be, Mg) and IIIA Group Metal(Al, Ga, In) Complexes of Alkylidenetriphenylphosphoranes

Yoshihisa YAMAMOTO

Faculty of Pharmaceutical Science, Higashi Nippon Gakuen University, Ishikari-Tobetsu, Hokkaido 061-02

(Received November 15, 1982)

The reactions of $(C_6H_5)_3P{=}CH_2$ (**L**) with $BeCl_2$ or $MgCl_2$ in the mole ratio of 2 : 1 or 4 : 1 yield new dimeric compounds of di-μ-chloro-bis[(methylenetriphenylphosphorane)metal] dichloride, $[(C_6H_5)_3PCH_2\text{-}M\langle^{Cl}_{Cl}\rangle M\text{-}CH_2P(C_6H_5)_3]Cl_2$ (M: Be and Mg). The configuration of these metals is trigonal. The reactions of **L** with $AlCl_3$, $GaCl_3$ or $InCl_3$ in the mole ratio of 2 : 1 yield new compounds of di-μ-chloro-bis[bis(methylenetriphenylphosphorane)-metal] tetrachloride, $[\{(C_6H_5)_3PCH_2\}_2M\langle^{Cl}_{Cl}\rangle M\{CH_2P(C_6H_5)_3\}_2]Cl_4$ (M: Al, Ga, and In). The reactions of **L** with $AlCl_3$ or $GaCl_3$ in the mole ratio of 3 : 1 or 5 : 1 yield new compounds of μ-chloro-bis[tris(methylenetriphenylphosphorane)metal] pentachloride, $[\{(C_6H_5)_3PCH_2\}_3M\text{-}Cl\text{-}M\{CH_2P(C_6H_5)_3\}_3]Cl_5$ (M: Al, Ga). These dimers, bridged by chloride anions, are thermally stable.

Many investigations[2] of IIA Group and IIIA Group metal complexes with methylenetri(or di)alkylphosphoranes have been reported, but there have been few investigations of metal complexes with triphenylphosphorane derivatives. A previous paper has been concerned with IVA Group metal (Ge, Sn, Pb) complexes[3] of alkylidenetriphenylphosphoranes. The present paper will deal with the preparation and properties of di-μ-chloro-bis[(methylenetriphenylphosphorane)metal] dichloride, $[(C_6H_5)_3PCH_2M\langle^{Cl}_{Cl}\rangle MCH_2P(C_6H_5)_3]Cl_2$ (M: Be, Mg), di-μ-chloro-bis[bis(methylenetriphenylphosphorane)metal] tetrachloride, $[\{(C_6H_5)_3PCH_2\}_2M\langle^{Cl}_{Cl}\rangle M\{CH_2P(C_6H_5)_3\}_2]Cl_4$ (M: Al, Ga, In), and μ-chloro-bis[tris(methylenetriphenylphosphorane)metal] pentachloride, $[\{(C_6H_5)_3PCH_2\}_3M\text{-}Cl\text{-}M\{CH_2P(C_6H_5)_3\}_3]Cl_5$ (M: Al, Ga).

Results and Discussion

Beryllium, Magnesium, and Calcium Complexes. Di-μ-chloro-bis[(alkylidenetriphenylphosphorane)metal (Be, Mg)] dichlorides have been isolated from a reaction mixture of alkylidenetriphenylphosphorane, $(C_6H_5)_3P{=}CHR$ (**L** (R : H) and **L'** (R: CH_3)), with $BeCl_2$ or $MgCl_2$. Complexes **1** and **2** are soluble only in acidic solvents, such as sulfuric acid, nitric acid, hydrochloric acid, and acetic acid. Complex **3** is soluble in DMF,

$$4(C_6H_5)_3P{=}CH\text{-}R + nMCl_2 \longrightarrow$$

M	Be	Mg
n	2	1

$$[(C_6H_5)_3P\overset{R}{C}H\text{-}M\langle^{Cl}_{Cl}\rangle M\text{-}\overset{R}{C}HP(C_6H_5)_3]Cl_2$$

No.	1	2	3
M	Be	Be	Mg
R	H	Me	H

DMSO, MeOH, and water, but insoluble in chloroform and dichloromethane. They are all highly hygroscopic. No calcium complex could be isolated from the reaction mixture of **L** and $CaCl_2$ in the mole ratio of 2 : 1 or 4 : 1.

The ^1H NMR spectrum of **3** showed a doublet signal for the methylene group at 2.17 ppm and a multiplet signal for phenyl groups at 7.3—8.0 ppm (in the ratio of 2 : 15) in CD_3OD at −80 °C. The chemical shift of the methylene group is at a lower field than that[4] (0.13 ppm) of **L**. The coupling constant ($^2J_{HCP}$) of **3** is 12.3 Hz, larger than that[4] (7.5 Hz) of **L**. These features are similar to those of bis(methylenetriphenylphosphorane)metal chloride, $[(C_6H_5)_3PCHR\text{-}M\text{-}CHRP(C_6H_5)_3]Cl_n$ (**4**) (R: H, M: IB Group and IIB Group metal[5]) and (methylenetriphenylphosphorane)-triphenylmetal chloride, $[(C_6H_5)_3PCH_2\text{-}M(C_6H_5)_3]Cl$ (**5**) (M: IVA Group metal[3]). Thus, the ylide **L** is bonded to the metal atom through the carbanionic donor atom.[3,5] Complexes **1** and **2** are unstable in 3.6 mol dm^{-3} D_2SO_4 at −34 °C, giving a alkyltriphenylphosphonium chloride, $[(C_6H_5)_3PCH_2\text{-}R]Cl$ (R: H (**6a**), CH_3 (**6b**)). The decomposition temperatures did not agree with the melting points of the ylides or salts **6**. Their colors are white. These properties resemble those of **4** (R: CH_3, $CH(CH_3)_2$),[5] and the ylides seem to be bonded to the beryllium atom in the solid state.[3] Two structures for the beryllium compounds have been considered possible: either a tetrahedral (monomeric,[6] dimeric,[7] and polymeric[8]) or a trigonal (monomeric,[9] dimeric,[10] and trimeric[11]) configuration. In the cases of **1**—**3**, they are not soluble in chloroform and dichloromethane. This is different from the **4**[5] (linear configuration), and **5**[3] and IIIA Group metal complexes (tetrahedral configuration). The elemental analyses of **1**—**3** agreed with that of $[LMCl_2]_n$. Complex **3** has free anion from the equivalent conductance. Thus, we suggest that the structure of **1**—**3** can be neither a linear nor tetrahedral configuration, but a dimeric trigonal structure.

Aluminium, Gallium, Indium, and Thallium Complexes. 2 : 1 Complexes: Di-μ-chloro-bis[bis(methylenetriphenylphosphorane)metal (Al, Ga, In)] tetrachlorides have been isolated from a reaction mixture of **L** and $AlCl_3$,

$GaCl_3$ or $InCl_3$ in the mole ratio of 2 : 1. Complexes **7**—**9** are soluble in alcohols, chloroform, dichloromethane, DMF, DMSO, and water, but are unstable in these solvents at room temperature and are changed to the corresponding phosphonium chloride (**6a**). In

$$4(C_6H_5)_3P{=}CH_2 + 2MCl_3 \longrightarrow \left[\begin{matrix}(C_6H_5)_3PCH_2 & Cl & CH_2P(C_6H_5)_3\\ & M \quad M & \\ (C_6H_5)_3PCH_2 & Cl & CH_2P(C_6H_5)_3\end{matrix}\right] Cl_4$$

No.	7	8	9
M	Al	Ga	In

dichloromethane, **7** and **8** are stable at −80 °C. Complex **9** was slowly changed to **6a** in dichloromethane at −80 °C, the ^1H NMR spectrum of **9** showing signals of both **9** and **6a**. No thallium complex could be isolated from the reaction mixture of **L** and TlI in the mole ratio of 2 : 1.

The ^1H NMR spectra of **7** and **8** showed a doublet signal for CH_2P at 3.2 and 2.7 ppm respectively and a multiplet signal for phenyl groups at 7.4—7.9 ppm in a ratio of 2 : 15 at a low temperature in dichloromethane-d_2. In complexes **7**—**9**, the coupling constants ($^2J_{HCP}$) of the methylene group are larger than that of **L** and the chemical shifts are at a lower field than that of **L**, the chemical shift of **7** being the lowest, as is shown in Table 1. The configuration of these metals is assumed to be tetrahedral from the following facts: **7**—**9** are not polymeric, because they are soluble in dichloromethane and alcohols. The elemental analyses of **7**—**9** agreed with that of $[L_2MCl_3]_n$. The structures of $AlCl_3$, $GaCl_3$, $InCl_3$ and related compounds are of a dimeric, tetrahedral configuration.[12] Complexes **7** and **8** have free anion, judging from the equivalent conductance. Thus, it is suggested that **7**—**9** are dimers bridged by chloride anions and with a tetrahedral configuration.

3 : 1 Complexes: μ-Chloro-bis[tris(methylenetriphenylphosphorane)metal (Al, Ga)] pentachlorides have been isolated from a reaction mixture of **L** with $AlCl_3$ or $GaCl_3$ in the mole ratio of 3 : 1 or 5 : 1. The complexes are soluble in alcohols, chloroform, dichloromethane, DMF, DMSO, and water. The gallium complex **11** is stable in dichloromethane at −62 °C, though the aluminium

$$3(C_6H_5)_3P{=}CH_2 + AlCl_3 \longrightarrow 5(C_6H_5)_3P{=}CH_2 + GaCl_3$$

$$\left[\begin{matrix}(C_6H_5)_3PCH_2 & & CH_2P(C_6H_5)_3\\ (C_6H_5)_3PCH_2\text{–}M\text{–}Cl\text{–}M\text{–}CH_2P(C_6H_5)_3\\ (C_6H_5)_3PCH_2 & & CH_2P(C_6H_5)_3\end{matrix}\right] Cl_5$$

M	Al	Ga

complex **10** is unstable under the same conditions, giving the corresponding phosphonium salt (**6a**). The ^1H NMR spectrum of **11** showed a doublet signal for the methylene group at 2.8 ppm and a multiplet signal for the phenyl groups at 7.4—7.9 ppm, in the ratio of 2 : 15, at −62 °C. The chemical shift and the coupling constant ($^2J_{HCP}$: 16.7 Hz) of the methylene group of **11** are very similar to those of **8** as is shown in Table 1. The

elemental analyses of **10** and **11** agreed with that of $[L_3MCl_3]_n$. Complex **11** has free anion, judging from the equivalent conductance. Thus, **10** and **11** can also be assumed to be dimers bridged by a chloride anion.

The stable alkylidenetriphenylphosphorane complexes in dichloromethane are those with metals of IB Group (Cu, Ag, Au),[5b–d] IIB Group (Zn, Cd)[5a] and IIIA Group (Al, Ga) and with Pb.[3]

Experimental

Measurements. The ^1H NMR spectra were measured with R-40 (Hitachi) and SXP4-100 pulse ST (Bruker) spectrometers. The electric conductivities of solutions were determined by the use of a conductmetric meter, CM-30 (Shimadzu) in methanol for **3** or in dichloromethane for **7**, **8**, and **11** at a low temperature.

Starting Materials. The methylene-[13] and ethylidenetriphenylphosphoranes[5d] were prepared from the corresponding phosphonium bromides by the sodium-amide method.

Preparation of Complexes. Di-μ-chloro-bis[(methylenetriphenylphosphorane)beryllium] Dichloride (1): Beryllium dichloride (0.07 g, 0.876 mmol) was added to a dry THF (6 cm^3) solution of **L** (0.55 g, 1.99 mmol) at room temperature under a nitrogen atmosphere. The mixture was stirred for 12 h, then the white complex thus precipitated was filtered under nitrogen, washed with dry ether, and dried under a vaccum. Yield: 0.27 g (86.5%). Decomp 224 °C. Found: C, 64.81; H, 5.19%. Calcd for $C_{38}H_{34}P_2Be_2Cl_4$ (MW 712.46) C, 64.05; H, 4.81%.

Di-μ-chloro-bis[(ethylidenetriphenylphosphorane)beryllium] Dichloride(2): This complex was prepared from a reaction mixture of beryllium dichloride (0.06 g, 0.751 mmol) and **L′** (0.436 g, 1.50 mmol) in THF (6 cm^3). After 10 h, the white complex thus precipitated was filtered, washed with dry ether, and dried. Yield: 0.10 g (36.0%). Decomp 220 °C. Found: C, 63.41; H, 5.40%. Calcd for $C_{40}H_{38}P_2Be_2Cl_4$ (MW 740.50) C, 64.88; H, 5.17%.

Di-μ-chloro-bis[(methylenetriphenylphosphorane)magnesium] Dichloride (3): Complex **3** was prepared from magnesium dichloride (0.035 g, 0.368 mmol), **L** (0.41 g, 1.48 mmol), and THF (6 cm^3) at room temperature. After 4 d, the white complex thus precipitated was filtered under nitrogen, washed with ether, and dried. Yield: 0.10 g (73.2%). Decomp 60 °C. Found: C, 61.16; H, 4.78%. Calcd for $C_{38}H_{34}P_2Mg_2Cl_4$ (MW 743.06) C, 61.42; H, 4.61%.

Di-μ-chloro-bis[bis(methylenetriphenylphosphorane)aluminium] Tetrachloride (7): Aluminium trichloride (0.12 g, 0.9 mmol) was added to a dry THF (8 cm^3) solution of **L** (0.49 g, 1.77 mmol) under nitrogen. After 22 h, the white complex thus precipitated was filtered under nitrogen, washed with dry pentane, and dried under a vacuum. Yield: 0.4 g (64.8%). Decomp 225 °C. Found: C, 66.67; H, 5.18%. Calcd for $C_{76}H_{68}$-

$P_4Al_2Cl_6$ (MW 1371.92) C, 66.54; H, 5.00%.

Di-μ-chloro-bis[bis(methylenetriphenylphosphorane)gallium] Tetrachloride (8): Gallium trichloride (0.43 g, 2.44 mmol) was added to a THF (20 cm^3) solution of **L** (1.35 g, 4.88 mmol). The color of the **L** changed from yellow to colorless. The white complex thus precipitated was filtered after 2 h, washed with dry ether and dried. Yield: 1.61 g (90.5%). Decomp 187 °C. Found: C, 63.14; H, 5.08%. Calcd for $C_{76}H_{68}P_4Ga_2Cl_6$ (MW 1457.40) C, 62.63; H, 4.70%.

Di-μ-chloro-bis[bis(methylenetriphenylphosphorane)indium] Tetrachloride (9): Indium trichloride (0.08 g, 0.36 mmol) was added to a THF (10 cm^3) solution of **L** (0.20 g, 0.72 mmol). The yellow color of **L** changed to colorless. The white complex thus precipitated was filtered after 10 h, washed with dry ether, and dried. Yield: 0.18 g (64.3%). Decomp 197 °C. Found: C, 59.11; H, 4.21%. Calcd for $C_{76}H_{68}P_4In_2Cl_6$ (MW 1547.62) C, 58.98; H, 4.43%.

μ-Chloro-bis[tris(methylenetriphenylphosphorane)aluminium] Pentachloride (10): This complex was prepared from $AlCl_3$ (0.08 g, 0.6 mmol) and **L** (0.5 g, 1.81 mmol) in THF (10 cm^3). After 22 h, the white complex was filtered. Yield: 0.38 g (65.8%). Decomp 231 °C. Found: C, 70.02; H, 6.08%. Calcd for $C_{114}H_{102}P_6Al_2Cl_6$ (MW 1924.56) C, 71.15; H, 5.34%.

μ-Chloro-bis[tris(methylenetriphenylphosphorane)gallium] Pentachloride (11): This complex was prepared from $GaCl_3$ (0.09 g, 0.511 mmol), **L** (0.77 g, 2.79 mmol), and THF (12 cm^3). After 10 h, the white complex thus precipitated was filtered, washed with ether, and dried. Yield: 0.12 g (23.4%). Decomp 204 °C. Found: C, 67.11; H, 5.47%. Calcd for $C_{114}H_{102}P_6Ga_2Cl_6$ (MW 2010.04) C, 68.12; H, 5.12%.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 554190 from the Ministry of Education, Science and Culture.

The Synthesis and Color of Pyrido[1′,2′ : 1,2]pyrimido[4,5-*b*]-acridine-7,15-diones

Yasukazu YOKOYAMA

Tokyo Laboratory, Toyo Soda Manufacturing Co., Ltd., Hayakawa, Ayase, Kanagawa 252

(Received September 24, 1981)

Some derivatives of pyrido[1′,2′: 1, 2]pyrimido[4,5-*b*]acridine-7,15-diones have been synthesized, their absorption spectra have also been investigated in order to elucidate the relationship between the color and the chemical constitution in contrast to the related compounds, quinacridone and pyrido[2,1-*b*]pyrido[1′,2′ : 1,2]pyrimido-[4,5-*g*]quinazoline-7,15-dione. The absorption spectra in DMSO and in concentrated sulfuric acid show a good correlation with the electronic effect of the substituents. The absorption spectra of the solid are more influenced by the position of the substituents than by the electronic effect.

Linear *trans*-quinacridone (**1**) is a valuable organic pigment because of its excellent properties. Therefore, much attention has heen paid to the synthesis and the electronic spectral studies of quinacridones and some derivatives with similar chemical constitutions.[1] The substituents of quinacridones have little effect on the visible spectra in concentrated sulfuric acid, but a marked effect on the solid color.[2] In a previous paper, we showed that the introduction of methyl groups into the 1,9- and 4,12-positions of pyrido[2,1-*b*]pyrido-[1′,2′ : 1,2]pyrimido[4,5-*g*]quinazoline-7,15-dione (**2**) gives rise to a hypsochromic shift from red to orange in the solid color.[3] Altiparmakin has reported that the effect of the substituents of **2** on the electronic spectra is practically negligible in contrast to the case of **1**, since the substituents are, in fact, isolated from chromophore.[4]

It is interesting to make clear the relationship between the color and the chemical constitution of those compounds. Therefore, in this study, some derivatives of 5*H*-pyrido[1′,2′: 1,2]pyrimido[4, 5-*b*]acridine-7,15-dione (**3a**) were synthesized, and their electronic spectra in solutions and their reflectance spectra in the solid were compared with those of **1** and **2**.

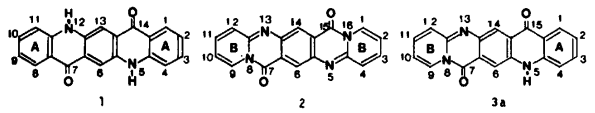

Fig. 1.

Experimental

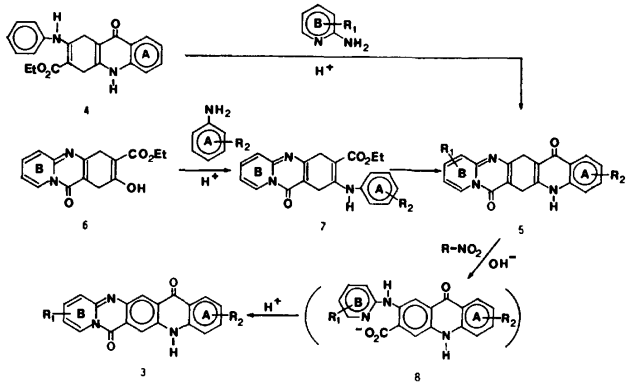
The IR, VS, and ^{1}H-NMR spectra were recorded on a Shimadzu IR-27G spectrophotometer, a Hitachi 306 spectrophotometer, and a Varian HA-100 spectrometer respectively. The color measurements were obtained using a Hitachi Trichromatic Integrator.

Materials. All the reagents except those listed below were obtained from commercial sources and were used without further purification.

Improved methods for the preparation of **3a** were employed to obtain substituted **3**, whose A or B ring carries substituents (Scheme 1).

The synthetic intermediates, 2-anilino-3-ethoxycarbonyl-1,4-dihydro-9(10*H*)-acridone (**4**) and 7-ethoxycarbonyl-6,9-dihydro-8-hydroxypyrido[2,1-*b*]quinazolin-10-one (**6**) were prepared according to the methods described in the literature.[5]

6, 14-Dihydropyrido[1′, 2′ : 1, 2]pyrimido[4, 5-b]acridine-7, 15-diones (5). *a)*: The reaction of **4** and 2-aminopyridines



Scheme 1.

were carried out according to the methods described in a previous paper.[4] Pale pink solids of **5a—e** were obtained.

b): A mixture of 5.0 g, of **6** and 19 g of *p*-toluidine was heated to reflux in 50 ml of acetic acid for 2.5 h while being stirred under a nitrogen atmosphere. When the reddish orange solution was then cooled, a pale orange solid precipitated. The solid was collected on a filter, washed with methanol, and dried at 60 °C. The solid (5.0 g) was heated in 70 g of polyphosphoric acid for 1 h. The resulting solution was diluted with large excess of water to give **5f** as a pale pink solid. The other substituted derivatives were prepared analogously.

In this reaction, the methoxyl-group at the 2-position of **5** was hydrolyzed to the 2-hydroxy derivative **5h**. The methoxyl-group at the 4-position of **5** was not hydrolyzed under the same reaction conditions. Some pertinent data on **5** are also shown in Table 1.

Pyrido[1′,2′ : 1,2]pyrimido[4,5-b]acridine-7,15-diones (3).

a): The dehydrogenation of **5** was carried out, using sodium *m*-nitrobenzenesulfonate as a dehydrogenating agent, by the method described in our previous paper.[6]

b): A mixture of 5.0 g of **5b**, 5.0 g of sodium *m*-nitrobenzene-sulfonate, 9 g of a 33% aqueous sodium hydroxide solution, and 100 g of ethylene glycol was heated at 100—130 °C for 2 h. The resulting red solution was cooled and neutralized with an aqueous sulfuric acid solution. The precipitate was filtered, washed with water, and dried at 60 °C.

Three grams of the brown colored powder were heated at 90—100 °C for 2 h in 50 g of polyphosphoric acid. The resulting red solution was cooled to room temperature and then diluted with 200 ml of water. The reddish orange crystals thus precipitated were filtered, washed with water, and dried at 60 °C. The yield was 2.3 g (76.7%).

The compounds **3** were conveniently purified by the following procedure. To a suspension of 3 g of crude **3a—1** in 100

ml of ethylene glycol we added 10 g of a 20% aqueous sodium hydroxide solution. The mixture was heated with continuous stirring at 100—120 °C for 2 h. The resulting red solution was cooled and acidified with 20 g of a 20% aqueous sulfuric acid solution. The slurry thus formed was heated at 70—80 °C for 1 h. The product was collected by filtration and washed with hot ethylene glycol and then water. Recrystallization from DMSO afforded reddish orange crystals (2.7 g, 90% recovery).

The yields and some pertinent data for **3** are listed in Table 2.

Picrate. a): A mixture of 100 ml of ethanol, 2.0 g of **2**, and 5.0 g of picric acid was heated to reflux for 2 h. The resultant yellow solid was collected by filtration, washed with ethanol, and dried at 60 °C. The yield was 4.2 g. The product was determined to be picrate (**2** : picric acid = 1 : 2, M/M, 1 M = 1 mol dm^{-3}) by means of IR spectroscopy and elemental analysis. Found: C; 47.09, H; 2.24, N; 18.29%. Calcd for $C_{30}H_{16}N_{10}O_{16}$: C; 46.64, H; 2.09, 18.13%. IR (KBr) C=O 1705 cm^{-1}. *b)*: From 2.0 g of **3a** and 5.0 g of picric acid, 3.4 g of orange crystals were obtained by means of the procedure described above. The product was determined to be picrate (**3a**: picric acid = 1 : 1, M/M) by IR spectroscopy and elemental analysis. Found: C; 55.51, H; 2.50, N; 15.96%. Calcd for $C_{25}H_{14}N_6O_9$; C; 55.35, H; 2.58, N; 15.50%. IR(KBr) C=O 1723 cm^{-1}. *c)*: The 4,12-dimethyl derivative of **2** and the 4-methyl derivative of **3a**(**3e**) formed no picrate.

Color Measurements. The visible absorption maxima of the solid were obtained from the reflectance spectra on the dispersion of the solid diluted with TiO_2(1/5) in cellulose acetate butyrate.

Spectral Measurements. The visible spectra of **1**, **2**, and **3** were measured on both DMSO and concentrated sulfuric acid solutions, ranging in concentration from 1×10^{-3} to 1×10^{-5} M. The spectra were independent of the concentration in this concentration range.

a) Obtained from a reflectance spectrum on a dispersion of a solid diluted with TiO_2(1/5) in CAB resin film. b) λ_d shows the dominant wave length, while λ_c represents the complementary wavelength. They were obtained from the C.I.E. Chromaticity Diagram by using Tristimulas Values available from the integration of the reflectance spectra with a trichromatic integrator. c) Shoulder.

Results and Discussion

Dihydro derivatives **5** were synthesized according to the two methods previously reported,[6] as is shown in Scheme 1. The first method gives **5** directly. Amine exchange and intramolecular cyclization spontaneously occurred on the heating of **4** with substituted amino pyridines in acetic acid. The second method involved the preparation of esters **7**, which were obtained by the condensation of **6** with substituted anilines. The cyclization of **7** was carried out in polyphosphoric acid. In this reaction, the *p*-methoxy group (R_2=*p*-OCH_3) of **7** was hydrolyzed to give 2-hydroxy derivative (**5h**), but the *o*-methoxy group was not hydrolyzed under the same reaction conditions. The dehydrogenation of **5** gave the corresponding **3** in high yields.

The compounds **3** are microcrystalline powders and range from orange to red in color. They do not melt or decompose up to 300 °C and are slightly soluble in organic solvents, such as dimethylformamido and dimethylsulfoxide (DMSO). The compounds **3**, as well as compound **2**, are weak bases and are soluble in aqueous solutions of strong acids, such as hydrochloric acid and sulfuric acid. The compounds **2** and **3** formed picrates, the 1 : 2 adduct of **2** and the 1 : 1 adduct of **3** with picric acid. However, the 4,12-dimethyl derivative of **2** and the 4-methyl derivative of **3a**(**3e**) formed no picrate. This is probably due to the steric hindrance between the methyl group adjacent to imino nitrogen and the voluminous nitro group of picric acid.

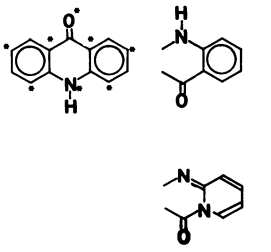
The absorption spectra of **3** were measured and compared with those of **1** and **2** in order to clarify the influences of substituents and of the measurement medium upon the electronic spectra. The ^{1}H-NMR data for **1**, **2**, and **3** are listed in Table 3. The coupling pattern of **2** is similar to that of **1**, but the proton signals of **2** are distributed over a wider range than those of **1**. The coupling constants for **2** are slightly smaller than those of **1**. The spectra of **3** appear almost as a superimposition of those of **1** and **2**. The chemical shifts of the aromatic protons of **3** are scarcely influenced by the electronic effects of their substituents.

The visible absorption spectra of **1**, **2**, and **3** in various media are listed in Table 4. The compounds **1** and **2** show visible absorptions at considerably shorter wavelengths in DMSO than in a solid. However, in concentrated sulfuric acid the spectrum of **1** shows a strong bathochromic shift, and that of **2**, a remarkable hypsochromic shift. On the other hand, the spectrum of **3a** is little affected by either solvent.

The strong bathochromic shift of **1** in concentrated sulfuric acid can be explained by the increased acceptor capacity of the carbonyl group for the protonation on the carbonyl oxygens. The hypsochromic shift of **2** in concentrated sulfuric acid may be attributed to the protonation at the imino nitrogens.[7] The imino protonation will destroy the polymethine chromophore. In the case of **3**, the bathochromic effect of the protonated acridone skeleton is counteracted by the protonation of the quinazolone skeleton, and the spectral shift is, consequently, small.

These spectral shifts can be interpreted on the basis of the assumption of protonated species, as is shown in Fig. 2. The protonated species **14** and **12** are regarded as the aza-replaced compounds of **1** and its mono protonated structure, **9**, respectively. The aza replacement at the 7a and 14a positions of **1** shows a remarkable hypsochromic shift. The observed shift is in accordance with the color rules.[8]

The compound **3a** absorbs at shorter wavelengths than **1**. This can easily be explained in terms of the replacement of an electron-donor substituent, NH, with an electron-accepter substituent, C=N, at the starred position of an acridone molecule.



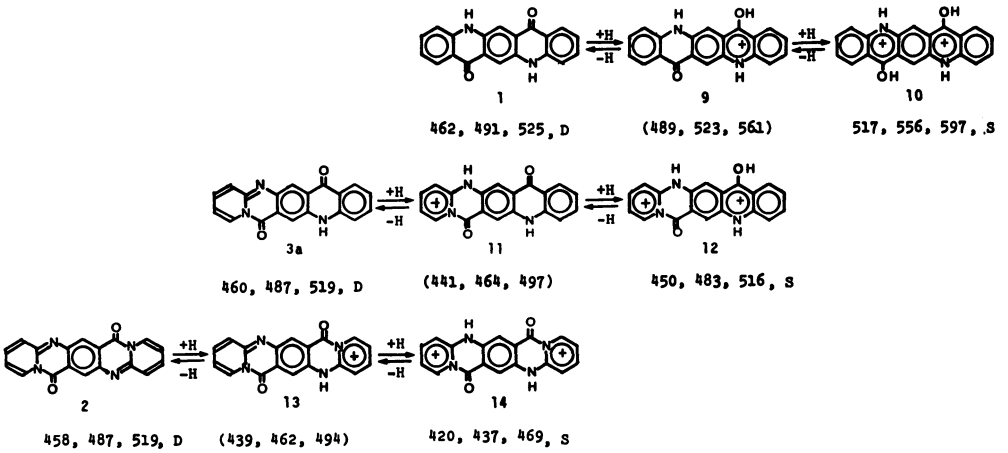


Fig. 2. Structure and spectral wavelength of compounds **1**, **2**, and **3** and their assumed protonated speacies, λ_{max}, (speculated values), nm. D: in DMSO, S: in concentrated sulfuric acid.

In the case of the substituted derivatives of **3a**, it is predictable that an electron-donating substituent at the starred position will show a bathochromic effect. The observed visible spectra of the derivatives of **3a** in the solutions show a good correlation with the electronic effect of the substituents, though the effect is small. Electron-donating substituents cause a bathochromic effect in DMSO and a hypsochromic effect in concentrated sulfuric acid. The substituent effect on protonated **3** is opposed to that on the unprotonated species. The opposite wavelength shifts by the protonation are not observed in the substituents of **1**. The observed wavelength shifts of **3** give straight-line relationship with Hammett σ constants, as is shown in Fig. 3. The relationship to the reactive substituent constant is explained by the fact that the shifts are closely related to the protonation equilibria of **3**. That is, the electron-donating substituents increase the donating ability of the acridone NH group, hence, the bathochromic shift is observed in DMSO. On the other hand, the electron-acceptor groups accelerate the protonation of the acridone skeleton, and the bathochromic shift is observed in concentrated sulfuric acid.

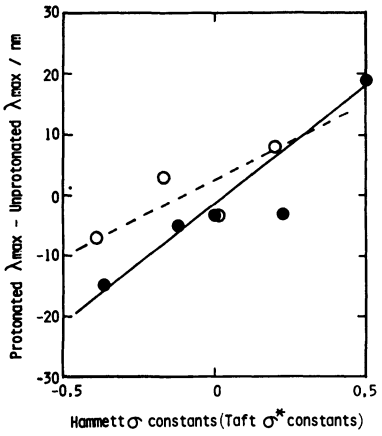

Fig. 3. Spectral longest-wavelength shifts observed with the protonation of **3** plotted against Hammett σ constants (para) ——, and Taft σ^* constants (ortho) ·····.

The substituents of **3** show a pronounced effect on their solid colors. The shades of the solid are also listed in Table 4 in terms of the dominant wavelength values, λ_d or λ_c. The substituents at the 2-position exert a bathochromic effect. The shift is larger than that in DMSO, but shows a poor correlation with the electronic effect of the substituents. The substituents at the 4-position exert almost no effect, and the λ_{max} values are almost the same as those of unsubstituted **3a** either in a solid or in DMSO. The 9, 10, 11, and 12-methyl substituted derivatives absorb light of wavelengths longer than **3a**, but the shift is smaller than that of the 2-methyl substituted derivative, **3g**. On the basis of this spectroscopy, the following conclusions were deduced: the effect of the substituent on the A ring of **3** upon the absorption spectra is larger than that of the substituent on the B ring, and the absorption spectra are more influenced by the position of the substituent than by the electronic effect of the substituent.

The authors wish to thank Professor Mitsuhiko Hida of Tokyo Metropolitan University for his valuable discussion and Mr. Kenichi Sato of the Sagami Chemical Research Center for obtaining the ^{1}H-NMR spectra.

An Interpretation of the Asymmetric Induction Observed in Rhodium-Bis(dibenzophosphole) Complex Catalyzed Hydroformylation According to an X-Ray Molecular Structure Analysis of an Iridium-(2*R*,3*R*)-2,3-*O*-Isopropylidene-1,4-bis(5*H*-dibenzophosphol-5-yl)-2,3-butanediol Complex

(Received April 3, 1982)

An X-ray molecular structure analysis of [(2*R*, 3*R*)-2,3-*O*-isopropylidene-1,4-bis(5*H*-dibenzophosphol-5-yl)-2,3-butanediol((−)-DIPHOL)](1,5-cyclooctadiene)chloroiridium(I) was carried out. The complex takes a distorted trigonal bipyramidal structure, and the chelate ring of (−)-DIPHOL makes a chair form, which decreases the distances of atoms in the chelate ring from the P–Ir–P coordination plane. Thus, the chiral coordination structure of DIPHOL becomes remarkably different from that of DIOP. Through a comparison of the results of X-ray analyses, the results obtained in asymmetric hydroformylation (predominant absolute configuration and optical yield of products) catalyzed by the rhodium-complexes were explained on the basis of some well-grounded assumptions.

X-Ray molecular structure analyses of presumed chiral complex catalysts have been studied in order to elucidate the mechanism of the asymmetric induction, especially in the asymmetric hydrogenation of prochiral olefins catalyzed by rhodium-optically active ligand-complexes.[1] However, no attempt has yet been made in the field of symmetric hydroformylation, probably because the active catalyst species has not yet been made definite, as the reaction is a multistage one and proceeds under more severe conditions than in the case of hydrogenation, namely, at a higher reaction temperature and under a high carbon monoxide pressure.

A rhodium-catalyzed asymmetric hydroformylation reaction had been carried out by the use of chiral monophosphines[2,3] and (2*R*,3*R*)-2,3-*O*-isopropylidene-1,4-bis(diphenylphosphino)-2,3-butanediol[(−)-DIOP][4-6] as ligands. As the present authors reported previously, the enantioselectivity in rhodium-catalyzed asymmetric hydroformylation is considerably enhanced by the use of bis(5*H*-dibenzophosphole)s as chiral ligands in place of the corresponding bis(diphenylphosphine)s (Table 1).[7,8] It was surprising that the prevailing absolute configurations of aldehydes obtained from styrene, 1-butene, and *cis*-2-butene by the use of (−)-DIPHOL or (1*R*,2*R*)-1,2-bis(5*H*-dibenzophosphol-5-ylmethyl)cyclobutane were the opposite of those obtained by the use of (−)-DIOP or (1*R*,2*R*)-1,2-bis(diphenylphosphinomethyl)cyclobutane respectively, though they have the same chiral backbone. An exception was observed in the case of *trans*-2-butene, from which the aldehyde with a very low optical yield was produced.

In the case of the rhodium–triphenylphosphine-complex catalyzed hydroformylation reaction, $HRh(CO)_2PPh_3$ (in the dissociative mechanism) or $HRh(CO)_2(PPh_3)_2$ (in the associative mechanism) is presumed as a key intermediate;[13] only the former follows 18-electron rule upon coordination with a substrate. Similarly, when a bidentate ligand, (−)-DIOP, is used in place of PPh_3, the key intermediate is considered to have only one molecule of DIOP chelating as in HRh(CO)[(−)-DIOP], which may well be supported by the following facts: 1) The optical yield in the hydroformylation of styrene was always higher than those obtained using C-chiral monophosphines,[10] and 2) when the P/Rh atomic ratio in the system was increased, the optical yield levelled out at around the P/Rh value of 3.[14] Therefore, the conformation of (+)-DIOP in an X-ray analysis of a pentacoordinated iridium complex

For the reaction conditions, see Ref. 8. The optical purities in Ref. 8 were recalculated on the basis of the value $[\alpha]_D = -238°$ of optically pure (−)-(*R*)-2-phenylpropanal; see Ref. 8.

—IrCl(COD)[(+)-DIOP] (**A**)[15,16]—is informative with regard to the conformation of (−)-DIOP in the catalytically active species.

The results in Table 1 seem to suggest that (−)-DIPHOL, upon coordination to rhodium, takes a chelate ring conformation essentially different from that of (−)-DIOP, which is a phenomenon caused by 5*H*-dibenzophospholyl (DBP) substitution for Ph_2P.

In order to compare the coordination structures of (−)-DIPHOL and (−)-DIOP, the present authors prepared IrCl(COD)[(−)-DIPHOL] (**B**) complex and determined its X-ray molecular structure. The mechanism of the asymmetric induction in the hydroformylation reaction will be described on the basis of both the structures.

Experimental

[(2*R*,3*R*)-2,3-*O*-Isopropylidene-1,4-bis(5*H*-dibenzophosphol-5-yl)-2,3-butanediol](1,5-cyclooctadiene)chloroiridium(I) (**B**) was prepared according to the procedure used for the corresponding (+)-DIOP complex.[15] Single crystals were obtained from the EtOH–toluene solution as yellow platelets. Found: C, 56.49; H, 4.89%. Calcd for $C_{39}H_{40}ClIrO_2P_2$: C, 56.41; H, 4.86%.

X-Ray Data Collection. A crystal with dimentions of $0.08\times0.32\times0.44$ mm^3 was sealed in a glass capillary under a nitrogen atmosphere. After determining the preliminary data with the Weissenberg photographs, the unit-cell dimensions were refined by the least-squares procedure with the setting angle of 20 reflections ($26.0°<2\theta<34.3°$) on a Rigaku four circle diffractometer with LiF-monochromatized Mo $K\alpha$ radiation ($\lambda=0.71069$ Å). Two sets of intensity data were measured in the θ-2θ scan mode: Data 1 with Mo $K\alpha$ radiation, $2\theta\leq60°$, $\lambda=0.71069$ Å; Data 2 with Co $K\alpha$ radiation, $2\theta\leq82°$, $\lambda=1.5418$ Å. In both cases, the θ scan width was $(1.2°+0.45\tan\theta)$ with the scan rate of 2° min^{-1} (2θ). No significant changes were observed in the intensities of the four standard reflections monitored every 50 measurements throughout the data-collection. Lorentz and polarization corrections were usually applied, but no absorption correction was made. A total of 4075 reflections with $F_o>3\sigma(F)$ in Data 1 were used in the subsequent calculations. The 1181 reflection pairs of $F_o(hkl)$ and $F_o(\bar{h}\bar{k}\bar{l})$ with $F_o>3\sigma(F)$ of Data 2 were used only to confirm the absolute configuration, since the observed number was insufficient for the number of parameters to be refined, and the absorption correction was not taken into account.

Crystal Data: $IrClP_2O_2C_{39}H_{40}$, $M_r=830.4$, orthorhombic, space group $P2_12_12_1$, $a=16.803(3)$, $b=18.969(3)$, $c=10.928(2)$ Å, $V=3483.3(9)$ Å^3, $Z=4$, $D_x=1.56$ gcm^{-3}, μ(Mo $K\alpha$)$=42.1$ cm^{-1}, $F(000)=1608$, μ(Cu $K\alpha$)$=90.2$ cm^{-1}.

Structure Determination and Refinement. The structure was solved by the heavy-atom method and refined by the block-diagonal least-squares method. The quantity minimized was $\sum w(|F_o|-|F_c|)^2$, and the weight parameter was $(14.1/|F_o|)^2$ in the absolute scale. After several cycles with anisotropic non-hydrogen atoms, two enantiomorphic forms, one of which was made by inverting the atomic parameters of the other, were refined separately with anomalous dispersion correction. The R values of the forms were 0.087 and 0.093. Since the R-ratio, the number of observations, and the number of refined parameters were 1.16, 4075, and 407 respectively, the (2*S*,3*S*)-structure could be rejected at the 0.005 significance level.[17] To confirm the configuration, separate refinements with $F_o(hkl)$ and $F_o(\bar{h}\bar{k}\bar{l})$ were carried out with Data 2, which possessed a higher intensity (about four times) than Data 1. The R values and the R ratio were 0.082, 0.087, and 1.061 respectively, so the results agreed with those of Data 1. Table 2 compares the observed and calculated structure amplitudes between several Bijvoet pairs with Data 2.

The final refinement with Data 1 was calculated with anisotropic non-hydrogen atoms, anomalous dispersion corrections for Ir, Cl, and P atoms, and isotropic hydrogen atoms, which were geometrically located and which were given a constant temperature parameter of 4.5 Å^2. The final R and R_w values were 0.076 and 0.079 respectively. The maximun parameter shift to its e.s.d. ratio was less than 0.5. The atomic scattering factors and anomalous dispersion corrections for Ir, Cl, and P atoms were taken from the International Tables for X-ray Crystallography.[18] All the computations were carried out at the Computer Center of the University of Tokyo with the UNICS program system.[19] The final atomic coordinates are shown in Table 3.[20]

Results

Some selected bond distances and angles of **B** are given in Table 4. An ORTEP[21] drawing and the numbering of the atoms are shown in Fig. 1. The Ir–Cl distance (2.549 Å) is fairly large in comparison with those in $IrCl(CO)(P\text{-}o\text{-}Tol_3)_2$[22] (2.43 Å) and in $IrCl(CO)_2$-

$(PPh_3)_2$[23] (2.37 Å), while it is similar to that in **A** (2.599 Å).[15] The Ir–P distances (2.303 Å/2.310 Å) are similar not only to those in **A** (2.327 Å/2.339 Å),[15] but also to those in $IrCl(CO)(PMePh_2)_2$[24] (2.342 Å/2.320 Å), $IrCl(CO)_2(PPh_3)_2$[23] (2.341 Å/2.322 Å), and $IrMe(COD)\mathbf{P}_2$ ($\mathbf{P}_2$=2PPhMe$_2$,[25] DPPE,[26] and DPPP[27]) (2.316 Å/2.329 Å, 2.309 Å/2.337 Å, 2.308 Å/2.308 Å). The Ir–(C=C) distances are 2.02 Å for C(1/2) and 2.19 Å for C(5/6), similar to those in $IrMe(COD)\mathbf{P}_2$ (2.078 Å/2.117 Å, 2.033 Å/2.127 Å, 2.011 Å/2.106 Å). C(1/2) and C(5/6) represent the midpoints of the C(1)=C(2) and C(5)=C(6) double bonds. Regarding the DIPHOL ligand, the P–C, C–C, and C–O distances in the chelate ring and in the dioxolane ring are similar to those in DIOP complexes–**A**, HRh[(+)-DIOP]$_2$,[28] and HRuCl-[(+)-DIOP]$_2$.[29] The bond distances and angles in the DBP moieties are reasonable in comparison with those in dibenzophosphole complexes, $Ni(CN)_2(DBP\text{-}R)_3$ (R=Me and Et),[30] $NiBr_2(DBP\text{-}Me)_2$.[31] The distances of the C–C and C=C bonds in the COD ligand are 1.40—1.53 Å for sp^3–sp^3 and sp^2–sp^3 bonds and 1.31—1.38 Å for sp^2–sp^2 bonds, which are comparable with

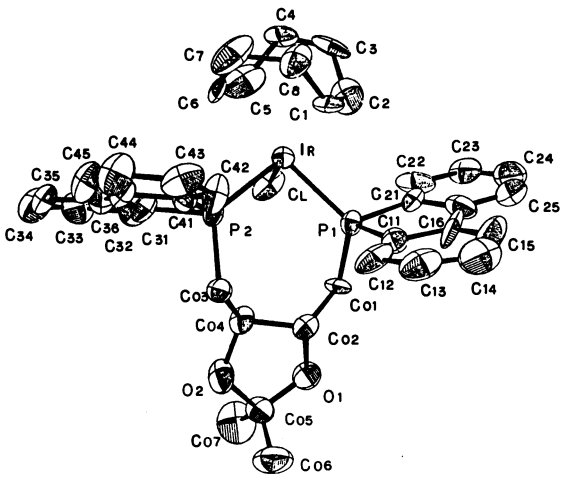

Fig. 1. An ORTEP drawing of IrCl(1,5-COD)[(−)-DIPHOL] (**B**).

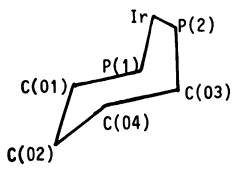
the values in IrMe(COD)$\mathbf{P}_2$.[25-27]

The coordination structure around the Ir atom is regarded as a distorted trigonal bipyramid with P(1) and C(5/6) in apical positions, according to the following results: 1) The ∠P(1)IrCl, ∠P(1)IrP(2), and ∠P(1)-IrC(1/2) angles are between 83.4—96.5°, and ∠C(5/6)-IrC(1/2), ∠C(5/6)IrCl, and ∠C(5/6)IrP(2) are between 82.1—94.7°, while ∠P(1)IrC(5/6)=168.5°. 2) The distance of Ir–C(1/2) is smaller than that of Ir–C(5/6). In all trigonal bipyramidal IrMe(COD)$\mathbf{P}_2$ complexes,[25-27] the distances of the equatorial C=C from Ir are shorter than those of the apical one (2.01—2.08 Å/2.11, 2.13 Å). 3) The dihedral angles between the faces of the polyhedron which cross at Cl–C(1/2), C(1/2)–P(2), and P(2)–Cl are 38.9°, 44.1°, and 75.7° respectively. As has been pointed out by Muetterties and Guggenberger,[32] the three smaller angles in the ideal trigonal bipyramid are all 53.1°, while those in the ideal square pyramid are 0.0°, 75.7°, and 75.7°. The comparison of the sum of the squares of each deviation in the angles indicated that the structure of the polyhedron of **B** is nearly trigonal bipyramidal.



The chelate ring makes a chair form with an almost flat "back" which consists of P(1)–Ir–P(2)–C(03) and a "foot" which consists of C(02). As a result of this chair-form conformation, the dihedral angles between the P(1)–Ir–P(2) plane and the two DBP moieties represented by C(11)–P(1)–C(21) and C(31)–P(2)–C(41) are 60.4° and 82.5° respectively. That is, the DBP moiety containing P(2) is almost perpendicular to the P(1)–Ir–P(2) plane, while that containing P(1) is skewed.

The molecular structures of **A**[15] and **B** are presented in Fig. 2 so that each Cl–P(1)–Ir–P(2) structure takes a similar direction. **A** has (+)-DIOP as the ligand, while the hydroformylation reactions in Table 1 were

IrCl(COD)[(+)-DIOP] (A) S. Brunie, J. Mazan, N. Langlois, and H. B. Kagan, *J. Organomet. Chem.*, 114, 225 (1976). (Ref. 15)

IrCl(COD)[(-)-DIPHOL] (B) in this work

Fig. 2. X-Ray molecular structures of IrCl(1,5-COD)–chiral diphosphine complexes.

carried out by the use of (−)-DIOP and (−)-DIPHOL, with (2*R*,3*R*)-chirality in the backbones. The chelate-ring conformation in **A**[16] takes a skewed chair form[33,34] with a skewed "back" which consists of CH_2–P–Ir–P and with a "foot" which consists of *t*-CH in DIOP. The displacements of fluxional Ph_2P groups in **A** by rigid DBP groups must increase the steric repulsion between aromatic groups; this may well be removed by a slight distortion of the chelate-ring conformation from the skewed chair form to the chair form described above. Thus, the dihedral angle between the C(03)–P(2)–Ir and P(2)–Ir–P(1) planes, which is 30.0° in **A**,[16] is reduced to 8.4° in **B**. Consequently, C(03)–P(2)–Ir–P(1)–C(21) makes an approximate plane, since a dihedral angle between the P(2)–Ir–P(1) and Ir–P(1)–C(21) planes is also small in **B** (7.2°). These conformational distortions of the chelate ring caused a fairly large difference in the structure of the complex; that is, the distance from the quart-C in the dioxolane ring to the P(1)–Ir–P(2) plane is reduced from 3.98 Å in **A** to 2.22 Å in **B**. Therefore, the mode of the protrusion of aromatic rings of the diphosphines into the coordination site for substrates or reactants, *i.e.*, the steric environment in the site, is profoundly changed, as will be shown below.

Discussion

Although the mechanism of asymmetric induction in hydroformylation has not yet been established, the difference between the stability of the diastereomeric intermediates, the hydridorhodium–(carbonyl)–(π-olefin)–diphosphine complexes, must play a part in the determination of the chirality of products. This is why the three kinds of butenes—1-butene, *cis*-2-butene, and *trans*-2-butene—all of which must go through the same *s*-butyl intermediate to be transformed to optically active 2-methylbutanal, gave aldehydes of different chiralities and different optical yields. (Table 1) The results in Table 1 can be explained on the basis of the molecular structures of **A** and **B** according to the following well-grounded assumptions: 1) The coordination structures of diphosphines in the diastereomeric rhodium–(π-olefin)–intermediate complexes are the same as in the iridium complexes, **A** and **B** respectively. 2) The coordination structures around the rhodium atom in the intermediate complexes are trigonal bipyramidal. 3) H and CO occupy apical positions. 4) The bulkier ligands, a chelating diphosphine and π-olefin, occupy equatorial positions, with angles of about

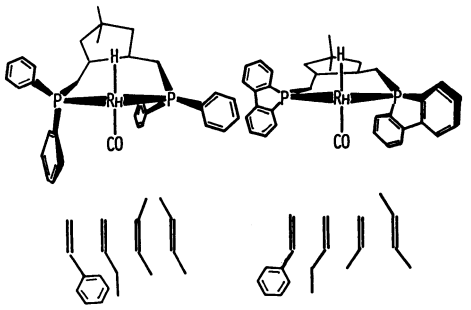

Fig. 3. Schematic coordination structures and conceivable modes of olefin π-coordination.

120° to each other, in order to release the steric congestions. If one of the three bulky ligands happens to occupy an apical position, it must have an angle of 90° with one of the other two in the equatorial position. Assumptions 2—4) can be explained by the X-ray molecular structure of $HRh(CO)(PPh_3)_3$,[35] which has a trigonal bipyramidal structure with H and CO in the apical positions and with three bulkier PPh_3's in the equatorial positions. 5) H in the rhodium intermediate complexes occupies the position of Cl in **A** and **B**; that is, the smallest ligand occupies the same side as the chelating diphosphine with regard to the P–Ir–P plane. This last assumption is acceptable if one considers the steric repulsion between the said apical position and the bridgehead CH or methylene CH_2 in the chelate ring.[36] This repulsion in the DIOP complex may be reduced to some extent in the DIPHOL complex, because the atoms comprising the chelate ring are placed nearer to the P–Ir–P plane, that is, farther from the apical H ligand, in the DIPHOL complex than in the DIOP complex.

In view of the above considerations, the steric environment of the two complexes is considered to be as is schematically drawn in Fig. 3, viewed from the coordination site of π-olefin. Although the difference in the conformations of the chelate rings is small between DIOP and DIPHOL complexes, the steric environment around the π-olefin coordination site is greatly changed, as one can recognize from Fig. 2 and, more directly, from Fig. 3.

As the present X-ray analysis shows, the chelate ring of (−)-DIPHOL is closer to the P–Ir–P coordination plane than is that of (−)-DIOP. Consequently, in the (−)-DIPHOL complex, the plane of the left DBP group becomes perpendicular to the P–Ir–P plane and parallel to the π-olefin coordination site, while the right DBP group protrudes into the middle of the π-olefin coordination site, as if it were a large wing.

In contrast with the case of the asymmetric hydrogenation of enamides or dehydroamino acid derivatives, the substrate olefins in Table 1 have no functional group which can exert an attractive interaction with the rhodium center or other part of the complex. The high reaction temperature and pressure are also disadvantageous to such an interaction. Therefore, the coordination structure of the substrates must be controlled by the steric repulsion only. In addition, olefins need to π-coordinate to the rhodium atom with the

substituents downward (the opposite side to hydrido with regard to the P–Ir–P plane) in order to be transformed into optically active branched aldehydes. Thus, the substrates prefer to π-coordinate to the rhodium center of the (−)-DIPHOL complex as is shown in Fig. 3. (Superimpose the double bonds of the substrates on the rhodium center.)

On the other hand, in the Rh–(−)-DIOP complex, the free rotation of the lower-left phenyl group is restricted by the other phenyl groups, and the steric hindrance by the *ortho*-CH in the coordination site for olefins seems to be significant. Therefore, the substrates prefer to π-coordinate to Rh–(−)-DIOP as is shown in Fig. 3, which leads to the prevailing configuration of products being the opposite of those when Rh–(−)-DIPHOL is used. However, since the upper-right phenyl group is parallel to, but also protrudes into the π-olefin coordination site, the chiral environment around the coordination site for substrates must be less selective. Consequently, the optical yields of products formed by the use of (−)-DIPHOL as a chiral ligand are higher than those formed by the use of (−)-DIOP. Thus, the results in Table 1 can be explained.

The authors wish to express their hearty thanks to Professor H. B. Kagan for sending them his detailed data on the X-ray molecular structure analysis of IrCl(COD)[(+)-DIOP] and for permitting them to reproduce the figure of Ref. 15. They also appreciate very much the permission for the reproduction given by Elsevier Sequoia S. A.

Asymmetric Transfer Hydrogenation of Prochiral α,β-Unsaturated Acids and Their Esters by Achiral or Chiral Alcohols with Ruthenium Chiral Diphosphine Complexes

Kohji Yoshinaga,* Taketoshi Kito, and Katsutoshi Ohkubo†

Department of Material Engineering, Kyushu Institute of Technology, Sensui-cho, Tobata-ku, Kitakyushu 804

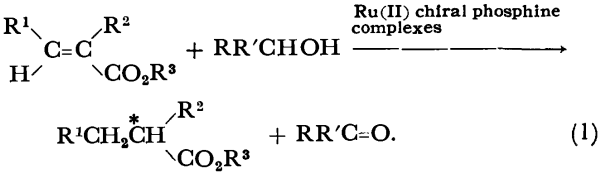
†*Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860*

(Received September 30, 1982)

Asymmetric transfer hydrogenations of α,β-unsaturated acids ($MeCH{=}C(Me)CO_2H$, $PhCH{=}C(Me)CO_2H$, $CH_2{=}C(CH_2CO_2H)CO_2H$, and $HO_2CCH{=}C(Me)CO_2H$) and esters ($MeCH{=}C(Me)CO_2R$; R=achiral and chiral group) by alcohols ($PhCH_2OH$, (*RS*)-PhCH(Me)OH, and α-D-glucofuranose derivatives) were carried out with $RuCl_2(PPh_3)_3$ or Ru_2Cl_4((+) or (−)-diop)$_3$ (diop=2,3-*O*-isopropylidene-1,4-bis(diphenylphosphino)-2,3-butanediol) at 160—190 °C. The optical purity (3.4—16.4%) of hydrogenated acids obtained with $PhCH_2OH$ and Ru_2Cl_4((−)-diop)$_3$ is in the order $MeCH{=}C(Me)CO_2H > PhCH{=}C(Me)CO_2H > CH_2{=}C(CH_2CO_2H)CO_2H > HO_2CCH{=}C(Me)CO_2H$, suggesting that the substrates possessing two carboxyl groups would provide an asymmetrically unfavorable coordination to the Ru(II) complex for this asymmetric reaction. In the transfer hydrogenation of $MeCH{=}C(Me)CO_2R$ by $PhCH_2OH$ or (*RS*)-PhCH(Me)OH at 190 °C, the extent of asymmetric induction of Ru_2Cl_4((−)-diop)$_3$ (1.7—11.4% e.e. with $PhCH_2OH$ and 7.4—18.2% e.e. with (*RS*)-PhCH(Me)OH) decreases with increase in bulkiness of groups R (R=H, Me, Et, *n*-Bu, and $PhCH_2$) and is not enhanced by the introduction of any groups R with chiral carbon atoms into esters (maximum 15.4% e.e.). The structural change of hydrogen donors from $PhCH_2OH$ to (*RS*)-PhCH(Me)OH appreciably increases the optical purity of the saturated acids and esters, and the chiral α-D-glucofuranose derivatives afford optically active saturated products, even with achiral $RuCl_2(PPh_3)_3$. Features of the present reaction are discussed in relation to the reaction mechanism.

Catalytic asymmetric synthesis of optically active compounds is recently receiving considerable attention,[1] and rhodium chiral phosphine complexes have successfully been used in homogeneous hydrogenations for formation of α-amino acid derivatives.[2-4] Chiral ruthenium complexes, as compared with rhodium ones, have been subjected to limited investigations on their catalytic activity for the asymmetric synthesis.[5,6]

Since ruthenium chiral phosphine complexes are effective catalysts for enantiomer-differentiating dehydrogenation of racemic secondary alcohols as found in our laboratory,[7] we have investigated the catalytic efficiency of chiral ruthenium complexes for the asymmetric transfer hydrogenation of prochiral olefins by alcohols, to examine the asymmetric hydrogenation without molecular hydrogen at the atmospheric pressure.



$$R^1R^2C{=}CH(CO_2R^3) + RR'CHOH \xrightarrow{\text{Ru(II) chiral phosphine complexes}} R^1CH_2\overset{*}{C}H(R^2)(CO_2R^3) + RR'C{=}O. \quad (1)$$

In this paper, we describe effects of the chirality and bulkiness of substituent groups in reactants on the extent of asymmetric induction in the transfer hydrogenation of prochiral α,β-unsaturated acids and esters by alcohols with $RuCl_2(PPh_3)_3$ or Ru_2Cl_4((+) or (−)-diop)$_3$ (diop =2,3-*O*-isopropylidene-1,4-bis(diphenylphosphino)-2,3-butanediol), and discuss on the reaction mechanism with particular reference to the enantio-differentiating catalysis by the ruthenium complexes.

Experimental

Materials. (+) and (−)-Diop and Ru_2Cl_4 ((+) or (−)-diop)$_3$ were prepared by Kagan's[8] and James'[5a] methods, respectively. α-D-Glucose derivatives, 1,2-*O*-isopropylidene-1,2 : 5,6-*O*-diisopropylidene-, 1,2-*O*-cyclohexylidene-, and 1,2 : 5,6-*O*-dicyclohexylidene-α-D-glucofuranose were synthesized by the methods reported.[9,10] Several α-methylcrotonates (1-phenylethyl, α-(ethoxycarbonyl)benzyl, (1*R*,2*R*)-1,2-bis(ethoxycarbonyl)-2-hydroxyethyl, and *l*-menthyl esters) were prepared *via* the reaction of α-methycrotonoyl chloride and the corresponding hydroxy compounds (1-phenylethanol, ethyl mandelate, diethyl (2*R*, 3*R*)-tartarate, and *l*-menthol, respectively). Alcohols, prochiral acids, and esters were purified by fractional distillation or recrystallization before use.

Transfer Hydrogenation. A mixture of prochiral olefin and alcohol was allowed to react in the presence of the chiral ruthenium complex in a sealed tube at the desired temperature controlled within ±1 °C in a nitrogen atmosphere. The reaction mixture was refluxed in a 10% NaOH-methanol solution, and the insoluble catalyst was separated from the solution by the filtration. The filtrate was washed with water, acidified with dilute HCl solution in the range of pH 3—4, and extracted with ether. The ethereal phase was washed with water, dried over magnesium sulfate, and evaporated to dryness. The unreacted prochiral olefin and hydrogenated product were identified by GLC analysis (at 170 °C using a 1 m column packed with 15% EGA on Uniport B) or by the proton NMR (100 MHz) method. The optical rotation of the hydrogenated product was measured with a high-sensitivity Union PM-101 polarimeter.

Results and Discussion

Asymmetric Transfer Hydrogenation of α,β-Unsaturated Carboxylic Acids and Esters. The asymmetric reduction of the carbon-carbon double bond in prochiral α,β-unsaturated mono- and dicarboxylic acids by benzyl or *p*-methoxybenzyl alcohol was first carried out with Ru_2Cl_4((−)-diop)$_3$. The results are summarized in Table 1. The optical purity of hydrogenated products for the unsaturated monocarboxylic acids is relatively high as compared with that for the unsaturated dicarboxylic acids. The bulky carboxyl groups might hinder the

a) Catalyst, 4 mmol dm^{-3}; substrate, 40 mmol; alcohol, 80 mmol. b) Calculated on the basis of the following values of optically pure acids: $[\alpha]_D^{23}$+12.17° (*c* 5, C_2H_5OH) for (*S*)-(+)-$CH_3CH_2CH(CH_3)CO_2H$;[11] $[\alpha]_D^{25}$+20.68° (neat) for (*S*)-(+)-$CH_3CH_2CH(CH_3)CO_2H$;[12] $[\alpha]_D^{20}$+16.88° (*c* 2.16, C_2H_5OH) for (*R*)-(+)-$CH_3CH(CO_2H)CH_2CO_2H$;[13] $[\alpha]_D^{20}$ −17.27° (*c* 5.0, C_2H_5OH) for (*S*)-(−)-$HO_2CCH_2CH(CH_3)CO_2H$.[14]

asymmetrically favorable coordination of the carbon-carbon double bond in the substrate to the chiral Ru(II) complex in the step of asymmetric induction.

It is also noteworthy that the optical purity of the saturated products derived from α-methylcrotonic or α-methylcinnamic acid (16.4 and 15.4%, respectively) is higher than the reported values (maxima 6.9 and 1.5%, respectively)[6c] for transfer hydrogenations of the same species with $H_4Ru_4(CO)_8$((−)-diop)$_8$ at 120 °C by 2-propanol, indoline, dioxane, *etc.*

Asymmetric transfer hydrogenation of a series of esters of α-methylcrotonic acid by benzyl alcohol or 1-phenylethanol was carried out with the Ru(II)-(−)-diop complex. The results are shown in Table 2. The ester derivatives of α-methylcrotonic acid, as compared with α-methylcrotonic acid itself, are easily hydrogenated to give their hydrogenated products with very low optical purities, which decrease with increasing bulkiness of the ester groups. The bulky ester moiety might decrease the extent of asymmetric induction considerably by suppressing the approach of the ester to the chiral catalyst during the enantio-face differentiating process.

The extent of asymmetric induction is also affected by the structure of hydrogen donor. Such an achiral alcohol as benzyl alcohol results in a low magnitude of asymmetric induction than 1-phenylethanol in the hydrogenation of α-methylcrotonic acid. Although benzyl alcohol gives saturated esters enriched in (*S*)-enantiomer, racemic 1-phenylethanol affords products enriched in the antipode with higher optical purity.

When a hydrogen transfer is effected with the Ru(II)-(−)-diop complex from alcohol to such an unsaturated acid as α-methylcrotonic acid, the reaction is considered to proceed *via* two courses I and II specified in Scheme 1. In course I, a partial esterification of the saturated acid is followed by a reduction of the carbon-carbon double bond of the unsaturated acid, and in course II, an unsaturated ester is formed before the corresponding acid is hydrogenated by alcohol in the presence of Ru(II) catalyst. In order to elucidate which course is predominant in the asymmetric transfer hydrogenation of unsaturated acid, we determined the time dependence of the chemical yield of products in the Ru(II)-(−)-diop complex catalyzed transfer hydrogenation of α-methylcrotonic acid or 1-phenylethyl α-methylcrotonate by 1-phenylethanol.

As can be seen from Fig. 1, α-methylcrotonic acid is

a) Ru_2Cl_4((−)-diop)$_3$, 4 mmol dm^{-3}; alcohol, 33 mmol; olefin, 67 mmol. b) Optical purities of saturated esters were calculated for the α-methylbutyric acids obtained from the esters by base hydrolysis. c) The reaction was carried out at 170 °C. d) Ru_2Cl_4((+)-diop)$_3$ was used.

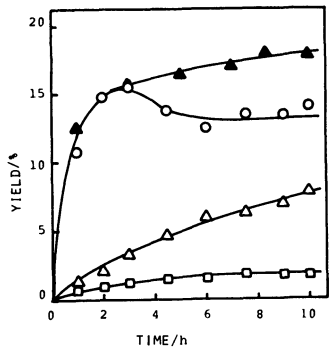

Fig. 1. Changes of product yields with time in the transfer hydrogenation of α-methylcrotonic acid (3.0 mol dm^{-3}) by 1-phenylethanol (5.8 mol dm^{-3}) with Ru_2Cl_4-(−)-diop)$_3$ (4.0 mmol dm^{-3}) at 190 °C.
Product: α-methylbutyric acid (○), 1-phenylethyl α-methylbutyrate (△), 1-phenylethyl α-methylcrotonate (□), 1-phenylethyl α-methylbutyrate (▲) obtained with 1-phenylethyl α-methylcrotonate (2.3 mol dm^{-3}) and 1-phenylethanol (4.7 mol dm^{-3}) at 190 °C.

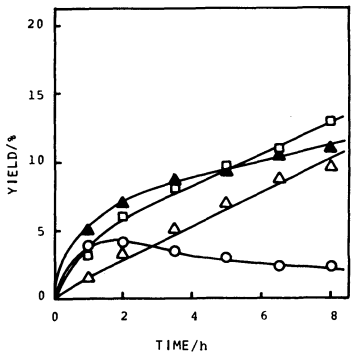

Fig. 2. Changes of product yields with time in the transfer hydrogenation of α-methylcrotonic acid (2.9 mol dm^{-3}) by benzyl alcohol (7.0 mol dm^{-3}) with Ru_2Cl_4-((−)-diop)$_3$ (4.0 mmol dm^{-3}) at 190 °C.
Product: α-methylbutyric acid (○), benzyl α-methylbutyrate (△), benzyl α-methylcrotonate (□); benzyl α-methylbutyrate (▲) obtained with benzyl α-methylcrotonate (1.5 mol dm^{-3}) and benzyl alcohol (6.8 mol dm^{-3}) at 190 °C.

hydrogenated smoothly by 1-phenylethanol with a small extent of esterification of the unsaturated acid, and rates of hydrogen transfers from 1-phenylethanol to α-methylcrotonic acid and to 1-phenylethyl α-methylcrotonate do not differ distinctly from each other. Strictly speaking, the hydrogenation of α-methylcrotonic acid includes a rate drop by the slow esterification of acid. Thus, the chiral Ru(II) complex catalyzed reaction of α-methylcrotonic acid with 1-phenylethanol proceeds mainly *via* course I with formation of α-methylbutyric acid as a main product.

On the other hand, the esterification of α-methylcrotonic acid by benzyl alcohol is relatively rapid, and benzyl α-methylcrotonate is easily reduced to benzyl α-methylbutyrate. From the gradual decrease in the yield of α-methylbutyric acid after the reaction period of 2 h (Fig. 2), it is evident that the saturated ester is produced from α-methylbutyric acid *via* course I, and that benzyl α-methylbutyrate is formed from α-methylcrotonic acid and benzyl alcohol *via* both courses I and II; the later path seems predominant. It should be stressed that in the transfer hydrogenation of α-methylcrotonate with benzyl alcohol or 1-phenylethanol, no hydrolysis of unsaturated or saturated esters was observed. Thus the difference in reactivity between hydrogen donors (alcohols) affects the transfer hydrogenation process, allowing 1-phenylethanol to give a higher optical purity (18.2%) than that (11.4%) obtained with benzyl alcohol in the hydrogenation of α-methylcrotonic acid (Table 2). Since the saturated product from benzyl α-methylcrotonate has a considerably low optical purity (1.7%) and contains the prevailing (*S*)-enantiomer, opposite to the predominant enantiomer found with α-methylcrotonic acid, the easy esterification of α-methylcrotonic acid by benzyl alcohol is taken to be responsible for the decreased optical purity of the saturated product.

For the present reaction the effective asymmetric induction by racemic 1-phenylethanol was actually recognized, and this is attributable to the chiral circumstances enriched in one specific enantiomer of the unreacted alcohol. In fact, in the transfer hydrogenation of α-methylcrotonic acid or its esters by racemic 1-phenylethanol, an enantiomer-differentiation of the alcohol was observed, and the optically active unreacted alcohol (maximum e.e. 4.2%) could be separated; the prevailing enantiomers are the (*S*)-isomer in the case of Ru(II)-(−)-diop complex and the (*R*)-isomer in the case of Ru(II)-(+)-diop complex. One of the enantiomers of 1-phenylethanol might contribute to the asymmetric induction through coordination to the chiral Ru(II) complex.

Asymmetric Transfer Hydrogenation of α-Methylcrotonic Acid by Chiral Alcohol. Since the chirality of hydrogen donors is anticipated to affect the extent of asymmetric induction in the transfer hydrogenation of unsaturated species with the chiral Ru(II) complex, we carried out a reaction of α-methylcrotonic acid with chiral alcohol as follows: (1) an asymmetric transfer hydrogenation using α-D-glucofuranose derivatives as chiral alcohols with an achiral catalyst $RuCl_2(PPh_3)_3$, and (2) a double asymmetric transfer hydrogenation by the chiral hydrogen donors with a chiral catalyst Ru_2Cl_4((+) or (−)-diop)$_3$. Results are listed in Table 3.

$$RR'\overset{*}{C}HOH + CH_3CH{=}C(CH_3)CO_2H \xrightarrow[2.\ Ru_2Cl_4((+)\text{ or }(-)\text{-diop})_3]{1.\ RuCl_2(PPh_3)_3} CH_3CH_2\overset{*}{C}H(CH_3)CO_2H + RR'C{=}O \quad (2)$$

In the case of the transfer hydrogenation of α-methylcrotonic acid with the chiral alcohol and $RuCl_2(PPh_3)_3$, the optically active α-methylbutyric acid (0.3—8.9% e.e.) was produced with the prevailing (*R*)-enantiomer, and the use of 1,2 : 5,6-*O*-diisopropylidene- and 1,2-*O*-isopropylidene-α-D-glucofuranose gave rise to higher optical purities (6.7—8.9%) than those (0.3—3.1%) obtained with 1,2 : 5,6-*O*-dicyclohexylidene- and 1,2-*O*-cyclohexylidene-α-D-glucofuranose.

In the double asymmetric reaction with the chiral

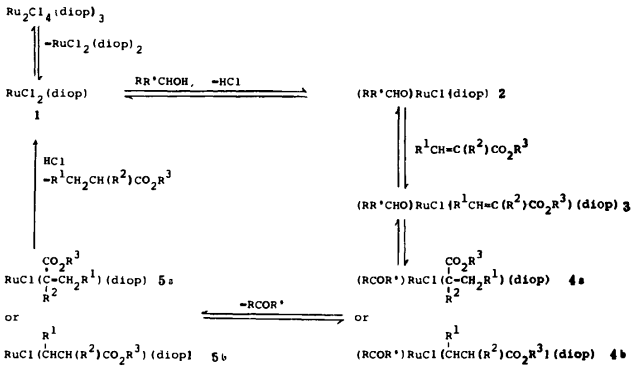
a) Catalyst, 4 mmol dm^{-3}; alcohol, 33 mmol; ester, 67 mmol. b) Optical purities were determined in the same way as in Table 2. c) Ru_2Cl_4((+)-diop)$_3$ was used.



Scheme 2. The sign of the optical rotation of diop is omitted.

alcohol and Ru_2Cl_4((−)-diop)$_3$, the Ru(II) complex substantially increases the optical purity of α-methylbutyric acid enriched in (*R*)-enantiomer with a maximum optical purity of 22.5% in the case of 1,2-*O*-isopropylidene-α-D-glucofuranose. However, the Ru(II)–(+)-diop complex gave a lower optical purity of the saturated product than that obtained with $RuCl_2(PPh_3)_3$, and changed the enriched enantiomer in the product from (*R*)- to (*S*)-isomer in the case of 1,2-*O*-isopropylidene-α-D-glucofuranose.

At any rate, the chiral alcohols (α-D-glucofuranose derivatives) contribute to enhancing the extent of asymmetric induction, even though the maximum optical purity of 22.5% is lower than that (26.4%) attained with 1-phenylethanol.

Asymmetric Transfer Hydrogenation of α-Methylcrotonate Including Racemic or Chiral Ester Groups. In the present transfer hydrogenation, the double asymmetric induction, including the diastereo-face differentiation of unsaturated esters by the chiral catalyst, can also be expected by the use of unsaturated ester substrates containing chiral carbon atoms in the ester moiety, achiral alcohol, and the Ru(II) complex.

When an asymmetric transfer hydrogenation of racemic or optically active α-methylcrotonate by 1-phenylethanol was effected with the Ru(II)–(−)-diop complex, no effective double asymmetric induction was realized (Table 4); optical purities of hydrogenated products were low (maximum 15.4%). Presumably, the steric bulkiness of the ester group in the substrates decreases the enantio-face differentiating ability of the chiral Ru(II) complex through depression of the substrate coordination to the complex.

Reaction Mechanism. It is obvious that the present asymmetric hydrogen transfer from alcohol (RR'CHOH) to unsaturated substrate ($R^1CH=C(R^2)CO_2R^3$) is effected by the coordination of both the reactants to the Ru(II) complex. From the fact that the chirality of the alcohol substantially affects the extent of asymmetric induction by the Ru(II)–(+) or (−)-diop catalyst, the asymmetric induction can be expected in the process of coordination of $R^1CH=C(R^2)CO_2R^3$ to the unsoluble ruthenium–alkoxide complex (*viz.*, the steric approach control over enantio-face differentiation[15]), which has previously been formed from the

active ruthenium species and the alcohol.

As for the catalytically active species in the present catalysis, $RuCl_2$((+) or (−)-diop) (**1**) has already been suggested as the plausible species by our previous ^{31}P NMR analysis of Ru_2Cl_4((−)-diop)$_3$ at −10—70°C;[16] $RuCl_2$((+) or (−)-diop)$_2$ simultaneously formed seems inactive for the present reaction because of the lack of active sites.

Therefore, the present transfer hydrogenation is thought to proceed along the catalytic cycle in Scheme 2, where the participation of HCl in the step of coordination of the alcohol to species **1** and of the elimination of the hydrogenated product has already been proposed by Sasson and Blum[17] in the transfer hydrogenation of unsaturated ketones by alcohols with $RuCl_2(PPh_3)_3$. Ruthenium–alkyl complexes **4a** and **5a** are more plausible than complexes **4b** and **5b** in the light of the contribution of the d-π conjugation between the ruthenium metal and carbonyl group to the stabilization.[18] A more detailed study on the reaction mechanism, especially regarding the asymmetric induction of the Ru(II)-(+) or (−)-diop complex, is now in progress.

Electrochemical Additions of the Allyl and the Benzyl Groups of Allyl and Benzyl Halides to Acetone

Shohei SATOH,† Hiroshi SUGINOME, and Masao TOKUDA*
Department of Chemical Process Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060
(Received October 12, 1982)

Electrolysis of allyl chloride and five molar excess of acetone in hexamethylphosphoric triamide containing 0.5 M†† tetrabutylammonium perchlorate gave an addition product, 2-methyl-4-penten-2-ol, in a 53% yield. Allyl groups of 1-chloro-2-methyl-2-propene, 1-chloro-2-butene(**3**), 3-chloro-1-butene(**4**), 1-chloro-3-methyl-2-butene(**5**), and 3-chloro-3-methyl-1-butene(**6**), and benzyl groups of benzyl chloride, benzyl bromide, and 1-chloro-1-phenylethane can similarly be added to acetone by electrolysis to give the corresponding alcohols in fair to good yields. Among these electrochemical reactions, those of **3**, **4**, **5**, and **6** with acetone give respectively two isomeric homoallyl alcohols, one of the isomers is not accessible by the usual chemical reaction between allylic organometallics and acetone.

The electrochemical cleavage of the carbon-halogen bond of organic halides generates radical and/or carbanion as the important intermediates.[1] Dimers and hydrocarbons have been the only products isolated in these studies.[1] Although radical or carbanion generated by ordinary chemical reaction is being used in a variety of organic syntheses, carbanion or radical, which was electrochemically generated, has rarely been used for C–C bond formation.[2] For instance, with regard to a nucleophilic addition of a carbanion generated electrochemically to a carbonyl carbon, only the additions of tetrachloromethane[3,4] or ethyl trichloroacetate[3] to carbonyl compounds and the additions of allyl or benzyl chloride to carbon dioxide[2e] have been reported.[5]

In this paper we report successful additions of the carbanions generated electrochemically from substituted allyl and benzyl halides to ketones in hexamethylphosphoric triamide (HMPA) under mild conditions.

Results and Discussions

Electrochemical addition of the allyl group of allyl chloride (**1a**) to acetone was successfully carried out by using HMPA as a solvent. Thus, electrolysis of **1a** in the presence of five molar excess of acetone in HMPA containing 0.5 M tetrabutylammonium perchlorate (TBAP) as a supporting electrolyte using an undivided cell gave 2-methyl-4-penten-2-ol (**9**) in a 53% yield.

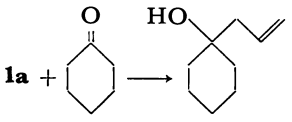
$$CH_2{=}CHCH_2X + CH_3COCH_3 \longrightarrow CH_2{=}CHCH_2\overset{\displaystyle CH_3}{\underset{\displaystyle OH}{C}}CH_3$$

1a: X = Cl
b: X = Br
c: X = I

9

Table 1 summarizes the results of this electrochemical addition carried out under several different electrolytic conditions. The Table indicates that HMPA is the best solvent and gives a yield of **9** much higher than that obtained by using other solvents such as DMF or THF (runs 1—3). The ratio of acetone to **1a** is important (runs 3—6) and increasing the ratio of acetone to **1a** generally gives a higher yield of **9**. The use of ten molar excess of acetone, however, resulted in a lower yield of **9**. This lower yield can probably be attributed to a lack of sufficient HMPA (2 ml). (The total volume of the solution was kept nearly constant in all runs and the volume of HMPA in usual runs was 5.5 ml). With regard to the electrode material, platinum cathode gave the best yield of **9** while mercury and carbon as the cathode gave a yield lower than platinum (runs 7 and 8). A change of the current density from 10 to 50 mA/cm^2 did not show any appreciable change in the yield (runs 11—14). The electrolysis at a cathode using a divided cell under the same conditions as that of run 3 in Table 1 gave only 19% yield of **9**. Thus, the use of an undivided cell rather than a divided cell may be preferable although this electrochemical reaction is a cathodic reaction.

Electrochemical reaction of **1a** with cyclohexanone under the same conditions as that of run 3 in Table 1 gave 1-allylcyclohexanol (**10**) in a 42% yield. Controlled potential electrolysis at −2.2 V *vs* Ag/AgI gave **10** in a 55% yield.



10

Electrochemical additions of the allyl- or the benzyl groups of various allyl halides or benzyl halides to acetone in HMPA containing 0.5 M TBAP gave the corresponding alcohols **9**—**17** and the results are summarized in Table 2. 1,5-Hexadiene from the electrochemical reactions of allyl bromide (**1b**) or allyl iodide (**1c**) with acetone, and bibenzyl from the reaction of benzyl bromide (**7b**) were obtained as by-products. The allyl anion generated by a two electron reduction of **1b** or **1c** underwent a nucleophilic attack on **1b** or **1c** to give 1,5-hexadiene[1e,2e] along with a nucleophilic addition reaction giving **9**. The presence of the side reaction pathway in the reactions of **1b** and **1c** would have led to a lower yield of **9**, whereas the electrochemical reaction of **1a** gave only **9** because of its lower reactivity towards allyl anion.

It should be noted that the addition products such

† Present address: Nippon Engelhard, Ltd., Ichikawa 272.

†† 1 M=1 mol dm^{-3}.

as **13** and **15** obtained in the electrochemical reactions of **3**, **4**, **5**, or **6** with acetone in the present study can not be obtained by the reaction of allylic organometallics derived from these halides with ketone. The organometallic reactions give exclusively the products **12** or **14** having the allyl group attached at the more heavily substituted carbon terminus.[6,7,8] The reactions of a metal with allyl halides **3** and **4** lead to the same organometallic compound which contains mainly the primary type of allylic organometallics, irrespective of the

TABLE 1. RESULTS OF ELECTROHCEMICAL REACTION OF ALLYL CHLORIDE (**1a**) WITH ACETONE[a]

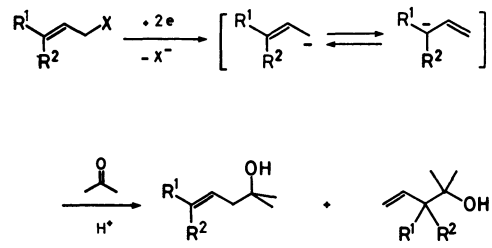
a) A mixture of halide (10 mmol) and acetone (50 mmol) in 5.5 ml of HMPA containing 0.5 M Bu_4NClO_4 was electrolyzed at 0 °C using platinum plate electrodes. Current density was 25 mA/cm^2 and electricity passed was 2.0 *F* per mol of halide. b) Yields are based on halides used. Numbers in parentheses are also a current yield of each product.

structure of the starting halides **3** or **4**.[6] Such organometallics derived from **3** or **4** undergo the addition reaction to acetone to give exclusively **12** with a complete allylic rearrangement.[6] On the other hand, the electrochemical reactions of **3** or **4** with acetone produced different proportions of **12** and **13**. These depended on the properties of the electrode material, the readiness of the reduction of the substrates, or other electrolytic conditions. For instance, the electrochemical addition of **4** to acetone on a platinum cathode gave **12** and **13** in the ratio of 62 : 38 whereas on a carbon cathode the ratio was 29 : 71.[9] An effect of the readiness of the reduction of the substrates on these regiochemistries was observed in the electrochemical conjugate additions of **5** to α,β-unsaturated esters.[20,9] Although the electrochemical conjugate addition of **5** to diethyl fumarate which is more readily reduced than **5** took place at the less heavily substituted carbon terminus of **5**, the addition of **5** to ethyl crotonate which is less readily reduced than **5** occurred at the more heavily substituted carbon of **5**.[20,9] These regiochemistries are of considerable interest from the mechanistic and synthetic points of views, and this will be discussed more fully in later papers.



Scheme 1.

A probable path, which involves nucleophilic addition of allyl or benzyl anion to a carbonyl carbon, is shown in Scheme 1. Cyclic voltammetry shows that the reduction peak of acetone does not appear at a potential less negative than −2.5 V *vs.* Ag/AgI whereas the reduction peaks of **1a**, **1b**, **1c**, **2**, **3**, **4**, **7a**, and **7b** were observed at −2.35, −1.90, −1.43, −2.40, −2.40, −2.20, −2.00 and −1.80 V *vs.* Ag/AgI, respectively. Thus, a two electron reduction of allylic or benzylic halides is involved in this electrolysis to give the corresponding carbanions,[1e] which react with a carbonyl carbon.

One of the roles of HMPA as a solvent would be to stabilize carbanion intermediates leading to an increased yield of **9** as compared to those in other solvents. We found that a controlled potential electrolysis of **1a** and acetone in HMPA at −2.0 V or −1.5 V *vs.* Ag/AgI, which is a reduction potential less cathodic than that of **1a**, gave 30—34% yield of **9**. This may be partly due to a specific property of HMPA which has been suggested to be selectively adsorbed on the metal surface.[10] It may be also due to some difference of the reduction potentials between the microelectrolysis and the macroelectrolysis.[11] It should be noted that the electrochemical reduction of naphthalene in HMPA took place at a potential less cathodic than the half-wave potential of naphthalene[11] although this electrolytic system was considerably different from that of the present electrochemical reaction with acetone. The exact roles of HMPA during the course of the present electrochemical reaction are now under investigation.

Experimental

All the products were isolated and purified by distillation and by preparative GLPC with a JEOL JGC-20K or a Varian Autoprep 700 instrument. Spectroscopic measurements were carried out as described previously.[20] Quantitative GLPC analyses were carried out with a Hitachi 063 instrument using an internal standard method.

Materials. Hexamethylphosphoric triamide (HMPA) was dried over calcium hydride and distilled before use over lithium aluminium hydride under nitrogen at a reduced pressure. Acetone was treated with potassium permanganate and distilled. Most of the allyl or benzyl halides were commercially available and were distilled before use. 1-Chloro-3-methyl-2-butene (**5**) and 3-chloro-3-methyl-1-butene (**6**) were prepared from isoprene by the described procedure.[12] **5** (43%): bp 107—109 °C.[20] **6** (70%): bp 10—12 °C/20 mmHg (1 mmHg ≈133.322 Pa); ^{1}H NMR, δ 1.66 (6H, s), 5.15—6.1 (3H, m).

General Procedure for Electrolysis. For most of the preparative electrolyses, a normal undivided cell (2.8 cm dia.) equipped with a magnetic stirrer, a reflux condenser, and a serum cap for introduction of nitrogen gas was used. Electrolysis was carried out under a nitrogen atmosphere at a constant current using two platinum plate electrodes (2×2 cm^2). A typical procedure is as follows: A mixture of halide (10 mmol) and acetone (50 mmol) in 5.5 ml of HMPA containing 0.5 M Bu_4NClO_4 was electrolyzed at 0 °C with a current desity of 25 mA/cm^2 until 2.0 F of electricity per mol of halide was passed. After electrolysis, the reaction mixture was dissolved in diethyl ether and the solution was washed with thiosulfate solution and water, and dried over magnesium sulfate. The usual work-up of the solution gave a product mixture which was subjected to distillation and preparative GLPC to give pure products. Some physical properties of the products are recorded below.

*2-Methyl-4-penten-2-ol (**9**)*: n_D^{21} 1.4240; IR (neat) 3370, 3080, 1150, and 915 cm^{-1}; ^{1}H NMR ,δ 1.13 (6H, s), 1.48 (1H, s), 2.15 (2H, d), 5.1 (2H, m), and 5.85 (1H, m); MS *m/z* (rel intensity) 85 (M^+-CH_3, 4), 59 (100), and 43 (51). Calcd for $C_6H_{11}O$ (M^+-1): *m/z* 99.081. Found: *m/z* 99.081

*1-Allycylohexane (**10**)*: n_D^{25} 1.4729; IR (neat) 3380, 980, and 910 cm^{-1}; ^{1}H NMR, δ 1.19 (1H, s), 1.45 (10H, m), 2.17 (2H, d), 5.1 (2H, m), and 5.85 (1H, m); MS *m/z* (rel intensity) 122 (M^+-H_2O, 19), 99 (86), and 81 (100). Calcd for $C_9H_{16}O$: *m/z* 140.118. Found: *m/z* 140.118.

*2,4-Dimethyl-4-pentent-2-ol (**11**)*: n_D^{25} 1.4318; IR (neat) 3380, 3075, and 890 cm^{-1}; ^{1}H NMR, δ 1.18 (6H, s) 1.30 (1H, s), 1.83 (3H, s), 2.15 (2H, s), 4.73 (1H, m), and 4.90 (1H, m); MS *m/z* (rel intensity) 96 (M^+-H_2O, 10), 81 (73), and 59 (100). Calcd for $C_7H_{14}O$: *m/z* 114.104. Found: *m/z* 114.103.

*2,3-Dimethyl-4-penten-2-ol (**12**)*: n_D^{21} 1.4325; IR (neat) 3400, 3080, and 915 cm^{-1}; ^{1}H NMR, δ 0.95 (3H, d), 0.96 (1H, s), 1.07 (6H, s), 2.07 (1H, qi), 5.00 (2H, m), and 5.75 (1H, m); MS *m/z* (rel intensity) 96 (M^+-H_2O, 16), 81 (71), and 59 (100). Calcd for $C_7H_{14}O$: *m/z* 114.104. Found: *m/z* 114.104.

trans-*2-Methyl-4-hexen-2-ol* (t-*13*): n_D^{20} 1.4321; IR (neat) 3370, 3030, and 970 cm^{-1}; ^{1}H NMR, δ 1.01 (1H, s), 1.08 (6H, s), 1.65 (3H, m), 2.02 (2H, m), and 5.42 (2H, m); MS *m/z* (rel intensity) 96 (M^+-H_2O, 16), 81 (100), and 59 (79). Calcd for $C_7H_{14}O$: *m/z* 114.104. Found: *m/z* 114.104.

cis-*2-Methyl-4-hexen-2-ol* (c-*13*): n_D^{20} 1.4370; IR (neat) 3370,

3020, 1655, and 690 cm^{-1}; ^1H NMR, δ 1.04 (1H, s), 1.13 (6H, s), 1.59 (3H, d), 2.12 (2H, d), and 5.50 (2H, m); MS *m/z* (rel intensity) 96 (M^+-H_2O, 45), 81 (100), and 59 (78). Calcd for $C_7H_{14}O$: *m/z* 114.104. Found: *m/z* 114.105.

*2,3,3-Trimethyl-4-penten-2-ol (**14**)*: n_D^{20} 1.4453; IR (neat) 3450, 3080, 915 cm^{-1}; ^1H NMR, δ 1.03 (6H, s), 1.12 (6H, s), 1.26 (1H, s), 5.05 (2H, m), and 6.05 (1H, m); MS *m/z* (rel intensity) 70 (32), 59 (100), and 43 (57). Calcd for $C_8H_{15}O$: *m/z* 127.112. Found: *m/z* 127.114.

*2,5-Dimethyl-4-hexen-2-ol (**15**)*: n_D^{20} 1.4437; IR (neat) 3370, and 850 cm^{-1}; ^1H NMR, δ 1.15 (6H, s). 1.64 (3H, s), 1.75 (3H, s), 2.10 (2H, d), and 5.24 (1H, m); MS *m/z* (rel intensity) 70 (52), 59 (100), and 43 (57). Calcd for $C_8H_{16}O$: *m/z* 128.120. Found: *m/z* 128.120.

*2-Methyl-1-phenyl-2-propanol (**16**)*: n_D^{24} 1.5110; IR (neat) 3350, 720, and 695 cm^{-1}; ^1H NMR, δ 1.16 (6H, s), 1.64 (1H, s), 2.69 (2H, s), and 7.21 (5H, s); MS *m/z* (rel intensity) 92 (100) and 59 (95). Calcd for $C_{10}H_{14}O$: *m/z* 150.105. Found: *m/z* 150.105.

*2-Methyl-3-phenyl-2-butanol (**17**)*: n_D^{24} 1.5113; IR (neat) 3370, 765, and 695 cm^{-1}; ^1H NMR, δ 1.10 (3H, s), 1.12 (3H, s), 1.32 (3H, d), 1.42 (1H, s), 2.71 (1H, q), and 7.22 (5H, s); MS *m/z* (rel intensity) 106 (100), 91 (97), and 59 (95). Calcd for $C_{11}H_{16}O$: *m/z* 164.120. Found: *m/z* 164.121.

Cyclic Voltammetry. Cyclic voltammetry was carried out with a Yanaco V8 potentiostat at a sweep rate of 0.2 V s^{-1} using a platinum disk electrode (1 mm dia.) in HMPA containing 0.1 M Bu_4ClO_4. A potential was measured in V *vs* Ag/AgI.

A Route from 1,1,1,3-Tetrachloro-3-phenylpropane to Ethynyl Phenyl Ketone Involving Elimination of Hydrogen Chloride and 1,3-Proton Transfer

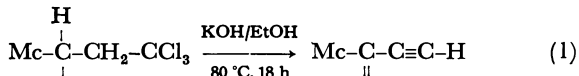
Takeo Akiyama,* Yasuki Yoshida, Tokiko Hanawa, and Akira Sugimori

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho 7-1, Chiyoda-ku, Tokyo 102

(Received October 18, 1982)

The treatment of 1,1,1,3-tetrachloro-3-phenylpropane with alkali in ethanol affords ethynyl phenyl ketone and its acetal in good yields. This reaction proceeds through the elimination of hydrogen chloride and an efficient 1,3-proton transfer catalyzed by base. Ethyl cinnamate is obtained in only 2% yield.

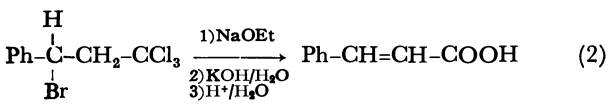
We have already reported the formation of ethynyl metallocenyl ketones in the reaction of 1,1,1-trichloro-3-alkoxy-3-metallocenylpropanes with alkali in ethanol.[1] The expected product, ethyl 3-metallocenylacrylate (Mc–CH=CH–COOEt) has not been obtained.



$$\mathrm{Mc{-}\overset{\displaystyle H}{\overset{|}{C}}{-}CH_2{-}CCl_3} \xrightarrow[80\ ^\circ\mathrm{C},\ 18\ \mathrm{h}]{\mathrm{KOH/EtOH}} \mathrm{Mc{-}\overset{\displaystyle OR}{\overset{|}{C}}{-}C{\equiv}C{-}H} \quad (1)$$

Mc: $(\eta^5\text{-}C_5H_5)_2M$, M = Fe, Ru; R = $-CH_3$, $-C_2H_5$

On the other hand, Kharasch *et al.* reported[2] that the treatment of 1,1,1-trichloro-3-bromo-3-phenylpropane, a bromotrichloromethane adduct to styrene, with sodium ethoxide in ethanol followed by hydrolysis gave cinnamic acid.



$$\mathrm{Ph{-}\overset{\displaystyle H}{\overset{|}{C}}{-}CH_2{-}CCl_3} \xrightarrow[2)\mathrm{KOH/H_2O}\ 3)\mathrm{H^+/H_2O}]{1)\mathrm{NaOEt}} \mathrm{Ph{-}CH{=}CH{-}COOH} \quad (2)$$
$$\mathrm{Br}$$

In order to clarify whether the unusual reaction shown in Eq. 1 is favored specifically by metallocenyl group attached at 3-position or whether it occurs in the normal carbon tetrachloride adduct of alkenes, we reinvestigated the solvolysis of 1,1,1,3-tetrachloro-3-phenylpropane (**1**) in the alkali–ethanol systems.

Experimental

Materials. Styrene (Wako Pure Chemical Co., G. R.) was distilled under reduced pressure just before use. Chlorotris (triphenylphosphine)ruthenium(II) was prepared according to the method given in the literature.[3] Sodium ethoxide was prepared from sodium metal and absolute ethanol. Ethanol-*d* (CH_3CH_2OD) (Commissariat a l'Energie Atomique, France, deuterium content: 99%) was used as received.

1,1,1,3-Tetrachloro-3-phenylpropane(**1**) was prepared from styrene according to Matsumoto *et al.*[4] Styrene (15.6 g, 0.15 mol) and chlorotris(triphenylphosphine)ruthenium(II) (0.78 g, 0.8 mmol) were dissolved in carbon tetrachloride (76 g, 50 cm³) and the solution was refluxed for 5 h under nitrogen atmosphere. After the reaction, carbon tetrachloride was removed under reduced pressure and the residue was submitted to column chromatography on silica gel (Wakogel C-200, 200 mesh, eluent: C_6H_6). **1** was obtained in 95% yield. The spectral data (IR and ^{1}H NMR spectra) of **1** were identical with those obtained by Matsumoto[5a] and Asahara.[5b] 1,1,1,3-Tetrachloro-4-phenylbutane (**13**) was prepared by the similar method from allylbenzene and carbon tetrachloride in 82% yield. The IR and ^{1}H NMR spectra of **13** were identical with those obtained by Matsumoto.[6]

Measurements. ^{1}H NMR spectra were recorded on a Hitachi R-22 (90 MHz) spectrometer. IR spectra were measured on a Hitachi 260-50 spectrophotometer. Mass spectra and GC-mass spectra were obtained on a JEOL JMA D-300 GC-mass spectrometer (column: OV-1, 5%, 1 m glass column).

Quantitative gas chromatography was performed on a Shimadzu GC-6AFP gas chromatograph (column: OV-1, 5%, 2 m glass column, temperature: 90—120 °C) equipped with an integrator (Shimadzu Chromatopak, E-1a).

Reactions. Reaction of 1,1,1,3-tetrachloro-3-phenylpropane (1) with Potassium Hydroxide in Ethanol Solution: **1** (3.0 g, 11.6 mmol) and potassium hydroxide (10 g, 0.178 mol) were added to ethanol (100 cm³) and the solution was refluxed for 18 h at 80 °C. After the reaction, the reaction mixture was neutralized with aqueous sulfuric acid (0.1 mol dm^{-3}) and the organic substances were extracted with dichloromethane. After the solvent was removed under reduced pressure, the residue was submitted to column chromatography on silica gel (Wakogel C-200, eluent: C_6H_6). Compounds **2**, **3**, **6**, **8**, and **9** were obtained in almost pure form.

Reaction of 1,1,1,3-tetrachloro-4-phenylbutane (13) with Potassium Hydroxide in Ethanol Solution: The procedure is the same as described for the reaction of **1**. **13** (2.0 g, 7.3 mmol) was added to the ethanol solution containing potassium hydroxide (10 g/100 cm³) and the solution was refluxed for 18 h.

Reaction of 1,1,1,3-tetrachloro-3-phenylpropane (1) with Sodium Ethoxide in Ethanol Solution. To the absolute ethanol solution of sodium ethoxide (12.0 g, 0.176 mol in 100 cm³) was added 3 g of **1** (11.6 mmol) and the solution was refluxed for 18 h at 80 °C. The separation method of the reaction products was the same as described above.

Reaction of 1,1-dichloro-3-ethoxy-3-phenylpropane (10) with Sodium Ethoxide in Ethanol Solution: **10** (200 mg, 0.86 mmol) was refluxed in a sodium ethoxide–ethanol solution (3 g in 25 cm³) for 18 h at 80 °C. After the reaction, the solution was neutralized and the organic substances were extracted with dichloromethane. Dichloromethane was removed under reduced pressure and the residue was dissolved in carbon tetrachloride for ^{1}H NMR spectra measurement. The ^{1}H NMR spectra of the product mixture show the presence of only three compounds, **2**, **3**, and **5** (100% conversion). A trace of **4** was detected by GC-mass spectra of the mixture. The yields of the products were calculated from the integrals of the peak areas.

Reaction of 1,1-dichloro-3-ethoxy-3-phenylpropane (10) with Sodium Ethoxide in Ethanol-d (C_2H_5OD) Solution: **10** (300 mg, 1.3 mmol) was refluxed in sodium ethoxide–ethanol-*d* solution (1.0 g in 30 cm³) for 8 h at 80 °C. After the reaction, the products were extracted with dichloromethane and the solvent was removed under reduced pressure. The residue was dissolved in carbon tetrachloride for the measurement of ^{1}H NMR spectra. The ^{1}H NMR spectra showed the presence

of **5**, **5**-*d*, **2**, **2**-*d*, **10**, **10**-*d*, and **3**. The ratio of **5** *versus* **5**-*d* was calculated based on the area of the peak of proton; the ratio of the area $\delta=5.76$ (s, –CH=CDCl) *versus* $\delta=5.76$ (d, $J=13$ Hz, –CH=CHCl) was 2 : 1. Similar calculations were done for **2**, **2**-*d*, **10**, **10**-*d*. The ratios obtained were: 2/2-*d*=2/1, and 10/10-*d*=1/1. No deuterium incorporation was observed for **3**. The similar reaction was carried out at 60 °C for 2 h in order to detect the compound **11**. The ^{1}H NMR spectra showed the peaks of compound **10**, **3**, and **5**. No deuterium incorporation was observed for these compounds. The peak attributable to the presence of **11** could not be observed. The GC-mass spectra of the same sample showed no increase of the intensities of the fragment peaks plus one (P+1) compared with those of the compounds **10**, **3**, and **5** which were obtained in the reaction of **10** in sodium ethoxide–ethanol system.

Identification of the Products. *1-Phenyl-2-propyn-1-one-(Ethynyl Phenyl Ketone) (**2**)*: A colorless liquid substance. IR (neat) 3240 (≡C–H), 3055, 3030 (arom. C–H), 2095 (C≡C), and 1650 cm^{-1} (C=O). ^{1}H NMR (CCl_4) $\delta=3.34$ (1H, s, C≡C–H), 7.30—7.65 (3H, m, meta and para protons of C_6H_5–), and 8.00—8.20 (2H, m, ortho protons of C_6H_5–). GC–MS (OV-1, 110 °C, 23 eV) *m/e* (rel intensity) 130 (M^+, 100), 105 (Ph–CO, 5.27), 102 (M^+-CO, 77.09), 78 (C_6H_6, 5.88), and 77 (C_6H_5, 2.54). Found: *m/e* 130.0440. Calcd for C_9H_6O: M, 130.0418.

*3,3-Diethoxy-3-phenyl-1-propyne (**3**)*: A pale yellow liquid substance. IR (neat) 3270 (≡C–H), 3060, 3030 (arom. C–H), 2980, 2930, 2880 (aliph. C–H), 2110 (C≡C), 1110 and 1045 cm^{-1} (C–O–C). ^{1}H NMR (CCl_4) $\delta=1.19$ (6H, t, $-OCH_2-CH_3$), 2.59 (1H, s, C≡C–H), 3.53 (4H, m, $-OCH_2-CH_3$), and 7.20—7.55 (5H, m, C_6H_5–). GC–MS (OV-1, 126 °C, 70 eV) *m/e* (rel intensity) 204 (M^+, 1.54), ($M^+-C_2H_5$, 29.7), 159 ($M^+-OC_2H_5$, 100), 131 ($M^+-O(C_2H_5)_2+H$, 65.4), and 77 (C_6H_5, 1.9). Found: *m/e* 204.1131. Calcd for $C_{13}H_{16}O_2$: M, 204.1150.

*(Z)3-Chloro-1-phenyl-2-propen-1-one (**4**)*: A colorless liquid substance. IR (neat) 3060, 3030 (arom. C–H), 1670 (C=O), 1650 (C=C), and 670 cm^{-1} (*cis* CH=CHCl). ^{1}H NMR (CCl_4) $\delta=6.63$ (1H, d, $J=8$ Hz, –CH=CHCl), 6.87 (1H, d, $J=8$ Hz, –CH=CHCl), and 7.15—7.6 (5H, m, C_6H_5–). GC–MS (OV-1, 110 °C, 23 eV) *m/e* (rel intensity) 166 (M^+, 41.1, $M^+ +2/M^+=0.322$ (Cl×1)), 138 (M^+-CO, 13.3), 131 (M^+-Cl, 55.5), 105 (Ph–CO, 100), and 77 (C_6H_5, 36.7). Found: *m/e* 166.0168. Calcd for C_9H_7OCl: M, 166.01861.

*(E)1-Chloro-3,3-diethoxy-3-phenylpropene (**5**)*: A colorless liquid substance. IR (neat) 3070, 3030 (arom. C–H), 2980, 2940, 2880 (aliph. C–H), 1660 (C=C), 1070—1060 (C–O–C), and 942 cm^{-1} (*trans* CH=CHCl). ^{1}H NMR (CCl_4) $\delta=1.17$ (6H, t, $-OCH_2-CH_3$), 3.36 (4H, m, $-OCH_2-CH_3$), 5.76 (1H, d, $J=13$ Hz, –CH=CHCl), 6.50 (1H, d, $J=13$ Hz, –CH=CHCl), and 7.10—7.55 (5H, m, C_6H_5–). GC–MS (OV-1, 96 °C, 70 eV) *m/e* (rel intensity) 240 (M^+, 0.12, $M^+ +2/M^+=0.323$ (Cl×1)), 205 (M^+-Cl, 100), 195 ($M^+-OC_2H_5$, 79.23), 167 ($M^+-O(C_2H_5)_2+H$, 60.35), 131 ($M^+-O(C_2H_5)_2-Cl$, 70.84), 105 (Ph–CO, 86.63), and 77 (C_6H_5, 62.92). Found: *m/e* 240.0925. Calcd for $C_{13}H_{17}O_2Cl$: M, 240.09181.

*3,3-Diethoxy-1-phenyl-1-propanone (**6**)*: The dimethyl acetal of **6** which was prepared from **4** with sodium methoxide was reported by T. Matsumoto, *et al.*[7] A colorless liquid substance. IR (neat) 3070, 3030 (arom. C–H), 2980, 2940, 2890 (aliph. C–H), 1690 (C=O), and 1125 cm^{-1} (C–CO–C). ^{1}H NMR (CCl_4) $\delta=1.13$ (6H, t, $-OCH_2-CH_3$), 3.17 (2H, d, $J=5$ Hz, $-CH_2-CH(OC_2H_5)_2$), 3.61 (4H, m, $-CH_2-CH_3$), 5.03 (1H, t, $J=5$ Hz, $-CH_2-CH(OC_2H_5)_2$), 7.11—7.66 (3H, m, meta and para protons of C_6H_5–), and 7.77—8.11 (2H, m, ortho protons of C_6H_5–). GC–MS (OV-1, 110 °C, 23 eV) *m/e* (rel intensity) 222 (M^+, 1.33), 193 ($M^+-C_2H_5$, 29.86), 177 ($M^+-OC_2H_5$, 5.87), 176 ($M^+-HOC_2H_5$, 5.53), 147 ($M^+-O(C_2H_5)_2+H$, 12.27), 133 ($M^+-(OC_2H_5)_2+H$, 13.99), 105 (Ph–CO, 100), and 78 (C_6H_6, 8.59). Found: *m/e* 222.1264. Calcd for $C_{13}H_{18}O_3$: M, 222.12564.

*3,3-Diethoxy-1-phenylpropyne (**7**)*: A colorless liquid substance. IR and ^{1}H NMR spectra of this compound were identical with those reported by Kiely *et al.*[8] Found: *m/e* 204.1164. Calcd for $C_{13}H_{16}O_2$: M, 204.1150.

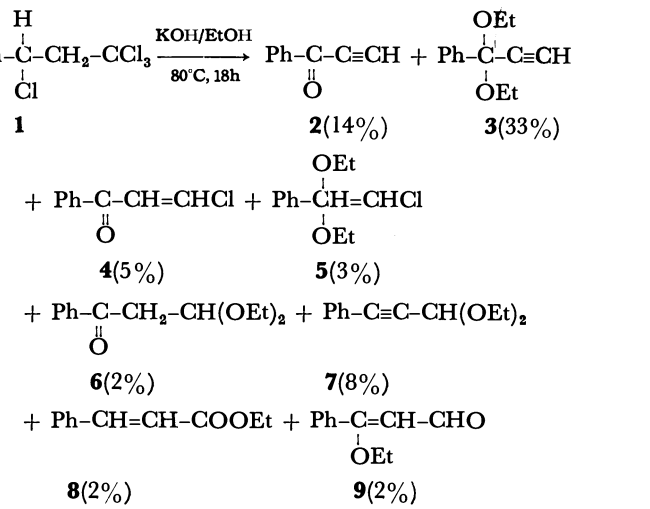
*Ethyl Cinnamate (**8**)*: The IR and ^{1}H NMR spectra of **8** were identical with those of authentic sample.

*3-Ethoxy-3-phenyl-2-propenal (**9**)*: A colorless liquid substance. IR (neat) 3070, 3030 (arom. C–H), 2980, 2940, 2880 (aliph. C–H), 1660 (–C=C–CHO), and 1378 cm^{-1} (C–H of CHO). ^{1}H NMR (CCl_4) $\delta=1.13$ (3H, t, $-OCH_2-CH_3$), 3.36 (2H, q, $-OCH_2-CH_3$), 5.47 (1H, d, $J=8$ Hz, =CH–CHO), 7.0—7.51 (5H, m, C_6H_5–), and 9.30 (1H, d, $J=8$ Hz, CHO). GC–MS (OV-1, 110 °C, 23 eV) *m/e* (rel intensity) 176 (M^+, 20.92), 175 (M^+-H, 31.98), 147 (M^+-CHO, 25.49), 131 ($M^+-OC_2H_5$, 100), and 78 (C_6H_6, 13.10). Found: *m/e* 176.0841. Calcd for $C_{11}H_{12}O_2$: M, 176.08376.

*1,1-Dichloro-3-ethoxy-3-phenylpropene (**10**)*: A pale yellow liquid substance. IR (neat) 3060, 3030 (arom. C–H), 2960, 2920, 2890 (aliph. C–H), and 1610 cm^{-1} (C=C). ^{1}H NMR (CCl_4) $\delta=1.13$ (3H, t, $-OCH_2-CH_3$), 3.38 (2H, m, $-OCH_2-CH_3$), 5.03 (1H, d, $J=8$ Hz, $-CH(OEt)-CH=CCl_2$), 5.93 (1H, d, $J=8$ Hz, $-CH(OEt)-CH=CCl_2$), and 7.0—7.4 (5H, m, C_6H_5–). GC–MS (OV-1, 110 °C, 23 eV) *m/e* (rel intensity) 230 (M^+, 0.26, $M^+ +2/M^+=0.66$ (Cl×2)), 195 (M^+-Cl, 100), 185 ($M^+-OC_2H_5$, 5.94), 167 ($M^+-Cl-C_2H_5+H$, 36.64), 131 ($M^+-2Cl-C_2H_5$, 15.90), and 105 (Ph–CO, 6.3). Found: *m/e* 230.0198. Calcd for $C_{11}H_{12}OCl_2$: M, 230.0264.

Results and Discussion

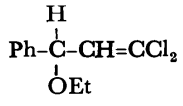
When **1** (3.0 g, 11.6 mmol) was refluxed in an ethanolic solution of potassium hydroxide (10 g/100 cm^3) for 18 h followed by neutralization with acid, eight compounds were obtained. The main products were ethynyl phenyl ketone (**2**) (14%) and its acetal (**3**) (33%); these are the phenyl analogs of the compounds obtained in the case of 1,1,1-trichloro-3-ethoxy-3-metallocenylpropane.[1]



These facts indicate that this type of unusual reaction is favored not only by a metallocenyl group attached to the 3-position but also by a phenyl group at the 3-position.

The products from **1** except for **8** which is the product expected from the report by Kharasch *et al.*[2] have one similar feature, *i.e.* these compounds have a hydrogen atom at the terminal carbon which originally had three chlorine atoms.

When the reaction of **1** was carried out with ethanolic sodium ethoxide (12 g/100 cm^3), compounds **2**, **3**, **4**, **5**, and **10** were obtained in 59, 2, 2, 2, and 22% yields, respectively.

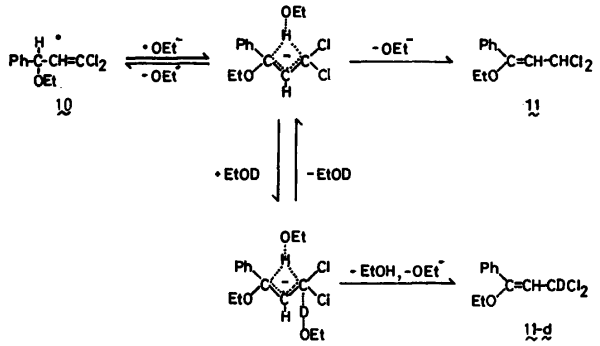


10 (22%)

Compound **10** has a different type of structure from **2**, **3**, **4**, and **5** and is considered to be a precursor to **2** and **3**, since i) **10** is the compound which is formed by the normal substitution of chloride ion by ethoxide ion at benzylic position of **1**; ii) the hydrogen atom at the benzylic position in **1** is still at the original position in **10**; and iii) the terminal carbon has no hydrogen atom yet.

The treatment of **10** (200 mg) with sodium ethoxide in ethanol (3 g/25 cm^3) afforded a mixture of products, the composition of which is similar to that of the product from **1** on treatment with sodium ethoxide except for **10**. **2**, **3**, **4**, and **5** were obtained in 18, 72, <1, and 9% yields, respectively.

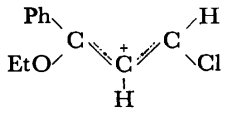
The formation of **5** from **10** strongly suggests that the base-catalyzed 1,3-proton transfer[9] takes place effectively and this results in the formation of the rearranged product **11** as shown in Scheme 1.



Scheme 1.

If this 1,3-proton transfer occurs intramolecularly, the incorporation of deuterium from the solvent (EtOD) would not be observed in the products. The results that the alkali-solvolysis of **10** (300 mg) with sodium ethoxide in monodeuterated ethanol (EtOD) (1.0 g/30 cm^3) at 80 °C for 8 h shows the 33% incorporation of deuterium in **5** but no incorporation of deuterium in **3** indicate that the 1,3-proton transfer occurs mainly intramolecular fashion. Cram and Uyeda[9] reported the base-catalyzed rearrangement of 3-phenyl-1-butene to *cis*-2-phenyl-2-butene and they showed that both intra- and intermolecular 1,3-hydrogen transfer were involved in the rearrangement. However, the fact that no deuterium incorporation was observed for **3** indicates that the primary reaction of **10** with ethoxide ion to produce **11** is almost intramolecular fashion and the secondary solvolysis of **11** is faster than H–D exchange reaction. When the reaction of **10** with sodium ethoxide in EtOD was carried out at 60 °C for 2 h, formation of **3** and **5** without deuterium were observed, although the formation of **11** was not observed. These results strongly suggest that the intramolecular 1,3-proton transfer occurs effectively in this reaction, when the H–D exchange process is slow enough compared with the solvolysis.

The tentative reaction pathway from **11** to **5** is as follows; i) the rearranged product **11** loses one of the two chlorine atoms as a chloride ion and forms carbenium ion, such as **12**, and ii) **12** is attacked by ethoxide ion at the α-position to phenyl group to produce **5**.



12

No similar reaction involving 1,3-proton transfer was observed in the treatment of 1,1,1,3-tetrachloro-4-phenylbutane (**13**), a carbon tetrachloride adduct to allylbenzene, with potassium hydroxide in ethanol solution.[10]

For this base-catalyzed 1,3-proton transfer reaction, the stabilization of the transition state by conjugation with an aromatic group seems to play an important role: When an ethoxide ion attacks the hydrogen atom at the 3-position of **10** and abstracts it as a proton, the negative charge is delocalized in a conjugate system involving phenyl group. After the proton transfer is completed, the removal of a chloride ion from **11** produces an allyl cation **12** which is also stabilized by the phenyl group. The results that the products **2**, **3**, **4**, **5**, and **6** consist of 82% of the whole products strongly suggest that the carbon atom having phenyl and ethoxyl group in **12** is preferentially attacked by ethoxide ion to produce **5**. These results agree with those obtained in the case of metallocene derivatives of **1**.

The formation of **2**, **3**, **4**, and **5** may be explained by a mechanism in which a transposition of the carbon side chain resulting in the exchange of 1- and 3-positions is involved. However, this mechanism is excluded by the experiment using 1,1,1-trichloro-3-ethoxy-3-(3-ethylferrocenyl)propane. When it was refluxed with potassium hydroxide in ethanol at 80 °C for 18 h, only 3-ethyl ferrocenyl ethynyl ketone was obtained and no product *via* carbon side chain transposition, such as 2-ethylferrocenyl ethynyl ketone or 1′-ethylferrocenyl ethynyl ketone was obtained.

The authors are grateful to Professor Naoki Inamoto for helpful discussions. We also thank Dr. Hideyuki Matsumoto for sending us spectral data of **1** and **13**.

10) The only product which has molecular weight less than 300 could be identified by GC-MS (OV-1, 110 °C, 23 eV). The parent peak (M^+, *m/e* 208, $M^+ + 2/M^+ = 0.335$) and fragment pattern suggest the presence of 1-chloro-3-ethoxy-4-phenyl-1-butyne.

Reaction of Malonaldehyde with Nucleic Acid. I. Formation of Fluorescent Pyrimido[1,2-*a*]purin-10(3*H*)-one Nucleosides

Hiroshi SETO,* Taisuke OKUDA,† Tomoyuki TAKESUE,† and Tadashi IKEMURA†

Tokyo Metropolitan Research Laboratory of Public Health, Shinjuku-ku, Tokyo 160

†*College of Science and Technology, Nihon University, Chiyoda-ku, Tokyo 101*

(Received November 10, 1982)

The reactions of malonaldehyde with guanosine and 2′-deoxyguanosine proceed slowly under acidic conditions to give new pyrimidopurine nucleosides, **3a** and **3b**, respectively. These compounds emit strong yellow fluorescence and are hydrolyzed by NaOH into malonaldehyde and guanosine from **3a** (2′-deoxyguanosine from **3b**). From chemical and spectroscopic evidence, these compounds were deduced to be 3-β-D-ribofuranosylpyrimido[1,2-*a*]-purin-10(3*H*)-one (**3a**) and 3-(2-deoxy-β-D-*erythro*-pentofuranosyl)pyrimido[1,2-*a*]purin-10(3*H*)-one (**3b**). No products were detected in the reaction mixture of malonaldehyde with 1-methylguanosine, adenosine, cytidine, uridine, thymidine, 2′-deoxyadenosine, or 2′-deoxycytidine.

Malonaldehyde (**1**) has been found to be one of the decomposition products of many oxidized lipid materials.[1,2] The presence of **1** in foods[3–5] and in living organs[6,7] in which the lipid fraction has undergone oxidation may be of physiological significance.

It has been reported that **1** initiates skin carcinogenesis in mice[8] and that it has mutagenic activity.[9,10] DNA is modified by **1** under acidic conditions, and becomes fluorescent.[11] The compound **1** presumably cross-links the amino groups of DNA in solution, probably through the formation of Schiff bases.[11] Brooks *et al.*[12] suggested that **1** is associated preferentially with the guanine and cytosine moieties of the DNA core. However, the mechanism of interaction between DNA and **1** still remains obscure.

When we attempted the reaction of several nucleosides with **1**, guanosine (**2a**) and 2′-deoxyguanosine (**2b**) yielded new orange-yellow fluorescent compounds, **3a** and **3b**, respectively. Lee *et al.*[13] had reported a similar fluorescent compound as a simple guanosine-malonaldehyde adduct. We previously reported a preliminary form[14] and proposed structure for the modified guanosine. In this paper, we describe the formation of the compounds in detail, and present evidence supporting the proposed structures. The physiological significance of these results is discussed.

Results and Discussion

Product Analysis of Nucleoside-malonaldehyde Reaction Mixture by HPLC. Some HPLC chromatograms are shown in Fig. 1, together with the control. Fluorescent products (p1 and p2) appeared on the reaction of **1** with **2a** and **2b**, respectively. Peaks in the fluorescence (FL) chromatograms appeared later than in the UV traces because of the capacity of the connecting tube, but the FL chromatograms shown in the figure have been corrected for this effect.

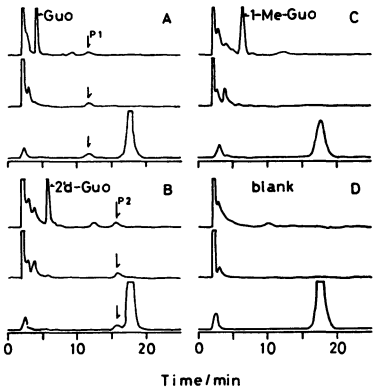

Fig. 1. HPLC chromatograms of nucleoside-malonaldehyde reaction mixtures. (upper): UV 254 nm, range 16, 10 μl inj., (middle): UV 330 nm, range 8, 50 μl inj., (bottom): FL 365—460 nm, 50 μl inj., A time lag of each FL chromatogram is excluded.

DNA was allowed to react with **1** to form fluorescent products with max. emission at 460 nm when excited at 390 nm, and a new absorption peak at 325 nm was also formed.[11] The present products, peaks p1 and p2, showed the same spectral characteristics. However, peaks having these spectral characteristics were not detected in the reaction mixtures of **1** with other nucleosides: 1-methylguanosine, adenosine, cytidine, uridine, thymidine, 2′-deoxyadenosine, and 2′-deoxycytidine. From these findings, it seems that the sugar moiety is not modified by **1**, since **3a** and **3b** have different sugar moieties. Usually, under the chromatographic conditions used, a 2′-deoxyribonucleoside has a longer retention time than the corresponding ribonucleoside.

Our results suggest that one or more sites on the guanine moiety of DNA is reactive to **1**.

Structure of the Modified Nucleoside Formed by Guanosine-malonaldehyde Reaction. Compound **3a** (peak p1) was isolated as a yellow solid (34 mg), mp 195 °C (decomp), by repeated liquid chromatography. The purity of **3a** was 99.7% as determined by HPLC analysis.

Compound **3a** was hygroscopic and highly soluble in water and in dimethyl sulfoxide (DMSO). **3a** was partially hydrolyzed by 0.05 M NaOH (1 M=1 mol dm^{-3}) into **2a** and **1**. The Molish test for sugar was positive. No carbonyl group of ketone and/or aldehyde was detected in the 2,4-dinitrophenylhydrazine test. On the other hand, the TBA (2-thiobarbituric acid) test, which is used for the detection of malonaldehyde and its precursor or adduct, was positive. The pH profile of UV absorption of compound **3a** is shown in Fig. 2. The pK_a value was calculated spectrophotometrically as 1.03.

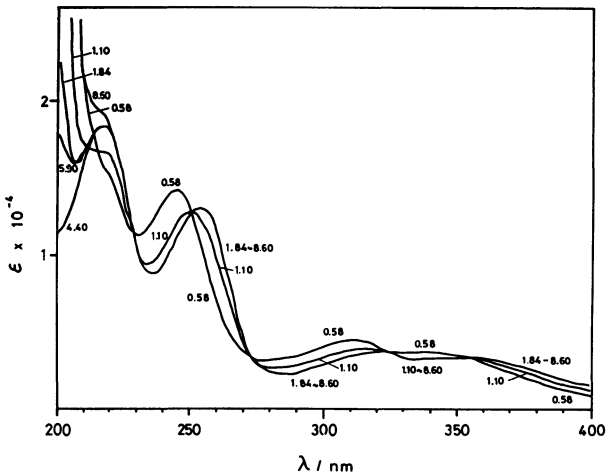

Fig. 2. UV absorption spectra of compound **3a** at various pH.

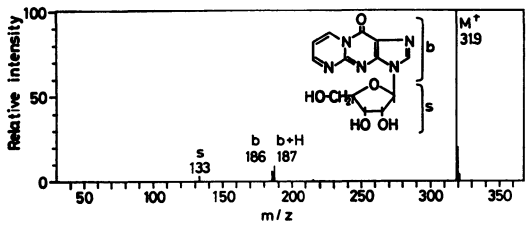

Fig. 3. FD mass spectrum of compound **3a**.

The FD mass spectrum of **3a** indicated m/z values of 319 (M), 187 (base+H) and 133 (ribose) (Fig. 3). The EI and CI mass spectra were obtained after trimethylsilylation of **3a**. The molecular ion peak of the trimethylsilyl (TMS) derivative was observed at an m/z value of 535 (m/z was 536 for CI with methane). Therefore, the number of substitutable active hydrogens by TMS is three. The molecular formula of **3a**, $C_{13}H_{13}N_5O_5$, was established by high resolution mass spectrometry (Found: m/z 535.2099. Calcd for $C_{13}H_{10}N_5O_5(TMS)_3$: M, 535.2102).

The IR(KBr) and UV(H_2O) spectra showed absorption bands at 3350 (O–H), 1723 (C=O) and 1630

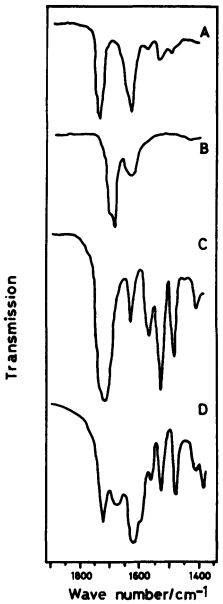

Fig. 4. IR spectra of compound **3a** and **2a**. (A), (B): **3a** and **2a** in acetonitrile, (C), (D): **3a** and **2a** in solid phase.

(C=C, C=N) cm^{-1} and 215 (ε 18600), 251 (ε 13200), 308 (ε 2700), 319 (ε 3140), and 348 (ε 2750) nm, respectively. There were serious differencies between **3a** and **2a** in respect to the absorption in the C=O stretching region. When **3a** was examined in dilute solution (acetonitrile), the relative strength of C=O to C=C and C=N absorption (Fig. 4A) was considerably weaker than that of **2a** (Fig. 4B). On the other hand, in the solid state, the C=O absorption of **2a** was influenced by intermolecular hydrogen bonding, and a complex spectrum was observed (Fig. 4D). In the FL spectrum, the E_x and E_m maxima were 360 and 500 nm, respectively.

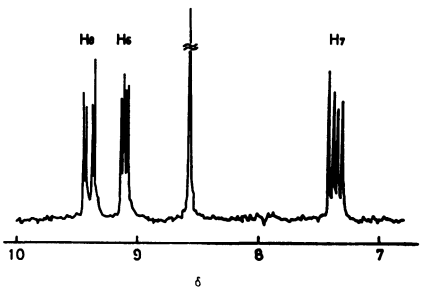

Fig. 5. Proton-NMR spectrum of compound **3a**.

The ^{1}H-NMR spectrum of **3a** (Fig. 5) exhibited typical AMX-type signals due to the –CH=CH–CH= group (δ 7.33 (J=3.9 and 6.8 Hz), 9.08 (J=2.0 and 3.4 Hz) and 9.38 (J=2.0 and 7.3 Hz), each 1H, dd). The signal of the exocyclic amino group of **2a** could no longer be seen. There were no changes in the signals of C_2 methine and ribose protons. The ^{13}C-NMR spectrum showed the existence of three carbons (δ 110.5, 141.0 and 161.8 (each d)) in addition to those of **2a**. The singlet signal of C_{10} was shifted to higher magnetic field in comparison with the original compound **2a**. It

$C_{5'}$–H	3.65	2H (brds., m)	3.59	2H (brds., m)

s: Singlet, d: doublet, dd: double doublet, t : triplet, m : multiplet, brds: broads, J values are in Hz, *:$C_{2'}$–H gave a overlap with the solvent (δ 2.4—2.6).

seems noteworthy that 1-methylguanosine was unreactive to malonaldehyde (**1**), as shown in Fig. 1C.

These results led us to conclude that the structure of the strongly fluorescent compound is 3-β-D-ribofuranosylpyrimido[1,2-*a*]purin-10(3*H*)-one.

The fluorescent nucleoside (peak p2) from **2b** showed similar properties. Spectroscopic evidence led us to assign the structure 3-(2-deoxy-β-D-*erythro*-pentofuranosyl)pyrimido[1,2-*a*]purin-10(3*H*)-one. The base moieties of these modified nucleosides were the same.

The yields of products were only 1.4% from **2a** and 1.8% from **2b**.

The products formed by reactions of amino compounds[15] or protein[16,17] with **1** were found to be positive in the TBA test. Aldehyde **1** reacted with lysine residues of casein (37 °C for 24 h).[18] The reaction proceeded in two steps: the formation of enamine structure (O=CHCH=CHNHR) and then the formation of aminoiminopropene structure (RN=CHCH=CHNHR) with the characteristic fluorescence spectra.[18] Our results suggest a similar reaction mechanism in the present case. The formation of pyrimidopurine is attributed to an ionic reaction of nucleophilic nitrogen atoms at the 1 and N_2 positions of guanine with carbonium ions of malonaldehyde. The reaction, involving cyclization, is very slow, though some substituted malonaldehydes were reported to react readily with guanine.[19]

The biological significance of our results is not clear at present. Reiss *et al.*[11] reported that the formation of fluorescent products correlates linearly with loss of DNA template activity. It can be assumed that the modified guanine base is unable to form a base-pair with cytosine of DNA. Thus, the decrease of the template activity can probably be attributed to the modification of guanine by **1**. Moreover, such modification is likely to be a major cause of cancer and mutation initiated by **1**. Structural determination of the fluorescent products derived from DNA modified by **1** is in progress.

Experimental

Apparatus. Melting points are uncorrected. IR, UV and FL spectra were recorded on Hitachi EPI-G3, Union Giken SM-401 and Shimadzu RF-500 spectrophotometers, respectively. NMR spectra were obtained on JEOL FX-100 and FX-270 spectrometers with TMS as an internal standard in DMSO-d_6 at room temperature. Mass spectra were recorded on JEOL JMS D-300 (EI, CI and high resolution) and 01SG-2 (FD) mass spectrometers. TLC analyses were carried out with WAKO polyamide FM plates (5 cm × 10 cm). Analytical HPLC was carried out with a Shimadzu LC-2 machine equipped with UV (254 and 330 nm) and FL (E_x 365 nm, E_m 460 nm) detectors, on a Unisil C-18, 5 μm (4 mmϕ × 25 cm) column (the mobile phase was 5% acetonitrile–water). The inlet of the FL detector was connected to the outlet of the UV detector.

Reactions of Malonaldehyde with Nucleosides. All reagents were purchased from commercial sources, and the purity of the nucleosides was checked by HPLC. Aldehyde **1** was prepared by the hydrolysis of 1,1,3,3-tetraethoxypropane. A mixture (pH 4.5) of 0.1 M malonaldehyde (1 ml), 0.01 M nucleosides (1 ml), and 0.1 M dipotassium hydrogenphosphate (8 ml) was heated at 37 °C for 10 d. The mixture was analyzed by HPLC. No growth of microorganisms was apparent during the reaction.

Isolation of the Fluorescent Nucleoside from Guanosine-malonaldehyde Reaction Mixture. Aldehyde **1** was obtained by the hydrolysis of 1,1,3,3-tetraethoxypropane (2.2 g, 0.01 mol) with 0.1 M HCl (100 ml). The mixture was heated at 40 °C for 40 min, then adjusted to pH 4.5. A mixture of **1** (0.01 mol), **2a** (700 mg, 2.5 mmol) and dipotassium hydrogenphosphate (13.6 g, 0.1 mol) in one liter of water was heated at 37 °C for 10 d. The mixture was concentrated to about 100 ml at 40 °C. Acetonitrile (600 ml) was added to the residue. The mixture was stored overnight in a refrigerator (4 °C), then the precipitate was filtered off and washed with 90% acetonitrile. The filtrate was concentrated to 50 ml, then stored overnight at 4 °C. The precipitate was filtered off. The filtrate was cleaned-up by polyamide (Woelm) column chromatography (50 mmϕ × 30 cm) with water as the eluent. The eluate was concentrated to 50 ml. The solution was chromatographed on a Lichroprep RP-18 (Merck, 22 mmϕ × 30 cm) column with 7% acetonitrile as the eluent. The fraction including **3a** was concentrated to 50 ml. The chromatography was repeated twice. Subsequently, the solution was further chromatographed on a Lichroprep RP-18 column (10 mmϕ × 25 cm) with 5% acetonitrile as the eluent. The chromatography was repeated 3 times. All operations of the synthesis and purification procedure described above were repeated 6 times. Guanosine (**2a**) used, therefore, amounted to 4.2 g (14.8 mmol). The final eluate was collected after each synthesis. The pooled eluates were dried and concentrated *in vacuo*.

The fluorescent product **3b** from the 2′-deoxyguanosine-malonaldehyde reaction was synthesized and isolated in a similar manner, but on a smaller scale: 2′-deoxyguanosine (**2b**) used totalled 1.85 g (6.9 mmol).

Trimethylsilylation. To prepare the TMS derivative, acetonitrile (100 μl) and *N,N*-bis(trimethylsilyl)trifluoroacet-

amide containing 1% trimethylchlorosilane (150 μl) were added to the dried nucleoside (100 μg). Then the mixture was heated at 75 °C for 3 h (1.5 h for the 2'-deoxy deriv.) in a reaction vial.

3a: Mp 195 °C (decomp), R_f 0.74 ppc/H_2O, 0.86 polyamide/H_2O, pK_a 1.03, ^{13}C-NMR(DMSO-d_6) 61.3(t), 70.0(d), 74.0(d), 85.7(d), 87.4(d), 110.5(d), 117.9(s), 137.4(d), 141.0(d) 149.0(s), 149.7(s), 152.3(s), 161.8(d).

3b: Mp 145 °C (decomp), R_f 0.80 ppc/H_2O, 0.74 polyamide/H_2O, pK_a 1.05, UV (H_2O) 214 (ε 23700), 253 (ε 16400), 308 (ε 3500), 320 (ε 3800), 350 nm (ε 3200), FL Ex max. 360 nm, Em max. 500 nm, IR(KBr) 3320 (O–H), 1723 (C=O), 1630 cm^{-1} (C=C, C=N), MS FD 303 (M^+), 187 (base+H), 186(base), 117(s), EI(TMS deriv.) 447(M^+), 187(base+H), CI(TMS deriv. isobutane) 448(QM^+), 188(base+2H), ^{13}C-NMR(DMSO-d_6) 61.8(t), 70.9(d), 83.8(d), 88.1(d), 110.7(d), 118.0(s), 137.4(d), 140.9(d), 149.1(s), 149.5(s), 152.5(s), 161.9(d). The $C_{2'}$ signal overlapped with the solvent signal.

We are grateful to Mr. Tsuyoshi Hashimoto for his technical assistance and to Dr. Kazuyuki Akiyama, Tokyo Metropolitan Res. Lab. Pub. Health, for helpful discussions.

Stereospecific and Stereoselective Reactions. IX.[1] Preparation of Ethyl (2*E*,7*R*)-7-Acetoxy-4-oxo-2-octenoate from D-Glucose

Sumio Yokota, Mitsuru Nishida, and Oyo Mitsunobu*

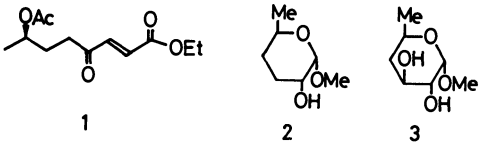
Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157

(Received November 20, 1982)

Reaction of methyl 2,3-anhydro-4,6-dideoxy-α-D-*ribo*-hexopyranoside with MgI_2 exclusively afforded methyl 3,4,6-trideoxy-3-iodo-α-D-*xylo*-hexopyranoside which was dehalogenated by treatment with $LiAlH_4$ to give methyl 3,4,6-trideoxy-α-D-*erythro*-hexopyranoside (**2**). Hydrolysis of **2** and subsequent treatment with ethoxycarbonylmethylenetriphenylphosphorane gave ethyl (2*E*, 4*R*, 7*R*)-4,7-dihydroxy-2-octenoate (**10**). Oxidation of **10** by active MnO_2 resulted in the formation of an equilibrium mixture of ethyl (2*E*, 7*R*)-7-hydroxy-4-oxo-2-octenoate (the carbon skeleton of pyrenophorin) and cyclic hemiacetal. On treatment with acetic anhydride, the mixture afforde dethyl (2*E*, 7*R*)-7-acetoxy-4-oxo-2-octenoate.

Carbohydrates have been utilized as potential starting materials for the construction of natural products having multiple centers of chirality.[2] In spite of many elegant approaches have been reported so far, there is still a need to develop convenient methods for stereospecific and regioselective transformation of a hydroxyl group of carbohydrates. 2,3-Anhydro sugars are attractive chiral intermediates for the transformation of carbohydrates. The opening of the oxirane ring on locked pyranosides system by nucleophiles has been much discussed and a clear pattern has emerged, while the reaction of flexible 2,3-anhydropyranosides with nucleophiles are more complicated and the factors determining the reaction site are not fully elucidated.[3]

We report here a simple synthesis of ethyl (2*E*,7*R*)-7-acetoxy-4-oxo-2-octenoate (**1**), the carbon skeleton of pyrenophorin, from methyl 3,4,6-trideoxy-α-D-*erythro*-hexopyranoside (**2**) which was obtained by a sequence of reactions involving regioselective oxirane ring-opening of readily available methyl 2,3-anhydro-4,6-dideoxy-α-D-*ribo*-hexopyranoside.[4]

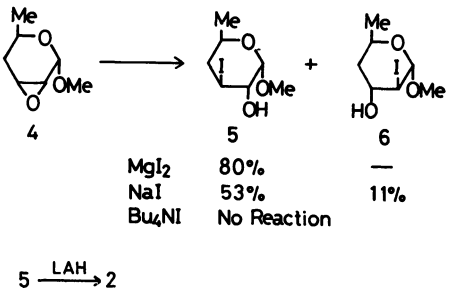


Scheme 1.

Reductive oxirane ring-opening of 2,3-anhydropyranoside has been reported.[5] Thus, methyl 4,6-dideoxy-α-D-*xylo*-hexopyranoside (**3**) was converted into methyl 2,3-anhydro-4,6-dideoxy-α-D-*ribo*-hexopyranoside (**4**) by the reaction with diethyl azodicarboxylate (DEAD) and triphenylphosphine (TPP).[6] It was found, however, that catalytic hydrogenation (Raney-Ni (W-2); 100—120 kg/cm² H_2, 80 °C) or $LiAlH_4$ reduction (−2—0 °C, ether) of **4** afforded the desired **2** in only 18% or 29% yields, respectively.

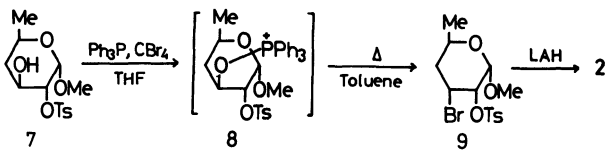
Next, a two-step procedure was examined. When **4** was allowed to react with MgI_2 in tetrahydrofuran (THF), methyl 3,4,6-trideoxy-3-iodo-α-D-*xylo*-hexopyranoside (**5**) was obtained in 80% yield without any detectable formation of 2-iodo isomer (**6**).[7] The sequence thus allowed net replacement of the 3-hydroxyl group of **3** by iodo substituent with retention of configuration. The reaction of **4** with NaI in the presence of sodium acetate and acetic acid in acetone gave **5** and **6** in 53 and 11% yields, respectively. It is noteworthy that no reaction occurred when **4** was treated with tetrabutylammonium iodide under the similar conditions (THF, refluxed for 6 h). Thus these results suggest that metal cations play an important role in the cleavage of the oxirane-ring of **4**.[8]

Compound **5** reacted smoothly with $LiAlH_4$ to give **2** in 95% yield.



Scheme 2.

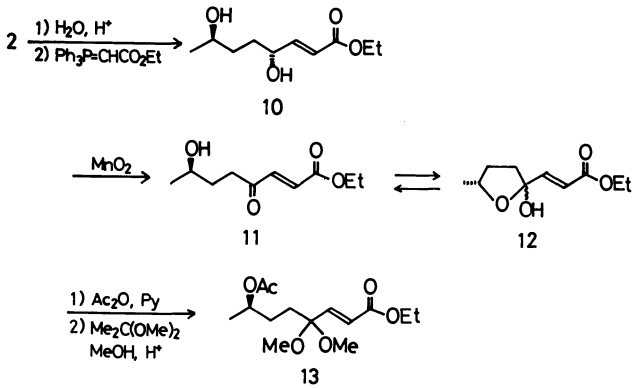
An alternative route to **2** was also examined. Methyl 4,6-dideoxy-2-*O*-*p*-tosyl-α-D-*xylo*-hexopyranoside (**7**) was allowed to react with carbon tetrabromide and TPP in THF at room temperature for 24 h giving an oily product which was assumed to be an alkoxyphosphonium bromide (**8**). The solvent was then replaced by toluene and the resulting mixture was refluxed for 2 h affording methyl 3-bromo-3,4,6-trideoxy-2-*O*-*p*-tosyl-α-D-*ribo*-hexopyranoside (**9**) in 54% yield. Although the configuration at the 3-position could not be determined, in view of the nature of the bromination reaction, D-*ribo*-configuration was tentatively assigned.[9] By treatment with $LiAlH_4$, **9** gave **2** in 73% yield.



Scheme 3.

Acid hydrolysis of **2** gave free sugar (83% yield) which was converted into ethyl (2*E*,4*R*,7*R*)-4,7-dihy-

droxy-2-octenoate (**10**) by the reaction with ethoxycarbonylmethylenetriphenylphosphorane in 75% yield. Selective oxidation of the 4-hydroxyl group of **10** could be accomplished by the reaction with active MnO_2.[10] As indicated by ^{1}H-NMR spectrum, however, the product is an about 1 : 1 mixture of desired ethyl (2*E*,7*R*)-7-hydroxy-4-oxo-2-octenoate (**11**) and cyclic hemiacetal (**12**; 74% total yield). In order to displace the equilibrium to the open chain compound, the mixture was treated with acetic anhydride in pyridine affording the expected ethyl (2*E*,7*R*)-7-acetoxy-4-oxo-2-octenoate (**1**) in 78% yield. Acetalization of **1** afforded ethyl (2*E*,7*R*)-7-acetoxy-4,4-dimethoxy-2-octenoate (**13**) in 91% yield.



Scheme 4.

Bakuzis *et al.* have reported the synthesis of *dl*-pyrenophorine from ethyl *dl*-7-acetoxy-4,4-ethylenedioxy-2-octenoate by the use of DEAD and TPP in the cyclization step.[11] Since the lactonization using DEAD and TPP has been shown to proceed through inversion of configuration at the reaction site of the alcoholic component,[4,12] the synthesis of **13** indicates a relay approach to (*S*,*S*)-pyrenophorin.

Experimental

Nuclear magnetic resonance (NMR) spectra were measured on Hitachi R-20 spectrometer (60 MHz) using tetramethylsilane as an internal standard. Optical rotations were measured on JASCO DIP-4 digital polarimeter using a 1-dm cell in the solvent indicated. Preparative thin layer chromatography (PLC) and column chromatography were performed on Merck Kieselgel 60 PF_{254} (20 cm × 20 cm or 20 cm × 30 cm plate) and Kieselgel 60 (70—230 mesh), respectively. All evaporations were performed under reduced pressure. For distillation of small amount of product, Kugelrohr (Büchi) apparatus was used and oven temperature is indicated.

*Preparation of Methyl 2,3-Anhydro-4,6-dideoxy-α-*D*-*ribo*-hexopyranoside (**4**) from Methyl 4,6-Dideoxy-α-*D*-*xylo*-hexopyranoside (**3**).* *a) Two-step Procedure*: *p*-Tosyl chloride (35 g, 184 mmol) was added to a suspension of **3** (11.8 g, 73 mmol)[13] in pyridine (150 ml) at 0 °C. After the mixture had been stirred for 80 h at room temperature, chloroform (150 ml) was added. The mixture was washed successively with 10% H_2SO_4 and saturated aqueous $NaHCO_3$, dried ($MgSO_4$), and evaporated. The residue was crystallized from methanol, affording methyl 4,6-dideoxy-2,3-di-*O*-*p*-tosyl-α-D-*xylo*-hexopyranoside (29.7 g, 86%, mp 110—112 °C). NMR ($CDCl_3$ δ=1.15 (d, H-6), 1.45—2.4 (m, H-4), 2.45 (s, $C\underline{H}_3$–C_6H_4–), 3.30 (s, CH_3O–), 3.5—4.15 (m, H-5), 4.2—4.5 (dd, H-2), 4.65—5.2 (m, H-3), 4.83 (d, H-1). Found: C, 53.54; H, 5.58%. Calcd for $C_{21}H_{26}S_2O_8$: C, 53.60; H, 5.57%.

Sodium methoxide in methanol (prepared from 0.87 g of sodium and 20 ml of methanol) was added to a suspension of the ditosylate (6.31 g, 13.4 mmol) in methanol (30 ml) at room temperature. The mixture was refluxed for 6 h with stirring, and then evaporated. Water was added to the residue and extracted with dichloromethane and ether. The organic layer was dried ($MgSO_4$) and evaporated. Methanol was added to the residue and evaporated to a small volume. Unreacted ditosylate was filtered off (1.18 g, 19% recovery). The filtrate was evaporated and the residue was chromatographed (benzene–ethyl acetate=5 : 1) to give **4** (1.11 g, 57%). $[\alpha]_D^{20}$ +61.7° (*c* 0.3, $CHCl_3$). NMR ($CDCl_3$) δ=1.1 (d, H-6), 1.2—2.2 (m, H-4), 3.2—4.2 (m, H-2,3,5), 3.3 (s, CH_3O–), 4.78 (d, H-1, $J_{1,2}$=2.8 Hz). Found: C, 58.65; H, 8.53%. Calcd for $C_7H_{12}O_3$: C, 58.31; H, 8.39%.

b) One-step Procedure: A solution of diethyl azodicarboxylate (1.04 g, 6 mmol) in benzene (2 ml) was added dropwise to a mixture of **3** (0.649 g, 4 mmol) and triphenylphosphine (1.57 g, 6 mmol) in benzene (7 ml) at room temperature. The mixture was refluxed for 2 h, allowed to cool to room temperature, and evaporated. Ether was added to the residue to precipitate triphenylphosphine oxide and diethyl hydrazinedicarboxylate which were filtered off. The filtrate was concentrated and the residue was distilled giving **4** [oven temperature 80—120 °C/22 Torr (1 Torr=133.322 Pa)]. The distillate was contaminated with a small amount of diethyl hydrazinedicarboxylate which was removed by passing through silica-gel column (benzene–ethyl acetate=1 : 5). The yield of **4** was 75% (431 mg). Thin layer chromatography of the crude reaction mixture indicated the presence of a trace of methyl 2,3-anhydro-4,6-dideoxy-α-D-*lyxo*-hexopyranoside. However, the isomer could not be isolated.

*Reaction of Methyl 2,3-Anhydro-4,6-dideoxy-α-*D*-ribo-hexopyranoside (**4**) with Iodide.* *a) Reaction with MgI_2*: MgI_2 was prepared by the reaction of activated magnesium[14] with I_2. After a mixture of potassium (2.54 g, 65 mmol) and $MgCl_2$ (3.22 g, 34 mmol) in THF (20 ml) had been refluxed with stirring under N_2 for 2 h, a solution of I_2 (8.21 g, 32 mmol) in THF (20 ml) was added, followed by a solution of **4** (2.15 g, 15 mmol) in THF (15 ml). The mixture was heated under reflux for 6 h. Saturated aqueous NH_4Cl (10 ml) was added to the cooled reaction mixture and filtered through Hyflosupercel. The filtrate was evaporated, the residue being extracted with chloroform. The organic layer was washed with aqueous sodium thiosulfate, dried ($MgSO_4$), and evaporated affording chromatographically (TLC) pure methyl 3,4,6-trideoxy-3-iodo-α-D-*xylo*-hexopyranoside (**5**; 3.94 g, 97%). Purification by means of PLC (ether–chloroform=1 : 20) afforded pure **5** (80% yield) which was recrystallized from hexane, mp 57—59 °C. $[\alpha]_D^{21}$ +140° (*c* 1.08, $CHCl_3$). NMR ($CDCl_3$) δ=1.16 (d, H-6), 1.9—2.7 (m, H-4, OH), 3.4 (s, CH_3O–), 3.5—4.6 (m, H-2,3,5), 4.66 (d, H-1, $J_{1,2}$=*ca.* 3.5 Hz). Found: C, 31.17; H, 4.95%. Calcd for $C_7H_{13}O_3I$: C, 30.91; H, 4.81%.

b) Reaction with NaI: A mixture of **4** (0.309 g, 2.14 mmol), NaI (1.61 g, 10.7 mmol), sodium acetate (0.0882 g, 1.08 mmol), and acetic acid (2.5 ml) in acetone (10.5 ml) was refluxed with stirring for 2 h. After the solvent had been removed, chloroform was added, washed successively with saturated aqueous $NaHCO_3$ and aqueous sodium thiosulfate, and dried ($MgSO_4$). Solvent was removed and the residue was separated by PLC (ethyl acetate–chloroform=1 : 20) giving **5** (0.309 g, 53%) and **6** (0.0662 g, 11%). NMR for **6** ($CDCl_3$) δ=1.27 (d, H-6), 3.4 (s, CH_3O–), 5.12 (br s, H-1).

c) Reaction with Tetrabutylammonium Iodide: A mixture of **4** (0.144 mg, 1 mmol) and tetrabutylammonium iodide (1.85 g, 5 mmol) in THF (60 ml) was refluxed with stirring for 6 h. The mixture was allowed to cool to room temperature. The precipitated tetrabutylammonium iodide was recovered by filtration (96%). From the filtrate, 76% of **4** was recovered by means of PLC (benzene–ethyl acetate=5 : 1).

*Methyl 3,4,6-Trideoxy-α-*D*-*erythro*-hexopyranoside (**2**).*

*a) From Methyl 3,4,6-Trideoxy-3-iodo-α-*D*-*xylo*-hexopyranoside (**5**)*: A solution of **5** (4.42 g, 16.3 mmol) in THF (30 ml) was added to a suspension of $LiAlH_4$ (0.679 g, 17.9 mmol) in THF (20 ml) with stirring at room temperature, and then refluxed with stirring for 6 h. The mixture was allowed to cool to room temperature, quenched by water (15 ml), filtered through Hyflosupercel, and concentrated. The residue was extracted with dichloromethane. The extracts were washed with water, dried ($MgSO_4$), and evaporated giving **2** (2.27 g, 95%), which was practically pure as indicated by GLC (Carbowax 20M, 1 m, 100 °C). The product could be purified by distillation (oven temperature 60—80 °C/14 Torr) or column chromatography (benzene–ethyl acetate=1 : 5). $[\alpha]_D^{20}+142°$ (*c* 1.08, $CHCl_3$). NMR (CCl_4) δ=1.05 (d, H-6), 1.1—2.0 (m, H-3,4), 3.3—4.0 (m, H-2,5), 3.34 (s, CH_3O–), 4.46 (d, H-1). Found: C, 56.95; H, 9.68%. Calcd for $C_7H_{14}O_3$: C, 57.51; H, 9.65%.

*b) From Methyl 4,6-Dideoxy-2-*O*-p-tosyl-α-*D*-xylo-hexopyranoside (**7**)*: A solution of carbon tetrabromide (1.68 g, 5.06 mmol) in THF (2 ml) was added dropwise to a solution of **7** (949 mg, 3 mmol)[15] and TPP (917 mg, 3.5 mmol) in THF (8 ml) at room temperature with stirring. After the mixture had been stirred for 24 h at room temperature, the solvent was removed. Toluene (10 ml) was added to the residue and refluxed for 2 h. The resulting mixture was concentrated and separated by PLC (ether–petroleum ether=2 : 1) to give methyl 3-bromo-3,4,6-trideoxy-2-*O*-*p*-tosyl-α-D-*ribo*-hexopyranoside as an oil (**9**; 615 mg, 54%) and 8.5% of **7** was recovered. The **9** was used in the next step without further purification. NMR for **9** (CCl_4) δ=1.12 (d, H-6), 1.85—2.25 (m, H-4), 2.4 (s, CH_3–C_6H_4–), 3.2 (s, CH_3O–), 3.85—4.4 (m, H-3,5), 4.12 (d, H-1,2, $J_{1,2}$=*ca.* 2.5 Hz).

A mixture of **9** (570 mg, 1.5 mmol) in THF (5 ml) was added to $LiAlH_4$ (379 mg, 10 mmol) in THF (10 ml) at room temperature and heated under reflux for 20 h. After the addition of water (10 ml) and 2 M (1 M=1 mol dm^{-3}) H_2SO_4 (30 ml), the mixture was extracted with chloroform (120 ml). The organic layer was washed with 2 M Na_2CO_3 and water, dried, and concentrated. The residue was chromatographed (benzene–ethyl acetate=1 : 5) to give **2** (160 mg, 73%) and 20% of **9** was recovered.

*Ethyl (2*E*,4*R*,7*R*)-4,7-Dihydroxy-2-octenoate (**10**).* A mixture of **2**, (1.99 g, 13.6 mmol) and Dowex 50 (H^+) (3.50 g) in water (50 ml) was refluxed with stirring for 4.5 h. After filtration, the filtrate was concentrated to a small volume and extracted with chloroform. The aqueous layer was evaporated to dryness giving 3,4,6-trideoxy-D-*erythro*-hexopyranose (1.30 g, 72%; mp 47—53 °C) which was used in the next step without purification.

A solution of 3,4,6-trideoxy-D-*erythro*-hexopyranose (779 mg, 5.9 mmol), ethoxycarbonylmethylenetriphenylphosphorane (2.222 g, 6.4 mmol), and benzoic acid (30 mg, 0.25 mmol) in benzene (20 ml) was refluxed with stirring for 8 h. After evaporation, ether was added to precipitate triphenylphosphine oxide which was filtered off. The filtrate was evaporated and the residue was separated by chromatography (ethyl acetate) giving about 2 : 1 mixture of desired **10** and triphenylphosphine oxide. The yield of **10** was estimated to be 75% from the integration of the signal of NMR spectrum. The mixture was used in the next step. NMR (CCl_4) δ=1.15 (t, C<u>H</u>$_3$CH$_2$O–), 1.58 (d, H-8), 1.1—2.0 (br one peak, H-5,6), 3.25—5.25 (m, H-4,7 and two OH), 4.08 (q, CH$_3$C<u>H</u>$_2$O–), 5.96 (dd, H-2, $J_{2,3}$=16 Hz, $J_{2,4}$=1.5 Hz), 6.88 (dd, H-3, $J_{3,4}$=4 Hz).

*Ethyl (2*E*,7*R*)-7-Acetoxy-4-oxo-2-octenoate (**1**).* A 2 : 1 mixture of ethyl (2*E*,4*R*,7*R*)-4,7-dihydroxy-2-octenoate (**10**) and triphenylphosphine oxide (containing 4.37 mmol of **10**) was stirred with active MnO_2 (3.00 g)[16] in chloroform (50 ml) for 7 h at room temperature. After filtration, the filtrate was evaporated. The residue was chromatographed (benzene–ethyl acetate=1 : 1), giving about 1 : 1 mixture of ethyl (2*E*,7*R*)-7-hydroxy-4-oxo-2-octanoate (**11**) and cyclic hemiacetal (**12**) in 74% (649 mg) yield. The ratio was determined from the integration of the signal of NMR spectrum.

Acetic anhydride (0.1 ml) was added to a solution of the mixture (105 mg, 0.525 mmol) in pyridine (2 ml) at room temperature. After the solution had been stirred for 22 h at room temperature, water (1 ml) was added. The resulting mixture was evaporated and distilled to give **1** (99 mg, 72%, oven temperature 100—120 °C/0.4 Torr). NMR (CCl_4) δ=1.24 (d, H-8), 1.31 (t, C<u>H</u>$_3$CH$_2$O–), 1.54—2.1 (m, H-6), 1.95 (s, CH_3CO), 2.68 (t, H-5), 4.24 (q, C<u>H</u>$_3$CH$_2$O–), 4.87 (sext, H-7), 6.55 and 7.02 (AB q, olefin, J=16 Hz).

*Ethyl (2*E*, 7*R*)-7-Acetoxy-4,4-dimethoxy-2-octenoate (**13**).* Acetalization was performed by the analogous procedure reported by Hase *et al.*[17] A solution of 2,2-dimethoxypropane (122 mg, 1.17 mmol) in methanol (1 ml) was added to anhydrous *p*-toluenesulfonic acid (6 mg) at −70 °C, followed by ethyl (2*E*,7*R*)-7-acetoxy-4-oxo-2-octenoate (**1**, 49 mg, 0.202 mmol) in methanol (5 ml). The mixture was stirred for 4 h at −50 °C and then for 18 h at room temperature. The mixture was diluted with ether (5 ml), neutralized (3% $NaHCO_3$), and evaporated. The residue was extracted with chloroform. The organic layer was washed with water, dried ($MgSO_4$), and evaporated giving practically pure **13** (53 mg, 91%). Purification by PLC (ether–hexane=2 : 3) gave **13** in 60% yield. $[\alpha]_D^{19}$ +7.9° (*c* 1.53, $CHCl_3$). NMR (CCl_4) δ=1.18 (d, H-8), 1.31 (t, C<u>H</u>$_3$CH$_2$O–), 1.3—2.0 (m, H-5,6), 1.96 (s, CH_3CO), 3.13 (s, two CH_3O–), 4.25 (q, CH$_3$C<u>H</u>$_2$O–), 4.85 (sextet, H-7), 6.03 and 6.56 (AB q, olefin, J=15.6 Hz). An analytical sample was obtained by distillation (oven temperature 125—128 °C/0.4 Torr). Found: C, 58.08; H, 8.27%. Calcd for $C_{14}H_{24}O_6$: C, 58.31; H, 8.39%.

(Received November 22, 1982)

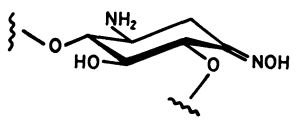
The titled compounds were prepared from 3,6′-bis(*N*-benzyloxycarbonyl)-3″-*N*-(trifluoroacetyl)kanamycin A (**1**). Oxidation of **1** with hydrogen peroxide in the presence of sodium tungstate gave the 1-hydroxyimino derivative, which, after deblocking, gave 1-deamino-1-dehydro-1-hydroxyiminokanamycin A (**6**). Reduction of **6** with Raney nickel–hydrogen in aqueous ammonia gave a mixture of kanamycin A and 1-epikanamycin A (**9**), which were separated through derivation to the corresponding tetrakis-*N*-(*t*-butoxycarbonyl) derivatives, which showed different solubility in chloroform. 1-*N*-[(*S*)-4-Amino-2-hydroxybutyryl]-1-epikanamycin A was prepared from **9** by the zinc acetate–ethyl trifluoroacetate method [to give 3,6′-bis(*N*-benzyloxycarbonyl)-1-epi-3″-trifluoroacetamidokanamycin A] followed by a regiospecific 1-*N*-acylation with (*S*)-4-benzyloxycarbonylamino-2-hydroxybutyryl group and successive deblocking.

Epimerization of a group at special position of amino glycoside antibiotics is of interest in connection with the role of the group in the antibacterial action. Recently we reported the synthesis of 3″-epidihydrostreptomycin,[1] which was active against resistant bacteria. In this paper we report on the epimerization of the 1-amino group of kanamycin A and the preparation of the 1-*N*-[(*S*)-4-amino-2-hydroxybutyryl] derivative of the epimer of kanamycin A. The (*S*)-4-amino-2-hydroxybutyryl side chain is known to enhance the antibacterial activity of kanamycin A as shown by amikacin.[2] Recently Igarashi *et al.*[3] prepared 1-deamino-1-epihydroxykanamycin A through a 1-oxo intermediate obtained by oxidation of a protected free 1-aminokanamycin A with 3,5-di-*t*-butyl-1,2-benzoquinone.[4]

As the starting material, we utilized 3,6′-bis(*N*-benzyloxycarbonyl)-3″-*N*-(trifluoroacetyl)kanamycin A (**1**),[5] which has a free amino group only at C-1, and prepared readily from kanamycin A by the zinc acetate–ethyl trifluoroacetate method.[5] Since oxidation of the 1-$CHNH_2$ group of **1** to ketoxime (–C=NOH) (not to carbonyl) is desirable for the present synthesis, **1** was treated with hydrogen peroxide in the presence of sodium tungstate according to the procedure by Kahr and Berther.[6] The desired 1-hydroxyimino derivative (**2**) was obtained in 86% yield. To confirm the structure, the compound (**2**) was led to the tris(*N*-benzyloxycarbonyl)-per-*O*-acetyl derivative (**5**). Deacylation of **2** with aqueous ammonia in oxolane gave the 3″-amino derivative (**3**), which, after reprotection of the amino group with *N*-(benzyloxycarbonyloxy)succinimide[2] [to give the 3,6′,3″-tris(*N*-benzyloxycarbonyl) derivative (**4**)], was acetylated with acetic anhydride in pyridine to afford the octaacetyl derivative (**5**). Compound **4** was also prepared directly from **6** in high yield by treating with *N*-(benzyloxycarbonyloxy)succinimide.

The presence of octaacetyl group in **5**, confirmed by the ^{1}H-NMR spectrum, indicated that all hydroxyl groups including the hydroxyimino group were acetylated. The position of the acetoxyimino group (at C-1) evident from the chemical pathway was further confirmed from the ^{1}H-NMR spectrum. The splitting pattern of each of the C-2-methylene protons (δ 3.00 and 3.56) was pure double doublets, one of them being clearly brought from geminal $^2J_{2a,2b}$ (=16.5 Hz) coupling, indicated that the methylene hydrogens had only one vicinal hydrogen (at C-3). This indicates that another adjacent group to the methylene is the C-acetoxyimino group. A doublet (J 6.5 Hz) was recognized at low field (δ 4.99), which is not assigned to H-1′ or -1″ from the J-value, should be assigned to a proton of the methine (C-6) adjacent to the carbon carring the acetoxyimino group, because only the two anomeric and the methine protons can show a doublet, respectively. Furthermore, the proton (H-6) was found to be coupled to a proton, resonating at low field (δ 5.80) as a triplet (J 6.5 Hz, H-5); this indicates that the hydroxyl group at C-5 is acetylated. The above-described result was rather unexpected because, in tetrakis(*N*-benzyloxycarbonyl)-4″,6″-*O*-cyclohexylidenekanamycin A[7] and other related compounds, 5-*O*-acetylation scarcely occurred under reaction conditions similar to that described here. This easy acetylation may be ascribed to the conformation of the aminocyclitol portion of **4**, which is expected not to be chair as in the case of **5** (see ^{1}H-NMR data in Experimental section).

Hydrogenolysis of the *N*-benzyloxycarbonyl groups of **3** in the presence of palladium black gave the 1-(hydroxyimino)kanamycin A (**6**), in 83% yield (based on **2**), with slight kanamycin A. The presence of the hydroxyimino group was supported by appearance of a resonance at low field (δ 154 ppm, C-1) in the ^{13}C-NMR spectrum (see Table 1). Non-chair conformation of the aminocyclitol portion of **6** was also revealed from the ^{1}H-NMR data. This discrepancy from chair conformation, judged from the J values, will be originated from instability of the chair form I caused by interaction between coplaner



I (unstable)

6-hydroxyl and 1-hydroxyimino groups.[8,9] Possible conformation would be that of slightly flattered skew with 5- and 6-hydroxyl groups pseudoaxial.

Attempts to produce 1-epikanamycin A (**9**) from **6** by catalytic hydrogenation with palladium catalyst under several conditions failed, only giving kanamycin A. However, when **6** was hydrogenated in the presence of Raney nickel in aqueous ammonia, a mixture of kanamycin A and 1-epikanamycin A (**9**) was produced in a ratio approximately 2 : 1. As the direct separation of the products was proved difficult, several *N*-protected derivatives were prepared to seek suitable derivatives for the separation. Among them, a mixture of tetrakis-(*N*-*t*-butoxycarbonyl) derivatives, prepared by treating the mixture of kanamycin A and 1-epikanamycin A with *O*-*t*-butyl *S*-(4,6-dimethyl-2-pyrimidinyl) thiocarbonate[10] (Boc-*S* reagent), was found successful; the tetra-*N*-Boc-kanamycin A (**7**) and tetra-*N*-Boc-1-epikanamycin A (**8**) were separated by the difference of solubility in chloroform.

Deblocking of **7** gave kanamycin A identical with the authentic sample, and deblocking of **8** gave 1-epikanamycin A (**9**). The 1-epi structure of **9** was established by the small *J*-values, in its ^{1}H-NMR spectrum, relating to H-1 (the aminocyclitol portion took chair form). In the ^{13}C-NMR spectrum, large up-field shifts were observed at C-1 and -6, in comparison to the corresponding shifts of kanamycin A (Table 1).

TABLE 1. THE ^{13}C CHEMICAL SHIFTS[a] OF KANAMYCIN A[b] (KMA), 1-DEAMINO-1-DEHYDRO-1-HYDROXYIMINO-KANAMYCIN A (**6**), 1-EPIKANAMYCIN A (**9**), AND 1-*N*-[(*S*)-4-AMINO-2-HYDROXYBUTYRYL]-1-EPIKANAMYCIN A (**14**) MEASURED IN 20% ND_3 IN D_2O

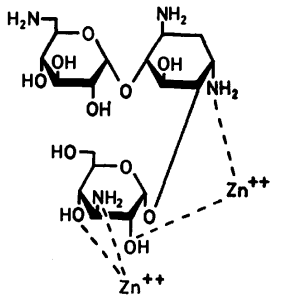
a) In ppm downfield from TMS calculated as $\delta^{TMS} = \delta^{dioxane} + 67.4$ ppm. b) Shift assignments were based on the shifts of kanamycin A reported[11]. Selective irradiation at (denoted c) or near (denoted d or d′; carried out when c was inadequate) the resonance of the proton attached to the carbon, respectively. e—h) The values cited may be reversed, respectively.



II

The 1-epikanamycin A (**9**) was led to 1-*N*-[(*S*)-4-amino-2-hydroxybutyryl]-1-epikanamycin A (**14**). For that, selective protections of the 3-, 6′-, and 3″-amino groups of **9** are requisite. This was performed by applying the zinc acetate-ethyl trifluoroacetate method.[5] In spite of the 1-epiamino structure of **9**, zinc ions completely protected the 1- and 3″-amino groups as in the case of kanamycin A. If Nagabhushan's proposal[11] for nickel, copper and cobalt is applied to this case, zinc chelation such as II may be considered as a candidate. Treatment of **9** with *N*-(benzyloxycarbonyloxy)succinimide[2] in the presence of zinc acetate in dimethyl sulfoxide gave 3,6′-bis(*N*-benzyloxycarbonyl)-1-epikanamycin A (**10**) in 83% yield after purification. The 3″-amino protection of **10** was also readily carried out by using ethyl trifluoroacetate to give the corresponding 3″-trifluoroacetamide derivative (**11**) in almost quantitative yield.

Coupling (*S*)-4-benzyloxycarbonylamino-2-hydroxybutyric acid to the free amino group at C-1 of **11** was readily performed by utilizing the active ester[2] of the acid to give the product (**12**) in 79% yield. De(trifuoroacetyl)ation of **12** (to give **13**) followed by catalytic de(benzyloxycarbonyl)ation gave the final product (**14**) in 92% yield. The structure of **14** was elucidated by the ^{1}H-NMR spectral data. The resonances of H-1 proton, confirmed by the decoupling method, appeared at δ 4.51 as a narrow quartet, the shift-value being fairly high in comparison to that (δ 3.5) of 1-epikanamycin A (**9**); this difference in shift-value indicates that the 1-amino group of **9** was acylated as expected. The ^{13}C-NMR spectrum of **14** was shown in Table 1.

TABLE 2. MINIMAL INHIBITORY CONCENTRATION (μg/ml) OF **9**, **14**, AND KANAMYCIN A

Antibacterial spectra of **9** and **14** were shown in Table 2 with the spectrum of kanamycin A. This result shows that epimerization of the 1-amino group of kanamycin A greatly reduced the original activity. 1-(Hydroxyimino)kanamycin A (**6**) was almost devoid of antibacterial activity.

Experimental

Specific rotations were measured with a Perkin-Elmer Model 241 polarimeter. ^{1}H- and ^{13}C-NMR spectra were recorded in the FT mode with a Bruker WM 250 spectrometer operating at 250 and 62.9 MHz, respectively. In the ^{1}H-NMR spectra, tetramethylsilane (δ=0) was used as the internal standard in both organic solvents and deuterium oxide. Thin-layer chromatography (TLC) was carried out on E. Merck precoated silica gel 60 plates with the spray of sulfuric acid or 0.5% ninhydrin in pyridine for detection. For silica-gel column chromatography, Wakogel C-200 was used.

*3,6′-Bis(*N*-benzyloxycarbonyl)-1-deamino-1-dehydro-1-hydroxyimino-3″-*N*-(trifluoroacetyl)kanamycin A (2).* To a solution of **1** (7.73 g, as the base) and sodium tungstate dihydrate (0.6 g) in aqueous oxolane (1 : 2, 160 ml) was added 30% aqueous hydrogen peroxide (8.8 ml), and the solution was kept at room temperature overnight. On checking by TLC with chloroform–methanol–20% aqueous acetic acid (1 : 1.2 : 1, lower layer), the solution showed a single spot at R_f 0.4 (*cf* **1**: R_f 0.25). Concentration of the pale-yellow solution gave a residue, which was washed with water, dried, and washed with ether to give a solid, 6.76 g (86%), $[\alpha]_D^{24}$ +100° (*c* 2, *N*,*N*-dimethylformamide).

^{1}H-NMR (pyridine-d_5–D_2O=30 : 1): δ=4.00 (1H dd, $J_{1'',2''}$ 3.5, $J_{2',3'}$ 9.5 Hz, H-2′), 4.26 (1H dd, $J_{1'',2''}$ 3.5, $J_{2'',3''}$ 10.5 Hz, H-2″), 5.08 (1H t, $J_{3'',4''}$ 10.5 Hz, H-3″), 5.42 (1H d, H-1″), 5.65 (1H d, H-1′).

Found: C, 50.09; H, 5.36; N, 6.48; F, 6.47%. Calcd for $C_{36}H_{45}F_3N_4O_{17}$: C, 50.12; H, 5.26; N, 6.49; F, 6.61%.

*3,6′,3″-Tris(*N*-benzyloxycarbonyl)-1-deamino-1-dehydro-1-hydroxyiminokanamycin A (4).* A solution of **2** (6.38 g) in a mixture of 2 M (1 M=1 mol dm^{-3}) aqueous ammonia–oxolane (1 : 1, 250 ml) was kept at room temperature overnight. The solution showed a single spot at R_f 0.2 (*cf* **2**: R_f 0.3), on TLC with chloroform–methanol–28% aqueous ammonia (1 : 1 : 1, lower layer). Concentration gave a crude solid of **3** (6.58 g). To a solution of the solid (100 mg) in aqueous *N*,*N*-dimethylformamide (1 : 2, 3 ml) was added *N*-(benzyloxycarbonyloxy)-succinimide[2] (32 mg) and the solution was kept for 1 h at room temperature. Concentration gave a syrup, which was washed with water, then with ether to give a chromatographically homogeneous solid, 88 mg (85% based on **2**), $[\alpha]_D^{24}$ +95° (*c* 1, *N*,*N*-dimethylformamide).

Found: C, 55.13; H, 5.78; N, 6.11%. Calcd for $C_{42}H_{52}N_4O_{18}\cdot H_2O$: C, 54.90; H, 5.92; N, 6.10%.

*1-Acetoxyimino-5,2′,3′,4′,2″,4″,6″-hepta-*O*-acetyl-3,5′,3″-tris(*N*-benzyloxycarbonyl)-1-deamino-1-dehydrokanamycin A (5).* To a solution of **4** (140 mg) in pyridine (2.8 ml) was added acetic anhydride (0.3 ml), and the solution was kept overnight at room temperature. Addition of water (0.3 ml) followed by standing for 0.5 h at room temperature and concentration of the solution gave a syrup, which was dissolved in chloroform. The solution was then processed in a usual manner to give a crude product, which was passed through a short column of silica gel with chloroform–ethyl methyl ketone (3 : 1) to give a pure solid of **5**, 147 mg (78%), $[\alpha]_D^{23}$ +90° (*c* 1, chloroform).

^{1}H-NMR (pyridine-d_5): δ=2.00, 2.01, 2.03, 2.05 (6H), 2.16, 2.17, 2.24 (each s, Ac); 3.00 (1H dd, $J_{2a,2e}$ 16.5, $J_{2a,3}$ 11.5 Hz, H-2a), 3.56 (1H dd, $J_{2e,3}$ 5 Hz, H-2e), 4.99 (1H d, $J_{5,6}$ 6.5 Hz, H-6), 5.80 (1H t, $J\approx$6.5 Hz, H-5); Irradiation of H-6 collapsed the triplet of H-5 to a doublet, and irradiation of H-5 caused the signals at $\delta\approx$4.70 (H-4) to simplify.

Found: C, 56.31; H, 5.54; N, 4.53%. Calcd for $C_{58}H_{68}N_4O_{26}$: C, 56.06; H, 5.75; N, 4.42%.

1-Deamino-1-dehydro-1-hydroxyiminokanamycin A (6). A solution of crude **3** (6.20 g; described in the preparation of **4**) in aqueous oxolane (1 : 2, 300 ml) was hydrogenated in the presence of palladium black and acetic acid (5 ml) under atmospheric pressure of hydrogen for 2 h at room temperature. After filtration, the solution was neutralized with 28% aqueous ammonia (5 ml), and concentrated to give a syrup. Separation of the products by column chromatography of the syrup

with CM-Sephadex C-25 with aqueous ammonia (0→0.15 M, the concentration was gradually changed) gave a solid of **6** (from the earlier frations), 3.06 g (83% as the hemicarbonate, based on **2**) and a solid of kanamycin A (from the later fractions), 0.17 g (4.7% as the hemicarbonate, based on **2**). **6**: $[\alpha]_D^{22}$ +180° (*c* 1, water); ^{1}H-NMR (20% ND_3 in D_2O): δ= 2.06 (1H dd, H-2a), 2.74 (1H dd, H-6'a), 3.00 (1H dd, H-6'b), 3.04 (1H t, H-3"), 3.09 (1H dd, H-2e), ≈3.17 (1H m, H-3), 3.25 (1H t, H-4"), 3.27 (1H t, H-4'), 3.41 (1H dd, H-2"), 3.53 (1H dd, H-4), 3.56 (1H dd, H-2'), 3.69 (1H t, H-3'), 3.92 (1H t, H-5), 4.24 (1H d, H-6), 4.92 (1H d, H-1"), 5.35 (1H d, H-1'); $J_{2a,2e}$ 15.0, $J_{2a,3}$ 11.0, $J_{2e,3}$ ≈4.5, $J_{3,4}$ ≈9, $J_{4,5}=J_{5,6}$ 6.0, $J_{1',2'}$ 3.8, $J_{2',3'}=J_{3',4'}=J_{4',5'}$ 9.5, $J_{5',6'a}$ 7.5, $J_{5',6'b}$ 2.5, $J_{6'a,6'b}$ 13.5, $J_{1'',2''}$ 3.8, $J_{2'',3''}=J_{3'',4''}=J_{4'',5''}$ 10.0 Hz.

Found: C, 42.28; H, 6.70; N, 10.43%. Calcd for $C_{18}H_{34}N_4O_{12}\cdot 1/2\,H_2CO_3$: C, 42.04; H, 6.48; N, 10.60%.

*1,3,6',3"-Tetrakis(*N-t-*butoxycarbonyl)kanamycin A* (**7**) *and 1,3,6',3"-Tetrakis(*N-t-*butoxycarbonyl)-1-epikanamycin A* (**8**). A solution of **6** hemicarbonate (2.00 g) in 1 M aqueous ammonia (40 ml) was shaken in the presence of Raney nickel under 3 atmospheric pressure of hydrogen for 5 h at room temperature. On checking by TLC with chloroform–ethanol–1-propanol–17% aqueous ammonia (2 : 7 : 4 : 7), the solution showed a single spot at R_f 0.16 (*cf* **6**: R_f 0.23). Filtration followed by concentration gave a residue, which was passed through a column of CM-Sephadex C-25 with aqueous ammonia (concentration gradually changed from 0 to 0.15 M) and the ninhydrin-positive fractions were concentrated to give a mixture (1.21 g) of kanamycin A and 1-epikanamycin A (**9**).

To an aqueous solution (4 ml) of the mixture (1.00 g) were added triethylamine (3.5 ml) and Boc-*S* reagent (3.0 g, dissolved in 8 ml 1,4-dioxane), and the mixture was stirred for 24 h at 40°C. Concentration gave a residue, which was extracted with chloroform. The nonextractable residue (1.05 g), which gave R_f 0.47 on TLC with chloroform–methanol–20% aqueous acetic acid (1 : 1 : 1, lower layer) was washed successively with acetone to give a solid of **7**, 0.97 g (34%), $[\alpha]_D^{23}$ +79° (*c* 1, pyridine); Found: C, 50.44; H, 7.54; N, 6.46%. Calcd for $C_{38}H_{68}N_4O_{19}\cdot H_2O$: C, 50.54; H, 7.81; N, 6.20%.

The chloroform layer was washed with 0.5 M aqueous sodium hydroxide to remove the concomitant 4,6-dimethyl-2-pyrimidinethiol, and then with 3% aqueous sodium sulfate, dried over sodium sulfate, and concentrated to give a solid of **8**, 0.51 g (18%), which gave R_f 0.55 on TLC with the above-described developing mixture, $[\alpha]_D^{23}$ +81° (*c* 1, pyridine); Found: C, 50.79; H, 7.55; N, 6.16%. Calcd for $C_{38}H_{68}N_4O_{19}\cdot H_2O$: C, 50.54; H, 7.81; N, 6.20%.

1-Epikanamycin A (**9**). A solution of **8** (1.74 g, as the monohydrate) in aqueous trifluoroacetic acid (1 : 19, 17 ml) was kept for 30 min at room temperature. Evaporation *in vacuo* at room temperature with several additions of toluene gave a residue, which was charged on a column of CM-Sephadex C-25 and developed with aqueous ammonia (0→0.15 M) to give **9** as the carbonate, 960 mg (91%), $[\alpha]_D^{25}$ +166° (*c* 2, water); ^{1}H-NMR (20% ND_3 in D_2O): δ=1.45 (1H slightly deformed dt, H-2a), 1.95 (1H dt, H-2e), 2.74 (1H dd, H-6'a), 2.95 (1H dd, H-6'b), 3.10 (1H t, H-3"), ≈3.11 (1H m, H-3), 3.26 (1H t, H-4'), 3.28 (1H t, H-4), 3.28 (1H t, H-4"), 3.45 (1H dd, H-2"), ≈3.48 (1H narrow m, H-1), 3.55 (1H dd, H-2'), 3.63 (1H dd, H-6), 3.67 (1H t, H-3'), ≈3.75 (1H m, H-5'), 3.92 (1H t, H-5), 4.97 (1H d, H-1"), 5.32 (1H d, H-1'); $J_{1,2a}=J_{1,2e}$ ≈3.5, $J_{1,6}$ 4.0, $J_{2a,2e}$ 14.0, $J_{2a,3}$ ≈13, $J_{2e,3}$ ≈3.5, $J_{3,4}=J_{4,5}=J_{5,6}$ 10, $J_{1',2'}$ 3.8, $J_{2',3'}=J_{3',4'}=J_{4',5'}$ 9.5, $J_{5',6'a}$ 7.5, $J_{5',6'b}$ 2.5, $J_{6'a,6'b}$ 13.5, $J_{1'',2''}$ 3.8, $J_{2'',3''}=J_{3'',4''}=J_{4'',5''}$ 10 Hz.

Found: C, 41.91; H, 7.27; N, 9.98%. Calcd for $C_{18}H_{36}N_4O_{11}\cdot H_2CO_3$: C, 41.76: H, 7.01; N, 10.25%.

*3,6'-Bis(*N-*benzyloxycarbonyl)-1-epikanamycin A* (**10**). To a suspended mixture of **9** (100 mg, as the carbonate) in dimethyl sulfoxide (1.5 ml, dried over molecular sieves 4A) was added zinc acetate dihydrate (180 mg), and the mixture was stirred overnight at room temperature. To the resulting clear solution was gradually added *N*-(benzyloxycarbonyloxy)-succinimide (105 mg) and the mixture was kept for 1 h at room temperature. Addition of ether gave a syrup, which was thoroughly washed with ether. The resulting syrup was charged on a column of Amberlite CG 50 (20 ml, an equal-volume mixture of H^+ and NH_4^+ forms was used) and, after washing the column with aqueous oxolane (1 : 1), the product was developed with aqueous oxolane (1 : 1) containing ammonia (the concentration gradually changed from 0.5 to 1 M). The fractions containing **10** [checked by TLC with chloroform–methanol–aqueous 20% acetic acid=5 : 7 : 5 (lower layer) giving R_f 0.32] were concentrated to a volume of ≈5 ml and further concentrated with occasional additions of water and occasional introductions of carbon dioxide (without this procedure, intermolecular *N*-acyl migration or 1,3-ureylene compound[12] may occur to give a contaminated mixture) to give a zinc-ion free (tested by diphenylcarbazide-ammonia[13]) solid of **10** as the carbonate, 124 mg (83%), $[\alpha]_D^{24}$ +95° (*c* 1, aqueous oxolane=1 : 2).

Found: C, 51.56; H, 6.16; N, 6.84%. Calcd for $C_{34}H_{48}N_4O_{15}\cdot H_2CO_3$: C, 51.59; H, 6.19; N, 6.88%.

*3,6'-Bis(*N-*benzyloxycarbonyl)-1-epi-3"-*N-*(trifluoroacetyl)kanamycin A* (**11**). To a solution of **10** (130 mg, as the carbonate) in dry dimethyl sulfoxide (0.8 ml) was added ethyl trifluoroacetate (0.025 ml) and the solution was kept for 20 min at room temperature. On checking by TLC with chloroform–methanol–aqueous 20% acetic acid=5 : 7 : 5 (lower layer), the solution showed a single spot at R_f 0.5. Addition of ether gave a syrup, which was thoroughly washed with ether. The syrup was dissolved in small volume of methanol (0.5 ml) and precipitated by addition of ether. The procedure was repeated twice more to give a dimethyl sulfoxide-free solid of **11**, 137 mg (99%), $[\alpha]_D^{23}$ +93° (*c* 1, methanol).

Found: C, 50.27; H, 5.90; N, 6.19; F, 6.84%. Calcd for $C_{36}H_{47}F_3N_4O_{16}\cdot 1/4\,H_2CO_3$: C, 50.38; H, 5.54; N, 6.48; F, 6.59%.

*3,6'-Bis(*N-*benzyloxycarbonyl)-1-*N-*[(S)-4-benzyloxycarbonylamino-2-hydroxybutyryl]-1-epi-3"-*N-*(trifluoroacetyl)kanamycin A* (**12**). To a solution of **11** (100 mg) in aqueous oxolane (1 : 1, 3 ml) was gradually added *N*-hydroxysuccinimide ester[2] (83 mg) of (*S*)-4-benzyloxycarbonylamino-2-hydroxybutyric acid dissolved in oxolane (1.5 ml), and the mixture was kept at room temperature for 30 min. The resulting acidic solution was neutralized with sodium carbonate (13 mg) and then concentrated. The resulting residue, after being washed with ether, was dissolved in water-saturated 1-butanol (the solid was scarcely soluble in usual organic solvents immiscible with water) and the solution was washed with 1-butanol-saturated aqueous sodium hydrogencarbonate solution (saturated), and 1-butanol-saturated water to remove inorganic impurities. Concentration of the butanol solution gave a residue, which was chromatographed on a silica-gel column with chloroform–methanol=6 : 1 to give a solid of **11**, 98.5 mg (79%), $[\alpha]_D^{25}$ +67° (*c* 1, methanol).

Found: C, 53.11; H, 5.70; N, 6.33; F, 5.16%. Calcd for $C_{48}H_{60}F_3N_5O_{20}$: C, 53.18; H, 5.58; N, 6.46; F, 5.26%.

*1-*N-*[(S)-4-Amino-2-hydroxybutyryl]-1-epikanamycin A* (**14**). A solution of **12** (170 mg) in mixture of 2 M aqueous ammonia–oxolane (1 : 1, 8.5 ml) was kept overnight at room temperature. On checking by TLC with chloroform–methanol–20% aqueous acetic acid (1 : 1 : 1, lower layer), the solution showed a single spot of **13** at R_f 0.15 (*cf* **12**: R_f 0.32). Concentration

gave a residue, which was dissolved in aqueous oxolane (1 : 1, 8 ml) containing acetic acid (1.0 ml), and the solution was hydrogenated in the presence of palladium black under atmospheric pressure of hydrogen for 2 h at room temperature. The resulting product was isolated by column chromatography on CM-Saphadex C-25 with aqueous ammonia (0→0.5 M) to give a solid of **14** as the carbonate, 93 mg (92%), $[\alpha]_D^{23}$ +128° (*c* 1, water); ^{1}H-NMR (20% ND_3 in D_2O): δ=1.52 (1H slightly deformed dt, H-2a), 1.75 (1H apparent sextet, $J\approx$7.5, $\approx$7.5, $\approx$7.5, and 14.5 Hz, H-3″a), 1.90 [1H two dt, J=4, $\approx$7.5, $\approx$7.5, and 14.5 (=$J_{3'''a,3'''b}$) Hz, H-3‴b], 2.09 (1H br dt, H-2e), 2.74 (2H t, J7.5 Hz, H-4″ a,b), $\approx$2.97 (H-3), 2.75 (1H dd, H-6′a), 2.98 (1H dd, H-6′b), 3.04 (1H t, H-3″), 3.27 (1H t, H-4″), 3.28 (1H t, H-4′), 3.36 (1H t, H-4), 3.39 (1H dd, H-2″), 3.57 (1H dd, H-2′), 3.69 (1H t, H-3′), $\approx$3.75 (H-5′), 3.82 (dd, H-6), 3.91 (1H t, H-5), 4.22 (1H dd, $J_{2''',3'''a}$ 8.5, $J_{2''',3'''b}$ 4.0 Hz,H-2‴), 4.51 (1H br q, $J\approx$4 Hz, H-1), 4.91 (1H d, H-1″), 5.35 (1H d, H-1′); $J_{1,2a}$=$J_{1,2e}$ $\approx$3.5, $J_{1,6}\approx$4, $J_{2a,2e}$ 14.0, $J_{2a,3}$ $\approx$12, $J_{2e,3}$ $\approx$3.5, $J_{3,4}$ $\approx$9, $J_{4,5}$=$J_{5,6}$ 9.5, $J_{1',2'}$ 3.8, $J_{2',3'}$=$J_{3',4'}$=$J_{4',5'}$ 9.5, $J_{5',6'a}$ 7.5, $J_{5',6'b}$ 2.5, $J_{6'a,6'b}$ 13.5, $J_{1'',2''}$ 3.5, $J_{2'',3''}$=$J_{3'',4''}$=$J_{4'',5''}$ 10 Hz.

Found: C, 42.62; H, 7.10; N, 10.65%. Calcd for $C_{22}H_{43}N_5O_{13}\cdot H_2CO_3$: C, 42.65; H, 7.00; N, 10.81%.

Synthesis of Potential Antineoplastic Anthracenedione Derivatives. II. 1,2-Dihydroxy Derivatives

Katsumi NAKAMURA, Tomoyuki ASAI, Tamio HARA,
Naoki MINORIKAWA, and Tetsuo SUAMI*
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama, 223

(Received January 17, 1983)

In continuation of the preceding paper in this series,[1] four derivatives of 1,2-dihydroxy-5,8-bis[2-(2-hydroxyethylamino)ethylamino]-9,10-anthracenedione: a positional isomer of mitoxantrone have been prepared to establish a relationship between the position of the hydroxyl groups on the A ring and antineoplastic activity against experimental leukemia L1210 in mice. Two compounds were found to be fairly active.

In continuation of the preceding paper in this series,[1] 1,2-dihydroxy-5,8-bis[2-(2-hydroxyethylamino)ethylamino]-9,10-anthracenedione (**2**): a positional isomer of mitoxantrone has been synthesized, together with the 1-, 2- and 1,2-di-*O*-methyl derivatives in order to establish the role of hydroxyl groups in an appearance of antitumor activity. It has been described by J. R. Brown[2] that 2-substituted anthraquinones were active against leukemia L1210 in mice. Also, 1,2-dihydroxyanthraquinone derivatives were found to be cytotoxic and antileukemic compounds.[3]

While, a DNA-intercalating drug, mitoxantrone is a 1,4-dihydroxy analog of **2** and exhibits high antitumor activity against leukemia L1210 in mice.[4-7] The effective binding to DNA is achieved in the C ring and multiple substitutions with hydroxyl groups in the A ring in an anthraquinone skeleton.[2]

From the facts that mitoxantrone (1,4-dihydroxy analog) and 1-hydroxy analog are active,[5] it has been deduced that an existence of a hydroxyl group on the C-1 position is favorable for antitumor activity. In the present study, a role of another hydroxyl group on the C-2 position will be discussed.

Results and Discussion

A treatment of quinalizarin (**1**) with 2-(2-aminoethylamino)ethanol at elevated temperature gave 1,2-dihydroxy-5,8-bis[2-(2-hydroxyethylamino)ethylamino]-9,10-anthracenedione **2** as a crude product.[7-9] The product was converted into the partially protected compound (**6**) in 19% yield. Removal of the protective groups in **6** with methanolic HCl yielded **2** in 79% yield. Overall yield of **2** from quinalizarin was 15%. Mild hydrolysis of **6** in aq acetic acid afforded the partially deprotected compound (**7**) in 34% yield. Tritylation of **7** gave the ditrityl derivative (**8**) in 73% yield. Also, **8** was obtained by an alternative reaction process as follows. Tritylation of **6** afforded the compound (**9**) in 75% yield, which was converted, by heating with potassium carbonate in acetone, to **8** in 94% yield.

To protect one of the hydroxyl groups on the C-2 position selectively, protection of **8** with *p*-methoxybenzyl chloride yielded 2-*O*-(*p*-methoxybenzyl) derivative (**10**) in 87% yield. Methylation of **10** with dimethyl sulfate and potassium carbonate in acetone gave a 1-*O*-methyl derivative (**11**) in 77%, which was further converted into the dihydrochloride (**3**), by treating with methanolic HCl, in 70% yield.

To prove the structure, **3** was converted into a pentaacetyl derivative (**12**), whose ^{1}H NMR spectrum was identical with the proposed structure.

The positional isomer of **3** (**4**), 2-*O*-methyl derivative was prepared by the following process.

Methylation of **8** with dimethyl sulfate and potassium carbonate gave a 2-*O*-methyl derivative (**13**) exclusively in 93% yield. Deprotection of **13** in methanolic HCl

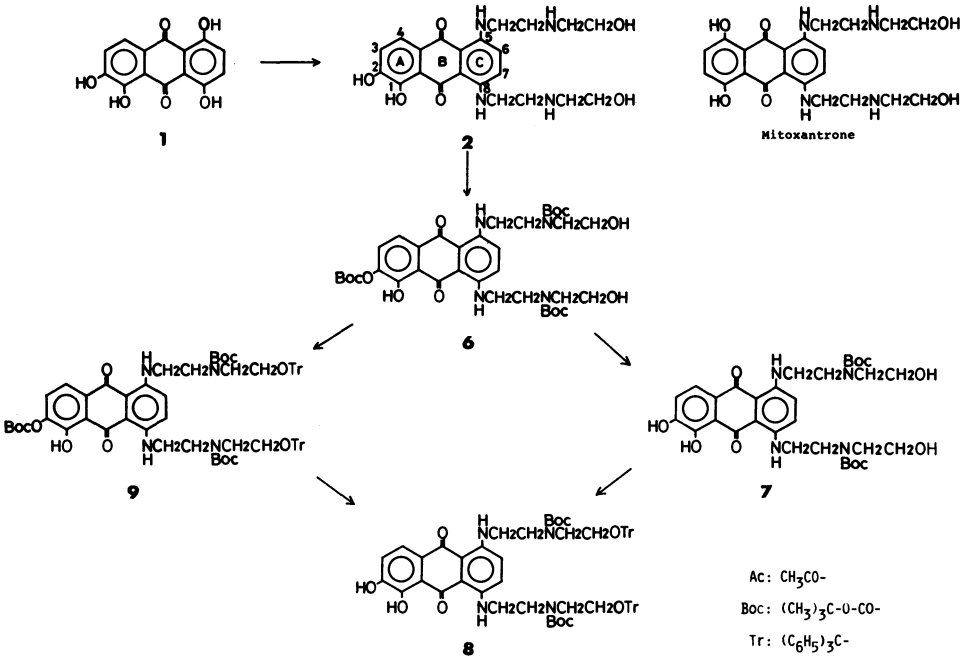
a) Male BDF_1 hybrid mice were inoculated intraperitoneally with 10^6 cells of lymphoid leukemia L1210. Compounds were dissolved in distilled water and administered intraperitoneally at a volume of 0.1 ml/animal once at 24 h after the tumor implantation. b) Percentage increase in life span of treated animals compared with control tumor bearers [100(T/C-1)].



Scheme 1.

gave **4** in 56% yield.

Compound **4** was also obtained by another route as follows. Methylation of **9** with dimethyl sulfate and potassium carbonate afforded a 1-*O*-(*t*-butoxycarbonyl)-2-*O*-methyl derivative (**14**) in 64% yield. The reaction involved a migration of the *t*-butoxycarbonyl (Boc) group from 2-*O* to 1-*O*. Deprotection of **14** in methanolic HCl gave **4** in 87% yield.

Compound **4** was converted to a tetraacetyl derivative (**15**) and a pentaacetyl derivative (**16**), whose ^{1}H NMR spectrum were identical with the proposed structure.

Finally, the 1,2-di-*O*-methyl derivative (**5**) was prepared by the analogous methylation for a prolonged period and successive deprotection in methanolic HCl from **8** *via* compound (**17**).

Acetylation of **5** gave a tetraacetyl derivative (**18**).

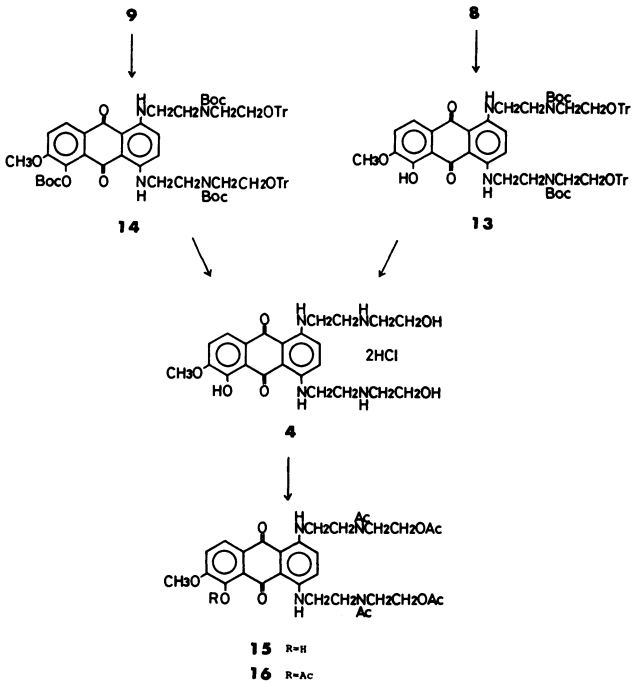
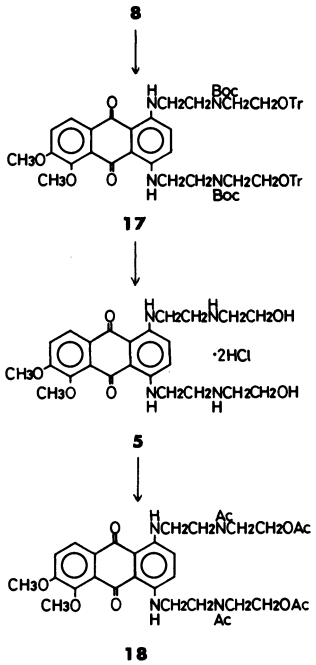


Scheme 3.



Scheme 4.

When ^{1}H NMR spectra of **12**, **16**, and **18** were compared each other, characteristic chemical shifts of acetoxyl groups on C-1 and 2 provided a good evidence for the structures. The chemical shift of the acetoxyl group on C-2 was attributable to δ 2.37 and that of the acetoxyl group on C-1 was δ 2.46, since the latter was deshielded to the down field by the quinone carbonyl group on C-9.[10]

Antitumor activities of **2**, **3**, **4**, and **5** were determined against experimental leukemia L1210 in mice.[11] Compound **2** was highly active, producing ILS value (>757%) and curing all mice by day 60. While mitoxantrone produced the same ILS value (>757%) but was curing 3 animals in 5 mice by day 60. Therefore, **2** is some what superior to mitoxantrone in number of curing animals by day 60. In the case of **5** where the two hydroxyl groups on C-1 and 2 were methylated, the compound did not show any activity. When the hydroxyl group on C-1 was methylated, **3** retained considerable activity producing 114% ILS value. While, the hydroxyl group on C-2 was methylated, **4** was fairly toxic. Considering from these facts, an existence of the free hydroxyl group on C-2 enhances antitumor activity, together with a presence of the hydroxyl group on C-1.

Experimental

General Methods. The same methods were used as described in the preceding paper.[1]

1,2-Dihydroxy-5,8-bis[2-(2-hydroxyethylamino)ethylamino]-9,10-anhracenedione Dihydrochloride (2). *(a) From quinalizarin (1)*: To a suspension of quinalizarin (**1**, 3.00 g) in 1-butanol (30 ml), a solution of 2-(2-aminoethylamino)ethanol (6.0 g) in 1-butanol (20 ml) was added under N_2 and stirred at 150 °C for 8 h. To the mixture, hexane was added and stirred overnight. The supernatant liquid was removed by decantation and the residue was washed with hot ethanol to give 4.56 g of **2**.

(b) From **6**: Compound **6** (200 mg) was dissolved in methanolic HCl (8 ml) under ice cooling. After 7 h, the precipitates were collected by filtration and recrystallized from 5 : 5 : 2 (v/v) ethanol–methanol–water to give 109 mg (79%) of **2**, mp 214—219 °C; UV (H_2O) 245 (log ε, 4.56), 591 (4.28), 635 nm (4.27); IR (KBr) 1615 cm^{-1} (quinone). ^{1}H NMR (D_2O): δ=3.33—3.93 (12H, m, CH_2 of side chain), 4.00—4.27 (4H, m, CH_2 of side chain), 6.63 (1H, d, J=9.0 Hz, aromatic proton), 6.85—7.33 (3H, m, aromatic protons).

Found: C, 49.72; H, 5.77; N, 10.16; Cl, 12.93%. Calcd for $C_{22}H_{30}N_4Cl_2O_6 \cdot H_2O$: C, 49.35; H, 6.02; N, 10.46; Cl, 13.24%.

2-(t-Butoxycarbonyloxy)-5,8-bis[2-(N-t-butoxycarbonyl-2-hydroxyethylamino)ethylamino]-1-hydroxy-9,10-anthracenedione (6). To a stirred solution of crude **2** (2.00 g) in 1 M NaOH solution (50 ml) and dioxane (25 ml) (1 M=1 mol dm^{-3}), di-*t*-butyl dicarbonate (4.91 g) was added. After 16 h, 1 M HCl solution (50 ml) was added under ice cooling, and the mixture was extracted with ethyl acetate. The Organic layer was washed with water, dried over anhydrous Na_2SO_4 and concentrated. The residue was purified on a column using 1 : 3 (v/v) acetone–toluene. Fractions homogeneous (R_f 0.47) on TLC in 1 : 1 (v/v) acetone–toluene were collected and concentrated. The residue was recrystallized from benzene–hexane to give 651 mg (19%) of **6**, mp 154—155 °C; UV ($CHCl_3$) 260 (log ε, 4.41), 381 (3.68), 606 (4.25), 656 nm (4.36). ^{1}H NMR: δ= 1.46 (18H, s, NBoc×2), 1.61 (9H, s, OBoc), 2.93—3.61 (12H, m, NHC$\underline{H}_2$C$\underline{H}_2$N(Boc)C$\underline{H}_2$CH_2OH), 3.64—3.90 (4H, m, CH_2C$\underline{H}_2$OH), 6.73—6.89 (2H, m, H-6 and 7), 7.29 (1H, d, J=9.0 Hz, H-3), 7.58 (1H, d, J=9.0 Hz, H-4), 10.12 (1H, bs, aromatic NH), 10.77 (1H, bs, aromatic NH), 13.73 (1H, s, 1-OH).

Found: C, 59.43; H, 6.89; N, 7.25%. Calcd for $C_{37}H_{52}N_4O_{12}$: C, 59.66; H, 7.04; N, 7.52%.

5,5-Bis[2-(N-t-butoxycarbonyl-2-hydroxyethylamino)ethylamino]-1,2-dihydroxy-9,10-anthracenedione (7). Compound **6** (400 mg) was dissolved in 80% aqueous acetic acid (10 ml) and stirred at 100 °C for 30 min. The mixture was concentrated and the residue was purified on a column using 1 : 7 (v/v) ethanol–toluene. Fractions homogeneous (R_f 0.43) on TLC in 1 : 5 (v/v) ethanol–toluene were collected and concentrated. The residue was recrystallized from benzene–hexane to give 118 mg (34%) of **7**, mp 164—166 °C; UV ($CHCl_3$) 260 (log ε, 4.36) (shoulder), 274 (4.26) (shoulder), 565 (3.87) (shoulder), 602 (4.19), 650 nm (4.27). ^{1}H NMR: δ=1.47 (18H, s, NBoc×2), 3.44 (12H, bs, NHC$\underline{H}_2$C$\underline{H}_2$N(Boc)C$\underline{H}_2$CH_2OH), 3.76 (4H, bs, CH_2C$\underline{H}_2$OH), 6.54—7.54 (5H, m, aromatic protons and 2-OH), 9.81 (1H, bs, aromatic NH), 10.51 (1H, bs, aromatic NH), 13.48 (1H, s, 1-OH).

Found: C, 59.82; H, 6.89; N, 8.41%. Calcd for $C_{32}H_{44}N_4O_{10}$: C, 59.61; H, 6.88; N, 8.69%.

5,8-Bis[2-[N-(t-butoxycarbonyl)-2-(trityloxy)ethylamino]ethylamino]-1,2-dihydroxy-9,10-anthracenedione (8). *(a) From 7*: To a stirred solution of **7** (80 mg) in pyridine (5 ml), trityl chloride (206 mg) was added. After 17 h at 60 °C, the mixture was poured into ice cold water. Precipitates were collected by filtration and purified on a column using 1 : 10 (v/v) ethyl acetate–toluene. Fractions homogeneous (R_f 0.36) on TLC in 1 : 5 (v/v) ethyl acetate–toluene were collected and concentrated. The residue was recrystallized from ethanol to give 101 mg (73%) of **8**, mp 140—143 °C; UV ($CHCl_3$) 261 (log ε, 4.56) (shoulder), 560 (4.02), (shoulder), 602 (4.36), 652 nm (4.46). ^{1}H NMR: δ=1.40 (18H, bs, NBoc×2), 2.96—4.75 (16H, m, CH_2 of side chain), 6.63 (1H, bs, 2-OH), 6.83—7.54 (33H, m, H-3,6,7 and C($C_6\underline{H}_5$)$_3$), 10.10 (1H, bs, aromatic NH), 10.76 (1H, bs, aromatic NH), 13.65 (1H, bs, 1-OH).

Found: C, 74.24; H, 6.47; N, 4.71%. Calcd for $C_{70}H_{72}$-

N_4O_{10}: C, 74.44; H, 6.43; N, 4.96%.

(b) From ***9***: To a stirred solution of **9** (636 mg) in acetone (15 ml), potassium carbonate (358 mg) was added and heated under reflux. After 7 h, the mixture was filtered and filtrate was concentrated. The residue was dissolved in ethyl acetate, washed with water, dried over anhydrous Na_2SO_4 and concentrated to give 501 mg (94%) of **8**.

*2-(t-Butoxycarbonyloxy)-5,8-bis[2-[N-(t-butoxycarbonyl)-2-(trityloxy) ethylamino] ethylamino]-1-hydroxy-9, 10-anthracenedione (****9****).* Compound **6** (100 mg) was tritylated analogously as described in the preparation of **8**. Fractions homogenous (R_f 0.22) on TLC in 1 : 3 (v/v) ethyl acetate–hexane were collected and concentrated. The residue was recrystallized from ethanol–methanol to give 114 mg (75%) of **9**, mp 190—215 °C; UV (EtOH) 210 (log ε, 4.93), 368 (3.77), 564 (3.96), 603 (4.33), 652 nm (4.45). ^{1}H NMR: δ=1.35 (18H, bs, NBoc×2), 1.53 (9H, s, OBoc), 3.00—3.77 (16H, m, CH_2 of side chain), 6.93—7.60 (33H, m, H-3,6,7 and $C(C_6\underline{H}_5)_3$), 7.80 (1H, d, J=9.0 Hz, H-4), 10.50 (1H, bs, aromatic NH), 11.05 (1H, bs, aromatic NH), 13.85 (1H, bs, 1-OH).

Found: C, 73.38; H, 6.65; N, 4.33%. Calcd for $C_{75}H_{80}N_4O_{12}$: C, 73.27; H, 6.56; N, 4.56%.

*5,8-Bis[2-[N-(t-butoxycarbonyl)-2-(trityloxy)ethylamino]ethylamino]-1-hydroxy-2-(p-methoxybenzyloxy)-9,10-anthracenedione (****10****).* To a stirred solution of **8** (300 mg) in dichloromethane (5 ml) and DMF (5 ml), *p*-methoxybenzyl chloride (0.5 ml) and potassium carbonate (184 mg) were added. After 4 h, the mixture was filtered and filtrate was washed with water, dried over anhydrous Na_2SO_4, and concentrated. The residue was washed with hexane and purified on a column using 1 : 3 (v/v) ethyl acetate–hexane. Fractions homogeneous (R_f 0.40) on TLC in 1 : 2 (v/v) ethyl acetate–hexaen were collected and concentrated. The residue was crystallized from ethanol to give 289 mg (87%) of **10**, mp 103—106 °C; UV ($CHCl_3$) 260 (log ε, 4.51) (shoulder), 280 (4.34) (shoulder), 568 (3.95) (shoulder), 602 (4.28), 654 nm (4.38). ^{1}H NMR: δ=1.17—1.63 (18H, m, NBoc×2), 3.01—3.66 (16H, m, CH_2 of side chain), 3.76 (3H, s, $CH_2C_6H_4OC\underline{H}_3$), 5.17 (2H, s, $C\underline{H}_2C_6H_4OCH_3$), 6.86 (2H, d, J=9.0 Hz, aromatic protons of MBn[13]), 6.99—7.51 (35H, m, aromatic protons), 7.73 (1H, d, J=9.0 Hz, H-4), 10.30 (1H, bs, aromatic NH), 10.83 (1H, bs, aromatic NH), 13.62 (1H, bs, 1-OH).

Found: C, 75.13; H, 6.51; N, 4.41%. Calcd for $C_{78}H_{81}N_4O_{11}$: C, 74.92; H, 6.53; N, 4.48%.

*5,8-Bis[2-[N-(t-butoxycarbonyl)-2-(trityloxy) ethylamino] ethylamino]-1-methoxy-2-(p-methoxybenzyloxy)-9,10-anthracenedione (****11****).* To a stirred solution of **10** (1.43 g) in acetone (20ml), dimethyl sulfate (0.5 ml) and potassium carbonate (794 mg) were added, heated under reflux. After 6 h, the mixture was filtered snd the filtrate was diluted with ethyl acetate. The solution was washed with water, dried over anhydrous Na_2SO_4, and concentrated. The residue was purified on a column using 15 : 1 (v/v) benzene–ethyl acetate. Fractions homogeneous (R_f 0.58) on TLC in 5 : 1 (v/v) benzene–ethyl acetate were collected and concentrated. The residue was recrystallized from ethanol to give 1.11 g (77%) of **10**, mp 101—106 °C; UV ($CHCl_3$) 273 (log ε, 4.56), 597 (4.23), 645 nm (4.26). ^{1}H NMR: δ=1.17—1.59 (18H, m, NBoc×2), 3.02—3.64 (16H, m, CH_2 of side chain), 3.76 (3H, s, $CH_2C_6H_4OC\underline{H}_3$), 3.95 (3H, s, 1-$OCH_3$), 5.15 (2H, s, $C\underline{H}_2C_6H_4OCH_3$), 6.85 (2H, d, J= 9.0 Hz, aromatic protons of MBn), 6.98—7.51 (35H, m, aromatic protons), 8.08 (1H, d, J=9.0 Hz, H-4), 10.23 (2H, bs, aromatic NH).

Found: C, 74.91; H, 6.61; N, 4.44%. Calcd for $C_{79}H_{83}N_4O_{11}$: C, 75.04; H, 6.62; N, 4.43%.

*2-Hydroxy-5,8-bis[2-(2-hydroxyethylamino)ethylamino]-1-methoxy-9,10-anthracenedione dihydrochloride (****3****).* To a stirred solution of **11** (1.11 g) in dichloromethane (5 ml), methanolic HCl (20 ml) was added under ice cooling. The precipitates were collected by filtration and recrystallized from 95% aqueous ethanol to give 342 mg (70%) of **3**, mp 209—211 °C; UV (H_2O) 217 (log ε, 4.50), 239 (4.50), 271 (4.50), 586 (4.20), 629 nm (4.20); IR (KBr) 1640 cm^{-1} (quinone). ^{1}H NMR (D_2O): δ=3.33—3.65 (8H, m, $NHCH_2C\underline{H}_2NHC\underline{H}_2CH_2OH$), 3.68—3.95 (7H, m, $NHC\underline{H}_2CH_2NH$ and 1-OCH_3), 3.95—4.20 (4H, m, $CH_2C\underline{H}_2OH$), 7.00—7.28 (3H, m, H-3,6 and 7), 7.55 (1H, d, J=9.0 Hz, H-4).

Found: C, 49.56; H, 5.83; N, 9.70; Cl, 13.05%. Calcd for $C_{23}H_{30}N_4O_6\cdot 2HCl\cdot 1.5\,H_2O$: C, 49.47; H, 6.31; N, 10.03; Cl, 12.69%.

*2-Acetoxy-5,8-bis[2-(N-acetyl-2-acetoxyethylamino)ethylamino]-1-methoxy-9,10-anthracenedione (****12****).* Compound **3** (15 mg) was acetylated with acetic anhydride (0.5 ml) in pyridine (1 ml) under ice cooling. The mixture was extracted with ethyl acetate and washed with H_2O, dried over Na_2SO_4. The solution was concentrated to give 22 mg (quantative yield) of **12** as an amorphous solid. ^{1}H NMR: δ=2.05, (6H, s, Ac×2), 2.15 (6H, s, Ac×2), 2.37 (3H, s, 2-OAc) 3.09—3.78 (12H, m, $NHC\underline{H}_2C\underline{H}_2N(Ac)C\underline{H}_2CH_2OAc$) 3.92 (3H, s, 1-$OCH_3$), 4.18 (4H, t, J=6.0 Hz, $CH_2C\underline{H}_2OAc$), 7.22—7.48 (3H, m, H-3,6 and 7), 8.15 (1H, d, J=9.0 Hz, H-4), 10.46 (2H, bs, aromatic NH).

*5,8-Bis[2-[N-(t-butoxycarbonyl)-2-(trityloxy) ethylamino] ethylamino]-1-hydroxy-2-methoxy-9,10-anthracedione (****13****).* Compound **8** (70 mg) was methylated analogously as described in the preparation of **11**. The crude product was purified on a column using 1 : 10 (v/v) ethyl acetate–toluene. Fractions homogeneous (R_f 0.43) on TLC in 1 : 5 (v/v) ethyl acetate–toluene were collected and concentrated. The residue was recrystallized from ethanol to give 66 mg (93%) of **13** as amorphous solids, mp 110—114 °C; UV ($CHCl_3$) 262 (log ε, 4.52) (shoulder), 278 (4.38), 564 (3.99) (shoulder), 520 (4.33), 652 nm (4.43). ^{1}H NMR: δ=1.35 (18H, bs, NBoc×2), 2.97—3.63 (16H, m, CH_2 of side chain), 3.82 (3H, s, 2-OCH_3), 6.80—7.67 (33H, m, H-3,6,7 and $C(C_6\underline{H}_5)_3$), 7.78 (1H, d, J=9.0 Hz, H-4), 10.30 (1H, bs, aromatic NH), 10.87 (1H, bs, aromatic NH), 13.79 (1H, bs, 1-OH).

Found: C, 74.75; H, 6.71; N, 4.90%. Calcd for $C_{71}H_{74}N_4O_{10}$: C, 74.58; H, 6.52; N, 4.90%.

*1-(t-Butoxycarbonyloxy)-5,8-bis[2-[N-(t-butoxycarbonyl)-2-(trityloxy)ethylamino]ethylamino]-2-methoxy-9,10-anthracenedione (****14****).* Compound **9** (400 mg) was methylated analogously as described in the preparation of **11**. The crude product was purified on a column using 1 : 4 (v/v) ethyl acetate–hexane. Fractions homogeneous (R_f 0.16) on TLC in 1 : 3 (v/v) ethyl acetate–hexane were collected and concentrated. The residue was recrystallized from ethanol to give 257 mg (64%) of **14**, mp 108—111 °C; UV ($CHCl_3$) 272 (log ε, 4.63), 599 (4.32), 646 nm (4.37). ^{1}H NMR: δ=1.37 (18H, bs, NBoc×2), 1.55 (9H, s, OBoc), 2.90—3.67 (16H, m, CH_2 of side chain), 3.83 (3H, s, 2-OCH_3), 6.90—7.67 (33H, m, H-3,6,7 and $C(C_6\underline{H}_5)_3$), 8.32 (1H, d, J=9.0 Hz, H-4), 10.62 (2H, bs, aromatic NH).

Found: C, 73.13; H, 6.69; N, 4.26%. Calcd for $C_{76}H_{82}N_4O_{12}$: C, 73.41; H, 6.65; N, 4.51%.

*1-Hydroxy-5,8-bis[2-(2-hydroxyethylamino)ethylamino]-2-methoxy-9,10-anthracenedione dihydrochloride (****4****).* *(a) From* ***13***: Compound **13** (150 mg) was treated with methanolic HCl (10 ml) under ice cooling. After 4 h, precipitates were collected and recrystallized from methanol to give 39 mg (56%) of **4**, mp 199—201 °C; UV (H_2O) 227 (log ε, 4.24) (shoulder), 243 (4.45), 260 (4.38), 589 (4.15), 635 nm (4.17); IR (KBr) 1640 cm^{-1} (quinone). ^{1}H NMR (D_2O): δ=6.73—7.00 (4H, m, H-3,4,6 and 7).

Found: C, 48.77; H, 5.85; N, 9.54; Cl, 12.50%. Calcd for $C_{23}H_{30}N_4O_6 \cdot 2HCl \cdot 2H_2O$: C, 48.68; H, 6.39; N, 9.87; Cl, 12.49%.

(b) From ***14***: Compound **14** (150 mg) was treated analogously as described above in (a) to give 56 mg (87%) of **4**,.

*5,8-Bis[2-(*N*-acetyl-2-acetoxyethylamino) ethylamino]-1-hydroxy-2-methoxy-9,10-anthracenedione (**15**).* Compound **4** (30 mg) was acetylated with acetic anhydride (0.5 ml) in pyridine (0.5 ml) under ice cooling. The solution was diluted with ethyl acetate and washed with water, dried over anhydrous Na_2SO_4. The solution was concentrated and the residue was purified on a column using 1 : 6 (v/v) ethanol–toluene were collected and concentrated to give 23 mg (66%) of **15** as syrup. ^{1}H NMR: δ=2.04 (6H, s, Ac×2), 2.14 (6H, s, Ac×2), 3.57 (12H, bs, NHC$\underline{H_2}$C$\underline{H_2}$N(Ac)C$\underline{H_2}$CH$_2$OAc), 3.96 (3H, s, 2-OCH$_3$), 4.17 (4H, t, J=6.0 Hz, CH$_2$C$\underline{H_2}$OAc), 6.87—7.51 (3H, m, H-3,6, and 7), 7.70 (1H, d, J=9.0 Hz, H-4), 10.19 (1H, bs, aromatic NH), 10.72 (1H, bs, aromatic NH), 13.42—13.78 (1H, m, 1-OH).

*1-Acetoxy-5,8-bis[2-(*N*-acetyl-2-acetoxyethylamino) ethylamino]-2-methoxy-9,10-anthracenedione (**16**).* Compound **4** (30 mg) was acetylated analogously as described in the preparation of **15**. Fractions homogeneous (R_f 0.30) on TLC in 1 : 3 (v/v) ethanol–toluene were collected and concentrated to give 13 mg (35%) of **16** as amorphous solids, UV ($CHCl_3$) 274 (log ε, 4.48), 594 (4.14), 640 nm (4.17). ^{1}H NMR: δ=2.02 (6H, s, Ac×2), 2.13 (6H, s, Ac×2), 2.46 (3H, s, 1-OAc), 3.24—3.80 (12H, m, NHC$\underline{H_2}$C$\underline{H_2}$N(Ac)C$\underline{H_2}$CH$_2$OAc), 3.92 (3H, s, 2-OCH$_3$), 4.16 (4H, t, J=6.0 Hz, CH$_2$C$\underline{H_2}$OAc), 6.98—7.67 (3H, m, H-3,6 and 7), 8.25 (1H, d, J=9.0 Hz, H-4), 10.56 (2H, bs, aromatic NH).

Found: C, 59.25; H, 6.01; N, 8.09%. Calcd for $C_{33}H_{40}N_4O_{11}$: C, 59.32; H, 6.03; N, 8.39%.

*5,8-Bis[2-[*N*-(*t*-butoxycarbonyl)-2-(trityloxy) ethylamino]ethylamino]-1,2-dimethoxy-9,10-anthracenedione (**17**).* Compound **8** (110 mg) was methylated analogously as described in the preparation of **11**. The product was purified on a column using 1 : 8 (v/v) ethyl acetate–toluene. Fractions homogeneous (R_f 0.56) on TLC in 1 : 3 (v/v) ethyl acetate–toluene were collected and concentrated. The residue was recrystallized from hexane to give 37 mg (32%) of **17**, mp 85—90 °C; UV (EtOH) 212 (log ε, 4.83), 271 (4.49), 593 (4.18), 640 nm (4.21). ^{1}H NMR: δ=1.22 (18H, bs, NBoc×2), 3.01—3.72 (16H, m, CH$_2$ of side chain), 3.94 (6H, s, OCH$_3$×2), 6.89—7.50 (33H, m, H-3,6,7 and C(C$_6\underline{H_5}$)$_3$), 8.13 (1H, d, J=9.0 Hz, H-4), 10.19 (2H, bs, aromatic NH).

Found: C, 74.18; H, 6.91; N, 4.85%. Calcd for $C_{72}H_{76}N_4O_{10}$: C, 74.72; H, 6.62; N, 4.84%.

*5,8-Bis[2-(2-hydroxyethylamino) ethylamino]-1,2-dimethoxy-9,10-anthracenedione dihydrochloride (**5**).* Compound **17** (100 mg) was dissolved in methanolic HCl (4 ml), after 2 h, precipitates were collected by filtration and recrystallized from ethanol to give 35 mg (81%) of **5**, mp 203—205 °C; UV (H_2O) 221 (log ε, 4.39), 239 (4.41), 272 (6.41), 584 (4.12), 627 nm (4.12); IR (KBr) 1635 cm^{-1}. ^{1}H NMR (D_2O): δ=7.10 (2H, bs, H-6 and 7), 7.32 (1H, d, J=9.0 Hz, H-3), 7.72 (1H, d, J=9.0 Hz, H-4).

(Received January 20, 1983)

The rate of photo-methoxylation of methyl 2-pyridinecarboxylate(**1**) in acidic methanol is accelerated by 4-substituted pyridines and their analogs, 4,4'-bipyridine and pyrazine. The photo-methoxylation of **1** is not promoted by triplet sensitizers, electron donors, or electron acceptors. Detailed analyses on the **1**–4-pyridinecarbonitrile(**3**) system including wavelength dependence lead to a mechanism for the promotion *via* an excited complex formed from an excited **1** and **3** in the ground state.

The promotion and inhibition of photoreactions are an important theme in the studies of photochemistry from the viewpoints of both mechanistic and synthetic organic photochemistry. The promotion and inhibition *via* energy transfer[1] and electron transfer[2] have been investigated extensively.

The field of photosensitization is, however, wide and studies from new aspects are needed. Increasing interest has been paid to the sensitization *via* excited complexes. For the apparently peculiar "quencher-sensitized" photo-dimerization of anthracene derivatives,[3,4] the participation of an exciplex has been proposed.[3] The selectivity and specificity due to complex formation are important. Photochemical formation of optically active *trans*-cyclooctene and 1,5-cyclooctadiene induced by chiral sensitizers has been explained in terms of the exciplex formation.[5,6]

We describe here the specific promotion of photo-methoxylation of methyl 2-pyridinecarboxylate by 4-substituted pyridines and propose a mechanism for the promotion *via* an exciplex.[7] Concerning the photo-methoxylation of methyl 2-pyridinecarboxylate in the absence of sensitizers, we have observed remarkable concentration dependence and proposed a mechanism *via* an excimer.[8]

Results and Discussion

Indices Describing (Promoting or Inhibiting) Effects of Additives, Y- and A-Value. In the case where the additive and the substrate absorb the incident light competitively, the effects of addititives should be analyzed by taking the distribution of light absorption between the substrate and the additive into consideration.

In a system where the incident light is completely absorbed by the substrate even in the absence of the additive, an index, A, defined below can be used for describing the promoting or inhibiting effect by the additive:

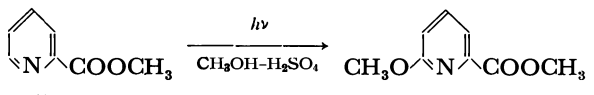
$$A = Y/L$$

$$Y = \frac{\text{Yield in the presence of additive}}{\text{Yield in the absence of additive}}$$

$$L = \frac{\text{Light absorbed by substrate (1)}}{\text{Light absorbed both by substrate (1) and by additive (S)}} = \frac{c_1\varepsilon_1}{c_1\varepsilon_1 + c_S\varepsilon_S},$$

where c_1 and c_S represent the concentrations of **1** and additive, and ε_1 and ε_S are the molar absorption coefficients of **1** and of additive at the wavelength of the photolyzing light, respectively. $A>1$ indicates promotion by the additive and $A<1$ means inhibition.

Effects of Triplet Sensitizer, Triplet Quencher, Electron Donor, and Electron Acceptor. UV-irradiation of methyl 2-pyridinecarboxylate (**1**) in methanol acidified with sulfuric acid gives methyl 6-methoxy-2-pyridinecarboxylate (**2**).



(**1**) (**2**)

Table 1. Effects of triplet sensitizer, electron donor, and electron acceptor on photo-methoxylation of methyl 2-pyridinecarboxylate (**1**) $[H_2SO_4]=5\times10^{-2}$ mol dm^{-3}; Irradiated with 254 nm light.

Additive	10^3 [**1**] / mol dm^{-3}	10^3 [Additive] / mol dm^{-3}	L	Y	A
Benzene	1.0	1.0	0.96	0.83	0.86
	1.0	10	0.68	0.62	0.91
Naphthalene	1.0	6.0	0.16	0.055	0.34

Nitrobenzene	0.25	1.0	0.27	0.0	0.0

As reported earlier,[8] the photo-methoxylation has a remarkable concentration dependence on **1**: at 32 °C, quantum yields for **2** at $[\mathbf{1}]=5\times10^{-4}$, 1.0×10^{-3}, 2.0×10^{-3}, 5.0×10^{-3}, and 2.0×10^{-2} mol dm^{-3} are 0.009, 0.02, 0.025, 0.051, and 0.17, respectively.

We studied the effects of additives on photo-methoxylation of **1** at $[\mathbf{1}]=1.0\times10^{-3}$ mol dm^{-3}, where the photo-methoxylation is not so efficient. In Table 1 are listed the effects of several typical sensitizers, electron donors, and electron acceptors. The photo-methoxylation of **1** is not promoted by acetophenone, benzene, and naphthalene, and is not inhibited by 1,3-pentadiene (Fig. 1). These results indicate that the photo-methoxylation proceeds *via* a singlet excited state. Anisole, naphthalene, ferrocene, nitrobenzene, and 1,2,4,5-tetracyanobenzene, which can be expected to undergo electron transfer type interactions, have no promoting effect.

Effects of Pyridine Derivatives on Photo-methoxylation of ***1****.* The results of a systematic survey of effects of pyridine derivatives on photo-methoxylation of **1** are shown in Table 2. It should be noted that 4-substituted pyridines

Table 2. Effects of substituted pyridines and related compounds on photo-methoxylation of methyl 2-pyridinecarboxylate (**1**) $[H_2SO_4]=5\times10^{-2}$ mol dm^{-3}; Irradiated with 254 nm light.

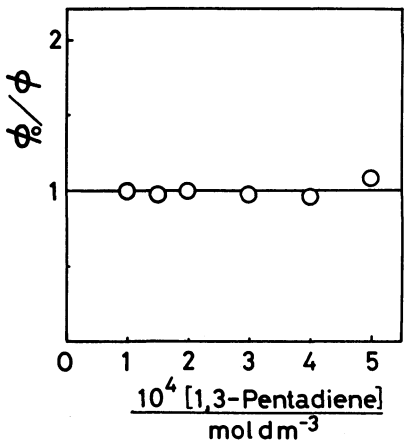

Fig. 1. Stern-Volmer plot for quenching of photo-methoxylation of methyl 2-p ridinecarboxylate (**1**) by 1,3-pentadiene. $[\mathbf{1}]=1.0\times10^{-3}$ mol dm^{-3}; $[H_2SO_4]=5\times10^{-2}$ mol dm^{-3}.

show remarkable promoting effects independently of the electron-accepting or electron-donating character of the substituents. Pyrazine and 4,4'-bipyridine, which can be regarded as analogs of 4-substituted pyridines, show high promoting effects.

Some 2-substituted pyridines accelerate the photo-methoxylation of **1**, but less effectively than 4-substituted pyridines. 3-Substituted pyridines have no promoting effects.

*Characteristics of Promotion by 4-Pyridinecarbonitrile (**3**).* Among 4-substituted pyridines, 4-pyridinecarbonitrile has a large promoting effect. In the methyl 2-pyridine-carboxylate (**1**)-4-pyridinecarbonitrile (**3**) system, the characteristics of the promotion was studied in detail. In Table 3, are shown the data of photosensitization by **3** at $[\mathbf{1}]=1.0\times10^{-3}$ mol dm^{-3} at various concentrations of **3** in the irradiation with 254 nm light. From Table 3 the following points should be noted.

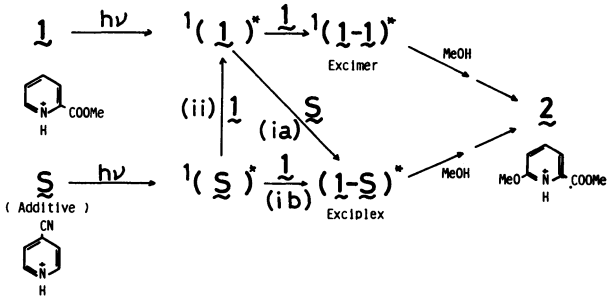
1) The additive, **3**, was recovered almost quantitatively. This means that **3** works as a "true catalyst" (not sacrificially). For example, we analyze the data of line 2 in Table 3. By the irradiation of the solution containing 10^{-3} mol dm^{-3} of **1** and 10^{-4} mol dm^{-3} of **3**, 2.5×10^{-5} mol dm^{-3} of **2** are formed and 5×10^{-7} mol dm^{-3} of **3** are consumed. The formation of **2** is 50 times greater than the consumption of **3**.

2) Both *A*-values, which are indices of promotion normalized on the basis of the light absorbed by **1**, and also *Y*-values, which are indices of promotion without the correction of light absorption are larger than 1.

3) The presence of **3** increases both the consumption of **1** and the selectivity for **3** (selectivity=[**2** formed]/[**1** reacted]). The combination of these two effects results in the large *A*- and *Y*-values.

The promotion by **3** is greater than that *via* self-catalysis by **1**: the addition of 10^{-3} mol dm^{-3} of **3** to 10^{-3} mol dm^{-3} of **1** increased the yield of **2** 7.4 times (in *Y*-value), while the yield of **2** at $[\mathbf{1}]=2\times10^{-3}$ mol dm^{-3} is only 1.23 times of the yield at $[\mathbf{1}]=1\times10^{-3}$ mol dm^{-3} at 32 °C.

Mechanism for Promotion by 4-Pyridinecarbonitrile. For the promotion of photo-methoxylation of **1** by additives, the following mechanisms are conceivable (Scheme 1).



Scheme 1.

(i) Mechanism *via* exciplex formation
It is subdivided into three categories:
(ia) Mechanism *via* an exciplex formed from an excited **1** and a ground state-additive
(ib) Mechanism *via* an exciplex formed from an excited additive and a ground state- **1**.
(ic) Mechanism in which (ia) and (ib) operate simultaneously.
(ii) Singlet energy transfer mechanism

As stated in the previous section, the photo-methoxylation is neither promoted by triplet sensitizer nor inhibited by triplet quencher. A triplet energy transfer mechanism is thus excluded.

The above postulated mechanisms were further examined in the **1**—**3** system.

Table 3. Dependence of promotion of photo-methoxylation of methyl 2-pyridinecarboxylate (**1**) on concentration of added 4-pyridinecarbonitrile (**3**) in irradiation with 254 nm light

Irradiation time, 2 min; $[\mathbf{1}]=1.0\times10^{-3}$ mol dm^{-3}; $[H_2SO_4]=5\times10^{-2}$ mol dm^{-3}.

10^4 [**3**] / mol dm^{-3}	*L*	10^5 [**2**] / mol dm^{-3}	10^5 [**1** reacted] / mol dm^{-3}	*Y*	*A*	[**2** formed] / [**1** reacted]	Recovery of **3** / %
0.0	1.00	0.84	2.3			0.36	
1.0	0.96	2.5	6.2	3.0	3.1	0.40	99.5
3.0	0.89	3.2	7.5	3.9	4.4	0.42	100
5.0	0.83	3.7	7.4	4.7	5.6	0.51	100
6.0	0.80	3.9	6.1	4.8	6.0	0.65	100
7.0	0.78	5.4	7.3	6.7	8.6	0.74	100
8.0	0.75	5.6	6.9	7.0	9.4	0.83	100
10.0	0.71	6.0	7.3	7.4	10.4	0.83	100

A singlet energy transfer mechanism (ii) can be excluded on the basis of the data in Table 3. *Y*-values in the **1**—**3** system are greater than 1. If Mechanism (ii) operates, *Y* can not exceed 1, because in the system, where all the incident light are completely absorbed by **1** and **3**, the sum of singlet excited states of **1** and **3** is constant and the number of the excited **1** in the presence of additive can not exceed the number of the excited **1** in the absence of additive, even if the efficiency of the singlet energy transfer is 100%.

In order to answer the question whether (ia), (ib), or (ic) is more plausible, the wavelength dependence of the promotion is studied. The spectra of **1** differ from those of **3**: 254 nm light is absorbed more efficiently by **1** (ε=4350) than by **3** (ε=1800), while 280 nm light is absorbed more efficiently by **3** (ε=4330) than by **1** (ε=1200).

If the promotion is effected *via* an exciplex from an excited **1** and a ground state- **3** (Mechanism (ia)), *A*-values at the different wavelengths should be the same. In Mechanism (ia), the fate of the excited **1** (to form an excimer (**1**—**1**)* or to form an exciplex (**1**—**3**)*) is determined by the concentrations of **1** and **3**. Therefore, *A*-value, which is the relative yield on the basis of the quantity of the excited **1**, should not change by varying the distribution of light absorption, as long as the concentrations of **1** and **3** remain the same. In Mechanism (ia), the *A*-value, however, should be dependent on the concentrations of **1** and **3**.

In Mechanism (ib) the *A*-value should depend on the wavelength and a higher *A*-value should be expected in the irradiation with light of a wavelength at which **3** absorbs more than **1**.

If the process (ia) and (ib) occur in parallel, the *A*-value for the wavelength at which light is absorbed less by **1** than **3** should be greater than that for the wavelength at which light is absorbed more by **1** than by **3**, because the light absorbed by **3** should be effective for the formation of **2**.

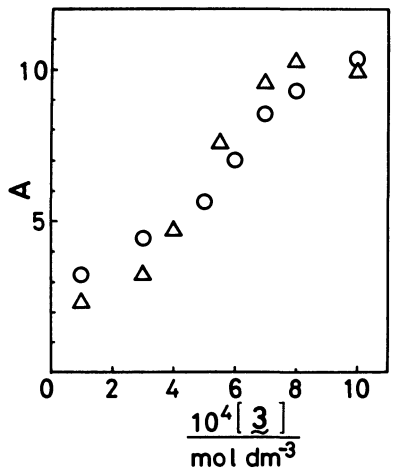


Fig. 2. Wavelength dependence of promotion of photo-methoxylation of methyl 2-pyridinecarboxylate (**1**) by 4-pyridinecarbonitrile (**3**).
Promoting effect is expressed in *A*-value. [**1**]=1.0×10^{-3} mol dm^{-3}. ○, Irradiated with 254 nm light. △, Irradiated with 280 nm light.

Figure 2 shows the wavelength dependence of the promotion of photo-methoxylation of **1** by **3**. The *A*-values in the irradiation at 254 nm light agree with those in the irradiation at 280 nm light in the region of 10^{-4}—10^{-3} mol dm^{-3} of [**3**]. This indicates that Mechanism (ia) should operate in the promotion of photo-methoxylation by **3**.

A question why an exciplex between **1** and **3** has higher reactivity for methoxylation than an excimer of **1** is difficult to answer. However, the higher reactivity of an exciplex could be partially ascribed to the greater polarity of an exciplex than an excimer: The polarity generated in a complex formed between different species should be greater than that in a complex formed from the same species. The greater polarity should result in the increase in the higher reactivity for ionic reaction.

Experimental

Materials. Commercial methyl 2-pyridinecarboxylate (GR grade reagent of Tokyo Kasei Co.) was purified by vacuum distillation (bp, 130—131 °C/27 mmHg, 1 mmHg ≈133.322 Pa). 4-Pyridinecarbonitrile (GR grade of Wako Junyaku Co.) was recrystallized from ether (mp, 82—83 °C). The other reagents used were commercial GR or EP grade reagents.

Preparation of Solution for Irradiation. Solutions (20 cm^3) containing **1** (normally [**1**]=1.0×10^{-3} mol dm^{-3}), sulfuric acid (normally [H_2SO_4]=5×10^{-2} mol dm^{-3}), and additive in methanol were deaerated by bubbling nitrogen through them for at least 45 min.

UV-Irradiation. For the irradiation with 254 nm light, a merry-go-round irradiation apparatus equipped with a 17 W low-pressure mercury lamp was employed. The merry-go-round apparatus was set up in a thermostat and the temperature was maintained at 25.5 °C. For 280 nm light irradiation, a monochrometer (made by Shimadzu-Bausch-Lomb Co.) equipped with a super-high-pressure mercury lamp was used. The resolution in our experimental condition was ±10.5 nm.

Quantitative Analyses. The quantities of **2** formed were determined either by spectrophotometric or by gas-chromatographic method.

i) For the spectrophotometric determination of **2**, its characteristic absorption at 287 nm was used. By means of the spectral method the following systems were analyzed: **1**–benzene, anisole, ferrocene, 1,2,4,5-tetracyanobenzene, nitrobenzene, 2-methylpyridine, 2-pyridinecarboxamide, 3-methylpyridine, 3-pyridinol, 3-pyridinecarboxamide, 3-pyridinecarbonitrile, 4-methylpyridine, 4-*t*-butylpyridine, 4-phenylpyridine, 4-benzylpyridine, 4-pyridinamine, 4-pyridinecarboxamide, 4-acetylpyridine, 2,2′-bipyridine, or pyrimidine.

ii) Gas-chromatographic method was applied for the analyses of the following systems: **1**–naphthalene, acetophenone, 2-pyridinol, 2-pyridinamine, 2-pyridinecarbonitrile, 3-pyridinamine, 4-pyridinol, methyl 4-pyridinecarboxylate, 4-pyridinecarbonitrile, 4,4′-bipyridine, dimethyl 2,4-pyridinedicarboxylate, dimethyl 2,5-pyridinedicarboxylate, or pyrazine.

A typical example applied for the analysis of the **1**—**3** system was done in the following way. After the irradiation, methanol was evaporated under reduced pressure. The solution was neutralized with aqueous $NaHCO_3$ solution and was extracted repeatedly with dichloromethane. The dichloromethane extract was analyzed gas-chromatographically in the following conditions: apparatus, Shimadzu GC-6A; column, 2 m column

of Triton QS-15 (15%) on Uniport B (60/80 mesh); column temperature, 160 °C; internal standard, 3-acetylpyridine.

The present work was partially supported by a Grant-in-Aid from the Asahi Glass Foundation for Industrial Technology.

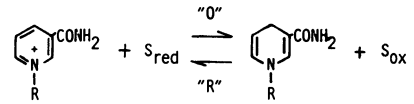
NAD(P)$^+$-NAD(P)H Model. 43. Formation of 1,4-Dihydronicotinamide in the Reaction of Pyridinium Salt and Glyceraldehyde

Atsuyoshi Ohno,* Satoshi Ushida, and Shinzaburo Oka
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received January 26, 1983)

It has been found that *N*-substituted 1,4-dihydronicotinamides are produced by the reaction of *N*-substituted 3-carbamoylpyridinium salts with glyceraldehyde and its analogous compounds. A mechanism of the reaction is suggested.

The reduced and oxidized forms of nicotinamide adenine dinucleotide act as redox reagents in biological reactions. The reactions have been accepted with great interest because of a variety of excellent features promised by enzymes and have prompted organic chemists to design model reactions. As one of typical model compounds for NAD$^+$ and NADH, 1-benzyl-3-carbamoylpyridinium salt (BNA$^+$) and 1-benzyl-1,4-dihydronicotinamide (BNAH) have widely been used.



NAD$^+$: R = RPPA NADH : R = RPPA

BNA$^+$: R = CH_2Ph BNAH : R = CH_2Ph

(RPPA represents the dinucleotide residue of NAD$^+$)

As to the reaction of "R" direction many kinds of model reactions have been achieved and valuable insights have been accumulated.[1] However, its reverse reaction, that is, the reduction of pyridinium salt to 1,4-dihydropyridine[2] as a model reaction of "O" direction has not so widely been investigated despite the redox reactions between NAD$^+$ and NADH are reversible in biological systems. This makes it difficult to establish a cyclic reaction system where an NADH model is catalytically used.[3]

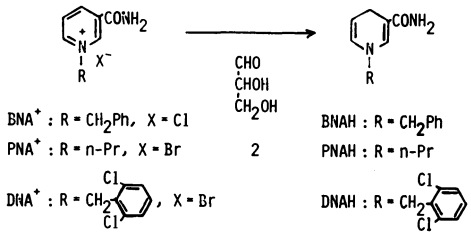
For the preparation of BNAH from BNA$^+$ sodium dithionite is an effective and exclusive reductant from the view points of the yield and selectivity toward 1,4-dihydropyridine derivative over its 1,6-isomer. On the other hand, the reducion with sodium borohydride produces large amounts of 1,6-dihydropyridine and tetrahydropyridine derivatives as well as the desired product. The use of other reductants such as sodium cyanoborohydride[4] and formic acid[5] the 1,4-selectivity does not afford good results, neither.

As a model for alcohol dehydrogenases, reduction of pyridinium salt by alkoxides[6] and alcohol[7] has been reported, although the results are not satisfactory. Deazaflavin[8] and 3-hydroxymethylacridinium iodide[9] that have partial structures similar to NAD$^+$ can be reduced by alcohol easily and various excellent reactions including cyclic reaction systems are reported. However, these systems are hardly be regarded as suitable models for NAD$^+$. From this standpoint it is desired to establish more efficient system for "O" directed reaction using, especially, organic compounds as reductants.

It is well known that glyceraldehyde 3-phosphate dehydrogenase (GAPDH) catalyzes the reduction of NAD$^+$ by glyceraldehyde 3-phosphate (**1**) coupled with oxidative phosphorylation of **1**.[10] The model reaction of this enzyme has not been reported yet. Previously it was reported that glyceraldehyde (**2**) reacts with NAD$^+$ to form a product which has a UV-absorption at 340 nm, similarly to NADH. The product, however, had no ability as the reduced coenzyme.[11] This product was thought to be an adduct of NAD$^+$ and **2** containing a 1,4-dihydropyridine moiety. When we tried the reaction of the same type using BNA$^+$ and **2**, reduced product, BNAH, was obtained in addition to such an adduct.[12] We will describe herein the details of the reaction as well as the reaction mechanism.

Results and Discussion

A borate-buffered solution of BNA$^+$ and **2** was refluxed in the presence of chloroform. The color of the aqueous layer turned yellow. At the same time reduced product with a UV-absorption at 355 nm was extracted to the organic layer. The product was ascertained to be BNAH by comparison of its NMR spectrum with that of the authentic sample. It was also confirmed that the extracted product was almost pure *N*-substituted 1,4-dihydronicotinamide contaminated by less than 3% of its 1,6-isomer. No other product was detected. The results are summarized in Table 1.



The reduction must be carried out under alkaline conditions. Though the rate of the reaction increased at elevated pH's, the yield of BNAH was not improved appreciably. The yield was also independent of the presence or absence of air and light.

Limitation of structure for the reductant was examined. Sugars such as D-ribose and D-glucose, simple aldehydes such as formaldehyde, acetaldehyde, and glyoxal exerted no ability for the reaction of BNA$^+$. Since α-ketols are known to be good reducing agents for flavins,[13] they might be promising candidates for the

Table 1. Reduction of pyridinium salts[a)]

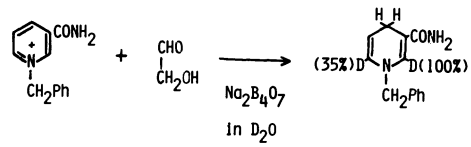
a) In 0.05 M $Na_2B_4O_7$ in the presence of chloroform at its reflux temperature. b) 0.01 M. c) Yields based on pyridinium salt were determined by the intensity of an absorbance at 355 nm (ε=6100 for BNAH). Values in parentheses indicate the yields measured on an NMR spectrometer using *p*-nitrotoluene as an internal standard. d) Reaction under nitrogen in the dark. e) 0.05 M.

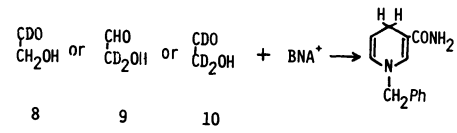
present reduction. As shown in Table 1, glycolaldehyde (**3**), dihydroxyacetone (**4**), 2-hydroxypropanal (**5**), acetol (**6**), and L-ascorbic acid (**7**) were effective. On the other hand, acetoin, methyl lactate, lactamide, and lactic acid were not.

In order to confirm the origin of the hydrogen on the 4-position of produced BNAH, several reactions were undertaken using deuterated materials. First of all the reaction of BNA+ with **3** was carried out in D_2O and isotope contents in BNAH were found to be 100% on the 2-position, 35% on the 6-position, and 0% on the 4-position, respectively. Since the hydrogens on the 2- and 6-positions of BNA+ are replaced by protons from the solvent appreciably under the same conditions as that for the reaction described above except for the absence of **3**, there is no doubt that deuteriums in the BNAH produced were introduced before the reduction and the hydrogens on the 4-position came from somewhere else other than water.



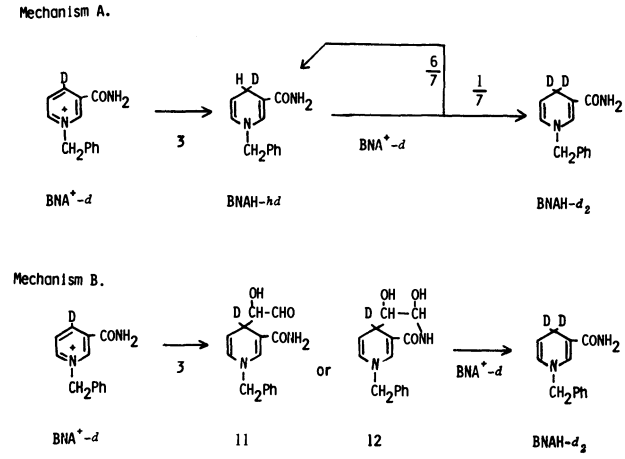
This result excludes the mechanism which, as suggested for the reduction of flavin,[14)] involves an electron-transfer process from the enediol derived from the corresponding α-ketol to the model. The isomerization of initially formed 1,6-isomer to the 1,4-derivative[15)] is also implausible.

Secondly, deuterated glycolaldehydes were employed. Three types of mono- or dideuterated compounds (**8**, **9**, and **10**) were synthesized and subjected to the reaction with BNA+. In any case, however, produced BNAH contained no deuterium so far as in the limitation of NMR spectroscopy.



A suggested mechanism for the reduction of NAD+ catalyzed by GAPDH involves a Cannizzaro-type direct hydride transfer from the carbonyl carbon of **1** to the 4-position of NAD+, which is supported by the experiment using tritium labelled on the carbonyl carbon of **1**.[16)] On the other hand, in the present system neither direct hydrogen transfer nor introduction of a proton from water was observed and the oxidized product from **3** could not be detected in spite of our best efforts.

When BNA+ whose 4-position was deuterated (BNA+-*d*) was employed for the reaction with **3**, both hydrogens on the 4-position of BNAH were deuterated.



Scheme 1.

In order to account for the result that the origin of the deuterium is not other than that on the 4-position of BNA+-*d*, following two possibilities can be considered. One is a mechanism which involves a fast transhydrogenation between BNAH and BNA+ and the other is the one which involves a formation of an adduct containing a 1,4-dihydropyridine moiety and the adduct is the true reductant (Scheme 1). Mechanism A shown in Scheme 1 indicates that by transhydrogenation, which is a well known reaction,[17)] initially produced BNAH-*hd* reduces BNA+-*d* to afford BNAH-*hd* and BNAH-d_2 with the ratio of 6 to 1 because of the isotope effect of 6.[17)] If the reaction was fast enough to occur 10 times before the BNAH is extracted, BNAH-d_2 might be accumulated in 80% of total BNAH. However, the transhydrogenation is not so fast: when the solution of BNAH-*hd* is added to the aqueous solution of BNA+-*h* dropwise at the reflux temperature of chloroform recovered dihydropyridine in chloroform layer was BNAH-*hd*. If the transhydrogenation occured, BNAH-h_2 should be extracted from the reaction mixture.

This result leads us to the conclusion that the transhydrogenation shown by Mechanism A does not occur before the extraction of BNAH. Moreover, it is also to be referred that the extracted BNAH had no ability for the transhydrogenation: the fact was confirmed by

recovering 90% of BNAH-*hd* after the reflux of aqueous solution of BNA^+-*h* in the presence of a chloroform solution of BNAH-*hd* for 18 h under vigorous stirring.

Alternative mechanism that can explain the result is that the true reductant is an adduct of BNA^+ with **3** (Mechanism B). Burton and Kaplan already reported that, with **2**, **3**, **4**, and so on, NAD^+ forms adducts containing 1,4-dihydropyridine structure[11] and that the adduct has an ability to reduce potassium hexacyanoferrate(III),[18] although they did not isolate NADH from this reaction system.

The same type of adducts were afforded by the reaction of BNA^+ and **2**—**6**. During the reaction colored product with an absorption maximum at around 365 nm was formed in aqueous layer. This product which is not extracted to chloroform is expected to be 1,4-dihydropyridine derivative **11** or **12** as proposed by Burton and Kaplan. It was confirmed that this adduct reduced 1-methylacridinium iodide and BNA^+ in aqueous solution. From the reaction mixture BNAH was isolated by extraction with chloroform and remaining BNA^+ was precipitated as the salt of tetraphenylborate. A number of examples concerning such adducts of pyridinium salts with nucleophiles, especially with carbonyl compounds that have an α-hydrogen, are known.[2,19] It is reported that among them the adduct with pyruvate has an ability to reduce pyridinium salt.[20]

Table 2. Dependency of yields of BNAH on the concentrations of reactants[a]

$[BNA^+]$/M	[**2** or **3**]/M	Yield/%[b]
0.01	0.01(**2**)	21[c]
0.01	0.02(**2**)	20[c]
0.01	0.05(**2**)	17[c]
0.02	0.02(**2**)	24[c]
0.05	0.05(**2**)	26[c]
0.01	0.01(**3**)	22[d]
0.02	0.01(**3**)	29[d]
0.05	0.01(**3**)	37[d]
0.10	0.01(**3**)	45[d]

a) The reaction was carried out in 0.05 M $Na_2B_4O_7$ in the presence of chloroform at its reflux temperature. b) Determined by the intensity of an absorbance at 355 nm. c) Based on BNA^+. d) Based on **3**.

According to the Mechanism B, the yield of the BNAH might increase to 50% when equimolar BNA^+ and **2** are used. However, the yield was not so high as expected as listed in Table 1 because decomposition of the adduct in aqueous media competes with its oxidation. Table 2 shows that the yield of BNAH based on **3** increases as the increase in the concentration of BNA^+. On the other hand, the increase in the concentration of **2** exerts no effect toward the yield. The reaction in relatively concentrated solution affords BNAH in slightly high yield. These results are consistent with the idea that the transhydrogenation from the adduct to BNA^+ is slow enough to compete with its degradation.

In conclusion, by the reaction of BNA^+ with glyceraldehyde or its analogues, BNAH is produced with a high 1,4-selectivity. The mechanism is, however, different from that suggested for the reaction catalyzed by GAPDH.

Experimental

Instruments. UV and NMR spectra were obtained on a Union Giken SM-401 and a JEOL JNMFX-100, respectively.

Materials. BNA^+, PNA^+, and DNA^+ were prepared by quarterization of nicotinamide with benzyl chloride, propyl bromide, and 2,6-dichlorobenzyl bromide, respectively.

BNA^+-*d* was prepared from BNA^+ by twice repetition of reduction with sodium dithionite in D_2O and oxidation by Malachite Green.[21] Deuterium content in BNA^+ was 91± 1%.

2-Hydroxypropanal was synthesized by the condensation of dithiane and acetaldehyde followed by the dethioacetalization with mercury(II) chloride and mercury(II) oxide.[22]

Deuterated glycolaldehydes were prepared by the condensation of 1,3-dithiane and formaldehyde by an appropriate combination of deuterated materials (perdeuterioparaformaldehyde from Merck Inc. and 1,3-dithiane-2,2-d_2 synthesized by three times proton exchange using butyl lithium and D_2O), followed by dethioacetalization with mecury(II) chloride and mercury(II) oxide.

Reaction of BNA^+ and **2**. *A Typical Procedure*: BNA^+ (50 mg) and **2** (16 mg) were dissolved in 20 cm^3 of 0.05 M aqueous solution (1 M = 1 mol dm^{-3}) of sodium tetraborate. The solution was heated in the presence of 20 cm^3 of chloroform at its reflux temperature. After confirming that the intensity of the absorption of extracted BNAH in the organic layer did not increase any more, the chloroform layer was separated, dried over anhydrous sodium sulfate and evaporated to afford the reduced product. The product was identified as BNAH on an NMR spectrometer and the yield of BNAH was measured on a UV-spectrometer by means of absorbance of the chloroform solution at 355 nm(ε=6100)and/or on an NMR spectrometer using *p*-nitrotoluene as an internal standard.

^1H NMR ($CDCl_3$, δ from TMS): 3.16 (m, 2H), 4.25 (s, 2H), 4.75 (dt, 1H), 5.75 (m, 1H), 5.59 (bs, 2H), 7.16 (s, 1H), and 7.28 (s, 5H). The amount of 1,6-isomer measured on the NMR signal from benzyl proton at δ=4.19 was less than 3%.

Reaction of BNA^+-d and **3**. The reaction was carried out in a similar manner as described above. The NMR spectrum of the reduced product was identical with that of BNAH-d_2. No signal for the hydrogen on the 4-position (δ=3.16) was observed and the splitting of the signal for the hydrogen on the 5-position due to the hydrogens on the 4-position disappeared.

Reactivity of the Adduct. The reaction of BNA^+ (50 mg) and **3** (12 mg) was carried out and stopped after an appropriate reaction time. From the aqueous layer BNAH was removed by extraction and remaining BNA^+ was removed as a precipitate of tetraphenylborate. The solution exerted a UV-absorption at around 365 nm which disappeared quantitatively by the addition of 1-methylacridinium iodide. To the aqueous layer, BNA^+ (50 mg) was added again and further reduction was undergone as described above in the typical procedure. BNAH was extracted to the chloroform layer about half amount as compared with the case without interruption.

Methylation of Deoxynucleotides with Trimethyl Phosphate in Aqueous Phase

Toshizumi TANABE, Kiyoshi YAMAUCHI,* and Masayoshi KINOSHITA
Department of Applied Chemistry, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received February 3, 1983)

Action of trimethyl phosphate on thymidine 5′-phosphate, deoxycytidine 5′-phosphate, deoxyadenosine 5′-phosphate, and deoxyguanosine 5′-phosphate at 37—60 °C, and pH 7—10 gave their methyl esters and base-methylated derivatives. Esterification took place in all deoxyribonucleotides to the almost same extent and its rate was enhanced by the reaction temperature, while being independent of pH in the range 7—10. On the other hand, methylation of the base moieties was affected by both the reaction temperature and pH of the reaction medium. The reactivity order of the four kinds of base moieties w s; at pH 7, cytosine base (N-3)>guanine base (N-7)>adenine base (N-1)≫thymine base (N-3); at pH 10, thymine base (N-3)>guanine base (N-1>N-7)>cytosine base (N-3)>adenine base (N-1).

A wide variety of methylated nucleosides have been found in nucleic acids, especially in the 5′-terminal of mRNA[1] and the loop regions of tTNA.[2] The biological roles of the modified nucleic acid-regions have been discussed with respect to the special structures. On the other hand, factitious alkylation of nucleic acids, especially DNA, by means of alkylating agents has been considered an origin of mutagenic effects since the alkylation may furnish the modified nucleotide units which will no longer be capable of performing the normal biological functions.[3] In this context, alkylations of nucleic acids have been studied using various reagents in order to relate the sites and extents of alkylation with mutagenesis.[4-7] The reactions, however, were conducted in a heterogeneous mixture of water and organic solvents mainly because of water-insoluble and -labile properties of the alkylating agents used. We, therefore, employed recently trimethyl phosphate (TMP) as a water-soluble methylating agent, and estimated the reactivity of nucleic acid-bases and nucleosides.[8-11] This paper deals with the study of an action of TMP toward four principal 5′-deoxyribonucleotides (**1**, **5**, **11**, and **16**). Although these monoalkyl phosphates are not the best models for nucleic acids, it was hoped that the study would furnish information about base-methylation and esterification which would be relevant to the methylation of nucleic acids. The reactivity of four deoxyribonucleotides will be also compared.

Results

The reactions were carried out at 37 and 60 °C by stirring a mixture of deoxynucleotide and TMP in water at an appropriate pH. The yields of the products were determined by a thin-layer chromatography (TLC)-UV method. The products were identified conveniently from the mobilities (R_f) in TLC, and spectral characteristics (UV and NMR), or the comparison of the physical constants with those of authentic samples or literature values. Generally, UV spectra were very useful to determine the sites of methylation in the base-rings. The results are summarized in Tables 1—4.

*Thymidine 5′-Phosphate (**1**).* A treatment of **1** with TMP resulted in the formation of three products

		13			10	Tr	Tr
		14			31	76	85

a) Reaction size: pdA (0.05 mmol)–TMP (1.5 mmol)–H_2O (0.5 ml). b) These values were measured on cellulose TLC using 1-propanol–concentrated aqueous ammonia–water (7 : 1 : 2). R_f value of pdA was 0.19. c) UV spectra at pH 1 and pH 13 were identical with literature value. d) Tr refers to a trace yield.

(**2**, **3**, and **4**) (Table 1). By comparison of the mobilities in TLC and the UV spectra of the aqueous extracts of the spots with those of authentic samples, they were identified as thymidine 5′-(methyl hydrogenphosphate), 3-methylthymidine 5′-phosphate, and 3-methylthymidine 5′-methyl hydrogenphosphate, respectively. It appeared that TMP did not esterify the dialkyl phosphate (**2** and **4**) to afford the respective 5′-dimethyl phosphates. The N-3 methylation on the thymine ring was accelerated significantly with the increase of the pH value, while the esterification rate was almost independent of the pH (7—10). The increase in the reaction temperature was found to promote both the N-3 methylation and the esterification; *viz.* **1** was converted quantitatively into **4** after 24 h at 60 °C and pH 10.

Deoxycytidine 5′-Phosphate (5). A reaction of **5** with TMP in an aqueous solution afforded five UV-absorbing products (**6**, **7**, **8**, **9**, and **10**), of which **9** and **10** were observed only in the reaction at 60 °C (Table 2). Compound **6** was isolated and identified as deoxycytidine

a) Reaction size: pdG (0.05 mmol)–TMP (1.5 mmol)–H_2O (0.5 ml). b) These values were measured on cellulose TLC using 1-propanol–concentrated aqueous ammonia–water (7 : 1 : 2). R_f value of pdG was 0.06. c) UV spectra of products **17**—**23** at pH 1 and 13 pH were identical with literature value. d) Tr refers to a trace yield. e) The yields of unknown products were determined by postulating their extinction coefficient at λ_{max} as 10000. s) Shoulder.

5′-methyl hydrogenphosphate through its physical properties. Products **7** and **8** were identified tentatively as 3-methyldeoxycytidine 5′-phosphate and its methyl ester, respectively, from their R_f values and UV spectra which were almost similar to those of 3-methyldeoxycytidine. Compounds **9** and **10** were identified as 3-methyldeoxyuridine 5′-phosphate and its methyl ester, respectively, by comparison of their R_f values and UV spectra with those of authentic samples which were prepared from the reaction of deoxyuridine 5′-phosphate with trimethylsulfonium hydroxide.[9)] The compound **9** may be originated from the hydrolysis of the 3-methylcytosine ring of **7**. Similarly, 3-methyldeoxycytidine 5′-(methyl hydrogenphosphate) may be the precursor of **10**, though it may be also produced by the secondary reaction of **9** with TMP.

The esterification of **5** was hardly affected by pH of the solution whereas the N-3 methylation of the cytosine ring was found to decrease slightly with the increase of pH. The increase in the reaction temperature promoted the esterification, the N-3 methylation, and the hydrolysis of **7**, and **8**.

*Deoxyadenosine 5′-Phosphate (**11**).* A treatment of **11** with TMP gave rise to four products (**12**—**15**) as observed in the TLC of the reaction mixture (Table 3). Compounds **12**, **13**, and **14** were identified as deoxyadenosine 5′-(methyl hydrogenphosphate), N^6-methyldeoxyadenosine 5′-phosphate, and N^6-methyldeoxyadenosine 5′-(methyl hydrogenphosphate), respectively, by comparison of R_f values and UV spectra with those of authentic samples. Furthermore, hydrolysis of **12**, and **14** with 1 M hydrochloric acid (1 M=1 mol dm^{-3}) gave adenine and N^6-methyladenine, respectively. Meanwhile, **15** was assigned tentatively 1-methyldeoxyadenosine 5′-(methyl hydrogenphosphate) from the UV spectra (pH 1, 7, and 12) which were very similar to those of 1-methyldeoxyadenosine. As expected, the R_f value was smaller than that of the nucleoside. It would be most likely that the N^6-methylated products (**13**, and **14**) were formed from the Dimroth rearrangement[12)] of the 1-methyl isomers rather than direct methylation at the exocyclic amino groups of the adenine ring, since the external amino group was not as strong in nucleophilicity as the N-1 atom. The esterification, and the N-1 methylation were found to be enhanced by the increase in the reaction temperature, while being almost independent on the pH of the solution.

*Deoxyguanosine 5′-Phosphate (**16**).* Action of TMP on **16** at pH 7 and 37 °C afforded deoxyguanosine 5′-

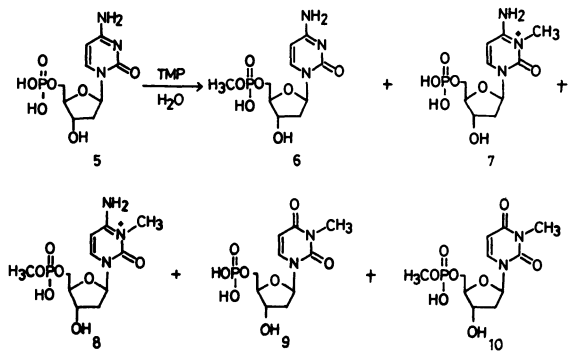

Fig. 2.

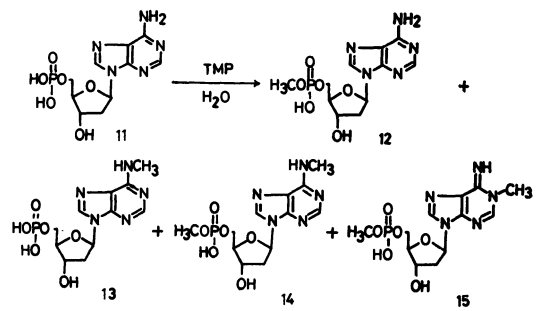

Fig. 3.

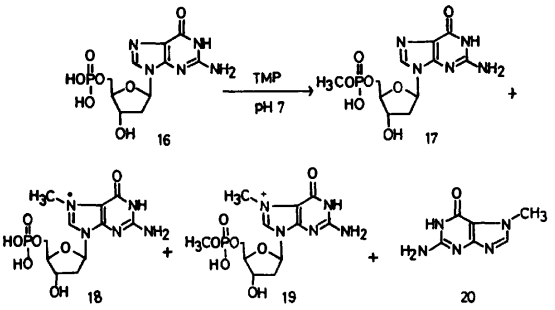

Fig. 4.

(methyl hydrogen phosphate) (**17**), 7-methyldeoxyguanosine 5′-phosphate (**18**), 7-methyldeoxyguanosine 5′-(methyl hydrogenphosphate) (**19**), and 7-methylguanine (**20**).

On the other hand, in the reaction at pH 10 and 37 °C, N-1 methylation took place in preference to both N-7 methylation and esterification, giving chiefly 1-methyldeoxyguanosine 5′-phosphate (**21**). The imidazole ring-opened compounds (**22** and **23**) might be produced by the attack of hydroxide ions at the C-8 position of the 7-methylguanine rings of the corresponding precursors (for instance, **18** for **22**). The reaction mixture also contained two unidentified compounds.

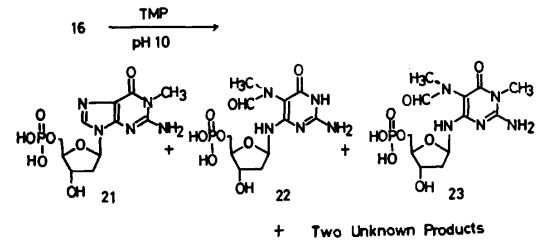

Fig. 5.

All the products other than **22**, and **23** were identified through the comparison of the UV spectra and R_f values with those of authentic samples. Methylation at the N-7 position of the guanine ring was easily acknowledged by the strong fluorescence under the UV light which was characteristic to 7-alkylated guanine ring. The identification of the compounds (**22** and **23**) was tentative, but they had the UV spectra similar to those of the corresponding nucleosides.[11]

Discussion

In a homogeneous aqueous phase TMP was found to methylate the four principal deoxynucleotides at the base moieties (base-methylation) and the phosphate moieties (esterification). As expected, the base methylation proceeded in a manner similar to that of the corresponding nucleosides. Thus, the N-3 of the cytosine ring of **5**, the N-1 of the adenine ring of **11** and the N-7 of the guanine ring of **16** were nucleophilic to be attacked easily by TMP, giving the corresponding products. The pH of the solutions had no effect on methylation at these sites except the N-3 of the cytosine ring which became less susceptive in methylation to the increasing pH. By contrast, the –CO–NH–CO– group of the thymine ring (N^3H) and the –CO–NH– group of the guanine ring (N^1H), which have low pK_a values (9—10), became increasingly active toward methylation with the increasing pH. The reactivity of the base moieties thus can be summarized as follows: pH 7, cytosine (N-3)> guanine (N-7)> adenine (N-1); pH 10, thymine (N-3)> guanine (N-1)> guanine (N-7)> cytosine (N-3).

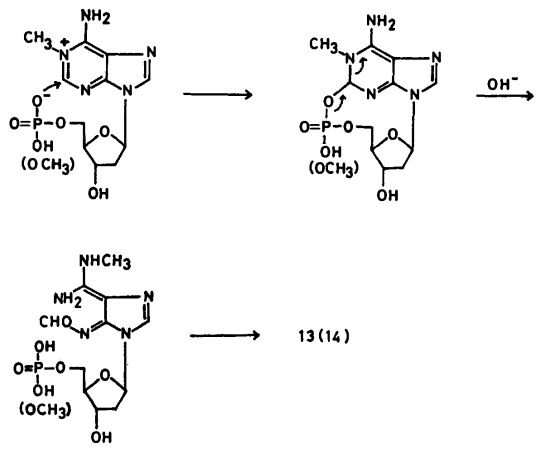
On the other hand, the esterification was hardly affected by the pH but by temperature. Further, variation of the base moieties had no influence on the degree of esterification. Since the nucleotides are monoalkyl phosphates with pK_a of approximately 1 and 6.[13] TMP should attack the dianionic forms of the nucleotides, furnishing the monomethyl ester such as **2**, **6**, **12**, and **17**. Interestingly, the reagent did not methylate further the monomethyl esters to give the dimethyl esters; the results suggest that nucleic acids which are poly(dialkyl phosphates) may not be methylated by TMP at the internucleotide bonds.

Meanwhile, the 5′-phosphate moieties were found to affect the hydrolysis of the 3-methylcytosine ring to the 3-methyluracil ring, and the rearrangement of 1-methyladenine ring to the N^6-methyladenine ring. For instance,

(a) Under the conditions of pH 10, 37 °C, and 24 h, and TMP/substrate=30 mol/mol, 3-methyldeoxycytidine was hydrolyzed more readily than the nucleotides (**7** and **8**); *e.g.* the extent of total N^3-methylation[14] *vs.* that of the hydrolysis was 18% : 2% in the nucleoside,[8] and 17% : 0% in the 5′-nucleotide (Table 2).

(b) Under the conditions of pH 7, 60 °C, and 24 h, deoxyadenosine 5′-phosphate gave predominantly the N^6-methyl derivatives (**13**, and **14**) in the combined yields of *ca.* 19% (Table 3). By contrast, a treatment of deoxyadenosine with TMP under similar neutral conditions produced 1-methyl-, and N^6-methyldeoxyadenosines in the yields of 38%, and trace, respectively.[9]

Plausibly, the phosphate anionic moieties in **7** and **8** were somewhat effective to shield the C-4 positions of the 3-methylcytosine rings from the attack of OH^- ions, thus decreasing the extent of the hydrolysis. On the other hand, the Dimroth rearrangement, which has been considered to occur by the attack of OH^- ions on the C-2 position of the 1-methyladenine ring, might be



Scheme 1.

assisted by the 5'-phosphate moiety as depicted in the Scheme 1. Indeed, adenosine 2'(3')-phosphate reacted with TMP to give chiefly the 1-methyl derivatives under the conditions (pH 7 and 60 °C) which were the same as those used in the present study.

Dimethyl sulfate, methyl iodide and other S_N2 type reagents have also been reported[4,6,15] to alkylate the deoxynucleotides at the sites similar to those attacked by TMP though the extents of base-alkylation and esterification varied with the reagents used. Highly potent carcinogens, diazomethane and related compounds, have been known to alkylate not only the base nitrogen atoms but also the external oxygen atoms such as thymine ring (O-2 and O-4) and guanine ring (O-6) in addition to the phosphate moieties.[1] The moderate mutagenicity of TMP,[16] thus, may be ascirbed to the predominant methylation at nitrogen atoms, which, except methylation at the N-3 of the cytosine ring, may not disturb significantly the Watson-Crick base pairings.

Experimental

UV spectra were measured with a Hitachi 3T spectrometer. NMR spectra were recorded on a Hitachi Perkin-Elmer R-20 spectrometer, with a dilute solution in deuterioxide and the soldium salt of 3-(trimethylsilyl)propionic-2,2,3,3-d^4 acid as an internal standard. Thin-layer chromatography was performed on cellulose (13254, Eastman) or silica-gel (GF_{254} (type 60), Merck). Column chromatography was carried out using silicagel (Merck, Art. 7734, 70—230 mesh) or aluminium oxide Merck, Art. 1097 .

Commercially available disodium salts of thymidine 5'-phosphate (**1**), deoxyguanosine 5'-phosphate (**16**) and deoxyuridine 5'-phosphate, and the free form of deoxyadenosine 5'-phosphate (**11**) were used without further purification. Deoxycytidine 5'-phosphate (**5**) was prepared according to the procedure of Yoshikawa *et al.*[17] Trimethyl phosphate (TMP) was distilled prior to use.

Reactions of the nucleotides and ethereal diazomethane produced the following known methylated nucleotides,[4,6] which were used to identify the products obtained in the present study: **2**—**4**, **6**, **7**, **9**, **10**, **12**, **15**, **17**—**20**. Some authentic nucleotides were synthesized as follows. They were homogeneous in silica gel- and cellulose-TLC's with the same R_f values as those of known compounds, if any, and had UV spectra and NMR spectra which agreed with the assigned structures.

*Thymidine 5'-(Methyl Hydrogenphosphate) (**2**).* The condensation reaction of thymidine 5'-phosphate (**1**, 93 mg, 0.27 mmol) and methanol (0.25 ml) by dicyclohexylcarbodiimde (300 mg, 1.5 mmol) in pyridine (3.0 ml) at 30 °C for 24 h afforded **2**, which was purified through column chromatography and reprecipitation with diethyl ether (60 mg, 66%); NMR (D_2O) δ=1.94 (3H, d, 5-CH_3, J=1.2 Hz), 3.63 (3H, d, p-OCH_3, J=11 Hz), and 7.77 (1H, d, H^6, J=1.2 Hz); UV, λ_{max} (H_2O) 267.0 nm.

*3-Methylthymidine-5'-(Methyl Hydrogenphosphate) (**4**).* A mixture of **3** (60 mg, 0.2 mmol) and methanolic solution of 0.5 M trimethylsulfonium hydroxide (0.4 ml)[10] was concentrated to give a colorless residue, which was dissolved in DMF (3 ml) and heated at *ca.* 80 °C for 30 min with stirring magnetically. The solvent was evaporated from the reaction mixture, and the resulting residue was applied to a silica-gel column using 1-propanol–concentrated aqueous ammonia–water (7 : 1 : 2 v/v) as a solvent. The title compound was obtained as powder upon mixing the concentrated fraction with diethyl ether, 43 mg (71%), NMR (D_2O) δ=1.96 (3H, d, 5-CH_3, J=1.2 Hz), 3.32 (3H, s, N^3—CH_3), 3.63 (3H, d, p-OCH_3, J=11 Hz), and 7.80 (1H, d, H^6, J=1.2 Hz), UV λ_{max} (H_2O) 266.0 nm.

General Methylation Procedure of Deoxyribonucleotide and TMP. A deoxynucleotide (0.05 mmol) was dissolved in water (0.5 ml) of appropriate pH (7—10), and the solution was treated with TMP (1.5 mmol) at 37 or 60 °C. The pH of the reaction mixture was maintained within $\pm$0.5 unit by the occasional addition of 0.5 M sodium hydroxide throughout the reaction. At an appropriate reaction time, 6 μl of reaction mixture was spotted on a cellulose TLC and developed immediately. The product on each spot was scraped from the plate and extracted with 3 ml of water. The yield of each product was calculated by means of a procedure similar to that mentioned in a previous paper,[10] the result of which is summarized in Tables 1—4. The structure of each product was determined mainly by the comparison of its R_f value and UV spectrum with those of the authentic sample.

Methyl ester of deoxycytidine 5'-phosphate (**6**) was isolated from the reaction mixture as follows. After 50-h stirring of a mixture of disodium salt of deoxycytidine 5'-phosphate (**5**, 350 mg, 1.0 mmol) and TMP (4.25 g, 30.0 mmol) in water (10 ml) at 60 °C, pH 7, TMP was removed by extraction with chloroform. The aqueous layer was concentrated to give a residue, which was subjected to alumina column chromatography (1.5×50 cm). Elution with 1-propanol–concentrated aqueous ammonia–water (7 : 1 : 2) afforded **6** (34 mg, 10%); NMR (D_2O) δ=3.67 (3H, d, p-OCH_3, J=11 Hz), 6.22 (1H, d, H^5, J=8 Hz), and 8.07 (1H, d, H^6, J=8 Hz),

Products from the reaction mixture of deoxyadenosine 5'-phosphate (**11**) with TMP were further analyzed through the isolation and subsequent acid hydrolysis as follows. Each product in the reaction mixture was separated by silica-gel column (1.5×15 cm) which was eluted with 1-propanol–water (3 : 1). Subsequently, each product was hydrolyzed by 1 M hydrochloric acid at 90 °C for 3 h. Adenine was obtained near quantitatively from **12**, and N^6-methyladenine from **13** and **14**, and 1-methyladenine from **15**. The products were identified by UV spectra and comparison of R_f values with those of the authentic sample using several solvent systems.

Manufacture of Pure Titanium(IV) Oxide by the Chloride Process. II. Selective Extraction of Titanium(IV) and Iron(III) from Hydrochloric Acid Leach Liquor of Ilmenite Ore by Tributyl Phosphate

Eiichi NARITA,* Hitoshi TAKEUCHI, Hitoshi ICHIKAWA,
Takao ODAGAWA, and Taijiro OKABE
Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980

(Received July 29, 1982)

The selective recoveries of titanium(IV) and iron(III) from the synthetic hydrochloric acid leach liquor of ilmenite, *i.e.*, 1.8—11 M (1 M = 1 mol dm^{-3}) hydrochloric acid solutions containing 0.25—0.57 M titanium(IV) and 0.27—0.29 M iron(III), or each single metal ion, were investigated by solvent extraction with benzene solutions of various tributyl phosphate (TBP) concentrations under the volume ratio (Org/Aq) of unity at 25 °C. Iron(III) was extracted into the TBP phase over a wide concentration range of hydrochloric acid studied, and the extraction was considerably accelerated by the salting-out effect of the coexisting titanium(IV). Since no extraction of titanium(IV) was observed at hydrochloric acid concentrations lower than 6 M, iron(III) could be recovered selectively from 3—6 M hydrochloric acid solutions under the conditions of the molar ratio $[TBP]_{org}/[Fe(III)]_{init\ aq} \leqq 3.0$. On the other hand, titanium(IV) in the residual aqueous phase was also extracted as $TiCl_4 \cdot 3TBP$ at a concentration range of chloride ion higher than 7 M. The coextractions of other metal ions and free hydrochloric acid could be prevented by controlling the TBP concentration in the organic phase as $[TBP]_{org}/[Ti(IV)]_{init\ aq} \leqq 3.5$. The problem in applying the solvent extraction technique to actual leach liquor is discussed, as well as the recovery of free hydrochloric acid from the residual leach liquor.

Although titanium(IV) oxide has been produced industrially by the sulfate process and by the vapor phase oxidation of titanium(IV) tetrachloride, both processes have serious disadvantages, such as the treatments of byproducts in the former and the lack of raw rutile minerals in the latter.[1,2] The authors have endeavored to develop a new manufacturing process for titanium(IV) oxide, which would be based on the leaching of ilmenite ore in concentrated hydrochloric acid solution and the selective recovery of titanium(IV) from the resulting leach liquor by solvent extraction with neutral organophosphorus compounds. In this process ilmenite ore, which occurs abundantly in nature, can be used. One other important feature is that the hydrochloric acid used as the leachant allows easier recovery of reusable acid from the waste solution than does sulfuric acid. Therefore, the manufacturing process that we have proposed may solve the serious disadvantages of most methods for the production of titanium(IV) oxide. It is well known that the dissolution of titanium and iron in ilmenite ore can be achieved satisfactorily by using concentrated hydrochloric acid solution over a temperature range of 70—90 °C.[3-5]

A solvent extraction technique has been applied extensively to a hydrometallurgical process not only of highly valuable metals but of nonferrous metals such as Cu, Ni, and Co[6-8] and is becoming more and more common, even for the extraction of iron from the waste solution of steel cleansing,[9] the acid leach liquor of clay,[10] and the waste solution of the sulfate process of titanium(IV) oxide production[11,12] because of the higher selectivity of the solvent extraction operation. For the production of titanium(IV) oxide by leaching ilmenite ore in hydrochloric acid, the preferential removal of iron from the resulting leach liquor has been attempted using trialkyl phosphates,[13] trialkylamines,[13] and organic ketones,[14] However, no attempt has been made to extract titanium(IV) from the leach liquor by solvent extraction with neutral organophosphorus compounds, although several reports concerning solvent extraction of iron(III)[15,16] and titanium(IV)[17-21] with tributyl phosphate (TBP) have been published.

This paper deals with the selective recoveries of titanium(IV) and iron(III) from the synthetic hydrochloric acid leach liquor of ilmenite ore by solvent extraction with TBP in benzene under practical conditions in which the concentrations of metal ions and acid in the leach liquor are sufficiently high.

Experimental

Reagents. All the reagents were of analytical reagent grade. Synthetic hydrochloric acid leach liquor was prepared by dissolving titanium(IV) chloride and/or iron(III) chloride in hydrochloric acid solution. In one part of the experiment, other metal ions incorporated generally to ilmenite ore were also dissolved in the synthetic leach liquor. Since no differences between the extraction results using the commercial and purified TBP were observed, TBP was used without further purification.

Procedure. A 20 cm^3 portion of the hydrochloric acid leach liquor containing known amounts of metal ions was transferred to a 100 cm^3 pear shaped separatory funnel, together with 20 cm^3 portions of benzene solution of various TBP concentration. The extraction was carried out by shaking it vigorously for 10 min at 25 °C, and then leaving it until the phases separated clearly. The metal ions in the aqueous phase were analyzed by colorimetry and atomic absorption spectroscopy. The percentage extractions and distribution coefficients of the metals were calculated from the metal concentrations in the aqueous phase before and after the extraction. In one part of the experiment, the extraction behaviors of acid and chloride ion were also investigated by neutralization and the Volhard method, respectively.

Results and Discussion

Recovery of Iron. The extraction behavior of iron(III) and iron(II) in the presence of titanium(IV) as a function of the initial concentration of hydrochloric

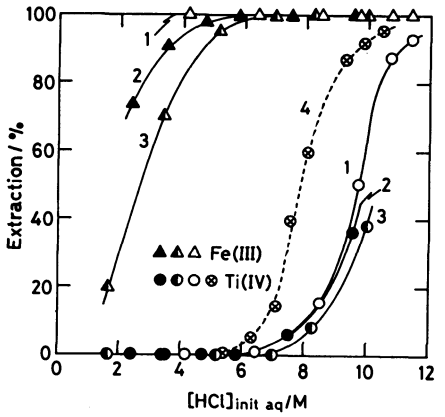

Fig. 1. Extraction of Fe(III) and Ti(IV) *vs.* concentration of HCl in aqueous phase.
1: 0.29 M Fe(III)+0.55 M Ti(IV), 1.8 M TBP, 2: 0.29 M Fe(III) +0.55 M Ti(IV), 0.92 M TBP, 3: 0.29 M Fe(III)+0.29 M Ti(IV), 0.92 M TBP, 4: 0.55 M Ti(IV), 1.8 M TBP.

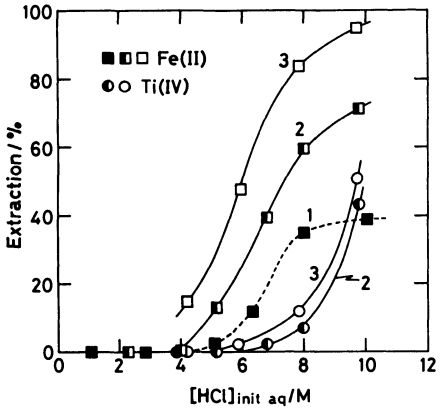

Fig. 2. Extraction of Fe(II) and Ti(IV) *vs.* concentration of HCl in aqueous phase.
1: 0.28 M Fe(II), 2: 0.28 M Fe(II)+0.26 M Ti(IV), 3: 0.28 M Fe(II)+0.57 M Ti(IV), 1, 2, 3: 0.92 M TBP.

acid is shown in Figs. 1 and 2, respectively. The percentage extraction of iron(III) was increased with increasing concentration of hydrochloric acid in the aqueous phase and TBP in the organic phase. Another important feature is that the coexisting titanium(IV) accelerated the extraction of iron(III) by the salting-out effect. Although similar behavior was observed in the extraction of iron(II), the percentage extraction was much lower than that of iron(III). Since the selective recovery of iron(II) was difficult, as can be seen in Fig. 2, iron(II) should be oxidized to iron(III) before applying solvent extraction. Titanium(IV) and minor constituents of ilmenite ore such as manganese(II), aluminum(III), magnesium(II), and chromium(III) were not extracted along with iron(III) from the leach liquor at hydrochloric acid concentrations lower than 6 M. Therefore, it was concluded that the selective recovery of iron from 3—6 M hydrochloric acid leach liquor was possible by solvent extraction with TBP after the oxidation of all iron(II) to iron(III).

The concentration of TBP in organic phase is an important factor in extracting iron(III) without contamination by titanium(IV). Figure 3 shows the plots of log D, distribution coefficient, *versus* log $[TBP]_{org}/[Fe(III)+Ti(IV)]_{init\ aq}$. As expected from Fig. 1, the selectivity, $\beta=D_{(Fe)III}/D_{Ti(IV)}$, was low at high concentrations of hydrochloric acid in aqueous phase because of the coextraction of titanium(IV). At hydrochloric acid concentrations lower than 6 M, β became as high as 1×10^3—1×10^4. The purity of the extracting iron(III) could be increased by controlling TBP concentration in the organic phase as $[TBP]_{org}/[Fe(III)]_{init\ aq} \leqq 3.0$, which was obtained from the result in Fig. 3. Islam *et al.*[22] have reported that the reverse selectivity, $\beta'=D_{Ti(IV)}/D_{Fe(III)}$, by solvent extraction with bis(2-ethylhexyl) hydrogenphosphate (B2EHP) was about 60. For the mutual separation of titanium(IV) and iron(III), TBP was superior to B2EHP.

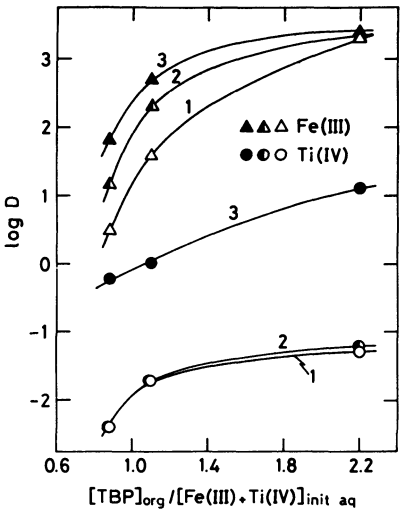

Fig. 3. Dependence of distribution ratios of Fe(III) and Ti(IV) on TBP concentration in organic phase.
1, 2, 3: 0.29 M Fe(III)+0.54 M Ti(IV), HCl(M)—1: 4.2, 2: 6.0, 3: 11.4.

Hydrochloric acid is extracted by an excess of TBP in organic phase.[23,24] The effect of the TBP concentration in the organic phase on the extraction of hydrochloric acid and iron(III) is shown in Fig. 4, which

TABLE 1. THE EFFECT OF SALTS ADDED ON THE EXTRACTION OF Ti(IV) WITH 0.92 M TBP IN BENZENE

Concentration in initial solution		Extraction of Ti(IV)/%									
		[H+]/M					[Cl-]/M				
Ti(IV) M	Salt M	6	8	9	10	11	7	9	10	11	12
0.25	—	1	20	65	87	96	1	20	65	87	96
0.25	KCl 0.25	1	25	70	90	93	1	20	64	86	97
0.25	NaCl 0.25	2	27	73	90	92	1	21	66	87	96
0.25	$MgCl_2$ 0.34	4	47	92	93	98	1	18	68	87	97
0.25	$MnCl_2$ 0.27	1	23	74	88	94	1	17	62	83	94
0.25	$AlCl_3$ 0.33	6	63	83	94	99	2	17	63	83	96

gives the percentage extraction of iron(III) and the molar ratio of $[H^+]/[Fe(III)]$ in the organic phase in tests conducted for the leach liquor containing only iron(III). At 4.9—6.1 M acid concentration, the ratio of $[H^+]_{org}/[Fe(III)]_{org}$ decreased with increasing TBP concentration, whereas the percentage extraction of iron(III) increased. This result indicates that the competitive extractions of $FeCl_3$ and HCl would occur at moderate acid concentrations as follows:

$$n[HCl]_{aq} + [TBP]_{org} = [nHCl \cdot TBP]_{org} \quad n=1,2 \qquad (1)$$

$$[FeCl_3]_{aq} + 2[TBP]_{org} = [FeCl_3 \cdot 2TBP]_{org}. \qquad (2)$$

At 10.1 M acid concentration, the ratio of $[H^+]_{org}/[Fe(III)]_{org}$ were approximately constant as 0.75—1.0; which means that iron(III) is extracted mainly as $HFeCl_4$:

$$[H^+]_{aq} + [FeCl_4^-]_{aq} + 2[TBP]_{org} = [HFeCl_4 \cdot 2TBP]_{org}. \qquad (3)$$

Since the slopes of log $D_{Fe(III)}$/log TBP obtained from the results in Fig. 4 were 1.90—1.95, two extractive species of iron(III) such as $FeCl_3 \cdot 2TBP$ and $HFeCl_4 \cdot 2TBP$ have been postulated. On the other hand, the ratio of $[H^+]_{org}/[Fe(III)]_{org}$ became greater than unity under the conditions that the acid concentration was 10.1 M and the ratio of $[TBP]_{org}/[Fe(III)]_{init\ aq}$ was greater than 3.5. The dependence of the acid extraction behavior on the TBP concentration was approximately identical with that obtained without iron(III). Therefore, it is reasonable to assume that the extraction of free hydrochloric acid occurs at high TBP concentration as Eq. 1.

Recovery of Titanium. As shown in Fig. 1, the recovery of titanium(IV) can be performed by increasing the hydrochloric acid concentration in the residual aqueous phase and by extracting with fresh TBP in benzene. The shift of the extraction curve of titanium(IV) toward the low acid side by the removal of iron(III) makes it possible to extract titanium(IV) from the leach liquor at hydrochloric acid concentrations higher than 8 M.

The effect of various chlorides in the leach liquor on the extraction behavior of titanium(IV) is given in Table 1. The extraction of titanium(IV) was apparently accelerated in the presence of these chlorides judged from the same acid concentration, but not accelerated judged from the same chloride ion concentration. This was deduced by following the extraction curves based on the data in the left column in Table 1. This result indicates that these cations did not contribute to the salting-out effect. Under the conditions in which these experiments were conducted, all metal ions listed in Table 1 were not extracted. This result also indicates that the extraction of titanium(IV) will be accelerated by the addition of chlorides of magnesium(II) and aluminum(III) into the leach liquor of acid concentration range of 8—9 M.

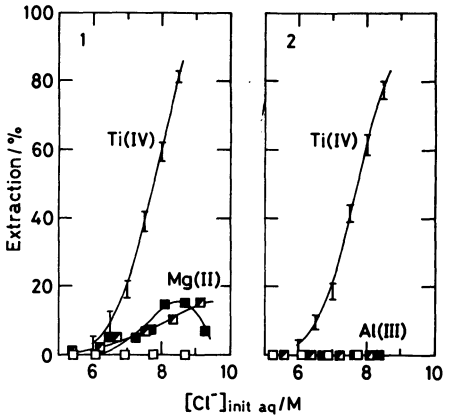

Fig. 5. Extraction of Ti(IV) and other metal ions *vs.* concentration of chloride in aqueous phase.
1: 0.56 M Ti(IV), 1.8 M TBP, 2: 0.27 M Ti(IV), 0.92 M TBP, HCl(M) —□: 4.0, ◩: 5.0, ■: 6.0.

Figure 5 shows the extraction behavior of titanium(IV) from 4—6 M hydrochloric acid solutions as a function of chloride ion concentration when $MgCl_2$ or $AlCl_3$ was added. The extraction of titanium(IV) was accelerated with increasing chloride ion; behavior quite similar to that observed in changing only hydrochloric acid concentration as shown in Fig. 1. The acceleration effect by these compounds was apparently dependent upon the increase of chloride ion. The salting-out effect by chlorides such as $MgCl_2$[25] and $CaCl_2$[20] on the extraction of titanium(IV) into the TBP phase had previously been investigated.

Figure 6 shows the plots of log D *versus* log $[TBP]_{org}$ in tests conducted for 7.0—10.3 M hydrochloric acid solution containing only titanium(IV). The slope of log $D_{Ti(IV)}$/log TBP was about unity at 7 M acid concentration, and increased with increasing acid concentration in aqueous phase; the value of which became 2.7 at 10.3 M acid concentration. It means that the ratio of TBP to titanium(IV) in the extracted

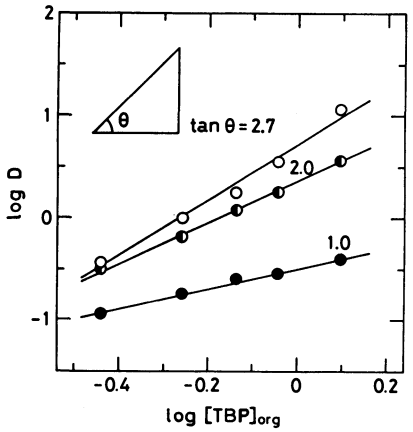

Fig. 6. Dependence of distribution ratio of Ti(IV) on TBP concentration in organic phase.
0.51 M Ti(IV), HCl(M) —●: 7.0, ◐: 8.8, ○: 10.3.

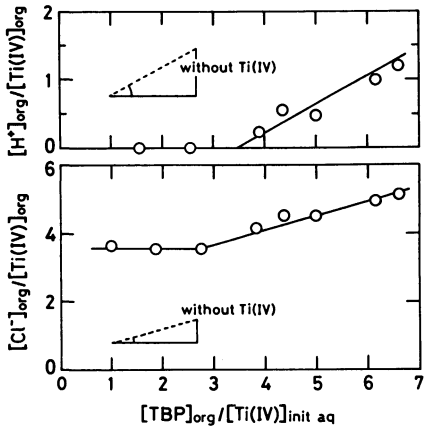

Fig. 7. Dependence of extraction ratio of H^+/Ti(IV) and Cl^-/Ti(IV) on TBP concentration in organic phase.
0.54 M Ti(IV)+10.3 M HCl.

species in organic phase was changed from 1 to 3 according to the acid concentration. Under the conditions conducted here, no free acid was extracted.

The effect of TBP concentration in the organic phase on the extraction of acid and chloride together with titanium(IV) is shown in Fig. 7, which gives the molar ratio of $[H^+]/[Ti(IV)]$ and $[Cl^-]/[Ti(IV)]$ in organic phase in tests conducted for 10.3 M hydrochloric acid solution containing only titanium(IV). At ratios of $[TBP]_{org}/[Ti(IV)]_{init\ aq}$ lower than 3, the ratio of $[Cl^-]_{org}/[Ti(IV)]_{org}$ was constant at 3.6; which suggests that titanium(IV) is extracted as a 1 : 3 complex of $TiCl_4$ and TBP:

$$[TiCl_4]_{aq} + 3[TBP]_{org} = [TiCl_4 \cdot 3TBP]_{org}. \quad (4)$$

As a minor species of titanium(IV) in organic phase, $TiOCl_2$ was inferred. At such high TBP concentration in organic phase as the ratio of $[TBP]_{org}/[Ti(IV)]_{init\ aq} \geqq 3.5$, the equal amounts of Cl^- and H^+ were extracted together with titanium(IV). Because the dependence of acid extraction behavior on TBP concentration in the organic phase was identical with that obtained without titanium(IV), hydrochloric acid would be extracted with an excess of TBP in the organic phase as Eq. 1.

According to Startsev *et al.*,[19,21] titanium(IV) was extracted as $H_2TiCl_6 \cdot 3TBP$, *i.e.*, $[TiCl_4 \cdot 2TBP][2HCl \cdot TBP]$ at high concentrations of hydrochloric acid in aqueous phase and of TBP in organic phase. Our results on the extracted species of titanium(IV) agreed with that reported by Startsev *et al.*

Conclusion

It is generally known that the optimum conditions which realize an effective dissolution of ilmenite ore are as follows: grain size of ore, under 150 mesh; concentration of HCl, higher than 10 M; amount of HCl to ore, 2—4 times in weight; temperature, 70—90 °C.[3,13,14] As can be seen from Eq. 5, the concentration

$$FeTiO_3 + 4HCl = TiOCl_2 + FeCl_2 + 2H_2O \quad (5)$$

of hydrochloric acid decreases with the progress of the leaching reaction, finally becoming 4—6 M. Thus the extraction with TBP can be applied to the leach liquor after the oxidation of iron(II) to iron(III) to recover iron selectively. By the thermal decomposition method,[26,27] iron(III) oxide of higher than pigment grade can be recovered with free hydrochloric acid from the back-extracted solution. This technique is now being applied to the upgrading of ilmenite ore[28] and steel cleansing.[29,30]

Titanium(IV) extracted in organic phase as $TiCl_4 \cdot 3TBP$ should be back-extracted by using 4—6 M hydrochloric acid solutions. The significant acid concentration dependence of the extraction behavior of titanium(IV) was preferable for the back-extraction because titanium(IV) tends to be hydrolyzed easily in weak acid solutions. Since the resulting aqueous solution containing titanium(IV) was not contaminated with any impurities, highly pure titanium(IV) oxide can also be obtained by the thermal decomposition method[28,29] or by the thermal hydrolysis.[31,32] The recovery of free hydrochloric acid from the residual solution after the extractions of iron(III) and titanium(IV) is now a feasible operation.[29,30,33]

Theoretical Study of Proton and Solvent Effects on Molecular Stacking

Felice ZUCCARELLO,* Antonio RAUDINO, Giuseppe BUEMI, and Carmelo RIGANO†

Istituto Dipartimentale di Chimica e Chimica Industriale, Università di Catania, Viale A. Doria 6, 95125 Catania, Italy

†*Seminario Matematico dell'Università di Catania, Viale A. Doria 6, 95125 Catania, Italy*

(Received November 10, 1981)

Molecular stacking between π-electron systems was analyzed in connection with effects of external charge and solvent. A perturbation approach was used for calculating intermolecular energies and a discrete plus continuum model was used for solvent effects. The solvent favors stacking in unprotonated systems by hydrophobic forces. In the presence of an external charge the solvent induces dissociative effects on the molecular pairs by electrostatic solvation forces.

It is well known that molecular stacking plays an important role in many biological processes. Indeed, intramolecular stacking favors conformational preferences in large flexible molecules (FAD, NAD, *etc.*), while intermolecular stacking is one of the causes for binding of molecules to enzymes, base pairing, *etc.* Generally, these molecular systems are characterized by large π-electron systems which interact with one another essentially through van der Waals-type forces. Since in biological environments these large systems are imbedded in a liquid or quasi-liquid (membrane) medium, and frequently they are in a protonated form ($NAD\text{-}H^+$, $FAD\text{-}H^+$), we think it to be interesting to study associated effects of proton-charge and of solvent on interactions among some π-electron systems.

Following an approach already adopted by us,[1] we select simple systems which partially simulate relevant characteristics of more complex biological systems. Consequently, in the present work we study, both in vacuum and in water, interactions between two π-electron clouds, unperturbed as well as perturbed by a proton localized in a site. In the present approach we study interactions in vacuum between two π-systems, one of which is affected by the presence of a neighboring proton. Successively, we add solvation energy, which allows us to examine effects of both hydrophobic interactions and electrostatic solvation energies on the association of these π-systems.

Intermolecular forces, which are responsible for stacking, can be efficiently described in the framework of the second order perturbation approach of Murrell *et al.*[2] This method is particularly suitable for studying medium- and long-range forces; moreover, it allows an insight into different natures of working intermolecular forces. Practically, to interaction energies we add solvation energies calculated according to the discrete plus continuum model, and draw the trend of total energies at various intermolecular distances.

Description of the Method

The following pair systems were considered in the present work: i) protonated ethylene–ethylene, ii) protonated ethylene–benzene, and iii) protonated benzene–ethylene, each case including the corresponding unprotonated pair. The approaching pathways for the neutral pairs are shown in Fig. 1, where the variable parameters are also defined. The positive charge is located at 1.1 Å[3] from the ethylene plane for systems

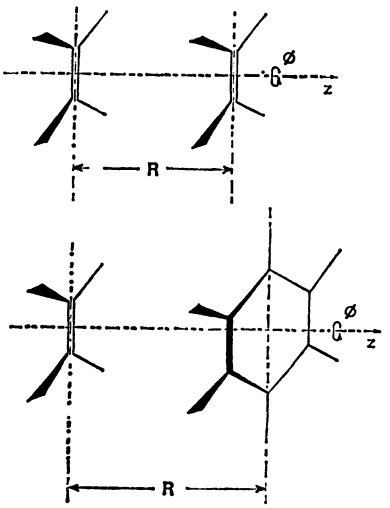

Fig. 1. Approach pathways and variable parameters for ethylene–ethylene and benzene–ethylene pair systems.

i) and ii), and at 0.85 Å from the benzene plane†† for system iii). In all cases it is located along the principal symmetry axis outside the intermolecular space. In evaluating the solvent effect for the unprotonated systems the continuum model was adopted. For the protonated systems the discrete plus continuum model was used; that is, a planar H_3O^+ molecule, perpendicular to the ethylene or benzene plane, was bound to the π-system inside an elliptic cavity of a continuum dielectric medium. Geometrical parameters of H_3O^+ and of the neutral molecules were taken from Refs. 4 and 5. For each value of intermolecular distance, R, and for some relative spatial arrangements, the interaction energy was first calculated, and then the corresponding solvation energy was added.

The intermolecular interaction energy was calculated by the second order perturbation theory of Murrell *et al.*,[2] developed on the LCAO approximation by Fueno *et al.*;[6] this method has been utilized successfully by several authors.[1d,7,8] The method describes quite well the medium and long range forces and allows a useful energy partitioning into five contributions: coulombic (E_Q), exchange repulsion (E_K), induction (E_I), dispersion (E_D), and charge transfer (E_{CT}) energies. The approximations, used in calculating intermolecular integrals, and the structure of the computer

†† This value was optimized by a MINDO/3 calculation.

program used were described in a previous paper.[1d]

Solvation energy was evaluated by means of an approximation††† which divides it into electrostatic, cavitation, dispersion, and short-range contributions. The first contribution was calculated on the reaction field approximation, taking into account the elliptic shape of cavity and the actual position of charges inside. Supermolecule dipole moment was evaluated as the dipole moment induced by a positive charge on polarizable molecules. Polarizability components were evaluated according to a perturbative approach.[9] Cavity contribution was related to the surface tension and to the elliptic surface of solute.[10] Dispersion and short-range energies were calculated by

$$E_{\mathrm{disp}} = \frac{\delta}{2}\int_{\sigma}^{\infty} U(\rho)g^{(2)}(\rho)\langle A(\rho)\rangle d\rho,$$

where δ is the number density of solvent and $U(\rho)$ is a Lennard-Jones potential corrected for the three-body interaction.[11] The coefficient of potential $U(\rho)$ was put equal to

$$\frac{3}{2}\bar{\alpha}_{\mathrm{w}}\bar{\alpha}_{\mathrm{s}}\frac{I_{\mathrm{w}}I_{\mathrm{s}}}{I_{\mathrm{w}}+I_{\mathrm{s}}}(2\sigma)^{-6}.$$

Solute ionization potential (I_{s}) and polarizability (α_{s}) have been theoretically calculated;[9] the ethylene σ value was taken from Ref. 7, while the other values were evaluated from density data.[12,13] $\langle A(\rho)\rangle$ is the spherical average surface of solute, and $g^{(2)}(\rho)$ is the distribution function, here set equal to zero for $\rho<\sigma$ and 1 otherwise.

Results in Gas Phase

Table 1 shows perturbation interaction energy values for the ethylene–ethylene and protonated ethylene–ethylene systems, together with single energy contributions. It can be noted that for the former system, at shorter distances, the exchange repulsion contribution (E_{K}) is the most important, whereas the coulombic (E_{Q}) and dispersion (E_{D}) energies nearly balance each other; at longer distances the total energy arises essentially from the dispersion term, the figures being in agreement with previous calculations.[7] Further calculations showed that the total energy is not affected by rotation of one ethylene molecule around the intermolecular symmetry axis.

When a proton is added (the latter system), we note an increase in E_{K} and a decrease in E_{Q}, while the induction (E_{I}) and charge transfer (E_{CT}) terms are appreciable. Then the total energy shows, with respect to the unprotonated system, a slight deepening of the minimum, which now lies at nearly the same

††† Details of the method are described in Ref. 1b.

distance as in the neutral system (Fig. 2, a and a' curves).

At first sight it could appear strange that, in Table 1, the coulombic terms vary rapidly with distance as compared with the corresponding exchange terms. However, we must bear in mind that in the ethylene–ethylene system the first nonvanishing term of coulomb interaction is the quadrupole-quadrupole term. A similar situation occurs in the protonated ethylene–ethylene system, where the monopole-quadrupole term is nearly zero on symmetry ground.

Calculations were carried out to test the effect due to the proton–ethylene distance on each energy term: The main effect (at 1—2 Å) is a small increasing of E_K nearly balanced by a small lowering of E_Q when the proton–ethylene distance decreases.

Calculations on the benzene–ethylene system evidenced a higher dispersion energy than the ethylene–ethylene one owing to the increased π-system size, in addition to decreases in E_Q and E_K.** The benzene–ethylene energy curve is shown in Fig. 3 (curve a), together with the corresponding curve for the protonated benzene–ethylene system (curve a').*** We can see that the unprotonated benzene–ethylene system shows a minimum more pronounced and at shorter distances than the ethylene dimer.

Protonation has a stabilizing effect, though small (0.3 kcal mol^{-1}) (1 cal=4.184 J); the energy curves appear deeper and wider with the minima lying at slightly greater distances than in the corresponding unprotonated systems. Indeed, the stabilization should be more extensive; in fact, it is well known that the limited basis set will cause underestimation of dispersive forces,[14,15] so that a more negative dispersion energy is to be expected.

Results in Aqueous Solution

Since the energies involved in these molecular associations are small, we expect that solvation energy plays an important role in determining the stability of molecular pairs. Following the scheme outlined in the calculation section, we added the solvation energy to the energy for the gas phase and constructed curves for the resulting total energy *vs.* intermolecular distance. Figures 2 and 3 show solvation and total energy for the pair systems studied.

The solvation energy for the unprotonated systems (curves b) increases with intermolecular distance, R, the cavitation term prevailing and the dispersion term being nearly constant;§ the slope is greater in the wider benzene–ethylene system (Fig. 3) than in the ethylene dimer (Fig. 2). The solvation causes drastic deepening of the potential well in the short distance range in both the cases (curves c). Moreover, for

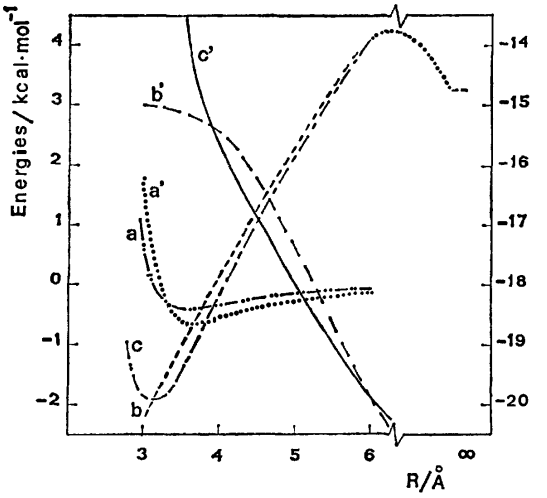

Fig. 3. Benzene–Ethylene system.
a: Gas-phase energy, unprotonated a': gas-phase energy, protonated; b: solvation energy, unprotonated, b': solvation energy, protonated, c: total energy, unprotonated; c': total energy, protonated. Scale on the right refers to b' and c' curves.

each pair in solution the energy minimum is lower than the energy of the two single solvated components at infinite distance. Therefore, to dissociate these unprotonated pairs, we must overcome a potential barrier. This explains how hydrophobic forces induce the stacking of π-electron molecular systems in solution.

The present approach is not capable of allowing us to calculate the exact dissociation barrier, leaving the intermolecular potential variable in a periodic fashion with intermolecular distance as far as this distance is comparable, or greater than, solvent molecular radii.[16,17] However, from an inspection of the curves we expect barriers of 2—3 kcal mol^{-1} for the ethylene–ethylene pair and 5—6 kcal mol^{-1} for the benzene–ethylene one.

When the proton is bound to one of pairing molecules, main consequences from the solvent effect are the disappearence of short range minima and the strong dissociative power in all the cases considered (curves c'). This is accounted for in terms of the appreciable electrostatic contribution to solvation energy. This contribution increases greatly with intermolecular distance because the charge is located in the proximity of cavity wall; this geometric fashion makes remarkable the effect of ellipticity on the electrostatic solvation energy. Such increase in electrostatic solvation energy has been pointed out by several authors[18,19] and evidenced by us in our previous work.[1b] On this ground the cavitation energy here plays a minor role, in contrast to the unprotonated systems.

By comparing the shapes of the solvation energy curves (b') in Figs. 2 and 3, it can be deduced that increasing the size of unsaturated systems will result in lowering the slope of solvation energy curves at short distances. We, therefore, think that the interaction between very extended unsaturated systems could cause inversion in the slope of the above curves for protonated systems so that stacking effects induced by

** No values of the energy components are reported because their trend is quite similar to that of the corresponding ethylene–ethylene system.

*** The curve for the protonated ethylene–benzene system, not reported here, is nearly equal to curve a', apart from a slight destabilization.

§ No significant variations were observed on changing the rotation angle ϕ (see Fig. 1).

the solvent could be reliable. No curves for the protonated ethylene–benzene (both in the gas phase and in solution) are reported in Fig. 3; they are similar to those for the protonated benzene–ethylene system.

We can conclude that in water solution the stacking effect, though weak, can occur between unsaturated molecules, provided that no proton is bound to anyone of the interacting molecules (hydrophobic stacking). On the contrary, when a net charge is held by one of the two molecules, any stacking effects are not possible; at the most, only in very extended unsaturated systems they should be taken into account.

This work was supported partially by the Italian Consiglio Nazionale delle Ricerche (CNR), Rome.

On the Interaction of CrO_2Cl_2 Vapor with the Surface of γ-Al_2O_3 and the Formation of a Chromium Oxide Covering

Damyan DAMYANOV* and Lubomir VLAEV
Higher Institute of Chemical Technology, 8010 Burgas, Bulgaria
(Received March 31, 1982)

Samples of γ-Al_2O_3 containing different amounts of residual hydroxyl groups were obtained by thermal treatment. The possibility of interaction of the surface hydroxyl groups of γ-Al_2O_3 with chromyl chloride vapor was studied by IR spectroscopy. The hydrogen chloride evolved as a result of the reaction interacts with both strained Al–O–Al bridges and the surface OH groups. Different types of OH groups show different reactivities with respect to the interaction with CrO_2Cl_2. Bands at 3780 and 3700 cm^{-1} are due to OH groups which have a much higher reactivity than the OH groups responsible for bands at 3744 and 3733 cm^{-1}. Not all of the OH groups participate in the surface reaction. Decrease in their surface density results in increase in the reactivity. Modification of the γ-Al_2O_3 surface is achieved by reaction cycles consisting of treatment with CrO_2Cl_2 vapor and hydrolysis of the compounds obtained by water vapor. As a result, an increase in the chromium oxide amount on the surface of γ-Al_2O_3 is observed. This is ascribed to the "secondary" OH groups formed after the hydrolysis.

It is well known that chemical modification of the surface of Al_2O_3 with halogen compounds leads to essential changes in its acidic properties and catalytic activities. In the literature there are a number of studies using hydrogen halides,[1-4] halogenated hydrocarbons,[5,6] $SiCl_4$,[7] various silanes,[8] *etc.* as modifying agents. However, there are no investigations on reactions of the Al_2O_3 surface with vapors of valatile halides or halide oxides of transition metals, which are known to ensure a more uniform deposition of a transition metal and a halogen on the surface than the classical methods of catalysts preparation. In addition, hydrolysis of the surface compound obtained can proceed with formation of "secondary" OH groups, which in turn can interact with the vapor of the same or another halide. Thus, a possibility is found to perform controllable deposition of active components on the surface of supports and to prepare new types of catalysts.

The purpose of the present paper is to investigate the interaction of the surface of γ-Al_2O_3 with CrO_2Cl_2 vapor and the deposition of chromium oxide phases as a result of alternate treatment with chromyl chloride vapor and hydrolysis with water vapor.

Experimental

Samples of γ-Al_2O_3 (Leuna, GDR), with particle sizes of 0.25—0.64 mm, specific surface area of 190 m^2/g, and pore volume of 0.64 cm^3/g, were used for the experiments.

To obtain samples with different amounts of OH groups, the initial γ-Al_2O_3 was calcined for 3 h in air with a view to eliminating organic impurities, after which it was subjected to additional calcination for 3 h *in vacuo* (5×10^{-5} Torr) (1 Torr=133.322 Pa) at suitable temperatures.

The samples thus prepared were brought into contact with CrO_2Cl_2 vapor at an experimentally established temperature of 150 °C. It was found that at lower temperatures, 25 °C, physical adsorption proceeds to a great extent, whereas above 170 °C partial polymerisation of chromyl chloride occurs.[9] The weight gain as a result of chemisorption was determined with a McBain balance. With samples showing no weight change, the residual chromyl chloride vapor and the gaseous products were removed by evacuation for 1 h at 150 °C. The amount of OH groups was determined gravimetrically by assuming complete dehydration of the surface at 1150 °C.

Chromyl chloride was synthesized under laboratory conditions and used after redistillation.[10] Extraction of Cr and Cl^- from the sample was achieved by treatment with 2 M NaOH (1 M=1 mol dm^3). The Cr content was determined iodometrically, and that of Cl^-, by amperometric titration.

The specific surface area was determined by the BET method using low-temperature nitrogen adsorption.

Samples of γ-Al_2O_3 (10×30 mm) weighing 13—15 mg/cm^2 were studied by IR spectroscopy. They were obtained from fine Al_2O_3 powder under a pressure of 200 kg/cm^2. The thermal treatment, the surface modification by CrO_2Cl_2 and the hydrolysis with water vapor as well as the recording of spectra were carried out in a spectral vacuum quartz cell with NaCl windows. The spectra were taken at room temperature with a UR-20 (Carl Zeiss Jena, GDR) apparatus, an optical attenuator being placed in the reference beam.

Results

Table 1 contains data from thermogravimetric measurements of the amount of OH groups. The surface density of OH groups was calculated on the basis of specific surface area. Evidently, all the parameters shown in Table 1 decrease with increasing temperature of precalcination. It should be taken into account that the values of α_{OH} and ω_{OH} are approximate and higher than the real ones. This is indicated by preliminary IR spectroscopy studies. The latter confirmed works of other authors,[11,12] according to which within the above temperature range there is coordination water on the surface of the initial Al_2O_3. It can be assumed that above 400 °C the data on the hydroxyl coverage are real since the weight losses established are due only to dehydration of the surface at the expense of neighboring or favorably oriented OH groups.

Three samples precalcined at 250, 550, and 750 °C, respectively, were treated with CrO_2Cl_2 vapor. It was taken into account that at 250 °C there is still coordination water on the surface of Al_2O_3. At 550 and 750 °C there is no such water but the Al–O–Al bridges formed as a result of dehydration differ in number and stability. In addition, the temperature of 750 °C is limited for the γ-θ-transition of Al_2O_3.

The kinetics of the reaction of CrO_2Cl_2 with the surface of Al_2O_3 are illustrated by the gravimetric

Table 1. Dependence of amount of OH groups (α_{OH}), the specific surface area (S), and surface density of hydroxyl groups (ω_{OH}) on the precalcination temperature of γ-Al_2O_3

	Temp/°C							
	170	250	350	450	550	650	750	850
$\frac{\alpha_{OH} \times 10^{-21}}{\text{numbers g}^{-1}}$	2.37	1.91	1.59	1.20	0.79	0.47	0.27	0.16
$S/m^2\,g^{-1}$	190	188	175	172	179	126	113	90
ω_{OH}/number nm^{-2}	12.49	10.20	9.09	7.00	4.44	3.63	2.35	1.74

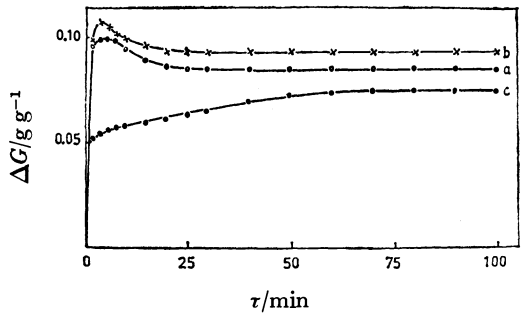

Fig. 1. Kinetic curves of CrO_2Cl_2 chemisorption at 150 °C on γ-Al_2O_3 precalcined at 250 °C (a), 550 °C (b), and 750 °C (c).

Table 2. Dependence of the Cl^- and Cr contents and their ratio on the precalcination temperature of γ-Al_2O_3

No.	Tem/°C	Numbers/10^{-20} g		Cl^-/Cr
		Cl^-	Cr	
1	250	1.93	3.49	0.55
2	550	2.77	3.67	0.75
3	750	2.65	2.35	1.13

curves presented in Fig. 1. The steep course of the curves in their initial portions indicates a rapid interaction. Contrary to the kinetic curves for samples calcined at 250 and 550 °C, the curve for the sample treated at 750 °C shows no maximum, which is probably due to differences in the diffusion of reaction products. After the initial portion of the curves there is a horizontal part indicating equilibrium. The data from chemical analysis (Table 2) show different contents of Cl^- and Cr, their ratios and the weight gain being presented by the kinetic curves. Obviously, the surface density of hydroxyl coverage affects the interaction which, however, is incomplete since the amounts of deposited Cl^- and Cr are much less than the theoretically calculated amounts needed for complete interaction of the available OH groups.

Figure 2 shows changes in IR spectra due to contact of the Al_2O_3 sample calcined at 550 °C with increasing CrO_2Cl_2 amount (the portions of 1.9 μmol).

The spectrum of the initial Al_2O_3 has absorption bands at 3780, 3744, 3733, and 3700 cm^{-1} which, according to the model of Peri,[1] correspond to the srtetching vibrations of isolated OH groups. No bands are discernible in the low-frequency region. The bands at 3780 and 3700 cm^{-1} are not observed in the spec-

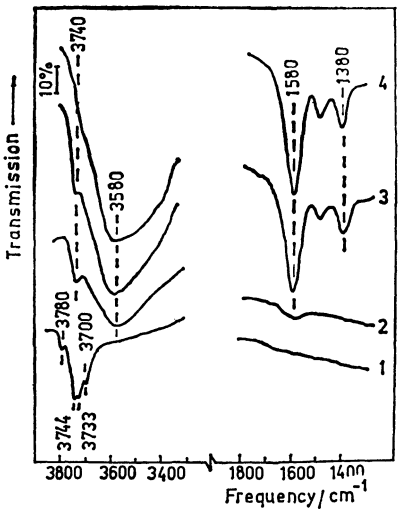

Fig. 2. IR spectra of initial γ-Al_2O_3 calcined for 3 h in air and outgassed in vacuum for 3 h at 550 °C (1), after successive interactions at 150 °C with 1.9 μmol CrO_2Cl_2 vapor (2), with 3.8 μmol CrO_2Cl_2 (3), and upon complete saturation (4).

trum after the first portion of chromyl chloride vapor, whereas the bands at 3744 and 3733 cm^{-1} appear as a single band of lower intensity (spectrum 2). In addition, there is a broad band with a maximum at about 3580 cm^{-1}. According to literature data,[11] this band is due to OH groups interacting by strong hydrogen bonds. Obviously, a chemical reaction with participation of the surface OH groups proceeds. The introduction of new CrO_2Cl_2 portions (spectra 3 and 4) leads to a more pronounced band at 3580 cm^{-1} which is broadened in the low-frequency region where three new bands appear at 1380, 1490, and 1580 cm^{-1}.

To elucidate the nature of the first two bands, spectra of initial γ-Al_2O_3 were taken after its thermal treatment up to 500 °C. A gradual decrease in the intensity of these bands with increasing temperature was observed. At 500 °C they completely disappeared. This means that they are of the same nature and are in some way associated with the presence of coordination water on the γ-Al_2O_3 surface. In Refs. 14 and 15 the band at 1380 cm^{-1} is attributed to the overtone of the Al–OH stretching vibration, where the OH group vibrates as a whole and whose fundamental frequency should be at 660—700 cm^{-1}. In view of what has been mentioned above, the bands at 1380 and 1490 cm^{-1} could, according to our opinion, be the overtone of the coordination bond $>Al{:}OH_2$

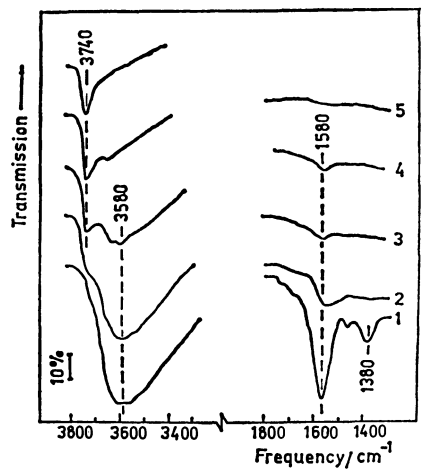

Fig. 3. IR spectra of γ-Al_2O_3 after its modification with CrO_2Cl_2 vapor at 150 °C (1), and after successive outgassing in vacuum and calcination 5 h at 250 °C (2), at 350 °C (3), at 450 °C (4), and at 550 °C (5).

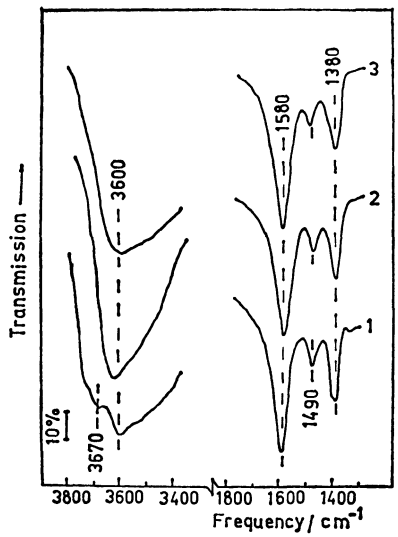

Fig. 4. IR spectra of initial γ-Al_2O_3 calcined for 3 h in air and outgassed in vacuum for 3 h at 250 °C (1), and after successive interactions with 1.9 μmol (2), and 3.8 μmol (3) CrO_2Cl_2.

in tetrahedrally and octahedrally coordinated surface aluminium atoms.

According to Refs. 11, 15, and 16, the band at 1580 cm^{-1} indicates the presence of coordination water. The IR spectra in Fig. 3 demonstrate its thermal stability. Spectrum 1 in Fig. 3 is identical with those given in Figs. 2—4. Evidently, with increasing temperature from 250 to 450 °C, the band at 1580 cm^{-1} gradually reduced its intensity and disappeared at 550 °C. A similar behavior is observed with the broad band at 3580 cm^{-1} which is shifted to higher frequences. Simultaneously, the composite band at 3740 cm^{-1} becomes more pronounced. Its presence may be attributed to (1) the formation of "secondary" OH groups as a result of the interaction of the evolved hydrogen chloride with Al–O–Al bridges; (2) the appearance of unreacted and "masked" OH groups; and

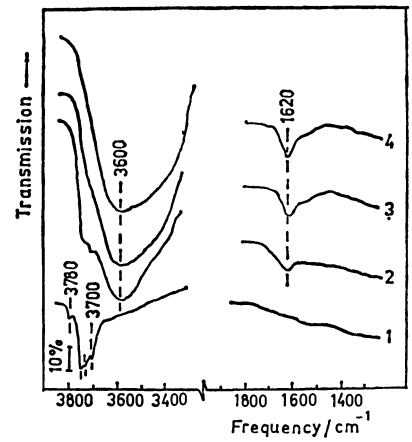

Fig. 5. IR spectra of initial γ-Al_2O_3 calcined for 3 h in air and outgassed in vacuum for 3 h at 750 °C (1), after successive interactions at 150 °C with 1.9 μmol (2), and 3.8 μmol CrO_2Cl_2 (3), and complete saturation (4).

(3) the hydrolysis of the Al–Cl bond by the coordination water during calcination. These assumptions are based on the investigations by Peri[1] on the interaction of Al_2O_3 with hydrogen chloride and on our experimental data indicating an incomplete participation of the free OH groups in the chemical interaction as well as on the absence of chlorine in the samples after their calcination at 550 °C.

The spectrum of the sample preliminarily dehydrated and outgassed at 250 °C (Fig. 4. 1) has no pronounced characteristic bands of free OH groups due to the presence of coordination water (the bands at 1580 and 3600 cm^{-1}). Only a very weak band at 3670 cm^{-1} appears and is no more discernible after the introduction of the CrO_2Cl_2 vapor. The band at 1580 cm^{-1} preserves its intensity, which indicates that the coordination water does not interact with CrO_2Cl_2. The above spectra illustrate very well the behavior of the Al_2O_3 surface in the presence of coordination water and unambiguously confirm that the reaction between this surface and CrO_2Cl_2 leads to the formation of new OH groups and molecular water coordinatively bonded to the surface.

Figure 5 shows changes in the IR spectrum of a sample calcined at 750 °C after interaction with chromyl chloride vapor. The behavior of the bands at 3780 and 3700 cm^{-1} differs from that for the sample calcined at 550 °C. Contrary to the band at 3780 cm^{-1}, the one at 3700 cm^{-1} is also observed after the introduction of the first chromyl chloride portion. In addition, the band at 1620 cm^{-1} appears due to the OH deformation vibration and has a much lower intensity. The above facts confirm the assumption about certain variations in the mechanism of interaction between Al_2O_3 and CrO_2Cl_2 depending on the surface density of the hydroxyl groups.

From the spectra in Fig. 3 it is evident that part of the hydroxyl coverage on the support can be restored. This allows subsequent modification of the surface with CrO_2Cl_2 vapor with a view to increasing the amount of chromium oxide. This possibility is also ensured by the surface compounds with water

vapor. For this reason, the following reaction cycle was carried out: treatment with CrO_2Cl_2 vapor of Al_2O_3 dehydrated at 550 °C; hydrolysis at 100 °C with water vapor of the surface compound obtained; calcination at 550 °C followed by a repetition of the above cycle. Table 3 shows data from chemical analysis of the samples obtained in this way. Here, ΔCr is the increase in Cr amount with each treatment cycle consisting of hydrolysis with water vapor, calcination at 550 °C, and modification with CrO_2Cl_2 vapor. Figure 6 presents changes in the IR spectra. Obviously, the chromium content increases with each treatment cycle. Simultaneously, the Cl^- amount and the $Cl^-/\Delta Cr$ ratio decrease, which is indicative of a hydrolysis process and a participation of the newly formed OH groups in the repeated modification. The spectra in Fig. 6 show a decreasing intensity of the composite band at 3740 cm^{-1} with increasing number of treatment cycles. In addition, the band due to strongly interacting OH groups is shifted from 3560 to 3600 cm^{-1}. It is noteworthy that after the second and subsequent treatments with chromyl chloride the bands at 3780 and 3700 cm^{-1} (coordination water) are not observed. Therefore, the amount of chromium oxides increases as a result of an interaction between chromyl chloride and OH groups giving rise to absorption bands at 3744 and 3733 cm^{-1}.

Table 3. Dependence of the amounts of Cl^- and Cr fixed on the Al_2O_3 surface and $Cl/\Delta Cr$ ratio on the number of modification cycles consisting of treatment with CrO_2Cl_2 and hydrolysis with water vapor

Cycle No.	Numbers/10^{-20} g			$Cl^-/\Delta Cr$
	Cl^-	Cr	ΔCr	
I	2.77	3.67	3.67	0.75
II	1.45	6.75	3.08	0.47
III	0.54	8.19	1.44	0.38

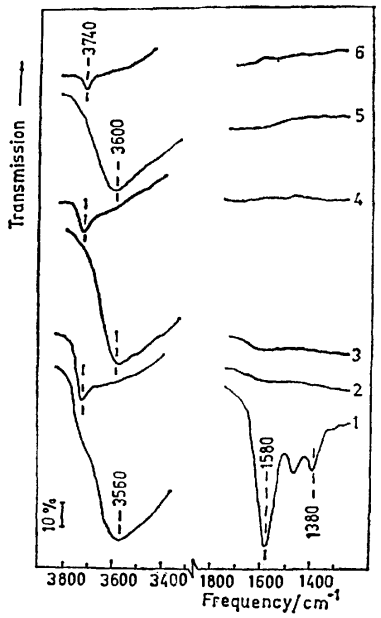

Fig. 6. IR spectra of γ-Al_2O_3 after successive treatments with CrO_2Cl_2 vapor at 150 °C (1, 3, and 5) and hydrolysis with water vapor at 100 °C and calcination at 550 °C (2, 4, and 6).

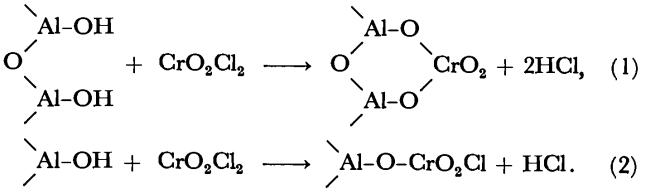
Discussion

The data from IR spectroscopy indicate defferent chemical activities for the different types OH groups. The OH groups of the highest frequency (absorption band at 3780 cm^{-1}) appear to possess the highest reactivity. Next in reactivity come OH groups of the lowest frequency band (3700 cm^{-1}). After participating in an interaction, these OH groups cannot be restored by hydrolysis. This is evidence for sufficient stability of the Al–O–Cr bond formed. The OH groups responsible for the bands at 3744 and 3733 cm^{-1} are relatively less active. The absence of these bands in the spectrum after the treatment with higher CrO_2Cl_2 amounts should not be interpreted as the indication of complete consumption of these types of OH groups, but should rather be attributed to screening of the latter by the reaction products. As a result, their bands cannot be resolved and appear as one broader band.

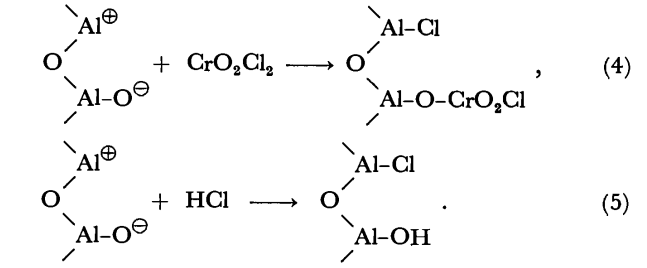
The absence of bands at 3780 and 3700 cm^{-1} in the IR spectrum of Al_2O_3 treated with CrO_2Cl_2 and both the decrease in intensity of the bands at 3744 and 3733 cm^{-1} and the presence of Cr^{6+} alone (according to EPR data) indicate electophilic interaction of CrO_2Cl_2 and removal of a proton from the hydroxyl group:



However, the reaction does not stop here. The appearance of a new absorption band at 1580 cm^{-1} indicates formation of water. This can occur only as a result of additional interaction of the hydrogen chloride with the surface OH groups according to the following scheme:

The investigation of Peri[1] on the reaction of hydrogen chloride with Al_2O_3 confirms this scheme.

Since on the surface of Al_2O_3 strained Al–O–Al bridges occurred in addition to the groups, a nucleophilic addition of Cl^- to the surface aluminium atoms can also be expected:



The fact that the first CrO_2Cl_2 portion (Fig. 2) leads to a gecrease in intensity of the bands characterizing the isolated OH groups and that a band of coordination water appears with the subsequent portions, shows that the first stage of the reaction proceeds according to Schemes 1 and 2. The hydrogen chloride evolved interacts first with the strained Al–O–Al bridges according to Scheme 5, which is confirmed by the band at 3680 cm^{-1} due to OH groups connected by hydrogen bonds. Only after this step the hydrogen chloride can interact with hydroxyl groups according to Scheme 3 and form water molecules which are coordinatively bound to the surface (the band at 1580 cm^{-1}). Herewith one answers the question about the constancy in intensity of the band at 1580 cm^{-1} after treatment with CrO_2Cl_2 of γ-Al_2O_3 calcined at 250 °C. The coordination centres of this sample are preliminarily occupied by water molecules and there is no possibility of additional coordination of the water formed as a result of the reaction. This type of reaction is confirmed by the spectra of the samples modified by calcination at 750 °C (Fig. 5). In this case, the band of coordination water is less pronounced due to the decrease in surface density of the hydroxyl groups and the larger amount of Al–O–Al bridges. Since dehydration at 750 °C leads to the formation of "isolated" OH groups alone, the interaction according to scheme 1 should be excluded. In view of the low density of OH groups on the surface (Table 1), the small amount of deposited chromium is quite natural. A comparison of the surface density of the hydroxyl groups with the amount of chromium per unit alumina surface leads to a conclusion that at 750 °C CrO_2Cl_2 interacts mainly according to Scheme 2. At lower temperatures the interaction proceeds partly according to Scheme 1. This is confirmed by the lower Cl^-/Cr ratio at these temperatures of precalcination.

The absence of maximum in the kinetic curve of the sample calcined at 750 °C and the much less pronounced band of deformation vibrations of water which is shifted to a higher frequency in this case, lead us to conclude that during dehydration the nucleophilic addition of Cl^- to the surface of Al_2O_3 is prevailing due to the evolution of hydrogen chloride.

The reaction according to Scheme 4 is not very propable since, in the case of the sample calcined at 750 °C and dehydrated to the highest degree so as to have the largest number of Al–O–Al bridges, the largest amount of chromium should be deposited, and the Cl^-/Cr ratio should be 2, which has not practically been observed. In addition, Scheme 4 shows no evolution of HC which would react according to Eq. 3 and lead to the band observed at 1620 cm^{-1} due to the presence of coordinatively linked water molecules.

The appearance of a band at 3740—3730 cm^{-1} upon hydrolysis or calcination of samples modified by CrO_2Cl_2 is indicative of restoration of part of the hydrate coverage on the carrier. This increase in the chromium amounts Table 3 as a result of successive cycles of halogenation and hydrolysis, which is accompanied by a decrease in intensity of the band at 3740—3730 cm^{-1}, confirms the formation of layers of chromium oxides on the Al_2O_3 surface. The absence of any bands at 3780 and 3700 cm^{-1} after hydrolysis of the samples, on the one hand, and of any band at 1580 cm^{-1} after the second and subsequent halogenations, on the other, confirms that the OH groups responsible for the appearance of the bands of highest and lowest frequencies have the highest reactivity. The OH groups giving rise to bands at 3744 and 3733 cm^{-1} and the eventually formed Cr–OH groups are probably responsible for the subsequent reactions of molecular deposition of chromium oxides. The bands caused by Cr–OH groups were not detected in the range investigated owing to too small an amount of deposited chromium oxide phase and the masking effect of the OH groups on the support.[17,18] The broad absorption band produced by the γ-Al_2O_3 skeleton, which appears in the range 800—1000 cm^{-1}, does not permit any observation of the characteristic band for the Cr–O bond.[17,19] We are of the opinion that the treatment with water vapor leads to hydrolysis of the structure obtained according to Eqs. 2, 3, and 5. Thus, repeated treatment with CrO_2Cl_2 vapor leads to both horizontal densification and vertical growth of the chromium oxide coverage. The continuous increase in the fixed chromium content and the decrease in amount of the chlorides with each cycle of treatment is very significant in this respect.

Conclusion

The surface OH groups of γ-Al_2O_3 react with CrO_2Cl_2 vapor, as a result of which hydrogen chloride is evolved. Part of the latter additionally interacts with the strained Al–O–Al bridges forming new Al–OH and Al–Cl groups. After the consumption of the strained Al–O–Al bridges the hydrogen chloride interacts with the Al–OH groups. As a result, water is formed which is coordinatively bound to the surface. On the sites where the halogen is bound to the surface, new "secondary" OH groups appear due to hydrolysis with water vapor or to calcination. They can interact again with the vapor of CrO_2Cl_2. The hydrogen chloride evolved does not interact with these surface hydroxyl groups. Successive reaction cycles consisting of treatment with CrO_2Cl_2 vapor and hydrolysis with water vapor may increase the amount of chromium oxides of the surface of γ-Al_2O_3.

Kinetics of Gas Phase Addition Reactions of Trichlorosilyl Radicals. VI.[1] Orientation of Additions to 2-Pentenes

Takaaki DOHMARU* and Yoshio NAGATA
Radiation Center of Osaka Prefecture, Shinke-cho, Sakai, Osaka 593
(Received October 8, 1982)

Synopsis. Addition reactions of $\cdot SiCl_3$ radicals to *cis*- and *trans*-2-pentene have been studied in the gas phase between 30 and 136 °C. The ratio of the rate of formation of 2- with 3-trichlorosilylpentane, R_2/R_3, was found to vary with temperature or with $HSiCl_3$ concentrations (1.47—17.6 μmol cm^{-3}). This variation was successfully interpreted by the decomposition of an adduct radical, $CH_3CH(SiCl_3)\dot{C}HCH_2CH_3$.

Quantitative studies of silyl radicals are of general interest now. Previously,[2] we reported that the addition of $\cdot SiCl_3$ radicals to *cis*-2-pentene gave 2- and 3-trichlorosilylpentane (2- and 3-TSP) and that the ratio of formation of the two isomers, R_2/R_3, was 0.47 invariant either with temperature (133—182 °C) or with $HSiCl_3$ concentrations (1.34—5.38 μmol cm^{-3}). It was then found, however, that R_2/R_3 was *ca.* 1.2 in a radiation induced reaction of $HSiCl_3$ with *cis*-2-pentene in cyclohexane at room temperature which was performed to prepare authentic samples of 2- and 3-TSP. It is of interest that the value of R_2/R_3 in the liquid phase is quite different from that in the gas phase. Further, orientation of addition in unsymmetrical olefins may be of importance in relation to the nature of the transition state.[3]

In this connection, we studied the variation of R_2/R_3 with $HSiCl_3$ concentrations and with temperature between 30 and 136 °C to cover the temperature range below that of the previous study.

Experimental

Materials and procedures are essentially similar to those described earlier.[2] Mixtures of CH_3COCH_3, 2-pentene, and $HSiCl_3$ were introduced into a cylindrical Pyrex cell of 137 cm^3 which was heated in an electric oven. The light source was a 50 W medium pressure mercury arc. During this series of experiments, the rate of absorption of light was 7×10^{-12} einstein cm^{-3} min^{-1}. After photolysis, the reaction mixture was passed to a gas sampling loop and was immediately analyzed by GLC.

Results and Discussion

Mixtures of CH_3COCH_3 (2.90 μmol cm^{-3}), $HSiCl_3$ (8.70 μmol cm^{-3}) and *cis*- or *trans*-2-pentene (0.58 μmol cm^{-3}) were photolyzed between 30 and 136 °C in the gas phase. Products were almost exclusively $(CH_3)_2CHOSiCl_3$ (A), 2-, and 3-TSP. The ratio of the rate of formation of the two isomers, R_2/R_3, are shown in Fig. 1 as a function of temperature. R_2/R_3 was *ca.* 1.2 at 30 °C but decreased with an increase in temperature. At 136 °C it agreed with the value of 0.47 previously[2] obtained at higher temperatures. In addition, there was no significant difference in reactivity between *cis*- and *trans*-2-pentene.

The Arrhenius plots of the rate of formation of the respective products are given in Fig. 2.

The plot of log R_A against $1/T$ is seen to be linear; the least-mean-squares treatment of the plot gives

$$\log(R_A/\mu mol\ cm^{-3}\ min^{-1}) = 2.52 \pm 0.14 - (2.26\pm0.05)\times10^3/T. \quad (1)$$

In the photolysis of CH_3COCH_3 in the presence of $HSiCl_3$ and 2-pentene, the addition of $\cdot SiCl_3$ radicals to CH_3COCH_3[4] and to 2-pentene[2] is known to constitute chain propagating steps as shown in the following.

$$\cdot SiCl_3 + CH_3COCH_3(Ac) \longrightarrow (CH_3)_2\dot{C}OSiCl_3(\dot{A}) \quad (2)$$

$$\cdot A + HSiCl_3(TCS) \longrightarrow (CH_3)_2CHOSiCl_3(A) + \cdot SiCl_3 \quad (3)$$

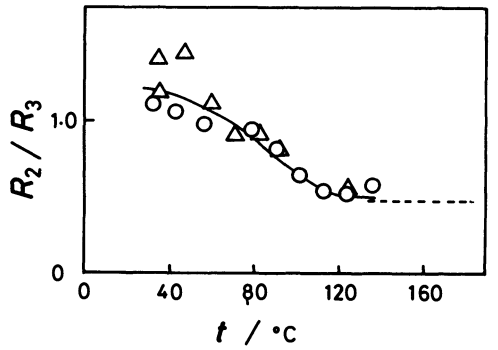

Fig. 1. Variation of R_2/R_3 with temperature.
○: *cis*-Δ^2-C_5H_{10}, △: *trans*-Δ^2-C_5H_{10}, ------: from Ref. 2. $[\Delta^2\text{-}C_5H_{10}]=0.58$, $[CH_3COCH_3]=2.90$, $[HSiCl_3]=8.70$ μmol cm^{-3}.

$$\cdot SiCl_3 + \Delta^2\text{-}C_5H_{10}(P) \rightleftharpoons CH_3\dot{C}HCHCH_2CH_3(\dot{P}_2) \quad (4,-4)$$
$$\qquad\qquad\qquad\qquad\qquad\quad SiCl_3$$
$$\cdot SiCl_3 + \Delta^2\text{-}C_5H_{10}(P) \rightleftharpoons CH_3\dot{C}HCHCH_2CH_3(\dot{P}_3) \quad (4',-4')$$
$$\qquad\qquad\qquad\qquad\qquad\quad SiCl_3$$

$$\cdot P_2 + HSiCl_3 \longrightarrow 2\text{-TSP} + \cdot SiCl_3 \quad (5)$$

$$\cdot P_3 + HSiCl_3 \longrightarrow 3\text{-TSP} + \cdot SiCl_3 \quad (5')$$

Chain terminating radicals are probably[4] $\cdot A$, $\cdot P_2$, and $\cdot P_3$. Irreversibility of reaction (2) up to 253 °C has already been shown[4] in this laboratory.

In the scheme above, three chain cycles resulting in the adducts A, 2-, 3-TSP occur concurrently. Assuming low conversions of the reactants and long reaction chains, one obtain the following rate equations by the conventional steady state treatment.

$$R_2/R_A = ([P]/[Ac])(k_4/k_2)\{1+(k_{-4}/k_5)[TCS]^{-1}\}^{-1}, \quad (6)$$

$$R_3/R_A = ([P]/[Ac])(k_{4'}/k_2)\{1+(k_{-4'}/k_{5'})[TCS]^{-1}\}^{-1}, \quad (6')$$

where R_2, R_3, and R_A denote the rates of formation of 2-, 3-TSP, and A, respectively.

Recently,[2] we obtained the following rate constant ratios for *cis*-2-pentene between 133 and 182 °C using Eqs. 6 and 6'.

$$\log(k_4/k_2) = 0.57,\ \log(k_{4'}/k_2) = 0.89$$
$$\log(k_{-4}/k_5) = 5.39 - 20500/2.3RT(\text{mol cm}^{-3}),$$
$$\text{and}\quad \log(k_{-4'}/k_{5'}) = \log(k_{-4}/k_5). \quad (7)$$

Based upon these values, Eqs. 6, 6', and 1 allow the values of $\log R_2$ and $\log R_3$ to be calculated in the extended temperature range. These calculated values are illustrated in Fig. 2 as dotted lines. It is interesting to note that while $\log R_3$ agrees with the dotted line over the temperature range adopted, $\log R_2$ behaves quite differently with the extended value especially at low temperatures.

The results in Fig. 2 imply that the change in orientation of addition illustrated in Fig. 1 may be caused only by the change in R_2.

Another series of experiments was carried out to ascertain this implication. With other conditions being kept constant, the dependence of the rate of formation of the products on $HSiCl_3$ concentrations was studied at 61 °C. The results are shown in Fig. 3. To check the third body effect, 17.6 μmol cm^{-3} of CO_2 was added at $[HSiCl_3]=1.47$ μmol cm^{-3}, but there was almost no effect.

The results in Fig. 3 show that the variation of $[HSiCl_3]$ has almost no effect on R_3/R_A but has strong effect on R_2/R_A. This fact suggests that some reactions eliminating $\cdot P_2$ radicals compete with reaction (5). The most probable reactions as such are (8), (9), and (−4).

$$\cdot P_2 + \cdot R(\text{any radicals}) \longrightarrow \text{products} \quad (8)$$
$$\cdot P_2 + P \longrightarrow \text{telomer} \quad (9)$$

Reaction (8) is indeed occurring as one of the terminating reactions. But the kinetic chain length of reaction (5) is estimated to be >10 in this experiment, *i.e.*, $R_8/R_2<0.1$, so reaction (8) cannot contribute to the change in R_2 to such an extent as is shown in Fig. 3.

Since $\cdot P_2$ is more reactive than $\cdot P_3$ (stabilized by CH_3–) or $\cdot A$ (tertiary radical), reaction (9) may be reasonably assumed more important than the similar

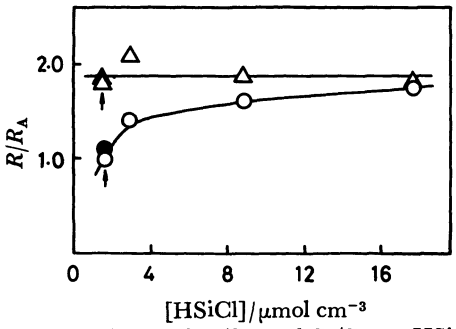

Fig. 3. Dependence of R_2/R_A and R_3/R_A on $HSiCl_3$ concentrations.
△: R_3/R_A, ○: R_2/R_A, ▲, ●: 17.6 μmol cm^{-3} of CO_2 was added. ↑: Formation of *trans*-Δ^2-C_5H_{10} was checked in this run. [*cis*-Δ^2-C_5H_{10}]=0.58, [CH_3COCH_3]=2.90 μmol cm^{-3}.

telomerization reactions involving $\cdot P_3$ or $\cdot A$. When reaction (9) is tentatively included in the mechanism, R_2/R_A is derived as in Eq. 10.

$$R_2/R_A = ([P]/[Ac])(k_4/k_2)\{1+(k_{-4}/k_5)[TCS]^{-1} + (k_9/k_5)([P]/[TCS])\}^{-1} \quad (10)$$

The result in Fig. 3 could be interpreted in terms of Eq. 10 if $k_9/k_5=2.5$ at 61 °C were assumed. But this ratio is clearly too large because alkyl radicals abstract H atoms from $HSiCl_3$[5] faster than they add to alkenes.[6]

Reaction (−4) would accompany *cis-trans* isomerization of 2-pentene. Under the condition indicated in Fig. 3, we checked the formation of *trans*-2-pentene and found that *cis-trans* rearrangement occurred ($R_{trans}=2.3\times10^{-4}$ μmol cm^{-3} h^{-1}) to the extent comparable to the difference between R_3 and R_2 ($R_3-R_2=3.8\times10^{-4}$ μmol cm^{-3} h^{-1}). Without $HSiCl_3$, however, the isomerization occurred ($R_{trans}=1.4\times10^{-4}$ μmol cm^{-3} h^{-1}) as might be expected from the study by Cundall and Davies.[7] Comparison of the rates of isomerization with and without $HSiCl_3$, shows clearly that $\cdot SiCl_3$ radicals enhance isomerization.

Based upon the fact that $\cdot P_2$ radicals decompose at moderate temperatures the values of k_{-4}/k_5 and k_4/k_2 were obtained by iterative calculation to satisfy the result in Fig. 2 (trial and error calculations were made).

$$\log(k_{-4}/k_5) = 4.89 - 19500/2.3RT$$
$$\log(k_4/k_2) = -0.54 + 2190/2.3RT \quad (11)$$

The curve for $\log R_2$ based upon Eq. 11 is shown in Fig. 2.

Induced Circular Dichroism of Two Chromophores Included in γ-Cyclodextrin

Nagao KOBAYASHI,* Yoshihiro HINO, Akihiko UENO,* and Tetsuo OSA
Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980

(Received October 22, 1982)

Synopsis. Induced circular dichroism (ICD) has suggested that γ-cyclodextrin (γ-CDx) accommodates two molecules of naphthalene and its derivatives with nearly axial inclusion but that it includes two Acridine Orange (AO) molecules with *S*-helicity.

In contrast to α- and β-CDxs which form mainly one host-one guest complexes with small arenes,[1] recent fluorescent studies have suggested that γ-CDx can include two arene molecules.[2-5] However, only a few studies have appeared on the ICD of two arene molecules in γ-CDx,[6-9] although ICD has been substantiated to be a powerful approarch to elucidate types of inclusion and configuration of arene molecules in CDxs.[10,11] Quite recently, we have shown that two pyrene molecules trapped in γ-CDx have *S*-helicity.[7,8] In this report, we describe the results for ICD of AO and naphthalene and its derivatives in the presence of γ-CDx.

Experimental

Materials. Naphthalene and its derivatives were recrystallized several times from appropriate solvents. 3,4-Bis[2-[2-(2-naphthyloxy)ethoxy]ethoxy]benzoic acid (**1**) was prepared in this laboratory.[12] AO (Chroma 1B-307, Germany) was purified according to the literature method.[13] γ-CDx was provided by Dr. N. Nakamura.

Measurements. Fluorescence spectra were recorded on a Shimadzu RF-500 spectrofluorophotometer, absorption spectra on a Shimadzu UV-360 spectrophotometer, and ICD spectra on a JASCO J-400X spectropolarimeter with a DP-500 data-processor at ambient temperature.

Results and Discussion

Figure 1 shows the absorption and ICD spectra of the γ-CDx–AO system. Absorption peaks appeared at 204, 230, 265, and 463 nm. Although the band position and shape of AO are known to be sensitive to temperature, ionic strength, and pH of the solution,[14,15] the present system seems to be composed mainly of dimeric AOs with a little amount of aggregated AOs. This is due to the fact that the bands of monomeric, dimeric, and aggregated AOs occur at *ca.* 490, 470, and 450 nm, respectively.[14,16] In the ICD spectrum, a curve with a change in sign from plus to minus and further to plus viewing from the longer wavelength side was observed in the visible region. As seen, two cross points well correspond to the absorption shoulder and/or peak. These facts indicate that this ICD originates from a dipole coupling between two AO molecules in γ-CDx. The situation is also the same for the UV region. Since the bands at 265 and 463 nm are both assigned to a polarization along the long axis,[17] the results of above ICD indicate that the two AO molecules are included in γ-CDx with *S*-helicity.

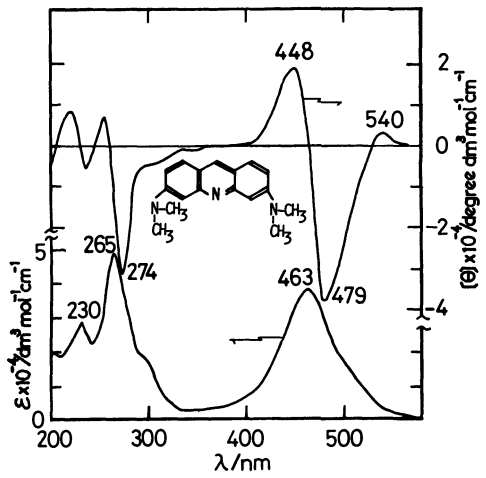

Fig. 1. Absorption (bottom) and ICD (top) spectra of AO in the presence of γ-CDx. [AO]/mol·l^{-1}=1×10^{-4}, [γ-CDx]/mol·l^{-1}=10^{-2}, Solvent: 0.5 mol·l^{-1} phosphate buffer, pH 6.1. Pathlength: 0.2 mm.

Two-guest inclusion of naphthalene and its derivatives into γ-CDx was examined similarly. The results for naphthalene and **1** are demonstrated in Figs. 2 and 3, respectively. As revealed, the intensity ratio of excimer/monomer fluorescence (ratio of emission at 396/334 nm) of naphthalene was larger for a system containing γ-CDx than that containing β-CDx, suggesting inclusion of more than one naphthalene in γ-CDx. Although a monomer fluorescence had still a comparable intensity as that of excimer, ICD spectrum was measured in the presence of γ-CDx. Simple peaks or troughs were

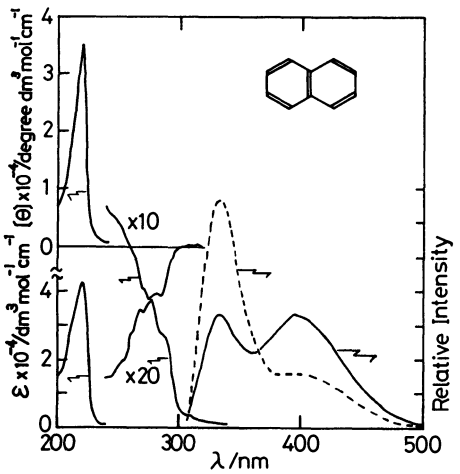

Fig. 2. Absorption (left bottom), ICD (left top), and fluorescence (right) spectra of naphthalene in the presence of γ-CDx (solid line) or β-CDx (dotted line). [naphthalene]/mol·l^{-1}=1.2×10^{-4},[γ-CDx]/mol·l^{-1}=[β-CDx]/mol·l^{-1}=10^{-2}. Solvent: 0.1 mol-l^{-1} phosphate buffer, pH 6.8. Pathlength: 10 mm except for 200—240 nm region (1 mm). In the fluorescence spectra, excitation was at 290 nm.

observed nearly accurately at the wavelengths where ^1L_b, ^1L_a, and ^1B_b transitions appear, but a dipole coupling type spectrum was not recognized.

To clarify the features in Fig. 2, **1** was used (Fig. 3).

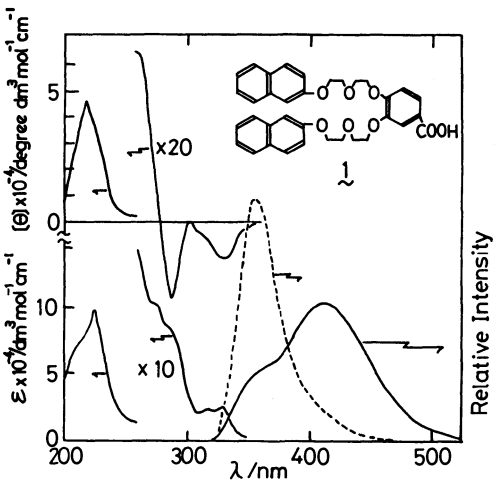

Fig. 3. Absorption (left bottom), ICD (left top), and fluorescence (right) spectra of **1** in the presence (solid line) or absence (dotted line) of γ-CDx. [**1**]/mol·l^{-1}= 1.1×10^{-4}, [γ-CDx]/mol·l^{-1}=10^{-2}. Solvent: 0.1 mol·l^{-1} borate buffer, pH 9.2. Pathlength: 10 mm except for 200—260 nm region (1 mm). In the fluorescence spectra, excitation was at 290 nm.

As shown, **1** showed only monomer fluorescence in the absence of γ-CDx. However, by the addition of γ-CDx, it revealed mainly excimer fluorescence alone, suggesting the inclusion of two naphthalene moieties. The ICD spectrum of this solution showed a single peak associated with the ^1B_b transition. For the interpretation of this phenomenon, two possibilities are deduced. One is that two naphthalene moieties are trapped with their long axes nearly parallel to each other, and another is that even two naphthalene moieties of **1** are not so much bulky for the large cavity of γ-CDx so that it may not have a fixed configuration to produce a clear dipole coupling type spectrum. However, the latter possibility may be small because free movement of the naphthalene moieties of **1** in γ-CDx is restricted by the alkyl chain connecting them.

After convincing the fair development of excimer fluorescence by the addition of γ-CDx, we measured also the ICD spectra of 1- or 2-naphthylacetic acid, 1- or 2-naphthoic acid, and 1- or 2-(naphthyloxy)acetic acid. However, in no case was found a dipole coupling type spectrum.

One plausible reason for the above difference in the ICD spectra between AO and naphthalene derivatives might be ascribed to the difference of the character of guest molecule themselves such as sizes and tendency toward aggregation.

Thus, the ICD spectroscopy coupled with electronic absorption or fluorescence spectroscopy has suggested that γ-CDx accepts two Acridine Orange molecules with *S*-helicity, but that it accommodates two naphthalene molecules with nearly axial inclusion.

We thank Dr. Y. Sato of this institute for his variable comments, and Dr. N. Nakamura (Japan Maize Products Co. Ltd.) for kindly providing γ-CDx. This research was partly supported by a Grant-in-Aid for Scientific Research No. 57771477 from the Ministry of Education, Science and Culture.

†Institute for Molecular Science, Myodaiji, Okazaki 444

(Received November 15, 1982)

Synopsis. From the measurements of the fluorescence lifetimes and the 0-1 emission maxima in solutions, it is concluded that the solvent dependence of the nonradiative transition rates of the lowest excited singlet states of 9-bromoanthracene and 9,10-dibromoanthracene is due to the different extent to which the lowest excited singlet and adjacent higher excited triplet states are stabilized by solvents.

The nonradiative process of the fluorescing state in anthracene derivatives has been studied extensively,[1,2] and it is well known that the fluorescence quantum yields of 9- and 9,10-substituted anthracenes in fluid media decrease as the temperature is increased. This temperature dependence has been attributed to thermally activated intersystem crossing (isc) from the lowest excited singlet state S_1 to an adjacent higher excited triplet state T_n.

Our direct measurements of the temperature dependence of the fluorescence lifetimes of 9-bromoanthracene (BA) and 9,10-dibromoanthracene (DBA)[2] have allowed the determination of the rate constant for isc in the form $k_{isc}=A_{isc}\exp(-\Delta E/kT)$, with activation energies of 600 and 1100 cm^{-1} for BA and DBA in 3-methylpentane, respectively.

From the measurements of the 0-1 emission maxima and of the fluorescence lifetimes by single photon counting method in solutions, Wu and Ware[3] have concluded that the solvent dependence of the nonradiative transition rate of the lowest excited singlet state in DBA is due to the different extent to which S_1 and T_n are stabilized by the solvent.

Since the S_1 lifetimes of BA are very short and the single photon counting method in subnanosecond region sometimes gives some errors, this article reports the results of the solvent effects on the S_1 lifetimes of BA and DBA using a streak camera by picosecond laser photolysis in order to see whether Wu and Ware's relation can generally be applied or not.

Experimental

9-Bromoanthracene (EP grade) was purchased from Tokyo Kasei Kogyo Co., Ltd., and 9,10-dibromoanthracene was synthesized by bromination of anthracene.[4] After repeated crystallization from methanol, both samples were purified by vacuum sublimation. G.R.-grade 3-methylpentane (Wako) and spectral-grade ethanol (Nakarai), diethyl ether (Merck) and all the other solvents (Dojin) were used without further purification. The sample solution were degassed by several freeze-pump-thaw cycles. By the excitation of the sample using the third harmonic (355 nm) with a pulse width of 15 ps from a mode-locked Nd^{3+}: YAG laser, the decay of $S_1\rightarrow S_0$ fluorescence was measured by a Hamamatsu C-979 streak camera with an S-20 cathode. The streak image was detected by a TV camera and treated by a Hamamatsu C-1098 microprocessor. Steady-state fluorescence spectra were taken with a Shimadzu RF-502 fluorescence spectrophotometer. All the experiments were carried out at room temperature (296 K) and the concentration of the sample was about 1×10^{-4} mol dm^{-3}.

Results and Discussion

A typical fluorescence decay of BA is shown in Fig. 1. The smooth curve (dotted line) in Fig. 1 is calculated by

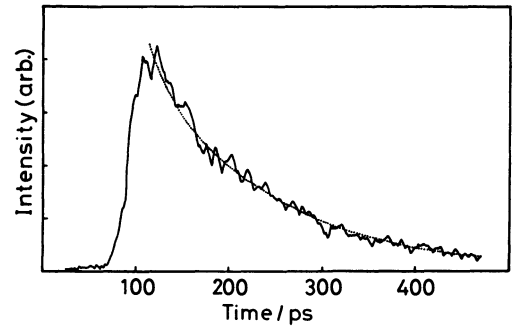

Fig. 1. Fluorescence decay curves of 9-bromoanthracene in acetonitrile at 296 K. ——: Observed curve by a streak camera, ……: simulated curve based on a single exponential decay with $k=6.25\times10^9$ s^{-1}.

a least-squares method assuming a single exponential decay of fluorescence. All the experimental fluorescence decays could be fitted with high precision to a single exponential decay function, that is, the average deviation for fitting to the experimental data was within $\pm0.3\%$ and the standard deviations of the best fit rate constants (k) were between 3 and 8%.

As the relative energy of the S_1 state, the wave number of the 0-1 emission band, $\bar{\nu}(0,1)$, of the fluorescence spectrum was taken instead of that of the 0-0 emission band, $\bar{\nu}(0,0)$, because $\bar{\nu}(0,1)$ could be determined more accurately. Table 1 gives the values of S_1 lifetimes ($\tau=k^{-1}$) and $\bar{\nu}(0,1)$ of BA and DBA.

Although the fluorescence lifetimes of DBA are consistent with those observed by Wu and Ware[3] and Cherkasov *et al.*,[5] the values of BA are an order of magnitude shorter than those observed by Cherkasov *et al.*[5] and Dreeskamp and Pabst.[6] This discrepancy is probably due to uncertainty of their single photon counting method in the subnanosecond region, because the fluorescence lifetimes of BA in acetonitrile are 0.16 ns by the present Nd^{3+} : YAG laser photolysis and 0.5 ns by our single photon counting method, the latter value being the lowest measurable value which the apparatus can give.

As have described in our previous paper,[2] the total rate of the S_1 decay process is expressed as

Table 1. Values of S_1 lifetimes and $\bar{\nu}(0,1)$ of BA and DBA in various solvents

	Solvent	BA		DBA	
		Lifetime τ/ps	$\bar{\nu}(0,1)$ / cm^{-1}	Lifetime τ/ns	$\bar{\nu}(0,1)$ / cm^{-1}
(1)	Hexane	113±6	24100	1.12±0.01	23220
(2)	Diethyl ether	124±8	24040	1.21±0.02	23180
(3)	3-Methylpentane	126	24050	1.11	23250
(4)	Cyclohexane	137	24010	1.46	23150
(5)	Methanol	145±2	24030	0.94±0.02	23220
(6)	Ethanol	148±3	24000	1.39	23170
(7)	Acetonitrile	160	23920	1.27±0.02	23150
(8)	Methylcyclohexane	203±5	24000	3.36	23120
(9)	Acetone	269±2	23920	1.41	23120

(14)	Chloroform	335	23780	2.73±0.02	22940
(15)	Bromobenzene	483±7	23570	3.67±0.14	22720
(16)	1,2-Dichloroethane	370	—	3.15	22960

$$k = k_r + A_{isc}\exp(-\Delta E/kT), \quad (1)$$

where k_r is the rate constant for the $S_1 \rightarrow S_0$ fluorescence, and the temperature-dependent component for the $S_1 \rightarrow T_n$ intersystem crossing is described by an Arrhenius term of frequency factor A_{isc} and activation energy ΔE.

Assuming the Arrhenius parameter A_{isc} is constant through the series of solvents, Wu and Ware[3] gave the following relation between activation energy and $\bar{\nu}(0,1)$ for DBA,

$$(\alpha-1)[\bar{\nu}(0,1)-\bar{\nu}_0(0,1)] = \Delta E - \Delta E_0, \quad (2)$$

where $\bar{\nu}_0(0,1)$ and ΔE_0 refer to a reference solution and α is the ratio of the solvent stabilization energies of the T_n state to that of the S_1 state, *i.e.*, $\alpha = 0.31 \pm 0.02$.

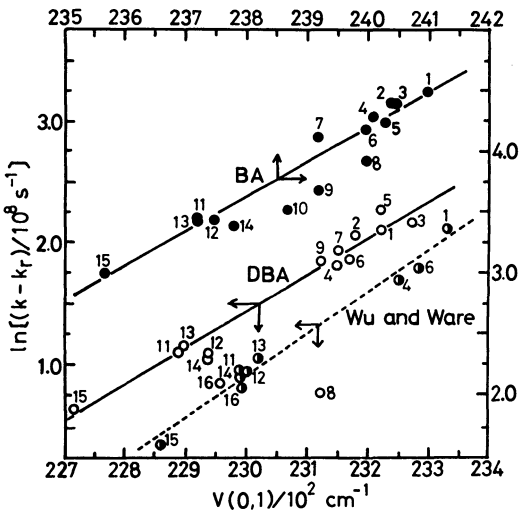

Fig. 2. Plots of $\ln[(k-k_r)/10^8\ s^{-1}]$ *vs.* $\bar{\nu}$ (0, 1). Numbers of the points refer to Table 1. Dotted line show the results of Wu and Ware for DBA.[3]

Plots of $\ln(k-k_r)$ *vs.* $\bar{\nu}(0,1)$ for BA and DBA are shown in Fig. 2 together with the result of Wu and Ware for DBA,[3] where k_r is the average of the radiative rate constants at 77 K in 3-methylpentane and EPA (ether/isopentane/ethanol=5 : 5 : 2 in volume ratio), that is, $k_r = 7.81 \times 10^7$ and $8.20 \times 10^7\ s^{-1}$ for BA and DBA, respectively.[2] It is obvious from Fig. 2 that all the experimental points lie reasonably close to a straight line. The values of α obtained by the least-squares method are 0.43±0.01 for BA and 0.39±0.06 for DBA, that is, the stabilization energy of T_n by solvents is about 40% to that of S_1 stabilization. Our values of α and $(k-k_r)$ for DBA is nearly equal to those obtained by Wu and Ware. As can be seen from Fig. 2, the solid line for DBA comes to the dotted line (Wu and Ware) by the horizontal shift of 1—2 nm. Thus, one can say that our result is identical with that obtained by Wu and Ware for DBA.

In conclusion, the relation obtained by Wu and Ware may be applicable to 9- and 9,10-substituted anthracenes who have activation energies in isc processes.

(Received January 22, 1983)

Synopsis. A graph-theoretical formula was derived for ring currents induced in a polycyclic conjugated system by a uniform magnetic field. Two advantages of this formula are that ring currents can be evaluated by inspecting a geometry of a conjugated system, and that they can be attributed to the individual π-electron rings.

In previous papers[1-6] we developed the theory of London (or ring-currents) diamagnetism[7-9] using graph-theoretical terms. This approach was found to be best suited for analyzing magnetic properties of a polycyclic conjugated system in conjunction with its structural features. We now extend our graph theory to uncover geometrical aspects of ring currents induced in a polycyclic system by a uniform magnetic field. Ring currents themselves were first formulated by Pople and McWeeny in 1958.[9-11]

We clarified before[2] that London (or ring-currents) susceptibility of a polycyclic conjugated system G, χ_G, can be partitioned exactly among the constituent π-electron rings, namely,

$$\chi_G = \sum_i^G \chi_i, \tag{1}$$

where χ_i is a susceptibility contribution from the ith π-electron ring, and i runs over all π-electron rings defined in Sachs' sense.[12] Explicitly, χ_i is expressed as[2]

$$\chi_i = -4\left(\frac{e}{c\hbar}\right)^2 \beta S_i^2 \sum_{j=1}^{n} \frac{P_{G-r_i}(X_j)}{P_G'(X_j)}. \tag{2}$$

Here, $P_G(X)$ is a characteristic polynomial for G; $P_G'(X)$ is a first derivative of $P_G(X)$ with respect to X; X_j is the jth largest root of the equation $P_G(X)=0$, *i.e.*, the jth orbital energy given relative to the carbon Coulomb integral and in units of β; n denotes the highest occupied orbital; r_i is the ith π-electron ring; G-r_i is a subsystem of G, obtained by deleting from G the ith π-electron ring and all π bonds incident to it; S_i is an area of the ith π-electron ring; and e, c, and $\hbar$ are the standard constants with these symbols.

The external magnetic field H provokes an induced moment M_G opposing it and given by the expression:

$$M_G = \chi_G H = \sum_i^G \chi_i H. \tag{3}$$

We define a partial moment of the ith π-electron ring by

$$M_i = \chi_i H. \tag{4}$$

Our hypothesis is that M_i arises from an induced ring current I_i circulating around the ith π-electron ring, *i.e.*,

$$M_i = \frac{I_i S_i}{c}. \tag{5}$$

The assumed ring current I_i is then expressible as

$$I_i = \frac{c\chi_i H}{S_i} = -4\frac{e^2}{c\hbar^2}\beta S_i H \sum_{j=1}^{n} \frac{P_{G-r_i}(X_j)}{P_G'(X_j)}. \tag{6}$$

When there are degenerate orbitals in G, Eq. 2 cannot be applied to them. We instead verified that four π electrons in doubly degenerate orbitals contribute to χ_i by the amount:[2]

$$\Delta\chi_i = -4\left(\frac{e}{c\hbar}\right)^2 \beta S_i^2 \times \frac{U(X_{j*})P_G'_{-r_i}(X_{j*}) - U'(X_{j*})P_{G-r_i}(X_{j*})}{U(X_{j*})^2}, \tag{7}$$

where X_{j*} is a degenerate orbital energy, and

$$U(X) = \frac{P_G(X)}{(X-X_{j*})^2}. \tag{8}$$

Owing to Eq. 7, we can still define a partial moment for each π-electron ring. A ring current induced in benzene, I_0, is calculated as

$$I_0 = -\frac{2}{9}\frac{e^2}{c\hbar^2}\beta S_0 H, \tag{9}$$

where S_0 is an area of the benzene ring.

Finally, a ring current induced in a given π-electron ring of a polycyclic system is estimated in units of I_0 as

$$\frac{I_i}{I_0} = 18\frac{S_i}{S_0}\sum_{j=1}^{n}\frac{P_G'_{-r_i}(X_j)}{P_G'(X_j)}. \tag{10}$$

Ring currents thus calculated for all π-electron rings of four compounds are presented in Fig. 1. We assumed that

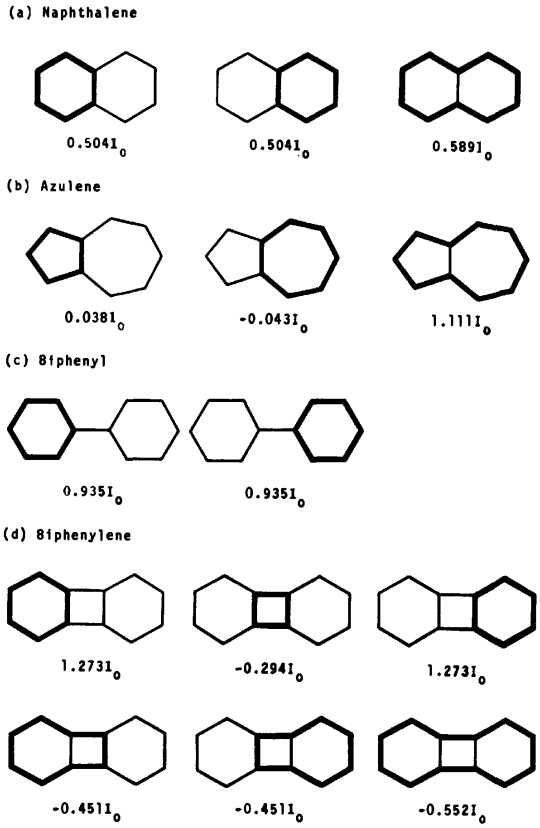

Fig. 1. Constituent π-electron rings and ring currents.

these compounds are structurally combinations of regular polygons with sides equal to a standard carbon-carbon π-bond length. Summing up all ring currents flowing through a given π bond, we obtain an overall current induced there. Overall currents estimated in this manner were found to be exactly the same as those reported by Pople,[10] McWeeny,[13] and Memory.[14] Mathematically, this way of reasoning is identical with that of Pople.[9,10] In this sense, our postulate given as Eq. 5 seems to be quite reasonable. It is to be noted that at the limit of zero field strength ring currents induced in different π-electron rings do not interact with each other, and that the overall current flowing at each π bond is simply an additive sum of individual ring currents defined by Eq. 6.

Salem[9] stated that, for naphthalene and azulene, the central π bond hardly perturbs the annulenic conjugated system formed by the perimeter of ten sp^2-carbon atoms. However, our analysis revealed that the ring current induced in each six-membered ring of naphthalene is comparable in magnitude with that induced in the peripheral ten-membered ring. It is now obvious that the central π bond plays an important role in determining the magnitude of the peripheral current. A weak paramagnetic ring current is predicted along the seven-membered ring of azulene.

In summary, two advantages of our graph theory are that ring currents can be evaluated easily by inspecting the geometry of a cyclic conjugated system, and that they can be assigned uniquely to the individual π-electron rings. We no longer need to expand the field-dependent secular determinant into a polynomial in X and H. The present approach thus presents a novel way of analyzing structural aspects of ring currents and related proton chemical shifts.

Kinetics of Oxidative Coupling of Phenols. Oxidation of Guaiacol by Alkaline Hexacyanoferrate(III)

Sukham Nabakishwar SINGH, Mitra BHATTACHARJEE, and Mahendra Kumar MAHANTI*

Department of Chemistry, North-Eastern Hill University, Shillong 793 003, India

(Received May 25, 1982)

Synopsis. The reaction between guaiacol and alkaline hexacyanoferrate(III), at constant ionic strength, gave a coupled product, 3:3′-dimethoxydiphenoquinone. The rate of the reaction was dependent on the first orders of the concentrations of substrate, oxidant, and alkali. The rate determining step involved the formation of a radical intermediate, which was detected by ESR spectroscopy.

Kinetic studies on the oxidation of phenols by hexacyanoferrate(III) in alkaline medium have not received much attention.[1,2] The oxidation of phenols gives rise to radicals, which can yield coupled products. Guaiacol has been chosen for purposes of oxidation by alkaline hexacyanoferrate(III). A survey of the literature revealed that the oxidation of guaiacol had yielded coupled products.[3-5]

Experimental

IR spectra were recorded on an IR-297(Perkin-Elmer) spectrophotometer; NMR spectra on an EM-390(Varian) 90 MHz NMR spectrometer; ESR spectra on an E-4(Varian) EPR spectrometer.

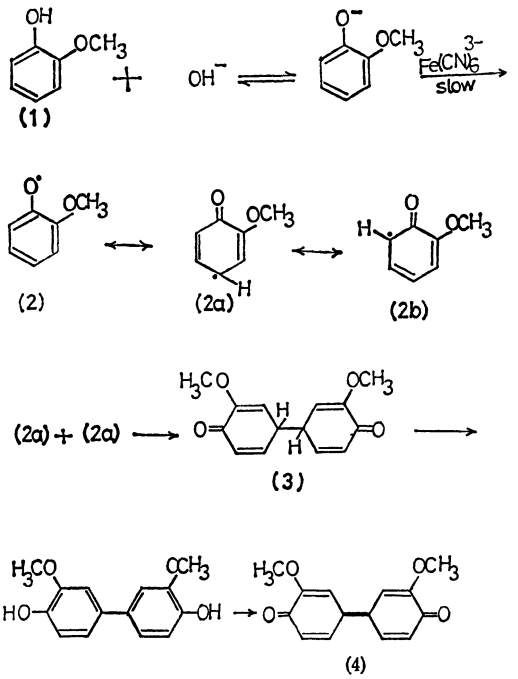
Materials. Guaiacol(SISCO) was distilled before use (bp 204 °C), and its purity confirmed by IR analysis.[6] Methanol (E. Merck) was distilled before use. $K_3Fe(CN)_6$, $K_4Fe(CN)_6$, and NaOH were IDPL samples. $HClO_4$ (E. Merck, 70%) was neutralized with NaOH; the solution was concentrated, and the crystals of $NaClO_4$ obtained were filtered, recrystallized from water, and dried over silica gel under vacuum. The ionic strength of the medium was maintained by the addition of the requisite amount of $NaClO_4$.

Methods. Solutions of guaiacol in aqueous methanol, and $K_3Fe(CN)_6$ in methanol, NaOH, $NaClO_4$, and water were separately thermostated at 30 °C for 3 h under nitrogen, and then mixed in equal volumes. The progress of the reaction was followed by monitoring the disappearance of $[Fe(CN)_6]^{3-}$, spectrophotometrically.[7]

Stoichiometry. Reaction mixtures containing an excess of oxidant were allowed to react to completion, and the $[Fe(CN)_6]^{3-}$ which was left was analyzed, spectrophotometrically. The results gave a ratio of substrate to oxidant according to the equation:

$$2C_7H_8O_2 + 4[Fe(CN)_6]^{3-} + OH^- \longrightarrow C_{14}H_{12}O_4 + 4[Fe(CN)_6]^{4-} + H_2O + 3H^+.$$

Product Analysis. Guaiacol (2.0 g) in 70% methanol (v/v) was mixed with 11.0 g of $K_3Fe(CN)_6$ containing NaOH (0.05 M†) and 70% methanol(v/v), and the mixture refluxed at 60 °C for 3 h under nitrogen. After cooling and filtration, removal of the solvent gave a red residue (0.072 g). The insoluble portion of the mixture was washed with $CHCl_3$, and after removal of $CHCl_3$, a red residue (1.615 g) was obtained. The mp of both these residues was 245 °C. IR analysis of both these residues, in $CHCl_3$, showed them to be identical with 3:3′-dimethoxydiphenoquinone, **4**. A sharp band at 1640 cm^{-1} was obtained, corresponding to the carbonyl stretching of the C=O groups in two rings of an extended quinonoid structure.[8] The $\nu(OCH_3)$ band at 1020 cm^{-1} was also present in the IR spectrum of **4**, indicating that the OCH_3 group was unaffected by the oxidation. The NMR spectrum of **4**, in $CHCl_3$, (internal standard TMS, sweep width 10 ppm), gave a peak at 6.1 τ (OCH_3), and four doublets in the vinylic proton region at 3.20 τ, 3.10 τ, 2.30 τ, and 2.20 τ.



Scheme 1.

Results and Discussion

Kinetic Results. The rate data are shown in Table 1. Under the present experimental conditions, the rate law can be expressed as:

$$\text{Rate} = -\frac{d[Fe(CN)_6]^{3-}}{dt} = k_{obsd}[\text{Guaiacol}][Fe(CN)_6^{3-}][OH^-]. \quad (1)$$

The pseudo first order rate constant, k_{obsd}, was determined by keeping the concentrations of two of the three reactants constant, and was calculated from the equation:[9]

$$k_{obsd} = \frac{2.303}{t}\log\frac{D_0}{D_t}. \quad (2)$$

The effect of temperature was studied (Table 1) and the activation parameters evaluated: $E=23.0\pm0.8$ kJ mol^{-1}; $A=9.5\pm0.5$ s^{-1}; $\Delta H^{\neq}=20.4\pm0.8$ kJ mol^{-1}; $\Delta S^{\neq}=-28.0\pm1.2$ J K^{-1} mol^{-1}.

† 1 M=1 mol dm^{-3}.

Table 1. Rate data for the oxidation of guaiacol

[Guaiacol] 10^3 M	$[K_3Fe(CN)_6]$ 10^4 M	[NaOH] 10^2 M	Temp/°C (±0.1 °C)	$10^3 \times k_{obsd}$ s^{-1}
5.0	10.0	5.0	30.0	1.05
10.0	10.0	5.0	30.0	2.09
20.0	10.0	5.0	30.0	4.20
25.0	10.0	5.0	30.0	5.24
5.0	2.5	5.0	30.0	1.06
5.0	5.0	5.0	30.0	1.10
5.0	7.5	5.0	30.0	1.05
5.0	10.0	2.5	30.0	0.52
5.0	10.0	7.5	30.0	1.57
5.0	10.0	10.0	30.0	2.10
5.0	10.0	5.0	35.0	1.43
5.0	10.0	5.0	40.0	1.86
5.0	10.0	5.0	45.0	2.05
5.0	10.0	5.0	50.0	2.68

Methanol=70%(v/v); μ=0.50 M; all values of rate constants were the average of two or more experiments, with agreements being ±1.5% or better.

The variation of the ionic strength (0.10 M to 0.50 M $NaClO_4$) and the addition of $K_4Fe(CN)_6$ in the concentration range 1.0×10^{-4} M to 1.0×10^{-3} M, did not have any effect on the rate of the reaction.

Increasing proportions of methanol from 60% to 75% (v/v) decreased the rate constant $10^3\times k_{obsd}/s^{-1}$ from 1.41 to 0.90 at [guaiacol]$=5\times10^{-3}$ M, $[K_3Fe(CN)_6]=1\times10^{-3}$ M, [NaOH]$=5\times10^{-2}$ M, μ=0.50 M and temp=30 °C. From the linear plot of $\log k_{obsd}$ *versus* $1/D$, the value of r, the distance of approach between the ions, was calculated from the Scatchard equation[10] to be 3.1 Å, which was of the right order of magnitude.

Radical Intermediate. Phenols are known to give rise to stable radicals, which have been detected and characterized.[11,12] In this investigation, the ESR spectrum of the radical obtained from the oxidation of guaiacol was a spectrum consisting of 9 lines, which were rather broad. This spectrum was interpreted in a manner similar to that in an earlier investigation.[13] For the present, it can be concluded that the rate determining step of the reaction involved the formation of a radical intermediate, which could be stabilized by resonance. It was further observed that this radical intermediate showed a typical absorption band at 1560 cm^{-1} in the IR spectrum. In general, phenoxyl radicals have been characterized by their electronic spectra.[14,15]

Mechanism. Pummerer *et al.*[16,17] had postulated a free phenoxyl radical as the first intermediate in the reactions of phenol coupling. The observed coupling positions, ortho and para, show that a free phenoxyl radical would be reactive only on the oxygen and on the ortho and para carbon atoms of guaiacol. The resonance structures for the radical would symbolize a high density of the unpaired electron at these positions. Guaiacol can be oxidized to the corresponding phenoxyl radical, **2**↔**2a**↔**2b**. Combination of **2a** +**2a** would result in the formation of the dimer, **3**, which would undergo tautomerization rapidly in methanol, and would be oxidized further to yield the extended quinone, **4**. No other intermediate product(s) could be recovered. The mechanism is shown in Scheme 1.

We thank the technical staff of the Regional Sophisticated Instrumentation Centre, IIT, Madras, for recording the ESR spectra. Financial assistance to one of us(MB) from the CSIR, Government of India, is gratefully acknowledged.

The Consecutive Determination of Serum Ammonia and Leucine Amino Peptidase with an Ammonia Gas-sensing Electrode

Masakatsu HATO,* Yukio SHIMURA, Tomiko AKIYAMA, and Hiroko NAKAYAMA
Research Institute for Polymers and Textiles, Yatabehigashi 1-1-4, Tsukuba-gun, Ibaraki-305
(Received October 29, 1982)

Synopsis. A simple method for the consecutive determination of serum ammonia and the activity of leucine amino peptidase (LAP) with an ammonia gas-sensing electrode is described. The values determined by the present method agree with those determined by conventional methods within 6%.

The serum ammonia and LAP level is of clinical significance; *i.e.*, elevated levels have been found in a number of conditions of the liver.[1] Many procedures have been proposed for the determination of serum ammonia.[2-5] However, these methods have various shortcomings;[6] *e.g.*, the ammonia concentration is considerably affected by the diffusion conditions, such as the temperature and the diffusion time. Nitrogenous compounds other than ammonia are destroyed by alkali during the diffusion period, liberating ammonia and giving erroneously high ammonia values. The method proposed by Dienst,[7] which was later improved by Fenton,[8] seems to be complicating.[1] More recently, Okuda *et al.*[9] have developed a usable method. However, their method needs a fairly large amount of serum (0.5—1.0 ml)[10] and requires the deproteinization of the serum and a long incubation time.

In the previous paper, we have reported on the use of an ammonia gas-sensing electrode (abbreviated to an NH_3-electrode) in a kinetic assay of serum LAP,[11,12] where the time course of ammonia production in the reaction, L-leucine amide $\xrightarrow{\text{LAP}}$ L-leucine+NH_3, is directly monitored in buffered serum by means of an NH_3-electrode. The LAP activity thus determined agreed well with that determined by the conventional methods.[12,16] This suggests that, with a minor modification of the procedure, the method can be extended to the determination of serum ammonia as well. In the present communication, the consecutive determination of serum ammonia and LAP with an NH_3-electrode is described.

Experimental

Apparatus and Procedures. The experimental apparatus is illustrated in Fig. 1a. An Orion model 95-10 NH_3-electrode (a) was dipped in a buffer (1.5 ml; 0.2 M TrisHCl pH=8.5, 10 μM NH_4Cl) stirred by a magnetic stirrer (c). The whole apparatus was kept at 25±0.1 °C by circulating thermostated water through a glass jacket (d). The electrode was pre-equilibrated with the buffer. At time $t=0$, male rabbit serum was added through an inlet (e) and the electromotive force (E) was recorded as a function of the time by means of an Orion model 801 mV meter and a Yokogawa 3047 strip-chart recorder. After the equilibrium E value was reached, 0.1 ml of a 110 mM L-leucine amide buffer (a substrate for LAP, 0.2 M TrisHCl pH=8.5) was added to the buffered serum in order to initiate the LAP reaction; the E was recorded as a function of time. The pH was constant throughout the experiment. To examie the accuracy of the present method, the serum ammonia was also determined by means of an Ammonia Test Wako® (Wako Chem. Co.). The LAP activity was also determined by the method of Hjemdahl-Monsen *et al.*[12,16]

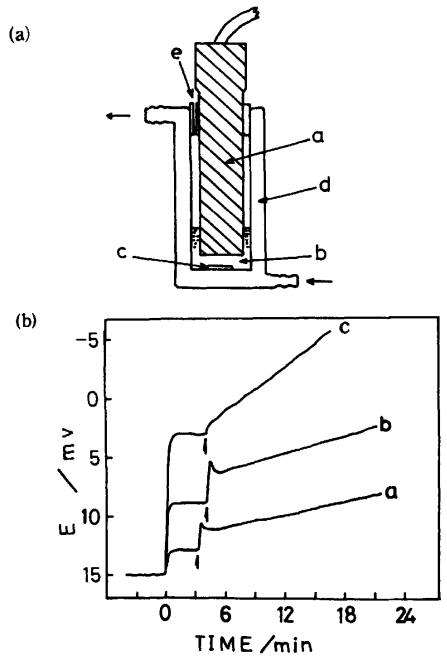

Fig. 1.(a) Schematic illustration of experimental apparatus.
(b) Typical electrode response to serum ammonia and LAP as a function of volume of male rabbit serum (25 °C).

Results and Discussion

Electrode Response to Serum Ammonia and LAP Reaction. Figure 1b shows a typical electrode response to serum ammonia and LAP. With the addition of 10 μl (Curve a), 20 μl (Curve b), and 50 μl (Curve c) of serum at time $t=0$, the E decreased steeply and attained equilibrium values within 1—2 min. The substrate buffer was then added at the times indicated by arrows (+). The initial irregular changes in the E were attributable to the electrode response to the ammonia present in L-leucine amide. The E decreased continuously with time. This reflects the continuous increase in the ammonia concentration due to the LAP reaction in the reaction mixture. The E *vs.* time curves were converted into concentration *vs.* time curves *via* an E *vs.* log (concentration) curve (Fig. 2). The activity of LAP was calculated from the slope of the concentration *vs.* time curve.[12] Measurable activity range is estimated to be from 0.1 μM·min^{-1} to 20 μM·min^{-1}.[11,12] The addition of NH_4Cl in advance to the buffer is important not only to eliminate errors caused by the contamination of ammonia (from the atmosphere or from the

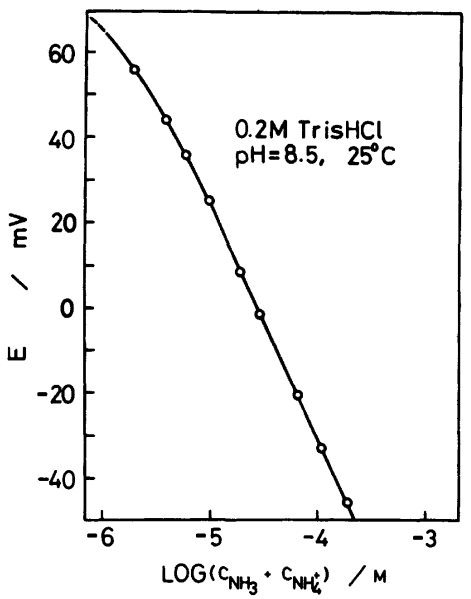

Fig. 2. Electromotive force (E) of the electrode as a function of total ammoniacal concentration (calibration curve).
1 M=1 mol·dm^{-3}. 1 μM=1.4 μg·NH_3-nistrogen/dl.

human body), but also to increase the electrode-response rate.[11] When there is no need to determine the LAP activity, several serum samples can be analyzed consecutively. Five different samples could be analyzed within 7—8 min. The serum ammonia concentration C was calculated from a calibration curve (Fig. 2) and from the equation;

$$C = [(V_i+v)C_f - C_iV_i]/v, \quad (1)$$

where V_i, v, C_i, and C_f are the initial volume of the buffer (or buffered serum), the volume of the added serum, and the initial and final ammonia concentration of the reaction mixture respectively. The measurable ammonia concentration range is estimated to be from 70 to at least 10^4 μgNH_3-nitrogen/dl at $v/V_i=0.01$ and from 20 to at least 10^4 μgNH_3-nitrogen/dl at $v/V_i=0.1$.

Accuracy and Stability of the Electrode Response.

Table 1. Comparison of the serum ammonia and LAP determined by the present method with those determined by conventional methods

Sample	Serum ammonia (μg·NH_3-nitrogen/dl)		LAP activity (μM/min[d])	
	This method[a]	O-F method[b]	This method[a]	H-P-R method[c]
1	134	128	—	—
2	97	92	—	—
3	168	171	0.21	0.20
4	170	175	0.62	0.65

a) Average of 2 measurements. The relative standard deviation for three identical measurements was 6%. b) Average of three measurements[10] c) Average of two measurements[12,16] d) 1 M=1 mol·dm^{-3}.

The serum ammonia and LAP activity determined by the present method are compared with those determined by conventional methods in Table 1. The analytical values agreed with each other within 6%. This indicates that the present method is effective in the determination of serum ammonia and LAP.

Practical difficulties accompanying an NH_3-electrode, *e.g.*, the clogging of the gas-permeable membrane in biological fluid, have often been pointed out.[13,14] However, provided a volume fraction of serum ranging from 0.005—0.25 was used, the electrode response in the buffered serum was stable for at least 3 weeks (10 assays/day). When the fraction exceeded 0.3, errors tended to increase because of the adsorption of serum components on the membrane. Similar effects have also been observed for the case of urea determination in whole blood with an NH_3-electrode based urea electrode.[15] When the fraction was less than 0.005, the electrode response became too small to get accurate results. The NH_3-electrode seems to have no serious practical limitations when employed in moderately diluted serum.

The advantages of the present method are: (1) The consecutive determination of serum ammonia and LAP is possible. (2) Only a small amount of serum is needed; *e.g.*, 10—50 μl is sufficient. (3) A long color-development time for the conventional method is unnecessary. (4) Strong acidic and alkaline reagents are unnecessary, and therefore the procedures for waste disposal are simple.

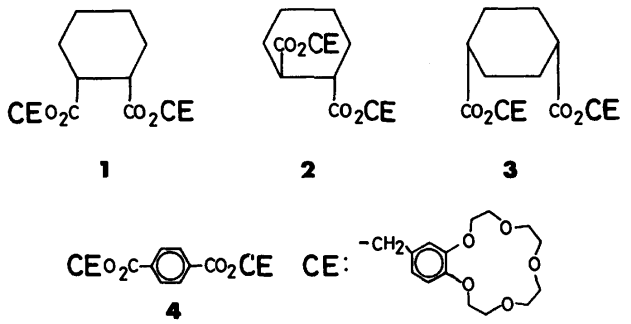
Potassium-selectivities of Bis(benzo-15-crown-5) Derivatives Obtained from Cyclohexanedicarboxylic Acids

Keiichi KIMURA,* Atsuo ISHIKAWA, Hiroshi TAMURA, and Toshiyuki SHONO*
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-oka 2-1, Suita, Osaka 565
(Received November 25, 1982)

Synopsis. Several bis(benzo-15-crown-5) derivatives containing a cyclohexane or benzene ring in the bridge chain were synthesized as neutral carriers of coated-wire potassium-selective electrodes. The bis(benzocrown ether) derivative obtained from *cis*-1,2-cyclohexanedicarboxylic acid was found to be outstandingly potassium-selective.

Macrobicyclic polyethers containing benzo-15-crown-5 moieties at the end of a short bridge chain, which are commonly referred to as bis(benzo-15-crown-5) derivatives, have received considerable attention because of their attractive cation-binding properties.[1-5] They can form stable sandwich-type 2 : 1 crown ether ring to cation complexes with K^+ intramolecularly, which results in high K^+-selectivity of them on binding alkali and alkaline earth metal ions. Accordingly, some of the bis(benzo-15-crown-5) derivatives have turned out to be good neutral carriers for poly(vinyl chloride) (PVC) membrane K^+-selective electrodes,[6-8] although their K^+-selectivities depend more or less upon the configuration of bis(benzocrown ether) derivatives[7] and the length of the chain connecting two crown ether moieties.[6]

We would like to report here the K^+-selectivities of bis(benzo-15-crown-5) derivatives containing a cyclohexane or benzene ring in the bridge chain in the coated-wire type of K^+-selective electrodes based on them.



Experimental

Chemicals. Bis(benzo-15-crown-5) derivatives **1** through **4** were synthesized by the reaction of 4'-bromomethylbenzo-15-crown-5 with appropriate dicarboxylic acid potassium salts in acetonitrile, in a similar way to that reported previously.[9] The purification of them was performed by gel permeation chromatography. (**1**—**3**: colorless oil; **4**: colorless crystal, mp 100—102 °C) The plasticizer, *o*-nitrophenyl octyl ether (NPOE), was prepared in a usual manner,[10] and then purified by repeated distillation.

Electrode Construction. The coated-wire ion-selective electrodes were constructed using a silver wire, according to the procedure reported elsewhere.[11] The coating solution consists of 15 mg crown ether, 200 mg NPOE, 100 mg PVC, and 3 ml tetrahydrofuran. The external reference electrode was a standard calomel electrode with a 0.1 M (1 M=1 mol/dm^3) NH_4NO_3 electrolyte bridge. No special conditioning of the ion-selective electrodes was performed before use.

Measurement. All of the emf measurements were made at 25±0.1 °C. Standard K^+ aqueous solutions for calibration plots were obtained by gradual dilution of 1 M KCl solution. Selectivity coefficients (k_{KM}) were determined by a mixed solution method, by taking a constant background of an interfering ion and varying K^+ concentration. The constant concentrations of Na^+, Rb^+, Cs^+, and NH_4^+ are 1×10^{-1}, 1×10^{-3}, 1×10^{-3}, and 1×10^{-2} M, respectively.

Results and Discussion

Three kinds of cyclohexanedicarboxylate-type bis(benzo-15-crown-5) derivatives **1**, **2**, and **3**, which are derived from *cis*-1,2-, *trans*-1,2-, and *cis*-1,4-cyclohexanedicarboxylic acids, respectively, were synthesized for the purpose of obtaining lipophilic and ion-selective neutral carriers for K^+-selective electrodes. Terephthalate-type bis(crown ether) derivative **4** was also prepared for comparison. The K^+-selectivities of the bis(benzo-15-crown-5) derivatives were elucidated by measuring the electrochemical selectivity of coated-wire ion-selective electrodes based on them, which can be easily made up owing to the simple construction.

The electrode properties are summarized in Table 1. The electrodes of bis(crown ether) derivatives **1** and **3** showed a linear response to K^+ activity in the range 10^{-4}—10^{-1} M, the slope of calibration plots being 55 and 58 mV per decade of activity change at 25 °C. The electrodes based on **2** and **4** exhibited a little poorer

Table 1. Electrode properties of coated-wire K^+-selective electrode based on bis(benzo-15-crown-5) derivatives **1** through **4**

Bis(crown ether)	Maximal[a] slope mV/decade	Range[b] pK	k_{KM}			
			Na^+	Rb^+	Cs^+	NH_4^+
1	55	4—1	5×10^{-4}	5×10^{-2}	5×10^{-3}	2×10^{-1}
2	46	4—1	3×10^{-1}	1×10^{-1}	3×10^{-2}	1×10^{-2}
3	58	4—1	3×10^{-3}	2×10^{-1}	5×10^{-2}	3×10^{-1}
4	51	4—2	2×10^{-3}	3×10^{-1}	8×10^{-2}	5×10^{-2}

a) emf change in ten-time change of K^+ activity. b) pK=−log [K^+].

response than that of **1** and **3**.

It should be noted that bis(benzo-15-crown-5) derivatives **1**, **3**, and **4** are better in the K^+-selectivity over Na^+ than **2**. Particularly, the electrode of **1**, *cis*-cyclohexanedicarboxylate type of bis(benzo-15-crown-5) derivative, possesses an excellent k_{KNa} value, 5×10^{-4}. It has been reported previously that a *cis*-bis(benzo-15-crown-5) derivative obtained from maleic acid is easy to form sandwich-type complexes with K^+ intramolecularly, being rather K^+-selective compared to the corresponding *trans* isomer derived from fumaric acid.[3,7] This is also the case in these cyclohexanedicarboxylate type of bis(benzo-15-crown-5) derivatives. That is to say, the bis(benzo-15-crown-5) derivatives containing *cis* configuration, **1** and **3**, are much more K^+-selective than that containing *trans* configuration, **2**. Also, the k_{KNa} value for the electrode based on **1** is about one order of magnitude smaller than that of **3**, implying that the two crown ether moieties in the latter bis(benzo-15-crown-5) derivative are a little too far apart for the formation of the stable intramolecular sandwich-type K^+ complexes. The terephthalate unit of bis(crown ether) derivative **4** may be unfavorable again due to the rigidity of benzene ring.

Thus, the bis(benzo-15-crown-5) derivative obtained from *cis*-1,2-cyclohexanedicarboxylic acid is a highly K^+-selective neutral carrier for the ion-selective electrode. The response time of the electrode was within 10 s on measuring by an incremental method. In the stability and reproducibility of the emf reading, the electrode is similar to that based on the previous bis(benzo-15-crown-5) derivative.[11] Bis(benzo-15-crown-5) derivative **1** is surely superior to the previous ones[6,7] in the lipophilicity which is definitely required as the neutral carrier of the ion-selective electrodes, although they all seem to resemble in the K^+-selectivity.

Enthalpies of Transfer of Monovalent Ions from Water to Water-Acetonitrile Mixtures

Kiyoshi MIYAJI* and Kenichi MORINAGA
Department of Chemistry, Faculty of Science, Saitama University, Urawa 338
(Received December 3, 1982)

Synopsis. Ionic enthalpies of transfer from water to water–acetonitrile mixtures were estimated for Na^+, K^+, Rb^+, Cs^+, Ag^+, Tl^+, Me_4N^+, Et_4N^+, n-Pr_4N^+, n-Bu_4N^+, Ph_4As^+, Ph_4B^-, Cl^-, Br^-, I^-, NCS^-, NO_3^-, ClO_4^-, and picrate ion on the basis of the assumption $\Delta H_t^\circ(Ph_4As^+)=\Delta H_t^\circ(Ph_4B^-)$.

Several papers are concerned with enthalpies of solution in water–aprotic solvent mixtures.[1] In connection with the conductivity measurement,[2] we measured enthalpies of solution for twenty-three electrolytes in water–acetonitrile (W–AN) mixtures.

Experimental

Tetraphenylarsonium salts were recrystallyzed from acetone.[3] Tetraalkylammonium salts were purified according to the literature.[4] The other salts were of reagent grade and purified by the standard methods. The method for purification of solvents were reported elsewhere.[2] Enthalpies of solution were measured at 25.00±0.02 °C by using a heat-exchange type calorimeter.[5] They were independent of electrolyte concentration (10^{-2}—10^{-3} mol dm^{-3}) within experimental error. Usually three to five measurements were made and the average of values agreeing within ±0.4 kJ mol^{-1} was taken to be the standard enthalpies of solution (ΔH_s°).

Results and Discussion

The ΔH_s° values in Table 1 agree with those in the literature[6] within ±0.7 kJ mol^{-1} in aqueous solutions except for CsI and Et_4NPi (Pi=picrate) and within ±1.1 kJ mol^{-1} in acetonitrile solutions except for Me_4NBr, respectively. The ΔH_t° values for ions estimated on the basis of the assumption $\Delta H_t^\circ(Ph_4As^+)=\Delta H_t^\circ(Ph_4B^-)$ are given in Table 2. The differences between the ΔH_t°(W→AN) values and those in the literature[3,6] are less than ±1.0 kJ mol^{-1} for Na^+, K^+, Me_4N^+, Et_4N^+, n-Pr_4N^+, n-Bu_4N^+, Ph_4As^+, Ph_4B^-, Br^-, and I^- ions, and $-2._7$, $+1._5$, and $+2._0$ kJ mol^{-1} for Rb^+, Cl^-, and ClO_4^- ions, respectively.

As Cox *et al.* have suggested,[1e] there is no doubt that a rapid decrease in ΔH_t° for Ag^+ ion in W-rich region is due to the selective solvation by acetonitrile and an increase in ΔH_t° for Na^+ and Cl^- ions in AN-rich region is due to the selective hydration. Since the specific interaction of Ag^+ ion with acetonitrile at x_{AN} (mole fraction of acetonitrile)=0—1.0 has been established,[8] a slight increase in ΔH_t° at $x_{AN}=0.3$—0.8 and a decrease at $x_{AN}=0.8$—1.0 can be concluded to be characteristic of the type of ion, the cosphere of which is enriched with more acetonitrile than water relative to the bulk composition of solvent mixtures. The ΔH_t° values for alkali metal ions at $x_{AN}=0.2$ follow the order: $Li^+>Na^+>K^+>Rb^+\approx Cs^+$. This is consistent with that of decreasing ΔH_t°-increase in AN-rich region. A marked decrease in ΔH_t° at $x_{AN}=0.2$—0.8 for Li^+ ion can be concluded to be characteristic of a selectively hydrated ion. An endothermic maximum for n-Bu_4N^+, Ph_4As^+, and Ph_4B^- ions at $x_{AN}=0.05$—0.1 is common to a hydrophobic structure-making ion in W–aprotic solvent mixtures.[1a,1g] In contrast to the positive values for n-Bu_4N^+ ion at $x_{AN}=0$—1.0, those for Ph_4As^+ ion are negative at $x_{AN}=0.15$—1.0. The extent of endothermicity for tetraalkylammonium ions decreases with decreasing size, and Me_4N^+ ion behaves like alkali metal ions.[9]

Anions show a variety of ΔH_t° dependences: The ΔH_t° values for all the anions reach a maximum at $x_{AN}=0.15$—0.3, decrease in an intermediate region, and, except for ClO_4^- and Pi^- ions, reach a minimum at $x_{AN}=0.7$—0.95. From the ΔH_t°-increase in AN-rich

a) The ionic values for Li^+ ion were calculated from ΔH_t° for $LiClO_4$[1b]. b) Ref. 6.

region the order in decreasing hydration can be concluded: $Cl^- > NO_3^- > Br^- > NCS^- > I^- > Pi^- > ClO_4^-$. The x_{AN} value corresponding to ΔH_t° minimum shifts to a higher value from Cl^- through Br^- to I^-. However, the ΔH_t° maximum appears at nearly equal x_{AN}. The extent of endothermicity follows the order: $Cl^- > Br^- > I^-$. As compared with aqueous solution, the solvent structure at x_{AN}=*ca.* 0.3 may be the least favorable for the hydration of halide ions owing to the destruction of water lattice caused by the addition of acetonitrile.[10] In contrast to the positive ΔH_t° values for Cl^- and Br^- ions at x_{AN}=0—1.0, those for I^- ion are negative at x_{AN}=0—0.1 and 0.6—1.0. The behavior of NCS^- ion as a softer ion than I^- ion at x_{AN}=0—0.95 and as a harder ion at x_{AN}=0.95—1.0 may be related to the fact that linear NCS^- ion has two kinds of terminal atoms. The behavior of NO_3^- ion resembles that of Br^- ion. The ΔH_t° values for Pi^- ion suggest that it interacts weakly with either water or acetonitrile.

Electrocatalytic Reaction of $Fe^{2+/3+}$ Aqua Ions by $[Mo(CN)_8]^{4-/3-}$ Complexes

Keiichi SATO,† Takeo OHSAKA, Hiroaki MATSUDA,† and Noboru OYAMA*

Department of Applied Chemistry for Resources, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184

†*Department of Electronic Chemistry, Tokyo Institute of Technology, Midori-ku, Yokohama 227*

(Received January 24, 1983)

Synopsis. The catalysis of the oxidation of Fe^{2+} aqua ion by $[Mo(CN)_8]^{3-}$ ion, which is formed on an electrode surface, and that of the reduction of Fe^{3+} aqua ion by $[Mo(CN)_8]^{4-}$ ion were examined by means of hydrodynamic voltammetry at a rotating disk pyrolytic graphite electrode. The rate constants of the electron transfer cross-reaction of the $Fe^{2+}/[Mo(CN)_8]^{3-}$ and $Fe^{3+}/[Mo(CN)_8]^{4-}$ systems were estimated to be $(7.0\pm0.5)\times10^6$ and $(6.6\pm0.5)\times10^6$ $cm^3\ mol^{-1}\ s^{-1}$, respectively.

In previous papers[1,2] we have examined the catalysis of the electrode process of $Fe^{2+/3+}$ redox couple by $[Mo(CN)_8]^{4-/3-}$ complexes bound electrostatically to graphite electrodes coated with the protonated poly(4-vinylpyridine) (PVP) film. It has been shown therein that $[Mo(CN)_8]^{4-/3-}$ complexes are strongly incorporated into the protonated PVP film and the resulting metalated film electrode can catalyze both the oxidation of Fe^{2+} aqua ion and the reduction of Fe^{3+} aqua ion present in a bulk solution. The catalytic reaction of the $Fe^{2+}/[Mo(CN)_8]^{3-}$ and $Fe^{3+}/[Mo(CN)_8]^{4-}$ systems can be considered to be simple and outer-sphere electron transfer cross-reaction. However, no kinetic study on the catalytic reaction of both systems in a bulk solution at an uncoated electrode has been reported yet.

In this paper, we will thus examine the catalysis of the oxidation of Fe^{2+} ion by $[Mo(CN)_8]^{3-}$ ion, which is formed on a graphite electrode surface, and that of the reduction of Fe^{3+} ion by $[Mo(CN)_8]^{4-}$ ion by means of hydrodynamic voltammetry at a rotating disk pyrolytic graphite electrode.

Experimental

Electrochemical apparatus and the experimental procedures have been described previously.[1-3,8] The exposed area of each electrode was 0.17 cm^2. Potassium octacyanomolybdate(IV) dihydrate ($K_4[Mo(CN)_8]\cdot2H_2O$) was synthesized according to the standard procedure.[4] Solutions were freed of air with prepurified argon prior to the electrochemical measurements. Experiments were conducted at 25 °C. Potentials are reported with respect to a sodium chloride saturated calomel electrode (SSCE).

Results and Discussion

Current-potential curves A, B, and C shown in Fig. 1 demonstrate typical steady-state current-potential curves obtained at a rotating disk graphite electrode in an each 0.2 M CF_3COONa solution containing 0.2 mM $[Mo(CN)_8]^{4-}$, 2 mM Fe^{2+} and 0.2 mM $[Mo(CN)_8]^{4-}$+2 mM Fe^{2+} ions. When the current-potential curves were measured at a graphite electrode in the solution containing both 0.2 mM $[Mo(CN)_8]^{4-}$ and 2 mM Fe^{2+} ions, two waves were observed and each of their half-wave potentials were about 0.5 and 0.7 V *vs.* SSCE. The first wave observed at about 0.5 V corresponds to the oxidation of $[Mo(CN)_8]^{4-}$ ion. The conventional log-plot of $\log\{i/(i-i_{lim})\}$ against E (where i_{lim} is the limiting current and i is the current at any potential,

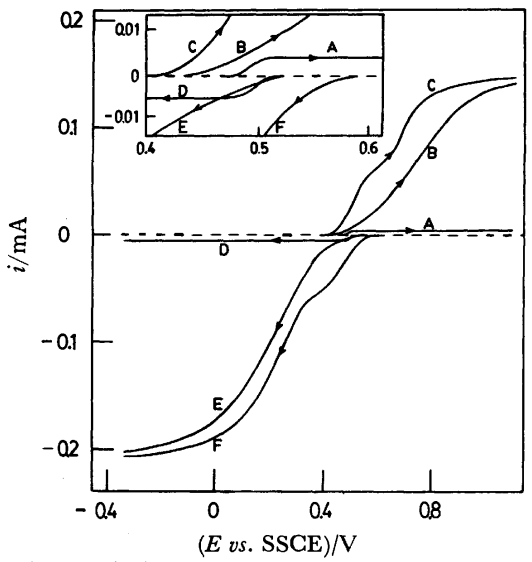

Fig. 1. Typical steady-state current-potential curves demonstrating the catalysis of the oxidation of Fe^{2+} ion by $[Mo(CN)_8]^{3-}$ ion and of the reduction of Fe^{3+} ion by $[Mo(CN)_8]^{4-}$ ion at rotating disk pyrolytic graphite electrodes.
Oxidation of (A): 0.2 mM $[Mo(CN)_8]^{4-}$; (B): 2 mM Fe^{2+}; (C): 0.2 mM $[Mo(CN)_8]^{4-}$+2 mM Fe^{2+}; Reduction of (D): 0.2 mM $[Mo(CN)_8]^{3-}$; (E): 2 mM Fe^{3+}; (F): 0.2 mM $[Mo(CN)_8]^{3-}$ +2 mM Fe^{3+}.
Supporting electrolyte: 0.2 M CF_3COONa-CF_3COOH (pH 1.5). Electrode rotation rate: 800 min^{-1}.

E) of the current-potential curve A yields straight lines with the reciprocal slopes of 59±1 mV, in accordance with the fact that the first wave is the reversible one-electron oxidation wave. From the similar log-plot of the current-potential curve B, the oxidation of Fe^{2+} ion was proved to be close to irreversible. The standard heterogeneous rate constant for the oxidation of Fe^{2+} ion at a graphite electrode is 6×10^{-5} cm s^{-1}.[8] As can readily be seen from the comparison of the limiting currents of the steady-state current-potential curves A and C shown in Fig. 1, the limiting current for the oxidation of $[Mo(CN)_8]^{4-}$ ion in the solution containing Fe^{2+} ion is several times larger than the corresponding limiting current in the absence of Fe^{2+} ion. As the concentration of Fe^{2+} ion increased under the constant concentration of $[Mo(CN)_8]^{4-}$ ion, the height of the first wave increased, but the half-wave potential at about 0.5 V remained constant. At the constant concentrations of Fe^{2+} and $[Mo(CN)_8]^{4-}$ ions, the height of the first wave unchanged with changes in the rotation rate between 400 and 3600 min^{-1}, but the total limiting current was proportional to the square root of the rotation rate. These facts suggest the catalytic oxidation of Fe^{2+} ion by $[Mo(CN)_8]^{3-}$ ion, which is formed on an electrode surface by the electrochemical oxidation of the $[Mo(CN)_8]^{4-}$ ion present in a bulk solution.

Thus, the overall electrode reaction can be expressed by the following scheme:

$$[Mo(CN)_8]^{4-} - e \rightleftharpoons [Mo(CN)_8]^{3-} \quad (1)$$

$$[Mo(CN)_8]^{3-} + Fe^{2+} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} [Mo(CN)_8]^{4+} + Fe^{3+}. \quad (2)$$

Under the conditions that the concentration of Fe^{2+} ion is so high compared with that of $[Mo(CN)_8]^{4-}$ ion, it can be assumed that the concentration Fe^{2+} ion remains constant during the whole electrochemical process. Thus, we obtain Eq. 3 which characterizes the catalytic current, i_{cat}, of the reaction process expressed by Eqs. 1 and 2, together with the conditions expressed by Eq. 5 which must be fulfilled to maintain the validity of Eq. 3:[5,6]

$$\frac{i_{cat}}{i_L} = \frac{\sqrt{\lambda}}{\tanh\sqrt{\lambda}}, \quad (3)$$

with

$$\lambda = (1+K)k_1 C_{Fe^{2+}}\delta^2/D, \quad (4)$$

and

$$\frac{C_{Fe^{2+}}}{C_{[Mo(CN)_8]^{3-}}} \gg \frac{i_{cat}}{i_L}, \quad (5)$$

where i_L is the Levich current[5] for the oxidation of $[Mo(CN)_8]^{4-}$ ion, k_1 and k_2 are the forward and backward rate constants of reaction 2, respectively, the equilibrium constant, K, is k_2/k_1, $C_{[Mo(CN)_8]^{3-}}$ and $C_{Fe^{2+}}$ denote the concentrations of $[Mo(CN)_8]^{3-}$ and Fe^{2+} ions, respectively, D is the common value of the diffusion coefficients of $[Mo(CN)_8]^{4-}$ and $[Mo(CN)_8]^{3-}$ ions and δ is the steady-state thickness of the diffusion layer ($\delta = 1.62\, D^{1/3}\nu^{1/6}\omega^{-1/2}$, ν: the kinematic viscosity, ω: the electrode rotation rate).

Figure 2 shows the plots of the ratio i_{cat}/i_L against the inverse square root of the electrode rotation rate at the various concentrations of Fe^{2+} and $[Mo(CN)_8]^{4-}$ ions, together with the similar plots for the $Fe^{3+}/[Mo(CN)_8]^{4-}$ system. The value of k_1 was evaluated by curve fitting method and estimated to be $(7.0\pm0.5)\times10^6$ cm^3 mol^{-1} s^{-1} by using $\nu = 1\times10^{-2}$ cm^2 s^{-1},[7] $K=4.7$ (calculated using the standard redox potentials,[1] *i.e.*, 0.49 and 0.53 V *vs.* SSCE for $Fe^{2+/3+}$ and $[Mo(CN)_8]^{4-/3-}$ couples, respectively) and $D = 5.0\times10^{-6}$ cm^2 s^{-1}. The value of D was the average value of the diffusion coefficients for $[Mo(CN)_8]^{4-}$ and $[Mo(CN)_8]^{3-}$ ions obtained from the limiting currents of the steady-state current-potential curves by using the Levich equation.[5] The solid lines shown in Fig. 2 represent the best fit curves calculated by using Eq. 3, which are seen to reproduce the experimental results. As can easily be seen from Fig. 2, the plots of i_{cat}/i_L *vs.* $\omega^{-1/2}$ give the straight lines whose slopes are proportional to the square root of the concentration of Fe^{2+} ion, indicating that in this case the r.h.s. of Eq. 3 can be reduced to $\sqrt{\lambda}$, *i.e.*, $\tanh\sqrt{\lambda}\approx1$, as can be expected for a fast catalytic reaction. By introducing the obtained value of k_1 and other known values of D, ν, ω and $C_{Fe^{2+}}$ into the right-hand side of the inequality (Eq. 5), it was confirmed that this inequality is fulfilled under the experimental conditions employed.

From the current-potential curves E and F shown in Fig. 1, it is also apparent that the reduction of Fe^{3+} ion present in a bulk solution is catalyzed by the $[Mo(CN)_8]^{4-}$ ion formed on a graphite electrode surface. By means of the same method as described above, the rate constant (k_2) of the electron transfer cross-reaction between Fe^{3+} and $[Mo(CN)_8]^{4-}$ ions was estimated to be $(6.6\pm0.5)\times10^6$ cm^3 mol^{-1} s^{-1}.

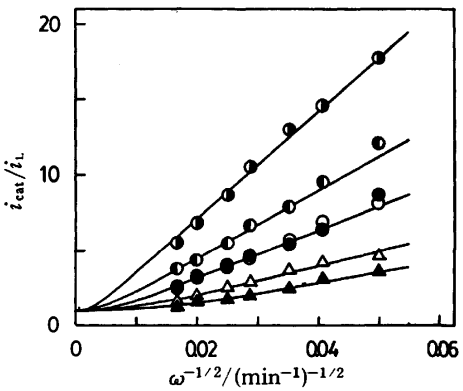

Fig. 2. Plot of the ratio, i_{cat}/i_L, against the inverse square root of the rotation rate, $\omega^{-1/2}$.
○: 0.2 mM $[Mo(CN)_8]^{4-}$+2 mM Fe^{2+}; ◐: 0.2 mM $[Mo(CN)_8]^{4-}$ +4 mM Fe^{2+}; ◑: 0.2 mM $[Mo(CN)_8]^{4-}$ +10 mM Fe^{2+}; ●: 0.05 mM $[Mo(CN)_8]^{4-}$+2 mM Fe^{2+}; ▲: 0.2 mM $[Mo(CN)_8]^{3-}$+2 mM Fe^{3+}; △: 0.2 mM$[Mo(CN)_8]^{3-}$+4 mM Fe^{3+}.
Supporting electrolyte and scan rate of electrode potential are the same as in Fig. 1. Solid lines are the best fit curves calculated by Eq. 3.

The values of k_1 and k_2 are by 1 to 2 orders of magnitude larger than those ($k_1 = 3.8\times10^5$ and $k_2 = 1.0\times10^4$ cm^3 mol^{-1} s^{-1}) reported in a previous paper,[2] where the $[Mo(CN)_8]^{4-}$ or $[Mo(CN)_8]^{3-}$ ion was bound electrostatically to the protonated poly(4-vinylpyridine) (PVP) film on a graphite electrode and Fe^{2+} or Fe^{3+} ion was present in a bulk solution. The similar results have been previously reported in the case of the catalysis of the oxidation of Fe^{2+} ion by the $[IrCl_6]^{2-}$ ion bound to the protonated PVP film on an electrode or present in a bulk solution.[8] This may be mainly attributed to the differences in the reaction media in which the rate constants were measured.

Solid State Reactions of 2,4-Dinitrotoluene. Detection and Semiquantitative Determination of Indole, Diphenylamine, and *p*-Dimethylaminobenzaldehyde

Syed Ashfaq NABI, Ali MOHAMMAD, and Pushkin Mohammad QURESHI*

Department of Chemistry, Aligarh Muslim University, Aligarh-202001, India

(Received May 24, 1982)

Synopsis. Solid state colour reactions of 2,4-dinitrotoluene have been used for the selective detection of organic compounds and semiquantitative determination of indole, *p*-dimethylaminobenzaldehyde and diphenylamine in a glass capillary. Phloroglucinol and tryptophan do not interfere with the determination of indole. A glass wool plug modification makes the selective test almost specific for indole.

2,4-Dinitrotoluene (DNT) gives interesting colours with a number of compounds.[1-5] A recent study has proposed the use of DNT for the detection of amines.[6] In this note we present methods for the solid state detection and semiquantitative determination of some organic compounds.

Reagents. DNT (Fluka) and *p*-dimethylaminobenzaldehyde (*p*-DAB) (E. Merck) were used. All other reagents were reagent grade and used without further purification. Apparatus: VSU-2(GDR) reflectance spectrophotometer and Perkin Elmer 621 spectrometer were used for obtaining UV-visible reflectance and IR transmission spectra respectively.

Procedure

Solid State Detection. About 5—10 mg of the solid (or 5—10 μl for liquids) was rubbed with several mg of powdered DNT in the depression of a white spot plate. This was to check the colours in neutral medium. To see the effect of acidic or basic medium sodium carbonate or oxalic acid was added to the test substance and DNT; the content was again rubbed and the colour observed was then noted.

Detection by the Capillary Solid State Tests. The well powdered reagent was introduced from one end of a 10 cm capillary (3 mm bore) with the help of an iron rod. The test material was introduced similarly from another end till the two materials came in close contact with one another. Both the ends of the capillary were closed with the help of two cotton plugs. The capillary was kept in an oven at 42±2 °C for one hour. This temperature was chosen as some of the solids used in this study melted at 45 °C. The colour of the product formed at the junction was recorded. No product gave any fluorescence under a UV lamp.

The limits of identification of indole, *p*-DAB, and diphenylamine (DPA) were determined by mixing weighed amounts of well powdered sodium carbonate as a diluent. The mixture was triturated in a small mortar till it became homogeneous. Such a mixture is termed as a synthetic mixture in this paper. The synthetic mixtures contained 1—10% of the test substance. Tests were conducted in the capillary as described above. The synthetic mixture containing the largest percentage of the test substance was tried first and the colour at the junction noted. The procedure was repeated with synthetic mixtures containing lower percentages of the test material till no colour was produced at the junction. In this way the limit of identification was determined for each test substance.

Semiquantitative Determination by Capillary Solid State Tests. Approximately 400 mg of the reagent was introduced from one end of the capillary. Synthetic mixtures containing 10—100% of the test material were then introduced as described above. Three types of synthetic mixtures were tried *i.e.* those diluted with sodium carbonate oxalic acid and starch. The set of capillaries containing different percentages of indole or DPA were heated in an oven at 45± 2 °C for 1 h. This temperature was chosen as indole melts at 52 °C and DPA at 54 °C. As *p*-DAB melts at 75 °C the capillaries containing *p*-DAB were allowed to react at 65 °C for 1 h. The length of the coloured boundary formed at the junction was proportional to the concentration of the test material.

Semiquantitative Determination of Indole in the Presence of Tryptophan and Phloroglucinol. For the semiquantitative determination of indole in phloroglucinol or tryptophan mixtures, various synthetic mixtures of indole were prepared using phloroglucinol or tryptophan as diluents. These two substances were chosen as they generally interfere in the tests of indole.[7] The capillaries containing the reagent and the synthetic mixture were kept at 45±2 °C for 1 h. Capillaries were filled with synthetic mixtures containing 10—100% of indole. The same slope was obtained when a calibration curve for indole was prepared by using potassium chloride or sodium carbonate as a diluent instead of phloroglucinol or tryptophan (Fig. 1). This implies that the latter two compounds do not interfere with the determination of indole. The starch plot does not pass through the origin, hence starch should not be used as a diluent. Similar studies show that DPA can be determined in the presence of *N,N'*-diphenylthiourea and tryptophan.

Glass Wool Plug Modification for Selective Determination of Indole. When a glass wool plug was introduced between DNT and the test samples, a yellow colour was obtained at the DNT-glass wool boundary only in the case of indole. None of the substances in Table 1 and their mix-

a) Y: Yellow, B: Brown, BR: Brick red, O: Orange, Bl: Blue, OR: Orange red.
b) TR: Thin ring.

tures gave any colour. The test is therefore specific for indole.

Results and Discussion

The colours obtained by direct trituration of test material with DNT are given in Table 1.

The colour reactions with DNT were not altered when performed in the presence of oxalic acid or sodium carbonate. The colour reactions of DNT were studied with representative members of aliphatic amines, phenols, substituted phenols, ketones, aldehydes, ureas, sugars, amino acids, acids, alcohols, hydrocarbons, and their derivatives, and ethers. No substance except those reported in Table 1 gave any colour.

As benzidine gives a characteristic colour with DNT it was detected by triturating with DNT at 35 °C in the presence of phloroglucinol, tryptophan, *p*-DAB, brucine, DPA, *p*-chlorobenzaldehyde, *o*- or *m*-nitroaniline, 2-hydroxy-3-methylbenzaldehyde, maltose, glucose, phenylthiourea, citric acid, nicotinic acid, and *p*-toluidine.

The limits of identification for indole, *p*-DAB and DPA by the capillary solid state test are 7.7, 2.3, and 1.9 μg respectively. The limit of identification for indole when a glass wool gap of 4 mm was introduced between the reagent and indole is 155 μg. Each point in Fig. 1 is an average of five readings with precision and accuracy of 3—4%.

Of the 138 compounds studied, only aromatic amines, phenols, naphthols, indole, *p*-DAC, brucine, and 8-quinolinol gave coloured reactions with DNT.

The UV, visible, and IR spectra of the compounds formed by mixing DNT with DPA, *p*-DAB, or indole

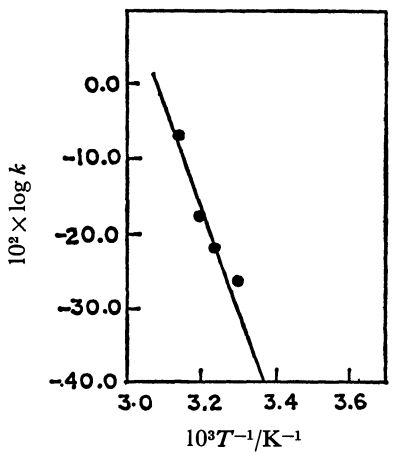

Fig. 2. Dependence of reaction rate on temperature for the DNT–DPA solid-state reaction, whereby:
$$\xi = k \log t,$$
where t is time in h, and ξ is length of coloured boundary.

are in consonance with the formation of weak charge transfer complexes.[8-14)]

The coloured boundary was found to increase with time and temperature. Thus a plot of $\log k$ *vs.* $1/T$ obtained for the DNT–DPA reaction is given in Fig. 2. The plot was used in another connection that is to obtain the energy of activation of the DNT–DPA solid-state reaction.[15)] Similar plots are expected for the DNT–*p*-DAB and DNT–indole reactions.

The authors thank Prof. W. Rahman for research facilities. The C. S. I. R. (India) is thanked for financial assistance.

Polarographic Study of Mixed Ligand (*o*-Mercaptobenzoate–Citrate) Complexes of Cadmium(II), Lead(II), and Thallium(I)

Keval C. GUPTA* and Kalpana K. SHARMA

Post Graduate Department of Chemistry, Govt. College, Kota (Raj), India

(Received July 12, 1982)

Synopsis. The mixed ligand complex formation of *o*-mercaptobenzoic acid and citric acid with Cd(II), Pb (II), and Tl(I) in aqueous KNO_3 ($\mu=1.0$ mol dm^{-3}) solutions containing Triton X-100 (0.001%) has been investigated by polarography. It was shown that only one mixed ligand entity MA_iX_j is formed, where i is two for Cd (II) and one for Tl(I) j is one for all complexes and A and X are the *o*-mercaptobenzoate and citrate ligands respectively. The stability constants have been evaluated.

o-Mercaptobenzoic acid, which figures prominently in the disscussion of sulfur containing ligands has a wide variety of applications in biological, pharmaceutical and analytical fields, such sulfur-containing compounds provide two co-ordination sites *viz.* –COOH and –SH groups. Most of the earlier workers have studied the complexation by using these compounds as simple ligands. Polarography of the *o*-mercaptobenzoic acid in aqueous methanol and dioxone has been studied by K. C. Gupta and Tejinder Kaur.[1] As a part of our investigations on the polarographic study of mixed ligand complexes of sulfur containing organic compounds in combination with several metal ions, the present study of mixed ligand (*o*-mercaptobenzoate and citrate) complexes with Cd(II), Pb(II), and Tl(I), has been initiated, for which no reference could be traced out in the literature. The composition and stability constants of the complexes formed have been studied by polarographic technique.

Experimental

o-Mercaptobenzoic acid (95%, Evan's Chemetics, Inc., New York) and citric acid (B.D.H. AnalaR) as their sodium salts were used as complexing agents. All other reagents used were also of AnalaR (B.D.H.) grade. Stock solutions were prepared in doubly-distilled air-free conductivity-water. Triton X-100 (0.001%) was used as maximum suppressor and KNO_3 ($\mu=1.0$ mol dm^{-3}) as supporting electrolyte. A southern manual polarograph (Surrey, England) with scalmp galvanometer was used for recording current voltage curves. The capillary characterstics in KNO_3 ($\mu=1.0$ mol dm^{-3}) at *Ed.e*$=-0.7$ V in conjuction with respect to SCE were $m^{2/3}t^{1/6}=2.4436$ mg$^{2/3}$ s$^{-1/2}$ ($h=45$ cm). All measurements were done with the cell immersed in thermostatic bath. Dissolved air was removed by bubbling hydrogen through the cell and the necessory corrections for the IR drop and charging current were made as usual.

Results and Discussion

The formation of each mixed ligand complex was studied at 30 °C by recording polarograms of two different sets.

Set I: 1.0 mM Cd $(NO_3)_2$ or Pb $(NO_3)_2$ or Tl NO_3, 0.001% Triton X-100 and KNO_3 ($\mu=1.0$ mol dm^{-3}) with constant citrate concentration ($C_X=40.0\times10^{-3}$ mol dm^{-3}) and varying concentration of *o*-mercaptobenzoate ($C_A=10.0\times10^{-3}$ mol dm^{-3} to 80.0×10^{-3} mol dm^{-3}).

Set II: 1.0 mM Cd $(NO_3)_2$ or Pb $(NO_3)_2$ or Tl NO_3, 0.001% Triton X-100 and KNO_3 ($\mu=1.0$ mol dm^{-3}) with constant *o*-mercaptobenzoate ($C_A=40.0\times10^{-3}$ mol dm^{-3}) and varying concentration of citrate ($C_X=10.0\times10^{-3}$ mol dm^{-3} to 80.0×10^{-3} mol dm^{-3}).

All the plots of $\log(i/(id-i))$ *versus* $-Ed.e.$ yielded straight lines with slopes, which agree with the theoretical value corresponding to $n=2$ for Cd(II) and Pb(II) system and $n=1$ for TI(I) system respectively. The mean values of the slopes for two different series were 0.0302 and 0.0297 for Cd^{2+}, 0.0299 and 0.0301 for Pb^{2+} 0.0589 and 0.0599 for Tl^+ system, showing the reversibility of the reduction. Linear plots of id *versus* $h^{1/2}$ passing through the origin, established the diffusion-controlled nature in each case. The $E_{1/2}$ values from the log plots of the above mentioned c-v curves and corresponding diffusion current values have been recorded (Tables 1a, 1b, and 1c). The $E_{1/2}$ values were found to shift towards more negative values with increasing concentration of complexing agents, showing the complex formation.

Souchay and Faucherre[2] derived an equation where a metal ion complex with two kinds of ligand species simultaneously in solution. If the complexing reaction of the following type is considered.

$$M + iA + jX \rightarrow MA_iX_j \qquad (1)$$

With the restriction that single mixed ligand entity MA_iX_j is formed, then the shift in the $E_{1/2}$ of the polarographic wave of the metal ion as a function of the concentration of added reagents A and X is given by

$$\Delta E_{1/2} = \frac{2.303RT}{nF}\log\left(\frac{D_{free}}{D_{Comp}}\right)^{1/2} - \frac{2.303RT}{nF}\log K_{MA_iX_j} - i\frac{2.303RT}{nF}\log C_A - j\frac{2.303RT}{nF}\log C_X. \qquad (2)$$

The ratio D_{free}/D_{Comp} was obtained from the values of the limiting current. From plots of $\Delta E_{1/2}$ *versus* $\log C_A$ with C_X kept constant and $\Delta E_{1/2}$ *versus* $\log C_X$ with C_A kept constant, values for "i" and "j" can be obtained by intersect method because on differentiation.

$$\left(\frac{\partial(\Delta E_{1/2})}{\partial(\log C_A)}\right)_{C_X} = -\frac{2.303RT}{nF} \qquad (3)$$

$$\left(\frac{\partial(\Delta E_{1/2})}{\partial(\log C_X)}\right)_{C_A} = -\frac{2.303RT}{nF} \qquad (4)$$

Plots of (I) $\Delta E_{1/2}$ *versus* C_A (C_X kept constant), (II) $\Delta E_{1/2}$ *versus* $\log C_X$ (C_A kept constant) yielded straight lines. Figure 1, curves I and II, for Cd^{2+}, curves I′ and II′ for Pb^{2+}, curves I″ and II″ for Tl^+ systems and thus establish the formation of a single mixed ligand entity MA_iX_j. The coordination numbers i

and j of ligands A and X were determined from the plot (I) and (II) at 30 °C and found to be i=2.18 for Cd^{2+} 2.05 for Pb^{2+} and 0.94 for Tl^{+} respectively. Integral values of "i" and "j" were used in the calculation of the stability constants $K_{MA_iX_j}$, using Eq. 2 and were found to be 14.023 for Cd^{2+}, 13.988 for Pb^{2+} and 3.757 for Tl^{+} respectively. The present investigation suggests the formation of only one kind of mixed ligand species $[CdA_2X]^{-5}$, $[PbA_2X]^{-5}$, $[TlAX]^{-4}$ with mixed ligand (*o*-mercaptobenzoate–citrate) system.

The authors wish to express their sincere thanks to prof. K. G. Sing, Head of the Chemistry Department and to prof. R. S. Bhargava, Principal, for providing research fascilities.

Photochemical Reaction of *S*-Alkyl 3-Oxobutanethioate

Tadashi HASEGAWA,* Toshio SHIMIZU, Kazuhiko IWASAKI, and Shōshichi OGUCHI
Department of Chemistry, Tokyo Gakugei University, Nukuikitamachi, Koganeishi, Tokyo 184
(Received September 6, 1982)

Synopsis. Irradiation of *S*-alkyl 3-oxobutanethioate (**1**) in benzene or ethanol yielded the disulfide **2**. Irradiation of *S*-alkyl α-bromothioacetate also gave the disulfide **2**. The photochemical reaction of the 3-oxobutanethioate **1** involves the Norrish Type I reaction followed by rapid fragmentation of the radical $\cdot CH_2COSR$ to the thiyl radical **5**.

The Norrish Type I reaction of ketones has been thoroughly investigated[1] and work has also been done on the photochemistry of α-substituted β-dicarbonyl compounds.[2] However, β-dicarbonyl compounds which possess no α-substituents are inert toward the Type I reaction.[3,4] We report here that *S*-alkyl 3-oxobutanethioates **1**, which possess no α-substituents, undergo the Type I reaction to give the disulfides **2**, but no thioacetates **6**.

When a benzene solution of *S*-propyl 3-oxobutanethioate (**1a**) was irradiated under nitrogen with a 450 W high-pressure mercury lamp through a Pyrex filter, dipropyl disulfide (**2a**) was obtained in 26% yield. Similarly, irradiation of the 3-oxobutanethioates **1b**—**e** under the same conditions gave the corresponding disulfides **2b**—**e**. In these cases no *S*-alkyl thioacetates, which are expected to be produced through the Type I reaction, and no thiolactones, which are expected to be formed *via* δ-hydrogen abstraction by ketone carbonyl, were detected.

Formation of the disulfide **2** can be explained in terms of the Type I reaction of the 3-oxobutanethioate **1** followed by the fragmentation of the radical $\cdot CH_2COSR$ (**3**) to the thiyl radical **5** (path A).

An alternative path B, which involves the direct cleavage of the sulfur-acyl bond, may be considered. The sulfur-acyl bond of the excited enethiol esters cleaves homolitically to give enethiyl radicals.[5] However, the path B seems to be improbable because the direct or acetone-sensitized irradiation of *S*-propyl thioacetate **6a** in benzene gave no disulfides. More evidence for exclusion of the path B mechanism has been obtained. Loveridge *et al.* reported that irradiation of *S*-phenyl thioacetate in benzene gave diphenyl disulfide; however, no products were obtained when the thioacetate was irradiated in alcohols.[5b] Their results prompted us to investigate the photoreaction of the 3-oxobutanethioate **1** in alcohols. Irradiation of *S*-phenyl 3-oxobutanethioate (**1e**) in ethanol also gave the disulfide **2e** in 22% yield. Similarly, irradiation of the 3-oxobutanethioate **1b** in ethanol gave the disulfide **2b** in 14% yield. These results indicate that the mechanism of the photoreaction of 3-oxobutanethioate **1** is different from that of the photolysis of the enethiol esters. Therefore, path B, which involves the direct sulfur-acyl bond cleavage, seems to be excluded.

TABLE 1. THE YIELDS OF THE DISULFIDE **2** IN THE PHOTOLYSIS OF **1** AND **8**

Compound	Solvent	Yield/% of **2**[a]
1a	PhH	26
1b	PhH	59
	EtOH	14

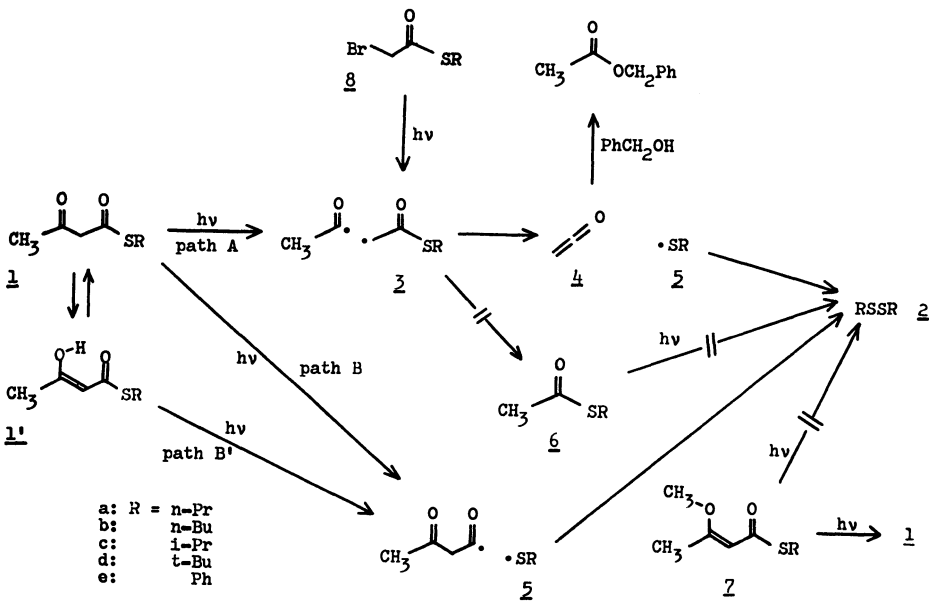
1e	PhH	49
	EtOH	22
8b	PhH	37
8e	EtOH	19

a) Conversion yield.



Scheme 1.

The other pathway which involves the direct cleavage of the sulfur-acyl bond from the enol form of the 3-oxobutanethioates may be considered (path B'). The 3-oxobutanethioates **1** exhibited keto-enol tautomerism. The 3-oxobutanethioate **1b** contained 71% of the keto form and 29% of the enol form in deuterated chloroform. However, this pathway seems to be improbable for the following reasons. When a benzene solution of *S*-butyl 3-methoxy-2-butenethioate (**7**), which is a model compound for the enol form of the 3-oxobutanethioate **1b**, was irradiated under the same conditions, *O*-demethylated product **1b** was obtained in 86% yield. A trace of the disulfide **2b** was detected by GLC; however, the disulfide **2b** seems to be a secondary photoproduct from the 3-oxobutanethioate **1b** because of the very low yield.

Although the attempt to trap the radical **3** from **1b** and **1e** with ethanethiol was unsuccessful, evidence in support of the above mechanism (path A) was obtained from the following experiments. When the 3-oxobutanethioate **1b** was irradiated in benzene containing 20% of benzyl alcohol, the ketene **4** was trapped as benzyl acetate which was detected by GLC. Irradiation of an ethanol solution of *S*-phenyl α-bromothioacetate (**8e**), which is expected to form the radical **3**,[6] gave the disulfide **2e** in 19% yield. In this case *S*-phenyl thioacetate could not be detected. Similarly, irradiation of *S*-butyl α-bromothioacetate (**8b**) in benzene gave the disulfide **2b** in 37% yield. These results suggest that the 3-oxobutanethioate **1** undergoes the Type I reaction to yield the radical $\cdot CH_2COSR$ (**3**) and the radical **3** rapidly fragments to the thiyl radical **5**.

The photoreaction of the 3-oxobutanethioate **1b** was efficiently quenched with 1,3-pentadiene, so that the Type I reaction takes place from the n,π^* triplet state of the keto form of the 3-oxobutanethioate **1**.

Experimental

Chemicals. The 3-oxobutanethioates **1a**—**e**, the thioacetate **6a**, and the α-bromothioacetates **8b** and **8e** were prepared according to previously described methods.[7,8] The butenethioate **7** was prepared by treatment of **1b** with diazomethane.[9]

General Procedure for Photolysis of 3-Oxobutanethioate 1 and α-Bromothioacetate 8. A 3-oxobutanethioate **1** or a thioacetate **8** (300 mg) in benzene or ethanol (70 ml) was irradiated for about 100 h under nitrogen with a 450 W high-pressure mercury lamp (Ushio Elec. Co.) through a Pyrex filter. After removal of the solvent, the residue was chromatographed on silica gel. Elution with benzene gave a disulfide **2**. The structure of **2** was determined by direct comparison with authentic samples.[10]

Photoreaction of S-Butyl 3-Methoxy-2-butenethioate (7). A solution of **7** (101 mg) in benzene (50 ml) was irradiated in a Pyrex vessel under nitrogen for 28 h. After removal of the solvent, the residue was chromatographed on silica gel (benzene–ethyl acetate 5 : 1) to give 80 mg of **1b**.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 56740205 from the Ministry of Education, Science and Culture.

Stereochemistry of Nucleophilic Substitution of Menthyl Derivatives with Anion of Diphenylphosphine Oxide by an Action of Sodium Dihydridobis(2-methoxyethanolato)aluminate

Mitsuji YAMASHITA,* Yukio SOEDA, Nobuyoshi SUZUKI, Manabu YAMADA, Kenji TSUNEKAWA, Tatsuo OSHIKAWA, and Saburo INOKAWA†

(Received September 22, 1982)

Synopsis. The reaction of an anion of diphenylphosphine oxide prepared by the action of sodium dihydridobis(2-methoxyethanolato)aluminate on the oxide with various menthyl or neomenthyl halides and sulfonates were studied to clarify the sterochemistry of the substitution. The reaction gave neomenthyl- and methyl-diphenylphosphine oxide in ratios from 100 : 0 to 0 : 100.

In a sequence of reactions to synthesize phosphorus-sugars, that have a phosphorus atom in the hemiacetal ring instead of an oxygen atom, the formation of a phosphorus-carbon bond was the key step. Some addition reactions of phosphorus compounds to C=C, C=N, or C=O double bond have been used to prepare a phosphorus-carbon bond on a sugar skeleton, and the process afforded usually a couple of the stereoisomeric products.[1-3] Therefore stereospecific reactions should be much more desirable for the preparation of phosphorus-carbon bond.

Preparation of phosphide anions by an action of sodium dihydridobis(2-methoxyethanolato)aluminate (SDMA) and the reaction of the anion with alkyl halides have been reported.[4,5] Stereochemistry of nucleophilic substitution reaction of metal phosphide was reported,[6] however, no report has been published concerning that of phosphorus anion prepared by SDMA from a phosphorus compound with alkyl halides or sulfonates. This note deals with the stereochemistry of nucleophilic substitution of an anion prepared by the reaction of diphenylphosphine oxide with SDMA together with the properties of leaving groups of menthyl derivatives.

Results and Discussion

The reaction of diphenylphosphine oxide with SDMA gave the phosphide anion at 0 °C. The reaction of the anion with various types of alkyl halides or *p*-toluenesulfonates gave alkyldiphenylphosphine oxide in good yield.[7] The reaction of several derivatives of menthol with the anion was carried out in order to investigate the stereochemistry of the nucleophilic substitution reaction.

$$Ph_2\overset{O}{\overset{\|}{P}}H \xrightarrow{SDMA} Ph_2\overset{O}{\overset{\|}{P}}^- \qquad (1)$$

The reaction of the anion of diphenylphosphine oxide with menthyl chloride in tetrahydrofuran for 10 h at 65 °C gave a mixture of neomenthyl- and menthyl-diphenylphosphine oxide in a ratio of 10 : 1. The same reaction with menthyl iodide gave them in a ratio of 1 : 1. The reactions of the anion with menthyl *p*-toluenesulfonate and menthyl methanesulfonate gave

Table 1. Reaction of menthyl or neomenthyl derivatives (RX) with diphenylphosphine oxide in the presence of SDMA

RX		Solvent	Reaction temp/°C	Reaction time/h	Recovered RX/%	Yield of phosphines[a]/%	Ratio of neomenthyl- to menthyl-diphenylphosphine oxide

a) Yields of neomenthyl- and menthyl-diphenylphosphine oxides isolated by preparative TLC. b) One equivalent of sodium iodide was added. c) Not determined. d) Isolated by liquid chromatography. e) *p*-Toluenesulfonate. f) Methanesulfonate. g) Trifluoromethanesulfonate.

the ratios of 99 : 1 and of 82 : 18, respectively. These results are summarized in Table 1.

These findings will suggest that in the reaction the anion of diphenylphosphine oxide attacked on the carbon of menthyl chloride, bromide, and *p*-toluenesulfonate mainly in an S_N2, whereas that the anion attacked on the carbon of menthyl iodide and methanesulfonate mainly in an S_N1 manner.

The lower reactivity and the higher selectivity of inversion for neomenthyl bromide than those for menthyl bromide may attribute to the presence of an assistance by equatorial isopropyl group in breaking the equatorial carbon-bromine bond in menthyl bromide, and to the absence of it in breaking the axial carbon-bromine bond in neomethyl bromide.

Experimental

Apparatus. IR spectra were measured by Hitachi-Perkin-Elmer 337 and Japan Spectroscopic Co., Ltd. JASCO A-3 spectrophotometers, UV spectra were measured by Hitachi 340 Recording Spectrophotometer, ^{1}H-NMR spectra were run on Hitachi R-20 (60 MHz) spectrometer, mass spectra were measured by Hitachi RMU DMG GC-MS spectrometer, optical rotations were determined by Japan Spectroscopic Co., Ltd. DIP-4 digital polarimeter. Liquid chromatography and high performance liquid chromatography were carried out using Toyo Scientific Industry UVICON-540M and Japan Spectroscopic Co., Ltd. UNIFLOW-211, respectively.

Materials. Commercially available SDMA (70% benzene or toluene solution) was used. Menthyl chloride [bp 80.8 °C/8 mmHg,[8] $[\alpha]_D^{15}$ −47.7° (*c* 2.4, EtOH)],[9] menthyl bromide [bp 113 °C/22 mmHg, $[\alpha]_D^{28}$ −29.0° (*c* 1.22, EtOH)],[7] and menthyl *p*-toluenesulfonate [mp 93—95 °C, $[\alpha]_D^{25}$ −70.8° (*c* 1.0, $CHCl_3$)][10] were prepared from *l*-menthol.

Synthesis of Neomenthyl Bromide. Bromination of *l*-menthol (3.1 g) was performed by a treatment of lithium bromide (3.5 g) and chlorotrimethylsilane (5.4 g) in 40 ml of acetonitrile for 20 h under reflux. Extraction of the reaction mixture with ether followed by work-up and evaporation *in vacuo* gave neomenthyl bromide in 72% yield, bp 91 °C/7 mmHg, mp 37—40 °C, $[\alpha]_D^{15}$ −49.8° (*c* 1.04, EtOH). ^{1}H-NMR ($CDCl_3$), δ 0.78 (d, 3H, J=8.0 Hz, CH_3), 0.20—2.55 (m, 15H, C_8H_{15}), and 3.10—3.62 (m, 1H, CHBr).

Iodination of l-*Menthol.* Iodination of *l*-menthol by sodium iodide and chlorotrimethylsilane as described above gave neomenthyl iodide in 40% yield, bp 50 °C/7 mmHg, $[\alpha]_D^{15}$ 0.48° (*c* 1.1, EtOH), ^{1}H-NMR ($CDCl_3$) δ 1.01 [d, 6H, J=4.3 Hz, $CH(C\underline{H}_3)_2$], 0.30—2.77 (m, 12H, C_7H_{12}), and 4.65—5.47 (m, 1H, CHI), and menthyl iodide in 46% yield, bp 93 °C/7 mmHg, $[\alpha]_D^{15}$ −0.58° (*c* 1.0, EtOH), ^{1}H-NMR ($CDCl_3$) δ 0.88 (d, 3H, J=3.8 Hz, CH_3), 0.26—2.85 (m, 9H, C_6H_9), and 3.78—5.39 (m, 1H, CHI).

Synthesis of Menthyl Methanesulfonate. Methanesulfonyl chloride (5.7 g) in pyridine was added to a pyridine solution of *l*-menthol (7.8 g). The work-up of chloroform solution of the product followed by sublimation gave the methanesulfonate in 77% yield, mp 32—36 °C, $[\alpha]_D^{15}$ −63.5° (*c* 1.0, EtOH). ^{1}H-NMR ($CDCl_3$) δ 0.77 (d, 3H, J=3.0 Hz, CH_3), 0.93 (d, 6H, J=7.3 Hz, $CH(C\underline{H}_3)_2$), 2.99 (s, 3H, CH_3SO_2), 0.25—3.64 (m, 9H, C_6H_9), and 4.28—4.88 (m, 1H, CH-O).

Synthesis of Menthyl Trifluoromethanesulfonate. The trifluoromethanesulfonate was prepared by *l*-menthol and trifluoromethanesulfonic anhydride in 32% yield, $[\alpha]_D^{15}$ −6.3° (*c* 1.2, EtOH).

Reaction of Menthyl Derivatives with Diphenylphosphine Oxide in the Presence of SDMA. To a solution of a mixture of diphenylphosphine oxide (1.5 mmol) and SDMA (3.5 mmol) menthyl derivatives (1.5 mmol) were added, and then the solution was allowed to react for several hours. The work-up (addition of water and activated carbon to the reaction mixture followed by filtration, extraction with chloroform, dehydration, and evaporation of the solvent *in vacuo*) of the reaction mixture followed by analysis of the product by HPLC, spectra, and optical rotation revealed that the product consisted of neomenthyldiphenylphosphine oxide and menthyldiphenylphosphine oxide in various ratios. The reaction condition, recovered starting materials, and isolated yields and ratios of the produced phosphine oxides were summarized in Table 1.

Neomenthyldiphenylphosphine oxide showed spectra as follows: ^{1}H-NMR ($CDCl_3$), δ 0.25—3.05 (m, 19H, Me, CH-$(CH_3)_2$, and ring protons) and 7.01—8.02 (m, 10H, 2×Ph); MS, 340 (M^+) and 201 [$P(O)Ph_2$]; IR ν_{max}^{KBr} 1440 (P–Ph), 1193 (P=O), and 720 cm^{-1} (P-C). Menthyldiphenylphosphine oxide showed the similar spectra. HPLC with JASCO SS-05 column eluted by chloroform–hexane (1 : 1) under 100 kg/cm^2 pressure showed peaks of menthyldiphenylphosphine oxide at 15.6 min and of neomenthyldiphenylphosphine oxide at 23.6 min, which were detected by JASCO UVIDEC-100 II UV detector at a wave length of 260.4 nm.

The authors wish to express their thanks to professor M. Suzuki's laboratory of Shizuoka University for giving facility for measurement of optical rotation. This work was partially supported by a Grant-in-Aid for Scientific Research No. 475661 from the Ministry of Education, Science and Culture.

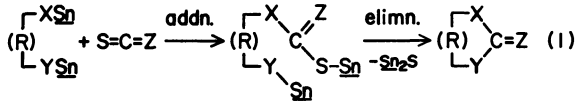
Cyclization Reaction of Bis(tributylstannylated) α-Ketols with Heterocumulenes. Preparation of *O,O*-Vinylene Imino- and Thiocarbonates

Shizuyoshi SAKAI,* Masashi MURATA, Nobuto WADA, and Tatsuo FUJINAMI
Department of Applied Chemistry, Faculty of Engineering, Shizuoka University, Johoku 3, Hamamatsu 432
(Received September 27, 1982)

Synopsis. Aromatic α-ketols reacted with diethylaminotributylstannane at 60 °C to afford a mixture of (*Z*)- and (*E*)-1,2-bis(tributylstannyloxy)-1,2-diarylethenes, which were allowed to react with organic isothiocyanates and carbon disulfide to give substituted *O,O*-vinylene imino- and thiocarbonates, respectively. Aliphatic α-ketol, 3-hydroxy-2-butanone, was treated by the aminostannane, followed by the reaction with carbon disulfide to form (*E*)-1,2-bis(tributylstannylthio)-2-butene.

β-Keto derivatives of the group IV organometalloids are well documented.[1,2] These metalloid compounds are generally used as their tautomers, organometallic enol ethers, which are important intermediates in many kinds of carbon-carbon bond formation.[2] Our interest has been focused on both the reactivities of heteroatom-Sn bonds and the cyclization reaction of the saturated compounds having two heteroatom-Sn bonds with sulfur-containing heterocumulenes to form heteroatom-carbon bonds in carbonate syntheses (Eq. 1).

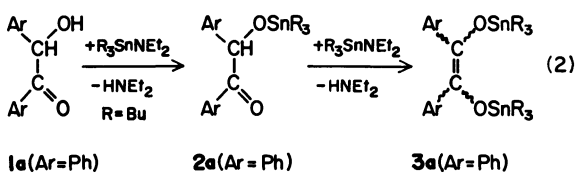


X, Y, Z = O, S, or NR'; (R) = $(CH_2)_{2,3}$; Sn = Bu_3Sn or $Bu_2Sn/2$

This work describes a bis(tributylstannylation) reaction of α-ketol to form bis(tributylstannyloxy)ethenes and their reactions with heterocumulene such as organic isothiocyanates or carbon disulfide to afford imino- or thiocarbonic *O,O*-diester.

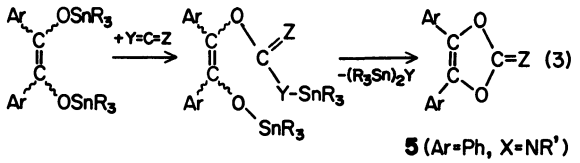
Results and Discussion

Formation of Bis(tributylstannyloxy)ethenes. Aromatic α-ketol, 2-hydroxy-1,2-diphenylethane-1-one (**1a**), was allowed to react with an equimolar amount of diethylaminotributylstannane at room temperature to form *O*-tributylstannylated compound (**2a**). A second mole of the aminostannane was added to **2a**, and the mixture was heated at 60 °C to accomplish the stannylation of α-H of carbonyl group in **2a**; this was followed by tautomerization (or *vice versa*) to give **3a** (Eq. 2). The reddish brown liquid (**3a**), prepared *in situ*, showed the strong band of (*E*)-C=C group at 1680 cm^{-1}, the weak band of (*Z*)-C=C group at 1640 cm^{-1}, and the strong band of vinyloxy group at 1330 cm^{-1} in its IR spectrum. These data will suggest that the bis(tributylstannylated) compound (**3a**) exists as a mixture of (*E*)- and (*Z*)-bis(tributylstannyloxy)ethenes. A mixture of (*E*)- and (*Z*)-bis(tributylstannyloxy)-1,2-bis(4-methylphenyl)ethenes (**3b**) was also obtained from the reaction of 2-hydroxy-1,2-bis(4-methylphenyl)ethane-1-one (**1b**) and two equivalents of diethylaminotributylstannane.



1a(Ar=Ph) 2a(Ar=Ph) 3a(Ar=Ph)
1b(Ar=4-MeC_6H_4) 2b(Ar=4-MeC_6H_4) 3b(Ar=4-MeC_6H_4)

Cyclization Reaction of 3 with Heterocumulenes. An equimolar reaction of **3a**, prepared *in situ* from **1a** and the aminostannane, with phenyl isothiocyanate at room temperature gave a small amount of 2-phenylimino-4,5-diphenyl-1,3-dioxolene (**5**; R'=Ph).



3a or **3b** **4a** or **4b** **5** (Ar=Ph, X=NR') **6a** or **6b** (X=S)
(**a**: Ar=Ph, **b**: Ar=4-MeC_6H_4)

Furthermore, **5** (R'=Ph) was formed in an improved yield (80%), when the reaction mixture was heated for 2 more hours at 100 °C. These results suggest that (*E*)-**3a** will slowly isomerize to (*Z*)-**3a**, which is easily cyclized with an isothiocyanate to give a high yield of **5a**.

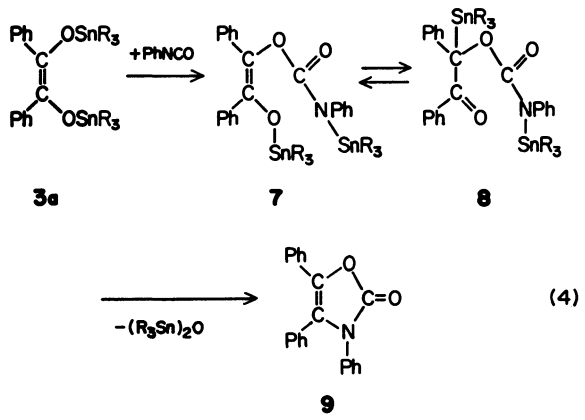
4-Methylphenyl isothiocyanate was also allowed to react with **3a** to afford **5** (R'=4-MeC_6H_4). Aliphatic isothiocyanates such as ethyl and cyclohexyl isothiocyanates were less reactive and reacted partially even under severe reaction conditions.

Carbon disulfide is known to be a thiocarbonylating reagent for bis(organostannyloxy)alkanes.[3] Here, unsaturated bis(organostannylated) compound, **3a** or **3b**, was submitted to a reaction with an excess amount of carbon disulfide under reflux for 24 h to afford the substituted *O,O*-vinylene thiocarbonate (**6a** or **6b**) in a moderate yield.[4] On the occasion, *O,O*-vinylene thiocarbonate was prepared from **1** and thiophosgene[5] or from vinylene carbonate and phosphorus pentasulfide.[6] Therefore, the reaction (Eqs. 2 and 3) gives a new route to prepare **6** from the aminostannane, carbon disulfide, and **1**.

Carbonyl sulfide and carbon dioxide inserted across the Sn–O bond in **3a** to afford **4a** (X=O, Y=S or O). However, the starting material **3a** was recovered by distillation. Thus carbonylation of the enediol-type organostannyl compound **3a** was unsuccessful.

Phenyl isocyanate was reported to react with saturated bis(organostannyloxy) compound to form a carbamate-type adduct which was never cyclized even under severe reaction conditions.[3] Bis(organostannyl) enediol-type compound (**3a**) reacted with the isocyanate for 7 h under reflux in toluene to afford 3,4,5-triphenyl-2(3*H*)-oxazolone (**9**). In the light of the scheme for the reaction

of vinylene carbonate with amines to form 2(3*H*)-oxazolones, reaction path (4) was tentatively proposed.



Organostannylation of Aliphatic α-Ketol and Its Reaction with Carbon Disulfide. When 3-hydroxy-2-butanone (**10**) was allowed to react with diethylaminotributylstannane at 60 °C, the methine proton signal in **10** completely disappeared, and methyl and butyl signals only were observed in the NMR spectrum of the reaction mixture; this suggests the formation of bis(tributylstannylated) compound (**11**), which will exist mainly as an (*E*)-enediol-type organostannyl compound, because the band of (*E*)-C=C bond appeared in its IR spectrum. The compound (**11**) reacted with carbon disulfide to form not the corresponding *O,O*-vinylene thiocarbonate but (*E*)-2,3-bis(tributylstannylthio)-2-butene (**12**). Transformation of the bis(organostannyloxy)ethene (**11**) to the bis(organostannylthio)ethene (**12**) is a new type of the reaction of organostannyl-oxygen bond with sulfur-containing heterocumulene.[8]

Experimental

*Reaction of **1a** with Diethylaminotributylstannane.* The compound **1a** (2.12 g, 10.0 mmol) and diethylaminotributylstannane (3.36 g, 10.0 mmol) were stirred under dry nitrogen atmosphere and then *in vacuo* at room temperature to form a transparent liquid (**2a**). IR (neat) 1720 cm^{-1} (C=O); NMR (CCl_4) δ=6.04 (s, 1H, CH). Subsequently, diethylaminotributylstannane (3.36 g, 10.0 mmol) was added to **2a**, and heated at 60 °C for 2 h *in vacuo* to form a reddish brown liquid (**3a**). **3a** could be isolated neither by vacuum distillation nor by recrystallization. **3a**: IR (CCl_4) 1640 ((*Z*)-C=C), 1690 ((*E*)-C=C), and 1330 cm^{-1} (C=C–O).

*Reaction of **3a** with Aryl Isothiocyanate.* Aryl isothiocyanate (10 mmol) was added to **3a** (10 mmol), prepared *in situ*, at room temperature. Soon after the addition, a small amount of white crystals of **5** were precipitated. Then, the reaction mixture was heated at 100 °C for 1 h, filtered, and washed with hexane to afford crude **5**. **5** (R'=Ph): yield 80%; MS *m/e* 313 (M^+); IR ($CHCl_3$) 1730 (C=N) and 1680 cm^{-1} (C=C); NMR ($CDCl_3$) δ=7.3—7.6 (15H, Ph), and **5** (R'=4-MeC_6H_4): yield 60%; mp 148—149 °C; MS *m/e* 327 (M^+); IR ($CHCl_3$) 1735 (C=N) and 1680 cm^{-1} (C=C); NMR ($CDCl_3$) δ=7.1—7.4 (14H, br., Arom.) and 2.30 (3H, s, CH_3). Found: C, 80.50; H, 5.25; N, 4.31%. Calcd for $C_{22}H_{17}NO_2$: C, 80.71; H, 5.23; N, 4.23%.

*Reaction of **3a** or **3b** with Carbon Disulfide.* The compound (**3a** or **3b**; 5.3 mmol) was allowed to react with carbon disulfide (1.5 ml) for 24 h under reflux. Hexane was added to the reaction mixture to precipitate crystals of **6a** or **6b**. **6a**: yield 50%; mp 118—119 °C (Ref. 6 124 °C); IR (CCl_4) 1310 cm^{-1}, and **6b**: mp 183—184 °C; IR ($CHCl_3$) 1320 cm^{-1}; NMR ($CDCl_3$) δ=2.32 (6H, s, CH_3) and 7.3 (8H, d,d-type, Arom.). Found: C, 72.31; H, 5.03; S, 11.12%. Calcd for $C_{17}H_{14}O_2S$: C, 72.31; H, 5.00; S, 11.36%.

*Reaction of **3a** with Phenyl Isocyanate.* Phenyl isocyanate (0.92 g, 7.1 mmol) was added to **3a** (4.9 mmol) in methylbenzene (8 ml) to form **7**; IR 1570 and 1590 cm^{-1}. The reaction mixture was refluxed for 6 h and distilled to remove the solvent. Hexane was added to the residue to separate white crystals of **9**; yield 70%; mp 191—193 °C; IR ($CHCl_3$) 1760 (C=O) and 1685 cm^{-1} (C=C); NMR (CH_2Cl_2) δ=7.0—7.6 (15H, m, Ph). Found: C, 80.52; H, 5.04; N, 4.32%. Calcd for $C_{19}H_{15}NO_2$: C, 80.52; H, 4.82; N, 4.47%.

*Treatment of **10** with Diethylaminotributylstannane Followed by the Reaction with Carbon Disulfide.* Acetoin (**10**; 2.25 g, 25.2 mmol) was treated with two equivalents of diethylaminotributylstannane (21.6 g, 58.6 mmol) *in vacuo* at 60 °C for 5 h to form the bis(tributylstannylated) compound (**11**); IR 1685 cm^{-1} (C=C); NMR ($CDCl_3$) δ=1.8 (6H, br., CH_3) and 0.8—1.9 (m, BuSn). **10** was refluxed with an excess of carbon disulfide. The reaction mixture was then submitted to the sublimation under vacuum (10 Pa) at 130 °C to separate a small amount of **11**; mp 84.5—86.0 °C; MS *m/e* 698 (M^+); IR ($CHCl_3$) 960 cm^{-1} ((*E*)-C=C); NMR (CCl_4) δ=0.7—1.6 (54H, m, Bu) and 1.92 (6H, s, CH_3). Found: C, 48.14; H, 8.85; S, 9.04%. Calcd for $C_{28}H_{60}S_2Sn_2$: C, 48.16; H, 8.66; S, 9.04%.

The present work was partially supported by Grant-in-Aid for Scientific Research No. 165197 from the Ministry of Education, Science and Culture.

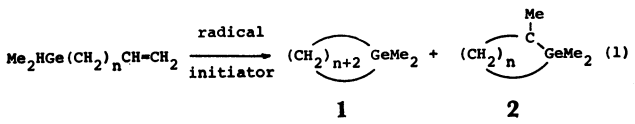
8) The Mechanism of the formation of **12** has not been established. A probable scheme is the addition of CS_2 on O–Sn bond in 3-tributylstannyl-3-tributylstannyloxy-2-butanone, an isomer of **11**, to give the xanthate, which will isomerize to dithiocarbonic *S,S*-diester, followed by the elimination of COS to afford 3-tributylstannyl-3-tributylstannylthio-2-butanone, an isomer of 3-tributylstannyl-3-tributylstannyloxybutane-2-thione. These reaction will be repeated again to give **12**.

The Thermal Reactions of Allyl-substituted Germyl Radicals

Kunio MOCHIDA* and Isoo MIYAGAWA
Department of Chemistry, Faculty of Sciences, Gakushuin University, 1-5-1 Mejiro, Tokyo 171
(Received October 20, 1982)

Synopsis. The allyldibutylgermyl and dibutyl(2-methylallyl)germyl radicals in benzene at 80 °C afforded diallyldibutylgermane and dibutylgermane, and dibutylbis(2-methylallyl)germane and dibutylgermane, respectively. The mechanism of these reactions is discussed.

Although numerous publications on addition of organogermyl radicals to olefinic double bonds have appeared,[1] there are few reports on the reactions of olefinic germyl radicals.[1a,2] The reactions of olefinic germyl radicals lead to cyclic products and are of interest both in synthesis and in mechanistic problems. In a previous paper,[2] we have reported on the reactions of ω-alkenyldimethylgermyl radicals, $Me_2\dot{G}e(CH_2)_n$-$CH{=}CH_2$, (n=2—5) (Eq. 1). ω-Alkenyldimethylgermyl



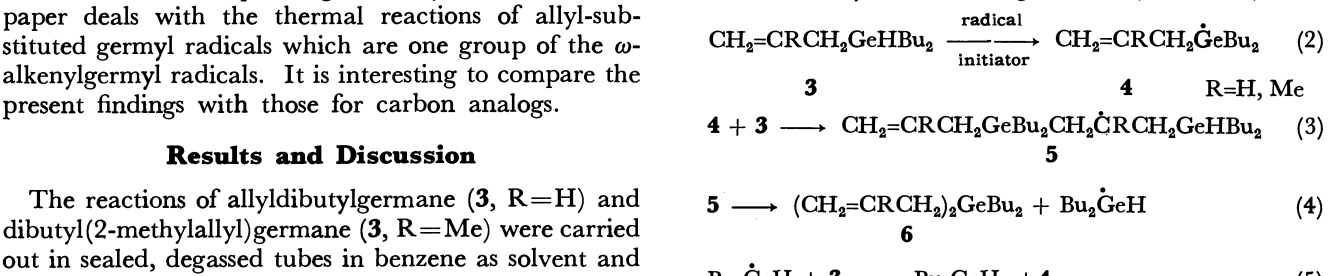
radicals afford cyclization products, with the exo isomer (**1**) predominating. These results are in striking contrast to those of the corresponding ω-alkenyl radicals.[3] This paper deals with the thermal reactions of allyl-substituted germyl radicals which are one group of the ω-alkenylgermyl radicals. It is interesting to compare the present findings with those for carbon analogs.

Results and Discussion

The reactions of allyldibutylgermane (**3**, R=H) and dibutyl(2-methylallyl)germane (**3**, R=Me) were carried out in sealed, degassed tubes in benzene as solvent and dibenzoyl peroxide (BPO) as initiator at 80 °C. Products were isolated by preparative GLC and their structures were verified by comparing the retention times on GLC and IR and NMR spectra with those of authentic samples. The main products obtained in the thermal reactions of allyldibutylgermane (**3**, R=H) and dibutyl(2-methylallyl)germane (**3**, R=Me) under various conditions are summarized in Table 1.

As shown in Table 1, the allyldibutylgermyl radical (**4**, R=H) in benzene afforded diallyldibutylgermane (**6**, R=H) and dibutylgermane. The dibutylbis(2-methylallyl)germyl radicals (**4**, R=Me) in benzene gave dibutylbis(2-methylallyl)germane (**6**, R=Me) and dibutylgermane. Several organic products with much higher boiling points were also detected in both reactions. No cyclization products were detected. The allyldibutylgermyl radical (**4**, R=H) was more reactive than the dibutyl(2-methylallyl)germyl radical (**4**, R=Me). The thermal reactions of allyl-substituted germanes were promoted by BPO, radical generator.

The reversibility of the addition to an olefinic double bond is not a favorable process for carbon radicals at least at low temperature, but is progressively favored for elements lower in group 4B in the periodic table.[4] Therefore, the formation of diallyldibutylgermanes (**6**) and dibutylgermane suggests that the following addition-elimination process may occur in the thermal reactions of allyl-substituted germanes (Scheme **1**):



Thus, the addition of the germyl radicals (**4**) generated from the hydrogermanes (**3**) to the carbon-carbon double bond of the hydrogermanes (**3**) intermolecularly gives the intermediate radicals (**5**). The intermediate

a) Based on the consumed hydrogermanes **3**.

radicals (**5**) undergo degradation to form diallyldibutylgermanes (**6**) and dibutylgermyl radical. The dibutylgermyl radical abstracts a hydrogen atom from the hydrogermanes (**3**) to give dibutylgermane and the germyl radicals (**4**). The reactions of allyl-substituted germyl radicals proceed by a free-radical chain mechanism. However, the mass balance in these reactions is bad. Moreover, the theoretical ratio of diallyldibutylgermanes (**6**) and dibutylgermane is not always obtained. These facts suggest that the intermolecular addition of organogermyl radicals to olefinic bonds and/or dimerization of organogermyl radicals, along with the addition-elimination process shown in Scheme 1, may proceed in these reactions resulting in the formation of unidentified materials.

The present results of the thermal reactions of allyl-substituted germyl radicals are clearly different from those of the corresponding 3-butenyl and allylsilyl radicals. 1,2-Vinyl shifts proceeding *via* cyclopropylmethyl radicals are well known in the reactions of 3-butenyl radicals.[3a,4b] It has been reported that vinylsilanes are formed by loss of methylene from the allyl groups[5] or by loss of a methyl group originallyl bound to silicon[6] in the reactions of allylsilyl radicals.

Experimental

Materials. Bu_2GeCl_2: bp 120 °C/10 mmHg,[7] Bu_2GeH_2: bp 86 °C/46 mmHg,[8] Bu_2GeHCl: bp 105 °C/17 mmHg,[8] and $(CH_2{=}CHCH_2)GeBu_2H$: bp 36 °C/0.2 mmHg[9] were prepared as described in the cited references.

Preparation of Dibutyl(2-methylallyl)germane. A (2-methylallyl)magnesium chloride was prepared from 2-methylallyl chloride (3.3 g, 36.0 mmol) and magnesium (0.9 g, 36.0 mmol) in 50 ml of dry THF. To this, (2-methylallyl)magnesium chloride, dibutylchlorogermane (2.0 g, 9.0 mmol) dissolved in 10 ml of dry ether was added. The reaction mixture was stirred with reflux for 3 h. After hydrolysis with water, organic substances were extracted with ether and the extract was dried over sodium sulfate. Fractional distillation gave dibutyl(2-methylallyl)germane (1.6 g, 6.6 mmol, 73.5%), bp 38.5—39.5 °C/0.04 mmHg; n^{20} 1.4689; NMR (δ in $CDCl_3$) 0.88—1.73 (m, 23H), 3.80 (m, 1H), 4.52 (s, 2H); IR (neat, cm^{-1}) 2050 (Ge–H). Found: C, 59.20: H, 10.64%, Calcd. for $C_{12}H_{26}Ge$: C, 59.33; H, 10.79%.

Preparation of Diallyldibutylgermane. An allylmagnesium chloride was prepared from allyl chloride (1.0 g, 14.0 mmol) and magnesium (0.32 g, 14.0 mmol) in 50 ml of dry THF. To this, allylmagnesium chloride, dibutyldichlorogermane (1.5 g, 58 mmol) dissolved in 10 ml of dry ether was added. The reaction mixture was stirred with reflux for 4 h. After hydrolysis with water, organic substances were extracted with ether and the extract was dried over sodium sulfate. Fractional distillation gave diallyldibutylgermane (1.2 g, 4.5 mmol, 76.9%). bp 125 °C/18 mmHg; n^{20} 1.4766; NMR (δ in $CDCl_3$) 0.88—1.32 (m, 18H), 1.69 (d, J=8.0 Hz, 4H), 4.70—4.92 (m, 4H), 5.53—6.02 (m, 2H). Found: C, 62.76: H, 10.24%. Calcd for $C_{14}H_{28}Ge$: C, 62.52: H, 10.49%.

Preparation of Dibutylbis(2-methylallyl)germane. Dibutylbis(2-methylally)germane was prepared from 2-methylallylmagnesium chloride and dibutyldichlorogermane in 76.3% yield, bp 83 °C/0.8 mmHg; n^{20} 1.4818; NMR (δ in CCl_4) 0.80—1.83 (m, 28H), 4.51 (m, 2H). Found: C, 64.64: H, 10.92%. Calcd for $C_{16}H_{32}Ge$: C, 64.70: H, 10.86%.

Thermal Reactions of Hydrogermanes in Benzene. A hydrogermane, BPO, and benzene were placed in a Pyrex glass tubes. The tube was sealed after degassing and immersed in a constant temperature bath kept at 80 °C. The reaction mixture was analyzed by GLC (Shimadzu GC 6A with SE30 20% or Apiezen L 30% 2m). The amounts of products were determined by an internal-standard method. Each product was isolated by preparative GLC and the structure was verified by comparing the retention time on GLC and IR and NMR spectra with those of authentic samples.

Reactions of 2,4-Azetidinedione with Nucleophilic Reagents

Kazuhiro MARUYAMA* and Yoshihiro ARITA
Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606
(Received December 21, 1982)

Synopsis. The reaction of 2,4-azetidinedione with a variety of nucleophiles was compared with that of *N*-methylsuccinimide. 2,4-Azetidinedione gave ring-cleaved addition products, while *N*-methylsuccinimide afforded simply addition products to the carbonyl group.

It is known that imide compounds show a variety of reactivity with nucleophilic reagents depending on their structures.[1] For instance, *N*-phenylsuccinimide reacts with ethylmagnesium bromide to give 2-ethyl-2-hydroxy-1-phenylpyrrolidine (**1**), while arylmagnesium bromides react with *N*-substituted maleimides to yield *N*-substituted 5-aryl-5-hydroxy-2-pyrrolidones (**2**) (See Fig. 1).[2] Under certain conditions, the imide ring is

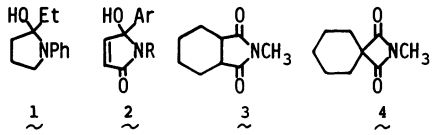

Fig. 1.

cleaved by the Grignard reagent, *i.e.*, *N*-methyl keto amide was the product of the reaction of *N*-methylsuccinimide with ethylmagnesium bromide.[3] Diphenyl and diethyl substituted *N*-phenylmalonimides react with three equivalents of aryl Grignard reagents to give the disubstituted *N*-phenylacetamides and the tertiary alcohols derived from the Grignard reagents.[4]

Recently, the authors[5] reported photochemistry of *N*-methyl-*cis*-1,2-cyclohexanedicarboximide (**3**), which afforded four-membered ring imide, 2,4-azetidinedione **4**.[6] In this report, the reaction of this photoproduct **4** with some nucleophiles has been studied and compared with the reactivity of succinimide **3**.

Results and Discussion

Reactions of **3** and **4** with various Grignard reagents (RMgX) were summarized in Scheme 1 and Table 1. Grignard reagents reacted with **3** to give the hydroxy lactams **5**. The yields of **5** were fairly good. The corresponding reaction of **4** afforded ring-cleaved products **6**, **7**, and **8**. The β-keto amide **6** was the primary product and an excess amount of Grignard reagents reacted with keto carbonyl group of **6** to give the double alkylated products **7** and the reduced products **8**. Because the primary product **6** is sterically hindered by the tertiary carbon, reduction of **6** to **8** occurs mainly when R is bulky. Especially when $R=i$-Pr, t-Bu, octyl, and cyclohexyl, reduction products **8** (**8c**, **8e**, **8f**, and **8g**) were exclusively produced and none of double alkylation products **7** was detected.

a) **7k**: 
The difference of the reactions between **3** and **4** may be explained as follows. Grignard reagents attack one of the carbonyl carbons of the imide **3** to form the five-membered ring intermediate. The same type of the intermediate is perhaps produced in the reaction of **4**. Since ring strain of four-membered ring is larger than that of five-membered ring, the four-membered ring intermediate could immediately isomerize to the ring-cleaved intermediate,[4] the precursor of **6**, **7**, and **8**.

Reductions of **3** and **4** with sodium borohydride of lithium aluminum hydride proceeded similarly. The imide **3** was reduced to the hydroxy lactam **5**, (R=H), while the imide **4** gave the formyl amide **6**, (R=H). Here, it seems to be general that four-membered imides are ring-cleaved but five-membered imides are not cleaved in the course of the reaction.

When lithium reagents were used as the nucleophile, a new reaction was observed. Thus, phenyllithium reacted with **3** to give the ring-cleaved keto amide **9** as well as **5h**. The imide **4** afforded the amide **10** with addition of an excess amount of phenyllithium in the reacting mixture (See Fig. 2). The lithium reagent is a stronger base than the Grignard reagent and also **3** has a hydrogen at the position adjacent to the carbonyl group. These facts may cause the difference between the reactions of Grignard reagents and lithium reagents. The formation of **10** may be explained by retro-Aldol type reaction. Actually, treatment of **7h** with phenyl-

lithium afforded the same product **10** and triphenylmethanol.

Fig. 2.

It is general that only one of the carbonyl carbons of imides photochemically behaves like a simple ketone.[7] In the present study, it is realized that ring size of cyclic imides strongly affects its chemical reaction pathway.

Substituent Effects on the Dissociation Constants of 1-Aryl-5-hydroxy-2-hydroxymethyl-4-pyridones

Kimiaki IMAFUKU,* Kumio TAKAHASHI,† and Hisashi MATSUMURA††
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860
(Received December 25, 1982)

Synopsis. Six new 1-aryl-5-hydroxy-2-hydroxymethyl-4-pyridones were synthesized and their dissociation constants were measured. Hammett analysis of pK_a values for proton gain and proton loss gave the following equations: $pK_1 = 2.74 - 0.34\sigma$ and $pK_2 = 8.80 - 0.36\sigma$, respectively.

Hahn *et al.*[1,2] obtained 1-aryl-3-hydroxy-4-pyridones by the reactions of comenic acid and meconic acid with aniline derivatives. However, there is no further investigation in a detailed manner.

In the present work, we wish to report the synthesis of 1-aryl-5-hydroxy-2-hydroxymethyl-4-pyridones from kojic acid and the effects of the substituent in the benzene ring on the dissociation constants.

Results and Discussion

Synthesis. Condensation of kojic acid (**1**) with six anilines (**2a**—**f**) were respectively carried out, according to the Hahn's method,[1,2] to afford 1-aryl-5-hydroxy-2-hydroxymethyl-4-pyridones (**3a**—**f**). However, their yields were not necessarily good. All of the 4-pyridones gave a violet color with iron(III) chloride solution.

f R=*p*-$COCH_3$

Dissociation Constants. The dissociation constants of six 1-aryl-5-hydroxy-2-hydroxymethyl-4-pyridones were determined spectrophotometrically in water at 25 °C. The results are summarized in Table 1, where pK_1 and pK_2 values represent respectively the dissociation constants for the proton gain and proton loss of the 4-pyridones. Both pK_1 and pK_2 values are respectively smaller than those of 6-substituted 3-hydroxy-1-methyl-4-pyridones,[3] because of inductive effect of the aryl group. When these pK values were plotted against Hammett σ constants,[4] the following equations were obtained by the least-square method.

$$pK_1 = 2.74 - 0.34\sigma \quad (r=0.867,\ s=0.04)$$
$$pK_2 = 8.80 - 0.36\sigma \quad (r=0.980,\ s=0.02)$$

The ratio of the ρ value for **3** against the ρ value for 1-methyl-3-hydroxypyridones[3] is 0.29 for the proton gain and 0.34 for the proton loss. These values are comparable to the transmission factor (π=0.3) for *m*- and *p*-phenylene groups.[5]

Experimental

All the melting points were measured on a Yanagimoto MP-S2 melting point measuring apparatus and are uncorrected. The IR and UV spectra were taken on a JASCO IRA-1 and on a Hitachi EPS-3T spectrophotometer, respectively. The pH values were measured by a Hitachi-Horiba F-5 pH meter. The p*K*a determination was carried out according to the method of Albert and Serjeant.[6]

5-Hydroxy-2-hydroxymethyl-1-phenyl-4-pyridone (3a). A mixture of kojic acid (**1**) (1.0 g) and aniline (**2a**) (1.3 ml) in water (3.3 ml) was heated in the presence of 12 M (1 M=1 mol dm^{-3}) hydrochloric acid (0.5 ml) in a sealed tube on a water bath for 4 h. Water (6.7 ml) was added to the mixture to precipitate **3a** (280 mg, 18.3%). Mp 231 °C (from methanol); IR (KBr) 1653 cm^{-1}; UV (CH_3OH) 224 (sh, log ε 4.33), 287 nm (4.25). Reduction of Organic Halides with Diethyl Phosphonate and Triethylamine

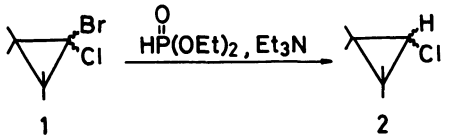
Toshikazu HIRAO, Shuichiro KOHNO, Yoshiki OHSHIRO,* and Toshio AGAWA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-oka, Suita, Osaka 565
(Received December 27, 1982)

Synopsis. Reduction of organic halides [*gem*-bromochlorocyclopropanes, 1,1,1-trichloromethane derivatives, 1,1-dibromo-2-benzyloxyethylene, methyl α-bromocinnamate, α,*p*-dibromoacetophenone, and (1,2-dibromoethyl)benzene] with diethyl phosphonate and triethylamine is surveyed.

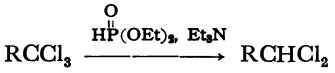
We have developed a novel method for reduction of *gem*-dibromocyclopropanes and *gem*-dibromoalkenes with diethyl phosphonate and triethylamine into the corresponding monobromides, respectively.[1] Furthermore, α-bromo-α,β-unsaturated ketones or 1,1-dibromo-2-trimethylsiloxycyclopropanes are shown to be converted to β,γ-unsaturated ketones with diethyl phosphonate and triethylamine.[2] These findings suggest a versatility of diethyl phosphonate–triethylamine as a reducing agent. Now we wish to extend the generality of reduction with diethyl phosphonate–triethylamine.

Treatment of *gem*-bromochlorocyclopropanes **1** with diethyl phosphonate and triethylamine gave the corresponding chlorocyclopropanes **2** exclusively, without formation of bromocyclopropanes (Table 1).



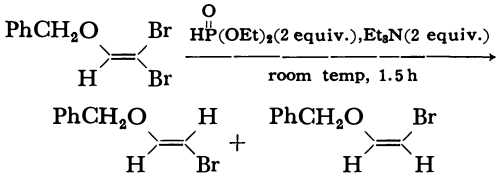
1 2

One of the chlorine atoms of the trichloromethane derivatives **3** was, however, reduced to yield the dichloromethane ones **4**, which were inert under the present reaction conditions, giving no further reduced compounds[3] (Table 1).

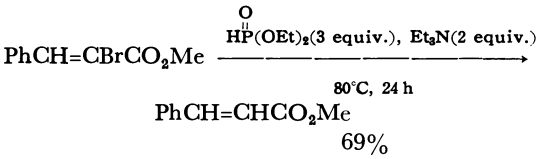


3 **4**

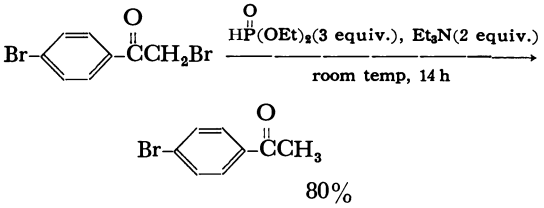
These results are considered to indicate that only activated halogen atom is reactive towards reduction. The following observation also supports this reactivity. Reduction of α-bromostyrene and (*E*)-β-bromostyrene was not achieved even at a high reaction temperature (80 °C), though β,β-dibromostyrene is reduced to (*E*)-β-bromostyrene.[1] The present method is effective for reduction of 1,1-dibromo-2-benzyloxyethylene, producing (*E*)- and (*Z*)-1-bromo-2-benzyloxyethylene in 29 and 51% yields, respectively.



It is of interest to note that methyl α-bromocinnamate was allowed to be reduced into methyl cinnamate in 69% yield, which is in contrast with addition of diethyl phosphonate to methyl cinnamate.[4]



Furthermore, the α-bromine atom of ketones is reduced, as exemplified in the transformation of α,*p*-bromoacetophenone into *p*-bromoacetophenone. In the special cases, the similar kinds of reduction have been reported.[5]



(1,2-Dibromoethyl)benzene was treated with diethyl phosphonate and triethylamine to give styrene as a main product. Since α- and β-bromostyrene were not subjected to reduction as mentioned above, styrene is presumably derived by direct debromination of (1,2-dibromoethyl)benzene, not reduction of the dehydro-

Table 1. Reduction of **1** and **3** with diethyl phosphonate and triethylamine

1 or **3**	$HP(O)(OEt)_2$ (equiv.)	Et_3N (equiv.)	Reaction conditions: Temp/°C	Reaction conditions: Time/h	**2** or **4** (Isolated yield/%)

brominated compounds (α- or β-bromostyrene).

$$PhCHBrCH_2Br \xrightarrow[\text{room temp, 6 h}]{HP(O)(OEt)_2\text{(3 equiv.)}, Et_3N\text{(2 equiv.)}} PhCH{=}CH_2 + PhCBr{=}CH_2 + PhCH{=}CHBr$$

58% 10% trace

The attack of diethyl phosphonate or its anion on the bromine or chlorine atom is assumed to be the first step in the reduction reaction.[6] The present procedure provides a convenient and selective method for reduction of activated halogenated compounds.

Experimental

Materials. *gem*-Bromochlorocyclopropanes,[7] α-bromostyrene,[8] methyl α-bromocinnamate,[9] and (1,2-dibromoethyl)benzene[10] were prepared by the reported methods. 1,1-Dibromo-2-benzyloxyethylene was obtained by the reaction of dibromocarbene with benzyl formate.[11] The other reagents are commercially available and purified by usual methods before use.

Reduction of 1-Bromo-1-chloro-2-phenylcyclopropane. To a mixture of diethyl phosphonate (1.10 g, 8 mmol) and triethylamine (0.40 g, 4 mmol) was added 1-bromo-1-chloro-2-phenylcyclopropane (0.46 g, 2 mmol) dropwise at room temperature. The resultant mixture was stirred at 90 °C for 20 h. The reaction proceeded with deposition of $Et_3N \cdot HBr$, which was filtered off and washed with ether. Upon evaporation of the filtrate *in vacuo*, the residue was chromatographed on a silica-gel column to give 0.23 g (76%) of 1-chloro-2-phenylcyclopropane. This product was identified by comparison of the IR and NMR spectra with those of the authentic sample.[12]

Reduction of other organic halides was carried out in the similar manner as mentioned above. The molar ratio of diethyl phosphonate or triethylamine, and reaction conditions are shown in Table 1 or equations.

Debromination of (1,2-Dibromoethyl)benzene. A mixture of (1,2-dibromoethyl)benzene (1.32 g, 5 mmol), diethyl phosphonate (2.07 g, 15 mmol) and triethylamine (1.01 g, 10 mmol) was stirred at room temperature for 6 h. The salt was filtered off and washed with ether. Upon concentration of the filtrate *in vacuo*, the residue was chromatographed on a silica-gel column to give 0.30 g (58%) of styrene, 0.09 g (10%) of α-bromostyrene, and a trace amount of β-bromostyrene.

Effects of Cation on Transport Efficiency and Selectivity of Amino Acid Derivative Anions through Macrocyclic Carrier-containing Liquid Membrane

Hiroshi TSUKUBE

Department of Chemistry, College of Liberal Arts and Science, Okayama University, Okayama 700

(Received January 7, 1983)

Synopsis. New aspects of amino acid transport mediated by macrocyclic carriers were reported. Its transport "efficiency" and "selectivity" were demonstrated to be controlled by the appropriate choice of co-transported cation and employed carrier-type.

Recently we demonstrated that several macrocyclic crown ethers[1] and their derivatives[2] effectively mediate the passive and active transport of amino acid and oligopeptide derivative anions. In this transport system (see Fig. 1), the macrocyclic carrier, dissolved in the membrane, facilitates the transport of guest anion and co-transported cation from the source phase through the membrane to the receiving phase by solubilizing co-transported cation and guest anion into the membrane.

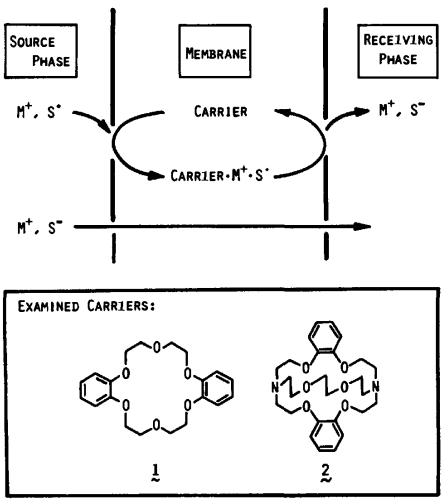

Fig. 1. Liquid membrane and macrocyclic carriers for transport of amino acid derivatives. M^+: Co-transported cation, S^-: guest anion.

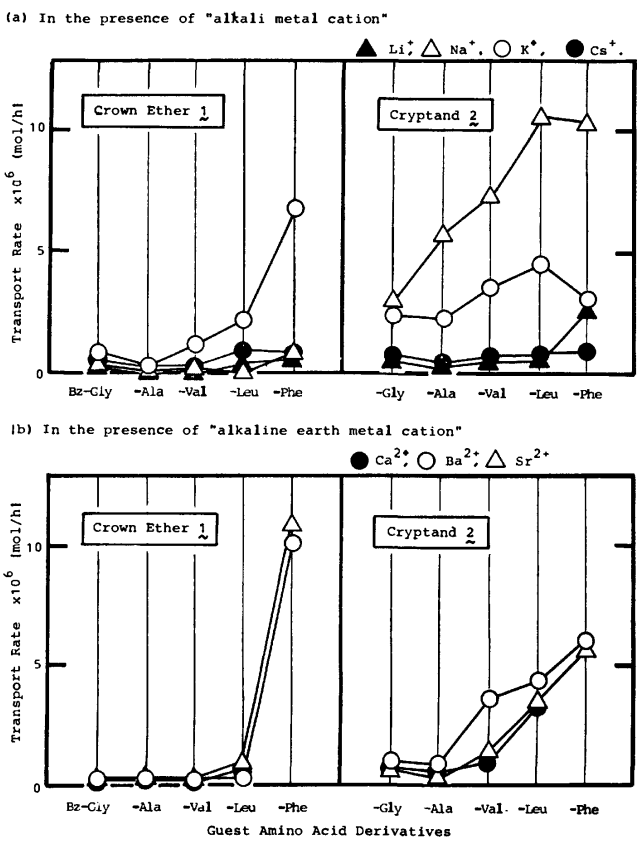

Fig. 2. Transport rates of several *N*-benzoyl amino acid anions by macrocyclic carriers **1** and **2**.
Transport conditions: Source phase; *N*-benzoyl amino acid, 0.250 mmol co-transported cation chloride, 2.50 mmol/0.05 mol dm^{-3} LiOH, 5 ml. Membrane; carrier, 0.0557 mmol/$CHCl_3$, 12 ml. Receiving phase; distilled water, 5 ml. Other conditions were indicated in Experimental.

In the previous publications,[1,2] we showed that the transport rates of some guest anions were largely influenced by the natures and concentrations of co-transported cations. Here we report a further detailed study of co-transported cation effects on the transport phenomena, and provide a new possibility of controlling the transport "selectivity." By using typical two macrocyclic carriers **1** and **2**, we measured the transport rates of amino acid derivatives in the presence of various metal cations (Li^+, Na^+, K^+, Cs^+, Ca^{2+}, Sr^{2+}, and Ba^{2+}), and found that the natures of these cations significantly governed both the transport "selectivity" and "efficiency." Typical results are illustrated in Fig. 2.

Figure 2(a) clearly shows that alkali metal cation has a large effect on the transport "selectivity" and "efficiency" for amino acids. When the crown ether **1** was employed as carrier, Bz–Phe and Bz–Leu anions (Bz= benzoyl) were effectively transported, together with K^+ cation. These transport properties were found to simply depend on the stability constant of crown ether **1**·metal cation complex ($Li^+ < Na^+ < K^+ > Cs^+$)[3] and hydrophobicity of guest anion (Bz–Gly≲Bz–Ala<Bz–Val<Bz–Leu<Bz–Phe). Similar conclusions have been presented in the crown ether-mediated transport of alkali metal–inorganic anion salts by Lamb *et al.*[4] In a marked contrast, the cryptand carrier **2** exhibited unique and interesting transport property. Its transport selectivity was largely affected by the natures of co-transported metal cations: For Li^+; Bz–Gly≈Bz–Ala≈Bz–Val≈Bz–Leu<Bz–Phe. For Na^+; Bz–Gly<Bz–Ala<Bz–Val<Bz–Leu≈Bz–Phe. For K^+; Bz–Gly≈Bz–Ala≲Bz–Val≲Bz–Leu>Bz–Phe. It was of particular interest that Bz–Leu anion was more effectively transported with K^+ cation than Bz–Phe and other guest anions.

Since the cryptand **2** is a much stronger complexing agent for Na^+ and K^+ cations than the crown ether **1**,[5] highly hydrophobic Bz–Phe anion could be accumulated into the membrane as very stable cryptand–cation–guest anion complex rather than being transported. Recently some transition metal complexes were found to successfully mediate the artificial transport of amino acid derivatives anions.[6] In such systems, the amino acid anions with lower hydrophobicities allowed fast transport: Bz–Gly>Bz–Ala>Bz–Val>Bz–Leu>Bz–Phe. Thus, transport selectivity could be dramatically modified and controlled by alterations of the employed metal cation and ligating agent.

The effects of alkaline earth metal cations on this transport process were also examined (Fig. 2(b)). Both two macrocyclic carriers **1** and **2** selectively transported hydrophobic guest anions (Bz–Phe and Bz–Leu), together with Ba^{2+} and Sr^{2+} cations, while they hardly transported hydrophilic anions (Bz–Gly and Bz–Ala). Several investigators have studied the crown ether-mediated transport of alkaline earth metal salts, and found that their transport rates were generally much lower than those of alkali metal salts.[7] Although crown ethers form highly stable complexes with alkaline earth metal cations in the solution systems,[3,5] the heterogeneous complexation reactions at the water/membrane interfaces slowly occurred.[8] Probably, hydrophobic Bz–Phe and Bz–Leu anions could promote the heterogeneous complexation and provide higher transport rates.

These results obtained here clearly show that there is an optimum combination of carrier and metal cation for efficient and selective transport of a given guest anion. This principle[6,9] could be used for effective control of the transport "selectivity" and "efficiency."

Experimental

Materials. The macrocyclic carriers **1** and **2** were purchased from Merck Japan Ltd. The used *N*-benzoyl amino acids were obtained from Nakarai Chem. Ltd. and Tokyo Chem. Ltd. All other chemicals were of analytical grade and employed as received.

Transport Procedure. The transport experiments (Fig. 2) were carried out at room temperature in an U-shaped glass cell (2.0 cm, i.d.) as described before.[6] The carrier in chloroform (12 ml) was placed in the base of the U-tube, and two aqueous phases (5 ml, each) were placed in the arms of the U-tube, floating on the chloroform membrane.The membrane phase was stirred with a magnetic stirrer. The transport rates were calculated from the initial rates of appearance of guest anions into the receiving phase, which were determined spectroscopically. Reproducibility was confirmed as $\pm 15\%$ or better.

The author thanks Professor T. Iwachido of Okayama University for his helpful discussion. This research was supported in part by a Grant-in-Aid for Scientific Research No. 57740267 from the Ministry of Education, Science and Culture.

Potassium Fluoride on Alumina. An Efficient Solid Base for Elimination, Addition, and Condensation

Junko YAMAWAKI, Takehiko KAWATE, Takashi ANDO,* and Terukiyo HANAFUSA
The Institute of Scientific and Industrial Research, Osaka University, Mihogaoka, Ibaraki, Osaka 567
(Received January 18, 1983)

Synopsis. Alumina coated with potassium fluoride proved to be a versatile solid base for olefin- and acetylene-forming elimination, the Michael addition, aldol condensation, and the Darzens condensation.

The utility of fluoride salts as potential bases in a variety of synthetic reactions has been recognized in recent years.[1,2] However, low solubilities of fluoride salts in ordinary solvents hamper their wide applications in organic synthesis. On the other hand, there has been increasing use of inorganic solid supports as reagents or reaction media in recent years.[3,4] In our previous papers,[5-7] we reported that alumina coated with potassium fluoride (KF-alumina) is a versatile solid-supported reagent for promoting *C*-, *N*-, *O*-, and *S*-alkylations with alkyl halides. In the present paper, we describe the application of KF-alumina as a solid base for elimination, addition, and condensation.

β-Elimination reaction of alkyl bromides was carried out with KF-alumina (*ca.* 2.5 equiv. KF) in acetonitrile or diglyme with stirring at room temperature or with heating below 100 °C. Typical examples are summarized in Table 1. Elimination of phenethyl, 2-phenoxyethyl, and secondary alkyl bromides proceeded smoothly to give the corresponding olefins. For example, an 86% yield of styrene was obtained from phenethyl bromide at room temperature after 24 h; the elimination did not proceed when KF powder or alumina was used separately. These results show the high reactivity of KF-alumina for β-elimination. When a simple primary alkyl bromide was used as a substrate, hydrolysis became the main reaction in preference to elimination to form substantial amounts of an alcohol and an ether together with an olefin.

KF-Alumina was also applicable to the synthesis of acetylenes. Phenylacetylene and diphenylacetylene were obtained in good yields from the corresponding vicinal bromides under milder reaction conditions than those of

4		$CH_2(CN)_2$	DME	15		55
5	PhCHO	PhCHClCN	Benzene	4		82[c]

a) At room temperature. Molar ratio of A:B:KF-alumina was 1:20:0.2 for run 1, 1:1:0.25 for run 2 and 4, 1:1:0.5 for run 3, and 1 : 1 : 5 for run 5. b) Unless otherwise mentioned, isolated yields after purification are shown. c) Yield determined by ^{1}H-NMR using an internal standard. The ratio of *cis* to *trans* was 56 : 44. When 1,2-dimethoxyethane was used as solvent, the ratio decreased to 28 : 72, while the addition of 0.5 and 1.0 equiv. water to KF in benzene increased the ratio to 61 : 39 and 71 : 29, respectively.

conventional methods using strong bases (Table 1). Interestingly, in the elimination of *meso*-stilbene dibromide there was difference in composition of products by the solvent used. After 44 h at 50 °C in 1,2-dimethoxyethane diphenylacetylene and (*E*)-α-bromostilbene were formed in 24 and 66% yields, respectively. On the other hand, the reaction in acetonitrile gave a 30% yield of *trans*-stilbene, the debromination product, in addition to the above two products in 52 and 12% yields, respectively. This is the first observation of debromination by KF, although the debromination by NaI or LiBr in *N,N*-dimethylformamide has been reported already.[8]

KF-Alumina was found to promote the generation of dichlorocarbene from chloroform, which was trapped with cyclohexene to give a 31% yield of 7,7-dichlorobicyclo[4.1.0]heptane after 48 h at 25 °C. This α-elimination by KF-alumina, however, is not so efficient as the well-known method using phase transfer catalysts.

A catalytic amount of KF-alumina promoted the Michael addition and aldol condensation under mild conditions in satisfactory yields as shown in Table 2. No reaction took place when alumina without KF was added to the mixture of benzaldehyde and benzyl cyanide (run 3). The Darzens condensation of benzaldehyde and α-chlorophenylacetonitrile proceeded smoothly with KF-alumina in benzene to give 2,3-diphenyloxirane-2-carbonitrile (Table 2, run 5). Interestingly, the ratio of *cis*- to *trans*-isomer varied from 3 : 7 to 7 : 3 depending not only on the solvent used but also on the added water to the reaction system (Table 2, footnote c).[9] This phenomenon may give a valuable clue to suggest the characteristics of inorganic solid-organic liquid interfacial reaction, and a further mechanistic study along this line is under way.

In all cases studied, work-up was simple and nonaqueous. Reaction products were isolated by filtration of the solid and evaporation of the solvent; purification by distillation, recrystallization or column chromatography was done when necessary. In conclusion, these results confirmed the utility of KF-alumina as a solid base for a variety of synthetic reactions.

Experimental

General. Unless otherwise mentioned, reagents were obtained commercially and used without further purification. α-Chlorophenylacetonitrile was prepared from α-hydroxyphenylacetonitrile and thionyl chloride.[10] Solvents were dried with molecular sieves 3A or 4A. Neutral alumina was purchased from Merck Japan Ltd. (type 90 for column chromatography, activity I, 70—230 mesh) and used as obtained.

KF-Alumina Reagent. Alumina (30 g) was mixed with KF (20 g) in 200 cm³ of water, and the water was removed at 50—60 °C in a rotary evaporator. This impregnated alumina was then dried in a vacuum drying oven at 75 °C for several hours.

Typical experimental procedures are described in the following three examples.

Styrene: A mixture of phenethyl bromide (3.70 g, 20 mmol) and KF-alumina (15 g, *ca.* 100 mmol KF) without solvent was agitated mechanically by a Mini Vapour S-3 vibrating apparatus (Tokyo Rikakikai Co., Ltd.) at room temperature for 20 h. Purification by distillation gave 1.55 g of the product (74.5%): bp 26—27 °C/2.67 kPa (lit,[11] bp 54 °C/4.00 kPa); purity by GLPC 99.4%.

Phenylacetylene: A mixture of styrene dibromide (12.0 g, 45 mmol) and KF-alumina (74.8 g, *ca.* 450 mmol KF) in 30 cm³ of Penta Ether (tetraethylene glycol dibutyl ether) was mechanically stirred at 100 °C for 6 h. The solid material was filtered off and washed with ether, and the ether was evaporated. Purification by distillation gave 3.13 g of the product (70.4%): bp 62—72 °C/8.00—9.33 kPa (lit,[12] bp 39—40 °C/1.87 kPa); purity by GLPC 97%.

Benzylidenemalononitrile: Condensation of malononitrile (1.32 g, 20 mmol) and benzaldehyde (2.12 g, 20 mmol) in 15 cm³ of acetonitrile in the presence of KF-alumina (0.78 g, *ca.* 5 mmol KF) was carried out at room temperature for 3 h. The alumina was filtered off, and the solvent was evaporated. Purification by column chromatography (silica gel, benzene) gave 2.64 g of the product (85.7%): mp 83.5—84.0 °C (lit,[13] mp 83.5—84.0 °C).

Identification of the Products. All the products are the known compounds, and all the isolated products in Tables 1 and 2 were identified by the spectroscopic (IR, ^{1}H NMR, and UV) and other physical data (mp, bp, and elemental analysis), which were compared with those of the authentic samples or the following literatures: phenoxyethylene,[14] 1,3-diphenyl-4-nitrobutanone,[15] α-phenylcinnamonitrile,[16] cyclohexylidenemalononitrile,[17] and diphenyloxirane-2-carbonitrile.[18]

The present work was supported in part by a Grant-in-Aid for Scientific Research No. 57740264 from the Ministry of Education, Science and Culture.

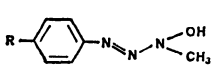
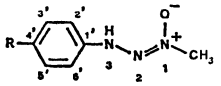
(Received July 23, 1982)

Synopsis. The structure of 3-aryl-1,3-dimethyltriazene 1-oxides has been demonstrated by comparison with other triazenes and triazene *N*-oxides by mass spectrometry and ^{1}H and ^{13}C NMR.

Aryldimethyltriazene *N*-oxides exhibit interesting pharmacological properties. 1-Aryl-3-hydroxy-3-methyltriazenes, **1a**, which are the proton tautomers of 3-aryl-1-methyltriazene 1-oxides, **1b**, have been described as immunosuppressive[1,2] and antiinflammatory agents.[3]

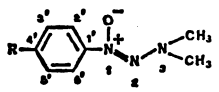


1a

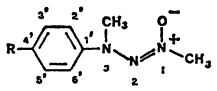


1b

Some 1-aryl-3,3-dimethyltriazene 1-oxides, **2**, were found useful in the treatment of phlogistic processes.[4] The same activity was observed for a third class of triazene *N*-oxides, **3**, obtained from the methylation of 3-aryl-1-methyltriazene 1-oxides, **1b**, with methyl iodide in the presence of the irreversible proton acceptor sodium hydride.[3]

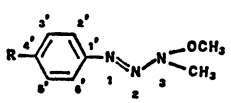


2



3

In view of preparing new derivatives of **3**, we wished to establish the actual structure of this reaction product; no such evidence could in fact be found in the literature. Bamberger and Renauld[5] reacted the *p*-nitro derivative of **1b** with methyl iodide and potassium hydroxide and postulated structure **4** for the isolated reaction product. Later, Boese *et al.*[6] assumed the same structure for the product resulting from the reaction of *N*,*O*-dimethylhydroxylamine with *p*-nitrobenzenediazonium chloride; evidence for the assignment was obtained by hydrolyzing the product to the starting amine with hydrochloric acid. The melting point of Bamberger's compound differed widely (142 °C *vs.* 66 °C) from that of Boese's. In a recent review this assignment was deemed reasonable on a synthetic basis and structure **4** and **5** were then proposed for Bamberger's compound.[7] We set up to establish the actual structure of the compound on firmer grounds. Incidentally, structure **2** and **5** are of interest, being potential oxidative metabolites of the antitumor agents aryldimethyltriazenes, **6**.[8]



4

6

Experimental

The following compounds were synthesized for comparative purposes according to reported procedures: 3-aryl-1-methyltriazene 1-oxide (**1b**; R=*p*-nitro,[5] and *p*-chloro,[9] mp 149 °C after recrystallization from methanol, lit,[9] unreported), 1-(*p*-chlorophenyl)-3,3-dimethyltriazene 1-oxide (**2**, R=*p*-chloro[3]), 1-(*p*-chlorophenyl)-3-methoxy-3-methyltriazene (**4**, R=*p*-chloro, mp 18—19 °C after recrystallization from petroleum ether at low temperature), 1-(*p*-nitrophenyl)-3-methoxy-3-methyltriazene (**4**, R=*p*-nitro[6]), Bamberger's triazene[5] and its *p*-chloro analog, synthesized according to the same procedure using four equivalents of potassium hydroxide and methyl iodide in order to drive the reaction to completion, mp 90.5—91.5 °C after recrystallization from hexane.

The ^{1}H and ^{13}C NMR spectra were recorded using TMS as internal standard with JEOL JNM-C60HL and JNM-FX-90Q FT spectrometers respectively. Mass spectra here reported were recorded with an LKB mass Spectrometer, *via* sublimation at room temperature into the ion source kept at 200 °C; ionization energies were at nominal 20 and 70 eV. Reported mp's are uncorrected.

Results and Discussion

^{1}H Spectral characteristics of *p*-chloro- and *p*-nitro-substituted triazenes are summarized in Table 1; the corresponding ^{13}C NMR spectral characteristics are shown in Table 2. The methyl groups in 1-(*p*-chlorophenyl)-3,3-dimethyltriazene, **6** (R=*p*-Cl), appeared as a singlet at δ=3.25 (in $CDCl_3$) and δ=3.26 (in acetone-d_6 at room temperature, whereas in the corresponding 1-(*p*-nitrophenyl)-3,3-dimethyltriazene, **6** (R=*p*-NO_2), the methyl groups appeared as two signals at δ=3.26 and δ=3.60 (in acetone-d_6) or δ=3.28 and 3.50 (in $CDCl_3$) because of the restricted rotation around N_2–N_3 bond, which coalesced at higher temperatures. Similarly, both methyl groups in 1-(*p*-chlorophenyl)-3,3-dimethyltriazene 1-oxide, **2**, appeared as a singlet at room temperature. On the other hand, two methyl groups appeared as two singlets at δ=4.13 and 3.29

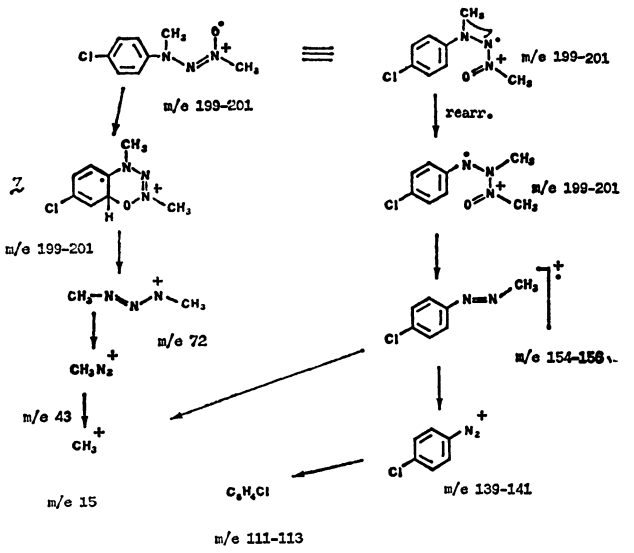
a) The ^{13}C chemical shifts of the aryl carbon atoms have been assigned on the basis of literature references: T. Axenrod, P. Mangiaracina, and P. S. Pregosin, *Helv. Chim. Acta*, **59**, 1655 (1976).

in the compound obtained by Bamberger by methylation of the corresponding 3-(*p*-nitrophenyl)-1-methyltriazene 1-oxide, **1b**. The large chemical shift difference observed for these methyl groups ($\Delta\delta=0.84$ ppm) and the absence of coalescence at higher temperatures, indicated that they were attached at different positions, leaving thus the 1-(*p*-nitrophenyl)-1,3-dimethyltriazene 1-oxide (structure **3**) as the most plausible one. Analogous evidence could be found also for the product obtained by methylation of 3-(*p*-chlorophenyl)-3-methyltriazene 1-oxide, **1b**. In ^{13}C NMR spectra, long range coupling constants $J^3_{H-C-N-}{}^{13}C=$



3.6 Hz were observed for all compounds having both methyl groups attached to the same nitrogen atom, *i.e.* in 1-(*p*-nitrophenyl)-3,3-dimethyltriazene, **6** (R=*p*-NO_2), 1-(*p*-chlorophenyl)-3,3-dimethyltriazene, **6** (R=*p*-Cl), and in the corresponding N_1-oxide (**2**, R=*p*-Cl). Since this coupling was not observed for the Bamberger's methylation product and its *p*-chloro analogue, structure **5** had to be excluded, leaving thus the nitrogen close to the phenyl ring as the only possible position at which methylation could occur. Mass spectrometry supported this evidence. Bamberger's *p*-chloro derivative under electron impact at 20 eV showed intense peaks for the parent ions (*m/e* 201 and 199), and doublets separated by two mass units at *m/e* 154—156, 139—141, and 111—113. This fragmentation is clearly incompatible with structure **5**, but could be readily reconciled with structure **3**, by postulating a 3,2-methyl shift in the parent cation radical produced upon ionization. Any thermal rearrangement prior to ionization in the course of sublimation into the ion source could be ruled out by the fact that the process occurred at room temperature. A second pathway could be given by rebonding of the parent ion to the bicyclic system **7**, which eventually collapsed to the dimethyltriazenyl ion (*m/e* 72), then cascading to methane diazonium (*m/e* 43) and methyl (*m/e* 15) cations.

A Practical Synthesis of Olivetol

Ramesh Chander ANAND* and Harish RANJAN

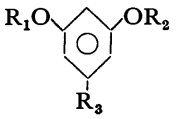
Department of Chemistry, Indian Institute of Technology, Hauz Khas, New Delhi-110 016, India

(Received September 18, 1982)

Synopsis. A simple and practical synthesis of olivetol has been described in 55% overall yield from α-resorcylic acid.

Recently there have been large interests in psychotomimetically active compounds of marijuana (hashish) because of their extensive biological activity.[1] This has stimulated a number of synthetic efforts towards cannabinoids.[2] The syntheses of these compounds depend largely on the availability of the key intermediate olivetol (5-pentyl-1,3-benzenediol) (**1**). This compound was first obtained by degrading lichen acid and olivetonic acid[3] but later a number of synthetic routes have been developed.[4] Most of the syntheses reported involve unsatisfactory overall yields, and/or the intermediates reported are predominantly liquids, the purification of which are relatively cumbersome. Moreover, the syntheses recorded are through the protection of two hydroxyl groups as their methyl ethers, the conversion of which into olivetol requires high temperature and this results in inferior quality product.

In the present communication, we wish to report a simple, efficient and practical synthesis of olivetol starting from commercially available α-resorcylic acid (3,5-dihydroxybenzoic acid) (**2**). The intermediates isolated are solid, crystalline compounds and the deprotection of two benzyloxyl groups at the end is carried out under mild reaction conditions. The synthesis of the title compound is as follows:



1 $R_1, R_2 = H$; $R_3 = n\text{-}C_5H_{11}$
2 $R_1, R_2 = H$; $R_3 = COOH$
3 $R_1, R_2 = CH_2C_6H_5$; $R_3 = COOCH_2C_6H_5$
4 $R_1, R_2 = CH_2C_6H_5$, $R_3 = CH_2OH$
5 $R_1, R_2 = CH_2C_6H_5$; $R_3 = CHO$
6 $R_1, R_2 = CH_2C_6H_5$; $R_3 = CH(OH)C_4H_9(n\text{-})$

α-Resorcylic acid (**2**) was benzylated with potassium carbonate and benzyl chloride in DMF to give benzyl 3,5-bis(benzyloxy)benzoate (**3**) in 97% yield. Lithium aluminium hydride reduction of the benzyl ester followed by oxidation of the resulting alcohol (**4**) with pyridinium chlorochromate[5] afforded 3,5-bis(benzyloxy)benzaldehyde (**5**). Grignard reaction of butylmagnesium bromide on the aldehyde (**5**) furnished the alcohol (**6**). Refluxing of **6** with *p*-toluenesulfonic acid in benzene under Dean and Stark apparatus followed by hydrogenation of the resulting product with 10% Pd/C at room temperature afforded olivetol in 55% overall yield.

Experimental

Benzyl 3,5-Bis(benzyloxy)benzoate(3). This compound was prepared by refluxing and stirring a mixture of α-resorcylic acid (20 g; 0.129 mol), DMF (150 ml), K_2CO_3(107.64 g, 0.78 mol), and benzyl chloride (98.28 g, 0.78 mol), Reaction was monitored by TLC, after completion of the reaction (12 h), it was diluted with cold water and extracted with ether. Evaporation of solvent and crystallization of the residue with benzene–hexane afforded benzyl-bis(benzyloxy)-benzoate (54.2 g, 97%), mp 63—66 °C, ν_{max} 3090, 3060, 3035, 2925, 1740, 1600, 1490, 1450, 1375, 1350, 1300, 1260, 1225, 1170, 1110, 1060—1030, 985, 945, 920, 875, 855—835, 760 cm^{-1}. NMR: δ 4.88 (s, 4H), 5.24 (s, 2H), 6.64—7.2 (m, 18H).

3,5-Bis(benzyloxy)benzyl Alcohol(4). Benzyl ester (**3**, 54.0 g, 0.12 mol) was reduced with lithium aluminium hydride (9.12 g, 2 mol) in dry ether. It was decomposed with 5% hydrochloric acid. Removal of the solvent followed by crystallization from benzene–hexane gave the alcohol (38.5 g, 95%), mp 81.5—82 °C, ν_{max} 3370, 3040, 2920, 1610, 1470, 1220, 1160, 1050, 840, 770 cm^{-1}. NMR: δ 2.0 (s, 2H), 4.54 (s, 2H), 5.02 (s, 4H), 6.52—6.56 (m, 3H), 7.32 (m, 10H).

3,5-Bis(benzyloxy)benzaldehyde(5). To a stirred mixture of pyridinium chlorochromate (40 g), sodium acetate (3 g) in anhydrous dichloromethane was added the alcohol (**4**) (38 g, 0.118 mol). After stirring for 1 h, it was diluted with dry ether (80 ml) and the dichloromethane–ether layer was decanted. The residue was washed with dry ether and the total organic layer was passed through silica-gel column. Removal of the solvent followed by crystallization with benzene–hexane furnished aldehyde (35.05 g, 93%) mp 76.5—77 °C, ν_{max} 3100—2830, 2740, 1690, 1600, 1460, 1390, 1350, 1260, 1220, 1160, 1085, 1060, 955, 910, 840, 735 cm^{-1}. NMR: δ 4.96 (s, 4H), 6.64—7.28(m, 13H), 9.72(s, 1H).

1-[3,5-Bis(benzyloxy)phenyl]-1-pentanol (6). To a solution of butylmagnesium bromide (prepared from 30.14 g of butyl bromide and 5.76 g of magnesium) in anhydrous ether, was added aldehyde (**5**, 35.0 g, 0.11 mol) in anhydrous ether under N_2 at 0 °C with stirring. It was stirred at room temperature for 2 h and then decomposed with 5% H_2SO_4. Organic layer was separated and the aqueous layer extracted with ether. The combined organic layer after washing with brine was stripped off the solvent and the residue was crystallized from acetone–benzene to give the alcohol (**6**) 38.1 g, 92%), mp 88 °C, ν_{max} 3420, 3085—3035, 2940, 2870, 1610, 1460, 1380, 1300, 1220, 1160, 1060, 910, 840, 735 cm^{-1}. NMR: δ 0.88 (t, 3H), 1.28—2.08 (m, 6H), 4.64 (t, 1H), 4.96 (s, 4H), 6.48 (m, 3H), 7.28 (m, 10H).

5-Pentyl-1,3-benzenediol (Olivetol) (1). A solution of 1-[3,5-bis(benzyloxy)phenyl]-1-pentanol (**6**, 38 g, 0.1 mol), *p*-toluenesulfonic acid (0.6 g) in benzene (350 ml) was refluxed under Dean and Stark apparatus till no more water separated. It was washed with $NaHCO_3$ and brine solutions. Solvent was evaporated and the residue was dissolved in ethanol (300 ml). It was hydrogenated with 10% Pd/C (1 g). After filtration, the solvent was evaporated to have a thick residue which was distilled under vacuum to procure olivetol (12.1 g, 66.7%). IR and NMR are in agreement with those reported for authentic sample.[4d]

The Molecular Structure of Trimethylamine-Boron Triiodide as Studied by Gas Electron Diffraction

Kinya Iijima and Shuzo Shibata*

Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422

(Received August 23, 1982)

The molecular structure of trimethylamine–boron triiodide $(CH_3)_3N\cdot BI_3$ has been determined from gas electron-diffraction data. The molecular parameter values and their uncertainties are r_g(B–I) = 2.245±0.004 Å, r_g(N–B) = 1.663±0.013 Å, r_g(C–N) = 1.497±0.005 Å, r_g(C–H) = 1.103±0.010 Å, ∠IBI = 108.6±0.4°, and ∠CNC = 106.0±0.8°. The potential barrier around the N–B bond has also been estimated to be about 3.5 kcal mol^{-1} (1 cal = 4.184 J).

The molecular structures of the trimethylamine complexes of boron trifluoride, boron trichloride, and boron tribromide have been determined in both the gas[1–3] and solid phases,[4–6] while that of the boron triiodide complex has been done only in the solid phase.[6] These studies have given the results that the N–B bond distances of the first three complexes are significantly shorter and the B–X and C–N bond distances are longer in the solid phase than in the gas phase, and thus it is concluded that the dative bonding in trimethylamine–boron trihalides is enhanced in the solid phase.

It has also been reported that in the gas phase the fractional changes of the molecular parameters by the complex formation become larger as the atomic number of the halogen atoms involved in the complex increases,[2] correlating to the reorganization energies of boron trihalides.[7] It has also been found that the height of the rotational barrier about the N–B bond of trimethylamine–boron trihalide varies in the order $(CH_3)_3N\cdot BF_3$[1] < $(CH_3)_3N\cdot BBr_3$[2] < $(CH_3)_3N\cdot BCl_3$.[2] It is therefore interesting to determine the molecular structure of gaseous trimethylamine–boron triiodide, $(CH_3)_3N\cdot BI_3$, and the rotational barrier about the N–B bond by the electron diffraction method.

Experimental

The gas of trimethylamine that was produced by dropwise additions of an aqueous solution of sodium hydroxide to trimethylamine hydrochloride[8] was dried through soda lime and allowed to react with boron triiodide in benzene. The crude complex was dissolved in chloroform and impurities were eliminated by adding activated charcoal. The purity of the complex was checked by IR spectra.[9]

Electron diffraction photographs were taken by the use of an r^3-sector on Kodak Electron-Image plates at camera distances of 294 and 144 mm. The sample was vaporized at 483 K by means of a high temperature nozzle. An accelerating voltage was 40 kV and the wavelength was determined from the diffraction patterns of thallium(I) chloride.[10] The exposure times were about 13 and 30 s for the long and short camera distance photographs, respectively, with an electron-beam current of 0.8 μA. The pressure in the diffraction chamber was 1×10^{-5} Torr (1 Torr = 133.322 Pa) during the experiment. Three plates were selected for each camera distance and their optical densities were measured at 0.4 mm intervals by the use of a digital microphotometer. The electron diffraction unit and the digital microphotometer used in the present study have been described elsewhere.[11]

Analysis and Results

Molecular Intensity and Radial Distribution. The scattering intensities in the range of s = 2.5—14.8 Å^{-1} were obtained from the long camera distance plates and those in the range of s = 7.5—34.6 Å^{-1} from the short camera distance plates. They were leveled by theoretical backgrounds, and then the intensities for each camera distance were averaged. The elastic and inelastic scattering factors were taken from the tables prepared by Schäfer *et al.*[12] and by Cromer and Mann,[13] respectively. The inelastic scattering factor for the hydrogen atom was taken from the table by Tavard *et al.*[14]

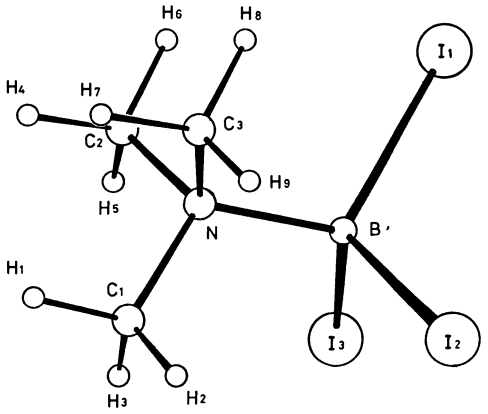

Fig. 1. Numbering of atoms in trimethylamine–boron triiodide (symmetry C_{3v}).

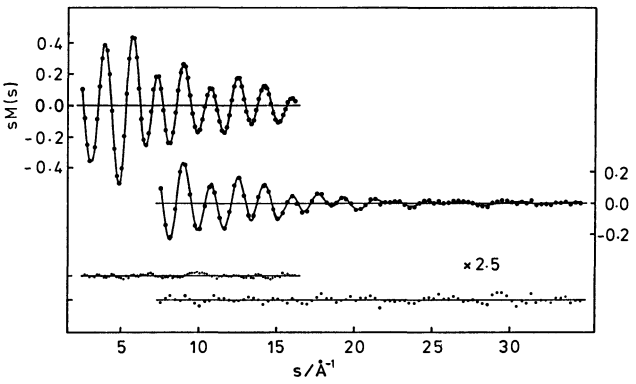

Fig. 2. Molecular intensities for trimethylamine–boron triiodide. The two upper curves are long and short camera-distance data. Dots represent observed ones, solid curves calculated ones, and their residuals are shown below.

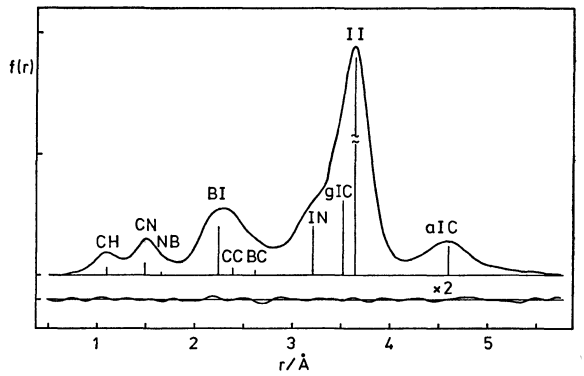

Fig. 3. Experimental radial distribution curve for trimethylamine–boron triiodide. Lower curve represents two times the difference between the experimental and the calculated curves.

The molecular intensities obtained by drawing backgrounds smoothly on the experimental intensities[15] are shown in Fig. 2. The radial distribution function corrected for the large difference[16] in the atomic numbers of the atoms contained in $(CH_3)_3N\cdot BI_3$ is shown in Fig. 3.

Vibrational Amplitudes and Shrinkage Corrections. Root-mean-square amplitudes of the atomic pairs in the staggered form were calculated on the basis of the Urey-Bradley force field obtained from the vibrational spectra of solid $(CH_3)_3N\cdot BI_3$.[9] However, the calculated l(I···I) disagreed with the observed one in the gas phase as will be described later. The force constant F(II) was adjusted to give a better agreement between the calculated and observed l(I···I) amplitudes, since it greatly contributes to the l(I···I). The corrected force constant yielded the decrease of about 50 cm^{-1} in wave numbers for the symmetric and antisymmetric deformations of BI_3. The mean amplitudes and the shrinkage corrections, r_a-r_α,[17] were calculated on the basis of the force constants listed in Table 1, as shown in Table 2.

Molecular Structure and Potential Barrier Height. The molecular parameters of $(CH_3)_3N\cdot BI_3$ have been determined by the least-squares analysis of molecular intensities. Both of the donor and acceptor parts in the complex molecule were assumed to have the C_{3v} symmetry. The methyl groups were also assumed to have the C_{3v} symmetry in a staggered form with respect to the C–N bonds. The geometrical parameters determined by the least-squares analysis are as follows: r(B–I), r(N–B), r(C–N), r(C–H), r(I···I), r(C···C), and ∠NCH. The mean amplitudes of some atom pairs were refined by the least-squares analysis as listed in Table 3. The mean amplitudes of other bonds and atom pairs which are independent of the rotation around the N–B bond were fixed to the values listed in Table 2. The shrinkage corrections for all the atom pairs were also fixed to the values listed in Table 2. The asymmetry parameters, κ, for the B–I, N–B, C–N, and C–H bonds were estimated to be 16, 7.9, 2.6, and 12×10^{-6} Å^3, respectively, by the diatomic approximation[18] and those for the other atom pairs were ignored.

The torsional vibration around the N–B bond contributes greatly to the mean amplitude of the *gauche* I···C atom pair. The analysis assuming a high barrier approximation,[19] however, could not give a reasonable value for that amplitude, so the potential barrier around the N–B bond seemed to be pretty small. Thus the molecule was treated in a low barrier approximation.[19] The mean amplitudes of the rotation-dependent atom pairs were calculated at various torsional angles on the basis of the force field in Table

Table 1. Urey-Bradley force field for $(CH_3)_3N\cdot BI_3$

K(NB)	1.3	H(NCH)	0.3
K(BI)	0.9	F(II)	0.2

I···N	0.086 (9)	0.087

a) Results obtained from the least-squares analysis of electron-diffraction data. Limits of error are shown in parentheses. b) Values calculated from the force constants in Table 1.

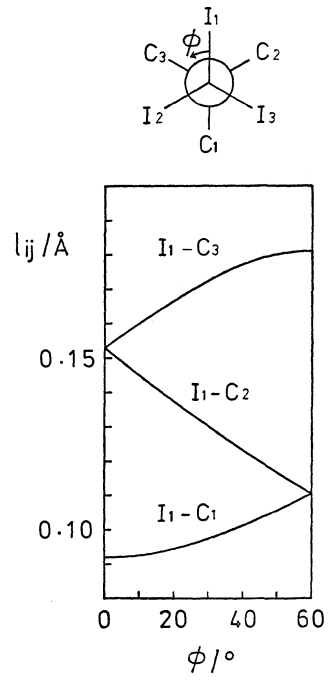

Fig. 4. Calculated mean amplitudes for the atomic pairs which are dependent on the rotation around the N–B bond. The ϕ is the rotational angle from the staggered position.

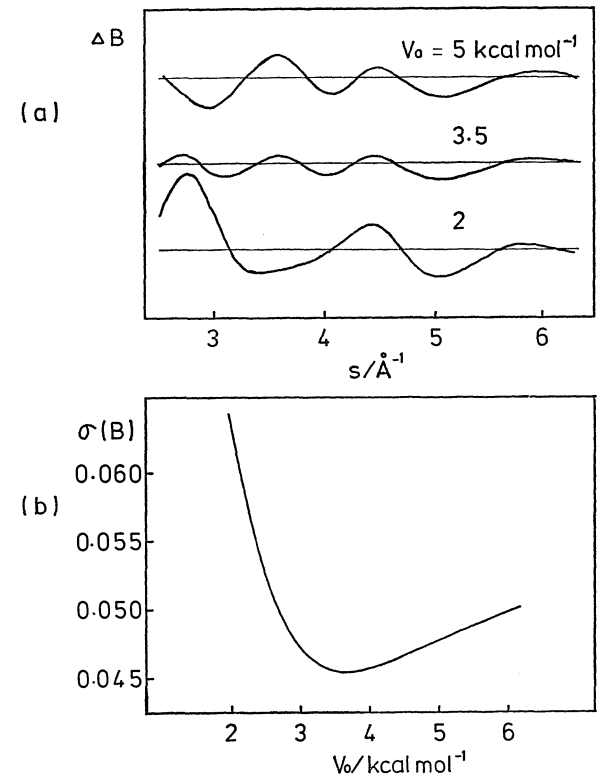

Fig. 5. (a) The difference curves between the smooth and the calculated backgrounds in the small angle range. The V_0 is the assumed potential-barrier height around the N–B bond. (b) The root-mean-square value of ΔB versus the assumed potential-barrier height around the N–B bond.

1. The dependence of these amplitudes on the torsional angle ϕ is shown in Fig. 4. They were fixed throughout the analysis. The molecular intensities were calculated at 6° intervals of the torsional angles and summed with the weights of the Boltzmann distribution. The scattering intensities in a small-angle range depend considerably on the height of the potential barrier. Therefore the potential-barrier height was determined by inspecting the shape of the backgrounds calculated from both the experimental intensities and the theoretical molecular intensities for models with various potential barriers, since the experimental backgrounds should be smooth.[20] The differences between the experimental backgrounds and the calculated backgrounds, ΔB, are shown in Fig. 5(a), and the root-mean-square values of ΔB are shown for each potential-barrier height in Fig. 5(b). These figures indicate that the potential barrier around the N–B bond is about 3.5 kcal mol^{-1}.

The geometrical parameters obtained by the least-squares calculation, in which the potential-barrier height was assumed to be 3.5 kcal mol^{-1}, are listed in Table 4 with the limits of error. The random errors were 2.6 times as large as the errors estimated by the least-squares calculations. The systematic errors were estimated from the errors in both the measurements of camera distance (0.04%) and wavelength (0.09%). The best-fit theoretical molecular intensities are shown in Fig. 2. The experimental intensities, the experimental smooth backgrounds, and the correlation matrix for the molecular parameters are deposited in Document No. 8328 at the Office of the Editor of the Bulletin of the Chemical Society of Japan. The calculations of the mean-amplitudes and the shrinkage corrections and the least-squares analysis were carried out on a HITAC M-200H computer in the Computer Center of the University of Tokyo.

Discussion

The molecular parameters for the trimethylamine-boron trihalide complexes in the gas phase are listed in Table 5, together with those in the solid phase[4–6] and those for the component molecules.[21–25] As seen for all of trimethylamine–boron trihalide complexes, the distances of B–X and C–N bonds increase and the angles of XBX and CNC decrease on the complex

TABLE 5. COMPARISON OF MOLECULAR PARAMETERS

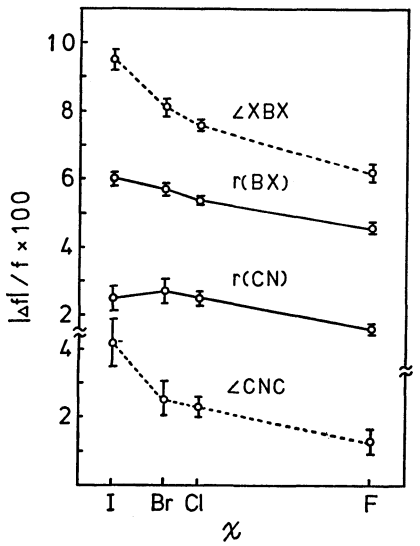

Fig. 6. Parameter changes on complex formation. The abscissa shows the magnitude of the electronegativity χ of the halogen atoms in the acceptor molecules. Solid curves represent positive Δf and dashed curves negative Δf.

formation and the magnitudes of the structural changes of the acceptor molecules are larger than those of the donor molecules. The fractional differences of the parameters, $\Delta f/f$, between the complex and the corresponding free molecules are plotted in Fig. 6 *versus* the electronegativity values of the halogen atoms[26] in the complexes. The differences are in the order $(CH_3)_3N\cdot BF_3 < (CH_3)_3N\cdot BCl_3 < (CH_3)_3N\cdot BBr_3 < (CH_3)_3N\cdot BI_3$, while the N–B bond distances in the trimethylamine complexes are nearly constant in the gas phase as well as in the solid phase with no systematic change by the halogen atoms. This order agrees with the order of heat of reaction of boron trihalides with pyridine from the calorimetric measurements,[27] and also with the order of the relative acceptor power of boron trihalides from the gas-phase displacement reactions,[28,29] though there have been no data for the $(CH_3)_3N\cdot BI_3$ complex. Thus it may be concluded that a complex formed with larger heat of reaction is subject to greater distortion and that a stable complex is not necessarily accompanied by the dative bond with a short distance. However, it is noted that these structural changes found in trimethylamine–boron trihalides are in contrast with those in the complexes of trimethylphosphine–boron trihalides;[30] on the complex formation of trimethylphosphine–boron trihalide the change of the molecular parameters for the complex with larger halogen atom is smaller in spite of the larger heat of reaction.[31,32] This situation cannot be reasonably explained at the present stage.

In the solid phase the B–I and C–N distances are larger and the IBI and CNC angles are smaller than in the gas phase. The structural changes on the complex formation seem to be magnified in the solid phase. The N–B bond distance of $(CH_3)_3N\cdot BI_3$ is smaller than in the gas phase by 0.08 Å. The same trends are seen in other trimethylamine–boron trihalide complexes. Thus it will be concluded that in all trimethylamine–boron trihalides the donor–acceptor bondings are enhanced in the solid phase.

The rotational barrier around the N–B bond in $(CH_3)_3N\cdot BI_3$ is about 3.5 kcal mol^{-1}. In the series of the trimethylamine–boron trihalide complexes, the rotational barriers decrease in the sequence of $(CH_3)_3N\cdot BCl_3$ (>18 kcal mol^{-1}),[2] $(CH_3)_3N\cdot BBr_3$ (10 kcal mol^{-1}),[2] and $(CH_3)_3N\cdot BI_3$. However, the rotational barrier height of $(CH_3)_3N\cdot BF_3$ was found to be 4.3 kcal mol^{-1},[1] which is nearly equal to that of the $(CH_3)_3N\cdot BI_3$ complex. These results are consistent with the results from NMR measurements.[33] The rotation around the N–B bond seems to be mainly hindered by repulsion between the methyl groups and the halogen atoms. The distances of $X_1\cdots H_6$ (see Fig. 1), which are considerably shorter than their van der Waals distances, increase as the atomic numbers of the halogen atoms involved become larger, and therefore their potential barriers are considered to become smaller. However, the barrier height of $(CH_3)_3N\cdot BF_3$ is much smaller than that of $(CH_3)_3N\cdot BCl_3$. This may be due to that the van der Waals radius of a fluorine atom is comparatively small and the $X_1\cdots H_6$ distance is nearly equal to the van der

Waals distance.

The Cation-Cation Interactions in Aqueous Mixed Electrolyte Solutions of Quaternary Phosphonium Chlorides

Katsuko TAKAIZUMI* and Toshiki WAKABAYASHI
The College of General Education, Tohoku University, Kawauchi, Sendai 980

(Received September 20, 1982)

Density measurements were carried out at six temperatures between 1 and 55 °C for three series of aqueous mixed electrolyte solutions, each of which contained $(n\text{-Bu})_4PCl$ and Ph_4PCl with the mole ratios, 3:1, 1:1, and 1:3, respectively. The mixed solutions are assumed to be the model solutions of the phosphonium chlorides, $(n\text{-Bu})_{4-n}Ph_nPCl$($n=1,2$, and 3), with respect to the pair-wise interactions between the cations, for which a model has been proposed in a previous paper.[1] The volume B-coefficients(B_v) determined for the model salts are in good agreement with those for the corresponding pure salts and those reproduced by the equation derived from the model. The results indicate that the phenyl groups affect weakly the butyl cospheres in both the intermolecular processes and intramolecular processes and that among the ion-ion interactions the cation-cation interactions are the main factor for determining the B_v's. These can be decomposed into three parts, arising from the butyl-butyl, phenyl-phenyl, and butyl-phenyl interactions.

In a previous paper[1], we reported the volume behavior of the quaternary phosphonium salts, $(n\text{-Bu})_{4-n}Ph_nPCl$($n=1$—4) and Bu_4PBr, in aqueous solutions in the temperature range 1—55 °C. The volume B-coefficients(B_v), which would reflect the effects arising from the pair-wise interactions between ions through the ionic cospheres,[2] were determined. It was possible to reproduce the numerical values for B_v of the salts with n from 1 to 3 from those of the salts with n of 0 and 4 by the equation derived from these assumptions: (a) the B_v's are determined mainly by the effects resulting from the cation-cation interactions; (b) when any two cations approach each other, the interaction takes place between a cosphere of one of the hydrocarbon groups on a cation and that on another cation, and we have three types of the interactions, butyl-butyl, phenyl-phenyl, and butyl-phenyl; (c) each interaction takes place on a purely chance basis, that is, in proportion to the 'concentration' of the group. If these assumptions are adequate, we may anticipate that, in the aqueous mixed electrolyte solutions containing $(n\text{-Bu})_4PCl$ and Ph_4PCl with the mole ratio, $(4\text{-}n):n$, the B_v's found for the mixed salts(model salts) should be the same as those found for the pure salts.

In this paper, we report the volumetric properties of three kinds of model salts corresponding to the pure salts with $n=1$, 2, and 3, respectively, and $(n\text{-Bu})_4PCl$ in aqueous solutions at the temperatures 1, 5, 10, 25, 40, and 55 °C.

Experimental

The $(n\text{-Bu})_4PCl$ was obtained from Alfa Division Ventron and was purified as follows. The salt was dissolved in water, washed repeatedly with a small amount of CH_2Cl_2 to remove colored substances, extracted in the presence of NaCl(*ca.* 2 mol kg^{-1}) into $CHCl_3$ phase, which was then washed with a small amount of deionized water, and finally extracted into conductivity-grade water. The aqueous solution was degassed to remove $CHCl_3$ at about 40 °C under reduced pressure and then filtered through a Millipore filter. The clathrate-like hydrate, obtained by cooling the aqueous solution, was collected. The aqueous solution was analyzed gravimetrically for the anion content using $AgNO_3$. The methods for purifying the Ph_4PCl and for preparing the stock solution were the same as previously reported.[1,3]

Three kinds of mixed stock solutions were prepared by mixing both the stock solutions on a weight basis to give the mole ratios of Bu_4PCl to Ph_4PCl, 3:1, 1:1, and 1:3. The solutions for density measurement were obtained by dilution from the mixed stock solutions on a weight basis.

General procedures and reproducibility for the density measurements were essentially the same as those reported previously.[1,3] The measurements were carried out over the concentration range from about 0.04 to 1.5 mol dm^{-3} for each series of the mixed solutions and at the temperatures, 1, 5, 10, 25, 40, and 55 °C. The temperatures of the water bath, in which the pycnometers were immersed, were controlled to 0.01 °C for the measurements at 1, 5, and 55 °C, 0.005 for 25 °C, and 0.007 for 10 and 40 °C.

Results and Discussion

The apparent molar volumes, ϕ_v, for the model salts corresponding to Bu_3PhPCl, Bu_2Ph_2PCl and $BuPh_3PCl$, at six temperatures are listed in Table 1. The ϕ_v's for Bu_4PCl, which had not been determined in the previous work,[1] are also listed.

The ϕ_v's were obtained from the density data by the usual equation:

$$\phi_v = \frac{1}{m}\left(\frac{1000+mM}{d_{soln}} - \frac{1000}{d_o}\right), \quad (1)$$

where m and M are the molality and molecular weight of the model salt which equals that of $(n\text{-Bu})_{4-n}Ph_nPCl$.

The ϕ_v's are assumed to follow the equation;

$$\phi_v = \phi_v^\circ + A_v c^{1/2} + B_v c + C_v c^2 + D_v c^3, \quad (2)$$

where ϕ_v° is the standard partial molar volume of the model salt, A_v the Debye-Hückel limiting slope, and the other coefficients are empirical parameters. The values for A_v at various temperatures were taken from the table compiled by Redlich and Meyer.[4] The other coefficients were determined by the least-squares method to fit the ϕ_v's to the equation.

The numerical values for these coefficients are presented in Table 2, together with the uncertainties (σ_1) of the coefficients and the standard deviations(σ) between the observed and reproduced ϕ_v's. The corresponding coefficients for the pure salts are also listed, for comparison. The differences between ϕ_v's for Bu_4PCl in this work and those in the previous work[1],

which were obtained from ϕ_v's for Bu_4PBr by subtracting the differences in the anionic partial molar volume, $\phi_{v,-}^{\circ}(Br^-) - \phi_{v,-}^{\circ}(Cl^-)$[3], are within 0.08% except for the difference at 1 °C, about 0.15% (Table 2).

Figure 1 shows the ϕ_v's of the mixed salts as a function of the square root of concentration (mol dm^{-3}), together with those of the pure salts. The ϕ_v curves of the three mixed salts are very similar to those for the corresponding pure salts in the low concentration range, while at higher concentrations the similarity in the ϕ_v behavior is not found. This aspect is re-

flected in the agreement of the B_V value for the mixed salts with that for the pure salts(Fig. 2 and Table 2). This may be an important clue for interpreting the physical meaning of the B_V's obtained as empirical parameters. Before discussing the subject, we note that the B_V value is very close to half of B_{2V} which is the coefficient of the linear term of c in the equation for the partial molar volume.[15] Some discussion about B_V will follow.

For dilute solutions, we may reasonably expect that, besides the long-range interactions among ions due to the coulombic force, there may be pairwise interactions between ions at short distances originating from various kinds of potentials. (The potentials other than the coulombic one used by Friedman and coworkers[7,8] are the following; the core repulsion potential, the potential of the ion-cavity interaction between two ions, and the Gurney potential representing the effect of the overlap of the cospheres when the ions come close together. The B_V coefficient would contain the contributions derived from all these potentials.) The agreement in B_V, therefore, suggests strongly that in any given mixed system at low concentrations the ion-ion interactions would take place in a way similar

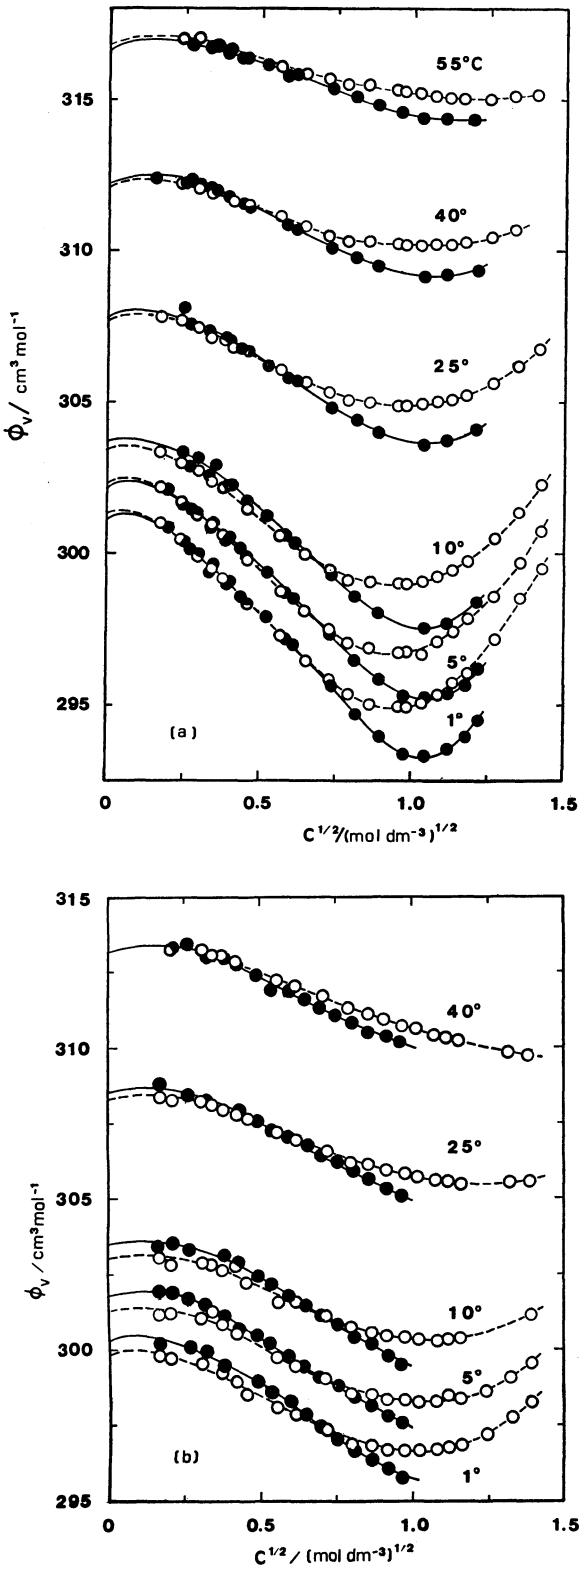

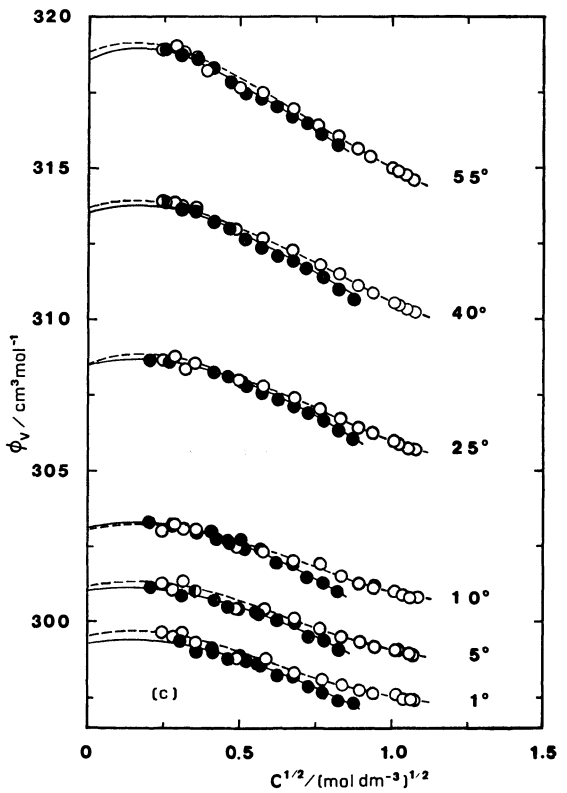

Fig. 1. Comparison of ϕ_V's for the model salts with those for the pure ralts.
Model salt; —●—. Pure salt; --○--. (a) 3:1 model salt and Bu_3PhPCl, (b) 1:1 model salts and Bu_2Ph_2PCl, (c) 1:3 model salt and $BuPh_3PCl$.

to those in the corresponding pure system. Since the actual species in the mixed systems are quite different from those in the pure systems, we should obtain B_V values for the mixed systems different from those for the pure systems, if the B_V's determined from experimental data reflect significantly the effects from short-range interactions among more than two ions, and if the states of cosphere water around a group, say, butyl (or phenyl) group on the cations with n from 1 to 3 differ considerably from those around the butyl(or phenyl) groups on the Bu_4P^+(or Ph_4P^+) ion. Thus we may conclude that the present B_V's reflect mainly pairwise interactions between ions: ++, +−, and −−, and that the cosphere around a group on the cations(n=1—3) is affected weakly by the unlike groups, as concluded in previous papers.[1,18]

There are indications that the cation-cation interactions are the dominant contribution to the excess volumes of some salts containing large-sized organic cations. As may be seen from Table 2, the concentration dependence of ϕ_V of Bu_4PCl at all temperatures examined is very similar to that of Bu_4PBr; the differences between their B_V's are only around 10% and the higher coefficients, C_V and D_V, are in agreement within the experimental uncertainties. If the cation-anion interactions contribute largely to the excess volume, different results would have been obtained because the two anions are known to affect the water structures differently. The situation is similar for the cations containing phenyl groups: the B_V values at 25 °C of Bu_3PhPCl and Bu_3PhPBr are −10.5(±.28) and −11(±.4), and those of Bu_2Ph_2PCl and Bu_2Ph_2PBr, −7.87(±.26) and −7(±.5) cm^3 mol^{-2} dm^3, respectively.[1,3] Volume behavior peculiar to the hydrophobic salts such as n-Bu_4NX[5,6] and (n-Bu)$_3$N(CH$_2$)$_8$N(n-Bu)$_3$Br$_2$[16] in aqueous solutions has been interpreted in terms of the clathrate-like model

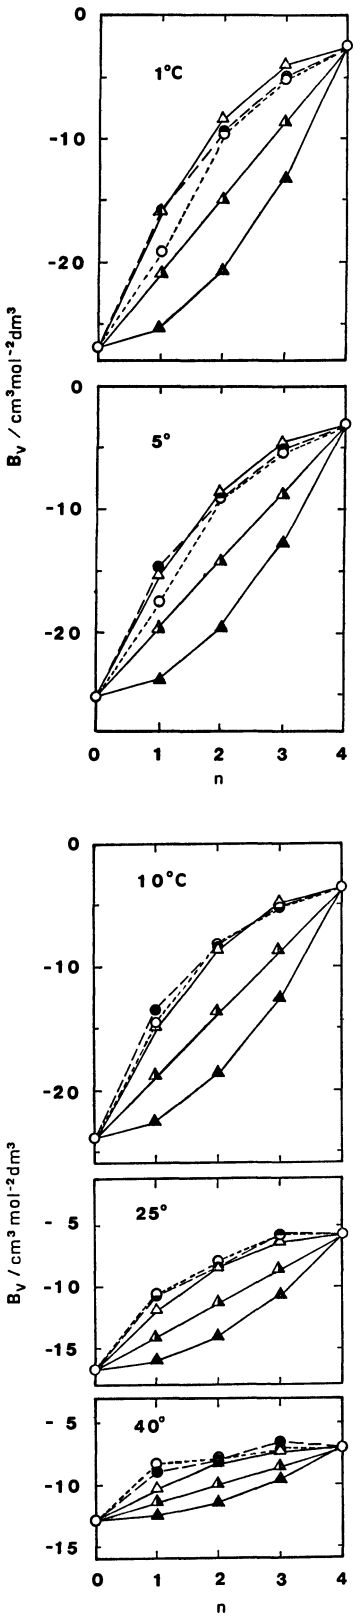

Fig. 2. Comparison of the B_V-coefficients.

of hydration, in which the cation-cation pairing through water sheath were assumed to be the dominant effect in determining their volume behavior. The results of a model calculation for tetraalkylammonium halides (R_4NX) by Streng and Wen[9,10] shows that, of the three excess volume parameters, V_{++}, V_{+-}, and V_{--}, V_{++} is negative and several times larger in magnitude than V_{+-} for higher three cations(from R=ethyl to *n*-butyl) but is comparable with tetramethylammonium halides, in the calculation V_{--} was assumed to be zero and the anions were the Cl^- and Br^- ions. One reason for these observations is suggested by the cosphere overlap model: the contribution to the excess volume from cosphere overlapping depends on the volume(V_{mu}) of the cosphere-overlap region, from which the cosphere material(water) relaxes to the bulk water. This process results in volume changes of the system caused by the change of the state of water, both in the cosphere region shared by the two ions and in the relaxing part. The V_{mu} is reasonably expected to become increasingly larger as the size of the participant ions increases.

From the above, we assume that the B_V obtained here reflect all the effects resulting from the pairwise interactions between cations. This is of course an oversimplified interpretation for B_V, but is a first step in approaching the volumetric properties of the salts which contain large-sized ions. For a nonelectrolyte solute, the B_V coefficient may have a more distinct meaning,[2] that is, it may be correlated with the pressure derivative of the pair interaction coefficient in the virial-type expression for the chemical potential of the solute.

Based on this assumption, a further analysis for B_V is possible. In a given mixed system, there happen three types of cation-cation interactions: Bu_4P^+–Bu_4P^+, Ph_4P^+–Ph_4P^+, and Bu_4P^+–Ph_4P^+. Since the present cations have nearly the same molar volume and are roughly spherical in shape, we assume approximately that a given cation i would encounter another cation j at a short distance, where the cosphere overlap takes place(cation pairing), with a relative probability proportional only to the number density of species j.[17] Thus, for the mixed system containing Bu_4PCl and Ph_4PCl with the mole ratio, $(4-n):n$, we can express a conditional probability $P_{ij}(n)$, with which we find the cations i and j in a cation pair, by the equation:

$$P_{BB}(n) = \left(\frac{4-n}{4}\right)^2, \quad P_{PP}(n) = \left(\frac{n}{4}\right)^2,$$

$$P_{BP}(n) = 2\left(\frac{4-n}{4}\right)\left(\frac{n}{4}\right), \qquad (3)$$

where the subscripts B and P stand for the cations Bu_4P^+ and Ph_4P^+, respectively. The $B_V(n)$, the B_V coefficient expected for the mixed system, therefore, can be given by

$$B_V(n) = B_V(0)P_{BB}(n) + B_V(4)P_{PP}(n) + bP_{BP}(n), \qquad (4)$$

where $B_V(0)$ and $B_V(4)$ are the observed B_V's for Bu_4PCl and Ph_4PCl in each pure solution, respectively. Here, b is the volume contribution from pairwise interactions between the unlike cations. The b value is unknown and three limiting cases are examined.

1) $b=[B_V(0)+B_V(4)]/2$, 2) $b=B_V(4)$, and 3) $b=B_V(0)$. In Fig. 2, the limiting cases are compared together with the observed B_V's.[14] Clearly, case 2 is most suitable throughout these n values and temperatures. In terms of the cosphere overlap model, case 2 means that when unlike two cations interact at a short distance, a part of the cosphere water around a phenyl group relaxes to the bulk water in a way similar to the case of the Ph_4P^+–Ph_4P^+ interaction, while the butyl cosphere is maintained.

Equation 4 is quite the same as that for the pure systems, if we read the subscripts B and P as the butyl and phenyl group and $P_{ij}(n)$ as the conditional probability with which we find group i and j in a cation pair(two like cations containing n phenyl groups). This is the reason for examining the present systems as the model systems for the aqueous solutions of the $Bu_{4-n}Ph_nPCl$ salts.

In essence, Eq. 4 is derived by neglecting the effects arising from the coulombic interactions, except for the limiting long-range coulombic interaction, which is partially taken into account through the second term in Eq. 2. It is expected, therefore, that the present approach would be more reasonable for nonelectrolyte solutes. Wood and coworkers[11,12] have developed a method to assign pairwise group-group interaction parameters for enthalpies and chemical potentials of nonelectrolytes in aqueous solutions. The basic assumptions in our previous work[1] (the assumptions b and c in this introduction) are essentially the same as theirs. Whether or not the approach presented here is reasonable would depend on the relative magnitudes of two contributions: from short-range pairwise interactions and from the coulombic interactions. It seems that the short-range interactions become relatively more important as ion size increases. In this respect, the result obtained by Visser *et al.*[13] should be noted; they applied Savage and Wood's concept to several tetraalkylammonium bromides in aqueous solutions and found that values of the functional group interaction parameters(enthalpy) for both nonelectrolytes and electrolytes are in reasonable agreement.

We believe that the present results support the simple assumptions made in the previous work for interpreting the B_V coefficients found experimentally for the phosphonium halides in aqueous solutions, and that the present approach can be an empirical way to test the validity of the simple additivity rule assumed for splitting the pairwise interaction parameters for enthalpy and free energy as well as volume into contributions from group-group interactions.

14) The B_V values for Ph_4PCl were taken from Ref. 1: −2.48, −3.05, −3.54, −5.77, and −6.98 $cm^3\ mol^{-2}\ dm^3$ at 1, 5, 10, 25, and 40 °C, respectively.

15) The partial molar volume of 1:1 salt can be expressed as

$$\overline{V}_2 = \phi_V^\circ + \frac{3}{2}A_V c^{1/2} + B_{2V}c + B_{3V}c^2 + B_{4V}c^3 + \cdots. \quad (A)$$

Converting the ϕ_V to $\overline{V}_2$ by the usual way, we can determine the coefficients B_{2V}, B_{3V}, *etc.* For all the present salts, the B_{2V} values agreed well with the B_V values times 2 within about 0.3%. The agreement is what is expected. Using the coefficients for ϕ_V (Eq. 2), we obtain the expression for $\overline{V}_2$ as a polynomial in $c^{1/2}$:

$$\overline{V}_2 = \phi_V^\circ + \frac{3}{2}A_V c^{1/2} + 2B_V c + [-A_V\phi_V^\circ/2000]c^{3/2} + [\ \ ]c^2 + \cdots.$$

The $c^{3/2}$ term is negligible, *i.e.*, *ca.* 0.3 $cm^3\ mol^{-1}$ even at 1 mol dm^{-3}. Hence B_{2V} in Eq. A is very close to $2B_V$.

16) T. L. Broadwater and D. F. Evans, *J. Phys. Chem.*, **73**, 164 (1969).

17) The pair correlation function g_{ij} is determined by the free energy of pairwise interaction between i and j. The Gurney potential for, say, butyl-butyl overlapping may differ considerably from those for other overlappings, and hence the relative probability to find a cation pair is not proportional to the concentration product(c_ic_j) only, even if other potentials are assumed to be the same. However, the same assumption as used in this work has usually been made in empirical approaches,[11-13] and may be a permissible one in view of the present stage of theory.

††*Escuela de Ingeniería, CIPM, Universidad de Sonora, Hermosillo, Sonora, Mexico*

(Received October 9, 1982)

Electron spin resonance spectra were recorded on highly conducting $CuL(TCNQ)_2$ (L: 2,2′-bipyridine or ethylenediamine) at different temperatures. The observed g values increased with decreasing temperature. On the basis of the g shift and the static susceptibility observed, a local magnetic susceptibility contributed from Cu and that from TCNQ were evaluated individually. The local Cu susceptibility is of the Curie type. The Curie constant indicates that each Cu atom carries 0.05 umpaired electron on the average in $Cu(bpy)(TCNQ)_2$ and 0.07 in $Cu(en)(TCNQ)_2$: the average oxidation number of copper is equal to 1.05 in the former and 1.07 in the latter. The local susceptibility of TCNQ can be interpreted by a narrow band model in which the susceptibility is given by the sum of the Curie term and a temperature-independent paramagnetic term. This suggests that the TCNQ arrays have inherently metallic nature.

High electrical conductivity has been observed for a series of $CuL(TCNQ)_2$ (L:ethylenediamine, 2,2′-bipyridine, 1,10-phenanthroline, or their derivatives; TCNQ: 7,7,8,8-tetracyanoquinodimethan).[1,2] The powder conductivity amounts to 0.004—1.9 Ω^{-1} cm^{-1} at 300 K depending on the coordinating ligand.[1-3] These values are comparable to the powder conductivities observed for quinolinium$(TCNQ)_2$ and I_2-doped Ni-phthalocyanine whose single crystals exhibit metallic properties.[4-6] The presence of unpaired electrons has been pointed out to be required for the so-called synthetic metals.[7] Therefore, the magnetic study of conducting materials is essential to clarify the mechanism of the electrical conduction. Recently, we have briefly reported the magnetic susceptibilities of some typical $CuL(TCNQ)_2$ complexes.[2] The results suggested that the copper atoms have an intermediate oxidation state due to the so-called equilibrium in solids:

$$\dot{C}u^{2+}L(TCNQ)_2^{2-} \rightleftarrows \ddot{C}u^{+}L(TCNQ)_2^{-}. \quad (1)$$

The resulting incomplete electron transfer yields conduction electrons in TCNQ arrays. The purpose of the present investigation is to obtain further information about the role of unpaired electrons in the electrical conduction. In this point of view, we have recorded the ESR spectra of the Cu complexes at different temperatures, and analyzed the magnetic susceptibilities in detail by taking the ESR results into account.

Experimental

The materials were prepared by the same method as reported previously.[1,2] The ESR spectra were recorded by means of a JEOL SCXA X-band spectrometer in a temperature range of 90—300 K. The temperature of the samples was controlled within ±1 K by a cold-gas flow method, and it was determined by two copper-constantan thermocouples placed near either side of the specimen along the gas flow. Mn^{2+}/MgO was employed as a marker.

Results and Discussion

ESR Spectra. Figure 1 shows ESR spectra observed for $Cu(en)(TCNQ)_2$ and $Cu(bpy)(TCNQ)_2$ at different temperatures. A sharp signal observed at g=2.00 in each spectrum is attributed to free $TCNQ^-$ ions involved as impurities in the samples. The intrinsic spectrum of each compound consists of a simple derivative curve with a g value intermediate between 2.003 of Li(TCNQ) and 2.1 of normal Cu(II) complexes. This indicates that Cu(II) and $TCNQ^-$ ions interact magnetically with a spin-exchange energy

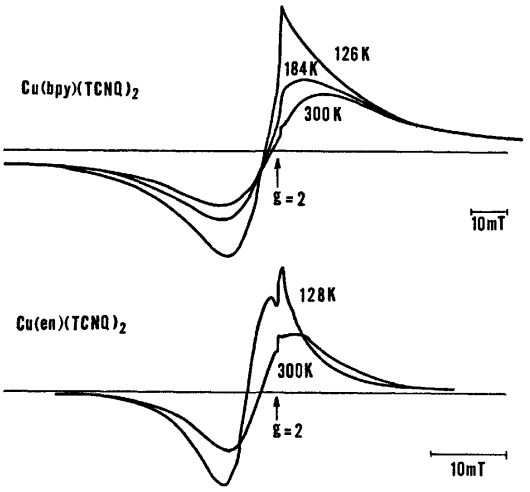

Fig. 1. ESR spectra observed for $Cu(bpy)(TCNQ)_2$ and $Cu(en)(TCNQ)_2$ at different temperatures. They were recorded in the same spectrum condition for each compound.

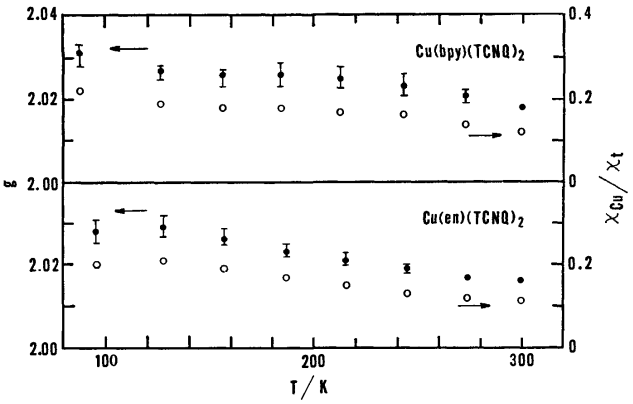

Fig. 2. g factor and the ratio of the local Cu susceptibility to the total susceptibility χ_{Cu}/χ_t.

much larger than that of the g value difference mentioned above. The g value of each compound fluctuated from sample to sample at low temperatures. This is probably due to the fluctuation of the impurity-signal strength. Figure 2, however, shows that the g value obviously increases with decreasing temperature.

Cu(phen)(TCNQ)$_2$ exhibited a spectrum resembling that of Cu(bpy)(TCNQ)$_2$, but an impurity signal at $g=2.00$ was too strong to determine the g value of the intrinsic signal.

Static Magnetic Susceptibility. The magnetic susceptibilities[8] χ of the complexes deviated from the Curie-Weiss law[2] and obeyed the following experimental equation as shown in Figs. 3 and 4:

$$\chi = \gamma/T + \alpha. \quad (2)$$

The parameters[8] were evaluated as $\gamma=0.052$ emu K mol^{-1} and $\alpha=4.6\times10^{-4}$ emu mol^{-1} for Cu(bpy)-(TCNQ)$_2$ and $\gamma=0.093$ emu K mol^{-1} and $\alpha=2.2\times10^{-4}$ emu mol^{-1} for Cu(en)(TCNQ)$_2$. These large α values of the temperature-independent paramagnetic term result in the deviation of the susceptibilities from the Curie-Weiss law. The uncertainty of diamagnetic correction may give an error in determining small spin susceptibility. The α values, however, are comparable to the employed diamagnetic corrections:[2] 3.47×10^{-4} emu mol^{-1} for Cu(bpy)(TCNQ)$_2$ and 2.88×10^{-4} emu mol^{-1} for Cu(en)(TCNQ)$_2$. These values of the corrections were based on diamagnetic susceptibilities observed for the constituent molecules,[9,10] and the uncertainty is estimated to be equal to at most 10%. Therefore, the large α values are not caused by the uncertainty of the diamagnetic corrections, but are ascribed to the intrinsic nature of the complexes. The following ESR results show that the γ/T term also is intrinsic to the complexes. 1) In each spectrum, the integrated intensity of the impurity signal due to isolated TCNQ$^-$ ions was very small compared with that of the intrinsic signal. 2) Every spectrum showed no appreciable impurity signal assignable to isolated Cu(II) ions. 3) The intrinsic signal became strong with decreasing temperature similarly to the temperature dependence of the static susceptibility, although its integrated intensity was difficult to evaluate accurately owing to the impurity signal at $g=2.00$.

g Value and Local Susceptibility. The g value of a spin system in which Cu(II) ions interact with TCNQ$^-$ radical ions is given by an average of the individual g values, g_{Cu} and g_{TQ} (TQ stands for TCNQ), in a strong coupling approximation:[11]

$$g = (\chi_{Cu}g_{Cu}+2\chi_{TQ}g_{TQ})/\chi_t, \quad (3)$$

where χ_{Cu} and χ_{TQ} are local magnetic susceptibilities contributed from Cu and TCNQ, respectively. The total susceptibility χ_t given by

$$\chi_t = \chi_{Cu} + 2\chi_{TQ} \quad (4)$$

can be equated with the observed static susceptibility. The factor 2 comes from the number of TCNQ radicals involved in the chemical unit. If g_{Cu} and g_{TQ} are reasonably assumed, χ_{Cu} and χ_{TQ} can be determined individually from the g factor and the static susceptibility. g_{TQ} can be assumed to be equal to the g value 2.003 of Li(TCNQ). Cu(bpy)$(NO_3)_2\cdot3H_2O$ exhibited an ESR spectrum characteristic of Cu(II) complexes having an axial symmetry: $g_\parallel=2.260$ and $g_\perp=2.067$. The averaged g factor $g_{av}=[(g_\parallel{}^2+2g_\perp{}^2)/3]^{1/2}=2.133$ can be employed as g_{Cu}. Thus, χ_{Cu} and χ_{TQ} of Cu(bpy)(TCNQ)$_2$ were determined as plotted against $1/T$ in Fig. 3. In the same procedure, χ_{Cu} and χ_{TQ} were determined for Cu(en)(TCNQ)$_2$ by use of $g_{av}=2.125$ (calculated with $g_\parallel=2.257$ and $g_\perp=2.056$ observed for Cu(en)$SO_4\cdot3H_2O$) as g_{Cu}. Figure 4 shows the resulting χ_{Cu} and χ_{TQ} as functions of $1/T$.

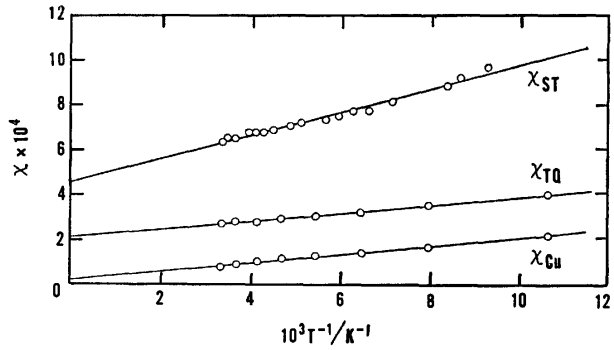

Fig. 3. Static magnetic susceptibility χ_{st}, the local Cu susceptibility χ_{Cu}, and the local TCNQ susceptibility χ_{TQ} (in emu) of Cu(bpy)(TCNQ)$_2$.

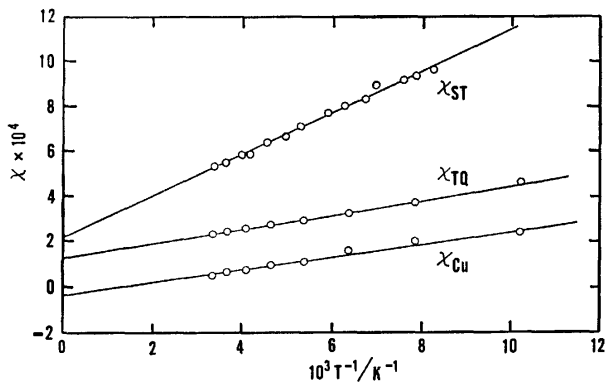

Fig. 4. Static magnetic susceptibility χ_{st}, the local Cu susceptibility χ_{Cu}, and the local TCNQ susceptibility χ_{TQ} (in emu) of Cu(en)(TCNQ)$_2$.

Figure 2 shows that the ratio χ_{Cu}/χ_t signifying the Cu(II) spin contribution to the ESR signal increases with decreasing temperature. If the ratio is temperature independent, it gives the unpaired electron density of Cu atoms.[3] On the contrary, the observed temperature-dependent ratio suggests that more detailed interpretation is required for the local susceptibility.

Local Cu Susceptibility. Figures 3 and 4 show that the local Cu susceptibility changes linearly to $1/T$. The temperature dependence of χ_{Cu} is reproduced by Eq. 2 employed for the interpretation of the static susceptibility. The parameters of Eq. 2 related to χ_{Cu} were determined as $\gamma_{Cu}=0.018$ emu K mol^{-1} and $\alpha_{Cu}=0.3\times10^{-4}$ emu mol^{-1} for Cu(bpy)-(TCNQ)$_2$ and $\gamma_{Cu}=0.028$ emu K mol^{-1} and $\alpha_{Cu}=-0.3\times10^{-4}$ emu mol^{-1} for Cu(en)(TCNQ)$_2$. The Cu(II) contribution to the ESR spectrum increases

with decreasing temperature as mentioned above. This shows that the paramagnetism expressed by γ_{Cu}/T is inherent to the complexes, although the γ_{Cu} values are very small. The absolute values of α_{Cu} fall in the range of the uncertainty (*ca.* 10%) of the diamagnetic corrections made for the static susceptibilities: the α_{Cu} negative in sign may be caused by an underestimation of the correction and the positive α_{Cu} by an overestimation. The α_{Cu} term probably arises from the uncertainty of the corrections and/or the experimental errors. Therefore, the local Cu susceptibilities of the complexes are thought to be of the Curie type intrinsically. Magnetic interaction between a copper atom and its neighboring paramagnetic ions is very weak as compared with the thermal energy in the temperature range investigated.

Local TCNQ Susceptibility. Figures 3 and 4 show that χ_{TQ} can be reproduced with an equation having the same functional form as Eq. 2. The parameters corresponding to χ_{TQ} were evaluated as $\gamma_{TQ}=0.017$ emu K mol^{-1} and $\alpha_{TQ}=2.2\times10^{-4}$ emu mol^{-1} for $Cu(bpy)(TCNQ)_2$, and $\gamma_{TQ}=0.032$ emu K mol^{-1} and $\alpha_{TQ}=1.2\times10^{-4}$ emu mol^{-1} for $Cu(en)(TCNQ)_2$. The α values of the static susceptibilities observed for the complexes agree very well with the respective $2\alpha_{TQ}$ values. Accordingly, the large temperature-independent paramagnetism is ascribed to electrons delocalized extensively in the TCNQ arrays. This supports the previous presumption that TCNQ carries conduction electrons.[2]

The γ_{TQ}/T term shows that the local susceptibility of TCNQ conduction electrons cannot be interpreted simply in terms of the Pauli paramagnetism. As has been pointed out,[7] TCNQ columns hardly form a wide conduction band having a large Fermi energy E_F. If the band has so narrow width that $E_F \gg kT$ does not hold, the paramagnetic susceptibility is temperature-dependent with an effective magnetic moment smaller than that predicted for localized electrons.[12] At high temperatures, χT approaches asymptotically a constant predicted for localized electrons with increasing temperature.[13] No exact expression has been given for the susceptibility. However, a qualitative plot of χT against T suggests that the temperature dependence can be approximated with the following equation in a given narrow temperature range:[13]

$$\chi T = A(T+B). \tag{5}$$

In the expression, the parameters A and B should be temperature-dependent, but they can be presumed to be practically temperature-independent in a very narrow temperature range. The equation is rewritten by the same functional form as Eq. 2 reproducing χ_{TQ}:

$$\chi = AB/T + A. \tag{6}$$

The AB value is equated with γ_{TQ}, which is smaller than the Curie constant of a localized electron system. This shows that Eq. 6 holds for χ_{TQ}, and hence that the narrow band model explains χ_{TQ} satisfactorily.

Other possible explanation may be suggested for the γ_{TQ}/T term: for example, 1) a chain-end effect arising from crystal imperfections, and 2) a thermally activated electron transfer between Cu and TCNQ. If the end effect dominates the paramagnetic increase, the ratio of γ_{TQ} to the Curie constant 0.375 emu K mol^{-1} of a free electron system gives approximately the concentration of the crystal imperfection. It yields an improbable concentration equal to 5% for $Cu(bpy)(TCNQ)_2$ and 9% for $Cu(en)(TCNQ)_2$. If the electron transfer accompanying the equilibrium Eq. 1 is thermally activated, χ_{TQ} exhibits a temperature dependence of thermal activation. The semilogarithmic plot of χ_{TQ} T against $1/T$ (the simplest model of thermal activation) did not yield any straight line. We attempted computer analysis about the observed g shift assuming various models of thermal activation. However, we have obtained no satisfactory result. No conclusive evidence has been obtained for thermally activated electron transfer between Cu and TCNQ.

Electrical Conduction. In $CuL(TCNQ)_2$, two nitrogen atoms from an ethylenediamine or 2,2′-bipyridine molecule are thought to coordinate on a copper atom occupying *cis* positions around the copper atom. Probably, $TCNQ^-$ ions also coordinate to a copper atom to occupy the otherwise vacant positions around the central metal, because the first coordination sphere of copper scarecely has vacant *cis* positions. In spite of the plausible Cu–TCNQ bonding, the magnetic interaction between Cu and TCNQ is very weak. The ratio $\gamma_{Cu}/0.375$ gives an unpaired electron density ρ_{Cu} carried by each copper atom on the average: $\rho_{Cu}=0.05$ for $Cu(bpy)(TCNQ)_2$ and $\rho_{Cu}=0.07$ for $Cu(en)(TCNQ)_2$. The small ρ_{Cu} values are obviously caused by an incomplete electron transfer between Cu and TCNQ accompanying the equilibrium in solids (Eq. 1), in which Cu(II) ions act as electron acceptors against $TCNQ^-$ (on the contrary, Cu(I) ions do as electron donors against $TCNQ^0$). The average oxidation number of copper is equated with $1+\rho_{Cu}$: 1.05 in $Cu(bpy)(TCNQ)_2$ and 1.07 in $Cu(en)(TCNQ)_2$. In our previous paper,[2] the unpaired electron densities were evaluated on the assumption that the paramagnetic term γ/T of the static susceptibility arises only from the copper atoms. The densities reported previously were overestimated. However, the present investigation supports the preceding conclusion that the equilibrium given by Eq. 1 lies so far to the right.[2,3]

The electrical conductivities σ observed for the compressed pellets of the complexes obey

$$\sigma = \sigma_\infty \exp(-E/kT). \tag{7}$$

The activation energy E was determined as 0.036 eV for the bpy complex and 0.12 eV for the en complex.[1] The energy of the former complex is of the order of an energy barrier predicted for contact resistance between powder particles. Possibly, the electrical conduction within the particles is inherently metallic. This is supported by the present magnetic study showing that the local TCNQ susceptibility involving the large temperature-independent paramagnetic term can be interpreted in terms of the narrow band model.

In conclusion, electric current in the $CuL(TCNQ)_2$ complexes flows through a narrow band formed by the TCNQ arrays, and the Cu(II) ions act as electron acceptors against $TCNQ^-$ ions to yield conduction

electrons in the band.

Charge-transfer Interaction of a Series of Trifluoromethylated Benzenes in the Ground and Excited States

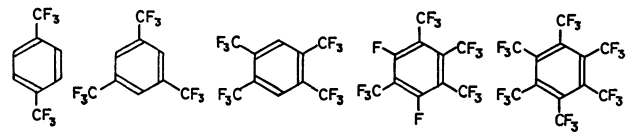
Yuji YAMAGUCHI, Takashi NOGAMI,* Hiroshi MIKAWA, Itsumaro KUMADAKI,† and Yoshiro KOBAYASHI†

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-oka, Suita, Osaka 565
†*Tokyo College of Pharmacy, 1432-1 Horinouchi, Hachioji, Tokyo 192-03*

(Received October 19, 1982)

Charge-transfer interaction of a series of trifluoromethylated benzenes with several donor molecules was investigated by measuring electronic absorption and fluorescence spectra. Half-wave reduction potentials of acceptors were determined by cyclic voltammetry. Charge-transfer absorption bands were observed for several systems. Thermal one-electron transfer reactions were observed for solutions of hexakis(trifluoromethyl)benzene and several aromatic amines even in nonpolar solvents. Charge-transfer fluorescence was observed for solutions of hexakis(trifluoromethyl)benzene or tetrakis(trifluoromethyl)benzene and weak donor molecules such as benzene, toluene, or *p*-xylene.

Spectroscopic studies on the charge-transfer (CT) interaction between donor and acceptor molecules have extensively been made both in the ground and excited states.[1] Acceptors in those studies were mainly aromatic molecules possessing electron withdrawing groups such as halogeno, cyano, nitro, and carbonyl groups. Trifluoromethyl group is known to have a strong electron withdrawing property.[2] However, no study has been made with aromatic acceptor molecule possessing trifluoromethyl group from the viewpoint of CT-interaction. We have measured electronic absorption and fluorescence spectra of the following acceptor molecules (A_2—A_6) with various donor molecules. We have also measured half-wave reduction potentials of these acceptors by cyclic voltammetry.



A_2 A_3 A_4 A_{4F} A_6

The names of the acceptor molecules are abbreviated to A_2, A_3, A_4, A_{4F}, and A_6 as specified above. We have found that the above molecules behave as a new family of acceptors both in the ground and excited states.

Experimental

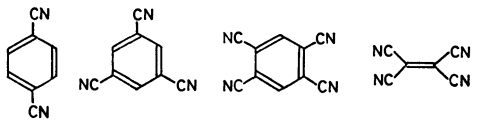
Materials. Hexakis(trifluoromethyl)benzene (A_6) was synthesized *via* a trimerization reaction of bis(trifluoromethyl)acetylene.[3] 1,3-Difluoro-2,4,5,6-tetrakis(trifluoromethyl)-benzene (A_{4F}) was obtained by a pyrolysis of A_6.[4] 1,2,4,5-Tetrakis(trifluoromethyl)benzene (A_4), 1,3,5-tris(trifluoromethyl)benzene (A_3), and 1,4-bis(trifluoromethyl)benzene (A_2) were synthesized *via* reactions of the corresponding carboxylic acids with sulfur tetrafluoride.[5] All of them were purified by vacuum distillation. Aniline, *N,N*-dimethylaniline, *N,N*-diethylaniline, and *N,N*-dibutylaniline were purified by vacuum distillation. *N,N,N′,N′*-Tetramethyl-*p*-phenylenediamine and *N,N*-dimethyl-*p*-phenylenediamine were obtained by neutralizing their dihydrochlorides with aqueous ammonia, followed by extracting them with diethyl ether. The crude materials obtained after evaporating diethyl ether were finally purified by vacuum sublimation. Benzene, toluene, and *p*-xylene were purified by treating them with sulfuric acid, dried over calcium chloride, refluxed over sodium for at least 8 h, and distilled twice. Hexane was purified by treating it with sulfuric acid, and dried over calcium chloride. It was then passed through a column composed successively of acidic, neutral, and basic aluminas, refluxed over sodium for more than 8 h, and finally distilled. Acetonitrile was purified by passing it through a column composed successively of acidic, neutral, and basic aluminas, refluxed over calcium hydride for more than 8 h, and finally distilled.

Cyclic Voltammetry. Cyclic voltammetry was run on an apparatus made by us. Acetonitrile was used as a solvent. Tetrabutylammonium perchlorate (0.1 mol dm^{-3}) was used as the supporting electrolyte; the concentration of the acceptor molecule was 1.0×10^{-3} mol dm^{-3}. An Ag/Ag^+ electrode, comprising an acetonitrile solution of silver nitrate (0.1 mol dm^{-3}) was used as a reference electrode.

Electronic Absorption and Fluorescence Spectra. Electronic absorption spectra were measured on a Shimadzu UV-200 double beam spectrophotometer. Fluorescence spectra were measured on a Hitachi MPF-3 fluorescence spectrometer.

Results and Discussion

Cyclic Voltammetry. An cyclic voltammetry on A_4, A_{4F}, and A_6 in acetonitrile solution was conducted to obtain their reduction potentials. The reduction potentials of 1,2,4,5-tetracyanobenzene (TCNB), 1,3,5-tricyanobenzene (TCB), and *p*-dicyanobenzene (DCB) were also measured for comparison. An Ag/Ag^+ electrode was used as a reference electrode. Table 1 summarizes the half-wave reduction potentials of A_6, A_{4F}, A_4, TCNB, TCB, and DCB. This table shows that the absolute reduction potentials decrease in the order DCB>TCB>A_4>A_{4F}>TCNB≈A_6. The absolute reduction potentials increase with decreasing number of substituent CF_3 groups. From a comparison of the absolute reduction potentials of the CF_3-substituted benzenes with those of the corresponding CN-substituted benzenes, it is clear that the cyano group is a stronger electron withdrawing group than the trifluoromethyl group. The reduction potentials of A_3



DCB TCB TCNB TCNE

TABLE 1. HALF-WAVE REDUCTION POTENTIALS OF ACCEPTORS

Acceptor	($E_{1/2}$ *vs.* Ag/Ag$^+$)/V

and A_2 could not be measured due to occurrence of an interference with the cathodic current by the electrolyte.

Charge-transfer Interaction of Trifluoromethylated Benzenes with Weak Aromatic Donor Molecules. CT-interaction of A_4 and A_6 with such a weak aromatic donor molecule as benzene, toluene, or *p*-xylene was investigated by measuring electronic absorption spectra. Figure 1 shows the absorption spectra of cyclohexane solutions of A_6, *p*-xylene, and a mixture of A_6 and *p*-xylene. Subtracting the absorbances of the component molecules from that of the mixture of A_6 and *p*-xylene, a new absorption band shown by the broken lines was obtained as a shoulder. This absorption band is ascribable to a CT-band. CT-absorption bands were also observed as shoulders on the absorption bands of the component molecules in cyclohexane solution for the following systems: A_6–benzene, A_6–toluene, A_4–benzene, A_4–toluene, and A_4–*p*-xylene.

In order to examine the stoichiometry of the CT-complexes in these systems, the absorbance of the CT-band as a function of donor concentration was analysed on the basis of the modified Benesi-Hildebrand equation.[6]

$$\frac{L[A]_0}{I-\varepsilon_A[A]_0L-\varepsilon_D[D]_0L} = \frac{1}{K(\varepsilon_C-\varepsilon_A)}\frac{1}{[D]_0}+\frac{1}{\varepsilon_C-\varepsilon_A}, \quad (1)$$

where, I, ε_D, ε_A, ε_C, $[D]_0$, $[A]_0$, L, and K denote the absorbance, the molar extinction coefficients of the donor, acceptor, and CT-complex, the initial concentrations of the donor and acceptor molecules, the path length, and the equilibrium constant for the CT-complex, respectively. The Benesi-Hildebrand equation[7] could not be used owing to overlap of the absorption band of CT-complex with those of the component molecules. Plots of $L[A]_0/(I-\varepsilon_AL[A]_0-\varepsilon_DL[D]_0)$ against $1/[D]_0$ gave straight lines for all of the above systems. Thus, the compositions of the CT-complexes are one to one in these systems.

Charge-transfer Interaction of A_2, A_3, A_4, and A_6 with Strong Donor Molecules. *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine (TMPD) and *N,N*-dimethyl-*p*-phenylenediamine (DMPD) are known to be strong donor molecules. The CT-interaction of A_2, A_3, A_4, and A_6 with TMPD and DMPD was studied by measuring absorption spectra of mixed solutions of donor and acceptor molecules. In the case of benzene solutions of A_2, A_3, and A_4 with TMPD, new absorptions ascribable to CT-bands were observed as shoulders of the component molecules. The CT-band shifted to the longer wavelength region with increasing electron accepting power of the acceptors. However, when tetrahydrofuran (THF) was used as a solvent, one-electron transfer reaction as well as CT-complex formation was observed in the same donor–acceptor systems. Figure 2 shows the absorption spectra of THF solutions of TMPD mixed with A_2, A_3, or A_4. Besides the CT-absorption bands around at 400—500 nm, characteristic vibrational structures ascribable to the TMPD cation radical (λ_{max}=570, 620 nm)[8] were observed.

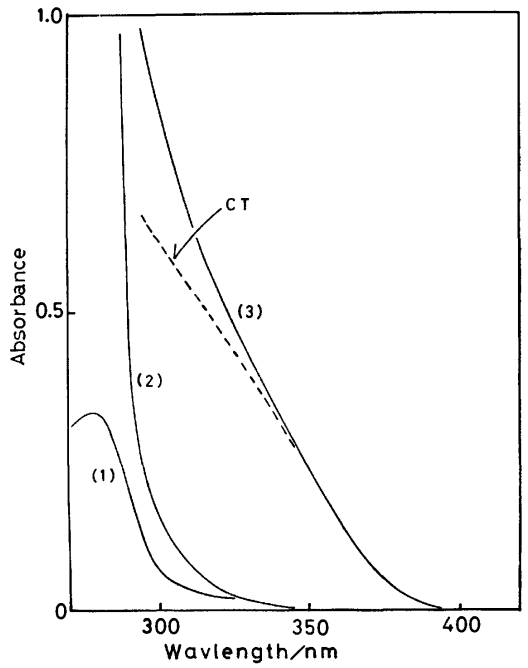

Fig. 1. Electronic absorption spectra of the cyclohexane solutions of (1) A_6, (2) *p*-xylene, and (3) the mixture of *p*-xylene and A_6. The broken line shows the charge-transfer absorption band. $[A_6]=1.23\times10^{-3}$ mol dm^{-3}, [*p*-xylene]=6.53 mol dm^{-3}.

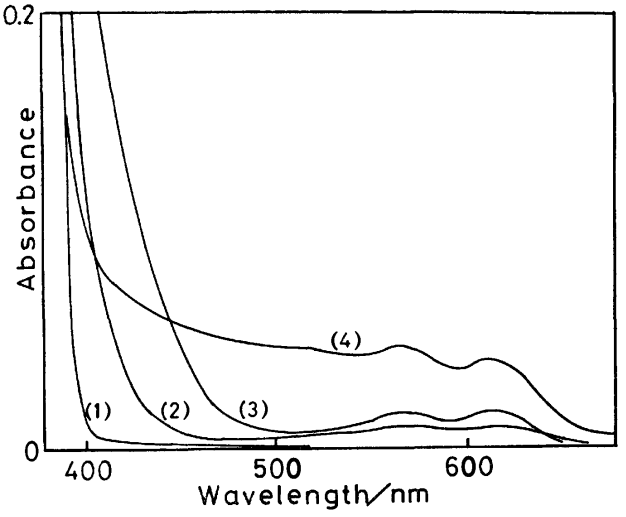

Fig. 2. Electronic absorption spectra of the THF solutions of TMPD and TMPD mixed with acceptors. [TMPD]=0.0743 mol dm^{-3}. (1) TMPD, (2) TMPD–A_2 (0.136 mol dm^{-3}), (3) TMPD–A_3 (0.11 mol dm^{-3}), (4) TMPD–A_4 (0.0139 mol dm^{-3}).

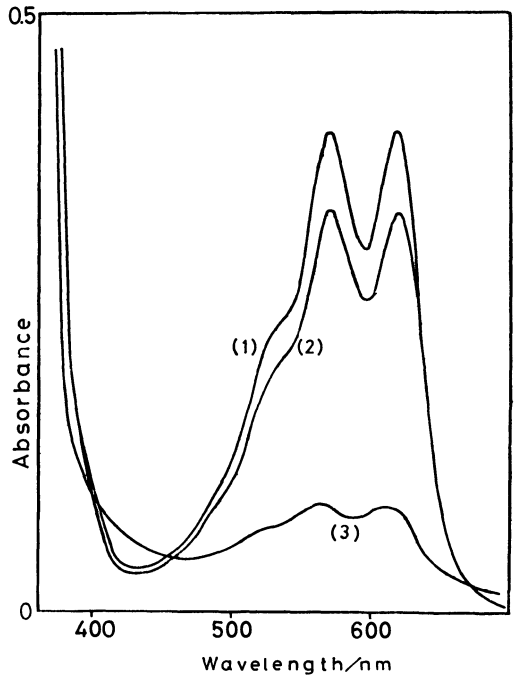

Fig. 3. Electronic absorption spectra of A_6–TMPD system in various solvents. $[A_6]=3.9\times10^{-3}$ mol dm^{-3}, $[TMPD]=3.4\times10^{-3}$ mol dm^{-3}. (1) THF, (2) benzene, (3) cyclohexane.

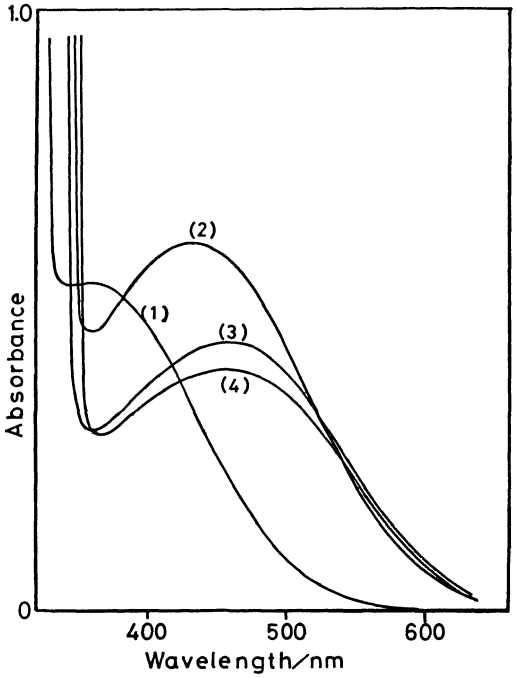

Fig. 4. Charge-transfer absorption spectra of A_6 mixed with liquid donors. $[A_6]=1.8\times10^{-3}$ mol dm^{-3}. (1) A_6–aniline, (2) A_6–*N*,*N*-dimethylaniline, (3) A_6–*N*,*N*-diethylaniline, (4) A_6–*N*,*N*-dibutylaniline.

These findings indicate that A_2, A_3, and A_4 form CT-complexes with strong donors such as TMPD and DMPD in nonpolar solvent. However, in a slightly more polar solvent like THF, these systems allowded not only CT-complex formation but also one-electron transfer from donor to acceptor molecule.

To our surprise, one-electron transfer from TMPD or DMPD to A_6 occurred not only in THF but also in such nonpolar solvents as benzene and cyclohexane. Figure 3 shows the absorption spectra of the TMPD–A_6 system in THF, benzene, or cyclohexane. The absorptions due to the TMPD cation radical were clearly observed in benzene and in cyclohexane. A similar phenomenon was also observed for the DMPD–A_6 system in benzene; the absorption of the DMPD cation radical (λ_{max}=508, 532 nm)[9] as well as that of a dimer cation radical $(CDMPD^+)_2$, (λ_{max}=680 nm)[9] was observed. Tetracyanoethylene (TCNE) is known to be one of the strongest electron acceptor molecules. However, we observed only CT-absorption band even in the TMPD–TCNE system in benzene or cyclohexane. A_6 is, of course, a much weaker electron acceptor than TCNE, judging from its half-wave reduction potential. In spite of this, A_6 behaves as if it were a stronger acceptor than TCNE at least in the nonpolar solvents. We can now give no explanation for these unusual phenomena.

Upon mixing TMPD with A_6, or DMPD with A_6 in such a polar solvent as methanol or acetonitrile, one-electron transfer from donor to acceptor was observed.

Charge-transfer Interaction of A_6 with Aniline and Its Derivatives without Use of Solvents. CT-interaction of liquid donor molecules with A_6 was investigated without use of any solvents. Figure 4 shows the CT-absorption bands observed by mixing A_6 directly with aniline, *N*,*N*-dimethylaniline (DMA), *N*,*N*-diethylaniline (DEA), and *N*,*N*-dibutylaniline (DBA). The absorption bands observed at 380—600 nm are ascribable to CT-bands. The peak positions of the CT-bands shifted to the longer wavelength region with increasing length of alkyl groups attached to the amino-nitrogen: λ_{max}=365 nm (aniline–A_6); λ_{max}=435 nm (DMA–A_6); λ_{max}=465 nm (DEA–A_6); λ_{max}=465 nm (DBA–A_6). These findings can be accounted for in terms of the decrease in the ionization potentials of aniline derivatives due to the hyperconjugation of alkyl groups.

Fluorescence Spectra of Donor–Acceptor Systems. Fluorescence spectra of cyclohexane or hexane solutions of the following systems were measured at room temperature in order to examine the CT-interaction in the excited state: A_4–benzene (in cyclohexane), A_4–toluene (in hexane), A_4–*p*-xylene (in hexane), A_6–benzene (in hexane), A_6–toluene (in hexane), A_6–*p*-xylene (in cyclohexane). Selective excitation of the CT-bands was impossible in these systems except for the A_6–*p*-xylene system due to overlap of the absorption of CT-complex with those of the component molecules. However, the absorbances due to the CT-complexes were much higher than those of the component molecules at the following excitation wavelengths: A_4–benzene, 280 nm; A_4–toluene, 296 nm; A_4–*p*-xylene, 310 nm; A_6–benzene, 325 nm; A_6–toluene, 325 nm; A_6–*p*-xylene, 330 nm. The concentration of the acceptors was kept constant, and that of the donor molecules was varied widely.

Figure 5 shows the fluorescence spectra of the A_4–toluene system as a typical example. The charac-

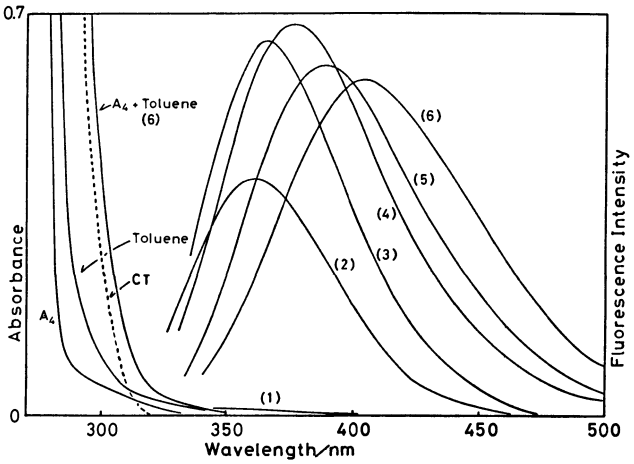

Fig. 5. Absorption and fluorescence spectra of A_4–toluene system in hexane excited at 296 nm. The fluorescence intensities were corrected on the basis of the absorbances at 296 nm. $[A_4]=2.32\times10^{-3}$ mol dm^{-3}. The concentrations of toluene are as follows (mol dm^{-3}); (1) 0, (2) 0.374, (3) 0.751, (4) 1.88, (5) 3.74, (6) 7.51.

teristic points of the system are as follows: (1) new fluorescence bands appeared at the longer wavelength region than the fluorescences of the component molecules; (2) the peak positions of the new fluorescences shifted to the longer wavelength region with increasing donor concentration. These fluorescence bands are ascribed to the CT-fluorescence, since the excitation spectra correspond to the CT-absorption bands. The fluorescence spectra of Fig. 5 were normalized on the basis of the absorbance at the excitation wavelength. The relative intensities of the fluorescences in the A_4–toluene system increased initially and then decreased as the donor concentration increased. The above two characteristic phenomena were also observed in the other systems. However, the dependence of the fluorescence intensity on the donor concentration was somewhat different between the A_4–donor systems and the A_6–donor systems. The fluorescence intensities in the latter systems decreased monotonously with increasing donor concentration.

Discussion on CT-Fluorescence. The fluorescence due to CT-complex was observed in the above systems.[10] It is well known that the Stokes shift of CT-fluorescence is much larger than those of usual organic compounds.[11] The Stokes shifts in the present systems could not be obtained correctly, since the absorption peak positions of the CT-complexes were hidden under the absorptions of the component molecules. However, a rough estimation of Stokes shifts gave values larger than 8×10^3 cm^{-1} in agreement with the above-mentioned tendency.

Let us discuss on the red-shift of the CT-fluorescence with increasing donor concentration. The ground states of the 1:1 CT-complexes are assumed to have mainly no-bond structures, because benzene, toluene, and *p*-xylene are weak donor molecules. The first excited states of the CT-complexes are assumed to have more polar structure than the ground states. The situations of the present systems are quite similar to that of the TCNB–toluene system;[12] the red shift of the CT-fluorescence was also observed as the concentration of toluene increased. Mataga and Murata accounted for the large Stokes shift and red shift of the CT-fluorescence in terms of two factors:[12] (1) the reorientation of the excited CT-complex from the Franck-Condon states to a stabler configuration in the excited CT-states; (2) the reorientation of the Franck-Condon ground states to the stablest configuration of the CT-complex in the ground state.

In the case of the present systems, two possibilities can be considered for the red shift of the CT-fluorescence with increasing donor concentration. One possibility is the same as that mentioned above in connection with the TCNB–toluene system. In this case, as the donor concentration increases, the energy stabilization of CT-complex in the excited states and the energy destabilization in the ground state are induced more and more effectively as a result of the electronic interaction between the CT-complex and donor molecules; this fact accounts for the red shift of CT-fluorescence. The other possibility is that the red shift of CT-fluorescence arises from CT-excited states with different stoichiometries, *e.g.*, different donor to acceptor ratios such as one to one, two to one, three to one,.., *etc.* We cannot conclude which of these two possibilities is applicable to the present systems.

Summary

CT-interaction of a series of trifluoromethylated benzenes with several donor molecules was investigated in the ground and excited states. The trifluoromethylated benzenes acted as electron acceptors to induce CT-complex formation and/or one-electron transfer in the ground state. One-electron transfer reaction was observed for strong donor–A_6 systems even in nonpolar solvents. Fluorescences due to CT-complexes were observed for weak donors–A_4 systems and for weak donor–A_6 systems. The trifluoromethylated benzenes in the present study have been found to be a new family of electron acceptor molecules for study on the electron donor–acceptor interaction.

We are grateful to Dr. Hiroshi Masuhara, Faculty of Engineering Science, Osaka University for his valuable discussion.

6) Equation 1 is derived as follows: The following two

relations 1 and 2 are set by definition:

$$I/L = \varepsilon_C[DA] + \varepsilon_D([D]_0-[DA]) + \varepsilon_A([A]_0-[DA]), \quad (1)$$

$$K = [DA]/([D]_0-[DA])([A]_0-[DA]) \quad (2)$$

$$\approx [DA]/[D]_0([A]_0-[DA]), \quad (3)$$

where $[DA]$ denotes the concentration of CT-complex. Since the experiments were performed under the condition $[D]_0 \gg [A]_0$, the equilibrium constant of the CT-complex can be approximated to Relation 3. Cancelation of $[DA]$ from Relations 1 and 3 gives Eq. 1. In the case of $\varepsilon_D=\varepsilon_A=0$, Eq. 1 gives the Benesi-Hildebrand equation.

(Received October 29, 1982)

Heats of adsorption of ammonia and pyridine on H–Y zeolites and other solids were measured using a microcalorimeter in the temperature range of 313 to 673 K. Infrared spectra of adsorbed ammonia and pyridine were obtained in order to interpret the calorimetric data. There appeared two kinds of the temperature dependence of heats of adsorption. One is that heats of adsorption on H–$Y_{5.0}$ and silica-alumina do change with coverage to a greater extent at high temperature range (above 473 K) than low temperature range. The difference in the shape of the heat curves was found to be attributable to the difference in the selectivity of adsorption at different temperatures, that is, adsorption occurred on stronger acidic sites is preference to weaker or non-acidic sites in the high temperature range, while random adsorption occurred simultaneously on acidic and non-acidic sites in the low temperature range. The other kind of temperature dependence was recognized to appear as a slight decrease in heats of adsorption with a temperature rise, which were observed in cases of ammonia adsorption on H–Y zeolites above 473 K and on Na–Y and silica above 313 K while the shapes of heat curves were similar to one another irrespective of the adsorption temperature. Such decrease may be attributed to the fact that the temperature dependence of the heat of adsorption was thermodynamically defined by the difference in molar heat capacity between adsorbed state and gaseous state.

Heats of adsorption of basic gases on solid acid catalysts have been widely measured using a microcalorimeter near room temperatures in order to estimate their acidic characters.[1–7]

Since solid acid catalysts are generally used for reactions at high temperatures, it will be interesting to measure heats of adsorption at high temperatures. Auroux *et al.*[8] measured heats of adsorption of ammonia at 416 K. However, a temperature dependence of heats of adsorption has not extensively been studied in the range of room temperature to high temperature.

In the present work, heats of adsorption of ammonia and pyridine were respectively measured on H–Y zeolites in the temperature range of 313 to 673 K using a twin-conduction type microcalorimeter. Likewise, heats of adsorption of ammonia on silica-alumina, Na–Y zeolite, and silica were measured.

Experimental

NH_4–Y zeolite was prepared by treating repeatedly Na–Y zeolite, SK-40, with 1 mol dm^{-3} NH_4Cl solution at *ca.* 323 K. The zeolite was then washed with distilled water until no chlorine ion was detected. The chemical composition was $0.72(NH_4)_2O \cdot 0.15Na_2O \cdot Al_2O_3 \cdot 5.0SiO_2$. It was converted to H–$Y_{5.0}$ zeolite by the pretreatment at 673 K before each measurement. Silica-alumina (Al_2O_3 content, 13%) and Aerosil 380 were supplied by Catalysts and Chemicals Ind. Co., Ltd. and Nippon Aerosil Co., Ltd., respectively. All samples were used in granular form of 28—60 mesh.

Ammonia and pyridine were obtained from Matheson Co. and Wako Pure Chemicals Co., respectively. Both were purified by the freeze-thaw method.

Heats of adsorption were measured using a twin-conduction type microcalorimeter. The calorimeter and the procedure of measurements were described in a previous paper.[9] The sample weighing from 0.25 to 1.0 g in the sample cell was outgassed at 673 K under a pressure of 10^{-3} Pa for 5 h and set in the calorimeter. The adsorbed amount was calculated from the pressure change before and after adsorption.

Infrared spectra were obtained by the *in situ* method. The sample was pressed into wafers of thickness of *ca.* 10 mg cm^{-2} under a pressure of 1.6×10^3 kg cm^{-2} and outgassed for 5 h at 673 K before the measurement. The transmission was converted into the absorbance and the spectrum intensity was determined from its band area. The influence of emission was negligible in the temperature range up to 473 K permitting quantitative analysis, but qualitative analysis of the spectra was possible even up to 673 K.

Results and Discussion

Differential Heats of Adsorption of Pyridine and Ammonia on H–$Y_{5.0}$ at 313 and 473 K. Differential heats of adsorption of pyridine on H–$Y_{5.0}$ were measured at 313 and 473 K as shown in Fig. 1. The curve of heats of adsorption obtained at 473 K had a plateau leveling at *ca.* 145 kJ mol^{-1} in the initial stage, thereafter decreasing sharply. On the other hand, the curve obtained at 313 K showed a more monotonic change with coverage, thereafter intersecting the one obtained at 473 K. Differential heats of adsorption of ammonia were measured at 313, 473, 573, and 673 K as shown in Fig. 2. In cases of ammonia adsorption, the difference between heat curves at 313 and 473 K was less explicit than the case of pyridine adsorption. The temperature dependence above 473 K will be discussed later. In case of both adsorbates, measurable pressures of the adsorbate were present even at lower coverage at 473 K or above, while not at 313 K, therefore the equilibrium proved to be obtained in the former system.

The IR measurements were performed to ascertain the temperature dependence of the shape of heat curves. In these experiments, the spectra measured at room temperature were used for contrasting them

with the data of heats of adsorption at 313 K because analogous IR data were obtained at these two temperatures. First, the experiment was performed on H-$Y_{5.0}$-pyridine system. Since no Lewis acid site existed judging from the absence of 1450 cm^{-1} band[10] for pyridine, most active sites on H-$Y_{5.0}$ proved to be limited to Brønsted acid sites. Figure 3 shows the spectra of OH bands after pyridine adsorption on H-$Y_{5.0}$ measured at room temperature and 473 K. The spectra measured at 573 and 673 K were analogous to those measured at 473 K. In the temperature range of 473 to 673 K, the 3640 cm^{-1} band was preferentially perturbed, indicating that the selective adsorption occurred on the 3650 cm^{-1}-OH sites in preference to the 3550 cm^{-1}-OH sites. On the other hand, both of the 3640 and 3550 cm^{-1} bands decreased simultaneously in their intensity at room temperature, indicating that random adsorption occurred. The results presented here are in good agreement with the observations of Hughes and White[11] and others[12,13] on the difference in the interaction of two types of hydroxyl groups with pyridine.

In addition to above, temperature dependence of the formation of pyridinium ions was investigated by heating H-$Y_{5.0}$-pyridine system as shown in Table 1. The experimental procedures employed were as follows. After addition of a certain amount of pyridine

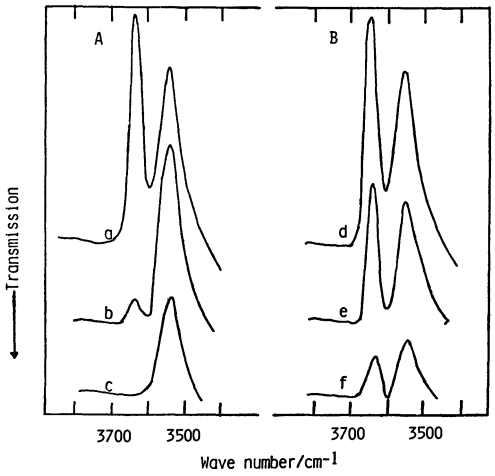

Fig. 3. Changes of bands on H-$Y_{5.0}$ after adsorption of pyridine (A) at 473 K and (B) at room temperature. (a): Evacuated at 673 K then cooled to 473 K; (b): after addition of 1 mmol g^{-1} of pyridine to (a); (c): after addition of 2 mmol g^{-1} of pyridine to (a); (d): evacuated at 673 K then cooled to room temperature; (e): after 1 mmol g^{-1} of pyridine added to (d); (f): after 2 mmol g^{-1} of pyridine added to (d).

Table 1. Enhancement of pyridinium ion formation after heating H-$Y_{5.0}$-pyridine system

	Amount of pyridinium ions/Arb. unit			
	Pyridine adsorbed/mmol g^{-1}			
Temperature/K	0.5	1.0	2.0	3.0
Room temp	0.24	0.47	1.00	1.00

673	—	0.85	—	—

on H-$Y_{5.0}$ at room temperature, the zeolite was heated for 1 h at a desired temperature, then, the relative amount of pyridinium ions formed was determined from the integrated intensities of 1545 cm^{-1} band which is known to be characteristic of pyridinium ions[10] before and after the heat-treatment. The amount at room temperature after pyridine adsorption of 3 mmol g^{-1} was referred to 1.00. At lower coverage, the amount of pyridinium ions increased with a temperature rise below 473 K, then, remained constant up to 673 K. Moreover, spectra in Fig. 4 showed that pyridine molecules adsorbed on the 3550 cm^{-1}-OH sites at room temperature did migrate to the 3640 cm^{-1}-OH sites on heating in agreement with the results in Table 1. It was indicated that the adsorption occurred simultaneously on the 3650 cm^{-1}-OH sites and on other sites at room temperature, but that the adsorbed base on the latter sites migrated to the former sites on heating and was protonated. At higher coverage region, however, the amount remained unchanged on heating, which would tell that the 3650 cm^{-1}-OH sites are wholly saturated at room temperature so that no migration occurred.

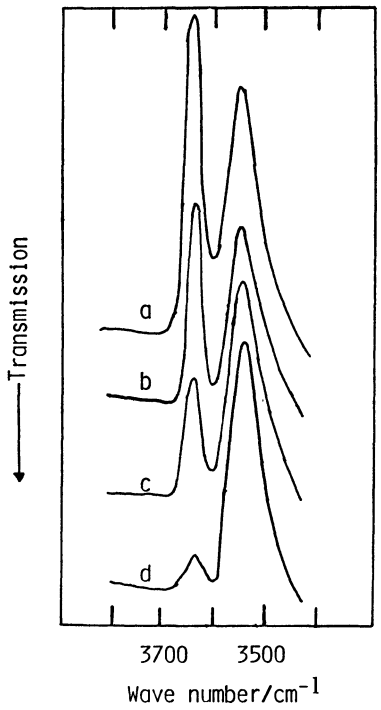

Fig. 4. Redistribution of pyridine on H-$Y_{5.0}$. Spectra were taken at room temperature. (a): Evacuated at 673 K then cooled to room temperature; (b): after adsorption of 1 mmol g^{-1} of pyridine to (a); (c): after heat-treatment of (b) at 423 K for 1 h; (d): after heat-treatment of (c) at 473 K for 1 h.

Table 2. Enhancement of ammonium ion formation after heating H-$Y_{5.0}$-ammonia system

	Amount of ammonium ions/Arb. unit				
	Ammonia adsorbed/mmol g^{-1}				
Temperature/K	0.5	1.0	2.0	3.0	4.0
Room temp	0.20	0.38	0.70	0.98	1.00
373	—	0.40	—	—	—
423	—	0.45	—	—	—
473	0.25	0.46	0.74	0.98	1.00
573	—	0.46	—	—	—
673	—	0.46	—	—	—

By direct comparison with IR spectral results, it seems likely that heats of adsorption of pyridine at 473 K reflect the selective adsorption on the 3640 cm^{-1}-OH sites at lower coverages. At 313 K, however, heats were evolved by rather non-selective adsorption either on the 3640 cm^{-1}-OH sites or other sites, then a monotonic heat curve was obtained.

In case of ammonia adsorption on H-$Y_{5.0}$, both of the 3640 and 3550 cm^{-1}-OH bands were effective for the formation of ammonium ions[14] and were almost simultaneously perturbed at 473 K as well as at room temperature as shown in Fig. 5. However, the amount of ammonium ions increased on heating H-$Y_{5.0}$-ammonia system as shown in Table 2, suggesting that migration of adsorbed ammonia occurred at higher temperature. The experimental procedure employed was the same as that employed in case of H-$Y_{5.0}$-pyridine system and the amount of ammonium ions was calculated from integrated intensities of characteristic bands at 1475 and 1435 cm^{-1}.[10] The results obtained by IR measurements imply that some difference should also be observed in the shape of heat curves obtained by ammonia adsorption and that the extent of the difference should be smaller than the case of pyridine adsorption, which was well confirmed by comparing the heat curves in Figs. 1 and 2. In addition, it is also concluded that the strength of acid sites should preferably be determined by the heat curve obtained at 473 K rather than at 313 K because of more selective adsorption.

The temperature dependence of the selective adsorption on the strongest sites observed in our results will not be reasonably explained on the basis of chemical equilibrium, but chemical kinetics should be introduced to explain the behavior of such an irreversible adsorption. The theoretical analysis of selective adsorption on different sites is now in progress and will be published later.

Differential Heats of Adsorption of Ammonia on H-Y Zeolites at 473, 573, and 673 K. The shapes of heat curves of ammonia adsorption on H-$Y_{5.0}$ obtained were almost similar to one another as shown in Fig. 2. However, the heats decreased slightly as a whole with a temperature rise. Provided that the selectivity of adsorption varies in this temperature range as is predicted by chemical equilibrium, the shape of the heat curve should change with temperature. Therefore, analogous shapes of these three heat curves suggest that the effect expected from the aspect of chemical equilibrium may not be so significant as to influence the shape of the heat curves.

A slight decrease of heats should be explained by the following thermodynamic equation representing

Table 3. Temperature dependence of the enthalpy of the reaction; $NH_3(g)+HCl(g) \rightarrow NH_4Cl(s)$

Reaction temperature/K	$-\Delta H$/kJ mol^{-1}
313	177
473	171
573	166
673	160

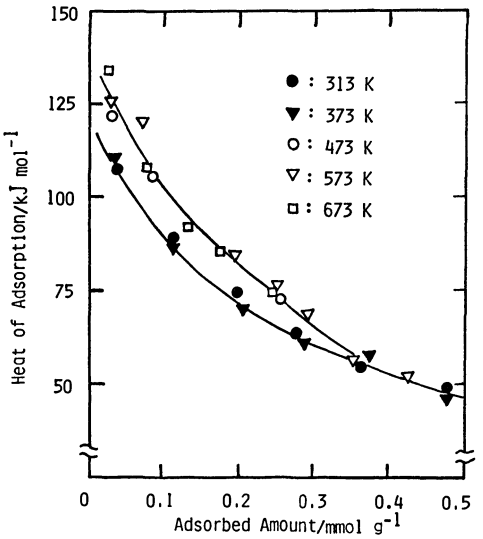

Fig. 6. Differential heats of adsorption of ammonia on silica-alumina.

temperature dependence of a heat evolved from a certain site,

$$(q_{ad})_{T_2} - (q_{ad})_{T_1} = \int_{T_1}^{T_2} \Delta C_v dT, \quad (1)$$

where $(q_{ad})_{T_1}$ and $(q_{ad})_{T_2}$ represent heats of adsorption at temperatures T_1 and T_2, respectively, and ΔC_v, the difference of the molar heat capacity between the gaseous state and the adsorbed state at a constant volume. Since C_v in the adsorption system is difficult to be calculated, the change of the enthalpy in the following reaction in Eq. 2 was calculated as a function of temperature from the tabulated values of molar heat capacities[15] as one of typical instances of the acid-base reactions as shown in Table 3.

$$HCl\ (gas) + NH_3(gas) \longrightarrow NH_4Cl\ (solid) \quad (2)$$

A decrease of the exothermic heats with a temperature rise in Table 4 probably corresponds to that observed in case of ammonia adsorption on the H–Y zeolites.

Differential Heats of Adsorption of Ammonia on Other Solids. Heats of adsorption of ammonia on silica-alumina were measured at 313, 373, 473, 573, and 673 K as shown in Fig. 6. Heats of adsorption at the former two temperatures were smaller than those at the latter three temperatures in the low coverage region. Moreover, the heat-treatment of silica-alumina–ammonia system resulted in the enhancement of the amount of protonated ammonia likewise observed in case of H–$Y_{5.0}$–ammonia system. Accordingly, the relatively low values of heats in the low coverage region measured at 313 and 373 K are considered to be an average of the heats from stronger and weaker or non-acidic sites.

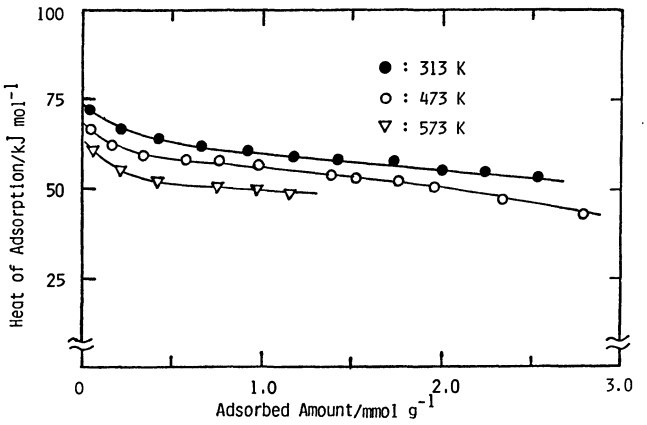

Fig. 7. Differential heats of adsorption of ammonia on Na–$Y_{5.0}$.

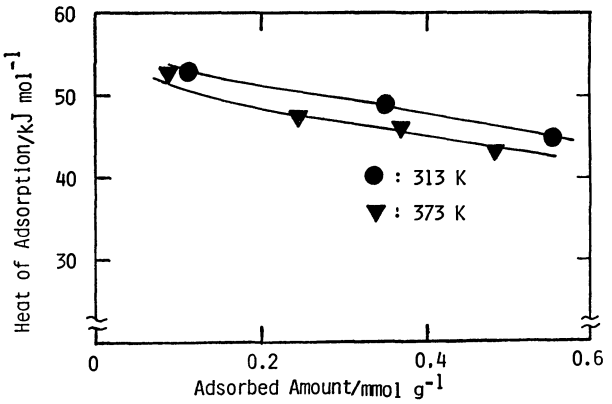

Fig. 8. Differential heats of adsorption of ammonia on silica.

Heats of adsorption of ammonia on Na–Y zeolite resulting from ion-dipole interactions were measured at 313, 473, and 573 K as shown in Fig. 7. Heats on silica resulting from hydrogen bonding were also measured at 313 and 373 K as shown in Fig. 8. In these cases, heats of adsorption showed the same behavior as the case of H–Y zeolites in the temperature range of 473 to 673 K, suggesting similar type of the temperature dependence. In cases of ammonia adsorption on Na–Y and silica, no specific phenomenon was observed on the heat curve because of the weak interaction between ammonia molecule and adsorption site.

Direct Measurement of the Interaction Energy between Solids and Gases. X. Acidic Properties of Hydroxyl Sites of H-Y Zeolite Determined by High-temperature Calorimetry

Yoshio MITANI,† Kazuo TSUTSUMI,*,†† and Hiroshi TAKAHASHI

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

††*Toyohashi University of Technology, Tempaku-cho, Toyohashi 440*

(Received October 29, 1982)

Differential heats of adsorption of bases on H-Y zeolite were measured at 473 K and separated into those evolved at 3640 and 3550 cm^{-1}-OH sites respectively by a combined use of calorimetric and IR measurements, and then the acid strength of two OH sites was compared each other. In case of pyridine, heats of adsorption were larger on OH sites at 3640 cm^{-1} than 3550 cm^{-1}, which was in agreement with the results obtained by many authors by IR measurements. However, heats of adsorption on 3640 cm^{-1}-OH sites were only slightly higher than those on 3550 cm^{-1}-OH sites in case of ammonia, and almost the same in case of piperidine. The difference in heats of adsorption between the OH sites was explained by positional difference between the two OH sites, molecular size of the titrated bases and proton mobility induced by a strong base. The order of the strength of bases was determined by replacing a base molecule with another one on H-Y zeolite as follows; piperidine>pyridine>ammonia. This differs from the order expected from their pK_a values in solution.

Infrared measurements have revealed that 3640 cm^{-1}-OH sites were stronger in their acidity than 3550 cm^{-1}-OH sites.[1,2] However, heats of adsorption of bases have not yet been measured on the respective OH sites until now. In the present work, bases were adsorbed on original and poisoned H-Y zeolites at 473 K and heats of adsorption were then measured. Since the selective adsorption on the acid sites occurred at 473 K in each case of pyridine and ammonia as was confirmed previously,[3] heats of adsorption could be separated into those resulted from 3640 and 3550 cm^{-1}-OH sites respectively by a combined use of calorimetric and IR measurements.

Experimental

NH_4-Y zeolite was prepared by treating Y-type zeolite, SK-40, which was supplied by Linde Co. in the sodium form, several times with 1 mol dm^{-3} NH_4Cl solution at *ca.* 323 K. The chemical composition of the sample was analyzed as follows; $0.72(NH_4)_2O \cdot 0.15Na_2O \cdot Al_2O_3 \cdot 5.0SiO_2$. It could be converted to H-Y zeolite by the pretreatment before measurements. The sample was used in granular form of 28—60 mesh for calorimetric measurements. Ammonia was obtained from Matheson Co., and pyridine and piperidine from Wako Pure Chemicals Co. They were purified by the freeze-thaw method.

Differential heats of adsorption were measured at 473 K by a twin-conduction type microcalorimeter as described in a previous paper.[4] IR measurements were carried out by the *in situ* method described elsewhere.[3] Samples were outgassed for 5 h under a pressure of 10^{-3} Pa at 673 K before calorimetric and IR measurements.

Results

Heats of Adsorption and IR Spectra. Heats of adsorption of bases on H-Y were measured at 473 K and shown in Fig. 1. The H-Y was estimated to possess 4.73 mmol g^{-1} of positively charged sites from the view point of chemical composition. Heats of adsorption could be measured over a wide range in case of ammonia, but only below *ca.* 3 mmol g^{-1} in cases of pyridine and piperidine. This can be attributed to pore structure of the zeolite and molecular size of a base. In fact, the amount of adsorption at relative pressure of 0.25 was measured as 3.65 and 3.47 mmol g^{-1} at 293 K for pyridine and piperidine respectively, and as 9.3 mmol g^{-1} at 252 K for ammonia.

Figure 2 shows changes of hydroxyl bands with adsorption or desorption of bases. Since no Lewis acid site on H-Y was detected on the spectra between 1800—1200 cm^{-1} after adsorption of bases, only OH sites (Brønsted acid sites) were taken into account hereafter. In adsorption and desorption processes, only 3640 cm^{-1}-OH band was preferentially perturbed by pyridine (Fig. 2-D,E), while both of the 3640 and 3550 cm^{-1}-OH bands were simultaneously perturbed by ammonia (Fig. 2-B,C) and the behavior of perturbation by piperidine was intermediate between the former two cases (Fig. 2-F,G,H).

Separation of Heats of Adsorption into Heats Evolved at 3640 and 3550 cm^{-1}-OH Sites. Since the 3640 cm^{-1}-OH band was preferentially poisoned by pyridine,

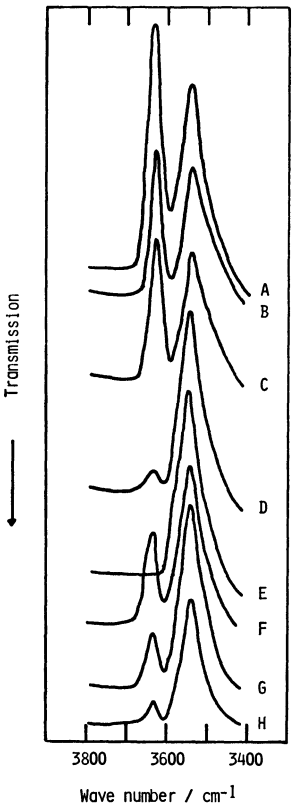

Fig. 2. Hydroxyl bands on H–Y after adsorption or desorption of bases. A: Original H–Y evacuated at 673 K then cooled to 473 K, B: 1 mmol g^{-1} of ammonia added to A, C: evacuated at 473 K after ammonia addition, D: 1 mmol g^{-1} of pyridine added to A, E: evacuated at 473 K after pyridine addition, F: 1 mmol g^{-1} of piperidine added to A, G: evacuated at 673 K after piperidine addition, H: evacuated at 573 K after piperidine addition.

one could easily obtain the H–Y which posessed only 3550 cm^{-1}-OH sites (Fig. 2-E). Heats of adsorption of pyridine were measured on the original and poisoned H–Y as shown in Fig. 3. The heat curve of the poisoned H–Y was almost superimposed on the original H–Y in the coverage above 1.6 mmol g^{-1}. Therefore, heats of adsorption of pyridine on the 3640 cm^{-1}-OH sites proved to correspond to a region above 105 kJ mol^{-1} involving the plateau leveling at *ca.* 145 kJ mol^{-1} and those on the 3550 cm^{-1}-OH sites, to a region below 105 kJ mol^{-1}.

Figure 4 shows heats of adsorption of ammonia on the original and pyridine-poisoned H–Y. On the original H–Y, the heat should result from the simultaneous adsorption on both 3640 and 3550 cm^{-1}-OH sites (Fig. 2-B). In addition, the acid strength of the 3550 cm^{-1}-OH sites must be weakened by poisoning the 3640 cm^{-1}-OH sites with pyridine. In fact, the band near 3550 cm^{-1} shifted by about 8 cm^{-1} to a lower frequency by pyridine adsorption. Moreover, a semi-quantitative IR analysis revealed that the amount of ammonia irreversibly adsorbed on the 3550 cm^{-1}-OH sites of the poisoned H–Y after addition of excess ammonia and subsequent evacuation at 473 K was one-third of that of the original H–Y. For these reasons, the difference between two curves does not necessarily

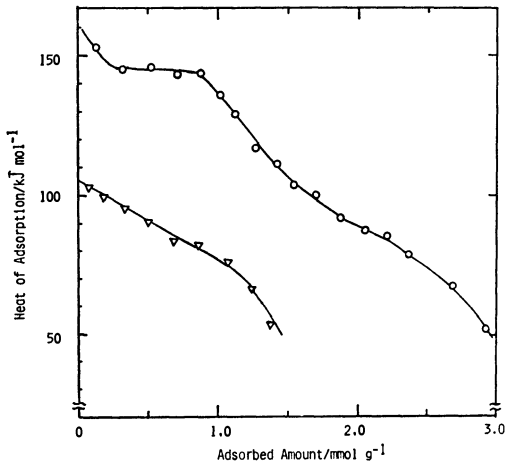

Fig. 3. Differential heats of adsorption of pyridine measured at 473 K. ○: On original H–Y, ▽: on the H–Y after pyridine addition followed by evacuation at 473 K, only 3640 cm^{-1}-OH sites were thus poisoned (see Fig. 2-E)

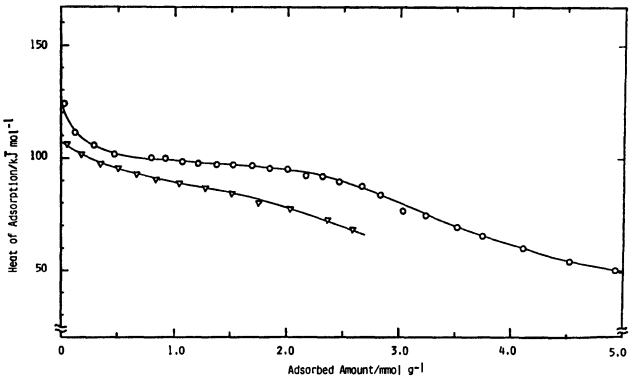

Fig. 4. Differential heats of adsorption of ammonia measured at 473 K. ○: On original H–Y, ▽: on the H–Y after pyridine addition followed by evacuation at 473 K, only 3640 cm^{-1}-OH sites were thus poisoned (see Fig. 2-E).

correspond to actual difference in heats of adsorption between two types of OH sites. However, it seems likely that the difference would not be negligible but remarkably smaller than that obtained in case of pyridine.

In case of piperidine adsorption, the pyridine-poisoned H–Y was not available, because pyridine was easily replaced by piperidine on the surface as discussed later. The H–Y was, therefore, poisoned by piperidine, and heats of adsorption of piperidine were measured on it (Fig. 5). Although the poisoning by piperidine was not necessarily selective as shown in Fig. 2-G,H, the result obtained on the poisoned H–Y by piperidine addition and subsequent evacuation at 673 K could be considered to reflect the heat evolved by adsorption mainly on the 3640 cm^{-1}-OH sites. From the fact that heats of adsorption on this sample and on the original H–Y were almost equivalent, it is suggested that both OH sites were energetically same for piperidine adsorption. A decrease in heats at higher coverage which was more explicit in samples evacuated at lower temperatures after piperidine poi-

soning can best be explained by a decrease in the number of specific adsorption sites.

Determination of the Order of Basic Strength. The order of basic strength has often been taken as piperidine>ammonia>pyridine, considering their pK_a values in aqueous solutions (piperidine, 11.1; ammonia, 9.3; pyridine, 5.2).[1,5] However, in the present work, the order was examined directly by means of replacing basic molecules with another one on H–Y surface. First, in order to compare basic strength of piperidine with that of pyridine, the poisoned H–Y with pyridine (Fig. 2-E or Fig. 6-A) was exposed to excess piperidine under a pressure of *ca.* 1 kPa, and followed by evacuation at 473 K. A band at 1545 cm^{-1} for pyridinium ions almost disappeared, and that at 1610 cm^{-1} for piperidinium ions newly appeared as shown in Fig. 6-B.[6] The spectra obtained after completion of the replacement (Fig. 6-B) were almost the same as those obtained by piperidine adsorption on the original H–Y. On the other hand, no piperidine molecule held on H–Y was replaced upon exposure to pyridine vapour. Moreover, ammonia molecules were also easily replaced by piperidine, while no piperidine molecule was replaced by ammonia. Thus, piperidine proved to be the strongest of the three.

Similar treatments were performed on H–Y zeolite–pyridine–ammonia system. The poisoned H–Y with pyridine (Fig. 6-A) was exposed to excess ammonia under a pressure of *ca.* 1 kPa, and followed by evacuation at 473 K. Bands at 1475 and 1435 cm^{-1} for ammonium ions newly appeared, while that of pyridinium ions at 1545 cm^{-1} was unchanged as shown in Fig. 6-C.[6] Ammonium ions must be formed on 3550 cm^{-1}-OH sites, because 3550 cm^{-1}-OH band was slightly perturbed. They could not be removed by successive addition of pyridine followed by evacuation at 473 K. In addition, these spectra agreed with those obtained on exposure of ammonia-loaded H–Y to pyridine vapor.

In consequence, apparent order of the basic strength seemed to depend on whether acidic sites are 3640 or 3550 cm^{-1}-OH sites. The order at 3640 cm^{-1} was determined as piperidine>pyridine>ammonia, and that at 3550 cm^{-1} as piperidine>ammonia>pyridine. However, since all bases are considered to be accessible to the 3640 cm^{-1}-OH sites as described later, the basic strength should be judged on the 3640 cm^{-1}-OH sites; the order obtained here was in good agreement with the finding of Kebarle *et al.* who determined proton exchange equilibria of bases in vapor phase by mass spectrometer.[7]

Discussion

The positional assignments of hydroxyl sites in H–Y have been widely studied. Eberly[8] assigned the positions on the basis of the interaction of OH groups with olefins. He considered that 3640 cm^{-1}-OH sites existed in supercages having maximum entrance diameter of *ca.* 9 Å and that 3550 cm^{-1}-OH sites existed in hexagonal prisms having maximum entrance diameter of 2.2—2.5 Å (Fig. 7). In contradiction to this, Hughes and White[1] suggested that both OH sites were located on O_1, or O_4 oxygen atoms and accessible to large molecules. Olson and Dempsey[9] assigned 3640 cm^{-1} band to O_1–H groups and 3550 cm^{-1} band to O_3–H groups, using single crystal X-ray techniques. This model was in analogy with Eberly's first observations[8] and agreed with his positional assignments. Additional confirmation was obtained by Ward from exchange of cesium ions into NH_4–Y.[10] Hence, we take Eberly's assignments in order to explain heats of adsorption hereafter.

The 3640 cm^{-1}-OH groups form pyridinium ions in the presence of pyridine while 3550 cm^{-1}-OH groups

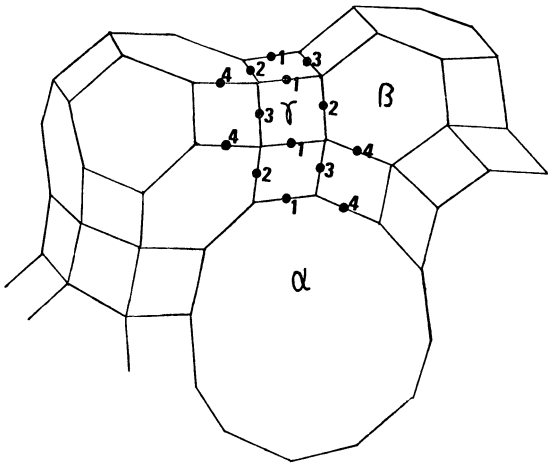

Fig. 7. Framework indication of H–Y zeolite. α: Supercage cavity having maximum entrance diameter of about 9 Å, β: sodalite cavity having maximum entrance diameter of 2.2—2.5 Å, γ: hexagonal prism having maximum entrance diameter 2.2—2.5 Å. The figures 1 through 4 represent oxygen atoms.

form only hydrogen bonds as shown in the formation of 1440 cm^{-1} band. These facts observed by Hughes and White,[1] and other authors[2,11] were confirmed also in the present work. The large molecular size of pyridine prevents it from approaching 3550 cm^{-1}-OH sites and thus it cannot be protonated. Higher heats of adsorption on OH sites at 3640 cm^{-1} must reflect such a situation. Although piperidine is also too large in size to approach the 3550 cm^{-1}-OH sites, it could be actually protonated by these sites as well as the 3640 cm^{-1}-OH sites, which may be rationalized in terms of proton mobility. Strong bases such as piperidine are known to be able to induce proton movement even at lower temperatures.[9,10] The protonation must result in the evolution of similar heats of adsorption on both OH sites at 3550 and 3650 cm^{-1}.

Ammonia was found to be the weakest base of the three, however, it was protonated on the 3550 cm^{-1}-OH sites,[12] then heats of adsorption were not much different on the 3550 and the 3640 cm^{-1}-OH sites. This might originate from the fact that ammonia was small enough to access to the 3550 cm^{-1}-OH sites and to be protonated in spite of its weaker basicity than pyridine. In order to confirm the interaction of ammonia with the 3550 cm^{-1}-OH sites, the following adsorption and/or poisoning measurements of pyridine and ammonia were carried out. The original H–Y (referred to A) was evacuated at 673 K and its weight was taken as reference. Two kinds of poisoned samples were prepared from the evacuated H–Y; one was poisoned with pyridine followed by evacuation at 473 K (B) and the other was further poisoned with ammonia followed by evacuation at 293 K (C). In B, the 3640 cm^{-1}-OH sites were poisoned by pyridine, and in C, the 3550 cm^{-1}-OH sites were also poisoned but by ammonia. All samples were exposed to pyridine vapor at 298 K and their weight change was measured. A weight increase in A coincided with that in B, which reflects the reproducibility in pyridine adsorption. On the other hand, a weight increase in C was higher than that in A by a corresponding value of 1.2 mmol g^{-1} of ammonia. This finding indicates that ammonia interacts with the 3550 cm^{-1}-OH sites, not in supercages but by entering hexagonal prisms or being adsorbed to the 3550 cm^{-1}-OH sites which are inaccessible for pyridine.

Direct Measurement of the Interaction Energy between Solids and Gases. XI. Calorimetric Measurements of Acidities of Aluminum Deficient H-Y Zeolites

Yoshio MITANI,†† Kazuo TSUTSUMI,*,† and Hiroshi TAKAHASHI
Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106
†*Toyohashi University of Technology, Tempaku-cho, Toyohashi 440*
(Received December 2, 1982)

Heats of adsorption of pyridine and ammonia were respectively measured on aluminum deficient H-Y zeolites using a microcalorimeter at 473 K. The calorimetrically determined acidity was discussed in relation to the positional difference between 3640 and 3550 cm^{-1}-OH acidic sites and compared with the catalytic activity. Dealumination generally brings about a decrease in the acid site concentration. However, the extent of the decrease varied with the kind of titrated base and a significant change was observed in the ratio of acid site concentration when titrated with pyridine. This may be explained by the fact that the pore size of the zeolite becomes widely distributed as dealumination proceeds; 3550 cm^{-1}-OH sites in supercages must become accessible to such a large molecule as pyridine. Also observed with dealumination was a slight increase in the heat of adsorption from initial to the middle stage of adsorption, which reflected the enhancement in acid strength of each OH site. The catalytic activity for cumene cracking increased with dealumination, which agreed with the acidity determined by the adsorption of pyridine rather than ammonia.

The acid strength of catalysts has widely been studied in relation to catalytic activity by use of butylamine and coloured indicators.[1-3] However, since it was not certain whether adsorption of butylamine selectively occurred on strong sites in preference to weak sites and whether the molecular size of butylamine was same with that that of reactant, the concentration obtained often deviated from the true value.[4]

In our previous papers,[5,6] the selective adsorption of bases was confirmed to occur onto strong sites in high temperature range above *ca.* 473 K and acid strength was determined as heats of adsorption by calorimetry. In addition, the relative acid strength changed with the kind of titrated base. Thus, the acid strength of solid surfaces should be investiated with respect to basic properties of adsorbate in high temperature range.

In the present work, the acid strength of Al-deficient H-Y zeolites was measured by pyridine and ammonia adsorption. The difference in acid strength between 3640 and 3550 cm^{-1}-OH sites will be discussed in correlation to the positional difference, which is useful for correlating calorimetric acid strength with catalytic activity.

Experimental

NH_4-Y zeolite was obtained by repeated ion exchange of Na-form zeolite (Linde SK 40) in 1 mol/dm^3 NH_4Cl solution at *ca.* 323 K. Al-deficient zeolites were prepared by means of a slow addition of ethylenediaminetetraacetic acid (H_4EDTA) as described by Kerr.[7] Table 1 shows chemical compositions of zeolites determined by chemical analysis. Ammonia and pyridine were purified by the freeze-thaw method before use.

TABLE 1. ZEOLITE COMPOSITIONS

Sample	Composition
$H\text{-}Y_{5.0}$	$0.72(NH_4)_2O\cdot 0.15Na_2O\cdot Al_2O_3\cdot 5.0SiO_2$
$H\text{-}Y_{7.4}$	$0.68(NH_4)_2O\cdot 0.19Na_2O\cdot Al_2O_3\cdot 7.4SiO_2$
$H\text{-}Y_{10.3}$	$0.67(NH_4)_2O\cdot 0.16Na_2O\cdot Al_2O_3\cdot 10.3SiO_2$

After the sample (0.25—0.50 g) was outgassed for 5 h at 673 K under a pressure of 1 mPa, differential heats of adsorption of bases were measured at 473 K using a twin-conduction type microcalorimeter as described previously.[8] IR spectra were obtained at 473 K by the *in situ* method as described elsewhere.[5]

Catalytic activity for cumene cracking reaction was tested in a microreactor made of stainless steel of 0.3 cm in inner diameter, connected to a conventional gas chromatography assembly with a product trap. The catalyst (0.25 g) was pretreated in a stream of helium at 673 K for 3 h. The cracking activity was determined at 543 K by injecting cumene (10^{-2} cm^3 as liquid) into the carrier gas, He, stream (60 cm^3/min). The gas chromatographic separation of the products was carried out with a column of 20 wt% dioctyl sebacate on 100—120 mesh Uniport B at 473 K. Catalytic activity was given in terms of the conversion of cumene to propylene and benzene during the first pulse reaction.

Results and Discussion

Heats of adsorption of ammonia and pyridine were measured on $H\text{-}Y_{5.0}$, $H\text{-}Y_{7.4}$, and $H\text{-}Y_{10.3}$ as shown in Figs. 1 and 2. The change of acid site strength with dealumination could be compared each other in both

cases of ammonia and pyridine adsorption on the basis of heat curves. Dealumination generally brought about a decrease in the number of OH sites, which corresponded to a decrease in the plateau region on heat curves. The ratio of the adsorbed amount in the plateau region to the total number of OH sites which was calculated from zeolite compositions may be assumed to reflect a relative concentration of effective acid sites. Its value depended on the kind of adsorbates, and the proportions of the value obtained by pyridine adsortipn to that by ammonia were 0.4 for H–$Y_{5.0}$, 0.45 for H–$Y_{7.4}$, and 0.55 for H–$Y_{10.3}$. This suggests that some OH sites become accessible to pyridine in progress of dealumination.

Figures 3 and 4 show changes of IR spectra of hydroxyl bands with adsorption of ammonia and pyridine, respectively. Acid sites of H–Y zeolites are known to originate from 3640 and 3550 cm^{-1}-OH sites, and the 3750 cm^{-1}-OH sites are to be silicious sites. On H–$Y_{5.0}$, the strength of both acidic OH sites was found to be approximately similar for the adsorption of ammonia, however, only 3640 cm^{-1}-OH sites acted as strong acid sites for pyridine because of differences in accessibility.[6] A consideration of these facts must account for observations that both OH sites interacted with ammonia on H–$Y_{5.0}$ and their band intensities decreased simultaneously (Fig. 3-A) while that only the 3640 cm^{-1}-OH sites interacted with pyridine and the intensity of the 3550 cm^{-1}-OH band remained unchanged (Fig. 4-A). However, preferential adsorption of pyridine on the 3640 cm^{-1}-sites became less significant as revealed in the change of intensity ratios of the 3640 cm^{-1} band to the 3550 cm^{-1} one with progress of dealumination (Fig. 4-B, C). This suggests that a part of the 3550 cm^{-1}-OH sites became somewhat accessible to pyridine. On the other hand, intensity ratios remained almost constant in case of ammonia adsorption (Fig. 3-B, C), which suggests that accessibility of both OH sites to ammonia seemed not to change with dealumination.

Structural change with dealumination was also examined in relation to accessibility to bases of both OH sites. A half width and integral intensity of X-ray profiles suggested that the framework structure of H–

Table 2. Catalytic activity for cumene cracking reaction at 543 K

Catalyst	Conversion/%
$H–Y_{5.0}$	56
$H–Y_{7.4}$	76
$H–Y_{10.3}$	76

$Y_{10.3}$ was partially destroyed, while that of $H–Y_{7.4}$ was almost unchanged. Figure 5 shows nitrogen adsorption isotherms on zeolites. The rectangular shape of the isotherm on $H–Y_{5.0}$ suggested that the zeolite was of a regular pore structure. However, the pore size must become widely-distributed with dealmination as revealed in the shapes of isotherms on $H–Y_{7.4}$ and $H–Y_{10.3}$. The positional assignments were demonstrated by Eberly[9] and others[10,11] that H-atoms contained in 3550 cm^{-1}-OH sites existed in hexagonal prisms with maximum entrance diameter of 2.2—2.5 Å and that those in 3640 cm^{-1}-OH sites in supercages with maximum entrance diameter of *ca.* 9 Å. In consideration of both structural change with dealumination and positional assignments of OH sites, 3550 cm^{-1}-OH sites were concluded to become accessible to large molecule of pyridine in respect of size as dealumination proceeded. Since ammonia was considered to be adsorbed close to 3550 cm^{-1}-OH sites even on $H–Y_{5.0}$,[6] the accessibility of OH sites did not change with dealumination. On the other hand, 3640 cm^{-1}-OH sites on these three zeolites were considered to be equally accessible to both pyridine and ammonia in respect of size. These results in Al-deficient zeolites supported the previous discussion[6] that the difference in the acid strength between two OH sites was explained in terms of positional differences. The acid site strength on Al-deficient zeolites proved to be somewhat larger than that on $H–Y_{5.0}$ as judged by heats of adsorption at plateau region in Figs. 1 and 2.

The catalytic activity for cumene cracking was weaker on $H–Y_{5.0}$ than on Al-deficient $H–Y_{7.4}$ and $H–Y_{10.3}$ as shown in Table 2. A comparison of the result with the acidic properties shown in Figs. 1 and 2 suggested that the activity seemed to correlate with the acidity determined by pyridine rather than by ammonia. In case of pyridine adsorption, it was found that the acid site concentration remained nearly constant and its strength was rather enhanced on dealumination. In case of ammonia adsorption, however, the acid site concentration decreased significantly with dealumination. Ward[12] demonstrated on the basis of IR measurements on $H–Y_{5.0}$ that only 3640 cm^{-1}-OH sites were affected by cumene at 523 K. In a previous paper,[6] piperidine was found to affect simultaneously both 3640 and 3550 cm^{-1}-OH sites. This was considered to be attributable to strong basicity of piperidine, while its molecular size is almost the same as that of pyridine. All the data lead to the notion that the activity for acid-catalyzed reaction should be discussed in relation to the surface acidity only in cases in which the basic molecule used has similar size to that of the reactant and selectively interacts with active sites.

A Localized Molecular Orbital Approach to the Bond Moment Theory

Hiroyuki SHINODA*,† and Tomoo MIYAZAKI

Department of Applied Chemistry, Faculty of Science and Engineering, Waseda Uuiversity, Ohkubo, Shinjuku-ku, Tokyo 160

(Received October 29, 1982)

The bond moment theory was reinvestigated by use of localized molecular orbitals derived from INDO canonical orbitals. Bond moments were defined in terms of localized molecular orbital and, together with their derivatives with respect to a C–H stretching motion, were evaluated for some simple molecules; the bond moments of acetylene and hydrogen cyanide in the C–H bending geometry were also calculated. It is concluded that the first-order approximation for the bond moment theory is inadequate to interpret infrared absorption intensity. In the C–H stretching vibration the change in *trans*-sited bond moment is considerably large.

Some properties of a molecule have been analyzed by relating them to several characteristic values of bonds in the molecule. Furthermore, those values for particular kinds of bonds, *e.g.*, the C–H bond, are expected to be capable of being transfered from one molecule to another. A method of analyzing infrared absorption intensities along this line is well known as the bond moment theory.

Experimental approaches to the bond moment theory have been involved in some difficulties. The most serious one is that the number of intensity parameters needed for the application of the theory usually exceeds the number of pieces of experimental information. In practical treatments, therefore, we have been obliged to approximate the theory by neglecting a large part of parameters. Another difficulty is that the sign of dipole moment derivative with respect to the normal coordinate can not be decided uniquely from the experimental intensity.

There are some reports in which infrared absorption intensities were subjected to molecular orbital calculations.[1,2] In most studies molecular orbital calculations played only a supplemental role in the decision of the sign, which constitutes the second difficulty in experimental approach.[1] Recently, with the advance of electronic computer and with the popularization of molecular orbital calculations, infrared absorption intensities as well as vibrational frequencies have been calculated by the molecular orbital method, and successful results have been obtained.[2] Up to now, however, there are not so many reports on the bond moment theory conducted on the basis of molecular orbital calculations.

In this study, localized molecular orbitals (LMOs) which had been transformed from INDO canonical orbitals[3] by the Edmiston and Ruedenberg method[4] were used to define bond moments. The Edmiston and Ruedenberg method is based on maximization of the sum of intraorbital Coulomb repulsion energies and is called the energy localization method. Three other methods for determining LMOs were proposed by Foster and Boys,[5] von Niessen,[6] and Magnasco and Perico.[7] The agreement among results obtained by these four methods was generally good.[8] Figeys *et al.*[9] compared LMOs from *ab initio* canonical orbitals with those from semiempirical canonical orbitals, pointing out that the choice of canonical orbitals is important to gain a quantitative reliability. In this study, however, INDO canonical orbitals were used, because the main aim of the study lies in a qualitative check of the approximations which have been introduced into the bond moment theory and because INDO method gives fairly good electron distributions as compared with the other semiempirical methods. Bond moment derivatives with respect to a C–H stretching were calculated for several small molecules and also bond moments of acetylene and hydrogen cyanide were calculated with a condition of the C–H bond being bent.

The bond moment theory and the approximations introduced into it are described in the following section.

The Bond Moment Theory

The infrared absorption intensity A_a of the fundamental band for a normal vibration a is expressed, with the assumption of the harmonic oscillator approximation, as follows:[10]

$$A_a = \frac{N\pi}{3c}\sum_m\sum_n\left(\frac{\partial\mu}{\partial R_m}\right)_0\cdot\left(\frac{\partial\mu}{\partial R_n}\right)_0 L_{ma}L_{na}, \quad (1)$$

where μ is the molecular total dipole moment, c the velocity of light, N the Avogadro number, L_{ma} the element of the well-known transformation matrix between the internal coordinates $\{R_m\}$ and the normal coordinates $\{Q_a\}$. The starting point of the bond moment theory is that the total dipole moment μ in Eq. 1 is given as the sum of bond moments, μ_k's:

$$\mu = \sum_k \mu_k. \quad (2)$$

Introducing this expression, we rewrite Eq. 1 as follows:

$$A_a = \frac{N\pi}{3c}\sum_m\sum_n\sum_k\sum_l\left(\frac{\partial\mu_k}{\partial R_m}\right)_0\cdot\left(\frac{\partial\mu_l}{\partial R_n}\right)_0 L_{ma}L_{na}. \quad (3)$$

As seen from this equation, the infrared absorption intensity can be interpreted in the terms of $(\partial\mu_k/\partial R_m)_0$'s, bond moment derivatives with respect to the internal coordinates.

In the first stage of investigation, each bond moment was supposed to be parallel to any one bond in the molecule and its magnitude not to be changed without change in the bond length. Therefore, the bending mode which does not change the bond length will

† Present address: Faculty of Pharmaceutical Science, Toyama Medical and Pharmaceutical University, 2630 Sugitani, Toyama 930-01.

cause a variation in the total dipole moment only through a reorientational contribution of the bent bond. Within the restricted supposition, the calculated intensity did not agree with the experimental.[11] Hornig and McKean loosened the supposition,[12] adopting the following three approximations:

(a) When a bond is stretched by an amount dr, a moment $(\partial\mu/\partial r)dr$ is produced in the direction of the bond.

(b) When a bond is bent through an angle $d\alpha$, a moment $\mu^e d\alpha$, where μ^e is the "*effective*" bond moment, is produced in the plane of bending and perpendicular to the direction of the bond.

(c) When any one bond is bent or stretched, no moments are produced in the other bonds.

They investigated experimental infrared intensities of many molecules on the basis of these approximations and concluded that the "*effective*" bond moment of a given bond is not constant, that is, intensities of two different vibrational modes including the bond derive different values of the "*effective*" bond moment. They also concluded that in molecules containing lone pair electrons their effect must be taken into account explicitly. Orville-Thomas and his coworkers studied infrared absorption intensities of several triatomic molecules on the bond moment theory.[13-15] They concluded that the approximations introduced by Hornig and McKean are inadequate to interpret intensities. Therefore, they replaced the approximation (c) given above by a new approximation as follows:

(c′) When a particular bond is bent or stretched, a moment is produced in adjacent bonds.

They called the new set of approximations the "first-order bond moment theory" in contrast with the old one called the "zero-order bond moment theory." The intensity parameters in the new approximations are so many as to make impossible their evaluation from experimental intensities. Then, they had to elaborate some parameters in the form of composite term.[14] They also revealed that in bending modes atomic polarization terms of dipole moment, called rehybridization terms, are significant for interpreting intensities.[15]

Anyway, the investigations described above were founded on the assumption that each bond moment μ_k in Eq. 2 must belong to a certain bond in a molecule. Therefore, the lone pair electrons and the atomic polarization terms had to be treated as if they were new kinds of moments. Some investigations on the bond moment have been carried out by use of some terms of LMOs.[16,17] They will be discussed in comparison with our results.

Methods of Calculation

LMOs $\{\phi_i\}$ were calculated by the Edmiston and Ruedenberg method. The degree of localization was judged in our program as follows: The weight of atom A, w_A, in LMO ϕ_i is calculated by summing the squares of the LCAO coefficients of the atomic orbitals which belong to the atom. When w_A is larger than 0.9, LMO ϕ_i is regarded to be localized on atom A and the degree of localization is given by w_A. When any one w_A does not exceed 0.9 and the sum of w_A and w_B is larger than 0.9, LMO ϕ_i is regarded to be localized at bond A–B and the degree of localization is given by w_A+w_B.

The definition of localized orbital moment for each LMO follows that of Gordan and England[16] as follows:

(1) When LMO ϕ_i is localized at bond A–B, the localized orbital moment is expressed as

$$\mu_i = -2\langle\phi_i|e\boldsymbol{r}|\phi_i\rangle + (\boldsymbol{R}_A+\boldsymbol{R}_B)e. \quad (4)$$

(2) When LMO ϕ_i is localized on atom A as lone pair orbitals or as inner shell orbitals, the localized orbital moment is expressed as

$$\mu_i = -2\langle\phi_i|e\boldsymbol{r}|\phi_i\rangle + 2\boldsymbol{R}_A e. \quad (5)$$

In the above expressions $\boldsymbol{R}_A$ is the position vector of atom A and $\boldsymbol{r}$ is that of an electron. In the INDO calculation the second type of LMO always corresponds to a lone pair orbital. In this study the bond moment is defined as follows:

(1) The bond moment of bond A–B is the sum of the localized bond moments of the LMOs which are localized at the bond.

(2) If LMO ϕ_i is a lone pair orbital, its localized orbital moment itself is regarded as a kind of bond moment. The definitions, particularly (2), are useful in comparing bond moments and their derivatives between various molecules.

Bond moment derivatives with respect to a C–H stretching were calculated from bond moments for the C–H bond displaced +0.1 Å from the equilibrium length.

Results and Discussion

dipole moment values is shown in Fig. 1. The numbering of atoms and the designation of lone pair orbitals in each molecule are also shown.

Values of bond moments and their components and of angles between bond moments and corresponding bonds were calculated for the equilibrium geometries. The results are listed in Table 1, except those which are clear from the geometrical properties. The values of angles for the C–H bonds are not so large and are in the same order as those reported by Gordon and England.[16] Bruns *et al.*[18] calculated the dipole moment derivatives of ammonia with respect to the symmetry coordinates. In their report the angles between the bond moment and the corresponding N–H bond is 2.15°. On the other hand in our results, the values for the N–H and C–N bonds in methylamine and for the O–H and C–O bonds in methanol are somewhat large. From these results it may be said that the bond moment direction of an X–Y bond, where X and/or Y have lone pair orbitals, largely deviates from the bond and that hydrogen cyanide, formaldehyde, and ammonia fall in special cases where highly symmetrical geometries are possessed.

Since the Edmiston and Ruedenberg method for calculating LMOs has no guarantee for giving full localization, the degree of localization was tested for molecules in equilibrium geometry. It was greater than 0.99 for the bond localized orbital, while for the lone pair orbital it was less than 0.99 with a minimum of 0.969 for hydrogen cyanide. Gordon and England[16] calculated the degree of localization for many hydrocarbons and concluded that the overflow of electrons due to a very small delocalization, which they called tail, was not negligible for some properties of molecules. Therefore, each bond moment of hydrogen cyanide and formaldehyde which reveal the large delocalization was divided into two contribution parts, *i.e.*, the *intra*-LMO part and the *extra*-LMO part. The calculated results are listed in Table 2. It is seen from the table that the contribution of the *extra*-LMO part is at most 5%.

It is found from the first column of Table 1 that the absolute values of the C–H bond moments are varied in the range from 1.96 to 2.28 D (1 D = 3.33564×10^{-30} C m). Their average and standard deviations are 2.077 and 0.096 D, respectively. The deviation is somewhat large as compared with the results of Kapuy and Kozmutza,[17] who investigated prop-

erties of LMOs by the *ab initio* molecular orbital calculation. If the LMO of C–H bond is fully localized, the bond moment is a function of the C–H distance vector, the bond polarization of the electron distribution in the LMO, and the s-character of the hybrid orbital in the carbon atom. When the bond polarization does not appear, it is a function of only the s-character and the values of the bond moments are 2.258, 2.128, and 1.955 D for the sp-, sp^2-, and sp^3-hybrid orbitals, respectively; that is, the bond moment changes with the increase in s-character. The s-character of atom X in the X–H bond is shown in the last column of Table 1. It is shown that the order of magnitude for the calculated C–H bond moments does not agree with that of the s-character. Thus it is concluded that the C–H bond moment is determined by not only the s-character but also the bond polarization. The latter factor is dominantly affected by the environment of the C–H bond, so that the

a) See footnote a) in Table 1. b) The stretching C–H bond is referred to in the parentheses.

transferability of bond moment is permitted only in rather limited congeners.

Bond moment derivatives with respect to the change in C–H bond length were calculated and are listed in Table 3. In most of the molecules the values of many off-diagonal terms are larger than that of the diagonal term. In the cases of acetylene and hydrogen cyanide the derivative of the neighbouring bond moment is small in comparison with that of the non-neighbouring bond moment. Furthermore, the direction of the vector for the non-neighbouring bond moment derivative is opposite to that of the diagonal term so that a large part of derivatives may be cancelled. In ethylene and formaldehyde the derivatives of the neighbouring and the *trans*-sited bond moments are larger than the diagonal term. A similar situation is also found in the results of ethane, methylamine, and methanol. The values of the diagonal terms are in the range of 0.130 to 0.367 D/Å with a standard deviation of 33.5%. Due to their large deviation, the expectation for the transferability between them must be abandoned. In Fig. 2 are illustrated the vectors of the bond moment derivatives for the planar molecules and the projections of the vectors on the plane of symmetry which includes the stretching C–H bond for the nonplanar molecules. The derivatives of the total dipole moments are also shown in the figure. It is found from the figure that the direction of each bond moment derivative is neither along the bond itself nor along the stretching bond, but that the derivative of the total dipole moment has a direction nearly along the stretching bond. It is noteworthy that the overall configuration of bond moment derivatives in a molecule resembles that in another one. It is concluded from the results that if the bond moment theory is developed with LMOs, the first-order approximation is inadequate to explain the change in dipole moment.

Some investigators have claimed that the hybridization term of dipole moment is significant to interpret the infrared absorption intensity, especially for bending modes. In our calculations, each bond moment can be divided into the (bond) polarization and hybridization terms. Change in bond moment for a C–H bending motion was studied for acetylene and hydrogen cyanide. The results are listed in Table 4. In the table $\Delta\mu=\mu_{10}-\mu_{eq}$, where μ_{10} is the bond moment when a C–H bond is bent 10° and μ_{eq} is that for the equilibrium geometry. It is concluded from the table that the x-components are caused to change slightly and that a main contribution to the change in the y-component arises from the hybridization terms; in the y-component of the diagonal term, *i.e.*, the bond moment change in the bent bond, the hybridization term is opposite in sign to the polarization term. This conclusion seems similar to the conclusion reported by Galabov and Orville-Thomas.[19] But these two conclusions cannot be regarded as the same since in Ref. 19 the rehybridization term is calculated as the atomic polarization for the central atom of bending, whereas in our results the corresponding atomic polarization is divided into the hybridization terms of two bond moments relating to the central atom. Anyway, it is concluded that the hybridization term is important to interpret the bond moment. It is noticeable that the polarization terms for the y-components of the off-diagonal terms are very small but not to be taken as zero. If the LMOs are fully localized at the bonds, the polarization terms do not change.

Therefore, their nonzero values are due to the delocalization to the bent bond.

Although localized molecular orbitals are useful to investigate bond moments and their derivatives with respect to an appropriate coordinate, the transferability of intensity parameters in the bond moment theory should carefully and extensively be examined. If the intensity parameters need to be discussed with quantitative accuracy, it is important to use good canonical orbitals.

The Physicochemical Properties of Aqueous Solutions of Sodium Alkanesulfonates. Apparent Molar Volumes, Viscosity *B* Coefficients, Heats of Solution, and Surface Tensions

Kunio Tamaki,* Yōko Ōhara, Masahiro Inabe, Tetsushi Mori, and Fumio Numata

Department of Chemistry, Yokohama City University, Kanazawa-ku, Yokohama 236

(Received November 8, 1982)

The apparent molar volumes, viscosity *B* coefficients, heats of solution, and surface activity of sodium alkanesulfonates (RSO_3Na, methyl to hexyl) in water were measured. The limiting apparent molar volumes at 25 °C increase with the number of carbon atoms in the alkyl chain; the increment per methylene group is about 16 $cm^3\ mol^{-1}$. The viscosity *B* coefficients of $MeSO_3Na$ and $EtSO_3Na$ increase with the temperature, while those of *n*-$BuSO_3Na$ decrease with an increase in the temperature. The changes in heat capacity for dissolution in water, ΔC_p°, as calculated from the heats of solution at 15, 25, and 35 °C, were negative for $MeSO_3Na$ and $EtSO_3Na$, while the ΔC_p° values for *n*-$PrSO_3Na$ and higher homologs were positive. $MeSO_3Na$ raises the surface tension of water, while $EtSO_3Na$ and higher homologs reduce it. The structural changes in the solvent water upon the dissolution of sodium alkanesulfonates are discussed in comparison with those of sodium alkyl sulfates previously reported.

The behavior of amphiphilic organic ions in water may be interpreted approximately in terms of a balance of two types of interaction: hydrophobic hydration due to the nonpolar parts, and electrostrictive hydration due to the ionic parts.[1] Both sodium alkanesulfonates (RSO_3Na) and sodium alkyl sulfates ($ROSO_3Na$) are typical amphiphilic organic electrolytes. The temperature dependence of the heats of solution and the viscosity *B* coefficients for a homologous series of $ROSO_3Na$ were reported in previous papers.[2,3] In this paper, experimental results will be reported on the apparent molar volumes, viscosity *B* coefficients, heats of solution, and surface activity of a series of RSO_3Na in water. The main object of this work is to compare the role of the alkyl group of RSO_3Na in the structural influence in water with that of $ROSO_3Na$ previously reported.

Experimental

Materials. The organic chemicals used were commercial products from the Tokyo Kasei Kogyo Co., Ltd. Sodium methane- and ethanesulfonates were prepared by the neutralization of the corresponding sulfonic acids with a solution of sodium hydroxide, after which the water was evaporated to dryness. The sodium salts were twice recrystallized from ethanol–water solutions. The other sodium alkanesulfanates were synthesized by the Strecker method.[4] Alkyl bromides were refluxed with a saturated water solution of sodium sulfite for several days, after which the mixtures were dried in air. The sodium salts were extracted with ethanol and then further purified by repeated recrystallization from ethanol–water solutions until the salts obtained were free from Br^- ion. All the products of sodium alkanesulfonates were subjected to air-drying under a relative humidity of 50%. Analysis using an electrobalance showed that sodium methanesulfonate was anhydrous, while the other ethane-, 1-propane-, 1-butane-, 1-pentane-, and 1-hexanesulfonates were exactly monohydrates. The monohydrate samples were very stable in air. The conversion from monohydrate salts to anhydrous salts was found to be very troublesome, especially for $EtSO_3Na$; therefore, the monohydrate samples were used for the measurements for density, viscosity, and surface tension. Sodium alkyl sulfates used for the measurements of the surface tension were the same samples as were employed in previous studies.[2,3] Water was triply distilled.

Density Measurement. The densities were measured using a vibrating-tube densimeter, twin-type SS-D-200, manufactured by the Shibayama Scientific Co., Ltd. Two measuring vessels were immersed in a water bath with a capacity of about 40 dm^3 controlled to ±0.002 °C. One of the measuring vessels was used for the density measurement of a solution; the other measuring vessel was used for monitoring the density of water. The apparatus constant of the meter was determined using water and dry air as standard substances; their densities were taken from the literature.[5]

Viscosity Measurement. The viscosities were measured with an automatic viscometer manufactured by the Shibayama Scientific Co., Ltd. The flow times of Ubbelohde-type viscometers were about 250 s at 25 °C for water, measuring to 0.01 s. The viscosity, η, was calculated from the average flow time, t, and the density, ρ, based on the equation:

$$\eta = \rho k_1(t - k_2/t). \quad (1)$$

The k_1 and k_2 constants were determined from the measurements for water at 25 and 40 °C. The viscosity values of water at these temperature were taken from the literature.[6]

Calorimetry. The heats of solution of the anhydrous salts in water were measured at 15, 25, and 35 °C with a twin isoperibol calorimeter TIC-2C, manufactured by the Tokyo Riko Co., Ltd. To obtain anhydrous samples, all the salts were dried *in vacuo* at 100 °C for several days. The glass ampoules filled with samples were further dried *in vacuo* at 100 °C for about 6 h and then sealed. The sample and blank ampoules were, respectively, set in the measuring and reference Dewar vessels, each containing 200 cm^3 of water, resting in depressions in an aluminum block controlled to ±0.01 °C. After thermal equilibrium had been attained, the sample and blank ampoules were broken simultaneously. The difference in temperature, as measured by a pair of thermistors, was recorded on a chart recorder. The calorimeter was checked by measuring the heat of solution of potassium chloride at 25 °C. The value obtained was within 1% of that reported in the literature.[7]

Surface-tension Measurement. The surface tensions were measured at 25±0.01 °C by means of the drop-volume method using a micrometer syringe, similar to that described in a previous paper.[8]

Results and Discussion

Apparent Molar Volumes. The apparent molar volumes, ϕ_v, in $cm^3\ mol^{-1}$ were calculated from the densities using the following equation:

$$\phi_v = \frac{1}{m}\left(\frac{1000+mM}{\rho} - \frac{1000}{\rho_0}\right), \quad (2)$$

where m is the molal concentration in $mol\ kg^{-1}$; M, the molar mass in $g\ mol^{-1}$, and ρ_0 and ρ, the densities in $g\ cm^{-3}$ of water and of a solution respectively. The solutions were made by weight. When the sample of $RSO_3Na \cdot H_2O$ was dissolved in water, the quantity of the water was made equal to the total of the weighed quantity of water in a weighing bottle plus the liberated water from the weighed quantity of solid $RSO_3Na \cdot H_2O$; the quantity of the latter was calculated from the chemical formula. The apparent molar volume of electrolytes is given by the equation:[9]

$$\phi_v = \phi_v^\circ + A_v c^{1/2} + B_v c, \quad (3)$$

where ϕ_v° is the limiting value, which is identical with the partial molar volume at an infinite dilution; A_v and B_v, the constants, and c, the molar concentration in $mol\ dm^{-3}$. The value of constant A_v is 1.868 $cm^3\ dm^{3/2}\ mol^{-3/2}$ for water at 25 °C;[9] the relation ϕ_v—$1.868\,c^{1/2}$ *versus* c for a series of RSO_3Na is shown in Fig. 1. The values of ϕ_v° and B_v are given in Table 1. It is found that the ϕ_v° values increase as the alkyl-chain length increases and that the increments in the ϕ_v° values per methylene group from $EtSO_3Na$ to higher homologs are about 16 $cm^3\ mol^{-1}$; this value corresponds approximately to the value of other homologous compounds, such as alkanoates and alkylammonium salts.[10-13] The B_v values of RSO_3Na are found to decrease with an increase in the number of carbon atoms, as is shown in Table 1; this fact is in accord with the results for other homologous compounds.[10-13]

Table 1. Limiting apparent molar volumes of RSO_3Na at 25 °C

RSO_3Na	ϕ_v°/$cm^3\ mol^{-1}$	B_v/$dm\ cm^3\ mol^{-2}$
Methyl	53.99	0
	53.88[a]	
Ethyl	69.31	−1.15
	71.56[a]	
Propyl	85.08	−1.9
Butyl	101.08	−2.25
Pentyl	117.02	−2.7
Hexyl	132.98	−2.8

a) Ref. 11.

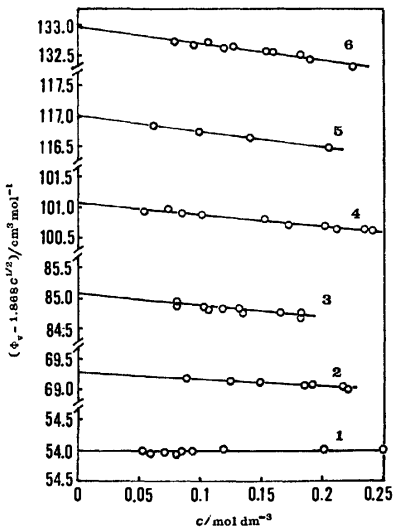

Fig. 1. Apparent molar volumes of RSO_3Na at 25 °C. 1, methyl; 2, ethyl; 3, propyl; 4, butyl; 5, pentyl; 6, hexyl.

Viscosity. The viscosities of RSO_3Na at 25 °C were reported in a previous paper.[1] In this work, the temperature dependence of the viscosity B coefficients for RSO_3Na (methyl to butyl) were reinvestigated by means of a more elaborate apparatus. The viscosity of aqueous electrolyte solution is given by the Jones-Dole equation:[13]

$$\eta/\eta_0 = 1 + A_\eta c^{1/2} + B_\eta c, \quad (4)$$

where η_0 and η are the viscosity of water and the solution respectively; A_η, the constant arising from the interaction between the ions, and B_η, the viscosity B coefficient, which is interpreted in terms of a specific solute-solvent interaction. Equation 4 may be converted to:

$$(\eta/\eta_0 - 1)/c^{1/2} = A_\eta + B_\eta c^{1/2}. \quad (5)$$

For example, Fig. 2 shows the results of the plotting

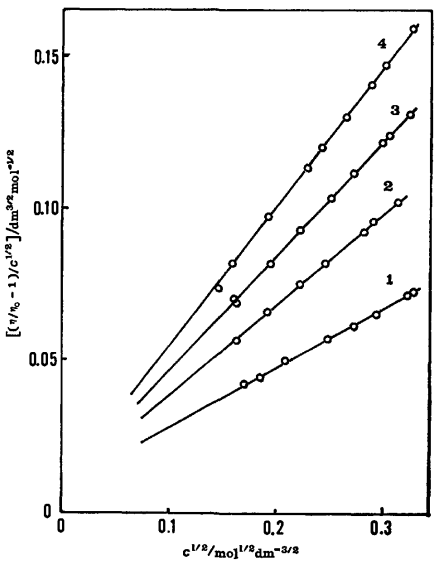

Fig. 2. Plot of $(\eta/\eta_0 - 1)/c^{1/2}$ against $c^{1/2}$ for RSO_3Na at 25 °C. 1, methyl; 2, ethyl; 3, propyl; 4, butyl.

Table 2. Viscosity B/$dm^3\ mol^{-1}$ coefficients of RSO_3Na

RSO_3Na	25 °C	40 °C
Methyl	0.198	0.208
Ethyl	0.304	0.310
Propyl	0.383	0.383
Butyl	0.468	0.436

of Eq. 5 at 25 °C. The B_7 values obtained at 25 and 40 °C are summarized in Table 2. It may be seen in Table 2 that the B_7 values for $MeSO_3Na$ and $EtSO_3Na$ increase with the temperature and that the B_7 values of n-$PrSO_3Na$ are insensitive to the temperature. With n-$BuSO_3Na$, the B_7 values decrease with an increase in the temperature. In a previous work[3] on the viscosity of $ROSO_3Na$ solutions, it was found that $MeOSO_3Na$ showed a slight increase in the B_7 values with the temperature and that the B_7 values of n-$PrOSO_3Na$ decreased slightly with an increase in the temperature. Kay *et al.*,[14] reported an increase in the B_7 values with the temperature for a solvent-structure-breaking salt such as tetramethylammonium salt and a decrease in the B_7 values with an increase in the temperature for a solvent-structure-making salt such as tetrapropyl- and tetrabutylammonium salts. On comparing the viscosity B coefficients of RSO_3Na with those of $ROSO_3Na$, it is found that the hydrophobicity of RSO_3Na is weaker than that of $ROSO_3Na$.

Heat of Solution. Heat-of-solution measurements were carried out in the concentration range of $(1—5)\times10^{-3}$ mol dm^{-3}. In this concentration range, any dependence of the heat of solution on the concentration is within the limit of experimental error, so the average of three or more measurements has been taken as the heat of solution at an infinite dilution, $\Delta H_s°$. The $\Delta H_s°$ values of anhydrous RSO_3Na in water are listed in Table 3. The $\Delta H_s°$ values at 25 °C reported in the literature[15,16] are also included in Table 3. The $\Delta H_s°$ values obtained in this work are slightly more positive than those reported by Krishnan and Friedman.[16] Results from the $\Delta H_s°$ values were used to calculate the change in the heat capacity for dissolution at an infinite dilution, $\Delta C_p°$:

$$\Delta C_p° = d\Delta H_s°/dT, \quad (6)$$

where T is the temperature. The results for $\Delta H_s°$ were represented by the equation:

$$\Delta H_s° = a + bT + cT^2, \quad (7)$$

Table 3. Heats of solution and heat-capacity changes of RSO_3Na

RSO_3Na	$\Delta H_s°$/kJ mol^{-1}			$\Delta C_p°$/J K^{-1} mol^{-1}
	15 °C	25 °C	35 °C	25 °C
Methyl	7.87	6.92	6.17	−85
		6.95[a]		
		6.40[b]		
Ethyl	−2.82	−3.16	−3.48	−33
		−3.60[b]		
Propyl	−6.13	−5.84	−5.63	25
		−6.19[b]		
Butyl	0.08	0.93	1.77	85
		0.84[b]		
Pentyl	−3.59	−2.24	−0.97	131
		−2.68[b]

		0.25[b]		

a) Ref. 15. b) Ref. 16.

and by:

$$\Delta C_p° = b + 2cT, \quad (8)$$

where a, b, and c are the experimental constants; the $\Delta C_p°$ values obtained at 25 °C are also listed in Table 3. As may be seen in Table 3, $MeSO_3Na$ and $EtSO_3Na$ show negative $\Delta C_p°$ values, while n-$PrSO_3Na$ and higher homologs show the positive $\Delta C_p°$ values, which increase with the number of carbon atoms in the alkyl chain. In an earlier work[2] on a series of $ROSO_3Na$, $MeOSO_3Na$ showed only the negative value of $\Delta C_p°$ and $EtOSO_3Na$ showed insensitive $\Delta H_s°$ values with an increase in the temperature. Further, n-$PrOSO_3Na$ and higher homologs showed positive $\Delta C_p°$ values. Figure 3 shows the $\Delta C_p°$ values as a function of the number of carbon atoms in the alkyl chain of both the RSO_3Na and $ROSO_3Na$ series. The magnitude and sign of $\Delta C_p°$ can be taken as a relative measure of the structural effect upon the solvent water.[17,18] The $\Delta C_p°$ values of simple salts indicate negative values, whereas the $\Delta C_p°$ values of hydrophobic solutes indicate positive values.[18] Therefore, the results (Table 3 and Fig. 3) indicate that the hydrophobic effect of RSO_3Na is weaker than that of $ROSO_3Na$.

Surface Tension. In this paper, the change in the surface tension, $\Delta\sigma$, is defined as:

$$\Delta\sigma = \sigma_0 - \sigma, \quad (9)$$

where σ_0 and σ are the surface tension of water and a solution respectively. Figure 4 shows the change in the surface tension of aqueous solutions of RSO_3Na as a function of the logarithmus of the molar concentration. It may be seen that $MeSO_3Na$ raises the surface tension of pure water, whereas $EtSO_3Na$ and higher homologs reduce the surface tension of water. For comparison, the results[19] for $ROSO_3Na$ presented earlier are shown in Fig. 5. In this case, all the salts represent the surface-active property. The shape of the surface tension-*versus*-concentration curve for an organic salt in aqueous solutions is considered to give a rough criterion of the behavior of the salt in water; simple salt raises the surface tension of water, whereas hydrophobic salts reduce it.[21] In a previous paper[21] on the surface tension of a series of alkylammonium chlorides in aqueous solutions, ethylammonium chloride

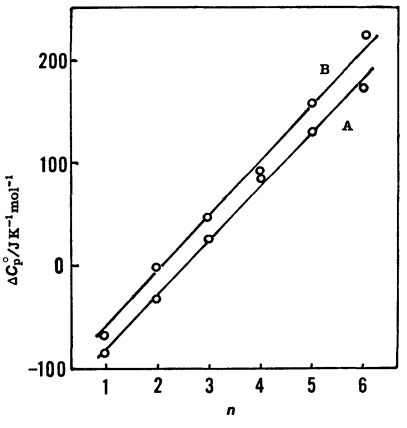

Fig. 3. Plot of $\Delta C_p°$ against number of carbon atoms in the alkyl chain, n. A, RSO_3Na; B, $ROSO_3Na$.

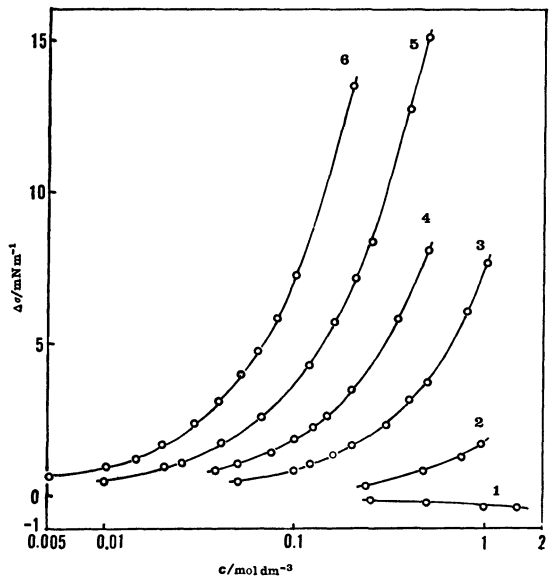

Fig. 4. Change in surface tension as a function of $\log c$ for RSO_3Na. 1, methyl; 2, ethyl; 3, propyl; 4, butyl; 5, pentyl; 6, hexyl.

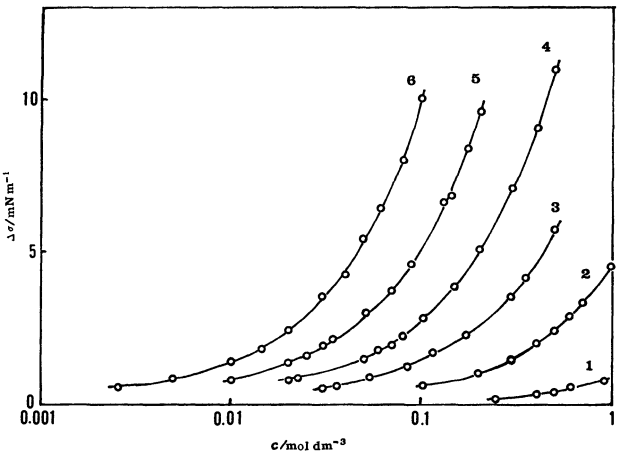

Fig. 5. Change in surface tension as a function of $\log c$ for $ROSO_3Na$. 1, methyl; 2, ethyl; 3, propyl; 4, butyl; 5, pentyl; 6, hexyl.

exhibited a weak surface-active property, while this salt was classified as a weak structure-breaker from the measurement of $\Delta C_p°$.[18] This inclination must be kept in mind when one makes any remark about the behavior of salts in water on the basis of the surface-tension data alone. Nevertheless, as may be seen in Figs. 4 and 5 it is obvious that the surface activity of RSO_3Na in water is rather weaker than that of $ROSO_3Na$.

In order to compare the strength of the surface activity for homologous compounds, the Traube factors are obtained using the $\Delta\sigma$ values *versus* the molar concentration curves shown in Figs. 4 and 5. The Traube factor means the ratio of the molar concentrations of equal $\Delta\sigma$ values when the chain of an aliphatic compound is lengthened by one methylene group. The Traube factors are found to be about 2 for the homologous compounds from *n*-$PrSO_3Na$ to *n*-$C_6H_{13}SO_3Na$ as well as for those from *n*-$PrOSO_3Na$ to *n*-$C_6H_{13}OSO_3Na$ inclusive. This is a characteristic feature of a homologous series of surface-active electrolytes with one alkyl chain.[22]

General Considerations. The classification of the behavior of amphiphilic electrolytes in water is dependent on the experimental method adopted and its interpretation. One should be particularly cautious about the classification when the absolute values of the structural measure are rather small. In general, from the experimental results obtained in this work it may be concluded that the hydrophobic character of RSO_3Na is slightly reduced compared with that of $ROSO_3Na$. In the case of $ROSO_3Na$ studied earlier, $MeOSO_3Na$ is a simple salt, $EtOSO_3Na$ is a borderline solute, and *n*-$PrOSO_3Na$ and higher homologs are hydrophobic structure-makers. On the other hand, in the case of RSO_3Na studied in this work, $MeSO_3Na$ and $EtSO_3Na$ may be classified as simple salts; *n*-$PrSO_3Na$, as a borderline or a weak hydrophobic structure-maker, and *n*-$BuSO_3Na$ and higher homologs, as excellent hydrophobic structure-makers. In this connection, Klevens[23] pointed out that all straight-chain saturated surface-active agents of equal chain length have approximately the same critical micelle concentrations, and that C_{12} sulfonate and C_{11} sulfate belong to the same C_{12} family. In this case, the chain length was measured from the hydrogen of the ultimate carbon to the charged atom at the hydrophilic end of the alkyl chain. From the results of experiments with $\Delta C_p°$, shown in Fig. 3, it is found that the solvent-structure-making effect of the extra –O– group in $ROSO_3Na$ is comparable to about a half of that of a methylene group.

Kinetic Instability of Nonbenzenoid Aromatic Hydrocarbons

Jun-ichi AIHARA

Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422

(Received November 29, 1982)

Aromatic hydrocarbons have thermodynamically stable cyclic conjugated systems. There is a tacitly accepted view that not only aromatic stabilization but also kinetic stability arise from the same cyclic conjugation of π electrons. In order for this view to be examined criticaly, two reactivity indices, *i.e.*, localization energy and superdelocalizability, were adopted for a variety of cyclic conjugated hydrocarbons, and were compared with those defined for their olefinic reference structures. Interestingly, it was found that chemical reactivity of some constituent carbons might often overcome aromatic stabilization of an entire conjugated system. Not a few nonbenzenoid aromatic hydrocarbons were predicted to have reactive carbons which are olefinic in reactivity. These hydrocarbons constitute unstable aromatic compounds. Thus, it has been clarified that thermodynamic and kinetic stabilities do not always concur in the case of nonbenzenoid hydrocarbons.

An aromatic compound is thermodynamically stable by definition.[1] It is supposed to be more stable than its olefinic reference structure with "localized" π bonds.[1,2] The resonance energy defined in our graph theory of aromaticity is an excellent index of such thermodynamic stability.[3-5] If a given cyclic conjugated system has a large positive resonance energy, it is considered thermodynamically stable and aromatic.[1-5] The predicted aromaticity is due entirely to stabilization by cyclic conjugation.[4]

Our experience tells us that thermodynamic and apparent stabilities of a cyclic conjugated system are closely related to each other. This implies that a thermodynamically stable compound usually has a large kinetic stability. There has been a widely accepted view that aromatic compounds must be stable in a commonplace sense. Thus, thermodynamic stability has long been confused with kinetic stability when one has to decide as to whether a given compound is aromatic or not. Many compounds have been classified as aromatic because of their isolability or low chemical reactivity,[1-5] which are terms of kinetic stability.

Exactly speaking, whether a compound is isolable or not depends not only on the thermodynamic stability, but also on the stability of possible conversion products.[6] A compound predicted to be thermodynamically stable may not be isolable because it can go to still more stable species. Conversely, a high-energy compound may be apparently stable if it has no easy conversion routes available.[6] In principle, all possible reaction paths must be considered to predict kinetic or chemical stability of a cyclic conjugated system.

In fact, all aromatic compounds are neither chemically stable, nor all antiaromatic compounds chemically unstable.[6] Although calicene is predicted to exhibit aromatic stabilization,[2-5,7] it has neither been observed nor isolated. Dimethylenecyclohexadienes are not antiaromatic species,[2-5,8] but they are not isolable. These notable exceptions suggest that chemical stability of a compound might sometimes be determined by factors other than thermodynamic stability. So far there have been few systematic analyses of kinetic stability or instability of cyclic conjugated systems.

The purpose of this paper is to examine kinetic stability of typical aromatic hydrocarbons in conjunction with their aromaticity. I point out that thermodynamic and kinetic stabilities do not always concur in the case of nonbenzenoid aromatic hydrocarbons, and that not a few aromatic hydrocarbons are obviously unstable due to high reactivity toward some kinds of reagents. In order for this feature to be seen explicitly, two reactivity indices, *i.e.*, localization energy[9,10] and superdelocalizability[10,11] are adopted for 42 conjugated hydrocarbons, and are compared with those defined for their olefinic reference structures.

Theoretical Background

The sign and the magnitude of our resonance energy[3-5] are used as an index of aromaticity for cyclic conjugated systems. The degree of aromatic stabilization is given by the resonance energy, divided by the energy of the olefinic reference structure, and then multiplied by 100.[12,13] This quantity is termed a percent resonance energy (%*RE*). Compounds listed in Table 2 are arranged in order of decreasing percent resonance energy. An aromatic compound is said to have as much thermodynamic stability as its resonance energy.

It is impossible to devise a good single index of kinetic stability because there are very many reactions associated with cyclic conjugated systems. In this sense, thermodynamic stability is a much simpler concept than kinetic stability. As will be seen, Wheland's localization energy[9,10] and Fukui's superdelocalizability[10,11] are suitable for surveying one aspect of kinetic stability. These reactivity indices have been defined to elucidate reactivity of conjugated hydrocarbons toward electrophiles and nucleophiles.

Electrophilic substitution, as well as electrophilic addition, involves a reaction with an electrophilic species. Electrophile addition results in a new conjugated system of one less atom and two less π electrons, which is termed a σ complex or Wheland intermediate. Localization energy and superdelocalizability are primary indices when the transition state resembles the σ complex. Abundant evidence has been reported to support the formation of a σ complex as a key intermediate in aromatic substitution.[10]

The reactivity will be different for different hydrocarbons, and also for different positions of attachment of the electrophile in a given hydrocarbon in which there are two or more nonequivalent positions. A conjugated system of a given σ complex is denoted by G-v, where G is a conjugated system of the starting hydrocarbon, and v is a carbon to which the electrophile is attached. Localization energy corresponding to this σ complex with a $+1$ formal charge is denoted by $L_G(v,+1)$. It is defined by[9,10]

$$L_G(v,+1) = E_G(0) - E_{G-v}(+1), \quad (1)$$

where $E_G(0)$ is a total π-electron energy of the starting hydrocarbon with zero formal charge, and $E_{G-v}(+1)$ is that of the σ complex with a $+1$ formal charge. Localization energy is thus a measure of the energy change on going from a given hydrocarbon to the σ complex. Smaller localization energies indicate more susceptible carbons.

Superdelocalizability is another measure of the energy difference between a given hydrocarbon and the σ complex. A possible importance of hyperconjugation through the electrophile-substituted methylene group is stressed in the derivation of superdelocalizability.[11] For a hydrocarbon with N conjugated carbons it is defined by[10,11]

$$S_G(v,+1) = \sum_{i=1}^{N} \frac{g_i P_{G-v}(X_i)}{X_i P_G'(X_i)}. \quad (2)$$

Here, $P_G(X)$ and $P_{G-v}(X)$ are characteristic polynomials for G and G-v, respectively; X_i is the ith energy coefficient, *i.e.*, the ith largest root of the equation $P_G(X)=0$; and g_i is the corresponding occupation number. Superdelocalizability and localization energy are highly correlative with each other.[10]

The fact that stability is always relative leads us to the concept of reference states. We have been using a reference polynomial defined graph-theoretically to describe an olefinic reference structure of a cyclic conjugated system,[3-5,13-17] and interpreted it as a characteristic polynomial for the reference structure. This type of polynomial is denoted by $R_G(X)$. Exactly speaking, $R_G(X)$ is not a characteristic polynomial for the reference structure because it is not a polynomial obtained by expanding the secular determinant; an appropriate secular determinant cannot be defined within the framework of our graph theory.[3-5] Therefore, our olefinic reference structure is hypothetical in nature.

Nevertheless, it is very true that the reference polynomial can be viewed in many respects as a characteristic polynomial for this hypothetical reference structure. Many features of the reference polynomials for cyclic conjugated hydrocarbons are really those of acyclic polyenes:

(a) $R_G(X)$ can be defined in the same manner as a characteristic polynomial for acyclic polyenes,[3] namely,

$$R_G(X) = X^N + \sum_{k=1}^{[N/2]} (-1)^k p(k) X^{N-2k}, \quad (3)$$

where $p(k)$ is the number of ways of choosing k disjoint π bonds from a conjugated system G, and $[N/2]$ is a maximum integer not larger than $N/2$.

(b) The Hess-Schaad reference structure[2] can be considered as an olefinic structure in the singlet ground state since it is constructed using π bonds scissored from acyclic polyenes in the singlet ground state. The energy of this Hess-Schaad reference structure can be reproduced by means of $R_G(X)$, on the assumption that the reference structure defined by this polynomial is in the singlet ground state.[3,16]

(c) The energy levels given as roots of the equation $R_G(X)=0$ satisfy the pairing theorem.[3,4,18] The charge distribution estimated from $R_G(X)$ is uniform over the entire conjugated system.[17] These facts imply that our hypothetical reference structure is a kind of alternant hydrocarbon. Acyclic polyenes are all alternant hydrocarbons.

(d) Neither diamagnetic susceptibility exaltation nor diatropicity are expected in this type of reference structures.[15] The same is true for acyclic polyenes. The above features strongly support our view that $R_G(X)$ is a good characteristic polynomial for the hypothetical reference structure, and that the reference structure defined by $R_G(X)$ is very olefinic in nature. Therefore, we can safely assume that $R_G(X)$ practically represents an olefinic reference structure of a cyclic conjugated system. This interpretation has been consistent with every phase of aromatic chemistry.

On this theoretical basis, we can define reactivity indices for an olefinic reference structure of a cyclic conjugated system. Localization energy for the olefinic reference structure defined by $R_G(X)$ can be defined by

$$L_G^\circ(v,+1) = E_G^\circ(0) - E_{G-v}^\circ(+1), \quad (4)$$

where $E_G^\circ(0)$ and $E_{G-v}^\circ(+1)$ are the total π-electron energies of the reference structures of G and G-v, respectively. In the same manner, superdelocalizability for the reference structure can be defined by

$$S_G^\circ(v,+1) = \sum_{i=1}^{N} \frac{g_i R_{G-v}(X_i^\circ)}{X_i^\circ R_G'(X_i^\circ)}, \quad (5)$$

where X_i° is the ith largest root of the equation $R_G(X)=0$. $L_G^\circ(v,+1)$ and $S_G^\circ(v,+1)$ are reactivity indices which the system G would have if it were free of aromaticity. They are expected to represent the tendency of the reference structure to undergo electrophilic reactions.

Reactivity indices can likewise be defined to describe the tendency to undergo nucleophilic substitution (or addition) reactions. In this case, the intermediate σ complex must have a -1 formal charge. Its total π-electron energy is denoted by $E_{G-v}(-1)$, where v is a carbon to which the nucleophile is attached. Localization energy related to this σ complex is defined by[9,10]

$$L_G(v,-1) = E_G(0) - E_{G-v}(-1). \quad (6)$$

The corresponding superdelocalizability is defined by[10,11]

$$S_G(v,-1) = \sum_{i=1}^{N} \frac{(g_i-2)P_{G-v}(X_i)}{X_i P_G'(X_i)}. \quad (7)$$

For alternant hydrocarbons, such as acyclic polyenes and benzenoid hydrocarbons, $L_G(v,-1)=L_G(v,+1)$ and $S_G(v,-1)=S_G(v,+1)$, so the nucleophilic reactivity

is identical with the electrophilic one. As mentioned before, olefinic reference structures of cyclic conjugated hydrocarbons can also be considered as a kind of alternant hydrocarbons. For these reference structures, indices of nucleophilic reactivity are exactly the same as those of electrophilic reactivity. Therefore,

$$L_G^\circ(v, -1) = L_G^\circ(v, +1) \quad (8)$$

and

$$S_G^\circ(v, -1) = S_G^\circ(v, +1). \quad (9)$$

Localization energy and superdelocalizability can be regarded as indices of kinetic stability (or instability) common to cyclic and acyclic conjugated systems. These indices can be applied equally to aromatic, antiaromatic, and nonaromatic systems to see their electrophilic and nucleophilic reactivities. Whatever the reaction products may be, highly reactive compounds must be very unstable in a kinetic sense. This is a primary reason to choose localization energy and superdelocalizability for the present study of kinetic stability.

Reactivity indices for the olefinic reference structures will give reasonable criteria for estimating the effect of aromaticity on the electrophilic and nucleophilic reactivities. In order to see possible interrelation between aromaticity and reactivity, it is instructive to evaluate the reactivity indices relative to those for the olefinic reference structures, namely,

$$\Delta L_G(v, \pm 1) = L_G(v, \pm 1) - L_G^\circ(v, \pm 1), \quad (10)$$

and

$$\Delta S_G(v, \pm 1) = S_G(v, \pm 1) - S_G^\circ(v, \pm 1). \quad (11)$$

These differences in reactivity index can naturally be ascribed to aromaticity, *i.e.*, cyclic π-electron conjugation of the type $\beta_{ij}\beta_{jk}\cdots\beta_{pq}\beta_{qi}$, where β's are resonance integrals between bonded carbons.[14,15] $\Delta L_G(v, \pm 1)$ and $\Delta S_G(v,\pm 1)$ are hence interpreted as a portion of contribution of aromaticity to kinetic stability. If a given constituent carbon has a small $\Delta L_G(v,\pm 1)$ value or a large $\Delta S_G(v,\pm 1)$ value, it must be olefinic in reactivity.

Results and Discussion

Conjugated carbons in hydrocarbons are classified as shown in Fig. 1. Edge carbons, *i.e.*, exomethylene carbons, are called primary carbons. Carbons shared by two π bonds are called secondary carbons. When a given carbon is shared by three π bonds, it is called a tertiary carbon. Primary, secondary, and tertiary carbons are denoted by Pn, Sn, and Tn, respectively, where the suffixes n indicate nonequivalent carbons.

First, stability considerations are made on the basis of localization energies. Localization energies calculated for all carbons in 42 conjugated hydrocarbons are listed in Tables 1 and 2. Ethylene (**1**), butadiene (**2**), and hexatriene (**3**) in Table 1 are nonaromatic species. In these polyenes, constituent carbons have a variety of localization energies. It is clear that, even in a single conjugated hydrocarbon free of aromaticity, carbons are quite diverse in reactivity. Edge carbons have considerably smaller localization energies than inner carbons. Kinetic stability of a conjugated hydrocarbon is determined by the most reactive carbons. For acyclic polyenes, electrophilic and nucleophilic reactivities are determined primarily by the edge or primary carbons. Each acyclic polyene is identical with its olefinic reference structure.[3-5] Therefore, kinetic stability expressed in terms of localization energy is the same for the two structures.

Table 1. Localization energies for acyclic polyenes

Compound	v	$L_G(v, \pm 1)$
Ethylene (**1**)	P1	2.000
Butadiene (**2**)	P1	1.644
	S1	2.472
Hexatriene (**3**)	P1	1.524
	S1	2.516
	S2	2.159

Let us examine reactivities of cyclic conjugated systems listed in Table 2. Localization energies for the olefinic reference structures, $L_G^\circ(v,\pm 1)$, are now useful for analyzing those for real conjugated systems, $L_G(v, \pm 1)$, in detail. As in the case of acyclic polyenes, $L_G^\circ(v,\pm 1)$ is very small at primary carbons, ranging from 1.22 to 1.48. Secondary carbons have $L_G^\circ(v,\pm 1)$ in the range 1.85—2.40, and tertiary carbons in the range 2.33—3.00. Among tertiary carbons, those next to primary carbons have $L_G^\circ(v,\pm 1)$ larger than 2.81, and those surrounded by three tertiary carbons have $L_G^\circ(v,\pm 1)$ less than 2.41. The values of $L_G^\circ(v,\pm 1)$ at primary carbons never overlap with those at secondary and tertiary carbons. Secondary carbons scarcely overlap with tertiary carbons in this sense. Thus, it is obvious that $L_G^\circ(v,\pm 1)$ is determined by the type of the carbon. If a given conjugated hydrocarbon were deprived of aromaticity, electrophilic and nucleophilic reactivities would be determined primarily by the molecular geometry. Such regularity of the $L_G^\circ(v,\pm 1)$ values further supports the validity of these reference indices.

Benzenoid hydrocarbons **5**—**11** and **14** are highly aromatic since they have large percent resonance energies. These compounds have positive $\Delta L_G(v,\pm 1)$ values at all constituent carbons, so they must be much less reactive than their olefinic reference structures. This means that all the carbons are stabilized by aromaticity, *i.e.*, cyclic π-electron conjugation. All carbons in benzene (**5**) have the same $L_G(v,\pm 1)$ value of 2.536 and the same $\Delta L_G(v,\pm 1)$ value of 0.273. These large values show that benzene is kinetically very stable in accord with its chemical behavior. Naphthalene (**8**) and other condensed benzenoid hydrocarbons are predicted to be a little more reactive than benzene since some of the secondary carbons have smaller $L_G(v,\pm 1)$ values; when $L_G(v,\pm 1)$ is small at carbon v, $\Delta L_G(v,\pm 1)$ usually is small there. Smaller $\Delta L_G(v,\pm 1)$ values naturally indicate enhanced olefinic reactivity. In fact, when appropriate reagents coexist with these compounds, they are not so stable as benzene. In the case of biphenyl (**6**), triphenylene (**7**), naphthelene (**8**), phenanthrene (**9**), and anthracene (**14**), not only substitution but also addition products are formed by reaction with molecular chlorine.[19]

Especially, carbon Sl in anthracene is very reactive and olefinic since $L_G(Sl,\pm1)$ and $\Delta L_G(Sl,\pm1)$ are very small. All other carbons in benzenoid hydrocarbons have $\Delta L_G(v,\pm1)$ in the range 0.172—0.441.

Fluoranthene (**12**) contains a five-membered ring, but this is similar in reactivity to benzenoid hydrocarbons. All constituent carbons are highly stabilized by aromaticity. The same is true for the second member of aromatic annulenes, [10]annulene (**19**). All carbons are moderately stabilized. However, this compound is far from isolable because of heavy steric hindrance.[20]

Stilbene (**13**) and styrene (**15**) are aromatic compounds, but can be regarded as substituted ethylenes. Carbons at ethylenic portions have small $L_G(v,\pm1)$ values and small positive or negative $\Delta L_G(v,\pm1)$ values, and tend to undergo addition reactions. They are located outside of the aromatic rings. Acenaphthylene (**16**) is olefinic in reactivity at carbon Sl. In accord with this, $L_G(Sl,\pm1)$ and $\Delta L_G(Sl,\pm1)$ are very small. Biphenylene (**21**) has small positive resonance energy. However, $\Delta L_G(Tl,\pm1)$ is negative, suggesting that carbon Tl is highly destabilized by the antiaromatic central four-membered ring. Several addition reactions are known to occur around this ring.[21]

Other nonbenzenoid hydrocarbons generally have reactive carbons with smaller localization energies. Azulene (**20**) has long been recognized to be the first example of nonbenzenoid aromatics. This compound undergoes various electrophilic and nucleophilic substitution reactions only under mild conditions.[22] These observations may be rationalized by the negative values of $\Delta L_G(S1,-1)$, $\Delta L_G(S3,-1)$, and $\Delta L_G(S4,+1)$. These negative values, however, indicate that azulene is more reactive than its olefinic reference structure. In fact, oxidative decomposition and hydrogenation easily take place.[23]

Two asymmetric fulvalenes **4** and **17** are predicted to be highly aromatic with large resonance energies. However, there is no experimental evidence for aromatic stabilization.[24] Calicene (**4**) has defied all attempts of isolation. Both compounds are supposed to be very olefinic in reactivity; either $\Delta L_G(v,+1)$ or $\Delta L_G(v,-1)$ is small or negative at each carbon. Therefore, all carbons must be very reactive toward electrophiles or nucleophiles. We might say that the entire π-electron frameworks of these fulvalenes are really aromatic but very unstable.

All radialenes **27** and **29**—**31**, fulvenes **18**, **26**, and **28**, and dimethylenecyclohexadienes **22** and **24** are all predicted to be essentially nonaromatic with small percent resonance energies. They have one or more primary carbons, at which $L_G(v,\pm1)$ is very small as in the case of acyclic polyenes. Secondary and tertiary carbons are also olefinic with $\Delta L_G(v,\pm1)\approx0$. These compounds are very olefinic in their chemical behavior. Triafulvene (**18**) and dimethylenecyclohexadienes are too reactive to be isolated in any form. The same is true for dimethylenecyclobutene (**35**). This compound does readily polymerize in the presence of air.[25] Conjugated hydrocarbons with exomethylene groups are thus extremely reactive. Benzene, fulvene, and dimethylenecyclobutene form an interesting set of isomers, being respectively aromatic, nonaromatic, and antiaromatic, but the first species alone is of great kinetic stability.

Cyclopent[*cd*]azulene (**23**) and cyclopenta[*ef*]heptalene (**25**) are substantially nonaromatic. These nonalternant hydrocarbons are not highly symmetric in shape, so they necessarily have reactive carbons with negative $\Delta L_G(v,+1)$ or $\Delta L_G(v,-1)$ values. These carbons determine the degree of kinetic stability associated with electrophilic and nucleophilic reactivities.

In marked contrast to asymmetric fulvalenes, symmetric fulvalenes **33**, **36**, and **40** are all typically antiaromatic; either $\Delta L_G(v,+1)$ or $\Delta L_G(v,-1)$ at each carbon takes a large negative value. Therefore, they are predicted to be much more reactive than their olefinic reference structures. This is in agreement with their chemistry.[24] Triafulvalene (**40**) has not been isolated yet. Other antiaromatic hydrocarbons belong to the group of such chemically very unstable species. Among them are heptalene (**32**), pentalene (**34**), bicyclo[6.2.0]decapentaene (**37**), benzocyclobutene (**38**), cyclooctatetraene (**39**), butalene (**41**), and cyclobutadiene (**42**). They tend to polymerize readily, or are obtained as a dimer which may arise by way of a self-Diels-Alder reaction. Some carbons in each of these hydrocarbons again have small localization energies together with large negative $\Delta L_G(v,+1)$ or $\Delta L_G(v,-1)$ values. This indicates that antiaromatic instability itself is relaxed by forming appropriate σ complexes. Especially, all carbons in cyclooctatetraene, butalene, and cyclobutadiene have negative $\Delta L_G(v,\pm1)$ values.

We have been examining the values of $L_G(v,\pm1)$ and $\Delta L_G(v,\pm1)$ to discuss the discrepancy between aromaticity and kinetic stability. Essentially the same discussion can be made using Fukui's concept of superdelocalizability, $S_G(v,\pm1)$.[10,11] The magnitude of superdelocalizability for the olefinic reference structure of a cyclic conjugated hydrocarbon, $S_G^\circ(v,\pm1)$, depends primarily on the type of the carbon.[26] Although there are several exceptions, $S_G^\circ(v,\pm1)$ is larger at primary carbons than at secondary carbons, and at secondary carbons than at tertiary carbons. If a given carbon v is stabilized by the cyclic conjugation of π electrons, $S_G(v,\pm1)$ becomes smaller than $S_G^\circ(v,\pm1)$, so the difference $\Delta S_G(v,\pm1)$ becomes negative in sign. When $S_G(v,\pm1)$ is large at carbon v, $\Delta S_G(v,\pm1)$ usually is large there. Reactive carbons specified in terms of $S_G(v,\pm1)$ and $\Delta S_G(v,\pm1)$ are essentially the same as those specified in terms of $L_G(v,\pm1)$ and $\Delta L_G(v,\pm1)$. Such a parallelism can be rationalized partly by noting that $L_G(v,\pm1)$ is theoretically interrelated with $S_G(v,\pm1)$.[27]

In brief, benzenoid hydrocarbons, fluoranthene, and [10]annulene are thermodynamically stable with large $\%_0RE$ values, and are predicted to be rather resistant to electrophiles and nucleophiles. Stilbene, styrene, acenaphthylene, azulene, biphenylene, cyclopent[*cd*]-azulene, cyclopenta[*ef*]heptalene, dimethylenecyclohexadienes, radialenes, and asymmetric fulvalenes must be very reactive toward electrophiles and/or nucleophiles whether these hydrocarbons are aromatic with positive resonance energies or not. All other hydro-

carbons investigated must be much more reactive than nonaromatic polyenes. This aspect of kinetic stability or instability is in good agreement with their chemical behavior.[28]

Concluding Remarks

Thermodynamic stability of a cyclic conjugated system may correlate with its kinetic stability. However, there are such notable exceptions as aromatic compounds for which all synthetic attempts failed. These compounds must have conversion routes to others with still larger kinetic stability. The present approach complements the stability considerations based solely on aromaticity. Using the concepts of localization energy and superdelocalizability, we found that the kinetic stability of a cyclic conjugated system can be conjectured well from its electrophilicity and nucleophilicity. In this sense, localization energy and superdelocalizability are representative indices of kinetic stability. $\Delta L_G(v,\pm 1)$ and $\Delta S_G(v,\pm 1)$ serve as indices of olefinic reactivity. Highly electrophilic and/or nucleophilic carbons were shown to be very olefinic in reactivity. Therefore, hydrocarbons having such carbons are reluctant to retain their original cyclic conjugated systems. When they are attacked by an electrophile or a nucleophile, reaction paths to compounds other than substitution products will be chosen preferentially.

Most nonbenzenoid hydrocarbons have reactive carbons whether they are aromatic or not. In these hydrocarbons not only aromaticity but also reactivity are induced by the same cyclic interactions of π electrons. Many of the anomalies found in the aromaticity-stability relationship can be rationalized in this manner. Examination of reactivities other than electrophilic and nucleophilic ones would further clarify the essence of kinetic stability. In view of excellent correlation between calculated reactivity indices and chemical behavior, we emphasize that aromatic compounds are quite diverse in kinetic stability. Thermodynamic and kinetic stabilities do not always concur in the case of nonbenzenoid hydrocarbons. Some compounds may appear to be chemically stable because their conjugate acids and bases are both stable.[1] According to the present approach, these will be predicted to be reactive and unstable.

If only cyclic unsaturated compounds characterized by low chemical reactivity and high thermodynamic stability are regarded as aromatic compounds, they will be limited to benzenoid hydrocarbons and some semibenzenoids such as fluoranthene. All carbons in these compounds are really stabilized by the cyclic π-electron conjugation. Most nonbenzenoid hydrocarbons will become nonaromatic in this sense. However, we choose to call them unstable aromatic compounds, retaining the original definition of aromaticity based on thermodynamic stability.

It is interesting to see that the most reactive carbons sometimes vary on going from a real conjugated system to its olefinic reference structure. However, the most reactive carbons in benzenoid hydrocarbons usually remain the same in their olefinic reference structures. This indicates that aromaticity, *i.e.*, cyclic π-electron conjugation, scarcely affects relative reactivities of constituent carbons in these compounds.

Finally, one comment must be made concerning the π-electron densities. Localization energy and superdelocalizability are applicable only to the reaction with an electrophile or a nucleophile for which the transition state resembles the σ complex. If the transition state occurs early in the same reaction, that is, if the transition state resembles the initial reactants, the π-electron densities will be a primary index.[10,29] Here, an electrophile or a nucleophile acts as an opposite-charge-seeking species. It follows that if the reaction proceeds via an early transition state, any nonalternant hydrocarbon would be more reactive than its olefinic reference structure, where the charge distribution is uniform as in the case of alternant hydrocarbons.[17] This implies that nonalternant hydrocarbons must be more reactive toward electrophiles and nucleophiles than alternant hydrocarbons including acyclic polyenes. This is possibly another reason why many nonalternant hydrocarbons are much more reactive than are predicted from their resonance energies.

Excitation Energy Dependence of Intramolecular Exciplex Formation and Electronic Relaxation in the Collision-free Vapor

Michiya ITOH*, Yukio HANASHIMA, Naoko WADA, and Ichiro HANAZAKI†

Faculty of Pharmaceutical Sciences, Kanazawa University, Takara-machi, Kanazawa 920

†*Institute for Molecular Science, Myodaiji, Okazaki 444*

(Received December 14, 1982)

The excitation energy dependence of the intramolecular exciplex formation and the electronic relaxation has been studied in the collision-free vapor of 1-(9,10-dicyano-2-anthryl)-3-(pentamethylphenyl)propane. The fluorescence quantum yields and lifetimes of the 9,10-dicyanoanthryl moiety and the intramolecular exciplex in the collision-free vapor were observed to depend on the excitation energy within the S_1 absorption band. From the quantum yields and the decay rate constants, the excitation energy dependence of the association and dissociation rate constants of the intramolecular exciplex formation were determined. The association rate constant of the exciplex formation increases more remarkably with increasing excitation energy than the nonradiative rate constants of 9,10-dicyanoanthryl moiety and the exciplex. The excitation energy dependence of the association rate constant was discussed in terms of the nonradiative transition from the initial optical state to the final exciplex and the level density of the final state, which were calculated in the simple model system by means of the semi-classical mechanics.

The exciplex formation in the vapor phase was reported in the 9-cyanoanthracene and/or substituted 9-cyanoanthracene and alkylamine systems[1,2] and in the tetracyanobenzene (TCNB) and *p*-xylene system.[3] Okajima and Lim[4] reported that the exciplex formed from the vibrationally hot S_1 state of TCNB and the ground state of *p*-xylene is almost nonfluorescent and decays rapidly via nonradiative process. Recently, Itoh *et al.*[5,6] reported that the intramolecular exciplex of 1-(9,10-dicyano-2-anthryl)-3-(1- or 2-naphthyl)propane ($\beta\alpha$- or $\beta\beta$-DCAN) in the collision-free vapor phase exhibits the excitation energy dependence of the fluorescence spectra and lifetimes of the exciplex. They suggested that exciplex formation from the vibrationally hot S_1 state of the electron acceptor and the ground state donor moieties followed by the fluorescent relaxation from the upper vibrational state of the exciplex takes place. In the intermolecular electron donor acceptor system, the concentration of the electron donor (or acceptor) amounts to 10^{-2}—10^{-3} mol dm^{-3} in the vapor phase, which corresponds to the gas pressure of approximately 50 Torr (1 Torr=133.322 Pa). The donor molecules in this pressure may act as a collisional relaxer of the vibrationally hot S_1 state of the acceptor.[7] Therefore, the vibrational effect on the exciplex formation and the electronic relaxation can not be measured in the intermolecular system. The electronic interaction between the electron donor–acceptor system can be investigated only in the isolated molecular condition of the intramolecular electron donor acceptor system. Further, Itoh and Hanashima[8] reported the excitation energy dependence of the rate constants of intramolecular exciplex formation in the collision-free vapor. The rate constant of the exciplex formation increases remarkably on the excitation of the upper vibrational S_1 state. Very recently, Felker *et al.*[9] also reported the excess energy dependence of the exciplex fluorescence in the jet-cooled molecules of the intramolecular electron donor acceptor system.

On the other hand, the excitation energy dependence of the fluorescence lifetimes, quantum yields, and the radiative and nonradiative rate constants has been reported in the single vibronic level (SVL) fluorescence of some aromatic compounds. Further, numerous investigations of the vibrational level dependence of the photochemical reaction such as dissociation and isomerization of small molecules have been published.[10] However, no excitation energy dependence of the molecular complex formation and bimolecular reaction in the excited state has been reported except two papers mentioned above, though the important role of the S_1 excess energy on the photochemical reaction was pointed out.[11] This paper is further concerned with the excitation energy dependence of the association and dissociation rate constants of the exciplex formation in the collision-free vapor of 1-(9,10-dicyano-2-anthryl)-3-(pentamethylphenyl)propane (DCAB).[12] The rate constants of the exciplex formation and dissociation increase with increasing vibrational energy of the S_1 state of the 9,10-dicyanoanthryl (DCA) moiety. In order to investigate the excitation energy dependence, the transition probability from the initial locally excited state of DCA to the final exciplex was estimated in the model system by means of the semi-classical mechanics. The results suggest that the excess energy dependence may be mostly attributable to the density of the vibrational levels of the exciplex state.

Experimental

Preparation and purification of the sample were described in the previous papers.[12] 2-Methyl-9,10-dicyanoanthracene was prepared by bromination and cyanogenation of 2-methylanthracene (Nakarai Chem. GR), and purified by repeated column chromatography (silica gel. benzene–hexane) followed by recrystallization. 1-(9,10-Dicyano-2-anthryl)-3-(pentamethylphenyl)propane was synthesized from the starting materials of 2-anthraldehyde and pentamethylacetylbenzene, and purified by repeated column chromatography and recrystallization.[12] The rectangular quartz cell (10 mm) with graded seals containing samples was degassed and sealed off from the vacuum line. Fluorescence and absorption spectra were measured in a quartz dewar at controlled temperature by heated air flow. The fluorescence and absorption spectra were measured by Hitachi MPF-4 and 220 spectrophotometers, respectively. The fluorescence lifetimes

and decay curves were measured in the excitations by a nitrogen laser and its pumped dye laser (Molectron UV-12 and DL-14), and by an HTVR666 photomultiplier and a Tektronix 7904 (7A19 and 7B85) oscilloscope. Observed decay curves were analyzed by a computer-simulated deconvolution. The fluorescence quantum yields were determined by using a quinine sulfate solution as a standard (1×10^{-5} mol dm^{-3} in 0.25 mol dm^{-3} sulfuric acid; $\phi=0.54$ at room temperature)[13] where the fluorescence spectra of the standard solution were measured in the almost completely same experimental set-up as those of the vapor phase.

Results and Discussion

The absorption spectrum of DCAB in the vapor phase at 500—550 K shows a very weak absorption intensity as shown in Fig. 1, because of a very low vapor pressure. Assuming that the absorption intensity of DCAB in the vapor phase may be almost identical to that in the nonpolar solution, the concentration and pressure of DCAB in the vapor phase at this temperature were estimated to be 10^{-6}—10^{-7} mol dm^{-3} and 10^{-2}—10^{-3} Torr, respectively. Since the intermolecular collisional rate of the S_1 state of the molecule in the gas pressure of p is estimated to be 10^7p Torr^{-1} s^{-1} by a hard sphere collision model,[14] the molecules of DCAB in the experimental condition may be regarded to be an intermolecularly collision-free condition, that is the isolated molecular condition.

The fluorescence and excitation spectra of this collision free vapor of DCAB are shown in Fig. 1. The excitation spectra monitored at 450 and 500 nm are in good consistency with that of the absorption spectrum. Further, the fluorescence spectrum of 2-methylanthracene (2-Me-DCA) in the collision-free condition is also shown in Fig. 1. From comparison of the fluorescence spectrum of DCAB with that of 2-Me-DCA, the shorter wavelength fluorescence (400—460 nm) and the longer wavelength one (450—520 nm) are ascribed to the 9,10-dicyanoanthryl (DCA) moiety and the intramolecular exciplex in the vapor phase, respectively. The fluorescence intensity of the collision-free vapor of DCAB was observed to exhibit a remarkable excitation energy dependence. Figure 2 shows the relative fluorescence quantum spectra in the excitations at several wavelengths, the relative intensity decreases with increasing excitation energy. Further, the fluorescence spectral distribution shifts to the shorter wavelength region with increasing excitation energy, as shown in Fig. 3.

The photochemical reaction scheme and kinetics in the intramolecular exciplex formation are expressed by the following wellknown equations;[15]

$$\mathrm{D} + \mathrm{A}^* \underset{k_4}{\overset{k_3}{\rightleftharpoons}} (\mathrm{DA})^*$$

$$(\mathrm{DA})^* \xrightarrow{k_1} \mathrm{D} + \mathrm{A} + h\nu, \quad (\mathrm{DA})^* \xrightarrow{k_2} \mathrm{D} + \mathrm{A}$$

$$(\mathrm{DA})^* \xrightarrow{k_5} \mathrm{D} + \mathrm{A} + h\nu', \quad (\mathrm{DA})^* \xrightarrow{k_6} \mathrm{D} + \mathrm{A}$$

$$[\mathrm{A}^*] = c_1\exp(-\lambda_1 t) + c_2\exp(-\lambda_2 t), \tag{1}$$

$$[(\mathrm{DA})^*] = c_3\exp(-\lambda_1 t) - c_3\exp(-\lambda_2 t), \tag{2}$$

$$2\lambda_1,\ 2\lambda_2 = (X+Y) \pm \{(Y-X)^2 + 4k_3k_4\}^{1/2},$$

$$X = k_1 + k_2 + k_3, \qquad Y = k_4 + k_5 + k_6,$$

where A and D are DCA and phenyl moieties, respec-

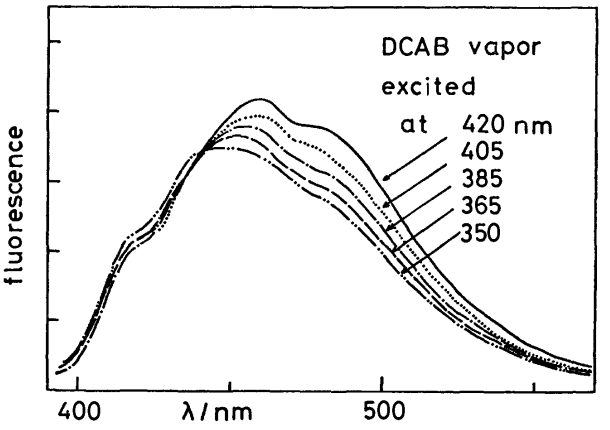

Fig. 3. The excitation wavelength dependence of the fluorescence spectral distribution of the collision-free vapor of DCAB at 529 K. The spectra are normalized in intensity at 440 nm and uncorrected.

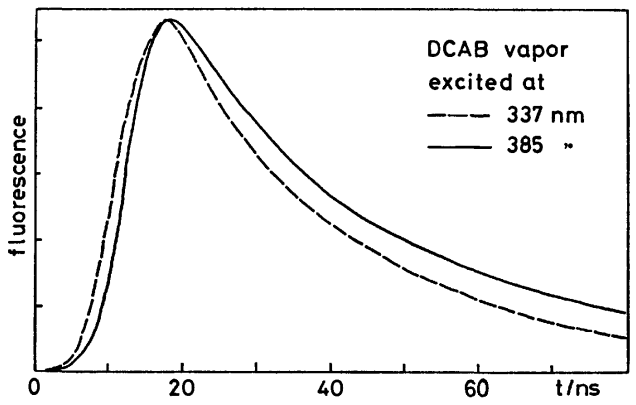

Fig. 4. Typical fluorescence decay curves (monitored at 430 nm) of the DCAB vapor at 525 K. The curve (— — —) was excited at 337 nm (pulse FWHM $\approx$10 ns) and analyzed for $A\exp(-\lambda_2 t)+(1-A)\exp(-\lambda_1 t)$, $\lambda_1^{-1}=28.94$, $\lambda_2^{-1}=1.47$ ns, and $A=0.7675$; the curve (——) excited at 385 nm (pulse FWHM $\approx$7 ns), $\lambda_1^{-1}=41.42$, $\lambda_2^{-1}=7.09$ ns, and $A=0.4984$.

tively. In the collision-free vapor, A* and (DA)* imply the upper vibrational states of their S_1 states depending on the excitation energy. Spears and Rice reported that the quantum yields and the lifetimes of the SVL fluorescence of benzene vapor exhibit different excitation energy dependences from each other according to the vibrational sequence.[16] However, the intramolecular vibrational energy redistribution (randomization) might take place at a rather high temperature.[17] If the considerable fast redistribution of the vibrational energy may take place, A* and (DA)* may be expressed by each sum of several vibrational states, and the decay of these states may be expressed by multi-exponential or an average from these vibrational states. The decay curves of A* and (DA)* were observed to be approximately double (at 430 nm) and single (at 580 nm) exponentials, respectively. Therefore, A* and (DA)* are considered as a quasi-single vibronic state in equilibrium. The typical decay curves of the collision-free vapor of DCAB excited at 337 and 385 nm are shown in Fig. 4. Therefore, the decay rate constants λ_1 and λ_2 were obtained from the A* fluorescence decay (Eq. 1) for respective excitation energies. However, no significant rise time (λ_2^{-1}) of the (DA)* fluorescence (Eq. 2) was observed because of the spectral overlap of A* and (DA)* fluorescences, as will be mentioned later, though the same decay rate constant λ_1 was obtained from the (DA)* fluorescence as that of A*. These decay rate constants are summarized in Table 1 for several excitation wavelengths.

The fluorescence quantum yield and lifetime of the collision free vapor of 2-Me-DCA were observed to depend on the excitation energy. From these excitation energy dependences, radiative and nonradiative rate constants were determined at 523 K, as summarized in Table 1. On the other hand, the fluorescence quantum yields of A* (ϕ_a) and (DA)* (ϕ_e) in DCAB are expressed as follows;

$$\phi_a = k_1 Y/(XY-k_3k_4) \quad (4)$$

$$\phi_e = k_3k_5/(XY-k_3k_4). \quad (5)$$

Table 1. Excitation wavelength dependence of fluorescence quantum yields (ϕ_a and ϕ_e), and decay (10^7 s^{-1}) and reaction rate constants (10^7 s^{-1}) of the intramolecular exciplex formation in DCAB vapor at 523—526 K

Excitation	337 nm	365 nm	385 nm	405 nm

a) Determined from the collision-free vapor of 2-Me-DCA; errors are approximately $\pm$10%. b) Errors are approximately $\pm$20%.

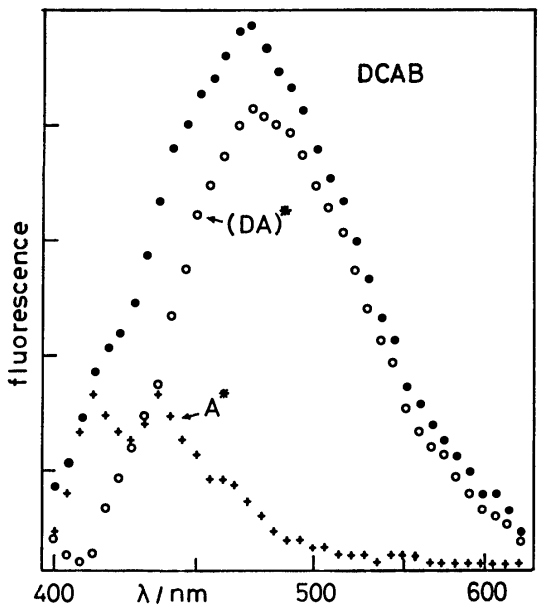

Fig. 5. An example of the separation of the fluorescence spectra (corrected) of the collision-free vapor of DCAB into those of DCA moiety and exciplex.

The fluorescence spectra of A* and (DA)* overlap very close each other. Therefore, assuming that the fluorescence spectrum of DCA moiety (A*) in DCAB is identical to that of 2-Me-DCA in the several excitation energies, the fluorescence spectrum (corrected) obtained was divided into the A* and (DA)* fluorescence spectra by the computer simulation as shown in Fig. 5. Then, the quantum yields ϕ_a and ϕ_e were obtained in the respective excitation energies. Furthermore, assuming k_1 and k_2 to be identical to the radiative and nonradiative rate constants of 2-Me-DCA, respectively, the rate constants k_3, k_4, k_5, and k_6 were determined from decay rate constants λ_1 and λ_2, and quantum yields (ϕ_a and ϕ_e). These data

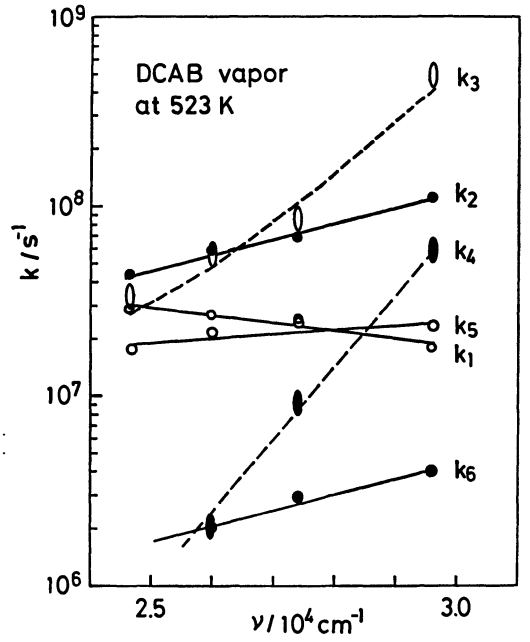

Fig. 6. The plots of rate constants *vs.* excitation energy (wavenumber unit) shown in Table 1.

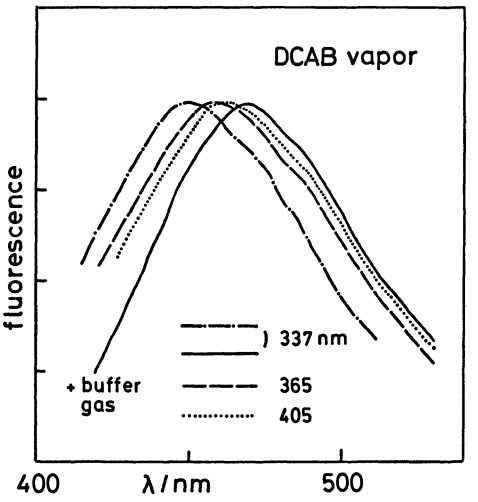

Fig. 7. Time-resolved fluorescence spectra of the DCAB vapor (523 K) in the excitations at several wavelengths. The spectra were depicted at 50 ns after a laser pulse; (—●—●—) 337 nm, (— — —) 365 nm, (·····) 405 nm for the collision-free vapor. The spectrum (——) of the collisionally relaxed vapor by 50 Torr hexane gas excited at 337 nm. The spectra are normalized in intensity.

are summarized in Table 1.

The quantum yield of the DCA moiety, ϕ_a, decreases remarkably and λ_2 increases with increasing excitation energy. As the results, the association (k_3) and dissociation (k_4) rate constants of the exciplex formation increase with increasing excitation energy in the DCAB vapor. Similar excitation energy dependence of the exciplex formation in the collision-free vapor of $\beta\beta$-DCAN and also the intramolecular excimer formation in *N,N,N',N'*-tetramethylpropanediamine vapor were reported in the previous papers.[8,18] Figure 6 shows log plots of these rate constants *vs.* excitation energy (wave number). The nonradiative rate constants of the DCA moiety (k_2) and the exciplex (k_6) increase markedly with increasing excitation energy. The nonradiative rate constants of polyatomic molecules are known to depend linearly on the exponential of the excitation energy.[19,20] The observed excitation energy dependence of k_2 and k_6 exhibits a reasonable trend from this point of view. However, it is noteworthy that $\log k_3$ and $\log k_4$ increase extraordinarily with increasing vibrational energy level, and shows a significant deviation from a linear relationship with respect to the energy; the reason will be discussed later.

The collision-free vapor of DCAB shows the excitation energy dependence of the spectral distribution of the exciplex, as mentioned above. Figure 3 exhibits that the exciplex fluorescence seems to shift to the longer wavelength region with decreasing excitation energy, while the fluorescence of 2-Me-DCA was observed to exhibit conversely a little blue shift. In order to demonstrate the shift of the exciplex fluorescence, the time-resolved fluorescence (Fig. 7) was depicted at ≈50 ns after a laser pulse. The spectral distribution shows red shift with decreasing excitation energy. However, the spectra of the collisionally relaxed vapor of DCAB by the buffer gas (≈500 Torr hexane gas) shows the longest wavelength fluorescence irrespective of the excitation energy. Halpern and Gartmen reported the similar excitation energy dependence of the fluorescence spectrum of *N,N'*-dimethylpiperidine vapor and suggested it to be the fluorescence from the unrelaxed state.[21] The fluorescence spectral distribution depending excitation energy is attributable to the fluorescent deactivation from the upper vibronic S_1 states. The excitation energy dependence of the spectra provides an important information of potential energy surfaces of both ground and excited states of the exciplex. The fluorescence spectra of usual aromatic compounds such as 2-Me-DCA in the collision-free vapor exhibit a faint red shift with increasing excitation energy. The fact is usually interpreted by a consideration that the potential curve of the fluorescent state may be shallower than that of the ground state. In the exciplexes, however, the ground state corresponding to the exciplex is considered to be repulsive and very shallow. Therefore, the fluorescence from the upper vibrational level may shift to the shorter wavelength region than that from the lower level.

An extraordinary vibrational energy dependence of the rate constant was reported in an atom molecular reaction such as $KCl+H=K+HCl$.[22] The rate constant from the vibrational state $v=1$ of HCl is approximately 100 times as large as that from $v=0$. Numerous experimental and theoretical investigations have been reported in the vibrational and rotational energy dependence on the reaction rate constants.[23,24] However, it is not properly interpreted how these observed effects of vibrational energy to the reaction rate constants are to be attributable to the activation energy and/or the pre-exponential factor in the reaction rate equation. Further, in the excited-state electron donor–acceptor interaction, the rate constant of the

exciplex formation between the vibrationally hot S_1 state (*via* S_2) of TCNB and the ground state of *p*-xylene (7×10^{12} mol^{-1} dm^3 s^{-1}) was suggested to be an order of magnitude greater than that from the vibrationally relaxed S_1 state (7×10^{11} mol^{-1} dm^3 s^{-1}).[4] It is noteworthy that these rate constants of the excited-state interaction show an unusual dependence on the vibrational energy of the S_1 state reported here and also in the previous papers.[8,18] Very recently, Felker *et al.* reported the excitation energy dependence of the exciplex fluorescence spectra and decay rate in the jet-cooled molecular EDA system, as mentioned in the introductory section. The extent of the excitation energy dependence of the exciplex fluorescence lifetimes seems to be more remarkable in the jet-cooled molecule than those in the collision-free vapor at rather high temperature,[6-8,18] though Felker *et al.* did not determine any excitation energy dependence of the association and dissociation rate constants of the exciplex in the jet-cooled molecule. These facts are quite reasonable in the jet-cooled molecule, because the randomization of the vibrational energy may be limited at low temperature. However, the kinetic determination of the association rate constant of the exciplex formation seems to be almost impossible, since the estimation of the fluorescence quantum yield is very difficult in the supersonic expansion.

The nonradiative rate constant of the electronic excited state is usually discussed in terms of the transition probability of the Fermi Golden rule for the nonradiative process.[25-28] Further, the excited-state proton transfer is also considered as the nonradiative process between the double minimum potential of the hydrogen bonding system.[29] However, this theory of the nonradiative transition can not be strictly applicable to (DA)* formation because of the repulsive potential in the initial optical state of A* and D, as shown in Fig. 8. In the excitation into the upper vibrational states of the 9,10-dicyanoanthryl moiety in DCAN and DCAB, which is connected to the electron donor moiety by trimethylene chain, the vibrational energy in the aromatic ring system seems to dissipate to the methylene chain by the vibrational-vibrational ($V-V$) energy transfer. Then, stretching and/or bending vibrations in trimethylene chain of DCAN and DCAB are induced by the $V-V$ energy transfer. This means that the vibrational to translational ($V-T$) energy transfer occurs through the trimethylene chain, and that the DCA moiety obtains translational energy.

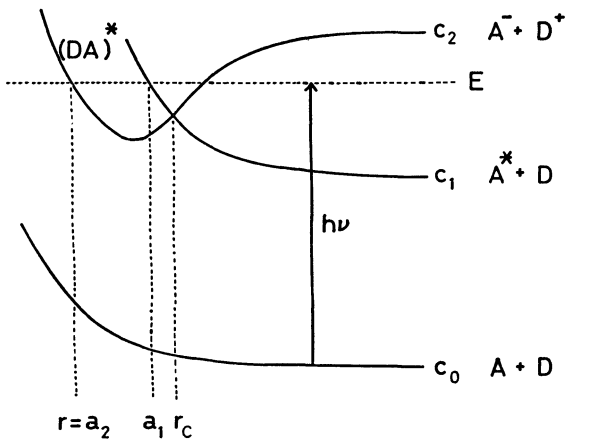

Fig. 8. Schematic potential energy curves of the exciplex formation.

In order to simplify the theoretical consideration, the electronic interaction between the electron donor acceptor is assumed to be a kind of Coulomb interaction between D and A* which are assumed simply to be two atoms. Figure 8 shows the potential energy curves of D+A (C_0), D+A* (C_1), and $(D^+ + A^-)$* (C_2) along the reaction coordinate. Here, the following assumptions are made in order to solve the problem by means of the semi-classical mechanics; the C_2 potential is considerably lower than C_1 at the stable interatomic distance of (DA)* and the CT interaction between C_1 and C_2 is small so that the potential curve for (DA)* can be approximately by C_2. The transition from the initial state (D+A*) to the complex state (DA)* occurs at the crossing point of $r=r_c$, where the energy and also momentum are conserved. According to the Landau's theory,[30] the transition probability (w) from the initial state (D+A*) to the (DA)* state is expressed as following equation;

$$w=\frac{2\pi}{h\nu}\left\{\left|\int X_2^* V(r) X_1 \mathrm{d}r\right|\right\}^2, \tag{6}$$

where $V(r)$ is a perturbation energy of interaction between two states, and X_1 and X_2 are semi-classical wave functions in the (D+A*) and (DA)* states, respectively. From the simple model calculation, the estimated transition probability (w) was ploted *vs.* the excess energy from the potential barrier, as shown in Fig. 9. The transition probability exhibits a considerable decrease with increasing excess energy, but does not depend greatly on the excess energy.

Okajima and Lim[4,31] suggested an importance of the Franck Condon factor associated with the transition

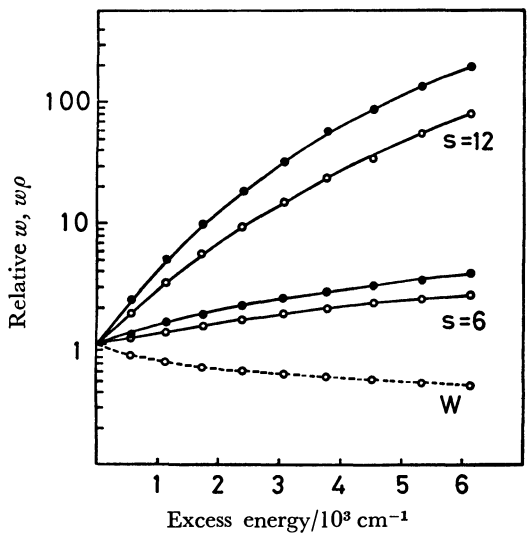

Fig. 9. Relative transition porbability (w, --O--O--) and the product of w and the level density (ρ) calculated by the semiclassical mechanics for the simple model system; (—●—●—) $\Delta E=1800$ cm^{-1}, (—O—O—) $\Delta E=2500$ cm^{-1}. Data are normalized at zero excess energy (see text).

from the uncomplexed to complexed component molecules in the vibrational energy dependence of the association rate constant (k_3). The Franck-Condon factor is expected to be large for a vibration. Further, they suggested that the vibrational excitation in a good accepting mode render the vibration a better accepting mode, then the rate constant may be increased by vibrational excitation.[31] On the other hand, since the actual molecules such as DCAB and DCAN have a large number of vibrational and rotational energy levels, the reaction rate constant of the exciplex formation may be proportional to the product of the transition probability (w) and the vibrational level density (ρ) of the final exciplex state. The semiclassical approximation for the density of vibrational energy levels of polyatomic molecules was proposed by Haarhoff,[32] where the density is expressed as follows;

$$\rho = (E+E_0)^{s-1}/[(s-1)!h\nu_1]. \quad (9)$$

Here ν_1 is the wave number of normal mode i; s is the number of the vibrational freedom. In this paper, the level density of the final state (ρ) was estimated at several excess energies (E_x) for a simple model system of two atoms as mentioned above. Figure 9 shows the product of transition probability and the estimated level density *vs.* the excess energy from the potential barrier (ΔE), of which level is higher than the zero point energy; $E=E_x+\Delta E$. The excess energy dependence of $w\rho$ in the case of $s=10$—12 and $\Delta E=1800\ \mathrm{cm}^{-1}$ seems qualitatively to interpret that of the rate constant k_3 (Fig. 6), though the model calculation of $w\rho$ is not accurate and the profiles of the curves of the excess energy dependence are considerably different from each other. Therefore, Fig. 9 may tentatively suggest that the excess energy dependence of k_3 seems to be attributable to the level density of the final exciplex state.

Thermodynamic Study on Penetration of Pentadecanoic Acid Monolayer by Dodecylammonium Chloride

Yoshiteru HAYAMI,† Makoto ARATONO, Shozo URYU, Kinsi MOTOMURA, and Ryohei MATUURA*

Department of Chemistry, Faculty of Science, Kyushu University 33, Fukuoka 812

(Received January 5, 1983)

In order to show that our thermodynamic treatment [*J. Colloid Interface Sci.*, **87**, 333 (1982)] is useful in the study on the monolayer penetration, the surface tension has been measured with the system consisting of pentadecanoic acid monolayer and dodecylammonium chloride solution. Applying the thermodynamic equations to the experimental data, the surface density of dodecylammonium chloride, and entropy and energy of penetration have been estimated numerically. It has been found that the surface density, entropy, and energy all decrease with increasing the concentration of film-forming substance. Therefore, it has been concluded that the penetration of monolayer of this system is caused by the decrease of the energy of penetration which compensates the decrease of the entropy of penetration.

The investigation of monolayer penetration has been made by many workers from the practical and biological points of view.[1-9] Since the penetrated monolayer is a mixed monolayer consisting of film-forming and penetrating molecules, it is also important from the physico-chemical viewpoint to clarify the monolayer penetration. In the previous paper,[10] rigorous thermodynamic equations have been derived for the penetrated monolayer. Application of these equations to experimental data is expected to provide useful information regarding the behavior of film-forming and penetrating molecules in the monolayer state. It seems useful to employ the system consisting of spread monolayer of pentadecanoic acid and adsorbed monolayer of dodecylammonium chloride because they show the phase transitions from an expanded to a condensed state and from a gaseous to an expanded state.

The object of this paper is to measure the surface tension of the pentadecanoic acid monolayer penetrated by dodecylammonium chloride and to evaluate the thermodynamic quantity of penetration with the aid of the thermodynamic equations.

Experimental

Pentadecanoic acid was recrystallized from hexane after fractionation by vacuum distillation, and its purity was checked by gas-liquid chromatography. Dodecylammonium chloride was prepared by the method described previously.[11] Water was distilled from aqueous alkaline permanganate solution after reflux for one day. Hexane used as the spreading solvent was distilled after passing through an activated alumina column.

Surface tension was measured by a Wilhelmy plate technique combined with a Shimadzu recording microbalance. The aqueous solution of dodecylammonium chloride was placed in a glass culture dish of 12 cm diameter, and it was covered doubly so as for the solution not to evaporate and contaminate. On spreading, a micro pipette of 10 μl was used to facilitate the evaporation of hexane. After about half an hour, as the surface tension reached a constant value, the spreading was repeated. This equilibration time varied from 15 min to 2 h as the surface pressure was raised in this experimental range.

† Present address: Chikushi Jogakuen Junior College, Dazaifu, Fukuoka, 818-01.

Results and Discussion

The surface tension γ of pentadecanoic acid monolayer on the aqueous solution of dodecylammonium chloride was measured as a function of area A per pentadecanoic acid molecule, concentration m_2^w of dodecylammonium chloride, and temperatrue T under atmospheric pressure. The variation of the γ *vs.* A curve with m_2^w at 293.15 K is shown in Fig. 1. In the absence of dodecylammonium chloride (curve 1), the pentadecanoic acid monolayer is heterogeneous in the range between areas indicated by A and B; gaseous and expanded films coexist in equilibrium.[12] The monolayer becomes the expanded film at the area B and remains homogeneous up to the area C where the monolayer is transformed into the condensed film. Increasing the concentration of dodecylammonium chloride, the homogeneous expanded monolayer region is found to shift to a larger area and broaden significantly. It is also seen that the surface tension decreases greatly with increasing m_2^w. Such a behavior can clearly be ascribed to the penetration of penta-

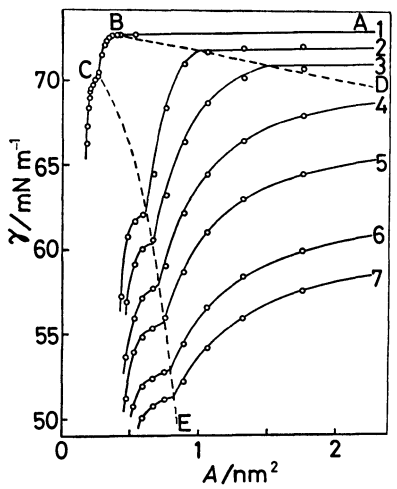

Fig. 1. Surface tension *vs.* area curves of pentadecanoic acid monolayer on dodecylammonium chloride solution at constant concentration at 293.15 K: (1) m_2^w = 0 mmol kg^{-1}; (2) 0.315; (3) 0.714; (4) 1.31; (5) 1.83; (6) 2.62; (7) 3.07.

decanoic acid monolayer by dodecylammonium chloride molecules.

It has been shown previously[13] that the adsorbed film of dodecylammonium chloride at air/water interface transfers from a gaseous to an expanded phase at 1.38 mmol kg^{-1}. To specify the state of the penetrated monolayer, it may be necessary to recognize how the transition point between two phases on the γ *vs.* m_2^w curve varies with A. The variation of γ *vs.* m_2^w curve with A is shown in Fig. 2, where the curve of the condensed film is excluded because of its uncertainty. The break point, denoted by D, on the curve 1 represents the phase transition of dodecylammonium chloride film from the gaseous to the expanded state. On the other hand, the point B on the ordinate represents the corresponding phase transition of pentadecanoic acid monolayer. Therefore, the broken line BD is the equilibrium γ *vs.* m_2^w curve between gaseous and expanded phases. Moreover, the broken line CE is proved to be the equilibrium γ *vs.* m_2^w curve between expanded and condensed phases. Comparing Fig. 1 with Fig. 2, we notice that the penetrated monolayer behaves as the expanded film in the area DBCE on Fig. 1 and the gaseous film is never realized at concentrations larger than 1.38 mmol kg^{-1}.

Let the penetrated monolayer be an expanded film at the area A. When the concentration m_2^w is larger than 1.38 mmol kg^{-1}, the monolayer is homogeneous in the area range from A to infinity. In this instance we can use Eq. [10] of Ref. 10, referred to as Eq. (Ref. 10, 10), to calculate the surface density Γ_2^H of dodecylammonium chloride:

$$\Gamma_2^H = \Gamma_2^H(0) - [1/A(\partial\mu_2/\partial m_2^w)]\int_A^\infty (\partial\Pi/\partial m_2^w)_{T,p,A}\mathrm{d}A, \quad (1)$$

where $\Gamma_2^H(0)$ is the value of Γ_2^H at $A=\infty$, μ_2 the chemical potential of dodecylammonium chloride, and Π the surface pressure defined as the difference between the surface tension of a subsolution and that of a monolayer on the subsolution by Eq. (Ref. 10, 8). On the solution of the concentration $m_2^w<1.38$ mmol kg^{-1}, on the other hand, the monolayer is attended by the phase transition from gaseous to expanded film, the value of Γ_2^H being not calculated by Eq. 1. Evidently Eq. (Ref. 10, 40) is applicable to the calculation of Γ_2^H at the area A^e of the expanded film which is in equilibrium with the gaseous film. Integrating Eq. (Ref. 10, 9) from A to A^e and combining the resulting equation with Eq. (Ref. 10, 40), we can obtain the expression

$$\Gamma_2^H = \Gamma_2^H(0) - [1/A(\partial\mu_2/\partial m_2^w)]\left[\int_A^{A^e}(\partial\Pi/\partial m_2^w)_{T,p,A}\mathrm{d}A + \int_{A^e}^{A^g}(\partial\Pi^{eq}/\partial m_2^w)_{T,p}\mathrm{d}A + \int_{A^g}^{\infty}(\partial\Pi/\partial m_2^w)_{T,p,A}\mathrm{d}A\right], \quad (2)$$

where A^g is the area of the gaseous film in equilibrium with the expanded film and Π^{eq} the equilibrium surface pressure.

Now we can calculate the value of Γ_2^H from the experimental data. Inspecting Fig. 3 which is made from Fig. 2, it is seen that the slope of Π *vs.* m_2^w curve decreases markedly with increasing A. This is clearly shown in Fig. 4 where $\partial\Pi/\partial m_2^w$ is plotted against A. Furthermore, the slope of Π^{eq} *vs.* m_2^w curve (broken line BD in Fig. 3) is found to be negligibly small. In the case of the system under consideration, it might be possible to assume that the values of $\partial\Pi/\partial m_2^w$ at large areas give negligible contributions to the integrals of Eqs. 1 and 2, and these equations are replaced by the approximation

$$\Gamma_2^H = \Gamma_2^H(0) - (m_2^w/2ART)\int_A^{A'}(\partial\Pi/\partial m_2^w)_{T,p,A}\mathrm{d}A, \quad (3)$$

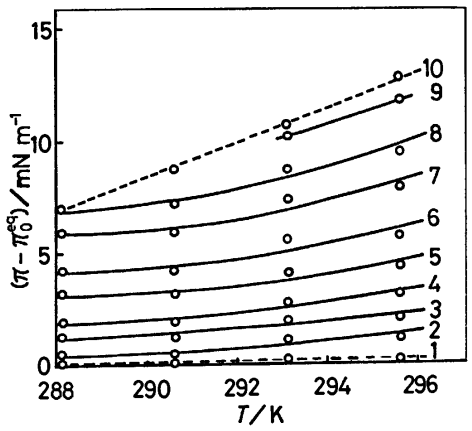

Fig. 6. Surface pressure difference *vs.* temperature curves at constant area at $m_2^w=1.00$ mmol kg^{-1}: (1) $A^e<A<A_0^g$; (2) $A=1.50$ nm^2; (3) 1.30; (4) 1.15; (5) 1.00; (6) 0.90; (7) 0.80; (8) 0.75; (9) 0.70; (10) $A^c<A<A^e$.

where A' is taken as the area extrapolated to $\partial\Pi/\partial m_2^w=0$ when $m_2^w>1.38$ mmol kg^{-1} and as A^e when $m_2^w<1.38$ mmol kg^{-1}. We have also assumed that the dodecylammonium chloride solution behaves ideally. The calculation of Γ_2^H was performed on a FACOM OS IV computer. The values calculated at several areas at 293.15 K are plotted against m_2^w in Fig. 5. The curve at $A=\infty$ is the $\Gamma_2^H(0)$ *vs.* m_2^w curve and accordingly its discontinuous change displays the phase transition between gaseous and expanded phases.[13] It is observed from Fig. 5 that the value of Γ_2^H decreases with decrease in A. At first glance this looks like a strange result. Adding the surface density of pentadecanoic acid Γ_1^I to Γ_2^H, however, the sum is undoubtedly larger than the value of $\Gamma_2^H(0)$. Therefore, we may conclude that the present result is reasonable and the adsorption of dodecylammonium chloride is enhanced by the presence of pentadecanoic acid monolayer. Here, attention should be called to the fact that Γ_2^H has a negative value at a concentration around 1 mmol kg^{-1}. It might be said that Eq. 3 is a poor approximation of Eq. 2 at this concentration because of a considerable contribution of the term involving $\partial\Pi^{eq}/\partial m_2^w$ which is positive. In order to shed light on this point, it will be required to measure the surface pressure accurately at large areas.

Let us now proceed to evaluate the entropy of penetration Δs. Since the pure pentadecanoic acid monolayer carries out the phase transition, Eq. (Ref. 10, 45) can be used when the concentration of dodecylammonium chloride is higher than 1.38 mmol kg^{-1}:

$$\Delta s=\Delta s(0)-(1/A)\left[\int_A^{A_0^g}(\partial(\Pi-\Pi_0^{eq})/\partial T)_{p,A,m_2^w}dA+\int_{A_0^g}^{\infty}(\partial(\Pi-\Pi_0)/\partial T)_{p,A,m_2^w}dA\right], \quad (4)$$

where A^g is the area of the aqueous phase of the pure pentadecanoic acid monolayer in equilibrium with the expanded phase and Π_0 the surface pressure of the pure monolayer. At concentration lower than 1.38 mmol kg^{-1}, we must use the extended equation of Eq. 4:

$$\Delta s=\Delta s(0)-(1/A)\left[\int_A^{A^e}(\partial(\Pi-\Pi_0^{eq})/\partial T)_{p,A,m_2^w}dA+\int_{A^e}^{A_0^g}(\partial(\Pi^{eq}-\Pi_0^{eq})/\partial T)_{p,m_2^w}dA+\int_{A_0^g}^{A^g}(\partial(\Pi^{eq}-\Pi_0)/\partial T)_{p,A,m_2^w}dA+\int_{A^g}^{\infty}(\partial(\Pi-\Pi_0)/\partial T)_{p,A,m_2^w}dA\right], \quad (5)$$

where we have assumed $A^e<A_0^g<A^g$.

Further measurements of the surface tension were made at 288.15, 290.65, and 295.65 K. In Fig. 6, the results at $m_2^w=1.00$ mmol kg^{-1} are depicted in the form of $\Pi-\Pi_0^{eq}$ *vs.* T plot. It appears that the values of $\Pi-\Pi_0^{eq}$ show some scatter. This might be attributable partly to a small change of the surface tension with temperature and partly to the difficulty of measuring the equilibrium surface tension. It is found by drawing a smooth curve that the slope of the curve decreases with increase in A. At the areas between A^e and A_0^g, the value of $\Pi^{eq}-\Pi_0^{eq}$ seems to be nearly independent of T. Therefore, Eqs. 4 and 5 may be approximated by the expression

$$\Delta s=\Delta s(0)-(1/A)\int_A^{A'}(\partial(\Pi-\Pi_0^{eq})/\partial T)_{p,A,m_2^w}dA, \quad (6)$$

which corresponds to Eq. 3 for Γ_2^H. By applying Eq. 6 to the experimental data, the value of Δs was computed. The variation of the Δs *vs.* m_2^w curve with A at 293.15 K is shown in Fig. 7. The curve at $A=\infty$ represents the $\Delta s(0)$ *vs.* m_2^w curve which has the small, although definite, discontinuous change corresponding to the change of the $\Gamma_2^H(0)$ *vs.* m_2^w curve. As the area is reduced, the curve is found to shift significantly to a negative value of Δs. It is also seen that the value of Δs decreases remarkably with increasing m_2^w. These facts indicate that the entropy of penetrated monolayer is smaller than that of spread

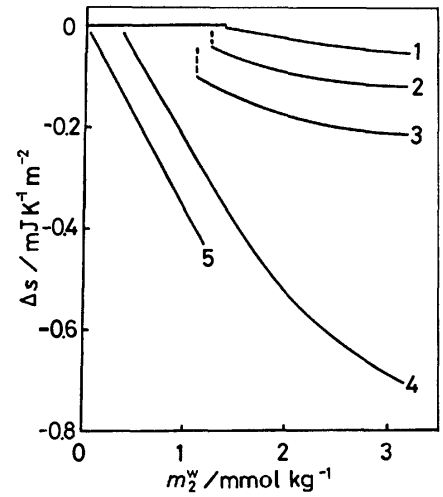

Fig. 7. Entropy of penetration *vs.* molality curves at constant area at 293.15 K: (1) $A=\infty$ nm^2; (2) 3.00; (3) 2.00; (4) 1.00; (5) 0.70.

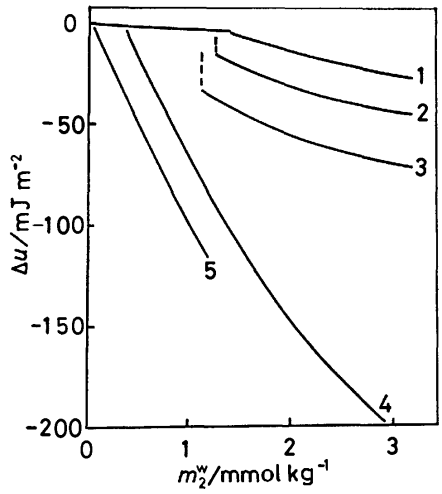

Fig. 8. Energy of penetration *vs.* molality curves at constant area at 293.15 K: (1) $A=\infty$ nm^2; (2) 3.00; (3) 2.00; (4) 1.00; (5) 0.70.

film of pentadecanoic acid and decreases with increase in the total surface density. Therefore it is proved that the penetration is an unfavorable process from the viewpoint of entropy. We may also say that the film-forming and penetrating molecules are forced to take highly restricted conformation in the penetrated monolayer.

Further, we can evaluate the energy of penetration Δu. Evidently an equation similar to Eqs. 3 and 6 is expected to hold. Taking account of Eqs. (Ref. 10, 27) and (Ref. 10, 46), it may be written in the form

$$\Delta u = \Delta u(0) + (1/A)\int_A^{A'} (\partial[(\Pi-\Pi_0^{eq})/T]/\partial(1/T))_{p,A,m_2^w} dA. \quad (7)$$

Now we can use Eq. 7 to calculate the value of Δu from the experimental data. The value obtained at 293.15 K is plotted against m_2^w at constant A in Fig. 8. Comparing Fig. 8 with Fig. 7, the variation of Δu with m_2^w and A is observed to be quite similar to that of Δs. It is clear that the penetration by dodecylammonium chloride diminishes the energy of pentadecanoic acid monolayer. Therefore, we may conclude that the penetration is brought about by the energy decrease which results predominantly from the mutual interaction between pentadecanoic acid and dodecylammonium chloride. This is in harmony with the observation that the mixed monolayer of tetradecanoic acid and octadecylammonium chloride shows a negative azeotropic transformation between expanded and condensed films.[14]

The above thermodynamic analysis of experimental results demonstrates that the equations derived by us[10] are useful to make clear the penetration of monolayers.

Studies on Aqueous Solutions of Saccharides. II. Viscosity *B*-Coefficients, Apparent Molar Volumes, and Activity Coefficients of D-Glucose, Maltose, and Maltotriose in Aqueous Solutions

Koichiro MIYAJIMA,* Masahiro SAWADA, and Masayuki NAKAGAKI

Faculty of Pharmaceutical Sciences, Kyoto University, Yoshida Shimoadachi-cho, Sakyo-ku, Kyoto 606

(Received January 14, 1983)

Viscosities, apparent molar volumes, and activity coefficients of aqueous solutions for D-glucose, maltose, and maltotriose were measured at various concentrations. The signs of B_{st}, the increment of viscosity *B*-coefficient arising from structural change of water, were positive for these three saccharides, and the signs of dB/dT, the temperature dependence of B, were negative. The magnetudes of B_{st} and $|dB/dT|$ increased with the number of glucose residue. Activity coefficients were larger than unity and increased with concentration, and their magnitudes also increased with the number of glucose residue. These results indicate that D-glucose, maltose, and maltotriose are structure forming solutes, and that their abilities lie in the order of D-glucose < maltose < maltotriose.

Many studies[1,2] concerning the properties of aqueous solutions of saccharides have been published, because they are not only biochemically important compounds but also the typical nonelectrolytes with hydrophilic hydoxyl groups, which are capable of hydrogen bonding. Stokes and Robinson[3] interpreted the concentration dependences of activity coefficients of D-glucose and sucrose in terms of the semi-ideal solution theory.† This idea that the solute-solvent interactions govern the concentration dependences of thermodynamic quantities seems to be fundamentally correct, since Raman[4] and NMR relaxation[5] studies of aqueous solutions of mono- and disaccharides suggested an absence of solute-solute interactions even at relatively high concentrations.

Kabayama and Patterson[6] postulated that not only the number of hydroxyl groups but also the stereochemical orientation of hydroxyl groups, *i.e.* axial and equatorial, play an important role on the hydration of saccharides. In other words, the spacing of oxygen atoms of equatorial OH groups of monosaccharides in chair conformation nearly fit the spacing of oxygen atoms of ice-like structure of water. This hydration model for saccharides is so called "specific hydration model." The people who favour this model, Franks school of England, regard monosaccharide, which takes mainly the chair conformation, as a structure maker. Harvey *et al.*[7] are suspicious of the validity of this model because of the similarity of NMR spectra of monosaccharides between aqueous and alcoholic solutions. Rowlinson *et al.*[8] and Kawaizumi *et al.*[9] classified mono- and disaccharides as structure makers in terms of excess partial molar entropy and heat capacity. While Goring *et al.*[10] classified the hydrophilic solutes including D-glucose and sucrose as structure breakers, on the basis of positive temperature dependences of apparent molar volumes.

To solve the puzzling situation of the effect of saccharide on water structure, we measured viscosity *B*-coefficients, apparent molar volumes and activity coefficients of D-glucose homologues; D-glucose, maltose and maltotriose, and discussed the effects of these compounds on water structure.

† Water molecules and hydrated saccharide molecules mix ideally.

Experimental

Materials. Reagent grade D-glucose, maltose, and maltotriose purchased from Nakarai Chemical Co. Ltd., were dried *in vacuo* over P_2O_5 at room temperature for several days before use. Under these conditions, the water of hydration of maltose monohydrate was reported to be stable.[11] Reagent grade sodium chloride obtained from Matsunaga Chemical Co. Ltd., was dried *in vacuo* at 110 °C for a day. These compounds are dissolved in purified water by distillations and deionization.

Method. The viscosity measurements were carried out at 15, 25, and 35±0.03 °C using an Ostwald type viscometer with an efflux time of *ca.* 540 s for water at 25 °C. The detail procedure and kinetic correction of viscometer were described elsewhere.[12] The experimental determination of an efflux time was precise to ±0.05 s.

Density of a solution was measured by Seiko SDM 420 and 421 vibration densimeter at 15, 25, and 35±0.01 °C. Pure water and 6 mol dm^{-3} aqueous sodium chloride solution were used as the standards for the calibration of the apparatus. Measurements were done at least twice for every solution and were accurate within $\pm 10^{-5}$ g cm^{-3}. Apparent molar volume, ϕ_v of solute was calculated by Eq. 1.

$$\phi_v = 1000(d_o - d)/cd_o + M_2/d, \quad (1)$$

where d_o and d are the densities of solvent and solution, respectively. M_2 is molecular weight of solute.

Osmotic coefficients of maltose and maltotriose were measured at 25±0.02 °C by isopiestic comparison method described elsewhere.[13] Sodium chloride was used as a reference solute. Experimental determination of isopiestic concentration was precise to ±0.2%.

Results and Discussion

Relative viscosity, η_{rel}, of nonelectrolyte solution in relatively high concentration range (0.1—1.0 mol dm^{-3}) is expressed by

$$\eta_{rel} = \eta/\eta_o = 1 + Bc + Dc^2, \quad (2)$$

where η_o and η are the viscosities of solvent and solution, respectively, and c is the molarity of solute. At constant pressure and temperature, B and D are the characteristic constants depending on the combination of solute and solvent. The constant B is so called "viscosity *B*-coefficient", which is related to the solute-solvent interaction. The constant D is the coefficient

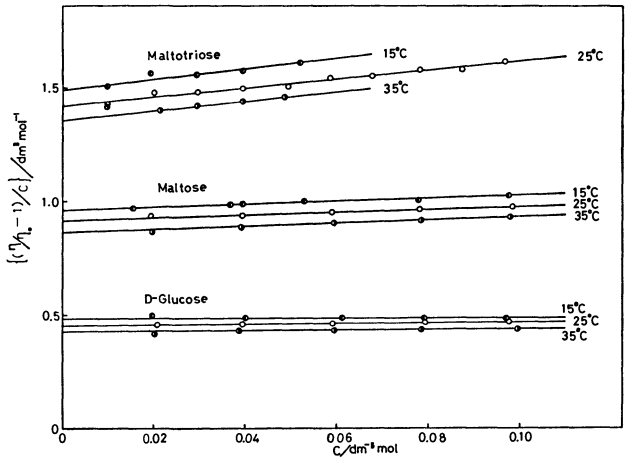

Fig. 1. Relations between $(\eta/\eta_0-1)/c$ and c for saccharides at 15, 25, and 35 °C.

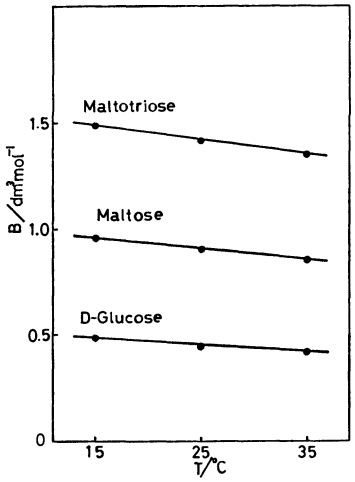

Fig. 2. Temperature dependences of B-coefficients for saccharides.

representing the interactions of solute-solvent and solute-solute, but the physical meaning of D-coefficient is not yet clarified.

As shown in Fig. 1, B and D coefficients are obtained from the intercepts and the slopes of $(\eta_{rel}-1)/c$ *vs.* c curves. B-coefficient is usually expressed by the sum of two terms, *i.e.* B_{size} and B_{st}. The former is the contribution of hydrodynamic obstruction effect arising from the size and the shape of solute molecule, and the latter the contribution of the structural change of solvent by solute-solvent interactions. For the estimation of B_{size}, the Einstein-Simha viscosity equation for colloidal suspension is usually applied to the solution of low molecular weight solute.

$$\eta_{rel} = 1 + \nu\phi, \tag{3}$$

where ϕ is the volume fraction of colloidal particle and ν is a function of the axial ratio of ellipsoid. The ν value is equal to 2.5 for spherical colloidal suspension, which corresponds to the Einstein equation. Assuming that the effective rigid volume of solute equals to the partial molar volume of solute at infinite dilution ($\overline{V}^\circ$), ϕ is equal to $c\overline{V}^\circ/1000$. Hence B_{st} can be expressed by

$$B_{st} = B - \nu\overline{V}^\circ/1000. \tag{4}$$

Scheraga's table[14] was combined with the axial ratio of oblate given by Edward[15] to obtain the ν value for D-glucose. We adopted the ν values of cellobiose and cellotriose as those of maltose and maltotriose. The values of $\overline{V}^\circ$ were obtained from the densities of the solutions described later.

The temperature dependences of B-coefficients for three saccharides are shown in Fig. 2. Each slope of the curves (dB/dT) is negative, and the absolute values increase with the number of glucose residue. The values of B at 15, 25, and 35 °C, and the values of B_{st} and dB/dT at 25 °C are listed in Table 1. The values of B and dB/dT for D-glucose are in fair agreement with those calculated from Goring's data[16]. As seen in Table 1, the positive signs of B and the negative signs of dB/dT indicate that these solutes are structure makers. As shown in Fig. 3(a), the negative values of dB/dT increase with the number of glucose

Table 1. The values of B, B_{st}, dB/dT, $\overline{V}^\circ$, and α^* for saccharides

	Temp/°C	D-Glucose	Maltose	Maltotriose
B/dm³ mol⁻¹	15	0.49	0.96	1.49
	25	0.45	0.91	1.42
	35	0.43	0.86	1.36
B_{st}/dm³ mol⁻¹	25	0.14	0.31	0.41
$(dB/dT)\times10^3$ / dm³ mol⁻¹ K⁻¹	25	−3.0	−5.0	−6.5
$\overline{V}^\circ$/cm³ mol⁻¹	15	110.3	205.5	304.0
	25	111.3	209.0	309.0
	35	112.5	211.0	312.5
$\alpha^*\times10^3$ / cm³ mol⁻¹ K⁻¹	25	1.0	1.3	1.4

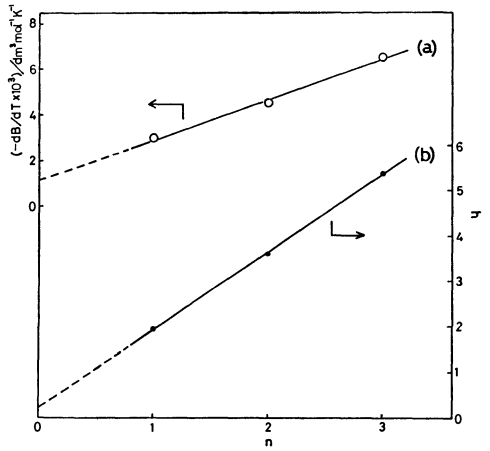

Fig. 3. Plots of dB/dT (a) and h (b) against n.

residue (n). It is noteworthy that the intercept of the straight line drawn through the three points gives positive value in dB/dT *vs.* n plots. This fact means the structure making effects of maltose and maltotriose are not twice and three times as large as that of D-glucose, indicating that the formation of α-1,4 linkage reduces the structure making effects of saccharides.

Apparent molar volume of nonelectrolyte is expressed by

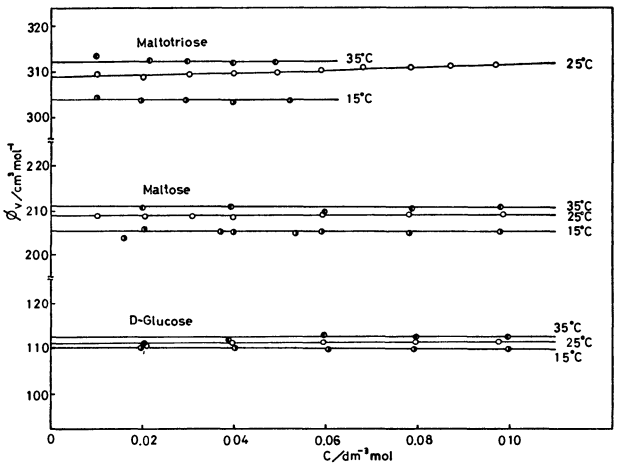

Fig. 4. Relations between ϕ_V and c for saccharides at 15, 25, and 35 °C.

$$\phi_V = \overline{V}^\circ + b_V c, \tag{5}$$

where $\overline{V}^\circ$ is the partial molar volume at infinite dilution and b_V is an empirical constant reflecting the solute-solute interactions. As shown in Fig. 4, ϕ_V values for three saccharides at 15, 25, and 35 °C are linearly related to the concentration. The slopes of ϕ_V *vs.* c curves correspond to b_V, which are nearly zero at 15 °C and slightly positive at 25 and 35 °C. The small values of b_V indicate that the solute-solute interactions are weak in the systems. Table 1 shows the partial molar volumes at infinite dilution at 15, 25, and 35 °C and the coefficients of thermal expansion (α^*) at 25 °C. The values of $\overline{V}^\circ$ for these three saccharides at 25 °C are in fair agreement with the literature.[11] The volume increment for glucose residue is about 100 cm³ mol⁻¹. α^* values were calculated by Eq. 6.

$$\alpha^* = (\mathrm{d}\overline{V}^\circ/\mathrm{d}T)/\overline{V}^\circ. \tag{6}$$

The values of α^* increase with the number of glucose residue, indicating that the amount of unstructured water per glucose residue increases with the number of glucose residue, because the expansibility of disordered water must be larger than that of structured water.

Osmotic (ϕ) and activity (γ) coefficients for maltose and maltotriose are shown in Table 2. The values of ϕ for maltose are in fair agreement with those reported by Uedaira.[17] As seen in Fig. 5, activity coefficients for three saccharides increase with concentration and their magnitudes lie in the order of D-glucose<maltose<maltotriose. The fact that activity coefficients for these saccharides are larger than unity implies that strong solute-solvent interactions exist in these solutions, since solute-solute interactions are weak or absent.[4,5] Using the following equation derived from the semi-ideal theory,

$$\phi = -\frac{1}{0.018m}\ln\left[\frac{1-0.018mh}{1-0.018m(h-1)}\right], \tag{7}$$

the hydration numbers (h) for these saccharides were calculated from osmotic coefficients at 2 mol kg⁻¹, and relation between h and n is shown in Fig. 3(b). The hydration number increases linearly with the number of glucose residue (n), indicating that the hydration number per glucose residue is nearly constant among these low molecular weight homologues. The point given by extrapolating the straight line to $n=0$ shows the positive value. As seen in Fig. 3(a), this behavior is similar to the relation between $\mathrm{d}B/\mathrm{d}T$ and n, and indicates that the formation of α-1,4 ether linkage from the two monosaccharides results in the decrease of hydration numbers of saccharides. The possible explanation for these results may be due to the decrease of the sites of hydrogen bond and/or the increase of structural incompatibility by the formation of α-1,4 ether linkage, because the disagreement of geometric factors of oligosaccharide with ice-like structure of water is considered to occur due to the fact that C–O–C linkage has two degrees of rotational freedom.

TABLE 2. OSMOTIC AND ACTIVITY COEFFICIENTS FOR SACCHARIDES AT 25 °C

	Maltose		Maltotriose	
m	ϕ	γ	ϕ	γ
0.1	1.002	1.003	1.002	1.003

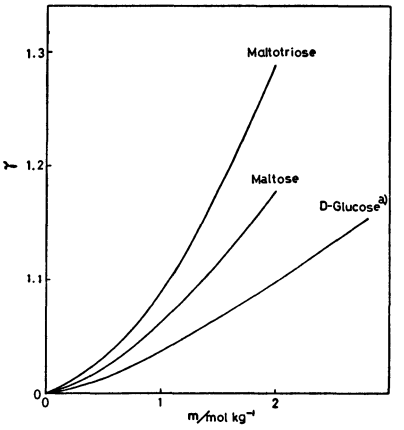

Fig. 5. Activity coefficients of saccharides at 25 °C.
a) see Ref. 2.

Judging from the specific hydration model, it seems to be reasonable that the value of dB/dT or hydration number per glucose residue decrease with increase of the number of glucose residue, because the incompatibility of orientation of hydrogen bond between a saccharide molecule and water molecules of ice-like structure would increase with the number of α-1,4 ether linkage as stated above.

As seen in Fig. 3, however, the value of dB/dT or hydration number is nearly proportional to the number of glucose residue. This result implies that the hydration behavior of di- and trisaccharides are more consistent with the prediction of simple hydration model[††] rather than that of the specific hydration model. As stated previously, the validity of the specific hydration model for monosaccharide solutions is still in controversy. Our results seem to indicate the inadequacy of the specific hydration model for the application of oligosaccharide solutions.

Based on the results of viscosity B-coefficients, apparent molar volumes, and activity coefficients, these saccharides are structure forming solutes, and their abilities lie in the order of D-glucose<maltose<maltotriose.

†† The hydration number of saccharide depends on the number of hydroxyl group in the molecule at the constant water activity.[1)]

Competitive Effects in Polymer Adsorption and Exchangeability of Adsorption Layer

Kunio FURUSAWA* and Kazuaki YAMAMOTO†

The University of Tsukuba, Department of Chemistry, Sakura-mura, Ibaraki 305

(Received January 28, 1983)

Critical experimental data on competitive adsorption and exchangeabllity of adsorbed polymer are produced under the various conditions using the gel permeation chromatography technique. It is apparent that the competitive effects and the exchangeability were found to depend not only on the molecular weight of the polymer, but also on the concentration of each component at which the corresponding adsorption is carried out. This can be explained as follows; the conformation of the adsorbed polymer would be influenced extensively by the polymer concentration in bulk. The polymer molecules adsorbed from a dilute solution would take on a flat conformation being rich in train segments, but the polymer layer formed under a concentrated solution would occupy a small of sites and adopt an extended loop configuration which would be desorbed more easily than the flat one. Also, in the mixed sample the effects of adsorption Kinetics play an important role on the structure of the adsorption layer, because at first the surface is convered by an adsorption layer of small components due to its rapid adsorption rate.

Among the various branches of surface and polymer chemistry, the problem on polymer adsorption at solid-liquid interface is still new and much attention has been paid to it, both theoretically and experimentally. Especially, the problems on (ir)reversibility of polymer adsorption are fundamental and essential ones, because these are concerned with the thermodynamic background in these approaches.

On the question of whether or not polymer molecules adsorb reversibly on a solid surface, experimental data sometimes give conflicting answers. For example, often no detectable desorption can be observed upon dilution,[1,2] whereas the adsorbed polymer is easily desorbed by altering the quality of the solvent.[3] Similar confusing facts can be observed in the theoretical field.[4] Some theories predict irreversible properties, and others reversible ones.

Recently, Cohen Stuart *et al.*[5] showed that many experimental observations ascribed to irreversibility can be explained in therms of polydispersity of the sample, *i.e.*, in a polydisperse sample, preferential adsorption of a large molecule over a smaller one occurs.[6,7] Especially, with increasing molecular weight(M) the polymers adsorb progressively more strongly and exchanges for molecules of smaller M. If the polymer concentration is increased, larger molecules are available to replace smaller ones. Therefore, the molecular weight distribution on the adsorption layer changes with the amount of adsorption and may differ considerably from that in the bulk phase. This fractionation process continues as long as there are larger molecules in the bulk phase than on the adsorption layer and the adsorption isotherm is strongly influenced by the molecular weight distribution of the sample. Hence, in such an adsorption, it is impossible practically to follow the isotherm back by dilution alone and the process appears to be irreversible.

Under the concept proposed by Cohen Stuart *et al.*, it is important to obtain an exact knowledge of competitive effects of polymer molecules and exchangeability of the adsorbed polymer. In this work, competitive and displacement effects in a polymer adsorption process, were examined in some detail using polystyrene samples with narrow-molecular-weight distribution at the Θ-conditions. Furthermore, much attention has been paid to the effects from adsorption kinetics which were neglected in the Cohen Stuart theory, because at the beginning the adsorption layer of a mixed sample is occupied entirely by the small components due to their rapid adsorption rate. These analyses were performed quantitatively by the gel permeation chromatography technique. We believe that these data will shed some light on the problem of (ir)reversibility of polymer adsorption.

Experimental

Materials. Linear polystyrene samples having a narrow molecular weight distribution were supplied by Toyo Soda Co. Ltd., (Shinnanyo, Yamaguchi, Japan). The characteristics of the samples used are given in Table 1.

Cyclohexane, employed as the theta solvent, was purified by the procedure described in a previous paper.[8] Commercial porous glass beads with a particle size of 120—200 mesh were mainly used as substrate which were supplied by Electron-Nucleonics Inc.(Fairfield, N.J.) and designated as CPG-10. The surface area and the average pore-radius of these beads were reported by the supplier to be 15.0 m^2/g and 1000 A, respectively. The pore radius is about 3—30 time larger than the radius of gyration of the dissolved polymers in cyclohexane at 35 °C. Under these conditions, the effect of the porosity of the adsorbent can be ignored

in the adsorption process of these polymers.[9] The glass beads were cleaned carefully by the method described previously.[9]

Adsorption Experiments. The determination of the amount of polymer adsorbed was carried out by measuring the change in concentration of the supernatant liquid using a digital precision density meter(Anton paar. K.G. PHA02C). The temperature of the adsorption tube was controlled within 0.05 °C. The details concerning the adsorption process and the analysis of these data were reported previously.[9]

GPC Measurements. The measurements were carried out with a Toyo Soda Model 803-A GPC at 25 °C, with chloroform as a solvent. The GPC chromatograph was equipped with two 7.5 mm×600 mm stainless-steel columns, types TKS-DMH and G200H. 0.4-ml portions of the polymer solution with 1.0 to 2.0 g m^{-3} was injected and eluted at 25 °C under a flow rate of 1-ml/min.

Measurements of Competitive Adsorbability. In order to determine the competitive(or preferential) adsorbability between different molecular weight species, adsorption isotherms of mixtures were constructed. The total adsorption amounts of the mixtures were determined by the usual procedure using the density meter. For evaluation of each component in the adsorption layers, the GPC technique was employed. After the adsorption period(usual adsorption time is 24 h), the supernatant solution of the mixture and the original solution were evaporated, and the polystyrene films obtained were subsequently dissolved in benzene for freeze drying. The polymer was allowed to remain to a vacuum line for 12 h in 10^{-3} Torr (1 Torr≈133.322 Pa). Both samples were finally dissolved in chloroform within the concentration range 1.0 to 2.0 g m^{-3} so as to present no appreciable concentration effect on the elution curve. In Fig. 1, an example of GPC chromatograms obtained for both samples is illustrated. The amounts of adsorption for individual components in the binary mixture were calculated by the following relations deduced from a simple mass balance analysis:

$$A_a = A_t(\alpha+\alpha\beta'-\alpha'\beta),$$
$$A_b = A_t(\beta+\alpha'\beta-\alpha\beta'). \quad (1)$$

Here, A_a, A_b, and A_t indicate the amounts of adsorption for the components a, b, and their total, and α, β, α', and β' show the areas of normalized chromatograms for components a and b before and after the adsorption process. For a tertiary mixture, the chromatogram was also analyzed under the same consideration.

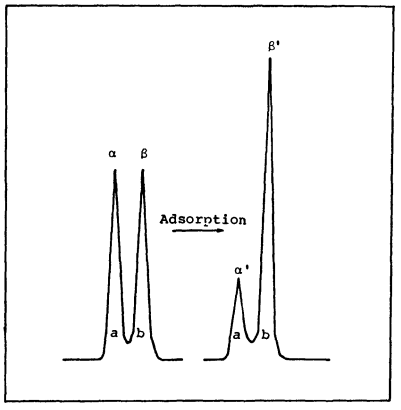

Fig. 1. Gel permeation chromatograms showing relative change of two components before (a,b) and after (a',b') the adsorption process. (α,β), (α',β'): Areas of normalized chromatogram for the components before and after adsorption.

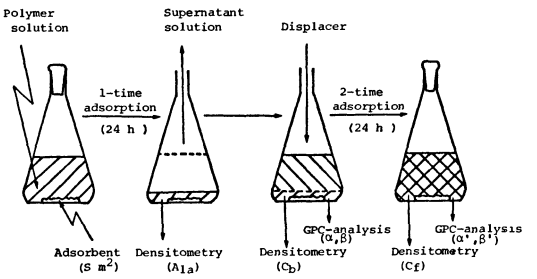

Fig. 2. A schematic picture for showing the procedure to determine the exchangeability of absorption layer.

Measurements of Exchangeability of Adsorption Layer. The exchangeability of the adsorbed polymer was also measured by the GPC technique. A schematic picture of the procedure is shown in Fig. 2. The surface of the adsorbent was first occupied with one polymer species according to the usual adsorption process and then the amounts of adsorption was determined by measuring the residual concentration of the polymer. Thereafter, the supernatant was substituted with another polymer solution used as displacer(usually the concentration of displacer is 35 g m^{-3}). The half-volume of the new supernatant was immediately taken from the tube and after determining the concentration(C_b), the solution was prepared as the GPC sample to analyse the components at the beginning time. Then, the "second-time adsorption" was performed in the other half-volume of the displacer. After the adsorption period of 24 h, the determination of polymer concentration(C_f) and the GPC analysis for the supernatant were conducted in the same way as described above. From these measurements, the adsorption amounts of the total(A_{2t}) and each component(A_{2a}, A_{2b}) in the adsorption layer after completion of the second adsorption process, can be calculated by the following relations which were deduced by a simple analysis and the mass balances,

$$A_{2t} = A_{1a} + \frac{(C_b-C_f)}{S}, \quad (2)$$

$$A_{2a} = A_{1a} + \frac{(C_b-C_f)}{S}(\alpha+\alpha\beta'-\alpha'\beta), \quad (3)$$

$$A_{2b} = \frac{(C_b-C_f)}{S}(\beta+\alpha'\beta-\alpha\beta'). \quad (4)$$

Where A_{1a} is the amount of adsorption for the component "a" after the first-time adsorption, S the total surface area of adsorbent employed, C_b and C_f the total polymer concentrations before and after the second-time adsorption.

Results and Discussion

Adsorption Rate of Mixed Sample. To measure the apparent rate of adsorption, the adsorbed amounts of mixed polymers were determined at various time intervals from 0.1 to 24 h at an initial polymer concentration of 60 g m^{-3} which gives enough saturated amount of adsorption. Figure 3 shows a plot of adsorption rate for a mixture containing two components of different molecular weight samples(S-18.6 and S-77.5) in 1:1 ration. In the same figure, the calculated adsorptions of individual component in the mixture which were determined by the GPC analysis, are also shown. It is seen that the apparent adsorption of

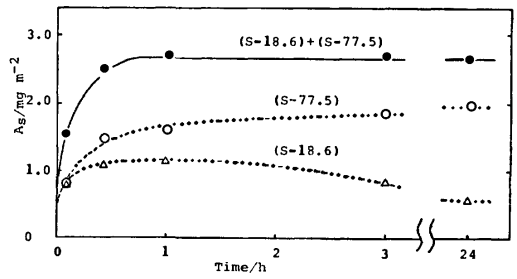

Fig. 3. Adsorption rate of a mixture containing two components (C_p=60 g m^{-3}, in cyclohexane, 35 °C).

the mixture reach an equilibrium within 1 h, but the relative change of each component in the adsorption layer continued for a long time. This tendency can be explained by the differences of the adsorption rates of each polymer species. The surface of the adsorbent will be occupied at first by the law molecular weight species because of their rapid adsorption rate and then exchanged by the later arrivals with higher molecular masses, displaying, as a rule preferential adsorbability. In Fig. 4, we have plotted adsorption rates for a mixture containing three components of different molecular weights(S-1.7, S-18.6, and S-77.5) in 1:1:1 ratio. As may be seen in the figure, the time required for attaining real equilibrium is very long and is barely established after 20 h. From these data, we can imagine that an enormous period will be necessary for a polydisperse sample to attain real equilibrium of adsorption.

Competitive Effects of Polymers Having Different Molecular Weights. In Fig. 5, a molecular weight dependence of saturated adsorption, A_s, for a series of different molecular weight species, is shown in the form of a $\log A_s$ *vs.* $\log M_w$ plot. As may be seen in the figure, $\log A_s$ and $\log M_w$ are related by a straight line and the molecular weight dependence parameter for the adsorption($\nu=\mathrm{dlog}\, A_s/\mathrm{dlog}\, M_w$) was calculated to be $\nu=0.29_5$ from the slope of the line. Thus there will be a competitive effect between the different molecular weight species when a mixed sample is used as the adsorbate.

Figure 6 shows an example of an adsorption isotherm for a mixture containing three components of different molecular weights in 1:1:1 ratio. The mixture isotherm shows a round shape as may be expected from the Cohen Stuart's theory and finally tends to an adsorption of the highest-molecular-weight component. In the same figure, the calculated adsorptions of individual components in the mixture are also shown. It appears that the preference for large molecules over smaller ones can be seen over the whole concentration region and the composition of the adsorption layer is much dependent on the solution concentration at which the corresponding adsorption is carried out. However, it is noteworthly that some adsorption of the lowest-molecular-weight species are found over the the whole concentration region. This result suggests that preferential adsorption of large molecules over smaller ones is not complete and the composition of both the bulk and the adsorption layer varies smoothly with the molecular weight of the polymer.

Exchangeability of the Adsorption Layer. From analysis of the exchange process of one adsorbed polymer by another, we can get much knowledge on the peculiarity of polymer adsorption. Figures 7, 8, and 9 show the results for three combinations of different molecular weight species. In these figures, demonstrating the degree of displacement of adsorption layers formed under the various residual concentrations (C_{eq-1}) by a definite displacer solution(usually we

fixed the concentration at 35 g m^{-2}). For the sake of comparison, Figs. 7 and 8 include isotherms of the adsorbate and the displacer themselves. As may be seen from these figures, the small component adsorbing on the surface is displaced extensively by the large-size molecules used as a displacer. The degree of displacement is greatly dependent on the difference of molecular weights of both polymers: *i.e.*, in a much different combination(Fig. 7), the degree of displacement is extensive and in the small differences(Figs. 8 and 9), the degree is not so extensive. A striking feature seen from these figures is that the exchangeability is found to depend not only on the molecular weight of the adsorbed polymer but also on the solution concentration at which the corresponding initial adsorption was carried out. It appears that the polymer molecules adsorbed at high concentrations are ex-

changed more easily than the polymer layer formed at low concentrations. If the exchangeability is related to the number of adsorbed segments, this suggests that the polymer layer formed at high concentrations has smaller adsorbed segments than the layer formed at low concentrations. This can be explained by the polymer molecules in a dilute solution arriving at the sparsely populated surface and adopting a relatively flat conformation; however the polymer molecules in a more concentrated solution, especially when some later arrivals come to the surface, would occupy a smaller number of sites and therefore must adopt a considerably extended loop conformation which would be desorbed more easily than the flat ones. Also, it is interesting to notice that the total adsorbances after the second-time adsorption show an increasing tendency with decreasing the equivalent concentrations of the displacer. This will be due to different couples of residual molecules with a flat conformation and dis-

placed molecules with an extended conformation.

Another peculiarity in the polymer adsorption is shown in Fig. 10, where the large molecules adsorbed previously are exchanged by a displacer having a small molecular weight, though such a trend is not as pronounced as those found in the opposite combination. However, this result shows crucially that the preference in polymer adsorption depends not only on the molecular weight of the adsorbate, but also on the solution concentration of each species. Furthermore, Fig. 10 shows another indication that the big molecules remaining in the adsorption layer are maintained constant over the whole concentration region of the displacer. This shows that there are "weakly adsorbed matters" in the adsorption layer(*ca.* 25%) and they are classified essentially with the other firmly adsorbed components. Existence of the "weakly adsorbed matters" were also found by Terashima *et al.*[10] in their direct adsorption measurements using microbalance.

In this article, we have attempted to produce critical experimental data on the competitive effects in the polymer adsorption and exchangeability of the adsorption layer. All these data support the Cohen Stuart's theory and are well explained by the concept of reversible adsorption of the polymer.

Polarographic Studies of the Ion-pair Formation and Conjugation Reactions of Acetate and Benzoate Ions in Acetonitrile

Masashi Hojo* and Yoshihiko Imai

Department of Chemistry, Faculty of Science, Kochi University, Kochi 780

(Received May 25, 1982)

An acetate ion (A^-) formed a homoconjugated species, $A^-(HA)_2$, with 2 molecules of acetic acid (HA) in the presence of a large excess of HA in an acetonitrile solution. In the presence of both acetic acid and $LiClO_4$, one molecule of HA was derived from $A^-(HA)_2$ by means of a lithium ion to from an ion-paired species, HA_2^-Li, as follows: $A^-(HA)_2+Li^+ \overset{K_{ex}}{\rightleftharpoons} HA_2^-Li^+ + HA$. The equilibrium constant, K_{ex}, was evaluated as 1.1×10^4 from the shift in the anodic half-wave potential of the acetate ion. As for the benzoate ion (A'^-) and HA', similar reactions occured, and the constant of the exchange reaction was evaluated as 6×10^3. The effect of the sodium ion and HA (or HA') on the A^- (or A'^-) ion was complicated. On the other hand, the presence of $[M(A')_2]^-$ (M=Li, Na, K) was proved by the shift of the cathodic wave of the alkali metal. The addition of water caused the apparent stability constant of $[Li(A')_2]^-$ to decrease extremely.

Polarography has been a powerful means to determine the stability constants of metal complexes. The difference in half-wave potential between a complex and the free metal ion is used in a usual calculation. In some cases,[1] however, the anodic wave-height was measured in order to evaluate the concentration of the uncomplexed ligand in the solution.

Reilley *et al.*[2] have reported an interesting method to obtain a stability constant; their method is based on the shift of the anodic wave of the complex-forming agent in the presence of an excess of the metal ions. At the same time, however, they pointed out a limiting feature of that method: the wave-height decreased in the cases of interactions between EDTA and Pb^{2+}, *etc.* in aqueous solutions. Therefore, we have modified the relationship proposed by Reilley *et al.* and successfully applied it to an ion-pair formation reaction in a nonaqueous solvent. Using this method, we have evaluated the equilibrium constants from the shift in the half-wave potential of the anodic wave of acetate or benzoate ions in the presence of an excess of alkali metal ions. This method was also extended to a reaction for not only an ion-pair formation, but also a homo- or heteroconjugation.

Kolthoff *et al.*[3,4] have reported, based on potentiometric or conductometric measurements, that acetate or benzoate ions associate (homoconjugate) with one molecule of acetic or benzoic acid in acetonitrile. In the same solvent, on the other hand, Pawlak *et al.*[5] showed the association of acetate and other carboxylate ions with 2 molecules of the corresponding acid. We were much interested in the above inconsistency and the fact that the solubilities of alkali carboxylates are much increased by the addition of a large amount of acetic acid in a protophobic solvent.

In the present paper, we studied, by means of polarography, the conjugation and ion-pair formation reactions for acetate and benzoate ions in the presence of large amounts of acetic and benzoic acids, and alkali metal ions in acetonitrile. In acetonitrile, the acetate ion or its homoconjugated ion gives a well-defined anodic wave,[6] although the polarographic anodic wave of the acetate ion is difficult to observe in an aqueous solution. On the other hand, the formation of alkali metal dibenzoate complexes were proved by the shift of the cathodic wave of the alkali metal in the presence of a large excess of the benzoate ion. Moreover, the effect of water on the apparent stability constant for the lithium dibenzoate complex was examined in the solvent.

Experimental

The tetraethylammonium acetate and benzoate were prepared according to the procedure of Kolthoff *et al.*[3,7] The methods of purifying acetonitrile (MeCN) and of preparing Et_4NClO_4, $LiClO_4$, $NaClO_4$, and $KClO_4$ have been described elsewhere.[8] Benzoic acid of a GR grade was dried in a vacuum at room temperature. The other GR-grade chemicals were used without further purification. Polarograms were recorded with a Yanagimoto Polarograph, Model p-1000, and a Watanabe X-Y recorder, Model WX-4401-L0. The rate of the potential sweep was 2 mV/s. The dropping mercury electrode had the following open-circuit characteristics: $m=1.26$ mg/s and $\tau=3.2$ s in a 0.1 M** Et_4NClO_4-MeCN solution at $h=50$ cm. All the polarographic measurements were carried out in an H-type cell at 25.0+0.2 °C. The reference electrode was a silver-silver perchlorate electrode, Ag/0.1 M $AgClO_4$-MeCN.

Results and Discussion

Effects of Acetic Acid and Lithium Ion on Anodic Wave of Acetate Ion. The acetate ion gave an anodic wave at −0.45 V (0.35 mM) in acetonitrile containing 0.1 M Et_4NClO_4 as a supporting electrolyte. The wave height was linear to the concentration of the acetate ion over the range of 0.1—1 mM. The half-wave potential shifted slightly to the negative side with an increase in the concentration of the depolarizer. The anodic wave is certainly based on the dissolution of the mercury(I) ion in an acetonitrile solution, judging from the linearity of the relation of E *vs.* $\log(i_d-i)$ and the extremely small solubility of $Hg_2(CH_3COO)_2$ in the solvent. The variation in the limiting current with the height of the mercury head (h) indicated diffusion control.

When acetic acid (HA) was added to the solution of the acetate ion, the half-wave potential of the anodic wave shifted greatly to the positive potential. Figure 1 shows the shift of the half-wave potential in the presence of acetic acid. The ten-fold increase in the

** Throughout this paper, 1 M=1 mol dm^{-3}.

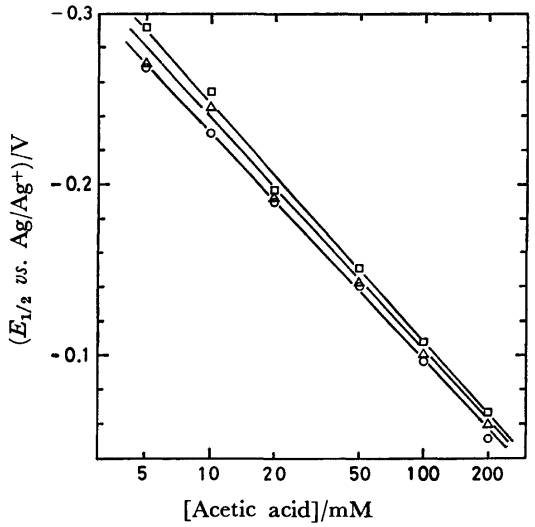

Fig. 1. Effect of acetic acid on the anodic half-wave potential of acetate ion in acetonitrile solutions containing 0.1 M Et_4NClO_4. (○) 0.18, (△) 0.35, (□) 0.70 mM of acetate ion.

concentration of acetic acid caused the half-wave potential for the acetate ion to shift 120 mV positively. The anodic waves were diffusion-controlled and reversible when 10 mM or more of acetic acid was added to 0.35 mM of the acetate ion. We applied the following equation to the homoconjugation reaction:

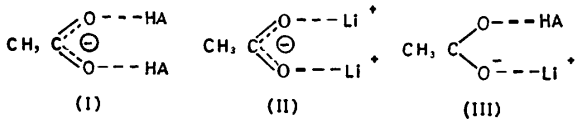
$$(E_{1/2})_c = (E_{1/2})_s + \frac{0.059}{n}\log K_{homo} + \frac{0.059}{n}p\log[HA], \quad (1)$$

assuming the activity and diffusion coefficients of A^- and the homoconjugated species to be equal to each other; here, $(E_{1/2})_s$ is the half-wave potential of the acetate ion, $(E_{1/2})_c$ is the $E_{1/2}$ of the homoconjugated species for the acetate ion, and K_{homo} is the formation constant of the homoconjugation reaction. We obtained $p=2.0$ and $K_{homo}=ca.\ 5.7\times10^7\ M^{-2}$ from the slope of the graph and the $(E_{1/2})_c-(E_{1/2})_s$ value, since $n=1$ in the case of the formation of the mercury(I) salt.[9] The above results show that the acetate ion forms a very stable homoconjugated species, $A^-(HA)_2$ with 2 molecules of acetic acid (see also Scheme 1):

$$A^- + 2HA \overset{K_{homo}}{\rightleftarrows} A^-(HA)_2. \quad (2)$$

The addition of another acid, such as propionic and benzoic acid or phenol, to a solution of the acetate ion also gave a slope of *ca.* 120 mV, which indicated that heteroconjugated species, $A^-(HX)_2$ were formed.

Acetate ion gave an anodic wave in a 0.1 M $LiClO_4$–MeCN solution at an extremely positive potential (+0.06 V) compared with that in an Et_4NClO_4 solution. The shift of $E_{1/2}$ to the positive potential was



Scheme 1.

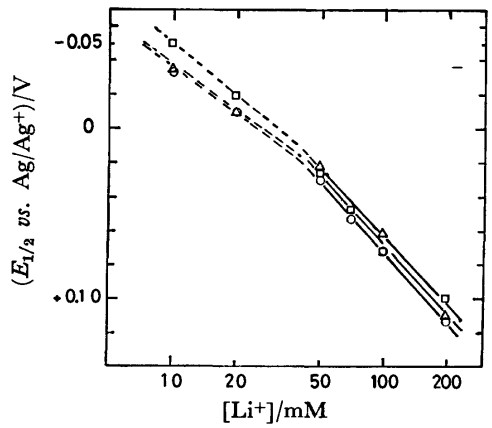


Fig. 2. Effect of Li^+ on the $E_{1/2}$ of acetate ion. (○) 0.18, (△) 0.35, (□) 0.70 mM of acetate ion. Total ionic strength was kept formally 0.1 M with Et_4NClO_4, except 0.2 $LiClO_4$ solution.

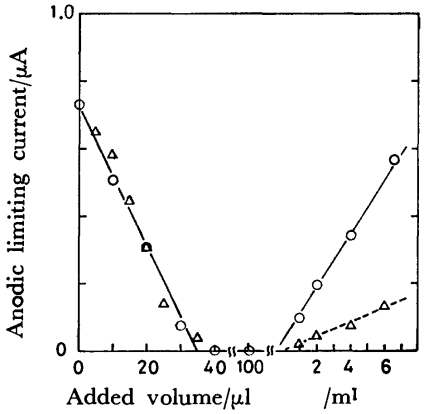

Fig. 3. Amperometric titration curves for 0.35 mM acetate ion of 20 ml by 0.2 M $LiClO_4$ and $NaClO_4$. (○) $LiClO_4$, (△) $NaClO_4$. The changes of total volume were corrected.

considered to be caused by ion-pair (or complex) formation between Li^+ and the acetate ion. The effect of the Li^+ concentration on the half-wave potential for the acetate ion was also examined, as shown in Fig. 2. However, when the concentration of $LiClO_4$ was low (1—20 mM) for the 0.35 mM acetate ion, the wave-height of the acetate ion was extremely depressed. The decrease in the anodic wave-height would be caused by the precipitation of CH_3COOLi. This strange phenomenon was clearly exhibited when 20 ml of a 0.35 mM acetate-ion solution was titrated by a 0.2 M $LiClO_4$–MeCN solution, as shown in Fig. 3. The anodic wave (−0.45 V) of the acetate ion disappeared at the 1:1 equivalent point. Again, an anodic wave from the acetate ion appeared at −0.05—+0.06 V for the addition of a large excess of Li^+. From an analysis similar to that above, with 50—200 mM of $LiClO_4$, we concluded that, in the presence of a large excess of Li^+, the acetate ion exists in the form of $CH_3COO^-(Li^+)_2$, which is electrochemically active. We had the formation constant of $K_f=1\times10^{11}\ M^{-2}$ for the following reaction:

$$CH_3COO^- + 2Li^+ \overset{K_f}{\rightleftarrows} CH_3COO^-(Li^+)_2. \quad (3)$$

When 0.1 M $NaClO_4$ was used as the supporting electrolyte, the solution of the acetate ion formed a white precipitate (CH_3COONa, $pK_{sp}=9.1$ by Kolthoff and Chantooni[10]) and showed only a very small anodic wave at −0.1 V. A titration curve for the 0.35 mM acetate ion obtained by the use of 0.2 M $NaClO_4$ is also shown in Fig. 3.

Next, we shall consider the interaction between $A^-(HA)_2$ and Li^+. We added both acetic acid and the Li^+ ion in various concentrations to solutions of the acetate ion, and then recorded the half-wave potentials. The waves were diffusion-controlled and were reversible when sufficient amounts of acetic acid and Li^+ were added. If the $E_{1/2}$ of $A^-(HA)_2$ is taken as the standard,[11] we obtain the following equation by assuming conditions similar to Eq. 1:

$$(E_{1/2})_c = (E_{1/2})_s + 0.059 \log K_{ex} + 0.059\, p \log[HA] + 0.059\, q \log[Li^+], \quad (4)$$

where $(E_{1/2})_s$[12] is the half-wave potential of $A^-(HA)_2$ and $(E_{1/2})_c$ is the $E_{1/2}$ of the resultant species. From the data in Fig. 4, we obtained $p=-1$ and $q=1$. If the value of p were zero ($p=0$), the following equation would be realized. $A^-(HA)_2+Li^+ \rightleftharpoons A^-(HA)_2Li^+$. However, in practice, $p=-1$, which shows that one HA is present on the right-hand side of the reaction equation. Also, the fact that $q=1$ shows that one

	$K_{ex}=1.1\times10^4$		

a) See the text.

Li^+ ion reacts with $A^-(HA)_2$ as follows:

$$A^-(HA)_2 + Li^+ \overset{K_{ex}}{\rightleftharpoons} HA_2^-Li^+ + HA. \quad (5)$$

The above equation shows the formation of the species HA_2^- Li^+, which consists of an acetate ion, an acetic acid, and a lithium ion. In Eq. 4, if we take [HA]=[Li^+], the value of K_{ex} can be easily obtained from the value of $(E_{1/2})_c-(E_{1/2})_s$, since $-p=q=1$. The experimental results are shown in Table 1. The obtained values coincide well with one another for 0.18—0.7 mM) of the acetate ion containing 20—200 mM of the acid and the Li^+ ion (*e.g.*, [HA]=[Li^+]=50 mM). As an average, we obtain the equilibrium constant of the exchange reaction (the formation constant of the species) $K_{ex}=1.1\times10^4$. Therefore, when the acetate ion is present with both acetic acid and the Li^+ ion in acetonitrile, $HA_2^-Li^+$ is the predominant species and the concentration of $A^-(HA)_2$ becomes negligibly small.

Kolthoff *et al.*[3] reported $K_{homo}=5\times10^3$ M^{-1} as the homoconjugation reaction of the acetate ion ($A^-+HA \overset{K_{homo}}{\rightleftharpoons} HA_2^-$) in acetonitrile. With the help of the value given by them, we obtained the ion-pair formation constant $K_{ion}=ca.$ 1×10^8 M^{-1} for the following reaction: $HA_2^-+Li^+ \overset{K_{ion}}{\rightleftharpoons} HA_2^-$ Li^+.

Effects of Benzoic Acid and Lithium Ion on Anodic Wave of Benzoate Ion. The benzoate ion gave an anodic wave at a slightly more positive potential (−0.36 V at 0.3 mM) than the acetate ion in an acetonitrile solution containing 0.1 M Et_4NClO_4 as the supporting electrolyte. The wave-height was linear to the concentration of the benzoate ion over the range of 0.2—1 mM. The other behavior of the anodic wave of the benzoate ion was similar to that of the acetate ion.

The addition of benzoic acid (HA′) to the benzoate solution caused the half-wave potential of the anodic wave to shift positively. From the analysis of Eq. 1, we obtained $p=2.0$ and $K_{homo}=ca.$ 1×10^7 M^{-2} with 0.2—0.4 mM of the benzoate ion and 20—200 mM of benzoic acid. Here, the formation of homoconjugated species, $A'^-(HA')_2$, with 2 molecules of benzoic acid (HA′) was proved to be present, as in the case of the acetate ion.

In a 0.1 M $LiClO_4$–MeCN solution, the anodic wave from the benzoate ion appeared at *ca.* +0.085 V. However, the calibration curve did not show a linearity, for the solution formed a white precipitate (C_6H_5COOLi) at higher concentrations of benzoate (more than 0.4 mM). Despite this, the formation constant of $C_6H_5COO^-(Li^+)_2$ was evaluated to be *ca.* 1×10^9 M^{-2} with 0.2 mM benzoate and 100—200 mM $LiClO_4$.

When both benzoic acid and Li^+ were present with the benzoate ion, the half-wave potential of the benzoate ion shifted in a manner similar to that in the case of the acetate ion, shown in Fig. 4. From the same analysis as Eq. 4, we obtained the equilibrium constant of 6×10^3 for the following exchange reaction:

$$A'^-(HA')_2 + Li^+ \overset{K_{ex}}{\rightleftharpoons} HA'^-_2Li^+ + HA'. \quad (6)$$

The addition of benzoic acid and Na^+ instead of Li^+

to a benzoate solution caused the half-wave potential of the benzoate ion to shift in a strange manner: the value of $q=1$, but $p=ca.$ −0.5, so the results could not be explained well. Incidentally, the behavior of the acetate ion in the presence of acetic acid and Na^+ was much more complicated.

Other Interactions between Benzoate Ion and Alkali-metal Cations. When a benzoate-ion solution was amperometrically titrated by $LiClO_4$, the height of the anodic wave of the benzoate ion decreased and the wave disappeared at 1:1 equivalent point. Then, again, with a large excess of $LiClO_4$ an anodic wave from the benzoate ion appeared at a much more positive potential (+0.05—0.08 V) than the initial potential (−0.36 V), in a manner similar to that in the case of the acetate ion, shown in Fig. 3. However, the decrease in the benzoate wave-height was completely different from that in the case of the acetate ion: the wave of the acetate ion decreased linearly with the addition of $LiClO_4$. On the other hand, the total wave of the benzoate ion did not decreased so much with the addition of $LiClO_4$, at first, but then it suddenly disappeared at the equivalent point (see Fig. 5). By a detailed examination of the wave, the anodic wave of benzoate could be divided into two parts, that is, the first wave of *ca.* −0.36 V and the second wave of around −0.16 V. The first wave disappeared at a half of the 1:1 equivalent point. The second wave gradually became large and reached its maximum at the half-equivalent point. The composition ratio of Li^+ to the benzoate ion is 1:2 at the maximum point. Therefore, the formation of the lithium dibenzoate complex, $[Li(C_6H_5COO)_2]^-$, was suggested in the presence of an excess of benzoate ions. Therefore, the following experiments were performed in order to prove the formation of the complex. The cathodic wave of the lithium ion (0.5 mM) being used as the indicator, the shift of the wave was measured in the presence of a large amount of benzoate ions (5—20 mM). The half-wave potential of lithium shifted greatly to a negative potential, *e.g.*, 0.75 V at 10 mM of benzoate, and the presence of more than 50 mM of benzoate caused a wave shift behind the cut-off. The analysis of the results proved the presence of a 1:2 complex and gave the formation constant, K_f, of $10^{16.7}\ M^{-2}$;

$$Li^+ + 2C_6H_5COO^- \overset{K_f}{\rightleftarrows} [Li(C_6H_5COO)_2]^-. \quad (7)$$

When 0.48 mM of the benzoate ion was titrated by the use of 0.2 M $NaClO_4$, the anodic wave of the benzoate ion did not decrease linearly; therefore, the formation of the sodium dibenzoate complex was suggested. Similar experiments for 0.5 mM of sodium ions with 50—100 mM of benzoate ions gave the formation constant, K_f, of $10^{8.4}\ M^{-2}$ for $[Na(C_6H_5COO)_2]^-$. Even the potassium ion was complexed by the benzoate ion in an acetonitrile solution. The formation constant for $[K(C_6H_5COO)_2]^-$ was given as $10^{4.2}\ M^{-2}$ by experiments with 0.5 mM K^+ and 30—100 mM benzoate ions. When the 0.48 mM benzoate ion was titrated by $KClO_4$, however, the anodic wave of the benzoate ion did not completely disappear, even in the presence of a large excess of $KClO_4$. This phenomenon is probably the result of the large solubility of C_6H_5COOK in acetonitrile. The value of the solubility products for potassium benzoate could not easily be found in the literature, although the values for lithium and sodium benzoates in acetonitrile have been reported to be $pK_{sp}=10.5$[4] and 8.7[10] respectively.

The effect of water on the stability constant of the lithium dibenzoate complex was also examined. As is shown in Fig. 6, the apparent stability constant of the lithium dibenzoate complex decreased extremely with an increase in the concentration of water. In the calculation of the constant, the shift of the half-wave potential of the free lithium ion was corrected because the half-wave potential of the lithium ion was negatively shifted by the addition of water to an acetonitrile solution without a benzoate ion. The shift in the half-wave potential might be caused by the difference in the liquid-junction potential or solvation. By extrapolation, the formation constant of the lithium dibenzoate complex was estimated to be $\log K_f \approx 0$ for 100% water. This fact suggests that the lithium dibenzoate complex does not actually form in an aqueous

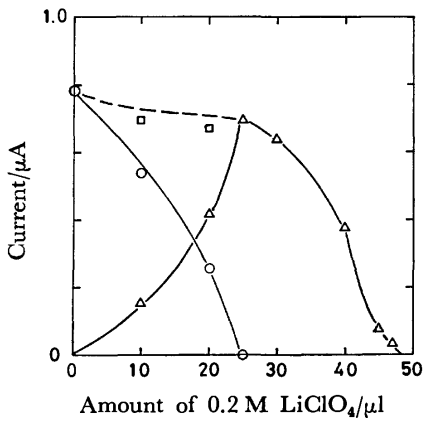

Fig. 5. Amperometric titration curves for 0.48 mM benzoate ion of 20 ml by 0.2 M $LiClO_4$. (○) the first wave of ca. −0.36 V, (△) the second wave of around −0.16 V, (□) total of the two waves.

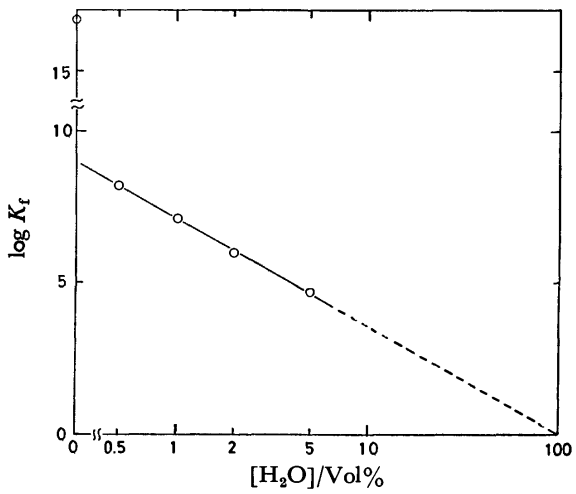

Fig. 6. Effect of water on the apparent stability constant, K_f.

solution. Another experiment showed that a benzoate ion is conjugated by 2 molecules of H_2O in an acetonitrile solution.

The interaction between the acetate ion and alkali metal cations was not fully examined because the behavior of complex reactions for them was complicated, and also because the solubility of tetraethylammonium acetate was much smaller (less than 30 mM) than that of the benzoate (≈200 mM) in acetonitrile.

Conclusion

The results reported in this paper indicate that the formation of homoconjugation for acetate or benzoate is affected by the alkali metal ions in acetonitrile; this is the cause of the difficulty in measuring the precise formation constant of a conjugation reaction by the solubility method.

The authors wish to express their thanks to Emeritus Professor Taitiro Fujinaga and Dr. Satoshi Okazaki, Kyoto University, for their helpful discussions. This work was partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

9) Because of the formation of the insoluble salt with mercury, $E=E^0_{Hg_2^{2+}}+\frac{0.059}{2}\log S-0.059\log[A^-]_0 = E^{0\prime}-0.059\log[A^-]_0$, where $S=[Hg_2^{2+}]_0[A^-]_0^2$. The diffusion of acetate ions towards the electrode surface is governed by the Ilkovic equation: $-i=\kappa([A^-]-[A^-]_0)=-I_d-\kappa[A^-]_0$. Substituting for $[A^-]_0$ in the former equation leads to: $E=E^{0\prime}-0.059\log\frac{i-I_d}{\kappa}$, $E_{1/2}=E^{0\prime}-0.059\log\frac{(-I_d)}{2\kappa}=E^{0\prime}-0.059\log\frac{[A^-]}{2}$. As for the homoconjugated species; $-i=\kappa'([A^-(HA)_p]-[A^-(HA)_p]_0)=-I_d'-\kappa'[A^-(HA)_p]_0=-I_d'-\kappa'[A^-]_0K[HA]_0^p$, $E=E^{0\prime}-0.059\log\frac{i-I_d'}{\kappa'}+0.059\log K[HA]_0^p$. As sufficient [HA] is present, $E_{1/2}=E^{0\prime}-0.059\log\frac{(-I_d')}{2\kappa'}+0.059\log K[HA]^p=E^{0\prime}-0.059\log\frac{[A^-(HA)_p]}{2}+0.059\log K[HA]^p$. When $[A^-]\approx[A^-(HA)_p]$, $(E_{1/2})_c-(E_{1/2})_s=0.059\log K+0.059\,p\log[HA]$. Therefore, $n=1$ in Eq. 1.

11) We can take $A^-(Li^+)_2$ as the standard, and the conclusion is as follows: $A^-(Li^+)_2+HA \overset{K}{\rightleftharpoons} HA_2^-Li^+ + Li^+$, $K=ca.\ 1.4\times10$.
12) For example, when [HA]=50 mM and $[Li^+]=100$ mM, $(E_{1/2})_s$ is the $E_{1/2}$ of $A^-(HA)_2$ at [HA]=50 mM and Li^+-free.

Spectrophotometric Determination of Palladium and Bismuth(III) with Semimethylxylenol Blue

Joichi UEDA* and Kyoko KADOWAKI

Department of Chemistry, Faculty of Education, Kanazawa University, Marunouchi, Kanazawa 920

(Received October 26, 1982)

Procedures are described for the spectrophotometric determination of palladium and bismuth(III) with Semimethylxylenol Blue (SMXB). SMXB reacts with palladium and bismuth(III) to form reddish-violet 1:1 complexes. The optimum pH ranges for the color development are pH 1.0—1.7 for palladium and pH 1.0—1.4 for bismuth(III). The absorption maxima of the colored solutions lie at 565—568 nm and at 568—570 nm, respectively. Beer's law is obeyed over the range of 0.4—3.2 μg cm^{-3} of palladium and 0.4—4.0 μg cm^{-3} of bismuth(III), and the sensitivities of the determinations are 4.0×10^{-3} μg Pd cm^{-2} and 6.1×10^{-3} μg Bi cm^{-2} for 0.001 of absorbance. For the palladium determination, gallium, tin(IV), bismuth(III), scandium, zirconium, and iron(III) interfere, but tin(IV), scandium, zirconium, and iron(III) can be masked by the addition of fluoride. For the bismuth(III) determination, gallium, tin(IV), scandium, zirconium, and iron(III) interfere, but the effect of iron(III) is eliminated by the addition of L-ascorbic acid, and tin(IV) and scandium can be masked by fluoride. A consecutive determination of palladium and bismuth(III) by the difference of the rates of color developments for their complexes was also studied.

Semimethylxylenol Blue (SMXB) is obtained as one of the products in the synthesis of Methylxylenol Blue. In the previous papers, we described photometric methods for the determination of thorium,[1] iron(III),[2] aluminium,[2] zirconium,[3] and gallium[4] using SMXB. In this work, we examined the usefulness of this reagent as the spectrophotometric reagent for palladium and bismuth(III), and observed that SMXB was a suitable reagent for these elements in respect to sensitivity and selectivity. Comparing the present methods for palladium and bismuth(III) with other methods which use reagents with structures similar to that of SMXB, for bismuth(III), SMXB is less sensitive than Semixylenol Orange,[5] but more sensitive than Xylenol Orange,[5,6] Methylxylenol Blue,[7,8] and Methylthymol Blue.[9] For palladium, this reagent has nearly the same sensitivity as Xylenol Orange.[10] As for the selectivity, the present methods are nearly as specific as the methods using the above reagents.[5-10] In the proposed methods, the color development for the bismuth(III) complex is rapid at room temperature, but that for the palladium complex is very slow, especially in the presence of chloride. Thus, utilizing the difference of the rates of color developments, 20—80 μg of palladium and 20—120 μg of bismuth(III) could be determined consecutively from the solution containing both elements. This paper describes the fundamental conditions for the spectrophotometric determination of palladium and bismuth(III), and for the consecutive determination of the two elements.

Experimental

Reagents. *Standard Palladium Solution*: A solution containing about 1 mg cm^{-3} of palladium was prepared by dissolving guaranteed reagent grade palladium chloride in 1.5 mol dm^{-3} nitric acid. The solution was standardized by the complexometric back titration with a standard solution of thorium using Xylenol Orange as an indicator. This solution was diluted as required.

Standard Bismuth(III) Solution: A solution containing about 1 mg cm^{-3} of bismuth(III) was prepared by dissolving guaranteed reagent grade bismuth(III) nitrate in 2 mol dm^{-3} nitric acid. The solution was standardized by the complexometric titration using Xylenol Orange as an indicator. This solution was diluted as required.

SMXB Solution: A 0.05% SMXB solution was prepared by dissolving in distilled water a weighed amount of the SMXB which had been synthesized by the Mannich condensation and purified by means of cellulose column chromatography.[1,2]

1 mol dm^{-3} nitric acid and 1 mol dm^{-3} aqueous ammonia was used for pH adjustments.

All the other reagents used were of guaranteed reagent grade.

Apparatus. A Hitachi-Perkin-Elmer model 139 spectrophotometer with 1 cm glass cells was used for the absorbance measurements, and a Hitachi-Horiba model M-5 glass electrode pH meter for the pH measurements.

Recommended Procedures. *Determination of Palladium*: A sample solution containing 10—80 μg of palladium is taken into a 50 cm^3 Erlenmeyer's flask, and adequate amounts of 1 mol dm^{-3} nitric acid and 3 cm^3 of 0.05% SMXB solution are added. Then, the total volume is made about 20 cm^3 with water. After being kept for 5 min in a boiling water bath, the solution is cooled with running water, transferred to a 25 cm^3 volumetric flask, and diluted to the mark with water (the final pH:1.1). The absorbance is measured at 568 nm against the reagent blank.

Determination of Bismuth(III): A sample solution containing 10—100 μg of bismuth(III) is transferred to a 25 cm^3 volumetric flask. Then, adequate amounts of 1 mol dm^{-3} nitric acid and 3 cm^3 of 0.05% SMXB solution are added. After increasing the volume to 25 cm^3 (the final pH:1.1), the absorbance is measured at 568 nm against the reagent blank.

Consecutive Determination of Palladium and Bismuth(III): The sample solution containing 20—80 μg of palladium and 20—120 μg of bismuth(III) is divided equally. In one solution, the absorbance of bismuth(III) complex is measured by the recommended procedure for bismuth(III), by adding 3 mg of chloride before the addition of the SMXB solution. In this case, the measurements must be done within 4 min after color development. From this absorbance, bismuth(III) is determined by using calibration curve III in Fig. 3. In the other, the total absorbance of the palladium and bismuth(III) complexes is measured by the recommended procedure for palladium, by adding 3 mg of chloride before the addition of the SMXB solution. Then, palladium is determined by subtracting the absorbance due to bismuth(III) from the total absorbance and using calibration curve

II in Fig. 3.

Result and Discussion

Absorption Curves. Figure 1 shows the absorption curves of palladium and bismuth(III) complexes obtained by the recommended procedures. The absorption maxima of the colored solutions of the complexes are at 565—568 nm and at 568—570 nm, respectively.

The Effect of pH. The effect of pH on the color development of the complexes was examined. As shown in Fig. 2, the ranges in which the maximum and nearly constant absorbance was obtained were pH 1.0—1.7 for palladium and pH 1.0—1.4 for bismuth(III). When sulfuric acid, perchloric acid and hydrochloric acid were used instead of nitric acid for the pH adjustment on the palladium determination, sulfuric acid and perchloric acid gave nearly the same results as nitric acid, while hydrochloric acid reduced the absorbance. In the bismuth(III) determination, all of these acids gave almost the same results.

The Effect of the Reagent Concentration. Various amounts of 0.05% SMXB solution were added to a solution containing 40 μg of palladium or 50 μg of bismuth(III). The maximum and reasonably constant absorbances were obtained by adding from 1.5 to 7 cm^3 of SMXB solution for each element.

The Stability of the Color. The color development for the palladium complex is very slow at room temperature. However, heating in a boiling water bath hastened the color development and the maximum absorbance was obtained within a few minutes. Heating for 5 min in a boiling water bath, therefore, was adopted in further experiments. On the other hand, the full color development for bismuth(III) complex occurred immediately after the reagent was added, and the color intensity was independent of heating for at least 20 min in a boiling water bath. The color of the both complexes, once developed, was very stable, and the absorbances remained constant for at least 3 h.

Calibration Curves. The calibration curves for palladium and bismuth(III) which were prepared by the recommended procedures are shown in Fig. 3. Linear relationships between absorbance and concentration held over the range of 0.4—3.2 μg cm^{-3} of palladium and 0.4—4.0 μg cm^{-3} of bismuth(III); the molar absorptivities calculated from the curves were 2.64×10^4 and 3.43×10^4, respectively. The relative standard deviations for five replicate determinations were 1.4% for 40 μg of palladium and 1.2% for 50 μg of bismuth(III). In Fig. 3, the calibration curve for palladium in the presence of 3 mg of chloride is also shown. In this case, the absorbance decreased about 10% compared with that in the absence of chloride, but Beer's law was obeyed over the range of 0.4—3.2 μg cm^{-3} of palladium.

The Effect of Diverse Ions. Table 1 shows the effect of diverse ions on the determination of 40 μg of palladium and 50 μg of bismuth(III). Palladium could be determined within 5% errors in the presence of 1 mg each of 20 cations such as alkali metals, alkaline earth metals, lead, zinc, lanthanoids, manganese(II), cobalt, and nickel, and in the presence of 10 mg each of 6 anions such as fluoride, oxalate, citrate, *etc.*

A: Effect on palladium determination (40 μg of palladium was taken). B: Effect on bismuth(III) determination (50 μg of bismuth(III) was taken). a) 10 mg of fluoride was added. b) 1 mg of fluoride was added. c) 3 cm^3 of 4% L-ascorbic acid solution was added. d) Absorbance was measured immediately after color development.

Gallium, tin(IV), bismuth(III), scandium, zirconium, and iron(III) interfered with the determination, but tin(IV), scandium, zirconium, and iron(III) could be masked by the addition of fluoride. For the bismuth(III) determination, interfering ions such as tin(IV) and scandium, could be masked by fluoride and the effect of iron(III) is eliminated by ascorbic acid. Gallium and zirconium, however, interfered seriously.

Consecutive Determination of Palladium and Bismuth(III). The color development for the palladium complex is slow at room temperature. The speed of this reaction becomes slower by the addition of chloride, and as a result, no color development occurs for about 3 min immediately after preparation of the color system. After that, the color development occurs gradually, but the increase of the absorbance in the next 5 min is only about 4% of the absorbance which is obtained when the color develops fully. So, if the absorbance is measured within 4 min after preparation of the color system, the absorbance from palladium complex is negligible. The order of the addition of chloride is important, and if chloride is added after the addition of the SMXB solution, it has no effect on the rate of color development. On the other hand, the color formation of the bismuth(III)

TABLE 2. CONSECUTIVE DETERMINATION OF PALLADIUM AND BISMUTH(III)

Taken (μg)		Found (μg)

pH: 1.1, [M]+[SMXB] (mol dm^{-3})—I, III: 5.64×10^{-5}, II: 3.23×10^{-5}, M—I, III: Pd, II: Bi(III), wavelength(nm)—I, II: 568, III: 520.

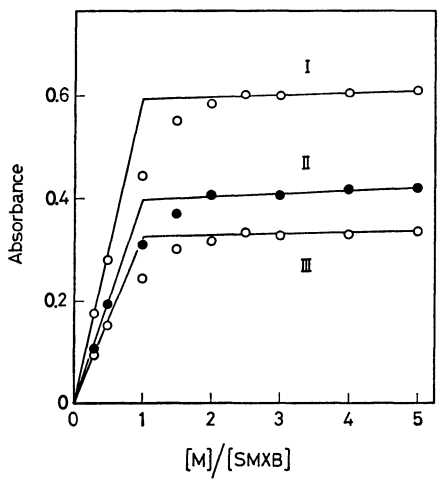

Fig. 5. Mole ratio method.
pH: 1.1, [M] (mol dm^{-3})—I, III: 2.26×10^{-5}, II: 1.34×10^{-5}, M—I, III: Pd, II: Bi(III), wavelength (nm)—I, II: 568, III: 520.

complex is rapid, and the maximum absorbance is obtained instantaneously. Utilizing these facts, the fundamental conditions for the consecutive determination of the two elements have been examined. As shown in Table 2, satisfactory results of the determinations were obtained with the solution containing 20—80 μg of palladium and 20—120 μg of bismuth(III).

The Composition of the Complexes. As shown in Figs. 4 and 5, the continuous variation and the mole ratio methods indicated that both palladium and bismuth(III) formed the 1:1 complexes with SMXB.

(Received October 28, 1982)

The restricted rotation about carbon-nitrogen bonds of unsymmetrical palladium(II) dithiocarbamate chelates has been investigated by high-performance liquid chromatography. At higher temperatures, the rotation is so rapid that two rotamers have not been distinguished, and a single sharp peak has appeared on chromatograms, whereas at lower temperatures, they have been separated. The activation energy of the rotation of palladium(II) dithiocarbamate ($\Delta H^{*}=83\pm5$ kJ mol^{-1} for $Pd(C_6H_5CH_2CH_2NHCSS)_2$) is smaller than usual values of the energy barrier to rotate double bonds, but larger than those to rotate single bonds.

In our previous reports[1-3] it was shown that fast equilibrium including ternary complex formation between two different dithiocarbamate chelates of nickel(II) or copper(II) ($MA_2+MB_2\rightleftharpoons 2MAB$) could be traced by high-performance liquid chromatography (HPLC), while the labile ternary complex MAB was eluted without disproportionation. When kinetically unstable species are chromatographed, they are transformed gradually into other species in the column. The chromatogram patterns vary whether or not the separation is faster than the transformation. When the separation is much faster, the transformation during chromatography will be negligible, and kinetically unstable species will be eluted without any change in the column. On the other hand, when the separation is much slower, unstable species is not detected. Between these two extremes, the separation and the transformation will compete and complicated chromatograms will be obtained. Therefore, in order to trace fast reactions in solution by HPLC, kinetically unstable species should be stabilized in the column by some ways, and the following methods are suggested. (1) Temperature control: Since the rate of reaction decreases with decreasing temperature, kinetically unstable species will be stabilized when HPLC is performed at low temperatures. (2) Flow rate control: Since the residence time of each species in the column decreases with increasing flow rate of the eluent, this brings a similar result to temperature decrease. (3) Sample amount: The effect of sample amount on chromatograms should differ whether the reaction proceeds according to the first-order or the second-order rate law. The progress of second-order reactions is slow, when low initial concentrations of reactants are chosen. Thus, different chromatogram patterns will be obtained, when samples of different initial concentrations with the same sample volume are supplied to HPLC. Contrary to this, when a reaction proceeds according to the first-order rate law, the progress of the reaction should be indifferent to sample amounts, giving unchanged chromatogram patterns. Thus the change of sample concentrations might give a useful information on the reaction mechanism.

In this report equilibria between various kinetically unstable species present in the solution of palladium(II) dithiocarbamate chelates have been scrutinized by means of HPLC.

Experimental

Reagents. Sodium or ammonium salts of various *N,N*-disubstituted and *N*-monosubstituted dithiocarbonic acids were prepared by mixing corresponding aliphatic amine, carbon disulfide, and sodium hydroxide (or aqueous ammonia).[4] The following amines were used: symmetrical secondary amines (dimethylamine, diethylamine, dipropylamine, dibutylamine, pyrrolidine, piperidine, perhydroazepine, morpholine, and dibenzylamine), unsymmetrical secondary amines (*N*-methylbenzylamine, *dl*-2-methylpiperidine, and *l*-ephedrine), and primary amines (methylamine, ethylamine, propylamine, butylamine, benzylamine, and phenethylamine). Standard solutions of palladium(II) and nickel(II) (0.1 mol dm^{-3}) were prepared by dissolving $PdCl_2$ and $NiCl\cdot 6H_2O$ in dilute hydrochloric acid.

Apparatus. The HPLC apparatus is of our own construction. A two-plunger reciprocal pump (Model KHD-W-294, Kyowa Seimitsu Co. Ltd.), a variable sample injector (Model KHP-U1-130, Kyowa Seimitsu Co. Ltd.), a silica-gel column, and a variable wavelength UV-visible detector (Model SPD-1, Shimadzu) were combined. Silica-gel packings (LiChrosorb SI 100, 5 μm, E. Merck Darmstadt; Polygosil 50-5, 5 μm, M. Nagel, Duren; Wako-gel LC 10 H, 10 μm, Wako Pure Chemicals Co. Ltd.) were slurry-packed into stainless steel columns (diameter 4 mm, length 25 cm). Absorbance of palladium(II) dithiocarbamate chelates was measured by a double-beam spectrometer (Model 124, Hitachi).

Procedure. In order to carry out HPLC at low temperatures, column and solvent reservoir were immersed into refrigerant composed of water-methanol in a bath (Model Cryocool CC-80f, Neslab Instruement Inc.). When sillica-gel packings and mixed solvent sysrems of hexane-isopropyl acetate were combined, HPLC was made possible even at −70 °C, though column efficiency was reduced below −40 °C. For the determiantion of rate constants, the HPLC apparentus was modified as depicted in Fig. 1. The procedure was as follows. An equilibrated solution composed of two isomers ($X\rightleftharpoons Y$) was supplied to HPLC through injector I and the portion corresponding to X (or Y) was collected into a reservoir thermostated in the bath. The collected solution was stirred and then stood for a few minutes. After the flow path was changed by the six-way valve, the solution in the reservoir was sucked in from injector II. The injection was repeated for a definite interval. Since the reaction $X\rightarrow Y$ (or $Y\rightarrow X$) proceeded gradually in the thermostated solution, peak of Y (or X) grew while that of X (or Y) fell with each injection. Thus the progress of the

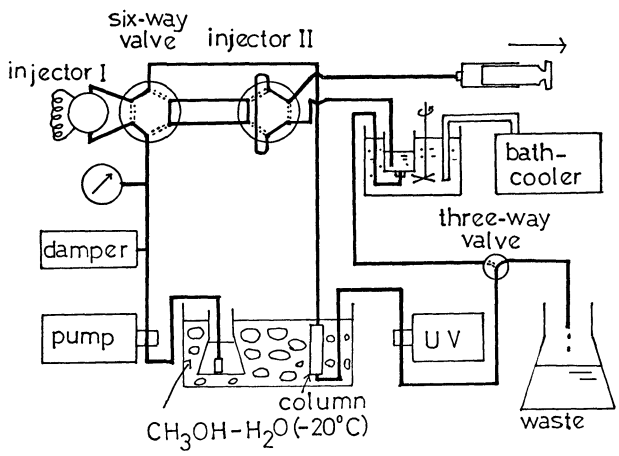

Fig. 1. Block diagram of HPLC apparatus.

reaction was traced by HPLC. All the measurements were repeated three times.

Theoretical

HPLC of Two Isomers in the Equilibrium State. Two different species (X and Y) exist in the equilibrated state in solution, fast interconversion of two isomers being an example.

$$X \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Y , \quad (1)$$

$$K_1 = y_e/x_e = k_1/k_{-1}. \quad (2)$$

Here, x_e and y_e are concentrations of X and Y in the equilibrium state, respectively. Possible chromatogram patterns will be considered first. It is assumed that intrinsic retention time of X is smaller than that of Y, and K_1 is close to 1.0. (1) When k_1 and k_{-1} are very small and separation is achieved promptly, two species X and Y will be eluted separately without interconversion. In this case the obtained chromatograms will be similar to those of the separation of two stable species (Fig. 2(a)). (2) With the increase of k_1, partial interconversion will commence to occur during the course of chromatography. When a part of species X with smaller retention time is converted into Y, its linear velocity passing through the column is reduced, and the peak of X tends to cause tailing (Fig. 2(b)). Similarly the peak of Y will cause leading. (3) When the rate of interconversion is moderately fast, and separation and interconversion occur competitively in the column, complicated chromatograms will be obtained (Figs. 2(c) and 2(d)). (4) When the interconversion is much faster than the separation and consequently the equilibrium in Eq. 1 is maintained throughout the HPLC process, a single peak will appear on chromatograms, and the retention time is the mean of the intrinsic retention times of X and Y (Fig. 2(e)). A fall of column temperature and an increase of flow rate will bring the change of chromatogram patterns, Fig. 2(e)→Fig. 2(d)→Fig. 2(c)→Fig. 2(b)→Fig. 2(a), because interconversion will be retarded by these procedures. The decrease of initial concentration of the sample will bring a similar result provided that the interconversion proceeds according to the second-order rate law.

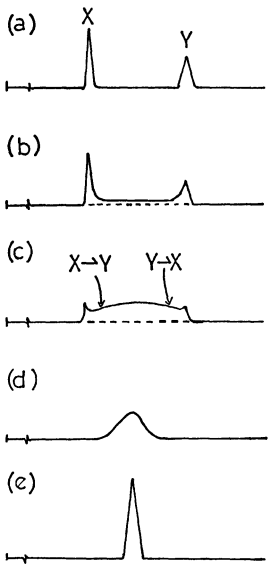

Fig. 2. Possible chromatogram patterns of the system of two kinetically unstable species in equilibrium state.

Determination of Equilibrium and Rate Constants. There exists some difficulty in the determination of the equilibrium and the rate constants, since species X and Y are hardly obtained in a pure state. The measurement of two peak areas in Fig. 2(a) does not give K_1 values directly due to the difference of absorption coefficients of X and Y. The determination of K_1 should thus be carried out by the following procedure, if a chromatogram pattern shown in Fig. 2(a) is obtained. The equilibrated solution is supplied to HPLC, and two fractions corresponding to X and Y are collected. These two solutions are diluted to a definite volume with an HPLC solvent. After standing enough time to attain the equilibrium ($X \rightleftharpoons Y$), K_1 can be determined by one of the following alternative methods. (1) The measurement of absorbance of these two solutions gives K_1 values. (2) When a portion of these two solutions is rechromatographed, chromatogram patterns shown in Fig. 2(a) will be obtained again. The measurements of peak heights (or peak areas) of these two solutions give K_1 values. The calibration curves of X and Y are obtained when K_1 values are determined.

The determination of k_1 and k_{-1} will be carried out as follows. If X (or Y) can be obtained in a pure state, k_1 and k_{-1} are determined easily. This assumption, though being hardly attained in case of a fast equilibrium, will be useful to extend the discussion. Therefore, we consider first using this assumption. In this case, rate constants are determined by dissolving pure X (or Y) and after standing for a definite time a portion of the solution is supplied to HPLC. When the injection is repeated at a definite interval, the peak of Y (or X) will grow while that of X (or Y) will fall. The rate constants are expressed by the following alternative equations whether the reaction proceeds according to the first-order (3) or the second-order (4) rate law.[5]

$$k_1 = (y_e/x_0t)\ln\{y_e/(y_e-y)\}, \quad (3)$$

$$k_1 = [y_e/\{2x_0t(x_0-y_e)\}] \times \ln[\{y(x_0-2y_e)+x_0y_e\}/\{x_0(y_e-y)\}]. \quad (4)$$

Here, x_0, y, and y_e denote initial concentration of X, concentration of Y at t and at equilibrium state, respectively.

Since the aforementioned premise is not satisfied actually, some modification of the formulation is required. The fraction of X (or Y) is collected by HPLC and then the solution is kept in the thermostated bath. After standing for some minutes, a portion of the thermostated solution is rechromatographed. At this time t', the reaction X→Y (or Y→X) already proceeds partially, and we denote the concentrations of X and Y at t' as x' and y', respectively. After a definite interval Δt, a portion of the solution is injected repeatedly. Eqs. 3 and 4 are modified as follows.

$$k_1 = \{y_e/x_0(t'+\Delta t)\}\ln\{y_e/(y_e-y'-\Delta y)\}, \quad (3')$$

$$k_1 = [y_e/\{2x_0(t'+\Delta t)(x_0-y_e)\}] \times \ln[\{(y'+\Delta y)(x_0-2y_e)+x_0y_e\}/\{x_0(y_e-y'-\Delta y)\}]. \quad (4')$$

Here, $y'+\Delta y$ is the concentration of Y at $t'+\Delta t$.

Results and Discussion

Comparison of HPLC of Palladium(II) and Nickel(II) Dithiocabamate Chelates. Chromatographic behavior of various palladium(II) dithiocarbamate chelates was compared with that of nickel(II) dithiocarbamate chelates. As mentioned in our previous report,[6] retention times of each palladium(II) dithiocarbamate were very close to those of corresponding nickel(II) dithiocarbamate when silica gel packings and mixed solvent systems of hexane–isopropyl acetate were used. The characteristic feature of the chromatograms of palladium(II) chelates is an appearance of very broad peaks in some cases, as exemplified in Fig. 3. When

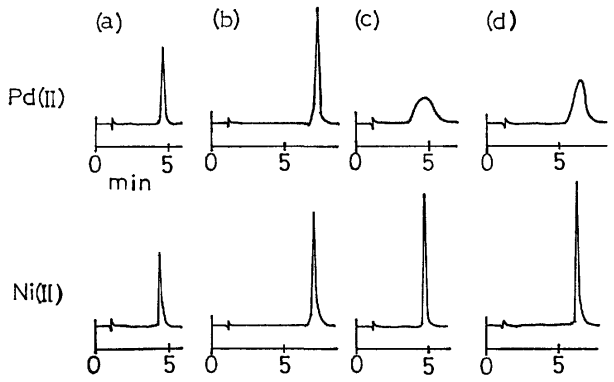

Fig. 3. Comparison of HPLC of dithiocarbamate chelates of Pd(II) and Ni(II).
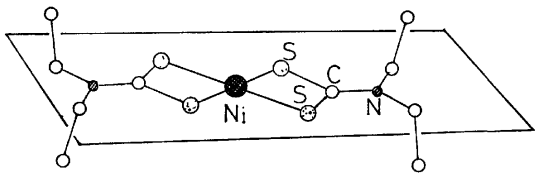
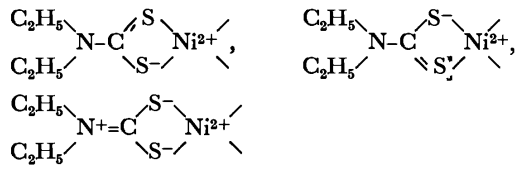
Column: Polygosil 50-5 (4 mm×25 cm). Eluent: hexane:isopropyl acetate=100:15 (water saturated). Flow rate: 1.5 cm³/min. Detector: 305 nm (Pd), 325 nm (Ni). Sample size: 0.01 cm³. Sample: MA_2 A= (a) $(CH_3)_2NCSS^-$, (b) O(CH₂CH₂)₂NCSS⁻, (c) $(C_6H_5CH_2CH_2)HNCSS^-$, (d) $(CH_3CH_2)HNCSS^-$.

palladium(II) chelates were derived from symmetrical secondary amines such as diethylamine and piperidine, peaks were always sharp. However, *N*-monosubstituted dithiocarbamate chelates derived from primary amines gave broad peaks. This seems to be attributable to the decomposition of the chelates since *N*-monosubstituted dithiocarbamate chelates of some metal ions are less stable chemically than *N*,*N*-disubstituted dithiocarbamate chelates.[7] This explanation, however, is not valid because solutions of *N*-monosubstituted dithiocarbamate chelates of palladium(II) did not give any change in absorption spectra after 10 d. Furthermore, dithiocarbamate chelates derived from unsymmetrical secondary amines such as *N*-methylbenzylamine also gave broad peaks. The characteristic feature of the chromatograms is summarized that peaks are broadened when unsymmetrical palladium(II) dithiocarbamates are chromatographed.

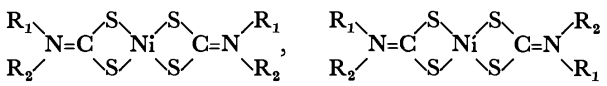
Separation of Two Rotamers of Palladium(II) Dithiocarbamates. The X-ray conformational study of nickel(II) diethyldithiocarbamate has shown[8] that this chelate has a structure as shown below. All the atoms except terminal methyl groups lie in the same plane.



The carbon-nitrogen bond length is 1.33 Å (1 Å= 10^{-10} m), which is much shorter than that of the usual carbon–nitrogen single bond (1.47 Å), but slightly longer than that of the carbon-nitrogen double bond (1.30 Å). The bond lengths of two carbon-sulfur bonds are identical (1.71 Å) within the experimental error. These results suggest that the contribution of the following three canonical forms is possible and that of the last form is largest.



It is well known that the carbon-nitrogen double bonds are rigidly fixed, similarly to the carbon-carbon double bonds. On the other hand, the carbon-nitrogen single bonds rotate freely at room temperature. When two different substituents (R_1 and R_2) are linked to each nitrogen atom, two geometric isomers shown below might be separated, provided that the carbon-nitrogen bond has a double bond character.



A similar explanation is valid for palladium(II) chelates because palladium(II) has been well known to form square-planer complexes. We chromatographed several unsymmetrical palladium(II) dithiocarbamates at various temperatures. An example of chromatograms of palladium(II) dithiocarbamate derived from

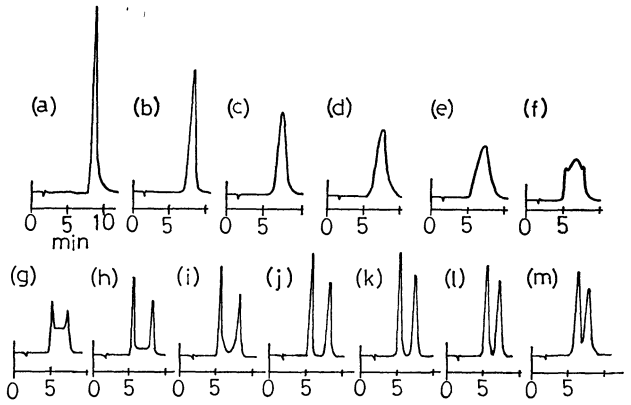


Fig. 4. Chromatograms of Pd(II) dithiocarbamate derived from phenethylamine at various temperatures. Column: Wakogel LC-10H (4 mm×25 cm). Eluent: hexane:isopropyl acetate=100:15 (water saturated). Flow rate: 1.5 cm³/min. Detector: 305 nm. Sample size: 0.01 cm³. Sample: 1.0×10^{-3} mol dm^{-3} Pd-$[(C_6H_5CH_2CH_2)HNCSS]_2$ (a) 50 °C, (b) 40 °C, (c) 30 °C, (d) 25 °C, (e) 20 °C, (f) 15 °C, (g) 10 °C, (h) 0 °C, (i) −10 °C, (j) −20 °C, (k) −30 °C, (l) −40 °C, (m) −50 °C.

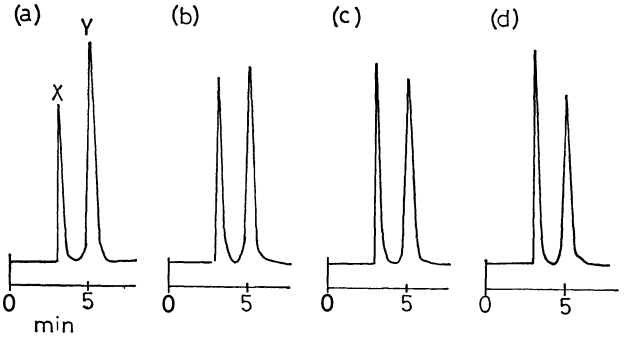

Fig. 5. Change of chromatogram patterns during the course of interconversion of two rotamers of Pd(II) dithiocarbamate derived from phenethylamine. Column: LiChrosorb SI 100 (5 μm, 4 mm×25 cm). Eluent : hexane : isopropyl acetate=100:15 (water saturated). Flow rate: 2.5 cm³/min. Detector: 305 nm. Sample size: 0.2 cm³. Sample: A 0.025 cm³ solution of 2×10^{-3} mol dm^{-3} Pd$[(C_6H_5CH_2CH_2)$-$NHCSS]_2$ was supplied to HPLC and the fraction corresponding to the latter peak was collected. After thermostated at 0 °C for a few minutes, a 0.2 cm³ portion of the solution was supplied to HPLC. The initial concentration of Y ($=y_0$) was determined to be 2.0×10^{-5} mol dm^{-3}. (a) at t_0, (b) at $t_0+5.0$ min, (c) at $t_0+10.0$ min, (d) at t_0+30 min(equilibrium). The value k_1 ($=k_{-1}$) was determined to be 1.1×10^{-3} s^{-1} in this case.

phenethylamine is shown in Fig. 4, which gave the broadest peak at room temperature. These chromatograms suggest that partial rotation around the carbon-nitrogen bond does occur during chromatography at intermediate temperatures. At lower temperatures (<−20 °C), the rotation is negligible because neither tailing nor leading was observed. When the temperature was lowered down to −40 °C, two peaks gradually overlapped due to the decrease of column efficiency. At higher temperatures (>50 °C), the rotation is so rapid that two isomers cannot be distinguished by HPLC. Other palladium(II) chelates derived from unsymmetrical amines such as ethylamine and *N*-methylbenzylamine gave similar results. Contrary to palladium(II) chelates, unsymmetrical nickel(II) chelates always gave single peaks at any temperatures. From these results, it can be concluded that palladium(II) chelates undergo relatively slow intramolecular carbon-nitrogen bond rotation, while for nickel(II) chelates the rotation is rapid even at lower temperature. This suggests that a lone-pair electron on the nitrogen atom is withdrawn by palladium(II) ion more strongly than by nickel(II) ion.

Reaction Mechanism of the Rotation. In order to elucidate whether the rotation proceeds according to the first- or second-order rate law, HPLC conditions such as flow rate and initial concentration of the sample were varied. When the flow rate was doubled at 15 °C, the chromatogram was found to be similar to that shown in Fig. 4(g) (at 10 °C), suggesting that the reaction is approximately doubled with 5 °C rise in temperature. Then the sample solution was diluted various times, and 0.01 cm³ each of the solution was supplied to HPLC at 15 °C. The chromatogram pattern was independent of initial concentration, suggesting the first-order reaction mechanism.

Determination of K_1 and k_1. The equilibrium constants K_1 and the rate constants k_1 of palladium(II) chelate derived from phenethylamine were determined at various temperatures according to the procedure described in the previous theoretical section. The K_1 values were always equal to 1.0 within the experimental error. Two peak areas in Figs. 4(i)—4(l) were also the same, suggesting that two rotamers have almost the same absorption coefficients. These results seem to be in good agreement with the fact that no steric hindrance exists for these two rotamers. Since $K_1=1.0$, Eq. 3′ will be simplified to

$$k_1 = k_{-1} = \{0.5/(t'+\Delta t)\} \ln \{x_0/(x_0-2y'-2\Delta y)\}. \quad (5)$$

An example of the change of chromatogram patterns at 0 °C is shown in Fig. 5. Here X and Y denote the former and the latter peaks, respectively, because it is not always possible to conclude which rotamer is eluted faster. The k_1 value at 0 °C was thus determined to be $(1.1\pm0.1)\times10^{-3}$ s^{-1}. The energy barrier of rotation ΔH^* was obtained by measuring k_1 at different temperatures, and the results are plotted in Fig. 6. Since the rotation is so rapid at higher temperatures that the determination of k_1 was impossible above 10 °C. The energy barrier ΔH^* was determined to be 83±7 kJ mol^{-1}. This value is much larger than that to rotate usual single bonds, but smaller than that to rotate double bonds. For example, the activation energy to rotate carbon–carbon single and double bonds are well known to be about 12 and 260 kJ mol^{-1}, respectively.[9] Since the upper limit of the thermal energy of molecules in solution is 63—85 kJ mol^{-1},[9] a value of 83 kJ mol^{-1} seems to be near the limit that the reaction proceeds promptly at room temperature. The k_1 value at room temperature is extraporated to be 3.6×10^{-2} s^{-1} (at 25

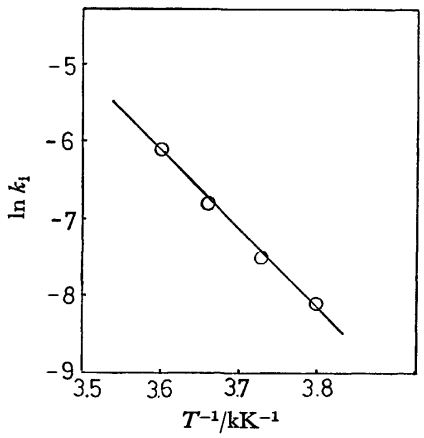

Fig. 6. Activation energy of the carbon-nitrogen bond rotation. Chromatographic conditions were similar to those shown in Fig. 5. The values of k_1 were determined at various temperatures with the similar procedure shown in Fig. 5. The value ΔH^* was determined from the following equation: $k_1 = A_0 \exp(-\Delta H^*/RT)$.

°C) from Fig. 6. From this result it is calculated that the interconversion reaction X→Y proceeds to 50% within 10 s at 25 °C.

Ternary Complex Formation. When chloroform solutions of two different dithiocarbamate chelates of palladium(II) (MA_2 and MB_2) were mixed, ternary complex formation was found to occur similarly to the cases of nickel(II) and copper(II).[1]

$$MA_2 + MB_2 \underset{k_-}{\overset{k}{\rightleftharpoons}} 2MAB, \quad (6)$$

$$K = [MAB]^2/[MA_2][MB_2]. \quad (7)$$

An example of chromatograms of ternary complex formation is shown in Fig. 7. The equilibrium constant K is 4.0, which suggests that similarly to copper(II) and nickel(II) ternary complex formation is controlled by a statistical factor. Rate constants k were measureed for several systems, and the results were tabulated in Table 1 together with the data on nickel(II) and copper(II) complexes described in our previous reports.[1,3] The values of palladium(II) complexes are much smaller than those of nickel(II), which is in agreement with the fact that palladium(II) forms more inert complexes than nickel(II).

Ternary complex formation, which was found to proceed according to the second-order rate law, should

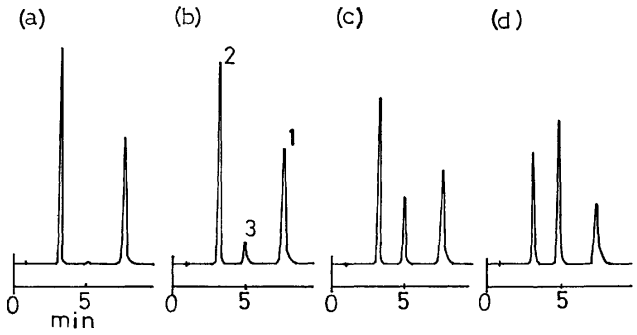

Fig. 7. Ternary complex formation of two Pd(II) dithiocarbamates.
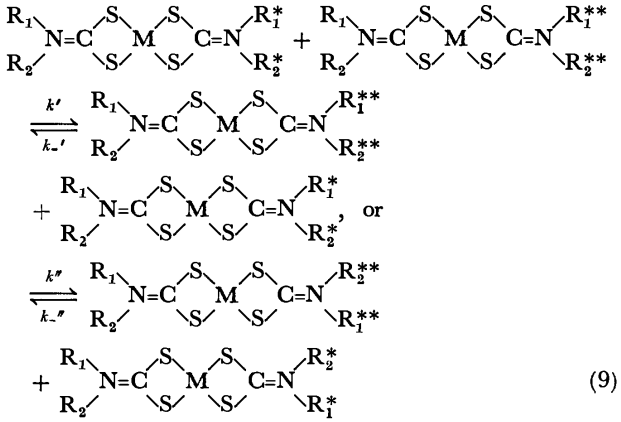
Column: Polygosil 50-5 (4 mm×25 cm). Eluent: hexane:isopropyl acetate=100:3 (water saturated). Flow rate: 2.0 cm^3/min. Detector: 305 nm. Sample size: 0.01 cm^3. Sample: 5×10^{-4} mol dm^{-3} PdA_2+ 5×10^{-4} mol dm^{-3} PdB_2 in $CHCl_3$, A=Pd[$(CH_3CH_2)_2$-NCSS]$_2$, B=Pd[$(CH_3CH_2CH_2)_2$NCSS]$_2$. 1) PdA_2, 2) PdB_2, 3) PdAB. (a) After mixing 1.0 min, (b) 10 min, (c) 290 min, (d) 3 d (equilibrium). The mixed solution was thermostated at 25 °C.

be accompanied by cleavage of metal–sulfur bond and the exchange of ligand, dithiocarbamates. A similar reaction occurs when B=A in Eq. 6.

$$MA_2 + MA_2^* \rightleftharpoons 2MAA^*. \quad (8)$$

Here * is added to distinguish two MA_2. When A is a symmetrical dithiocarbamate, no net reaction will occur and the reaction cannot be traced by HPLC. On the other hand, when A is an unsymmetrical dithiocarbamate, the reaction shown in Eq. 9 should occur.



(9)

$(C_6H_5CH_2CH_2)HNCSS^-$	——	——	$(1.9\pm0.2)\times10^{-2}$ c)

A: $(CH_3CH_2)_2NCSS^-$ a) Ref. 1, b) Ref. 3, c) this work. For experimental conditions of a) and b), see Refs. 1 and 3. Experimental conditions of c) are described in Fig. 7.

The latter pathway in Eq. 9 should be accompanied by the isomerization reaction, while the former does not bring any reaction. Thus, the presence of another path of the isomerization reaction is suggested. Since the reactions shown in Eqs. 6 and 8 are essentially similar, it will reasonably be concluded that $k'+k''$ is close to k shown in Table 1. Both k_1 and k'' of palladium(II) dithiocarbamates will be of the order 10^{-2} on the assumption that $k' \approx k''$. There exists, however, an essential difference between k_1 and k'' that k_1 is a first-order rate constant, while k'' second-order. Therefore, at higher concentrations such as 1 mol dm^{-3}, the isomerization will occur according to two competitive pathways (Eqs. 1 and 9). On the other hand, at lower concentrations such as 10^{-3} mol dm^{-3} at which the major parts of the present experiments were carried out, bond rotation will be a predominant process.

†*Department of Chemistry, Faculty of Science, Hiroshima Uuiversity, Higashisenda, Naka-ku, Hiroshima 730*

(Received November 1, 1982)

The partial molal volumes, $\overline{V}°$, of $[M(phen)_3]Cl_2$ (M=Fe(II), Co(II), Ni(II), Cu(II), and Zn(II)) and 1,10-phenanthroline were determined from density measurements at 25 °C. From the values for $\overline{V}°$ of $[M(phen)_3]^{2+}$, M^{2+} and phen the volume changes for complex formation of $[M(phen)_3]^{2+}$, $\Delta\overline{V}°$, were caluculated. Values for $\overline{V}°$ of $[M(phen)_3]Cl_2$ varied from 445.1 $cm^3\ mol^{-1}$ for $[Fe(phen)_3]Cl_2$ to 458.1 $cm^3\ mol^{-1}$ for $[Zn(phen)_3]Cl_2$ and were in the order, $[Fe(phen)_3]^{2+}<[Co(phen)_3]^{2+}>[Ni(phen)_3]^{2+}<[Cu(phen)_3]^{2+}<[Zn(phen)_3]^{2+}$. The $\Delta\overline{V}°$ of $[Fe(phen)_3]^{2+}$ was significantly small, 4.7 $cm^3\ mol^{-1}$. While those of other metal chelate ions were similar values, *ca.* 20 $cm^3\ mol^{-1}$. The smaller $\Delta\overline{V}°$ of $[Fe(phen)_3]^{2+}$ is considered to be due to the spin change from the high-spin aqua ion, $[Fe(OH_2)_6]^{2+}$, to the low-spin complex ion, $[Fe(phen)_3]^{2+}$.

Metal chelate cations such as $[Fe(phen)_3]^{2+}$ are widely used for the determination of a large number of anions by solvent extraction of ion pairs.[1] Extensive studies have been reported to understand the mechanisms of solvent extraction of ion pairs and solute-solvent interactions of metal chelate electrolytes through viscosities,[2] conductivities,[3] solubilities,[4] and salting effects on the solubilities on nonelectrolytes in water.[5] The partial molal volumes and volume changes of complexation are effective in elucidating the solute-solvent interactions, yet few studies have been reported, especially for volume changes of the complex formation reactions of these metal chelates.

In this study, the partial molal volumes of tris(1,10-phenanthroline) complexes of the first transition metal ions (Fe(II), Co(II), Ni(II), Cu(II), and Zn(II)) are determined and volume changes on complex formation are estimated. The specific aspect of $[Fe(phen)_3]^{2+}$ has been discussed by the spin change on complexation.

Experimental

The metal chelate electrolytes, $[Fe(phen)_3]Cl_2\cdot 7.5H_2O$, $[Ni(phen)_3]Cl_2\cdot 7.5H_2O$ and $[Co(phen)_3]Cl_2\cdot 7.5H_2O$ were prepared by the literature methods.[2,6,7] $[Cu(phen)_3]Cl_2\cdot 7.5H_2O$ and $[Zn(phen)_3]Cl_2\cdot 7.5H_2O$ were prepared by a method similar to that for the Ni-complex. 1,10-Phenanthroline monohydrate (Hanawa Pure Chemical Industries, Ltd.) was used without further purification. Purity of the products was checked by analysis.

The metal chelate electrolytes were dehydrated by drying to constant weigh under reduced pressure over P_2O_5. All solutions were prepared by weight with deionized and distilled water.

The densities of the sample solutions were measured using a digital densimeter (Shibayama Scientific Co., Ltd. Model SS-D-200) with an external measuring cell which was completely immersed in a water bath controlled to 25.00± 0.002 °C. The system was calibrated with dry air and pure water. The accuracy of the system was checked by measuring the densities of NaCl solutions.[8] The errors in the density measurements were estimated within 3×10^{-6} g cm^{-3}.

Results

The apparent molal volumes, ϕ_v, of the solutes have been calculated from the densities of the solutions using the equation:

$$\phi_v = \frac{1000(d°-d)}{md°d} + \frac{M}{d}, \quad (1)$$

where M is the molecular weight of the solute, m is the molality, $d°$ and d are the densities of the solvent and the solution, respectively. The density of pure water at 25 °C was taken from the literature.[9]

The apparent molal volumes of the metal chelate electrolytes were fitted to the Redlich-Mayer equation in order to extrapolate them to infinite dilution:[10]

$$\phi_v = \phi_v° + S_vC^{1/2} + b_vC, \quad (2)$$

where $\phi_v°$ is the apparent molal volume at infinite dilution (equal to the partial molal volume, $\overline{V}°$), S_v is given by the limiting Debye-Hückel law as 9.706 $cm^3\ dm^{3/2}\ mol^{-3/2}$ for 2:1 electrolytes in water at 25 °C, b_v is a constant and c is the concentration.[10] Equation 2 was rearranged to

$$(\phi_v - S_vC^{1/2}) = \overline{V}° + b_vC, \quad (3)$$

and plots of the left side of Eq. 3 against C are shown in Fig. 1. The parameters, $\overline{V}°$ and b_v, for the molal volumes of $[Fe(phen)_3]Cl_2$ and $[Ni(phen)_3]Cl_2$ are obtained by the least squares method and are given in Table 1. The plots of Eq. 3 for the molal volumes of $[Co(phen)_3]Cl_2$, $[Cu(phen)_3]Cl_2$ and $[Zn(phen)_3]Cl_2$ deviated from linearity at low concentrations due to partial ligand dissociations. However, when measurements were done in 0.01 mol dm^{-3} solutions of 1,10-phenanthroline, the molal volumes showed normal concentration dependences as shown in Fig. 1. Then, by fitting the apparent molal volumes of these chelates in 0.01 mol dm^{-3} solutions of 1,10-phenanthroline to the equation:

$$\phi_v = \overline{V}° + A_vC^{1/2} + B_vC, \quad (4)$$

$\overline{V}°$ and fitting parameters, A_v and B_v, are obtained. These $\overline{V}°$ values are assumed to be those in pure water and are given in Table 1.

The apparent molal volumes of free 1,10-phenanthroline in water were determined at five different concentrations, (1.0×10^{-2}—1.5×10^{-2} mol dm^{-3}), which did not show any concentration dependence over the range of experimental errors. Therefore, the mean value of ϕ_v, (142.2±0.1 $cm^3\ mol^{-1}$), is regarded as the value at infinite dilution.

The volume changes of the complex formation of

tris(1,10-phenanthroline) complexes, $\Delta\overline{V}^\circ$, can be estimated with the partial molal volumes of the reactants and products according to the relationship:

$$\Delta\overline{V}^\circ = \overline{V}^\circ([M(phen)_3]^{2+}) + 6\overline{V}^\circ(H_2O) - \overline{V}^\circ([M(OH_2)_6]^{2+}) - 3\overline{V}^\circ(phen), \quad (5)$$

where $\overline{V}^\circ([M(phen)_3]^{2+})$, $\overline{V}^\circ(H_2O)$, $\overline{V}^\circ([M(OH_2)_6]^{2+})$, and $\overline{V}^\circ(phen)$ are the partial molal volumes of metal chelate ions, water, aqua ions and 1,10-phenanthroline, respectively. The partial molal volumes of the hexaaqua complex ions can be estimated in good approximation by the equation:

$$\overline{V}^\circ([M(OH_2)_6]^{2+}) = \overline{V}^\circ(M^{2+}) + 6\overline{V}^\circ(H_2O), \quad (6)$$

where $\overline{V}^\circ(M^{2+})$ is the partial molal volume of the transition metal cation, which is generally obtained in the literature. By substituting Eq. 6 into Eq. 5, we obtain a simpler relation:

$$\Delta\overline{V}^\circ = \overline{V}^\circ([M(phen)_3]^{2+}) - \overline{V}^\circ(M^{2+}) - 3\overline{V}^\circ(phen), \quad (7)$$

Table 2. Ionic partial molal volumes and volume changes for the formation of $[M(phen)_3]^{2+}$ [a]

M(II)	$\overline{V}^\circ(M^{2+})$ / cm³ mol⁻¹	$\overline{V}^\circ([M(phen)_3]^{2+})$ / cm³ mol⁻¹	$\Delta\overline{V}^\circ$ / cm³ mol⁻¹
Fe(II)	−32.6 [b]	398.7	4.7
Co(II)	−36.2 [c]	409.9	19.5
Ni(II)	−39.2 [c]	407.8	20.4
Cu(II)	−35.9 [d]	410.1	19.4
Zn(II)	−35.5 [c]	411.7	20.6

a) Estimated values using $\overline{V}^\circ(Cl^-) = 23.2$ cm³ mol⁻¹ and $\overline{V}^\circ(ClO_4^-) = 49.5$ cm³ mol⁻¹. b) Ref. 11. c) Ref. 13. d) Ref. 12.

which means that $\Delta\overline{V}^\circ$ can be estimated from the partial molal volumes of metal chelate ions, transition metal cations and 1,10-phenanthroline. The partial molal volumes of the transition metal cations were estimated from the literature values for $FeCl_2$, $Co(ClO_4)_2$, $Ni(ClO_4)_2$, $Cu(ClO_4)_2$, and $Zn(ClO_4)_2$ using the additivity principle with $\overline{V}^\circ(Cl^-) = 23.2$ and $\overline{V}^\circ(ClO_4^-) = 49.5$ cm³ mol⁻¹.[11-13] The ionic partial molal volumes are given in Table 2.

Discussion

Partial Molal Volumes and the Solvation of the $[M(phen)_3]^{2+}$ Ions. The $\overline{V}^\circ$ of the aqua ions are in a sequence, $[Fe(OH_2)_6]^{2+} > [Co(OH_2)_6]^{2+} > [Ni(OH_2)_6]^{2+} < [Cu(OH_2)_6]^{2+} < [Zn(OH_2)_6]^{2+}$. The molal volumes of the chelate cations are in the same sequence except for the molal volume of $[Fe(phen)_3]^{2+}$, that is, $[Fe(phen)_3]^{2+} < [Co(phen)_3]^{2+} > [Ni(phen)_3]^{2+} < [Cu(phen)_3]^{2+} < [Zn(phen)_3]^{2+}$. From the results of X-ray analysis, the bond lengths of M–N are 1.97 Å and 2.09 Å in $[Fe(phen)_3]^{2+}$ and $[Ni(phen)_3]^{2+}$, respectively.[14,15] The Cu–N distances in $[Cu(phen)_3]^{2+}$ are 2.04 Å and 2.33 Å in the equatrial position and in the axial position, respectively.[16] From the M–N bond lengths, the molal volumes of these chelate cations are expected in the order, $[Fe(phen)_3]^{2+} < [Ni(phen)_3]^{2+} < [Cu(phen)_3]^{2+}$, which is in agreement with the observed sequence of the molal volumes of these chelate cations. However the M–N bond lengths could not be a direct measure of the molal volumes of these chelate ions. That is, if one assumes a rigid sphere for these chelates, then the radius of $[M(phen)_3]^{2+}$ is estimated about 5.5 Å from

its molal volume. For such a sphere, a difference of 0.1 Å in radius due to the M–N bond length yields a difference about 20 to 25 $cm^3 mol^{-1}$ in the molal volume, which is about one order larger than the observed differences of these complexes except for $[Fe(phen)_3]^{2+}$.

The radius of the circumscribed sphere of $[Fe(phen)_3]^{2+}$ was estimated as 7 Å,[17] with the volume of 865 $cm^3 mol^{-1}$.[5] However, the molal volumes are in the range from 398.7 $cm^3 mol^{-1}$ for $[Fe(phen)_3]^{2+}$ to 411.7 $cm^3 mol^{-1}$ for $[Zn(phen)_3]^{2+}$, which are about 4 to 6% smaller than the three times of the molal volume of the free 1,10-phenanthroline, (426.6 $cm^3 mol^{-1}$). These facts indicate that water creates a solvation cage closely surrounding the three-bladed propeller of 1,10-phenanthroline, each moiety around each 1,10-phenanthroline is almost the same as the solvation cage of the free 1,10-phenanthroline molecule except around the nitrogen atoms. Such a closely surrounding solvation cage is consistent with a fact that, in aqueous solutions of the complex $[Cr(phen)_3]^{2+}$, water molecules can enter into the pockets between the ligands, penetrating the radius about 7 Å of the complex by about 2 Å.[18]

Volume Changes on Complexation. The partial molal volumes in the present work allow one to estimate the volume changes, $\Delta\overline{V}^\circ$, on the complex formation of,

$$[M(OH_2)_6]^{2+} + 3phen \rightarrow [M(phen)_3]^{2+} + 6H_2O.$$

As shown in Table 2, the $\Delta\overline{V}^\circ$ values are almost equal except for the very small $\Delta\overline{V}^\circ$ of $[Fe(phen)_3]^{2+}$.

The exceptionally small $\overline{V}^\circ$ and the resultant small $\Delta\overline{V}^\circ$ of $[Fe(phen)_3]^{2+}$ can be related to the contraction of the volume due to the spin change from high to low on the complex formation. Such an effect of spin change on complex formation was also observed for the entropy change.[19] That is, the formation of $[Fe(phen)_3]^{2+}$ at 20 °C is accompanied by a negative change in the entropy but for the other chelate cations the changes are positive.

On complexation of alkali or alkaline earth ions with crown ethers or criptands, the $\Delta\overline{V}^\circ$ values vary in a wide range from 0 to 28 $cm^3 mol^{-1}$ depending on the sizes of the ions and ligands.[20,21] In these complexes, metal ions have more than one water molecule and the charges are not completely screened from the water.[20]

For the complexation of Ni^{2+} with EDTA and MIDA, $\Delta\overline{V}^\circ$ are 25.5 and 26.8 $cm^3 mol^{-1}$, respectively.[22] These rather larger values are attributed to the partial neutralization of charges on complexation and to the delocalization of the residual charges on the chelate complexes.[22]

A volume change due to the electrostriction for a 2:2 electrolyte can be estimated from $\Delta\overline{V}^\circ$ on an ion pair formation. The $\Delta\overline{V}^\circ$ for $CaSO_4$ is 25.2 $cm^3 mol^{-1}$,[23] but $\Delta\overline{V}^\circ$ of $MgSO_4$ is less than 10 $cm^3 mol^{-1}$,[24] where the former is known to form a contact ion pair, but the latter, predominantly an outer sphere one.

In the present system, though charges are not neutralized, they are delocalized in the large aromatic ligands, which is responsible for the hydrophobic character on these complexes.[2,5] The volume changes of the present reaction, which are comparable to those of the contact ion pair formation and the complexation of Ni–EDTA or Ni–MIDA, may be due to the volume changes of water molecules released from the electronic fields of the central metal ions.

The Change of the Hydration Number on Complexation. On complexation, it may be assumed that the ligand hydration is almost the same for the free and coordinated ligand and only the hydration water of the aqua ions are released to the bulk. By using a simple model for the electrostriction of the ions the change of the hydration number, Δn_H, accompanied on the complexation can be estimated through an equation:[23–26]

$$\Delta n_H = \Delta\overline{V}^\circ/(\overline{V}^\circ_B - \overline{V}^\circ_E), \quad (8)$$

where $\overline{V}^\circ_B$ and $\overline{V}^\circ_E$ are partial molal volumes of the bulk and electrostricted water, respectively. Using Padova's estimation,[25] $\overline{V}^\circ_E - \overline{V}^\circ_B = -2.1$ $cm^3 mol^{-1}$, Δn_H of about 10 is obtained for these chelates except for $[Fe(phen)_3]^{2+}$. Of course this calculation depends on the estimation of the molal volume of the electrostricted water, and the number of released water molecules is not absolute. However the present estimation of Δn_H of 10 seems reasonable in comparison with the hydration number of the transition metal cations. That is, most of these were found in the range of 8 to 12,[27–29] except for the value of 6 estimated for coordinated water from NMR[30] and adiabatic compressibility[31] measurements.

Crystal and Molecular Structure of (+)-(3*R*,4*S*,8*R*,9*S*)-Quinidinium *Δ*-(−)$_{546}$-Bis(oxalato)(1,10-phenanthroline)chromate(III) Monohydrate and Its Implication in the Pfeiffer Effect of the Corresponding System

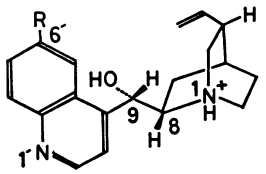
Hiroyuki Ohbo, Hiroshi Okazaki, Katsuhiko Miyoshi, and Hayami Yoneda*

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-senda-machi, Naka-ku, Hiroshima 730

(Received December 3, 1982)

The crystal structure of the title compound *d*-quinidinium (−)$_{546}$-[Cr(ox)$_2$(phen)]·H$_2$O has been determined by a single-crystal X-ray analysis and refined to $R=0.078$ for 2172 reflections. The crystals are orthorhombic, space group $P2_12_12_1$ with unit cell dimensions of $a=9.943(2)$, $b=11.265(2)$, $c=30.716(6)$ Å, and $Z=4$. The known configurations of *d*-quinidinium ion revealed that (−)$_{546}$-[Cr(ox)$_2$(phen)]$^-$ has a *Δ* configuration in accord with the earlier assignment based on its CD spectrum. Following characteristics were noted with regard to intermolecular interactions in the crystal; i) complex anions are linked with one another through the hydrogen bonds to intervening water molecules, to form chains along two-fold screw axes parallel to the a-axis, ii) intermolecular hydrogen bonds connect the complex anion closely with *d*-quinidinium cation which is further hydrogen-bonded to each other forming infinite chains along two-fold axes parallel to the b-axis, and iii) partial stacking is observed between aromatic phen and quinoline rings. These interaction modes were discussed in relation to the Pfeiffer Effect of the corresponding system in water.

The Pfeiffer Effect[1] is a shift in chiral equilibrium between two antipodes of an initially racemic complex upon the addition of a certain chiral compound called an environment substance in solution. It is, thus, a prototype of so-called first-order asymmetric transformations of coordination compounds. In our previous paper,[2] it was reported that an appreciable equilibrium shift is attained for a mixed-chelate complex, [Cr(ox)$_2$(phen)]$^-$ (ox=oxalate dianion and phen=1,10-phenanthroline), when monohydrochloride salts of cinchona alkaloids are mixed with in water. In particular, *d*-quinidinium chloride (=6′-methoxy-*d*-cinchoninium



R = H; cinchoninium ion
R = MeO; quinidinium ion

chloride) and *l*-quininium chloride (=6′-methoxy-*l*-cinchonidinium chloride) are found much more effective in inducing an equilibrium shift of [Cr(ox)$_2$(phen)]$^-$ than their parent alkaloids *d*-cinchoninium and *l*-cinchonidinium chlorides, suggesting some important roles played by the MeO group on the quinoline ring in the stereoselective interaction with the complex anion in water. These observations led us to presume that more extensive association takes place between the cinchona alkaloid cations and the complex anion than is expected for usual 1:1 electrolytes. In fact, molecular model consideration indicates that hydrophobic stacking interaction is possible between aromatic phen and quinolyl groups in addition to electrostatic and/or hydrogen-bonding interactions of ox ligand(s) with the protons on the N(1) atom and of the OH group on the C(9) atom of the alkaloid cation.

In the present study, an X-ray analysis was performed on a diastereomeric salt of *d*-quinidinium ion with (−)$_{546}$-[Cr(ox)$_2$(phen)]$^-$ to get some information on their intermolecular interactions in the solid state, which, we expect, might help us to elucidate their stereoselective interactions involved in the Pfeiffer Effect of the corresponding system in water.

Experimental

Preparation of Compounds. Potassium salt of [Cr(ox)$_2$(phen)]$^-$ was prepared as described in the literature,[3] and was identified by its absorption spectrum.[4] Aqueous *rac*-K[Cr(ox)$_2$(phen)]·4H$_2$O (8 mM, 50 ml) was mixed with aqueous *d*-quinidinium chloride dihydrate (8 mM, 50 ml), and a small amount of ethanol (1—2 ml) was added to facilitate the crystal formation. After the solution was allowed to stand at room temperature in the dark for 2 d, purple-red plate-like crystals were separated out. Found: C, 57.67; H, 4.57; N, 7.59%. Calcd for $C_{36}H_{35}CrN_4O_{11}$: C, 57.52; H. 4.69; N, 7.45%.

Data Collection. A crystal with the size of 0.49×0.42×0.09 mm^3 was used for reflection data collection. Determination of the unit cell dimensions and data collection were carried out on a Syntex R3 automated four-circle diffractometer with Mo *Kα* radiation monochromated by a graphite plate ($\lambda=0.71069$ Å). In Table 1 are given cell constants and their estimated standard deviations which were derived from a least-squares refinement for 22 strong, general reflections ($20°<2\theta<35°$). Other crystal data are also collected in Table 1. From systematic absences for *h*00 with *h* odd, 0*k*0 with *k* odd, and 00*l* with *l* odd, the space group was uniquely identified as $P2_12_12_1$. Reflection intensities were measured up to $2\theta=50°$ using the *ω*-scan technique with a scan speed of 3—30°/min (50 kV, 20 mA). Three reference reflections monitored after every cycle of 200 measurements, showed no significant variation in intensity during the data collection. Out of 3470 reflections measured, 2172 reflections with $|F_o|>3\sigma(F_o)$ were selected and were used for the structure determination. They were corrected for the Lorentz-polarization factor, but no absorption correction was

Table 1. Crystal data

Orthorhombic Space Group $P2_12_12_1$	
a = 9.943(2) Å	$D_o=1.41$ g cm^{-3}
b = 11.265(2) Å	$D_c=1.43$ g cm^{-3}
c = 30.716(9) Å	$Z=4$
$U=3440(1)$ Å^3	μ(Mo *Kα*) = 4.2 cm^{-1}

applied since the linear absorption coefficient was low.

Solution and Refinement of Crystal Structure

The structure was solved by a conventional heavy-atom method. Atomic scattering factors for all atoms were taken from Ref. 5 and were corrected for real and imaginary parts of anomalous scattering.[6]

The position of the Cr atom was deduced from the three-dimensional Patterson synthesis. The remaining atoms were located from successive difference Fourier syntheses. After all nonhydrogen atoms were located, the block-diagonal least-squares refinement using anisotropic thermal parameters for these atoms reduced an R value, $\Sigma||F_o|-|F_c||/\Sigma|F_o|$, to 0.091. At this stage, initial positions of hydrogen atoms were deduced from the geometrical calculations, and the least-squares refinement was continued with all the parameters fixed for hydrogen atoms. Two cycles of the refinement finally performed with all parameters variable, converged an R value to 0.078 and an R_w value,

a) For the nonhydrogen atoms, anisotropic thermal parameters are listed in Table 6 (supplementary material). $B=8\pi^2(U_{11}+U_{22}+U_{33})/3$.

$[\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_c|^2]^{1/2}$, to 0.055. The quantity minimized was $\Sigma w(|F_o|-|F_c|)^2$ and the weighting scheme employed was $w=[\sigma^2+g^2|F_o|^2]^{-1}$ for the final refinement, where σ is a standard deviation obtained from the counting statistics for each reflection and the value of g used is 0.01. The final electron density difference map showed no unusual features, and there was no residual peak higher than 0.3 e/Å^3.

Fourier syntheses, least-squares refinement, and geometrical calculations were performed using programs $P2_12_12_1$,[7] HBLS,[8] and DAPH[9] with slight modification, respectively on a HITAC M-200H computer at the Hiroshima University Information Processing Center.

The final atomic parameters and their estimated standard deviations are listed in Table 2 with averaged isotropic thermal parameters. Anisotropic thermal parameters and complete lists of the $|F_o|$ and $|F_c|$ values have been preserved by the Chemical Society of Japan (Document No. 8327).

Results and Discussion

The asymmetric unit within the unit cell is illustrated in Fig. 1 with the numbering scheme adopted for respective atoms.

Molecular Structure of Complex Anion. The bond distance and selected bond angles in $[Cr(ox)_2(phen)]^-$ are given in Table 3. The mean C–O bond distance is 1.939(7) Å somewhat shorter than the corresponding distances of 1.969(2) Å found in *rac*-$K_3[Cr(ox)_3]\cdot 3H_2O$[10] and of 1.965(2), 1.952(7), and 1.962(5) Å in *fac*-$[Cr(gly)_3]\cdot H_2O$,[11] *rac*-$[Cr(acac)_3]$,[12] and Δ-$[Cr(acac)_3]$,[13] respectively. Somewhat greater anisotropy in the thermal parameters might be in part responsible for the shorter Cr–O distances found in the present crystal. The mean Cr–N bond distance found is 2.065 (8) Å, which coincides well with the corresponding distances of 2.066(10) Å in $[Cr(phen)_2(OH)]_2I_4\cdot 4H_2O$[14] and of 2.068(5) Å in *fac*-$[Cr(gly)_3]\cdot H_2O$.[11]

The averaged O–Cr–O and N–Cr–N bond angles are 83.5(3)° and 81.5(3)°, respectively. They compare well within e.s.d.'s with the values of 82.3(1)° and 79.7(3)° reported for *rac*-$K_3[Cr(ox)_3]\cdot 3H_2O$[10] and $[Cr(phen)_2(OH)]_2I_4\cdot 4H_2O$,[14] respectively.

Intramolecular bond distances within phen and ox chelate ligands are all in good agreement with the comparable values reported in the literature.[10,14] Ox chelates have two kinds of C–O bonds; one forms a "free" carbonyl group and the other is directly associated with the complex formation with Cr(III) ion. A general trend[10] that the latter bond is longer, is also noted in this case. In a phen chelate, the N(A1)–C(A2) and N(A10)–C(A9) distances, for example, are a little shorter than the N(A1)–C(A12) and N(A10)–C(A11) distances, respectively, as is usually the case.[14] Similarly, some deviations are also seen in the C–C bond distances. If e.s.d.'s are taken into account, the C–N and C–C bond distances in a phen chelate seem to correlate with their π-bond orders estimated.[14,15]

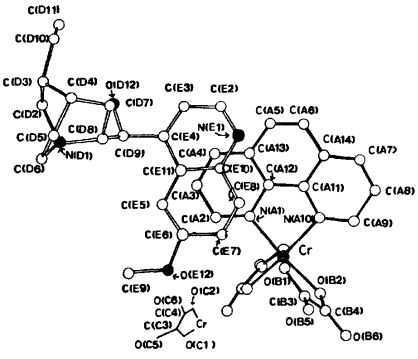

Fig. 1. Asymmetric unit within the unit cell of *d*-quinidinium Δ-$[Cr(ox)_2(phen)]\cdot H_2O$ with the numbering scheme.

In Table 4 are presented the equations of the least-squares plane through the chelate ligands and the distances from the plane to the respective atoms. The Cr(III) atom lies approximately on the plane of one ox chelate (C), but off the plane of another ox chelate (B) which is hydrogen-bonded to both the H–N$^+$(D1) and H–O(W) protons. Similarly, the Cr(III) atom is not coplanar with the phen chelate plane (A), which is probably due to the repulsive interaction with the neighboring quinolyl group of *d*-quinidinium ion.

The absolute configuration of $(-)_{546}$-$[Cr(ox)_2(phen)]^-$ forming a less-soluble diastereomer with *d*-quinidinium cation is assigned as Δ on the basis of the known configurations (3*R*,4*S*,8*R*,9*S*) of *d*-quinidinium cation.[16] This assignment is in accord with that made earlier by the CD spectrum.[4]

Molecular Structure of d-*Quinidinium Cation.* The bond distances and angles within *d*-quinidinium cation (Table 3) are very close to those reported earlier by an X-ray analysis on several cinchona alkaloids,[16–18] with somewhat a shorter C(D10)–C(D11) bond distance. The quinuclidine part has a skew conformation. When it is viewed along the N(D1)–C(D4) direction, the bonds N(D1)–C(D2), N(D1)–C(D6), and N(D1)–C(D8) are rotated about 10° from the eclipsed position over the bonds C(D4)–C(D3), C(D4)–C(D5), and C(D4)–C(D7), in keeping with the results obtained by earlier studies.[16,17] The quinoline ring is regarded as planar within experimental error.

Crystal Packing. The molecular packing in the crystal seen down the a-axis is depicted in Fig. 2. The crystal structure is characterized simply by four types of intermolecular hydrogen bonds by which the composite molecules, complex ion, *d*-quinidinium ion, and water are held together; other intermolecular

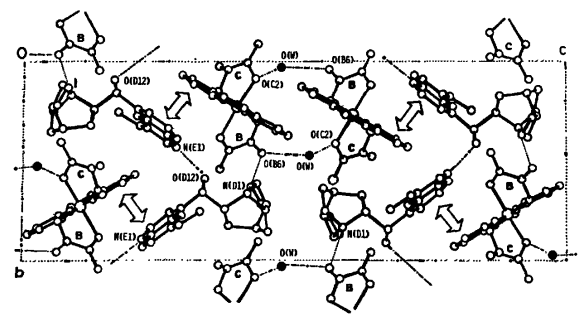

Fig. 2. Crystal packing in *d*-quinidinium Δ-$[Cr(ox)_2(phen)]\cdot H_2O$ viewed down the a-axis.

contacts being due to normal van der Waals interactions. The intermolecular distances shorter than 3.4 Å are given in Table 5. In the following, the crystal packing is discussed with particular reference to intermolecular interactions involved.

First of all, infinite chains of *d*-quinidinium cations hydrogen-bonded to one another (O(D12)–H···N(E1)) are aligned along the two-fold screw axes parallel to the b-axis (O(D12)···N(E1) 2.74 Å). Each *d*-quinidinium cation in the chain is further connected to the ox chelate (B) through the N^+(D1)–H···O(B6) hydrogen bond (N(D1)···O(B6) 2.78 Å). In short, a particular *d*-quinidinium ion participates in the two types of intermolecular hydrogen-bonding, *i.e.*, the N(E1) and H–O(D12) atoms are employed for the interaction with another *d*-quinidinium ion and the H–N^+(D1) proton for the interaction with the complex anion.

The crystal structure of *d*-quinidinium salt with 1,1′-dimethylferrocene-3-carboxylate has been reported.[16] In this crystal, both of the H–N^+(D1) and H–O(D12) protons are associated with the hydrogen

bonds to the carboxylate group on the ferrocene, and the N(E1) atom on the quinolyl group is completely indifferent to the intermolecular interaction. Similarly, the N(E1) atom does not participate at all in any intermolecular interactions in the crystal of free *d*-cinchonine where both of the H–O(D12) and N(D1) atoms are used for the hydrogen-bonding interactions with another *d*-cinchonine molecule.[18] In this way, our present crystal structure seems peculiar in that the N(E1) atom plays as a proton acceptor an essential role in the crystal packing.

Remaining two types of hydrogen bonding found in the present crystal structure are associated with water molecules of crystallization; the complex anions are linked with one another through the hydrogen bonds to the intervening water molecules (O(W)–H···O(B6) and O(W)–**H**···O(C2)) to form another screw chain parallel to the a-axis. The intermolecular distances are as follows; O(W)···O(B6) 2.69 Å and O(W)···O(C2) 2.83 Å.

One more interaction mode to be noted is partial intermolecular stacking between aromatic phen and quinoline rings (Fig. 1). The spacing between the two rings is 3.3—3.5 Å and the tilt angle between the normals of the ring planes is 9.5°. Similar stacking is often observed in the crystal structures of mixed-ligand metal complexes having phen or bpy ligand(s) as a chelate.[19]

Implication to the Interactions Involved in the Pfeiffer Effect. As noted in the introduction, the chiral equilibrium of $[Cr(ox)_2(phen)]^-$ is substantially shifted in favor of its *Δ*- and *Λ*-enantiomers in the presence of *d*-quinidinium and *l*-quininium cations, respectively. Under certain experimental conditions, the enantiomer excess actually attained amounts to almost 20%, which is by far greater than those usually observed (2—3%).[2] In order to account for the much greater Pfeiffer Effect observed, a following association model is proposed for the stereoselective interaction between *Δ*-$[Cr(ox)_2(phen)]^-$ and *d*-quinidinium ions in aqueous solution (Fig. 3-a).

In this model, it is one ox chelate(B) of the complex anion that interacts with quinidinium cation through the two hydrogen bonds; one between the free carbonyl oxygen atom and the H–N$^+$(1) proton, and the other between another carbonyl oxygen atom coordinated to the Cr(III) ion and the OH group on the C(9) atom. Similar hydrogen-bonding interactions have been actually found between the carboxylate group and *d*-quinidinium ion in the solid state.[16] The other ox chelate(C) is not concerned at all with the interaction with *d*-quinidinium ion. In addition to these hydrogen bonds, hydrophobic stacking[20] interaction between the aromatic phen and quinoline rings contributes to the stereoselective association. The presence of stacking interaction is suggested by the findings

TABLE 5. INTERMOLECULAR DISTANCES

The e.s.d. is at most 0.02 Å for each distance.

that organic additives like dioxane[21] diminish the Pfeiffer Effect of the present system greatly and the association constant estimated is 57 which is too great to be accounted for by the electrostatic attraction alone.[22] Furthermore, if the MeO group on the quinoline ring also participates in the hydrophobic interaction[23,24] with the phen chelate, stronger association with the complex anion is expected, and thus a much greater equilibrium shift induced by *d*-quinidinium (6′-methoxy-*d*-cinchoninium) ion than by *d*-cinchoninium ion may be rationalized.

In short, the association model shown in Fig. 3-a is constructed on the assumption that *d*-quinidinium cation recognizes the chirality of $[Cr(ox)_2(phen)]^-$ by interacting with the two chelate ligands, ox and phen, simultaneously through the hydrogen-bonding and hydrophobic stacking interactions, respectively. The simultaneous interactions with *d*-quinidinium cation come into play effectively when the complex anion has a *Δ* configuration, as seen in Fig. 3-a. The *Δ*-enantiomer cannot associate with *d*-quinidinium ion in such a way that the two interactions contribute simultaneously. In this way, the *Δ*-enantiomer is favored over the *Λ*-enantiomer, the former being thereby enriched at equilibrium in the presence of *d*-quinidinium

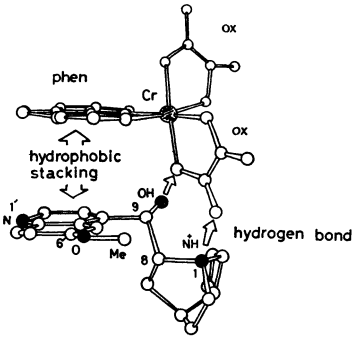

Fig. 3-a. Proposed model for stereoselective association between *Δ*-$[Cr(ox)_2(phen)]^-$ and *d*-quinidinium ions. The conformations of the latter are the same as those assumed in the solid state.

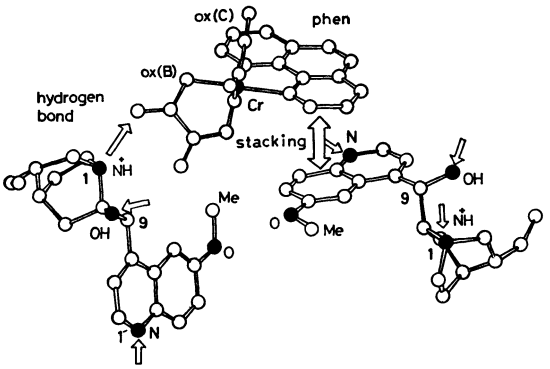

Fig. 3-b. Intermolecular interactions found in *d*-quinidinium *Δ*-$[Cr(ox)_2(phen)]\cdot H_2O$.

ion.

Now, turning to the intermolecular interactions found in the crystal structure of *d*-quinidinium *Δ*-$[Cr(ox)_2(phen)]\cdot H_2O$, one ox chelate(B) of the complex anion actually interacts with *d*-quinidinium cation through the hydrogen bond between the free carbonyl group and the H–N^+(1) proton, but the OH group on the C(9) atom is hydrogen-bonded not to the ox chelate but to the N(1′) atom of another *d*-quinidinium ion, thereby forming infinite chains of *d*-quinidinium cations. Furthermore, the phen ring of the complex anion is stacked with *d*-quinidinium cation, but the stacking is partial (Fig. 1) and is with the quinoline ring of another *d*-quinidinium ion hydrogen-bonded to another complex anion. The above-mentioned situations are easily visualized in Fig. 3-b, where a particular complex anion and two *d*-quinidinium cations interacting with it are projected along an appropriate axis.

It cannot be stated whether the intermolecular interactions found in the solid state persist also in solution. In fact, the metal complex anion interacts directly with two *d*-quinidinium cations simultaneously in the present crystal structure, while 1:1 association is dominant in solution.[2] Thus, the association modes in solution are not directly deduced from the crystal structure. However, the intermolecular interactions found in the solid state are often informative in discussing how the composite ions interact with each other in solution.[19]

As seen in Fig. 3-b, both the OH and N^+–H groups

of *d*-quinidinium ion are associated with the intermolecular hydrogen bonds, and the quinolyl group is stacked, though partially, with the phen chelate in the present crystal structure. These observations imply that the complex and *d*-quinidinium ions are held together in solution also by both the hydrogen-bonding and hydrophobic stacking interactions. As a result, we suppose that the association modes shown in Fig. 3-a are fairly plausible and are probably responsible for the substantial equilibrium shift attained by the Pfeiffer Effect in water.

Finally, the MeO group on the quinoline ring is found not to participate at all in the interaction with the phen chelate in the solid state (Fig. 1). However, an appreciable up-field shift[23,24] has been observed in the pmr spectrum of the MeO group of *l*-quininium ion upon the addition of $[Co(ox)_2(phen)]^-$ in D_2O,[22] suggesting attractive interaction of the MeO group with the phen chelate of the complex anion in water. This observation supports the idea that the MeO group is also involved in the hydrophobic interaction with the phen part of the complex anion. Our proposed model allows the above interaction to work at least for the Δ-enantiomer and thus provides a possible interpretation to the fact that *d*-quinidinium and *l*-quininium cations induce a much greater equilibrium shift in $[Cr(ox)_2(phen)]^-$ than *d*-cinchoninium and *l*-cinchonidinium cations.

Kinetics and Mechanisms of Anation and Exchange Reactions in Pentakis(*N,N*-dimethylformamide)dioxouranium(VI) Ion in Nonaqueous Media

Hideo Doine, Yasuhisa Ikeda, Hiroshi Tomiyasu, and Hiroshi Fukutomi*

Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received December 8, 1982)

The exchange reaction of *N,N*-dimethylformamide (dmf) in $[UO_2(dmf)_5]^{2+}$ ion and the anation reactions by SCN^- and N_3^- have been studied by the NMR method in CD_2Cl_2 and the stopped-flow method in DMF, respectively. For the dmf exchange reaction, rate $=(k_d+k_IK_{os}[DMF])[UO_2(dmf)_5^{2+}]/(1+K_{os}[DMF])$, where k_d, k_I, and K_{os} are $(1.30\pm0.21)\times10^2$ s^{-1}, $(2.94\pm0.07)\times10^3$ s^{-1}, and 1.59 ± 0.11 mol^{-1} kg at -50 °C, respectively. For the anation reactions by SCN^- and N_3^-, the pseudo-first-order rate constant (k_{obsd}) is expressed by $k_{obsd}=\{k_{-1}+(k_1+k_{-1})K_{os}[X]\}/(1+K_{os}[X])$ (X=SCN^- and $[UO_2(dmf)_5]^{2+}$ for the anation reactions by SCN^- and N_3^-, respectively). The values of k_1, k_{-1}, and K_{os} at 25 °C are 1.95×10^2 s^{-1}, 4.27×10^2 s^{-1}, 1.48×10^2 M^{-1} (1 M=1 mol dm^{-3}), and 1.64×10^3 s^{-1}, 3.72×10^2 s^{-1}, 1.80×10^2 M^{-1} for SCN^- and N_3^- anation reactions, respectively. These results suggest that the substitution reaction in $[UO_2(dmf)_5]^{2+}$ ion proceeds through the associative interchange mechanism. The difference of reactivities for SCN^- and N_3^- toward $[UO_2(dmf)_5]^{2+}$ ion seems to be related to the pK_a values for acids, HSCN and HN_3.

Ligand exchange reactions in the equatorial plane of uranyl complexes have been extensively studied by using NMR,[1–7] and it is proposed that the ligand exchange reactions in most of the uranyl complexes proceed through the dissociative(D) or dissociative interchange(I_d) mechanism.[8] There have been a few studies on the anation reactions of uranyl aqua complex with some anions in aqueous solution,[9–11] and very few studies have been concerned with the ligand substitution of uranyl complexes in nonaqueous solvent.

Hence a detailed kinetic analysis of ligand substitution reactions for $[UO_2(dmf)_5]^{2+}$ ion was performed for the following reactions,

$$[UO_2(dmf)_5]^{2+} + DMF^* \rightleftharpoons [UO_2(dmf)_4dmf^*]^{2+} + DMF, \quad (1)$$

$$[UO_2(dmf)_5]^{2+} + SCN^- \rightleftharpoons [UO_2(dmf)_4NCS]^+ + DMF, \quad (2)$$

$$[UO_2(dmf)_5]^{2+} + N_3^- \rightleftharpoons [UO_2(dmf)_4N_3]^+ + DMF, \quad (3)$$

where an asterisk is used to denote the exchanging species. The dmf exchange reaction has been already reported by Lincoln *et al.*[5] They studied the dmf exchange by measuring the NMR line-broadening of the methyl protons of free and coordinated DMF and proposed that the dmf exchange proceeded through the D mechanism.

In the present study, the NMR line broadening of the formyl proton in DMF was measured by changing the free DMF concentration over a 50 fold concentration range and compared with the Lincoln's results. The reaction mechanism is discussed by comparing the results of kinetic studies of reactions (1), (2), and (3).

Experimental

Synthesis of Complexes. The $[UO_2(dmf)_5](ClO_4)_2$ complex was prepared in the atomosphere of nitrogen by refluxing hydrated uranyl perchlorate with triethyl orthoformate at 50—60 °C for one hour, followed by the addition of *N,N*-dimethylformamide at room temperature. The resulting light yellow crystals were filtered, washed with ethyl ether and dried *in vacuo* for 2 d. Anal. Calcd for $[UO_2(dmf)_5](ClO_4)_2$: C, 21.59; H, 4.22; N, 8.39. Found: C, 21.65; H, 4.20; N, 8.50. Elemental analysis of the complexes was carried out in the Institute of Physical and Chemical Research.

Other Materials. Dichloromethane-d_2 (CD_2Cl_2, Merck 99%), which was used as a solvent in the exchange reaction of dmf in $[UO_2(dmf)_5]^{2+}$ complex, was died over 4A molecular sieves (Wako Pure Chemical Ind., Ltd.). *N,N*-Dimethylformamide (Wako) was distilled twice under reduced pressure and stored over 4A molecular sieves. Triethyl orthoformate (Wako) was of guaranteed grade and used without further purification. Sodium thiocyanate (Wako) was used without further purification. The concentration of azide ion in DMF solution was determined by measuring sodium ion concentration with a Varian-Techtron 1100 flamespectrophotometer. The amount of water contained in DMF solvent was measured by a Mitsubishi CA-02 moisturemeter and the maximum concentration was found to be less than 0.01 M. Anhydrous sodium prechlorare (Wako) was used to adjust the ionic strength of solutions.

Preparations of NMR Samples. Sample solutions for NMR measurements were prepared by weighing sample substances in a 1 cm^3 volumetric flask and some of each solution was placed in an NMR sample tubes and sealed. All samples were prepared in a glove box filled with dry nitrogen. Sample solutions were placed in a dark room to avoid the photochemical redox reactions.[12]

Measurement of NMR and IR Spectra. ^{1}H NMR spectra were measured at 100 MHz on a JEOL JNM-FX 100 FT-NMR spectrometer equipped with a JNM-VT-3B temperature controller. Infrared spectra of $[UO_2(dmf)_5]^{2+}$ complex in CD_2Cl_2 were recorded in 200—4000 cm^{-1} range by using a JASCO DS-701G IR spectrophotometer.

Measurement of Equilibrium Constants. The equilibrium constants between $[UO_2(dmf)_5]^{2+}$ and SCN^- or N_3^- ions were measured spectrophotometrically by using a Shimadzu UV-210A double-beam spectrophotometer with a cell compartment thermostated at 25 °C. The ionic strength of sample solutions was adjusted to 0.2 M by using sodium perchlorate.

Kinetic Measurements. The dmf exchange reaction in $[UO_2(dmf)_5]^{2+}$ complex was measured by the NMR line-broadening method as described in the previous paper.[13]

As is mentioned later, the methyl proton signal of the coordinated dmf, which should have two peaks, gave a single peak. This implies that the use of the methyl proton signal for the kinetic measurements is liable to produce an uncertain error. From this reason, the formyl proton signal was employed in the present study.

The anation rates were measured by using a Durrum 110 stopped-flow spectrophotometer with a thermostated cell compartment. The pseudo-first-order rate constants were obtained from the plot of $\ln\{(A_t-A_\infty)/(A_0-A_\infty)\}$ *vs.* time. The symbols, A_0, A_∞, and A_t represent the absorbance at time zero, infinity, and t, respectively.

Results and Discussion

Structure of $[UO_2(dmf)_5](ClO_4)_2$ *in* CD_2Cl_2. Figure 1 shows the ^1H NMR spectrum of a solution containing $[UO_2(dmf)_5](ClO_4)_2$, DMF, and CD_2Cl_2 at -80 °C. From the comparison with the ^1H NMR spectrum of pure DMF, the signals (a) and (b) were assigned to the methyl protons of free and coordinated DMF, respectively. The signals (c) and (d) were attributed to the formyl protons of free and coordinated DMF, respectively. It is noted that the methyl proton signal of the coordinated dmf is a single peak, while that of the free DMF has two equivalent peaks. This result is consistent with that of Lincoln *et al.*[5] The signal of methyl protons of the coordinated dmf should originally have two peaks. In fact, this kind of single peak has not been observed in other dmf complexes, *e.g.* $[Al(dmf)_6]^{3+}$, $[Ga(dmf)_6]^{3+}$, and $[Be(dmf)_4]^{2+}$.[14-16] This phenomenon may be due to the rotation round the C–N bond in coordinated dmf molecules, which is assumed to be too fast on the NMR time scale at this temperature, or to the equalization of chemical shifts of both methyl groups of the coordinated dmf molecules caused by the magnetic anisotropy of the uranyl ions as proposed by Lincoln *et al.*[5] The former is not likely because the IR spectrum of $[UO_2(dmf)_5]^{2+}$ complex in CD_2Cl_2 gives the value of 1642 cm^{-1} for the C–O stretching of dmf, which is 33 cm^{-1} lower than that observed for pure DMF (1675 cm^{-1}). This fact suggests that the dmf molecules coordinate to the uranyl ion through oxygen, since the C–O stretching, so called Amide I, is shifted to a lower side when the dmf molecule coordinates to metal ion through oxygen.[17-19] This coordination tends to increase the double bond character of the C–N group and hence make more difficult the rotation round the C–N bond.

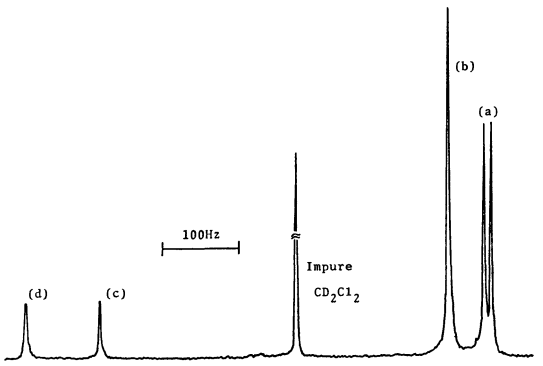

Fig. 1. The ^1H NMR spectrum of a solution consisting of $[UO_2(dmf)_5]^{2+}$ (0.00433 mol kg^{-1}), DMF (0.0216 mol kg^{-1}), and CD_2Cl_2 (11.4 mol kg^{-1}) at -80 °C.

On the other hand, it is more likely that the magnetic anisotropy of the uranyl ion may introduce the degeneration of two signal peaks arising from the methyl groups of the coordinated dmf. Pople *et al.*[20] give the equation for the chemical shift ($\Delta\delta$) caused by the anisotropic field

$$\Delta\delta = \Delta\chi_{atomic}(1-3\cos^2\gamma)/3R^3, \quad (4)$$

where $\Delta\chi_{atomic} = \chi_{atomic}$(parallel to axis) $- \chi_{atomic}$ (perpendicular to axis), in which the axis is taken to be the O=U=O axis, R is the distance between the proton and the uranium atom, and γ is the angle between a straight line connecting the proton and uranium atom and the O=U=O axis. From this equation, it is expected that the chemical shifts of both methyl groups of the coordinated dmf become identical at the particular values of γ and R. Lincoln *et al.*[5] estimated the value of $\Delta\delta$ for both methyl groups of the coordinated dmf by using Eq. 4 and found that the calculated values were consistent with the experimental ones. Furthermore, the dmf methyl proton signal of $UO_2(acac)_2dmf$ (acac=acetylacetonate) in CD_3COCD_3 and CD_2Cl_2 has two equivalent peaks[12] in spite of the coordination of dmf in the same equatorial plane of uranyl ion and the differences of chemical shifts between two peaks are 0.03 and 0.14 ppm in CD_3COCD_3 and CD_2Cl_2, respectively. These phenomena can be explained by the differences of the values for γ and R in $UO_2(acac)_2dmf$ and $[UO_2(dmf)_5]^{2+}$ complexes.

The number of the coordinated dmf molecules were determined by area integrations of the methyl and formyl proton signals of free and coordinated DMF, respectively and the results are listed in Table 1. The absence of any significant variation of the number

Table 1. Solution compositions and coordination numbers (CN) for the exchange of dmf in $[UO_2(dmf)_5]^{2+}$

No.	$[UO_2(dmf)_5^{2+}]$ / 10^{-3} mol kg^{-1}	DMF / 10^{-2} mol kg^{-1}	$[CD_2Cl_2]$ / mol kg^{-1}	CN[a]

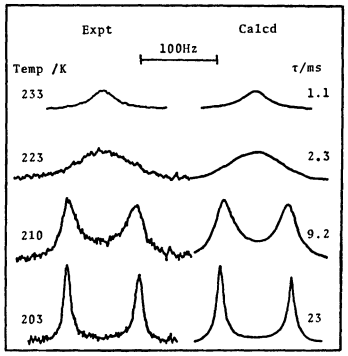

Fig. 2. Experimental (left-hand side) and best-fit calculated ^1H NMR lineshapes of a solution consisting of $[UO_2(dmf)_5]^{2+}$ (0.00433 mol kg^{-1}), DMF (0.0216 mol kg^{-1}), and CD_2Cl_2 (11.4 mol kg^{-1}). Temperatures and best-fit τ-values are shown at left- and right-hand side of the figure, respectively.

of coordinated dmf molecules over a wide concentration range (Table 1) indicates that neither CD_2Cl_2 nor perchlorate ion enters into the first coordination sphere of uranyl ion. The absence of any splitting of the coordinated dmf formyl proton signal indicates also that the five molecules of the coordinated dmf occupy the equivalent equatorial positions of the uranyl ion. These results confirm that the structure of $[UO_2(dmf)_5]^{2+}$ ion in CD_2Cl_2 is pentagonal bipyramidal.

Exchange Reaction of DMF in $[UO_2(dmf)_5]^{2+}$ Ion in CD_2Cl_2. A typical temperature dependence of lineshape for the formyl proton signals of the coordinated and free DMF is shown at the left side in Fig. 2. This figure shows that the dmf exchange reaction occurs between the coordinated and free sites. The best-fit life times (τ-values) were determined by using the computer program for two site exchange[21] and are shown at the right side in Fig. 2 together with the corresponding lineshapes. From these τ-values, the first-order rate constants, k_{ex}, were calculated by the following equations,

$$\tau = P_F\tau_c = P_c\tau_F, \tag{5}$$

$$k_{ex} = 1/\tau_c = \text{rate}/5[UO_2(dmf)_5^{2+}] = (kT/h)\exp(-\Delta H^*/RT)\exp(\Delta S^*/R), \tag{6}$$

where τ and P with the subscripts of F and c are the life times and mole fractions of the free and coordinated sites, respectively.

The same measurements were carried out for the solutions with different compositions listed in Table 1. Figure 3 shows the plots of k_{ex} against the DMF concentration, which do not yield a simple linear relationship but the intercepts and the limiting values at high concentration region. This result suggests that the dmf exchange reaction proceeds through two paths, that is, one is the independent path of the DMF concentration and another is the path which depends on the DMF concentration in its low region and becomes independent of the DMF concentration in its high region.

These paths are assumed to proceed through the D and I mechanism[8] as follows.

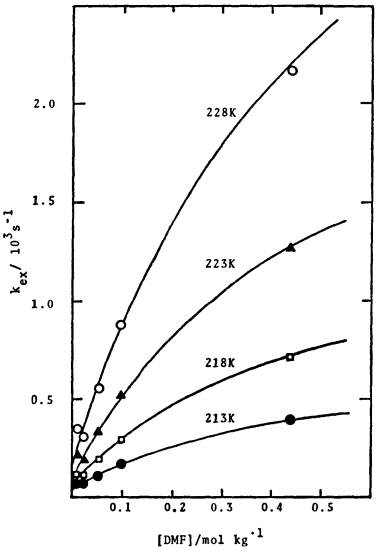

Fig. 3. Plots of k_{ex} *vs.* [DMF] for the exchange of dmf in $[UO_2(dmf)_5]^{2+}$. The solid lines denote the least-squares best-fit lines.

$$[UO_2(dmf)_5]^{2+} + DMF^* \xrightarrow[\text{slow}]{k_d} [UO_2(dmf)_4]^{2+} + DMF + DMF^* \xrightarrow[\text{fast}]{} [UO_2(dmf)_4dmf^*]^{2+} + DMF,$$

$$[UO_2(dmf)_5]^{2+} + DMF^* \overset{K_{os}}{\rightleftharpoons} [UO_2(dmf)_5]^{2+}\cdots DMF^* \xrightarrow[\text{slow}]{k_I} [UO_2(dmf)_4dmf^*]^{2+}\cdots DMF \xrightarrow[\text{fast}]{} [UO_2(dmf)_4dmf^*]^{2+} + DMF,$$

where K_{os} is the outer-sphere complex formation constant. These mechanisms lead to the following equation for k_{ex}[22]

$$k_{ex} = \frac{k_d + k_I K_{os}[DMF]}{1 + K_{os}[DMF]}. \tag{7}$$

This equation can be simplified to $k_{ex} = k_d + k_I K_{os} \times [DMF]$ when $K_{os}[DMF] \ll 1$. This corresponds to the dependence of k_{ex} on the DMF concentration in the low concentration region. If the value of $K_{os}[DMF]$ is much larger than unity, Eq. 7 becomes $k_{ex} \simeq k_I$, which agrees with the fact that the dmf exchange rate becomes independent of the DMF concentration in its high region.

The values of k_d, k_I, and K_{os} were calculated by

using the nonlinear least-squares method. The results are shown in Table 2. The solid lines in Fig. 3 are the best-fit lines obtained from the calculated values of k_d, k_I, and K_{os} and indicate that the calculated values are in fair agreement with the experimental data. The activation parameters for k_d and k_I were obtained from the Eyring plot and are listed in Table 3.

The present results are different from those of Lincoln *et al.*[5] They reported that the rate of dmf exchange was independent of the free DMF concentration and that this exchange reaction proceeded through the D mechanism. In their experiments, the first-order rate constants are obtained from the lineshape analysis of the methyl proton signals of the free and coordinated DMF and the concentration range of free DMF (0.00213—0.04323 M) is lower than that of the present experiment (0.0123—0.588 M). Hence the different results in two works might be due to the differences in the experimental conditions.

Equilibrium between $[UO_2(dmf)_5]^{2+}$ and SCN^-. Figure 4 shows spectral changes of $[UO_2(dmf)_5]^{2+}$ with varying the concentration of thiocyanate ion from 0.01 M to 0.04 M in DMF. Although an isosbestic point is not observed, the most probable reaction corresponding to the spectral change is

$$[UO_2(dmf)_5]^{2+} + SCN^- \overset{K}{\rightleftharpoons} [UO_2(dmf)_4NCS]^+ + DMF. \quad (8)$$

The equilibrium constant K for this process was obtained from the following equation.

$$\frac{[UO_2(dmf)_5^{2+}]}{Abs-\varepsilon_1[UO_2(dmf)_5^{2+}]} = \frac{1}{\varepsilon_2-\varepsilon_1} + \frac{1}{(\varepsilon_2-\varepsilon_1)K[SCN^-]}, \quad (9)$$

where Abs is the observed absorbance, and ε_1 and ε_2 are the molar extinction coefficients of $[UO_2(dmf)_5]^{2+}$ and $[UO_2(dmf)_4NCS]^+$, respectively. If $[UO_2(dmf)_5^{2+}]/(Abs-\varepsilon_1[UO_2(dmf)_5^{2+}])$ is plotted against $1/[SCN^-]$, the plot should be linear. Indeed, Fig. 5 shows this linear relationship, which supports the validity of the reaction given by Eq. 8. From the slope and the intercept, the value of K was calculated and is listed in Table 4.

Equilibrium between $[UO_2(dmf)_5]^{2+}$ and N_3^-. When azide ions were added to a DMF solution of $[UO_2(dmf)_5]^{2+}$, a change in the absorption spectrum of $[UO_2(dmf)_5]^{2+}$ was much larger than that by the addition of thiocyanate ion. Therefore, the measurement of the equilibrium constant K for $[UO_2(dmf)_4N_3]^+$, was carried out under the conditions of $[UO_2(dmf)_5^{2+}] \gg [N_3^-]$ in order to avoid other complex formation. In this case, the value of K was calculated from the slope and the intercept in the plot of $[N_3^-]/(Abs-\varepsilon_1[UO_2(dmf)_5^{2+}])$ *vs.* $1/[UO_2(dmf)_5^{2+}]$ at 437 nm. The result is shown in Table 4.

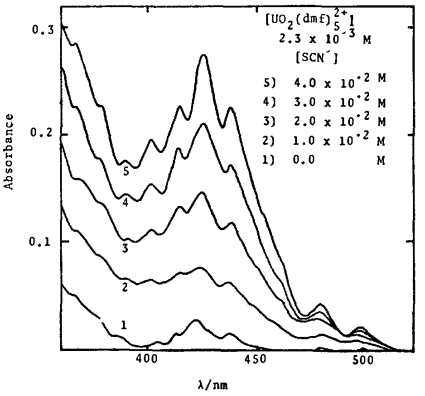

Fig. 4. The spectral change of $[UO_2(dmf)_5]^{2+}$ with varying the concentration of thiocyanate ion in DMF at 25 °C and μ=0.2 M ($NaClO_4$).

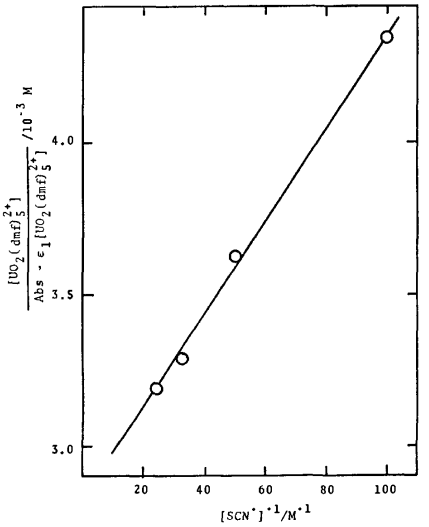

Fig. 5. The plot of $[UO_2(dmf)_5^{2+}]/(Abs-\varepsilon_1[UO_2(dmf)_5^{2+}])$ *vs.* $[SCN^-]^{-1}$ for the substitution reaction of $[UO_2(dmf)_5]^{2+}$ by thiocyanate ion at 25 °C, 437 nm, and μ=0.2 M ($NaClO_4$).

Anation Reaction. On the basis of the results of equilibrium constants measured spectrophotometrically, the pseudo-first-order rate constants, k_{obsd}, for the anation reactions by SCN^- and N_3^- were measured under the conditions of $[SCN^-]>[UO_2(dmf)_5^{2+}]$ and $[UO_2(dmf)_5^{2+}]>[N_3^-]$, respectively.

Figures 6 and 7 show the plots of k_{obsd} against $[SCN^-]$ and $[UO_2(dmf)_5^{2+}]$, respectively, which do not display a simple linear relationship, and the values of k_{obsd} approach each limiting value at high concentration region of $[SCN^-]$ and $[UO_2(dmf)_5^{2+}]$. Attempts were also made to examine the effect of the water on the anation reaction, in which the concentration of water was changed from 0.01 M to 0.1 M. It was found that water made no effect on the present anation reaction in this concentration range.

Table 4. Equilibrium constants at 298 K[a)]

Ligand	K / M^{-1}	K_{calcd} / M^{-1}
SCN^-	186±26	215±42

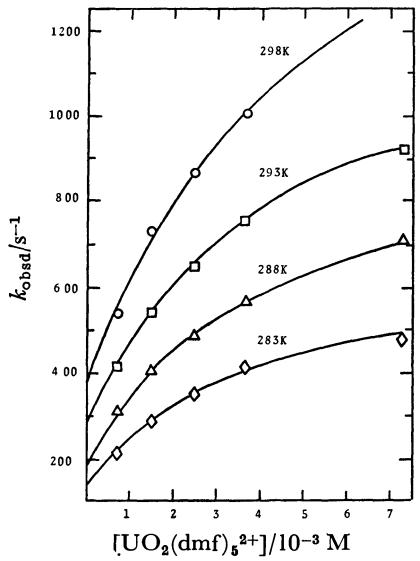

Fig. 7. Plots of k_{obsd} *vs.* $[UO_2(dmf)_5^{2+}]$ for the anation reaction by N_3^-.
The solid lines denote the least-squares best-fit lines.

Taking into account the result that the dmf exchange reaction in $[UO_2(dmf)_5]^{2+}$ seems to proceed predominantly through the I mechanism as described above, the following I mechanism appears to be the most plausible mechanism for the present anation reactions.

$$[UO_2(dmf)_5]^{2+} + L^- \overset{K_{os}}{\rightleftharpoons} [UO_2(dmf)_5]^{2+}\cdots L^-$$

$$[UO_2(dmf)_5]^{2+}\cdots L^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [UO_2(dmf)_4L]^+ + DMF,$$

where L^- is the SCN^- or N_3^- ion, and K_{os} is the outer-sphere complex formation constant. According to this mechanism, the observed rate constant, k_{obsd}, is given by Eq. 10

$$k_{obsd} = \frac{k_{-1}+(k_1+k_{-1})K_{os}[X]}{1+K_{os}[X]} \quad (10)$$

where X is SCN^- and $[UO_2(dmf)_5]^{2+}$ for the anation reactions by SCN^- and N_3^-, respectively, since these anation reactions were carried out under the conditions of $[UO_2(dmf)_5^{2+}]<[SCN^-]$ and $[UO_2(dmf)_5^{2+}]>[N_3^-]$, respectively. When $K_{os}[X]\ll 1$, Eq. 10 can be simplified to $k_{obsd}=k_{-1}+(k_1+k_{-1})K_{os}[X]$. This is in good agreement with the dependence of k_{obsd} on [X] in the low concentration region. If the value of $K_{os}[X]$ is much larger than unity, Eq. 10 becomes $k_{obsd}=k_1+k_{-1}$, which is consistent with the fact that the limiting values of k_{obsd} are obtained at high [X].

The values of k_1, k_{-1}, and K_{os} were calculated by the nonlinear least-squares method and are listed in Table 5. The solid lines obtained from the calculated values agree with the experimental results. The activation parameters for k_1 and k_{-1} obtained from the Eyring plots are shown in Table 3.

The outer-sphere complex formation constants for both reactions are nearly the same as shown in Table 5, while the interchange rate constants are fairly different. This seems to be reasonable since SCN^- and N_3^- ions have the same charge, nearly the same size and structure. Thus the interatomic distance between $[UO_2(dmf)_5]^{2+}$ and SCN^- or N_3^- in the outer-sphere

Table 5. Kinetic parameters of ligand substitution reaction[a)]

Ionic strength=0.2 M($NaClO_4$). a) The quoted errors represent the standard deviations.

complexes is assumed to be the same. In this case, the Fuoss equation[23] gives the same value for the outer-sphere complex formation constant. When the anation reaction proceeds through the interchange mechanism, the relationship between the equilibrium constant (K) and the outer-sphere complex formation constant (K_{os}) is generally given by the following equation.[24]

$$K = K_{ob}(1+k_1/k_{-1}) \quad (11)$$

The calculated values of K were obtained from Eq. 11 by using the values of k_1, k_{-1}, and K_{os} derived from kinetic measurements. It is found that the calculated K values (Table 4) are in remarkable agreement with those obtained spectrophotometrically. This fact also supports that the anation reactions by SCN^- and N_3^- proceed through the interchange mechanism. Table 3 indicates that the interchange rate constants (k_1) for the anation by SCN^- and N_3^- are smaller than that of dmf exchange reaction by a factor of about 10^3, and the values of ΔH^* for the anation reactions are larger than that for the dmf exchange reaction. These facts suggest that the anation reactions by SCN^- and N_3^- proceed through the associative interchange (I_a) mechanism. If the anation reaction proceeds through the dissociative interchange (I_d) mechanism, the interchange rate constants and ΔH^* values for the anation reactions should be consistent with those for the dmf exchange reaction. Additional evidence for the I_a mechanism is given by the interchange rate constants k_1 (Table 5), which depend strongly on the nature of the entering ligands SCN^- and N_3^-. The difference of the reactivities, *i.e.* $k_1^{N_3^-}/k_1^{SCN^-} \approx 10$, cannot be attributed to the outer-sphere complex formation, because the value of this ratio is much larger than the corresponding value for K_{os}, $K_{os}^{N_3^-}/K_{os}^{SCN^-}=1.2$ at 25 °C. Thus the different reactivity may be due to a difference in the nucleophilicity of SCN^- and N_3^- toward $[UO_2(dmf)_5]^{2+}$. The value of pK_a for HN_3 is much larger than that for HSCN.

It is concluded that the anation reactions by SCN^- and N_3^- proceed through the I_a mechanism since the interchange rate constants depend strongly on the nature of entering ligands, SCN^- and N_3^-. If it is reasonable to regard the anation reaction as a special case of the solvent exchange reaction where an anion in the second coordination sphere becomes the entering ligand rather than a solvent molecule in the same region,[22] it may be supposed that the k_I path in the dmf exchange reaction also proceeds through the I_a mechanism.

The authors wish to express their thanks to Dr. Roderick D. Cannon of the University of East Anglia, Messrs. Takashi Kojima and Masayuki Harada for their helpful discussions. This work was partly supported by the Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Preparation and Spectroscopic Studies of (Diethylenetriamine)cobalt(III) Complexes with L-Penicillaminate or Its Derivative

Katsuhiko WAKAYAMA,† Ken-ichi OKAMOTO,* Hisahiko EINAGA,†† and Jinsai HIDAKA

Department of Chemistry, University of Tsukuba, Sakura, Ibaraki 305

(Received December 11, 1982)

The (diethylenetriamine)(L-penicillaminato)cobalt(III) complex, $[Co(L\text{-pen})(dien)]^+$, was chromatographically separated into three isomers, *trans*(N_1N), *trans*(N_1O) and *trans*(N_1S). Each of these gave a corresponding isomer of the (diethylenetriamine)(*S*-methyl-L-penicillaminato)cobalt(III) complex, $[Co(L\text{-smp})(dien)]^{2+}$, by the reaction with dimethyl sulfate. The (triammine)(*S*-methyl-L-penicillaminato)cobalt(III) complex was also derived from the corresponding L-pen complex, $[Co(L\text{-pen})(NH_3)_3]^+$. The absorption and CD spectra of the L-pen complexes were compared with those of the L-smp ones to specify the geometrical configurations. The L-pen complexes exhibited characteristic absorption behavior and CD spectra in the region of $(14—30)\times10^3$ cm^{-1}.

Cobalt(III) complexes with the thioether type terdentate-*N*,*S*,*O* ligands such as *S*-methyl-L-cysteinate and L-methioninate have been characterized on the basis of their absorption and CD spectra.[1-6] However, the absorption and CD spectral behaviors of the complexes with the thiolato type ligands have not been clarified yet.[6,7] The thiolato type complexes generate the thioether ones by the reaction with dimethyl sulfate.[6] This reaction is useful for the investigations of the spectrochemical and stereochemical properties for the thiolato type complexes.

In this work, the (diethylenetriamine)(L-penicillaminato)cobalt(III) complex, $[Co(L\text{-pen})(dien)]^+$, was prepared and chromatographically separated into three geometrical isomers, *trans*(N_1N), *trans*(N_1O), and *trans*(N_1S) (Fig. 1). Each of the L-pen isomers gave the corresponding isomer of the (diethylenetriamine)(*S*-methyl-L-penicillaminato)cobalt(III) complex, $[Co(L\text{-smp})(dien)]^{2+}$, on reaction with dimethyl sulfate. The (triammine)(*S*-methyl-L-penicillaminato)cobalt(III) complex, $[Co(L\text{-smp})(NH_3)_3]^{2+}$, was derived from the corresponding L-pen complex, $[Co(L\text{-pen})(NH_3)_3]^+$, by the same reaction as that for the dien complex. The structural assignments of the isomers for $[Co(L\text{-smp})(dien)]^{2+}$ are fairly difficult, because the three L-smp isomers which belong to a *cis*(*SO*)-$[Co(S)(O)(N)_4]$ type show quite similar absorption spectra. Therefore, one of $[Co(L\text{-pen})(dien)]^+$ isomers was preliminarily determined to have a *trans*(N_1N) configuration by the X-ray crystal structure analysis.[8] On the basis of the absorption and CD spectra of *trans*(N_1N)-$[Co(L\text{-pen})(dien)]^+$ and the result derived from the reaction of the *trans*(N_1N) L-pen isomer with dimethyl sulfate, the absorption and CD spectra of the L-pen and L-smp complexes will be discussed to specify their geometrical configurations.

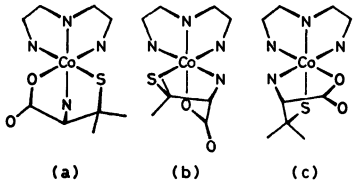

Fig. 1. Three geometrical isomers of $[Co(L\text{-pen or L-smp})(dien)]^{+ \text{ or } 2+}$; (a) *trans*($N_1N$), (b) *trans*($N_1O$), and (c) *trans*($N_1S$).

Experimental

1) (Diethylenetriamine)(L-penicillaminato)cobalt(III) Chloride. *[Co(L-pen)(dien)]Cl*: This complex was prepared and separated into three isomers by the method described in the previous paper.[8] Dark-brown needle crystals were obtained from the first eluate (A-1) of the three brown bands eluted, A-1, A-2, and A-3. The A-1 isomer was determined to have a *trans*(N_1N) isomer by the X-ray crystal structure analysis.[8] Found for A-1: C, 30.51; H, 6.73; N, 15.12%. Found for A-2: C, 30.04; H, 6.67; N, 15.56%. Calcd for $[Co(L\text{-pen})(dien)]Cl\cdot H_2O = CoC_9H_{22}N_4O_2SCl\cdot H_2O$: C, 29.80; H, 6.69; N, 15.44%. Found for A-3: C, 30.37; H, 6.28; N, 16.00%. Calcd for $[Co(L\text{-pen})(dien)]Cl\cdot 0.25H_2O$: C, 30.95; H, 6.49; N, 16.04%.

2) (Diethylenetriamine)(S-methyl-L-penicillaminato)cobalt(III) Chloride. *[Co(L-smp)(dien)]Cl_2*: This complex was prepared by the reaction of $[Co(L\text{-pen})(dien)]^+$ obtained in 1) with dimethyl sulfate. About 10 cm^3 of dimethyl sulfate was added drop by drop to a solution containing 0.5 g of the A-1 isomer of $[Co(L\text{-pen})(dien)]^+$ in 10 cm^3 of water and the mixture was mechanically stirred for a few minutes. When the mixture had been allowed to stand at room temperature for a while, it separated into two layers: a brown (upper) layer and a cloudy colorless (lower) layer. The former changed gradually from brown to reddish orange. After being allowed to stand at room temperature for about 5 h, the reddish orange solution was separated and poured onto a column of SP-Sephadex C-25 (Na^+ form, 3×40 cm). After the column was swept with water, the adsorbed reddish orange band was eluted with a 0.15 mol dm^{-3} aqueous solution of sodium chloride. Only one reddish orange band was eluted and fractionated. It was found, from the absorption and CD spectra of the fractionated eluates, that the eluate contained only one isomer (B-1). Then the fractions were combined and concentrated to a small volume with a rotary evaporator at about 20 °C. The deposited sodium chloride was filtered off. After a large amount of ethanol was added to the filtrate, the solution was kept in a refrigerator overnight. The B-1 isomer obtained was recrystallized from a small amount of water by the addition of acetone. Similarly, the B-2 and B-3 isomers were derived from the A-2 and A-3 isomers by a reaction with dimethyl

sulfate. Found for B-1: C, 29.82; H, 6.46; N, 13.68%. Calcd for $[Co(L\text{-}smp)(dien)]Cl_2 \cdot 0.5H_2O = CoC_{10}H_{25}N_4O_2SCl_2 \cdot 0.5H_2O$: C, 29.71; H, 6.48; N, 13.86%. Found for B-2: C, 28.00; H, 6.62; N, 13.31%. Calcd for $[Co(L\text{-}smp)(dien)]Cl_2 \cdot 1.5H_2O$: C, 28.44; H, 6.68; N, 13.27%. Found for B-3: C, 26.92; H, 6.82; N, 12.95%. Calcd for $[Co(L\text{-}smp)(dien)]Cl_2 \cdot 2.5H_2O$: C, 27.28; H, 6.87; N, 12.73%.

3) (Triammine)(L-penicillaminato)cobalt(III) Ion. *[Co(L-pen)(NH$_3$)$_3$]$^+$*: A hot solution (*ca.* 40 °C) containing 4.5 g of $[Co(NH_3)_6]Cl_3$[9] in 50 cm^3 was adjusted to pH *ca.* 2.5 by the addition of 15% hydrochloric acid. To this solution were added 2 g of L-penicillamine and a small amount of activated charcoal. The mixture was mechanically stirred at 40 °C for 15 min. The resultant mixture was filtered in order to remove the activated charcoal, after cooling to room temperature. The filtrate was poured onto a column of SP-Sephadex C-25 (Na^+ form, 5×40 cm). After the column was swept with water, the adsorbed brown band was eluted with a 0.075 mol dm^{-3} aqueous solution of sodium perchlorate. Two colored bands, a large amount of the brown band and a small amount of the yellow one, were eluted in this order. Of the two eluates, the yellow eluate was found to contain a by-product without the coordinated sulfur atom, because the absorption spectrum of this eluate did not show the charge transfer band in the region of (30—35)×10^3 cm^{-1}. The absorption spectrum of the brown eluate was similar to that of *trans(N$_1$N)*-[Co(L-pen)(dien)]$^+$[8] in the whole region and showed the charge transfer band at 34.7×10^3 cm^{-1}. As described in 4), furthermore, the brown eluate gave $[Co(L\text{-}smp)(NH_3)_3]^{2+}$ after treatment with dimethyl sulfate. These facts suggest that the brown eluate contained only $[Co(L\text{-}pen)(NH_3)_3]^+$. However, the complex was so unstable that it could not be isolated in solid state. The absorption and CD spectra of $[Co(L\text{-}pen)(NH_3)_3]^+$ were measured with a solution passed through a cation exchange column; they are illustrated with an arbitrary scale in Fig. 5.

4) (Triammine)(S-methyl-L-penicillaminato)cobalt(III) Perchlorate. *[Co(L-smp)(NH$_3$)$_3$](ClO$_4$)$_2$*: This complex was prepared by the same procedure as in 2), using the brown eluate obtained in 3) instead of $[Co(L\text{-}pen)(dien)]^+$. The complex treated with dimethyl sulfate was chromatographed on the column (SP-Sephadex C-25, Na^+ form) as in 2). Only one reddish orange band was eluted. It was found, from the comparison of the absorption spectrum of the brown eluate to those of $[Co(L\text{-}smp)(dien)]^{2+}$ isomers in 2), that the eluate contained only $[Co(L\text{-}smp)(NH_3)_3]^{2+}$. The eluate was concentrated to a small volume with a rotary evaporator at about 20 °C. The deposited sodium perchlorate was filtered off and to the filtrate was added a small amount of ethanol. The complex which precipitated was collected and recrystallized from as little water as possible by the addition of acetone. The pure complex was washed with ethanol and ether, and then dried in a vacuum desiccator over $CaCl_2$. Found: C, 15.08; H, 4.50; N, 11.66%. Calcd for $[Co(L\text{-}smp)(NH_3)_3](ClO_4)_2 \cdot 0.25H_2O = CoC_6H_{21}N_4O_{10}SCl_2 \cdot 0.25H_2O$: C, 15.15; H, 4.56; N, 11.78%.

Measurements. The electronic absorption spectra were recorded with a JASCO UVIDEC-1 spectrophotometer, and the CD spectra with JASCO J-20 and J-500 spectropolarimeters. All measurements were carried out in aqueous solution at room temperature.

The ^{1}H NMR spectra were recorded in deuterium oxide on a JEOL JNM-FX-100 NMR spectrometer at the probe temperature. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as an internal reference.

Results and Discussion

Structural Assignment. For $[Co(L\text{-}pen)(dien)]^+$ and for $[Co(L\text{-}smp)(dien)]^{2+}$, three geometrical isomers are possible. These isomers are designated as *trans(N$_1$N)*, *trans(N$_1$O)*, and *trans(N$_1$S)* with respect to the coordinated atoms as shown in Fig. 1, where N_1 denotes the imino nitrogen atom of the coordinated dien. The three isomers, B-1, B-2, and B-3, of $[Co(L\text{-}smp)(dien)]^{2+}$ were derived from the A-1, A-2, and A-3 isomers of $[Co(L\text{-}pen)(dien)]^+$ by the reaction with dimethyl sulfate. Of the three L-pen isomers, the A-1 isomer was preliminarily determined to have a *trans(N$_1$N)* configuration by the X-ray crystal structure analysis[8] which is a basis of the present work. As shown in Figs. 2—4 and Table 1, the absorption spectra of the three L-smp isomers resemble one another

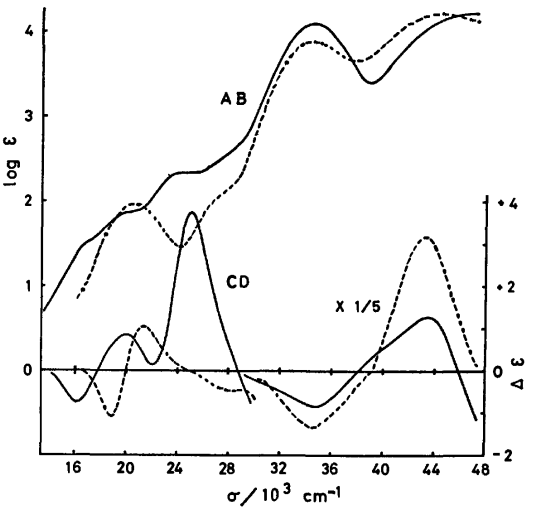

Fig. 2. Absorption and CD spectra of *trans(N$_1$N)*-$[Co(L\text{-}pen)(dien)]^+$ (——) and *trans(N$_1$N)*-$[Co(L\text{-}smp)(dien)]^{2+}$ (----).

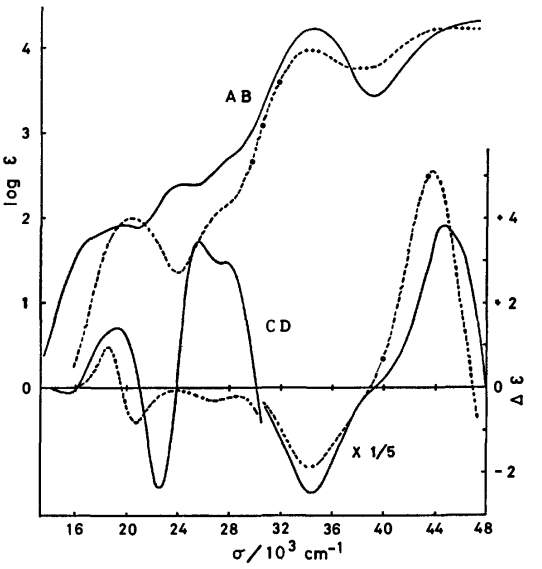

Fig. 3. Absorption and CD spectra of *trans(N$_1$O)*-$[Co(L\text{-}pen)(dien)]^+$ (——) and *trans(N$_1$O)*-$[Co(L\text{-}smp)(dien)]^{2+}$ (----).

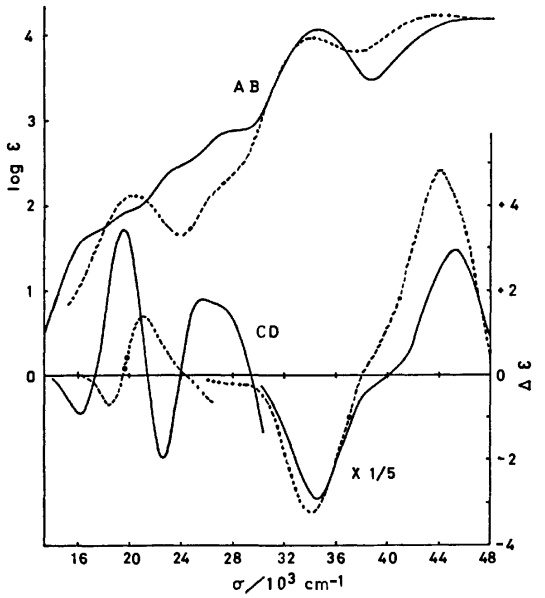

Fig. 4. Absorption and CD spectra of *trans*(N_1S)-[Co(L-pen)(dien)]$^{+}$ (——) and *trans*(N_1S)-[Co(L-smp)-(dien)]$^{2+}$ (----).

in the whole region, because these isomers belong to a *cis(SO)*-[Co(S)(O)$(N)_4$] type having a thioether group. The absorption spectra of the three L-pen isomers, which have a thiolato instead of a thioether group, differ remarkably from those of the L-smp isomers in the region of $(14—30)\times10^3$ cm^{-1}. A difference in absorption spectral behavior is also observed between the triammine complexes, [Co(L-pen)$(NH_3)_3$]$^{+}$ and [Co(L-smp)$(NH_3)_3$]$^{2+}$, as shown in Fig. 5 and Table 1.

Trans(N_1N*)*-[Co(L-pen)(dien)]$^{+}$ (A-1 isomer) did not isomerize in aqueous solution and gave only one isomer (B-1) of [Co(L-smp)(dien)]$^{2+}$ by the reaction with dimethyl sulfate. In a previous paper,[6] the reaction of the coordinated thiolato donor atoms of *trans(N)*- or *trans(O)*-[Co(D-pen)$_2$]$^{-}$ with dimethyl sulfate was accompanied by the geometrical isomerization and the three isomers of [Co(D-smp)$_2$]$^{+}$, *trans(N)*, *trans(O)*, and *trans(S)*, were obtained. Similar isomerization in aqueous solution was also observed for the cobalt(III) complexes with the tripod-like terdentate ligands such as *S*-methyl-L-cysteinate, L-histidinate, and L- or D-aspartate.[6,10-12] When these facts are taken into account, the present result suggests that the reaction of the A-1 isomer with dimethyl sulfate proceeded with retention of the *trans(*N_1N*)* configuration, namely, the B-1 isomer of [Co(L-smp)-(dien)]$^{2+}$ held the *trans(*N_1N*)* configuration because of the rigidity of the coordinated dien.[13] Each of the remaining two L-pen isomers (B-2 and B-3) also gave only one isomer of the L-smp complex by the reaction with dimethyl sulfate, respectively. Namely, the B-2 isomer of [Co(L-smp)(dien)]$^{2+}$ was derived from the A-2 isomer of [Co(L-pen)(dien)]$^{+}$ and the B-3 L-smp isomer from the A-3 L-pen one. The consideration used for the *trans(*N_1N*)* isomers suggests that the B-2 and B-3 isomers retain the geometrical configurations of the A-2 and A-3 ones.

a) sh denotes a shoulder.

In the first absorption band region, the B-1, B-2, and B-3 isomers of the L-smp complex commonly show a sharp band at around 20×10^3 cm^{-1} (Figs. 2—4 and Table 1), as in the isomers of [Co(ida)(dien)]$^{+}$ (ida; iminodiacetate),[14] [Co(L-alama)(dien)]$^{+}$ (L-alama; *N*-

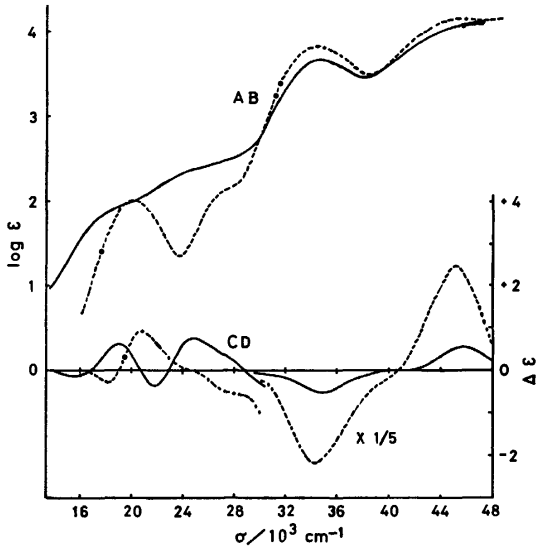

Fig. 5. Absorption and CD spectra of [Co(L-pen)-$(NH_3)_3]^+$ (——) and $[Co(L\text{-smp})(NH_3)_3]^{2+}$ (----). The L-pen complex is illustrated with arbitrary scale.

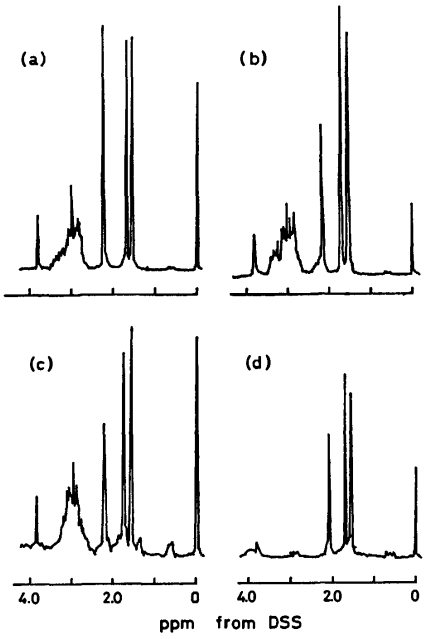

Fig. 6. ^1H NMR spectra of the L-smp complexes; (a) *trans*(N_1N), (b) *trans*(N_1O), and (c) *trans*(N_1S) for $[Co(L\text{-smp})(dien)]^{2+}$, and (d) $[Co(L\text{-smp})(NH_3)_3]^{2+}$.

(carboxylatomethyl)-L-alaninato),[14] and [Co(L- or D-asp)(dien)]$^+$ (asp; aspartate),[15] indicating the proximity of the thioether and COO^- groups in the spectrochemical series.[3-6] The CD spectra of the L-smp isomers in the corresponding region give useful information for the assignments of their geometrical configurations. As shown in Fig. 1, (b) and (c) are quasi-antipodal in overall form, while (a) is symmetrical in comparison with (b) and (c), as in the case of the three isomers of [Co(D-asp)(dien)]$^+$.[15] Indeed, the CD spectrum of the B-1 isomer assigned to *trans*-(N_1N) configuration shows a quite similar CD pattern to that of $[Co(L\text{-smp})(NH_3)_3]^{2+}$, which has no chirality arising from the skew pair of the chelate rings (Figs. 2 and 5, and Table 1). On the other hand, the B-2 and B-3 isomers exhibit an almost enantiomeric CD spectral pattern in the first absorption band region, reflecting a quasi-antipodal relationship between the two isomers. The relationship of the B-2 and B-3 isomers is comparable with that of the u^1-*cis* and u^2-*cis* isomers of [Co(L-asp)(dien)]$^+$,[16] namely, the CD spectra of the B-2 and B-3 isomers correspond to those of the u^2-*cis* and u^1-*cis* isomers of [Co(L-asp)(dien)]$^+$,[15] respectively, in the first absorption band region. From this viewpoint, the B-2 and B-3 isomers are tentatively assigned to *trans*(N_1O) and *trans*(N_1S), respectively. The same conclusion is also obtained by comparing the CD spectra of the B-2 and B-3 isomers with those of the *Δ*- and *Δ-unsym-cis*(*O*) isomers of [Co(ida)-(dien)]$^+$ and [Co(L-alama)(dien)]$^+$.[14] Namely, in the first absorption band region, the B-2 isomer shows the CD pattern corresponding to the *Δ-unsym-cis*(*O*) isomer and prefers *trans*(N_1O), while the B-3 isomer shows the pattern appropriate to the *Δ-unsym-cis*(*O*) isomer and prefers *trans*(N_1S). The CD spectral behavior of the L-smp isomers in the first absorption band region and the results that the reaction of the L-pen isomers with dimethyl sulfate proceeded with retention of their geometrical configurations allow us to assign the A-2 and B-2 isomers as *trans*(N_1O), and the A-3 and B-3 isomers as *trans*(N_1S).

The thioether type sulfur atom takes the *R*(*S*) or *S*(*S*) configuration when coordinated with a cobalt(III) ion. As shown in Fig. 6, each isomer of [Co(L-smp)-(dien)]$^{2+}$, and $[Co(L\text{-smp})(NH_3)_3]^{2+}$ exhibit a single peak in the *S*-methyl protons region (2.23 ppm for *trans*(N_1N), 2.22 ppm for *trans*(N_1O) and 2.18 ppm for *trans*(N_1S) of the dien complex, and 2.07 ppm for the triammine complex). In general, for the cobalt-(III) complexes with the thioether type ligands having *S*-methyl group, the *S*-methyl protons signals of the *R*(*S*) and *S*(*S*) configurations can be distinguished.[5,6,17,18] The present results suggest that the sulfur atoms of the four complexes take either *R*(*S*) or *S*(*S*). If the sulfur center in the *trans*(N_1N) and *trans*(N_1O) isomers takes *R* configuration, a repulsion exists between an *S*-methyl group and an ethylenediamine moiety of the dien. There is no such repulsion in the *S*-form coordination. Accordingly, it is probable that the sulfur atoms of the *trans*(N_1N) and *trans*-(N_1O) isomers take *S* configuration. Similarly, model inspection of the interligand interaction between the *S*-methyl group and amino group for the *trans*(N_1S) isomer or ammine group for the triammine complex suggests that the coordinated sulfur atoms have *S* configuration.

Absorption and CD Spectra. In the energy region higher than the charge transfer band at about 34×10^3 cm^{-1}, the absorption and CD spectra of the isomers of [Co(L-pen)(dien)]$^+$ are quite similar to those of the L-smp isomers (Figs. 2—4 and Table 1). The triammine complexes, $[Co(L\text{-pen})(NH_3)_3]^+$ and $[Co(L\text{-smp})(NH_3)_3]^{2+}$, also exhibit similar absorption and CD spectral behavior to the dien complexes (Fig. 5 and Table 1). The CD pattern of the triammine complexes are due to the coordination of L-pen and

L-smp, respectively. In this region, the CD pattern of the present complexes seems to depend mainly on the absolute configuration of L-thiolato and L-thioether type ligands. In the higher energy region, the similarity of CD pattern in the present L-pen and L-smp isomers should be noted and compared with the difference in CD pattern between the corresponding isomers of $[Co(D\text{-pen})_2]^-$ and $[Co(D\text{-smp})_2]^+$.[6] In the lower energy region [$(14—30)\times10^3$ cm^{-1}], in contrast to the higher energy region, the absorption and CD spectra of the L-pen isomers deviate from those of the L-smp ones. First, the first absorption bands of the L-pen isomers shift to lower energy than those of the L-smp ones and are broader because of a thiol coordination.[6,7,19] The CD spectra of the [Co(L-pen)(dien)]$^+$ isomers consist of three components in the first absorption band region, as seen in Figs. 2—4. This CD pattern corresponds well with that of $[Co(L\text{-pen})(NH_3)_3]^+$ and it seems that the coordinated dien contributes little to the CD pattern in the first absorption band region. Secondly, the absorption and CD spectral differences between the L-pen and L-smp isomers are remarkable in the region of $(24—30)\times10^3$ cm^{-1}. The L-smp isomers exhibit the second absorption band as a shoulder, while the L-pen isomers exhibit two more intense absorption bands in the corresponding region (Figs. 2—4 and Table 1). The CD spectra of the *trans(N$_1$O)* and *trans(N$_1$S)* isomers of [Co(L-pen)(dien)]$^+$ consist of two positive bands, which correspond well with the two absorption components in this region. *Trans(N$_1$N)* isomer of [Co(L-pen)(dien)]$^+$ and $[Co(L\text{-pen})(NH_3)_3]^+$ which are more symmetrical in configuration than the *trans(N$_1$O)* and *trans(N$_1$S)* isomers show a positive CD band with a vague shoulder in the higher energy side (Figs. 2 and 5). Similar absorption and CD spectral behavior can also be observed for the other penicillaminato mixed complexes of [Co(L-pen)(terdentate)] type, where terdentate denotes L-histidinate, L-2,4-diaminobutylate and L-ornithinate.[20] The sign of the two CD bands depends on the absolute configuration of the optically active penicillaminate coordinated, namely, a positive sign for the L-pen and negative one for the D-pen,[20] as in the case of *trans(N)*- and *trans(O)*-$[Co(D\text{-pen})_2]^-$.[6] The L-pen mixed complexes commonly show two positive CD bands, while the $[Co(D\text{-pen})_2]^-$ isomers seem to show a negative CD band in the corresponding region.[6] This difference in CD pattern may be due to the lowering of symmetry of the thiolato type complexes.

(Received January 20, 1983)

A new procedure for the spectrophotometric determination of iron(II) after collection of its ternary complex with 1,10-phenanthroline and tetraphenylborate on microcrystalline naphthalene is described. In the presence of tetraphenylborate, the tris(1,10-phenanthroline)iron(II) ion is quantitatively collected on microcrystalline naphthalene as the ion-association complex. The system conforms to Beer's law over the range 3—50 μg of iron in 10 ml of the solvent. The molar absorptivity was 1.2×10^4 l mol^{-1} cm^{-1} at 514 nm. The effect of various factors, such as wavelength, pH, amounts of reagent and naphthalene, shaking time, and diverse ions, were also studied. The procedure method was satisfactorily applied to the determination of iron in standard aluminium alloy, aluminium, and magnesium metals.

1,10-Phenanthroline is a sensitive and selective reagent for iron(II) and it has been widely employed for the spectrophotometric determination of iron and the method has been applied to the determination of iron[1] in alloys, metals and water samples.

The water-soluble complex ferroin, $[Fe(phen)_3]^{2+}$ produced with this is insoluble in organic solvents, but some of its ion-association complexes with colorless inorganic anions, such as ClO_4^-, I^-, SCN^-, CN^-, BF_4^-, $PtCl_6^-$, $AuCl_4^-$, $AuBr_4^-$, and with some organic anions such as pentachlorophenolate, trichloroacetate, and 1,2-bis(octyloxycarbonyl)ethanesulfonate, are extractable by suitable organic solvents and may be used for the extractive colorimetric determination of metals[2-4] or of the associated anions.[5-7]

Since 1969, we have developed a new method[8-12] for the spectrophotometric determination of trace metals using naphthalene as an extractant or collector, as well as by solvent extraction in chloroform or benzene. In the present communication, the technique described above was used for the collection of iron ion which forms ion-association complex with complexing reagent at room temperature.

We have observed that the cationic complex $[Fe(phen)_3]^{2+}$ reacts with sodium tetraphenylborate to form a very stable water-insoluble colored ternary complex. This ternary complex is difficult to be dissolved in organic solvents except with nitrobenzene because of low solubility of the complex in solvent. However, this complex can be easily collected on microcrystalline naphthalene even by vigorous shaking for a few seconds and is freely soluble in acetonitrile and *N,N*-dimethylformamide, which are miscible with water. This simple and inexpensive procedure can be successfully applied for analysis of iron in metal alloys.

Experimental

Reagents. Standard iron(III) solution, 1000 ppm. Prepared by dissolving 0.8635 g of ammonium iron(III) sulfate dodecahydrate in 100 ml of 0.5 M (1 M = 1 mol dm^{-3}) H_2SO_4 and by diluting to 500 ml with water.

1,10-Phenanthroline(phen) solution, 0.2%. Prepared by dissolving 0.2 g of the reagent in a small volume of concentrated hydrochloric acid and diluting to 100 ml with water.

Hydroxylammonium chloride solution, 2% in water.

Sodium tetraphenylborate solution, 1% water.

Naphthalene solution, 20% in acetone.

Buffer solutions were prepared by mixing 1 M acetic acid and 1 M ammonium acetate solution for pH 3—6, and 1 M aqueous ammonia and 1 M ammonium acetate solution for pH 8—11.

Naphthalene, acetone, *N,N*-dimethylformamide, and all other reagents were of analytical-reagent grade, and were used without further purification.

Apparatus. The absorbance measurements were made with a Bausch and Lomb spectronic-70 spectrophotometer, using 1 cm cells.

All the pH measurements were done with a Beckman Model H-2 pH meter.

Procedure. Transfer a sample solution containing 3—50 μg of iron(III) to a tightly stoppered Erlenmeyer flask (100 ml), add 1.0 ml of 2% hydroxylammonium chloride solution and 5.0 ml of 0.2% 1,10-phenanthroline solution and adjust pH to 4.5 with 2.0 ml of acetate buffer. Mix the solution, add 1.0 ml of 1% sodium tetraphenylborate solution and let stand for 10 min. Add 2.0 ml of 20% naphthalene solution in acetone to this sample solution using a small nozzled pipe attached to a rubber bulb, and shake the mixture vigolously for 30 s. Collect the colored naphthalene mixture on a filter paper placed flat on a Teflon filter plate in a funnel or a sintered glass filter (No. 2) by filtration. Wash it with water and dry at 50—60 °C. Then dissolve the mixture in *N,N*-dimethylformamide and dilute to exactly 10 ml. Measure the absorbance of the solution in a 1-cm glass cell against the reagent blank.

Results and Discussion

Absorption Spectra. Sample solution containing 30 μg of iron(II), 5.0 ml of 0.2% 1,10-phenanthroline solution and 1.0 ml of 1% sodium tetraphenylborate solution was prepared by the procedure. The absorption spectrum of the iron(II)–phen–TPB complex in naphthalene–*N,N*-dimethylformamide solution is shown in Fig. 1, together with that of the reagent blank. The ternary complex has its absorbance maximum at 514 nm. The reagent blank does not absorb at wavelengths longer than 430 nm. Therefore, 514 nm was

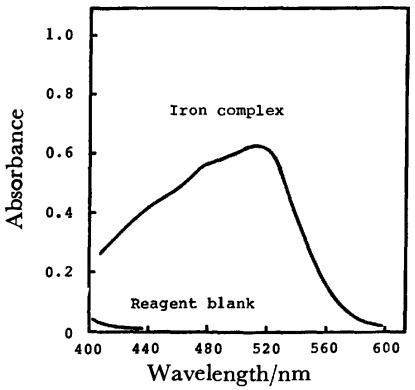

Fig. 1. Absorption spectra of 1,10-phenanthroline and ternary complex with sodium tetraphenylborate in naphthalene-*N*,*N*-dimethylformamide solution.
Iron(II): 30 μg; pH: 4.5; 0.2% 1,10-phenanthroline: 5.0 ml; 1% sodium tetraphenylborate: 1.0 ml; reference: water.

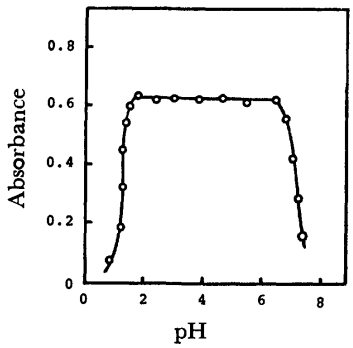

Fig. 2. Effect of pH.
Iron(II): 30 μg; wavelength: 514 nm; 0.2% 1,10-phenanthroline: 5.0 ml; 1% sodium tetraphenylborate: 1.0 ml; naphthalene: 1.5 g; shaking time: 30 s; standing time: 30 min, reference: reagent blank.

chosen as an optimum wavelength.

Effect of pH. The effect of pH on the absorbance of the ternary complex was investigated with a sample containing 30 μg of iron. The pH of the solution after collection was measured at room temperature. The pH for the collection of the ternary complex on microcrystalline naphthalene was varied between 0.5 and 7.7. The optimum pH for quantitative collection was 1.7—6.4, as shown in Fig. 2. Hence pH 4.5 was chosen for convenience.

Effect of Hydroxylammonium Chloride Concentration. Varying amounts of hydroxylammonium chloride as a reducing agent were added to the sample containing 30 μg of iron(III). Iron(III) was completely reduced to iron(II) with 0.2 ml of 2% solution to 5.0 ml of 10% hydroxylammonium chloride solution. In this study, 1.0 ml of 2% solution was used.

Effect of 1,10-Phenanthroline and Sodium Tetraphenylborate Concentration. The effect of 1,10-phenanthroline concentration on the absorbance was examined with a solution containing 30 μg of iron. With other variables held constant, 0.3 ml of 0.2% 1,10-phenanthroline solution was found to be sufficient for full color development for 30 μg of iron. The absorbance remained constant even with 8.0 ml of the reagent (Fig. 3).

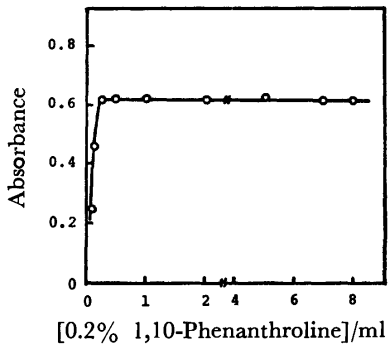

Fig. 3. Effect of 1,10-phenanthroline concentration.
Iron(II): 30 μg; wavelength: 514 nm; pH: 4.5; rest of the conditions were the same as above. Reference: reagent blank.

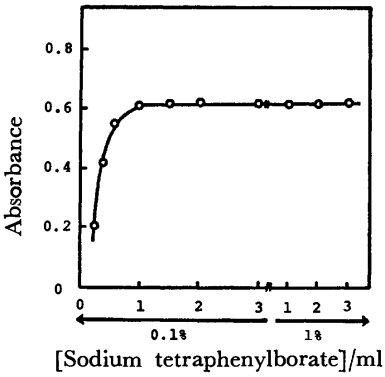

Fig. 4. Effect of sodium tetraphenylborate concentration.
Iron(II): 30 μg; wavelength: 514 nm; rest of the conditions were the same as above. reference: reagent blank.

Similar studies with a sodium tetraphenylborate showed that the absorbance remained unchanged over the range of 1.0 ml of 0.1% TPB solution to 3.0 ml of 1% TPB solution (Fig. 4). In this work, 5.0 ml of 0.2% 1,10-phenanthroline solution and 1.0 ml of 1% sodium tetraphenylborate solution were used.

Effect of Addition of Buffer Solution and Digestion Time. Addition of 0.5—5.0 ml of the acetate buffer did not cause practically variation in the absorbance. Thus 1.5 ml of the buffer was added for collection. A solution containing the iron(II)-phen-TPB complex was digested at room temperature (20—25 °C). The rate of formation of this ion-association complex is very fast at room temperature. The complex was found to be stable even at a temperature of 81 °C. It was scarcely dissociated in aqueous solution.

Effect of Naphthalene Concentration and Shaking Time. The collection of the ternary complex in the solution was carried out with addition of 0.5—4.0 ml of 20% naphthalene solution in acetone by vigorous shaking for 30 s. The collection did not cause any change with increasing amount of naphthalene. Thus, 2.0 ml of 20% naphthalene solution was taken as the suitable amount. Two ml of 20% naphthalene solution was added to the solution containing the ternary complex, and the mixed solution was shaken vigorously for 90 s. The complex was completely collected on naphthalene by vigorous shaking for a few seconds. Shaking

for 30 s was found to be satisfactory for complete collection.

Effect of Volume of Aqueous Phase. The volume of aqueous phase was varied between 40 and 2400 ml, and the effect of volume of aqueous phase on the absorbance was examined. The absorbance was almost constant over the range of up to 2200 ml, but decreased gradually with increase in the volume of aqueous phase. For larger volumes of aqueous phase, the collection of the complex on naphthalene was carried out by using a larger volumes of the reagent solutions and shaking and digestion for longer time. In this series of tests, 10 ml of 0.2% 1,10-phenanthroline solution and 2.5 ml of 1% sodium tetraphenylborate solution were taken; the mixed solution was shaken for 2 min and digested for 20 min, 3.0 ml of 20% naphthalene solution being used.

Effect of Standing Time. The collected naphthalene mixture was dissolved in *N,N*-dimethylformamide. The color of the complex thus obtained is very stable, and the absorbance remained constant for a long time.

Calibration Curve. Based on the optimum conditions described above, a calibration curve was constructed according to the procedure. Beer's law was obeyed for 3—50 μg of iron(II) in 10 ml of *N,N*-dimethylformamide, at 514 nm. The molar absorptivity at 514 nm was found to be 1.2×10^4 l mol^{-1} cm^{-1}. The sensitivity was 0.0047 μg/cm^2 in *N,N*-dimethylformamide and 0.0050 μg/cm^2 in aqueous medium for 0.001 absorbance. Ten parallel determinations of 30 μg of iron gave a standard deviation of 0.00421 μg with relative standard deviation of 0.66%.

Choice of Solvent. Tests were made with various organic solvents to dissolve the collected naphthalene mixture. This mixture is easily soluble in *N,N*-dimethylformamide and acetonitrile, but insoluble in dioxane, chloroform, benzene, toluene, xylene, *o*-dichlorobenzene, isopentyl acetate, isobutyl methyl ketone (MIBK), carbon tetrachloride, methanol, ethanol, chlorobenzene, *etc*, at room temperature.

Effect of Diverse Ions. The effect of diverse ions on the iron determination was studied by adding various amounts of diverse ions in question to a solution containing 30 μg of iron and applying the procedure. The tolerance limits (error<5%) for the diverse ions are listed in Table 1. Most of the alkali salts did not interfere, but only 2 and 7 mg of KCN and sodium oxalate respectively could be tolerated. Larger amounts of inorganic anions such as thiocyanate and perchlorate, which form the ion-association complex, did not interfere in the determination. Bi^{3+} (100 μg) and Sn^{2+}(300 μg) also would be tolerated. If the iron content in practical samples is lower and diverse metal ions interfere with iron determination, extraction by organic solvents(MIBK or diethyl ether) is very efficient for the iron determination.

Analysis of Iron in Reference Material and Metal Samples. The proposed method was applied to the determination of iron in the reference material(aluminium alloy), metallic aluminium and magnesium samples, and the results (Table 2) are in reasonably good agreement with those obtained by the standard spectrophotometric procedure employing 2,4,6-tripyridyl-*s*-triazine (TPTZ) method[13-14]. The analytical procedures were as follows: 1.0 g of standard aluminium alloy (NBS, SRM-85b) was accurately taken in a 100-ml beaker to which were added 40—50 ml of hydrochloric acid (1+1) and 3 ml of 30% hydrogen peroxide. This was heated over the boiling water for about 10 min, the mixture dissolved completely and the excess of hydrogen peroxide decomposed. After cooling the volume of sam-

		Zn^{2+}	4000 μg

Iron(II): 30 μg; pH: 4.5; 0.2% 1,10-phenanthroline: 5.0 ml. a) Error <5%.

TABLE 2. ANALYSIS OF SAMPLES FOR ION

Sample	Composition of alloy/%	Iron, certified value/%	Iron content[a)]/%	
			Present method	TPTZ method
N. B. S. SRM-85b Al alloy	Cu:3.99, Cr:0.21 Mn:0.61, Ni:0.089 Si:0.18, Ti:0.022 Zn:0.03, Ga:0.019 V:0.006, Pb:0.021	0.24	0.239±0.002	0.238±0.001
Aluminium metal (powder)	—	—	0.136±0.001	0.138±0.001
Magnesium metal (powder)	—	—	0.0024±0.0002	0.0025±0.0001

a) Average of 5 individual samples.

ple was completed to 200 ml with water. An aliquot of this sample was taken in a separatory funnel, followed by 40 ml of hydrochloric acid (1+1). Iron(III) in this sample was extracted by vigorous shaking for 5 min with 20 ml of MIBK.[15] It was then back-extracted from the organic phase with 25 ml of water and the proposed method and TPTZ procedure were applied.

Metallic aluminium powder was analyzed in the same way as for the case of the standard aluminium alloy.

Metallic magnesium powder was analyzed in the same way as described above.

In the present work, the collection of the ternary complex on naphthalene is easily achieved merely by contact with microcrystalline naphthalene or by vigorous shaking for a few seconds. A very small amount (0.5 g) of the organic phase (naphthalene) is required for the complete collection which enhances the sensitivity as the whole of the organic phase may be taken for the analysis. Generally diverse metal ions and alkali metal salts (Table 1) even at higher concentrations level have very little influence on the analytical determination compared with the 1,10-phenanthroline procedure in aqueous medium[1] or organic solvent extraction.[16] Furthermore no remarkable difference was observed in the molar absorptivity, sensitivity and precision of the ternary complex for the above described procedures.

In conclusion, this inexpensive and relatively simple procedure can be successfully employed for the determination of iron in standard aluminium alloy and metal samples.

(Received January 24, 1983)

An electron transfer process of $[Mo(CN)_8]^{4-/3-}$ redox couple at the graphite electrode/protonated poly(4-vinylpyridine) (PVP) interfaces was examined by the normal pulse voltammetry. It became apparent that electrode reaction of the electroactive species confined in the polymer film on electrode surface obeys the conventional Butler-Volmer equation which characterizes the ordinary electrode reaction at electrode/solution interface. From the analysis of the dependences of the current-potential curves upon the sampling time the relevant kinetic parameters (*i.e.*, the standard rate constant, k° and the transfer coefficient, α) of the electrode reaction were evaluated. The value of k° decreased from 9.7×10^{-4} to 1.7×10^{-4} cm s^{-1} and the value of α was almost constant (0.50), when the molar ratio of the incorporated $[Mo(CN)_8]^{4-}$ to pyridine group of the PVP film, Γ_M/Γ_{PVP}, was increased from 0.0025 to 0.22. The apparent diffusion coefficient, D_{app}, for the process of charge transport within the film was also determined from the dependence of the limiting current upon the sampling time. The value of D_{app} decreased from 4.4×10^{-8} to 2.5×10^{-9} cm^2 s^{-1}, when the ratio Γ_M/Γ_{PVP} was increased from 0.0025 to 0.22.

Electrochemical reaction of solution species mediated by "redox polymer" films bound to the electrode surfaces, where the polymer itself is electroactive or the electroactive species are confined in the electroinactive polymer film, has recently received considerable attention.[1-4] It is now well recognized that the kinetics of electrochemical reactions mediated by "redox polymer" films is controlled by the interplay of the three rate-limiting factors, *i.e.*, (1) the diffusion-like propagation of the electrons through the film from the electrode surface toward the film/solution interface, (2) the diffusion of the substrate from the film/solution interface toward the electrode surface and (3) the electron cross-exchange reaction between the substrate and the active form of the redox mediator.[1,2,5-13] The theoretical approaches that take into account the interplay of these three factors, together with the diffusion of substrate in the solution, have been developed with regard to rotating disk electrode voltammetry.[4,9,14] Experimental studies also have actively been carried out in line with much success of such theoretical approaches.[1,2,6-8,11-15] However, no attempt to study in detail the kinetics on the electron transfer process at the electrode/film interface has yet been reported to our knowledge.

In order to conduct such a kinetic study, it seems to be at first indispensable to examine whether the Butler-Volmer theory[16] being proposed for the conventional electrode reaction at the electrode/solution interface is applicable to the electrode reaction of electroactive species confined in the polymer domains on electrode surface or not. For this purpose, it seems to be convenient to examine the behavior of the electrode coated with polymer film, in which electroactive species are confined by some interaction (*e.g.*, electrostatic interaction,[1,2,6,15,17-22] hydrophobic interaction,[23,24] and coordination bond[20-22,25] between the electroactive species and the polymer domain), in a solution containing only the supporting electrolyte. In this case, the overall electrode reaction consists of the electron transfer process at the electrode/film interface and the process of charge transport within the film. The latter process has been considered as the diffusion process of electroactive species to the electrode surface within the film and/or the hopping process of a series of electrons between adjacent pairs of oxidized and reduced reactants that serves to shuttle electrons from the electrode to reactants which are located away from the electrode surface.[1,2,15,17-19,23,24,26-35] So far, it has become apparent that in either case (or with combinations of the two) the process of charge transport within the film can be described in terms of apparent diffusional motion.[36,37]

This paper represents a first example on the kinetic study of the electron transfer process at the electrode/film interface. The main purpose of this work is to examine if the current-potential relationship[16] of the Butler-Volmer type usually employed for the electrode reactions at electrode/solution interface is applicable to the electron transfer process of electroactive species confined in the polymer films on electrode surface. The $[Mo(CN)_8]^{4-/3-}$ redox couple which is electrostatically bound to the protonated poly(4-vinylpyridine) (PVP) film on a pyrolytic graphite electrode is chosen as a suitable system for this purpose, because the process of charge transport of this system within the film has been previously studied in detail by means of chrono-amperometry, -coulometry and -potentiometry and has been recognized to be treated as a diffusion process which obeys Fick's second law.[19] The normal pulse voltammetric technique (NPV) is employed as a means of the measurement. Among the numerous pulse techniques, NPV has proved to be most suitable for the examination of electrode kinetics in polarographically quasi-reversible electrode processes and the current-potential curves of NPV are similar to that of d.c. polarography, so that the analysis

of the current-potential curves in NPV can be easily carried out by using a similar procedure to that of d.c. polarography.[38-42] The apparent diffusion coefficients for the process of charge transport within the film are also determined by using NPV.

Experimental

Materials. The pyrolytic graphite (Union Carbide Corp.) disk electrodes were prepared and mounted in a glass holder as previously described.[21] The exposed area of each electrode was 0.17 cm^2. The average molecular weight of PVP reprecipitated from methanol-diethyl ether was 7.4×10^5. $K_4[Mo(CN)_8]\cdot2H_2O$ was synthesized according to the standard procedure.[43]

Apparatus and Procedures. Adherent coatings of PVP were produced by transferring aliquots of a 0.5 weight percent methanolic solution of the polymer to the surface of a freshly cleaved graphite electrode and then evaporating the solvent at room temperature. The resulting coatings were swelled in an aqueous solution but remained insoluble.

The $[Mo(CN)_8]^{4-}$ complex was firmly held within the domain of the protonated PVP film.[2] The quantities of $[Mo(CN)_8]^{4-}$ incorporated into the protonated PVP coatings were determined by the following procedure: After incorporation of the $[Mo(CN)_8]^{4-}$ complex, the electrodes were washed and transferred to solutions containing only supporting electrolyte (0.2 M $CF_3COONa+CF_3COOH$, pH 1.5) (1 M=1 mol dm^{-3}). Then, the electrode potential was scanned from a value before the oxidation of the incorporated $[Mo(CN)_8]^{4-}$ ion to a value well beyond the voltammetric peak potential for oxidation and thereafter maintained until the current falls to background levels. The quantity of incorporated reactant was calculated from the integration of the current with correction for background contributions.

Normal pulse voltammograms and cyclic voltammograms were obtained with instruments which were constructed in our laboratory and were recorded with a X-Y recorder (Watanabe Corp.). Positive feed-back circuitry was employed to compensate the resistances associated with the PVP coatings as much as possible. In normal pulse voltammetric experiments, the pulse width of 50 ms and the interval of 20 to 50 s between successive pulses were employed. Thus it can be safely considered that the depletion layer of reactants produced during the precedent pulse completely disappears before the following pulse starts. Solutions were deaerated with pre-purified argon and experiments were conducted at 25 °C. Potentials were measured and are quoted with respect to a sodium chloride saturated calomel electrode (SSCE).

Results and Discussion

It has been well known that multiply-charged transition metal complexes can be incorporated into and confined in various polyelectrolytes coated on electrode surfaces by electrostatic interaction between the polyelectrolyte layer and metal complexes carrying the opposite charge.[1,2,6,15,17-22] The $[Mo(CN)_8]^{4-}$ complex can also be electrostatically attached to the protonated PVP coating on electrode.[2] When the PVP film is sufficiently thin, the cyclic voltammogram for the oxidation and reduction of the $[Mo(CN)_8]^{4-/3-}$ couple bound to the protonated PVP coatings yields symmetrical, identically shaped, anodic and cathodic

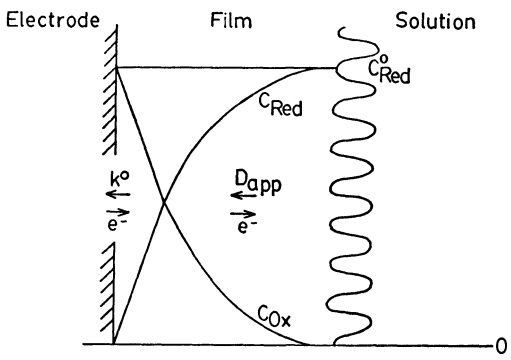

Fig. 1. Concentration profile of redox couple within polymer film at limiting current.

waves and peak currents vary linearly with scan rates. These results are characteristic of the surface redox-reaction.[37,44] With thickening the polymer film, the shape of the cyclic voltammograms becomes less symmetric and the peak currents exhibit the proportionality to the square root of scan rate.[22] The separation between anodic and cathodic peak potentials becomes large even at the ordinary scan rate such as 50 mV s^{-1} and at fast scan rate (*e.g.*, 0.5 V s^{-1} with IR compensation) the separation is larger than $\approx$59 mV, typical of a Nernstian solution process. This suggests that the overall rate of the electrode reaction is limited by the charge transport within the film and the electron transfer at the electrode/film interface.[22,34,37]

From the results obtained previously[19] by means of potential-step chronoamperometry, potential-step chronocoulometry and chronopotentiometry, the process of charge transport within the film can be treated as a semi-infinite diffusion process (Fig. 1), when the electrolysis time is below *ca.* 30 ms. In the present work, normal pulse voltammograms were taken at the sampling times between 2 and 16 ms. Therefore, the present experimental condition satisfies the condition of such a semi-infinite diffusion.

According to the usual kinetic theory[16] of a simple electrode reaction, Red$\rightleftharpoons$Ox+ne, the faradaic current, i, can be expressed by

$$i = nFA\{\vec{k}(E)C^s_{Red} - \overleftarrow{k}(E)C^s_{Ox}\}, \quad (1)$$

where $\vec{k}(E)$ and $\overleftarrow{k}(E)$ are the forward and backward rate constants, respectively, C^s_{Ox} and C^s_{Red} are concentrations of Ox and Red at the electrode surface, respectively, A is the electrode area, n is the number of electrons involved in the electron-transfer process and F is the Faraday constant.

By assuming that the Nernst equation can be applicable to an equilibrium situation of Ox and Red, Eq. 1 can be transformed into

$$i = nF\vec{A}k(E)\left\{C^s_{Red} - C^s_{Ox}\exp\left[-\frac{nF}{RT}(E-E^\circ)\right]\right\}, \quad (2)$$

where E is the electrode potential, E° is the formal standard potential of the reaction: Red$\rightleftharpoons$Ox+ne, and R and T have their usual significance. In the case of normal pulse voltammetry, the forward rate constant, $\vec{k}(E)$, can be given by[41]

$$\ln\{\vec{k}(E)\} = -\ln\left(\frac{4}{\sqrt{3}}\frac{\sqrt{\tau}}{\sqrt{D_{\mathrm{Red}}}}\right) + \ln\left\{x\left[\frac{1.75+x^2(1+\exp(-\zeta))^2}{1-x(1+\exp(-\zeta))}\right]^{1/2}\right\}, \quad (3)$$

with

$$\zeta = (nF/RT)(E-E^{\tau}_{1/2}), \quad (4)$$

$$x = i/(i_{\mathrm{d}})_{\mathrm{Cott}}, \quad (5)$$

$$E^{\tau}_{1/2} = E^{\circ} - (RT/nF)\ln\sqrt{D_{\mathrm{Ox}}/D_{\mathrm{Red}}}, \quad (6)$$

where $E^{\tau}_{1/2}$ is the reversible half-wave potential, τ is the sampling time, D_{Red} and D_{Ox} are the diffusion coefficients of Red and Ox, respectively, $(i_{\mathrm{d}})_{\mathrm{Cott}}$ denotes the diffusion current expressed by the Cottrell equation in the following manner:[45]

$$(i_{\mathrm{d}})_{\mathrm{Cott}} = nFAC^{\circ}\sqrt{D_{\mathrm{app}}/\pi\tau}, \quad (7)$$

with

$$D_{\mathrm{app}} = (D_{\mathrm{Ox}})^{\alpha}(D_{\mathrm{Red}})^{1-\alpha}, \quad (8)$$

where C° is the bulk concentration of Ox or Red in the film, and α is the anodic transfer coefficient.

Figure 2 shows the typical normal pulse voltammograms for the oxidation of $[Mo(CN)_8]^{4-}$ incorporated into the PVP film at various sampling times. The S-shaped waves shown in Fig. 2 are similar to those observed for redox species present in a solution at an uncoated electrode. The half-wave potential of the normal pulse voltammograms shifted to anodic direction with decreasing sampling times.

As shown in Fig. 3, plots of the anodic limiting currents of these normal pulse voltammograms against the inverse square root of the sampling times were found to be linear. This means that the limiting current is diffusion-controlled and the values of diffusion coefficients, D_{app}, for the process of charge transport within the film can be obtained from the anodic limiting currents by using Eq. 7.

Figure 4 shows the logarithmic plot of D_{app} *vs.* the molar ratio of the incorporated $[Mo(CN)_8]^{4-}$ ion to pyridine group of the protonated PVP, $\Gamma_{\mathrm{M}}/\Gamma_{\mathrm{PVP}}$, together with D_{app} for the reduction of $[Mo(CN)_8]^{3-}$.[38] This plot shows clearly the dependence of D_{app} on the concentration of the incorporated $[Mo(CN)_8]^{4-}$. As the ratio $\Gamma_{\mathrm{M}}/\Gamma_{\mathrm{PVP}}$ decreases, the apparent diffusion coefficient increases. Similar results have also been obtained in a previous work[19] where anionic reactants, $[Mo(CN)_8]^{4-/3-}$, $[Fe(CN)_6]^{4-/3-}$, and $[W(CN)_8]^{4-/3-}$, were incorporated into the PVP coating and the diffusion coefficients of the incorporated anions were evaluated by chronoamperometric, chronocoulometric and chronopotentiometric measurements.[46] The results shown in Fig. 4 and the previous data[19] suggest that the physical motion of $[Mo(CN)_8]^{4-}$ through the polymer film dominates its diffusional rate at the lower concentrations. One factor that contributes to the larger values of D_{app} may be the smaller extent of electrostatic cross-linking[6,15,17-19,30] of the $[Mo(CN)_8]^{4-}$ ion with the surrounding cation sites, as the concentration of the $[Mo(CN)_8]^{4-}$ ion decreases. At higher concentrations of $[Mo(CN)_8]^{4-}$, *i.e.* $\Gamma_{\mathrm{M}}/\Gamma_{\mathrm{PVP}} > 15\%$, the value of D_{app} becomes smaller but constant. In this

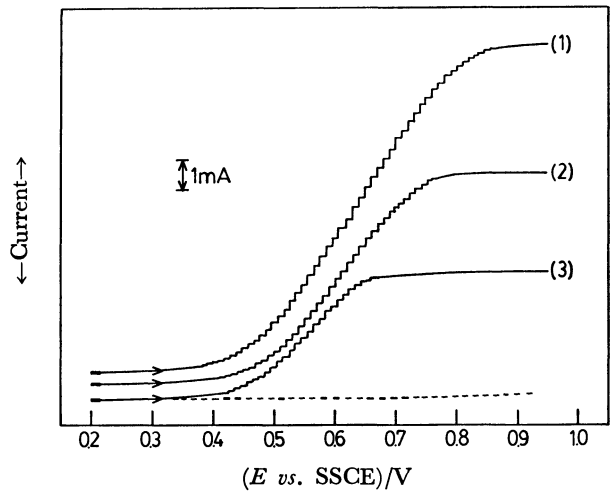

Fig. 2. Typical normal pulse voltammograms for the oxidation of $[Mo(CN)_8]^{4-}$ incorporated into the protonated PVP film on BPG electrode in 0.2 M CF_3COONa–CF_3COOH (pH 1.5) solution. Sampling time; (1) τ=2 ms, (2) 4 ms, and (3) 8 ms. Concentration of $[Mo(CN)_8]^{4-}$ incorporated into PVP, Γ_{M}: 7.0×10^{-8} mol cm^{-2}; Concentration of PVP coated on electrode, Γ_{PVP}: 4.6×10^{-7} mol cm^{-2} of pyridine as PVP. Dotted line shows a residual current.

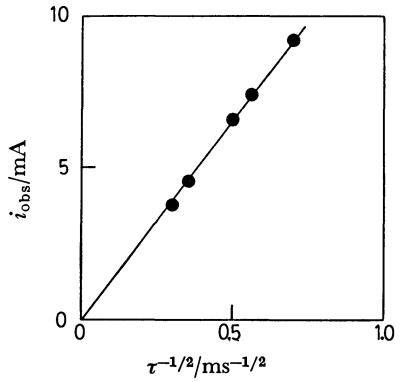

Fig. 3. Plots of observed limiting current (i_{obs}) *vs.* (sampling time)$^{-1/2}$ for the oxidation of $[Mo(CN)_8]^{4-}$ incorporated into the protonated PVP film on BPG electrode. Other conditions are the same as in Fig. 2.

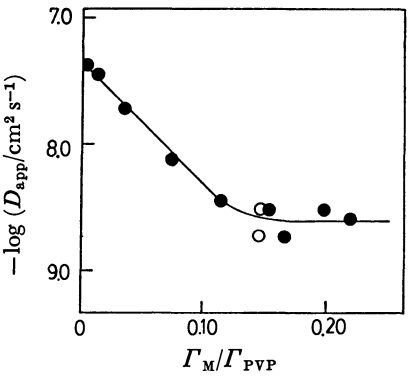

Fig. 4. Logarithmic plot of D_{app} *vs.* the molar ratio of incorporated $[Mo(CN)_8]^{4-}$ ions to protonated pyridine groups of PVP, $\Gamma_{\mathrm{M}}/\Gamma_{\mathrm{PVP}}$. Anion incorporated: (●) $[Mo(CN)_8]^{4-}$; (○) $[Mo(CN)_8]^{3-}$. Supporting electrolyte: 0.2 M CF_3COONa–CF_3COOH (pH 1.5).

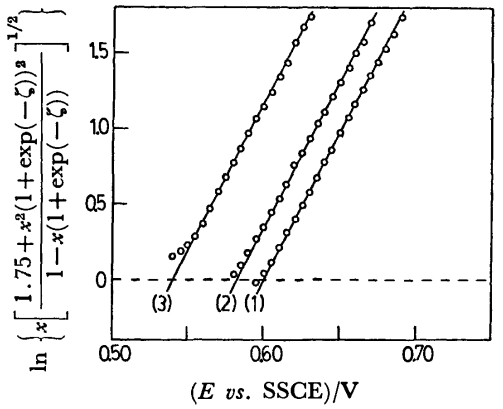

Fig. 5. Modified log-plots of normal pulse voltammograms for the oxidation of $[Mo(CN)_8]^{4-}$ incorporated into the protonated PVP film. Sampling time; (1) $\tau=2$ ms, (2) 4 ms, and (3) 8 ms. Other experimental conditions are the same as in Fig. 2.

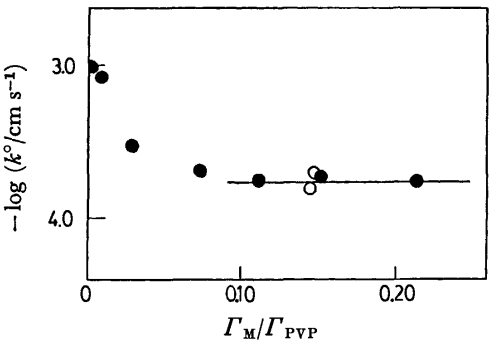

Fig. 6. Logarithmic plot of the standard rate constant, k°, against the molar ratio of incorporated $[Mo(CN)_8]^{4-}$ ions to protonated pyridine groups of PVP. Anion incorporated: (●) $[Mo(CN)_8]^{4-}$; (○) $[Mo(CN)_8]^{3-}$. Other experimental conditions are the same as in Fig. 5.

case, physical motion of the $[Mo(CN)_8]^{4-}$ ions through the film may be more difficult because of the higher extent of electrostatic cross-linking.[6,15,17-19,30] The fact that the D_{app} values are independent of the concentration of the incorporated $[Mo(CN)_8]^{4-}$ ion probably suggests that the structural changes caused by cross-linking may have reached their limit so that this factor no longer affects the measured values of D_{app}.[19]

Equation 3 indicates that the plot of $\ln(x[\{1.75+x^2(1+\exp(-\zeta))^2\}/\{1-x(1+\exp(-\zeta))\}]^{1/2})$ *vs.* E manifests the potential dependence of the forward rate constant. Figure 5 shows the typical examples of such log-plots of the normal pulse voltammograms, in which the logarithm of the second term on r.h.s. of Eq. 3 is plotted against E for the oxidation of $[Mo(CN)_8]^{4-}$ incorporated into the protonated PVP coatings. These plots gave the straight lines the slopes of which were constant at the different sampling times within experimental errors. This fact concludes that the electrode reaction of the electroactive species confined in the polymer film on electrode surfaces obeys the conventional Butler-Volmer equation[16] which characterizes the electrode reaction at electrode/solution interface. Thus, the forward rate constant, $\vec{k}(E)$, can be expressed as follows:

$$\vec{k}(E) = k^\circ \exp[(\alpha nF/RT)(E-E^\circ)], \quad (9)$$

where k° is the standard rate constant.

As can readily be seen from the comparison of Eqs. 3 and 9, the slope of the straight lines shown in Fig. 5 is equal to $(\alpha nF/RT)$ and the value, E^*, of the intersect of these lines with the zero-line can be expressed by

$$E^* = E^r_{1/2} - \frac{RT}{\alpha nF}\ln\left(\frac{4}{\sqrt{3}}\frac{k^\circ\sqrt{\tau}}{\sqrt{D_{app}}}\right), \quad (10)$$

under the assumption that $D_{Red}=D_{Ox}$, so that $E^\circ=E^r_{1/2}$. Thus, the anodic transfer coefficient was evaluated from the slopes of the straight lines shown in Fig. 5 and its value was 0.50 ± 0.05. The values of α were independent of Γ_M/Γ_{PVP}. The standard rate constants of electron transfer process at electrode/film interface were evaluated by introducing the experimental values of D_{app}, α and $E^r_{1/2}$ into Eq. 10, where the value of $E^r_{1/2}$ was estimated as the average of the anodic and cathodic peak potentials of the cyclic voltammogram for the oxidation-reduction of $[Mo(CN)_8]^{4-/3-}$ couple.

Figure 6 shows the dependence of k° upon the ratio of Γ_M to Γ_{PVP}. The value of k° decreased gradually with increasing the ratio Γ_M/Γ_{PVP} and in the region of $\Gamma_M/\Gamma_{PVP}=10$—20% the values of k° were constant and 2×10^{-4} cm s^{-1}. This value of the standard rate constant was in agreement with that obtained from the reduction of $[Mo(CN)_8]^{3-}$ confined in the protonated PVP on a graphite electrode (see open circles in Fig. 6) and the value of cathodic transfer coefficient was 0.50 ± 0.02. The standard rate constant of the electrode reaction of $[Mo(CN)_8]^{4-/3-}$ redox couple at an uncoated platinum electrode has been reported as 5×10^{-1} cm s^{-1}, which has been obtained with $[Mo(CN)_8]^{4-/3-}$ redox couple dissolved in an aqueous solution.[49] It is very interesting that the largely different values of k° were obtained, depending upon the experimental conditions where the electroactive species exist in the polymer film or the solution. In the former case, the electroactive species are firmly bound to the polymer films by electrostatic force. There is no such a special interaction in the latter case.

From the fact that there is a linear relation between $\ln(x[\{1.75+x^2(1+\exp(-\zeta))^2\}/\{1-x(1+\exp(-\zeta))\}]^{1/2})$ and electrode potential (E) (see Fig. 5), in the case of the electrode reaction at the polymer-coated electrode the formation of electrical double layer and the electron transfer process at the electrode/film interface can be considered to be essentially the same as those in an ordinary electrode reaction at electrode/solution interface. As can readily be seen from the essential ground (*i.e.*, electrostatic interaction) of the incorporation of $[Mo(CN)_8]^{4-/3-}$ redox couple into the protonated PVP film, $[Mo(CN)_8]^{4-/3-}$ couple is strongly interacting with its surroundings, *i.e.*, polymeric domains.[2,19] Under these circumstances, thus, the formation of "activated complex"[47,48] prior to the electron transfer seems to be more difficult than in the case of electron transfer reactions in a bulk solution.

The free energy required to reorganize the surrounding medium (outer shells) prior to the electron transfer becomes to be larger,[50-53] under the assumption that the free energy required to reorganize the inner coordination shells of the reactants can be almost the same for the electrode reactions of both the electroactive species present in a bulk solution and the electroactive species confined in the polymer film. Thus it seems to be likely that a large difference between the values of k° obtained in this study and the value obtained with $[Mo(CN)_8]^{4-/3-}$ redox couple dissolved in a bulk solution originates from the difference of the energy needed for the solvent reorganization occuring outside the inner coordination shells of $[Mo(CN)_8]^{4-/3-}$ couple prior to (and necessary for) electron transfer in the reaction media in which the rate constants were measured. Similarly, the dependence of k° on Γ_M/Γ_{PVP} shown in Fig. 5 appears to arise from the change of the solvent reorganization energy by Γ_M/Γ_{PVP}.

A kinetic study on the electrode reactions at polymer-coated electrodes has just been started[38,42] and the present experimental data concerning the electrode reactions of this type are scarce. Many experimental data should thus be accumulated in order to give a successful explanation for some interesting problems mentioned above. It is of great interest to examine the dependence of k° on temperature and to obtain the activation parameters of these electrode reactions. Study on the effect of ion strength and the kind of supporting electrolyte upon the kinetic parameters of electrode reactions would also give further information.

The Preparation and Photoreation of Spiro[oxirane-2,6′-tricyclo[3.2.1.0^{2,7}]-oct[3]en]-8′-ones. An Intramolecular Cycloaddition of Photochemically Generated Ketene with the Epoxide Ring[1]

Makoto NITTA,* Akihiko OMATA, and Hazime NAKATANI

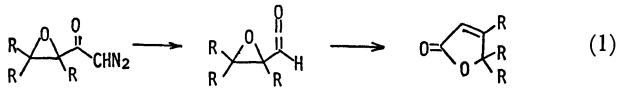
Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160

(Received August 13, 1982)

The oxidations of 1,5-dimethyl- and 1,3,5-trimethyl-6-methylenetricyclo[3.2.1.0^{2,7}]oct-3-en-8-ones with 3-chloroperbenzoic acid or thallium(III) acetate resulted in the formation of 1′,5′-dimethyl and 1′,3′,5′-trimethylspiro[oxirane-2,6′-tricyclo[3.2.1.0^{2,7}]oct[3]en]-8′-ones (**2a** and **2b**). The oxidation occured stereoselectively on the exocyclic double bond from the *exo*-side. The photochemical reactions of **2a** and **2b** resulted in the formation of 4,8-dimethyl- and 4,6,8-trimethyl-3,4-dihydro-1H-2-benzopyran-3-ones, both of which would be derived from an ene-type reaction of the ketene intermediate with the exoxide ring involved in the [$4\pi+2\sigma$] electronic system. The intermediacy of the ketene was assessed by low-temperature infrared spectroscopy as well as by a trapping experiment, the mechanistic pathways were confirmed by conducting the photoreaction in deuterated methanol.

Recently, the stereoselectivities of the electrophilic reaction of molecules containing a proximal π-bond have been explored.[2] In connection with these studies and our own previous work,[1,3] the peroxy-acid oxidation and the thallium(III) acetate-induced oxidation of 1,5-dimethyl- and 1,3,5-trimethyl-6-methylenetricyclo[3.2.1.0^{2,7}]oct-3-en-8-ones (**1a** and **1b**) were investigated. The products, 1′,5′-dimethyl and 1′,3′,5′-trimethylspiro[oxirane-2,6′-tricyclo[3.2.1.0^{2,7}]oct[3]en]-8′-ones (**2a** and **2b**), have a skeleton of photolabile 3-methyl-4-caren-2-one, which has been shown to photoisomerize to a ketene derivative.[4] Therefore, **2a** and **2b** were expected to be promising precursors of a ketene possessing another functional group of an epoxide involved in the [$4\pi+2\sigma$] electronic system.

Although the intramolecular cycloaddition of photochemically generated ketenes has been widely known,[5] little is known about the reaction of such ketenes with an electronic system which involves both π-bonds and a polar or bent σ-bond such as an epoxide ring. Some information on the reaction of an epoxide

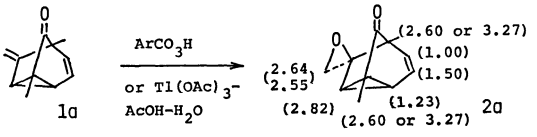


(1)

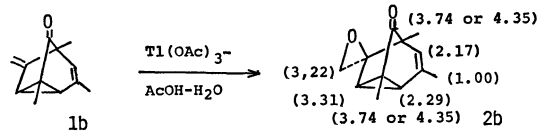
with a ketene has, however been shown. The epoxide attacks the C=O or C=C bond to afford the acetal or lactone.[6] The epoxyketene, on the other hand, undergoes a vinylcyclopropane–cyclopentene-type rearrangement, leading to butenolide (Eq. 1)[7] On understanding some unknown behavior of the epoxide toward a reactive ketene, the photochemical reactions of **2a** and **2b** were investigated.

Results and Discussion

*The Epoxidation of 1,5-Dimethyl- and 1,3,5-Trimethyl-6-methylenetricyclo[3.2.1.0^{2,7}]oct-3-en-8-ones (**1a** and **1b**).* The treatment of **1a** with 3-chloroperbenzoic acid afforded 1′,5′-dimethylspiro[oxirane-2,6′-tricyclo-[3.2.1.0^{2,7}]oct[3]en]-8′-one (**2a**) in a 55% yield, along with the starting meterial, **1a**, in a 29% yield. The structure of **2a** was deduced from its spectral properties. The stereochemistry of the epoxide ring was determined by means of the pseudo-contact NMR spectra obtained by using Eu(fod)$_3$. The relative downfield shifts of δ's are given in parentheses in the structural formula **2a**. The relatively small shifts for the hydrogens of the allylic moiety suggest that the coordination of Eu(fod)$_3$ occurs on the epoxide-oxygen. The large shifts of the two methyl groups and the proton at the 7′-position suggest that the epoxide-oxygen is located *syn* to the carbonyl group. Thus, the stereochemistry of the epoxide was assessed.



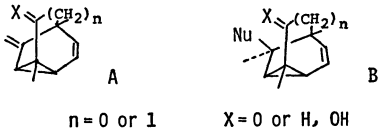
1a 2a



1b 2b

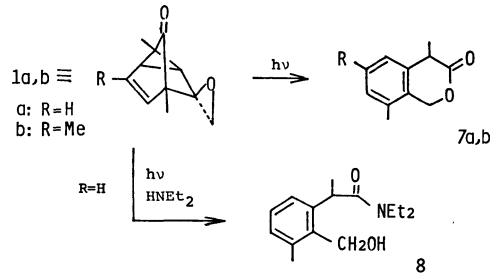
The epoxidation of alkenes with thallium(III) acetate has also been shown.[8] Thus, the reaction of **1a** with thallium(III) acetate in H_2O–AcOH afforded the epoxide **2a** in a 61% yield. The reaction of the trimethyl analogue **1b** in a similar way also afforded the epoxide **2b** in a 59% yield, along with *ca.* 5% of an unidentified compound, **6**. The orientation of the epoxide-oxygen for **2b** was deduced to be *syn* to the carbonyl group from the pseudo-contact NMR spectra, which were obtained by using Eu(fod)$_3$. The relative downfield shifts of δ's, which are presented in parentheses in the structural formula **2b**, exhibited a trend similar to that of **2a**.

In our previous papers, the solvomercuration-demercuration reaction on the exocyclic double bond of **1a** and its related compounds with the general structure of [**A**] was described as exhibiting a remarkable stereoselectivity to give [**B**].[3] The stereoselectivity was ex-



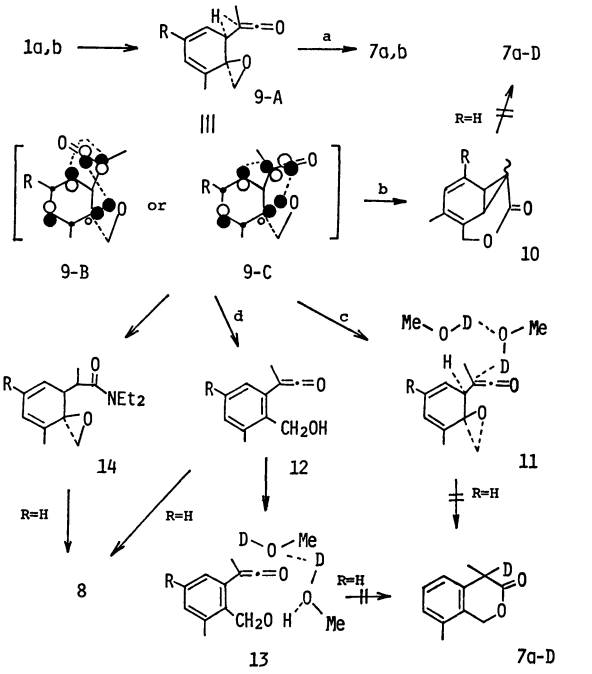
plained by the steric and/or electronic factor of the mercurinium-ion formation and the subsequent incorporation of the nucleophile.[3] In the present reactions, epoxide-oxygen was also stereoselectively incorporated on the exocyclic double bond from the *exo*-side.

Photochemical Reactions of the Epoxide ***2a*** *and* ***2b***. The photoirradiation of **2a** in acetonitrile under a nitrogen atmosphere resulted in the formation of 4,8-dimethyl-3,4-dihydro-1*H*-2-benzopyran-3-one (**7a**) in a 61% yield. Similarly, **2b** afforded 4,6,8-trimethyl-3,4-dihydro-1*H*-2-benzopyran-3-one (**7b**) in a 77% yield. The structures of **7a** and **7b** were deduced from the spectral properties, as well as by comparison with the spectral data of 1,5-dimethyl-3,4-dihydro-1*H*-2-benzopyran-3-one, which had been derived from the oxidation of 1,4-dimethyl-2-indanone.[9] The irradiation of **2a** was also carried out in acetonitrile containing a ten-fold excess of diethylamine, **7a** and the amide **8** were then obtained in 44% and 15% yields respectively.



From the formation of **1a**, **7b**, and **8**, the ketene **9** was proposed as the common intermediate. Support for the intermediacy of this ketene was obtained by conducting the irradiation of the film of **2a** at 77 K. During the irradiation, the intensity of the band due to the carbonyl group in the low-temperature IR spectrum slowly decreased. A distinct new band, attributable to the ketene function, appeared at 2120 cm^{-1} after 3 h. On warming to room temperature, the 2120 cm^{-1} band disappeared completely, while there appeared a new band at 1730 cm^{-1} corresponding to **7a**, hence, the intermediacy of the ketene was clarified.

The photoreaction of **2a** in methanol also gave **7a**, while the methanol adduct to the ketene moiety was not obtained. Thus, the pathway for the formation of **7a,b** seems to be the concerted ene-type cyclization represented in the structural formula **9-A** (Scheme 1, Path a). Another possible routes can be envisaged to explain the formation of **7a,b** in acetonitrile or methanol: i) the intramolecular cycloaddition of the ketene moiety with the $[4\pi+2\sigma]$ electronic system to give the norcaradiene intermediate **10** *via* **9-B** or **9-C**, followed by aromatization (Path b),[10] ii) the nucleophilic reaction of the epoxide ring assisted by methanol *via* **11** (Path C), iii) the rearrangement of the ketene **9** to **12** followed by methanol-assisted lactonization to give **7a,b** *via* **13** (Path d).[11] Judging from the forbidden 1,3-hydrogen migration required for the isomerization of **9** to **12**, however, the intermediacy of 12 seems unlikely under neutral conditions.[12] In order to clarify the possibilities of Path b, Path C, or



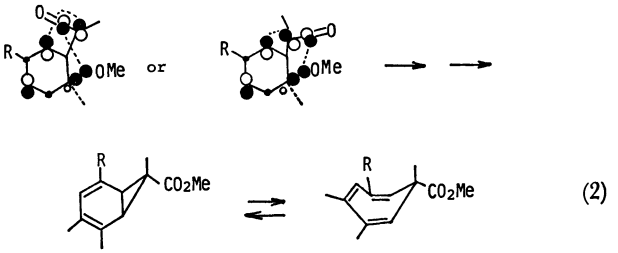
Scheme 1.

TABLE 1.

Time/h	4	7	14
7a/**7a**—**D**	10	2.3	1.0
2a (%)	60	30	16

Path d, the photoreaction of **2a** was carried out in 98%-deuterated MeOD. However, the deuterium-incorporated product **7a**—**D**, which could be expected from Path b, Path c, or Path d, could not be obtained at the early stage of the reaction. The prolonged irradiation, which continued to about 50% of the **2a** has been consumed, caused a deuterium-incorporation at the C-4 position of **7a** (Table 1). Furthermore, the independent irradiation of **7a** in MeOD underwent deuterium exchange at the C-4 position of **7a**. Therefore, the deuterium-incorporation to **7a** seems to result from the subsequent photoreaction of **7a**. This fact suggests that Path b, Path c, or Path d could not be involved in the present photoreaction in methanol or acetonitrile.

On the other hand, the formation of the amide **8** in the presence of diethylamine is suggestive of the isomerization of the ketene **9** to the ketene **12**, which undergoes the addition of diethylamine to give **8**, and/or the amine addition to **9** to give **14**, which undergoes aromatization to give **8**, under the basic conditions in the presence of diethylamine.



(2)

In the present photoreaction, the intramolecular cycloaddition of the ketene with the suitably located [4π+2σ] electronic system represented by **9-B** or **9-C** (Path b) is prohibited. The photochemical or thermal reaction of *exo*-6-methoxy-1,5,6-trimethyltricyclo-[3.2.1.0^{2,7}]oct-3-en-8-one has been shown to undergo this type of cycloaddition (Eq. 2).[10] Since compound **10** seems to be very constrained, therefore, this reaction pathway (Path b) is less energetically favored than the ene-type reaction (Path a).

Experimental

The IR spectra were recorded on a Shimadzu IR-400 spectrometer The mass spectral studies were conducted using an Hitachi, RMU-60 spectrometer, All the NMR spectra were recorded on a JEOL PS-100 high-resolution spectrometer, using tetramethylsilane as the internal standard. The shift data were obtained by adding small increments of Eu(fod)$_3$ to the sample and by then nothing the extent to which each peak was shifted. The relative-shift slopes were obtained by dividing each slope by the slope of the least-shifted signal. The VPC analyses and separation were performed on a Shimadzu GC-6A or a Varian Model-920 chromatograph, using a column packed with 5% SE-30 on Chromosorb W. The analyses were performed by the Science and Engineering Research Ladoratory of Waseda University.

Irradiation was carried out using a Rayonet RPR-100 Photoreactor fitted with RPR-300 nm lamps. The solution to be irradiated was placed in a Pyrex tube and was, after deoxygenation with a stream of nitrogen, sealed with a serum cap.

*Oxidation of 1,5-Dimethyl-6-methylenetricyclo[3.2.1.0^{2,7}]oct-3-en-8-one (**1a**) and 3-Chloroperbenzoic Acid.* A solution of **1a** (800 mg, 5 mmol) and 3-chloroperbenzoic acid (860 mg, 5 mmol) in dichloromethane (10 cm^3) was stirred at room temperature for 2 h. The 3-chlorobenzaic acid thus precipitated was removed by filtration, and the filtrate was washed with aqueous sodium hydrogencarbonate and dried over sodium sulfate. The subsequent removal of the solvent gave 671 mg of an oil, which was then chromatographed on silica gel, using benzene as the eluent, to give 228 mg (29%) of the starting material **1a** and 443 mg (55%) of the epoxide **2a**: IR (film), 3040, 2974, 2939, 2865, 1742, 993 cm^{-1}; NMR (CCl), δ=0.72 (3H, s), 1.25 (3H, s), 1.64 (1H, d, J=8.0 Hz), 2.02—2.34 (1H, m), 2.64 (1H, d, J=4.0 Hz), 2.68 (1H, d, J=4.0 Hz), 5.42 (1H, dxd, J=8.0, 3.0 Hz), 6,02 (1H, dxd, J=8.0, 5.5 Hz); MS, *m/e* (rel intensity), 176 (M$^+$, 13) 118 (11). Found: C, 74.91; H, 6.68%. Calcd for $C_{11}H_{12}O_2$: C, 74.97; H, 6.86%.

*Oxidation of **1a** with Thallium(III) Acetate.* A solution of **1a** (1.6 g, 10 mmol) and thallium(III) acetate (7.62 g, 20 mmnl) in 60 cm^3 of an acetic acid-water (1/1) mixture was stirred at room temperature overnight and then neutralized with aqueous sodium hydrogencarbonate. To this reaction mixture, was added saturated aqueous sodium chloride, after which the percipitate was removed by filtration. The filtrate was extracted with ether and dried over sodium sulfate. After the removal of the solvent, the residue was distilled to give 1.07 g (61%) of **2a**.

*Oxidation of 1,3,5-Trimethyl-6-methylenetricyclo[3.2.1.0.^{2,7}]-oct-3-en-8-one (**1b**) with Thallium(III) Acetate.* The oxidation was carried out as has been described above, using 1.0 g (0.57 mmol) of **1b** and 4.57 g (12 mmol) of thallium-(III) acetate. A subsequent workup similar to that described above gave an oil. This oil was separated by TLC on silica gel using chloroform-benzene (1/1) as the eluent. The first band from the TLC plates afforded 640 mg (59%) of **2b**: bp 108—111 °C/798.6 Pa (bath temperature); IR (CCl_4), 3040, 2949, 2859, 1737, 992 cm^{-1}; NMR (CCl_4), δ=0.80 (3H, s), 1.33 (3H, s), 1.64 (1H, d, J=8.0 Hz), 1.80—2.08 (1H, m), 1.94 (3H, d, J=3.0 Hz), 2.78 (1H, d, J=4.5 Hz), 2.89 (1H, d, J=4.5 Hz), 5.22—5.37 (1H, m). Found: C, 75.82; H, 7.47%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%.

The second band for the TCL plates contained 50 mg (5%) of **6**: IR (CCl_4), 3049, 2976, 2941, 2874, 1742, 1689 (shoulder), 1449, 1379 cm^{-1}; NMR (CCl_4), δ=1.08 (3H, s), 1.25 (3H, s), 1.09 (3H, s), 2.17—2.43 (3H, m), 2.44 (2H, s), 5.30 (1H, m).

*Irradiation of **2a**.* A solution of **2a** (50 mg, 0.28 mmol) in 10 cm^3 of anhydrous acetonitrile was irradiated at room temperature. The photoreaction, followed by VPC, was completed in 32 h. The photolysate was separated by TLC on silica gel, using benzene as the eluent, to give 41 mg (80%) of **7a**: mp 75—76 °C; IR (KBr), 1730 cm^{-1}; NMR (CCl_4), δ=1.60 (3H, d, J=7.0 Hz), 2.36 (3H, s), 3.50 (1H, q, J=7.0 Hz), 5.18 (1H, d, J=14.0 Hz), 5.38 (1H, d, J=14.0 Hz), 7.00—7.36 (3H, m); MS, *m/e* (rel intensity), 176 (M$^+$, 17), 132 (100). Found: C, 74.77; H, 7.11%. Calcd for $C_{11}H_{12}O_2$: C, 74.97; H, 6.88%.

Oxidation of 1,4-Dimethyl-2-indanone with 3-Chloroperbenzoic Acid. A solution of 1,4-dimethyl-2-indanone (480 mg, 3 mmol) and 3-chloroperbenzoic acid (692 mg, 4 mmol) was stirred overnight. To this reaction mixture, we then added 5 cm^3 of saturated aqueous $Na_2S_2O_3$ and water, after with the reaction mixture was extracted with dichloromethane. The evaporation of the dried organic portion and subsequent recrystallization gave 288 mg (55%) of 1,5-dimethyl-3,4-dihydro-1*H*-2-benzopyran-3-one: mp 114—115 °C; IR (CCl_4), 1754 cm^{-1}; NMR (CCl_4), δ=1.73 (1H, d, J=6.6 Hz), 2.34 (3H, s), 3.62 (1H, d, J=18.6 Hz), 3.87 (1H, d, J=18.6 Hz), 5.55 (1H, q, J=6.6 Hz), 7.20—7.50 (3H, m); MS, *m/e* (rel intensity), 176 (M$^+$, 27), 132 (100). Found: C, 75.36; H, 6.81%. Calcd for $C_{11}H_{12}O_2$: C, 74.94; H, 6.86%.

*Irradiation of **2b**.* A solution of **2b** (64 mg, 0.36 mmol) in 10 cm^3 of anhydrous acetonitrile was irradiated for 19 h. The photolysate was purified by column chromatography on Florisil, using benzene as the eluent, to give 49 mg (77%) of lactone **7b**: mp 117—118 °C; IR (CCl_4), 1736 cm^{-1}; NMR ($CDCl_3$), δ=1.77 (3H, d, J=7.5 Hz), 2.53 (3H, s), 2.60 (3H, s), 3.94 (1H, q, J=7.5 Hz), 5.80 (1H, d, J=13.5 Hz, 5.94 (1H, d, J=13.5 Hz), 7.66—7.83 (2H, broad s); MS, *m/e* (rel intensity), 190 (M$^+$, 100), 146 (84). Found: C, 75.44; H, 7.25%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%.

*Irradiation of **2a** in the Presence of Diethylamine.* A solution of **2a** (88 mg, 0.5 mmol) and diethylamine (365 mg, 5 mmol) in 10 cm^3 of anhydrous acetonitrile was irradiated for 3 h in a quartz tube with RPR-300 nm lamps at room temperature. After the evaporation of the solvent, the photolysate was separated by TLC on silica gel, using benzene as the eluent. The first band from the TLC plates gave 39 mg (44%) of **7a**. The second band contained 19 mg (15%) of the amide **8**: mp 121—122 °C; IR ($CHCl_3$), 3300, 1610 cm^{-1}; NMR ($CDCl_3$), δ=0.80—1.30 (6H, broad m), 1.40 (3H, d, J=6.5 Hz), 2.16 (1H, s), 2.41 (3H, s), 2.82—3.80 (4H, broad m), 4.21 (1H, q, J=6.5 Hz), 4.78 (2H, s), 7.00—7.30 (3H, m); MS, *m/e* (rel intensity), 249 (M$^+$, 16), 100 (100). Found: C, 72.53; H, 9.41; N, 5.66%. Calcd for $C_{15}H_{23}O_2N$: C, 72.25; H, 9.30; N, 5.62%.

Trap of the Ketene Intermediate by Low-temperature IR Spectroscopy. A glassy film of **2a** was placed on an infrared cell and irradiated externally with a 450-W medium-pressure mercury lamp through a CaF_2 cell window for infrared spectroscopy at *ca.* 77 K. A distinct new band, attributable to the ketene intermediate, appeared at 2120 cm^{-1} after 3 h. This ketene band gradually disappeared with the rise in the temperature to the ambient temperature, a new band appeared at 1730 cm^{-1} due to the carbonyl group of **7a**.

*Irradiation of **2a** in Methanol-*d_1. Three Pyrex tubes containing 27 mg (0.15 mmol) of **2a** in 0.4 cm^3 of MeOD were irradiated for several hours. The irradiation time and the ratio of the photoproducts of **7a**—**D** to **7a** (as determined by NMR spectroscopy using the signals of the methine proton at δ 3.50 and the methyl protons at δ 1.60), and the recovery yields of **2a** after separation through TLC, are listed in Table 1.

*Irradiation of **7a** in Methanol-*d_1. A solution of **7a** (22 mg, 0.13 mmol) in 1 cm^3 of MeOD was irradiated for 8 h. The photolysate was purified by TLC on silica gel, using benzene as the eluent, to give 18 mg (85%) of a mixture of **7a** and **7a**—**D** in a ratio of 1/1, as determined by means of the NMR spectrum.

The authors wish to thank to Professor Masaru Tada of Waseda University for low-temperature infrared spectroscopy and Mr. Shuji Okada for a part of the experimental work.

Revision of Structures of Nellionol and Dehydronellionol

Takashi MATSUMOTO,* Sachihiko IMAI, Shoji TAKEDA, and Masanori MITSUKI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

(Received November 29, 1982)

The structures of nellionol and dehydronellionol were revised respectively to 6α,11,12,16-tetrahydroxyabieta-8,11,13-trien-7-one (**12**) and 6,11,12,16-tetrahydroxyabieta-5,8,11,13-tetraen-7-one (**13**) by the following syntheses. A mixture of (15*R*)- and (15*S*)-12-methoxyabieta-8,11,13-trien-16-ol, prepared from 13-acetyl-12-methoxypodocarpa-8,11,13-triene, was converted into 11,12,16-triacetoxyabieta-8,11,13-trien-7-one (**22**) *via* 16-acetoxy-12-benzoyloxyabieta-8,11,13-trien-11-ol. Treatment of **22** with isopropenyl acetate, followed by oxidation with *m*-chloroperbenzoic acid and subsequent acetylation, afforded 6α,11,12,16-tetraacetoxyabieta-8,11,13-trien-7-one, which was hydrolyzed with dilute hydrochloric acid to **12**. The ketone **22** was also converted into **13** *via* 11,12,16-triacetoxyabieta-8,11,13-trien-6-one. The spectral data of **12** and **13** were in good agreement with those of natural nellionol and dehydronellionol.

The novel tricyclic aromatic diterpenes, nellionol and dehydronellionol, have recently been isolated from the root bark of *Premna latifolia* Roxb. by Rao *et al.*[1] On the basis of chemical and spectroscopic studies, they deduced the structures of nellionol and dehydronellionol to be 6α,11,14,16-tetrahydroxyabieta-8,11,13-trien-7-one (**1**) and 6,11,14,16-tetrahydroxyabieta-5,8,11,13-tetraen-7-one (**2**), respectively. Among many naturally-occurring tricyclic diterpenes possessing abietane skeleton, several compounds have two oxygen functions in the C-ring. In these compounds, the oxygen functions are usually present at the C-11 and C-12 positions; this is true for cryptojaponol (**3**),[2] galdosol (**4**),[3] carnosolone (**5**),[4] and carnosic acid (**6**).[5,6] However, Rao *et al.* proposed very unique structures (**1** and **2**) possessing two oxygen functions at the C-11 and C-14 positions and no oxygen function at the C-12 position. It is of interest to confirm the validity of their proposed structures. We therefore examined the published spectral data of these natural products. The ^{1}H NMR spectra of nellionol tetraacetate and dehydronellionol tetraacetate showed, respectively, an aromatic proton signal at δ 8.04 and 8.12. These chemical shifts assigned to the C-12 protons in the proposed structures are in an unusually low field; similar compounds, methyl 11,14-diacetoxy-7-oxoabieta-8,11,13-trien-18-oate (**7**) and 11,14-diacetoxy-13-(acetoxymethyl)podocarpa-8,11,13-trien-7-one (**8**),[7] showed the C-12 proton signals at δ 7.04 and 7.09, respectively. On the other hand, the ^{1}H NMR spectra of carnosolone diacetate (**9**),[4] methyl 11,12-diacetoxy-7-oxoabieta-8,11,13-trien-20-oate (**10**),[3] and methyl 11,12-diacetoxy-7-oxoabieta-5,8,11,13-tetraen-20-oate (**11**)[5] showed singlet signals due to the C-14 aromatic proton at δ 8.23, 8.04, and 8.15, respectively. These spectral data strongly suggested that the aromatic protons in the new natural products are placed at the C-14 position ortho to a carbonyl group. From these ^{1}H NMR spectral analyses together with consideration of the other spectral data, we deduced 6α,11,12,16-tetrahydroxyabieta-8,11,13-trien-7-one (**12**) and 6,11,12,16-tetrahydroxyabieta-5,8,11,13-tetraen-7-one (**13**) to be more preferable structures of nellionol

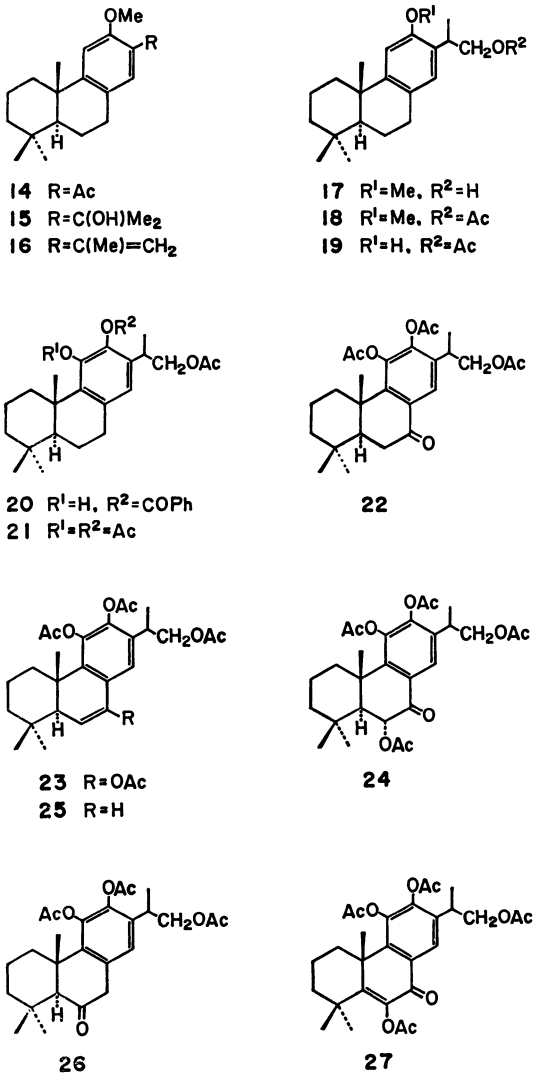
and dehydronellionol, respectively. To confirm the validity of our proposal, independent syntheses of **12** and **13**, starting from 13-acetyl-12-methoxypodocarpa-8,11,13-triene (**14**),[8,9] have been attempted.

Grignard reaction of **14** with methylmagnesium iodide in refluxing ether, followed by dehydration of the resulting alcohol (**15**: 86%) in refluxing acetic acid, afforded 12-methoxyabieta-8,11,13,15-tetraene (**16**: 95%), whose ^{1}H NMR spectrum showed singlet signals at δ 2.06 (3H) and 4.96 (2H) due to an isopropenyl group. The tetraene **16** was converted into an epimeric mixture at C-15 of 12-methoxyabieta-8,11,13-trien-16-ol (**17**: 70%) by hydroboration and subsequent oxidation with alkaline hydrogen peroxide. Separation of these epimeric alcohols was unsuccessful. Therefore, the mixture was used in the following reactions. Acetylation of **17** with acetic anhydride in pyridine yielded the corresponding acetate (**18**: 94%), which was treated at room temperature with anhydrous aluminium chloride and ethanethiol in dichloromethane to give 16-acetoxyabieta-8,11,13-trien-12-ol (**19**: 91%). To introduce an oxygen function at the C-11 position, the phenol **19** was oxidized at room temperature with benzoyl peroxide[10] in chloroform to afford 16-acetoxy-12-benzoyloxyabieta-8,11,13-trien-11-ol (**20**: 40%). This was then converted into 11,12,16-triacetoxyabieta-8,11,13-triene (**21**: 90%) by treatment with lithium aluminium hydride in refluxing ether, followed by acetylation with acetic anhydride in pyridine. The ^{1}H NMR spectrum of **21** showed signals due to three acetoxyl groups at δ 1.95 (3H) and 2.22 (6H), and an aromatic proton signal at δ 6.77. Oxidation of **21** with chromium trioxide in acetic acid afforded the corresponding 7-oxo compound (**22**: 73%), whose ^{1}H NMR spectrum showed a singlet signal at δ 8.03 due to an aromatic proton. The downfield shift of the aromatic proton signal from δ 6.77 in **21** to δ 8.03 in **22** must be caused by a deshielding effect of the carbonyl group at the C-7 position. This supported the location of the aromatic proton at C-14. The 7-oxo compound **22** was refluxed with isopropenyl acetate in the presence of *p*-toluenesulfonic acid monohydrate to give 7,11,12,16-tetraacetoxyabieta-6,8,11,13-tetraene (**23**). The ^{1}H NMR spectrum of **23** showed a doublet signal due to an olefinic proton at δ 5.61 and a singlet signal due to an aromatic proton at δ 6.95. Oxidation of **23** with *m*-chloroperbenzoic acid in dichloromethane, followed by acetylation[11] with acetic anhydride in pyridine, afforded 6α,11,12,16-tetraacetoxyabieta-8,11,13-trien-7-one (**24**: 86% from **22**). The α-configuration of the acetoxyl group at the C-6 position in **24** was supported by its ^{1}H NMR spectrum, which showed a doublet signal due to the C-6 proton at δ 5.83 with a coupling constant of 14 Hz, suggesting the β orientation. Hydrolysis of **24** with dilute hydrochloric acid in refluxing ethanol yielded the desired **12** (55%). The ^{1}H NMR spectra of the synthetic **12** and **24** were in good agreement with those of natural nellionol and its tetraacetate.

Subsequently the 7-oxo compound **22** was reduced at room temperature with sodium borohydride in methanol to give a mixture of epimeric alcohols at C-7, which was immediately converted into 11,12,16-triacetoxyabieta-6,8,11,13-tetraene (**25**) by treatment with dilute hydrochloric acid in refluxing methanol and subsequent acetylation[12] with acetic anhydride in pyridine. The ^{1}H NMR spectrum of **25** showed two double doublet signals due to two olefinic protons at δ 5.93 (J=9 and 3 Hz, C_6–H) and 6.45 (J=9 and 3 Hz, C_7–H). The tetraene **25** was further converted into 11,12,16-triacetoxyabieta-8,11,13-trien-6-one (**26**: 40% from **22**) by a series of reactions: oxidation with *m*-chloroperbenzoic acid in dichloromethane at room temperature, treatment with dilute hydrochloric acid in refluxing methanol, and acetylation[12] with acetic anhydride in pyridine. Oxidation of **26** with Jones reagent, followed by treatment with sodium acetate in refluxing acetic anhydride, afforded 6,11,12,16-tetraacetoxyabieta-5,8,11,13-tetraen-7-one (**27**: 52%). Hydrolysis of **27** with dilute hydrochloric acid in refluxing methanol produced the desired **13** (38%). The ^{1}H NMR spectra of the synthetic **13** and **27** were also in good agreement with those of natural dehydronellionol and its tetraacetate.

From the present studies, it is clear that the proposed structures (**1** and **2**) of nellionol and dehydronellionol must be revised to **12** and **13**. However, the stereochemistry of the C-15 position in these natural com-



pounds remained unsettled.

Experimental

The IR spectra were measured in chloroform and the ^{1}H MNR spectra in carbon tetrachloride at 60 MHz, with tetramethylsilane as an internal standard, unless otherwise stated. The chemical shifts are presented in terms of δ values; s: singlet, bs: broad singlet, d: doublet, bd: broad doublet, dd: double doublet, m: multiplet. The column chromatography was performed using Merck silica gel (0.063 mm).

*Methyl 11,14-Diacetoxy-7-oxoabieta-8,11,13-trien-18-oate (**7**).* A mixture of methyl 11,14-dihydroxy-7-oxoabieta-8,11,13-trien-18-oate[13] (19 mg), acetic anhydride (0.4 ml), and pyridine (0.4 ml) was refluxed for 1 h. After the usual work-up, the crude product was chromatographed on silica gel (5.0 g), using ether-benzene (3:97) as the eluent, to give methyl 11-acetoxy-14-hydroxy-7-oxoabieta-8,11,13-trien-18-oate (2 mg: 9%), whose IR spectrum was identical with that of the authentic sample.[13] Further elution with ether-benzene (5:95) gave **7** (15 mg: 64%) as an oil; IR: 1760, 1723, 1684 cm^{-1}; ^{1}H NMR ($CDCl_3$), 90 MHz): 1.05 (3H, d, J=7 Hz) and 1.09 (3H, d, J=7 Hz) (-CH($C\underline{H}_3$)$_2$), 1.29 (3H, s) and 1.33 (3H, s) (C_4-CH_3 and C_{10}-CH_3), 2.32 (3H, s) and 2.34 (3H, s) (2-OCOCH_3), 3.65 (3H, s, -CO_2CH_3), 7.04 (1H, s, C_{12}-H). Found: C, 67.84; H, 7.51%. Calcd for $C_{25}H_{32}O_7$: C, 67.55; H, 7.26%.

*12-Methoxyabieta-8,11,13-trien-15-ol (**15**).* 13-Acetyl-12-methoxypodocarpa-8,11,13-triene (**14**)[8,9] was prepared from (+)-dehydroabietic acid. A solution of **14** (13.1 g) in dry ether (40 ml) was added dropwise to an ethereal solution of methylmagnesium iodide prepared from magnesium turnings (1.3 g) and methyl iodide (3.3 ml) in dry ether (40 ml). The mixture was refluxed for 1.5 h, cooled, poured into ice-dilute hydrochloric acid, and then extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (150 g), using benzene and then ether-benzene (9:91) as the eluent, to give **15** (11.8 g: 86%); IR: 3530 cm^{-1}; ^{1}H NMR: 0.96 (6H, s, -$\dot{C}(CH_3)_2$), 1.18 (3H, s, C_{10}-CH_3), 1.52 (6H, s, -C($C\underline{H}_3$)$_2$OH), 3.57 (1H, s, -OH), 3.83 (3H, s, -OCH_3), 6.67 (1H, s) and 6.88 (1H, s) (C_{11}-H and C_{14}-H).

*12-Methoxyabieta-8,11,13,15-tetraene (**16**).* A solution of **15** (11.5 g) in acetic acid (30 ml) was refluxed for 5 min, cooled, neutralized with aqueous sodium hydroxide, and extracted with ether. The ether extract was weshed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (100 g), using hexane-benzene (1:1) as the eluent, to give **16** (10.3 g: 95%); ^{1}H NMR: 0.96 (6H, s, -$\dot{C}(CH_3)_2$), 1.19 (3H, s, C_{10}-CH_3), 2.06 (3H, s, C_{15}-CH_3), 3.73 (3H, s, -OCH_3), 4.96 (2H, bs, -$\dot{C}$=CH_2), 6.61 (1H, s) and 6.72 (1H, s) (C_{11}-H and C_{14}-H).

*12-Methoxyabieta-8,11,13-trien-16-ol (**17**).* A solution of boron trifluoride etherate (2.4 ml) in dry tetrahydrofuran (4.0 ml) was added dropwise at −5—0 °C to a stirred mixture of **16** (4.0 g) and sodium borohydride (530 mg) in dry tetrahydrofuran (35 ml) in a stream of nitrogen. After the mixture had been stirred at 0—5 °C for 2 h, there were added successively aqueous tetrahydrofuran (50%: 6.0 ml), aqueous sodium hydroxide (12%: 6.3 ml), and hydrogen peroxide (30%: 6.3 ml) at −5—0°C. The mixture was stirred at −5—0 °C for 30 min and then at room temperature for 1 h, diluted with water, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (200 g), using benzene as the eluent, to give a mixture of C-15 epimers (**17**) (2.9 g: 70%); IR: 3592, 3456 cm^{-1}; ^{1}H NMR: 0.96 (6H, s, -$\dot{C}(CH_3)_2$), 1.16 (3H, bd, J=7 Hz, C_{15}-CH_3), 1.17 (3H, s, C_{10}-CH_3), 1.52 (1H, s, -OH), 3.22 (1H, m, C_{15}-H), 3.46 (2H, bs, -$C\underline{H}_2$OH), 3.74 (3H, s, -OCH_3), 6.59 (1H, s) and 6.67 (1H, s) (C_{11}-H and C_{14}-H).

*16-Acetoxy-12-methoxyabieta-8,11,13-triene (**18**).* A mixture of **17** (1.2 g), acetic anhydride (2.0 ml), and pyridine (5.0 ml) was stirred at 80—85 °C for 1.5 h. After the usual work-up, the crude product was purified by column chromatography on silica gel (50 g), using benzene as the eluent, to give **18** (1.3 g: 94%); IR: 1725 cm^{-1}; ^{1}H NMR: 0.97 (6H, s, -$\dot{C}(CH_3)_2$), 1.19 (3H, s, C_{10}-CH_3), 1.20 (3H, d, J=7 Hz, C_{15}-CH_3), 1.97 (3H, s, -$OCOCH_3$), 3.78 (3H, s, -OCH_3), 4.05 (2H, bd, J=7 Hz, -CH_2O-), 6.63 (1H, s) and 6.70 (1H, s) (C_{11}-H and C_{14}-H).

*16-Acetoxyabieta-8,11,13-trien-12-ol (**19**).* A mixture of **18** (1.3 g), anhydrous aluminium chloride (2.9 g), and ethanethiol (2.7 ml) in dichloromethane (20 ml) was stirred at 0—5 °C for 5 min and then at room temperature for 1 h. The mixture was poured into dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (50 g), using ether-benzene (1:99) as the eluent, to give **19** (1.1 g: 91%); IR: 3605, 3405, 1720 cm^{-1}; ^{1}H NMR: 0.95 (6H, s, -$\dot{C}(CH_3)_2$), 1.13 (3H, s, C_{10}-CH_3), 1.26 (3H, d, J=7 Hz, C_{15}-CH_3), 2.05 (3H, s, -$OCOCH_3$), 3.8—4.4 (2H, m, -CH_2O-), 6.38 (1H, s, C_{12}-OH), 6.55 (1H, s) and 6.64 (1H, s) (C_{11}-H and C_{14}-H).

*16-Acetoxy-12-benzoyloxyabieta-8,11,13-trien-11-ol (**20**).* A solution of **19** (862 mg) and benzoyl perpxide (3.0 g) in chloroform (10 ml) was allowed to stand at room temperature for 50 h. The chloroform solution was diluted with ether. This ether solution, after addition of acetic acid (9.0 ml) and aqueous potassium iodide (30%: 30 ml), was stirred at room temperature for 4 h. The mixture was washed successively with water, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and brine. After being dried over sodium sulfate, the solvent was evaporated *in vacuo* and the residue was purified by column chromatography on silica gel (70 g), using benzene as the eluent, to give **20** (446 mg: 40%). IR: 3575, 3375, 1730 cm^{-1}; ^{1}H NMR: 0.97 (6H, s, -$\dot{C}(CH_3)_2$), 1.15 (d, J=7 Hz) and 1.18 (d, J=7 Hz) (3H, C_{15}-CH_3), 1.34 (3H, s, C_{10}-CH_3), 1.86 (3H, s, -$OCOCH_3$), 3.93 (2H, m, -CH_2O-), 5.65 (1H, s, C_{11}-OH), 6.45 (1H, s, C_{14}-H), 7.30—7.65(m) and 8.00—8.30(m) (5H, -C_6H_5).

*11,12,16-Triacetoxyabieta-8,11,13-triene (**21**).* A stirred mixture of **20** (327 mg) and lithium aluminium hydride (60 mg) in dry ether (7.0 ml) was refluxed for 2 h. The mixture was poured into ice-dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo* to give the crude triol (289 mg).

The crude triol (289 mg) was acetylated with acetic anhydride (1.0 ml) in pyridine (1.0 ml) at room temperature for 17 h. After the usual work-up, the crude product was purified by column chromatography on silica gel (15 g), using ether-benzene (3:97) as the eluent, to give **21** (290 mg: 90%). IR: 1761, 1731 cm^{-1}; ^{1}H NMR: 0.95 (6H, s,

$-\dot{C}(CH_3)_2$), 1.20 (3H, bd, $J=7$ Hz, C_{15}-CH_3), 1.22 (3H, s, C_{10}-CH_3), 1.95 (3H, s, C_{16}-$OCOCH_3$), 2.22 (6H, s, C_{11}-$OCOCH_3$ and C_{12}-$OCOCH_3$), 3.97 (2H, bd, $J=7$ Hz, $-CH_2O-$), 6.77 (1H, s, C_{14}-H).

*11,12,16-Triacetoxyabieta-8,11,13-trien-7-one (**22**).* A mixture of **21** (340 mg) and chromium trioxide (120 mg) in acetic acid (5.0 ml) was stirred at 0—5 °C for 15 min and then at room temperature for 22 h. The mixture was diluted with water and extracted with ether. The ether extract was washed successively with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaported *in vacuo*. The residue was chromatographed on silica gel (15 g), using ether-benzene (4:96) as the eluent, to give **22** (255 mg: 73%). IR: 1773, 1727, 1683, 1607 cm^{-1}; ^1H NMR ($CDCl_3$): 0.96 (3H, s) and 0.98 (3H, s) ($-\dot{C}(CH_3)_2$), 1.24 (d, $J=7$ Hz) and 1.28 (d, $J=7$ Hz) (3H, C_{15}-CH_3), 1.35 (3H, s, C_{10}-CH_3), 2.03 (3H, s, C_{16}-$OCOCH_3$), 2.35 (6H, s, C_{11}-$OCOCH_3$ and C_{12}-$OCOCH_3$), 4.06 (d, $J=7$ Hz) and 4.09 (d, $J=7$ Hz) (2H, $-CH_2O-$), 8.03 (1H, s, C_{14}-H).

*7,11,12,16-Tetraacetoxyabieta-6,8,11,13-tetraene (**23**).* A mixture of **22** (112 mg) and *p*-toluenesulfonic acid monohydrate (10 mg) in isopropenyl acetate (2.0 ml) was refluxed for 14 h. The mixture was cooled and diluted with ether. The ether solution was washed with brine, dried over sodium sulfate, and evaporated *in vacuo* to give the crude **23** (139 mg) which, without purification, was used in the next reaction. ^1H NMR: 0.97 (3H, s) and 1.05 (3H, s) ($-\dot{C}(CH_3)_2$), 1.25 (3H, s, C_{10}-CH_3), 5.61 (1H, d, $J=2.5$ Hz, C_6-H), 6.95 (1H, s, C_{14}-H).

*6α,11,12,16-Tetraacetoxyabieta-8,11,13-trien-7-one (**24**).* A mixture of the crude **23** (139 mg) and *m*-chloroperbenzoic acid (85%: 58 mg) in dichloromethane (3.0 ml) was stirred at 0—5 °C for 10 min and then at room temperature for 24 h. The mixture was diluted with ether and washed successively with aqueous potassium iodide, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and brine. After being dried over sodium sulfate, the ether solution was evaporated *in vacuo* to give a mixture of 6α-acetoxy and 6α-hydroxy derivatives (147 mg), which was immediately acetylated with acetic anhydride (1.0 ml) in pyridine (1.0 ml) at room temperature for 20 h. After the usual work-up, the crude product was chromatographed on silica gel (5.0 g). Elution with ether-benzene (5:95) gave **24** (101 mg: 86% from **22**); IR: 1774, 1734, 1700, 1607 cm^{-1}; ^1H NMR ($CDCl_3$: 90 MHz): 1.07 (3H, s) and 1.14 (3H, s) ($-\dot{C}(CH_3)_2$), 1.25 (3H, d, $J=7$ Hz, C_{15}-CH_3), 1.52 (3H, s, C_{10}-CH_3), 2.00 (3H, s, C_{16}-$OCOCH_3$), 2.23 (1H, d, $J=14$ Hz, $C_{5\alpha}$-H), 2.24 (3H, s) and 2.31 (6H, s) (C_6-$OCOCH_3$, C_{11}-$OCOCH_3$, and C_{12}-$OCOCH_3$), 3.1—3.5 (1H, m, C_{15}-H), 4.05 (d, $J=7$ Hz) and 4.08 (d, $J=7$ Hz) (2H, $-CH_2O-$), 5.83 (1H, d, $J=14$ Hz, $C_{6\beta}$-H), 7.99 (1H, s, C_{14}-H). The ^1H NMR spectrum of **24** was in good agreement with that of natural nellionol tetraacetate,[1] except for the signals due to the corresponding C-15 epimer. Found: C, 65.14; H, 7.11%. Calcd for $C_{28}H_{36}O_9$: C, 65.10; H, 7.02%.

*6α,11,12,16-Tetrahydroxyabieta-8,11,13-trien-7-one (**12**).* A mixture of **24** (83 mg) and dilute hydrochloric acid (10%: 0.5 ml) in ethanol (2.0 ml) was refluxed for 3 h. The mixture was cooled, diluted with water, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silicic acid (Mallinckrodt CC-4: 4.0 g), using hexane-chloroform (1:4) as the eluent, to give **12** (32 mg: 55%). IR: 3492, 3400—3050, 1663, 1608 cm^{-1}; ^1H NMR (DMSO-d_6: 90 MHz): 1.16 (3H, s) and 1.18 (3H, s) ($-\dot{C}(CH_3)_2$), 1.18 (3H, d, $J=6$ Hz, C_{15}-CH_3), 1.48 (3H, s, C_{10}-CH_3), 1.68 (1H, bd, $J=12$ Hz, $C_{5\alpha}$-H), 3.55 (2H, bd, $J=6$ Hz, $-CH_2O-$), 4.47 (1H, bd, $J=12$ Hz, $C_{6\beta}$-H), 7.33 (1H, s, C_{14}-H). The ^1H NMR spectrum of **12** was in good agreement with that of natural nellionol,[1] except for the signals due to the corresponding C-15 epimer.

*11,12,16-Triacetoxyabieta-6,8,11,13-tetraene (**25**).* A mixture of **22** (167 mg) and sodium borohydride (30 mg) in methanol (3.0 ml) was stirred at 0—5 °C for 30 min and then at room temperature for 1 h. The mixture was acidified with dilute hydrochloric acid (10%: 0.5 ml) refluxed for 1 h, and evaporated *in vacuo*. The residue was extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residual oil was acetylated[12] with acetic anhydride (1.0 ml) in pyridine (1.0 ml) at 60—70 °C for 3 h to give the crude **25** (160 mg) which, without purification, was used in the next reaction. IR: 1765, 1730 cm^{-1}; ^1H NMR: 0.96 (3H, s) and 1.03 (3H, s) ($-\dot{C}(CH_3)_2$), 1.11 (3H, s, C_{10}-CH_3), 1.18 (d, $J=7$ Hz) and 1.23 (d, $J=7$ Hz) (3H, C_{15}-CH_3), 1.95 (3H, s, C_{16}-$OCOCH_3$), 2.20(3H, s) and 2.23 (3H, s) (C_{11}-$OCOCH_3$ and C_{12}-$OCOCH_3$), 3.93 (d, $J=7$ Hz) and 4.00 (d, $J=7$ Hz) (2H, $-CH_2O-$), 5.93 (1H, dd, $J=9$ and 3 Hz, C_6-H), 6.45 (1H, dd, $J=9$ and 3 Hz, C_7-H), 6.77 (1H, s, C_{14}-H).

*11,12,16-Triacetoxyabieta-8,11,13-trien-6-one (**26**).* A mixture of the crude **25** (160 mg) and *m*-chloroperbenzoic acid (85%: 180 mg) in dichloromethane (4.0 ml) was stirred at 0—5 °C for 1 h and then at room temperature for 14 h. The mixture was diluted with ether and washed successively with aqueous potassium iodide, aqueous sodium thiosulfate aqueous sodium hydrogencarbonate, and brine. The ether solution was dried over sodium sulfate and evaporated *in vacuo*. The residual oil was refluxed with dilute hydrochloric acid (10%: 0.5 ml) in methanol (4.0 ml) for 1 h. The mixture was evaporated *in vacuo*, diluted with water, and extracted with ether. The ether extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo* to give an oil (155 mg). This oil was acetylated[12] with acetic anhydride (0.5 ml) in pyridine (0.5 ml) at 75—85 °C for 3 h. After the usual work-up, the crude product was purified by column chromatography on silica gel (7.0 g), using ether-benzene (3:97) as the eluent, to give **26** (64 mg: 40% from **22**). IR: 1767, 1733, 1720 cm^{-1}; ^1H NMR ($CDCl_3$): 1.05 (3H, s) and 1.23 (3H, s) ($-\dot{C}(CH_3)_2$), 1.22 (d, $J=7$ Hz) and 1.24 (d, $J=7$ Hz) (3H, C_{15}-CH_3), 1.34 (3H, s, C_{10}-CH_3), 2.05 (3H, s, C_{16}-$OCOCH_3$), 2.34 (6H, s, C_{11}-$OCOCH_3$ and C_{12}-$OCOCH_3$), 2.60 (1H, bs, C_5-H), 3.64 (2H, br, $-COCH_2-$), 4.06 (d, $J=7$ Hz) and 4.09 (d, $J=7$ Hz) (2H, $-CH_2O-$), 6.90 (1H, s, C_{14}-H).

*6,11,12,16-Tetraacetoxyabieta-5,8,11,13-tetraen-7-one (**27**).* A solution of **26** (84 mg) in acetone (2.0 ml) was oxidized with Jones reagent [2.5 M (1 M=1 mol dm^{-3}): 0.1 ml] at 0—5 °C for 10 min and then at room temperature for 2 h. The mixture was diluted with water and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residual oil (78 mg) was refluxed with acetic anhydride (4.0 ml) in the presence of anhydrous sodium acetate (200 mg) for 2.5 h with stirring. The mixture was diluted with water and benzene, evaporated *in vacuo*, and extracted with ether. The ether extract was washed successively with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (4.0 g), using ether-benzene (5:95) at the eluent, to give **27** (49 mg: 52%). IR: 1776, 1728, 1658, 1612 cm^{-1}; ^1H NMR ($CDCl_3$: 90 MHz): 1.29 (d, $J=$

7 Hz) and 1.31 (d, $J=7$ Hz) (3H, C_{15}-CH_3), 1.40 (6H, s, -$\dot{C}(CH_3)_2$), 1.65 (3H, s, C_{10}-CH_3), 2.00(s) and 2.01(s) (3H, C_{16}-$OCOCH_3$), 2.32 (3H, s) and 2.36 (6H, s) (C_6-$OCOCH_3$, C_{11}-$OCOCH_3$, and C_{12}-$OCOCH_3$), 3.24 (1H, m, C_{15}-H), 4.07 (d, $J=7$ Hz) and 4.10 (d, $J=7$ Hz) (2H, -CH_2O-), 8.11 (1H, s, C_{14}-H). The ^{1}H NMR spectrum of **27** was in good agreement with that of natural dehydronellionol tetraacetate,[1] except for the signals due to the corresponding C-15 epimer. Found: C, 65.06; H, 6.74%. Calcd for $C_{28}H_{34}O_9$: C, 65.36; H, 6.66%.

*6,11,12,16-Tetrahydroxyabieta-5,8,11,13-tetraen-7-one (**13**).* A mixture of **27** (35 mg) and dilute hydrochloric acid (10%: 0.3 ml) in methanol (2.0 ml) was refluxed for 1 h. The mixture was diluted with water and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silicic acid (Mallinckrodt CC-4: 3.0 g), using hexane-chloroform (1:4) as the eluent, to give **13** (8.9 mg: 38%). IR: 3515, 3450—3050, 1630, 1600 cm^{-1}; ^{1}H NMR ($CDCl_3$: 90 MHz): 1.38 (3H, d, $J=7$ Hz, C_{15}-CH_3), 1.46 (6H, s, -$\dot{C}(CH_3)_2$), 1.67 (3H, s, C_{10}-CH_3), 3.70—4.14 (2H, m, -CH_2O-), 7.09 (1H, s, -OH), 7.59 (1H, s, C_{14}-H). The ^{1}H NMR spectrum of **13** was in good agreement with that of natural dehydronellionol,[1] except for the signal due to the corresponding C-15 epimer.

The authors are grateful to Arakawa Chemical Co. Ltd. for a generous gift of rosin. Thanks are also due to Professor Ch. B. Rao for kindly supplying the spectral data of the natural products.

The Synthesis of (+)-Pisiferol and (+)-Pisiferal

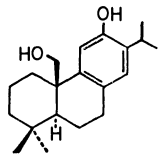
Takashi Matsumoto,* Yoshinori Endo, and Masaru Okimoto

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

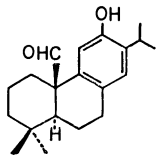
(Received January 12, 1983)

Reduction of abieta-8,11,13,-trien-6-one with lithium aluminium hydride, followed by treatment with lead tetraacetate and iodine, afforded 6*β*,20-epoxyabieta-8,11,13-triene. This was converted into a separable mixture of abieta-8,11,13-trien-20-ol (**13**) and 5*βH*-abieta-8,11,13-trien-20-ol (**14**) by a series of reactions; ether cleavage with acetic *p*-toluenesulfonic anhydride, catalytic hydrogenation, and reduction with lithium aluminium hydride. Acetylation of **13** and **14** gave the corresponding acetates, 20-acetoxyabieta-8,11,13-triene (**11**) and 20-acetoxy-5*βH*-abieta-8,11,13-triene (**12**). Friedel-Crafts acylation of **11** with acetyl chloride in the presence of anhydrous aluminium chloride afforded 20-acetoxy-12-acetylabieta-8,11,13-triene, which was converted into pisiferol by oxidation with *m*-chloroperbenzoic acid and subsequent treatment with lithium aluminium hydride. The synthetic pisiferol was oxidized with Jones reagent to give pisiferal. Similarly, 5*βH*-abieta-8,11,13-triene-12,20-diol was synthesized from **12**. Conversion of the cis A/B ring junctions in **12** into the trans ones is also described.

Pisiferol (**1**) and pisiferal (**2**), rare naturally-occurring tricyclic diterpenes possessing an oxidized angular methyl group, have recently been isolated from the leaves of *Chamaecyparis pisifera* (Cupressaceae) by Yatagai *et al.*[1,2] As a part of our synthetic studies on the naturally-occurring diterpenes, we have attempted the syntheses of these rare natural compounds. This paper will describe the syntheses of (+)-pisiferol (**1**) and (+)-pisiferal (**2**), starting from (+)-abieta-8,11,13-trien-6-one (**3**)[3-5] which was prepared from an epimeric mixture of 7*α*- and 7*β*-acetoxyabieta-8,11,13-triene (**4**)[3] in an improved yield.



1



2

Treatment of the mixture **4** with 10% hydrochloric acid in refluxing ethanol afforded abieta-6,8,11,13-tetraene (**5**)[3-5] (84.4%). The tetraene **5** was oxidized at 0—5 °C with *m*-chloroperbenzoic acid in dichloromethane to give an epoxide (**6**) which, without purification, was converted into **3** (82.3% from **5**) by refluxing with *p*-toluenesulfonic acid in benzene. Reduction of **3** with lithium aluminium hydride in refluxing ether yielded abieta-8,11,13-trien-6*β*-ol (**7**: 87.3%). The stereochemistry of the hydroxyl group at C-6 in **7** was assigned to be *β*-configuration from its ^{1}H NMR spectrum, which showed a signal due to the angular methyl group at C-10 in a lower field (δ 1.51) than that of the corresponding signal (δ 1.29) in **3**. These down-field shift suggested a 1,3-diaxial *cis*-relationship between the angular methyl group and the hydroxyl group at C-6. In order to oxidize the angular methyl group by transannular oxidation, the alcohol **7** in benzene was treated with lead tetraacetate in the presence of iodine at room temperature under a stream of nitrogen. Purification of the crude product by column chromatography on silica gel afforded 6*β*,20-epoxyabieta-8,11,13-triene (**8**: 86.3%). The structure of **8** was supported by the appearance of signals due to methylene protons [ABq at δ 3.51 (d, J=8 Hz) and 3.82 (d, J=8 Hz)] in its ^{1}H NMR spectrum and by the disappearance of the signal due to the angular methyl group. Treatment of **8** with acetic *p*-toluenesulfonic anhydride[6] in dichloromethane at room temperature produced a mixture of 20-acetoxyabieta-5,8,11,13-tetraene (**9**) and 20-acetoxyabieta-6,8,11,13-tetraene (**10**) in 87.1% yield. The ^{1}H NMR spectrum of the mixture showed the presence of **9** [δ 3.33 (2H, d, J=4 Hz, C_7–H_2) and 6.17 (1H, t, J=4 Hz, C_6–H)] and **10** [δ 2.31 (1H, t, J=3 Hz, C_5–H), 5.97 (1H, dd, J=3 and 10 Hz, C_6–H), and 6.55 (1H, dd, J=3 and 10 Hz, C_7–H)] in a ratio of *ca.* 5:8. The mixture of **9** and **10** in acetic acid was submitted to catalytic hydrogenation over PtO_2 at room temperature to afford a mixture of 20-acetoxyabieta-8,11,13-triene (**11**) and its cis isomer (**12**). Because of the difficulty of the separation of **11** and **12**, the mixture was immediately treated with lithium aluminium hydride in refluxing ether. The repeated column chromatography of the crude product using silica gel afforded abieta-8,11,13-trien-20-ol (**13**) and its cis isomer (**14**) in 66.1% and 20.0% yields from the mixture of **9** and **10**. The *cis*-configuration of the A/B ring junction in **14** was supported by the appearance of a signal due to one of the *gem*-dimethyl groups at C-4 in very high field (δ 0.41) owing to the shielding effect of the aromatic C ring. Acetylation of **13** and **14** with acetic anhydride in pyridine gave the corresponding acetates, **11** (98.4%) and **12** (93.5%). The Friedel-Crafts acylation of **11** with acetyl chloride in dichloromethane in the presence of anhydrous aluminium chloride yielded 20-acetoxy-12-acetylabieta-8,11,13-triene (**15**: 85.4%), whose IR spectrum showed carbonyl bands at 1732 and 1680 cm^{-1}. The ^{1}H NMR spectrum of **15** showed two singlets at δ 6.94 and 7.30 due to the two aromatic protons. These spectral data of **15** supported the presence of an acetyl group at C-12. The Baeyer-Villiger oxidation of **15** with *m*-chloroperbenzoic acid in the presence of *p*-toluenesulfonic acid in refluxing 1,2-dichloroethane afforded 12,20-diacetoxyabieta-8,11,13-triene (**16**: 69.3%). Treatment of **16** with lithium aluminium hydride in refluxing ether yielded abieta-8,11,13-triene-12,20-diol (pisiferol) (**1**: 96.4%) which, on methylation with methyl iodide and anhydrous potassium carbonate in refluxing ethyl methyl ketone, afforded 12-methoxyabieta-8,11,13-trien-20-ol (**17**: 98.4%). The IR and

^{1}H NMR spectra of the synthetic **1** were identical with those of natural pisiferol. Oxidation[1] of **1** with Jones reagent at 0—5 °C afforded 12-hydroxyabieta-8,11,13-trien-20-al (pisiferal)[1,2] (**2**: 47.6%). Similarly, the cis acetate **12** was also converted into 5βH-abieta-8,11,13-tricne-12,20-diol (**20**: 98.5%) *via* 20-acetoxy-12-acetyl-5βH-abieta-8,11,13-triene (**18**: 57.2 %) and 12,20-diacetoxy-5βH-abieta-8,11,13-triene (**19**: 61.8%).

Subsequently, conversion of the cis A/B ring junctions into the trans ones was carried out as follows. The cis acetate **12** was oxidized with Jones reagent at room temperature to give 20-acetoxy-5βH-abieta-8,11,13-trien-7-one (**21**: 52.3%[7]) and 20-acetoxy-5βH-abieta-8,11,13-triene-6,7-dione (**22**: 28.8[7]). Bromination of **21** with pyridinium tribromide in dichloromethane at room temperature afforded 20-acetoxy-6β-bromo-5βH-abieta-8,11,13-trien-7-one (**23**: 97.3%) which was converted into 20-acetoxyabieta-5,8,11,13-tetraen-7-one (**24**: 87.8%) by treatment with lithium carbonate and lithium bromide in *N,N*-dimethylformamide at 110—130 °C under a stream of nitrogen. The tetraene **24** in ethyl acetate was catalytically hydrogenated with 10% Pd–C in the presence of perchloric acid to give the trans acetate (**11**: 98.9%). The 6,7-dioxo acetate **22** was refluxed with anhydrous sodium acetate in acetic anhydride to give the corresponding enol acetate (**25**: 77.9%). The enol acetate **25** in ethyl acetate was then submitted to catalytic hydrogenation over 10% Pd–C in the presence of perchloric acid. Purification of the crude product by column chromatography on silica gel afforded **11** (28.8%) and a mixture (53.2%) of 6α,20- (**26**) and 6β,20-diacetoxyabieta-8,11,13-triene (**27**) (*ca.* 1:1 ratio).

Experimental

All melting points are uncorrected. The IR spectra and optical rotations were measured in chloroform and the ^{1}H NMR spectra in carbon tetrachloride at 60 MHz, with tetramethylsilane as an internal standard, unless otherwise stated. The chemical shifts are presented in terms of δ values; s: singlet, bs: broad singlet, d: doublet, bd: broad doublet, dd: double doublet, t: triplet, m: multiplet. The column chromatography was performed using Merck silica gel.

*Abieta-6,8,11,13-tetraene (**5**).* The epimeric mixture of 7α- and 7β-acetoxyabieta-8,11,13-triene (**4**)[3] was prepared from (+)-dehydroabietic acid.

A mixture of **4** (5.830 g) and dilute hydrochloric acid 10%: 8.5 ml) in ethanol (50 ml) was refluxed for 2.5 h and evaporated *in vacuo*. The residue was diluted with water and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (50 g), using hexane as the eluent, to give **5**[3-5] (4.023 g: 84.4%), $[\alpha]_D$ −124° (*c* 4.67).

*Abieta-8,11,13-trien-6-one (**3**).* A mixture of **5** (16.77 g) and *m*-chloroperbenzoic acid (80%: 17.50 g) in dichloromethane (170 ml) was stirred at 0—5 °C for 1.5 h. The mixture was diluted with ether and then washed successively with aqueous potassium iodide, aqueous sodium thiosulfate apueous sodium hydrogencarbonate, and brine. The solution was dried over sodium sulfate and evaporated *in vacuo* to give a crude epoxide (**6**) (17.38 g); ^{1}H NMR: 1.09, 1.14, and 1.20 (each 3H and s, $-\underline{C}(CH_3)_2$ and C_{10}-CH_3), 1.26 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.83 (1H, m, $-C\underline{H}(CH_3)_2$), 3.29 (1H, t, J=4 Hz, $C_{6\beta}$-H), 3.61 (1H, d, J=4 Hz, $C_{7\beta}$-H), 6.98 (2H, bs, C_{11}-H and C_{12}-H), 7.24 (1H, bs, C_{14}-H).

A mixture of the crude epoxide **6** (17.38 g) and *p*-toluenesulfonic acid monohydrate (1.50 g) in dry benzene (250 ml) was refluxed for 1 h. The benzene solution was washed successively with water, aqueous sodium hydrogencarbonate, and brine. The solution was dried over sodium sulfate and evaporated *in vacuo*. The crude product was chromatographed on silica gel (300 g), using hexane-benzene (1:1) as the eluent, to give **3**[3-5] (14.63 g: 82.3% from **5**), $[\alpha]_D$ +125° (*c* 2.64), IR: 1710 cm^{-1}.

Abieta-8,11,13-trien-6β-ol (7). A mixture of **3** (3.196 g) and lithium aluminium hydride (420 mg) in dry ether (50 ml) was stirred at 0—5 °C for 5 min and then refluxed for 1.5 h. The mixture was poured into ice-dilute hydrochloric acid, and exteacted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (150 g), using benzene as the eluent, to give **3** (89 mg: 2.8%). Further elution with the same solvent afforded **7** (2.808 g: 87.3%) as a solid, mp 100—101 °C, $[\alpha]_D$ +40.8° (*c* 5.15); IR: 3615, 3480 cm^{-1}; ^1H NMR: 0.99 and 1.23 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.22 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.51 (3H, s, C_{10}-CH_3), 4.50 (1H, bs, $W_{1/2}$=9.5 Hz, $C_{6\alpha}$-H), 6.73 (1H, bs, C_{14}-H), 6.85 (1H, bd, J=8 Hz, C_{12}-H), 7.10 (1H, d, J=8 Hz, C_{11}-H). Found: C, 83.85; H, 10.75%. Calcd for $C_{20}H_{30}O$: C, 83.86; H, 10.56%.

6β,20-Epoxyabieta-8,11,13-triene (8). A mixture of **7** (13.18 g), lead tetraacetate (87.5%: 32.2 g), and iodine (16.6 g) in dry benzene (250 ml) was stirred for 2 h under a stream of nitrogen with cooling in a water bath. The mixture was diluted with benzene and the organic solution was washed successively with aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and brine. The dried solution was evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (500 g), using benzene as the eluent, to give **8** (11.30 g: 86.3%), $[\alpha]_D$ −64.4° (*c* 2.10); ^1H NMR: 0.93 and 1.02 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.20 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.76 (1H, m, $-C\underline{H}(CH_3)_2$), 2.92 (2H, bd, J=2.5 Hz, C_7-H_2), 3.51 and 3.82 (ABq, each 1H and d, J=8 Hz, $-CH_2O-$), 4.35 (1H, t, J=2.5 Hz, $-\dot{C}HO-$). Found: C, 84.53; H, 10.21%. Calcd for $C_{20}H_{28}O$: C, 84.45; H, 9.92%.

Ether Cleavage of 8. A mixture of **8** (8.131 g) and acetic *p*-toluenesulfonic anhydride (18.40 g) in dichloromethane (150 ml) was stirred at room temperature for 2.5 h and then diluted with ether. The ether solution was washed successively with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was chromatographed on silica gel (500 g), using benzene as the eluent, to give a mixture (8.13 g: 87.1%) of 20-acetoxyabieta-5,8,11,13-tetraene (**9**) and 20-acetoxyabieta-6,8,11,13-tetraene (**10**) in a ratio of *ca.* 5:8 by ^1H NMR spectrum analysis. ^1H NMR of **9** ($CDCl_3$, 90 MHz): 1.85 (3H, s, $-OCOCH_3$), 3.33 (2H, d, J=4 Hz, $=CHC\underline{H}_2-$), 4.13 (2H, s, $-C\underline{H}_2OCOCH_3$), 6.17 (1H, t, J=4 Hz, C_6-H). ^1H NMR of **10** ($CDCl_3$, 90 MHz): 1.74 (3H, s, $-OCOCH_3$), 2.31 (1H, t, J=3 Hz, $C_{5\alpha}$-H), 4.23 and 4.38 (ABq, each 1H and d, J=11 Hz, $-C\underline{H}_2OCOCH_3$), 5.97 (1H, dd, J=3 and 10 Hz, C_6-H), 6.55 (1H, dd, J=3 and 10 Hz, C_7-H).

Abieta-8,11,13-trien-20-ol (13) and 5βH-Abieta-8,11-13-trien-20-ol (14). A mixture (9.180 g) of **9** and **10** in acetic acid (25 ml) was submitted to catalytic hydrogenation using PtO_2 (1.0 g) at room temperature.

The crude product (8.848 g) was immediately treated for 2 h with lithium aluminium hydride (2.04 g) in refluxing ether (100 ml). The excess lithium aluminium hydride was decomposed with ethyl acetate. The mixture was poured into ice-dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was purified by repeated column chromatography on silica gel, using ether-benzene (1:99) as the eluent, to give **13** (5.323 g: 66.1%) and **14** (1.614 g: 20.0%). Alcohol **13**: $[\alpha]_D$ +41.6° (*c* 4.93); IR: 3580, 3440 cm^{-1}; ^1H NMR: 0.97 (6H, s, $-\dot{C}(CH_3)_2$), 1.20 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.45 and 3.73 (ABq, each 1H and bd, J=11 Hz, $-C\underline{H}_2OH$). Found: C, 84.02; H, 10.61%. Calcd for $C_{20}H_{30}O$: C, 83.86; H, 10.56%. Alcohol **14**: $[\alpha]_D$ +17.4° (*c* 2.24); IR: 3610, 3580, 3430 cm^{-1}; ^1H NMR: 0.41 (3H, s, $C_{4\alpha}$-CH_3), 0.95 (3H, s, $C_{4\beta}$-CH_3), 1.21 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.27 (2H, bs, $-C\underline{H}_2OH$), 6.77 (1H, bs, C_{14}-H), 6.83 (1H, dd, J=1.5 and 8 Hz, C_{12}-H), 7.10 (1H, d, J=8 Hz, C_{11}-H). Found: C, 83.98; H, 10.70%. Calcd for $C_{20}H_{30}O$: C, 83.86; H, 10.56%.

20-Acetoxyabieta-8,11,13-triene (11). A mixture of **13** (885 mg) and acetic anhydride (1.0 ml) in pyridine (2.0 ml) was heated at 70—80 °C for 2 h. After the usual work-up, the crude product was chromatographed on silica gel (40 g), using benzene as the eluent, to give **11** (999 mg: 98.4%), $[\alpha]_D$ +56.0° (*c* 3.89), IR: 1733 cm^{-1}; ^1H NMR: 0.99 (6H, bs, $-\dot{C}(CH_3)_2$), 1.21 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.79 (3H, s, $-OCOCH_3$), 4.03 and 4.43 (ABq, each 1H and d, J=11 Hz, $-C\underline{H}_2OCOCH_3$). Found: C, 80.17; H, 10.01%. Calcd for $C_{22}H_{32}O_2$: C, 80.44; H, 9.83.

20-Acetoxy-5βH-abieta-8,11,13-triene (12). A mixture of **14** (403.1 mg) and acetic anhydride (0.5 ml) in pyridine (1.0 ml) was heated at 70—80 °C for 2 h. After the usual work-up, the crude product was chromatographed on silica gel (30 g), using ether-benzene (1:99) as the eluent, to give **12** (432.0 mg: 93.5%), $[\alpha]_D$ +29.0° (*c* 8.14), IR: 1726 cm^{-1}; ^1H NMR: 0.39 (3H, s, $C_{4\alpha}$-CH_3), 0.94 (3H, s, $C_{4\beta}$-CH_3), 1.21 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.93 (3H, s, $-OCOCH_3$), 3.63 and 3.97 (ABq, each 1H and d, J=11 Hz, $-C\underline{H}_2OCOCH_3$), 6.78 (1H, bs, C_{14}-H), 6.86 (1H, bd, J=8 Hz, C_{12}-H), 7.13 (1H, d, J=8 Hz, C_{11}-H). Found: C, 80.56; H, 10.13%. Calcd for $C_{22}H_{32}O_2$: C, 80.44; H, 9.83%.

20-Acetoxy-12-acetylabieta-8,11,13-triene (15). Anhydrous aluminium chloride (1.20 g) was added at 0—5 °C to a stirred solution of **11** (962.3 mg) and acetyl chloride (0.65 ml) in dichloromethane (16 ml). The mixture was stirred at this temperature for 5 min and then at room temperature for 3 h, poured into ice-dilute hydrochloric acid, and extracted with ether. The ether extract was washed successively with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (60 g), using ether-benzene (3.97) as the eluent, to give **15** (927.8 mg: 85.4%), $[\alpha]_D$ +30.6° (*c* 13.02); IR: 1732, 1680 cm^{-1}; ^1H NMR: 0.99 (6H, s, $-\dot{C}(CH_3)_2$), 1.18 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.80 (3H, s, $-OCOCH_3$), 2.44 (3H, s, C_{12}-$COCH_3$), 3.45 (1H, m, $-C\underline{H}(CH_3)_2$), 4.01 and 4.47 (ABq, each 1H and d, J=11 Hz, $-C\underline{H}_2OCOCH_3$), 6.94 (1H, bs, C_{14}-H), 7.30 (1H, s, C_{11}-H). Found: C, 78.07; H, 9.39%. Calcd for $C_{24}H_{34}O_3$: C, 77.80;H, 9.25%.

12,20-Diacetoxyabieta-8,11,13-triene (16). A mixture of **15** (906.0 mg), *m*-chloroperbenzoic acid (80%: 1.05 g), and *p*-toluenesulfonic acid monohydrate (30 mg) in 1,2-dichloroethane (23 ml) was refluxed for 2 h. The mixture was cooled, diluted with ether, and washed successively with aqueous potassium iodide, aqueous sodium thiosulfate,

aqueous sodium hydrogencarbonate, and brine. The dried ether solution was evaporated *in vacuo*. The residue was chromatographed on silica gel (60 g), using ether–benzene (0.5:99.5) as the eluent, to give **16** (655.4 mg: 69.3%), $[\alpha]_D$ +51.9° (*c* 2.37·; IR: 1750 sh, 1732 cm^{-1}; ^1H NMR: 0.97 6H, s, $-C(CH_3)_2$), 1.15 (6H, d, J=7 Hz, $-CH(CH_3)_2$), 1.82 (3H, s, C_{20}-$OCOCH_3$), 2.21 (3H, s, C_{12}-$OCOCH_3$), 4.00 and 4.37 (ABq, each 1H and d, J=11 Hz, $-CH_2OCOCH_3$), 6.69 and 6.13 (each 1H and s, C_{11}-H and C_{14}-H). Found: C, 74.58; H, 8.95%. Calcd for $C_{24}H_{34}O_4$: C, 74.57; H, 8.87%.

*Abieta-8,11,13-triene-12,20-diol (Pisiferol) (**1**).* A mixture of **16** (495.7 mg) and lithium aluminium hydride (195 mg) in dry ether (5.0 ml) was refluxed for 2 h. The mixture was poured into ice-dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (25 g), using ether–benzene (7:93) as the eluent, to give **1** (373.9 mg: 96.4%), which was recrystallized from hexane, mp 147—148.5 °C, $[\alpha]_D$ +79.6° (*c* 2.21); IR: 3580, 3330 cm^{-1}; H^1 NMR ($CDCl_3$, 90 MHz): 0.90 and 0.94 (each 3H and s, $-C(CH_3)_2$), 1.22 (6H, d, J=7 Hz, $-CH(CH_3)_2$), 3.18 (1H, m, $-CH(CH_3)_2$), 3.57 and 3.98 (ABq, each 1H and d, J=11 Hz, $-CH_2OH$), 6.03 (1H, bs, -OH), 6.71 (1H, s) and 6.91 (1H, bs) (C_{11}-H and C_{14}-H). Found: C, 79.71; H, 10.19%. Calcd for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00%. The IR and ^1H MNR spectra of the synthetic **1** were identical with those of natural pisiferol. However, the melting point of the synthetic **1** was higher than that reported (mp 108—110 °C) for natural pisiferol.[8]

*12-Hydroxyabieta-8,11,13-trien-20-al (Pisiferal) (**2**).* A solution of **1** (127.3 mg) in acetone (4.0 ml) was oxidized with Jones reagent [2.5 M (1 M=1 mol dm^{-3}): 0.2 ml] at 0—5°C for 1 min. The mixture was diluted with water and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (10 g), using ether–benzene (1:99) as the eluent, to give **2** (60.2 mg: 47.6%), which was recrystallized from hexane, mp 125.5—127 °C, $[\alpha]_D$ +386° (*c* 0.29); IR: 3595, 3360, 2745, 1700 cm^{-1}; ^1H NMR ($CDCl_3$, 90 MHz): 0.82 and 1.00 (each 3H and s, $-C(CH_3)_2$), 1.20 (6H, d, J=7 Hz, $-CH(CH_3)_2$), 2.92 (2H, *t*, J=6 Hz, C_7-H_2), 3.15 (1H, m, $-CH(CH_3)_2$), 5.63 (1H, bs, C_{12}-OH), 6.64 (1H, s) and 6.92 (1H, bs) (C_{11}-H and C_{14}-H), 9.90 (1H, d, J=1.5 Hz, -CHO); MS (*m/e*): 300 (M^+). The IR and ^1H NMR spectra of the synthetic **2** were identical with those of natural pisiferal. However, the melting point of the synthetic **2** was also higher than that reported (mp 80—82 °C[9]) for natural pisiferal.

*12-Methoxyabieta-8,11,13-trien-20-ol (**17**).* A stirred mixture of **1** (48.3 mg), methyl iodide (0.1 ml), and anhydrous potassium carbonate (220 mg) in ethyl methyl ketone (2.0 ml) was refluxed for 8 h. The mixture was diluted with water and extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (5.0 g), using ether–benzene (2:98) as the eluent, to give **17** (49.6 mg: 98.4%), $[\alpha]_D$ +61.9° (*c* 0.70); IR: 3580, 3450 sh cm^{-1}; ^1H MNR: 0.97 (6H, s, $-C(CH_3)_2$), 1.16 (6H, d, J=7 Hz, $-CH(CH_3)_2$), 3.78 (3H, s, $-OCH_3$), 6.61 (1H, s) and 6.73 (1H, bs) (C_{11}-H and C_{14}-H). Found: C, 79.70; H, 10.47%. Calcd for $C_{21}H_{32}O_2$: C, 79.70; H, 10·19%.

*20-Acetoxy-12-acetyl-5βH-abieta-8,11,13-triene (**18**)* Anhydrous aluminium chloride (540 mg) was added at 0—5 °C to a stirred solution of **12** (428.3 mg) and acetyl chloride (0.29 ml) in dichloromethane (7.0 ml). The mixture was stirred at this temperature for 5 min and then at room temperature for 3 h. After the same work-up as described for the preparation of **15**, the crude product was purified by column chromatography on silica gel (20 g), using benzene and then ether–benzene (1:99) as the eluent, to give **18** (276.4 mg: 57.2%), $[\alpha]_D$ +18.8° (*c* 5.32); IR; 1733, 1680 cm^{-1}; ^1H NMR: 0.41 (3H, s, $C_{4\alpha}$-CH_3) 0.97 (3H, s, $C_{4\beta}$-CH_3), 1.20 (6H, d, J=7 Hz, $-CH(CH_3)_2$), 1.96 (3H, s, $-OCOCH_3$), 2.50 (3H, s, C_{12}-$COCH_3$), 3.70 and 3.97 (ABq, each 1H and d, J=11 Hz, $-CH_2OCOCH_3$), 6.98 (1H, bs, C_{14}-H), 7.40 (1H, s, C_{11}-H). Found: C, 77.65; H, 9.42%. Calcd for $C_{24}H_{31}O_3$: C, 77.80; H, 9.25%.

*16,20-Diacetoxy-5βH-abieta-8,11,13-triene (**19**)* A mixture of **18** (283.9 mg), *m*-chloroperbenzoic acid (80%: 330 mg), and *p*-toluenesulfonic acid monohydrate (5.0 mg) in 1,2-dichloroethane (6.0 ml) was refluxed for 2 h. After the same work-up as described for the preparation of **16**, the crude product was chromatographed on silica gel (50 g), using ether–benzene (1:99) as the eluent, to give **19** (185.8 mg: 61.8%), $[\alpha]_D$ +25.9° (*c* 3.13); IR: 1750 sh, 1732 cm^{-1}; ^1H NMR: 0.39 (3H, s, $C_{4\alpha}$-CH_3), 0.94 (3H, s, $C_{4\beta}$-CH_3), 1.17 (6H, d, J=7 Hz, $-CH(CH_3)_2$), 1.94 (3H, s, C_{20}-$OCOCH_3$), 2.24 (3H, s, C_{12}-$OCOCH_3$), 3.86 (2H, s, $-CH_2OCOCH_3$), 6.80 (1H, s) and 6.85 (1H, bs) (C_{11}-H and C_{14}-H). Found: C, 74.74; H, 9.11%. Calcd for $C_{24}H_{34}O_4$: C, 74.57; H, 8.87%.

*5βH-Abieta-8,11,13-triene-12,20-diol (**20**).* A mixture of **19** (153.3 mg) and lithium aluminium hydride (60 mg) in dry ether (5.0 ml) was refluxed for 2 h. After the same work-up as described for the preparation of **1**, the crude product was chromatographed on silica gel (10 g), using ether–benzene (8:92) as the eluent, to give **20** (125.7 mg: 98.5%). This was recrystallized from hexane, mp 113.5—115 °C, $[\alpha]_D$ +27.4° (*c* 2.60); IR: 3600, 3350 cm^{-1}; ^1H NMR ($CDCl_3$): 0.44 (3H, s, $C_{4\alpha}$-CH_3), 0.93 (3H, s, $C_{4\beta}$-CH_3), 1.22 (6H, d, J=7 Hz, $-CH(CH_3)_2$), 3.15 (1H, m, $-CH(CH_3)_2$), 3.38 (2H, bs, $-CH_2OH$), 6.65 (1H, s) and 6.79 (1H, bs) (C_{11}-H and C_{14}-H). Found: C, 79.37; H, 10.27%. Calcd for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00%.

*Oxidation of **12**.* A solution of **12** (175.0 mg) in acetone (3.0 ml) was oxidized with Jones reagent (2.5 M: 0.3 ml) at room temperature for 2.5 h and then diluted with ether. The ether solution was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (10 g), using benzene as the eluent, to give the starting **12** (79.7 mg: 45.5%). Subsequent elution with ether–benzene (3:97) afforded 20-acetoxy-5β*H*-abieta-8,11,13-trien-7-one (**21**) (52.0 mg: 28.5%; 52.3%[7]), $[\alpha]_D$ +40.0° (*c* 5.88); IR: 1735, 1672, 1608 cm^{-1}; ^1H NMR: 0.69 (3H, s, $C_{4\alpha}$-CH_3), 0.99 (6H, d, J=7 Hz, $-CH(CH_3)_2$), 1.05 (3H, s, $C_{4\beta}$-CH_3), 1.66 (3H, s, $-OCOCH_3$), 2.49 (2H, bd, J=5.5 Hz, $-CH_2CO-$), 2.64 (1H, m, $-CH(CH_3)_2$), 3.43 and 3.74 (ABq, each 1H and d, J=12 Hz, $-CH_2OCOCH_3$), 6.98 (2H, bs, C_{11}-H and C_{12}-H), 7.52 (1H, bs, C_{14}-H). Found: C, 77.31; H, 9.05%. Calcd for $C_{22}H_{30}O_3$: C, 77.15; H, 8.83%.

Further elution with the same solvent afforded 20-acetoxy-5β*H*-abieta-8,11,13-triene-6,7-dione (**22**) (29.8 mg: 15.7%; 28.8%[7]), $[\alpha]_D$ +50.2° (*c* 6.15); IR: 1748, 1727, 1688, 1608 cm^{-1}; ^1H NMR: 0.66 (3H, s, $C_{1\alpha}$-CH_3), 1.00 (6H, d, J=7 Hz, $-CH(CH_3)_2$), 1.06 (3H, s, $C_{4\beta}$-CH_3), 1.48 (3H, s, $-OCOCH_3$), 2.21 (1H, s, $C_{5\beta}$-H), 3.25 and 3.65 (ABq, each 1H and d, J=11 Hz, $-CH_2OCOCH_3$), 6.99 (1H, d, J=9 Hz C_{11}-H), 7.18 (1H, dd, J=1.5 and 9 Hz, C_{12}-H),

7.58 (1H, d, $J=1.5$ Hz, C_{14}-H); MS (*m/e*): 356 (M^+).

20-Acetoxy-6β-bromo-5βH-abieta-8,11,13-trien-7-one (23) A mixture of **21** (68.5 mg) and 80% pyridinium tribromide (80 mg) in dichloromethane (1.5 ml) was stirred at room temperature for 1 h. The mixture was diluted with water and extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and water, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (10 g), using ether-benzene (3:97) as the eluent, to give **23** (82.0 mg: 97.3%); IR: 1735, 1680, 1608 cm^{-1}; ^1H NMR: 0.26 (3H, s, $C_{4\alpha}$-CH_3), 1.13 (3H, s, $C_{4\beta}$-CH_3), 1.29 (6H, d, $J=7$ Hz, -CH($C\underline{H}_3$)$_2$), 1.99 (3H, s, -OCOCH_3), 2.61 (1H, s, $C_{5\beta}$-H), 2.94 (1H, m, -C$\underline{H}$(CH_3)$_2$), 3.81 and 4.12 (ABq, each 1H and d, $J=11.5$ Hz, -C$\underline{H}_2$OCOCH_3), 4.72 (1H, s, $C_{6\alpha}$-H), 7.15—7.5 (2H, m, C_{11}-H and C_{12}-H), 7.77 (1H, bs, C_{14}-H); MS (*m/e*): 422 (M^++2), 420 (M^+),

20-Acetoxyabieta-5,8,11,13-tetraen-7-one (24). A mixture of **23** (364.0 mg), lithium carbonate (192 mg), and lithium bromide (150 mg) in *N*,*N*-dimethylformamide (4.5 ml) was stirred at 110—130 °C for 4 h under a stream of nitrogen. The mixture was cooled, poured into ice-dilute hydrochloric acid, and extraced with ether. The ether extract was washed successively with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (20 g), using ether-benzene (3:97) as the eluent, to give **24** (258.3 mg: 87.8%). This was recrystallized from hexane, mp 75—76 °C, $[\alpha]_D$ −17.5° (*c* 5.15); IR: 1735, 1650, 1608 cm^{-1}; ^1H NMR: 1.28 (6H, d, $J=7$ Hz, -CH($C\underline{H}_3$)$_2$), 1.30 (6H, s, -$\dot{C}$(CH_3)$_2$), 1.72 (3H, s, -OCOCH_3), 2.95 (1H, m, -C$\underline{H}$(CH_3)$_2$), 4.05 and 4.43 (ABq, each 1H and d, $J=11$ Hz, -C$\underline{H}_2$OCOCH_3), 6.45 (1H, s, C_6-H), 7.28 (2H, bs, C_{11}-H and C_{12}-H), 7.79 (1H, bs, C_{14}-H). Found: C, 77.46; H, 8.34%. Calcd for $C_{22}H_{28}O_3$: C, 77.61; H, 8.29%.

Catalytic Hydrogenation of 24. A mixture of **24** (280 mg), 10% Pd-C (200 mg), and 60% perchloric acid (0.2 ml) in ethyl acetate (7.0 ml) was stirred at room temperature for 7.5 h in an atmosphere of hydrogen. The mixture was filtered and the filtrate was washed with brine. The dried solution was evaporated *in vacuo* to give an oil (267 mg: 98.9%), whose IR and ^1H NMR spectra were identical with those of the authentic **11**.

6,20-Diacetoxyabieta-5,8,11,13-tetraen-7-one (25). A mixture of **22** (220.0 mg) and anhydrous sodium acetate (900 mg) in acetic anhydride (9.0 ml) was refluxed for 28.5 h. The reaction mixture was cooled and diluted with ether. The ether solution was washed with water and evaporated *in vacuo*. The residue was extracted with ether. The ether extract was washed successively with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (20 g), using ether-benzene (3:97) as the eluent, to give **25** (191.6 mg: 77.9%), $[\alpha]_D$ +13.1° (*c* 2.68); IR: 1760, 1740, 1664, 1614 cm^{-1}; ^1H NMR: 1.28 (6H, d, $J=7$ Hz, -CH($C\underline{H}_3$)$_2$), 1.29 and 1.34 (each 3H and s, -$\dot{C}$(CH_3)$_2$), 1.77 (3H, s, C_{20}-OCOCH_3), 2.30 (3H, s, C_6-OCOCH_3), 2.94 (1H, m, -C$\underline{H}$(CH_3)$_2$), 3.88 and 4.56 (ABq, each 1H and d, $J=11$ Hz, -C$\underline{H}_2$OCOCH_3), 7.33 (2H, bs, C_{11}-H and C_{12}-H), 7.80 (1H, bs, C_{14}-H); MS (*m/e*): 398 (M^+).

Catalytic Hydrogenation of 25. A mixture of **25** (175.0 mg), 10% Pd-C (175 mg), and 60% perchloric acid (0.2 ml) was submitted to catalytic hydrogenation at room temperature for 9 h. After the same work-up as described for the preparation of **11**, the crude product was chromatographed on silica gel (15 g), using benzene as the eluent, to give **11** (41.6 mg: 28.8%). Further elution with ether-benzene (1:99) afforded, without further separation, a mixture (90.3 mg: 53.2%) of 6α,20-diacetoxyabieta-8,11,13-triene (**26**) and 6β,20-diacetoxyabieta-8,11,13-triene (**27**) in a ratio of *ca.* 1:1. ^1H NMR of **26** ($CDCl_3$): 0.87 and 1.04 (each 3H and s, -$\dot{C}$(CH_3)$_2$), 1.69 and 1.98 (each 3H and s, C_6-OCOCH_3 and C_{20}-OCOCH_3), 4.32 (2H, s, -C$\underline{H}_2$OCOCH_3), 5.44 (1H, m, $W_{1/2}=14$ Hz, $C_{6\beta}$-H). ^1H NMR of **27** ($CDCl_3$): 1.04 and 1.07 (each 3H and s, -$\dot{C}$(CH_3)$_2$), 1.99 and 2.02 (each 3H and s, C_6-OCOCH_3 and C_{20}-OCOCH_3), 4.45 and 4.80 (ABq, each 1H and d, $J=12$ Hz, -C$\underline{H}_2$OCOCH_3), 5.65 (1H, m, $W_{1/2}=10$ Hz, $C_{6\alpha}$-H).

The authors are grateful to Dr. M. Yatagai, Forestry and Forest Products Research Institute, for kindly supplying the spectral data of natural products.

Synthesis of [0]Orthocyclo[2]orthocyclo[0](1,1′)ferrocenophane and [0]Paracyclo[2]paracyclo[0](1,1′)ferrocenophane

Iwao Shimizu, Hiroshi Umezawa, Toshihiro Kanno, Taeko Izumi, and Akira Kasahara*

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992

(Received December 10, 1982)

syn- and *anti*-[0]Orthocyclo[2]orthocyclo[0](1,1′)ferrocenophan-7-enes were synthesized *via* an intramolecular reductive coupling of 1,1′-bis(*o*-formylphenyl)ferrocene with low valent titanium reagents. *syn*- and *anti*-[0]Orthocyclo[2]orthocyclo[0](1,1′)ferrocenophanes and [0]paracyclo[2]paracyclo[0](1,1′)ferrocenophane were prepared by the reaction of 1,1′-bis[*o*-(bromomethyl)phenyl]ferrocene and 1,1′-bis[*p*-(bromomethyl)phenyl]-ferrocene with butyllithium. The transannular π-electronic interactions between two aromatic rings in these compounds were examined on the basis of the NMR and electronic spectra.

Recently a wide variety of cyclophane compounds containing benzene or heteroaromatic rings has been synthesized in order to study the effect of transannular π-electronic interactions on their physical and chemical properties.[1] Many ferrocenophanes of [*m*] (1,2)-, [*m*]-(1,1′)- or [*m.n*] (1,1′)-type are known in which one or more intramolecular bridges link homo- or heteroannular positions within one or two ferrocene moieties,[2] but there have been only a few investigations of ferrocenophanes having transannular π-electronic interactions: [2.2]ferrocenophane-1,13-diyne,[3] [2.2]ferrocenophane-1,13-diene,[4] [3.3]- and [5.5] (1,1′)ferrocenophane derivatives,[5] and [2]paracyclo[2]paracyclo-[2] (1,1′)ferrocenophane derivatives.[6] Moreover, as a part of our studies on metallocenophane chemistry, we have reported the synthesis of [0]metacyclo-[2]metacyclo[0](1,1′)ferrocenophan-7-ene, in which substantial repulsive interactions exist between the two aryl rings.[7] These results have encouraged us to study the synthesis of [0]orthocyclo[2]orthocyclo[0]-(1,1′)ferrocenophanes (**1**) and [0]paracyclo[2]paracyclo[0] (1,1′)ferrocenophane (**2**).

Results and Discussion

Synthesis. Although a number of synthetic methods have recently been developed for [2.2]paracyclophanes,[8] a reductive coupling of carbonyl compounds with low valent titanium reagents[9] is still very convenient and advantageous for the synthesis of cyclophane compounds because of the availability of the intermediary compounds.[5–7,10] In the present work, we attempted to synthesize by the same method the unsaturated ferrocenophanes: [0]orthocyclo[2]orthocyclo[0] (1,1′)ferrocenophan-7-enes (**3s** and **3a**) and [0]-paracyclo[2]paracyclo[0] (1,1′)ferrocenophan-7-ene (**4**). In connection with the synthesis of **3s**, **3a**, and **4**, it became desirable to synthesize 1,1′-bis(*o*-formylphenyl)ferrocene (**5a**) and 1,1′-bis(*p*-formylphenyl)ferrocene (**5b**) in quantity.

The syntheses of the intermediates, **5a** and **5b**, were carried out by the Gomberg's arylation of ferrocene with diazonium salts (**6a** and **6b**) derived from methyl anthranilate and ethyl *p*-aminobenzoate, subsequent reduction with $LiAlH_4$, and oxidation with MnO_2 in chloroform.

The reductive coupling of **5a** to the ferrocenophanes (**3s** and **3a**) with low valent titanium reagents was carried out according to Mukaiyama's procedure ($TiCl_4$–Zn).[9a] Separation of the reaction products by silica-gel column chromatography gave 1,1′-di-*o*-tolylferrocene (**8a**), **3s**, and **3a**, and 1,1′-bis[*o*-(hydroxymethyl)phenyl]ferrocene (**7a**). On the other hand, the intramolecular reductive coupling of **5b** with $TiCl_4$–Zn for preparing the unsaturated ferrocenophane **4**, was unfortunately unsuccessful and led to the formation of reduction products: 1,1′-bis[*p*-(hydroxymethyl)phenyl]ferrocene (**7b**) and 1,1′-*p*-tolylferrocene (**8b**).

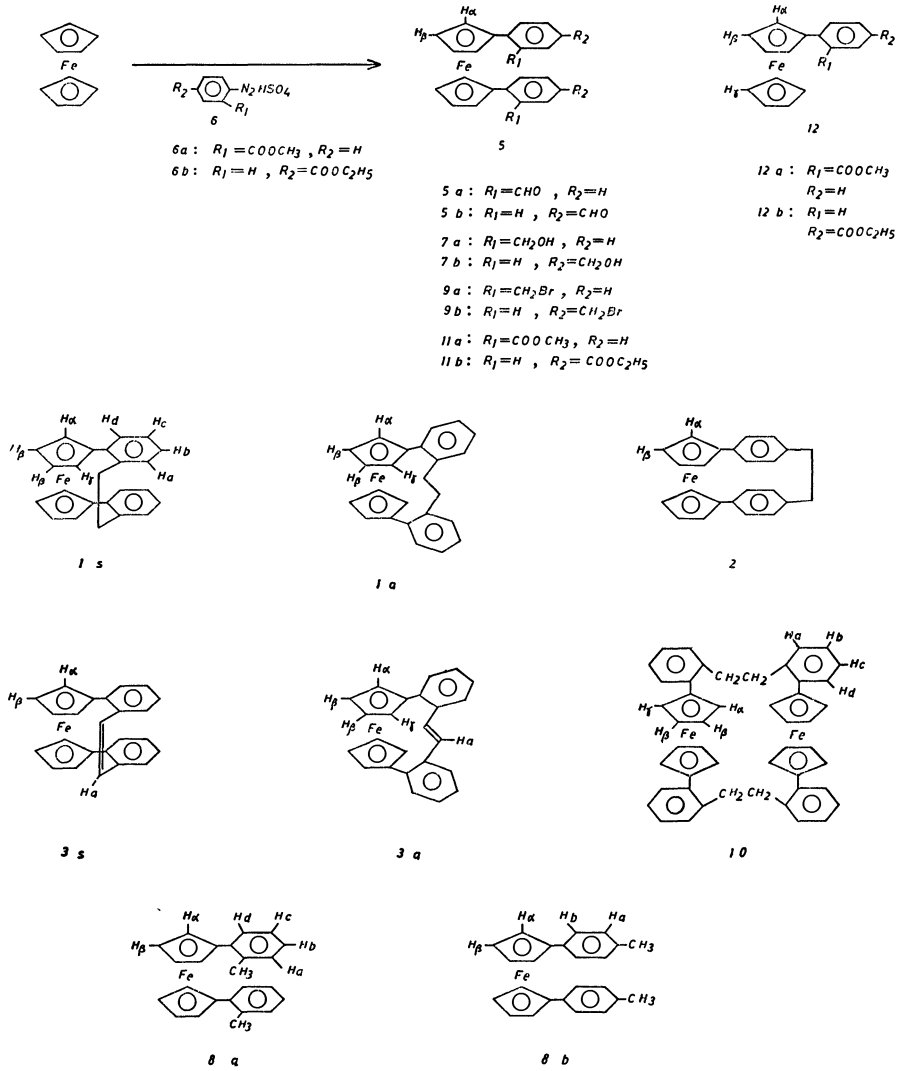
The ferrocenophanes, **3s** and **3a**, are exceedingly insoluble in common solvents and olefinic bond of the compounds is sterically hindered. Therefore, attempts to reduce catalytically to saturated ferrocenophanes, **1s** and **1a**, were made without results. Thus, the **1s** and **1a**, were prepared by the ring closure of 1,1′-bis[*o*-(bromomethyl)phenyl]ferrocene (**9a**) with butyllithium according to Trampe's procedure.[11] The separation of the reaction products by silica-gel column chromatography led to the isolation of **1s**, **1a**, and the dimer: [0]orthocyclo[2]orthocyclo[0] (1,1′)-ferroceno[0]orthocyclo[2]orthocyclo[0] (1,1′)ferrocenophane (**10**). The reaction of 1,1′-bis[*p*-(bromomethyl)-phenyl]ferrocene (**9b**) with butyllithium afforded the saturated ferrocenophane **2**.

The synthesis of the intermediates, **9a** and **9b**, were carried out by the reaction of the alcohols, **7a** and **7b**, with chlorotrimethylsilane and lithium bromide.[12]

Structures. The structures of the ferrocenophanes, **1s**, **1a**, **2**, **3s**, and **3a**, were determined on the basis of the IR, NMR, and mass spectra, and the elementary analyses. The NMR and IR spectra data of all ferrocenophanes and the reference compounds are summarized in Tables 1 and 2, respectively.

In the unsaturated ferrocenophanes (**3s** and **3a**), the mass spectra show the pattern containing a molecular ion peak at *m/e* 362, indicating that the two are isomeric. The configuration of olefinic bond in **3s** was confirmed to be *cis*, because the IR spectrum of **3s** exhibited a band of 730 cm^{-1} which was characteristic of *cis* vinylene linkage and the characteristic C–H out of deformation modes of *trans* vinylene linkage at near 960 cm^{-1} were absent. On the other hand, the configuration of olefinic bond in **3a** was confirmed to be *trans*, because the IR spectrum of **3a** exhibited a band of 960 cm^{-1} which was characteristic of *trans* vinylene linkage.

In ferrocene, the distance between the two cyclo-



Scheme 1.

pentadienyl rings is 3.32 Å,[13] while the van der Waals separation between parallel π-system is 3.4 Å.[14] Thus, in **3s**, substantial repulsive interactions exist probably between the two aromatic rings which are bound together by vinylene bridges at both *ortho*-positions. In the NMR spectrum of **3s**, the aromatic protons (δ, 6.87) appear at higher fields than the corresponding protons of **3a** (δ, 7.18—7.33) and the reference compound **8a** (δ 7.13 and 7.60). This phenomenon indicates that the two benzene rings in **3s** are held face to face in close proximity by a vinylene bridge and the *syn*-conformation for **3s** can be accommodated. The aromatic proton signals of **3a** were observed at nearly the same positions as those of the reference compound **8a**. This suggests that the two benzene rins in **3a** are not held in a face to face conformation and the *anti*-conformation for **3a** can be accommodated.

In the saturated cyclophanes (**1s** and **1a**), the mass spectra also show the same pattern containing a molecular ion peak at *m/e* 364. This fact confirms that the two are isomeric, similar to the case of **3s** and **3a**. The structural difference between **1s** and **1a** is unequivocally realized in the NMR spectra. The aromatic protons of **1s** (δ, 6.58 and 7.06) exhibit an upfield shift, due to the diamagnetic shielding effect of the opposed aromatic ring, whereas the aromatic proton signals of **1a** were observed at nearly the same positions as those of the reference compound **8a**. These data are best accommodated by the *syn*-structure for **1s** and the *anti*-structure for **1a**.

In ferrocenophane **2**, the IR spectra revealed the presence of 1,1′-disubstituted ferrocene and *p*-disubstituted benzene rings. The molecule probably exists in the conformation with the phenyl rings approximately parallel to one another and approximately coplanar to the plane of the cyclopentadienyl ring. Thus, in **2**, substantial repulsive interactions must exist between the two benzene rings which are bound together by a methylene bridge at both *para*-positions. In the NMR spectra of **2**, as expected, the aromatic protons (δ, 6.62) appeared at higher fields than the corresponding protons of the reference compound, **8b** (δ, 6.98 and 7.18). This phenomenon is probably due to diamagnetic shielding effect due to opposed aromatic ring.

The electronic spectra of the ferrocenophanes (**1s**, **1a**, **2**, **3s**, **3a**, and **10**) and the reference compounds (**8a** and **8b**) are shown in Figs. 1 and 2. It is well known that the transannular electronic interactions in cyclophanes result in the bathochromic and hyperchromic shifts of absorption bands in electronic spectra.[1,8] Toluene shows no absorption in the long wavelength region above 270 nm.[15] The electronic spectra of **1s**, **3s**, and **2** showed somewhat bathochromic and hyperchromic shifts and unambiguous broadening in a range 220—300 nm, compared with those of the reference compounds, **8a** and **8b**. This may be due to transannular π-electronic interactions between the two benzene chromophores in **1s**, **3s**, and **2**; these phenomena are also explained by *syn*-structure, but not by *anti*-structure. On the other hand, in 240—300 nm region, the electronic spectra of **1a** and **3a**, are very similar to the spectra of the reference compound, **8a**. This phenomenon and the small shielding effects on aromatic protons in the NMR spectra of **1a** and **3a** indicate that the interactions between the two benzene rings in **1a** and **3a** are relatively weak and the *anti*-conformations are accommodated.

The IR, NMR, and mass spectra of the dimer **10** were all consistent with the proposed structure. The fragmentation pattern observed in the mass spectra of **10** consisted of only three predominant peaks: *m/e* 56, 364, and 728, corresponding to Fe^+, a doubly charged parent species, and a parent ion respectively. This fragmentation pattern is normally observed in [0.0]-,[16] [1.1]-,[17] [2.2]-,[3,4] and [3.3] (1,1′)ferrocenophanes.[5] The IR spectra revealed the presence of 1,1′-disubstituted ferrocene and *o*-disubstituted benzene rings. In the NMR spectrum of **10**, the aromatic proton signals were observed at nearly the same positions as those of the reference compound, **8a**. Moreover, in the 240—300 nm region of the electronic spectrum of **10**, the intensity was somewhat increased, but the shape of the spectrum was very similar to that of **8a**. These phenomena indicate that the interactions between the benzene rings in **10** are relatively weak.

The electronic spectrum of ferrocene have two main absorptions, *viz.*, 325 and 440 nm. Both the position and the intensity of the 440 nm are particularly sensitive to ferrocene ring-tilt distortion.[18] In the 330—450 nm region, the intensity of the spectra of **1s**, **1a**, **3s**, **3a**, and **10** was somewhat increased, but the shape of the spectra was practically identical with that of the reference compound **8a** bearing an untilted ferrocene ring. These phenomena suggest that, due to the short length of the side chain which is bridging at the *ortho* position of the benzene ring, the planes of the cyclopentadienyl and benzene rings in these compounds have a nonplanar orientation, and accordingly the ferrocene ring tilt distortions are relatively weak. The electronic spectrum of **2** in the 330—450 nm region shows an increased intensity and a bathochromic shift to higher wavelength (475 nm), compared with that of **8b** bearing an untilted ferrocene ring. This suggests that, in **2**, a ferrocene ring-tilt distortion occurs due to the short length of the side chain which is bridging at the *para* position in benzene rings.

The IR spectra of [2.2]paracyclophane system have several obvious features.[19] One is the increase of the intensity of the band in 1530—1600 cm^{-1}, which is related to the increased double bond character due to the distortion of the benzene rings. The other is the appearance of a strong new maximum near the 710 cm^{-1} region. Longgone and Warren[19b] reported that the strong maximum at 725 cm^{-1} in [2.2]paracyclophane and at 710 cm^{-1} in 4,7,12,15-tetramethyl[2.2]-paracyclophane might be a characteristic band associated with the distortion benzene ring in [2.2]paracyclophane system. Otsubo *et al.*[19c] also reported the same phenomena in the multilayered [2.2]paracyclophane system. In practice, besides the strong peak around 1600 cm^{-1}, the ferrocenophane **2** exhibits a strong new band around 710 cm^{-1}, whereas the reference compound **8b** bearing strain-free benzene rings exhibits no band in this region. This indicates that the compound **2** bears strained benzene rings due to the interactions between the two aromatic rings. On

2	3100, 810 (1,1′-disubstituted ferrocene ring), 1600, 1500, 820 (*p*-disubstituted benzene ring), 710, 685 (distorted benzene ring)
8b	3100, 805 (1,1′-disubstituted ferrocene ring), 1600, 1500, 825 (*p*-disubstituted benzene ring)

the other hand, near the 700 cm^{-1} region, the IR spectra of **1s**, **1a**, **3s**, **3a**, and **10** are quite similar to those of the open-chain model **8a**. This may be due to the non-distortion of benzene rings in these compounds.

Experimental

Measurements. All the melting points are uncorrected. The IR, NMR, mass, and electronic spectra were recorded with Hitachi 260-10, Hitachi R-22, Hitachi RMU-6M, and Hitachi 200-10 spectrometers, respectively.

1,1′-Bis[o-(*methoxycarbonyl*)*phenyl*]*ferrocene* (**11a**). Methyl anthranilate (15.1 g, 0.10 mol) was diazotized in 10% sulfuric acid (300 cm^3) at 0—5 °C with sodium nitrite (7.1 g, 0.102 mol). After diazotization had been completed, the diazotized salt solution was added rapidly to a solution of ferrocene (7.44 g, 0.04 mol) in acetic acid (500 cm^3) under an atmosphere of nitrogen. The resulting dark brown solution was stirred overnight at room temperature, and was then poured into water. The reaction mixture was extracted with chloroform and the chloroform extract was washed with 5% aqueous sodium hydrogencarbonate solution, and brine, dried over anhyd $MgSO_4$, filtered, and concentrated. The residue was purified by column chromatography (silica gel-benzene). First elution with benzene gave the starting material: ferrocene (1.23 g, 16.5%), mp 173 °C.

Second elution with benzene afforded 1.34 g (10.4% yield based on ferrocene) of [*o*-(methoxycarbonyl)phenyl]ferrocene (**12a**), raddish crystals, mp 74—76 °C (lit,[20] mp 74—75 °C). IR (KBr): 3100, 1100, 1000. 805 (monosubstituted ferrocene ring), 1720 (-COOMe), 1600, 1500, 760, 735 cm^{-1} (*o*-disubstituted benzene ring). ^{1}H NMR ($CDCl_3$): δ=3.68 (s, 3H, $-C\underline{H}_3$), 4.02 (s, 5H, $\underline{H}_\gamma$), 4.26 (t, 2H, $\underline{H}_\beta$), 4.42 (t, 2H, $\underline{H}_\alpha$), 7.11—7.82 (m, 4H, Ar-$\underline{H}$). Found: C, 67.47; H, 4.87%; M^+, 320. Calcd for $C_{18}H_{16}FeO_2$: C, 67.52; H, 5.03%; M, 320.

Third elution with benzene gave 4.42 g of **11a** (23.3% yield based on ferrocene), reddish crystals, mp 92—94 °C. IR (KBr): 3100, 805 (1,1′-disubstituted ferrocene ring), 1720 (-COOMe), 1600, 1500, 760, 735 cm^{-1} (*o*-disubstituted benzene ring). ^{1}H NMR ($CDCl_3$): δ=3.69 (s, 6H, $-C\underline{H}_3$), 4.19 (t, 4H, $\underline{H}_\beta$), 4.33 (t, 4H, $\underline{H}_\alpha$), 7.18—7.60 (m, 8H, Ar-$\underline{H}$). Found: C, 68.86; H, 4.95%; M^+, 454. Calcd for $C_{25}H_{22}FeO_4$: C, 68.73; H, 4.88%; M, 454.

1,1′-Bis[p-(*ethoxycarbonyl*)*phenyl*]*ferrocene* (**11b**). Gomberg's arylation of ferrocene with diazonium salts (**6b**) derived from ethyl *p*-aminobenzoate, was carried out in the same way as descrived for **11a**, and [*p*-(ethoxycarbonyl)-phenyl]ferrocene (**12b**, mp 87—88 °C, reddish crystals, (lit,[21] mp 88—90 °C) and **11b** (reddish yellow crystals, mp 130—131 °C) were obtained in 14 and 26% yields, respectively.

12b: IR (KRr): 3100, 1100, 800 (monosubstituted ferrocene ring), 1715 (-COOEt), 1600, 820 cm^{-1} (*p*-disubsti-

tuted benzene ring). ^{1}H NMR ($CDCl_3$): δ=1.33 (t, 3H, -CH$_3$), 3.97 (s, 5H, H$_\gamma$), 4.33 (t, 2H, H$_\beta$), 4.37 (q, 2H, -CH$_2$-), 4.65 (t, 2H, H$_\alpha$), 7.44 (d, 2H, Ar-H), 7.92 (d, 2H, Ar-H). Found: C, 68.16; H, 5.26%; M$^+$, 334. Calcd for $C_{19}H_{18}FeO$: C, 68.28; H, 5.42%; M, 334.

11b: IR (KBr): 3100, 805 (1,1′-disubstituted ferrocene ring), 1720 (-COOEt), 1600, 820 cm^{-1} (*p*-disubstituted benzene ring). ^{1}H NMR ($CDCl_3$): δ=1.36 (t, 6H, -CH$_3$), 4.24 (t, 4H, H$_\beta$), 4.37 (q, 4H, -CH$_2$-), 4,49 (t, 4H, H$_\alpha$), 7.22 (d, 4H, Ar-H), 7.80 (d, 4H, Ar-H). Found: C, 69.25; H, 5.37%; M$^+$, 482. Calcd for $C_{28}H_{26}FeO_4$: C, 69.37; H, 5.43%; M, 482.

1,1′-Bis[o-*(hydroxymehyl)phenyl*]*ferrocene* (**7a**). To a suspension of $LiAlH_4$ (1.41 g, 0.037 mol) in anhydrous diethyl ether (160 cm^3) was added dropwise a solution of **11a** (8.17 g, 0.018 mol) in dry benzene (100 cm^3) at room temperature during 1 h, and the reaction mixture was then heated under reflux for an additional 5 h. After the mixture had been decomposed with a small amount of cold water, the organic layer was washed successively with 5% hydrochloric acid, 5% sodium hydrogencarbonate solution, and brine, and dried over anhyd $MgSO_4$. After removal of the solvents, the residue was purified by column chromatography on silica gel (chloroform) to afford **7a** as reddish yellow crystals, which were recrystallized from ethanol, mp 103—104 °C (6.73 g, 94% yield). IR (KBr): 3300, 1020 (-OH), 3100, 810 (1,1′-disubstituted ferrocene ring), 1600, 1500, 750 cm^{-1} (*o*-disubstituted benzene ring). ^{1}H NMR ($CDCl_3$): δ=2.20 (br-s, 2H, -OH), 4.24 (m, 4H, H$_\beta$), 4.36 (m, 4H, H$_\alpha$), 4.56 (s, 4H, -CH$_2$-), 7.13—7.35 (m, 8H, Ar-H). Found: C, 72.49; H, 5.67%; M$^+$, 398. Calcd for $C_{24}H_{22}FeO_2$: C, 72.37; H, 5.56%, M, 398.

1,1′-Bis[p-*(hydroxymethlyl)phenyl*]*ferrocene* (**7b**). A reduction of **11b** with $LiAlH_4$ was carried out in the same way as described above, and **7b** (reddish crystals mp 210—212 °C) was obtained in 89% yield. IR (KBr): 3200 (-OH), 3100, 805 (1,1′-disubstituted ferrocene ring), 1600, 1500, 820 cm^{-1} (*p*-disubstituted benzene ring). ^{1}H NMR ($CDCl_3$): δ=4.12 (t, 4H, H$_\beta$), 4.47 (m, 8H, H$_\alpha$+-CH$_2$-), 5.07 (br-s, 2H, -OH), 7.11 (d, 4H, Ar-H), 7.26 (d, 4H, Ar-H). Found: C, 72.31; H, 5.48%; M$^+$, 398. Calcd for $C_{21}H_{22}FeO_2$: C, 72.37; H, 5.56%; M, 398.

1,1′-Bis(o-*formylphenyl*)*ferrocene* (**5a**). At room temperature, active manganese(IV) oxide (100 g) was added to a solution of **7a** (6.76 g, 0.017 mol) in chloroform (200 ml) and the mixture was stirred in the dark for 12 h. After filtration to remove MnO_2, the reddish chloroform solution was evaporated to dryness and the residue was chromatographed by elution of benzene on silica gel to afford reddish crystals **5a** (5.88 g, 87% yield), mp 124—125 °C. IR (KBr): 2820, 1680 (-CHO), 3100, 810 (1,1′-disubstituted ferrocene ring), 1600, 1500, 740 cm^{-1} (*o*-disustituted benzene ring). ^{1}H NMR ($CDCl_3$): δ=4.38 (m, 4H, H$_\beta$), 4.47 (m, 4H, H$_\alpha$), 7.33—7.85 (m, 8H, Ar-H), 10.31 (s, 2H, -CHO). Found: C, 73.27; H, 4.73%; M$^+$, 384. Calcd for $C_{24}H_{18}FeO_2$: C, 73.11; H, 4.60%; M, 384.

1,1′-Bis(p-*formylphenyl*)*ferrocene* (**5b**). An oxidation of **7b** with active manganese(IV) oxide was carried out in the same way as described above, and reddish crystal **5b** (mp 220—221 °C) were obtained in 54% yield. IR (KBr): 2820, 1695, (-CHO), 3100, 805 (1,1′-disubstituted ferrocene ring), 1600, 1500, 820 cm^{-1} (*p*-disubstituted benzene ring). ^{1}H NMR ($CDCl_3$): δ=4.33 (m, 4H, H$_\beta$), 4.58 (m, 4H, H$_\alpha$), 7.28 (d, 4H, Ar-H), 7.61 (d, 4H, Ar-H), 9.92 (s, 2H, -CHO). Found: C, 73.02; H, 4.45%; M$^+$, 384. Calcd for $C_{24}H_{18}FeO_2$: C, 73.11; H, 4.60%; M, 384.

1,1-Bis[o-*(bromomethyl)phenyl*]*ferrocene* (**9a**). Under an atmosphere of nitrogen, chlorotrimethylsilane (5.43 g, 0.05 mol) was added to a solution of anhyd lithium bromide (3.48 g, 0.04 mol) in dry acetonitrile (50 cm^3) with stirring at room temperature. The alcohol **7a** (3.62 g, 0.01 mol) was then added and the reaction mixture was heated under reflux for 12 h. After cooling, the mixture was extracted with diethyl ether (300 cm^3), and the extract was washed successively with water, 5% sodium hydrogencarbonate solution, and brine, and dried over anhyd $MgSO_4$ Removal of the solvents and subsequent recrystallization from benzene-hexane afforded orange crystals **9a** (2.10 g, 40% yield), mp 150—152 °C. IR (KBr): 3100, 810 (1,1′-disubstituted ferrocene ring), 1600, 1500, 760 cm^{-1} (*o*-disubstituted benzene ring). ^{1}H NMR ($CDCl_3$): δ=4.27 (m, 4H, H$_\beta$), 4.34 (s, 4H, -CH$_2$-), 4.51 (m, 4H, H$_\alpha$), 7.11—7.64 (m, 8H, Ar-H). Found: C, 54.87; H, 3.73%. MS: 364 (M$^+$ −2Br), 444 (M$^+$ −Br), 524 (M$^+$). Calcd for $C_{24}H_{20}Br_2Fe$: C, 55.00; H, 3.48%; M, 524.

1,1′-Bis[p-*(bromomethyl)phenyl*]*ferrocene* (**9b**). The reaction of the alcohol **7b** with Me_3SiCl-LiBr in acetonitrile was carried out in the same way as described above, and the reaction product **7b** was purified by column chromatography on silica gel using benzene as eluent in 43% yield, reddish crystals, mp 136—138 °C (decomp). IR (KBr): 3100, 805 (1,1′-disubstiuted ferrocene ring), 1600, 1500, 825 cm^{-1} (*p*-disubstituted benzene ring). ^{1}H NMR ($CDCl_3$): δ=4.23 (t, 4H, H$_\beta$), 4.48 (m, 8H, H$_\alpha$+-CH$_2$-), 7.17 (br-s, 8H, Ar-H). Found: C, 54.87; H, 3.33%. MS: 364 (M$^+$ −2Br), 444 (M$^+$−Br), 524 (M$^+$). Calcd for $C_{24}H_{20}Br_2Fe$: C, 55.00; H, 3.48%; M, 524.

The Intramorecular Reductive Coupling of **5a** *with* $TiCl_4$-*Zn*. Under an atomosphere of nitrogen, zinc dust (7.8 g, 0.12 mol) was added in small portions to a stirred solution of $TiCl_4$ (11,3 g, 0.06 mol) in dry THF (180 cm^3) at 0—5 °C. After the mixture was refluxed for 2 h, a solution of **5a** (4.72 g, 0.012 mol) and dry pyridine (0.90 g) in dry THF (600 cm^3) was added over 21 h under refluxing, followed by an additional 10 h period of reflux and quenched by addition of 200 cm^3 of saturated K_2CO_3 solution. The mixture was stirred for 0.5 h, diluted with chloroform, and filtered through Celite. The chloroform layers were washed with brine and dried over anhyd $MgSO_4$. After removal of the solvents, the residue was dissolved in hexane and chromatographed on silica gel.

The first fraction, eluted with hexane and followed by evaporation and recrystallization from ethanol, gave yellow orange crystals (0.10 g, 2.3% yield). These were identified as 1,1′-*o*-tolylferrocene (**8a**, mp 67—68 °C), by a comparison of the IR, NMR, and mass spectra and by a mixed-melting-point determination with the authentic sample, which was prepared by Gomberg's reaction of ferrocene with diazonium salts derived from *o*-toluidine.[22] Found: C, 78.55; H, 5.04%; M$^+$, 366. Calcd for $C_{24}H_{22}Fe$: C, 78.69; H, 6.05%; M, 366.

The second fraction, eluted with hexane-benzene (1:1) and followed by evaporation and recrystallization from ethanol, gave reddish crystals (0.62 g, 14.3% yield), mp 181—182 °C, which were determined to be *syn*-[0]orthocyclo[2]-orthocyclo[0](1,1′)ferrocenophan-7-ene (**3s**). Found: C, 79.65; H, 5,11%; M$^+$, 362. Calcd for $C_{24}H_{18}Fe$: C, 79.57; H, 5.03%; M, 362.

The third fraction, eluted with benzene and followed by evaporation and recrystallization from benzene-hexane gave yellowish red crystals (5.23 g, 5.3% yield), mp 230—231 °C, which were determined to be *anti*-[0]orthocyclo[2]orthocyclo-[0](1,1′)ferrocenophan-7-ene (**3a**). Found: C, 79.51; H, 5.08%; M$^+$, 362. Calcd for $C_{24}H_{18}Fe$: C, 79.57; H, 5.03%;

M, 362.

The fourth fraction, eluted with chloroform and followed by evaporation and recrystallization from ethanol gave reddish yellow crystals (0.79 g, 16.5% yield), mp 103—104 °C, which were identified as 1,1′-bis[*o*-(hydroxymethyl)phenyl]-ferrocene (**7a**) by a comparison of the IR and NMR spectra and by a mixed-melting-point determination with **7a**.

The Reaction of ***5b*** *with* $TiCl_4$*–Zn.* The reaction of **5b** with $TiCl_4$–Zn was carried out in the same way as described above, and 1,1′-di-*p*-tolylferrocene [**8b**, reddish crystals, mp 167—169 °C (lit,[23] mp 168—169 °C)] and 1,1′-bis[*p*-(hydroxymethyl)phenyl]ferrocene (**7b**), mp 103—104 °C, were obtained in 47 and 24% yields, respectively.

The Intramolecular Coupling of ***9a*** *with Butyllithium.* Under an atmosphere of nitrogen, a 15% solution of butyllithium in hexane (8 cm^3) was added dropwise to a solution of **9a** (2.41 g, 0.0046 mol) in dry THF (320 cm^3) at −50 °C, followed by stirring at the same temperature for 2 h and then at 0 °C for 2 h. After a successive addition of water (20 cm^3) and 1 M hydrochloric acid (40 cm^3), the mixture was extracted with chloroform. The chloroform extracts were washed successively with 1 M hydrochloric acid, brine, 5% sodium hydrogencarbonate solution, and brine, and dried over anhyd $MgSO_4$. After removal of the solvents, the residue was dissolved in benzene–hexane (1:1) and chromatographed on silica gel.

The first fraction, eluted with benzene–hexane (1:1) and followed by evaporation and recrystallization from benzene–hexane, gave reddish crystalls (0.10 g, 6% yield), mp 164—165°C, which were determined to be *syn*-[0]orthocyclo[2]-orthocyclo[0](1,1′)ferrocenophane (**1s**). Found: C, 79.01; H, 5.39%; M^+, 364. Calcd for $C_{24}H_{20}Fe$: C, 79.13; H, 5.53%, M, 364.

The second fraction, eluted with benzene–hexane (1:1) and followed by evaporation and recrystallization from ethanol affored reddish crystals (0.10 g, 6% yield), mp 182—183 °C, which were determined to be *anti*-[0]orthocyclo[2]-[2]orthocyclo[0](1,1′)ferrocenophane (**1a**). Found: C, 78.96; H, 5.41%; M^+, 364. Calcd for $C_{24}H_{20}Fe$: C, 79.13; H, 5.53%; M, 364.

The third fraction, eluted with benzene–hexane (1:1) and followed by evaporation and recrystallization from ethanol gave yellow orange crystals (0.70 g, 42% yield), mp 245—247 °C (decomp), which were determined to be [0]orthocyclo [2] orthocyclo [0] (1, 1′) ferroceno [0] orthocyclo [2] orthocyclo[0](1,1′)ferrocenophane (**10**). Found: C, 78.91; H, 5.44%. MS: 56 (Fe^+), 364 ($M^+/2$), 728 (M^+). Calcd for $C_{48}H_{40}Fe_2$: C, 79.13; H, 5.53%; M, 728.

*[0]Paracyclo[2]paracyclo[0](1,1′)ferrocenophane (****2****).* The intramolecular coupling of **9b** with butyllithium was carried out in the same way as described above, and the ferrocenophane **2** was separated by column chromatography on silica gel using benzene as eluent, followed by recrystallization from benzene (yield 20%), mp 230 °C (decomp), reddish crystals. Found: C, 78.98; H, 5.44%; M^+, 364. Calcd for $C_{24}H_{20}Fe$: C, 79.13; H, 5.53%; M, 364.

Baeyer-Villiger Oxidation with $Me_3SiOOSiMe_3$ under Assistance of $SnCl_4$ or $BF_3 \cdot OEt_2$

Seijiro MATSUBARA, Kazuhiko TAKAI,* and Hitosi NOZAKI

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received January 25, 1983)

Treatment of ketones with bis(trimethylsilyl) peroxide and Lewis acid such as $SnCl_4$ or $BF_3 \cdot OEt_2$ in dichloromethane at room temperature affords esters in fair to excellent yields. Jasmine lactone is synthesized from 2-[(*Z*)-2-pentenyl]cyclopentanone by means of $Me_3SiOOSiMe_3$–$BF_3 \cdot OEt_2$ system without any protection of the carbon-carbon double bond. The oxidation of enol acetates of ketones to α-hydroxy (or α-acetoxy) ketones with $Me_3SiOOSiMe_3$–$FeCl_3$ system is also disclosed.

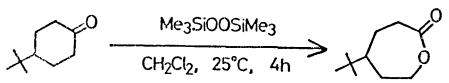
The Baeyer-Villiger oxidation is one of the most important processes in organic synthesis.[1] Recent publication[2] by Noyori and his coworkers on this oxidation using $Me_3SiOOSiMe_3$–Me_3SiOTf prompted us to disclose our independent work.

Usual Baeyer-Villiger oxidants[3] such as H_2O_2 or peroxy acids react with the coexisting carbon–carbon double bond of the substrate under epoxidation.[4] To overcome this difficulty, we examined the oxidation with $Me_3SiOOSiMe_3$[5] in the presence of Lewis acids[6] being added in order to activate the carbonyl function (Table 1). Among those examined, $SnCl_4$ was found to effectively assist the oxidation in general. No reaction occurred in the absence of Lewis acid.

The reaction rate with $BF_3 \cdot OEt_2$ is comparable with that by means of $SnCl_4$ in the case of cyclopentanones. Other cycloalkanones reacted in the presence of $BF_3 \cdot OEt_2$ to produce generally cyclic peroxides,[7] which decomposed slowly to afford a mixture of the desired lactones and the starting ketones. The results of the Baeyer-Villiger oxidation with $Me_3SiOOSiMe_3$–$SnCl_4$ or –$BF_3 \cdot OEt_2$ system are summarized in Table 2.

Although aliphatic ketones were oxidized in good to excellent yields (runs 1,2), aromatic ketones such as acetophenone gave complex mixtures.[8] The observed Baeyer-Villiger reaction in preference to C=C bond attack (runs 3—6) features the present oxidation procedure over the peroxy acid one.

TABLE 1. EFFECTS OF VARIOUS LEWIS ACIDS ON THE TRANSFORMATION OF 4-*t*-BUTYLCYCLOHEXANONE TO 4-*t*-BUTYL-6-HEXANOLIDE[a]



1 **2**

Lewis acid	Yield/%	Lewis acid	Yield/%
$SnCl_4$	84	$ZrCl_4$	34
$BF_3 \cdot OEt_2$	88[b]	$TiCl_4$	27
$FeCl_3$	72	$ZnCl_2$	<5
$AlCl_3$	38		

a) Two mol of $Me_3SiOOSiMe_3$ and one mol of Lewis acid were employed per mol of 4-*t*-butylcyclohexanone. b) The reaction rate was inconveniently low. The reaction required 2 d for completion.

TABLE 2. BAEYER-VILLIGER OXIDATION WITH $Me_3SiOOSiMe_3$–$SnCl_4$ AND –$BF_3 \cdot OEt_2$ SYSTEMS[a]

Run	Ketone	Lewis acid (mol equiv)	Time / h	Ester	Yield[b] / %
1		$SnCl_4$ (1.0)	5		93
2		$SnCl_4$ (1.0)	11		69
3		$SnCl_4$ (1.0) $BF_3 \cdot OEt_2$ (2.0)	9 7		25, 38[c] 17, 28[c]
4		$SnCl_4$ (1.0)	4		80[d]
5		$SnCl_4$ (1.0) $BF_3 \cdot OEt_2$ (2.0)	3 4		64 58
6		$BF_3 \cdot OEt_2$[e] (2.0)	4		44[e,f]

a) Reactions were performed on 1.0 mmol scale at 25 °C. b) Isolated yield. c) Based on the consumed starting material. d) Ref. 1a. e) Ref. 4. f) Reaction with $SnCl_4$ gave a complex mixture in which the desired lactone was absent.

TABLE 3. OXIDATION OF SIMPLE CYCLIC KETONES TO GIVE THE CORRESPONDING LACTONES AND/OR α-HYDROXY KETONES[a]

n		5	6	7	8	10	11	12
Time/h		3	3	3.5	4	3	4	2.5
	Yield[b] %	85	83	50	11	24	30	62
	Yield %	0[c]	0[c]	4[c]	42	35	33	20

a) Reactions were done at 25 °C in CH_2Cl_2. Two mol of $Me_3SiOOSiMe_3$ and 1 mol of $SnCl_4$ were employed per mol of carbonyl compounds. b) Isolated yield. c) GLPC yield.

Table 3 summarizes the reaction of simple cyclic ketones[9] in the presence of $SnCl_4$. The product distributions depend on the sizes of the ring. In the case of 5, 6, 7, and 12 membered ring the corresponding lactones were obtained in good yields. Meanwhile, medium ring (8, 10, and 11 membered) cycloalkanone gave α-hydroxy ketones.[10] This is tentatively ascribed to the oxidation of enol forms of the substrates.[11]

Treatment of silyl enol ethers with $Me_3SiOOSiMe_3$ in the presence of $SnCl_4$, $BF_3 \cdot OEt_2$, or $FeCl_3$ gave the starting ketones. In contrast, enol acetates are oxidized to the corresponding α-acetoxy and/or α-hydroxy ketones by means of $Me_3SiOOSiMe_3$–Lewis acid system. Yields of α-acetoxy and α-hydroxy acetophenone in the oxidation of 1-phenylethenyl acetate and $Me_3SiOOSiMe_3$ in dichloromethane at 25 °C for 12 h were as follows: $SnCl_4$, 28%, 41%; $BF_3 \cdot OEt_2$, 28%, 0%. Iron(III) chloride proved to be the best promoter for the oxidation (Fig. 1).[12]

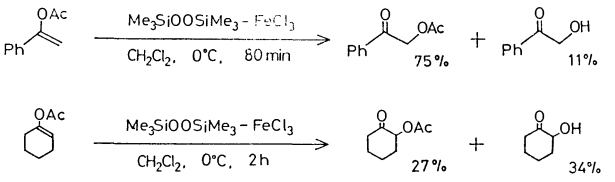


Fig. 1.

Relative migratory aptitude in the cleavage of unsymmetrical ketones with $Me_3SiOOSiMe_3$–$SnCl_4$ and –$BF_3 \cdot OEt_2$ systems were examined (Fig. 2). The present reactions have the same tendency as those with peroxy acids.[13] The selectivity was poor in the case of 2-methylcyclohexanone.

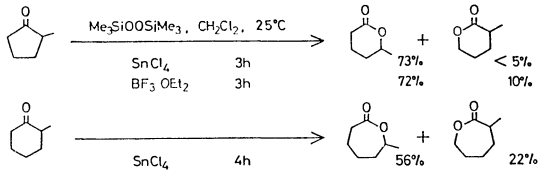

Fig. 2.

Jasmine lactone (**4**) is synthesized from 2-[(*Z*)-2-pentenyl]cyclopentanone (**3**) in several steps.[14] Protection of the olefinic bond is prerequisite in the previous procedures with perbenzoic acid, as treatment of the ketone **3** with *m*-chloroperbenzoic acid (1.5 equiv) in dichloromethane gave epoxide in 89% yield in our hand. The Baeyer-Villiger oxidation in preference to the epoxidation has now been achieved with $Me_3SiOOSiMe_3$–$BF_3 \cdot OEt_2$ system (Fig. 3). Addition of portions of $Me_3SiOOSiMe_3$ (2.2 equiv) and $BF_3 \cdot OEt_2$ (2.0 equiv) to the ketone **3** in dichloromethane gave the lactone **4** in 50% yield along with the hydroxy carboxylic acid (**5**) in 8% yield.[15]

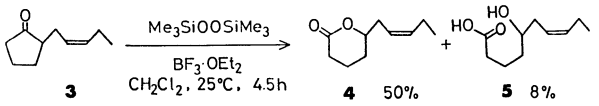

Fig. 3.

Although the yields of the oxidation with $Me_3SiOOSiMe_3$–$SnCl_4$ (or $BF_3 \cdot OEt_2$) system are better than, or at least comparable to, those with Me_3SiOTf, easy accessibility of the Lewis acids characterizes this system as a useful method for the Baeyer-Villiger oxidation.

Experimental

The IR Spectra were determined on a Shimadzu IR-27-G spectrometer, the mass spectra on a Hitachi M-80 machine, and the NMR spectra on a Varian EM-390 spectrometer. The chemical shifts are given in δ, with TMS as an internal standard. The analyses were carried out by the staff at the Elemental Analyses Center of Kyoto University. Dichloromethane was dried on P_2O_5 and distilled. Bis(trimethylsilyl) peroxide was prepared according to the reported procedure and purified by distillation (bp 40—41 °C/30 Torr, 1 Torr = 133.322 Pa).[5] All the experiments were carried out under an argon atmosphere. Purification of products were performed by preparative thin layer chromatography (TLC) or column chromatography on silica gel (Wakogel C-100). Analytical GLPC was performed with a Yanagimoto GCG-550-F and a Shimadzu GC-4CPT.

4-t-Butyl-6-hexanolide (**2**): To a stirred solution of 4-*t*-butylcyclohexanone (**1**, 0.15 g, 1.0 mmnl) and bis(trimethylsilyl) peroxide (0.18 g, 1.0 mmol) in CH_2Cl_2 (10 ml) at 0 °C tin(IV) chloride (0.26 g, 1.0 mmol) was added slowly at this temperature. After being stirred at 0 °C for 15 min and 25 °C for 1 h, bis(trimethylsilyl) peroxide (0.18 g, 1.0 mmol) was added and the whole was stirred at 25°C for 3 h. The resulting mixture was poured into aq $Na_2S_2O_3$ (10 ml) and extracted with ether. The combined organic layers were washed with aq $NaHCO_3$ (10 ml) and brine, dried and con-

centrated. Purification by preparative TLC on silica gel (hexane-ethyl acetate, 2:1) gave **2** as a white solid (0.14 g, 84%). Mp 55 °C (hexane); IR (CCl_4): 1743, 1200, 1190, 1140, 1080 cm^{-1}; NMR (CCl_4): δ=0.90 (s, 9H), 1.10—2.30 (m, 5H), 2.40—2.66 (m, 2H), 3.80—4.40 (m, 2H); MS *m/e* (%): 170 (M^+, 2), 155 (2), 114 (80), 86 (60), 68 (13), 57 (100). The compound was identical with an authentic sample.[16]

Hexyl Heptanoate:[17] Bp 120 °C (bath temp, 3 Torr); IR (neat): 1742, 1380, 1170, 1102 cm^{-1}; NMR (CCl_4): δ= 0.72—1.83 (m, 22H), 2.17 (t, J=7 Hz, 2H), 3.94 (t, J= 7 Hz, 2H), MS *m/e* (%): 131 (7), 84 (25), 69 (18), 61 (19), 60 (12), 56 (44), 43 (100), 42 (27).

9-Decenyl Acetate:[18] Bp 100 °C (bath temp, 3 Torr); IR (neat): 1750, 1645, 1245, 910 cm^{-1}; NMR (CCl_4): δ=1.10—2.20 (m, 14H), 1.96 (s, 3H), 3.94 (t, J=7 Hz, 2H), 4.70—5.10 (m, 2H), 5.68 (ddt, J=16.5, 10, 7 Hz, 1H); MS *m/e* (%): 198 (M^+, 0.3), 155 (6), 138 (24), 110 (40), 96 (80), 82 (90), 68 (100), 54 (50).

2-Oxabicyclo[3.3.0]oct-6-en-3-one:[1] Bp 80 °C (bath temp, 1 Torr); IR (neat): 3090, 1780, 1180, 1020, 923, 720 cm^{-1}; NMR (CCl_4): δ=2.10—2.90 (m, 4H), 3.30—3.66 (m, 1H), 5.00—5.20 (m, 1H), 5.50—6.10 (m, 2H); MS *m/e* (%): 124 (M^+, 16), 96 (54), 95 (49), 79 (60), 68 (38), 67 (100), 66 (54).

7-Octen-5-olide:[14] Bp 75 °C (bath temp, 3 Torr); IR (neat): 3090, 1740, 1645, 1245, 1050, 996, 924 cm^{-1}; NMR (CCl_4): δ=1.15—2.95 (m, 8H), 3.96—4.10 (m, 1H), 4.78—5.30 (m, 2H), 5.30—6.10 (m, 1H); MS *m/e* (%): 140 (M^+, 5), 100 (57), 99 (92), 71 (96), 67 (21), 55 (100), 43 (87).

8-Methyl-7-nonen-5-olide: Bp 95 °C (bath temp, 0.15 Torr); IR (neat): 1740, 1242, 1175, 1048, 920 cm^{-1}; NMR (CCl_4): δ=1.13—2.50 (m, 8H), 1.63 (s, 3H), 1.72 (s, 3H), 3.80—4.40 (m, 1H), 4.90—5.30 (bt, 1H); MS *m/e* (%): 168 (M^+, 6), 99 (85), 71 (100), 69 (12), 55 (34), 43 (54): Found: C, 71.41; H, 9.47%, Calcd for $C_{10}H_{16}O_2$: C, 71.39, H, 9.59%.

7-Heptanolide: The above procedure using cycloheptanone (0.11 g, 1.0 mmol) afforded after usual workup and purification by preparative TLC (hexane-ethyl acetate, 2:1) a mixture of 7-heptanolide and 2-hydroxycycloheptanone in 54% yield (69 mg) in a ratio of 93:7 as determined by GLPC (5% PEG 20 M, 1.5 m, 128 °C). 7-Heptanolide (T_r=4.5 min) and 2-hydroxycycloheptanone (T_r=6.5 min) were identical with authentic sample.[19,10] 7-Heptanolide had bp 90 °C (bath temp, 20 Torr); IR (neat): 1715, 1240, 1150, 1098 cm^{-1}; NMR (CCl_4): δ=1.36—2.13 (m, 8H), 2.35 (t, J=6 Hz, 2H), 4.25 (t, J=6 Hz, 2H): MS *m/e* (%): 128 (M^+, 12), 110 (44), 100 (78), 98 (100), 96 (60), 82 (74), 81 (85), 71 (55), 68 (92), 67 (52), 57 (75).

2-Hydroxycycloheptanone: Bp 83 °C (bath temp, 3 Torr); IR (neat): 3490. 1705, 1078, 930 cm^{-1}; NMR (CCl_4): δ=1.10—3.00 (m, 10H), 3.45 (d, J=4 Hz, 1H), 3.90—4.30 (m, 1H); MS *m/e* (%): 128 (M^+, 0.3), 126 (0.4), 110 (5), 82 (7), 67 (100), 44 (32).

8-Octanolide: The above procedure with cyclooctanone (0.13 g, 1.0 mmol) gave a mixture of 8-octanolide (16 mg, 11%) and 2-hydroxycyclooctanone (60 mg, 42%). These compounds were identical with authentic samples.[19,10] 8-Octanolide had bp 130 °C (bath temp, 20 Torr); IR (neat): 1740, 1142, 1032 cm^{-1}; NMR (CCl_4): δ=1.10—2.00 (m, 10H), 2.10—2.36 (m, 2H), 4.28 (t, J=6 Hz, 2H); MS *m/e* (%): 142 (M^+, 5), 124 (6), 112 (25), 99 (77), 96 (48), 84 (50), 82 (69), 70 (43), 68 (100), 43 (46).

2-Hydroxycyclooctanone: Bp 100 °C (bath temp, 3 Torr); IR (neat): 3500, 1705, 1450, 1100, 950 cm^{-1}; NMR (CCl_4): δ=0.80—2.80 (m, 12H), 3.30—3.75 (m, 1H), 4.00 (dd, J =3, 6 Hz, 1H); MS *m/e* (%): 142 (M^+, 2), 124 (52), 98 (100), 81 (57), 80 (39), 68 (38), 57 (93), 55 (60), 44 (43).

10-Decanolide:[19] Bp 130 °C (bath temp, 20 Torr), IR (neat): 1720, 1480, 1450, 1080 cm^{-1}; NMR (CCl_4): δ= 1.10—1.93 (m, 14H), 2.05—2.40 (m, 2H), 4.00—4.30 (m, 2H); MS *m/e* (%): 170 (M^+, 2), 144 (6), 111 (14), 98 (100), 84 (34), 69 (16), 55 (20).

2-Hydroxycyclodecanone:[10] Bp 110 °C (bath temp, 0.15 Torr): IR (neat): 3500, 1700, 1475, 1100, 1085, 995 cm^{-1}; NMR (CCl_4): δ=0.83—3.40 (m, 16H), 3.50 (bs, 1H), 3.97—4.27 (m, 1H); MS *m/e* (%): 170 (M^+, 2), 134 (4), 96 (19), 82 (31), 68 (47), 57 (100), 55 (44).

11-Undecanolide:[19] Bp 105 °C (bath temp, 3 Torr): IR (neat): 1705, 1480, 1192. 1090 cm^{-1}; NMR (CCl_4): δ= 1.10—3.00 (m, 18H), 4.20 (dd, J=6, 8Hz, 2H); MS *m/e* (%): 184 (M^+, 25), 166 (14), 125 (23), 112 (25), 98 (100), 84 (33), 82 (39), 69 (66).

2-Hydroxycycloundecanone:[10] Bp 140°C (bath temp, 3 Torr); IR (neat): 3500, 1705, 1470, 1100, 1045 cm^{-1}; NMR (CCl_4): δ=1.10—3.00 (m, 18H), 3.20—3.50 (bs, 1H), 4.15 (t, J= 4.5 Hz, 1H); MS *m/e* (%): 184 (M^+, 10), 119 (41), 111 (53), 98 (58). 82 (100), 81 (58), 68 (78), 55 (54).

12-Dodecanolide:[19] Bp 120 °C (bath temp, 1 Torr); IR (neat): 1740, 1465, 1280, 1140, 1050 cm^{-1}; NMR (CCl_4): δ=1.20—1.95 (m, 18H), 2.20—2.50 (m, 2H), 4.25 (t, J= 4.5 Hz, 2H); MS *m/e* (%): 198 (M^+, 6), 180 (16), 138 (33), 110 (34), 98 (100), 96 (67), 84 (72), 82 (63).

2-Hydroxycyclododecanone:[10] Mp 79 °C (hexane/ether); IR (CCl_4): 3500, 1710, 1470, 1075, 1010 cm^{-1}; NMR (CCl_4): δ=0.80—3.30 (m, 21H), 4.25 (t, J=4 Hz, 1H); MS *m/e* (%): 198 (M^+, 6), 180 (10), 136 (20), 124 (22), 111 (23), 98 (53), 96 (49), 95 (47), 82 (100), 81 (44), 68 (56), 67 (37), 57 (36).

5-Hexanolide:[20] The same procedure with 2-methylcyclopentanone (98 mg, 1.0 mmol) and $BF_3 \cdot OEt_2$ gave a mixture of 5-hexanolide and 2-methyl-5-pentanolide in 81% yield (92 mg). GLPC (5% PEG 20 M, 1.5 m, 130 °C) indicated two peaks, T_r=24 min (5-hexanolide, 88%), T_r=22 min (2-methyl-5-pentanolide, 12%). 5-Hexanolide had bp 70 °C (bath temp, 3 Torr); IR (neat): 1745, 1380, 1250, 1070 cm^{-1}; NMR (CCl_4): δ=1.33 (d, J=6 Hz, 3H), 1.44—2.10 (m, 4H), 2.20—2.50 (m, 2H), 4.33 (qt, J=6, 3 Hz, 1H); MS *m/e* (%): 114 (M^+, 0.5), 71 (11), 70 (17), 55 (36), 42 (100).

2-Methyl-5-pentanolide:[21] Bp 70 °C (bath temp, 3 Torr); IR (neat): 1745, 1380, 1150, 1075 cm^{-1}; NMR (CCl_4): δ= 1.28 (d, J=6 Hz, 3H), 1.30—2.73 (m, 5H), 4.28 (t, J= 6 Hz, 2H); MS *m/e* (%): 114 (M^+, 28). 70 (22), 56 (48), 55 (100), 42 (82).

6-Heptanolide:[20] The same procedure with 2-methylcyclohexanone (0.11 g, 1.0 mmol) and $SnCl_4$ (0.26 g, 1.0 mmol) afforded a mixture of 6-heptanolide and 2-methyl-6-hexanolide in 93% yield (0.12 g) in a ratio of 72:28 as determined by ^1H-NMR (the absorption of the methyl proton). 6-Heptanolide had bp 93 °C (bath temp, 3.5 Torr); IR (neat): 1735, 1180. 1078. 1018 cm^{-1}; NMR (CCl_4): δ=1.31 (d, J=6 Hz, 3H), 1.20—2.10 (m, 6H), 2.35—2.73 (m, 2H), 4.10—4.50 (m, 1H); MS *m/e* (%): 128 (M^+, 2), 84 (40), 56 (69), 55 (73), 41 (100).

2-Methyl-6-hexanolide: Bp 88 °C (bath temp, 3 Torr); IR (neat): 1735, 1175, 1080, 1050 cm^{-1}; NMR (CCl_4): δ=1.13 (d, J=5 Hz, 3H), 1.20—2.13 (m, 6H), 2.30—2.80 (m, 1H), 4.00—4.30 (m, 2H); MS *m/e* (%): 128 (M^+, 4), 70 (5), 69 (14), 56 (32), 55 (38), 43 (20), 42 (100), 41 (63), 40 (14); Found: C, 65.56; H, 9.52%, Calcd for $C_7H_{12}O_2$: C, 65.59, H, 9.44%.

(Z)-7-Decen-5-olide (4):[14] To a stirred solution of 2-[(*Z*)-2-pentenyl]cyclopentanone (**3**, 0.15 g, 1.0 mmol) and

$Me_3SiOOSiMe_3$ (0.21 g, 1.2 mmol) in CH_2Cl_2 (10 ml) under an argon atmosphere $BF_3 \cdot OEt_2$ (0.14 g, 1.0 mmol) was added slowly at 0 °C. The resulting mixture was stirred at 0 °C for 15 min and 25 °C for 1.5 h. Additional $BF_3 \cdot OEt_2$ (0.14 g, 1.0 mmol) and $Me_3SiOOSiMe_3$ (0.18 g, 1.0 mmol) were added and the whole was stirred at 25 °C for 3 h. The mixture was poured into aq $NaHCO_3$ (10 ml) and extracted with ether. The combined organic layer was washed with brine, dried and concentrated. Purification by preparative TLC (hexane-ethyl acetate, 2:1) gave (*Z*)-7-decen-5-olide (jasmine lactone, **4**, 84 mg, 50%) along with the hydroxy carboxylic acid **5**. The hydroxy carboxylic acid **5** was heated at 100 °C under reduced pressure (10 Torr) for 1 h. Purification by preparative TLC afforded the desired lactone **4** in 8% yield (13 mg): Bp 125 °C (bath temp, 0.2 Torr); IR (neat): 3020, 1740, 1240, 1049, 928 cm^{-1}; NMR (CCl_4): δ=0.99 (t, J=7 Hz, 3H), 1.20—2.93 (m, 10 Hz), 4.00—4.50 (m, 1H), 5.06—5.75 (m, 2H); MS *m/e* (%): 168 (M^+, 14), 150 (10), 127 (6), 108 (6), 99 (100), 81 (10), 71 (40), 55 (18).

2-Acetoxyacetophenone:[22] Iron(III) chloride (0.16 g, 1.0 mmol) was added in portions to a stirred solution of 1-phenylethenyl acetate (0.16 mg, 1.0 mmol) and $Me_3SiOOSiMe_3$ (0.21 g, 1.2 mmol) at 0°C under an argon atmosphere. After stirring at 0 °C for 80 min, the resulting mixture was poured into brine (5 ml) and extracted with ether. The combined organic layers were dried and concentrated. Purification by preparative TLC (hexane-ethyl acetate, 2:1) gave 2-acetoxyacetophenone in 75% yield (0.13 g) and 2-hydroxyacetophenone in 11% yield (14 mg). 2-Acetoxyacetophenone had bp 107 °C (bath temp, 3 Torr); IR (neat): 1755, 1708, 1600. 1215. 1080, 955. 750, 685 cm^{-1}; NMR (CCl_4): δ=2.13 (s, 3H), 5.13 (s, 2H), 7.15—7.63 (m, 3H), 7.70—7.93 (m, 2H); MS *m/e* (%): 178 (M^+, 1), 118 (12), 106 (23), 105 (100), 91 (12), 77 (71).

2-Acetoxycyclohexanone:[23] Bp 90 °C (bath temp, 3 Torr); IR (neat): 1755, 1728, 1375, 1240, 1082, 1065 cm^{-1}; NMR (CCl_4): δ=1.00—2.55 (m, 8H), 2.10 (s, 3H), 4.96 (dd, J=7, 11 Hz, 1H); MS *m/e* (%): 156 (M^+, 14), 114 (27), 113 (76), 85 (26), 76 (38), 57 (10), 43 (100).

2-Hydoxycyclohexanone:[10] Bp 78 °C (bath temp, 3 Torr); IR (neat): 3500, 1715, 1262, 1100, 1025, 885 cm^{-1}; NMR (CCl_4): δ=1.10—2.70 (m, 8H), 3.36 (m, 1H), 3.94 (dd, J=8, 11 Hz, 1H); MS *m/e* (%): 114 (M^+, 11), 96 (7), 68 (9), 67 (15), 58 (16), 43 (100).

Financial support by the Ministry of Education, Science and Culture, Japanese Government, (Grant-in-Aid Nos. 57750744, 57307007) is acknowledged.

Further Polarographic Studies on the Condensation Products of Dehydro-L-ascorbic Acid with *o*-Phenylenediamine in Acetate Buffer, pH 3.6

Mitsuaki OHMORI,† Yuji TSUJIMOTO,† and Masanosuke TAKAGI*

Laboratory of Food Chemistry, College of Agriculture, University of Osaka Prefecture, Sakai 591

†*Osaka City Institute of Public Health and Environmental Sciences, Tennoji-ku, Osaka 543*

(Received January 28, 1983)

Three polarographic reduction waves, which appear when dehydro-L-ascorbic acid (DAA) is treated with *o*-phenylenediamine (OPD) in acetate buffer, pH 3.6, were reinvestigated by comparing with those of the synthesized products from DAA and OPD. A reaction scheme of DAA with OPD is presented and the characteristics of the reactions are discussed.

As previously known, dehydro-L-ascorbic acid (DAA), the oxidized form of L-ascorbic acid (AA), reacts with *o*-phenylenediamine (OPD) in acidic buffers to give three cathodic DC-waves ($E_{1/2}$: −0.240, −0.412, and −0.634 V *vs.* SCE, at pH 3.6), and this polarographic behavior differs appreciably from that of the other dehydro-reductones with OPD.[1] The third wave ($E_{1/2}$: −0.634 V), observed at an early stage of the measurement, is characteristic of DAA and can be used to detect both AA and DAA.[1,2] When the amount of OPD exceeds that of DAA, the ratio of the three wave heights changes with time, the sum of the three decreasing slightly.

With regard to the condensation products of DAA with OPD, many works have been reported.[3-12] Repeated discussions on the formulae of the products from 1 mole of DAA with 1 or 2 mol of OPD have not successfully assigned them to the three cathodic DC-waves.[1,13]

In the present work, each compound, synthesized according to the literature,[4,5,8,12] is studied polarographically at pH 3.6 and its polarographic behavior is compared with that of the three waves obtained when DAA is treated with OPD in the same buffer. In addition, the reaction mechanism of DAA with OPD is discussed, considering the bicyclic DAA structure recently suggested.[14-16]

Experimental

Chemicals. *o*-Phenylenediamine (reagent grade, Katayama Chemical Co., Osaka) was recrystallized before use. L-Ascorbic acid, acetone, methanol, and the chemicals used were of reagent grade. A pH 3.6 acetate buffer [0.2 M (mol dm^{-3})] was chosen. Norit "Extra" activated charcoal and O_2 gas of high purity were also employed.

Preparation of DAA. DAA-methanol solution was first prepared as before.[17] The evaporation of methanol under reduced pressure gave a viscous DAA-methanol adduct, which was directly diluted to a desired concentration of DAA with buffer solution of pH 3.6, for electrolyte solution. For solid preparation, DAA was prepared as previously described.[18]

Synthesis of the Condensation Products of DAA with OPD and Related Compounds. The condensation product of 1 mol DAA with 1 mol OPD (**A**)[5,12] was prepared according to Ogawa[5] or El Ashry *et al.*[12] and that of 1 mol DAA with 2 mol OPD (**B**)[4,5,8] according to Hasselquist.[4] The product **B** was refluxed in absolute methanol to give yellow crystals (**B′**).[4,8] A hydrolysis product from **B** in dilute HCl (**C**) was prepared according to Hasselquist.[4] The product **C** was also obtained from **B′**.

Apparatus. Polarographic measurements were carried out with a Yanagimoto Polarograph Type P-8, the characteristics of the capillary being $m=1.86$ mg/s, $t=4.50$ s^{-1} when the Hg level was 72.5 cm, and −0.6 V was applied. All the polarographic experiments were carried out at 25± 0.2 °C. ^{13}C-NMR Spectra were recorded on a JEOL FX-100 spectrometer.

*Preparation of Electrolyte Solutions of **B** and **B′**.* Neither **B** nor **B′** dissolved sufficiently in pH 3.6 acetate buffer, but both were freely soluble in *N,N*-dimethylformamide (DMF). For a stock solution, 0.1 M **B** or **B′** DMF solution was prepared. The solution was diluted 100 times with the acetate buffer before use, and the diluted solution was directly applied to the polarographic measurements.

Results and Discussion

Polarograms of the Condensation Products of DAA with OPD. The DAA concentration was kept constant at approximately 1×10^{-3} M, and the OPD concentration was changed. The polarograms shown in Fig. 1 were taken 1 h after mixing OPD with DAA in the buffer solution. As shown in Fig. 1(a), when the OPD concentration was below the DAA concentration, two reduction waves were observed, the half-wave potentials being −0.240 and −0.634 V (*vs.* SCE). The wave with more negative $E_{1/2}$ was much higher in

Concn of DAA: *ca.* 1×10^{-3} M, concn of OPD: (a) 5×10^{-4} M, (b) 5×10^{-3} M, temp: 25 °C. Polarograms were taken 1 h after mixing OPD with DAA in the buffer solution.

wave height than the other. The relationships between the condensation time and the wave heights of the two reduction waves are shown in Fig. 2(a). The wave heights did not change after they reached equilibrium. When the OPD concentration was higher than the DAA concentration, another reduction wave appeared between the two waves (Fig. 1(b)). The half-wave potential was −0.412 V (*vs.* SCE). The three wave heights changed in a complex way with time as shown in Fig. 2(b). The third wave height decreased, while the first and second wave heights increased gradually. The total wave height of the three waves gradually decreased, though not large, as seen in Fig. 2(b).

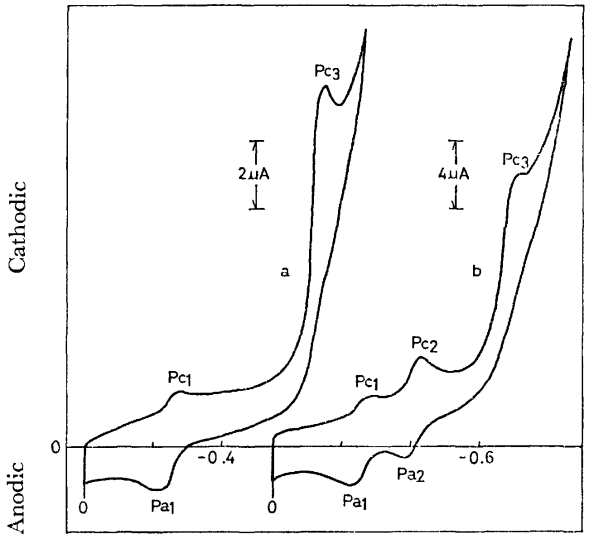

Fig. 3. CV curves of the condensation products of DAA with OPD in acetate buffer pH 3.6.
Concn of DAA: *ca.* 1×10^{-3} M, concn of OPD: (a) 5×10^{-4} M, (b) 5×10^{-3} M, temp: 25 °C, sweep rate: 50 mV/s, electrode: hanging mercury electrode (HME).

were recorded under the same experimental conditions as for the DC-polarograms. When the OPD concentration was below that of DAA, two cathodic peaks (P_{c1} and P_{c3}) corresponding to the first and the third DC-waves, respectively, and one anodic peak (P_{a1}) corresponding to the P_{c1} product, were observed, as shown in Fig. 3(a). When the OPD concentration was higher than that of DAA, three cathodic peaks (P_{c1}, P_{c2}, and P_{c3}) corresponding to the first, the second and the third DC-waves, and two anodic peaks (P_{a1} and P_{a2}) corresponding to the P_{c1} and P_{c2} products, were observed as shown in Fig. 3(b). These results indicate that the first and the second waves are reversible but the third wave is irreversible.

Polarograms of the Synthesized Products from DAA with OPD and Related Compounds. The polarogram of **A** (Fig. 4) was identical with that in Fig. 1(a), since the two reduction waves corresponded to the first and third waves. We attributed the polarogram shown in Fig. 1(a) to the equimolar condensation product of DAA with OPD.

For the polarograms of **B**, as shown in Fig. 5, two reduction waves were observed, whose wave heights changed with time. The two waves corresponded to the first and the second waves. The polarograms of

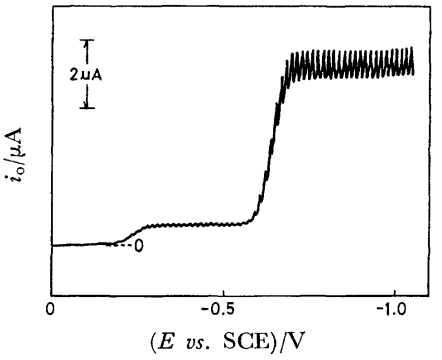

Fig. 4. Polarogram of **A**.

Concn of **B**: 3.54 mg/10 ml of buffer solution, temp: 25 °C, a: immediately after dissolving **B**, b: one day after.

B′ were similar to those of **B** shown in Fig. 5. It was also found by a separate experiment that **B′** changed to **B** quantitatively when refluxed with a mixture of methanol and water (4:1). The electronic spectra showed that **B** is favored whenever water is added.

The polarogram of **C** is shown in Fig. 6. Only one reduction wave, corresponding to the first wave, was observed.

The polarograms of the further reaction products of **A** with OPD were recorded after the direct dissolution of excess OPD into the buffer solution containing **A**. Three reduction waves appeared, and the polarogram which was recorded 1 h after the addition of OPD agreed with that shown in Fig. 1(b). The time courses of the reaction of **A** with OPD observed by the change of heights of three waves are shown in Fig. 7. The polarographic behavior of the reaction products of **A** with OPD in the buffer was similar to that previously observed in Fig. 2(b). It is probable that, when DAA is treated with excess OPD, the condensation product, corresponding to **A**, is first produced and then it reacts further with another 1 mol of OPD.

By comparing this behavior with that of **B** or **B′**, and considering that the total wave height of the three waves began to decrease gradually as soon as the second wave appeared, we came to the conclusion that the appearance of the second wave and the increase in the first wave were caused by the formation of the condensation product of 1 mol DAA with 2 mol OPD as either **B** or **B′**.

The decrease of the total wave height with time may be explained by a decrease of the diffusion constant of the depolarizer caused by the addition of one more OPD to **A**. However, the total wave height reaches its maximum value at the final equilibrated state, when the chemical species corresponding to **B** or **B′** is scarce. That is, when DAA reacts with OPD, the formation of **B** or **B′** is transitory, if the concentration of OPD is not much larger than that of the DAA; say maximum 3 times of DAA. When OPD is more than 10 times of DAA, the final state shows the presence of **C** and **B** or **B′** only. The equilibrium between **C** and **B** (**B′**) is approximately 3:1, coinciding with the observation by Erlbach and Ohle for iso-DAA with OPD.[3]

Reaction Mechanism of DAA with OPD. Recently, it has been confirmed that the structure of DAA is predominantly a bicyclic form, shown as **1** at the top of Scheme 1, in solution, and the bicyclic form of DAA changes to the compound **2** with time.[14,16] We measured ^{13}C-NMR spectra of DAA in the mixture of D_2O and hydrochloric acid (about pH 3.0) to identify the structure of DAA in acidic solution. Six signals at 174.2, 92.0, 106.3, 73.6, 88.3, and 76.8 ppm were found. They were in accord with the chemical shifts in D_2O solution (C-1: 174.2, C-2: 92.0, C-3: 106.3, C-4: 73.5, C-5: 88.2, and C-6: 76.8 ppm), which were assigned to **1** by Hvoslef and Pedersen.[14] We thus conclude that DAA is predominantly in the form of structure **1** in acidic solution.

The structure of **A** has recently been correctly described as **3** by El Ashry *et al.*[11] The anomeric structure of **C** was first reported to be that of **4** by Erlbach and Ohle[3] in a reaction system of iso-DAA with OPD, and then **4** was reported by Ogawa,[5] Hasselquist,[4] and Dahn and Moll[8] in a reaction system of DAA with OPD.

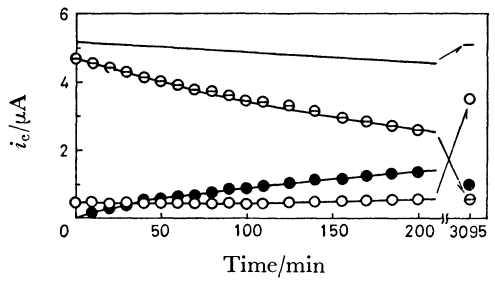

Fig. 7. Time courses of the reaction of **A** with OPD by the change of heights of the three waves.
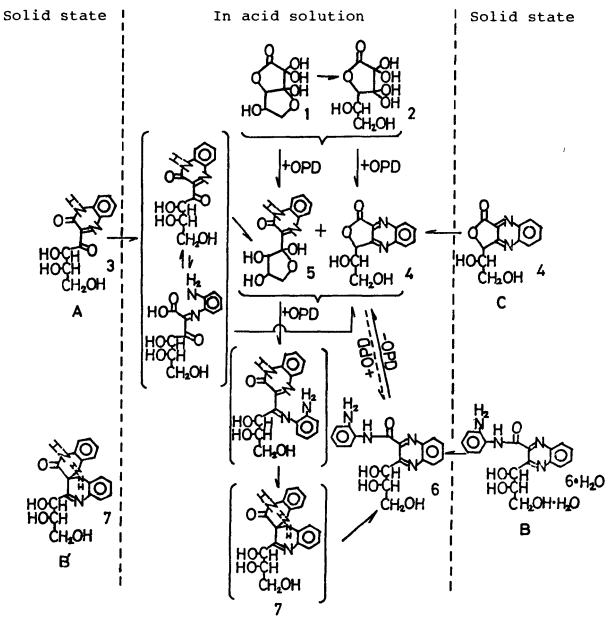
Concn of **A**: 2.64 mg/10 ml of buffer solution, concn of OPD: 4×10^{-3} M, temp: 25 °C, pH 3.6. ○: 1st wave, ●: 2nd wave, ⊖: 3rd wave, ——: total wave height.



Scheme 1. Reaction mechanism of DAA with OPD in acetate buffer pH 3.6.

As previously mentioned, DAA reacts equimolarly with OPD to exhibit two reduction waves. The first wave seems to be caused by **C**, which is formed by the reaction of **2** with OPD, whereas the characteristic wave, corresponding to the third, seems to be due to the reaction product of bicyclic DAA with OPD.

With regard to the structure of **B**, Dahn and Moll[8] corrected the structure suggested by earlier workers[3,4] and reported **6** for **B**, while **B'** has not been confirmed. Recently, we have studied the structures of **B** and **B'** on the basis of elemental analysis and spectroscopic data, and have concluded that **B** seemed to be a monohydrate of **6** and that **B'** might be 7.[19]

When OPD is in excess in the reaction with DAA the condensation product of 1 mol DAA with 2 mol OPD seems to be produced *via* **5**. Because **B'** could easily change to **B** in aqueous solution, **B'** is probably first produced *via* product **5** and seems to change immediately to **B**. This possibility is supported by the fact that the polarographic behavior of **B'** was identical with that of **B**. The product **B** was then hydrolyzed to **C**. When the polarogram of **C** was recorded with a large excess of OPD, the second wave was observed as well as the first. The reverse reaction from **C** to **B** seems to proceed when there is a large excess of OPD. This explains why the increment of the first wave was low in Fig. 2(b) and in Fig. 7.

Consequently, the reaction mechanism may be as shown in Scheme 1. Refering to the two-electron transfer found for each electrode reaction,[1] and the cyclic voltammetric results of the three waves, it is reasonable to assume that the electrode reaction of the first and the second waves occurs reversibly with a two-electron transfer for the quinoxalines of **4** and **6**. In contrast, the electrode reaction of the third wave occurs irreversibly in a two-electron transfer which results in the quinoxalinone, **5**.

The authors are grateful to the staff of the Application Center, Scientific Instrument Project, JEOL, Ltd., for the measurement of ^{13}C-NMR spectra of DAA in aqueous solution.

Synthesis of 6- and 8-Phenyl-substituted Flavonoids

Hisashi Matsumura,† Toshio Tsuchiya,†† Tsuneko Takeda,†††
and Kimiaki Imafuku*

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

(Received Junuary 29, 1983)

3-Acetylbiphenyl-4-ol and -2-ol were condensed with substituted benzaldehydes to give respectively 5′- and 3′-phenyl-substituted chalcones (**1a—k**), which were cyclized to afford 6- and 8-phenylflavanones. The chalcones (**1a—k**) also gave the corresponding 6- and 8-phenylflavones *via* dibromides. The effects of the phenyl group on the spectral data are also discussed.

Flavonoids are well-known as the main constituent of yellow pigments of plant and possess many pharmacological actions. These flavonoids occur as hydroxy or methoxy-substituted compounds or glucosides. On the other hand, compounds having alkyl, halogen, amino, or nitro group have been obtained in synthetic materials. However, phenyl-substituted flavonoids have not been found in nature and in synthetic materials, except for a few reports.[1-3] One of them described synthesis of 5′-phenylchalcones[1] and the others described synthesis of 4-phenylchalcones[2] and 4′-phenyl-substituted flavanones and flavones.[3]

In this paper, we wish to report the synthesis of 5′- and 3′-phenylchalcones and the corresponding 6- and 8-phenyl-substituted flavanones and flavones.

Results and Discussion

The starting materials, 3-acetylbiphenyl-4-ol and -2-ol, were already prepared from biphenyl-4-ol and -2-ol by their *O*-acetylation and Fries rearrangement.[4] When Nencki-type reaction with boron trifluoride–acetic acid complex was applied to biphenyl-4-ol, 3-acetylbiphenyl-4-ol was easily obtained in one step and in good yield. However, the preparation of 3-acetylbiphenyl-2-ol by this method was failed.

These 3-acetylbiphenyl-4-ol and -2-ol were condensed with substituted benzaldehydes to give 2′-hydroxy-5′-phenylchalcones (**1a—h**) and 2′-hydroxy-3′-phenylchalcones (**1i—k**) in good yields, except for **1e** (16%) and **1h** (20%). The spectral data are summarized in Table 1. The IR spectra show the carbonyl absorption at 1635—1645 cm^{-1}. The UV spectra of **1a** and **1i** are shown in Fig. 1, together with the spectrum of the parent 2′-hydroxychalcone [λ (CH_3OH):[5] 221 (log ε 4.11) and 316 nm (4.36)]. The phenyl group at the 3′- and 5′-positions of **1a** and **1i** shows no appreciable effect because the phenyl group exists at the *meta* position against the cinnamoyl group. Substituents in the B ring caused bathochromic shift of the maximum of absorption band at *ca.* 320 nm of **1a** and **1i** to 330—390 nm. Particularly, the spectrum of a red colored compound **1d** showed maximum of absorption bands at 260 and 437 nm. In the NMR spectra of all the chalcones (**1a—k**), the signal for the hydrogen-bonded 2′-OH group was found at δ *ca.* 13.

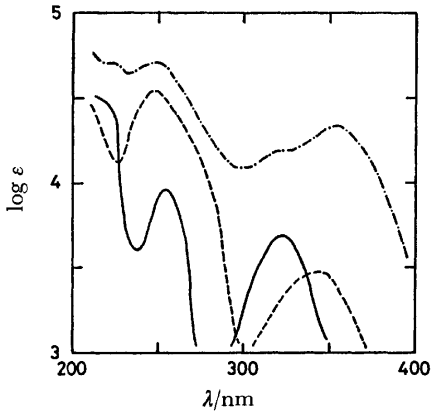

Fig. 2. UV Spectra of flavanones.
——: Flavanone, ----: **3a**, —·—·—: **3i**.

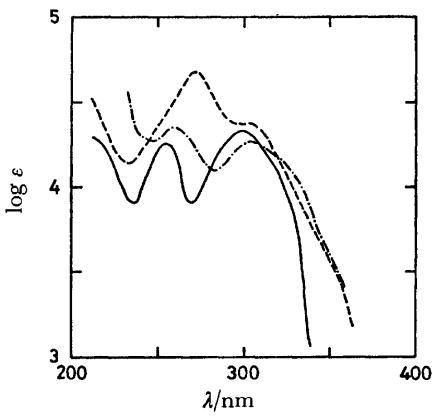

Fig. 3. UV Spectra of flavones.
——: Flavone, ----: **4a**, —·—·—: **4i**.

listed in Table 2. The compound **2d** was not isolated as crystal form and used for the flavone synthesis in this semisolid state.

The chalcones (**1a**—**k**) in acetone–ethanol were refluxed for 2 h in the presence of alkali to cyclize to 6- and 8-phenylflavanones (**3a**—**k**). The characteristic data are summarized in Table 3. In the IR spectra, the carbonyl absorptions were observed at 1705—1710 cm^{-1}, except for **3e** (1670 cm^{-1}). The UV spectra of 6- and 8-phenylflavanones (**3a** and **3i**) are shown in Fig. 2, together with the spectrum of flavanone itself [λ (CH_3OH):[5] 250 (log ε 3.86) and 320 nm (3.37)]. Introduction of the phenyl group at the 6- or 8-position produced bathochromic shifts of the absorption band at 320 nm by 15—25 nm. The NMR spectra showed the typical ABX pattern of 2-, 3e-, and 3a-protons.

The chalcone dibromides (**2a**—**k**) were treated with alkali to afford 6- and 8-phenylflavones (**4a**—**k**) in good yields. These results are summarized in Table 4. The IR spectra showed the carbonyl absorption at 1640—1650 cm^{-1}. The UV spectra of 6- and 8-phenylflavones (**4a** and **4i**) are shown in Fig. 3, together with flavone itself [λ (CH_3OH):[5] 250 (log ε 4.06) and 297 nm (4.20)]. The spectra of the flavones (**4a**—**k**) also showed bathochromic shifts of the absorption maximum at 300—330 nm by introduction of substituent in the B ring. Particularly, the maximum of absorption bands of the dimethylamino-substituted compound **4d** was observed at 257, 333, and 400 nm. In the NMR spectra, the 3-H protons were recorded at δ 6.6—6.8 as a sharp singlet peak.

Experimental

The melting points were determined with a Yanagimoto MP-S2 melting point-measuring apparatus and are uncorrected. The IR spectra were taken on a JASCO IRA-1

and JASCO 403G spectrophotometers, and the UV spectra on a Hitachi EPS-3T spectrophotometer. The NMR spectra were recorded with a Hitachi R-24 spectrometer (60 MHz).

3-Acetylbiphenyl-2-ol. This compound was prepared by the method of Cheetham and Hey.[4]

3-Acetylbiphenyl-4-ol. A mixture of biphynyl-4-ol (21.3 g) and boron trifluoride-acetic acid complex (50 ml) was heated on a water bath for 2 h. The mixture was treated with water and extracted with ether. The ethereal solution was washed with water and dried over anhydrous sodium sulfate. After removal of the solvent, the residue was recrystallized from ethanol to afford 3-acetylbiphenyl-4-ol. Yield, 16.5 g (62%). Mp 61—62.5 °C (lit,[4] 61.5—62 °C).

*2'-Hydroxy-5'- or 3'-phenylchalcones (**1a—k**).* A solution of 3-acetylbiphenyl-4-ol or -2-ol (2.1 g, 10 mmol) and substituted benzaldehyde (10 mmol) in ethanol (10 ml) was stirred at 50—60 °C in the presence of 60% potasium hydroxide solution (7.5 ml). The mixture was neutralized with 3 M hydrochloric acid (1 M=1 mol dm^{-3}) to give a precipitate of 2'-hydroxy-5'- or 3'-phenylchalcone (**1a—k**), which was collected and recrystallized from methanol or acetone.

*2'-Hydroxy-5'- or 3'-phenylchalcone Dibromides (**2a—k**).* A bromine (320 mg, 2 mmol) solution in carbon tetrachloride (2 ml) was added dropwise to a solution of 2'-hydroxy-5'- or 3'-phenylchalcone (**1a—k**) (500 mg, 1.5—1.6 mmol) in carbon tetrachloride (5 ml) at room temperature. The mixture was allowed to stand for 30 min. After evaporation of an excess of bromine and the solvent under reduced pressure, the residue was treated with benzene to afford 2'-hydroxy-5'- or 3'-phenylchalcone dibromide (**2a—k**).

*6- and 8-Phenylflavanones (**3a—k**).* To a solution of 2'-hydroxy-5'- or 3'-phynylchalcone (**1a—k**) (500 mg, 1.5—1.6 mmol) in acetone (5 ml)-ethanol (10 ml) was added 1% potassium hydroxide solution (1 ml). After refluxing for 2 h on a water bath, the reaction mixture was slightly acidified with 3 M hydrochloric acid and allowed to stand overnight at room temperature to precipitate 6- or 8-phenylflavanone (**3a—k**), which was collected and recrystallized from methanol or acetone.

*6- and 8-Phenylflavones (**4a—k**).* To a suspended solution of 2'-hydroxy-5'- or 3'-phenylchalcone dibromide (**2a—k**) (500 mg) in acetone (1 ml) was added 20% potassium hydroxide solution (1 ml) at room temperature. The mixture was diluted with water and slightly acidified with 3 M hydrochloric acid to give 6- or 8-phenylflavone (**4a—k**) as a precipitate, which was collected and recrystallized from methanol or acetone.

We are grateful to Sanko Chemical Co., Ltd. for a supply of biphenyl-2-ol and -4-ol.

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received February 8, 1983)

Synthesis of the ring A, a cyclic sulfide peptide part containing dehydroalanine residue, in peptide antibiotic nisin was successfully achieved by applications of two novel procedures. First, a sulfide ring was derived from a cyclic disulfide peptide by desulfurization with $P(Et_2N)_3$. Secondly, for the preparation of dehydroalanyl residue, a simple and convenient method through Hofmann degradation of 2,3-diaminopropionyl residue was newly exploited in the presence of sulfide linkage.

Nisin, a peptide antibiotic, was isolated from culture broth of *Streptococcus lactis* by Mattick *et al.* in 1947,[2] and Berridge *et al.* in 1952.[3] However, in spite of the early isolation, the structure of nisin was first proposed by Gross *et al.* in 1970.[4] As shown in Fig. 1, nisin has a quite unique structure composed of thirty four amino acids including three dehydroamino acid residues and five sulfide rings named A, B, C, D, and E from the *N*-terminal in the molecule.

An antimalarial activity as well as an inhibition of growth of *Staphylococcus aureus* were known as typical biological activities of this peptide.[5] However, few works are reported about the structure-biological activity relationships except a role of dehydroalanine residue for an exhibition of the antibacterial activity.[5] Thus, we started the synthetic study of nisin from the standpoint of not only a synthetic interest in such a complicated structure but also a confirmation of its unique structure and detailed elucidation on structure-activity relationships of this antibiotic.

For accomplishment of the synthesis of nisin, we are required to resolve two problems in the synthetic procedures, *i.e.*, i) introduction of the dehydroamino acid residue; ii) formation of the sulfide ring. Especially, both points are very important to carry out the synthesis of the ring A (Fig. 2) as the first target of the total synthesis of nisin. We attempted to solve the first problem by application of our novel method for the dehydroalanine synthesis through Hofmann degradation of 2,3-diaminopropionic acid (A_2pr).[6]

The second problem concerns to how to prepare lanthionine moiety in a cyclic peptide. For synthetic strategies of cyclic lanthionine peptide, possibly the following three procedures may be considered (Fig. 3). First of all, a cyclization can be performed by amide bond formation between carboxyl and amino groups at suitable positions in a lanthionyl peptide. Indeed, Photaki and her coworkers applied this concept to prepare ring A of nisin based on their extensive knowledge of lanthionine chemistry.[7] Although, a route a) seems to be quite reasonable, much efforts are required for preparation of the *meso*-lanthionyl residue. For instance, four functional groups in lanthionine moiety must be differentially protected and also made free step by step. This is not so easy task, and furthermore, a yield of cyclization by amide bond formation is sometimes not so high.

Therefore, we attempted to find more convenient method for sulfide ring formation. One of the promising ways may be an addition of mercapto group to the dehydroalanyl residue as described in route b). Although highly expensive D-cysteine is not required in this case, crucial disadvantage of this route is no assurance of stereoselective addition to obtain a desired steric form of lanthionine. Therefore, a final route c) seems to be most attractive procedure, if desulfurization of a cyclic disulfide peptide will successfully proceed, because a formation of –S–S– bond is rather easier than a cyclization by amide bond formation.

Based on the above considerations, the linear peptide **8** containing two cysteine residues of D- and L-configurations and 2,3-diaminopropionic acid residue as precursors of *meso*-lanthionine and dehydroalanine, respectively, was prepared as shown in Fig. 4. Protection of the mercapto groups in Cys residues and S–S bond formation were made by reference to Kamber's elucidation, which suggested an oxidative disulfide formation effected with I_2 from ~~Cys(Acm)~~Cys(Acm)~~ in DMF or ~~Cys(Trt)~~Cys(Acm)~~ in MeOH.[8] For reasons of easiness of *S*-tritylation compared to *S*-acetamidomethylation, convenience of experimental procedure in MeOH than DMF, and possible prevention of the intermolecular S–S linkage formation, the latter combination of protecting groups seemed to be preferable. On the other hand, N^{β}-amino group of A_2pr residue was protected with benzyl-

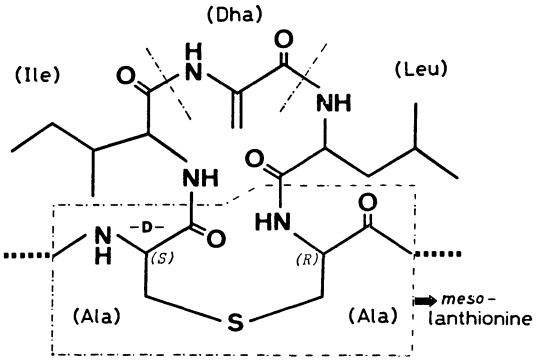

Fig. 2. The chemical structure of the ring A part in nisin.

oxycarbonyl (Z) group which is removable by the catalytic hydrogenation even though in the presence of sulfide moiety.[9] The peptide elongation was performed starting from the *C*-terminal by use of an active ester method.

The fully protected linear pentapeptide **8** thus obtained was then subjected to the preparation of the cyclic disulfide **9**. The oxidation was carried out smoothly to give the monomeric disulfide, whose molecular weight was confirmed by both mass spectrometry (FD, *m/z* 782; calcd 782) and osmometry (750± 37; calcd 783), in a good yield as expected.

The desulfurization reaction for the cystine peptide **9**, one of the important targets in this study, was achieved using tris(diethylamino)phosphine ($P(Et_2N)_3$) reported by Harpp for the preparation of lanthionine itself.[10] When the reaction was carried out in $CHCl_3$, the yield of the sulfide compound **10** was not reproducible and always poor. In order to check the reaction conditions, we then examined an effect of solvent on the desulfurization using a model compound, $(Z\text{-}Cys\text{-}OCH_3)_2$. The desirable lanthionine derivative was obtained only in DMF presumably *via* path (a) based on the concerted mechanism as shown in Fig. 5, while in solvents such as $CHCl_3$, THF, dioxane, or benzene, the dehydroalanine derivative was found to be a major product as a result of intramolecular β-elimination as shown in path (b). Thus, the cyclic disulfide compound **9** was successfully desulfurized in DMF to produce cyclic *meso*-lanthionyl peptide **10** without a formation of dehydroalanyl peptide. In this case, care must be taken to dry DMF absolutely, otherwise another side reaction as shown in Fig. 6 occurs.[11] The formation of *meso*-lanthionyl residue in this reaction was clearly ascertained by amino acid analysis of the hydrolyzate of **10**. (Fig. 8b)

A conversion of the A_2pr residue into the dehydroalanine residue was originally performed by a permethylation with CH_3I in the presence of $KHCO_3$.[6] However, according to this procedure, a methylation onto sulfur atom also occurred resulting in the undesirable formation of another dehydroalanyl residue. For example, *S*-methylcysteinyl peptide **14** as a model peptide gave a mixture of monodehydroalanyl peptide **15** and didehydroalanyl peptide **16**. (Fig. 7) Even under the most preferable conditions, the yield of **15** was less than 70% and the by-product **16** was still obtained in a yield of 10%.[6a] In order to prevent this undesirable *S*-methylation, we attempted to increase a reactivity of β-amino group of A_2pr compared to that of sulfide part. For this purpose, the β-amino group was once methylated to increase its basicity by an application of reductive *N*-alkylation with $NaBH_3CN$ and HCHO.[12] From model experiments using two simple peptides **14** and **18**, it was revealed that the former compound **14** gave dimethyl derivative **17**, while the latter **18** gave monomethyl one **19**. (Fig. 7) Probably, N^{α}-Boc group might sterically hinder the introduction of the second methyl group in the case of the methylation of **18**. These compounds were then subjected to Hofmann degradation. Interestingly, both **17** and **19** produced solely monodehydroalanyl peptides in good yields by use of a limited amount of CH_3I in the presence of an excess $KHCO_3$, respectively. The fact clearly indicated that the first *N*-methylation would be a rate-determining step during permethylation procedure in Hofmann reaction. By this modification, it has become feasible that our method for dehydroalanine synthesis is applicable to the A_2pr peptide involving the sulfide amino acid.

Along the above consideration, a final step of our synthesis of ring A was performed. Cyclic pentapeptide **10** was first debenzyloxycarbonylated by hydrogenation in the presence of Pd black catalyst which was required in more amount than that in usual case. When the hydrogenation did not proceed smoothly, the first catalyst was removed and then fresh catalyst

(a) When *meso*-lanthionine (*meso*-Lan) was treated under the hydrolytic conditions (6 M HCl, 110 °C, 20 h), a part of the sample was racemized to produce DL-lanthionine (Lan). (b) The hydrolyzate of desulfurization product **11** with 6 M HCl at 110 °C for 20 h. A chart of neutral component was shown. (c) The hydrolyzate of protected ring A **12**. A longer hydrolysis (6 M HCl, 110 °C, 40 h) caused more racemization of the *meso*-lanthionine residue.

must have been added. The hydrogenation product was immediately subjected to *N*-methylation with $NaBH_3CN$ and HCHO. Actually in the case of the cyclic peptide **10**, we could obtain dimethyl derivative **11** whose structure was confirmed by the molecular weight determination with FD-MS. Finally, the pentapeptide **11** could be converted through addition of 1.0—1.5 equivalent of CH_3I into desired dehydroalanyl peptide **12**, *i.e.*, protected ring A. The structure of the final product was definitely ascertained both chemically and physically. For example, the molecular weight was confirmed by FD-MS and the existence of the dehydroalanyl residue was confirmed from NMR spectrum. Furthermore, amino acid analysis of a hydrolyzate of the final product proved the presence of 11 amino acids constituting ring A. (Fig. 8c)

As mentioned above, we could satisfactorily exploit a novel method for preparation of the dehydroalanine through Hofmann degradation in the synthesis of ring A in peptide antibiotic nisin. Thereby, it proved that this method is very useful and applicable even for syntheses of other complex natural products containing dehydroalanine residue such as AM-toxins. Furthermore, the successful application of desulfurization reaction from cystinyl peptide made the preparation of lanthionyl peptide possible and opened a promising way for the convenient syntheses of other rings in nisin. Indeed, we recently performed the synthesis of ring B in this extention and the result will be reported elsewhere.

Experimental

All melting points are uncorrected. NMR spectra were obtained with a Varian XL-100-15 and JEOL FX-90Q spectrometers using TMS as an internal standard. FD-MS spectra were obtained with a JEOL 01SG spectrometer. Molecular weights were measured with a Knauer vapor pressure osmometer. The specific rotations were obtained with a Perkin-Elmer 141 polarimeter. UV spectra were recorded on a Hitachi 124 spectrophotometer. Amino acid analyses were carried out with a Hitachi KLA-5 analyzer using the following conditions: neutral and acidic amino acids were run on 0.9×55 cm column warmed at 55 °C with citrate buffer of pH 3.25 to 4.25 and basic components were analyzed on 0.9×7 cm column with citrate buffer of pH 5.28. Samples for the analysis were hydrolyzed with constant boiling 6 M (1 M=1 mol dm^{-3}) HCl in a sealed tube at 110 °C for 20 h.

*Boc-Leu-Cys(Acm)-OMe (**1**).* To a solution of Boc-Leu-OSu[13] (20 g, 60.9 mmol) and HCl·H-Cys(Acm)-OMe[14] (17.7 g, 72.8 mmol) in 200 ml of DMF was added triethylamine (14.8 g, 0.146 mol) under ice cooling. The reaction mixture was stirred at room temperature overnight. Triethylamine hydrochloride was filtered off and the filtrate

was concentrated *in vacuo*. Ethyl acetate solution of the residue was washed with aqueous 10% citric acid, saturated $NaHCO_3$, and saturated NaCl solutions. The organic layer was dried over $MgSO_4$ and then concentrated *in vacuo*. The oily residue was crystallized from hexane to obtain colorless needles in a yield of 24.5 g (96.1%). Analytical sample was prepared by recrystallization from ethyl acetate and hexane: mp 79—81 °C; $[\alpha]_D^{17}$ −16.4° (*c* 1.42, AcOEt).

Found: C, 51.32; H, 7.85; N, 9.82; S, 7.71%. Calcd for $C_{18}H_{33}N_3O_6S$: C, 51.53; H, 7.93; N, 10.02; S, 7.64%.

*HCl·H-Leu-Cys(Acm)-OMe (**3**).* Compound **1** (1.00 g, 2.38 mmol) was dissolved in 5.4 ml of 4.4 M HCl/THF. To a reaction mixture allowed to stand at room temperature for 1 h was added 300 ml of ether under cooling in an ice bath. The precipitate filtered was reprecipitated from isopropyl alcohol and ether: yield 0.69 g (82%); mp 156—158 °C; $[\alpha]_D^{15}$ −14.5° (*c* 1.45, MeOH).

Found: C, 43.33; H, 7.33; N, 11.24; S, 8.83; Cl, 9.71%. Calcd for $C_{13}H_{26}N_3O_4SCl\cdot 0.4H_2O$: C, 43.00; H, 7.44; N, 11.57; S, 8.83; Cl, 9.76%.

*Boc-A_2pr(Z)-Leu-Cys(Acm)-OMe (**4**).* To a solution of **3** (4.05 g, 11.4 mmol) in 80 ml of DMF were added Boc-A_2pr(Z)-OSu[15] (4.50 g, 10.3 mmol) and triethylamine (2.08 g, 20.6 mmol) under cooling in an ice bath. After stirring at room temperature overnight, triethylamine hydrochloride precipitated was filtered off. The residue obtained by concentration of the filtrate was dissolved in ethyl acetate. The solution was washed with aqueous 10% citric acid, saturated $NaHCO_3$, and saturated NaCl solutions. The organic layer was dried over $MgSO_4$ and concentrated *in vacuo*. Crystalline residue obtained was recrystallized from AcOEt: yield 5.60 g (84.7%); mp 119—122 °C; $[\alpha]_D^{13}$ −53.6° (*c* 1.45, MeOH).

Found: C, 54.29; H, 7.03; N, 10.71; S, 4.79%. Calcd for $C_{29}H_{45}N_5O_9S$: C, 54.44; H, 7.09; N, 10.95; S, 5.01%.

*HCl·H-A_2pr(Z)-Leu-Cys(Acm)-OMe (**5**).* Protected tripeptide **4** (1.00 g, 1.56 mmol) was dissolved in 5.7 ml of 4.1 M HCl/THF. After the solution was allowed to stand at room temperature for 40 min, ether was added to precipitate **5** under cooling in an ice bath. White powder obtained was filtered and reprecipitated from isopropyl alcohol and hexane: yield 0.91 g (quantitative); mp 103—105 °C; $[\alpha]_D^{13}$ −46.4° (*c* 1.01, MeOH).

Found; C, 48.56; H, 6.60; N, 11.73; S, 5.75; Cl, 6.23%. Calcd for $C_{24}H_{38}N_5O_7SCl$: C, 48.81; H, 6.76; N, 11.86; S, 5.43; Cl, 6.00%.

*Boc-Ile-A_2pr(Z)-Leu-Cys(Acm)-OMe (**6**).* To a solution of tripeptide hydrochloride **5** (7.46 g, 13.0 mmol) in 50 ml of DMF were added Boc-Ile-OSu [3] (4.26 g, 13.0 mmol) and triethylamine (2.63 g, 26.0 mmol) under ice cooling. The reaction mixture was stirred at room temperature overnight. Triethylamine hydrochloride was filtered off and the filtrate was concentrated *in vacuo*. The residue was once dissolved in a small amount of hot AcOEt and the solution was cooled in an ice bath. The gelatinous precipitate filtered was reprecipitated from methanol and water: yield 8.65 g (88.6%); mp 169—170 °C (decomp); $[\alpha]_D^{15}$ −56.5° (*c* 1.00, MeOH).

Found: C, 55.46; H, 7.42; N, 11.15; S, 4.30%. Calcd for $C_{35}H_{56}N_6O_{10}S\cdot 1/4\,H_2O$: C, 55.50; H, 7.52; N, 11.10; S, 4.23%.

*HCl·H-Ile-A_2pr(Z)-Leu-Cys(Acm)-OMe (**7**).* To a solution of protected tetrapeptide **6** (5.60 g, 7.44 mmol) in 22 ml of MeOH was added 16 ml of 4.7 M HCl/THF. The mixture was allowed to stand at room temperature for 1 h and then ether was added to precipitate hydrochloride under cooling in an ice bath. Crude product was reprecipitated from methanol and ether: yield 4.80 g (93.6%); mp 197—198 °C; $[\alpha]_D^{17}$ −36.0° (*c* 1.00, MeOH).

Found: C, 51.59; H, 7.15; N, 12.03; S, 4.87; Cl, 5.11%. Calcd for $C_{30}H_{49}N_6O_8SCl$: C, 51.60; H, 7.22; N, 12.04; S, 4.59; Cl, 5.08%.

*Boc-D-Cys(Trt)-Ile-A_2pr(Z)-Leu-Cys(Acm)-OMe (**8**).* Boc-D-Cys(Trt)-OH·DCHA[16] (1.40 g, 2.18 mmol) was treated with ethyl acetate and 10% aqueous citric acid. Ethyl acetate layer taken was washed with water three times and dried over $MgSO_4$. Oily residue obtained by vacuum concentration was dissolved in 10 ml of absolute THF. To the solution was added *N*-hydroxysuccinimide (250 mg, 2.18 mmol) and then DCC (448 mg, 2.18 mmol) under ice cooling. The mixture was stirred at 0 °C for 1 h and at room temperature for 2 h. *N,N'*-Dicyclohexylurea precipitated was filtered off and the filtrate was concentrated *in vacuo*. Oily residue thus obtained and **7** (1.50 g, 2.18 mmol) were dissolved in 20 ml of DMF. To the solution was added triethylamine (0.44 g, 4.4 mmol) under cooling in an ice bath. The reaction mixture was stirred at 0 °C for 30 min and at room temperature overnight. Triethylamine hydrochloride was filtered off and the filtrate was concentrated *in vacuo*. Oily residue was triturated with cold ether to make powder which was reprecipitated from methanol and 2% aqueous acetic acid. The precipitate filtered was washed with water and ether: yield 1.85 g (77.4%); mp 169—172 °C; $[\alpha]_D^{26}$ −45.4° (*c* 1.00, MeOH).

Found: C, 61.09; H, 6.84; N, 8.93; S, 5.62%. Calcd for $C_{57}H_{75}N_7O_{11}S_2\cdot H_2O$: C, 61.30; H, 6.95; N, 8.82; S, 5.74%.

*Boc-D-Cys-Ile-A_2pr(Z)-Leu-Cys-OMe (**9**).* To a solution of linear peptide **8** (4.60 g, 4.19 mmol) in 840 ml of MeOH was added I_2 (3.19 g, 12.6 mmol) in 125 ml of MeOH under vigorous stirring in a minute. The oxidation was accomplished for 1 h at room temperature and stopped by an addition of 0.1 M $Na_2S_2O_3$ solution until the color of I_2 disappeared. The reaction mixture was concentrated *in vacuo* and the residue was dissolved in water. Extraction with $CHCl_3$ was performed three times and the extract was concentrated *in vacuo* after drying over $MgSO_4$. The oily residue thus obtained was crystallized by an addition of ether to obtain pure material as a powder: yield 2.63 g (80.2%); mp 178—180 °C; $[\alpha]_D^{26}$ +2.3° (*c* 1.0, DMF); MW 750±37 (Calcd 783); FD-MS, *m/z* 782 (M^+).

Found: C, 53.12; H, 6.93; N, 10.42; S, 8.33%. Calcd for $C_{35}H_{54}N_6O_{10}S_2\cdot 1/2\,H_2O$: C, 53.08; H, 7.00; N, 10.61; S, 8.10%.

*Boc-D-Ala-Ile-A_2pr(Z)-Leu-Ala-OMe (**10**).* To a solution of the cyclic disulfide **9** (200 mg, 0.255 mmol) in 80 ml of anhydrous DMF was added tris(diethylamino)-phosphine (1.26 g, 5.11 mmol) in 20 ml of anhydrous DMF. The reaction mixture was stirred at 50 °C for 2 d and then concentrated *in vacuo*. The residue was once dissolved in AcOEt and washed with 10% citric acid and saturated NaCl solution. Organic layer was dried over $MgSO_4$ and concentrated *in vacuo*. The oily residue was easily crystallyzed by trituration with hexane in a yield of 164 mg (85.4%). Although the product was pure enough to be supplied for the next reaction, a part of the sample was recrystallized from methanol to obtain an analytical sample: mp 226.5—227 °C; $[\alpha]_D^{26}$ −47.6°C (*c* 1.00, DMF); FD-MS, *m/z* 750 (M^+). Amino acid analysis: Lan[17] (0.33), *meso*-Lan (0.72), Ile (0.76), Leu (1.00), A_2pr (1.15).

Found: C, 55.56; H, 7.18; N, 11.04; S, 4.31%. Calcd for $C_{35}H_{54}N_6O_{10}S$: C, 55.98; H, 7.25; N, 11.19; S, 4.27%.

Boc-D-Ala-Ile-$A_2pr(Me_2)$-Leu-Ala-OMe (**11**). The sulfide compound **10** (279 mg, 0.356 mmol) in 60 ml of methanol was hydrogenated in the presence of acetic acid (2.0 ml) by use of Pd black catalyst (*ca.* 2 g) under a gentle bubbling of hydrogen. A progress of the reaction was followed on TLC. After the hydrogenolysis was finished, the catalyst was filtered off. The filtrate was concentrated *in vacuo* and the residue was immediately dissolved in 25 ml of methanol for the following permethylation. To the solution were added 35% formaldehyde (153 mg, 1.78 mmol) and $NaBH_3CN$ (45 mg, 0.72 mmol). The reaction mixture was stirred at room temperature for 2 h and then concentrated *in vacuo*. The residue was treated with ethyl acetate and a saturated aqueous $NaHCO_3$. The organic layer was washed once with a saturated $NaHCO_3$ solution and three times with a saturated NaCl solution. The ethyl acetate extract was dried over $MgSO_4$ and concentrated *in vacuo*. The residue was reprecipitated from ethyl acetate and hexane: yield 179 mg (78.3%); mp 192—193 °C; $[\alpha]_D^{24}$ −44.0° (*c* 1.00, MeOH); FD-MS, *m/z* 644 (M^+).

Found: C, 54.24; H, 8.09; N, 13.02; S, 4.61%. Calcd for $C_{29}H_{52}N_6O_8S$: C, 54.02; H, 8.13; N, 13.03; S, 4.97%.

Boc-D-Ala-Ile-Dha-Leu-Ala-OMe (Boc-Ring A-OMe) (**12**). To a solution of dimethyl derivative **11** (140 mg, 0.217 mmol) in 5 ml of methanol were added $KHCO_3$ (326 mg, 3.26 mmol) and CH_3I (30.8 mg, 0.217 mmol). Since a part of CH_3I vaporized during the reaction at room temperature, a small amount of CH_3I (3.1 mg) was added four times every 10—12 h. The reaction mixture was finally cooled in an ice bath to precipitate a desired product. The precipitates filtered were washed with a 10% critic acid solution and water to remove inorganic salts: yield 40.6 mg (31.2%); mp 228—229 °C; $[\alpha]_D^{17}$ −68.2° (*c* 1.00, DMF); FD-MS, *m/z* 599 (M^+); UV(MeOH)λ_{max}, 250 nm (ε, 1500). Amino acid analysis: Lan[17] (0.40), *meso*-Lan (0.70), Ile (0.94), Leu (1.00).

Found: C, 53.91; H, 7.56; N, 11.55; S, 5.27%. Calcd for $C_{27}H_{45}N_5O_8S$: C, 54.07; H, 7.56; N, 11.68; S, 5.35%.

The authors are deeply indebted to Professor Kenji Okawa and Dr. Kiichiro Nakajima, Kwansei Gakuin University, for their kindness given for the use of an osmometer. Synthesis of Some New Aza Tricyclic Compounds with a Cyclopropane Ring *via* Photolysis of Dihydromayurone Oximes and the Related Compounds

Hajime Takahashi and Masaaki Ito*

Chemistry Laboratory, Department of General Education, Higashi Nippon Gakuen University, Ombetsu, Hokkaido 088-01

(Received October 12, 1982)

Oximation of dihydromayurone and 6,10,10-trimethyltricyclo[4.4.0.0^{1,3}]decan-4-one gives new isomeric oximes, respectively. The Beckman rearrangement of (*Z*)- or (*E*)-dihydromayurone oxime and (*Z*)- or (*E*)-6,10,10-trimethyltricyclo[4.4.0.0^{1,3}]decan-4-one oxime with polyphosphoric acid takes place prior to the *Z*-*E* equilibration of these isomers, respectively. Photolysis of the oximes gives two pairs of the isomeric lactams, 4-aza-8,12,12-trimethyltricyclo[6.4.0.0^{1,3}]dodecan-5-one, 5-aza-8,12,12-trimethyltricyclo[6.4.0.0^{1,3}]dodecan-4-one, 4-aza-7,11,11-trimethyltricyclo[5.4.0.0^{1,3}]undecan-5-one, and 5-aza-7,11,11-trimethyltricyclo[5.4.0.0^{1,3}]undecan-4-one. The reaction of either dihydromayurone or 6,10,10-trimethyltricyclo[4.4.0.0^{1,3}]decan-4-one with hydroxylamine-*O*-sulfonic acid in acetic acid affords only the lactam arising from the migration of the less substituted carbon.

Since the first study on the photo-Beckmann rearrangement of aromatic aldoximes by de Mayo,[1] a number of the related investigations have been reported. The mechanistic aspects of this intriguing and potentially useful photo chemical rearrangement have also been discussed for aromatic aldoximes,[2] and naphthalenone oxime,[3] styryl ketone oximes,[4] and alicyclic ketone oximes.[5–13] The formation of amides by photolysis of oximes is considered to take place *via* oxaziridine intermediates formed rapidly from the excited state oximes, which have been proved to be of a singlet state for the aromatic aldoximes[2] and the styryl ketone oxime rearrangement.[4]

In the photo-Beckmann rearrangement of the steroidal ketone oximes, we have recently reported[8,9] that the original configuration of C-α in the produced lactam with respect to the hydroxyimino group of the starting oxime was retained, irrespective of the configuration of the hydroxyimino group of the starting oxime.

We wish to report the photolysis and the Beckmann rearrangement of dihydromayurone oximes and 6,10,10-trimethyltricyclo[4.4.0.0^{1,3}]decan-4-one oximes, derived[14,15] both from a sesquiterpene thujopsene. We also report the reaction of the starting ketones (**1**) and (**4**) with hydroxylamine-*O*-sulfonic acid.[16,17] Considering that photolysis and the Beckmann rearrangement of an α,β-unsaturated ketone oxime are generally inferior to those of an alicyclic ketone oxime, we believe that the reactions of cyclopropyl ketone system which has a partial property of α,β-unsaturated ketone are important both from the synthetic and mechanistic points of view.

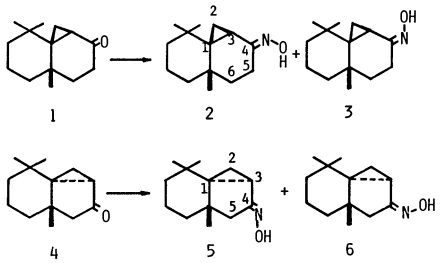
Results and Discussion

Preparation of Dihydromayurone Oximes (2), (3), and 6,10,10-Trimethyltricyclo[4.4.0.0^{1,3}]decan-4-one Oximes (5), (6). It was found that oximation of dihydromayurone[14] (**1**) gave a 2 : 1 mixture of new two isomeric oximes, which could be separated by preparative TLC into a less polar crystlline **2**, mp 136—137 °C and a more polar crystalline **3**, mp 160—161 °C. On the other hand, oximation of 6,10,10-trimethyltricyclo[4.4.0.0^{1,3}]decan-4-one[15] (**4**) also afforded the two isomeric crystalline oximes **5**, mp 103—105 °C and **6**, mp 106—107 °C in the ratio of 1.3:1, which could be separated by TLC.

The configurations of **2**, **3**, **5**, and **6** were established both by the following ^{1}H NMR spectra and the Beckmann rearrangement.

Generally, hydrogens on an α-carbon atom to the oximino group are known to appear downfield[18] and especially, a *Z*-hydrogen disposed coplanar with a hydroximino hydroxyl group considerably downfield in the ^{1}H NMR spectrum.

In the ^{1}H NMR spectra of **2**, **3**, **5**, and **6**, the signals of C-5-H$_2$ of **2** and **5** appeared more downfield, and the signals of C-3-H of **2** and **5** appeared more upfield



Scheme 1.

Table 1. ^{1}H NMR spectra [δ, $CDCl_3$, TMS] of C-3-H and C-5-H$_2$ of the oximes (**2**), (**3**), (**5**), and (**6**)

Oxime	C-3-H(J/Hz)[a]	C-5-H$_2$(J/Hz)
2	1.90 (dd, J=5 and 10 Hz)	2.20—2.40 (m)
3	2.41 (dd, J=5 and 10 Hz)	2.10 (m)
5	2.03 (dd, J=4 and 8 Hz)	1.71 and 2.50 (AB-q, J=17 Hz)
6	2.56 (dd, J=4 and 8 Hz)	1.81 and 2.00 (AB-q, J=16 Hz)

a) This assignment was confirmed by the decoupling study with C-2-H$_2$.

than those of **3** and **6**, as shown in Table 1. These results indicated that **2**, **5** and **3**, **6** were assigned to *E*- and *Z*-configuration, respectively. These assignments were supported by the following Beckmann rearrangement.

Beckmann Rearrangement of the Oximes (2) and (3). Treatment of **2** with polyphosphoric acid[19] (PPA) at 90 °C for 10 min afforded the two new lactams (**7**), mp 156—161 °C, and (**8**), mp 118—120 °C, in 40 and 7% yields (by GLC analysis), respectively. On the other hand, the Beckmann rearrangement of **3** under the same conditions afforded **7** and **8** in 10 and 41% yields. The new lactams **7** and **8** were identified as 4-aza-8,12,12-trimethyltricyclo[6.4.0.0^{1,3}]dodecan-5-one and 5-aza-8,12,12-trimethyltricyclo[6.4.0.0^{1,3}]dodecan-4-one, respectively, on the ^{1}H NMR spectral ground.

In the spectrum of **7**, signals due to protons at C-3, C-6, and N atoms appeared as a double doublet at δ 2.57 (J=4 and 9 Hz), as a multiplet at δ 2.10, as a broad singlet at δ 6.62 (W_H=12 Hz), respectively. It is noteworthy that one proton signal was observed abnormally at down field as a double doublet at δ 2.91 (J=8, 12, and 12 Hz). Irradiation at δ 2.10 (C-6-H$_2$) collapsed the double double doublet at δ 2.91 into a double doublet (J=8 and 12 Hz), indicating the signal in question to be assigned to one proton at C-7. With an aim to clarify the structure of **7**, dihydromayurone (**1**) was treated with *m*-chloroperbenzoic acid (MCPBA) in dichloromethane giving a lactone, 8,12,12-trimethyl-4-oxatricyclo-[6.4.0.0^{1,3}]dodecan-5-one (**9**). The ^{1}H NMR spectrum of **9** was similar to that of **7**; the signals of C-3-H, C-7-H, and C-6-H$_2$ appeared as a double doublet (δ 3.77, J=4 and 8 Hz), a double double doublet (δ 3.01, J=8, 12, and 12 Hz), and a multiplet (δ 2.30), respectively. While the C-7 proton of **9** appeared downfield by 0.1 ppm from the corresponding proton of **7**, and displayed the same splitting pattern, supporting the structure of **7** and **9**.

In the ^{1}H NMR spectrum of **8**, the signal due to N-proton was observed as a broad singlet at δ 7.18 (W_H=20 Hz). Moreover, the signal due to two C-6-protons appeared as two multiplets at δ 3.13 (1H) and 3.82 (1H). By addition of D_2O, the signal due to N-proton disappeared and the two multiplets were converted into a double double doublet and a double doublet centered at δ 3.82 (J=5, 12, and 14 Hz) and 3.13 (J=6 and 14 Hz), respectively. This also supports the structure of **8** as depicted in Scheme 2.

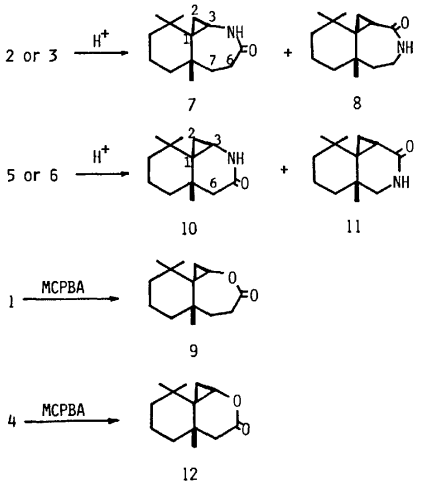
In the Beckmann rearrangement of oximes in general, it is well known[20] that the C–C bond oriented at the antiposition with respect to the hydroximino hydroxyl group migrates. Our results indicated that the equilibration between **2** and **3** took place to some extent prior to rearrangement under our experimental conditions. However, judging from the results, its rearrangement proceeded faster than the isomerization. These facts strongly suggested that the *E*- and *Z*-configurations were reasonably assigned to **2** and **3**, respectively.

Beckmann Rearrangement of the Oximes (5) and (6). Treatment of **5** with PPA at 90 °C for 5 min gave the two new lactams (**10**), mp 206—207 °C, and (**11**), mp 149—151 °C in 46 and 10% yields, respectively. On the other hand, the same treatment of **6** afforded **10** and **11** in 12 and 40% yields. On the basis of the ^{1}H NMR spectra, these lactams were assigned to the respective formulas, 4-aza-7,11,11-trimethyltricyclo[5.4.0.0^{1,3}]undecan-5-one and 5-aza-7,11,11-trimethyltricyclo[5.4.0.0^{1,3}]undecan-4-one, shown in Scheme 2. In the spectrum of **10**, signals due to protons at C-3, C-6, and N atoms appeared as a double doublet at δ 2.81 (J=5 and 10 Hz), as an AB-quartet at δ 1.80 and 2.12 (J=16 Hz) and as a broad singlet at δ 8.27 (W_H=16 Hz), respectively. Moreover, a new lactone, 7,11,11-trimethyl-4-oxatricyclo[5.4.0.0^{1,3}]-undecan-5-one (**12**) was prepared by treatment of **4** with MCPBA, and the structure of **10** was confirmed by the comparison with the spectra of **12**.

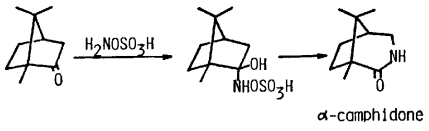
In the ^{1}H NMR spectrum of **11**, the signals of two C-6-protons appeared as a doublet at δ 2.91 (1H, J=13 Hz) and a double doublet at δ 2.48 (1H, J= 6 and 13 Hz). Addition of D_2O collapsed the double doublet at δ 2.48 into a doublet (J=13 Hz). The signal due to C-3-proton was not observed at downfield in the spectrum, again supporting the structure of **11** as indicated in Scheme 2.

These results confirmed the orientation of each hydroximino hydroxyl group of **5** and **6**.

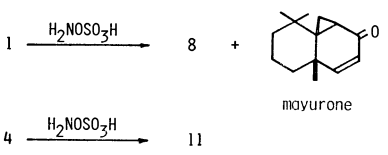
Reaction of the Ketones (1) and (4) with a Hydroxylamine-O-sulfonic Acid. It has been reported that treatment of ketone with hydroxylamine-*O*-sulfonic acid[16] produced lactam, and camphor was converted into only α-camphidone[17] which is produced from less substituted α-carbon. Since the migration in the Beckmann rearrangement usually occurs from the more substituted α-carbon, the above result suggests "unusual" Beckmann rearrangement. Then, we attempted the reaction of the cyclopropyl ketone systems **1** and **4**.



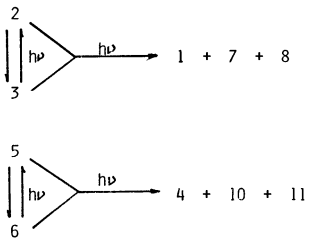
Scheme 2.



Scheme 3.



Scheme 4.



Scheme 5.

Treatment of **1** with hydroxylamine-*O*-sulfonic acid in acetic acid under reflux for 20 h gave **8** and mayurone in 33 and 24% yields, respectively. On the other hand, treatment of **4** under the same conditions afforded only **11** in 86% yield. These results indicated that the migration of less substituted α-carbon (C-5) took place predominantly (unusual Beckmann type).

Photolysis of Dihydromayurone Oximes (2) and (3). The photo-Beckmann rearrangement of **2** and **3** was carried out in methanol under nitrogen atmosphere at room temperature with a 15 W low pressure mercury lamp placed in the solution. Examination of the reaction by TLC indicated that a rapid photostationary equilibration between the *E*- and *Z*-forms took place, and, after 3 h, nearly equal amounts of *E*- and *Z*-forms were present in the solution. However, the photolysis for 20 h led to formation of several products, which were separated roughly into three fractions by column chromatography over silica gel. The least polar fraction consisted mainly of **1** in 40% yield, while the middle and the most polar fractions were found to contain **4** and **5** in the 10 and 13% yields, respectively. These products were identified by direct comparison with the spectra of the authentic samples.

The Photo-Beckmann Rearrangement of 5 and 6. The photo-Beckmann rearrangements of **5** and **6** were carried out under the same conditions as in the case of **2** and **3**. Examination of the reaction mixture after 5 h by TLC also revealed the presence of nearly equal amounts of *E*- and *Z*-forms in the solution. Further photolysis for 20 h resulted only in partial transformation of the oximes giving several products. Since further irradiation appeared to cause secondary photochemical decomposition of the initial products, the irradiation was stopped at this stage. The products were separated into four fractions by column chromatography over silica gel. The least polar fraction was found to be **4** in 24% yield by its spectra. The second least polar fraction (41%) consisted of a 1:1 mixture of the unreacted oximes. The third least and most polar fractions (3 and 5%) contained lactams **10** and **11**, respectively.

The results of the photolysis were summarized as follows. (i) The photo-Beckmann rearrangement of the conjugated cyclopropyl ketone oximes afforded the corresponding lactams. (ii) However, the yields of lactams were poor probably owing to the steric effect in the starting oximes and a property of a partial unsaturation of the cyclopropane ring. The major portion of products was the parent ketone arising from elimination of the nitrogen moiety of the intermidiary oxaziridines.

Experimental

All melting points were determined with a Shimadzu micro-apparatus. IR and ^1H NMR were determined with a Shimadzu IR-400 spectrometer and with a JEOL JNM-PMX-60 and/or a JEOL PS 100 high resolution spectrometer (solvent, chlorofrom-*d*; internal reference, tetramethylsilane), respectively. TLC and column chromatography were carried out on Wakogel B and on Cica Silica gel. GLC was carried out on a Shimadzu 4BM (column; 1.5% SE-30, 1.5 m). Elemental analysis were determined with a Hitachi CHN Analyzer. Mass spectra were taken by the staff of the Faculty of Pharmaceutical Science, Hokkaido University, with a RMU-6E spectrometer.

Dihydromayurone Oximes (2) and (3). Dihydromayurone (**1**) (2.06 g) in 90% aq ethanol (150 ml) was refluxed for 2 h with hydroxylamine hydrochloride (1.00 g) and sodium acetate (1.50 g). After removal of solvent, the reaction mixture was mixed with ether. The ether layer was washed with water, dried (Na_2SO_4), and evaporated to leave crystals, which were found to consist of two isomeric compounds by the ^1H NMR and TLC. These compounds were separated by repeated preparative TLC with a 4:1 mixture of benzene and acetone into **2** (1.04 g) and **3** (0.50 g).

Oxime **2**, mp 136—137 °C (from ethanol); MS, *m/e* 221 (M^+, 18%), 204 ($M^+ - OH$); IR ν_{max} (KBr) 3250 (-OH), 3020 (cyclopropane), and 1650 cm^{-1} (-C=N-); ^1H NMR, δ 1.90 (dd, 1H, $J=5$ and 10 Hz, C-3-H), 2.20—2.40 (m, 2H, C-5-H_2), 0.64, 1.14 and 1.19 each (s, 3H, -CH_3); Found: C, 75.76; H, 10.61; N, 6.20%. Calcd for $C_{14}H_{23}NO$: C, 75.97; H, 10.47; N, 6.33%.

Oxime **3**, mp 160—161 °C (from ethanol); MS, *m/e* 221 (M^+, 22%), 204 ($M^+ - OH$, 7); IR, ν_{max} (KBr) 3250 (-OH), 3020 (cyclopropane), and 1650 cm^{-1} (-C=N-); ^1H NMR, δ 2.41 (dd, 1H, $J=5$ and 10 Hz, C-3-H), 2.10 (m, 2H, C-5-H_2), 0.66, 1.10, and 1.16 each (s, 3H, -CH_3), Found: C, 75.88; H, 10.58; N, 6.32%. Calcd for $C_{14}H_{23}NO$: C, 75.97; H, 10.47; N, 6.33%.

6,10,10-Trimethyltricyclo[4.4.0.0^{1,3}]decan-4-one Oximes (5) and (6). The starting ketone (**4**) (0.96 g) in 90% aq ethanol (50 ml) was refluxed for 1 h with hydroxylamine hydrochloride (0.50 g) and sodium acetate (0.54 g). After removal of solvent, the reaction mixture was mixed with ether. The ether solution was washed with water, dried (Na_2SO_4), and evaporated to leave crystals, which were separated by repeated preparative TLC with a 5:1 mixture of benzene and acetone to afford **5** (460 mg) and **6** (350 mg).

Oxime **5**, when recrystallized from ethanol, had mp 103—105 °C; MS, *m/e* 207 (M^+, 17%), 190 ($M^+ - OH$, 25); IR, ν_{max} (KBr) 3280 (-OH), 1650 cm^{-1} (-C=N-); ^1H NMR, δ 2.03 (dd, 1H, $J=4$ and 8 Hz, C-3-H), 2.50 and 1.71 (AB-q, $J=17$ Hz, C-5-H_2), 0.60, 1.06, and 1.16 each (s, 3H, -CH_3); Found: C, 75.25; H, 10.05; N, 7.01%. Calcd for $C_{13}H_{21}NO$: C, 75.31; H, 10.21; N, 6.76%.

Oxime **6**, when recrystallized from ethanol, had mp 206—207 °C; MS, *m/e* 207 (M^+, 14%), 190 ($M^+ - OH$, 28); IR; ν_{max} (KBr), 3300 (OH), and 1650 cm^{-1} (-C=N-); ^1H NMR, δ 2.56 (dd, 1H, $J=4$ and 8 Hz, C-3-H), 1.81 and 2.00 (AB-

q, 2H, J=16 Hz, C-5-H_2), 0.63, 1.06, and 1.14 each (s, 1H, -CH_3); Found: C, 75.31; H, 10.24; N, 7.22%. Calcd for $C_{13}H_{21}NO$: 75.31; H, 10.21; N, 6.76%.

Rearrangement of ***2*** *with PPA.* **2** (400 mg) was added into polyphosphoric acid (20 g) at 90 °C, stirred with glass stick for 10 min, and cooled. To the reaction mixture was added 10% aq sodium carbonate and ether. The ether solution left oily residue, which was separated by column chromatography over silica gel to afford lactam **7** (123 mg) and **8** (25 mg).

Lactam **7**, mp 156—160 °C (from hexane); MS, *m/e* 221 (M^+, 19%); IR, ν_{max} (KBr) 3010 (cyclopropane), 3200 (-NH), and 1670 cm^{-1} (carbonyl); ^1H NMR, δ 2.57 (dd, 1H, J=4 and 9 Hz, C-3-H), 2.10 (m, 2H, C-6-H_2), 2.91 (ddd, 1H, J=8, 12, and 12 Hz, C-7-H), 6.62 (broad s, 1H, W_H=12 Hz, NH), 0.56, 0.85, and 1.18 each (s, 3H, -CH_3); Found: C, 75.68; H, 10.58; N, 6.18%. Calcd for $C_{14}H_{23}NO$: C, 75.97; H, 10.47; N, 6.33%.

Lactam **8**, mp 118—120 °C (from hexane); MS, *m/e* 221 (M^+, 24%); IR, ν_{max} (KBr) 3200 (-NH) and 1670 cm^{-1} (carbonyl); ^1H NMR, δ 3.13 and 3.82 each (m, 1H, C-6-H), 7.18 (broad s, 1H, W_H=20 Hz), 0.63, 0.83, and 1.13 each (s, 3H, -CH_3); Found C, 75.69; H, 10.55; N, 6.06%. Calcd for $C_{14}H_{23}NO$: C, 75.97; H, 10.47; N, 6.33%.

Rearrangement of ***3*** *with PPA.* **3** (400 mg) was added into polyphosphoric acid (20 g) at 90 °C and stirred with glass stick for 10 min. Usual work-up afforded **7** (400 mg) and **8** (164 mg).

*8,12,12-Trimethyl-4-oxatricyclo[6.4.0.0^{1,3}]dodecan-5-one (**9**).* **1** (300 mg) and *m*-chloroperbenzoic acid (700 mg) in dichloromethane (20 ml) were refluxed for 20 h, and then cooled. After addition of 10% aq sodium carbonate, the mixture was extracted with dichloromethane. The dichloromethane solution was washed with water and dried (Na_2SO_4). The residue, obtained by removal of solvent by column chromatography over silica gel to afford crystals (154 mg), which on recrystallization from hexane gave lactone **9**, mp 120—122 °C; MS, *m/e* 222 (M^+, 0.3%); IR, ν_{max} (KBr) 1750 and 1270 cm^{-1} (lactone); ^1H NMR δ 3.77 (dd, 1H, J=4 and 8 Hz, C-3-H), 2.30 (m, 2H, C-6-H_2), 3.01, (ddd, 1H, J=8, 12, and 12 Hz, C-7-H), 0.59, 0.88, and 1.19 each (s, 3H, -CH_3); Found: C, 75.68; H, 9.81%. Calcd for $C_{14}H_{22}O_2$: C, 75.63; H, 9.97%.

Rearrangement of ***5*** *with PPA.* **5** (200 mg) was added into warm polyphosphoric acid (10 g) at 100 °C and stirred with grass stick for 10 min, and cooled. To the reaction mixture was added 10% aq sodium carbonate, and ether. The ether sulution was washed with water, and dried (Na_2SO_4); the residue obtained by removal of solvent was separated by column chromatography over silica gel to give two lactams **10** (92 mg) and **11** (20 mg).

Lactam **10**, when recrystallized from hexane, had mp 206—207 °C; MS, *m/e* 207 (M^+, 25%); IR, ν_{max} (KBr) 3180 (NH) and 1680 cm^{-1} (carbonyl); ^1H NMR, δ 2.81 (dd, 1H, J=5 and 10 Hz, C-3-H), 1.80 and 2.12 (AB-q, J=16 Hz, C-6-H_2), 8.27 (broad s, 1H, W_H=16 Hz, NH), 0.59, 1.07, and 1.22 each (s, 3H, -CH_3); Found: C, 74.96; H, 9.91; N, 6.69%. Calcd for $C_{13}H_{21}NO$: C, 75.30; H, 10.21; N. 6.76%.

Lactam **11**, when recrystallized from hexane, had mp 149—151 °C; MS, *m/e* 207 (M^+, 25%); IR, ν_{max} (KBr) 3330 (NH), and 1670 cm^{-1} (carbonyl); ^1H NMR, δ 2.91 (d, 1H, J=13 Hz, C-6-H) and 2.48 (dd, 1H, J=6 and 13 Hz, C-6-H), 7.35 (broad s, 1H, W_H=8 Hz, NH), 0.62, 1.55, and 1.55 each (s, 3H, -CH_3); Found: C, 75.10; H, 10.20; N, 6.54%. Calcd for $C_{13}H_{21}NO$: C, 75.31; H, 10.21; N, 6.76%.

Rearrangement of ***6*** *with PPA.* **6** (200 mg) was converted into lactams **10** (23 mg) and **11** (80 mg) under the same conditions with rearrangement of **5**.

*7,11,11-Trimethyl-4-oxatricyclo[5.4.0.0^{1,3}]undecan-5-one (**12**)* **4** (220 mg) and *m*-chloroperbenzoic acid (700 mg) in dichloromethane (20 ml) were refluxed for 20 h. After being cooled, the reaction mixture was washed with 10% aq sodium carbonate and water, dried (Na_2SO_4), and evaporated to leave oily residue, which was purified by column chromatography over silica gel to yield lactone **12** (150 mg) in pure state.

Lactone **12**, recrystallization from hexane, mp 129—131 °C; MS, *m/e* 208 (M^+, 0.3%); IR, ν_{max} (KBr) 1740 and 1240 cm^{-1} (lactone); ^1H NMR, δ 4.13 (dd, 1H, J=4 and 8 Hz, C-3-H), 1.98 and 2.22 (AB-q, 2H, J=17 Hz, C-6-H_2), 0.61, 1.05, and 1.21 each (s, 3H, -CH_3); Found: C, 74.75; H. 9.63%. Calcd for $C_{13}H_{20}O_2$; C, 74.96; H, 9.68%.

Reaction of ***1*** *with Hydroxylamine-O-sulfonic Acid.* **1** (412 mg) and hydroxylamine-*O*-sulfonic acid (452 mg) in acetic acid (5 ml) were refluxed for 20 h under nitrogen atmosphere. After being cooled, to the reaction mixture was added 10% aq sodium hydroxide (20 ml) and ether. The ether layer was washed with water, and dried (Na_2SO_4). The products were separated by column chromatography over silica gel, using benzene, ether and acetone as solvent. Elution with 2:1 mixture of benzene and ether gave a single crystal (100 mg), which was identified with authentic mayurone. On the other hand, elution with 1:1 mixture of ether and acetone afforded a single crystal **8** (140 mg).

Reaction of ***4*** *with Hydroxylamine-O-sulfonic Acid.* **4** (190 mg) and hydroxylamine-*O*-sulfonic acid (170 mg) in acetic acid (3 ml) were refluxed for 20 h. After being cooled, to the reaction mixture was added 10% aq sodium hydroxide and ether. The ether layer was washed with water and dried (Na_2SO_4). Removal of solvent gave a crystal (176 mg), which was identified with **11**.

Photolysis of ***2*** *and* ***3***. A 2:1 mixture of **2** and **3** (1.50 g) in methanol (400 ml) was irradiated for 20 h with 15 W low pressure arc Hg lamp, while nitrogen was slowly bubbled through the solution. Removal of methanol left oily residue, which was separated by column chromatography over silica gel to give **1** (600 mg, from 2:1 mixture of benzene and ether), **7** (150 mg, from ether), and **8** (200 mg, from 1:1 mixture of ether and acetone). They were identical with authentic compounds, respectively.

Photolysis of ***5*** *and* ***6***. A 1.3:1 mixture of **5** and **6** (2.0 g) in methanol (400 ml) was irradiated for 20 h with 15 W low pressure arc Hg lamp, while nitrogen was slowly bubbled through the solution. The oily residue, obtained removal of methanol, was separated by column chromatography over silica gel to afford **4** (447 mg, from 2:1 mixture of benzene and ether), **5** and **6** (825 mg, from 1:1 mixture of benzene and ether), **10** (67 mg, from ether) and **11** (100 mg, from 1:1 mixture of ether and acetone), which were identical with the respective authentic compounds.

The authors wish to express their thanks to Professor Tadashi Masamune and Professor Hiroshi Suginome of Hokkaido University for many helpful suggestions.

Photochemical Activation of Zinc-Carbon and Zinc-Sulfur Bonds in Zinc Porphyrins

Masahiro NUKUI, Shohei INOUE,* and Yasukazu OHKATSU

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received December 3, 1982)

Ethyl(*N*-methyltetraphenylporphinato)zinc (NMTPPZnEt **2**) reacts with thiol (RSH: R=Pr^n, Bu^t, Ph) and hydrogen sulfide (H_2S) to form *N*-methyltetraphenylporphinatozinc sulfide (NMTPPZnSR: R=Pr^n, Bu^t, Ph, H). Irradiation with visible light enhances the reactivity of **2** in the reaction with Bu^{t}SH and brings about the homolytic cleavage of the zinc-sulfur bond of NMTPPZnSPr^n in dichloromethane.

The photochemistry of metalloporphyrins is of current interest in connection with the conversion of solar energy into chemical energy.[1-3] We have been studying the photochemical behavior of metalloporphyrins of aluminium and zinc which have an axial ligand bound to the metal *via* a σ-bond, and have found some very interesting effects of visible light on the reactivity of the axial ligand of the metalloporphyrins.

Ethyl(tetraphenylporphinato)aluminium (TPPAlEt **1**), which is unreactive to carbon dioxide in the dark, is activated by visible light and carbon dioxide is inserted into the aluminium-carbon bond in the presence of *N*-methylimidazole (Im).[4]

$$\underset{\mathbf{1}}{\text{TPPAlEt}} + CO_2 \xrightarrow[\text{Im}]{h\nu\ (>420\text{ nm})} \text{TPPAl-OC-Et} \quad (1)$$

The zinc-carbon bond of ethyl(*N*-methyltetraphenylporphinato)zinc (NMTPPZnEt **2**) was found to be subject to homolytic cleavage under irradiation with visible light in dichloromethane solution.[5]

$$\underset{\mathbf{2}}{\text{NMTPPZnEt}} \xrightarrow[\text{in } CH_2Cl_2]{h\nu\ (>420\text{ nm})} [\text{NMTPPZn}\cdot] + \text{Et}\cdot \quad (2)$$

In these reactions, the metal-carbon bond which may not absorb visible light is indirectly activated by photoexcitation of the porphyrin macrocycle.

In this paper we report the photochemical activation of the zinc-carbon bond of NMTPPZnEt (**2**) in the reaction with thiol having a bulky group, and of the zinc-sulfur bond in porphinatozinc alkyl sulfide (NMTPPZnSR), resulting in the homolytic cleavage of zinc-sulfur bond.

Experimental

Materials. Benzene and hexane were distilled under nitrogen over sodium wire. Dichloromethane was refluxed and distilled over calcium hydride under nitrogen. Diethylzinc was distilled under reduced pressure and stored in nitrogen. *N*-Methyltetraphenylporphyrin (NMTPPH) was prepared from α, β, γ, δ-tetraphenylporphyrin and methyl fluorosulfate.[6] NMTPPZnEt (**2**) was prepared by the reaction of NMTPPH and diethylzinc according to the method previously reported.[5] 1-Propanethiol and 2-methyl-2-propanethiol were dried over calcium sulfate (Drierite), distilled and stored under nitrogen. Benzenethiol was dried over calcium sulfate, distilled under reduced pressure, and stored under nitrogen. Hydrogen sulfide was generated by heating "H_2S Powder" (Kanto Chemical Co., Inc.) and used after passing through a column packed with calcium chloride.

Measurements. ^{1}H NMR spectra were recorded using a JEOL-CW-PS-100. Visible spectra were obtained on a JASCO UVIDEC-1 spectrometer. ESR spectra were recorded on a JEOL JES-PE spectrometer under irradiation with visible light (Xe lamp, >420 nm) using nitrosodurene as the radical trapping reagent.

Synthesis of Ethylzinc Propyl Sulfide (EtZnSPr^n). EtZnSPr^n was synthesized according to the method for the preparation of MeZnSPr^n.[7] Diethylzinc (1.10 cm^3, 10.7 mmol) was added to dry, oxygen-free hexane (15 cm^3) in a Pyrex flask (20 cm^3 capacity, fitted with a three-way cock) using a syringe under nitrogen, and the solution was cooled to 0 °C in an ice bath. 1-Propanethiol (0.90 cm^3, 10.0 mmol) was then added dropwise with a syringe to the stirred solution, and the mixture was allowed to warm slowly to room temperature. When gas evolution had ceased, the mixture was heated to reflux to dissolved the solid. The product crystallised on cooling the mixture to room temperature. Ethylzinc propyl sulfide was obtained as colorless short broad needles (1.03 g, 61%), soluble in benzene and dichloromethane. ^{1}H NMR (CH_2Cl_2) δ= 0.36 (2H, q, CH_2-Zn), 0.94 (3H, t, CH_3-CH_2-Zn), 1.15 (3H, t, CH_3-CH_2-CH_2-S), 1.66 (2H, m, -CH_2-CH_2-S), 2.68 (2H, t, -CH_2-S). Found: Zn, 38.3%. Calcd for $C_5H_{12}SZn$: Zn, 38.6%.

Reaction of NMTPPH with EtZnSPr^n. In an attempt to prepare *N*-methyltetraphenylporphinatozinc propyl sulfide (NMTPPZnSPr^n **3**), NMTPPH was allowed to react with an equimolar amount of EtZnSPr^n. NMTPPH (15.7 mg, 0.025 mmol) was dissolved in dichloromethane (1 cm^3) under nitrogen in a Pyrex tube (10 cm^3 capacity) wrapped in aluminium foil and equipped with a three-way cock, and a dichloromethane solution (0.1 cm^3) of EtZnSPr^n (0.025 mmol) was added using a syringe at room temperature in the dark. The reaction mixture was transferred to an NMR tube with a syringe under nitrogen in the

dark and subjected to NMR analysis. The NMR investigation indicated that $EtZnSPr^n$ can react with NMTPPH by both zinc-ethyl bond and zinc-propylthio bond to give NMTPPZnSPr^n (**3**) and NMTPPZnEt (**2**), respectively (Eqs. 3 and 4), and the propylthio group is substituted for the ethyl group of NMTPPZnEt (**2**) thus formed (Eq. 5).

$$\text{NMTPPH} + \text{EtZnSPr}^n \rightarrow \text{NMTPPZnSPr}^n + \text{EtH} \quad (3)$$

$$\text{NMTPPH} + \text{EtZnSPr}^n \rightarrow \text{NMTPPZnEt} + \text{Pr}^n\text{SH} \quad (4)$$

$$\text{NMTPPZnEt} + \text{Pr}^n\text{SH} \rightarrow \text{NMTPPZnSPr}^n + \text{EtH} \quad (5)$$

The last reaction suggests a good procedure for the formation of NMTPPZnSR, as described below.

Reaction of NMTPPZnEt (2) with Thiol (RSH). To a benzene solution (1 cm^3) of NMTPPZnEt (**2**) (0.025 mmol) was added 1-propanethiol (0.09 cm^3, 1 mmol), 2-methyl-2-propanethiol (0.11 cm^3, 1 mmol), or benzenethiol (0.10 cm^3, 1 mmol) using a syringe in nitrogen at room temperature. The resulting mixture was stirred for an hour in the dark. Removal of the solvent and unreacted thiol under reduced pressure at room temperature left a green solid, which was dissolved in benzene or dichloromethane and subjected to NMR analysis.

Reaction of NMTPPZnEt (2) with H_2S. Hydrogen sulfide was bubbled through a benzene solution (1 cm^3) of NMTPPZnEt (**2**) (0.025 mmol) for 5 min. After being stirred for an hour at room temperature in the dark, the solution was evaporated under reduced pressure to give green powder as the residue; this was dissolved in benzene and subjected to NMR analysis.

Reaction of NMTPPZnEt (2) and Bu^{t}SH under Irradiation. To a benzene solution (0.4 cm^3) of NMTPPZnEt (**2**) (0.01 mmol) in an NMR tube, a benzene solution (0.04 cm^3) of 2-methyl-2-propanethiol (0.01 mmol) was added using a syringe under nitrogen in the dark. The reaction was carried out under irradiation using 500 W Xe lamp (Ushio UXL-500 D-O). The distance between the NMR tube and the lamp was about 30 cm, and a glass filter was used to cut the light of wave length shorter than 420 nm. After the prescribed time of irradiation, the ^{1}H NMR spectrum of the reaction mixture was measured in the dark. The conversion of NMTPPZnEt (**2**) was determined on the basis of the signal intensities due to ethyl protons of **2** and *N*-methyl protons.

Results and Discussion

Photochemical Activation of Zinc-Carbon Bond of NMTPPZnEt (2) in the Reaction with Thiol. The reaction of NMTPPZnEt (**2**) with a large excess of thiol RSH (R=Pr^n, Bu^t, Ph) in the dark in benzene was examined by inspecting the ^{1}H NMR spectrum of the reaction mixture (Fig. 1). The reaction generally proceeded rapidly at room temperature. The signals due to ethyl protons of NMTPPZnEt (**2**) (δ= −2.10 (t), −5.00 (q)) disappeared, and new signals due to strongly shielded protons ascribed to alkylthio (or arylthio) group appeared at much higher magnetic field than those of thiol (Table 1), indicating that alkylthio (or arylthio) group is attached to the zinc atom in the porphyrin ring and is affected by its ring current. The equimolar ratio of the alkylthio (or arylthio) group and the *N*-methyl group of the porphyrin was confirmed on the basis of the signal intensities of their protons. The visible spectrum of the reaction mixture changed from that of NMTPPZnEt (**2**) (Table 2). These results suggest that NMTPPZnEt (**2**) reacts with thiol to form a porphinatozinc alkyl (aryl) sulfide. Similarly, the reaction of NMTPPZnEt (**2**) with hydrogen sulfide was found to give a porphinatozinc hydrogensulfide.

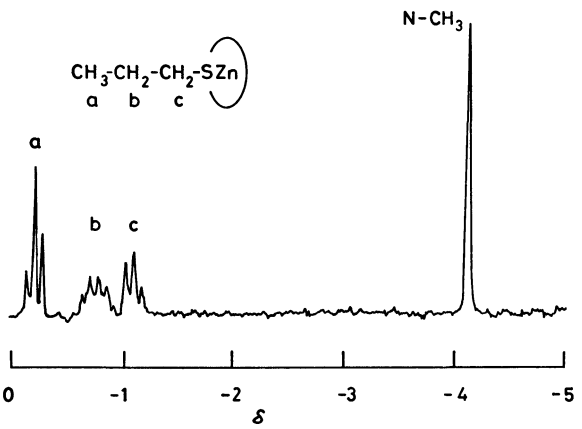

Fig. 1. ^{1}H NMR spectrum of the reaction mixture of NMTPPZnEt (**2**) and Pr^{n}SH in benzene.

$$\text{NMTPPZnEt} + \text{RSH} \rightarrow \text{NMTPPZnSR} + \text{EtH} \quad (6)$$

(R=Pr^n, Bu^t, Ph, H)

The reaction of NMTPPZnEt (**2**) was rather slow in the case of a thiol with bulky group such as 2-methyl-2-propanethiol (Bu^{t}SH). For example, when NMTPPZnEt (**2**) was allowed to react with Bu^{t}SH in an equimolar ratio at room temperature in the dark, it was found by ^{1}H NMR spectroscopy that the conversion of NMTPPZnEt (**2**) was 21% after 25 min. On the other hand, the substitution reaction was accelerated by irradiation with visible light (Fig. 2); NMTPPZnEt (**2**) reacted with Bu^{t}SH completely under irradiation after 20 min, and NMTPPZnSBu^t (**4**) was

Table 1. ^{1}H NMR data of NMTPPZnSR[a)]

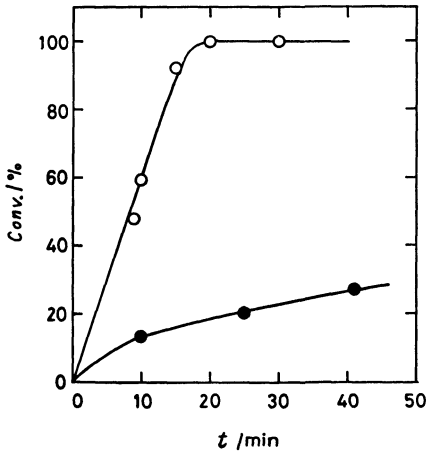

Fig. 2. Formation of NMTPPZnSBu^t by the reaction of NMTPPZnEt (**2**) and Bu^{t}SH at room temperature in benzene. ○: Under irradiation, ●: in the dark. [NMTPPZnEt]=[Bu^{t}SH]=0.01 mmol. Conversion of NMTPPZnEt was determined by ^{1}H NMR spectrum on the basis of ethyl protons of NMTPP-ZnEt and N-CH_3 protons.

found to be the sole product on the basis of the ^{1}H NMR spectrum of the reaction mixture.

Thus, irradiation with visible light has an interesting effect in enhancing the nucleophilicity of the ethyl group of NMTPPZnEt (**2**) in the reaction with thiols.

Photochemical Cleavage of Zinc-Sulfur Bond in Porphinatozinc Alkyl Sulfide (NMTPPZnSR). N-Methyltetraphenylporphinatozinc propyl sulfide (NMTPP-ZnSPr^n **3**) was found to be decomposed in dichloromethane by the irradiation with visible light, although it was stable under nitrogen in the dark. The ^{1}H NMR spectrum of NMTPPZnSPr^n (**3**) showed that the intensity of signals due to propylthio group decreased upon irradiation, while the signals due to dipropyl disulfide appeared [^{1}H NMR (CH_2Cl_2) δ= +0.80 (6H, t), +1.54 (4H, m), +2.45 (4H, t)]. When the signals of the propylthio group of NMTPPZnSPr^n (**3**) disappeared completely (2 h), the formation of dipropyl disulfide was quantitative. The main product derived from porphyrin macrocycle is considered to be N-methyltetraphenylporphinatozinc chloride (NMTPPZnCl) on the basis of the chemical shift of N-methyl protons (δ (CH_2Cl_2)=−3.90[5]) observed in the irradiated solution.

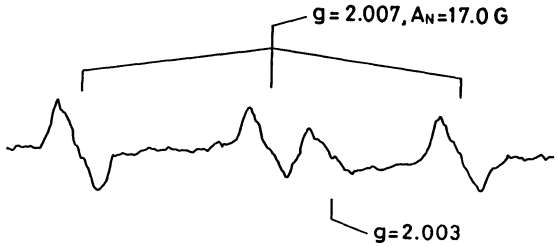

Fig. 3. ESR spectrum of photo-irradiated NMTPP-ZnSPr^n (**3**) in dichloromethane at r. t. using nitrosodurene as trapping reagent.

$$\underset{\mathbf{3}}{\text{NMTPPZnSPr}^n} \xrightarrow[\text{in } CH_2Cl_2]{h\nu\ (>420\text{nm})} \text{NMTPPZnCl} + \text{Pr}^n\text{SSPr}^n \quad (7)$$

In contrast with NMTPPZnSPr^n (**3**), EtZnSPr^n was unchanged in dichloromethane under irradiation with visible light. These results indicate that zinc-sulfur bond of NMTPPZnSPr^n (**3**), which does not absorb visible light, is activated by the photoexcitation of the porphyrin ring. In the solution in benzene or in the solid state, NMTPPZnSPr^n (**3**) was found to be almost unaltered by the irradiation with visible light. In the cases of NMTPPZnSBu^t (**4**), NMTPPZnSPh (**5**), and NMTPPZnSH (**6**), the ^{1}H NMR spectra in dichloromethane did not show any change after irradiation with visible light.

Figure 3 shows the ESR spectrum of the dichloromethane solution of NMTPPZnSPr^n (**3**) in the presence of nitrosodurene under visible light. NMTPPZnSPr^n (**3**) did not show any ESR signal in the dark. When the solution of NMTPPZnSPr^n (**3**) in the ESR cavity was irradiated with visible light, two different signals appeared immediately, at g=2.007 (A_N=17.0 G) and g=2.003. The former signal was assigned to propylthio radical trapped by nitrosodurene.[8] The g value of the latter radical was in agreement with that observed in the irradiation of NMTPPZnEt (**2**) with visible light.[5]

$$\underset{\mathbf{3}}{\text{NMTPPZnSPr}^n} \xrightarrow[\text{in } CH_2Cl_2]{h\nu\ (>420\text{ nm})} [\text{NMTPPZn}\cdot] + \text{Pr}^n\text{S}\cdot \quad (8)$$

This study was supported by Grant-in-Aid for Scientific Research No. 56045029 from the Ministry of Education, Science and Culture. The authors are grateful to Mr. Masaru Hirai and Miss Mitsue Inada for their assistance in some of the experiments.

(Received October 6, 1982)

Azulene analogs of biological active amines were synthesized. Reaction of azulene or guaiazulene with 1-butanoylaziridine or with 1-butanoyl-2-methylaziridine in the presence of Lewis acid catalyst formed the corresponding *N*-butanoyl-1-(1-azulenyl)-, *N*-butanoyl-2-(1-azulenyl)-, and *N*-butanoyl-2-(1-guaiazulenyl) derivatives of ethanamine, or 1-propanamine, or of 2-propanamine, respectively (**5**—**9**). Reaction of guaiazulene with 2-methyl-, or 1,1-dimethylaziridinium, or with 1,1,2,2-tetramethylaziridinium ions gave the corresponding 1-(1-guaiazulenyl)- and 2-(1-guaiazulenyl) derivatives of ethanamine, or 1-propanamine, or of 2-propanamine. 2-(1-Azulenyl)- and 2-(4,6,8-trimethyl-1-azulenyl) derivatives of ethanamine were also obtained by the action of 1,1-diethylaziridinium ion on azulene or on 4,6,8-trimethylazulene. Compounds **5**, **6**, and **9** were active *in vitro* in the inhibition of prostaglandin 15-hydroxydehydrogenase and of cyclic AMP-phosphodiesterase.

2-Arylethanamine derivatives constitute an important class of physiologically active compounds.[1] Natural compounds exhibit a variety of structural modifications and hundreds of additional derivatives have been synthesized in the search for therapeutic agents. A literature search did not reveal any examples having a nonbenzenoid aryl moiety. The low toxity of guaiazulene as an anti-inflammatory agent[2] led us to investigate the preparation of some 2-(1-azulenyl)ethanamine derivatives.

An earlier study had revealed that azulene reacted readily with tetracyanoethylene oxide to give concomitant epoxide ring opening and aromatic substitution.[3] An analogous behavior toward the aziridine ring would lead to the desired structure.

Results and Discussion

1-Butanoylaziridine (**1**) and 1-butanoyl-2-methylaziridine (**2**) were selected as reactants and were readily formed by the method of Brown and Tsukamoto,[4] with variation of the solvent as needed. From the treatment of **1** with azulene (**3**) in dichloromethane in the presence of aluminium chloride a 21% yield of *N*-butanoyl-2-(1-azulenyl)ethanamine (**5**) was obtained.

Similarly, from **2** and azulene (**3**) 20% of *N*-butanoyl-2-(1-azulenyl)-1-propanamine (**6**) was isolated. When the solvent was changed to benzene, the reaction of **3** with **2** formed **6** (21%) and a product (15%) having spectral and analytical data consistent with the isomeric structure **7**. Analogous reactions with guaiazulene (**4**) with **1** (in ether) and **2** (in dichloromethane) gave **8** (8%) and **9** (57%), respectively.

The structural assignments for **5**—**9** were based on spectral analyses. These were consistent with substitution at the azulene 1-position and the presence of the amide function for all the products. ^{1}H NMR spin-decoupling was used for the characterization of the propyl side-chain moieties in **6** and **9**. In **6**, for example, irradiation at δ 3.68 (–CH) caused the doublet at δ 1.40 ($-CH_3$) to become a singlet, and irradiation at δ 3.42 and δ 3.92 ($-CH_2-$) did not affect the doublet at δ 1.40 ($-CH_3$). The $-CH_2-$ pattern exhibited coupling with the amide hydrogen (J=5 Hz) and with the methine hydrogen (J=5 and 7 Hz).

The isolation only of **6** in one experiment, and of **6** and **7** in another, suggests two reaction paths, one (*a*) dominant in dichloromethane and both (*a* and *b*) appreciably operative in benzene, as proposed by Milstein[5] and shown in Scheme 1. In *a* the more stable of the two possible carbocations is formed and leads to **6**. In *b* direct nucleophilic attack on the aziridinium ion occurs at the less hindered methylene and leads to **7**.

A second approach to this type of compound was by the reaction of guaiazulene with a simple (protonated) or quaternary aziridinium ion. 2-Methylaziri-

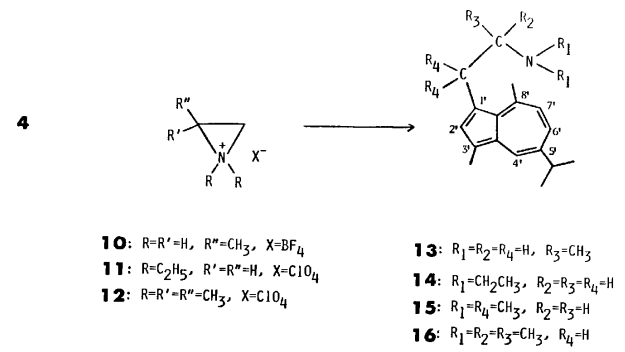

Chart 2.

dinium tetrafluoroborate (**10**)[6] was used for the former. A number of solvents, temperatures, and reaction times were tried (neat, 160—180 °C, 20 min; dichloromethane, *ca.* 20 °C, 1 h; 1,2-dimethoxyethane, 93 °C, 48 h; 1,2-diethoxyethane, 124 °C, 16 h; bis(2-methoxyethyl) ether, 160 °C, 4 h; bis(2-ethoxyethyl) ether, 190 °C, 1 h) but the yields of **13** were uniformly low (0.08—8%) and appreciably unchanged guaiazulene was recovered. The aziridinium salt was only slightly soluble in the solvents.

Treatment of guaiazulene with 1,1-diethylaziridinium perchlorate (**11**) in 1,2-dichloroethane gave a 35% yield of **14**. Under the same conditions but with a thirteen times longer reaction time, however, reaction with 1,1,2,2-tetramethylaziridinium perchlorate (**12**) afforded only 0.07% of **15** and 0.1% of **16** with 79% recovery of unchanged guaiazulene.

Similarly, reaction of azulene (**3**) with **11**, followed by treatment with hydrochloric acid, gave a 12% yield of the hydrochloride (**20**), from which **18** (78%) was regenerated by alkali treatment. Moreover, 4,6,8-trimethylazulene (**17**) reacted with **11** to afford 53% of **19**. The identities of **13**—**16**, **18**, and **19** were shown by ultraviolet-visible, infrared, ^{1}H nuclear magnetic resonance, and mass spectral characteristics, all of which were in agreement with the assigned structures.

However, some ambiguity was observed in ^{1}H NMR of **14**, **18**, and **19**. For instance, 1- and 2-methylene protons showed two multiplets, the pattern of which was exactly the same in three compounds. Thus, ^{13}C NMR was used for the characterization of **18** (in the form of **20**) and **19**. In this case, the methylene carbon signals appeared as clear triplets in good accordance with the structure. In the mass spectra of all 2-(1-azulenyl)ethanamine derivatives, allyl fission of aminoethyl side chain gave rise the most abundant ion, which was also used for structural assignments.

Compounds **5**, **6**, and **9** have been found to be

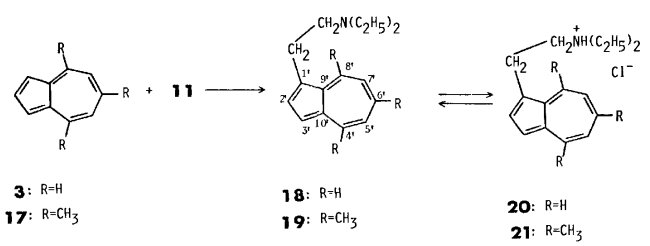

Chart 3.

active *in vitro* (20 μg in 1 cm^3) in the inhibition of prostaglandin 15-hydroxydehydrogenase (71, 69, and 50%, respectively), and of cyclic AMP–phosphodiesterase (24, 47, and 70%, respectively).[7] Details of the biological activities will be described elsewhere.

Experimental

Spectral data were recorded on the following instruments: UV, Hitachi 624 digital spectrometer with a Hitachi 056 recorder; IR, Hitachi 260-10 spectrometer; ^{1}H NMR, JEOL MH-100 except for JNM-FX 100 for **13**; ^{13}C NMR, JNM-FX 100; MS, JEOL-D300 at 70 eV. GLC were done on a Shimadzu GC-3AH instrument and TLC were done on Merck precoated alumina sheet, silica gel 70 (Art. 5553), or neutral alumina 60F$_{254}$ type E (Art. 5550). A Schlenk apparatus[8] was used to exclude moisture for the preparation of **5**—**9**.

N-Butanoyl-2-(1-azulenyl)ethanamine (5). To an ice-cooled, stirred solution of 643 mg (5.02 mmol) of azulene in 50 cm^3 of dry dichloromethane was added 1.33 g (9.98 mmol) of aluminium chloride (washed in with 5 cm^3 of dichloromethane) (blue color changed to light yellow) and then, dropwise, a solution in 17 cm^3 of dry ether of *ca.* 10 mmol of 1-butanoylaziridine [prepared from 1.1 g (10.3 mmol) of butanoyl chloride, 430 mg (9.98 mmol) of aziridine, and 1.01 g (9.98 mmol) of triethylamine].[4] The light yellow color changed to blue. Stirring was continued at 0 °C for 1 h and the mixture was then added to 500 cm^3 of cold (0 °C) 10% sodium chloride–10% hydrochloric acid. The blue solution obtained by extraction (twice each) with 150, 100, and 50 cm^3 portions of chloroform was washed with 150 cm^3 of saturated sodium chloride, twice with 150 cm^3 of 10% sodium hydroxide and then dried (sodium sulfate). Removal of the solvent (reduced pressure) gave blue crystals (two major components by TLC on silica gel). Chromatography on a silica-gel column (elution with 3:1 hexane–THF) gave 549 mg of violet crystals, which on rechromatography (elution with hexane) afforded 429 mg (3.35 mmol) of unchanged azulene. Successive blue eluates (3:1 hexane–THF) yielded 545 mg of blue oil, which was rechromatographed to give 254 mg (1.05 mmol, 21%) of **5**. Further colored fractions removed by hexane–THF, acetone, and methanol were not characterized. In order to get analytical specimen, **5** was further purified by extraction of a benzene (30 cm^3) solution with 10 cm^3 of 85% phosphoric acid, washing the acid extract with 3×20 cm^3 of benzene, dilution with 300 cm^3 of 17% sodium chloride, and extraction with 3×100 cm^3 of benzene. Chromatography of the concentrate from the dried (potassium carbonate) benzene solution over silica gel (3:1 hexane–THF) gave 61.6 mg (11%) of **5** as a blue oil which formed tiny prisms, mp 48—50 °C, on refrigeration: UV (C_2H_5OH) 237 (log ε 4.12), 259 (sh, 4.13), 264 (sh, 4.30), 268 (sh, 4.44), 274 (sh, 4.57), 278 (4.64), 282 (sh, 4.39), 287 (sh, 4.44), 297 (sh, 3.64), 320 (sh, 3.22), 328 (sh, 3.39), 334 (sh, 3.42), 343 (3.58), 358 (3.27), 516 (ε sh, 104), 534 (sh, 144), 558 (sh, 199), 580 (sh, 232), 597 (226), 618 (sh, 234), 652 (223), 683 (sh, 111), and 722 nm (80); IR (CCl_4) 3460 (nonassoc N-H), 3350 (assoc N-H), and 1685 cm^{-1} (amide C=O); ^{1}H NMR ($CDCl_3$) δ=0.88 (3H, t, J=7.5 Hz, γ-CH_3), 1.60 (2H, sext, J=7.5 Hz, β-CH_2), 2.06 (2H, t, J=7.5 Hz, α-CH_2), 3.30 (2H, t, J=7.0 Hz, 2-CH_2), 3.66 (2H, sext, J=7.0 and 5.0 Hz, 1-CH_2), 5.52 (1H, br m, NH), 7.16 (2H, t, J=10.0 Hz, 5'- and 7'-H), 7.40 (1H, d, J=4.0 Hz, 3'-H), 7.62 (1H, t, J=10.0 Hz, 6'-H), 7.82 (1H, d, J=4.0 Hz, 2'-H), 8.32 (1H, d,

J=10.0 Hz, 4′-H), and 8.36 (1H, d, J=10.0 Hz, 8′-H); MS *m/e* (rel intensity) 241 (M^+, 18), 154 ($M^+-C_4H_9NO$, 90), and 141 ($M^+-C_3H_7CONHCH_2$, 100).

Found: C, 79.60; H, 7.92; N, 5.72%. Calcd for $C_{16}H_{19}NO$: C, 79.63; H, 7.94; N, 5.80%.

N-*Butanoyl-2-(1-azulenyl)-1-propanamine (**6**).* *A*: The reaction of 640 mg (4.99 mmol) of azulene in 50 cm³ of dichloromethane, 1.33 g (9.98 mmol) of aluminum chloride and *ca.* 9.9 mmol of 1-butanoyl-2-methylaziridine [from 1.10 g (10.3 mmol) of butanoyl chloride, 570 mg (9.98 mmol) of 2-methylaziridine, and 1.01 g (9.98 mmol) of triethylamine in 17 cm³ of ether][4] was carried out as described for **5** except that the crude reaction mixture was added to 500 cm³ of cold (0 °C) 10% hydrochloric acid prior to extraction successively with 150, 50 (thrice), and 60 cm³ of dichloromethane. The organic extracts were washed with 100 cm³ (thrice) of water before drying (sodium sulfate) and removal of the solvent. Chromatography of the residue over alumina (9:1 benzene-chloroform) gave 586 mg of violet crystals and 667 mg of blue oil. Rechromatography of the violet crystals (silica gel; hexane) gave 440 mg (69%) of unchanged azulene. From the blue oil after chromatography over silica gel twice (elution with chloroform and then 5:1 hexane-THF) was obtained 254 mg (20%) of **6** as a blue oil. This compound was further purified by washing a benzene (150 cm³) solution with 150 cm³ (thrice) of 10% sodium hydroxide and 100 cm³ (thrice) of water, drying (sodium sulfate), removal of the solvent, resolution into 120 cm³ of 5:1 hexane-benzene, and extraction into 85% phosphoric acid (50 cm³, then 30 cm³ twice). Dilution of the acid extract with 500 cm³ of water and basification with solid potassium carbonate was followed by extraction into benzene (200 cm³ then 100 cm³ twice). Chromatography on silica gel (3:1 hexane-THF) of the residue from the washed (3×105 cm³ of water), dried (sodium sulfate) benzene solution gave 68.2 mg (6%) of analytical specimen of **6** as a blue oil: UV (C_2H_5OH) 238 (log ε 4.03), 258 (sh, 4.00), 263 (sh, 4.18), 268 (sh, 4.35), 274 (sh, 4.49), 278 (4.55), 282 (sh, 4.51), 288 (sh, 4.34), 296 (sh, 3.55), 320 (sh, 3.12), 333 (sh, 3.33), 343 (3.51), 359 (3.23), 517 (ε sh, 82), 534 (sh, 116), 557 (sh, 162), 579 (sh, 192), 597 (221), 621 (sh, 190), 686 (sh, 81), and 722 nm (60); IR (CCl_4) 3450 (nonassoc N-H), 3350 (assoc N-H), and 1680 cm⁻¹ (amide C=O); ¹H NMR ($CDCl_3$) δ=0.81 (3H, t, J=7.0 Hz, γ-CH_3), 1.40 (3H, d, J=7.0 Hz, 3-CH_3), 1.50 (2H, sext, J=7.0 Hz, β-CH_2), 1.94 2H, t, J=7.0 Hz, α-CH_2), 3.42 (1H, sext, J=13.0, 5.0, and 5.0 Hz, one H of 1-CH_2), 3.68 (1H, decet, J=7.0, 7.0, and 5.0 Hz, 2-CH), 3.92 (1H, octet, J=13.0, 7.0, and 5.0 Hz, one H of 1-CH_2), 5.60 (1H, br t, J=5.0 Hz, NH), 7.09 (2H, t, J=10.0 Hz, 5′- and 7′-H), 7.36 (1H, d, J=4.0 Hz, 3′-H), 7.54 (1H, t, J=10.0 Hz, 6′-H), 7.82 (1H, d, J=4.0 Hz, 2′-H), 8.25 (1H, d, J=10.0 Hz, 4′-H), and 8.35 (1H, d, J=10.0 Hz, 8′-H); MS *m/e* (rel intensity) 255 (M^+, 9), 168 ($M^+-C_3H_7CONH_2$, 24), and 155 ($M^+-C_3H_7CONHCH_2$, 100).

Found: C, 79.68; H, 8.37; N, 5.43%. Calcd for $C_{17}H_{21}NO$: C, 79.96; H, 8.29; N, 5.49%.

B: The reaction of 128 mg (1.00 mmol) of azulene in 30 cm³ of dry benzene, 400 mg (3.00 mmol) of aluminum chloride and *ca.* 3.00 mmol of 1-butanoyl-2-methylaziridine [from 321 mg (3.0 mmol) of butanoyl chloride, 171 mg (3.00 mmol) of 2-methylaziridine, 303 mg (3.00 mmol) of triethylamine in 7 cm³ of benzene at 5 °C][4] was carried out as described for **5** except for the change in solvent and a reaction temperature of 5 °C. The hydrolyzed (10% hydrochloric acid) mixture was extracted with 100 cm³ of ether (4 times) and the extracts washed successively with 150 cm³ of water (twice), 150 cm³ of sodium hydroxide (twice), and 175 cm³ of water (thrice). Chromatography of the crude product (isolated as described for **5**) over silica gel (3:1 hexane-THF) gave 101 mg of violet crystals, 37 mg of blue oil, and 171 mg of blue oil. Rechromatography of the violet crystals (silica gel; hexane) gave 70.6 mg (55%) of unchanged azulene. The first blue fraction was characterized as *N*-butanoyl-1-(1-azulenyl)-2-propanamine (**7**) (15%): IR (CCl_4) 3460 (nonassoc N-H), 3350 (assoc N-H), and 1680 cm⁻¹ (amide C=O); ¹H NMR ($CDCl_3$) δ=0.93 (3H, t, J=7.0 Hz, γ-CH_3), 1.47 (3H, d, J=7.0 Hz, 3-CH_3), 1.58 (2H, sext, J=7.0 Hz, β-CH_2), 2.17 (2H, t, J=7.0 Hz, α-CH_2), 3.59 (2H, m, 1-CH_2), 4.10 (1H, 12 lines, J=7.0 and 3.0 Hz, 2-CH), 6.74 (1H, br d, J=3.0 Hz, NH), 7.03 (1H, t, J=10.0 Hz, 5′-H), 7.07 (1H, t, J=10 Hz, 7′-H), 7.36 (1H, d, J=4.0 Hz, 3′-H), 7.57 (1H, t, J=10.0 Hz, 6′-H), 7.82 (1H, d, J=4.0 Hz, 2′-H), 8.25 (1H, d, J=10.0 Hz, 4′-H), and 8.37 (1H, d, J=10.0 Hz, 8′-H);[9] MS *m/e* (rel intensity) 255 (M^+, 33), 226 ($M^+-C_2H_5$, 83) 156 ($M^+-C_5H_9NO$, 100), and 141 ($M^+-C_3H_7CONHCHCH_3$, 10).

Found: N, 5.39%. Calcd for $C_{17}H_{21}NO$: N, 5.49%.

Rechromatography of the last blue fraction afforded 53.6 mg (21%) of blue oil identical (TLC, IR, MS) with **6** obtained from *A*.

N-*Butanoyl-2-(1-guaiazulenyl)ethanamine (**8**).* To an ice-cooled, stirred solution of *ca.* 9.9 mmol of 1-butanoylaziridine [from 430 mg (9.98 mmol) of aziridine, 1.10 g (10.3 mmol) of butanoyl chloride, 1.01 g (9.98 mmol) of triethylamine][4] in 6 cm³ of ether was added slowly (syringe) a solution of 990 mg (5.00 mmol) of guaiazulene in 3 cm³ of ether and then 2.60 g (10.0 mmol) of tin(IV) chloride. The color changed from blue to green and the mixture solidified. After 1 h at room temperature, 50 cm³ of water was added and the solution was made alkaline with aqueous ammonium hydroxide. The mixture was extracted with ether and the ether solution filtered. The green-blue filtrate, including ether washings of the precipitate, was extracted with 50 cm³ of saturated sodium carbonate (twice), 50 cm³ of water (four times) and dried (sodium sulfate). Removal of the solvent and chromatography of the residue (silica gel; 9:1 benzene-chloroform) gave 660 mg of blue oil and 129 mg (8%) of **8** as blue crystals. Rechromatography of the blue oil over silica gel (hexane) separated unchanged guaiazulene (494 mg, 50%) and a green oil which, after rechromatography (silica gel; 9:1 hexane-benzene) amounted to 12.5 mg of green crystalline product identical (mp, TLC, UV, IR, MS) with authentic specimen of 3,3′-biguaiazulene.[10]

Rechromatography (silica gel; chloroform) and recrystallization (from 80% ethanol) of the blue crystals gave the analytical sample of **8** as tiny blue prisms, mp 108—109 °C: UV (C_2H_5OH) 202 (log ε 4.13), 218 (4.06), 247 (4.26), 287 (4.54), 290 (sh, 4.54), 306 (4.08), 338 (sh, 3.47), 352 (3.66), 369 (3.63), 577 (ε sh, 275), 621 (344), 673 (sh, 278), and 744 nm (sh, 95); IR ($CHCl_3$) 3470 (nonassoc N-H), 3350 (assoc N-H), and 1685 cm⁻¹ (amide C=O); ¹H NMR ($CDCl_3$) δ=0.90 (3H, t, J=7.0 Hz, γ-CH_3), 1.32 (6H, d, J=7.0 Hz, 5′-CH(C$\underline{H}_3$)$_2$), 1.62 (2H, sext, J=7.0 Hz, β-CH_2), 2.08 (2H, t, J=7.0 Hz, α-CH_2), 2.59 (3H, s, 3′-CH_3), 2.94 (3H, s, 8′-CH_3), 3.08 (1H, sept, J=7.0 Hz, 5′-C$\underline{H}$(CH$_3$)$_2$), 3.51 (4H, quint, J=6.8 Hz, 1- and 2-CH_2), 5.82 (1H, br s, NH), 6.81 (1H, d, J=10.6 Hz, 7′-H), 7.24 (1H, q, J=10.6 and 2.0 Hz, 6′-H), 7.44 (1H, s, 2′-H), and 8.06 (1H, d, J=2.0 Hz, 4′-H); MS *m/e* (rel intensity), 311 (M^+, 23), 224 ($M^+-C_3H_7CONH_2$, 48), and 211 (M^+

$-C_3H_7CONHCH_2$, 100).

Found: C, 81.16; H, 9.38; N, 4.50%. Calcd for $C_{21}H_{29}NO$: C, 80.98; H, 9.38; N, 4.50%.

Reaction of Guaiazulene with 1-Butanoyl-2-methylaziridine. To an ice-cooled, stirred solution of 990 mg (5.00 mmol) of guaiazulene and *ca.* 15 mmol of 1-butanoyl-2-methylaziridine [from 860 mg (15.1 mmol) of 2-methylaziridine, 1.60 g (15.0 mmol) of butanoyl chloride, and 1.52 g (15.0 mmol) of triethylamine in 10 cm³ of dichloromethane at *ca.* −5 °C][4] in 50 cm³ of dichloromethane was added gaseous boron trifluoride below the surface until the solution was saturated. The mixture was then stirred for 1 h, added to 500 cm³ of ice water, and extracted with one 200 cm³ and three 150 cm³ portions of chloroform. The green-blue organic extracts were washed with 150 cm³ of 10% sodium hydroxide (twice), 150 cm³ of water (thrice) and dried (sodium sulfate). The solvent was removed and chromatography of the residue (silica gel; 3:1 hexane–THF) gave three fractions. From fraction 1 (blue oil) was recovered 46.9 mg (0.237 mmol) of unchanged guaiazulene. Fraction 2 (blue oil) was rechromatographed (silica gel; 3:1 hexane–THF) and the main blue fraction combined with fraction **3** (blue oil) to give 932 mg (57%) of blue oil. The spectral properties of this product were in good agreement with those expected for *N*-butanoyl-2-(1-guaiazulenyl)-1-propanamine (**9**): UV (C_2H_5OH) 202 (log ε 4.31), 218 (4.14), 247 (4.22), 287 (4.40), 305 (4.04), 353 (3.55), 369 (3.47), 574 (ε sh, 250), 617 (283), 670 (sh, 226), and 752 nm (sh, 76); IR (CCl_4) 3470 (nonassoc N–H), 3360 (assoc N–H), and 1690 cm⁻¹ (amide C=O); ¹H NMR ($CDCl_3$) δ=0.82 (3H, t, *J*=7.0 Hz, γ-CH_3), 1.36 (9H, t, *J*=7.0 Hz, 5′-CH($C\underline{H}_3$)$_2$ and 3-CH_3), 1.46 (2H, sext, *J*=7.0 Hz, β-CH_2), 2.00 (2H, t, *J*=7.0 Hz, α-CH_2), 2.64 (3H, s, 3′-CH_3), 2.98 (3H, s, 8′-CH_3), 3.05 (1H, sept, *J*=7.0 Hz, 5′-C$\underline{H}$(CH_3)$_2$), 3.42 (1H, sext, *J*=13.0, 5.0, and 5.0 Hz, one H of 1-CH_2), 3.74 (1H, decet, *J*=7.0, 7.0, and 5.0 Hz, 2-CH), 4.10 (1H, octet, *J*=13.0, 7.0, and 5.0 Hz, one H of 1-CH_2), 5.64 (1H, br m, NH), 6.92 (1H d, *J*=10.0 Hz, 7′-H), 7.34 (1H, q, *J*=10.0 and 2.0 Hz, 6′-H), 7.68 (1H, s, 2′-H), and 8.18 (1H, d, *J*=2.0 Hz, 4′-H); MS *m/e* (rel intensity) 325 (M^+, 18), 238 ($M^+-C_3H_7CONH_2$, 20), and 225 ($M^+-C_3H_7CONHCH_2$, 100).

*1-(1-Guaiazulenyl)-2-propanamine (**13**).* A suspension of *ca.* 15 mmol of colorless 2-methylaziridinium tetrafluoroborate in dichloromethane was prepared from 860 mg (15.1 mmol) of 2-methylaziridine in 10 cm³ of dry dichloromethane and 2.46 g (15.1 mmol) of tetrafluoroboric acid in ether (54%, Merck) according to the method of Harder *et al.*[11] and was used without further purification.

To the salt suspension was added, under nitrogen with stirring, dropwise (10 min) a solution of 990 mg (5.00 mmol) of guaiazulene in 20 cm³ of 1,2-dimethoxyethane (monoglyme). After distillative removal of the ether and dichloromethane, the mixture was refluxed for 48 h and then cooled and poured onto 300 g of crushed ice. A 50% solution of potassium carbonate (200 g) was added and the mixture then extracted with 3×100 cm³ of chloroform. The combined extracts were washed twice with a 29% sodium chloride (100 g) solution and dried (sodium sulfate). Removal of the solvent (ambient temperature at 2700 Pa and then 30 °C at 133—266 Pa) left a blue oil which gave two major TLC spots (alumina, chloroform: R_f 0.12 for **13** and 0.86 for guaiazulene). Chromatography over alumina with chloroform separated 1072 mg of material which yielded 510 mg (52%) of pure, unchanged guaiazulene after rechromatography over silica gel (hexane). The blue oil fractions obtained by further elution with chloroform and, finally, with acetone amounted to 420 mg. Rechromatography (alumina, 95:5 benzene–methanol) gave 101 mg (8%) of **13** as a blue oil: UV (C_2H_5OH) 217 (log ε 4.07), 247 (4.22), 287 (4.47), 306 (4.05), 341 (sh, 3.48), 353 (3.62), 369 (3.55), 581 (ε sh, 290), 622 (334), 673 (sh, 288), and 751 nm (sh, 111); IR (CCl_4) 3380 and 3310 (nonassoc N–H), 3190 (assoc N–H), and, 1380 and 1370 cm⁻¹ (δ_s CH_3); ¹H NMR ($CDCl_3$) δ=1.16 (3H, d, *J*=6.0 Hz, propane-CH_3), 1.34 (6H, d, *J*=7.0 Hz, 5′-CH($C\underline{H}_3$)$_2$, 1.36 (2H, s, NH_2), 2.63 (3H, s, 3′-CH_3), 2.98 (3H, s, 8′-CH_3), 3.02—3.72 (4H, m, CH-CH_2 and 5′-C$\underline{H}$(CH_3)$_2$, 6.90 (1H, d, *J*=11.0 Hz, 7′-H), 7.33 (1H, q, *J*=11.0 and 2.0 Hz, 6′-H), 7.54 (1H, s, 2′-H), and 8.14 (1H, d, *J*=2.0 Hz, 4′-H); MS *m/e* (rel intensity) 255 (M^+, 6%), 211 ($M^+-CH_3CHNH_2$, 100), and 44 (CH_3CHNH_2, 75%).

Found: C, 84.24; H, 9.88; N, 5.33%. Calcd for $C_{18}H_{25}N$: C, 84.65; H, 9.87; N, 5.48%.

N,N-*Diethyl-2-(1-guaiazulenyl)ethanamine (**14**).* From 17.1 g (0.100 mol) of *N*,*N*-diethyl-2-chloroethanamine hydrochloride was prepared a 44% solution of the corresponding amine in benzene as determined by GLC analysis (Silicone SE 30 on Chromosorb W, 1 m column, 50 °C, 20 cm³ min⁻¹ He, t_R=1.8 min), and a solution of 5.02 g (37.0 mmol) of this amine (obtained from an aliquot portion of the benzene solution) was converted to 1,1-diethylaziridinium perchlorate [7.00 g, 95%, IR (CCl_4) 3125 cm⁻¹, mp 188—192 °C decomp] (Ref. 12; 192 °C decomp) as described by Leonard and Paukstelis[12] except that the crude salt was purified twice by dissolving it in 10 cm³ of dichloromethane and then precipitation by the addition of 200 cm³ of ether.[13]

A mixture of 200 mg (1.01 mmol) of guaiazulene, 300 mg (1.50 mmol) of 1,1-diethylaziridinium perchlorate and 5 cm³ of 1,2-dichloroethane was refluxed for 6 h, then taken up in 100 cm³ of chloroform, washed with 2×50 cm³ of saturated aqueous potassium carbonate, 3×50 cm³ of water and dried (sodium sulfate). Solvent removal (reduced pressure) left a green oil which gave two TLC spots (alumina, chloroform; R_f 0.65 for **14** and 0.82 for guaiazulene). Chromatography (alumina, 9:1 benzene–chloroform then chloroform) gave 85.1 mg of blue oil, which yielded 67.8 mg (34%) of guaiazulene on rechromatography (silica gel, hexane), and 161 mg of green-blue oil. Rechromatography (alumina, chloroform) of the green-blue oil afforded 104 mg (35%) of **14** (green-blue oil, R_f=0.65 on alumina with chloroform): UV (C_2H_5OH) 218 (log ε 4.06), 246 (4.22), 287 (4.46), 304 (sh, 4.04), 339 (sh, 3.49), 352 (3.68), 369 (3.56), 582 (ε sh, 256), 622 (298), 675 (sh, 235), and 751 nm (sh, 78); IR (CCl_4) 2960 (ν_{as} CH), 2925 (ν_{as} CH_2), 2870 (ν_s CH), 1460 (δ_{as} CH_3), and, 1380 and 1370 cm⁻¹ (δ_s CH_3); ¹H NMR ($CDCl_3$) δ=1.08 (6H, t, *J*=7.0 Hz, $CH_2C\underline{H}_3$), 1.32 (6H, d, *J*=7.0 Hz, 5′-CH($C\underline{H}_3$)$_2$), 2.61 (3H, s, 3′-CH_3), 2.66 (4H, q, *J*=7.0 Hz, $C\underline{H}_2CH_3$), 2.78 (2H, m, 1-CH_2), 3.37 (2H, m, 2-CH_2), 6.84 (1H, d, *J*=10.5 Hz, 7′-H), 7.28 (1H, q, *J*=10.5 and 2.0 Hz, 6′-H), 7.52 (1H, s, 2′-H), and 8.10 (1H, d, *J*=2.0 Hz, 4′-H); MS *m/e* (rel intensity) 297 (M^+, 2), 211 ($M^+-CH_2NEt_2$, 7), and 86 ($Et_2NCH_2^+$, 100).

N,N-*Dimethyl-2-(1-guaiazulenyl)-2-methyl-1-propanamine (**15**) and* N,N-*Dimethyl-1-(1-guaiazulenyl)-2-methyl-2-propanamine (**16**).* From 13.0 g (70.0 mmol) of *N*-isopropylidenedimethylammonium perchlorate, mp 298—300 °C,[6] was prepared 5.57 g (40%) of 1,1,2,2-tetramethylaziridinium

perchlorate [^{1}H NMR (CH_2Cl_2) δ=1.74 (6H, s, C(CH_3)$_2$), 3.08 (2H, s, CH_2), and 3.18 (6H, s, $(CH_3)_2N^+$] [Ref. 14; δ=1.72 (6H, 3.02 (2H), and 3.16 (6H)] as described.[14]

A mixture of 990 mg (5.00 mmol) of guaiazulene and 2.00 g (10.0 mmol) of the above aziridinium salt in 25 cm^3 of 1,2-dichloroethane under nitrogen was stirred at reflux temperature for 80 h, then treated as described for the preparation of **14** (500 cm^3 of chloroform; 2×100 cm^3 of 25% potassium carbonate; 2×100 cm^3 of water). From the chromatography of the crude blue oil (alumina; 9:1 benzene–chloroform) were obtained 942 mg of blue oil and 24.4 mg of green-blue oil. Rechromatography of the blue oil (silica gel, hexane) gave 786 mg (79%) of unchanged guaiazulene. Preparative TLC on alumina (9:1 benzene–chloroform) of the green-blue oil afforded 1.04 mg (0.07%) of **15** as a green oil (R_f=0.25) and 1.69 mg (0.1%) of **16** as a blue oil (R_f=0.15).

N,N-*Diethyl-2-(4,6,8-trimethyl-1-azulenyl)ethanamine* (**19**). From 172 mg (1.01 mmol) of 4,6,8-trimethylazulene and 300 mg (1.50 mmol) of 1,1-diethylaziridinium perchlorate was obtained, as described for **14** except that the mixture was refluxed for 23 h; a violet oil was obtained as the crude product. Chromatography (alumina, 9:1 hexane–ethyl acetate) of a solution of the oil in a small volume of acetone separated 25.1 mg (15%) of unchanged trimethylazulene from 143 mg (53%) of **19** (blue oil, R_f=0.30 on alumina with 9:1 hexane–ethyl acetate): UV (C_2H_5OH) 246 (log ε 4.42), 278 (sh, 4.40), 284 (sh, 4.57), 288 (4.66), 293 (4.65), 298 (sh, 4.61), 327 (sh, 3.46), 338 (3.58), 352 (3.68), 367 (sh, 3.18), 555 (ε sh, 368), 564 (428), 607 (sh, 340), and 667 nm (sh, 129); IR (CCl_4) 2975 (ν_{as} CH), 2930 (ν_{as} CH_2), 2880 (ν_s CH), 1470, 1462, 1445 and 1426 (δ_{as} CH_3), and, 1382 and 1372 cm^{-1} (δ_s CH_3); ^{1}H NMR ($CDCl_3$) δ=1.06 (6H, t, J=7.0 Hz, CH_2CH_3), 2.48 (3H, s, 6′-CH_3), 2.63 (4H, q, J=7.0 Hz, CH_2CH_3), 2.75 (3H, s, 4′-CH_3), 2.76 (2H, m, 1-CH_2), 2.96 (3H, s, 8′-CH_3), 3.34 (2H, m, 2-CH_2), 6.81 (2H, s, 5′- and 7′-H), 7.22 (1H, d, J=4.0 Hz, 3′-H), and 7.44 (1H, d, J=4.0 Hz, 2′-H); ^{13}C NMR ($CDCl_3$) δ=11.5 (q, CH_2CH_3), 25.4 (q, 4′-CH_3), 27.4 (q, 8′-CH_3), 28.3 (q, 6′-CH_3), 29.6 (t, 2-C), 46.8 (t, CH_2CH_3), 56.0 (t, 1-C), 115.2 (d, 3′-C), 126.0 (d, 5′-C), 128.2 (d, 7′-C), 129.0 (s, 1′-C), 132.2 (s, 9′-C), 135.8 (d, 2′-C), 137.0 (s, 10′-C), 144.7 (s, 4′-C), 145.5 (s, 6′-C), and 146.1 (s, 8′-C); MS *m/e* (rel intensity) 269 (M^+, 4), 183 ($M^+-CH_2N(C_2H_5)_2$, 4), and 86 ($(C_2H_5)_2NCH_2^+$, 100).

A solution of 111 mg (0.412 mmol) of **19** in 60 cm^3 of benzene was extracted with 1 mol dm^{-3} hydrochloric acid (3×35 cm^3), and the hydrochloric acid layer was extracted with chloroform (6×35 cm^3). The chloroform solution was dried (sodium sulfate), concentrated (reduced pressure), and chromatographed on a silica gel column (elution with 8:2 chloroform–methanol) to give 84.4 mg (67%) of **21** as a purple oil: UV (C_2H_5OH) 247 (log ε 4.44), 277 (sh, 4.38), 283 (sh, 4.55), 288 (4.63), 293 (4.63), 297 (sh, 4.60), 336 (3.56), 345 (sh, 3.57), 351 (3.61), 552 (ε 334), 592 (sh, 276), and 647 nm (sh, 108); IR ($CHCl_3$) 2470, 2440, 2400, 2355, and 2330 (NH^+), and 1195 cm^{-1} (C–N);

^{1}H NMR ($CDCl_3$) δ=1.43 (6H, t, J=7.0 Hz, $CH_2C\underline{H}_3$), 2.16 (1H, s, NH^+), 2.60 (3H, s, 6′-CH_3), 2.84 (3H, s, 4′-CH_3), 3.07 (3H, s, 8′-CH_3), 3.25 (q, 4H, J=7.0 Hz, $C\underline{H}_2CH_3$), 3.27 (2H, m, 1-CH_2), 3.85 (2H, m, 2-CH_2). 7.08 (2H, s, 5′- and 7′-H), 7.39 (1H, d, J=4.0 Hz, 3′-H), and 7.60 (1H, d, J=4.0 Hz, 2′-H).

Found: C, 74.99; H, 9.88; N, 4.71; Cl, 11.23%. Calcd for $C_{19}H_{28}NCl$: C, 74.60; H, 9.23; N, 4.58; Cl, 11.59%.

The Copper-catalyzed Autoxidation of Cysteine. The Amount of Hydrogen Peroxide Produced under Various Conditions and the Stoichiometry of the Reaction

Akira HANAKI* and Hiroko KAMIDE

National Institute of Radiological Sciences, Anagawa-4-chome, Chiba 260

(Received January 31, 1983)

Hydrogen peroxide is shown to be produced as an intermediate from oxygen in the copper-catalyzed autoxidation of cysteine. The amounts of cysteine oxidized and of hydrogen peroxide formed varied depending on the reaction conditions employed. The perpxide upon forming was spontaneously utilized for the oxidation of cysteine. As a result, the ratio of the concentration of hydrogen peroxide formed to cysteine oxidized is variable depending on the conditions. But, in dilute solutions, where the oxidation by the peroxide was slow, a stiochiometric relation of 2:1 was obtained between cysteine consumed and hydrogen peroxide produced. The rate of autoxidation is dependent on the concentration of oxygen dissolved. The double reciprocal plot of the rate against the concentration of oxygen gives a straight line, which indicates a possibility of the Michaelis-Menten type mechanism concerning the reoxidation or oxygenation of Cu(I) species.

Copper ion catalyzes effectively the autoxidation of cysteine (CySH) to cystine(CyS–SCy). Typical features of this autoxidation are that the substrate forms very strong complexes with both Cu(I) and Cu(II) ions and the redox process is assumed to take place within a copper thiolate complex.[1] At high pH and in the presence of excess cysteine, a 2:1(CySH/Cu) complex is formed,[2,3] but this complex is not considered as an intermediate; because it is relatively stable under the conditions.[4] Therefore, a 1:1(CySH/Cu) complex, which has not hitherto been detected by spectroscopic methods, is postulated as a reaction intermediate. During the autoxidation, various amounts of H_2O_2 are formed and subsequently decomposed depending on pH.[2,5] Thus, the primary process of the reaction can be written by Eq. 1, but the stoichiometric relation between cysteine consumed and H_2O_2 formed has not been reported so far.

$$2CySH + O_2 \longrightarrow CyS\text{-}SCy + H_2O_2 \quad (1)$$

Aims of the present work are to verify the stiochiometric relation shown in Eq. 1 and to elucidate the role of oxygen in the reaction. In this paper, we wish to report the following results. 1) The rate of autoxidation depends on the concentration of oxygen. The double reciprocal plot of the rate against the concentration of oxygen gives a straight line, which indicates a possibility that the reoxidation or oxygenation process of Cu(I) species obeys the Michaelis-Menten type mechanism. 2) The stiochiometric relation between cysteine and H_2O_2 was proved to be 2:1. The Cu(I) species may be reoxidized *via* a two-equivalent process.

Experimental

A stock solution of Cu(II) ion was prepared from copper foil of 99.999% purity (Kishida Chemical & Co., Ltd.), which was weighed out and dissolved in a small amount of concd HNO_3. The Cu(II) nitrate solution thus prepared was diluted with deionized, doubly distilled water to a desired concentration. The concentration of the Cu(II) solution was determined by titration with standard 0.01 M EDTA (1M=1 mol dm^{-3}) in ammonium-ammonia buffer at pH 10 with murexide as an indicater[6]. Cysteine, 5,5′-dithiobis(2-nitrobenzoic acid), abbreviated as DTNB, $TiCl_4$ and other reagents were of analytical grade and were used without further purification.

The oxidation was conducted in a 200 ml water-jacketted beacker under pure oxygen or oxygen-nitrogen mixtures (4:1—1:4) at 20 °C. The solution was saturated with oxygen or oxygen-nitrogen mixtures by bubbling for 20 min prior to the kinetic run. The reaction was started by adding the cysteine solution last. Gas bubbling at a rate of 100 ml/min and vigorous agitation by a magnetic stirrer were continued during the reaction. Aliquots were withdrawn at periodic intervals from the reaction mixtures, and applied to the determination of cysteine and H_2O_2. The determination of cysteine and H_2O_2 was carried out spectrophotometrically by using a Hitachi 101 spectrophotometer. Cysteine was determined at 415 nm with DTNB[7], and H_2O_2 at 410 nm with a $TiCl_4$ reagent[8]. The determination of the dissolved oxygen was done before a kinetic run with a Beckman Fieldlab oxygen analyzer, which had been calibrated against air saturated water.

Plots of the decrease of cysteine against time gave a straight line for over 60% reaction. In the kinetic study, the initial rate was calibrated with a graphical method.

Results and Discussion

The oxidation was conducted over the pH range of 6.5 and 7.8. The rate of cysteine autoxidation depended on the concentration of the dissolved oxygen in the medium. Martell *et al.* reported that the rate of the ascorbate oxidation catalyzed by iron chelates was linearly proportional to the concentration of oxygen, and on the basis of this observation they postulated the formation of the ascorbate–Fe(III)–O_2 ternary complex as an intermediate.[9] But, in the autoxidation of cysteine, the rate *vs.* the concentration of oxygen plot did not give a straight line.

Of much importance is that the double reciprocal plot; *i.e.*, the Lineweaver-Burk plot, of the rate against the oxygen concentration gives a straight line as shown in Fig. 1. A series of reciprocal plots for various cysteine concentrations appear to intercept at one point on the abscissa. Only the slope is affected by the variation in the cysteine concentration. The intercept at the abscissa is $-1/K_{0.5}$, where $K_{0.5}$ represents the half saturation concentration of oxygen for the autoxidation. The intercept at the ordinate is $1/V_{max}$,

where V_{max} represents the maximal velocity. The existence of the linear Lineweaver-Burk plot suggests the kinetic association of the metal catalyst and oxygen during the course of the reaction. Probably, the oxygen dissolved in the medium may associate with Cu(I) to form an adduct, Cu(I)–O_2, through which the electron transfer from Cu(I) to oxygen proceeds.

When a small amount of EDTA, less than 10^{-4} M, was added to the medium, the reaction was considerably enhanced.[10] In this case, a Lineweaver-Burk plot also gives a straight line, but a series of the plots appear to be parallel. The $K_{0.5}$ value becomes significantly small in the presence of a small amount of EDTA. Those kinetic parameters are summarized in Table 1.

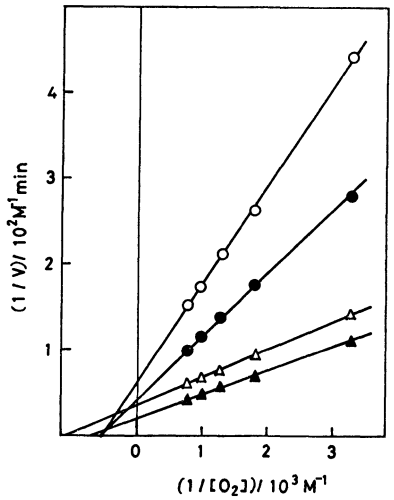

Fig. 1. Double reciprocal plot of the rate against the concentration of the oxygen dissolved in the medium. $[Cu(II)]_0 = 1.38 \times 10^{-6}$ M, $[CySH]_0 = 2.00 \times 10^{-3}$ M(○) and 4.00×10^{-3} M(●) in the absence of EDTA; $[CySH]_0 = 2.00 \times 10^{-3}$ M(△) and 4.00×10^{-3} M(▲) in the presence of EDTA, Buffer: 0.016 M glycylglycine.

The rate of autoxidation was affected by buffers with chelating abilities. Glycylglycine used as a buffer appeared to retard the oxidation, while phosphate did not affect or rather increased the rate of reaction. When the reaction was carried out in buffers containing both glycylglycine and phosphate and the concentration of phosphate was varied, the rate increased significantly with an increase of phosphate ion. This trend is obvious in the pH range of 7—7.5. The examples are shown in Table 2. When the oxidation was conducted in the buffer containing phosphate only, the rate increased approximately 20% as compared with the rate observed in both glycylglycine and phosphate containing buffer. Thus, phosphate is considered to enhance the oxidation.

Since glycylglycine is present excessively; *i.e.*, approximately at 10^4-fold concentration over copper ion, the main species for Cu(II) complex in the medium is $[Cu^{II}(H_{-1}glygly)(glygly)]^-$ (λ_{max}=620 nm, ε=85 $M^{-1}\,cm^{-1}$).[11-13] This 2:1 complex competes with cysteine for coordination site on the Cu(II) catalyst. In addition, glycylglycine is present at tenfold concentration over the substrate. Then, the competition

$[Cu(II)]_0 = 1.38 \times 10^{-6}$ M, $[CySH]_0 = 2.00 \times 10^{-3}$ M, buffer: 0.016 M glycylglycine(△; 100% O_2, ▲; 40% O_2), 0.016 M glycylglycine-0.01 M phosphate(○; 100% O_2, ●; 40% O_2).

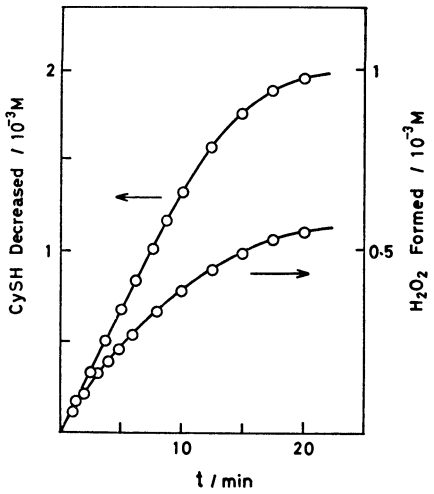

Fig. 3. Time course of the cysteine consumption and the formation of H_2O_2 at pH 7.4.
$[Cu(II)]_0 = 1.38 \times 10^{-6}$ M, $[CySH]_0 = 2.00 \times 10^{-3}$ M, buffer: 0.016 M glycylglycine-0.01 M phosphate, partial pressure of O_2: 100% at 760 mmHg.

of cysteine with glycylglycine; *i.e.*, the ligand substitution from glycylglycine to cysteine in the Cu(II) ion, may be much more retarted. When an equivalent amount of phosphate to glycylglycine is added to the medium, the absorption spectrum of $[Cu^{II}(H_{-1}glygly)(glygly)]^-$ undergoes red shift ($\lambda_{max} = 640$ nm, $\varepsilon = 83$ M^{-1} cm^{-1} at pH 7.1), which suggests that the chelation between Cu(II) and glycylglycine is loosed and is likely dissociated. Under these conditions, the association of cysteine with Cu(II) becomes facilitated and the oxidation is stimulated.

The rate of autoxidation and the amounts of H_2O_2 formed depended on pH. The pH-rate profile gave bell-shaped curves in both buffer systems as shown in Fig. 2A. But, the profile is different in detail. The maximal rates appeared at pH 7.25 in glycylglycine and at pH 7.45—7.5 in glycylglycine–phosphate buffers. The most considerable differences appeared in the relation between the amounts of H_2O_2 formed and pH. Typical examples are shown in Fig. 2B. The amounts of H_2O_2 formed in glycylglycine buffer, which was determined after cysteine had been completely consumed, decreased monotonously with pH, while in phosphate containing buffer the pH profile also gave a bell-shaped curve. In the latter case, a maximal value for the ratio of the concentration of H_2O_2 formed to the initial concentration of cysteine; *i.e.*, $[H_2O_2]/[CySH]_0$, is approximately 0.3 under pure oxygen. As mentioned above, Cu(II) in glycylglycine buffer possesses a relatively low catalytic ability. In the presence of excess cysteine and at high pH, the 2:1(CySH/Cu) complex is formed increasingly and stabilized with an increase of pH.[14] As a result, the oxidation of cysteine by copper in glycylglycine buffer is reduced at high pH, while the rate of oxidation of cysteine by H_2O_2, which is also catalyzed by copper, is shown to increase with pH.[15] Then, the formation and subsequent decomposition of H_2O_2 may be concerted and thereby the amounts of detectable H_2O_2 is apparently reduced.

Various amounts of H_2O_2 were formed concomitantly with the decrease of cysteine. Under the condition at $[Cu(II)]_0 = 1.38 \times 10^{-6}$ M, $[CySH]_0 = 2.00 \times 10^{-3}$ M and the partial pressure of oxygen in the gas phase=20—100% at 760 mmHg (1 mmHg≈133.322 Pa), a certain stoichiometric relation between the concentrations of cysteine consumed and H_2O_2 formed did not exist. A reason why the stoichiometry does not observed may be due to the consumption of H_2O_2 during the reaction. When cysteine has been almost consumed, the concentration of H_2O_2 remained is kept at constant, which indicates that H_2O_2 is utilized; *i.e.*, decomposed, in the presence of the substrate but not decomposed in the absence of the substrate. The time course for the cysteine consumption and H_2O_2 formation at pH 7.4 is shown in Fig. 3.

H_2O_2 is assumed to be a primary product from oxygen in the autoxidation process. If H_2O_2 formed were inert to the substrate, it would be accumulated quantitatively relative to the amounts of cysteine consumed. But, H_2O_2 upon forming does react inevitably and rapidly with cysteine. If the reaction proceeds at a very slow rate, the stoichiometric relation might be estimated; because the extent of H_2O_2 decomposition may be negligible. In an attempt to estimate the stoichiometry of the cysteine autoxidation, the reaction was carried out at various concentrations of cysteine from 5×10^{-4} M to 4×10^{-3} M, where the concentration of the copper catalyst and oxygen were kept at constant. The plot of the initial concentration of cysteine against $[H_2O_2]/[CySH]_0$ is shown in Fig. 4. Expectedly, as the initial concentration of cysteine reduced, the rate decreased and the ratio increased. The value of $[H_2O_2]/[CySH]_0$ was extraporated to 0.5 at the infinitively dilute concentration of cysteine. This fact indicates that the first-step in the autoxidation process involves naturally a two-equivalent oxidoreduction, in which oxygen is reduced to H_2O_2 directly, or two one-equivalent reduction, in which oxygen is reduced *via* superoxide as an intermediate. But. the

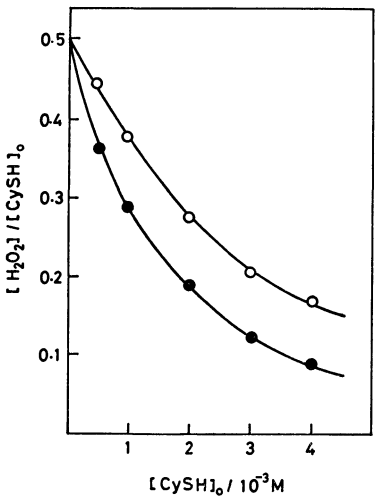

Fig. 4. Relation between the initial concentration of cysteine and $[H_2O_2]/[CySH]_0$; estimation of the stoichiometric relation of the cysteine autoxidation. $[Cu(II)]_0 = 1.38 \times 10^{-6}$ M, partial pressure of O_2: 100%(○) and 40%(●).

superoxide, O_2^-, could not be detected. Accordingly, it is proposed that the autoxidation of cysteine catalyzed by copper involves a two-equivalent process as shown by Eq. 1.

Lead Tetraacetate Oxidation of Humulene and Conformational Analysis of the Produced Humulatrienediols

Haruhisa SHIRAHAMA,* Kiyoharu HAYANO, Gurdial Singh ARORA, Eiji ŌSAWA and Takeshi MATSUMOTO

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received February 12, 1983)

Humulene was oxidized by lead tetraacetate in benzene to give 2,5,9-humulatrien-7-ol acetate and 1,5,9-humulatriene-3,7-diol diacetates. Conformational analysis of 1,5,9-humulatriene-3,7-diols was performed by NMR spectroscopy and molecular mechanics calculations.

Oxidation of the double allylic methylene group (C-8) of humulene (**1**) was previously attempted by Sukh Dev[1] in order to make a conversion of humulene to zerumbone (8-ketohumulene) (**2**). The oxidation seemed to be facile. However, even by using various reagents it was practically so difficult that the conversion was not fruitful. We also tried the oxidation of humulene and all of attempts at oxidizing C-8 methylene group of humulene were unsuccessful. The conversion to zerumbone was recently achieved through a roundabout way after all.[2] During these studies, a rather clean oxidation reaction of humulene by lead tetraacetate was realized.[3] The reaction could be applicable to syntheses and modifications of humulanoids.

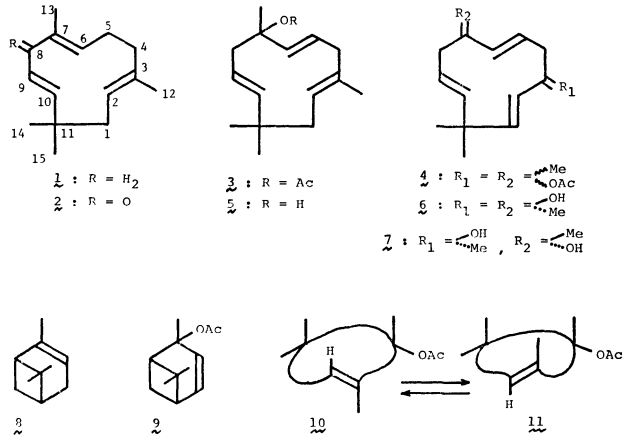

Fig. 1.

Humulene (1 mol) was treated with 1 mol of lead tetraacetate in benzene at 70 °C to give an acetate **3** (45%) and a diastereoisomeric mixture of diacetates **4** (23%). Oxidation with 3 mol of the reagent afforded the mixture of diacetates **4** exclusively. The ^{1}H NMR spectrum of the acetate **3** in the presence of a shift reagent (LIS-^{1}H NMR) (Table 1) showed that following partial structures were there in the molecule:

They led us readily to figuring formula **3**. The ^{13}C NMR and MS spectra also supported the formula. On treatment with $LiAlH_4$ the acetate **3** gave an alcohol **5** whose ^{1}H NMR spectrum was identical to that of the compound obtained also through oxidation of humulene by Matsubara *et al.*[3b,4]

The mixture of diacetates **4** first seemed to be a single compound whose structure was presumed to be **4** by its ^{1}H NMR and molecular weight referring to the structure of monoacetate **3**. It was, however, found to be a mixture of two diacetates (1:1) after converting it to corresponding alcohols which could be separated by chromatography. Both diols **6** and

a) Assignment to 12 and 13 alternates for **6** and **7**. b) LIS values = $\Delta\delta$/[Eu]/[substrate].

7 exhibited the same M^+ by high resolution MS and their ^1H NMR spectra were so similar that these were implied to be stereoisomers. LIS-^1H NMR revealed that the both diols **6** and **7** and the following structural fragments:

Assembling these parts on a humulene skeleton gave readily formula **6** or **7** except stereochemistry. Relative configuration of the two hydroxyl groups was deduced from LIS value ($\Delta\delta$/[Eu]/[Substrate]). The compound whose *gem*-dimethyl group shifted separately by addition of the shift reagent, namely, **6** was assigned to a *cis*-diol and the other one showing equivalent shift for each of the *gem*-dimethyl groups was allotted to a *trans*-diol.

The mode of lead tetraacetate oxidation of olefinic compounds is not uniform but the above reaction followed the one that exhibited by the oxidation of α-pinene (**8**→**9**).[5] Reaction of 6,7-double bond first took place and then the oxidation of 2,3-double bond followed. The ratio (1:1) of formation of the diastereoisomeric diacetates **6** and **7** could be regarded as a support[6] for equal existence of two stable conformers (**10** and **11**) of the acetate **3** because three *trans* double bonds must have been placed perpendicular to the 11-membered ring and attack of reagent must have been made from outside of the ring.

Conformational Analysis of 1,5,9-Humulatriene-3,7-diol. The coupling constants of methylene protons of **6** were not averaged and suggested that the compound existed either in a predominant conformation or in an equilibrium among several conformations. Strain energy and population for each of eight possible conformations[7] of **6** were thus estimated by means of molecular mechanics calculations.[8] Analysis of possible conformers for **6** followed our previous work[9] in which the conformations of humulene were fully analysed. Arrangement of three double bonds of **6** in cycloundecane ring was the same as those of humulene itself (1,4,8-undecatriene) and thus basic four conformations of humulene (CT, CC, TC, and TT)[9] were modified by proper substitutions (Fig. 2). Energy minimization of the eight conformers were successfully achieved to give their precise geometries and strain energies (Table 2). The conformation *RRR*-CC[10] was found to be most stable and the compound **6** was suggested to be equilibrated mostly among three conformers (*RRR*-CC, *SSS*-CC, and *RRS*-TC). The coupling constants (J_{AC}, J_{BC}, J_{DF}, and J_{EF}) (see Fig. 2) allotted to partial structures, $C(4)H_2C(5)H=$ and $C(8)H_2$–$C(9)H$–, were

a: Dihedral angles for the moieties indicated in the first line. *J*: *J* values estimated for the dihedral angles shown in the upper line. *J'*: Contributing fraction = *J* × population.

obtained from the estimated conformations referring Karplus relationship.[11] Weighted averages (sum of each conformer's *J* × population) of the calculated *J* values well coincided with observed values (Table 3).

The coupling constants of methylene protons of **7** were averaged and indicated that this compound was freely mobile and did not exist in a particular stable conformation. The different situation between the two diastereoisomers, **6** and **7**, may be readily understood since in **6** two methyl groups at C(3) and C(7) will take equatorial-like orientation while in **7** the both will take always opposite (equatorial- and axial-like) orientations each other.

Experimental

Melting point was uncorrected. IR spectra were measured with JASCO IR-S spectrometer. ^{1}H NMR and ^{13}C NMR spectra were recorded on a HITACHI R20B (60 MHz) and a JEOL JNM FX-100 (25 MHz) instrument using TMS as an internal standard respectively. High resolution mass spectra were measured on a JEOL JMS D-300 mass spectrometer.

Lead Tetraacetate Oxidation of Humulene (1). To a stirred mixture of $Pb(OAc)_4$ (1.2 g, 2.71 mmol) and dry benzene (20 ml) was added a solution of humulene (500 mg, 2.45 mmol) in benzene (10 ml) under argon. The mixture was stirred at 65—70 °C for 8 h and washed with water, aqueous $NaHCO_3$ solution and brine. The benzene solution was dried over Na_2SO_4 and evaporated under reduced pressure to leave paste. The crude product was chromatographed on a silica-gel column using hexane, 5% Et_2O-hexane and 13% Et_2O-hexane in turn as eluents to give an acetate **3** (289 mg, 45%) and a diasteroisomeric mixture of diacetates **4** (180 mg, 23%) which was not separable on TLC and VPC.

(E,E,E)-2,5,9-Humulatrien-7-ol Acetate (3): IR (neat) 1745, 1245, and 965 cm^{-1}; ^{1}H NMR δ=1.0, 1.02, and 1.99 (each 3H, s), 1.59 (6H, s), 2.4—2.8 (3H, m), and 4.8—5.9 (5H, complex); ^{13}C NMR δ=17.6(q), 22.0 (q), 22.3 (q), 26.4 (q), 27.4 (q), 38.9 (s), 40.5 (t×2), 47.3 (t), 82.8 (s), 120.2 (d), 123.6 (d), 129.1 (d), 134.3 (d), 137.9 (s), 143.5 (d), and 169.6 (s). Found: *m/z* 262.1924. Calcd for $C_{17}H_{26}O_2$: M, 262.1926.

(E,E,E)-1,5,9-Humulatriene-3,7-diol Diacetates (4): IR (neat) 1745, 1240, and 965 cm^{-1}; ^{1}H NMR δ=1.19 (6H, s), 1.51 (3H, bs), 1.58 (3H, s), 1.95, 1.96 (each 3H, s), and 4.9—5.7 (6H, complex). Found: *m/z* 320.2026. Calcd for $C_{19}H_{28}O_4$: 320.1980.

(E,E,E)-2,5,9-Humulatrien-7-ol (5). A solution of the acetate **3** (29 mg) in dry THF (1 ml) was stirred with $LiAlH_4$ (8 mg) at 0 °C under argon. The reaction was followed by TLC. After completion of the reaction, aqueous NH_4Cl solution was added and the mixture was extracted with ether three times. The combined extracts were dried (Na_2SO_4) and evaporated to leave an oil **5** (23 mg, 95%) which was purified by chromatography (silica gel, 5% AcOEt-hexane): IR (neat) 3420, 1660, 1110, and 965 cm^{-1}; ^{1}H NMR δ=1.03 and 1.37 (each 3H, s), 1.65 (3H, d, *J*=1 Hz), 1.94 (2H, d, *J*=8 Hz), 2.55 (2H, d, *J*=7 Hz), 5.05 (3H, m), 5.33 (1H, d, *J*=16 Hz), and 5.73 (1H, dt, *J*=16 and 7 Hz). Found: *m/z* 220.1815. Calcd for $C_{15}H_{24}O$: 220.1821.

*(E,E,E)-1,5,9-Humulatriene-*cis*-3,7-diol (6) and (E,E,E)-1,5,9-Humulatriene-*trans*-3,7-diol (7).* A solution of the diacetates **4** (40 mg) in dry THF (0.5 ml) was added to a well stirred slurry of $LiAlH_4$ (15 mg) and dry THF (0.5 ml) at 0 °C under argon. After completion of the reaction (checked by TLC), an excess of the $LiAlH_4$ was decomposed by addition of ice-water and extracted with EtOAc three times. The combined extracts were dried and evaporated to give 30 mg (quantitative) of paste which was shown to be a mixture (1:1) of two diols by its NMR spectrum. The mixture was separated by chromatography on a silica-gel column using a mixed solvent of hexane and ether (4:1) to afford a pair of diastereomeric diols **6** and **7**.

Diol 6: Mp 124—125 °C, IR ($CHCl_3$) 3640, 3480, 1090, and 970 cm^{-1}; ^{1}H NMR δ=1.18, 1.22, 1.28, and 1.35 (each 3H, s), 1.66—2.6 (6H, m), 5.08 and 5.46 (2H, ABq, *J*=16 Hz), and 5.1—5.5 (4H, m). Found: *m/z* 236.1772, Calcd for $C_{15}H_{24}O_2$: 236.1777.

Diol 7: Colorless oil, IR ($CHCl_3$) 3640, 3480, 1090, and 970 cm^{-1}; ^{1}H NMR δ=1.18 (6H, s), 1.27 and 1.33 (each 3H, s), 1.9—2.5 (6H, m), and 4.8—5.6 (6H, m). Found: *m/z* 236.1763. Calcd for $C_{15}H_{24}O_2$: 236.1777.

We thank Prof. Y. Matsubara (Kinki University) for sending ^{1}H NMR spectrum of compound **5**.

Double Cycloaddition Reaction of Imidazolium Methylides. Intermolecular 1,3-Dipolar and Intramolecular Diels-Alder Cycloaddition Reactions

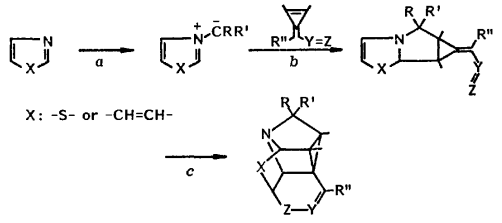
Otohiko Tsuge,* Shuji Kanemasa, and Shigeori Takenaka

Research Institute of Industrial Science, and Department of Molecular Science and Technology, Interdisciplinary Graduate School of Engineering Sciences, Kyushu University, Kasuga, Kasuga, Fukuoka 816

(Received February 21, 1983)

Such imidazolium methylides as imidazolium dicyanomethylide and bis(ethoxycarbonyl)methlide react with the methylenecyclopropenes with unsaturated substituents at the 4-position in the fashion of double cycloaddition reaction, leading to the novel cage compounds, which involves an intermorecular 1,3-dipolar cycloaddition reaction and an intramolecular Diels-Alder reaction.

Since the reaction of thiazolium methylides with the methylenecyclopropenes having unsaturated substituents at the 4-position presented the first example of double cycloaddition reaction that included at least a 1,3-dipolar cycloaddition reaction,[1,2] it has been reported that pyridinium methylides can be also employed in the similar reaction with methylenecyclopropenes leading to the cage compounds.[3]



Scheme 1.

As shown in Scheme 1, these reactions have provided a new methodology for the double functionalization of nitrogen-containing aromatic heterocycles such as thiazole and pyridine: The heterocycles are converted into the corresponding azomethine ylide 1,3-dipoles (the step *a* as the first functionalization), the 1,3-dipolar cycloaddition reaction of the ylides across the endocyclic double bond of methylenecyclopropenes forms the [3+2] cycloadducts leading to the collapse of aromatic character of the starting heterocycles (the step *b* as the second functionalization), and the intramolecular Diels-Alder reaction takes place across the newly formed olefinic double bond giving the cage compounds (the step *c*).

According to the general reaction pattern mentioned above, imidazole would be also doubly functionalized by the ylide formation and the reaction with methylenecyclopropenes having unsaturated substituents at the 4-position, while no examples for the 1,3-dipolar cycloaddition reaction of imidazolium ylides to olefinic dipolarophiles have been reported so far.[4]

This paper describes the first example for the double cycloaddition reaction of imidazolium methylides that react with methylenecyclopropenes having unsaturated substituents at the 4-position leading to the novel cage compounds.

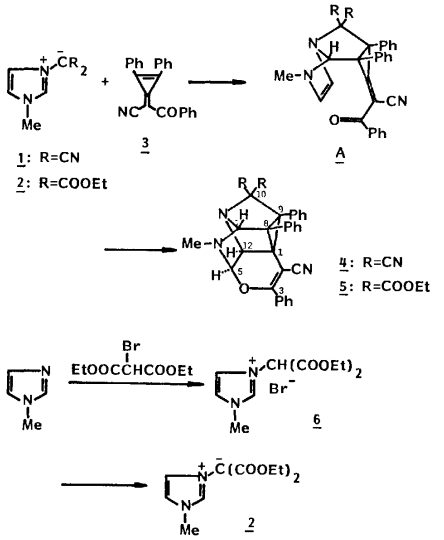
Results and Discussion

The Reaction with 2-Benzoyl-2-(2,3-diphenyl-2-cyclopropenylidene)acetonitrile. The reaction of 1-methyl-1*H*-imidazol-3-ium dicyanomethylide (**1**) with 2-benzoyl-2-(2,3-diphenyl-2-cyclopropenylidene)acetonitrile (**3**) in ethanol under reflux gave the 1:1 adduct **4** as a colorless solid in a good yield (Table 1). The IR spectrum exhibits no carbonyl stretching indicating that the benzoyl group of **3** has participated in a cyclization. The structure of **4** was easily assigned to the pentacyclic cage structure shown in Scheme 2 by comparison of the NMR spectral data with those of the similar cage compounds obtained in the reaction of thiazolium methylides.[1] The ^{1}H-NMR spectrum shows three methine hydrogens, two of which couple each other (J_{5-12}=4.0 Hz), and the ^{13}C-NMR indicates the existence of a cyclopropane ring (28.17, 41.85, and 50.28 ppm as each singlet), three methine carbons (66.18, 88.59, and 97.56 ppm as each doublet), and another quaternary carbon (65.69 ppm as a singlet).

Although the zwitterionic dicyanomethylides of nitrogen-containing heterocycles are stable enough to be isolated and have been conveniently used in the study of cycloaddition reactions, the major problem is their hard solubility in organic solvents. So a new imidazolium methylide, 1-methyl-1*H*-imidazol-3-ium bis(ethoxycarbonyl)methylide (**2**), was synthesized. The reaction of 1-methylimidazole with diethyl 2-bromomalonate in acetone afforded 1-methyl-3-[bis(ethoxycarbonyl)methyl]-1*H*-imidazol-3-ium bromide (**6**) in a quantitative yield. Treatment of the salt **6** with aqueous sodium carbonate gave the expected ylide **2** as a colorless solid also in a quantitative yield. The ylide **2** is less stable than the dicyanomethylide **1**,[5] but readily soluble in aprotic organic solvents such

Table 1. Reaction of imidazolium methylides with methylenecyclopropenes

Reactant		Reaction conditions: Temperature	Time / h	Solvent	Product	Yield / %
1	**3**	Reflux	29	Ethanol	**4**	76
2	**3**	Reflux	2	THF	**5**	99
7	**8**	Room temperature	4	THF	**9**	28
1	**8**	Reflux	24	Ethanol	**10**	36
					11	30
2	**8**	Reflux	48	THF	**12**	90



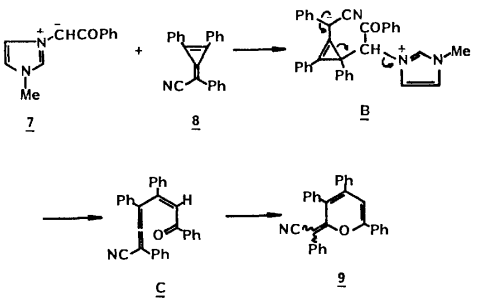
Scheme 2.

as chloroform and tetrahydrofuran.

The imidazolium bis(ethoxycarbonyl)methylide **2** thus synthesized reacted with **3** under reflux in tetrahydrofuran for 2 h to give the similar cage compound **5** in an almost quantitative yield (Table 1). The structure of **5** was confirmed on the basis of the spectral data.

The reaction pathway for the formation of the pentacyclic cage compounds **4** and **5** is illustrated in Scheme 2. It should be emphasized that the imidazolium methylides **1** and **2** have cycloadded stereo- and regioselectively to the endocyclic double bond of the methylenecyclopropene **3** to form the intermediary *endo* [3+2] cycloadducts **A** whose structures are favored for the subsequent intramolecular Diels-Alder cycloaddition reaction.

The Reaction with 2-Phenyl-2-(2,3-diphenyl-2-cyclopropenylidene)acetonitrile. The reaction of 1-methyl-1*H*-imidazol-3-ium phenacylide (**7**), which was generated *in situ* from 1-methyl-3-phenacyl-1*H*-imidazol-3-ium bromide and triethylamine, with 2-phenyl-2-(2,3-diphenyl-2-cyclopropenylidene)acetonitrile (**8**) in tetrahydrofuran at room temperature gave a red-colored product **9** in 28% yield. The product **9** has a molecular formula derived from the 1:1 adduct between **7** and **8** with the loss of 1-methylimidazole, and was determined as 2-(α-cyanobenzylidene)-3,4,6-triphenyl-2*H*-pyran on the basis of the IR (no carbonyl stretching), ^{1}H-NMR (an olefinic singlet at 6.47 ppm), and ^{13}C-NMR spectra (no sp^3 carbon). The elimination of heterocyclic moiety from the N-ylides of nitrogen-containing heterocycles has been observed quite often.[6] In the reaction of pyridinium phenacylide with 4,4-diacylmethylenecyclopropenes, Eicher has reported the formation of red-colored pyran derivatives as the pyridine-eliminated products.[7] The formation of **9** is explained by the reaction pathway shown in Scheme 3: The nucleophilic addition of the ylide carbon of **7** to the endocyclic double bond of **8** forms the intermediary zwitterion **B**, 1-methylimidazole is kicked out to give the allene intermediate **C**, and finally the 6π-cyclization occurs leading to the isolated product **9**.



Scheme 3.

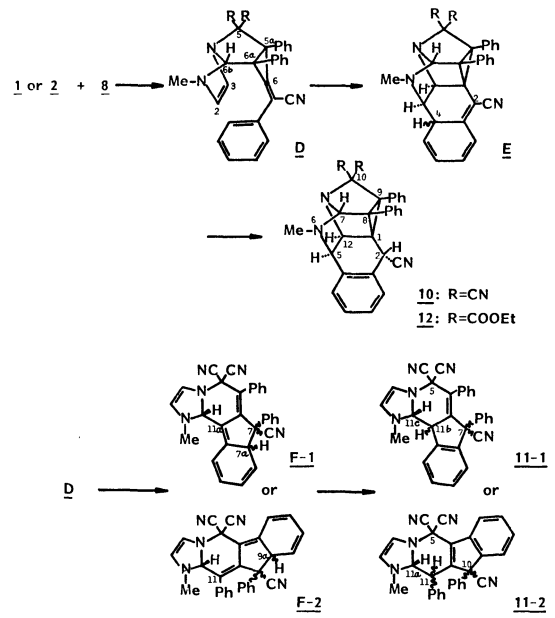
On the other hand, the reaction of the dicyanomethylide **1** with the methylenecyclopropene **8** under reflux in ethanol gave two kinds of the 1:1 adducts **10** and **11** in 36 and 30% yields, respectively. The analysis of the spectral data confirmed the pentacyclic cage structure of **10** and the imidazoindenopyridine structure of **11**.

The ^{1}H-NMR and ^{13}C-NMR spectra of **10** show four methine hydrogens and carbons (4.11^s, 4.15^d (J= 4.0 Hz), 4.50^d, and 4.92^s ppm in the ^{1}H-NMR, and 27.53, 66.99, 68.10, and 93.17 ppm as each doublet in the ^{13}C-NMR spectra) and three singlet carbons assigned to the carbons of cyclopropane moiety (33.17, 36.93, and 48.14 ppm). The stereochemistry at the 2-position was determined as shown in Scheme 4 on the ground of the high chemical shift of the 2-methine hydrogen.[8]

The ^{1}H-NMR spectrum of **11** shows only two methine hydrogens which couple each other with a coupling constant of 7.0 Hz (5.58 and 6.10 ppm). The ^{13}C-NMR spectrum exhibits two quaternary carbons (67.36 and 68.05 ppm) as well as two methine carbons (40.28 and 94.81 ppm). The absence of a cyclopropane moiety in **11** indicates that the cyclopropane ring and one of the phenyl groups of **8** have interacted to give the product **11**. Although there are two skeletons possible for **11** (the 5,7,11b,11c-tetrahydro-1*H*-imidazo-[1,2-*a*]indeno[1,2-*c*]pyridine(**11-1**) and 5,10,11,11a-tetrahydro-1*H*-imidazo[1,2-*a*]indeno[2,1-*d*]pyridine (**11-2**)) on the basis of the reaction modes mentioned later, it was impossible to assign the correct structure.

On the other hand, the bis(ethoxycarbonyl)methylide **2** gave the pentacyclic cage compound **12** as the single product in an excellent yield (Table 1). The spectral data are consistent with the proposed structure.

The reaction of the imidazolium methylides **1** and **2** with the methylenecyclopropene **8** proceeds also stereo- and regioselectively forming the *endo* [3+2] cycloadducts **D** which then cyclize through the intramolecular Diels-Alder reaction to give the other intermediates **E**. A 1,3-hydrogen shift of the 4-methine hydrogen to the 2-position affords the cage compounds **10** and **12**. In the case of the intermediate **D** derived from the dicyanomethylide **1**, another type of cyclization takes place. The Cope rearrangement concerned with the phenyl group at the 6a- or 5a-position leads to the intermediate **F-1** or **F-2**, respectively, while it is not clear which phenyl group has participated in the rearrangement. A 1,3-hydrogen shift of the 7a-hydrogen of **F-1** or a 1,5-hydrogen shift of the 9a-



Scheme 4.

hydrogen of **F-2** gives the product **11-1** or **11-2**, respectively. The similar Cope rearrangement has been observed in the [2+2] cycloadduct of an enamine to **8**.[9]

Experimental

General. Melting points were determined on a Yanagimoto micro melting point apparatus and are uncorrected. IR spectra were taken with a JASCO IRA-1 or a JASCO A-102 spectrometer. ^{1}H-NMR spectra were recorded on a Hitachi R-40 at 90 MHz or a JEOL FX-100 spectrometer at 100 MHz and ^{13}C-NMR spectra were obtained on a JEOL FX-100 instrument at 25.05 MHz. Chemical shifts are expressed in parts per million downfield from tetramethylsilane. Mass spectra were measured with a JEOL JMS-01SG-2 spectrometer at 75 eV of ionization energy. Elementary analyses were performed on a Hitachi 026 CHN analyzer. Thin-layer chromatography (TLC) was accomplished on 0.2-mm precoated plates of silica gel 60 F-254 (Merck) or on 0.2-mm precoated plates of aluminum oxide 60 F-254 type E (Merck). Visualization was with ultraviolet light (254 and 365 nm) and iodine. Preparatory column chromatography was performed on silica gel Wako C-300 (Wako). Solvents were evaporated with a Tokyo Rikakikai rotary vacuum evaporator type V at about 50 °C unless otherwise stated.

Tetrahydrofuran was distilled from sodium immediately before use. Triethylamine was distilled and stored on potassium hydroxide. Acetone was dried over anhydrous potassium carbonate.

Materials. 2-Benzoyl-2-(2,3-diphenyl-2-cyclopropenylidene)acetonitrile(**3**) (pale yellow needles from 2-propanol, mp 168—170 °C (lit,[10] mp 162—163 °C)) and 2-phenyl-2-(2,3-diphenyl-2-cyclopropenylidene)acetonitrile (**8**) (orange needles from benzene-hexane, mp 178—180 °C (lit,[11] mp 182—183 °C)) were prepared according to the reported methods. 1-Methyl-1*H*-imidazol-3-ium dicyanomethylide (**1**) (beige leaflets from ethanol, mp 142—143 °C (lit,[12] mp 143—144 °C)) was synthesized by the reaction of 1-methylimidazole with tetracyanoethylene oxide. 1-Methyl-3-phenacyl-1*H*-imidazol-3-ium bromide (colorless needles from acetonitrile, mp 154 °C (lit,[13] mp 153—155 °C) was obtained in 96% yield in the reaction of 1-methylimidazole with phenacyl bromide. 1-Methylimidazole and diethyl 2-bromomalonate are commercially avaliable.

*Reaction of 1-Methyl-1*H*-imidazol-3-ium Dicyanomethylide (**1**) with 2-Benzoyl-2-(2,3-diphenyl-2-cyclopropenylidene)acetonitrile (**3**).* A mixture of **1** (73 mg, 0.5 mmol) and **3** (169 mg, 0.5 mmol) in ethanol (20 ml) was refluxed for 29 h during which time all the starting materials were consumed (on TLC). After complete evaporation of the solvent *in vacuo*, the residue was chromatographed over silica gel using benzene as an eluent to give **4** (182 mg, 76%): Colorless needles from ether-hexane, mp 185—188 °C (decomp)). IR (KBr) 2180 cm^{-1} (C≡N); ^{1}H-NMR ($CDCl_3$) δ=2.94 (3H, s, 6-Me), 4.13 (1H, d, J_{12-5}=7.0 Hz, 12-H), 5.13 (1H, s, 7-H), 5.58 (1H, d, J_{5-12}=7.0 Hz, 5-H), and 6.70—7.82 ppm (15H, m, ArH); ^{13}C-NMR ($CDCl_3$) δ=28.17 (s, 1-C), 41.18 (q, 6-Me), 41.85, 50.28 (each s, 8- and 9-C), 65.69 (s, 10-C), 66.18 (d, 12-C), 88.59 (d, 7-C), 97.56 (d, 5-C), 110.71, 116.22 (each s, 10-CN), 121.97 (s, 2-CN), and 168.94 ppm (s, 3-C); MS *m/e* 479 (M^+, 4%). Found: C, 77.39; H, 4.41; N, 14.59%. Calcd for $C_{31}H_{21}ON_5$: C, 77.66; H, 4.38; N, 14.67%.

*1-Methyl-1*H*-imidazol-3-ium Bis(ethoxycarbonyl)methylide (**2**).* A mixiture of 1-methylimidazole (2.5 g, 0.03 mol) and diethyl 2-bromomalonate (7.2 g, 0.03 mol) in dry acetone (50 ml) was stirred at room temperature for 24 h. The acetone was evaporated *in vacuo* giving a colorless viscous oil of **6** (9.7 g, 100%). The salt **6** (9.7 g, 0.03 mol) was dissolved in water (5 ml) and treated with saturated aqueous sodium carbonate under vigorous stirring precipitating colorless solid of **2** (7.2 g, 100%): Colorless prisms from chloroform-acetone, mp 164—165 °C. IR (KBr) 1690, 1640 (C=O), and 1580 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.24 (6H, t, $CH_2C\underline{H}_3$), 3.92 (3H, s, *N*-Me), 4.09 (4H, q, $C\underline{H}_2CH_3$), 7.09 (2H, m, 4- and 5-H), and 8.25 ppm (1H, br, s, 2-H).

*Reaction of **2** with **3**.* A mixture of **2** (120 mg, 0.5 mmol) and **3** (167 mg, 0.5 mmol) in dry tetrahydrofuran (20 ml) was refluxed until **3** no longer showed its spot on a TLC plate (2 h). The tetrahydrofuran was evaporated *in vacuo* and then the residue was chromatographed over silica gel using benzene as an eluent to give **5** (284 mg, 99%): Colorless prisms from ether-light petroleum, mp 175 °C. IR (KBr) 2204 (C≡N) and 1738 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=1.02, 1.19 (each 3H, t, 10-$COOCH_2C\underline{H}_3$), 2.94 (3H, s, 6-Me), 3.97 (1H, d, J_{12-5}=4.0 Hz, 12-H), 4.12, 4.22 (each 2H, q, 10-$COOC\underline{H}_2CH_3$), 5.40 (1H, s, 7-H), 5.54 (1H, d, J_{5-12}=4.0 Hz, 5-H), and 6.60—7.58 ppm (15H, m, ArH); ^{13}C-NMR ($CDCl_3$) δ=13.56, 13.74 (each q, 10-$COOCH_2\underline{C}H_3$), 29.53 (s, 1-C), 41.10 (q, 6-Me), 44.09, 47.61 (each s, 8- and 9-C), 61.82 (t, 10-$COOCH_2CH_3$), 65.52 (d, 12-C), 85.30 (s, 10-C), 87.77 (d, 7-C), 97.93 (d, 5-C), 117.18 (s, 2-CN), 166.15 (s, 10-$\underline{C}OOEt$), and 168.26 ppm (s, 3-C); MS *m/e* 573 (M^+, 63%) and 500 ($M^+-COOEt$, 33%). Found: C, 73.00; H, 5.45; N, 7.33%. Calcd for $C_{35}H_{31}O_5N_3$: C, 73.28; H, 5.45; N, 7.33%.

*Reaction of 1-Methyl-1*H*-imidazol-3-ium Phenacylide (**7**) with 2-Phenyl-2-(2,3-diphenyl-2-cyclopropenylidene)acetonitrile (**8**).* To a stirred suspension of 1-methyl-3-phenacyl-1*H*-imidazol-3-ium bromide (141 mg, 0.5 mmol) and **8** (153 mg, 0.5 mmol) in 25 ml of dry tetrahydrofuran was added dropwise triethylamine (0.07 ml, 0.5 mmol). After the mixture was stirred at room temperature for 4 h, a colorless solid precipitated (triethylammonium bromide) was filtered off

and washed with 5 ml of tetrahydrofuran. The combined filtrate and washing were evaporated *in vacuo*. The residue was chromatographed over silica gel using benzene as an eluent to afford **3** (60 mg, 28%): Red needles from 2-propanol, mp 187 °C. IR (KBr) 2250 cm^{-1} (C≡N); ^{1}H-NMR ($CDCl_3$) δ=6.47 (1H, s, 5-H) and 6.80—7.85 ppm (20H, m, ArH); ^{13}C-NMR ($CDCl_3$) δ=104.95 (s, CN), 124.90 (d, 5-C), 127.36 (s, =C(CN)Ph), 143.33 (s, 4-C), 154.68 (s, 6-C), and 161.40 ppm (s, 2-C); MS *m/e* 423 (M^+, base peak), 105 ($PhCO^+$, 57%), and 77 (Ph^+, 37%). Found: C, 88.12; H, 5.09; N, 3.56%. Calcd for $C_{31}H_{21}ON$: C, 87.94; H, 4.96; N, 3.31%.

Reaction of **1** *with* **8**. A solution of **1** (73 mg, 0.5 mmol) and **8** (153 mg, 0.5 mmol) in ethanol (20 ml) was refluxed for 24 h. No trace of **8** was detected on a TLC plate after 24 h. The solvent was completely removed off by evaporation *in vacuo*. The residue was chromatographed over silica gel using benzene as an eluent. The first colorless fraction gave **10** (82 mg, 36%) and the second yellow fraction afforded **11** (68 mg, 30%).

10: Colorless needles from ether-light petroleum, mp 251—252 °C (decomp). IR (KBr) 2250 cm^{-1} (C≡N); ^{1}H-NMR ($CDCl_3$) δ=2.81 (3H, s, 6-Me), 4.11 (1H, s, 2-H), 4.15 (1H, d, J_{12-5}=4.0 Hz, 12-H), 4.50 (1H, d, J_{5-12}=4.0 Hz, 5-H), 4.92 (1H, s, 7-H), and 6.40—7.64 ppm (14H, m, ArH); ^{13}C-NMR ($CDCl_3$) δ=27.53 (d, 2-C), 33.17 (s, 1-C), 36.93, 48.14 (each s, 8- and 9-C), 44.56 (q, 6-Me), 63.30 (s, 10-C), 66.99 (d, 12-C), 68.10 (d, 5-C), 93.17 (d, 7-C), 111.08, 111.95 (each s, 10-CN), and 119.00 ppm (s, 2-CN); MS *m/e* 451 (M^+, base peak). Found: C, 79.91; H, 4.70; N, 15.55%. Calcd for $C_{30}H_{21}N_5$: C, 79.80; H, 4.69; N, 15.51%.

11: Yellow prisms from ether-light petroleum, mp 132—133 °C. IR (KBr) 2250 cm^{-1} (C≡N); ^{1}H-NMR ($CDCl_3$) δ=2.84 (3H, s, 1-Me), 5.58 (1H, d, J=7.0 Hz, CH), 6.10 (1H, d, J=7.0 Hz, CH), and 6.75—7.64 ppm (16H, m, ArH, 2- and 3-H); ^{13}C-NMR ($CDCl_3$) δ=40.28 (d, CH), 44.44 (q, 1-Me), 67.36, 68.05 (each s, quart-C), 94.81 (d, CH), 111.72, 114.42, and 118.34 ppm (each s, CN); MS *m/e* 451 (M^+, base peak). Found: C, 79.63; H, 4.60; N, 15.53%. Calcd for $C_{30}H_{21}N_5$: C, 79.80; H, 4.69; N, 15.51%.

Reaction of **2** *with* **8**. A mixture of **2** (120 mg, 0.5 mmol) and **8** (153 mg, 0.5 mmol) in dry tetrahydrofuran (20 ml) was refluxed for 48 h. The tetrahydrofuran was eveporated *in vacuo* and the residue was chromatographed over silica gel using benzene as an eluent to give **12** (245 mg, 90%): Colorless prisms from ether-light petroleum, mp 192 °C. IR (KBr) 2220 (C≡N) and 1740 cm^{-1} (C=O); ^{1}H-NMR δ=1.13, 1.19 (each 3H, t, 10-$COOCH_2C\underline{H}_3$), 2.77 (3H, s, 6-Me), 4.02 (1H, d, J_{12-5}=4.3 Hz, 12-H), 4.14, 4.23 (each 2H, q, 10-$COOC\underline{H}_2CH_3$), 4.16 (1H, s, 2-H), 4.40 (1H, d, J_{5-12}=4.3 Hz, 5-H), 5.11 (1H, s, 7-H), and 6.50—7.50 ppm (14H, m, ArH); ^{13}C-NMR ($CDCl_3$) δ=13.77 (q, 10-$COOCH_2\underline{C}H_3$), 28.86 (d, 2-C), 33.98 (s, 1-C), 39.16, 45.31 (each s, 8- and 9-C), 44.82 (q, 6-Me), 62.01, 62.16 (each t, 10-$COO\underline{C}H_2CH_3$), 66.36 (d, 12-C), 67.53 (d, 5-C), 83.25 (s, 10-C), 92.62 (d, 7-C), 120.16 (s, 2-CN), 167.09 and 167.72 ppm (each s, 10-$\underline{C}OOEt$); *m/e* 545 (M^+, 15%) and 472 (M^+−COOEt, base peak). Found: C, 74.82; H, 6.12; 7.51%. Calcd for $C_{34}H_{31}O_4N_3$: C, 74.84; H, 5.73; N, 7.70%.

Pseudo-sugars. X. Synthesis of Several Branched-chain Unsaturated Cyclitols and Their Derivatives[1]

Seiichiro Ogawa, Takao Hattori, Tatsushi Toyokuni, and Tetsuo Suami*

Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223

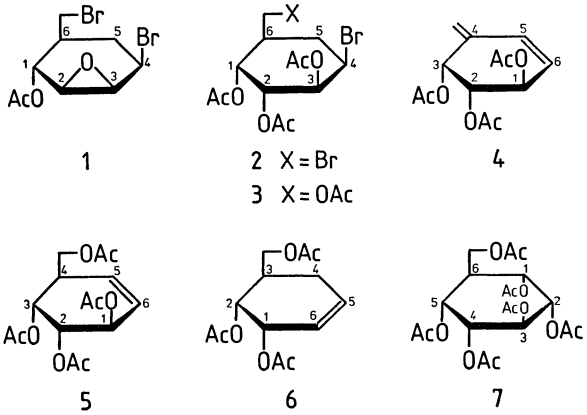
(Received February 23, 1983)

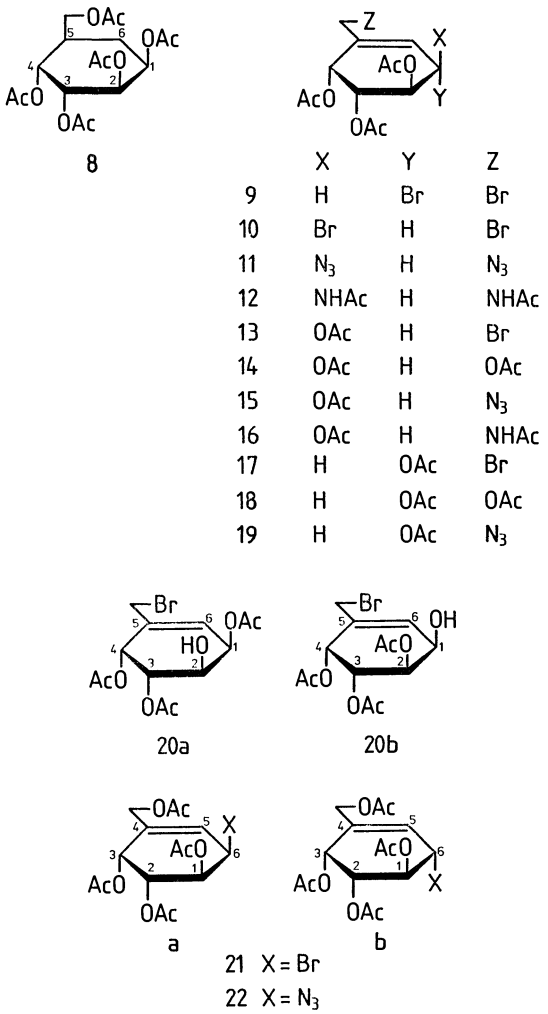
Some racemic (hydroxymethyl)cyclohexenepolyols and their derivatives of biological interest have been synthesized from DL-1,2,3-tri-*O*-acetyl-(1/2,3)-4-methylene-5-cyclohexene-1,2,3-triol derived from the corresponding dibromide by treatment with sodium acetate in hexamethylphosphoric triamide.

In connection with the previous paper,[2] several (hydroxymethyl)cyclohexenepolyols and its derivatives have been synthesized as peracetates from readily available DL-1-*O*-acetyl-2,3-anhydro-(1/2,3,4,6)-4-bromo-6-bromomethyl-1,2,3-cyclohexanetriol (**1**).[3]

Compound **1** was treated with aqueous acetone containing 1% concd sulfuric acid at reflux, followed by acetylation with acetic anhydride in pyridine, to produce DL-1,2,3-tri-*O*-acetyl-(1,2/3,4,6)-4-bromo-6-bromomethyl-1,2,3-cyclohexanetriol (**2**) in 87% yield. Opening of the epoxide ring proceeds selectively *via* an anchimeric assistance of the C-1 acetoxyl group at C-2. As the corresponding (1,3/2,4,6)-isomer,[3] **2** was expected to be a versatile synthetic intermediate for various kinds of branched-chain cyclitol derivatives.[4,5]

Treatment of **2** with 4 molar equiv. of sodium acetate in *N*,*N*-dimethylformamide (DMF) at 80 °C for 8 h resulted in a preferential replacement of the primary bromo group with an acetate ion to give the tetraacetate **3** in 75% yield, along with the elimination product, DL-1,2,3-tri-*O*-acetyl-(1/2,3)-4-methylene-5-cyclohexene-1,2,3-triol (**4**, 14%). When the similar reaction was carried out at an elevated temperature (110 °C) for 32 h, the elimination of hydrobromic acid between C-4 and C-5 further occurred to give DL-1,2,3-tri-*O*-acetyl-(1,4/2,3)-4-acetoxymethyl-5-cyclohexene-1,2,3-triol (**5**) in 48% yield, along with **4** (22%). On the other hand, hexamethylphosphoric triamide (HMPA) was used as the solvent instead of DMF, **4** was obtained predominantly in 69% yield, after having been heated at 120 °C for 2 h. Whereas, a reaction of **3** with zinc dust in acetic acid at 65 °C for 35 h gave DL-1,2-di-*O*-acetyl-(1,2/3)-3-acetoxymethyl-5-cyclohexene-1,2-diol (**6**) in 51% yield. The structures of **5** and **6** were deduced on the basis of analytical data and ^{1}H NMR spectra, and finally established by converting them into branched-chain cyclitols. Thus, the conventional osmium tetraoxide-oxidation of **5** and **6**, followed by acetylation, afforded mainly the peracetyl (hydroxymethyl)cyclohexanepentol **7** and tetrol **8**[6] in 33 and 70% yields, respectively. The ^{1}H NMR spectrum of **7** showed the signals due to six acetoxyl methyl groups as four singlets with 2:1:2:1 relative intensity, indicative of the presence of the plane of the symmetry in the molecule, being consistent with the assigned structure. The postulated structure of **8** was supported by the ^{1}H NMR spectral





Scheme 1.

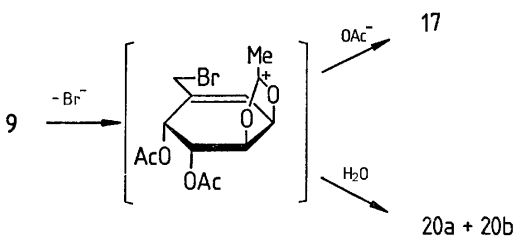
signal-pattern similar to that of **3** in the region of the ring protons attached to the carbon atoms bearing the acetoxyl groups, and finally confirmed by identification with the compound derived by the alternative synthetic route.[7]

The structure of **4** was confirmed by the appearance of the signal for the exocyclic methylene protons at δ=5.22 as a two-proton doublet (J=6 Hz) and that for the olefinic proton at δ=6.19 as a doublet (J=10 Hz) in the ^{1}H NMR spectrum. In contrast to the corresponding (1,3/2)-isomer,[8] **4** is unstable and readily polymerizes during purification. But it can be preserved as an ethyl acetate solution for several days.

Bromination of **4** with bromine in acetic acid–acetic anhydride (1:3) at room temperature gave a mixture of the 1,4-addition products, which were fractionated by a silica-gel column to give the dibromides **9** (30%) and **10** (3%), along with the monobromide **13** (5%). The ^{1}H NMR spectrum of **9** revealed the olefinic proton as a narrow doublet (J=3 Hz) at δ=6.12, in support of a pseudoequatorial orientation of the C-6 bromo group.[9] Compounds **9** and **10** are interconvertible each other in the presence of a bromide ion, and the more thermodynamically stable isomer **9** predominates in the reaction mixture. Compound **13** seems to be formed from **9** by an attack of an acetate ion at C-6 from the pseudoaxial direction.

The structure of **9** was further confirmed by the reaction with silver acetate (4 molar equiv.) in acetic acid, which proceeded through a neighboring group participation reaction of the C-1 acetoxyl group at C-6 giving rise to an intermediate 1,6-cyclic acetoxonium ion.[4] When the reaction was carried out in aqueous acetic acid, the acetoxonium ion was attacked by water to give a mixture of DL-1,3,4- (**20a**) and 2,3,4-tri-*O*-acetyl-(1,2/3,4)-5-bromomethyl-5-cyclohexene-1,2,3,4-tetrol (**20b**) in 72% yield. While, under anhydrous conditions (in acetic acid–acetic anhydride), the acetoxonium ion was likely to undergo a back side attack by an acetate ion at the allylic position giving the pentaacetate **18** with the inversion of the configuration at C-6. On the other hand, a molar equiv. of silver acetate was used in the above reaction, the secondary bromo group was only displaced to give the bromo tetraacetate **17** in 48% yield. The mixture of **20a** and **20b** was converted into the pentaacetate **14** by further treatment with sodium acetate in aqueous DMF, followed by acetylation.

Nucleophilic substitution reactions of the bromides thus obtained were then studied. Treatment of **9** with an azide ion in DMF at room temperature gave smoothly a single diazido compound **11** in 67% yield



Scheme 2.

via an S_N2 reaction with inversion of the configuration at C-6. In the ^{1}H NMR spectrum of **11**, the signal for the olefinic proton appeared as a doublet (J=4.5 Hz) at δ=5.86, in support of the assigned structure. Reduction of **11** with hydrogen sulfide, followed by acetylation, gave bis(acetamide) **12** in 78% yield. Similar azidolysis of **17** and **20a,b** gave the corresponding azides **19** and **15** (after acetylation) in 59 and 69% yields, respectively. Compound **15** could easily be converted into the acetamide **16** in 52% yield.

Finally, in order to introduce a desired nucleophile into the C-6 position, attempts to displace first the primary bromo group of **9** by an acetate ion were made. Treatment of **9** with a molar equiv. of sodium acetate in DMF at room temperature gave a mixture of the unstable 6-bromo compounds **21a** and **21b** in 67% yield. Compounds **21a** and **21b** are interconvertible each other in the presence of a bromide ion, and are isolated as an equilibrium mixture. Without further purification, the mixture was directly treated with sodium azide in DMF at room temperature yielded a mixture of the azides **22a** and **22b** in 74% yield. The ^{1}H NMR spectrum of the mixture showed the methylene signal as a singlet at δ=4.44, in support of the presence of the acetoxyl group at the branched-chain carbon atom. Therefore, **21a,b** would be useful as a synthon for preparation of some isomeric validoxylamine A[10] and α-glucosidase inhibitors.[11]

Experimental

General. Melting points were determined on a Büchi 510 capillary melting point apparatus and are uncorrected. Unless otherwise noted, ^{1}H NMR spectra were taken on Varian EM-390 (90 MHz) in chloroform-*d* with reference to tetramethylsilane as an internal standard. The peak positions were given in terms of δ-values and values given for coupling constants were of first-order. TLC was performed on a precoated silica gel 60 F-254 plates (Merck, Darmstadt; 0.25 mm thickness). The silica gel used for a column chromatography was Wakogel C-300 (Wako Pure Chemical Industries, Ltd.).

DL-*1,2,3-Tri*-O-*acetyl-(1,2/3,4,6)-4-bromo-6-bromomethyl-1,2,3-cyclohexanetriol (2).* A solution of DL-1-*O*-acetyl-2,3-anhydro-(1/2,3,4,6)-4-bromo-6-bromomethyl-1,2,3-cyclohexanetriol (**1**)[3] (3.0 g) in acetone (27 ml) containing 10% sulfuric acid (3 ml) was refluxed for 3 h. The reaction mixture was neutralized with sodium hydrogencarbonate and then evaporated to dryness. The residue was treated with acetic anhydride (6 ml) and pyridine (6 ml) at room temperature overnight. The reaction mixture was poured into ice water and the precipitates were collected by filtration. Recrystallization of the crude product from ethanol gave 3.4 g (87%) of **2** as plates: mp 126.5—127.5 °C; ^{1}H NMR ($CDCl_3$) δ=2.00 (3H, s), 2.11 (3H, s), and 2.19 (3H, s) (OAc), 3.18—3.54 (2H, m, CH_2Br), 4.40 (1H, ddd, J=3, 5.5, and 12 Hz, H-4), 4.98 (1H, dd, J=3 and 10.5 Hz, H-1), 5.25 (1H, dd, J=3 and 4 Hz, H-3), and 5.34 (1H, dd, J=3 and 4 Hz, H-4).

Found: C, 36.08; H, 4.01; Br, 36.84%. Calcd for $C_{13}H_{18}Br_2O_6$: C, 36.30: H, 4.22; Br, 37.16%.

DL-*1,2,3-Tri*-O-*acetyl-(1,2/3,4,6)-6-acetoxymethyl-4-bromo-1,2,3-cyclohexanetriol (3).* A mixture of **2** (0.30 g), sodium acetate (0.25 g), and *N,N*-dimethylformamide (DMF)

(5 ml) was stirred at 80 °C for 8 h. The reaction mixture was concentrated and coevaporated with 1-butanol and toluene. The residue was extracted with chloroform and the extracts were filtered through a short column of alumina. The filtrate was concentrated and the residue was fractionated on a silica-gel column (12 g) with ethyl acetate–hexane (1 : 2) as an eluent. The first fraction (R_f 0.14) gave an oil, which was recrystallized from ethanol to give 0.21 g (75%) of **3** as prisms: mp 104.5—105 °C; ^{1}H NMR ($CDCl_3$) δ=1.97 (3H, s), 2.06 (3H, s), 2.11 (3H, s), and 2.18 (3H, s), (OAc), 3.97 (2H, d, J=4 Hz, C$\underline{H}_2$OAc), 4.37 (1H, ddd, J=3, 6, and 11 Hz, H-6), 4.95 (1H, dd, J=3 and 11 Hz, H-3), 5.20 (1H, dd, J=3 and 4 Hz, H-1), and 5.25 (1H, dd, J=3 and 4 Hz, H-2).

Found: C, 44.00; H, 5.01; Br, 19.06%. Calcd for $C_{15}H_{21}BrO_8$: C, 44.03; H, 5.17; Br, 19.53%.

The second fraction (R_f 0.29) gave 24 mg (14%) of DL-1,2,3-tri-*O*-acetyl-(1/2,3)-4-methylene-5-cyclohexene-1,2,3-triol (**4**) as an oil: ^{1}H NMR ($CDCl_3$) δ=2.04 (3H, s) and 2.08 (6H, s) (OAc), 5.09 (1H, dd, J=3 and 7.5 Hz, H-2), 5.22 (2H, d, J=6 Hz, C=C$\underline{H}_2$), 5.58—5.80 (3H, m, H-1, H-3, and H-6), and 6.19 (1H, d, J=10 Hz, H-5).

This compound was very unstable and a satisfactory analytical data were not obtained. Therefore, practically pure sample was directly used in the succeeding reactions.

Reaction of **2** *with Sodium Acetate.* *a) In DMF*: A mixture of **2** (4.0 g), sodium acetate (3.3 g, 4 molar equiv.), and DMF (35 ml) was stirred at 110 °C for 32 h. TLC indicated the formation of two products [R_f 0.47 and 0.25, ethyl acetate–hexane (1 : 5)]. The reaction mixture was concentrated and the residue was chromatographed on a silica-gel column (120 g) with ethyl acetate–hexane (1 : 2) as an eluent. The first fraction gave 0.48 g (22%) of **4** as an oil, which was identical with the compound obtained before. The second fraction gave 1.45 g (47.5%) of DL-1,2,3-tri-*O*-acetyl-(1,4/2,3)-4-acetoxymethyl-5-cyclohexene-1,2,3-triol (**5**) as an oil: ^{1}H NMR ($CDCl_3$) δ=2.05 (6H, s) and 2.06 (6H, s) (OAc), 2.75 (1H, br q, J=*ca.* 5 Hz, H-4), 4.09 (2H, d, J=5 Hz, C$\underline{H}_2$OAc), 5.05—5.36 (3H, m, H-1, H-2, and H-3), and 5.71 (2H, s, H-5 and H-6).

Found: C, 54.68; H, 6.02%. Calcd for $C_{15}H_{20}O_8$: C, 54.88; H, 6.14%.

b) In Hexamethylphosphoric Triamide (HMPA): A mixture of **2** (0.30 g), sodium acetate (0.23 g, 4 molar equiv), and HMPA (5 ml) was stirred at 120 °C for 2 h. TLC indicated the formation of one main component [R_f 0.55, ethyl acetate–hexane (1 : 4)], along with four minor components. The reaction mixture was diluted with ethyl acetate (20 ml) and washed thoroughly with water, and dried over anhydrous sodium sulfate. Evaporation of the solvent gave an oil, which was rapidly chromatographed on a silica-gel column (6 g) with ethyl acetate–hexane (1 : 4) as an eluent. The main fraction gave 0.12 g (69%) of **4** as an oil, which could be preserved as an ethyl acetate solution in a refrigerator.

DL-*1,2-Di*-O-*acetyl-(1,2/3)-3-acetoxymethyl-5-cyclohexene-1,2-diol (***6***).* A mixture of **3** (0.40 g) and zinc dust (1.95 g) in acetic acid (10 ml) was stirred at 65 °C for 35 h. The reaction mixture was filtered and the insoluble material was washed thoroughly with acetic acid. The filtrate and washings were combined and concentrated to give crystals, which were recrystallized from ethanol to give 0.14 g (51%) of **6** as prisms: mp 57.5—59 °C; ^{1}H NMR ($CDCl_3$) δ=1.99 (3H, s), 2.01 (3H, s), and 2.05 (3H, s) (OAc), 3.85—4.25 (2H, m, C$\underline{H}_2$OAc), 4.93 (1H, dd, J=3.5 and 11 Hz, H-2), 5.42 (1H, br t, J=3.5 Hz, H-1), 5.61 (1H, br dd, J=3.5 and 10 Hz, H-6), and 5.92 (1H, ddd, J=2.5, 4, and 10 Hz, H-5).

Found: C, 57.51; H, 6.64%. Calcd for $C_{13}H_{18}O_6$: C, 57.77; H, 6.71%.

Osmium Tetraoxide-oxidation of **5**. To a solution of **5** (0.34 g) in *t*-butyl alcohol (8 ml) containing 30% hydrogen peroxide (2 ml) was added *t*-butyl alcohol (2.5 ml) containing osmium tetraoxide (0.01 g), and the mixture was stirred at room temperature for 1 d. The reaction mixture was diluted with water and the excess hydrogen peroxide was destroyed by addition of sodium sulfite. The mixture was concentrated to dryness and the residue was treated with acetic anhydride and pyridine in the usual way. The product was purified by passage through a short column of alumina with chloroform. The filtrate was concentrated to give crystals, which were recrystallized from ethanol to give 0.15 g (33%) of 1,2,3,4,5-penta-*O*-acetyl-(1,2,4,5/3,6)-6-acetoxymethyl-1,2,3,4,5-cyclohexanepentol (**7**) as prisms: mp 170.5—171.5 °C; ^{1}H NMR ($CDCl_3$) δ=2.01 (6H, s), 2.02 (3H, s), 2.06 (6H, s), and 2.11 (3H, s) (OAc), 2.65 (1H, m, H-6), 4.11 (2H, d, J=3 Hz, C$\underline{H}_2$OAc), and 5.10—5.30 (5H, m, H-1, H-2, H-3, H-4, and H-5).

Found: C, 50.81; H, 5.88%. Calcd for $C_{19}H_{26}O_{12}$: C, 51.12; H, 5.87%.

Osmium Tetraoxide-oxidation of **6**. Compound **6** (0.62 g) was treated with osmium tetraoxide in *t*-butyl alcohol similarly as described in the preparation of **7**. The product was acetylated and then purified by a short column of alumina with chloroform. Recrystallization of the crude product from ethanol gave 0.62 g (70%) of DL-1,2,3,4-tetra-*O*-acetyl-(1,2,5/3,4)-5-acetoxymethyl-1,2,3,4-cyclohexanetetrol (**8**) as prisms: mp 105—106.5 °C; ^{1}H NMR ($CDCl_3$) δ=1.97 (6H, s), 2.01 (3H, s), 2.07 (3H, s), and 2.09 (3H, s) (OAc), 4.03 (2H, d, J=5 Hz, C$\underline{H}_2$OAc), 5.03 (1H, dd, J=3.5 and 10 Hz, H-4), and 5.03—5.36 (3H, m, H-1, H-2, and H-3); (Found: C, 52.87; H, 6.24%). It was identical with the compound (mp 106—107 °C) derived by the alternative route.[7]

The mother liquor of **8** was concentrated and the residue was chromatographed on a silica-gel column (15 g) with ethyl acetate–hexane (1 : 2) as an eluent. The first fraction (R_f 0.55) gave 12 mg (1.8%) of 2,6-diacetoxy-4-methylene-2,5-cyclohexadiene-1-one as an oil: ^{1}H NMR ($CDCl_3$) δ=2.04 (3H, s) and 2.23 (3H, s) (OAc), 4.94 (2H, s, C=C$\underline{H}_2$), and 7.08 (2H, s, H-3 and H-5). The second fraction (R_f 0.43) gave 19 mg (2.1%) of DL-(hydroxymethyl)-cyclohexanetetrol pentaacetate as an oil: ^{1}H NMR ($CDCl_3$) δ=1.93 (3H, s), 1.97 (3H, s), 2.00 (3H, s), 2.04 (3H, s), and 2.08 (3H, s) (OAc), 3.90 (1H, dd, J=3.5 and 11 Hz) and 4.09 (1H, dd, J=5 and 11 Hz) (C$\underline{H}_2$OAc). These compounds were not further characterized because of minute quantities.

Reaction of **4** *with Bromine in Acetic Acid and Acetic Anhydride.* An 1 : 3 mixture of acetic acid and acetic anhydride was heated at reflux for 2 h before use as a solvent. To a stirred solution of crude **4** (0.35 g) in the mixture of solvent (7 ml) was added dropwise 5% bromine-acetic acid (1.35 ml) at room temperature, and then the stirring was continued for 1.5 h. TLC indicated the formation of one major component (R_f 0.53), along with two mionr components (R_f 0.51 and 0.36) [irrigated two times in ethyl acetate–hexane (1 : 4)]. The reaction mixture was diluted with ethyl acetate, washed thoroughly with saturated sodium hydrogencarbonate, and dried. Evaporation of the solvent gave an oil, which was fractionated on a silica-gel column (30 g) with ethyl acetate–hexane (1 : 4) as an eluent.

The first fraction gave crystals, which were recrystallized

from ethanol to give 0.17 g (30%) of DL-1,2,3-tri-*O*-acetyl-(1/2,3,6)-6-bromo-4-bromomethyl-4-cyclohexene-1,2,3-triol (**9**) as prisms: mp 108.5—109 °C; ^{1}H NMR ($CDCl_3$) δ= 1.99 (3H, s), 2.08 (3H, s), and 2.13 (3H, s) (OAc), 3.87 (2H, s, C$\underline{H}_2$Br), 4.54 (1H, br dd, J=3 and 7.5 Hz, H-6), 5.02 (1H, dd, J=4 and 10.5 Hz, H-2), 5.63 (1H, dd, J= 7.5 and 10.5 Hz, H-1), 5.80 (1H, d, J=4 Hz, H-3), and 6.12 (1H, d, J=3 Hz, H-5).

Found: C, 36.18; H, 3.77; Br, 37.15%. Calcd for $C_{13}H_{16}Br_2O_6$: C, 36.48; H, 3.77; Br, 37.33%.

The second fraction gave 16 mg (3%) of DL-1,2,3-tri-*O*-acetyl-(1,6/2,3)-6-bromo-4-bromomethyl-4-cyclohexene-1,2,3-triol (**10**) as an oil: ^{1}H NMR ($CDCl_3$) δ=2.00 (3H, s), 2.08 (3H, s), and 2.12 (3H, s) (OAc), 3.84 (2H, s, C$\underline{H}_2$Br), 4.90—5.16 (2H, m, H-2 and H-6), 5.27—5.62 (1H, m, H-1), 5.86 (1H, d, J=4 Hz, H-3), and 6.15 (1H, d, J=4 Hz, H-5). Compound **10** was not stable enough to give satisfactory analytical data. The third fraction gave crystals, which were recrystallized from ethanol to give 26 mg (5%) of DL-1,2,3,4-tetra-*O*-acetyl-(1,2/3,4)-5-bromomethyl-5-cyclohexene-1,2,3-triol (**13**) as prisms: 120.5—121 °C; ^{1}H NMR ($CDCl_3$) δ=2.00 (3H, s), 2.02 (3H, s), 2.06 (3H, s), and 2.08 (3H, s) (OAc), 3.84 (2H, s, C$\underline{H}_2$Br), 5.20—5.50 (2H, m, H-2 and H-3), 5.63 (1H, br dd, J=2.5 and 5 Hz, H-1), 5.87 (1H, d, J=3 Hz, H-4), and 5.94 (1H, d, J=5 Hz, H-6).

Found: C, 43.98; H, 4.62; Br, 19.29%. Calcd for $C_{15}H_{19}BrO_8$: C, 44.25; H, 4.70; Br, 19.62%.

DL-*1,2,3,4-Tetra*-O-*acetyl-(1,2/3,4)-5-acetoxymethyl-5-cyclohexene-1,2,3,4-tetrol* (**14**). A mixture of **9** (0.30 g), silver acetate (0.13 g, 4 molar equiv.), and 90% aqueous acetic acid (10 ml) was stirred at room temperature for 20 h in the dark. The reaction mixture was filtered and the filtrate was concentrated to an oil, which was chromatographed on a silica-gel column (15 g) with 2-butanone-toluene (1 : 3) as an eluent. The main fraction gave 0.18 g (72%) of a mixture of 1,3,4- (**20a**) and 2,3,4-tri-*O*-acetyl-(1,2/3,4)-5-bromomethyl-5-cyclohexene-1,2,3,4-tetrol (**20b**) as an oil: ^{1}H NMR ($CDCl_3$) for **20a** δ=2.05 (3H, s), 2.06 (3H, s), 2.10 (3H, s), and 2.12 (3H, s) (OAc), 2.27—2.53 (1H, m, O$\underline{H}$), 3.81 (2H, s, C$\underline{H}_2$Br), 4.12 (1H, dd, J=4 and 9 Hz, H-2), 5.16—5.50 (2H, m, H-1 and H-3), 5.82 (1H, d, J=4 Hz, H-4), and 5.97 (1H, d, J=4 Hz, H-6). The signal due to the C-1 proton of **20b** appeared as a narrow multiplet at δ=4.43—4.54, of which intensity was estimated at *ca.* one third of that of **20a**.

Found: C, 42.39; H, 4.66; Br, 22.20%. Calcd for $C_{13}H_{17}BrO_7$: C, 42.76; H, 4.69; Br, 21.88%.

A 0.12 g portion of the mixture was treated with sodium acetate (30 mg) in 90% aqueous DMF (3 ml) for 8 h. The reaction mixture was diluted with ethyl acetate, washed with water, and dried. The residue was acetylated in the usual way and the product was purified by a short column of alumina with chloroform. The product was recrystallized from ethanol to give 63 mg (49%) of **14** as prisms: mp 118.5—119 °C; ^{1}H NMR ($CDCl_3$) δ=1.98 (3H, s), 2.00 (3H, s), and 2.06 (9H, s) (OAc), 4.45 (2H, br s, C$\underline{H}_2$-OAc), 5.36 (2H, m, H-2 and H-3), 5.55—5.80 (2H, m, H-1 and H-4), and 5.87 (1H, br d, J=5.5 Hz, H-6).

Found: C, 53.08; H, 5.80%. Calcd for $C_{17}H_{22}O_{10}$: C, 52.85; H, 5.74%.

DL-*1,2,3,4-Tetra*-O-*acetyl-(1,3,4/2)-5-acetoxymethyl-5-cyclohexene-1,2,3,4-tetrol* (**18**). A mixture of silver acetate (0.31 g, 4 molar equiv.) in acetic acid (6 ml) and acetic anhydride (6 ml) was refluxed for 2 h, and then **9** (0.20 g) was added to it, and the mixture was refluxed for 8 h. The reaction mixture was filtered and the filtrate was concentrated. The residue was chromatographed on a silica-gel column with ethyl acetate-hexane (1 : 1) as an eluent. The product was recrystallized from ethanol to give 79 mg (26%) of **18** as prisms: mp 93—94 °C; ^{1}H NMR ($CDCl_3$) δ=1.95 (3H, s), 2.00 (3H, s), 2.04 (6H, s), and 2.07 (3H, s) (OAc), 4.43 (2H, s, C$\underline{H}_2$OAc), 5.07 (1H, ddd, J=3.5, 8.5, and 12 Hz, H-2), 5.45 (1H, br d, J=8.5 Hz, H-1), 5.62 (1H, d, J=3.5 Hz, H-4), and 5.74 (1H, br s, H-6).

Found: C, 52.91; H, 5.72%. Calcd for $C_{17}H_{22}O_{10}$: C, 52.85; H, 5.74%.

DL-*1,2,3,4-Tetra*-O-*acetyl-(1,3,4/2)-5-bromomethyl-5-cyclohexene-1,2,3,4-tetrol* (**17**). A mixture of silver acetate (0.12 g, a molar equiv.), acetic acid (8 ml), and acetic anhydride (8 ml) was refluxed for 2 h, and then **9** (0.30 g) was added to it, and the mixture was refluxed for 2 h. The reaction mixture was processed as described in the preparation of **18**. The product was chromatographed on a silica-gel column with ethyl acetate-hexane (1 : 2) to give 0.14 g (48%) of **17** as an oil: ^{1}H NMR ($CDCl_3$) δ=1.97 (3H, s), 2.00 (3H, s), 2.04 (3H, s), and 2.10 (3H, s) (OAc), 3.83 (2H, s, C$\underline{H}_2$Br), 5.03 (1H, m, H-3), 5.42 (1H, d, J=7.5 Hz, H-2), 5.33—5.53 (1H, m, H-1), 5.79 (1H, d, J=3.5 Hz, H-4), and 5.83 (1H, br d, J=1.5 Hz, H-6).

Found: C, 44.42; H, 4.68; Br, 19.35%. Calcd for $C_{15}H_{19}BrO_8$: C, 44.25; H, 4.70; Br, 19.62%.

DL-*1,2,3-Tri*-O-*acetyl-(1,6/2,3)-6-azido-4-azidomethyl-4-cyclohexene-1,2,3-triol* (**11**). A mixture of **9** (0.30 g), sodium azide (0.18 g, 3 molar equiv.), and DMF (10 ml) was stirred at room temperature for 1 h. The reaction mixture was diluted with ethyl acetate, washed with water, and dried. Evaporation of the solvent gave an oil, which was purified by a silica-gel column (7 g) with ethyl acetate-hexane (1 : 2) to give crystals. Recrystallization from ethanol gave 0.17 g (67%) of **11** as needles: mp 80—81 °C; ^{1}H NMR ($CDCl_3$) δ=2.00 (3H, s), 2.07 (3H, s), and 2.12 (3H, s) (OAc), 2.75 (2H, s, C$\underline{H}_2N_3$), 4.30—4.55 (1H, br s, H-6), 5.33 (2H, br s, H-1 and H-2), 5.61 (1H, br s, H-3), and 5.86 (1H, br d, J=4.5 Hz, H-5).

Found: C, 44.15; H, 4.60; N, 23.55%. Calcd for $C_{13}H_{16}N_6O_6$: C, 44.32; H, 4.58; N, 23.85%.

DL-*1,2,3-Tri*-O-*acetyl-(1,6/2,3)-6-acetamido-4-acetamidomethyl-4-cyclohexene-1,2,3-triol* (**12**). Compound **11** (0.11 g) was dissolved in a mixture of pyridine (4 ml) and water (4 ml), and hydrogen sulfide was bubbled into it at room temperature for 1 h. Excess hydrogen sulfide was removed by a nitrogen stream and then the reaction mixture was concentrated. The residual product was acetylated in the usual way and the product was chromatographed on a silica-gel column (5 g). The column was eluted in turn with toluene and with ethanol-toluene (1 : 3). The product was recrystallized from acetone to give 95 mg (78%) of **12** as prisms: mp 224—225 °C; ^{1}H NMR (DMSO-d_6) δ=1.77 (6H, s), 1.88 (3H, s), 1.90 (3H, s), and 2.00 (3H, s) (NAc and OAc), 3.59 (2H, br d, J=5.5 Hz, C$\underline{H}_2$-NHAc), 4.68 (1H, br dt, J=4.5, 4.5, and 9 Hz, H-6), 4.95 (1H, dd, J=4.5 and 10.5 Hz, H-1), 5.22 (1H, dd, J=4 and 10.5 Hz, H-2), 5.36 (1H, d, J=4 Hz, H-3), 5.51 (1H, br d, J=4.5 Hz, H-5), and 7.80—8.00 (2H, m, N$\underline{H}$Ac).

Found: C, 52.51; H, 6.21; N, 7.19%. Calcd for $C_{17}H_{24}N_2O_8$: C, 53.12; H, 6.29; N, 7.29%.

DL-*1,2,3,4-Tetra*-O-*acetyl-(1,2/3,4)-5-azidomethyl-5-cyclohexene-1,2,3,4-tetrol* (**15**). A mixture of **20a** and **20b** (0.18 g) was treated with sodium azide (65 mg, 2 molar equiv.) in DMF (5 ml) at room temperature for 2.5 h. The reaction mixture was processed as described in the preparation of **11**. The product, after the conventional acetylation, was purified by

crystallization from ethanol to give 0.13 g (69%) of **15** as prisms: mp 109.5—110 °C; ^{1}H NMR ($CDCl_3$) δ=1.98 (3H, s), 2.00 (3H, s), 2.04 (3H, s), and 2.06 (3H, s) (OAc), 3.74 (2H, s, C$\underline{H}_2N_3$), 5.33 (2H, m, H-2 and H-3), 5.50—5.73 (2H, m, H-1 and H-4), and 5.86 (1H, br d, J=4.5 Hz, H-6).

Found: C, 48.99; H, 5.17; N, 11.56%. Calcd for $C_{15}H_{19}N_3O_8$: C, 48.78; H, 5.19; N, 11.38%.

DL-*1,2,3,4-Tetra*-O-*acetyl-(1,3,4/2)-5-azidomethyl-5-cyclohexene-1,2,3,4-tetrol* (**19**). Compound **17** (0.14 g) was treated with sodium azide (44 mg, 2 molar equiv.) in DMF (5 ml) at room temperature for 18 h. The reaction mixture was processed as described in the preparation of **11** to give 73 mg (59%) of **19** as an oil: ^{1}H NMR ($CDCl_3$) δ=1.98 (3H, s), 2.03 (3H, s), 2.09 (3H, s), and 2.14 (3H, s) (OAc), 3.79 (2H, s, C$\underline{H}_2N_3$), 5.11 (1H, m, H-3), 5.50 (1H, d, J=7 Hz, H-2), 5.35—5.60 (1H, m, H-1), 5.64 (1H, d, J=3.5 Hz, H-4), and 5.88 (1H, br s, H-6).

Found: C, 48.60; H, 5.26; N, 11.12%. Calcd for $C_{15}H_{19}N_3O_8$: C, 48.78; H, 5.19; N, 11.38%.

DL-*1,2,3,4-Tetra*-O-*acetyl-(1,2/3,4)-5-acetamidomethyl-5-cyclohexene-1,2,3,4-tetrol* (**16**). Compound **15** (61 mg) was reduced with hydrogen sulfide as described in the preparation of **12**. The product was acetylated in the usual way. Recrystallization of the crude crystals from ethanol gave 33 mg (52%) of **16** as prisms: mp 181—182 °C; ^{1}H NMR ($CDCl_3$) δ=1.99 (3H, s), 2.01 (6H, s), 2.06 (3H, s), and 2.09 (3H, s) (NAc and OAc), 3.85 (2H, d, J=6 Hz, C$\underline{H}_2$NHAc, changing to a singlet on deuteration), 5.37 (2H, m, H-2 and H-3), 5.51—5.81 (4H, m, H-1, H-4, H-6, and N$\underline{H}$).

Found: C, 53.12; H, 6.06; N, 3.46%. Calcd for $C_{17}H_{23}NO_9$: C, 52.98; H, 6.02; N, 3.64%.

DL-*1,2,3-Tri*-O-*acetyl-(1,6/2,3)-* (**22a**) *and -(1/2,3,6)-4-acetoxymethyl-6-azido-4-cyclohexene-1,2,3-triol* (**22b**). A mixture of **9** (0.20 g), sodium acetate (38 mg, a molar equiv.), and DMF (5 ml) was stirred at room temperature for 38 h. TLC indicated the disappearance of **9** (R_f 0.48) and the formation of one major component [R_f 0.33, ethyl acetate-hexane (1 : 2)]. The reaction mixture was diluted with ethyl acetate and washed with water and dried. Evaporation of the solvent gave an oil, which was chromatographed on a silica-gel column with ethyl acetate-hexane (1 : 2) to give 0.13 g (67%) of a mixture of the 6-bromo compounds (**21a** and **21b**) as an unstable oil. Without further purification, these compounds were used in the next step.

A 0.13 g portion of the mixture was treated with sodium azide (41 mg, 2 molar equiv.) in DMF (5 ml) at room temperature for 19 h. The reaction mixture was processed as described above and the product was purified by use of a silica-gel column with ethyl acetate-hexane (1 : 2) to give 85 mg (74%) of a mixture of the azides (**22a** and **22b**) as a pale yellow oil: ^{1}H NMR ($CDCl_3$) δ=1.98, 1.99, 2.01, 2.02, 2.03, and 2.07 (12H, six s, OAc), 3.90—4.50 (1H, m, H-6), 4.44 (2H, s, C$\underline{H}_2$OAc), 4.98 (0.5H, dd, J=3.5 and 11 Hz, H-2 of **22a**), 5.27—5.48 (1.5 H, m, H-1 and H-2), 5.56—5.71 (1H, m, H-3), and 5.73—5.90 (1H, m, H-5).

Found: C, 48.75; H, 5.27; N, 11.36%. Calcd for $C_{15}H_{19}N_3O_8$: C, 48.78; H, 5.19; N, 11.38%.

The authors wish to express their thanks to Mr. Saburo Nakada for elemental analyses.

Restricted Rotation Involving the Tetrahedral Carbon. IL. Singly *peri*-Substituted 9-Isopropyltriptycenes Revisited[1)]

Gaku YAMAMOTO and Michinori ŌKI*

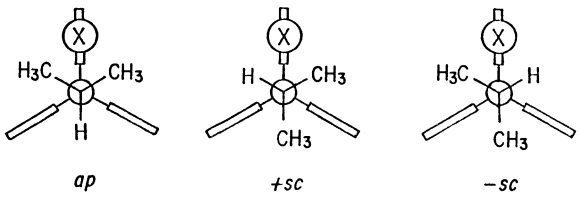
Department of Chemitsry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received March 16, 1983)

9-Isopropyltriptycene derivatives carrying a fluoro, chloro, bromo, or *t*-butyl substituent in a *peri*-position were synthesized and their dynamic NMR behavior was studied to see the dependence of the barrier to rotation of the bridgehead substituent upon the bulkiness of the *peri*-substituent. The data obtained in this work together with those reported earlier disclose that, among the derivatives in which the *peri*-substituent is not buttressed by the 2-substituent, the *peri*-methoxy compound has the highest barrier and the barrier decreases as the bulkiness of the *peri*-substituent increases. 1,2,3,4-Tetrachloro and tetrabromo derivatives show the slightly positive buttressing effect.

In 1974, we reported the rotational barriers in a *peri*-unsubstituted 9-isopropyltriptycene (**1**) and several singly *peri*-substituted derivatives (**2**—**5**).[2)] The data are included in Table 2 and Fig. 1. One of the interesting features is that the barrier heights have no apparent correlation with the bulkiness of the *peri*-substituent as judged from the van der Waals radii of the groups. The low barrier of **3** was ascribed to the gearing of the *peri*-methyl group[2)] but the explanation was criticized that the results could be interpreted on the basis of the buttressing effect.[4)]

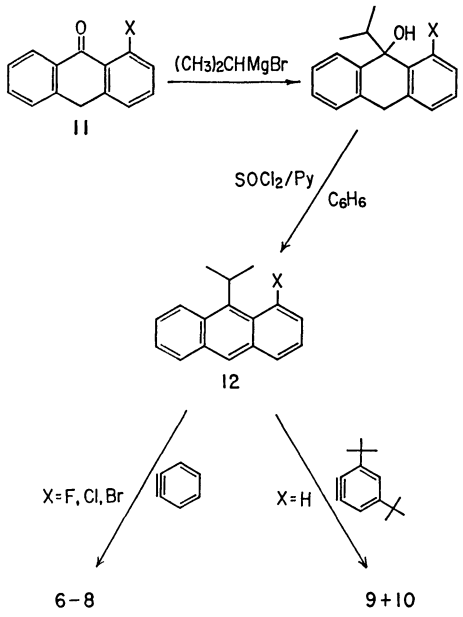
	X	Y	Z	W
1	H	CH_3	H	CH_3
2	OCH_3	H	H	OCH_3
3	CH_3	H	H	CH_3
4	Cl	Cl	Cl	Cl
5	Br	Br	Br	Br
6	F	H	H	H
7	Cl	H	H	H
8	Br	H	H	H
9	t-Bu	H	t-Bu	H
10	H	t-Bu	H	t-Bu



In view of the intriguing dependence of the rotational barriers in singly *peri*-substituted 9-(1,1-dimethyl-2-phenylethyl)triptycenes upon the *peri*-substituents, in which the *peri*-fluoro derivative has the highest barrier in the series,[5,6)] a reexamination of the rotational barriers in 9-*s*-alkyltriptycenes will be of value. 9-Isopropyltriptycenes exhibited a plateau in the diagram of the rotational barrier *vs.* the bulkiness of the *peri*-substituent.[2)] Other 9-*s*-alkyltriptycenes hitherto studied appear to give the maximal barriers in the 1,2,3,4-tetrachloro or tetrabromo derivatives.[7)] However it is desirable to erase the buttressing effect if we wish to discuss the relationship between the rotational barrier and the bulkiness of the *peri*-substituent in any detail. Such a work will also constitute a partial answer to the criticism for neglecting the buttressing effect.[4)] We therefore prepared 1-halo-9-isopropyltriptycenes (**6**—**8**) and determined the barriers to rotation in these compounds to compare with those in the tetrahalo counterparts **4** and **5**. In order to see the effect of an extremely bulky *peri*-substituent, the 1-*t*-butyl derivative (**9**) was also prepared.

Results and Discussion

1-Halo-9-isopropyltriptycenes (**6**—**8**) were synthesized by reactions of benzyne with 1-halo-9-isopropylanthracenes (**12**: X=F, Cl, and Br), which were prepared by Grignard reactions of isopropylmagnesium bromide with 1-haloanthrones (**11**) followed by dehydration. The reaction of 3,5-di-*t*-butylbenzyne[8)] with **12** (X=H) afforded two isomeric 9,10-adducts, **9** and **10**, in a ratio of *ca.* 1:2, which were separated by liquid chromatography.



NMR Spectra and Rotamer Distributions. ^1H NMR spectral data of compounds **6**—**10** taken in chloroform-*d* at *ca.* 35 °C are given in Table 1. Rotation about the bridgehead-to-substituent bond in these compounds is sufficiently slow on the NMR time scale under these conditions to observe the signals due to the diastereotopic methyl groups separately.

Compound **6** carrying a fluoro substituent in a *peri*-position is shown by NMR spectroscopy to exist in

Table 1. ^{1}H NMR data in $CDCl_3$ at *ca.* 35 °C[a)]

a) Chemical shifts are given in δ. Signals are singlets unless otherwise noted; d: doublet, dd: double doublet, sep: septet, d sep: double septet. In parentheses are coupling constants in Hz. Those in italics are couplings with ^{19}F. b) Presumably a doublet. Obscured by overlap with the signal due to $\pm sc$.

two rotameric states, *ap* and $\pm sc$. ^{19}F NMR spectrum of **6** exhibits a small peak at 58.9 ppm downfield from internal hexafluorobenzene together with a large peak at 49.7 ppm with an intensity ratio of 1:9. The ^{1}H NMR spectrum of **6** is complex not only because of the existence of two rotamers but also due to the presence of long-range ^{1}H-^{19}F spin-spin couplings. The methyl protons of the isopropyl group of the major rotamer appear as two sets of double doublets suggesting the diastereotopicity of the two methyl groups, while those of the minor rotamer as a double doublet reflecting the enantiotopicity of the methyl groups. These features clearly show that the major isomer is the $\pm sc$ rotamer and the minor *ap*. The existence of the *ap* rotamer in **6** should be a reflection of the small bulkiness of the *peri*-fluoro group, because the *ap* rotamer is not detected if the *peri*-substituent is bulkier than fluorine: Methyl protons of the isopropyl group in compounds **7**—**9** appear as a pair of equally intense doublets, indicating that these compounds reside solely in the $\pm sc$ rotamer.

Compound **10** lacking a *peri*-substituent shows two singlets with an intensity ratio of 2.1:1 for each of the *t*-butyl groups indicating the existence of the $\pm sc$ and *ap* rotamers in almost a statistical ratio. The slight preference for the $\pm sc$ rotamer may be due to the larger effective bulkiness of the 1-hydrogen than the other *peri*-hydrogens because of the buttressing effect of the 2-*t*-butyl group.

Dynamic NMR Studies. The double doublet signal for the isopropyl methyl groups of compounds **7**—**9** broadened and coalesced into a doublet upon raising the temperature. Rate constants (k_c) for the $+sc \rightleftharpoons -sc$ interconversion at the coalescence temperatures (T_c) were obtained graphically according to Jaeschke *et al.*,[9)] regarding the signal as two overlapping sets of mutually coalescing singlets. The coalescence phenomenon of the *t*-butyl signals in compound **10** gave the rate constants for the $ap \rightleftharpoons \pm sc$ interconversion at two temperatures. The kinetic data obtained are compiled in Table 2 together with those obtained before, some of which are recalculated to express in terms of the free energies of activation at the coalescence temperatures.

As for the methyl signals in **6**, three overlapping sets of double doublets coalesce into a double doublet on elevation of the temperature by two processes of $+sc \rightleftharpoons -sc$ and $ap \rightleftharpoons \pm sc$. The change should therefore be analyzed as a three-site exchange problem of an eight-spin system ($A_3B_3MX \rightleftharpoons B_3A_3MX \rightleftharpoons C_6KY$). Such an analysis was beyond the capacity of the computer simulation program available[10)] and was abandoned. Neglecting the presence of a small amount of the *ap* rotamer and simulating the spectra as a mutually exchanging four spin system (ABMX$\rightleftharpoons$BAMX) gave a rough estimate of the barrier to the $+sc \rightleftharpoons -sc$ interconversion as 22—23 kcal mol^{-1} (1 cal=4.184 J) at the temperature range of 110—150 °C.

The dependence of the barrier in **1**—**10** on the bulkiness of the *peri*-substituent as represented by the van der Waals radii is shown in Fig. 1. Although the data for **1** were obtained by observing the $ap \rightleftharpoons \pm sc$ process, the barrier height should not differ significantly from that for the $+sc \rightleftharpoons -sc$ process, because the two processes should have the identical barrier height in the absence of the buttressing effect by the 2-substituent; the buttressing effect of the 2-methyl group is negligible. Points for the unbuttressed compounds form a flat curve with a maximum at the *peri*-methoxy compound (**2**) and those for the tetrahalo compounds (**4** and **5**) deviate upward from the curve manifesting the positive buttressing effect.

Appearance of a maximum at a rather small *peri*-substituent is a similar trend as was found in 9-(1,1-dimethyl-2-phenylethyl)triptycene derivatives,[5)] although the variation of the barrier heights is far smaller. It can therefore be inferred that the lowering of the barrier height with a bulky *peri*-substituent is not a special phenomenon exhibited only by 9-*t*-alkyl derivatives but is also observable in 9-*s*-alkyltriptycenes.

As discussed in some detail in the previous paper,[5)]

TABLE 2. DYNAMIC NMR DATA[a)]

a) Data for **1** and **10** refer to the $ap \rightarrow \pm sc$ process, and those for the others to the $+sc \rightleftarrows -sc$ process. b) According to Charton: M. Charton, *J. Am. Chem. Soc.*, **91**, 615 (1969). c) Reliable to ± 0.1 kcal mol^{-1}, which comes from the uncertainty of ± 2 °C for determination of T_c. d) TCE: Tetrachloroethylene. HCB: Hexachloro-1,3-butadiene. e) Calculated using ΔH^{*} and ΔS^{*} values reported in Ref. 2. f) Values in the upper row are obtained from the higher field pair of the *t*-butyl signals due presumably to the one at 2-position. g) Re-evaluated. *cf.* Ref. 7a. h) $(r_{v,min}+r_{v,max})/2$.

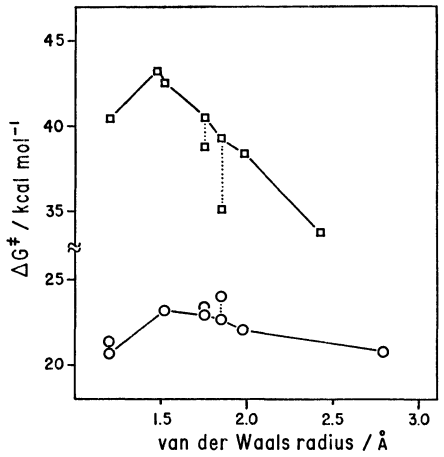

Fig. 1. Dependence of the rotational barriers on the bulkiness of the *peri*-substituent. ○: ΔG_c^{*} for 1-substituted 9-isopropyltriptycenes. □: ΔG_{500}^{*} for 1-substituted 9-(1,1-dimethyl-2-phenylethyl)triptycenes. Points for the unbuttressed compounds are connected by a solid line. Points deviated from the lines are those for the buttressed derivatives.

the phenomenon seems to be partly explained in terms of the molecular deformation in highly congested systems which causes the lesser stabilization of the transition state for rotation than the ground state upon introduction of a bulky *peri*-substituent. Because the congestion in the 9-*s*-alkyl series is considerably smaller than that in the 9-*t*-alkyl one, even such a bulky *peri*-substituent as a *t*-butyl group destabilizes the ground and the transition states rather similarly, resulting in only a small decrease in the barrier.

The small positive buttressing effect found in **4** and **5** is in sharp contrast with the large negative effect found in 1,2,3,4-tetrachloro- and tetrabromo-9-(1,1-dimethyl-2-phenylethyl)triptycenes.[6)] In the less congested system, the transition state may be destabilized to a greater extent than the ground state upon introduction of the buttressing substituent reflecting the increased rigidity of the 1-halogen substituent.

The barrier to the $ap \rightleftarrows \pm sc$ process in the 2,4-di-*t*-butyl derivative (**10**) is somewhat higher than that in the 2,4-dimethyl one (**1**). This may be ascribed to the positive buttressing effect on the 1-hydrogen exerted by the 2-*t*-butyl group. The $+sc \rightleftarrows -sc$ barrier in **10** may be slightly lower than the $ap \rightleftarrows \pm sc$ barrier because the 1-hydrogen eclipses the methyl group in the latter process while it eclipses the methine hydrogen in the former.

We have made it clear through our investigation on the dependence of the rotational barrier of the 9-substituent of triptycene systems upon the *peri*-substitution that the barrier height does not always increase with the bulkiness of the *peri*-substituent and shows a rather complex behavior. This comes from the fact that *peri*-substituents affect not only the transition state for rotation but also the ground state in congested sp^3–sp^3 systems. This is quite different from the cases in sp^2–sp^2 systems in which substituents close to the rotating bond does not significantly affect the ground state energy of the system and even a quantitative correlation between the barrier heights and the bulkiness of the substituents can be made.[11)]

From the data presented above, the low barrier to rotation in the 1,4-dimethyl compound (**3**) can be attributed to the raise of the ground state energy, although the possibility of gearing is not completely erased.

Experimental

Melting points are not corrected. The routine ^1H and ^{19}F NMR spectra were recorded on a Varian EM-390 spectrometer at 90.0 and 84.67 MHz, respectively, at *ca.* 35 °C. ^{19}F chemical shifts are shown in ppm downfield from internal hexafluorobenzene. Variable temperature ^1H NMR spectra were obtained on a Hitachi R-20B spectrometer operating at 60.0 MHz. Temperatures were calibrated by using an ethylene glycol sample.[12)] High performance liquid chromatography was carried out on a Waters M6000A system using a Microporasil semipreparative column with

hexane as an eluent.

*1-Bromoanthrone (**11**: X=Br).* To a magnetically stirred solution of 2.87 g (10.0 mmol) of 1-bromoanthraquinone in 50 mL of concentrated sulfuric acid was added portionwise 1.0 g of aluminium powder. The mixture was stirred at room temperature for 20 h and poured onto ice. The solid formed was collected by filtration, washed with water and dried in air. Recrystallization from benzene-hexane gave 1.71 g (63%) of **11** (X=Br) as yellow crystals, mp 129—130 °C. Found: C, 61.35; H, 3.18; Br, 29.72%. Calcd for $C_{14}H_9BrO$: C, 61.56; H, 3.32; Br, 29.26%. ^{1}H NMR ($CDCl_3$, δ): 4.31 (2H, s), 7.2—7.7 (6H, m), 8.24 (1H, s).

*General Procedure for Preparation of 1-Halo-9-isopropylanthracenes (**12**).* To an ethereal solution of the Grignard reagent prepared from 1.0 g (8.1 mmol) of isopropyl bromide was added portionwise 3.0 mmol of 1-haloanthrone. The mixture was stirred under reflux for 1 h and decomposed with aqueous ammonium chloride to afford 1-halo-9,10-dihydro-9-isopropyl-9-anthrol. The alcohol was, without further purification, heated with 1.5 mL of thionyl chloride and 3 mL of pyridine in 50 mL of benzene for 15 min. The reaction mixture was washed with water and dried over magnesium sulfate. Column chromatography on alumina with hexane as an eluent gave the desired anthracene as a yellow oil, which was used in the subsequent reaction.

*1-Fluoro-9-isopropylanthracene (**12**: X=F)* was obtained from 1-fluoroanthrone[5] in 38% yield by way of 1-fluoro-9,10-dihydro-9-isopropyl-9-anthrol [^{1}H NMR ($CDCl_3$, δ): 0.65 (3H, dd, J=6.8 and 0.6 Hz), 0.92 (3H, dd, J=6.8 and 1.2 Hz), 2.14 (1H, m), 3.21 (1H, br s), 3.90 (2H, s), 6.7—8.1 7H, m)]. ^{1}H NMR ($CDCl_3$, δ): 1.67 (6H, dd, J=7.3 and 2.4 Hz), 4.71 (1H, d sept, J=7.3 and 5.0 Hz), 6.8—8.7 (8H, m).

*1-Chloro-9-isopropylanthracene (**12**: X=Cl)* was obtained from 1-chloroanthrone[13] in 33% yield by way of 1-chloro-9,10-dihydro-9-isopropyl-9-anthrol [^{1}H NMR ($CDCl_3$, δ): 0.54 (2H, d, J=6.7 Hz), 1.03 (3H, d, J=6.9 Hz), 2.50 (1H, sept, J=6.8 Hz), 3.73 (1H, br s), 3.95 (2H, s), 6.8—8.0 (7H, m)]. ^{1}H NMR ($CDCl_3$, δ): 1.70 (6H, d, J=7.0 Hz), 5.07 (1H, sept, J=7.0 Hz), 7.0—8.0 (6H, m), 8.17 (1H, s), 8.4—8.6 (1H, m).

*1-Bromo-9-isopropylanthracene (**12**: X=Br)* was obtained from 1-bromoanthrone in 35% yield by way of 1-bromo-9,10-dihydro-9-isopropyl-9-anthrol [^{1}H NMR ($CDCl_3$, δ): 0.49 (3H, d, J=7.0 Hz), 1.01 (3H, d, J=7.0 Hz), 2.54 (1H, sept, J=7.0 Hz), 3.10 (1H, br s), 3.83 and 4.00 (2H, AB-q, J=19.5 Hz), 6.8—8.3 (7H, m)]. ^{1}H NMR ($CDCl_3$, δ): 1.70 (6H, d, J=7.2 Hz), 5.13 (1H, sept, J=7.2 Hz), 6.9—8.0 (6H, m), 8.15 (1H, s), 8.4—8.6 (1H, m).

*General Procedure for Preparation of 1-Halo-9-isopropyltriptycenes (**6**—**8**).* To a boiling solution of 3.0 mmol of 1-halo-9-isopropylanthracene (**12**) and 1.5 mL of isopentyl nitrite in 30 mL of 1,2-dimethoxyethane (DME) was added a solution of 1.0 g (7.3 mmol) of anthranilic acid in 15 mL of DME during the course of 1 h and the mixture was heated under reflux for 1 h. Column chromatography on alumina with hexane as an eluent followed by recrystallization from tetrahydrofuran-hexane gave the desired triptycene as colorless crystals.

*1-Fluoro-9-isopropyltriptycene (**6**)* was obtained from **12** (X=F) in 74% yield, mp 202—203 °C. Found: C, 87.89; H, 5.80%. Calcd for $C_{23}H_{19}F$: C, 87.87; H, 6.09%. ^{19}F NMR ($CDCl_3$): 49.65 (m, $\pm sc$), 58.86 (m, *ap*).

*1-Chloro-9-isopropyltriptycene (**7**)* was obtained from **12** (X=Cl) in 32% yield, mp 178—180 °C. Found: C, 83.33; H, 5.49; Cl, 10.83%. Calcd for $C_{23}H_{19}Cl$:C, 83.50; H, 5.79; Cl, 10.71%.

*1-Bromo-9-isopropyltriptycene (**8**)* was obtained from **12** (X=Br) in 60% yield, mp 211—213 °C. Found: C, 73.87; H, 5.25; Br, 21.17%. Calcd for $C_{23}H_{19}Br$: C, 73.60; H, 5.10; Br, 21.30%.

*1,3-Di-t-butyl-9-isopropyltriptycene (**9**) and 2,4-Di-t-butyl-9-isopropyltriptycene (**10**).* To a boiling solution of 683 mg (3.1 mmol) of 9-isopropylanthracene (**12**: X=H)[14] and 1 mL of isopentyl nitrite in 20 mL of DME was added dropwise a solution of 1.10 g (4.4 mmol) of 3,5-di-*t*-butylanthranilic acid[8] in 20 mL of DME during the course of 1.5 h and the mixture was heated under reflux for 1 h. ^{1}H NMR spectrum of the crude reaction mixture indicated the presence of **9** and **10** in a ratio of *ca.* 1:2. Separation of the isomers was affected by liquid chromatography. The 2,4-di-*t*-butyl derivative (**10**) eluted faster than the other isomer and was recrystallized from tetrahydrofuran-ethanol, mp 170—172 °C. Found: C, 90.95, H, 8.94%. Calcd for $C_{31}H_{36}$: C, 91.12; H, 8.88%. The 1,3-di-*t*-butyl derivative (**9**) was recrystallized from dichloromethane-hexane, mp 202—204 °C. Found: 91.34; H, 9.04%. Calcd for $C_{31}H_{36}$: C, 91.12; H, 8.88%.

The Adsorption of Chloromethanes on KCl. The Role of the Surface Ions as Adsorption Sites

Masatoshi Chikazawa, Masatoshi Amada, and Takafumi Kanazawa*

Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158

(Received September 6, 1982)

The adsorbed amounts of chloro-substituted methanes, such as CH_2Cl_2, $CHCl_3$, and CCl_4, for KCl particles were measured by a volumetric method at various temperatures, and the isosteric heats of adsorption and differential entropies of the adsorbed molecules were estimated from the adsorption isotherms. The order of magnitude of the heats of adsorption at a coverage of $\theta=0.5$ was found to be $CH_2Cl_2>CHCl_3>CCl_4$. Moreover, a plot of the dipole moments of the three adsorbates *vs.* the adsorption heat values gave a straight line. Therefore, the differences among the adsorption heats of the three adsorbates is mainly caused by an orientation of their dissimilar dipoles to the surface. It may be concluded that the chloro-substituted methanes are adsorbed on surface anions of KCl powder.

Alkali halide crystals are used as adsorbents to investigate various adsorption phenomena, because of their simple surface structure and a regular configuration of the surface ions. Many theoretical calculations have been carried out about the heats of adsorption of nonpolar gasses on alkali halides.[1-3] On the other hand, in cases of polar substances, such heat calculations have been made for only a few systems,[4] and the subjects concerning adsorption sites, *i.e.* the role of surface ions in their adsorptions has not yet been resolved.

In the present study, the adsorbed amounts of chloro-substituted methanes, such as $CHCl_3$, CH_2Cl_2, and CCl_4, on KCl particles were measured at various temperatures, and the isosteric heats of adsorption and the differential entropies of the adsorbed molecules were calculated from the adsorption isotherms obtained. The adsorption characteristics of chloro-substituted methanes are discussed in relation to the dipole moments and the cross-sectional areas of the polar adsorbates.

Experimental

Materials. Potassium chloride was purified by twice recrystallization of special-grade reagents using distilled water. An aqueous solution of KCl was added to about a five-fold volume of ethanol cooled to −80—−90 °C with stirring. The sample thus obtained was filtered and washed four times with absolute ethanol and then dried at a reduced pressure of 1.33×10^{-1} Pa. This precipitate was found to be very small cubic crystals (≈5 μm) by electron microscopy. The sample was evacuated with an oil diffusion pump under a reduced pressure of 1.33×10^{-4} Pa for 20—30 h at room temperature prior to the adsorption measurements. The three adsorbates were purified by twice distillation of the respective special-grade reagents, and their purities were confirmed to be apporoxymatly 100% by gas chromatography.

Adsorption Measurement. The apparatus for measuring adsorbed amounts was reported previously by the present authors.[5] The equilibrium pressures of the adsorbates were determined using a mercury manometer and a reading magnifier with a resolution of 10 μm.

Surface Area Measurement. The specific surface areas of the samples were determined prior to the adsorption measurements of the chloro-substituted methanes by applying the BET equation to the nitrogen-adsorption data obtained at 77 K, assuming the cross-sectional area of a nitrogen molecule to be 16.2 Å^2. The obtained values were about 0.21 m^2/g.

Results and Discussion

Adsorption Isotherms. The adsorption isotherms of CH_2Cl_2 on KCl are given in Fig. 1. In this case, a linear BET plot was not obtained in the BET region. On the other hand, the adsorption isotherms at adsorbed amounts above 0.13 cm^3 STP/m^2 gave a straight line with increasing pressure, and the point "B" showing a monolayer completion was determined easily. The capacity of the monolayer adsorption was estimated to be 0.13 cm^3 STP/m^2. This value is slightly smaller than the monolayer capacity (0.15 cm^3 STP/m^2) which is calculated from the cross-sectional area (24.3 Å^2) of CH_2Cl_2 and the surface area obtained by N_2 adsorption, assuming that the sample surface is covered with the close-packed monolayer. The cross-sectional area is estimated from the liquid density of CH_2Cl_2 at the measurement temperature. The relative vapor pressure at the point B was higher, compared with the values determined from the adsorptions of polar substances such as CH_3OH,[6] $(CH_3)_2CO$,[7] and H_2O.[8]

The isosteric heats of CH_2Cl_2 adsorption and the differential entropies of the adsorbed molecules are shown in Fig. 2. The latter values are calculated by Eq. 1, where $\overline{S_s}$, S, and S_g are the differential entropy of the adsorbed molecule on KCl, molar entropies

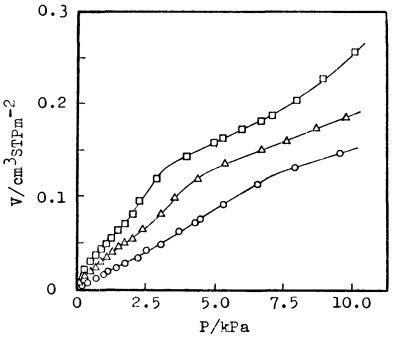

Fig. 1. Adsorption isotherms of CH_2Cl_2 on KCl. Temperature/°C: □: −6, △: 0, ○: 10,

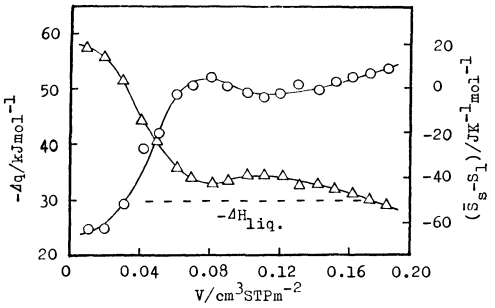

Fig. 2. Isosteric heat of CH_2Cl_2 adsorption and differential entropy of CH_2Cl_2 adsorbed on KCl.
△: Isosteric heat of adsorption, ○: differential entropy.

of liquid adsorbate and vapor molecule, respectively, A is the heat of vaporization and x a relative vapor pressure.

$$(\bar{S}_s - S_l) = (\bar{S}_s - S_g) + A/T - R \ln x \quad (1)$$

The adsorption heat at low coverage was found to be large, but it decreased rapidly with adsorbed amounts. A peak was observed at $V=0.12$ cm³ STP/m². This value is nearly equal to the monolayer capacity described above. Therefore, the appearance of such a peak can be explained in terms of a lateral interaction among the adsorbed molecules. A slightly stepwise rise recognized in the isotherm before the monolayer completion may be also due to this lateral interaction.

On the other hand, the differential entropies obtained in the region of the adsorbed amount 0—0.06$_5$ cm³ STP/m² were smaller than the molar entropy of liquid CH_2Cl_2 at the measurement temperature, and at the adsorbed amounts above 0.06$_5$ cm³ STP/m² the entropy values were approximately equal to the molar entropy of liquid CH_2Cl_2. The former result shows that CH_2Cl_2 molecules are adsorbed strongly on the KCl surface and the mobility of the adsorbed molecules are restrained. Whereas, the latter fact indicates that the adsorbed molecules can move easily in the adsorbed layer as in liquid CH_2Cl_2. Figure 2 indicates a minimum at the monolayer completion in the entropy curve. Such change in the differential entropy corresponds to the existence of the lateral interaction described above.

Figure 3 shows the adsorption isotherms of $CHCl_3$ on KCl. The isosteric heat of $CHCl_3$ adsorption and the differential entropies of the adsorbed molecules are given in Fig. 4. The isotherms resembled in shape those obtained for the CH_2Cl_2 adsorption. A maximum was also recognized in the heat curve at about the monolayer completion ($V=0.11$ cm³ STP/m²). Therefore, it is considered that a lateral interaction will occur similarly as is shown in the case of CH_2Cl_2 adsorption. The differential entropies of adsorbed $CHCl_3$ at low coverage are larger than the molar entropy of liquid $CHCl_3$. This result is different from the case of CH_2Cl_2 adsorption.

The adsorption isotherms of CCl_4 on KCl are given

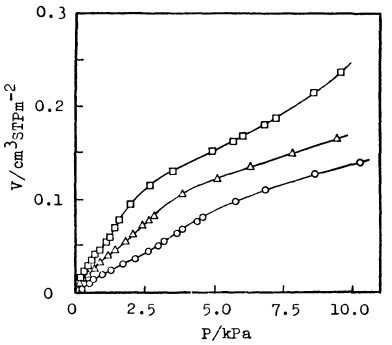

Fig. 3. Adsorption isotherms of $CHCl_3$ on KCl.
Temperature/°C: □: 10, △: 20, ○: 30.

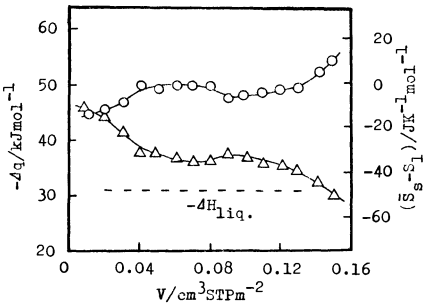

Fig. 4. Isosteric heat of $CHCl_3$ adsorption and differential entropy of $CHCl_3$ adsorbed on KCl.

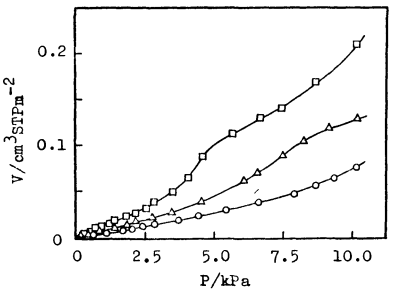

Fig. 5. Adsorption isotherms of CCl_4 on KCl.
Temperature/°C: □: 20, △: 30, ○: 40.

in Fig. 5. The isotherms were classified into the BDDT III type, judging only from their profile in the early stage $V<0.1$ cm³ STP/m². However, the point B was determined at a high vapor pressure and the monolayer capacity was obtained. According to the BDDT classification, an interaction between the surface of a KCl particle and CCl_4 molecules will be weaker than those in cases of CH_2Cl_2 and $CHCl_3$ adsorptions. In Fig. 6 the isosteric heats of CCl_4 adsorption and the differential entropies of the adsorbed molecules are shown. The adsorption heats at low coverages were determined precisely in this case on account of the large equilibrium pressures. As is shown in Fig. 6, the adsorption heat value at adsorbed amounts below 0.01 cm³ STP/m² is higher than the liquefaction heat of CCl_4 vapor, but it becomes less

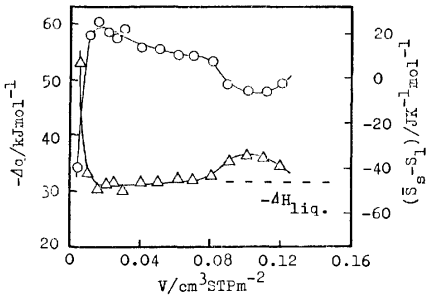

Fig. 6. Isosteric heat of CCl_4 adsorption and differential entropy of CCl_4 adsorbed on KCl.

Coverage (θ): △: 0.4, ○: 0.5.

than the liquefaction heat at amounts above 0.01 cm^3 STP/m^2. The latter result indicates that the interaction between the KCl surface and CCl_4 molecules is weak as described above. Such estimation of the surface property is supported by the fact that the differential entropy of adsorbed CCl_4 is larger than the molar entropy of liquid CCl_4. Then the adsorption heat increased gradually with the increment of the adsorbed amount and a peak produced by the lateral interaction was observed in the heat curve at V=0.11 cm^3 STP/m^2. This value is equal to the monolayer capacity obtained from the isotherm. Moreover, the height of the peak was the largest among the three adsorbates. However, the differential entropy at the monolayer completion is less than the molar entropy of liquid CCl_4 and shows a minimum. From these results, the lateral interaction in CCl_4 adsorption is considered to be stronger than those of CH_2Cl_2 and $CHCl_3$ adsorptions. For the two polar adsorbates, if the molecules are adsorbed on the KCl surface orienting their dipole moments to the surface at the monolayer completion, the lateral interaction will decrease owing to the repulsive forces generated by the dipole moments which are parallel oriented. On account of this effect, the height of the peak observed in the heat curve is expected to diminish in CH_2Cl_2 and $CHCl_3$ adsorptions.

The large heat of adsorption observed in the early stage indicates the existence of active sites on the salt surface. The fraction of the active sites on the KCl surface for CCl_4 adsorption is estimated to be about 9% of the total sites. In the case of NaF prepared by the same method in the present study, Yao[9] concluded that 4% of the total surface is active from the comparison of adsorption characteristics of four polar substances he used. This fact shows that such an assessment concerning the active sites on KCl surface is reasonable.

Adsorption Mechanism. The heats of adsorption of the three adsorbates for KCl surface are, for convenience, repeatedly shown in Fig. 7. At low coverage, the adsorption heats of the chloromethanes differ considerably from each other and the value is influenced by the dipole moment of the adsorbate molecule. To clarify this point, the heats of adsorption of chloromethanes at coverages of 0.4 and 0.5 are plotted in Fig. 8 as a function of the dipole moments of the adsorbates. The other polar substances, $(CH_3)_2CO$, CH_3OH and H_2O, are also given in this figure. A linear relationship was found between the heats of adsorption and the dipole moments, expect for $(CH_3)_2CO$ and H_2O. The present authors have clarified already that one CH_3OH molecule is adsorbed on a surface anion of KCl particles,[6] whereas one $(CH_3)_2CO$ molecule is adsorbed on a surface cation conversely.[7] The adsorption heat value of CH_3OH was plotted in the straight line. However, in case of $(CH_3)_2CO$ adsorption where the mechanism is different from that of CH_3OH adsorption, the plot deviates greatly from linearity. Therefore, we conclude that the adsorption of chloromethanes on a KCl surface will occur by a similar mechanism to that proposed for CH_3OH adsorption. In other words, chloromethanes having dipole moments are adsorbed on the surface anions orienting their dipoles to the KCl surface. For H_2O adsorption one water molecule is adsorbed on two adjacent surface anions.[8] The plot of heat of H_2O adsorption also deviates from a straight line on account of the difference of the adsorptive mechanism. Considering these results, it will be concluded that the surface anions or cations play an important role in the adsorptions of polar substances on a KCl surface and that the adsorptive mechanisms largely depend on the molecular structures of the adsorbates used.

IR Spectra of Solid State Reaction Products of TTF and Iodine

Susumu MATSUZAKI, Naoto KOGA, Ichiro MORIYAMA,
and Koichi TOYODA*

Department of Chemistry, Faculty of Science, Kumamoto University, Kumamoto 860

(Received October 12, 1982)

IR spectra of the mixture of tetrathiafulvalene (TTF) and iodine showed that the two components react with each other in the solid state. Spectral changes with an increase in iodine content were analyzed on the basis of the spectra of TTF and the cations, and it was found that TTF is oxidized by iodine up to the dication in the solid state in contrast to the reaction in solution.

Tetrathiafulvalene (TTF) is known to form good electric conductors with various organic acceptors, *e.g.*, tetracyano-*p*-quinodimethan (TCNQ). The high electrical conductivity of the organic charge transfer salts such as TTF–TCNQ arises from the segregated stack crystal structure and the mixed-valence ground electronic state.[1] Such charge transfer salts have two stacks of donors and acceptors, both of which can potentially conduct, so that considerable complexities are encountered in the analysis of the solid state properties. On the other hand, TTF forms good conductors also with some inorganic anions, *e.g.*, halogens, which have only donor stacks. The single stack compounds should in principle provide simpler model systems for study on the electrical conductivity.

Recently Scott *et al.*[2] studied the crystal chemistry and phase compositions of TTF–halide systems to determine the compositional phase diagrams and to relate them to the important questions of structure and stability of these compounds. They obtained the salts by the reaction in solution. However, all the possible phases of the system are not always obtained as solid precipitates by the method because of the solubilities and the equilibria between the species. Other preparation methods should, therefore, be tried to obtain the whole phase diagram. We found the solid state reaction of TTF–iodine system. In this report, the IR spectra of the reaction products are measured and some information on the compositional phase diagram is obtained from the analysis of the spectra.

Experimental

TTF was synthesized by the method of Wudl *et al.*,[3] and recrystallized twice from hexane–cyclohexane and sublimed *in vacuo*. Iodine was obtained commercially and sublimed *in vacuo* from potassium iodide. Solid state reaction products were obtained by mixing of TTF and iodine in an agate mortar for several minutes at room temperature. A ratio of iodine atoms to TTF molecules is represented by the symbol "*n*". Composition of the mixtures ranged from $n=0.2$ to 40. A mixed-valence salt, $TTF \cdot I_{0.7}$, was prepared by the mixing of the stoichiometric amounts of the components in acetonitrile, and recrystallized from the solvent. A cation salt, $TTF \cdot I_3$, was prepared by the dropwise addition of the acetonitrile solution of TTF into the solution of excess iodine, and recrystallized from the solvent. A dication salt, $TTF \cdot Br_x$, was also obtained by the similar dropwise method in acetonitrile, but the recrystallization was not feasible because of the poor solubility. Elemental analyses showed that $x=ca.$ 6; therefore, this salt is probably formulated as TTF^{2+} $(Br_3^-)_2$. All the sample prepared were dispersed in KBr, and the IR spectra were recorded on a JASCO DS-403G spectrometer.

Results and Discussion

IR spectra of TTF, $TTF \cdot I_{0.7}$, and $TTF \cdot I_3$ are shown in Fig. 1. The spectra of TTF and $TTF \cdot I_{0.7}$ agreed with those in the literature.[4,5] The spectrum of $TTF \cdot I_3$ also agreed with that of $TTF \cdot Br_{1.0}$ reported by Bozio *et al.*[4] except the small frequency shifts which are probably due to the difference in the counter ions. IR spectrum of $TTF(Br_3)_2$ is shown in Fig. 3a, which is similar to that of $TTF(BF_4)_2$ reported by Siedle *et al.*[6] except additional bands of BF_4^- in the latter. These results support the identification of the salts.

Of the features in these spectra, two absorption bands near 1500 and 1350 cm^{-1} are most suitable indications of the valence of TTF. The former, assigned to b_{1u} ν_{18} of TTF,[4] shows a large frequency shift with the change of the valence. The frequencies are: TTF, 1528 cm^{-1}; $TTF \cdot I_{0.7}$, 1500 cm^{-1}; $TTF \cdot I_3$, 1474 cm^{-1}; $TTF(Br_3)_2$, 1422 cm^{-1}. The other characteristic band near 1350 cm^{-1} is assigned to the out-of-phase combination mode of TTF a_g ν_3.[4] The vibronic interaction between the unpaired electron and the molecular vibration of TTF is responsible for the IR activity of this band;[4] therefore, the band appears only in the spectra of $TTF \cdot I_{0.7}$ and $TTF \cdot I_3$. The band of the former is much broader than that of the latter, and the two species, $TTF \cdot I_{0.7}$ and $TTF \cdot I_3$, are easily distinguished from the difference in the width. We analyze the IR spectrum of the solid state

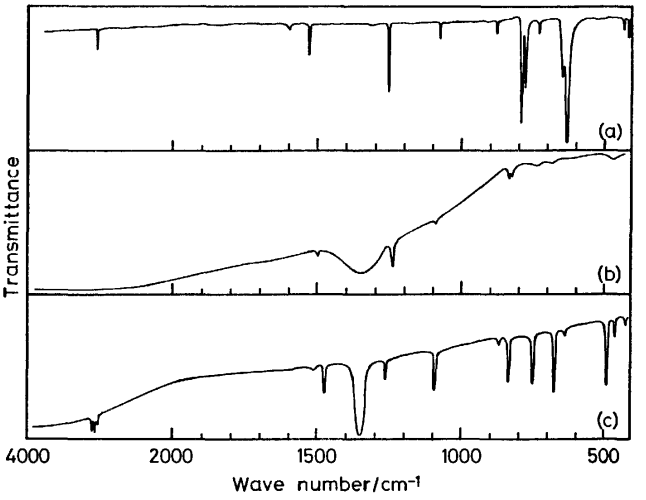

Fig. 1. IR spectra of (a) TTF, (b) $TTF \cdot I_{0.7}$, and (c) $TTF \cdot I_3$.

reaction products on the basis of the results for these TTF salts.

Spectral changes of TTF–iodine system with an increase in n are shown in Fig. 2. The changes may be interpreted as the stepwise oxidation of TTF, *i.e.*, $TTF \rightarrow TTF^{0.7+} \rightarrow TTF^{+} \rightarrow TTF^{2+}$, although a controversial feature is observed in the range, $n<0.7$: this will be discussed later. Absorption bands of TTF are decreasing with an increase in n. At $n=1$, features of $TTF^{0.7+}$ dominate the spectra and those of $TTF \cdot I_3$ also appear. The features of $TTF \cdot I_3$ grow up with n, and absorption bands of a new species appear at $n=4$. When n increases further, the new species comes to dominate the spectra, and only absorption bands of this species are observed at $n=20$. No further spectral changes occurred when n was increased up to 40; therefore, this species is probably the end product of this solid state reaction. The spectrum at $n=20$ is practically the same as that of $TTF(Br_3)_2$ as shown in Fig. 3. The result shows that iodine oxidizes TTF up to the dication in the solid state reaction. The sample of $n=20$ gave practically the same IR spectrum in Nujol mull as in the KBr disk. The former is black because of excess iodine whereas the latter is brown which may be attributed to the presence of I_2Br^- ion.

In the solution reaction, no dication salts have been obtained for TTF–iodine system. We also attempted to react TTF with a large excess of iodine to prepare the dication salt, but $TTF \cdot I_3$ was only obtained. Chlorine and bromine, on the other hand, easily oxidize TTF to the dication in solution.[2] The difference among the halogens is probably attributable to the weaker oxidizing ability of iodine than the others. Formation constant of the dication is expected to be rather small in the equilibrium, $TTF^{+}+nI_2 \rightleftharpoons TTF^{2+}\text{-}(I_x^-)_2$. In the solid state, the environment of TTF remains iodine-rich during the whole oxidation processes and the dication species is formed. In solution, on the other hand, no dication salts will be obtained because TTF probably escapes from the iodine-rich environment, *i.e.*, the solution, as a precipitate of $TTF \cdot I_3$ before the further oxidation occurs.

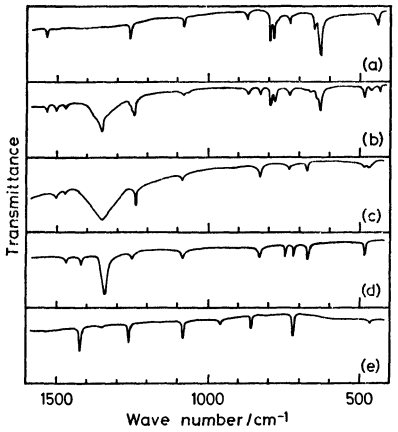

Fig. 2. IR spectra of solid state reaction products of TTF and iodine. (a) $n=0$; (b) 0.4; (c) 1; (d) 4; (e) 20.

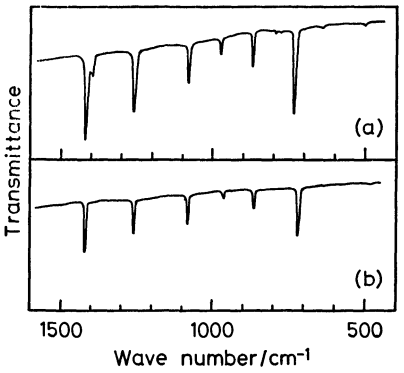

Fig. 3. IR spectra of (a) $TTF(Br_3)_2$ and (b) sample of $n=20$.

No IR features of species other than TTF^{+} and TTF^{2+} are observed in the spectrum of $n>4$. The result shows that no homogeneous mixed-valence salt exists between the cation and the dication in contrast to the case between the neutral molecule and the cation, where $TTF^{0.7+}$ exists. Siedle *et al.*[6] reported a mixed-valence salt formulated as $(TTF^{+})(TTF^{2+})_2\text{-}(CuCl_2^-)_5$, but the vibrational spectra are reasonably explained as a superposition of those of TTF^{+} and TTF^{2+}. Therefore, no valence fluctuation[7] occurs in this salt, in the time scale of molecular vibrations. The result shows striking difference in comparison with the case of homogeneous mixed-valence compounds such as $TTF \cdot I_{0.7}$, where two valence states, TTF and TTF^{+}, are indistinguishable from the vibrational spectra because the features of the two species are averaged out by the valence fluctuation.[8] The salt of Siedle *et al.* should, therefore, be considered inhomogeneous from the viewpoint of the vibrational characteristic time. The result in the present work does not rule out the possibility that such an inhomogeneous mixed-valence salt exists in TTF–iodine system.

In the range, $0<n<0.7$, an anomaly is observed

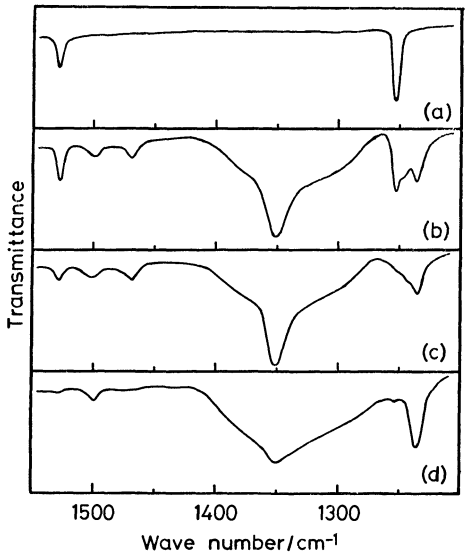

Fig. 4. IR spectra of solid state reaction products of TTF and iodine. (a) $n=0$; (b) 0.3; (c) 0.4; (d) 0.7.

in the spectra, as mentioned above. In order to show the detailed feature of the spectra, the region of 1200—1600 cm^{-1} is given in an expanded scale (Fig. 4). IR spectra of the samples were obtained also in Nujol and hexachlorobutadiene mull, and the spectra agreed well with those in the KBr disk. The samples of $n=$ 0.3 and 0.4 clearly exhibit three absorption bands at 1528, 1500, and 1470 cm^{-1}, which are attributable to the b_{1u} ν_{18} modes of TTF, $TTF^{0.7+}$, and TTF^{+}, respectively. Another triplet structure is observed also in the region of b_{2u} ν_{23}, 1230—1250 cm^{-1}.[4] Furthermore, the characterictic broad band near 1350 cm^{-1} has an anomalous profile, which is probably due to the superposition of sharp and broad features of TTF^{+} and $TTF^{0.7+}$. These results clearly show that the reaction product contains not only $TTF^{0.7+}$ but also TTF^{+} even under the condition of a fairly small iodine content. The equilibrium is expected to shift to TTF^{+}, if n is increased. However, the result was obtained contrary to this expectation as shown in Fig. 4; *i.e.*, $TTF^{0.7+}$ came to dominate the spectrum with an increase in n. The TTF^{+} species above is not probably the triiodide salt because the iodine content is fairly small and the frequency of the vibronically allowed band, 1355 cm^{-1}, is distinct from that of $TTF \cdot I_3$, 1345 cm^{-1}. Only the candidate will be $TTF \cdot I_{1.0}$, which has not been obtained by the reaction in solution.

The cause of this anomaly may be attributable to a cluster structure of the cation in TTF–iodine mixture. The ionization potential of TTF is small and the electron affinities of halogens are large, so that TTF is present only as the fully ionic form, TTF^{+} and $(TTF^{+})_2$,[9] in the solution of TTF–halides. In the crystals of nonstoichiometric TTF–halides, on the other hand, the mixed-valent state is stabilized by the balance of the energy cost with the ionization of the donor–acceptor pairs and the energy gain by the electrostatic interaction (crystal Madelung energy);[10] in other words, mixed-valent states are stable only in the crystal. These facts suggest that TTF molecules have the fully ionic and the mixed-valent states in the small and large clusters respectively, *i.e.*, the state changes at a boundary size of the cluster. The fraction of the large clusters increases with an increase in n, and this will result in the spectral change observed. Such a fully ionic-to-mixed-valent transition of TTF state is interesting from the viewpoint of the stability of mixed-valent TTF salts. Some information will be obtained from, *e.g.*, vibrational spectra of the aggregates of TTF^{+} in an inert gas matrix at low temperature.

The Heat Capacities of Lithium, Sodium, Potassium, Rubidium, and Caesium Nitrates in the Solid and Liquid States

Kazuhiko Ichikawa* and Toshiyuki Matsumoto

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received December 24, 1982)

The heat capacities, C_p, of the alkali metal nitrates, MNO_3 (M=Li, Na, K, Rb, and Cs), in the solid and liquid states have been measured between 50 and 450 °C by means of adiabatic calorimetry. We have measured with a fair degree of accuracy the C_p values for the MNO_3 systems, because the existing data on $NaNO_3$ and KNO_3 above 250 °C are quite scanty. Some empirical rules, some of which may extend to other salts, have been obtained from the results on C_p for the five alkali nitrates in the solid and liquid states. For the molten MNO_3, the heat capacities at a constant volume, C_V, were obtained from the thermodynamical relationship between C_V and C_p, using the experimental values of C_p; the C_V values have been interpreted in terms of the interionic and intraionic portions.

It has become a common theme of research to develop technology for the storage of thermal energy and for heat transfer, employing molten salts; the study of their thermal properties has thus acquired a practical meaning. The salt of most interest is molten alkali-metal nitrate, for it has better physical and chemical properties than other salts. Some of these properties are its low melting point, t_{mp}, its nonvolatile, nondecomposite, and noncorrosive characteristics, and its high heat capacity. The existing data on the heat capacity at constant pressure C_p, for $NaNO_3$ and KNO_3, which were obtained from the slopes of the curves of the heat content *versus* temperature,[1] are quite scanty, in particular just below and above t_{mp}. The thermal property[2] of most interest in this paper is the heat capacity as an important parameter. This work describes briefly an adiabatic calorimeter used to measure high-temperature heat capacities with a fair degree of accuracy (2.0%). The C_p results are shown for the five alkali-metal nitrates MNO_3 (M= Li, Na, K, Rb, and Cs) in the solid and liquid states between 50 and 450 °C. Their heat-capacity data have given rise to some empirical rules, which may extend to other salts. The high heat-capacities observed will also be discussed in terms of their interionic and intraionic contributions.

Experimental

Materials. The salts used were pure-grade recrystallized reagents. The KNO_3 was supplied by Prof. G. J. Janz, Rensselaer Polytechnic Institute, and the $NaNO_3$ and $LiNO_3$ of a special grade, by Wako. The purity of the $RbNO_3$ and $CsNO_3$ purchased from Alfa was 99.9%. Metallic impurities indicated: for KNO_3, Si 0.1—0.5, Mg 0.1—0.5, Fe 0.1—0.5, and Ca 0.5—2.0 ppm; for $NaNO_3$, Pb 0.007, K 0.008, Cu 0.002, Fe 0.003 mass percentage; for $LiNO_3$, Pb 0.001, Na 0.05, K 0.05, Cu 0.0005, Mg 0.005, Ca 0.01, Ba 0.001, Fe 0.005 mass percentage.

Apparatus and Procedure. Measurements of the high-temperature heat capacity, C_p, were made with an adiabatic calorimeter. The adiabatic shield control consists of a PID-SCR circuit, a constant wattage supply, a heater of platinum-wire, and multi-junction thermocouples. The temperature difference between the sample in a calorimetric ampoule (*i.e.*, a platinum cylindrical vessel of *ca.* 7.5 cm^3) and the adiabatic shield was controlled within 0.1 °C between 50 and 450 °C. Since the heat emissivity of the gold metal is very small, the inner adiabatic jacket and the outer vessel of the sample container are gold-plated. The adiabatic calorimeter may be sufficiently protected from the heat leakage due to thermal radiation. In order to get avoid any oxidation and corrosion of the interior of the calorimeter over the entire temperature range of this work, heat-capacity measurements were made under Ar gas of *ca.* 2.5×10^4 Pa at room temperature introduced into the vacuum cell of the calorimeter. The values of C_p in J K^{-1} g^{-1} were computed from the following equation:

$$C_p = (W\cdot\Delta t)/(M\cdot\Delta\theta) - (M'/M)C_p', \quad (1)$$

where W (in watts) is the electric power supplied by the internal heater, Δt (in seconds) is the time required for increasing the temperature by $\Delta\theta$ degrees and is determined by the clock timer unit, and M is the weight (*i.e.*, 10—15 g) of the sample. The heat capacity of the empty calorimeter, $M'C_p'$, was obtained in a preliminary measurement. The temperature measurement was carried out with a Pt-Rh thermocouple calibrated by a cryoscopic method for pure-grade recrystallized reagents, KNO_3, K_2SO_4, Ag_2SO_4, and $KClO_4$.

The experimental errors may originate from two major sources. Firstly, sample characteristics associated with endothermic reactions, such as decomposition and evaporation, should be considered.[3] In this work, however, the weight-loss of the sample between 50 and 450 °C ranged from 0.01% to 0.06%. Thus, the endothermic heat resulting from the decomposition or evaporation of MNO_3 may not affect any magnitudes of C_p within the present experimental uncertainty. Secondly, the calorimeter operation was tested by measuring the C_p of standard synthetic sapphire (99.99 wt% purity). The magnitude of the experimental error

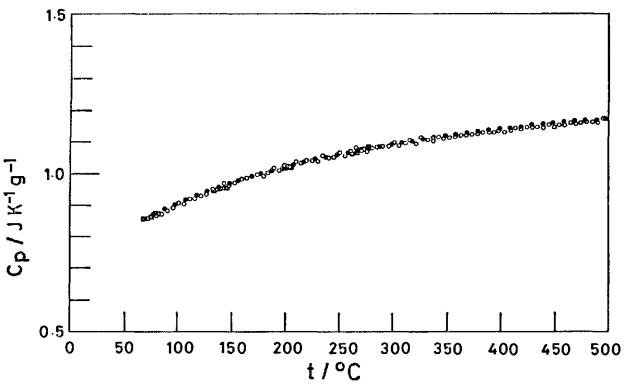

Fig. 1. Temperature dependence of the heat capacity of synthetic sapphire: ○, this work; ●, Ref. 4; □ Ref. 5.

attributable to the heat leakage was less than two per cent of C_p of the sample for the temperatures of interest; Fig. 1 shows that our results of synthetic sapphire agree with the selected values cited in the text published by TPRC[4] and with the existing data, which were measured by a reliable adiabatic calorimeter and which prove the precision to be ±0.3% and give an accuracy of ±0.6%.[5] This agreement is sufficient for our present purposes. The amount of argon gas in the interior of the stainless-steel vacuum vessel did not affect the data of C_p within the limits of experimental uncertainty of ±1.0% between 50 and 500 °C.

Results and Discussion

The experimental results on C_p in J K^{-1} g^{-1} of $LiNO_3$ and $NaNO_3$ between 50 and 400 °C, and of KNO_3, $RbNO_3$, and $CsNO_3$ between 50 and 450 °C are presented in Figs. 2—6 respectively. Their molar heat capacities in J K^{-1} mol^{-1} are listed in Table 1. It is worthy while focussing on the accuracy of the results, because the literature data are quite scattered above the level of precision of each of the data (*e.g.*, Fig. 3 for $NaNO_3$).[1,6–16]

$NaNO_3$: Figure 3 demonstrates that the many existing data on the C_p of $NaNO_3$ in the solid and liquid states are quite scanty and not in good agreement. Our data are in close agreement with the data of Sokolov and Schmidt,[11] and of Carling[16] except for the neighborhood of the solid-state transition temperature, t_{tr}, which depends on the literature (*i.e.*,

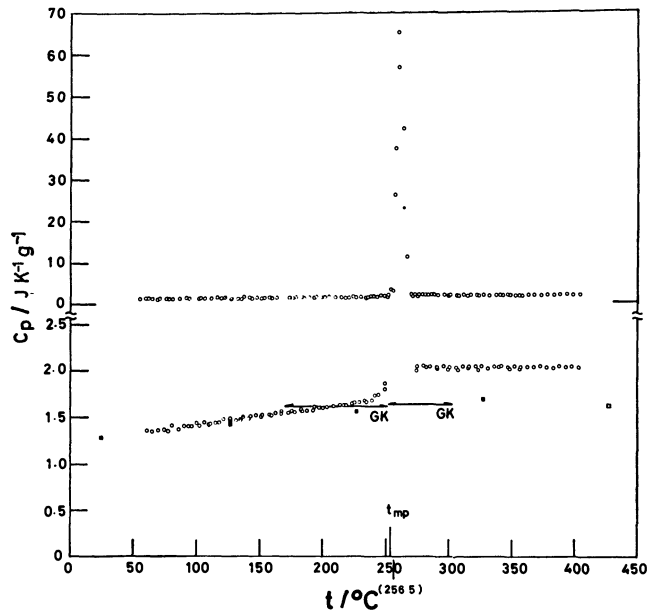

Fig. 2. Temperature dependence of the heat capacity of $LiNO_3$: ○, this work; GK, Ref. 1; ■(solid) and □(liquid), Ref. 21. In this and in Figs. 3—6 the temperatures of t_{tr} and t_{mp} shown by the vertical lines were referred from the literature data and the temperature in parentheses, the location of which is pointed out by an arrow, was determined in this work.

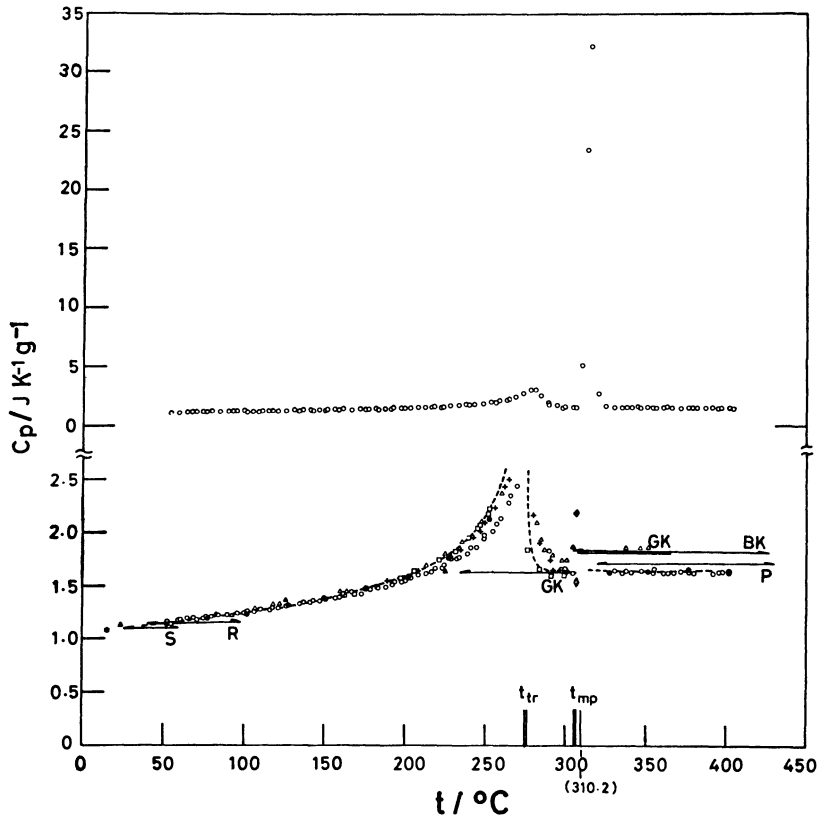

Fig. 3. Temperature dependence of the heat capacity of $NaNO_3$: ○, this work; R, Ref. 6; P, Ref. 7; S, Ref. 8; GK, Ref. 1; ★ Ref. 9; +, Ref. 10; ----, Ref. 11; △, Ref. 12; ◆(solid) and ◇(liquid), Ref. 13; □, Ref. 14; ▲ and BK, Ref. 15; ●, Ref. 16.

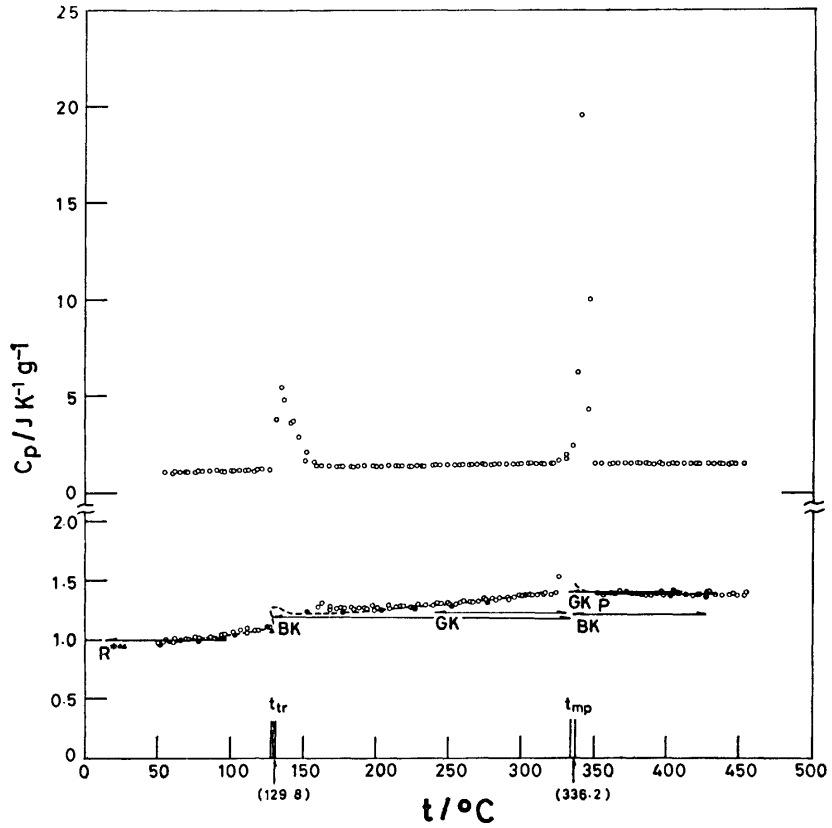

Fig. 4. Temperature dependence of the heat capacity of KNO_3: ○, this work; ----, Ref. 17; the other symbols should be referred in Fig. 3.

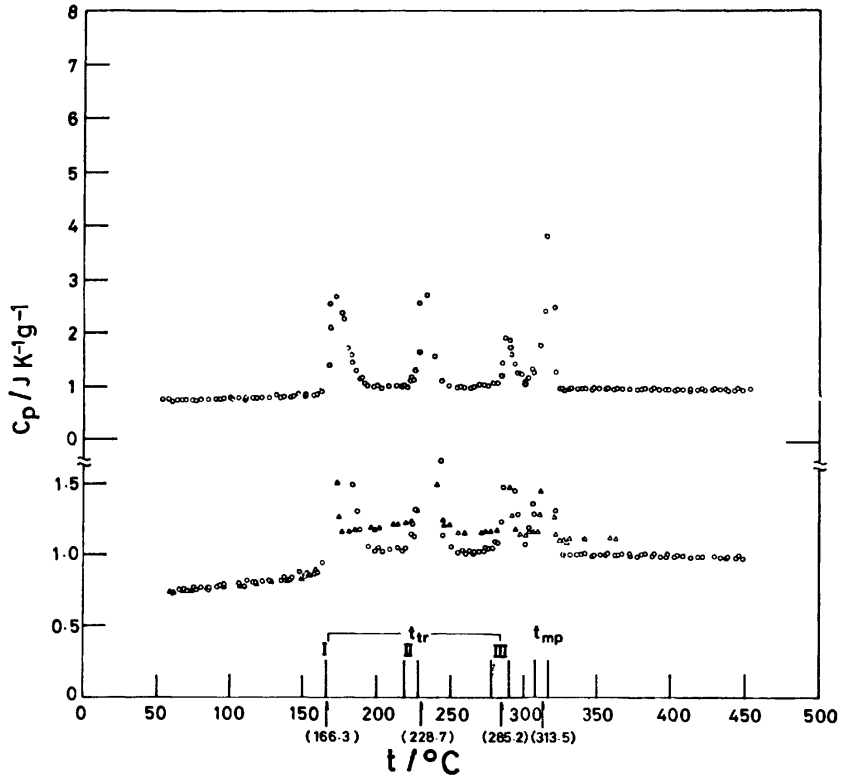

Fig. 5. Temperature dependence of the heat capacity of $RbNO_3$: ○, this work; △, Ref. 19. The three reversible solid-transitions I, II, and III,[33] have been observed and their temperatures and t_{mp} are some what scattered in the literature data.

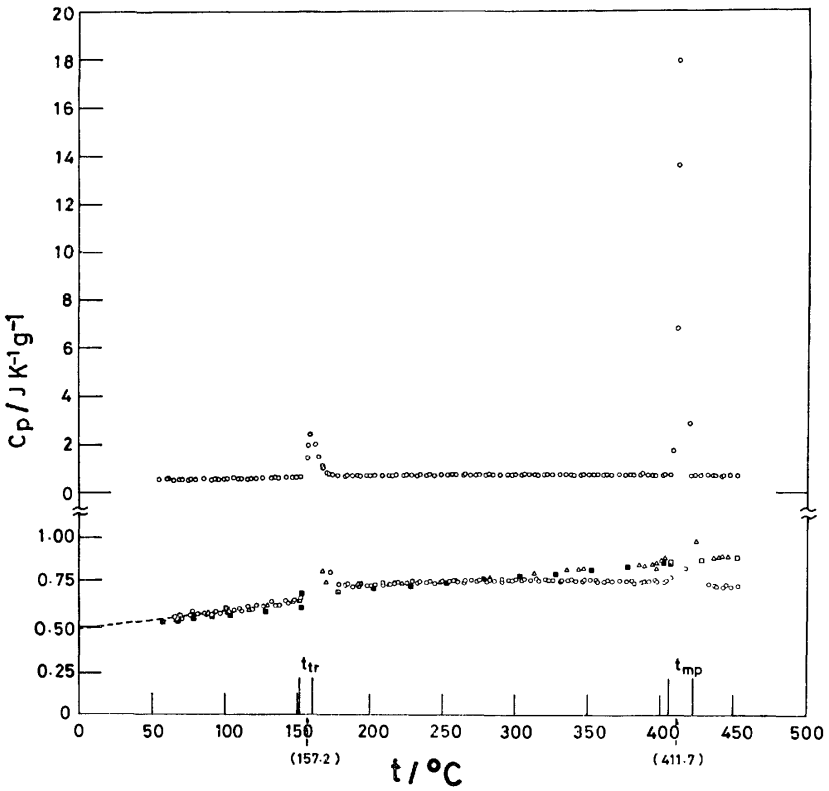

Fig. 6. Temperature dependence of the heat capacity of $CsNO_3$: ○, this work; ----, Ref. 22; △, Ref. 20; ■(solid) and □(liquid), Ref. 23.

275 and 276 °C). Our data also agree with the data of Miekk-oja[10] between t_{tr} and t_{mp}; the data of Reinsborough and Wetmore[14] immediately below t_{mp} are slightly less than ours. On the other hand, Mustajoki's data[12] (for heating) above t_{mp}, which are located above the C_p values (see the horizontal arrows in Fig. 3) obtained from the temperature dependence of enthalpy by Goodwin and Kalmus[1] and by Barir and Knacke,[15] are larger than the data of this work, Sokolov and Schmidt,[11] and Carling[16] by *ca.* 14% above the level of precision of each of the data. It may also be noted that Goodwin and Kalmus'[1] data just below t_{mp} agree satisfactorily with those of this work, Sokolov and Schmidt,[11] and Carling,[16] but the former does not show any broad cusp-shaped peak in the heat capacity curve. The change in the heat capacity on fusion at t_{mp}, $\Delta C_p^\circ(t_{mp})$, is given as the difference between the heat capacities just below t_{mp} and immediately above t_{mp}, wherein the experimental values which show the peak of C_p around the temperature, t_p, located slightly higher than t_{mp} should be omitted. Thus, $\Delta C_p^\circ(t_{mp})$ may be defined by:

$$\Delta C_p^\circ(t_{mp}) \equiv \lim_{\delta\to 0}[C_p^l(t_{mp}+\delta)] - \lim_{\delta'\to 0}[C_p^s(t_{mp}-\delta')], \qquad (2)$$

where the suffixes l and s stand for the liquid and solid states respectively. The mark of $\lim_{\delta \text{ or } \delta'\to 0}$ indicates the extrapolation of C_p until t_{mp}; δ and δ' are positive. Under an ideal condition that both δ and δ' are equal to zero, t_p should be equal to t_{mp}. Figure 3 shows that $\Delta C_p^\circ(t_{mp})$ for $NaNO_3$ is almost zero, as well as KNO_3. On the other hand, $\Delta C_p^\circ(t_{mp})$ in the literature data is either negative or positive (*i.e.*, Goodwin and Kalmus[1]: 15.0 J K^{-1} mol^{-1}, Mustajoki[12]: 3.3, Janz *et al.*[13]: −56.0, Barin and Knacke[15]: −2.6, and Sokolov and Schmidt[11]: 2.9). The magnitude of *ca.* 3 J K^{-1} mol^{-1} is almost comparable with the experimental uncertainty in the C_p values.

KNO_3: There exist data in the literatures which are scattered similar to $NaNO_3$. Our data are in close agreement with the data of Sokolov and Schmidt[17] and of Carling[16] as in the case of $NaNO_3$. Further, our data have reproduced also the data of Person[7] and of Goodwin and Kalmus.[1] To our knowledge there exist no data for KNO_3 above t_{tr} (*i.e.*, the 129.8 °C observed in this work), though Mustajoki[18] reported the data for MNO_3 (M=Na,[12] Rb,[19] and Cs[20]) in the solid and liquid states. In this work, $\Delta C_p^\circ(t_{mp})=0$, and in Carling's data it also seems to be zero, but in the literature data 17.4 J K^{-1} mol^{-1} has been reported by Goodwin and Kalmus[1] and 2.9 by Barin and Knacke.[15] For both $NaNO_3$ and KNO_3, the values extrapolated to room temperature agree well with their heat capacities at the low temperatures measured by Southard and Nelson,[9] as is shown in Figs. 3 and 4.

The magnitudes and the temperature dependence of the C_p values were not determined from the slopes of the curves of the heat content and the corresponding temperatures with sufficient accuracy, for the differences in the C_p values between our data and the data of Goodwin and Kalmus or the data tabulated by Barin and Knacke are dependent on the systems above

TABLE 1. EXPERIMENTAL HEAT CAPACITIES OF ALKALI METAL NITRATES MNO_3 (M=Li, Na, K, Rb, AND Cs) IN THE SOLID AND LIQUID STATES

t_{mp}. In comparison with the former our data are larger by *ca.* 23% for $LiNO_3$, smaller by *ca.* 10% for $NaNO_3$ and equivalent in magnitude for KNO_3; in comparison with the latter, our data are smaller by *ca.* 12% for $NaNO_3$ and larger *ca.* 12% for KNO_3. The temperature coefficients of C_p below t_{mp} are quite different between the previously reported data (*i.e.*, Barin and Knacke,[15] Goodwin and Kalmus,[1] Schüller,[8] and Regnault,[6]) and our data for $NaNO_3$ and KNO_3. It may thus be concluded that the reli-

ability of the literature data above t_{mp} is satisfactory only in the cases of Sokolov and Schmidt, and Carling. We had better say that the thermodynamic values of Gibbs free energy tabulated by Barin and Knacke are sufficiently accurate.

$LiNO_3$: Above 150 °C no satisfactory results were previously obtained.[1,21] No broad peaks associated with the reversible solid-state transition have been observed in the C_p measurements with an increase in the temperature. The substance of $LiNO_3$ is unique among the other alkali-nitrates because the difference $\Delta C_p^\circ(t_{mp})$ is not zero: $\Delta C_p^\circ(t_{mp})=23.2$ J K^{-1} mol^{-1}, and no reversible solid-state transition takes place.

$RbNO_3$: To our knowledge, the only existing data on C_p are the data measured by Mustajoki.[19] The three reversible thermal transitions below t_{mp} and the solid-liquid transition are shown in Fig. 5. The data of Mustajoki above the first solid-phase transition temperature, which varies with the authors (*e.g.*, 160 °C was reported by Mustajoki while it is 166.3 °C in this work), are larger than ours by *ca.* 11%, as in the system of $NaNO_3$. The value of $\Delta C_p^\circ(t_{mp})$ may be slightly negative or almost zero, though it can not be estimated with accuracy because of the phase transition immediately below t_{mp}; the value reported by Mustajoki[19] is -14.2 J K^{-1} mol^{-1}.

$CsNO_3$: The data of this work agree satisfactorily with the data by Sato[22] (see the dashed line in Fig. 6 between 0 and 100 °C but these temperatures are located below t_{tr}). The data of Mustajoki[20] and Flotow *et al.*[23] above 300 °C are larger than ours by less than *ca.* 19%. The values of t_{tr} and t_{mp} (*i.e.*, 151.5 °C and 405.5 °C, and 152 °C and 406 °C as reported by Mustajoki and by Flotow *et al.*, respectively) are rather low compared with ours (*i.e.*, 157.2 °C and 411.7 °C, which lie below each of the data in the other literature), as is shown in Fig. 6. The experimental values of C_p reported by Flotow *et al.* increase linearly with an increase in the temperatures over the entire temperature range above t_{tr}, except for the neighborhood of t_{mp}. Our data show that the heat capacities in the liquid state are almost independent of temperature for all the alkali metal nitrates. The C_p values below t_{tr} in the Flotow *et al.* data are smaller than ours and Mustajoki's. The value of $\Delta C_p^\circ(t_{mp})$ measured by Mustajoki depends on the systems, *i.e.*, 15.0 J K^{-1} mol^{-1} for $NaNO_3$, -14.2 for $RbNO_3$ and *ca.* 0 for $CsNO_3$; in this work $\Delta C_p^\circ(t_{mp})=0$ J K^{-1} mol^{-1} for all the alkali metal nitrates which show a reversible solid-state transition. The values of t_{tr} and t_{mp} determined in this work are given by the figures in parentheses. The literature values are shown by the vertical lines in Figs. 2—6.

Some empirical rules which are possibly suitable for other typical salts have been obtained from the experimental results of C_p for the five alkali metal nitrates:

(1) The $\Delta C_p^\circ(t_{mp})$ defined in Eq. 2 is almost zero for MNO_3 accompanying the reversible solid-state transitions, *i.e.*, $NaNO_3$, KNO_3, $RbNO_3$, or $CsNO_3$.

(2) The heat capacities are independent of the temperatures above t_{mp} for all the nitrates. They increase linearly with an increase in the temperature until the first phase-transition temperatures (*i.e.*, 1.8×10^{-3} J K^{-2} g^{-1} between 50 and 230 °C for $LiNO_3$, 2.3×10^{-3} between 50 and 150 °C for $NaNO_3$, 1.5×10^{-3} between 50 and 125 °C for KNO_3, 1.2×10^{-3} between 50 and 150 °C for $RbNO_3$, and 1.0×10^{-3} between 50 and 150 °C for $CsNO_3$); according to Southard and Nelson,[9] whose data near room temperature are shown by ★ in Figs. 3 and 4, the temperature coefficients of C_p for $NaNO_3$ and KNO_3 over the 100 °C range below room temperature are 2.1×10^{-3} J K^{-2} g^{-1} and 1.5×10^{-3}, respectively. Therefore, between -100 °C and 150 °C the C_p values of $NaNO_3$ and KNO_3 increases linearly with an increase in the temperatures.

(3) Roughly speaking, the magnitude of the discontinuity, ΔC_p^{app}, at the temperature, t_p, corresponding to the maximum value of C_p is in inverse proportion to the thermal expansion α_T for the molten MNO_3 systems except for $RbNO_3$, which has three phase transition points below t_{mp}.

(4) Each of the $NaNO_3$, KNO_3, and $RbNO_3$ systems has nearly the same magnitude of enthalpy required for all the reversible solid-transitions, though the profile of C_p at t_{tr} and the number of the transitions below t_{mp} are dependent on the specific substances.

We shall confine our attention here to the heat capacities of MNO_3 in the liquid state. Starting from a formula for the difference between C_p and C_V, one obtains

$$\frac{C_p}{C_V}-1=\frac{u^2\alpha_T^2MT}{C_p} \tag{3}$$

or:

$$C_p-C_V=\frac{\alpha_T^2v_mT}{\beta_T}, \tag{4}$$

where u, α_T, M, v_m, and β_T are the sound velocity, the thermal expansivity, the molar weight, the molar volume and the isothermal compressibility, respectively.[24] Equation 3 or 4 is useful because we can determine C_V directly from the measured values of C_p and u or β_T. The values of C_V at $1.1\times T_{mp}$ are listed in Table 2, together with the data of β_T, u, α_T, and v_m. The magnitudes of C_V obtained from the compressibility data[25,26] are slightly larger than the C_V values obtained from the velocity data,[27-29] for the molten $CsNO_3$ or $RbNO_3$ with a large molar volume, as is shown in Table 2. No substantial difference between the values of C_V determined using the ultrasonic velocity data[27] and using the hypersonic velocity data[28,29] was found for fused $LiNO_3$ and $NaNO_3$. It is very interesting that the γ ratio, which is defined as C_p/C_V or β_T/β_s (β_s: adiabatic compressibility), increases roughly with an increase in the molar volume, v_m, among the five alkali-metal nitrates in the liquid state. The heat capacity C_V at a constant volume for the MNO_3 melts, consisting of monatomic univalent cations, M^+, and complex univalent anions, NO_3^-, can be divided into the interionic and intraionic portions:

$$C_V=C_V^{inter}+C_V^{intra}, \tag{5}$$

where C_V^{inter} is the sum of the contributions from the translation and configuration for both M^+ and NO_3^- ions and where C_V^{inter} is constructed of vibrational,

TABLE 2. HEAT CAPACITY AT A CONSTANT PRESSURE OR VOLUME OF MOLTEN ALKALI-METAL NITRATES

a) Obtained from the measurement of $(\partial T/\partial P)_s$ in 26) and from the p-V-T studies in 25). b) Hypersonic velocities in 28) and 29), and ultrasonic velocities in 27). c) This work. d) Obtained using Eq. 3 or 4.

rotational and electronic parts in the NO_3^- ion.[30] The values of C_V^{vib}/N_Ak_B and C_V^{rot}/N_Ak_B are 6 and 1.5 respectively, in accord with the classical theory of the heat capacity of an assembly of independent, rigid, non-linear molecules for NO_3^- ions.[30]

Under the assumption of a point charge model for the univalent melts, the C_V^{trans}, C_V^{config}, and C_V^{elec} values of the molten MNO_3 are equal to 3, 3, and 0 respectively in units of N_Ak_B. The estimated value of C_V/N_Ak_B, 13.5, should be compared with the results of the C_V/N_Ak_B values of the five molten MNO_3 at $1.1\times T_{mp}$ cited in Table 2, in which the disagreement may originate mainly from the short estimation of C_V^{config} for molten MNO_3. The molten alkali nitrates have a higher heat capacity (*i.e.*, *ca.* $15\times N_Ak_B$) at a constant volume than that (*ca.* $6.0\times N_Ak_B$) of molten alkali chlorides because of the vibrational and rotational contributions associated with NO_3^-. The hard-sphere models[31,32] applied to the thermodynamic properties of simple molten salts are not adequate for the molten nitrates which consist of complex anions, NO_3^-, and monatomic cations M^+.

Once again let us focus on the difference, ΔC_p^{app}, between the maximum value of C_p near t_{mp} and the value of C_p corresponding to the horizontal line linking the open circles shown in the upper part of Figs. 2—6. The ΔC_p^{app} quantity should not be confused with the $\Delta C_p^{\circ}(t_{mp})$ defined in Eq. 2 and should be infinite, though it is apparently finite in the experimental results. Such values of ΔC_p^{app} may originate from the sudden appearance of the communal entropy at the melting point because each ion can move anywhere in the liquid, whereas in the crystal the ions are localized systems.

Some of the techniques used have serious drawbacks, since some previously reported data on heat capacities in the liquid state are much too high, and their temperature coefficients are not certainly less than the positive values in the solid state.[34] The conclusion in this work is that the heat capacity of each molten alkali-metal nitrate is in the range from 138 to 148 J K^{-1} mol^{-1} and is probably independent of the temperature. At this point, it should be possible to regard some sets of results above t_{mp} as better than others.

We wish to thank Professor Hideaki Kita for his encouragement during the course of this work. We also greatly appreciate the help of Professor G. J. Janz in supplying the sample of KNO_3 used in this work and for showing us a number of references on the heat capacities of ionic melts which were retrieved by the Molten Salt Data Center, Rensselaer Polytechnic Inst., USA. We also wish to thank Dr. D. K. Tödheide for his comments on the compressibility and velocity data of the molten nitrates. This work was supported by a Grant-in-Aid for Scientific Research No. 56470001 from the Ministry of Education, Science and Culture.

Self-diffusion and Melting in the Plastic Phases of Neopentane as Studied by NMR Relaxation at High Pressures

Sadamu TAKEDA, (the late) Gen SODA, and Hideaki CHIHARA*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received December 2, 1982)

Proton spin-lattice relaxation time T_1 in the plastic phase of 2,2-dimethylpropane (neopentane) was measured at 10 MHz up to 170 MPa between 192.7 and 308.2 K. T_1 near the melting point is determined by self-diffusion. The enthalpy and volume of activation of this motion suggest that self-diffusion occurs through a single vacancy mechanism. The correlation time of self-diffusion at the melting point (T_f) is $(3.2 \pm 0.5) \times 10^{-7}$ s irrespective of external pressure. The diffusion rate is a function only of T_f/T, *i.e.* the law of corresponding states holds. The feature of activation properties of self-diffusion is strongly correlated with the melting phenomenon. The melting curve of the phase diagram was also determined and a possibility of existence of another plastic phase was found above 40 MPa.

Molecular motions in plastic crystals (ODIC, the orientationally disordered crystals) have been studied by a variety of experimental methods.[1] These crystals are characterized by a small entropy of fusion (less than 21 J K^{-1} mol^{-1}) and existence of a phase transition below which the crystal becomes brittle. In general, overall rotation of a molecule is highly excited in the plastic phase and even self-diffusion is seen by the NMR and other methods below the melting point in many plastic crystals.[2] There is an empirical law that the correlation time of self-diffusion becomes about 10^{-7} s at the melting temperature in different plastic crystals.[2] It leads us to believe that on-set of self-diffusion acts as a dynamical trigger of the melting phenomenon in these crystals. A large amount of experimental data have already been accumulated about the self-diffusion in plastic crystals but most of them are the results under ordinary pressure. It is the purpose of the present study to make a "corresponding state" type of analysis of the melting from the self-diffusion data on 2,2-dimethylpropane (neopentane) obtained under different pressures.

Neopentane is a typical compound having a plastic crystalline phase and a relatively large amount of experimental information is now available. The plastic phase of neopentane has the f.c.c. structure (a= 8.82 Å)[3,4] containing four molecules a unit cell. The melting and transition temperatures are 256.5 and 140.5 K, respectively, and their associated entropy changes are 12.0 and 18.7 J K^{-1} mol^{-1}.[5] The state of molecular motion in the plastic and brittle crystalline phases are fairly well understood by the NMR[6-10] and other methods.[11-13] Thus, it is generally substantiated that overall molecular tumbling is highly excited in the plastic phase with an activation enthalpy of 4.2 kJ mol^{-1}, while the activation enthalpy for self-diffusion was reported to be between 25 and 34 kJ mol^{-1}.[6,8,9]

The pressure dependence of molecular motion in the plastic neopentane has also been reported by Allen *et al.*[7] However, they dealt only with a limited temperature range. Therefore, we now extended the measurements of proton spin-lattice relaxation time of the plastic phase of neopentane under pressure up to the melting point and also determined its melting curve. The results were then analyzed to derive motional parameters related to self-diffusion and melting.

Experimental

High Pressure Vessel and Pressure Measurement. The high pressure vessel used in this experiment was a clamped type which is essentially the same as the one that has been reported elsewhere.[14] The seal materials were fluoride rubber, Teflon, and lead metal, which constitute a conventional Bridgeman-type pressure seal. The design of the electrical leads from the interior of the pressure vessel to the outside is similar to that used by Terry and Ruoff,[15] with a heat shrinkable Teflon tube (NSTube-910-2, Nitto Denko, Japan) and epoxy putty XD580 (Japan CIBA GEIGY) used for the seal materials.[14]

The pressure-transmitting medium is the sample itself and its pressure was measured by means of a "manganin gage" whose resistance was determined by the four-terminal method. The gage was calibrated for temperature- and pressure-coefficients. First, the pressure coefficient was determined at 293 K with reference to the standard Heise gage up to 200 MPa. Secondly, the temperature coefficient was determined at the ambient pressure between 175 and 330 K. The pressure coefficient also depends on temperature but it is reported that the effect is small; if we put $\Delta = \{R(P) - R(0)\}/R(0)$, the value of $(d\Delta/dT)/\Delta$ is less than 3×10^{-4} K^{-1}.[16-18] Therefore, we used $\Delta/P = 2.442 \times 10^{-5}$ $(MPa)^{-1}$ (at 293 K) throughout the temperature range studied in the present work (192 K to 308 K). The temperature coefficient of the resistance of manganin is not very small at low temperatures, *e.g.* 2×10^{-4} K^{-1} at 200 K, and this required a good precision of temperature measurement and control. The temperature of the specimen could be controled to within $\pm 1/30$ K and it was measured by several Chromel-P-Constantan thermocouples attached on the outside periphery of the vessel. The overall uncertainty in the pressure determination was about ± 2.5 MPa.

Preparation of the Sample and T_1 Measurement. A sample of neopentane of commercial origin (Takachiho Kagakukogyo, Co.) was dried over Molecular Sieves 3A, 4A, and 5A in vacuum, purified by repeated vacuum distillation, and degassed by several freeze-pump-thaw cycles. The specimen was then distilled into the high pressure vessel through an adapter which connected the pressure vessel to the purification line.[14] The final purity of the specimen was better than 99.8 mol% by gas chromatography. The specimen was compressed at room temperature by use of a hydraulic press and the T_1 measurements were made under conditions of effectively constant volume.

Proton spin-lattice relaxation time (T_1) was measured using 90° train$-\tau-$90° pulse sequences at an operating frequency of 10.0 MHz. A series of T_1 values under pres-

sure were measured by varying the temperature after the specimen had been compressed at room temperature. The temperatures at which the T_1 measurement was performed were fixed within ± 0.1 K throughout the different series. Because the pressure inside the vessel changed when the specimen temperature changed, the primary experimental results of the different series were reorganized to show the pressure dependence of T_1 at a constant temperature.

It should be noted that the materials used to pressure-seal of the vessel did not contaminate the specimen as far as the T_1 values were concerned; we obtained completely reversible and reproducible results within the experimental uncertainty for the 10-d old sample held in the vessel as well as for a virgin specimen.

Results and Discussion

Self-diffusion and Its Activation Properties. The representative pressure dependence of the proton spin-lattice relaxation time in the plastic phase of neopentane at various temperatures are shown in Fig. 1. The plots for the measurements at seven additional intermediate temperatures (308.2, 293.2, 272.4, 252.5, 233.8, 214.0, and 192.7 K) fall between the curves but for the sake of clarity they were not included in this figure. The two motional processes, molecular rotation and self-diffusion, have been discussed from the continuous wave and pulsed NMR experiments in the plastic phase.[6-10]

There is a maximum in T_1 when it is plotted as a function of pressure for a constant temperature. This has been clearly demonstrated by Allen *et al.*[9] and its high-pressure side corresponds to the region where molecular tumbling is the dominant mechanism of the spin-lattice relaxation. The present study is essentially restricted to the low-pressure side of the T_1 maximum where self-diffusion mainly governs the relaxation rate. Where comparison is possible, our results are in reasonable agreement with the results of Allen *et al.* (who used 24.4 MHz for measurements).[9] Therefore, we will deal only with self-diffusion in this paper.

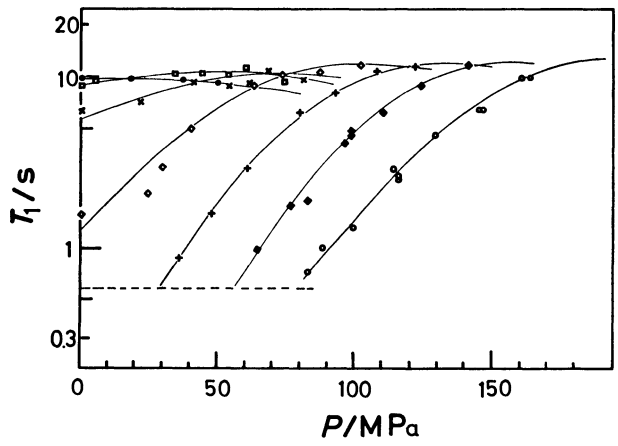

Fig. 1. Pressure dependence of the proton spin-lattice relaxation time at different temperatures; ○ 297.4 K, ◆ 281.0 K, + 263.6 K, ◇ 242.9 K, × 223.9 K, □ 214.0 K, ● 202.5 K. The dashed line shows the alignment of the melting points.

We assume the Arrhenius type of activation process for self-diffusion,

$$\tau_{SD} = A \exp(\Delta G^*/RT) = \tau^0_{SD} \exp(\Delta H^*/RT), \quad (1)$$

where τ_{SD} is the correlation time of self-diffusion and ΔG^*, the Gibbs energy of activation, is defined by

$$\Delta G^* = \Delta H^* - T\Delta S^*$$

or

$$\Delta G^* = \Delta E^* + P\Delta V^* - T\Delta S^*. \quad (2)$$

Then, the activation volume ΔV^* and the activation enthalpy ΔH^* can be derived from the equations,[19]

$$\Delta V^* = RT\{\partial(\ln\tau_{SD})/\partial P\}_T, \quad (3)$$

$$\Delta H^* = R\{\partial(\ln\tau_{SD})/\partial(1/T)\}_P, \quad (4)$$

where the activation entropy ΔS^* has been assumed to be constant over the present temperature and pressure region.[19] Because what we observed is the low temperature branch ($\omega_0\tau_{SD} \gg 1$) of the T_1 curve due to self-diffusion, τ_{SD} is proportional to $T_{1\,SD}$, where $T_{1\,SD}$ is the relaxation time due to self-diffusion. Thus, τ_{SD} in Eqs. 3 and 4 can be replaced by $T_{1\,SD}$ because the change of intermolecular dipole-dipole interaction can be safely ignored in the present pressure range.[9] One can obtain $T_{1\,SD}$ from the equation,

$$T_1^{-1}{}_{obsd} = T_1^{-1}{}_{SD} + T_1^{-1}{}_{RO}, \quad (5)$$

where $T_1^{-1}{}_{obsd}$ is the observed spin-lattice relaxation rate (Fig. 1) and $T_1^{-1}{}_{RO}$ is the spin-lattice relaxation rate due to molecular reorientation. Now, we try to separate the two contributions in Eq. 5. The second term of Eq. 5 was evaluated in the following way. Since the slope of $T_{1\,obsd}$ on the high pressure side of the maximum (Fig. 1) agrees with the slope as determined by Allen *et al.* where comparison is possible, we used their slope so that smooth extrapolation of our T_1 curve to high pressure may be made. This extrapolation enables us to estimate $T_1^{-1}{}_{RO}$ from the high-pressure branch of the $T_1^{-1}{}_{obsd}$ curve.

The activation volume ΔV^* was then derived from linear plots of $\ln(T_{1\,SD})$ against P at different temperatures. The activation volume ΔV^* (Fig. 2) thus derived was 133 ± 18 cm^3 mol^{-1} between 252.5 and

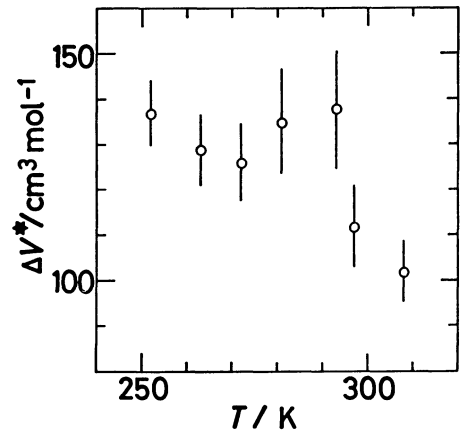

Fig. 2. Temperature dependence of the activation volume of self-diffusion.

293.2 K. The result is nearly equal to that obtained by Allen *et al.*[9] The two points above 297.4 K in Fig. 2 lie much lower than the other points; this may indicate possible existence of another phase transition as will be discussed below. The ratio of ΔV^* to the molecular volume V_m, which was determined to be 102 $cm^3\ mol^{-1}$ at 220 K from X-ray experiments,[3,4] is about 1.3. Because each of the formation and migration volume of a vacancy is not considered to be equal to V_m, the comparison of ΔV^* with V_m does not have a definite meaning. But the fact, $\Delta V^*/V_m = 1.3$, probably suggests that the self-diffusion in plastic neopentane is mainly controled by a single vacancy.

The feature of single-vacancy diffusion in plastic neopentane is assisted by the value of activation enthalpy ΔH^*. The plot in Fig. 1 can be rearranged to show the temperature dependence of T_1 at constant pressure. Through a similar procedure to the derivation of ΔV^*, the activation enthalpy ΔH^* of self-diffusion was calculated by use of Eq. 4 from the $\ln(T_{1\,SD})$ *vs.* $1/T$ plot. Unfortunately, large errors involved in the determination of ΔH^* did not permit to determine its temperature coefficient but the average value of ΔH^* was 43.5 ± 8.4 kJ mol^{-1} between 0.1 and 80 MPa which is somewhat larger than the value reported by Stejeskal *et al.*,[6] Roeder and Douglass,[8] and Allen *et al.*[9] The activation enthalpy ΔH^* is the sum of enthalpy of vacancy formation and enthalpy of migration,[20] each of which is usually considered to be nearly equal to the heat of sublimation L_s if self-diffusion proceeds *via* single vacancy mechanism.[2,21,22] In the case of neopentane, the ratio of ΔH^* to L_s[23] is

$$\Delta H^*/L_s = 43.5\ \text{kJ mol}^{-1}/23.4\ \text{kJ mol}^{-1} = 1.9 \quad (6)$$

at an ordinary pressure, which fact therefore suggests that self-diffusion in plastic neopentane is also controled by a single vacancy.

Phase Diagram. The melting point of neopentane under pressure was determined from the point where dP/dT changed its slope. It was also seen by a discontinuous change in T_1. The results are shown in Fig. 3. The equilibrium curve must follow the Clapeyron-Clausius equation,

$$dT_f/dP = \Delta V_f T_f/\Delta H_f, \quad (7)$$

where ΔH_f is the enthalpy of fusion and ΔV_f is the change in molecular volume at T_f, the melting temperature. By substituting the appropriate values to ΔH_f (3.09 kJ mol^{-1}),[5] ΔV_f (7×10^{-6} $m^3\ mol^{-1}$),[24] and T_f (256.5 K),[5] one obtains $dP/dT_f = 1.7$ MPa K^{-1}. The value found from Fig. 3 is 1.8 MPa K^{-1}, being consistent with Eq. 7.

There is possibility for existence of another solid phase which we designate Phase I′ between the plastic f.c.c. solid and the liquid phases above 40 MPa. It was inferred from a break in the curve of pressure *vs.* temperature at a prefixed volume. This curve is also shown in Fig. 3 as a dotted curve. According to Art-Ming Chen and Kai-Chow Chan who measured the density at 50 MPa at different temperatures, the density linearly decreases up to 273.5 K but it is smaller

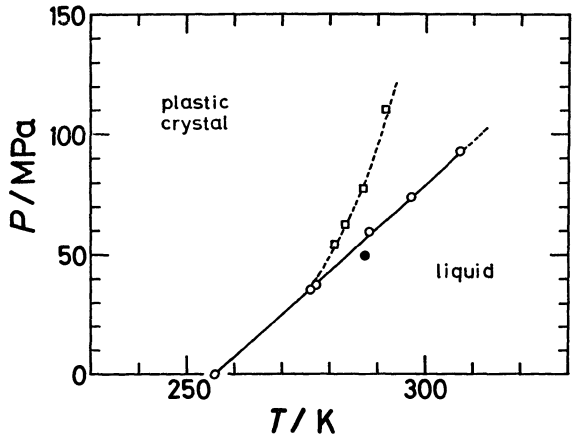

Fig. 3. Phase diagram of neopentane. Solid line shows the melting curve (○), while dashed line indicates a new transition line (see text). Full circle (●) is the melting point at 50 MPa determined by Art-Ming Chen and Kai-Chow Chain.[24]

by about 3.2% at 286.3 K than may be predicted from a linear extrapolation. This also supports existence of a new Phase I′. It is difficult to speculate about the nature of Phase I′ or the new transition at this point, but there is no discernible change in the T_1 values on going from the f.c.c. phase to Phase I′. Also the fact that the melting curve of Fig. 3 is almost linear suggests that changes in physical properties at the new transition point will be small.

The two points in Fig. 2 above 297.4 K correspond to the region where Phase I′ is stable. It is interesting to note that ΔV^* is smaller in Phase I′ than in Phase I (f.c.c.).

Corresponding State. If $\log(T_{1\,SD})$ is plotted against T_f/T, one obtains a good straight line irrespective of the pressure. This is illustrated for some selected pressures in Fig. 4. The fact that they all fall on a single straight line indicates that the law of corresponding states holds for the spin-lattice relaxation time at least to within the bounds of scatter of points in Fig. 4. In other words, the diffusion rate is also a function of T_f/T only, since the correlation time τ_{SD} is related to $T_{1\,SD}$ in the present case through

$$T_1^{-1}{}_{SD} = 2.29\gamma^2 M_2(\omega_0{}^2\tau_{SD})^{-1}, \quad (8)$$

which is derived using Torrey's correlation functions[25-27] for random walk in a f.c.c. lattice, where M_2 is the part of intermolecular second moment that is modulated by self-diffusion.

The threshold value of τ_{SD} at the melting point may be calculated from Eq. 8 using $M_2 = 1.1$ G^2 obtained at the ambient pressure.[7,10] It is $(3.2 \pm 0.5) \times 10^{-7}$ s at T_f although T_f varies from 256.5 K (at 0.1 MPa) to 306 K (at 90 MPa). It seems that the threshold value of τ_{SD} is not only independent of pressure but it is a kind of constant of plastic crystal because most of the plastic crystals ever examined melt when the threshold value of τ_{SD} reaches a value of about 10^{-7} s.[2,28]

The linear relation of Fig. 4 shows that τ_{SD} is em-
