Table 1 lists the ν_{NO} and $\Delta\nu_{1/2}$ values (the full width in wavenumbers at a half-height in absorbance) and the equilibrium constants in benzene and 1,2-dichloroethane. The ν_{NO} values in 1,2-dichloroethane with a greater polarity are smaller than in benzene by about 10 cm^{-1}, and the equilibrium constants in 1,2-dichloro ethane with a hydrogen-bonding ability are also smaller. These trends are consistent with those reported previously.[1f]

Figures 1 and 2 show, respectively, the plots of the ν_{NO} value and the equilibrium constant in 1,2-dichloroethane against the $pK_a(BH^+)$ value. Figures similar

Numbers refer to bases in Table 1. The Straight line was obtained by the use of least-squares method.

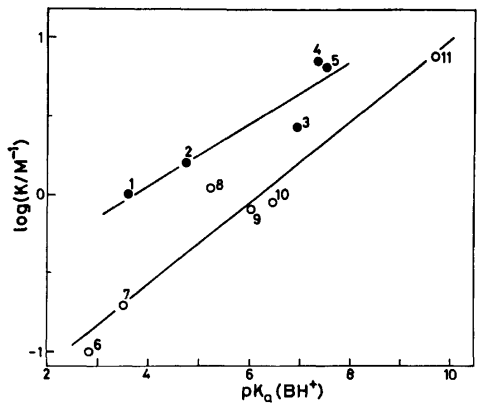

Fig. 2. A plot of log K against pK_a (BH^+) value for [Fe(ppdme)(NO)] complexes with imidazoles (●) and pyridines (○) in 1,2-dichloroethane. Numbers refer to bases in Table 1. The straight line was obtained by the use of least-squares method.

to Figs. 1 and 2 were also made by the plots in benzene against $pK_a(BH^+)$. The ν_{NO} value and the equilibrium constants, respectively, decrease and increase linearly with the basicity. The plots for imidazoles, pyridines, cyclic amines, and aliphatic amines are on separate lines.

Accordingly, the σ-electron donated from the base to the iron can increase with the basicity of the base to intensify the iron-to-base bond, resulting in an increase in the equilibrium constant. Then, since a molecular orbital consisting primarily of the d_{z^2} and the π^*(NO) orbitals is formed in the complexes with a bent Fe–N–O unit,[3,8,9] the contribution of the π^*(NO) orbital to the molecular orbital will be increased when the d_{z^2} orbital can be destabilized accompanying the σ-electron donation. Consequently, the increased antibonding character of the NO bond may induce the observed decrease in the ν_{NO} value. The concomitant increase in the energy of the d_{z^2} orbital also induces an observed decrease in EPR g values toward the free-electron value, as has been reported previously.[1c,e,7]

As is shown in Fig. 1, the ν_{NO} values decrease in the following order for bases: cyclic amines≥aliphatic amines>pyridines>imidazoles. As is shown in Fig. 2, the equilibrium constants for imidazoles are larger than those for pyridines. These tendencies have also been observed in the relation of the EPR g values for [Fe(ppdme)(NO)] complexes with various nitrogenous bases to the $pK_a(BH^+)$ values of the bases.[1c,e] These results indicate that the extra stabilization of an iron-to-base bond arises from d_π-p_π bonding formation, involving the destabilization of the π^*(NO) orbital, and that the imidazoles have a greater ability for π bonding than do the pyridines.

Experimental

The nitrosyl(protoporphyrin IX dimethyl ester)iron(II) was prepared as has been described previously.[1a] The nitrogenous bases were obtained commercially and purified by distillation, recrystallization, and sublimation as has been described previously.[1] The benzene and 1,2-dichloroethane were of a spectral grade and were used without further purification. The oxygen was removed from the solvents and the liquid bases by bubbling with pure N_2 prior to use. The samples were prepared under N_2 atmosphere.

The IR absorption spectra were recorded in the absorbance mode on a JASCO A-302 apparatus with a DP-A300 data processor. The details of the IR measurements were essentially the same as those reported in a previous paper.[1f]

The equilibrium constants were evaluated from the intensity change in the NO stretching band as has been described previously.[1f]

Synthesis and Magnetic, Spectral, and Electrochemical Properties of Strati-bis Cobalt(II) Complexes

Masaaki NAKAMURA

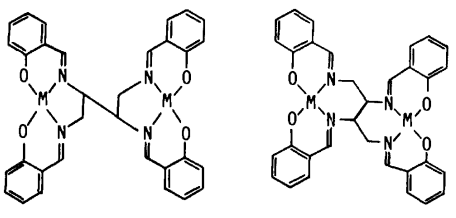
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812

(Received January 13, 1983)

Synopsis. Strati-bis cobalt(II) complexes, $[Co_2(sata)]\cdot 2H_2O$ and $[Co_2(sacta)]$ have been prepared, where H_4(sata) and H_4(sacta) denote 1,2,3,4-tetrakis(salicylideneamino)-2,3-dimethylbutane and 1,2-bis(salicylideneamino)-1,2-bis(salicylideneaminomethyl) cyclohexane, respectively. Since their magnetic moments are 4.89 and 4.73 BM at room temperature, respectively, the cobalt(II) ions in $[Co_2(sata)]$ and $[Co_2(sacta)]$ have a high spin d^7 configuration. From the temperature dependence of magnetic susceptibilities of these complexes the antiferromagnetic interaction exists between the two cobalt(II) ions. The oxidation potentials for $Co^{II}\rightarrow Co^{III}$ are observed at lower potentials compared with those of corresponding mononuclear cobalt(II) complexes.

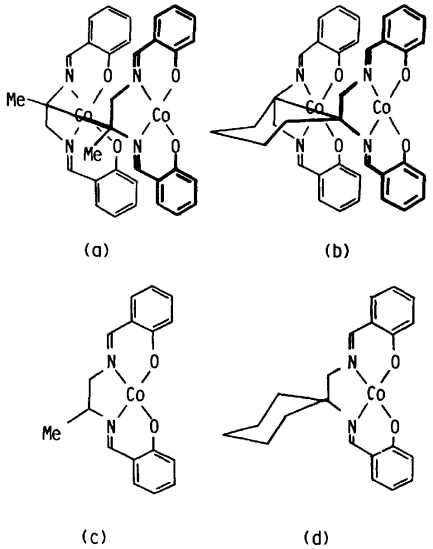
Recently there is a growing interest in chemistry of strati-bis binuclear metal complexes in which two metal coordination planes are held in juxtaposition by flexible or nonflexible linkages. In the previous papers,[1-3] it was reported the synthesis and characterization of strati-bis copper(II)–copper(II) and copper(II)–nickel(II) complexes of 1,2,3,4-tetrakis(R-salicylideneamino)-2,3-dimethylburane (H_4(R-sata)) and 1,2-bis(R-salicylideneamino)-1,2-bis(R-salicylideneaminomethyl) cyclohexane (H_4(R-sacta)), where R are the substituents on salicylaldehyde. In these complexes, the following characteristics have been recognized: 1) an "en"-chelated structure (Fig. 1a) and the existence of an equilibrium between the stacked and non-stacked forms as in the face to face manner of the MN_2O_2-planes, 2) electron delocalization over the whole molecule through the ligand π-systems, 3) one electron transfer process, Cu^{II}–$Cu^{II}\rightarrow Cu^{II}$–$Cu^{I}$, occurring at a higher potential compared with the corresponding mononuclear copper(II) complexes.

In the present study the author has prepared the strati-bis complexes, $[Co_2(sata)]$ and $[Co_2(sacta)]$ and their corresponding mononuclear cobalt(II) complexes, [Co(salpn)] and [Co(sacda)], where H_2(salpn) and H_2(sacda) denote *N,N'*-disalicylidene-1,2-propanediamine and 1-(salicylideneamino)-1-(salicylideneaminomethyl)cyclohexane, respectively. Chemical structures of $[Co_2(sata)]$, $[Co_2(sacta)]$, [Co(salpn)], and [Co(sacda)] are shown in Fig. 2.



(a) (b)

Fig. 1. Possible structures for strati-bis M(II) complexes: "en"-chelated and "tn"-chelated structures.



(a) (b) (c) (d)

Fig. 2. Chemical structures of a) $[Co_2(sata)]$, b) $[Co_2(sacta)]$, c) [Co(salpn)], and d) [Co(sacda)].

Experimental

Syntheses. The ligands were synthesized by the method previously reported.[1-3]

[Co(salpn)] and [Co(sacda)]: These complexes were synthesized by the literature method.[4]

$[Co_2(sata)]$: Cobalt(II) acetate tetrahydrate (0.97 g), H_4(sata) (1.1 g), and NaOH (0.3 g) were dissolved in absolute methanol, and the solution was stirred for 6 h at room temperature under nitrogen. The orange-red fine crystals were obtained. Found: C, 57.30; H, 4.58; N, 7.55%. Calcd for $C_{34}H_{30}N_4O_4Co_2\cdot 2H_2O$: C, 57.31; H, 4.81; N, 7.86%.

$[Co_2(sacta)]$: Cobalt(II) acetate tetrahydrate (0.25 g), H_4(sacta) (0.3 g), and NaOH (0.082 g) were dissolved in absolute methanol and the solution was stirred for 12 h at room temperature under nitrogen. The orange fine crystals were obtained. Found: C, 61.75; H, 4.85; N, 7.68%. Calcd for $C_{36}H_{32}N_4O_4Co_2$: C, 61.55; H, 4.59; N, 7.97%.

Measurements. Infrared spectra were measured with a Hitachi Infrared Spectrometer Model 215 on a KBr disk. Electronic spectra were recorded on a Shimadzu spectrophotometer MPS-5000 in dichloromethane. Magnetic susceptibilities were measured by Faraday method in the range from liquid nitrogen temperature to room temperature. Diamagnetic correction was made using Pascal's constants.[5] Effective magnetic moments were calculated by the equation, $\mu_{eff}=2.828(\chi_A\times T)^{1/2}$, where χ_A is the susceptibility per cobalt(II) ion. Differential pulse polarograms and cyclic voltammograms were recorded on a Yanagimoto Voltammetric Analyzer Model P-1000 in dichloromethane containing 0.1 M tetrabutylammonium perchlorate as the supporting electrolyte. A three electrode cell was used for measurements, in which the working electrode is a glassy carbon and the auxiliary electrode a platinum coil. A saturated calomel electrode (SCE)

was used as the reference electrode. In practice, instead of the reference electrode an internal standard, the ferrocene/ferricinium(1+) couple was utilized.[6]

Results and Discussion

The IR spectra of [Co_2(sata)] and [Co_2(sacta)] resemble those[1,2] of previously reported [Ni_2(sata)], [Cu_2(sata)], and [Cu_2(sacta)], and also that of mononuclear [Co(salpn)],[7] all of which have the "en" chelated structures. However, the IR spectra of the cobalt complexes do not resemble that of [Co(saltn)][8] (H_2(saltn) = *N*, *N'*-disalicylidene-1,3-propanediamine), which is the mononuclear complex of the "tn"-chelated structure. Based on these resemblance between the IR spectra, [Co_2(sata)] and [Co_2(sacta)] seem to have the "en"-chelated structure (Fig. 2).

The effective magnetic moments per cobalt(II) ions of [Co_2(sata)] and [Co_2(sacta)] are 4.89 and 4.73 BM at room temperature, respectively, and 4.48 and 4.09 BM at liquid nitrogen temperature, respectively. These results suggest that the cobalt(II) ions in [Co_2(sata)] and [Co_2(sacta)] have a high spin d^7 configuration. On the other hand, the related mononuclear cobalt(II) complex, [Co(salpn)],[9,10] has a low spin d^7 configuration. Thus, the spin states of cobalt(II) ions change to high spin on forming binuclear complexes. This may be caused by the stacking of two CoN_2O_2 moieties in the face to face manner. The magnetic moments of [Co_2(sata)] and [Co_2(sacta)] decrease with lowering of temperature. The χ_A *vs.* T^{-1} plots reveal that they obey the Curie-Weiss law $\chi_A = C/(T-\theta)$. The negative Weiss constants obtained for [Co_2(sata)] and [Co_2(sacta)], $\theta = -24$ and -42 K, respectively, imply the existence of an antiferromagnetic spin-exchange interaction.

Electronic spectra of [Co_2(sata)], [Co_2(sacta)], [Co(salpn)], and [Co(sacda)] measured in dichloromethane are shown in Fig. 3. Absorption bands in the near-infrared region of [Co(salpn)] and [Co(sacda)] are characteristic of the low spin square-planer cobalt(II) complexes,[10,11] whereas the same spectra of [Co_2(sata)] and [Co_2(sacta)] do not show sharp peaks. This difference implies that the binuclear cobalt(II) complexes have different spin states from those of mononuclear cobalt(II) complexes in solution as well.

Electrochemical properties of the cobalt(II) complexes studied by means of differential pulse polarography (D.P.P.) and cyclic voltammetry (C.V.) are given in Table 1. For mononuclear cobalt(II) complexes, [Co(salpn)] and [Co(sacda)], the one-electron oxidation from Co^{II} to Co^{III} was observed at +0.01 and +0.11 V, respectively, positive to the internal reference standard, the ferrocene/ferricinium(1+) couple.[6] In contrast, for the binuclear complexes, [Co_2(sata)] and [Co_2(sacta)] the two oxidation waves were observed at more cathodic region. These two oxidation waves may also be assigned to the oxidation from Co^{II} to Co^{III}. These electrochemical behaviors seem to reflect the presence of intramolecular spin-delocalization in the strati-bis cobalt(II) complexes.

Photodimerization Mechanism of *m*-Methoxystyrene *via* Its Cation Radical. Open Type Dimer Cation Radical as Its Intermediate

Masahide YAMAMOTO,* Hiroaki YOSHIKAWA, Tetsuya GOTOH, and Yasunori NISHIJIMA
Department of Polymer Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606
(Received July 29, 1982)

Synopsis. Two isomeric tetralin type dimers were obtained by UV excitation of *m*-methoxystyrene in the presence of an electron acceptor. Stepwise electrophilic dimerization mechanism through the dimer cation radical was confirmed. The scheme was analyzed with the aid of MO calculation.

Photodimerization of vinyl compounds conjugated to an aromatic nucleus (electron donors) has been studied extensively by direct photoexcitation,[1] or in the presence of electron acceptors.[2-10] In the presence of electron acceptors, vinyl compounds are photoionized in polar solvents to produce the cation radicals when either the ground state EDA complexes are photoexcited or the exciplexes are formed. The cation radical thus produced gives either [2+2] cyclobutane type dimers[2-6] or [2+4] tetrahydronaphthalene (tetralin) type dimers.[7-10] It has been shown that the dimerizations *via* cation radicals are nonconcerted and stepwise: the intermediates are 1,4-cation radicals.[2,10] However, the factor to determine the path to either cyclobutane type dimer or tetralin type dimer is still ambiguous: *N*-vinylcarbazole,[3] *p*-methoxystyrene,[5] *N,N*-dimethylaminostyrene,[6] *etc.* give mainly the former cyclobutanes; 1,1-diphenylethylene,[7] styrene, *α*-methylstyrene,[8] *etc.* give the latter tetralin type dimer. In this work, the reactivity of *m*-methoxystyrene cation radical was studied and this was found to give two isomers of tetralin type dimer: the one is predominant compared with the other. The mechanism is explained by the intramolecular electrophilic reaction of the 1,4-cation radical, which is supported by MO analysis.

Photoirradiation of *m*-methoxystyrene (**1**) in the presence of *m*-dicyanobenzene (**2**) in various solvents gave two isomeric tetralin type dimers:[11] 8-methoxy-1-(3-methoxyphenyl)-1,2,3,4-tetrahydronaphthalene (**3**) and 6-methoxy-1-(3-methoxyphenyl)-1,2,3,4-tetrahydronaphthalene (**4**) as shown in Table 1. Quantum yield of the dimerization in MeCN solvent (Run 1) was 0.016 with excitation wavelength of 313 nm. Effect of solvent polarity on the dimer yield and the fraction of the dimers are shown in Table 1, Runs 1, 2, and 3. In polar solvent MeCN, the rate is faster than those in less polar solvents, THF and CH_2Cl_2, and the ratio of **3**/**4** is smaller than those in less polar solvents. Runs 4, 5, and 6 show the time course of photodimerization. Dimer yields increase with irradiation time, but the ratios of **3**/**4** decrease with time. This decrease seems to be due to the variation of the partitioning between **3** and **4** with reaction time. In the limit of $t=0$, the ratio of **3**/**4** is 7.7. As for other exciplex acceptors, *p*-dicyanobenzene and dimethyl terephthalate are also effective and gave the same products with approximately the same rates and product ratios. Temperature dependence of the dimer yield was hardly observed in the range from −30 to +30 °C.

Table 1. Dimerization yields and fractions

Run	**1** / mM	**2** / mM	Solvent	Time/h	Dimer yield / %	Fraction/% **3**	Fraction/% **4**

Fig. 2. 1,4-Cation radical intermediates **C-3** and **C-4** prior to $\mathbf{3}^{+}$ and $\mathbf{4}^{+}$.

The reaction scheme is shown in Fig. 1. The monomer cation radical $\mathbf{1}^{+}$ which is produced by the interaction of **1** with **2** (fluorescence quenching constant $k_q=9\times10^9\ M^{-1}\ s^{-1}$ in MeCN solvent), reacts with the monomer to form an open type dimer cation radical. Electrophilic attack of the carbenium ion to ortho-positions *o* or *o'* of phenyl ring and subsequent intramolecular proton migration give $\mathbf{3}^{+}$ and $\mathbf{4}^{+}$, respectively.[12] Back electron transfer from $\mathbf{2}^{\cdot-}$ to the dimer cation radicals gives either **3** or **4**. Yamaguchi[13] showed

Table 2. Formal charge and spin density for C-3 and C-4 conformations

Atom No.	C-3		C-4	
	Formal charge	Spin density	Formal charge	Spin density
C 7	0.158	0.182	0.140	0.183
C11	−0.065	0.061	−0.046	0.025
C12	0.072	−0.019	0.048	0.002
C13	−0.030	0.089	−0.052	0.016
C14	0.082	−0.035	0.085	−0.029
C15	−0.093	0.022	−0.070	0.084
C16	0.253	−0.006	0.268	−0.012
C17	0.010	0.647	0.019	0.635

by theoretical analysis that the dimerization of olefin cation radical with neutral olefin proceeds *via* open type cation radical.

Preferred formation of **3** to **4** can be estimated by the MO analysis. In this calculation, a reaction path to tetralin is assumed: **C-3** and **C-4** in Fig. 2 correspond to two conformations just before C7–C15 and C7–C13 bond formations, which lead to **3** and **4**, respectively. In Fig. 2, the coefficients of HOMO are also roughly shown by the size of lobes. Formal charge density, and total spin density of the dimer cation radical are given in Table 2. The carbenium ion was found to be at carbon 7, while the radical was at site C17 as can be seen from Table 2. The carbenium ion (C7) attacks *o* position (C15 in **C-3**) or *o'* position (C13 in **C-4**).[12] Electron density of *o* position (C15) for **C-3** (−0.093) is higher than that of *o'* position (C13) for **C-4** (−0.052). Formal charge at C7 for **C-3** (+0.158) is more positive than that for **C-4** (+0.140). Furthermore the AO bond population[14] between C7 and C15 in **C-3** is 0.250 and the one between C7 and C13 in **C-4** is 0.236. Therefore, it can be understood that the dimer **3** is produced more favorably than the dimer **4**. This result supports the stepwise electrophilic dimerization. In the LUMO of the styrene cation radical $\mathbf{1}^+$, the α- and β-carbons have the same sign, but in the HOMO of styrene **1** the signs of the β- and *o*-carbons are opposite, hence these do not interact in a concerted way and the products **3** and **4** are not produced by a concerted mechanism.

Experimental

^{1}H-NMR spectra were taken on a Varian HA-100 spectrometer with TMS as an internal standard. Mass spectra were taken on a Hitachi RMU-60 mass spectrometer. Photolysis was carried out through Pyrex vessel wall with a 300 W high-pressure mercury lamp (Toshiba 300H) at room temperature. Analysis of the sample solutions was performed with a Shimadzu GC-3BF with a 1 m column packed with Apiezon grease L (230 °C), using phenanthrene as an internal standard.

8-Methoxy-1-(3-methoxyphenyl)-1,2,3,4-tetrahydronaphthalene(3): After photolysis of degassed MeCN solution of **1** and **2**, the dimer fraction was collected by silica gel column eluted with dichloromethane–hexane (1 : 1) and the fraction of **3** was collected by GLPC. Recrystallization from CCl_4–dichloromethane gave an analytical sample **3**: mp 87—90 °C; IR (KBr-pellet) 1600, 1580, 1480 (phenyl), 1245 (C–O), 870 (isolated ring H atom), 790, 770 cm^{-1} (three adjacent ring H atoms); NMR (CCl_4) δ=1.44—2.86 (m, CH_2, 6H), 3.53 (s, OCH_3, 3H), 3.67 (s, OCH_3, 3H), 4.27 (m, CH, 1H), 6.36—7.10 (m, phenyl, 8H). MS (70 eV), *m/e*: 268 (M^+, main), 160 (M^+−anisole).

6-Methoxy-1-(3-methoxyphenyl)-1,2,3,4-tetrahydronaphthalene(4): In the final separation procedure of **3** from the dimer fraction, **4** was also collected. Uncrystallized. IR (neat) 1605, 1580, 1500 (phenyl), 1250 (C–O), 870, 855 (isolated ring H atom), 830 (two adjacent ring H atoms), 780 cm^{-1} (three adjacent ring H atoms); NMR (CCl_4) δ=1.20—2.90 (m, CH_2, 6H), 3.66 (s, OCH_3, 3H), 3.69 (s, OCH_3, 3H), 3.97 (m, CH, 1H), 6.40—7.20 (m, phenyl, 8H); MS (70 eV), *m/e*: 268 (M^+, main), 160 (M^+−anisole).

Method of Calculation. The calculation was carried out with the unrestricted SCF INDO method.[15] It is assumed that the effect of the contaminating spin components of the S^2 operator is negligible. The geometry of the dimer cation radical in Fig. 2 is as follows: R(C⋯C of aromatic ring)=1.40 Å, R(C4–C7)=1.47 Å, R(C7–C8)=1.51 Å, R(C8–C18)=1.54 Å, $R(C\text{–}H_{aromatic})$=1.08 Å, $R(C\text{–}H_{aliphatic})$=1.09 Å, R(C–O)=1.36 Å, ∠C17–C14–C15=110° (**C-3**), ∠C17–C14–C13=130° (**C-3**), ∠C18–C17–C14=110°, ∠C17–C18–C8=90°, ∠C18–C8–C7=100°, C7 and C17 have sp^2 shape, R(C7–C15 or C7–C13)=2.283 Å. In Fig. 2, atoms 9 and 19 are oxygen, and hydrogen atoms are not shown. The calculations were carried out on the FACOM-230-75 computer at the Computer Center of Kyoto University.

Thermally Derived Dimers of *o*-Vinylphenol: *trans*- and *cis*-2′-Hydroxy-4-methylflavans

Yen-Yuan CHEN, Ryuichi OSHIMA, and Ju KUMANOTANI*
Institute of Industrial Science, The University of Tokyo, 7-22-1 Roppongi, Minato-ku, Tokyo 106
(Received August 27, 1982)

Synopsis. *o*-Vinylphenol dimerizes thermally to yield quantitatively two isomers, *trans*- and *cis*-2′-hydroxy-4-methylflavans. The analysis of the dimers of *o*-vinylphenol-*O*-*d* suggests that a quinone-methide intermediate is responsible for the formation of these flavanoid compounds.

Although a number of papers have been published concerning the radical polymerization of *o*-vinylphenol,[1-5] little is known of its dimers formed in the course of the polymerization or during storage.[1] Flavanoid compounds were previously found in our laboratory to be obtained by the dimerization of *o*-vinylphenol; they were assumed to be mixtures of *cis* and *trans* isomers.[2] In this paper, we report the identification of each isomer of the dimers separated by gel-permeation chromatography (GPC) and liquid-solid chromatography (LSC).

Experimental

Thermal Dimerization. *o*-Vinylphenol (1.0 g) (bp 61 °C/3—4 mmHg (1 mmHg=133.322 Pa), made by the decarboxylation of *o*-coumaric acid)[6,7] was heated at 90 °C for 12 h in an ampoule displaced with nitrogen; the dimers were thus obtained almost quantitatively, along with a trace of higher-molecular-weight substances (less than 1%), which has been separated by GPC on a preparative TSK-gel 2000HG8 column (2.2 cm I.D.×60 cm×2), using chloroform as the eluent. The dimers were fractionated by LSC (1 : 3 in a peak-area ratio with a UV detector at 254 nm) on a semi-preparative silica column (Nomura Chemical, Develosil 60-3, 8 mm I.D.×25 cm), using hexane–ethyl acetate (95.5: 2.5 v/v) as the eluent.

The ^{1}H NMR spectra of these two isomers were recorded at 90 MHz with a Varian EM 390 spectrometer, using tetramethylsilane as the internal standard in $CDCl_3$.

The minor isomer was obtained as a white solid; mp 86 °C; mass spectrum, *m/e* 240 (M^+). Found: C, 79.61; H, 6.73%. Calcd for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71%.

The major isomer was obtained as a pale yellow viscous liquid; mass spectrum, *m/e* 240 (M^+). Found: C, 79.31; H, 6.75%. Calcd for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71%.

Dimerization of o-*Vinylphenol*-O-d. A mixture of 1.0 g of *o*-vinylphenol, 10 ml of carbon tetrachloride, and 1 ml of deutrium oxide was shaken vigorously for 20 min, after which the separated oily layer was again shaken with new deuterium-oxide (1 ml) for 30 min. The oily layer was separated and dried over sodium sulfate. The IR spectrum of the solution confirmed the complete H–D exchange at the hydroxyl group of *o*-vinylphenol. Then the solution was transferred into an ampoule. After the removal of carbon tetrachloride *in vacuo*, the ampoule was sealed under nitrogen and heated at 90 °C for 12 h. The dimers were then separated into two isomers by means of LSC, as has been described above. Mass spectra for both isomers: *m/e* 241 (M^+).

Results and Discussion

Each of the fractionated isomers showed the same *m/e* value (240) for the molecular ion and similar IR spectra. In the IR spectra of the isomers, the absorption bands due to a vinyl group (1630, 1420, and 910 cm^{-1}) were completely eliminated, and a new band, presumably due to an ether group, appeared at 1050 cm^{-1}. The ^{1}H NMR spectra of both isomers are shown in Fig. 1. By extensive decoupling experiments, each resonance

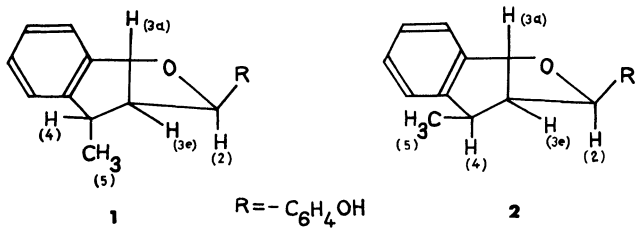
Table 1. ^{1}H NMR data of *trans*- and *cis*-2′-hydroxy-4-methylflavans

Chemical shift[a] (δ) of	*trans*	*cis*
H_2(1H)	5.30	5.25
H_{3e}(1H)	1.95	2.28
H_{3a}(1H)	2.43	1.97
H_4(1H)	3.10	3.17
H_5(3H)	1.45	1.37
Coupling constants/Hz		
3a, 3e	14	15
3e, 4	2	7
2 , 3e	3	3
3a, 4	6	13
2 , 3a	12	12
4 , 5	8	8

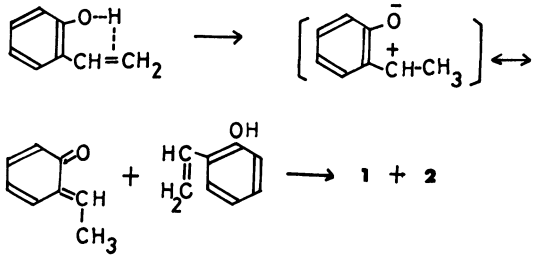
a) Measured at 90 MHz in $CDCl_3$. Chemical shifts (center of multiplet) are shown in δ.



was assigned as is summarized in Table 1: in the minor product, $J_{3e,4}$ (2 Hz) corresponds to $J_{eq,eq}$, and $J_{3a,4}$ (6 Hz) to $J_{ax,eq}$, while in the major product, $J_{3e,4}$ (7 Hz) and $J_{3a,4}$ (13 Hz) stand for $J_{eq,ax}$ and $J_{ax,ax}$ respectively. From these results, it is obvious that the minor isomer has the 2,4-*trans* structure (**1**) with a quasi-axial methyl group, while the major isomer has the 2,4-*cis* structure (**2**) with a quasi-equatorial methyl group at C-4 of the flavanoid compounds. The coupling constants also indicate that the *o*-C_6H_4OH group is in the quasi-equatorial position for both isomers.[8] Accordingly, it may be concluded that the minor and major isomers are *trans*- and *cis*-2′-hydroxy-4-methylflavans, respectively.

The predominant formation of the *cis* isomer may be explained on steric effect: the *cis* isomer has both substituents at quasi-equatorial positions with less crowding than in the *trans* isomer, which has the quasi-axially oriented methyl group.

The dimers from *o*-vinylphenol-*O*-*d* showed a weak C–D absorption band at 2230 cm^{-1} and an *m/e* value of 241 for M^+. In the ^{1}H NMR spectra, no significant difference could be detected for the peaks due to H_2, H_{3a}, and H_{3e}. However, peaks from H_4 and H_5 of both isomers were obviously different from those of undeuterated dimers. The integrated intensity of the resonance of H_5 for both isomers decreased to 2/3 of that for undeuterated isomers, and the peak became a doublet of triplets with a new, small coupling (J=1.2 Hz) which can be attributed to a geminal deuterium-proton coupling.[9] The splitting of the H_4 peak is also consistent with the calculated ones.[10] (see Fig. 2)



Scheme 1. A mechanism of thermal dimerization of *o*-vinylphenol.

Consequently, Scheme 1 can be taken as a mechanism of the dimerization of *o*-vinylphenol. It may be suggested that the initial migration of the proton of the phenolic hydroxyl group, making a hydrogen-bond bridge with the neighbouring vinyl group, leads to the formation of quinone methide[11] through a dipolar intermediate. Then it may react with an olefin (*o*-vinylphenol) to give the dimers by means of a Diels-Alder reaction.[12,13] This mechanism may also account for the formation of a similar type of flavanoid compound obtained from 4-isopropenyl-*m*-cresol.[14–16] When compared with styrene, which thermally gives *cis*- and *trans*-1,2-diphenylcyclobutanes as the dimers,[17] the phenolic hydroxyl group may play a significant role in the thermal dimerization of *o*-vinylphenol.

Induced Circular Dichroism in the Complex of Poly(L-arginine) Hydrochloride with Azo Dyes

Hiroyuki YAMAMOTO* and Ayako NAKAZAWA

Institute of High Polymer Research, Faculty of Textile Science and Technology, Shinshu University, Ueda 386

(Received December 13, 1982)

Synopsis. The induced circular dichroism (CD) spectra of the poly(L-arginine) hydrochloride–azo dye complexes were measured. The induced CD arose from the azo dyes bound to the polypeptide in the α-helical conformation. The configuration of the transition dipole moments of dye was examined by the exciton chirality method.

The induced optical activities of complexes of synthetic poly(L-glutamic acid) (PLG) with cationic dyes, such as Acridine Orange (AO) and pseudoisocyanine, in the pH range from 4.2 to 6.5 were first reported by Stryer and Blout.[1,2] Induced optical activities have been reported mostly on the PLG complexes. Lately, however, the complexes of poly(*S*-carboxymethyl-L-cysteine)-AO[3] and poly(L-lysine) (PLL)–azo dyes[4-6] have been reported to induce optical activity.

The first complete synthesis of poly(L-arginine) (PLA) by the *N*-carboxy anhydride method and a conformational study of the polypeptide have been reported from this laboratory.[7,8] In the course of our study of the induced CD of biopolymers, we wish to report our findings on the induced CD due to the interaction between the cationic PLA and anionic azo dyes.

Experimental

The average degree of polymerization of the PLA hydrochloride (HCl) used was 70. The three analogous azo dyes, *p*-(4-aminophenylazo)benzenesulfonic acid sodium salt (AA), *p*-(4-dimethylaminophenylazo)benzenesulfonic acid sodium salt (Methyl Orange, MO) and *p*-(4-diethylaminophenylazo)-benzenesulfonic acid sodium salt (Ethyl Orange, EO), were guaranteed reagents (Wako). The mixtures were prepared by adding the dye solutions to the PLA solution; the pH values of the solutions were then brought up to the desired pH by the addition of NaOH or HCl. The final concentrations of the dyes were 2×10^{-5} M, and the ratio of polypeptide residues to dye molecules (R/D) was less than 5. The absorption and the CD spectra were measured with JASCO UVIDEC-1 and CD J-40A instruments respectively. The ellipticity, $[\theta]$ (degree cm^2 dmol^{-1}), or molar extinction coefficient, ε (1 mol^{-1} cm^{-1}), was expressed on the basis of the dye concentration.

Results and Discussion

The CD and absorption spectra of the three azo dyes with and without polypeptide (R/D=0—5) were measured in the pH range from 2.0 to 13.6. Figure 1 shows the induced CD and absorption spectra of the PLA HCl–MO system at pH 8.7 and 10.3 for R/D=1. MO showed a single visible absorption band at 467 nm with ε_{467}=25600 (and ε_{378}=8100) at pH 7. When a complex was formed with PLA HCl, the spectrum showed an additional peak at 378 nm. The blue-shifted band at 378 nm has been considered to reflect a nearly parallel orientation of the MO molecules.[4,9] The values at R/D=1 were ε_{467}=11400 and ε_{378}=12400

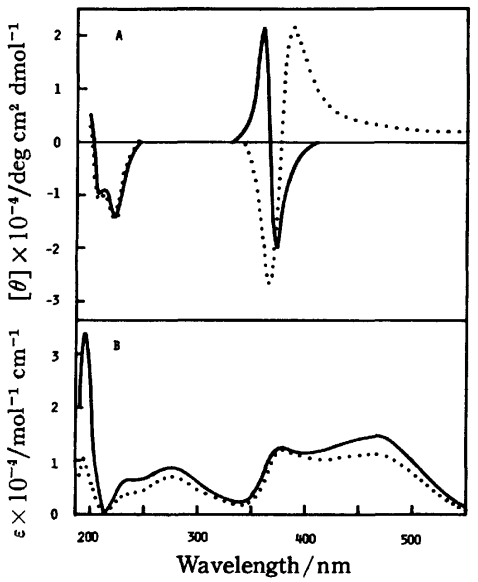

Fig. 1. Induced CD (A) and absorption (B) spectra of the PLA HCl–MO complex at R/D=1: (·····) at pH 8.7 and (——) at pH 10.3.

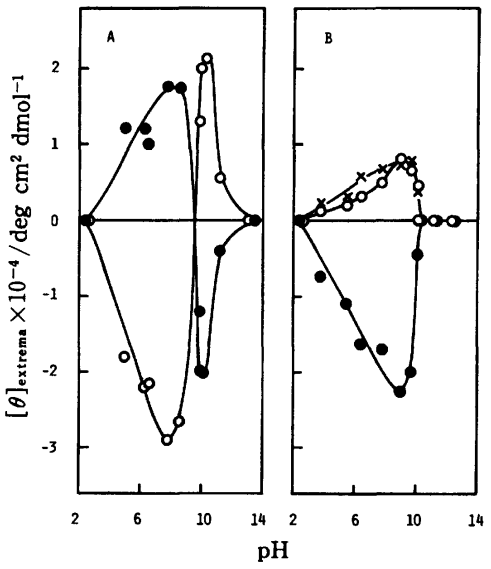

Fig. 2. Induced CD values at extrema of the PLA HCl–dye complexes as a function of pH at R/D=1. (A) PLA HCl–MO complex: ○ at 370 nm and ● at 390 nm; (B) PLA HCl–EO complex: ○ at 378 nm, ● at 400 nm, and × at 450 nm.

at pH 8.7, and ε_{467}=14600 and ε_{378}=12600 at pH 10.3. EO showed similar changes in the absorption spectra, but no change was found in AA.

Figure 2 shows the induced CD values at the extrema of the PLA HCl–azo dye complexes as a function of the pH at R/D=1. The PLA HCl–MO complex showed a

Table 1. Characteristic of CD in the PLA HCl–dye complexes

Dye	R/D	pH	ε_{max}/nm		Induced CD $[\theta]_{extrrema}$/nm		
MO	0.5	8.1	19100(467)	10900(378)		3400(390)	−4700(370)
		10.3	18500(467)	8800(378)[a]		−4200(374)	2400(361)
	1	8.7	11400(467)	12400(378)		21400(390)	−26300(370)
		10.3	14600(467)	12600(378)		−19800(374)	21500(361)
	5	8.0	9000(467)	18800(378)		35400(390)	−47200(370)
		10.4	11400(467)	10700(378)		−22100(374)	28800(361)

a) Shoulder.

positive CD band at 390 nm and a negative CD band at 370 nm below pH 9.6, while it showed a negative CD band at 374 nm and a positive CD band at 361 nm above pH 9.6. On the other hand, the PLA HCl–EO complex induced three CD extrema, at 450 and 378 nm (positive) and at 400 nm (negative), in the pH range of 4—10.5 (Table 1).

Both the PLA HCl–MO and EO complexes showed $[\theta]_{222}$ values of −13000—−16000 at R/D=1 in the pH range of 4—10. The positions and magnitudes of the extrema suggest that the two PLA HCl complexes are mostly in a helical conformation, since the n-π^* peptide transitions of PLA have been reported to have the ellipticity values of $[\theta]_{222}=-19000$ for a helical structure[8] and of $[\theta]_{217}=3000$—3900 for a random-coil structure.[10,11]

Many rules correlating the signs of ellipticity with the absolute configuration have been proposed including the validity of the exciton chirality method for aromatic compounds[12–15] and for polypeptide–dye complexes.[4,5] The sign of the longer wavelength CD extremum was in agreement with the sense of the handedness of the interacting transition dipole moments.[12] Since the transition of bound MO in the visible wavelength region was determined to be long-axis polarized by the stretched polyvinyl alcohol film method,[16] the CD spectra of the PLA HCl–MO complex were examined by means of the exciton chirality method. The interacting transition dipole moments of dimeric dye can be assumed to have the clockwise *R*-chirality for the PLA HCl–MO complex below pH 9.6 and the *S*-chirality for the same complex above pH 10, while the PLA HCl–EO complex showed a multiple induced CD band in the pH range of 4—10.5. When the pH was raised, the *R*-to-*S* configurational inversion of the PLA HCl–MO complex was found at pH 9.8. The reason is not clear at present, since no significant conformational differences between the two PLA HCl–MO and EO complexes were found. It is, however, conceivable that the delicate interaction of the polarized transition dipole moments affects the dihedral angle or the C_2 rotation axis of the dimeric MO molecules[17,18] accompanying the helix-to-coil conformational transition of the PLA HCl–MO complex around pH 9.8.

The authors wish to thank Professor Tadao Hayakawa of Shinshu University for his encouragement.

The Lithium Diisopropylamide-induced Fragmentation of 1,3-Dithiolane Derivatives of Several Ketones Having α-Hydrogen

Hideyuki IKEHIRA,* Shigeo TANIMOTO,* and Tatsuo OIDA
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received February 7, 1983)

Synopsis. The reaction of 1,3-dithiolane derivatives of ketones having α-hydrogen with lithium diisopropylamide results in fragmentation to the corresponding thioketone followed by further conversion in a few steps to the other intermediate species which, on trapping with alkyl halide, leads to a vinylic sulfide and/or a sulfide bearing a secondary alkyl group.

It has been known for a long time that 1,3-dithiolane derivatives of aldehydes are easily deprotonated at the 2-positions of the rings by strong base and the generated anions undergo facile elimination to form ethylene.[1,2] Recently, Wilson and his co-workers[3] described that the treatment of 1,3-dithiolane derivatives of saturated ketones with an excess of butyllithium in ether leads to fragmentation to the corresponding thioketones, which afforded methyl sulfides by quenching the reaction mixture with methyl iodide or underwent a subsequent reduction with butyllithium to secondary thiols. They also comment that the reaction proceeds by a mechanism involving deprotonation at the 4-position of the ring as the first step. This report prompted us to publish the results of our independent studies in which the products obtained are somewhat different from those described by the above-quoted authors. Thus, we have found that the metalation of 1,3-dithiolane derivatives of several ketones having α-hydrogen with the less nucleophilic lithium diisopropylamide (LDA) in tetrahydrofuran results in fragmentation to the corresponding thiocarbonyl compounds followed by further conversion in a few steps to the other intermediate species. These, on trapping with alkyl halide, lead to vinylic sulfides and/or sulfides bearing a secondary alky group depending on choice of the starting 1,3-dithiolane derivatives. For example, when 2-methyl-2-phenyl-1,3-dithiolane (**1a**) was treated with an excess of LDA in tetrahydrofuran solution, followed by addition of an alkyl halide, we obtained the corresponding α-(alkylthio)styrene (**6a**) in excellent yield together with alkyl vinyl sulfide (**10**). The formation of the intermediate thioacetophenone (**3a**) and ethylenethiolate anion (**4**) is certain from the analogy to the reaction mode proposed by Wilson and his co-workers.[3] Presumably, **3a** is further converted to α-styrenethiolate anion (**5a**) *via* α-proton abstraction by a second LDA molecule. On quenching with alkyl halide, this leads to **6a**.

When 2-ethyl-2-phenyl-1,3-dithiolane (**1b**) was submitted to a similar fragmentation-alkylation sequence, two products, α-alkylthio-β-methylstyrene (**6b**) and 1-alkylthio-1-phenylpropane (**9b**), were isolated. Supposedly, the mechanism of the conversion of **3b** into **9b** involves three steps. The first step is a one-electron transfer between **3b** and LDA to afford a radical anion species (**7b**). The second step is the charge neutralization by alkyl halide to generate the radical species (**8b**); the last stage is the abstraction of a hydrogen radical, in which tetrahydrofuran may be serving as a donor, eventually providing **9b**. There is no direct evidence for the intermediary presence of **7b** and **8b**. However, the feasibility of the one-electron transfer is supported by analogy to the mode of reaction of thioketones, such as thiobenzophenone and di-*t*-butyl thioketone, with organometallics proposed by Ohno and his co-workers.[4] When 2-phenyl-2-propyl-1,3-dithiolane (**1c**) was cleaved under the same conditions and further quenched with methyl iodide, two products, α-methylthio-β-ethylstyrene (**6c**) and 1-methylthio-1-phenylbutane (**9c**) were also isolated, suggesting that the intermediate propyl phenyl thioketone (**3c**) behaves similarly to **3b**. The use of 2-isopropyl-2-phenyl- (**1d**) or 2-benzyl-2-phenyl-1,3-dithiolanes (**1e**) as the starting substrate and methyl iodide as the trapping agent in this reaction resulted in the exclusive formation of **9d** and **9e**, respectively. This means that in the initially formed isopropyl phenyl thioketone (**3d**) and benzyl phenyl thioketone (**3e**) a steric hindrance at their α-position may be preventing formation of the substituted ethylenethiolate anions (**5d** and **5e**). Thus, an obvious difference in behavior among the 1,3-dithiolane derivatives (**1**) submitted to this fragmentation-alkylation sequence has been noted. These experiments are summarized in Table 1, along with the ^{1}H-NMR spectroscopic data of the products.

Several 2-alkylthio-2-bornenes (**12**) have also been made in 97—99% yields from 1,3-dithiolane derivative

(**11**) of (+)-camphor by the present procedure. Presumably, the intermediate (+)-thiocamphor[5] in the reaction could be easily deprotonated by LDA at the 3-position. The yields as well as the ^{1}H-NMR spectroscopic data of the produced **12** are shown in Table 2.

Experimental

Reaction Summarized in Tables 1 and 2. General Procedure: A solution of diisopropylamine (0.35 g, 3.5 mmol) in tetrahydrofuran (7 ml) was cooled to −78 °C under nitrogen, treated with 1.56 molar solution (2.12 ml, 3.3 mmol) of butyllithium in hexane, and then stirred at the same temperature for 30 min and further at −15 °C for 10 min. The solution of LDA thus prepared was cooled to −78 °C and a solution of either the 2-alkyl-2-phenyl-1,3-dithiolanes (**1**) or the 1,3-dithiolane derivative (**11**) of (+)-camphor (1.3 mmol) in tetrahydrofuran (4 ml) was added. After an additional 1 h at −15 °C, the solution was cooled again to −78 °C, and an alkyl halide (3.3 mmol) was added with stirring. The stirring was continued for 1 h at −5——10 °C and for a further 24 h at room temperature. The mixture was then quenched with 100 ml of water and 20 ml of saturated aqueous solution of NH_4Cl, and extracted with ether (3×60 ml). The combined organic layer was dried over $MgSO_4$ and concentrated *in vacuo* to give a pale yellow residue, which was subjected to column chromatography.

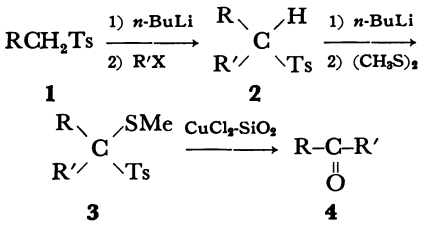
A Convenient Method for the Synthesis of Acyclic Ketones. Synthesis of Sex Pheromone of Douglas Fir Tussock Moth

Yasue MURATA, Katsuhiko INOMATA, Hideki KINOSHITA, and Hiroshi KOTAKE*
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920
(Received February 17, 1983)

Synopsis. (α-Alkyl-α-methylthio)alkyl *p*-tolyl sulfones derived from the reaction of α-alkylated alkyl *p*-tolyl sulfones with dimethyl disulfide could be easily hydrolyzed by $CuCl_2$–SiO_2 to give the corresponding ketones in fairly good yields. This method was applied to the synthesis of Douglas Fir Tussock Moth Pheromone.

The development of the general method for the synthesis of acyclic ketone is a major point of interest in the organic synthesis and a variety of methods have been reported. In connection with our continuing interest to extend the synthetic utility of sulfones, in the preceding paper,[1] a new method for the preparation of aromatic ketones *via* chlorination of α-substituted benzyl *p*-tolyl sulfones followed by hydrolysis was described. However, the reaction was limited to the formation of aryl ketones, and drastic conditions using silver perchlorate in refluxing trifluoroacetic acid for hydrolysis were required. Recently, a convenient method for the hydrolysis of a ketone dithioacetal *S*,*S*-dioxide leading to the corresponding carbonyl group has been reported by Ogura and co-workers,[2] in which hydrochloric acid in refluxing methanol was used for hydrolysis.



Scheme 1.

In this paper, we wish to report a more mild synthetic method of acyclic ketones (**4**) starting from alkyl *p*-tolyl sulfones (**1**), which were subjected to alkylation followed by treatment with *n*-BuLi and $(CH_3S)_2$ to afford α-(methylthio)alkyl *p*-tolyl sulfones (**3**). Subsequently, on treatment of **3** with $CuCl_2$–SiO_2 in dichloromethane at room temperature without further purification, hydrolysis to ketone compounds took place very smoothly to give the desired products (**4**) in fairly good yields as shown in Table 1.

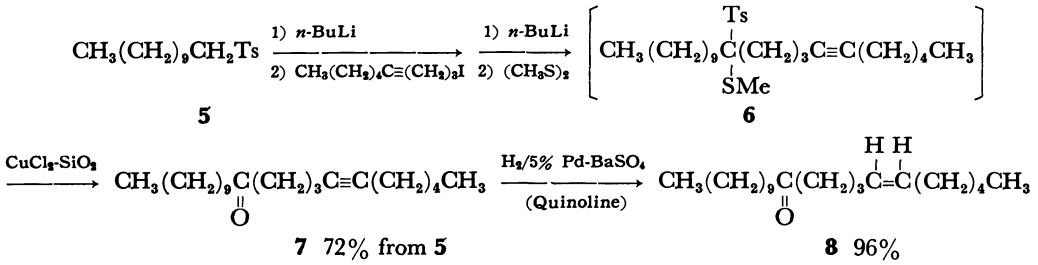
Next, this method was applied to the synthesis of Douglas Fir Tussock Moth Pheromone[3] starting from *p*-tolyl undecyl sulfone (**5**) according to the following scheme. The reaction proceeded smoothly, and acetylenic ketone (**7**) was obtained in high yield in a similar manner above mentioned. A catalytic hydrogenation of **7** over 5% Pd–$BaSO_4$ (deactivated by quinoline) gave the desired pheromone (**8**) in an excellent yield.

Experimental

All the melting points are uncorrected. The NMR and IR spectra were recorded on JEOL/PMX-60 and JASCO IRA-1 spectrometers, respectively.

Materials. Freshly distilled THF from potassium under nitrogen was used. Thin-layer chromatography (TLC) was performed on Merck's silica gel 60 PF_{254} (Art. 7749).

A Typical Experimental Procedure for the Preparation of the Ketones. To a solution of phenethyl *p*-tolyl sulfone (123 mg, 0.5 mmol) in dry THF (5 ml) was added *n*-BuLi (0.55 mmol, hexane solution) dropwise at −20 °C under N_2. The reaction mixture was allowed to warm to room temperature in a period of 20 min and then a solution of phenethyl bromide



Scheme 2. Synthesis of Douglas Fir Tussock Moth Pheromone.

TABLE 1. THE SYNTHESIS OF ACYCLIC KETONES FROM ALKYL *p*-TOLYL SULFONES (**1**)

No.	R	R'X	$CuCl_2 \cdot SiO_2$	Reaction conditions	Yield of **4**[a]/%
1	$CH_3(CH_2)_9$	$C_6H_5CH_2Br$	2 equiv.	r.t., 20 min	62 (**4a**)
2	$CH_3(CH_2)_9$	$C_6H_5(CH_2)_2Br$	2 equiv.	r.t., 40 min	58 (**4b**)
3	C_6H_5	$CH_3(CH_2)_4C{\equiv}C(CH_2)_3I$	2 equiv.	r.t., 1 h	69 (**4c**)
4	C_6H_5	$C_6H_5(CH_2)_2Br$	2 equiv.	r.t., 30 min	80 (**4d**)
5	$C_6H_5CH_2$	$CH_3(CH_2)_4C{\equiv}C(CH_2)_3I$	2 equiv.	r.t., 2.5 h	67 (**4e**)
6	$C_6H_5CH_2$	$C_6H_5(CH_2)_2Br$	2 equiv.	r.t., 1 h	59 (**4f**)

a) Based on **1**.

(102 mg, 0.55 mmol) in dry THF (2 ml) was added slowly at −78 °C. The temperature of the solution was raised to room temperature, cooled down again at −20 °C, and treated with *n*-BuLi (0.55 mmol) followed by the addition of a solution of $(CH_3S)_2$ (52 mg, 0.55 mmol) in dry THF (2 ml) at −78 °C. The reaction temperature was gradually raised to room temperature, quenched with buffer solution of pH=7 ($NaOH+KH_2PO_4$) (5 ml) and HCl, extracted with AcOEt, dried over Na_2SO_4 and concentrated *in vacuo*. The resulting residue was dissolved in CH_2Cl_2 (5 ml) and treated with $CuCl_2$–SiO_2 (752 mg) for 1 h at room temperature. After filtration and concentration, the residue was subjected to preparative TLC (solvent : benzene) to give the desired ketone in 59% yield (66 mg) based on phenethyl *p*-tolyl sulfone (**1**).

The Active $CuCl_2$–SiO_2. After a mixture of $CuCl_2 \cdot 2H_2O$ (0.85 g), SiO_2 (3.5 g), and water (8 ml) was air-dried for 1 h, it was heated up at 110—130 °C for 3 h and allowed to cool to room temperature. The mixture thus obtained must be used immediately.

Preparation of 1-Iodo-4-decyne. Preparation of 1-Chloro-4-decyne: To a solution of 1-heptyne (15.8 mmol) in dry THF (15 ml) was added a solution of *n*-BuLi (15.8 mmol) in hexane (10 ml) at −78 °C under N_2. After the reaction temperature was raised to room temperature, a solution of 1-bromo-3-chloropropane (17.4 mmol) in dry THF (12 ml) was added to the reaction mixture and refluxed for 21 h. After the solvent was removed *in vacuo*, quenched with buffer solution ($NaOH+KH_2PO_4$) (20 ml) and HCl followed by extraction with AcOEt. The AcOEt extract was distilled under reduced pressure. Bp 83 °C/6 Torr, (61% yield).

Conversion of the Chloride to the Corresponding Iodide: A solution of 1-chloro-4-decyne (7.4 mmol) and NaI (7.4×4.5 mmol) in dry acetone (20 ml) was refluxed for 15 h. After the solvent was removed, AcOEt was added and the AcOEt extract was distilled under reduced pressure to give 1-iodo-4-decyne in 86% yield. Bp 73 °C/0.03 Torr; IR (neat) 2930, 1450, 1220 cm^{-1}; NMR ($CDCl_3$) δ 0.63—1.08 (distored t, 3H), 1.08—1.73 (m, 6H), 1.73—2.63 (m, 6H), 3.23 (t, 2H, J=6 Hz).

Preparation of p-*Tolyl Undecyl Sulfone*: A suspension of 1-bromoundecane (2.35 g, 10 mmol) and sodium *p*-toluenesulfinate tetrahydrate (3.75 g, 15 mmol) in EtOH (20 ml) was refluxed for 8.5 h. Then, the reaction mixture was poured into a lot of ice-water to result in precipitation of the crude product, which was collected and dried. Recrystallization from MeOH gave a pure compound. Yield 2.68 g (87%). Mp 70—71 °C. Found: C, 69.49; H, 9.98%. Calcd for $C_{18}H_{30}O_2S$: C, 69.63; H, 9.74%.

Identification of Products (4a—f). **4a**: Oil, *m/e*: 260 (M^+), IR (neat) 2930, 1710, 1600, 1495, 1450 cm^{-1}. NMR ($CDCl_3$) δ 0.73—1.04 (distored t, 3H), 1.04—1.76 (m, 16H), 2.35 (t, 2H, J=7.0 Hz), 3.55 (s, 2H), 7.08 (s, 5H).

4b: Oil, *m/e* 274 (M^+), IR (neat) 2930, 1710, 1600, 1495, 1450 cm^{-1}; NMR ($CDCl_3$) δ 0.6—1.02 (distored t, 3H), 1.02—1.73 (m, 16H), 2.33 (t, 2H, J=7 Hz), 2.50—3.07 (m, 4H), 7.10 (s, 5H).

4c: Oil, *m/e* 242 (M^+), IR (neat) 2940, 1680, 1600, 1580, 1450 cm^{-1}; NMR ($CDCl_3$) δ 0.70—1.05 (distored t, 3H), 1.05—1.68 (m, 6H), 1.68—2.48 (m, 6H), 3.05 (t, 2H, J= 7.0 Hz), 7.15—7.50 (m, 3H), 7.68—7.95 (m, 2H).

4d: Mp 70.5—71.5 °C; IR (neat) 3032, 1708, 1600, 1172, 750 cm^{-1}; NMR ($CDCl_3$) δ 2.62—2.87 (m, 4H), 3.53 (s, 2H), 6.38—7.50 (m, 10H), Found: C, 85.40; H, 6.77%. Calcd for $C_{15}H_{14}O$: C, 85.68; H, 6.71%.

4e: Oil, *m/e* 256 (M^+), IR (neat) 2920, 1710, 1600, 1495, 1450 cm^{-1}; NMR ($CDCl_3$) δ 0.70—1.05 (distored t, 3H), 1.05—1.67 (m, 8H), 1.67—2.35 (m, 4H), 2.55 (t, 2H, J= 7.0 Hz), 3.67 (s, 2H), 7.22 (s, 5H).

4f: Oil, *m/e* 224 (M^+), IR (neat) 2930, 1710, 1600, 1490, 1450 cm^{-1}; NMR ($CDCl_3$) δ 2.43—3.08 (m, 4H), 3.60 (s, 2H), 6.87—7.67 (m, 10H).

The Reaction Condition for the Synthesis of Pheromone (8).

Preparation of 6-Heneicosyn-11-one (7) from 5: A synthetic procedure was the same manner above mentioned. *p*-Tolyl undecyl sulfone (**5**) (310 mg, 1 mmol), 1-iodo-4-decyne (264 mg, 1 mmol), and dimethyl disulfide (94 mg, 1 mmol) were used for the formation of **6** (479 mg). The procedure for the conversion of **6** to **7** is as follows: To a solution of **6** (96 mg, 0.2 mmol) in CH_2Cl_2 (6 ml) was added $CuCl_2$–SiO_2 (820 mg, 1 mmol), and the suspension was stirred for 2 d at room temperature. The usual work-up gave 44 mg of **7**. Total yield of **7** was 72% based on **5**.

IR (neat) 2910, 2850, 1705, 1460, 1370, 1090 cm^{-1}; NMR ($CDCl_3$) δ 0.62—1.05 (distored t, 6H), 1.05—2.23 (m, 28H), 2.37 (t, 2H, J=7 Hz), 2.47 (t, 2H, J=7 Hz).

IR and NMR spectra of **7** were identical with those of literature.[3]

Preparation of Pheromone (8) from 7. A methanol solution (15 ml) of **7** (116 mg, 0.38 mmol) containing one drop of quinoline was hydrogenated over 5% Pd–$BaSO_4$ (20 mg) under atmospheric pressure for about 5 h. The catalyst was filtered off and the filtrate was concentrated *in vacuo* to give a residue which was taken up into AcOEt. The AcOEt solution was washed with dil-HCl, brine, dried over Na_2SO_4, and concentrated *in vacuo* to give the desired material as a single product in 96% yield (112 mg). Its IR and NMR data were identical with the reported values.[4] IR (neat) 3000, 2920, 2850, 1715, 1455, 1370, 1125, 1080 cm^{-1}; NMR ($CDCl_3$) δ 0.75—1.05 (distored t, 6H), 1.05—1.75 (m, 24H), 1.95 (m, 4H), 2.34 (t, 4H, J=7 Hz), 5.27 (m, 2H).

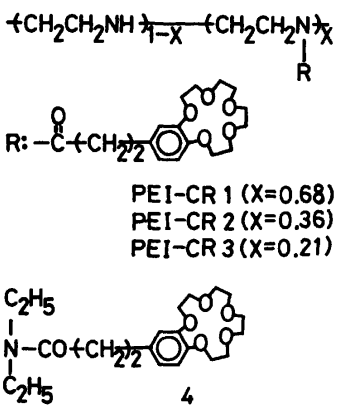
Cation Transport through Liquid Membranes Facilitated by Crown Ether-modified Poly(iminoethylene)s

Jun-ichi ANZAI, Yoko SAKATA, Yasuhiro SUZUKI, Akihiko UENO, and Tetsuo OSA*
Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980

(Received February 24, 1983)

Synopsis. Poly(iminoethylene)s containing benzo-15-crown-5 moieties as pendant groups can transport Rb^+ cation more effectively than the other alkali cations through an organic liquid membrane. The transport selectivities of the polymers diminish drastically with decreasing crown ether content in the polymer chain.

Much effort has been invested in effecting selective transport of alkali cations through artificial liquid membranes using crown-type synthetic carriers.[1-3] A desirable characteristic of crown ethers as cation carriers is their high degree of selectivity. In this connection, it may be interesting to employ polymeric crown ethers as carriers since they are endowed with high selectivities in cation binding.[4] Hence we have prepared crown ether-modified poly(iminoethylene)s (PEI-CR's **1**—**3**) and their monomer model **4** and have recently reported their cation binding properties.[5,6] The purpose of this note is to elucidate their cation transporting properties in liquid membrane systems containing a single cation species in the source aqueous phase. The results are discussed in relation to the crown ether contents in the polymer chain.



4

Experimental

Materials. The synthetic procedure of **1**—**4** was described previously.[5,6] A commercially available poly(iminoethylene) (PEI) with a molecular weight of 40000—50000 (from Tokyo Kasei) was used. The PEI has a highly branched structure and the ratio of primary, secondary, and tertiary amino groups is about 1 : 2 : 1.

Cation Transport. The transport of alkali cations was performed within a U-shaped glass tube with 17 mm diameter at 23 °C. A 20 ml of dichloromethane (CH_2Cl_2) dissolving one of the carrier compounds was put into the tube as a liquid membrane. A 5 ml of picrate solution was placed in the left arm of the tuve (source phase) and the right arm was filled with the equal volume of water (receiving phase). All three phases were stirred at a constant rate. The amount of metal picrate transported across the membrane was monitored by UV spectroscopy at 354 nm. The plots of the amount of the picrate transported *vs.* time gave good straight lines, from which the transport rates were determined. The amount of cation leakage, estimated from blank experiments, was always less than 1.25×10^{-7} mol dm^{-3} h^{-1}. At the end of the measurement the concentration of alkali picrate in the membrane was determined.

Liquid-Liqud Extraction. Liquid-liquid extractions were carried out employing a H_2O–CH_2Cl_2 system. After good agitation of two layers for 5 min at 23 °C, equilibrium was attained. The detailed procedure of extraction and subsequent analysis has been described elsewhere.[5,6]

Results and Discussion

In order to evaluate the cation binding efficiency and selectivity of **1**—**4**, liquid-liquid extractions were performed. The results are expressed as percentages of extracted picrate salts (Table 1). It is obvious that the polymers **1**—**3** extract the metal picrates more effectively than the monomer model **4**, especially in the cases of K^+ and Rb^+ cations. The selectivity sequence in extracting picrate salts with **1**—**3** is $K^+>Rb^+>Cs^+>Na^+$, while with **4** the sequence is $K^+>Na^+>Rb^+>Cs^+$. These characteristics of polymers in cation binding are believed to arise from the complex formation based on a 1 : 2 cation to crown stoichiometry intramolecularly.[4,6]

The transport rates of alkali cations through CH_2Cl_2 membranes facilitated by **1**—**4** are listed in Table 2

TABLE 1. LIQUID-LIQUID EXTRACTION OF ALKALI CATIONS

Crown ether	Extracted picrate salts (%)			
	Na	K	Rb	Cs
1	30	90	78	39
2	38	88	82	46
3	35	77	76	38
4	8.5	13	4.3	2.1

Aqueous phase: [Picrate salt]$=5\times10^{-4}$ mol dm^{-3}, [Metal hydroxide]$=1\times10^{-2}$ mol dm^{-3}; CH_2Cl_2 phase: [Crown ether]$=1\times10^{-3}$ mol dm^{-3}.

TABLE 2. ION TRANSPORT THROUGH CH_2Cl_2 MEMBRANE

Crown ether	Transport rate of alkali cations/10^{-6} mol dm^{-3} h^{-1}			
	Na	K	Rb	Cs
1	2.7	11	23	9.4
2	3.9	8.8	19	13
3	9.5	12	18	9.8
4	4.3	7.8	3.2	2.7

Source phase: 2.5×10^{-3} mol dm^{-3} of metal picrate in 5 ml of water; Receiving phase: 5 ml of water; Membrane: 1.25×10^{-4} mol dm^{-3} of crown ether in 20 ml of CH_2Cl_2.

2	3.1	6.7	5.9	5.2
3	5.0	7.2	6.7	5.2
4	0.2	0.4	0.1	<0.1

a) These values were determined at the end of the transport rate measurements reported in Table 2.

and the transport selectivities relative to Na^+ cation are illustrated in Fig. 1. Polymers **1**—**3** transport Rb^+ cation more effectively than the other cations examined ($Rb^+ > K^+ \approx Cs^+ > Na^+$) under our experimental condition. The observed Rb^+ selectivity of **1**—**3** in cation transport is apparently incompatible with the data shown in Table 1 suggesting their K^+ selectivity. This discrepancy between the transport and extraction selectivities of polymers can interpreted reasonably based on the fact that there is an optimum range in value of the cation–carrier complex stability constant for the maximum cation transport.[7,9)] In our case, polymers **1**—**3** can transfer K^+ cation more effectively than the other cations from the source phase into the membrane but can not release it rapidly to the receiving phase owing to the high stability of polymer–K^+ complexes in the membrane. Alternatively, Rb^+ cation, which binds to polymers rather loosely, can be released rapidly at the interface from the membrane to the receiving phase. In the case of **4**, the transport selectivity is in accord with the sequence of the binding selectivity ($K^+ > Na^+ > Rb^+ > Cs^+$). In the case of the relatively low stability complexes such as **4**–cation complexes, the uptake process of cations from the source phase into the membrane seems to determine the overall transport rates. On the contrary, as for the relatively high stability complexes such as the polymer–cation complexes, the overall rates of transport are probably governed by the releasing process. The importance of the rate of release is also suggested from the data of cation concentration in the membrane (Table 3). These data indicate that K^+ cation, in all polymer systems, is transported less effectively than Rb^+ in spite of higher concentration of K^+ in the membrane. As is obvious from the above discussion, a moderately stable complex formation in the membrane is required for the effective transport of cations.

Figure 1 shows that the transport selectivity of **1**—**3** diminishes drastically with decreasing crown ether content in the polymer chains. The Rb^+/Na^+ selectivities of **1**—**3** are 8.3, 4.7, and 1.8 for **1**, **2**, and **3**, respectively. These remarkable differences in selectivity among the polymers can not be explained only from the extraction data. The unsubstituted amino groups in the polymer backbone, which were shown to bind alkali cations weakly with no selectivity,[6)] may participate in the transport process, resulting in the low selectivity of **2** and **3**. Although the reason for the remarkable dependence of the trasport selectivity on the contents of the crown ether moieties in the polymers is not obvious, it should be noted that a high degree of crown ether contents in the polymer chain is an essential requirement for the selective carriers of alkali cations. Thus it appears that PEI–CR's **1**—**3** function as Rb^+ selective carriers in liquid membrane systems containing a single cation species in the source aqueous phase.

Diazomethane Ring-expansion of (−)-D_3-Trishomocubanone. Preparation and Chiroptical Properties of a Series of [*m*.1.1]Triblattanes

Masao NAKAZAKI,* Koichiro NAEMURA, and Masaki HASHIMOTO
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received March 31, 1983)

Synopsis. Optically active [3.1.1], [4.1.1], [5.1.1], and [6.1.1]triblattanes were prepared through the diazomethane ring-expansion of (−)-D_3-trishomocubanone. The absolute molecular rotations of [*m*.1.1]triblattanes were found to increase with *m* begining from *m*=0 till *m*=2. On going from *m*=2 to *m*=3, $[M]_{D\ abs.}$ abruptly drops, then the value remains almost constant till *m*=6.

Since our first preparation of twistane (**3**)[1] in an optically active modification, we have been interested in the preparation, stereochemistry, and biological transformations of series of cage-shaped compounds which possess the D_3-twisted bicyclo[2.2.2]octane framework **1** as a common structural feature (Fig. 1). We have classified these hydrocarbons into three categories according to the number of their diagonal bridgings, and have coined for them the generic names [*m*], [*m.n*], and [*m.n.p*]triblattanes,[2] from German, Blatt= leaf, where *m*, *n*, and *p* are the number of CH_2's in each diagonal bridge.

Figure 1[1,3] illustrates the triblattanes so far prepared in optically active forms in our laboratory and reveals the interesting chiroptical feature that all triblattanes having the D_3-twisted bicyclo[2.2.2]octane moiety with M helicity as the central core are levorotatory. Another conspicuous chiroptical property observed in [*m*.2.2], [*m*.2.1], [*m*.1.1], and [*m*]triblattanes having *m*<3 (Fig. 2), is the linear dependence of the absolute molecular rotations ($[M]_{D\ abs.}$) on the bridge span.[4] Owing to their short diagonal bridges (*m*<3), all triblattanes so far prepared in optically active forms are conformationally rigid, and this situation prompted us to prepare a series of optically active [*m*.1.1]triblattanes where *m* is greater than 2.

Results and Discussion

An obvious way for preparing optically active [3.1.1], [4.1.1], [5.1.1], and [6.1.1]triblattanes of known absolute configuration is extention of the diazomethane ring-expansion reaction which has proved successful in our synthesis of (−)-[2.1.1]triblattane (**8**) from (−)-D_3-trishomocubanone (**14**).

Our preliminary experiment utilizing (±)-**14** indicated that when kept at 0 °C an ethereal solution of (±)-**14** containing 10 equiv. of diazomethane gave a mixture of [2.1.1]triblattanone (**15**) and [3.1.1]triblattanones (**16**) with unknown location of the carbonyl group in the expanded bridge (Table 1). Addition of boron trifluoride was found to push the ring-expansion further furnishing a product consisting of higher homologs. An ethereal solution of (±)-**14** containing excess of diazomethane and 1 equiv. of BF_3–etherate was kept at 0 °C for 24 h. The reaction product was a mixture of ring-expanded ketones, again of unknown structure as to the location of the carbonyl group in the expanded bridges. To reveal composition of the mixture, the product was converted into a mixture of hydrocarbons by Wolff-Kishner reduction and the reaction product was analyzed by means of GLC. The results are summerized in Table 2.

We carried out the preparative experiment with a larger amount of (−)-**14**, $[\alpha]_D$ −26.0° (30% optical purity)[3] which was dissolved in an ethereal solution of 3 molar equiv. of diazomethane. The mixture was kept at 0 °C for 8 d, and routine workup furnished a 3 : 2 mixture of **15** and **16**, chromatography of which on alumina provided a 3.5% yield of **16**. Wolff-Kishner reduction of this [3.1.1]triblattanone (**16**) afforded [3.1.1]-triblattane (**20**), $[\alpha]_D$ −46.5°.

The major fraction obtained from the above chromatography was a 1 : 3 mixture of **15** and **16**, and this was dissolved in ether and subjected to further ring-expansion with 10 equiv. of diazomethane and 1 equiv. of BF_3–etherate. The solution was kept at 0 °C for

Scheme 1.

24 h, and routine workup gave a mixture of **16**, **17**, **18**, and **19** from which **16** was removed by alumina chromatography. Wolff-Kishner reduction of the remaining mixture of **17**, **18**, and **19** furnished a 48 : 26 : 26 mixture (by GLC analysis) of **21**, **22**, and **23**. Preparative GLC separated and purified these [*m*.1.1]-triblattanes.

The known optical purity of our starting material (−)-**14** permitted calculation of the absolute molecular rotation of these new hydrocarbons; $[M]_{D\ abs.}$ −268°, −321°, −255°, and −287° for **20**, **21**, **22**, and **23** respectively. These values are plotted in Fig. 2, inspection of which indicates that the $[M]_{D\ abs.}$ of [*m*.1.1]-triblattanes drop abruptly on going from $m=2$ to $m=3$, then remain almost constant till $m=6$. This behavior could be explained in terms of the expected conformational mobility of $(CH_2)_m$ bridge in these higher [*m*.1.1]-triblattanes which should annihilate the $[M]_D$ contribution from this part of molecule.

Experimental

Product Distribution in the Diazomethane Ring-expansion Product of (±)-D_3-Trishomocuban-4-one (14). Without Catalyst: An ethereal solution (100 mL) of diazomethane (1.5 g, 35 mmol) was added with stirring to an ice-cooled solution of (±)-**14**[5] (500 mg, 3.13 mmol) in dry ether (20 mL). The reaction mixture was allowed to stand at 0 °C, and aliquots were analyzed by GLC at 1, 3, 5, and 8 d period.

With BF_3-etherate Catalyst: The following experimental procedure is typical. An ethereal solution (100 mL) of diazomethane (1.5 g, 35 mmol) was added to a stirred and chilled (0 °C) solution of (±)-**14** (500 mg, 3.13 mmol) and freshly distilled BF_3-etherate (0.4 mL, 3.2 mmol) in dry ether (20 mL). After the resulting mixture was kept at 0 °C for 24 h, a deposited solid was removed by filtration and the filtrate was washed with aq $NaHCO_3$ and water, dried ($MgSO_4$) and concentrated to give an oily product (460 mg). The product (400 mg) was mixed with 100% hydrazine hydrate (0.35 mL), KOH (190 mg) and triethylene glycol (4 mL) and the mixture was heated for 1 h at 110—120 °C and for an additional 4 h at 190—200 °C. The product (310 mg) was analyzed by GLC.

Preparation of (−)-[3.1.1]Triblattane (20). An ethereal solution of diazomethane (11 g, 0.26 mol) was added to a stirred and chilled (0 °C) solution of (−)-**14**, $[\alpha]_D$ −26.0°[3] (13.5 g, 84.4 mmol) in dry ether (100 mL), and the mixture was kept at 0 °C for 8 d. After the remaining diazomethane was destroyed with a small amount of acetic acid, the mixture was washed with aq $NaHCO_3$ and water, and dried ($MgSO_4$). Removal of the solvent left an oily product which was analyzed by GLC and was found to be a 3 : 2 mixture of **15** and **16**. When the mixture was chromatographed on alumina, earlier pentane eluents containing **16** (≥98% estimated by GLC) (550 mg) was followed by fractions containing a 1 : 3 mixture (4.30 g) of **15** and **16** which was reserved for further ring-expansion reaction (*vide infra*). Wolff-Kishner reduction of **16** 240 mg, (1.27 mmol) was carried out by the same procedure described above. The product was chromatographed on alumina and elution with pentane provided **20** (175 mg). The analytical sample was purified by sublimation at 55 °C (15 mm); mp 73—73.5 °C (in a sealed tube); $[\alpha]_D^{22}$ −46.5° (*c* 0.212, $CHCl_3$); MS, *m/e* 174 (M^+); ^{13}C NMR ($CDCl_3$) δ 24.47 (t), 29.32 (t), 35.54 (t), 39.91 (d), 42.31 (d), 46.60 (d), 47.30 (d); GLC, *Rt.* 4′10″ (at 120 °C); Found: C, 89.65; H, 10.36%. Calcd for $C_{13}H_{18}$: C, 89.59; H, 10.41%.

Preparation of (−)-[4.1.1], (−)-[5.1.1], and (−)-[6.1.1]-Triblattanes. Ring-expansion reaction of the 1 : 3 mixture (4.00 g) of **15** and **16** obtained as described above was carried out with 1 L of ethereal solution of diazomethane (10 g, 0.23 mol) and BF_3-etherate (3.0 mL, 23 mmol) at 0 °C for 24 h. The same workup afforded a mixture (3.50 g) of **16**, **17**, **18**, and **19**. In order to remove **16**, the mixture was chromatographed on alumina, and earlier pentane eluents provided a semi-solid (630 mg) which was found to be free from **16** by GLC. Wolff-Kishner reduction of this fraction (600 mg) was carried out with 100% hydrazine hydrate (0.5 mL), KOH (260 mg), and triethylene glycol (6 mL). The same workup as described above gave a 48 : 26 : 26 mixture (232 mg) of **21**, **22**, and **23**. Preparative GLC (at 140 °C) provided specimens of (−)-**21** (80 mg), *Rt.* 8′20″, (−)-**22** (45 mg), Rt. 12′05″ and (−)-**23** (40 mg), *Rt.* 15′10″. (−)-[4.1.1]Triblattane (**21**); An oil; $[\alpha]_D^{20}$ −51.5° (*c* 0.344, $CHCl_3$); MS, *m/e* 188 (M^+); Found: C, 89.26; H, 10.70%. Calcd for $C_{14}H_{20}$: C, 89.29; H, 10.71%. (−)-[5.1.1]Triblattane (**22**); An oil; $[\alpha]_D^{24}$ −37.9° (*c* 0.796, $CHCl_3$); MS, *m/e* 202 (M^+); Found: C, 88.96; H, 10.97%. Calcd for $C_{15}H_{22}$: C, 89.04; H, 10.96%. (−)-[6.1.1]Triblattane (**23**); mp 64 °C; $[\alpha]_D^{25}$ −39.9° (*c* 1.46, $CHCl_3$); MS, *m/e* 216(M^+); Found: C, 88.67; H, 11.14%. Calcd for $C_{16}H_{24}$: C, 88.82; H, 11.18%.

Laser Excitation Spectrum of the $\tilde{A}^2A'(004) \leftarrow \tilde{X}^2A''(000)$ Band of HSO Radical

Masayoshi SATOH, Nobukimi OHASHI,* and Shin-ichi MATSUOKA
Institute for Spectroscopic Study of Matter, Faculty of Science, Kanazawa University, Maruno-uchi, Kanazawa 920
(Received June 21, 1982)

The dye laser excitation spectrum of the $\tilde{A}^2A'(004)\leftarrow\tilde{X}^2A''(000)$ vibronic band of HSO was observed and analyzed in the frequency range from 17132 to 17182 cm^{-1}. 414 spectral lines were assigned to an ordinary c-type transition and 21 lines to an axis-switching transition. The rotational constants of HSO in the $\tilde{A}^2A'(004)$ state were used to calculate the inertia defect of 0.518 u $Å^2$ for this state. A relatively large dependence of the centrifugal distortion constant on the vibrational quantum number was also found.

The HSO radical is expected to play an important role in various oxidations, for example, that of hydrogen sulfide. Recently, spectroscopic studies on this radical have been made by several workers[1–4] and the existence of this radical in gas phase has been established.

Schurath *et al.*[1] observed the chemical luminescence spectrum of $\tilde{A}^2A'\leftarrow\tilde{X}^2A''$ band of HSO and DSO, and deduced some vibrational frequencies: $\nu_3'(HSO)=702$, $\nu_3''(HSO)=1013$, $\nu_3'(DSO)=702$, $\nu_3''(DSO)=1030$ cm^{-1} for the SO bond stretching, and $\nu_2'(DSO)=600$ and $\nu_2''(DSO)=770$ cm^{-1} for the bending vibration.

Kakimoto *et al.*[2] observed the laser excitation spectrum of the $\tilde{A}^2A'(003)\leftarrow\tilde{X}^2A''(000)$ vibronic transition of HSO and determined the rotational constants and centrifugal distortion constants precisely.

Ohashi *et al.*[3] determined the structural parameters of HSO in the ground and the excited states by combining the rotational constants of HSO and DSO; they also estimated an approximate force field. For the $\tilde{X}^2A''$ ground state, they determined a simple valence force field by using the observed centrifugal distortion constants of HSO. The force field reproduced fairly well the fundamental frequencies obtained by Schurath *et al.*, the centrifugal distortion constants, and the inertia defects of HSO and DSO. For the $\tilde{A}^2A'$ excited state, however, they could not obtain a satisfactory force field by applying the same procedure as they had used for the ground state. The centrifugal distortion constants may depend strongly on the vibrational quantum numbers in this case. The failure in determining the force field for the excited state is considered to originate from the v-dependence of the centrifugal distortion constants.

In the present study, $\tilde{A}^2A'(004)\leftarrow\tilde{X}^2A''(000)$ band of HSO was observed and analyzed with the intention of obtaining further information on the centrifugal distortion constants and the inertia defects.

Experimental

The experimental setup for recording the laser excitation spectrum was similar to that used by Kakimoto *et al.*,[2] except that the dye laser was a ring laser (Spectra Physics, Model 380A) and the frequency scanning was in 200 MHz mode-hopping. The present measuring system for the excitation spectrum of unstable molecules has been fully described elsewhere.[5]

The wavenumber determination of spectral lines was made by using iodine lines as standard. The precision was about 0.02 cm^{-1}, which was about ten times worse than that obtained by Kakimoto *et al.*[2] because of the mode-hopping.

The generation of the HSO radical was made in the following reaction system:

$$C_2H_5SH + O_2 \text{ (MW discharge)},$$

where partial pressures measured with a Pirani gauge were 30 mTorr (1 Torr = 133.322 Pa) for C_2H_5SH and 100 mTorr for O_2. The laser output power was about 100 mW.

Results and Discussion

The excitation spectrum of the HSO radical was recorded in the spectral range of 17132 to 17182 cm^{-1}. The spectrum observed in the present work corresponds to a vibronic band of $\tilde{A}^2A'(004)\leftarrow\tilde{X}^2A''(000)$ and obeys a c-type rotational selection rule. The assignment of the spectral lines could be done easily by using a simulation spectrum calculated from the determined ground state constants[4] and the assumed upper state constants. Most of the observed lines could be assigned; 414 lines were assigned to ordinary c-type transitions. Besides these transitions, 21 lines were assigned to $\Delta K_a=0$ and $+2$ type transitions allowed by axis switching,[6] because the H–S–O angle in the excited state is smaller by about 11° than that in the ground state.

The following Hamiltonian was used in the least squares analysis:

$$H = H_{rot} + H_{cd} + H_{sr}, \tag{1}$$

$$H_{rot} = AN_a^2 + BN_b^2 + CN_c^2, \tag{2}$$

$$H_{cd} = -\Delta_N N^4 - \Delta_{NK} N^2 N_a^2 - \Delta_K N_a^4 - 2\Delta_N N^2(N_b^2 - N_c^2) - \delta_K[(N_b^2 - N_c^2)N_a^2 + N_a^2(N_b^2 - N_c^2)], \tag{3}$$

$$H_{sr} = \varepsilon_{aa} N_a S_a + \varepsilon_{bb} N_b S_b + \varepsilon_{cc} N_c S_c, \tag{4}$$

for both the upper and lower states. In the above analysis, the ground state constants were fixed to the values determined by Endo *et al.*[4] in the microwave measurements.

In Table 1, the obtained molecular constants for $\tilde{A}^2A'(004)$ of HSO are given. The rms deviation between the observed and calculated wavenumbers is

Values in brackets are estimated ones.

0.015 cm^{-1}. In Fig. 1, the observed spectrum is compared with the simulated one, which was calculated from the obtained constants. In the present calculation of the simulated spectrum, the axis-switching effect was not taken into account, because the axis-switching angle is very small(θ_T=1.65°). The good agreement between the observed and simulated spectra indicates that (1) the observed band is free from any perturbation and (2) the spectral lines attributable to other bands of HSO or to other species than HSO do not exist in the observed spectral region (17132 to 17182 cm^{-1}).

The inertia defect for the $\tilde{A}^2A'(004)$ state was obtained to be 0.518 u Å^2 from the determined rotational constants. The value for the $\tilde{A}^2A'(000)$ state was deduced to 0.074 u Å^2 by extrapolation from 0.407 u Å^2 for the (003) state[2] and 0.518 u Å^2 for the (004) state.

Using the force constants given in Table 5 of Ref. (3), values of the inertia defect for the $\tilde{A}^2A'(000)$, $\tilde{A}^2A'(003)$, and $\tilde{A}^2A'(004)$ states of HSO were calculated to be 0.088, 0.192, and 0.226 u Å, respectively. Thus, the calculated value of the (000) state agreed well with the extrapolated value, but the agreement between the calculated and observed values was poor for the (003) and (004) states.

Improvement of the force field was tried by adding the present value of inertia defect to the reported data.

(1). A valence force field was determined by using inertia defects for the (003) and (004) states of HSO and for the (003) state of DSO, and ν_3(HSO), ν_2(DSO), and ν_3(DSO). The obtained force constants, and the frequencies and inertia defects reproduced by these force constants, are summarized in column (1) of Table 2. As seen from the table, the agreement between observed and calculated values is good for vibrational frequencies of HSO and DSO, but the calculated values of inertia defects were too small, compared with the observed values. The contribution of the frequencies to the determination of the force field was thus dominant and that of the inertia defect was small. Indeed, the force field could not be determined by using data of inertia defects only.

(2). A force field was determined by using ν_3 (HSO) and $\Delta(003)$ and $\Delta(004)$ of HSO. These force constants are listed in column (2) of Table 2, together with other constants deduced from this field. In this case, close agreement between the calculated and observed values of inertia defect for HSO was obtained, but the calculated value of the inertia defect for DSO is still smaller than the observed value.

The force field, determined by data of HSO only, reproduced fairly well all the constants except $\Delta(003)$ for DSO (see column (2) in Table 2). The discrepancy of $\Delta(003)$ for DSO is considered to originate from non-diagonal components of the force field, but these can not be obtained because of lack of data. There may be some other perturbations which have an effect to this constant, but it is difficult to make these problems clear until the measurements on the (012) and (021) states are carried out.

For the centrifugal distortion constants, the obtained value in the (004) state clearly differs from that in the (003) state, in spite of the wide experimental errors (Table 1). Therefore, it can be said that the centrifugal distortion constant depends on the vibrational quantum number. This v-dependence is surely the main reason why the reasonable force field for the $\tilde{A}^2A'$ state could not be obtained from the centrifugal distortion constants. Essentially, the force field for the $\tilde{A}^2A'$ state must be determined from the centrifugal distortion constants for the vibration-free (000) state, which can be obtained by extrapolation of values of the (004) and (003) states. But the precision of obtained distortion constants is not high enough to allow us to extrapolate. The centrifugal distortion constants for the (000) state were calculated by using the force field of column (2) in Table 2, the values are Δ_N=0.0369, Δ_{NK}=1.064, Δ_K=16.592, δ_N=0.00256,

The Location and Microenvironment of Dimerizing Cationic Dyes in Lipid Membranes as Studied by Means of Their Absorption Spectra

Tetsurou HANDA, Chikako ICHIHASHI, Izumi YAMAMOTO, and Masayuki NAKAGAKI*

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606

(Received October 30, 1982)

The absorption spectra of three cationic dyes, Methylene Blue (MB), 3,3′-dipropyl-2,2′-thiadicarbocyanine (diS-C_3(5)), and 9-aminoacridine (9-AA), were measured in aqueous suspensions of a phospholipid membrane and a surfactant micelle. The dyes were intensely partitioned into the membrane phase and dimerized to exhibit a remarkably large reduction in absorbance. The increase in the amount of the membrane beyond the amount where all the dye molecules were dimerized in the membrane phase resulted in a gradual increase in the absorbance due to the increase in the available membrane volume and the dilution of dye in the membrane phase. The changes in the wave lengths of the absorption maxima of the dye monomers by the partitioning into membrane thus obtained were interpreted in terms of the effective polarities of the dye surroundings (microenvironments). It was found that the rather hydrophobic diS-C_3(5) penetrates deeply into the membranes and the micelles and is located in considerably nonpolar microenvironments, while MB remains at the polar-surface regions of the membranes and the micelles. On the basis of these results, the structures of the micelles and membranes are discussed.

Membranes, micelles, and microemulsions provide wide ranges of small environments and have great effects on chemical equilibria, kinetics, and structure organizations.[1] To estimate local effective polarities in micelles and microemulsions, various spectral methods have been employed. Charge-transfer bands of pyridinium iodide and 2,6-diphenyl-4-(2,4,6-triphenyl-1-pyridino)phenoxide exhibit considerably large shifts according to the nature of the dye surroundings.[2,3] Also, the vibronic structures of aromatic hydrocarbons, such as benzene, naphthalene, and pyrene, in absorption and fluorescence spectra show strong dependencies on the solvent, micellar, and microemulsion environments.[4,5]

With respect to lipid membranes, which offer promising prospects of understanding the complex natures of biological membranes and also for pharmaceutical and industrial uses, many fluorescent dyes have been employed.[1,6] However, the fluidity-dependent shift of the fluorescence maxima associated with solvent relaxation during the lifetime of the excited state introduces potential difficulties in the estimation of the local effective polarity of the membrane, which is regarded as a small heterogeneous fluid system.[7,8]

In this study, microenvironments in phospholipid membranes (liposomes), in addition to surfactant micells, were evaluated from measurements of the visible spectra of three cationic dyes, Methylene Blue, 3,3′-dipropyl-2,2′-thiadicarbocyanine, and 9-aminoacridine. These dyes partition into the membrane phase and dimerize to exhibit remarkably large reductions in absorbance and fluorescence. The increases in the amount of membrane over the amount at which all dye molecules are dimerized in the membrane phase give rise to dilutions of the dyes in the membrane and, thereby, to restorations of the absorbance. The absorbance maxima of the dye monomer accommodated in the membranes, which are shifted from those in aqueous media, were translated into the effective polarities of the dye surroundings.

Experimental

Materials. Egg yolk phosphatidylcholine (PC) was prepared by the method of Singleton *et al.*[9] Bovine brain phosphatidylserine (PS) and L-α-dipalmitoylphosphatidic acid (PA) were obtained from the Sigma Chemical Co. The heptaethylene glycol monododecyl ether (HED) and sodium tetradecyl sulfate (STS) were purchased from the Nikko Chemicals Co., Ltd., and ICN Pharmaceuticals, Inc., respectively. The disodium hexadecyl phosphate (SHP) was synthesized by the method of Nelson.[10] The 9-aminoacridine (9-AA) and Methylene Blue (MB) were obtained from the Nakarai Chemicals Co., Ltd., and the 3,3′-dipropyl-2,2′-thiadicarbocyanine (diS-C_3(5)) was purchased from the Japanese Research Institute for Photosensitizing Dye Co., Ltd. All the solvents were distilled before use.

Preparation of Lipid Membrane (Liposome). Aliquots of phospholipid were removed from the stock solution in chloroform, after which the solvent was evaporated and dried under a vacuum for 15 h. The complete removal of the chloroform was essential. Trace amounts of the solvent remaining will introduce error in the spectroscopic measurement of dye in the membrane phase. The lipid was suspended in 1 mM (1 M = 1 mol dm^{-3}) Tris-HCl (pH 7.3) and dispersed ultrasonically for 20 min. The solvent was cooled in ice during this process. The ultrasonic device used was an UR-200P apparatus from the Tomy Seiko Co., Ltd. The ultrasonically dispersed lipid was then centrifuged for 30 min at 20000 g to remove the titanium dust from the ultrasonic tip and a small amount of untreated lipid. The lipid-membrane suspension was diluted with the 1 mM Tris-HCl buffer solution for measurement. The HED and STS micellar solutions were prepared in the 1 mM Tris-HCl buffer. For the SHP micellar solution, the pH was adjusted to 10.0 with a very dilute NaOH solution to prevent H^+ binding to the phosphate. The variation in the pH from 7.3 to 10.0 did not affect the absorption spectra of dyes in aqueous media.

Absorption Spectra. The spectra of dyes in an aqueous solution with phospholipid membranes (liposomes) or surfactant micelles were recorded with a Shimadzu UV-180 spectrophotometer. The amount of membrane composed

of an anionic phospholipid, PS or PA, in dye solutions was very small (less than 0.15 mg of the lipid in 1 ml of a medium). In the case of the PC membrane, the amout in solution went up to 8 mg in 1 ml of a medium, and the turbidity from the membrane gave rise to less accurate absorption spectra. Such data are marked in Table 1. The temperature was maintained constant at 25 °C by water circulation through the cuvet holder of the spectrophotometer. The dye concentrations of the MB, 9-AA, and diS-C_3(5) used were 2, 2, and 0.73 μM respectively, low enough for us to neglect the dimerizations in the aqueous phases.[11,12]

Results

Absorption Spectra of Cationic Dyes with Membranes and Micelles. In Figs. 1 and 2, the absorption spectra of MB (2 μM) and diS-C_3(5) (0.73 μM) in the buffer solutions with PS membranes are shown. It is shown that the monomer absorbance maxima of MB (664 nm) and diS-C_3(5) (648 nm) decrease with an increase in the amount of the lipid membrane. The dimer absorbance maxima of MB and diS-C_3(5) have been reported as 600 and 590 nm respectively.[11,12] Also, on an increase in the concentration of NaCl, the absorbances increased gradually. The 98% absorbance of MB is restored with 4 mM NaCl, while more than 100 mM NaCl recovered only 74% of the initial absorbance of diS-C_3(5). In the case of diS-C_3(5) with various amounts of PS (Fig. 2a), the small turbidity arising from the membrane (0.003 in absorption unit) disturbs the isosbestic point at 570 nm. Furthermore, the increases in the amount of the membrane beyond the amount at which the minimum absorbance was observed resulted in a gradual increase in the absorbance. The data for MB and diS-C_3(5) are shown in Fig. 3. As will be discussed later, the cationic dyes intensely bind to anionic lipid membranes or anionic surfactant micelles; the resulting enhancements in the concentrations of the dyes in the membrane phase prompt the formation of the dimer forms, which have lower extinction coefficients than the monomers. Therefore, an increase in the membrane amount beyond the amount at which almost all the dye molecules are in the membrane phase resulted in a gradual increase in the absorbance due to the decrease in the concentration of dyes in the membrane phase. The minimum absorbances of MB, diS-C_3(5), and 9-AA obtained with anionic membranes or micelles were 16, 25, and 36% of the initial absorbance values, which corresponded to the respective ratio of the extinction coefficients of a dimer to a monomeric dye and indicated that almost all the dye molecules formed dimers in the membrane or the

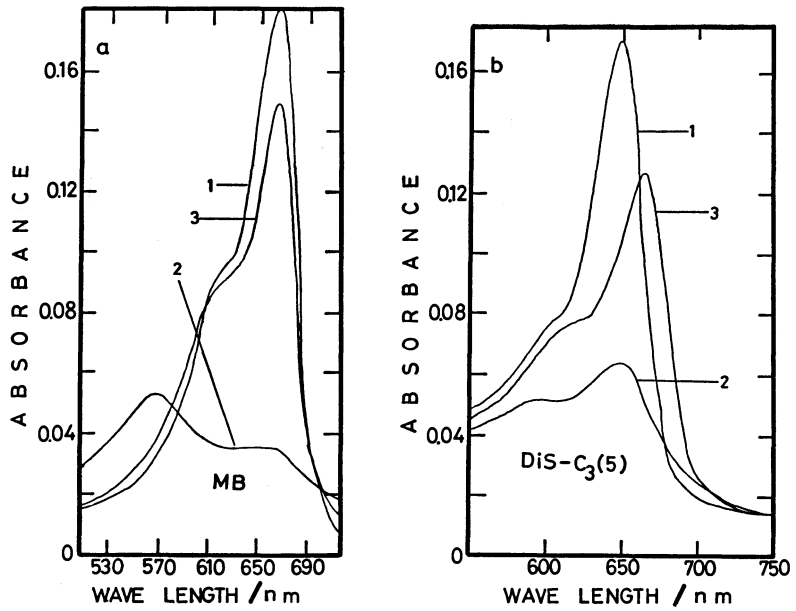

Fig. 3. Dye spectral change upon addition of PS membranes.

micellar phases at the minimum points. Spectra 1 and 3 in Fig.3 are in the aqueous media and in the PS membranes respectively of MB and diS-C_3(5). In the case of MB, the wavelengths of the absorption maxima in an aqueous medium and in the membrane phase were very close, 664 and 662.8 nm. In contrast, diS-C_3(5) exhibited quite a large red shift of the absorption maximum in the membrane (648→664 nm).

In Table 1, the absorption maxima (in nm) of MB, diS-C_3(5), and 9-AA in anionic membranes and micelles (PS, PA, STS, and SHP) and in an electrically neutral membrane and micelle (PC and HED) are shown. Into the neutral membrane and micelle, the cationic dyes were not so intensely partitioned as to complete the dimerization. Therefore, we added amounts of the PC membrane and the HED micelle which were greater than the amounts at which the spectral shifts of dyes arose due to partitioning from aqueous media to the membrane or the micellar phases were complete. The accuracies of some absorption maximum values were judged to be less (±0.5 nm) than others (±0.2 nm), where appreciable turbidities from PC membranes were observed.

Solvent Effects on Absorption Spectra of the Cationic Dyes. The solvent effects on the visible spectra of MB, diS-C_3(5), and 9-AA were also studied. The absorption maxima (λ_{max}) of dyes obtained in various pure solvents and solvent mixtures are shown in Table 2. The polarities of solvents and solvent mixtures are characterized by their dielectric constants and also Reichardt-Dimorth's $E_T(30)$.[3b] The latter is empirically correlated with the solvatochromism of 2,6-diphenyl-4-(2,4,6-triphenyl-1-pyridino)phenoxide at 25 °C. The dielectric constants of methanol-water mixtures have been known to be related to the weight fraction of methanol, w_{MeOH}, as $\varepsilon=78.5-(78.5-32.6)\,w_{MeOH}$.[13] DiS-$C_3$(5) and 9-AA showed monotonous increases in λ_{max} with a reduction of the solvent polarity, while MB has a minimum value around that of methanol. It was also found that the addition of concentrated NaCl (4—5 M) to the methanol–water

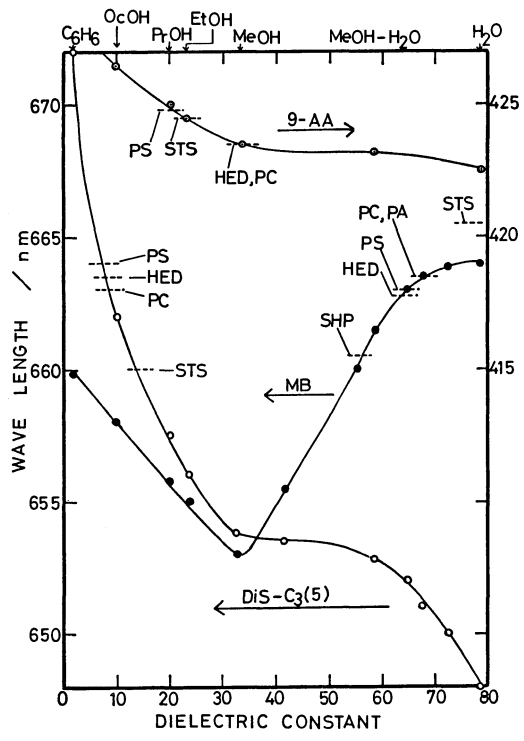

Fig. 4. Solvent effect on the wave length of absorption maximum of cationic dye monmer.
The values on the abscissa indicate dielectric constant of solvent. The wave lengths obtained in membranes and micelles are shown by the horizontal broken lines. The numerical values of effective dielectric constant estimated here are represented in Table 1.

TABLE 1. ABSORPTION MAXIMA, λ_{max}, OF CATIONIC DYE MONOMERS AND EFFECTIVE DIELECTRIC CONSTANTS, ε, IN MEMBRANES AND MICELLES

Membranes and Micelles	MB		DiS-C_3(5)		9-AA	
	λ_{max}/nm	ε	λ_{max}/nm	ε	λ_{max}/nm	ε

mixtures gives rise to red shifts in the absorbance maxima of the cationic dyes used here. In Fig. 4, the λ_{max} values of dyes in membranes and micelles are compared with the values in solvents. The effective dielectric constants around dyes in micelles and membranes, ε, obtained in this figure are shown in Table 1.

Dimerization of Cationic Dyes in Membranes. The absorbance, A, of a cationic dye in an aqueous suspension of a lipid membrane is given by:

$$A = (\varepsilon_m n_m + 2\varepsilon_d n_d)/V, \quad (1)$$

where n_m and n_d are the moles of the dye monomer and the dimer, and where $n_m+2n_d=n_0$; here, n_0 is the total number of moles of the dye. V is the volume of the buffer solution containing the dye. The volume of the membrane phase, V_M, is very small and so can be neglected in Eq. 1. ε_m and ε_d are the extinction coefficients of the dye molecule in monomeric and dimeric forms. $\varepsilon_m/\varepsilon_d$ for MB at 664 nm has been established to be 0.157.[14] The $\varepsilon_m/\varepsilon_d$ values for diS-C_3(5) and 9-AA were estimated from the linear relations between the absorbance and fluorescence of the dyes in aqueous suspensions of anionic lipid membranes as 0.25 (at 648 nm) and 0.35 (at 422.5 nm) respectively (the dimers are nonfluorescent at the monomer fluorescence-maximum wavelength).[12] The absorbance of the same solution without a membrane, A_0, is given as:

$$A_0 = (\varepsilon_m n_0)/V. \quad (2)$$

From Eqs. 1 and 2, n_m and n_d are calculated as:

$$n_d = \frac{1}{2} n_0 (1 - A/A_0)/(1 - \varepsilon_d/\varepsilon_m), \quad (3)$$

and:

$$n_m = n_0 - 2n_d. \quad (3')$$

The equilibrium between monomeric and dimeric dyes in the membrane is represented by a dimerization constant, k_d, as:

$$C_{Md}/C_{Mm}^2 = k_d, \quad (4)$$

where C_{Md} and C_{Mm} are the concentrations of monomeric and dimeric dyes in the membrane phase. On the other hand, the partition equilibrium of a monomer between the membrane phase and the bulk phase can be written as:

$$C_{Mm}/C_{Bm} = P. \quad (5)$$

Here, P is a partition coefficient. From Eqs. 4 and 5, Eq. 6 is obtained:[15]

$$C_{Md}/C_{Bm}^2 = P^2 k_d. \quad (6)$$

Also:

$$C_{Md} = n_d/V_m = n_d/(vm). \quad (7)$$

Here, v is the partial specific volume of a phospholipid membrane, and m is the weight of a dried phospholipid in solution. Also,

$$C_{Bm} = (n_m - n_{Mm})/V \approx n_m/V. \quad (8)$$

n_{Mm} is the moles of the monomer in the membrane phase and is negligible when m is very small.[15] From Eqs. 6, 7, and 8, Eq. (9) is obtained:

$$V(n_d/n_m^2) = K(m/V), \quad \text{and } K = P^2 k_d v, \quad (9)$$

P involves the effects caused by both hydrophobic and electrostatic interactions between dye and membrane. When the pH and the ionic strength in an aqueous suspension of a PS membrane are maintained constant, P and, thereby, K can be regarded as constant for a dye.

In Fig. 5, the values of $V(n_d/n_m^2)$ calculated by means of Eq. 3 for an aqueous PS membrane suspension are plotted against the concentration of the membrane, m/V. The linear relations obtained for 9-AA, MB, and diS-C_3(5) are considered to be additional evidence for the formation of dye dimers in the membrane. Similar results were found for PA membrane and for STS, and SHP micelles.

Discussion

Microenvironments Provided by Membranes. To estimate the local effective polarities of membrane and

micelle on the basis of spectroscopic measurements with probing dyes, the data obtained for the membrane and the micelle should be interpreted in terms of some numerical indices representing the effective polarities of dye surroundings. Mainly, two factors can be proposed to account for the effective polarities in membranes and micelles: (a) the presence of a hydrocarbon environment in an aqueous medium, and (b) the presence of a high local concentration of charges arising from the head groups and the counter ions.[16] To estimate (a), alcohols and methanol–water mixtures have been considered to be better for the calibration solvents because of their hydrogen-bonding abilities with dyes.[16,22] Dipolar aprotic solvents have been found to be unsuitable for use with 2,6-diphenyl-4-(2,4,6-triphenyl-1-pyridino)phenoxide as the probing dye.[3a]

As is shown in Table 2 and Fig. 4, the simple rule for solvatochromism predicted from the change in the permanent dipole moment of the electronic transition, $\pi \rightarrow \pi^*$, cannot explain the experimental results. Alternatively, the interaction between the rapid-fluctuating transition moment of the dye molecule and the solvent is taken into account. The symmetric polymethin dyes, *e.g.*, diS-$C_3(5)$, have been known to show very little defference in the permanent dipole moments of the ground and excited (Frank-Condon) states: therefore, the dispersive effect on the transition moment due to the dye-solvent interaction seems to exert the predominant effect on the solvatochromism of diS-$C_3(5)$.[17] Thus, diS-$C_3(5)$ has a blue shift with an increase in the solvent polarity. While the solvent effects on MB and 9-AA are substantially described by similar explanations, an anomalous minimum in the λ_{max} of MB around methanol must be understood in terms of the specific solvation of water molecules, *e.g.*, hydrogen bonding with MB or solvent-cage effects on the ground-state dipole moment of MB. The deviation in the absorption maximum of MB from linearity in methanol–water mixtures also suggests the preferential solvation of water molecules.

From the results shown in Tables 1, 2, and Fig. 4, it may be found that the local effective polarities sensed by diS-$C_3(5)$ and MB are represented by those in 1-octanol and in a water–methanol mixture respectively. Therefore, diS-$C_3(5)$ penetrates deeply into membranes and micelles and is located in quite nonpolar environments. This is compatible with the fact that the dye is able to permeate through cell and lipid membranes.[18] On the other hand, MB is thought to be located at polar environments, that is, the surface regions of membranes and micelles. It is noteworthy that the λ_{max} of MB in STS is largely red-shifted and not covered by the calibration solvents used here. In the outermost regions of membranes and micelles, in addition to water molecules, electrical charges arising from the head groups and the counter ions have important effects on the microenvironments. As may be seen in Table 2, the addition of concentrated NaCl to methanol–water mixtures resulted in red-shifts of the MB adsorptions, covering the MB spectrum in the STS micelle. This indicates that the MB molecules located at the surface region, apart from the effect of alkyl chains, really experience the effect from the (b) factor. The locations of the MB molecules evaluated here are also consistent with the fact that they cannot penetrate cell and lipid membranes.[14,15]

It is also noteworthy that, even when the bulk dielectric constants are close, the dyes used here exhibit reversed spectral shifts in a methanol (dielectric constant=32.6) and in a 5 M NaCl aqueous solution (dielectric constant=35[19]). The dielectric constant reflects only the average properties of the medium, while the microenvironment evaluated spectroscopically is to be understood as the effective polarity in the close vicinity of the probing dye molecule.[16] Very often, it has been found that there is no correlation between the dielectric constant and the rate of the equilibrium constant of a solvent-dependent chemical reaction[3b]

According to the oldest chemical rule that "like dissolves like," it is concluded that the rather hydrophobic dye, diS-$C_3(5)$, and the hydrophilic dye, MB, prefer nonpolar and polar hydrophilic environments respectively, even in the same membrane or micelle.

Partition and Dimerization Equilibrium of Cationic Dye in Membrane. The cationic dyes employed in this study are intensely concentrated to dimerize in anionic membranes and micelles. Although the stacking interaction generally gives not only the dimer, but also *n*-meric forms, the isosbestic points observed in Figs. 1 and 2 suggest that the two major species, monomer and dimer, are in equilibrium and that the formation of higher aggregates is remarkably reduced in lipid membranes. Aggregations of dye ions have been known to occur much more favorably in aqueous environments than in nonaqueous environments. These facts have been interpreted in terms of water-structure promotion around the dye ions and consequent hydrophobic effects, and also in terms of the effect of the higher dielectric constant of water in reducing the repulsive force between the similarly charged dye ions in the aggregate.[11,20] These effects are more remarkable for the higher polymeric dye aggregates.

The effects of increasing amounts of NaCl on the absorbance of dyes shown in Figs. 1 and 2 suggest that the partitioning of an MB to a PS membrane is mainly attributable to electrostatic force, whereas, in the partitioning of diS-$C_3(5)$, effects other than the electrostatic one seem to play an important role. Assuming that the intrinsic partition coefficients of the dyes to membranes are independent of the lipid composition, the surface potentials of the membranes composed of PC and PA or of PC and PS were estimated from the partition equilibria of the dyes and discussed in relation to the Gouy-Chapman double-layer theory.[15] The potential obtained with MB substantially agreed with the theory, while the potential change with the NaCl concentration, as estimated with diS-$C_3(5)$, deviated greatly from the theory.[21] Also, Table 1 and Fig. 4 show that the surrounding microenvironments of MB in PC, PA, and PS membranes are similarly polar (ε=65—68). For diS-$C_3(5)$, the microenvironments in PC, PA, and PS are found to be nonpolar (ε=7.5—8.5). These results indicate that

the hydrophobic interaction may be an important factor in the partitioning of diS-C_3(5) into the lipid membranes.

Structures of Micelle and Membrane. In many other studies, the effective polarities for ionic surfactant micelles have been evaluated to be in the range between 30 and 40 in terms of the dielectric constant, ε.[1-6,22,23] These results have been interpreted on the basis of Stigter's two-state model (a modification of the Hartley model)[22,24] or explained by the use of Menger's porous model, which is inconsistent with the former model.[23] The effective polarities estimated for micelles in this study show a remarkably great variation; $\varepsilon=11\pm3$ by diS-C_3(5), 28 ± 5 by 9-AA, and 60 ± 4 by MB. These facts suggest that, in surfactant micelles, considerably nonpolar environments exist; this is in conflict with the porous model. For a nonionic micelle (Triton X-100), a micropolarity with $\varepsilon=5$—8 has been reported.[25] Table 1 and Fig. 4 also indicate that STS, SHP, and HED micelles contain various polar environments, from quite polar ($\varepsilon=60$) to moderately polar ($\varepsilon=28$), along the radial direction and, again, in contradistinction to the two-state model on which a micelle is represented as a combination of a nonpolar interior ($\varepsilon<10$) and a thin polar surface layer ($\varepsilon=30$—40).[22,24] Therefore, the following model for micelles will be proposed in this study: that micelles contain both nonpolar and polar regions, and, that the polar regions have a finite thickness with a polarity gradient.

With respect to phospholipid membranes, fairly thick polar regions have been clarified by X-ray-diffraction experiments.[26] The results on the membranes in this study show that the lipid bilayer membranes also supply a wide variety of microenvironments, from polar to nonpolar, along the normal direction to the membrane surface.

These wide varieties in environment are considered to be an important effect provided by membranes and micelles for understanding chemical equilibria, kinetics, and structure organizations in these systems. We have also found that photoinduced charge separations mediated by thiacarbocyanine dyes in lipid membranes and micelles are remarkably affected by the natures of the microenvironments around the dye.[27]

A Study of the Redistribution Reaction of Tetramethyltin with Dimethyltin Dichloride in Several Aprotic Solvents

Yukihide YAMASHITA, Koji SAITO, Akihiro YOSHINO, and Kensuke TAKAHASHI*

Department of Industrial Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466

(Received December 4, 1982)

The redistribution reaction of tetramethyltin with dimethyltin dichloride was studied in eight aprotic solvents by using the ^{1}H NMR technique. The second-order rate constant of the reaction ($\ln k_2$) is proportional to the dielectric constant of the solvent. There is a weak relation between the rate constants ($\ln k_2$) and the values of ^2J(Sn-H) of Me_2SnCl_2 in several solvents, which are considered to be related to the coordination ability of the solvents. The rate constants are also related to Kosower's Z values of the solvents. The activation entropies of the reaction in four typical solvents have large negative values. This predicts that the reaction proceeds *via* a four-center transition state.

There have thus far been many reports concerning redistribution reactions (or radical exchange reactions) of organometallic compounds.[1-5]

The redistribution reaction, shown in Scheme 1, reported by Dessy *et al.*, was interpreted to proceed *via* a four-center transition state.[6] This four-center

$$R_2Hg + HgX_2 \xrightarrow{\text{solvent}} 2RHgX$$

Scheme 1.

transition state is not yet decisive in interpreting the mechanism of similar kinds of reactions, but one piece of evidence is considered to be that the reaction has a large negative activation entropy. Another typical example of the reactions is shown in Scheme 2. This

$$Me_4Sn + Me_2SnCl_2 \xrightarrow{\text{solvent}} 2Me_3SnCl$$

Scheme 2.

is the reaction between tetramethyltin and dimethyltin dichloride which forms trimethyltin chloride. The equilibrium constant between the left- and right-hand systems has been reported to be 330.[5] Plazzogna *et al.* reported the reaction in methanol and showed it to be a second-order reaction.[7]

During the course of studying the ^{1}H and ^{119}Sn NMR spectra of some organotin compounds, our attention was drawn to the large solvent effects on the NMR parameters of many organotin compounds.[8] Therefore, we have examined the reaction in Scheme 2 in several aprotic solvents and found that the reaction rates are largely dependent upon the solvents. The results have been analyzed as a second-order reaction and discussed in terms of dielectric constants, coordination ability, and Kosower's Z values of the solvents.

Experimental

The materials, the reactants, and the solvents were commercial ones and were used without further purification except for chloroform and acetone-d_6. Acetone-d_6 was dried by keeping it on a molecular sieve, while chloroform was purified by the conventional manner to remove traces of the stabilizer (ethanol). The reactants were weighed into an NMR sample tube, and then a solvent was added. The ^{1}H NMR measurement was carried out by means of a Hitachi R-20B spectrometer at 60 MHz with a variable-temperature controller. The reaction was followed by taking the methyl proton spectrum of the reaction mixture at intervals. The chemical shifts are referred to the signal of tetramethylsilane in a sealed Pyrex capillary inserted into each sample tube. The sweep width and time were 120 Hz and 200 s. The peak area of each methyl proton was measured by cutting and weighing the area under the peak on the chart, which was adjusted to have no wiggle. The temperature was measured by both a thermometer inserted into the probe and the chemical-shift difference of the two signals of ethylene glycol. The temperatures measured by the two methods were consistent within an error of ±0.5 °C.

Results and Discussion

Table 1 summarizes the equimolar second-order rate constants of the reaction as observed in eight solvents. The initial concentration of each reactant was

taken to be 0.5 mol l^{-1}. One example of the rate analysis is given in Fig. 1. The second-order rate constant(k_2) increases with an increase in the dielectric constant(D) of the solvent. A linear relationship between $\ln k_2$ and D has been shown in Fig. 2 at the temperature of 305.5 K. Similar relationships between the rate constants and the dielectric constants have also been reported in other organotin compounds.[9-11]

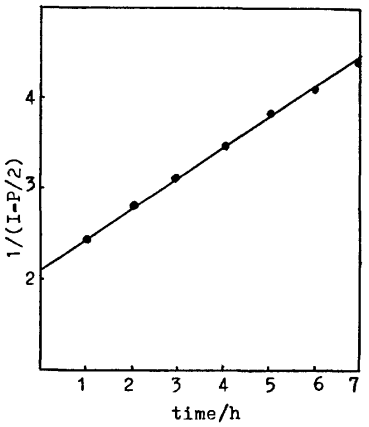

Fig. 1. An example of the concentration change of the reactant (ordinate; $1/(I-P/2)$) against time (abscissa) obtained for the reaction studied in acetonitrile at 305.5 K where I is the initial concentration of the reactant (*ca.* 0.5 mol/l) and P is the concentration of the product.

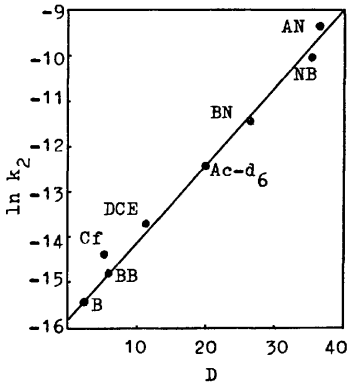

Fig. 2. Correlation between $\ln k_2$ and D for the eight solvents studied whose kinds are shown in the figure with abbreviated letters.

As is shown in Table 1, the rate observed in acetonitrile is 500 times faster than the slowest one observed in benzene. The observed thermodynamic data of the reaction are summarized in Table 2. The activation energy in acetonitrile is the largest one, but the other three values are similar in magnitude. The activation entropy change in acetonitrile is different from the other three in magnitude, although these values are negative and large, suggesting that the reaction proceeds *via* a four-center transition state, as has been suggested by Weingarten and Van Wazer.[2] The solvent used in the reaction significantly affects the activation entropy more than the activation energy.

The ^2J(H–Sn) values of the related compounds are tabulated in Table 3 as determined in several solvents. The change is small for tetramethytin, but large for dimethyltin dichloride. Similar changes in the coupling constants have been reported.[12,13] The change is interpreted by the coordination of the solvent to the tin atom and by the hybridization change. Therefore, the coupling constant change observed largely manifests the coordination power of the solvent. The value in acetone-d_6 is larger than that in acetonitrile. This tendency is consistent with that observed for trimethyltin chloride, as reported by Bolles and Drago.[12] Therefore, acetone has a larger coordination power than acetonitrile for the tin compounds in question.

As has been stated before, the activation entropies of the reaction change with the kinds of solvents with large negative values. Therefore, the transition state of the reaction may be considered to be a rather ordered state. The entropy of the reaction system is considered to be dependent upon the coordination power of the solvent used. Therefore, it is suggested

Benzene	0.44	0.24	0.03

a) The values are referred to the external tetramethylsilane.

that the rate will be parallel to the coordination ability of the solvent. As is plotted in Fig. 3, there is a weak relation between the rate and ^2J(Sn–H), which is a measure of the coordination ability. The correlation coefficient of the points in Fig. 3 is 0.72; this is smaller than that calculated for Fig. 2 (0.99).

The ^{1}H chemical shifts are tabulated in Table 4. The chemical shifts change in a reasonable order with the successive substitution of an electronegative chlorine atom in the molecule. Chlorination causes a downfield shift of about 0.6 ppm per chlorine atom in four solvents from the top of the table. However, benzene shows a different behaviour. The observed chemical shift values may reflect the form of coordination. In this sense, the coordination may be supposed to be different for benzene and other four solvents. Bromobenzene is intermediate between the two.

There are many parameters which express the nature of the solvent. Figure 4 shows the relation between the ln k_2 value and Kosower's Z values of the solvents.[14)] Four points fall on a straight line, but not those of benzene and bromobenzene. Such exceptions of benzenes have previously been reported in the Menschtkin reaction.[15)] The rates become larger with larger Z values of the solvents.

The reaction was also studied in the methanol solution by Plazzogna *et al.*[7)] They reported that tetramethyltin suffered an electrophilic attack by the Me_2Sn^{2+} species which is formed by the dissociation of Me_2SnCl_2. However, the ion, Me_2Sn^{2+}, is difficult to produce in acetone or acetonitrile. Therefore, they also stated that the reaction is very slow in acetone or

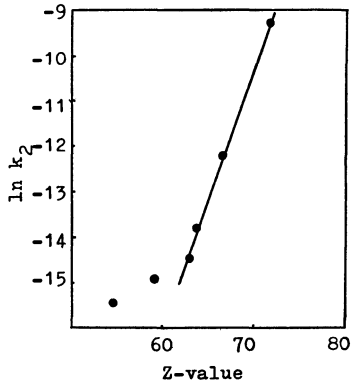

Fig. 4. Plotting of $\ln k_2$ against the Z-values.

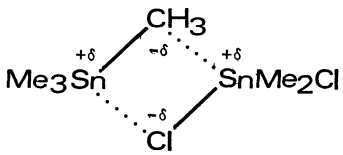
acetonitrile. The rate observed by them in methanol is much greater than ours in Table 1, although the systems are different. The rate in methanol deviates greatly from the line plotted in Fig. 2. Therefore, it is reasonable to consider that the reaction mechanism in the aprotic solvents is different from that in the protic solvents.

We propose here a mechanism of the reaction which is dependent upon the dielectric constants of the solvents. The polarization of the reactants is important. Although one of the reactants, tetramethyltin, is nonpolar, the local polarization of the molecule occurs in the bond between the carbon and the tin atoms because of the different electronegativities of the atoms. The electrostatic attractive force leads to the four-center transition state shown in Scheme 3, which is supported by the negative activation entropies described above. The polarization of the reactants becomes larger in the polar solvents. The larger the dielectric constant of the solvent, the faster the reaction rate.



Scheme 3.

Conclusion

The redistribution reaction between tetramethyltin and dimethyltin dichloride has been studied in eight aprotic solvents. The logarithm of the rate of the reaction in the equimolar solutions is proportional to the dielectric constants of the solvents, and falls on a straight line. A weak relation is also observed between the rates and the ^2J(Sn–H) values, which are supposed to be measures of the coordination power of the solvents. The rate is almost parallel to Kosower's Z values of the solvents. The reaction has a large negative activation entropy. This is considered to be evidence of a reaction which proceeds *via* the four-center transition state.

ESR Studies of Bunsen-type Methane-Air Flames. I. Effects of the Entrainment and Diffusion of Secondary Air on the Chemical Reactions in the Flame

Ola Claesson,† Shoji Noda,†† and Hiroshi Yoshida*

Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060

(Received January 5, 1983)

H atoms in a Bunsen-type methane-air flame have been studied by observing their ESR signals at different flow rates of O_2 and N_2 in a synthetic secondary air. The optical emissions from excited CH, C_2, and OH radicals in the same flame have been also studied. It has been found that an increased O_2 flow rate produces changes in the intensity of the ESR and emission signals, and that it also increases the burning velocity in the inner-cone flame. An increased N_2 flow rate, on the other hand, has almost no effect on the flame. The inner-cone of a Bunsen-type flame is, therefore, not a completely premixed flame; it is affected chemically by the secondary air.

A Bunsen flame is roughly characterized as a double flame: an inner, premixed flame propagating through the combustible gas mixture(usually fuel-rich) against the gas stream, and an outer, diffusion flame where further combustion of the gas mixture is assisted by the surrounding secondary air. Secondary air plays an important role in stabilizing a Bunsen flame.[1] Its entrainment and diffusion into the flame have great effects on the flame characteristics and flame chemistry, but these effects have not yet been elucidated.

Electron spin resonance(ESR) has been proved to be a convenient means for observing atomic and free radical intermediates in combustion reactions.[2-5] Recently we ourselves have reported an ESR study of methane combustion where the nature of the H atom ESR signal and the spatial distribution of H atoms were studied by inserting a flame burning under ambient pressure directly into the resonant cavity.[3] Although such a flame-in-cavity method allows neither the detection of species other than H atoms(because of the collisional broadening of the resonance lines) nor a detailed examination of the distribution of the H atoms, it is a convenient and useful method for studying the chemical aspects of flames by observing the dependence of the total H-atom concentration on the burning conditions. Our previous investigation has, therefore, now been extended to get a picture of the chemical effects of the entrainment and diffusion of secondary air by examining the H-atom concentrations at different flow rates and compositions of a mixture of O_2 and N_2 acting as the secondary air. Some excited radicals were also detected in the flame by using optical-emission spectrophotometry.

Experimental

A burner with three concentric quartz tubes, one outside the other, was constructed. In the innermost tube (4 mmϕ) the premixed combustible gas was allowed to flow. The flame was anchored on top of this tube. The second tube (18 mmϕ) was the combustion room, and the secondary air was let flow through it. The outermost tube (22 mmϕ) was for the flowing of the coolant air. All gas-flow rates were regulated by flow meters with precision needle valves. The premixed combustible gas consisted of a mixture of methane (99.0% purity), 90 cm^3/min, and air, 500 cm^3/min. The secondary air was a mixture of O_2 and N_2. Its composition and flow rate were varied by keeping the rate of one component in the mixture constant while varying the other. Thus, for an O_2 flow of 65 cm^3/min, N_2 was varied between 50 and 260 cm^3/min, and for a N_2 flow of 170 cm^3/min, O_2 was varied from 58 to 95 cm^3/min. These constant flows were chosen because an O_2/N_2 mixture with these flow rates maximized the ESR signal of the H atoms.

The flame height was estimated from close-up color photographs taken of the flame under different burning conditions. The scale of the pictures was determined by comparing the diameter of the innermost tube as measured on the photographs with its real size.

The H atoms present in the flame were detected by means of ESR (a Varian E-109 spectrometer, X-band with 100 kHz modulation) using the flame-in-cavity method, which has been described elsewhere.[3] A recent improvement of the experimental method was the use of a cylindrical TE_{011} large-access cavity (Varian, Model E-235), which accepts a large burner. A large burner was needed for the flame to be stabilized under a variety of burning conditions.

The excited radicals in the flame were studied from their optical emission spectra. These were recorded by inserting the burner into the detection chember of a conventional fluorescence spectrophotometer (Hitachi, Model, MPF-2A).

Results and Discussion

Apparent Burning Velocity. The flame showed a bright blue inner-cone flame and a faint bluish outer flame. The height of the inner flame decreased with an increase in the O_2 content in the secondary air, as is shown in Fig. 1A. At an O_2 flow rate of less than 55 cm^3/min, the flame was not stably anchored at the top of the burner, but started to lift off. Under the present experimental conditions, the apparent burning velocity in the inner flame can be roughly approximated as inversely proportional to the inner-flame height.[6] The apparent burning velocity thus increases with an increase in the O_2 flow rate in the secondary air. At an increasing N_2 flow, the tip of

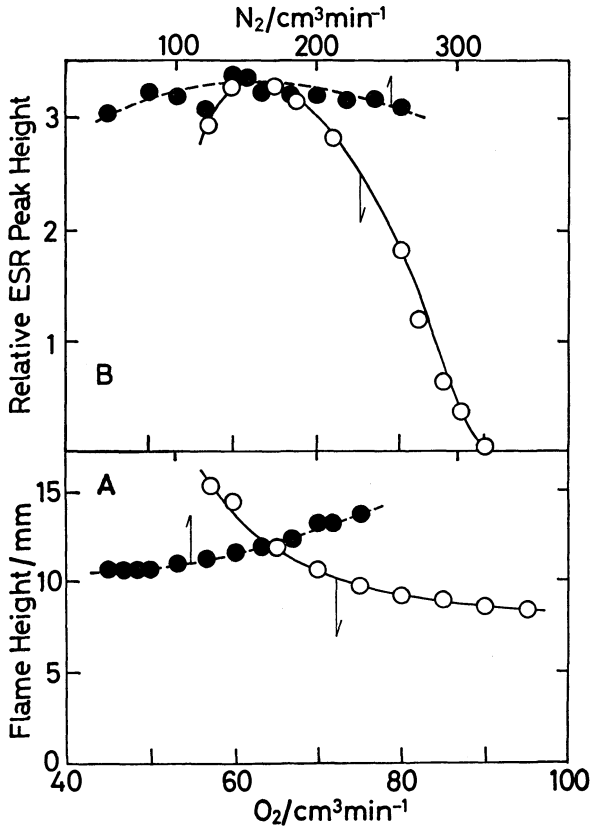

Fig. 1. Dependence of (A) the height of the inner cone flame and (B) the ESR intensity of the H atoms in a Bunsen-type methane-air flame on the composition of the secondary air. Data shown by open circles were obtained for a constant N_2 flow of 170 cm^3/min. Data shown by closed circles were for a constant O_2 flow of 65 cm^3/min.

the inner flame became less and less luminous, and the outer flame disappeared. The inner cone height increased, as is shown in Fig. 1A, indicating a decrease in the apparent burning velocity.

These observations agree well with Kimura and Ukawa's results obtained from a propane/air flame where an increased $O_2/(O_2+N_2)$ ratio raised the burning velocity.[7] Apparently the secondary air affects the combustion characteristics in the inner flame.

H Atoms in the Flame. The ESR spectrum observed from the flame consisted of two sharp lines with a hyperfine separation of 51.0 mT centered at 330 mT. It is assigned to H atoms. The sensitivity of the ESR measurements depends on the position in the resonant cavity. As a matter of fact, the spectral intensity varied depending on the location of the burner in the cavity along the cavity axis. This dependece was more pronounced in the present study than in the previous study.[3] The difference is attributed to the fact that, in the present study, the H atoms are confined in a more limited region of the flame burning in a wider combustion room. This is consistent with our previous result, obtained by the point-to-point probe-sampling method,[4] that the H atoms are mostly located within 1 cm downstream from the flat inner flame of a free-burning methane-air Bunsen flame.

The spectral intensity of the H atoms in the flame under different burning conditions was examined by locating the burner so as to maximize the intensity. It was found to depend drastically on the flow of O_2 in the secondary air, as can be seen in Fig. 1B. The O_2 content in the secondary air apparently affects the chemical reaction in the inner cone. The N_2 flow, however, can be changed over a wide interval, thereby changing the total flow of the secondary air, without having much effect on the H-atom signal. As an increase in the N_2 flow is accompanied by a decrease in the apparent burning velocity, it seems that even though the reaction zone is broadened (diluent effect), the chemical reactions are essentially unaffected.

Neither the concentration profile in the flame nor the absolute concentration was determined in the present study. However, the observed ESR intensity can be regarded as a measure of the H-atom steady-state concentration averaged over the whole flame. The confinement of the H atoms in a narrow region excludes the possibility that the change in the ESR intensity with the varying O_2 flow may be primarily due to the change in the flame shape. Actually, the intensity changed little, though the reaction zone was apparently broadened with the increase in the N_2 flow. The temperature in the flame monitored with a fine Pt–Rh thermocouple was the highest in or close to the inner-cone flame and changed from 1620 to 1760 K, depending on the burning conditions. The ESR intensity shown in Fig. 1B has not been corrected with the flame temperature, because the temperature effect is of no significance.

It has previously been demonstrated by probe-sampling a Bunsen flame and ESR detection that H atoms are abundant in the fuel-rich inner flame and that they are consumed by reacting with O_2, probably coming from the secondary air:[4]

$$H + O_2 \rightarrow O + OH. \quad (1)$$

Here we have found that the apparent burning velocity in the inner flame increases at higher O_2 flow rates, while the H-atom steady-state concentration is tremendously reduced(see Fig. 1). This results from Reaction 1, effectuated by the involvement of O_2 from the secodary air even in the inner flame. The overall combustion reactions are accelerated, the lifetime of the H atoms being reduced. The chain-carrying intermediates which support the flame at a low O_2 content in the atmosphere surrounding the flame are H atoms, while at a high O_2 content O atoms and OH radicals are chain carriers. These observations are consistent with Pickering and Linnett's analysis of the relations among the O_2%, the burning velocity, and the calculated equilibrium concentrations of H, O, and OH for a premixed ethylene/air flame.[8]

Excited Free Radicals in the Flame. An example of the optical emission spectra recorded from the flame is shown in Fig. 2. According to the literature data,[9] the observed spectrum is composed of emission lines due to OH, CH, and C_2 radicals and a broad continuum due to CO_2. Weak emission lines due to CHO radicals are also discernible. It is known that

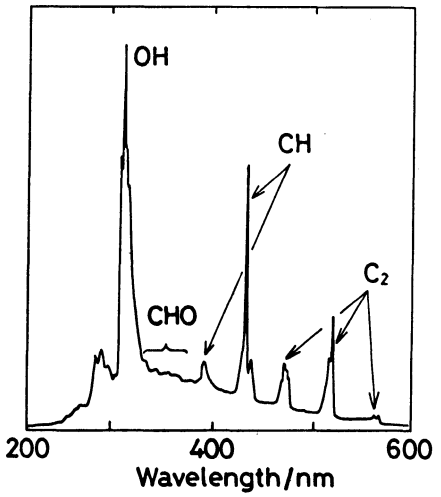

Fig. 2. An example of optical emission spectra recorded from the luminous inner cone flame of a Bunsen-type methane-air flame. No correction of the photometer sensitivity was made.

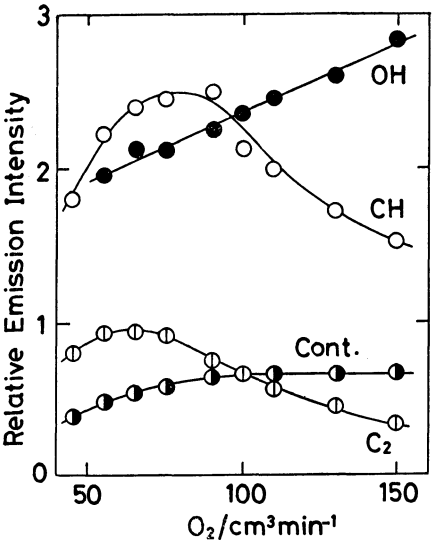

Fig. 3. Dependence of the optical emission from excited free radicals (and continuum spectrum due to CO_2) on the flow rate of O_2 in the secondary air. The N_2 flow rate was kept constant at 170 cm³/min. The emission comes mostly from the luminous inner cone.

the emissions of Bunsen flames almost exclusively originate from the inner premixed flame and that they are chemiluminescence in nature.[9] The exception is the OH emission, which comes from the outer flame as well.

The effects of the composition of the secondary air on those chemiluminescences are pictured in Fig. 3. The emission intensities are sensitively dependent on the O_2 flow rate in the secondary air. The OH emission intensity increases steadily with an increase in the O_2 flow rate. The CH and C_2 emissions have maximum intensities at the O_2 flow rates of 90 and 60 cm³/min respectively. These emissions come from the corresponding electronically excited radicals, which are generated through side-reactions in the overall process of combustion.[9] However, the dependence of these intensities on the O_2 flow rate indicates the far-reaching involvement of O_2 from the secondary air in the chemical reactions in the inner flame. Similar intensity variations have been reported for the CH and C_2 emissions in low-pressure premixed hydrocarbon flames with a varied fuel-to-air ratio.[9]

Conclusions. Bunsen-type burners are now incorporated in many gas appliances, yet the combustion chemistry of these burners has been but little elucidated because of their complexity as chemical reaction systems. The present investigation has been focussed on one of the principal reaction intermediates of combustion, the H atoms, in the methane-air Bunsen-type flame. It has been found that the H-atom ESR spectrum is significantly affected by the O_2 content in the secondary air. These results, combined with those of the optical-emission study of the excited free radicals, indicate that the inner cone of the Bunsen-type flame is not a wholly premixed flame, but that it is affected by the entrainment and diffusion of the secondary air. This provides a convenient experimental method to study the chemical reactions in combustion by simply mixing an additive in the secondary air.

ESR Studies of Bunsen-type Methane-Air Flames. II. The Effects of the Addition of Halogenated Compounds to the Secondary Air on the Hadrogen Atoms in the Flame

Shoji NODA,† Susumu FUJIMOTO, Ola CLAESSON,†† and Hiroshi YOSHIDA*

Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060

(Received January 5, 1983)

Hydrogen atoms in a methane-air Bunsen-type flame were detected by the flame-in-cavity ESR method. The addition of a halogenated compound to the secondary air was found to reduce the H-atom concentration linearly with an increase in the additive concentration. The eight halogenated compounds examined showed an increased effectiveness in scavenging H atoms in this order; $HCl < CF_2Cl_2 < CHCl_3 < CH_3Cl < CH_2Cl_2 < CFCl_3 < CCl_4 < CH_3Br$. This chemical effect of the halogenated compounds on the combustion reactions agrees well with the inhibitor index for these compounds.

Extensive studies have been carried out on the effects of additives such as halogenated compounds on the inhibition of premixed flames.[1-6] The relative effectiveness of a flame inhibitor has been evaluated from the change in the burning velocity of the flame upon the addition of the inhibitor, according to this equation:

$$\phi_v = ([O_2]/[In])(\delta V/V_0), \quad (1)$$

where $[O_2]$ and [In] are the initial concentrations of O_2 and the inhibitor respectively, where V_0 is the burning velocity in the absence of the inhibitor, and where δV is the decrease in the burning velocity due to the presence of the inhibitor.[1,7] There has been few reports on the inhibition of diffusion flames.[8,9] The addition of hydrogen halides to the surrounding air has been found to quench diffusion flames more effectively than direct addition to the fuel.[8] It has been suggested that CH_3Br quenches diffusion flames chemically, though no mechanism for this has been discussed.[9]

Flame inhibition is a combination of the chemical and physical effects of an inhibitor. The chemical effects are mostly the scavenging of the carriers of the chain reactions in the combustion, like H, O, and OH. There have, however, been no reports showing the correlation between flame inhibition and radical scavenging.

In a preceeding paper (Part I of this study)[10] we found, by using the flame-in-cavity electron-spin-resonance (ESR) method, that the concentration of H atoms in the Bunsen-type methane-air flame is reduced when the O_2 content in the secondary air is increased. This indicates that O_2 diffuses from the secondary air into the inner zone of the flame, as the H atoms are most abundant in the fuel-rich inner reaction zone.[11] This also shows that the flame-inhibition effect can be studied by adding inhibitors to the secondary air around Bunsen-type flames and by detecting the H atoms in the flame by means of ESR. Because of the collisional broadening of the resonance lines, the reaction intermediates observable by the flame-in-cavity ESR method from a flame at atmospheric pressure are atoms whose electronic ground state is a S-state like $H(^2S)$ or $N(^4S)$. In spite of this limitation, the flame-in-cavity ESR method is a useful method for studying H atoms under a variety of burning conditions.

Experimental

The Bunsen-type burner used consisted of three concentric quartz tubes and was the same as that reported previously.[10] The premixed combustible gas consisted of a mixture of methane (99.0% purity), 88 cm^3/min, and air, 380 cm^3/min. The flow rate of the secondary air was 430 cm^3/min. These flow rates were chosen to maximize the ESR signal of the H atoms. The added inhibitor was injected into the secondary air using a 200-cm^3 glass syringe and a microfeeder. Five different flow rates of an added inhibitor, ranging from 0.067 to 0.33 cm^3/min, could be attained by using different combinations of driving gears on the microfeeder. The halogenated compounds used as inhibitors were HCl (purity 99%, Takachiho), CH_3Cl (99%, Takachiho), CH_2Cl_2 (Spectrograde, Eastman Kodak), $CHCl_3$, CCl_4, CF_2Cl_2, $CFCl_3$, and CH_3Br (all reagent grade, Tokyo Kasei). As they were liquid at room temperature, they were evaporated in a heated chamber, while the syringe and secondary air were preheated to keep them from condensing.

The H atoms in the flame were detected by ESR using a flam-in-cavity method which has been described elsewhere.[10,12] The spectrometer (Varian, Model E-109) was operated in the X-band with a magnetic-field modulation of 100 kHz.

Results

ESR Spectra of the Flame Gases. H atoms were detected in both the presence and absence of a halogenated compound in the secondary air. The H-atom spectrum showed two lines with a hyperfine separation of 51.0 mT, the same as has been reported previously.[10-12] O_2 molecules have been demonstrated to cause a broadening of the H-atom lines in the ESR spectrum from a flame.[12] We found that the spectral linewidth of the H-atom signal was independent of the concentration of all the halogenated compounds added except for the case of CH_3Br. On the addition of CH_3Br, the linewidth increases with an increase in the CH_3Br concentration in the secondary air, as can be seen in Fig. 1.

An ESR linewidth is inversely proportional to the

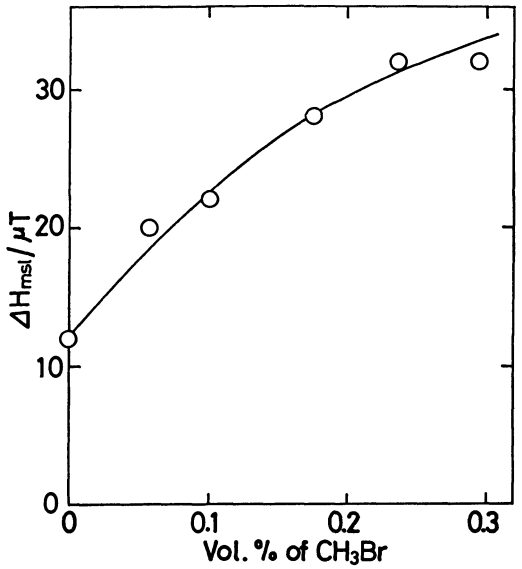

Fig. 1. Dependence of the peak-to-peak width of the derivative ESR spectrum of H atoms in a Bunsen-type methane-air flame on the concentration of CH_3Br added into the secondary air. 1 G=0.1 mT.

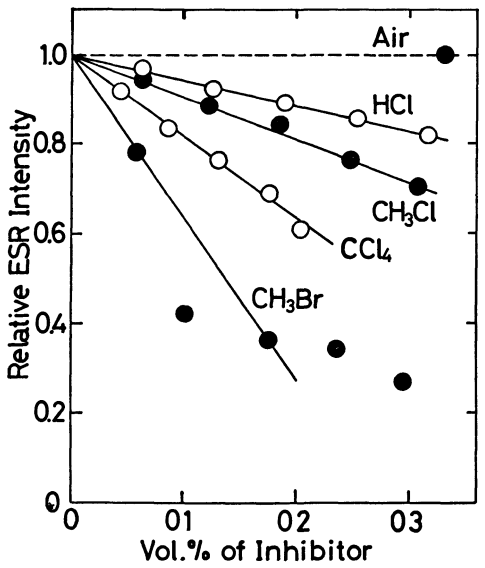

Fig. 2. Dependence of the ESR intensity of the H atoms in a Bunsen-type methane-air flame on the concentration of halogenated compounds added into the secondary air. For simplicity, the data for CH_2Cl_2, $CHCl_3$, CF_2Cl_2, and $CFCl_3$ were omitted.

spin-spin relaxation time, T_2, which can be expressed as:

$$\frac{1}{T_2} = \frac{1}{T_2'} + \frac{1}{2T_1}, \tag{2}$$

where T_2' is the spin-dephasing time and where T_1 is the spin-lattice relaxation time. The latter is related to the lifetime of the spin sublevels.[13] The most important intermolecular process in the gas phase is collision broadening; on each collision, the phase memory of the spin precession is lost. This will make the first term on the right-hand side of Eq. 2 comparatively important and will determine the ESR linewidth. The presence of halogenated compounds is expected to produce paramagnetic halogen atoms, like Cl and Br.[4,7] The Br atoms have a rapid spin-lattice relaxation which makes them an efficient sink of the spin energy of the H atoms. The presence of Br atoms will thus shorten the T_1 of the H atoms and cause a line-broadening due to the second term. The H-atom concentration in the flame as deduced from ESR was corrected for this variation in linewidth.

Effect of Inhibitors on H-atom Concentration. The amount of H atoms in a Bunsen flame has been found to depend on the concentration of O_2 in the secondary air.[10] It has also been demonstrated that H atoms react with O_2 molecules which diffuse into the flame from the surrounding air.[11]

The introduction of halogenated compounds into the secondary air reduced the amount of H atoms in the flame to a varying extent, depending on the inhibitor. The observed results are shown in Fig. 2 for some of the inhibitors. As a blank test, excess air was added to the secondary air in place of an inhibitor, but no appreciable reduction in the amount of the H atoms was observed. This indicates that the change in the H-atom concentration arises from the chemical reactions of the added inhibitors, and not from any physical modification of the flame caused by the addition of the inhibitors.

The observed ESR signal intensity of the H atoms decreases linearly with the concentration of the halogenated compound added, as is shown in Fig. 2. This linearity comes fortuitously through the complex combustion reactions in the flame. However, the negative slope of the straight lines in Fig. 2 serves to determine the chemical effectiveness of the inhibitors, as

$$\phi_\tau = \frac{[H]_0 - [H]}{[H]_0} \cdot \frac{1}{[In]}, \tag{3}$$

where [H] and $[H]_0$ are the amounts of H atoms in the presence and in the absence of an inhibitor respectively. The ϕ_τ values thus obtained are shown in Fig. 3 for all the halogenated compounds examined.

Discussion

For halogenated compounds, Fristrom and Van Tiggelen[1] derived an inhibitor index, ϕ_ν, as:

$$\phi_\nu = n_C\phi_C + n_H\phi_H + \Sigma n_X\phi_X, \tag{4}$$

where n_C, n_H, and n_X are the numbers of carbon, hydrogen, and halogen atoms in a halogenated compound and where ϕ_C, ϕ_H, and ϕ_X are the atomic-inhibitor indices for the corresponding atoms. The atomic-inhibitor indices have been derived from the observed change in the burning velocity of a premixed flame caused by the inhibitors based on kinetic considerations of combustion reactions.[1] They have also been shown to depend on the fuel and also on equivalence ratio, though not strongly. Although the equivalence ratio can not be defined for a Bunsen-type flame, one can obtain a good linear relationship between ϕ_τ and ϕ_ν, as can be seen in Fig. 3, by using a typical set of values:[1] $\phi_C=1.0$, $\phi_H=0.25$, $\phi_F=1.0$, $\phi_{Cl}=1.5$, and $\phi_{Br}=12.3$. The general trend is that

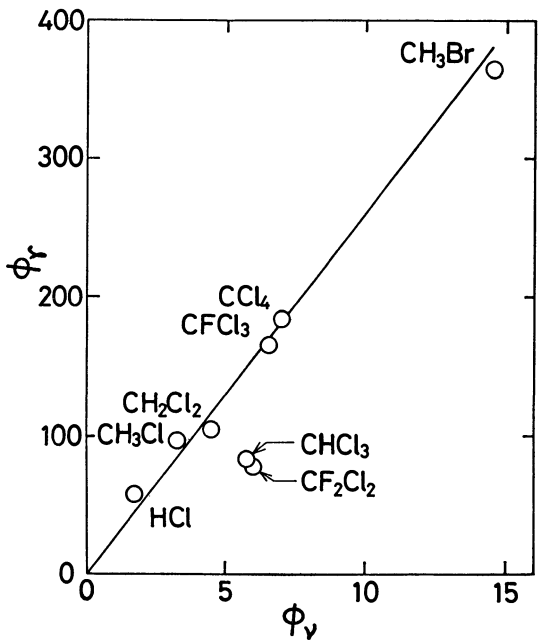

Fig. 3. Correlation between the effectiveness, ϕ_r, of halogenated compounds in scavenging H atoms in a methane-air flame determined by the ESR method and the inhibitor index, ϕ_v, determined from their effect on the burning velocity.[1]

an increase in the number of Cl atoms in the inhibitor molecule results in a more pronounced reduction in the amount of H atoms in the flame. The halogen atoms reduce the amount of H atoms in this increasing order: F<Cl<Br.

A halogenated compound inhibits flame reactions by scavenging H atoms, which are the principal reactive intermediates in hydrocarbon combustion. The reduction in the amount of H atoms observed above is not necessarily due to the direct scavenging of H atoms by the inhibitors; it can also be an indirect result of the scavenging of other reactive intermediates, like O atoms and OH radicals. However, because, in a fuel-rich hydrocarbon flame, H atoms are the most abundant reactive intermediates,[7] we will focus our discussion on the scavenging of H atoms.

Halogenated compounds can scavenge H atoms and convert them into stable molecules and unreactive radicals by reactions like:

$$H + RX = HX + R, \quad (5)$$

$$H + HX = H_2 + X. \quad (6)$$

In addition, halogen atoms can assist the cyclic recombination of H atoms in reaction sequences where the halogen atom is rapidly regenerated:[1]

$$H + X + M \rightarrow HX + M, \quad (7)$$

followed by Reaction 6. The equilibrium of Reaction 6 tends to be shifted far to the right in a high-temperature flame when X is Br and I.[5,6] As a matter of fact, about 70% of the bromine has been shown to exist in the atomic form in a HBr-inhibited methane-air flame.[14] From the ϕ_v data, the rate constant of the forward reaction, 7, for Br (and I) has been evaluated to be about nine times larger than that for Cl.[1] Thus, the efficient decrease in the amount of H atoms caused by CH_3Br compared to the chlorinated and fluorinated methane found in this study is consistent.

An inhibitor molecule containing more than one halogen atom (*e.g.*, CCl_4) can be stripped of its halogen atoms by successive reactions with H atoms:

$$CCl_4 + H \rightarrow CCl_3 + HCl, \quad (8)$$

$$CCl_3 + H \rightarrow CCl_2 + HCl, \quad (9)$$

and so forth.[5] Therefore, HCl can be expected to scavenge one H atom by means of Reaction 6, while CH_3Cl scavenges two H atoms by the combined reactions of 5 and 6, and CCl_4 even more by successive reactions of the 9 type. The observed ϕ_r values agree qualitatively with what can be expected, except for the cases of $CHCl_3$ and CF_2Cl_2.

The authors are grateful to the Toyota Foundation for its financial support (1977—1979) in initiating the study. One of the present authors (O. C.) acknowledges the support of the Yamada Foundation and the Swedish National Science Council for his stay at Hokkaido University.

Ultraviolet Photoelectron Spectra of α- and β-Polymorphs of Copper Phthalocyanine

Chen Shang Xian,† Kazuhiko Seki, Hiroo Inokuchi,* Shi Zurong,†† and Qian Renyuan††

Institute for Molecular Science, Myodaiji, Okazaki 444

†† *Institute of Chemistry, Academia Sinica, Beijing, China*

(Received January 14, 1983)

The ultraviolet photoelectron spectra have been measured for α- and β-forms of copper phthalocyanine at 183 °C, to investigate the correlation of photoemissive behavior with crystal structure. Their threshold ionization potentials were 4.8_8 and 4.6_2 eV,** with polarization energy of 1.2_7 and 1.5_3 eV, respectively. This difference could not be explained by calculation with point charge-point dipole approximation, but calculation with distributed charge on the cation and distributed induced dipoles on the nearest neighbor two molecules gave semi-quantitative agreement with the experimental findings.

The phthalocyanines are used as pigments or photoreceptors, and their structures are similar to those of porphyrins such as chlorophyll and hemoglobin; accordingly they have been extensively studied.[1–5] Copper phthalocyanine (CuPc) is representative. In 1963, Vilesov *et al.*[6] measured its photoelectron spectrum. In 1968, Schechtman and Spicer[7] reexamined this and compared the density of the occupied states of CuPc from experimental results with that derived from theoretical calculations. This revealed a good agreement between them. In 1978, Berkowitz[8] measured the photoelectron spectra of various phthalocyanine compounds in the gas phase.

As is well known,[9–10] CuPc exists in different crystal structures as α-, β-, and x-forms. The β-form is the most stable and the others are metastable at room temperature. It is interesting to study the dependence of photoemissive behaviors on their polymorphism. From these measurements we could establish a correlation between the molecular packing and the electronic structure.

In this paper, we report the threshold ionization potential of α- and β-CuPc by means of ultraviolet photoelectron spectroscopy (UPS). There is 0.2_6 eV difference in the threshold ionization potentials between them. We believe this to be the first UPS study of polymorphs of organic crystal with known structures, which permit a detailed analysis of the origin of the difference between the two forms.

Experimental

Two samples of CuPc were used and gave the same results. One of them was prepared and purified as described previously.[11] The other was supplied by Dainihon Ink Co. Ltd., and was used without further purification. The sample film was prepared on a Cu-substrate by evaporation and measured *in situ* in vacuum of 10^{-5} to 10^{-6} Pa; the film thickness was controlled around 50 nm and measured with a quartz thickness monitor. The α- and β-polymorphs were prepared by evaporation on the substrate at room temperature and 250 °C, respectively. The resultant structures were examined by X-ray diffraction, and the data agreed with those in the literature.[9,10]

The light source of the photoemission machine was a Hinteregger-type hydrogen-discharge lamp used in conjunction with a 0.5 m Seya-Namioka-type monochromator. The energy of the photoelectron was analyzed with a retarding-potential-type energy analyzer as reported previously.[12] The energy resolution was about 0.2 eV. All the observed values were reproducible within ±0.05 eV.

Results and Discussion

Initially, we tried to measure the photoelectron spectra of α- and β-CuPc at room temperature. The measurement of the α-form was not difficult, but for the β-form there was a severe charging of the sample. This is probably due to the low conductivity of the β-form at room temperature. As reported by Wihksne, dark conductivity of β-metal free phthalocyanine is 10^5 times lower than that of α-form at 180 °C, and further, this difference is expected to increase at room temperature.[11] It is reasonable to assume similar relations for the α- and β-CuPc. This experimental difficulty was revolved by elevating the temperature to increase the conductivity of the β-form. We found that the α-form does not change to β-form below 200 °C, then both forms could be measured at the same temperature (183±2 °C).

The photoeletron spectra of the β- and α-forms at this temperature, 183±2 °C, and that of α-form at room temperature using a photon energy of 7.8 eV are shown in Fig. 1 as curve a, b, and c, respectively. Table 1 lists the photoemission threshold values I_s^{th} obtained from these curves using the Einstein relation $I_s^{th}=h\nu-E_k^{max}$, where E_k^{max} is the maximum kinetic energy of the photoeletrons.

From Table 1, we see that I_s^{th} of the α-form at 183 °C is a little lower than that at room temperature. Most of this we can ascribe to the coupling of ionizing electronic excitation with low-energy modes of lattice phonon which satisfy $\hbar\omega \ll kT$, where $\hbar\omega$ is the phonon energy quantum, k the Boltzmann factor, and T the temperature. Using the theory of Duke,[13] a lowering of I_s^{th} proportional to $T^{1/2}$ is expected. With a theoretical value of proportional constant for benzene with all lattice phonon modes taken into account,[13] we can estimate a lowering of ≈0.18 eV, which is comparable with the observed value for α-CuPc. Since all the lattice phonon modes of phthalocyanines

TABLE 1. THE THRESHOLD IONIZATION POTENTIALS AND POLARIZATION ENERGIES OF α- AND β-COPPER PHTHALOCYANINE

Crystal form	Threshold ionization potential / eV			Polarization energy / eV	
	Crystal at RT	Crystal at 183 °C	Gas	Crystal at RT	Crystal at 183 °C
α	$5.0_9\pm0.05$	$4.8_8\pm0.05$	6.15[a]	1.0_6	1.2_7
β	—	$4.6_2\pm0.05$	6.15[a]	—	1.5_3

a) Estimated from Berkowitz's data (Ref. 8).

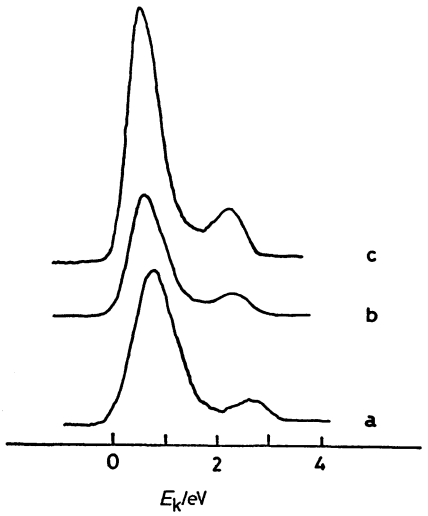

Fig. 1. Photoelectron spectra of copper phthalocyanine at $h\nu=7.8$ eV in kinetic energy (E_k) scale. a: β-form at 183 °C, b: α-form at 183 °C, and c: α-form at room temperature.

will appear in the region $\hbar\omega \ll 100$ cm^{-1},[14] all modes will contribute to the temperature dependence in both the α- and β-forms. Therefore we can expect that the temperature dependence of I_s^{th} is almost common in the two phases, and its difference will not play an important role in discussing the I_s^{th} difference of α- and β-forms at the same temperature.

From Table 1, it can be seen that there is a small but distinct difference 0.2_6 eV in threshold ionization potentials between the two crystal forms. According to Lyons,[15] the ionization potential of solid is determined by gas phase ionization potential and its lowering due to the electric polarization of the molecules surrounding the cation, which is called polarization energy. In Table 1, the polarization energies obtained by using gas phase threshold ionization potential of 6.15 eV[8] are also listed.

The present results indicate that the polarization energies of the two crystalline forms are different. Our work offers the first experimental evidence for the dependence of photoelectron spectra on polymorphs of known strucure. In 1978, Nielsen[16] reported the substrate dependent ionization and polarization energies of dibenzotetrathiafulvalene and explained the experimental results as due to the formation of different structure or orientations. However, he did not show the direct evidence to demonstrate the existence of different crystalline forms.[17]

The polarization energy of molecular solid constructed with nonpolar molecules can be considered as the interaction energy of the charge of the cation and electric multipoles induced on surrounding molecules.[15] For simplicty, we will neglect multipoles higher than dipole and the interaction among dipoles.

In general, the charge on the cation and the dipole for the neutral molecules are distributed over each molecule. If we represent them by a point charge and a point dipole at the center of the molecule, the polarization energy can be expressed as[15]

$$P_s = \sum_i \frac{e^2}{2r_i^6} \boldsymbol{r}_i \alpha \boldsymbol{r}_i, \tag{1}$$

where $\boldsymbol{r}_i$ is the distance vector of i-th molecule from the cation, r_i, its absolute value, e, electronic charge, α, the molecular polarizability tensor, and summation is taken over all the molecules in the crystal except the ionized molecule.

To obtain a roughly correct order of P_s, calculations with more simplified forms[18,19]

$$P_s = ke^2\bar{\alpha}d^{-4/3}, \tag{2a}$$

or

$$P_s = (e^2/2\rho)(1-1/\varepsilon), \tag{2b}$$

are known to be useful, where k is a constant, $\bar{\alpha}$, the averaged molecular polarizability, d, the density, ρ, half of r_i of the nearest neighbor molecule, ε, the optical permissivity which can be estimated from $\bar{\alpha}$ and k. In the present case of CuPc, $\bar{\alpha}$ is common to the α- and β-forms, and d is also almost the same (1.62 and 1.61) for α- and β-forms, respectively.[20-22] Therefore, such simple formulae cannot be used to explain the difference in P_s in these forms.

We calculated P_s of both forms using Eq. 1. Since there seems to be no experimental data of α, we expressed the polarizability perpendicular and parallel to the molecular plane as α_0 and $b\alpha_0$, respectively. The data for other molecules suggest that $\alpha_0 \approx 30\times 10^{-27}$ m^3 [23] and b is between 2 and 3.[23,24] The crystal structures of α- and β-forms[4] are shown in Fig. 2. The summation in Eq. 1 was taken for molecules within cubes of edge length of $l=60$, 80, 120, and 200 Å. They showed good linear relationships with $1/l$, and the extrapolation to $l=\infty$ gave the values P_1 in Table 2. The values for the α-form are larger than those of the β-form, which does not agree with the observed results. Further, the calculated values are too large.

In order to improve this situation, we took account of the distribution of charges and dipoles on the cation

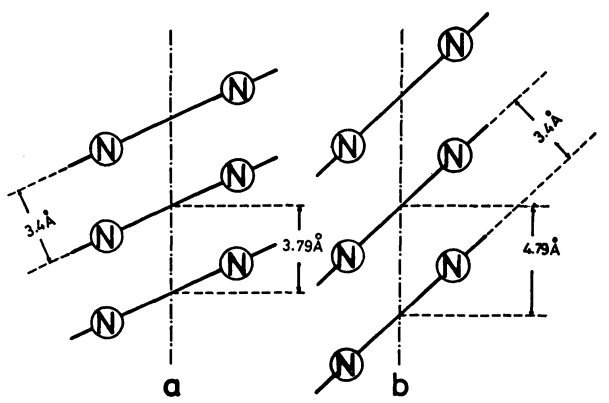

Fig. 2. Molecular arrangements in copper phthalocyanine crystals of (a) α- and (b) β-forms.[18] —·—·—: b-Axis, N-N: Molecular plan. The angle between the b-axis and the molecular plane for the α- and β-forms are 65.2° and 45.7°, respectively.

Table 2. Calculated polariztion energies

Anisotropy parameter b	Form	P_1/eV	B/eV	P_2/eV
2	α	3.35	0.85	1.45
	β	2.24	1.01	1.53
3	α	4.06	1.15	1.86
	β	3.05	1.41	2.05

and the nearest neighboring two molecules. As seen in Fig. 2, the overlap of the cation and nearest neighbors is large in both forms of CuPc, and the validity of the point-charge and point-dipole is dubious for the interaction among these molecules. When we divide P_1 into the contribution from the nearest neighbors A_1 and that from the other molecules B ($P_1=A_1+B$), A_1 is overwhelmingly large as shown in Table 3. Thus the examination of A_1 is important.

The highest occupied orbital of CuPc is known to be the π-orbital shown by the bold line in Fig. 3.[7,8,25] We approximated this with a dotted square in Fig.3, and assumed a uniform charge distribution of total amount of e. As for the dipole distribution, we adopted the "submolecular concept," [26,27] where we regard a large aromatic molecule as an aggregate of independently polarizable aromatic rings. This treatment is known to give reasonable dielectric properties for large molecules.[26,27] We treated CuPc as 12 aggregated rings in Fig. 3, with each ring represented by a dipole at its center. The polarizability of each ring was assumed to be 1/12 of α_0 and $b\alpha_0$.

Initially, we calculated the electric field at the center of each ring by the distribution charge on the cation, and calculated the induced dipole and the dipole-electric field interaction energy. These were summed for the twelve rings to give the total contribution A_4 from the nearest neighboring two molecules. For comparison, we also calculated the values for point charge-distributed dipole(A_2) and distributed charge-point dipole (A_3) approximations. Table 3 lists these values. We see that the values of both forms decrease by the consideration of distributions, but the change of α-form is much more than that of β-form. As a result, the difference between the two forms becomes

Table 3. Contributions of Nearest neighbor two molecules to polarization energy calculated with various approximation for $b=2$.

Form	A_1/eV[a]	A_2/eV[b]	A_3/eV[c]	A_4/eV[d]
α	2.50	1.28	0.75	0.60
β	1.23	0.96	0.72	0.52

a) Point charge-point dipole, b) Point charge-distributed dipole, c) Distributed charge-point dipole, d) Distributed charge-distributed dipole.

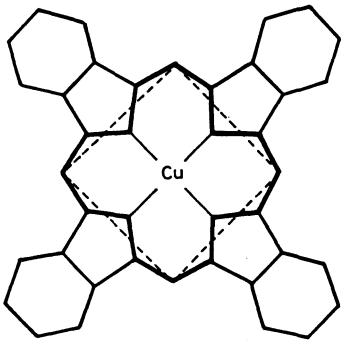

Fig. 3. Molecular structure and the highest occupied π-orbital (bold line) of copper phthalocyanine. The dotted line indicates the approximated charge arrangement.

very small, in particular for the distribution of the positive charge in the cation.

The values of P_s reevaluated as $P_2=A_4+B$ is shown in Table 2. The values of α-form become larger than those of β-form, in agreement with the experimental findings. Further, the absolute magnitude of P_2 is comparable with the observed values, although the estimation of α_0 may include considerable error. We should note that the ratio of P_2 values of α- and β-forms does not depend on α_0 but only on b.

Although the above estimation of P_s is very approximate, we may safely say that the extended distrubution of charges on the cation(and maybe the distribution of dipoles on neutral molecules and the anisotropy of polarizability) results in a very small difference for the contribution of the nearest neighbor. This made the total P_s difference to be determined by a larger difference of B. This is instructive about the role of the charge distribution, since at first glance of Fig. 2 we may expect a larger P_s of α-form because of the smaller center-to-center distance and a larger overlap of molecules than in the β-form. Studies of the P_s of aromatic hydrocarbon crystals using a similar formulation will be interesting, since those molecules are not stacked as in CuPc, and the effect of charge distribution may be not so important as in the present case. The validity of simplified formulae Eq. 2a and 2b can be also examined.

Finally we wish to stress the usefulness of studying polymorphs for a detailed examination of the theory of polarization energy. If the theory is satisfactory, it should explain the data of two or more polymorphs using the same molecular parameter α, and this will restrict the degree of freedom in adjusting the theore-

tical parameters much more than in studying different compounds. Further future studies of various polymorphs with known structures are therefore desired.

The authors would like to express their sincere thank to Prof. I. Koyano and Dr. N. Sato for their helpful discussion, and to Dr. T. Kobayashi for the information of far-infrared spectral data. One of the authors (Chen Shang Xian) is indebted to Yamada Science Foundation for the financial support.

Surface Treatment of Inorganic Pigments by N^{ε}-Acyllysine

Kunio Esumi,* Shigeki Yoshida, and Kenjiro Meguro

Department of Applied Chemistry, Institute of Colloid and Interface Science, Science University of Tokyo, Kagurazaka 1-3, Shinjuku-ku, Tokyo 162

(Received February 2, 1983)

Inorganic pigments(calcium carbonate, iron oxide, and titanium dioxide) were treated with N^{ε}-lauroyl-L-lysine, which is almost insoluble in both polar and nonpolar solvents. Two methods were employed for the treatment: (1) grinding of various weight proportional mixtures of pigment and the *N*-acyllysine; (2) adsorption of the *N*-acyllysine from its calcium ethylate solution on pigment. In method(1), the sufficient hydrophobic treatment was made when the weight percent of the *N*-acyllysine in the mixture was above about 30%. On the other hand, in method(2), although the amount adsorbed of the *N*-acyllysine was about in the range of 10^{-6} mol/g, the treated pigment showed a hydrophobicity. The critical surface tension of the treated samples estimated by using various mixtures of methanol and water was in the range from 23 to 39 dyn/cm.†

The surface treatment of solids[1-3], especially pigments, by surface active agents, polymers, and coupling agents are very important for preparing a good dispersion in the paint and printing industries. However, the above methods are not always suitable due to the detachment of the treating agents from the pigments in suspensions.

In general, it is known that amino acids and their derivatives[4,5] show surface activities for modifying wettability of solids. Especially, N^{ε}-Acyllysine is an interesting material because it is insoluble in both ordinary polar and nonpolar solvents due to its strong hydrogen bonding within the molecules. If the *N*-acyllysine could be applied to treat surface of pigments, a strong coating would be expected without detaching the *N*-acyllysine from the treated surfaces.

In this work, surface treatment of inorganic pigments by an *N*-acyllysine such as N^{ε}-lauroyl-L-lysine is described.

Experimental

Materials. The pigments used in this study were calcium carbonate (calcite) supplied by Kokusan Chemicals Co., Ltd., and iron oxide (R-110-A) and titanium dioxide (rutile) supplied by Titan Kogyo Co., Ltd.

N^{ε}-Lauroyl-L-lysine prepared from lauric acid and L-lysine[6] was kindly supplied by Ajinomoto Co., Ltd. This structural formula is shown as follows:

$$n\text{-}C_{11}H_{23}CONH(CH_2)_4CH(NH_2)COOH.$$

Calcium ethylate[7] was prepared by heating calcium chloride and ethyl alcohol together until calcium chloride completely dissolved.

Apparatus and Procedure. Two methods were employed for the surface treatment of pigments by N^{ε}-lauroyl-L-lysine.

(1) The Coating by Grinding: Calcium carbonate and N^{ε}-lauroyl-L-lysine were ground together in various proportions (total weight, 20 g) by a grinder (Type AOA of Ishikawa Kojo Co.). The various proportions of calcium carbonate to N^{ε}-lauroyl-L-lysine were as follows: sample No. 1, 1:10; No. 2, 1:5; No. 3, 1:3; No. 4, 1:2; No. 5, 1:1; No. 6, 2:1; No. 7, 3:1; No. 8, 5:1; No. 9, 10:1. The change of crystal form of the ground samples was measured by X-ray diffraction consisting of a Geigerflex diffractometer with nickel filtered copper radiation. The specific surface areas of the ground samples were measured by a Sorptograph Model ADS-1B (Shimadzu Seisakusho Co., Ltd.). To measure the sedimentation volume of the ground samples, water was added to 1 g of the ground sample in a 30 ml graduated cylinder to adjust a total volume of 30 ml.

(2) The Coating by Adsorption of N^{ε}*-Lauroyl-L-lysine from Its Calcium Ethylate Solution*: One gram of pigment was placed in a L-shaped test tube and N^{ε}-lauroyl-L-lysine solution of calcium ethylate was added. Then the L-shaped test tube was shaken at 25 °C. After at leat 2 h, having reached adsorption equilibrium, the sample was separated by centrifuging and dried *in vacuo*. The amount of N^{ε}-lauroyl-L-lysine adsorbed was determined from the difference of the concentrations of N^{ε}-lauroyl-L-lysine before and after the adsorption, by means of an UV spectrophotometer (Type ESP-3T of Hitachi).

The critical surface tension of the pigment coated with N^{ε}-lauroyl-L-lysine was estimated by using various mixtures of methyl alcohol and water at 20 °C.[8]

Results and Discussion

(1) The Coating by Grinding. The intensities of all the reflections of calcium carbonate alone in the X-ray diffraction diagrams decreased and became weaker during the grinding process. Similarly, all the reflections of N^{ε}-lauroyl-L-lysine alone decreased with the grinding time. Further, although the X-ray diffraction measurement was carried out on the ground samples of calcium carbonate and N^{ε}-lauroyl-L-lysine, the change of crystal forms of the ground samples was difficult to estimate due to a remarkable difference of their intensities. Since the original crystal forms of calcium carbonate and N^{ε}-lauroyl-L-lysine were not changed by up to 1 h grinding, the grinding time was taken as 1 h to study an effect of coating without considering any crystal transformation.

The specific surface areas of all the ground samples are plotted against the weight percent of N^{ε}-lauroyl-L-lysine, as shown in Fig. 1. The specific surface areas of the ground samples had a minimum value and increased gradually with an increase of content of N^{ε}-lauroyl-L-lysine in the mixture; finally they reached the value of N^{ε}-lauroyl-L-lysine alone. This might be interpreted by assuming that the grinding of calcium carbonate is interfered with by the addition of N^{ε}-lauroyl-L-lysine and the calcium carbonate becomes

† 1 dyn = 10^{-5} N.

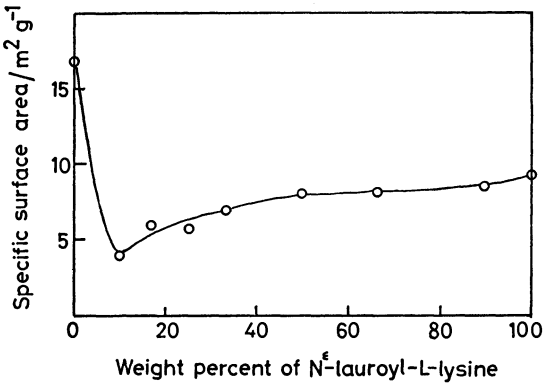

Fig. 1. Specific surface areas of ground samples as a function of weight percent of *N*$^{\varepsilon}$-lauroyl-L-lysine.

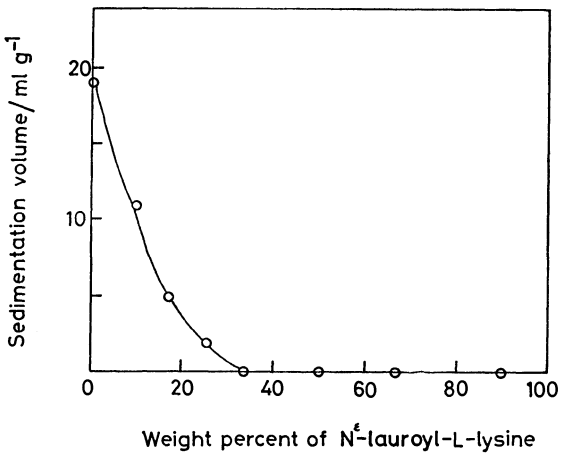

Fig. 2. Sedimentation volumes of ground samples as a function of weight percent of *N*$^{\varepsilon}$-lauroyl-L-lysine.

covered with *N*$^{\varepsilon}$-lauroyl-L-lysine with an increase of the amount of *N*$^{\varepsilon}$-lauroyl-L-lysine.

Figure 2 gives the sedimentation volume of all the ground samples in water *vs.* the weight percent of *N*$^{\varepsilon}$-lauroyl-L-lysine in the mixtures. Calcium carbonate alone completely sedimented, while *N*$^{\varepsilon}$-lauroyl-L-lysine formed a compact layer at the air/water interface. In the mixtures from No. 1 to No. 6, the particles were attached to the air/water interface like *N*$^{\varepsilon}$-lauroyl-L-lysine alone. The sedimentation of particles was observed distinctly in mixture No. 7, and further the volume ratio of the floating particles to the sedimented ones was nearly unity in mixture No. 9. Here, all the sedimented particles were confirmed to be calcium carbonate by the X-ray diffraction measurement. Thus, the above results indicate that when the weight percent of *N*$^{\varepsilon}$-lauroyl-L-lysine in the mixture is above about 30%, the efficient coating for calcium carbonate can be obtained which will show a strong hydrophobicity like *N*$^{\varepsilon}$-lauroyl-L-lysine alone.

(2) The Coating by Adsorption of N$^{\varepsilon}$*-Lauroyl-L-lysine from Its Calcium Ethylate Solution.* Figure 3 shows the adsorption isotherms of *N*$^{\varepsilon}$-lauroyl-L-lysine on pigments at 25 °C. It can be seen from Fig. 3 that, except for iron oxide, the amount of *N*$^{\varepsilon}$-lauroyl-L-lysine adsorbed increases with an increase of the concentration of *N*$^{\varepsilon}$-lauroyl-L-lysine. In the case of

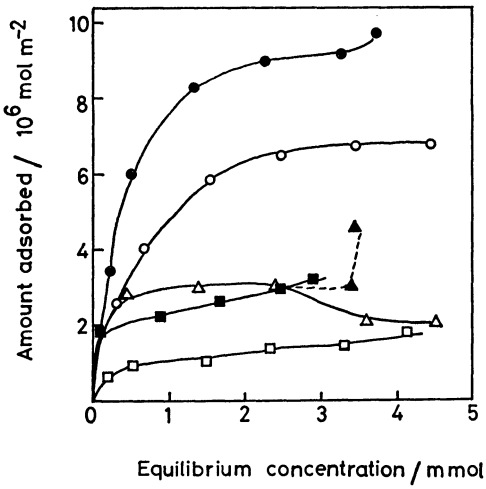

Fig. 3. Adsorption isotherms of *N*$^{\varepsilon}$-lauroyl-L-lysine on pigments: no addition of water; ○ $CaCO_3$, △ α-Fe_2O_3, □ TiO_2, addition of water (5 vol%); ● $CaCO_3$, ▲ α-Fe_2O_3, ■ TiO_2.

Table 1. The area occupied per *N*$^{\varepsilon}$-lauroyl-L-lysine molecule on pigments

Pigment	Area occupied/Å^2	
	(I)	(II)
Calcium carbonate	24.6	18.0
Iron oxide	67.0	53.2
Titanium dioxide	125.8	51.9

(II) lists the values obtained by the addition of water.

calcium carbonate, the adsorption isotherm follows a Langmuir type. Also, Fig. 3 gives the adsorption isotherms of *N*$^{\varepsilon}$-lauroyl-L-lysine on each pigment by the addition of water(5 vol%) into the solution. In all cases, the amount of *N*$^{\varepsilon}$-lauroyl-L-lysine adsorbed was enhanced compared with that for no addition of water. This result can be explained as a lowering of the solubility of *N*$^{\varepsilon}$-lauroyl-L-lysine in calcium ethylate solution by the addition of water. Further, the area occupied per molecule of *N*$^{\varepsilon}$-lauroyl-L-lysine on the pigment at the equilibrium concentration of 3 mmol dm^{-3} is obtained and their values are listed in Table 1. It is found that the area occupied for calcium carbonate is smaller than that for the other pigments, indicating that *N*$^{\varepsilon}$-lauroyl-L-lysine molecules on calcium carbonate are much more "collapsed" than that for the others. This difference might be interpreted by the acid-base property of pigments.

Generally, it is known[9] that calcium carbonate is a basic pigment, while the others(iron oxide and titanium dioxide) are neutral or acidic. As the pH of the *N*$^{\varepsilon}$-lauroyl-L-lysine solution in this study ranges between 4.5—5.0, it is anticipated that the adsorption capacity of *N*$^{\varepsilon}$-lauroyl-L-lysine on calcium carbonate can be enhanced by the acid-basic interaction.

(3) Wettability of the Pigment Coated by N$^{\varepsilon}$*-Lauroyl-L-lysine.* The results of wettability experiments for the pigment coated by the adsorption of *N*$^{\varepsilon}$-lauroyl-L-lysine are given in Fig. 4. The critical surface

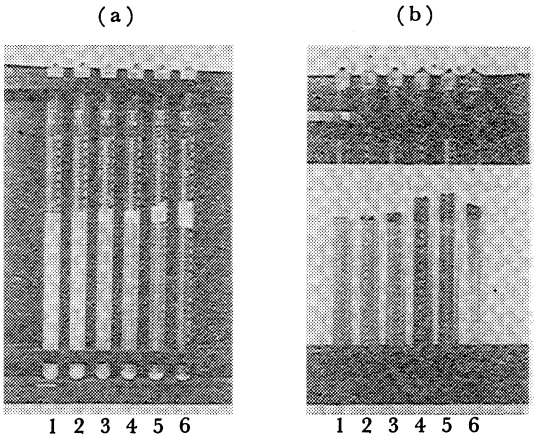

Fig. 4. Results of wettability experiments in aqueous methanol solutions: (a) calcium carbonate, (b) iron oxide; surface tension(dyn/cm), 1=23, 2=30, 3=39, 4=50, 5=60, 6=71.

tension of the pigment coated by N^{ϵ}-lauroyl-L-lysine was determined by using a series of aqueous methanol solutions. The pigment coated by N^{ϵ}-lauroyl-L-lysine became completely wet in solutions with surface tension below its critical surface tension. The critical surface tension of calcium carbonate coated with N^{ϵ}-lauroyl-L-lysine (No. 1—6) by grinding and by the adsorption had almost the same value, ranging between 30 and 39 dyn/cm. Also, the critical surface tension of iron oxide coated with N^{ϵ}-lauroyl-L-lysine by the adsorption was in the range between 23 and 30 dyn/cm.

Although the wettability of calcium carbonate coated with N^{ϵ}-lauroyl-L-lysine is not so different for the two methods, there is an extraordinary difference of the amount of N^{ϵ}-lauroyl-L-lysine required to render the surface hydrophobic sufficiently; the amount required by grinding is about 1.3 mmol/g, while that by the adsorption ranges as low as 10^{-3} mmol/g.

It is very important to elucidate how strong the attachment of N^{ϵ}-lauroyl-L-lysine is against organic solvents, to determine the stability of coating. So, the following test was carried out to estimate the strength of coating of N^{ϵ}-lauroyl-L-lysine on the pigment; the iron oxide coated with N^{ϵ}-lauroyl-L-lysine by the adsorption was treated in toluene at its boiling point for 10 min and then the sample was dried in a vacuum oven to eliminate toluene. The critical surface tension of the treated sample was then determined by the previous method. If N^{ϵ}-lauroyl-L-lysine is removed from the coated sample by the above treatment, the critical surface tension of the treated sample would show a higher value compared with that for the untreated sample. In this experiment, the critical surface tension of the treated sample showed almost the same value as that without the treatment. This result shows that the attachment of N^{ϵ}-lauroyl-L-lysine on the iron oxide is strong enough against the toluene treatment.

The Long-wavelength nπ* Phosphorescence Spectra of *p*-Quinones in Polycrystalline Solutions at 77 K

Akira KUBOYAMA,* Yoshikuni KOJIMA,† and Sanae Y. MATSUZAKI

National Chemical Laboratory for Industry, Tsukuba Research Center, Yatabe, Ibaraki 305

† *The Tokyo Metropolitan Industrial Technology Center, Kita-ku, Tokyo 115*

(Received February 10, 1983)

Besides the usual nπ* phosphorescence spectra, broad, long-wavelength nπ* phosphorescence spectra are observed in normal paraffine solutions, such as a heptane solution, of 1,4-naphthoquinone, and in a benzene solution of 5,14 : 7,12-pentacenediquinone at 77 K. The energy difference between the two spectra are *ca.* 750 and 980 cm^{-1} respectively. The intensity of the long-wavelength spectra relative to the short-wavelength spectra becomes weaker with decreases in the concentrations of the quinones, and the lifetimes of the long-wavelength spectra are shorter than those of the short-wavelength spectra. These long-wavelength spectra are assigned to those of the quinone aggregates. The excitation spectra of these phosphorescences have also been obtained. An explanation of the above red-shift of the nπ* phosphorescence spectra of the aggregates is presented; in it, the phosphorescence state of the aggregates corresponds to the nπ* triplet excimer state.

Heretofore, we have studied the phosphorescence spectra of quinones in solutions at 77 K.[1] normal paraffin polycrystalline solutions, such as a heptane solution, of 1,4-naphthoquinone(NQ)[1e] at 77 K show a regular broad phosphorescence spectrum besides a sharp nπ* phosphorescence spectrum; the broad spectrum is at considerably longer wavelengths than the sharp spectrum. A similar, broad, long-wavelength phosphorescence spectrum is also found in a benzene crystalline solution of 5,14 : 7,12-pentacenediquinone (PDQ)[2] at 77 K. In this work, these broad, long-wavelength phosphorescene spectra of the *p*-quinones have been studied.

Experimental

Measurements. The phosphorescence spectra in solutions at 77 K were measured using an Aminco-Bowman spectrofluorometer (Instrument I, PM tube R105UH) and an SPF-500 spectrofluorometer (Instrument II, PM tube R777) in the manner described in previous papers.[1a,1c,1e] The phosphorescence excitation spectra were obtained using Instrument II, equipped with a photon counter (PM tube 1P28). The energy distribution of the exciting light (a 250-W Xenon arc lamp) and the spectral transmittance of the monochromator have not been taken into account. The temperature dependence of the phosphorescence spectra was measured by means of the Instrument II equipped with a cryostat (Model CF 204, Oxford Electric Instrument, Ltd.). Two kinds of cooling speeds, fast and slow, were used.[1b] normal paraffin and benzene solutions, and methylcyclohexane and toluene solutions, formed polycrystalline and glassy states respectively at 77 K.

Materials. Commercially-available NQ was purified in the same manner as has been described in a previous work.[1e] PDQ of the Tojin Gosei Kogyo Co. was purified by means of vacuum sublimation, and its purity was checked by the TLC method. The solvents used were all of spectro-grade except for dodecane. Dodecane of GR grade of the Tokyo Kasei Kogyo Co. was used.

Results. The phosphorescence spectra and their excitation spectra obtained are shown in Figs. 1, 2, 4, and 5, and Figs. 3 and 6, respectively. The peak wavelengths of the phosphorescence spectra obtained are shown in Table 1. The broad, long-wavelength phosphorescence spectra observed in the heptane and octane solutions of NQ (Figs. 1 and 2) and the benzene solution of PDQ (Figs. 4 and 5) can not be observed using the phosphoroscope (10600 min^{-1}) because of their short lifetimes. They are weaker in slow-cooling than in rapid-cooling, as in the

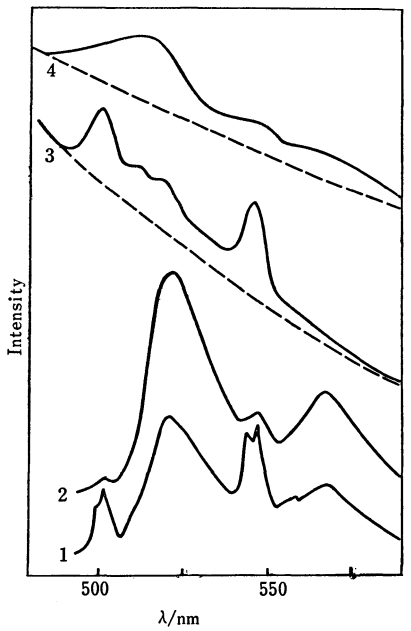

Fig. 1. Phosphorescence spectra of NQ in the heptane solution at 77 K.
1: 3×10^{-3} M, 313 nm ex., 2: 3×10^{-3} M, 365 nm ex., 3: 10^{-5} M, 313 nm ex., 4: 10^{-5} M, 365 nm ex. (In Figs. 1 and 5, ex. denotes excitation.)

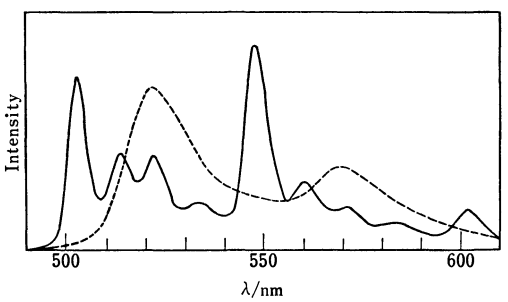

Fig. 2. Phosphorescence spectra of NQ in solutions at 77 K.
——: Methylcyclohexane, 1.6×10^{-3} M, ----: octane, 1.9×10^{-3} M.

case of the short-wavelength spectra. In NQ, the short-wavelength spectrum of the heptane solution also can not be observed using the phosphoroscope, but the corresponding phosphorescence spectrum of the hexane solution is barely observable using the phosphoroscope. The phosphorescence spectra of the hexane and toluene solutions of PDQ (Fig. 4) can be observed using the phosphoroscope; the observed lifetimes are 1.8 and 3.2 ms respectively. The observed lifetime of the short-wavelength phosphorescence spectrum of the benzene solution of PDQ (Fig. 5) is *ca.* 2 ms. The phosphorescence spectrum of PDQ crystals (Fig. 4) can not be observed using the phosphoroscope.

a) I and II denote the short- and long-wavelength spectra respectively.

Discussion

In normal paraffine solutions, such as pentane, hexane, and heptane solutions, a regular, broad phosphorescence spectrum appears at wavelengths longer by *ca.* 750 cm^{-1} than the sharp nπ* phosphorescence spectrum,[1e] and the intensity of the former spectrum relative to the latter becomes weaker with decreases in the concentrations of the solutions, as may be seen from a comparison of the 1 and 3 spectra in Fig. 1.[3] The long-wavelength spectrum appears most strongly in the heptane solution, though it is relatively weak. In the heptane solution, it is observed even at the low concentration of NQ (10^{-5} mol/l), as may be seen in Fig. 1. In the octane solution, it appears alone, as may be seen in Fig. 2. The long-wavelength spectrum is clearly different from that of the NQ crystals.[5] Therefore, the long-wavelength spectrum is thought to be due to NQ aggregates. Since the lifetime of the short-wavelength spectrum of the heptane solution is thought to be close to that of the hexane solution, it may be longer than that of the long-wavelength spectrum. As the long-wavelength spectrum shows the C–O stretching vibrational structre and its lifetime is short, it may be assigned to the nπ* phosphorescence spectrum. No such broad, long-wavelength spectrum has been observed in the other solutions of NQ studied.

In the phosphorescence excitation spectra of NQ in Fig. 3, the main broad spectra are assigned to the low-energy ππ* absorption spectrum.[6] The correspondence between these excitation spectra and the ππ* absorption spectra is qualitative, because the absorption in this wavelength region is very strong in the light of the NQ concentrations of the solutions used. Figure 3, however, proves that the ππ* absorption spectrum in the heptane solution is at considerably longer wavelengths than that in the methylcyclohexane solution.[7] The spectra corresponding to the S–S nπ* absorption spectra at the long wavelengths could not be accurately observed. However, the corresponding spectrum in the heptane solution is qualitatively observed to be at shorter wavelengths than that in the methylcyclohexane solution. As may be seen in Fig. 1, the intensity of the broad spectrum relative to that of the sharp spectrum is far larger at the 365 nm excitation than at the 313 nm excitation. This fact can reasonably be explained by the above results.

In Fig. 4, the phosphorescence spectra of the hexane and toluene solutions of PDQ are reasonably assigned to the nπ* spectrum because of their C–O stretching vibrational structure and short lifetime. The spectrum of the toluene solution is at shorter wavelengths than that of the hexane solution; this is a result of the

charge-transfer interaction between toluene and PDQ, as in the cases of other quinones.[1e,1f] As may be seen in Fig. 4, PDQ[2] also shows a broad, long-wavelength phosphorescence spectrum, with the C–O stretching vibrational structure, in the benzene solution at 77 K. This spectrum is also different from that of the PDQ crystals. A similar phosphorescence spectrum has not been observed in other solutions. In the benzene solution, as may be seen in Fig. 5, a new phosphorescene spectrum appears at the wavelengths shorter by *ca.* 980 cm^{-1} than the above long-wavelength spectrum as the concentration of PDQ decreases; the former can be observed through the phosphoroscope. This short-wavelength spectrum is situated close to the phosphorescence spectrum of the hexane solution and is similar in shape to that of the toluene

solution. From these results, the long- and short-wavelength spectra in the benzene solution are also assigned to the nπ* phosphorescence spectra of the quinone aggregates and isolated molecules respectively, as in the case of NQ.

In the phosphorescence excitation spectra[8] of PDQ in Fig. 6, the long-wavelength weak and structured spectra and the short-wavelength strong spectra are assigned to the S–S nπ* and ππ* absorption spectra respectively.[2,9] In the benzene and toluene solutions, the correspondence between the short-wavelength spectra and the ππ* absorption spectra is also thought to be qualitative, as in the case of NQ in Fig. 3. In the benzene solution, the ππ* absorption spectrum is at considerably longer wavelengths than those in other solutions studied, while the nπ* absorption spectrum is at shorter wavelengths than that in the dodecane solution as in the case of the heptane solution of NQ. At 77 K, since the S–S nπ* absorption spectrum in the benzene solution is, as has been mentioned above, at shorter wavelengths than that in the dodecane solution, the T–S nπ* absorption spectrum[10] in the benzene solution is also thought to be at shorter wavelengths than that in the dodecane solution, while the nπ* phosphorescence spectrum in the benzene solution is at considerably longer wavelengths than that in the hexane solution. A similar situation is also found in the case of NQ. It can, therefore, be concluded that, in the phosphorescence state, the geometry of the NQ and PDQ aggregates changes from that at the ground state in such a manner that the phosphorescent nπ* level of the aggregates becomes considerably lower than that of the isolated quinone molecules.

In the long-wavelength phosphorescence spectrum of the benzene solution of PDQ in Fig. 4, a very weak shoulder on the shorter-wavelength side of each peak is observed. This shoulder may be due to aggregates of another form, different from the aggregates showing the peaks. As for the temperature dependence of the long-wavelength phosphorescence spectrum in the benzene solution, it almost disappears at 100 K, while the phosphorescence spectrum in the dodecane solution can still be clearly observed at 200 K.

The shorter lifetimes of the phosphorescence spectra of these quinone aggregates relative to those of the isolated quinone molecules are thought to be due to the intermolecular interaction between the components of the aggregates. The aggregates of NQ and PDQ are thought to be favorably formed in the heptane and benzene crystals respectively. These host-guest combinations may correspond to that of key and keyhole. As for the structure of the aggregates of these quinones, it is thought probable that the aggregates consist of two quinone molecules, because large-sized aggregates can not be favorably formed in the solvent crystals, and that they take the form of a slipped sandwich-type dimer,[11] since the π-electronic exchange interaction between the component molecules of these quinone aggregates may not be very small, in view of the aforementioned large red-shift of the low-energy ππ* absorption spectrum.

The aforementioned large red-shift of the nπ* phosphorescence spectra of these aggregates may be explained as follows. The three kinds of intermolecular interaction in the aggregates, the electrostatic, dispersion-force, and π-electronic exchange interactions, may affect the shift of the nπ* spectra. The electrostatic interaction usually brings about the blue-shift for the nπ* transition spectra. On the other hand, the dispersion-force interaction is thought to be too weak to bring about such a large red-shift as that. Therefore, the exchange interaction is thought to raise the above red-shift. In the ground-state geometry of the aggregates, the eletrostatic interaction, which is a long-range interaction, may be the predominant factor in the shift of the nπ* absorption spectra, resulting in the aforementioned blue-shift of the nπ* absorption spectrum of the PDQ aggregates. On the other hand, in the nπ* phosphorescent-state geometry of the aggregates, the exchange interaction, which is a short-range interaction, may become the predominant factor in the shift of the nπ* phosphorescence spectra, resulting from a decrease in the distance between the components of the aggregates, accompanied by the formation of a state corresponding to the nπ* triplet excimer state.[13] In this explanation, therefore, the phosphorescent state of the aggregates corresponds to the nπ* triplet excimer state.

This red-shift of the nπ* phosphorescence spectra which is brought about by the π-electronic exchange interaction may be explained using a simple one-electron model as follows. In the nπ* phosphorescent state of the aggregates, in comparison with the case of the isolated quinone molecules, the degenerate π*-levels will split to some extent through the intermolecular π-electronic exchange interaction, while the degenerate n-levels will remain almost unchanged, because the overlap between the π*-orbitals of the component molecules may not be small, while that between the n-orbitals is very small. Threfore, the nπ* phosphorescence spectra of the aggregates may shift considerably to the red in comparison with that of the isolated quinone molecules. Such a long-wavelength nπ* phosphorescence spectrum as is studied in this work can be expected to be found in other p-quinones.

Laser-induced Fluorescence of the NaCs Molecule

Kyoko Onomichi and Hajime Katô*,†

Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe 657

(Received February 18, 1983)

Laser-induced fluorescence of NaCs is observed when a mixture of sodium and cesium is irradiated by the 5682 Å laser line. The spectroscopic constants of the ground state $X\,^1\Sigma^+$ have been determined and the potential energy curve was calculated by the RKR method. The excited state was identified as $D\,^1\Pi$, and the potential curve was estimated from the analysis of the fluorescence intensities.

The alkali heteronuclear diatomic molecule NaCs coexists with sodium and cesium atoms and Na_2 and Cs_2 molecules in the vapor of a mixture of sodium and cesium metals. Liveing and Dewar[1] referred an absorption in the yellow-green either to Cs_2 or to NaCs. Walter and Barratt[2] concluded that this absorption is due to the NaCs molecule, and they found another band of NaCs molecule in the violet region between 4315 and 3930 Å. Weizel and Kulp[3] assigned the lines observed by Walter and Barratt. According to their study, the vibrational constants ω_e are 98 ± 1, 65 ± 2, and 60 ± 3 cm^{-1} for the ground state, the yellow-green band, and the violet band, respectively.

The absorption of NaCs in the yellow-green region is overlapped with that of Cs_2, and spectroscopic analysis of the absorption spectrum is very difficult. However, a suitably chosen laser line may excite the NaCs molecule to only one specific rotational-vibrational level of the excited state. The resulting fluorescence will be simple, and it will be superior for studying such mixed alkali metal molecules. Nevertheless, no study of the laser-induced fluorescence of NaCs has been reported. We have succeeded in observing the fluorescence spectrum of the NaCs molecule; the results will be reported in this article.

As in the case for NaK,[4] we denote the ground and low-lying molecular states resulting from ground and excited atoms of Na and Cs as follows: $X\,^1\Sigma^+$ and $a\,^3\Sigma^+$ (from Na 3 ^{2}S+Cs 6 ^{2}S); $A\,^1\Sigma^+$, $b\,^3\Pi$, $B\,^1\Pi$, and $c\,^3\Sigma^+$ (from Na 3 ^{2}S+Cs 6 ^{2}P); $C\,^1\Sigma^+$, $d\,^3\Pi$, $D\,^1\Pi$, and $e\,^3\Sigma^+$ (from Na 3 ^{2}P+Cs 6 ^{2}S);···. In addition to these, there are molecular states resulting from Na 3 ^{2}S and Cs 5 ^{2}D. The states will have a shallow potential minimum at long internuclear distance, but the excited state of the yellow-green band is known to have a potential curve of $\omega_e=65\pm2$ cm^{-1} and the anharmonicity is not so large.[3] Therefore we will not take account of these states in the present analysis.

Experimental

Cesium metal, which was 99.9% pure and contained sodium as 0.1% impurity, was enclosed in an optical cell and heated to a temperature of about 570 K. The vapor pressure of Na, Na_2, Cs, and Cs_2 at 570 K are 1.3×10^{-2}, 1.2×10^{-4}, 2.2, and 1.3×10^{-2} Torr (1 Torr=133.322 Pa), respectively,[5] and that of NaCs is estimated to be 2.6×10^{-3} Torr by means of the Gibson-Heitler equation.[6] The experimental arrangement to observe the fluorescence spectrum is the same as our previous report.[7] A polarization scrambler was placed in front of the entrance slit of the spectrometer. Polarization of the fluorescence line was observed by placing a polarization analyser between the sample and the polarization scrambler. The intensity of the fluorescence line polarized parallel to the polarization of the laser line, $I_{//}$, and the one polarized perpendicular to the direction of polarization of laser line, $I_\perp$, were observed.

† Adjunct Associate Professor of Institute for Molecular Science (April 1981—March 1983).

Results and Discussion

When the cell which contained a mixture of sodium and cesium was irradiated by the 5682 Å Kr^+ laser line, several series of fluorescence lines with a vibrational spacing of about 99 cm^{-1} at the high energy end were observed in the region between 17000 and 18400 cm^{-1}. The vibrational spacing is close to that of NaCs, which was assigned by Weizel and Kulp.[3] The vibrational constants ω_e of the coexisting molecules Cs_2 and Na_2 are known to be about 42 and 159 cm^{-1}, respectively.[8] Therefore the observed lines can be identified as those of the NaCs molecule. One of the fluorescence spectra is shown in Fig. 1. The predominant lines are a series of P and R doublets of a large rotational quantum number J. When the frequency of the laser line was changed slightly by changing the angle of the etalon installed within the laser cavity, another series of fluorescence lines, as shown in Fig. 2, was observed. Whether an observed series of line is formed by a Q-branch or closely spaced P- and R-branches of small J has been distinguished by measuring the degree of polarization. The degree of polarization[9]

$$P_l = \frac{I_{//}-I_\perp}{I_{//}+I_\perp}, \tag{1}$$

of the lines of singlet bands in resonance fluorescence excited by linearly polarized light are given by[10]

$$P_l[P \text{ branch excited by } P(J) \text{ line}] = \frac{2J^2-5J+3}{14J^2+5J+1}, \tag{2}$$

$$P_l[R \text{ branch excited by } P(J) \text{ line}] = \frac{1}{7}, \tag{3}$$

$$P_l[P \text{ branch excited by } R(J) \text{ line}] = \frac{1}{7}, \tag{4}$$

$$P_l[R \text{ branch excited by } R(J) \text{ line}] = \frac{2J^2+9J+10}{14J^2+23J+10}, \tag{5}$$

$$P_l[Q \text{ branch excited by } Q(J) \text{ line}] = \frac{4J^2+4J-3}{8J^2+8J-1}. \tag{6}$$

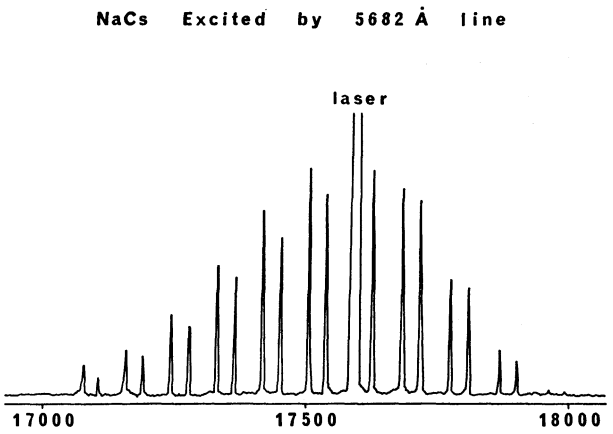

Fig. 1. Fluorescence spectrum of NaCs excited by a single mode 5682 Å line of Kr^+ laser. This P and R doublet series is assigned as the $D\,^1\Pi(v'=0,\ J'=109)\rightarrow X\,^1\Sigma^+(v'', J''=108$ and $110)$ transitions.

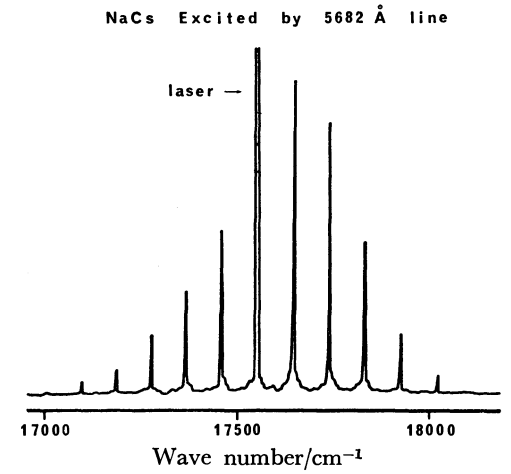

Fig. 2. Fluorescence spectrum of NaCs excited by another single mode 5682 Å line of Kr^+ laser. This fluorescence is assigned as a Q-line series of $D\,^1\Pi(0,\ J)\rightarrow X\,^1\Sigma^+(v'',\ J)$ transition. The value of J could not be assigned.

The fluorescence lines in Fig. 2 are identified as a Q line from the polarization measurement, since the degree of polarization was observed to be 0.5 The intensity decreases monotonically on either side of a single intensity maximum, and this is the same for fluorescence in Fig. 1. This result suggests that the fluorescence in Figs. 1 and 2 originates from the $v'=0$ level.

After the same procedure of changing the laser line, another series of fluorescence lines, shown in Fig. 3, was observed. This spectrum exhibits three intensity maxima. Therefore, it is reasonable to suppose that the fluorescence originates from the $v'=2$ level. Each fluorescence line in a low resolution spectrum was found to be composed of doublet lines of different intensities in a high resolution spectrum (See Fig. 3). If the doublet lines are P and R doublets from the same upper state(v', J') level, the rotational quantum number J' is estimated to be about 18 from the spacing

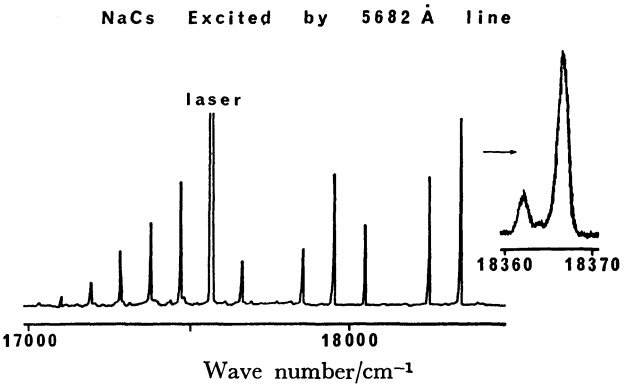

Fig. 3. Fluorescence spectrum of NaCs excited by another single mode 5682 Å line of Kr^+ laser. Each line at low resolution is composed of doublet lines of different intensities at high resolution as shown on the right. These lines are assigned as a series of $D\,^1\Pi(2,\ 18)\rightarrow X\,^1\Sigma^+(v'', J''=17$ and $19)$ transitions and a series of $D\,^1\Pi(2,\ 12)\rightarrow X\,^1\Sigma^+(v'',\ 12)$ transitions. The transitions $D\,^1\Pi(2,\ 18)\rightarrow X\,^1\Sigma^+(v'',\ 17)$ and $D\,^1\Pi(2,\ 12)\rightarrow X\,^1\Sigma^+(v'',\ 12)$ could not be resolved in the present resolution limit.

between the P line and the R line. The line strengths of P and R doublets of such J' are expected to have almost the same magnitude.[9] The degree of polarization was 0.1 for the line on the low-energy side and 0.3 for the line on the high-energy side. Thus we identified a fluorescence series of P and R lines and another fluorescence series of a Q line for the spectrum in Fig. 3, where an R line of a P and R doublets fluorescence series is overlapped with a Q line of another fluorescence series.

For a $^1\Pi$–$^1\Sigma$ transition, only Q lines appear in fluorescence for excitation by a Q line and both P and R lines appear for excitation by a P or R line. On the other hand, only $\Delta J=\pm 1$ transitions are allowed for $^1\Sigma$–$^1\Sigma$ transition and $\Delta J=0$ is forbidden.[9] We observed both Q-line series and P- and R-lines series for the yellow-green band of NaCs, but not P, Q, and R triplets from the same upper state(v', J') level. This band system is thus identified as a $^1\Pi$–$^1\Sigma$ transition.

Since the vibrational quantum numbers v' of the excited levels are small in the present case, it is easy to assign the v'' and v' quantum numbers to each line. The rotational numbering is more difficult, especially for Q-line series. It is necessary to know the rotational constant B_e in order to assign J, but the value is not known yet. We assumed therefore a tentative constant B_e which was estimated by additivity of atomic radii,[11] and we estimated the rotational numbering for a P and R doublet series. The rotational constants are determined by making a least-squares fit of the spacing between the two doublet members (v'', $J'+1$) and (v'', $J'-1$) of fluorescence series against v''. Then the members of another series are identified and assigned. This procedure is repeated until all the observed series can be assigned consistently. The spectroscopic constants of the ground state are improved by making a least-squares fit to all the lines in different series. The resulting spectroscopic constants of the $X\,^1\Sigma^+$ ground state are listed in Table

Table 1. Spectroscopic constants for the $X\,^1\Sigma^+$ and $D\,^1\Pi$ states of the NaCs molecule (cm^{-1})

	$X\,^1\Sigma^+$	$D\,^1\Pi$

a) Estimated value. See text.

1, and the assignment of each fluorescence series is described in the caption of each spectrum.

Since the excited state is found to be $^1\Pi$, the state is either the $B\,^1\Pi$ state, which decomposes into Na(3 ^{2}S) and Cs(6 ^{2}P), or the $D\,^1\Pi$ state, which decomposes into Na(3 ^{2}P) and Cs(6 ^{2}S). The dissociation energy of the $X\,^1\Sigma^+$ ground state is roughly estimated as 4800 cm^{-1}, which is the average value of dissociation energies of Na_2 and Cs_2. The dissociation limit of the $B\,^1\Pi$ state will be then 16532 cm^{-1} from the bottom of the potential curve of the $X\,^1\Sigma^+$ state, where 16532 cm^{-1} is the sum of the dissociation energy of the $X\,^1\Sigma^+$ state and the energy of the atomic line Cs($6\,^2P_{3/2}\rightarrow 6\,^2S_{1/2}$). The excitation energy of the 5682 Å (17595 cm^{-1}) laser line exceeds the dissociation limit. The excited state is therefore identified as the $D\,^1\Pi$ state. Although there will be some error in the estimation of the dissociation energy of the $X\,^1\Sigma^+$ state, we are convinced this identification to be correct because the 5682 Å laser line excited to the levels of small vibrational quantum numbers v'; hence the excited level should be close to the potential minimum.

Since the number of excitations is small in the present study, we could not determine the spectroscopic constant of the excited state from the analysis of energies of the excited levels alone. Since the vibrational quantum number of the excited level is small, we would be able to estimate the equilibrium internuclear distance with a reasonable accuracy from the analysis of the intensity distribution of the fluorescence lines.

The intensity for the emission of a light quantum $h\nu$ in an electric dipole transition can be written as

$$I(e'v'J' \rightarrow e''v''J'') \propto \mu_e^2 \nu^4 |\langle v'|v''\rangle|^2, \quad (7)$$

where μ_e is the electronic transition moment and $|v'>$ and $|v''>$ are the vibrational wave functions of the initial and final state. Here the electronic transition moment is assumed to be independent of the internuclear distance in the range of vibration, since the vibrational quantum number of the excited level is small. The vibrational wave functions appropriate to any one-dimensional potential are obtained by solving the radial Schrödinger equation,[12] and the Franck-Condon factor $|\langle v'|v''\rangle|^2$ can be calculated.

The potential curve of the $X\,^1\Sigma^+$ state is calculated

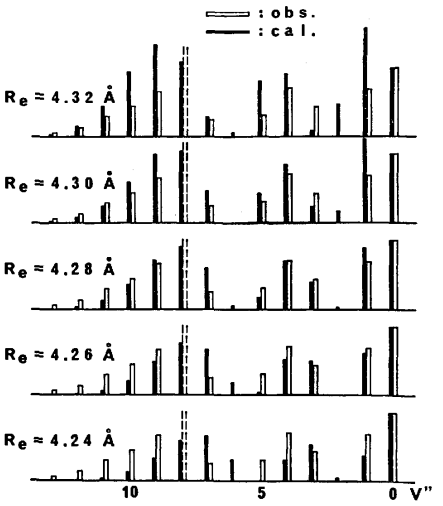

Fig. 4. Comparison of the observed (open bars) and calculated (full bars) intensity distribution $\nu^4|\langle v'|v''\rangle|^2$ of the $D\,^1\Pi(v'=2)\rightarrow X\,^1\Sigma^+(v'')$ transitions for five different values of equilibrium internuclear distance of the $D\,^1\Pi$ state.

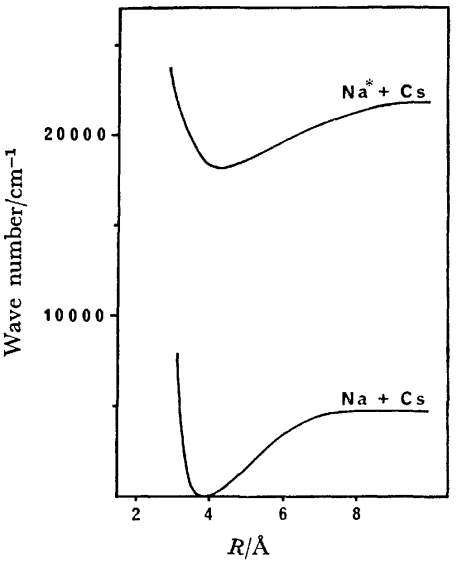

Fig. 5. Potential energy curves for NaCs. The potential curve of the $X\,^1\Sigma^+$ state is calculated by the RKR method. The potential curve of the $D\,^1\Pi$ state is approximated by a Morse function. The spectroscopic constants of these are listed in Table 1.

by the RKR method[13] from the molecular constants listed in Table 1. The potential curve of the $D\,^1\Pi$ state is approximated by a Morse function. The vibrational constant ω_e is assumed to be 65 cm^{-1}. The dissociation limit will be at 16956 cm^{-1} above the dissociation limit of the $X\,^1\Sigma^+$ state, where 16956 cm^{-1} is the energy of the atomic line Na($3\,^2P_{1/2}\rightarrow 3\,^2S_{1/2}$). The energy of the excited vibrational level is known from the assignment. The Morse function is therefore fixed if the equilibrium internuclear distance R_e is determined.

We have calculated the intensity distribution of the fluorescence lines as a function of R_e. The results are schematically shown in Fig. 4. The equilibrium

internuclear distance of the $D\,^1\Pi$ state is determined to be 4.28 ± 0.01 Å. The resulting molecular constants are listed in Table 1, and the potential curves of the $X\,^1\Sigma^+$ and $D\,^1\Pi$ states are schematically shown in Fig. 5.

H. K. thanks the Ministry of Education, Science and Culture for Grant-in-Aid for Scientific Researchs of Nos. 56540278 and No.58490020. The calculations were carried out at the computer center of IMS.

The Selectivity Characteristics of Surfactant Ion-sensitive Nitrobenzene-membrane Electrode

Iwao SATAKE,* Shun-ichi NODA, and Tamaki MAEDA

Department of Chemistry, Faculty of Science, Kagoshima University, Korimoto, Kagoshima 890

(Received February 28, 1983)

The selectivity coefficients of nitrobenzene-membrane electrode containing dodecyltrimethylammonium dodecyl sulfate as an ion exchanger were determined. For a homologous series of surfactant ions, the logarithm of the selectivity coefficient was found to increase linearly with increasing hydrocarbon chain length. The selectivity sequence for anionic surfactant ions with the same alkyl chain length became alkylbenzenesulfonate ion > alkyl sulfate ion ≫ alkanesulfonate ion, while that for cationic ones became alkyltrimethylammonium ion ≈ 1-alkylpyridinium ion ≫ alkylammonium ion. These results can reasonably be interpreted in terms of the partition coefficient of surfactant ion between aqueous and membrane phases. A tentative estimation based on the theory of liquid-membrane electrode led to $-2900\ \mathrm{J\ mol^{-1}}$ for the standard free energy of transfer of a methylene group from water to nitrobenzene.

The utility of the liquid-membrane electrode sensitive to a surfactant ion both in analytical and physicochemical studies of ionic surfactant solutions is now well recognized. However, only a few works[1-4] have been concerned with the determination of the selectivity coefficients of these electrodes for various interferents. It has been found that *o*-dichlorobenzene-membrane electrodes[1-3] with an appropriate ion exchanger are highly selective for a surfactant ion over common inorganic ions but subject to serious interference from surfactant ions with longer alkyl chain length than the measuring ion. For a homologous series of surfactant such as sodium alkyl sulfates[1-3] and sodium alkanoates,[2,3] the selectivity coefficient was found to increase regularly with increasing hydrocarbon chain length. A similar result, though confined to sodium alkyl sulfates, was also obtained for a nitrobenzene-membrane electrode[4] which is an another typical liquid-membrane electrode sensitive to the surfactant ion. So far as we know, however, the selectivity characteristics of nitrobenzene-membrane electrode have yet not been fully elucidated. In this work, we investigated the effects of the nature of ionic head group as well as the alkyl chain length of interfering surfactant ion on the selectivity coefficient of nitrobenzene-membrane electrode which contains dodecyltrimethylammonium dodecyl sulfate as an ion exchanger.

Experimental

Materials. Sodium alkyl sulfates with 8, 10, and 12 carbon atoms were synthesized by esterification of the corresponding long-chain alcohols which had been purified by vacuum distillation. Sodium alkanesulfonates with 9, 11, and 13 carbon atoms (Tokyo Kasei Kogyo Co. Ltd.) were further extracted with petroleum ether for 40 h and recrystallized twice from ethanol. Dodecylammonium chloride was prepared from dodecylamine according to the method of Kolthoff and Stricks.[5] 1-Dodecylpyridinium chloride (Wako Pure Chemical Industry Co. Ltd.) was dissolved in ethanol and refluxed overnight with active carbon. After removal of the active carbon, the precipitate was purified further by repeated recrystallization from acetone. Dodecyltrimethylammonium chloride (DTAC, Tokyo Kasei Kogyo Co. Ltd.) was recrystallized twice from acetone. Sodium dodecylbenzenesulfonate (purity >99%, Wako Pure Chemical Industry Co. Ltd.) and tetraalkylammonium chlorides of guaranteed grade were used without further purifications. An ion exchanger, dodecyltrimethylammonium dodecyl sulfate (DTADS) was prepared by mixing the dilute solutions of DTAC and sodium dodecyl sulfate (SDS). The resulting complex was recrystallized twice from acetone and dissolved in nitrobenzene in a concentration of about $5\times10^{-4}\ \mathrm{mol\ dm^{-3}}$.

Membrane Potential Measurements. Since the nitrobenzene-membrane electrode containing DTADS as an ion exchanger responds both to anionic and cationic surfactant ions, the measurements were made with the following cells which have the experimental setup shown in Fig. 1.

Reference electrode (Ag-AgCl) | 1 mol $\mathrm{dm^{-3}}$ NH_4Cl agar bridge | Reference solution (SDS or DTAC, 5×10^{-4} mol $\mathrm{dm^{-3}}$) | Nitrobenzene (5×10^{-4} mol $\mathrm{dm^{-3}}$ DTADS) | Sample solution (SDS or DTAC, C_1; Interferent, C_J) | 1 mol $\mathrm{dm^{-3}}$ NH_4Cl agar bridge | Reference electrode (Ag-AgCl).

The electromotive force (E) of the cell was measured with an accuracy of ±0.1 mV at 25 °C, by using a digital voltmeter connected to a voltage follower amplifier (input impedance $\approx10^{13}\ \Omega$). The selectivity coefficient was determined by the mixed solution method,[6] *i.e.*, E was followed as a function of the measuring ion concentration, C_1, under the conditions of a constant interferent concentration, C_J.

Results and Discussion

In Fig. 2 is shown the typical semilogarithmic plots of E *vs.* SDS concentration in the presence and

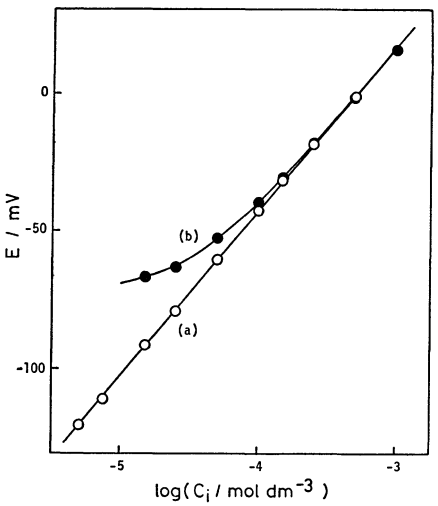

Fig. 2. Plots of the electromotive force (E) of the cell *vs.* the logarithm of SDS concentration (C_i) at 25 °C.
(a); In the absence of interferent, (b); in the presence of 1.5×10^{-4} mol dm^{-3} SDeS.

absence of sodium decyl sulfate(SDeS). In the absence of interfering ion, the electrode responds to the dodecyl sulfate ion down to 5×10^{-6} mol dm^{-3} with a slope of 59.7 mV per decade change in SDS concentration. This is also the case for the cationic surfactant ion sensitive electrode in which SDS is replaced by DTAC. An excellent agreement between the observed slope and an ideal Nernst slope (59.2 mV at 25 °C) suggests that the inorganic counterions such as Na^+ and Cl^- do not interfere appreciably with the electrode response to the surfactant ion. As is shown in Fig. 2 by the curve(b), however, the presence of a surfactant ion other than the dodecyl sulfate ion causes a remarkable interference. Under constant concentration of SDeS, the deviation from Nernstian response becomes progressively greater as SDS concentration decreases. Similar results were also obtained for all the interferents studied.

On the basis of these experimental results, we estimated the selectivity coefficient, K_{ij}, defined by

$$E = E_a + (RT/F)\ln[(C_i+K_{ij}C_j)/C_i^\circ], \quad (1)$$

where the subscript i refers to the measuring ion, *i.e.*, dodecyl sulfate ion or dodecyltrimethylammonium ion, j to the interfering ion, superscript ° to the reference solution, and E_a to the asymmetric potential of overall cell system, respectively; other symbols have their usual meanings. Under our experimental conditions, the activity coefficients can be ignored without loss of accuracy. The calculation was made by applying the graphical curve-fitting method described elsewhere.[7] The selectivity coefficients for various interferents, taken with respect to the dodecyl sulfate ion or the dodecyltrimethylammonium ion, are summarized in Table 1. In conformity with the results obtained both for liquid[1-4] and plastic[7,8] membrane electrodes, the selectivity coefficient for a homologous series of surfactant ions increases quite regularly with increasing alkyl chain length. As is shown in Fig. 3, the semilogarithmic plot of K_{ij} *versus* the number

TABLE 1. THE SELECTIVITY COEFFICIENTS OF NITROBENZENE MEMBRANE ELECTRODE FOR VARIOUS INTERFERENTS AT 25 °C

Measuring ion (i)	Interferent (j)	K_{ij}
Dodecyl sulfate ion	$C_nH_{2n+1}SO_4Na$	
	$n=10$	9.0×10^{-2}
	$n=8$	9.3×10^{-3}
	$C_nH_{2n+1}SO_3Na$	
	$n=13$	6.3×10^{-2}
	$n=12$	(1.8×10^{-2})[a]
	$n=11$	5.3×10^{-3}
	$n=9$	5.9×10^{-4}
	$C_{12}H_{25}C_6H_4SO_3Na$	8.9
Dodecyltrimethyl ammonium ion	$C_{12}H_{25}C_5H_5N^+Cl^-$	9.3×10^{-1}
	$C_{12}H_{25}NH_3^+Cl^-$	2.5×10^{-2}
	$(C_nH_{2n+1})_4N^+Cl^-$	
	$n=1$	2.0×10^{-5}
	$n=2$	2.0×10^{-4}
	$n=3$	1.0×10^{-2}

a) Estimated from Fig. 3.

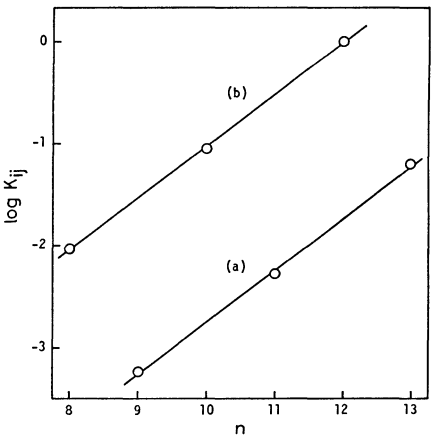

Fig. 3. The semilogarithmic plots of the selectivity coefficients for the homologous series surfactant ions *vs.* the number of carbon atoms in the alkyl chain at 25 °C.
(a); Sodium alkanesulfonate, (b); sodium alkyl sulfate.

of carbon atoms, n, in the alkyl chain gives the straight line with a slope virtually independent of the nature of ionic head group. This fact leads immediately to the selectivity coefficient of 1.8×10^{-2} for sodium dodecanesulfonate. Thus the present electrode gives the selective sequence for anionic surfactant ions with the same alkyl chain length as alkylbenzenesulfonate ion > alkyl sulfate ion ≫ alkanesulfonate ion. In the case of cationic surfactant ions, the selective sequence becomes alkyltrimethylammonium ion ≈ 1-alkylpyridinium ion ≫ alkylammonium ion. The interference of the tetraalkyl ammonium ion with shorter chain length is negligibly small.

According to the theory[9] of liquid-membrane electrode in which the dissolved ion exchanger is completely dissociated, the selectivity coefficient is described in terms of the mobility, u^*, in the membrane phase and the partition coefficient, k, as

$$K_{ij} = u_j^* k_j / u_i^* k_i. \quad (2)$$

It is somewhat doubtful whether DTADS is completely dissociated in such medium as nitrobenzene having comparatively low relative permittivity of 34.8 at 25 °C. However, the use of Eq. 2 still shed light on the fundamental factors which determine the selectivity sequence shown in Table 1. Substituting the thermodynamic expression for the partition coefficient in Eq. 2, we have

$$RT\ln K_{ij} = RT\ln(u_j^*/u_i^*) + (\Delta\mu_i^\oplus - \Delta\mu_j^\oplus), \quad (3)$$

where, $\Delta\mu^\oplus$ denotes the standard free energy of transfer of surfactant ion from aqueous medium to membrane phase. If, therefore, the mobilities of surfactant ions of similar size are comparable to each other in nitrobenzene phase, $\ln K_{ij}$ for a homologous series of the surfactant ions should be linearly dependent on n, since $\Delta\mu_j^\oplus$ is known to be a linear function of n.[10] This is exactly what was found with sodium alkyl sulfates and alkanesulfonates. We can thus expect that the slope of the straight lines in Fig. 3 represents the increment of $\Delta\mu_j^\oplus$ per methylene group, *i.e.*, the free energy change, w, for transfering a methylene group from aqueous medium to organic phase. A tentative estimation based on the result in Fig. 3 leads to -2900 J mol^{-1} for w from water to nitrobenzene at 25 °C. This figure is in good agreement with the value of -3100 J mol^{-1} for w from water to *bis*(2-ethylhexyl) phthalate estimated in a previous study of cationic surfactant ion-sensitive poly(vinyl chloride)-membrane electrode containing a neutral carrier[7]. It is also worth noting that the value of w estimated above is close to the free energy change of about -2700 J mol^{-1} associated with the transfer process of a methylene group from water to the hydrophobic interior of surfactant micelle at 25 °C.[11] Apart from the underlying assumptions, therefore, Eq. 2 seems to explain reasonably the observed selectivity characteristics of nitrobenzene-membrane electrode. It has already been pointed out by several authors[1-4,7,8] that the partition coefficient plays the most important role in determining the selectivity sequence of liquid and plastic membrane electrodes for the homologous series surfactant ions.

An interesting comparison may also be made between the selectivity coefficients for surfactant ions with the same alkyl chain length. If we denote the contribution of the head group to the transfer free energy of the surfactant ion by w^h, Eq. 3 can be rewritten as follows.

$$RT\ln(K_{ij}/K_{ii}) \approx w_i^h - w_j^h \quad (4)$$

In Table 2 are given the values of $w_i^h - w_j^h$ estimated for various combinations of surfactant ions with dodecyl chain at 25 °C. Since dodecanesulfonate and dodecylbenzenesulfonate have the same ionic group, the estimated value for these ions is presumed to be close to the transfer free energy of phenylene group from water to nitrobenzene. Indeed, the numerical value in Table 2 is comparable with the free energy change of -1.9×10^4 J mol^{-1} for transfering benzene molecule from water to pure liquid benzene.[12] This fact not only supports the validity of Eq. 4 but suggests that the marked difference in the selectivity coefficients for dodecylbenzenesulfonate and dodecanesulfonate comes virtually from the difference in their partition coefficients. In view of the fact that the value of $w_i^h - w_j^h$ for dodecyltrimethylammonium ion and 1-dodecylpyridinium ion is negligibly small, the hydrophobicity of trimethylammonium group is considered to be nearly identical with that of pyridinium ring. The lack of the hydrophobic part in the ionic head group will probably be responsible for the pronounced decrease in the selectivity coefficient for dodecylammonium ion. Unfortunately, we are unable to give any reasonable account of the observed value of $w_i^h - w_j^h$ for dodecyl sulfate and dodecanesulfonate, since an information about the free energy change associated with the dehydration process of ionic group in nitrobenzene phase is unavailable at the present stage.

Table 2. The calculated values of $w_i^h - w_j^h$ for various surfactant ions with a dodecyl chain at 25 °C

Surfactant ion i	Surfactant ion j	$(w_i^h - w_j^h)$/J mol^{-1}
$-C_6H_4SO_3^-$	$-SO_3^-$	-1.5×10^4
$-SO_3^-$	$-SO_4^-$	9.9×10^3
$-N^+C_5H_5$	$-N^+(CH_3)_3$	180
$-NH_3^+$	$-N^+(CH_3)_3$	9.1×10^3

Stereochemical Studies of the Electrolytic Reactions of Organic Compounds. Part 18. Comparative Study of Hydrogenation on Metal-black Cathodes and Catalysts

Tsutomu NONAKA,* Masahiko TAKAHASHI, and Toshio FUCHIGAMI
Department of Electronic Chemistry, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama, 227
(Received March 10, 1983)

Stereoselective hydrogenation on metal-black cathodes and catalysts, which were prepared by electrodeposition under the same conditions, was comparatively investigated. Stereoisomeric ratios of alcohols formed from the ketones on the Pd- and Pt-black cathodes seemed to be almost equal to those on the corresponding metal-black catalysts, while the yields were quite different between the cathodic and catalytic hydrogenations. On the other hand, results of the hydrogenation of the acetylenes on the cathodes were also different, in not only the yield but also the isomeric ratio, from those on the catalysts. In addition to stereoselectivity, relative hydrogenation rates between *cis*- and *trans*-olefins were compared in both the cathodic and catalytic hydrogenations. It was also found that a mercury pool cathode gave quite different stereochemical results in the hydrogenation of the unsaturated compounds from those obtained with either the metal-black cathodes or the catalysts.

A variety of studies on stereoselective and stereospecific hydrogenations of unsaturated compounds on metal catalysts has been extensively reported, while such studies using catalytically-active metal cathodes have been more rarely reported. Campbell[1] and Sakuma[2] reported that some acetylenic compounds could be hydrogenated on spongy nickel and Pd-black cathodes, respectively, to give the corresponding *cis*-olefins as major products. Kita *et al.*[3] have recently indicated the ratio of *cis*-2-butene to *trans*-2-butene formed as minor products in the cathodic hydrogenation of 1,3-butadiene on a Pt-black cathode. However, these results were not compared with the hydrogenation on catalysts consisting of the same metal components and/or might be incomplete in isomeric analysis of the products. In this work, the hydrogenation of unsaturated compounds to the corresponding stereoisomeric product mixtures on metal-black cathodes and catalysts was comparatively investigated. In addition to this, results obtained were compared with those of the reductive hydrogenation on a mercury cathode which induces a typical cathodic reaction by direct electron-transfer between the cathode and substrates.

In an earlier work,[4] we supposed that the hydrogenation of nitriles on a Pd-black cathode may resemble that on Pd-black catalysts in view of substituent effect. Moreover, it may be consentient that the cathodic hydrogenation on the active metal cathodes resembles the catalytic hydrogenation in gross natures, since the general course of the cathodic hydrogenation is seemed to be very similar to that of the catalytic hydrogenation, as illustrated in Fig. 1. However, it should be difficult to exclude completely that there may be some differences between the both hydrogenations, because of few comparative studies reported. In this viewpoint, it is interesting to compare the cathodic hydrogenation with the catalytic hydrogenation on the same metal: If the both hydrogenations give the same result, the cathodic hydrogenation may be able to be an excellent method, instead of catalytic one in some cases, without any gaseous hydrogen sources, air-tight reactors and efficient stirring equipments, while it can be used as a characteristic method in a case where the both give otherwise results. In addition, comparative studies of the both hydrogenations may result in some new informations available for a mechanistic discussion on the hydrogenations.

A metal catalyst surface is electrically neutral or slightly positive.[5] On the catalyst surface, hydrogen molecules dissociate and the resulting atomic hydrogen adsorbs. An unsaturated compound molecule contacts with the catalyst surface and its π-electron is donated to the unoccupied d-band of the catalyst to form a π-adsorption state. This is an oxidized state rather than reduced one. An active adsorbing species, which is a π-complex-adsorption or σ-adsorption state, is formed by the back-donation of an electron from the catalyst, and the hydrogenation is completed *via* a partially hydrogenated state resulted by the attack of the adsorbing atomic hydrogen and the consequent fission of a bond between the catalyst and the substrate. In Fig. 1, the general course of the hydrogenation on metal catalysts and also cathodes is illustrated.[5]

In the case of hydrogenation on catalytic cathodes, hydrogen is formed by the discharge of protons on the cathode surface. Since the cathode surface should be more negative than the catalyst surface, some differences between the cathodic and catalytic hydrogenations on the same kind of metal may be found.

In a previous work,[6] it was found that the stereoisomeric ratio cis/trans of 4-*t*-butylcyclohexanol formed in the cathodic and catalytic hydrogenation of 4-*t*-butylcyclohexanone on Pt-black in a strongly acidic solution was greatly affected by the preparative method of Pt-black: The ratio cis/trans varied in the ranges of 0.9—4.3 and 0.9—2.7 in the cathodic and catalytic hydrogenation, respectively.

In this work, similar stereochemical comparison was made under a variety of reaction conditions, extending the substrate compounds to an open-chain ketone and also acetylenic and olefinic compounds. For a successful investigation, following situations should be required: (a) The cathode and the catalyst prepared

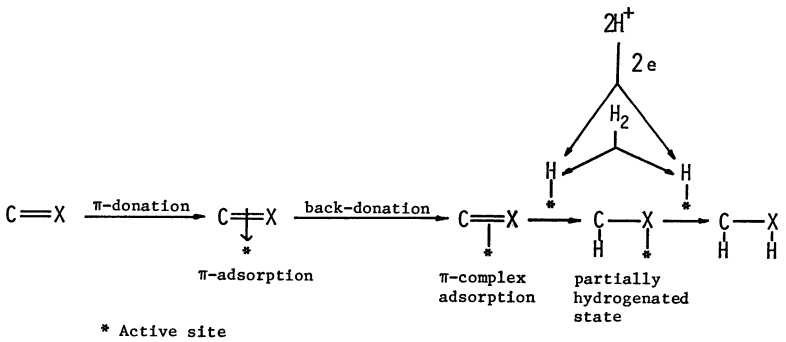

Fig. 1. General course of hydrogenation of unsaturated bond on active metal cathode and catalyst.

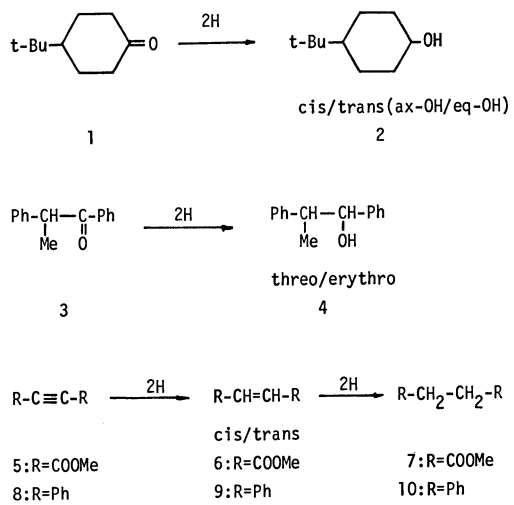

Fig. 2. Hydrogenation of unsaturated compounds.

Table 1. Hydrogenation of 4-*t*-butylcyclohexanone (**1**) on Pt- and Pd-black cathodes and catalysts

from the same kind of metal by the same method can be used. (b) The same type of reaction of the same substrate compound can occur on the cathode and the catalyst prepared thus. (c) The cathodic and catalytic reactions can proceed under the same conditions to give detectable stereochemical results. Items (a) and (b) could be almost completely satisfied, while it seemed to be difficult to give the strictly same reaction conditions(Item (c)) for the cathodic and catalytic hydrogenation because of no catalytic reaction factors corresponding to current density and amount of charge passed in the electrolytic reaction.

Results and Discussion

In this work, the hydrogenation of ketones(*t*-butylcyclohexanone (**1**) and 1,2-diphenyl-1-propanone (**3**)), acetylenes (dimethyl acetylenedicarboxylate (**5**) and diphenylacetylene (**8**)) and olefins (dimethyl maleate (cis-**6**), dimethyl fumarate (*trans*-**6**), *cis*-stilbene (*cis*-**9**), and *trans*-stilbene (*trans*-**9**)) on metal (Pt and/or Pd)-black cathodes and catalysts were comparatively investigated under the same reaction conditions. Results on a mercury cathode were also given for comparison with the above hydrogenation.

Metal-black Cathodes and Catalysts. Generally, hydrogenation is greatly affected by the preparative procedure of catalysts. Therefore, in comparative studies of cathodic and catalytic hydrogenation on metal-blacks, the preparative procedure should be strictly controlled. Pt-black electrodeposited on Pt-plates from a chloroplatinic acid solution containing a small amount of lead(II) acetate was used in this work, because Pt-black prepared thus gave more reproducible results in both the cathodic and catalytic hydrogenations than others.[6] Pd-black was also electrodeposited on Pd-plates from a palladium chloride solution without lead(II) acetate.

One of the metal-black plates prepared at the same time, under the same conditions and by the same procedure was used as a cathode in an electrolytic cell, and another one was placed in a margen-flask for catalytic hydrogenation.

Stereoselective Hydrogenation of Ketones. As shown in Table 1, 4-*t*-butylcyclohexanone (**1**) was hydrogenated on both Pt-black cathode and catalyst in a wide pH range to give 4-*t*-butylcyclohexanol (**2**). Although the isomeric ratio of **2** formed in the cathodic hydrogenation was slightly influenced by current density, the ratio seemed almost equal to that in the catalytic hydrogenation.

On the other hand, **1** could not be hydrogenated on the Pd-black catalyst in both strongly acidic(A-solution) and basic(B-solution) media. In contrast, **1** could be hydrogenated on the Pd-black cathode in the A-solution to give **2** in 30% yield. This result

may suggest that an oxygen-Pd bonding(Fig. 1) on the cathode in a partially hydrogenated state is weakened by its negative polarization and consequently that the hydrogenation can proceed more easily.

The hydrogenation of methylcyclohexanones on the Pd-black cathode in the A-solution hardly proceeded to result in only 1—2% yields. Comparison of this fact with the result obtained in the hydrogenation of **1** suggests that steric hindrance between the cathode surface and the *t*-butyl group weakens the oxygen-Pd bonding in the partially hydrogenated state and promotes the progress of the hydrogenation to the final state.

In the B- and weakly acidic (WA) solutions, the isomeric ratios of **2** formed on the Pt-black cathode were equal to those on the Pt-black catalyst, as described above, but the yields were extremely lower. The cathode should be more negetively polarized in the B- and WA-solutions than the A-solution. Therefore, the lower yields may be due to such a more negative polarization of the Pt-black cathode.

As a conclusion, the yield of **2** is influenced by the polarization of cathode and catalyst, while the isomeric ratio is not. More exactly describing, the negative polarization of the Pt-black suppresses the adsorption of substrate on it and decreases the yield, while on the Pd-black the polarization assists to cleave the oxygen-Pd bonding in the partially hydrogenated state and increases the yield. Such a difference between the Pt- and Pd-blacks may be caused by the stronger adsorption[7] and bonding[8] in the latter.

A mercury-pool cathode, which is a typical high hydrogen overvoltage one, resulted in the isomeric ratio smaller than the thermodynamic equilibrium value(0.25[9]) in the A-solution, while larger in the B-solution. Different stereochemical results between the metal-black and mercury-pool cathodes should be due to different reaction mechanism between the both cathodes.

At the next stage of the investigation, the stereoselective hydrogenation of open-chain ketones was attempted: Among 1,2-diphenyl-1-propanone (**3**), 3-phenyl-2-butanone, and 4-phenyl-2-pentanone, only **3** could be hydrogenated on either the Pd-black cathode or catalyst, and others could not.

As shown in Table 2, **3** could be hydrogenated on Pt- and Pd-black cathodes and catalysts to give 1,2-diphenyl-1-propanol (**4**) in good yields. The isomeric ratio threo/erythro of **4** formed in the cathodic hydrogenation seemed almost equal to that in the catalytic hydrogenation, except for the result obtained on the Pd-black in the WA-solution. It seems difficult to rationalize this exceptional result. An Hg-cathode gave some different isomeric ratios from those on the metal-black cathodes.

Table 2. Hydrogenation of 1,2-diphenyl-1-propanone (**3**) on Pt- and Pd-black cathodes and catalysts

a) Strongly acidic. b) Weakly acidic. c) Strongly basic. d) Electrolyzed at 2.0 A dm^{-2} (at 0.5 A dm^{-2} unless stated otherwise).

Stereoselective Hydrogenation of Acetylenes. Dimethyl acetylenedicarboxylate (**5**) was hydrogenated on the Pd-black cathode and catalyst to give the corresponding olefin(dimethyl maleate; *cis*-**6** and fumarate; *trans*-**6**), as shown in Table 3. In this hydrogenation, a part of **6** formed seemed to be hydrogeanated further to dimethyl succinate (**7**). Therefore, in order to discuss strictly stereochemical results obtained, some correction should be made for the estimation of isomeric ratio cis/trans of **6**. For the correction, the relative hydrogenation rate ratio k_c/k_t of *cis*-**6** to *trans*-**6** was used. The detailed description of k_c/k_t is given in the following item.

Both the uncorrected and corrected isomeric ratios of **6** obtained in the cathodic hydrogenation were smaller than those in the catalytic hydrogenation in

Table 3. Hydrogenation of dimethyl acetylenedicarboxylate (**5**) on Pd-black cathode[a] and catalyst

	B[e]	0.96	1.11
Stilbene (**9**)	A[c]	0.84	0.28
	WA[d]	0.84	0.82
	B[e]	0.99	1.39

a) Electrolyzed at 0.5 A dm^{-2}. b) Equimolar mixtures of *cis*- and *trans*-olefins were incompletely hydrogenated and the ratio k_c/k_t was calculated from amounts of unreacted olefins. c) Strongly acidic. d) Weakly acidic. e) Strongly basic.

the same solution. The cathodic hydrogenation of diphenylacetylene (**8**) on the Pd-black also gave smaller cis/trans ratios of stilbene (**9**) than the catalytic hydrogenation, as shown in Table 4.

Generally, disubstituted acetylenes are hydrogenated on metal catalysts to give the *cis*-olefins, which are thermodynamically less stable than the corresponding *trans*-olefins, in excess.[10] As illustrated in Fig. 3, an acetylene molecule adsorbs in the *cis*-olefin form(sp^2) on the catalyst[11] and hydrogenated *via* the partially hydrogenated state.[12] If the adsorption is loosed by steric hindrance between the adsorbing species and the catalyst, so-called the catalyst hindrance, the formation of the *cis*-olefin is suppressed in some extent.[13] The stronger adsorption reasonably causes the higher catalyst hindrance. Therefore, the more negative polarization of the Pd-black also causes the weaker adsorption and the lower hindrance, and cosequently the supression of the *cis*-olefin formation. This is a rationalization for the smaller cis/trans ratio in the cathodic hydrogenation than the catalytic hydrogenation.

The cis/trans ratio decreased in the B-solution in both the cathodic and catalytic hydrogenations. This may be rationalized as due to weak adsorption in basic solution[14,15] or the isomerization of olefin formed,[16] though the hydrogenation was not carried out under so drastic that the isomerization occurs easily.

It is noticeable that the hydrogenation of **8** on the Pt-black resulted in a reversed situation, comparing with that on the Pd-black, though any corrected isomeric ratios of **9** could not be given. It may be also interesting to note that the Hg-pool cathode afforded the completely reversed isomeric ratios of **9** to the metal-blacks.

Hydrogenation Rate Ratio of cis-*Olefins to the* trans-*Olefins.* Mixtures of *cis*- and *trans*-olefins (**6** and **9**) were hydrogenated with insufficient amounts of electricity and hydrogen on the Pd-black cathode and catalyst, respectively. The hydrogenation rate ratio (k_c/k_t) of the *cis*-olefin to the *trans*-olefin was calculated from amounts of the unreacted olefin isomers, considering their average concentrations during the hydrogenation:

$$k_c/k_t = \frac{(c_1-c_2)}{(t_1-t_2)} \cdot \frac{(t_1+t_2)/2}{(c_1+c_2)/2} = \frac{(c_1-c_2)(t_1+t_2)}{(t_1-t_2)(c_1+c_2)},$$

where c_1 and c_2 are the initial and final concentrations of the *cis*-olefin, and t_1 and t_2 are those of the *trans*-olefin. Table 5 shows k_c/k_t values obtained in the hydrogenation of the equimolar mixtures of the isomers ($c_1=t_1$).

Results for each olefin are apparently clear and interesting, as shown in Table 5. However, it seems difficult to rationalize comprehensively these kinetic data, because (a) the hydrogenation course involves several activation steps,[17] and (b) the rate-determining step can not be specified.[18]

Experimental

Materials. *Ketones*: Cyclic ketones (**1** and three methylcyclohexanones) were commercially supplied from Tokyo Kasei Co., while open-chain ketones (**3**, 3-phenyl-2-butanone and 4-phenyl-2-pentanone) were prepared by methods of our earlier works.[19,20]

Acetylenes and Olefins: All the compounds (**5**, **6**, **8**, and **9**) were commercially supplied.

Standard Samples of Products: The compounds **2**, **6**, **7**, and **10** were commercially supplied, while *threo*- and *erythro*-**4** were prepared by the method of earlier work.[19]

Metal-blacks: Pt-black was electrodeposited on a Pt plate (Area, 7.7 cm^2) from 33 ml of an aqueous solution containing chloroplatinic acid (1.0 g as $H_2[PtCl_6]\cdot 6H_2O$) and lead(II) acetate (7 mg) by passing electricity at 2 $A\cdot dm^{-2}$ of current density for 10 min. Pd-black was also deposited on a Pd plate (area, 7.7 cm^2) from 33 ml of 1 M (1 M= 1 mol dm^{-3}) HCl containing palladium chloride (0.2 g) by the same procedure as the above. The Pt- and Pd-blacks prepared thus were repeatedly washed with cold water, and then cathodically treated at 2 A dm^{-2} in 1 M H_2SO_4 for 30 min and sulfuric acid was rinsed out with warm water.

Usually, two pieces of the metal-blacks were prepared for the cathodic and catalytic hydrogenations at same time.

Reaction Solutions: Three kinds of solutions were used: A-solution, 1 M H_2SO_4-CH_3OH (1:1, v/v); WA-solution, 3 M AcONa-3 M AcOH-CH_3OH (1:1:2, v/v); B-solution, 2 M NaOH-CH_3OH (1:1, v/v). 100 ml of the solution containing the substrate in 10—50 mM was used for each experiment.

Hydrogenation. *Cathodic Hydrogenation*: 2 F/mol was passed for each electrolysis at 0.5 A dm^{-2} and room temperature, except for the case of **3** where 20 F/mol was passed.

Catalytic Hydrogenation: The hydrogenation was carried out in a margen-flask, in which the metal-black plate was placed, at atmospheric pressure and room temperature. The concentration of substrate was same as that in the corresponding cathodic hydrogenation. The margen-flask was continuously shaken till 1 mol H_2/1 mol substrate was taken up.

Product Analysis. After the hydrogenation, the reaction solution was neutralized with aqueous sulfuric acid or sodium hydroxide and then extracted repeatedly with ether. The combined ethereal extract was dried over anhydrous sodium sulfate. The solution concentrated by evaporation was subjected to gas-chromatographic analysis under following conditions: A 2.25 m PEG 20 M column at 90 °C for **1**, **2**, and **5**—**7**; a 4 m PEG 20 M column at 200 °C for **8**—**10**; a 4 m Apiezon Grease L column at 200 °C for **3** and **4**.

In the hydrogenation of **1** and **3**, the corresponding alkanes and hydrodimers were also formed as by-products, but these were not analyzed quatitatively.

The authors wish to thank professor Taro Sekine for his helpful suggestions and discussions. This work was partly supported by a Grant-in-Aid for Scientific Research No. 0055320 from the Ministry of Education, Science and Culture.

Synergistic Solvent Extraction of Crown Ether Complexes with Alkali Metal Picrates by Neutral Donor Solvents

Yasuyuki TAKEDA

Department of Chemistry, Faculty of Science, Chiba University, Yayoi-chō, Chiba 260

(Received March 25, 1983)

The solvent extraction of rubidium and caesium picrates has been studied at 25 °C with mixtures of crown ether and tributyl phosphate (TBP) or trioctylphosphine oxide (TOPO) in benzene, and the adduct-formation constants in the benzene solution have been calculated. The crown ethers used in this work were 12-crown-4 (12C4), 15-crown-5 (15C5), and benzo-15-crown-5 (B15C5). The stoichiometric composition of any extracted complex under the present experimental conditions is alkali metal ion : crown ether : TBP or TOPO : picrate ion = 1 : 1 : 1 : 1. The TOPO complex is more extractable than the corresponding TBP complex. The extractability of the Rb^+ complex is larger than that of the corresponding Cs^+ complex. For both TBP and TOPO, the adduct-formation constant value sequences of Rb^+ and Cs^+ are B15C5 > 12C4 > 15C5 and 12C4 > B15C5 > 15C5, respectively.

Extractions of crown ether complexes with metal picrates are enhanced by the addition of a neutral donor solvent such as tributyl phosphate (TBP) and trioctylphosphine oxide (TOPO).[1-3] This enhancement is attributed to the fact that the crown ether complexes with the metal picrates form adducts with the neutral donor solvents. The crown ether complex (metal ion : crown ether : picrate ion = 1 : 1 : 1) accepts one or two neutral donor solvents. The magnitude of the adduct-formation constant in the organic phase reflects the chemical nature of the metal ion trapped in the crown ether cavity.

At present, only a few quantitative data have been reported on the synergistic solvent extraction study for crown ethers.

In the present study, the solvent extraction of rubidium and caesium picrates has been investigated at 25 °C with mixtures of crown ether and TBP or TOPO in benzene. The compositions of the extracted complexes have been determined and the adduct-formation constants in a benzene solution have been calculated. The crown ethers used in this work were 12-crown-4 (12C4), 15-crown-5 (15C5), and benzo-15-crown-5 (B15C5). Since it is known that TOPO forms more stable adducts than TBP, TOPO was chosen in the hope that the higher extractabilities for alkali metal ions compared with TBP could be obtained.

Experimental

Materials. 12-Crown-4 and TBP were obtained from Wako-Pure Chemicals, Ltd., 15C5 from Nisso Co., Ltd., and TOPO from Dojin-Do Co., Ltd. They were used without further purification. The method of the purification of B15C5 (Merck Japan Ltd.) was described elsewhere.[1] Analytical-grade benzene was washed three times with distilled water.

Procedure. An aqueous phase contained alkali metal hydroxide ($(2.0—6.5)\times10^{-3}$ M; 1 M = 1 mol dm^{-3}) and picric acid ($(1.0—8.9)\times10^{-3}$ M). A benzene phase contained one of the extractants (TBP: 9.0×10^{-2}—6.5×10^{-1} M, TOPO: 2.4×10^{-2}—1.8×10^{-1} M, crown ether: 1.4×10^{-3}—1.3×10^{-1} M), or both TBP (8.8×10^{-2}—6.6×10^{-1} M) or TOPO (2.4×10^{-2}—1.8×10^{-1} M) and crown ether (1.4×10^{-3}—1.3×10^{-1} M). The two phases in stoppered glass tubes (30 ml) were shaken in a thermostated water bath for 45 min at 25±0.2 °C and then centrifuged. The initial valume of each phase was 10 ml in all cases. The extractions were carried out at pH 5.8—6.2. The alkali metal in the benzene phase was back-extracted into 8 ml of a 0.1 M HNO_3 aqueous solution, and the alkali metal concentration was determined by atomic absorption spectrometry.

Results

The equilibrium constants for this solvent extraction system can be defined by the following equations:

$$K\mathrm{ex(MLL'A)} = [\mathrm{MLL'A}]_o[\mathrm{H^+}]/[\mathrm{M^+}][\mathrm{L}]_o[\mathrm{L'}]_o[\mathrm{HA}]_o, \quad (1)$$

$$K_{\mathrm{D,L}} = [\mathrm{L}]_o/[\mathrm{L}], \quad (2)$$

$$K\mathrm{ex(HA)} = [\mathrm{HA}]_o/[\mathrm{H^+}][\mathrm{A^-}], \quad (3)$$

$$K_{\mathrm{MLL'A,o}} = [\mathrm{MLL'A}]_o/[\mathrm{MLA}]_o[\mathrm{L'}]_o, \quad (4)$$

where the subscript "o" and the lack of a subscript denote the organic and the aqueous phase, respectively; M^+, A^-, L, and L′ refer to an alkali metal ion, a picrate ion, crown ether, and another neutral ligand, respectively. The all activity coefficients of the chemical species in this study have been assumed as unity. The Kex(HA) value was spectrophotometrically determined to be 247.

When the benzene phase contains both L and L′, the distribution ratio is represented by

$$D = [\mathrm{MLL'A}]_o/[\mathrm{M^+}]. \quad (5)$$

The substitution of Eqs. 1 and 3 into Eq. 5 gives

$$D = K\mathrm{ex(MLL'A)}K\mathrm{ex(HA)}[\mathrm{L}]_o[\mathrm{L'}]_o[\mathrm{A^-}]. \quad (6)$$

The log $(D/[A^-])$ *vs.* log $[L]_o$ plots for the 15C5-TOPO system are given in Fig. 1. The log$(D/[A^-])$ *vs.* log$[L']_o$ plots for the 15C5-TOPO system are illustrated in Fig. 2. The plots of the other systems (12C4-TBP, 12C4-TOPO, and B15C5-TOPO) were similar, and so have been omitted. For each system, the plots of both Rb and Cs have a slope of 1 (*e.g.*, Figs. 1 and 2). Thus, the Kex(MLL′A) in this study can be described by Eq. 1. The value of $[L']_o$ in Eq. 6 was presumed to be nearly equal to that of $[L']_t$, and those of $[L]_o$ and $[A^-]$ were calculated from Eqs. 7 and 8 respectively:

$$[\mathrm{L}]_o = ([\mathrm{L}]_t - [\mathrm{MLL'A}]_o)/(1 + K_{\mathrm{D,L}}{}^{-1}), \quad (7)$$

$$[\mathrm{A^-}] = [\mathrm{HA}]_t - [\mathrm{MLL'A}]_o, \quad (8)$$

where the subscript "t" denotes the total concentration. The equilibrium constants obtained from these data

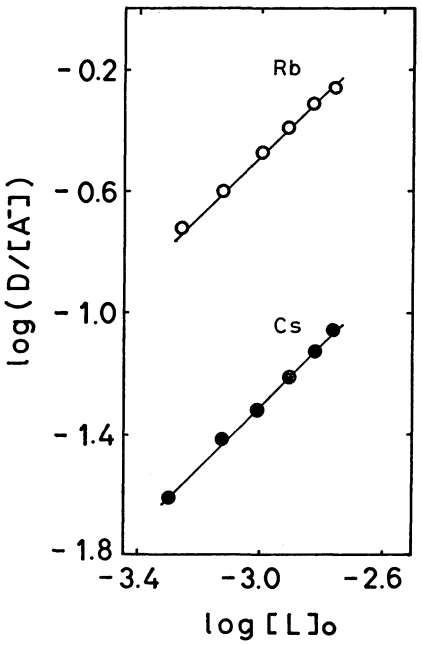

Fig. 1. Plots of log (D/[A$^-$]) *vs.* log [L]$_o$ for the 15C5-TOPO system (L=15C5).

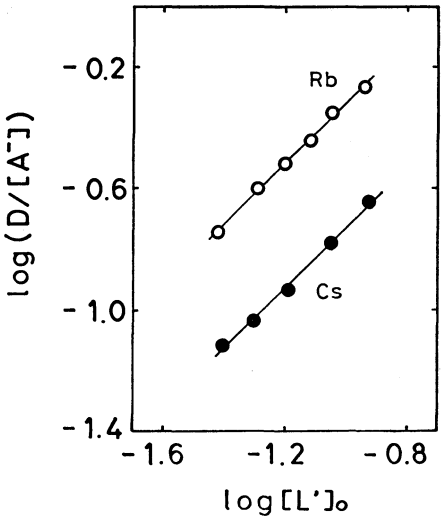

Fig. 2. Plots of log (D/[A$^-$]) *vs.* log [L']$_o$ for the 15C5-TOPO system (L'=TOPO).

are listed in Table 1.

Discussion

In the case of the same crown ether, the extractability of the same alkali metal ion increases in the order TBP<TOPO<crown ether except Cs(12C4)$_2$A (Table 1). For the same L and L' system, Rb$^+$ is more extractable than Cs$^+$, and extraction-selectivity for Rb$^+$ compared to Cs$^+$ is enhanced in the order TBP< TOPO<crown ether (Table 1).

$K_{MLL'A,o}$ represents the formation constant for the MLL'A complex in a benzene solution. For each of Rb$^+$ and Cs$^+$, the log $K_{MLL'A,o}$ value of the same crown ether increases in the order TBP<TOPO< crown ether except for the case of Cs(12C4)$_2$A. The reason why the TOPO complex is more stable than the TBP complex may be attributed to the higher basicity of TOPO compared with that of TBP. It is interesting that, although the number of donor oxygen atoms is much larger for 12C4 than for TOPO, the Cs(12C4)$_2$A complex is slightly less stable than the Cs(12C4)(TOPO)A complex. The fact that the other sandwich complexes with two crown ethers are more stable than the corresponding TOPO complexes may reflect the larger number of donor oxygen atoms of the crown ether compared to that of TOPO.

For both TBP and TOPO, the log $K_{MLL'A,o}$ value sequences of Rb$^+$ and Cs$^+$ are B15C5>12C4>15C5 and 12C4>B15C5>15C5, respectively. It thus appears that the electron density in the crown ether cavity is one of the most important factors in determining the stabilities of the TBP- and TOPO-adducts.[1] In each case of the ML(TOPO)A and ML(TBP)A complexes, the stability for Rb$^+$ is larger than that for Cs$^+$. This is probably due to the higher charge density of Rb$^+$ compared to Cs$^+$.

The MLA complex in the series of our synergistic solvent extraction studies[1,2] accepts a TBP or a TOPO molecule in a benzene solution, while, a dibenzo-18-crown-6 complex with silver picrate accepts two TOPO molecules in a $CHCl_3$ solution.[3]

Phosphorescence Spectra of *p*-Dichlorobenzene in Various Matrices at 1.4 K

Minoru KINOSHITA,* Narito GOTO,† and Noriko IWASAKI

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received April 1, 1983)

The phosphorescence spectra of *p*-dichlorobenzene have been obtained at 1.4 K in various hosts; benzene, *p*-xylene, *p*-dichlorobenzene, *p*-dichlorobenzene-d_4, and *p*-dibromobenzene. The long progressions in the b_{2g}, C–Cl bending vibration are indicative of a molecular distortion in the out-of-plane direction. With the aid of the technique of optical detection of zero-field magnetic resonance, the intense 1580 cm^{-1} band previously ascribed to the a_g, ν_{8a} vibration is found to be due to the b_{3g}, ν_{8b} vibration. The appearance of the b_{3g} band with strong intensity suggests a possibility of an additional in-plane distortion of phosphorescent *p*-dichlorobenzene.

The electronic structure and the molecular geometry of phosphorescent *p*-dichlorobenzene (DCB) have been the subjects of extensive studies in these years. It was first proposed from polarized T←S absorption spectra that the orbital symmetry of the lowest triplet state of DCB is B_{2u}.[1] However, optically detected magnetic resonance (ODMR) experiments[2–6] performed afterwards have shown that the symmetry is most probably described by B_{1u}.

The phosphorescence spectra of the exciton[7,8] and the traps[3,8] in a neat DCB crystal exhibit long progressions in the b_{2g}, C–Cl bending vibration. This suggests that the DCB molecule is distorted in the phosphorescent state. The out-of-plane position of the two chlorine atoms has been proposed by Buckley and Harris[2] from the observation of somewhat large (≈8%) reductions in the ^{35}Cl quadrupolar coupling constant from −69.662 MHz in the ground state to −64.5 MHz in the triplet state. Furthermore, recent ODENDOR experiments[6] also indicate that the C–H fragments are not positioned in the moleculalr plane.

The phosphorescence spectrum of the 23 cm^{-1} trap-(x-trap) in a neat DCB crystal shows a strong vibrational band at 1579 cm^{-1} from the electronic origin.[3,8] This band corresponds to the extremely strong band due to the e_{2g}, ν_8 skeletal vibration in the phosphorescence spectrum of benzene. In benzene, it has been shown that the appearance of this band with remarkable intensity is due to a strong vibronic coupling or the pseudo Jahn-Teller interaction between the lowest $^3B_{1u}$ state and the second lowest $^3E_{1u}$ state.[9–11] This interaction causes potential curve distortions along the coordinate of the ν_8 mode in the interacting electronic states and a deviation of the triplet electron distribution from the hexagonal symmetry.

It is quite natural to expect that the strong 1579 cm^{-1} band in the DCB phosphorescence also results from a similar cause. In DCB, the ν_8 vibration splits into the a_g, ν_{8a} and the b_{3g}, ν_{8b} vibration. In most works, however, the band at approximately 1580 cm^{-1} was assigned as being due to the a_g vibration,[7,8] but Buckley *et al.*[3] ascribed it to a superposition of the a_g and the b_{3g} vibration. The PMDR(phosphorescence microwave double resonance) spectra by these authors clearly indicate a marked difference in the behaviour of this band and that of other a_g bands; this suggests a b_{3g} possibility. However, the relative radiative decay rates of the T_y and T_z spin sublevels are found to be $k_y^r/k_z^r=1.4$ in this band, which is unfavorable for the b_{3g} assignment.

The main purpose of this paper is to demonstrate that the band is superposed by the a_g and b_{3g} vibrations with vibrational frequencies slightly different from each other and that the b_{3g} band appears more strongly in most cases. The latter relates to a possibility of an in-plane distortion in the triplet spin distribution in addition to the out-of-plane distortion of the molecule proposed.[2]

Experimental

p-Dichlorobenzene was purchased from Wako Pure Chemical Industries, Ltd. and purified by recrystallizations from ethanol and then by zone-refining (more than 150 passes). *p*-Dichlorobenzene-d_4 was purchased from Merck, Sharp & Dohme, Canada Ltd. and purified by zone-refining (more than 150 passes). Commercially available zone-refined *p*-dibromobenzene was used without further purification. Crystals were grown by the Bridgman method. Benzene and *p*-xylene were used after purification by vacuum distillation.

The samples were excited with light of 313 nm from a super-high pressure mercury arc lamp (Orc CH-612, 1 kW) through a saturated $NiSO_4$ aqueous solution filter and a Toshiba UV-D33S filter. The phosphorescence emission from a sample was isolated by a Spex 1700-III 3/4 m spectrometer in conjunction with a pair of rotating disk choppers and detected by an EMI-9789SB photomultiplier tube and a PAR-128A lock-in amplifier.

ODMR experiments were carried out at 1.4 K with an HP-8620A sweep oscillator equipped with appropriate plug-ins and a Weinschell model 221 sweep oscillator with an H-408 plug-in. Details of the ODMR experiments were described in previous papers.[12,13]

Phosphorescence Spectra

The phosphorescence spectra of DCB in various hosts were detected at 1.4 K. The spectra obtained in *p*-dibromobenzene (DBB) and in DCB-d_4 are shown in Fig. 1. It is to be noted that the position of the 0,0 band in the spectrum of DCB in DCB-d_4 coincides with that of the exciton phosphorescence origin[7] and the T←S absorption origin[1] of crystalline DCB. The phosphorescence spectra of DCB in *p*-xylene and 23 cm^{-1} trap in the neat crystal are found to be essentially

† Present address: Konishiroku Photo Industry Co., Ltd., Sakura-cho, Hino, Tokyo 191.

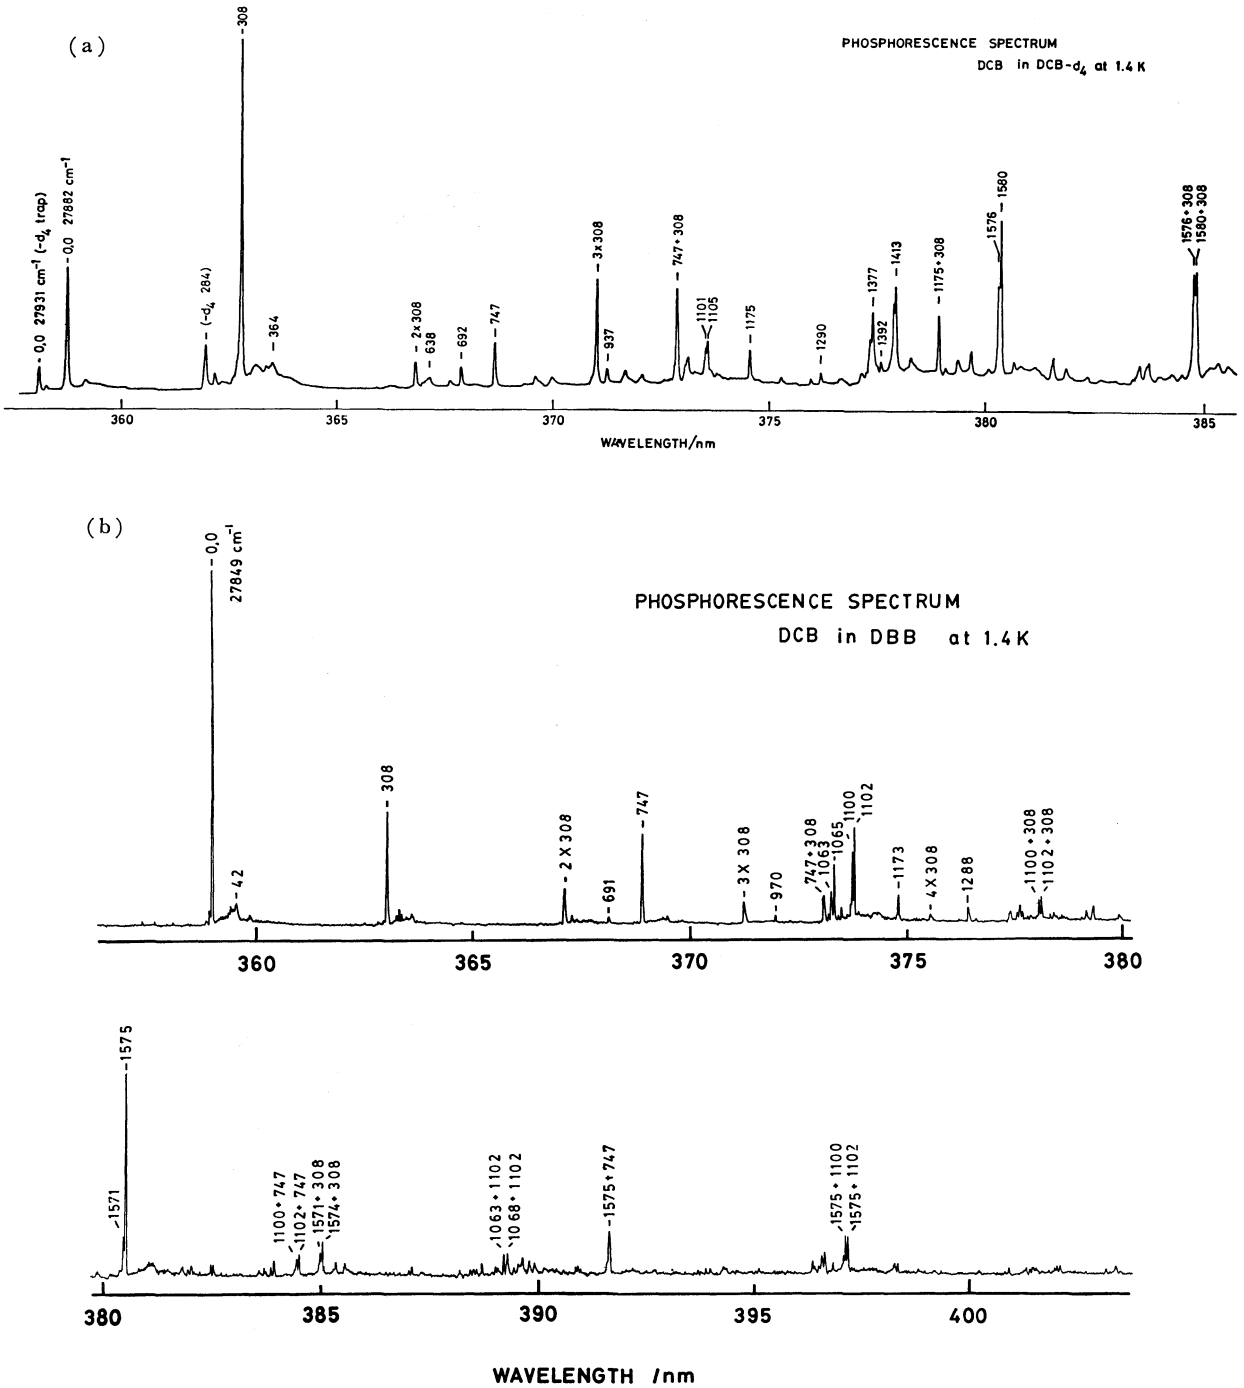

Fig. 1. The phosphorescence spectra of *p*-dichlorobenzene in (a) *p*-dichlorobenzene-d_4 and in (b) *p*-dibromobenzene at 1.4 K.

the same as those reported previously.[3,4,8] The spectrum in benzene shows a multi-site emission consisting of broad vibrational bands.

The band at about 310 cm^{-1} from the electronic origin has been assigned as being due to the progression-forming b_{2g}, C–Cl out-of-plane bending vibration. The progression can be followed through the fifth member in all the spectra obtained but in benzene. The spectra shown in Fig. 1 display a marked contrast in the intensity of the fundamental band of this mode. The band at 0—308 cm^{-1} is the strongest band in the spectrum of DCB in DCB-d_4. A similar feature is observed in the spectra of DCB in *p*-xylene and in benzene. In the spectrum of DCB in DBB, on the other hand, the corresponding band is weaker than the 0,0 band. The spectrum of the x-trap in the neat crystal also exhibits a similar trend.

Zero-field Splitting and Decay Rates

The zero-field splitting and the molecular symmetry axes are shown in Fig. 2. The zero-field splittings and the decay rates of the individual spin states of

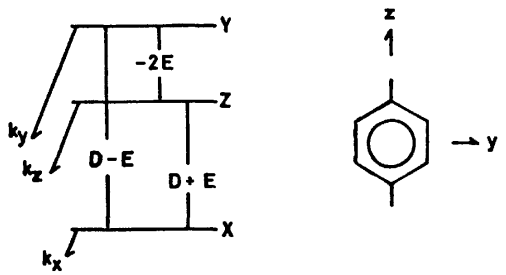

Fig. 2. The definition of the molecular symmetry axes and the zero-field splitting of *p*-dichlorobenzene.

Table 1. The positions of phosphorescence origin bands, zero-field splittings and phosphorescence decay rates of the individual spin sublevels of *p*-dichlorobenzene in various matrices at 1.4 K

	p-Xylene	Benzene (site II)	DBB	Neat cryst.	DCB-d_4
$\nu_{0,0}$/cm^{-1}	27415	27786	27849	27859	27882
D/GHz	4.324	4.421	4.472	4.483	4.505
$-2E$/GHz	1.369	(1.634)	(1.778)	1.758	1.849
k_y/s^{-1}	73.5	56.5	71.4	73.6	55.6
k_z/s^{-1}	7.0	21.7	57.1	35.6	18.8
k_x/s^{-1}	0.65	1.6	11.9	2.1	1.1

DCB in these matrices are determined by the MIDP (microwave-induced delayed phosphorescence) method. The results are listed in Table 1. The sublevel ordering has been determined to be $T_y > T_z > T_x$ in the *p*-xylene and neat crystal systems.[3,4] The same ordering is deduced for the other systems from the similarity in the splitting and from the relation of $k_y > k_z > k_x$. This relation has been commonly observed in various mono- and 1,4-dihalobenzenes.[4,13]

The zero-field splitting parameters, D and E, vary slightly depending on the matrix used. It may be pertinent to point out that the variation of the zero-field splitting parameters exhibits a good correlation with the shift of the phosphorescence origin band as shown in Table 1, although a slight discrepancy is seen between the neat crystal system and the DBB host system. A similar correlation has also been observed in the case of pyrazine.[14]

The values of k_z and k_x are small in the *p*-xylene system, but become large in the other systems, even in benzene. The increase in k_z and k_x in the DCB and DBB crystalline systems are related to the external heavy atom effect. However, the k_z and k_x values for the trap in the neat crystal seem to have an influence from other sources in addition to the external heavy atom effect, because these values are about twice those for DCB in DCB-d_4. As a possible cause for this, we presently consider a distortion or a rotation of the trap molecules from the results of T←S excitation experiments.[15] The values for DCB in benzene seem to be affected by spin-lattice relaxation.

Table 2. Relative radiative decay rate constants of *p*-dichlorobenzene at 1.4 K

System	Band	Symmetry	k_y^r	k_z^r	k_x^r
In *p*-xylene	0, 0		1	0.008	0.008

Relative Radiative Decay Rates

The relative radiative decay rate constants of the three spin sublevels of DCB in the hosts used are determined at 1.4 K in some of the main vibrational bands. The results are summarized in Table 2. The values for the 0,0 and b_{2g} bands in the spectrum of DCB in *p*-xylene are essentially in agreement with the results reported previously.[4] The assignments of the bands appearing at approximately 0—1580 cm^{-1} will be discussed in detail below.

If the electron distribution in DCB is retained in the D_{2h} symmetry in the triplet state, the transition from the T_z sublevel in the 0,0 band and the transitions from the T_x sublevel in the b_{2g} bands are strictly forbidden as shown in Table 3. The fact that these bands originate from all the spin sublevels suggests that the electron distribution is deformed from

Table 3. Polarizations of radiative transitions from the triplet state sublevels in four bands of the phosphorescence spectrum of *p*-dichlorobenzene as expected from group theoretical considerations

Orbital symmetry	Magnetc sublevel	Spin-orbit symmetry	Vibrationl band polarization

D_{2h} to C_{2h} or a lower symmetry by small perturbations. In particular, the b_{2g} progression alternates in intensity with the members of odd quanta being the strongest. Therefore, a distortion along the out-of-plane direction is most probable. Possible perturbations for this have already been discussed by Buckley *et al.*[3]

Sublevel Spectra and Vibrational Analysis

The phosphorescence spectrum of DCB in *p*-xylene is resolved into two sublevel spectra as shown in Fig. 3. The T_y spectrum recorded by phase-sensitively detecting the MIDP signals produced 100 ms after the excitation cutoff by irradiating the microwaves resonant with the $T_y \leftrightarrow T_z$ transition. The T_z+T_x spectrum was taken by sampling the tail portions(100—150 ms) of the phosphorescence decay. As the contribution from the T_x emission is small, the T_z+T_x spectrum can be regarded as consisting mainly of the emission from T_z.

The 0,0 band and the band at 0—303 cm^{-1} appear very strongly in the T_y spectrum, but weakly in the T_z+T_x spectrum. Therefore, the bands appearing strongly in the T_y spectrum and weakly in the other can be ascribed to a_g or b_{2g} vibrations. Referring to the results of the Raman studies[16] and the previous phosphorescence works,[3,4,7,8] we assigned the bands

at 0—751, 0—1112, 0—1171, and 0—1577 cm^{-1} as being due to the a_g fundamentals and the bands at 0—303 and 0—694 cm^{-1} as being due to the b_{2g} fundamentals. The assignment of the 1577 cm^{-1} band will be described in the following section. One of the bands at 0—938 and 0—965 cm^{-1} may also be ascribed to b_{2g}. Although the latter is consistent with the Raman results, we tentatively assign the former to the band due to the b_{2g} vibration, because the former band appears relatively strongly in all the spectra studied. In addition to the bands assigned above, there are many overtone and combination bands of a_g and b_{2g} symmetries. Of these, the band at 0—1078 cm^{-1} ($2\times b_{1u}$) is in Fermi resonance with the 1112 cm^{-1} a_g vibration.

The bands at 0—821, 0—1297, and 0—1573 cm^{-1} differ in behavior in the sublevel spectra from the bands due to a_g and b_{2g} vibrations. These bands appear relatively strongly in the T_z+T_x spectrum. The band at 0—637 cm^{-1} is also stronger than the 0,0 band in the T_z+T_x spectrum, but is much weaker than the 0,0 band in the T_y spectrum. Therefore, these bands may be attributed to either b_{1g} or b_{3g} vibration.

The MIDP sublevel spectra for the x-trap were also obtained in a similar manner. The MIDP signals due to the $T_y\leftrightarrow T_x$ and $T_z\leftrightarrow T_x$ transitions were sampled in this case to obtain the T_y and T_z spectra. The spectra showed essentially the same feature as the am-PMDR subspectra obtained by Buckley *et al.*[3] The results of the vibrational analysis are given in Table 4 for the fundamentals identified. The results for the x-trap and DCB in *p*-xylene are used for the analyses of the other systems.

The 1580 cm^{-1} Vibrations

In this work, a particular attention is paid to the assignment of the band appearing at approximately 0—1580 cm^{-1} in all the systems studied. In Fig. 4(a), the 1573 cm^{-1} band in the spectrum of DCB in *p*-xylene is shown under magnification. The band seems to have a shoulder at 0—1577 cm^{-1}. The same band recorded under different conditions are shown in Figs. 4(b) and 4(c). The band in Fig. 4(b) was taken by sampling the emission between 100 and 150 ms after the excitation cutoff. The intensity of the shoulder band is diminished. As the population in T_y has been almost completely exhausted before the sampling time, the shoulder band is regarded as the band originating mainly from T_y. The band shown in Fig. 4(c) was recorded in the same sampling time but with the microwave pulses which initiate the $T_y\leftrightarrow T_z$ transition 100 ms after the excitation cutoff. The peak decreases in intensity, but the shoulder increases. This can be seen clearly in Figs. 4(d) and 4(e), where the MIDP signals produced by the microwave pulses($T_y\leftrightarrow T_z$) at about 190 ms for the peak and for the shoulder position are shown, respectively. The changes in intensity result from the population transfer from T_z to T_y. Thus the peak emission has its origin in the T_z sublevel, whereas the shoulder emission in the T_y sublevel.

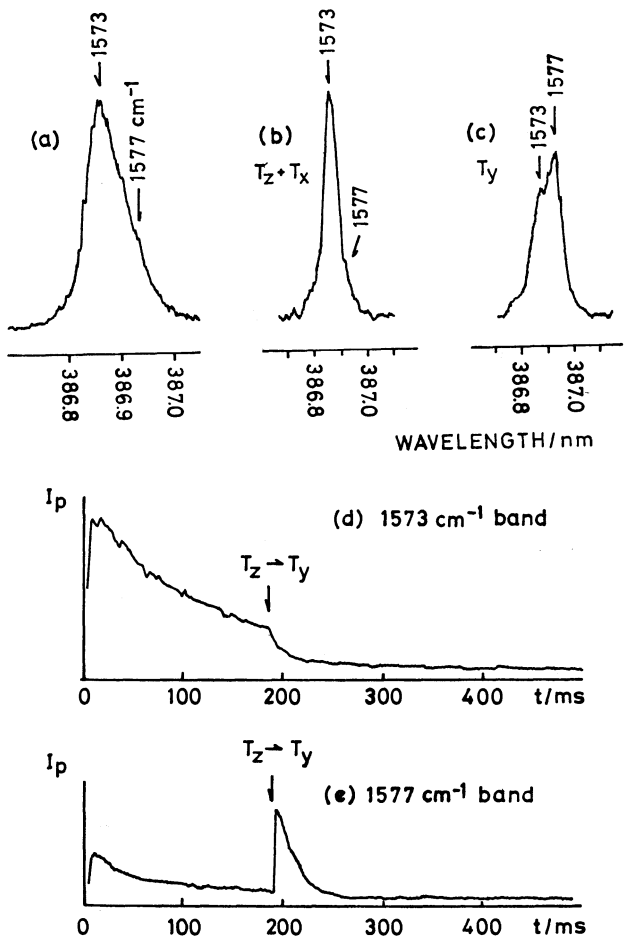

Fig. 4. The 1573 cm^{-1} band in the phosphorescence spectrum of *p*-dichlorobenzene in *p*-xylene at 1.4 K under various conditions(a—c; see the text) and the MIDP signals obtained by monitoring the emission at slightly different wavelengths (d and e).

Similar results have also been obtained in all the other systems but in benzene. As another example, the 1581 cm^{-1} band observed in the spectrum of the x-trap is shown in Fig. 5. In this case, the T_y and T_z spectra were taken by applying the microwaves resonant with the $T_y\leftrightarrow T_x$ and the $T_z\leftrightarrow T_x$ transitions, respectively. It is clear from the figure that the peak band originates mainly from T_z while the shoulder from T_y.

In the system of DCB in DCB-d_4, a splitting of the band is recognized even in the phosphorescence spectrum in Fig. 1. The MIDP experiments on this system and the system of DCB in DBB also showed that the peak band originates mainly from T_z. The spectrum in benzene is too broad to obtain conclusive results.

As discussed above, the shoulder band originating from T_y has to be assigned as being due to the a_g, ν_{8a} vibration. The vibration involved in the peak band is therefore unambiguously assigned to the b_{3g}, ν_{8b} vibration. It is to be noted that in all these systems the peak positions correspond to the band due to the b_{3g} vibration. In this regard, the previous assignment[7,8] to the a_g vibration should be revised. In the high resolution spectrum of the x-trap reported

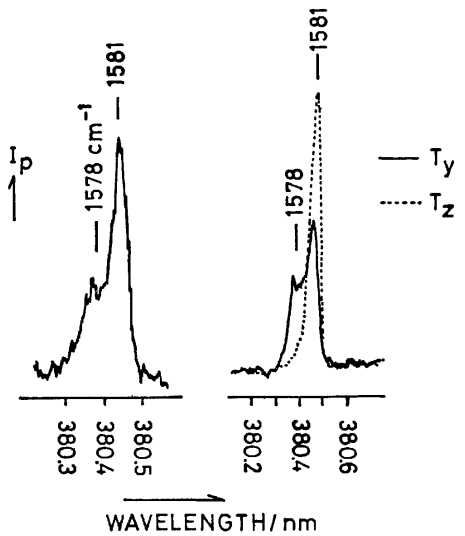

Fig. 5. The 1581 cm^{-1} band in the phosphorescence spectrum of the x-trap (23 cm^{-1}) in the neat *p*-dichlorobenzene crystal(left) and the same band observed with microwave perturbations (right; see the text).

by Gash *et al.*,[8] the band of present interest is clearly split, but they ascribed the both components to the a_g vibration, since they observed some of other a_g bands as doublets. However, they also observed the 749 and 1178 cm^{-1}, a_g bands without splitting. In view of this and our present results, the band at 0—1579.0 cm^{-1} in their spectrum is to be attributed to the b_{3g} vibration.

In the case of benzene, the ν_8 band in the phosphorescence spectrum appears with remarkable intensity, because of the strong vibronic coupling between the $^3B_{1u}$ and $^3E_{1u}$ states through the ν_8 mode. It seems that a similar situation is retained in DCB. Therefore, the main mechanism by which the ν_{8b}, b_{3g} band acquires the dipole activity is described by the second order spin-orbit vibronic coupling scheme of $^3B_{1u} \leftarrow b_{3g} \rightarrow {}^3B_{2u} \leftarrow H_{so}(T_z) \rightarrow {}^1B_{3u}$. The emission to the b_{3g} vibrational levels steals its intensity mainly from the $^1B_{3u} \rightarrow {}^1A_g$ transition as the emission to the a_g vibrational level does. The differentiation of a_g and b_{3g} vibrations are therefore not feasible from the phosphorescence polarization measurements. A similar situation has also been found in *p*-chloroaniline.[13]

As mentioned above, the coupling between the $^3B_{1u}$ and $^3E_{1u}$ states through the ν_8, e_{2g} mode in benzene results in pseudo Jahn-Teller instability, which combined with the crystal field of lower symmetry causes a distortion of the hexagonal symmetry of both the nuclei and the electronic structure. Indeed, various experiments[17-25] have shown that the lowest triplet state of benzene has a non-hexagonal electronic structure; *i.e.*, the in-plane distortion along the e_{2g} mode. Therefore, it is very probable that the DCB molecule is also subject to a similar distortion along the b_{3g} mode.

This kind of distortion would result in a deviation of the in-plane principal axes of the fine structure tensor from the molecular symmetry axes. Vergragt *et al.*[26,27] have demonstrated that the in-plane principal axes of toluene and *p*-xylene are skew in the triplet state by approximately $70(\pi/180)$ rad with respect to the axes expected for an undistorted molecule. In DCB, such a large deviation of the principal axes may not be expected, because the radiative decay rate ratio, k_z^x/k_y^x, for the 0,0 band is small in *p*-xylene and in DCB-d_4 as shown in Table 2. Recently, it has been shown from NQR experiments for DCB in DBB[28,29] that the in-plane principal axes are rotated by about 10 $(\pi/180)$—$12(\pi/180)$ rad about the axis normal to the molecular plane. Furthermore, an out-of-plane deviation of the principal axis, y, by about $20(\pi/180)$ rad is also deduced from the NQR experiments.[28] These results, though somewhat large in the DBB host, are consistent with our present expectations.

The present work is partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Kinetic Pressure and Substituent Effects on the Thermal Isomerization of Triphenylformazans

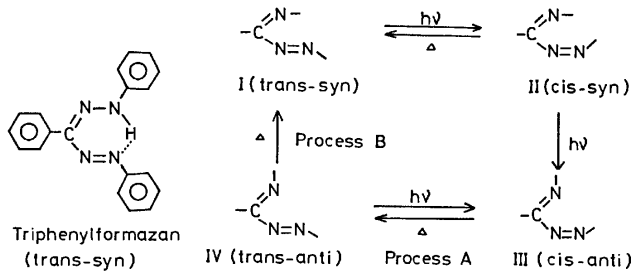
Yoshimi Sueishi* and Norio Nishimura

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received April 2, 1983)

The rates of the thermal isomerizations around N=N (Process A) and C=N (Process B) of substituted triphenylformazans were followed spectrophotometrically at various temperatures and under high pressures, and the activation parameters were determined. The values of the activation energy, entropy, and volume were found to be *ca.* 70 kJ mol^{-1}, *ca.* -20 J K^{-1} mol^{-1}, and *ca.* -5.0 cm^3 mol^{-1} respectively for Process A, and *ca.* 40 kJ mol^{-1}, *ca.* -200 J K^{-1} mol^{-1}, and *ca.* -10 cm^3 mol^{-1} respectively for Process B. It was suggested that the thermal isomerizations both for Processes A and B proceed by the inversion mechanism. Furthermore, in the transition state of Process B, a quasi six-membered ring was assumed to form. The very large negative entropy of Process B was discussed in terms of the restricted internal rotations, and others.

Formazans have two double bonds. There are some reports with regard to their conformations and electronic and IR spectra.[1,2] However, there are very few reports regarding its isomerization mechanism. Kuhn and Weitz[3] suggested the following isomerization scheme.



Scheme 1.

But they did not give a full detail of mechanism of the thermal isomerization.

In the preliminary communication,[4] it was shown that the kinetic substituent effects really reverse above and below the isokinetic temperature. In spite of the low activation energy,[3] the rate of the thermal isomerization for Process B is so slow that it seems to us worth while investigating the reaction mechanism in some detail.

In analogy with the isomerizations of azobenzenes and azomethines, there are two possible mechanisms for the thermal isomerizations of triphenylformazans, one *via* a rotation around the double bonds and involves a π-bond rupture, the other *via* an inversion on the nitrogen atom, the π-bond remaining intact.[5,6]

This paper presents the substituent and pressure effects on the rate of the thermal isomerization of several formazans and their mechanistic implications are discussed.

Experimental

Reagents. Substituted triphenylformazans were prepared according to the method by Kuhn and Weitz[3] and recrystallized from a chloroform–ethanol mixture. Melting point and IR spectra were used for identification.

1,3,5-Triphenylformazan: mp 173 °C (lit, 173.5 °C), 3-(*p*-methoxyphenyl)-1,5-diphenylformazan: mp 157—158 °C (lit, 156—158 °C), 3-(*p*-methylphenyl)-1,5-diphenylformazan: mp 171—172 °C, 3-(*p*-chlorophenyl)-1,5-diphenylformazan: mp 199—200 °C (lit, 178—179 °C), 3-(*p*-bromophenyl)-1,5-diphenylformazan: mp 209—210 °C, 3-(*p*-cyanophenyl)-1,5-diphenylformazan: mp 221—222 °C, 3-(*p*-nitrophenyl)-1,5-diphenylformazan: mp 230—231 °C (lit, 204 °C), 3-(*m*-nitrophenyl)-1,5-diphenylformazan: mp 185.7 °C (lit, 185 °C), 1,5-bis(*o*-methylphenyl)-3-phenylformazan: mp 129—130 °C (lit, 130 °C, 1,5-bis(*p*-methylphenyl)-3-phenylformazan: mp 164—165 °C), 1,5-bis(*p*-chlorophenyl)-3-phenylformazan: mp 184—185 °C (lit, 183—184 °C).

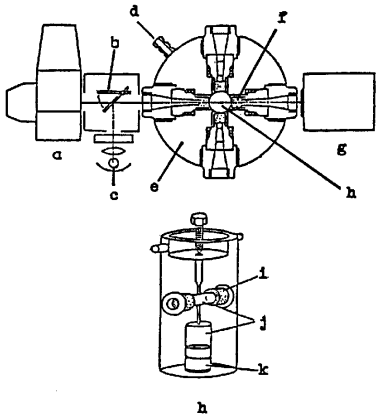


Fig. 1. Schematic diagram for spectrophotomeric measurement (top view) and inner cell.
a, Monochromator; b, turn mirror; c, tungsten lamp for excitation; d, water inlet; e, high pressure vessel; f, sapphire window; g, photomultiplier; h, teflon inner cell; i, sapphire window; j, sample cell; k, liquid separation piston.

Solvents. Toluene was dried over metallic sodium and distilled. Hexane of reagent grade was used as received.

Measurements under Atmospheric Pressure. An appropriate concentration of the sample solution was irradiated for 1 h with a 100W tungsten lamp to produce a *cis-anti* isomer (III). In the dark, the *cis-anti* isomer (III) isomerizes to a *trans-anti* isomer (IV) and the *trans-anti* isomer (IV) turns back to a *trans-syn* isomer (I) (Scheme 1), both in accordance with the first-order kinetics. The reaction rates for Processes A and B were estimated spectrophotometrically, by following the maximum absorbance at *ca.* 400 nm for the former by a Union 401 spectrophotometer, and the maximum absorbance at *ca.* 500 nm for the latter

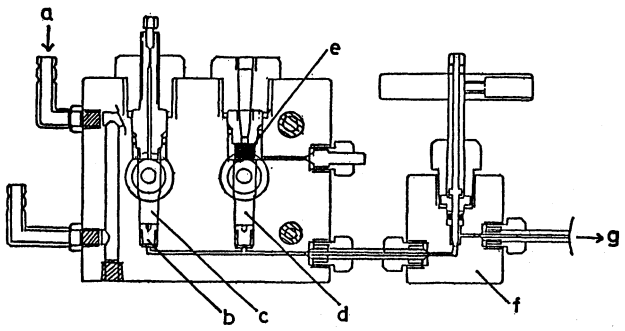

Fig. 2. High pressure vessel for spectral measurement (side view).
a, Water inlet; b, liquid separation piston; c, reference cell; d, sample cell; e, sapphire window for excitation light; f, stop valve; g, to pump system.

by a Hitachi 101 spectrophotometer. These are checked by several runs.

Measurements under High Pressures. The thermal *cis*-to-*trans* isomerization (Process A) was followed by using a pressure vessel made of SNCM-8 stainless steel and equipped with an inner cell, optical windows, and a water jacket (Fig. 1.). The pressure was generated by means of a plunger-pump. The pressure was measured by a Haise Bourdon gauge. The reaction temperature was controlled by circulating the thermostated water through the water jacket. Sample solutions were charged in the inner cell which is made of teflon and consists of two parts connected with a narrow tube, in order that an irradiated part of the solution for optical measurements does not mix with an unirradiated part of the solution. The solution was compressed, and then irradiated with a 650 W tungsten projection lamp for 1 min. After irradiation, the mirror b was turned by 45° and the change in the absorbance with time was followed with a Hitachi 139 spectrophotometer.

The rate of the thermal *anti*-to-*syn* isomerization (Process B) was so slow that this process was followed by using a high pressure vessel made of 17-4PH stainless steel (Fig. 2). The pressure vessel have two cells for sample and reference solutions, equipped with sapphire windows in horizontal direction for spectral measurements and one window in vertical direction for irradiation. The reaction solution in the pressure vessel was brought up to the required pressure, and then the stop valve was closed. The vessel was separated at the stop valve from the pump system. After the reaction solution had been irradiated with a 650 W tungsten projection lamp for 2 min, the pressure vessel was set in a Hitachi 100-50 double-beam spectrophotometer and the absorbance was recorded.

Results and Discussion

The thermal *cis*-to-*trans* and *anti*-to-*syn* isomerizations of substituted triphenylformazans were carried out at various temperatures. The rate constants estimated

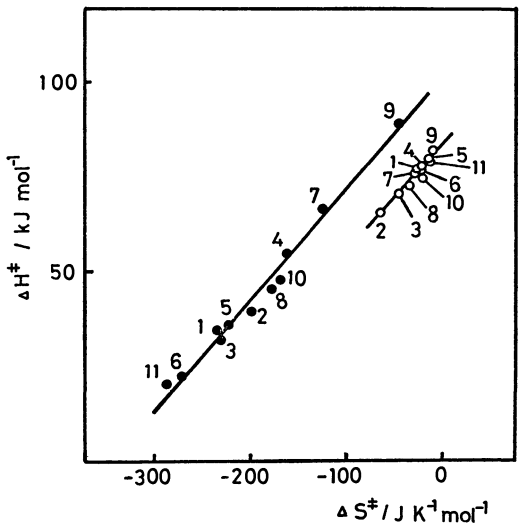

Fig. 3. $\Delta H^* - \Delta S^*$ relationships for Processes A (○) and B (●).

from the first-order plots and the activation parameters are listed in Tables 1 and 2. It is interesting to note that the activation entropies for Process B are surprisingly small except **9**. Therefore, the rate constants for Process B are about 10^4 smaller than those for Process A, in spite of the very low activation energies. In **9**, the steric effect by the *ortho*-CH_3 substituent may be severe in the transition state and this may be responsible for both the increased activation energy and entropy. Figure 3 shows the linear relationships between the activation enthalpy and entropy. This linear enthalpy-entropy relationship suggests that in Process B as well as A, a single mechanism is operating.[7] Similarly, a linear relationship between ΔH^* and ΔS^* has been reported for the thermal *cis*-to-*trans* isomerization of substituted azobenzenes.[8]

Arrhenius Parameters. It has been shown theoretically that the activation energies for the *syn*-to-*anti* isomerization of oximes[9–12] by the inversion mechanism are lower than those by the rotation mechanism. Moreover, Warren *et al.*[13] calculated the energy barrier for the isomerization of *N*-benzylideneaniline *via* the inversion to be 88.8 kJ mol^{-1} and the barrier to the rotation around the C=N double bond was calculated to be 252 kJ mol^{-1} by means of the CNDO/2 method. Experimental values of various kinds of azobenzenes and azomethines are about 80 kJ mol^{-1}. Most of the activation entropies for the thermal isomerizations of azobenzenes and azomethines fall in the range of about −60 to 0 J K^{-1} mol^{-1}. Judging from these, our results for Process A (Table 1) seem to be compatible with the inversion mechanism.

Recently, Bach and Wolber[9] reported that electron-withdrawing substituents at nitrogen markedly increase the inversion barrier and that an allyl type molecular orbital containing the nitrogen lone pair contributes most significantly to the activation energy. On the other hand, it has been suggested that if substituents at carbon strongly polarize the π-electron of the C=N bond, the rotation mechanism accompanying the charge separation might be possible.[10,14] Moreover, Bauer *et al.*[15] and Taylor and Bartulin have reported that the activation energies for the rotational isomerizations of guanidine salts around the C=N bond and of some olefines around the C=C bond are as low as 80 kJ mol^{-1} or even less. Therefore, the activation energy less than 80 kJ mol^{-1} may not necessarily afford a conclusive evidence for the inversion mechanism.

The extraordinarily small values of the Arrhenius parameters for Process B (Table 2) are noteworthy. There are some examples of such small values of the activation entropy for second-order reactions. As far as we are aware, however, the values of the activation entropy for first-order reactions are much larger than this. The above findings have lead us to the idea that the transition state might be much more product-like and hence its molecular conformation is similar to that of *trans-syn* for which a quasi six-membered ring is formed, internal rotations being severely restricted.

Since an internal rotation interacts with other modes of rotations and vibrations, it is difficult to calculate the exact contribution of the internal rotation to entropy. However, if we use a proper model, the rotational entropy can approximately be estimated. Figure 4 shows a model of the cyclic transition state of triphenylformazan. If a quasi six-membered ring for-

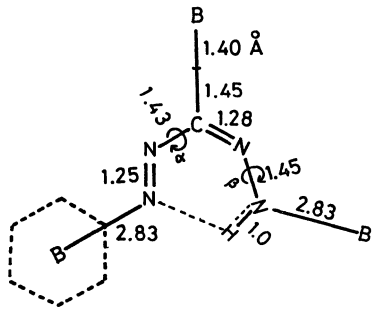

Fig. 4. Model of the cyclic transition state of triphenylformazan. The bond lengths (Å) of azobenzene derivative[17] and *N*-benzylideneaniline[13] were used. B, Phenyl group; C, carbon; N, nitrogen; H, hydrogen.

mation occurs in the transition state, rotations around the C–N and N–N bonds as depicted become impossible. Now, for brevity, we assume that the two possible internal rotation axes agree with these bond-axes. The entropy of an internal rotation can be calculated by

$$S_{\mathrm{rot}} = NkT(\mathrm{d}\ln q_{\mathrm{rot}}/\mathrm{d}T) + Nk\ln q_{\mathrm{rot}}, \quad (1)$$

where q_{rot} is the one-dimensional rotational partition function and is given by

$$q_{\mathrm{rot}} = (8\pi^2 IkT/h^2)^{1/2}\pi^{1/2}/\sigma, \quad (2)$$

for which σ is the symmetry number and the reduced moment of inertia I is given by $I=I_1I_2/(I_1+I_2)$ in which I_1 and I_2 are the moment of inertia around the common axis. Therefore, S_{rot} is expressed as follows.

$$S_{\mathrm{rot}} = Nk\left[\frac{1}{2}+\frac{1}{2}\ln(8\pi^3 IkT/h^2)-\ln\sigma\right]$$
$$= R\left[\frac{1}{2}\ln(I/\mathrm{amu\ Å^2})+\frac{1}{2}\ln(T/\mathrm{K})-\ln\sigma-0.522\right]. \quad (3)$$

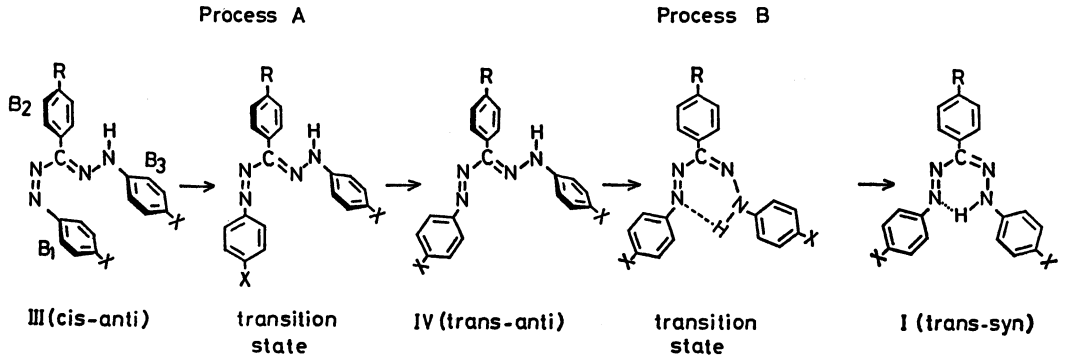
Substituting the numerical values into these equations, the entropies for the internal rotations around the C–N and N–N bonds at 25 °C are calculated to be S_{rot}(C–N)=38.6 J K^{-1} mol^{-1} and S_{rot}(N–N)=44.1 J K^{-1} mol^{-1}. Therefore, the total entropy loss due to these restricted rotations may be about 80 J K^{-1} mol^{-1} on going from the initial to the transition state.

It may be instructive to compare the entropy loss with those of similar reactions. For example, some Claisen and Cope rearrangements[18,19] have been reported to proceed *via* a cyclic transition state. The entropies of activation for the Claisen rearrangement of allyl ethers have been reported as −50——120 J K^{-1} mol^{-1}.[18] Assuming that only two rotations around the O–CH_2 and CH_2–CH bonds become forbidden upon activation, the total entropy losses for the corresponding species can be estimated as −50——90 J K^{-1} mol^{-1}. For 3-phenyl-2-propenyl phenyl ether, the discrepancy is *ca.* 30 J K^{-1} mol^{-1} probably owing to the restriction of other modes of internal rotations involving two phenyl rings upon activation.

Now, in our case, the steric hindrance in the transition state may become less severe than in the ground state, and hence one might imagine that the free rotations involving the benzene rings become possible (see Scheme 2). However, as we have advocated in the case of the thermal isomerization of azobenzenes,[5] the most important factor for determining the conformation of such a "soft" species involving aromatic rings connected by single bonds is mesomeric one. Therefore, the mesomeric effects which tend to keep the three benzene rings coplanar would overwhelm the tendency for them to rotate freely, resulting in the net loss of entropy upon activation. Indeed, the absorption maxima of the conjugation band are 495 nm for the *trans-syn* isomer (I) and 405 nm for the *trans-anti* isomer (IV), suggesting a drastic change in the molecular conformation (coplanality).

There is a vast of reports for hydrogen bond formation.[20] The reported values of ΔH and ΔS for the H-bond formation vary depending on the type of bonding and others, but ΔH is generally *ca.* −20 kJ per H-bond per mol, and ΔS is *ca.* −50 J K^{-1} mol^{-1}. If the H-bond formation takes place in the transition state for Process B, further entropy loss of *ca.* 50 J K^{-1} mol^{-1} could be expected. The contribution from the solvation may be responsible for at least a part of the remaining entropy loss.

The very low values of the activation energy for Process B (Table 2) seem to be worth to pay attention. According to the Hammond postulate, among a group of similar reactions, the less exothermic ones have the later transition states and *vice versa*. Since Process B involves a formation of the hydrogen bond, it must be exothermic ($\Delta H \approx -20$ kJ mol^{-1}, *vide supra*). At first sight, it seems that the reaction may have the earlier transition state compared with similar types of isomerizations, and this is apparently against the



Scheme 2.

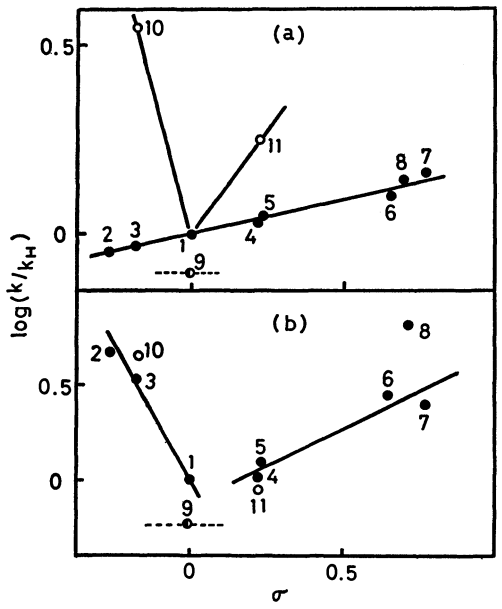


Fig. 5. Plots of log (k/k_H) against the Hammett σ for (a) Process A at 20 °C and (b) Process B at 25 °C. ●: Substituents R, ○: substituents X, ◐: **9**.

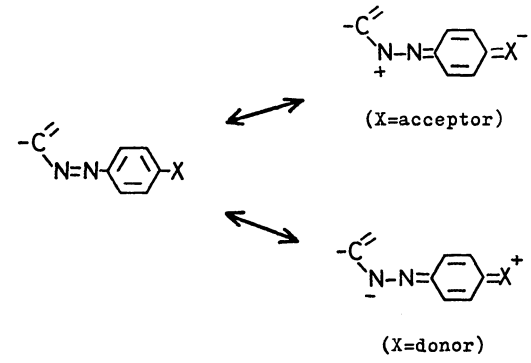
above assumption that the conformation of the transition state is similar to I. However, as seen above, the entropy factor plays a very important role in this process, and the reaction is controlled by the activation energy as well as the activation entropy. The isokinetic temperature (*ca.* 300 K) estimated from the slope of the linear ΔH^* *vs.* ΔS^* plot in Fig. 3 is very near the experimental temperatures. In such a case as this, the Hammond postulate must be invalidated, since the postulate tacitly assumes that reactions in question are energy-controlled. It is noted that the true reaction coordinate must be drawn in terms of the free energy. Therefore, in spite of the low activation energy, the barrier of the free energy will be at the later stage of reaction coordinate.

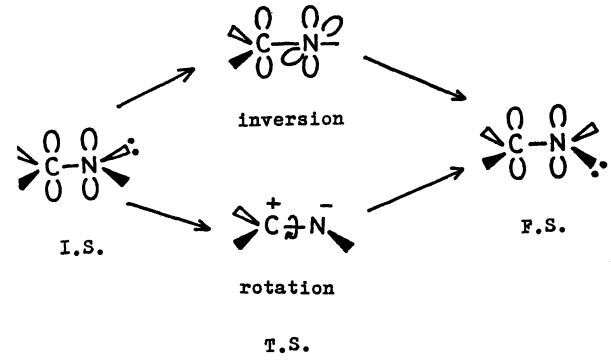
Substituent Effects. In the preliminary communication,[4] we reported that the strictly linear ΔH^*–ΔS^* relationship holds for a limited series of substituted triphenylformazans and the isokinetic temperature at which substituent effects should vanish does exist (Process A). Figure 5(a) shows the substituent effect for the thermal isomerizations of 11 kinds of triphenylformazans. The Hammett plots of **1**, **10**, and **11** show a V-line. Moreover, the *ortho*-substituent retards the isomerization rate (**9**). On the other hand, a linear Hammett relationship approximately holds for **1**—**8**. The above findings are considered as follows. In the *cis-anti* conformation, the three benzene rings (B_1, B_2, and B_3 in Scheme 2) must be twisted to one another owing to the steric repulsion (III in Scheme 2). In the inversion transition state, however, a conjugation between the reaction center (the N=N bond) and the substituent X in B_1 becomes possible, thus resulting in the extra free energy depression in analogy with the case of azobenzene derivatives,[5] as depicted in Scheme 3:



Scheme 3.

The acceleration effect irrespective of the nature of substituents is accounted for by this reason. On the contrary, in **1**—**8**, a conjugation of the reaction center (the N=N bond) and the substituent R in B_2 is impossible. Therefore, the substituent R would exhibit a mild inductive effect, thus accounting for the usual Hammett relationship. In the rotational mechanism, these substituent effects can be explained in no way.

There are two possible routes also for Process B (Scheme 4).



Scheme 4.

The isomerizations of azomethines[20,21] are also characterized by a V line. Herkstroeter[21] and Hall *et al.*[22] explained the V plot in terms of the change in mechanism. As explained earlier,[4] we have a different idea. If the inversion transition state is assumed for Process B, B_2, B_3, and the connecting C=N–N group would become coplanar. This makes the conjugation between the substituent R and the C=N–N group possible, but the conjugation between the substituent X and the C=N group is impossible. Therefore, the kinetic behavior of a series of the substituents R (the V plot in Fig. 5(b)) and of X can well be accounted for by the same way as explained for Process A. On the contrary, if the rotational transition state is assumed, the introduction of the electron-donating groups (R) would help the polarization (Scheme 4) and hence the isomerization rate is accelerated and *vice versa*. Thus we may expect the linear Hammett plot. This is against the experimental observations. The detail of the discussion on this problem has been reported elsewhere.[5]

Pressure Effects. The entropy of activation often affords important informations about the manner of

Table 3. Pressure effects (k_p/k_1) and activation volumes for Processes A and B

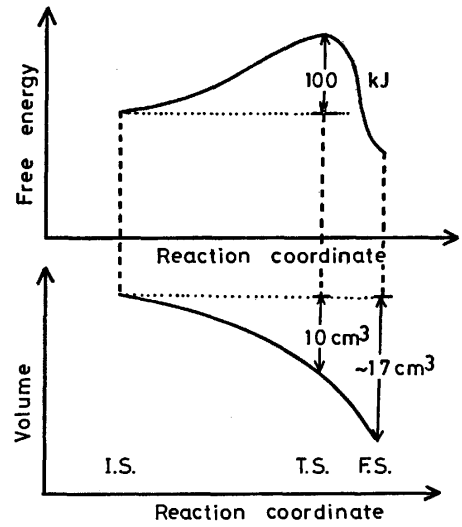

Fig. 7. Free energy and volume profiles for Process B.

bonding, the change in freedom, the extent of solvation, *etc.* However, since ΔH^* and ΔS^* can be obtained as a set from the Arrhenius plot, inevitable errors are often involved in ΔS^*, which, as pointed out by Petersen,[23] might lead to the misunderstanding for the existence of the isokinetic temperature. On the other hand, the volume of activation can be estimated from the slope of $\ln k$ *versus* P plot, in accordance with Eq. 4,

$$(\partial \ln k/\partial P)_T = -\Delta V^*/RT, \quad (4)$$

and the concept of volume is more straightforward than that of entropy. The activation volume is usually divided into two terms:

$$\Delta V^* = \Delta V_1^* + \Delta V_2^*, \quad (5)$$

where ΔV_1^* represents the difference in the intrinsic volume of reacting molecules between the initial and the transition state, and ΔV_2^* is the change in volume of surrounding solvents. Therefore, if no substantial intrinsic volume change is expected as may be so for Process A, ΔV^* obtained experimentally may be ascribed to ΔV_2^*.

Pressure effects on the thermal isomerizations for Processes A and B are given in Table 3. The rate constants in logarithmic scale were plotted against P (Fig. 6), and the estimated activation volumes are given in Table 3.

The small negative values of the activation volume for Process A indicate that the polarity change is, if any, not so large as suggested for the rotational transition state.[24] These values are, together with the values of E_a and ΔS^*, very similar to those for the isomerization of azobenzene derivatives for which the inversion mechanism has been advocated.[5,8]

Judging from the very small activation entropy for Process B, the transition state might be highly polar. However, the activation volume indicates that it is not so. If the isomerization for Process B proceeds *via* a cyclic transition state, the activation volume may be similar to those of the Claisen and Cope rearrangements.[25,26] The activation volumes reported are −9—−18 cm^3 mol^{-1} for these reactions, and are −9.5 ($\alpha\rightarrow\gamma$) and −7.9 ($\gamma\rightarrow\alpha$) cm^3 mol^{-1} for the equilibration of α- and γ-methylallylazide[27] respectively. It has been considered that these reactions proceed *via* moderately polar cyclic transition states. Judging from the values in Table 3, the isomerization for Process B will proceed *via* a moderately polar and cyclic transition state. It may safely be considered that the difference in the molar volumes between the *trans-syn* isomer (I) and the *trans-anti* isomer (IV) is similar to that between 1-hexene and cyclohexane (−17 cm^3 mol^{-1}).[26] On the basis of the activation parameters and on the assumptions stated above, the presumed free energy and volume profiles for Process B could be sketched as shown in Fig. 7.

In conclusion, the kinetic substituent and pressure effects, together with the activation parameters, are in favor of the inversion mechanism *via* the moderately polar transition states both for Processes A and B, and against the rotational mechanism *via* the very polar transition states.

The Synthesis, Properties, and Structure of Bis(*N,N*-dimethylacetamide)-tris(*O,O'*-diisopropyl dithiophosphato)lanthanum(III)

Kiyofumi NAGAI,* Yoshiyuki SATO, Satoshi KONDO, and Akira OUCHI

Department of Chemistry, College of General Education, The University of Tokyo, Komaba 3-8-1, Meguro-ku, Tokyo 153

(Received January 11, 1983)

The new complex indicated in the title has been synthesized, and its crystal and molecular structure has been determined by the X-ray diffraction method. The crystal was triclinic; space group $P\bar{1}$, $Z=2$, $a=23.071(9)$, $b=11.060(11)$, $c=10.793(13)$ Å, $\alpha=120.0(1)$, $\beta=97.2(2)$, $\gamma=88.9(2)°$. The final R value for 5969 reflections is 0.047. The central lanthanum(III) atom is an octa-coordination and in a dodecahedron geometry, being coordinated with six sulfur atoms of three *O,O'*-diisopropyl dithiophosphate ligands (iPr_2dtp), which span at three *m* edges, and with two oxygen atoms of both the *N,N*-dimethylacetamide ligands (dma) at both ends of the remaining *m* edge. The other $[Ln(iPr_2dtp)_3L_2]$-type complexes, where Ln=La or Nd; L=dma or *N,N*-dimethylformamide, have also been obtained. The P=S double bond of the iPr_2dtp ligand in the title complex is almost completely delocalized.

Some lanthanoid metal compexes, where sulfur atoms are coordinated to metal, such as their dialkyldithiocarbamates,[1–6] dialkyldithiophosphinates,[7–10] and *O,O'*-dialkyl dithiophosphates(R_2dtp),[8,11,12] had previously been synthesized and investigated, though the lanthanoid elements are known as "hard acid" according to the HSAB theory.[13] The structures of a number of these complexes were also clarified; the octa-coordination of the central metal is common for the complexes of light lanthanoid elements,[5,6,11,12] except for those where voluminous ligands are coordinated.[7,10]

The authors had previously found that some amine adducts of cobalt(II) *O,O'*-dialkyl dithiophosphates are more stable than the original complexes.[14,15] Although triphenylphosphine oxide–*O,O'*-diethyl dithiophosphate(Et_2dtp) mixed complexes of lanthanoid (III) elements had already been investigated,[11b] almost no other such type of mixed complex was known yet. Therefore, the syntheses and the structure determination of the adducts of lanthanoid(III) *O,O'*-dialkyl dithiophosphates was started in our laboratory. Thus far, the title complex and some related ones have been obtained; their structure and properties will be shown below.

Experimental

*Synthesis of Bis(*N,N*-dimethylacetamide)tris(*O,O'*-diisopropyldithiophosphato)lanthanum(III).* Sodium *O,O'*-diisopropyl dithiophosphate ($Na(iPr_2dtp)$) was obtained from diphosphorus pentasulfide and 2-propanol (sodium carbonate was used for the neutralization of the free acid), by applying the method used for synthesizing the sodium *O,O'*-diethyl dithiophosphate ($Na(Et_2dtp)$).[16] Sodium tetrakis(*O,O'*-diisopropyl dithiophosphato)lanthanate(III) ($Na[La(iPr_2dtp)_4]$) was obtained by a reaction between lanthanum(III) chloride and $Na(iPr_2dtp)$ in a 2-propanol medium, using the method of synthesizing $Na[La(Et_2dtp)_4]$, written by Pinkerton.[8]

The sodium salt (0.83 g, 0.82 mmol) and *N,N*-dimethylacetamide (dma) (0.14 g, 2.2 mmol) were refluxed in 20 cm^3 of diisopropyl ether for 20 minutes; then it was filtered off to remove a turbid white mass and the residue while warm, and the filtrate was left standing for several hours. The product was precipitated as white crystals. The crude product was dissolved in 20 cm^3 of diisopropyl ether (60—65 °C), a turbid white mass was filtered off, the solution was left standing in a silica-gel desiccator overnight, and the complex was precipitated. Yield: 0.63 g (81%). The crystals thus obtained were submitted to X-ray diffraction after having been checked by means of Weissenberg photography. Found: La, 14.45; C, 32.68; H, 6.35; N, 2.89%. Calcd for $LaC_{26}H_{60}N_2O_8S_6P_3$: La, 14.58; C, 32.77; H, 6.35; N, 2.94%.

Syntheses of Other $Ln(iPr_2dtp)_3L_2$-type Complexes, Where Ln=La, Nd; L=Amides. These mixed complexes were obtained by almost the same technique as that used for the title complex. The neodymium(III) complexes were obtained via sodium tetrakis(*O,O'*-diisopropyl dithiophosphato)neodymate(III), which has been synthesized similarly. To synthesize the *N,N*-dimethylformamide (dmf) adducts, the optimum ratio of the starting materials was: the sodium salt:dmf=1:3 (in mol/mol).

$Nd(iPr_2dtp)_3(dma)_2$: Found, Nd, 15.68; C, 32.08; H, 6.26; N, 2.63%. Calcd for $NdC_{26}H_{60}N_2O_8S_6P_3$: Nd, 15.05; C, 32.59; H, 6.13; N, 2.92%. Yield, 73%. Magnetic moment of the solid, 3.4_2 BM† (22 °C). $La(iPr_2dtp)_3(dmf)_2$: Found, La, 14.82; C, 30.54; H, 6.12; N, 2.99%. Calcd for $CaC_{24}H_{56}N_2O_8S_6P_3$: La, 15.03; C, 31.18; H, 6.11; N, 3.03%. Yield, 62%. $Nd(iPr_2dtp)_3(dmf)_2$: Found, Nd, 15.77; C, 30.55; H, 6.07; N, 2.93%. Calcd for $NdC_{24}H_{56}N_2O_8S_6P_3$: Nd, 15.51; C, 31.00; H, 6.07; N, 3.01%. Yield, 76%. Magnetic moment of the solid, 3.4_1BM (22 °C).

Single-crystal X-Ray Analysis. A crystal with dimensions of $0.3\times0.3\times0.2$ mm^3 was used for the measurement. All its edges were ground off, but it was not shaped into a sphere.

The crystallographic data are: $LaC_{26}H_{60}N_2O_8S_6P_3$: F.W. =952.91, triclinic, space group $P\bar{1}$, $Z=2$, $a=23.071(9)$, $b=11.060(11)$, $c=10.793(13)$ Å, $\alpha=120.00(11)$, $\beta=97.17(16)$, $\gamma=88.92(24)°$, $D_x=1.34$, $D_m=1.37(3)$ Mg m^{-3}, μ(Mo $K\alpha$)=1.08 mm^{-1}. The reflections within the range of $2\theta<50°$ were collected on a Philips PW 1100 automated four-circle diffractometer with Mo $K\alpha$ radiation, the $\theta-2\theta$ scan technique being employed. Due to the limitation of our computation program (upper limit of the numbers of reflections=6000), 5969 $|F_o|>5.5\sigma(|F_o|)$ reflections from the 6753 independent ones measured were used for the calculation. The intensities were corrected for Lorentz and polarization factors, but no correction was made for absorption or extinction.

All the calculations were carried out on a HITAC M-

† 1 BM=$9.274078(36)\times10^{-24}$ J T^{-1}.

a) The equivalent isotropic temperature factors were computed using the following expressing: $B_{eq}=(4/3)(B_{11}a^2+B_{22}b^2+B_{33}c^2+B_{12}ab\cos\gamma+B_{13}ac\cos\beta+B_{23}bc\cos\alpha)$. The B_{ij}'s are defined by: $\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2klB_{23}+2hlB_{13}+2hkB_{12})]$.

200H computer at the Computer Center of The University of Tokyo, using the local version of the UNICS program.[17] The atomic-scattering factors were taken from the tables.[19]

Structure Determination. The structure was solved by the heavy-atom method. The positions of the lanthanum, phosphorus, and sulfur atoms were deduced from a three-dimensional Patterson map, while all the other non-hydrogen atoms were located by means of successive Fourier syntheses. Their positional and thermal parameters were refined by the block-diagonal least-squares method. All attempts to determine hydrogen-atom positions were unsuccessful, and so they were not included in the calculation. In the last cycle of the refinement with anisotropic temperature factors for all atoms, almost all the parameter shifts were less than one-third of the corresponding standard deviations; the exceptions were only slightly higher than one-third of the corresponding standard deviations. The final R value obtained was 0.047.[19]

Other Measurements. The X-ray powder patterns of these complexes were obtained by the use of a diffractometer, Model DX-GO-F JEOL, using Cu $K\alpha$ radiation, in the range from 6° to 50° in 2θ. The magnetic moments of the solid samples were measured using a Gouy balance at an ambient temperature. The infrared absorption spectra of the samples were obtained by means of a JASCO A-202 grating infrared spectrophotometer, using Nujol and hexachloro-1,3-butadiene mull. The visible absorption spectra of the solutions, as well as the diffuse reflectance spectra of the solid samples, were measured by means of a Hitachi 124 spectrophotometer. The ^{1}H-NMR spectra were measured by means of a Varian EM-390 NMR-spectrometer, using tetramethylsilane (TMS) as the internal standard.

Results and Discussion

The final atomic parameters of the title complex are listed in Table 1,[20] while the bond lengths as well as the bond angles are tabulated in Table 2. The perspective drawing of the complex around the central lanthanum atom, together with the numbering scheme, is shown in Fig. 1, and the crystal packing diagram, in Fig. 2.

The complex molecules in the crystal are discrete, and neither bridges nor hydrogen bonds are recognized between different molecules. As is shown in Fig. 3, the central lanthanum(III) atom is in an octa-coordination and in a distorted dodecahedron geometry, coordinated to six sulfur atoms of three iPr_2dtp ligands, which span at m edges of the dodecahedron, and to two oxygen atoms of two dma ligands, which bond at both the ends of its remaining m edge. The plane equations of the two trapezia of the dodecahedron are shown as follows.

(x, y, and z in the equations are taken in the a, b, and c directions of the unit cell respectively, and are shown in Å units):

a) La, S(1), S(2), S(3), and S(4) plane:
$-0.040x-0.480y-0.876z+0.960=0.0$.
Deviations (in Å): La, 0.080; S(1), −0.105; S(2), 0.088; S(3), −0.113; S(4), 0.093.

b) La, S(5), S(6), O(100), and O(200) plane:
$-0.997x+0.076y-0.008z+5.288=0.0$.
Deviations (in Å): La, 0.030; S(5), 0.077; S(6), −0.053; O(100), −0.092; O(200), 0.043 Å.

The dihedral angle of both the planes is 89.4 °.

As is shown in Table 2, all the La–S bond lengths are in the range of 3.046(7)—2.988(3) Å; they are almost equal. All the P–S bond lengths are also almost the same; 1.986(6)—1.964(6) Å. Therefore, it is likely that the P=S double bond of the ligand is almost completely delocalized in the complex. The oxygen atom of iPr_2dtp, and the nitrogen atom of the dma ligand are not coordinated to the central metal atom.

The La–S bond length of this complex is comparable with those of $La(Et_2dtp)_3\{(C_6H_5)_3PO\}_2$ (2.98—3.07

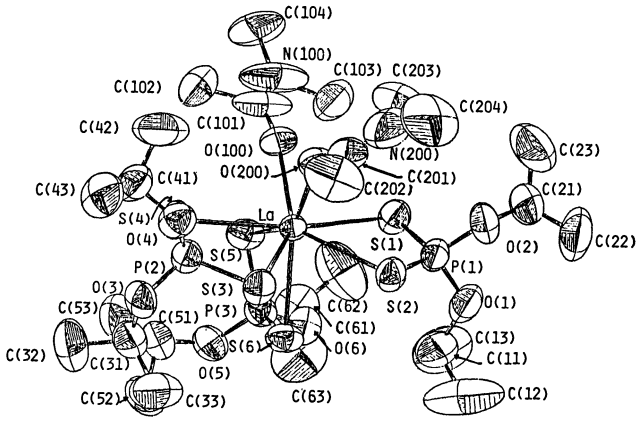

Fig. 1. A perspective drawing of the title complex with the numbering scheme.

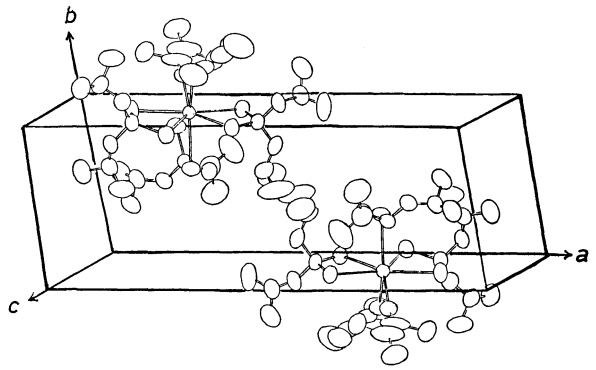

Fig. 2. Crystal packing diagram of the title complex.

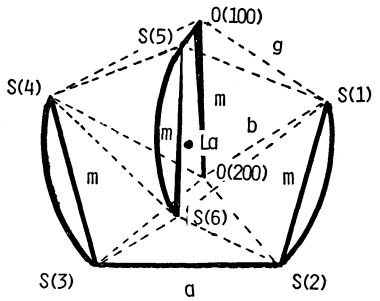

Fig. 3. Dodecahedron geometry around La^{III}.

Å),[11a] and $[As(C_6H_5)_4][La(Et_2dtp)_4]$ (2.96—3.01 Å).[12] The La–O bond lengths of this complex(2.41, 2.43 Å) are also almost equal to those of $La(Et_2dtp)_3\{(C_6H_5)_3PO\}_2$(2.42, 2.46 Å).[11a] The bond lengths are slightly shorter than those of the common lanthanum(III) complexes in which the oxygen atoms of the ligands are coordinated(about 2.5 Å).[21–24] Consequently, the bond between La^{III} and dma in this complex can be expected to be very strong.

The configuration of the central metal of the title complex is different from that of $La(Et_2dtp)_3\{(C_6H_5)_3PO\}_2$, which is in the square-antiprism geometry, and the two triphenylphosphine oxide ligands are located on opposite sides of the molecule.[11a] The discrepancy between them is probably due to the bulkiness of the triphenylphosphine oxide ligands in the latter complex, for the ligands cannot be located side by side on the coordination sphere due to the steric hindrance.

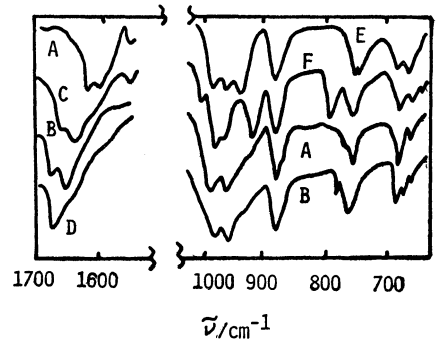

Fig. 4. Infrared absorption spectra of the title complex and the related compounds. A: $La(iPr_2dtp)_3(dma)_2$; B: $La(iPr_2dtp)_3(dmf)_2$; C: dma; D: dmf; E: $Na(iPr_2dtp)$; F: $Na[La(iPr_2dtp)_4]$.

In tetrakis(4-thioxo-2-pentanonato)zirconium(IV), where the central metal is in a square-antiprism geometry, four sulfur atoms and four oxygen atoms of the ligands are located side by side.[25] Similarly, it is expected that, in the comlpexes with high-coordination-number geometry, if two kinds of ligating atoms exist, the same kind of atoms may be apt to be located side by side on the coordination polyhedron if their "hardness" (in the HSAB concept) is different from that of the others, unless no steric interference exists.

Although the positions and thermal parameters of the lanthanum(III) atom and the atoms near it are exactly determined, those of the isopropyl carbon atoms have relatively large standard deviations; the hydrocarbon chains are not tightly fixed.

From the powder X-ray diffraction patterns of $Ln(iPr_2dtp)_3L_2$, where Ln=La or Nd; L=dma or dmf, both of the dma complexes, as well as both of the dmf complexes, may be said to be isostructural with each other.

The infrared absorption spectral patterns of the dma adducts of the lanthanum(III) and neodymium (III) complexes, as well as of their dmf adducts, resemble each other. The infrared spectra of the title complex and of some related compounds are shown in Fig. 4. The ν(CO) of dma shifts to the lower-wave number side when it is coordinated with the lanthanoid metal; *i.e.* 1657, 1640→1620, 1597 cm^{-1}. On the other hand, the ν(CO) of dmf makes only a small shift, but splits into two peaks, 1668→1680, 1643 cm^{-1}, when it is coordinated to La^{III} or Nd^{III} in this type of complex.

In the infrared spectra of these metal R_2dtp complexes, the characteristic strong peak, which is probably to be assigned as a mixed band of ν(P–S) and ν(P–O), appears near 750 cm^{-1}.[26] In the case of $Na[La(iPr_2dtp)_4]$, the band is split into two peaks; 760 and 741 cm^{-1}. On the other hand, in the case of the title adduct, the peak appears as a single one at 760 cm^{-1}. The X-ray diffraction data shows that, in the $[La(Et_2dtp)_4]^-$ ion, the La–S pair as well as the P–S bond lengths of a Et_2dtp ligand are a little different from each other,[11a] probably because of the partial localization of the P=S double bond of the ligand. In the title complex, as was shown above, the P=S double bond is delocalized almost completely. There-

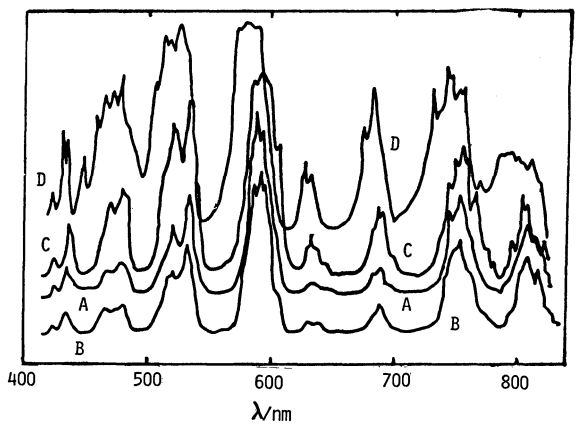

Fig. 5. Diffuse reflectance spectra of the neodymium-(III) complexes and its chloride hexahydrate. A: $Nd(iPr_2dtp)_3(dma)_2$; B: $Nd(iPr_2dtp)_2(dmf)_2$; C: $Na[(iPr_2dtp)_4]$; D: $NdCl_3 \cdot 6H_2O$.

fore, some relation between the splitting of the peak and the delocalization degree of the P=S double bond of the ligand is to be expected. In the infrared spectra of the dmf adduct, the main, strong peak is found at 766 cm^{-1}, although a small additional one appears at 788 cm^{-1}.

The diffuse reflectance spectra of $Nd(iPr_2dtp)_3(dma)_2$ and of the related compounds are shown in Fig. 5. The general features of the spectra resemble each other; however, all the bands of the R_2dtp-containing complexes, $Na[Nd(iPr_2dtp)_4]$ and $Nd(iPr_2dtp)_3L_2$(where L=dma or dmf), make red shift compared with the corresponding peaks of $NdCl_3 \cdot 6H_2O$. The $Nd(iPr_2dtp)_3(dma)_2$ complex is soluble in chloroform, and the visible absorption spectra of the solution show the maxima which are also found in the reflection spectra of its solid. The absorption maxima are as follows:

808(1.2); 754(0.9_5); 590(1.5); 532, 518(0.9_5, 0.8_2) (concentration of the samples: 8×10^{-3} mol dm^{-3}; figures are shown by λ/nm; log ε in parentheses).

When dma is added to the solution, these peaks make a blue shift; their intensities decrease a little at the same time, and its spectral pattern tends to become the same as that of the $NdCl_3$ dissolved in chloroform containing dma. Although the quantitative study has not yet been completed, the change in the spectra is likely to be due to the displacement of the iPr_2dtp ligand with dma in the solution when the concentration of dma increases.

The ^{1}H-NMR spectra of the title complex and some related compounds are shown in Table 3. The samples were dissolved in chloroform-*d*(about 5 wt%). As is shown in the table, the methyl proton signals of dma or dmf in the complexes appeared in a lower-magnetic-field region compared with those of the respective free amides. This shows that such amide ligands are coordinated to the lanthanoid metal, acting as donors even in a solution.

The authors wish to thank Professor Yoichi Iitaka, The Faculty of Pharmaceutical Sciences, The University of Tokyo, for the collection of the intensity data. They are also greatly obliged to The Shin-Etsu Chemical Co., Ltd., for aiding in this study by presenting the highly pure lanthanoid oxides. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 57430011 from the Ministry of Education, Science and Culture.

(Received January 26, 1983)

The Raman spectra were measured for the complete series of cobalt(III) complexes, $[Co(gly)_x(ox)_y(en)_z]^{(3-x-2y)+}$, where gly, ox, and en denote glycinate, oxalate, and ethylenediamine, respectively, and $x+y+z$ is equal to 3, in aqueous solution in the skeletal vibration region to deduce their structure-spectra relation. The spectra could be classified into four categories: polarized bands in the 610—520 cm^{-1} region due to a totally symmetric stretching vibration mode, depolarized bands in the 520—400 cm^{-1} region due to Co-O and Co-N stretching vibration modes, depolarized bands in the 400—300 cm^{-1} region due to the metal-ligand skeletal bending deformation mode, and polarized bands in the 300—200 cm^{-1} region due to the chelate ring deformation mode. The depolarized bands due to the stretching vibration mode could be used for the differentiation of C_2-*cis* and C_1-*cis* isomers of $[Co(N)_4(O)_2]$ and $[Co(N)_2(O)_4]$ type complexes.

Elucidation of the spectra-structure relations of coordination compounds is of practical importance for the study of their stereochemistry. The Raman spectroscopy in the skeletal vibration region of cobalt(III) complexes has produced several studies on their spectral characteristics,[1–13] which were found to be available for differentiation of some of their geometrical isomers, such as *cis* and *trans* ones of $[Co(a)(b)(NH_3)_4]$,[12] $[Co(a)(b)(en)_2]$,[10] and $[Co(a)(b)(tn)_2]$[13] type complexes, where a and b stand for unidentate ligands and en and tn denote ethylenediamine and trimethylenediamine, respectively.

The present study was attempted to deduce more general information on the relation between geometrical structure and the Raman spectra in the skeletal vibration region of cobalt(III) complexes. A series of $[Co(gly)_x(ox)_y(en)_z]^{(3-x-2y)+}$ complexes, where gly and ox denote glycinate and oxalate and $x+y+z$ is equal to 3, were chosen as a typical example and their Raman spectra were measured in the 610—200 cm^{-1} region in aqueous solution in order to avoid contribution of lattice vibrations observed in the solid state.

Experimental

Complexes. The complete series of $[Co(gly)_x(ox)_y(en)_z]^{(3-x-2y)+}$ complexes were prepared and characterized according to standard literature procedures; $[Co(en)_3]Cl_3\cdot 3H_2O$,[14] $[Co(gly)(en)_2]I_2\cdot H_2O$,[15] $[Co(ox)(en)_2]Cl\cdot H_2O$,[16] C_1-*cis(O)*-$[Co(gly)_2(en)]Cl\cdot 3H_2O$,[17] C_2-*cis(O)*-$[Co(gly)_2(en)]Cl\cdot 0.5H_2O$,[17] *trans(O)*-$[Co(gly)_2(en)]Cl\cdot H_2O$,[18] *mer(N)*-$[Co(gly)(ox)(en)]$,[18] *mer(N)*-$[Co(gly)_3]\cdot 1.5H_2O$,[19] *fac(N)*-$[Co(gly)_3]\cdot H_2O$,[19] *fac(N)*-$[Co(gly)(ox)(en)]$,[18] *trans(N)*-$K[Co(gly)_2(ox)]$,[17] C_2-*cis(N)*-$Na[Co(gly)_2(ox)]$,[17] C_1-*cis(N)*-$Na[Co(gly)_2(ox)]$,[17] $Na[Co(ox)_2(en)]\cdot 2.5H_2O$,[16] $Na_2[Co(gly)(ox)_2]\cdot 2H_2O$,[20,21] and $K_3[Co(ox)_3]\cdot 2H_2O$.[22] $[Co(NH_3)_6]Cl_3$ was also prepared according to the literature procedure.[23]

Measurements. The Raman spectra were recorded on a JASCO Laser Raman Spectrometer, which was constructed specially from a double monochromator, model CT-25, a He-Ne laser, model NEC GLS-8500, and a data processor, model DP-500 as the main components. The sample solution was excited at 632.8 nm and the Raman spectra were calibrated with indene.

Results and Discussion

General Aspect. Raman spectral data of $[Co(gly)_x(ox)_y(en)_z]^{(3-x-2y)+}$ complexes are summarized in Table 1. The Raman spectra of $[Co(NH_3)_6]^{3+}$, $[Co(en)_3]^{3+}$, and $[Co(ox)_3]^{3-}$ shown in Fig. 1 clearly demonstrate that $[Co(en)_3]^{3+}$ and $[Co(ox)_3]^{3-}$ give the same spectral characteristics; a polarized band in the 610—520 cm^{-1} region(depolarization ratio: ≈ 0), two

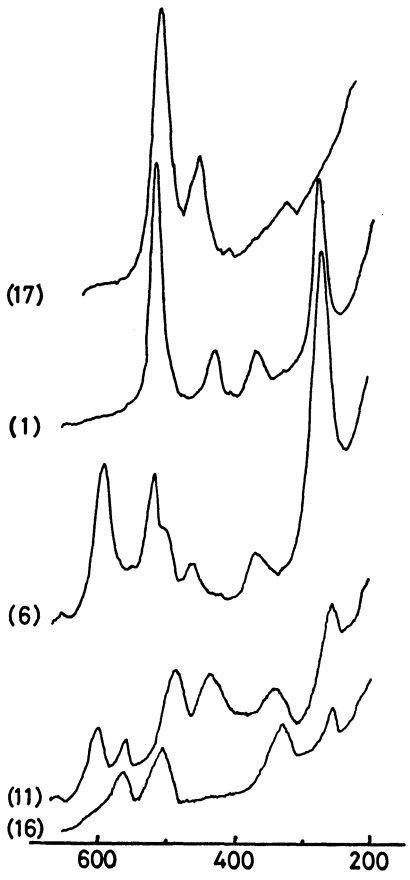

Fig. 1. Raman spectra of $[Co(NH_3)_6]^{3+}$, $[Co(en)_3]^{3+}$, $[Co(ox)_3]^{3-}$, *trans(O)*-$[Co(gly)_2(en)]^+$, and *trans(N)*-$[Co(gly)_2(ox)]^-$. Numbers in parentheses correspond to those in Table 1.

a) Numerical data in the parentheses are for the N-deuterated complexes. b) The following abbreviations were used: s, strong; m, medium; w, weak; vw; very weak; sh, shoulder; p, polarized; dp, depolarized; ν_{ts}, totally symmetric stretching vibration mode; ν, stretching vibration mode, excluding the totally symmetric one; δ_{sbd}, metal-ligand skeletal bending deformation mode; δ_{crd}, chelate ring deformation mode; and L, donor atom(N and/or O). c) Consult the text.

depolarized bands in the 520—400 cm^{-1} and 400—300 cm^{-1} regions(depolarization ratio: $\approx$0.75), and a polarized one in the 300—200 cm^{-1} region(depolarization ratio: 0.12—0.16). Furthermore, it is evident that the Raman bands of $[Co(en)_3]^{3+}$ can well be correlated to those of $[Co(NH_3)_6]^{3+}$ having an O_h symmetry[9] except the polarized one in the 300—200 cm^{-1} region, which relates to the en chelate ring.

It has been pointed out that, based on the depolarization characteristics and the comparison with $[Co(NH_3)_6]^{3+}$, $[Co(en)_3]^{3+}$ has an effective symmetry[9] of O_h for the skeletal vibrations. This simplified treatment can be supported by two depolarized bands in the 520—400 cm^{-1} region of *trans(O)*-$[Co(gly)_2(en)]^+$ and of *trans(N)*-$[Co(gly)_2(ox)]^-$ (*cf.* Fig. 1) having the effective symmetry of D_{4h}(Co–O and Co–N stretching vibration modes(except totally symmetric one): $A_{1g}+B_{1g}$) rather than the true symmetry of C_2. (Polarized bands in the 610—520 cm^{-1} region show a peculiar aspect(*cf.* Table 1) and will be treated separately.) Hence we may expect that, so far as the skeletal vibrations of the octahedral tris(bidentate)cobalt(III) complexes with five-membered chelate rings are concerned, the Raman spectra are treated in terms of the effective symmetry which is mainly specified by arrangement of coordinated atoms around the central metal atom. Accordingly, the polarized band in the 610—520 cm^{-1} region, the depolarized bands in the 520—400 cm^{-1} region, and the depolarized band in the 400—300 cm^{-1} region can be assigned to totally symmetric metal-ligand stretching, Co–O and Co–N stretching, and metal-ligand skeletal bending deformation modes,[1-4,6,8,9] respectively. The polarized band in the 300—200 cm^{-1} region with the depolarization ratio of 0.12—0.16 can be assigned to the chelate ring deformation mode which is totally symmetric.[9,10] The contribution of the totally symmetric stretching character of the metal-ligand to this has been pointed out by Flint and Matthews[24] based on vibronic spectra in the d-d transition region($^1A_{1g}$—$^1T_{1g}(O_h)$) of $[Co(en)_3]^{3+}$.

It is interesting to note that the intensities of the polarized bands of $[Co(ox)_3]^{3-}$, $[Co(gly)(ox)_2]^{2-}$, and *trans(N)*-$[Co(gly)_2(ox)]^-$ decreased when the first absorption band($^1A_{1g}$—$^1T_{1g}(O_h)$) of the complexes is in the proximity of the excitation wavelength (632.8 nm) (*cf.* Table 1). This de-enhancement of the Raman intensities may be due to a sort of anti-resonance Raman effect.[9]

Polarized Bands in the 610—520 cm^{-1} Region.
Figure 2 depicts the spectra-structure relation of $[Co(gly)_x(ox)_y(en)_z]^{(3-x-2y)+}$ complexes in the totally symmetric stretching vibration region. It is noteworthy that *mer(N)*- and *fac(N)*-$[Co(gly)_3]$ show only one Raman band and that the Raman bands of $[Co(en)_3]^{3+}$ and $[Co(ox)_3]^{3-}$ as well as *mer(N)*- and *fac(N)*-$[Co(gly)_3]$ become doublets for $[Co(gly)_x(ox)_y]^{(3-x-2y)+}$, $[Co(gly)_x(en)_z]^{(3-x)+}$, and $[Co(ox)_x(en)_z]^{(3-2y)+}$ and triplets for [Co(gly)(ox)(en)] irrespective of the geometry. These splittings of the Raman bands may be caused by relaxation of the selection rule with respect to the effective symmetry of the complexes. It is evident from Table 1 that the coordinated en, ox, and gly ligands have characteristic bands in the regions 542—521 cm^{-1}, 570—564 cm^{-1}, and 608—584 cm^{-1}, respectively. Inconsistency in metal-coordinated atom bond strengths and totally symmetric stretching frequencies of coordinated en relative to gly and ox reflects the contribution of rigidity of the framework of the chelate ring. These results demonstrate that the coordinated bidentate ligands with five-membered chelate rings behave, for the totally symmetric stretching vibration, as a unit, owing to restrictions by the chelate rings. The Raman bands in this region are characteristic of coordinated ligands for the tris(bidentate)cobalt(III) complexes with five-membered chelate rings.

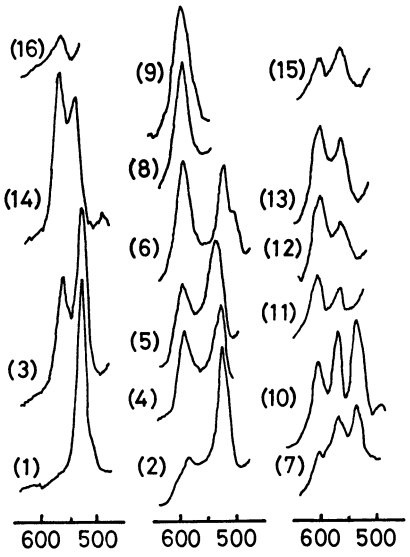

Fig. 2. Raman spectra of $[Co(gly)_x(ox)_y(en)_z]^{(3-x-2y)+}$ complexes in the totally symmetric stretching vibration region. Numbers in parentheses correspond to those in Table 1.

Depolarized Bands in the 520—400 cm^{-1} Region.
Unlike those in the 610—520 cm^{-1} region, the Raman bands in this region show some unique aspects: the Co–N stretching mode lies as a general rule in the region below 460 cm^{-1} and the Co–O stretching mode above 470 cm^{-1}, respectively,[25] and numbers of the Raman bands reflect the effective symmetry of $[Co(gly)_x(ox)_y(en)_z]^{(3-x-2y)+}$ complexes. $[Co(N)_6]$ and $[Co(O)_6]$ type complexes with the effective symmetry of O_h give only one band, which becomes a doublet for *trans(O)*-$[Co(N)_4(O)_2]$ and *trans(N)*-$[Co(N)_2(O)_4]$ complexes with that of D_{4h}. The doublet for $[Co(N)_5(O)]$ and $[Co(N)(O)_5]$ type complexes, $[Co(gly)(en)_2]^{2+}$ and $[Co(gly)(ox)_2]^{2-}$, with that of C_{4v}(Co–O and Co–N stretching vibration modes(except totally symmetric one): A_1+B_1+E) may be explained by correlation of the E mode to the Raman inactive E_u mode of the D_{4h} symmetry, whereas the A_1 and B_1 modes of the former correspond to the A_{1g} and B_{1g} modes of the latter, respectively. Thus the E mode may be almost undetectable[12] in the Raman spectra of the complexes with the effective symmetry of C_{4v}.

Figures 3 and 4 show the spectra-structure relations of $[Co(N)_4(O)_2]$ and $[Co(N)_2(O)_4]$ type complexes and

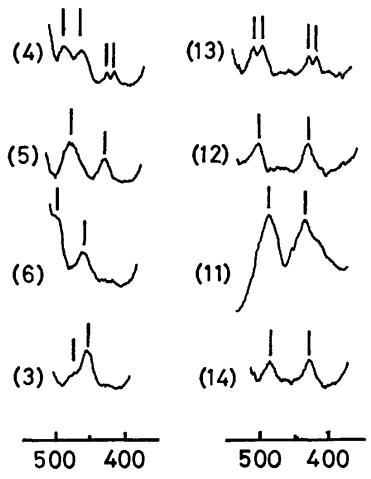

Fig. 3. Raman spectra of *trans*, C_2-*cis*, and C_1-*cis* isomers of $[Co(gly)_2(en)]^+$ and $[Co(gly)_2(ox)]^-$ and of $[Co(ox)(en)_2]^+$ and $[Co(ox)_2(en)]^-$ in the Co–O and Co–N stretching vibration region. Numbers in parentheses correspond to those in Table 1.

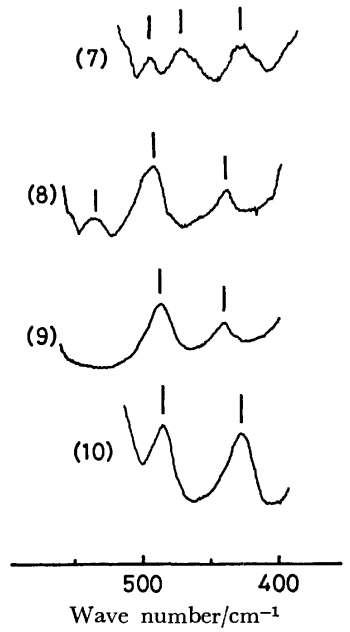

Fig. 4. Raman spectra of *mer* and *fac* isomers of $[Co(gly)_3]$ and $[Co(gly)(ox)(en)]$ in the Co–O and Co–N stretching vibration region. Numbers in parentheses correspond to those in Table 1.

of $[Co(N)_3(O)_3]$ type complexes, respectively. C_2-*cis(O)* and C_2-*cis(N)* isomers of $[Co(gly)_2(en)]^+$ and $[Co(gly)_2(ox)]^-$ give doublets, which however split into quartets on going from the C_2-*cis* to C_1-*cis* isomers. Here, the configuration of the chelate rings comes to play a role in the effective symmetry because both of the isomers belong to C_{2v} symmetry for the arrangement of the coordinated atoms. $[Co(ox)(en)_2]^+$ and $[Co(ox)_2(en)]^-$ with the effective symmetry of C_{2v} also give doublet in this region. Analogously, the *fac* isomers of $[Co(gly)_3]$ and $[Co(gly)(ox)(en)]$ with the higher effective symmetry give doublets, whereas the *mer* isomers with the lower symmetry give triplets. In the latter isomers, the middle bands of 476 cm^{-1} for *mer(N)*-$[Co(gly)(ox)(en)]$ and 496 cm^{-1} for *mer(N)*-$[Co(gly)_3]$ (*cf.* Table 1) may have a largely Co–O stretching character.

These results, together with considerations on numbers of the Raman active stretching vibrations for $[Co(a)_{6-n}(b)_n]$ and $[Co(AB)_3]$ type complexes, reveal that the effective symmetry of the $[Co(gly)_x(ox)_y(en)_z]^{(3-x-2y)+}$ complexes is higher than the true symmetry. In fact, the *fac(N)* isomers of $[Co(gly)_3]$ and $[Co(gly)(ox)(en)]$ can be treated uniformly as *fac(N)*-$[Co(N)_3(O)_3]$ type with the effective symmetry of C_{3v} and likewise the *mer(N)* isomers can be treated as having C_{2v}-type effective symmetry.

In summary, the Raman bands in this region are characteristic of the geometry of the $[Co(N)_4(O)_2]$ and $[Co(N)_2(O)_4]$ type complexes and of $[Co(N)_3(O)_3]$ type complexes. They can be used for the differentiation of the *fac* and *mer* isomers of the latter and of the C_2-*cis* and C_1-*cis* isomers of the former. This is considered to be of practical importance, although the differentiation by comparison of the d-d transition energies and the molar absorptivities in the first ($^1A_{1g}$—$^1T_{1g}$-(O_h)) and the second absorption band($^1A_{1g}$—$^2T_{1g}$-(O_h)) may also be possible.[17]

Depolarized Bands in the 400—300 cm^{-1} Region. The Raman spectra in the metal-ligand skeletal bending deformation region show only one band, except for $[Co(ox)_x(en)_z]^{(3-2y)+}$, which gives a major band accompanied with a very weak one in its lower wavelength side. Numbers of the Raman bands depend neither on the composition nor on the geometry of the complexes, indicating that N–Co–N, N–Co–O, and O–Co–O bending deformation modes are mostly degenerate. However, correlation was noticed between an increase in the Raman shift and an increase in the d-d transition energies in the first and the second absorption bands, as is readily deduced from Table 1. This means that the bending deformation mode reflects coordinate bond strength.

Polarized Bands in the 300—200 cm^{-1} Region. A polarized Raman band is observed in this region for $[Co(en)_3]^{3+}$, $[Co(ox)_3]^{3-}$, and $[Co(gly)_3]$, and for all the mixed-ligand complexes as well. Hence, the totally symmetric chelate ring deformation modes of en, ox, and gly are considered to be degenerate. The same correlation as that found in the skeletal bending deformation was noticed for the chelate ring deformation.

Studies on Lanthanoids-Antimony-Chalcogenides. I. Synthesis and Crystal Data of Three New Lanthanum Antimony Chalcogenides

Jin-zhang GAO,† Izumi NAKAI, and Kozo NAGASHIMA*

Department of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 305

(Received February 2, 1983)

Three new La-Sb chalcogenides were synthesized by hydrothermal or evacuated silica tube methods. (1) $LaSbO_2S_2$: a bright-red needle crystal; crystal system, hexagonal; space group, $P6_3/m$; lattice constants, $a=14.954(3)$, $c=3.898(2)$ Å, and $Z=6$. (2) $La_6Sb_8S_{21}$: a blackish-red columnar crystal with metallic luster, orthorhombic, $P222$, $a=14.317(2)$, $b=15.239(4)$, $c=8.685(1)$ Å, and $Z=2$. (3) $La_3Sb_3S_{10}$: a bright-red plate-like crystal, monoclinic, $a=13.209(6)$, $b=14.229(6)$, $c=5.583(1)$ Å, $\beta=94.54(3)°$, and $Z=2$.

There has been much attention in rare earth chalcogenides because of their interesting electric, magnetic, and optical properties. However, so far very few investigations have been made concerning the preparation of single crystals of rare earth antimony chalcogenides. Lemoine *et al.*,[1] reported the synthesis and the structure analysis of $Eu_3Sb_4S_9$, yet it has been mentioned that the oxidation number of europium is +2, not the general oxidation number for rare-earth elements. The only well characterized rare-earth antimony sulfide containing Ln^{3+} is $Pr_8Sb_2S_{15}$[2].

This work has been done as a part of our study on the crystal chemistry of sulfosalt compounds having a general chemical formula $A_mB_nX_p$, where A=metal, B=As,Sb, and X=O,S,Se.[3,4] These compounds have been characterized by the chemical nature of the element A.[5] The purpose of this study is to elucidate the crystal chemical behavior of rare-earth elements in sulfosalt compounds. This paper reports the methods of preparation of single crystals and the crystal data of three new lanthanum antimony chalcogenides.

Experimental

Two methods of syntheses were employed for the preparation of the three compounds. One is an evacuated silica tube method. A double silica tube method was adopted to protect against explosion, because a silica tube was easily attacked at high temperature. The other is a hydrothermal method, which was applied to the single crystal growth of $LaSbO_2S_2$. The reagents used were lanthanum metal chips (99.9%), sulfur powder (99.99%), and antimony trisulfide (99.99%).

Syntheses of La-Sb-S ternary compounds by the silica tube method were carried out as follows. Weighed quantities of La, Sb, S, and Sb_2S_3 were mixed and placed in a double silica tube, and then sealed under vacuum (less than 10^{-3} Torr, 1 Torr≈133.322 Pa). The reaction tube was placed in an electric furnace. The synthesis was usually continued over a week, in which the tube was first maintained at the reaction temperature of 1200 °C or 1000 °C, then kept at 1000 °C or 900 °C for three days at least, and finally the temperature was slowly lowered to room temperature.

The hydrothermal synthesis was made using a stellite bomb of the test-tube type. A starting material was a polycrystalline material obtained by the silica tube method. About 70 mg of the starting material and 0.07 ml of solvent (H_2O, 3%NaOH or 5%Na_2S) were sealed in a gold tube (length: 35 mm, inner diameter: 2.8 mm). Conditions employed were: the temperature range 350—500 °C; the pressure 800—1000 kg/cm² for 5—10 d.

The products were examined by the X-ray powder diffraction method, Weissenberg and precession cameras, SEM-XMA, and an automatic four-circle diffractometer. Chemical analyses were made by an electron microprobe analyzer using an operating voltage of 20 kV and a probe current of 0.015 μA. Synthetic Sb_2S_3 and La_2TiO_5 were used as the standards.

Results and Discussion

Three new compounds have been obtained from our synthesis. Their chemical compositions are given in Table 1.

Characterization of Crystals. $LaSbO_2S_2$ is a needle crystal and bright-red in color. The maximum size of the single crystal is $0.3\times0.03\times0.03$ mm³. The presence of oxygen in $LaSbO_2S_2$ was determined by the appearance of Sb–O absorption in the IR spectra (see *Infrared Spectroscopy*). The starting material did not contain any oxygen. The source of oxygen is considered to be the silica tube used as a container, since it was easily attacked at high temperature. The melting point of $LaSbO_2S_2$ is higher than 1000 °C.

$La_6Sb_8S_{21}$ is a columnar crystal of $0.4\times0.1\times0.05$ mm³ in maximum size. It is blackish-red with metallic luster. Thermal analysis showed that it melted incongruently at 985 °C into $La_3Sb_3S_{10}$ and liquid Sb_2S_3. The crystal is stable in air at room temperature and dissolved in diluted HNO_3 solution.

$La_3Sb_3S_{10}$ is a plate-like crystal of $0.3\times0.3\times0.01$ mm³. The crystal is bright-red and transparent. The melting point is higher than 1000 °C. Unfortunately,

Table 1. Electron microprobe chemical analysis of the three compounds

	$LaSbO_2S_2$		$La_6Sb_8S_{21}$		$La_3Sb_3S_{10}$	
	wt%	Atomic ratio	wt%	Atomic ratio	wt%	Atomic ratio

Total	97.71		95.28		99.79	

† On leave from Department of Chemistry, Northwestern Teachers College, Lanchow, China.

the chemical formula of $La_3Sb_3S_{10}$ remains in question. The formula appears not to hold the electrical neutrality, if La and Sb are considered to be trivalant and S is divalent. Moreover, as mentioned later in this paper, $La_3Sb_3S_{10}$ has a superstructure. The limited amount of the specimen available precluded a precise wet chemical analysis. At the present stage, it is difficult to conclude whether it is $La_3^{3+}Sb_3^{3+}S_8(S_2)^{2-}$, or a mixed valence compound $La_3^{3+}Sb_2^{3+}Sb^{5+}S_{10}$ or a nonstoichiometric compound from the electron microprobe data.

Conditions of Formation. The experimental results of the silica tube method are summarized in Table 2. The purpose of maintaining the tube at the growth temperature is to obtain large crystals. However, in the case of $LaSbO_2S_2$, the crystal growth rate was slow and only polycrystalline materials were obtained. The results show that the appearance of a phase largely depends upon the temperature, but not on the ratio of the starting materials. For example, we could not obtain $La_3Sb_3S_{10}$ from the synthesis under conditions of the reaction temperature 1100 °C and the growth temperature 900 °C. Contrariwise, when the reaction temperature was 1200 °C and the growth temperature was 1000 °C, the crystals of $La_6Sb_8S_{21}$

were not observed.

The results of hydrothermal experiments are given in Table 3. Single crystals of $LaSbO_2S_2$ have been obtained from the synthesis. $La_6Sb_8S_{21}$ and $La_3Sb_3S_{10}$ were found to be unstable under the hydrothermal conditions. Three kinds of liquids, *i.e.* H_2O, 3% NaOH, 5% Na_2S solutions, were examined as solvents. In the case of 3% NaOH or 5% Na_2S solutions, only La_2O_3 and Sb_2S_3 were observed as the products.

Crystallographic Data. Crystallographic data for the three compounds are summarized in Table 4. The crystal systems and space groups were determined by Weissenberg and precession photographs. X-Ray diffraction spots of $La_3Sb_3S_{10}$ were very diffuse, probably due to the thermal strain and very thin thickness of the crystal. Oscillation photographs (rotation axis =c) exhibited very weak super structure reflections with c=3c'. However, the super lattice could not be determined because of the diffuse nature and the weakness of the diffraction spot intensities. The average lattice is given in Table 4.

Unit cell dimensions were first determined from the photographs. The final cell parameters were calculated by a least-squares treatment of 2θ values centered automatically on the automatic four-circle diffractometer using monochromated Mo $K\alpha$ radiation (λ=0.70926Å). X-Ray powder diffraction data were obtained with the Gandolfi camera using Ni filtered Cu $K\alpha$ radiation and are given in Table 5.

Morphology of the single crystal of $LaSbO_2S_2$ is a hexagonal column elongated along c axis. $La_6Sb_8S_{21}$ is a plate crystal having well developed (010) faces. The elongation axis is c. $La_3Sb_3S_{10}$ is a very thin plate with well developed (100) faces and the elongation axis is c.

Infrared Spectroscopy. IR spectra were measured by the conventional KBr method in the region from 4000 to 250 cm^{-1} to examine the absorption bands of H_2O, OH, and Sb–O bonds. Figure 1-(1) shows the spectra of the three compounds in the region from 4000 to 2900 cm^{-1}, in which these spectra indicate the absence of any hydroxide ion or water of hydration. Figure 1-(2) shows the spectra of the three compounds and Sb_2O_3 for comparison. Two rather strong absorption bands at 695 and 555cm^{-1} were observed in $LaSbO_2S_2$. These bands are attributed to the Sb–O vibration from analogy with the spectrum of Sb_2O_3. From these results, $LaSbO_2S_2$ is considered to be oxide-sulfide but not to be hydrated sulfide nor sulfate of La and Sb. Both $La_6Sb_8S_{21}$ and $La_3Sb_3S_{10}$ exhibit featureless spectra even in the low wave number regions.

The authors wish to express their thanks to Mr. Ritsuro Miyawaki for his help in the electron microprobe analysis.

Note added in proof: The crystal structure of $LaSbO_2S_2$ has been determined from Patterson and Fourier syntheses using intensity data collected on the four-circle diffractometer. The structure was refined by a full-matrix least-square method to a conventional R of 0.065 for 738 observed reflections. The structure consists of the $[La_3O_6]_\infty$ hexagonal prism and $[Sb_2S_4]_\infty$ double chain. They are parallel to the c-axis and linked each other by the weak La–S bonds.

Enrichment and Determination of Trace Amounts of Iron as the Colored Complex on the Thin Layer of Ion-exchange Resins

Kunio Ohzeki,* Yuhko Satoh, Yoshito Kawamura, and Tomihito Kambara
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received February 28, 1983)

A trace amount of iron was extracted as the complex with 4,7-diphenyl-1,10-phenanthrolinedisulfonic acid from aqueous solution using finely divided anion and cation exchange resins. The mixed resins were collected on a filter paper as the disk of thin layer. The colored complex in the resin phase was determined with the use of a densitometer at 540 nm. The calibration graph was linear over the range 0.1—0.5 μg of iron(II). The relative standard deviation for 0.5 μg of iron(II) in 50 ml of the test solution was 2.1% (n= 5). The method was applied to the trace determination of total iron in water samples.

The concentration procedure is usually required for the spectrophotometric determination of trace amounts of ions in water samples. Although the most popular method is the extraction of colored species into a nonaqueous solvent, the utilization of solid adsorbents is of interest. For example, Wills and Sangster[1] used Amberlite XAD-2 for the extraction of iron(II)–1,10-phenanthroline complex. The complex fixed on the resin was then eluted by a small amount of organic solvent and determined. It was possible to concentrate the iron by a factor greater than 200. Nigo *et al.*[2] used the cation exchanger, Dowex 50W-X4, to collect the iron(II)-complex. The determination was made by the direct measurement of the resin phase absorbance using a 1-mm cell.

The combined use of finely divided anion and cation exchange resins have been reported.[3,4,5] The colored species were collected in the thin layer of mixed resins and determined spectrophotometrically[3,4] or densitometrically.[5] The volume of resin phase is about 0.07 cm^3, and so it is possible to concentrate the colored species in a 50-ml sample solution by a factor greater than 700. In the present paper, the rapid extraction of iron(II)–4,7-diphenyl-1,10-phenanthrolinedisulfonate into the resin phase is studied and the results are applied to the determination of trace amounts of iron in water samples.

Experimental

Reagents. Hydrochloric acid used was of super special grade (SSG reagent, Wako). All other chemicals used were of analytical reagent grade. Deionized redistilled water was used.

Standard stock solutions (1000 ppm) of iron(II) and iron(III) were prepared by dissolving 7.021 g of ammonium iron(II) sulfate hexahydrate and 8.634 g ammonium iron(III) sulfate dodecahydrate, respectively, in 1 dm^3 of water containing hydrochloric acid. The pH of both solutions was around 1.5. Respective working solutions, 10 ppm in iron(II) and iron(III), were prepared fresh daily by dilution with diluted hydrochloric acid solution (pH *ca.* 1.5).

The reagent, 4,7-diphenyl-1,10-phenanthroline (Bathophenanthroline, abbreviated as BP; Dotite), was used as received. A 1 mM (1 M=1 mol dm^{-3}) solution was made by dissolving 33 mg of the reagent in 50 ml of ethanol and then diluting with water to 100 ml.

Disodium salt of 4,7-diphenyl-1,10-phenanthrolinedisulfonic acid (Bathophenanthroline disulfonic acid, Na_2 salt, abbreviated as BPS; Dotite) was used as received. An aqueous 1 mM solution was prepared.

An aqueous 10 w/v% solution of hydroxylammonium chloride was prepared and purified by extracting the impurity iron as the BP complex into isopentyl alcohol.

Sodium acetate was dissolved in water to give 10 w/v% solution. The impurity iron was removed extraction as the BP complex in the presence of purified hydroxylammonium chloride.

Ion-exchange Resin Suspension. The macroreticular type ion-exchangers, Amberlyst 15 and A-27 (Rohm and Haas), were used in RSO_3H and $RN(CH_3)_3Cl$ forms, respectively. The cation exchange resin suspension (CRS) and the anion exchange resin suspension (ARS) were prepared according to the method already reported.[6] The ion-exchange capacities of CRS and ARS were determined by conductometric titration with standard sodium hydroxide and silver nitrate solutions, respectively. The capacities were 11.8 μequiv. ml^{-1} for CRS and 7.00 μequiv. ml^{-1} for ARS. When a 2-ml portion of CRS is mixed with 3 ml of ARS, both resins were almost completely coagulated and quantitatively collected on a filter paper on a holder. For masking any iron present as impurity, 10 ml of 0.01 M EDTA were added to 240 ml of CRS and ARS, respectively.

Apparatus. A Toyo KG-25 filter holder was used with filter paper of No. 5B (Toyo Roshi) for preparing thin layer of the mixed resins by filtration.

The densitometer used was a Shimadzu Chromatoscanner CS-920. Numerical values corresponding to the integrated absorbance were printed out automatically. Experimental conditions were as follows; *i.e.*, wavelength 540 nm, scanparameter, x=24 mm and y=30 mm, linearizer 1. A Shimadzu spectrophotometer UV-240 was also used.

Micropipets (Finnpipett) were used for pipetting out the working solution and hydrochloric acid.

A Corning hot plate, PC-100, was used. The 100-ml beakers containing sample solutions were placed on the hot plate and covered with a 5-dm^3 beaker. Nitrogen gas was introduced in the covering beaker and samples were heated.

All glasswares were immersed overnight in 6 M nitric acid, and then rinsed thoroughly with deionized water.

Procedure. Place a sample solution, containing usually less than 0.5 μg of iron, in a 100-ml beaker. Add 100 μl of 20% hydrochloric acid and 2.0 ml of 10% hydroxylammonium chloride. Heat on the hot plate for 15 min under nitrogen atmosphere, and cool the sample to room temperature. Add 1.0 ml of 1 mM BPS solution and 2.0 ml of sodium acetate solution. Adjust the volume to 50 ml with water. The pH of final solution is 4.5. Allow the mixture to stand for 20 min and then add 2.0 ml of CRS and 3.0 ml of ARS. Stir the mixture for 5 min. Collect the resulting coagulated resins on a filter paper strip placed on the holder by suction. A disk of thin layer, 17 mm in

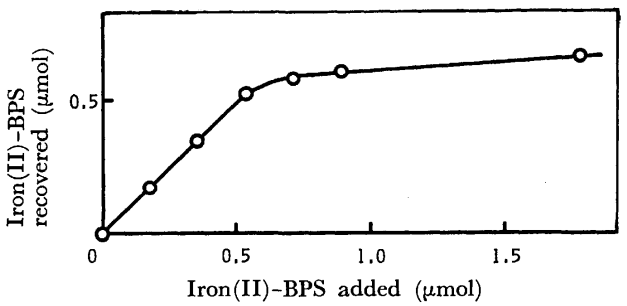

Fig. 1. Recovery of iron(II)–BPS complex on the resin mixture of 3.0 ml of ARS and 2.0 ml of CRS. Test solution 50 ml, ionic strength 0.01.

diameter and about 0.3 mm in thickness, is obtained. Keep the filter strip wet in water for 10 min, and place it on a white plastic plate fixed on a scanning board in the chromatoscanner. Measure the absorbance twice and determine the mean of duplicate values, which coincided each other within less than 0.1%.

The calibration graph was prepared using the iron(II) standard solution, the heating step being omitted. There was no significant difference between the blank values obtained with and without heating step.

Results and Discussion

Masking of Impurity Iron in CRS and ARS. The impurity in hydroxylammonium chloride, as well as in sodium acetate solution, was removed successfully by extraction as iron(II)–BP complex, but the extraction procedure could not be applied to the purification of ion-exchange resins. The use of EDTA was found to be efficient. When EDTA was previously added to ARS and CRS, the formation of iron(II)–BPS complex from the impurity in the resins was masked effectively, while the complex once formed was stable in the presence of EDTA.

Preparation of Thin Layer of Mixed Resins. In the course of 5-min stirring, the iron(II)–BPS complex was fixed on the anion exchange resin and the resin was coagulated with the cation exchanger. The resin mixture was collected on a filter paper by filtration with suction within 5 min. The stable coloration was kept for at least 3 h, when the thin layer was stored in wet in water. The absorption spectrum of the iron(II)–BPS complex was compared with that in the solution. A small shift of the maximum wavelength was observed, *i.e.*, from 533 nm in the solution to 540 nm in the resin phase.

Recovery of Iron(II)–BPS Complex. The extraction of the complex into the resin mixture of 3.0 ml of ARS and 2.0 ml of CRS was examined in the presence of 0.01 M sodium chloride to keep a constant ionic strength. Up to 0.54 μmol, the complex was quantitatively fixed on the mixed resins (Fig. 1). The recovery of 0.5 μg of iron(II) as the BPS complex on the mixed resins was also studied by varying added amounts of BPS from 0.5 to 3.5 μmol. A constant recovery was obtained over the range studied.

Calibration Graph. The least-squares regression equation for iron(II) over the range 0.1—0.5 μg was $y=5.79\times10^4x+2.58\times10^4$, where y is the integrated absorbance of the resin phase, as measured against the filter paper, and x is the amount of iron(II) in μg. The intercept at $x=0$ is due to the background absorbance of the thin layer prepared from the test solution without addition of iron(II). The mean value with the standard deviation was $(2.60\pm0.05)\times10^4$ ($n=5$) for the blank and $(5.48\pm0.03)\times10^4$ ($n=5$) for 0.5 μg of iron(II). Thus, the net value for 0.5 μg of iron(II) was $(2.88\pm0.06)\times10^4$, and the relative standard deviation was 2.1%.

Effect of Copper. As well known, 1,10-phenanthroline and the analogous compounds are selective colorimetric reagents for iron.[7] Among cations likely to be present, only the interference of a large amount of copper is reported. The recovery of 0.5 μg of iron(III) as the iron(II)–BPS complex was examined in the presence of varying amounts of copper(II).

Table 1. Effect of copper(II) on determination of iron(III)[a]

Cu(II) added (μg)	Net value of chromatoscanner absorbance for iron(II)-BPS $\times10^{-4}$	Recovery (%)
0	2.94	100
5	2.95	100
10	2.92	99
20	3.00	102
50	0.66	22

a) Iron(III) taken: 0.5 μg.

Table 2. Determination of total iron in water samples

Sample	Sample amount (ml)	Iron(II) added (μg)	Iron found (μg)	Iron in sample (μg)	Iron in sample (ng ml^{-1})
Tap water					
Sep. 17, 1981	50	0.00	0.20_4	0.20_4	4.1
	50	0.10	0.30_0	0.20_0	4.0
	50	0.20	0.40_1	0.20_1	4.0
Nov. 17, 1981	50	0.00	0.07_6	0.07_6	1.5
	50	0.10	0.18_1	0.08_1	1.6
	50	0.20	0.27_9	0.07_9	1.6
Mineral	5	0.00	0.20_2	0.20_2	40.4
	5	0.10	0.30_4	0.20_4	40.8
	5	0.20	0.39_0	0.19_0	38.0

The recovery was quantitative in the presence of 20 μg of copper (Table 1). In the presence of 50 μg of copper, however, copper(I)–BPS complex is predominantly formed and the recovery of iron was suppressed.

Determination of Total Iron in Water Samples. The total iron in the tap water supplied to our laboratory from the well in our University campus was determined. After the running of water longer than 20 min, the 50-ml portions were taken. The recovery of added amounts of iron(II) was quantitative (Table 2). The iron content in a commercially available mineral water was also determined successfully.

The present method is very sensitive and only a small sample amount is required, which is especially advantageous to the determination of total iron, since the sample is easily heated without contamination from the vessel and atmosphere.

The solvent extraction method[8] requires a 200-ml sample solution and a 4-cm cuvette for the determination of iron in the ppb range as the iron(II)–BP complex. The solvent extraction process using a large volume of sample water is tedious.

Determination of Ethylenediaminetetraacetic Acid and Nitrilotriacetic Acid as Their Iron(III)-Complexes by Reversed Phase High Performance Liquid Chromatography

Akihiro YAMAGUCHI, Allah Rakha RAJPUT,** Kunio OHZEKI,* and Tomihito KAMBARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received March 10, 1983)

The iron(III) complexes with ethylenediaminetetraacetic acid (EDTA, H_4edta) and nitrilotriacetic acid (NTA, H_3nta) were separated by the ion-association reversed phase high performance liquid chromatography. The retention behavior of iron(III)-nta complex on the column (4.6 mm i.d., 25 cm long) packed with ZORBAX-ODS was seriously affected by the pH of eluent composed of phosphate buffer solution containing tetrabutylammonium bromide and acetonitrile. A mixture of edta and nta in a synthetic sample solution containing the commonly present metal ions was converted to the corresponding iron(III) complexes and determined successfully by the present method.

The importance of analysis of naturally occurring and pollutant chelating agents has been claimed[1] and a method was proposed in which the copper(II) complexes of amine-*N*-carboxylic acids, such as EDTA and NTA, were separated by liquid chromatography and detected by atomic absorption spectrometry. The detection sensitivity was enough, but the separation of the chelates on a weak anion exchange resin column was insufficient. Recently, reversed phase high performance liquid chromatography (RPLC) was successfully applied to the separation of edta complexes of bismuth(III), iron(III), and copper(II).[2]

This paper describes a simple RPLC method for determining iron(III)–edta and –nta complexes. The conversion of free and complexed edta and nta to iron(III) complexes is made quantitatively by heating a sample solution in the presence of excess iron(III).[3] The excess iron(III) is removed by a cation exchange resin column and the effluent is directly subjected to the analysis by RPLC.

Experimental

Apparatus. The liquid chromatograph employed was a Shimadzu product, type LC-3A, equipped with a UV-detector, model SPD-2A (195—350 nm), and a data processor Chromatopac C-R1A. A prepacked ODS column (ZORBAX, Du Pont) was consisted of a stainless steel tube, 4.6 mm i.d. and 25 cm long. A Shimadzu spectrophotometer, UV-240, was used for measurements of absorption spectra.

Reagents. All chemicals used were of analytical reagent grade. Dotite reagents, Na_2H_2edta·$2H_2O$ and H_3nta were used. A 10^{-2} M (1 M = 1 mol dm^{-3}) edta stock solution was prepared by dissolving dried reagent (80 °C, 2 h) in deionized water. A 10^{-2} M nta stock solution was prepared by dissolving dried acid (110 °C, 2 h) in sodium hydroxide solution, the pH of the final solution being around 8. Ammonium iron(III) sulfate dodecahydrate was dissolved into acidified water to give 10^{-2} M solution (pH = 1). Tetrabutylammonium bromide (TBAB) was obtained from Wako Pure Chemicals.

Ion Exchange Resin. The sodium-form Dowex 50W-X8 (100—200 mesh) resin was packed in a column, 1 cm i.d., 23 cm long, in a 1-cm bed.

Preparation of Mobile Phase. To a one-liter flask containing 500 ml of redistilled water, were added 1.15 g of ammonium dihydrogenphosphate, 17.5 ml of 10^{-2} M TBAB solution, 50 ml of acetonitrile, and 6 ml of 1.67 M phosphoric acid. The mixture was filled up to the mark with redistilled water. The pH of the final solution was 2.5. The solution was then filtered through a membrane filter of 0.45 μm pore size.

Procedure. The sample solution containing edta and nta was taken into a 50-ml volumetric flask and 2.5 ml of 0.05 M sulfuric acid, 1 ml of 0.01 M iron(III) solution, and 3 ml of sodium formate were added successively. When the sample contained metal ions, it was heated in the presence of excess iron(III) before the addition of formate. The mixture was made up to the volume with water, the pH of the final solution being around 3. A part of the solution was passed through the sodium-form resin column at the flow rate of 2—3 ml min^{-1}. The first 10-ml portion of effluent was discarded and the next 5-ml portion was collected. The test solution thus obtained was filtered with the use of MILLEX-SR (Millipore Co.) unit with 0.5 μm membrane filter. A 10-μl portion of the filtrate was injected with a 25-μl syringe to the column. Ion-assosiation chromatography with organic modifier was applied. Tetrabutylammonium (TBA) ion was used as the counter ion and acetonitrile as the organic modifier in the phosphate buffer solution. Chromatographic conditions were summerised in Table 1. The wavelength was fixed to the absorption maximum of iron(III)-edta complex.

Table 1. Chromatographic conditions

Column:	ZORBAX-ODS (4.6×250 mm)
Mobile phase:	0.02 M phosphate buffer solution (pH 2.5)
	0.175 mM TBAB
	5% acetonitrile
Flow rate:	1 ml min^{-1}
Pressure:	95 kg cm^{-2}
UV-detection:	255 nm
Injection size:	10 μl

Results and Discussion

Effect of pH. The pH of mobile phase was adjusted with the use of phosphate buffer solution. The retention time and peak area of iron(III)–nta complex were drastically influenced by the pH values,

** Present address: Abbott Laboratories (Pak.) Ltd. P.O. Box No. 7229, Landhi, Karachi, Pakistan.

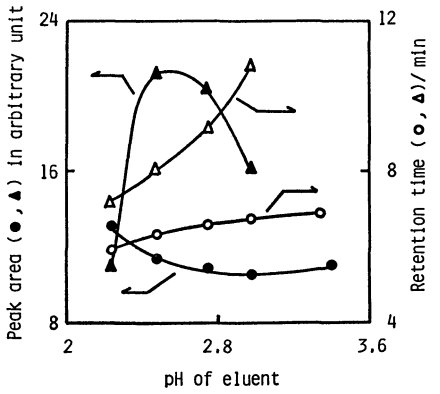

Fig. 1. Effects of pH on retention time (○, △) and peak area (●, ▲).
(○, ●): 20.1 μM iron(III)–edta, (△, ▲): 81.3 μM iron(III)–nta. Conditions except pH of eluent are the same as in Table 1.

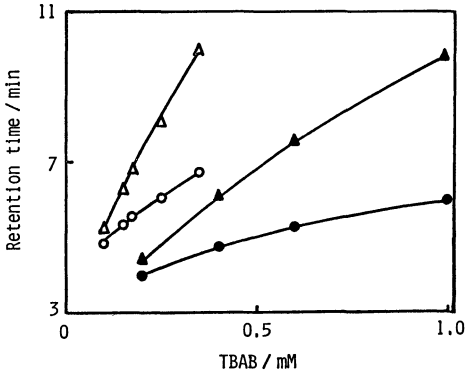

Fig. 2. Effect of concentrations of TBAB and acetonitrile.
Retention time of 20.1 μM iron(III)–edta: (○) 5% acetonitrile, (●) 10% acetonitrile; retention time of 81.3 μM iron(III)–nta: (△) 5% acetonitrile, (▲) 10% acetonitrile. The conditions are the same as in Table 1.

compared with those of iron(III)–edta complex (Fig. 1). The peak width of iron(III)–nta complex broadened with increasing pH, and pH>3.5, the peak was no longer detectable.

Effect of Tetrabutylammonium Ion and Acetonitrile. The retention time of both compounds increased with increasing concentration of TBA ion and decreased with increasing concentration of acetonitrile (Fig. 2). The peak shape of iron(III)–nta complex was also extremely affected by the concentrations of TBA ion and acetonitrile. The distorted peak was observed when the phosphate buffer mobile phase contained 0.35 mM TBA ion and 5% acetonitrile, or 1.0 mM TBA ion and 10% acetonitrile. The combained use of 0.175 mM TBA ion and 5% acetonitrile were pertinent. A typical chromatogram was shown in Fig. 3.

Calibration Curve. The calibration curves of edta and nta were linear over the concentration range 2—20 μM and 6—50 μM, respectively, while the curve for nta did not pass through the origin. The relative standard deviations (n=5) were in the range of 2.0 to 1.7% for edta and 7.3 to 3.1% for nta, respectively.

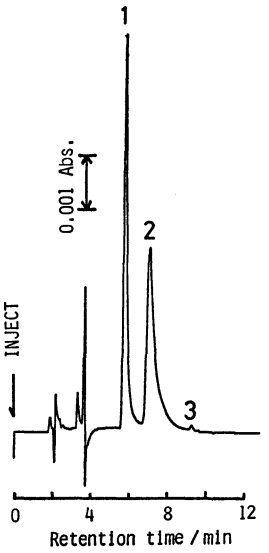

Fig. 3. Typical chromatogram.
(1) 20.1 μM iron(III)–edta, (2) 50.8 μM iron(III)–nta, (3) unknown peak, column: ZORBAX-ODS, Eluent: 0.02 M phosphate buffer solution containing 0.175 mM TBAB and 5% acetonitrile (pH 2.5). Flow rate: 1 ml min^{-1}, temperature: ambient, injection size: 10 μl, UV-detection: 255 nm

TABLE 2. EFFECT OF METAL(II) IONS

[edta]/μM			[nta]/μM

14.1	14.1	0	35.6	35.0	−1.7

Mg, Ca each in 1 mM, Co, Cd, Zn, Ni, and Cu each in 0.1 mM.

Effect of Diverse Ions. The quantitative conversion of free edta and nta or the complexes with metal ions commonly present was carried out by heating sample solution in the presence of excess iron(III).[3] The excess iron(III) and metal ions were removed by the cation exchange resin column, and hence the present method was essentially free from interference of metal ions (Table 2).

Among the anions studied, a high concentration of nitrate ion gave the peak which had almost the same retention time as iron(III)–nta and caused the positive error (Table 3). In the presence of considerable amounts of phosphate, white precipitate formed by the addition of excess iron(III). However, the precipitate being removed by the sodium form resin column, no interference was observed. The anionic surfactant, dodecylbenzenesulfonate is expected to block TBA cation in the mobile phase, but no effect was found.

Absorption Spectra of Iron(III)–edta and –nta. The spectrum of iron(III)–nta complex in the formate buffer solution was different from that in the phosphate buffer solution, and both spectra were different from that in the dilute sulfuric acid solution (Fig. 4). The mixed ligand complexes of iron(III)–nta with formate or phosphate were postulated. The spectra of iron-

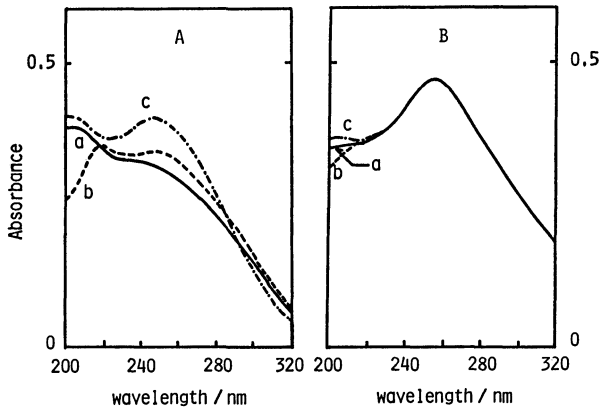

Fig. 4. Absorption spectra of iron(III)–nta and iron(III)–edta.
Spectra of (A) 50 μM iron(III)–nta and (B) 50 μM iron(III)–edta: (a) in dilute sulfuric acid, pH 3.0; (b) in 0.05 M HCOOH–0.01 M HCOONa, pH 2.9; (c) in 0.02 M phosphate buffer solution, pH 2.5.

(III)–edta complex in the varying media coincided each other (Fig. 4). The TBA ion and acetonitrile gave no effect on the absorption spectra. The absorption profiles of iron(III)–edta and –nta in the mobile phase were obtained by plotting each peak area against wavelength, the peak areas having been determined at different wavelength. The profiles were in close agreement with the absorption spectra in the phosphate buffer solution.

Separation of Iron(III)–edta and –nta by Means of an Open Column. Both complexes were found to be retained by the anion exchange resin and eluted with formate buffer solution. The chromatogram obtained on a 1-cm open column packed with sulfate-form Dowex 1-X4 (100—200 mesh) was shown in Fig. 5. The eluate was fractionated and analysed by the present method. Evidently both chelates are negatively charged.

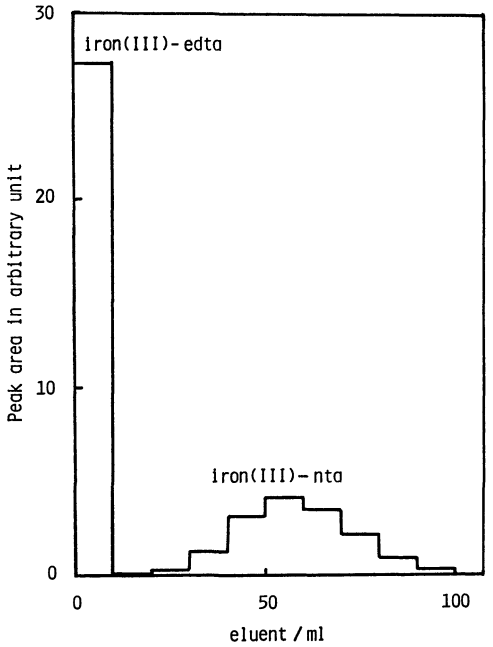

Fig. 5. Separation of iron(III)–nta and –edta by use of a sulfate-form anion exchange resin column.
The mixture of 0.5 μmole iron(III)–edta and 1.0 μmole iron(III)–nta was retained on the column from aqueous solution and eluted by formate buffer solution (0.05 M HCOOH–0.01 M HCOONa).

The Coagulated Ion-exchanger Colorimetry of Cobalt(II)–Thiocyanate Complex

Kin-ya Suzuki, Kunio Ohzeki, and Tomihito Kambara*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received March 14, 1983)

The coagulated ion-exchanger colorimetry was applied to the determination of a trace amount of cobalt(II). Cobalt(II)–thiocyanate complex was fixed by a batch method on the coagulated material composed of fine particles of anion and cation exchangers. The coagulated material was collected on a filter paper and a colored thin layer was prepared. The coloration of the compound was further intensified by dipping the thin layer in a concentrated thiocyanate solution, and the absorbance was determined by a densitometer. The calibration curve showed a good linearity in the range of 1—15 μg of cobalt(II). Iron(III) and copper(II) showed interfering coloration, but these ions were effectively masked by the addition of fluoride and egta, respectively. Zinc(II) gave seriously negative error.

The blue coloration of cobalt(II)–thiocyanate complex is specific for cobalt(II) and is applied to the spot test.[1] The coloration is intensified in the presence of organic solvents such as acetone and ethanol. The increase in the coloration is also observed when the complex is fixed on an anion exchange resin. Therefore, for cobalt(II), the spot test on the resin phase developed by Fujimoto[2] showed higher sensitivity than that for the ordinary solution method. The ion-exchanger colorimetry[3] was applied to the determination of cobalt(II) in which the thiocyanate complex fixed on the anion exchange resin was determined in a 1-mm cell. The combined use of finely divided anion and cation exchange resins was introduced to the colorimetric determinations of chromium(VI),[4] phosphate,[5,6] and hexacyanoferrate(III).[7] The mixed resins fixing the colored complex were collected on a filter paper as a thin layer and the coloration was determined by spectrophotometry[4,5,6] or densitometry.[7]

In the present study, cobalt(II)–thiocyanate complex is rapidly concentrated on the mixed resins and determined by densitometry. The sensitivity of the method and the effects of foreign ions are discussed.

Experimental

Reagents. All chemicals used were of analytical reagent grade.

Standard cobalt(II) solution, 1 mg Co dm^{-3}, was prepared by dissolving cobalt(II) chloride hexahydrate in 1 dm^3 of deionized water containing 10 ml (1 ml = 1 cm^3) of concentrated hydrochloric acid. More dilute standard solutions were prepared as required by diluting the stock solution.

The 0.5 M (1 M = 1 mol dm^{-3}) sodium fluoride and 8 M potassium thiocyanate solutions were prepared.

The dipping aqueous solution was composed of 80 w/v% potassium thiocyanate and 0.2% sodium fluoride.

Ion Exchange Resin Suspensions. The ion-exchangers used were macroreticular type Amberlyst 15 and A-27 (both Rohm and Haas Co.) in RSO_3H and $RN(CH_3)_3Cl$ forms, respectively. The anion exchange resin suspension (ARS) and the cation-exchange resin suspension (CRS) were prepared according to the reported method.[8] The stock suspensions were stored in 5-dm^3 polyethylene bottles, respectively, and were well shaken before being pipetted out. The exchange capacities, as determined by conductometric titration, were 4.40 μequiv. ml^{-1} for ARS and 8.02 μequiv. ml^{-1} for CRS. The resins in 4—6 ml of ARS were almost completely coagulated with those in 2 ml of CRS.[8] The combination of 4 ml of ARS and 2 ml of CRS was used throughout the following experiments.

Apparatus. A Shimadzu Chromatoscanner CS-920 was used for measurement of reflecting absorbance of colored complex in the thin layer of mixed resins. A Shimadzu UV-visible recording spectrophotometer, type UV-240, was used for measuring absorpion spectra. A Hitachi-Horiba pH meter, type F-7_{LC}, was employed. A Toyo KG-25 filter holder was served for the preparation of thin layer of the coagulated material by filtration with suction. Filter papers of No. 5B (Tokyo Roshi) were used. Micropipets were used for pipetting out the standard solution.

Procedure. An aliquot of sample solution containing more than 1 μg of cobalt(II) is placed in a 100-ml beaker. A 2-ml portion of 0.5 M of sodium fluoride is added for masking iron(III) ion in the sample. A 1 ml portion of 8 M of potassium thiocyanate is added. After the volume is adjusted to 40 ml with deionized water, 2 ml of CRS and 4 ml of ARS are added. The mixture is stirred by means of a magnetic stirrer for 10 min. The resulting coagulated material is collected on the filter paper, placed between cylindrical filter holder, by suction. A disk of thin layer of colored resin is formed, which is 17 mm in diameter and about 0.3 mm in thickness. It it then dipped into the dipping solution for 30 min, then the color becomes more intense. The wet filter paper holding the colored resin is placed on a white plastic plate fixed on a scanning board in the densitometer. A light beam (1.2 × 1.2 mm) scans the disk of thin layer in a range of 24 mm wide and 30 mm long and the integrated absorbance is printed out on the chart paper. The measurement is performed using linearizer in mode 1 at 625 nm against the filter paper substrate. All procedures were carried out at room temperature.

Results and Discussion

Absorption Spectra. Absorption spectra of cobalt(II)–thiocyanate complex in the resin phase are shown in Fig. 1. The spectrum against the blank thin layer was the same as that of the complex in acetone having an absorption maximum at 625 nm, which was prepared as described by Snell's.[9]

Effect of Dipping Solution. The coloration in the thin layer of mixed resins faded gradually during the strage in water. Therefore, for the stabilization of color, the resin phase was dipped in the thiocyanate solution together with filter paper before absorption

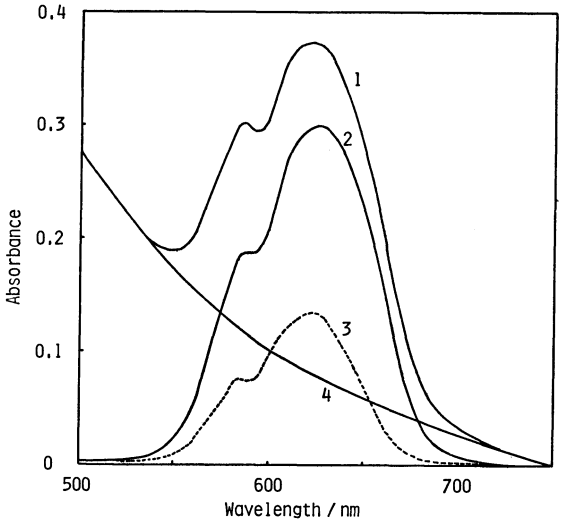

Fig. 1. Absorption spectra of cobalt(II)–thiocyanate complex.

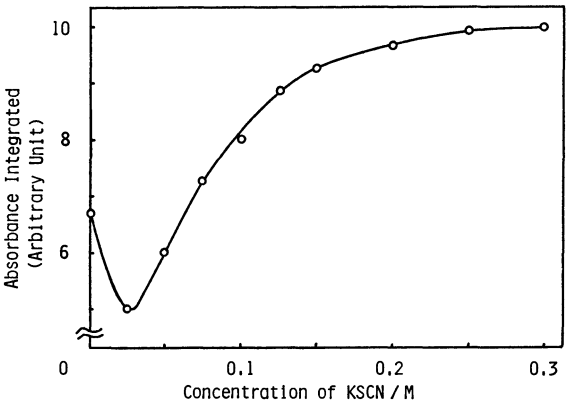

Fig. 2. Recovery of cobalt(II).
Cobalt(II) taken 10 μg; sodium fluoride 1 mmol; sample volume 40 ml; wavelength 625 nm.

measurement. The dipping solution containing 0.2% sodium fluoride was used for masking impurity iron(III). The coloration was intensified with increasing thiocyanate concentration. However, for the concentration over 85%, the solubility of sodium fluoride decreased. Consequently, 80% potassium thiocyanate solution was used throughout the experiments. About 15 min were necessary for obtaining a constant coloration, which was stable at least for 24 h.

Recovery of Cobalt(II). The effect of thiocyanate concentration on the recovery of cobalt(II) was investigated. The amount of cobalt(II) fixed on the mixed resin was first decreased with the addition of thiocyanate and then increased with increasing thiocyanate concentration (Fig. 2). The minimum recovery is probably due to the formation of neutral cobalt(II)–thiocyanate complex. The subsequent experiments were carried out in 0.2 M thiocyanate solution, since the longer filtration time was required with increasing thiocyanate concentration.

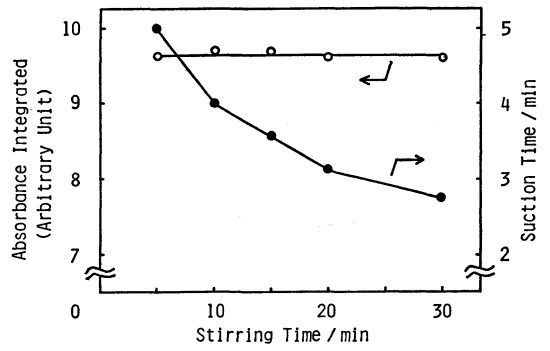

Fig. 3. Effect of stirring time.
Cobalt(II) taken 10 μg; sample volume 40 ml; wavelength 625 nm.

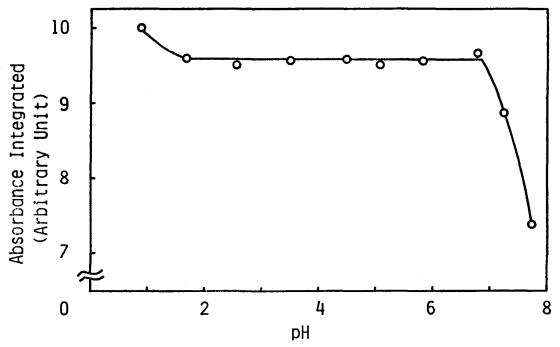

Fig. 4. Effect of pH of sample solution.
Cobalt(II) taken 10 μg; sample volume 40 ml; wavelength 625 nm.

Effect of Stirring Time. During the course of stirring, cobalt(II)–thiocyanate complex is fixed on the anion exchanger in the coagulated mixed resins. The rate of adsorption is very fast and a constant coloration was obserbed in the range of 5 to 30 min studied. On the other hand, the suction time for collecting the mixed resins decreased with increasing stirring time (Fig. 3), since the mixed resins coagulated to form a bulky material during the longer stirring time.

Effect of pH. The effect of pH on the absorbance of complex at 625 nm is shown in Fig. 4. The pH was adjusted by the addition of hydrochloric acid or phosphate buffer solution. A constant absorbance was observed in the range of pH 1.7 to 6.7. The higher value was found at pH 0.9. This is due to the red coloration of iron(III)–thiocyanate complex, the masking of iron(III) by fluoride ion being impossible in this pH region. Above pH 7, cobalt hydroxide being formed, the absorbance decreased.

Calibration Curve. The calibration curve showed a good linearity in the range of 1—15 μg of cobalt(II). The relative standard deviation was 0.89% (n=6) for 10 μg of cobalt(II). The lowest determinable concentration was 25 μg dm^{-3} in 80 ml of sample volume.

Effect of Sample Volume. The effect of sample volume was studied, the thiocyanate concentration being kept to 0.2 M. A constant absorbance was obtained in the range of 30 to 80 ml. For the volume above 80 ml, the filtration time increased seriously. Moreover, the surface of the resulting thin layer did not become uniform and the absorbance decreased.

Effect of Foreign Ions. Most anions studied did

a) All solutions contained HCl in 0.1 M and NaCl in 5%. b) Effluent taken: 25 ml, mean value of duplicate analyses. c) The pH of effluent was adjusted to 4 and 5 μmol of edta were added.

not interfere with the determination of 10 μg of cobalt(II) (Table 1). However, 100-fold hexacyanoferrate(II) gave negative error, since cobalt(II)–hexacyanoferrate(II) is more stable than the thiocyanato complex. The effect of divers cations was summarized in Table 2. Interference by iron(III) was eliminated with sodium fluoride, as stated before. Copper(II) salts, giving a red-brown coloration with thiocyanate, were masked by the addition of egta (3,6-dioxaoctane-1,8-diamine-*N*,*N*,*N*′-*N*′-tetraacetic acid). The 10-fold amount of chromium(III) and nickel(II) gave positive errors, while mercury(II) a negative one. Zinc(II) gave a serious negative error. No interference being found in the solution method, an additional reaction would occur between thiocyanate complexes of cobalt(II) and zinc(II) on the resin phase. Zinc(II) ions were easily removed from the sample solution as their chlorocomplex by use of an anion exchange resin of strong base type.[10]

Analysis of Synthetic Sample Solution. The synthetic sample solutions containing 0.4 μg ml^{-1} of cobalt(II) and 4 μg ml^{-1} of various foreign ions were analyzed (Table 3). An anion exchange resin column was prepared to remove zinc(II). The column (25 cm × 1 cm i.d.) was packed with 1.5 g of Dowex 1-X8 (100—200 mesh) in the chloride form and washed with 50 ml of 2 M hydrochloric acid solution. The sample solution containing 0.1 M hydrochloric acid and 5% sodium chloride was passed through the column. The first 10 ml were discarded and the next 25 ml of effluent were taken and neutralized with sodium hydroxide. Then, the solution was submitted to the analysis according to the above method. The results obtained were satisfactory.

The Formation of Tetrasulfur Dinitride during the Mild Pyrolysis of Tetrasulfur Tetranitride

Yoshiyuki KUDO and Shuichi HAMADA*

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received March 1, 1983)

Tetrasulfur dinitride was formed by the mild pyrolysis of tetrasulfur tetranitride in the presence of a large amount of sulfur. The stoichiometric correlations of the pyrolytic products indicated a step-by-step degradation of the tetrasulfur tetranitride. Differential scanning calorimetry of an interrupted pyrolysis and determinations of the products gave the enthalpy of the formation of gaseous tetrasulfur dinitride as 351 ± 3 kJ mol^{-1}, which was reasonable judging from the bond enengies calculated by Sanderson's method and those deduced from known bond energies. The obtained standard enthalpy of the formation of tetrasulfur tetranitride was 469 ± 1 kJ mol^{-1}, which agreed with the value reported by Barker *et al.*

Heal[1] mentiond that tetrasulfur tetranitride, S_4N_4, decomposed slowly above 120 °C in the presence of a large amount of sulfur, whereas the pure crystals broke down explosively to sulfur and nitrogen upon heating at 190 °C.[1,2] Backens[3] pointed out that tetrasulfur dinitride, S_4N_2, appeared on the mild pyrolysis of tetrasulfur tetranitride mixed with sulfur above 125 °C. Little information on the pyrolysis of tetrasulfur dinitride is available because of its thermal instability.[1,4] In this work, the formation of tetrasulfur dinitride during mild pyrolysis was studied quantitatively. Furthermore, the enthalpy of the formation of tetrasulfur dinitride was estimated and discussed.

Experimental

Materials. The tetrasulfur tetranitride was prepared using the method described by Jolly and Becke-Goehring[5] as follows. Disulfur dichloride vapor was reacted with ammonium chloride pellets at 200 °C for 48 h. The crude product was purified by column chromatography and then recrystallized repeatedly from a benzene solution. Thin-layer chromatograph (TLC) analysis showed that the tetrasulfur tetranitride thus obtained was pure enough to be used in this work. The sulfur was recrystallized several times from a carbon disulfide solution. A homogeneous mixture of sulfur and tetrasulfur tetranitride powder was obtained by a thorough grinding of the compounds at molar ratios ranging from 0.20 to 0.80.

Procedures. Differential thermal analysis (DTA) and thermal gravimetry (TG) were carried out on samples heated at a rate of 3 °C min^{-1} in an argon atmosphere with a Rigaku Denki Thermoflex, model 8002, differential thermal analyzer.

The mixed sample (100—220 mg), placed in a reaction tube, was pyrolyzed at specified temperatures, which were kept constant to ±0.1 °C using a thermostated aluminium block. Volatile pyrolytic products were removed from the reaction tube by the use of a carbon dioxide carrier gas at a flow rate of 30 cm^3 min^{-1} and finally trapped at -30 °C. The trapped product and the solid that remained in the reaction tube were dissolved in small volumes of carbon tetrachloride and used for the identification and determination of the constituent species. The concentrations of tetrasulfur tetranitride, tetrasulfur dinitride, and sulfur in the solution were obtained from a spectrum over the wave-length region from 320 to 480 nm based on the corresponding molar absorption coefficients previously determined (Fig. 1). A freshly prepared pure tetrasulfur dinitride[6] was used to determine its own spectrum. The amount of nitrogen resulting from the decomposition of tetrasulfur tetranitride was estimated with an azotometer after trapping the volatile products.

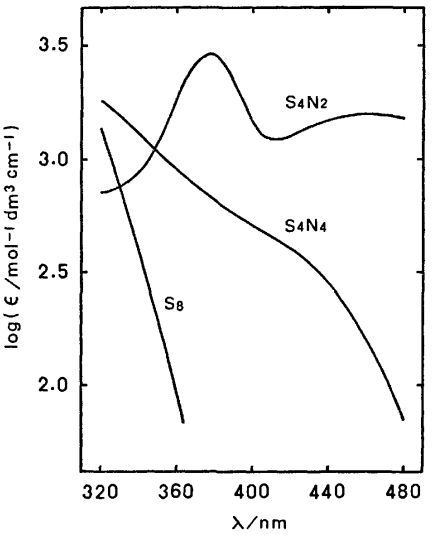

Fig. 1. Absorption spectra of S_4N_2, S_4N_4, and S_8 in CCl_4 solutions.

The heat of decomposition of the sample was measured with a Perkin-Elmer model DSC-1B differential scanning calorimeter at the heating rate of 4 °C min^{-1}. The sample was tightly sealed in an aluminium container under an argon atmosphere, and the equipment was calibrated with indium of a 99.999% purity under the same conditions.

Results

Differential Thermal Analysis of Tetrasulfur Tetranitride Mixd with Sulfur and Its Pyrolytic Products. The pure tetrasulfur tetranitride decomposed abruptly at 190 °C in the argon atmosphere, as is shown in Fig. 2a. The DTA of the mixed sample showed a broad exothermic peak in addition to the endothermic peaks resulting from the fusion of sulfur. The exothermic-peak temperature became lower as the sulfur content increased(Figs. 2b and 2c). The TG also indicated an enhanced decomposition of the mixed sample, while a decrease in the weight of the pure sample resulted from its sublimation.[7] Judging from these results, it is obvious that the pyrolysis of tetrasulfur tetranitride is accelerated in the presence of sulfur.

The tetrasulfur dinitride and the sulfur were con-

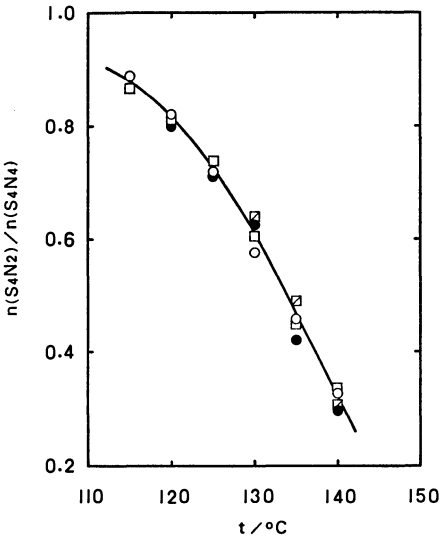

Fig. 3. Molar ratios of produced S_4N_2 at different temperatures.
Molar ratios of original samples, $n(S_4N_4)/n(S_8)$, are 0.65 (▨), 0.50 (●), 0.35 (□), and 0.20 (○), respectively.

firmed as solid products during the pyrolysis of the mixed sample under an atmosphere of either argon or carbon dioxide by IR spectrophotometry[8] and by TLC.[9] Only nitrogen was identified as a gaseous product of the mixed sample by gas chromatography.

Stoichiometry of Products during Mild Pyrolysis of Tetrasulfur Tetraniride. The molar ratios of the pyrolysis products, $n(S_4N_2)/n(S_4N_4)$ and $n(N_2)/n(S_4N_4)$, were determined in order to elucidate the degradation process of tetrasulfur tetranitride mixed with sulfur. The symbols $n(S_4N_2)$ and $n(N_2)$ designate the moles of tetrasulfur dinitride and nitrogen produced, and $n(S_4N_4)$, the moles of pyrolyzed tetrasulfur tetranitride. The amount of the sample used in the experiment did not affect these molar ratios under the specified conditions; for instance, samples ranging from 102 to 221 mg(molar ratio of S_4N_4=0.20), when pyrolyzed at 130 °C for 60 min, gave essentially constant values of $n(S_4N_2)/n(S_4N_4)=0.58\pm0.01$ and $n(N_2)/n(S_4N_4)=1.36\pm0.01$. The values of $n(N_2)/n(S_4N_4)$ were slightly smaller than those calculated from the mass balance because some nitrogen bubbles remained in the molten sample. Reaction times between 40 and 120 min at 125 °C also had little effect on the above molar ratios.

Figure 3 shows that the $n(S_4N_2)/n(S_4N_4)$ ratio remained nearly constant for a given temperature of pyrolysis regardless of the variation in the original composition of the sample, whereas the amount of tetrasulfur dinitride produced increased at high contents of sulfur. The value of $n(S_4N_2)/n(S_4N_4)$ approached unity with a lowering of the temperature of pyrolysis. A decrease in this ratio at higher temperatures arose from the thermal instability of tetrasulfur dinitride.[4] A predominant decomposition of tetrasulfur tetranitride to its elements in the presence of sulfur should yield a value of $n(S_4N_2)/n(S_4N_4)$ much smaller than unity, even at low temperatures of pyrolysis. Based on these observations, the dominant pyrolytic process of tetrasulfur tetranitride mixed with sulfur can be expressed as:[10]

$$S_4N_4 = S_4N_2 + N_2 \text{ (in the presence of sulfur)}, \quad (1)$$

$$S_4N_2 = \frac{1}{2}S_8 + N_2. \quad (2)$$

Enthalpy Change during Pyrolysis of Tetrasulfur Tetranitride. The final products of either pure tetrasulfur tetranitride or of samples containing sulfur were identfied as sulfur and nitrogen when the pyrolysis was carried out in a closed system. Therefore, assuming the temperature dependence of the heat of decomposition to be negligible, the heat of decomposition (q) during the complete pyrolysis yields the standard enthalpy of the formation of tetrasulfur tetranitride, $\Delta H_f^\circ(S_4N_4)$, according to:

$$\Delta H_f^\circ(S_4N_4) = \frac{q}{a} + 2RT + \frac{1}{2}\Delta H_{trans}(S_\mu) + \frac{1}{2}\Delta H_{fus}(S_\lambda), \quad (3)$$

where a are the moles of the tetrasulfur tetranitride, and $\Delta H_{trans}(S_\mu)$ and ΔH_{fus} (S_λ) are the enthalpies of the transition from S_λ to S_μ [13.3 kJ mol^{-1} (as S_8 unit)][11] and of the fusion of S_α [17.0 kJ mol^{-1} (as S_8 unit)][11] respectively. Table 1 shows the results obtained according to Eq. 3 for the decomposition of tetrasulfur tetranitride in a closed system over the temperature range from 115 to 220 °C. The $\Delta H_f^\circ(S_4N_4)$ was estimated to be 469 ± 1 kJ mol^{-1}, which agreed well with the value reported by Barker *et al.*,[12] 460 ±8 kJ mol^{-1}.

When the pyrolysis of the mixed sample is interrupted, Eqs. 1 and 2 show that a moles of tetrasulfur tetranitride will change to $(a-x)$ moles of tetrasulfur dinitride, $(a+x)$ moles of nitrogen, and $x/2$ mol of sulfur (as S_8 units). Assuming that the tetrasulfur dinitride

Table 1. Standard enthalpy of formation of tetrasulfur tetranitride

0.80	8.52	381	467
0.80	9.33	420	470
0.65	8.95	403	470
0.65	10.4	472	474
0.65	11.3	502	464
		Average	469±1

Table 2. Enthalpy of formation of gaseous tetrasulfur dinitride

Molar ratio of S_4N_4	$a=n(S_4N_4)\times10^7$ / mol	$(a-x)=n(S_4N_2)\times10^7$ / mol	$q\times10^3$ / J	$\Delta H_f(S_4N_2)$ / kJ mol^{-1}
0.80	6.64	1.50	249	349
0.80	4.78	1.17	175	360
0.80	8.40	1.65	322	354
0.65	5.44	1.31	201	353
0.65	6.67	1.15	262	343
0.65	14.7	3.80	537	344
			Average	351±3

thus produced is in the gaseous state under the present experimental conditions, the enthalpy of the formation of gaseous tetrasulfur dinitride, $\Delta H_f(S_4N_2)$, is given by:

$$\Delta H_f(S_4N_2) = \left[a\Delta H_f^\circ(S_4N_4) - q - (a+x)RT - \frac{x}{2}\Delta H_{trans}(S_\mu) - \frac{x}{2}\Delta H_{fus}(S_\lambda)\right] \Big/ (a-x), \quad (4)$$

where q is the heat of decomposition observed on the interrupted pyrolysis during the DSC measurement. On reaching≈175 °C, which is the approximate peak temperature of the exothermic change, the sample container was immediately removed from the DSC equipment to stop the pyrolysis, and then the solid quickly dissolved in a small volume of carbon tetrachloride, followed by the spectrophotometric determination of species.

Table 2 shows the results obtained according to Eq. 4. The $\Delta H_f(S_4N_2)$ was estimated to be 351±3 kJ mol^{-1}, which was nearly constant regardless of the difference in the composition of the samples.

Discussion

Tetrasulfur dinitride can be prepared by several processes,[13–15] including the pyrolysis of tetrasulfur tetraimide.[9] Tetrasulfur tetranitride degrades easily to tetrasulfur dinitride in the presence of sulfur, whereas the vapor at a low pressure in the absence of sulfur dissociates to disulfur dinitride, S_2N_2, around 250 °C.[16,17] For example, the degree of decomposition of a sample kept at 130 °C for 60 min increased from 18 to 53% when the molar ratio of sulfur was raised from 0.20 to 0.80, while the $n(S_4N_2)/n(S_4N_4)$ ratio remained constant(0.59—0.61). A step-by-step degradation was confirmed by the quantitative relationship of the pyrolysis products of the mixed sample as a function of the temperature.

Table 3. Bond lengths and bond energies in tetrasulfur dinitride

Bond	Bond length[21] r/pm	Bond energy, E/kJ mol^{-1}	
		Calcd(1)[a]	Deducd(2)
S-S	206.1	262	257[22]
S-N	167.1	250	247[b]
S=N	156.1	339	352[b]
$\Delta H_f[S_4N_2(1)]$/kJ mol^{-1}			361
$\Delta H_f[S_4N_2(2)]$/kJ mol^{-1}			350
$\Delta H_f[S_4N_2$(This work)]/kJ mol^{-1}			351±3

a) Calculated according to Sanderson's method.[20] b) Deduced from the linear correlation between the bond lengths and bond energies of the S≈N bonds.

Using the standard enthalpy of the formation of tetrasulfur tetranitride, $\Delta H_f^\circ(S_4N_4)$, of 469±1 kJ mol^{-1}, the standard enthalpies of the formation of atomic nitrogen and sulfur (473 and 279 kJ mol^{-1} respectively),[18] and the enthalpy of sublimation (89 kJ mol^{-1}),[7] the S–N bond energy (nominal bond order, n=1.5) in tetrasulfur tetranitride was calculated to be 306 kJ mol^{-1}, which is close to the values reported by Barker *et al.* (308 kJ mol^{-1})[12] and by Fleig and Becke-Goehring (301 kJ mol^{-1}).[19]

The calculations described by Sanderson[20] gave the S–S, S–N, and S=N bond energies in the six-membered ring molecule of tetrasulfur dinitride as 262, 250, and 339 kJ mol^{-1} respectively, as is shown in Table 3. Based on these bond energies and the standard enthalpies of the formation of atomic nitrogen and sulfur,[18] the enthalpy of the formation of gaseous tetrasulfur dinitride, $\Delta H_f[S_4N_2$ (1)], was calculated to be 361 kJ mol^{-1}.

The bond energies can also be deduced from other known parameters. The S–S bond length and the S–S–S bond angle (206.1 pm and 102.9°)[21] in tetrasulfur dinitride are very close to those in cyclohexasulfur, S_6, (205.7 pm and 102.2°),[22] so that the S–S bond energy in tetrasulfur dinitride can assumed to be the same as in cyclohexasulfur (257 kJ mol^{-1}).[23] From the linear relationships between the bond lengths and the bond energies of the S≈N bond [158 pm[24] and 335 kJ mol^{-1} [19] for $S_3N_2O_2$ (n=2), 161.6 pm[25,26] and 306 kJ mol^{-1} for S_4N_4 (n=1.5), and 167.4 pm[27,28] and 249 kJ mol^{-1} [19] for $S_4(NH)_4$ (n=1)], the S–N and S=N bond energies in tetrasulfur dinitride were deduced to be 247 and 352 kJ mol^{-1} respectively, as is shown in Table 3. These latter values, combined with the deduced S–S bond energy and the standard enthalpies of the formation of atomic nitrogen and sulfur,[18] gave the enthalpy of the formation of gaseous tetrasulfur dinitride, $\Delta H_f[S_4N_2$ (2)], of 350 kJ mol^{-1}. The corresponding value obtained in this work (351±3 kJ

mol^{-1}) agrees exceedingly well with those calculated above and by Sanderson.[20]

Tetrasulfur dinitride has a melting point of 23.5 °C,[29] and it gives a viscous liquid on melting. The vapor pressure of the latter and the enthalpy of vaporization have not been reported. Heal[1] mentioned that tetrasulfur dinitride evaporated easily at 30—40 °C under a pressure of 670 Pa. Sato[30] showed that the enthalpy of vaporization for a normal liquid, ΔH_{vap}, could be calculated (to within an error of 5%) from the following equation, which was derived from Hildebrand's rule:

$$\frac{\Delta H_{vap}}{T} = 176.8\left(\frac{p}{T}\right)^{-0.119}, \quad (5)$$

where p is the vapor pressure and T, the absolute temperature. Assuming that Eq. 5 is applicable to liquid tetrasulfur dinitride and that its vapor pressure is 670 Pa at 35 °C, the enthalpy of vaporization was calculated to be 50 kJ mol^{-1}. Consequently, the standard enthalpy of the formation of tetrasulfur dinitride, $\Delta H_f^\circ(S_4N_2)$, was estimated to be 301 kJ mol^{-1}, involving an uncertainty caused by the lack of a reliable value of the enthalpy of vaporization.

(Received March 8, 1983)

Five cobalt(III) complexes of [Co(terdentate-$N,S,O)_2$] and [Co(sexidentate-N_2,S_2,O_2)] types were prepared; here terdentate-*N,S,O* denotes *S*-ethyl-L-cysteinate (L-sec) and *S*-benzyl-L-cysteinate (L-sbc), and sexidentate-N_2,S_2,O_2 denotes *N,N'*-trimethylenebis(*S*-methyl-L-cysteinate) (L,L-tbsmc), *S,S'*-ethylenebis(L-cysteinate) (L,L-ebc), and *S,S'*-trimethylenebis(L-cysteinate) (L,L-tbc). Three isomers, *trans(S)*, *trans(N)*, and *trans(O)*, were chromatographically isolated for each of the bis L-sec and L-sbc complexes, while only the *trans(O)* isomer was isolated for each of the L,L-tbsmc, L,L-ebc, and L,L-tbc complexes. These isomers were characterized from their absorption, CD, and ^1H and ^{13}C NMR spectra. The *trans(O)* isomers of the bis type and L,L-tbsmc complexes, which were assigned to a mixture of *R(S),R(S)*, *R(S),S(S)*, and *S(S),S(S)* configurations concerning the coordinated sulfur atoms, showed a similar CD spectral behavior to each other in the whole region. The *trans(O)-R(S),R(S)* L,L-ebc isomer and *trans(O)-S(S),S(S)* L,L-tbc one showed characteristic absorption and CD spectral behavior in the sulfur-to-metal charge transfer band region.

Cobalt(III) complexes with multidentate thioether type ligands such as *S*-methyl-L-cysteine, L-methionine, and their derivatives exhibited an extreme specificity concerning the formation of geometrical isomers.[1–12] The causes for the specificity were mostly related to the stereochemical property of the coordinated sulfur atoms of the thioether ligands.[8,9,11] The stereochemical behavior of the chiral sulfur donor atoms was reflected in the CD spectra of the complexes.[5,8,11] However, it is difficult to specify directly the contribution due to the chiral sulfur donor atoms to the CD spectra of the complexes, because of the overlap with the CD contribution due to other optically active sources in the complexes and an apprehension of sulfur inversion.[7,9] The present work was attempted to investigate the contribution of the chiral sulfur donor atoms of the thioether ligands such as *S*-alkyl-L-cysteine and its derivatives to the CD spectra of the cobalt(III) complexes, especially in the sulfur-to-metal charge transfer band region.

Cobalt(III) complexes with thioether type terdentate-*N,S,O* ligands, $[Co(L\text{-sec})_2]^+$ and $[Co(L\text{-sbc})_2]^+$, were prepared and chromatographically separated into three geometrical isomers: *trans(S)*, *trans(N)*, and *trans(O)*. For cobalt(III) complexes with a thioether type sexidentate-N_2,S_2,O_2 ligand, $[Co(L,L\text{-tbsmc})]^+$, where two nitrogen donor atoms were bridged by trimethylene (*N,N*-bridge), and $[Co(L,L\text{-ebc})]^+$ and $[Co(L,L\text{-tbc})]^+$, where two sulfur donor atoms were bridged by ethylene and trimethylene (*S,S*-bridge), only *trans(O)* isomers were selectively obtained. All isomers were characterized from their absorption and CD spectra in comparison with those of the three isomers of bis(*S*-methyl-L-cysteinato)cobalt(III) complex, $[Co(L\text{-smc})_2]^+$,[10] and the configurations of the coordinated sulfur atoms of the isomers were suggested on the basis of the ^1H and ^{13}C NMR spectra. The CD spectral change due to the substitution of the *S*-alkyl group in the L-terdentate-*N,S,O* ligands was investigated for each of the three isomers of the bis type complexes. The CD spectral differences among the *trans(O)* isomers of the bis type, the *N,N*-bridge and the *S,S*-bridge complexes are discussed in relation to the configurations of the chiral sulfur donor atoms of the thioether ligands.

Experimental

Preparation of Ligands. *1)*: *S*-Ethyl-L-cysteine was prepared from L-cysteine and ethyl iodide according to the method of Frankel *et al.*[13] Found: C, 40.18; H, 7.39; N, 9.44%. Calcd for L-Hsec = $C_5H_{11}NO_2S$: C, 40.24; H, 7.43; N, 9.38%.

2): *N,N'*-Trimethylenebis(*S*-methyl-L-cysteine) was prepared by the same procedure as that for *N,N'*-ethylenebis(*S*-methyl-L-cysteine),[9] using 1,3-dibromopropane instead of 1,2-dibromoethane. Found: C, 39.29; H, 7.07; N, 8.37%. Calcd for L,L-H_2tbsmc·1.5H_2O = $C_{11}H_{22}N_2O_4S_2$·1.5H_2O: C, 39.15; H, 7.46; N, 8.30%.

3): *S,S'*-Ethylenebis(L-cysteine) was prepared from L-cysteine and 1,2-dibromoethane according to the method of Magee *et al.*[2] Found: C, 35.72; H, 5.96; N, 10.47%. Calcd for L,L-H_2ebc = $C_8H_{16}N_2O_4S_2$: C, 35.80; H, 6.01; N, 10.43%.

4): *S,S'*-Trimethylenebis(L-cysteine) was prepared by the same procedure as in 3), using 1,3-dibromopropane instead of 1,2-dibromoethane. Found: C, 38.04; H, 6.35; N, 9.73%. Calcd for L,L-H_2tbc = $C_9H_{18}N_2O_4S_2$: C, 38.28; H, 6.42; N, 9.92%.

Preparation of Complexes. *5) Bis(S-methyl-L-cysteinato)cobalt(III) Perchlorate*: $[Co(L\text{-}smc)_2]ClO_4$. This complex was prepared and separated into three geometrical isomers: *trans(S)*, *trans(N)*, and *trans(O)*, by the method described in a previous paper.[10]

6) Bis(S-ethyl-L-cysteinato)cobalt(III) Bromide: $[Co(L\text{-}sec)_2]Br$. This complex was prepared by the same procedure as that for $[Co(L\text{-}smc)_2]ClO_4$ described in 5), using L-Hsec instead of L-Hsmc. The reaction mixture was poured onto a column (3 cm × 50 cm) containing Dowex 50W-X8 resin (200—400 mesh, NH_4^+ form). After sweeping the column with water, the adsorbed band was eluted with 0.3 mol dm^{-3} aqueous solution of NH_4Br. Three bands: violet (A-1), red (A-2), and blue-violet (A-3), were eluted in this order. Their absorption and CD spectra of the fractions showed that A-1 contained the *trans(S)* isomer, A-2 the *trans(O)* one, and A-3 the *trans(N)* one. The formation ratio of the isomers, *trans(S)* : *trans(O)* : *trans(N)*, was about 3 : 2 : 1. The three eluates were separately concentrated to a small volume in a rotary evaporator. The deposit, NH_4Br, was filtered off and to each of the filtrates was

added a large amount of ethanol. The crude isomers, A-1, A-2, and A-3, were recrystallized from as little water as possible by cooling in an ice bath after adding an appropriate amount of ethanol. Found for *trans(S)* isomer (A-1): C, 27.57; H, 4.57; N, 6.59%. Found for *trans(O)* isomer (A-2): C, 27.33; H, 4.40; N, 6.60%. Calcd for $[Co(L\text{-sec})_2]Br = CoC_{10}H_{20}N_2O_4S_2Br$: C, 27.59; H, 4.63; N, 6.43%. Found for *trans(N)* isomer (A-3): C, 26.44; H, 4.84; N, 6.17%. Calcd for $[Co(L\text{-sec})_2]Br \cdot H_2O$: C, 26.50; H, 4.89; N, 6.18%.

7) Bis(S-benzyl-L-cysteinato)cobalt(III) Chloride: *[Co(L-sbc)$_2$]Cl*. To a solution of L-Hsbc (5.0 g) in 400 cm^3 of hot water–ethanol (1 : 1.4) mixture were added a solution of $Co(CH_3COO)_2 \cdot 4H_2O$ (4.0 g) in 60 cm^3 of water and lead dioxide (10 g). The mixture was stirred at 65 °C for 10 min, whereupon the solution became violet. The reaction mixture was cooled to room temperature and filtered to remove insoluble materials. The filtrate was concentrated to *ca.* 200 cm^3 in a rotary evaporator and then poured onto a column (4 cm × 100 cm) containing SP-Sephadex C-25 resin (Na^+ form). After sweeping the column with water, the adsorbed band was eluted with 0.03 mol dm^{-3} aqueous solution of NaCl. Three bands: red-violet (B-1), violet (B-2), and dark violet (B-3), were eluted in this order. The absorption and CD spectra of the fractions showed that B-1 contained the *trans(O)* isomer, B-2 the *trans(S)* one, and B-3 the *trans(N)* one. The formation ratio of the isomers, *trans(S)* : *trans(O)* : *trans(N)*, was about 6 : 3 : 1. The three eluates were separately concentrated to a small volume in a rotary evaporator. To each solution was added a large amount of ethanol. The deposit, NaCl, was filtered off and the filtrates were again separately concentrated almost to dryness in a rotary evaporator. The resultant crystals of the three isomers, B-1, B-2, and B-3, were collected by filtration and washed with acetone and ether, and then dried in a vacuum desiccator. Found for *trans(O)* isomer (B-1): C, 45.42; H, 4.63; N, 5.38%. Calcd for $[Co(L\text{-sbc})_2]Cl \cdot 0.5H_2O = CoC_{20}H_{24}N_2O_4S_2Cl \cdot 0.5H_2O$: C, 45.85; H, 4.81; N, 5.35%. Found for *trans(S)* isomer (B-2): C, 40.07; H, 4.46; N, 5.02%. Calcd for $[Co(L\text{-sbc})_2]Cl \cdot H_2O \cdot NaCl$: C, 40.62; H, 4.43; N, 4.74%. Found for *trans(N)* isomer (B-3): C, 44.03; H, 4.90; N, 5.24%. Calcd for $[Co(L\text{-sbc})_2]Cl \cdot 1.5H_2O$: C, 44.32; H, 5.02; N, 5.17%.

8) N,N'-Ethylenebis(S-methyl-L-cysteinato)cobalt(III) Perchlorate: *[Co(L,L-ebsmc)]ClO$_4$*. This complex was prepared by the method described in a previous paper,[9] and only *trans(O)* isomer was isolated.

9) N,N'-Trimethylenebis(S-methyl-L-cysteinato)cobalt(III) Perchlorate: *[Co(L,L-tbsmc)]ClO$_4$*. This complex was prepared by the same procedure as that for $[Co(L,L\text{-ebsmc})]ClO_4$ described in 8), using L,L-H_2tbsmc instead of L,L-H_2ebsmc. The reaction mixture was filtered to remove the excess of lead dioxide. The filtrate was poured onto a column (3 cm × 35 cm) containing Dowex 50W-X8 resin (200—400 mesh, Na^+ form). After sweeping the column with water, the adsorbed band was eluted with 0.2 mol dm^{-3} aqueous solution of $NaClO_4$. Two bands, pink-violet and violet, were eluted in this order. It was found, from their absorption and CD spectra of the fractions, that the earlier eluate contained the *trans(S)* isomer and the later eluate the *trans(O)* one. The formation ratio of the isomers, *trans(S)* : *trans(O)*, was about 3 : 7. The two eluates were separately concentrated to a small volume in a rotary evaporator below 30 °C and the deposit, NaCl, was filtered off. To each of the filtrates was added an appropriate amount of ethanol and then kept in a refrigerator. Dark-red crystals appeared for each of the filtrates. The absorption and CD spectra showed that both crystals were *trans(O)* isomer. Namely, the *trans(S)* isomer in the earlier eluate isomerized to the *trans(O)* one during the procedure after elution. Found: C, 27.54; H, 4.35; N, 5.87%. Calcd for $[Co(L,L\text{-tbsmc})]ClO_4 \cdot H_2O = CoC_{11}H_{20}N_2O_8S_2Cl \cdot H_2O$: C, 27.25; H, 4.57; N, 5.78%.

10) N,N'-Ethylenebis(L-methioninato)cobalt(III) Perchloride: *[Co(L,L-ebm)]ClO$_4$*. This complex was prepared and isolated by the same procedure as that for $[Co(L,L\text{-ebsmc})]ClO_4$ described in 8), using L,L-H_2ebm.[2] The only isomer obtained showed the identical absorption and CD spectra with those of *trans(O)*-$[Co(L,L\text{-ebm})]^+$ prepared by Magee *et al.*[2] Found: C, 29.64; H, 4.63; N, 5.70%. Calcd for $[Co(L,L\text{-ebm})]ClO_4 = CoC_{12}H_{22}N_2O_8S_2Cl$: C, 29.98; H, 4.61; N, 5.83%.

11) S,S'-Ethylenebis(L-cysteinato)cobalt(III) Chloride and Nitrate: *[Co(L,L-ebc)]X*; *X$^-$ = Cl$^-$, NO$_3^-$*. A suspension of L,L-H_2ebc (4.1 g) in 250 cm^3 of water was adjusted to pH 8 by the addition of an aqueous solution of NaOH (1 mol dm^{-3}). To this were added a solution of $CoCl_2 \cdot 6H_2O$ (4.1 g) in 50 cm^3 of water and lead dioxide (10 g). The mixture was stirred at 60 °C for 20 min, whereupon the solution became purple. The reaction mixture was cooled to room temperature and filtered to remove insoluble materials. The filtrate was poured onto a column (4 cm × 60 cm) containing SP-Sephadex C-25 resin (Na^+ form). After sweeping the column with water, the adsorbed band was eluted with a 0.1 mol dm^{-3} aqueous solution of NaCl. Only one purple band was eluted and fractionated. The absorption and CD spectra of the fractions showed that the eluate contained only *trans(O)* isomer. The eluate was concentrated to a small volume in a rotary evaporator and the deposit, NaCl, was filtered off. To the filtrate was added an appropriate amount of ethanol and then ether. The resultant violet complex was recrystallized from water by adding ethanol. Found: C, 24.90; H, 4.31; N, 7.51%. Calcd for $[Co(L,L\text{-ebc})]Cl \cdot H_2O = CoC_8H_{14}N_2O_4S_2Cl \cdot H_2O$: C, 25.37; H, 4.27; N, 7.40%. This chloride salt was converted to the nitrate salt by use of an anion-exchange column containing QAE-Sephadex A-25 resin (NO_3^- form). The nitrate salt showed the identical absorption and CD spectra to those of the chloride salt. Found: C, 23.26; H, 3.97; N, 10.28%. Calcd for $[Co(L,L\text{-ebc})]NO_3 \cdot H_2O = CoC_8H_{14}N_3O_7S_2 \cdot H_2O$: C, 23.71; H, 3.98; N, 10.37%.

12) S,S'-Trimethylenebis(L-cysteinato)cobalt(III) Chloride and Nitrate: *[Co(L,L-tbc)]X*; *X$^-$ = Cl$^-$, NO$_3^-$*. This complex was prepared by the same procedure as that for $[Co(L,L\text{-ebc})]X$ described in 11), using L,L-H_2tbc instead of L,L-H_2ebc. The absorption and CD spectra of the chloride and nitrate salts were identical. Found for chloride salt: C, 26.31; H, 4.80; N, 6.42%. Calcd for $[Co(L,L\text{-tbc})]Cl \cdot 2H_2O = CoC_9H_{16}N_2O_4S_2Cl \cdot 2H_2O$: C, 26.31; H, 4.92; N, 6.82%. Found for nitrate salt: C, 25.18; H, 4.43; N, 9.92%. Calcd for $[Co(L,L\text{-tbc})]NO_3 \cdot 1.5H_2O = CoC_9H_{16}N_3O_7S_2 \cdot 1.5H_2O$: C, 25.24; H, 4.47; N, 9.81%.

Measurements. The electronic absorption spectra were recorded with a JASCO UVIDEC-1 spectrophotometer, and the CD spectra with a JASCO J-20 spectropolarimeter. All measurements were carried out in aqueous solution at room temperature.

The ^1H and ^{13}C NMR spectra were recorded in deuterium oxide on a JEOL JNM-MH-100 or FX-100 NMR spectrometer at the probe temperature. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as an internal reference.

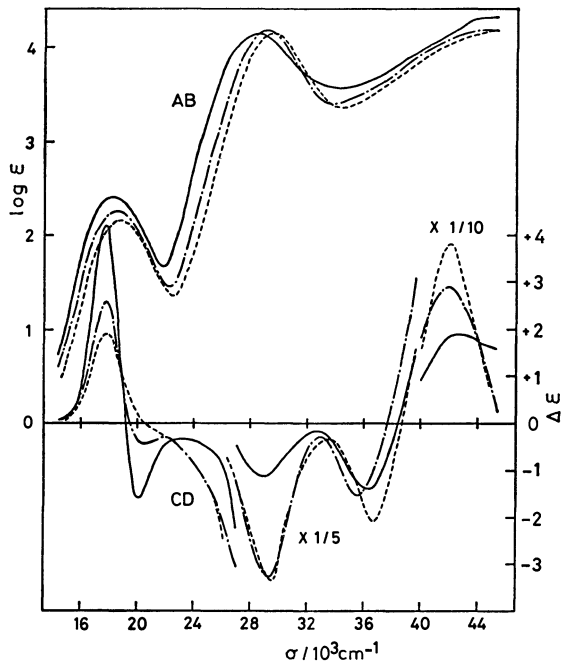

Fig. 2. Absorption and CD spectra of *trans(S)* isomers: [Co(L-sbc)$_2$]$^+$ (——), [Co(L-sec)$_2$]$^+$ (—·—·—), and [Co(L-smc)$_2$]$^+$ (-----).

Results and Discussion

*Structural Assignments. Bis(L-terdentate-*N,S,O*) Type Complexes*: For the [Co(L-sec)$_2$]$^+$ and [Co(L-sbc)$_2$]$^+$ complexes which belong to a [Co(N)$_2$(S)$_2$(O)$_2$] type, three geometrical isomers, *trans(S)*, *trans(N)*, and *trans(O)*, are possible (Fig. 1(a)). Their absorption and CD spectra are shown in Figs. 2—4, together with those of the [Co(L-smc)$_2$]$^+$ isomers; the data are summarized in Tables 1 and 2. Splitting patterns of

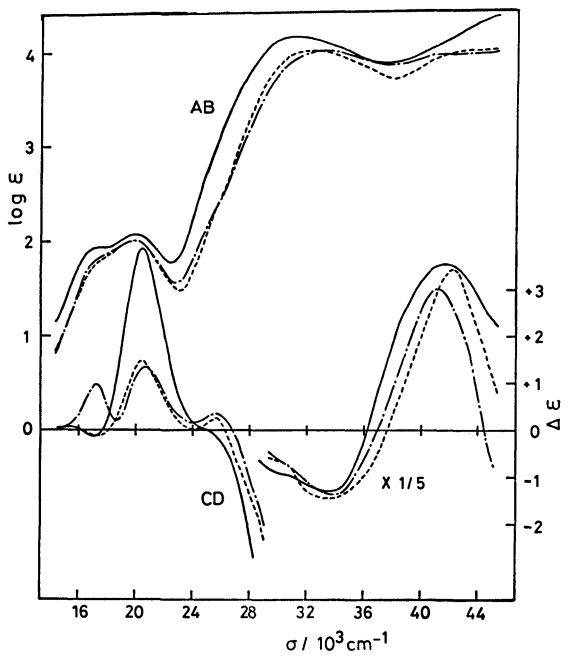

Fig. 3. Absorption and CD spectra of *trans(N)* isomers: [Co(L-sbc)$_2$]$^+$ (——), [Co(L-sec)$_2$]$^+$ (—·—·—), and [Co(L-smc)$_2$]$^+$ (-----).

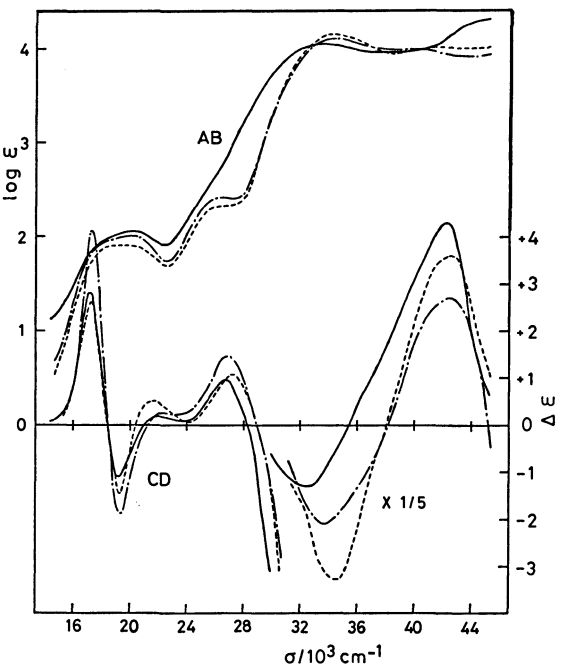

Fig. 4. Absorption and CD spectra of *trans(O)* isomers: [Co(L-sbc)$_2$]$^+$ (——), [Co(L-sec)$_2$]$^+$ (—·—·—), and [Co(L-smc)$_2$]$^+$ (-----).

the first absorption bands and maximum positions of the sulfur-to-metal charge transfer bands of the present isomers correspond well with those of the three isomers of [Co(L-smc)$_2$]$^+$.[10] Their CD spectral behavior could be classified into CD patterns of the three L-smc isomers (Figs. 2—4). Accordingly, A-1 and B-2 isomers can be assigned confidently as *trans(S)*, A-2 and B-1 isomers as *trans(O)*, and A-3 and B-3 isomers as *trans(N)*. The formation of the three geometrical isomers de-

TABLE 1. ABSORPTION DATA OF [Co(terdentate-$N,S,O)_2$] AND [Co(sexidentate-N_2,S_2,O_2] TYPE COMPLEXES

a) Ref. 10. b) Ref. 9. Wave numbers and log ε values (in parentheses) are given in 10^3 cm^{-1} and mol^{-1} dm^3 cm^{-1}, respectively. Sh denotes a shoulder.

creases with the order of *trans(S)*, *trans(O)*, and *trans(N)* for both of [Co(L-sec)$_2$]$^+$ and [Co(L-sbc)$_2$]$^+$. This order runs parallel to the crowdedness of the *S*-alkyl groups of the ligands in each isomer.

Another type of three isomers arising from the chiralities of the coordinated sulfur atoms of the ligands, *R(S),R(S)*, *R(S),S(S)*, and *S(S),S(S)*, are possible for each of the three geometrical isomers. The ^{1}H NMR spectrum of the *trans(S)* L-sec isomer exhibits only one set of triplet peaks in the methyl proton region (1.48 ppm from DSS), while the spectra of the *trans(O)* and *trans(N)* L-sec isomers show two sets of triplet peaks, respectively (1.39 and 1.52 ppm for the *trans(O)*, and 1.39 and 1.43 ppm for the *trans(N)*). The *trans(S)* L-sbc isomer shows a single peak due to the aromatic protons (7.36 ppm), while the *trans(O)* and *trans(N)* isomers show a peak with a shoulder at the higher magnetic field (7.44 ppm for the *trans(O)* and 7.43 ppm for the *trans(N)*). Furthermore, the ^{13}C NMR spectrum of the *trans(S)* isomer shows four peaks due to the aromatic carbons (128.4, 129.9, 130.5 and 139.6 ppm), while the *trans(O)* and *trans(N)* isomers show multiple peaks in the corresponding region. These NMR spectral behaviors of the L-sec and L-sbc isomers are quite similar to those of the three isomers of [Co(L-smc)$_2$]$^+$.[10] Inspection of models suggests that the *trans(S)* isomers take the *S(S),S(S)* configuration, the *trans(N)* isomers a mixture of *R(S),S(S)* and *S(S),S(S)* ones, and the *trans(O)* isomers a mixture of *R(S),R(S)*, *R(S),S(S)*, and *S(S),S(S)* ones, as in the case of the three isomers of the L-smc complex.[10]

N,N- *and* S,S-*Bridge(*L,L-*sexidentate*-N_2,S_2,O_2*) Type Complexes*: The possible geometrical isomers for [Co(L,L-ebsmc)]$^+$ [9] and [Co(L,L-tbsmc)]$^+$ are limited to two: *trans(S)* and *trans(O)*, because the two nitrogen donor atoms of the ligands were bridged by ethylene (L,L-ebsmc) and trimethylene (L,L-tbsmc) (Fig. 1(b)). Of the two isomers, only the *trans(O)* isomer was selectively formed and isolated for the L,L-ebsmc complex.[9] For the L,L-tbsmc complex, the *trans(S)* and *trans(O)* isomers were formed, but only the *trans(O)* isomer could be isolated, because the *trans(S)* L,L-tbsmc isomer isomerized to the *trans(O)* one during the procedure after elution. Two geometrical isomers, *trans(O)* and *trans(N)*, are possible for [Co(L,L-ebc)]$^+$ and [Co(L,L-tbc)]$^+$, where the two sulfur donor atoms of the ligands were bridged by ethylene (L,L-ebc) and trimethylene (L,L-tbc) (Fig. 1(c)). For each of the two *S,S*-bridge complexes, only the *trans(O)* isomer was selectively formed and isolated. The four isomers of the *N,N*- and *S,S*-bridge complexes which belong to a [Co$(N)_2(S)_2(O)_2$] type were assigned to *trans(O)* from the comparison of the absorption and CD spectra with the isomers of the bis type complexes mentioned above (Figs. 5 and 6 and Tables 1 and 2).

The *N,N*-bridge complexes, [Co(L,L-ebsmc)]$^+$ and [Co(L,L-tbsmc)]$^+$, have another chirality arising from the two nitrogen donor atoms. Of the two complexes, [Co(L,L-ebsmc)]$^+$ was confirmed to be *trans(O)-R(N),R(N)* isomer by the X-ray diffraction study.[9] Taking the rigid framework of the parental isomer, *trans(O)*-[Co(L-smc)$_2$]$^+$, into consideration, it is certain that the *trans(O)* L,L-tbsmc isomer prefers the *R(N),R(N)* configuration. The ^{1}H NMR spectrum of the *trans(O)* L,L-ebsmc isomer indicated that the two sulfur donor atoms took a mixture of *R(S),R(S)*, *R(S),S(S)*, and *S(S),S(S)* configurations,[9] as in the case of *trans(O)*-[Co(L-smc)$_2$]$^+$. The ^{1}H NMR spectrum of the *trans(O)* L,L-tbsmc isomer shows multiple peaks in the *S*-methyl proton region, suggesting that the

chiral sulfur atoms take a mixture of *R*(*S*),*R*(*S*), *R*(*S*),*S*(*S*), and *S*(*S*),*S*(*S*) configurations, like the *trans*-*(O)* L,L-tbsmc isomer does.

For each of the two *S*,*S*-bridge isomers, *trans(O)*-[Co(L,L-ebc)]$^+$ and *trans(O)*-[Co(L,L-tbc)]$^+$, the possible configurations of the sulfur donor atoms are limited to two: *R*(*S*),*R*(*S*) (C_2 symmetry) and *R*(*S*),*S*(*S*) (C_1 symmetry) for the L,L-ebc isomer, and *S*(*S*),*S*(*S*) (C_2 symmetry) and *R*(*S*),*S*(*S*) (C_1 symmetry) for the L,L-tbc isomer. As shown in Fig. 7(a), the ^{13}C NMR spectrum of the *trans(O)* L,L-ebc isomer shows four peaks for the eight carbons of the ligand. This means that the L,L-ebc isomer takes the *R*(*S*),*R*(*S*) configuration having C_2 symmetry, where the backbone five-membered chelate ring takes an asymmetric gauche form with δ conformation. Similarly, the *trans(O)* L,L-tbc isomer takes *S*(*S*),*S*(*S*) configuration having a skew-boat form with δ conformation for the backbone six-membered chelate ring, because the ^{13}C NMR spectrum shows five peaks for the nine carbons of the ligand (C_2 symmetry) (Fig. 7(b)).

Absorption and CD Spectra. As shown in Figs. 2—4, the absorption spectra in each group of the three geometrical isomers of the bis L-smc, L-sec, and L-sbc complexes are similar to each other except that the sulfur-to-metal charge transfer bands of the L-sbc isomers shift to somewhat lower energies in comparison with those of the L-smc and L-sec isomers. The overall CD pattern is similar in each group. However, some notable differences due to the substitution of the *S*-alkyl group can be observed in more minute detail. In the first absorption band region, the *trans(S)*-

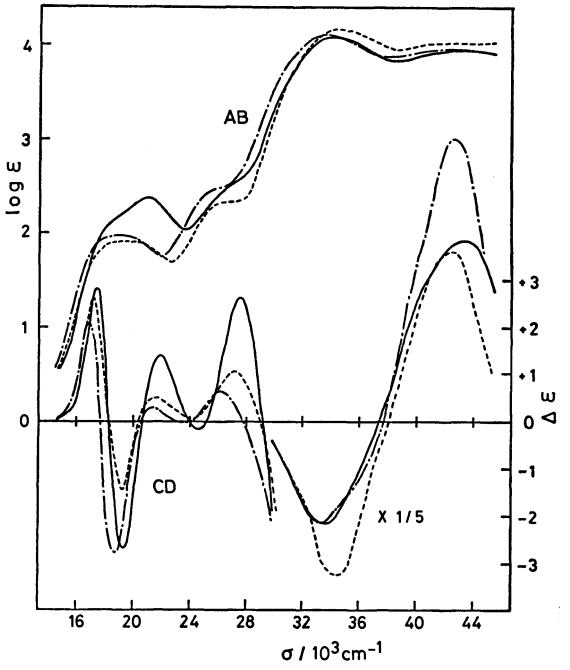

Fig. 5. Absorption and CD spectra of *trans(O)* isomers: [Co(L,L-ebsmc)]$^+$ (——), [Co(L,L-tbsmc)]$^+$ (—·—·—), and [Co(L-smc)$_2$]$^+$ (-----).

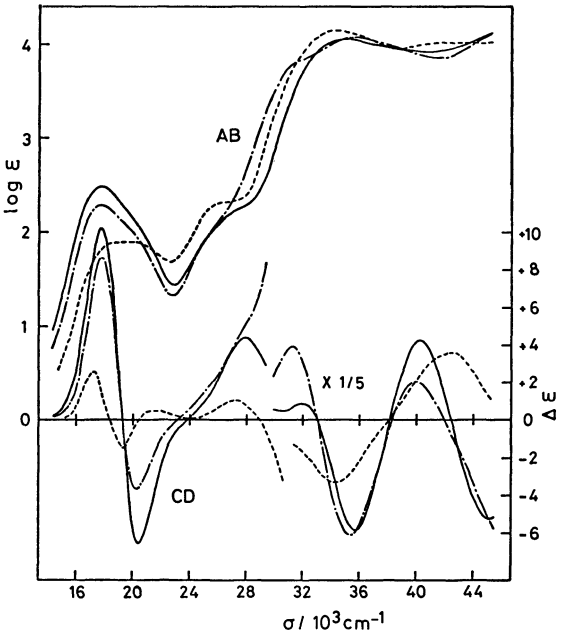

Fig. 6. Absorption and CD spectra of *trans(O)* isomers: [Co(L,L-ebc)]$^+$ (——), [Co(L,L-tbc)]$^+$ (—·—·—), and [Co(L-smc)$_2$]$^+$ (-----).

S(S),S(S) isomers commonly show a positive CD band (at *ca.* 18.0×10^3 cm^{-1}) whose intensity decreases with the order of the L-sbc, L-sec, and L-smc isomers, and a negative band at higher energy disappears in the L-smc isomer (Fig. 2). The *trans(N)* isomers assigned to the mixture of *R(S),S(S)* and *S(S),S(S)* configurations commonly show a positive CD band at 20.5×10^3 cm^{-1}. The L-smc and L-sbc isomers show two additional weak CD bands ((+) and (−) from lower energy), while the L-sec isomer shows one positive band

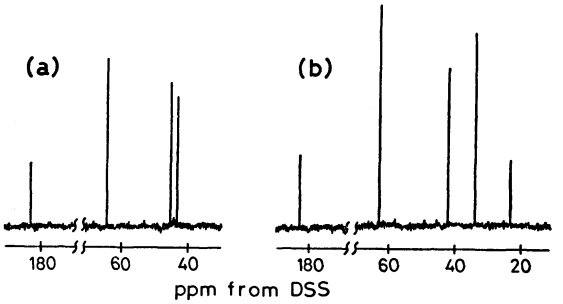

Fig. 7. ^{13}C NMR spectra of *trans(O)*-[Co(L,L-ebc)]$^+$ (a) and *trans(O)*-[Co(L,L-tbc)]$^+$ (b).

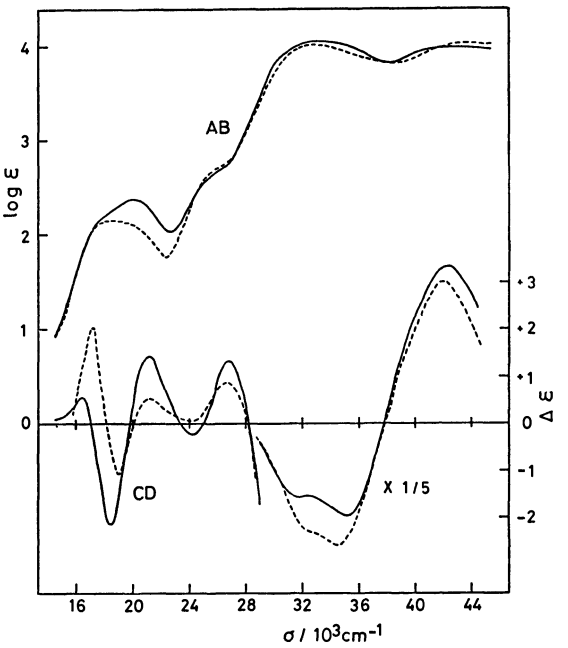

Fig. 8. Absorption and CD spectra of *trans(O)* isomers: [Co(L,L-ebm)]$^+$ (——) and [Co(L-met)$_2$]$^+$ (-----).

in the corresponding region (Fig. 3). In contrast to the *trans(S)* and *trans(N)* isomers, the *trans(O)* isomers assigned to the mixture of *R(S),R(S)*, *R(S),S(S)*, and *S(S),S(S)* configurations show quite similar CD spectral behavior in the whole region, with no significant differences. This good agreement in CD spectra seems to suggest that the CD contribution due to the coordinated sulfur atoms in the *trans(O)* isomers was almost cancelled out because of the mixture of *R(S),R(S)*, *R(S),S(S)*, and *S(S),S(S)* configurations.

The absorption and CD spectra of the *N,N*-bridge complexes are shown in Fig. 5, together with those of *trans(O)*-[Co(L-smc)$_2$]$^+$. The *trans(O)* L,L-ebsmc and L,L-tbsmc isomers show a CD pattern quite similar to that of *trans(O)*-[Co(L-smc)$_2$]$^+$ in the whole region, though the former two have an additional chilarity, *R(N),R(N)*, due to the bridged nitrogen donor atoms of the ligands. This result suggests that the CD contribution due to the chiral nitrogen atoms of the *N,N*-bridge *trans(O)* isomers is inconspicuous except for some increase in CD intensity. This trend is also valid for the CD spectra of *trans(O)*-[Co(L-met)$_2$]$^+$ [1] and *trans(O)*-[Co(L,L-ebm)]$^+$, where the two nitrogen donor atoms were bridged by ethylene (Fig. 8), though two

conformations, chair and skew-boat, are probable for the six-membered N–S ring of the coordinated L-met. A similar CD spectral behavior was observed for a series of *cis*-$[Co(ida)_2]^-$, $[Co(edta)]^-$, and $[Co(1,3\text{-pdta})]^-$.[14] In contrast to the *N,N*-bridge isomers, the CD spectral behaviors of the *S,S*-bridge *trans(O)* isomers differ significantly from that of *trans(O)*-$[Co(L\text{-smc})_2]^+$ (Fig. 6 and Table 2). In the first absorption band region, the CD spectra of the *trans(O)* L,L-ebc and L,L-tbc isomers are remarkedly intensified in comparison with that of *trans(O)*-$[Co(L\text{-smc})_2]^+$. Of the three CD bands in the first absorption band region of *trans(O)*-$[Co(L\text{-smc})_2]^+$, the two CD bands in the higher energy side change to one negative band, though the positive band at the lowest energy side remains unchanged. A remarkable deviation in absorption and CD spectra from *trans(O)*-$[Co(L\text{-smc})_2]^+$ are observed in the region of $(28\text{—}38)\times10^3$ cm^{-1}. Especially, it is noteworthy that the *trans(O)* L,L-tbc isomer shows another intense absorption component (at *ca.* 32.3×10^3 cm^{-1}) in addition to the charge transfer band (at 35.59×10^3 cm^{-1}) which commonly appears for the other *trans(O)* isomers. In this absorption band region, a new positive CD band appears for each of the two *S,S*-bridge isomers, namely, $\Delta\varepsilon=+19.7$ at 31.35×10^3 cm^{-1} for the L,L-tbc isomer and $\Delta\varepsilon=+6.9$ at 32.00×10^3 cm^{-1} for the L,L-ebc one. This positive CD band for the L,L-ebc isomer suggests that the isomer also has an absorption component in the corresponding region, as in the L,L-tbc isomer. This absorption component seems to arise from the splitting of the multiple thioether charge transfer band.[15] The appearance of the new positive CD band (at *ca.* 31.5×10^3 cm^{-1}) for the two *S,S*-bridge isomers suggests that *R(S),R(S)*, *R(S),S(S)*, and *S(S),S(S)* configurations in the *trans(O)*-$[Co(L\text{-smc})_2]^+$ were unified to only one configuration (*R(S),R(S)* for the *trans(O)* L,L-ebc isomer and *S(S),S(S)* for the L,L-tbc one) by bridging the sulfur atoms of the two cysteinates.

Reaction Process of Zirconium Tetrachloride with Ammonia in the Vapor Phase and Properties of the Zirconium Nitride Formed

Akimasa YAJIMA, Yutaka SEGAWA, Ryoko MATSUZAKI, and Yuzo SAEKI*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received March 24, 1983)

The reaction products of gaseous $ZrCl_4$ with ammonia were $ZrCl_4 \cdot 2NH_3$ at 300 °C; $ZrCl_4 \cdot 2NH_3$, ZrClN, and NH_4Cl at 350—700 °C; $ZrCl_4 \cdot 2NH_3$, ZrClN, ZrN_x, Zr_3N_4, and NH_4Cl at 750 °C; ZrClN, ZrN_x, Zr_3N_4, and NH_4Cl at 800—950 °C; ZrN_x, Zr_3N_4, and NH_4Cl at 1000—1050 °C; and ZrN_x, NH_4Cl, and HCl at 1100—1400 °C. The N/Zr atomic ratios, x, of the ZrN_x formed was 1.28 at 1100 °C, 1.24 at 1200 °C, 1.18 at 1300 °C, and 1.12 at 1400 °C. The lattice constants of the ZrN_x formed were shown. The reaction process of gaseous $ZrCl_4$ with ammonia can be represented as follows: The reaction of gaseous $ZrCl_4$ with ammonia to form $ZrCl_4 \cdot 2NH_3$ occurs first. Above *ca.* 330 °C, the $ZrCl_4 \cdot 2NH_3$ reacts with ammonia to form ZrClN. Above *ca.* 750 °C, the ZrClN reacts with ammonia to form ZrN_x and Zr_3N_4. Above *ca.* 1000 °C, ZrN_x was also formed by the thermal decomposition of the Zr_3N_4. On heating the $ZrN_{x(x=1.28)}$, formed by the vapor-phase reaction, at temperatures higher than 700 °C in an argon atmosphere, the value of x decreased and became close to that of the stoichiometric nitride, being 1.03 at 1100—1300 °C.

The vapor-phase reaction of transition metal chlorides with ammonia has recently become important for the preparation of fine powders of transition metal nitrides, which are aquiring importance as new industrial materials. Concerning the formation of zirconium nitride from zirconium tetrachloride ($ZrCl_4$) by the vapor-phase reaction, Okabe *et al.*[1] have reported the preparation of zirconium nitride powders by a vapor-phase reaction of the $ZrCl_4$–NH_3–N_2–H_2 system at 1000—1500 °C with emphasis on the effect of reaction conditions on the conversion of the $ZrCl_4$ to zirconium nitride. However, no information is at present available on the reaction process of $ZrCl_4$ with ammonia in the vapor phase.

In this paper, the reaction products of gaseous $ZrCl_4$ with ammonia at 300—1400 °C were examined in detail. The possible reactions which were considered to occur during the reaction process on the basis of the above experiments were examined. The N/Zr atomic ratios, lattice constants, and thermal stability of the zirconium nitrides formed were also examined. The zirconium nitrides which formed were also examined by electron microscopy.

Experimental

Materials. The $ZrCl_4$ used was prepared by the reaction of zirconium sponge (Reactor grade, Nippon Mining Co., Ltd.) with chlorine at 330 °C and purified by fractional sublimation. The chemical analysis gave Zr, 39.1; Cl, 60.8% (calcd for $ZrCl_4$: Zr, 39.14; Cl, 60.86%). The ammonia was dried by passing it over sodium hydroxide granules and barium oxide powders.

Experimental Procedures. A transparent quartz or alumina tube (1000 mm length) was used for examining the reaction products of gaseous $ZrCl_4$ with ammonia. Gaseous $ZrCl_4$ was formed by heating solid $ZrCl_4$ (14 g) at 280 °C and was carried by a stream of argon (50 cm³/min) into the reaction zone (28 mm i.d., 250 mm length) held at a specified temperature. The $ZrCl_4$ inlet tube consisted of two concentric tubes. Gaseous $ZrCl_4$ carried by argon was introduced through the inner tube and the outer tube was utilized for introducing argon (50 cm³/min) as a sheath gas to prevent formation of the product deposits at the chloride inlet tube. Ammonia was simultaneously introduced at a flow-rate of 100 cm³/min into the reaction zone through a separate tube. The mean flow-rate of gaseous $ZrCl_4$ was 6.0 cm³/min. A quartz or alumina tube was inserted inside the reaction tube to make the removal of the reaction product easier. The reaction was allowed to proceed for 2 h.

The by-product ammonium chloride (NH_4Cl) which deposited outside the reaction zone together with the zirconium nitride formed was separated by heating the mixture *in vacuo* at 400 °C.

Analytical. Chemical analyses of the reaction products were performed as follows: The zirconium content of the $ZrCl_4$–NH_3 adduct was gravimetrically determined as ZrO_2 using mandelic acid as a precipitating agent, after dissolving the sample in water. The chlorine and ammonia contents were determined by a gravimetric method as AgCl and by the Kjeldahl method from the aqueous solution. The zirconium content of zirconium chloride nitride (ZrClN) was gravimetrically determined as ZrO_2 after hydrolyzing the sample in water. The chlorine and nitrogen contents were determined by the gravimetric method and by the Kjeldahl method, respectively, from the filtrate.

X-Ray analysis of the product was performed with an X-ray powder diffractometer equipped with a proportional counter using Ni filtered Cu radiation. The sample chamber of the diffractometer was maintained under a dry nitrogen atmosphere, if necessary, to prevent any contamination of the sample with atmospheric moisture during the irradiation.

The sensitivity of the quartz helix used for thermogravimetry (TG) was approximately 113 mm/g. The sample (0.2 g) was heated at a rate of 2.5 °C/min and the flow-rate of ammonia was maintained at 50 cm³/min.

The N/Zr atomic ratio of the zirconium nitride formed was evaluated as follows: The sample zirconium nitride was oxidized to ZrO_2 by heating in an oxygen atmosphere to 700 °C, using a Shimadzu high-sensitive thermal balance, Model TGA31. The zirconium content of the sample was calculated from the amount of ZrO_2 formed. The amount of nitrogen was determined as the difference between the amount of the initial sample and that of the zirconium. The value of the N/Zr atomic ratio was evaluated with an accuracy within ±0.01.

The lattice constant of the zirconium nitride was calculated based on the X-ray diffraction data obtained by using silicon powders as an internal standard and under the scanning speed of 1/2—1/4° min^{-1}.

Throughout this work, the $ZrCl_4$ and the reaction products were handled in an argon atmosphere or *in vacuo* to prevent contamination by atmospheric moisture.

Results and Discussion

Reaction Products of Gaseous Zirconium Tetrachloride with Ammonia. The products formed by heating gaseous $ZrCl_4$ in an ammonia stream at various temperatures were examined by both X-ray analysis[2-5] and chemical analysis. Reaction temperatures above 300 °C were employed, because gaseous $ZrCl_4$ was generated at 280 °C.

The product formed at 300 °C showed a hitherto unknown X-ray diffraction pattern which was clearly different from those of known zirconium compounds. The chemical analysis of the product gave Zr, 34.1; Cl, 53.0; NH_3, 12.8%. The ratio of Zr : Cl : NH_3 was calculated to be 1:4.00:2.01. This was considered to indicate that the product formed at 300 °C had a composition of $ZrCl_4 \cdot 2NH_3$ (calcd for $ZrCl_4 \cdot 2NH_3$: Zr, 34.15; Cl, 53.10; NH_3, 12.75%). The X-ray diffraction data of the $ZrCl_4 \cdot 2NH_3$ formed are shown in Table 1. Based on these data, $ZrCl_4 \cdot 2NH_3$ could be indexed on cubic lattice with $a_0=10.13$Å, as shown in Table 1.

Table 1. X-Ray diffraction data of $ZrCl_4 \cdot 2NH_3$

1.461	12	4 4 4	1.462

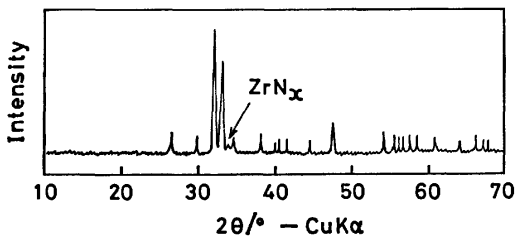

Fig. 1. X-Ray diffraction pattern of the product obtained inside the reaction zone at 950 °C.

X-Ray analysis of the product formed at 750—1050 °C showed a hitherto unknown X-ray diffraction pattern in addition to those of the known α-ZrClN,[2] β-ZrClN,[3] ZrN_x,[4] NH_4Cl,[5] and the above $ZrCl_4 \cdot 2NH_3$. As shown in Fig. 1, the product obtained at 950 °C inside the reaction zone showed an X-ray diffraction pattern consisting of the unknown pattern and a very weak diffraction line corresponding to the strongest line of ZrN_x ($2\theta=34.0°$). The product was thus examined by chemical analysis. The chlorine content of the product was first checked after heating the sample in molten sodium carbonate. The result showed that the product contained no chlorine. This indicated that the product was zirconium nitride. The N/Zr atomic ratio of the product was found to be 1.33. As described above, this product contained a slight amount of ZrN_x. As seen from the results shown in Table 5 described later, the N/Zr atomic ratio of ZrN_x formed by the vapor-phase reaction increased with the decrease in the reaction temperature, the N/Zr atomic ratio of ZrN_x formed at 1100 °C being 1.28. Considering these facts and the accuracy of the measurement of the N/Zr atomic ratio (±0.01), the presence of a slight amount of ZrN_x caused no significant error in the measurement of the N/Zr atomic ratio of the product showing the unknown X-ray diffraction pattern. From these results and the fact that the presence of Zr_3N_4 in addition to ZrN_x had been reported[6-8] as zirconium nitride, the product showing the unknown X-ray pattern, formed at 750—1050 °C, was found to be Zr_3N_4.

Table 2. Reaction products of gaseous $ZrCl_4$ with ammonia at various temperatures

Temp/°C	Products	
	In the reaction zone	Outside the reaction zone
300	$ZrCl_4 \cdot 2NH_3$	$ZrCl_4 \cdot 2NH_3$
350—400	$ZrCl_4 \cdot 2NH_3 \gg ZrClN[\alpha]$	$ZrCl_4 \cdot 2NH_3$; NH_4Cl
500—550	$ZrClN[\alpha]$	$ZrCl_4 \cdot 2NH_3$; NH_4Cl
600	$ZrClN[\alpha \gg \beta]$	$ZrCl_4 \cdot 2NH_3 \gg ZrClN[\alpha]$; NH_4Cl
650	$ZrClN[\alpha > \beta]$	$ZrCl_4 \cdot 2NH_3 \gg ZrClN[\alpha]$; NH_4Cl

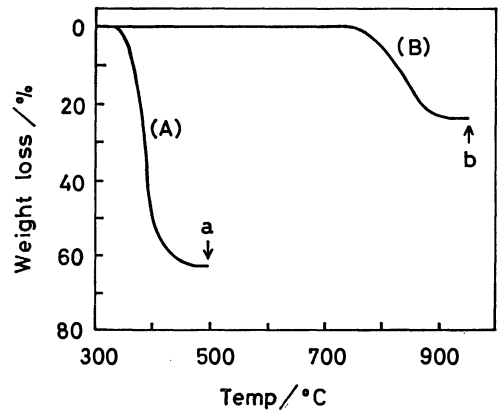

Fig. 2. TG curves of $ZrCl_4 \cdot 2NH_3$ and ZrClN in an ammonia stream.
(A): $ZrCl_4 \cdot 2NH_3$, (B): ZrClN.

The reaction products of gaseous $ZrCl_4$ with ammonia at various temperatures above 300 °C are summarized in Table 2. The symbols α and β in the parentheses represent the modifications of ZrClN.

Unreacted $ZrCl_4$ was not observed throughout the temperature range of this work. The products which formed below 750 °C were obtained inside and outside the reaction zone. Above 800 °C, a large portion of the products were obtained outside the reaction zone, and above 1100 °C, all the products were obtained outside the reaction zone. Above 1100 °C, HCl was formed in addition to by-product NH_4Cl. The percentage of HCl formed to the total amount of chlorine introduced as $ZrCl_4$ was <1% at 1100 °C, 10% at 1200 °C, 25% at 1300 °C, and 60% at 1400 °C. The value is nearly the same as that of the HCl formed by the thermal decomposition of NH_4Cl at each temperature under the experimental conditions in this work.[9] This was considered to indicate that the HCl formed was due to the decomposition of the by-product NH_4Cl.

Reaction Process of Gaseous Zirconium Tetrachloride with Ammonia. To elucidate the reaction process of gaseous $ZrCl_4$ with ammonia, the behavior of the $ZrCl_4 \cdot 2NH_3$, the ZrClN, and the Zr_3N_4, which had been formed during the reaction process, on heating in an ammonia stream were examined.

Behavior of $ZrCl_4 \cdot 2NH_3$ on Heating in an Ammonia Stream: The TG curve of $ZrCl_4 \cdot 2NH_3$ in an ammonia stream is shown in Fig. 2 (A).

$ZrCl_4 \cdot 2NH_3$ lost weight above 330 °C. It was observed that NH_4Cl and a small amount of $ZrCl_4 \cdot 2NH_3$ deposited outside the heating zone during the weight loss. The sample after the heating to point a was found to be α-ZrClN by X-ray analysis. The final weight loss was 62.8%. This value was considerably larger than the calculated value, 47.33%, based on the reaction, $ZrCl_4 \cdot 2NH_3 + 2NH_3 \rightarrow ZrClN + 3NH_4Cl$. This was considered to be due to the vaporization of a part of the $ZrCl_4 \cdot 2NH_3$.

In order to obtain more detailed information on the behavior of $ZrCl_4 \cdot 2NH_3$ on heating in an ammonia stream, $ZrCl_4 \cdot 2NH_3$ (1.0 g) in a quartz boat (70 mm length, 15 mm width, 7 mm depth) was placed in a straight reaction tube (28 mm i.d., 1000 mm length). Ammonia was introduced into the reaction tube at a flow-rate of 100 cm^3/min. The sample part was then placed in the centre of an electric furnace (300 mm heating length) maintained at a specified temperature for 1 h. The products obtained inside and outside the boat were examined by X-ray analysis and chemical analysis. The results are shown in Table 3.

From these results, it was found that on heating $ZrCl_4 \cdot 2NH_3$ in an ammonia stream, $ZrCl_4 \cdot 2NH_3$ reacted with ammonia above about 330 °C to form ZrClN and NH_4Cl and that the reaction was accompanied by the vaporization of a part of $ZrCl_4 \cdot 2NH_3$. The formation of ZrClN outside the boat was considered to indicate that the reaction of gaseous $ZrCl_4 \cdot 2NH_3$ with ammonia to form ZrClN also occurred.

Behavior of ZrClN on Heating in an Ammonia Stream: The TG curve of ZrClN in an ammonia stream is shown in Fig. 2(B). α-ZrClN obtained inside the reaction zone by the reaction of gaseous $ZrCl_4$ with ammonia at 500 °C was used. ZrClN lost weight above 750 °C. The sample after the heating to point b was found to be a mixture of ZrN_x and a small amount of Zr_3N_4 by X-ray analysis. It was observed that NH_4Cl alone was deposited outside the heating zone during the weight loss.

In order to obtain more detailed information on the behavior of ZrClN on heating in an ammonia stream, the products obtained by heating ZrClN(α) (0.5 g) in a quartz boat in an ammonia stream (100 cm^3/min) for 1 h at a specified temperature were examined by X-ray analysis and chemical analysis. The results are shown in Table 4.

These results showed that, on heating ZrClN(α) in an ammonia stream, the transition of α-ZrClN to β-ZrClN occurred above about 600 °C and that the reaction of ZrClN with ammonia occurred above about 750 °C to form ZrN_x, Zr_3N_4, and NH_4Cl at 750—1000 °C and ZrN_x and NH_4Cl at 1100 °C.

Behavior of Zr_3N_4 on Heating in an Ammonia Stream: The products obtained by heating Zr_3N_4 (0.2 g) in an ammonia stream (100 cm^3/min) for 1 h at various temperatures were examined. The sample Zr_3N_4 used was the Zr_3N_4 containing a slight amount of ZrN_x,

Table 4. Experimental results for ZrClN on heating in an ammonia stream

Heating temp/°C	Products		Unreacted ZrClN/%
	In the boat	Outside the boat	
550	ZrClN[α]	—	100
600—700	ZrClN[$\alpha > \beta$]	—	100
750	ZrClN[$\alpha > \beta$], $ZrN_x > Zr_3N_4$	NH_4Cl	64
800	$ZrN_x >$ ZrClN[β], Zr_3N_4	NH_4Cl	25
850	$ZrN_x > Zr_3N_4 >$ ZrClN[β]	NH_4Cl	10
900	$ZrN_x > Zr_3N_4$	NH_4Cl	—
1000	$ZrN_x \gg Zr_3N_4$	NH_4Cl	—
1100	ZrN_x	NH_4Cl	—

Table 5. N/Zr atomic ratios and lattice constants of the ZrN_x formed

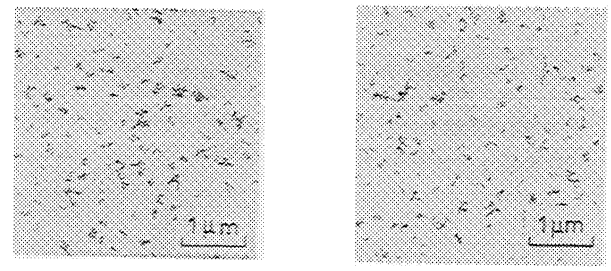
Formation temp/°C	x in ZrN_x	a_0/Å
1100	1.28	4.560
1200	1.24	4.564
1300	1.18	4.568
1400	1.12	4.571

which was formed by the reaction of qaseous $ZrCl_4$ with ammonia at 950 °C, because Zr_3N_4 alone was not obtained throughout the experiments in this work. X-Ray analysis of the sample after the heating at each temperature showed it to be $Zr_3N_4 \gg ZrN_x$ (unchanged) at 900 °C, Zr_3N_4, ZrN_x at 1000 °C, and $ZrN_x > Zr_3N_4$ at 1100 °C. The results showed that Zr_3N_4 decomposed to ZrN_x above about 1000 °C in an ammonia stream.

From the results, it was considered that ZrN_x formed by heating ZrClN in an ammonia stream at temperatures lower than 1000 °C (Table 4) was formed without passing through Zr_3N_4. Consequently, it may be concluded that on heating ZrClN in an ammonia stream, it reacts with ammonia above about 750 °C to from ZrN_x and Zr_3N_4. Above about 1000 °C, ZrN_x was also formed by the thermal decomposition of the Zr_3N_4 formed.

Based on the above experimental results, the reaction process of gaseous $ZrCl_4$ with ammonia was discussed. As shown in Table 2, $ZrCl_4 \cdot 2NH_3$ alone was formed at 300 °C. This fact indicates that the reaction of gaseous $ZrCl_4$ with ammonia to form $ZrCl_4 \cdot 2NH_3$ occurs first. The ZrClN formed at 350—950 °C is considered to be due to the reaction of $ZrCl_4 \cdot 2NH_3$ with ammonia, because the $ZrCl_4 \cdot 2NH_3$ reacts with ammonia above about 330 °C to form ZrClN, as described above. The ZrN_x and Zr_3N_4 formed above 750 °C are considered to be due to the reaction of ZrClN with ammonia, because the ZrClN reacts with ammonia to form ZrN_x and Zr_3N_4 above about 750 °C. Above about 1000 °C, ZrN_x is considered to be formed also by the thermal decomposition of Zr_3N_4, because Zr_3N_4 decomposes to ZrN_x in an ammonia stream above about 1000 °C.

From the above-mentioned results, the reaction process of $ZrCl_4$ with ammonia in the vapor phase can be represented as follows: The reaction of gaseous



(a) 1200 °C (b) 1400 °C

Fig. 3. Electron micrographs of the ZrN_x formed at various temperatures.

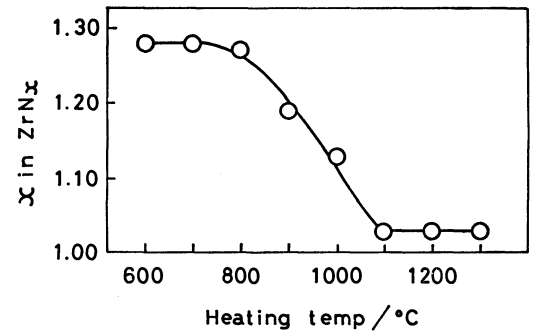


Fig. 4. N/Zr atomic ratios of ZrN_x obtained after heating $ZrN_{1.28}$ at various temperatures in an argon atmosphere.

$ZrCl_4$ with ammonia to form $ZrCl_4 \cdot 2NH_3$ occurs first. Above about 330 °C, the $ZrCl_4 \cdot 2NH_3$ reacts with ammonia to form ZrClN. Above about 750 °C, the ZrClN reacts with ammonia to form ZrN_x and Zr_3N_4. Above about 1000 °C, ZrN_x is also formed by the thermal decomposition of the Zr_3N_4.

Properties of the ZrN_x Formed. The N/Zr atomic ratios of ZrN_x formed outside the reaction zone by the reaction of geseous $ZrCl_4$ with ammonia at 1100—1400 °C are shown in Table 5. Prior to this examination, the presence of residual NH_4Cl in the ZrN_x, obtained after the removal of NH_4Cl at 400 °C *in vacuo*, was checked by chemical analysis,[10] after the heating of the ZrN_x sample in molten sodium carbonate. The NH_4Cl content in the ZrN_x was 1.5% for the ZrN_x formed at 1100 °C, 0.9% at 1200 °C, 0.4% at 1300 °C, and <0.1% at 1400 °C. For the evaluation of the N/Zr atomic ratio of the ZrN_x formed, the initial weight of the sample was corrected by subtracting the amount of NH_4Cl contained, because the NH_4Cl was

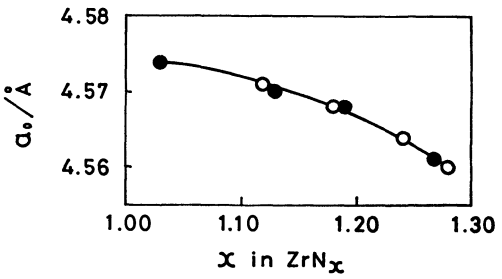

Fig. 5. Lattice constants of the ZrN_x with various x values.
○: From ZrN_x formed by the reaction of gaseous $ZrCl_4$ with ammonia, ●: From ZrN_x obtained after the heating of $ZrN_{1.28}$.

vaporized during the oxidation.[9]

It has been known that the ZrN_x phase has a NaCl structure.[4] The lattice constant of ZrN_x formed at each temperature is also shown in Table 5.

The ZrN_x formed by the reaction of gaseous $ZrCl_4$ with ammonia above 1100 °C were examined by electron microscopy. Typical micrographs of the ZrN_x are shown in Fig. 3.

As seen from Fig. 3, the ZrN_x formed is uniform, ultrafine powders with the particle diameters of the order of 1/100 μm.

Finally, to obtain knowledge of the thermal stablilty of the ZrN_x formed, the N/Zr atomic ratios of the samples obtained by heating $ZrN_{x(x=1.28)}$ at various temperatures in an argon atmosphere for 1 h were examined. The results are shown in Fig. 4. In addition, it was found that the residual NH_4Cl in the ZrN_x was completely removed by the heating above 900 °C.

The results indicated that when the ZrN_x formed was heated in an argon atmosphere at temperatures higher than 700 °C, the N/Zr atomic ratio decreased and became close to that of the stoichiometric nitride. The value of x was 1.03 at the heating temperatures of 1100—1300 °C.

The lattice constants of the ZrN_x with various x values, obtained in this work, are shown in Fig. 5.

The present work was partially supported by a Grant-in-Aid for Scientific Research No.56470058 from the Ministry of Education, Science and Culture.

(Received November 8, 1982)

The binding isotherm of sodium dodecyl sulfate to amylose was potentiometrically investigated by using amyloses of various degrees of polymerization from 32 to 1100. From the Scatchard plots, the binding was found to be cooperative for the amyloses of DP≧76 and Langmuir type for those of DP≦57. By analogous experiments using a series of sodium alkyl sulfates, it was clarified that (1) eight carbon atoms of surfactant are required for the complexation and (2) more than twelve carbon atoms of surfactant are required for the cooperative binding. Thus, the amylose has an interrupted helical structure in solution and the cooperativity arises from the hydrophobic interaction between the surfactants included partly in the helic of amylose.

A number of investigations[1-7] have been performed on the complex formation of amylose with various reagents, in connection with the biological significance of the amylose structure in solution. Three representative models have been proposed, *i.e.*, an interrupted helix,[8,9] an entirely random coil,[10] and a deformed helix.[11,12] In previous papers,[13,14] we have proposed the interrupted helical structure as the most adequate model for amylose conformation in solution from the kinetic and static investigations on the amylose–iodine complex formation by using the amyloses of various degrees of polymerization, DP.

In extension of our studies on the structure of amylose, the binding isotherm of sodium dodecyl sulfate, SDS, to amylose was investigated with use of amyloses of various DPs. Further, the same experiment was performed for the homologue of SDS using the amylose of DP 1100, and the effect of the chain length of alkyl group of surfactant on the binding isotherm was examined.

Experimental

Materials. Potato amylose, purchased from Pierce Chemical, was purified by precipitation three times from 1-butanol. Amyloses of various DPs were prepared as described in a previous paper.[13] The molecular weight, $\bar{M}_w$, of the amylose was estimated from the elution profile of the gel chromatography on a Sepharose 4B column (2.5×62 cm), using the following relationship obtained by Dextran T10, T20, T70, T150, and T500.

$$\log \bar{M}_w = 7.05 - 3.19 K_{av}, \quad (1)$$

with

$$K_{av} = \frac{V_e - V_v}{V_t - V_v}, \quad (2)$$

where K_{av} is the partition coefficient;[15] V_v, V_t, and V_e are the void volume, total volume, and elution volume, respectively. The amylose was used in the form of the wet 1-butanol complex.[10] Sodium alkyl sulfates, $CH_3(CH_2)_{n-1}SO_4Na$ with n=6, 8, 10, 12, and 14, were synthesized according to the method of Dreger.[16] Dodecyltrimethylammonium dodecyl sulfate was prepared according to the method of Satake and Yang.[17]

Measurements. The concentration of bound SDS was determined by its electromotive force (emf) using a cell constructed as follows:[17,18]

|reference electrode|agar bridge|reference solution; 0.6×10^{-4} M** SDS|nitrobenzene; 1×10^{-4} M $(C_{12}H_{25}(CH_3)_3N)^+(SO_4C_{12}H_{25})^-$|sample solution; 5×10^{-3} M amylose in AGU, SDS|agar bridge|reference electrode|.

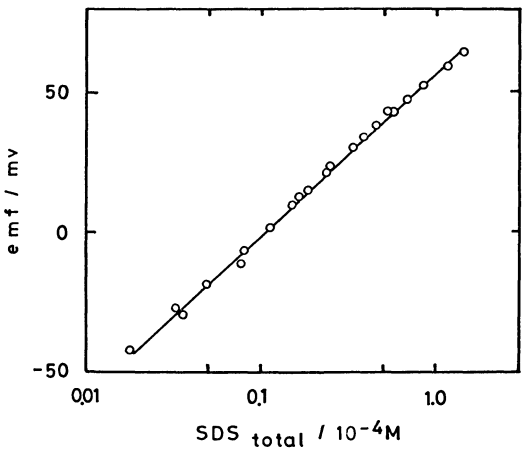

Fig. 1. Plot of emf *vs.* the logarithm of the concentration of SDS at 30 °C.

Calibration of the apparatus was performed by measuring the emf of the SDS solution without amylose. To attain a stable and accurate responce of the liquid membrane, 21.3 mM of sodium chloride was added to each solution. Figure 1 shows the semilogarithmic plot of the emf *vs.* SDS concentration. The slope of the line, 59 mV at 30 °C, agrees well with the ideal Nernst slope (60 mV at 30 °C), which implies that the liquid membrane responds exclusively to a surfactant ion.[19] The pH of the solutions ranged from 5.5 to 6.2, since no buffer solution was used. Amylose solution was freshly prepared immediately before the measurements and the concentration in anhydroglucose residue unit was determined by the phenol-sulfuric acid method.[20] To rule out any effect due to the micellization, the concentration of surfactant was kept below the critical micelle concentration. All measurements were carried out at 30 °C.

Results and Discussion

Typical potentiometric titration curves obtained with SDS in the presence and absence of amylose are shown in Fig. 2. Since the SDS bound to amylose can not contribute to the emf, the concentration of the bound SDS is equal to the difference in the SDS concentrations required to give the same emf on curves a and b in Fig. 2. The concentration of the bound SDS estimated for the various DPs of amylose is plotted against the free SDS concentration in Fig. 3. As seen

** 1 M=1 mol dm^{-3}.

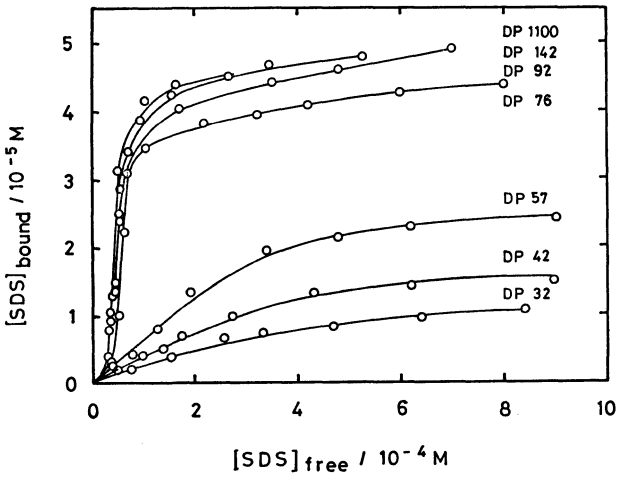

Fig. 3. Binding isotherms of SDS for a series of amyloses at 30 °C.

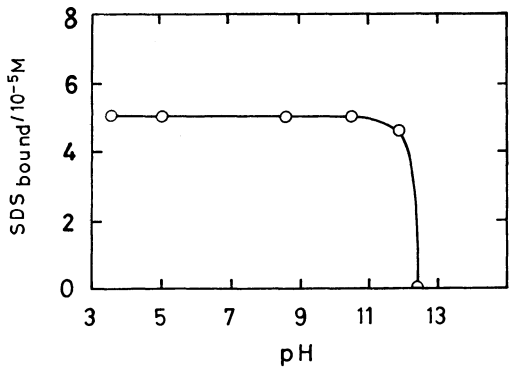

Fig. 4. pH dependence of the total amount of bound SDS to amylose (DP 1100, 1 mM) at 30 °C.

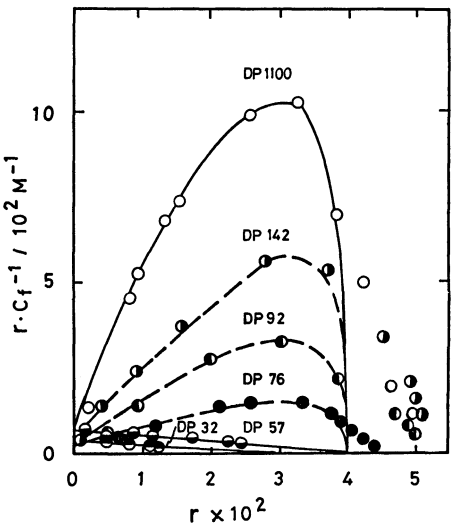

Fig. 5. Representative Scatchard plots of binding isotherms of SDS to amyloses. Solid lines show theoretical curves obtained by Eqs. 2 and 3. The dotted lines have no theoretical meaning. (○); DP 1100, (◑); DP 142, (◐); DP 92, (●); DP 76, (◒); DP 57, (◓); DP 32.

in this figure, the total amount of the bound SDS increases with the DP of amylose.

As for the pH dependence of the concentration of bound SDS, no alteration takes place up to pH 10.6, but a sudden decrease appears at around pH 12, as shown in Fig. 4. A similar drastic change in the conformation of amylose with pH has been reported; this was ascribed to the break-down of the helical structure.[4] From a consideration of these two experimental results, it can be deduced that the SDS molecule binds to the helical part of amylose.

The binding equilibrium of amylose–SDS system is written as

$$A + SDS_f \rightleftharpoons SDS_b, \quad (3)$$

where A is the binding site of amylose and SDS_f and SDS_b are the free and bound SDS, respectively. The Scatchard equation for Reaction 3 is given by

$$r/C_f = K(n-r), \quad (4)$$

where r is the ratio of bound SDS to total amylose in anhydroglucose residue units, n is the maximum amount of bound SDS per anhydroglucose residue, C_f is the concentration of free SDS, and K is the apparent equilibrium constant. The representative Scatchard plots for the amyloses of various DPs are shown in Fig. 5. At first glance, an obvious difference can be seen in the plots, *i.e.*, straight lines with negative slope for the amyloses of DP≦57, and curvature with upward convex for those of DP≧76. The straight lines indicate the Langmuir type binding of SDS to amylose, while the curvature indicates the cooperative binding. A similar change in the binding profile around DP 60 has been also recognized in the amylose–iodine complex formations, as previously reported.[13] These facts give support for the interrupted helix model of the conformation of amylose in solution.

For the Langmuir type binding, n and K_L (the subscript L means the Langmuir type binding) were evaluated from the intercept and the slope of the straight line, respectively. These values are listed in Table 1 together with the number of binding sites of SDS on one amylose molecule, m. The value of m increases with DP of amylose, whereas the equilibrium constant, K_L, remains constant.

As for the cooperative binding, the equilibrium con-

Table 1. The binding parameters of the complex formation

DP	m	$n\times10^2$	Langmuir type binding	Cooperative binding

42	1.22	2.90	1.4±0.6	—	—
57	2.30	4.00	2.0±0.2	—	—
1100	59	4.00	—	2.0±0.7	22±2

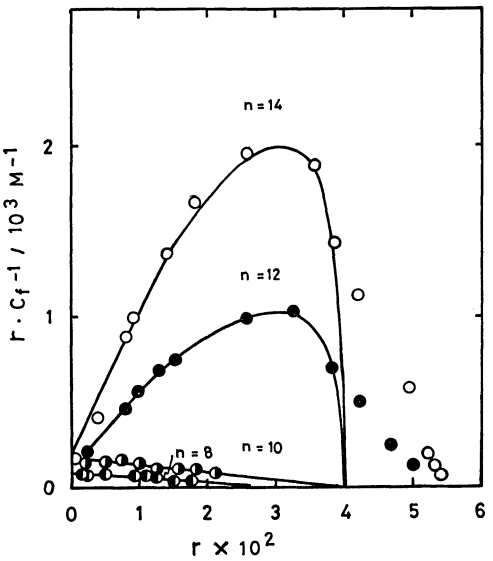

Fig. 6. Scatchard plots of binding isotherms of surfactants to amylose (DP 1100). Solid lines show theoretical curves obtained by Eqs. 2 and 3. (○); $n=14$, (●); $n=12$, (◑); $n=10$, (◐); $n=8$.

stant K in Eq. 4 can be rewritten according to the one-dimensional Ising model by McGhee and von Hippel;[22]

$$K = K_0\left\{\frac{n-2r+R}{2(n-r)}\right\}^2, \quad (5)$$

with

$$R = [(n-2r)^2 + 4K_c r(n-r)]^{1/2}, \quad (6)$$

where K_0 is the equilibrium constant for the intrinsic binding of SDS to amylose (intrinsic equilibrium constant) and K_c is the cooperative parameter. The values of K_0 and K_c were determined for the amylose of DP 1100 so as to give the best fit of the data to the Scatchard equation, and are listed in Table 1. As can be seen in Fig. 5, experimental points deviate from the theoretical curve in the region of $r\geqq0.04$ for DP 1100. These data were disregarded for analysis because of their low reliability. A good agreement between values of K_0 for DP 1100 and K_L for DP$\leqq$57 in Table 1 implies the similarity in the mechanism of the isolated binding and the Langmuir binding. Meanwhile, the value of K_c for the amylose of DP 1100 means positive cooperativity, *i.e.*, the cooperative interaction contributes to the stabilization of the complex. In the cases of amyloses of DP 76 to 142, the Scatchard plots are also indicative of the cooperativity, as seen in Fig. 5. Further quantitative analysis of these plots, however, was not carried out because Eq. 5 can not be applied to these small amyloses.[22]

Table 2. Effect of the chain length of alkyl group of surfactants on the binding parameters of the complex formation

Alkyl group	$n\times10^2$	Langmuir type binding	Cooperative binding	
		K_L / $10^3\ M^{-1}$	K_0 / $10^3\ M^{-1}$	K_c
n-C_8H_{17}	2.1	2.1±0.2		
n-$C_{10}H_{21}$	4.0	2.2±0.2		
n-$C_{12}H_{25}$	4.0		2.0±0.7	22±2
n-$C_{14}H_{29}$	4.0		2.2±0.9	36±8

In order to clarify the effect of the chain length of alkyl group of surfactant on the complexation, the binding isotherms of a series of sodium alkyl sulfates $CH_3(CH_2)_{n-1}SO_4Na$ with n=8, 10, 12, and 14 to amylose of DP 1100 were investigated. The Scatchard plots for these surfactants are shown in Fig. 6. These plots showed large differences in the binding profiles; the binding of surfactants of n=8 and 10 is Langmuir type, whereas that of n=12 and 14 is cooperative. These results suggest that a certain length of the alkyl chain of surfactant ($n\geqq12$) is necessary for the cooperative binding. Meanwhile, sodium alkyl sulfate with n=6 did not bind to amylose. Consequently at least eight carbon atoms of surfactant molecule should be required for the complex formation. Table 2 summarizes the binding parameters obtained for each surfactant system. As can be seen from this table, the values of K_L for surfactants of n=8 and 10 are in good agreement with that of K_0 for n=12 and 14, which implies that the alkyl chain length included in a helix of amylose is approximately equal for each surfactant system.

The binding parameters of SDS to the amylose of DP 1100 were obtained at various temperatures; their temperature dependences are shown in Fig. 7. From these, thermodynamic parameters were obtained and are listed in Table 3. It is seen that the intrinsic complex formation is enthalpy-determined while the cooperative interaction between bound SDS is entropy-determined.

Finally, the possibility of two other models for amylose structure was examined. Three experimental facts already noted above: noncooperative binding of two SDS molecules to an amylose of DP 57, sudden appearance of the cooperative binding of SDS to the amylose of DP 76, and noncooperative binding of

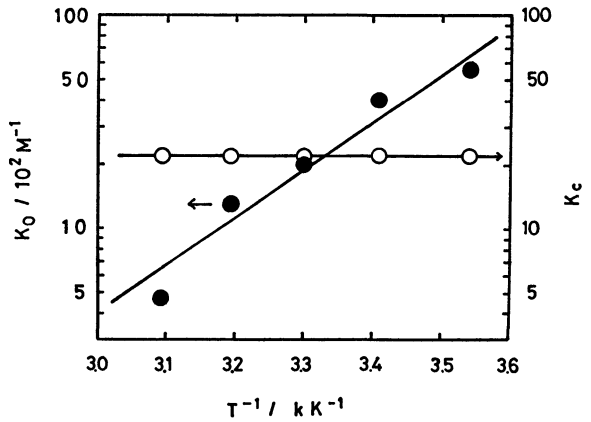

Fig. 7. The temperature dependence of the binding parameters of SDS to the amylose of DP 1100.

alkyl sulfates of n=8 and 10 to the amylose of DP 1100, exclude the possibility of two models: that of the entirely random coil and that of the deformed helix, for the structure of amylose in solution.

We have revealed the existence of two types of binding of SDS to amylose, as shown schematically in Fig. 8. One was ascribed to the Langmuir type binding due to an inclusion of SDS at the end of a helical segment of amylose, and the other to the cooperative binding due to the interaction of the outer part of alkyl chain of SDS bound to the interrupted helix of amylose. Furthermore, on the basis of the present work, the binding isotherms of fatty acids and alcohols with amylose, which have been hitherto reported as showing only Langmuir adsorption, should be reinvestigated from the standpoint of the cooperative binding with use of amylose of various DPs.

The Ruthenium Catalyzed *N*-Alkylation of Amides with Alcohols

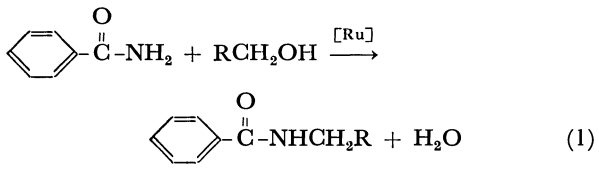
Yoshihisa WATANABE,* Tetsuo OHTA, and Yasushi TSUJI
Department of Hydrocarbon Chemistry, Kyoto University, Sakyo-ku, Kyoto 606

(Received December 23, 1982)

Amides reacted with primary alcohols in the presence of a catalytic amount of $RuCl_2(PPh_3)_3$ at 180 °C to give the corresponding *N*-monoalkyl amides in fairly good yields. Thus, benzamide reacted with 1-octanol to give *N*-octylbenzamide in 76% yield with excellent product selectivity. Little esterification of amides with alcohols occurred and selectivity to the *N*-alkylation was high. Most of the amides gave *N*-monoalkyl amides but no *N,N*-dialkyl amides. But formamide reacted with 1-butanol to give *N,N*-dibutylformamide, as well as *N*-butylformamide, in low yield. $RuCl_2(PPh_3)_3$ was the most effective catalyst for this reaction and $RuHCl(PPh_3)_3$ also had some catalytic activity.

N-Alkylation is important for selective synthesis of substituted amines; various methods have been developed. A conventional alkylating reagent is alkyl halide. On the other hand, *N*- and *C*-alkylation using alcohols as the alkylating reagent in the presence of Ni catalyst[1] have been reported and recently in the presence of Rh and Ru catalysts.[2-4]

We have previously demonstrated that ruthenium complexes were effective for the activation of alcohols and that they were excellent catalysts for *N*-alkylation and *N*-heterocyclization of aminoarenes and nitroarenes using alcohols.[3,4] This paper describes the alkylation



$$\text{PhCONH}_2 + \text{RCH}_2\text{OH} \xrightarrow{[\text{Ru}]} \text{PhCONHCH}_2\text{R} + \text{H}_2\text{O} \qquad (1)$$

of amides with alcohols in the presence of ruthenium catalyst (Eq. 1).

Results and Discussion

Benzamide was *N*-alkylated with various alcohols in the presence of $RuCl_2(PPh_3)_3$. The results are summarized in Table 1. Ethanol, 1-propanol, 1-hexanol, 1-octanol, and 1-dodecanol are employed as alkylating reagents to give *N*-ethyl-, *N*-propyl-, *N*-hexyl-, *N*-octyl-, and *N*-dodecylbenzamide, respectively. The selectivities of the products were high. The conversions of benzamide increased with elongating a carbon chain of the alcohols; 1-octanol gave the best result. Benzyl alcohol gave *N*-benzylbenzamide with 94% selectivity(Run 8), but prolonging the reaction time induced a decrease in its selectivity. However, methanol and secondary alcohol, 2-propanol, gave almost no *N*-alkylbenzamides in this procedure. A similar tendency was observed in the ruthenium-catalyzed *N*-alkylation of aminoarenes using alcohols,[3] where methanol and secondary alcohols were much less reactive as alkylating reagents than primary alcohols were.

By the present procedure, benzamide was converted to *N*-alkylbenzamide selectively, *N,N*-dialkylbenzamide was not obtained as the product, even in the presence of excess alcohol. This result is in striking contrast to that of the *N*-alkylation of aniline,[3] where *N,N*-dialkylanilines were the major products under similar reaction conditions. The *N,N*-dialkylation of aniline appears to proceed stepwise *via* *N*-monoalkylation. The reaction is not controlled at the *N*-monoalkylation stage and proceed readily to the *N,N*-dialkylation step. Thus, these observations reveal that the amides are less reactive than aminoarenes in the *N*-alkylation by alcohols, presumably owing to a neighboring carbonyl group.

The results of the *N*-alkylation of other amides are listed in Table 2. *p*-Chlorobenzamide reacted with 1-butanol to give *N*-butyl-*p*-chlorobenzamide with high selectivity. The conversion of the amide slightly decreased as compared with that of benzamide. Furthermore, acetamide, phenylacetamide, and butanamide were also *N*-alkylated with alcohols. However,

a) A mixture of benzamide(10 mmol), ethanol(5 ml), and a catalyst(0.1 mmol) was heated at 180 °C for 4 h. b) Determined by GLC based on an amount of benzamide used. c) Determined by GLC based on the conversion of benzamide. d) Catalyst(0.2 mmol) was used.

in these cases the conversions of the amides decreased considerably and the selectivities were not high. 6-Hexanelactam and 3-pyridinecarboxamide were not converted at all. Secondary amides cannot be alkylated by the present systems as indicated by the result that no *N*,*N*-dialkyl amides were obtained while the *N*-alkyl amides formed. From the reaction solution of 3-pyridinecarboxamide, red crystals were obtained. These crystals had no catalytic activity in the *N*-alkylation of benzamide with ethanol.

Acrylamide reacted with ethanol in the presence of $RuCl_2(PPh_3)_3$ to give propanamide. Since $RuCl_2(PPh_3)_3$ is known as an effective catalyst for hydrogen transfer form alcohol,[5] propanamide was obtained by the transfer hydrogenation of acrylamide by ethanol.

Catalytic Activity. Several ruthenium and rhodium compounds were examined as catalysts for this reaction (Table 3). The catalytic activities decreased in the order of $RuCl_2(PPh_3)_3$, $RuHCl(PPh_3)_3$, and $RuHCl(CO)(PPh_3)_3$. $Ru(CO)_3(PPh_3)_2$ and $RuCl_3 \cdot nH_2O$ showed little catalytic activities. $RuH_2(PPh_3)_4$, $RuCl(PPh_3)_3$, and $RhH(PPh_3)_4$ also had no catalytic activities, though these complexes were reported to have the catalytic activities of the *N*-alkylation of aliphatic amines by alcohols.[2]

Reaction Conditions. The reaction of benzamide with ethanol was carried out at 150, 180, and 220 °C. The highest yield of *N*-ethylbenzamide was obtained at 180 °C. The conversion of benzamide was low at 150 °C. The selectivity of *N*-ethylbenzamide was low at 220 °C, although the conversion was high. Prolonging the reaction time and an increase in an amount of a catalyst did not improve the yield of *N*-ethylbenzamide appreciably.

In conventional *N*-alkylation of amides, alkyl halides or esters of sulfuric or sulfonic acids can be employed as the alkylating reagent.[6] Amides are very weak bases, far too weak to attack alkyl halides. Therefore, the amides must first be converted to their salts. There was no example of the transition-metal-catalyzed alkylation of amides using alcohols. Reid[7] reported

29	0.1	220	4	88	51
30	0.1	180	5.5	57	90
31	0.1	180	6.5	62	80
2	0.2	180	4	57	97

a) A mixture of benzamide(10 mmol), ethanol(5 ml), and $RuCl_2(PPh_3)_3$ was heated. b) Determined by GLC based on the amount of benzamide used. c) Determined by GLC based on the conversion of benzamide.

that benzamide reacted with alcohols without catalyst at 220 °C for more than 60 h to give *N*-alkylbenzamides with low selectivities(30—70%) and a considerable amount of by-products by solvolysis.

This $RuCl_2(PPh_3)_3$–alcohol system has several advantages. The reaction proceeds under neutral conditions. The amides do not need to be activated to their salts. In comparison with the results of Reid, the ruthenium-catalyzed reaction is performed in shorter reaction time at lower reaction temperature. Furthermore the selectivities of the *N*-alkyl amides are high and no *N*,*N*-dialkyl amides are obtained except formamide(*vide infra*).

Two reaction paths, path A and path B, are possible for this reaction. In path A, alcohol is oxidized to aldehyde by a ruthenium complex and then the aldehyde reacts with amide to give *N*-acyl amino alcohol which undergoes dehydration; the dehydrated product is hydrogenated by hydride on the ruthenium complex or by ruthenium catalyzed transfer hydrogenation from alcohol.

Path A

$$R'CH_2OH \xrightarrow{[Ru]} R'CHO$$

$$R'CHO + RC(=O)-NH_2 \longrightarrow RC(=O)-N(H)-CH(OH)R'$$

1

$$\xrightarrow[-H_2O]{} RC(=O)-N=CHR' \xrightarrow{[Ru]} RC(=O)NHCH_2R'$$

2

The oxidation of alcohol by a ruthenium complex[8] has been reported by several authors and this step was assumed in the *N*-alkylation of aliphatic and aromatic amines with alcohols.[2,3] In the reaction of amide with aldehyde, the formation of *N*-acyl amino alcohol(**1**)[9] and its dehydrated product(**2**)[10] was ascertained.

Path B

$$RCNH_2 + R'CH_2OH \longrightarrow RCOCH_2R' + NH_3$$

$$NH_3 + R'CH_2OH \longrightarrow NH_2CH_2R' + H_2O$$

$$RCOCH_2R' + NH_2CH_2R' \longrightarrow RCNHCH_2R' + R'CH_2OH$$

In path B, alcoholysis of amide partially occurs, to give ester and ammonia. Then ammonia is alkylated with alcohol to alkylamine. The ester reacts with the alkylamine to produce *N*-alkyl amide.

The *N*-alkyl amides seem to be formed *via* path A, since ammonia, alkylamine, and ester were not produced substantially. Furthermore, addition of aldehyde gave a better yield of *N*-alkyl amides.[11] In a separate experiment ammonia reacted with alcohol to give trialkylamine, and monoalkylamine was not obtained.[12] These results indicate that path A is more plausible.

Formamide showed different results. Formamide reacted with 1-butanol for 24 h at 180 °C in the presence of $RuCl_2(PPh_3)_3$ to give *N*-butylformamide and *N*,*N*-dibutylformamide in 9 and 18% isolated yields, respectively (Eq. 2). Tributylamine was detected in 14% yield (based on formamide charged) in the reaction mixture after 8 h reaction time. *N*,*N*-Dialkyl amides were not obtained from other amides but only from formamide. Therefore, *N*,*N*-dibutylformamide seems to be produced from a different mechanism (path B'). Ammonia or alkylamine produced by Path B'

$$HCNH_2 + 1\text{-Butanol} \xrightarrow[180\,^\circ C,\ 24\,h]{RuCl_2(PPh_3)_3} HCN(Bu)_2 + HCNH(Bu) \quad (2)$$

18% 9%

$$HCNH_2 + R'CH_2OH \xrightarrow{\text{path A}} HCNHCH_2R'$$

$$HCNHR + R'CH_2OH \longrightarrow HCOCH_2R' + NH_2R$$

$$NH_2R + R'CH_2OH \longrightarrow N(CH_2R')_2R$$

$$HCNHR + N(CH_2R')_2R \longrightarrow HCN(CH_2R')_2$$

R: H or CH_2R'

the alcoholysis of amide is alkylated to di- or trialkylamine. The di- or trialkylamine formed reacts with the amide, not with the ester, since butyl formate did not react with tributylamine (Eq. 3).[13] The exchange of amine was reported in the reaction of formamide with amine.[14] Path B' is also supported by the result that formamide reacted with tributylamine in 1-butanol to give *N*,*N*-dibutylformamide and no *N*-butylformamide (Eq. 4).[15]

$$HCOBu + N(Bu)_3 \xrightarrow[n\text{-BuOH},\ 180\,^\circ C,\ 24\,h]{RuCl_2(PPh_3)_3} \text{no reaction} \quad (3)$$

$$HCNH_2 + N(Bu)_3 \xrightarrow[n\text{-BuOH},\ 180\,^\circ C,\ 24\,h]{RuCl_2(PPh_3)_3} HCN(Bu)_2 + N(Bu)_3 \quad (4)$$

Experimental

Analytical Procedure. GLC analysis was performed on a Shimadzu GC-3BT. The ^1H NMR spectra were obtained at 60 MHz with a JEOL JNM-60 NMR spectrometer or 100 MHz with a JEOL pulsed Fourier Transform spectrometer, model FX-100, and the ^{13}C NMR spectra were recorded at 25.05 MHz with a JEOL pulsed Fourier Transform spectrometer, model FX-100, using tetrametylsilane as an internal standard. IR spectra were measured on a Hitachi model 215 grating spectrophotometer. Elemental analysis were performed at the Microanalytical Center of Kyoto University. The mass spectra were recorded on a JMS 01SG mass spectrometer.

Materials. All substrates used were commercial products. The amides and alcohols were distilled or recrystallized before use. $RuCl_3 \cdot nH_2O$, $RhCl_3 \cdot nH_2O$, and PPh_3 were commercial products. $RuCl_2(PPh_3)_3$,[16] RuHCl-

$(PPh_3)_3$,[17] $RuHCl(CO)(PPh_3)_3$,[18] $Ru(CO)_3(PPh_3)_2$,[18] $RuH_2(PPh_3)_4$,[19] $RhCl(PPh_3)_3$,[20] and $RhH(PPh_3)_4$[18] were prepared according to the methods in the literature.

General Procedure. A stainless steel autoclave(50 ml) containing a glass liner was used in the reaction. Alcohol (5 ml), amide(10 mmol), and $RuCl_2(PPh_3)_3$ (0.2 mmol) were put into it with a magnetic stirring bar under argon flow. The reactor was sealed and degassed by three 15 atm pressurization-depressurization cycles with argon. The autoclave was heated at 180 °C in an oil bath for 4 h. The conversion of the amide and the selectivity of the product were determined with GLC(3 mmϕ×2.9 m column packed with 20% DEGA on Uniport B 80—100 mesh or with 10% Silicone SE-30 on Chromosorb W AW DMCS 80—100 mesh) by the internal standard method. The products were isolated by medium pressure column chromatography (silica gel 60, 40—64 μm, Merck). *N*-Ethylbenzamide,[21] *N*-propylbenzamide,[22] *N*-benzylbenzamide,[23] *N*-ethylacetamide,[24] *N*-butyl-*p*-chlorobenzamide,[25] *N*-butylformamide,[26] and *N*,*N*-dibutylformamide[27] were identified by comparison of their ^1H NMR spectral data with those in the literature. The identifications were confirmed with their ^{13}C NMR spectra. *N*-Ethylphenylacetamide was identified by comparison of ^{13}C and ^1H NMR spectra of authentic sample (mp 69 °C, lit, 69.5 °C) which was synthesized by the literature method.[28] The identities of other compounds were confirmed by IR, ^1H NMR, ^{13}C NMR, mass spectra, and elemental analysis.

The analytical data of the products are described below.

N-*Ethylbenzamide.* ^{13}C NMR($CDCl_3$) δ=14.7(q), 34.9 (t), 127.1(d,2C), 128.2(d,2C), 131.0(d), 134.7(s), 167.8(s). ^1H NMR (100 MHz)($CDCl_3$) δ=1.17(t, 3H), 3.41(d of q, 2H), 7.36(m, 4H), 7.80(m, 2H).

N-*Propylbenzamide.* ^{13}C NMR($CDCl_3$) δ=11.4(q), 22.9 (t), 41.7(t), 126.6(d,2C), 128.1(d,2C), 130.9(d), 134.5(s), 167.3(s). ^1H NMR (60 MHz) ($CDCl_3$) δ=0.95(t, 3H), 1.63 (Hex,2H), 3.38(q, 2H), 6.38(s, 1H), 7.18—7.88(m, 5H).

(Received January 26, 1983)

The compound 3-(3-hydroxy)propylidene-piperazine-2,5-dione, derived from ethyl 4-ethoxycarbonyl-2-chloroacetylamino-2-butenoate, was treated with *N*-bromosuccinimide (NBS) in chloroform to give the spiro-[oxolane-2,2′-piperazine]-3′,6′-dione derivative. The spiro compound was further treated with NBS in water to give the corresponding spiro[oxolane-2,2′-piperazine]-3′,5′,6′-trione and -3′,6′-dione-5′-ol. The latter compound and a new spiro-5′,6′-dione-3′-ol derivative were also obtained by the reduction of the spiro-3′,5′,6′-trione. The structural confirmation of all the new products is discussed.

Bicyclomycin, which has been produced by *Streptomyces (St.) sapporonensis*[1] and *St. aizunenensis*,[2] was degraded with various acids by heating to give the dispiropiperazinedione derivatives.[3] Although the total synthesis of bicyclomycin is very attractive and much attention has by now been devoted to the bioactivity, the chemistry of the degradation products, spiro- or dispiro-piperazinedione derivatives, are also very interesting. There have been a few reports on the synthesis of the spiro derivatives by three routes,[3–5] but the synthesis and the reaction have not been investigated in detail.

Previously, we reported briefly the synthesis of 3-(3-hydroxy)propylidene-piperazine-2,5-dione (**3a**) and its conversion into the corresponding spiro[oxolane-2,2′-piperazine]-3′,6′-dione {[oxolane-2,2′-piperazine]-3′,6′-dione=PDO} derivatives.[6] Here, we wish to report in detail the synthesis of the various spiro-PDO derivatives by the reaction of **3a** with NBS, followed by the hydrogenolysis and further reaction with NBS, in water. Moreover, the structural confirmation of the spiro-PDO is discussed.

Results and Discussion

Synthesis of 3-Alkylidene-piperazine-2,5-dione. According to the method reported previously,[7] ethyl 4-ethoxycarbonyl-2-oxobutanoate was condensed with chloroacetamide in benzene in the presence of a mixture of $POCl_3$ and concentrated H_2SO_4 under reflux to give the starting ethyl 4-ethoxycarbonyl-(*Z*)-2-chloroacetylamino-2-butenoate (**1**) in a 57% yield. After the halogen-exchange reaction of **1** with potassium iodide,[8,9] the resulting 2-iodoacetylamino derivative was immediately cyclized with benzylamine to give 1-benzyl-3-(2-ethoxycarbonyl)ethylidene-piperazine-2,5-dione (**2**) in an 80% yield. By the usual method, the subsequent selective reduction of exocyclic 2-ethoxycarbonyl group of **2** with $LiAlH_4$ in THF was achieved to give the expected **3a** in a 60% yield.

In order to ascertain and to protect the 3-hydroxyl group, the **3a** compound was subjected to acylation and alkylation, followed by the addition of methanol to the exocyclic carbon-carbon double bond. The acetylation and the benzoylation of **3a** with acetic anhydride and with benzoyl chloride, in the usual ways, gave 1-benzyl-3-(3-acetoxy)- and -(3-benzoyloxy) propylidene-piperazine-2,5-diones (**3b** and **3c**) in 82 and 86% yields respectively. On the other hand, the alkylation of **3a** with 2,3-dihydropyrane gave 1-benzyl-3-(3-tetrahydropyrane-2-yloxy)propylidene-piperazine-2,5-dione (**3d**) in an 82% yield. Furthermore, the **3a,b,d** compounds thus obtained were treated with methanol in the presence of NBS to give the corresponding 1-benzyl-3-(1-bromo)alkyl-3-methoxy-piperazine-2,5-dione derivatives (**4a,b,d**) in *ca.* an 88% yield. Subsequently, the catalytic hydrogenolysis of **4b,d** with 10% Pd/C in the presence of triethylamine was carried out to give the corresponding 1-benzyl-3-alkyl-3-methyl-piperazine-2,5-dione derivatives (**5b,d**) in *ca.* a 78% yield.

The characteristic absorption of the IR spectra, the chemical shifts, and the coupling constants of **2** and **3** were assigned as is shown in Table 1. In the NMR spectra, the signals of the olefinic protons appeared in the δ 6.30 and δ 6.18—6.26 regions as a triplet, while the β-alkyl protons were shifted to the δ 3.26 and δ 2.40—2.64 regions. From the comparison of the NMR spectral data of **2** and **3** with that of the *E*-isomer of the α-dehydroamino acid ester and its cyclic dipeptide derivative prepared by us,[10] Compounds **1**, **2**, and **3** could be readily confirmed to have a *(Z)*- geometric structure. In addition, the IR and NMR spectral data of **4** and **5** are summarized in Table 2.

Synthesis of Spiro-PDO Derivatives. In order to synthesize the desired spiro-PDO derivatives, Compound **3a** was led to cyclization by the intramolecular addition of the 3-hydroxylpropylidene group to the exocyclic carbon-carbon double bond. The treatment of **3a** with NBS in chloroform gave a viscous syrup, which was found to consist of two stereoisomers. From the spectral data and the satisfactory elemental analysis of the two kinds of crystals separated, the new products were identified as 4′-benzyl-3-bromospiro-PDO (**6a** and **6b**) as diastereomers in an 86% total yield. The catalytic hydrogenolysis of each isomer with 10% Pd/C in methanol gave exactly the same crystals as these identified as 4′-benzyl-spiro-PDO (**7**) in a 91% yield from **6a** and in a 90% yield from **6b**. Subsequently, the prolonged catalytic redution of **7** for 24 h was found to give 1-benzyl-3-(3-hydroxy) propyl-

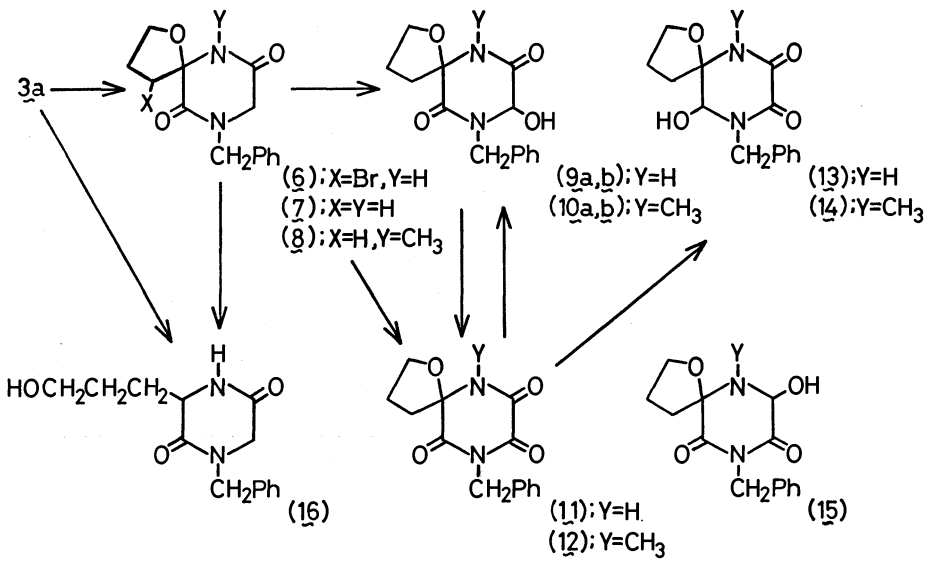

Scheme 2.

piperazine-2,5-dione (**16**) in a 64% yield, by the carbon-oxygen bond fission of the spiro ring. Compound **16** was entirely in agreement with the product prepared independently by the hydrogenation of **3a** with 10% Pd/C.

When Compound **7** was further treated with NBS in a mixture of water and chloroform, three kinds of products were obtained in fairly good yields. Based on the NMR spectral data, the compound from the first fraction was confirmed to be 4′-benzyl-spiro [oxolane-2,2′-piperazine]-3′,5′,6′-trione (**11**) in a 31% yield; the other two kinds of compounds, which were stereoisomers with each other, were obtained from the second and the final fractions in 51% and 10% yields respectively. The two stereoisomers separated were also characterized as 4′-benzyl-spiro[oxolane-2,2′-piperazine]-3′,6′-dione-5′-ol (**9a** and **9b**).

In order to generalize the above reactions, after the methylation of the 1′-position of **7** with methyl iodide, according to a method previously reported by us,[9] the resulting 4′-benzyl-1′-methylspiro-PDO (**8**) was similarly treated with NBS in water. The expected corresponding 1′-methylspiro-3′,5′,6′-trione derivative (**12**) was obtained in a 40% yield, while 1′-methylspiro-3′,6′-dione-5′-ol derivatives (**10a** and **10b**) as diastereomers were also obtained in 20 and 28% yields respectively. The subsequent reduction of the 1′-methyl trione derivative (**12**) with $NaBH_4$ in methanol was carried out to give another new compound (**14**) with **10a** in a 19% yield. Moreover, the similar reduction of **11** was worked up to also give a new compound (**13**) alone.

The structural assignment and the conformational analysis of **6**—**13** and **14** have also been elucidated

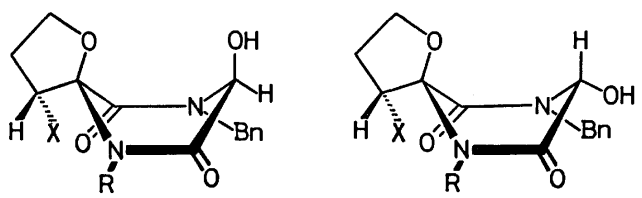

Fig. 1.

from their spectroscopic data and satisfactory elemental analyses (see Table 3). Consequently, the two new compounds could be readily identified as 4′-benzyl- and 4′-benzyl-1′-methylspiro[oxolane-2,2′-piperazine]-5′,6′-dione-3′-ol (**13** and **14**) in 86 and 68% yields respectively, not the spiro[oxolane-2,2′-piperazine]-3′,5′-dione-6′-ol derivative (**15**).

In the NMR spectrum of **6**, the chemical shift of the 3-proton on the spiro ring is in the δ 5.05 (**6a**; J=7.5 Hz) and δ 4.28 (**6b**; J=3.0 Hz, J=7.5 Hz) regions as a double doublet. On the other hand, the 3-proton signals on the spiro ring of **7**, derived from both **6a** and **6b**, also appeared in the δ 2.7—3.1 and δ 1.7—2.3 regions as splitting multiplets. This fact indicates that the spiro-PDO structure is maintained during the hydrogenolysis. From the above results, it may be supposed that one proton of the 3-position on the spiro ring of **6a** and **7** resonating in the lower magnetic field is due to the coplanar interaction between the 3-proton and the 3′-carbonyl groups on the boat structural piperazine-2,5-dione ring. Accordingly, it is assumed that all the spiro compounds obtained here have the boat structure, as is illustrated in Fig. 1. In fact, the Dreiding model of the spiro-PDO structure and the following facts further support the above presumption. In addition, the NMR spectrum of **9a** showed a long-range coupling at δ 4.86 (6-H, $J_{4,6}$=1.0 Hz, $J_{6,OH}$=11.0 Hz) as a double doublet, due to the *W*-letter relationship between two protons at the 3- and 5′-positions. On the other hand, in the NMR spectrum of **9b**, the signal at δ 5.05 (6-H, $J_{6,OH}$= 4.0Hz), appearing as only a doublet, is attributable to the two protons between 5′-H and the hydroxyl group. By a comparison of the chemical shifts and the coupling constants, the orientation of the hydroxyl group of **9a** appearing at an upper magnetic field was determined to be axial and that of **9b** at a lower field, to be equatorial, as is illustrated in Fig. 1. Similarly, based on the above results, the orientation of the hydroxyl group of **10a** appearing at a comparatively high field (δ 4.93, d, J=9.0 Hz) was also confirmed to be axial, and that of **10b** at a lower field (δ 4.94, d, J=6.0 Hz and J=7.0 Hz), to be equatorial. Furthermore, since the NMR spectrum of **13** showed a long-range coupling (J=1.0Hz) at δ 4.58 between 3′- and 1′-protons, the orientation of the hydroxyl group at the 3′-position could be unambiguously inferred to be axial.

Consequently, even if the spiro-PDO derivatives were transformed to the piperazine-3′,5′,6′-trione and -3′,6′-dione-5′-ol, the spiro and the boat conformational structures were found to be maintained.

Experimental

All the melting and boiling points are uncorrected. The IR spectra were recorded with a Hitachi EPI-G3 Spectrometer. The NMR spectra were measured with a JNM-PS-100 Spectrometer (Japan Electron Optics Laboratory Co., Ltd.,), using tetramethylsilane as the internal standard.

Starting Material. Compound **1** was prepared by the condensation of ethyl 4-ethoxycarbonyl-2-oxobutanoate (70 g, 347 mmol) with chloroacetamide (36 g, 385 mmol) in the presence of $POCl_3$ (7 ml) and concentrated H_2SO_4 (3 ml), according to the method reported previously.[7] Yield, 57%; bp 162—164 °C/2 mmHg (1 mmHg≈133.322 Pa). IR (KBr): 3280, 1730, 1690, 1515 cm^{-1}. NMR ($CDCl_3$): δ 6.94 t, 7.36 t (-CH=, J=7.0 Hz), 8.28 and 8.68 (NH), Found: C, 47.78; H, 6.02; N, 4.88%. Calcd for $C_{11}H_{16}NO_5Cl$: C, 47.57; H, 5.81; N, 5.04%.

Preparation of 2. After the halogen exchange of **1** (3.0 g, 10.81 mmol) with potassium iodide,[8,9] into the resulting solution in ethanol (40 ml), we stirred benzylamine (2.9 g, 27.03 mmol) in, drop by drop, at room temperature for 2 h. The crystals thus precipitated were collected and recrystallized from ethanol to give **2** as colorless needles.

Preparation of 3a. Into a mixture of $LiAlH_4$ (200 mg, 5.3 mmol) in THF (30 ml), we stirred a solution of **2** (1.0 g, 3.3 mmol) in THF (30 ml) at −10 °C. After treating the excess $LiAlH_4$ in the solution with 1 M HCl (1M= 1 mol dm^{-3}), the insoluble substance was filtered off, and then the filtrate was concentrated. The crude residual syrup was purified on a silica-gel column, using a mixture of $CHCl_3$ and ethanol (30 : 1 v/v) as the eluent. After the eluted fraction had been concentrated, the crystalline residue was recrystallized from ethyl acetate to give **3a** as colorless prisms.

Preparation of 3b—d. Into a solution of **3a** (200 mg, 0.769 mmol) in pyridine (3 ml), we stirred acetic anhydride (100 mg, 0.980 mmol) at room temperature for 3 h. The resulting solution was poured into CH_2Cl_2 (30 ml) and washed successively with 3 M HCl and water, and then dried over anhydrous Na_2SO_4. The removal of the solvent gave crude crystals, which were recrystallized from ethyl acetate to give **3b** as colorless needles.

In a similar manner, a solution of **3a** (1.0 g, 3.85 mmol) and benzoyl chloride (650 mg, 4.62 mmol) in pyridine (3 ml) was worked up under cooling for 1 h to give crystals. The subsequent recrystallization of the crystals from ethyl acetate gave **3c** as colorless needles.

Similarly, a mixture of **3a** (520 mg, 2.0 mmol), 3,4-dihydro-2*H*-pyran (346 mg, 4.0 ml), and *p*-toluenesulfonic acid (4 mg) in CH_2Cl_2 (10 ml) was worked up at room temperature for 6 h to give crystals. Recrystallization from dibutyl ether gave **3d** as colorless needles.

Preparation of 4a, 4b, and 4d. Into a solution of **3d** (770 mg, 2.23 mmol) in methanol (30 ml), we stirred NBS (438 mg, 2.46 mmol) at room temperature for 10 min. The subsequent removal of the solvent gave crude crystals, which were collected and then washed with water. The recrystallization of the crystals from methanol gave **4a** as colorless needles.

In a similar manner, a mixture of **3b** (1.6 g, 5.30 mmol) and NBS (943 mg, 530 mmol) in methanol (40 ml) was worked up to give a syrupy residue. The residue was dissolved in $CHCl_3$ (30 ml), and the resulting solution was washed twice with water and then dried over anhydrous Na_2SO_4. The removal of the solvent gave a viscous oil,

which was purified on a silica-gel column, using a mixture of $CHCl_3$ and acetone (20 : 1 v/v), to give **4b** as a viscous syrup.

Similarly, a mixture of **3d** (600 mg, 1.74 mmol) and NBS (310 mg, 1.74 mmol) in methanol (30 ml) gave **4c** as a viscous syrup.

*Preparation of **5b** and **5c**.* A solution of **4b** (1.9 g, 4.60 mmol) in methanol (50 ml) in the presence of triethylamine (500 mg, 4.95 mmol) was hydrogenolyzed with 10% Pd/C (200 mg) at room temperature for 15 min. After the Pd/C had been filtered off, the resulting solution was concentrated to give residual syrupy crystals, which were dissolved in CH_2Cl_2 (50 ml). The solution was washed twice with water and then dried over anhydrous Na_2SO_4. After the removal of the solvent, the residual oil was purified on a silica-gel column, using a mixture of $CHCl_3$ and acetone (15 : 1 v/v) as the eluent. The fraction thus obtained was concentrated to give **5b** as a viscous syrup.

In a similar manner, a solution of **4d** (900 mg, 1.98 mmol) and potassium *t*-butoxide (244 mg, 2.18 mmol) in methanol (50 ml) was worked up to give **5d** as a viscous syrup.

*Preparation of **6**.* Into a solution of **3a** (800 mg, 3.08 mmol) in $CHCl_3$ (20 ml), we stirred NBS (548 mg, 3.08 mmol) at room temperature for 10 min. The resulting solution was washed twice with water, dried over anhydrous Na_2SO_4, and then concentrated. The residual syrup thus obtained was chromatographed on a silica-gel column, using a mixture of $CHCl_3$ and acetone (25 : 1 v/v) as the eluent. From the two fractions thus separated, two diastereomeric isomers, **6a**,**b**, were obtained. The first fraction was concentrated to give crude crystals, which were then recrystallized from ethanol to give **6a** as colorless needles. Similarly, the second fraction gave **6b** as colorless needles from benzene.

*Preparation of **7**.* A solution of **6a** and **6b** (560 mg, 1.65 mmol) in methanol (50 ml) in the presence of triethylamine (170 mg, 1.68 mmol) was hydrogenolyzed with 10% Pd/C (60 mg) at room temperature for 20 min. After the removal of the Pd/C, the reaction solution was concentrated and the residue thus obtained was dissolved in CH_2Cl_2 (20 ml). The resulting solution was washed twice with water and then dried over anhydrous Na_2SO_4. The evaporation of CH_2Cl_2 gave crystals, which were subsequently recrystallized from diethyl ether to give **7** as colorless needles.

*Preparation of **8**.* Into a solution of **7** (500 mg, 1.92 mmol) in THF (20 ml), we stirred 55% NaH (84 mg, 1.92 mmol) at room temperature. After the evolution of hydrogen had ceased in a few minutes, we stirred methyl iodide into the resulting solution at room temperature for 6 h. The reaction solution was neutralized with acetic acid and then concentrated. The residue thus obtained was dissolved in $CHCl_3$ (30 ml), and the resulting solution was washed with water and then dried over anhydrous Na_2SO_4. After the removal of the $CHCl_3$, the residue was purified on a silica-gel column, using a mixture of $CHCl_3$ and acetone (15 : 1 v/v) as the eluent. The concentration of the fraction gave crystals, which were subsequently recrystallized from diethyl ether to give **8** as colorless needles.

*Preparation of **9** and **11**.* Into a solution of **7** (1.0 g, 3.85 mmol) in $CHCl_3$ (30 ml) and water (3 ml), we stirred NBS (690 mg, 3.85 mmol) at room temperature for 3 h. The $CHCl_3$ layer was separated, washed with water, and finally dried over anhydrous Na_2SO_4. After the removal of the $CHCl_3$, the residue was chromatographed on a silica-gel column, using a mixture of $CHCl_3$ and acetone (15 : 1 v/v) as the eluent. Three fractions were obtained, and then each fraction was concentrated. The first fraction gave **11** as colorless prisms from a mixture of benzene and hexane, while the second and third fractions gave **9a** as colorless needles from CCl_4 and **9b** as colorless prisms from benzene respectively.

*Preparation of **10** and **12**.* In a similar manner, the treatment of **8** (820 mg, 2.99 mmol) in a mixture of $CHCl_3$ (30 ml) and water (5 ml) with bromine (580 mg, 3.62mmol) was worked up for 6 h to give three fractions. The first fraction gave colorless needles **12** from a mixture of benzene and hexane. The second and the third fractions gave colorless needles **10a** and **10b** from benzene-hexane.

Moreover, similarly, in the case of the reaction of **8** (1.35 g, 4.93 mmol) with *ca.* two moles of NBS (1.8 g). Compound **12** alone was obtained in *ca.* a 92% yield.

*Reduction of **11**.* Into a mixture of **11** (1.2 g, 4.17 mmol) in methanol (50 ml), we stirred $NaBH_4$ (160 mg, 4.21 mmol), portion by portion, under cooling for 10 min. After a few drops of acetic acid had been added and the methanol evaporated, the residue thus obtained was chromatographed on a silica-gel column, using a mixture of $CHCl_3$ and ethanol (15 : 1 v/v) as the eluent. From the first fraction, Compound **9a** was obtained, while the second fraction gave **13** as colorless prisms from ethanol.

*Reduction of **12**.* A similar hydrogenation of **12** was worked up to give **10a** and **14**.

*Preparation of **16**.* *From **7***: The catalytic reduction of **7** (360 mg, 1.38 mmol) with 10% Pd/C (70 mg) in methanol (50 ml) at room temperature overnight, and the concentration of the resulting solution, gave **16** as colorless needles from ethyl acetate. Yield, 64%; mp 103—104 °C. IR (KBr): 3500, 3200, 1670, 1640 cm^{-1}. NMR ($CDCl_3$): δ 1.4—1.2 m (-CH_2-, 4H), 4.10 m (3-H), 3.82 (OH), 8.12 (NH). Found: C, 64.20; H, 6.99; N, 10.58%. Calcd for $C_{14}H_{18}N_2O_3$: C, 64.10; H, 6.92; N, 10.68%.

*From **3a***: In a similar manner, the reduction of **3a** (500 mg, 1.93 mmol) with 10% Pd/C (50 mg) in methanol (50 mg) was worked up for 20 min to give **16** in a 93% yield.

The Reaction of Sulfur Dioxide with Thiols Catalyzed by Boron Trifluoride Etherate. Evidence for a Possible Intervention of Dithiosulfite as a Reaction Intermediate

Fuminori Akiyama

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Sendai 980

(Received February 21, 1983)

The reaction of sulfur dioxide (SO_2) with 1-propanethiol (NPT), 2-propanethiol (IPT), or 2-methyl-2-propanethiol (TBT) catalyzed by boron trifluoride ethrate (BF_3OEt_2) was investigated. The ratios of dialkyl trisulfide to dialkyl disulfide obtained (RSSSR/RSSR) at an early stage of the reaction were larger than 1 for the reaction of TBT and less than 1 for the reaction of NPT or IPT. The reaction of dithiosulfites with BF_3OEt_2 in the presence or absence of thiol was investigated. From a consideration of the similarity of the composition of the sulfides formed in the reaction of dithiosulfites with BF_3OEt_2 to those in the reaction of SO_2 with thiol in the presence of BF_3OEt_2, the possibility of the intervention of dithiosulfite as a reaction intermediate in the reaction of SO_2 with thiol was discussed.

In previous papers it was reported that the reaction of SO_2 with 1-alkanethiols took place in the presence of tertiary amine or acids.[1] The reaction of SO_2 with thiols catalyzed by triethylamine or pyridine proceeded to only a small extent for the reaction of thiols with a secondary alkyl group adjacent to the SH group, and scarcely occurred for the reaction of thiols with a tertiary alkyl group.[2] The reaction mechanism of the reaction of SO_2 with thiols has not yet been elucidated, although a mechanism including dithiosulfite as one of the reaction intermediates has been proposed in previous papers.[1a,c] In the present report it is reported that the reaction of SO_2 with not only 1-alkanethiols, but also with thiols having a secondary or tertiary alkyl group, occurs in the presence of BF_3OEt_2. Also, evidence which suggests the possible intervention of dithiosulfite as one of the reaction intermediates is presented.

Results and Discussion

The yields of the products of the reaction of SO_2 with NPT, IPT, or TBT in the presence of BF_3OEt_2 are shown in Table 1. In this table the ratios of trisulfide to disulfide are calculated, and the decrease in the proportion of trisulfide and the increase in the proportion of disulfide as the reaction proceeds are shown. Since the reason for these changes was considered to be the disproportionation of the trisulfide formed, the reactions of dialkyl trisulfides with BF_3OEt_2 were carried out; the change in the composition with the reaction time is shown in Fig. 1. Contrary to the reported result in the literature that the homolitical disproportionation reaction of dialkyl trisulfide gave equal amounts of dialkyl di- and tetrasulfide,[3] Fig. 1 shows that the value of RSSSSR/RSSR given in the disproportionation by BF_3OEt_2 is in the order of R= *t*-Bu (0.7)>*i*-Pr (0.6)>*n*-Pr (0.3). In the reaction of dialkyl trisulfide with BF_3OEt_2, presumably not only the disproportionation of trisulfide to give di- and tetrasulfide, but also the removal of the sulfur atom from trisulfide to give disulfide preferentially, occurs. It is well known that the removal of sulfur atom from trisulfide to give disulfide occurs in the reaction of trisulfide with triphenylphosphine.[4] Table 1 indicates that the yields of tetrasulfide for the reactions of three sorts of thiols with SO_2 for a prolonged reaction time are in the order of R=*t*-Bu>*i*-Pr>*n*-Pr, which is same as that of the reaction shown in Fig. 1, although, the absolute amount of tetrasulfide is larger in Fig. 1 than in Table 1 because the reactions in Fig. 1 are carried out using pure trisulfide, while in the reactions in Table 1 trisulfide increases as the reaction proceeds. Therefore, the change in the composition of three sulfides during the reaction of SO_2 with thiol may be attributed to the disproportionation reaction of the

Table 1. Yields of the dialkyl sulfides from the reaction of SO_2 with alkanethiols in the presence of BF_3OEt_2 at 25 °C[a]

a) 40 mmol of thiol and 20 mmol of SO_2 were used. b) 100× (mol of product)/0.5× (mol of thiol used).

Table 2. Yields of the dialkyl sulfides in the reaction of dialkyl dithiosulfites with BF_3OEt_2 in the presence or absence of thiol at 25 °C[a]

Entry	O RSSSR (mmol)	RSH (mmol)	BF_3OEt_2 (mmol)	Sulfides formed[b] RSSR (mmol)	RSSSR (mmol)	RSSSSR (mmol)
1	R=Pr^i, 1	2	1	0.95	0.98	Trace
2	Pr^i, 1	0	1	0.44	0.21	0.09
3	R=Bu^t, 1	2	1	0.68	0.96	Trace
4[c]	Bu^t, 1	0	1	0.056	0.28	0.15[d]

a) Average values of two runs for each experiment are listed. The reactions were carried out in 2.9 ml of the CH_2Cl_2 solution. Although all of the dithiosulfite was consumed immediately after the addition of BF_3OEt_2, analyses were done 3 min after the addition of BF_3OEt_2 (The compositions did not depend on when analyses were done for several minutes after addition). b) No polysulfides higher than tetrasulfide were observed. c) Isobutene was identified in the gas over the reaction mixture. d) A explanation of the formation of the considerable amount of tetrasulfide is presented in Ref. 8.

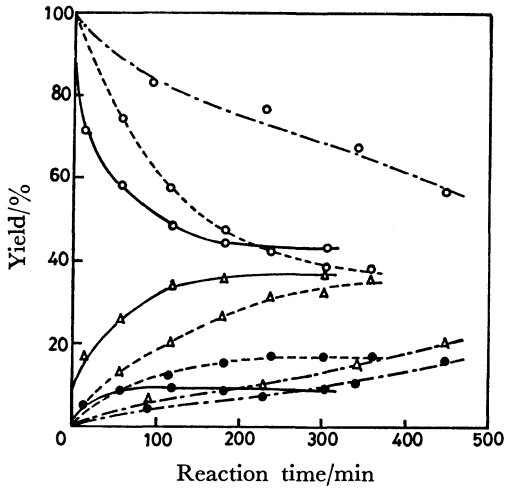

Fig. 1. Disproportionation reaction of dialkyl trisulfides catalyzed by BF_3OEt_2 to give disulfides and tetrasulfides in CH_2Cl_2 at 25 °C. $[RS_3R]=0.33$ mol/l, $[BF_3OEt_2]=0.33$ mol/l. ○: Decrease of RSSSR; △: increase of RSSR; ●: increase of RSSSSR. ——: R=*n*-Pr; -----: R=*i*-Pr; ————: R=*t*-Bu. Reactions were carried out in 3.0 ml of CH_2Cl_2 solution. Higher polysulfides than tetrasulfide were scarcely observed.

trisulfide formed. Therefore, the compositions of the products obtained at early stage of the reaction reflect the reaction mechanism of SO_2 with thiol.

The kinetics of the reaction of SO_2 with thiols is hampered by the acceleration of the reaction rate as the reaction proceeds, which disturbs the reaction and prevents it from fitting the first- or second-order rate law.[5] Although, in hope of seeing a signal of the reaction intermediates, the proton NMR of the reaction mixture was measured, there were no paticular signal other than those of the reactant, products, and catalyst. Kice *et al.* have reported that signals of the intermediates of the reaction of selenite with thiols were not observed.[6] Probably the concentration of the intermediates does not build up to a level sufficient to be detected because of the instability (*vide infra*) of the intermediates.

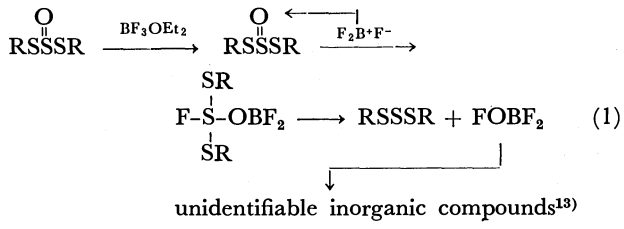
In a previous paper[1a] three sorts of reaction intermediates, I, II, and III, were proposed:

I II III

Although there is no way to synthesize I or II, dithiosulfite(III), which seems to indicate the most stable compounds of the three structures, can be synthesized (dithiosulfite, having a primary alkyl group, can not be synthesized).[7] Since direct proofs (kinetic or spectroscopic observation of the reaction intermediates in the reaction mixture) were impossible, as has been mentioned above, indirect proof of the reaction intermediate, especially dithiosulfite(III), was attempted as follows. If dithiosulfite intervenes as a reaction intermediate, dithiosulfite may react with BF_3OEt_2 and/or thiol. Therefore, the reaction of dithiosulfites with BF_3OEt_2 in the presence or absence of thiol was tried; the results are shown in Table 2. This table indicates that the compositions of the products of the reaction of dithiosulfite with BF_3OEt_2 are similar to the composition at an early stage of the reaction of SO_2 with thiols (see Table 1) in the sense that the value of RSSSR/RSSR is larger than 1 for R=*t*-Bu and close to 1 or a little less than 1 for R=*i*-Pr. This fact suggests the possibility that one of the reaction intermediates is dithiosulfite.

Field and Lacefield have assumed that the lower decomposition velocity of dithiosulfites with a tertiary alkyl group than that of dithiosulfites with a secondary alkyl group could be attributed to a bimolecular decomposition mechanism.[7] Since the reaction of di-*t*-butyl dithiosulfite (TBDS) with TBT or another molecule of TBDS suffers steric hindrance, TBDS would have chance to react with BF_3OEt_2 without being attacked by TBT or another molecule of TBDS. The reduction of sulfoxide by acids such as hydrogen iodide,[9,10] phosphorus trichloride,[11] or phosphorus pentachloride,[12] has been reported to give monosulfide. If a similar reduction mechanism works also for the reaction of this dithiosulfite with BF_3OEt_2, the preferential formation of trisulfide in the reaction of TBDS

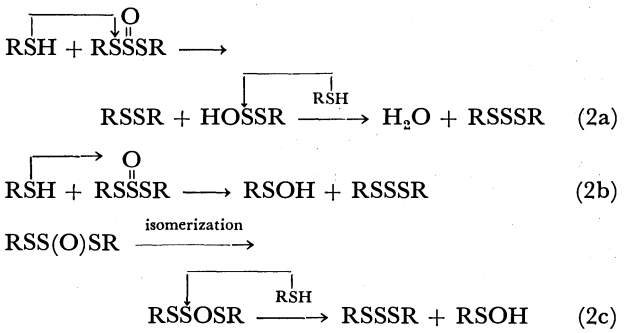
with BF_3OEt_2 may be explained (Entries 3 and 4 in Table 2):



$$RSSSR \xrightarrow{BF_3OEt_2} RSSSR \xrightarrow{F_2B^+F^-} F\text{-}S\text{-}OBF_2 \longrightarrow RSSSR + FOBF_2 \quad (1)$$

unidentifiable inorganic compounds[13]

The reaction of IPDS (Entry 1) or TBDS (Entry 3 in Table 2) in the presence of IPT or TBT, respectively, occurs by reaction paths other than Eq. 1 (a part of the TBDS would react with BF_3OEt_2 without being attacked by TBT even in the presence of TBT). The reaction schemes proposed by Kice *et al.* for the reaction of RSSe(O)SR with thiol[6] are reasonable (2a—c):



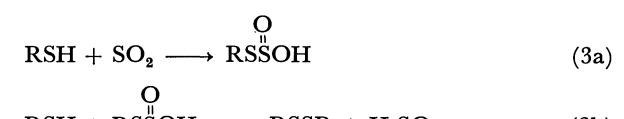
$$RSH + RSSSR \longrightarrow RSSR + HOSSR \xrightarrow{RSH} H_2O + RSSSR \quad (2a)$$

$$RSH + RSSSR \longrightarrow RSOH + RSSSR \quad (2b)$$

$$RSS(O)SR \xrightarrow{\text{isomerization}} RSSOSR \xrightarrow{RSH} RSSSR + RSOH \quad (2c)$$

Kice *et al.* considered that the reaction of thiol with RSSe(O)SR proceeded by a reaction of type 2b or 2c in order to interpret the formation of the thiosulfonic *S*-ester (RSO_2SR), which was considered to be formed from the reaction of RSOH. In the present reaction of SO_2 with thiol, the formation of the thiosulfonic *S*-ester was not observed at all.[14] Therefore, dithiosulfite probably disappears by means of the process shown in Eq. 2a in the reaction in the presence of thiol. The reaction of TBDS most likely occurs by means of both Eqs. 1 and 2a: It gives a ratio of RSSSR/RSSR larger than 1. For the reaction of IPDS, Eq. 1 would not contribute so much: Instead, Eq 2a would contribute to a large extent.

If, in the reaction of NPT or IPT with SO_2, sulfides form through only the reaction of dithiosulfite (Eq. 2a), an equal amount of di- and trisulfide must form. However, a little larger amount of disulfide than trisulfide forms at an early stage of the reaction of NPT or IPT with SO_2. This fact suggests that a reaction path giving disulfide preferentially also most likely contributes to some extent. One possible reaction path is shown in Eq. 3:



$$RSH + SO_2 \longrightarrow RSSOH \quad (3a)$$

$$RSH + RSSOH \longrightarrow RSSR + H_2SO_2. \quad (3b)$$

The reduction of SO_2 with 1-alkanethiol in the presence of an equal amount of triethylamine to give disulfide and thiosulfuric acid preferentially[15] can be explained by means of Eq. 3 (Thiosulfuric acid forms by the reaction of H_2SO_2). A part of the reaction of NPT or IPT with SO_2 most likely passes through Eq. 3, even in the case of a reaction catalyzed by BF_3OEt_2. On the other hand, the reaction of TBT with SO_2 would not pass through Eq. 3, since the attack of TBT on the sulfenyl sulfur of RSS(O)OH (R=*t*-Bu) is suppressed because of steric hindrance between *t*-Bu groups of TBT and RSS(O)OH.

Finally, the aspects of the reaction of thiols with SO_2 catalyzed by BF_3OEt_2 may be summarized as follows. In the reaction of NPT or IPT with SO_2 the dithiosulfite formed decomposes through Eq. 2a, which gives equal amounts of di- and trisulfide. In addition to this reaction path, Eqs. 3a and 3b occur to some extent. Therefore, the value of RSSSR/RSSR at an early stage of the reaction of NPT or IPT with SO_2 is little less than 1. On the other hand, in the reaction of TBT with SO_2, the dithiosulfite formed decomposes through both Eqs. 1 and 2a. In this case, the reactions in Eq. 3 scarcely occur. Therefore, the value of RSSSR/RSSR at an early stage of the reaction of TBT with SO_2 is considerably larger than 1. In the reactions of three sorts of thiols with SO_2 the disproportionation reaction of trisulfide formed to give di- and tetrasulfide takes place as the reaction proceeds, giving a lesser value than 1 of RSSSR/RSSR at a prolonged reaction time.

Experimental

Procedure for the Reaction of SO_2 with Thiols Catalyzed by BF_3OEt_2. The reagents were introduced and the reaction was started by the same method reported in a preceding paper.[1c] At an appropriate time, 20 ml of dichloromethane, appropriate amounts of hexamethylbenzene (an internal standard for sulfides), and cyclohexane (an internal standard for residual thiol) were added to make a uniform solution, which was then analyzed by means of GLC using SE-30, 15%, on a chromosorb W column.

Separation and Identification of Dialkyl Sulfides. Two mixtures, each of which contains thiol (80 mmol), BF_3OEt_2 (40 mmol), and SO_2 (40 mmol), were allowed to stand for 2 d. The upper layers of the two reaction mixtures thus obtained were combined and washed with water, a dilute alkaline aqueous solution, and water again: They were then dried over anhydrous magnesium sulfate and distilled to give pure di- and trisulfide. The structures of the disulfides and trisulfides isolated were established on the basis of the following data (the date for dipropyl di- and trisulfide were reported in Ref. 3):

Diisopropyl Disulfide: Bp 50—51 °C/6.5 mmHg (1 mmHg≈133.322 Pa) (lit,[16] 54—55 °C/7.5 mmHg). $\delta(CDCl_3)=1.33$ (6H, d, $J=6.5$ Hz, 2Me), 3.05 (1H, septet, $J=6.5$ Hz, $SC\underline{H}(CH_3)_2$). Found: C, 47.70; H, 8.99; S, 42.25%. Calcd for $C_6H_{14}S_2$: C, 47.95; H, 9.39; S, 42.66%.

Diisopropyl Trisulfide: Bp 78—79 °C/6.5 mmHg (lit,[16] 75—76 °C/5 mmHg). $\delta(CDCl_3)=1.41$ (6H, d, $J=6.5$ Hz, 2Me), 3.28 (1H, septet, $J=6.5$ Hz, $SC\underline{H}(CH_3)_2$), ν_{max} 500 cm^{-1} (S-S). Found: C, 39.23; H, 7.70; S, 52.30%. Calcd for $C_6H_{14}S_3$: C, 39,52; H, 7.74; S, 52.74%.

Di-t-butyl Disulfide: Bp 47 °C/1 mmHg (lit,[16] 64 °C/5.5 mmHg). $\delta(CDCl_3)=1.30$ (s). Found C, 54.24; H, 10.07; S, 35.76%. Calcd for $C_8H_{18}S_2$: C, 53.87; H, 10.17; S, 35.95%.

Di-t-butyl Trisulfide: Bp 70—71 °C/1 mmHg (lit,[16] 86 °C/

4 mmHg). $\delta(CDCl_3)=1.38$ (s), ν_{max} 500 cm^{-1}. Found: C, 45.59; H, 8.41; S, 45.33%. Calcd for $C_8H_{18}S_3$: C, 45.66; H, 8.62; S, 45.71%.

Isolation of dialkyl tetrasulfides was not attempted, because the yields of tetrasulfide were quite low. Instead, the retention time in the glc of the compounds obtained in this study was compared with that of dialkyl tetrasulfides synthesized by literature method:[17,18] The results showed a good coincidence.

Preparation and Purification of Dithiosulfites. TBDS was synthesized and purified by the method of Field *et al.*[7] The compound purified by chromatography (on Florisil), which had a mp of 48.5—49.5 °C (lit,[7] 48—49.5 °C), NMR $\delta(CDCl_3)=1.56$ (singlet) (lit,[7] 1.50) and IR 1105 cm^{-1} (lit,[7] 1110 cm^{-1}) was used for the reaction with BF_3OEt_2 without further recrystallization. IPDS was also synthesized by the same method.[7] Although Field *et al.* using crude IPDS without purification for their decomposition experiment,[7] their purification method using Florigil for TBDS was found to be also effective for IPDS. Purified IPDS (liq) showed NMR signals at $\delta(CDCl_3)=1.51$ (doublet, 6H, $J=6.5$ Hz) and at 3.66 (septet, 1H, $J=6.5$ Hz), IR absorption at 1110 cm^{-1} (lit,[7] 1110 cm^{-1}). The preservation of purified IPDS as a $CDCl_3$ solution (10%) at room temperature for 10 d and at −20 °C for 4 months gave about 50% and only a slight decomposition respectively. Therefore, purified IPDS was used for the reaction with BF_3OEt_2 after preservation in a refrigerator (−20 °C) for a few days.

The author wishes to thank Professor Minoru Matsuda of this Institute for his comments and suggestions.

The Baeyer-Villiger Oxidation of 8-Oxabicyclo[3.2.1]octan-3-ones. Substituent Effects on the Regioselectivity[1,2]

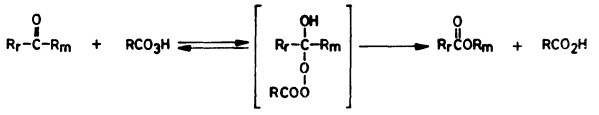
Ryoji Noyori,* Tsuneo Sato, and Hiroshi Kobayashi

Department of Chemistry, Nagoya University, Chikusa-ku, Nagoya 464

(Received February 23, 1983)

8-Oxabicyclo[3.2.1]octan-3-one derivatives serve as excellent models that elucidate factors controlling the reactivities and selectivities in the Baeyer-Villiger oxidation. The regioselectivity of the oxidation with trifluoroperacetic acid is markedly affected by the electronic properties of substituents at position α or β to the carbonyl function. Remote effects of the γ-substituents are also of significance. This study has disclosed yet unrecognized through-bond electronic influence and regioselection based on chiral orientation of hydroxyl group in the transient tetrahedral intermediate.

Oxidation of ketones by peroxy acids (Baeyer-Villiger reaction)[3] proceeds by way of transient tetrahedral intermediates,[4] which undergo fragmentation to give esters and carboxylic acids. Migration of R_m (sp^3)



R_m=migrating group
R_r=remaining group

group to the adjacent electron-deficient oxygen atom occurs in a concerted manner with retention of configuration. The migratory aptitude appears to be related to the ability of a group to support a positive charge developing in the transition state.[5] Besides such electronic effects, conformational factors are also important in determining the regiochemistry.[6] 8-Oxabicyclo[3.2.1]octan-3-one structures serve as excellent models for examining factors which control the reactivity and selectivity in the reaction, because the C_s symmetry incorporated in the basic skeleton is not distorted to any great extent by introduction of substituents. In connection with our program of *C*-nucleoside synthesis,[7] we had an opportunity of examining the oxidation of a series of the substituted oxabicyclic ketones and found several unique substituent effects.

Results and Discussion

The oxidation of the ketonic substrates was carried out in dichloromethane at 15—25 °C by using three- to seven-fold excess of trifluoroperacetic acid in the presence of anhydrous disodium hydrogenphosphate. Most reaction proceeded smoothly, but the reaction mixture was routinely stirred for 10—36 h to ensure the completion. The structures of the products were elucidated by spectroscopic methods, particularly ^{1}H NMR measurement. The isomeric ratio of the products was conveniently determined by ^{1}H NMR or high-performance liquid chromatography (HPLC) analysis.

Reaction of the α-Substituted Ketones. The Baeyer-Villiger oxidation of the α-substituted ketones, **1**—**3**, proceeded rapidly and, as expected,[3] only single lactonic isomers, **5**—**7**, were obtained in high yield.[8] In a like manner, oxidation of the dimethylated ketone **4** afforded the lactone **8** as a sole product. The complete regioselectivity is based on the positive charge-stabilizing ability of the alkyl or phenyl group at position α to the carbonyl function.

8, $R^1=R^2=CH_3$

Reaction of the β-Substituted Ketones. This class of compounds afforded a mixture of the regioisomeric lactones.[9] ^{1}H NMR spectra of the products arising from α-carbon migration exhibited an AB quartet due to the CH_2OCO protons, whereas the spectra of the α'-migrated isomers showed the same pattern of signals at higher field due to the CH_2COO protons. β-Alkyl substituents appear to direct the regiochemistry to only slight extent, giving the α- and α'-migration products in nearly equal amounts (Table 1). However, introduction of phenyl group which possesses ability of stabilizing positive charge partially developing at the α-methylene group resulted in greater α/α' ratio, **14a**/**14b**=88:12.[10,11]

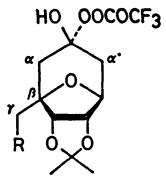
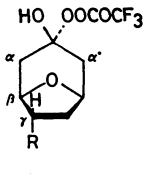
in 80—100% yield. As is seen from Table 2, the isomeric ratio is highly dependent on the nature of γ-substituent R. The general trend indicates that the regioselectivity is determined by remote electronic effects of R group. Model inspection provides no indication for significance of steric or conformational factors. Notably electron-accepting substituents favor the α'-carbon migration over the α-carbon rearrangement. The relative α'-directing capabilities decrease in the order of OSO_2R > OCOR > OR > alkyl or H; OSO_2CF_3 > OSO_2CH_3; $OCOCF_3$ > $OCOC_6H_5$ > $OCOCH_3$; $OCH_2C_6H_5$>$OSi(CH_3)_2$-t-C_4H_9. By contrast, electron-donating groups exhibited slight preference for the α-migration. The feeble but definite α-selection observed with **9** is to be noted. The well-known Si^+O^- polarization[12] also resulted in some α-regioselection. These findings can be rationalized by considering the mode of transmission of through-

bond electronic effects.[13] The C(γ)–R bond polarization caused by an electronegative R group decreases electron density of the γ-and α-positions in the tetrahedral intermediate **31**, whereas an electron-donating R group makes these two carbon atoms more eletropositive. The α-position is unaffected through such electronic perturbation. As a consequence, the observed regiochemical bias is resulted.



31



32

This type of induced electronic directing effect was noticed also in the oxidation of the ketones **33**—**37** which proceeds *via* the intermediate **32** (Table 2). The structures, **38a**—**42a** and **38b**—**42b**, were readily differentiated by ^{1}H NMR; the isomers of **a** series gave the C*H*R signal at a lower field than the **b** regioisomers owing to the anisotropic effect of the lactone oxygen atom. Thus electron-withdrawing groups attached to the γ-carbon atom showed a moderate degree of α'-regioselection. Here the substituent effects would be less straightforward, because (1) R group in **32** is accommodated in the seven-membered ring and exerts electronic influence not only the α-carbon but also the α'-position, though less effectively, and (2) the R–C(γ)–C(β)–C(α) backbone is distorted to some extent from normal zig-zag arrangement. Nevertheless the observed regioselectivity is compatible qualitatively with the above described interpretation.

These unprecedented remote interactions between the directing substituent and the migrating group should be a reflection of the regidity of the σ framework that facilitates the through-bond electronic influence. Some indication for the efficiency of electronic transmission in these systems may be offered by ^{13}C NMR measurement of the parent ketones; the carbonyl carbon signal appears to move *upfield* considerably with an increase in electron-withdrawing ability of γ-substituents (Table 2).

B. Steric Effects. Oxidation of the oxabicyclic ketones **43**—**50** with trifluoroperacetic acid was examined, and the structures of the regioisomeric lactone products were verified again easily by ^{1}H NMR as the case with the reaction of **33**—**37**. Here ease with which the oxidation takes place was found to be influenced profoundly by bulkiness of the substituent having endo configuration. The parent ketone (R= H) was readily transformed to the lactone, but introduction of methyl group, for instance, reduced the reaction rate by a factor of 4, as revealed by a competition experiment. The *t*-butyl derivative **45** was totally inert to the peroxy acid oxidation. This is obviously ascribable to steric screening effect of R group. Nucleophilic addition of trifluoroperacetic acid to the bicyclic ketones is expected to occur stereoselectively from the less hindered side[14] and, therefore, formation of the tetrahedral adducts of type **58** would be retarded by the presence of a bulky R group which introduces substantial steric repulsion with the hydroxyl.

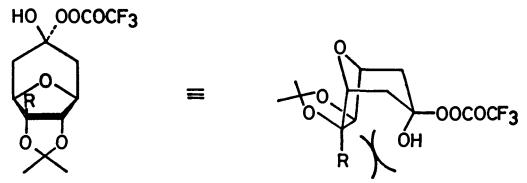
a) Reaction with 3 equiv of CF_3CO_3H in CH_2Cl_2 at 20 °C for 36 h (for **43**, at 25 °C for 36 h). b) Isolated yield. Based on consumed starting material. c) Determined by HPLC analysis. d) Obtained by ^1H NMR analysis.

In usual, rate-determining step of the Baeyer-Villiger oxidation has been considered to be the fragmentation of the tetrahedral intermediate,[15] but in the present case equilibrium concentration of the intermediate **58** is also important.[16]



58

Regioselectivity is also affected by the γ-substituents. Presence of the substituent groups, regardless of the electronic properties, provided a marked bias toward the α′-methylene migration (Table 3). We would postulate that this regioselection relies primarily on a yet unreported controlling factor, chiral orientation of the hydroxyl group in the transient tetrahedral intermediate. *A priori* three types of transition states, **59**—**61**, are conceivable for the concerted fragmentation. The cyclic structures, however, can hardly explain the preference of R_m migration. The five-membered ring **59** is rather rigid and, when an oxabicyclic ketone is employed as starting material, this has basically C_s symmetry. The seven-membered structure **60** is more flexible but the fragmentation *via* such transition state is symmetry-forbidden in nature. On the other hand, the acyclic, extended transition state **61** has a chiral basic geometry; R_m and R_r are clearly diastereotopic each other and are to be differentiated during the concerted fragmentation process.[17] In order for R_m to migrate to O(1) atom with concomitant carboxylic acid ejection, two prerequisites must be satisfied. Firstly, R_m–C–O(1)–O(2) should lie in an antiperiplanar manner. Secondly, since the electron release from the hydroxyl oxygen to the migration origin attached to it is crucial to promote the shift of R_m,[18] one of the hydroxyl nonbonding electron pairs has to be anti to R_m. On the basis of such stereoelectronic requirements, only **61A** and **61B** are the reactive conformers. Conformer **61C** is unreactive. When this consideration is applied to the reaction of the oxabicyclic ketones **43**—**50**, four structures, **58A**, **58B**, **58A′**, and **58B′**, emerge as reactive conformers; **58A** and **58B** lead to the α-methylene migration product, whereas **58A′** and **58B′** result in α′-carbon rearrangement. Here when the nonbonded repulsion between R and the hydroxyl hydrogen is taken into consideration, the relative stabilities are estimated to be **58A′**>**58A**≫**58B**≈**58B′**, consistent with the observed α′-regioselection.[19] Thus chiral arrangement of the hydroxy group in the tetrahedral intermediate seems quite significant in controlling the regiochemical outcome. In this system, through-bond electronic effects of the γ substituents are less important compared with the above described series, because of the stereochemical arrangement is not appropriate for the transmission.[20]

Experimental

General. All melting and boiling points are uncorrected. IR spectra were recorded on a JASCO IRA-1 spectrometer in $CHCl_3$ solution unless otherwise stated. ^1H NMR spectra were obtained using a Varian NV-21 or HA-100 spectrometer, and ^{13}C NMR spectra were recorded at 20 MHz on a Varian CFT-20 spectrometer or at 25 MHz on a JEOL FX-100 spectrometer. The chemical shifts are recorded in parts per million relative to tetramethylsilane as an internal standard. Singlet, doublet, triplet, and multiplet were abbreviated to s, d, t, and m, respectively. Low-resolution mass spectra were measured on a JEOL D 100 instrument and only a parent peak or prominent fragment peaks are described. Exact mass spectra were obtained at Center Research Laboratory of Ono Pharmaceutical Co. Elemental analyses were performed at the Research Laboratory of Fujisawa Pharmaceutical Co., Faculty of Engineering of Nagoya University, and Institute of Pharmaceutical Sciences of Meijo University. Drying of organic extracts was done over anhyd Na_2SO_4. For concentration of organic solvents, a vacuum (50—100 mmHg)** rotary evaporator was used. Bulb-to-bulb short-path distillation was performed by using a Büchi Kugelrohrofen. The cited temperatures for these distillations refer to the maximum temperature attained by the oven during the distillation and are thus not true boiling points.

Chromatography. Thin-layer chromatography (TLC) was done using 0.25-mm layers of silica gel 60 PF_{254} obtained from E. Merck and preparative TLC using 20×20-cm glass plates coated with a 1.0-mm layer of silica gel 60 PF_{254}. Analytical plates were visualized by spraying with a solution of 2% $Ce(SO_4)_2$ in 5% H_2SO_4 or 2% *p*-anisaldehyde in 5% ethanolic H_2SO_4 followed by heating on a hot plate. The position of spots is shown by R_f values. For column chromatography, E. Merck Kieselgel 60 (70—230 mesh) was used. High-performance liquid chromatography (HPLC) was performed with a Waters Model 6000A liquid chromatograph equipped with a Radial Pak B column (4.0ϕ×250) and a refractive index detector or a UV index detector. The position of peaks is shown by V_R (retention volume) values.

Solvents and Materials. DMF, pyridine, *t*-C_4H_9OH, and furan were used after distillation from CaH_2. Acetone and CH_2Cl_2 were distilled from P_2O_5. THF and ether were distilled from sodium benzophenone ketyl. CH_3OH was distilled over magnesium ribbons. Preparation of Zn/Ag couple,[21] Zn/Cu couple,[22] pyridinium *p*-toluenesulfonate,[23] polybromo ketones,[24] pyridinium chlorochromate,[25] trimethylsilyl triflate,[26] 3-pentylfuran,[27] 3-*t*-butylfuran,[28] 3-phenylfuran,[29] 2-phenylfuran,[30] trifluoromethanesulfonic anhydride,[31] *N*-methylmorpholine *N*-oxide monohydrate,[32] 8-oxabicyclo[3.2.1]oct-6-en-3-one,[21b] (1*S**, 2*R**, 5*S**)-2-methyl-8-oxabicyclo[3.2.1]oct-6-en-3-one,[21b] and 2,2-dimethyl-8-oxabicyclo[3.2.1]oct-6-en-3-one[21b] was performed according to the known procedures. Other commercially supplied materials and solvents were used as received.

Preparation of 2-Pentylfuran.[33] To a solution of *n*-C_4H_9Li, prepared from THF (200 ml)*** and *n*-C_4H_9Li in hexane (1.5 mol dm^{-3} solution, 293 ml, 0.44 mol), was added furan (29.1 ml, 0.40 mol) at −10 °C under argon. After stirring for 6 h at the same temperature, 1-bromopentane (54.5 ml, 0.44 mol) was added to this mixture. The resulting mixture was stirred at 25 °C for 12 h and then poured into ice water (300 ml). The organic layer was separated and the aqueous layer was extracted with ether (150 ml×2). The combined extracts were dried and evaporated. The residue was distilled under reduced pressure (64—65 °C/40 mmHg) to give 2-pentylfuran (31.5 g, 57%). ^1H NMR ($CDCl_3$) δ 0.90 (t, J=6.2 Hz, 3H), 1.1—1.9 (m, 6H), 2.62 (t, J=7.0 Hz, 2H), 5.99 (m, 1H), 6.27 (m, 1H), 7.30 (m, 1H).

Preparation of 3-(Benzyloxymethyl)furan. To a mixture of $LiAlH_4$ (760 mg, 20 mmol) in THF (10 ml) was added ethyl 3-furoate (2.80 g, 20 mmol) in THF (5 ml) at 0 °C under argon. After stirring for 1 h at the same temperature, the reaction mixture was diluted with ether (15 ml). To this was added carefully 1 mol dm^{-3} NaOH (1 ml) and the insoluble material was removed by filtration. The filtrate was evaporated to give a colorless oil. To a suspension of NaH (50% oil dispersion, 1.25 g, 26 mmol) in DMF (10 ml) was added the oil in DMF (5 ml) at room temperature. After stirring for 1 h at 50 °C, the mixture was cooled to room temperature. To this was added benzyl chloride (4.62 ml, 40 mmol) and the reaction mixture was stirred for 12 h and poured into ice water (40 ml) and extracted with ether (50 ml×2, 30 ml×1). The ether layer was dried and evaporated to give an oil. Chromatography of this oil on a silica-gel column (10:1 hexane–ethyl acetate) afforded 3-(benzyloxymethyl)furan (3.86 g, 100%). R_f= 0.39 (4:1 hexane–ethyl acetate); ^1H NMR ($CDCl_3$) δ 4.42 (s, $C\underline{H}_2OCH_2C_6H_5$), 4.52 (s, $CH_2\underline{H}_2C_6H_5$), 6.44 (s, H_4), 7.32 (s, C_6H_5), 7.40 (s, H_2 and H_5).

Preparation of 3-(Tetrahydropyran-2-yloxymethyl)furan. A mixture of ethyl 3-furoate (28.0 g, 0.20 mol) and $LiAlH_4$ (7.60 g, 0.20 mol) in THF (300 ml) was stirred for 1 h at 0 °C under argon. To this was added slowly 1 mol dm^{-3} NaOH (20 ml) and the resulting white precipitate was filtered off. The filtrate was evaporated to afford a colorless oil. A solution of this oil, 3,4-dihydro-2*H*-pyran (23.7 ml, 0.26 mol), and pyridinium *p*-toluenesulfonate (5.0 g) in CH_2Cl_2 (150 ml) was stirred for 12 h at 20 °C under argon. The mixture was washed with brine (50 ml×3), dried ($MgSO_4$), and evaporated to give a colorless oil. Chromatography of this oil on a silica-gel column using a 3:1 hexane–ethyl acetate mixture to afford 3-(tetrahydropyran-2-yloxymethyl) furan (29.3 g, 80%) as a colorless oil. R_f=0.19 (3:1 hexane–ethyl acetate); ^1H NMR ($CDCl_3$) δ 1.1—2.2 (m, CH_2), 3.4—4.1 (m, $CH_2C\underline{H}_2O$), 4.41 (d, J=12.4 Hz, $C\underline{H}_aH_b$-OTHP), 4.65 (d, J=12.4 Hz, $CH_a\underline{H}_b$OTHP), 4.69 (m, $CH_2OC\underline{H}OCH_2$), 6.43 and 7.42 (m, H_1, H_2, and H_4).

Preparation of 8-Oxabicyclo[3.2.1]octan-3-one. A mixture of 8-oxabicyclo[3.2.1]oct-6-en-3-one (133 mg, 1.07 mmol), 10% Pd/C (20 mg), and ether (4 ml) was stirred for 16 h at 25 °C under hydrogen and the insoluble material was removed by filtration and the filtrate was evaporated to afford the title compound (129 mg, 95%). ^1H NMR ($CDCl_3$) δ 1.70—2.20 (m, H_6 and H_7), 2.32 (dd, J=1.0, 15.5 Hz, H_{2a} and H_{4a}), 2.77 (dd, J=5.0, 15.5 Hz, H_{2b} and H_{4b}), 4.75 (m, H_1 and H_5); ^{13}C NMR ($CDCl_3$) δ 29.66, 49.75, 74.84, 206.67.

Preparation of 8-Oxabicyclo[3.2.1]oct-6-en-3-one Derivatives. *(1S*,2R*,5S*)-2-Pentyl-8-oxabicyclo[3.2.1]oct-6-en-3-one*: To a mixture of Zn/Ag couple (68.7 g, 1.05 g-atom), furan (240 ml, 3.5 mol), and THF (600 ml) was added 1,1,3,3-tetrabromo-2-octanone (310 g, 0.7 mol) in THF (600 ml) over 1 h at −10 °C under argon. The reaction mixture was stirred at the same temperature for 1 h and then at 25 °C for 39 h. The insoluble material was filtered off and the filtrate was concentrated to dryness. The residue was dissolved in 1.2 l of CH_3OH saturated with NH_4Cl and to this was added Zn/Cu couple (240 g, 3.6 g-atom). The mixture was stirred for 1 h at 25 °C and the insoluble material

** 1 mmHg≈133.322 Pa.

*** 1 ml=0.001 dm^3.

was removed by filtration. The filtrate was diluted with H_2O (300 ml) and saturated disodium dihydrogen ethylenediaminetetraacetate (Na_2H_2edta) (300 ml) and then extracted with CH_2Cl_2 (500 ml×1, 200 ml×2), dried (Na_2SO_4), evaporated to afford a yellow oil. This oil was chromatographed on a silica-gel column using a 10:1 to 3:1 hexane–ethyl acetate mixture to give the title compound (63.2 g, 47%). Analytically pure sample was obtained by bulb-to-bulb distillation (130 °C/0.01 mmHg). R_f=0.31 (3:1 hexane–ethyl acetate); IR 1715 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 0.90 (t, J=6.0 Hz, CH_3), 1.30 (m, CH_2), 1.26 (d, J=5.0 Hz, H_{4a}), 1.70 (m, H_2), 1.74 (dd, J=5.0, 15.0 Hz, H_{4b}), 4.96 (d, J=5.0 Hz, H_1), 5.02 (d, J=5.0 Hz, H_5), 6.27 (s, H_6 and H_7); MS m/z 194 (M^+). Found: C, 74.32; H, 9.02%. Calcd for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34%.

(1S,2S*,5S*)-2-Phenyl-8-oxabicyclo[3.2.1]oct-6-en-3-one*: A mixture of 1-phenyl-1,1,3,3-tetrabromo-2-propanone (90 g, 0.20 mol), Zn/Ag couple (19.5 g, 0.30 g-atom), furan (72.7 ml, 1.0 mol), and THF (250 ml) was stirred for 12 h at 25 °C. Reduction with Zn/Cu couple (65 g, 1.0 g-atom) in NH_4Cl/CH_3OH (700 ml) followed by ordinary extractive workup gave a dark oil. Chromatography of this oil on a silica-gel column using a 3:1 to 1:1 hexane–ethyl acetate mixture afforded 19.2 g (48%) of the title compound. Analytically pure sample was obtained by recrystallization from hexane. Mp 112.8—113.1 °C; R_f=0.35 (1:1 hexane–ethyl acetate); IR 1715 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 2.23 (dd, J=2.5, 16.4 Hz, H_{4a}), 2.88 (dd, J=4.7, 16.4 Hz, H_{4b}), 4.42 (d, J=4.9 Hz, H_2), 5.00 (dd, J=1.5, 4.9 Hz, H_1), 5.13 (ddd, J=1.5, 2.5, 4.7 Hz, H_5), 6.31 (dd, J=1.5, 7.0 Hz, H_6), 6.45 (dd, J=1.5, 7.0 Hz, H_7), 7.10 and 7.30 (m, C_6H_5); MS m/z 200 (M^+). Found: C, 78.05; H, 6.09%. Calcd for $C_{13}H_{12}O_2$: C, 77.98; H, 6.04%.

(1R,5S*)-1-Methyl-8-oxabicyclo[3.2.1]oct-6-en-3-one*: A solution of $\alpha,\alpha,\alpha',\alpha'$-tetrabromoacetone (212 g, 0.60 mol) in THF (200 ml) was added to a mixture of Zn/Ag couple (39.0 g, 0.60 g-atom), 2-methylfuran (30.0 ml, 0.30 mol), and THF (200 ml) over 1 h at −10 °C. The resulting mixture was stirred for 1 h at the same temperature and then for 24 h at 25 °C. Reductive workup with Zn/Cu couple (130 g, 2.0 g-atom) in NH_4Cl/CH_3OH (400 ml) followed by ordinary extractive workup gave a brown oil. Purification of this oil by chromatography on a silica-gel column (4:1 hexane–ethyl acetate) afforded the title compound (25.0 g, 60%) as an oil. R_f=0.22 (4:1 hexane–ethyl acetate); IR (neat) 1718 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.50 (s, CH_3), 2.1—2.9 (m, H_2 and H_4), 5.06 (ddd, J=1.2, 1.8, 5.0 Hz, H_5), 6.05 (d, J=5.8 Hz, H_7), 6.20 (dd, J=1.8, 5.8 Hz, H_6); MS m/z 138 (M^+). Found: m/z 138.0682. Calcd for $C_8H_{10}O_2$: M, 138.0681.

(1R,5S*)-1-Pentyl-8-oxabicyclo[3.2.1]oct-6-en-3-one*: A mixture of $\alpha,\alpha,\alpha',\alpha'$-tetrabromoacetone (112 g, 0.30 mol), Zn/Ag couple (13.0 g, 0.20 g-atom), 2-pentylfuran (15.0 g, 0.10 mol), and THF (250 ml) was stirred for 12 h at 25 °C. Reduction with Zn/Cu couple (100 g, 1.54 g-atom) in NH_4Cl/CH_3OH (300 ml) followed by extractive workup gave a brown oil. This oil was purified on a silica-gel column (4:1 hexane–ethyl acetate) to afford the title compound (9.70 g, 50%) as an oil. R_f=0.37 (4:1 hexane–ethyl acetate); IR (neat) 1718 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 0.91 (t, J=6.5 Hz, CH_3), 1.1—1.9 (m, CH_2), 2.1—2.8 (m, H_2 and H_4), 5.06 (ddd, J=1.1, 1.9, 5.0 Hz, H_5), 6.05 (d, J=6.0 Hz, H_7), 6.19 (dd, J=1.9, 6.0 Hz, H_6); MS m/z 194 (M^+). Found: m/z 194.1328. Calcd for $C_{12}H_{18}O_2$: M, 194.1307.

(1R,5S*)-1-Phenyl-8-oxabicyclo[3.2.1]oct-6-en-3-one*: A mixture of $\alpha,\alpha,\alpha',\alpha'$-tetrabromoacetone (77.8 g, 0.208 mol), Zn/Ag couple (9.0 g, 0.139 g-atom), 2-phenylfuran (10 g, 69.4 mmol), and THF (170 ml) was stirred for 48 h at 25 °C. Reduction with Zn/Cu couple (70 g, 1.08 g-atom) in NH_4Cl/CH_3OH (200 ml) followed by ordinary extractive workup gave a brown oil. Purification of this oil on a silica-gel column using a 4:1 hexane–ethyl acetate mixture afforded the title compound (8.60 g, 62%). Mp 94—96 °C (hexane–chloroform); R_f=0.29 (4:1 hexane–ethyl acetate); IR (neat) 1720 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 2.39 (dd, J=1.0, 16.0 Hz, H_{4a}), 2.82 (s, H_2), 2.83 (dd, J=5.0, 16.0 Hz, H_{4b}), 5.26 (dd, J=1.0, 5.0 Hz, H_5), 6.30 (s, H_6 and H_7), 7.42 (m, C_6H_5); MS m/z 200(M^+). Found: C, 78.24; H, 6.06%. Calcd for $C_{13}H_{12}O_2$: C, 77.98; H, 6.04%.

(1S,5S*)-1-Acetoxymethyl-8-oxabicyclo[3.2.1]oct-6-en-3-one*: A mixture of $\alpha,\alpha,\alpha',\alpha'$-tetrabromoacetone (3.74 g, 10 mmol), Zn/Ag couple (981 mg, 15.0 mg-atom), furfuryl acetate (7.0 g, 50 mmol), and THF (35 ml) was stirred for 12 h at 20 °C and worked up in a usual manner to give a dark oil. Chromatography on a silica-gel column using a 7:1 to 3:1 hexane–ethyl acetate mixture afforded 1.73 g (52%) of (1*S**, 2*R**,4*S**,5*R**)-1-acetoxymethyl-2,4-dibromo-8-oxabicyclo-[3.2.1]oct-6-en-3-one as a yellow solid. Pure sample was obtained by recrystallization from hexane–ethyl acetate. Mp 115—116.5 °C; R_f=0.14 (7:1 hexane–ethyl acetate); IR 1745 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 2.18 (s, CH_3CO), 4.54 (d, J=13.5 Hz, $\underline{H}_a\underline{H}_bCOC{=}O$), 4.67 (d, J=13.5 Hz, $H_a\underline{H}_bCOC{=}O$), 4.90 (d, J=4.5 Hz, H_4), 4.95 (s, H_2), 5.12 (dd, J=2.0, 4.5 Hz, H_5), 6.32 (d, J=6.5 Hz, H_7), 6.60 (dd, J=2.0, 6.5 Hz, H_6). Found: C, 33.95; H, 2.71; Br, 44.99%. Calcd for $C_{10}H_{10}O_4Br_2$: C, 33.93, H, 2.85; Br, 45.15%.

Treatment of this dibromo ketone (1.50 g, 4.44 mmol) with Zn/Cu couple (6.0 g, 92.3 mg-atom) in CH_3OH–CH_3COCH_3 (5:1, 30 ml) saturated with NH_4Cl at 20 °C for 1 h followed by extractive workup afforded the title compound (776 mg, 89%) as a yellow oil. Analytical sample was obtained by bulb-to-bulb distillation (bp 120 °C/0.01 mmHg). R_f=0.22 (2:1 hexane–ethyl acetate); IR 1722 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 2.12 (s, CH_3CO), 2.2—2.9 (m, H_2 and H_4), 4.34 (s, $CH_2OC{=}O$), 5.13 (m, H_5), 6.09 (d, J=6.0 Hz, H_7), 6.30 (dd, J=2.0, 6.0 Hz, H_6); ^{13}C NMR ($CDCl_3$) δ 45.07, 47.57, 65.25, 77.73, 84.83, 132.73, 134.54, 170.18, 204.00. Found: C, 61.10; H, 6.28%. Calcd for $C_{10}H_{12}O_4$: C, 61.24; H, 6.17%.

(1S,5S*)-1-Benzyloxymethyl-8-oxabicyclo[3.2.1]oct-6-en-3-one*: A mixture of $\alpha,\alpha,\alpha',\alpha'$-tetrabromoacetone (113 g, 0.3 mol), Zn/Ag couple (13.0 g, 0.2 g-atom), 2-(benzyloxymethyl)-furan (18.0 g, 95.7 mmol), and THF (300 ml) was stirred for 48 h at 30 °C and worked up in a usual manner to give a dark oil. Treatment of this oil with Zn/Cu couple (98 g, 1.5 g-atom) in NH_4Cl/CH_3OH (250 ml) at 25 °C for 1 h followed by silica-gel column chromotography using a 3:1 hexane–ethyl acetate mixture to afford 8.17 g (35%) of the title compound as a yellow oil. R_f=0.50 (1:1 hexane–ethyl acetate); IR (neat) 1720 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 2.1—2.9 (m, H_2 and H_4), 3.65 (s, $C\underline{H}_2OC\underline{H}_2C_6H_5$), 4.62 (s, $C\underline{H}_2C_6H_5$), 6.08 (d, J=6.0 Hz, H_7), 6.23 (dd, J=2.0, 6.0 Hz, H_6), 7.33 (s, C_6H_5).

(1R,5R*,6S*)-6-Benzoyloxy-8-oxabicyclo[3.2.1]octan-3-one* (**37**): To a solution of 8-oxabicyclo[3.2.1]oct-6-en-3-one (5.70 g, 50 mmol)[21b] in dry toluene (50 ml) was added diisobutylaluminium hydride in toluene (1.5 mol dm^{-3} solution, 44 ml, 65 mmol) at −78 °C under argon. After stirring for 3 h, the mixture was diluted with ether (50 ml) and to this was added slowly saturated NH_4Cl (10 ml). The mixture was warmed up to room temperature and stirred for 1 h. The insoluble material was removed by a Celite 545

pad and the filtrate was evaporated to give 8-oxabicyclo-[3.2.1]oct-6-en-3-ol (4.73 g, 82%) as a white semi-solid. This material was used in the next step without further purification. R_f=0.17 (1:1 hexane–ethyl acetate); IR (neat) 3380 cm^{-1} (OH); ^1H NMR ($CDCl_3$) δ 1.6—2.5 (m, H_2 and H_4), 4.0 (m, H_3), 4.74 (m, H_1 and H_5), 6.10 and 6.44 (s, 28:72 ratio).

A mixture of this alcohol (4.30 g, 37.1 mmol), pyridinium *p*-toluenesulfonate (931 mg, 3.71 mmol), 3,4-dihydro-2*H*-pyran (4.06 ml, 44.5 mmol), and CH_2Cl_2 (30 ml) was stirred for 48 h at 20 °C. The mixture was washed with brine (30 ml), dried, and evaporated to give a dark oil. Chromatography of the residue on a silica-gel column using a 4:1 hexane–ethyl acetate mixture afforded 3-(tetrahydropyran-2-yloxy)-8-oxabicyclo[3.2.1]oct-6-ene (6.68 g, 86%) as a colorless oil. R_f=0.39 (4:1 hexane–ethyl acetate); ^1H NMR ($CDCl_3$) δ 1.4—2.4 (m, 10H), 3.5 (m, 1H), 4.0 (m, 2H), 4.7 (m, 3H), 6.22 (m, 2H).

To a solution of this THP ether (3.30 g, 15.7 mmol) in dry THF (10 ml) was added BH_3 in THF (1.0 mol dm^{-3} solution, 6.8 ml, 6.8 mmol) at 0 °C under argon. The mixture was stirred for 1.5 h at 20 °C and to this was added H_2O (1 ml). After stirring for 10 min, 3 mol dm^{-3} NaOH (2.5 ml, 7.5 mmol) and 30% H_2O_2 (2.24 ml, 20.4 mmol) were added. The mixture was stirred for 1 h at 50 °C, cooled to room temperature, and diluted with ether (20 ml). The organic layer was separated, washed with brine, dried, and evaporated to give a colorless oil. To this oil in pyridine (10 ml) was added benzoyl chloride (2.39 ml, 20.4 mmol) under argon. The mixture was stirred for 12 h at 20 °C and evaporated. The residue was diluted with ether (50 ml), washed with brine, neutralized with 1 mol dm^{-3} HCl, dried, and evaporated to give a yellow oil. Chromatography of this oil on a silica-gel column using a 3:1 hexane–ethyl acetate mixture afforded (1*S**,5*R**,6*S**)-6-benzoyloxy-3-(tetrahydropyran-2-yloxy)-8-oxabicyclo[3.2.1]-oct-6-ene (4.64 g, 89%) as a colorless oil. R_f=0.31 (2:1 hexane–ethyl acetate); IR 1720 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.5—2.4 (m, 8H), 2.70—3.14 (m, 1H), 3.40—3.66 (m, 1H), 3.76—4.22 (m, 2H), 4.30—4.82 (m, 3H), 5.37 (m, 1H), 5.76 (dd, J=3.0, 7.1 Hz) and 5.93 (dd, J=2.2, 7.1 Hz) (total 1H), 7.30 and 8.06 (m, C_6H_5).

A mixture of this benzoate (4.60 g, 13.9 mmol), pyridinium *p*-toluenesulfonate (349 mg, 1.39 mmol), and CH_3OH (30 ml) was stirred for 20 h at 20 °C. The mixture was evaporated and the residue was diluted with ether (50 ml). The ether layer was washed with brine, dried, and evaporated to give a colorless oil. To a mixture of pyridinium chlorochromate (5.89 g, 27.8 mmol), sodium acetate (658 mg, 8.34 mmol), and CH_2Cl_2 (30 ml) was added the oil, obtained above, in CH_2Cl_2 (15 ml). The mixture was stirred for 2 h at 20 °C and diluted with hexane (20 ml). The insoluble material was removed by filtration and the filtrate was evaporated and chromatographed on a silica-gel column (1:1 hexane–ethyl acetate) to afford 2.20 g (58%) of **37** as a white solid. Mp 142—143 °C (hexane–chloroform); R_f=0.49 (1:2 hexane–ethyl acetate); IR 1720 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 2.2—2.9 (m, H_2, H_4, and H_7), 4.75 (d-like, J=5.2 Hz, H_5), 4.92 (m, H_1), 5.29 (dd, J=4.7, 5.2 Hz, H_6), 7.30 and 8.04 (m, C_6H_5); ^{13}C NMR ($CDCl_3$) δ 38.13, 46.26, 49.10, 74.69, 78.14, 80.18, 128.44, 129.69, 133.22, 133.57, 166.23, 204.86. Found: C, 68.45; H, 5.69%. Calcd for $C_{14}H_{14}O_4$: C, 68.28; H, 5.73%.

*(1*R*,5R*,6S*)-6-Benzyloxy-8-oxabicyclo[3.2.1]octan-3-one* (**33**): To a mixture of **37** (492 mg, 2 mmol), 1,2-bis(trimethylsiloxy)ethane (492 mg, 2.4 mmol), and dry CH_2Cl_2 (5 ml) was added trimethylsilyl triflate in CH_2Cl_2 (0.05 mol dm^{-3} solution, 4 ml, 0.2 mmol) at 0 °C under argon. The mixture was stirred for 30 min at 20 °C and to this was added pyridine (0.1 ml). The reaction mixture was washed with brine, dried, and evaporated to afford ethylene acetal of **37** (580 mg, 100%) as white crystals. Mp 92—93 °C; R_f=0.47 (1:1 hexane–ethyl acetate); IR 1718 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.70 (d-like, J=14.7 Hz, 1H), 1.95—2.23 (m, 4H), 2.80 (dd, J=7.8, 14.7 Hz, 1H), 3.92 (m, OCH_2CH_2O), 4.45 (m, H_5), 4.66 (m, H_1), 5.69 (dd, J=2.7, 7.3 Hz, H_6), 7.45 and 8.02 (m, C_6H_5).

A mixture of this ethylene acetal (2.03 g, 7 mmol), lithium hydroxide (40 mg), and CH_3OH (25 ml) was stirred for 48 h at 15 °C under argon. The mixture was evaporated and the residue was diluted with ether (50 ml). The organic layer was washed with saturated NH_4Cl (10 ml), brine, dried, and evaporated to give a yellow oil. To a suspension of NaH (50% oil dispersion, 323 mg, 6.72 mmol) in DMF (10 ml) was added the above obtained oil in DMF (5 ml). The mixture was stirred for 1 h at 50 °C under argon. After the mixture was cooled to 0 °C, benzyl chloride (1.19 ml, 10.3 mmol) was added. The reaction mixture was stirred for 12 h at 15 °C and evaporated. The residue was diluted with ether (20 ml) and the ether layer was washed with brine, dried, and evaporated to give a yellow oil. Chromatography of this oil on a silica-gel column using a 1:1 hexane–ethyl acetate mixture afforded a colorless oil (1.14 g, 80%). ^1H NMR ($CDCl_3$) δ 1.55—2.19 (m, 5H), 2.59 (dd, J=7.0, 12.7 Hz, 1H), 3.89 (m, OCH_2CH_2O), 4.41 (m, 1H), 4.49 (s, $C\underline{H}_2C_6H_5$), 4.61 (m, 1H), 7.34 (s, C_6H_5).

A mixture of this oil (1.14 g, 4.14 mmol), oxalic acid (100 mg), THF (10 ml), and H_2O (10 ml) was stirred for 8 h at 50 °C. The mixture was evaporated, extracted with chloroform (30 ml), washed with brine, dried, and concentrated to give 872 mg (91%) of **33** as a white solid. Mp 55—57 °C (ether–hexane); R_f=0.35 (1:1 hexane–ethyl acetate); IR (neat) 1719 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 2.02—2.80 (m, H_2, H_4, and H_7), 3.94 (dd, J=3.2, 6.0 Hz, H_6), 4.46 (s, $C\underline{H}_2C_6H_5$), 4.64 (d-like, J=5.0 Hz, H_5), 4.80 (m, H_1), 7.30 (s, C_6H_5); ^{13}C NMR ($CDCl_3$) δ 38.50, 46.80, 49.24, 71.23, 74.71, 79.55, 82.36, 127.72, 128.45, 137.85, 205.66. Found: C, 72.13; H, 6.90%. Calcd for $C_{14}H_{16}O_3$: C, 72.39; H, 6.94%.

*(1*R*,5R*,6S*)-6-Hydroxy-8-oxabicyclo[3.2.1]octan-3-one*: A mixture of **37** (10.0 g, 40.7 mmol), lithium hydroxide (293 mg, 12.2 mmol), and dry CH_3OH (100 ml) was stirred for 15 h at 20 °C under argon. The mixture was evaporated and the residue was chromatographed on a silica-gel column using 3:1 hexane–ethyl acetate to pure ethyl acetate afforded 9.39 g (98%) of the title compound as a colorless oil. R_f=0.18 (3:1 ethyl acetate–hexane); IR (neat) 3380 (OH), 1720 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 2.0—2.8 (m, H_2, H_4, and H_7), 3.15 (s, OH), 4.27 (dd, J=3.2, 6.0 Hz, H_6), 4.51 (d-like, J=6.0 Hz, H_5), 4.84 (m, H_1); ^{13}C NMR ($CDCl_3$) δ 41.27, 46.14, 49.47, 74.70, 75.45, 82.69, 206.09.

*(1*R*,5R*,6S*)-6-t-Butyldimethylsiloxy-8-oxabicyclo[3.2.1]-octan-3-one* (**34**): A mixture of **37** (2.00 g, 8.13 mmol), lithium hydroxide (60 mg, 2.5 mmol), and CH_3OH (10 ml) was stirred for 12 h at 20 °C. The reaction mixture was evaporated to dryness and coevaporated with benzene (5 ml × 3). To the residue in DMF (10 ml) were added *t*-butyldimethylsilyl chloride (1.83 g, 12.2 mmol) and imidazole (1.66 g, 24.4 mmol) in DMF (15 ml).[34] The mixture was stirred for 12 h at 20 °C and evaporated. The residue was diluted with ethyl acetate, washed with brine, dried, and evaporated to give a pale yellow oil. This oil was chromatographed on a silica-gel column using a 2:1 hexane–ethyl acetate mixture to afford 1.83 g (90%) of **34** as a colorless oil. R_f=

0.45 (2:1 hexane–ethyl acetate); IR (neat) 1720 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 0.02 (s, t-$C_4H_9(C\underline{H}_3)_2Si$), 0.85 (s, t-$C_4\underline{H}_9(CH_3)_2Si$), 1.94—2.79 (m, H_2, H_4, and H_7), 4.20 (dd, J=3.8, 6.0 Hz, H_6), 4.41 (d-like, J=5.2 Hz, H_5), 4.80 (m, H_1); ^{13}C NMR ($CDCl_3$) δ 18.01, 25.78, 42.02, 46.78, 49.28, 74.93, 76.08, 83.02, 205.76.

(1R,5R*,6S*)-6-Acetoxy-8-oxabicyclo[3.2.1]octan-3-one (**35**)*: A mixture of (1*R**,5*R**,6*S**)-6-hydroxy-8-oxabicyclo[3.2.1]-octan-3-one (426 mg, 3 mmol), pyridine (2 ml), and acetic anhydride (2 ml) was stirred for 12 h at 20 °C under argon. The reaction mixture was evaporated and the residue was chromatographed on a silica-gel column using a 2:1 ethyl acetate–hexane mixture to afford 564 mg (100%) of **35** as a white solid. Mp 57—58 °C (hexane–chloroform); R_f= 0.40 (2:1 ethyl acetate–hexane); IR 1732 and 1723 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 2.07 (s, CH_3CO), 2.14—2.88 (m, H_2, H_4, and H_7), 4.62 (d-like, J=5.2 Hz, H_5), 4.88 (m, H_1), 5.06 (dd, J=4.7, 6.0 Hz, H_6); ^{13}C NMR ($CDCl_3$) δ 20.81, 38.02, 46.15, 49.05, 74.58, 77.32, 80.06, 170.40, 204.78. Found: C, 58.58; H, 6.63%. Calcd for $C_9H_{12}O_4$: C, 58.69; H, 6.57%.

(1R,5R*,6S*)-6-Pivaloyloxy-8-oxabicyclo[3.2.1]octan-3-one (**36**)*: To a solution of (1*R**,5*R**,6*S**)-6-hydroxy-8-oxabicyclo[3.2.1]octan-3-one (426 mg, 3 mmol) in dry pyridine (7 ml) was added pivaloyl chloride (0.75 ml, 6 mmol) at 0 °C under argon. After stirring for 12 h at 20 °C, the mixture was concentrated. The residue was chromatographed on a silica-gel column using a 1:1 hexane–ethyl acetate mixture to give **36** (687 mg, 100%) as a white solid. Mp 57—58 °C (ether–hexane); R_f=0.50 (1:1 hexane–ethyl acetate); IR 1723 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.19 (s, t-C_4H_9), 2.08—2.86 (m, H_2, H_4, and H_7), 4.55 (d-like, J=5.5 Hz, H_5), 4.86 (m, H_1), 5.01 (dd, J=4.0, 6.0 Hz, H_6); ^{13}C NMR ($CDCl_3$) δ 27.04, 38.02, 38.51, 46.32, 49.04, 74.64, 77.42, 80.14, 178.04, 204.77. Found: C, 63.40; H, 8.11%. Calcd for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%.

6-Methyl-8-oxabicyclo[3.2.1]oct-6-en-3-one: To a mixture of Zn/Ag couple (39.0 g, 0.60 g-atom), 3-methylfuran (4.6 g, 0.3 mol), and THF (300 ml) was added a solution of α,α,α′,α′-tetrabromoacetone (337 g, 0.9 mol) in THF (150 ml) over 1 h at 0 °C. After stirring for 14 h at 25 °C, the mixture was concentrated. Reduction with Zn/Cu couple (293 g, 4.5 g-atom) in NH_4Cl/CH_3OH (500 ml) followed by ordinary extractive workup afforded a brown oil. Chromatography of this oil on a silica-gel column using a 5:1 hexane–ethyl acetate mixture afforded the title compound (35.8 g, 86%) as an oil. R_f=0.26 (5:1 hexane–ethyl acetate); IR (neat) 1718 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.78 (s, CH_3), 2.16—2.82 (m, H_2 and H_4), 4.70 (d, J=5.0 Hz, H_5), 4.94 (m, H_1), 5.78 (m, H_7); ^{13}C NMR ($CDCl_3$) δ 11.75, 45.04, 45.44, 77.08, 79.94, 126.24, 142.96, 204.25; MS m/z 138 (M^+).

6-Pentyl-8-oxabicyclo[3.2.1]oct-6-en-3-one: A mixture of 3-pentylfuran (3.59 g, 26 mmol), Zn/Ag couple (3.36 g, 52 mg-atom), α,α,α′,α′-tetrabromoacetone (29.2 g, 78 mmol), and THF (66 ml) was stirred for 48 h at 30 °C under argon. Reduction with Zn/Cu couple (26 g, 0.39 g-atom) in NH_4Cl/CH_3OH (100 ml) followed by ordinary extractive workup gave a brown oil. Purification of this oil on a silica gel column using a 6:1 hexane–ethyl acetate mixture afforded 984 mg (20%) of the title compound as an oil. R_f=0.43 (3:1 hexane–ethyl acetate); IR (neat) 1718 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 0.90 (m, CH_3), 1.1—1.7 (m, CH_2), 2.0—2.9 (m, CH_2, H_2, and H_4), 4.79 (d, J=4.8 Hz, H_5), 4.99 (m, H_1), 5.81 (m, H_7); ^{13}C NMR ($CDCl_3$) δ 13.96, 20.50, 27.22, 31.67, 46.37, 77.81, 79.46, 125.56, 148.81, 205.37.

6-t-Butyl-8-oxabicyclo[3.2.1]oct-6-en-3-one: A mixture of 3-*t*-butylfuran (9.18 g, 74 mmol), Zn/Ag couple (9.56 g, 148 mg-atom), α,α,α′,α′-tetrabromoacetone (83.2 g, 222 mmol), and THF (177 ml) was stirred for 60 h at 20 °C under argon. Reduction with Zn/Cu couple (73 g, 1.11 g-atom) in NH_4Cl/CH_3OH (300 ml) followed by ordinary extractive workup gave a brown oil. Chromatography of this oil on a silica-gel column using a 5:1 to 1:1 hexane–ethyl acetate afforded the title compound (3.06 g, 23%) as an oil. R_f=0.50 (2:1 hexane–ethyl acetate); IR (neat) 1716 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.10 (s, t-C_4H_9), 2.1—3.0 (m, H_2 and H_4), 4.96 (m, H_1 and H_5), 5.82 (m, H_7); ^{13}C NMR ($CDCl_3$) δ 29.55, 31.73, 46.42, 48.13, 77.16, 77.56, 124.17, 128.34, 204.96.

6-Phenyl-8-oxabicyclo[3.2.1]oct-6-en-3-one: A mixture of 3-phenylfuran (5.51 g, 38.3 mmol), Zn/Ag couple (4.97 g, 76.6 mg-atom), α,α,α′,α′-tetrabromoacetone (42.9 g, 115 mmol), and THF (100 ml) was stirred for 48 h at 19 °C. Reduction with Zn/Cu couple (49.8 g, 766 mg-atom) in NH_4Cl/CH_3OH (100 ml) followed by ordinary extractive workup afforded 1.69 g (22%) of the title compound as a solid. Mp 94.0—96.5 °C (ether–hexane); R_f=0.69 (2:1 ethyl acetate–hexane); IR 1715 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 2.3—3.0 (m, H_2 and H_4), 5.16 (m, H_1), 5.40 (m, H_5), 6.48 (d, J=2.2 Hz, H_7), 7.34 (s, C_6H_5); ^{13}C NMR ($CDCl_3$) δ 45.87, 46.56, 77.97, 78.54, 125.90, 126.26, 128.85, 128.96, 131.45, 204.53.

6-(Tetrahydropyran-2-yloxymethyl)-8-oxabicyclo[3.2.1]oct-6-en-3-one: A mixture of 3-(tetrahydropyran-2-yloxymethyl)furan (17.0 g, 43.3 mmol), Zn/Ag couple (12.2 g, 0.187 g-atom), α,α,α′,α′-tetrabromoacetone (105 g, 280 mmol), and THF (224 ml) was stirred for 60 h at 20 °C. Reduction with Zn/Cu couple (91 g, 1.4 g-atom) in NH_4Cl/CH_3OH (500 ml) followed by ordinary extractive workup gave the title compound (6.93 g, 31%) as a brown oil. R_f=0.44 (1:1 hexane–ethyl acetate); IR (neat) 1715 cm^{-1} (C=O), ^1H NMR ($CDCl_3$) δ 1.4—1.9 (m, 6H), 2.19—2.92 (m, H_2 and H_4), 3.32—3.95 (m, 2H), 4.14 (d, J=13.6 Hz, $\underline{H}_a\underline{H}_b$COTHP), 4.36 (d, J=13.6 Hz, $H_a\underline{H}_b$COTHP), 4.60 (br, OCHO), 4.98 (m, H_1 and H_5), 6.08 (m, H_7).

Preparation of 6,7-Isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one Derivatives. (1R,2R*,5S*,6S*,7R*)-6,7-Isopropylidenedioxy-2-methyl-8-oxabicyclo[3.2.1]octan-3-one (**1**)*: To a mixture of (1*S**,2*R**,5*S**)-2-methyl-8-oxabicyclo[3.2.1]oct-6-en-3-one (8.0 g, 57.9 mmol), acetone (60 ml), t-C_4H_9OH (6 ml), ether (6 ml), and OsO_4 (30 mg) was added 30% H_2O_2 (19.0 ml, 174 mmol) over 10 min at 0 °C. After stirring for 12 h at 25 °C, the mixture was cooled to 0 °C. To this was added slowly $Na_2S_2O_3 \cdot 5H_2O$ (30 g) and the reaction mixture was stirred for 3 h at 0 °C and concentrated. The residue was extracted with ethyl acetate (60 ml×4) and the organic extracts were dried and evaporated to give a dark solid. To a solution of this solid in acetone (100 ml) was added $CuSO_4$ (13 g) and p-toluenesulfonic acid (15 mg) and the mixture was stirred for 18 h at 25 °C. The insoluble material was removed by filtration and the filtrate was evaporated to give a yellow oil. Chromatography of this oil on a silica-gel column using a 2:1 to 1:1 hexane–ethyl acetate mixture afforded **1** (6.82 g, 56%). Mp 126.1—127.5 °C (ether); R_f=0.46 (1:1 hexane–ethyl acetate); IR 1710 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.28 (d, J=7.0 Hz, CH_3), 1.29 and 1.50 (s, isopropylidene CH_3), 2.34 (d, J=16.0 Hz, H_{4a}), 2.73 (dd, J=6.0, 16.0 Hz, H_{4b}), 2.80 (m, H_2), 4.39 (d, J=5.5 Hz, H_1), 4.46 (s, H_6 and H_7), 4.60 (d, J=6.0 Hz, H_5); MS m/z 197 (M^+—15). Found: C, 61.85; H, 7.72%. Calcd for $C_{11}H_{16}O_4$: C, 62.25; H, 7.60%.

(1R,2R*,5S*,6S*,7R*)-6,7-Isopropylidenedioxy-2-pentyl-8-oxabicyclo[3.2.1]octan-3-one (**2**)*: To a mixture of (1*S**,2*R**,5*S**)-2-pentyl-8-oxabicyclo[3.2.1]oct-6-en-3-one (26.8 g, 138

mmol), acetone (250 ml), ether (20 ml), t-C_4H_9OH (20 ml), and OsO_4 (200 mg) was added 30% H_2O_2 (75.9 ml, 691 mmol) over period of 1 h. After stirring for 24 h at 25 °C, OsO_4 (100 mg) and 30% H_2O_2 (50 ml) were further added. The mixture was stirred for 12 h and worked up in a usual manner to afford a pale green oil. This oil was dissolved in 150 ml of dry acetone and to this was added $CuSO_4$ (40 g) and p-toluenesulfonic acid (300 mg). The resulting mixture was stirred for 12 h at 25 °C and worked up in a usual manner to give a yellow oil. Chromatography of this oil on a silica-gel column using a 3:1 hexane–ethyl acetate mixture afforded 18.5 g (50%) of **2**. Analytically pure sample was obtained by bulb-to-bulb distillation (160 °C/0.03 mmHg). Mp 45—47 °C; R_f=0.54 (1:1 hexane–ethyl acetate); IR 1719 cm^{-1} (C=O); ^1H NMR (C_6D_6) δ 0.84 (t-like, J=6.0 Hz, CH_3), 1.09 and 1.51 (s, isopropylidene CH_3), 1.20 (m, CH_2), 1.83 (d, J=15.0 Hz, H_{4a}), 2.16 (dd, J=6.0, 15.0 Hz, H_{4b}), 2.20 (m, H_2), 4.08 (d, J=6.0 Hz, H_6), 4.27 (d, J=6.0 Hz, H_7), 4.40 (m, H_1 and H_5); MS m/z 253 (M^+-15). Found: C, 67.34; H, 9.01%. Calcd for $C_{15}H_{24}O_4$: C, 67.13; H, 9.02%.

(1S,5S*,6S*,7S*)-2,2-Dimethyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one (**4**)*: A mixture of 2,2-dimethyl-8-oxabicyclo[3.2.1]oct-6-en-3-one (12.8 g, 84.2 mmol), acetone (240 ml), t-C_4H_9OH (24 ml), ether (24 ml), OsO_4 (100 mg), and 30% H_2O_2 (28 ml, 253 mmol) was stirred for 12 h at 25 °C and worked up in a usual manner to afford a white solid. To a solution of this solid in acetone (150 ml) was added $CuSO_4$ (20 g) and p-toluenesulfonic acid (100 mg) and the mixture was stirred for 12 h at 25 °C. Usual workup left a yellow oil. Chromatography of the residue on a silica-gel column using a 3:1 hexane–ethyl acetate mixture afforded **4** (11.2 g, 59%). Mp 109.5—110 °C (ether); R_f=0.34 (2:1 hexane–ethyl acetate); IR 1709 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.11 and 1.34 (s, CH_3), 1.31 and 1.50 (s, isopropylidene CH_3), 2.20 (d, J=16.0 Hz, H_{4a}), 2.91 (dd, J=6.0, 16.0 Hz, H_{4b}), 4.02 (s, H_1), 4.44 (d, J=5.5 Hz, H_6), 4.52 (d, J=6.0 Hz, H_5), 4.60 (d, J=5.5 Hz, H_7); MS m/z 226 (M^+). Found: C, 63.74; H, 8.07%. Calcd for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%.

(1R,2S*,5S*,6S*,7R*)-6,7-Isopropylidenedioxy-2-phenyl-8-oxabicyclo[3.2.1]octan-3-one (**3**)*: A mixture of (1*S**,2*S**,5*S**)-2-phenyl-8-oxabicyclo[3.2.1]oct-6-en-3-one (5.10 g, 25.5 mmol), acetone (50 ml), ether (5 ml), t-C_4H_9OH (5 ml), and OsO_4 (30 mg) was added 30% H_2O_2 (7 ml, 63 mmol) at 0 °C. The resulting mixture was stirred for 24 h at 25 °C and worked up in a usual manner to give a yellow solid. To a solution of this solid in 30 ml of dry acetone was added $CuSO_4$ (5 g) and p-toluenesulfonic acid (10 mg) and the mixture was stirred for 20 h at 25 °C. Usual workup in a usual manner followed by purification on a silica-gel column using a 2:1 hexane–ethyl acetate mixture afforded **3** (3.55 g, 51%). Mp 162.3—162.8 °C (hexane–ethyl acetate); R_f=0.42 (1:1 hexane–ethyl acetate); IR 1710 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.28 and 1.50 (s, isopropylidene CH_3), 2.48 (d, J=16.0 Hz, H_{4a}), 2.88 (dd, J=6.0, 16.0 Hz, H_{4b}), 4.02 (d, J=5.0 Hz, H_2), 4.61 (d, J=5.7 Hz, H_6), 4.65 (m, H_1 and H_5), 4.78 (d, J=5.7 Hz, H_7); MS m/z 274 (M^+). Found: C, 70.17; H, 6.46%. Calcd for $C_{16}H_{18}O_4$: C, 70.05; H, 6.61%.

(1R,5S*,6S*,7S*)-6,7-Isopropylidenedioxy-1-methyl-8-oxabicyclo[3.2.1]octan-3-one (**9**)*: To a solution of (1*R**,5*S**)-1-methyl-8-oxabicyclo[3.2.1]oct-6-en-3-one (25.0 g, 181 mmol), acetone (181 ml), t-C_4H_9OH (18 ml), ether (18 ml), and OsO_4 (400 mg) was added 30% H_2O_2 (39.3 ml, 362 mmol) and the resulting mixture was stirred for 12 h at 25 °C. The mixture was subjected to usual workup to give oily residue. A mixture of the resulting oil, $CuSO_4$ (50 g), p-toluenesulfonic acid (170 mg), and acetone (180 ml) was stirred for 12 h at 25 °C. The mixture was usually worked up to give a black oil, which was purified on a silica-gel column using a 5:1 to 3:1 hexane–ethyl acetate to afford **9** (20.3 g, 53%). Mp 76—77 °C (hexane–chloroform); R_f=0.40 (2:1 hexane–ethyl acetate); IR 1719 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.30 and 1.52 (s, isopropylidene CH_3), 1.42 (s, CH_3), 2.2—2.8 (m, H_2 and H_5), 4.30 (d, J=5.7 Hz, H_7), 4.51 (d, J=5.7 Hz, H_6), 4.55 (dd, J=1.8, 5.2 Hz, H_5); ^{13}C NMR ($CDCl_3$) δ 20.11, 24.99, 26.15, 45.12, 52.70, 78.99, 83.72, 84.45, 84.68, 112.39, 205.59; MS m/z 197 (M^+-15). Found: C, 61.97; H, 7.84%. Calcd for $C_{11}H_{16}O_4$: C, 62.25, H, 7.60%.

(1R,5S*,6S*,7S*)-6,7-Isopropylidenedioxy-1-pentyl-8-oxabicyclo[3.2.1]octan-3-one (**10**)*: A mixture of (1*R**,5*S**)-1-pentyl-8-oxabicyclo[3.2.1]oct-6-en-3-one (9.70 g, 50.0 mmol), OsO_4 (100 mg), 30% H_2O_2 (11 ml, 100 mmol), acetone (150 ml), t-C_4H_9OH (15 ml), and ether (15 ml) was stirred for 24 h at 25 °C. The resulting mixture was worked up in a usual manner to produce a brown oil. A mixture of this oil, $CuSO_4$ (10 g), p-toluenesulfonic acid (100 mg), and acetone (100 ml) was stirred for 48 h at 25 °C and then worked up in a usual manner to give a brown oil. Chromatography of this oil using a 7:1 to 4:1 hexane–ethyl acetate mixture afforded **10** (7.0 g, 56%) as an oil. R_f=0.50 (4:1 hexane–ethyl acetate); IR 1719 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 0.91 (t, J=7.0 Hz, CH_3), 1.2—2.0 (m, CH_2), 1.29 and 1.50 (s, isopropylidene CH_3), 2.2—2.8 (m, H_2 and H_4), 4.33 (d, J=5.8 Hz, H_7), 4.49 (d, J=5.8 Hz, H_6), 4.55 (dd, J=1.7, 6.0 Hz, H_5); ^{13}C NMR ($CDCl_3$) δ 13.95, 22.55, 23.40, 25.05, 26.17, 32.39, 33.68, 45.52, 50.10, 78.88, 84.14, 84.44, 86.39, 112.29, 205.88; MS m/z 253 (M^+-15).

(1R,5S*,6S*,7S*)-6,7-Isopropylidenedioxy-1-phenyl-8-oxabicyclo[3.2.1]octan-3-one (**11**)*: A mixture of (1*R**,5*S**)-1-phenyl-8-oxabicyclo[3.2.1]oct-6-en-3-one (14.7 g, 73.1 mmol), acetone (150 ml), t-C_4H_9OH (15 ml), ether (15 ml), OsO_4 (200 mg), and 30% H_2O_2 (16.2 ml, 146 mmol) was stirred at 25 °C. After stirring for 12 h, 30% H_2O_2 (8.1 ml, 73.1 mmol) was further added. After further stirring for 12 h, the reaction mixture was worked up in a usual manner to afford a black oil. A mixture of this oil, $CuSO_4$ (35 g), p-toluenesulfonic acid (200 mg), and acetone (100 ml) was stirred for 24 h at 25 °C and worked up in a usual manner to afford a brown solid. Chromatography of this solid using a silica-gel column (7:1 to 4:1 hexane–ethyl acetate) afforded **11** (10.1 g, 51%). Mp 166—168 °C (hexane–chloroform); R_f=0.48 (4:1 hexane–ethyl acetate); IR 1720 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.24 and 1.34 (s, isopropylidene CH_3), 2.3—3.0 (m, H_2 and H_4), 4.61 (d, J=5.5 Hz, H_7), 4.69 (d, J=5.5 Hz, H_6), 4.77 (dd, J=1.5, 5.5 Hz, H_5), 7.2—7.6 (m, C_6H_5); ^{13}C NMR ($CDCl_3$) δ 24.93, 26.00, 45.30, 53.01, 78.94, 84.48, 85.33, 87.48, 112.63, 125.51, 127.59, 128.26, 139.55, 205.50; MS m/z 259 (M^+-15). Found: C, 69.58, H, 6.76%. Calcd for $C_{16}H_{18}O_4$: C, 70.05; H, 6.61%.

(1S,5S*,6S*,7S*)-1-Acetoxymethyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one (**17**)*: A mixture of (1*R**,5*S**)-1-acetoxymethyl-8-oxabicyclo[3.2.1]oct-6-en-one (13.1 g, 66.7 mmol), acetone (150 ml), t-C_4H_9OH (15 ml), ether (15 ml), OsO_4 (200 mg), and 30% H_2O_2 (14.7 ml, 133 mmol) was stirred for 20 h at 25 °C and worked up as usual. The residual oil was dissolved in acetone (150 ml) and to this was added $CuSO_4$ (20 g) and p-toluenesulfonic acid (100 mg). The resulting mixture was stirred for 12 h at 25 °C and worked up usual. Purification on a silica-gel column using a 3:1 to 1:1 hexane–ethyl mixture afforded 11.2 g

(62%) of **17** as a yellow oil. Analytically pure sample was obtained by recrystallization from hexane–chloroform. Mp 84—86 °C; R_f=0.40 (1:1 hexane–ethyl acetate); IR 1732 and 1720 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ 1.30 and 1.50 (s, isopropylidene CH_3), 2.12 (s, CH_3CO), 2.2—2.9 (m, H_2 and H_4), 4.36 (s, CH_2OC=O), 4.46 (d, J=6.0 Hz, H_7), 4.56 (d, J=6.0 Hz, H_6), 4.63 (m, H_5); ^{13}C NMR ($CDCl_3$) δ 20.44, 24.69, 25.85, 44.78, 47.57, 64.25, 79.45, 83.66, 84.01, 112.69, 170.02, 204.19. Found: C, 57.39; H, 6.66%. Calcd for $C_{13}H_{18}O_6$: C, 57.77; H, 6.71%.

(1S,5S*,6S*,7S*)-1-Benzyloxymethyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one (**16**)*: A mixture of (1*R**,5*S**)-1-benzyloxymethyl-8-oxabicyclo[3.2.1]oct-6-en-3-one (1.50 g, 6.14 mmol), acetone (20 ml), ether (2 ml), *t*-C_4H_9OH (2 ml), OsO_4 (30 mg), and 30% H_2O_2 (1.35 ml, 12.3 mmol) was stirred for 12 h at 25 °C. Usual workup left a brown oil, which was mixed with acetone (20 ml), $CuSO_4$ (5 g), and *p*-toluenesulfonic acid (10 mg), and kept for 12 h at 25 °C. Usual workup left a brown oil. Purification of this oil on a silica-gel column using a 4:1 hexane–ethyl acetate mixture afford **16** (1.07 g, 55%) as a yellow oil. R_f=0.23 (4:1 hexane–ethyl acetate); IR (neat) 1721 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ 1.24 and 1.45 (s, isopropylidene CH_3), 2.1—3.0 (m, H_2 and H_4), 3.63 (d, J=11.0 Hz, H_aH_b-$COCH_2C_6H_5$), 3.78 (d, J=11.0 Hz, $H_aH_bCOCH_2C_6H_5$), 4.40 (d, J=6.0 Hz, H_6), 4.50 (d, J=6.0 Hz, H_7), 4.58 (d, J=4.2 Hz, $H_aH_bCC_6H_5$), 4.68 (d, J=4.2 Hz, $H_aH_bCC_6H_5$), 4.72 (m, H_5), 7.33 (s, C_6H_5); ^{13}C NMR ($CDCl_3$) δ 24.88, 26.04, 45.16, 48.13, 70.46, 73.71, 79.50, 84.03, 85.36, 112.52, 127.71, 128.39, 138.21, 205.41.

(1S,5S*,6S*,7S*)-1-Hydroxymethyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one*: A mixture of **17** (113 mg, 0.419 mmol) and lithium hydroxide (5 mg) in CH_3OH (2.5 ml) was stirred for 12 h at 20 °C under argon. The mixture was evaporated and the residue was triturated with CH_2Cl_2 (10 ml). Evaporation of the organic solvent afforded the title compound (96 mg, 96%) as a yellow oil. Analytically pure sample was obtained by recrystallization from ether–ethyl acetate–hexane. Mp 89—91 °C; R_f=0.31 (1:1 hexane–ethyl acetate); IR 3500 (OH), 1720 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ 1.28 and 1.50 (s, isopropylidene CH_3), 1.97 (br, OH), 2.2—2.9 (m, H_2 and H_4), 3.79 (d, J=11.5 Hz, H_aH_bCOH), 3.97 (d, J=11.5 Hz, H_aH_bCOH), 4.47 (d, J=5.5 Hz, H_7), 4.56 (d, J=5.5 Hz, H_6), 4.62 (m, H_5). Found: C, 57.84; H, 7.07%. Calcd for $C_{11}H_{16}O_5$: C, 57.88; H, 7.07%.

(1S,5S*,6S*,7S*)-6,7-Isopropylidenedioxy-1-pivaloyloxymethyl-8-oxabicyclo[3.2.1]octan-3-one (**18**)*: To a mixture of (1*S**, 5*S**,6*S**,7*S**)-1-hydroxymethyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one (500 mg, 2.1 mmol) in pyridine (10 ml) was added pivaloyl chloride (0.52 ml, 4.1 mmol) at 0 °C under argon. The mixture was stirred for 30 min at the same temperature and for 12 h at 25 °C. The mixture was evaporated and the residue was partitioned between ethyl acetate and brine. The organic layer was dried and evaporated. The residue was chromatographed on a silica-gel column using a 4:1 hexane–ethyl acetate mixture to afford 639 mg (98%) of **18** as a colorless oil. Analytical sample was obtained by recrystallization from ether–hexane. Mp 88—90 °C, R_f=0.64 (1:1 hexane–ethyl acetate); IR 1724 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ 1.24 (s, *t*-C_4H_9), 1.29 and 1.50 (s, isopropylidene CH_3), 2.2—2.9 (m, H_2 and H_4), 4.35 (s, CH_2OC=O), 4.45 (d, J=6.0 Hz, H_7), 4.55 (d, J=6.0 Hz, H_6), 4.63 (m, H_5); ^{13}C NMR ($CDCl_3$) δ 24.82, 25.98, 27.19, 38.89, 45.03, 47.87, 64.37, 79.57, 83.83, 84.07, 84.27, 112.78, 117.59, 204.44. Found: C, 61.54; H, 7.80%. Calcd for $C_{16}H_{24}O_6$: C, 61.52; H, 7.75%.

(1S,5S*,6S*,7S*)-1-Benzoyloxymethyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one (**19**)*: To a solution of (1*S**, 5*S**,6*S**,7*S**)-1-hydroxymethyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one (500 mg, 2.10 mmol) in pyridine (10 ml) was added benzoyl chloride (0.49 ml, 4.2 mmol) at 0 °C. The mixture was stirred for 30 min at 0 °C and then 12 h at 25 °C. The mixture was evaporated and the residue was diluted with benzene. The organic layer was washed with brine, 1 mol dm^{-3} HCl, saturated $NaHCO_3$, and then dried, and evaporated to give a yellow oil. Chromatography of this oil on a silica-gel column using a 3:1 hexane–ethyl acetate mixture afforded 615 mg (88%) of **19** as a white solid. Mp 152—153 °C (hexane–chloroform); R_f=0.55 (1:1 hexane–ethyl acetate); IR 1722 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ 1.30 and 1.52 (s, isopropylidene CH_3), 2.2—2.9 (m, H_2 and H_4), 4.56 (s, CH_2OC=O), 4.62 (s, H_6 and H_7), 4.66 (m, H_5), 7.3—7.6 and 8.0—8.1 (m, C_6H_5); ^{13}C NMR ($CDCl_3$) δ 24.93, 26.05, 45.09, 48.02, 64.86, 79.69, 83.90, 84.17, 113.01, 128.48, 129.74, 133.21, 204.49. Found: C, 64.76; H, 6.01%. Calcd for $C_{18}H_{20}O_6$: C, 65.05; H, 6.07%.

(1S,5S*,6S*,7S*)-6,7-Isopropylidenedioxy-1-trifluoroacetoxymethyl-8-oxabicyclo[3.2.1]octan-3-one (**20**)*: To a solution of (1*S**,5*S**,6*S**,7*S**)-1-hydroxymethyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one (100 mg, 0.420 mmol) in CH_2Cl_2 (2 ml) was added trifluoroacetic anhydride (135 μl, 0.840 mmol) at 0 °C. The mixture was stirred for 50 min at the same temperature and evaporated. Chromatography of the residue on a silica-gel column using a 4:1 hexane–ethyl acetate mixture afforded 103 mg (76%) of **20** as a colorless oil. Mp 84—85 °C (ether–hexane); R =0.57 (1:1 hexane–ethyl acetate); IR 1785 and 1725 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ 1.28 and 1.50 (s, isopropylidene CH_3), 2.2—2.9 (m, H_2 and H_4), 4.4—4.8 (m, H_5, H_6, H_7, and H_2COC=O); ^{13}C NMR ($CDCl_3$) δ 24.65, 25.86, 44.80, 47.35, 67.64, 79.84, 83.41, 83.66, 84.19, 113.24, 158.04, 203.34. Found: C, 47.77; H, 4.80%. Calcd for $C_{13}H_{15}O_6F_3$: C, 48.15; H, 4.66%.

(1S,5S*,6S*,7S*)-6,7-Isopropylidenedioxy-1-mesyloxymethyl-8-oxabicyclo[3.2.1]octan-3-one (**21**)*: To a mixture of (1*S**, 5*S**,6*S**,7*S**)-1-hydroxymethyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one (500 mg, 2.1 mmol), triethylamine (0.59 ml, 4.2 mmol), and CH_2Cl_2 (10 ml) was added methanesulfonyl chloride (0.33 ml, 4.2 mmol). The mixture was stirred for 30 min at 0 °C and then 12 h at 28 °C. The mixture was diluted with CH_2Cl_2 (10 ml) and the organic layer was washed with brine, dried, and evaporated. Chromatography of the residue on a silica-gel column using a 1:1 hexane–ethyl acetate mixture afforded 635 mg (99%) of **21** as a white solid. Mp 149—151 °C (hexane–chloroform); R_f=0.31 (1:1 hexane–ethyl acetate); IR 1726 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ 1.28 and 1.51 (s, isopropylidene CH_3), 2.2—2.9 (m, H_2 and H_4), 3.08 (s, CH_3), 4.4—4.7 (m, H_5, H_6, H_7, and CH_2OC=O); ^{13}C NMR ($CDCl_3$) δ 24.71, 25.98, 37.53, 44.85, 47.42, 69.57, 79.81, 83.60, 84.15, 113.13, 203.62. Found: C, 46.73; H, 5.74; S, 10.40%. Calcd for $C_{12}H_{18}O_7S$: C, 47.05; H, 5.92; S, 10.47%.

(1S,5S*,6S*,7S*)-1-t-Butyldimethylsiloxymethyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one (**15**)*: A mixture of (1*S**,5*S**,6*S**,7*S**)-1-hydroxymethyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one (500 mg, 2.10 mmol), *t*-butyldimethylsilyl chloride (479 mg, 3.15 mmol), and imidazole (428 mg, 6.30 mmol) in dry DMF (8 ml) was stirred for 12 h at 25 °C and then evaporated. The residue was partitioned between ethyl acetate and brine, and organic layer was separated, dried, and evaporated, leaving a colorless oil. Chromatography of this oil on a silica-gel column

using a 5:1 hexane–ethyl acetate mixture afforded 715 mg (100%) of **15** as a colorless oil. R_f=0.67 (1:1 hexane–ethyl acetate); IR (neat) 1724 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 0.08 (s, *t*-$C_4H_9(C\underline{H}_3)_2Si$), 0.92 (s, *t*-$C_4\underline{H}_9(CH_3)_2Si$), 1.28 and 1.50 (s, isopropylidene CH_3), 2.1—3.0 (m, H_2 and H_4), 3.86 (s, H_2COSi), 4.41 (d, J=5.7 Hz, H_7), 4.51 (d, J=5.7 Hz, H_6), 4.57 (m, H_5); ^{13}C NMR ($CDCl_3$) δ 18.35, 24.90, 25.92, 36.22, 45.31, 47.99, 63.94, 79.45, 83.68, 84.08, 86.09, 112.35, 205.85.

(1S,5S*,6S*,7S*)-6,7-Isopropylidenedioxy-1-trifluoromesyloxymethyl-8-oxabicyclo[3.2.1]octan-3-one (**22**)*: To a mixture of (1*S**,5*S**,6*S**,7*S**)-1-hydroxymethyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one (100 mg, 0.438 mmol), pyridine (70 μl, 0.876 mmol) in CH_2Cl_2 (3 ml) was added trifluoromethanesulfonic anhydride (111 μl, 0.657 mmol). The mixture was stirred for 15 min at 0 °C and diluted with CH_2Cl_2 (7 ml). To this was added saturated NaCl (1 ml) and the organic layer was dried and evaporated to give a yellow solid. Chromatography of this solid on a silica-gel column using a 2:1 hexane–ethyl acetate mixture afforded 138 mg (88%) of **22** as a white solid. Mp 103—104 °C (ether–hexane); R_f=0.65 (2:1 ethyl acetate–hexane); IR 1725 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.26 and 1.49 (s, isopropylidene CH_3), 2.22—2.91 (m, H_2 and H_4), 4.40—4.84 (m, H_5, H_6, H_7, and CH_2OSO_2); ^{13}C NMR ($CDCl_3$) δ 24.64, 25.81, 44.71, 47.03, 75.55, 80.81, 83.06, 83.60, 84.28, 113.50, 202.74. Found: C, 40.20; H, 4.33; S, 9.36%. Calcd for $C_{12}H_{15}O_7SF_3$: C, 40.00; H, 4.20; S, 8.90%.

(1S,5R*,6R*,7S*)-6,7-Isopropylidenedioxy-6-methyl-8-oxabicyclo[3.2.1]octan-3-one (**43**)*: *Method A.*[35] To a solution of 20% aqueous $(C_2H_5)_4NOH$ (0.59 ml, 0.80 mmol) and 6-methyl-8-oxabicyclo[3.2.1]oct-6-en-3-one (1.00 g, 7.25 mmol) in *t*-C_4H_9OH (13 ml) were added 70% *t*-C_4H_9OOH (2.24 ml, 17.4 mmol) and OsO_4 in *t*-C_4H_9OH (0.02 mol dm^{-3} solution, 3.62 ml, 0.0725 mmol) at 0 °C. After stirring for 1 h at 0 °C and for 12 h at room temperature, the mixture was cooled to 0 °C. To this were added renewedly 70% *t*-C_4H_9OOH (0.45 ml, 3.84 mmol) and OsO_4 in *t*-C_4H_9OH (0.02 mol dm^{-3} solution, 0.72 ml, 0.0144 mmol) and the mixture was further stirred for 24 h at room temperature. After the mixture was cooled to 0 °C, 20% aqueous $NaHSO_3$ (10 ml) was added. The mixture was stirred for 1 h and evaporated. The residue was dissolved in acetone (40 ml) and the insoluble material was removed by filtration. The filtrate was concentrated and the residue was dissolved in ethyl acetate (40 ml), dried, and evaporated to give a white solid. A mixture of this solid, $CuSO_4$ (3 g), *p*-toluenesulfonic acid (30 mg) and acetone (50 ml) was stirred for 1 h at room temperature. Usual workup left a pale yellow solid. Chromatography of this solid on a silica-gel column using a 3:1 to 1:1 hexane–ethyl acetate mixture afforded **43** (962 mg, 63%) as a white solid. Analytical sample was obtained by recrystallization from chloroform–hexane. Mp 72.0—73.0 °C; R_f=0.58 (1:1 hexane–ethyl acetate); IR 1720 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.41 (s, CH_3), 1.41 and 1.50 (s, isopropylidene CH_3), 2.2—2.9 (m, H_2 and H_4), 4.15 (s, H_7), 4.45 (t-like, J=5.0 Hz, H_1 and H_5); ^{13}C NMR ($CDCl_3$) δ 21.09, 27.62, 28.26, 45.21, 45.39, 80.85, 83.23, 89.76, 91.17, 112.83, 204.86. Found: C, 62.28; H, 7.72%. Calcd for $C_{11}H_{16}O_4$: C, 62.25; H, 7.60%.

Method B.[32] To a solution of *N*-methylmorpholine *N*-oxide monohydrate (172 mg, 1.27 mmol) in H_2O (0.4 ml) and acetone (0.2 ml) were added a solution of OsO_4 in *t*-C_4H_9OH (0.02 mol dm^{-3} solution, 0.41 ml, 0.81×10^{-2} mmol) and 6-methyl-8-oxabicyclo[3.2.1]oct-6-en-3-one (138 mg, 1 mmol) at 20 °C. After stirring for 10 h, *N*-methylmorpholine *N*-oxide monohydrate (70 mg, 0.52 mmol) and OsO_4 in *t*-C_4H_9OH (0.02 mol dm^{-3} solution, 0.41 ml, 8.1×10^{-3} mmol) were added. The reaction mixture was stirred for an additional 12 h at 20 °C and to this was added a suspension of $Na_2S_2O_4$ (30 mg) and magnesol (300 mg) in H_2O (1.2 ml). After stirring for 10 min, the mixture was diluted with acetone (10 ml). The insoluble material was removed by filtration and the filtrate was evaporated. The residue was coevaporated with C_2H_5OH (10 ml×2). The crude material was dissolved in acetone (20 ml) and to this were added $CuSO_4$ (1.5 g) and *p*-toluenesulfonic acid (25 mg). The mixture was stirred for 2 h at 20 °C and worked up in a usual manner to give a yellow solid. Chromatography of this solid on a column of silica gel using a 3:1 hexane–ethyl acetate mixture afforded **43** (165 mg, 78%).

(1S,6R*,5R*,7S*)-6,7-Isopropylidenedioxy-6-pentyl-8-oxabicyclo[3.2.1]octan-3-one (**44**)*: To a solution of *N*-methylmorpholine *N*-oxide monohydrate (1.00 g, 7.14 mmol) in H_2O (2.0 ml) and acetone (1 ml) were added OsO_4 in *t*-C_4H_9OH (2.0×10^{-5} mol dm^{-3} solution, 2.38 ml, 47.6 μmol) and 6-pentyl-8-oxabicyclo[3.2.1]oct-6-en-3-one (924 mg, 4.76 mmol). The mixture was stirred for 96 h at 15 °C and to this were added $Na_2S_2O_3\cdot5H_2O$ (242 mg) and magnesol (2.42 g) in H_2O (5 ml). Usual workup left a yellow oil. The mixture of this oil, dissolved in acetone (30 ml), $CuSO_4$ (2 g), and *p*-toluenesulfonic acid (500 mg) was stirred at 15 °C. After stirring for 1 h, *p*-toluenesulfonic acid (100 mg) was further added. The reaction mixture was stirred for 1 h and worked up in a usual way to afford a yellow solid. Chromatography of this solid on a silica-gel column using a 3:1 ethyl acetate–hexane mixture afforded **44** (718 mg, 56%). Mp 82—84 °C (hexane); R_f=0.84 (2:1 ethyl acetate–hexane); IR 1720 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 0.89 (m, CH_3), 1.2—1.7 (m, CH_2), 1.41 and 1.53 (s, isopropylidene CH_3), 2.3—2.8 (m, H_2 and H_4), 4.14 (s, H_7), 4.50 (d-like, J=5.8 Hz, H_1 and H_5); ^{13}C NMR ($CDCl_3$) δ 13.88, 22.45, 24.31, 27.90, 28.68, 32.13, 34.45, 45.29, 45.78, 80.79, 82.44, 89.50, 94.77, 113.33, 205.07. Found: C, 66.95; H, 9.20%. Calcd for $C_{15}H_{24}O_4$: C, 67.13; H, 9.02%.

(1S,5R*,6R*,7S*)-6-t-Butyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one (**45**)*: To a solution of 6-*t*-butyl-8-oxabicyclo[3.2.1]oct-6-en-3-one (1.00 g, 5.56 mmol) in THF (10 ml) was added OsO_4 (1.69 g, 6.65 mmol) in pyridine (7 ml). The mixture was stirred for 60 h at 30 °C in the dark and washed with ether (30 ml×3). The residue was dissolved in C_2H_5OH (10 ml) and H_2O (10 ml) and to this was added Na_2SO_3 (7.0 g). The mixture was heated at reflux for 6 h and the insoluble material was removed by filtration and the filtrate was evaporated to give a black solid. After this solid was coevaporated with C_2H_5OH, the residue was acetonized by standard method, as described above, to give 218 mg (15%) of **45**. Mp 121—123 °C (hexane–ether–ethyl acetate); R_f=0.71 (1:1 hexane–ethyl acetate); IR 1722 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.00 (s, *t*-C_4H_9), 1.46 and 1.62 (s, isopropylidene CH_3), 2.0—2.9 (m, H_2 and H_4), 4.38 (s, H_7), 4.3—4.6 (m, H_1 and H_5); ^{13}C NMR ($CDCl_3$) δ 27.79, 28.14, 34.68, 44.20, 46.13, 80.53, 82.41, 85.82, 100.97, 113.48, 204.66. Found: C, 66.04; H, 8.76%. Calcd for $C_{14}H_{22}O_4$: C, 66.11; H, 8.72%.

(1S,5R*,6R*,7S*)-6,7-Isopropylidenedioxy-6-phenyl-8-oxabicyclo[3.2.1]octan-3-one (**46**)*: To a solution of *N*-methylmorpholine *N*-oxide monohydrate (1.69 g, 12.1 mmol) in H_2O (3.24 ml) and acetone (1.67 ml) were added OsO_4 in *t*-C_4H_9OH (2.0×10^{-5} mol dm^{-3} solution, 4.03 ml, 80.5 μ mol) and 6-phenyl-8-oxabicyclo[3.2.1]oct-6-en-3-one (1.61 g, 8.05 mmol). After stirring for 72 h at 20 °C, *N*-methylmorpholine *N*-oxide monohydrate (0.56 g, 4.03 mmol) was further added. The mixture was further stirred for 72 h

and to this were added $Na_2S_2O_3 \cdot 5H_2O$ (410 mg) and magnesol (4.1 g) in H_2O. This mixture was worked up in a usual way to give a yellow solid. The solid was mixed acetone (40 ml) with $CuSO_4$ (5 g), and *p*-toluenesulfonic acid (0.2 g), and stirred at room temperature. After stirring for 1 h, *p*-toluenesulfonic acid (0.2 g) was further added. The resulting mixture was stirred for 3 h and worked up in a usual manner. Chromatography of the residue on a silica-gel column using a 4:1 to 1:1 hexane–ethyl acetate mixture afforded **46** (1.26 g, 57%). Mp 134—135 °C (hexane–ether–ethyl acetate); R_f=0.76 (2:1 ethyl acetate–hexane); IR 1720 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.02 and 1.56 (s, isopropylidene CH_3), 1.7—3.0 (m, H_2 and H_4), 4.61 (d-like, J=6.5 Hz, H_1 and H_5), 4.92 (s, H_7), 7.34 (s, C_6H_5); ^{13}C NMR ($CDCl_3$) δ 27.18, 36.29, 44.30, 45.45, 81.08, 83.31, 86.88, 95.92, 112.50, 126.14, 128.53, 128.83, 139.01, 204.54. Found: C, 69.77; H, 6.67%. Calcd for $C_{16}H_{18}O_4$: C, 70.05; H, 6.61%.

(1S,5R*,6R*,7S*)-6-Hydroxymethyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one*: To a solution of *N*-methylmorpholine *N*-oxide monohydrate (4.41 g, 32.7 mmol) in H_2O (8.5 ml) and acetone (4.3 ml) was added OsO_4 in *t*-C_4H_9OH (0.02 mol dm^{-3} solution, 11.7 ml, 0.21 mmol). 6-(Tetrahydropyran-2-yloxymethyl)-8-oxabicyclo[3.2.1]oct-6-en-3-one (5.00 g, 21.0 mmol) was subjectedly added. The reaction mixture was stirred for 36 h at 20 °C and to this were added $Na_2S_2O_3$ (630 mg) and magnesol (6.3 g) in H_2O (25 ml). Usual workup left a yellow oil. A mixture of this oil, $CuSO_4$ (8 g), *p*-toluenesulfonic acid (300 mg), and acetone (50 ml) was stirred at the room temperature. After stirring for 3 h, *p*-toluenesulfonic acid (300 mg) was further added. The resulting mixture was stirred for 1 h and worked up in a usual way. Chromatography of the residue on a silica-gel column using a 4:1 to 1:1 hexane–ethyl acetate mixture afforded (1*S**,5*R**,6*R**,7*S**)-6,7-isopropylidenedioxy-6-(tetrahydropyran-2-yloxymethyl)-8-oxabicyclo[3.2.1]octan-3-one (1.07 g, 16%), mp 126—130 °C (ether–hexane); R_f=0.68 (2:1 ethyl acetate–hexane); IR 1721 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.42 and 1.54 (s, isopropylidene CH_3), 1.62 (m, 6H), 2.2—2.9 (m, H_2 and H_4), 3.3—4.1 (m, CH_2O), 4.3—4.7 (m, H_1, H_5, H_7, and OCHO). Found: C, 61.40; H, 7.87%. Calcd for $C_{16}H_{24}O_6$: C, 61.52; H, 7.75%, and the title compound (1.92 g, 40%). Mp 138—140 °C; R_f=0.35 (2:1 ethyl acetate–hexane); IR 3590 (OH), 1721 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.40 and 1.52 (s, isopropylidene CH_3), 2.2—2.9 (m, H_2 and H_4), 3.65 (d, J=12.0 Hz, $\underline{H}_aH_bCOH$), 3.85 (d, J=12.0 Hz, $H_a\underline{H}_bCOH$), 4.24 (s, H_7), 4.58 (m, H_1 and H_5); ^{13}C NMR ($CDCl_3$) δ 27.77, 28.57, 44.90, 45.27, 63.90, 80.87, 81.82, 86.60, 95.20, 114.07, 205.11. Found: C, 58.04; H, 7.22%. Calcd for $C_{11}H_{16}O_5$: C, 57.88; H, 7.07%.

Deprotection of (1S,5R*,6R*,7S*)-6,7-Isopropylidenedioxy-6-(tetrahydropyran-2-yloxymethyl)-8-oxabicyclo[3,2,1]octan-3-one.* A mixture of (1*S**, 5*R**, 6*R**,7*S*)-6,7-isopropylidenedioxy-6-(tetrahydropyran-2-yloxymethyl)-8-oxabicyclo[3.2.1]octan-3-one (6.13 g, 19.6 mmol) and oxalic acid dihydrate (819 mg, 6.5 mmol) in THF (19.6 ml) and H_2O (6 ml) was stirred at 50 °C. After stirring for 2 h, oxalic acid dihydrate (819 mg, 6.5 mmol) in H_2O (5 ml) was further added. After stirring for 4 h, the reaction mixture was evaporated. The residue was extracted with chloroform (40 ml×4) and the organic layer was dried and evaporated to give a yellow solid which was washed with ether. (1*S**,5*R**,6*R**,7*S**)-6-Hydroxymethyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]-octan-3-one was obtained as a white solid, 3.50 g (78%). The mother liquid was concentrated and the residue was chromatographed to afford the same compound (0.18 g, 4%). Total amount was 3.68 g (82%).

(1S,5R*,6R*,7S*)-6-t-Butyldimethylsiloxymethyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one (47)*: To a solution of (1*S**,5*R**,6*R**,7*S**)-6-hydroxymethyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one (1.86 g, 8.16 mmol) in dry DMF (25 ml) was added a solution of *t*-butyldimethylsilyl chloride (1.88 g, 12.5 mmol) and imidazole (1.70 g, 25 mmol) in dry DMF (25 ml).[34] The mixture was stirred for 30 min at 0 °C and for 20 h at 20 °C. The reaction mixture was evaporated and the residue was diluted with ether (250 ml). The organic layer was washed with brine, dried, and evaporated. The residual oil was chromatographed on a silica-gel column using a 4:1 hexane–ethyl acetate mixture to afford **47** (2.52 g, 90%) as a colorless oil. R_f=0.50 (3:1 hexane–ethyl acetate); IR (neat) 1725 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 0.08 (s, *t*-$C_4H_9(C\underline{H}_3)_2Si$) 0.90 (s, *t*-$C_4\underline{H}_9(CH_3)_2Si$), 1.40 and 1.52 (s, isopropylidene CH_3), 2.2—2.9 (m, H_2 and H_4), 3.66 (d, J=11.5 Hz, $\underline{H}_aH_bCOSi$), 3.86 (d, J=11.5 Hz, $H_a\underline{H}_bCOSi$), 4.24 (s, H_7), 4.50 (m, H_1 and H_5); ^{13}C NMR ($CDCl_3$) δ 18.41, 25.93, 27.87, 28.42, 44.53, 45.01, 65.10, 80.85, 82.08, 86.40, 95.15, 113.76, 204.60.

(1S,5R*,6R*,7S*)-6-Benzyloxymethyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one (48)*: To a solution of *N*-methylmorpholine *N*-oxide monohydrate (210 mg, 1.5 mmol) in H_2O (0.4 ml) and acetone (0.2 ml) were added OsO_4 in *t*-C_4H_9OH (2.0×10^{-5} mol dm^{-3} solution, 0.5 ml, 0.01 mmol) and 6-benzyloxymethyl-8-oxabicyclo[3.2.1]oct-6-en-3-one (244 mg, 1 mmol). The reaction mixture was stirred for 84 h at 20 °C and to this were added $Na_2S_2O_3$ (31 mg) and magnesol (310 mg) in H_2O (1.2 ml). Usual workup left a yellow oil. The mixture of this oil, dissolved in acetone (20 ml), $CuSO_4$ (1.5 g), and *p*-toluenesulfonic acid (50 mg) was stirred at 20 °C. After stirring for 30 min, *p*-toluenesulfonic acid (50 mg) was further added. The mixture was stirred for 2 h and worked up in a usual way. The residue was purified on a silica-gel column using a 4:1 hexane–ethyl acetate mixture to afford **48** (206 mg, 65%). Mp 90.5—91.5 °C (hexane–ethyl acetate); R_f=0.71 (2:1 ethyl acetate–hexane); ^1H NMR ($CDCl_3$) δ 1.34 and 1.50 (s, isopropylidene CH_3), 2.2—2.8 (m, H_2 and H_4), 3.48 (d, J=10.5 Hz, $\underline{H}_aH_bCOCH_2C_6H_5$), 3.66 (d, J=10.5 Hz, $H_a\underline{H}_bCOCH_2C_6H_5$), 4.26 (s, H_7), 4.4—4.6 (m, H_1 and H_5), 4.54 (s, $C\underline{H}_2C_6H_5$), 7.32 (s, C_6H_5); ^{13}C NMR ($CDCl_3$) δ 27.82, 28.30, 44.72, 45.01, 71.33, 73.85, 80.73, 82.09, 86.88, 93.98, 114.05, 127.99, 128.52, 137.50, 204.56. Found: C, 68.19; H, 7.20%. Calcd for $C_{18}H_{22}O_5$: C, 67.91; H, 6.97%.

(1S,5R*,6R*,7S*)-6,7-Isopropylidenedioxy-6-pivaloyloxymethyl-8-oxabicyclo[3.2.1]octan-3-one (49)*: To a solution of (1*S**,5*R**,6*R**,7*S**)-6-hydroxymethyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one (456 mg, 2.00 mmol) in pyridine (10 ml) was added pivaloyl chloride (0.5 ml, 4.0 mmol) at 0 °C. The mixture was stirred for 30 min at 0 °C and for 12 h at 20 °C. After the mixture was evaporated, the residue was dissolved in ethyl acetate (50 ml). The ethyl acetate layer was washed with brine, dried, and evaporated. Chromatography of the residue on a silica-gel column using a 4:1 hexane–ethyl acetate mixture afforded 468 mg (75%) of **49**. Mp 97.0—98.5 °C (hexane–ether); R_f=0.55 (1:1 hexane–ethyl acetate); IR 1730 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.20 (s, *t*-C_4H_9), 1.40 and 1.51 (s, isopropylidene CH_3), 2.40 (dd, J=6.4, 17.0 Hz, H_{4a}), 2.76 (dd, J=3.0, 17.0 Hz, H_{4b}), 3.94 (d, J=12.5 Hz, $\underline{H}_aH_bCOC$=O), 4.38 (s, H_7), 4.54 (d, J=12.5 Hz, $H_a\underline{H}_bCOC$=O), 4.45—4.55 (m, H_1 and H_5); ^{13}C NMR ($CDCl_3$) δ 27.22, 27.77, 28.27, 39.00, 44.92, 45.53, 65.13, 81.09, 81.93, 86.43, 93.20, 114.39, 177.80, 204.23. Found: C, 61.22; H, 7.70%. Calcd

for $C_{16}H_{24}O_6$: C, 61.52; H, 7.75%.

(1S,5R*,6R*,7S*)-6-Benzoyloxymethyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one (**50**)*: To a solution of (1*S**, 5*R**,6*R**,7*S**)-6-hydroxymethyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one (456 mg, 2.0 mmol) in pyridine (10 ml) was added benzoyl chloride (0.47 ml, 4.0 mmol) at 0 °C. The reaction mixture was stirred for 30 min at 0 °C and for 12 h at 20 °C and evaporated. The residue was dissolved in benzene (10 ml) and washed with brine, 1 mol dm^{-3} HCl, saturated $NaHCO_3$, dried, and the benzene layer was evaporated. The residue was purified on a silica-gel column using a 3:1 hexane–ethyl acetate mixture to afford **50** (586 mg, 88%). Mp 164—168 °C (hexane–ether–ethyl acetate); R_f=0.59 (1:1 hexane–ethyl acetate); IR 1728 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ 1.41 and 1.54 (s, isopropylidene CH_3), 2.3—3.0 (m, H_2 and H_4), 4.35 (d, J=12.2 Hz, $\underline{H}_a H_b COC{=}O$), 4.44 (s, H_7), 4.5—4.8 (m, H_1 and H_5), 4.70 (d, J=12.2 Hz, $H_a \underline{H}_b COC{=}O$), 7.3—7.8 (m, C_6H_5); ^{13}C NMR ($CDCl_3$) δ 27.82, 28.32, 45.00, 45.59, 65.33, 81.22, 81.97, 86.86, 93.21, 114.68, 128.58, 128.97, 129.90, 130.67, 133.36, 134.51, 166.03, 204.20. Found: C, 65.18; H, 5.79%. Calcd for $C_{18}H_{20}O_6$: C, 65.05; H, 6.07%.

*Baeyer-Villiger Oxidation of α-Substituted Ketones. Oxidation of **1***: A mixture of **1** (6.80 g, 32.1 mmol) and Na_2HPO_4 (82.4 g, 580 mmol) in CH_2Cl_2 (100 ml) was cooled in an ice bath and stirred magnetically. To this was added dropwise over 15 min trifluoroperacetic acid, which had been prepared from 90% H_2O_2 (3.70 ml, 96.3 mmol) and trifluoroacetic anhydride (16.4 ml, 116 mmol) in CH_2Cl_2 (50 ml). The reaction mixture was stirred for 16 h at 25 °C under argon and to this was added $NaHSO_3$ (79 g) and $NaHCO_3$ (15 g). After stirring for 1 h, the insoluble material was removed by filtration. The filtrate was evaporated and the resulting yellow residue was chromatographed on a silica-gel column using a 1:1 to 1:2 hexane–ethyl acetate mixture to afford (1*R**,2*R**,6*S**,7*S**,8*R**)-7,8-isopropylidenedioxy-2-methyl-3,9-dioxabicyclo[4.2.1]nonan-4-one (**5**) (6.20 g, 85%). Mp 126.2—127.8 °C(chloroform–hexane); R_f= 0.34 (2:1 hexane–ethyl acetate); IR 1732 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ 1.26 and 1.42 (s, isopropylidene CH_3), 1.31 (d, J=7.0 Hz, CH_3), 2.92 (m, H_5), 4.14 (s, H_1), 4.28 (t-like, J=4.0 Hz, H_6), 4.58 (q, J=7.0 Hz, H_2), 4.61 (d, J=6.0 Hz, H_7), 4.87 (d, J=6.0 Hz, H_8); MS m/z 213 (M^+—15). Found: C, 57.82; H, 6.91%. Calcd for $C_{11}H_{16}O_5$: C, 57.88, H, 7.07%.

*Oxidation of **2***: To a mixture of **2** (12.0 g, 44.7 mmol), Na_2HPO_4 (115 g, 0.807 mol), and CH_2Cl_2 (150 ml) was added slowly trifluoroperacetic acid in CH_2Cl_2 (1.53 mol dm^{-3} solution, 146 ml, 0.224 mol) under argon. After stirring for 8 h at 25 °C, solid $NaHCO_3$ (50 g) was added to the mixture. Usual workup left an oil, chromatography of which on a silica-gel column using a 5:1 hexane–ethyl acetate mixture afforded (1*R**,2*R**,6*S**,7*S**,8*R**)-7,8-isopropylidenedioxy-2-pentyl-3,9-dioxabicyclo[4.2.1]nonan-4-one (**6**) (9.80 g, 78%). Mp 64—65 °C (hexane); R_f=0.24 (3:1 hexane–ethyl acetate); IR 1732 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ 0.90 (t, J=6.0 Hz, CH_3), 1.30 and 1.49 (s, isopropylidene CH_3), 1.50 (m, CH_2), 2.90 (dd, J=4.5, 16.5 Hz, H_{5a}), 3.07 (dd, J=3.0, 16.5 Hz, H_{5b}), 4.26 (s, H_1), 4.40 (m, H_6 and H_2), 4.65 (d, J=5.8 Hz, H_7), 4.93 (d, J= 5.8 Hz, H_8); MS m/z 269 (M^+—15). Found: C, 63.07; H, 8.67%. Calcd for $C_{15}H_{24}O_5$: C, 63.36; H, 8.51%.

*Oxidation of **3***: Trifluoroperacetic acid in CH_2Cl_2 (1.37 mol dm^{-3} solution, 28 ml, 38.3 mmol) was added slowly to a mixture of **3** (3.50 g, 12.7 mmol), Na_2HPO_4 (19.6 g, 138 mmol), and CH_2Cl_2 (30 ml) at 0 °C. After stirring for 11 h at 25 °C, solid $NaHCO_3$ (10 g) and $NaHSO_3$ (6 g) were added. The mixture was worked up in a usual manner to give a solid. Purification of this solid on a silica-gel column using a 2:1 to 1:1 hexane–ethyl acetate mixture afforded (1*S**,2*S**,6*S**,7*S**,8*S**)-7,8-isopropylidenedioxy-2-phenyl-3,9-dioxabicyclo[4.2.1]nonan-4-one (**7**) (2.45 g, 67%). Mp 160.8—161.2 °C (ether); R_f=0.30 (1:1 hexane–ethyl acetate); IR 1739 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ 1.31 and 1.46 (s, isopropylidene CH_3); 3.00 (dd, J=2.5, 16.0 Hz, H_{5a}), 3.20 (dd, J=4.5, 16.0 Hz, H_{5b}), 4.41 (dd, J= 2.5, 4.5 Hz, H_6), 4.50 (s, H_1), 4.77 (d, J=6.0 Hz, H_7), 5.07 (d, J=6.0 Hz, H_8), 5.57 (s, H_2), 7.42 (br s, C_6H_5); MS m/z 290 (M^+). Found: C, 65.98; H, 6.23%. Calcd for $C_{16}H_{18}O_5$: C, 66.19; H, 6.25%.

*Oxidation of **4***: To a mixture of **4** (11.2 g, 49.6 mmol), Na_2HPO_4 (127 g, 0.895 mol), and CH_2Cl_2 (150 ml) was added trifluoroperacetic acid in CH_2Cl_2 (1.14 mol dm^{-3} solution, 131 ml, 149 mmol) at 0 °C. After stirring for 6 h at 25 °C, solid $NaHCO_3$ (15 g) and $NaHSO_3$ (7 g) were added. Usual workup left a yellow oil. Chromatography of the residue on a silica-gel column using a 2:1 hexane–ethyl acetate mixture afforded (1*S**,6*S**,7*S**,8*S**)-2,2-dimethyl-7,8-isopropylidenedioxy-3,9-dioxabicyclo[4.2.1]nonan-4-one (**8**) (9.70 g, 81%). Mp 158.5—159.2 °C (ether); R_f=0.35 (2:1 hexane–ethyl acetate); IR 1730 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ 1.34 and 1.56 (s, isopropylidene CH_3), 1.46 and 1.50 (s, CH_3), 2.88 (dd, J=3.0, 17.0 Hz, H_{5a}), 3.12 (dd, J=4.0, 17.0 Hz, H_{5b}), 4.10 (s, H_1), 4.33 (dd, J=3.0, 4.0 Hz, H_6), 4.64 (d, J=6.0 Hz, H_7), 4.97 (d, J=6.0 Hz, H_8); MS m/z 227 (M^+—15). Found: C, 59.20; H, 7.46%. Calcd for $C_{12}H_{18}O_5$: C, 59.49; H, 7.49%.

*The Baeyer-Villiger Oxidation of β-Substituted Ketones. Oxidation of **9***: To a mixture of **9** (9.35 g, 44.1 mmol), Na_2HPO_4 (61.8 g, 0.435 mol), Na_2H_2edta (3 g), and CH_2Cl_2 (150 ml) was added trifluoroperacetic acid in CH_2Cl_2 (1.74 mol dm^{-3} solution, 76 ml, 132 mmol) at 0 °C. The mixture was stirred for 10 h at 20 °C and usual workup left a white solid. ^{1}H NMR analysis of this material indicated that (1*R**,6*S**,7*S**,8*S**)-7,8-isopropylidenedioxy-1-methyl-3,9-dioxabicyclo[4.2.1]nonan-4-one (**12a**) and (1*S**,6*R**,7*S**,8*S**)-7,8-isopropylidenedioxy-6-methyl-3,9-dioxabicyclo[4.2.1]-nonan-4-one (**12b**) were produced in 53:47 ratio. Chromatography of this solid on a silica-gel column using a 3:1 ether–petroleum ether mixture afforded **12a** (5.5 g, containing 15% of **12b** determined by ^{1}H NMR) and **12b** (4.0 g, containing 10% of **12a** determined by ^{1}H NMR). Total yield was 90% (9.5 g). Pure samples of **12a** and **12b** were obtained by rechromatography and recrystallization from chloroform–hexane. **12a**: Mp 100—102 °C; R_f=0.35 (2:1 ether–petroleum ether); IR 1735 cm^{-1} (C=O); ^{1}H NMR (C_6D_6) δ 1.01 (s, CH_3), 1.07 and 1.40 (s, isopropylidene CH_3), 2.25 (dd, J=2.9, 15.5 Hz, H_{5a}), 2.45 (dd, J=4.1, 15.5 Hz, H_{5b}), 3.38 (d, J=14.0 Hz, H_{2a}), 3.56 (d, J=14.0 Hz, H_{2b}), 3.93 (dd, J=2.9, 4.1 Hz, H_6), 4.41 (d, J=6.0 Hz, H_7), 4.48 (d, J=6.0 Hz, H_8); MS m/z 213 (M^+—15). Found: C, 57.30; H, 7.05%. Calcd for $C_{11}H_{16}O_5$: C, 57.88; H, 7.07%. **12b**: Mp 100—101 °C; R_f=0.30 (2:1 ether–petroleum ether); IR 1735 cm^{-1} (C=O); ^{1}H NMR (C_6D_6) δ 1.05 and 1.38 (s, isopropylidene CH_3), 1.16 (s, CH_3), 2.34 (d, J=16.0 Hz, H_{5a}), 2.54 (d, J=16.0 Hz, H_{5b}), 3.36 (dd, J=4.0, 13.8 Hz, H_{2a}), 3.60 (d, J=13.8 Hz, H_{2b}), 3.91 (d, J=4.0 Hz, H_1), 4.33 (d, J=6.0 Hz, H_7), 4.67 (d, J=6.0 Hz, H_8); MS m/z 228 (M^+). Found: C, 57.90; H, 7.12%. Calcd for $C_{11}H_{16}O_5$: C, 57.88; H, 7.07%.

*Oxidation of **10***: Trifluoroperacetic acid in CH_2Cl_2 (1.54 mol dm^{-3} solution, 14.2 ml, 21.8 mmol) was added to a mixture of **10** (835 mg, 3.12 mmol), Na_2HPO_4 (10.2 g, 72.0

mmol), Na_2H_2edta (500 mg), and CH_2Cl_2 (20 ml) at 0 °C. The mixture was stirred for 15 h at 20 °C and the usual workup gave a white solid. ^1H NMR analysis of this solid indicated that (1*R**,6*S**,7*S**,8*S**)-7,8-isopropylidenedioxy-1-pentyl-3,9-dioxabicyclo[4.2.1]nonan-4-one (**13a**) and (1*S**,6*R**,7*S**,8*S**)-7,8-isopropylidenedioxy-6-pentyl-3,9-dioxabicyclo[4.2.1]nonan-4-one (**13b**) were produced in 50:50 ratio. Chromatographic separation (silica gel, 1:1 ether–petroleum ether) yielded 400 mg (45%) of **13a** and 406 mg (46%) of **13b**. Total yield was 91% (806 mg). **13a**: Mp 60—61 °C (chloroform–hexane); R_f=0.46 (2:1 ether–petroleum ether); IR 1734 cm^{-1} (C=O); ^1H NMR (C_6D_6) δ 0.85 (t, J=6.0 Hz, CH_3), 1.0—1.8 (m, CH_2), 1.07 and 1.42 (s, isopropylidene CH_3), 2.40 (m, H_5), 3.67 (s, H_2), 3.99 (dd, J=3.0, 4.7 Hz, H_6), 4.51 (s, H_7 and H_8); MS *m/z* 284 (M^+). Found: C, 63.19; H, 8.71%. Calcd for $C_{15}H_{24}O_5$: C, 63.36; H, 8.51%. **13b**: Mp 106—107 °C (chloroform–hexane); R_f=0.38 (2:1 ether–petroleum ether); IR 1735 cm^{-1} (C=O); ^1H NMR (C_6D_6) δ 0.86 (t, J=6.0 Hz, CH_3), 1.07 and 1.40 (s, isopropylidene CH_3), 1.2—1.9 (m, CH_2), 2.41 (d, J=15.5 Hz, H_{5a}), 2.72 (d, J=15.5 Hz, H_{5b}), 3.43 (dd, J=4.1, 13.2 Hz, H_{2a}), 3.66 (d, J=13.2 Hz, H_{2b}), 3.98 (d, J=4.1 Hz, H_1), 4.45 (d, J=5.9 Hz, H_7), 4.73 (d, J=5.9 Hz, H_8); MS *m/z* 284 (M^+). Found: C, 63.25; H, 8.62%. Calcd for $C_{15}H_{24}O_5$: C, 63.36; H, 8.51%.

Oxidation of ***11***: A mixture of **11** (12.0 g, 43.8 mmol), Na_2HPO_4 (103 g, 723 mmol), Na_2H_2edta (5 g), and CH_2Cl_2 (150 ml) was stirred at 0 °C and to this was added a CH_2Cl_2 solution of trifluoroperacetic acid (1.86 mol dm^{-3}, 118 ml, 219 mmol). After stirring for 12 h at 25 °C, the usual workup afforded a yellow residue. ^1H NMR analysis of this residue indicated that (1*R**,6*S**,7*S**,8*S**)-7,8-isopropylidenedioxy-1-phenyl-3,9-dioxabicyclo[4.2.1]nonan-4-one (**14a**) and (1*S**,6*R**,7*S**,8*S**)-7,8-isopropylidenedioxy-6-phenyl-3,9-dioxabicyclo[4.2.1]nonan-4-one (**14b**) were in 88:12 ratio. Purification of the residue on a silica-gel column using a 1:1 ether–petroleum ether mixture afforded **14a** (10.6 g, 84%) and **14b** (1.2 g, 9%). Total yield was 93% (11.8 g). **14a**: Mp 156—158 °C (chloroform–hexane); R_f=0.27 (1:1 ether–petroleum ether); IR 1735 cm^{-1} (C=O); ^1H NMR (C_6D_6) δ 1.13 and 1.30 (s, isopropylidene CH_3), 2.45 (m, H_5), 3.75 (d, J=13.5 Hz, H_{2a}), 4.01 (d, J=13.5 Hz, H_{2b}), 4.13 (m, H_6), 4.61 (d, J=6.0 Hz, H_7), 4.95 (d, J=6.0 Hz, H_8), 7.0—7.5 (m, C_6H_5); MS *m/z* 290 (M^+). Found: C, 66.09; H, 6.22%. Found: C, 65.54; H, 6.10%. Calcd for $C_{16}H_{18}O_5$: C, 66.19; H, 6.25%.

Baeyer-Villiger Oxidation of γ-Substituted Ketones. A. Results in Table 2: General. Unless otherwise stated, the Baeyer-Villiger oxidation was performed as follows. A mixture of a ketonic substrate (1 equiv), Na_2HPO_4 (9 equiv), and CH_2Cl_2 (3 ml/1 equiv of ketone) was cooled in an ice bath and stirred magnetically. To this was added dropwise a 1.0 mol dm^{-3} CH_2Cl_2 solution of trifluoroperacetic acid (3 equiv). The resulting mixture was stirred for 12 h at 25 °C and diluted with CH_2Cl_2 (5—10 ml/1 equiv of ketone). To this was added $Na_2S_2O_3\cdot5H_2O$ (0.8—1.6 g/1 equiv of ketone) at 0 °C and the mixture was stirred for 3 h at 25 °C. The insoluble material was removed by filtration and the filtrate was evaporated to give a crude product. The corresponding lactonic products were obtained as a mixture of two regioisomers. The isomeric ratio was determined by ^1H NMR and listed in Table 2. The regioisomers were separated by the silica-gel column chromatography and HPLC progress. The progress of elution of column chromatography was monitored by analytical TLC and fractions containing the desired product were combined and evaporated. Samples for elemental analysis were obtained by recrystallizations of the chromatographed products.

Typical Procedure. Oxidation of ***15***: Trifluoroperacetic acid in CH_2Cl_2 solution (1.0 mol dm^{-3}, 2.8 ml, 2.8 mmol) was added to a stirred, ice-cooled mixture of Na_2HPO_4 (1.20 g, 8.42 mmol) and **15** (320 mg, 0.936 mmol) in CH_2Cl_2 (2.8 ml). The mixture was stirred for 12 h at 25 °C and diluted with CH_2Cl_2 (10 ml). To this was added $Na_2S_2O_3\cdot5H_2O$ (1.5 g) at 0 °C and the resulting mixture was stirred for 3 h at 25 °C. The insoluble material was removed by filtration and the filtrate was evaporated. The residue (343 mg, 100%) consisted of (1*S**,6*S**,7*S**,8*S**)-1-*t*-butyldimethylsiloxymethyl-7,8-isopropylidenedioxy-3,9-dioxabicyclo[4.2.1]-nonan-4-one (**23a**) and (1*S**,6*S**,7*S**,8*S**)-6-*t*-butyldimethylsiloxymethyl-7,8-isopropylidenedioxy-3,9-dioxabicyclo[4.2.1]-nonan-4-one (**23b**) (55:45 ratio as determined by ^1H NMR analysis). Silica-gel column chromatography (1:1 ether–hexane) gave samples of **23a** and **23b**. **23a**: Mp 75—76 °C (ether–hexane); R_f=0.50 (3:1 ether–petroleum ether); IR 1735 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 0.08 (s, *t*-$C_4H_9(C\underline{H}_3)_2Si$), 0.91 (s, *t*-$C_4\underline{H}_9(CH_3)_2Si$), 1.32 and 1.49 (s, isopropylidene CH_3), 2.99 (m, H_5), 3.61 (d, J=10.5 Hz, $\underline{H}_aH_bCOSi$), 3.95 (d, J=10.5 Hz, $H_a\underline{H}_bCOSi$), 4.30 (d, J=13.2 Hz, H_{2a}), 4.31 (t-like, J=3.8 Hz, H_6), 4.58 (d, J=13.2 Hz, H_{2b}), 4.68 (d, J=6.0 Hz, H_7), 4.86 (d, J=6.0 Hz, H_8). Found: *m/z* 343.1601. Calcd for $C_{16}H_{27}O_6Si$: (M−CH_3), 343.1575. **23b**: Mp 64—65 °C (ether–hexane); R_f=0.38 (3:1 ether–petroleum ether); IR 1738 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 0.09 (s, *t*-$C_4H_9(C\underline{H}_3)_2Si$), 0.92 (s, *t*-$C_4\underline{H}_9(CH_3)_2Si$), 1.32 and 1.49 (s, isopropylidene CH_3), 2.92 (d, J=16.0 Hz, H_{5a}), 3.23 (d, J=16.0 Hz, H_{5b}), 3.65 (d, J=10.5 Hz, $\underline{H}_aH_bCOSi$), 3.90 (d, J=10.5 Hz, $H_a\underline{H}_bCOSi$), 4.29—4.53 (m, H_1 and H_2), 4.60 (d, J=5.9 Hz, H_7), 5.00 (d, J=5.9 Hz, H_8). Oxidation of ***34***: Oxidation of **34** led to (1*R**,6*R**,8*S**)-8-*t*-butyldimethylsiloxy-3,9-dioxabicyclo[4.2.1]nonan-4-one (**39a**) and (1*R**,6*R**,7*S**)-7-*t*-butyldimethylsiloxy-3,9-dioxabicyclo[4.2.1]nonan-4-one (**39b**). **39a**: Mp 70—72 °C (ether–hexane); R_f=0.18 (1:1 ether–hexane); V_R=20.0 ml (5:1 hexane–ethyl acetate); IR 1738 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ 0.03 (s, *t*-$C_4H_9(C\underline{H}_3)_2Si$), 0.90 (s, *t*-$C_4\underline{H}_9(CH_3)_2Si$), 1.4—2.5 (m, H_7), 2.81 (dd, J=5.0, 16.0 Hz, H_{5a}), 3.06 (dd, J=2.3, 16.0 Hz, H_{5b}), 4.18—4.43 (m, H_1 and H_2), 4.63 (m, H_6), 4.75 (dd, J=3.4, 6.9 Hz, H_8). **39b**: Mp 48—51 °C (ether–hexane); R_f=0.18 (1:1 ether–hexane); V_R=23.6 ml (5:1 hexane–ethyl acetate); IR 1735 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ 0.02 (s, *t*-$C_4H_9(C\underline{H}_3)_2Si$), 0.87 (s, *t*-$C_4\underline{H}_9(CH_3)_2Si$), 2.30—2.69 (m, H_8), 2.92 (m, H_5), 4.06 (dd, J=4.1, 13.8 Hz, H_{2a}), 4.12 (m, H_6), 4.40 (dd, J=3.0, 7.0 Hz, H_7), 4.42 (d, J=13.8 Hz, H_{2b}), 4.68 (m, H_1).

Regioisomeric ratio of **39a** and **39b** was determined as follows. To a solution of the lactones (53 mg, 0.195 mmol) in THF (1.0 ml) was added (n-$C_4H_9)_4NF$ in THF (0.822 mol dm^{-3} solution, 0.356 ml, 0.293 mmol) at 15 °C under argon. After stirring for 20 min, the reaction mixture was worked up to give a yellow oil. To this oil dissolved in pyridine (1 ml) was added benzoyl chloride (0.048 ml, 0.39 mmol) at 0 °C under argon. After stirring for 12 h at 15 °C, the reaction mixture was worked up to give a mixture of **42a** and **42b** (50 mg) as an oil. This oil was analyzed by HPLC.

Oxidation of ***33***: Oxidation of **33** afforded (1*R**,6*R**,8*S**)-8-benzyloxy-3,9-dioxabicyclo[4.2.1]nonan-4-one (**38a**) and (1*R**,6*R**,7*S**)-7-benzyloxy-3,9-dioxabicyclo[4.2.1]nonan-4-one (**38b**). This mixture was subjected to elemental analysis. Found: C, 67.38; H, 6.51%. Calcd for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50%. **38a**: colorless oil; R_f=0.19 (6:1 ether–hexane); V_R=19.0 ml (2:1 hexane–ethyl acetate); IR 1738 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ 2.75 (t-like, J=5.0 Hz, H_7), 2.94 (m, H_5), 4.1—4.7 (m, H_1, H_2, H_6, and H_8), 7.29 (s, C_6H_5). **38b**: Mp 103—104 °C (ether–hexane); R_f=0.19 (6:1 ether–hexane); V_R=20.4 ml (2:1 hexane–ethyl acetate); IR 1739 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ 2.0—2.7 (m, H_8), 2.88 (d-like, J=3.5 Hz, H_5), 4.02 (dd, J=4.0, 13.9 Hz, H_{2a}), 4.19 (dd, J=4.1, 7.8 Hz, H_7), 4.30 (m, H_6), 4.40 (d, J=13.9 Hz, H_{2b}), 4.48 (s, $C\underline{H}_2C_6H_5$), 4.64 (m, H_1), 7.32 (s, C_6H_5).

Ratio of **38a** and **38b** was determined as follows. The mixture of lactones (20 mg, 0.0862 mmol), 10% Pd/C (2 mg), and ethyl acetate (1 ml) was stirred for 12 h at 15 °C under atmospheric pressure of hydrogen. The insoluble material was removed by filtration and the filtrate was evaporated to give a colorless oil. To this oil dissolved in pyridine (0.44 ml) was added benzoyl chloride (0.021 ml, 0.172 mmol) at 0 °C under argon. After stirring for 10 h at 15 °C, the reaction mixture was worked up to give a mixture of **42a** and **42b** (22 mg) as a yellow oil, which was analyzed by HPLC.

Oxidation of ***35***: The reaction of **35** led to (1*R**,6*R**,8*S**)-8-acetoxy-3,9-dioxabicyclo[4.2.1]nonan-4-one (**40a**) and (1*R**,6*R**,7*S**)-7-acetoxy-3,9-dioxabicyclo[4.2.1]nonan-4-one (**40b**). This mixture was subjected to elemental analysis. Found: C, 54.01; H, 6.20%. Calcd for $C_9H_{12}O_5$: C, 53.99; H, 6.04%. **40a**: colorless oil; R_f=0.19 (7:1 ether–hexane); V_R=12.5 ml (1:1 hexane–ethyl acetate); IR 1735 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ 2.08 (s, CH_3CO), 2.22—2.38 (m, H_7), 2.88 (dd, J=4.5, 15.1 Hz, H_{5a}), 3.12 (dd, J=2.7, 15.1 Hz, H_{5b}), 4.40 (s, H_2), 4.42 (m, H_1), 4.62 (m, H_6), 5.47 (dd, J=4.0, 6.5 Hz, H_8). **40b**: Mp 80—82 °C (ether–hexane); R_f=0.14 (7:1 ether–hexane); V_R=14.0 ml (1:1 hexane–ethyl acetate); IR 1738 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ 2.07 (s, CH_3CO), 2.10—2.34 (m, H_{8a}), 2.64 (dd, J=7.9, 14.2 Hz, H_{8b}), 2.89 (dd, J=2.9, 15.1 Hz, H_{5a}), 3.14 (dd, J=4.5, 15.1 Hz, H_{5b}), 4.10 (dd, J=4.1, 13.6 Hz, H_{2a}), 4.31 (m, H_6), 4.44 (d, J=13.6 Hz, H_{2b}), 4.70 (m, H_1), 5.13 (dd, J=3.0, 7.9 Hz, H_7).

Oxidation of ***36***: Oxidation of **36** gave (1*R**,6*R**,8*S**)-8-pivaloyloxy-3,9-dioxabicyclo[4.2.1]nonan-4-one (**41a**) and (1*R**,6*R**,7*S**)-7-pivaloyloxy-3,9-dioxabicyclo[4.2.1]nonan-4-one (**41b**). Elemental analyses of this mixture were: Found: C, 59.54; H, 7.78%. Calcd for $C_{12}H_{18}O_5$: C, 59.49; H, 7.49%. **41a**: Colorless oil; R_f=0.24 (3:1 ether–hexane); V_R=12.2 ml (2:1 hexane–ethyl acetate); IR 1732 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ 1.18 (s, *t*-C_4H_9), 2.0—2.7 (m, H_7),

2.85 (dd, J=5.0, 16.5 Hz, H_{5a}), 3.06 (dd, J=2.0, 16.5 Hz, H_{5b}), 4.32 (m, H_1), 4.36 (s, H_2), 4.58 (m, H_6), 5.45 (dd, J=3.7, 6.8 Hz, H_8). **41b**: Mp 82—83 °C (ether–hexane); R_f=0.22 (3:1 ether–hexane); V_R=15.3 ml (2:1 hexane–ethyl acetate); IR 1735 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.18 (s, t-C_4H_9), 2.08 (ddd, J=3.2, 8.0, 13.8 Hz, H_{8a}), 2.63 (dd, J=7.8, 13.8 Hz, H_{8b}), 2.87 (dd, J=3.0, 16.0 Hz, H_{5a}), 3.15 (dd, J=4.8, 16.0 Hz, H_{5b}), 4.08 (dd, J=4.0, 13.1 Hz, H_{2a}), 4.25 (m, H_6), 4.43 (d, J=13.1 Hz, H_{2b}), 4.67 (m, H_1), 5.10 (dd, J=3.2, 7.8 Hz, H_7).

B. Results of Table 3. General: The Baeyer-Villiger oxidation and workup were generally performed as follows. To a mixture of a ketone (1 equiv), Na_2HPO_4 (11.9—12.8 g/l equiv of ketone), and CH_2Cl_2 (2.0—2.5 ml/l equiv of ketone; for **43**, 60 mg/(1 equiv of the ketone) of Na_2H_2edta was used) was added 1.0 mol dm^{-3} CH_2Cl_2 solution of trifluoroperacetic acid (3 equiv) at 0 °C. After stirring for 36 h at 20 °C (at 25 °C for **43**), the mixture was diluted with CH_2Cl_2 (1.5—5.5 ml/l equiv of ketone). To this was added $Na_2S_2O_3\cdot5H_2O$ (0.66—1.6 g/l equiv of ketone) at 0 °C and the resulting mixture was stirred for 2 h at 20 °C (for 4 h at 25 °C for **43**). The insoluble material was removed by filtration and the filtrate was evaporated to give a solid. The residue was subjected to silica-gel column chromatography to afford the desired lactones and an unreached starting material. Elution course of the column chromatography was monitored by TLC. The lactone was obtained as a mixture of two regioisomers. The product ratio was determined by ^1H NMR (for **43**, **44**, and **46**) or HPLC (for **47**, **48**, **49**, and **50**) and given in Table 3. The isomers were separated by rechromatography on silica gel (except for **43**). Samples for elemental analysis were obtained by recrystallizations of chromatographed products.

Typical Procedure. Oxidation of 43: Trifluoroperacetic acid in CH_2Cl_2 (1.0 mol dm^{-3} solution, 141 ml, 141 mmol) was added dropwise to a stirred, ice-cooled mixture of Na_2HPO_4 (64.8 g, 569 mmol), Na_2H_2edta (3 g), **43** (10.0 g, 47.4 mmol), and CH_2Cl_2 (200 ml). The mixture was stirred for 36 h at 25 °C and diluted with CH_2Cl_2 (200 ml). To this was added $Na_2S_2O_3\cdot5H_2O$ (75 g) at 0 °C and the resulting mixture was stirred for 4 h at 25 °C. The insoluble material was removed by filtration and the filtrate was evaporated. Chromatography of the residue on a silica gel column using a 9:1 mixture of hexane and ethyl acetate to pure ethyl acetate afforded a 33:67 mixture (determined by ^1H NMR) of (1*R**,6*S**,7*R**,8*R**)-7,8-isopropylidenedioxy-8-methyl-3,9-dioxabicyclo[4.2.1]nonan-4-one (**51a**) and (1*S**,6*R**,7*R**,8*S**)-7,8-isopropylidenedioxy-7-methyl-3,9-dioxabicyclo[4.2.1]nonan-4-one (**51b**) (5.59 g, 52%, 84% based on consumed **43**). In addition, unreacted **43** was obtained (3.80 g). Compounds **51a** and **51b** were separated by fractional recrystallizations from hexane–chloroform. **51a**: Mp 129.5—130 °C; R_f=0.46 (1:1 hexane–ethyl acetate); IR 1736 cm^{-1} (C=O); ^1H NMR (C_6D_6) δ 1.32 (s, CH_3), 1.34 and 1.48 (s, isopropylidene CH_3), 2.24 (dd, J=3.0, 16.0 Hz, H_{5a}), 2.52 (dd, J=4.8, 16.0 Hz, H_{5b}), 3.38 (dd, J=3.2, 14.0 Hz, H_{2a}), 3.62 (d, J=14.0 Hz, H_{2b}), 3.78 (m, H_1 and H_6), 4.14 (s, H_7); ^{13}C NMR ($CDCl_3$) δ 20.24, 27.87, 29.07, 42.94, 70.51, 79.69, 85.62, 91.47, 113.19, 171.70. Found: C, 58.14; H, 7.22%. Calcd for $C_{11}H_{16}O_5$: C, 57.88; H, 7.07%. **51b**: Mp 132—133 °C; R_f=0.46 (1:1 hexane–ethyl acetate); IR 1731 cm^{-1} (C=O); ^1H NMR (C_6D_6) δ 1.28 (s, CH_3), 1.28 and 1.48 (s, isopropylidene CH_3), 2.26 (dd, J=3.2, 17.0 Hz, H_{5a}), 2.52 (dd, J=4.2, 17.0 Hz, H_{5b}), 3.38 (dd, J=3.3, 14.6 Hz, H_{2a}), 3.58 (d, J=14.6 Hz, H_{2b}), 3.82 (m, H_1 and H_6), 4.34 (s, H_8); ^{13}C NMR ($CDCl_3$) δ 19.62, 27.68, 28.68, 42.02, 71.88, 82.01, 84.44, 86.82, 92.19, 113.12, 172.83. Found: C, 57.93; H, 7.05%. Calcd for $C_{11}H_{16}O_5$: C, 57.88; H, 7.07%.

Oxidation of 44: The reaction of **44** formed (1*R**,6*S**,7*R**,8*R**)-7,8-isopropylidenedioxy-8-pentyl-3,9-dioxabicyclo[4.2.1]nonan-4-one (**52a**) and (1*S**,6*R**,7*R**,8*S**)-7,8-isopropylidenedioxy-7-pentyl-3,9-dioxabicyclo[4.2.1]nonan-4-one (**52b**). Elemental analysis was performed as a mixture of **52a** and **52b**. Found: C, 63.13; H, 8.56%. Calcd for $C_{15}H_{24}O_5$: C, 63.36; H, 8.51%. **52a**: R_f=0.56 (3:1 ether–petroleum ether); IR 1736 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 0.8—1.8 (m, n-C_5H_{11}), 1.36 and 1.50 (s, isopropylidene CH_3), 2.28 (dd, J=2.6, 16.2 Hz, H_{5a}), 2.52 (dd, J=5.0, 16.2 Hz, H_{5b}), 3.3—4.0 (m, H_1, H_2, and H_6), 4.20 (s, H_7). **52b**: R_f=0.50 (3:1 ether–petroleum ether); IR 1732 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 0.8—1.8 (m, n-C_5H_{11}), 1.30 and 1.49 (s, isopropylidene CH_3), 2.34 (dd, J=3.2, 16.8 Hz, H_{5a}), 2.62 (dd, J=4.0, 16.8 Hz, H_{5b}), 3.42 (dd, J=3.8, 13.6 Hz, H_{2a}), 3.64 (dd, J=1.2, 13.6 Hz, H_{2b}), 3.80 (d-like, J=3.2 Hz, H_6), 3.96 (t-like, J=3.2 Hz, H_1), 4.44 (s, H_8).

Oxidation of 45: To a mixture of **45** (252 mg, 0.992 mmol), Na_2HPO_4 (1.81 g, 12.7 mmol), and CH_2Cl_2 (2.0 ml) was added dropwise trifluoroperacetic acid in CH_2Cl_2 (1.0 mol dm^{-3} solution, 3.0 ml, 3.0 mmol) at 0 °C. After stirring for 36 h at 20 °C, the reaction mixture was worked up as usual to give 220 mg of a white solid. TLC and NMR analysis of this solid indicated complete recovery of the starting material.

Oxidation of 46: Oxidation of **46** afforded (1*R**,6*S**,7*R**,8*S**)-7,8-isopropylidenedioxy-8-phenyl-3,9-dioxabicyclo[4.2.1]nonan-4-one (**53a**) and (1*S**,6*R**,7*R**,8*S**)-7,8-isopropylidenedioxy-7-phenyl-3,9-dioxabicyclo[4.2.1]nonan-4-one (**53b**). **53a**: Mp 148—149 °C (chloroform–hexane); R_f=0.42 (3:1 ether–petroleum ether); IR 1738 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.02 and 1.50 (s, isopropylidene CH_3), 3.10 (m, H_5), 3.80 (dd, J=3.6, 13.8 Hz, H_{2a}), 4.28 (d, J=13.8 Hz, H_{2b}), 4.38 (m, H_6), 4.60 (d-like, J=3.2 Hz, H_1), 5.16 (s, H_7), 7.3—7.6 (m, C_6H_5). Found: C, 65.80; H, 6.31%. Calcd for $C_{16}H_{18}O_5$: C, 66.19; H, 6.25%. **53b**: Mp 142—143 °C (chloroform–hexane); R_f=0.28 (3:1 ether–petroleum ether); IR 1741 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.04 and 1.52 (s, isopropylidene CH_3), 2.44 (dd, J=4.2, 17.4 Hz, H_{5a}), 2.88 (dd, J=3.0, 17.4 Hz, H_{5b}), 4.4—4.6 (m, H_1, H_2, and H_6), 5.52 (s, H_8), 7.3—7.6 (m, C_6H_5). Found: C, 65.58; H, 6.29%. Calcd for $C_{16}H_{18}O_5$: C, 66.19; H, 6.25%.

Oxidation of 47: Oxidation of **47** gave (1*R**,6*S**,7*R**,8*S**)-8-*t*-butyldimethylsiloxymethyl-7,8-isopropylidenedioxy-3,9-dioxabicyclo[4.2.1]nonan-4-one (**54a**) and (1*S**,6*R**,7*R**,8*S**)-7-*t*-butyldimethylsiloxymethyl-7,8-isopropylidenedioxy-3,9-dioxabicyclo[4.2.1]nonan-4-one (**54b**). **54a**: Mp 99.0—100 °C (ether–hexane); R_f=0.48 (2:1 hexane–ethyl acetate); V_R=11.2 ml (4:1 hexane–ethyl acetate); IR 1732 cm^{-1} (C=O); ^1H NMR (C_6D_6) δ 0.08 (s, t-$C_4H_9(C\underline{H}_3)_2Si$), 0.96 (s, t-$C_4\underline{H}_9(CH_3)_2Si$), 1.38 and 1.54 (s, isopropylidene CH_3), 2.29 (dd, J=2.8, 16.2 Hz, H_{5a}), 2.54 (dd, J=5.0, 16.2 Hz, H_{5b}), 3.6—4.2 (m, H_1, H_2, and H_6), 4.00 (s, H_7), 4.20 (s, CH_2OSi); ^{13}C NMR ($CDCl_3$) δ 18.37, 25.93, 27.98, 28.92, 42.88, 65.83, 70.78, 79.98, 84.58, 85.85, 96.04, 113.96, 171.77. Found: C, 56.52; H, 8.30%. Stereocontrolled General Synthesis of Pyrimidine *C*-Nucleosides Having Branched-chain Sugar Moieties[1]

Tsuneo SATO, Makoto WATANABE, Hiroshi KOBAYASHI, and Ryoji NOYORI*

Department of Chemistry, Nagoya University, Chikusa-ku, Nagoya 464

(Received February 23, 1983)

A variety of pyrimidine *C*-nucleosides bearing branched-chain sugars can be synthesized starting from adequately substituted (1*R**,6*S**,7*S**,8*R**)-7,8-isopropylidenedioxy-3,9-dioxabicyclo[4.2.1]nonan-4-ones. The general procedure consists of condensation with *t*-butoxybis(dimethylamino)methane, giving the corresponding α-dimethylaminomethylene lactones, base-catalyzed heterocycle formation with urea, thiourea, or guanidine, and acid-promoted removal of the isopropylidene protective group. The overall transformation proceeds with retention of the stereochemistry to afford only *C*-β-glycosyl nucleoside structures.

We have recently developed a novel method[2] for the synthesis of pseudouridine (**1**), a component of tRNA, and its analogues such as 2-thiopseudouridine (**2**) and pseudoisocytidine (**3**)[3] *via* a common intermediate, (1*R*,6*S*,7*S*,8*R*)-7,8-isopropylidenedioxy-3,9-dioxabicyclo[4.2.1]nonan-4-one (**4**), which possesses a rigid *C*-β-glycoside structure. Realization of this method relies on the efficiency of the transition metal aided [3+4] annulation using polybromo ketones and furans[4] and the stereoregulation of the subsequent oxidative transformation. The great flexibility of this new procedure prompted us to prepare a variety of the synthetic analogues. So far interest in the synthesis of *C*-nucleoside analogues has centered around the compounds having an arabionsyl or deoxyribosyl residue.[5] Being stimulated by the discovery of the antibiotics, angustomycin A and C[6] and nucleosidin,[7] which exhibit cytostatic or virostatic activity, we were particularly interested in *C*-nucleosides bearing a branched-chain ribofuranosyl moiety. Although a number of routes to branched-chain sugars have been developed during the past few years,[8] there were reported no efficient total syntheses which gave directly and stereospecifically such sugar derivatives. The present paper describes a completely stereocontrolled entry to pyrimidine *C*-nucleosides containing branched-chain sugar moieties.

Results and Discussion

Synthesis of 5′-Modified Pyrimidine C-*Nucleosides.*[9] The iron carbonyl- or Zn/Ag couple-promoted cyclocoupling of polybromo ketones and furan provides a general way to give the adducts of type **5**.[4] The bicyclic ketone **5a** thus obtained can be transformed oxidatively to **6a** under perfect stereo- and regiochemical control.[1] Heating of a mixture of the lactone **6a** and a Bredereck reagent, t-$C_4H_9OCH[N(CH_3)_2]_2$[10] (excess), in DMF at 50 °C afforded the dimethylaminomethylene lactone **7a** (*Z*:*E*=70:30) in a good yield. Condensation of **7a** and urea with ethanolic sodium ethoxide formed the uracil derivative **8a** in 48% yield. The β stereochemistry at the anomeric 1′ position was confirmed by the ^{1}H NMR analysis in pyridine-d_5. The isopropylidene methyl signals appeared at δ 1.41 and 1.67 (Δδ=0.26 ppm), in accord with the Imbach's empirical rule.[11] The spin-spin coupling constant, $J_{4',5'}$=3.7 Hz, also supported this assignment.[12] Subsequent treatment of **8a** with 10% HCl in methanol at 25 °C furnished (±)-5′,5′-dimethylpseudouridine (**9a**). No pyranose derivatives were formed by this deprotection procedure.

When **7a** was treated with thiourea in refluxing ethanolic sodium ethoxide, the thiouracil derivative **10a** was obtained. The glycol protective group was then removed by 10% HCl in methanol to give (±)-5′,5′-dimethyl-2-thiopseudouridine (**11a**).

The base-catalyzed condensation of **7a** with guanidine furnished the pseudoisocytidine derivative **12a**, which, by treatment with 10% HCl in methanol, afforded (±)-5′,5′-dimethylpseudoisocytidine (**13a**) in quantitative yield.

In a similar manner, the 5′-monoalkylated or -phenylated pseudouridines **9b—d**, the 5′-monosubstituted 2-thiopseudouridines **11b—d**, and 5′-monosubstituted pseudoisocytidines **13b—d** were prepared from the corresponding ketones **5b—d**. In addition to the complete stereochemical control achieved in this synthesis, the configurational relationship between the carbonyl α position in **5** and the 5′ carbon of the resulting nucleosides, **9**, **11**, and **13**, is noteworthy. Since the chiral center created in the initial reductive [3+4] cyclocoupling of polybromo ketones and furan remains intact during the subsequent transformation, the stereochemistry inherent in **5b**, for example, leads to the 6′-deoxyallofuranosyl structure, **9b**, **11b**, and **13b**. Thus this approach allows a general entry to pyrimidine *C*-nucleosides possessing various carbon substituents at the 5′ position.[13]

Synthesis of 1′- and 4′-Modified Pyrimidine C-*Nucleosides. A. 4′-Alkylated Pyrimidine* C-*Nucleosides*:[14,15] The readily available lactone **14a**[1] was condensed with t-$C_4H_9OCH[N(CH_3)_2]_2$ to afford the dimethylaminomethylene derivative **15a** in 70% yield. Conversion of **15a** to a uracil derivative **16a** was accomplished by heating **15a** with urea (10 equiv) in ethanolic sodium ethoxide in a fair yield. The assignment of

β configuration of the uracil base was made on the basis of the ^1H NMR chemical shifts of the isopropylidene methyls (δ 1.40 and 1.66, $\Delta\delta$=0.26 ppm).[11] Exposure of **16a** to 10% HCl in methanol formed (±)-4′-methylpseudouridine (**17a**) in quantitative yield. Preparation of (±)-4′-methyl-2-thiopseudouridine (**19a**) was effected by heating **15a** with thiourea in ethanolic sodium ethoxide, followed by acidic removal of the isopropylidene group. Condensation of **15a** with guanidine followed by removal of the isopropylidene protective group produced (±)-4′-methylpseudoisocytidine (**21a**) in 64% yield.

When an alkylated lactone **14b**[1] was used as the starting material, the 4′-pentyl pyrimidine *C*-nucleosides, **17b**, **19b**, and **21b**, were obtained according to similar synthetic procedures.

The otherwise unaccessible 4′-arylated pyrimidine *C*-nucleoside analogues, **17c**, **19c**, and **21c**, have been prepared by this completely stereocontrolled recipe starting from the phenylated lactone **14c**, derived from 2-phenylfuran and $\alpha,\alpha,\alpha',\alpha'$-tetrabromoacetone.[18]

B. 1′-Alkylated Pyrimidine C-*Nucleosides*:[14] When the methylated lactone **22a**[1] was treated with *t*-$C_4H_9OCH[N(CH_3)_2]_2$ (neat, 90 °C), there was obtained the dimethylaminomethylene lactone **23a**, displaying IR absorptions at 1670 (C=O) and 1590 cm^{-1} (C=C). This was subjected immediately to the condensation with urea in ethanolic sodium ethoxide to afford **24a**. The reaction proceeded only sluggishly and the yield was only 7% based on **22a**. The ^1H NMR spectrum of **24a** indicated that the product has β configuation at C-1′ position; the singlets due to the isopropylidene methyls occurred at δ 1.39 and 1.65 ($\Delta\delta$=0.26 ppm).[11] Removal of the isopropylidene block with 10% HCl in methanol yielded (±)-1′-methylpseudouridine (**25a**). The lactone **23a** underwent the sodium ethoxide-promoted condensation with thiourea in refluxing ethanol to produce the acetonide **26a**. Subsequent deprotection with 10% HCl in methanol liberated (±)-1′-methyl-2-thiopseudouridine (**27a**). Construction of the heterocyclic nucleus with guanidine gave rise to **28a**, methanolysis of which catalyzed by HCl afforded hydrochloride salt of **29a**. In a like manner, 1′-pentyl pyrimidine *C*-nucleosides, **25b**, **27b**, and **29b**, were obtained by employing the lactone **22b**.[1] Elaboration of heterocycles onto **22** was achieved less effectively because of the severe steric hindrance caused by the C-1′ alkyl substitution. Nevertheless, this method realized the first synthesis of 1′-alkylated *C*-nucleosides.[22]

C. 1′- and 4′-Hydroxymethylated Pyrimidine C-*Nucleosides*:[23] Condensation of the lactone **30**[1] with *t*-$C_4H_9OCH[N(CH_3)_2]_2$ in DMF at 90 °C provided the dimethylaminomethylene compound **31** in 91% yield.

Treatment of **31** with urea in the presence of sodium ethoxide constructed the uracil skeleton and simultaneous removal of the benzoyl moiety gave **32** in a moderate yield. Deprotection of the isopropylidene group by 10% HCl in methanol formed (±)-4′-hydroxymethylpseudouridine (**33**) in 89% yield. Similarly, treatment of **31** with thiourea under the basic conditions, giving **34**, followed by deprotection afforded (±)-4′-hydroxymethyl-2-thiopseudouridine (**35**). The base-catalyzed cyclization of **31** with guanidine, giving **36**, followed by removal of the isopropylidene block furnished (±)-4′-hydroxymethylpseudoisocytidine (**37**) as hydrochloride salt.

In a parallel fashion, the lactone **39**, derived from **38** by the reaction with *t*-$C_4H_9OCH[N(CH_3)_2]_2$, was convertible to 1′-hydroxymethylated pyrimidine *C*-nucleosides such as (±)-1′-hydroxymethyl-2-thiopseudouridine (**41**). Thus the base-promoted condensation of **39** and thiourea affording the acetonide **40** and subsequent removal of the protective group gave the *C*-nucleoside **41** which consists of psicose and a pyrimidine base.[22]

D. 1′,4′-Dialkylated Pyrimidine C-*Nucleosides*:[24] Bishydroxylation of **42a**[25] using hydrogen peroxide (3 equiv) in the presence of a catalytic amount of osmium tetraoxide in a 10:1:1 mixture of acetone, *t*-butyl alcohol, and ether, followed by acetonidation with $CuSO_4$ and *p*-toluenesulfonic acid in acetone gave **43a**. The α stereochemical assignment was made on the basis of the ^1H NMR spectrum which exhibited the H_6 and H_7 signal as a singlet at δ 4.30.[26] Then exposure of **43a** to trifluoroperacetic acid gave the lactone **44a** in 77% yield. Subsequent reaction with neat tris(dimethylamino)methane[27] at 90 °C afforded the (*Z*)-dimethylaminomethylene lactone **45a** in 38% yield (88% based on consumed **44a**) as a single isomer. Condensation of **45a** with urea with ethanolic sodium ethoxide formed **46a** in 28% yield, which was then treated with 10% methanolic HCl to give (±)-1′,4′-dimethylpseudouridine (**47a**). The ^1H NMR spectrum giving the isopropylidene methyl signals at δ 1.28 and 1.50 ($\Delta\delta$=0.22 ppm) confirmed the β heterocycle stereochemistry assigned for **46a**.[11,28] When thiourea was employed for the analogous cyclization, there was obtained in 60% yield the 2-thiouracil derivative **48a**, leading to **49a** after deprotection. Use of guanidine in place of urea gave rise to **51a** as HCl salt *via* **50a** in 75% yield.

In a usual manner, the 1′,4′-dipentyl analogues, **47b**, **49b**, and **51b**, have also been prepared starting with **42b**.

Thus present way appears to provide a facile, general entry to 1′,4′-disubstituted pyrimidine *C*-nucleosides which are not available by the conventional approaches

Synthesis of 2′-Alkylated Pyrimidine C-*Nucleosides*:[29] Treatment of **52a**[1] with excess *t*-$C_4H_9OCH[N(CH_3)_2]_2$ at 70 °C afforded the corresponding condensation product **53a** in 52% yield. The base-aided reaction with excess urea led to the uracil derivative **54a** in 20% yield, deprotection of which by methanolic HCl gave (±)-2′-hydroxymethylpseudouridine (**55a**) in 95% yield. The β stereochemistry at the anomeric position was established chemically by converting the acetonide **54a** to the cyclo-*C*-nucleoside **57a**. Thus reaction of **54a** and methanesulfonyl chloride in pyridine and subsequent treatment with 1,8-diazabicyclo[5.4.0]-undec-7-ene (DBU) in acetonitrile gave **57a** in *ca.* 60% yield.[30] Formation of the expected product was substantiated by comparison of the UV spectrum in methanol (λ_{max} 295 nm, ε 3720) showing a well-known, characteristic bathochromic shift, with that of the starting open-form **54a** (λ_{max} 266 nm, ε 7150).[21]

When the lactone **53a** was annulated with thiourea,

the protected nucleoside **58a** was obtained in high yield. Brief treatment of **58a** with methanolic HCl afforded (±)-2′-hydroxymethyl-2-thiopseudouridine (**59a**). Similarly, treatment of **53a** with guanidine, giving **60a**, and acid-assisted deprotection under the standard conditions led to (±)-2′-hydroxymethylpseudoisocytidine (**61a**) as HCl salt.

In a like fashion, 2′-methylated pyrimidine *C*-nucleosides, **55b**, **59b**, and **61b**, were synthesized by use of **52b**.[1)]

This method allows ready construction of the difficult-to-make hamamelose and 2′-methylribofuranose skeletons and introduction of pyrimidine rings at the 1′-position.[31)]

As has been outlined above, this approach is synthetically very flexible and a variety of *C*-nucleoside analogues can be made by parallel routes. The possibility was examined only with achiral or racemic precursors, but the optical resolution of the intermediates, leading to the "natural" configurations, could be done most conveniently at the stage of the lactones of type **4**.[2)]

Experimental

General. All melting and boiling points are uncorrected. IR spectra were recorded on a JASCO IRA-1 spectrometer in $CHCl_3$ solution unless otherwise stated. ^1H NMR spectra were obtained using a Varian NV-21 or HA-100 spectrometer, and ^{13}C NMR spectra were recorded at 20 MHz on a Varian CFT-20 spectrometer or at 25 MHz on a JEOL FX-100 spectrometer. The chemical shifts are recorded in parts per million relative to tetramethylsilane as an internal standard. Singlet, doublet, triplet, and multiplet are abbreviated to s, d, t, and m, respectively. Exact mass spectra were obtained at Central Research Laboratory of Ono Pharmaceutical Co. Elemental analyses were performed at the Research Laboratory of Fujisawa Pharmaceutical Co. and Faculty of Engineering of Nagoya University. Drying of organic extracts was done over anhydrous Na_2SO_4. For concentration of organic solvents, a vacuum (50—100 mmHg)** rotary evaporator was used.

Chromatography. Thin-layer chromatography (TLC) was done using a glass plate coated with 0.25-mm layers of silica gel 60 PF_{254} obtained from E. Merck and for preparative TLC, 20×20-cm glass plates coated with a 1.0-mm layer of silica gel 60 PF_{254} were employed. Analytical plates were visualized by spraying with a solution of 2% $Ce(SO_4)_2$ in 5% H_2SO_4 or 2% *p*-anisaldehyde in 5% ethanolic H_2SO_4 followed by heating on a hot plate. The position of spots are shown by R_f values. For column chromatography, E. Merck Kieselgel 60 (70—230 mesh) was used. For separation of the dimethylaminomethylene lactones, silica gel treated with diluted aqueous ammonia was used.[33)]

Solvents and Materials. DMF, acetonitrile, *t*-C_4H_9OH, and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) were used after distillation from CaH_2. Acetone and CH_2Cl_2 were distilled from P_2O_5. Ethanol was distilled over magnesium ribbons. THF and ether were distilled from sodium benzophenone ketyl. Preparations of Zn/Ag couple,[34)] Zn/Cu couple,[35)] 2-pentylfuran,[1)] α,α,α′,α′-tetrabromoacetone,[36)] *t*-butoxybis(dimethylamino)methane,[10)] and tris(dimethylamino)methane[27)] were performed according to the known procedures. Other commercially supplied materials and solvents were used as received.

Preparation of Methyl [(2S,3S*,4S*,5R*)-5-Hydroxymethyl-3,4-isopropylidenedioxy-5-phenyltetrahydrofuran-2-yl]acetate.* A mixture of **14c** (111 mg, 0.383 mmol),[1)] sodium methoxide (31.0 mg, 0.574 mmol), and CH_3OH (3 ml)*** was stirred at 0 °C for 1 h under argon and to this was added oxalic acid (100 mg). Evaporation followed by extraction with chloroform afforded the title compound (115 mg, 91%) as a white solid. R_f=0.28 (1:1 hexane–ethyl acetate); IR 3580 (OH), 1732 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.04 and 1.28 (s, isopropylidene CH_3), 2.74 (dd, J=6.0, 14.5 Hz, $\underline{H}_aH_bCC{=}O$), 2.96 (dd, J=4.8, 14.5 Hz, $H_a\underline{H}_bCC{=}O$), 3.62 (d, J=12.5 Hz, $\underline{H}_aH_bCOH$), 3.77 (s, OCH_3), 3.86 (d, J=12.5 Hz, $H_a\underline{H}_bCOH$), 4.40 (m, H_2), 4.56 (t-like, J=6.0 Hz, H_3), 5.02 (br, OH), 5.16 (d, J=6.0 Hz, H_4), 7.35 (m, C_6H_5); ^{13}C NMR ($CDCl_3$) δ 25.80, 26.70, 37.21, 51.94, 69.33, 79.65, 83.86, 84.06, 90.23, 114.44, 126.50, 127.27, 127.82, 138.12, 171.69. Found: *m/z*, 291.1231. Calcd for $C_{16}H_{19}O_5$: (M−OCH_3), 291.1232.

Preparation of 2,5-Dipentylfuran. To a mixture of *n*-C_4H_9Li (1.6 mol dm^{-3} hexane solution, 288 ml, 0.461 mol) and THF (350 ml) was added 2-pentylfuran (60.6 g, 0.439 mol) at −10 °C under argon. After the mixture was stirred at the same temperature for 6 h, pentyl iodide (91.3 g, 0.461 mol) was added. The reaction mixture was stirred at 20 °C for 12 h and then poured into ice-water (200 ml). The organic layer was separated and the aqueous layer was extracted with ether (150 ml×3). The combined organic extracts were dried ($MgSO_4$) and evaporated to leave a yellow oil, which was distilled under reduced pressure to give 2,5-dipentylfuran (68.2 g, 75%, bp 103—108 °C/9 mmHg (lit,[37)] 99—100 °C/5 mmHg)) as a colorless oil. ^1H NMR ($CDCl_3$) δ 0.91 (t, J=6.3 Hz), 1.1—1.8 (m), 2.57 (t, J=7.0 Hz), 5.84 (s); MS *m/z* 208 (M^+).

*1,5-Dimethyl-8-oxabicyclo[3.2.1]oct-6-en-3-one (**42a**).* To a mixture of Zn/Ag couple (26.0 g, 0.40 g-atom) and 2,5-dimethylfuran (21.3 ml, 0.20 mol) in THF (150 ml) was added a solution of α,α,α′,α′-tetrabromoacetone (224 g, 0.60 mol) in THF (200 ml) over 30 min at −10 °C under argon. The mixture was allowed to warm up to 20 °C and stirred at the same temperature for 12 h. The mixture was evaporated and the residue was dissolved in CH_3OH saturated with NH_4Cl (400 ml). To this was added portionwise Zn/Cu couple (130 g, 2.0 g-atom) over 2 h at 0 °C. The mixture was stirred at 20 °C for an additional 1 h and diluted with water (400 ml) and saturated disodium dihydrogen ethylenediaminetetraacetate (Na_2H_2edta) solution (400 ml). The insoluble material was removed by filtration and the filtrate was extracted with CH_2Cl_2 (300 ml×3). The combined organic layers were dried (Na_2SO_4) and concentrated. Chromatography of the residue on a silica-gel column using a 3:1 hexane–ethyl acetate mixture afforded **42a** (20.0 g, 66%) as a white solid. Mp 64—66 °C (hexane–chloroform); R_f=0.47 (3:1 hexane–ethyl acetate); IR 1715 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.50 (s, CH_3), 2.32 (d, J=16.1 Hz, H_{2a} and H_{4a}), 2.51 (d, J=16.1 Hz, H_{2b} and H_{4b}), 5.97 (s, H_6 and H_7); ^{13}C NMR ($CDCl_3$) δ 23.30, 51.12, 83.83, 136.42, 207.07. Found: C, 71.55, H, 8.06%. Calcd for $C_9H_{12}O_2$: C, 71.02; H, 7.95%.

*1,5-Dipentyl-8-oxabicyclo[3.2.1]oct-6-en-3-one (**42b**).* A mixture of Zn/Ag couple (39.0 g, 0.60 g-atom), 2,5-dipentylfuran (62.4 g, 0.30 mol), α,α,α′,α′-tetrabromoacetone (337 g, 0.9 mol), and THF (400 ml) was stirred at 20 °C for 24 h. Reduction of the reaction mixture with Zn/Cu couple (292 g, 4.50 g-atom) in CH_3OH (500 ml) saturated with NH_4Cl

** 1 mmHg≈133.322 Pa.

*** 1 ml=0.001 dm^3.

followed by extractive workup with CH_2Cl_2 gave a brown oil. Chromatography of the residue on a silica-gel column using a 10:1 hexane–ethyl acetate mixture afforded **42b** (32.5 g, 41%) as a colorless oil. R_f=0.35 (10:1 hexane–ethyl acetate); IR (neat) 1720 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 0.90 (t, J=6.5 Hz, CH_3), 1.1—1.9 (m, CH_2), 2.28 (d, J=16.0 Hz, H_{2a} and H_{4a}), 2.48 (d, J=16.0 Hz, H_{2b} and H_{4b}), 5.95 (s, H_6 and H_7); ^{13}C NMR ($CDCl_3$) δ 14.00, 22.59, 23.65, 32.18, 36.65, 50.53, 86.59, 135.42, 207.25. Found: *m/z*, 264.2092. Calcd for $C_{17}H_{28}O_2$: M, 264.2089. In addition, unreacted 2,5-dipentylfuran (12.9 g) was recovered.

(1S,5R*,6S*,7R*)-1,5-Dimethyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one (**43a**).* To a mixture of **42a** (25.0 g, 0.164 mol) and OsO_4 (300 mg, 1.18 mmol) in acetone (200 ml), t-C_4H_9OH (20 ml), and ether (20 ml) was added 30% H_2O_2 (36.2 ml, 0.329 mol). The mixture was stirred at 19 °C for 15 h and to this was added renewedly 30% H_2O_2 (18.1 ml, 0.165 mol). The mixture was stirred for an additional 12 h and cooled to 0 °C. To this was added powder of $Na_2S_2O_3 \cdot 5H_2O$ (77 g) and stirring was continued at 20 °C for 3 h. The residue obtained by evaporation was extracted with ethyl acetate (250 ml×3). The combined organic layers were dried (Na_2SO_4) and evaporated. The residue was dissolved in acetone (250 ml) and to this was added $CuSO_4$ (30 g) and p-toluenesulfonic acid (250 mg). The resulting mixture was stirred at 20 °C for 12 h. The insoluble material was removed by filtration and the filtrate was concentrated to afford a dark oil, which was chromatographed on a silica-gel column using a 3:1 hexane–ethyl acetate mixture to afford **43a** (22.5 g, 61%). Mp 67—68 °C (hexane–chloroform); R_f=0.32 (3:1 hexane–ethyl acetate); IR 1720 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.30 and 1.52 (s, isopropylidene CH_3), 1.41 (s, CH_3), 2.28 (d, J=15.0 Hz, H_{2a} and H_{4a}), 2.50 (d, J=15.0 Hz, H_{2b} and H_{4b}), 4.30 (s, H_6 and H_7); ^{13}C NMR ($CDCl_3$) δ 20.12, 25.00, 26.12, 51.71, 82.59, 85.30, 112.42, 206.90. Found: *m/z*, 211.0971. Calcd for $C_{11}H_{15}O_4$: (M−CH_3), 221.0970.

(1S,5R*,6S*,7R*)-1,5-Dipentyl-6,7-isopropylidenedioxy-8-oxabicyclo[3.2.1]octan-3-one (**43b**).* A mixture of **42b** (11.8 g, 44.7 mmol), acetone (70 ml), t-C_4H_9OH (7 ml), ether (7 ml), OsO_4 (100 mg), and 30% H_2O_2 (14.7 ml, 134 mmol) was stirred at 20 °C for 12 h and to this was added $Na_2S_2O_3 \cdot 5H_2O$ (33.5 g) at 0 °C. The resulting mixture was stirred at 20 °C for 3 h. After the usual workup, the residue was dissolved in acetone (150 ml). To this was added $CuSO_4$ (15 g) and p-toluenesulfonic acid (100 mg). After stirring at 20 °C for 24 h, the usual workup and chromatographic isolation (silica gel, 10:1 hexane–ethyl acetate) yielded **43b** (6.50 g, 43%) as a colorless oil. R_f=0.36 (10:1 hexane–ethyl acetate); IR 1720 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 0.90 (t, J=6.0 Hz, CH_3), 1.28 and 1.50 (s, isopropylidene CH_3), 1.1—1.9 (m, CH_2), 2.30 (d, J=14.5 Hz, H_{2a} and H_{4a}), 2.48 (d, J=14.5 Hz, H_{2b} and H_{4b}), 4.30 (s, H_6 and H_7); ^{13}C NMR ($CDCl_3$) δ 16.64, 25.19, 26.12, 27.78, 28.80, 35.03, 36.43, 52.18, 87.39, 87.59, 114.78, 210.07.

(1R,6S*,7R*,8S*)-1,6-Dimethyl-7,8-isopropylidenedioxy-3,9-dioxabicyclo[4.2.1]nonan-4-one (**44a**).* Trifluoroperacetic acid prepared from trifluoroacetic anhydride (46.5 ml, 0.328 mol) and 90% H_2O_2 (11.8 ml, 0.312 mol) in CH_2Cl_2 (150 ml) was added dropwise to a stirred, ice-cooled mixture of Na_2HPO_4 (140 g, 0.984 mol), Na_2H_2edta (1 g), and **43a** (35.2 g, 0.156 mol) in CH_2Cl_2 (200 ml). The mixture was stirred at 20 °C for 13 h and diluted with CH_2Cl_2 (200 ml). To this was added $Na_2S_2O_3 \cdot 5H_2O$ (78 g) at 0 °C and the resulting mixture was stirred at 20 °C for 3 h. The insoluble material was removed by filtration and the filtrate was evaporated. Chromatography of the residue on a silica-gel column using a 3:1 to 2:1 hexane–ethyl acetate mixture afforded **44a** (28.9 g, 77%). Mp 123—124 °C (hexane–chloroform); R_f=0.15 (3:1 hexane–ethyl acetate); IR 1735 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.27 and 1.35 (s, CH_3), 1.35 and 1.51 (s, isopropylidene CH_3), 2.83 (d, J=16.0 Hz, H_{5a}), 3.07 (d, J=16.0 Hz, H_{5b}), 4.11 (d, J=13.5 Hz, H_{2a}), 4.33 (d, J=13.5 Hz, H_{2b}), 4.56 (d, J=6.0 Hz, H_7), 4.88 (d, J=6.0 Hz, H_8); ^{13}C NMR ($CDCl_3$) δ 17.95, 22.16, 24.73, 26.01, 49.44, 75.96, 81.12, 83.63, 85.52, 112.57, 172.09. Found: C, 59.47; H, 7.60%. Calcd for $C_{12}H_{18}O_5$: C, 59.49, H, 7.49%.

(1R,6S*,7R*,8S*)-1,6-Dipentyl-7,8-isopropylidenedioxy-3,9-dioxabicyclo[4.2.1]nonan-4-one (**44b**).* To a mixture of **43b** (15.5 g, 45.9 mmol), Na_2HPO_4 (64.8 g, 0.456 mol), and CH_2Cl_2 (100 ml) was added trifluoroperacetic acid in CH_2Cl_2 (1.08 mol dm^{-3} solution, 128 ml, 0.138 mol) at 0 °C. After stirring at 20 °C for 12 h, the reaction mixture was worked up to give a white solid, which was purified on a silica-gel column (10:1 hexane–ethyl acetate) to give **44b** (12.2 g, 77%) as a white solid. Mp 60—62 °C (chloroform–hexane); R_f=0.37 (5:1 hexane–ethyl acetate); IR 1736 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 0.89 (t, J=6.0 Hz, CH_3), 1.31 and 1.49 (s, isopropylidene CH_3), 1.1—1.9 (m, CH_2), 2.28 (d, J=15.5 Hz, H_{5a}), 2.99 (d, J=15.5 Hz, H_{5b}), 4.17 (d, J=13.9 Hz, H_{2a}), 4.32 (d, J=13.9 Hz, H_{2b}), 4.52 (d, J=5.9 Hz, H_7), 4.98 (d, J=5.9 Hz, H_8); ^{13}C NMR ($CDCl_3$) δ 13.96, 22.41, 23.52, 24.57, 25.92, 32.26, 32.86, 35.56, 46.74, 75.06, 83.17, 85.11, 85.30, 112.12, 173.12. Found: C, 67.79; H, 9.76%. Calcd for $C_{20}H_{34}O_5$: C, 67.76; H, 9.67%. In addition, unreacted ketone **43b** (1.90 g) was recovered.

Preparation of the α-Dimethylaminomethylene Lactones. *General Procedure*: Unless otherwise stated, the dimethylaminomethylenation was performed as follows. A mixture of a lactone, t-butoxybis(dimethylamino)methane or tris(dimethylamino)methane, and DMF (in some reactions, DMF was not used) was magnetically stirred at the stated temperature under argon. After stirring for the stated period, the mixture was concentrated under reduced pressure (0.01 mmHg) at 25—50 °C. Chromatography was done on a silica-gel column using the described solvent system as eluent. Elution course of the column chromatography was monitored by TLC and fractions including the desired product were combined and evaporated. A sample for elemental analysis was obtained by recrystallizations of the chromatographed product.

(1S,6R*7R*,8S*)-2,2-Dimethyl-5-(dimethylaminomethylene)-7,8-isopropylidenedioxy-3,9-dioxabicyclo[4.2.1]nonan-4-one (**7a**).* A mixture of **6a**[1] (520 mg, 1.75 mmol), DMF (5 ml), and t-butoxybis(dimethylamino)methane (2.5 ml) was heated at 50 °C for 3 h. The reaction mixture was subjected to the usual workup. Pure **7a** (442 mg, 85%) was obtained by silica-gel column chromatography (5:1 to 1:1 hexane–ethyl acetate). Mp 136.5—137.2 °C (ether); R_f=0.35 (ethyl acetate); IR 1670 (C=O), 1590 cm^{-1} (C=C); ^1H NMR ($CDCl_3$) δ 1.33 and 1.51 (s, isopropylidene CH_3), 1.44 and 1.47 (s, CH_3), 2.93 and 3.14 (s, $N(CH_3)_2$, 3:7 ratio), 6.58 and 7.39 (s, =C<u>H</u>N$(CH_3)_2$, 3:7 ratio); MS *m/z* 297 (M^+); UV λ_{max} (CH_3OH) 300 nm (ε 15850). Found: C, 60.24; H, 7.79; N, 4.55%. Calcd for $C_{15}H_{23}O_5N$: C, 60.59; H, 7.80; N, 4.71%.

(1R,2R*,6R*,7R*,8R*)-5-(Dimethylaminomethylene)-7,8-isopropylidenedioxy-2-methyl-3,9-dioxabicyclo[4.2.1]nonan-4-one (**7b**).* A mixture of **6b**[1] (35 mg, 0.15 mmol), t-butoxybis(dimethylamino)methane (0.3 ml), and DMF (1 ml) was stirred at 50 °C for 1 h. After the usual workup, the crude product was purified by preparative TLC (ethyl acetate) to give

7b (20 mg, 47%). Mp 120.1—121.3 °C (ether–hexane); R_f=0.33 (ethyl acetate); IR 1680 (C=O), 1590 cm^{-1} (C=C); ^{1}H NMR ($CDCl_3$) δ 1.34 and 1.53 (s, isopropylidene CH_3), 1.38 (d, J=7.3 Hz, CH_3), 2.94 and 3.14 (s, $N(CH_3)_2$, 35:65 ratio), 6.66 and 7.34 (s, =C<u>H</u>N$(CH_3)_2$, 35:65 ratio); MS m/z 283 (M^+); UV λ_{max} (CH_3OH) 298 nm (ε 16590). Found: C, 59.42; H, 7.64; N, 4.85%. Calcd for $C_{14}H_{21}O_5N$: C, 59.35; H, 7.47; N, 4.94%.

(1R,2R*,6R*,7R*,8R*)-5-(Dimethylaminomethylene)-7,8-isopropylidenedioxy-2-pentyl-3,9-dioxabicyclo[4.2.1]nonan-4-one* (**7c**). A mixture of **6c**[1] (2.37 g, 8.36 mmol), *t*-butoxybis(dimethylamino)methane (12.0 ml), and DMF (15 ml) was stirred at 50 °C for 5 h. After the usual workup, the crude product was chromatographed on silica gel using ethyl acetate as the eluent to give **7c** (2.45 g, 86%). Mp 86.2—87.8 °C (ether–hexane); R_f=0.53 (ethyl acetate); IR 1680 (C=O), 1595 cm^{-1} (C=C); ^{1}H NMR ($CDCl_3$) δ 0.89 (t-like, J=6.0 Hz, CH_3), 1.32 and 1.50 (s, isopropylidene CH_3), 2.94 and 3.12 (s, $N(CH_3)_2$, 37:63 ratio), 6.65 and 7.32 (s =C<u>H</u>N$(CH_3)_2$, 37:63 ratio); MS m/z 339 (M^+); UV λ_{max} (CH_3OH) 298 nm (ε 23980). Found: C, 63.62; H, 8.75; N, 4.01%. Calcd for $C_{18}H_{29}O_5N$: C, 63.69; H, 8.61; N, 4.13%.

(1S,2S*,6R*,7R*,8R*)-5-(Dimethylaminomethylene)-7,8-isopropylidenedioxy-2-phenyl-3,9-dioxabicyclo[4.2.1]nonan-4-one* (**7d**). A mixture of **6d**[1] (98 mg, 0.338 mmol), *t*-butoxybis(dimethylamino)methane (0.5 ml), and DMF (2 ml) was stirred at 50 °C for 3.5 h. The usual workup and preparative TLC (2:1 ethyl acetate–hexane) yielded **7d** (74.0 mg, 64%) as a foam. R_f=0.51 (ethyl acetate); IR 1680 (C=O), 1590 cm^{-1} (C=C); ^{1}H NMR ($CDCl_3$) δ 1.28 and 1.47 (s, isopropylidene CH_3), 2.94 and 3.15 (s, $N(CH_3)_2$, 38:62 ratio), 6.73 (s, =C<u>H</u>N$(CH_3)_2$, *E*-isomer); MS m/z 345 (M^+); UV λ_{max} (CH_3OH) 299 nm (ε 13810).

(1R,6R*,7S*,8S*)-5-(Dimethylaminomethylene)-7,8-isopropylidenedioxy-1-methyl-3,9-dioxabicyclo[4.2.1]nonan-4-one* (**15a**). A mixture of **14a**[1] (952 mg, 4.18 mmol), tris(dimethylamino)methane (4.5 ml), and DMF (1 ml) was stirred at 70 °C for 1 h. To this was renewedly added tris(dimethylamino)methane (1.2 ml). After 2 h, tris(dimethylamino)methane (0.5 ml) was added again and stirring was continued for 3 h. The usual workup and chromatography on silica gel with a 1:1 hexane–ethyl acetate mixture to pure ethyl acetate afforded **15a** (831 mg, 70%). Mp 118—120 °C (ether); R_f=0.37 (ethyl acetate); IR 1680 (C=O), 1590 cm^{-1} (C=C); ^{1}H NMR ($CDCl_3$) δ 1.26 and 1.51 (s, isopropylidene CH_3), 1.33 (s, CH_3), 2.94 and 3.11 (s, $N(CH_3)_2$, 33:67 ratio), 6.67 and 7.34 (s, =C<u>H</u>N$(CH_3)_2$, 33:67 ratio); MS m/z 297 (M^+); UV λ_{max} (CH_3OH) 297 nm (ε 19800). Found: C, 59.18; H, 7.79; N, 4.92%. Calcd for $C_{14}H_{21}O_5N$: C, 59.35; H, 7.47; N, 4.92%.

(1R,6R*,7S*,8S*)-5-(Dimethylaminomethylene)-7,8-isopropylidenedioxy-1-pentyl-3,9-dioxabicyclo[4.2.1]nonan-4-one* (**15b**). A mixture of **14b**[1] (754 mg, 2.23 mmol), tris(dimethylamino)methane (2.6 ml) was stirred at 70 °C for 1 h. The reaction mixture was worked up and purified by silica gel column chromatography (1:1 hexane–ethyl acetate to ethyl acetate) to give **15b** (683 mg, 91%). Mp 117—118 °C (ether); R_f=0.46 (ethyl acetate); IR 1680 (C=O), 1595 cm^{-1} (C=C); ^{1}H NMR ($CDCl_3$) δ 0.89 (t-like, J=6.0 Hz, CH_3), 1.30 and 1.50 (s, isopropylidene CH_3), 2.94 and 3.13 (s, $N(CH_3)_2$, 31:69 ratio), 6.67 and 7.34 (s, =C<u>H</u>N$(CH_3)_2$, 31:69 ratio); MS m/z 339 (M^+); UV λ_{max} (CH_3OH) 297 nm (ε 18500). Found: C, 63.38; H, 8.94; N, 4.09%. Calcd for $C_{18}H_{29}O_5N$: C, 63.69; H, 8.61; N, 4.09%.

(1R,6R*,7S*,8S*)-5-(Dimethylaminomethylene)-7,8-isopropylidenedioxy-1-phenyl-3,9-dioxabicyclo[4.2.1]nonan-4-one* (**15c**). A mixture of **14c**[1] (987 mg, 3.40 mmol), tris(dimethylamino)methane (3.5 ml), and DMF (2 ml) was stirred at 70 °C for 1 h. Purification of the reaction mixture by silica-gel column chromatography (1:1 hexane–ethyl acetate to ethyl acetate) gave **15c** (1.08 g, 92%). Mp 233—235 °C (acetone); R_f=0.48 (ethyl acetate); IR 1680 (C=O), 1598 cm^{-1} (C=C); ^{1}H NMR ($CDCl_3$) δ 1.30 and 1.33 (s, isopropylidene CH_3), 2.98 and 3.20 (s, $N(CH_3)_2$, 37:63 ratio), 6.80 (s, =C<u>H</u>N$(CH_3)_2$, *E*-isomer); MS m/z 345 (M^+); UV λ_{max} (CH_3OH) 298 nm (ε 18300). Found: C, 66.21; H, 6.68, N, 4.02%. Calcd for $C_{19}H_{23}O_5N$: C, 66.07; H, 6.71, N, 4.06%.

(1R,6R*,7S*,8S*)-1-Benzoyloxymethyl-5-(dimethylaminomethylene)-7,8-isopropylidenedioxy-3,9-dioxabicyclo[4.2.1]nonan-4-one* (**31**). A mixture of **30**[1] (350 mg, 1.00 mmol) and *t*-butoxybis(dimethylamino)methane (1 ml) in DMF (1 ml) was stirred at 90 °C for 30 min. Workup followed by column chromatography (1:1 hexane–ethyl acetate to pure ethyl acetate) afforded **31** (368 mg, 91%) as a white foam. R_f=0.28 (1:2 hexane–ethyl acetate); IR 1725 and 1683 (C=O), 1590 cm^{-1} (C=C); ^{1}H NMR ($CDCl_3$) δ 1.31 and 1.50 (s, isopropylidene CH_3), 2.94 and 3.11 (s, $N(CH_3)_2$, 37:63 ratio), 6.70 (s, =C<u>H</u>N$(CH_3)_2$, *E*-isomer).

(1R,6R*,7R*,8R*)-6-Benzoyloxymethyl-5-(dimethylaminomethylene)-7,8-isopropylidenedioxy-3,9-dioxabicyclo[4.2.1]nonan-4-one* (**39**). A mixture of **38**[1] (696 mg, 2.0 mmol), *t*-butoxybis(dimethylamino)methane (2 ml), and DMF (1.5 ml) was stirred at 60 °C for 4 h. Chromatography on a silica-gel column using a 1:1 to 3:1 ethyl acetate–hexane mixture gave **39** (223 mg, 29%, 57% based on consumed starting material) as a white foam. R_f=0.46 (ethyl acetate); IR 1722 and 1690 (C=O), 1600 cm^{-1} (C=C); ^{1}H NMR ($CDCl_3$) δ 1.32 and 1.51 (s, isopropylidene CH_3), 2.84 and 3.16 (s, $N(CH_3)_2$, 80:20 ratio), 6.75 (s, =C<u>H</u>N$(CH_3)_2$, *E*-isomer). In addition, unreacted **38** was recovered (340 mg).

(1R,5Z,6R*,7R*,8S*)-5-(Dimethylaminomethylene)-1,6-dimethyl-7,8-isopropylidenedioxy-3,9-dioxabicyclo[4.2.1]nonan-4-one* (**45a**). A mixture of **44a** (7.92 g, 32.7 mmol) and tris(dimethylamino)methane (30 ml) was stirred at 90 °C for 8 h. Workup gave a solid, which was purified on a silica-gel column (1:1 hexane–ethyl acetate to pure ethyl acetate) to give **45a** (3.70 g, 38%). Mp 116—118 °C (ether); R_f=0.41 (ethyl acetate); IR 1680 (C=O), 1595 cm^{-1} (C=C); ^{1}H NMR ($CDCl_3$) δ 1.25 and 1.47 (s, CH_3), 1.33 and 1.53 (s, isopropylidene CH_3), 2.87 (s, $N(CH_3)_2$), 3.97 (d, J=13.0 Hz, H_{2a}), 4.16 (d, J=13.0 Hz, H_{2b}), 4.59 (d, J=5.9 Hz, H_7), 4.72 (d, J=5.9 Hz, H_8), 6.79 (s, =C<u>H</u>N$(CH_3)_2$); ^{13}C NMR ($CDCl_3$) δ 17.48, 20.41, 24.69, 26.04, 44.22, 75.17, 82.15, 84.26, 84.87, 88.33, 100.57, 112.10, 149.13, 170.40. Found: C, 60.25; H, 7.87; N, 4.57%. Calcd for $C_{15}H_{23}O_5N$: C, 60.59; H, 7.80; N, 4.71%. In addition, unreacted **44a** (4.51 g) was recovered.

(1R,5Z,6R*,7R*,8S*)-5-(Dimethylaminomethylene)-1,6-dipentyl-7,8-isopropylidenedioxy-3,9-dioxabicyclo[4.2.1]nonan-4-one* (**45b**). A mixture of **44b** (1.76 g, 4.97 mmol) and tris(dimethylamino)methane (5 ml) was stirred at 90 °C for 4 h. The usual workup of the reaction mixture gave an oily product, which was subjected to silica-gel chromatography with a 1:1 hexane–ethyl acetate mixture to pure ethyl acetate to afford **45b** (1.23 g, 61%) as a yellow oil. R_f=0.39 (1:1 hexane–ethyl acetate); IR 1688 (C=O), 1601 cm^{-1} (C=C); ^{1}H NMR ($CDCl_3$) δ 0.88 (t, J=6.0 Hz, CH_3), 1.33 and 1.51 (s, isopropylidene CH_3), 1.1—1.9 (m, CH_2), 2.84 (s, $N(CH_3)_2$), 3.88 (d, J=13.1 Hz, H_{2a}), 4.15 (d, J=13.1 Hz, H_{2b}), 4.52 (s, H_7 and H_8), 6.39 (s, =C<u>H</u>N$(CH_3)_2$); ^{13}C NMR ($CDCl_3$) δ 14.03, 22.41, 23.37, 24.87, 26.09, 32.44, 33.00, 35.19, 43.61, 71.50, 83.22, 85.29, 86.45, 88.98, 99.58, 112.03, 146.50, 171.43.

(1R,6S*,7R*,8R*)-5-(Dimethylaminomethylene)-7,8-isopropylidenedioxy-7-methyl-3,9-dioxabicyclo[4.2.1]nonan-4-one (**53b**).* A mixture of **52b**[1] (1.00 g, 4.41 mmol), *t*-butoxybis(dimethylamino)methane (11 ml), and DMF (1 ml) was stirred at 70 °C for 1 h. Purification of the crude product by silica-gel chromatography (1:1 hexane–ethyl acetate to pure ethyl acetate) afforded **53b** (789 mg, 63%). Mp 137—138 °C (hexane–ethyl acetate); R_f=0.45 (ethyl acetate); IR 1672 (C=O), 1592 cm^{-1} (C=C); ^1H NMR ($CDCl_3$) δ 3.44 and 3.52 (s, $N(CH_3)_2$, 3:2 ratio), 6.64 and 7.46 (s, =C<u>H</u>N-$(CH_3)_2$, 3:2 ratio); UV λ_{max} (CH_3OH) 300 nm (ε 16400). Found: C, 59.18; H, 7.41; N, 4.86%. Calcd for $C_{14}H_{21}O_5N$: C, 59.35; H, 7.47; N, 4.94%.

(1R,6S*,7R*,8R*)-7-t-Butyldimethylsiloxymethyl-5-(dimethylaminomethylene)-7,8-isopropylidenedioxy-3,9-dioxabicyclo-[4.2.1]nonan-4-one (**53a**).* A mixture of **52a**[1] (1.86 g, 5.20 mmol), *t*-butoxybis(dimethylamino)methane (14.7 ml), and DMF (1.2 ml) was stirred at 70 °C for 1 h. Usual workup followed by silica-gel chromatography (2:1 to 1:2 hexane–ethyl acetate) afforded **53a** (1.12 g, 52%). Mp 139—142 °C (hexane–ethyl acetate); R_f=0.37 (1:2 hexane–ethyl acetate); IR 1675 (C=O), 1581 cm^{-1} (C=C); ^1H NMR ($CDCl_3$) δ 2.95 and 3.14 (s, $N(CH_3)_2$, 1:2 ratio), 6.68 and 7.50 (s, =C<u>H</u>N$(CH_3)_2$, 1:2 ratio). Found: C, 57.64; H, 8.57; N, 3.21%. Calcd for $C_{20}H_{35}O_6NSi$: C, 58.08; H, 8.53; N, 3.39%.

Reaction of Dimethylaminomethylene Lactones with Urea, Thiourea, and Guanidine. General Procedure: Method A: A mixture of a dimethylaminomethylene lactone, urea, and a C_2H_5ONa in C_2H_5OH solution was heated at reflux under argon until the reaction completed. The mixture was cooled to room temperature and evaporated to dryness. The resulting residue was dissolved in H_2O. After careful neutralization with diluted hydrochloric acid, the aqueous solution was extracted with ethyl acetate. The organic layer was dried over anhydrous Na_2SO_4. The organic solution was concentrated under reduced pressure (50—90 mmHg), giving a crude material. The residue was subjected to preparative TLC. In TLC separation, silica-gel layer of the product area absorbing the 254-nm light was collected and extracted with a 1:1 chloroform–CH_3OH mixture. A sample for elemental analysis was obtained by repeated preparative TLC or recrystallization of the chromatographed product.

Method B: The reaction was carried out according to Method A. After the reaction was complete, the mixture was cooled to room temperature. The reaction mixture was evaporated and the resulting residue was taken up in water. To this was carefully added diluted hydrochloric acid until the solution was neutralized by monitoring with a pH test paper. The aqueous solution was concentrated and the resulting residue was diluted with ethanol. The insoluble material was removed by the filtration through a short column of Celite 545 and concentrated with a rotary evaporator under reduced pressure (50—90 mmHg) at 25—50 °C. The residue was subjected to preparative TLC and worked up as described above.

The same procedure was applied for the reaction using thiourea and guanidine hydrochloride instead of urea.

With Urea. 5-[(2R,3R*,4S*,5S*)-5-(1-Hydroxy-1-methylethyl)-3,4-isopropylidenedioxytetrahydrofuran-2-yl]uracil (**8a**)*: A mixture of **7a** (906 mg, 3.05 mmol), urea (1.90 g, 30.5 mmol), and 2.3 mol dm^{-3} C_2H_5ONa in C_2H_5OH solution (13 ml) was stirred for 5 h. The reaction mixture was subjected to the usual workup according to Method A. Pure **8a** (438 mg, 48%) was obtained by preparative TLC (5:1 chloroform–CH_3OH). Mp 153.1—156.8 °C (CH_3OH); R_f=0.42 (7:1 chloroform–CH_3OH); ^1H NMR (C_5D_5N) δ 1.41 and 1.67 (s, isopropylidene CH_3), 1.48 and 1.53 (s, CH_3), 4.12 (d, J=3.7 Hz, H_5), 5.08 (d, J=3.7 Hz, H_2), 5.30 (m, H_3 and H_4), 7.93 (s, =CH); UV λ_{max} (CH_3OH) 263 nm (ε 3890), λ_{max} (0.1 mol dm^{-3} NaOH) 286 nm (ε 5370). Found: C, 53.96; H, 6.40; N, 9.05%. Calcd for $C_{14}H_{20}O_6N_2$: C, 53.84; H, 6.45; N, 8.97%.

5-[(2R,3R*,4R*,5R*)-5-[(R*)-1-Hydroxyethyl]-3,4-isopropylidenedioxytetrahydrofuran-2-yl]uracil (**8b**)*: A mixture of **7b** (975 mg, 3.45 mmol), urea (2.10 g, 34.5 mmol), and 2.30 mol dm^{-3} C_2H_5ONa in C_2H_5OH (15 ml) was stirred for 5 h. After the usual workup according to Method A, the crude product was purified by preparative TLC (5:1 chloroform–CH_3OH) to afford **8b** (464 mg, 47%). Mp 264.5—266 °C (CH_3OH); R_f=0.37 (7:1 chloroform–CH_3OH); ^1H NMR (C_5D_5N) δ 1.40 and 1.66 (s, isopropylidene CH_3), 1.43 (d, J=5.2 Hz, CH_3), 4.27 (dd, J=3.0, 3.5 Hz, H_5), 4.30 (m, C<u>H</u>OH), 4.90 (br, OH), 5.10 (d, J=3.6 Hz, H_2), 5.30 (m, H_3 and H_4), 7.90 (s, =CH); UV λ_{max} (CH_3OH) 262 nm (ε 8310), λ_{max} (0.1 mol dm^{-3} NaOH) 285 nm (ε 7410). Found: C, 52.10; H, 5.97; N, 9.40%. Calcd for $C_{13}H_{18}O_6N_2$: C, 52.34; H, 6.08; N, 9.39%.

5-[(2R,3R*,4R*,5R*)-5-[(R*)-1-Hydroxyhexyl]-3,4-isopropylidenedioxytetrahydrofuran-2-yl]uracil (**8c**)*: A mixture of **7c** (546 mg, 1.61 mmol), urea (981 mg, 16.1 mmol), and 1.6 mol dm^{-3} C_2H_5ONa in C_2H_5OH (10 ml) was stirred for 5 h. The usual workup according to Method A and preparative TLC (5:1 chloroform–CH_3OH) gave **8c** (197 mg, 35%). Mp 209.5—212.0 °C (acetone); R_f=0.44 (7:1 chloroform–CH_3OH); ^1H NMR (C_5D_5N) δ 0.83 (t-like, J=6.0 Hz, CH_3), 1.10—1.90 (m, CH_2), 1.42 and 1.67 (s, isopropylidene CH_3), 4.19 (m, C<u>H</u>OH), 4.37 (t, J=3.0 Hz, H_5), 5.10 (d, J=4.5 Hz, H_2), 5.34 (m, H_3 and H_4), 7.91 (s, =CH); UV λ_{max} (CH_3OH) 263 nm (ε 6760), λ_{max} (0.1 mol dm^{-3} NaOH) 286 nm (ε 7400). Found: C, 57.47; H, 7.35; N, 7.98%. Calcd for $C_{17}H_{26}O_6N_2$: C, 57.61; H, 7.40; N, 7.91%.

5-[(2R,3R*,4R*,5S*)-5-[(S*)-α-Hydroxybenzyl]-3,4-isopropylidenedioxytetrahydrofuran-2-yl]uracil (**8d**)*: A mixture of **7d** (205 mg, 0.594 mmol), urea (361 mg, 5.94 mmol), and 2.0 mol dm^{-3} C_2H_5ONa in C_2H_5OH (3 ml) was stirred for 4 h. The reaction mixture was worked up according to Method A and separated by preparative TLC (5:1 ethyl acetate–hexane) to afford **8d** (90 mg, 42%). Mp 250.4—251.5 °C (CH_3OH); R_f=0.48 (7:1 chloroform–CH_3OH); ^1H NMR (C_5D_5N) δ 1.27 and 1.55 (s, isopropylidene CH_3), 4.75 (dd, J=2.2, 4.2 Hz, H_5), 5.08 (dd, J=1.9, 4.0 Hz, H_3), 5.40 (m, H_2, H_4, and C<u>H</u>OH), 7.30—7.80 (m, C_6H_5), 7.88 (s, =CH); UV λ_{max} (CH_3OH) 263 nm (ε 2390), λ_{max} (0.1 mol dm^{-3} NaOH) 285 nm (ε 7580). Found: C, 60.09; H, 6.02; N, 7.90%. Calcd for $C_{18}H_{20}O_6N_2$: C, 59.99; H, 5.59; N, 7.77%.

5-[(2R,3S*,4S*,5R*)-5-Hydroxymethyl-3,4-isopropylidenedioxy-5-methyltetrahydrofuran-2-yl]uracil (**16a**)*: A mixture of **15a** (537 mg, 1.90 mmol), urea (1.14 g, 19.0 mmol), and 1.58 mol dm^{-3} C_2H_5ONa in C_2H_5OH (12 ml) was stirred for 2 h. The reaction mixture was worked up according to Method A and purified by preparative TLC (10:1 chloroform–CH_3OH) to give **16a** (175 mg, 31%). Mp 200—205 °C (CH_3OH); R_f=0.60 (5:1 chloroform–CH_3OH); ^1H NMR (dimethyl-d_6 sulfoxide) δ 1.16 (s, CH_3), 1.24 and 1.51 (s, isopropylidene CH_3), 3.55 (br s, C<u>H</u>$_2$OH), 4.48—4.86 (m, H_2, H_3, and H_4), 7.56 (s, =CH), 10.94 (br, NH); (C_5D_5N) δ 1.40 and 1.66 (s, isopropylidene CH_3), 1.50 (s, CH_3), 3.79 (d, J=11.0 Hz, <u>H</u>$_a$H$_b$COH), 3.95 (d, J=11.0 Hz, H$_a$<u>H</u>$_b$COH), 5.07 (d, J=5.5 Hz, H_4), 5.15 (d, J=6.5 Hz, H_2), 5.44 (dd, J=5.5, 6.5 Hz, H_3), 7.92 (s, =CH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 18.18, 25.22, 26.80, 67.19, 79.12,

82.99, 84.28, 85.13, 110.38, 112.70, 140.27, 151.07, 163.61; UV λ_{max} (CH_3OH) 266 nm (ε 7230), λ_{max} (0.1 mol dm^{-3} NaOH) 285 nm (ε 7510). Found: C, 52.03; H, 6.14; N, 9.22%. Calcd for $C_{13}H_{18}O_6N_2$: C, 52.34; H, 6.08; N, 9.39%.

5-[(2R,3S*,4S*,5R*)-5-Hydroxymethyl-3,4-isopropylidenedioxy-5-pentyltetrahydrofuran-2-yl]uracil (**16b**)*: A mixture of **15b** (571 mg, 1.68 mmol), urea (1.01 g, 16.8 mmol), and 1.4 mol dm^{-3} C_2H_5ONa in C_2H_5OH (12 ml) was stirred for 2 h. Workup according to Method A followed by preparative TLC (10:1 chloroform–CH_3OH) gave **16b** (169 mg, 28%). Mp 219—221 °C (CH_3OH); R_f=0.72 (5:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 0.88 (t, J=5.7 Hz, CH_3), 1.27 and 1.49 (s, isopropylidene CH_3), 1.2—1.9 (m, CH_2), 3.36 (br s, C$\underline{H}_2$OH), 4.55 (d, J=5.0 Hz, H_4), 4.63 (d, J=6.2 Hz, H_2), 4.78 (dd, J=5.0, 6.2 Hz, H_3), 7.55 (s, =CH), 11.03 (br, NH); (C_5D_5N) δ 0.84 (t, J=6.0 Hz, CH_3), 1.1—2.2 (m, CH_2), 1.41 and 1.67 (s, isopropylidene CH_3), 3.86 (d, J=11.3 Hz, $\underline{H}_aH_bCOH$), 4.07 (d, J=11.3 Hz, $H_a\underline{H}_bCOH$), 5.03 (d, J=6.0 Hz, H_4), 5.20 (d, J=6.0 Hz, H_2) 5.51 (t, J=6.0 Hz, H_3), 7.96 (s, =CH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 13.71, 21.92, 22.66, 25.30, 26.95, 31.31, 32.15, 64.77, 79.66, 83.68, 86.74, 90.03, 110.30, 112.41, 140.37, 151.00, 163.52; UV λ_{max} (CH_3OH) 264 nm (ε 7830), λ_{max} (0.1 mol dm^{-3} NaOH) 285 nm (ε 7930). Found: C, 54.75; H, 7.32; N, 7.45%. Calcd for $C_{17}H_{26}O_6N_2\cdot H_2O$: C, 54.82; H, 7.58; N, 7.52%.

5-[(2R,3S*,4S*,5R*)-5-Hydroxymethyl-3,4-isopropylidenedioxy-5-phenyltetrahydrofuran-2-yl]uracil (**16c**)*: A mixture of **15c** (43.2 mg, 0.125 mmol), urea (75 mg, 1.25 mmol), and 0.83 mol dm^{-3} C_2H_5ONa in C_2H_5OH (1.5 ml, 1.25 mmol) was stirred for 2 h. Workup according to Method A gave an oil, which was purified by preparative TLC (5:1 chloroform–CH_3OH) to give **16c** (13.0 mg, 29%). Mp 282—285 °C (CH_3OH); R_f=0.62 (5:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 1.02 and 1.21 (s, isopropylidene CH_3), 3.50 (m, C$\underline{H}_2$OH), 4.78 (d, J=5.1 Hz, H_2), 4.84 (m, H_3), 5.08 (d, J=5.1 Hz, H_4), 7.32 (m, C_6H_5), 7.77 (s, =CH), 11.20 (br, NH); (C_5D_5N) δ 1.24 and 1.35 (s, isopropylidene CH_3), 4.01 (d, J=6.8 Hz, $\underline{H}_aH_bCOH$), 4.24 (d, J=6.8 Hz, $H_a\underline{H}_bCOH$), 5.20 (m, H_3), 5.62 (m, H_2 and H_4), 7.2—7.8 (m, C_6H_5), 8.13 (s, =CH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 25.59, 26.72, 68.29, 80.40, 83.38, 83.81, 89.50, 109.64, 112.51, 126.43, 127.24, 139.90, 141.34, 151.01, 164.00; UV λ_{max} (CH_3OH) 263 nm (ε 7990), λ_{max} (0.1 mol dm^{-3} NaOH) 285 nm (ε 7640). Found: C, 59.62; H, 5.50; N, 7.64%. Calcd for $C_{18}H_{20}O_6N_2$: C, 59.99; H, 5.59; N, 7.77%.

5-[(2R,3R*,4R*,5R*)-5-Hydroxymethyl-3,4-isopropylidenedioxy-2-methyltetrahydrofuran-2-yl]uracil (**24a**)*: A mixture of **22a** (619 mg, 2.72 mmol), and *t*-butoxybis(dimethylamino)-methane (2.8 ml) was stirred at 90 °C for 5 h under argon. The resulting solution was evaporated to give (1*R**,6*S**,7*R**,8*R**)-5-(dimethylaminomethylene)-7,8-isopropylidenedioxy-6-methyl-3,9-dioxabicyclo[4.2.1]nonan-4-one (**23a**) as a brown oil, which was used to the next step without purification. A mixture of crude **23a**, urea (2.45 g, 40.9 mmol), and 2 mol dm^{-3} C_2H_5ONa in C_2H_5OH (20 ml) was stirred. After 2 h, the reaction mixture was worked up according to Method A to give a brown solid, which was purified by preparative TLC (10:1 chloroform–CH_3OH) to give **24a** (54.2 mg, 7% based on **22a**) as a yellow foam. R_f=0.42 (5:1 chloroform–CH_3OH); ^{1}H NMR (C_5D_5N) δ 1.39 and 1.65 (s, isopropylidene CH_3), 1.94 (s, CH_3), 4.02 (m, C$\underline{H}_2$OH), 4.56 (m, H_5), 5.00 (dd, J=4.1, 6.2 Hz, H_4), 5.31 (d, J=6.2 Hz, H_3), 8.19 (s, =CH); UV λ_{max} (CH_3OH) 263 nm (ε 8450), λ_{max} (0.1 mol dm^{-3} NaOH) 288 nm (ε 10790). Found: *m/z*, 298.1156. Calcd for $C_{13}H_{18}O_6N_2$: M, 298.1149.

5-[(2R,3R*,4R*,5R*)-5-Hydroxymethyl-3,4-isopropylidenedioxy-2-pentyltetrahydrofuran-2-yl]uracil (**24b**)*: A mixture of **23b** prepared from **22b** (963 mg, 3.39 mmol) and *t*-butoxybis(dimethylamino)methane (3.4 ml), urea (2.03 g, 33.9 mmol), and 2.26 mol dm^{-3} C_2H_5ONa in C_2H_5OH (15 ml) was stirred for 2 h. Workup according to Method A and preparative TLC (7:1 chloroform–CH_3OH) afforded **24b** (45.8 mg, 4% based on **22b**) as a yellow foam. R_f=0.43 (5:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 0.81 (t, J=6.0 Hz, CH_3), 1.0—1.7 (m, CH_2), 1.28 and 1.46 (s, isopropylidene CH_3), 3.44 (m, C$\underline{H}_2$OH), 3.89 (m, H_5), 4.50 (dd, J=4.3, 5.8 Hz, H_4), 4.72 (d, J=5.8 Hz, H_3), 7.44 (s, =CH); UV λ_{max} (CH_3OH) 264 nm (ε 7930), λ_{max} (0.1 mol dm^{-3} NaOH) 289 nm (ε 5670). Found: *m/z*, 336.1731. Calcd for $C_{17}H_{24}O_5N_2$: ($M-H_2O$), 336.1777.

5-[(2R,3S*,4S*)-5,5-Bis(hydroxymethyl)-3,4-isopropylidenedioxytetrahydrofuran-2-yl]uracil (**32**)*: A mixture of **31** (594 mg, 1.47 mmol), urea (442 mg, 7.37 mmol), and 1 mol dm^{-3} C_2H_5ONa in C_2H_5OH (7 ml) was stirred for 5 h. After workup according to Method B, the residue was subjected to preparative TLC (5:1 chloroform–CH_3OH) to afford **32** (164 mg, 39%) as a white foam. R_f=0.37 (3:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 1.23 and 1.46 (s, isopropylidene CH_3), 3.50 (m, C$\underline{H}_2$OH), 4.53—4.86 (m, H_2, H_3, and H_4), 7.51 (s, =CH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 25.11 26.86, 60.39, 63.19, 79.81, 82.87, 84.00, 86.76, 110.19, 112.54, 140.54, 151.05, 163.55; UV λ_{max} (CH_3OH) 263 nm (ε 4910), λ_{max} (0.1 mol dm^{-3} NaOH) 284 nm (ε 4670). Found: *m/z*, 299.0879. Calcd for $C_{12}H_{15}O_7N_2$: ($M-CH_3$), 299.0880.

5-[(2R,3R*,4S*,5R*)-2,5-Dimethyl-5-hydroxymethyl-3,4-isopropylidenedioxytetrahydrofuran-2-yl]uracil (**46a**)*: A mixture of **45a** (118 mg, 0.397 mmol), urea (119 mg, 1.99 mmol), and 1 mol dm^{-3} C_2H_5ONa in C_2H_5OH (2 ml) was stirred for 24 h. The workup of the reaction product according to Method A gave an oil, which was subjected to preparative TLC (8:1 chloroform–CH_3OH) to afford **46a** (35.1 mg, 28%) as a white foam. Mp 126—134 °C (CH_3OH); R_f=0.51 (5:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 1.18 and 1.28 (s, CH_3), 1.28 and 1.50 (s, isopropylidene CH_3), 3.19 (m, C$\underline{H}_2$OH), 4.45 (d, J=6.2 Hz, H_3), 4.82 (d, J=6.2 Hz, H_4), 4.95 (br, OH), 7.47 (s, =CH), 10.80 (br, NH); (C_5D_5N) δ 1.42 and 1.70 (s, isopropylidene CH_3), 1.70 and 1.92 (s, CH_3), 3.78 (s, C$\underline{H}_2$OH), 4.85 (d, J=6.2 Hz, H_3), 5.46 (d, J=6.2 Hz, H_4), 8.32 (br s, =CH), 12.45 (br, NH), 13.04 (br, NH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 19.65, 24.41, 24.94, 25.59, 66.30, 82.95, 83.12, 84.71, 85.18, 111.36, 117.30, 138.01, 151.48, 163.18; UV λ_{max} (CH_3OH) 264 nm (ε 6680), λ_{max} (0.1 mol dm^{-3} NaOH) 217 nm (ε 10070), 287 (7610). Found: C, 53.29; H, 6.61; N, 8.24%. Calcd for $C_{14}H_{20}O_6N_2$: C, 53.84; H, 6.45; N, 8.97%.

5-[(2R,3R*,4S*,5R*)-2,5-Dipentyl-5-hydroxymethyl-3,4-isopropylidenedioxytetrahydrofuran-2-yl]uracil (**46b**)*: A mixture of **45b** (2.00 g, 4.89 mmol), urea (2.93 g, 48.9 mmol), and 1 mol dm^{-3} C_2H_5ONa in C_2H_5OH (49 ml) was stirred for 5 h. The reaction mixture was worked up according to Method A and the crude product was purified by preparative TLC (8:1 chloroform–CH_3OH) to give **46b** (472 mg, 23%) as a white foam. Mp>250 °C (CH_3OH); R_f=0.53 (10:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 0.84 (m, CH_3), 1.0—1.7 (m, CH_2), 1.26 and 1.46 (s, isopropylidene CH_3), 3.22 (m, C$\underline{H}_2$OH), 4.47 (d, J=6.6 Hz, H_3), 4.63 (br, OH), 4.77 (d, J=6.6 Hz, H_4), 7.37 (s, =CH),

10.82 (br, NH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 13.66, 21.96, 22.93, 31.73, 32.15, 24.44, 25.35, 63.89, 83.49, 84.90, 86.17, 111.16, 114.96, 138.88, 151.47, 162.89; UV λ_{max} (CH_3OH) 265 nm (ε 5820), λ_{max} (0.1 mol dm^{-3} NaOH) 289 nm (ε 4240). Found: C, 62.02; H, 8.57; N, 6.33%. Calcd for $C_{22}H_{36}O_6N_2$: C, 62.24; H, 8.55; N, 6.60%.

5-[(2S,3R*,4R*,5R*)-3-t-Butyldimethylsiloxymethyl-5-hydroxymethyl-3,4-isopropylidenedioxytetrahydrofuran-2-yl]uracil (**54a**)*: A mixture of **53a** (1.18 g, 2.86 mmol), urea (1.20 g, 8.58 mmol), and 0.41 mol dm^{-3} C_2H_5ONa in C_2H_5OH (21 ml) was stirred for 3 h. Workup according to Method B and preparative TLC (10:1 chloroform–CH_3OH) afforded **54a** (246 mg, 20%). Mp 238—242 °C (CH_3OH–acetone–petroleum ether); R_f=0.27 (10:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 0.06 (s, t-$C_4H_9(C\underline{H}_3)_2Si$), 0.84 (s, t-$C_4\underline{H}_9(CH_3)_2Si$), 1.33 and 1.51 (s, isopropylidene CH_3), 3.49 (s, CH_2OSi), 3.57 (m, $C\underline{H}_2OH$), 3.96 (m, H_5), 4.52 (d, J=2.8 Hz, H_4), 4.82 (s, H_2), 7.34 (br, =CH), 10.86 (br, NH), 11.02 (br s, NH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 17.74, 25.49, 26.84, 28.31, 61.01, 61.60, 80.44, 82.73, 83.02, 91.54, 107.86, 113.08, 138.68, 150.78, 162.56; UV λ_{max} (CH_3OH) 266 nm (ε 7150), λ_{max} (0.1 mol dm^{-3} NaOH) 289 nm (ε 6150). Found: C, 53.40; H, 7.54; N, 6.78%. Calcd for $C_{19}H_{32}N_2O_7Si$: C, 53.25; H, 7.53; N, 6.54%.

5-[(2S,3R*,4R*,5R*)-5-Hydroxymethyl-3,4-isopropylidenedioxy-3-methyltetrahydrofuran-2-yl]uracil (**54b**)*: A mixture of **53b** (730 mg, 2.58 mmol), urea (1.08 g, 18.1 mmol), and 0.9 mol dm^{-3} C_2H_5ONa in C_2H_5OH (20 ml, 18 mmol) was stirred for 3 h. Workup according to Method B followed by preparative TLC (4:1 chloroform–CH_3OH) gave **54b** (245 mg, 32%). Mp 126—128 °C; R_f=0.50 (4:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 1.12 (s, CH_3), 1.32 and 1.51 (s, isopropylidene CH_3), 3.52 (d-like, J=4.0 Hz, $C\underline{H}_2OH$) 3.92 (m, H_5), 4.30 (d, J=3.0 Hz, H_4), 4.80 (s, H_2), 7.34 (s, =CH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 20.37, 27.16, 28.38, 61.53, 81.39, 82.68, 87.28, 89.36, 109.17, 112.79, 139.33, 151.13, 162.89; UV λ_{max} (CH_3OH) 265 nm (ε 7430), λ_{max} (0.1 mol dm^{-3} NaOH) 289 nm (ε 7750). Found: m/z, 283.0939. Calcd for $C_{12}H_{15}N_2O_6$: (M−CH_3), 283.0930.

With Thiourea. *5-[(2R*,3R*,4S*,5S*)-5-(1-Hydroxy-1-methylethyl)-3,4-isopropylidenedioxytetrahydrofuran-2-yl]-2-thiouracil (**10a**)*: A mixture of **7a** (423 mg, 1.42 mmol), thiourea (868 mg, 9.94 mmol), and 1.14 mol dm^{-3} C_2H_5ONa in C_2H_5OH (10 ml) was stirred for 5 h. The reaction mixture was worked up according to Method A. Pure **10a** (332 mg, 71%) was obtained by preparative TLC (5:1 chloroform–CH_3OH). Mp 161.0—162.0 °C (ethyl acetate); ^{1}H NMR (acetone-d_6) δ 1.20 (s, CH_3), 1.32 and 1.51 (s, isopropylidene CH_3), 3.79 (d, J=3.1 Hz, H_5), 4.68 (dd, J=3.3, 4.5 Hz, H_3), 4.80 (d, J=3.3 Hz, H_2), 4.82 (dd, J=3.1, 4.5 Hz, H_4), 7.71 (s, =CH); UV λ_{max} (CH_3OH) 213 nm (ε 11100), 276 (13800), 290 (13000), λ_{max} (0.1 mol dm^{-3} NaOH) 222 nm (ε 14700), 264 (12000), 285 (9490). Found: C, 48.07; H, 6.29; N, 8.00%. Calcd for $C_{14}H_{20}O_5N_2S\cdot 1.2H_2O$: C, 48.04; H, 6.45; N, 8.00%.

5-[(2R,3R*,4R*,5R*)-5-[(R*)-1-Hydroxyethyl]-3,4-isopropylidenedioxytetrahydrofuran-2-yl]-2-thiouracil (**10b**)*: A mixture of **7b** (305 mg, 1.08 mmol), thiourea (660 mg, 8.64 mmol), and 1.23 mol dm^{-3} C_2H_5ONa in C_2H_5OH (7 ml) was stirred for 5 h. The reaction mixture was subjected to the Method A workup and preparative TLC (7:1 chloroform–CH_3OH) afforded **10b** (277 mg, 82%). Mp 201.2—202.5 °C (ether–CH_3OH); ^{1}H NMR (acetone-d_6) δ 1.19 (d, J=7.0 Hz, CH_3), 1.32 and 1.52 (s, isopropylidene CH_3), 3.87 (m, H_5 and $\underline{H}COH$), 4.66 (d, J=4.2 Hz, H_2), 4.82 (m, H_3 and H_4), 7.66 (s, =CH); UV λ_{max} (CH_3OH) 213 nm (ε 12500), 274 (14400), 286 (13100), λ_{max} (0.1 mol dm^{-3} NaOH) 223 nm (ε 16220), 264 (15140), 284 (11480). Found: C, 49.06; H, 5.85; N, 8.44%. Calcd for $C_{13}H_{18}O_5N_2S$: C, 49.67; H, 5.77; N, 8.91%.

5-[(2R,3R*,4R*,5R*)-5-[(R*)-1-Hydroxyhexyl]-3,4-isopropylidenedioxytetrahydrofuran-2-yl]-2-thiouracil (**10c**)*: A mixture of **7c** (491 mg, 1.45 mmol), thiourea (776 mg, 10.2 mmol), and 1.16 mol dm^{-3} C_2H_5ONa in C_2H_5OH (10 ml) was stirred for 5 h. After the Method A workup, the crude product was purified by preparative TLC (7:1 chloroform–CH_3OH) to give **10c** (365 mg, 68%). Mp 203.0—204.5 °C (ether); ^{1}H NMR (acetone-d_6) δ 0.91 (t, J=6.0 Hz, CH_3), 1.10—1.70 (m, CH_2), 1.31 and 1.51 (s, isopropylidene CH_3), 3.76 (m, $\underline{H}COH$), 3.95 (dd, J=3.1, 6.1 Hz, H_5), 4.65 (d, J=4.1 Hz, H_2), 4.86 (m, H_3 and H_4), 7.67 (s, =CH), 11.23 (br, NH); UV λ_{max} (CH_3OH) 214 nm (ε 12880), 276 (15850), 291 (14800), λ_{max} (0.1 mol dm^{-3} NaOH) 222 nm (ε 16990), 264 (13490), 283 (10960). Found: C, 54.56; H, 7.04; N, 7.39; S, 8.68%. Calcd for $C_{17}H_{26}O_5N_2S\cdot 0.25H_2O$: C, 54.45; H, 7.12; N, 7.46; S, 8.55%.

5-[(2R,3R*,4R*,5S*)-5-[(S*)-α-Hydroxybenzyl]-3,4-isopropylidenedioxytetrahydrofuran-2-yl]-2-thiouracil (**10d**)*: A mixture of **7d** (74 mg, 0.214 mmol), thiourea (115 mg, 1.50 mmol), and 0.85 mol dm^{-3} C_2H_5ONa in C_2H_5OH (2 ml) was stirred. After stirring for 5 h, the workup according to Method A and preparative TLC (5:1 chloroform–CH_3OH) afforded **10d** (59 mg, 73%). Mp 240—241 °C; ^{1}H NMR (C_5D_5N) δ 1.29 and 1.55 (s, isopropylidene CH_3), 4.75 (dd, J=3.9, 5.0 Hz, H_5), 5.17 (d, J=4.0 Hz, H_2), 5.38 (m, H_3, H_4, and $\underline{H}COH$), 7.3—7.9 (m, C_6H_5), 7.94 (s, =CH); UV λ_{max} (CH_3OH) 276 nm (ε 7940), 289 (7240), λ_{max} (0.1 mol dm^{-3} NaOH) 264 nm (ε 10970), 280 (8510). Found: C, 50.29; H, 5.57; N, 6.36%. Calcd for $C_{18}H_{20}O_5N_2S\cdot 3H_2O$: C, 50.22; H, 6.09; N, 6.51%.

5-[(2R,3S*,4S*,5R*)-5-Hydroxymethyl-3,4-isopropylidenedioxy-5-methyltetrahydrofuran-2-yl]-2-thiouracil (**18a**)*: A mixture of **15a** (284 mg, 1.00 mmol), thiourea (532 mg, 7.0 mmol), and 1.4 mol dm^{-3} C_2H_5ONa in C_2H_5OH (5 ml) was stirred for 2 h. The Method A workup and preparative TLC (5:1 chloroform–CH_3OH) gave **18a** (248 mg, 79%) as a yellow foam. R_f=0.67 (5:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 1.17 (s, CH_3), 1.28 and 1.50 (s, isopropylidene CH_3), 3.35 (br s, $C\underline{H}_2OH$), 4.54—4.86 (m, H_2, H_3, and H_4), 7.56 (s, =CH); (C_5D_5N) δ 1.40 and 1.65 (s, isopropylidene CH_3), 1.55 (s, CH_3), 3.77 (d, J=11.5 Hz, $\underline{H}_aH_bCOH$), 3.93 (d, J=11.5 Hz, $H_a\underline{H}_bCOH$), 5.09 (d, J=6.0 Hz, H_4), 5.17 (d, J=5.0 Hz, H_2), 5.36 (dd, J=5.0, 6.0 Hz, H_3), 8.05 (s, =CH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 18.20, 25.21, 26.70, 67.06, 78.93, 82.97, 84.56, 85.64, 112.69, 116.16, 139.44, 160.57, 175.38; UV λ_{max} (CH_3OH) 215 nm (ε 9490), 276 (14390), 290 (13190), λ_{max} (0.1 mol dm^{-3} NaOH) 223 nm (ε 9640), 264 (8700), 289 (6740). Found: C, 47.89; H, 5.67; N, 8.40%. Calcd for $C_{13}H_{18}O_5N_2S\cdot 0.7H_2O$: C, 47.75; H, 5.98; N, 8.57%.

5-[(2R,3S*,4S*,5R*)-5-Hydroxymethyl-3,4-isopropylidenedioxy-5-pentyltetrahydrofuran-2-yl]-2-thiouracil (**18b**)*: A mixture of **15b** (330 mg, 0.973 mmol), thiourea (517 mg, 6.81 mmol), and 0.85 mol dm^{-3} C_2H_5ONa in C_2H_5OH (8 ml) was stirred for 2 h. The reaction mixture was worked up according to Method A. Preparative TLC (10:1 chloroform–CH_3OH) gave **18b** (247 mg, 69%). Mp 181—183 °C (ether); R_f=0.64 (5:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 0.89 (t, J=5.7 Hz, CH_3), 1.28 and 1.50 (s, isopropylidene CH_3), 1.1—1.7 (m, CH_2), 3.38 (br s, $C\underline{H}_2OH$), 4.56—4.94 (m, H_2, H_3, and H_4), 7.55 (s, =CH), 12.40 (br, NH); (C_5D_5N) δ 0.89 (t, J=6.0 Hz, CH_3),

1.2—2.2 (m, CH_2), 1.45 and 1.70 (s, isopropylidene CH_3), 3.90 (d, J=11.2 Hz, $\underline{H}_aH_bCOH$), 4.06 (d, J=11.2 Hz, $H_a\underline{H}_bCOH$), 5.16 (d, J=6.0 Hz, H_4), 5.18 (d, J=5.0 Hz, H_2), 5.46 (dd, J=5.0, 6.0 Hz, H_3), 8.14 (s, =CH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 13.80, 21.93, 22.78, 25.42, 27.30, 31.67, 32.15, 65.62, 81.68, 82.99, 83.87, 86.52, 111.67, 112.39, 154.54, 156.20, 163.03; UV λ_{max} (CH_3OH) 213 nm (ε 13640), 276 (17330), 290 (sh, 15820), λ_{max} (0.1 mol dm^{-3} NaOH) 220 nm (ε 17230), 264 (13530), 282 (sh, 10910). Found: C, 55.06; H, 7.24; N, 7.56; S, 8.70%. Calcd for $C_{17}H_{26}O_5N_2S$: C, 55.12; H, 7.07; N, 7.56; S, 8.65%.

5-[(2R,3S*,4S*,5R*)-5-Hydroxymethyl-3,4-isopropylidenedioxy-5-phenyltetrahydrofuran-2-yl]-2-thiouracil (**18c**)*: A mixture of **15c** (36.8 mg, 0.107 mmol), thiourea (57 mg, 0.749 mmol), and 0.38 mol dm^{-3} C_2H_5ONa in C_2H_5OH (2 ml) was stirred for 2 h. The reaction mixture was worked up according to Method A. Preparative TLC (5:1 chloroform–CH_3OH) afforded **18c** (23.5 mg, 58%). Mp 210—213 °C; R_f=0.64 (5:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 1.01 and 1.21 (s, isopropylidene CH_3), 3.45 (d, J=11.1 Hz, $\underline{H}_aH_bCOH$), 3.72 (d, J=11.1 Hz, $H_a\underline{H}_bCOH$), 4.86 (m, H_2 and H_3), 5.05 (m, H_4), 7.33 (m, C_6H_5), 7.76 (s, =CH); (C_5D_5N) δ 1.20 and 1.34 (s, isopropylidene CH_3), 4.04 (d, J=12.0 Hz, $\underline{H}_aH_bCOH$), 4.25 (d, J=12.0 Hz, $H_a\underline{H}_bCOH$), 5.36 (m, H_3), 5.60 (m, H_2 and H_4), 7.2—7.9 (m, C_6H_5), 8.30 (s, =CH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 25.42, 26.47, 67.94, 80.05, 83.23, 83.92, 89.72, 112.35, 114.97, 126.31, 126.65, 127.09, 139.62, 141.23, 160.83, 175.59; UV λ_{max} (CH_3OH) 275 nm (ε 12780), 291 (sh, 11250), λ_{max} (0.1 mol dm^{-3} NaOH) 264 nm (ε 11530), 281 (sh, 9880). Found: C, 53.98; H, 5.78; N, 6.62; S, 7.70%. Calcd for $C_{18}H_{20}O_5N_2S\cdot 1.2H_2O$: C, 54.31; H, 5.67; N, 7.04; S, 8.06%.

5-[(2R,3R*,4R*,5R*)-5-Hydroxymethyl-3,4-isopropylidenedioxy-2-methyltetrahydrofuran-2-yl]-2-thiouracil (**26a**)*: A mixture of **23a** obtained from 1.03 g (4.50 mmol) of **22a** and *t*-butoxybis(dimethylamino)methane (4.5 ml) as described above and thiourea (2.39 g, 31.5 mmol) in 1 mol dm^{-3} C_2H_5ONa in C_2H_5OH (31.5 ml) was stirred for 2 h. Workup according to Method A followed by column chromatography (20:1 to 15:1 chloroform–CH_3OH) afforded **26a** (268 mg, 20% based on **22a**) as a yellow foam. R_f=0.60 (5:1 chloroform–CH_3OH); ^{1}H NMR (C_5D_5N) δ 1.95 (s, CH_3), 1.42 and 1.66 (s, isopropylidene CH_3), 3.90 (dd, J=5.0, 11.0 Hz, $\underline{H}_aH_bCOH$), 4.07 (dd, J=4.0, 11.0 Hz, $H_a\underline{H}_bCOH$) 4.59 (ddd, J=4.0, 4.0, 5.0 Hz, H_5), 4.99 (dd, J=4.0, 6.0 Hz, H_4), 5.27 (d, J=6.0 Hz, H_3), 8.29 (s, =CH); UV λ_{max} (CH_3OH) 214 nm (ε 9540), 275 (12850), 290 (11920), λ_{max} (0.1 mol dm^{-3} NaOH) 223 nm (ε 11880), 261 (11680), 292 (6800). Found: *m/z*, 314.0930. Calcd for $C_{13}H_{18}N_2O_5S$: M, 314.0936.

5-[(2R,3R*,4R*,5R*)-5-Hydroxymethyl-3,4-isopropylidenedioxy-2-pentyltetrahydrofuran-2-yl]-2-thiouracil (**26b**)*: A mixture of **23b** obtained from **22b** (577 mg, 2.03 mmol) and *t*-butoxybis(dimethylamino)methane (3 ml), thiourea (1.08 g, 14.2 mmol), and 2.0 mol dm^{-3} C_2H_5ONa in C_2H_5OH (7 ml) was stirred for 2 h. Workup according to Method A followed by column chromatography (30:1 to 20:1 chloroform–CH_3OH) gave **26b** (88.1 mg, 12% based on **22b**) as a foam. R_f=0.62 (5:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 0.80 (t, J=6.5 Hz, CH_3), 1.0—1.8 (m, CH_2), 1.25 and 1.45 (s, isopropylidene CH_3), 3.91 (m, H_5), 4.50 (dd, J=4.5, 6.0 Hz, H_4), 4.70 (d, J=6.0 Hz, H_3), 7.40 (s, =CH), $C\underline{H}_2OH$ peaks obscured by H_2O peak; UV λ_{max} (CH_3OH) 214 nm (ε 9430), 276 (13690), 289 (12700), λ_{max} (0.1 mol dm^{-3} NaOH) 232 nm (ε 13400), 261 (16840), 303 (8480). Found: C, 53.19; H, 6.90; N, 7.50%. Calcd for $C_{17}H_{26}O_5N_2S\cdot H_2O$: C, 52.56; H, 7.26; N, 7.21%.

5-[(2R,3S*,4S*)-5,5-Bis(hydroxymethyl)-3,4-isopropylidenedioxytetrahydrofuran-2-yl]-2-thiouracil (**34**)*. A mixture of **31** (337 mg, 0.84 mmol), thiourea (447 mg, 5.88 mmol), and 1 mol dm^{-3} C_2H_5ONa in C_2H_5OH (6 ml) was stirred for 3 h. The Method B workup gave a solid, which was purified by preparative TLC (5:1 chloroform–CH_3OH) to give **34** (160 mg, 63%) as a white foam. R_f=0.39 (5:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 1.24 and 1.46 (s, isopropylidene CH_3), 3.50 (d-like, J=7.5 Hz, $C\underline{H}_2OH$), 4.67 (m, H_2, H_3, and H_4), 5.5—8.0 (br, HN and OH), 7.56 (s, =CH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 25.11, 26.84, 60.42, 63.07, 79.80, 82.85, 84.25, 87.23, 127.89, 140.77, 160.68; UV λ_{max} (CH_3OH) 276 nm (ε 12770), 297 (11540), λ_{max} (0.1 mol dm^{-3} NaOH) 213 nm (ε 11320), 265 (9060), 292 (7320). Found: *m/z*, 330.0890. Calcd for $C_{13}H_{18}O_6N_2S$: M, 330.0884.

5-[(2R,3R*,4R*,5R*)-2,5-Bis(hydroxymethyl)-3,4-isopropylidenedioxytetrahydrofuran-2-yl]-2-thiouracil (**40**)*: A mixture of **39** (220 mg, 0.57 mmol), thiourea (303 mg, 3.99 mmol), and 1 mol dm^{-3} C_2H_5ONa in C_2H_5OH (5 ml) was stirred for 3 h. The reaction mixture was worked up according to Method B to give a yellow solid, which was purified by preparative TLC (5:1 chloroform–CH_3OH) to afford **40** (93.0 mg, 51%) as a white foam. R_f=0.50 (5:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 1.26 and 1.48 (s, isopropylidene CH_3), 3.3—3.8 (br, OH), 3.52 (d-like, J=7.5 Hz, $C\underline{H}_2OH$), 4.56—4.88 (m, H_3, H_4, and H_5), 7.52 (s, =CH); UV λ_{max} (CH_3OH) 214 nm (ε 8780), 276 (11350), 293 (10040), λ_{max} (0.1 mol dm^{-3} NaOH) 223 nm (ε 12910), 264 (8430), 289 (7080). Found: C, 44.63; H, 5.54; N, 8.00%. Calcd for $C_{13}H_{18}O_7N_2S$: C, 45.08; H, 5.24; N, 8.09%.

5-[(2R,3R*,4S*,5R*)-2,5-Dimethyl-5-hydroxymethyl-3,4-isopropylidenedioxytetrahydrofuran-2-yl]-2-thiouracil (**48a**)*: A mixture of **45a** (621 mg, 2.09 mmol), thiourea (1.11 g, 14.6 mmol), and 1 mol dm^{-3} C_2H_5ONa in C_2H_5OH (14 ml) was stirred for 5 h. After workup according to Method A, the residue was subjected to preparative TLC (8:1 chloroform–CH_3OH) to give **48a** (426 mg, 61%). Mp 90—95 °C (CH_3OH); R_f=0.67 (5:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 1.20 and 1.30 (s, CH_3), 1.30 and 1.50 (s, isopropylidene CH_3), 3.22 (m, $C\underline{H}_2OH$), 4.46 (d, J=6.2 Hz, H_3), 4.83 (d, J=6.2 Hz, H_4), 4.96 (t-like, J=4.2 Hz, OH), 7.49 (s, =CH), 12.16 and 12.34 (br, NH); (C_5D_5N) δ 1.42 and 1.70 (s, isopropylidene CH_3), 1.70 and 1.84 (s, CH_3), 3.72 (br s, $C\underline{H}_2OH$), 4.77 (d, J=6.2 Hz, H_3), 5.37 (d, J=6.2 Hz, H_4), 8.41 (s, =CH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 19.47, 24.41, 24.59, 25.59, 66.18, 83.00, 83.12, 84.89, 111.36, 122.89, 137.78, 160.25, 175.13; UV λ_{max} (CH_3OH) 215 nm (ε 12560), 276 (16180), 290 (14820), λ_{max} (0.1 mol dm^{-3} NaOH) 223 nm (ε 14860), 261 (14270), 292 (8650). Found: C, 51.02; H, 6.24; N, 8.67; S, 9.60%. Calcd for $C_{14}H_{20}O_5N_2S$: C, 51.21; H, 6.14; N, 8.53; S, 9.76%.

5-[(2R,3R*,4S*,5R*)-2,5-Dipentyl-5-hydroxymethyl-3,4-isopropylidenedioxytetrahydrofuran-2-yl]-2-thiouracil (**48b**)*: A mixture of **45b** (1.23 g, 2.80 mmol), thiourea (1.49 g, 19.6 mmol), and 1 mol dm^{-3} C_2H_5ONa in C_2H_5OH (20 ml) was stirred. After 5 h, the reaction mixture was worked up according to Method A and the crude product was purified by preparative TLC (10:1 chloroform–CH_3OH) to give **48b** (798 mg, 64%). Mp 207—210 °C (CH_3OH); R_f=0.47 (10:1 chloroform–CH_3OH); ^{1}H NMR (C_5D_5N) δ 0.84 (m, CH_3), 1.1—1.7 (m, CH_2, 14H), 1.44 and 1.74 (s, isopropylidene CH_3), 2.1—2.3 (m, CH_2, 2H), 3.73 (d, J=12.2 Hz, $\underline{H}_aH_bCOH$), 3.94 (d, J=12.2 Hz, $H_a\underline{H}_bCOH$), 4.81

(d, J=6.5 Hz, H_3), 5.37 (d, J=6.5 Hz, H_4), 8.51 (s, =CH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 13.82, 22.06, 23.12, 24.41, 25.35, 31.71, 32.18, 63.59, 83.36, 84.95, 85.71, 86.36, 111.24, 120.77, 138.77, 160.13, 175.18; UV λ_{max} (CH_3OH) 215 nm (ε 12820), 276 (16450), 290 (sh, 15290), λ_{max} (0.1 mol dm^{-3} NaOH) 227 nm (ε 9570), 261 (10640), 305 (6030). Found: C, 59.03; H, 8.06; N, 5.93%. Calcd for $C_{22}H_{36}O_5N_2S\cdot 0.5H_2O$: C, 58.76; H, 8.29; N, 6.23%.

5-[(2S,3R*,4R*,5R*)-3-t-Butyldimethylsiloxymethyl-5-hydroxymethyl-3,4-isopropylidenedioxytetrahydrofuran-2-yl]-2-thiouracil (**58a**)*: A mixture of **53a** (500 mg, 1.21 mmol), thiourea (645 mg, 8.47 mmol), and 0.94 mol dm^{-3} C_2H_5ONa in C_2H_5OH (9 ml) was stirred for 3 h. The Method B workup gave a crude product which was subjected to preparative TLC (10:1 chloroform–CH_3OH) to afford **58a** (333 mg, 62%). Mp 208—210 °C (acetone–hexane); R_f=0.27 (10:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 0.06 (s, t-$C_4H_9(C\underline{H}_3)_2Si$), 0.84 (s, t-$C_4\underline{H}_9(CH_3)_2Si$), 1.34 and 1.51 (s, isopropylidene CH_3), 3.30 (br, OH), 3.4—3.7 (m, C$\underline{H}_2$OH and CH_2OSi), 4.00 (m, H_5), 4.51 (d, J=3.0 Hz, H_4), 4.82 (s, H_2), 7.34 (s, =CH), 12.30 (br, NH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 17.74, 25.49, 26.90, 28.25, 60.95, 61.65, 80.21, 82.91, 83.14, 91.65, 113.26, 113.61, 138.22, 159.52, 174.61; UV λ_{max} (CH_3OH) 216 nm (ε 9160), 275 (11800), 299 (11200), λ_{max} (0.1 mol dm^{-3} NaOH) 224 nm (ε 9990), 262 (9110), 296 (6780). Found: C, 50.74; H, 7.55; N, 6.53%. Calcd for $C_{19}H_{32}O_6N_2SSi\cdot 0.5H_2O$: C, 50.30; H, 7.33; N, 6.18%.

5-[(2S,3R*,4R*,5R*)-5-Hydroxymethyl-3,4-isopropylidenedioxy-3-methyltetrahydrofuran-2-yl]-2-thiouracil (**58b**)*: A mixture of **53b** (200 mg, 0.707 mmol), thiourea (377 mg, 4.95 mmol), and 0.92 mol dm^{-3} C_2H_5ONa in C_2H_5OH (5.4 ml) was stirred for 3 h. The Method B workup and preparative TLC (4:1 chloroform–CH_3OH) afforded **58b** (155 mg, 70%). Mp 142—144 °C (CH_3OH); R_f=0.62 (5:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 1.14 (s, CH_3), 1.32 and 1.50 (s, isopropylidene CH_3), 3.56 (d-like, J=4.0 Hz, C$\underline{H}_2$OH), 3.96 (m, H_5), 4.31 (d, J=2.8 Hz, H_4), 4.80 (s, H_2), 7.38 (s, =CH), ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 20.26, 27.07, 28.32, 61.47, 81.21, 82.91, 87.30, 89.36, 112.84, 114.74, 138.92, 159.82, 175.16; UV λ_{max} (CH_3OH) 215 nm (ε 12600), 275 (15800), 297 (14900), λ_{max} (0.1 mol dm^{-3} NaOH) 221 nm (ε 13700), 262 (12100), 298 (8110). Found: *m/z*, 314.0949. Calcd for $C_{13}H_{18}O_5N_2S$: M, 314.0936.

With Guanidine Hydrochloride. 5-[(2R,3R*,4S*,5S*)-5-(1-Hydroxy-1-methylethyl)-3,4-isopropylidenedioxytetrahydrofuran-2-yl]isocytosine (**12a**)*: Guanidine hydrochloride (1.11 g, 11.8 mmol) was dissolved in 1.69 mol dm^{-3} C_2H_5ONa in C_2H_5OH (7 ml). To this was added **7a** (436 mg, 1.47 mmol) and the mixture was stirred for 5 h. The Method A workup followed by trituration of the residue with ether afforded **12a** (334 mg, 73%). Mp 242.0—243.1 °C (CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 1.10 (s, CH_3), 1.28 and 1.49 (s, isopropylidene CH_3), 3.67 (d, J=3.0 Hz, H_5), 4.51 (m, H_3), 4.68 (m, H_2 and H_4), 6.64 (br, NH_2), 7.66 (s, =CH); UV λ_{max} (CH_3OH) 227 nm (ε 5330), 290 (5370), λ_{max} (0.1 mol dm^{-3} NaOH) 233 nm (ε 7420), 276 (5940). Found: C, 54.16; H, 6.67; N, 13.30%. Calcd for $C_{14}H_{21}O_5N_3$: C, 54.01; H, 6.80; N, 13.50%.

5-[(2R,3R*,4R*,5R*)-5-[(R*)-1-Hydroxyethyl]-3,4-isopropylidenedioxytetrahydrofuran-2-yl]isocytosine (**12b**)*: A mixture of **7b** (952 mg, 3.36 mmol), guanidine hydrochloride (2.54 g, 26.9 mmol), and 2.69 mol dm^{-3} C_2H_5ONa in C_2H_5OH (10 ml) was stirred for 5 h. The reaction mixture was worked up according to Method A, and the product was subjected to trituration with ethyl acetate to give **12b** (665 mg, 67%). Mp 219.8—220.9 °C (CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 1.06 (d, J=6.0 Hz, CH_3), 1.27 and 1.48 (s, isopropylidene CH_3), 3.71 (m, H_5 and C$\underline{H}_2$OH), 4.71 (m, H_3), 4.74 (m, H_2 and H_4), 6.66 (br, NH_2), 7.64 (s, =CH); UV λ_{max} (CH_3OH) 226 nm (ε 7240), 290 (7240), λ_{max} (0.1 mol dm^{-3} NaOH) 232 nm (ε 9120), 276 (6920). Found: C, 52.50; H, 6.50; N, 13.97%. Calcd for $C_{13}H_{19}O_5N_3$: C, 52.51; H, 6.44; N, 14.13%.

5-[(2R,3R*,4R*,5R*)-5-[(R*)-1-Hydroxyhexyl]-3,4-isopropylidenedioxytetrahydrofuran-2-yl]isocytosine (**12c**)*: A mixture of **7c** (428 mg, 1.26 mmol), guanidine hydrochloride (951 mg, 10.1 mmol), and 1 mol dm^{-3} C_2H_5ONa in C_2H_5OH (10 ml) was stirred for 5 h. Workup according to Method A followed by trituration (ether) of the crude product gave pure **12c** (327 mg, 74%). Mp 212.0—213.9 °C (CH_3OH); ^{1}H NMR (C_5D_5N) δ 0.81 (t, J=6.0 Hz, CH_3), 1.2—1.8 (m, CH_2), 1.40 and 1.68 (s, isopropylidene CH_3), 4.18 (m, C$\underline{H}_2$OH), 4.42 (t-like, J=4.1 Hz, H_5), 5.06 (d, J=4.2 Hz, H_2), 5.38 (m, H_3 and H_4), 8.04 (s, =CH), 8.10 (br, NH_2); UV λ_{max} (CH_3OH) 227 nm (ε 10720), 290 (10720), λ_{max} (0.1 mol dm^{-3} NaOH) 233 nm (ε 11480), 277 (9330). Found: C, 57.05; H, 7.50; N, 11.91%. Calcd for $C_{17}H_{27}O_5N_3$: C, 57.77; H, 7.70; N, 11.89%.

5-[(2R,3R*,4R*,5S*)-5-[(S*)-α-Hydroxybenzyl]-3,4-isopropylidenedioxytetrahydrofuran-2-yl]isocytosine (**12d**)*: A mixture of **7d** (206 mg, 0.597 mmol), guanidine hydrochloride (394 mg, 4.18 mmol), and 3.2 mol dm^{-3} C_2H_5ONa in C_2H_5OH (1.5 ml) was stirred for 5 h. After workup according to Method A, the crude product was purified by trituration with ether to give **12d** (44 mg, 21%). Mp 273.8—275.0 °C (CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 1.18 and 1.42 (s, isopropylidene CH_3), 4.10 (dd, J=2.0, 4.0 Hz, H_5), 4.50 (d, J=4.3 Hz, H_2), 4.90 (m, H_3 and H_4) 5.82 (dd, J=2.0, 4.0 Hz, C$\underline{H}$OH), 6.60 (br, NH_2), 7.30 (m, C_6H_5), 7.64 (s, =CH), 11.0 (br, NH); UV λ_{max} (CH_3OH) 227 nm (ε 12310), 290 (13180), λ_{max} (0.1 mol dm^{-3} NaOH) 233 nm (ε 5490), 277 (4360). Found: C, 59.98; H, 6.05; N, 11.38%. Calcd for $C_{18}H_{21}O_5N_3$: C, 60.16; H, 5.89; N, 11.69%.

5-[(2R,3S*,4S*,5R*)-5-Hydroxymethyl-3,4-isopropylidenedioxy-5-methyltetrahydrofuran-2-yl]isocytosine (**20a**)*: A mixture of **15a** (705 mg, 2.49 mmol), guanidine hydrochloride (1.89 g, 19.9 mmol), and 1.4 mol dm^{-3} C_2H_5ONa in C_2H_5OH (14 ml) was stirred for 2 h. The workup according to Method A and trituration with ethyl acetate gave **20a** (434 mg, 64%). Mp 252—254 °C (CH_3OH); R_f=0.44 (5:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 1.14 (s, CH_3), 1.27 and 1.50 (s, isopropylidene CH_3), 3.34 (br s, C$\underline{H}_2$OH), 4.53 (d, J=5.2 Hz, H_4), 4.64 (d, J=6.0 Hz, H_2), 4.85 (dd, J=5.2, 6.0 Hz, H_3), 5.08 (br, OH), 6.82 (br, NH_2), 7.64 (s, =CH), 11.14 (br, NH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 18.14, 25.31, 27.10, 67.70, 80.83, 83.29, 83.50, 84.72, 111.88, 112.56, 154.10, 156.09, 163.00; UV λ_{max} (CH_3OH) 225 nm (ε 13890), 289 (11220), λ_{max} (0.1 mol dm^{-3} NaOH) 233 nm (ε 10320), 276 (7930). Found: C, 52.60; H, 6.27; N, 13.85%. Calcd for $C_{13}H_{19}O_5N_3$: C, 52.51; H, 6.44; N, 14.13%.

5-[(2R,3S*,4S*,5R*)-5-Hydroxymethyl-3,4-isopropylidenedioxy-5-pentyltetrahydrofuran-2-yl]isocytosine (**20b**)*. A mixture of **15b** (471 mg, 1.39 mmol), guanidine hydrochloride (1.06 g, 11.1 mmol), and 0.93 mol dm^{-3} C_2H_5ONa in C_2H_5OH (12 ml) was stirred for 2 h. The reaction mixture was worked up according to Method A. Trituration with ethyl acetate afforded pure **20b** (356 mg, 73%). Mp 228—230 °C (CH_3OH); R_f=0.51 (5:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 0.88 (t, J=6.0 Hz, CH_3), 1.28 and 1.51 (s, isopropylidene CH_3), 1.1—1.7 (m, CH_2), 3.39 (br s, C$\underline{H}_2$OH), 4.46 (d, J=6.0 Hz, H_4), 4.68 (d, J=6.0 Hz, H_2), 4.87 (t, J=6.0 Hz, H_3), 5.14 (br, OH), 6.81

(br, NH_2), 7.64 (s, =CH); (C_5D_5N) δ 0.83 (t, J=6.0 Hz, CH_3), 1.2—2.1 (m, CH_2), 1.38 and 1.68 (s, isopropylidene CH_3), 3.85 (d, J=11.5 Hz, H_aH_bCOH), 4.01 (d, J=11.5 Hz, H_aH_bCOH), 4.99 (d, J=5.5 Hz, H_4), 5.20 (d, J=5.5 Hz, H_2), 5.59 (t, J=5.5 Hz, H_3), 8.06 (s, =CH), 8.06 (br, NH_2); UV λ_{max} (CH_3OH) 227 nm (ε 9510), 290 (9540), λ_{max} (0.1 mol dm^{-3} NaOH) 216 nm (ε 9210), 233 (9750), 276 (7740). Found: C, 57.98; H, 7.78; N, 11.36%. Calcd for $C_{17}H_{27}O_5N_3$: C, 57.77; H, 7.70; N, 11.89%.

5-[(2R,3S*,4S*,5R*)-5-Hydroxymethyl-3,4-isopropylidenedioxy-5-phenyltetrahydrofuran-2-yl]isocytosine (**20c**)*: A mixture of **15c** (537 mg, 1.56 mmol), guanidine hydrochloride (1.19 g, 12.5 mmol), and 0.78 mol dm^{-3} C_2H_5ONa in C_2H_5OH (16 ml) was stirred for 2 h. Trituration with ethyl acetate gave **20c** (436 mg, 78%). Mp 270—272 °C (CH_3OH); R_f=0.53 (5:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 1.14 and 1.24 (s, isopropylidene CH_3), 4.63 (d, J=6.0 Hz, H_4), 5.01 (dd, J=5.8, 6.0 Hz, H_3), 5.13 (d, J=5.8 Hz, H_2), 6.75 (br, NH_2), 7.40 (m, C_6H_5), 7.67 (s, =CH), 11.50 (br, NH), CH_2OH peaks obscured by H_2O peaks; ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 25.66, 27.21, 68.71, 82.89, 83.84, 89.40, 111.99, 112.35, 126.22, 126.54, 127.37, 140.02, 154.47, 156.77, 164.22; UV λ_{max} (CH_3OH) 226 nm (ε 12330), 289 (10390), λ_{max} (0.1 mol dm^{-3} NaOH) 211 nm (ε 15210), 234 (11940), 276 (9020). Found: C, 60.00; H, 5.88; N, 11.69%. Calcd for $C_{18}H_{21}O_5N_3$: C, 60.16; H, 5.89; N, 11.69%.

5-[(2R,3R*,4R*,5R*)-5-Hydroxymethyl-3,4-isopropylidenedioxy-2-methyltetrahydrofuran-2-yl]isocytosine (**28a**)*: A mixture of crude **23a** [prepared from **22a** (248 mg, 1.09 mmol) and *t*-butoxybis(dimethylamino)methane (2 ml)], guanidine hydrochloride (1.06 g, 8.72 mmol), and 1.25 mol dm^{-3} C_2H_5ONa in C_2H_5OH (7 ml) was stirred for 2 h. Workup according to Method A followed by preparative TLC (5:1 chloroform–CH_3OH) afforded **28a** (53.4 mg, 17% based on **22a**) as a yellow foam. R_f=0.40 (5:1 chloroform–CH_3OH), ^{1}H NMR (C_5D_5N) δ 1.36 and 1.62 (s, isopropylidene CH_3), 1.91 (s, CH_3), 4.00 (d, J=5.2 Hz, CH_2OH), 4.54 (m, H_5), 5.01 (dd, J=4.1, 6.0 Hz, H_4), 5.39 (d, J=6.0 Hz, H_3), 8.04 (br, NH_2), 8.33 (s, =CH); UV λ_{max} (CH_3OH) 224 nm (ε 10400), 290 (8450), λ_{max} (0.1 mol dm^{-3} NaOH) 231 nm (ε 7710), 278 (5950). Found: *m/z*, 297.1312. Calcd for $C_{13}H_{19}N_3O_5$: M, 297.1325.

5-[(2R,3R*,4R*,5R*)-5-Hydroxymethyl-3,4-isopropylidenedioxy-2-pentyltetrahydrofuran-2-yl]isocytosine (**28b**)*: A mixture of crude **23b** [prepared from **22b** (632 mg, 2.23 mmol) and *t*-butoxybis(dimethylamino)methane (3 ml)], guanidine hydrochloride (1.69 g, 17.8 mmol), and 1 mol dm^{-3} C_2H_5ONa in C_2H_5OH (18 ml) was stirred for 2 h. Workup according to Method A and column chromatography (20:1 to 10:1 chloroform–CH_3OH) afforded **28b** (31.6 mg, 4% based on **22b**) as a yellow foam. R_f=0.42 (5:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 0.77 (t, J=6.0 Hz, CH_3), 1.0—2.0 (m, CH_2), 1.22 and 1.42 (s, isopropylidene CH_3), 3.38 (d, J=2.7 Hz, CH_2OH), 3.82 (m, H_5), 4.43 (dd, J=2.0, 6.0 Hz, H_4), 4.81 (d, J=6.0 Hz, H_3), 6.78 (br, NH_2), 7.61 (s, =CH); UV λ_{max} (CH_3OH) 225 nm (ε 5770), 292 (3680), λ_{max} (0.1 mol dm^{-3} NaOH) 230 nm (ε 6720), 278 (4770). Found: *m/z*, 335.1842. Calcd for $C_{17}H_{25}O_4N_3$: (M−H_2O), 335.1840.

5-[(2R,3S*,4S*)-5,5-Bis(hydroxymethyl)-3,4-isopropylidenedioxytetrahydrofuran-2-yl]isocytosine (**36**)*: A mixture of **31** (368 mg, 0.91 mmol), guanidine hydrochloride (608 mg, 6.37 mmol), and 1 mol dm^{-3} C_2H_5ONa in C_2H_5OH (7 ml) was stirred for 5 h. Workup according to Method B gave a yellow solid, which was purified by preparative TLC (3:1 chloroform–CH_3OH) to give **36** (128 mg, 45%). Mp 245—247 °C (CH_3OH); R_f=0.39 (3:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 1.25 and 1.46 (s, isopropylidene CH_3), 3.53 (m, CH_2OH), 4.0—5.0 (br, OH), 4.47 (d, J=5.5 Hz, H_4), 4.70 (d, J=5.5 Hz, H_2), 4.82 (t, J=5.5 Hz, H_3), 6.85 (br, NH_2), 7.63 (s, =CH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 25.24, 27.16, 60.71, 64.01, 81.74, 83.09, 86.44, 111.44, 112.46, 154.41, 156.45, 163.18, UV λ_{max} (CH_3OH) 227 nm (ε 5960), 290 (5720), λ_{max} (0.1 mol dm^{-3} NaOH) 233 nm (ε 10250), 277 (7770). Found: C, 49.54; H, 6.10; N, 13.40%. Calcd for $C_{13}H_{19}O_6N_3$: C, 49.83; H, 6.11; N, 13.41%.

5-[(2R,3R*,4S*,5R*)-2,5-Dimethyl-5-hydroxymethyl-3,4-isopropylidenedioxytetrahydrofuran-2-yl]isocytosine (**50a**)*: A mixture of **45a** (1.07 g, 3.60 mmol), guanidine hydrochloride (2.74 g, 28.8 mmol), and 1 mol dm^{-3} C_2H_5ONa in C_2H_5OH (30 ml) was stirred for 5 h. Workup according to Method A followed by trituration with ethyl acetate afforded **50a** (878 mg, 77%). Mp 255—257 °C (CH_3OH), R =0.43 (5:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 1.19 and 1.32 (s, CH_3), 1.32 and 1.49 (s, isopropylidene CH_3), 3.18 (d-like, J=4.8 Hz, CH_2OH), 4.48 (d, J=6.3 Hz, H_3), 4.91 (d, J=6.3 Hz, H_4), 6.46 (br, NH_2), 7.72 (s, =CH), 10.90 (br, NH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 19.82, 24.59, 24.94, 25.71, 66.71, 83.24, 83.30, 83.42, 84.59, 111.30, 119.42, 156.01; UV λ_{max} (CH_3OH) 225 nm (ε 9930), 292 (8160), λ_{max} (0.1 mol dm^{-3} NaOH) 231 nm (ε 8750), 278 (6930). Found: C, 52.90; H, 6.75; N, 12.89%. Calcd for $C_{14}H_{21}O_5N_3\cdot0.5H_2O$: C, 52.49; H, 6.92; N, 13.12%.

5-[(2R,3R*,4S*,5R*)-2,5-Dipentyl-5-hydroxymethyl-3,4-isopropylidenedioxytetrahydrofuran-2-yl]isocytosine (**50b**)*: A mixture of **45b** (1.31 g, 3.20 mmol), guanidine hydrochloride (2.43 g, 25.6 mmol), and 1 mol dm^{-3} C_2H_5ONa in C_2H_5OH (25 ml) was stirred. After 5 h, the mixture was worked up according to Method A to give an oil, which was triturated with ethyl acetate to give **50b** (528 mg, 39%). Mp 168—170 °C (CH_3OH); R_f=0.54 (5:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 0.86 (m, CH_3), 1.0—2.0 (m, CH_2), 1.26 and 1.46 (s, isopropylidene CH_3), 3.34 (m, CH_2OH), 4.49 (d, J=6.2 Hz, H_3), 4.74 (br, OH) 4.87 (d, J=6.2 Hz, H_4), 6.60 (br, NH_2), 7.62 (s, =CH), 11.10 (br, NH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 13.80, 22.02, 22.66, 23.13, 24.36, 25.42, 31.76, 32.11, 34.70, 63.58, 83.34, 85.01, 85.66, 85.95, 110.78, 116.83, 155.52; UV λ_{max} (CH_3OH) 225 nm (ε 7530), 292 (5810), λ_{max} (0.1 mol dm^{-3} NaOH) 231 nm (ε 5440), 279 (3980). Found: C, 61.28; H, 8.79; N, 9.39%. Calcd for $C_{22}H_{37}O_5N_3\cdot0.5H_2O$; C, 61.09, H, 8.86; N, 9.71%.

5-[(2S,3R*,4R*,5R*)-3-t-Butyldimethylsiloxymethyl-5-hydroxymethyl-3,4-isopropylidenedioxytetrahydrofuran-2-yl]isocytosine (**60a**)*: A mixture of **53a** (500 mg, 1.21 mmol), guanidine hydrochloride (809 mg, 8.47 mmol), and 0.94 mol dm^{-3} C_2H_5ONa in C_2H_5OH (9 ml) was stirred for 3 h. After the Method B workup, the residue was subjected to preparative TLC (10:1 chloroform–CH_3OH) to give **60a** (339 mg, 67%). Mp 231—233 °C (CH_3OH–acetone–hexane); R_f=0.25 (10:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 0.06 (s, *t*-$C_4H_9(CH_3)_2Si$), 0.85 (s, *t*-$C_4H_9(CH_3)_2Si$), 1.34 and 1.51 (s, isopropylidene CH_3), 3.4—3.7 (m, CH_2OH and CH_2OSi), 3.97 (m, H_5), 4.54 (d, J=3.0 Hz, H_4), 4.89 (s, H_2), 6.67 (br, NH_2), 7.59 (s, =CH), 11.00 (br, NH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 17.62, 25.37, 26.72, 28.31, 61.42, 81.03, 82.50, 82.73, 91.59, 108.92, 112.79, 128.29, 153.70, 155.18; UV λ_{max} (CH_3OH) 228 nm (ε 9500), 294 (8840), λ_{max} (0.1 mol dm^{-3} NaOH) 233 nm (ε 5090), 280 (3910). Found: C, 52.15; H, 7.67; N, 9.58%. Calcd for $C_{19}H_{33}O_6N_3Si\cdot0.5H_2O$: C, 52.27; H, 7.85; N, 9.62%.

5-[(2S,3R*,4R*,5R*)-5-Hydroxymethyl-3,4-isopropylidenedioxy-3-methyltetrahydrofuran-2-yl]isocytosine (**60b**)*: A mixture

of **53b** (200 mg, 0.707 mmol), guanidine hydrochloride (473 mg, 4.95 mmol), and 0.92 mol dm^{-3} C_2H_5ONa in C_2H_5OH (5.4 ml) was stirred for 3 h. The Method B workup of the reaction mixture gave a crude product which was subjected to preparative TLC (4:1 chloroform–CH_3OH) to afford **60b** (132 mg, 63%). Mp 178—180 °C (CH_3OH); R_f=0.45 (5:1 chloroform–CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 1.14 (s, CH_3), 1.34 and 1.51 (s, isopropylidene CH_3), 3.56 (d-like, J=5.0 Hz, C$\underline{H}_2$OH), 3.93 (m, H_5), 4.32 (d, J=2.8 Hz, H_4), 4.88 (s, H_2), 6.80 (br, NH_2), 7.58 (s, =CH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 20.55, 27.23, 28.44, 61.72, 82.22, 82.50, 87.37, 89.47, 110.76, 112.62, 152.83, 155.77, 162.22; UV λ_{max} (CH_3OH) 226 nm (ε 6830), 293 (6290), λ_{max} (0.1 mol dm^{-3} NaOH) 233 nm (ε 11000), 280 (8690). Found: C, 50.11; H, 6.51; N, 13.30%. Calcd for $C_{13}H_{19}O_5N_3\cdot 0.8H_2O$: C, 50.09; H, 6.66; N, 13.48%.

Deprotection of the 5-(5-Hydroxymethyl-3,4-isopropylidenedioxytetrahydrofuran-2-yl)pyrimidine C-Nucleosides by Methanolic Hydrogen Chloride. General Procedure: Unless otherwise stated, removal of the isopropylidene group was performed as follows. A mixture of a 5-(5-hydroxymethyl-3,4-isopropylidenedioxytetrahydrofuran-2-yl)pyrimidine *C*-nucleoside and 10% methanolic hydrogen chloride solution was stirred at the room temperature until the reaction was complete (TLC analysis). The reaction mixture was concentrated under reduced pressure (50—90 mmHg), giving a crude material, which was coevaporated with C_2H_5OH. The resulting solid was triturated with ether or ethyl acetate to give the desired deprotection product. A pure sample was collected by recrystallization.

5-[(2R,3R*,4R*,5R*)-3,4-Dihydroxy-5-[(R*)-1-hydroxyethyl]tetrahydrofuran-2-yl]uracil ((±)-5′-Methylpseudouridine)* (***9b***): To a solution of **8b** (51.2 mg, 0.172 mmol) in CH_3OH (2 ml) was added 10% HCl in CH_3OH (2 ml) and the mixture was stirred for 10 min. The above described workup gave **9b** (42.8 mg, 96%). Mp 237.2—239.1 °C (aqueous C_2H_5OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 1.06 (d, J=6.0 Hz, CH_3), 3.50 (m, H_5 and C$\underline{H}$OH), 4.0 (m, H_3 and H_4), 4.37 (d, J=6.0 Hz, H_2), 7.70 (d, J=6.0 Hz, =CH), 10.87 (d, J=6.0 Hz, NH), 11.08 (s, NH); UV λ_{max} (CH_3OH) 264 nm (ε 5620), λ_{max} (0.1 mol dm^{-3} HCl) 263 nm (ε 8130), λ_{max}(0.1 mol dm^{-3} NaOH) 287 nm (ε 8510). Found: C, 46.67; H, 5.39; N, 10.71%. Calcd for $C_{10}H_{14}O_6N_2$: C, 46.51; H, 5.47; N, 10.85%.

5-[(2R,3R*,4S*,5S*)-3,4-Dihydroxy-5-(1-hydroxy-1-methylethyl)tetrahydrofuran-2-yl]uracil ((±)-5′,5′-Dimethylpseudouridine)* (***9a***): To a solution of **8a** (218 mg, 0.699 mmol) in CH_3OH (4 ml) was added 10% HCl in CH_3OH (3 ml) and the resulting mixture was stirred for 10 min. Workup in a usual manner left pure **9a** (185 mg, 97%). Mp 221.4—224.8 °C; ^{1}H NMR (C_5D_5N) δ 1.53 and 1.57 (s, CH_3), 4.32 (dd, J=3.0, 5.0 Hz, H_4), 4.34 (d, J=3.0 Hz, H_5), 5.12 (dd, J=5.0, 6.5 Hz, H_3), 5.25 (d, J=6.5 Hz, H_2), 5.75 (br, OH and NH), 8.00 (s, =CH); UV λ_{max} (CH_3OH) 212 nm (ε 7940), 263 (6600), λ_{max} (0.1 mol dm^{-3} HCl) 264 nm (ε 8310), λ_{max} (0.1 mol dm^{-3} NaOH) 218 nm (ε 8310), 287 (10960). Found: C, 48.42; H, 6.02; N, 10.11%. Calcd for $C_{11}H_{16}O_6N_2$: C, 48.52; H, 5.92; N, 10.29%.

5-[(2R,3R*,4R*,5R*)-3,4-Dihydroxy-5-[(R*)-1-hydroxyhexyl]tetrahydrofuran-2-yl]uracil ((±)-5′-Pentylpseudouridine)* (***9c***): A mixture of **8c** (134 mg, 0.379 mmol) in CH_3OH (3 ml) and 10% HCl in CH_3OH (3 ml) was stirred for 10 min. The usual workup gave **9c** (71 mg, 60%). Mp 193.3—197.7 °C; ^{1}H NMR (C_5D_5N) δ 0.81 (t, J=6.0 Hz, CH_3), 1.10—1.90 (m, CH_2), 4.24 (m, C$\underline{H}$OH), 4.54 (t, J=2.8 Hz, H_5), 4.94 (dd, J=2.8, 4.3 Hz, H_4), 5.15 (m, H_2 and H_3), 5.50 (br, OH and NH), 7.95 (s, =CH); UV λ_{max} (CH_3OH) 212 nm (ε 8510), 265 (6910), λ_{max} (0.1 mol dm^{-3} HCl) 264 nm (ε 3540), λ_{max} (0.1 mol dm^{-3} NaOH) 217 nm (ε 10960), 286 (7240). 38) For this new compound, correct analytical data were not obtained. However, the spectral properties, together with the generality and straightforwardness of the synthetic route, fully support the assigned structure.

General Synthesis of Homo-*C*-nucleosides[1]

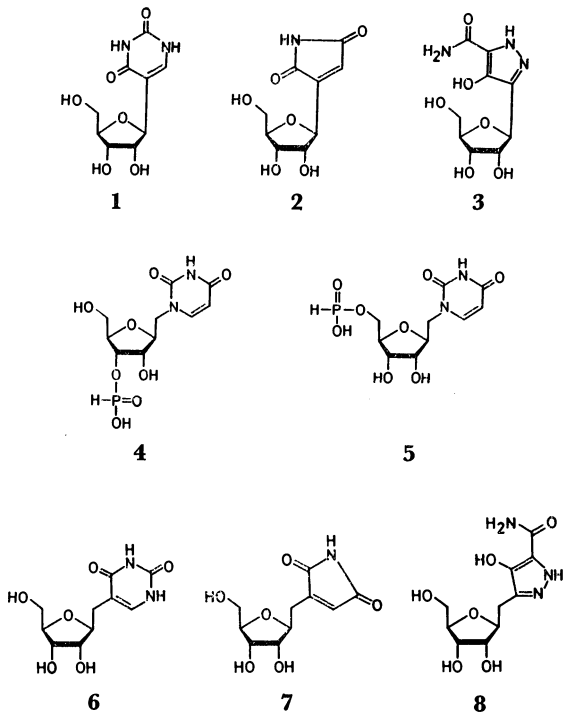
Tsuneo SATO and Ryoji NOYORI*

Department of Chemistry, Nagoya University, Chikusa-ku, Nagoya 464

(Received February 23, 1983)

Lithium aluminium hydride reduction of methyl (2,3-*O*-isopropylidene-5-*O*-trityl-β-D-ribofuranosyl)acetate gives 2-(2,3-*O*-isopropylidene-5-*O*-trityl-β-D-ribofuranosyl)ethanol. Subsequent tosylation, displacement by cyanide ion, nitrile hydrolysis, and diazomethane methylation afford methyl 3-(2,3-*O*-isopropylidene-5-*O*-trityl-β-D-ribofuranosyl)propionate. The base-promoted formylation followed by methylation with methyl iodide forms methyl 2-[(2,3-*O*-isopropylidene-5-*O*-trityl-β-D-ribofuranosyl)methyl]-3-methoxyacrylate. Base-catalyzed condensation of the methoxyacrylate and urea followed by deprotection produces 5-[(β-D-ribofuranosyl)methyl]-uracil. In a like manner, condensation of the methoxyacrylate with thiourea or guanidine gives, after deblocking, 5-[(β-D-ribofuranosyl)methyl]-2-thiouracil and 5-[(β-D-ribofuranosyl)methyl]isocytosine, respectively. Ozonolysis of the methoxyacrylate yields methyl 3-(2,3-*O*-isopropylidene-5-*O*-trityl-β-D-ribofuranosyl)pyruvate, which undergoes condensation with carbamoylmethylenetriphenylphosphorane to furnish a mixture of methyl 2-[(2,3-*O*-isopropylidene-5-*O*-trityl-β-D-ribofuranosyl)methyl]fumaramate and 2-[(2,3-*O*-isopropylidene-5-*O*-trityl-β-D-ribofuranosyl)methyl]maleimide. Deprotection of the latter leads to 2-[(β-D-ribofuranosyl)methyl]maleimide. Condensation of the keto ester with ethyl hydrazinoacetate followed by cyclization affords 3-[(2,3,*O*-isopropylidene-5-*O*-trityl-β-D-ribofuranosyl)methyl]-5-methoxycarbonyl-4-hydroxypyrazole. Ammonolysis of the methyl ester and deprotection furnishes 3-[(β-D-ribofuranosyl)methyl]-5-carbamoyl-4-hydroxypyrazole.

The naturally occurring *C*-nucleosides such as pseudouridine (**1**), showdomycin (**2**), pyrazomycin (**3**), *etc.*, have received considerable attention because of their unique structures and remarkable biological activities.[2] Derivatives of certain homonucleosides such as **4** and **5**[3] are also of importance from a biological point of view. As such we have been intrigued by the synthesis of homo-*C*-nucleosides, in which a carbon atom of the nitrogen base and C-1 atom of D-ribose are linked by a methylene unit.[4] This paper discloses an efficient method for the synthesis of this class of compounds, as exemplified by preparation of the *C*-nucleoside analogues, **6**—**8**.[5]



1 **2** **3** **4** **5** **6** **7** **8**

Results and Discussion

*Synthesis of Pyrimidine Homo-*C*-nucleosides.* The synthesis started from the chiral hydroxy ester **9**, which was readily obtainable from D-ribose[6] or by using the transition metal-promoted 3+4 annulation between α, α,α′,α′-tetrabromoacetone and furan as the key step.[7,8] Reduction of the tritylated derivative **10**[6] with lithium aluminum hydride in THF at −20 °C gave the alcohol **11** in 83% yield. Treatment of **11** with *p*-toluenesulfonyl chloride in pyridine gave the tosylate **12**, which was then transformed in 67% yield to the nitrile **13** by the reaction with 3 equiv of potassium cyanide and 0.1 equiv of perhydrodibenzo-18-crown-6 in acetonitrile.[9] Hydrolysis of **13** in ethylene glycol containing potassium hydroxide[10] was followed by methylation with diazomethane in ether to afford the methyl ester **14** in 32% overall yield (or 74% yield based on consumed **13**). This compound was then treated with lithium diisopropylamide in THF and methyl formate, leading to **15**, which without isolation was quenched with methyl iodide in DMF to give the *(E)*-enol ether **16**. The IR spectrum showed absorptions at 1696 and 1634 cm^{-1} characteristic of the carbonyl and olefinic functions, respectively. In the ^1H NMR spectrum, two methoxyl proton signals were observed at δ 3.69 ($COOCH_3$) and 3.75 ($=CHOCH_3$). Condensation of **16** with urea promoted by ethanolic sodium ethoxide gave the 5′-substituted uracil derivative **17** in 35% yield. The ^{13}C NMR signals of the isopropylidene methyl groups observed at δ 25.79 and 27.58 (Δδ 1.79 ppm) were consistent with the β configuration.[4c] Brief treatment of **17** with 10% methanolic hydrogen chloride furnished homopseudouridine (5-[(β-D-ribofuranosyl)methyl]uracil) (**6**).

The versatility of the intermediate **16** was demonstrated by the preparation of homo-2-thiopseudouridine (5-[(β-D-ribofuranosyl)methyl]-2-thiouracil) (**19**) and homopseudoisocytidine (5-[(β-D-ribofuranosyl)methyl]-isocytosine) (**21**). When a 1:7 mixture of **16** and thiourea was heated at reflux in ethanol containing so-

dium ethoxide, the protected homo-2-thiopseudouridine **18** was produced in 68% yield. Deprotection of **18** with methanolic hydrogen chloride afforded **19**. In a like manner, cyclization of **16** with guanidine, giving **20**, followed by treatment with 10% hydrogen chloride in methanol formed the HCl salt of **21**.

Synthesis of Homoshowdomycin and Homopyrazomycin. Homoshowdomycin (2-[(β-D-ribofuranosyl)methyl]-maleimide) (**7**) and homopyrazomycin (3-[(β-D-ribofuranosyl)methyl]-5-carbamoyl-4-hydroxypyrazole) (**8**) were also prepared starting from the key intermediate **16**.

Ozonolysis of **16** in dry ethyl acetate, followed by reductive workup with dimethyl sulfide,[11] afforded the labile keto ester **22**. This compound was then subjected to the Wittig reaction with carbamoylmethylenetriphenylphosphorane[12] in dry chloroform to give a 23:77 mixture of the maleimide derivative **23** and uncyclized compound **24** having an *E* double bond (66% yield based on **16**). In the ^{13}C NMR spectrum of the β structure **23** ($CDCl_3$), signals of the isopropylidene methyl groups appeared at δ 25.53 and 27.44 ($\Delta\delta$ 1.91 ppm).[4c] The IR spectrum of **23** showed absorptions due to carbonyl functions at 1781 and 1728 cm^{-1}, and for NH at 3440 cm^{-1}. The UV spectrum revealed the presence of a typical maleimide chromophore giving an absorption at 221 nm (sh, ε 13500). The compound **24** displayed the IR absorptions at 1708 (ester carbonyl) and 1668 cm^{-1} (amide carbonyl), and 3470 and 3310 cm^{-1} (NH). The ^1H NMR spectrum of **24** showed a singlet at δ 6.97 assigned to the vinylic proton. Direct conversion of **24** to **23** was not successful. However, **24** could be subjected to recycle use, since upon ozonolysis it reverted to the keto ester **22**. Treatment of **23** with a 9:1 trifluoroacetic acid–water mixture resulted in simultaneous removal of both trityl and isopropylidene protective groups to give crystalline homoshowdomycin (**7**) in 90% yield.

When the keto ester **22** was treated with ethyl hydrazinoacetate hydrochloride and sodium acetate in a 15:20:7 mixture of methanol, THF, and water, the hydrazone **25** was obtained in 47% yield based on **16**. Cyclization of **25** using sodium methoxide in methanol gave **26** in 37% yield.[13] The UV spectrum revealed the presence of a 4-hydroxypyrazole chromophore having absorption maxima at 228 (sh, ε 14200) and 268 nm (ε 4830). Treatment of **26** with ammonia at 25 °C in methanol giving the amide **27** (59%, or 79% based on consumed starting material), followed by deprotection with a 9:1 CF_3COOH–H_2O mixture gave crystalline homopyrazomycin (**8**) in 87% yield.

Thus straightforward construction of homo-*C*-nucleosides was realized. This method is quite general and stereochemically unambiguous. Since the starting materials of type **9** can be prepared from a variety of dibromo or further brominated ketones and furan derivatives,[7,8] this procedure finds wide flexibility in the synthesis of the analogues containing a branched-chain sugar moiety.

Preliminary *in vivo* testing indicated that homoshowdomycin (**7**) has moderate inhibitory activity against S-180 in mouse (T/C=152.8%, at 20 mg/kg) and L-1210 in mouse (T/C=113%, at 20 mg/kg).

Experimental

General. All melting points are uncorrected. The IR spectra were recorded on a JASCO IRA-1 spectrometer in chloroform. The ^1H NMR spectra were obtained using a Varian HA-100D spectrometer and the ^{13}C NMR spectra

*Methyl 2-(2,3-O-Isopropylidene-5-O-trityl-β-D-ribofuranosyl)-3-methoxyacrylate (**16**).* To a solution of lithium diisopropylamide freshly prepared from diisopropylamine (1.4 ml, 10 mmol) and *n*-C_4H_9Li (1.5 mol dm^{-3} hexane solution, 7.5 ml, 11 mmol) in THF (10 ml) under argon was added a solution of **14** (2.5 g, 5 mmol) in THF (20 ml) at −78 °C. The reaction mixture was stirred at the same temperature for 30 min and to this was added methyl formate (1.5 ml, 25 mmol). After stirring at −78 °C for an additional 30 min, the mixture was warmed up to 0 °C and allowed to stand for 4 h. The resulting mixture was evaporated to dryness. The resulting residue was dissolved in 15 ml of dry DMF and treated with methyl iodide (1.5 ml, 25 mmol) at 20 °C under argon. The mixture was stirred at 20 °C for 12 h and concentration, giving a residue. This was triturated with benzene (30 ml) and washed with brine (10 ml). The aqueous layer was extracted with benzene (15 ml). The organic layer was dried (Na_2SO_4) and evaporated to give rise to a residual oil, which was subjected to chromatography on silica gel. Elution with a 30:1 benzene–ethyl acetate mixture afforded 2.41 g (90%) of **16** as a colorless syrup: R_f=0.40 (9:1 benzene–ethyl acetate); IR 1634 (C=C), 1696 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ 1.30 and 1.49 (s, isopropylidene CH_3), 2.57 (m, CH_2C=), 3.15 (dd, J=5.0, 10.3 Hz, $H_{5'a}$), 3.29 (dd, J=4.8, 10.3 Hz, $H_{5'b}$), 3.69 and 3.75 (s, OCH_3), 4.11 (m, $H_{1'}$ and $H_{4'}$), 4.41 (dd, J=3.5, 6.2 Hz, $H_{2'}$), 4.42 (dd, J=4.0, 6.2 Hz, $H_{3'}$), 7.30 (m, Tr and a vinyl proton); ^{13}C NMR ($CDCl_3$) δ 25.87, 27.64, 28.75, 51.19, 61.35, 64.62, 82.75, 83.19, 83.49, 84.78, 86.79, 106.74, 113.64, 126.78, 127.00, 127.81, 128.96, 144.21, 160.32, 168.50.

*5-[(2,3-O-Isopropylidene-5-O-trityl-β-D-ribofuranosyl)methyl]uracil (**17**).* A mixture of **16** (883 mg, 1.66 mmol), urea (720 mg, 11.6 mmol), and 1 mol dm^{-3} ethanolic sodium ethoxide solution (12 ml, 12 mmol) was refluxed for 24 h under argon and evaporated under reduced pressure. The residue was taken up in 5 ml of water, neutralized with 1 mol dm^{-3} HCl, and then immediately extracted with ethyl acetate (7 ml×3). The ethyl acetate solution was dried over Na_2SO_4 and evaporated to dryness. The resulting oil was chromatographed on silica-gel plates using a 5:1 benzene–methanol mixture as an eluent. The compound **17** was obtained as a white foam. Yield was 312 mg (35%): $[\alpha]_D^{20}$ −13.7° (*c* 0.205, $CHCl_3$); R_f=0.26 (7:1 benzene–methanol); ^{1}H NMR ($CDCl_3$) δ 1.30 and 1.50 (s, isopropylidene CH_3), 2.66 (m, CH_2–uracil), 3.26 (m, $H_{5'}$), 4.13 (m, $H_{1'}$ and $H_{4'}$), 4.44 (dd, J=4.1, 6.3 Hz, $H_{2'}$), 4.62 (dd, J=3.5, 6.3 Hz, $H_{3'}$), 7.30 (m, Tr); ^{13}C NMR ($CDCl_3$) δ 25.79, 27.58, 30.26, 64.40, 82.41, 82.56, 82.91, 83.56, 84.65, 110.76, 114.42, 127.22, 127.91, 128.87, 138.72, 143.97, 152.57, 164.27; UV λ_{max} (CH_3OH) 264 nm (ε 6850). Found: C, 70.23; H, 6.23; N, 4.61%. Calcd for $C_{32}H_{32}O_6N_2$: C, 71.09; H, 5.97; N, 5.18%.

*5-[(2,3-O-Isopropylidene-5-O-trityl-β-D-ribofuranosyl)methyl]-2-thiouracil (**18**).* A mixture of **16** (535 mg, 1 mmol) and thiourea (532 mg, 7 mmol) in ethanol containing sodium ethoxide (7 ml, 7 mmol as ethoxide) was refluxed for 12 h under argon and evaporation under reduced pressure gave a residue, which was taken up in 10 ml of water, neutralized with 1 mol dm^{-3} HCl, and then extracted with ethyl acetate (20 ml, 10 ml×2). The ethyl acetate solution was dried over Na_2SO_4. Evaporation followed by chromatography on silica-gel plates using a 15:1 chloroform–methanol mixture as an eluent produced the compound **18** as a white foam (378 mg, 68%): $[\alpha]_D^{20}$ −14.1° (*c* 0.255, $CHCl_3$); R_f=0.43 (15:1 benzene–methanol); ^{1}H NMR ($CDCl_3$) δ 1.32 and 1.52 (s, isopropylidene CH_3), 2.63 (m, CH_2–2-thiouracil), 3.24 (m, $H_{5'}$), 4.16 (m, $H_{1'}$ and $H_{4'}$), 4.40 (dd, J=3.2, 6.0 Hz, $H_{2'}$), 4.60 (dd, J=3.0, 6.0 Hz, $H_{3'}$), 7.35 (m, Tr), 10.50 (br, NH); ^{13}C NMR ($CDCl_3$) δ 25.66, 27.68, 30.13, 64.33, 82.61, 82.71, 83.64, 84.50, 87.06, 114.60, 115.28, 127.11, 127.31, 127.94, 128.87, 138.63, 143.83, 144.06, 161.21, 174.93; UV λ_{max} (CH_3OH) 274 nm (ε 11400), 293 (9950). Found: *m/z*, 414.1845. Calcd for $C_{27}H_{26}O_4$: (M−(B+CH_2+H)), 414.1859.

*5-[(2,3-O-Isopropylidene-5-O-trityl-β-D-ribofuranosyl)methyl]isocytosine (**20**).* A mixture of **16** (535 mg, 1 mmol), guanidine hydrochloride (669 mg, 7 mmol), and 1 mol dm^{-3} ethanolic sodium ethoxide solution (7 ml) was refluxed for 19 h under argon. Removal of ethanol under reduced pressure left a viscous residue, which was taken up in 5 ml of water, neutralized with 1 mol dm^{-3} HCl, and then extracted with ethyl acetate (20 ml×3). After drying over Na_2SO_4, the organic solution was evaporated and subjected to preparative TLC on silica gel using a 15:1 benzene–methanol mixture as an eluent, giving the compound **20** as a white foam (350 mg, 65%): $[\alpha]_D^{20}$ −2.08° (*c* 0.24, CH_3OH); R_f=0.26 (7:1 benzene–methanol); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 1.20 and 1.37 (s, isopropylidene CH_3), 2.41 (m, CH_2–isocytosine), 3.06 (m, $H_{5'}$), 3.95 (m, $H_{1'}$ and $H_{4'}$), 4.47 (m, $H_{2'}$ and $H_{3'}$), 6.57 (br, NH_2), 7.40 (m, Tr), 11.00 (br, NH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 25.45, 27.28, 31.10, 64.40, 81.66, 82.70, 83.91, 86.13, 110.24, 113.11, 126.95, 127.80, 128.28, 143.65, 155.22, 163.02; UV λ_{max} (CH_3OH) 293 nm (ε 10300). Found: C, 71.85; H, 6.12; N, 7.06%. Calcd for $C_{32}H_{33}O_5N_3$: C, 71.22; H, 6.16; N, 7.79%.

*5-[(β-D-Ribofuranosyl)methyl]uracil (Homopseudouridine) (**6**).* A mixture of **17** (100 mg, 0.185 mmol) and 10% methanolic hydrogen chloride solution (3 ml) was stirred at 20 °C for 40 min. The solvent was evaporated *in vacuo* to give a syrup which was triturated with 2 ml of ether three times. The title compound **6** (44.4 mg, 93%) was obtained as a white powder: mp 184—186 °C; $[\alpha]_D^{20}$ −8.15° (*c* 0.135, CH_3OH); ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 2.36 (m, CH_2–uracil), 3.43 (m, $H_{5'}$), 3.62 (m, $H_{1'}$ and $H_{4'}$), 3.74 (m, $H_{2'}$ and $H_{3'}$), 3.1—4.9 (br, OH), 7.27 (m, H_6), 10.69 and 11.00 (br, NH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 30.06 (CH_2–uracil), 62.00 ($C_{5'}$), 71.11, 74.33, 81.10, 84.09 ($C_{1'}$—$C_{4'}$ of ribose), 127.79, 139.14, 151.23, 164.60; UV λ_{max} (CH_3OH) 265 nm (ε 7130), λ_{max} (1 mol dm^{-3} HCl) 266 nm (ε 7080), λ_{max} (1 mol dm^{-3} NaOH) 285 nm (ε 7100).[15]

*5-[(β-D-Ribofuranosyl)methyl]-2-thiouracil (Homo-2-thiopseudouridine) (**19**).* A mixture of **18** (300 mg, 0.539 mmol) and 10% methanolic hydrogen chloride solution (3 ml) was stirred at 20 °C for 40 min. The solvent was evaporated *in vacuo* to give a syrup which was triturated with 3 ml of ether three times. The compound **19** was obtained as a white powder (133 mg, 90%). ^{1}H NMR (dimethyl-d_6 sulfoxide) δ 2.41 (m, CH_2–2-thiouracil), 3.42 (m, $H_{5'}$), 3.61 (m, $H_{1'}$ and $H_{4'}$), 3.76 (m, $H_{2'}$ and $H_{3'}$), 4.03 (br, OH), 7.31 (m, H_6), 12.17 and 12.36 (br, NH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 30.12 (CH_2–2-thiouracil), 61.65 ($C_{5'}$), 70.86, 74.15, 80.14, 83.96 ($C_{1'}$—$C_{4'}$ of ribose), 114.49, 139.08, 161.45, 174.42; UV λ_{max} (CH_3OH) 216, 277, 290 nm (sh), λ_{max} (1 mol dm^{-3} HCl) 216, 277, 290 nm (sh), λ_{max} (1 mol dm^{-3} NaOH) 222, 261, 290 nm. This compound was so hygroscopic that optical extinction (ε value) could not be obtained.[15]

*5-[(β-D-Ribofuranosyl)methyl]isocytosine Hydrochloride (Homopseudoisocytidine Hydrochloride) (**21**).* A mixture of **20** (125 mg, 0.232 mmol) and 10% methanoli chydrogen chloride solution (3 ml) was stirred at 20 °C for 50 min. Concentration *in vacuo* gave a white solid which was coeva-

porated with ethanol (2 ml×3). The residue was triturated three times with 5 ml of ether. The compound **21** was obtained as a white powder (62 mg, 91%): mp 185—188 °C; $[\alpha]_D^{20}$ −48.9° (*c* 0.37, CH_3OH); ^1H NMR (dimethyl-d_6 sulfoxide) δ 2.47 (m, CH_2–isocytosine), 3.44 (m, $H_{5'}$), 3.64 (m, $H_{1'}$ and $H_{4'}$), 3.80 (m, $H_{2'}$ and $H_{3'}$), 3.8—5.0 (br, OH), 7.59 (s, H_6), 8.49 (br, NH_2); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 29.85 (CH_2–isocytosine), 61.79 ($C_{5'}$), 71.00, 74.23, 80.07, 84.30 ($C_{1'}$—$C_{4'}$ of ribose), 113.82, 138.05, 152.28, 160.27; UV λ_{max} (CH_3OH) 224 (ε 11500), 263 nm (7830), λ_{max} (1 mol dm^{-3} HCl) 223 (ε 12300), 264 nm (9420), λ_{max} (1 mol dm^{-3} NaOH) 232 (ε 11300), 281 nm (9100). Found: C, 40.27; H, 5.46; N, 13.60%. Calcd for $C_{10}H_{16}O_5N_3Cl\cdot 0.5H_2O$: C, 39.91; H, 5.63, N, 13.96%.

*2-[(2,3-O-Isopropylidene-5-O-trityl-β-D-ribofuranosyl)methyl]-maleimide (**23**).* A solution of olefinic ester **16** (1.07 g, 2 mmol) in 20 ml of dry ethyl acetate was treated with ozone at −78 °C. After dry nitrogen was blown through the solution to remove excess ozone, dimethyl sulfide (1.47 ml, 20 mmol) was added.[11] The mixture was stirred at −78 °C for 1 h, then at 0 °C for 1 h, finally at 25 °C for 1 h. The mixture was evaporated to give methyl 3-(2,3-*O*-isopropylidene-5-*O*-trityl-β-D-ribofuranosyl)pyruvate (**22**) as a colorless syrup. This material displayed no olefinic absorption in the IR spectrum. To a solution of the crude product in 15 ml of dry chloroform was added a solution of 829 mg (2.6 mmol) of carbamoylmethylenetriphenylphosphorane[12] in 10 ml of dry chloroform. The yellow solution was stirred at 25 °C for 30 min. Evaporation followed by chromatography on a silica-gel column with a 10:1 benzene–ethyl acetate mixture as an eluent gave **23** (162 mg, 15%). Elution with a 3:1 benzene–ethyl acetate mixture gave methyl 2-[(2,3-*O*-isopropylidene-5-*O*-trityl-β-D-ribofuranosyl)-methyl]fumaramate (**24**) (564 mg, 51%). **23**: $[\alpha]_D^{20}$ −7.1° (*c* 0.14, $CHCl_3$); R_f=0.46 (3:1 benzene–ethyl acetate); IR 3440 (NH), 1781 and 1728 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.34 and 1.54 (s, isopropylidene CH_3), 2.79 (m, CH_2–maleimide), 3.20 (dd, J=4.8, 10.5 Hz, $H_{5'a}$), 3.35 (dd, J=4.0, 10.5 Hz, $H_{5'b}$), 4.18 (m, $H_{1'}$ and $H_{4'}$), 4.45 (dd, J=4.9, 6.1 Hz, $H_{2'}$), 4.67 (dd, J=3.5, 6.1 Hz, $H_{3'}$), 6.51 (m, H_3), 7.30 (m, Tr), 7.94 (br, NH); ^{13}C NMR ($CDCl_3$) δ 25.53, 27.44, 29.34, 64.03, 81.96, 82.26, 83.47, 84.55, 86.74, 114.56, 127.09, 127.81, 128.59, 129.32, 143.63, 146.39, 171.09; UV λ_{max} (CH_3OH) 221 nm (sh, ε 13500). Found: C, 73.42; H, 6.17; N, 2.67%. Calcd for $C_{32}H_{31}O_6N$; C, 73.12; H, 5.95; N, 2.67%. **24**: $[\alpha]_D^{20}$ −1.6° (*c* 0.32, $CHCl_3$); R_f= 0.24 (3:1 benzene–ethyl acetate); IR 3470 and 3310 (NH), 1708 and 1668 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.32 and 1.52 (s, isopropylidene CH_3), 2.87 (dd, J=9.1, 13.1 Hz, $H_aH_bCC{=}C$), 3.11 (dd, J=5.0, 13.1 Hz, $H_aH_bCC{=}C$), 3.24 (dd, J=3.6, 12.8 Hz, $H_{5'a}$), 3.38 (dd, J=4.2, 12.8 Hz, $H_{5'b}$), 3.74 (s, OCH_3), 4.07 (m, $H_{1'}$ and $H_{4'}$), 4.45 (dd, J=5.0, 6.2 Hz, $H_{2'}$), 4.64 (dd, J=4.8, 5.0 Hz, $H_{3'}$), 6.44 (br, NH), 6.97 (s, $=CHCONH_2$), 7.30 (m, Tr); ^{13}C NMR ($CDCl_3$) δ 25.69, 27.57, 32.24, 51.34, 63.39, 81.64, 82.59, 83.17, 84.25, 87.03, 114.91, 127.29, 127.94, 128.72, 134.00, 135.03, 143.56, 167.08, 167.14. Found: C, 71.34; H, 6.13; N, 2.40%. Calcd for $C_{33}H_{35}O_7N$: C, 71.06; H, 6.33; N, 2.51%.

*2-[(β-D-Ribofuranosyl)methyl]maleimide (Homoshowdomycin) (**7**).* A mixture of **23** (203 mg, 0.387 mmol) and 9:1 CF_3COOH–H_2O (2 ml) was stirred at 25 °C for 45 min. Evaporation followed by chromatography on silica-gel plates with a 1:1 ethyl acetate–acetone mixture as an eluent afforded 85 mg (90%) of **7** as a white powder which was recrystallized from acetone–benzene: mp 150—154 °C; $[\alpha]_D^{20}$ −24° (*c* 0.20, CH_3OH); R_f=0.38 (1:1 acetone–ethyl acetate); ^1H NMR (acetone-d_6) δ 2.70 (m, CH_2–maleimide), 3.36 (m, $H_{5'}$), 3.82 (m, $H_{1'}$ and $H_{4'}$), 4.16 (m, $H_{2'}$ and $H_{3'}$), 4.0—5.0 (br, OH), 6.56 (m, H_3), 9.52 (br, NH); ^{13}C NMR (acetone-d_6) δ 61.36 ($C_{5'}$), 70.68, 74.39, 80.10, 84.30 ($C_{1'}$—$C_{4'}$ of ribose), 146.41, 173.32, CH_2–maleimide obscured by acetone peaks; UV λ_{max} (CH_3OH) 221 nm (ε 10200).[15]

*Preparation of **25**.* A mixture of **22** (from 2 mmol of **16**), ethyl hydrazinoacetate hydrochloride (620 mg, 4 mmol), and sodium acetate (328 mg, 4 mmol) in THF–CH_3OH–H_2O (15 ml, 20 ml, and 7 ml, respectively) was stirred at 25 °C for 12 h. After removal of the solvent, 50 ml of chloroform was added. The solution was dried over Na_2SO_4 and evaporated to dryness. The crude product was purified by chromatography on a column of silica gel using a 9:1 benzene–ethyl acetate mixture. Yield was 585 mg (47% based on **16**): R_f=0.24 (9:1 benzene–ethyl acetate); IR 3270 (NH), 1740 and 1703 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.12—1.50 (m, 3H), 1.29 and 1.51 (s, isopropylidene CH_3), 2.6—3.4 (m, 4H), 3.46 and 3.71 (s, OCH_3, 1:3 ratio), 3.9—4.7 (m, 8H), 7.4 (m, Tr).

*3-[(2,3-O-Isopropylidene-5-O-trityl-β-D-ribofuranosyl)methyl]-5-methoxycarbonyl-4-hydroxypyrazole (**26**).* To a solution of **25** (616 mg, 1 mmol) in 10 ml of methanol was added a 1 mol dm^{-3} methanolic sodium methoxide solution (4 ml). The solution was refluxed for 4.5 h and evaporated under reduced pressure.[13] The residue was taken up in 3 ml of water, neutralized with 1 mol dm^{-3} HCl, and then extracted with ethyl acetate (30 ml×3). The organic solution was dried (Na_2SO_4) and evaporated to dryness. The residue was purified by chromatography on a column of silica gel using a 3:1 benzene–ethyl acetate mixture. Compound **26** was obtained as a white foam (210 mg, 37%): $[\alpha]_D^{19}$ −24° (*c* 0.23, $CHCl_3$); R_f=0.31 (3:1 benzene–ethyl acetate); IR 3580—3200 (NH and OH), 1698 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.35 and 1.54 (s, isopropylidene CH_3), 2.92 (dd, J=7.3, 15.9 Hz, CH_aH_b–pyrazole), 3.15 (dd, J=4.6, 15.9 Hz, CH_aH_b–pyrazole), 3.25 (dd, J=5.0, 10.5 Hz, $H_{5'a}$), 3.41 (dd, J=4.0, 10.5 Hz, $H_{5'b}$), 3.95 (s, OCH_3), 4.12 (m, $H_{1'}$ and $H_{4'}$), 4.56 (m, $H_{2'}$ and $H_{3'}$), 7.32 (m, Tr); ^{13}C NMR ($CDCl_3$) δ 25.71, 27.56, 28.24, 51.74, 64.26, 82.39, 83.55, 83.87, 84.06, 87.14, 114.63, 127.21, 127.94, 128.82, 143.39, 143.84, 163.29; UV λ_{max} (CH_3OH) 228 nm (sh, ε 14200), 268 (4830). Found: C, 69.76; H, 6.18; N, 4.62%. Calcd for $C_{33}H_{34}O_7N_2$: C, 69.46; H, 6.01; N, 4.91%.

*3-[(2,3-O-Isopropylidene-5-O-trityl-β-D-ribofuranosyl)methyl]-5-carbamoyl-4-hydroxypyrazole (**27**).* A solution of the pyrazole **26** (320 mg, 0.575 mmol) in dry methanol (10 ml) was saturated with ammonia by passing the gas at 0 °C. The mixture was stirred at 25 °C for 4 d. The solvent was evaporated and the crude product was purified by chromatography on a column of silica gel using a 3:1 to 1:1 benzene–ethyl acetate mixture as an eluent to give a foam (184 mg, 59%): $[\alpha]_D^{19}$ −25° (*c* 0.20, $CHCl_3$); R_f=0.25 (1:1 benzene–ethyl acetate); IR 3580—3200 (NH and OH), 1675 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 1.30 and 1.50 (s, isopropylidene CH_3), 2.87 (dd, J=7.9, 15.1 Hz, CH_aH_b–pyrazole), 3.19 (dd, J=3.5, 15.1 Hz, CH_aH_b–pyrazole), 3.21 (dd, J=5.5, 10.3 Hz, $H_{5'a}$), 3.46 (dd, J=3.2, 10.3 Hz, $H_{5'b}$), 4.22 (m, $H_{1'}$ and $H_{4'}$), 4.49 (m, $H_{2'}$ and $H_{3'}$), 5.97 and 6.67 (br, NH_2), 7.30 (m, Tr), 8.03 (br, NH and OH); ^{13}C NMR ($CDCl_3$) δ 25.52, 27.43, 28.22, 64.13, 82.05, 83.68, 83.86, 84.08, 87.24, 114.90, 127.21, 127.82, 128.75, 141.40, 143.66, 164.29; UV λ_{max} (CH_3OH) 227 nm (sh, ε 14300), 268 (5100). Found: C, 69.37; H, 6.20; N, 7.57%. Calcd for $C_{32}H_{33}O_6N_3$: C, 69.17; H, 5.98; N, 7.56%. In addition, the unreacted **26** was recovered (77 mg, 25%).

3-[(β-D-Ribofuranosyl)methyl]-5-carbamoyl-4-hydroxypyrazole

(Homopyrazomycin) (8). A mixture of **27** (220 mg, 0.407 mmol) and 9:1 CF_3COOH–H_2O (4 ml) was stirred at 25 °C for 20 min. Concentration and subsequent chromatography on silica-gel plates using a 6:1:2:1 ethyl acetate–acetone–methanol–water mixture as an eluent yielded compound **8** as a white powder (128 mg, 87%) which was recrystallized from methanol–ethyl ether: mp 109—113 °C; $[\alpha]_D^{21}$ −22° (*c* 0.23, CH_3OH); R_f=0.24 (6:1:1:1 ethyl acetate–acetone–methanol–water); ^{1}H NMR (D_2O)[16] δ 3.01 (m, CH_2–pyrazole), 3.73 (m, $H_{5'}$), 3.90—4.30 (m, $H_{1'}$, $H_{2'}$, $H_{3'}$, and $H_{4'}$); ^{13}C NMR (D_2O)[16] δ 30.38 (CH_2–pyrazole), 64.82 ($C_{5'}$), 74.25, 77.20, 84.80, 86.78 ($C_{1'}$—$C_{4'}$ of ribose), 132.31, 169.22; UV λ_{max} (H_2O) 223 (ε 8630), 266 nm (5150), λ_{max} (0.1 mol dm^{-3} NaOH) 235 (ε 4330), 311 nm (5460).[15]

*Conversion of **24** to **23**.* To a solution of the unsaturated amide **24** (557 mg, 1 mmol) in 15 ml of dry ethyl acetate was passed ozone at −78 °C. Dry nitrogen was bubbled through the solution to remove excess ozone, and dimethyl sulfide (0.73 ml, 10 mmol) was added.[11] The mixture was stirred at −78 °C for 1 h, then at 0 °C for 1 h, finally at 25 °C for 1 h. Evaporation left a crude product, which was dissolved in 7 ml of dry chloroform and to this was added a solution of 415 mg (1.30 mmol) of carbamoylmethylenetriphenylphosphorane[12] in 3 ml of dry chloroform. The reaction mixture was stirred at 25 °C for 30 min and evaporated to dryness. The oily residue was chromatographed on a column of silica gel. Elution with a 3:1 benzene–ethyl acetate mixture gave **23** (67 mg, 13%). Continued elution with a 3:1 benzene–ethyl acetate mixture gave **24** (276 mg, 50%). Compounds **23** and **24** were identical in all respects with the authentic samples.

We thank Miss Keiko Marunouchi for her valuable contribution in some preliminary experiments. We are also indebted to Ajinomoto Co., Ltd. for a generous offer of D-ribose and for biological assay.

Electron Microscope Studies on Radiography. III.[1,2] Formation of Lumpish Developed Silver in Radiography

Hiroshi HARA

Tokyo Metropolitan Isotope Research Center, Fukazawa, Setagaya-ku, Tokyo 158

(Received October 27, 1982)

The shape of developed silver in industrial X-ray films exposed to a high energy radiation has been found mainly lumpish, which differs from the filamentary shape observed in ordinarily-developed photographic films. The formation process and crystalline states of lumpish silver were studied with an electron microscope in comparison with those of filamentary silver. Lumpish silver cannot be in a single uniform crystalline state under a kind of hindrance due to too active a development for regular crystal growth, the thickness of emulsion layer and the concentration of silver halide also have some effects.

It has been thought[3] that the developed silver of photographic film has a filamentary structure (Fig. 1) in normal development and that the reduced silver grows on development nuclei. However, according to the author's observation, the develoed silver in industrial X-ray film has a shape to be called "lumpish" (Fig. 2) and grows at sites apart from development nuclei. On the shape and the formation process for such silver, no paper has been reported with discrimination from ordinary ones.[3] To make clear the development characteristics of industrial X-ray film, the difference between the structures of lumpish and filamentary silvers and their formation conditions were studied.

Many electron microscopic studies on developed silver have been reported, and a lot of morphologic knowledge on developed silver is available. We also applied a transmission type electron microscope for this stuby. This equipment was also applied for an electron diffraction study to analyze the crystal structure and crystalline state of developed silver.

Fig. 1. An electron micrograph of developed silver in FUJI NEOPAN SS film developed with FUJIDOL. Crystalline state of the silver correspond to Figs. 4B—D.

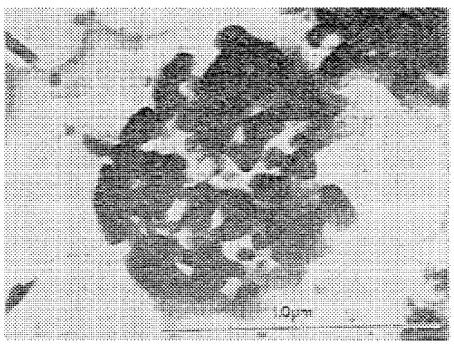

Fig. 2. An electron micrograph of developed silver in SAKURA RR industrial X-ray film developed with KONIDOL-X. Crystalline state of the silver correspond to Figs. 4B—G.

Many experimental methods which appeared in the past were carried out mostly under special conditions, *i.e.*, by using diluted monodispersed emulsion or by using partial development with a particular developer. These experiments disclosed that the tubic, Mueller's type developed silver[5] is formed in the dilute monodispersed emulsion layer and very thick filamentary silver[4] is formed via a particular physical development. These developed silvers are not observed in the conventional development. Therefore, in this study, the author has carried out an experiment by using commercial films under the ordinary conditions, *i.e.*, by exposing and developing them according to manufacturer's instruction, and the morphological variation of silver has been systematically observed in course of development.

Although the crystal structure of developed silver has already been determined by some workers, no information has been supplied of the structure of developed silver in course of development. In this study, therefore, the variation of the crystalline state of silver during development has also been traced systematically by the electron diffraction method.

Experimental

Specimens for electron micrscopic observation were prepared from several strips of Sakura RR industrial X-ray film in the following procedure. Test film strips were exposed uniformly to 150 kVp X-ray beam of optimum dose, 0.2 R (5.16×10^{-5} C/kg), and developed for 10, 30, 60, 90, 120, 150, 180, 240, or 300 s with Konidol-X, the commercial developer for Sakura industrial X-ray film. The specimens were prepared[6] from developed and stop-bathed, but not fixed, film strips. The degree of the degradation of gelatin in emulsion layer with enzyme which allows silver halide particles to be isolated, was controlled so that deformation of developed silver might be prevented. The rotation speed of the centrifuge used for washing silver and silver halide particles was also controlled so as to be kept as low as 800 rpm for the same purpose. The finished specimens were observed with a JEM Type-100 transmission electron micrscope, and morphological and crystallographical variations of silver in every step of development were studied. Magnifying powers of 5000—60 000 were applied according to the size of silver and silver halide particles

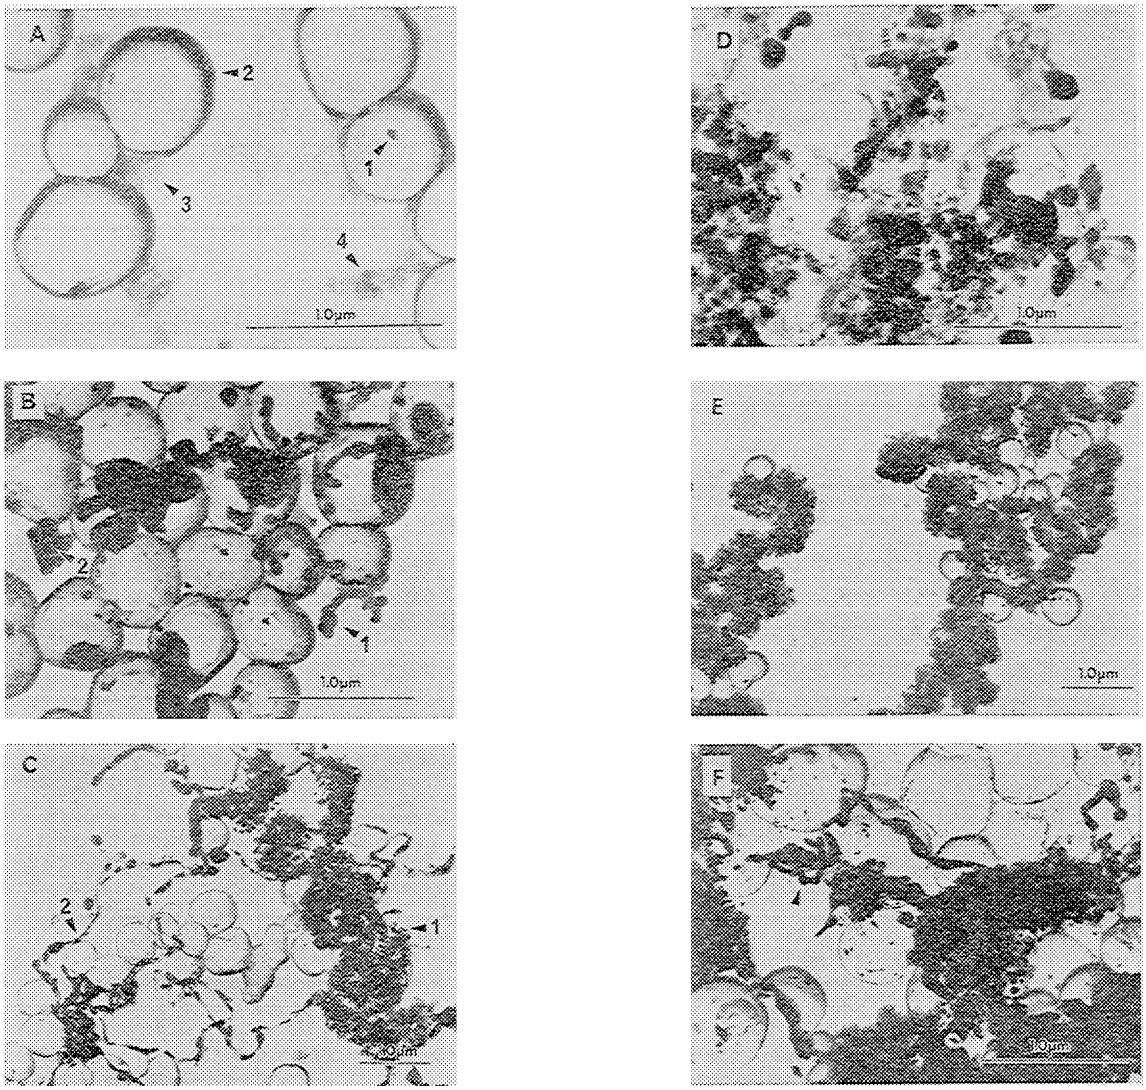

Fig. 3A—F. Variation of shape and crystalline state of the developed silver in SAKURA RR industrial X-ray film exposed to 150 kVp X-ray is developed for various times with KONIDOL-X.
Figs. A and B are for developed 30 s, Fig. C for 60 s, and Figs. D—F for 150 s respectively. Figs. A and B correspond to Figs. 4A and 4B, Fig. C to Figs. 4B—D, and Figs. D—F to Figs. 4B—G respectively.

and the electron diffraction apparatus equipped with the JEM Type-100 electron microscope was used for the measurement[7] of crystalline states of silver.

The formation process of filamentary silver, whose shape is well known as a general one, was also studied by the same method as used for lumpish silver, and the difference between these processes has been studied. The specimens for filamentary silver were prepared from Fuji Neopan SS (fine grain panchromatic negative film), uniformly exposed to sunlight, and developed for 30, 60, 90, 120, 150, 180, 240, 300, or 420 s with Fujidol, the commercial developer for Fuji Neopan SS.

Furthermore, factors influencing the shape of silver were also studied on other types of photographing materials by changing exposure and development conditions. These materials include Fuji 150 industrial X-ray, Sakura Konipan SS, Fuji Minicopy HR II, Sakura Color III, and Sakura NR-M2 nuclear liquid emulsion. For Sakura RR, Fuji Neopan SS, and Sakura NR-M2, some special materials were also prepared for which the concentration of silver halide and the thickness of emulsion layer were modified after decomposing film emulsion with enzyme. These materials were used for studying the relation between the shape of silver and the physical constitution of film material. All the materials were exposed to 150 kVp X-ray or to sunlight for studying the influence of radiation. Two type of developers, Konidol-X as an active developer and Fujidol as a moderate one, were used. Each developer was diluted so as to have a concentration of 100, 50, 25, 10, 5, 2, or 1% with water for studying the influence of developing conditions. The microscopic procedures used for these materials were the same as those for Sakura RR film used to observe lumpish silver, and the shape and crystalline state of silver on each material were studied at various stages of development.

Results and Discussion

The change in the shape of silver observed in the conventional development process of Sakura RR film is shown in Figs. 3A—F, and the change in the crystalline state of silver accompanying that in the shape is shown in Figs. 4A—H by electron diffraction patterns. The pattern of Fig. 4A indicates that the silver is in an amorphous state since it has no diffraction dot. Ac-

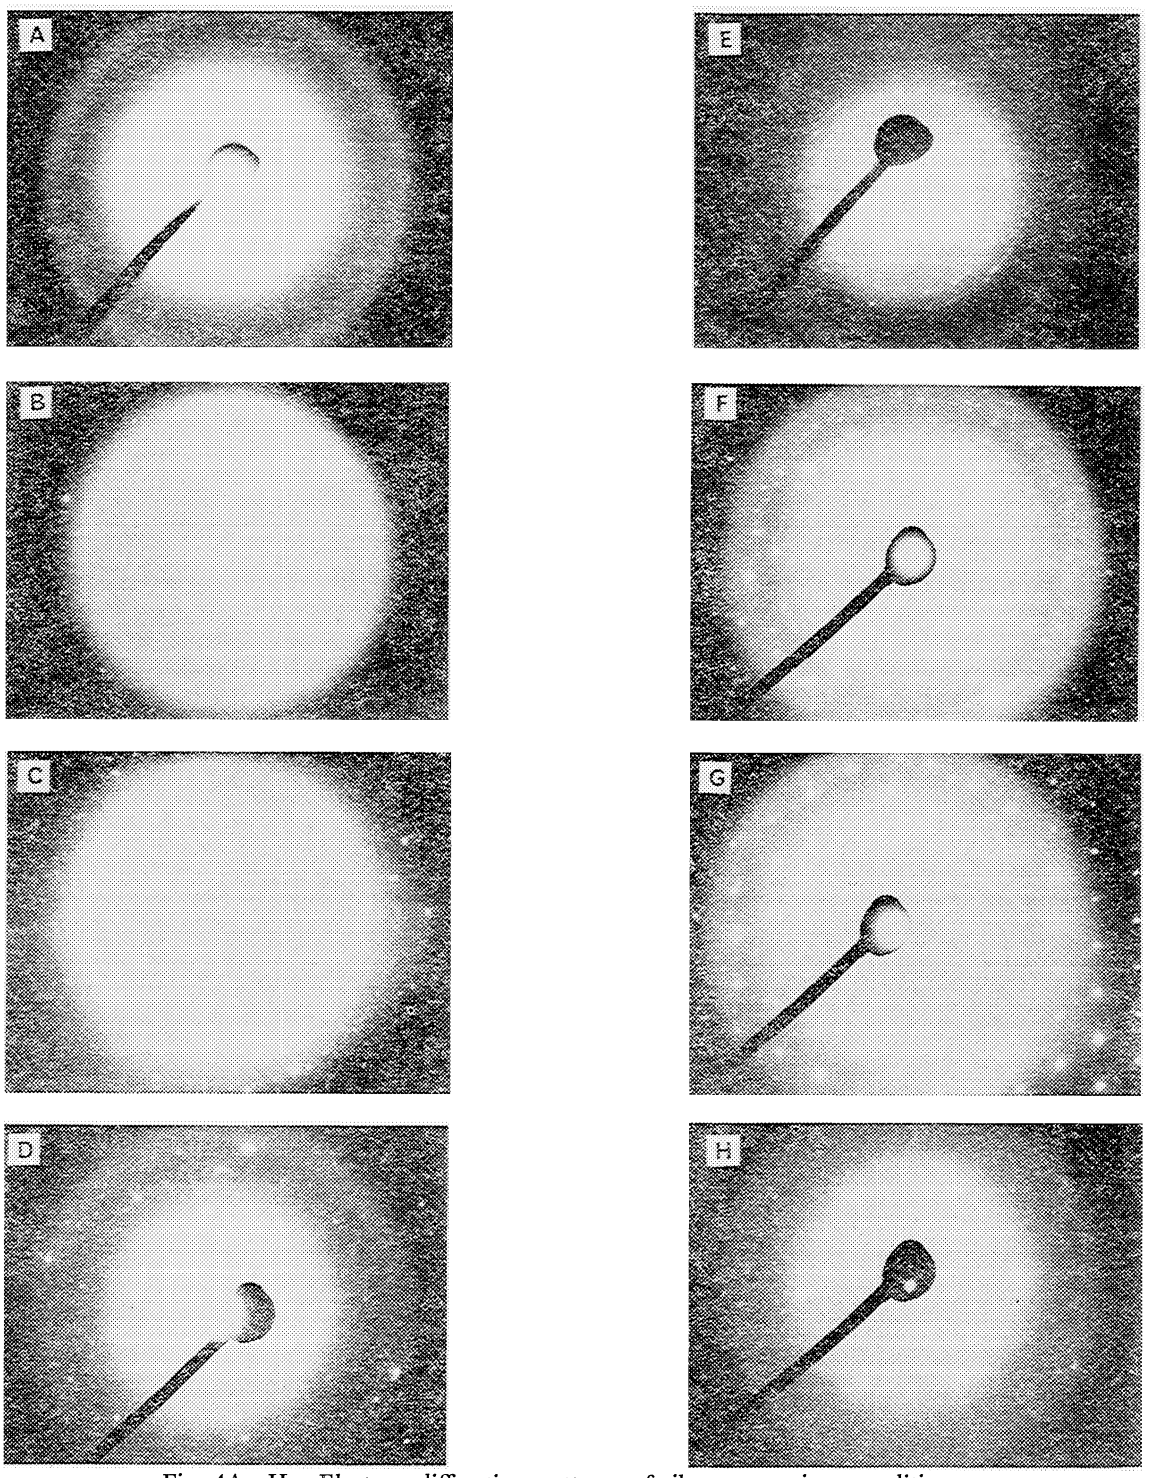

Fig. 4A—H. Electron diffraction patterns of silver on various conditions.
A: Amorphous, B—G: Progress of crystallization, H: Big crystal.

cording to the patterns of Figs. 4B—D, some crystallites are generated in the amorphous silver because some dots are found in the field. The increase in the number of dots means the increase in the amount of crystallites to be due to the progress of the crystallization of silver. The patterns of "Debye-Scherrer ring" in Figs. 4E and F indicate that almost all silver is finely crystallized in crystallites. The pattern in Fig. 4 G indicates a crystal growth of silver from a fine to coarse state. The pattern of "Laue" in Fig. 4 H indicates that the silver takes a structure of single crystal, and the Laue pattern of hexagon indicates that the crystal structure of developed silver is a face-centered cubic lattice.[7]

Several different shapes of developed silver are found in the early stage of development, *i,e.*, at 30 s development time, pointlike (Fig. 3A-1), bandlike (3A-2), and mistlike (3A-3) which are amorphous (Fig. 4A), and dendrite (3B-1). It seems that the mistlike silver will emerge from the silver-gelatin (complex) envelope[8] which is covering the silver halide particles (Fig. 3A-3

and -4). The mistlike silver thus having emerged then aggregates (Fig. 3B-2) as the amount of reduced silver increases and the crystallization progresses slightly (Fig. 4B). A further crystallization of aggregate silver was observed in the middle stage of development, *i.e.*, at 60 s, (Figs. 3C-1 and 4B—D). In the later stage of development, *i.e.*, at 150—300 s, the developed silver turned lumpish because of rapid progresses of aggregation and crystallization (Figs. 3D and 3E). The crystalline state of lumpish silver is complicated because the electron diffraction patterns obtained for several parts of the same lumpish silver are not the same (Figs. 4B—G). This means that the lumpish silver is produced as the result of a disorderly progress of crystallization.

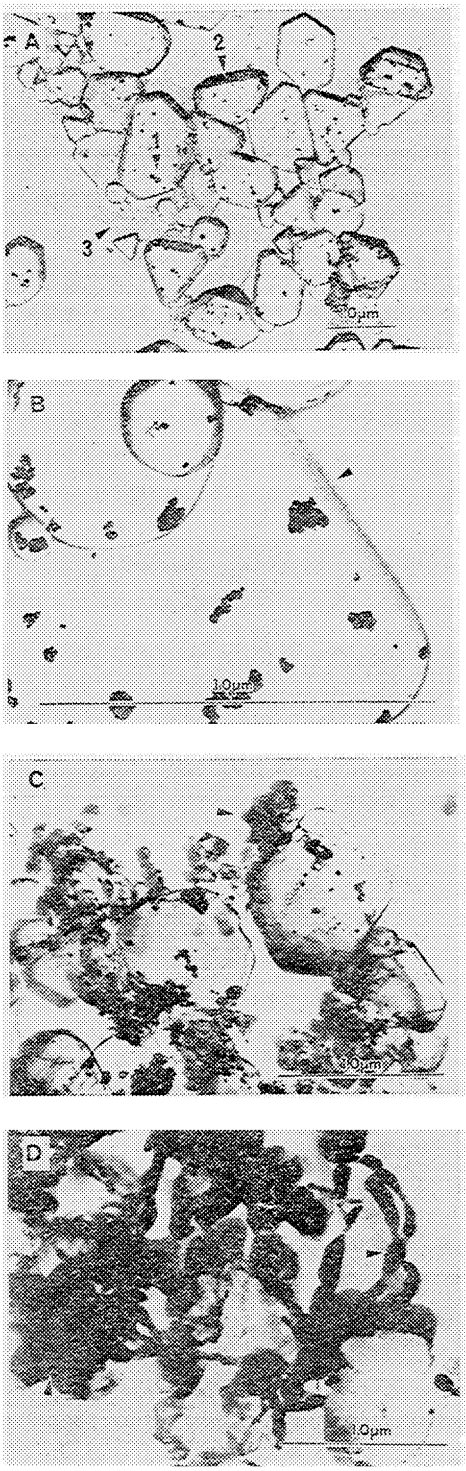

Fig. 5A—D. Variation of shape and crystalline state of the developed silver in FUJI NEOPAN SS film exposed to sunlight and developed for various times with FUJIDOL.
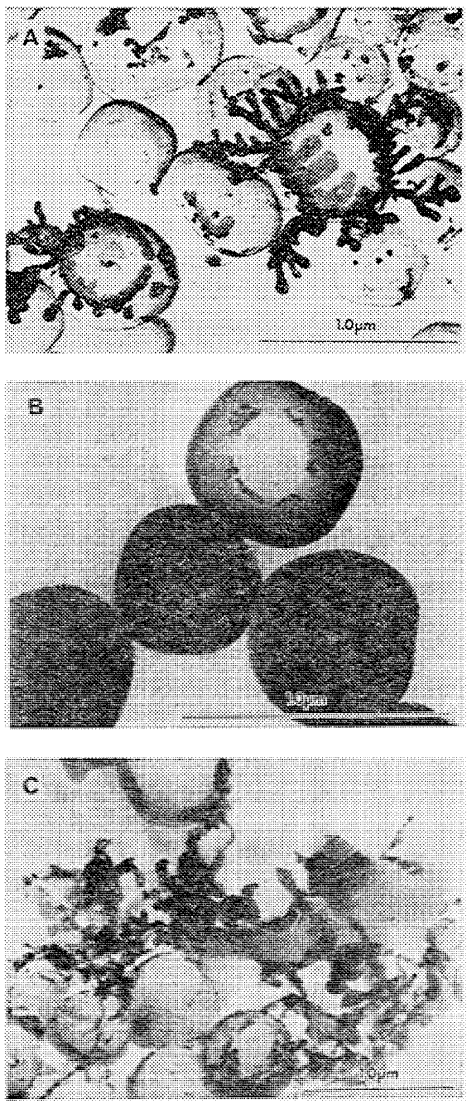
Figs. A and B are for developed 30 s, Fig. C for 60 s, and Fig. D for 150 s respectively. Figs. A and B correspond to Fig. 4A, Fig. C to Figs. 4A and 4B, Fig. D to Figs. 4B—D respectively.

Silver particles other than lumpish shape, such as dendritic, tubular, filamentary and pointlike ones, have also been found in a slight amount on Sakura RR film fully developed. The tubular silver generated in and after the middle stage of development is similar in shape to the silver which has been found by Mueller[5] (Fig. 3C-2), and their crystallization degrees are almost the same as that of the aggregate silver (Figs. 4B—D). A filamentary silver was also found in a somewhat unusual shape (Figs. 3F and 4B—D). The size and number of pointlike silver particles produced in the early stage of development change little, though the development progresses to the final stage (Figs. 3A and 3E). It has been clarified that the development process in radiography is complicated because of the existense of silvers having various shapes and being in various states of crystallization.

On the other hand, the shapes of silver observed in the process of ordinary development of Fuji Neopan SS film are shown in Figs. 5A—D and 1, and their crystalline states are shown in Figs. 4A—D. The silver reduced in the early stage of development, at 30 s, has a pointlike (Fig. 5A-1), bandlike (A-2), mistlike (A-3), or dendrite (in a rare case) shape, which are amorphous (Fig. 4A) except for dendrite. These results are the same as those obtained with Sakura RR (Fig. 3A). The mistlike silver was found to emerge from the silver–gelatin (complex) envelope (Figs. 5B and 4A) in the early stage and to aggregate in the next process (Figs. 5C, 4A, and 4B). However, the aggregate silver does not take a lumpish shape in the middle stage of development, at 150 s, but the filamentary silver grows up there (Fig. 5D). The crystallization of aggregate and filamentary silvers at this stage scarcely progresses (Figs. 4B and 4C). The greater parts of aggregate silver change to filamentary silver in the later stage of development, at 300—420 s (Fig. 1). The crystallization of filamentary silver in the final stage shows only a slight progress, in contrast with the lumpish silver (Figs. 4B—D). The crystalline state of filamentary silver is almost the same at any parts in a filament. The shapes of silver other than the filamentary one, such as tubular, lumpish, and dendritic, were seldem been found in this experiment. No growth or increase in number of pointlike silver are found in the later stage, nor any formation process of lumpish silver. There seem to be little information on the shape of lumpish silver or its formation process, and then the new results obtained here on the formation process of filamentary silver, in comparison with that of lumpish silver, cannot entirely be explained on the basis of the formation mechanism[3] for developed silver widely accepted at present. It is thus pointed out



Figs. 6A—C. Electron micrographs of developed silver obtained from modified SAKURA RR industrial X-ray film at various treatment conditions.
A: Gelation free silver halide particles are isolated perfectly from the gelatin layer. B: Extremely thick emulsion layer with silver halide of low concentration. C: Thin emulsion layer with silver halide of medium concentration.

that any appropriate development mechanisms should consider not only the reduction process of silver halide but also the crystallization process of reduced silver.

The factor determining the shape of silver has been studied more widely from the above point of view.

The popular shape of silver observed at a sufficient depth of ordinary development is either filamentary or lumpish. Neither the difference in film manufacturers nor the difference in exposure conditions is a dominating factor determining the shape of silver. Lumpish silver has been found to be formed only when industrial X-ray film is caused to be developed ordinarily and when other types of film materials are developed with higher-activity developers. However, the shape of developed silver of Sakura RR film which is lumpish, has been found to change variously according to the modification of the emulsion layer of film. For instance, gelatin-free silver halide particles

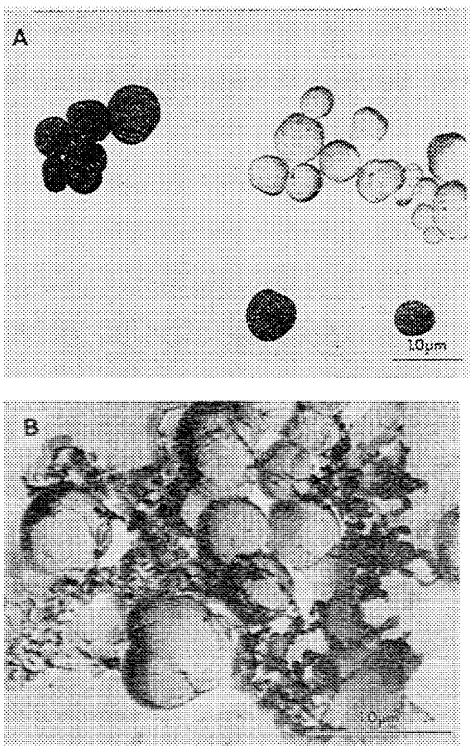


Fig. 7A—B. Electron micrographs of developed silver in SAKURA RR industrial X-ray film developed with KONIDOL-X of various dilution.
A: 1/25, B: 1/5.

obtained by an enzyme processing of Sakura RR film gave the dendritic silver after development (Figs. 6A and 4H). These gelatin-free silver halide particles were redispersed in gelatin solution and coated so as to have a thick emulsion layer with a low concentration of silver halide particles. This modified Sakura RR film gave spherical silver after development (Figs. 6B, 4A, and 4B). In the case of another type of film having extremely thin layer with a low concentration of silver halide particles gave the filamentary shape (Figs. 6C and 4B—D). Therefore, the constitution of emulsion layer, the concentration of silver halide, and the thickness of emulsion layer are effective factors determining the shape of silver.

On the other hand, another important factor determining the shape of silver is the activity of developer depending on the composition and development temperature. The shape of developed silver in Sakura RR film can easily be changed by varying the activity of the developer used; the spherical shape (Figs. 7A, 4A, and 4B) has been found at the lowest activity, the filamentary shape (Figs. 7B and 4B—D) at the medium activity, and the lumpish shape (Figs. 2 and 4B—G) at the highest activity.

Therefore, it has been clarified that the constitution of silver halide emulsion layers and the activity of developers are the most important factors that determine the shape of silver during the crystallization process of silver.

Conclusion

Most of developed silvers in industrial X-ray films

formed with ordinary X-ray film developers have a lumpish shape, which differs from the filamentary silver formed in negative films not only in shape but also in crystalline state.

When lumpish silver is formed, some dendrite, tubular, and filamentary silvers are also formed. Lumpish silver consists of amorphous and crystalline parts, and the latter is composed of fine crystallites with various degrees of crystallization. Therefore, in the formation process of lumpish silver, the progress of crystallization of developed silver is highly influenced by the constitution of emulsion layer and the conditions of development as compared with the case of filamentary silver.

At the early stage of development with ordinary developers, developed silvers of both negative type films and industrial X-ray films exist in amorphous and formless states. Furthermore, the following processes occur: (1) amorphous and formless silvers emerge in the gelatin matrix around silver halide particles, (2) aggregate there, and (3) crystallize.

In this process, the developed silver shows several shapes resulting from the asymmetrical progress of crystallization governed by the above-mentioned factors.

Static and Kinetic Studies of the Interaction of Tryptophan with Fluorescein Mercury(II) Acetate by Fluorescence and Absorption Spectrophotometry and by Fluorescence Stopped-flow Method[1)]

Masatake Ohnishi, Michio Taniguchi, and Keitaro Hiromi*

Department of Food Science and Technology, Kyoto University, Kitashirakawa, Sakyo-ku, Kyoto 606

(Received March 14, 1983)

Fluorescein mercury(II) acetate (FMA) was found to combine with tryptophan (Trp) to form the FMA-Trp complex. The interaction was interpreted in terms of a reversible single-step binding mechanism. The dissociation constant of the complex estimated kinetically by means of the stopped-flow method using the forward and backward rate constants was in good agreement with that obtained by the static method. From comparison with several derivatives of tryptophan, it was found that the protonated amino group and the indole moiety of tryptophan are essential for the complex formation.

Fluorescein mercury(II) acetate (FMA), a highly fluorescent dye, is known to react with a mercapto group, accompanied by a decrease in its fluorescence intensity as well as a change in its absorption spectrum[2)]. Because it has these characteristics, FMA is used for the chemical modification of cysteine(Cys) residues of protein[3,4)]. Recently, Takeuchi and Maeda have reported that the fluorescent dye binds to some kinds of nucleic acids at the nitrogen sites of thymine and guanine residues[5)]. The fluorescent dye FMA, therefore, is useful for the discrimination of the constituent residue(s) and the conformation of proteins and nucleic acids.

Kinetic studies of the reaction of FMA with Cys by the stopped-flow method have already been made in order to discriminate[6)] the fast-reacting Cys residues in proteins.[7)] However, the authors have noticed, in the case of amylases, that even certain other residues could react with FMA.[8)] In fact, Watt and Voss found that fluorescein, which has the same aromatic rings as FMA, interacts with Trp, leading to a decrease in its fluorescence intensity.[9)] Because of these findings, the interactions between Trp and FMA have to be examined in detail before FMA can be applied to the modification of proteins including both Cys and Trp residues.

In this work, the fast complex formation between Trp and FMA was studied statically and kinetically through the decrease in the fluorescence intensity and the change in the difference absorption spectrum. The complex formation was consistent with a single-step association mechanism.

Results and Discussion

Interaction between FMA and Trp as Studied by Static Fluorescence Spectrophotometery. Figure 1 shows the fluorescence emission spectrum of FMA, which has a peak at 525 nm when excited at 495 nm (Fig. 1, 0). The fluorescence intensity at 525 nm was found to decrease with an increase in the concentration of Trp (Fig. 1, 1 and 2). The interaction of Trp with FMA also shows a difference absorption spectrum, which has a trough at 492 nm, a peak at 516 nm, and an isosbestic point at 505 nm (Fig. 2). Thus, the interaction between Trp and FMA can be followed either through the absorption or by the fluorescence change. The fluorescence measurement is preferable because of its high sensitivity.

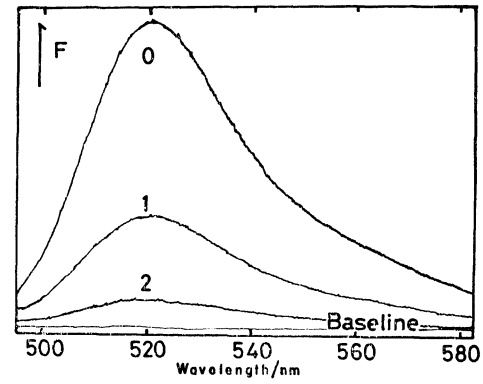

Fig. 1. Fluorescence emission spectra of FMA in the presence and absence of tryptophan.
[FMA]; 1.0 μM, [Trp]; 0; 0 M, 1; 5 μM, 2; 80 μM. Baseline means buffer solution. Excitation at 495 nm, pH 9.0, 25 °C.

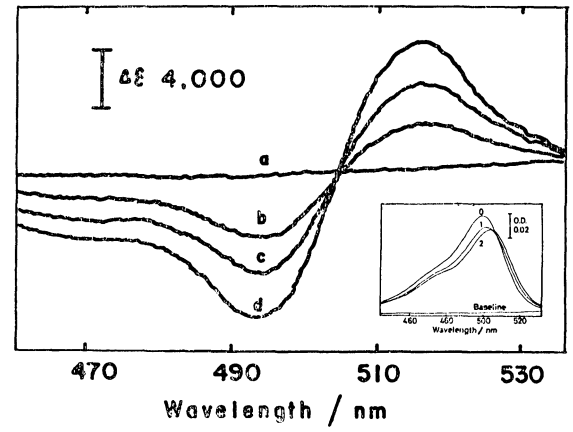

Fig. 2. Difference absorption-spectra of FMA produced by the addition of tryptophan.
[FMA]; 10.0 μM, [Trp]; a; 0 μM, b; 10 μM, c; 20 μM, d; 50 μM. Inset means the absorption spectra of FMA in the presence and absence of tryptophan. [Trp]; 0; 0 M, 1; 5 μM, 2; 80 μM, Baseline; buffer. [FMA]; 1.0 μM.

Figure 3 shows the dependence of the fluorescence intensity change (decrease), ΔF, on the initial concentration of Trp, where ΔF is expressed as the percentage of the change in the fluorescence intensity

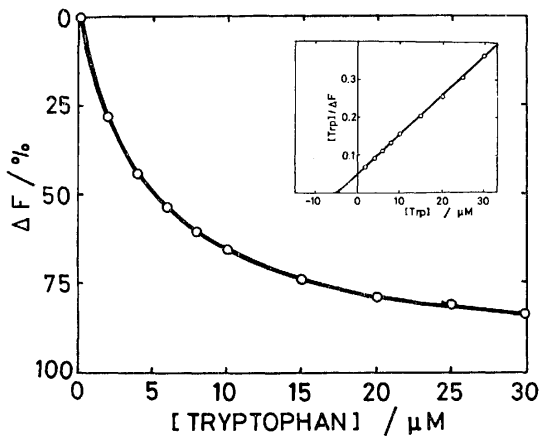

Fig. 3. Dependency of the fluorescence decrease of FMA, ΔF, upon the concentration of tryptophan. [FMA]; 1.0 μM, pH 9.0, 25 °C. Inset is the plots of [Trp]/ΔF *vs.* [Trp].

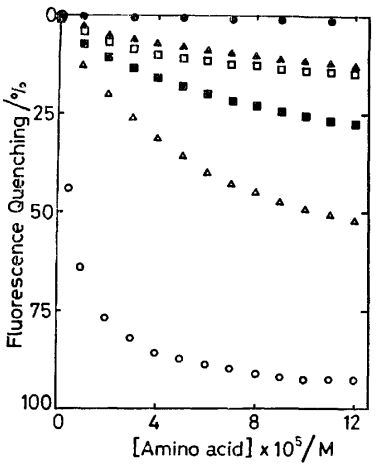

Fig. 4. Dependency of the fluorescence decrease of FMA upon the concentrations of amino acids. [FMA]; 0.2 μM, pH 9.0, 25 °C. ●; His, ▲; N^{α}-acetyl-Lys, □; Asp, ■; Phe, △; Tyr, ○; Trp.

relative to that of free FMA. The experimental points fit the characteristic hyperbolic curve, indicating a reversible complex formation between Trp and FMA:

$$\text{Trp} + \text{FMA} \rightleftharpoons \text{Trp-FMA}, \quad (1)$$

where Trp–FMA represents the Trp–FMA complex. The dissociation constant of the Trp–FMA complex, K_d, is defined as follows:

$$K_d = [\text{Trp}][\text{FMA}]/[\text{Trp-FMA}]. \quad (2)$$

A linear plot, [Trp]/ΔF against [Trp], is shown in the inset of Fig. 3, according to:

$$[\text{Trp}]/\Delta F = [\text{Trp}]/\Delta F_{max} + K_d/\Delta F_{max} \quad (3)$$

$$[\text{Trp}] \gg [\text{FMA}],$$

where ΔF_{max} is the maximum fluorescence decrease when FMA is saturated with Trp and where [Trp] is the initial concentration of Trp ([Trp]≫[FMA]). The experimental points fit a straight line, from which the K_d and ΔF_{max} values were obtained as 5.0×10^{-6} M (1 M=1 mol dm^{-3}) and 98% respectively. The solid lines in Fig. 3 (including the inset) are the theoretical ones drawn according to Eq. 3 with the obtained values of K_d and ΔF_{max}. The statically obtained experimental results are thus consistent with the mechanism represented by Eq. 1.

Complex Formation of FMA with Other Amino Acids. Tyrosine, phenylalanine, and three other amino acids besides Trp were examined for the complex formation with FMA in the manner described above. The fluorescence-intensity changes caused by the addition of each of the amino acids were measured at various concentrations. As is shown in Fig. 4, the decrease in the fluorescence intensity could be observed with all the amino acids examined, except for His. The degree of the decrease in the fluorescence intensity is strongly dependent on the nature of the amino acid. The values of K_d and ΔF_{max}, evaluated in the same way as for Trp, are summarized in Table 1. Tryptophan has the smallest K_d value and the largest ΔF_{max} value among the amino acids examined. Thus, it seems worthwhile to investigate the interaction of FMA with Trp in detail.

Table 1. The K_d and ΔF_{max} values of the FMA–amino acid complex formation

Amino acid	$K_d/10^{-6}$ M	ΔF_{max}/%
Asp	66	20
Arg	100	11
Gly	180	19
N^{α}-acetyl-Lys	95	12
Ser	25	22
Phe	87	36
Tyr	48	65
Trp	5.0	98

Excitation at 495 nm, emission at 525 nm, pH 9.0, 25 °C.

Some derivatives of Trp were also examined in order to ascertain what part of the Trp molecule contributes to the Trp–FMA complex formation. In this case, the difference absorption was used as a probe for measurement, since it is more suitable for quantitative analysis than the fluorescence measurement. The difference-absorption change measured at 492 nm, ΔA_{492}, was plotted against the concentration of the derivatives, as is shown in Fig. 5. The tryptophan methyl ester as well as tryptophan can form a complex with FMA to produce the difference absorption change, whereas neither *N*-acetyltryptophan nor the acetyltryptophan ethyl ester show any evidence of forming such a complex. These findings indicate that the amino group of the derivatives plays an essential role in the complex formation. Thus, both the indole and the amino group seem to be essential to the complex formation, whereas the carboxyl group is not essential.

Effect of pH on the Complex Formation of FMA with Trp. The dependence of ΔF on the concentration of Trp was studied at various pH's above 8, since FMA is not fluorescent at lower pH's. Figure 6 shows a part of the data showing the variation in the plots of ΔF *vs.* [Trp] at various pH's. The values of K_d and ΔF_{max} for the Trp–FMA complex at every pH were evaluated in the manner described above. The

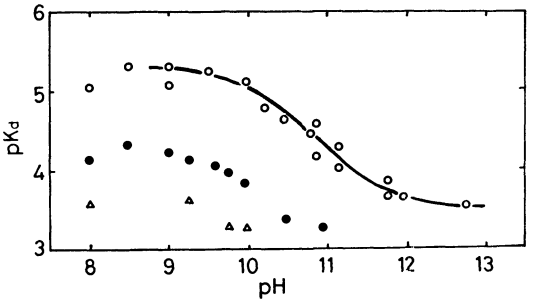

Fig. 7. pH dependency of K_d for Trp, Tyr, and Phe.
Solid line was obtained by the calculation with $pK_a = 10.8$ according to the scheme, $Trp\text{-}NH_2 + H \rightleftharpoons Trp\text{-}NH_3^+$. ○; Trp, ●; Tyr, △; Phe.

pH-dependence of pK_d ($= -\log K_d$) is shown in Fig. 7, together with those obtained with Tyr and Phe. The slope of the pK_d *vs.* pH plot is nearly unity; thus, one proton, which could be Trp ($pK \simeq 10.8$), contributes to the complex formation. The pK_d value of the Trp–FMA complex is appreciably larger than those of the two other amino acids, Tyr and Phe, over the pH range examined (pH 8—11).

Kinetics of the Trp–FMA Complex Formation. The formation of the Trp–FMA complex was studied kinetically by means of the fluorescence stopped-flow method in order to evaluate the nechamism by observing the rapid decrease in the fluorescence intensity. Figure 8 shows a typical example of the reaction curves obtained in an excess of Trp over FMA. The reaction obeys first-order kinetics, as may be seen from the straight line in the Guggenheim plot (the inserted figure in Fig. 8).[10,11] The apparent first-order rate constant, k_{app}, for the interaction was evaluated at variuos Trp concentrations. The results are shown in Fig. 9. The linearity of the plot is consistent with the following single-step binding mechanism, where k_{+1} and k_{-1} are the rate constants for the forward and backward processes respectively:

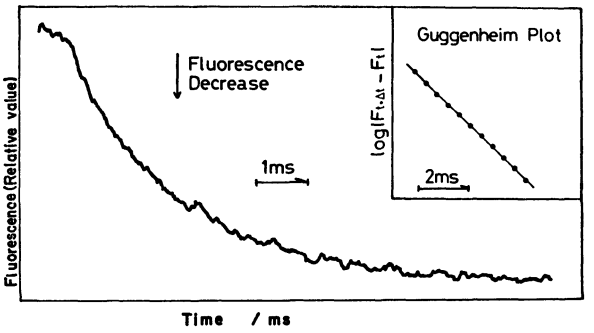

Fig. 8. A typical example of the reaction curves observed by a fluorescence stopped-flow spectrophotometer.
[FMA]; 0.2 μM, [Trp]; 12.5 μM, pH 8.5, 25 °C. Inset is the Guggenheim plot ($k_{app} = 499\ s^{-1}$).

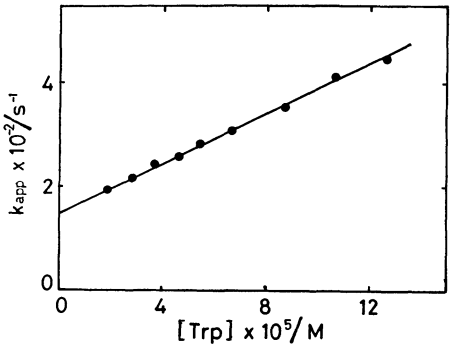

Fig. 9. Dependency of k_{app} upon the concentration of tryptophan.
The straight line was obtained by the given values, $k_{+1} = 2.37 \times 10^7\ M^{-1}\ s^{-1}$ and $k_{-1} = 149\ s^{-1}$ according to the scheme, Eq. 4 and $k_{app} = k_{+1}[Trp] + k_{-1}$, where [Trp] is the tryptophan concentration. [FMA]; 0.2 μM, pH 8.5, 25 °C.

$$Trp + FMA \underset{k_{-1}}{\overset{k_{+1}}{\rightleftharpoons}} Trp\text{-}FMA, \quad (4)$$

Based on the mechanism, k_{app} is expressed, when [FMA]≪[Trp], as follows:[12]

$$k_{app} = k_{+1}[Trp] + k_{-1}. \quad (5)$$

From the plot of k_{app} against [Trp], the rate constants, k_{+1} and k_{-1}, were evaluated by the use of the least-squares method to be $2.4 \times 10^7\ M^{-1}\ s^{-1}$ and $150\ s^{-1}$ respectively (pH 8.5). The solid line in Fig. 9 is the

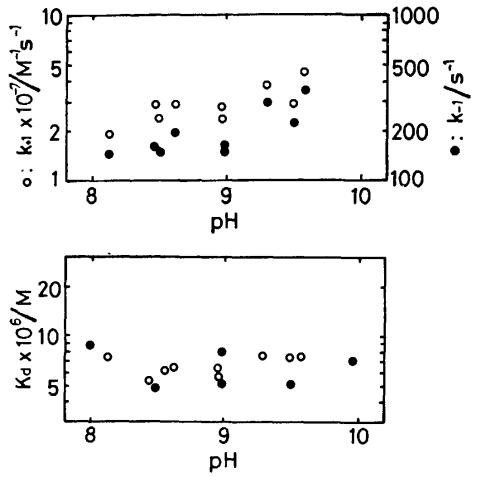

Fig. 10. pH dependencies of the rate constants, k_{+1} (open circle) and k_{-1} (closed circle) and the dissociation constant, K_d (Open circles were obtained by the kinetic observation with the stopped-flow method and closed circles were by the static observation).

theoretical one drawn according to Eq. 5, using the given rate constants. Thus, the interaction between FMA and Trp can reasonably be accounted for by a single-step binding mechanism, as has been described in Eq. 4, at least in the concentration range studied. The dissociation constant, K_d ($=k_{-1}/k_{+1}$), was evaluated from the rate constants to be 6.3×10^{-6} M (pH 8.5).

Figure 10 shows the two rate constants, k_{+1} and k_{-1} and the K_d values evaluated at various pH's in the range from 8 to 10. The K_d values obtained from the kinetic study are reasonably consistent with the values from the static measurements described above; they are nearly constant between pH 8 and 9.5, in spite of the fact that both k_{+1} and k_{-1} increase with an increase in the pH.

Experimental

Chemicals. Fluorescein mercury(II) acetate (FMA) was synthesized from uranine (fluorescein sodium salt) and mercuric acetate by the method of Karush *et al.*[2] and was purified by Sephadex G-15 column chromatography using a 20 mM aqueous ammonia solution as the eluent. The main fraction was shown by dithizone titration[5] to contain two mercury atoms per molecule; it is in agreement with the chemical structure assigned to FMA by Karush *et al.*[2] The concentration of FMA was determined spectrophotometrically using the molar absorption of 78000 at 499 nm.[2] Tryptophan (Trp) and its derivatives, tyrosine (Tyr), phenylalanine (Phe), and the other amino acids, and the chemicals used were all of a guaranteed grade, purchased from Kanto Chemical Industries Co. Ltd., Tokyo.

Measurements of Difference Absorption and Fluorescence Spectra. The difference-absorption spectrum (450—540 nm) of FMA caused by amino acid was measured in a 50 mM borate buffer, pH 9.0 at 25 °C, by means of a Union Giken SM-401 spectrophotometer. The fluorescence measurements were made with a Union Giken FS-401 fluorescence spectrophotometer. The excitation wavelength was 495 nm unless otherwise stated.

Kinetic Observation of the Interaction between FMA and Trp by the Fluorescence Stopped-flow Method. The time course of the change in the fluorescence intensity caused by the interaction of FMA with Trp was observed with a Union Giken SF-70 (piston driven type) or RA-1300 (gas-pressure driven type) stopped-flow spectrophotometer, with a 50-W tungsten lamp as the light source and a cylindrical cell with a 2 mm bore. The excitation wavelength was 495 nm, and the fluorescence emission was observed from a right angle through a cut-off filter (50% transmission at 530 nm). The reaction signals were usually accumulated 9 times to improve the signal-to-noise ratio, using a Union Giken RA-450 kinetic-data-averaging processer. All the reactions were carried out in a 50-mM borate buffer, pH 8—10, at 25 °C.

This study was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

The Catalytic Cracking of Slack Wax with Molten Mixtures Containing Aluminum Chloride and Bromide

Yasuo Ohtsuka,* Kazutoshi Oizumi, and Yasukatsu Tamai

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, 2-1-1 Katahira, Sendai 980

(Received March 16, 1983)

The catalytic cracking of slack wax with molten mixtures of $AlCl_3$ and $AlBr_3$ was investigated in an atmospheric semi-batch reactor at low temperatures of 100—160 °C. The cracking rate was proportional to the amount of unreacted wax. The conversion at 135 °C reached 25 wt% under typical reaction conditions. About 95 wt% of the cracking products consisted of isobutane, 2-methylbutane, and methylpentanes, *ca.* 50% of these isoparaffins being isobutane. The difference in cracking activity between this catalyst and a solid acid catalyst is discussed based on the product distribution. Hardly any reaction took place without HCl, which shows that the presence of HCl is essential for this cracking. The cracking rate increased sharply with an increase in the amount of the catalyst. The rate did not depend on the composition of the $AlCl_3$–$AlBr_3$ catalyst, but the product distribution did depend on it and the content of the gasoline fraction in the products increased with an increase in the concentration of $AlBr_3$. The cracking residue was characterized by IR and NMR spectroscopy. The results show that the cracking reaction probably occurs heterogeneously at the interface between the liquid wax and the molten catalyst.

Petroleum waxes are present in all crude oils, the content depending on the source. Among imported oils, the value is high in Minas and Taching crude, reaching 15—20 wt%. In such waxy crude oils, the upgrading of the waxes may be needed in the future.

Several works on the hydrocracking or hydroisomerization of paraffin wax have been carried out for the purpose of obtaining valuable lighter products.[1,2] Since such reactions are conducted over solid acid catalysts at high temperatures, the high isoparaffin yield attainable at low temperatures is sacrificed and expensive hydrogen is consumed. The use of Lewis acid catalysts, which are very active at low temperatures and without hydrogen, may be preferable for the cracking of paraffin wax. However, little work has been published in this connection. About thirty years ago, however, Potolovsky and Spektor shortly reported the cracking of paraffin wax with the $AlCl_3$ catalyst at temperatures of 200—250 °C.[3]

We now wish to report the cracking of slack wax, the wax obtained in the process of dewaxing lubricating oils, at low temperatures of 100—160 °C. We employed molten salt mixtures containing $AlCl_3$ and $AlBr_3$ as cracking catalysts, because they had been found in preliminary experiments to have low melting points (*ca.* 90 °C) and to show a high activity toward the conversion of lower normal paraffins. In this paper, the effect of some parameters on the cracking rate and the product distribution will be investigated, and the reaction process will be discussed.

Experimental

Materials. The slack wax used in this study was supplied by Idemitsu Kosan Co., Ltd. The properties were as follows: melting point, 53.0 °C; specific gravity at 100 °C, 0.770; kinematic viscosity at 98.9 °C, 4.38×10^{-6} $m^2 s^{-1}$; oil content, 6.0 wt%; average molecular weight, 400. The weight fractions of the normal alkanes, isoalkanes, cycloalkanes and aromatics in the wax were 57.5, 30.6, 10.8, and 1.1% respectively. The carbon numbers of the normal alkanes range mainly from 26 to 30. Anhydrous aluminum chloride and bromide, and sodium chloride were of a reagent grade, and they were used as received. Helium and hydrogen chloride were of a research grade.

Apparatus. The cracking of slack wax was carried out in a semi-batch reaction system. The reactor consisted of a Pyrex test tube onto which a water-cooling jacket was glassblown. This test tube was connected to a vacuum system, a carrier gas line, and a gas-chromatographic unit through three separate metal-glass joints. The reactor was heated electrically by nichrome wire wound onto it and insulated thermally by an annular Pyrex tube. This assembly made it possible to observe the appearance of the reaction process with the naked eye. The reaction temperature was measured with a chromel-alumel thermocouple located in a well embedded in a liquid mixture of slack wax and the catalyst melt.

Procedure and Analysis. In most runs, molten salt mixtures of $AlCl_3$ and $AlBr_3$ were used as cracking catalysts. First, the catalyst was prepared in the reactor by melting a powdery mixture of the two salts at *ca.* 100 °C. The details of the preparation have been described elsewhere.[4] Care was taken throughout the preparation to avoid contact between the catalyst and moisture. After the completion of the preparation, the reactor was kept at 60 °C under flowing He. At this temperature, the catalyst was solid.

Then, a fixed amount of liquid slack wax was quickly poured onto the catalyst and the reactor was rapidly heated up to a predetermined reaction temperature. Finally, HCl diluted with the He carrier, at a total flow rate of 76 cm^3 (STP)/min, was bubbled into the mixture of slack wax and the catalyst melt, and simultaneously the mixture was stirred magnetically. This time was taken as the start of the reaction. Typical cracking conditions were as follows: amount of catalyst, 18 g; its composition, 35 mol% $AlCl_3$–65 mol% $AlBr_3$; amount of slack wax, 54 g; volume fraction of HCl, 0.21; reaction time, 3 h.

The effluent from the reactor outlet was led to a gas-chromatographic unit; all the cracking products were analyzed periodically and separated by means of a 9-m column with 30 wt% propylene carbonate on C-22.

After a constant reaction time, the flow of HCl was stopped and the reactor was cooled to room temperature. The contents of the reactor were separated into two layers by allowing it to stand. The separated materials were then analyzed by IR and NMR spectroscopy method. The IR spectra were measured by sandwiching the sample between two KBr plates. The NMR spectra were deter-

mined as solutions in CCl_4 using TMS as a reference.

Results and Discussion

Cracking Rate. Figure 1 illustrates the first-order rate plots for the cracking of slack wax. The fractional conversion, X, is expressed as a weight fraction of the summation of all the cracking products in the effluent to the feed wax. In all runs, about 95 wt% of the products consisted of isobutane, 2-methylbutane, and methylpentanes. The detailed product distribution will be given later.

As is shown in the figure, a linear relationship between $-\ln(1-X)$ and time was observed at all reaction temperatures, except for the induction period at low temperatures. This result means that the cracking rate is proportional apparently to the amount of the unreacted wax. The rate constant of cracking is obtained from the slope of the straight line in Fig. 1; the values at 100, 135, and 160 °C were 1.1×10^{-3}, 1.6×10^{-3}, and 2.5×10^{-3} min^{-1} respectively. When the temperature was raised from 100 to 160 °C, the rate increased by a factor of 2.3.

The induction period was observed at low temperatures of 100 and 135 °C. The period may arise from the small contact area between wax and catalyst, because, at the beginning of the reaction, especially at 100 °C, the liquid wax and the molten catalyst were immiscible with each other, and thus there existed two separated layers. Such an incomplete mixing may be ascribed to the difference in viscosity between the two. As the cracking proceeded, the mixture apparently became homogeneous.

At high conversions at 160 °C, a little deviation from linearity was observed. The catalyst deterioration may be considered as one reason for this. It is possible that the catalyst reacts with olefinic or aromatic hydrocarbons which may be formed during the cracking, and thus loses its activity.[5]

Distribution of Cracking Products. The results are given in Table 1. The main products were isobutane, 2-methylbutane, and 2- and 3-methylpentane. The product yield increased with an increase in the cracking temperature, but the selectivity to each product depended hardly at all on the temperature. The selectivities to the above main products were 46—47, 32—33, and 14—15 wt% respectively. Thus, about 95% of the products consisted of such lower isoparaffins, which were all monomethylalkanes. The content of the gasoline fraction in the products was 51—53 wt%. No formation of olefinic and aromatic hydrocarbons was found in the products. H_2 and CH_4 were not formed, either.

C_8^+	—	6

a) Ref. 6. b) Values in parentheses denote the selectivity calculated by excluding the C_8^+ fraction.

It is interesting to examine the difference in cracking activity between this catalyst and the solid-acid one. For this purpose we compared our carbon-number distribution of cracking products with that for the cracking of cetane over the SiO_2–ZrO_2–Al_2O_3 catalyst at 500 °C.[6] These two examples differ in feed stock, but this point is insignificant, because it has been reported that the products from centane are similar to those from paraffin wax (approximately n-$C_{24}H_{50}$) over the above solid catalyst.[7] A comparison at the same conversion is made in Table 2. The charateristics of this cracking is that the selectivity to C_3 hydrocarbons is extremely low, while the selectivity to C_4 and C_5 hydrocarbons is considerably high. Furthermore, although it is not shown in the table, another point to be noted is that the iso-to-normal ratio in total paraffins with this catalyst is significantly high,

Table 3. Effect of hydrogen chloride on cracking at 135 °C[a]

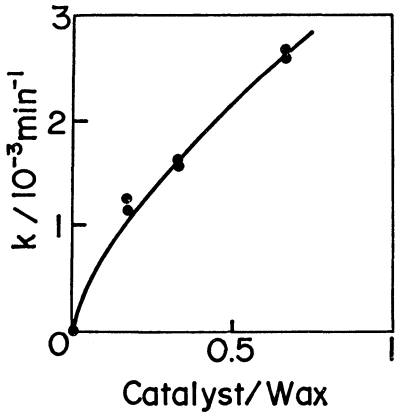

Fig. 2. Effect of amount of catalyst on the cracking of slack wax at 135 °C.

more than twenty times the ratio (*ca.* 3) with the solid-acid catalyst.[6] The low cracking temperatures in this work are one reason for the high iso-to-normal ratio. Since the catalytic cracking of slack wax with molten salts would proceed through the same carbonium-ion mechanism as the Lewis acid-catalyzed cracking,[5] the results shown in Table 2 may characterize this cracking as follows: normal secondary carbonium ions hardly break down into fragments of small molecules such as C_3 fragments, and such normal ions easily undergo skeletal isomerization to form tertiary carbonium ions, which then break down by β fission into fragments of C_4 or larger.

Effect of Hydrogen Chloride. As is generally accepted, hydrogen halide or an equivalent proton source is essential for the isomerization and cracking of paraffins by aluminum halide catalyst.[5] However, such reactions also take place even in the absence of these materials at around 150 °C.[4,8] Thus, the effect of HCl on the cracking of the slack wax was examined. The results are given in Table 3.

In the absence of HCl, a very small amount of the products was formed, and that only at the beginning of the reaction; thereafter, no appreciable cracking was observed. Consequently, the conversion was no more than 0.1 wt%. A trace amount of water present in the slack wax or catalyst probably serves as a proton source for the cracking at the initial reaction time. The addition of 10 vol% of HCl to the carrier gas increased the cracking rate considerably; the conversion reached about 20% in a reaction time of 3 h. An additional two-fold increase in the volume fraction of HCl further increased the cracking rate, but the increase in the rate seemed to level off. The presence of an optimum amount may be considered. It is evident from these results that the presence of HCl is essential for the cracking of slack wax with molten catalysts.

Table 4. Effect of catalyst composition on cracking conversion and product distribution at 135 °C[a]

Catalyst composition[b] (mole ratio)	$AlCl_3$–$AlBr_3$ (35:65)	$AlCl_3$–$AlBr_3$ (61:39)	$AlCl_3$–NaCl (61:39)

n-C_5H_{12}	t	t	1
i-C_5H_{12}	33	30	22
i-C_6H_{14}	15	10	4
i-C_7H_{16}	5	4	t

a) Under typical conditions. b) Catalyst amounts were 18, 15, and 14 g, in the order shown. c) First-order rate constant.

Effect of Amount of Catalyst. Figure 2 illustrates the effect of the catalyst amount on cracking at 135 °C. In this experiment, the weight of the molten catalyst (35 mol% $AlCl_3$–65 mol% $AlBr_3$) was varied from 9.0 to 36 g, while the weight of the wax was kept constant (54 g). In the figure, the first-order rate constants are plotted as a function of the weight ratio of the catalyst to the wax.

Without a catalyst, of course, no pyrolysis of wax was observed at temperatures of 100—160 °C. The catalyst promoted the cracking of the wax considerably, and the rate increased sharply with an increase in the amount of the catalyst. The plots of $\log k$ against log (catalyst/wax) gave a straight line, and from the slope of the line the order with respect to the amount of the catalyst was found to be about 0.6. A similar value has been reported for the liquid-phase isomerization of ethylcyclohexane in the presence of $AlCl_3$.[9]

Such a dependence of rate on the catalyst amount suggests that a stoichiometric reaction between catalyst and wax may occur or that the extent of contact between the two may be a key factor in determining the cracking rate. If the stoichiometric reaction between AlX_3 and paraffins in the wax in the presence of HCl is predominant, the rate will not vary against the catalyst weight above an equimolar amount with paraffins. As is shown in Fig. 2, however, the rate constant increased further even against the weight ratio above 0.50, the value which corresponds to the equimolar ratio of AlX_3 to paraffins. This discussion shows that such the reaction is a minor possibility.

As is shown in Fig. 1, the induction period appears at the beginning of the reaction; it may be ascribed to the small contact area between catalyst and wax. The length of the period decreased with an increase in the amount of the catalyst, and the period disappeared at the highest amount in Fig. 2. These results also suggest that the degree of the contact between the molten catalyst and the liquid wax determines

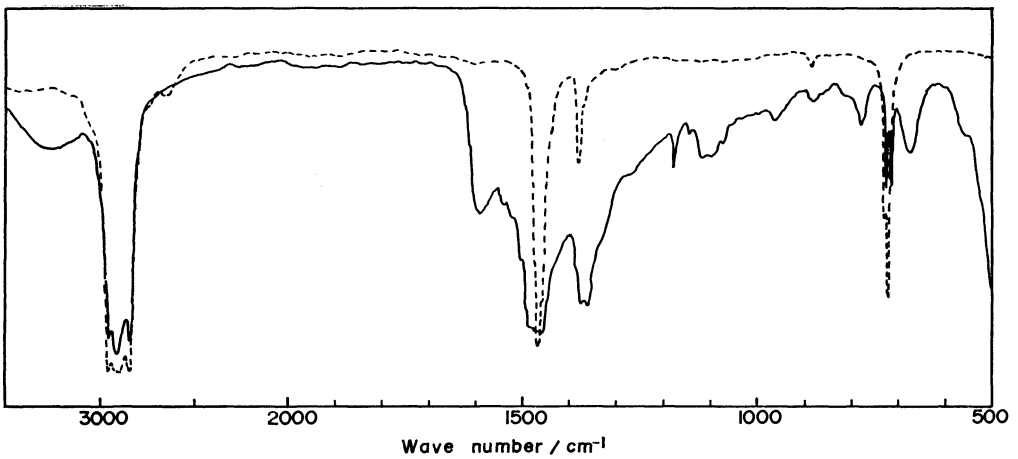

Fig. 3. IR spectra of feed wax (---) and tarry material (——).

the cracking rate to a considerable extent.

Effect of Catalyst Composition. The results are given in Table 4; three molten catalysts with different compositions were employed. The weight of each catalyst is somewhat different, as is shown in the footnote in Table 4, but the three catalysts are equal in the molar content of aluminum halide. For the $AlCl_3$–$AlBr_3$ catalyst, the cracking rate depended scarcely at all on the molar ratio of $AlCl_3$ to $AlBr_3$ within our experimental conditions, but the product distribution obviously did so depend. The selectivity to the C_4 components increased with an increase in the content of $AlCl_3$ in the catalyst, and instead the selectivity to the components above C_5 decreased. It is noteworthy that $AlCl_3$ has a higher activity to crack to lower molecules than $AlBr_3$, although the reason for this is not clear. In our unpublished work, a quite similar result was found for the catalytic conversion of lower paraffins, such as butane and pentane, on molten mixtures containing $AlCl_3$ or $AlBr_3$.

As is shown in the last two columns in the table, the substitution of NaCl for $AlBr_3$ in the $AlCl_3$–$AlBr_3$ catalyst affected both the cracking rate and the product distribution. The rate decreased by a factor of 0.3, and the selectivity to the gasoline fraction above the C_5 components decreased from 44 to 27 wt%. Therefore, the $AlCl_3$–NaCl catalyst is unsuitable for the production of a gasoline fraction by cracking slack wax. The low activity of this catalyst must be due to the decreased amount of free $AlCl_3$, which is the active species for the isomerization or cracking of lower paraffins by a molten $AlCl_3$–NaCl catalyst.[4] It is well accepted that $AlCl_3$ reacts with NaCl to form $Na^+AlCl_4^-$ in molten mixtures.[10,11] Thus, the addition of NaCl decreases the concentration of free $AlCl_3$.

Charaterization of Reaction Residue and Cracking Process.

As has been described in the Experimental section, the contents remaining in the reactor after the stop of the cracking were easily separated into two layers. The upper layer consisted of a white waxy material. No ash was found to be present in it, which shows that the waxy material contains no catalyst. Its NMR and IR spectra were identical with those of feed wax, and the two were equal in the ratio of methylene-to-methyl protons obtained by the NMR spectrum. These findings indicate that the white waxy material is the feed wax itself.

The lower of the two separated layers consisted of a black tarry material including the catalyst. The IR spectrum obviously differed from that of the feed wax. Figure 3 shows this. The spectrum of the feed wax is a typical one for paraffin wax, and every peak can be attributed to aliphatic absorption bands, in which the splitting peak at 720—730 cm^{-1} is assigned to methylene chains having four or more units.

With the spectrum for the tarry material, the intensity of the peak due to the chains decreased considerably. This indicates a decrease in the chain length of paraffins upon cracking. In addition, the major aliphatic absorptions at 2840—2950 cm^{-1} and 1450—1480 cm^{-1} decreased in intensity. The increase in the intensity of the peak for methyl groups at 1370 cm^{-1} and the splitting of this peak show the presence of branched paraffins; besides, the appearance of two new peaks at 1180 and 1155 cm^{-1} enables us to assign them to isopropyl groups. Judging from the absence of any appreciable absorptions in the range of 1200—1260 cm^{-1}, *t*-butyl groups and quarternary carbons seem to be absent. The presence of isopropyl groups in the catalyst layer corresponds to the evolution of a large quantity of monomethylalkanes (shown in Table 1).

Aromatic compounds are also present in the tarry material, because the absorption bands at 1500, 1590, and 3030 cm^{-1} appeared; the former two absorptions are assigned to aromatic-ring vibrations. Thus, the peaks at 680, 780, and 880 cm^{-1} may be attributed to substituted aromatic-ring structures. Evidently the aromatization takes place concurrently with the cracking. It has been suggested that the aromatization process of a normal paraffin, such as that of *n*-dodecane by an $AlCl_3$ catalyst without HCl, takes place predominantly *via* the dehydrogenation of the cycloparaffins formed.[12] However, no evolution of H_2 in this cracking of the wax suggests a mechanism other than the above. Since carbonium ions formed in acidic systems such as $AlCl_3$–HCl are in equilibrium with the corresponding olefins,[13,14] such olefins may undergo polymerization and aromatization reactions. The aromatic compounds may react with the catalyst, which may result in catalyst deactivation.

As has been mentioned above, the catalyst layer including the cracked fragments can be easily separated from the layer of unreacted wax by allowing the reaction mixture to stand. This means that the two layers are essentially immiscible. The cracking of the wax would occur at the interface between the molten catalyst and the liquid wax in the presence of HCl. Since little formation of normal paraffins was found in the cracking products, normal paraffins in the wax may first undergo skeletal isomerization and then the cracking reaction. Part of the cracked fragments may be carried with the carrier gas to the gas phase and observed as products. The rest of the fragments may dissolve in the catalyst phase, undergo further miscellaneous reactions, and finally be converted into lower paraffins and an asphaltene-like material. In conclusion, the catalytic cracking of slack wax by molten mixtures in the presence of HCl probably occurs heterogeneously at the interface between the molten catalyst and the liquid wax.

(Received January 13, 1983)

cis-β_1- and β_2-8-Quinolinolato or 2-methyl-8-quinolinolato(triethylenetetramine)cobalt(III) complexes, [Co()trien]$X_2 \cdot nH_2O$ (R: H, Me; X: Cl, NO_3), have been isolated from a reaction mixture of *cis*-α-dichloro(triethylenetetramine)cobalt(III) chloride, Ag_2O, and 8-quinolinol or 2-methyl-8-quinolinol. The separation of their *cis*-β_1 and β_2 isomers was achieved by the use of ion-exchange resin. The IR spectra of these complexes showed five or six absorption bands in the 990—1100 cm^{-1} region and four or five absorption bands in the 3000—3300 cm^{-1} region. This indicates that these complexes assume the β form. In *cis*-β_1-2-methyl-8-quinolinolato(triethylenetetramine)cobalt(III) complexes, the methyl group of the coordinated 2-methyl-8-quinolinolato ligand has a steric hindrance for the NH-side methylene protons of the coordinated trien ligand. On the other hand, no methyl group of the corresponding *cis*-β_2 form has steric hindrance for the methylene protons of the coordinated trien ligand. Therefore, the distinction of the *cis*-β_1 form and the β_2 form of these complexes has been clarified on the basis of their ^1H NMR spectra. Also, the ^{13}C NMR spectra of these complexes have shown two different configurations of the "*cis*-β_1 and β_2" forms.

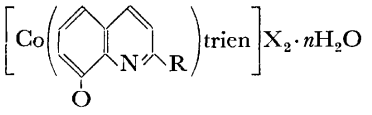
In an octahedral configuration, the isomers of bis(8-quinolinolato)metal complexes with dialkyl,[2] dichloro,[3] dicarbonyl,[4] chloro and nitrosyl,[5] diammine,[6] or ethylenediamine ligands[7] have been reported in recent years, but those of (8-quinolinolato)metal complex have not yet been described, except for the *cis*-β_1 and *cis*-β_2-8-quinolinolato(triethyleneteramine) cobalt(III) complexes.[8]

Previously, we have been concerned with the isomers (*cis*-β_1 and β_2) of salicylato(quadridentate amine) cobalt(III)chloride[9] and of 8-quinolinolato(triethylenetetramine)cobalt(III) chloride.[8] The X-ray studies of both the isomers of the above complexes and related complexes[10] have also never been described yet, because their crystals could not be obtained. Now, we have found that the methyl group of the coordinated 2-methyl-8-quinolinolato ligand in the *cis*-β_1-2-methyl-8-quinolinolato(triethylenetetramine)cobalt (III) complexes has a steric hindrance for the NH-side methylene protons of the coordinated trien ligand, though no methyl group of the corresponding *cis*-β_2 form has the steric hindrance. The present paper will, then, deal with the preparation and properties of *cis*-β_1 and β_2-2-methyl-8-quinolinolato(triethylenetetramine)cobalt(III) complexes and with the assignment of the *cis*-β_1 and β_2 isomers of their NMR spectra.

Results and Discussion

Complexes. *cis*-2-Methyl-8-quinolinolato(triethylenetetramine)cobalt(III) chloride hydrates have three isomeric forms–*cis*-β_1, *cis*-β_2, and *cis*-α, as is shown in Fig. 1. In the *cis*-β_1 form, the methyl group of the coordinated 2-methyl-8-quinolinolato ligand has a position very near the N(3)H-side methylene protons of the coordinated trien ligand, so the methyl group can show a steric hindrance for the N(3)H-side methylene protons. Thus, in the ^1H NMR spectra, the methylene proton signals of the coordinated trien ligand must be different from those of the corresponding 8-quinolinolato complexes. However, the methyl group in the *cis*-β_2 or *cis*-α form does not show the steric hindrance, because the methyl group has a position far from the methylene protons of the coordinated trien ligand; *i.e.*, the methylene proton signals of the coordinated trien ligand differ little from those of the corresponding 8-quinolinolato complexes in the ^1H NMR spectra. Then, the distinction of the *cis*-β_1 form and *cis*-β_2 form or *cis*-α form can be expected to be clarified on the basis of their NMR spectra. Thus, we have isolated the *cis*-β_1-2-methyl-8-quinolinolato(trien)cobalt(III) chloride dihydrate and the corresponding *cis*-β_2 form.

TABLE 1. THE ABBREVIATIONS OF THE 8-QUINOLINOLATO-(TRIEN)COBALT(III) COMPLEXES



No.	1	2	3	4	5	6	7	8
Form	β_1	β_1	β_2	β_2	β_1	β_1	β_2	β_2

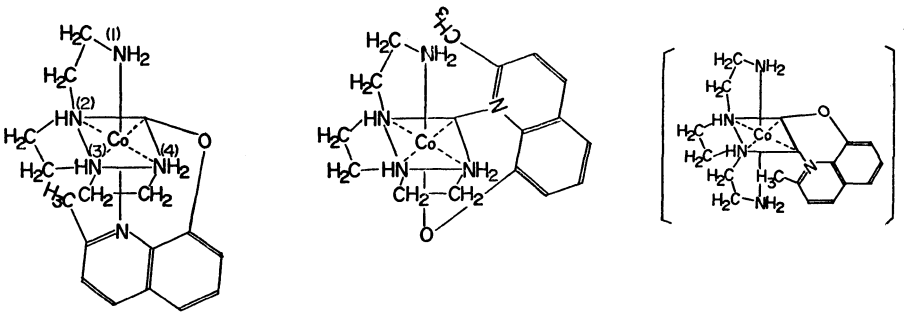
n	2	2	2	2	1	1	1	1

The abbreviations of the 8-quinolinolato- or 2-methyl-8-quinolinolato(trien)cobalt(III) complexes studied in this paper are listed in Table 1. A mixture of *cis*-β_1 and β_2-8-quinolinolato or 2-methyl-8-quinolinolato(trien)cobalt(III) chloride dihydrate was obtained from a reaction mixture of *cis*-α-dichloro(trien) cobalt(III) chloride,[11] Ag_2O, and 8-quinolinol or 2-



β_1 β_2 α

Solvent: 1) methanol.

methyl-8-quinolinol. The separation of the *cis*-β_1 and β_2 isomers was achieved by the use of ion-exchange resin. The *cis*-α form could not be isolated from the reaction mixture at pH 2—8.[12] From the reaction mixture of the *cis*-β_1 and β_2-8-quinolinolato or 2-methyl-8-quinolinolato(trien)cobalt(III) chloride dihydrate (**1**—**4**) and silver nitrate, the corresponding nitrate hydrates (**5**—**8**) have been prepared.

All the complexes are soluble in dimethyl sulfoxide, methanol, water, and acidic solvents, such as nitric acid, hydrochloric acid, but they are insoluble in the common organic solvents. Their β_1 forms are soluble in ethanol, though their β_2 forms are somewhat soluble in ethanol. The color in the solid state of **1** is reddish brown, **3** is yellowish brown, **2** and **5**—**7** are brown, and **4** and **8** are greyish black.

Their IR spectra showed five or six absorption bands in the 990—1100 cm^{-1} region and four or five absorption bands in the 3000—3300 cm^{-1} region, as is shown in Table 2. This indicates that they assumed the β form.[13]

NMR Spectra. The ^{1}H NMR spectra of **1**—**8** were measured in 1.8 mol dm^{-3} D_2SO_4. The signals of the methylene and amine protons of the coordinated trien ligands in **1**—**8** were assigned on the basis of the results in the previous papers.[9,10] The methylene protons of the coordinated trien ligand in **1** showed one signal, though those of the coordinated trien ligand in **3** showed two signals, in the 2.4—4.0 ppm region, as is shown in Table 3 and Fig. 2. The differences between **1** and **3** are similar to those between *cis*-β_1 and β_2-salicylato(trien)cobalt(III) chloride hydrate,[10] *cis*-β_1- and β_2-[Co(sal)trien]Cl·H_2O (**9**); therefore, the **1** and **3** complexes can be assigned to the *cis*-β_1 form

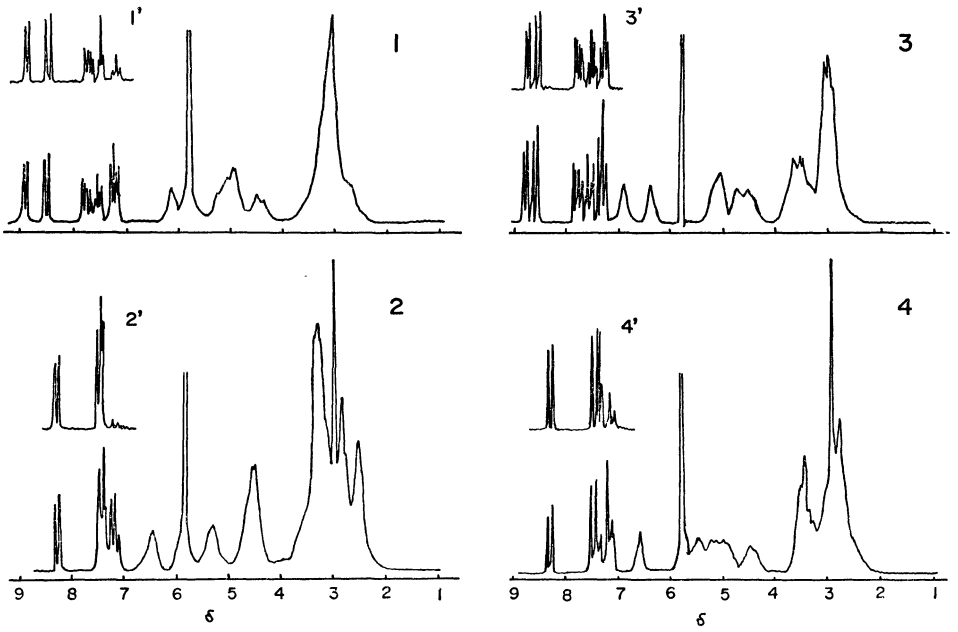

Fig. 2. The ^{1}H NMR spectra of **1**—**4** complexes.
1: *cis*-β_1-[Co(8-quinolinolato)trien]$Cl_2 \cdot 2H_2O$; 2: *cis*-β_1-[Co(2-methyl-8-quinolinolato)trien]$Cl_2 \cdot 2H_2O$; 3: *cis*-β_2-[Co(8-quinolinolato)trien)$Cl_2 \cdot 2H_2O$; 4: *cis*-β_2-[Co(2-methyl-8-quinolinolato)-trien]$Cl_2 \cdot 2H_2O$ in 1.8 mol dm^{-3} D_2SO_4.
The signals of **1**′—**4**′ are those in the 1.8 mol dm^{-3} D_2SO_4 solution after 25 min.

and *cis*-β_2 form respectively. In the ^{1}H NMR spectra of the **2** and **4** complexes, the methylene protons of **2** show three signals, and the intensity ratios are 2:2:8 in the 2.5—3.8 ppm region. These signals are different from those (one signal) of **1**, as is shown in Fig. 2. On the other hand, the methylene proton signals of **4** are little different from those of **3**. Therefore, the isomeric forms of **2** and **4** have been assigned to the *cis*-β_1 and *cis*-β_2 forms respectively.

In the **3** and **4** complexes, the signals at 2.2—3.2 ppm (8H) and 3.2—4.0 ppm (4H) have been assigned to the NH-side methylene protons and the NH_2-side methylene protons of the coordinated trien ligand respectively. The chemical shift of the NH-side methylene protons of the **3** and **4** complexes is at a higher field than that of the NH_2-side methylene protons. This property is different from that of **9**.[9] This can be attributed to the electronic and structural effects of the coordinated 8-quinolinolato and salicylato ligands. On the other hand, the signals of the amine protons of the coordinated trien ligand in **2** and **4** are different from those of **1** and **3**. This can be based on the electronic effect of the methyl group of the coordinated 2-methyl-8-quinolinolato ligand in the **2** and **4** complexes. The NMR spectral data of the nitrate complexes (**5**—**8**) are similar to those of the chloride complexes (**1**—**4**), as is shown in Table 3.

In the ^{1}H NMR spectra of **1**—**4**, both the ring proton signals (H-5 and H-7) of the coordinated 8-quinolinolato or 2-methyl-8-quinolinolato ligand changed to the proton signals of **1**′, **2**′, **3**′, and **4**′ after 25 min, as is shown in Fig. 2. Then, both the ring protons were replaced at deuterium in a 1.8 mol dm^{-3} D_2SO_4 solution. The order of the replacement is: **3**<**1**<**4**<**2**. Thus, the deuterium replacement of the *cis*-β_1

Solvent and standard: 1) 1.8 mol dm^{-3} D_2SO_4, internal DSS, 2) D_2O, internal dioxane (δ=67.4), 3) $CDCl_3$, internal $CDCl_3$ (δ=77.1). a): This signal overlapped with each solvent. **L**: 2-methyl-8-quinolinol.

form is faster than that of the *cis*-β_2 form. In both *cis*-β_1 and β_2 complexes, that of the 2-methyl-8-quinolinolato complexes is faster than that of the 8-quinolinolato complexes.

In the ^{13}C NMR spectra of the **1**—**4** complexes in D_2O, there have been observed four or five signals for the coordinated trien ligand and nine or ten signals for the coordinated 8-quinolinolato or 2-methyl-8-quinolinolato ligands. From Fig. 3, it can be seem that the spectrum of **4** is very similar to that of **3**, but the spectrum of **2** is different from that of **1** because of the steric hindrance of the methyl group. These results also suggest that the **3** and **4** complexes are *cis*-β_2 form, while the **1** and **2** complexes are *cis*-β_1 form. The chemical shifts of the coordinated 8-quinolinolato or 2-methyl-8-quinolinolato ligands[7] in **1**—**4** are assigned; they are collected in Table **3**. The carbon signals of C-2 of the coordinated 2-methyl-8-quinolinolato ligands in the **2** and **4** complexes shift to a low field. This is the effect of the methyl group[14] of the coordinated 2-methyl-8-quinolinolato ligand. The chemical shifts of the coordinated trien ligand in **1**—**4** are difficult to assign to the individual carbon atom, though they are collected in the two groups[9] of the NH-side methylene carbons and the NH_2-side methylene carbons.

Other Properties. The absorption spectra of **1**—**8** have three absorption bands around 325, 340, and 400 nm in methanol as is shown in Table 2. The absorption bands at 340 nm of the **1**, **3**, **5**, and **7** complexes are stronger than those at 325 nm, though the absorption bands at 340 nm of the **2**, **4**, **6**, and **8** complexes are weaker than those at 325 nm, as is shown in Table 2. This property is based on the substituted methyl group in the coordinated 8-quinolinolato ligand. The absorption bands around 400 nm are charge-transfer bands.[6,7] All the complexes are diamagnetic, and their electric conductivities in an aqueous solution are 225—250 S cm^2 equiv.$^{-1}$

Experimental

Measurements. The NMR spectra were recorded with an FX-60 spectrometer (JEOL) for ^{13}C NMR and with an R-40 apparatus (Hitachi) for ^{1}H NMR. The IR spectra were recorded over potassium bromide disks with a IR-27G spectrophotometer (Shimadzu). The visible absorption spectra were recorded with a Shimadzu MPS-5000 recording spectrophotometer. The electric conductivities of an aqueous solution were determined by the use of a conductmetric meter, CM-30 (Shimadzu), at room temperature. The pH was measured with a Corning pH-meter M-125. The magnetic susceptibilities were measured by Faraday's method using a magnetic balance (Shimadzu) at room temperature.

Preparation of Complexes. *cis-β-8-Quinolinolato(trien)-cobalt(III) Chloride Dihydrate (**A**) and cis-β-2-Methyl-8-quinolinolato(trien)cobalt(III) Chloride Dihydrate (**B**)*: A methanol solution (100 cm^3) of 8-quinolinol (4.35 g, 30 mmol) (or 2-methyl-8-quinolinol (4.78 g, 30 mmol)) was added, drop by drop, to an aqueous solution (100 cm^3) of $[CoCl(OH)-trien]^+$,[15] which had been prepared from *cis*-α-dichloro-(trien)cobalt(III) chloride[11] (9.35 g, 30 mmol), and Ag_2O, which had been prepared from $AgNO_3$ (5.1 g, 30 mmol) and KOH (1.69 g, 30.1 mmol). The mixture was then stirred for 30 h at 50 °C. In the reaction, *cis*-α-dichloro-(trien)cobalt(III) chloride isomerized to the corresponding β form. The reaction mixture was then concentrated on a rotary evaporater and dried over silica gel. Complex **A** (or **B**) was extracted with methanol from the dried mixture and was recrystallized from water. Yields: 6.10 g (44.6%) for **A**; 6.51 g (46.1%) for **B**.

*Separation of cis-β$_1$-8-Quinolinolato(trien)cobalt(III) Chloride Dihydrate (**1**), cis-β$_1$-2-Methyl-8-quinolinolato(trien)cobalt(III)*

Synthesis, Characterization, and Crystal-structure Analysis of the 2:1 Molecular Complexes between 1,3,5-Trinitrobenzene and Copper(II), Nickel(II), or Palladium(II) Complexes with the Schiff Base Ligands Derived from *o*-Hydroxynaphthaldehydes and Monoamines

Naohide Matsumoto,* Tadanori Hara, Akira Hirano, and Akira Ohyoshi

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kurokami 2-39-1, Kumamoto 860

(Received January 25, 1983)

The molecular complexes between 1,3,5-trinitrobenzene(TNB) and copper(II), nickel(II), or palladium(II) complexes with the Schiff base ligands derived from 1-hydoxy-2-naphthaldehyde or 2-hydroxy-1-naphthaldehyde and monoamines (RNH_2: R=CH_3, C_2H_5, *n*-C_3H_7, *i*-C_3H_7, *n*-C_4H_9) have been prepared and characterized. One of the molecular complexes bis(1-(isopropyliminomethyl)-2-naphtholato)palladium(II)-bis(1,3,5-trinitrobenzene) (Pd(2,1-*i*-$C_3H_7)_2\cdot$2TNB) has been subjected to the single-crystal X-ray analysis. Its crystal structure consists of alternately stacked donor (naphthalene moiety of the metal complex) and acceptor (TNB) molecules. The coordination geometry is a square planar with a markedly stepped chair-like shape, where the seat and the rests are formed by the coordination plane (PdO_2N_2) and two naphthalene moieties. The Pd atom is deviated by 0.62 Å from the least-squares plane of the naphthalene ring and the dihedral angle between the coordination plane and the naphthalene ring is 25.1°. When the crystal structure was viewed perpendicular to the donor or acceptor plane, the center of the TNB molecule coincides approximately the center of terminal benzene ring of the naphthalene moiety. Electronic spectra of the molecular complexes in Nujol mull showed a new band at about 18×10^3 cm^{-1}, which was not observed in solution spectra.

Previously[1,2] we have studied the 2:1 molecular complexes between TCNQ and the Schiff base metal complexes **1** or **2**, in order to investigate the structure of the molecular complex in which both the π–π type donor-acceptor interaction and the steric hindrance of the *N*-substituted alkyl group causing a tetrahedral distortion of the coordination geometry are operating simultaneously, where the abbreviations of the compounds are shown in Fig. 1. The results indicated that the donor-acceptor interaction can affect the coordination geometry and the steric hindrance between two neighboring acceptor molecules lied on the naphthalene moieties of the complex as well as the overlapping mode between donor and acceptor molecules is important for the formation of the molecular complex. TNB molecule takes C_{3v} symmetry, while TCNQ takes D_{2h} symmetry. Based on preliminary molecular model consideration, TNB molecule seems to be sterically much favorable for the formation of the molecular complex with **1** or **2** than TCNQ, although TNB is a weaker π-electron acceptor than TCNQ. In this study, TNB instead of TCNQ was used to examine whether the complexes **1** or **2** can form the molecular complexes with TNB. One of the molecular complexes with TNB, Pd(2,1-*i*-$C_3H_7)_2\cdot$2TNB has been subjected to the single-crystal X-ray analysis, in order to confirm the basic structure for a series of the molecular complexes with TNB and compare the overlapping mode of TNB adduct with that of TCNQ adduct.

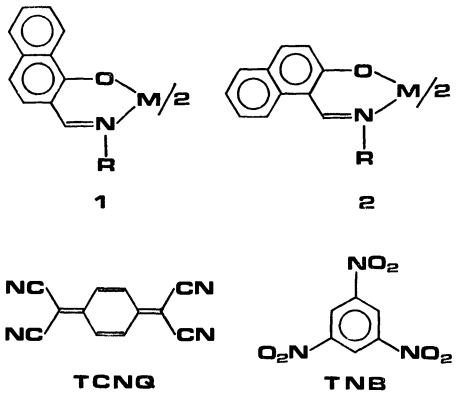

Fig. 1. Structures of Schiff base metal complexes **1** and **2**, and 7,7,8,8-tetracyanoquinodimethane (TCNQ), and 1,3,5-trinitrobenzene (TNB). Bis(2-(alkyliminomethyl)-1-naphtholato)metal(II) (**1**) and bis(1-(alkyliminomethyl)-2-naphtholato)metal(II) (**2**) are abbreviated as M(1,2-R)$_2$ and M(2,1-R)$_2$, respectively, where M and R denote metal ion and alkyl group, respectively.

Experimental

Physical Measurements. Elemental analyses were performed by Mr. Shinichi Miyazaki at the Technical Service Center of Kumamoto University. Electronic spectra were measured on a Shimadzu UV-200 spectrometer in Nujol mull and on a Hitachi recording spectrophotometer 323 in acetone-chloroform solution. Thermogravimetric analysis (TGA) was carried out on a Shimadzu TGC-20 type microthermobalance at the heating rate of 5 °C min^{-1}. Differential scanning calorimetry (DSC) was carried out on a Shimadzu DT-20Bs and DSC-20 and the calibration was made by the use of Indium metal.

Syntheses. 1-Hydroxy-2-naphthaldehyde was prepared by the method of Weil and Ostermeier.[3] 2-Hydroxy-1-naphthaldehyde was purchased from Tokyo Chemical Industry Co., Ltd.

*Parent Complexes **1** and **2**.* Bis(1-(alkyliminomethyl)-2-naphtholato)copper(II), -nickel(II), and -palladium(II) were prepared by the method of Chakravorty and Holm[4] from the Schiff base reaction of bis(1-formyl-2-phtholato)-coppor(II), -nickel(II), and -palladium(II) with monoamines, where the complexes are abbreviated as M(2,1-R)$_2$ (M=Cu^{2+}, Ni^{2+}, Pd^{2+}; R=CH_3, C_2H_5, *n*-C_3H_7, *i*-C_3H_7, *n*-C_4H_9, *i*-C_4H_9, *s*-C_4H_9, *t*-C_4H_9). Bis(2-(alkyliminomethyl)-1-naphtholato)copper(II) was also prepared according to the literature[4] and abbreviated as Cu(1,2-R)$_2$ (R=CH_3, C_2H_5,

n-C_3H_7, *i*-C_3H_7, *n*-C_4H_9, *i*-C_4H_9, *s*-C_4H_9, *t*-C_4H_9). The parent complexes are identified by their elemental analyses and melting points.[5]

Molecular Complexes with TNB. The method for the preparation of the molecular complexes is practically the same and exemplified by the synthesis of Pd(2,1-*i*-$C_3H_7)_2$·2TNB. A solution of Pd(2,1-*i*-$C_3H_7)_2$ (5 mmol) in 20 cm^3 of dichloromethane is added to a solution of TNB (10 mmol) in 20 cm^3 of acetone. The solution was warmed at 40 °C for 5 min in a water bath, which on standing overnight in a refrigerator precipitated red needle crystals. They were collected and dried *in vacuo*. The other molecular complexes were prepared under the same reaction condition described above.

*X-Ray Analysis of Pd(2,1-*i*-$C_3H_7)_2$·2TNB.* Red needle crystals were prepared by slow precipitation of an equivolume solution of dichloromethane and acetone at room temperature. A crystal with approximate dimensions of $0.2\times0.3\times0.5$ mm^3 was used for the X-ray diffraction study. The unit cell parameters and intensity data were measured on a Rigaku Denki AFC-5 automated four-circle diffractometer with a graphite monochromatized Mo $K\alpha$ radiation at 20±1 °C. The unit cell parameters were determined by the least-squares method based on 20 reflections in the range of $18°<2\theta<28°$. Crystal data: $PdO_{14}N_8C_{40}H_{34}$, F.W.=957.2, monoclinic, space group $P2_1/c$, $a=22.236(7)$, $b=7.255(1)$, $c=15.584(4)$ Å, $\beta=129.66(1)°$, $V=1935.2(10)$ Å^3, $D_m=1.63$ (by flotation method in aqueous KI solution), $D_x=1.643$ g cm^{-3} ($Z=2$), and $\mu=3.8$ cm^{-1} (Mo $K\alpha$).

Intensity data were collected by the $\theta-2\theta$ scan technique with a scan rate of 8° min^{-1}. For weak reflections the peak scan was repeated up to three times depending on their intensities. Three check reflections were monitored every 100 reflections throughout the set and displayed no decay of intensities. A total of 3392 independent reflections with $1.5°<2\theta<48°$ were collected, of which 2601 reflections with $|F_o|>3\sigma(|F_o|)$ were used for the structure analysis. Lorentz and polarization corrections were applied, but no correction for absorption was made because of the crystal size and low absorption coefficient.

TABLE 2. ELEMENTAL ANALYSES OF MOLECULAR COMPLEXES

Structure Determination. The Pd atom is required to lie at an inversion center from the consideration of the space group and the number of the formula unit in the unit cell. A Fourier synthesis based on the Pd atom revealed all the nonhydrogen atoms. Block-diagonal least-squares refinement was calculated by initially isotropic thermal parameters and the anisotropic ones, where the function minimized was $\sum w(|F_o|-k|F_c|)^2$ and $w=1/\sigma(|F_o|)^2$. At this stage, a difference Fourier synthesis was calculated and located all the hydrogen atoms at the chemically reasonable positions. Further refinement including the hydrogen atoms with anisotropic thermal parameters for nonhydrogen atoms and isotropic ones for hydrogen atoms was calculated to give final discrepancy indices of 6.26 and 6.95% for $R=\sum||F_o|-|F_c||/\sum|F_o|$ and $R_w=[\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2}$, respectively. A final difference Fourier synthesis showed no regions of significant electron density (less than 0.5 e Å^{-3}).

The neutral atomic scattering factors for H, C_{cov}, N, O, and Pd were taken from International Tables for X-Ray Crystallography, Vol. IV.[6] Anomalous dispersion corrections $\Delta f'$ and $\Delta f''$ for all the component atoms were also taken from the literature.[6] All the calculations were carried out on a FACOM M-200 computer at the Computer Center of Kyushu University by the use of local version[7] of the UNICS II Crystallographic Computing System.[8] Final positional parameters with their estimated standard deviations are given in Table 1. Lists of struc-

ture factors and anisotropic thermal parameters have been deposited as the supplementary data at the Chemical Society of Japan as Document No. 8338.

Results and Discussion

Preparations of Molecular Complexes with TNB. In this study, the 2:1 molecular complexes between TNB and Schiff base copper(II), nickel(II), or palladium (II) complexes with the structure of **1** or **2** have been isolated by mixing a dichloromethane solution of **1** or **2** and an acetone solution of TNB under the reaction conditions noted in the experimental section. Their elemental analytical data are given in Table 2. It seems that the parent complex **1** or **2** forms the molecular complex preferably with TNB rather than with TCNQ, because all the parent complexes which formed the molecular complexes with TCNQ[1] formed the molecular complexes with TNB and some of other **1** or **2** formed the molecular complexes with TNB.

Crystal and Molecular Structure of Pd(2,1-i-C_3H_7)$_2$·2TNB. Crystal structure projected along the b- and c-axis is presented in Figs. 2 and 3, respectively, showing the overlapping mode and the stacking of Pd (2,1-*i*-C_3H_7)$_2$ and TNB molecules. Bond distances and angles with their estimated standard deviations in parentheses are given in Table 3. Some selected least-squares planes with the deviations of atoms from the plane and the dihedral angles between them are given in Table 4. Donor-acceptor intermolecular distances are given in Table 5.

Dihedral angle between the planes	Plane 1-Plane 2 5.1° Plane 1-Plane 3 25.1°

As shown in Figs. 2 and 3, the crystal structure consists of π-π type molecular structure in which the donor (naphthalene ring of Pd(2,1-*i*-C_3H_7)$_2$) and the acceptor (TNB) molecules stack alternately. The structure has a center of symmetry and the Pd atom lies at an inversion center. Therefore the Pd atom has a square planar coordination geometry. As shown in Fig. 3, the complex assumes a markedly stepped chair-like shape, where the seat and the rests are formed by the coordination plane (PdO_2N_2) and two 1-(imonomethyl)-2-naphtholato moieties. The Pd atom is deviated by 0.62 Å from the least-squares plane of the naphthalene ring, and the dihedral angle between the coordination plane and the mean plane of the naphthalene ring is 25.1°. The plane of TNB molecule is approximately parallel to the naphthalene ring and the dihedral angle between them is 5.1°. If there was a difference of the molecular structure between the parent palladium(II) and the molecular complex, it should be the degree of the stepped structure, that is, the deviation of Pd atom from the mean plane of the naphthalene moiety, because palladium(II) demands strongly square planar coordination geometry.[9]

The structural feature of the present molecular complex is quite similar to that of Cu(2,1-*i*-C_3H_7)$_2$·2TCNQ,[1] suggesting the generality of the structure with a chair-like shape and the alternately stacking of the donor and acceptor molecules for a series of 2:1 molecular complexes between TCNQ or TNB and **1** or **2**. However, there is a significant difference between Cu(2,1-*i*-C_3H_7)$_2$·2TCNQ and Pd(2,1-*i*-C_3H_7)$_2$·2TNB. When the crystal structure was viewed perpendicular to the donor or acceptor plane, for Cu (2,1-*i*-C_3H_7)$_2$·2TCNQ, the center of TCNQ molecule coincides approximately the center of the naphthalene ring of the complex. On the other hand, for Pd(2,1-*i*-C_3H_7)$_2$·2TNB, the center of TNB molecule coincides approximately the center of terminal benzene ring.

The crystal structure of the 2:1 molecular complex between TNB and bis(*N*-methylsalicylideneaminato)-copper(II) (Cu(Sal-CH_3)$_2$·2TNB) has been determined by the single-crystal X-ray analysis.[10] The crystal structure consists of rather discrete Cu(Sal-CH_3)$_2$·

2TNB unit, because the TNB molecule is approximately parallel to the nearest salicylideneaminato moiety but is tilted to the another neighboring moiety with a tilt angle of 26.4°.

Thermal Analysis. It is well known that some of the bis(*N*-alkylsalicylideneaminato)metal(II) complexes exhibit the isomerization from a square planar form to tetrahedral or polymeric octahedral form in solid state by heating.[11–13] Then the thermal analysis (TGA and DSC) was carried out for the parent complexes Cu(2,1-R)$_2$ (R=C_2H_5, *n*-C_3H_7, *n*-C_4H_9, *i*-C_4H_9, *s*-C_4H_9, *t*-C_4H_9), Ni(2,1-R)$_2$ (R=CH_3, C_2H_5, *n*-C_3H_7), and Pd(2,1-R)$_2$ (R=*n*-C_4H_9, *t*-C_4H_9). Of which Cu(2,1-*n*-$C_4H_9)_2$ and Ni(2,1-$CH_3)_2$ showed isomerization peak in solid state by heating, as shown in Fig. 4. The DSC curve of Cu(2,1-*n*-$C_4H_9)_2$ posseses two endothermic peaks without weight loss, of which the second peak corresponds to phase transformation from solid to liquid. The endothermic peaks in the solid state can be attributed to the change of the coordination geometry, and the values of 1.80 kcal mol^{-1} for Cu(2,1-*n*-$C_4H_9)_2$ and 1.77 kcal mol^{-1} for Ni(2,1-$CH_3)_2$ are of the same order of the π-π type donor-acceptor interaction.[14] (1 cal=4.184 J) The palladium(II) complexes showed no isomerization peak, being consistent that palladium(II) strongly demands the square planar geometry.[9] It should be noted that their molecular complexes with TCNQ show no peaks corresponding to the isomerization.[15]

Electronic Spectra. Electronic spectra were measured in Nujol mull and in equivolume solution of acetone and chloroform. The solution spectra of the parent complex and its molecular complex with TNB are quite similar to each other in absorption coefficient and band maxima in the region of $(14-22)\times10^3$ cm^{-1}, in which TNB molecule shows no absorption. On the other hand, in Nujol mull, an intense band appeared at about 18×10^3 cm^{-1}. As a typical example, the electronic spectra of Ni(2,1-*i*-$C_3H_7)_2$ and Ni(2,1-*i*-$C_3H_7)_2$·2TNB in Nujol mull and in solution are shown in Fig. 5. Since all the molecular complexes of nickel(II), copper(II), and palladium(II) exhibit this band at about same wave number, this band may be attributable to a charge transfer band between TNB and naphthalene moiety. In the case of the palladium(II) complexes, it is well known that palladium(II) demands strongly square planar configuration[11–13] so that the coordination geometrical change associated with the formation of the molecular complex (at least from

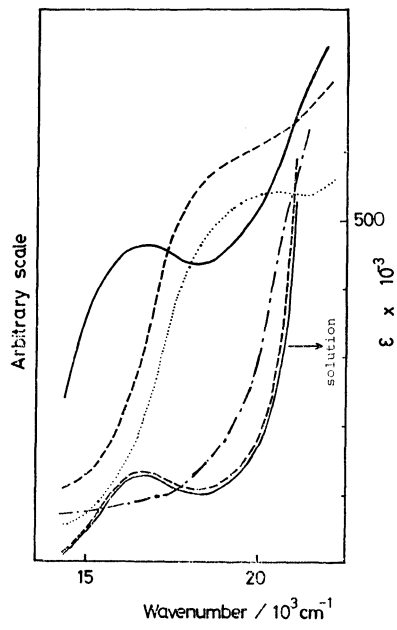

Fig. 5. Electronic spectra of Ni(2,1-n-C_3H_7)$_2$ (——) and Ni(2,1-n-C_3H_7)$_2$·2TNB (— — —) measured in Nujol mull and in a acetone-chloroform solution, and Nujol mull spectra of Pd(2,1-i-C_3H_7)$_2$ (—·—) and Pd(2,1-i-C_3H_7)$_2$·2TNB (·····).

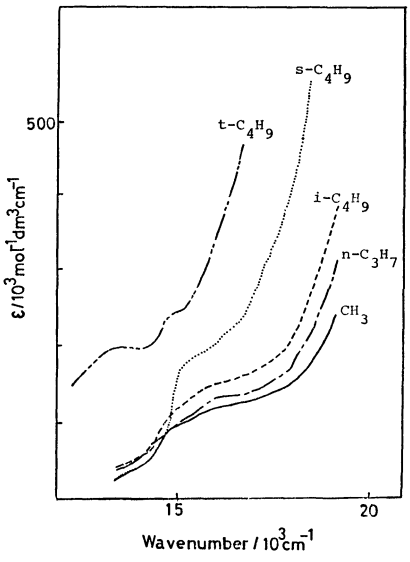

Fig. 6. Electronic spectra of Cu(2,1-R)$_2$ (R=CH_3, n-C_3H_7, i-C_4H_9, s-C_4H_9, t-C_4H_9) in chloroform solution.

tetrahedral to square planar) can be deleted. In addition, the electronic spectra of the parent complexes for a series of Pd(2,1-R)$_2$ (R=CH_3, C_2H_5, n-C_3H_7, i-C_3H_7, n-C_4H_9) are quite similar to each other and show no absorption band around 18×10^3 cm^{-1}. So this band can be arised from donor-acceptor interaction between TNB and terminal benzene ring. It must be noted that 1:1 molecular complex between naphthalene and TNB (Nap·TNB) did not exhibit the band at the wave number, where the center of Nap coincides the center of TNB so that the overlapping mode[16] is different from that of the present complex. In the case of the copper(II) complexes, the spectra of the parent complexes exhibit d-d transition bands in the region of $(12-18)\times10^3$ cm^{-1} which can provide the information of the coordination geometry, as shown in Fig. 6. Red shift and intensity enchancement of d-d bands are recognized indicators of the transformation from square planar to tetrahedral stereochemistry, as known by the well-established complexes.[17] However, the information with respect to the coordination geometrical change associated with the formation of the molecular complex with TNB is hidden by the intense band at 18×10^3 cm^{-1}.

We are grateful to Prof. Sigeo Kida at the Faculty of Science, Kyushu University, for allowing us to use the X-ray diffractometer. Thanks are also due to Mr. Yasuhiro Sagara and Mr. Toshiro Miyazaki for the assistance of the experiment.

Electrochemical Reduction of Some Tris(β-diketonato)ruthenium(III) Complexes in Acetonitrile and Interaction of the Reduced Anions with Lithium and Sodium Ions

Akira Endo

Department of Chemistry, Faculty of Science and Technology, Sophia University, 7-1 Kioicho, Chiyoda-ku, Tokyo 102

(Received February 21, 1983)

In tetraethylammonium perchlorate–acetonitrile solution, $[Ru(R_1\text{-}CO\text{-}CR_2\text{-}CO\text{-}R_3)_3]$ (R_1,R_3=$-CH_3$, $-CF_3$, $-C_6H_5$, $-C(CH_3)_3$; R_2=$-H$, $-C_6H_5$) was reversibly reduced at a dropping mercury electrode to the corresponding univalent anion. A linear relationship was found between the half-wave potential and the sum of the Hammett constants of the substituents of ligands. In some cases, the polarogram and the cyclic voltammogram were shifted to more positive potentials in the presence of lithium or sodium ions. This effect was explained quantitatively by the two-step association between the reduction product, $[Ru(R_1\text{-}CO\text{-}CR_2\text{-}CO\text{-}R_3)_3]^-$, and alkali metal ions. The association constants were calculated. The K_2 values were appreciable and the K_1 values were much larger than expected for a simple electrostatic interaction. Furthermore, the K_1 values were linearly related to the sum of the Hammett constants of the substituents of the ligands. These results suggest the importance of the local charge distribution on the complex anions. In the presence of lithium ion, $[Ru(acac)_3]^-$ forms $Li[Ru(acac)_3]$ which is insoluble in acetonirile.

The polarographic behavior of acetylacetonato complexes is affected by the properties of solvents and by the addition of perchlorate of alkali metal or alkaline earth metal. Murray and Hiller[1] first studied in detail the mechanism of polarographic reduction of $[Fe(acac)_3]$ in lithium perchlorate–acetonitrile solutions. They found that the reduction potential of $[Fe(acac)_3]$ was shifted to more positive potentials by the addition of $LiClO_4$. They have shown that the effect is caused by a coordinative relaxation reaction of the reduction product, $[Fe(acac)_3]^-$, in which an acetylacetonato ligand becomes transferred to lithium ion. Heineman *et al.*[2] have confirmed this interaction by means of the optically transparent thin-layer electrode. Misumi *et al.*[3] also examined this effect in *N*,*N*-dimethylformamide (DMF) and obtained similar results. Recently, Kalinowski and Ćmiel[4] investigated solvent effects on the interaction between $[Fe(acac)_3]^-$ and Li^+, Na^+, or K^+ and discussed them in terms of the donor-acceptor concept. The coordinative relaxation reaction was also observed in the systems of $[Cu(acac)_2]^-$–Li^+ (in acetonitrile)[5] and $[Eu(acac)_3]^-$–Li^+, Mg^{2+} (in DMF).[3] In the reduction of $[Mn(acac)_3]$,[6] the potential shifts were also observed on the addition of perchlorate of Li^+, Na^+, or K^+ in many nonaqueous solvents. These effects were qualitatively explained in terms of the ion-pair formation between $[Mn(acac)_3]^-$ and alkali metal ions. This explanation, however, appears to lack quantitative corroboration.

In the course of a polarographic study of tris(acetylacetonato)ruthenium(III) in aqueous and acetonitrile solutions,[7] we came to notice that the reduction step in acetonitrile is shifted to more positive potentials in the presence of sodium ions.

The present paper deals with the interaction of lithium and sodium ions with eight kinds of tris(β-diketonato)ruthenate(II) ions which are produced by the polarographic reduction of the corresponding Ru^{III} complexes. Effects of the substituents of the ligands are also discussed.

Experimental

Preparation of the Complexes.† Among the eight complexes, $[Ru(pfm)_3]$ and $[Ru(paa)_3]$ are new compounds. They were synthesized as described below. $[Ru(bzac)_3]$ and $[Ru(acac)_3]$ were prepared according to the published methods (Refs. 8 and 7, respectively). For the other complexes, see the appendix.

[Ru(pfm)$_3$]: Hydrated ruthenium trichloride (1 g, *ca.* 4 mmol as Ru), 3.3 g (17 mmol) of Hpfm and 0.5 g (5 mmol) of potassium hydrogencarbonate were refluxed at 120 °C for 10 h. An additional 1.2 g (12 mmol) of potassium hydrogencarbonate was added, and the reflux was continued at 150 °C for 20 h. The mixture was then extracted with dichloromethane several times. The extracts were combined and this mixture was washed in a separatory funnel successively with 2% potassium hydrogencarbonate solution, 2% HCl solution, and water. Removal of the solvent from extracts left an oily red material, which was steam-distilled. The first 5 cm^3 portion of the distillate being discarded, the distillate containing drops of red liquid was collected and left to stand overnight, during which the drops solidified. The solid was dried under vacuum and then ground to powder, which was again vacuum-dried at room temperature. Found: C, 42.5; H, 4.5%. Calcd for $RuC_{24}H_{30}O_6F_9$: C, 42.0; H, 4.40%.

[Ru(paa)$_3$]: A portion of ruthenium(III) chloride solution (5 mmol as Ru, dissolved in 40 cm^3 of 1 mol dm^{-3} HCl) was reduced with ethanol to the bivalent state, and the mixture was evaporated nearly to dryness on a water bath. The blue residue was dissolved in 50 cm^3 of water and the pH of the solution was adjusted to about 2 with 1 mol dm^{-3} NaOH solution. The solution was then refluxed on a water bath with 4 g (23 mmol) of Hpaa and 200 cm^3 of ethanol under nitrogen atmosphere. After 4 h, the pH

† The following ligand abbreviations will be used in this paper (in the order of Table 1): Hbzfa, 1,1,1-trifluoro-4-phenyl-2,4-butanedione; Hfac, 1,1,1-trifluoro-2,4-hexanedione; Hpfm, 1,1,1-trifluoro-5,5-dimethyl-2,4-pentanedione; Hdbm, 1,3-diphenyl-1,3-propanedione; Hbzac, 1-phenyl-1,3-butanedione; Hacac, 2,4-pentanedione; Hpaa, 3-phenyl-2,4-pentanedione; Hdpm, 2,2,6,6-tetramethyl-3,5-heptanedione.

a) Against a silver-silver ion electrode (0.01 mol dm^{-3} $AgNO_3$ in acetonitrile).

of the solution was readjusted to about 2, and the reflux was continued for *ca.* 10 h, when the color of the solution turned to reddish purple. The pH of the solution was then adjusted to about 6, and further refluxing was continued for 5 h. After removal of the solvent, the residue was extracted into several portions of benzene. The combined benzene solution was passed through a column of Merck Alminiumoxid 90 (Aktivitätsstufe II—III). The eluent was concentrated, and the complex was precipitated by adding ethanol. A red powdery material was obtained, which was dried under vacuum at room temperature. Found: C, 63.3; H, 5.5%. Calcd for $RuC_{33}H_{33}O_6$: C, 63.3; H, 5.3%.

Complexes **1**, **2**, **3**, and **5** have geometrical isomers, and each of the complexes has optical isomers. The isomeric mixtures were used, since the precision of the present method seemed too low to detect any difference among the isomers. Indeed, in the case of $[Ru(bzac)_3]$, the half-wave potentials of the *mer*- and *fac*-isomers were identical in both TEAP and $NaClO_4$ solutions.[9]

Other Chemicals: Tetraethylammonium perchlorate (TEAP) and tetrabutylammonium perchlorate (TBAP) were of special polarographic grade purchased from Nakarai Chemicals, Ltd. Anhydrous $LiClO_4$ of ICN Pharmaceutical, Inc., was dried under vacuum at 130 °C. Anhydrous $NaClO_4$ of guaranteed reagent grade of Kanto Chemical Co., Inc., was dried under vacuum at 120 °C. Purification of acetonitrile has been described previously.[7]

Measurement. All the potentials were measured against a silver-silver ion electrode (Ag/0.01 mol dm^{-3} $AgNO_3$ in acetonitrile), and all the electrochemical measurements were carried out at (25.0±0.1) °C. Deoxygenation of solutions was carried out with argon gas which had been passed through two wash bottles containing acetonitrile kept at 25 °C. Electrochemical measurement was carried out mainly by using a Fuso Polarograph Model 312 with a Fuso Potential Scanning Unit Model 321 and a Riken Denshi X-Y Recorder Model F-42CP. An H-type electrolytic cell with a glass frit was used. A dropping mercury electrode (DME) and a counter electrode of spiral platinum wire were both placed in one compartment and the reference electrode was connected to the other compartment through a bridge filled with 0.1 mol dm^{-3} TEAP solution. The DME had a flow rate of mercury of 1.38 mg s^{-1} under a mercury head of 50 cm. Cyclic voltammetry was carried out as previously described,[7] except that the silver-silver ion reference electrode was used and both compartments were filled with the supporting electrolyte solution. A Hitachi Model 200-20 Spectrophotometer was used for recording absorption spectra. An NEC PC 8001 Personal Computer was used for data processing. Elemental analyses of C, H, and N were carried out by means of a Shimadzu Seisakusho Ltd. CHN Analyzer CHN-1A. Lithium was determined by means of a Seiko SAS 740 Atomic Absorption/Flame Spectrophotometer. Ruthenium was determined spectrophotometrically according to the ruthenate method.[10]

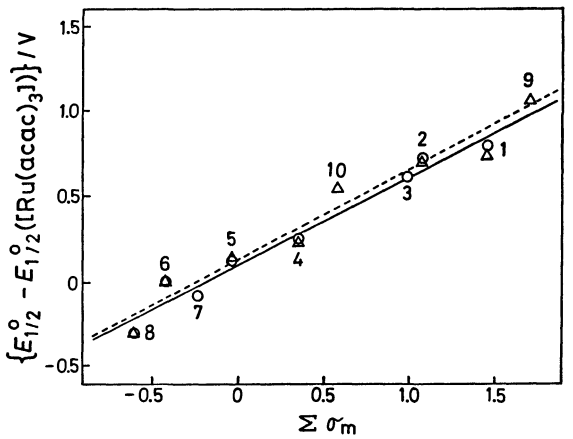

Fig. 1. Relationship between relative half-wave potential and the sum of the Hammett constants in 0.1 mol dm^{-3} TEAP at 25 °C. —○—, this work (in acetonitrile); ---△---, Patterson and Holm[11] (in DMF). Complexes are numbered as in Table 1 except for **9** ($[Ru(acac)(hfac)_2]$ and **10** ($[Ru(acac)_2(hfac)]$) (Hhfac, 1,1,1,5,5,5-hexafluoro-2,4-pentanedione).

Results and Discussion

TEAP Systems. In 0.1 mol dm^{-3} TEAP solution, every complex listed in Table 1 showed a reduction step with diffusion-controlled limiting current, which corresponded to Nernstian one-electron reduction to the univalent anion. The half-wave potentials ($E^\circ_{1/2}$) and the reciprocal slopes of the logarithmic plots of the reduction steps are presented in Table 1.

Patterson and Holm[11] investigated in DMF the substituent effect on the $E^\circ_{1/2}$ of a series of tris(β-diketonato)ruthenium(III) complexes including six of the present ones. In the present case, too, the plot of $E^\circ_{1/2}$ *vs.* the sum of the Hammett constant ($\Sigma\sigma_m$ or $\Sigma\sigma_p$) was a straight line. In Fig. 1, this relationship

is represented in terms of the half-wave potentials relative to that of $[Ru(acac)_3]$ and along with these authors' data, where $\Sigma\sigma_m$ is calculated by using the values given by Murov.[12] The agreement between the two sets of data is remarkable. This is not surprising since the relative permittivities of the two solvents are almost the same (ε_r(acetonitrile)=38 and ε_r(DMF)=37 at 25 °C[13]), if there is little specific solute-solvent interaction. Patterson and Holm[11] explained this linear relationship qualitatively as follows. Since Ru^{III} has the low spin, d^5 electronic configuration, the d electrons are localized in the t_{2g} metal orbital. The t_{2g} metal orbital which is a $d\pi$ orbital, forms a π molecular orbital with a π ligand orbital, and in the redox process the electron will be added to or subtracted from this molecular orbital. The substituents affect the eletron density of σ and π molecular orbitals. The Hammett constant is a measure of the electron-accepting character of the substituent. The more electron-accepting is the substituent, the more stabilized is the reduced form with respect to the oxidized form, hence the more positive is $E^\circ_{1/2}$.

A linear correlation between $E^\circ_{1/2}$ and the Hammett constant is known in many systems of organic substances.[14-16] For benzene derivatives, azo dyes,[16] and some heterocylic compound derivatives,[15] slopes ranging from +0.02 V to +0.37 V were observed. The slope of *ca.* +0.5 V obtained in the present case is somewhat larger, probably reflecting the more immediate influence of the substituents on the orbital energies of the metal chelate.

$LiClO_4$ and $NaClO_4$ Systems. In the presence of $LiClO_4$, the polarogram and cyclic voltammogram of $[Ru(acac)_3]$ were shifted to more positive potentials; but their shapes were so distorted by the presence of maxima, apparently owing to the formation of insoluble film, that no quantitative analyses of the waves were possible. When the large scale reduction at a mercury pool electrode was carried out in 0.1 mol dm^{-3} $LiClO_4$ with enforced stirring of the mercury surface, a brown precipitate was obtained. The precipitate was collected by the filtration and washed with deoxygenated acetonitrile under argon atmosphere. In the presence of atmospheric oxygen, the precipitate redissolved instantly to give the tervalent species. It was fairly stable when dry and was subjected to elemental analysis. The results were in good agreement with the calculated values for $Li[Ru(acac)_3]$. Found: Ru, 24.0; C, 44.2; H, 5.2; Li, 1.6%. Calcd for $Li[Ru(acac)_3]$: Ru, 24.9; C, 44.4; H, 5.2; Li, 1.7%. On reduction in the presence of lithium ions, therefore, the reduction product, $[Ru(acac)_3]^-$, forms the lithium salt, which is insoluble in acetonitrile.

In the presence of $NaClO_4$, the polarogram and the cyclic voltammogram of $[Ru(acac)_3]$ were also shifted to more positive potentials, as shown in Fig. 2, without changing the Nernstian characteristics (Table 2). The $E_{1/2}$ was independent of the depolarizer concentration at a given sodium perchlorate concentration. The addition of small amounts of water did not affect the $E_{1/2}$. When the $[Ru(acac)_3]$ was partially reduced at a mercury pool electrode in 0.1 mol dm^{-3} $NaClO_4$, a single redox step appeared at the same $E_{1/2}$. When

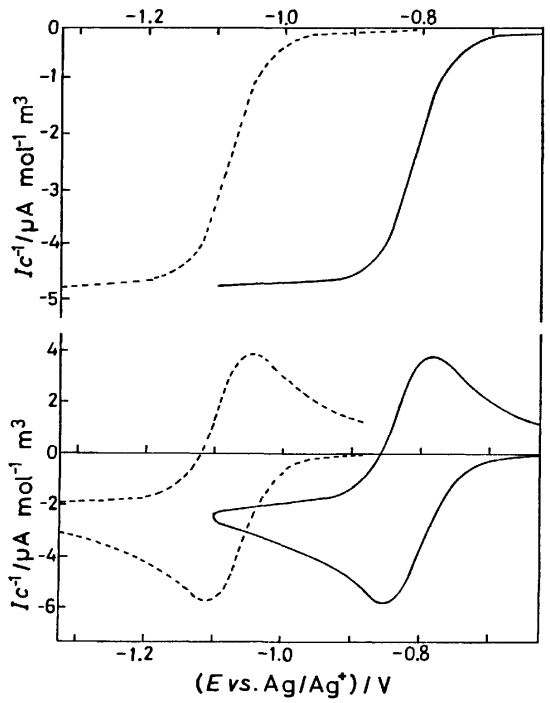

Fig. 2. DC polarograms and cyclic voltammograms of $[Ru(acac)_3]$ in acetonitrile. ----, in 0.1 mol dm^{-3} TEAP; ——, in 0.1 mol dm^{-3} $NaClO_4$; scan rate for CV=0.1 V s^{-1}, 25 °C.

Table 2. The dependence of $\Delta E_{1/2}$ of $[Ru(acac)_3]$ on the concentration of dissociated sodium ions in acetonitrile at 25 °C

$[Na^+]$/mol m^{-3}	$\Delta E_{1/2}$/mV[a]	Reciprocal slope/mV

20.6	207	−60.1
34.3	232	−59.7
48.0	246	−61.5
68.4	269	−59.6

a) Against a silver-silver ion electeode (0.01 mol dm^{-3} $AgNO_3$ in acetonitrile). Concentration of $[Ru(acac)_3]$ is 1 mol m^{-3}.

the cathodic diffusion currents recorded intermittently in the course of the electrolytic reduction were plotted against the quantity of electricity, the magnitude of the former decreased and that of the latter increased linearly. The plots indicate that the process is a one-electron reduction, without any complication owing to subsequent chemical reactions. The UV-visible spectra of $[Ru(acac)_3]$ were the same in both 0.1 mol dm^{-3} $NaClO_4$ and 0.1 mol dm^{-3} TEAP. It follows that the shift of $E_{1/2}$ is attributable to a specific interaction of sodium ions with $[Ru(acac)_3]^-$, not with $[Ru(acac)_3]$. The spectra of the reduced forms, in fact, were different in the two media.

Consequently, the shift of $E_{1/2}$ is interpreted in terms of the association equilibria between sodium or lithium ion (M^+) and $[Ru(acac)_3]^-$ subsequent to the electron transfer:

$$[Ru(acac)_3] + e^- \rightleftharpoons [Ru(acac)_3]^- \quad (1)$$

$$[Ru(acac)_3]^- + M^+ \rightleftharpoons M[Ru(acac)_3]$$

$$M[Ru(acac)_3] + M^+ \rightleftharpoons \{M_2[Ru(acac)_3]\}^+ \quad (2)$$

$$\cdots\cdots$$

$$\{M_{n-1}[Ru(acac)_3]\}^{(n-2)+} + M^+ \rightleftharpoons \{M_n[Ru(acac)_3]\}^{(n-1)+}.$$

When the electron transfer is Nernstian and the subsequent reactions are reversible and the large excess of M^+ is present, this relation holds:[17]

$$E = E^{o'} + (RT/F) \ln (\bar{D}_R/D_O)^{1/2} + (RT/F) \ln (1 + \sum_{i=1}^{n} \beta_i [M^+]^i) + (RT/F) \ln [(I_d - I)/I], \quad (3)$$

with

$$\beta_i = \prod_{j=1}^{i} K_j, \quad (4)$$

where D_O is the diffusion coefficient of $[Ru(acac)_3]$, and $\bar{D}_R$ is the mean diffusion coefficient of the reduced form, the other symbols having the usual meanings. K_j is the conditional stepwise formation constant of the jth associate in terms of amount-of-substance concentration:

$$K_j = C_j/[M^+]C_{j-1}, \quad (5)$$

where C_j is the concentration of $\{M_j[Ru(acac)_3]\}^{(j-1)+}$. Hence the half-wave potential is given by

$$E_{1/2} = E^{\circ}_{1/2} + (RT/F) \ln (\bar{D}_R/D_R)^{1/2} + (RT/F) \ln (1 + \sum_{i=1}^{n} \beta_i [M^+]^i), \quad (6)$$

where D_R is the diffusion coefficient of $[Ru(acac)_3]^-$ and $E^{\circ}_{1/2}$ is the half-wave potential at $[M^+]=0$. Since $\bar{D}_R$ and D_R are expected to be almost the same,

$$\Delta E_{1/2} = E_{1/2} - E^{\circ}_{1/2} = (RT/F) \ln (1 + \sum_{i=1}^{n} \beta_i [M^+]^i). \quad (7)$$

The β_i values were calculated by analysing the dependence of $\Delta E_{1/2}$ on $[M^+]$ according to the method presented by Momoki *et al.*[18] For this purpose the values of $[M^+]$ were calculated from the analytical concentration of the perchlorate by using the association constants of TEAP (7.3 mol^{-1} dm^3) and $MClO_4$ (4.0 mol^{-1} dm^3 for M=Li and 6.8 mol^{-1} dm^3 for M=Na at 25 °C) reported by Fujinaga *et al.*[19] Although those values are thermodynamic association constants, they were used in the present calculation without correction for the ionic strength, because their values were found to have little effect on the results of the following numerical analysis. It is assumed that the association between $[Ru(acac)_3]^-$ and tetraethylammonium ions is negligible; this assumption seems legitimate in view of the fact that the $E^{\circ}_{1/2}$ remained unchanged when the concentration of TEAP was changed from 0.05 mol dm^{-3} to 0.1 mol dm^{-3} or TEAP was replaced by TBAP. The total electrolyte concentration was, therefore, kept constant at 0.1 mol dm^{-3} with TEAP.

The maximum number of the bound cations, n, has to be known to carry out the calculation. For $n=1$, no reasonable fitting was obtained (Fig. 3); for $n=3$, β_3 resulted in a negative value. It was therefore decided that the association of up to two sodium ions per complex anion was meaningful under the experimental conditions. The $\Delta E_{1/2}$ values calculated on the basis of the β values for $n=2$ are in very good agreement with the experiment (Fig. 3).

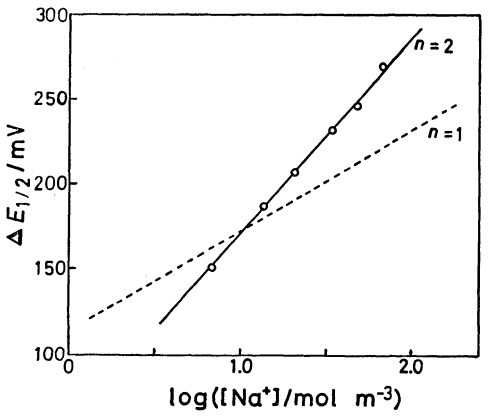

Fig. 3. $\Delta E_{1/2}$ *vs.* log ($[Na^+]$/mol m^{-3}) plot for $[Ru(acac)_3]^-$–Na^+ system in acetonitrile. ○, observed values; ----, calculated line for $n=1$; ——, calculated line for $n=2$. Total concentration of $NaClO_4$ = 0.01–0.1 mol dm^{-3}, 25 °C.

—, not detectable ($\log(K/mol^{-1}\,dm^3) < ca.\ 0.5$); #, not measurable.

The other tris(β-diketonato)ruthenate(II)–Li^+, Na^+ systems were analyzed in the same way, since the electrochemical behavior was quite similar except for $[Ru(paa)_3]^-$, of which the polarograms were distorted in the presence of Na^+ or Li^+ and the analysis was impossible.

In Table 3, the results are presented in terms of K_1 and K_2; for the first three cases, no shift of $E_{1/2}$ was detectable. These formation constants reveal that the interaction is not simply electrostatic ion-pairing.

First, the K_2 values are appreciable. It is reported that the anion radicals of a number of *p*-quinones produced by the one-electron reduction in DMF react with lithium or barium cations to form 2-cations-to-1-anion associates.[20,21] To the author's knowledge, the present systems are the first examples of 2 to 1 association for univalent anions of a metal complex.

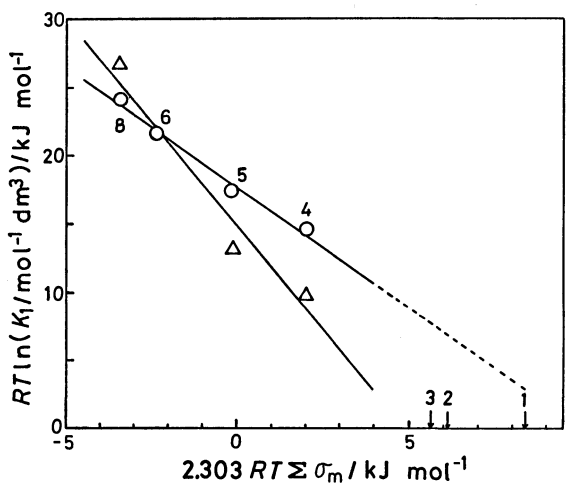

Fig. 4. Relationships between K_1 and the sum of the Hammett constants. —○—, Na^+ system; —△—, Li^+ system. Complex anions are numbered as in Table 3.

Second, the K_1 values are much larger than expected for simple ion-ion electrostatic attraction. For example, the Fuoss theory,[22] which can well explain the association constants of $LiClO_4$ and $NaClO_4$, predicts about 7 mol^{-1} dm^3 when the ion-ion distance is assumed to be 0.6 nm in the case of $[Ru(acac)_3]^-$–Na^+ system (crystallographic radius of $[Ru(acac)_3]$ molecule is *ca.* 0.5 nm[23]). Inversely, an unreasonably small value (*ca.* 0.1 nm) for the ion-ion distance would be required for a formation constant of 5.8×10^3 mol^{-1} dm^3 (experimental value in $[Ru(acac)_3]^-$–Na^+ system). Examination of the K_1 values indicates that the local charge distribution on the complex anion plays an important role. The K_1 seems to be independent of the bulkiness of the complex anion, since the diffusion current constants ($I_d/c\,m^{2/3}\,t^{1/6}$) of the complex were experimentally in the order of **4**, **5**, **8**, **6**. However, the value of K_1 depends on $E^\circ_{1/2}$: the more negative is $E^\circ_{1/2}$, the larger becomes K_1. $E^\circ_{1/2}$ is in turn linearly dependent on the sum of the Hammett constants of the substituents of the ligand, as mentioned earlier. The relationships between K_1 and $\Sigma\sigma_m$ for Li^+ and Na^+ systems are presented in Fig. 4, where the two quantities are expressed in energetic terms. The two straight lines can be explained as follows. When the substituents on the ligand are stronger electron acceptors, the electron density on the chelate rings will decrease. This decrease in the electron density, on one hand, will make the reduction of the neutral complex molecule easier (more positive $E^\circ_{1/2}$) and on the other hand will make it less easy for the cation to attach to the reduced complex anion. This picture implies that the association is attributable mainly to the chelate rings. There are similar cases: Kalinowski and Galazka[24] pointed out the possibility of interaction between Li^+ and the π electron system of the ligands of $[Cu(acac)_2]$ in some aprotic solvents, and Steinbach and Burns[25] found that $[M(acac)_3]$ ($M=Fe^{III}$, Al^{III}, or Cr^{III}), when recrystallized from chloroform, in corporated two solvent molecules to form the chloroformate and inferred that the hydrogen atom of chloroform was possibly attracted to the oxygens of the acetylacetonate. If the association accompanies desolvation of the cation, the stability will be determined by the balance of two antagonistic factors: the energy loss in desolvation and the energy gain in association. The former depends mainly on the cation size, and the latter on both the cation size and the density of the local negative charge on the ligand system. A high local negative charge will favor the association with a smaller cation, since the energy gain in association offsets the larger desolvation energy. When the local negative charge is low, however, the desolvation energy becomes predominant and a small cation will associate less easily. The two straight lines in Fig. 4 seem to reflect qualitatively this situation, although the examples are too few to allow a quantitative interpretation.

In connection with the present study only the effects of magnesium ion were studied, for potassium, rubidium, and caesium perchlorates were too sparingly soluble in acetonitrile. Magnesium ion does react with the complex anions. But the electrode process was complicated by rapid decomposition subsequent to the association. Besides, a small amount of water had a pronounced effect, making the situation more complicated experimentally. Some results of this study will be reported separately.

Appendix

Preparation of the Complex. *[Ru(bzfa)$_3$]*: "Hydrated ruthenium trichloride" (0.5 g, ca. 2 mmol as Ru), 0.4 g (4 mmol) of potassium hydrogencarbonate, 3.9 g (18 mmol) of Hbzfa were ground together in an agate motar. The resulting muddy solid was extracted with a few portions of carbon tetrachloride. After removal of the solvent, the residue was dissolved in ethanol, and the solution was passed through a column of Merck Alminiumoxid 90 (Aktivitätsstufe II—III). A red material obtained after removal of the solvent from the eluent was dried under vacuum at room temperature. Found: C, 49.3; H, 3.0%. Calcd for $RuC_{30}H_{18}O_6F_9$: C, 48.7; H, 2.6%.

[Ru(fac)$_3$]: A blue residue was obtained, as in the case of $[Ru(paa)_3]$, starting from 0.5 g of ruthenium(III) chloride (2.4 mmol as Ru, dissolved in 40 cm^3 of 1 mol dm^{-3} HCl); it was dissolved in 50 cm^3 of water. The pH was adjusted to about 3 with 1 mol dm^{-3} KOH solution, and then the solution was refluxed on a water bath with 5 g (33 mmol) of Hfac and 20 cm^3 of ethanol for 8 h. After being cooled, the solution was filtered, and the residue was extracted with ethanol. The ethanol solution was concentrated until small crystals began to appear on the surface. Crude $[Ru(fac)_3]$ was obtained on cooling. The product, after being washed with water, was recrystallized from ethanol and dried under a vacuum at room temperature. Found: C, 33.0; H, 2.1%. Calcd for $RuC_{15}H_{12}O_6F_9$: C, 33.8; H, 2.3%.

$[Ru(dbm)_3]$: This complex was prepared by the method of Wolf *et al.*[26] with slight modifications. $[Ru(acac)_3]$ (1.6 g, 4 mmol) and 5.4 g (24 mmol) of Hdbm were dissolved in 50 cm^3 of ethyl benzoate. The solution was refluxed at 160 °C for 12 h under nitrogen atmosphere. Then, 1.2 g of potassium hydrogencarbonate was added to the solution and the reflux was continued for 6 h. After removal of solvent, the residue was extracted with methanol. The

black crystalline material obtained by concentration of the extract was recrystallized from benzene and dried under vacuum at room temperature. Found: C, 70.6; H, 4.5%. Calcd for $RuC_{45}H_{33}O_6$: C, 70.1; H, 4.3%.

[*Ru(dpm)*$_3$]: "Hydrated ruthenium trichloride" (1.5 g, 7 mmol as Ru), 1.0 g (10 mmol) of sodium hydrogencarbonate, and 10 g (54 mmol) of Hdpm were refluxed for 6 h at 160 °C on an oil bath. An additional amount (2.0 g) of sodium hydrogencarbonate was introduced, and the reflux was continued for 18 h at 210 °C. Excess Hdpm and water were removed under reduced pressure, and the residue was extracted into carbon tetrachloride. After removal of the solvent, the residue was dissolved in benzene. This solution was passed through a column of Merck Alminiumoxid 90 (Aktivitätsstufe II—III) and the eluent was concentrated to about 5 cm^3. Acetonitrile and a small amount of water were added to the solution to precipitate the complex. Orange crystals collected by filtration were dried under vacuum. Found: C, 61.0; H, 8.6%. Calcd for $RuC_{33}H_{57}O_6$: C, 60.9; H, 8.8%.

The author wishes to express his thanks to professor Gen P. Satô and Asst. Professor Kunio Shimizu, Sophia University, for their invaluable discussions and encouragement. He thanks Hiroyuki Moriya, Yasuko Sakura, Ayako Shimazaki, and Yasushi Takeuchi for their helpful experimental assistance. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 547045 from the Ministry of Education, Science and Culture. The financial support by Saneyoshi Scholarship Foundation is gratefully acknowledged. Thanks are also due to Dr. F. Scott Howell, Sophia University, for correcting the manuscript.

Spectrophotometric Determination of Iron(II) after Extraction of Its 4′-(*p*-Methoxyphenyl)-2,2′ : 6′,2″-terpyridine Complex with Tetraphenylborate Anion into Molten Naphthalene

Jenn-Lin Lin, Lih-Fen Chang, and Masatada Satake*,†

Nat onal Taiwan College of Education, Changhwa, Taiwan, Republic of China

† *Faculty of Engineering, Fukui University, Fukui 910*

(Received February 24, 1983)

A new method is described for the extraction of ion-associated complex of iron(II) 4′-(*p*-methoxyphenyl)-2,2′ : 6′,2″-terpyridine (abbreviated as MPTP) cation with tetraphenylborate (TPB) anion into molten naphthalene. The solid mixture containing the colored complex is dissolved in *N*,*N*-dimethylformamide (DMF) and the absorbance was measured at 576 nm. The other factors such as pH, amounts of reagents and naphthalene, shaking time and diverse ions are studied. The method has been applied for the determination of iron in reference materials and practical samples and the results was compared with the conventional 2,4,6-tri(2-pyridyl)-1,3,5-triazine (TPTZ) procedure.

Extractive spectrophotometry has been widely employed for the analysis of trace amounts of metal ions. However, this method is not applicable when the solubility of metal complexes in solvents is small. By the aid of the extraction with molten naphthalene, such complexes have successfully been applied to the separation and concentration of metal ions.[1–4]

In the present paper, 4′-(*p*-methoxyphenyl)-2,2′:6′, 2″-terpyridine (MPTP) was recommended as a new extraction reagent for the spectrophotometric determination of iron(II) with naphthalene. MPTP reacts with iron(II) to form a water-soluble red complex cation.[5–7] In the presence of tetraphenylborate(TPB) anion, iron(II)–MPTP cation forms a water-insoluble, thermally stable ion-associated complex. This com plex can hardly be extracted into nonaqueous organic solvents because of the poor solubility of the complex in solvents and the incomplete phase separation, but easily extracted into molten naphthalene at temperatures above 81 °C. Compared with the ordinary solvent extraction method, the method is characterized by the greater extraction rate and the higher solubility of the complex into molten naphthalene.

Experimental

Reagents. Standard iron(III) solution, 100 ppm. Prepared by dissolving 0.8635 g of ammonium iron(III) sulfate dodecahydrate in 100 cm³ of 0.5 M (1 M = 1 mol dm⁻³) H_2SO_4 and by diluting to 500 cm³ with water.

4′-(*p*-Methoxyphenyl)-2,2′:6′,2″-terpyridine solution, 0.02%. Prepared by dissolving 0.02 g of this reagent in a few drops of concentrated hydrochloric acid and by diluting to 100 cm³ with water.

Hydroxylammonium chloride solution, 2% in water.

Sodium tetraphenylborate solution, 1% in water.

Buffer solutions were prepared by mixing 1 M acetic acid and 1 M ammonium acetate solution for pH 3—6, and 1 M aqueous ammonia and 1 M ammonium acetate solution for pH 8—11.

Naphthalene, acetone, *N*,*N*-dimethylformamide and all other reagents were of analytical-reagent grade, and used without further purification.

Apparatus. The absorbance measurements were made with a Hitachi Model 200-20 double beam spectrophotometer with 10-mm glass cells.

All the pH measurements were done with a Toa-Dempa HM-5A pH meter.

General Procedure. To about 25 cm³ of sample solution containing 1—19 μg of iron(III) in a 80-cm³ tightly stoppered Erlenmeyer flask, add 1.0 cm³ of 2% hydroxylammonium chloride solution, 2.0 cm³ of buffer solution (pH 5.0) and 3.0 cm³ of 0.02% MPTP solution. Mix the solution well and add 1.5 cm³ of 1% TPB solution. After warming on a water bath (50—60 °C) for 15 min, add 1.5 g of naphthalene and warm the mixture on a water bath at 90 °C to melt naphthalene completely. Shake it vigorously until the naphthalene solidifies forming many fine crystals. Filter the naphthalene mixture on a filter paper (No. 5A). Wash with water, blot the excess water with a dry filter paper and dry in an oven at 50—60 °C. Dissolve the naphthalene in *N*,*N*-dimethylformamide, dilute to 10 cm³, and measure the absorbance at 576 nm against a reagent blank prepared similarly.

Results and discussion

Absorption Spectra. Absorption spectrum of the ternary complex iron(II)–MPTP–TPB in naphthalene–*N*,*N*-dimethylformamide solution is shown in Fig. 1, together with that of the reagent blank. The complex has an absorption maximum at 576 nm, while the reagent blank showed no significant absorption at this wavelength.

Effect of pH. The effect of pH on the absorbance of the ternary complex was studied at 576 nm (Fig. 2). The pH of aqueous solution after extraction was measured at room temperature. The pH range 4.0—6.8 seems to be suitable for the extraction of the complex.

Effect of Hydroxylammonium Chloride Concentration. Varying volumes of 2% hydroxylammonium chloride solution were added to the sample containing 10 μg of iron(III). Iron(III) was completely reduced to iron (II) by the addition of 0.1—8 cm³ of 2% solution. Thus 1.0 cm³ of 2% solution was taken for the further work.

Effect of MPTP and TPB Concentration. Different amounts of MPTP were added to the sample containing 10 μg of iron(III). It was observed that the extraction was quantitative for 0.8—8.0 cm³ of 0.02% MPTP solution (Fig. 3). Thus 3.0 cm³ of 0.02% solution was added. Similar studies with sodium tetraphenylborate showed that the absorbance remained

constant over the range of 0.1—4.0 cm^3 of 1% TPB solution. Therefore, 1.5 cm^3 of 1% TPB solution was used.

Effect of Buffer Solution and Digestion Time. Varying volumes of buffer solution were added to the sample containing 10 μg of iron(III), other variables being kept constant. When the volumes between 1.0 and 4.0 cm^3 were added, the absorbance did not show any change. The solution containing iron(II)–MPTP–TPB complex at pH 5.0 was digested at 50—60 °C. The digestion time is not critical and only one minute was sufficient for the completion of the complex formation.

Effect of Addition of Naphthalene and of Shaking Time. The extraction of the complex into molten naphthalene was carried out by varying amounts of naphthalene from 0.5 to 3.0 g. In all cases the amount of naphthalene had no influence on the absorbance of the system. Thus 1.5 g of naphthalene was used as a

H_2edta^{2-}	6.2 μg	Co^{2+}	15 μg
		Bi^{3+}	2 μg

Iron(III): 10 μg; pH: 5.0; 0.02% MPTP: 3.0 cm^3

suitable amount. Naphthalene(1.5 g) was added to the solution containing the complex and the mixture was shaken vigorously for periods ranging 3 to 90 s. The experimental results showed that the complex is extracted quantitatively into molten naphthalene by vigorous shaking for about a few seconds. Consequently, 30 s of shaking time was selected for convenience.

Effect of Aqueous Phase Volume. Since the organic/aqueous phase ratio is important factor in such procedures, the effect of aqueous phase volume on the extraction of the complex was studied. The extraction was quantitative when the volume of aqueous phase did not exceed 70 cm^3. Above this volume of aqueous phase the extractability decreased gradually.

Effect of Standing Time. The mixture of the ternary complex and naphthalene was dissolved in *N*, *N*-dimethylformamide, and the effect of standing time on the absorbance was examined between 1 and 20 h. It was observed that the absorbance remained constant for these periods. Consequently, 20 min of standing time was selected for all absorbance measurements.

Calibration Curve. The absorbances for varying concentration of iron(III) were measured at 576 nm against a reagent blank under the optimum conditions

Table 2. Analysis of iron in metals

Sample	Composition of alloy (%)	Iron, certified value/%	Iron content[a]/%	
			Present method	TPTZ method
N.B.S. SRM-85b Al alloy	Cu: 3.99, Cr: 0.21 Mn: 0.61, Ni: 0.089 Si: 0.18, Ti: 0.022 Zn: 0.03, Ga: 0.019 V: 0.006, Pb: 0.021	0.24	0.242±0.003	0.253±0.002

a) Average of five determinations.

described above. The results followed Beer's law over the concentration range of 1—19 μg of iron(III) in 10 cm^3 of *N,N*-dimethylformamide. The molar absorptivity of the complex was calculated to be 2.9×10^4 $dm^3\ mol^{-1}\ cm^{-1}$, and the sensitivity was 0.00192 μg of iron(III) per cm^3 for 0.001 absorbance. Ten determinations of a sample containing 10 μg of iron(III) gave a mean absorbance of 0.522 with relative standard deviation of 1.34%.

Choice of Solvent. Various organic solvents were tested to dissolve the extracted mixture of the complex and naphthalene. The mixture is soluble in *N,N*-dimethylformamide, dimethyl sulfoxide, propylene carbonate and acetonitrile. *N,N*-dimethylformamide is sensitive and cheaper than other solvents mentioned above.

Effect of Diverse Ions. Various amounts of diverse ions were added to the sample containing 10 μg of iron(III). The tolerance limit (Table 1) was listed at the amounts required to cause 5% error. Among anions examined, only Na_2H_2 edta interfered even at the concentration equivalent to that of iron(III). The cations Bi^+ and Co^{2+} interfered seriously.

Iron Analysis in Reference Materials and Metallic Samples. This method has been successfully employed for the analysis of iron in reference materials and other metallic samples. The results are in reasonably good agreement with those obtained by the conventional spectrophotometric method employing 2, 4,6-tri(2-pyridyl)-1,3,5-triazine(TPTZ)[8–10], as shown in Table 2. The analytical procedures were as follows: a 1 g portion of reference aluminum alloy(N.B.S., SRM-85b) was gently dissolved in 40 cm^3 of hydrochloric acid(1+1) and 2 cm^3 of 30% hydrogen peroxide. The excess of hydrogen peroxide was decomposed by heating the mixture gently on a boiling-water bath. After cooling, the volume of the sample was adjusted to 500 cm^3 with water. A 2 cm^3 aliquot was transferred to a 100 cm^3 separatory funnel, and 40 cm^3 of hydrochloric acid (1+1) was added. The iron(III) in this sample was extracted by vigorous shaking for 5 min with 20 cm^3 of isobutyl methyl ketone(MIBK).[11] The iron(III) was then back-extracted from the organic phase with 25 cm^3 of water, and the proposed method and TPTZ procedure were applied.

A 100 mg portion of reference silicon bronze alloy (N.B.S., SRM-158a) was dissolved in the mixed solution of 10 cm^3 of hydrochloric acid(1+1), 1 cm^3 of concentrated nitric acid and 3 cm^3 of concentrated sulfuric acid. The mixture was gently heated on a boiling-water bath. The excess of the acids was evaporated and then the solution was diluted to 1000 cm^3 with water. This solution was used for both methods.

Metallic magnesium powder (10 g) and aluminum powder(2 g) were analyzed in the same way as in the case of the aluminum alloy.

In the present study, the extraction of the ternary complex into molten naphthalene is easily attained merely by contact with molten naphthalene or by vigorous shaking for a few seconds. Since a small amount (1.5 g) of organic phase (naphthalene) is required for the complete extraction of the complex, the method is useful for the concentration of trace iron ion from a large volume of aqueous solution, and proved to be more excellent in the sensitivity snd precision than the MPTP procedure[5–7] in aqueous medium.

(Received March 19, 1983)

The crystal and molecular structure of the diastereoisomeric salt, $(-)_{589}$-*trans*-$[Co(NCS)_2(trien)][Sb_2((+)\text{-tart})((+)\text{-tartH})]\cdot 4H_2O$, has been determined by the X-ray diffraction method. The red crystals were monoclinic, with the space group $P2_1$, $a=8.987(1)$, $b=15.949(2)$, $c=10.726(1)$ Å, $\beta=102.57(2)°$, and $Z=2$. The structure was solved by the heavy-atom method and refined by the block-diagonal least-squares method, using 2976 independent reflections, to the final R-value of 0.033. In the complex cation, the conformations of the three five-membered chelate rings are ($\delta\lambda\delta$), while the absolute configurations of the two asymmetric nitrogen atoms are both *S*. The mononegative anion has a dimeric structure of $[Sb_2((+)\text{-}C_4H_2O_6)((+)\text{-}C_4H_3O_6)]^-$, in which $(+)\text{-}C_4H_2O_6^{4-}$ and $(+)\text{-}C_4H_3O_6^{3-}$ coordinate to two Sb^{III} atoms. The extra hydrogen atom in $(+)\text{-}C_4H_3O_6^{3-}$ bonds to the free oxygen atom(OTB5) of the carboxylato group, and a short contact is formed between this oxygen atom and a water molecule(OW2); OTB5···OW2 2.43(1) Å. Though six N-H hydrogen atoms are present in the complex cation, three of them form N-H···O hydrogen bonds to the oxygen atoms of the dimeric anion; NTR3···OTA1 2.86(1), NTR4···OTA6 2.86(1), and NTR1···OTB4 3.19(1) Å.

Potassium bis(μ-(+)-tartrato(4−))diantimonate(III), tartar emetic, is a familiar resolving reagent for metal complexes.[1] From the X-ray structure analyses, the presence of a unique dinegative dimeric structure in which two tetranegative (*R*,*R*)-tartrate anions, $(C_4H_2O_6)^{4-}$ abbreviated (+)-tart, coordinate to two Sb^{III} atoms was proved.[2] Recently, *trans*-$[Co(NCS)_2(trien)]^+$ complexes were newly prepared and resolved by using this anion.[3] Under acidic conditions, red crystals of the optically active diastereoisomeric salt with the chemical formula of $[Co(NCS)_2(trien)][Sb_2((+)\text{-tart})((+)\text{-tartH})]\cdot 4H_2O$ were precipitated.[4] Since the ratio of cation *vs.* anion in this crystal is 1:1, the presence of a mononegative bis(μ-(+)-tartrato)diantimonate (III) anion is strongly suggested.

As a part of our structural studies of optical resolution, we recently determined several diastereoisomeric salts including the mononegative hydrogen (+)-tartrate anion, $d\text{-}C_4H_5O_6^-$, as the resolving reagent,[5] and compared their structures with those found in the diastereoisomeric salts with the dinegative (+)-tartrate anion, $d\text{-}C_4H_4O_6^{2-}$.[6] Thus, in order to determine the molecular structure of the mononegative bis(μ-(+)-tartrato)diantimonate(III) anion and the absolute configuration of $(-)_{589}$-*trans*-$[Co(NCS)_2(trien)]^+$ and in order to compare the crystal-packing mode with those found in diastereoisomeric salts including the $[Sb_2((+)\text{-tart})_2]^{2-}$ anion, we have undertaken the single-crystal X-ray structure analysis of the title compound.

Experimental

Preparation of Compound. Racemic *trans-RR,SS*-$[Co(NCS)_2(trien)]ClO_4$ was prepared by the method given in the literature.[3] The less-soluble diastereoisomeric salt, $(-)_{589}$-*trans*-$[Co(NCS)_2(trien)][Sb_2((+)\text{-tart})((+)\text{-tartH})]\cdot 4H_2O$, was prepared by the following procedure.[4] A solution of racemic *trans-RR,SS*-$[Co(NCS)_2(trien)]ClO_4$ (3×10^{-3} mol) was adsorbed on a column of SP-Sephadex C-25 (the total exchange capacity: 2.7 mequiv) and then eluted with an aqeous solution of $Ca[Sb_2((+)\text{-tart})_2]$ (1.3×10^{-3} mol). The eluent was concentrated to about 10 ml, and the diastereoisomeric salt was precipitated by the addition of 1.3 ml of 1 M HCl (1 M = 1 mol dm^{-3}). When the red precipitate thus obtained was recrystallized from a hot aqueous solution, red rectangular crystals were deposited. Found: C, 20.82; H, 3.42; N, 9.05%. Calcd for $C_{16}H_{31}O_{16}N_6S_2CoSb_2$: C, 20.66; H, 3.36; N, 9.04%.

Crystallographic Data Collection. The intensities and cell dimensions were measured on a SYNTEX-R3 diffractometer with Mo $K\alpha$ radiation ($\lambda=0.7107$ Å), monochromated by a graphite plate. The size of the crystal used for the X-ray measurement was $0.22\times0.20\times0.18$ mm^3. The systematic absences for $0k0$ ($k=2n+1$) suggested $P2_1$ or $P2_1/m$ as the possible space groups, but the latter was eliminated because of the optical activity of the compound. The unit cell dimensions were refined by a least-squares treatment of the setting angles of 25 reflections. The crystal data were as follows: monoclinic, space group $P2_1$, $a=8.987(1)$, $b=15.949(2)$, $c=10.726(1)$ Å, $\beta=102.57(2)°$, $D_m=2.04$ g cm^{-3} (by flotation in a chloroform-bromoform mixture), $Z=2$, and $D_c=2.06$ g cm^{-3}. The intensity data were collected in the ω-scan mode up to $2\theta=55°$. Of the 3128 unique observed reflections, 2976 reflections with $|F_o|>3\sigma(F_o)$ were used for the structure determination. Corrections for absorption effect were neglected (μ(Mo $K\alpha$) = 25.9 cm^{-1}).

Determination and Refinement of Crystal Structure. The coordinates of the Sb and Co atoms could be deduced from a Patterson map. The positions of the other lighter atoms, except for the hydrogen atoms, were revealed by the Fourier synthesis. Several cycles of the block-diagonal least-squares refinement with anisotropic temperature factors reduced the R-value ($R=\{\Sigma(|F_o|-|F_c|)/\Sigma|F_o|\}$) to 0.050. At this stage, a difference map was examined for the hydrogen-atom positions with reference to the calculated ones (1.0 Å for N-H and C-H bond distances and tetrahedral angle). There were clear indications for most of the hydrogen atoms. The final refinement including these H atoms with isotropic temperature factors caused the R-

value to converge to 0.033. In the refinement, the quantity minimized was $w(|F_o|-k|F_c|)^2$. The weighting scheme used was $w=(\sigma_{cs}^2+a|F_o|+b|F_o|^2)^{-1}$, where σ_{cs} is the standard deviation obtained from the counting statistics for each reflection; the a and b values were 0.2 and 0.0009 respectively.

All the atomic scattering factors, with corrections for the anomalous dispersion of Sb, Co, and S atoms, were taken from the International Tables for X-ray Crystallography, Vol. IV.[7] All the computations were carried out by a HITAC M-180 computer at the Hiroshima University Information Processing Center. The computer programs used were FOURP21[8] and HBLS-IV, with a slight modification.[9] An ORTEP drawing was carried out by the use of a computer system, XTL, in a SYNTEX-R3 diffractometer.[10] The final atomic parameters are listed in Table 1. The anisotropic thermal parameters and complete lists of the $|F_o|$ and $|F_c|$ values have been preserved by the Chemical Society of Japan (Document No. 8337).

Results and Discussion

The projections of the crystal structure along the a- and b-axes are shown in Figs. 1 and 2 respectively. The thermal ellipsoids in these figures are illustrated with a 50% probability.

Cation Geometry. Figure 3 shows a perspective drawing of the complex cation, which has an approximate two-fold axis through the midpoint of the CTR3-CTR4 bond and the central Co atom. The absolute structure of the crystal could be deduced, since the absolute configuration of (*R,R*)-tartrate was known.[11] Figure. 3 represents the absolute configuration of the complex cation correctly. The conformations of the three chelate rings of the triethylenetetramine ligand are of a $\delta\lambda\delta$ form, and the absolute configurations of the two asymmetric nitrogen atoms, NTR2 and NTR3, are both *S*.[12] Thus, the absolute configuration of the present $(-)_{589}$-*trans*-[Co(NCS)$_2$(trien)]$^+$ can be denoted as *trans-SS*-$\delta\lambda\delta$.

The bond lengths and angles within the complex cation are listed in Table 2. The Co–N(NCS) distances are 1.901(7) and 1.884(7) Å, while the Co–N–C angles are 162.0(7) and 161.4(7)°. The bond distances of the Co–N(trien) are 1.964(8) and 1.961(7) Å for the

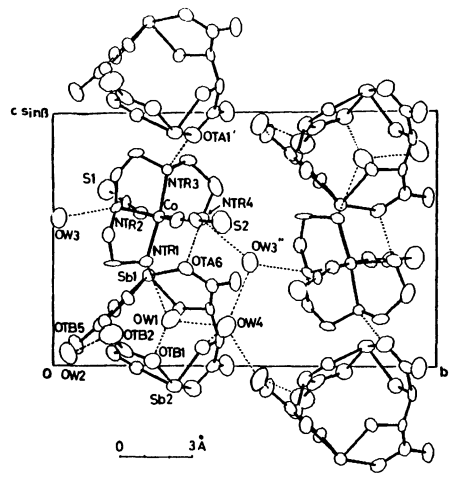

Fig. 1. A perspective drawing of the contents of the unit cell viewed down the a-axis. Possible hydrogen bonds are indicated by bloken lines. Hydrogen atoms are omitted for clarity.

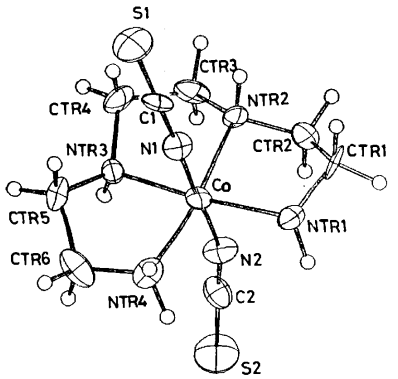

Fig. 3. An ORTEP drawing of the complex cation. All atoms are drawn with the 50% probability ellipsoids.

terminal nitrogen atoms and 1.923(7) and 1.927(6) Å for the middle nitrogen atoms respectively. The N–Co–N angles of the outer chelate rings are 86.0(3) and 86.0(3)°, while that of the central one is 86.8(3)°. These values are in good agreement with the values obtained for *trans-meso*-$[Co(CN)_2(trien)]ClO_4$.[13]

The two outer chelate rings have an unsymmetrical envelope conformation. The ring carbon atoms, CTR1 and CTR2, lie at -0.105 and -0.736 Å from the plane formed by NTR1, Co, and NTR2. The corresponding deviations of CTR5 and CTR6 from the plane of NTR3, Co, and NTR4 are 0.677 and 0.034 Å respectively. In the central chelate ring, CTR3 and CTR4 lie 0.347 below and 0.386 Å above the plane of NTR2, Co, and NTR3. These values are in good agreement with the values obtained for $(-)_{589}$-*trans*-$[Co(NO_2)_2$(L-3,8-dimetrien)$]ClO_4$.[14]

Anion Geometry. Figure 4 shows a perspective drawing of the dimeric anion with the water molecule OW2. The geometry of the mononegative dimeric anion, whose interatomic distances and angles are listed in Table 2, resembles the structure found for a number of dinegative bis(μ-(+)-tartrato(4−))-diantimonate(III).[2] The coordination geometry is pseudotrigonal bipyramidal, with average axial and equatrial angles of 150.8(2) and 99.3(2)° respectively

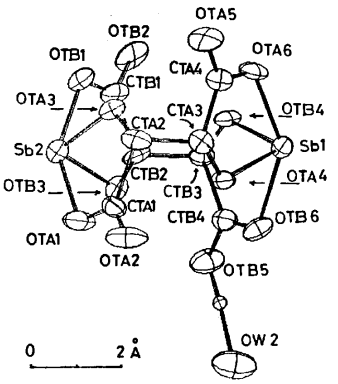

Fig. 4. Structure of the mononegative dimeric anion with including the water molecule OW2.

(compared with 150(2) and 100(4)° for $[Sb_2((+)$-tart$)_2]^{2-}$).[15]

Of great interest are the bond distances and angles given in Table 2 for the (+)-$C_4H_3O_6$(TB-tart) group. Though four –COO groups are present in this anion, only one –COO group in TB-tart has a symmetrical structure; CTB4–OTB5 1.266(11) and CTB4–OTB6 1.245(10) Å and CTB3–CTB4–OTB5 118.1(7), CTB3–CTB4–OTB6 118.8(7), and OTB5–CTB4–OTB6 123.1 (8)°, respectively. The other –COO group in TB-tart and two –COO groups in TA-tart have the usual unsymmetrical form, as is summarized in Table 2; the averaged C–O distances are 1.207(12) Å for free oxygen atoms and 1.306(12) Å for oxygen atoms bonded to Sb^{III}. Additionally, the Sb1–OTB6 distance, 2.252(6) Å, is longer than the other Sb–O(–COO distance); 2.084(6), 2.111(6), and 2.171(6) Å. Moreover, a short contact is found between OTB5 and the water molecule OW2; OTB5···OW2 2.43(1) Å. Thus, we can safely conclude that the extra hydrogen atom (proton) of the (+)-$C_4H_3O_6$ group bonds to the OTB5 carboxyl oxygen atom. It is noteworthy that the present short O(–COOH)···O(H_2O) contact, 2.43 Å, is nearly equal to the O(H_2O)···H···O(H_2O) 2.431 Å in $(H_5O_2)^+$ included in *trans*-$[CoCl_2(en)_2]Cl\cdot(H_5O_2)\cdot Cl$[16] and to the O(–COOH)···O(OOC–) 2.44 Å observed in $(+)_{589}$-[Co(ox)(en)$_2$]H-*d*-tart$\cdot H_2O$.[17]

Tapscott *et al.* recently determined the crystal structure of sodium hydrogen bis(μ-*meso*-tartrato)-bis(2,2′-bipyridyl) dichromate(III) heptahydrate.[18] They found that this mononegative Cr^{III} complex anion has a dimeric structure and that the extra hydrogen atom (proton) bridges the gap between the two hydroxyl oxygen atoms which belong to the *meso*-tartrate groups within the dimeric unit. This marked difference in the position of the extra hydrogen atom(proton) between the Sb^{III} and the Cr^{III} mononegative dimeric anions probably comes from the different structural features of these anions. The former, the present Sb^{III} complex anion, has two (+)-tartrate anions in the trigonal bipyramidal configuration, but the latter, the Cr^{III} complex, has two *meso*-tartrate anions in the distorted octahedral configuration. The O(hydroxyl)···O(hydroxyl) interatomic distances of the former, OTA3··· OTB3 2.986(8) and OTA4···OTB4 3.026(8) Å, are considerably longer than that in the latter, O(hydroxyl)···

O(hydroxyl) 2.418(6) Å.[18]

The relevant least-squares planes are listed in Table 3. The two planes of the C–C–C–C skeletons of TA-tart and TB-tart are quite parallel. The planes including five non-hydrogen atoms of each α-hydroxycarboxylate moiety are approximately coplanar. The angles between the two planes, 66.5° for TA-tart and 69.0° for TB-tart, are normal.[2]

Crystal-packing Mode and Waters of Crystallization. The packing features of the complex cations and dimeric anions are shown in Figs. 1 and 2. There are four waters of crystallization associated with the ionic species contained in the structural unit. The selected intermolecular distances, including the hydrogen-

Roman numerals as superscripts refer to the following equivalent positions, relative to the reference atom at (x, y, z): i ($-1+x$, y, z), ii ($1-x$, $-1/2+y$, $-z$), iii ($1+x$, y, z), iv ($1-x$, $-1/2+y$, $1-z$), v ($1-x$, $1/2+y$, $1-z$), vi ($1+x$, y, $1+z$), vii (x, y, $-1+z$).
D; Hydrogen donor, A; Hydrogen acceptor.

bonding modes, are summarized in Table 4.

The hydrogen-bonding features in this crystal are as follows:

(1) Along the a-axis, there are strong hydrogen bondings, OTB5···OW2···OTB2^{i}, and the dimeric anions are joined to each other by the water molecule OW2; OTB5···OW2 2.43(1) and OW2···OTB2^{i} 2.66 (1) Å. (2) Along the c-axis, there are bonds from the tartrate oxygens of (+)-$C_4H_2O_6$(TA-tart) to triethylenetetramine nitrogens, with distances of OTA6···NTR4 2.86(1) and NTR3···OTA1^{vi} 2.86(1) Å respectively. (3) Along the b-axis, near the $y=0$ and $y=1/2$ there are sheets of the waters of crystallization, as shown in Fig. 1. (4) The planes of C–C–C–C skeleton of the two (+)-tart groups(TA and TB-tart) are approximately perpendicular to the crystallographic b-axis(within 4°), and the cell length of the b-axis is probably determined by the size of the dimeric anion. (5) As a result, the *trans-SS* complex cation is surrounded by the four dimeric anions on the ac-plane, and they are piled up along the b-axis by the two-fold screw operations. The short contacts around the complex cation along the b-axis are NTR2···OW3 3.01(1) and NTR4···OW3^{v} 3.09(1) Å.

It is interesting to note that, though there are two tartrate groups in the present [Sb_2((+)-$C_4H_2O_6$)((+)-$C_4H_3O_6$)]$^-$ complex, only the (+)-$C_4H_2O_6$ group(TA-tart) has short contacts to the nitrogen atoms of the triethylenetetramine ligand. The other group, (+)-$C_4H_3O_6$ (TB-tart), has short contacts to the water molecules and forms the hydrogen-bonding chain mentioned above along the a-axis. If the absolute configurations of the two nitrogen atoms of the trien ligand (NTR2 and NTR3) change from *S* to *R*, the hydrogen-bonding modes around these nitrogen atoms change completely. Thus, the optical discrimination between the $(+)_{589}$-*RR*- and $(-)_{589}$-*SS*-*trans*-[Co(NCS)$_2$(trien)]$^+$ probably comes from the different contact modes between the (+)-$C_4H_2O_6$ (TA-tart) of the dimeric anion and the corresponding optically active complex cations.

In contrast, in diastereoisomeric salts containing [Sb_2((+)-tart)$_2$]$^{2-}$ as the resolving reagent, for example *cis*-[Co(NCS)$_2$(tn)$_2$]$_2$[Sb_2((+)-tart)$_2$]·$2H_2O$ and its Cr^{III} analogue, the dimeric anions lie exactly on a crystallographic two-fold axis and the two (+)-tart groups are equivalent.[19] In [Fe(phen)$_3$][Sb_2((+)-tart)$_2$]·$8H_2O$, the dimeric anion has a crystallographic two-fold axis again, and only the halves of the two (+)-tart groups are crystallographically independent.[20] Thus, the crystal-packing modes in these salts are different from the present one.

Another interesting point in this crystal is in the averaged O···O distances around the water molecules: 2.80 Å for OW1, 2.56 Å for OW2, 2.89 Å for OW3, and 2.76 Å for OW4. The oxygen atom (OTB5) of the (+)-$C_4H_3O_6$(TB-tart) group is linked by hydrogen bonding to OW2 with the following sequence of the water molecules, as is shown in Fig. 2: OTB5···OW2···OW4···OW1 or ···OW3. The averaged distances around the water molecules reflect the positive charges which spread from the OTB5 to the water molecules through the hydrogen bodings: these results confirm the presence of an extra hydrogen atom(proton) between the OTB5 and water molecule OW2.

Thiolate-bridged Metal Complexes. Nickel(II), Palladium(II), and Cobalt(III) Binuclear Complexes of 1,5-Diamino-3-pentanethiol

Ichiro MURASE*, Shigehiro UENO,† and Sigeo KIDA†

Laboratory of Chemistry, College of General Education, Kyushu University, 01, Chuo-ku, Fukuoka 810

† *Department of Chemistry, Faculty of Science, Kyushu University, 33, Hakozaki, Higashi-ku, Fukuoka 812*

(Received April 16, 1983)

A binucleating ligand with thiolate sulfur as a bridging atom, 1,5-diamino-3-pentanethiol (Hdpet) and its metal complexes, $Ni_2(dpet)_2X_2$ (X=Br, ClO_4, NO_3, BPh_4, and NCS) were synthesized. All the complexes are diamagnetic at room temperature. The Ni(II) and Pd(II) complexes assume binuclear thiolate-bridged square planar coordination. This structure is maintained even in aqueous solution. The electronic spectra of the Ni(II) complexes showed a band at 27.3×10^3 cm^{-1} corresponding to the 29.8×10^3 cm^{-1} band of $[Ni_2(dpl)_2]^{2+}$ which is characteristic of oxo-bridged Cu(II) and Ni(II) complexes and was assigned to the $p\pi(O)\rightarrow d\sigma$(metal) transition. Several trials by different methods only resulted in the separation of a single species of Co(III) complex, $Co_2(dpet)_3(ClO_4)_3$. This was characterized as a bioctahedron facially joined at the three thiolate sulfur atoms.

In contrast to a great number of alkoxo- and phenoxo-oxygen-bridged complexes, only few thiolate-sulfur-bridged complexes have been reported,[1] though thiolate coordination is important in bioinorganic chemistry. In this paper we report the synthesis of binucleating ligand, 1,5-diamino-3-pentanethiol (Hdpet), and its nickel(II), palladium(II), and cobalt (III) complexes. This ligand has no unsaturated bond, hence no absorption in the visible and the near-ultraviolet region ($<35\times10^3$ cm^{-1}). Thus, in the spectra of complexes with this ligand the d-d and CT bands would be easily identified in that region. This ligand is an analogue of 1,5-diamino-3-pentanol (Hdpl) whose copper(II) and nickel(II) complexes were previously reported.[2,3] The palladium(II) complex of dpl was newly prepared in this study. Thus, we can clearly see the effect of substitution of sulfur for bridging alkoxo-oxygen by comparing the properties of the dpet complexes with those of dpl analogs. The copper(II) and nickel(II) dpl complexes showed a band in the ultraviolet region which is characteristic of oxo-bridged structure and was assigned to the $p\pi$ (O)$\rightarrow d\sigma$(metal) transition.[2,4] It is interesting to see whether such a band is also observed in the dpet complexes.

Results and Discussion

$[Ni_2(dpet)_2]X_2$ (X=Br, ClO_4, NO_3, BPh_4, NCS). The elemental analysis data accord with the values calculated as the 1:1 complex for all the nickel complexes. The planar and binuclear structure as depicted in Fig. 1 was supposed for this series of complexes on the bases of the binucleating nature of the ligand and the analogy of the dpl complexes.[2,3] The square planar coordination was confirmed by the spectral and magnetic measurements; *i.e.*, all these complexes are diamagnetic at room temperature, and the electronic spectra show only one band in the visible region in solution (20.6×10^3 cm^{-1}, ε=360 in methanol) and in Nujol mull (21.1×10^3 cm^{-1} for the perchlorate). All the $[Ni_2(dpet)_2]^{2+}$ complexes except for the tetraphenylborate are soluble and stable in water forming an orange-red solution whose spectrum is almost identical with that of the methanol solution (*cf.* Figs. 2 and 3). This fact implies that the axial coordination of water molecule is very weak and the planar binuclear structure is maintained in aqueous solution.

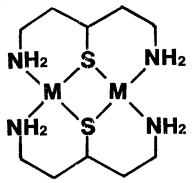

Fig. 1. $[M_2(dpet)_2]^{2+}$.

Nujol mull and powder reflectance spectra of the perchlorate, tetraphenylborate, and bromide showed the d-d band at almost the same position ((20.9—21)$\times10^3$ cm^{-1}), but in the case of the thiocyanate the d-d band shifts to 20.0×10^3 cm^{-1}. These facts imply that practically no axial coordination is present except for the thiocyanate, where a weak axial interaction with NCS^- may exist.

In the IR spectrum of $Ni_2(dpet)_2(ClO_4)_2$ there is also no indication of perchlorate coordination, either, since the splitting of the ν(Cl–O) band at about 1100 cm^{-1} is small (less than 70 cm^{-1}). The thiocyanate showed the band due to NCS^- at 2050 and 2075 cm^{-1}. This may be interpreted in terms of the assumption that one of the NCS^- ions weakly coordinates to the nickel ion while the other one is free, thus, the 2050 and 2075 cm^{-1} bands being assigned to the coordinated and the free NCS^-, respectively.[6] All these views deduced from IR data are quite consistent with those from the electronic spectra.

The band at 27.3×10^3 cm^{-1} (in methanol) should correspond to the near-ultraviolet band (29.8×10^3 cm^{-1}) of $Ni_2(dpl)_2(BPh_4)_2$ which is characteristic of alkoxo-bridged planar copper(II) and nickel(II) complexes, and was assigned to the $p\pi(O)\rightarrow d\sigma$(metal) transition.[2,4] Thus, the 27.3×10^3 cm^{-1} band is attributable to the CT transition from $p\pi$(S) to $d\sigma$(Ni). Here, it is to be noted that this is the first observation of the S→Ni CT transition which corresponds to the band characteristic of alkoxo-oxygen-bridged copper (II) and nickel(II) complexes.[4] The band at 33.2×10^3 cm^{-1} (in methanol) may be assigned to the σ(S)→$d\sigma$(Ni) transition. Similar sequence of the bands was observed for Ni_2LX_2 ($L=NH_2CH_2CH_2NH(CH_2)_nS^-$,

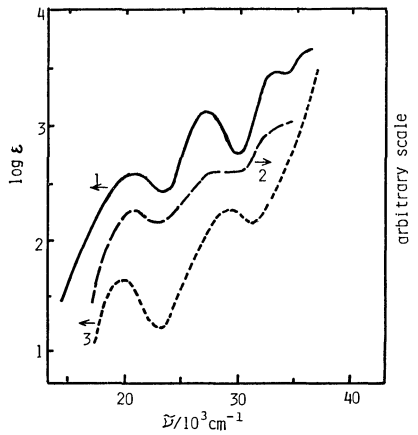

Fig. 2. Absorption spectra of $Ni_2(dpet)_2Br_2$ in methanol (1) and in Nujol mull (2), and $Ni_2(dpl)_2(Bph_4)_2$ in methanol (3).

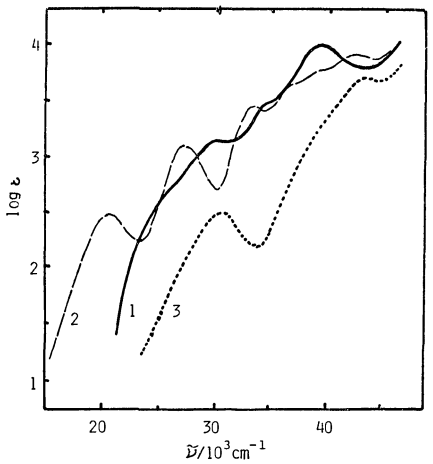

Fig. 3. Absorption spectra of $Pd_2(dpet)_2(ClO_4)_2$ (1), $Ni_2(dpet)_2(ClO_4)_2$ (2), and $Pd_2(dpl)_2(ClO_4)_2$ (3) in water.

X=Cl, Br); *e.g.*, 19.8 (ε=593), 28.2 (1510), and 32.9×10^3 cm^{-1} (5290) for n=2, X=Cl in methanol,[5] hence similar transitions can be assigned to these bands.

$Pd_2(dpet)_2(ClO_4)_2$. Infrared spectrum of this compound is nearly identical with that of the corresponding nickel analogue, indicating that the compound has a similar structure.

The electronic spectrum is, in general, much higher in intensity compared with that of $Pd_2(dpl)_2(ClO_4)_2$ and shifted to a higher frequency region compared with that of $Ni_2(dpet)_2(ClO_4)_2$ as shown in Fig. 3. The bands observed at ≈26 (shoulder), 30.3, and 35×10^3 cm^{-1} (shoulder) seem to correspond to the 20.8, 27.3, and 33.2×10^3 cm^{-1} bands of $Ni_2(dpet)_2^{2+}$ (*cf.* Fig. 3).

$Co_2(dpet)_3(ClO_4)_3$. Applying several different methods, and eluting the reaction products on a SP-Sephadex column, we have obtained only a single species of well defined cobalt(III) complex. The elemental analysis revealed that the crystals were formulated as $Co_2(dpet)_3(ClO_4)_3$. Since this compound is diamagnetic at room temperature, it is most likely to be a cobalt(III) complex. For the reasonable structure of this compound only the binuclear structure as depicted in Fig. 4 can be figured. It is to be remarked here that in the case of 1,3-diamino-2-propanethiol the mononuclear cis and trans 1:2 cobalt(III) complexes were obtained.[7]

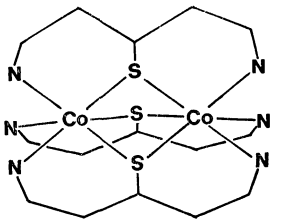

Fig. 4. The proposed structure of $[Co_2(dpet)_3]^{3+}$.

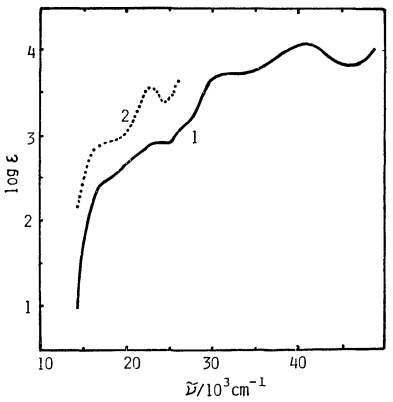

Fig. 5. Absorption spectra of $Co_2(dpet)_3(ClO_4)_3$ (1) and $[CdCo_2(mea)_6]^{2+}$ [8] (2).

The electronic spectrum of $[Co_2(dpet)_3](ClO_4)_3$ is shown in Fig. 5. This closely resembles the spectrum of $[CdCo_2(mea)_6]^{2+}$ (mea=2-aminoethanethiol) where the two *fac*-$[CoN_3S_3]$ chromophores are joined with the $[CdS_6]$ octahedron at the opposite faces.[8] The bands at 17.3×10^3 cm^{-1} (ε=280) and 23.3 (ε=791) are attributable to the spin-allowed d-d transitions, $^1A_{1g}\rightarrow{}^1T_{1g}$ and $^1A_{1g}\rightarrow{}^1T_{2g}$, respectively, in an approximation of O_h symmetry. It is known that the energy difference between the two spin-allowed bands can be a measure of the "nephelauxetic effect" of cobalt(III) complexes.[9] The value (6.3×10^3 cm^{-1}) for $[Co_2(dpet)_3]^{3+}$ is in between those for $[Co(en)_3]^{3+}$ (8.1×10^3 cm^{-1}) and $[Co(dtc)_3]$ (5.5×10^3 cm^{-1}), where dtc^- denotes diethyldithiocarbamate ion. This is consistent with the proposed structure and the assignment of the bands.

Experimental

Ligand Synthesis. 1,5-Diamino-3-pentanethiol was prepared as illustrated in the following scheme:

$$H_2NCH_2CH_2\underset{\underset{OH}{|}}{CH}CH_2CH_2NH_2\cdot2HCl \xrightarrow{HBr}$$

Hdpl

$$H_2NCH_2CH_2\underset{\underset{Br}{|}}{CH}CH_2CH_2NH_2\cdot2HBr \xrightarrow{Na_3SPO_3}$$

1

$$H_2NCH_2CH_2\underset{\underset{SPO_2H_2}{|}}{CH}CH_2CH_2NH_2 \xrightarrow[(HCl)]{H_2O}$$

2

$H_2NCH_2CH_2CHCH_2CH_2NH_2 \cdot 2HCl$
SH
3

1,5-Diamino-3-pentanol[2] (Hdpl) was converted to 3-bromo-1,5-pentanediamine (**1**) according to the standard method.[10] Conversion of (**1**) to the corresponding thiol (**3**) was best proceeded via the phosphorothioate (**2**), which was obtained by the reaction of **1** with trisodium phosphorothioate.[11]

3-Bromo-1,5-pentanediamine Dihydrobromide. A mixture of 1,5-diamino-3-pentanol dihydrochloride (50 g, 0.26 mol) and 47% hydrobromic acid (500 g, 2.9 mol) was heated in an oil bath with keeping the temperature of the bath at 145—150 °C, and 85 cm³ of hydrobromic acid was slowly distilled at bp 125 °C. The residual solution was refluxed for 1 h and then hydrobromic acid (45 cm³) was distilled off. This procedure was repeated additional two times and 37 cm³ and 28 cm³ of hydrobromic acid were recovered respectively. After refluxing the residual solution for 1 h, the bath temperature was raised to 155—160 °C and hydrobromic acid was distilled off so far as possible. In total 315 cm³ of hydrobromic acid has been recovered. The warm residue was poured into 500 cm³ of acetone and the resulting crystalline material was collected by filtration and dried in a vacuum desiccator. Crude yield was 83 g (92%). The sample was recrystallized from ethanol. Found: C, 18.00; H, 4.54; N, 8.32%. Calcd for $C_5H_{13}N_2Br \cdot 2HBr$: C, 17.51; H, 4.42; N. 8.17%.

1,5-Diaminopentane-3-phosphorothioic Acid. Trisodium phosphorothioate (21.6 g, 0.12 mol) was dissolved in 140 cm³ of water under nitrogen atmosphere at room temperature and diluted with 100 cm³ of water. To this was added 3-bromo-1,5-diaminopentane dihydrobromide (40.8 g, 0.12 mol) by portions, then *N,N*-dimethylformamide (120 cm³) was added dropwise during 30 minutes at 30 °C. The mixture was further stirred for 2 h at 30 °C and the resulting light brown solution was concentrated to a small volume under reduced pressure. Addition of ethanol (800 cm³) to the residual solution resulted white crystalline product, which was collected by filtration and washed with ethanol. The material (30 g) which contained appreciable amount of inorganic salts was used for the next reaction without purification.

1,5-Diamino-3-pentanethiol Dihydrochloride. A mixture of crude *S*-[3-amino-1-(2-aminoethyl)propyl] dihydrogenphosphorothioate (30 g) and 20% hydrochloric acid (180 g) was heated for 1 h in an oil bath at 100—110 °C under nitrogen atmosphere. The resulting clear solution was concentrated under reduced pressure and methanol (300 cm³) was added. The precipitates yielded were filtered off and the filtrate was concentrated. Acetone (500 cm³) was added to the residue and the mixture was kept in a refrigerator overnight. The crystalline powder was collected by filtration, washed with acetone, and dried under vacuum over P_2O_5. This highly hygroscopic material (18 g) contained inorganic salts, but it was used for complex synthesis without further purification. The pure sample was isolated as a tetraphenylborate which was recrystallized from methanol–water, mp 92 °C. Found: C, 80.08; H, 7.57; N, 3.49%. Calcd for $(C_5H_{16}N_2S)\ [B(C_6H_5)_4]_2 \cdot H_2O$: C, 80.29; H, 7.39; N, 3.53%.

Complex Synthesis. *$Ni_2(dpet)_2(ClO_4)_2$*: Crude 1,5-diamino-3-pentanethiol (Hdpet·2HCl, 0.8 g, ≈4 mmol) and nickel(II) perchlorate hexahydrate (1.5 g, 4 mmol) were dissolved in 20 cm³ of water and the pH of the solution was adjusted to ≈9 by the addition of triethylamine. The resulting deep red solution was heated on a water bath for ten minutes and undissolved material was filtered off. Addition of excess sodium perchlorate to the filtrate resulted orange-red crystals, which were collected by filtration, washed with methanol, recrystallized from water, and dried over P_2O_5 under vacuum at room temperature. Found: C, 20.55; H, 4.59; N, 9.57; Ni, 19.9%. Calcd for $Ni_2(C_5H_{13}N_2S)_2$: C, 20.61; H, 4.50; N, 9.61; Ni, 20.1%.

The bromide, thiocyanate, nitrate, and tetraphenylborate were also obtained from a warm concentrated aqueous solution of the perchlorate (above) by adding a sodium salt of the corresponding anion in excess and cooling to room temperature. The tetraphenylborate complex was recrystallized from acetone–methanol mixture and others were done from water and all dried over P_2O_5 under vacuum at room temperature.

$Ni_2(dpet)_2Br_2$: C, 21.99; H, 4.86; N, 10.18; Ni, 21.3%. Calcd for $Ni_2(C_5H_{13}N_2S)_2Br_2$: C, 22.09; H, 4.81; N, 10.30; Ni, 21.6%.

$Ni_2(dpet)_2(NCS)_2$: C, 28.82; H, 5.33; N, 16.72; Ni, 23.4%. Calcd for $Ni_2(C_5H_{13}N_2S)_2(SCN)_2$: C, 28.82; H, 5.24; N, 16.81; Ni, 23.5%.

$Ni_2(dpet)_2(NO_3)_2$: C, 23.71; H, 5.22; N, 16.43; Ni, 23.3%. Calcd for $Ni_2(C_5H_{13}N_2S)_2(NO_3)_2$: C, 23.65; H, 5.16; N, 16.55; Ni, 23.1%.

$Ni_2(dpet)_2(BPh_4)_2 \cdot C_2H_5OH$: C, 67.31; H, 6.70; N, 5.16%. Calcd for $Ni_2(C_5H_{13}N_2S)_2(C_{24}H_{20}B)_2 \cdot C_2H_6O$: C, 67.45; H, 6.79; N, 5.24%.

$Pd_2(dpet)_2(ClO_4)_2$ Potassium tetrachloropalladate(II) (0.48 g, 1.5 mmol) in 10 cm³ of water was mixed with Hdpet·2HCl (0.3 g, ≈1.5 mmol) in 10 cm³ of water and the pH of the mixture was brought to ≈9 by the addition of triethylamine at room temperature. The resulting yellow-orange precipitates were filtered off, and an excess of sodium perchlorate was added to the filtrate. The complex was obtained as pale yellow crystals, which were recrystalized from water. Found: C, 17.45; H, 3.77; N, 8.18%. Calcd for $Pd_2(C_5H_{13}N_2S_2)_2(ClO_4)_2$: C, 17.71; H, 3.86; N, 8.26%.

$Co_2(dpet)_3(ClO_4)_3$. A mixture of Hdpet·2HCl (0.6 g, ≈3 mmol) aud trisodium tricarbonatocobaltate(III) trihydrate (0.8 g, 2 mmol) in 10 cm³ of water was heated at 70 °C for ten minutes. The initial green solution turned deep red-brown with evolution of CO_2. The solution was cooled to room temperature, filtered, and an excess of sodium perchlorate was added to the warmed filtrate. Deep red crystals which were deposited on cooling was recrystallized from water, and dried over P_2O_5 under vacuum. Found: C, 22.09; H, 4.81; N, 10.29; Co, 14.6%. Calcd for $Co_2(C_5H_{13}N_2S)_3(ClO_4)_3$: C, 22.08; H, 4.82; N, 10.30; Co, 14.4%.

$Pd_2(dpl)_2(ClO_4)_2$. To a mixture of potassium tetrachloropalladate(II) (0.9 g, 2.7 mmol) and 1,5-diamino-3-pentanol dihydrochloride (Hdpl·2HCl, 0.5 g, 2.7 mmol) in 40 cm³ of water was added sodium carbonate (0.84 g, 8.1 mmol) by portions. The mixture was heated on a water bath until the resulting precipitates were dissolved to give a yellow solution. The hot solution was filtered and an excess of sodium perchlorate was added to the filtrate. The pale yellow precipitates were collected by filtration, washed with methanol, and recrystallized from water. Found: C, 18.65; H, 4.07; N, 8.57%. Calcd for $Pd_2(C_5H_{13}N_2O)_2(ClO_4)_2$: C, 18.59; H, 4.06; N, 8.67%.

The reaction of Hdpet·2HCl with copper(II) ion resulted in ligand oxidation, and any kind of copper complex could not be obtained so far.

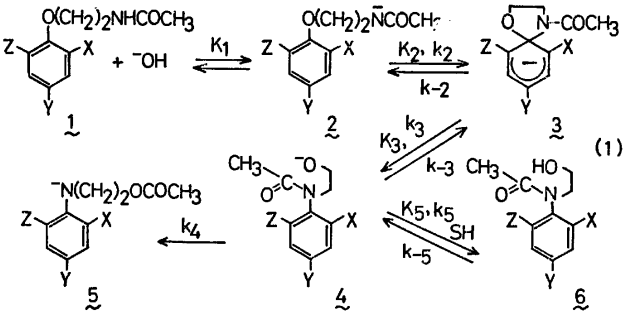
† *Department of Industrial Chemistry, Miyazaki University, 1-1-1 Kirishima, Miyazaki, Miyazaki 880*

(Received September 30, 1982)

The kinetics of the reactions of 2-(acetylamino)ethyl 2,6-dinitrophenyl ether (Smiles rearrangement) and *N*-acetyl-*N*-(2-hydroxyethyl)-2,6-dinitroaniline with sodium isopropoxide in the DMSO-2-propanol mixture (20 : 80 v/v) was studied. Both reactions were found to rapidly produce the same spiro anionic σ complex, giving *N*-(2-acetoxyethyl)-2,6-dinitroaniline. Although the rates for formation of the complex were different in both reactions, the rates for rearrangement were the same.

Previously we reported the OH^--catalyzed Smiles rearrangement of 2-(acetylamino)ethyl 2-X-4-nitrophenyl ether (**1a** X=Y=NO_2, Z=H; **1b** X=Br, Y=NO_2, Z=H; **1c** X=CN, Y=NO_2, Z=H), where the process **1**⇄**2**⇄**3** was very fast and the one **3**⇄**4**→**5** relatively slow (Scheme 1).[2-5]



Scheme 1.

Hence, the former process (hereafter called Stage I) can be followed by stopped-flow technique, whereas the latter (hereafter called Stage II) can be done by usual spectrophotometry.

As shown in previous work,[1] no information on the K_3 and K_5 processes was obtained in the kinetics of rearrangement of **1**.[3,5]

Although the kinetics of the reaction of **6** with bases should give such detailed information, the synthesis of **6a**, **6b**, and **6c** has been unsuccessful. More recently *N*-acetyl-*N*-(2-hydroxyethyl)-2,6-dinitroaniline [**6d** (X=Z=NO_2; Y=H)] has been synthesized.[1]

As the UV-VIS and NMR time-dependent spectra of the base-catalyzed rearrangements of 2-(acetylamino)ethyl 2,6-dinitrophenyl ether (**1d**, X=Z=NO_2, Y=H) and **6d** showed the reaction path shown in Scheme 1,[1] this paper reports the kinetics of the reactions of **1d** and **6d** with $NaOCH(CH_3)_2$ in the DMSO–2-propanol mixture (20:80 v/v) in order to elucidate the detailed reaction processes.

Results

*Stage I. Rearrangement of 2-(Acetylamino)ethyl 2,6-Dinitrophenyl Ether (**1d**)*: In carrying out the kinetic measurement of Stage I, one can neglect Stage II reaction. Accordingly, in the presence of excess $NaOCH(CH_3)_2$ the apparent first-order rate constant

(k_ψ^o) for formation of **3d** is expressed in Eq. 2. If K_1[$NaOCH(CH_3)_2$]≪1, Eq. 3 is derived. Table 1

$$k_\psi^o = k_{-2} + \frac{k_2K_1[NaOCH(CH_3)_2]}{1+K_1[NaOCH(CH_3)_2]} \quad (2)$$

$$k_\psi^o = k_{-2} + k_2K_1[NaOCH(CH_3)_2] \quad (3)$$

shows the dependence of k_ψ^o on [$NaOCH(CH_3)_2$], which is illustrated in Fig. 1. The results in Fig. 1 are compatible with Eq. 3. As a result, the k_{-2} and k_2K_1 values can be estimated from the intercept and slope in the linear plots, respectively (Table 3).

*Rearrangement of N-Acetyl-N-(2-hydroxyethyl)-2,6-dinitroaniline (**6d**)*: In the reaction of **6d** with $NaOCH(CH_3)_2$ the fast process **6d**⇄**4d**⇄**3d** occurs first, followed by the comparatively slow one **3d**⇄**4d**⇄**5d**.[1] Accordingly the similar kinetic procedure applies aptly

a) $[\mathbf{6d}]_0$ 3.71×10^{-5} M; μ 0.04 M ($NaClO_4$). b) Measured at 580 nm (λ_{max} for **3d**) with a stopped-flow method.

in this case, too. As a result, the following expression can be derived as to the apparent first-order rate constant (k_ψ^N) for formation of **3d** in the presence of excess $NaOCH(CH_3)_2$ (note the relationship between the directions of reactions and rate or equilibrium constants).

$$k_\psi^N = k_3 + \frac{\frac{k_{-3}}{K_5}[NaOCH(CH_3)_2]}{1+\frac{1}{K_5}[NaOCH(CH_3)_2]} \quad (4)$$

Therefore, the plot of k_ψ^N against $[NaOCH(CH_3)_2]$ would show the curvilinear dependence asymptotically approaching the fixed value unless $[NaOCH(CH_3)_2]/K_5 \gg 1$. If $[NaOCH(CH_3)_2]/K_5 \ll 1$, however, the linear dependence should be obtained (Eq. 5). Table 2

$$k_\psi^N = k_3 + \frac{k_{-3}}{K_5}[NaOCH(CH_3)_2] \quad (5)$$

shows the linear dependence of k_ψ^N on $[NaOCH(CH_3)_2]$ (not shown), giving the k_3 and k_{-3}/K_5 values from the intercept and slope in the linear plots (Table 3).

Table 3 shows the temperature dependence of k_2K_1, k_{-2}, $k_{-3}K_5^{-1}$, k_3, $K_3^{-1}K_5^{-1}$ for formation and decomposition of **3d**. Comparison of k_{-2} with k_3 shows that **3d** proceeds to **4d** faster than reverts to **2d**, which is compatible with the fact that alkoxyl groups of activated aromatics are easily displaced with amines.[6-8]

*Stage II. Rearrangement of 2-(Acetylamino)ethyl 2,6-Dinitrophenyl Ether (**1d**)*: In treatment of the kinetics of Stage II, Stage I reaction can be regarded as a fast mobile equilibrium lying almost entirely on the right (Table 3). Accordingly, as to the rate of Stage II reaction (k_{obsd}^o apparent first-order rate constant for rearrangement of **1d**) the following expression is obtained in the presence of excess $NaOCH(CH_3)_2$, provided that the k_4 stage is rate-determining and the K_5 and K_3 stages are fast mobile equilibria (Table 4).

$$k_{obsd}^o = \frac{k_4K_1K_2K_3[NaOCH(CH_3)_2]}{\left(1+K_1K_2K_3K_5+(K_1+K_1K_2+K_1K_2K_3)[NaOCH(CH_3)_2]\right)} \quad (6)$$

Although the relationship between k_{obsd}^o and $[NaOCH(CH_3)_2]$ is curvilinear (asymptotically approaching the fixed value), Eq. 7 would hold, if $(K_1+K_1K_2+K_1K_2K_3)\times[NaOCH(CH_3)_2] \gg 1+K_1K_2K_3K_5$. Therefore, k_{obsd}^o is independent of $[NaOCH(CH_3)_2]$ (Fig. 2). The re-

sults in Table 4 are compatible with Eq. 7.

$$k^O_{obsd} = \frac{k_4K_2K_3}{1+K_2+K_2K_3} \quad (7)$$

Rearrangement of N-*Acetyl*-N-*(2-hydroxyethyl)-2,6-dinitroaniline (6d)*: In the rearrangement of **6d**, the process **6d**⇄**4d**⇄**3d** is very fast, and the one **3d**⇄**4d**→**5d** relatively slow.[1] Therefore, in the kinetics of Stage II the K_3 and K_5 stages can be regarded as fast mobile equilibria. Accordingly, as to the rate of Stage II (k^N_{obsd} apparent first-order rate constant for rearrangement of **6d**) Eq. 8 is obtained in the presence of excess

	22.8	10.8
	38.6	11.3

a) $[\mathbf{6d}]_0$ 1.32×10^{-5} M; μ 0.04 M ($NaClO_4$). b) Estimated limit of error ±1.5%; measured at 580 nm (λ_{max} for **3d**).

$$k^N_{obsd} = \frac{\frac{k_4}{K_5}[\mathrm{NaOCH(CH_3)_2}]}{1+\frac{1}{K_5}\left(1+\frac{1}{K_3}\right)[\mathrm{NaOCH(CH_3)_2}]} \quad (8)$$

NaOCH$(CH_3)_2$, indicating the curvilinear dependence of k^N_{obsd} on [NaOCH$(CH_3)_2$] (asymptotically approaching the fixed value). Under the condition $1/K_5(1+1/K_3)$[NaOCH$(CH_3)_2$]$\gg$1, Eq. 9 is obtained, indicating that k^N_{obsd} is independent of [NaOCH$(CH_3)_2$]. Equation 9 is compatible with the results in Table 5.

$$k^N_{obsd} = \frac{k_4K_3}{1+K_3} \quad (9)$$

Most interestingly the k^N_{obsd} values are nearly equal to the k^O_{obsd} ones at each [NaOCH$(CH_3)_2$] (Fig. 2), which shows that either **1d** or **6d** is catalyzed with [NaOCH-$(CH_3)_2$] to substantially change into **3d** at first, and then undergoes the rearrangement, giving **5d**.

Discussion

Stage I. With **1d** and **6d** the k_2, K_1, k_{-3}, and K_5 values can not be estimated separately from Eqs. 3 and 5. With **6d**, however, the k_3, k_{-3}, and K_5 values at 15 °C could be determined as follows: when the rate measurement was carried out at higher [NaOCH-$(CH_3)_2$], the relationship between k^N_ϕ and [NaOCH-$(CH_3)_2$] was found to be curvilinear (asymptotically approaching the fixed value), in which the different ionic strengths did not affect the rate (Fig. 3). The result is compatible with Eq. 4. If the k_3 value (7.86 s^{-1}) can be obtained by extrapolation of [NaOCH-$(CH_3)_2$]→0 in Eq. 4, one can derive the following

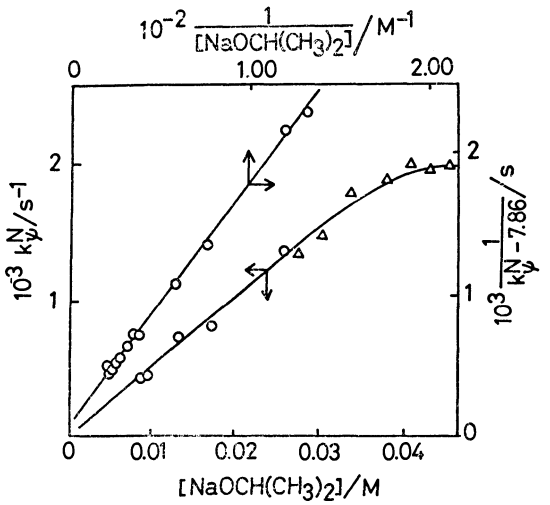

Fig. 3. Relationships between k_ψ^N and $[NaOCH(CH_3)_2]$ and between $1/(k_\psi^N-7.86)$ between $1/[NaOCH(CH_3)_2]$ in the reaction of *N*-acetyl-*N*-(2-hydroxyethyl-2,6-dinitroaniline (**6d**) with $NaOCH(CH_3)_2$ in the DMSO-2-propanol mixture (80:20 v/v at 15 °C): ○ at μ=0.04 M ($NaClO_4$); △ at μ=0.05 M ($NaClO_4$); $[\mathbf{6d}]_0$ 3.71×10^{-5} M.

equation (Eq. 10) by substituting this value into Eq. 4 and rearranging. Thus, k_{-3} and K_5 can be obtained from the slope and intercept in the plot of $1/(k_\psi^N-7.86)$ against $[NaOCH(CH_3)_2]$. The k_{-3}, K_5^{-1} (equilibrium constant for **6d**⇄**4d**), and K_3^{-1} (equilibrium constant for **4d**⇄**3d**) values were found to be 1.82×10^4 s^{-1}, 3.1 M^{-1}, and 2.3×10^3, respectively (all the values are average ones). As a result, the $K_3^{-1}K_5^{-1}$ value is calculated by using these values to be $7.1_3\times10^3$ M^{-1}, which is fairly in agreement with the value (7.2×10^3 M^{-1}) shown in Table 3. Furthermore, the K_5 value (0.32 M) is considered to be reasonable, compared with those by Hine and Hine[9] and Bowden,[10] although the solvents used are different. From these values, the equilibrium **3d**⇄**4d** lies almost on the side of **3d**, indicating that such anionic σ complexes as **3d** having activating substituents at 2- and 6-positions are extermely stable.[2-5,11,12] The equilibrium **6d**⇄**4d** was reasonably found to lie almost on the side of **4d**. Therefore, in the rearrangement of **1d**, the K_5 stage is considered to scarcely contribute to the process.

$$\frac{1}{k_\psi^N-7.86}=\frac{1}{k_{-3}}+\frac{K_5}{k_{-3}[NaOCH(CH_3)_2]} \qquad (10)$$

With **1d** such results as shown in Fig. 3 were not obtained. The K_1, k_2, and k_{-2} values, however, can be estimated with some accuracy. In a previous work on the rearrangement of 2-(acetylamino)ethyl 2-X-4-nitrophenyl ether (**1**),[3] those values were determined (for **1b**, k_2 1.18×10^2 s^{-1}, k_{-2} 1.10×10 s^{-1}, K_1 1.31×10^2 M^{-1}:; for the pyridyl derivative,[3] k_2 5.99×10^2 s^{-1}, k_{-2} 1.20×10 s^{-1}, K_1 9.33×10 M^{-1}).

2,6-Dinitrophenyl group is expected to be inferior in electron-withdrawing character to 2-X-4-nitrophenyl one owing to the steric hindrance. Accordingly the k_2 value is expected to be at least two orders or one in magnitude. Anyhow, the k_2 value is clearly smaller than the k_{-3} one, indicating that an alkoxide ion is superior in nucleophilicity to an acetamide ion, in which the negative charge on the nigrogen is reduced by the resonance effect of an acetyl group.

Stage II. Tables 4 and 5 interestingly show that k_{obsd}^O and k_{obsd}^N are almost the same within the experimental error.

The reason for this equality is as follows: the K_2 value is rationally expected to be far larger than one, based on the above discussion. Then, Eq. 7 is reduced to Eq. 11. As a result, k_{obsd}^O is equal to k_{obsd}^N (Eq. 9).

$$k_{obsd}^O=\frac{k_4K_3}{1+K_3}(=k_{obsd}^N) \qquad (11)$$

In conclusion, almost **1d** or **6d** is base-catalyzed to change into **3d** (K_1K_2 and $K_3^{-1}K_5^{-1}$ in Table 3), which, then, slowly rearranges to **5d** at the same rate as if the process **1d**⇄**2d**⇄**3d** were irreversible.[7]

At the end, one remark should be added: since there are two isomers ([*Z*] and [*E*]) for **6d**,[1] the equilibrium and rate constants might be the results from the composite effect of each isomer. The above-mentioned discussion, however, would not be affected by this fact.

Experimental

Meterials. The compounds (**1d** and **6d**) were prepared according to the methods described in the literature.[1]

Rate Measurement. As regards the kinetics of formation and decomposition of the spiro anionic σ complex (**3d**), the transmittance of complex was measured in order to estimate the apparent pseudo-first-order rate constants (k_ψ^O and k_ψ^N) with a thermostatted Union RA-1300 Stopped-Flow Analyzer (Union Giken). The kinetic measurements for decomposition of the complex (rearrangement (k_{obsd}^O and k_{obsd}^N) were made on a thermostatted Hitachi Model 200-10 Spectrophotometer for following the decrease in the absorbance due to **3d**.

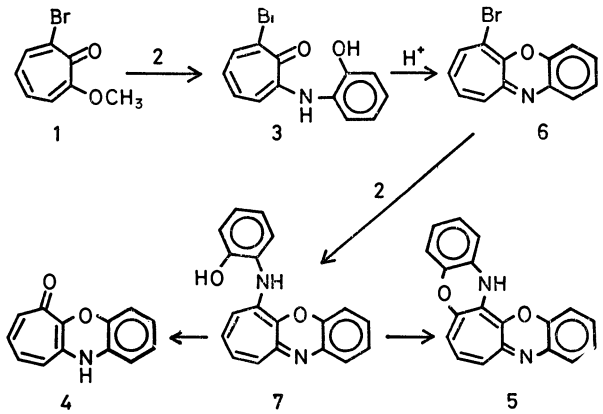
(Received December 3, 1982)

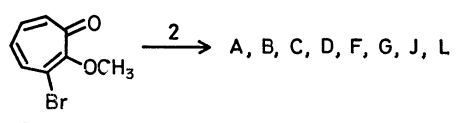
The reaction products of the title substances in hot acetic acid were separated by preparative TLC into compounds **A**—**L** according to the R_f-values, and the structural assignments for these products were now made as follows: **A**, 14*H*-[1,4]benzoxazino[3′,2′ : 3,4]cyclohepta[1,2-*b*][1,4]benzoxazine; **B**, 1-formylphenoxazine; **F**, cyclohepta[2,1-*b* : 2,3-*b*′]di[1,4]benzoxazine; **G**, cyclohepta[*b*][1,4]benzoxazin-10(11*H*)-one or its enolic form; **J**, cyclohepta[*b*][1,4]benzoxazin-6(11*H*)-one; **L**, 6-(*o*-hydroxyanilino)cyclohepta[*b*][1,4]benzoxazine hydrobromide. A small amount of 2-methylamino-3*H*-phenoxazin-3-one was also produced. Possible reaction pathways for the formation of these products are also discussed.

We reported in a previous paper[2] that the condensation of 2-bromo-7-methoxytropone (**1**) and *o*-aminophenol (**2**) in refluxing acetic acid mainly gave 2-bromo-7-(*o*-hydroxyanilino)tropone (**3**). In addition to this substitution product, a 4.7% yield of orange yellow needles and 0.5% of a dark violet pigment were isolated, to which the tentative structures **4** and **5** were respectively assigned on the basis of the elemental analyses and spectral data. These minor products were considered to be derived from a common intermediate **7** according to the pathways shown in Scheme 1,[2] since both compounds were produced upon treatment of the ring-closed product **6** with another equivalent of **2** in acetic acid.



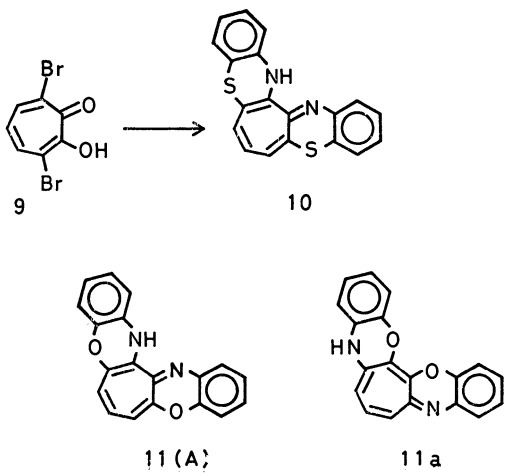
Scheme 1.

The formation of such minor products prompted us to examine the condensation of an isomeric tropone **8** (3-bromo-2-methoxytropone) with **2**. Separation of the reaction products by preparative TLC on silica gel gave at least twelve, colorful bands, which were referred to as **A**—**L** according to their R_f-values.[3] This paper describes the structures of these products, together with the possible reaction mechanism of the formation of these compounds.[4]



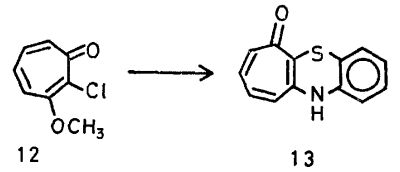
Results and Discussion

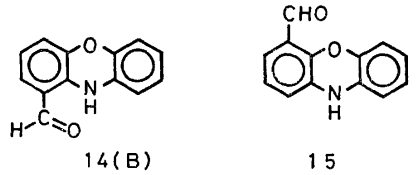
Compounds A and D. Compound **A** ($C_{19}H_{12}N_2O_2$), separated from the fastest-eluting fraction, was found to be identical with the dark violet pigment obtained previously from **1** or **6**.[2] However, the 360 MHz ^{1}H- and 47.3 MHz ^{13}C-NMR spectral analyses[5] performed later on this product clearly showed the presence of a nearly C_{2v} symmetry in the molecule on the grounds that: 1) the ^{13}C-NMR spectrum consisted of 10 signals, 2) the proton signals (in DMSO-d_6) of the seven-membered ring consisted of a slightly broadened doublet at δ 5.79 (2H; J=10.8 Hz) and a slightly broadened triplet at δ 6.00 (1H; J=10.8 Hz), and 3) the two benzene rings showed four-proton signals well-resolved at δ 6.5—6.9. Compound **A** showed an IR absorption at 3250 cm^{-1} due to a NH group, and the UV spectrum closely resembled that of **10** prepared from 3,7-dibromotropolone (**9**) and *o*-aminobenzenethiol.[6] These results, along with the mode of formation (see below), led us to revise the structure of compound **A** to 14*H*-[1,4]benzoxazino[3′,2′:3,4]cyclohepta[1,2-*b*][1,4]benzoxazine (**11**),[7] instead of the previously assigned structure **5**[2] or another isomeric structure **11a**, since these compounds (**5** and **11a**) are not likely to show a C_{2v} symmetry in the ^{1}H- and ^{13}C-NMR spectra, or to exhibit similar UV absorption to that of **10**. The assignments for the NMR signals of compound **A** are given in the Experimental section.



Compound **D** was shown to change readily to compound **A** by re-chromatography on silica gel, suggesting that compound **D** was most likely an air-sensitive dihydro form, such as **34**, of compound **A** as shown below (Scheme 3). However, compound **D** could not be isolated as a pure material

*Compounds **B** and **C**.* Compound **C** gradually degraded into compounds **2** and **B** ($C_{13}H_9NO_2$) on heating in methanol, and rapidly in the presence of a trace of dilute sulfuric acid. The latter compound **B** was identical with the orange-yellow needles, obtained previously from **1** or **6**[2] and assigned to **4** by the comparison of its IR and UV spectra with those of cyclohepta[*b*][1,4]benzothiazin-6(11*H*)-one (**13**), which had been prepared from 2-chloro-3-methoxytropone (**12**) and *o*-aminobenzenethiol.[6] However, as the ^{1}H- and ^{13}C-NMR spectra of compound **B** later indicated the presence of a formyl group, its structure was examined, and the compound **B** is now proved to be 1-formylphenoxazine (**14**)[8] by comparing the spectra and other data with those of other three, isomeric formylphenoxazines which are now available.[9] Thus, the previous formulations **4**[2] and **15**,[4] tentatively assigned to compound **B**, should now be replaced by **14**. The assignments of the NMR signals of compound **B** are shown in the Experimental section. The structure of compound **C**, together with those of other isomeric formylphenoxazines, will be published elsewhere.[9,10]





*Compounds **F** and **L**.* The compound **L** obtained from the slowest-eluting fraction was shown to have a composition $C_{19}H_{15}N_2O_2Br$ by elemental analysis and the mass spectrum. The structure of 6-(*o*-hydroxyanilino)cyclohepta[*b*][1,4]benzoxazine hydrobromide (**7a**) was assigned to compound **L** from the spectral data: see the Experimental section.

Compound **F** was isolated as yellow needles, when the uneluted fractions (with benzene) of the reaction mixture of **8** and **2** were re-chromatographed on silica gel TLC using acetone as the eluant, or, in better yields, when compound **L** was allowed to stand in methanol containing a slight excess of alkali or simply purified by alumina column chromatography. The structure cyclohepta[2,1-*b*:2,3-*b*']di[1,4]benzoxazine (**16**) was established for compound **F** by elemental analysis ($C_{19}H_{12}N_2O_2$) and the spectral data.

Compound **F** possessed only a moderately conjugated

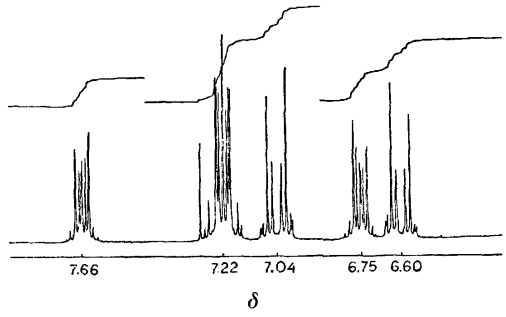


Fig. 1. The ^{1}H-NMR (200 MHz) spectrum of compound **F** in $CDCl_3$.

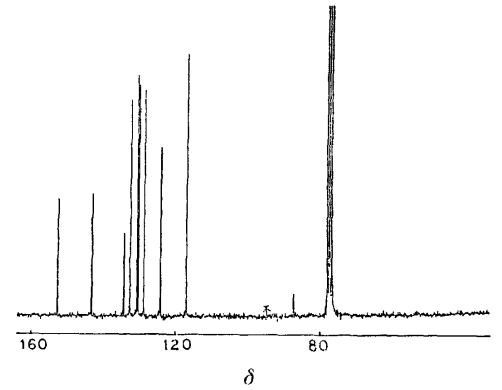

Fig. 2. The ^{13}C-NMR (50.3 MHz) spectrum of compound **F** in $CDCl_3$.

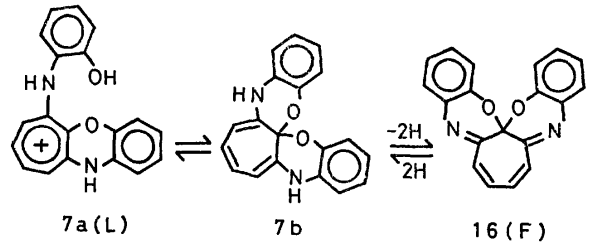
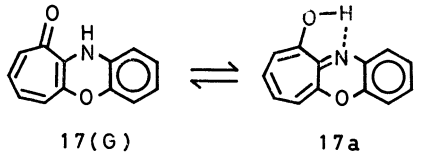
system (λ_{max} 378 nm). The IR spectrum showed that neither an OH nor an NH group was present in the molecule. The 200 MHz ^{1}H- and ^{13}C-NMR spectra[11] of compound **F** (Figs. 1 and 2) indicated the presence of a C_{2v} symmetry, as in the case of compound **A**, but of a different type. The singlet signal at δ 86.87 in the ^{13}C-NMR off-resonance spectrum was assignable to a sp^3 acetal carbon (see the Experimental section for the assignments of the NMR signals). It should be noted that compound **F** contains an interesting chiral center.[12] The salt **L** (**7a** as acetate) was regenerated from compound **F** by zinc dust reduction in acetic acid, further supporting the structure **7a** for compound **L**, which is considered to be derived from **6** by the normal substitution with **2**.

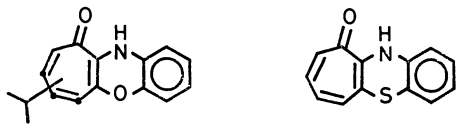


*Compounds **G** and **J**.* The structures of compounds **G** (red needles) and **J** (reddish brown needles) were now assigned to cyclohepta[*b*][1,4]benzoxazin-10(11*H*)-one (**17**) and cyclohepta[*b*][1,4]benzoxazin-6(11*H*)-one (**4**) respectively on the basis of the elemental analyses (both $C_{13}H_9NO_2$) and the spectral data,

Compound **G** showed NH and C=O absorptions at 3230 and 1605 cm^{-1}, and its UV spectrum resembled those of isopropylcyclohepta[*b*][1,4]benzoxazin-10-(11*H*)-ones (**19a**—**c**)[13] and the S-analog, cyclohepta-[*b*][1,4]benzothiazin-10(11*H*)-one (**20**).[14] The longest wavelength absorption (λ_{max} 483 nm) showed a considerable bathochromic shift compared with those of the normal tropones, suggesting that compound **G** may exist predominantly as the 10-hydroxy form (**17a**). The complete assignment for the ^{1}H-NMR signals was made by using a decoupling technique, and the result is shown in the Experimental section.

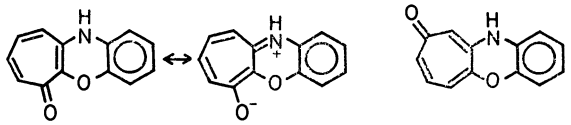


17(G) 17a



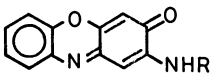
19a-c 20

Compound **J** showed NH and C=O absorptions at 3240 and 1640 cm^{-1}; the latter is slightly higher than that of compound **G**. Although the singlet at δ 7.68 was apparently due to NH, the rest of the proton signals of compound **J** were not well resolved at 90 MHz in acetone-d_6. However, a sufficiently resolved ^{1}H-NMR spectrum of **J** was available at 250 MHz in CF_3COOD,[15] and the signals at δ 7.45, 7.24, 7.40, and 7.03 were best assignable respectively to H-7, 8, 9, and 10 of structure **4**; the structure **18** proposed previously,[4] was thus revised to **4** on the ground of these NMR data. The relatively slow elution on TLC and the short retention time in the reversed phase HPLC[9] suggested a considerable contribution of the zwitterion form (**4a**) to the actual structure of compound **J**. However, neither methyl nor acetyl derivatives of compounds **G** and **J** were available upon treatment with diazomethane (or alkaline dimethyl sulfate) or acetic anhydride.



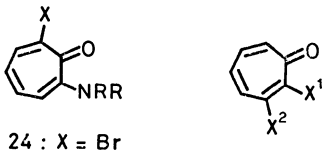
4 (J) 4a 18

Other Products. From the relatively slow-eluting fraction were further isolated small amounts of brown needles (**21**) and reddish violet needles (**22**). The structure 2-methylamino-3*H*-phenoxazin-3-one (**21**) was established for the former product by the elemental analysis and the spectral data; the UV spectrum of **21** closely resembled that of the known oxidative dimer 2-amino-3*H*-phenoxazin-3-one (**23**) of **2**, and the IR, ^{1}H-NMR, and the mass spectra supported the structure **21**. The origin of the methyl group in **21** is obscure at the moment. Although the violet-colored product (**22**) showed the molecular ion peak at *m/z* 502 and the longest wavelength absorption at 540 nm, its structure remained to be established. From fractions **E** and **I** were recovered small amounts of starting materials **8** and **2**, respectively.



21 : R = CH_3
23 : R = H

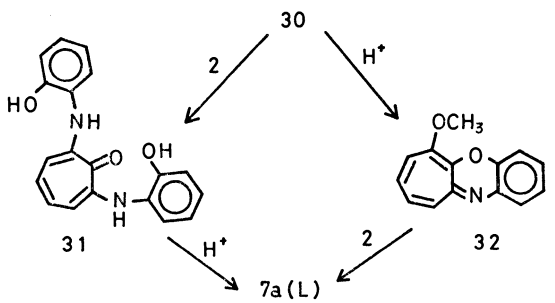
Possible Reaction Pathways for the Formation of the Products from 8 and 2. Nucleophilic reactions of troponoids bearing more than two leaving groups have attracted considerable notice in view of the regioselectivities.[16] Dipole moment[17] and X-ray[18] studies indicated that the 2-methoxyl group of **8** was forced to stay out of the plane of the seven-membered ring because of the steric congestion by the bulky bromine and carbonyl groups. Therefore, the nucleophilic displacement at C-2 of **8** is expected to be retarded or slow. Indeed, Takase *et al.*[19] recently found that the treatment of **1** with a monofunctional nucleophile such as morpholine or pyrrolidine first gave the monosubstituted product (**24**), then the 2,7-disubstituted tropone (**25**), whereas **8** first afforded a mixture of the normal and cine-substitution products (**26** and **27**), which eventually yielded 2,7- and 2,3-disubstituted tropones (**25** and **28**), respectively.



24 : X = Br
25 : X = NRR
27 : X = OCH_3
26 : X^1 = OCH_3, X^2 = NRR
28 : X^1 = X^2 = NRR

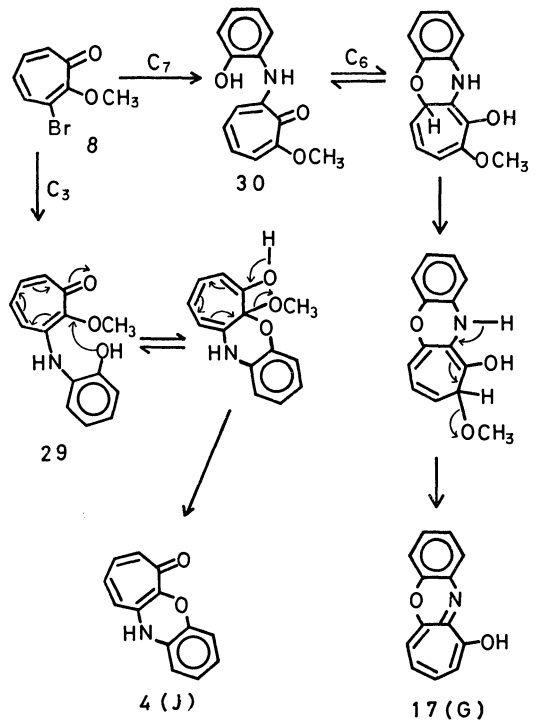
Similar reactivities are anticipated, at least in the initial stage, for **8** with nucleophile **2**. Thus the normal and cine-substitution of the bromine atom of **8** with the amino group of **2** should give the unstable intermediates **29** and **30**, which subsequently produce the 1:1 condensation products **4** (**J**) and **17** (**G**), respectively, after the ring-closure and hydrogen shift, followed by the removal of a molecule of methanol as illustrated in Scheme 2.[4]

Substitution of the 2-methoxyl group of **30** with another molecule of **2**, followed by the ring-closure at C-1, or substitution of 6-methoxy group of **32** with **2**, should afford **7** as the hydrobromide (**L**).

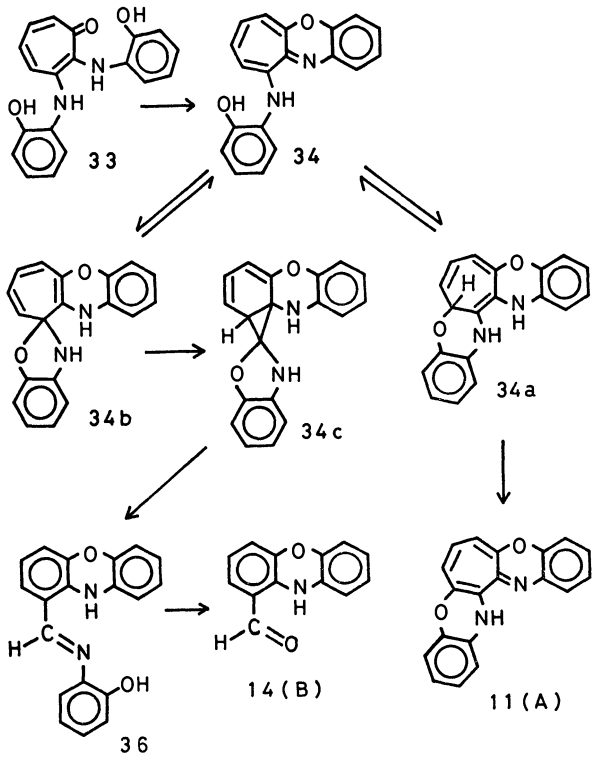


31 32 7a(L)

Compound **F** (**16**) is obviously derived from the



Scheme 2.



Scheme 3.

ring-closed tautomer (**7b**) of **7** through the air-oxidation as shown previously.

On the other hand, compounds **A**, **D**, **B**, and **C**[9,10] are presumably formed through the isomeric, common intermediate (**34**) derived from **29** *via* **33**, followed by the sequential steps illustrated in Scheme 3. The exact mechanism of this unusual substitution and the interesting ring closures accompanied by the rearrangement are currently under investigation in detail.[9,10] Nevertheless, the present experimental results clearly demonstrate a part of the diversity of the chemical reactions and the intricate character of troponoid compounds.

Experimental

Melting points are uncorrected. The IR and UV spectra were taken on a Hitachi EPI-G2 and a Hitachi 124 spectrometer, respectively; the UV spectra in acid and alkali were taken after adding three drops of 1 M HCl or 1 M NaOH (1 M = 1 mol dm^{-3}) to the sample solution. The NMR spectra were measured in $CDCl_3$ (unless otherwise specified) on a JEOL FX-90Q NMR spectrometer using TMS as the internal standard. The mass spectra were taken on a Hitachi RMU-6M mass spectrometer at 75 eV. The HPLC was carried out with Hitachi gel #3011 with MeOH–hexane (9:1) as solvent.

Reaction of 3-Bromo-2-methoxytropone (8) and o-Aminophenol (2). A solution of 4.9 g (22.8 mmol) of **8** and 3.7 g (34.2 mmol) of **2** in 20 ml of acetic acid was refluxed for 2 h. The solvent was removed *in vacuo*. The residue was separated by means of preparative TLC on silica gel (Merck, 20×40 cm, 2 mm thickness, 6 plates) using benzene as the eluant, thus affording crude compounds **A**, **B**, **C**, **D**, **G**, and the rest, according to the R_f values. The last fraction was eluted with methanol and re-chromatographed using acetone as the eluant, thus giving compounds **F**, **J**, **21**, **22**, and **L**.

Compound A: 14*H*[1,4]Benzoxazino[3′,2′:3,4]cyclohepta[1,2-*b*][1,4]benzoxazine (**11**); dark violet needles (240 mg, 3.9%); mp 246 °C (from hexane); UV_{max} (MeOH) 207, 254, 360, and 500 nm (log ε 4.10, 3.99, 3.43, and 3.68), (MeOH+HCl) 207, 223, 275, 325^{sh}, 410, and 535 nm (log ε 4.08, 4.02, 4.00, 3.57, 3.68, and 3.54); IR (KBr) 3250 cm^{-1} (NH); ^{1}H-NMR (360 MHz in $CDCl_3$)[5] δ=5.68 (2H, m, *J*=10.68 Hz, H-6,8), 5.84 (1H, m, *J*=10.68 Hz, H-7), the signals of H-7,6,8 were shown to be AB_2 spin system at $J/\Delta\delta$=0.177. 6.45 (2H, dd, *J*=7.2, 1.3 Hz, H-4,10), 6.62 (2H, dd, *J*=7.2, 1.3 Hz, H-1,13), 6.68 (2H, td, *J*=7.2, 1.3 Hz, H-2,12 or H-3,11), 6.72 (2H, td, *J*=7.2, 1.3 Hz, H-3,11 or H-2,12), and 7.55 (1H, s, NH), (360 MHz in DMSO-d_6)[5] δ=5.79 (2H, d, *J*=10.8 Hz, H-6,8), 6.00 (1H, t, *J*=10.8 Hz, H-7), 6.53 (2H, dd, *J*=7.2, 1.3 Hz, H-4,10), 6.75 (4H, m, H-2,3,11,12), and 6.88 (2H, dd, *J*=7.2, 1.3 Hz, H-1,13); ^{13}C-NMR (47.3 MHz)[5] δ=150.36, 145.16, 139.28, 132.69, 125.56, 124.56, 124.42, 119.30, 117.40, and 114.35.

Found: C, 76.25; H, 4.09; N, 9.38%; M$^+$, 300. Calcd for $C_{19}H_{12}N_2O_2$: C, 75.99; H, 4.03; N, 9.33%; M, 300.

Compound B: 1-Formylphenoxazine (**14**); orange yellow needles (140 mg, 3.1%); mp 115 °C (from hexane after TLC purification; lit,[8] mp 105—110 °C); UV_{max} (MeOH) 207, 227, 275, 310, and 435 nm (log ε 4.28, 4.43, 3.88, 3.48, and 3.74); IR (KBr) 3300 (NH) and 1650 cm^{-1} (C=O); ^{1}H-NMR (100 MHz) δ=9.74 (1H, s, CHO), 9.08 (1H, s, NH), 6.99 (1H, dd, *J*=7.0, 2.5 Hz, H-2), 6.55—6.80 (5H, m, H-3,4,6,7,8), and 6.46 (1H, m, H-9); ^{13}C-NMR (33.3 MHz) δ(off resonance)=193.59 (d, CHO), 144.89 (s), 135.99 (s), 128.41 (d), 124.08 (d), 122.88 (d), 119.36 (d), 118.38 (s), 115.67 (d), and 114.48 (d).

Found: C, 73.64; H, 4.27; N, 6.70%; M$^+$, 211. Calcd for $C_{13}H_9NO_2$: C, 73.92; H, 4.30; N, 6.63%; M, 211.

Compound D: Purification of the crude compound **D** by column chromatography on silica gel produced only **11** (13 mg), thus the pure compound **D** was not isolated.

Compound ***F***: Cyclohepta[2,1-*b*:2,3-*b'*]di[1,4]benzoxazine (**16**); yellow needles (275 mg, 4.1%); mp 191 °C (from ether after silica gel column purification); UV_{max} (MeOH) 208, 235, 287, and 378 nm (log ε 4.45, 4.29, 4.30, and 3.86); ^{1}H-NMR (200 MHz)[11] δ=7.66 (2H, m, H-4,11), 7.22 (4H, m, H-2,3,12,13), 7.04 (2H, m, H-6,9), 6.75 (2H, m, H-1,14), and 6.60 (2H, m, H-7,8); ^{13}C-NMR (50.309 MHz)[11] δ (off resonance)=86.87 (s, acetal carbon C-15a), 116.49 (d, C-1), 123.65 (d, C-4), 128.12 (d), 129.67 (d), 130.08 (d), 131.95 (d), 133.60 (s, C-5a, 9a), 142.48 (s, C-4a,10a), and 151.85 (s, C-14a,16a).

Found: C, 75.84; H, 3.79; N, 9.28%; M^+, 300. Calcd for $C_{19}H_{12}N_2O_2$: C, 75.99; H, 4.03; N, 9.33%; M, 300.

Compound ***G***: Cyclohepta[*b*][1,4]benzoxazin-10(11*H*)-one (**17**); red needles (830 mg, 18.1%); mp 175 °C from ethyl acetate after purification as the picrate, which was recrystallized from ethanol, decomposed with 1M NaOH, and finally extracted with benzene); UV_{max} (MeOH) 205, 227, 259, 270, 284, 305,^{sh} 320,^{sh} 415,^{sh} and 483 nm (log ε 4.24, 4.28, 4.21, 4.21, 4.05, 3.72, 3.59, 3.62, and 3.88); (MeOH+HCl) 205, 227, 260,^{sh} 271, 284, 320,^{sh} 420,^{sh} and 480 nm (log ε 4.15, 4.29, 4.14, 4.20, 4.19, 3.59, 3.68, and 3.83); (MeOH+NaOH) 213, 259, 270, 284,^{sh} 305,^{sh} 320,^{sh} 415,^{sh} and 483 nm (log ε 4.41, 4.17, 4.18, 4.05, 3.72, 3.59, 3.60, and 3.83); IR (KBr) 3230 (NH) and 1605 cm^{-1} (C=O); ^{1}H-NMR (200 MHz)[11] δ=7.53 (1H, s, NH), 7.09 (1H, br d, *J*=12.0 Hz, H-9), 6.95 (1H, ddd, *J*=12.0, 8.5, 1.5 Hz, H-8), 6.74 (1H, br d, *J*=12.0 Hz, H-6), 6.71 (2H, m, H-2,3), 6.59 (1H, ddd, *J*=12.0, 8.5, 1.5 Hz, H-7), and 6.49 (2H, m, H-1,4).

Found: C, 73.70; H, 4.28; N, 6.68%; M^+, 211. Calcd for $C_{13}H_9NO_2$: C, 73.92: H, 4.30; N, 6.63%: M, 211.

Compound ***J***: Cyclohepta[*b*][1,4]benzoxazin-6(11*H*)-one (**4**); red brown needles (290 mg, 6.3%); mp 270 °C (from ethanol); UV_{max} (MeOH) 205, 228, 260, 270,^{sh} 292, 310,^{sh} 323,^{sh} and 400 nm (log ε 4.40, 4.34, 4.20, 4.15, 4.10, 4.04, 3.91, and 3.88); (MeOH+HCl) 205, 228, 281, and 418 nm (log ε 4.35, 4.40, 4.28, and 3.93); (MeOH+NaOH) 260, 290, and 418 nm (log ε 4.20, 4.10, and 3.88); IR (KBr) 3240 (NH) and 1640 cm^{-1} (C=O); ^{1}H-NMR (250 MHz in CF_3COOD)[15] δ=7.45 (1H, dd, *J*=11.5, 1.5 Hz, H-7), 7.40 (1H, ddd, *J*=11.5, 9.0, 1.5 Hz, H-9), 7.24 (1H, ddd, *J*=11.5, 9.0, 1.0 Hz, H-8), 7.03 (1H, br d, *J*=11.5 Hz, H-10), 6.99 (2H, m, H-2,3), 6.84 (1H, m, H-1), 6.68 (1H, m, H-4).

Found: C, 73.91; H, 4.48; N, 6.47%; M^+, 211. Calcd for $C_{13}H_9NO_2$: C, 73.92; H, 4.30; N, 6.63%; M, 211.

*2-Methylamino-3*H*-phenoxazin-3-one (**21**).* The extract of the band between compounds **F** and **J** during the TLC purification using acetone (see above) was further purified by the silica gel column chromatography, thus affording 110 mg (2.2%) of **21** as brown needles, mp 225 °C (from chloroform); UV_{max} (MeOH) 205, 238, 270,^{sh} 420, and 435 nm (log ε 4.56, 4.57, 4.26, 4.40, and 4.41); (MeOH+HCl) 238, 465, and 520 nm (log ε 4.57, 4.02, and 3.90); IR (KBr) 3370 (NH) and 1580 cm^{-1} (C=O); ^{1}H-NMR (100 MHz) δ=7.70—7.35 (4H, m, H-6,7,8,9), 6.41 (1H, s, H-1), 6.19 (1H, s, H-4), 3.48 (1H, q, *J*=6.0 Hz, NH), and 2.99 (3H, d, *J*=6.0 Hz, N-CH_3).

Found: *m/z* 226.0722.[20] Calcd for $C_{13}H_{10}N_2O_2$: M, 226.0742.

22: The extract of the band between compounds **J** and **L** during the TLC purification using acetone was recrystallized from ethanol, thus affording 20 mg of **22** as reddish violet crystals, mp 235 °C decomp; UV_{max} (MeOH) 211, 235, 265,^{sh} 275, 303, 420,^{sh} and 540 nm (log ε 4.63, 4.34, 4.13, 4.07, 3.92, 3.68, and 3.75); (MeOH+NaOH) 235, 275, 300, 540, and 575 nm (log ε 4.58, 3.99, 3.95, 3.70, and 3.70). Found: C, 51.69; H, 3.64; N, 4.47%; M^+, 502.

Compound ***L***: 6-(*o*-Hydroxyanilino)cyclohepta[*b*][1,4]-benzoxazine hydrobromide (**7a**); a) A solution of 1.00 mg (4.65×10^{-3} mmol) of **8** and 0.91 mg (8.34×10^{-3} mmol) of **2** in 8 ml of acetic acid was heated at 100 °C for 2.5 h. After the removal of the solvent *in vacuo*, the residue was chromatographed on a column of silica gel first using benzene–methanol (10:1), then methanol as the eluant. The latter fraction was concentrated and allowed to stand in the refrigerator, thus depositing **7a** as dark brown needles. Recrystallization from methanol gave an analytical sample: mp >300 °C decomp; UV_{max} (MeOH) 265, 309, and 435 nm (log ε 4.32, 4.08, 4.05); (MeOH+0.1 M NaOH) 271, 463, and 485 nm (log ε 4.33, 4.12, and 4.07); Found: C, 61.35; H, 3.95; N, 7.67; Br, 18.98%. Calcd for $C_{19}H_{14}N_2O_2\cdot$HBr: C, 59.55; H, 3.95; N, 7.31; Br, 20.85%.

Found: *m/z* 302.1069.[20] Calcd for $C_{19}H_{14}N_2O_2$: M 302.1055.

The dark brown solution of **7a** in methanol and 0.1 M NaOH turned pale yellow after being set aside overnight at 20 °C, and the solution was found to contain compound **F** by means of TLC, reversed phase HPLC, and UV absorption.

b) From compound **F**: Zinc dust was added to a solution of compound **F** in acetic acid at room temp. The solution turned to reddish brown in a short period and was found to contain mainly compound **L** on the evidence of the reversed phase HPLC and UV absorption.

We thank Professors K. Takase, M. Yasunami (Tohoku Univ.), I. Murata (Osaka Univ.), H. Yamamoto (Okayama Univ.), Drs. Y. Naya, S. Imajo, H. Naoki (Suntory Inst. Bioorg. Res.), H. Tsuruta (Takasago Perfumery Co.), T. Takita (Institute of Microbial Chemistry), and Mr. K. Fujimori (Shinshu Univ.) for their helpful discussions and spectral measurements. We also thank Professor S. Ishikawa (Josai Univ.) for allowing his assistant (H. W.) to carry out the present research at Kao Soap Co.

(Received January 24, 1983)

The Rössing's reaction of 4-substituted 2-acylphenoxyacetic acids give a mixture of benzofurans and 2-benzofurancarboxylic acids. The relative yields of benzofurans and 2-benzofurancarboxylic acids depend on the substituents on the benzene ring of the 2-acylphenoxyacetic acids. Electron-withdrawing substituents such as nitro groups favor the formation of 2-benzofurancarboxylic acids. On the other hand, the formation of benzofurans is favored by the steric hindrance of 2-acyl groups in the reaction of 2-acyl-4-nitrophenoxyacetic acids with anhydrous sodium acetate and acetic anhydride.

Benzofurans are well-known heterocyclic compounds and have been prepared by Rössing's method.[1] This is a general procedure to obtain benzofurans from 2-acylphenoxyacetic acids by heating them with anhydrous sodium acetate and acetic anhydride. In this method 2-benzofurancarboxylic acids were obtained as minor products. The formation of 2-benzofurancarboxylic acids has not been noted because of their poor yields.[2] Burgstahler and Worden, however, reported that 2-benzofurancarboxylic acid was obtained in high yield (45%) by the reaction of 2-formylphenoxyacetic acid with anhydrous sodium acetate and acetic anhydride.[3] Recently, we reported that 2-acetyl-5-nitrophenoxyacetic acid gave 3-methyl-6-nitrobenzofuran and 3-methyl-6-nitro-2-benzofurancarboxylic acid in 58 and 42% yields, respectively.[4] Thus, substituents in 2-acylphenoxyacetic acids influence the relative yields of benzofurans and 2-benzofurancarboxylic acids. In the present paper, we examined the electronic and steric effects on the relative yields of benzofurans (**2**) and 2-benzofurancarboxylic acids (**3**) in the Rössing's method.

Results and Discussion

Some 2-acylphenoxyacetic acid derivatives (**1a**—**j**) were prepared in order to investigate substituent effects (R^1 and R^2) on the syntheses of benzofurans (**2a**—**j**) and 2-benzofurancarboxylic acids (**3a**—**j**). The syntheses of **1a**,[5] **1c**,[6] **1d**,[7] **1g**,[8] and **1h**[9], were carried out according to reported methods. The synthetic methods of **1b**, **1e**, **1f**, **1i**, and **1j**, are summarized in Scheme 1.

When 4-substituted 2-acylphenoxyacetic acids (**1a**—**j**) were heated with anhydrous sodium acetate and acetic anhydride at 110±1 °C for 3 h, benzofurans (**2a**—**j**) and 2-benzofurancarboxylic acids (**3a**—**j**) were obtained. The isolated and relative yields of **2a**—**j** and **3a**—**j** are summarized in Table 1.

Initially, the effects of R^2 were examined for $R^1=NO_2$ by changing R^2 from hydrogen to methyl, ethyl, or isopropyl groups. In the case of $R^2=H$, the relative yields of benzofuran (**2h**) and 2-benzofurancarboxylic acid (**3h**) were 25.5 and 74.5%, respectively. Therefore, the latter was the major product, whereas the yield (86.2%) of benzofuran (**2j**) exceeded that (13.8%) of 2-benzofurancarboxylic acid (**3j**) when R^2 was an isopropyl group. When R^2 were methyl or ethyl groups, the yields of **2e** and **3e** were 62.5 and 37.5%, and those of **2i** and **3i** were 66.4 and 33.6%, respectively. Thus, the formation of benzofurans (**2**) was favored as the steric bulk of R^2 increased. The results are explained in terms of steric effects of R^2, since the electronic effects of methyl, ethyl, and isopropyl groups are similar.

Scheme 2. The reaction pathways for the production of benzofurans (**2**) and 2-benzofurancarboxylic acids (**3**).

was assumed as an intermediate in the formation of benzofurans.[11] A similar intermediate was isolated recently in the syntheses of 4,5-dihydro-3*H*-naphtho-[1,8-*bc*]furan.[12]

A proposed reaction mechanism is depicted in Scheme 2. The reaction of 2-acylphenoxyacetic acids (**1**) with anhydrous sodium acetate and acetic anhydride will afford two intermediates (*cis*-**4** and *trans*-**4**). The relative ratio of *cis*-**4** to *trans*-**4** will be varied by changing R^2. In the case of **1h** ($R^2=H$), *trans*-**4h** will be preferentially produced because the steric repulsion between the acetoxyl group and the carboxylate ion of *cis*-**4h** is larger than that of *trans*-**4h**. On the other hand, **1j** ($R^2=CH(CH_3)_2$) will preferentially

give *cis*-**4j** because of the steric repulsion between the isopropyl group and the carboxylate ion. Preferential formation of benzofuran (**2j**) suggests that **2j** must be produced mainly through *cis*-**4j** by *syn* elimination of carbon dioxide and acetate ion, while 2-benzofurancarboxylic acid (**3h**) must be produced exclusively through *trans*-**4h** by *syn* elimination of acetic acid.[13]

Secondly, the effects of R^1 were examined. In the first case, R^2 was fixed as a methyl group, and R^1 was varied from hydrogen to methoxyl, methyl, nitro groups, or a chlorine atom. The reaction of **1a—d** with anhydrous sodium acetate and acetic anhydride gave a mixture of 3-methylbenzofurans (**2a—d**) and 3-methyl-2-benzofurancarboxylic acid (**3a—d**) in relative yields of 98.5—92.5 and 1.5—7.5%, respectively. Electronic effects of substituents R^1 did not influence the relative yields of **2a—d** and **3a—d**, while compound **1e** ($R^1=NO_2$) gave benzofuran (**2e**) and 2-benzofurancarboxylic acid (**3e**) in relative yields of 62.5 and 37.5%, respectively. The strongly electron-withdrawing nitro group makes the hydrogen atom attached at the C_2 carbon atom of *cis*-**4e** more acidic than that of *cis*-**4a—d** as illustrated in Scheme 2, and facile *anti* elimination of acetic acid gives 2-benzofurancarboxylic acid (**3e**).

In the second case, R^2 was fixed as hydrogen and R^1 was varied from hydrogen to methyl or nitro groups. The reaction of **1f** ($R^1=CH_3$) with anhydrous sodium acetate and acetic anhydride gave benzofuran (**2f**) and 2-benzofurancarboxylic acid (**3f**) in 44.5 and 55.5 % relative yields, respectively. Compound **1g** also afforded **2g** and **3g** in similar relative yields. On the other hand, compound **1h** ($R^1=NO_2$) gave benzofuran (**2h**) and 2-benzofurancarboxylic acid (**3h**) in relative yields of 25.5 and 74.5%, respectively. Therefore, nitro group of **1h** also favored the formation of 2-benzofurancarboxylic acid (**3h**) by its electron-withdrawing nature.

We wish to try to trap intermediates, *cis*-**4** and *trans*-**4**, and are continuing further research on the mechanism of furan ring formation.

Experimental

All melting points are uncorrected. The infrared absorption spectra were determined on a JASCO Model DS402G infrared spectrometer and a HITACHI EP1-G grating infrared spectrometer. Nuclear magnetic resonance spectra were determined at 100 MHz on a JEOL Model 4H-100 NMR spectrometer, using tetramethylsilane as an internal standard. GLC analyses were performed on a YANACO Gas Chromatograph Model G 80-FP equipped with a glass column (1.5 m; $\phi=4$ mm) packed with 5% Silicone Gum SE-30 on Chromosorb W AW-DMCS (80—100 mesh) at 110—200 °C for each case. The column chromatography was performed on silica gel (Wakogel C-200).

General Procedure for Determination of the Ratio of ***3*** *to* ***2*** *in the Reaction of* ***1***. A typical procedure will be described for the reaction of **1b**. A mixture of **1b** (1.04 g, 0.5 mmol), anhydrous sodium acetate (2.6 g, 31.6 mmol), and acetic anhydride (17 ml) was heated at 110±1 °C for 3 h. After cooling, the reaction mixture was poured into 100 ml of water and stirred for 1 h. This mixture was extracted with 250 ml of ether, and the ethereal solution was washed with water (40 ml×5). The ethereal solution was concentrated by evaporation to approximately 50 ml. An ethereal solution of diazomethane was added dropwise to the residue until the color of the solution turned yellow. The resulting solution was diluted with ether exactly to a total volume of 200 ml (sample 1). Five ml of the sample 1 was pipetted and was diluted with ether exactly to a total volume of 50 ml (sample 2). The quantity of **2b** in the sample 2 and that of **7b** in the sample 1 were determined by gas chromatography and the yield of **3b** was calculated from the quantity of **7b**. The resulting chromatograms were compared by measuring the areas of peaks by triangulation with those of the standard sample for which the concentration was known. The yield of **2b** was 96.0% and that of **3b** was 1.7%. The results of the reaction of **1a,c,d,f** and **1g** with anhydrous sodium acetate and acetic anhydride were obtained similarly and are listed in Table 1. Nitro compounds (**1e**, **1h—j**) were run in the same manner as described above. The separation and quantitative analyses of the products were carried out in the usual manner and the results are summarized in Table 1. Compounds **2h**[14] and **3h**[14] were identified by comparison of their IR and NMR spectra with those of authentic samples.

2e: Mp 89—90 °C. IR(KBr): ν_{max} 3088, 2920, 1625, 1586, 1516 (NO_2), 1442 (C=C), 1334 (NO_2), 887 (furan ring), 804 cm^{-1} (two adjacent aromatic hydrogen atoms). Found: C, 61.02; H, 4.04%. Calcd for $C_9H_7NO_3$: C, 61.02; H, 3.98%.

3e: Mp 285—286 °C (decomp). IR(KBr): ν_{max} 3100, 2800—2400, 1692 (CO_2H), 1620, 1580, 1525 and 1329 (NO_2), 903 (CO_2H), 832 cm^{-1} (two adjacent aromatic hydrogen atoms). Found: C, 54.32; H, 3.23%. Calcd for $C_{10}H_7NO_5$: C, 54.30; H, 3.19%.

2i: Mp 89—90 °C. IR (KBr): ν_{max} 3095, 2960, 1578, 1515 (NO_2), 1445 (C=C), 1342 (NO_2), 887 (furan ring), 830 cm^{-1} (two adjacent aromatic hydrogen atoms). Found: C, 62.72; H, 4.76%. Calcd for $C_{10}H_9NO_3$: C, 62.82; H, 4.74%.

3i: Mp 240—243 °C. IR (KBr): ν_{max} 3100, 2970, 2800—2400, 1678 (CO_2H), 1617, 1584, 1520 (NO_2), 1447, 1340 (NO_2), 924 (CO_2H), 831 cm^{-1} (two adjacent aromatic hydrogen atoms). Found: C, 56.12; H, 3.99%. Calcd for $C_{11}H_9NO_5$: C, 56.17; H, 3.85%.

2j: Mp 110.5—111.0 °C. IR (KBr): ν_{max} 3105, 2960, 2875, 1623, 1585, 1508 (NO_2), 1444 (C=C), 1335 (NO_2), 885 (furan ring), 818 cm^{-1} (two adjacent aromatic hydrogen atoms). Found: C, 64.34; H, 5.40%. Calcd for $C_{11}H_{11}NO_3$: C, 64.38; H, 5.40%.

3j: Mp 249—250 °C. IR (KBr): ν_{max} 3080, 2960, 2800—2400, 1674 (CO_2H), 1608, 1585, 1515 and 1340 (NO_2), 908 (CO_2H), 832 cm^{-1} (two adjacent aromatic hydrogen atoms). Found: C, 57.89; H, 4·48%. Calcd for $C_{12}H_{11}NO_5$: C, 57.83; H, 4.44%.

*Preparation of Materials (****1a—j****).* 2-Acetyl-4-methoxyphenoxyacetic acid (**1a**) was prepared by Whalley's method,[5] 2-acetylphenoxyacetic acid (**1c**) by Rosseels' method,[6] and 2-acetyl-4-chlorophenoxyacetic acid (**1d**) by Deorha's method.[7] 2-Formylphenoxyacetic acid (**1g**) was prepared by Dumont's method,[8] and 2-formyl-4-nitrophenoxyacetic acid (**1h**) by Jacobs' method.[9]

*2-Acetyl-4-methylphenoxyacetic Acid (****1b****).* A mixture of 2-hydroxy-5-methylacetophenone[15] (**5b**) (10 g), ethyl bromoacetate (16.5 g), anhydrous potassium carbonate (40 g), and acetone (200 ml) was refluxed at 70 °C for 6 h. After cooling, the insoluble salts were removed by filtration and the filtrate was concentrated under evaporation. The

residue was treated with ethanol (50 ml) and 3 M (1 M= 1 mol dm^{-3}) sodium hydroxide solution (50 ml) at room temperature for 30 min. The reaction mixture was poured into cold water (100 ml) and acidified with 6 M hydrochloric acid. The precipitates were filtered, washed with cold water, and dried under vacuum to give 12.9 g (92%) of **1b** as crystals. Recrystallization from aqueous methanol gave colorless plates, mp 156—157 °C. IR (KBr): ν_{max} 1773 (CO_2H), 1654 cm^{-1} (CO). NMR (CD_3COCD_3): δ= 2.29 (3H, s, $PhCH_3$), 2.67 (3H, s, $COCH_3$), 4.76 (2H, s, CH_2), 6.88 (1H, d, J=8.5 Hz, C_6-H), 7.28 (1H, dd, J= 8.5 and 2.5 Hz, C_5-H), 7.47 (1H, J=2.5 Hz, C_3-H). Found: C, 63.21; H, 5.89%. Calcd for $C_{11}H_{12}O_4$: C, 63.45; H, 5.81%.

*Ethyl 2-Acetyl-4-nitrophenoxyacetate (**6e**).* 2-Hydroxy-5-nitroacetophenone (**5e**) was prepared by Joshi's method.[16] A mixture of **5e** (10 g), ethyl bromoacetate (11 g), anhydrous potassium carbonate (30.4 g), and acetone (200 ml) was refluxed at 70 °C for 3 h. After cooling, insoluble salts were removed by filtration. The residue obtained upon evaporation of the acetone was purified by recrystallization from hexane-ethanol to give 12.4 g (84.3%) of **6e** as pale yellow short needles, mp 88.0—89.5 °C. IR (KBr): ν_{max} 1760 (-CO_2-), 1674 (CO), 1507 and 1338 (NO_2), 836 cm^{-1} (two adjacent aromatic hydrogen atoms). Found: C, 53.97; H, 4.97%. Calcd for $C_{12}H_{13}NO_6$: C, 53.93; H, 4.90%.

*2-Acetyl-4-nitrophenoxyacetic Acid (**1e**).* A mixture of **6e** (1 g), anhydrous potassium carbonate (0.5 g), and water (10 ml) was refluxed for 40 min. Insoluble material in the reaction mixture was filtered while hot, and the filtrate was acidified after cooling with 6 M hydrochloric acid. The precipitates were filtered, washed with cold water, and dried under vacuum to give 0.8 g (90%) of **1e** as crystals. Recrystallization from aqueous ethanol gave pale yellow short needles, mp 198—200 °C (decomp). IR (KBr): ν_{max} 1739 (CO_2H), 1675 (CO), 1516 and 1340 cm^{-1} (NO_2). NMR (CD_3OD): δ=2.72 (3H, s, $COCH_3$), 4.99 (2H, s, CH_2), 7.24 (1H, d, J=8.7 Hz, C_6-H), 8.35 (1H, dd, J=8.7 and 3.7 Hz, C_5-H), 8.51 (1H, d, J=3.7 Hz, C_3-H). Found: C, 50.31; H, 3.86%. Calcd for $C_{10}H_9NO_6$: C, 50.21; H, 3.79%.

*Ethyl 2-Formyl-4-methylphenoxyacetate (**6f**).* From 5-methylsalicylaldehyde[17] (**5f**) (3 g), **6f** (4 g, 81.6%) was obtained in the same manner as has been described for **6e** except that tetrahydrofuran was used as solvent instead of acetone. Recrystallization from aqueous ethanol gave colorless short needles, mp 51.5—52.5 °C. IR (KBr): ν_{max} 1767 (-CO_2-), 1671 (CHO), 837 cm^{-1} (two adjacent aromatic hydrogen atoms). Found: C, 65.01; H, 6.39%. Calcd for $C_{12}H_{14}O_4$: C, 64.85; H, 6.34%.

*2-Formyl-4-methylphenoxyacetic Acid (**1f**).* A mixture of **6f** (2.61 g), 20% potassium hydroxide solution (10 ml) and ethanol (12 ml) was warmed at 60 °C for 30 min. After cooling, 150 ml of water was poured into the reaction mixture and the mixture was acidified with 6 M hydrochloric acid. Resulting precipitates were filtered, washed with cold water, and dried under vacuum to give 1.9 g (83.3%) of **1f** as crystals. Recrystallization from aqueous acetone gave colorless plates, mp 147—148 °C (lit,[18] mp 151 °C). IR (KBr): ν_{max} 1745 and 1720 (CO_2H), 1690 (CHO), 927 (CO_2H), 822 cm^{-1} (two adjacent aromatic hydrogen atoms), (Found: C, 61.83; H, 5.29%).

*2'-Hydroxy-5'-nitropropiophenone (**5i**).* By the modified method of Joshi[16], **5i** (7.5 g, 35.7%) was prepared from the reaction of *p*-nitrophenol (15 g) with propionyl chloride (18.6 g) in nitrobenzene (150 ml) in the presence of anhydrous aluminium chloride (41 g) as catalyst. Recrystallization from methanol gave colorless short needles, mp 94.5—95.0 °C. IR (KBr): ν_{max} 3070, 1640 (CO), 1615, 1576, 1510 and 1338 (NO_2), 825 cm^{-1} (two adjacent aromatic hydrogen atoms). Found: C, 55.38; H, 4.71%. Calcd for $C_9H_9NO_4$: C, 55.38; H, 4.64%.

*Ethyl 4-Nitro-2-propionylphenoxyacetate (**6i**).* In the same manner as has been described for **6e**, **6i** (12.3 g, 63.4%) was prepared from **5i** (13.5 g). Recrystallization from aqueous ethanol gave colorless short needles, mp 58—59 °C. IR (KBr): ν_{max} 1730 (-CO_2-), 1682 (CO), 1510 and 1334 (NO_2), 833 cm^{-1} (two adjacent aromatic hydrogen atoms). Found: C, 55.59; H, 5.37%. Calcd for $C_{13}H_{15}NO_6$: C, 55.51; H, 5.38%.

*4-Nitro-2-propionylphenoxyacetic Acid (**1i**).* Acid **1i** (8.1 g, 90%) was obtained from **6i** (10 g) in the same way as described for the preparation of **1e**. Recrystallization of **1i** from benzene-acetone gave colorless plates, mp 128—129 °C. IR (KBr): ν_{max} 1752 and 1720 (CO_2H), 1663 (CO), 1522 and 1345 (NO_2), 834 cm^{-1} (two adjacent aromatic hydrogen atoms). Found: C, 52.27; H, 4.41%. Calcd for $C_{11}H_{11}NO_6$: C, 52.17; H, 4.37%.

*2'-Hydroxy-5'-nitroisobutyrophenone (**5j**).* By the modified method of Joshi[16], **5j** (2.7 g, 8.6%) was prepared from the reaction of *p*-nitrophenol (15 g) with isobutyryl chloride (21.3 g) in nitrobenzene (170 ml) in the presence of anhydrous aluminium chloride (41 g) as a catalyst. Recrystallization from methanol gave pale yellow short needles, mp 74.0—74.5 °C. IR (KBr): ν_{max} 3080, 1636 (CO), 1615, 1575, 1506 and 1334 (NO_2), 821 cm^{-1} (two adjacent aromatic hydrogen atoms). NMR (CD_3COCD_3): δ=1.28 (6H, d, J=7.5 Hz, -$CH(C\underline{H}_3)_2$), 3.95 (1H, m, J= 7.5 Hz, -$C\underline{H}(CH_3)_2$), 7.20 (1H, d, J=10 Hz, C_3-H), 8.42 (1H, dd, J=10 and 2.5 Hz, C_4-H), 8.86 (1H, d, J=2.5 Hz, C_6-H). Found: C, 57.37; H, 5.34%. Calcd for $C_{10}H_{11}NO_4$: C, 57.41; H, 5.29%.

*Ethyl 2-Isobutyryl-4-nitrophenoxyacetate (**6j**).* In the same manner as has been described for **6e**, **6j** (4.5 g, 77.7%) was prepared from **5j** (4.1 g). Recrystallization of **6j** from ethanol gave colorless short needles, mp 58—60 °C. IR (KBr): ν_{max} 1730 (-CO_2-), 1667 (CO), 1510 and 1334 cm^{-1} (NO_2). Found: C, 57.01; H, 5.87%. Calcd for $C_{14}H_{17}NO_6$: C, 56.94; H, 5.80%.

*2-Isobutyryl-4-nitrophenoxyacetic Acid (**1j**).* Acid **1j** (5.8 g, 95%) was obtained from **6j** (6.8 g) in the same way as described for the preparation of **1e**. Recrystallization of **1j** from benzene gave colorless short needles, mp 108—109 °C. IR (KBr): ν_{max} 1739 (CO_2H), 1667 (CO), 1515 and 1334 (NO_2), 910 (CO_2H), 826 cm^{-1} (two adjacent aromatic hydrogen atoms). Found: C, 53.86; H, 4.96%. Calcd for $C_{12}H_{13}NO_6$: C, 53.93; H, 4.90%.

*Preparation of Standard Compounds (**2a—d**, **2f,g**, **7a—d**, and **7f,g**) for Gas Chromatography Analyses.* 5-Methoxy-3-methylbenzofuran (**2a**) was prepared by Whalley's method,[5] **2c** by Rosseels' method,[6] **2d** by Deorha's method,[7] **2f** by Auwer's method,[19] and **2g** by Tanaka's method.[20] methyl ester **7a** was prepared by methylation of **3a** with diazomethane in ether.[5]

*3,5-Dimethylbenzofuran (**2b**).* A mixture of **1b** (5.0 g), anhydrous sodium acetate (13.0 g), and acetic anhydride (85.0 ml) was heated at 110±1 °C for 3 h. After cooling, the reaction mixture was poured into 200 ml of water and stirred for 1 h and then extracted with 300 ml of ether. The ethereal solution was washed with 3% potassium carbonate solution (40 ml×3), with water (40 ml×3), and dried over anhydrous sodium sulfate. Ether was removed by evaporation and the residue was distilled under reduced

pressure to give 2.74 g (72%) of **2b** as colorless oil, bp 83 °C at 12 Torr.† IR (neat): ν_{max} 3120, 3022, 2950, 2923, 1580, 1450, 1289, 868 (furan ring), 804 cm^{-1} (two adjacent aromatic hydrogen atoms). Found: C, 82.03; H, 6.96%. Calcd for $C_{10}H_{10}O$: C, 82.16; H, 6.89%.

*Methyl 3,5-Dimethyl-2-benzofurancarboxylate (**7b**).* Diazomethane in ether was added to an ethereal solution of **3b**[21] (1 g) until the reaction mixture turned yellow and the solution was allowed to stand at room temperature for 20 min. The residue (1.2 g) obtained upon evaporation of ether was recrystallized from aqueous methanol to give 0.7 g (84%) of **7b** as colorless short needles, mp 50—51 °C. IR (KBr): ν_{max} 1713 ($-CO_2-$), 844 (furan ring), 808 cm^{-1} (two adjacent aromatic hydrogen atoms). Found: C, 70.45; H, 5.94%. Calcd for $C_{12}H_{12}O_3$: C, 70.57; H, 5.92%.

*Methyl 3-Methyl-2-benzofurancarboxylate (**7c**).* In the same manner as has been described for **7b**, **7c** (3.82 g, 93%) was prepared from **3c**[22] (3.34 g). Recrystallization of **7c** from methanol gave colorless short needles, mp 69—70 °C. IR (KBr): ν_{max} 1705 ($-CO_2-$), 837 (furan ring), 763 cm^{-1} (four adjacent aromatic hydrogen atoms). Found: C, 69.41; H, 5.38%. Calcd for $C_{11}H_{10}O_3$: C, 69.46; H, 5.29%.

*Methyl 5-Chloro-3-methyl-2-benzofurancarboxylate (**7d**).* In the same procedure as the preparation of **7b**, ester **7d** (1 g, 94%) was obtained from **3d**[7] (1 g). Recrystallization of **7d** from methanol gave colorless short needles, mp 95.0—95.8 °C. IR (KBr): ν_{max} 1708 ($-CO_2-$), 813 cm^{-1} (two adjacent aromatic hydrogen atoms). Found: C, 58.89; H, 4.15%. Calcd for $C_{11}H_9ClO_3$: C, 58.81; H, 4.03%.

*Ethyl 5-Methyl-2-benzofurancarboxylate (**8f**).* A mixture of 5-methylsalicylaldehyde[17] (**5f**) (3 g), ethyl bromoacetate (10 g), and anhydrous potassium carbonate (12 g) was heated at 140 °C for 6 h. After cooling, acetone (100 ml) was added to the reaction mixture and the insoluble salts were removed by filtration. The residue obtained upon evaporation of acetone was purified by column chromatography and eluted with benzene to give crude **8f** (3.6 g, 80%). Recrystallization from hexane gave colorless short needles, mp 41—42 °C. IR (KBr): ν_{max} 3003, 2950, 2880, 1728 ($-CO_2-$), 1297, 1214, 820 cm^{-1} (two adjacent aromatic hydrogen atoms). Found: C, 70.52; H, 5.92%. Calcd for $C_{12}H_{12}O_3$: C, 70.57; H, 5.92%.

*5-Methyl-2-benzofurancarboxylic Acid (**3f**).* A mixture of **8f** (2.2 g) and 20% potassium hydroxide solution (25 ml) was refluxed for 1 h. After cooling, the reaction mixture was acidified with 6 M hydrochloric acid and the precipitates were filtered, washed with cold water, and dried under vacuum to give crude **3f** (1.8 g, 94.8%). Recrystallization from acetone gave colorless plates, mp 237—238 °C (lit,[23] mp 237 °C). IR (KBr): ν_{max} 1693 (CO_2H), 1623, 1585, 921 (CO_2H), 827 cm^{-1} (two adjacent aromatic hydrogen atoms), (Found: C, 68.29; H, 4.67%).

*Methyl 5-Methyl-2-benzofurancarboxylate (**7f**).* In the same procedure as the preparation of **7b**, ester **7f** (1.4 g, 87.5%) was obtained from **3f** (1.5 g). Recrystallization of **7f** from aqueous methanol gave colorless short needles, mp 58.5—59.5 °C. IR (KBr): ν_{max} 1723 ($-CO_2-$), 808 cm^{-1} (two adjacent aromatic hydrogen atoms). Found: C, 69.38; H, 5.34%. Calcd for $C_{11}H_{10}O_3$: C, 69.47; H, 5.29%.

*2-Benzofurancarboxylic Acid (**3g**).* A mixture of salicylaldehyde (**5g**) (10 g), ethyl bromoacetate (54.7 g), and anhydrous potassium carbonate (45 g) was heated at 100 °C for 1.5 h then at 140 °C for 4.5 h. After cooling, water (300 ml) was added to the reaction mixture, which was extracted with ether. The ethereal solution was washed with water, dried over anhydrous sodium sulfate, and concentrated by evaporation. The residue was hydrolyzed without purification as has been described for **3f** to give 7.4 g of **3g** in a 55.7% yield. Recrystallization from aqueous acetone gave colorless plates, mp 193.0—193.5 °C (lit,[20] mp 192—193 °C). IR (KBr): ν_{max} 1680 and 943 (CO_2H), 745 cm^{-1} (four adjacent aromatic hydrogen atoms), (Found: C, 66.77; H, 3.93%).

*Methyl 2-Benzofurancarboxylate (**7g**).* By the same procedure as the preparation of **7b**, ester **7g** (0.8 g, 82%) was prepared from **3g** (0.9 g). Recrystallization from aqueous methanol gave colorless short needles, mp 52—53 °C. IR (KBr): ν_{max} 1732 ($-CO_2-$), 758 cm^{-1} (four adjacent aromatic hydrogen atoms). Found: C, 68.36; H, 4.64%. Calcd for $C_{10}H_8O_3$: C, 68.17; H, 4.57%.

The authors wish to thank to Mr. Hideo Saisu for infrared analyses, to Mr. Takao Ohno for nuclear magnetic resonance analyses, and to Mr. Yoshiaki Takahashi for the elemental analyses.

† 1 Torr = 133.322 Pa.

Product Distribution in Degradation of Polypropylene over Silica-Alumina and CaX Zeolite Catalysts

Yoshio UEMICHI,* Yasunori KASHIWAYA, Masaya TSUKIDATE, Akimi AYAME, and Hisao KANOH

Department of Industrial Chemistry, Muroran Institute of Technology, Mizumoto-cho, Muroran 050

(Received March 14, 1983)

The composition of degradation products of polypropylene, especially liquid fraction, formed over silica-alumina and CaX zeolite catalysts was investigated extensively. The catalysts gave almost the same product distribution as a function of carbon number at the initial stages of the reaction. The liquid fractions were rich in the same isoalkanes and aromatics as those contained in the gasoline fraction. Most of the isoalkanes were methyl-branched, while the aromatics consisted mainly of those with one or more methyl groups. The catalytic degradations involved extensive aromatization, isomerization and hydrogen transfer as secondary reactions. The difference in catalytic behaviors between silica-alumina and CaX was most remarkable in coke deposition on the catalysts and more deposition on CaX led to greater saturation of the products. The H/C ratio of the products was regarded as a good measure for the degree of coke formation on the catalyst surfaces.

In recent years attention has been paid to the reuse of plastic wastes from the viewpoint of energy diversification, necessitating the development of processes capable of recovery as chemical resources or fuel. As the thermal degradation products of polypropylene are distributed in a wide range of carbon numbers,[1,2] the utility value of the products recovered is low, so that upgrading will be required for efficient utilization of them. On the other hand, a selective recovery of useful fractions is possible in catalytic degradation and further the product distribution is controlled more readily than the case of thermal degradation. Thus, the catalytic procedures are superior to thermal methods provided that the products are intended for resources. However, only a few investigation have been reported on catalytic degradation of polypropylene.[3-5] A great deal of emphasis is placed on the identification of the products in thermal degradation of polypropylene.[6-9] Similarly, a detailed analysis of the products is undoubted to be important also in catalytic degradation, but there has been no report on an extensive analysis of degradation products of polypropylene in the presence of acid catalysts because of complexity of the product composition. The authors have already reported the catalytic degradations of polypropylene over silica-alumina and CaX zeolite,[3] which were aimed at the formation of gaseous fractions so that the liquid fractions were characterized by gross properties such as average molecular weight, iodine number and infrared spectrum. However, it is expected that a survey of the composition of liquid fractions is very informative for clarifying the degradation mechanism, and further the survey will be a significant research for efficient utilization of the products.

From the point of view described above, the purpose of this study is to identify the degradation products, especially liquid fractions, of polypropylene over silica-alumina and CaX zeolite catalysts and to discuss the catalytic degradation mechanism.

Experimental

Apparatus and Procedures. The experiments were conducted in the same fixed-bed flow system, except that a water-cooler was connected at the outlet of a separator, as in the previous study.[3] Polypropylene sample was melted in a melter at 240 °C under an atmosphere of nitrogen. The melt of polypropylene was introduced into a reactor through a capillary of inside diameter of 2 mm. The feed rate of polypropylene was controlled by both the temperature of the capillary and the pressure of the nitrogen in the melter. They were kept constant through a run at given levels in the range of 280—320 °C and 0.3—0.4 kg/cm^2 G, respectively. Liquid products were collected in the separator at 20 min intervals. Because of high activities of the catalysts, the relatively low temperature of 477 °C was employed for catalytic degradation, rather than 526 °C which was used for the thermal degradation.

Materials. Isotactic polypropylene and silica-alumina and CaX catalysts were the same as those used in the previous study.[3] The average molecular weight of the polypropylene was 1.6×10^5 and its tacticity was characterized by pyrolysis-gas chromatographic method.[10] The catalysts were calcined before use in the air at 550 °C for 3 h and 3.0 g of each catalyst was used in a run. A reactor packed with glass beads of 3.5 mm in diameter was used in thermal degradation.

Analysis. The degradation products were analyzed by gas chromatography. Three columns, VZ-7 (5 m×3 mm i.d.), active carbon (1 m×3 mm i.d.) and OV-101 (50 m×0.28 mm i.d.), were used for the separation of components. Two methods were employed as supplementary techniques for the identification of the products. One was hydrogenation of alkenes using a column of supported palladium catalyst. The other was selective absorption of alkenes and aromatics using an absorbent column of supported mercury(II) perchlorate. The details of the two methods have been described elsewhere.[11] A splitter was independently held at 250 °C to attain reproducible splitting for the degradation products with a wide range of volatility. The peaks in a chromatogram were identified by co-injection of the products with standard materials. When pure materials were not available, the identification was based on a linear relation between boiling point and retention index. From a quantitative analysis using methylcyclohexane as internal standard, the products were found to contain nondetectable fractions under the gas chromatographic condition, and so they were summarized as high-boiling-point products (H.B.P).

Results and Discussion

polypropylene was simplified by the selective absorption of alkenes and aromatics, which resulted in a chromatogram consisting of saturated hydrocarbons only. The absorbed alkenes and aromatics were distinguished each other by the hydrogenation over palladium catalyst. The hydrogenation caused a transformation of alkenes to corresponding alkanes, although aromatics except for naphthalenes were not hydrogenated. Thus, the degradation products were classified into five groups of hydrogen, normal alkanes, isoalkanes, alkenes and aromatics. However, most of the alkenes were difficult to identify because of many possible isomers. The product distributions as a function of carbon number at the initial stages of the reaction are shown in Table 1. Both catalysts gave essentially the same distribution and the relative yield of C_3—C_6 fractions was very high. Isoalkanes were preferentially produced in C_4—C_6 fractions. The selectivity to aromatics became higher, while that to alkenes decreased, as carbon number increased. The products formed over CaX were more saturated than those over silica-alumina. The difference in the degree of saturation would be attributed to the extent of hydrogen transfer reaction. This will be described later. The normal alkane content was always smaller than that of isoalkanes and, as carbon number increased, the content of multibranched alkanes increased in proportion to the number of possible isomers. Figure 1 well illustrates these facts for the products formed over silica-alumina. Here, most of the branchings were methyl groups. CaX catalyst also gave the same distribution of alkane isomers. Further, detailed compositions of aromatics are shown in Table 2. Toluene, xylenes and trimethylbenzenes were the main aromatics. The aromatics with ethyl group were minor products and those with C_3 or C_4 alkyl group were little produced. Therefore, C_{10} aromatics in Table 2 would correspond

to those with methyl and/or ethyl groups.

In general, isomer distribution is strongly dependent on thermodynamics. Table 3 shows the comparison between isomer distribution and thermodynamic equilibrium.[12–14] Alkene and aromatic isomers were distributed approximately in accord with the corresponding thermodynamic equilibria, whereas the distribution of alkane isomers was entirely different and the content of branched alkanes exceeded the possible thermodynamic equilibrium concentration. These results indicate that equilibria of alkene and aromatic isomers are more rapidly attained than an equilibrium among alkanes. Although each component of alkenes larger than C_5 fraction was not identified, it is expected that alkenes show a higher ratio of linear to branched hydrocarbons than do the alkanes of the same carbon number. This is because of faster saturation of branched alkenes than linear alkenes.[15]

As mentioned above, the liquid products from catalytic degradation of polypropylene contained large amount of isoalkanes and aromatics which constitute the gasoline fraction.[16] The formation of a gasoline fraction seems to be advantageous for a utilization of the products. Further, the composition of the catalytic degradation products of polypropylene over silica-alumina resembled that of polyethylene.[11] A

TABLE 5. EFFECTS OF CONTACT TIME AND REACTION TIME ON COMPOSITION OF THE PRODUCTS FORMED OVER SILICA-ALUMINA[a]

a) Composition: mol%, reaction temperature: 477 °C. b) Reaction time.

similar result is probably available over CaX.

Since polypropylene is presumably decomposed thermally to some extent under conditions of catalytic degradation, the characterization of the products in thermal degradation is of great significance to clarify the catalytic degradation mechanism. The product distribution in thermal degradation is shown in Table 4. The composition of the liquid fractions was very complicated consisting of about ninety components of C_5—C_{24} fractions. The identification of each component was further complicated because of many diastereomeric isomers derived from methyl branchings along the polymer chain. However, the chromatogram was simplified after hydrogenation, because three peaks of alkane, alkamonoene and alkadiene with the same carbon skeleton became a single peak of alkane. So, the liquid products were identified from the analysis of the hydrogenated products according to the method by Sugimura *et al.*[10] Main products were propylene, 2-methyl-1-pentene (propylene dimer), 2,4-dimethyl-1-heptene (trimer), 2,4,6-trimethyl-1-nonenes (tetramers consisting of two diastereomeric isomers), and 2,4,6,8-tetramethyl-1-undecenes (pentamers of four diastereomeric isomers), the formations of which have been explained in terms of a radical mechanism involving intramolecular radical transfer to the tertiary carbon atoms in the secondary radicals and subsequent β-scission.[8] This product distribution was approximately in line with the results by other investigators.[6-8] The saturated hydrocarbons in the liquid fractions were pentane, 2-methylpentane, 4-methylheptane, and 4,6-dimethylnonanes (two diastereomeric isomers), but these hydrocarbons except for pentane were minor products. From the results obtained here, the thermal degradation of polypropylene is characterized as follows: The C–C bonds of the chain are preferentially broken and structual isomerization or demethylation of branchings hardly occurs. Most of the products are 1-alkenes. Monomethyl-branched hydrocarbons are limited to isobutylene, 2-methylpentane, 2-methyl-1-pentene and 4-methylheptane. The products of carbon number greater than 8 are branched hydrocarbons with two or more methyl branchings at the even-numbered carbons. Linear hydrocarbon except for C_1—C_3 fragments is pentane only.

As evident from the comparison between catalytic and thermal degradation products, the formation in a large quantity of aromatics and monomethyl-branched hydrocarbons, especially with branchings at the odd-numbered carbons, and higher degree of saturation of the products are remarkable in catalytic degradations. From these characteristics, the catalytic degradation of polypropylene can be considered to proceed to a large extent through aromatization, isomerization and hydrogen transfer reactions together with the C–C bond scission of the chain, and the tertiary carbonium ions which are readily formed because of methyl branchings along the polymer chain would be predominant intermediates.[4] If isomerization or aromatization hardly occurs, the hydrocarbons produced by β-scission of the tertiary carbonium ions should be the same types as those by β-scission of the tertiary radicals in thermal degradation, and further if no hydrogen transfer reaction occurs, most of the products should be alkenes. However, the difference in product distribution of catalytic and thermal degradations would indicate that such fragments listed in Table 4 as main components further isomerize, cyclize or are saturated in catalytic degradation, resulting in the formation of aromatics and monomethyl alkanes. At the present stage of this study, however, a detailed mechanism is not clear.

The effects of contact time and reaction time on the composition of the products obtained over silica-alumina are shown in Table 5. A longer contact time promoted further degradations of liquid fractions to give the increase in the relative yield of gaseous products. The further degradations would be attributed to those of aliphatic hydrocarbons, and aromatics would hardly undergo further degradation, because the amount of aromatics and their composition changed very little with contact time. This low reactivity of aromatics with methyl groups is readily expected from

their great stability. Therefore, the increase in the ratio of aromatics to aliphatics in C_6—C_{12} fractions with contact time is a reasonable result.

The product composition was also dependent on reaction time. More alkenes were produced (Table 5) and the distribution of the products shifted to higher carbon numbers (Table 1) as increasing reaction time, *i.e.*, progressing deactivation of silica-alumina catalyst. Even after 3 h, however, the products were concentrated on smaller carbon numbers compared to those obtained by thermal degradation. Similar results were obtained over CaX, but the catalyst deactivated with reaction time more rapidly than silica-alumina, as can be seen from the larger shift in product distribution shown in Table 1. Over both catalysts, high-boiling-point products were formed in increasing amount as reaction time lengthened, but the fractions of carbon number from 16 to 24 were absent in significant amounts. The gas chromatographic conditions used in the present study were enough to detect quantitatively the fractions of carbon number up to about 24. Therefore, the high-boiling-point products were estimated to be hydrocarbons with carbon number of at least greater than 24. Further, high viscous products showing wax-like aspect at room temperature were obtained when CaX catalyst was largely deactivated, suggesting the presence of such hydrocarbons with high molecular weight as estimated above. Although there is no evidence in the results obtained here for determining whether the degradation of polypropylene in the presence of the catalysts is initiated catalytically or thermally, the thermal initiation reaction would undoubtedly occur at reaction temperature of 477 °C and the catalytic initiation is also likely to occur. Kodaira *et al.*[4] showed by thermogravimetric analysis that polypropylene was decomposed at lower temperature by 50—100 °C in the presence of natural zeolite than that in the absence of the catalyst. This would suggest the participation of the zeolite catalyst in the initiation reaction and probably the catalytic initiation reaction takes place at external surface or neighborhood of pore mouth of the catalyst. In this study, therefore, it seems reasonable to assume that polypropylene is first decomposed thermally or catalytically to produce fragments of various sizes and then smaller fragments, which are able to diffuse into pores of the catalysts, selectively proceed to catalytic degradation, whereas larger fragments which can not diffuse into catalyst pores turn out as high-boiling-point products.

As described above, contact time and reaction time had large effects on alkene content, which was expected to be closely associated with coke deposition, and so the amount of coke deposited on catalyst was determined in each series of experiments by measuring the increase in catalyst weight. As is known commonly in catalytic cracking reaction, the relation between the weight percent of coke on catalyst, C, and reaction time, t,[17] is given as follows:

$$C = at^n,$$

where a and n are constant. The results of the present experiments using silica-alumina and CaX catalysts are shown in Fig. 2. The deposition of coke on silica-alumina followed the above relation. On the other hand, the relation in the case of CaX was satisfied only during the first 50 min on stream and after about 100 min the coke formation was substantially stopped. Figure 3 shows the dependence of the rate of coke formation on reaction time. Coke formation was extremely rapid in the initial reaction stages, at which CaX had nearly twice the rate of coke formation compared with silica-alumina, but the rate showed a severe decline with reaction time, while the decline was much less severe on silica-alumina. The amount of coke deposited during 3 h was nearly independent of feed rate over both catalysts. This observation means that the weight percent of coke on feed increases with contact time, that is, coke is more susceptible to deposition under a condition of longer contact time to produce less amount of alkenes.

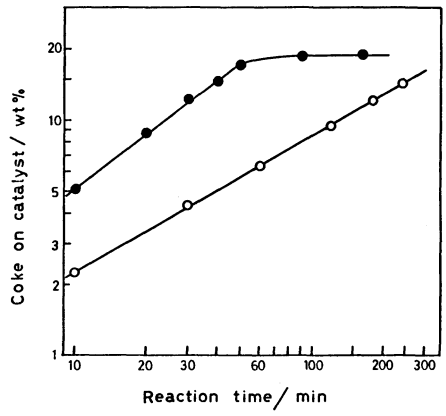

Fig. 2. Relation between coke deposition and reaction time at 477 °C.

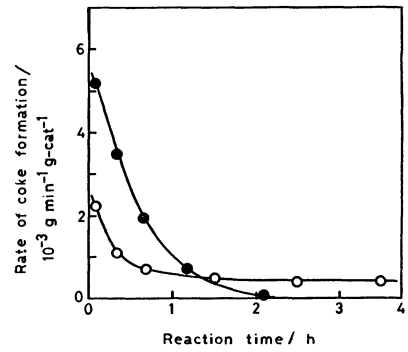

Fig. 3. Variation in rate of coke formation with reaction time.
Reaction conditions: See Fig. 2. ○: Silica-alumina, ●: CaX.

In this study, it was possible to evaluate the H/C ratio of the products. As the H/C ratio of polypropylene, $(C_3H_6)_n$, is 2, it should be also 2 for total degradation products provided that coke deposition is negligibly small. The ratio, in fact, was 2.03 in the thermal degradation. A slight deviation from the theoretical value of 2 would be due to the assumption that all of alkenes and high-boiling-point products were alkamonoenes. If some alkadienes are contained in

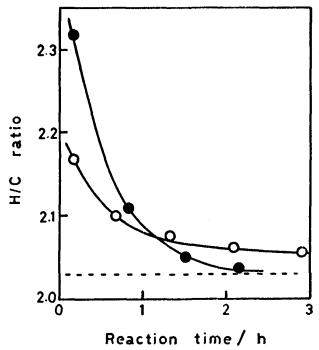

Fig. 4. Dependence of H/C ratio of products on reaction time.
Reaction conditions: See Fig. 2. ○: Silica-alumina, ●: CaX. ----: Level in thermal degradation under the same conditions as Table 4.

Reaction conditions: See Fig. 2. ○: Silica-alumina, ●: CaX.

the thermal degradation products, and this can probably be so, the ratio approaches 2. On the other hand, the H/C ratios of catalytic degradation products were greater than 2 and reduced with reaction time as shown in Fig.4. The curves in the figure resembled those of the rate of coke deposition (Fig. 3) in shape. When the rate over CaX became nearly zero in about 2 h, the ratio reached to the level of the products by thermal degradation. Therefore, the reduction of the H/C ratio with increasing reaction time is concluded to result from the decrease in coke deposition since the supply of hydrogen from a coke precursor to unsaturated molecules, *i.e.*, hydrogen transfer, leads the H/C ratio greater than 2. The hydrogen transfer occurs also in aromatization process, but it has no effect on the ratio. Thus, the H/C ratio of products will be a good and qualitative indicator for expressing the degree of formation of coke. By taking into account the coke deposition, the effects of contact time and reaction time on alkene content were reasonably explained. As aromatics are much more strongly adsorbed on acid catalysts than more saturated hydrocarbons, it seems reasonable to assume that aromatics, particularly of condensed rings such as naphthalenes, most closely relate to coke deposition.[18,19]

Figure 5 shows that the accumulation of coke exerts its effect by reducing surface area of the catalysts. About 95% loss in surface area was observed at 19 wt% of coke on CaX catalyst. This level of coke deposition would be close to a limiting degree in the reaction conditions. More pronounced reduction in surface area of CaX compared with silica-alumina makes possible to assume that CaX catalyst with smaller pores is susceptible to clogging of its pore structure by coke and consequent elimination of accessible surface. As the clogging disturbs the diffusion of reactants or products, coke itself is a diffusion barrier. This pore clogging may occur more or less on silica-alumina, but apparently it does not occur to the same extent as on CaX. The coke deposition, of course, is dependent on acidic properties of catalyst, but depends also on pore structure. Therefore, it seems clear that the formation of coke has large effect on catalyst diffusivity.

Electro-organic Reactions on Organic Electrodes. Part 2.[1] Electrochemical Asymmetric Reduction of Citraconic and Mesaconic Acids on Optically-active Poly(amino acid)-coated Electrodes[2]

Tsutomu NONAKA,* Shigemitsu ABE, and Toshio FUCHIGAMI

Department of Electronic Chemistry, Graduate School at Nagatsuta, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama, 222

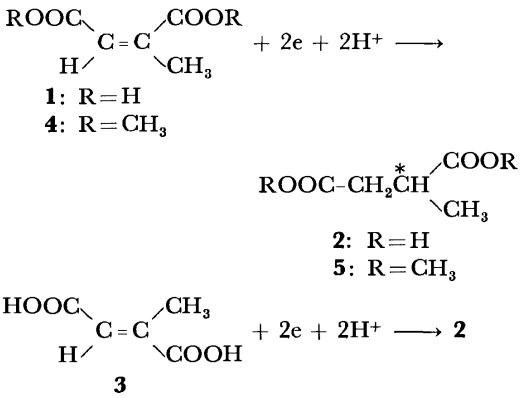
(Received March 23, 1983)

Influence of a number of electrolytic conditions on the asymmetric yield of methylsuccinic acid (**2**) formed in the electrochemical reduction of citraconic acid (**1**) on poly(amino acid)-coated electrodes was examined. The asymmetric yield was greatly affected by the conditions, while the absolute configuration of an excess enantiomer((*S*)-(−)-**2**) remained unchanged even when a polymer with the reversed configuration of the monomer unit was used. The configuration of the excess enantiomer was also unchanged in the asymmetric reduction of mesaconic acid which is the geometrical isomer of **1**.

Some methods for electrochemical asymmetric reduction of prochiral compounds had been reported, as summarized by Tilborg and Smit.[3] Among the methods, only the use of optically-active alkaloids as an asymmetry-inductor had resulted in high asymmetric yields over 40%.[4,5] Recently, Osa *et al.*[6] have reported a new method for the electrochemical asymmetric reduction: They obtained (*S*)-(+)-2-hexanol in 2—6% asymmetric yields from 2-hexanone using Raney-nickel powder electrodes modified with (*S,S*)-(−)-tartaric acid. More recently, we have found another new method[1]: 43 and 25% asymmetric yields were obtained in the reduction of 2-methylcoumarin and citraconic acid (**1**), respectively, on a poly(L-valine)-coated graphite cathode.

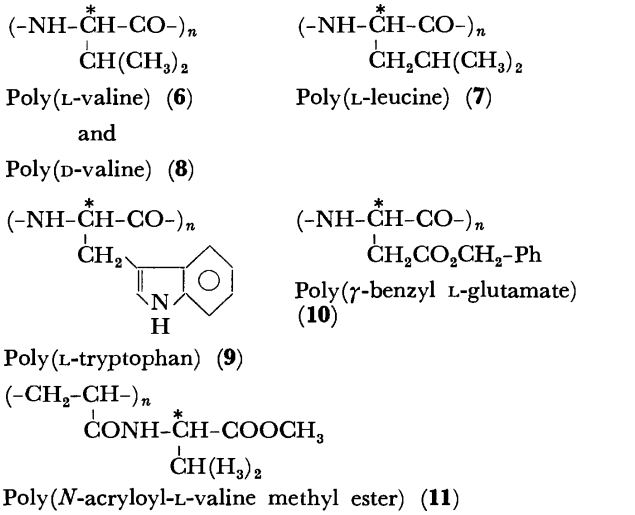
Although a number of studies on polymer-coated electrodes have been recently reported, few papers[7-9] dealing with their electrosynthetic utilization have been published.

In this work, as a part of studies on electrosyntheses of organic compounds using electrodes modified with organic materials, influences of a number of electrolytic conditions on the asymmetric reduction of **1**, its dimethyl ester (**4**), and mesaconic acid (**3**) on optically-active poly(amino acid)-coated electrodes were examined in detail.



Results and Discussion

*Reduction of Citraconic Acid (**1**) on Graphite Coated with Various Poly(amino acid)s.* Poly(amino acid)s (**6**—**11**) prepared from the corresponding optically-pure amino acids were coated on graphite base electrodes by a dipping method in their solutions. Molecular weights of the poly-amino acids except for poly(L-valine) (**6**) (*ca.* 2000[1]) were unknown.



As shown in Fig. 1, the asymmetric yield of methylsuccinic acid (**2**) has a clear relationship to optical rotating powers of the poly(amino acid)s (**6**—**11**), and poly(L-valine) gave the highest asymmetric yield oı 25%. The relationship of the secondary structure(α- and β-forms) of the poly(amino acid)s to the asymmetric yield does not seem to be clear.

Generally, if an asymmetry-inducing reagent with an absolute configuration results in the excess formation of an enantiomer of a compound in an asymmetry-induction reaction, the reagent with the inverted configuration should give another enantiomer inverted configurationaly in the same asymmetric yield under the same conditions. In this viewpoint of the asymmetry induction, it is interesting that both poly(L-valine) (**6**) and poly(D-valine) (**8**), which have the reverse optical rotations and consist of the valine units with the inverted configurations, resulted in the excess formation of the *S*-enantiomer of **2** in different asymmetric yields. This fact suggests that the asymmetry of **2** is induced by the chirality of not only the valine monomer units but also the whole structures of the poly-valines. More generally this should be regarded as one of polymer effects.[10] Electrochemical asymmetric reduction using optically-active polymer-coated

Configuration of excess enantiomer: *S*. c) Electrolytic conditions: pH, 4.7; current density, 1.2 A dm^{-2}; charge passed, 96500×2.0 C mol^{-1}; concentration of **1**, 0.145 M (mol dm^{-3}); temperature, 20 °C.

electrodes may be also characterized by this polymer effect.

*Reduction of Citraconic Acid (**1**) on Some Base Electrodes Coated with Poly(L-valine).* As shown in Table 1, graphite was better as a base electrode material than metals such as lead and zinc.

A poly(L-valine) (**6**) film may be fixed on a graphite surface by hydrogen bonding of the amido groups of **6** with oxygen functions such as COOH, CO and OH, while such a hydrogen bonding can not be formed on the metal surface. Even if the hydrogen bonding with surface oxides of the metals might be formed, it should be exhausively disappeared by reduction of the oxides during electrolysis. The adsorptivity of **6** on the base electrodes seems to be one of important factors in the asymmetric reduction.

*Reduction of Citraconic Acid (**1**) on Poly(L-valine) (**6**)-coated Graphite Electrode. Influence of Coating Thickness*: Because the thickness of coating films could not be directly measured, the relation between the number of chirality centers on the electrode and the asymmetric yield was examined. As shown in Fig. 2, the highest asymmetric yield was obtained using an electrode with 0.25×10^{22} cm^{-2} of the number of chirality centers. If the density of **6** is in the range of 0.8—1.4 similarly to ordinary organic polymers,[11] the thickness of the film is estimated as $(2.8—1.6)\times10^{-4}$ cm.

Increase of the thickness resulted in remarkable de-

crease of the asymmetric yield. This may be suggest that a key step for the asymmetry induction does not occur inside the film. The induction may occur in an interface between the film and the graphite.

Influence of pH: As shown in Fig. 3, the highest asymmetric yield was obtained at pH 6.0, while the cuurent efficiency decreased at pHs higher than 6.0 and **2** was not formed in alkaline solutions. Although such a pH dependence is interesting from an aspect of the asymmetry induction mechanism of this reaction,

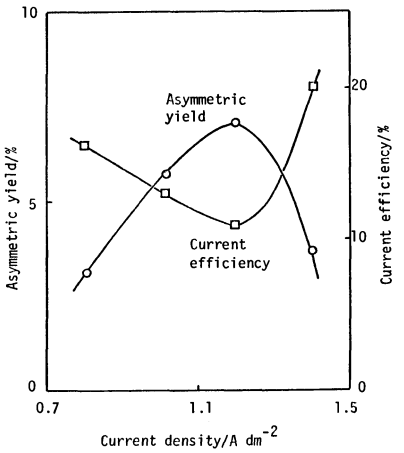

Fig. 6. Influence of current density on reduction of citraconic acid (**1**) to methylsuccinic acid (**2**) on poly(L-valine)-coated graphite electrode (number of chirality centers, 0.25×10^{22} cm^{-2}).
Electrolytic conditions: pH, 4.7; temperature, 20 °C; concentration of **1**, 0.145 M; charge passed, 96500×2.0 C mol^{-1}.
Configuration of excess enantiomer of **2**: *S*.

it is difficult to rationalize clearly the dependence. The asymmetry induction mechanism will be discussed from another aspect in a little more details in the final item of the text.

Influence of Temperature: As shown in Fig. 4, the highest asmmetric yield was obtained at *ca.* 0 °C. In most cases of asymmetric reactions, lower temperature is more favorable. A lower asmmetric yield at −20 °C in this work may be due to an undesirable change in film properties of **6** at such a low temperature, which may be close to its glass transition temperature.

Influence of Cathode Potential: Figure 5 indicates that lower potentials resulted in higher asymmetric yields and current efficiencies. This fact may suggest that hydrogen evolution on the graphite surface decreased the adsorptivity of the **6** film, because hydrogen bubbles might not smoothly go through the film, and consequently the asymmetry-inducing power of the coated electrode was decreased.

Influence of Current Density: The highest asymmetric yield and the lowest current efficiency were obtained at 1.2 A dm^{-2} of current density, as shown in Fig. 6.

Influence of Charge Passed: Influence of charge passed on the asymmetric yield and current efficiency was examined in controlled-potential electrolyses at −1.0 V *vs.* SCE. As shown in Fig. 7, passing of larger amounts of charge, in another word longer time of the electrolyses, resulted in decrease of both the asymmetric yield and current efficiency. The decrease of the former may be caused by the decrease of the asymmetry-inducing power of the **6** film due to contamination of the film-graphite interface during the electrolysis.

Reuse of Electrode: An electrode was repeatedly reused at 1.2 A dm^{-2} of current density passing 96500×2.0 C mol^{-1} of charge for each electrolysis. As shown in Fig. 8, the asymmetry inducing power of **6** was lost at the fifth electrolysis, the film of **6** remained

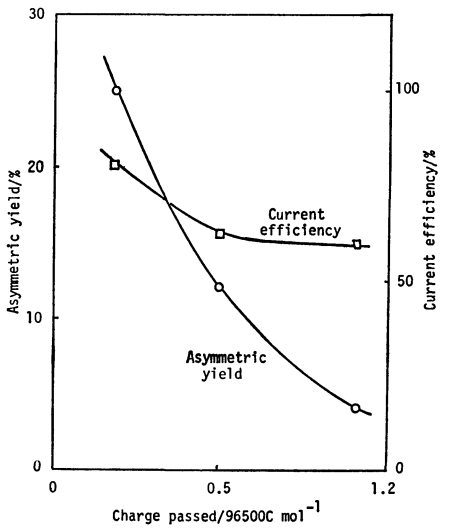

Fig. 7. Influence of charge passed on asymmetric reduction of citraconic acid (**1**) to methylsuccinic acid (**2**) on poly(L-valine)-coated graphite electrode (number of chirality centers, 0.25×10^{22} cm^{-2}).

on the electrode surface. The chemical yield did not change.

Optimization of Asymmetric Reduction of Citraconic Acid (1). The asymmetric reduction of **1** on the poly (L-valine)-coated graphite electrode is optimized under the conditions given in Table 2. From a synthetic aspect, it is undesirable that small amounts of charge passed and/or short electrolysis time are needed to obtain high asymmetric yields. To dissolve this problem, a high current concentration electrolysis using a high surface electrode may be recommended.

Table 2. Optimization of electrochemical asymmetric reduction of citraconic acid (**1**) to methylsuccinic acid (**2**) on poly(amino acid)-coated electrode

Condition	Optimum
Optically-active poly-amino acid	poly(L-valine)
Base eleactrode material	Graphite
Number of chirality centers on electrode	0.25×10^{22} cm^{-2}
pH	6.0
Cathode potential	-1.00 *vs.* SCE (Low as possibe)
Current density	1.2 A dm^{-2}
Temperature	0—5 °C
Charge passed	Small as possible
Reusing time of electrode	First use
Electrolysis time	Short as possible

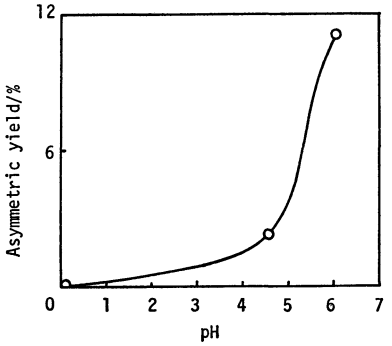

Fig. 9. Asymmetric reduction of mesaconic acid (**3**) to methylsuccinic acid (**2**) on poly(L-valine)-coated graphite electrode (number of chirality centers, 0.25 $\times10^{22}$ cm^{-2}).
Electrolytic conditions: current density, 1.2 A dm^{-2}; temperature, 0—5 °C; charge passed, 96500×2.2 C mol^{-1}; concentration of **1**, 0.145 M.
Current efficiency and yield: 33—45%. Configuration of excess enantiomer of **2**: *S*.

Asymmetric Reduction of Dimethyl Citraconate (4) to Dimethyl Methylsuccinate (5). As shown in Table 3, the asymmetric yield of **5** was extremely low compared with those of **2** formed under the same conditions. This fact suggests that hydrogen bonding of carboxyl groups of **1** contributes to the asymmetry induction.

Asymmetric Reduction of Mesaconic Acid (3) to Methylsuccinic Acid (2). As shown in Fig. 9, **3** gave **2** in lower asymmetric yields than **1**, while both **3** and **1** gave the enantiomer with the *S*-configuration in excess. These results seem to be important for the discussion of the asymmetry induction mechanism.

Asymmetry Induction Mechanism. The poly(amino acid) film coated on base electrode surface is not electroconductive and does not include any electron-carrier, and also is so thick that any electron can not go through the film. Protons and substrate molecules may go through the film, because electrolyses proceeded smoothly without any remarkable cell-voltage increase. Therefore, electron-transfer to the substrate seems to occur in the interface of the film and the base electrode.

Although the mechanism of electrochemical asym-

metry induction was discussed on the basis of steric interaction between prochiral substrate and chiral supporting salt molecules by Horner and Skaletz,[12] any essential conclusion has not been reported. Generally, it may be possible to suppose two types of the asymmetry induction mechanisms, as indicated below: (a) Asymmetric electron-transfer and (b) asymmetric protonation. As described above, **4** was not asymmetrically reduced. This fact may be as due to no interaction between S and I* (in the (a)-mechanism) by hydrogen bonding and thus support the (a)-mechanism. In addition, it may also support the (a)-mechanism that **1** and **3** gave **2** with the same configuration in different asymmetric yields: In the (b)-mechanism, **1** and **3** should give **2** in the same asymmetric yield, because an intermediate $H\bar{S}$ formed via no enantiodifferentiating step from either of **1** and **3** should be racemic. On the other hand, the (a)-mechanism is not in conflict with the above experimental results: Since *cis*- and *trans*-carboxylic groups interact with I*(**6**), **1** and **3** in somewhat different ways give the different asymmetric yields. Although it is difficult to give a concrete conclusion for the asymmetry induction mechanism, the (a)-mechanism is tentatively proposed for the asymmetry induction mechanism.

(a) $S + I^* \rightleftharpoons SI^* \overset{2e+H^+}{\rightleftharpoons} H\bar{S}^* + I^* \xrightarrow{H^+} HS^*H + I^*$

$H^+ + I^*$

(b) $S \overset{2e+H^+}{\rightleftharpoons} H\bar{S} \xrightarrow{H^+I^*} HS^*HI^* \longrightarrow HS^*H + I^*$

S: Prochiral substrate.
I: Chiral asymmetry-inducing reagent.
HSH: Product.
*: Chiral species.

Experimental

Materials. Citraconic acid (**1**) and mesaconic acid (**3**) were supplied from Tokyo Kasei Chemical Co., while dimethyl citraconate (**4**) was prepared by the esterification of **3** with diazomethane in ether and purified by silica-gel column chromatography (bp, 98 °C/15 Torr (lit,[13] 92.8 °C/10 Torr, 1 Torr≈133.322 Pa)).

Poly(L-valine) (**6**), poly(L-leucine) (**7**), poly(D-valine) (**8**), and poly(L-tryptophan) (**9**) were prepared from the corresponding optically pure amino acids by the NCA method.[1] Poly(γ-benzyl-L-glutamate) (**10**) was supplied from Dr. K. Komoto of Tokyo Institute of Technology and poly(*N*-acryloyl-L-valine methyl ester) (**11**) was prepared by a following method. To 10 ml of an aqueous solution containing 3.1 g (0.03 mol) of triethylamine and 5.0 g (0.03 mol) of L-valine methyl ester were dropwise added 3.0 g (0.033 mol) of acryloyl chloride and 11 ml (0.033 mol) of 3 mol dm^{-3} NaOH for 5 h under ice-cooling. After the the reaction mixture was acidified (pH 2—3) with 5 mol dm^{-3} HCl, it was extracted with ethyl acetate. By distillation of the extract in the presence of a small amount of hydroquinone, 3.4 g (62%) of *N*-acryloyl-L-valine methyl ester was obtained: bp, 128 °C/10 Torr (lit,[14] 102 °C/3 Torr); MS, *m/e* 185 (M^+); IR (film), 3300, 1760, 1660, and 1630 cm^{-1}. The ester (2.0 g, 0.011 mol) obtained thus was polymerized in 12 ml of dry methanol in the presence of 0.02 g of 2,2′-azobisisobutyronitrile at 50 °C for 2 h. The reaction mixture was poured into 100 ml of water and 0.72 g (36%) of **11** was obtained as precipitates: IR (KBr), 3350, 1750, and 1670 cm^{-1}. Found: C, 58.31; H, 8.27; N, 7.35%. Calcd for $(C_9H_{15}NO_3)_n$: C, 58.36; H, 8.16; 7.56%. The optical rotating powers of all the poly(amino acd)s (**6**—**11**) are given in Fig. 1. The secondary structures confirmed by IR spectra are also given in Fig. 1. The molecular weight (*ca.* 2000) of **6** only could be known.[1] As polymer properties (molecular weight distribution and secondary structure) of poly(amino acid)s are generally affected by their preparative methods and procedures, the same lot products were used for each set of experiments in this work.

Poly(amino acid)-coated Electrodes. The coated electrodes were prepared by the dipping method described in the previous work.[1] Amounts of **6** coated were estimated from its recovery which was made by washing repeatedly the electrode with trifluoroacetic acid or by shaving off the film of **6**: **6** recovered thus was weighed or its nitrogen content was was analyzed.

Electrolysis and Product Analysis. Electrolytic solutions were aqueous ethanol (50—80%) buffered: 1 M (1 M=1 mol dm^{-3}) H_2SO_4 (pH *ca.* 0); 0.5 M $ClCH_2COOH$-0.5 M $ClCH_2COONa$ (pH 2.8); 4 M CH_3COOH-4 M CH_3COONa (pH 4.0); 0.5 M CH_3COOH-0.5 M CH_3COONa (pH 4.7); 0.17 M KH_2PO_4-0.03 M Na_2HPO_4 (pH 6.0); 0.5 M CH_3COONH_4 (pH 6.7, unbuffered); 0.5 M $NaClO_4$ (pH 7.0, unbuffered; 0.05 M $NaHCO_3$-0.1 M Na_2CO_3 (pH *ca.* 10); 0.5 M NaOH (pH *ca.* 14). Procedures for the electrolysis and product analysis were similar to those in the previous work.[1] The asymmetric yields were calculated with reference to optical rotating powers reported for the optically-pure enantiomers: $[\alpha]_D^{20}$ +17.9° (*c* 4.4 in ethanol)[15] for *R*-**2** and $[\alpha]_D^{25}$ +6.1° (neat)[15] for *R*-**5**.

This work was performed as a preliminary investigation for a project supported financially by the Grant-

in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

A new class of bicyclic compounds containing a single silicon atom at the bridge, 2-exo- and endo-substituted 2-methyl-2-silabicyclo[2.2.1]heptanes, have been prepared from the corresponding 3-cyclopentenylmethylhydrosilane by the intramolecular hydrosilylation catalyzed by chloroplatinic acid, and their structures were unquivocally assigned by ^1H and ^{13}C NMR spectra. Dramatic crossover from inversion to retention was found in the phenylation of chlorosilanes with phenyllithium and phenylmagnesium bromide in ether. Regio- and stereoselective insertion of dichlorocarbene generated from phenyl(bromodichloromethyl)mercury, or from chloroform and sodium hydroxide in the presence of a phase transfer catalyst, into $C_{(6)}$–$H_{(exo)}$ bond of 2-silanorbornanes has been observed.

In spite of a large number of publications relating to silacycloalkanes, little attention has been paid to a class of bicyclic organosilicon compounds, except for bridgehead silicon compounds. We have prepared 2-silabicyclo[2.2.1]heptanes (**1**—**5**) by the intramolecular hydrosilylation of (3-cyclopentenylmethyl)hydrosilanes. Very recently Cremer and Blankenship have also reported the preparation of 2-silanorbornanes (**2** and **5**).[2)] Now we report our own results with respect to their characterizations by spectroscopic methods, some interesting stereochemical behaviors on the silicon atom and a remarkably regio- and stereoselective insertion of dichlorocarbene into the $C_{(6)}$ carbon–hydrogen bond.

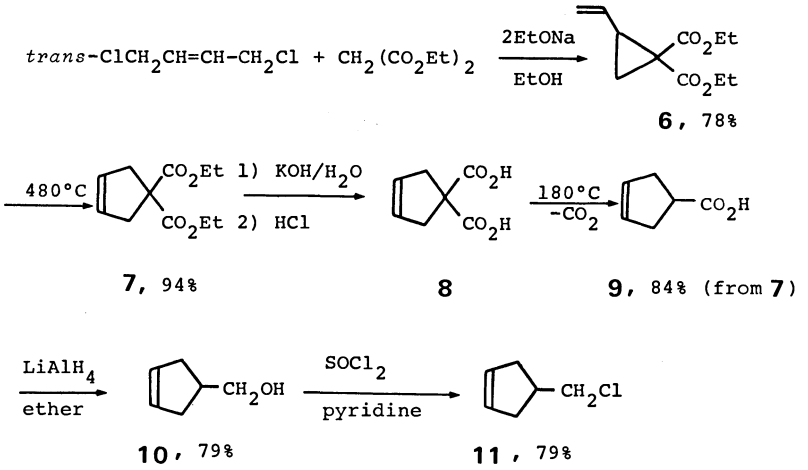
Hitherto optically active silicon compounds have been used almost exclusively in order to investigate the stereochemical behavior of reactions on a silicon atom.[4)] We have felt frequently, however, that these compounds give rise to rather limitations for exploring the stereochemistry of some reactions, *e.g.*, arylations or dearylations, since substituents in the case of optically active silicon compounds are mostly restricted in their kinds. After desiring to produce a quite new system involving geometrical isomers in organosilicon chemistry for several years,[3)] we recently realized this vision by means of the synthesis of 4-*t*-butylsilacyclohexane derivatives.[5)]

The present system possesses a similar molecular structure to the parent norbornane which shows a lot of unique reactivities in ionic[6)] and free radical process,[7)] and at the same time indicates practically the following merits to investigate the stereochemistry: (a) preparation of objective compounds is easily attained in good yield if we use the intramolecular hydrosilylation catalyzed by a transition metal, the procedure of which was already established;[9,10)] (b) resolution of exo and endo isomers is easy by GLC; (c) two isomers are determined by ^1H NMR because the chemical shift of Si–CH_3 protons is characteristic for each isomer; (d) hence it is possible to discuss the stereochemistry of reactions by using both of the geometrical isomers without optical resolution; (e) accordingly a small amount of substrate is sufficient to study the stereochemical behavior by NMR spectroscopy.

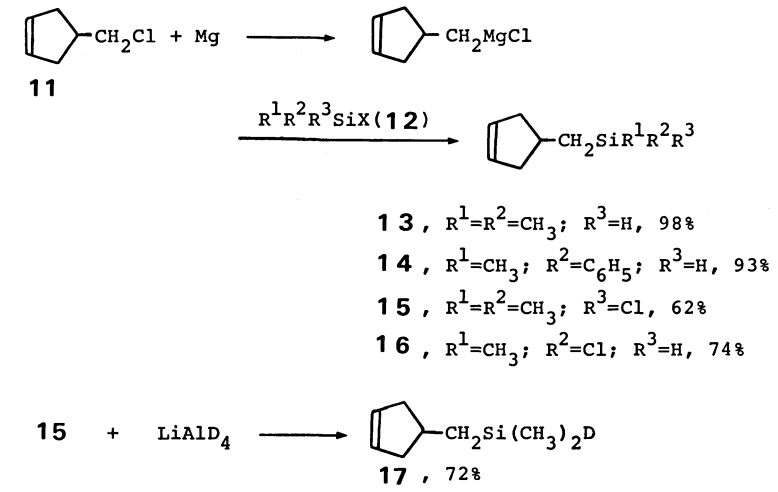
Results and Discussion

Preparation and Characterization. First 3-cyclopentenylmethyl chloride(**11**), the starting alkyl chloride, was prepared from *trans*-1,4-dichloro-2-butene and diethyl malonate in the presence of two equivalents of sodium ethoxide by a six-step synthesis through diethyl 2-vinyl-1,1-cyclopropanedicarboxylate (**6**), diethyl 3-cyclopentene-1,1-dicarboxylate (**7**), 3-cyclopentene-1,1-dicarboxylic acid (**8**), 3-cyclopentenecarboxylic acid (**9**), 3-cyclopentenylmethanol (**10**), as follows (Scheme 1).

The Grignard reagent from **11** in ether as well as (3-cyclopentenylethyl)magnesium bromide[8)] was quite stable, and did not cause any intramolecular cyclization due to the participation of a carbanionic carbon in the olefinic double bond. The addition of bromodimethylsilane and chloromethylphenylsilane to this solution afforded (3-cyclopentenylmethyl)dimethylsilane (**13**) and (3-cyclopentenylmethyl)methylphenylsilane (**14**), respectively, which were the precursors of 2-silanorbornanes, in good yields. (3-Cyclopentenylmethyl)chloromethylsilane (**16**) was prepared by the inverse addition of the Grignard reagent to excess dichloromethylsilane. Analogously (3-cyclopentenylmethyl)dimethyldeuteriosilane (**17**) was derived by the lithium aluminum deuteride reduction of (3-cyclopentenylmethyl)chlorodimethylsilane (**15**) which was conveniently obtained by the inverse addition of the Grignard reagent to dichloromethylsilane. (Scheme 2)



Scheme 1. Synthesis of 3-cyclopentenylmethyl chloride (**11**).



Scheme 2. Synthesis of (3-cyclopentenylmethyl)hydrosilanes (**13**—**17**).

During the investigation of transition metal-[9,10] or free radical-[9]catalyzed hydrosilylation, we[9] and Swicher *et al.*[10] had found that the intramolecular hydrosilylation took place more favorably and easily rather than the intermolecular reaction, provided that a double bond and a silicon–hydrogen bond were separated by three methylene groups, so that this should offer a general and good method to prepare a five or six membered ring compound. Accordingly it will be quite reasonable to consider that the bicyclic compounds involving a silicon atom could be derived intramolecularly from the hydrosilane which involves a cyclic olefin separated by three carbon atoms.

When a neat solution of (3-cyclopentenylmethyl)-dimethylsilane (**13**) was heated in the presence of a catalytic amount of chloroplatinic acid at 130 °C for 100 h in a sealed tube, 2,2-dimethyl-2-silabicyclo[2.2.1]-heptane (**1**) was obtained in 82% yield. Analogously, in the case of R^1=Me and R^2=Ph or Cl, the products **3** and **5** consisting of a mixture of two geometrical isomers at the ratio of *exo*-Me:*endo*-Me=65:35 or 63:37, respectively, were prepared in good yields (Eq. 1). More elevated temperature was required for the cyclization to bicyclic compounds than for that to a monocyclic compound as reported earlier.[9,10] Palladium on charcoal was also effective as a catalyst but free radical initiators not so good.

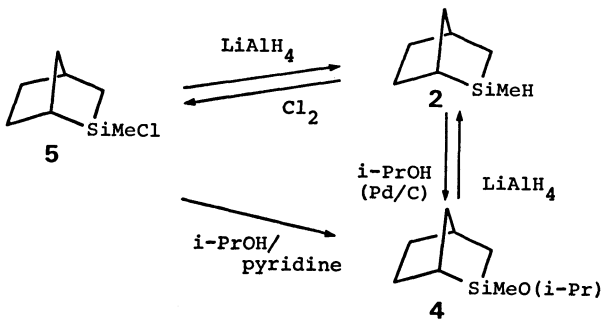
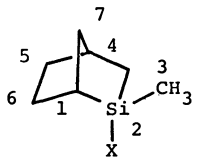
a) δ (ppm), downfield from TMS (0.00 ppm) in $CDCl_3$–$CHCl_3$ (2:1). b) The aromatic carbons resonated at 134.8, 128.0, 129.3 and 137.1 ppm (*o*, *m*, *p*, and *ipso* carbon, respectively). c) The aromatic carbons resonated at 134.1, 127.8, 128.9 and 138.6 ppm (*o*, *m*, *p*, and *ipso* carbon, respectively). d) The methine and methyl carbon of the isopropyl group resonated at 65.6 and 25.0 ppm, respectively. e) 65.3 and 25.0 ppm for the methine and methyl carbon.

Compounds **2** and **4** were mutually prepared from the chlorosilane **5** by the following transformations. (Scheme 3)

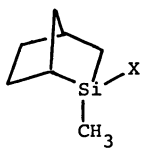


Scheme 3. Mutual transformations between **2**, **4**, and **5**.

Each of stereoisomer of **3** and **4** was readily isolated by fractional distillation and subsequent preparative GLC (Apiezon L, 20% 5 m) collection. In all the compounds investigated in this report the silicon atom has beared at least one methyl group, so that the exo and endo isomers were defined with respect to the methyl group throughout the paper for avoiding confusion. Thus, the exo means that the methyl group orients to exo direction and suffix a is given. Analogously the endo means its geometrical isomer and suffix b is given.



exo: a



endo: b

The unequivocal assignment of the stereochemistry of 2-silanorbornanes could be achieved on the basis of the ^1H and ^{13}C NMR spectroscopic studies where **2a** and **2b** were used. Although neither isomer of **2** could be isolated by GLC collection, a 200 MHz ^1H NMR spectrum of approximately 1:2 mixture of **2a** and **2b** shows that the characteristic signals due to Si–CH_3 and Si–H appear at δ 0.03 (d, J=4.0 Hz) and 0.12 (d, J=4.0 Hz) (3H as a total), and δ 3.72 (m) and 3.87 (m) (1H as a total), respectively. The signals due to 3-exo and 3-endo protons of **2a** and **2b** appear at δ 0.48 (m) as an unseparable multiplet peak, and at δ 0.07 (m) and 0.80 (m), respectively, in a integral ratio of approximately 4:1:1 (2H as a total). $H_{(1)}$, $H_{(4)}$, and $H_{(5),(6),(7)}$ signals of **2a** and **2b** are obtained as peaks which resonate at δ 1.4 (m), 2.5 (m) and 0.9—1.8 (m), respectively, in a ratio of 1:1:6. Irradiation of the higher field Si–CH_3 signal reveals a quartet of the Si–H proton, since the coupling constants due to three vicinal protons, $H_{(1)}$, $H_{(3exo)}$ and $H_{(3endo)}$, become equal (J=2.5 Hz) fortuitously. Thus, small $J_{(2),(3endo)}$ and $J_{(2),(3exo)}$ suggest that this isomer should be the exo (**2a**). On the other hand

Table 2. Si-CH_3 Proton chemical shifts of 2-silanorbornanes[a]

3	0.35	0.40	0.05
4	0.17	0.22	0.05
5	0.50	0.55	0.05

a) δ (ppm) from TMS in CCl_4. b) Difference in exo-endo methyl proton (ppm).

decoupling of Si–H signal in a lower field reveals that $J_{(2),(3exo)}$ is 5.5 Hz. Therefore this compound should be identified as the endo isomer (**2**b).

2-Silanorbornanes have a similar trend, though in a smaller extent, not only in the coupling constants but also in the chemical shifts originating in the exo and endo Si–H protons as is generally observed for the ^1H NMR spectra of norbornane derivatives.[11] The absorption of the 2-exo proton attached to a silicon appeared as a somewhat broad peak at 0.15 ppm lower field than the corresponding endo proton. Clearly it has been found that NMR spectra are most convenient and effective to investigate the stereochemistry in these systems.

These assignments were further supported by the ^{13}C NMR spectra shown in Table 1. The chemical shifts were decided relatively by their comparison with those of the norbornane systems, using both wide-band ^1H decoupled and off-resonance decoupling experiments. The $^{13}C_{(6)}$ carbon chemical shift is distinctly assigned by the complete decoupling of the $C_{(6)}$-deuterium labelled compound.

Depending upon the stereochemistry of a silicon bearing a methyl group, the $C_{(7)}$ carbon in **2**a and the $C_{(6)}$ carbon in **2**b revealed slightly up-field shifts by 1.5 ppm and 1.7 ppm, compared with the corresponding carbons in **2**b and **2**a, respectively. In general, it is well established that both of ^{13}C chemical shifts of two carbons which approach spatially each other cause up-field shift.[12] This phenomenon is called the steric compression shift.[13] Therefore, the upfield shifts associated with $C_{(6)}$- and $C_{(7)}$-carbons in each isomer could be reasonably explained by the steric shift.

The stereochemistry of **3**a and **3**b, and **4**a and **4**b is analgously determined by the results arising from ^{13}C NMR steric shift. Supporting evidence of the assignment with respect to the stereochemistry was further obtained from the results that the methyl group on the silicon atom in all these bicyclic systems exhibited configurationally dependent shieldings[13c] with endo groups more shielded than their exo counterparts (See Table 2). Thus the structures determined by the ^{13}C NMR spectra are in doubtless consistent with those assigned by ^1H NMR spectra. The relationship and some characteristics in ^1H and ^{13}C NMR spectra between 2-silanorbornane and norbornane derivatives[13c] are shown in Table 3.

Throughout these series, the exo isomers have shorter retention times on GLC (Apiezon L and SE 30) than do the endo ones, and in the IR spectra, although only groups of absorption bands characteristic of C–H and Si–CH_3 stretching were observed, any characteristic bands to be attributed to the bicyclic structure did not appear. The IR spectra therefore could not be effectively applied for the structural analysis so much.

Stereochemistry on a Silicon Atom. There have been extensively systematized studies with respect to the stereochemistry on an asymmetric silicon atom in a number of different chiral organosilane systems.[4] As results, it is known that the predominant stereochemistry depends largely on the nature of leaving groups and entering groups and frequently the solvent but not usually on the nature of substituents, even if the cis and trans geometrical isomers such as a series of 4-*t*-butylsilacyclohexanes were used.[5] However dramatic crossover from inversion to retention has been recently reported on the stereochemistry of some optical and geometrical isomers in which strained carbon-silicon bonds were substantially involved.[14–16]

Our new stereochemical systems may be suitable for the tests of the effect of angle strain at the silicon because of their longer Si–C bond length than C–C bond length in norbornanes.[17]

An interesting example of stereochemical behavior can be found in the case of phenylation of the chlorosilanes with both the Grignard reagent and the lithium reagent in ether. The results are shown in Table 4 along with some other stereochemical reactions (Scheme 4). Thus the result in which the chlorine atom in **5**a and **5**b was displaced in highly retentive way (>92% predominant stereochemistry) with both phen-

a) 90% retention means that the product was 90% retained and 10% inverted, if the pure starting material was used.

yllithium and phenylmagnesium bromide might be attributed to the angle strain.[16] In sharp contrast, however, Sommer et al. have observed that the inversive reaction *via* S_N2-Si mechanism took place in the reaction of the asymmetric chlorosilane with both organolithium and Grignard reagents[4,18] and we have also found the similar configuration inversion in 4-*t*-butylsilacyclohexane system,[19] in which the strained angle with the silicon will not be large in size so much.

On the other hand, the phenyl group was displaced by a chlorine atom with configuration inversion in the chlorodephenylation of **3**a and **3**b with iodine monochloride, in a manner analogous to that noted in our previous report.[19]

Reduction of **5** (**5**a:**5**b=83:17) with lithium aluminum hydride in ether gave the corresponding hydrosilane **2** (**2**a:**2**b=86:14) in quantitative yield. Interestingly the reduction of **5** (**5**a:**5**b=17:83) which was enriched by **5**b also led to a mixture of the similar composition of **2** (**2**a:**2**b=85:15). Apparently the equilibration to the thermodynamic controlled mixture of **2** occurred during the LAH reduction.[20]

Regio- and Stereoselective Dichlorocarbene Insertion into $C_{(6)}$–$H_{(6exo)}$ Bond of 2-Silabicyclo[2.2.1]heptanes. The problem of the high exo:endo rate ratio in the solvolysis of 2-norbornyl system is a topic in physical organic chemistry during a few decades.[6,21–23] 2-Silabicyclo[2.2.1]heptanes might be favorable to investigate a hyperconjugating ability of a silicon-carbon bond to an incipient positive charge at $C_{(6)}$-carbon, because they provide not only a polarized but also highly strained carbon-metal σ bonds which could afford significantly large stabilization of neighboring cation.[22]

We have found an interesting dichlorocarbene insertion into 6-carbon–hydrogen exo bond of 2-silanorbornanes (Eq. 2). Important features of this reaction are (a) regiospecific β-CH bond insertion at $C_{(6)}$ position, although there are three kinds of β-CH bond in **1**, (b) the overwhelmingly predominant insertion into the exo CH bond.

2,2-Dimethyl-2-silabicyclo[2.2.1]heptane (**1**) reacts

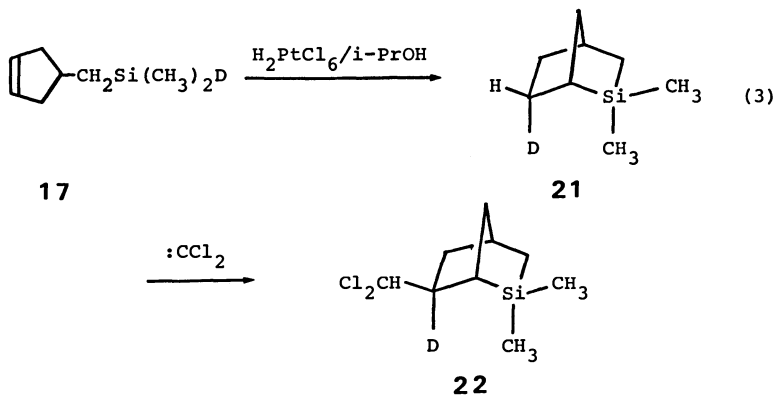
with phenyl(bromodichloromethyl)mercury in benzene at reflux to give a corresponding dichlorocarbene insertion product **18** in 22% yield, along with the recovered **1**. Quite similarly, only **18** was obtained in 71% yield by the reaction of **1** with the dichlorocarbene *in situ* generated from chloroform and sodium hydroxide in benzene-water medium in the presence of benzyltrimethylammonium chloride at room temperature.[24] From the 200 MHz NMR spectrum, the presence of both doublet proton resonance at δ 5.43 (J=9.0 Hz) assigned as the dichloromethyl proton and triply doublet resonance at δ 2.43 (J=9.0 Hz, 9.0 Hz, 6.0 Hz) assigned as the $C_{(6)}$ proton bearing dichloromethyl group clearly led to the suggestion that this compound could be identified as 6-*exo*-dichloromethyl-2,2-dimethyl-2-silabicyclo[2.2.1]heptane (**18**). It was found that the insertion product **18** was derived to 2,2,6-*exo*-trimethyl-2-silabicyclo[2.2.1]heptane (**20**) by the reduction with tributyltin hydride in the presence of free radical initiator (Eq. 2). Analogously 2-*exo*- and 2-*endo*-phenyl derivatives (**3a** and **3b**) afforded exclusively regio- and stereoselective dichlorocarbene insertion products, **19a** and **19b**, respectively, by the reaction with phenyl(bromodichloromethyl)mercury.

The characteristic cracking patterns of the mass spectra have appeared in all of insertion products. Namely the cation in which a dichloromethyl group was removed from the molecular ion peak was strikingly strong, resulting in a base peak.

The stereochemistry and the position at which the insertion of dichlorocarbene occurred were further unambiguously established by the structural analysis of the reaction product when 6-*endo*-deuterium labelled compound (**21**) was utilized as a substrate (Eq. 3).

Thus 6-*endo*-deuterio-2,2-dimethyl-2-silabicyclo[2.2.1]-heptane (**21**), which was derived intramolecularly by the cis addition[25] of (3-cyclopentenylmethyl)-dimethyldeuteriosilane (**17**) catalyzed by chloroplatinic acid, gave exclusively the $C_{(6)}$–H but not $C_{(6)}$–D insertion product (**22**) whose proton NMR spectrum revealed singlet resonance at δ 5.43 and no signals at δ 2.43 in (**18**) (Eq. 3).



(3)

In its mass spectrum, that the cation $[C_6H_{14}DSi]^+$ (m/e=140) appeared as a base peak would reveal the further evidence to demonstrate that the dichlorocarbene insertion was regio- and stereoselective.

Although the mechanism of insertion of the dichlorocarbene generated from phenyl(bromodichloromethyl)-mercury into C–H bonds has been investigated in details,[26] two distinct and important features should be instructive to discuss the present results. One is that the dichlorocarbene insertion takes place with retention with respect to the carbon configuration,[27] and the other is that only the activated C–H bonds such as α–CH bond of ethers,[28] β–CH bond of organometallic compounds[29] or tertiary CH bond,[30] show the enhanced reactivity due to the mildly electrophilic nature of free dichlorocarbene.[31] It is worth to note that, in our cases, the insertion of CCl_2 not only into the bridgehead tertiary C–H bond at $C_{(4)}$ but also into bridge methylene C–H bonds at $C_{(7)}$ could not compete at all with the insertion at $C_{(6)}$ position, although all of them were also located in β-position from the metal.

We suggest that the regio- and stereoselectivity in the present system, therefore, may be best understood in terms of the stabilization of the partial positive charge in exo direction in the transition state due to σ-π hyperconjugation using the strained carbon$_{(1)}$–silicon$_{(2)}$ σ bond. This represents a remarkably interesting example in which the existence of the stereoelectronic effect in σ-π hyperconjugation[32] was clearly demonstrated in chemical reactivity. The steric origin, leading to the high stereoselectivity, of course, should be appreciably considered, although it is hard to estimate precisely the steric effect in its extent. Studies on kinetics as well as products of hydride abstraction by trityl cation are presently in progress.

Experimental

General. All reactions were carried out under nitrogen. ^{1}H NMR spectra were recorded with Varian Associates T-60, HA-100 and XL-200 spectrometers. ^{13}C NMR spectra were taken with a Hitachi Perkin-Elmer R-26 spectrometer. GLC was used extensively in the analysis of reaction mixtures and for the isolation of products. Hitachi 063 for the analysis and Varian 90-P gas chromatographs for the collection were used. The columns packed with SE-30 silicone rubber gum or Apiezon L grease on Celite 545 were used. Mass spectra were taken with Hitachi RMU-6D and JEOL JMS-300D Mass spectrometers. Thin layer chromatography (TLC) was used to monitor the organomercurial reactions and to isolate the insertion products. Boiling points are uncorrected.

Bromodimethylsilane. According to the procedure of the S_H2 reaction of organodisilane with 1,2-dibromoethane,[33a] 1,2-dibromoethane (52.6 g, 0.28 mol) was added slowly to 1,1,2,2-tetramethyldisilane (33 g, 0.28 mol) in the presence a catalytic amount of dibenzoyl peroxide. During the addition, ethylene was evolved vigorously. The reaction mixture was distilled to give pure bromodimethylsilane[33b] (52.9 g, 68% yield). Bp 58 °C; NMR (CCl_4) δ 0.59 (6H, d, J=3.5 Hz, Si-CH_3), 4.80 (1H, septet, J=3.5 Hz, Si-H).

*Synthesis of Diethyl 2-Vinyl-1,1-cyclopropanedicarboxylate (**6**).* According to the procedure described in the literature,[34] the ester (**6**) (165 g) was obtained from sodium ethoxide (2.1 mol), diethyl malonate (160 g, 1.0 mol), and *trans*-1,4-dichloro-2-butene (125 g, 1.0 mol) in ethanol (1.5 l) in 78% yield. Bp 85 °C (2 mm) (lit,[34] 116—119 °C (16 mm)); NMR (CCl_4) δ 1.13 (3H, t, J=7.5 Hz, CH_3), 1.15 (3H, t, 7.5 Hz, CH_3), 1.33—1.59 (2H, m, cyclopropane-CH_2), 2.15—2.56 (1H, m, cyclopropane-CH), 4.07 (2H, q, J=7.5 Hz, CH_2), 4.08 (2H, q, J=7.5 Hz, CH_2), 4.85—5.47 (3H, m, CH=CH_2); IR (TF) 3100 (w), 2990 (s), 2850 (m), 1730 (s), 1640 (m), 1450 (m), 1375 (m), 1320 (m), 1275 (s), 1200 (s), 1130 (s), 1030 (m), 990 (w), 960 (w), 920 (m), 865 (s), 855 (m) cm^{-1}.

*Synthesis of 3-Cyclopentenecarboxylic Acid (**9**).*[34] The ester (**6**) (130 g, 0.61 mol) was pyrolyzed through a quartz tube at 480 °C to give diethyl 3-cyclopentene-1,1-dicarboxylate (**7**) (122 g, 94% yield). NMR (CCl_4) δ 1.21 (6H, t, J=7.5 Hz, CH_3), 2.91 (4H, s, cyclopentene-CH_2), 4.12 (4H, q, J=7.5 Hz, CH_2), 5.52 (2H, s, CH=). For the saponification, **7** (121 g, 0.57 mol), thus obtained, was heated with stirring with potassium hydroxide (100 g, 1.7 mol) in 80% ethanol (1 l) for 6 h. After evaporation of ethanol and water, the mixture was acidified with 6 M (1 M= 1 mmol dm^{-3}) hydrochloric acid and extracted with ether. The solvent was evaporated, and the residue was decarboxylated by heating at 180 °C and distilled to give pure 3-cyclopentenecarboxylic acid (**9**) 37.8 g (0.34 mol) in 84% yield. Bp 110 °C (22 mm) (lit,[34] 118—121 °C (20 mm)); NMR (CCl_4) δ 2.53—3.20 (5H, m, CH, CH_2), 5.61 (2H, s, CH=), 11.77 (1H, s, CO_2H); IR (TF) 3200 (s), 3050 (s), 2940 (s), 2850 (m), 1700 (s), 1640 (w), 1420 (m), 1340 (w), 1300 (m), 1230 (m), 1180 (m), 950 (m), 930 (m) cm^{-1}.

*Synthesis of 3-Cyclopentenylmethanol (**10**).*[35] The alcohol (**10**) (25 g, 0.255 mol) was obtained by the reduction of the carboxylic acid (**9**) (36.3 g, 0.324 mol) with lithium aluminum hydride (13.3 g, 0.35 mol) in ether (150 ml) in 79% yield. Bp 90 °C (50 mm) (lit,[35] 98—99 °C (57 mm)); NMR (CCl_4) δ 1.49—2.63 (5H, m), 3.39 (2H, d, J=6 Hz), 4.22 (1H, s), 5.57 (2H, s); IR (TF) 3400 (s), 3050 (m), 2930 (s), 2850 (m), 1650 (m), 1080 (m), 1040 (s), 950 (m), 940 (w), 900 (w) cm^{-1}.

*3-Cyclopentenylmethyl Chloride (**11**).* The alcohol (**10**) (31.9 g, 0.33 mol) was treated with thionyl chloride (42.9 g, 0.36 mol) in pyridine (28.2 g, 0.36 mol) under ice-cooling. After the mixture was heated moderately for an hour, the oily material was separated and immediately distilled under reduced pressure to give **11** (30.1 g, 79% yield). Bp 70 °C (94 mm); n_D^{20} 1.4698; NMR (CCl_4) δ 1.91—2.84 (5H, m, -CH_2-CH(CH_2Cl)CH_2-) 3.47 (2H, d, J=6 Hz, -CH_2Cl), 5.65 (2H, s, =CH-); IR (TF) 3075 (m), 2950 (s), 2850 (s), 1620 (w), 1580 (w) 1440 (s), 1340 (m), 1290 (m), 1210 (m), 1130 (m), 1060 (w), 1040 (w) cm^{-1}. Calcd for C_6H_9Cl: C, 61.81; H, 7.78%. Found: C, 61.98; H, 7.62%.

*(3-Cyclopentenylmethyl)dimethylsilane (**13**) and (3-Cyclopentenylmethyl)methylphenylsilane (**14**).* To the Grignard reagent prepared from 4.7 g (0.04 mol) of the chloride and 1.2 g (0.05 g-atom) of magnesium in 20 ml of dry ether was added 5.6 g (0.04 mol) of bromodimethylsilane. The mixture was stirred for 10 h and hydrolyzed. After work up as usual, distillation of the organic layer under reduced pressure gave 5.5 g (0.039 mol, 98% yield) of **13**. Bp 76 °C (74 mm); n_D^{20} 1.4504; NMR (CCl_4) δ 0.09 (6H, J=4 Hz, Si-CH_3) 0.71—1.04 (2H, m, Si-CH_2), 1.61—2.94 (5H, m, CH_2-CH-CH_2) 5.61 (2H, s, -HC=CH-); IR (TF) 3050 (m), 2900 (m), 2800 (s), 2100 (s), 1610 (w), 1440 (m), 1350 (m), 1250 (s), 1220 (s), 1110 (m), 1070 (m), 1040 (m), 940 (m), 850 (s) cm^{-1}; Mass *m/e* (rel intensity) 140 (11), 125 (11), 99 (60), 97 (78), 59 (100). Calcd for $C_8H_{16}Si$: C, 68.49; H, 11.50%. Found: C, 68.71; H, 11.50%. **14** (7.5 g, 0.037 mol) was analogously prepared from the Grignard reagent (from **11** (5.3 g) and magnesium (1.22 g)) and chloromethylphenylsilane[36] (6.25 mol, 0.04 mol) in 93% yield. Bp 102 °C (7 mm); n_D^{20} 1.5306; NMR (CCl_4) δ 0.29 (3H, d, J=3.5 Hz, Si-CH_3), 0.91—1.11 (2H, m, Si-CH_2), 1.61—2.68 (5H, m, CH_2-CH-CH_2), 4.37 (1H, m, J=3.5 Hz, Si-H), 5.51 (2H, s, -HC=CH-), 7.21—7.61 (5H, m, C_6H_5); IR (TF) 3050 (s), 2100 (s), 1950 (w), 1880 (w), 1820 (w), 1760 (w), 1590 (w), 1490 (w), 1430 (s), 1330 (w), 1260 (s), 1120 (s), 880 (s), 840 (s) cm^{-1}. Calcd for $C_{13}H_{18}Si$: C, 77.61; H, 8.97%. Found: C, 77.29; H, 9.34%.

*(3-Cyclopentenylmethyl)dimethylchlorosilane (**15**) and (3-Cyclopentenylmethyl)chloromethylsilane (**16**).* The Grignard reagent prepared from 5.9 g (0.05 mol) of the chloride (**11**) and 1.5 g (0.06 g-atom) of magnesium in dry ether was added to a dilute ether solution of 10.4 g (0.08 mol) of dichlorodimethylsilane and the mixture was stirred for 10 h with refluxing. Filtration and fractionation of the organic layer gave 5.5 g (0.031 mol, 62% yield) of pure **15**. Bp 70 °C (19 mm); n_D^{20} 1.4626; NMR (CCl_4) δ 0.42 (6H, s, Si-CH_3); 1.05 (2H, d, J=6 Hz, Si-CH_2), 1.60—2.85 (5H, m, $(CH_2)_2C$ 1.05 (2H, d, J=6 Hz, Si-CH_2), 1.60—2.85 (5H, m, $(CH_2)_2CH$), 5.65 (2H, s, =CH-); IR (TF) 3020 (s), 2900 (s), 2820 (s), 2115 (s), 1610 (m), 1440 (m), 1345 (m), 1335 (m), 1240 (s), 1195 (m), 1105 (m), 1065 (m), 930 (s), 925 (s), 890 (s), 825 (s), 790 (m), 765 (m) cm^{-1}. Calcd for $C_8H_{15}ClSi$: C, 54.99; H, 8.65%. Found: C, 55.16; H, 8.64%.

From **11** (2.9 g, 0.025 mol), magnesium (0.73 g, 0.03 g-atom), and methyldichlorosilane (5.75 g, 0.050 mol), **16** (3.0 g, 0.019 mol) was obtained in 74% yield. Bp 73 °C (38 mm); NMR (CCl_4) δ 0.45 (3H, d, J=3.5 Hz, Si-CH_3), 0.94—1.24 (2H, m, Si-CH_2), 1.71—2.81 (5H, m, CH_2-CH-CH_2), 4.79 (1H, m J=3.5 Hz, Si-H), 5.62 (2H, s, -HC=CH-); IR (TF) 3050 (m), 2950 (s), 2900 (s), 2850 (s), 2160 (s), 1615 (m), 1440 (m), 1350 (m), 1250 (s), 1210 (m), 1110 (m br), 940 (m) cm^{-1}. Calcd for $C_7H_{13}ClSi$: C, 52.31; H, 8.15%. Found: C, 52.29; H, 8.24%.

*(3-Cyclopentenylmethyl)dimethyldeuteriosilane (**17**).* A 6.0 g (0.034 mol) of **15** was reduced with lithium aluminum deuteride (>99% D) (0.42 g, 0.01 mol) in ether. After work up as usual, distillation gave 3.5 g (0.0248 mol) of **17** in 72% yield. Bp 62 °C (34 mm); n_D^{20} 1.4513. The GLC retention time of the product on Silicone gum SE-30, Apiezon L or PEG 20M column was identical with that of the undeuterated material (**13**). NMR (CCl_4) δ 0.07 (6H, s, Si-CH_3) 0.80 (2H, d, J=6 Hz, Si-CH_2), 1.70—2.78 (5H, m, -CH_2-CH-CH_2), 7.64 (2H, s, =CH-) and no Si-D chemical shift. The infrared spectra showed Si-D band at 1532 cm^{-1} and Si-CH_3 band at 1234 cm^{-1}. IR (TF) 3000 (m), 2930 (s), 2870 (s), 2800 (s), 1610 (w), 1540 (m), 1532 (s), 1440 (w), 1350 (w), 1234 (s), 1190 (w), 1100 (w), 1065 (m), 930 (s), 890 (w), 830 (s), 790 (m) cm^{-1}; MS *m/e* (rel intensity) 141 (M^+, 16.5), 126 (M^+-CH_3, 43.5), 100 (54), 99 (64), 98 (79.5), 97 (64), 60 (100), 59

(55.5). A deuterium analysis by the peak ratio at M^+-15 (126/125) by mass stectrum showed 94% replacement of one hydrogen by deuterium. Calcd for $C_8H_{15}DSi$ (d content 94%): C, 68.03; H (D), 12.09%. Found: C, 67.46; H (D), 11.97%.

*Preparation of 2-Silanorbornanes (**1**, **3**, and **5**) by Intramolecular Hydrosilylation. 2,2-Dimethyl-2-silabicyclo[2.2.1]heptane (**1**)*: **13** (2.5 g, 0.018 mol) was placed together with a catalytic amount of chloroplatinic acid in isopropyl alcohol (10^{-2} M, 2 μl) in a glass tube. The tube was sealed and immerced in an oil bath kept constant temperature at 130 °C for 100 h, and then opened. Distillation gave the product (**1**) (2.2 g, 82% yield). Bp 60 °C (38 mm); n_D^{20} 1.4735; NMR (CCl_4) δ 0.03 (3H, s, $Si-CH_{3(exo)}$), 0.09 (3H, s, $Si-CH_{3(endo)}$), 0.20 (1H, d, $J_{(3exo),(3endo)}=14$ Hz, $H_{(3endo)}$), 0.56 (1H, ddd, $J_{(3exo),(3endo)}=14$ Hz, $J_{(3exo),(4)}=5$ Hz, $J_{(3exo),(5exo)}=2$ Hz, $H_{(3exo)}$), 0.85—1.73 (7H, m, $H_{(1),(5),(6),(7)}$), 2.43 (1H, m, $H_{(4)}$); IR (TF) 2925 (s), 2875 (s), 1440 (w), 1400 (w), 1310 (w), 1250 (s), 1150 (w), 1090 (w), 1050 (m), 1020 (w), 1000 (w), 940 (m), 880 (m), 850 (s), 830 (s), 810 (s), 750 (s), 720 (s), 700 (w) cm^{-1}. Calcd for $C_8H_{16}Si$: C, 68.49; H, 11.50%. Found: C, 68.64; H, 11.66%.

*6-Deuterio-2,2-dimethyl-2-silabicyclo[2.2.1]heptane (**21**).* Analogously, from the deuteriosilane (**17**) (1.5 g, 0.11 mol) was obtained **21** (1.0 g, 67% yield). Bp 64 °C (40 mm); n_D^{20} 1.4738; NMR (CCl_4) δ 0.03 (3H, s, $Si-CH_{3(exo)}$), 0.09 (3H, s, $Si-CH_{3(endo)}$), 0.20 (1H, dm, $J_{(3endo),(3exo)}=14$ Hz, $H_{(3exo)}$), 0.56 (1H, ddm, $J_{(3exo),(3endo)}=14$ Hz, $J_{(3exo),(4)}=5$ Hz, $H_{(3exo)}$), 0.85—1.73 (6H, m, $H_{(1),(5),(6),(7)}$), 2.43 (1H, m, $H_{(4)}$); IR (TF) 2950 (s), 2870 (s), 2185 (m), 1470 (m), 1460 (m), 1410 (w), 1300 (m), 1255 (s), 1190 (m), 1095 (m), 1050 (s), 990 (m), 950 (m), 920 (w), 880 (s), 860 (s), 845 (s), 830 (s), 800 (w), 765 (w), 730 (w), 710 (m) cm^{-1}. IR showed only one C–D band at 2185 cm^{-1}. MS *m/e* (rel intensity) 141 (M^+, 40), 126 (24), 99 (100). A deuterium analysis by M^+-15 peaks of mass spectrum showed 72.5% replacement of one hydrogen by deuterium. Assuming that the addition has proceeded *via* cis stereochemistry,[25] it appears reasonable to conclude that the deuterium is located almost exclusively in the $C_{(6\text{-endo})}$ position, *i.e.*, the product is 2,2-dimethyl-6-endo-deuterio-2-silabicyclo-[2.2.1]heptane (**21**). The retention time on GLC was identical with that of **1**. Calcd for $C_8H_{15}DSi$ (d content 72.5%): C, 68.13; H (D), 11.95%. Found: C, 67.73; H (D), 11.92%.

*2-exo- and endo-Methyl-2-phenyl-2-silabicyclo[2.2.1]heptane (**3a** and **3b**).* According to the procedure described above, a mixture of compounds **3a** and **3b** (**3a**:**3b**=68:32) (4.0 g, 20 mmol) boiling over the range of 106—108 °C (5 mm) was obtained from **14**. (5.5 g, 27 mmol). Total yield of **3a** and **3b** was 73%. Either of isomers was readily isolated by preparative GLC (250 °C) equipped with a column packed with Apiezon L 20% (5m) on Celite 545. The retention time on GLC of the exo (**3a**) was shorter than that of the endo isomer (**3b**). **3a**: n_D^{20} 1.5504; NMR (CCl_4) δ 0.35 (3H, s, $Si-CH_{3(exo)}$), 0.78 (2H, m, $J_{(3exo),(4)}=J_{(3endo),(4)}=3$ Hz, $H_{(3endo),(3exo)}$), 1.30—1.77 (7H, m, $H_{(1),(5),(6),(7)}$), 2.61 (1H, m, $H_{(4)}$), 7.23—7.59 (5H, m, C_6H_5); IR (TF) 3090 (w), 3045 (w), 2940 (s), 2870 (m), 1450 (w), 1425 (m), 1400 (w), 1300 (w), 1255 (m), 1190 (w), 1120 (w), 1050 (m), 1000 (w), 940 (m), 880 (m), 860 (m), 820 (m), 800 (m), 780 (m), 740 (m), 700 (s), 680 (w), 640 (w), 600 (w) cm^{-1}. Calcd for $C_{13}H_{18}Si$: C, 77.16; H, 8.97%. Found: C, 77.43; H, 8.92%.

3b: n_D^{20} 1.5512; NMR (CCl_4) δ 0.40 (3H, s, $Si-CH_{3(endo)}$), 0.48 (1H, dm, $J_{(3endo),(3exo)}=14.5$ Hz, $H_{(3endo)}$), 1.08 (1H, dd, $J_{(3endo),(3exo)}=14.5$ Hz, $J_{(3exo),(4)}=6.5$ Hz, $H_{(3exo)}$), 1.22—1.88 (7H, m, $H_{(1)(5)(6)(7)}$), 7.23—7.57 (5H, m, C_6H_5). Calcd for $C_{13}H_{18}Si$: C, 77.16; H, 8.97%. Found: C, 76.90; H, 9.00%.

*2-exo- and endo-Methyl-2-chloro-2-silabicyclo[2.2.1]heptane (**5a** and **5b**).* A mixture of **5a** and **5b** (**5a**:**5b**=63:37) (1.47 g, 9.1 mmol) boiling over the range of 63—65 °C (17 mm) was obtained from **16** (1.61 g, 10 mmol) by the chloroplatinic acid catalyzed hydrosilylation, total yield being 91%. The mixture was used for the following derivatizations without the isolation of each isomer. NMR as a mixture of **5a** and **5b** (63:37) (CCl_4) δ 0.50 (s, $Si-CH_{3(exo)}$), 0.55 (s, $Si-CH_{3(endo)}$), 0.72 (2H, m, $H_{(3)}$), 1.00—1.85 (7H, m, $H_{(1),(5),(6),(7)}$), 2.62 (1H, m, $H_{(4)}$); IR (TF) 2900 (s), 2850 (s), 1454 (m), 1403 (m), 1300 (m), 1253 (s), 1215 (s), 1190 (m), 1140 (w), 1085 (m), 1048 (s), 1022 (w), 1000 (w), 930 (m), 880 (m), 850 (m) cm^{-1}. Calcd for $C_7H_{13}ClSi$: C, 52.31; H, 8.15%. Found: C, 52.59; H, 8.33%.

*Preparation of 2-Silanorbornanes (**2**, **3**, **4**, **5**) by Mutual Transformations. 2-exo- and endo-Methyl-2-silabicyclo[2.2.1]heptane (**2a** and **2b**)*: A mixture (1.29 g, 8.0 mmol) of **5a** and **5b** (**5a**:**5b**=63:37) was reduced with lithium aluminum hydride (LAH) (0.15 g) in dry ether (10 ml). Hydrolysis of the reaction mixture and drying and distillation of the organic layer gave **2** (1.02 g, 98% yield), as an isomeric mixture of **2a**:**2b**=74:26. Bp 142 °C; n_D^{20} 1.4796.

A mixture of **2a** and **2b** (**2a**:**2b**=70:30) was also derived from a mixture of **4a** and **4b** (**4a**:**4b**=70:30) by LAH reduction. NMR (200 MHz) as a mixture of **2a** and **2b** (CCl_4) δ 0.03 (3H, d, $J_{(CH_3),(2endo)}=4.0$ Hz, *exo*-CH_3), 0.48 (2H, m, $J_{(2endo),(3exo)}=J_{(2endo),(3endo)}=2.5$ Hz, $H_{(3exo)}$ and $H_{(3endo)}$), and 3.72 (1H, m, $J_{(2endo),(CH_3)}=4.0$ Hz, $J_{(2endo),(1)}=J_{(2endo),(3exo)}=J_{(2endo),(3endo)}=2.5$ Hz, $H_{(2endo)}$) which are attributed to **2a**, and δ 0.07 (1H, m, $J_{(3exo),(3endo)}=15.5$ Hz, $H_{(3endo)}$), 0.12 (3H, d, $J_{(CH_3),(2exo)}=4.0$ Hz, *endo*-CH_3), 0.80 (1H, m, $J_{(3exo),(3endo)}=15.5$ Hz, $J_{(3exo),(4)}=J_{(3exo),(2exo)}=5.5$ Hz, 3.87 (1H, m, $J_{(2exo),(3exo)}=5.5$ Hz, $J_{(2exo),(CH_3)}=4.0$ Hz, $H_{(2exo)}$) which belong to **2b**. Besides, the following complex multiplet signals are obtained from a mixture of **2a** and **2b**: δ 1.4 (1H, m, $H_{(1)}$), 2.5 (1H, m, $H_{(4)}$), 0.9—1.8 (6H, m, $H_{(5)}$, $H_{(6)}$ and $H_{(7)}$). IR (TF) 2910 (s), 2850 (s), 2130 (s), 1455 (w), 1410 (w), 1300 (w), 1250 (m), 1215 (s), 1188 (m), 1140 (w), 1087 (w), 1050 (m), 1028 (w), 1000 (w), 938 (s), 890 (s, br) cm^{-1}. Calcd for $C_7H_{14}Si$: C, 66.58; H, 11.18%. Found: C, 65.92; H, 10.93%.

*2-exo- and endo-Methyl-2-isopropoxy-2-silabicyclo[2.2.1]heptane (**4a** and **4b**).* A mixture of **5** (exo:endo=60:40) (3.2 g, 0.02 mol), isopropyl alcohol (1.8 g, 0.03 mol) and pyridine (2.4 g, 0.03 mol) was heated with stirring for 20 h in dry ether. After filtration of the salt and evaporation of the solvent, ditillation gave 3.1 g (0.017 mol, 84% yield) of the isopropoxy derivative (**4**), as an isomeric mixture of the ratio of **4a**:**4b**=82:18, boiling over the range of 72—76 °C (16 mm).

Alternatively 0.42 g (33% yield) of the compound **4**, as an isomeric mixture of **4a**:**4b**=53:47, boiling over the range of 72—14°/17 mm, was obtained from 0.91 g (7 mmol) **2** (**2a**:**2b**=74:26) and isopropyl alcohol (1 ml) in the presence of Pd–C (10%) (25 mg) in petroleum ether (10 ml) according to the procedure described previously.[37] Either of isomers was readily isolated by preparative GLC (220 °C) using a column packed with Apiezon L 20% (5 m) on Celite 545. The retention time of GLC of **4a** was shorter than that of the endo isomer (**4b**).

4a: n_D^{20} 1.4579; NMR (CCl_4) δ 0.17 (3H, s, $Si-CH_{3(exo)}$), 0.28 (1H, dd, $J_{(3endo),(3exo)}=14.6$ Hz, $J_{(3endo),(4)}=2.1$ Hz, $H_{(3endo)}$), 0.53 (1H, dd, $J_{(3exo),(3endo)}=14.6$ Hz, $J_{(3exo),(4)}=$

5.7 Hz, $H_{(3exo)}$), 1.16 (6H, d, J=6.3 Hz, -CH-$(CH_3)_2$), 1.25—1.90 (7H, m, $H_{(1),(5),(6),(7)}$), 2.43 (1H, m, $H_{(4)}$), 3.96 (1H, septet, J=6.3 Hz, OCH).

4b: n_D^{20} 1.4586; NMR (CCl_4) δ 0.22 (3H, s, Si-$CH_{3(endo)}$), 0.27 (1H, dd, $J_{(3endo),(3exo)}$=14.8 Hz, $J_{(3endo),(4)}$=2.1 Hz, $H_{(endo)}$), 0.72 (1H, dd, $J_{(3exo),(3endo)}$=14.8 Hz, $J_{(3exo),(4)}$=5.0 Hz, $H_{(3exo)}$), 1.13 (6H, d, J=5.9 Hz, -CH-$(CH_3)_2$), 0.97—1.80 (7H, m, $H_{(1),(5),(6),(7)}$), 2.54 (1H, m, $H_{(4)}$), 3.96 (1H, sept, J=5.9 Hz, OCH). Calcd for $C_{10}H_{20}OSi$: C, 65.15; H, 10.93%. Found: C, 65.15; H, 11.16%.

Chlorination of Compound **2**. Into a carbon tetrachloride solution of **2** (**2a**:**2b**=71:29) dry chlorine gas was passed through until the yellowish color was left in nmr tube. The yield of the chloride **5** was almost quantitative by GLC determination. The ratio of **5a**:**5b** was 71:29 by nmr determination.

Chlorodephenylation of **3** *and Phenylation of* **5**. The exo isomer **3a** (0.1 g), freshly isolated, was treated with iodine monochloride in carbon tetrachloride. Predominant formation of endo isomer **5b** (**5a**:**5b**=14.0:86.0) was observed by NMR determination. After carbon tetrachloride was substituted for dry ether, the mixture was treated with phenyllithium or phenylmagnesium bromide at ether refluxing temperature. After work up, the phenylated compound **3** as an isomeric mixture of **3a**:**3b**=19.5:80.5 or 19.4:80.6, respectively, was isolated by GLC in the pure state. In repeated runs, essentially the same result was obtained.

Analogously, the compound **3b** was chlorodephenylated, resulting in the predominant stereochemistry of the isomer **5a**, where **5a**:**5b**=77.5:22.5. Phenylation of the products with phenyllithium or phenylmagnesium bromide in ether gave the compound **3**, as an isomeric mixture of **3a**:**3b**=77.0:23.0. From the combination of the above reactions, the predominant stereochemistry in the phenylation with phenyllithium was 95.6% for **5a** and 92.9% for **5b**, and with phenylmagnesium bromide was 97.4% for **5a** and 96.5% for **5b**.

Reactions of 2-Silanorbornanes with Dichlorocarbene. Method A: The following general procedure was used. A mixture of 880 mg (2.0 ml) of phenyl(bromodichloromethyl)mercury, prepared by the reported procedure,[38] and 2.0 mmol of 2-silanorbornane in 3 ml of dry benzene was displaced into a 50 ml two necked flask equipped with a reflux condenser topped with a nitrogen inlet tube and magnetic stirring unit. The flask then was immersed into an oil bath kept at 90 °C. The solution was stirred and heated at reflux for 10 h. Filtration gave phenylmercury(II) bromide, yielding usually above 90% in good purity (mp 275 °C). The filtrate was free from the solvent, the remaining material subsequently was analyzed by NMR and GLC and the product was isolated by preparative TLC. The yields of the insertion product were 1) 22% for 6-*exo*-dichloromethyl-2,2-dimethyl-2-silabicyclo[2.2.1]heptane (**18**), 2) 11% for 6-*exo*-dichloromethyl-2-*exo*-methyl-2-*endo*-phenyl-2-silabicyclo-[2.2.1]heptane (**19a**), 3) 13% for 6-*exo*-dichloromethyl-2-*endo*-methyl-2-*exo*-phenyl-2-silabicyclo[2.2.1]heptane (**19b**). In each reaction, the starting material was almost recovered.

Method B: To a solution of 2,2-dimethyl-2-silabicyclo-[2.2.1]heptane (**1**) (10 g, 0.07 mol), 50% aqueous sodium hydroxide (145 ml), benzene (14.5 ml) and benzyltrimethylammonium chloride (0.29 g, 28 mmol), chloroform (43.5 ml, 0.25 mol) was added slowly with vigorous stirring for a period of 7.5 h at 60 °C. After additional stirring for 2 h, diethyl ether (50 ml) was added and the organic layer was centrifuged. After similar operation was carried out 10 times, the ethereal layer was dried over sodium sulfate and the solvent was removed by distillation. The residue was distilled under reduced pressure to give 6-*exo*-dichloromethyl-2,2-dimethyl-2-silabicyclo[2.2.1]heptane (**18**) (11.4 g, 0.05 mol) in 71.3% yield. Bp 117 °C (9 mmHg, 1 mmHg≈133.322 Pa); n_D^{20} 1.5116.

18: NMR (CCl_4) δ 0.12 (3H, s, Si-$CH_{3(exo)}$), 0.23 (3H, s, Si-$CH_{3(endo)}$), 0.32 (1H, d, J=14.5 Hz, $H_{3(endo)}$), 0.66 (1H, dd, $J_{(3exo),(3endo)}$=14.5 Hz, $J_{(3exo),(4)}$=6.0 Hz, $H_{(3exo)}$), 1.20—1.72 (5H, m, $H_{(1),(5),(7)}$), 2.43 (1H, ddd, $J_{(6endo),(6\text{-}exo\text{-}CH)}$=9.0 Hz, J=9.0 Hz, J=6.0 Hz, $H_{(6endo)}$), 2.57 (1H, m, $H_{(4)}$), 5.43 (1H, d, $J_{(6\text{-}exo\text{-}CH),(6endo)}$=9.0 Hz, $CHCl_2$); IR (TF) 2930 (s), 2830 (s), 1460 (w), 1440 (m), 1400 (m), 1300 (s), 1290 (m), 1280 (w), 1250 (s), 1210 (s), 1120 (s), 1050 (s), 1000 (w), 970 (m), 900 (m), 840 (s) cm^{-1}; MS *m/e* (rel intensity) 224 (M^++2, 0.1), 222 (M^+, 0.3) 140 (14), 139 (M^+-CHCl_2, 100), 95 (29), 93 (81), 79 (72), 59 (48); High resolution MS, $C_8H_{15}Si$ (M^+-CHCl_2), obsd *m/e* 139.0943 (calcd 139.0943). Calcd for $C_9H_{16}Cl_2Si$: C, 48.73; H, 7.23%. Found: C, 48.22; H, 7.08%.

19a: NMR (CCl_4) δ 0.32 (3H, s, Si-$CH_{3(exo)}$), 0.74—0.84 (2H, m, $H_{(3)}$), 1.25—1.82 (5H, m, $H_{(1),(5),(7)}$), 2.27 (1H, ddd, $J_{(6endo),(6\text{-}exo\text{-}CH)}$=8.5 Hz, J=8.5 Hz, J=6.0 Hz, $H_{(6endo)}$), 2.60—2.75 (1H, m, $H_{(4)}$), 5.39 (1H, d, $J_{(6endo),(6\text{-}exo\text{-}CH)}$=8.5 Hz, $CHCl_2$), 7.20—7.59 (5H, m, C_6H_5); MS *m/e* (rel intensity) 286 (M^++2, 0.1), 284 (M^+, 0.2), 201 (M^+-CHCl_2, 100), 157 (38), 155 (99), 123 (12), 121 (62), 105 (19), 93 (21), 91 (32), 79 (dd), 74 (10), 59 (19); High resolution MS, $C_{13}H_{17}Si$ (M^+-CHCl_2), obsd *m/e* 201.1095 (calcd 201.1098).

19b: NMR (CCl_4) δ 0.44 (3H, s, Si-$CH_{3(endo)}$), 0.49 (1H, dd, $J_{(3exo),(3endo)}$=14.2 Hz, $J_{(3endo),(4)}$=3.2 Hz, $H_{(3endo)}$), 1.10 (1H, dd, $J_{(3exo),(3endo)}$=14.2 Hz, $J_{(3exo),(4)}$=6.0 Hz, $H_{(3exo)}$), 1.23—1.92 (5H, m, $H_{(1),(5),(7)}$), 2.55 (1H, ddd, $J_{(6endo),(6\text{-}exo\text{-}CH)}$=9.0 Hz, J=9.0 Hz, J=6.0 Hz, $H_{(6endo)}$), 2.55—2.76 (1H, m, $H_{(4)}$), 5.47 (1H, d, $J_{(6\text{-}exo\text{-}CH),(6endo)}$=9.0 Hz, $CHCl_2$), 7.20—7.59 (5H, m, C_6H_5); MS *m/e* (rel intensity) 286 (M^++2, 0.1), 284 (M^+, 0.1), 201 (M^+-CHCl_2, 47), 157 (37), 155 (100), 121 (64), 105 (18), 93 (25), 91 (24), 79 (58); High resolution MS, $C_{13}H_{17}Si$ (M^+-CHCl_2), obsd *m/e* 201.1086 (calcd 201.1098).

*Reduction of the Insertion Product (***18***) with Tributyltin Hydride.* **18** (80 mg) was heated tributylin hydride (500 mg) in the presence of di-*t*-butyl peroxide (20 mg) at 140 °C for 15 h in a sealed tube. By a GLC collection (Apiezon L 30%, 3m, 190 °C) of the reaction mixture, 6-*exo*-methyl-2,2-dimethyl-2-silabicyclo[2.2.1]heptane (**20**) was obtained. NMR (CCl_4) δ 0.01 (3H, s, Si-$CH_{3(exo)}$), 0.09 (3H, s, Si-$CH_{3(endo)}$), 0.15 (1H, d, $J_{(3endo),(3exo)}$=14.5 Hz, $H_{(3endo)}$), 0.52 (1H, ddd, $J_{(3exo),(3endo)}$=14.5 Hz, $J_{(3exo),(4)}$=6.5 Hz, $J_{(3exo),(5exo)}$=2.8 Hz, $H_{(3exo)}$), 0.91 (3H, d, $J_{(6\text{-}exo\text{-}CH),(6endo)}$=6.8 Hz, 6-$CH_{3(exo)}$), 0.82—2.03 (6H, m, $H_{(1)(5),(6endo),(7)}$). Calcd for $C_9H_{18}Si$: C, 70.05; H, 11.76%. Found: C, 70.28; H, 11.84%.

*Reaction of 2,2-Dimethyl-6-*endo*-deuterio-2-silabicyclo[2.2.1]-heptane (***21***) with Phenyl(bromodichloromethyl)mercury.* The reaction of $PhHgCCl_2Br$ with the deuterio compound (**21**) (72.5% enriched by derterium) was carried out in a similar manner as described above. The product **22** was obtained in 17.4% yield. The retention time on GLC was identical with that of **18**. Deuterium analysis by NMR and mass spectrum showed 71% excess deuterium at 6-endo position in the product. IR spectrum showed 2160 cm^{-1} characteristic of C-D streching.

22: NMR (CCl_4) δ 0.12 (3H, s, Si-$CH_{3(exo)}$), 0.23 (3H, s, Si-$CH_{3(endo)}$), 0.32 (1H, d, $J_{(3endo),(3exo)}$=14.5 Hz, $H_{(3endo)}$), 0.66 (1H, dd, $J_{(3exo),(3endo)}$=14.5 Hz, $J_{(3exo),(4)}$=6.0 Hz, $H_{(3exo)}$), 1.20—1.72 (5H, m, $H_{(1),(5),(7)}$), 2.57 (1H, m, $H_{(4)}$), 5.44 (1H, s, $CHCl_2$); IR (TF) 2920 (s), 2850 (s), 2160 (w),

1470 (w), 1450 (m), 1410 (m), 1300 (m), 1290 (m), 1280 (w), 1250 (s), 1210 (s), 1120 (w), 1050 (s), 985 (s), 900 (m), 840 (s) cm^{-1}; MS *m/e* (rel intensity) 225 (M^++2, 0.2), 223 (M^+, 0.2), 141 (15), 140 (M^+-CHCl_2, 100), 139 (45), 95 (36), 93 (97), 80 (46), 79 (44), 59 (51); High resolution MS, $C_8H_{14}DSi$ (M^+-CHCl_2), obsd *m/e* 140.1002 (calcd 140.1004).

Silicon-Carbon Unsaturated Compounds. XVI.[1] Photorearrangement of an Adduct Derived from Reaction of a Silicon-Carbon Unsaturated Compound with *t*-Butyl Alcohol

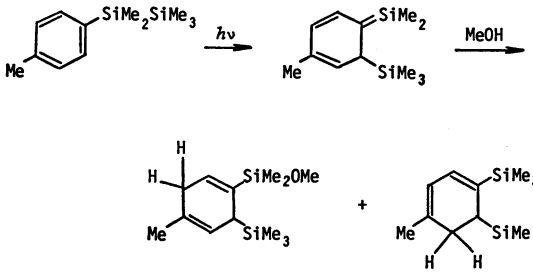
Mitsuo Ishikawa,* Michio Oda, Kunio Nishimura, and Makoto Kumada

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received April 14, 1983)

Photolysis of pentamethylphenyldisilane in the presence of *t*-butyl alcohol gave a mixture of adducts which were readily oxidized to 1-(*t*-butoxydimethylsilyl)-2-(trimethylsilyl)benzene by oxygen. Photolysis of *p*-tolylpentamethyldisilane in the presence of *t*-butyl alcohol afforded 4-(*t*-butoxydimethylsilyl)-1-methyl-5-trimethylsilyl-1,3-cyclohexadiene (**4**) as a primary photoproduct. The UV-irradiation of **4** gave ring opened products, 2-(*t*-butoxydimethylsilyl)-5-methyl-1-trimethylsilyl-1,3,5-hexatriene and 2-(*t*-butoxydimethylsilyl)-5-methyl-3-trimethylsilyl-1,3,5-hexatriene in a ratio of 1.8/1.

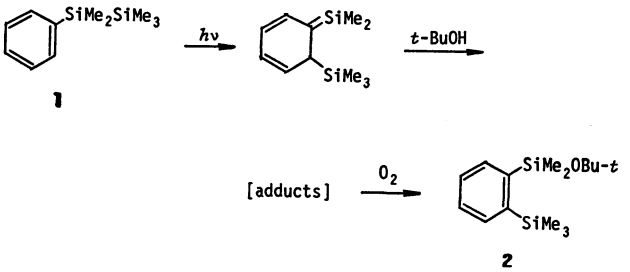
Previous studies in our laboratory have shown that the photolysis of aryldisilanes causes their rearrangement to isomeric silicon–carbon unsaturated compounds, which can react with many types of trapping agent.[2-4] As reported previously, the silicon-carbon unsaturated intermediate generated photochemically from pentamethyl(*p*-tolyl)disilane in a benzene solution reacts with methyl alcohol to give 1-(methoxydimethylsilyl)-4-methyl-6-trimethylsilyl-1,3- and 1,4-cyclohexadiene in the ratio of approximately 1/1 in high yield.[5] We now wish to report the reaction of this intermediate with *t*-butyl alcohol and the photochemistry of the resulting adduct.



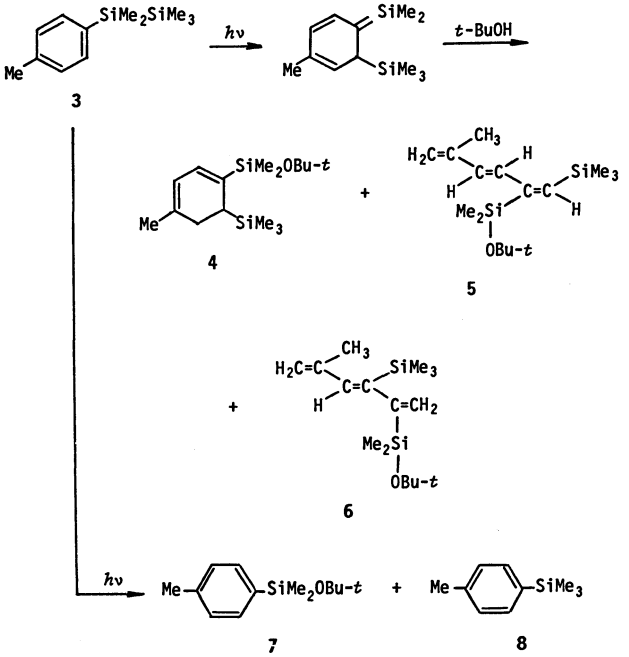
Results and Discussion

Photolysis of Aryldisilanes in the Presence of t-*Butyl Alcohol.* The photochemical studies were carried out with a low-pressure immersion mercury lamp having a Vycor filter.

First, we investigated the photolysis of pentamethylphenyldisilane (**1**) in the presence of *t*-butyl alcohol in benzene. In this case, a mixture of two isomers was obtained in 38% yield as reaction products; the ^{1}H NMR spectrum of the mixture showed two resonances in a ratio of 1/3 for *t*-butoxyl protons. Preparative GLC and column chromatography were used to isolate each isomer from the mixture, but they could not be separated under any of the conditions used. The mass spectrum of the mixture showed a parent peak at *m/e* 282, corresponding to the calculated molecular weight for $C_{15}H_{30}OSi_2$. The alcohol adducts can readily be oxidized by atmospheric oxygen. Thus, when the mixture of the adducts was allowed to stand for a week at room temperature in an oxygen atmosphere, 1-(*t*-butoxydimethylsilyl)-2-(trimethylsilyl)-benzene (**2**) was obtained in 65% yield, in addition to 17% of the starting adducts.



We then turned our attention to pentamethyl(*p*-tolyl)disilane (**3**) as a source of the silicon–carbon double-bonded intermediate. As we reported earlier, the photolysis of **3** in the presence of methyl alcohol afforded two addition products which could easily be separated by preparative GLC.[5] Interestingly, the photolysis of **3** in the presence of *t*-butyl alcohol in benzene at room temperature gave 4-(*t*-butoxydimethylsilyl)-1-methyl-5-trimethylsilyl-1,3-cyclohexadiene (**4**) as a primary photoproduct in 27% yield, when 70% of the starting disilane was photolyzed. At this stage, 2-(*t*-butoxydimethylsilyl)-5-methyl-1-trimethylsilyl-1,3,5-hexatriene (**5**) (6% yield) and 2-(*t*-butoxydimethylsilyl)-5-methyl-3-trimethylsilyl-1,3,5-hexatriene (**6**) (6% yield) were formed as secondary photoproducts. Small amounts of *t*-butoxydimethyl(*p*-tolyl)silane (**7**)



(3% yield) and *p*-tolyltrimethylsilane (**8**) (2% yield) were also produced. However, no isolable amount of the disilyl-substituted 1,4-cyclohexadiene isomer was obtained, whereas under similar conditions but using a lower primary alcohol such as methyl alcohol[5] and ethyl alcohol (see Experimental section) as a quencher, both the analogous 1,3- and 1,4-cyclohexadiene isomers were found to be produced.

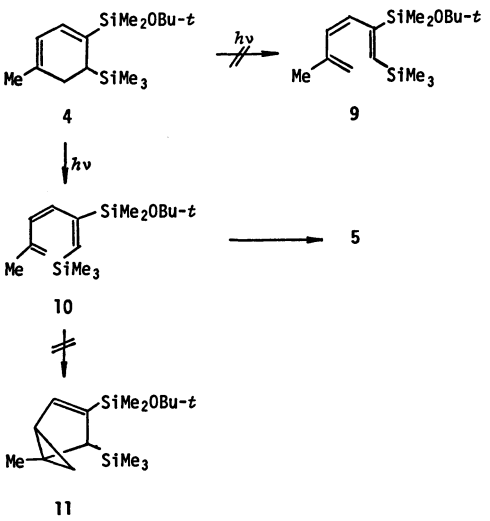
At present, no convincing explanation for the absence of the 1,4-cyclohexadiene in the product is available, but steric interactions arising from an approach of the alcohol to the silicon–carbon unsaturated compound would be important for the product distribution. We found that the adducts to the less hindered alcohols are photochemically more stable than those to the hindered alcohols under the used conditions. Thus, the photolysis of **3** in the presence of methyl alcohol afforded no isolable amounts of the ring opened products when 80% of **3** was photolyzed. On the other hand, compound **4** decomposed slowly to give photoproducts, **5** and **6**, under prolonged irradiation.

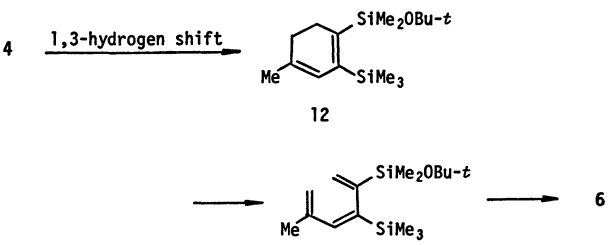
Compound **4** was identified by mass and NMR spectroscopic methods. Compound **4** exhibited proton absorptions at δ 0.01 (CH_3–$SiMe_2$, s, 9H), 0.23 (CH_3–SiOBu-*t*, s, 6H), 1.28 (*t*-BuO–Si, s, 9H), 1.6—2.0 (H–$CSiMe_3$, m, 1H), 1.76 (CH_3–C, broad s, 3H), 2.3—2.6 (H_2C–$CSiMe_3$, m, 2H), 5.59 (H–C=CMe, m, 1H) and 6.07 (H–C=CSiOBu-*t*, broad d, 1H, J=5 Hz).

Photochemical Isomerization of 4. In order to learn more about the photoisomerization of **4** to **5** and **6**, we investigated the photochemistry of **4**. When a solution of **4** in benzene was photolyzed at room temperature for 13.5 h, **5** and **6** were obtained in 43 and 24% yield, respectively, in addition to 24% of the starting substance. No other isomer such as a bicyclo[3.1.0]hexene derivative (**11**), which might be expected to be formed from formal intramolecular [2+4] cycloaddition of 1,3,5-triene (**10**), could be detected by spectroscopic analysis.[6–8] Furthermore, it was shown that compound **5**, which could easily be isolated by preparative GLC, did not undergo isomerization at all when irradiated under similar conditions. These results indicate that both the products, **5**, and **6**, must come independently from the photoisomerization of **4**. The *trans* triene structure for **5** is based on its NMR spectrum: δ=0.17 (CH_3–$SiMe_2$, s, 9H), 0.25 (CH_3–SiOBu-*t*, s, 6H), 1.25 (*t*-Bu–O, s, 9H), 1.87 (CH_3–C=C, broad s, 3H), 4.98 (H_2C=CMe, broad s, 2H), 6.17 (H–$CSiMe_3$, broad s, 1H), 6.48 (H–C–CMe, d, 1H, J=16 Hz), and 6.72 (H–C–CSi, d, 1H, J=16 Hz). The magnitude of the coupling constant requires that the geometrical configuration of **5** is *trans*.

Compound **6** can also be shown unambiguously to have the proposed structure by proton NMR spectroscopy: (δ) 0.17 (CH_3–$SiMe_2$, s, 9H), 0.29 (CH_3–SiOBu-*t*, s, 6H), 1.28 (*t*-Bu–O, s, 9H), 1.84 (CH_3–C=C, broad s, 3H), 4.91 (H_2C=CMe, broad, s, 2H), 6.30 (H_2C=CSi, s, 2H), and 6.64 (H–C=C, s, 1H).

Two modes of conrotatory motion are possible in the ring opening of **4**.[9,10] One involves the formation of the triene **9**, in which the two silyl groups are brought into a *cis* relationship, and the other comprises the production of the triene **10** having *E*-configuration for the two silyl groups. Unfortunately both compounds **9** and **10** could not be detected either by GLC or spectroscopic analysis. However, the former process seems to be unlikely, because *Z*-configuration of the two bulky silyl groups about the carbon-carbon double bond is sterically very unfavorable. Compound **10** thus formed would undergo rapid isomerization to afford the observed product **5**. The formation of **6** can be explained in terms of successive 1,3-sigmatropic hydrogen shifts in the compound **4**, followed by rapid ring opening and rearrangement of the resulting product (**12**).





Experimental

^{1}H NMR spectra were determined with a JEOL JNM-MH-100 spectrometer in carbon tetrachloride. Mass spectra were measured on a JEOL JMS-300 mass spectrometer equipped with a JMA-2000 data processing system. Ionization voltage was 24 eV for all compounds. A Shimazu Model GC-4B gas chromatograph with a column containing 30% methylsilicon polymer (5 mm×1.5 m) was used for analysis of the products. An Aerograph Model 90 gas chromatograph with a thermal conductivity detector was used for separation of the products reported here.

Materials. Pentamethylphenyldisilane[11] and pentamethyl(*p*-tolyl)disilane[12] were prepared as described in the literature. *t*-Butyl alcohol was purified fractional distillation. Benzene was dried over lithium aluminum hydride and distilled just before use.

Photolysis of Pentamethylphenyldisilane (1) in the Presence of t-Butyl Alcohol. A solution of 1.00 g (4.8 mmol) of **1** and 20 ml of *t*-butyl alcohol in 80 ml of dry benzene was photolyzed for 3 h at room temperature under bubbling nitrogen. The solvent benzene and unchanged *t*-butyl al-

cohol were evaporated, and the residue was distilled under reduced pressure. GLC analysis of the distillate showed that 37% yield of the adduct consisting of two isomers was produced in addition to phenyltrimethylsilane (2%), 1-(*t*-butoxydimethylsilyl)-2-(trimethylsilyl)benzene (**2**) (2.5%) and the starting compound (11.5%). The adduct was isolated by preparative GLC as a mixture. MS *m/e* 282; Found: C, 63.77; H, 10.54%. Calcd for $C_{15}H_{30}OSi_2$: C, 63.90; H, 10.70%.

Oxidation of the Adduct. The photolysis mixture containing 1.6 mmol of the adduct was concentrated and the residue was allowed to stand in an oxygen atmosphere for a week at room temperature. GLC analysis of the resulting mixture showed that 64% yield of **2** was produced, and 17% of the starting adduct was recovered. Pure **2** was isolated by preparative GLC; MS *m/e* 280; ^{1}H NMR δ=0.37 (CH_3–$SiMe_2$, s, 9H); 0.43 (CH_3–SiMeOBu-*t*, s, 6H), 1.30 (CH_3–CMe_2OSi, s, 9H) and 7.15—7.63(ring protons, m, 4H); Found: C, 64.62; H, 10.1%. Calcd for $C_{15}H_{28}OSi_2$: C, 64.42; H, 10.06%.

Photolysis of p-*Tolylpentamethyldisilane (**3**) in the Presence of Ethyl Alcohol.* A solution of 0.9896 g (4.45 mmol) of **3** and 10 ml of ethyl alcohol in 90 ml of benzene was photolyzed for 3 h at room temperature. The solvent benzene was evaporated and the residue was distilled under reduced pressure to give volatile products. GLC analysis showed the presence of 4-(ethoxydimethylsilyl)-1-methyl-5-trimethylsilyl-1,3-cyclohexadiene (**13**) and 4-(ethoxydimethylsilyl)-1-methyl-3-trimethylsilyl-1,4-cyclohexadiene (**14**) in 27 and 18% yield, respectively, along with 7% of ethoxydimethyl(*p*-tolyl)silane[13] and 27% of the starting **3**. A small amount of unidentified compounds (less than 5%) was also detected. For, **13**: MS *m/e* 268; ^{1}H NMR δ=-0.04 (CH_3–$SiMe_2$, s, 9H), 0.14 (CH_3–SiMeOEt, s, 6H), 1.16 (CH_3–CH_2O, t, 3H, J=6 Hz), 1.76 (CH_3–C, broad s, 3H), 1.85—2.47 (H_2C–CH, m, 3H), 3.65 (CH_2–O, q, 2H, J=6 Hz), 5.64 (H–C=CMe, m, 1H); 6.15 (H–C=CSi, d, 1H); Found: C, 62.89; H, 10.66%. Calcd for $C_{14}H_{28}OSi_2$: C, 62.62; H, 10.51%. For **14**: MS *m/e* 268; ^{1}H NMR δ=−0.03 (CH_3–$SiMe_2$, s, 9H), 0.17 (CH_3–SiMeOEt, s, 6H), 1.15 (CH_3–CH_2O, t, 3H, J=6 Hz), 1.70 (CH_3–C, broad s, 3H), 2.37—2.65 (H_2C and HC, m, 3H), 3.62 (CH_2–O, q, 2H, J=6 Hz), 5.45 (H–C=CMe, m, 1H), 6.00 (H–C=CSi, t, 1H); Found: C, 62.32; H, 10.75%. Calcd for $C_{14}H_{28}OSi_2$: C, 62.62; H, 10.51%.

*Photolysis of **3** in the Presence of* t-*Butyl Alcohol.* A solution of 1.0170 g (4.57 mmol) of **3** and 20 ml of *t*-butyl alcohol in 80 ml of benzene was irradiated for 4 h. The solvent benzene was evaporated and the residue was distilled under reduced pressure to give volatile products. GLC analysis showed that the distillate contained **4** (28%), **5** (6%), and **6** (6%), together with *t*-butoxydimethyl(*p*-tolyl)silane **7** (2%), *p*-tolyltrimethylsilane (**8**) (trace) and the starting disilane (30%). Compound **4** was isolated by preparative GLC. MS *m/e* 296; Found: C, 65.09; H, 11.01%. Calcd for $C_{16}H_{32}OSi_2$: C, 64.79; H, 10.87%. Compounds **7** and **8** were identified by comparison of their retention times on GLC with those of the authentic samples.

*Photoisomerization of **4**.* A solution of 472 mg (1.59 mmol) of **4** in 80 ml of dry benzene was irradiated for 13.5 h at room temperature. Distillation of the reaction mixture afforded **5** and **6** in 43 and 24% yield, respectively, together with 24% of the starting compound. Both **5** and **6** were isolated by preparative GLC. For **5**: MS *m/e* 296; Found: C, 64.59; H, 10.79%. Calcd for $C_{16}H_{32}OSi_2$: C, 64.79; H, 10.87%. For **6**: MS *m/e* 296; Found: C, 64.55; H, 10.64%. Calcd for $C_{16}H_{32}OSi_2$: C, 64.79; H, 10.87%.

The cost of this research defrayed by a Grant-in-Aid for Scientific Research by the Ministry of Education, Science and Culture and Toray Science and Technology Grant to which our thanks are due. We also express our appreciation to Toshiba Silicone Co., Ltd., Shinetsu Chemical Co., Ltd., and Toray Silicone Co., Ltd., for gift of organochlorosilanes.

Cyclotrimerization and Polymerization of 1-Hexyne Catalyzed by Group 5, 6 Transition Metal Chlorides[1)]

Toshio MASUDA, Yun-Xiang DENG,† and Toshinobu HIGASHIMURA*

Department of Polymer Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received April 20, 1983)

1-Hexyne could be cyclotrimerized selectively and quantitatively by $NbCl_5$ and $TaCl_5$. The cyclotrimer formed consisted of 1,2,4- and 1,3,5-isomers. The 1,2,4/1,3,5 isomer ratio of the product was about 70/30—80/20 with $NbCl_5$, and about 55/45—70/30 with $TaCl_5$. The polymerization of 1-hexyne by $MoCl_5$- and WCl_6-based catalysts afforded a methanol-insoluble polymer and methanol-soluble products in comparable amounts. The polymer (mol wt 3000—5000) was an orange-yellow viscous material with structure $\{CH=C(n\text{-Bu})\}_n$. For comparison, the cyclotrimerization and polymerization using Ziegler catalysts were also examined.

1-Hexyne can be cyclotrimerized by transition metal catalysts [$TiCl_4$–Et_3Al,[3)] $(Ph_3P)_2Ni(CO)_2$,[4)] and $(\eta^5\text{-}C_5H_5)_2V$[5)]]. The polymer and linear oligomer of 1-hexyne, however, are often formed as by-products in the cyclotrimerization. Further, the cyclotrimer formed (tributylbenzene) is usually a mixture of 1,2,4- and 1,3,5-isomers. The selectivity of the cyclotrimerization and the 1,2,4/1,3,5 isomer ratio of cyclotrimer have hardly been clarified.

1-Hexyne can be polymerized by transition metal catalysts [$TiCl_3$–Et_3Al,[6,7)] Fe(III) naphthenate-$(i\text{-Bu})_3Al$,[8)] and $PhCH_3\cdot Mo(CO)_3$[9)]]. High molecular weight poly(1-hexyne) ($[\eta]=2$—6 dl/g) is obtained with a Ziegler catalysts, Fe(III) naphthenate-$(i\text{-Bu})_3Al$. The yield of cyclotrimer as by-product and the geometric structure of the polymer, however, have not been studied.

Acetylene[10)] and phenylacetylene[11)] are cyclotrimerized by $NbCl_5$ and $TaCl_5$. Various acetylenes are polymerized by $MoCl_5$- and WCl_6-based catalysts.[12)] Therefore, it is interesting to examine the selectivity and product structure in the cyclotrimerization of 1-hexyne by $NbCl_5$ and $TaCl_5$, and in the polymerization of the monomer by $MoCl_5$ and WCl_6.

This paper deals with the cyclotrimerization and polymerization of 1-hexyne. It has been found that the cyclotrimerization by $NbCl_5$ and $TaCl_5$ selectively yields cyclotrimer, while not only polymer but also cyclotrimer is formed in the polymerization by $MoCl_5$ and WCl_6. For comparison, the cyclotrimerization and polymerization by Ziegler catalysts were also carried out.

Experimental

1-Hexyne was purchased from Farchan Labs, USA, and distilled twice from calcium hydride under nitrogen before use. Commercially available transition metal and organometallic compounds were used without further purification. Polymerization solvents were washed with acid and/or alkaline solutions and distilled from appropriate drying agents; care was exercised to dry and deaerate them sufficiently.

Two-component catalysts were aged in solution at 30 °C for 15 min before use. Reactions of 1-hexyne were carried out under nitrogen and terminated by adding ammoniacal methanol. Monomer consumptions (conversions) were determined by ges chromatography.

Cyclotrimerization was worked up by washing reaction mixtures with dilute hydrochloric acid and water and then evaporating the solvent. The ratio of cyclotrimer to linear oligomer was determined by liquid chromatography (JASCO Triroter II chromatograph; Shodex A802, A804 polystyrene gel columns). Two isomers of cyclotrimer (1,2,4- and 1,3,5-tributylbenzenes) could be separated by gas chromatography (Shimadzu GC3B chromatograph; Silicone DC550 supported on Chromosorb W (10%) 5 m, 195 °C). The isomer with a shorter retention time was identified as 1,3,5-tributylbenzene because it showed a singlet ($\delta=6.80$) in the aromatic region in ^1H NMR (a multiplet was observed for the other isomer). Therefore the ratio of the two isomers was determined by gas chromatography.

The polymeric product in polymerization was recovered by precipitation in a large amount of methanol, and its yield was determined by gravimetry. The oligomeric product was dealt with similarly to the cyclotrimerization product. Number-average molecular weights, $\overline{M}_n$, of polymers were obtained by vapor pressure osmometry (Hitachi 117 molecular weight apparatus). Differential thermal analysis (DTA) was performed under nitrogen with a Shimadzu 20B analyzer.

Results and Discussion

Cyclotrimerization. The cyclotrimerization of 1-hexyne by $NbCl_5$ and $TaCl_5$ proceeded quantitatively under the conditions shown in Table 1. Hydrocarbons and halogenated hydrocarbons were useful solvents, whereas ethers, esters and ketones were not. The products consisted exclusively of cyclotrimer, which was a mixture of two isomers, that is, 1,2,4- and 1,3,5-tributylbenzenes. The 1,2,4/1,3,5 isomer ratio of the product was about 70/30—80/20 with $NbCl_5$, and about 55/45—70/30 with $TaCl_5$; the former catalyst generally yielded more 1,2,4-isomer. The ratio was affected only slightly by the solvents used.

The effect of temperature on the cyclotrimerization was examined between 0 and 60 °C (Table 2). The reaction rate greatly reduced with decreasing temperature. The 1,2,4/1,3,5 isomer ratio of product somewhat decreased with both $NbCl_5$ and $TaCl_5$, as the reaction temperature was lowered.

Thus $NbCl_5$ and $TaCl_5$ effected highly selective cyclotrimerization of 1-hexyne similarly to the case of phenylacetylene.[11)] The 1,2,4/1,3,5 isomer ratio varied only in a range of 54/46—78/22 with reaction con-

† Present address: Zhongshen (Sun Yatsen) University, China.

Table 1. 1,2,4/1,3,5 Isomer ratios of products in the cyclotrimerization of 1-hexyne by NbCls and TaCls[a]

Cat	Benzene	Toluene	Hexane	Cyclohexane	CCl_4	$CHCl_3$	$(CH_2Cl)_2$

VCl_4	Et_3Al	95	26	26	43
$VOCl_3$	Et_2AlCl	90	52	38	0
$VOCl_3$	Et_3Al	95	13	11	71

a) $[1\text{-Hexyne}]_0=1.0$ mol dm^{-3}, $[cat]=30$ mmol dm^{-3}, $[cocat]=45$ mmol dm^{-3}, in toluene, 30 °C, 24 h; catalyst aging 30 °C, 15 min.

ditions (catalyst, solvent and temperature). This contrast with a larger variance of the ratio (17/83—94/6) in the cyclotrimerization of phenylacetylene with similar changes in reaction conditions. Metallacyclopentadienes should be involved as intermediates in the cyclotrimerizaton of acetylenes with transition metal catalysts.[13] Since the phenyl group is bulkier than the butyl group, it is reasonable that the orientation of two acetylene molecules during the formation of a metallacyclopentadiene is more dependent on reaction conditions in phenylacetylene than in 1-hexyne.

The cyclotrimerization of 1-hexyne by Ziegler catalysts was investigated for comparison. Though various combinations of transition metal chlorides and organoaluminums were employed as catalysts, most of them yielded not only cyclotrimer but also linear oligomer. Chlorides of Ti and V were most effective among various transition metal chlorides. $EtAlCl_2$ possessed a high Lewis acidity to give linear oligomer by the cationic mechanism. The catalyst systems that showed relatively high selectivity for cyclotrimerization are given in Table 3. The 1,2,4/1,3,5 isomer ratios were usually close to unity.

Polymerization. Table 4 shows results for the polymerization of 1-hexyne by $MoCl_5$- and WCl_6-based catalysts. Both $MoCl_5$- and WCl_6-based catalysts worked effectively, the latter being somewhat more active. Methanol-insoluble polymers were about half the whole products in quantity. The polymers had relatively low molecular weights (3000—5000). Methanol-soluble oligomers consisted of linear oligomer and cyclotrimer (both 1,2,4- and 1,3,5-isomers involved). The observed cocatalyst effect shows that both or either of methanol and Ph_4Sn is useful to increase conversion and polymer yield. Nonpolar solvents such as benzene, cyclohexane and carbon tetrachloride were preferable.

Table 4. Polymerization of 1-hexyne by $MoCl_5$ and WCl_6[a]

a) $[1\text{-Hexyne}]_0=1.0$ mol dm^{-3}, $[cocat]=10$ (CH_3OH) or 20 (Ph_4Sn) mmol dm^{-3}, 30 °C, 3 h. b) The methanol-insoluble product. c) Yields of methanol-soluble products: linear oligomer 19%, 1,2,4-cyclotrimer 7%, 1,3,5-cyclotrimer 11%. d) Yields of methanol-soluble products: limear oligomer 15%, 1,2,4-cyclotrimer 3%, 1,3,5-cyclotrimer 10%.

For comparison, the polymerization by Ziegler catalysts was examined. In acetylene polymerization, polymer is selectively formed only when both transition metal and organoaluminum compounds have low Lewis acidities.[14] Therefore, we chose combinations of transition metal acetylacetonates and Et_3Al as catalyst systems. A high polymer yield was achieved in the polymerization using $Fe(acac)_3$ in cyclohexane solution (Table 5). Though $VO(acac)_3$ and $Co(acac)_3$ were also effective, the polymer yields were rather low. The main products were methanol-insoluble polymers; small amounts of linear oligomer and cyclotrimer were also formed. Polymer molecular weights were 5000—13000, higher than those with $MoCl_5$- and WCl_6-based catalysts. Aliphatic and aromatic hydrocarbons were

Table 5. Polymerization of 1-hexyne by Ziegler catalysts[a]

a) Steric effect of the substituent in monomer. b) Relative yields of cyclotrimer to polymer.

useful polymerization solvents. It is not clear why the polymerization using the $Fe(acac)_3$ system did not occur in toluene.

Table 6 summarizes polymer molecular weights and cyclotrimer(by-product) yields in the $MoCl_5$- and WCl_6-catalyzed polymerization of monosubstituted acetylenes. As the substituent in the monomer becomes bulkier and shows a greater steric effect, polymer molecular weight clearly increases and cyclotrimer yield approaches zero. As an extreme case, *t*-butylacetylene affords a very high polymer and does not form cyclotrimer; on the contrary, Ziegler catalysts cannot polymerize this monomer.[17] It does not appear an important factor whether the substituent is an alkyl or an aryl group. Table 6 leads to the conclusion that $MoCl_5$- and WCl_6-based catalysts are particularly effective towards sterically hindered acetylenes [*e.g.*, HC≡C(*t*-Bu)], while not so effective to sterically unhindered acetylenes [*e.g.*, HC≡C(*n*-Bu)]. It has been inferred that two acetylene molecules coordinate to a transition metal to form the intermediate in cyclotrimerization,[13] while one acetylene molecule in polymerization.[12]

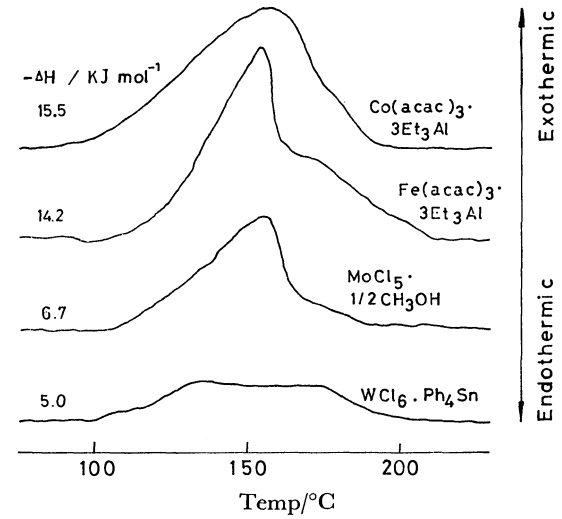

Fig. 1. DTA thermograms of poly(1-hexyne)s.

Therefore, polymerization will not suffer the steric effect so greatly as cyclotrimerization, which seems responsible for the selective polymerization of *t*-butylacetylene.

Spectral data of the poly(1-hexyne) obtained with $WCl_6\cdot Ph_4Sn$ in toluene are as follows: IR 1650—1600 cm^{-1} (w; conjugated C=C). ^{1}H NMR ($CDCl_3$) δ 5.87 (s, 1, –CH=), 2.21 (s, 2, $=CCH_2-$), 1.30 (s, 4, $-CH_2CH_2Me$), 0.90 (s, 3, CH_3). ^{13}C NMR ($CDCl_3$) δ 140.0 (C_2), 126.1 (C_1), 31.0 (C_3), 23.0, 22.6 (C_4, C_5), 14.0 (C_6). UV (hexane) λ_{max} 285 nm (ε 1600); the absorption continued as far as 450 nm. All the poly(1-hexyne)s obtained in the present study showed practically the same spectra. These data lead to the conclusion that the polymer has the conjugated polyene structure –[–CH=C(*n*-Bu)–]–.

In general, poly(1-hexyne) was an orange-yellow viscous material soluble in hydrocarbons and halogenated hydrocarbons. This polymer was gradually oxidized by air at room temperature, as confirmed by a carbonyl band at 1710 cm^{-1} in the IR spectrum. This contrasts with the fact that poly(*t*-butylacetylene), which cannot take a planar conformation, is very stable.[17]

Poly(1-hexyne)s obtained with several catalysts showed exothermic peaks of different magnitudes in the same temperature range in the DTA thermograms (Fig. 1). It is known that polyacetylene[18] and poly(phenylacetylene)[19] show exothermic peaks in DTA due to their isomerization from cis to more stable trans form. The cis content of poly(phenylacetylene) has been qualitatively estimated by the isomerization exotherm. Based on a similar discussion, one can conclude from Fig. 1 that the cis content of poly(1-hexyne) decreases in the following order of catalyst: $Co(acac)_3\cdot 3Et_3Al > Fe(acac)_3\cdot 3Et_3Al > MoCl_5\cdot(1/2)CH_3OH > WCl_6\cdot Ph_4Sn$. A similar order has been observed with poly(phenylacetylene): $Fe(acac)_3\cdot 3Et_3Al > MoCl_5\cdot(1/2)CH_3OH > WCl_6\cdot Ph_4Sn$.[19b] Thus $MoCl_5$- and WCl_6-based catalysts tend to give polymers with higher trans contents than do Ziegler catalysts.

Assignment of a Characteristic Infrared Absorption Band at 810 cm^{-1} in Heat-treated Polyacrylonitrile

Masao Okamoto

Department of Fiber and Polymer Engineering, Faculty of Engineering, Yamagata University, Jonan, Yonezawa 992

(Received August 10, 1982)

When polyacrylonitrile (PAN) was heat-treated at about 250 °C under nitrogen, a violent exothermic reaction took place. PAN lost weight and the infrared absorption at 2240 cm^{-1} disappeared, but there was little change in the atomic ratios of carbon, hydrogen, and nitrogen. This indicates that fragmentation is accompanied by rapid polymerization of cyano groups. The sample obtained after the completion of the exothermic reaction seems to be liable to oxidation, because a strong exothermic reaction and weight gain occur immediately if air is admitted to enter. During the oxidation the percentages of carbon and nitrogen did not change, but that of hydrogen largely decreased, indicating the occurrence of oxidation and subsequent dehydration in the moieties subjected to polymerization of cyano groups. Therefore, the tri-substituted carbon-carbon double bonds are formed in the six-membered ring systems. A new infrared absorption band which appears at 810 cm^{-1} is assigned to the C–H out-of-plane bending vibration in such a double bond.

Polyacrylonitrile (PAN) fiber is changed into flame-proof fiber by heat treatment in air at 200—300 °C.[1] Carbon fiber is produced by heating the flame-proof fiber in an inert atmosphere at 1000—1500 °C.[2] Thus a prior oxidative treatment is necessary in the preparation of carbon fiber from PAN fiber. In infrared absorption spectrum of PAN subjected to such an oxidative treatment, a strong absorption appears at 810 cm^{-1}. This was assigned to C–H out-of-plane bending vibration in –CH=C(C≡N)–,[3–8] but no absorption appeared at 810 cm^{-1} in the spectra of the products obtained by dehydrochlorination of poly(α-chloroacrylonitrile).[9] This fact is not consistent with the assignment.

Experimental

Preparation of PAN. The preparative method was reported in a previous work.[10]

Isothermal Heat Treatment. Heat treatment of PAN was carried out in a differential thermal analyzer (Rigaku CAT. No. 8001 Thermoflex) to observe the change of the sample temperature. The rate of the temperature rise is 20 °C/min.

Infrared Absorption Spectra. A Hitachi EPI-G_2 diffraction grating infrared spectrophotometer was used. Samples were examined as KBr disks. Normalized absorbance (A) of an absorption band was calculated by the equation:

$$A = \frac{a}{w} \times \frac{W}{W_0},$$

where a is the observed absorbance for w mg of the sample, and W (mg) is the amount left after heating W_0 (mg) of PAN. The yield given in Table 1 was calculated by

$$\text{Yield} = \frac{W}{W_0} \times 100 \ (\%).$$

Results and Discussion

Observation of an Exotherm in the Course of Heat Treatment. Change of the sample temperature was measured during the isothermal heat treatment (Fig. 1). Under nitrogen an exotherm due to polymerization of cyano groups was always observed when the heat-treatment temperature was above 230 °C. The

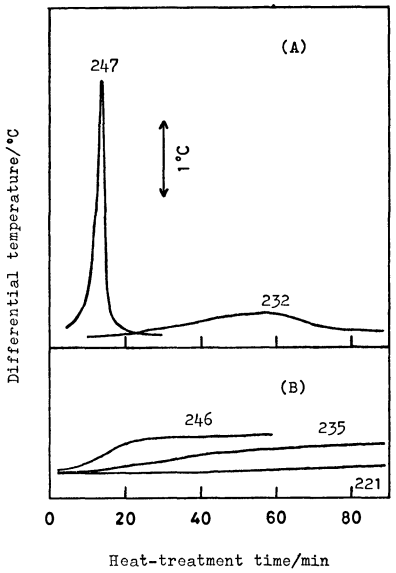

Fig. 1. Observation of an exotherm during isothermal heat treatment of 50 mg of PAN (A) under nitrogen and (B) in air. The heat-treatment temperature (°C) is given in the figure.

differential temperature increases with the treatment temperature. Especially, generation of heat was very sharp for the heat treatment at *ca.* 250 °C. In air an exotherm due to both polymerization of cyano groups and oxidation was observed at *ca.* 220 °C, but the peak was broad and weak even at 250 °C. This indicates that oxygen can retard a rapid polymerization of cyano groups at *ca.* 250 °C.

Compositions of Samples Heat-treated under Different Conditions. Samples 1, 2, 3, and 4 were heat-treated at 250 °C under the conditions given in Fig. 2. The yields and compositions are shown in Table 1. The percentage changes in carbon, hydrogen, and nitrogen due to the heat treatment are given in Table 2.

When PAN was heat-treated for 29 min under nitrogen, and for additional 10 min under reduced pressure, there was little change in the atomic ratios of carbon, hydrogen, and nitrogen although the weight loss was 6.3 wt%. This indicates fragmentation accompanied

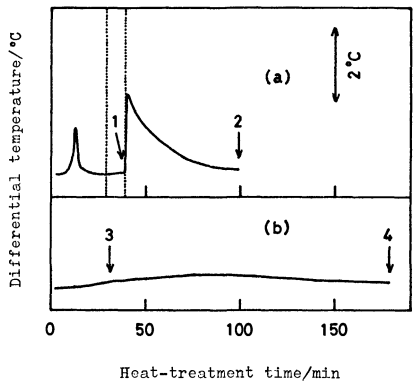

Fig. 2. Preparation of samples 1, 2, 3, and 4 by the isothermal heat treatment of 30 mg of PAN at 250 °C. The arrows indicate the end of heat treatment. Sample 1 was cooled by admitting nitrogen. Samples 2, 3, and 4 were cooled in a desiccator.
Atmosphere for heat treatment: (a) Nitrogen (0—29 min), reduced pressure (29—39 min), and air (39—99 min). (b) Air.

Table 1. Yields and analytical data of samples 1, 2, 3, and 4

Sample	Yield/%	Chemical compositions (%)				
		C	H	N	Ash	O (+Errors)
PAN	100	67.6	5.9	25.7	0.3	0.5
1	93.7	65.9	5.5	24.4	0.5	3.7
2	98.3	62.9	3.2	22.5	0.9	10.5
3	98.7	—	—	—	—	—
4	94.3	60.1	3.4	22.1	1.0	13.4

Table 2. Changes in weights of carbon, hydrogen, and nitrogen by heat-treating PAN

Sample	Residual weights (%)		
	C	H	N
PAN	100	100	100
1	91.3	87.3	88.9
2	91.5	53.4	86.1
4	83.8	54.4	81.1

by rapid polymerization of cyano groups. Sample 1 seems to be liable to oxidation, because a strong exothermic reaction and weight gain occur immediately if air is admitted to enter. Since weight loss of sample 2 obtained by heat-treating sample 1 in air for 60 min was 1.7 wt%, it is clear that oxygen combined with sample 1 to give weight gain of at least 4.6 wt%. During the oxidation the percentages of carbon and nitrogen did not change, but that of hydrogen decreased remarkably. This indicates that sample 1 was easily oxidized and subsequently dehydrated.

Sample 4 obtained by heat-treating PAN in air for 179 min resembles sample 2 and flame-proof fibers[1,11] in composition. Further there was no difference between the weight losses of hydrogen for a flame-proof fiber[11] and samples 2 and 4. The weight losses of

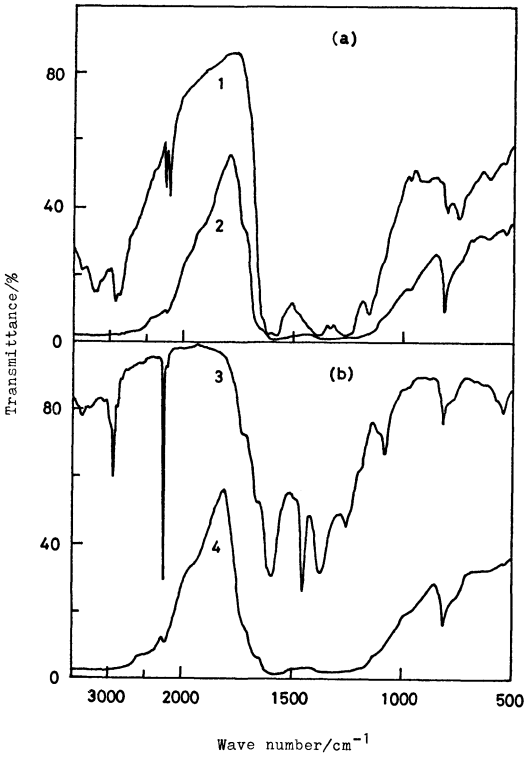

Fig. 3. Infrared absorption spectra of samples 1, 2, 3, and 4.

Table 3. Normalized absorbances at 2240, 2220, 2200, and 810 cm^{-1} in infrared absorption spectra of samples 1, 2, 3, and 4

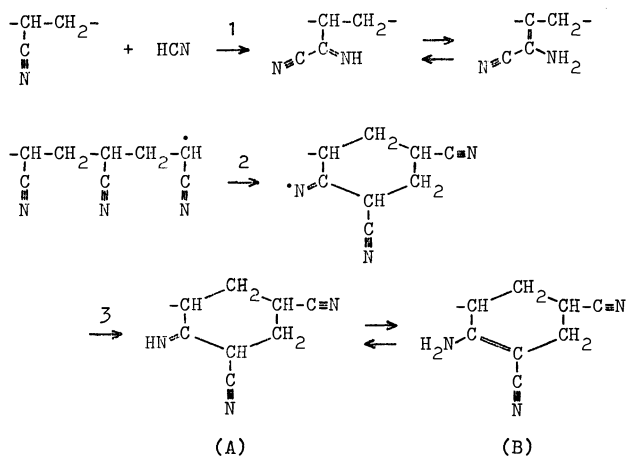
Sample	Normalized absorbances			
	2240 cm^{-1}	2220 cm^{-1}	2200 cm^{-1}	810 cm^{-1}
PAN	0.300			
1	0.054		0.072	—[a]
2		0.034		0.221
3	0.254		0.010	0.036
4		0.050		0.121

a) Only observed as a shoulder of the band at 800 cm^{-1}.

carbon and nitrogen for a flame-proof fiber[11] and sample 4, however, were much higher than those for sample 2. This indicates that the degree of degradation for a flame-proof fiber[11] and sample 4 is much higher than that for sample 2.

Infrared Spectra of Samples Heat-treated under Different Conditions. Infrared spectra of samples 1, 2, 3, and 4 are shown in Fig. 3. The normalized absorbances at 2240, 2220, 2200, and 810 cm^{-1} are given in Table 3.

Since sample 1 had rapid polymerization of cyano groups, the absorbance of the C≡N stretching vibration band at 2240 cm^{-1} was below 1/5 of the value for PAN. However, there is no reason why 4/5 of cyano groups are lost only by polymerization, because it is accompanied by the elimination of volatile fragments and the appearance of a band at 2200 cm^{-1}. The following reactions[12,13] will be related with the appearance of this band:



(A) (B)

In these reactions the atomic ratios do not change. The band at 2240 cm^{-1} disappears with reaction 1, but moieties A and B formed by six-membered ring formation 2 and subsequent hydrogen abstraction 3 have cyano groups which absorb at 2240 cm^{-1}. This explains why sample 1 obtained after the completion of rapid polymerization of cyano groups shows the band at 2240 cm^{-1}.

Sample 2 shows a strong absorption at 810 cm^{-1}, which is the characteristic band appearing in the spectra of PAN samples heat-treated in the presence of oxygen.[3-8,14] If this band is due to –CH=C(C≡N)– formed by the oxidation and subsequent dehydration in acrylonitrile repeating units,[4] its absorbance for sample 4 must be higher than that for sample 2, because the amount of acrylonitrile repeating units for sample 1 is below 1/5 of that for PAN. Since the reverse is the case, the band at 810 cm^{-1} cannot be assigned to the C–H out-of-plane bending vibration in –CH=C(C≡N)–. A band at 2220 cm^{-1} can be assigned to the C≡N stretching vibration in such a moiety. As stated above, the moieties subjected to polymerization of cyano groups are readily liable to oxidation followed by dehydration. Therefore, when sample 1 is heat-treated in air,  should be easily formed. Since sample 2 should have such a moiety and shows a strong band at 810 cm^{-1}, this band is assigned to the C–H out-of-plane bending vibration in this moiety.

When PAN is subjected to slow polymerization of cyano groups in air, a band at 810 cm^{-1} will appear after completion of the exothermic reaction caused by polymerization and oxidation. Consequently sample 4 is expected to show such a strong band at 810 cm^{-1}. However, the normalized absorbance observed was only 0.121, much lower value than that for sample 2. This seems to be related with a higher degree of degradation for sample 4 than for sample 2.

New Industrial Synthesis of Squalane

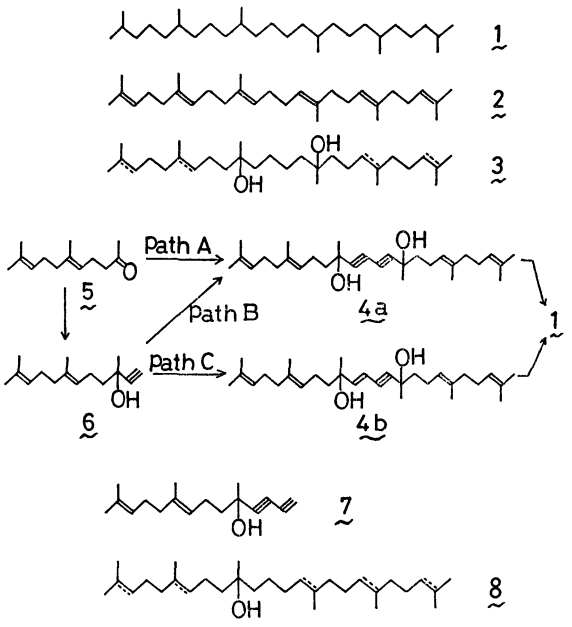
Takashi NISHIDA,* Yoichi NINAGAWA, Kazuo ITOI, and Yoshiji FUJITA
Central Research Laboratories, Kuraray Co., Ltd., Sakazu, Kurashiki, Okayama 710

(Received January 13, 1983)

Squalane is synthesized by the ethynylation reaction of geranylacetone with a complex of 1,3-butadiyne : *N*-methylpyrrolidone (=1 : 1) in the presence of a KOH catalyst and by hydrogenation with a Raney nickel catalyst, followed by hydrogenation hydrogenolysis with a mixed catalyst of nickel/diatomaceous earth and silica-alumina. An alternative synthesis of squalane from dehydronerolidol is also achieved by oxidative coupling reaction with a copper(II) catalyst under a helium atmosphere.

Squalane (**1**), a useful base oil for cosmetic formulations, has been commercially produced in large quantities by the hydrogenation of squalene (**2**) obtained from shark liver oil.[1] In spite of numerous studies of the stereoselective synthesis of **2**,[2] there have been few investigations directed toward an efficient total synthesis of **1**.[3] Among the various possible key intermediates for constructing this symmetrical structure, attention was focused on diol (**3**), which could be synthesized by the Grignard reaction of 1,4-dibromobutane and geranylacetone (**5**).[4] Compound **5** is available as a precursor of isophytol on the scale of several thousand tons/year. Thus, we examined the ethynylation of **5**, using 1,3-butadiyne as a key building block, instead of the Grignard reaction of 1,4-dibromobutane to obtain an analogous diol (**4a**) [Path A]. The industrial synthesis of pure squalane is now achieved by the hydrogenation of the unsaturated bonds of **4a**, followed by hydrogenation hydrogenolysis. Then, two alternative methods for deriving **4a** and **4b** from dehydronerolidol (**6**) *via* an oxidative coupling reaction in the presence of a copper(II) ion catalyts [Path B] or via dimerization with a rhodium catalyst under a helium atmosphere [Path C] are also described.

1,3-Butadiyne, one of the major by products of acetylene synthesis by the cracking of natural gas, can be separated from a mixture of other acetylenic compounds (vinylacetylene, 1-propyne, *etc.*) as a complex of 1,3-butadiyne:*N*-methylpyrrolidone (NMP) (=1:1) by passing the mixed gas through a NMP solution.[5] 1,3-Butadiyne is liberated from the complex by heating at *ca.* 40 °C under reduced pressure.



Scheme 1.

The ethylnyation of ketones with 1,3-butadiyne on both terminal sides gives good yields when a stoichiometric amount of sodium amide[6] or the Grignard reagent[7] is used and also, more economically, by means of a semicatalytic reaction with potassium or sodium hydroxide.[8] In this report a 1,3-butadiyne: NMP complex in an NMP solution was employed instead of explosive 1,3-butadiyne, and the reaction was carried out in liquid ammonia at 15 °C in the presence of a potassium hydroxide catalyst (7 mol% *vs.* **5**) [Favorskii conditions].[8] As is shown in Fig. 1, the maximum yield of **4a** (80%) was obtained at the theoretical molar ratio of 1,3-butadiyne:**5** of 0.5:1. However, the undesired alcohol (**7**) was also generated in *ca.* a 10% yields, and the selectivity of **4a** (=yield of **4a**/conversion of **5**×100) is *ca.* 85% under these conditions. On the other hand, the optimum condition of industrial operation was a molar ratio of *ca.* 0.4:1 at which the selectivity of **4a** was 92%, with *ca.* a 75% conversion of **5**. It is better to use **5** in an excess for the complete consumption of 1,3-butadiyne, and the unreacted **5** can be recycled by distillation after the hydrogenation of the ethynylation mixture. The distillation of **5** directly from the ethynylation mixture is dangerous. It was confirmed by gel-permeation chromatography (GPC) that the yield of **7** was less than *ca.* 3% at this molar ratio.

The direct synthesis of squalane from **4a** via hydro-

1) A 10-g sample of **4a** in 100 ml of a solvent was treated under various conditions. 2) The GC analyses of **1** are exhibited in Fig. 2.

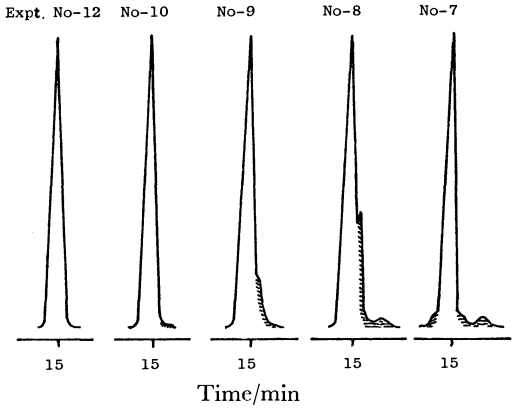

Fig. 2. GC-analyses of **1** prepared by hydrogenation hydrogenolysis of **4a** or **3**.
PEG-20M (2%), 2m, inject. temp, 350 °C, column temp. 150—240 °C (10 °C/min).

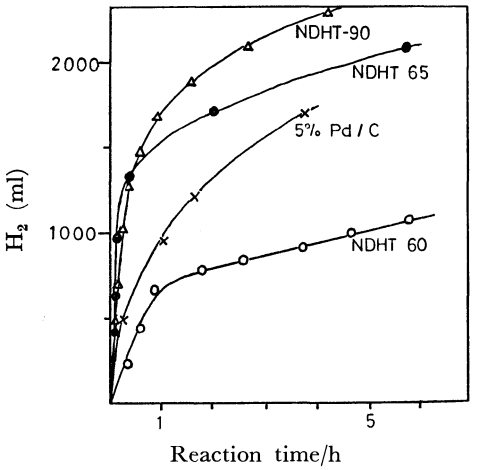

Fig. 3. Hydrogen absorption curve of **4a** with various Raney nickel or Pd/C catalyst. 10 g sample of **4a** in hexane (40 ml) at 100 °C; H_2 pressure 15—20 kg/cm^2; Raney nickel (5 wt%); Pd/C (2.5 wt%).

genation hydrogenolysis was carried out by using Pd/C or a mixed catalyst of Ni/diatomaceous earth and silica-alumina (Ni/Si–Al) under various conditions (Table 1). In the case of the Pd/C catalyst (Expt Nos. 1—7), the use of an acidic solvent such as acetic acid or isobutylic acid was indispensable to convert the diol (**3**) and monool (**8**) into **1** under a low hydrogen pressure and at a relatively low temperature. The addition of a catalytic amount of 3 M-hydrochloric acid (1 M=1 mol cm^{-3}) was effective in completing the conversion of **3** and **8**. The treatment of **4a** with a mixed catalyst of Ni/Si–Al under various conditions (high hydrogen pressure at high temperature) also yielded **1** almost quantitatively (Expt Nos. 8—10). In this reaction, the ratio of silica-alumina was critical to obtain **1** of a good quality. However, as is shown in Fig. 2, squalane synthesized by these procedures contained unknown impurities inseparable from **1** by rectification when **4a** was used as the starting material of the hydrogenation hydrogenolysis.

Consequently, as an industrial method we chose this three-step process: (i) the hydrogenation of the unsaturated triple (and partially some double) bonds of **4a** by means of a Raney nickel catalyst, (ii) the recovery of **5** by distillation, and (iii) the hydrogenation hydrogenolysis of the saturated diol (**3**) by means of a mixed catalyst of Ni/Si–Al. The hydrogenation of **4a** proceeded in the presence of *ca.* 5 wt% of the Raney Ni catalyst (NDH: trade name of Kawaken Fine Chem. Co.) in hexane at 100 °C, with a hydrogen-pressure range of 15—20 kg/cm^2 (Fig. 3).[9)]

After the separation of the catalyst, the unreacted **5** was recovered by distillation to obtain **3** as a residue. The results of the hydrogenation hydrogenolysis of **3** under various conditions are listed in Table 2. Expt Nos. 11—13 show the influence of the temperature, and Expt Nos. 14—17, the effect of the amount of the catalyst on the product distribution. Contrary to the previous direct synthesis of **1** from **4a**, good results were obtained in this case using much of the silica-alumina catalyst in order to complete the reaction without the formation of impurities (Fig. 2; Expt No. 12). This process is now employed for the industrial production of squalane in quantities amounting to several hundred tons a year.

An alernative method for the synthesis of the key

a) Determined by GC (PEG-20 M, 3 m, 190 °C), using eicosane as the internal standard. b) Determined by HPLC (butyl acetate/hexane=10/90), using solanesol as the internal standard; [ ]: isolated yield after silica gel column chromatography.

intermediate **4a** was also described in order to expand the production of squalane because of the limitation of the amount of 1,3-butadiyne obtained as a by product of the acetylene industry. The oxidative coupling reaction, which has been actively studied not only for its synthetic utility, but also for its mechanistic interest, seemed to be suitable for this purpose [Path B].[10] The reaction, which has been thought to need an excess amount of a copper catalyst,[11—13] was modified by Hay for practical usage as follows[14]: oxygen (air) was bubbled into a mixture of **6** and the copper catalyst (3 mol% *vs.* **6**) in hexane/pyridine in the temperature range of *ca.* 40—80 °C for 3 h to afford **4a** in a high yield. It is recommended to dissolve the catalyst before the introduction of the oxygen. If the catalyst was not completely dissolved, the reaction usually stopped before completion, particularly when the reaction was carried out under a lower temperature (room temperature to *ca.* 60 °C). According to our reinvestigation of the copper catalyst, copper(I) chloride and copper(II) acetate gave good results. Copper (II) acetylacetonate, copper(II) chloride, copper(II) sulfate, *etc.* were ineffective. Pyridine, which has been known to be a good solvent (ligand) in this reaction, has a strong effect on the reaction rate and the conversion of **6**. A pyridine/copper catalyst molar ratio of at least 10, and better, 20—30, is required to complete the reaction (Table 3).

Kinetic studies of this reaction showed that the consumption rate of **6** was proportional to the amount of the pyridine and the copper catalyst, and the activation energy (E_a) was calculated to be approximately 10.8 kcal/mol (Fig. 4) in the presence of an excess amount of oxygen. The order of the reaction was estimated to be zero in the initial stage (0—60% conversion of **6**), first at a 60—90% conversion, and second in the final stage (90% conversion). The reaction usually stopped when the conversion of **6** reached *ca.* 94—97%. The reverse ethynylation of **6** and **4a**, which has never before been reported, was observed in a large-scale experiment: The purification of the reaction mixture by column chromatography (ethyl acetate/hexane=10/90—25/75) yielded **5** (*ca.* 2%) and **7** (*ca.* 3—4%), which might be derived from **6** (or **4a**) and **4a** respectively. Acetylene was also trapped as a white precipitate of silver acetylide by passing the outlet gas of the reaction into a silver nitrate/ethanol solution; the amount of silver acetylide increased when the supply of oxygen was decreased. The amount of the higher-boiling products was relatively small (*ca.* 3%),

Table 4. Dimerization of 6 with Wilkinson catalyst

6 (mmol)	$RhX(PPh_3)_3$ (mmol)	Solvent (ml)	Reaction conditions: Temp/°C	Reaction conditions: Time/h	Conversion of 6/%[a]	Yield of 4b/% [isolated]

50	X=Cl (0.5)	Benzene (100)	85	12	84	72
50	X=Cl (0.3)	Toluene (100)	110	8	76	60
50	X=Cl (0.5)	Toluene (100)	110	8	97	83 [78]

a) Determined by GC (PEG-20 M, 3 m, 190 °C), using eicosane as the internal standard. b) Determined by HPLC (butyl acetate/hexane=10/90), using solanesol as the internal standard.

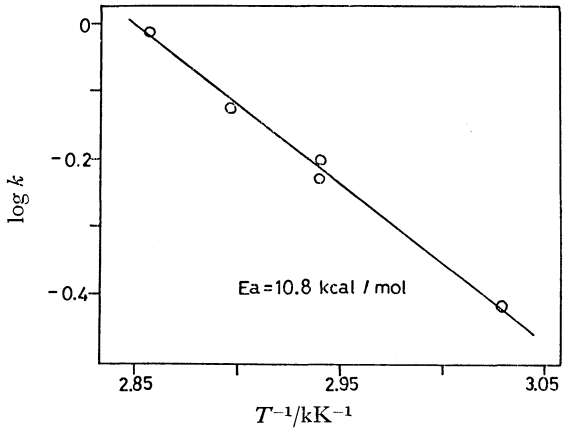

Fig. 4. Effect of temperature on rate constant (K) of disappearance of **6** in oxidative coupling reaction: **6** (37.6 mmol), $Cu(OAc)_2 \cdot H_2O$ (1.2 mmol), pyridine (24.8 mmol) in $C_{13}H_{28}$ (14.0 g); air 5.5 l/h.

and the yield of **4a** was approximately 87%, with a 95% conversion of **6**.

The dimerization of **6** to **4b** with the Wilkinson catalyst (Path C)[15] was also investigated. The treatment of **6** with $RhCl(PPh_3)_3$ (1—5 wt% *vs.* **6**) in dry benzene (toluene), sufficiently degassed with helium at 80—110 °C for 7 h, gave **4b** in a good yield (Table 4). If oxygen was contained in this reaction system, the reaction often stopped before completion and *ca.* 10% of the catalyst was required for completion. The almost pure product, **4b**, obtained by short-column chromatography on silica gel was converted to **1**, as has been mentioned in connection with the oxidative coupling process (total yield from **6**=77%). The di-substituted double bond of **4b** was identified as having an *E*-form. The economical recycling of this expensive catalyst, however, still remains open as a significant problem; it is now under investigation in our laboratories.[16]

In conclusion, we first employed the 1,3-butadiyne process (Path A) as an industrial squalane synthesis and are now also investigating the oxidative coupling process (Path B) as an alternative. The dimerization process with the Wilkinson catalyst (Path C) can not now be employed as a practical method unless the economical recycling of the catalyst can be achieved.

Experimental

The boiling points are uncorrected. The IR spectra were recorded with a Digilab FTS-20 C/D spectrometer. The NMR spectra were taken with a Varian EM 390 apparatus (with hexamethyldisiloxane as an internal standard), and the mass spectra, with a Finnigan 9500 or JEOL JMS-D 300 instrument. GC analyses were made by means of a Shimadzu GC-7AG gas chromatograph using a 3 mm×200 cm column of 10% Silicone DC-550, 10% PEG-20M, or OV-1 on Celite 545 with He as the carrier gas, and HPLC analyses, with a Waters Associates liquid chromatograph using a μ-Porasil P/N 27477 S/N column.

Geranylacetone (**5**) and dehydronerolidol (**6**), commercially available from the Kuraray Co., Ltd., NIC-division, are used as (*Z*)- and (*E*)-forms or as *Z*/*E*=4/6 mixture.

*2,6,10,15,19,23-Hexamethyl-2,6,18,22-tetracosatetraene-11,13-diyne-10,15-diol (**4a**). Ethynylation of Geranylacetone (**5**) with 1,3-Butadiyne*: In a 500-ml autoclave was placed a *Z*/*E*=4/6 mixture of 6,10-dimethyl-5,9-undecadien-2-one (**5**) [38.8 g; 0.2 mol], 40 g of a 10% solution of 1,3-butadiyne (0.08 mol) in NMP, and 3.92 g of a 20 wt% aqueous KOH catalyst in 200 ml of liquid ammonia to react at 15—20 °C for 3 h. The autoclave was then cooled to *ca.* −35 °C, and the reaction mixture was neutralized with ammonium chloride. After the ammonia had then been purged, 200 ml of hexane was added to the residue and the mixture was washed with water and dried over magnesium sulfate. The evaporation of hexane afforded crude **4a** (42.1 g), which was then analyzed by means of HPLC (butyl acetate/hexane=1/9; solanesol as the internal standard) and found to contain **5** (24%), **4a** (70%), and **7** (3%). **4a** was composed of three stereoisomers of (6*Z*,18*Z*)[HPLC retention time 14.2 min], (6*Z*,18*E*) [15.9 min], and (6*E*,18*E*) [18.0 min] in a ratio of *ca.* 1:3:2. The analytical sample of **4a** was purified by means of silica gel column chromatography (ethyl acetate/hexane=10/90—25/75): IR (neat) 3360, 2962, 2920, 2850, 1446, 1375, 1118 cm^{-1}. NMR ($CDCl_3$) δ=1.46 (s, 6H, CH_3COH), 1.57, 1.63, 1.64 (each s, 18H, CH_3), 2.23 (s, 2H, OH), 5.07 5.10 (each t, 4H, =CH, J=7.5 Hz). Found: C, 81.86; H; 10.33, O; 7.58. Calcd for $C_{30}H_{46}O_2$: C; 82.14, H; 10.57, O; 7.29.

Compound **7** was confirmed by the following data: GC-mass (OV-1, 2 m, 100—290 °C) *m*/*e*=229 (M^+-CH_3), 142, 127, 69. The hydrogenation of the ethynylation mixture with Pd/C afforded 5,9,13-trimethyl-5-tetradecanol, whose GC retention time agreed completely with that of the authentic sample prepared by the Grignard reaction of 1-bromobutane and 6,9-dimethyl-2-undecanone.

*Oxidative Coupling of Dehydronerolidol (**6**).* In a four-

necked flask fitted with a thermometer, a gas-inlet tube, and a condenser (−20 °C) was placed 400 ml of hexane, pyridine (95 g; 1.2 mol), and copper(II) acetate (5.45 g; 0.03 mol) to dissolve at room temp. After the addition of **6** (220 g; 1 mol), the reaction temp was elevated to 70 °C by introducing air at the rate of 5.5 l/h for 3 h. The reaction mixture was then successively washed with water (100 ml × 3), 5% sulfuric acid (100 ml × 3), and 5% sodium hydroxide (50 ml)/15% sodium sulfate (100 ml). Quantitative analyses of the product with HPLC showed that the conversion of **6** was 94% and that the yield of **4a** was 85.6%, containing 4% of **7**. The subsequent purification of the product by means of silica gel column chromatography gave 188.8 g of **4a** (yield, 86.2%).

A kinetic study of this reaction was carried out at various temperature ranges by using 8.27 g (37.6 mmol) of **6**, 0.12 g (0.6 mmol)—0.36 g (1.8 mmol) of copper(II) acetate monohydrate, 0.5—4 ml of pyridine, and 2.0 g of elicosane as an internal standard in 14.0 g of a tridecane solvent by bubbling an air at the rate of 5.5 l/h. The rate of the disappearance of **6** was monitored by means of GC (PEG-20 M, 3 m, 190 °C).

*2,6,10,15,19,23-Hexamethyl-2,6,11,18,22-tetracosapentaen-13-yne-10,15-diol (**4b**).* *Dimerization of 6 with Rhodium Catalyst*: A mixture of a chlorotris(triphenylphosphine)rhodium catalyst (0.925 g; 1 mmol) in dry toluene (100 ml) was sufficiently degassed under a helium atmosphere to make possible the addition of **6** (15.4 g; 70 mmol) in one portion. A reaction at 110 °C for 8 h, the evaporation of the solvent, and the purification of the residue by means of silica-gel column chromatography (ethyl acetate/hexane=10/90—25/75) afforded **4b** (11.8 g; 77%) as a dark red oil: IR (neat) 3380, 2960, 2920, 2850, 1450, 1375, 1105, 960 cm^{-1}. NMR ($CDCl_3$) δ=1.23, 1.45 (s, 6H, CH_3COH), 1.58, 1.66 (s, 18H, CH_3), *ca.* 5.10 (m, 4H, =CH), 5.72 (d, 1H, =CH, J=16 Hz), 6.15 (d, 1H, =CH, J=16 Hz). Found: C, 81.58, H; 10.62, O; 7.07. Calcd for $C_{30}H_{48}O_2$: C, 81.76, 10.98, O; 7.26.

*2,6,10,15,19,23-Hexamethyltetracosane (**1**).* *Direct Synthesis from **4a** with Pd/C catalyst*: Hydrogen was bubbled vigorously into a mixture of **4a** (10 g; 22.8 mmol), 3 M-hydrochloric acid (0.2 ml), and 5% Pd/C (1 g) in acetic acid (100 ml) at 100 °C for 12 h. After the filtration of the catalyst, the filtrate was poured into water and extracted with hexane. The organic layer was washed with 5% sodium carbonate and dried over magnesium sulfate. The evaporation of the solvent and subsequent distillation of the residue afforded **1** (9.04 g; 94%): bp 202—208 °C/0.3—0.4 mmHg.† The analyses of **1** by means of ^{13}C-NMR, IR, mass, and GC-retention time agreed with those of an authentic sample prepared by the hydrogenation of squalene.

*Direct Synthesis from **4a** with Mixed Catalyst of Nickel/Diatomaceous Earth and Silica-alumina.* In a 300-ml stainless steel autoclave was placed **4a** (10 g; 22.8 mmol), nickel/diatomaceous earth (0.4 g), and a silica-alumina (0.4 g) catalyst in hexane (100 ml). After the atmosphere had been sufficiently replaced with hydrogen, further hydrogen was introduced into the system until a pressure of *ca.* 30 kg/cm² was reached. The reaction temperature was then rapidly elevated to 230 °C, while carefully controlling the pressure range of 110—112 kg/cm²; stirring was then continued for 2 h. The subsequent filtration of the catalyst, evaporation of solvent, and distillation of the residue afforded **1** in a 95% yield.

*Step-by-step Synthesis from **4a** via **3**.* In a 300-ml autoclave, 50 g (114 mmol) of **4a**, 3.6 ml of Raney nickel (about 2.5 g), and 100 ml of hexane were placed, after which the mixture was hydrogenated at 100 °C under a hydrogen pressure of 15—20 kg/cm² for 6 h. After the reaction, the catalyst was filtered off and the hexane was removed under reduced pressure to give 49.5 g of a viscous brown liquid, **3**. Investigation by means of the ^{13}C-NMR spectra confirmed qualitatively that this liquid has no triple bond and that some parts of the double bonds were hydrogenated, but a considerable amount of the double bonds remained. The liquid in hexane (500 ml) with the nickel/diatomaceous earth (1 g)/silica-alumina (2 g) catalyst was reacted in an autoclave at 260 °C for 2 h under a hydrogen pressure of 105—115 kg/cm² to obtain 41.6 g of **1** (total yield from **4a** after distillation, 86%).

The authers wish to thank Mr. Masahisa Tanomura and Mr. Takuo Kawaguchi for their useful discussions throughout this research, Mr. Michihiro Ishiguro for the technical assistance with the kinetic studies of the oxidative coupling process, and Mr. Yoshin Tamai for an engineering studies. We also grateful to Dr. Shigetoshi Amiya for obtaining the NMR spectra, to Mr. Masanari Oka for the mass spectra, and to Mr. Isao Akuta for the HPLC and GPC analyses.

† 1 mmHg≈133.322 Pa.

Extraction-Spectrophotometric Determination of Molybdenum(V) with Imidoyl Derivatives and Thiocyanate

Khageshwar Singh PATEL*,† and Rajendra Kumar MISHRA
Department of Chemistry, Ravishankar University, Raipur-496 010 M.P., India
(Received January 29, 1982)

Three new organic reagents derived from *N*-phenylbenzimidoyl chloride and thiourea, phenylthiourea or thiosemicarbazide react with Mo(V) in strongly acidic media in the presence of thiocyanate ions to give rise red-orange complexes, insoluble in water but soluble in benzene. The nature of the ligands has been described to be as univalent, bidentate chelating agents which may coordinate to Mo(V) to form complexes with the composition of Mo 0.2SCN·SR (SCN denotes thiocyanate ion and SR, deprotonated form of the reagents). The molar absorptivity of the complexes was found to be in the range of $(0.8—1.4)\times10^4$ l mol^{-1} cm^{-1} at λ_{max}, 465 nm. The method is simple, rapid and highly selective for Mo. The ferroalloy elements which are associated with the metal do not interfere with the determination. The method was applied to the analysis of ore and alloy steel samples for Mo.

Many methods have been reported for the spectrophotometric determination of molybdenum in soils, ferroalloys, *etc.*[1-8] However, they suffered from many practical difficulties such as interference of cations including Mn^{2+}, Ni^{2+}, Co^{2+}, Cr^{3+}, Ti^{4+}, Zr^{4+}, V^{5+}, Nb^{5+}, Ta^{5+}, and W^{6+}; variation of color intensity of the complex with respect to amount of reagents and standing time; prolonged extraction of the metal with rigid control of some analytical variables; requirement of Fe^{2+} or Ti^{3+} for full color development.[1-2,5,8] In the present paper, a simple, convenient and highly selective extractive-spectrophotometric method is described for the determination of micro amounts of the metal with newly synthesized imidoyl derivatives, namely, (*N*-phenylbenzimidoyl)thiourea (PBTU), *N*-(*N*-phenylbenzimidoyl)-*N*-phenylthiourea (PBPTU) and 1-(*N*-phenylbenzimidoyl)thiosemicarbazide (PBTSC) in the presence of thicyanate ions. Of these, PBPTU has been preferred for detail study owing to wide acidity range for the extraction of the metal and high distribution coefficient of the reagent. They are stable towards heat, light and air, and their solutions can be stored for a long time without deterioration. Each compound may exist as the tautomers **1** and **2**, in the fashion similar to esters and amides and the species containing a SH group would react with Mb(V)–SCN^- to form benzene-extractable complexes.

$n=1$ or 2; Ar = phenyl; R = H or phenyl

Experimental

Apparatus, Reagents, and Solutions. The absorbances were read with an ECIL UV-VIS spectrophotometer model GS-865 matched 1-cm cells and recorded with a Carl-Zeiss Specord UV-VIS spectrophotometer.

All chemicals and reagents used were of Analytical grade. A stock solution of molybdenum(VI) was prepared by dissolving 2.01 g of ammonium molybdate in 1 l of distilled water and standardized gravimetrically.[9]

Imidoyl derivatives were prepared by the condensation of equimolar amount of *N*-phenylbenzimidoyl chloride with the respective substances like thiourea, phenylthiourea and thiosemicarbazide at 120 °C. The products were recrystallized from ethanol and characterized in terms of melting point, elemental analysis and ultraviolet and infrared spectra.[10]

About 0.2—0.4% (W/V) solutions of the reagents in benzene, 20% (W/V) solutions of L-ascorbic acid and ammonium thiocyanate and 10 M hydrochloric acid or sulfuric acid (1 M = 1 mol dm^{-3}) were used.

All the solutions employed were presaturated with benzene.

Procedure. A sample solution containing upto 100 μg of Mo was transferred to a 100-ml separatory funnel. Into this was added 3 ml each of L-ascorbic acid and ammonium thiocyanate solution in a final volume of 25 ml at desired acidity. The solution was equilibrated with 25 ml benzene solution of the relevant reagent for 2 min. After seperation of the two phases, the organic phase was dried with 2 g of anhydrous sodium sulfate in a 50-ml beaker. The absorbance of the benzene extract was measured at λ_{max} against a suitable reference.

Results and Discussion

Spectral Characteristics. The absorption spectra of PBPTU and its Mo(V)–SCN^- complex are shown in Fig. 1. The imidoyl derivative complexes showed a sharp λ_{max} around 465 nm and its position was intact with respect to variation of the amount of reagents and the acidity of the aqueous phase. The molar absorptivity of the complex was evidently affected by the type of functional grouping or substituent, as shown in Table 1.

Choice of Solvents and Reducing Agents. The Mo(V)-complexes are extracted into many organic solvents such as benzene, toluene, chloroform, carbon tetrachloride, acetophenone and 1-pentanol. Benzene was selected as the solvent beacuse of the highest extractability as well as the highest stability of the complex. L-Ascorbic acid and tin(II) chloride were tested for the reduction of Mo(VI) to Mo(V). Variation of the amount of L-ascorbic acid was insensitive to the absorbance of the complex. Tin(II) chloride is too strong as a reducing agent for Mo(VI); it did not

† Present address: Department of Chemistry, K. Govt. Arts and Science College, Raigarh-496 001, M.P., India.

Table 1. Spectral data of Mo(V)–SCN⁻–PBTU–PBPTU–PBTSC complexes in benzene at 2.0 M HCl

Compound	Acidity range M HCl	Molar absorptivity at λ_{max}, 465 nm $l\ mol^{-1}\ cm^{-1}$	Sandell's sensitivity $\mu g\ cm^{-2}$ of Mo
(*N*-Phenylbenzimidoyl)thiourea	1.2—2.5	8000	0.0120
N-(*N*-Phenylbenzimidoyl)-*N*-phenylthiourea	1.0—5.0	13000	0.00738
1-(*N*-Phenylbenzimidoyl)thiosemicarbazide	1.2—3.5	14000	0.00685

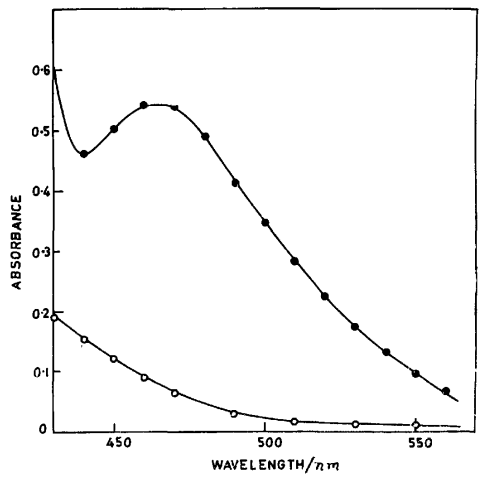

Fig. 1. Absorption spectra of PBPTU and its complex in benzene.
[HCl]: 4.0 M, [SCN]: 0.3 M, [PBPTU]: 0.006 M, [Mo]: 95 μg. —●—: Mo(V)–SCN⁻–PBPTU, —○—: 0.2%, W/V (0.006 M) PBPTU.

produce color as much as L-ascorbic acid and the color intensity of the complex gradually decreased as its concentration increased. The color can also be developed in the presence of thiocyanate ions which serve not only as a weak reducing agent for Mo(VI) but also as a ligand for Mo(V). In this case, however, a prolonged time was required for the full color development. Therefore, L-ascorbic acid was preferred for the experimental work.

Effect of Acidity. The effect of acidity on the extraction of Mo(V) with imidoyl derivatives in the presence of thiocyanate ions was studied with various acids like HCl, H_2SO_4, HNO_3, and CH_3COOH. Of these, only HCl and H_2SO_4 were found to be adequate for the extraction purpose. The optimum acidity ranges for the extraction of the metal with SCN^- and PBPTU lie between 1.0—5.0 M HCl/0.8—6.0 M H_2SO_4. The optimum acidity ranges for PBTU and PBTSC were examined in a similar way and shown in Table 1. The later experimental work was performed with PBPTU at 4 M HCl.

Effect of Other Variables. At least 130-fold molar excess of PBPTU was necessary for the complete extraction of the metal. Similarly, at least 0.05—1.0 M ammonium thiocyanate was required for the full color reaction. The order of addition of reagents was not critical. Variation of temperature from 15 to 35 °C and volume of the aqueous phase from 15 to 60 ml did not affect the color intensity of the complex. A period of 2 min was sufficient for the complete extraction of the complex and more extraction up to 30 min produced no measureable change in the absorbance. The metal complex was stable for at least 10 h at room temperature. The effect of salting out agents like NaCl, KCl, or $(NH_4)_2SO_4$ was studied and no remarkable change in the extraction of the metal was noticed up to 2 M.

N-Phenylbenzimidoyl Derivatives as Analytical Reagents. All the derivatives react with Mo(V) in hydrochloric acid solution in the presence of thiocyanate ions to give benzene-extractable red-orange complexes, the optimum acidity ranges being tabulated in Table 1. The colored systems obeyed Beer's law. When PBPTU was used as the reagent, Beer's law is obeyed over the range 0.5—7.0 ppm of Mo, the optimum concentration range for the determination being 0.8—6.5 ppm. The precision of the method was evaluated by determining 75 μg of Mo/25 ml and the relative standard deviation was found to be ±0.81% for 10 measurements. As shown in Table 1, the phenyl substitution on the thioureido group of PBTU improved the molar absorptivity of the complex and the optimum acidity for the extraction of the metal to a considerable extent. The high extractability of the complex may be attributed to the highly organophilic nature of PBPTU molecule. At least 2—3 times molar excess of PBTU and PBTSC to PBPTU was required for the complete extraction of Mo. Therefore, PBPTU was found to be the most convenient reagent for the spectrophotometric determination of Mo(V) in the present investigation.

Composition of the Complex. The composition of the complex was determined by curve-fitting method[11] using the relationship between log *D* (distribution ratio of the metal) and log [Reagent concentration]. The results obtained indicates the formation of a 1 : 2 : 1 (Mo : SCN^- : RS^-) red-orange ternary complex in benzene. The overall reaction can be expressed as follows:

$$MoO^{3+} + 2\,SCN^- + HSR_o \rightleftharpoons Mo\,0.2\,SCN{\cdot}SR_o + H^+.$$

Where, subscript o denotes organic phase.

Effect of Diverse Ions. The effect of diverse ions in the solvent-extraction and subsequent spectrophotometric determination of 3 ppm of Mo at 4 M HCl with

Table 2. Determination of molybdenum in ore and alloy steels with PBPTU

Sample	Mo found[a] (%)	Mo certified (%)	Relative standard deviation ±%
Ore[b]	2.086	2.091	0.62
BCS 64	4.092	4.11	0.78
BCS 219/3	0.595	0.60	0.86
BCS 225/2	0.340	0.34	0.84

a) Average of six determinations. b) Obtained from Indian Bureau of Mines, Nagpur, India. BCS, British Chemical Standard.

thiocyanate ions (0.3 M) and PBPTU (0.006 M) in benzene was examined. The following metal ions did not interfere up to 2 M Cl^-, Br^-, SO_4^{2-}, or alkali metals; up to 1 M Mn^{2+}, Ni^{2+}, Cr^{3+}, or U^{6+}; up to 0.5 M alkaline earth elements, lanthanoid, Zn^{2+}, Cd^{2+}, Fe^{2+}, Al^{3+}, $C_2O_4^{2-}$, citrate, tartrate, or phosphate. The tolerated amounts of other ions (in ppm) causing an error $<2\%$ are shown in parentheses: Fe^{3+}, Bi^{3+}, Sb^{3+}, Tl^{3+}, Th^{4+} (1500); Hg^{2+}, F^-, $S_2O_3^{2-}$ (1000); Pb^{2+}, Zr^{4+} (2000); I^-, AsO_4^{3-} (3000); Co^{2+}, Pd^{2+}, V^{5+}, Ta^{5+} (400); Nb^{5+}, or W^{6+} (200).

Application of the Method. The method was satisfactory applied to the determination of Mo in ore and some alloy steels, the results being tabulated in Table 2. A weighed sample containing about 2 mg of Mo was decomposed first with aqua regia (10 ml), and then with concentrated H_2SO_4 (3 ml). The sulfuric acid solution was heated to fumes of SO_2, cooled, dissolved with 0.5 M HCl and made up with water to a desired volume. The metal content of the solution was determined as described in the recommended procedure using a suitable reference.

(Received March 2, 1982)

Kinetics of electron transfer in the redox system containing hydroxylamine and tris(dimethylglyoximato)-nickelate(IV) ($[Ni(dmg)_3]^{2-}$), in the presence of catalytic amounts of added copper(II) ions, have been studied in aqueous medium in the pH range 8.04—11.81. The kinetics exhibit pseudo-zero-order disappearance of $[Ni(dmg)_3]^{2-}$ when excess $[NH_2OH]_0$ is present, in the presence and absence of added metal ions. While addition of Cu(II) results in significant catalysis, that of Co(II)/Co(III), Fe(II)/Fe(III), Ni(II) or Zn(II) does not. The pseudo-zero-order rate constants (k_0) are found to be linearly dependent on $[NH_2OH]_0$ and on added [Cu(II)]. The k_0 values register a decrease as $[OH^-]$ is increased in the pH range 8.04—*ca.*9.42, attaining a limiting value in the pH range *ca.* 9.8—*ca.*11.81. Results are interpreted in terms of a probable mechanism involving formation of precursor complexes from hydroxylamine and Cu(II) species, followed by rate-determining breakdown of the precursors with concomitant electron transfer. The Cu(II)·aq species reacts several orders of magnitude faster than the $Cu(OH)_2$·aq species. The Ni(IV) does not appear to have any kinetic role in the redox system and is involved only in rapid product formation steps. The stoichiometric ratios $(\Delta[Ni(IV)]/\Delta[NH_2OH])$ of *ca.* 1.0 in the lower pH region (7.8—8.6) and *ca.* 0.5 in the higher pH region (9.1—11.6) are explained in terms of differential product formation.

Hydroxylamine and its derivatives are versatile reducing agents and numerous reports are available on kinetics of their oxidation by various metal ions.[1–15] The electron transfer kinetics, as well as products of oxidation of hydroxylamine and their distribution and stoichiometry, are, among other factors, strongly pH-dependent, but most of these studies are restricted to reaction media of "acidic" pH conditions. A few studies[7,8,16] were, however, reported on metal ion-catalyzed reactions of hydroxylamine in aqueous alkaline media. Bridgart *et al.*[8] reported that the oxidation of hydroxylamine by alkaline hexacyanoferrate(III) exhibits first-order kinetics with respect to the initial stage of disappearance of hexacyanoferrate(III) and that the reaction is strongly catalyzed by copper(II). We have currently been interested[17–20] in the chemistry of tris-(dimethylglyoximato)nickelate(IV), $[Ni(dmg)_3]^{2-}$ (dmg^{2-} =dimethylglyoximate dianion) and came across an early qualitative mention by Simek[21] that hydroxylamine and hydrazine effectively reduce Ni(IV)[22] by two-electron transfer. While studying the kinetics of oxidation of hydroxylamine by Ni(IV), we observed that the disappearance of Ni(IV) was always zero-order irrespective of the source of samples employed, and that the reactions were tremendously retarded in the presence of added edta.[23] To substantiate the suspected extensive metal ion-catalysis in the redox cycle, we have collected results of investigations on metal ion-catalyzed electron transfers involving hydroxylamine and Ni(IV) in aqueous media and are reporting them in this communication.

Experimental

Materials and Methods. Freshly prepared doubly distilled water, distilled from an all-glass apparatus containing a dilute solution (*ca.* 1×10^{-4} M) (1 M=1 mol dm^{-3}) of edta, was exclusively used for preparation of solutions and in kinetic runs. Characterization of $[Ni(dmg)_3]^{2-}$ and preparation of its aqueous solutions were performed as described earlier.[17,18] Hydroxylammonium chloride (Poole, England) was of guaranteed reagent grade, was recrystallized twice before use, and its solutions were freshly prepared; the solutions were standardized by the acid bromate method.[24] The substrate solutions were appropriately diluted and their pH adjusted, as required, when they were employed for kinetic runs. Fresh stock solutions of BDH AnalaR grade samples of MCl_2 (M= Cu, Fe, Ni, Co, or Zn) were prepared and standardized;[24] requisite amounts from the stock were taken to prepare M(II) solutions for kinetic runs. Other reagents were of analytical grade and were used as such. Standard buffer solutions were prepared in water using potassium salts (BO_3^{3-}—H^+/OH^-, acetate—OH^-, $H_2PO_4^-$—H^+/OH^-, and CO_3^{2-}—HCO_3^-).

The reactions were monitored for disappearance of Ni(IV) at 460 nm (ε_{460}=9,600 M^{-1} cm^{-1}), continuously as a function of time, in a VSU 2-P or Pye Unicam SP 1800 UV-VIS spectrophotometer or in an Aminco stopped-flow assembly as described previously.[17–19] In a typical run, an aqueous solution of Ni(IV) containing the metal ion at its requisite catalytic concentration was rapidly mixed[25] with the hydroxylamine solution at the appropriate temperature (±0.1 °C), ionic strength (μ, supporting electrolyte being KCl), and pH; the decrease in absorbance of Ni(IV) was monitored. The pH values of the reaction medium were maintained with standard buffers; they were determined by a Systronics 335 digital pH meter both before and after the reaction and the average (which did not differ by more than ±0.01 unit from the measured values) was taken into record. Correction for ionic strength contribution[26] was applied in calculating $[OH^-]$ from the average pH value. The pseudo-zero-order rate constants were calculated from least-squares fits of absorbance and time data in accordance with the following function which was found valid for the range over 90% of the disappearance of Ni(IV):

** Parts I—IV are Refs. 17—20.

$$(A_t - A_\infty) = (A_0 - A_\infty) - \varepsilon_{460} k_0 t, \quad (1)$$

where A_t, A_0, and A_∞, refer respectively to the absorbance at time t, the initial absorbance of Ni(IV) before commencement of reaction, and the absorbance at effective infinite time. $Ni(dmgH)_2$, a product from reduction of Ni(IV), was found to have a negligible absorbance at 460 nm. For the major part of Ni(IV) disappearance, the reaction medium was found to be homogeneous; slow precipitation of $Ni(dmgH)_2$ towards the later stage did not significantly influence the kinetics at least for three half-lives of reaction. The proton-assisted[17,19] and metal ion-mediated acid-decomposition[20] of Ni(IV) was negligible under the conditions of investigation. The k_0 values, calculated from data obtained through monitoring the disappearance of Ni(IV) at other wavelengths (440—480 nm), matched well those calculated similarly through monitoring the disappearance at 460 nm. Replicate runs (2 to 7) were reproducible to ±5%. Reproducibility (within ±10%) in zero-order rate constants in the uncatalyzed system was also observed when different freshly prepared stock solutions of the same samples were used and intercomparisons were made.

Computations were done using a DCM Data Products Minicomputer Microsystem 1121.

Results

Stoichiometry. The stoichiometric experiments were conducted in an inert atmosphere in the pH range 7.75—11.6. In experiments employing $[Ni(IV)]_0 \gtrsim [NH_2OH]_0$, the unreacted [Ni(IV)] was estimated spectrophotometrically (Table 1); 4×10^{-6} M of added Cu(II) was present in all the experiments. In experiments employing $[NH_2OH]_0 > [Ni(IV)]_0$, the reaction mixture was acidified with HCl after completion of reaction and the left-over $[NH_2OH]$ was estimated by rapid bromatometric titration.[24] (Under acidic conditions, the oxidation of $dmgH_2$ was found to be so slow as to be negligible.) The observed stoichiometric ratios, $\Delta[Ni(IV)]/\Delta[NH_2OH]$, of *ca.* 1.0 and *ca.* 0.5, would conform to the following equations:

$$2[Ni(dmg)_3]^{2-} + 2NH_2OH \xrightarrow{Cu(II)} 2[Ni(dmgH)_2] + 2\,dmg^{2-} + H_2O + N_2O, \quad (2)$$

$$[Ni(dmg)_3]^{2-} + 2\,NH_2OH \xrightarrow{Cu(II)} [Ni(dmgH)_2] + dmg^{2-} + 2\,H_2O + N_2. \quad (3)$$

In another set of experiments at pH 8.0, 8.6, 9.1, 10.4, and 11.5, a solution of Ni(IV) (0.2 M, 50 mL) was allowed to react with a solution of hydroxylamine (0.2 M, 50 mL) in the presence of 4×10^{-6} M of added Cu(II), and the produced gases were qualitatively identified by a gas chromatographic procedure[27] using a Packard 377 instrument. $Ni(dmgH)_2$ was identified by IR after being filtered from the reaction mixture, recrystallized, and dried.

Kinetics. Even though a pseudo-first-order excess of $[NH_2OH]_0$ over $[Ni(IV)]_0$ was maintained, the disappearance of Ni(IV) in the Ni(IV)–NH_2OH reaction never followed a first-order pattern as evidenced from nonlinearity of log $(A_t - A_\infty)$ *vs.* time plots. Instead, plots of A_t *vs.* time were perfectly linear for several half-lives of disappearance. The zero-order disappearance of Ni(IV) was observed irrespective of the source of the samples employed, and in the absence of any added

a) Deviations from the average value of 2 to 4 replicates are within ±10%. b) All concentration units are expressed in M. c) Corrected pH. Buffers used (pH range): $H_2PO_4^-$—OH^- (7.4—7.7), BO_3^{3-}—H^+/OH^- (8.3—10.6), and HPO_4^{2-}— OH^- (11.3—13.0). d) Values in parentheses were obtained by employing different batches of solutions of the same samples. e—h) In the presence of 2×10^{-6}, 4×10^{-6}, 8×10^{-6}, and 20×10^{-6} M of added edta, respectively.

metal ion. There was progressive retardation of the pseudo-first-order rate constants (k_0', in the absence of any added metal ion) in the presence of added edta (Table 2) and this conformed to the empirical equation:

$$k_0' = p[\text{edta}]^{-1}/(1+q[\text{edta}]^{-1}), \quad (4)$$

where p and q are functions of NH_2OH, OH^-, and M^{n+} concentrations. (M^{n+} refers to metal ion impurities present in the reaction system). Thus there is significant metal ion-catalysis in the redox reaction.

Zero-order disappearance of Ni(IV) was also observed in the presence of a metal ion (M=Cu(II), Fe(II)/Fe(III), Ni(II), Co(II)/Co(III), or Zn(II)) added in small concentrations. Some representative plots are shown in Fig. 1. The pseudo-zero-order rate constants (k_0) were found to remain almost constant in the range $1\times10^{-5}\leq[\text{Ni(IV)}]_0\leq1.9\times10^{-4}$ M ($k_0\gg k_0'$). The k_0 values were linearly dependent on $[NH_2OH]_0$ (Table 3) as well as on added [Cu(II)] (Table 4). The pH dependence of k_0 is presented in Table 5 and that of k_2 ($=k_0/([NH_2OH]_0\,[\text{Cu(II)}])$) in Fig. 2. In the range $11.81\gtrsim\text{pH}\gtrsim9.8$, k_0 registered a marginal increase by only *ca.* 7% for a hundred-fold decrease in [OH^-], but the increase was more prominent below pH *ca.* 8.9.

The k_0 values were found to remain almost constant when different buffers were employed at the same pH

(Table 5). The k_0 values were also insensitive to variation of ionic strength of the medium (Table 3), indicating that at least one of the reactants might be neutral in charge.

The temperature dependence of k_0 was studied in the range 35—45 °C. The average values of the activation parameters $\Delta H^{\neq}$ (in kJ mol^{-1}) and $\Delta S^{\neq}$ (in J K^{-1} mol^{-1}) were calculated, respectively, to be 69 and −83 at pH=8.5, 47 and −165 at pH=9.0, and 43 and −184 at pH=10.2.

Table 6 compares the rate constants for the Ni(IV)–NH_2OH reaction in the presence of various added metal ions Ni(II), Fe(II)/Fe(III), Co(II)/Co(III), and Zn(II)). Cu(II) only appears to have a catalytic effect on the redox system.

Discussion

Mechanism and Rate Law. One scheme consistent with the observed kinetics can be given by Scheme 1. In the pH range of the study, hydroxylamine would

Scheme 1.

exist almost totally in the form of NH_2OH species since the proton-dissociation constant of NH_3OH^+ is $10^{-5.8}$ M at 35 °C.[28] The values of K_1 and K_2 employed for the calculation in the present study are 1.6×10^7 M^{-1} and 3.9×10^{11} M^{-1}, respectively, assuming enthalpy changes with temperature for the steps of Eqs. 5 and 6 to be minimal. The K_1 value was calculated using the reported[29] constant K_5 for Eq. 5 and the ionic product

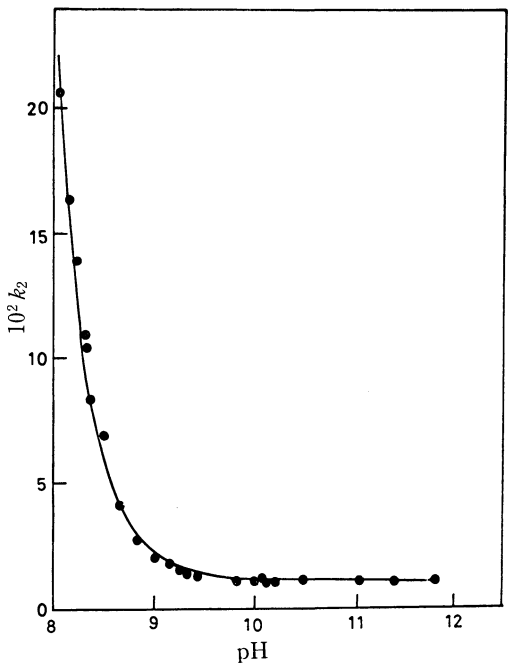

Fig. 2. The k_2 *vs.* pH Plot.
$k_2=k_0/([Cu(II)]\ [NH_2OH]_0)$.
Point and line respectively refer to experimental and calculated k_2.

Table 6. Average pseudo-zero-order rate constants for the oxidation of hydroxylamine
($[Ni(IV)]_0=(4—6)\times10^{-5}$, $[NH_2OH]_0=2\times10^{-2}$, $\mu=0.25$, and 35 °C)

Added metal Ion (M^{n+})	$10^6[M^{n+}]$	pH	10^8k_0/M s^{-1}
Co(II)/Co(III)	2	7.2	17.0

	2	8.6	7.0
	10	8.7	8.0
Ni(II)	2	6.6	40.0
	2	7.4	20.0
	2	9.7	4.1
	10	9.7	3.6
Zn(II)	2	7.2	25.0
	10	7.2	24.0

a) Deviations from the average value of 2 to 4 replicates are within ±5%. b) All concentration units are expressed in M.

of water K_w, and the K_2 value was calculated from Eq. 6 and the value of K_1:

$$Cu^{2+} + H_2O \rightleftharpoons [CuOH]^+ + H^+,\ K_5 = 10^{-6.8}\ M, \quad (5)$$
$$Cu(OH)_2 \rightleftharpoons Cu^{2+} + 2OH^-,\ K_6 = (K_1K_2)^{-1} = 1.6\times10^{-10}\ M^2. \quad (6)$$

The operation of other equilibria,[29] Eqs. 7 and 8, related to this system was considered negligible in the experimental concentration ranges of Cu(II) and OH^- employed in the present investigation:

$$Cu(OH)_2 + 2OH^- \rightleftharpoons CuO_2^{2-} + 2OH_2,\quad K_7 = 1.2\times10^{-3}\ M^{-2}, \quad (7)$$

$$2\,Cu^{2+} + 2\,H_2O \rightleftharpoons [Cu_2(OH)_2]^{2+} + 2H^+, \quad K_8 = 1.38 \times 10^{-11}\,M. \tag{8}$$

If it is assumed that $k_{nx} \gg k_{-nc}$ (where k_{-nc} is defined by $K_{nc}=k_{nc}/k_{-nc}$), a rate law can be derived from Scheme 1 as follows:

$$\frac{k_0}{[Cu(II)]_T[NH_2OH} = \frac{k_{1x}K_{1c}+k_{2x}K_{2c}K_1[OH^-]+k_{3x}K_{3c}K_1K_2[OH^-]^2}{1+K_1[OH^-]+K_1K_2[OH^-]^2}, \tag{9}$$

which on rearrangement becomes

$$\frac{k_0(1+K_1[OH^-]+K_1K_2[OH^-]^2)}{[Cu(II)]_T[NH_2OH]} = k_{1x}K_{1c} + k_{2x}K_{2c}K_1[OH^-] + k_{3x}K_{3c}K_1K_2[OH^-]^2. \tag{10}$$

A least-squares fit of the data of Table 5 results in the values of $k_{1x}K_{1c}$, $k_{2x}K_{2c}$, and $k_{3x}K_{3c}$ as $(7.8\pm0.4)\times10^9$ $M^{-1}\,s^{-1}$, $(4.6\pm0.2)\times10^8$ $M^{-1}\,s^{-1}$, and $(1.0\pm0.4)\times10^2$ $M^{-1}\,s^{-1}$, respectively. The calculated values of rate constants are found to match well those obtained experimentally, lending credence to the proposed rate law.

The envisaged mechanism in Scheme 1 depicts the reaction to proceed through equilibrium precursor complex formation involving the various species of Cu(II) and NH_2OH prior to rate-determining breakdown of the precursor complex(es) with concomitant electron transfer. The intermediate products containing Cu(I) species and $NH_2O\cdot$ radical[15] are rapidly oxidized by Ni(IV) in subsequent kinetically insignificant step(s) (*i.e.*, the composite reaction constant $k_p \gg k_{nx}$), thus resulting in zero-order disappearance kinetics of Ni(IV).

The overall picture of product formation can be formulated as

$$2Cu(I) + [Ni(dmg)_3]^{2-} + 2H_2O \longrightarrow 2Cu(II) + [Ni(dmgH)_2] + dmg^{2-} + 2OH^-, \tag{11}$$

$$NH_2O\cdot - e \longrightarrow HNO + H^+, \tag{12}$$

$$2HNO \longrightarrow N_2O + H_2O, \tag{13}$$

$$HNO + NH_2OH \longrightarrow N_2 + 2H_2O, \tag{14}$$

$$2NH_2O\cdot \longrightarrow N_2 + 2H_2O. \tag{15}$$

The Cu(I) in Eq. 11 may either be a Cu(I) hydroxo species or a Cu(I)–NH_2OH complex. Equations 11—15 will be very rapid and the magnitudes of their rates relative to the rates of the reaction are such that the present redox system in a nitrogen atmosphere does not initiate polymerization of a radical-trapping agent, *viz.*, acrylonitrile, nor was there any significant influence of added acrylonitrile on rates of the reaction (Table 3). Nevertheless, the formation of radicals is not precluded on the basis of this negative finding, because if k_{12}, k_{13}, k_{14}, or $k_{15} \gg k_{(\text{induced polymerization})}$, which is quite probable, the extent of the induced change may lie well below the limit of detectability, even under conditions favorable for this induced reaction, and also because that the absence of polymerization is not connected with a lack of radicals since measurements[30] show that in an acidic medium in the presence of dissolved oxygen, acrylonitrile does not polymerize even if the process is initiated by gamma-radiolysis or by thermal decomposition of peroxodisulfate.

It can be inferred from the stoichiometric experiments of Table 1 that the molar ratios of the reactants (and the product distribution) depend to a great extent on the ratio of the initial concentration of Ni(IV) to NH_2OH (at constant [Cu(II)]) and the pH of the reaction medium. The stoichiometric ratio of *ca.* 1.0 in the lower pH range (*ca.* 7.8—8.6) decreases to *ca.* 0.5 in the higher pH range (*ca.* 9.1—11.6) of the study. While N_2O appears to be the predominant product in the lower pH region, N_2 is predominantly formed in the higher pH region. When $[NH_2OH]_0$ is in excess over $[Ni(IV)]_0$, there is a tendency to form more N_2 in the lower pH region than is observed when $[Ni(IV)]_0 \geq [NH_2OH]_0$. The stoichiometric observations of the present study are in line with those predicted in several earlier reports.[15,16]

The values of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ at different pH values give some indication to the nature of the transition states formed in the reaction; the larger negative $\Delta S^{\neq}$ values at pH 9.0 and 10.2 are presumed to reflect an increased restriction in the transition state imposed by the formation of the (unstable) intermediate complex.

In deriving the rate law (Eq. 9), it was assumed that $k_{nc} \gg k_{-nc}$, *i.e.*, the precursor complex(es) would have only a limited stability under the conditions employed. In that event, the product of the equilibrium formation constant and the decomposition rate constant of the precursor complex, $K_{nc}k_{nx}$, is identifiable as a bimolecular second-order rate constant k'_{nx}. This assumption finds support from the observed kinetics which demonstrate that even over a wide range of $[NH_2OH]_0$ (*viz.*, 800-fold at pH 10.2), the k_0 values do not show any tendency to saturate at high relative $[NH_2OH]_0$.

The ligating properties of hydroxylamine have been shown earlier[31] and the formation of $[Cu(NH_2OH)_n]^{2+}$ ($n=1$, 2, or 4) complexes is firmly established in many reaction systems such as the Cu(II)-catalyzed $[Fe(CN)_6]^{3-}$–NH_2OH reaction,[8] the metal ion-catalyzed decomposition of hydroxylamine in strongly alkaline aqueous media,[16] and in oxidation reactions[9,10] of NH_2OH by Cu(II). However, the reported equilibrium constants[32] for the complexes of $[Cu(NH_2OH)_n]^{2+}$ ($n=1$ or 2) should be strongly pH-dependent. In a recent report, the state of Cu(II) in solutions containing hydroxylamine has been well documented;[10] while in ethanolic solution the $[Cu(NH_2OH)_n]^{2+}$ complexes appear to be stable, in aqueous solutions they decompose instantaneously with a tendency towards stabilization of Cu(I)–NH_2OH complexes.

Unfortunately, the Cu(II)–NH_2OH redox system could not independently be studied (to compare the results with those observed in the present study) due to the low molar absorptivity of Cu(II) and the precipitation of Cu_2O if high concentration of Cu(II) was employed. However, if the values of the (intercept)/(slope) of the plots of $[Cu(II)]/k_0$ *vs.* $1/[NH_2OH]_0$ are thought as representing the formation constants of the precursor in the medium, then the approximate values are ≤ 2, 40, and 220 (all expressed in M^{-1}) at pH 10.2, 9.05, and 8.35, respectively. Even though much importance cannot be attached to these values (which have been obtained from small values of intercepts of the plots), their magnitudes show the relative order

of stability of the precursors with respect to the pH of the medium. Incidentally, the formation constant of $[Cu(NH_2OH)]^{2+}$ has been reported as $10^{2.4}$ at 20 °C and $\mu=0.5$ M ($NaNO_3$) in aqueous medium.[32]

The reaction rate remains almost constant when different buffers are employed at the same pH and hence the reaction is subject to general acid catalysis. General acid catalysis should be observed when $k_{17} \gg k_{-16}$ [A^-] with respect to

$$[CuLOH]^{(n-1)+} + HA \underset{k_{-16}}{\overset{k_{16}}{\rightleftharpoons}} [CuLOH_2]^{n+} + A^-, \quad (16)$$

$$[CuLOH_2]^{n+} \xrightarrow{k_{17}} \text{products}. \quad (17)$$

This inference also draws its testimony from the fact that in the present reaction system, the rate is accompanied by an increase when the pH is lowered. The magnitudes of the resolved rate constants ($k_{1x}K_{1c} > k_{2x}K_{2c} \gg k_{3x}K_{3c}$) do follow the trend predicted by the electrostatic theory and are much below the rate constant for the exchange of water from the first coordination sphere of Cu^{2+}·aq ion (*ca.* 8×10^9 s^{-1} at 25 °C),[33] showing that the Cu(II)–NH_2OH precursors are indeed formed in the redox system.

In the reaction scheme presented, the Cu(II) species represent the aqua species. The dimethylglyoxime complexes of Cu(II) might be thought as being produced from a trace dimethylglyoxime impurity (which might have been produced due to proton-assisted decomposition[17,19] or Cu(II)-mediated acid-decomposition[20] of $[Ni(dmg)_3]^{2-}$). However, since the rates of the latter two reactions are insignificant in comparison with those of the present redox system, such a possibility, if at all exists, does not alter the discussion presented here. (The rate constants for proton-assisted decomposition of the $[Ni(dmg)_3]^{2-}$ range from 1.3×10^{-5} s^{-1} to 2.6×10^{-7} s^{-1} in the pH range 8.3—12.3 at 35 °C and $\mu=0.25$ M;[17,19] the rate constant for Cu(II)-mediated acid-decomposition[20] of Ni(IV) is 2.2×10^{-3} s^{-1} at 35 °C, $\mu=0.57$ M, pH=6.15, and $[Cu(II)]=4\times10^{-5}$ M).

The possibility of involvement of Cu(III) as an intermediate in the present system is also ruled out since strict zero-order kinetics in Ni(IV) have been observed. Moreover, the redox potential of Ni(IV)/Ni(III) (*ca.* 0.4 V)[34] is not sufficient to oxidize Cu(II)·aq to Cu(III)·aq.

It may be pertinent to remark here that in previous studies involving Cu(II)-catalyzed oxidation of hydroxylamine, the authors[6,8] were either not interested in considering the pH dependence of rate or were silent on this aspect. Another aspect which needs mention is that, while the Cu(II)-catalyzed oxidation of hydroxylamine by hexacyanoferrate(III) in aqueous alkaline media[8] exhibited first-order kinetics on $[Fe(CN)_6]^{3-}$ (with respect to the initial stage of disappearance of $[Fe(CN)_6]^{3-}$), the present system shows perfect zero-order kinetics with respect to several half-lives of disappearance of Ni(IV). Inasmuch as the oxidation potentials for the couples ($[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$ = 0.36 V[29] and $[Ni(dmg)_3]^{2-}/[Ni(dmgH)_2]=0.7$ V[35,36] in aqueous alkaline solutions are comparable, the reason for the above behavior is not clear. Some probable explanation may lie in the different methods of analysis of the experimental rate data and/or in the fact that, whereas in the former system $[Fe(CN)_6]^{3-}$ (d^5 low-spin O_h) is capable of forming with Cu(II) (a d^9 system) a heteronuclear intermediate[37] before the electron transfer process occurs, the $[Ni(dmg)_3]^{2-}$ (d^6 low-spin D_3) will participate only in rapid outer sphere oxidation of Cu(I) species and NH_2O· radicals formed. However, further probe appears necessary to authenticate the argument.

In sum, (1) the main course of the redox reaction involving $[Ni(dmg)_3]^{2-}$ and hydroxylamine is mediated by trace metal ion impurities present in solution and is strongly catalyzed by Cu(II); (2) the mechanism of the Cu(II)-catalyzed reaction proceeds through equilibrium formation of precursor complex and its rate-determining decomposition with concomitant electron transfer; (3) Ni(IV) does not have any kinetic role in the mechanism and is involved only in rapid product formation steps; (4) the hydroxo species of Cu(II) are less effective in catalysis of the redox system than the aqua species of Cu(II).

We thank the CSIR for award of fellowships (to SA and GN) and the UGC for award of National Associate Scheme and Scheme No. F. 23-930/79 (SR-II). We also thank the Director of CLRI for some facilities and Professor P. S. Radhakrishna Murti for helpful discussions.

(Received August 27, 1982)

Kinetics of electron transfer from hydrazine(L) to tris(dimethylglyoximato)nickelate(IV), $[Ni(dmg)_3]^{2-}$, follow pseudo-first-order disappearance in the Ni(IV) in aqueous medium in the range $5.0 \leqslant pH \leqslant 7.0$. The pseudo-first-order rate constants (k_{obsd}) increase with increasing $[L]_0$ and attain limiting values at higher relative $[L]_0$. The k_{obsd}-pH profiles at various $[L]_0$ show that the k_{obsd} values register steep decrease with increasing pH till $pH \approx 6.5$ tending to level off at higher relative pH. Results are consistent with probable interactions of the one-protonated and two-protonated Ni(IV) species with the protonated substrate, or with the metal ion-substrate complex that might have been formed from trace metal ion and the substrate. The two-protonated Ni(IV) complex apparently reacts several orders of magnitude faster than the one-protonated species.

Several important reports are available on kinetics of electron transfer from hydrazine to various oxidants.[1-6] While two-electron transfer[7] from hydrazine resulted, almost exclusively and often quantitatively, in water and nitrogen as products, the products of one-electron change[4,8,9] were nitrogen and/or ammonia. We have been currently interested in the chemistry of tris(dimethylglyoximato)nickelate(IV), $[Ni(dmg)_3]^{2-}$ (dmg^{2-}=dimethylglyoximate dianion) and reported its preparation (in part) and reaction with 1-phenylhydrazine[10a] and with hydroxylamine.[10b] The details of the preparative methods and characterization studies were also described.[10c] An early qualitative report mentioned that hydroxylamine or hydrazine effectively reduced the Ni(IV) complex, prepared by Simek[11], by a two-electron transfer. In the kinetics of oxidation of hydroxylamine by $[Ni(dmg)_3]^{2-}$, we observed that the disappearance of the nickel(IV) was always pseudo-zero-order irrespective of the source of the samples employed and that the zero-order reactions were tremendously catalyzed by added aquacopper(II).[10b] in contrast, the disappearance kinetics of the Ni(IV) follow a pseudo-first-order pattern in the Ni(IV)-hydrazine reaction. The preliminary results on kinetics of this reaction are presented in this communication.

Experimental

Materials and Methods. Freshly prepared doubly distilled water (distilled from an all-glass apparatus containing *ca.* 1×10^{-4} M†† of EDTA) were used throughout. Characterization of $[Ni(dmg)_3]^{2-}$ and preparation of its aqueous solutions were performed as described earlier.[10] Hydrazinium chloride (BDH, AnalaR) reagent was recrystallized twice before use, its solutions were freshly prepared, and standardized by acid bromate method.[12a] The substrate solutions were appropriately diluted and their pH adjusted, as required, when they were employed for kinetic runs. Fresh stock solutions of a BDH(AnalaR) grade sample of $CuCl_2$ were prepared and standardized;[12b] requisite amounts from the stock were taken to prepare Cu(II) solutions for kinetic runs. Other reagents were of analytical grade. Standard buffer solutions were prepared in water using potassium salts. KCl was used to maintain the ionic strength (μ) of the medium.

†† 1 M=1 mol dm^{-3}.

The reactions were monitored for the disappearance of the Ni(IV) at 460 nm (ε_{460}=9 600 M^{-1} cm^{-1}). In a typical experiment, an aqueous solution of the freshly prepared Ni(IV) complex[10a] was rapidly mixed with an equal volume of the substrate solution at the desired pH, μ and temperature ($\pm$0.1 °C), and the progress of the reaction was monitored, continuously as a function of time, on a Pye Unicam SP 1800, a Zeiss VSU 2-P UV-visible spectrophotometer or on an Aminco stopped-flow assembly, as described earlier.[10] The pH values of the solutions were measured before and after the reactions and the mean value (which did not differ by more than $\pm$0.01 units from the measured values) was taken into record after allowing due corrections for ionic strength effect. In experiments carried out in the presence of small amounts of added aquacopper(II), the Cu(II) was either taken along with the oxidant solution or with the substrate solution; in both the cases, the results obtained were practically the same. Pseudo-first-order rate constants were calculated from the usual expression and were found to remain practically constant for at least three half-lives of Ni(IV) disapperance in the 440—480 nm range or when the reactions were conducted in a nitrogen atmosphere in representative runs. Replicate runs (2 to 7) were reproducible to $\pm$5%.

Stoichiometry and Products. The stoichiometry experiments were conducted at pH values of 5.3, 6.2, and 7.0. In a set of experiments at each of the pH and with $[Ni(IV)]_0 > [hydrazine]_0$ ($[Ni(IV)]_0 = 0.8 \times 10^{-4} - 1.6 \times 10^{-4}$ M, $[hydrazine]_0 = 0.1 \times 10^{-4} - 0.6 \times 10^{-4}$ M), the unreacted Ni(IV) was spectrophotometrically estimated at the end of the reaction. Keeping $[hydrazine]_0 > [Ni(IV)]_0$ ($[hydrazine]_0 = 1 \times 10^{-3} - 4 \times 10^{-3}$ M, $[Ni(IV)]_0 = 0.4 \times 10^{-3} - 1 \times 10^{-3}$ M), the left-over [hydrazine] was estimated by acid bromate method.[12a] One mol equivalent of the substrate was found to have reacted with 2 ± 0.1 mol equivalents of Ni(IV) conforming to Eq. 1.

$$N_2H_5^+ + 2[Ni(dmg)_3]^{2-} + 3H^+ \longrightarrow N_2 + 2[Ni(dmgH)_2] + 2\,dmgH_2 \quad (1)$$

The products were identified by a procedure similar to the one described earlier.[10b] Nitrogen was qualitatively identified by a gas chromatographic procedure. Tests for ammonia by Nessler's reagent method[13a] gave negative results.

Potentiometric Measurements. The first proton-dissociation constant (K_a) of hydrazinium ion (LH^+) was determined potentiometrically in an atmosphere of nitrogen gas with a Systronics 335 digital pH-meter equipped with glass and saturated calomel electrodes. The concentration of H^+ was calculated from the measured pH values after applying due corrections for ionic strength effect.[13b] The value of pK_a was

Table 1. Average[a] pseudo-first-order rate constants for the oxidation of hydrazine by Ni(IV) complex (Aqueous medium, $\mu=0.25$,[b] 35 °C, $[N(IV)]_0=(3—5)\times10^{-5}$ M)

found to be 8.1±0.2 at 35 °C and $\mu=0.25$ M (KCl), which agreed with earlier reported values.[2,14]

Results

In order to examine possible pathways for electron transfer from hydrazine to the Ni(IV), a series of experiments was designed maintaining pseudo-first-order excess of $[L]_0$ over $[Ni(IV)]_0$. The pseudo-first-order rate constants for the Ni(IV) disappearance (k_{obsd}) were found to remain almost constant in the range of $1\times10^{-5}\leq[Ni(IV)]_0\leq1.4\times10^{-4}$ M at constant $[L]_0$, temperature, μ and pH. In presence of added Cu(II)·aq, the pseudo-first-order disappearance of Ni(IV) was still maintained, but the pseudo-first-order rate constants were found to have enhanced values.

Table 1 presents the values of the k_{obsd} for varying $[L]_0$ and pH of the medium at 35 °C and $\mu=0.25$ M. The k_{obsd} values were found to increase with increasing $[L]_0$, showing a tendency to attain limiting values at higher relative $[L]_0$. The k_{obsd} values were found to decrease steeply with increasing pH, tending to level off at higher relative pH (Fig. 1). While the log k_{obsd} *vs.* pH plots were almost linear up to pH ≈6.5 with slopes of *ca.* −1, the corresponding slopes were nearly equal to zero beyond this pH. These observations pointed to probable involvement of different orders of $[H^+]$.

The retarding effect of added EDTA (ethylenediaminetetraacetate added in the form of the disodium salt of the tetrabasic acid) on the k_{obsd}, shown in Table 1, suggested that the present reaction might be subject to influence of metal ions. It may be mentioned that the kinetics of the Ni(IV)-hydroxylamine reaction[10b] was influenced in the presence of metal ions, significantly retarded by added EDTA and tremendously catalyzed by aquacopper(II).

The values of the k_{obsd} were found to be almost insensitive to varying ionic strengths of the medium (Table 2). Added acrylonitrile also did not practically influence the values of the k_{obsd} (Table 2), nor was there

Table 3. Average[a] pseudo-first-order rate constants and average values of the activation parameters for the oxidation of hydrazine by Ni(IV) complex (Aqueous medium, $\mu=0.25$,[b] $[Ni(IV)]_0=(3—5)\times10^{-5}$, $[hydrazine]_0=4\times10^{-3}$)

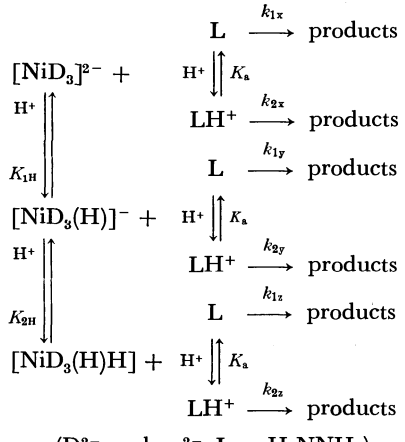
any detectable polymerization (in a nitrogen atmosphere) observed, implying that radical-trapping agents might not have significant effect on the kinetics of the oxidation.

From the temperature dependence of the k_{obsd} in the range 30—50 °C and at different pH values (Table 3), the activation parameters were evaluated.

Discussion

It was shown earlier[10a,d] that in alkaline solutions (pH $\gtrsim$11.5) the Ni(IV) complex was in the form of pseudooctahedral $[Ni(dmg)_3]^{2-}$ which underwent two successive protonations; the subsequent protonations were much below pH 1.23 and were not detectable kinetically. The potentiometrically determined values (at 35 °C in aqueous medium) of the first and second protonation constants, K_{1H} and K_{2H}, were 8.07×10^{10} M^{-1} and 2.24 M^{-1} at μ=0.57 M, and 7.08×10^{10} M^{-1} and 4.46 M^{-1} at μ=0.25 M; the K_{1H} value as determined from spectrophotometric pH titrations was 8.33×10^{10} M^{-1} at 35 °C and μ=0.57 M. It was also shown earlier that protonations of the complex assisted its decomposition (with concomitant intramolecular electron transfer). The first (outside-) protonation was at a dioximate oxygen, forming a hydrogen bonded structure O—H···O between the dioximate oxygens, without much alteration of c.f.s.e. of the original pseudooctahedral $[Ni(dmg)_3]^{2-}$, and the second protonation most probably occurred *via* a direct proton-transfer to a ring-opened (ligand) nitrogen site. The values of the solvent-assisted, first proton-assisted and second proton-assisted rate constants (k_{0d}, k_{1d}, and k_{2d}) were respectively 2.6×10^{-7} s^{-1}, 1.2×10^{-5} s^{-1} and 44.3 s^{-1} at 35 °C and μ=0.25 M in aqueous medium. However, since the proton-assisted decomposition reaction was much too slow compared to the rates of the present redox system, it would not enter into the rate picture in the present investigation.

One general scheme which is consistent with the observed kinetic behaviour of the redox system can be presented as in Scheme 1.



(D^{2-} = dmg^{2-}, L = H_2NNH_2)

Scheme 1.

The rate law derivable from this scheme with all the possible reacting species is as in Eq. 2.

$$k_{obsd}=\frac{\{k_{1x}K_a+(k_{2x}k_{1y}K_{1H}K_a)[H^+]+(k_{2y}K_{1H}+k_{1z}K_{1H}K_{2H}K_a)[H^+]^2+k_{2z}K_{1H}K_{2H}[H^+]^3\}}{(1+K_{1H}[H^+]+K_{1H}K_{2H}[H^+]^2)([H^+]+K_a)}, \quad (2)$$

where k_{nx}, k_{ny}, and k_{nz} are functions of $[L]_0$. Expressing the denominator terms as Y_1Y_2 and the coefficients of the $[H^+]$-independent, $[H^+]$, $[H^+]^2$, and $[H^+]^3$ terms in the numerator as a, b, p, and q respectively, Eq. 2 can be written in the form of Eq. 3 or 4.

$$k_{obsd}\,Y_1Y_2 = a + b[H^+] + p[H^+]^2 + q[H^+]^3 \quad (3)$$

$$\text{or } \frac{k_{obsd}\,Y_1Y_2}{[H^+]^2} = \frac{a}{[H^+]^2} + \frac{b}{[H^+]} + p + q[H^+] \quad (4)$$

It was seen that plots of $k_{obsd}\,Y_1Y_2/[H^+]^2$ *vs.* $[H^+]$ were linear (Fig. 2), implying that the terms containing the coefficients "*a*" and "*b*" were negligible in comparison with those containing the coefficients "*p*" and "*q*". In that event if the contributions of the $[NiD_3]^{2-}$ and the L species to the overall reactivity are assumed to be negligible under the conditions employed, Eq. 4 takes the form of Eq. 5.

$$\frac{k_{obsd}\,Y_1Y_2}{K_{1H}[H^+]^2} = k_{2y} + k_{2z}\,K_{2H}[H^+] \quad (5)$$

The values of k_{2y} and k_{2z} at varying $[L]_0$, as obtained from a least-squares fit of the data of Table 1 in accordance with Eq. 5, are listed in Table 4.

The limiting kinetics observed for varying $[L]_0$ can be explained in terms of Eqs. 6 and 7.

$$[Ni\,D_3(H)]^- + LH^+ \underset{}{\overset{K_{2C}}{\rightleftharpoons}} \underset{(C_1)}{[Ni\,D_3(H)LH]} \xrightarrow{k'_{2y}} \text{products} \quad (6)$$

$$[Ni\,D_3(H)H] + LH^+ \overset{K_{2D}}{\rightleftharpoons} \underset{(C_2)}{[Ni\,D_3(H)H\,LH]^+} \xrightarrow{k'_{2z}} \text{products} \quad (7)$$

whence it follows that

$$k_{2y} = \frac{k'_{2y}K_{2C}[L]_0}{1+K_{2C}[L]_0}, \quad (8)$$

and

$$k_{2z} = \frac{k'_{2z}K_{2D}[L]_0}{1+K_{2D}[L]_0}. \quad (9)$$

From plots of $1/k_{2y}$ *vs.* $1/[L]_0$ and $1/k_{2z}$ *vs.* $1/[L]_0$, the values of the constants of Eqs. 8 and 9 have been resolved (Table 4). The values of k_{calcd}, estimated using these resolved constants, match well the k_{obsd} values (Fig. 1).

The two-protonated oxidant species appears to react several orders of magnitude faster than the one-protonated one even though the abundance of the former species is very much lesser than the latter in the conditions employed. One probable reason for this reactivity order may be the structural difference in the protonated species. Whereas the one-protonated species continues to be almost pseudooctahedral, the two-protonated Ni(IV) complex is an unstable "kinetic intermediate" with a ring-opened structure.[10a,d] The latter species is, therefore, more prone to react either by a substitution-controlled mechanism or by an outer-sphere route, resulting in a higher reactivity. This is also borne out of the fact that the magnitudes of k_{2y} and k_{2z} almost

parallel (but are higher than) the k_{1d} and k_{2d} values pertaining to the one-protonated and two-protonated Ni(IV) complex respectively.

It is well established[15] that hydrazine transfers two electrons to an oxidant to form the diimide intermediate which on further very rapid two-electron loss gives nitrogen; the overall stoichiometry for this process would be e/[N_2H_4]=4. On the other hand, the loss of one electron (hydrogen atom) from hydrazine results in the incumbent hydrazyl radical,[8] two units of which give nitrogen and ammonia as products with a stoichiometric ratio of e/[N_2H_4]=1. The observed stoichiometry ratio

$$N_2H_4 - 2e \longrightarrow N_2H_2 + 2H^+ \quad (10)$$

$$N_2H_2 - 2e \longrightarrow N_2 + 2H^+ \quad (10a)$$

$$N_2H_4 - e \longrightarrow N_2H_4^{\cdot+} \longrightarrow N_2H_3 + H^+ \quad (11)$$

$$2N_2H_3 \longrightarrow 2NH_3 + N_2 \quad (11a)$$

(Δ[Ni(IV)]/Δ[hydrazine]) of $\approx$2 and nitrogen as the product of oxidation of hydrazine suggest that two-electron transfers might have taken place. If there would have been a discernible one-electron loss, two reactive species, Ni(III) and hydrazyl radical, would have been produced in the rate-limiting step for which the activation enthalpy would have been much too higher than what has been observed here.

Even though the kinetic observations have been most plausibly explained in terms of the rate equations (Eqs. 5—9), and the mechanism of an analogous redox reaction of Ni(IV) with phenylhydrazine was definitely established to be outer-sphere in nature,[10a] the actual mechanistic routes in the present redox system are complicated by several factors.

1. Whether C_1 and C_2 of Eqs. 6 and 7 represent (a) precursor complexes with inner-sphere substitution by the substrate unit at a ring-opened site of the Ni(IV) complex species (followed by rate-determining decomposition of the precursors with electron transfer), or (b) structures in which the Ni(IV) species and the substrate are held together (in an outer-sphere manner) by means of hydrogen bonding between a dioximate oxygen and a substrate unit, cannot be easily distinguished. Both routes (a) and (b) will exhibit almost negligible ionic strength effect and limiting kinetics at higher relative [L]$_0$, as have been observed.

2. Since the k_{obsd} values are tremendously retarded when the reactions are carried out in the presence of added EDTA (Table 1) and are enhanced in the presence of catalytic amounts of added aquacopper(II), an alternative to Scheme 1 can be written as in Scheme 2.

$$M^{n+} + LH^+ \overset{K_C}{\rightleftharpoons} [MLH]^{(n+1)+}$$

$$[MLH]^{(n+1)+} + [NiD_3(H)]^- \xrightarrow{k''_{2y}} \text{Intermediate products}$$

$$[MLH]^{(n+1)+} + [NiD_3(H)H] \xrightarrow{k''_{2z}} \text{Intermediate products}$$

$$\text{Intermediate products} + \text{Ni(IV)} \xrightarrow{\text{fast}} \text{products}$$

(M^{n+} represents the trace metal ion impurities present or Cu(II) added in catalytic concentrations).

Scheme 2.

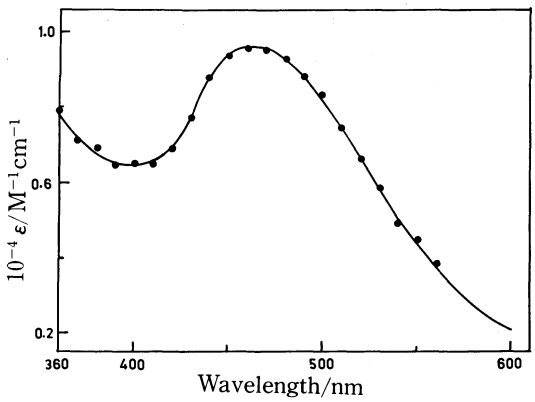

Fig. 3. Spectra of the nickel(IV) complex and reaction mixture.
Line: The Ni(IV) complex (1×10^{-4} M), points: the reaction mixture. ($[Ni(IV)]_0=1\times10^{-4}$ M, $[Hydrazine]_0=1\times10^{-3}$ M)
Aqueous medium, $\mu=0.25$ M, 35 °C, pH=7 (50 ms mode).

From the rate law of Scheme 2 it can be easily written that

$$k_{2y}=\frac{k''_{2y}K_C[L]_0}{1+K_C[L]_0} \quad (12)$$

and

$$k_{2z}=\frac{k''_{2z}K_C[L]_0}{1+K_C[L]_0}, \quad (13)$$

where k''_{2y} and k''_{2z} are the reaction constants of the metal ion-hydrazine complex with the one-protonated and two-protonated Ni(IV) complex under limiting (or trace impurity) concentrations of M^{n+}, and K_c is the formation constant of a 1 : 1 complex of metal ion and hydrazine. If the [L]-dependence of small quantities of k_{2y} (Eq. 12) is neglected, the K_c value from Eq. 3 is obtained as $\approx10^{3.1}$ M^{-1} at 35 °C and $\mu=0.25$ M (K_c and K_{2D} being identical). The 1 : 1 complex of Cu(II)-N_2H_4 has a reported value[14] of $10^{3.18}$ at 30 °C and $\mu=1.0$ M of ClO_4^-. Since the presence of Cu(II) in the reaction at an impurity level of 10^{-8}—10^{-7} M cannot be ruled out, these two values appear to be in excellent agreement.

3. Point-by-point spectra of reaction mixtures on the stopped-flow apparatus (in the 380—550 nm range) at pH 5.2, 6.3 and 7.0 are not different from those of the original Ni(IV) under the same pH conditions. For example, Fig. 3 presents representative spectra of the original Ni(IV) complex and a reaction mixture containing the Ni(IV) complex and hydrazine at pH= 7, 35 °C and $\mu=0.25$ M in aqueous medium. The Aminco stopped-flow assembly used[10] has a nominal mixing time of 2 ms and the point-by-point absorbance values were recorded at 10 nm wavelength intervals using a time scale on 50 ms mode.

4. Many apparently "uncatalyzed" redox systems have actually been found to be metal ion-catalyzed.[16]

5. The reactivity of $[Ni(dmg)_3(H)H]$ being several order higher than that of $[Ni(dmg)_3(H)]^-$ is also compatible with Scheme 2.

The inherent complexities of the redox system studied and the kinetics observed make unambiguous assignment of the reaction scheme difficult. Schemes 1(a) or (b) and 2 appear equally probable. Since the formation of Cu(II)–hydrazine complexes are well established,[17] Scheme 2 appears more likely in the presence of catalytic concentrations of Cu(II). However, further probes are needed for a definite choice.

We thank the CSIR and UGC, New Delhi for award of fellowships (to SA and GN) and National Associate Scheme and Scheme No. F. 23-930/79 (SR II). We also thank the Director of CLRI for some facilities and Prof. P. S. Radhakrishnamurti for helpful discussions.

A New Series of Heptamolybdonickelate(IV) and Manganate(IV). Investigation of the Unusual Magnetic and Electronic Spectral Behavior of the Nickel(IV) Compound

Ajoy Roy[1] and Muktimoy Chaudhury*

Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta 700 032, India

(Received July 9, 1982)

Two new heteropolymolybdates of nickel(IV) and manganese(IV) of composition $K_2H_8NiMo_7O_{28}\cdot 6H_2O$ and $K_2H_8MnMo_7O_{28}\cdot 4H_2O$ with a hitherto unknown 1 : 7 (Ni/Mn : Mo) stoichiometry are reported. X-Ray powder patterns show that they are isomorphous. The electronic spectrum of the nickel(IV) compound exhibits four absorption bands at 16.4, 17.5, 18.3, and 24×10^3 cm^{-1}, and the room temperature magnetic moment of the compound is abnormally high, 1.78 μB. The rationale for these observations is that there are Ni^{3+} impurity which occupy interstitial positions in the crystal lattice and as a consequence of dynamic Jahn-Teller distortion the high-spin $^4A_{2g}(^4T_{1g})$ state of the Ni^{3+} ion lies close to the low-spin ground state $^2A_{1g}(^2E_g)$ to get thermally populated to an appreciable extent leading to significant triplet state contribution.

Stabilization of higher oxidation states of nickel and manganese is a topic of current interest.[2,3] Most of the coordinating agents that stabilize the higher oxidation states of metal ions are organic molecules. Among the few inorganic ligands which are capable of forming higher valent metal complexes, isopolyanions are the prominent examples. Metal complexes of isopolymolybdates deserve special interest because of the diversity of their structural features. Crystal structure determinations have established their structures as hexa-, ennea-, deca-, and dodecamolybdometalates.[4-7]

Following the early discovery of nickel(IV) enneamolybdate by Hall,[8] several studies[5,9-11] have been reported on this and the analogous manganese(IV) species. However, to our knowledge, so far no hetero heptamolybdate has been reported in literature. This paper reports the preparation and characterization of nickel(IV) and manganese(IV) heptamolybdates.

Experimental

All chemicals were analytical grade and used without further purification.

Preparation of Dipotassium Octahydrogen Heptamolybdonickelate(IV), $K_2H_8NiMo_7O_{28}\cdot 6H_2O$. An aqueous solution (350 cm^3) of ammonium heptamolybdate (24.75 g, 20 mmol) was mixed with a solution (30 cm^3) of nickel(II) sulfate hexahydrate (2.65 g, 10 mmol). The solution was filtered, and to the filtrate 5.4 g (20 mmol) of potassium peroxodisulfate in small portions (addition required about 30 min) was added with constant stirring. During this addition the solution was maintained at 80 °C and stirred continuously. After $\approx$1 h a dark brown solution resulted which on standing overnight yielded dark brown shining crystals. The crystals were collected by filtration, washed several times with an aqueous solution of 0.1% $K_2S_2O_8$ followed by ice cooled water and finally dried over $CaCl_2$. Yield 6.3 g.

Dipotassium Octahydrogen Heptamolybdomanganate(IV), $K_2H_8MnMo_7O_{28}\cdot 4H_2O$. An aqueous solution (50 cm^3) of manganese(II) sulfate tetrahydrate (2.25 g, 10 mmol) was added to an aqueous solution (300 cm^3) of ammonium heptamolybdate (24.75 g, 20 mmol) with constant stirring. The solution turned yellowish in colour which was then filtered. The filtrate was heated on a steam bath and 5.4 g (20 mmol) of potassium peroxodisulfate was added in small portions (addition continued for 30 min) while stirring the solution vigorously. The colour of the solution gradually changed to orangeyellow. On standing at room temperature for $\approx$2 h, orangered shining crystals deposited. The product was collected on a glass frit and washed several times with 0.1% $K_2S_2O_8$ followed by ice cooled water and finally dried over $CaCl_2$. Yield 10.4 g.

Analyses. Chemical analyses were performed at least in triplicate. Manganese was estimated volumetrically by redox titration. Nickel and molybdenum were estimated gravimetrically using dimethylglyoxime and 8-quinolinol respectively as the reagents.[12] Water contents were determined thermogravimetrically.

Oxidation States†. About 30 mg of the compound was suspended in 25 cm^3 of water taken in an iodine flask. To this was added 2 g of iodate free potassium iodide and 10 ml of 2 mol dm^{-3} hydrochloric acid. 400 mg of sodium hydrogencarbonate was then added in small portions. The flask was stoppered immediately and the solution was stirred continuously for 2 h in dark with a magnetic stirrer. The solution was diluted to about 200 cm^3 and the liberated iodine was titrated with a standardized solution of sodium thiosulfate.

Measurements. The diffuse reflectance spectra were recorded (780—300 nm) on a Cary 14D spectrophotometer using magnesium oxide as the reference. Electronic spectra in solution were measured (800—200 nm) with a Pye Unicam SP8-150 spectrophotometer. Magnetic susceptibility measurements were made at room temperature on a Gouy balance with $Co[Hg(SCN)_4]$ as calibrant. X-Ray powder data were recorded with a Philips X-ray generator PW 1130 coupled with a Counter Diffractometer PW 1050,51 with nickel filtered Cu *Ka* radiation. Thermal analyses were carried out on a Shimadzu DT-30 thermal analysis system in an atmosphere of nitrogen at a heating rate of 5 °C min^{-1}.

Results and Discussion

The analytical results of the compounds shown in Table 1 are compatible with the assigned formulations. Both manganese and nickel are shown by the analytical data to possess the +4 oxidation state. The equivalent weight measurements as shown in Table 1 also support the 7 : 1 stoichiometry. In solid state, both the heptamolybdo compounds are indefinitely stable. The manganese(IV) compound is insoluble in water but the

† All solutions used in these measurements were prepared with deaerated water.

nickel(IV) compound is sparingly soluble in hot water (≈40 °C).

Table 2 summarizes the powder diffraction data of both $K_2H_8MnMo_7O_{28}\cdot 4H_2O$ and $K_2H_8NiMo_7O_{28}\cdot 6H_2O$. The identical *d*-spacings as well as intensities confirm that they are isomorphous. Similar isomorphism in other heteropolymetalates of Ni(IV) and Mn(IV) is well documented in literature.[11,13,14]

The number of water molecules present in the nickel(IV) and manganese(IV) compounds were determined from TGA and DTA. $K_2H_8NiMo_7O_{28}\cdot 6H_2O$ loses the six water molecules between 60 and 190 °C. The DTA shows that the water molecules are lost in two overlapping steps having the endothermic peaks at 105 and 135 °C. The observed weight loss, 7.51% agrees well with the calculated value, 7.58%. The thermolysis product arrested at 190 °C have the composition $K_2H_8NiMo_7O_{28}$ and the iodometric assay shows +4 oxidation state of nickel. On further heating, $K_2H_8NiMo_7O_{28}$ decomposes between 240—500 °C in a complicated way with the evolution of water along with oxygen as indicated by the appearance of two consecutive exotherms in the DTA. In $K_2H_8MnMo_7O_{28}\cdot 4H_2O$ the four water molecules are lost between 50 and 200 °C in a single step (DTA peak temperature, 120 °C). Above 230 °C further decomposition takes place in a way similar to the nickel(IV) compound. From the thermal analysis it may be stated that both the compounds contain two types of water, *viz.* the water of crystallization and the constitutional water which evolve at a considerably higher temperature (between 230—500 °C) compared to the water of crystallization.

Electronic Spectra and Magnetic Moments. The electronic spectrum of $K_2H_8NiMo_7O_{28}\cdot 6H_2O$ in saturated aqueous solution contains two bands at 17.8 and 47.4×10^3 cm^{-1}. The first one has also been observed in enneamolybdonickelate(IV)[11] and is assigned to nickel(IV) d-d ($^1A_{1g}\rightarrow{}^1T_{2g}$) transition. The other band at 47.4×10^3 cm^{-1} is most likely due to a charge transfer transition.

The diffuse reflectance spectra of the compounds with probable assignments are listed in Table 3. The electronic spectrum of the nickel(IV) compound in solid state as shown in Fig. 1 exhibits four bands at 16.4, 17.5, 18.3, and 24×10^3 cm^{-1}. The band at 17.5×10^3 cm^{-1} which is also observed in solution is the most

intense one, while the other three are of comparable intensities. It seems likely that due to their lower intensities they were not observed in the spectrum obtained with saturated aqueous solution.

In interpreting the electronic spectra of the nickel(IV) and manganese(IV) compounds we have considered that these metal ions are present in an octahedral array of oxygen atoms which is consistent with the structural information available for the heteropolymolybdates.

A common feature for most of the spin paired octahedral d^6 metal ions like nickel(IV) is that they give rise to two allowed ($^1A_{1g}\rightarrow{}^1T_{1g}$ and $^1A_{1g}\rightarrow{}^1T_{2g}$) and two spin forbidden ($^1A_{1g}\rightarrow{}^3T_{1g}$ and $^1A_{1g}\rightarrow{}^3T_{2g}$) ligand field transitions of which the $^1A_{1g}\rightarrow{}^1T_{2g}$ transition is of highest energy and maximum intensity.[15] Thus the most intense ligand field band observed at 17.5×10^3 cm^{-1} in the solid state spectrum of $K_2H_8NiMo_7O_{28}\cdot6H_2O$ can safely be assigned to $^1A_{1g}\rightarrow{}^1T_{2g}$ nickel(IV) transition. Since of the remaining three bands, two appear at still higher energies relative to the one at 17.5×10^3 cm^{-1}, their origin cannot be due to d-d transition of nickel(IV). However, the band at 16.4×10^3 cm^{-1} can tentatively be assigned to the second spin allowed nickel(IV) d-d transition, *viz.* $^1A_{1g}\rightarrow{}^1T_{1g}$.

In order to explain the appearance of two higher energy bands at 18.3 and 24×10^3 cm^{-1}, we invoke the presence of Ni^{3+} ion in the crystal lattice of $K_2H_8NiMo_7O_{28}\cdot6H_2O$. This assumption is based on the observation made from magnetic moment measurements (see later). It is conjectured that during the preparation of $K_2H_8NiMo_7O_{28}\cdot6H_2O$, some of the nickel(IV) sites are occupied by nickel(III) in the crystal lattice. These Ni^{3+} ions present in an octahedral array of oxygen should ordinarily have a low-spin ^2E_g ground state. It is well known[16] that for a ground state of E symmetry the octahedral environment undergoes tetragonal distortion by interaction with the ε_g vibrational mode leading to either elongation or compression along the four fold axis together with appreciable ground-state splitting. Reinen *et al.*[17,18] have shown from EPR and ligand field data that for a Ni^{3+} ion in an octahedral site, Jahn-Teller distortion sharply splits ^2E_g into $^2B_{1g}+{}^2A_{1g}$ while $^4T_{1g}$ undergoes a much smaller splitting into ^4E_g and $^4A_{2g}$. In effect, $^2A_{1g}$ becomes the ground state with $^4A_{2g}$ lying only slightly above it. The result is the equilibrium $^2A_{1g}\rightleftharpoons{}^4A_{2g}$. Similar tetragonal ground state splitting has also been considered by Warren *et al.*[19] during their attempt to explain the electronic spectrum of $[NiF_6]^{3-}$ ion.

Thus following the energy level diagram as proposed by Reinen,[18] the bands at 18.3 and 24×10^3 cm^{-1} can be assigned to ($^2A_{1g}\rightarrow{}^4E_g$) and ($^2A_{1g}\rightarrow{}^2B_{1g}$) transitions respectively. The lowest energy band at 16.4×10^3 cm^{-1} which has been previously indicated as due to $^1A_{1g}\rightarrow{}^1T_{1g}$ of nickel(IV) can alternatively be assigned to $^2A_{1g}\rightarrow{}^4A_{2g}$ nickel(III) d-d transition.

Table 3 shows that the spectrum of Mn(IV) compound contains four bands (also shown in Fig. 1). The ruby band observed at 14.3×10^3 cm^{-1} was also observed by Baker *et al.*[11] in enneamolybdomanganate(IV) and was assigned to $^4A_{2g}\rightarrow{}^2E_g$ transition. The next higher energy band at 15×10^3 cm^{-1} was also observed in the spectrum of hexamolybdochromate(III) and was interpreted as due to $^4A_{2g}\rightarrow{}^2T_{2g}$ transition.[11] The remaining two higher energy bands appeared at 20.4 and 27.9×10^3 cm^{-1} are considered to be due to first and second spin allowed transitions to excited $^4T_{2g}$ and $^4T_{1g}(F)$ states respectively following the arguements made by Jørgensen.[20]

The room temperature magnetic moment of the Mn(IV) compound is 3.95 BM which is in agreement with the value 3.88 BM calculated for a high-spin d^3 Mn(IV) configuration. Although on the basis of analytical and X-ray powder data one would expect that $K_2H_8NiMo_7O_{28}\cdot6H_2O$ should be diamagnetic; however, it is paramagnetic having a room temperature magnetic moment of 1.78 BM. This unusually high magnetic moment for a nickel(IV) compound can not be explained on the basis of its temperature independent paramagnetism which at the most can have a contribution of ≈0.6 BM.[21] Such unusual paramagnetic behavior was also observed in nickel(IV) periodate[22] and was explained from EPR studies as due to nickel(III) impurities.[23] The presence of nickel(III) impurity has been already considered in order to explain the electronic spectrum of $K_2H_8NiMo_7O_{28}\cdot6H_2O$. Obviously the concentration of nickel(III) is very low as the chemical composition indicates and literature[2] shows that nickel(III) species are almost invariably low-spin with one unpaired electron. Thus a small concentration of nickel(III) ion with a low-spin ground state (^2E_g) having no orbital contribution can not alone explain such a high room temperature magnetic moment. Hoppe *et al.*[24,25] in order to explain the unusually high magnetic moments of Ni^{3+} ion in alkali metal hexafluoronickelates considered thermal equilibrium between the high and low-spin forms. We also propose that because of the dynamic Jahn-Teller effect, the high-spin $^4A_{2g}$ ($^4T_{1g}$) state of the nickel(III) lies close enough to the low-spin ground state $^2A_{1g}(^2E_g)$ to get thermally populated to an appreciable extent leading to significant triplet state contribution towards the room temperature magnetic moment.

In conclusion we emphasize that the Ni^{3+} ion that is present as impurity in $K_2H_8NiMo_7O_{28}\cdot6H_2O$ provides a rare example of spin state equilibrium of nickel(III). To our knowledge such example is restricted only to alkalimetal hexafluoronickelates(III).

The authors are grateful to Dr. K. Nag of this department for many helpful discussions during the course of this investigation.

Heats of Solutions of Bolaform Electrolytes in Water

Kunio TAMAKI* and Kaoru IRIE

Department of Chemistry, Yokohama City University, Kanazawa-ku, Yokohama 236

(Received March 12, 1983)

Synopsis. The heats of solutions of polymethylenediammonium dichlorides $[H_3N(CH_2)_nNH_3]Cl_2$ (n=2—8, 10, and 12) and disodium polymethylene disulfates $Na_2[O_3SO(CH_2)_nOSO_3]$ (n=2—6, 8, and 10) in water were measured at 15, 25, and 35 °C. The changes in the heat capacity for dissolution, $\Delta C_p°$, were obtained from the relation between the heats of soultion and the temperature, and the results were compared with the $\Delta C_p°$ values for alkylammonium chlorides and sodium alkyl sulfates previously reported.

The physical properties of amphiphilic electrolytes in water have been discussed in terms of the resultant change in the water structure upon the introduction of ions into water. Nonpolar groups, such as alkyl groups and polymethylene groups, act as water-structure makers in water; that is, the water molecules form an icelike structure around the nonpolar groups. The study of the heat capacities of aqueous electrolyte solutions provides a useful method of obtaining information about the influence of ions on the structure of solvent water. In previous papers,[1,2] the results on the changes in the heat capacity for the dissolution in water, $\Delta C_p°$ for a series of alkylammonium chlorides ($C_nH_{2n+1}NH_3Cl$, which will be abbreviated as C_nCl) and sodium alkyl sulfates ($C_nH_{2n+1}OSO_3Na$, which will be abbreviated as, NaC_n) were reported. In this paper, the experimental results regarding the heats of solution and the $\Delta C_p°$ values for polymethylenediammonium dichlorides ($[H_3N(CH_2)_nNH_3]Cl_2$, which will be abbreviated as, C_nCl_2) and disodium polymethylene disulfated ($Na_2[O_3SO(CH_2)_nOSO_3]$, which will be abbreviated as, Na_2C_n) will be reported. This type of electrolyte, in which an ionic part is attached at each end of the chain, is called a bolaform eletrolyte. The main object of this paper is to compare the hydrophobic character of the polymethylene group in a bolaform electrolyte with that of the alkyl group for a monovalent electrolyte.

Experimental

Materials. The organic chemicals used were obtained from the Tokyo Kasei Kogyo Co., Ltd. C_7Cl_2, C_8Cl_2, $C_{10}Cl_2$, and $C_{12}Cl_2$ were prepared by the neutralization of the corresponding diamines in methanol with hydrochloric acid, and the solvents were evaporated to dryness. All the C_nCl_2 salts were recrystallizaed twice from ethanol–water solutions and dried *in vacuo* at room temperature. Na_2C_n salts were synthesized by the esterification of the corresponding alcohols by the use of concentrated sulfuric acid in cabon tetrachloride or chloroform below 15 °C. After removing the carbon tetrachloride or chloroform, the solutuions were neutralized with a concentrated solution of sodium hydroxide. The reaction mixtures were dried in air and extracted with ethanol–water solutions (about 60% ethanol). The products were further purified several times by recrystallizing them from ethanol–water solutions (about 80% ethanol) and then dried *in vacuo* at 100 °C. Water was triply distilled.

Calorimetry. The heats of solution in water were measured at 15, 25, and 35 °C with a twin isoperibol calorimeter TIC-2C, manufactured by the Tokyo Riko Co., Ltd. The sample and blank ampoules were, respectively, set in the measuring and reference Dewar vessels, each containing 200 cm^3 of water, resting in depressions in an aluminum block controlled to ±0.01 °C. After thermal equilibrium had been attained, the sample and blank ampoules were broken simultaneously. The difference in temperature measured by a pair of thermistors was recorded on a chart recorder. The calorimeter was checked by measuring the heat of solution of potassium chloride at 25 °C. The value obtained was within 1% of that reported in the literature.[3]

Results and Discussion

Heat-of-solution measurements have been carried out in the concentration range of 6×10^{-4}—2.5×10^{-3} mol dm^{-3}. In this concentration range, any dependence of the heat of solution on the concentration is within the limits of experimental error, so the average of three or more measurements has been taken as the heat of solution at an infinite dilution, $\Delta H_s°$. The $\Delta H_s°$ values of C_nCl_2 and Na_2C_n are listed in Table 1. Results from the $\Delta H_s°$ values were used to calculate the change in the heat capacity in going from the pure compounds to an aqueous solution at an infinite

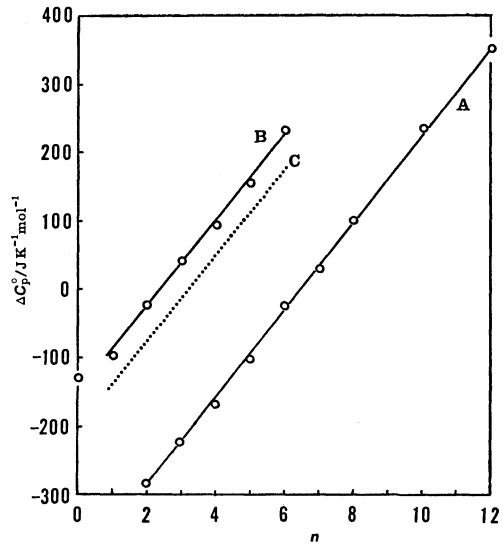

Fig. 1. Plot of ΔC_p° against n. A, $[H_3N(CH_2)_nNH_3]$-Cl_2; B, $C_nH_{2n+1}NH_3Cl$; C, $-(CH_2)_nNH_3Cl$.

dilution, ΔC_p°;

$$\Delta C_p^\circ = d\Delta H_s^\circ/dT,$$

where T is the temperature. The ΔC_p° values obtained at 25 °C are also listed in Table 1. The magnitude and sign of ΔC_p° can be taken as relative measures of the structural effect upon the solvent water.[1,4,5] The ΔC_p° values of simple salts indicate negative values, whereas the ΔC_p° values of hydrophobic solutes indicate positive values.

As may be seen in Table 1, the ΔC_p° values for C_2Cl_2, C_3Cl_2, C_4Cl_2, C_5Cl_2, and C_6Cl_2 are negative, while the ΔC_p° values become positive in the case of C_7Cl_2 and higher homologs. In an earlier work[1] on C_nCl series, C_1Cl and C_2Cl showed negative values of ΔC_p°, while C_3Cl and higher homologs showed positive values of ΔC_p°. Figure 1 shows the ΔC_p° values as a function of the number of carbon atoms, n, in the polymethylene or alkyl group for C_nCl_2 and C_nCl. If we take one-half the ΔC_p° values for C_nCl_2, the ΔC_p° values for a series of $-(CH_2)_nNH_3Cl$ can be estimated. The ΔC_p° *vs.* n relation thus obtained is plotted as a dotted line in Fig. 1. It is found that, for the same number of carbon atoms, the ΔC_p° values for $-(CH_2)_nNH_3Cl$ are lower than those for C_nCl. With the same ΔC_p° values, the difference in n between the two ΔC_p°-*vs.*-n lines for C_nCl and $-(CH_2)_nNH_3Cl$ corresponds to about 0.8.

Table 1 indicates that the ΔC_p° values for Na_2C_2, Na_2C_3, Na_2C_4, and Na_2C_5 are negative, while the ΔC_p° values for Na_2C_6 and higher homologs are positive. In a previous paper[2] on a NaC_n series, NaC_1 showed a negative value of ΔC_p°, while NaC_3 and higher homologs showed positive ΔC_p° values. Figure 2 shows the ΔC_p° values as a function of n for Na_2C_n and NaC_n. The dotted line in Fig. 2 represents the data for a $-(CH_2)_nOSO_3Na$ series. With the same ΔC_p° values, the differnce in n between the two ΔC_p°-*vs.*-n relations for NaC_n and $-(CH_2)_nOSO_3Na$ corresponds to about 0.7.

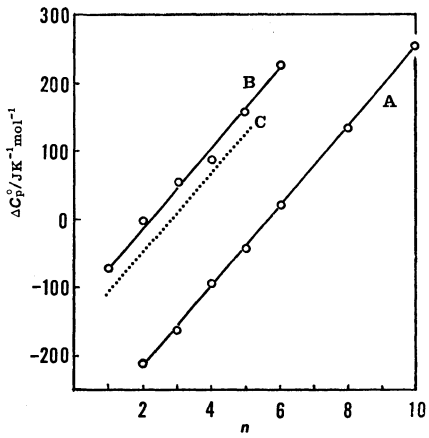

Fig. 2. Plot of ΔC_p° against n. A, $Na_2[O_3SO(CH_2)_n$-$OSO_3]$; B, $C_nH_{2n+1}OSO_3Na$; C, $-(CH_2)_nOSO_3Na$.

With bolaform electrolytes, the electrostrictive hydration due to the two ionic parts situated at opposite ends of a chain may interfere with the interaction of the hydrophobic polymethylene chain with water, and the smaller members of both series of C_nCl_2 and Na_2C_n are water-structure-breaking ions. When the charged groups are sufficiently far apart, the solvent-structuring effect of the hydrophobic polymethyene chain becomes important. However, the hydrophobic character of the polymethylene chain in bolaform electrolytes is considerably diminished as compared with that of the alkyl chain in monovalent electrolytes.

Thanks are due to Mr. Akihide Kudo, Mr. Shinichi Hata, and Ms. Izumi Makino for the preliminary experiments.

Colloidal Rhodium Dispersions Protected by Cyclodextrins

Makoto KOMIYAMA* and Hidefumi HIRAI

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received March 30, 1983)

Synopsis. Refluxing of an aqueous solution of rhodium(III) chloride and α- or β-cyclodextrin, followed by further refluxing in the presence of ethanol, gives a colloidal dispersion of rhodium particles of 28 Å in diameter. The colloidal dispersion exhibits effective catalyses in hydrogenation of olefins at 30 °C under an atmospheric pressure.

Interests in colloidal dispersions of metals have been rapidly increasing especially in this decade.[1,2]

Previously,[2-5] the present authors succeeded in the preparation of colloidal dispersions of noble metals by reducing their salts with alcohols such as ethanol and 1-propanol in the presence of various polymers. The polymers used were poly(vinyl alcohol), poly(*N*-vinylpyrrolidone), and poly(methyl vinyl ketone). The resulting colloidal dispersions were characterized both by quite small particle sizes and by narrow distributions in particle sizes.

This paper describes the preparation of colloidal rhodium dispersions through the reduction of rhodium(III) chloride with ethanol using cyclodextrins, cyclic oligomers of 6—8 glucose units, as protective colloids. The catalytic activities of these colloidal dispersions in the hydrogenation of olefins will be shown.

Experimental

Colloidal rhodium dispersions were prepared as follows. First, 7.0 mg (2.7×10^{-5} mol) of rhodium(III) chloride trihydrate (Nippon Engelhard, Ltd.) and various amounts of α-, β-, or γ-cyclodextrin (Nakarai Chemical Co.) were dissolved in 30 ml of water, and the solution was refluxed for 30 min. Then, 10 ml of ethanol was added and the solution was further refluxed for 10 min, resulting in the formation of colloidal rhodium dispersion as a dark brown solution.

Sample films of colloidal dispersions for electron microscopy were prepared by evaporating the solvent to dryness on a collodion film coated with a carbon layer. Electron micrographs were measured by a Hitachi Model H 500 electron microscope operated at 125 kV at the magnification of 100000.

Hydrogenation of olefins catalyzed by colloidal rhodium dispersions was carried out at 30.0 °C under an atmospheric hydrogen pressure, and was followed by reading the uptake of hydrogen.

Results and Discussion

Homogeneous colloidal rhodium dispersion was obtained using α- or β-cyclodextrin. The minimal molar ratios of cyclodextrin to rhodium(III) chloride, required for the preparation of the colloidal dispersions, were 0.5 for α-cyclodextrin and 0.1 for β-cyclodextrin. These results were markedly in contrast with the rapid formation of black precipitates in the absence of cyclodextrin. The precipitation took place immediately after the refluxing of the water-ethanol mixture started.

When γ-cyclodextrin was used in place of α- or β-cyclodextrin, rapid precipitation took place and colloidal dispersion was not obtained, even at the molar ratio unity of γ-cyclodextrin to rhodium(III) chloride.

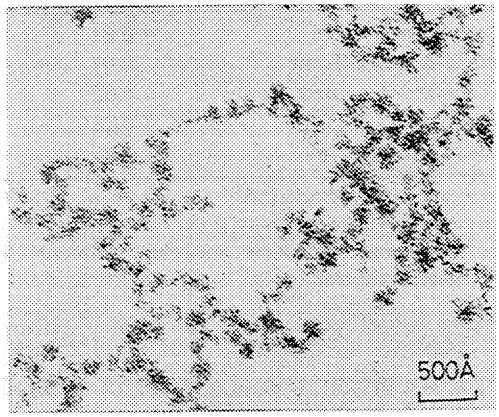

Fig. 1. Electron micrograph of colloidal rhodium dispersion prepared by using β-cyclodextrin equimolar to rhodium(III) chloride; ×100000.

From these results, it is concluded that the protecting abilities of cyclodextrins are in the following order:

β-cyclodextrin > α-cyclodextrin ≫ γ-cyclodextrin ≈ 0.

Figure 1 shows the electron micrograph of rhodium colloidal dispersion prepared in the presence of β-cyclodextrin equimolar to rhodium(III) chloride. Highly dispersed fine rhodium particles are observed. The average diameter of the particles is 28 Å.

In aqueous solutions, apolar particles of rhodium metal should be bound to the apolar cavities of cyclodextrins. Since the particles are too large to be totally included in the cavity of α- or β-cyclodextrin, they sit on the top of the cavity. Thus, the surface of the rhodium particles is mostly covered with several cyclodextrin molecules, which prevent aggregation of particles.

The proposed structures of the present colloidal particles are consistent with the larger protecting ability of β-cyclodextrin than that of α-cyclodextrin, since almost all of the guest compounds previously investigated showed stronger binding with β-cyclodextrin than with α-cyclodextrin.[6] Minimal protecting ability of γ-cyclodextrin is associated with less apolar property of the cavity. The order for the three kinds of cyclodextrins in the protecting abilities is also identical with the decreasing order in their solubilities in water.

The above arguments are supported by the fact that dextran (degree of polymerization, 360), which has no cavities, shows no measurable protecting ability at the molar ratio 7 to rhodium(III) chloride. Here, a glucose residue of dextran is taken as a unit. Furthermore, both poly(ethylene oxide) and poly(*N*-vinylpyrrolidone)(degree of polymerization, 110 and 90, respectively) exhibit no effective protection at the residual molar ratio unity with respect to rhodium(III) chloride.

Table 1. Catalytic activities of colloidal dispersion of rhodium prepared by using β-cyclodextrin in the hydrogenation of olefins[a)]

Substrate	Initial rate of hydrogen uptake (H_2 mol/Rh g-atoms·s)
3-Buten-2-one	0.24
3-Methyl-3-buten-2-one	0.07
3,4-Dimethyl-3-penten-2-one	0.32
Acrylonitrile	0.22
Methacrylonitrile	0.06

a) Hydrogenation conditions: temperature, 30.0 °C; total pressure, 1 atm; [Rh]=[β-cyclodextrin]=4×10^{-5} mol·dm^{-3}; [substrate]=2.5×10^{-2} mol·dm^{-3}; solvent, 19.5: 0.5 (v/v) water-ethanol.

The refluxing of aqueous solution of rhodium(III) chloride prior to the addition of ethanol is definitely required for the preparation of a homogeneous colloidal dispersion. When rhodium(III) chloride was directly dissolved in the 3:1 water–ethanol mixture and the solution was refluxed for 10 min, considerable amounts of precipitates were formed together with a homogeneous dark brown colloidal dispersion.

On refluxing an aqueous solution of rhodium(III) chloride and β-cyclodextrin for 30 min, the absorbance in the 200—350 nm region decreased and a shoulder appeared at 260 nm. These changes are attributable to complex formation of rhodium(III) chloride with β-cyclodextrin. Rhodium ions in the complexes were then reduced by the ethanol added, and the resulting colloidal dispersion showed a monotonic absorption without peaks.[4)]

As shown in Table 1, the rhodium colloidal dispersion prepared with β-cyclodextrin effectively catalyzed hydrogenation of water-soluble olefins at 30.0 °C under an atmospheric hydrogen pressure.

Methyl substitutions in the substrate at the β-position with respect to the carbonyl group enhance catalytic hydrogenation. The hydrogenation of 3,4-dimethyl-3-penten-2-one is about 4.6 times as fast as that of 3-methyl-3-buten-2-one. In contrast, methyl substitution at the α-position with respect to the carbonyl or cyano group suppresses the reaction. The rates for 3-methyl-3-buten-2-one and methacrylonitrile are 3 fold smaller than the values for the corresponding substrates without a methyl group at the α-position.

These results indicate the inclusion complex formation of the substrates with one of the β-cyclodextrins, located on the surface of the rhodium particles, prior to the catalytic functions of the particles. In order to make the catalyses effective, the penetration of the substrate in the cavity should be from the side involving the C–C double bond rather than from the side involving the polar groups. The alkyl substitution at the β-position enhances the inclusion of the substrate into the apolar cavity from the side involving the C–C double bond due to increase in the apolar character of this side. On the other hand, alkyl substitution at the α-position decreases the polar character in the side involving the polar group, resulting in the suppression of the inclusion from the side involving the C–C double bond.

The participation of β-cyclodextrin, located on the surface of rhodium particles, in the catalyses is further supported by the fact that the hydrogenation of 3-buten-2-one is almost totally inhibited by the addition of 10^{-2} mol dm^{-3} of cyclohexanol. In contrast, methanol exhibits no effect on the hydrogenation at the same concentration. The inhibition by cyclohexanol, which forms inclusion complex with β-cyclodextrin, is attributable to its competition with the substrate for the cavity of β-cyclodextrin.

In conclusion, complex formation of rhodium(III) chloride with α- or β-cyclodextrin, followed by the reduction of them with ethanol, gives a colloidal rhodium dispersion. The dispersion exhibits specific catalyses in the hydrogenation of olefins.

The authors would like to thank Mr. Hidehiko Wakabayashi in our laboratory for his help in electron micrograph measurements.

The Dissolution of Heat-treated Acenaphthylene Pitch

Yoshio YAMADA,* Minoru SHIRAISHI, Takeshi FURUTA, and Toshio YAMAKAWA
National Research Institute for Pollution and Resources, Yatabe, Ibaraki 305

(Received April 8, 1983)

Synopsis. About half of the pyridine insolubles in heat-treated acenaphthylene pitch was dissolved into hydrogenated pitch. Observation with optical and scanning electron microscopes showed that the components dissolved consisted of small mesophase spherules with an optically isotropic texture.

An optically anisotropic mesophase texture appears from isotropic pitch when the pitch is carbonized. Once the mesophase texture is formed, most of the anisotropic structures are insoluble, even in such powerful solvents as pyridine and quinoline.[1-3] In this study we attempt to dissolve the mesophase texture formed at an early stage of carbonization by using a hydrogenated pitch and a pyridine-soluble fraction containing molecular species near the mesophase constituent.

Experimental

A pitch (683-4) containing 15.2 wt% of pyridine insolubles (PI) and 8.6 wt% of quinoline insolubles (QI) was obtained by heat-treating acenaphthylene at 683 K for 4 h in a nitrogen atmosphere. The process of preparing the additives used for dissolution is shown in Fig. 1. Acenaphthylene was heated at 703 K for 2 h in a nitrogen stream and then evacuated at 623 K for 2 h to remove any volatile materials. The pitch (703-2) was hydrogenated with Li-ethylenediamine,[4] *i.e.*, by BenKeser reduction, and the product thus obtained was treated under a vacuum at 623 (703-2BK(623)) or 648 K (703-2BK(648)) for 2 h. On the other hand, the pyridine-soluble fraction from the pitch of 703-2 was evacuated at 623 (703-2PS(623)) or 648 K (703-2PS(648)) for 2 h.

The pitch of 683-4 was mixed with an equal portion of each additive, and the mixture was transferred into an ampule connected to a vacuum line to degas and seal it. After the sealed ampule had been heat-treated at 623 K for 1 h in a fluidized sand bath, all the product in the ampule was used to estimate the solubility. The amounts of PI and QI were determined by soxhlet extraction and the JIS-K2425 method respectively.

Results and Discussion

The infrared spectra of 703-2BK and 703-2PS are shown in Fig. 2. The peaks at 2850 and 2900 cm^{-1} due to aliphatic CH symmetric and antisymmetric stretching are largely enhanced by the hydrogenation of the pitch of 703-2. Since condensed aromatic hydrocarbons are mainly converted to saturated or partially saturated ring compounds by BenKeser reduction,[4] in this case also some naphthenic hydrocarbons are considered to be present in 703-2BK. The results of elemental analyses and the hydrogen-to-carbon atomic ratio of the additives are given in Table 1, along with that of 703-2. The hydrogen content increases with the BenKeser reduction, but some of the hydrogens added are eliminated by treatment *in vacuo* at these temperature ranges. The extent of dehydrogenation for 703-2BK is much higher than that for 703-2PS. This was confirmed by the analysis of the gas evolved on the heat-treatment of these samples. This suggests that the hydrogens in naphthenic rings formed by the saturation of the aromatic molecules are unstable. The average molecular weight for 430-2BK is comparable to that for 703-2PS at the same treatment temperature (Table 2). However, an increase in the temperature tends to raise the molecular weight and, at the same time, to form PI, although the QI are negligibly small for all the samples except for 703-2. The formation of PI may be considered to

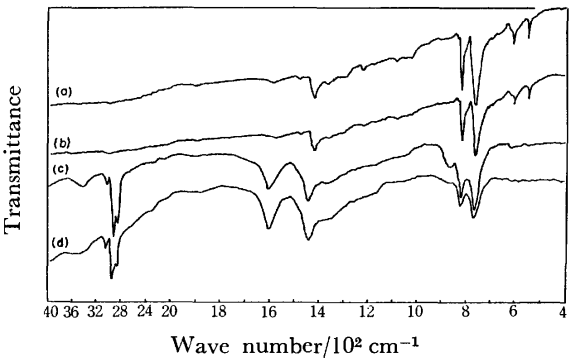

Fig. 2. Infrared spectra of additives, (a): 703-2PS (623), (b): 703-2PS(648), (c): 703-2BK(623), (d): 703-2BK(648).

TABLE 1. ELEMENTAL ANALYSIS OF ADDITIVES

Additive	C (wt%)	H (wt%)	H/C (atomic ratio)
703-2	96.68	4.27	0.526
703-2BK (623)	92.63	6.67	0.858
703-2BK (648)	93.44	5.92	0.745
703-2PS (623)	95.49	4.37	0.545
703-2PS (648)	95.66	4.30	0.536

Table 2. Molecular weight, PI, and QI of additives

Additive	Average molecular weight[a)]	PI (wt%)	QI (wt%)
703-2	—	18.6	10.3
703-2BK (623)	780	0.0	0.0
703-2BK (648)	1005[b)]	2.6	0.1
703-2PS (623)	670[b)]	4.7	0.4
703-2PS (648)	1025[b)]	5.6	0.4

a) Measured in pyridine by means of a vapor-pressure osmometer. b) Obtained on the sample without PI.

Table 3. Effect of addirives on PI and QI contents of 683-4

Additive	PI (wt%)	QI (wt%)
—	15.2	8.6
703-2BK (623)	8.1	7.1
703-2BK (648)	9.4	8.1
703-2PS (623)	14.0	8.0
703-2PS (648)	15.4	8.9

result from the condensation of large molecules and from a decrease in the fluidity due to the elimination of the molecules with comparatively low molecular weight on evacuation. No appreciable amount of PI could be detected when these additives were treated in a sealed ampule at 623 K for 1h.

Table 3 show the data for pyridine and quinoline insolubility when the mixture of the pitch of 683-4 and additives was treated at 623 K for 1 h. Since the insoluble fractions are already involved in 703-2BK (648), 703-2PS(623), and 703-2PS(648) (Table 2), the values of PI were corrected for the mixture with these additives. When the pitch hydrogenated was used as an additive, about half of the PI in the pitch of 683-4 was dissolved and converted to a component soluble in pyridine. On the contrary, when 703-2PS(623) and (648) were added and treated, no effect could be observed on the values of PI and QI. It can be presumed, on the basis of these results, that hydrogen transfer is needed to dissolve the pyridine-insoluble component, for the additives of 703-2BK contain the labile naphthenic hydrogens described above.

A microscopic observation of the whole sample of the 683-4 alone shows that the pitch contains both mesophase spherules with a wide range of distribution in terms of diameter and a flow texture which settles at the bottom of the sample tube. Also, the pyridine-insoluble fraction of this pitch consists of isotropic and anisotropic phases, whereas the QI fraction is composed of almost anisotropic textures where both large mesophase spherules and a partially coalesced flow domain are present. In the case of the mixture of 683-4 and 703-2BK, anisotropic components were predominantly observed in the PI of the mixture treated. These observations may indicate that the isotropic part and the small spheres in the PI of 683-4 are dissolved upon the addition of 703-2BK. The rough agreement between PI and QI values upon the addition of 703-2BK in Table 3 might be qualitatively consistent with the optical observations; both PI and QI are mainly composed of anisotropic textures with large spheres and flow domain.

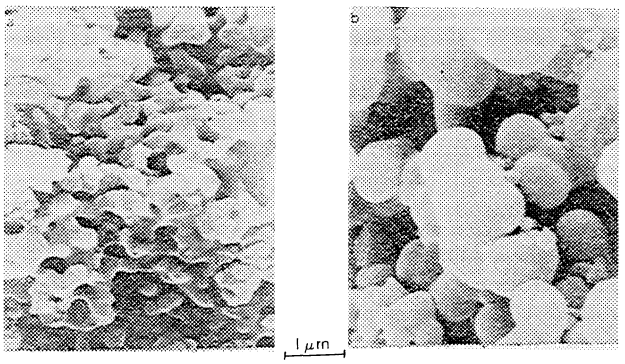

Fig. 3. Scanning electron microphotographs. (a): pyridine insoluble component from 683-4, (b): pyridine insoluble component from the mixture of 683-4 and 703-2BK(623).

The size and the shape of particles in PI were observed with a scanning electron microscope. While in the PI from the 683-4 pitch small spheres (0.3 μm) are partially fused and linked with each other in spherules of about 1 μm, spherical bodies of about 1 μm in size are agglomerated, and each body has round shape near a true sphere, in the case of the PI from the mixture of 683-4 and 703-2BK(623), as can be seen in Fig. 3.

It can be considered, therefore, that the hydrogenated pitch used as an additive dissolves small spherules and the optically isotropic texture connecting these spherules.

The Chemical Preparation of Tin Organosol

Sumio Ichiba,* Hiroaki Ono, Shunji Kawasaki, Sakae Nakagawa, and Masaaki Yamada
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received January, 8, 1983)

Synopsis. A stable colloidal tin suspension in an organic solvent was prepared by the chemical reduction of tin(II) chloride with sodium tetrahydridoborate in the presence of a protective agent. The tin organosol was examined by means of the Mössbauer absorption spectra of ^{119}Sn in the frozen solution and by means of an electron microscope.

Vernon *et al.* have extensively studied the chemical preparation of colloidal metal suspensions in non-aqueous solvents.[1,2] They have reported the preparation of a stable tin organosol of a very dilute concentration by reducing tin(II) chloride with phosphorus-hydrazine. We have tried to obtain tin organosols in concentrations higher than 0.2% by Vernon's method. However, it was difficult because tin(II) chloride was not reduced sufficiently, even at the raised temperature of 70 °C.

In this study, we have tried to prepare a colloidal tin suspension in ethanol by chemical reduction with the reducing agent of $NaBH_4$ in the presence of a protective agent.

Experimental

Freshly prepared anhydrous stannous chloride (0.17—1.36 mmol) was dissolved in dry ethanol (20 ml). Three times as much poly(vinylpyrrolidone) (PVP) as $SnCl_2$ was added to the solution as a protective agent. Then three times as much $NaBH_4$ as $SnCl_2$ was added at 3 °C under a nitrogen atmosphere, while the solution was stirred by means of ultrasonic waves. The solution became red-brown immediately, and after a few minutes it gave a homogenous black solution forming a stable tin suspension.

The tin microcrystals in the suspension were examined by means of the Mössbauer absorption spectra of ^{119}Sn in the frozen solution and by means of an electron microscope.

Results and Discussion

Stannous chloride is reduced to tin by $NaBH_4$ in ethanol according to this reaction:

$$SnCl_2 + 2NaBH_4 \xrightarrow[3\,°C]{\text{ethanol}} Sn + B_2H_6 + H_2 + 2NaCl$$

In confirmation of this reaction, the fine powder filtered out of the suspension were identified by means of X-ray diffraction as a mixture of β-tin and NaCl. Observation of the electron micrograph of the microcrystals in a suspension with a tin concentration of 1 mg cm^{-3} revealed that the particle size of the microcrystals was about 300 Å and that the microcrystals aggregated to a size of 1000 Å or more.

The Mössbauer absorption spectra of ^{119}Sn in frozen solutions with various tin concentrations at 90 K are shown in Fig. 1. The values of the isomer shift (δ) and the total area under the absorption peak derived from the spectra are shown in Table 1. The values of the isomer shift at the higher concentrations coincide with the value of the bulk of β-tin, 2.56 mm s^{-1}. However, at the lower concentrations the values turned out to be more negative.

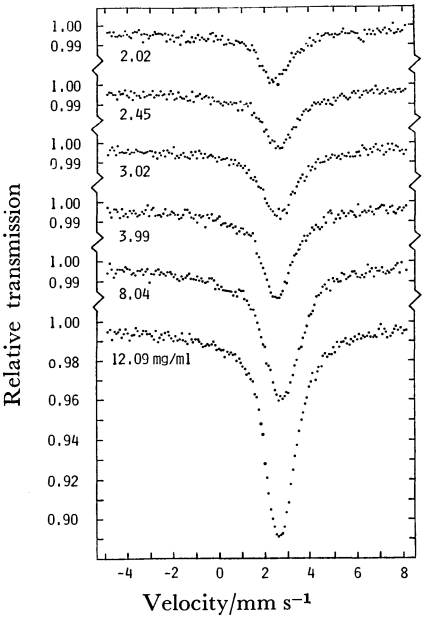

Fig. 1. Mössbuer absorption spectra of ^{119}Sn in the frozen solutions of tin suspension in ethanol at 90 K.

Table 1. ^{119}Sn Mössbauer data of tin organosol

Concentration / mg cm^{-3}	δ / mm s^{-1}	Area
1.01	2.22	0.035
2.02	2.42	0.056
2.45	2.59	0.075
3.02	2.53	0.049
3.99	2.47	0.114
8.04	2.69	0.186
12.09	2.60	0.258

The plots of the total area against the tin concentration are shown in Fig. 2. The area decreases linearly with the decreasing concentration, but it deviates from the line to the lower value at lower concentrations.

Suzdalev *et al.* have investigated, in an aerosol, tin particles with diameters of 250, 370, and 600 Å; they reported that the probability of the Mössbauer effect diminishes as the particle diameter decreases and that this result is associated with the influence of the surface.[3] With reference to their findings, it seems likely that the size of the mycrocrystals formed in the organic suspensions will be reduced with the decreasing tin concentration and that the surface effects will become manifest at concentrations lower than 3 mg cm^{-3}.

A few cases of isomer-shift differences between bulk and microcrystals have been reported and their origins

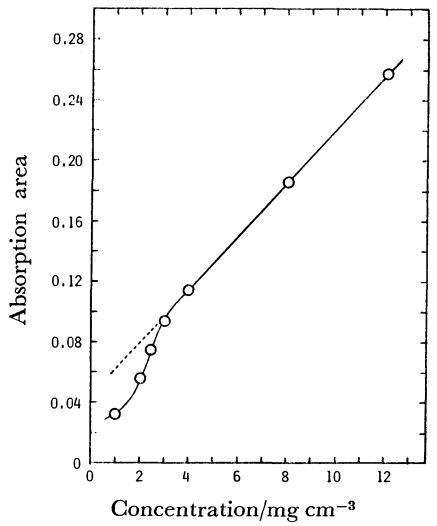

Fig. 2. Total area under the absorption peak *vs.* concentration of tin in suspension.

discussed by Schroeer.[4] The isomer-shift difference, *i.e.*, the decrease in the microcrystals formed at the lower concentration, is also observed in our study. In tin microcrystals, the negative isomer shift to a bulk value may occur through the second-order Doppler shift, surface bonding, and the conversion of β-tin to α-tin. However, it is difficult to make the origin clear.

The authors wish to express their thanks to Professor Yukitomo Komura and Dr. Seiji Takeda of Hiroshima University for obtaining electron micrographs. This work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Studies of the Cobalt(III) Complexes of 8-Amino-3,6-diazaoctanate Ion. V.[1] Optical Resolutions and Circular Dichroism Spectra of 8-Amino-3,6-diazaoctanato(glycinato)cobalt(III) Perchlorates

Kiyokatsu WATANABE

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama, Ehime 790

(Received January 31, 1983)

Synopsis. Three optically active isomers, $(+)_{589}$-, $(-)_{589}$-*cis(O)*-, and $(-)_{589}$-*trans(O)*-[Co(adao)(gly)]ClO_4, where adao and gly stand for 8-amino-3,6-diazaoctanate and glycinate, have been obtained. The structures have been determined on the basis of the absorption, circular dichroism, and proton NMR spectra.

All cobalt(III) complexes with 8-amino-3,6-diazaoctanate (adao)[2] are chiral, but the resolution has not been reported except for $[Co(adao)(en)]Cl_2$.[2,3] Therefore, it is significant to obtain the optically active isomers to clarify the relationship between the structures and circular dichroism (CD) spectra.

Experimental

Resolutions. *(1)* $(+)_{589}$- *and* $(-)_{589}$-cis(O)-[*Co(adao)(gly)*]ClO_4: *cis(O)*-[Co(adao)(gly)]ClO_4[4] was transformed into the chloride form by passing the solution through a column of an anion exchanger (Dowex 1-X8, Cl^- form). Orange red crystals pptd. by adding ethanol to the eluate were collected on a filter and washed with ethanol, ether in turn.

The *cis(O)*-[Co(adao)(gly)]Cl (3.28 g) was dissolved in 10 cm^3 of water and then NH_4bcs (1.64 g)[2] was added. The mixture was warmed at 45 °C for 5 min. Orange red crystals appeared were collected, and washed with an ethanol–ether mixture (1 : 1), and ether. The yield of diastereoisomeric salt was 2.07 g. The filtrate (named as F-A) was reserved for the isolation of the antipodal isomer.

The diastereoisomeric salt (2.0 g) was suspended in 20 cm^3 of water, and after adding 5 cm^3 of 6 M (1 M=1 mol dm^{-3}) $HClO_4$, the suspension was heated at 65 °C for 5 min. Orange red crystals appeared were filtered and washed with ethanol. The yield was 1.1 g. After the crystals were extracted with two 10 cm^3 portions of hot water (70 °C), the third extract with 20 cm^3 of hot water was cooled. The crystals deposited from the third extract were collected and washed with ethanol. The optically active isomer showed positive optical rotation at 589 nm. The yield of $(+)_{589}$-*cis(O)*-[Co(adao)(gly)]$ClO_4 \cdot H_2O$ (named as **1a**) was about 0.5 g. Found: C, 23.24; H, 5.10; N, 13.77%. Calcd for [Co(adao)(gly)]$ClO_4 \cdot H_2O = CoC_8H_{20}N_4O_9Cl$: C, 23.40; H, 4.91; N, 13.64%.

The F-A was concentrated to 5 cm^3 at 40 °C. After cooling, the precipitate was filtered off. To the filtrate was added 2 cm^3 of 6 M $HClO_4$, and the mixture was cooled. The crystals deposited were collected and washed with ethanol. The yield was 1.7 g. Recrystallization was carried out with the same method mentioned above. This enantiomer showed negative optical rotation at 589 nm. The yield of $(-)_{589}$-*cis(O)* enantiomer (named as **1b**) was 0.7 g.

(2) $(-)_{589}$-trans(O)-[*Co(adao)(gly)*]ClO_4: By using a similar method mentioned in *(1)*, *trans(O)*-[Co(adao)(gly)]-Cl was obtained from *trans(O)*-[Co(adao)(gly)]ClO_4.[4]

Silver oxide obtained from $AgNO_3$ (0.84 g) and 5 cm^3 of 1 M NaOH was added to a solution of $(+)_{589}$-tartaric acid (0.75 g) in 5 cm^3 of water, and the mixture was stirred at 65 °C for 5 min. To the suspension was added a solution of *trans(O)*-[Co(adao)(gly)]Cl (1.64 g) in 10 cm^3 of water. The mixture was heated at 65 °C for 5 min and cooled.

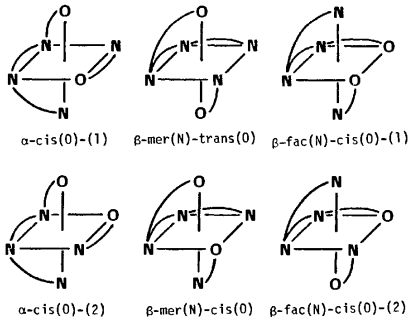

Fig. 1. The possible *Λ* enantiomers of $[Co(adao)(gly)]^+$.

After the removal of AgCl, the filtrate was concentrated to 3 cm^3. The solution was kept in a refrigerator overnight and the precipitate was filtered off. After the addition of a small amount of ethanol, the mixture was left in a refrigerator again for two months, whereupon one large red crystal deposited out. The crystal was separated from the mother liquor, and then washed with ethanol, and ether. The yield of diastereoisomeric salt was 0.8 g.

After the diastereoisomeric salt (0.8 g) was dissolved in 1 cm^3 of water, two drops of 6 M $HClO_4$ were added. Red crystals appeared. After cooling, the crystals were collected and washed with ethanol–ether (1 : 1). The optically active isomer showed negative optical rotation at 589 nm. Furthermore, its absorption (AB) spectrum was exactly the same as that of the racemic *trans(O)*-[Co(adao)(gly)]ClO_4.[4] The yield of $(-)_{589}$-*trans(O)*-[Co(adao)(gly)]ClO_4 (named as **2**) was 0.5 g.

Measurements. The AB and ^1H NMR spectra were recorded with similar methods reported in the previous paper.[1] The optical rotations and CD spectra were measured by a JASCO DIP-180 polarimeter and JASCO MOE-1 spectropolarimeter, respectively.

Results and Discussion

The Structures of [*Co(adao)(gly)*]ClO_4. As glycinate is an unsymmetrical N–O type ligand, $[Co(adao)(gly)]^+$ belongs to a type of $[CoN_4O_2]$. Without consideration of the adao's secondary amine (*s*-N) configurations, $[Co(adao)(gly)]^+$ has twelve optically active isomers (Fig. 1).

In Fig. 2 the AB spectra of **1a**, **1b**, and **2** are shown along with their CD ones. It is known that the first AB band of *trans(O)* isomer is more split than that of *cis(O)* in a type of $[CoN_4O_2]$.[4–6] On the basis of their first AB band shapes, **1a** and **1b** can be assigned to the *cis(O)* structure, and **2**, to the *trans(O)*. From Fig. 1 it is apparent that the adao coordination mode in **2** is the *β-mer(N)*. However, it is difficult to determine the adao coordination modes in **1a** and **1b** from the AB spectra alone. The ^1H NMR spectra of **1a** and **2** showed similar quartet patterns: for **1a**, (1.76, 1.93, 2.69, 2.86 ppm), and for **2**, (1.86, 2.03, 2.83, 3.00 ppm). This indicates that the adao's glycinate ring takes the apical disposition in these isomers,[1,4,7] and that **1a** takes the *α* or the *β-mer(N)* structure,

Table 1. AB and CD spectral data of $[Co(adao)(gly)]ClO_4$

	AB $\tilde{\nu}_{max}/cm^{-1}$ ($\varepsilon/mol^{-1}\,dm^3\,cm^{-1}$)		CD $\tilde{\nu}_{ext}/cm^{-1}$ ($\Delta\varepsilon/mol^{-1}\,dm^3\,cm^{-1}$)

(red)[a]	27870	(153)	28000	(+0.19)

a) Partial resolution.

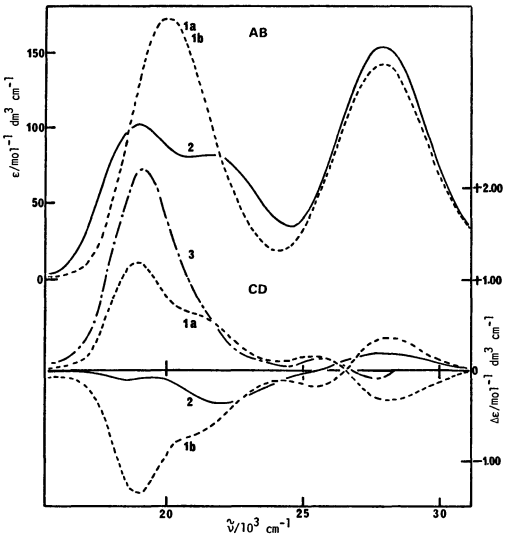

Fig. 2. The absorption (AB) and circular dichroism (CD) spectra.
----: *Λ-β-mer(N)-cis(O)*-$[Co(adao)(gly)]ClO_4$ (**1a**),
----: *Δ-β-mer(N)-cis(O)*-$[Co(adao)(gly)]ClO_4$ (**1b**),
——: *Λ-β-mer(N)-trans(O)*-$[Co(adao)(gly)]ClO_4$ (**2**),
————: *Λ-C$_1$-cis(O)*-$[Co(gly)_2(en)]I$ (**3**).

The CD curve of **1a** in the first AB band region shows two positive peaks (Fig. 2). The CD curve of **1b** is the mirror image to that of **1a**. The fact suggests that **1a** and **1b** are enantiomers. It is well known that the absolute configuration of a cobalt(III) complex with three bidentate ligands, in which each bidentate ligand forms a five membered chelate ring, can be assigned from the sign of major CD peak in the first AB band region, *i.e.*, the *Λ* complex has (+) major CD peak, and the *Δ* complex has (−) one.[8–12] By applying this empirical rule, **1a** and **1b** can be assigned to *Λ* and *Δ* structure, respectively.

The chelate ring pairs of *Λ-α-cis(O)-(1)-* and *Λ-β-mer(N)-cis(O)*-$[Co(adao)(gly)]^+$ are compared with those of *Λ-C$_1$-cis(O)*-$[Co(gly)_2(en)]I$ (named as **3**)[11] having the same *cis(O)*-$[CoN_4O_2]$ chromophore (Fig. 3). **3** and *Λ-α-cis(O)-(1)*-$[Co(adao)(gly)]^+$ have *ΛΛΛ* chelate ring pairs and *Λ-β-mer(N)-cis(O)*-$[Co(adao)(gly)]^+$ has *ΛΔΛΔ* (net **2***Λ*). When **1a** takes the *Λ(ΔΛΔ)-α* structure, its CD strength is expected to be similar to that of **3**. When **1a** takes the *Λ(ΔΛΔΛ)-β-mer(N)* structure, its CD strength is expected to be smaller than that of **3**. The CD strength of **3** is stronger than that of **1a**, as seen in Fig. 2. Therefore, it is appropriate to assign tentatively **1a** to the *Λ(ΔΛΔΛ)-β-mer(N)-cis(O)* structure, and **1b** to the *Δ(ΔΔΔΛ)-β-mer(N)-cis(O)* one.

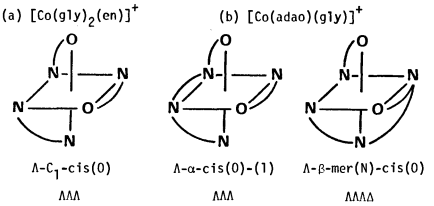

Fig. 3. The comparison of chelate ring pairs among *Λ*-C$_1$-*cis(O)*-$[Co(gly)_2(en)]^+$, *Λ-α-cis(O)-(1)*-$[Co(adao)(gly)]^+$, and *Λ-β-mer(N)-cis(O)*-$[Co(adao)(gly)]^+$.

In the chromatographic separation of reaction product of *β-mer(N)*-$[Co(adao)(Cl)(H_2O)]ClO_4$ and gly,[2] one *trans(O)* (red) and two *cis(O)* (orange red, pink red) racemic isomers were detected. The yield of the orange red isomer was higher than that of the pink red. It was reported that under weak alkaline conditions using *β-mer(N)*-$[Co(adao)(Cl)(H_2O)]ClO_4$ as the starting material, the yield of *α* isomer is lower than that of *β-mer(N)*.[1,7,13] Thus, the orange red *cis(O)* isomer can be assigned to the *β-mer(N)* structure. This chromatographic behavior supports the above assignments for the optically active *cis(O)* isomers.

The CD spectrum of **2** is shown in Fig. 2. From the two negative CD peaks in the first AB band region,[9–12] **2** is assignable to the *Δ(ΔΔΔΛ)* structure. Because of the weak CD strength, however, **2** seems to have been obtained as the partially resolved isomer. These AB and CD spectral data are summarized in Table 1.

The author is indebted to Professor Yoichi Shimura and Professor Kashiro Kuroda for useful suggestions.

The Thermal Decomposition of Manganese(III) Phosphate Monohydrate

Eiichi NARITA* and Taijiro OKABE

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980

(Received February 16, 1983)

Synopsis. Manganese(III) phosphate monohydrate begins to decompose at 200 °C by the dehydration accompanying the reduction of manganese(III) and changes completely to manganese(II) pyrophosphate at 500 °C. The reaction order and activation energy for the reduction process are 1.3 and 176.8 kJ mol^{-1}, respectively.

Manganese(III) phosphate monohydrate was just synthesized by Christensen[1] and is prepared conveniently by the reaction of manganese(III) acetate with phosphoric acid or by the oxidation of manganese(II) nitrate with nitric acid in the presence of phosphoric acid.[1,2] Although manganese(III) phosphate monohydrate is one of the few manganese(III) salts, no information is at present available concerning its properties. It has been reported that manganese(III) phosphate monohydrate loses water of crystallization slowly at 300 to 400 °C and rapidly at a red-heat with the simultaneous loss of oxygen.[2,3] However, this is doubtful. The present authors have shown that manganese(III) phosphate monohydrate precipitates *via.* $[Mn(PO_4)_2]^{3-}$ complex ion by the reduction of manganate(VII) ion in the presence of phosphoric acid and changes to manganese(II) pyrophosphate at 500 °C.[4]

In this study the thermal decomposition of manganese(III) phosphate monohydrate has been investigated by TG and DTA techniques.

Experimental

Material.[1] To a warm solution of 34.2 g of manganese(II) chloride tetrahydrate in 50 cm^3 of water, 30 g of concentrated phosphoric acid (87%) and 10 g of concentrated nitric acid (61%) were added. On concentrating slowly to near dryness, this mixture deposited a green-grey precipitate. After cooling, water was added and the precipitate filtered off, washed and dried overnight in an electric oven in air at 110 °C. According to chemical analyses,[4] the composition of the precipitate was: $Mn^{3+}:PO_4^{3-}:H_2O = 1:1.03:1.13$.

Decomposition Procedure. The thermal decomposition of manganese(III) phosphate monohydrate (32—36 mg) was carried out using a Rigaku Denki Thermoflex high temperature type TG-DTA instrument in air. Ignited α-Al_2O_3 was used as a reference material in the DTA sample block. The heating rate of the furnace was 5—20 deg/min.

Measurement. The X-ray diffraction patterns of the heated products were obtained using a Rigaku Denki Geigerflex 2013 with Ni filtered Cu $K\alpha$ radiation, with 30 kV and 10 mA. The IR absorption spectra were obtained using a Shimadzu I-430 spectrometer with the KBr pellet technique.

Results and Discussion

Thermal Decomposition Process. The TG and DTA curves for manganese(III) phosphate monohydrate are shown in Fig. 1. The weight loss in the heating process was indicated on the TG curve in three steps which corresponded to the endothermic peaks of the DTA curve at 263, 377, and 476 °C, respectively. The X-ray diffraction patterns of four samples obtained at A(110 °C), B(320 °C), C(420 °C), and D(520 °C) in Fig. 1 are shown in Fig. 2. Sample A was typical manganese(III) phosphate monohydrate. Although the pattern of sample B, which was obtained just after the first weight loss, indicated the partial disintegration of the crystal structure and the formation of a small amount of manganese(II) pyrophosphate,[5] it still was similar to that of sample A. Sample C obtained just after the second weight loss was manganese(II) pyrophosphate. The IR spectrum also indicated that it had lost the PO_4^{3-} structure and still contained a large amount of water. In spite of the largest third weight loss, the pattern of sample D was hardly changed in comparison with that of

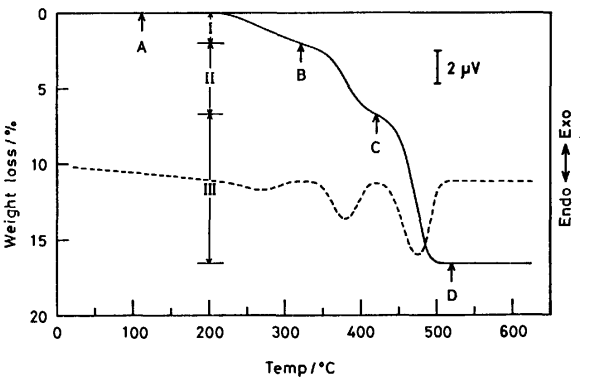

Fig. 1. TG and DTA curves of manganese(III) phosphate monohydrate under an air atmosphere. Heating rate of furnace: 10 (deg/min), sample weight: 32.6 (mg), ——: TG, ----: DTA.

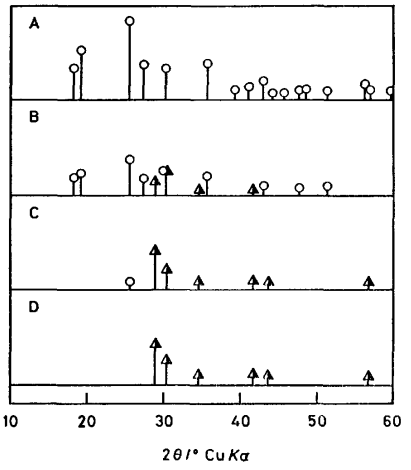

Fig. 2. X-Ray diffraction patterns of the heating products of manganese(III) phosphate monohyrate. A: 110 °C, B: 320 °C, C: 420 °C, D: 520 °C, ○; $MnPO_4 \cdot H_2O$, △: $Mn_2P_2O_7$.

sample C. On the basis of these results, manganese(III) phosphate monohydrate appears to decompose in three steps as follows:

$$MnPO_4 \cdot H_2O \longrightarrow MnPO_4 \cdot (1-x)H_2O + xH_2O\uparrow \quad \text{(Step I)}$$

$$2[MnPO_4 \cdot (1-x)H_2O] \longrightarrow Mn_2P_2O_7 \cdot 2(1-x)H_2O + 1/2\,O_2\uparrow \quad \text{(Step II)}$$

$$Mn_2P_2O_7 \cdot 2(1-x)H_2O \longrightarrow Mn_2P_2O_7 + 2(1-x)H_2O\uparrow. \quad \text{(Step III)}$$

The value of x was 0.25 from the TG curve in Fig. 1. The important feature in this process is that the reduction of manganese(III) phosphate monohydrate occurred even at 400 °C.

Kinetics. On the second weight loss (Step II), *i.e.*, the reduction of manganese(III) to manganese(II), the methods of Freeman-Carroll,[6] Coats-Redfern,[7] and Kissinger[8] were used to study the kinetics. The methods are generally used only when the reaction is a single elementary reaction.

The formula of the Freeman-Carroll method is written as

$$\Delta\log(dW/dt)/\Delta\log Wr = n - E\Delta(1/T)/2.303R(\Delta\log Wr), \quad (1)$$

where dW/dt is the weight change in mg per minute, n the order of the reaction, T the absolute temperature and $Wr = W - Wc$, where W is the weight(mg) at time t and Wc the weight(mg) of the sample at the end of the reaction, E the energy of activation. If the plot of the ratio $\Delta\log(dW/dt)/\Delta\log Wr$ values *vs.* $\Delta(1/T)/\Delta\log Wr$ lie on a straight line, the activation energy and the reaction order will be given by its slope and intercept, respectively. This is illustrated in Fig. 3. As given in Table 1, the reaction order and activation energy obtained by the Freeman-Carroll method were 1.3 and 184.9 kJ mol^{-1}, respectively.

When the reaction order is not 1.0, the formula of the Coats-Redfern method is written as

$$\log\{1-(1-x)^{1-n}/(1-n)T^2\} = \log(AR/\phi E)(1 - 2RT/E) - E/2.303RT, \quad (2)$$

where x is the fraction of reaction, ϕ the heating rate of furnace and A the frequency factor. Graphic representation of the $\log\{1-(1-x)^{1-n}/(1-n)T^2\}$ values as a function of $1/T$ gives a straight line of slope $-E/2.303R$ for the correct value of n. As also illustrated in Fig. 3, a good linear relationship was obtained when the value of n was postulated as 1.3. The activation energy was calculated as 169.4 kJ mol^{-1}.

According to the Kissinger method, the activation energy of the reaction is obtained from the change in peak temperature on the DTA curve when the heating rate of furnace, ϕ, was altered. The formula of the Kissinger method is written as

$$d\{\log(\phi/T_m^2)/d(1/T_m)\} = -E/2.303R, \quad (3)$$

where T_m is the sample temperature, $T_m = T_p - T_h$, where T_p is the absolute temperature of peak, T_h the height of peak(deg). Graphic representation of $\log(\phi/T_m^2)$ as a function of $1/T_m$ gives a straight line of slope $-E/2.303R$. In this experiment ϕ was altered as 5, 10, and 20 °C/min. A straight line of slope 9.20 was obtained and the activation energy was calculated as 176.1 kJ mol^{-1}.

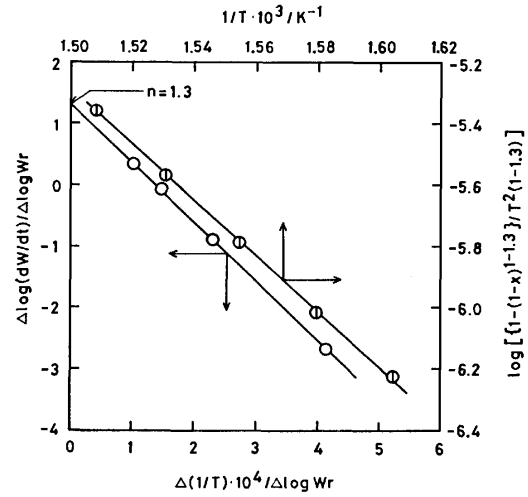

Fig. 3. Freeman-Carroll and Coats-Redfern straight lines for the thermal decomposition (reduction: Step II) of manganese(III) phosphate monohydrate.
○: Freeman-Carroll plots, ⓘ: Coats-Redfern plots.

Table 1. Reaction order and activation energy of the thermal decomposition (reduction: Step II) of manganese(III) phosphate monohydrate

Method	Activation energy / kJ mol^{-1}	Reaction order
Freeman-Carroll (TG)	184.9	1.3
Coats-Redfern (TG)	169.4	1.3
Kissinger (DTA)	176.1	—
Average	176.8	1.3

As can be seen in Table 1, the kinetics parameters obtained by the three methods agreed well with each other and the average reaction order and activation energy were 1.3 and 176.8 kJ mol^{-1}, respectively. On the first and third weight losses (Steps I and III), *i.e.*, the dehydration, the above analytical methods could not be used. However, it was found that a large part of the water of crystallization was lost after the reduction of manganese(III) to manganese(II) and the dehydration was completed at about 500 °C.

Halogenation of Mixed Ligand Cobalt(III) Complexes with 12- or 13-Membered Tetraaza Macrocycle and Acetylacetone, $[Co[Z]aneN_4(acac)](ClO_4)_2$ ($Z=12$, 13)

Akira HIRANO, Naohide MATSUMOTO,* and Akira OHYOSHI

Department of Industrial Chemistry Faculty of Engineering, Kumamoto University, Kurokami 2-39-1, Kumamoto 860

(Received March 11, 1983)

Synopsis. The parent cobalt(III) complex $[Co[12]aneN_4(acac)](ClO_4)_2$, $[Co[12]aneN_4(bzac)](ClO_4)_2$, or $[Co[13]aneN_4(acac)](ClO_4)_2$ reacts with *N*-halogenosuccinimide to give the substituted complex $[Co[12]aneN_4(Xacac)](ClO_4)_2$, $[Co[12]aneN_4(Xbzac)](ClO_4)_2$, or $[Co[13]aneN_4(Xacac)](ClO_4)_2$, where $[12]aneN_4$=1,4,7,10-tetraazacyclododecane, $[13]aneN_4$=1,4,7,10-tetraazacyclotridecane, acac=acetylacetonato, bzac=benzoylacetonato, X=Cl, Br.

Kuroda and coworkers[1,2] have studied the halogenation and nitration of $[CoA_4(acac)]^{2+}$ and succeeded to prepare the halogenated and nitrated complexes $[CoA_4(Xacac)]^{2+}$, where $A_4=(NH_3)_4$, (ethylenediamine)$_2$, 3,6-diazaoctane-1,8-diamine. Previously we reported the synthesis, spectral characterization, and X-ray analysis of $[Co[12]aneN_4(acac)](ClO_4)_2$ and its brominated complex $[Co[12]aneN_4(Bracac)](ClO_4)_2$, in which the cobalt ion is coordinated in a distorted octahedral fashion to four nitrogen atoms of $[12]aneN_4$ and two oxygen atoms of the acetylacetonato moiety in a cis position.[3] As an extension of the study, we wish to report the synthesis and spectral characterization of the halogenated complexes $[Co[Z]aneN_4(Xacac)](ClO_4)_2$ and $[Co[12]aneN_4(Xbzac)](ClO_4)_2$ ($Z=12$, 13; X=Cl, Br).

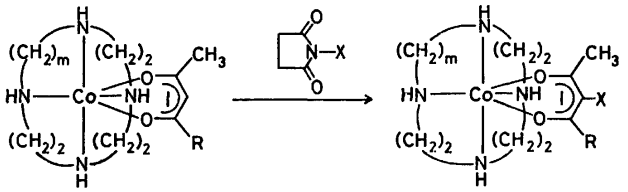

Fig. 1. Synthetic scheme and abbreviations of complexes $[Co[Z]aneN_4(Xacac)]^{2+}$: $Z=12$ ($m=2$), $Z=13$ ($m=3$), X=H, C, Br, R=CH_3; $[Co[12]aneN_4(Xbzac)]^{2+}$: X=H, Cl, Br, R=$C_6H_5$.

Experimental

Measurements. Infrared spectra were recorded as KBr disks on a Shimadzu IR-410, while visible and ultraviolet spectra were measured in aqueous solutions on a Hitachi recording spectrophotometer 323. Conductivity measurements were carried out by a Denki Kagaku AOC-10 at *ca.* 10^{-3} mol dm^{-3} in aqueous solutions at room temperature. The 100 MHz ^{1}H NMR spectra were recorded by a JEOL MH 100 spectrometer at room temperature. The solvent used was deuterium oxide and shift measurements were made relative to 3-(trimethylsilyl)-1-propanesulfonic acid sodium salt.

Syntheses. The macrocyclic ligands, 1,4,7,10-tetraazacyclododecane ($[12]aneN_4$) and 1,4,7,10-tetraazacyclotridecane ($[13]aneN_4$) were prepared according to the high yield synthetic method of Raymond *et al.*[4] which was applied for the synthesis of $[16]aneN_4$. The unsubstituted (parent) complexes $[Co[12]aneN_4(acac)](ClO_4)_2$ and $[Co[12]aneN_4(bzac)](ClO_4)_2$ were prepared by the reaction of $[Co[12]aneN_4CO_3]ClO_4$ and acetylacetone or benzoylacetone according to a similar method described previously.[3] The complex $[Co[13]aneN_4(acac)](ClO_4)_2$ was prepared by the reaction of cis/trans mixture of $[Co[13]aneN_4Cl_2]ClO_4$[5] and acetylacetone. To a solution of 2.0 g of cis/trans mixture of $[Co[13]aneN_4Cl_2]ClO_4$ in 10 cm^3 of water is added a solution of 1.5 cm^3 of acetylacetone in 10 cm^3 of 1 M NaOH. The solution was stirred at *ca.* 50 °C for 2 h. After the addition of several drops of 6 M $HClO_4$, the solution was left at room temperature to precipitate red crystals. They were collected and recrystallized from a dilute $HClO_4$ solution. The substituted complexes $[Co[Z]aneN_4(Xacac)](ClO_4)_2$ and $[Co[12]aneN_4(Xbzac)](ClO_4)_2$ ($Z=12$, 13; X=Cl, Br) were prepared according to a similar method of Kuroda *et al.* which was used for the preparation of $[CoA_4(Xacac)](ClO_4)_2$.[1,2]

Results and Discussion

The elemental analytical data for C, H, and N, along with the molar electrical conductances are given in Table 1. The molar electrical conductances are in the range of 197—236 S cm^2 mol^{-1} and these values are in the expected range for the 1:2 electrolytes,[6] and consistent with the formula of $[Co[Z]aneN_4(Xacac)]^{2+}$.

Spectral data of infrared, ^{1}H NMR, and electronic spectra are summerized in Table 2. The infrared spectra of unsubstituted complexes exhibit two strong bands in the region of 1500—1600 cm^{-1}, which are assignable to ν(C=O) and ν(C=C). On the other hand, the substituted complexes have only one band in the region. This spectral feature has been found in the well-characterized complexes such as $[M(Xacac)_3]$ (M=Cr^{3+}, Co^{3+}; X=H, Cl, Br, I),[7] providing an evidence of the substitution. Busch *et al.*[5] have shown that the infrared bands in the CH_2 rocking region (800—910 cm^{-1}) can be used to distinguish cis from trans isomers of $[Co[13—16]aneN_4CO_3]^+$. The infrared spectra of the present complexes $[Co[13]aneN_4(Xacac)](ClO_4)_2$ (X=H, Cl, Br) are in accord with the formation of the cis complexes.

The ^{1}H NMR spectra were measured to verify the substitution on the γ-carbon of the acetylacetonato residue. The methine proton resonance about 6.5 ppm of the unsubstituted complexes disappeared in the halogenated complexes, providing further evidence of the substitution on the γ-position. The methyl proton resonance around 2.3 ppm of the unsubstituted complexes shifted to lower magnetic field upon the substitution.

Some of the electronic spectra are shown in Fig. 2. Electronic spectra are quite similar to each other

Table 1. Elemental analytical data for C, H, and N, along with the molar electrical conductances

	Complex	C (%) Found (Calcd)	H (%) Found (Calcd)	N (%) Found (Calcd)	Conductance $S^{-1}\,mol^{-1}\,cm^2$

a) Evaluated by $10Dq^{av}=\nu^1T_{1g}\leftarrow{}^1A_{1g}+3800$.[5]

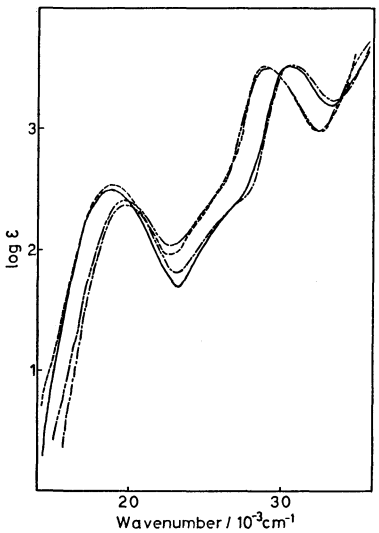

Fig. 2. Electronic spectra of $[Co[12]aneN_4(acac)](ClO_4)_2\cdot H_2O$ (——), $[Co[12]aneN_4(Bracac)](ClO_4)_2\cdot 0.5H_2O$ (·····), $[Co[13]aneN_4(acac)](ClO_4)_2\cdot 0.5H_2O$ (—·—), and $[Co[13]aneN_4(Bracac)](ClO_4)_2$ (—··—).

and to the related low-spin six-coordinated cobalt(III) complexes, such as $[CoA_4(Xacac)]^{2+}$.[1,2] The spectra exhibit two bands attributable to the d-d transitions, $^1T_{1g}\leftarrow{}^1A_{1g}$ and $^1T_{2g}\leftarrow{}^1A_{1g}$, in which the latter band appeared as shoulder. The average ligand field strength Dq^{av} can be evaluated to be 2250 and 2350 cm^{-1} for the 12- and 13-membered complexes, respectively. The data indicated that the ligand $[13]aneN_4$ provides a stronger ligand field than $[12]aneN_4$ does, being consistent with the result of $[Co[12—13]-aneN_4CO_3]^+$.[5] The spectra exhibit also a specific band attributable to the charge-transfer band from metal t_{2g} to ligand π^* orbital.[8] The specific band shifted to lower wave number upon the substitution, while the d-d transitions showed no shift.

(Received March 26, 1983)

Synopsis. The crystal and molecular structure of the title complex has been determined by X-ray analysis. It has been found that the *cis*-N_2O_4 octahedron about the cobalt(III) has a large distortion caused by the steric compression between the two adjacent *N*-methyl groups.

Recently, the *u-fac* bis(*N*-methyliminodiacetato)cobaltate(III) complex, *u-fac*-$[Co(mida)_2]^-$, was newly prepared and characterized.[1] It was expected that the steric repulsion between the two adjacent *N*-methyl groups would result in the large distortion into the *cis*-N_2O_4 coordination geometry about the Co atom. Indeed, the first absorption-band maximum of the complex was observed at a considerably lower energy than those of the *u-fac*-$[Co(ida)_2]^-$,[2] $[Co(edta)]^-$, and $[Co(1,3\text{-pdta})]^-$.[3] The *u-fac*-$[Co(mida)_2]^-$ decomposes easily in a basic aqueous solution, and the ligand decomposes.[1] In this note, we wish to report the results of the determination of the crystal and the molecular structure of the title compound. The highly strained *cis*-N_2O_4 geometry is compared with those related ones reported previously.

Experimental

Blue crystals were grown from an aqueous solution by adding methanol.[1] The cell dimensions and reflection intensities were measured on a SYNTEX-R3 diffractometer using Mo $K\alpha$ radiation(λ=0.7107 Å). The crystal data are as follows: $C_{10}H_{17}O_{9.5}N_2KCo$, M=415.3, monoclinic, a=29.057(3), b=7.144(1), c=15.783(2) Å, β=111.67(4)°, space group C2/c, D_m=1.80 g cm^{-3}, Z=8, D_c=1.81 g cm^{-3}. The intensity data were collected by the ω-scan technique up to 2θ=55°. The crystal used had approximate dimensions of 0.3×0.3×0.3 mm^3. A total of 2370 reflections were obtained, of which 2127 were non-zero reflections($|F_o| > 3\sigma(F_o)$). No corrections for absorption and extinction were made(μ(Mo $K\alpha$)=15.0 cm^{-1}).

Structure Determination and Refinement

The structure was solved by the heavy-atom method and refined by the block-diagonal least-squares method. The R-value was finally reduced to 0.038 for 2127 reflections. The weighting scheme used was $w=(\sigma_{cs}^2+a|F_o|+b|F_o|^2)^{-1}$, where σ_{cs} is the standard deviation for each reflection; the a and b values were 0.2 and 0.0009. The final positional parameters and equivalent isotropic temperature factors for non-hydrogen atoms are listed in Table 1.[4]

Results and Discussion

The structure viewed down the pseudo-two-fold axis of the complex molecule is shown in Fig. 1 (ORTEP program[5]), while that projected on the N_2O_2 plane is shown in Fig. 2, along with the selected bond distances and angles.[6] In the complex molecule, both *N*-methyliminodiacetato groups act as terdentate ligands and form a distorted *cis*-N_2O_4-type octahedron about the cobalt atom. The nonbonded short contact between the two adjacent methyl groups is 3.438(7) Å. This value is comparable with the intramolecular nonbonded $-CH_3\cdots H_3C-$ contact, 3.466(8) Å, observed in $[Co(NH_2CH_3)_5Cl](NO_3)_2$.[7] Recently, the nonbonded short contact of the $-CH_3$ group has aroused some interest in relation to the CH/π interactions.[8] The present result indicates that the minimum radius

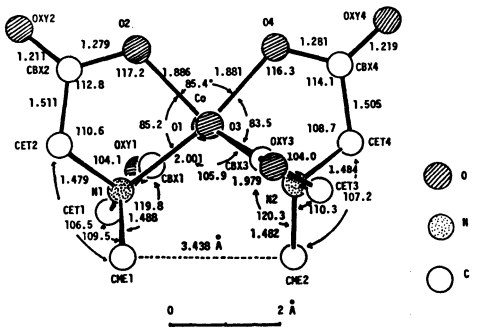

Fig. 2. The molecular structure projected on the N_2O_2 plane.

of the $-CH_3$ group in side contact is 1.72 Å. The Co–N–C(methyl) angles, 119.8(3)° for N1 and 120.3 (3)° for N2, are considerably larger than the tetrahedral value. If the tetrahedral angle around the nitrogen atoms is assumed (109.5°), the CME1···CME2 contact falls at 3.16 Å. Therefore, the relaxation of CME1···CME2 steric repulsion comes from three factors: (1) the elongation of the Co–N bonds, (2) the increase in the N–Co–N angle, and (3) the increase in the Co–N–C(methyl) angles.

The geometrical parameters of the N_2O_2 plane(N1, N2, O2, and O4) are listed in Table 2, along with the previously reported values of the related complexes: $NH_4[Co(edta)]\cdot 2H_2O$,[9] $K[Co(1,3\text{-pdta})]\cdot 2H_2O$,[10] and *u-fac*-$K[Co(ida)_2]\cdot 2.5H_2O$.[11] The values of the first absorption maxima of these complexes are also listed in Table 2. In the equatorial N_2O_2 plane, a gradual increase in the N–Co–N angle and a gradual decrease in the O–Co–O angle are observed in these *cis*-N_2O_4-type structures. The observed red shift in the first absorption maximum from $[Co(edta)]^-$ to *u-fac*-$[Co(mida)_2]^-$ reflects the distortion about the cobalt atom.

Oxidation of 9-Xanthenones with Lead(IV) Acetate. Formation of Di-γ-lactones

Hiroshi NISHINO* and Kazu KUROSAWA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860

(Received October 2, 1982)

Synopsis. The oxidation of 9-xanthenones with lead (IV) acetate afforded 3a,3b,6a,12b-tetrahydro-2*H*-difuro[3,2-*a*:3′,2′-*c*]xanthene-2,5,7(3*H*,6*H*)-triones in addition to other products. Characterization of the di-γ-lactones and the difference between the oxidation reaction of lead(IV) and manganese(III) acetates in the 9-xanthenone system are discussed.

Recently, we have reported that the oxidation of 9-xanthenones with manganese(III) acetate (MTA) affords carboxy-, carboxymethyl-, acetoxymethyl-, and diacetoxymethyl-9-xanthenones, and that carboxyl groups are preferentially introduced at the peri positions of the 9-xanthenones.[1] This regioselectivity was explained in terms of complexation between substrate and MTA.[1] In connection with the MTA oxidation, we have investigated the oxidation of 9-xanthenones with lead(IV) acetate (LTA)[2] to give di-γ-lactones, carboxymethyl, acetoxymethyl, and methyl derivatives.

When 9-xanthenone (**1a**) was oxidized with LTA for 3.2 h, di-γ-lactone (**2a**; 22%), 1-carboxymethyl-9-xanthenone (**3a**; 3%), 4-carboxymethyl-9-xanthenone (**4a**; 8%), 4-carboxymethyl-1-methyl-9-xanthenone (**5a**; 1%), 1-acetoxymethyl-9-xanthenone (**7a**; 1%), 4-acetoxymethyl-9-xanthenone (**8a**; 1%),[1] and 1-methyl-9-xanthenone (**10a**; 2%) were obtained. The com-

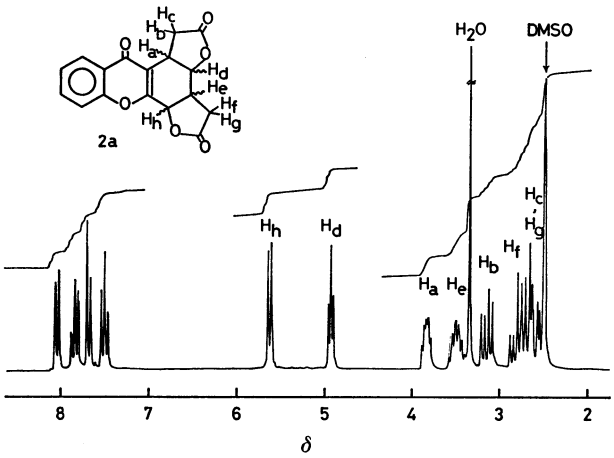

Fig. 2. ^{1}H-NMR spectrum of di-γ-lactone (**2a**) in DMSO-d_6 (δ ppm, 200 MHz).

pound (**2a**) showed a parent ion peak at *m/e* 312 in the MS spectrum, and strong IR absorption bands at 1775 and 1640 cm^{-1} in KBr. The ^{1}H-NMR spectrum (200 MHz) of **2a** in DMSO-d_6 is shown in Fig. 2. Decoupling the triplet at δ=4.95 (H_d) collapsed the multiplet at δ=3.85 (H_a) to four peaks. Decoupling the H_a collapsed the triplet of H_d and two double doublets at δ=3.15 (H_b) and 2.64 (H_c) to three doublets. When the multiplet at δ=3.50 (H_e) was decoupled, the doublet at δ=5.64 (H_h), the triplet (H_d), the double doublets at δ=2.82 (H_f) and 2.64 (H_g) were collapsed to a sharp singlet and three doublets, respectively. The coupling constants are as follows: J_{ab}=8.8, J_{ac}=4.4, J_{bc}=17.8, J_{ad}=5.9, J_{de}=4.9, J_{ef}=8.3, J_{eg}=4.4, J_{fg}=17.3, and J_{eh}=7.3 Hz. In the ^{13}C-NMR spectrum of **2a** seventeen peaks appeared. In addition, **2a** (44 mg) was hydrolyzed with 50% KOH–ethanol, then treated with 3 M (1 M= 1 mol dm^{-3}) sulfuric acid, followed by methylation to give 1,3-bis(methoxycarbonylmethyl)-4-methoxy-9-xanthenone (**11a**; 16 mg, 31%). It is known that the addition of a $\cdot CH_2COOH$ radical to olefins occurs by cis-addition.[3] Therefore, the γ-lactone rings of **2a** may add cis to the cyclohexene ring. From the results described above the structure of **2a** was deduced to be 3a,3b,6a,12b-tetrahydro-2*H*-difuro[3,2-*a*:3′,2′-*c*]-xanthene-2,5,7(3*H*,6*H*)-trione, though the configurations at C-3a, 3b, 6a, and 12b could not be determined.

The oxidation of 1-methoxy-3-methyl-9-xanthenone (**1b**) with LTA for 2.5 h gave 11-acetoxymethyl-8-methoxy-10-methyl-3a,3b,6a,12b-tetrahydro-2*H*-difuro-[3,2-*a*:3′,2′-*c*]xanthene-2,5,7(3*H*,6*H*)-trione (**2b**; 6%), 4-carboxymethyl-1-methoxy-3-methyl-9-xanthenone (**4b**; 3%), 5-carboxymethyl-1-methoxy-3-methyl-9-xanthenone (**4b′**; 1%),[1] 5-carboxymethyl-4-hydroxymethyl-1-methoxy-3-methyl-9-xanthenone (**6b**; 5%), 4-acetoxymethyl-1-methoxy-3-methyl-9-xanthenone (**8b**; 12%),[1] 4-acetoxymethyl-1-methoxy-3,8-dimethyl-9-xanthenone (**9b**; 1%), and 1-methoxy-3,8-dimethyl-9-

xanthenone (**10b**; 1%).

It is known that LTA decomposes in acetic acid to yield $\cdot CH_3$ radicals[4] which react with acetic acid to afford $\cdot CH_2COOH$ radicals.[5] The $\cdot CH_2COOH$ radicals attack aromatic compounds and the CH_2-COOH group is then introduced; this is also converted into a CH_2OAc group.[5] Therefore, these groups are substituted at the positions ortho or para to electron-donating groups because of the electrophilic nature of $\cdot CH_2COOH$ radicals.[6] $\cdot CH_3$ radicals also attack 9-xanthenones to yield methylated products, which can be further oxidized with LTA to give acetoxymethyl-9-xanthenones.[5] In MTA oxidation, on the other hand, $\cdot CH_2COOH$ radicals predominantly attack the peri positions regardless of the effect of the electron-donating groups.[1] However, in the present LTA oxidation such a tendency was not observed and the yields of products were not so good as those in MTA oxidation. Consequently, the interaction between the substrate and oxidant which was assumed in MTA oxidation is not important in LTA oxidation.[1] It is known that the reaction of olefins with LTA gives γ-lactones.[3] The present reaction is, however, the first example that $\cdot CH_2COOH$ radicals add to the aromatic rings to give di-γ-lactones.

Experimental

Measurements. The ^{1}H-NMR spectra were recorded on a Hitachi Perkin-Elmer R-24 spectrometer (60 MHz) in $CDCl_3$ and a JEOL FX-200 spectrometer (200 MHz), while the ^{13}C-NMR spectrum was measured on a JEOL FX-90Q spectrometer. The IR spectra were taken on a JASCO IRA-1 grating spectrometer in $CHCl_3$. The Mass spectra were measured on a JEOL DX-300 mass spectrometer. The UV spectra were recorded for methanol solution with a Hitachi EPS-3T spectrophotometer. The melting points were determined with a Yanagimoto micromelting point apparatus and were not corrected.

Oxidation of 9-Xanthenones. A mixture of 9-xanthenone (**1a** or **1b**; 1 mmol), LTA (5 mmol), and acetic acid (25 ml) was heated under reflux. The work-up procedure including the esterification of the acidic products was the same as described elsewhere.[1] The yields are based on the amount of substrate consumed.

2a: Mp 281—283 °C (EtOH); λ_{max} nm (log ε), 231 (4.28), 253^{sh} (3.95), 268^{sh} (3.73), 307 (3.80); ^{1}H-NMR δ= 2.64 (1H, dd, J=17.3, 4.4 Hz, H_c or H_g), 2.65 (1H, dd, J=17.8, 4.4 Hz, H_c or H_g), 2.82 (1H, dd, J=17.3, 8.3 Hz, H_f), 3.15 (1H, dd, J=17.8, 8.8 Hz, H_b), 3.50 (1H, m, H_e), 3.85 (1H, m, H_a), 4.95 (1H, t, H_d), 5.46 (1H, d, J=7.3 Hz, H_h), 7.5—8.1 (4H, m, ArH); ^{13}C-NMR δ=30.2 (t, CH_2), 31.4 (d, CH), 34.3 (t, CH_2), 36.1 (d, CH), 72.5 (d, H–C–O), 75.7 (d, H–C–O), 117.3 (d, ArC), 118.3 (s, ArC), 122.5 (s, ArC), 125.0 (d, ArC), 125.7 (d, ArC), 134.8 (d, ArC), 155.5 (s, C=), 156.0 (s, C=), 174.6 (s, C=O), 175.3 (s, C=O), 176.3 (s, C=O); *m/e* 312 (96), 268 (100), 226 (64), 197 (43). (Received December 23, 1982)

Synopsis. Partial benzylation of methyl α-D-galactopyranoside with benzyl chloride and LiOH selectively gave the 2,3,6-tribenzyl ether, while that using KOH or RbOH gave the 2,4,6-isomer as the main product. Methyl β-D-galactopyranoside afforded the 3,4,6-tribenzyl ether predominantly, irrespective of the alkali used.

Synthetic studies of oligosaccharides require the preparation of partially benzylated carbohydrates.[1] Such compounds have often been prepared by kinetic benzylation[2] of unprotected glycosides.[3,4b] This paper will deal with a direct partial benzylation of methyl α- and β-D-galactopyranosides (**1** and **6**) and the dependence of the selectivity upon the alkali used and the anomeric configuration of the substrates.

The kinetic tribenzylation of **1** was carried out using benzyl chloride and a variety of alkalis (Table 1). The benzylation using excess LiOH (8 equiv.) for 9 h at 140 °C gave methyl 2,3,6-tri-*O*-benzyl-α-D-galactopyranoside (**3**) in a 52% yield, together with small amounts of the other tribenzyl ethers (**4** and **5**). This result contrasts with the observation that the reactivity

a) Twenty parts of benzyl chloride was used. b) The reactions were conducted in 0.2—0.3 mmol scale.

of the axial OH-4 is higher than the equatorial OH-3 in the partial benzylation of methyl 2,6-di-*O*-benzyl-α-D-galactopyranoside (**11**) and methyl 6-deoxy-α-L-galactopyranoside with benzyl bromide and NaH in *N*,*N*-dimethylformamide.[4] The use of NaOH, KOH, or RbOH, however, changed the selectivity of the reaction to produce the 2,4,6-tribenzyl ether **4** predominantly. Its maximized yield was 42% for the reaction using RbOH (4.5 equiv.) for 3 h at 70 °C. Controlled benzylation with a limited amount of alkali formed the 2,6-, the 3,6-, and the 4,6-dibenzyl ethers (**11**, **12**, and **13**), whose yields depended on the alkali used: 10, 9, and 1% for LiOH (4.0 equiv.) and 4, 6, and 8% for RbOH (2.5 equiv.) Furthermore, the selectivity in the monobenzylation of these dibenzyl ethers was also dependent upon the alkali used (Table 1). Thus, the equatorial OH-3 of **11** and the OH-2 of **12** were selectively benzylated with LiOH, while the axial OH-4 of **11** and **12** were selectively benzylated with RbOH.

Partial benzylation of **6** gave the 3,4,6-tribenzyl ether (**10**) as the main product, irrespective of the alkali used; the best of the alkalis was KOH (Table 1). The controlled benzylation of **6** using KOH (2.0 equiv.) afforded the 2,6- 3,6-, and 4,6-dibenzyl ethers (**14**, **15**, and **16**) in 5, 15, and 12% yields: the lower reactivity of OH-2 of **6** is similar to that of OH-3 of the α-gluco- and the α-xylopyranosides,[3] both of which are located at the center of three contiguous equatorial hydroxyl groups. The OH-2 of **15** and **16** were also less susceptible to benzylation.

The structure of the tri- and the dibenzyl ethers were determined by examining ^{1}H NMR spectra of their acetates (Table 3). The new dibenzyl ethers were synthesized *via* alternative routes.

Experimental

General. See the previous papers.[3] LiOH·H_2O and **1**·H_2O (Pfanstiehl) were dehydrated *in vacuo* at 105 and

80 °C over P_2O_5.

*Procedure for the Partial Benzylation of Methyl α- and β-D-Galactopyranosides (**1** and **6**).* A mixture of **1** or **6** (1.0 g, 5.2 mmol) freshly crushed alkali, and $PhCH_2Cl$ (20 ml) was stirred under anhydrous conditions. After the usual work-up,[3)] chromatography (toluene:2-butanone=100:1→1:1, gradient) of the reaction mixture gave the totally and the partially benzylated derivatives of **1** or **6** (Table 1). Physical and analytical data of the tribenzyl ethers (**3**—**5** and **8**—**10**) and dibenzyl ethers (**11**—**16**) are listed in Table 2. The ^{1}H NMR data for the acetylated compounds derived from the tri- and dibenzyl ethers as well as the diallyl ethers desctibed below through the treatment with acetic anhydride in pyridine are given in Table 3.

*Methyl 2,6-Di-O-benzyl-α-D-galactopyranoside (**12**).* Methyl 3,6-di-*O*-trityl-α-D-galactopyranoside[5)] (0.75 g, 1.1 mmol) was refluxed in allyl bromide (7.5 ml) containing NaH (≈60% disp., 0.52 g) for 4 h. The filtrate of the reaction mixture was evaporated and heated in aq. AcOH (80%) at 100 °C for 1 h. After evaporation, chromatography (toluene:2-butanone=2:1) and recrystallization from toluene containing diisopropyl ether gave methyl 2,4-di-*O*-allyl-α-D-galactopyranoside (**18**), (0.22 g, 73%): mp 129.5—130 °C; $[\alpha]_D^{20}$ +123° (*c* 0.7, $CHCl_3$). Found: C, 57.03; H, 8.16%. Calcd for $C_{13}H_{22}O_6$: C, 56.92; H, 8.08%. Benzylation of **18** (0.22 g, 0.80 mmol) with $PhCH_2Cl$ (4.4 ml) and KOH (0.90 g) at 100 °C for 4.5 h, followed by chromatography (toluene:2-butanone=30:1), yielded the 2,3-diallyl-4,6-dibenzyl ether. This was then treated with chlorotris(triphenylphosphine)rhodium(I)[6)] (214 mg) in a mixed solvent (EtOH:benzene:H_2O=7:3:1, 22 ml) for 26 h, followed by refluxing in a mixture of aq HCl (1 mol dm^{-3}, 0.8 ml) and acetone (20 ml) for 30 min. After evaporation, chromatography (diisopropyl ether:ethyl acetate=7:1) afforded **12** (0.24 g, 80%).

*Methyl 4,6-Di-O-benzyl-α-D-galactopyranoside (**13**).* Methyl 4,6-*O*-benzylidene-α-D-galactopyranoside[7)] (1.4 g, 5 mmol) was refluxed in allyl bromide (35 ml) containing NaH (≈60% disp., 1.6 g) for 2 h. The filtrate of the reaction mixture was evaporated and heated in aq AcOH (80%) at 100 °C for 30 min. After evaporation, chromatography ($CHCl_3$:MeOH=50:1) gave methyl 2,3-di-*O*-allyl-α-D-galactopyranoside (**17**), (0.70 g, 51%): $[\alpha]_D^{20}$ +119° (*c* 4.4, $CHCl_3$). Found: C, 56.51; H, 8.14%. Calcd for $C_{13}H_{22}O_6$: C, 56.92; H, 8.08%. Compound **17** (0.45 g, 1.64 mmol) was benzylated with $PhCH_2Cl$ and KOH, and subsequently deallylated as described above to give **13** (0.36 g, 59%).

*Methyl 4,6-Di-O-benzyl-β-D-galactopyranoside (**16**).* Methyl 4,6-di-*O*-benzylidene-β-D-galactopyranoside[8)] (80 mg, 0.28 mmol) was similarly converted into methyl 2,3-di-*O*-allyl-β-D-galactopyranoside (**19**), (70 mg, 91%): $[\alpha]_D^{20}$ +1.7° (*c* 1.1, $CHCl_3$). Found: C, 56.50; H, 8.14%. Calcd for $C_{13}H_{22}O_6$: C, 56.92; H, 8.08%. Benzylation of **19** (70 mg, 0.26 mmol) and subsequent deallylation gave **16** (65 mg, 68%).

The Laser-flash Photolysis of 2-Hexanone and 5-Methyl-2-hexane for the Direct Detection of the Triplet 1,4-Biradical

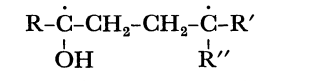
Ikuo NAITO

Department of Photography Kyushu Sangyo University, Matsugadai, Higashi-ku, Fukuoka 813

(Received December 23, 1982)

Synopsis. In the laser-flash photolysis of 2-hexanone and 5-methyl-2-hexanone (265 nm, 15 ns pulse), triplet 1,4-biradicals were detected directly. The absorption spectrum exhibits absorption maxima at $\lambda=250$ nm and at $\lambda=320$ nm. The decay-rate constant of the 1,4-biradical increases as follows: in methanol < in acetonitrile < in hexane < in dichloromethane [$(2—4)\times10^7$ s^{-1} (2-hexanone), $(3—6)\times10^7$ s^{-1} (5-methyl-2-hexanone)].

There have been many reports on the laser-flash photolysis of aromatic carbonyl compounds, and some transient species, *i.e.*, triplet-state and triplet 1,4-biradical intermediates on the Norrish Type-II reaction, have been identified. In the case of aliphatic caybonyl compounds, triplet 1,4-biradicals formed from 2-pentanone,[1] pentanal,[2] and 2-substituted cyclohexanone,[3] were trapped by HBr (gas phase)[1] and paraquat ions.[2,3]



(Triplet 1,4-biradical)

Recently, the triplet states of propanone,[4,5] butanone,[5] and 2-pentanone[5] and the triplet 1,4-biradical formed from poly(3-buten-2-one)[5] were detected. The photolysis of 2-hexanone and 5-methyl-2-hexanone are accepted as proceeding predominantly through the Norrish Type-II mechanism.[6] The laser-flash photolysis of these compounds were carried out in order to detect the triplet 1,4-biradical, directly.

Experimental

Materials. The 2-hexanone and 5-methyl-2-hexanone were dried on anhydrous sodium sulfate and distilled three times by using a splitting-tube column.

The dichloromethane (for fluorescence spectroscopy) was washed five times with a 5% sodium carbonate solution and five times with distilled water. After drying on calcium chloride, the dichloromethane was distilled twice by using the splittingtube column.

The acetonitrile (for spectroscopy) was purified by refluxing it five times on diphosphrus pentaoxide for ten hours and was then distilled twice by using the splitting-tube column.

The hexane (for fluorescence spectroscopy) was washed five times with sulfuric acid and five times with distilled water. After drying on calcium chloride and calcium hydride, the hexane was distilled twice by using the splitting-tube column.

The methanol (for spectroscopy) was purified by refluxing on a magnesium metal for one night and distilled twice by using the splitting-tube column.

The *cis*-1,3-pentadiene was used after two distillations.

Apparatus. The Nd laser apparatus has been described before (265 nm, 15 ns pulse).[7] The output of this laser apparatus was about 100 mJ. The intensity of the laser light was determined by means of the cycloreversion reaction of *r*-1,*t*-2,*t*-3,*c*-4-tetraphenylcyclobutane in 1-chlorobutane ($\phi=0.34$). Normal flashed photons: 2.0×10^{-8} einstein per flash. By choosing an appropriate solute concentration, the optical density was kept at 0.5 (*ca.* 3.0×10^{-2} mol dm^{-3}). The measured emission and absorption spectra were calibrated by the normal number of photons per flash.

Results and Discussion

The Nd laser-flash photolysis of 2-hexanone and 5-methyl-2-hexanone were carried out in dichloromethane in order to detect the triplet 1,4-biradical intermediate. Immediately after the flash, emission (fluorescence) and transient absorption spectra were monitored in the wavelength ranges from 300 nm to 540 nm and from 230 nm to 400 nm respectively. The transient absorption spectrum exhibits absorption maxima at $\lambda=250$ nm and at $\lambda=320$ nm, as it shows in Fig. 1. The triplet absorption spectra of propanone, butanone, and 2-pentanone do not exhibit a minor absorption maximum at $\lambda=320$ nm.[4,5] The acetyl radical absorbed the light in the wavelength range from 500 nm to 600 nm.[5,8] The measured spectra do not agree with those of the triplet state and acetyl radical. The transient absorption decay obeys first order kinetics, and its decay rate (k) is constant over all the wavelength ranges monitored [$k=3.9\times10^7$s^{-1} (2-hexanone), 6.0×10^7 s^{-1} (5-methyl-2-hexanone)]. Figure 2 shows the effect of absorbed photons on the transient absorption in methanol. Although the transient absorbance increases with the quantity of absorbed photons, k is independent of the quantity of absorbed photons.

The laser-flash photolysis were carried out in the presence of a triplet quencher, *cis*-1, 3-pentadiene[$(0.2-1.0)\times10^{-2}$ mol dm^{-3}]. The transient absorbance of 2-hexanone decreased with the quencher concentration. The quenching rate ($k_g\tau_T$) of 2-hexanone was de-

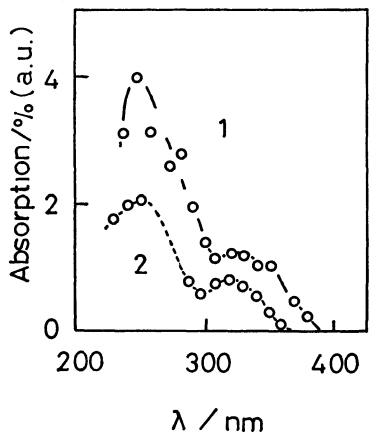


Fig. 1. Transient absorption spectra monitored in the laser flash photolysis of 2-hexanone (1) and 5-methyl-2-hexanone (2) in dichloromethane immediately at the end of the flash. Absorbed photons were normalized to 1.1×10^{-8} einstein per flash. Concentration: 3×10^{-2} mol dm^{-3}.

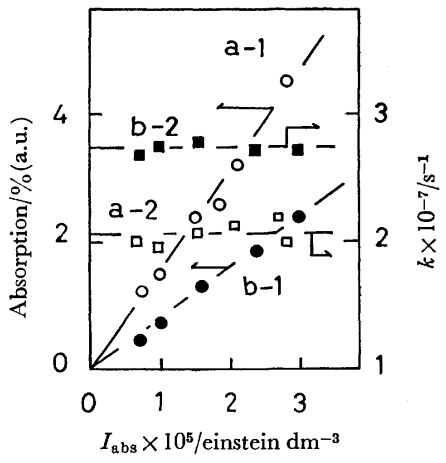

Fig. 2. Effect of absorbed photons on the transient absorption. The absorbance (1) and the decay rate (2) were plotted against the absorbed photons on the laser flash photolysis of 2-hexanone (a) and 5-methyl-2-hexanone (b) in methanol (3×10^{-2} mol dm^{-3}).

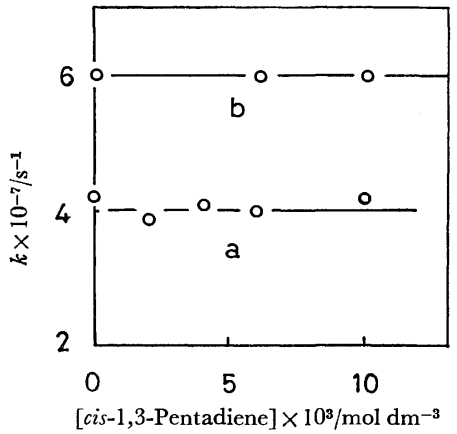

Fig. 3. Change of the decay rate (k) of the transient species in the concentration of *cis*-1,3-pentadiene on the laser flash photolysis of 2-hexanone (a) and 5-methyl-2-hexanone (b) in dichloromethane (3×10^{-2} dm^{-3}).

termined to be *ca.* 3×10 dm^3 mol^{-1} by means of the transient absorbance but the rate of 5-methyl-2-hexanone could not be determined because the results were scattered. Figure 3 shows the plots of k *vs.* the quencher concentration. The decay rates, k, did not increase with the quencher concentration. The quenching rate constant of *cis*-1,3-pentadiene in acetonitrile has been reported to be 4.4×10^9 dm^3 mol^{-1} s^{-1}.[9] If the transient species monitored were the triplet states, the k values were increased to *ca.* 8×10^7 s^{-1} (2-hexanone) and *ca.* 1×10^8 s^{-1} (5-methyl-2-hexanone) in the presence of 1×10^{-2} mol dm^{-3} of the quencher. The triplet decay rate (k_T) of 2-hexanone has been reported to be 1×10^9 s^{-1},[6] and the k_T values have been estimated to be 1×10^8 s^{-1} (2-hexanone) and 3×10^8 s^{-1} (5-methyl-2-hexanone) by means of the $K_g\tau_T$ values reported.[10] These k_T values are much larger than the k values. It can be stated that the transient species monitored is the triplet 1,4-biradical and that k is its decay-rate constant.

These laser-flash photolyses were carried out in acetonitrile, in hexane, and in methanol. The results are listed in Table 1. The k value increased as follows:

in dichloromethane < in hexane < in acetonitrile < in methanol.

Small and Scaiano reported that the 1,4-biradical formed from the aromatic carbonyl compound was stabilized in a polar solvent for the formation of hydrogen bonding with the solvent and a heavy-atom effect was also detected.[11] The characteristics of the triplet 1,4-biradical from the aliphatic carbonyl compounds agree with the results reported by Small and Scaiano.[11] The decay rates of the 1,4-biradical in the presence of oxygen (k') were determined by means of pseudo-first-order kinetics to be as one listed in Table 1. The rate, k', can be written in the form of the following equation;

$$k' = k + k_{O_2}[O_2]$$

where k_{O_2} is the reaction-rate constant of oxygen with the 1,4-biradical. Although the k' rate contains a relatively large error, k_{O_2} is a constant for every solvent ($k_{O_2}=ca.\ 1.5\times10^{10}$ dm^3 mol^{-1} s^{-1}).

I am grateful to Prof. Wolfram Schnabel of Hahn-Meitner-Institut for many supports and useful discussions and to Prof. Setuo Takamuku of Osaka University for his discussions.

Synthesis of 3-(4-Piperidylidene)-1,3-dihydro-2*H*-indol-2-one Derivatives

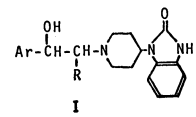
Hiroyuki OBASE,* Nobuhiro NAKAMIZO, Haruki TAKAI, and Masayuki TERANISHI

Tokyo Research Laboratory, Kyowa Hakko Co., Ltd., Asahimachi 3-6-6, Machida, Tokyo 194

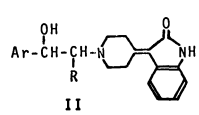
(Received January 11, 1983)

Synopsis. 3-[1-(2-Aryl-2-hydroxyethyl)-4-piperidylidene]-1,3-dihydro-2*H*-indol-2-one with structure **II**, as potential antihypertensive agent was synthesized. The intermediates, 3-[1-(2-aryl-2-oxoethyl)-4-piperidylidene]-1,3-dihydro-2*H*-indol-2-one (**5**) were prepared from 4-piperidone *via* 4 steps. Selective reduction of carbonyl group in **5** was realized using diisobutyl aluminium hydride to afford compound **II**.

As part of a research program aimed at the development of new antihypertensive agents we have investigated compounds showing a selective inhibitory activity against α-adrenoreceptor, and reported recently syntheses of 4-piperidylbenzimidazolinones (**I**), and their antihypertensive activities.[1-2] As an extension of our studies, we have attempted to modify I by replacing the benzimidazol-2-one group with other heterocycles. This paper describes the synthesis of compounds **II**, in which benzimidazole nitrogen is replaced by an sp^2 carbon atom.

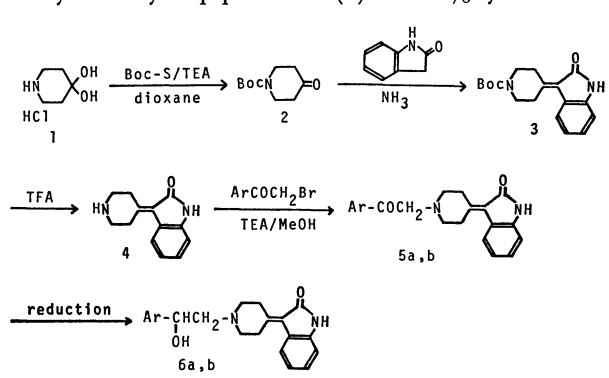


I



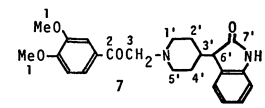
II

The target compounds were synthesized by the route indicated in the following chart. 4-Piperidone hydrate hydrochloride (**1**) reacted with *t*-butyl *s*-(4,6-dimethylpyrimidin-2-yl)thiocarbonate (Boc–S) in the presence of triethylamine (TEA) in dioxane to give 1-t-butoxycarbonyl-4-piperidone (**2**) in 81% yield.

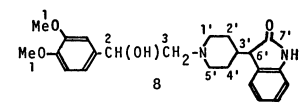


Boc : t-butoxycarbonyl
Ar : a=3,4-dimethoxyphenyl, b=3,4-methylenedioxyphenyl

Base-catalyzed condensation[3] of **2** with 2-oxindole afforded 68% of 3-(1-*t*-butoxycarbonyl-4-piperidylidene)-1,3-dihydro-2*H*-indol-2-one (**3**), which was treated with trifluoroacetic acid to produce 3-(4-piperidylidene)-1,3-dihydro-2*H*-indol-2-one (**4**) in an excellent yield. Bromoacetophenone derivatives were condensed with **4** in a similar manner as previously reported[1] to yield aminoketones **5**. It has been observed that the 3-exo double bond in 2-oxindole is reducible by several reducing agents.[3-6] Therefore, some studies were made on the selective reduction of carbonyl group in **5a**. Aminoketone **5a** was reduced with sodium cyanoborohydride in the presence of acetic acid in MeOH to afford 3-[1-[2-(3,4-dimethoxyphenyl)-2-oxoethyl]piperidin-4-yl]-1,3-dihydro-2*H*-indol-2-one (**7**) in 68% yield. [free **7**: oil, IR($CHCl_3$) 1705, 1680 (sh) cm^{-1}; **7** ·fumarate: mp 190—192 °C



7



8

(EtOH)]. The structure of **7** is based on its ^{13}C NMR spectrum,[7] in which **7** exhibited peaks at δ 195.0 (C-2 carbon), δ 140.6 (C-3′ carbon) and 156.6 (C-6′ carbon). Starting material **5a** was recovered in the Meerwein-Pondorf-Verley reduction despite of extensive examination of reducting conditions. Although certain compounds such as enolizable β-keto esters, β-diketones and sterically hindered ketones are known to be resistant to aluminium isopropoxide reduction,[8] no reduction of β-amino-ketones by this method has been reported yet. Since aluminium hydride (AlH_3) was found to be the most selective reagent for the reduction of α,β-unsaturated carbonyl group,[9] this reagent was tried. When **5a** was reduced with 3 mol equiv. of AlH_3, it afforded 3-[1-[2-(3,4-dimethoxyphenyl)-2-hydroxyethyl]piperdin-4-yl]-1-,3-dihydro-2*H*-indol-2-one (**8**) [free **8**: oil, IR ($CHCl_3$) 1705 cm^{-1}, ^1H NMR (DMSO-d_6) δ 4.60 (t, 1H, ArCHOH); **8** ·succinate: mp 166—167 °C (from EtOH)]. The structure of **8** is based on its ^{13}C NMR spectrum (δ 38.3 for C-3′ carbon, δ 50.0 for C-6′ carbon and δ 69.4 for C-2 carbon) and elemental analyses. Reduction with 1.5 mol equiv. of AlH_3 afforded a mixture of four products which were separated by preparative TLC to give **6a** (15%), **7** (7%), and **8** (26%) together with starting material **5a** (35%). In the ^1H NMR spectrum of **6a**, the C-2 proton signal was observed at δ 4.72 as a triplet, and the C-3′ and C-6′ carbon signals at δ 140.6 and 157.3, respectively in the ^{13}C NMR spectrum. In the infrared spectra, **6a** absorbed strongly at 1697 cm^{-1} due to a conjugated CONH group, while **8** absorbed at 1705 cm^{-1} due to an isolated CONH group. Although **6a** was obtained by this procedure, the yield was low and the isolation of the product was troublesome. Consequently, reduction using diisobutyl aluminium hydride ((DIBAH)[10]) was further studied. The reaction with 3.5 mol equiv. of DIBAH at room temperature in CH_2Cl_2 gave a 6:4 mixture of **6a** and **8**. However, the reaction carried out at low temperatures (−10—−20 °C) afforded **6a** almost exclusively. In this manner we succeeded in the practical synthesis of **6a** in a fairly good yield. Compound **6b** was also obtained by this procedure from **5b** in 56.3% yield.

Experimental

Infrared spectra were recorded on a Hitachi 215 grating infrared spectrometer. ^{1}H NMR spectra were measured on a JNM-PFT-100 spectrometer. ^{13}C NMR spectra were obtained at 25.1 MHz on a JNM-FX-100 spectrometer, operating in the Fourier transform mode with Me_4Si as an internal standard.

1-t-Butoxycarbonyl-4-piperidone (2). A solution of 4-piperidone hydrate hydrochloride (**1**, 9.3 g, 0.061 mol), triethylamine (12.5 g, 0.124 mol), and Boc–S (14.8 g, 0.062 mol) in 100 ml of dioxane and 30 ml of water was stirred at 20 °C for 6 h and concentrated under reduced pressure. The residue was extracted with AcOEt. The extract was worked up as usual to give crude crystals, which were recrystallized from petroleum ether to give 9.8 g (81.3%) of **2** ; mp 70—72 °C. IR (KBr) 1730 (sh), 1720, 1695 cm^{-1}. Found: C, 60.38; H, 8,78; N, 6.92%. Calcd for $C_{10}H_{17}NO_3$: C, 60.28; H, 8.60; N, 7.03%.

3-[1-(t-Butoxycarbonyl)-4-piperidylidene]-1,3-dihydro-2H-indol-2-one (3). NH_3 (2.4 g, 0.14 mol), **2** (1.51 g, 7,58 mmol), and oxindole (1.01 g, 7.59 mmol) in 25 ml of EtOH were made to react according to the reported procedure[3] to afford 1.62 g (67.9%) of **3**; mp 204—205 °C (EtOH). IR (KBr) 1700, 1690 (sh), 1670 cm^{-1}. Found: C, 68.66; H, 7.05; N, 8.82%. Calcd for $C_{18}H_{22}N_2O_3$: C, 68.77; H, 7.05; N, 8.91%.

3-(4-Piperidylidene)-1,3-dihydro-2H-indol-2-one (4). Compound **3** (7.5 g, 23,9 mmol) was treated with 25 ml of trifluoroacetic acid (TFA) at 0 °C. After stirring the solution for 2 h at 0 °C, TFA was removed *in vacuo* and the residue was made alkaline with 1 M NaOH. The crystals separated were collected and recrystallized from AcOEt to yield 4.4 g (85.9%) of **4**; mp 234—238 °C (decomp), IR (KBr) 1697, 1680 (sh) cm^{-1}. Found: C, 72.59; H, 6.60; N, 12,81%. Calcd for $C_{23}H_{14}N_2O$: C, 72.87; H, 6.59; N, 13.08%.

3-[1-[2-(3,4-Dimethyoxyphenyl)-2-oxoethyl]-4-piperidylidene]-1,3-dihydro-2H-indol-2-one (5a). Compound **5a** was obtained by the previously reported procedure[1] in 89.5% yield from **4** and 3,4-dimethoxybromoacetophenone; mp 145—146 °C (EtOH). IR (KBr) 1690 (br) cm^{-1}. ^{1}H NMR (DMSO-d_6) δ=3.9 (s, 2H, $COCH_2N$), 10.5 (NH). ^{13}C NMR (DMSO-d_6 δ=28.0, 31.2 (C-2′, C-4′), 53.1, 53.6 (C-1′, C-5′), 55.5, 55.7 (C-1), 62.8 (C-3), 140.6 (C-3′), 156.6 (C-6′), 168.7 (C-7′), 195.0 (C-2). Found: C, 70.20; H, 6.04; N, 7.04%. Calcd for $C_{23}H_{24}N_2O_4$: C, 70.39; H, 6.16; N, 7.14%. Compound **5b** was prepared in a similar manner as **5a** in 82.2% yield; mp 167.5—171 °C decomp. IR (KBr) 1698—1680 (br) cm^{-1}. NMR (DMSO-d_6) δ=3.80 ($COCH_2N$), 6.12 (OCH_2O), 10.3 (NH). Found: C, 69.96; H, 5.29; N, 7.33%. Calcd for $C_{22}H_{20}N_2O_4$: C, 70.20; H, 5.36; N, 7.44%.

Reduction of 5a with DIBAH. To a cooled solution of **5a** (2.73 g, 6.96 mmol) in 160 ml of CH_2Cl_2 was added DIBAH (5.0 g, 35.2 mmol) in 70 ml of CH_2Cl_2 at −20 °C over 2 h. The solution was stirred for additional 5 h at the same temperature. Then, 60 ml of MeOH and 200 ml of water were successively added to the solution. The organic layer was separated, washed with water, dried over $MgSO_4$, and concentrated. The residue was recrystallized from AcOEt to afford 1.3 g (47.4%) of **6a**; mp 98—99 °C. IR (KBr) 1697 cm^{-1}. ^{1}H NMR (DMSO-d_6) δ=4.72 (t, 1H, ArCHOH), 10.4 (NH). ^{13}C NMR (DMSO-d_6) δ 28.1, 31.3 (C-2′, C-4′), 53.7, 54.0 (C-1′, C-5′), 55.4, 55.5, (C-1), 65.4 (C-3), 69.7 (C-2), 14.06 (C-3′), 157.3 (C-6′), 168.8 (C-7′). Found: C, 69.89; H, 6.82; N, 6.59%. Calcd for $C_{23}H_{26}N_2O_4$; C, 70.03; H, 6.64; H, 7.10%.

Similar treatment of **5b** with DIBAH gave 56.3% of **6b**; mp 176—178 °C (from MeOH–CH_2Cl_2). IR (KBr) 1692 cm^{-1}. ^{1}H NMR (DMSO-d_6) δ=4.72 (t, 1H, ArCHOH), 5.95 (s, 2H, OCH_2O), 10.35 (br, 1H, NH). Found: C, 69.97; H, 5.84; N, 7.33%. Calcd for $C_{22}H_{22}N_2O_4$: C, 69.82; H, 5.86; N, 7.40%.

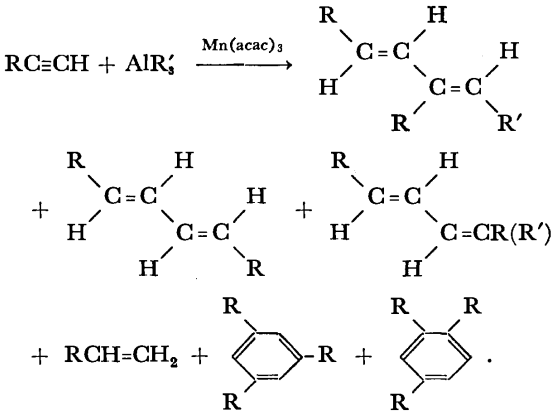
Bis(acetylacetonato)copper Catalyzed Cross-coupling Reaction of Alkenyldicyclohexylborane with 1-Bromo-1-alkyne or 3-Bromo-1-propene

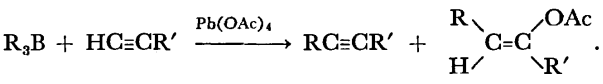
Masayuki Hoshi, Yuzuru Masuda, and Akira Arase*
Department of Applied Chemistry, Kitami Institute of Technology, Kitami 090
(Received January 22, 1983)

Synopsis. Bis(acetylacetonato)copper is capable of catalyzing cross-coupling reaction of alkenyldicyclohexylborane with 1-bromo-1-alkyne or 3-bromo-1-propene to give conjugated (*E*)-enyne or (*E*)-1,4-diene in a highly stereoselective manner, respectively.

Caporusso *et al.*[1] reported that trialkylaluminium reacted with 1-alkyne in the presence of tris(acetylacetonato)manganese to give a mixture of some unsaturated compounds:

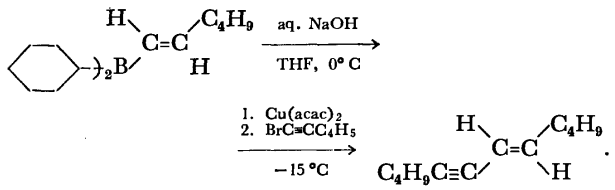


The present authors, on the other hand, have reported of coupling reactions of the alkyl groups of trialkylborane with such groups as SCN,[2,3] SeCN,[3,4] and $OCOCH_3$[5] bonded to some metals. They[6] also reported that trialkylborane reacted with 1-alkyne in the presence of lead(IV) acetate to give an internal alkyne together with an internal enol acetate:



In the course of our investigation on reactions of organoborane with metal complexes, we have come to get interested in the behavior of organoborane in the presence of metal acetylacetonate.

The reaction of trihexylborane with 1-hexyne was first examined in the presence of several metal acetylacetonates. However, such compounds as had been detected in the reaction of trialkylaluminium could not be found at temperatures ranging from −20 to 40 °C; thus 1-bromo-1-hexyne was used instead of 1-hexyne. In this case a considerably clean cross-coupling reaction occurred between trihexylborane and 1-bromo-1-hexyne in the presence of bis(acetylacetonato)copper to give 5-dodecyne in a yield above 60% as based on trihexylborane used.[7] A higher yield of cross-coupling product was obtained when 1-hexenyldicyclohexylborane was treated with aqueous sodium hydroxide and 1-bromo-1-hexyne in the presence of a catalytic amount of bis(acetylacetonato)copper (5%). Thus, 5-dodecene-7-yne, a coupling product of the hexenyl and the hexynyl group, was provided in 75% yield with a high isomeric purity (above 99%):

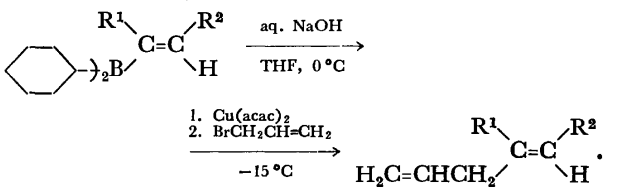


E-configuration of this enyne was assigned from the coupling constant between olefinic protons (J=16 Hz) in ^{1}H NMR spectrum and the absorption band at 965 cm^{-1} in IR spectrum. To obtain a highly pure (*E*)-5-dodecene-7-yne, it is necessary to keep the temperature below −15 °C during the addition of 1-bromo-1-hexyne. Otherwise, some by-products will appear and prevent easy isolation of the enyne from the reaction mixture.[8]

As shown in Table 1, a similar reaction also proceeded without any difficulty which produced the corresponding (*E*)-enyne when an internal alkenyldicyclohexylborane was used as the starting material. Similar results were also obtained when 1-bromo-2-phenylethyne was employed instead of 1-bromo-1-hexyne. High isomeric purities of (*E*)-enyne (above 99%) were obtained in all cases examined. These results suggest that the present reaction may provide a general method for the synthesis of conjugated (*E*)-enyne.

Miyaura *et al.*[9] reported of excellent cross-coupling reactions of alkenyldialkylborane with 1-bromo-1-alkyne; they obtained high yields (72—100%) of conjugated (*E*)-enyne in the presence of a catalytic amount of tetrakis(triphenylphosphine)palladium. The present reaction, though inferior to theirs in yield, is comparable in stereoselectivity of reaction.

The present reaction is also applicable to cross-coupling reaction of alkenyldicyclohexylborane with 3-bromo-1-propene; (*E*)-1,4-diene was afforded in a highly stereoselective manner:



Since the cross-coupling reaction of alkenyldialkylborane with 3-bromo-1-propene has already been studied extensively by several workers,[10] any investigation of this coupling reaction was not made with a variety of substrates.

The present bis(acetylacetonato)copper-catalyzed cross-coupling reaction is a new application of this reagent as a catalyst in the reaction of organoborane and seems to be an easy and inexpensive method for the synthesis of conjugated (*E*)-enyne or (*E*)-1,4-diene.

Table 1. $Cu(acac)_2$-catalyzed cross-coupling reaction of alkenyldicyclohexylborane with 1-bromo-1-alkyne or 3-bromo-1-propene

R^1	R^2	R^3	Compound No.	Product and yield/%[a] $R^3C{\equiv}CR^3$ A	B	$H_2C{=}CHCH_2$ A	B

Experimental

Instruments. IR spectra (film) were recorded with a Hitachi-285 spectrometer. ^1H NMR (60 MHz) spectra (CCl_4) were recorded on a Hitachi R-20A spectrometer. Mass spectra were recorded with a Hitachi M-52 mass spectrometer.

Reagents. Cyclohexene and THF were dried over lithium aluminium hydride and distilled before use. 1-Bromo-1-hexyne and 1-bromo-2-phenylethyne were prepared as described in the literature.[11] 1-Hexyne, 1-octyne, phenylacetylene, and 3-bromo-1-propene were dried over molecular sieves 5A. THF solution of BH_3 was prepared by the method described in the literature.[12]

General procedure. A 50 ml round bottomed flask, equipped with a gas inlet for argon, a sample inlet with serum cap, and a magnetic stirring bar, was flushed with argon, and used to prepare dicyclohexylborane by adding 40 mmol of cyclohexene to 20 mmol BH_3 in THF. To the solution, 20 mmol of alkyne was slowly added at 0 °C and the solution was stirred for 3 h at the same temperature. Then, 20 mmol of aqueous sodium hydroxide (2 mol dm^{-3}) was added at 0 °C and stirring was continued for 0.5 h at room temperature. The solution was cooled again to −15 °C, 1 mmol of $Cu(acac)_2$ was introduced into the reaction mixture under a slow argon flow, and then 20 mmol of 1-bromo-1-alkyne or 3-bromo-1-propene was added at the same temperature. After 1 h reaction at −15 °C, the reaction mixture was warmed to room temperature and kept stirred for 20 h, and then the residual organoborane was oxidized with alkaline hydrogen peroxide. The reaction mixture was extracted twice with 30 ml of hexane. The combined extracts were washed twice with NaCl-saturated water and dried over anhydrous calcium chloride. After removal of the solvents under reduced pressure, the reaction mixture was passed through a column packed with silica-gel (Wako-gel Q-50). The products were isolated by elution with hexane.

Analytical data for the products are as follows:

(E)-*5-Dodecen-7-yne (**1**)*: n_D^{20} 1.4732; ^1H NMR (CCl_4) δ= 0.88 (6H, t, J=7 Hz), 1.11 (8H, m), 1.83—2.40 (4H, m), 5.27 (1H, d, J=16 Hz), and 5.62—6.13 (1H, m); IR (film) 2230 and 965 cm^{-1}; MS *m/e* 164 (M^+). Found: C, 87.70; H, 12.15%. Calcd for $C_{12}H_{20}$: C, 87.73; H, 12.27%.

(E)-*4-Ethyl-3-decen-5-yne (**2**)*: n_D^{20} 1.4677; ^1H NMR (CCl_4) δ=0.70—1.30 (9H, m), 1.30—1.65 (4H, m), 1.65—2.40 (6H, m), and 5.55 (1H, t, J=7 Hz); IR (film) 2210 cm^{-1}; MS *m/e* 164 (M^+). Found: C, 87.68; H, 12.20%. Calcd for $C_{12}H_{20}$: C, 87.73; H, 12.27%.

(E)-*1-Phenyl-1-octen-3-yne (**3**)*: n_D^{20} 1.5873; ^1H NMR (CCl_4) δ=0.88 (3H, t, J=7 Hz), 1.10—1.70 (4H, m), 2.13 —2.45 (2H, m), 5.99 (1H, dt, J_t=16 Hz and J_d=2 Hz), 6.70 (1H, d, J=16 Hz), and 7.12 (5H, m); IR (film) 2190 and 960 cm^{-1}; MS *m/e* 184 (M^+). Found: C, 91.20; H, 8.72%. Calcd for $C_{14}H_{16}$: C, 91.25; H, 8.75%.

(E)-*1-Phenyl-3-octen-1-yne (**4**)*: n_D^{20} 1.5674; ^1H NMR (CCl_4) δ=0.88 (3H, t, J=Hz), 1.10—1.60 (4H, m), 1.87—2.31 (2H, m), 5.50 (1H, d, J=16 Hz), 5.87—6.40 (1H, m), and 7.05—7.50 (5H, m), IR (film) 2190 and 955 cm^{-1}; MS *m/e* 184 (M^+). Found: C, 91.24; H, 8.69%. Calcd for $C_{14}H_{16}$: C, 91.25; H, 8.75%.

(E)-*3-Ethyl-1-phenyl-3-hexen-1-yne (**5**)*: n_D^{20} 1.5620; ^1H NMR (CCl_4) δ=0.70—1.60 (6H, m), 1.90—2.20 (4H, m), 5.79 (1H, t, J=7 Hz), and 7.05—7.55 (5H, m), IR (film) 2190 cm^{-1}; MS *m/e* 184 (M^+). Found: C, 91.27; H, 8.78%. Calcd for $C_{14}H_{16}$: C, 91.25; H, 8.75%.

(E)-*1,4-Diphenyl-1-buten-3-yne (**6**)*: mp 87 °C; ^1H NMR (CCl_4) δ=6.20 (1H, d, J=16 Hz), 6.92 (1H, d, J=16 Hz), and 7.10—7.50 (10H, m); MS *m/e* 204 (M^+). Found: C, 94.01; H, 5.94%. Calcd for $C_{16}H_{12}$: C, 94.08; H, 5.92%.

(E)-*1,4-Undecadiene (**7**)*: n_D^{20} 1.4385; ^1H NMR (CCl_4) δ= 0.84 (3H, t, J=7 Hz), 1.10—1.70 (8H, m), 1.80—2.18 (2H, m), 2.50—2.80 (2H, m), and 4.70—6.10 (5H, m),; IR (film) 970 cm^{-1}; MS *m/e* 152 (M^+). Found: C, 86.73; H, 13.23%. Calcd for $C_{11}H_{20}$: C, 86.76; H, 13.24%.

(E)-*1-Phenyl-1,4-pentadiene (**8**)*: n_D^{20} 1.5513; ^1H NMR (CCl_4) δ=2.83 (2H, t, J=7 Hz), 4.98 (2H, m), 5.45—6.30 (3H, m), and 7.10 (5H, m); IR (film) 965 cm^{-1}; MS *m/e* 144 (M^+). Found: C, 91.55; H, 8.34%. Calcd for $C_{11}H_{12}$: C, 91.61; H, 8.93%.

Reaction of Some Compounds Having Both Endo and Exo Olefinic Bonds with 1,2,4-Triazoline-3,5-diones

Tatsuo OSHIKAWA* and Mitsuji YAMASHITA

Department of Applied Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu 432

(Received January 29, 1983)

Synopsis. Reaction of piperitenone, (+)-limonene, or styrene with 1,2,4-triazoline-3,5-dione (TAD) produces adducts by ene reaction. The reaction of (+)-limonene gives a 2:1 adduct which results from further addition of TAD to an intermediary ene reaction product. The reaction of styrene gives 2:1 adducts *via* further addition of TAD to the Diels-Alder reaction product.

1,2,4-Triazoline-3,5-dione (TAD) and its 4-phenyl (PTAD) and 4-methyl (MTAD) derivatives have widely been used as dienophiles or enophiles.[1] An extensive mechanistic study[1] revealed that derivatives of TAD were the most reactive dienophiles or enophiles. In the present study, we are interested in reactions of PTAD with two monoterpenoid ring compounds, *i.e.*, 3-methyl-6-isopropylidene-2-cyclohexen-1-one (piperitenone)[2] and (+)-limonene, and with styrene.

(+)-Pulegone and mesityl oxide are known to be reactive enophiles with PTAD,[3] however no studies have been reported on reactions with PTAD of such compounds as contain both endo and exo olefins, *e.g.*, piperitenone and (+)-limonene.

Results and Discussion

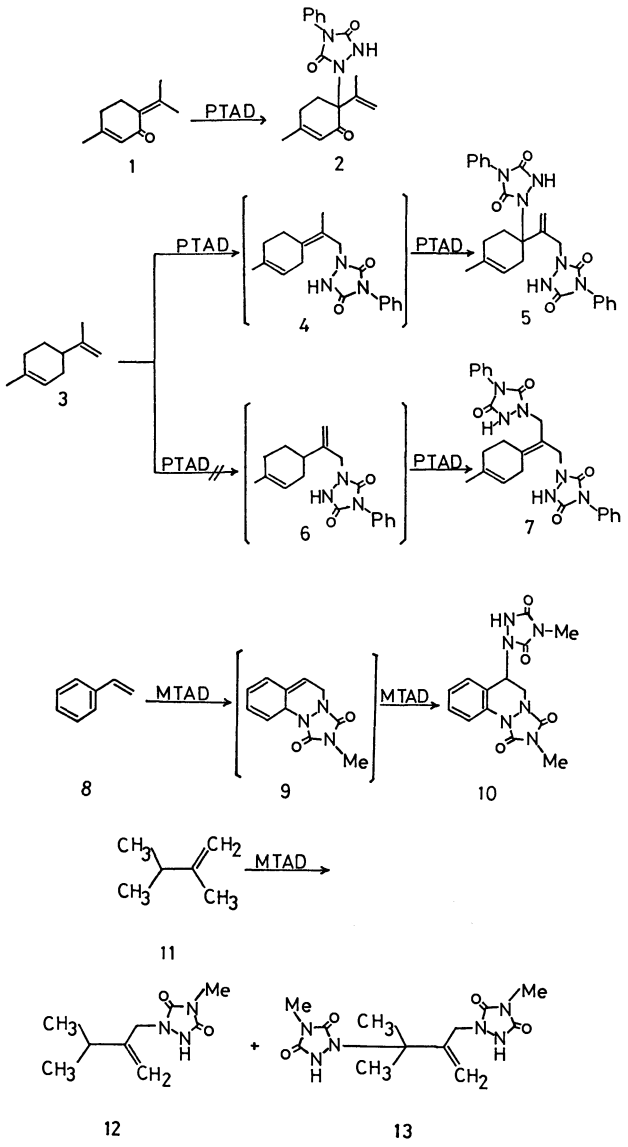
A reaction of equimolar amounts of PTAD and piperitenone (**1**) in ethyl acetate or dichloromethane for 12 h at ambient temperature gave, on work up, compound **2** in 64% yield. Under the same conditions (+)-limonene (**3**) gave adduct **5** in 64% yield.

The structures of products **2** and **5** were determined from ^{1}H NMR, mass, and IR spectra by identifying the olefin protons of the isopropenyl groups, the molecular ion peaks, and the absorption of the vinylidene olefin groups, respectively.

Adduct **2** is exactly of the same type as the compound afforded by the reaction of (+)-pulegone or mesityl oxide, which gives an isopropenyl group on the 6-position *via* a hydrogen abstraction from the methyl group. Product **5** is a 2:1 adduct, which we can easily infer to have been formed *via* an addition of PTAD to the isopropenyl group through ene reaction to give intermediate **4**, which is successively subject to an ene reaction on the 4-position with the second PTAD to generate product **5**. Formation *via* 1:1 adduct **6** of 2:1 adduct **7**, which should have no isopropenyl proton, is denied on the basis of ^{1}H NMR spectra.

Under the same conditions styrene (**8**) gave 2:1 adduct **10** in quantitative yield. The above results indicate that the ene reaction[4] of a reactive enophile of TAD derivative with the exo cyclic olefin in compound **4** or **9** takes place by involving a proton transfer, thus leading to a 2:1 adduct in the reaction of **3** or **8** with TAD. Diels-Alder adduct **9** possesses the structure of conjugated endo cyclic diene, however it gave 2:1 adduct **10**, as a result of ene reaction with the second MTAD, rather than the Diels-Alder reaction product.

The above results, have first revealed that the reaction of a compound having both endo and exo olefinic bonds with TAD proceeds predominantly *via* addition to the exo olefin. The reaction of 2,3-dimethyl-1-butene (**11**) with MTAD has clearly demonstrated that MTAD first attacks the isopropenyl group, with a subsequent reaction with another molecule of enophile leading to a 2:1 adduct.



Experimental

Measurements. Melting points were measured on a Yanagimoto Seisakusho micro melting point apparatus. ^{1}H

NMR spectra were recorded on a Hitachi R-24 (60 MHz) spectrometer with TMS as an internal standard, IR spectra on a JASCO A-3 infrared spectrophotometer, and mass spectra on a Hitachi RMU 7MG GC-MS spectrometer.

*Reaction of **1** with PTAD.* *Typical Procedure*: To a solution of 0.5 g (3.33 mmol) of **1** in 10 ml of ethyl acetate or dichloromethane, 0.6 g (3.33 mmol) of PTAD was added all at once. The mixture was stirred magnetically at room temperature with light excluded for protection until the red color of PTAD had faded completely (12 h) and a light yellow solution had appeared. The solution was poured into petroleum ether to precipitate colorless crystalline product **2** (0.7 g, 64% yield): mp 194—196 °C (needles from ethanol ethyl acetate); ^{1}H NMR ($CDCl_3$) δ=1.88 (s, 3H, CH_3), 1.95 (s, 3H, CH_3), 2.33 (br d, J=4.55 Hz, 2H, CH_2), 2.65 (br d, J=4.5 Hz, 2H, CH_2), 4.87 (s, 1H, ), 5.19 (s, 1H, ), 5.93 (s, 1H, endo olefin), 7.44 (s, 5H, Ph), and 8.72 (br, 1H, NH); IR ν_{max}^{KBr} 3360, 1780, 1700, and 1620 cm^{-1}; MS *m/e* 325 (M^+) and 149 (M^+—PTADH).

Found: C, 66.26; H, 5.83; N, 13.05%. Calcd for $C_{18}H_{19}N_3O_3$: C, 66.46; H, 5.85; N, 12.92%.

*Reaction of **3** with PTAD.* A reaction of **3** with PTAD in the same procedure as described above gave 2:1 adduct **5** in 64% yield: mp 150—151 °C; ^{1}H NMR ($CDCl_3$) δ= 1.97 (s, 3H, CH_2), 1.48 2.40 (br m, 6H, ring CH_2), 4.31 (br, 2H, N CH_3), 6.35 (br s, 2H, NH), 7.43 (s, 10H, Ph); IR ν_{max}^{KBr} 3460, 1785, 1725, and 1600 cm^{-1}; MS *m/e* 482 (M^+), and 130 (M^+—2PTADH).

Found: C, 64.78: H, 4.71; N, 17.46%. Calcd for $C_{26}H_{24}N_6O_4$: C, 64.46; H, 4.96; N, 17.36%.

*Reaction of **8** with MTAD.* As soon as MTAD was added all at once to **8** under the same condition as above, white crystals precipitated. After stirring for 15 min, the white precipitate, which is 2:1 adduct **10**, was collected by filtration in quantative yield: mp 270—273 °C; ^{1}H NMR (DMSO-d_6) δ=3.15 (s, 3H, N CH_3), 3.23 (s, 3H, N CH_3), 3.85 (d, J=12.5 Hz, 2H, CH_2), 5.76 (s, 1H, N CH), 7.33 (m, 4H, aryl), and 8.33 (br, 1H, NH); MS *m/e* 330 (M^+).

Found: C, 50.95; H, 4.21; N, 25.28%. Calcd for $C_{14}H_{14}N_6O_4$: C, 50.99; H, 4.24; N, 25.46%.

*Reaction of **11** with MTAD.* A reaction of **11** with MTAD gave 1:1 **12** and 2:1 **13** adducts in 73 and 15% yields, respectively. Major product **12**: oil; ^{1}H NMR (CCl_4) δ=1.46 (s, 3H, CH_3), 1.67 (s, 3H, CH_3), 2.17 (m, 1H, CH), 3.01 (s, 3H, N CH_3), 4.16 (s, 2H, CH_2), 4.96 ((s, 2H,), and 8.92 (br, 1H, NH). Minor product **13**: Colorless needles; mp 160—161 °C; ^{1}H NMR (DMSO-d_6) δ=1.46 (s, 3H, CH_3), 1.96 (s, 3H, CH_3), 3.04 (s, 6H, N CH_3), 4.30 (s, 2H, N CH_2), 4.87 (s, 1H,), 5.08 (s, 1H,), and 8.99 (br, 2H, NH); MS *m/e* 310 (M^+).

Found: C, 46.48; H, 5.88; N, 27.04%. Calcd for $C_{12}H_{18}N_6O_4$: C, 46.45; H, 5.81; N, 27.10%.

Synthesis of 3a,8a-Dihydrocyclopent[*a*]inden-3(8*H*)-one[1]

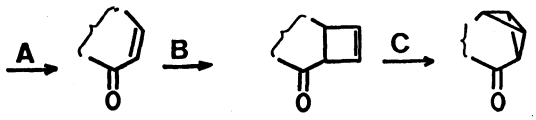
Yoshikazu SUGIHARA,* Takashi SUGIMURA, and Ichiro MURATA*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received February 7, 1983)

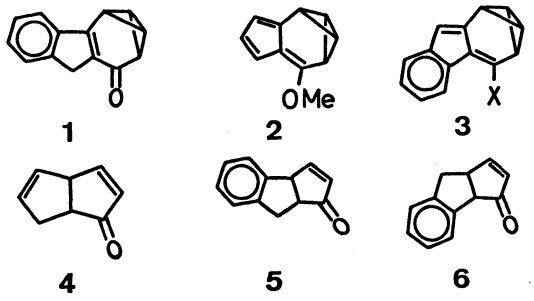
Synopsis. 3a,8a-Dihydrocyclopent[*a*]inden-3(8*H*)-one (**6**) was prepared from a known compound, 2,2-dichloro-2,2a,7,7a-tetrahydro-1*H*-cyclobut[*a*]inden-1-one, by a simple ketone 1,2-transposition followed by introduction of a double bond. The photochemical behavior of **6** was also examined.

The reaction sequence which involves the preparation of the appropriate enone (step-A), its photoannelation with acetylene (or its equivalents) (step-B), and photochemical construction of bicyclobutane (step-C), is our strategy for the synthesis of valene-type isomers of cyclic conjugated systems.[2]



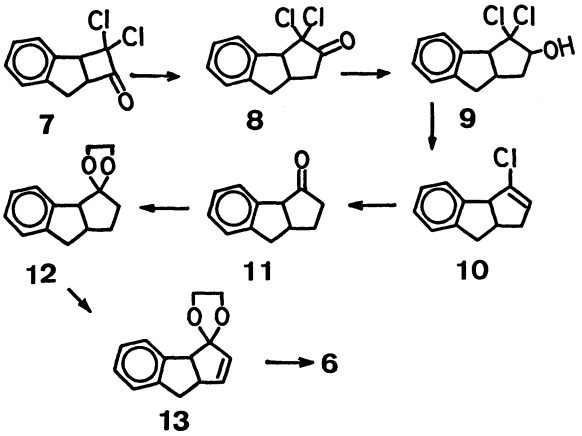
As already reported, enones **5** and **4** proved to be useful intermediates for our synthesis of **1**[2c] and **2**,[2d] respectively. 3a,8a-Dihydrocyclopent[*a*]inden-3(8*H*)-one (**6**) corresponds to the precursor for the synthesis of a benzazulvalene derivative **3** on the line of our methodology. Although the β,γ-unsaturated ketone chromophore in **6** is presumed to disturb the desired photochemical transformations,[3] synthesis and efficiency of photocycloaddition of **6** were pursued.

Enone **6** was prepared from the known compound **7**[4] by a simple ketone 1,2-transposition[5] followed by introduction of a double bond. Thus cyclobutanone



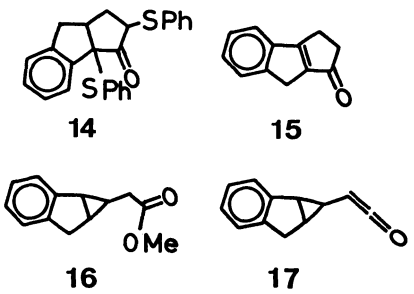
7 was subjected to ring enlargement[6] with diazomethane to afford **8** (87%), which was reduced with sodium borohydride in methanol to yield epimeric alcohols **9** as a colorless solid. Vinyl chloride **10** obtained from **9** through reduction with zinc dust in acetic acid was transformed to cyclopentanone **11** by hydrolysis with 90% sulfuric acid at room temperature for 30 min, in 40.6% yield based on **8**. Alcohol **9** and vinyl chloride **10** could be used without purification during the above transformations.

Because of the easy deprotonation at angular position α to carbonyl group of **11**, routine sulfenylation[7] (LDA 2 equiv., diphenyl disulfide 2 equiv.) afforded bissulfenylated ketone **14** as a sole product. However, a similar method used in the synthesis of **5**[2c,8] was applicable to regiospecific introduction of a double



bond to **11** in a yield of 80.4%. While the formation of enone **5** was accompanied with the formation of **15** (15%), none of the isomeric enone was produced during the formation of **6**.

Photoannelations of **6** with acetylene, 1,2-dichloroethylene or bis(trimethylsilyl)acetylene were unsatisfactory. In all cases, the yields of the desired adducts were less than 5% and reaction mixtures showed several spots on TLC and strong absorption band at 1820 cm^{-1} in their IR spectra. Upon photolysis in KBr disk, **6** showed infrared absorption band characteristic of a ketene at 2120 cm^{-1}. Furthermore, irradiation of **6** in a mixture of acetone–methanol afforded methyl ester **16** in 80% yield. Apparently, a Norrish-type I reaction of **6**, followed by formation of ketene **17**, overcomes photocycloaddition.



In conclusion, the synthetic method involving ketone 1,2-transposition is useful for the preparation of related cyclopentenones. Enone **6** is not appropriate to our purpose. The benzene ring must be masked. Studies in this line are in progress.

Experimental

^{1}H NMR (100 MHz) spectra were recorded on a Varian XL-100 spectrometer. Chemical shifts are reported in ppm (δ) downfield from TMS as internal standard and coupling constants are given in Hz. IR spectra were recorded on a JASCO A-100 instrument and mass spectra were obtained on a JEOL JMS-01SG-2 spectrometer.

3,3-Dichloro-3,3a,8,8a-tetrahydrocyclopent[a]*inden-2(1H)-one (8).* Ring expansion of **7** with diazomethane was carried out as described in the literature.[6] Yield: 87%; mp: 70—73 °C from ether: IR (KBr): 1761 cm^{-1}; ^1H NMR ($CDCl_3$): δ=2.44 (1H, dd, J=19.5 and 5.1 Hz), 2.72—3.44 (4H, m), 4.24 (1H, d, J=7.8 Hz), 7.15—7.35 (3H, m), 7.6 (1H, m). Found: C, 59.77; H, 4.20%. Calcd for $C_{12}H_{10}OCl_2$: C, 59.78; H, 4.18%.

3,3-Dichloro-1,2,3,3a,8,8a-hexahydrocyclopent[a]*inden-2-ol (9).* To a solution of 1.862 g of **8** in 40 ml of methanol was added 302.6 mg of sodium borohydride. After one hour stirring, 250 ml of ether was added. The mixture was washed (H_2O and then brine), dried ($MgSO_4$), and concentrated to yield 1.886 g of crude alcohol **9** as a colorless solid, which was used in a next step without purification.

3-Chloro-1,3a,8,8a-tetrahydrocyclopent[a]*indene (10).* 1.886 g of alcohol **9** was treated with 1.530 g of zinc in 20 ml of acetic acid at 90 °C for 1 h. After cooling, 100 ml of hexane was added. The mixture was washed (H_2O and then brine) and dried ($MgSO_4$). Removal of the solvent afforded an oil which was passed through a short plug of deactivated silica gel (10% water) with hexane to yield 884 mg of **10** as yellow oil, which was used in the next step without further purification.

1,2,8,8a-Tetrahydrocyclopent[a]*inden-3(3aH)-one (11).* Sulfuric acid (90%, 3 ml) was slowly added to 884 mg of **10** with stirring at 0 °C. After 30 min the mixture was poured onto ice. After routine treatment, chromatography over 8 g of deactivated silica gel (10% water), eluted with a mixture of hexane–benzene (9:1 v/v) afforded 540 mg of **11** as a colorless oil; bp: 65 °C/0.3 mmHg; IR (neat): 1740 cm^{-1}; ^1H NMR ($CDCl_3$): δ=1.58 (1H, m), 2.10—2.40 (3H, m), 3.20 (1H, m), 2.80, 3.24 (2H, AB-part of an ABX_n, J=14.0), 3.73 (1H, dm, J=8.0), 7.10—7.26 (3H, m), 7.43 (1H, m). Found: C, 83.81; H, 7.03%. Calcd for $C_{12}H_{12}O$: C, 83.94; H, 7.00%.

3a,8a-Dihydrocyclopent[a]*inden-3(8H)-one (6).* This material was obtained from the ketone **11** by using the general procedure (acetalization, bromination, dehydrobromination and deacetalization) of Eaton *et al.*[8] Yield: 80.4%; mp: 85.5—86.0 °C from hexane–ether, colorless needles; IR (KBr): 1695 cm^{-1}; ^1H NMR ($CDCl_3$): δ=2.92 (1H, d, J=16.5 Hz), 3.35 (1H, dd, J=16.5 and 9.0 Hz), 3.82 (1H, m), 3.87 (1H, m), 6.03 (1H, dd, J=5.7 and 1.6 Hz), 7.10—7.25 (3H, m), 7.50 (1H, m), 7.59 (1H, dd, J=5.7 and 2.5 Hz). Found: C, 84.32; H, 5.93%. Calcd for $C_{12}H_{10}O$: C, 84.68; H, 5.92%.

Attempted Photoannelation of 6. In a typical run, 222 mg of **6** was dissolved in 80 ml of dichloroethylene. After nitrogen was bubbled through for 1 h, the solution was irradiated at 0 °C. After **6** was disappeared on TLC examination, the solvent was removed under reduced pressure and the residue was checked by IR and NMR spectra for product analysis. Other conditions examined were: acetylene in acetone at −78 °C and bis(trimethylsilyl)acetylene in acetone or acetonitrile at 0 °C. In all cases, irradiations were conducted with a 100 W high pressure mercury lamp through Pyrex filter.

Photolysis of 6 in KBr Disk. 3 mg of **6** was placed in a KBr disk. The disk was irradiated using a 100 W high pressure mercury lamp through a Pyrex filter. The photolysis was followed by measuring the IR spectrum every 10 min. After 50 min, the absorption band attributable to ketene at 2120 cm^{-1} reached its maximum and then gradually decreased on further irradiation.

Photolysis of 6 in the Presence of Methanol. 100 mg of **6** was dissolved in a mixture (50 ml) of acetone–methanol (2:1 v/v). After nitrogen was bubbled through for 30 min, the solution was irradiated using 100 W high pressure mercury lamp through Pyrex filter. After 1 h, the solvent was removed under reduced pressure and the residue was chromatographed over deactivated silica gel (6% water) with benzene. An epimeric mixture of the methyl ester **16** (94 mg) was obtained as a colorless oil. IR (neat): 1720 cm^{-1}; MS: 202 (M^+, 10%), 143 ($M^+-C_2H_3O_2$, 23%), 142 ($M^+-C_2H_4O_2$, 46%), 141 ($M^+-C_2H_5O_2$, 40%), 129 ($M^+-C_3H_5O_2$, 42%), 128 (naphthalene cation, 100%), 115 (indenium ion, 60%); ^1H NMR ($CDCl_3$): δ=0.7 (0.6 H, m), 1.2—2.05 (2.4 H, m), 2.10—2.60 (2H, m), 2.70—3.50 (2H, m), 3.55 (1.2 H, s), 3.65 (1.8 H, s), 6.6—7.4 (4H, m).

The η^5-$C_9H_{11}Fe(CO)_2$(isobutylene)$^+BF_4^-$ Complex as a Protecting Group of Carbon-Carbon Double Bonds

Yasutaka Ishii,* Takashi Kagayama, Akihiro Inada, and Masaya Ogawa*

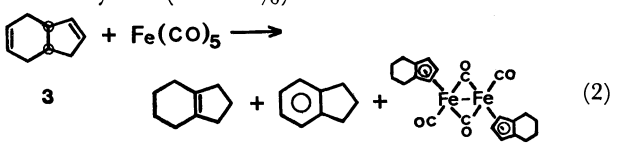
(Received February 12, 1983)

Synopsis. η^5-$C_9H_{11}Fe(CO)_2$(isobutylene)$^+BF_4^-$ (**6**), [Fpi(isobutylene)]$^+BF_4^-$, was prepared and used as a protecting group of carbon–carbon double bonds. The complex **6** undergoes ligand exchange with a variety of diolefins to give Fpi(diolefin)$^+BF_4^-$ complexes, whose subsequent hydrogenations on Pd/C give olefins hydrogenated regioselectively.

The dicarbonyl η^5-cyclopentadienyliron cation moiety, η^5-$C_5H_5Fe(CO)_2^+$ (Fp$^+$), serves as a good protecting group for the carbon–carbon double bond of olefins.[1,2] The Fp(isobutylene)$^+BF_4^-$ complex (**1**), which is readily available from the Fp dimer, undergoes ligand exchange with olefins under mild conditions to give Fp(olefin)$^+$-BF_4^- (**2**) (Eq. 1).

1 2 (1)

In a previous paper, we have reported the $Fe(CO)_5$ catalyzed disproportionation of *cis*-bicyclo[4.3.0]nona-3,7-diene (**3**) to bicyclo[4.3.0]non-1(6)-ene (**4**) and indan (Eq. 2).[3] In the course of the reaction, it was found that tetracarbonylbis(η^5-4,5,6,7-tetrahydroindenyl)diiron (**5**) (Fpi dimer), which is structurally analogous to the Fp dimer, was formed. The stoichiometric reaction of **3** and $Fe(CO)_5$ gave **5** in a moderate yield (35—46%).[4]

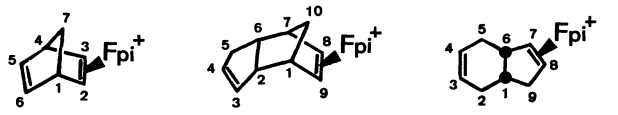


3 4 5 (2)

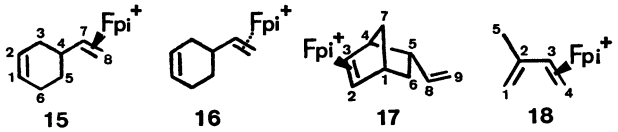
The Fpi moiety, which is more bulky than the Fp moiety, can be expected to provide a method for protecting the carbon–carbon double bonds. Thus, the Fpi(isobutylene)$^+BF_4^-$ complex (**6**) was prepared and used as a protecting group of the double bonds for various diolefins.

The preparation of **6** from **5** was achieved in 60—65% yields by a modification of the Rosenblum method[5] for the synthesis of **1**. Complex **6** reacted with a variety of diolefin **3**, **7**—**11** in 1,2-dichloroethane to afford Fpi(diolefin)$^+BF_4^-$ complexes **12**—**18** (Scheme 1). The yields of the Fpi(diolefin)$^+BF_4^-$ complexes were preferable to those of the ligand exchange between Fp(isobutylene)$^+BF_4^-$ and diolefins[1] (Scheme 1). The ^{13}C NMR chemical shifts of these complexes are listed in Tables 1 and 2.

The ligand exchange of **6** with bicyclo[2.2.1]hepta-2,5-diene **7** gave **12** in a 91% yield. In the ^{13}C NMR spectrum of **12**, the signal of the α-carbons (C-2 and C-3) shifted about 55 ppm upfield compared with those of **7**.[6] The *exo*-configuration of the Fpi$^+$ moiety in **12** was confirmed on the basis of the upfield shift (*ca.* 18 ppm) of the bridge carbon (C-7) attributable to the steric compression effect. The exchange of **6** with *endo*-tricyclo[5.2.1.$0^{2,6}$]deca-3,8-diene **8** proceeded



12 (91%) 13 (83%) 14 (60%)



15 (31%) 16 (31%) 17 (60%) 18 (95%)

Scheme 1.

regio- and stereoselectively, affording **13** in an 83% yield. A similar steric effect by the Fpi$^+$ moiety was observed at the bridge carbon (C-10) of **13**. This shows that the configuration of the Fpi$^+$ group in **13** has the *exo*-orientation.

The reaction of **6** with **3** gave exclusively complex **14**, in which the Fpi$^+$ group is probably located in an anti-direction. If the Fpi$^+$ moiety in **14** is situated in a sterically more crowded *syn*-geometry, obvious upfield shifts due to the steric compression effect must be observed in ^{13}C resonances of the fused cyclohexene ring.

The hydrogenation of **14** on Pd/C, followed by treatment with NaI, gave olefin (**19**) (Eq. 3).

19 (3)

The regiospecific formation of **14** is noteworthy, since the reactivities of the two double bonds in **3** closely resemble each other.

In the exchange of **6** with 4-vinyl-1-cyclohexene (**9**), the ^{13}C NMR spectra of resulting Fpi$^+$ complexes showed two pairs of signals having approximately equal intensities. Although the complexes could not be separated into components, from a consideration of their NMR spectra it was found that the exchange occurred regioselectively, but not stereoselectively, at the vinyl-double bond to give a stereoisomeric mixture of **15** and **16** whose subsequent hydrogenations led to the same olefin (**20**) (Eq. 4).

20 (4)

Previously, Nicholas[1] has reported that the exchange of **1** with 5-vinylbicyclo[2.2.1]hept-2-ene (**10**)[8] affords two regioisomers in which the Fp$^+$ group is coordinated to the vinyl- and bicyclo[2.2.1]heptenyl double bonds in a ratio of 65:35. However, the ligand exchange of **6** with **10** occurred preferentially at the bicyclo-[2.2.1]heptenyl double bond to give the Fpi complex **17**.[9]

a) 
b, c) An alternative assignment is also possible in each line.

The reaction of **6** with acyclic diene, isoprene **11**, took place regioselectively at the less hindered double bond to form Complex **18** in a 95% yield.

These results suggest that Complex **6**, which was readily prepared from the Fpi-dimer, serves as a good protecting group of carbon-carbon double bonds, especially toward the diolefins with a closely analogous reactivity. Furthermore, **6** shows a higher regioselectivity than Complex **1** in the exchange with certain diolefins.

Experimental

The IR spectra were taken with a JASCO-A202 spectrometer. The ^1H and ^{13}C NMR spectra were recorded with a JEOL PMX-60 and a JNM-PS-100 FT-NMR spectrometer respectively. The chemical shifts were obtained in a nitromethane-d_3 solution, containing TMS as the internal standard.

Materials. The Fpi dimer (**5**) was obtained in a manner similar to that described above.[3]

Fpi(isobutylene)$^+BF_4^-$ (**6**) was prepared by a modification of Rosenblum procedure.[5] To a solution of Fpi(η^1-2-methyl-2-propenyl) (33 mmol), which has been prepared from FpiNa and 2-methyl-2-propenyl chloride,[10] we added, drop by drop, 1 equiv of 42% HBF_4 in acetone (1:1) at 0 °C. Stirring was continued at 0 °C for 1 h. At the end of this time, 20 cm^3 of acetone was added, and then the solution was poured to a large amount of ether (500 cm^3). The orange crystals thus precipitated were collected and recrystallized from dichloromethane to give pure **6** in 60—65% overall yields; ^1H NMR (CD_3NO_2) δ=1.9 (m, 10H), 2.5 (m, 4H), 3.7 (s, 2H), 5.2 (s, 3H); ^{13}C NMR (CD_3NO_2) δ=21.4(t), 21.9(t), 27.7(q), 55.1(t), 84.0(d), 91.3(d), 110.1 (s), 122.7(s), 211.0(s); IR(Nujol) 3400, 2050, 1990, 1060, 1010 cm^{-1}.

*Ligand Exchange of **6** with Diolefins.* To a solution of diolefin (60 mmol) in 1,2-dichloroethane (200 cm^3) we added **6** (6 mmol) in 1,2-dichloroethane (80 cm^3). Stirring was continued at 65—70 °C for 10—15 min. After the subsequent removal of the solvent and unreacted diolefin *in vacuo*, the residue was dissolved in a minimum amount of acetone and filtered off. The filtrate was poured into 500 cm^3 of ether to precipitate Fpi(diolefin)$^+BF_4^-$ complexes in 60—95% yields.

Hydrogenation of Fpi(diolefin)$^+BF_4^-$ Complexes and Liberation of the Fpi Moiety from Complexes. The hydrogenations of **14**—**16** were accomplished according to the Nicholas procedure.[2] The hydrogenated complexes (0.8 mmol) were dissolved in nitromethane-d_3 (2 cm^3) containing sodium iodide (1.0 mmol), after with the mixture was refluxed for 3 h. After centrifugation, the supernatant was subjected to NMR measurements.

Hydrocyanation of α,ω-Diynes Catalyzed by Tetracyanonickelate. Regiospecific Synthesis of a New Series of Acyclic Dinitriles

Takuzo FUNABIKI,* Yoshihiro SATO, and Satohiro YOSHIDA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received February 17, 1983)

Synopsis. Hydrocyanation of α,ω-diynes without the use of HCN has been described. Cyanonickelate, prepared by reducing $[Ni(CN)_4]^{2-}$ with $NaBH_4$ or Zn in the presence of excess KCN in water or ethylene glycol, catalyzes hydrocyanation of α,ω-diynes, $HC{\equiv}C(CH_2)_nC{\equiv}CH$ to give quantitatively $CH_3CH(CN)(CH_2)_nCH(CN)CH_3$, a new series of acyclic dinitriles. Importance of the preliminary formation of a (π-acetylene)nickel(0) complex for the hydrocyanation has been suggested.

Previously we have reported the hydrocyanation of acetylenes, without the use of hydrogen cyanide, catalyzed by cyanocobaltate[1] and cyanonickelate.[2] The reaction is useful not only for synthesis of secondary saturated nitriles from acetylenes, but also for elucidation of mechanisms of hydrocyanation with the use of hydrogen cyanide, which have been little clarified. To extend the utility of this new method of synthesis of nitriles, we have studied the reaction of α,ω-diynes, $HC{\equiv}C(CH_2)_nC{\equiv}CH$ ($n=3$—6). The diynes were hardly hydrocyanated by cyanocobaltate. However, they were readily hydrocyanated by cyanonickelate to form $CH_3CH(CN)(CH_2)_nCH(CN)CH_3$ selectively. The nitriles synthesized here are new compounds except for the case $n=3$, in which the nitrile has been obtained by a complicated procedure, *i.e.*, by hydrogenation of $CH_3CH(CN)(CH_2)_2CH{=}C(CN)CH_3$ derived from 3,7-dicyano-3,7-dimethylperhydro-1,2-diazepine.[3] The chemistry of these dinitriles has not been studied, but it is well expected that the present method is applicable to the diynes irrespective to its chain length and that they are useful as starting materials for organic and polymer synthesis.

Results and Discussion

Hydrocyanation was performed under three different conditions, *i.e.*, $[Ni(CN)_4]^{2-}$ was reduced 1) by $NaBH_4$ in water, 2)by $NaBH_4$ in ethylene glycol (EG), or 3)by Zn in water, in the presence of excess cyanide ion. The results of hydrocyanation and the data for identification of products are shown in Tables 1 and 2, respectively. The reactivity of the diynes under the condition (1) ($NaBH_4$–H_2O) was low in contrast to the high reactivity of terminal monoacetylenes under the same condition.[2] The reactivity and selectivity for formation of dinitriles decreased with increasing chain length of the diyne. The reaction under the condition (2) ($NaBH_4$–EG) gave good yields of dinitriles regardless of the chain length, but the selectivity for the dinitrile synthesis decreased slightly with increasing chain length. The reactivity under the condition (3) (Zn–H_2O) was as high as that under the condition (2), but 1,6-heptadiyne formed mainly unsaturated mononitrile, $CH_2{=}C(CN)(CH_2)_4CH_3$. The reason for this peculiar reactivity is not clear at present.

Recently,[4] hydrocyanation of monoacetylenes has been performed by $Ni[P(OPh)_3]_4$ in the presence of hydrogen cyanide, but the hydrocyanation of terminal acetylenes forms not only the internal but also terminal nitriles, indicating that the regioselectivity is not so high as that in the present case. In addition, our procedure does not require the use of HCN. The yields of dinitriles in Table 1 indicate that the hydrocyanation proceeds catalytically. Because of good yields, very high regioselectivity, and experimental simplicity, the present hydrocyanation procedure is more useful for synthesis of internal dinitriles from α,ω-diynes than the conventional method.[4]

Table 1. Hydrocyanation of $HC{\equiv}C(CH_2)_nC{\equiv}CH$ by cyanonickelate[a]

a) $K_3[Ni(CN)_4]$ (0.8 mmol), KCN (1.6 mmol), diyne (0.8 mmol), at 45 °C, reaction time 6 h. b) $NaBH_4$ (4 mmol) or Zn (4 mmol) in 4 cm³ H_2O or ethylene glycol (EG). c) Determined by GLC analysis, based on added acetylenes. d) GLC and isolated (in parentheses, the reactions were performed in 20 cm³ of solvents) yields, based on added acetylenes.

It is known that in the presence of hydrogen cyanide $K_4[Ni(CN)_4]$ catalyzes hydrocyanation of activated olefins, and nonactivated olefins are hydrocyanated by other zero-valent nickel complexes such as $Ni[P(OR)_3]_4$.[5] In the absence of hydrogen cyanide, cyanonickelate catalyzes hydrogenation of olefins,[6] but not hydrocyanation. It has been proposed that in the hydrocyanation of olefins catalyzed by low-valent transition metal complexes (M) in the presence of HCN, H–M–CN is formed as an active species and olefins react with H–M–CN to form a σ-alkyl–M–CN complex (Eqs. 1 and 2).[5] Previously,[2] we have proposed a mechanism for hydrocyanation of acetylene, in which acetylene reacts directly with $[Ni(CN)_3H]^{2-}$ to form $[Ni(CN)_3(\sigma\text{-vinyl})]^{2-}$ in a similar way as shown in reactions (1) and (2). However, the mechanism cannot explain why olefins are not hydrocyanated in the absence of HCN. The peculiar reactivity of the complex with acetylene seems to be explained by assuming that the hydrocyanation proceeds *via* a (π-acetylene)nickel(0) complex. It is known that low-valent transition metal complexes form fairly stable

$$M + HCN \rightleftharpoons H\text{-}M\text{-}CN \quad (1)$$

$$H\text{-}M\text{-}CN + \rangle C{=}C\langle \longrightarrow \rangle CH\text{-}\underset{|}{C}\text{-}M\text{-}CN \quad (2)$$

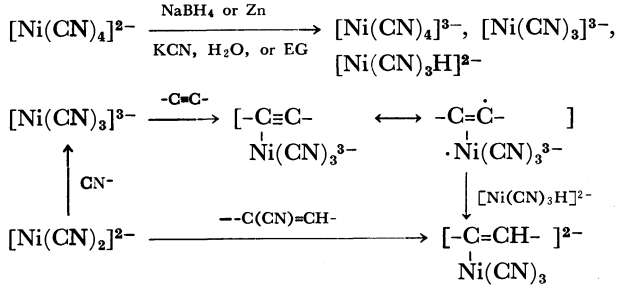
a) $CH_3CH(CN)CH_2)_nCH(CN)CH_3$. b) Oven temperature of Kugelrohr apparatus in the vaccum distillation (1 mmHg=133.322 Pa). c) A 3 m column of Silicone SE-30 (10% on Uniport B (60-80 mesh)), carrier gas flow 40 cm^3 min^{-1}, column temp 180 °C. A Shimadzu GC-4CM gas chromatograph was used, and data were analyzed by a Shimadzu Chromatopac E1A. d) ν_{CN}, observed with the neat film. e) Observed in $CDCl_3$, using TMS as an internal reference. JEOL FX-100 NMR spectroscopy was used. f) A mixture of two stereoisomers (the ratio is 2:3).



Scheme 1.

π-acetylene complexes.[7] The reaction solution may involve both zero- and univalent cyanonickelate,[6] but formation of the π-acetylene complex with Ni(0) seems more probable than with Ni(I). The coordinated acetylene may have some radical character,[7] and react with $[Ni(CN)_3H]^{2-}$ to form a (σ-vinyl)nickel(II) complex as shown in Scheme 1.

Experimental

The reaction was performed in a three-necked flask equipped with a cold finger at 45 °C under an atmosphere of nitrogen. $K_2[Ni(CN)_4]$ (0.8 mmol, 0.193 g), KCN (1.6 mmol, 0.101 g), $NaBH_4$ (4 mmol, 0.151 g), or Zn (4 mmol, 0.262 g) were placed in the flask. After purging the reaction vessel thoroughly with nitrogen, diyne, $HC{\equiv}C(CH_2)_nC{\equiv}CH$, (0.8 mmol, 0.09 cm^3 ($n$=3), 0.10 cm^3 ($n$=4), 0.12 cm^3 ($n$=5), 0.13 cm^3 ($n$=6), purchased from Tokyo Kasei Co. LTD) and 4 cm^3 of solvent (water or ethylene glycol) were added with syringes through a rubber serum cap, and the solution was stirred magnetically. The yellow reaction solution became dark red when the reaction was complete. The products were extracted with dichloromethane and analyzed by GLC, using a 3 m column of Silicone SE-30, with carrier gas flow of 40 cm^3 min^{-1}, at 180 °C. A larger scale reaction was also performed in a 20 cm^3 solvent, and the products were distilled by using Kugelrohr apparatus (Büchi's Glass Tube Oven KGR-50). Pure products were obtained by a preparative GLC. They gave satisfactory elemental analyses. Their structures were characterized by IR, ^{1}H, and ^{13}C NMR spectroscopy.

Synthesis of 2,9,23,30-Tetraoxa[2]paracyclo[2](1,1′)ferroceno[2]paracyclo-[2](1,1′)ferrocenophane-1,10,22,31-tetraone

Akira KASAHARA,* Taeko IZUMI, and Katsuo SAITO

(Received February 28, 1983)

Synopsis. Ferrocenophane, in which the two ferrocene rings are linked by ester bonds and *p*-substituted benzene rings, has been synthesized by the reaction of hydroquinone with 1,1′-bis(chloroformyl)ferrocene. The structure of the compound has been studied on the basis of the NMR and electronic spectra.

Although a considerable number of [*m*]ferrocenophanes with one or more bridges joining the two rings of ferrocene nucleus are known, the [*m.n*]ferrocenophane system in which two ferrocene nuclei are joined through two or more bridges has received little attention.[1] However, it has recently been reported that the [2.2]-,[2] [3.3]-,[3] and [5.5]ferrocenophanes[3] showed transannular π-electronic interactions owing to the relative proximity of the two bridging elements. In this report we wish to describe the synthesis of 2,9,23,30-tetraoxa[2]paracyclo[2](1,1′)ferroceno[2]paracyclo[2]-(1,1′)ferrocenophane-1,10,22,31-tetraone (**1**), in which the two ferrocene moieties are linked by ester linkages and *p*-substituted benzene rings.

The reaction of 1,1′-bis(chloroformyl)ferrocene (**2**) with an excess amount of hydroquinone (**3**) led to the formation of 1,1′-bis(*p*-hydroxyphenoxycarbonyl)-ferrocene (**4**), accompanied by a small amount of **1**. The reaction of **2** with **4** afforded **1** in 6% yield. Furthermore, in the presence of trifluoroacetic anhydride, the reaction of ferrocene-1,1′-dicarboxylic acid (**5**) with **3** afforded a mixture of **1** and **4**.

The reference compound, *p*-phenylene bis(ferrocenecarboxylate) (**6**), was prepared by the reaction of (chloroformyl)ferrocene (**7**) with **3**, accompanied by the formation of *p*-hydroxyphenyl ferrocenecarboxylate (**8**).

In the ferrocenophane **1**, the IR spectrum revealed the presence of 1,1′-disubstituted ferrocene and *p*-substituted benzene rings and ester linkage. In ferrocene, the distance between the two cyclopentadienyl rings is 3.32 Å,[4] while the van der Waals separation between the parallel π-systems is 3.345 Å.[5] The molecule of **1** probably exists in the conformation with the phenyl rings approximately parallel to each other and approximately coplanar to the plane of the cyclopentadienyl ring. Structural evidence for the structure of **1** mainly came from its ^{1}H NMR spectrum, which shows two peaks at δ 4.62 (m) and 5.01 (m) for the cyclopentadienyl protons and two peaks at δ 6.70 (d) and 6.99 (d) for the aromatic protons. The aromatic protons in **1** are shifted to higher field than the corresponding protons of the reference compound, *p*-phenylene bis(ferrocenecarboxylate) (**6**) (δ, 7.21 (s)). It has previously been reported that [2]paracyclo[2]-paracyclo[2](1,1′)ferrocenophane-1,9,17-triene, which has the parallel stacked configuration, shows an upfield shift of aromatic protons which lie in close proximity to opposed aromatic moiety.[6] So, the remarkable upfield shift of aromatic protons in **1** is probably due to a diamagnetic shielding effect to the opposed aromatic ring and clearly indicates a pallalel stacked configuration (**1**) rather than a cross-stacked one (**1a**).

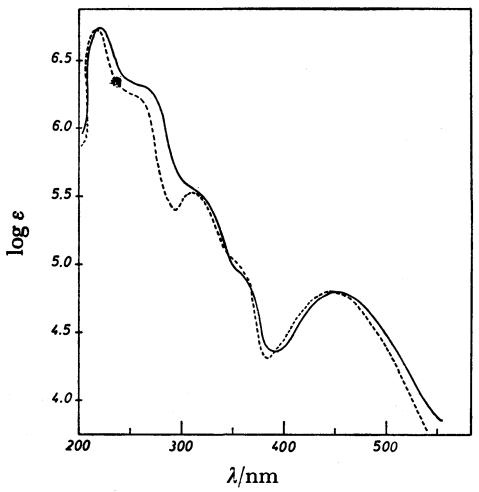

Fig. 1. Electronic spectra of **1** and **6** in tetrahydrofuran.
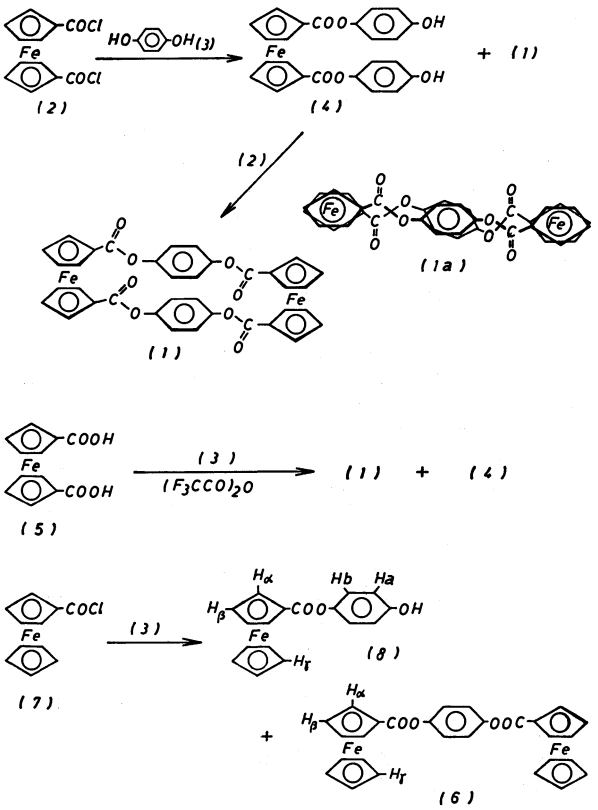
——: **1**, ----: **6**.



Scheme 1.

The electronic spectra of the ferrocenophane **1** and

the reference compound **6** are shown in Fig. 1. It is well known that the transannular electronic interactions in cyclophanes result in the bathochromic and hyperchromic shifts of absorption bands in electronic spectra.[7] The electronic spectrum of **1** showed somewhat bathochromic and hyperchromic shifts and an unambiguous broadening in a range 220—300 nm, compared with those of the reference compound **6**. This result may be due to transannular π-electronic interactions between the two aromatic chromophores in **1**. On the other hand, the electronic spectrum of ferrocene has two main absorptions at 325 and 440 nm, and it has been found that it is the 440 nm band which is most affected by the ferrocene ring tilt.[8] The electronic spectrum of **1**, in 330—450 nm region, is closely similar to those of open chain model **6**. This suggests that, in **1**, no ferrocene ring tilt distortion occurs.

Experimental

Measurements and Materials. All melting points are uncorrected. All reactions were performed under nitrogen. IR spectra were measured using a Hitachi 260-10 spectrophotometer. ^{1}H NMR spectra were obtained at 90 MHz with a Hitachi R-22 spectrometer using TMS as the internal standard. Mass spectra were recorded with a Hitachi RMU-6M spectrometer and electronic spectra with a Hitachi 200-10 spectrophotometer.

1,1′-Bis(chloroformyl)ferrocene (**2**)[9] and chloroformylferrocene (**7**)[10] were prepared by the methods described in the literature.

*The Reaction of 1,1′-Bis(chloroformyl)ferrocene (**2**) with Hydroquinone (**3**).* To a solution of **3** (6.93 g, 63 mmol) in dry acetonitrile (50 cm^3) was added dropwise a solution of **2** (6.52 g, 21 mmol) in dry benzene over 24 h under refluxing. After an additional 70 h period of reflux, the mixture was evaporated under reduced pressure. The reddish residue was chromatographed on silica gel.

The first fraction, eluted with chloroform–acetone (5:1) and followed by evaporation and recrystallization from ethanol, afforded orange crystals (3.65 g, 38% yield). These were determined to be **4** (mp 226—228 °C (decomp). IR (KBr): 3370 (–OH), 1690 (ester), 3100, 805 (1,1′-disubstituted ferrocene ring), and 865 cm^{-1} (*p*-substituted benzene ring). ^{1}H NMR (acetone-d_6): δ=4.68 (t, 4H, Hβ), 5.01 (t, 4H, Hα), 6.83 (d, J=9 Hz, 4H, Ha), 7.05 (d, J=9 Hz, 4H, Hb), and 8.49 (b-s, 2H, –OH). Found: C, 62.68; H, 3.81%; M$^+$, 458. Calcd for $C_{24}H_{18}FeO_6$: C, 62.90; H, 3.95%; M, 458.

The second fraction, eluted with chloroform-acetone (5:1) and followed by evaporation and recrystallization from benzene, afforded reddish orange crystals, mp 222—224 °C (decomp) (0.12 g, 0.82% yield). These were determined to be **1**. IR (KBr): 1720 (ester), 3100, 800 (1,1′-disubstiuted ferrocene ring), and 850 cm^{-1} (*p*-substituted benzene ring). ^{1}H NMR (tetrahydrofuran-d_8): δ=4.62 (m, 8H, Hβ), 5.01 (m, 8H, Hα), 6.70 (d, J=9 Hz, 4H, Ar–H), and 6.99 (d, J=9 Hz, 4H, Ar–H). Found: C, 61.93; H, 3.35%; M$^+$, 696. Calcd for $C_{36}H_{24}Fe_2O_8$: C, 62.09; H, 3.47%; M, 696.

*The Reaction of 1,1′-Bis(chloroformyl)ferrocene (**2**) with* 1,1′-*Bis(*p*-hydroxyphenoxycarbonyl)ferrocene (**4**).* The reaction of **2** (3.19 g, 10.3 mmol) with **2** (4.39 g, 9.6 mmol) was carried out in the same way as described above, and the ferrocenophane **1** was obtained in 6% yield.

*The Reaction of Hydroquinone (**3**) with Ferrocene-1,1′dicarboxylic Acid (**5**).* At room temperature, the solution of **3** (2.20 g, 20 mmol) in dry acetonitrile (25 cm^3) was added to the mixture of **5** (2.75 g, 10 mmol) and trifluoroacetic anhydride (5 cm^3) in dry benzene (30 cm^3). After an additional 30 h period of stirring, the solution was evaporated *in vacuo* and the residue was extracted with chloroform. The extracts were washed with 5% sodium hydrogencarbonate solution and then with brine, and the solvent was removed. The residue was purified by column chromatography on silica gel (chloroform–acetone (5:1)) to give **2** (25% yield) and 1 (11% yield).

*p-Phenylene Bis(ferrocenecarboxylate) (**6**).* The reaction of chloroformylferrocene (**7**) (9.92 g, 40 mmol) with **3** (1.84 g, 16.7 mmol) was carried out in the same way as has been described for the reaction of **2** with **3**, and the products were separated by chromatography on silica gel.

The first fraction, eluted with chloroform gave *p*-hydroxyphenyl ferrocenecarboxylate (**8**) as orange crystals, mp 179—180 °C, in 20% yield. IR (KBr): 3400 (–OH), 1690 (ester), 3100, 1100, 1000, 800 (monosubstituted ferrocene ring), and 850 cm^{-1} (*p*-substituted benzene ring). ^{1}H NMR (acetone-d_6): δ=4.30 (s, 5H, Hγ), 4.54 (t, 2H, Hβ), 4.92 (t, 2H, Hα), 6.87 (d, J=8 Hz, 2H, Ha), 7.05 (d, J=8 Hz, 2H, Hb), and 8.48 (b-s, 1H, –OH). Found: C, 63.30; H, 4.29%; M$^+$, 322. Calcd for $C_{17}H_{14}FeO_3$: C, 63.38; H, 4.38%; M, 322.

The second fraction, eluted with chloroform gave **6** as reddish orange crystals (mp 183—184 °C (decomp) in 40% yield. IR (KBr): 1725 (ester), 3100, 1100, 1000, and 800 (monosubstituted ferrocene ring). ^{1}H NMR ($CDCl_3$): δ= 4.29 (s, 10H, Hγ), 4.51 (t, 4H, Hβ), 4.97 (t, 4H, Hα), and 7.21 (s, 4H, Ar–H). Found: C, 62.83; H, 2.58%; M$^+$ 534. Calcd for $C_{28}H_{22}Fe_2O_4$: C, 62.95; H, 2.64%; M, 534.

2-(4-Chlorophenylseleno)-2-butenal as a New Dienophile for Diels-Alder Reaction

Kenji UNEYAMA, Kunikazu TAKANO, and Sigeru TORII*
Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700
(Received April 18, 1983)

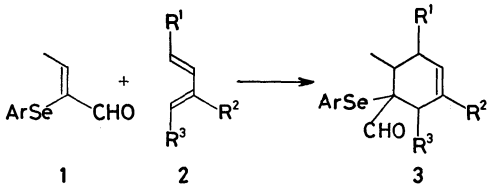
Synopsis. Diels-Alder reaction of 2-(4-chlorophenylseleno)-2-butenal with butadiene, isoprene, *trans*-1,3-pentadiene, and cyclopentadiene provided the corresponding adducts in 80—90% yields, which were subsequently transformed into cyclohexadienal derivatives.

Diels-Alder reactions of α,β-unsaturated carbonyl compounds have been extensively studied and well reviewed.[1] In the transition state a carbonyl group interacts significantly with π-bond of a diene giving an endo-product in preference to the exo-product.[1,2] Meanwhile, an α-substituent of α,β-unsaturated carbonyl compounds affects the reaction rate and regio- and stereoselectivity in both steric and electronic senses.[3] However, no report on the effect of selenium group has appeared. We describe here a prominent reactivity of 2-(4-chlorophenylseleno)-2-butenal (**1**) in Diels-Alder reaction with dienes.

Results and Discussion

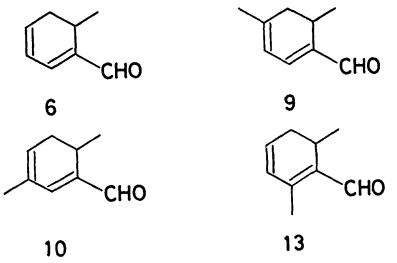
The seleno enal **1** was prepared by the electrochemical hydroxyselenenylation of 3-butyn-2-ol in acetonitrile–water in 87% yield.[4] The Diels-Alder reaction of **1** with butadiene proceeded at 115 °C, affording a normal cycloadduct **4** (81%) along with 1,4-cycloadduct **5** (9%).[5] The aluminum chloride-catalyzed reaction of **1** in dichloromethane proceeded smoothly at room temperature to give **4** (80%) as a sole product. In contrast to the successful cycloaddition of **1**, crotonaldehyde provided the desired adduct in 40% yield in similar reaction conditions (120 °C, 40 h), demonstrating that arylseleno group promotes the cycloaddition despite of the steric bulkyness. The usual oxidative deselenenylation of **4** provided the corresponding dienal **6** (89%).[6] Likewise, the reaction of **1** with isoprene provided a mixture of regioisomers in 92% yield (**7**:**8**=70:30). The structures of **7** and **8** were confirmed by the transformation into dienals **9** and **10**, respectively. The aluminum chloride-catalyzed reaction preferentially led to the formation of **7** (**7**:**8**=96:4). Oxidative deselenenylation of **7** provided **9** (95%, purity 99% by VPC). The apparent catalytic effect for the product selectivity with Lewis acids was consistent with those observed in the Diels-Alder reaction with acrylaldehyde and methyl vinyl ketone.[7] The reaction of **1** with *trans*-1,3-pentadiene gave two stereoisomers **11** and **12**.[8] Oxidative deselenenylation of a mixture of **11** and **12** gave dienal **13** (75%) which was subsequently dehydrogenated by the action of DDQ in a refluxing benzene, affording 2,6-dimethylbenzaldehyde in 66% yield.[9]

The selenide **1** added to cyclopentadiene, affording exo adduct **14** as a major product along with endo adduct **15** (**14**:**15**=62:38). The stereochemistry of **14** was elucidated by the examination of ^{1}H and ^{13}C NMR chemical shifts (Scheme 2). Consequently, methyl

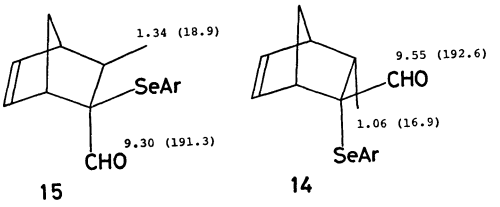


1 2 3

Scheme 1.



6 9 10 13



15 14

Scheme 2.

proton on C-3 of **15** was deshielded and in turn that of **14** was shielded. Taking into account of the endo preference in cycloaddition of cyclopentadiene with acrylaldehyde[2] and methyl acrylate,[10] the observed exo preference is quite unexpected. However, it is plausible that divalent selenide group would interact with π-bond of dienes as an electron accepting moiety.

Experimental

2-(4-Chlorophenylseleno)-2-butenal (1). A mixture of 3-butyn-2-ol (55% in water, 1.66 g, 13.0 mmol), bis(4-chlorophenyl) diselenide (495 mg, 1.3 mmol), Et_4NClO_4 (27 mg, 0.11 mmol), and concd H_2SO_4 (90 mg, 0.9 mmol) dissolved in MeCN (18 ml) and H_2O (3 ml) was electrolyzed at 65 °C under a constant current (3.3 mA/cm^2) for 58.5 h (16.8 F/mol) using platinum foils as electrodes in an undivided cell. Sat. $NaHCO_3$ (3 ml) was added. The organic layer was extracted with AcOEt. The extracts were washed with brine, dried over Na_2SO_4, and concentrated *in vacuo*. The residue was chromatographed (SiO_2) to give **1** as a pale yellow oil (585 mg, 87%): bp 90 °C/0.02 mmHg; ^{13}C NMR δ 190.3 (d), 158.6 (d), 136.9 (s), 133.0 (d), 132.7 (s), 129.2 (d), 127.7 (s), 19.0 (q); ^{1}H NMR δ 9.42 (s, 1H), 7.53—7.11 (m, 5H), 2.21 (d, J=4.6 Hz, 3H); IR (neat) 2720, 2675 (CHO), 1698 (C=O), 1617 cm^{-1} Found: C, 46.36; H, 3.48%. Calcd for $C_{10}H_9OClSe$: C, 46.27; H, 3.49%.

Thermal Diels-Alder Reaction of 1 with Dienes. A mixture of **1** (300 mg, 0.385 mmol), diene **2** (7.7 mmol) and

Convenient Preparation of Tetraarylphosphonium Halides

Toshihiko MIGITA,* Tohru NAGAI, Kazuhiko KIUCHI, and Masanori KOSUGI
Department of Chemistry, Faculty of Technology, Gunma University, Kiryu, Gunma 376

(Received May 6, 1983)

Synopsis. Tetraarylphosphonium halides, particularly iodides, can be conveniently prepared by the Pd-catalyzed reaction of aryl halides and triarylphosphines in good yields.

There have been known a few reactions which can be used for preparation of tetraarylphosphonium salts:

$$PhI + PPh_3 \xrightarrow[65\,°C,\ 46\,h]{h\nu} Ph_4P^+I^- \qquad 23\%^{1)}$$

$$PhN(NO)COCH_3 + PPh_3 \xrightarrow[PhH]{\text{aq. HBr}} Ph_4P^+Br^- \qquad 32\%^{2)}$$

$$PhMgBr + PhBr + PPh_3 \xrightarrow{CoCl_2} Ph_4P^+Br^- \qquad 55\%^{2)}$$

These reactions, which belong to a reaction of aryl radical with triarylphosphine, give relatively low yields, and the experimental procedures are not simple.

Previously aryl iodide and bromide activated by zero-valent palladium were shown to undergo nucleophilic substitution with soft nucleophiles such as thiolate and triphenylphosphine.[3] Here we wish to note utility of the Pd-catalyzed reaction of aryl halide with triarylphosphine for the preparation of tetraarylphosphonium halides.

$$Ar'X + PAr_3 \xrightarrow{[Pd]} Ar'P^+Ar_3X^-$$

The reaction takes place by heating a mixture of equimolar reactants, 1 mol% of $Pd(PPh_3)_4$ or more conveniently $Pd(OAc)_2$, and the solvent (aromatic hydrocarbon) at 120 °C for 25 h. The product, tetraarylphosphonium salt insoluble in the solvent, deposites as fine crystals, which can be easily collected and purified by recrystallization. Table shows a number of phosphonium salt obtained by using $Pd(OAc)_2$ as a catalyst.

The following tendencies about scope and limitation of the present method can be seen. Among halides, the best results were obtained by using aryl iodides as substrates. The reactions of aryl bromides gave only low yields and aryl chlorides hardly reacted with triarylphosphine under the conditions. Electron releasing substituents appear to enhance the reactivities of aryl halides. For example, *p*-methoxyiodobenzene reacts smoothly with triphenylphosphine even at lower temperature (100 °C), giving the corresponding quaternary salt in 96% yield. Reaction of negatively substituted iodobenzenes afforded poor yields such as given without the catalyst.

Perhaps due to steric hindrance, ortho substituents on aryl halide as well as triarylphosphine retard the reaction, giving quite low yields of phosphonium salts. Triarylphosphines bearing substituents which enhance the nucleophilicities of the phosphines gave better results.

Experimental

Material. Triarylphosphines were prepared by the known method from the corresponding arylmagnesium bromides and trichlorophosphine.[4] Commercially available products of palladium acetates and aryl halides were used without purification.

Procedure. A mixture of aryl halide (2 mmol), triarylphosphine (2 mmol), palladium acetate (0.02 mmol), and 3 cm^3 of a solvent (benzene or toluene) was placed in a tube. The tube was evacuated and sealed, then immersed in a bath kept at 120 °C for 25 h. In the course of the period the catalyst was dissolved and phosphonium salt separated from the solution. The salts were filtered, washed with benzene, and recrystallized from chloroform–benzene. The yield and analytical data of the products obtained by this procedure are listed in Table 1.

In the above procedure, the mixture was heated in an evacuated sealed tube to avoid Pd-catalysed oxidation of the phosphine by air,[5] but refluxing a solution of the reactants and the catalyst in xylene gave similar results. Thus from iodobenzene and triphenylphosphine, tetraarylphosphonium iodide was obtained in 80% yield by the refluxing method.

Nitrite Substitution on *cis*-Tetraamminediaquacobalt(III) Ion in HNO_2-NO_2^- Buffer Media

Manik Chandra GHOSH and Pradyot BANERJEE*
Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Jadavpur, Calcutta 700 032, India
(Received July 30, 1982)

Synopsis. The anation of the title complex by NO_2^- was followed spectrophotometrically. The anation proceeds in two steps. A simple second-order rate law applies to each step. No evidence has been furnished for the formation of any nitrito intermeidates.

Studies previously reported by Pearson *et al.*[1] showed that nitrite substitution reactions for pentaammineaquacobalt(III) and *cis*-aquabis(ethylenediamine)nitrocobalt(III) ions involve a nitrosation step followed by an intramolecular rearrangement to give stable nitro derivatives. Rates of the rearrangement reaction were found independent of the concentration of added nitrite. We report here some results from kinetic studies on reactions of *cis*-tetraamminediaquacobalt(III) ion with NO_2^-, which however has provided no evidence for *O*-nitrosation.

The formation of the dinitro complex was followed with a Pye-Unicam spectrophotometer SP8-150 by measuring the growth of its absorption maximum at 440 nm. Spectra of solutions which had ceased reacting were identical at nitrite concentrations exceeding *ca.* 0.04 M (1 M=1 mol dm^{-3}) at a given complex concentration (10^{-3} M) and agreed well with the spectrum of *cis*-tetraamminedinitrocobalt(III),[2] ensuring complete conversion to the product. Conventional pseudo-first-order plots of log $(A_\infty - A_t)$ *vs.* time (where A_t and A_∞ denote the absorbances at time=t and ∞ respectively) gave curved plots, suggestive of a biphasic nature of the reaction (Fig. 1) based on replacement of two coordinated water molecules, and were resolved following Weyh and Hamm.[3] At a constant pH the reaction was first-order dependent on $[NO_2^-]$ in each of the steps (Table 1). Variation of pH in the region 4.0—6.04 had no measurable effect on the first-step reaction rate ($k^{I}_{obsd}=(1.43\pm0.04)\times10^{-3}$ s^{-1} at $[NO_2^-]=0.1$ M, temp =40 °C, and $I=0.2$ M). The rate of the second-step reaction also remained constant upto pH *ca.* 5.6 ($k^{II}_{obsd}=(1.17\pm0.02)\times10^{-4}$ s^{-1} under the identical conditions), but on going above this pH, k^{II}_{obsd} dropped by as much as 30%. Experimental runs above pH 6.04 could not be conducted since the complex was found to decompose to form a brown precipitate.

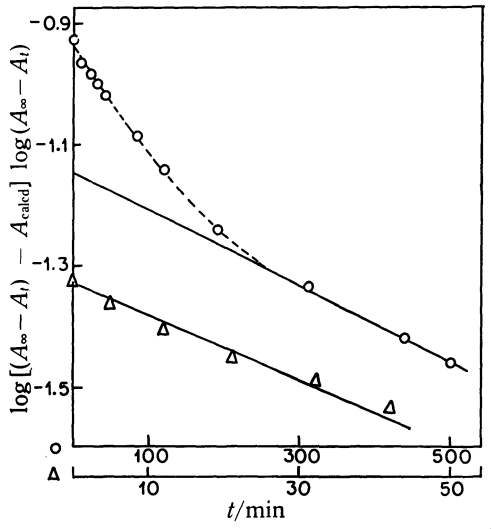

Fig. 1. A typical kinetic plot for the nitrite substitution of *cis*-$[Co(NH_3)_4(H_2O)_2]^{3+}$·[complex], 10^{-3} M; $[NO_2^-]$, 0.1 M; pH, (5.07±0.03); temp, 20 °C; I, 0.2 M ($NaClO_4$).
A_{calcd} at different times are extracted from the linear portion of the curve after extrapolation to zero time.

Except a few runs above pH 5.6, the anion and pH variation results are consistent with the rate law: rate= k[complex]$[NO_2^-]$. This simple rate law for the replacement of H_2O by NO_2^- is of some significance. In many $R_5Co(OH_2)^{3+}$–NO_2^- reactions[1,4] where R is an ammine, a nitrito intermediate is observed and the rate law assumes the form $-d[R_5Co(OH_2)^{3+}]/dt=k$[complex]$[NO_2^-]^2[H^+]$. This is generally the case when the water exchange rate is low and the second-order rate dependence on $[NO_2^-]$ arises from the involvement of N_2O_3. In the present system no nitrito intermediate could be detected and the NO_2^- dependence caused no measurable deviation from the first-order dependence. It may be that under the conditions adopted no formation of nitrito intermediate actually occurs. This points to a different mechanism operating here which involves rupture of the cobalt-oxygen bond. The pK_1[5] of the diaqua species under investigation is 5.69 at 20 °C. On going above pH 4.4, formation of aquahydroxo species starts. The absence of any pH effect on the first-step reaction suggests that both the

TABLE 1. RATE CONSTANTS IN THE NITRITE SUBSTITUTION REACTION OF *cis*-TETRAAMMINEDIAQUACOBALT(III) ION AT 20 °C

$10^2[NO_2^-]$ / M[a]	$10^4 k^{I}_{obsd}$ / s^{-1}	$10^3 k^{I}$ / $M^{-1}s^{-1}$[b]	$10^5 k^{II}_{(obsd)}$ / s^{-1}	$10^4 k^{II}$ / $M^{-1}s^{-1}$

a) pH=(5.07±0.03) held constant with $[NaNO_2]/[HClO_4]=100$; [complex]=1×10^{-3} M; ionic strength= 0.2 M ($NaClO_4$). b) Under the identical conditions, the second-order rate constants evaluated at 40 °C are $k^{I}=(1.35\pm0.10)\times10^{-2}$ $M^{-1}s^{-1}$ and $k^{II}=(1.19\pm0.04)\times10^{-3}$ $M^{-1}s^{-1}$.

diaqua and aquahydroxo species are kinetically indistinguishable with respect to the NO_2^- substitution. In the anation reaction of *trans*-$[Co(dmgH)_2(NO_2)(OH_2)]$ by NO_2^- ($dmgH^-$=dimethylglyoximate ion), Hague and Halpern[6] have shown two paths, one of which is pH independent (predominant at high pH) and the other pH dependent. The pH-independent path was shown to be first-order in $[NO_2^-]$. The pH-dependent path, though not studied in detail by the authors, has been presumed to be arising from attack of HNO_2 which apparently has stronger nucleophilicity than NO_2^-. The pH dependence on rate obtained for the mononitro species above pH 5.6 in our study may be attributed to the lower reactivity of the corresponding hydroxo species. The pK[5] (25 °C) of the second coordinated water in *cis*-$[Co(NH_3)_4(H_2O)_2]^{3+}$ is 8.0 and coordinated NO_2^- could have some effect for lowering this value significantly. This view is supported by known pK values[7] (25 °C) for closely comparable systems: 8.19 as the pK_2 of *cis*-$[Co(en)_2(H_2O)_2]^{3+}$ and 6.34 as the pK of *cis*-$[Co(en)_2(NO_2)(H_2O)]^{2+}$ (en=ethylenediamine).

Experimental

cis-Tetraamminediaquacobalt(III) perchlorate was prepared by the method described in the literature[8] and spectra of this compound matched well with those reported. Recrystallized sodium nitrite (AR grade) was used. Ionic strength was maintained with sodium perchlorate. Buffering was achieved by adding perchloric acid to sodium nitrite to a constant ratio.

Thanks are due to Dr. Mahesh Prasad Pujari for some technical assistance.

A Photochemical Storage Battery with an *n*-GaP Photoelectrode

Yoshiro YONEZAWA,* Makoto OKAI, Masato ISHINO, and Hiroshi HADA
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606
(Received December 27, 1982)

We have constructed a photochemical storage battery with an *n*-GaP Photoelectrode. A two-compartment cell, *n*-GaP|aqueous $K_3[Fe(CN_6]$–$K_4[Fe(CN)_6]$||aqueous $NiSO_4$|Pt, is capable of being charged by the irradiation of the photoelectrode. The current efficiency of nickel deposition on the storage electrode was 80%. When we drew electrical energy out of the dattery, the deposited nickel could act as a Ni electrode in the Ni^{2+} solution. The power efficiency of the storage battery amounted to about 2%. We could recharge the battery more than five times after discharge.

In an earlier paper, we proposed a concept of a solid-state photogalvanic cell.[1] We would now like to introduce a new term; a "photochemical storage battery," as a substitute, because it is less abstract and so less likely to cause unnecessary confusion regarding the concept. Active materials stored photoelectrochemically on the electrode surface can yield electrical energy whenever necessary. We have actually made up four kinds of batteries and found that the TiO_2|aqueous $Ce(SO_4)_2$–$Ce_2(SO_4)_3$||aqueous $AgNO_3$|Pt cell has especially excellent characteristics. Such a regenerative storage of light energy is one of the most remarkable advantages of photochemical storage batteries in contrast to usual photovoltatic cells. This aspect has been pointed out by several investigators recently.[2,3]

Two methods for storing light energy as solid materials on the electrode surface have been reported thus far. One of them, proposed by us,[1] is to use a half-cell of metal ion/metal, such as Ag^+/Ag and Cu^{2+}/Cu, while the other is to use a half-cell of either metal sulfide or metal hydroxide, such as $Ag_2S/Ag,S^{2-}$, $Ni(OH)_2/Ni$, OH^-, and $Cd(OH)_2/Cd,OH^-$, as introduced by Hodes *et al.*[2] and Ang and Sammells.[3] Though the *n*-TiO_2 photoanode is photochemically stable, the band-gap energy (3.05 eV, 405 nm) is rather large; therefore, the incident light available for energy storage is limited to the near-ultraviolet region. In contrast, *n*-GaP has a smaller band-gap energy (2.25 eV, 550 nm), but a photoanode made of it might suffer irreversible decomposition in an electrolyte solution. Recently, Memming has stressed that the anodic dissolution of the illuminated *n*-GaP electrode can be suppressed by adding the $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$ couple to the electrolyte at pH=6.5—9.5.[4] As the flat-band potential of *n*-GaP is *ca.* −1.0 V at pH=1 and the standard redox potential of this couple is +0.36 V *versus* a normal hydrogen electrode (NHE), various kinds of metal ion/metal combinations can be used as active materials for the storage electrode in the battery. In this report, we have chosen the Ni^{2+}/Ni couple (−0.25 V *versus* NHE) and tried to improve the power efficiency of the battery by using the *n*-GaP photoanode.

Experimental

The experimental setup of a photochemical storage battery and the procedure were almost the same as those reported previously.[1] A schematic representation of the battery was given in a figure of that paper. Single crystals of *n*-GaP, in the form of wafers 0.2—0.3 mm thick, were provided by the Sanyo Electric Co., Ltd. They were of a 99.999% purity, doped with S at the concentration of $(2—3)\times10^{17}$ cm^{-3}. The *n*-GaP photoelectrode(P) was prepared according to the method of Nakato *et al.*[5] The surface area to be exposed to the electrolyte solution was 1 cm^2. A storage electrode(A) was made of a platinum-black disk 3 cm^2 in area, while the counter electrode(C) was made of platinum and had a 5-cm^2 area. The two compartments were separated by three sheets of ion-exchange membrane(M). Each membrane was 1.7 cm^2 in area and *ca.* 0.2 mm thick. They were CSV (proton-permeable membrane), ACH-45 T (anion-specific membrane), and CSV, provided by the Tokuyama Soda Co., Ltd. Tne electrolyte solution in the compartment of the P- and C-electrodes consisted of aqueous solutions of 0.2 M-K_2SO_4, 0.05 M $K_3[Fe(CN)_6]$, and 0.05 M $K_4[Fe(CN)_6]$, while tnat in the A-electrode compartment consisted of aqueous solutions of 0.05 M K_2SO_4, 0.2 M $NiSO_4$, and 0.06 M $NiCl_2$. In order to keep the pH of the solutions between 6.5—7.0, it was sometimes necessary to add either H_3BO_3 or NH_4Cl to the electrolyte soulution in the A-electrode compartment. All the potentials given in this peper were measured *versus* NHE.

As the light source, a high-pressure 500 W mercury lamp (Ushio Denki Co., Ltd.) was used in combination with a cut-off filter VY-45 (Toshiba Co., Ltd.) and a water filter to select a longer-wavelength light of more than 450 nm. The incidentlight intensity between 450—540 nm was 3.1 mW cm^{-2} according to both ferric oxalate actinometry[6] and photoelectronic measurement by means of a photometer IL-600 (International Light Co., Ltd.). The amount of the Ni atom deposited on the storage electrode was determined by the aid of a Jarrel-Ash AA-780 atomic-absorption spectrophotometer.

Results and Discussion

The polarization curves of the *n*-GaP electrode were measured by using a potentiostat/galvanostat HA-104 (Hokuto Denko Co., Ltd.). The electrolyte solution was composed of K_2SO_4, $K_3[Fe(CN)_6]$, and $K_4[Fe(CN)_6]$, whose concentrations were the same as those used for the photochemical charging of the battery. The typical behavior of the *n*-type semiconductor electrode was observed: the dark current was not evident at an electrode potential more positive than −0.4 V, but it then increased steeply with the cathodic polarization. The anodic photocurrent flowed at an electrode potential more positive than −0.8 V, and

† 1 M=1 mol dm^{-3}.

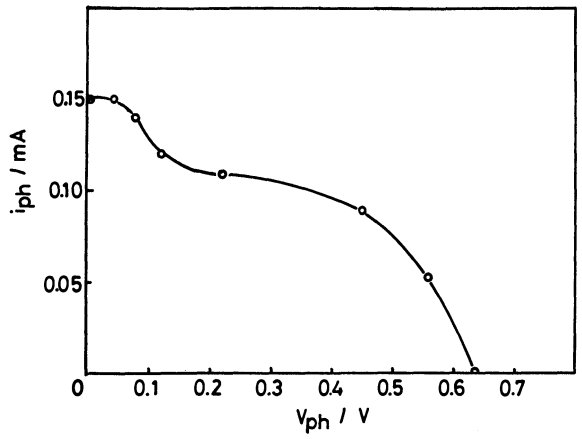

Fig. 1. Curve of photocurrent, i_{ph}, against photovoltage, V_{ph}, for the *n*-GaP battery: *n*-GaP|$K_3[Fe(CN)_6]$–$K_4[Fe(CN)_6]$||Ni^{2+}|Pt.

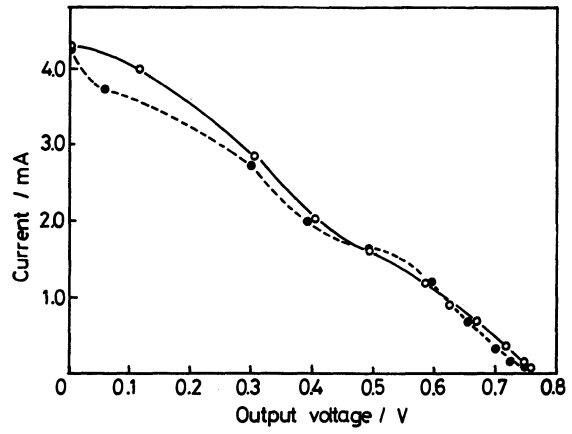

Fig. 2. The current-voltage characteristics of the battery: Pt|$K_3[Fe(CN)_6]$–$K_4[Fe(CN)_6]$||Ni^{2+}|Pt.

its saturated value was 155 μA cm^{-2}.

Figure 1 shows a curve of the photocurrent against the photovoltage during irradiation. The photocurrent flowed from a storage electrode to the GaP electrode. The net electrochemical reactions are as follows:

$$n\text{-GaP} + h\nu \longrightarrow e^- + p^+, \quad (1)$$

$$Ni^{2+} + 2e^- \longrightarrow Ni, \quad (2)$$

$$K_4[Fe(CN)_6] + p^+ \longrightarrow K_3[Fe(CN)_6], \quad (3)$$

where e^- and p^+ denote an electron and a positive hole respectively. The photocurrent under the short-circuit condition was 0.15 mA; the apparent quantum efficiency (the number of electrons passed per s divided by the number of incident photons for the 450—540 nm region per s) was *ca.* 13%. The photovoltage under the open-circuit condition was 0.63 V. On illuminating the battery for photochemical charging, the potential of the A-electrode shifted from +0.4 V to −0.2 V within 900 s, but after that it remained constant. After the cell had been illuminated for 7200 s (the quantity of electricity flowing was 1.08 C), the A-electrode was switched off from the P-electrode. Stored energy was stable in the dark for more than 24 h under the open-circuit condition. Electrical energy was drawn out by connecting the A- and C-electrodes through the external load resistance(L). We also tried to deposit the Ni atom on the A-electrode by using a galvanostat (electrochemical charging). Under a constant charging current of 2 mA, the potential of the A-electrode shifted from +0.4 to −0.3 V within 60 s, and after that remained constant. The current-voltage curve of the battery charged by 1.0 C in this manner was measured by changing the load resistance and was then compared with that charged photochemically (Fig. 2). The two cells show almost the same features: a short-circuit current of 4.3 mA and an open-circuit voltage of 0.75 V. The observed open-circuit voltage is somewhat larger than the difference in the standard electrode potential between Ni^{2+}/Ni and $[Fe(CN)_6]^{3-}$/$[Fe(CN)_6]^{4-}$. The discharge current with the load resistance was initially constant, but it gradually decreased with the discharge time. We could hardly draw any electrical energy out of the battery either before charging or after a nearly

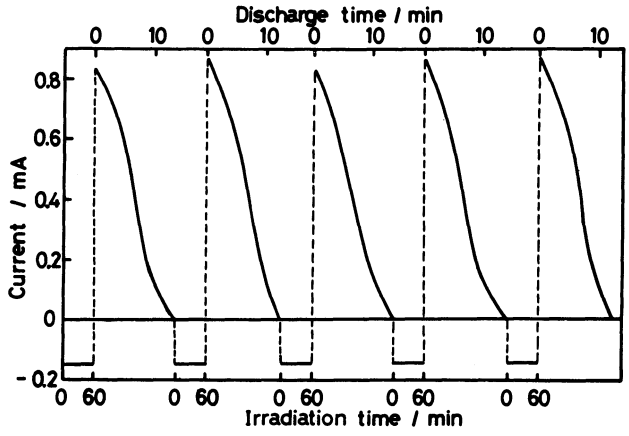

Fig. 3. Current of the battery during photochemical charging upon illumination of the *n*-GaP electrode and during discharge through A- and C-electrodes. The current of negative value corresponds to charging current when 2 Ω external resistance is inserted between P- and A-electrodes and that of positive value corresponds to discharge current with 700 Ω load.

complete discharge. The change in the performance of the battery during the cycle of photochemical charging and discharge has been examined (Fig. 3). The battery was capable of being recharged more than five times after discharge.

We have also examined the dependence of the amount of deposited Ni, Q_{Ni}, on the quantity of electricity passed through while charging the battery, Q_{ch}. The quantity of electricity flowing during irradiation was determined by integrating the total photocurrent. Figure 4 shows the linear relation observed for both photochemical and electrochemical charging. It is shown that the Ni deposition proceeds in this battery with a current efficiency of 80%. It should be noted, however, that the efficiency was considerably lowered when we used a platinum disk instead of the platinum-black disk as the A-electrode.

We have also investigated the behavior of the battery

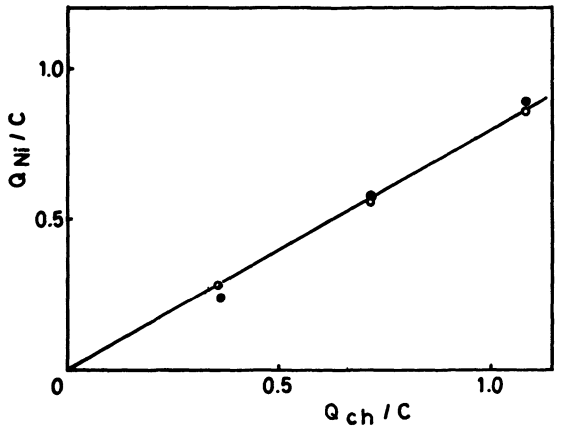

Fig. 4. Relation between the quantity of electricity flowed during charging, Q_{ch}, and the amount of Ni deposited on a platinum-black electrode, Q_{Ni}.

during discharge. After photochemical charging, the battery was discharged for an appropriate period, and the quantity of electricity flowing during that period, as determined from the discharge current, was compared with the amount of dissolved Ni. The latter value was evaluated approximately by subtracting the amount of Ni left on the A-electrode after discharge from the hypothetical amount of Ni deposited while charging the battery, *i.e.*, 80% of the quantity of electricity flowing during charging. Under such an approximation, it was deduced that the amount of Ni dissolved was almost the same as the quantity of electricity flowing during discharge; *i.e.*, Ni in quantities of about 0.0, 0.20, and 0.45 C was dissolved during the discharge of the battery by amounts of 0.0, 0.22, and 0.42 C respectively. We could thus determine that the deposited Ni at the A-electrode acts as a Ni electrode in the Ni^{2+} solution. Figure 5 shows the linear relation between the quantity of electricity flowing during discharge, Q_{dis}, and that during charging, Q_{ch}. In this case, Q_{dis} was determined by integrating the total current over the discharge time until the current fell off to *ca.* 1% of its initial value. Though the conversion efficiency of Q_{ch} to Q_{dis} seems to be sensitive to the discharge condition,[1] about 55% of the Q_{dis} could be drawn out of the battery as an effective discharge current. We suppose that the discrepancy between the efficiencies of conversion from Q_{ch} to Q_{Ni} and from Q_{ch} to Q_{dis} is due to the somewhat poor discharge condition; *i.e.*, some of the active materials stored during charging are still left on the A-electrode surface after discharge. We can also not overlook the possibility that the imperfect selectivity of on permeation of the separator(M) allows the self-discharge reaction to proceed to some extent during the prolonged discharge. According to a study of the electrochemical behavior of Ni in aqueous solutions,[7] it is likely that a passive film is formed in neutral and alkaline solutions under suitable conditions. However, judging from the fairly fine features, the formation of such a film seems not to be very likely in this battery. Nevertheless, it is possible that the electrode reaction

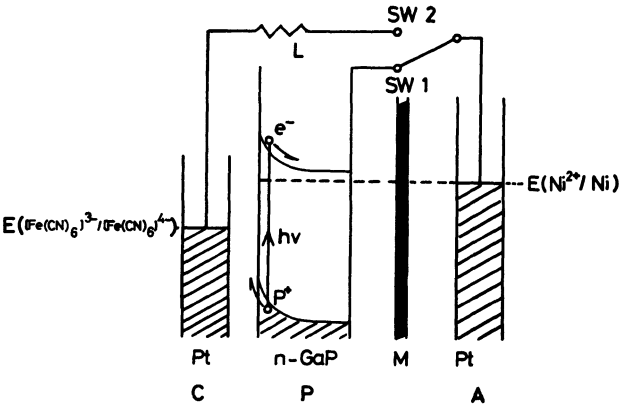

Fig. 6. Energy-level diagram of an illuminated battery.

of the $Ni(OH)_2/Ni,OH^-$ couple plays some role at the Ni electrode surface, resulting in a larger open-circuit voltage than that expected solely from the standard electrode potential of the Ni^{2+}/Ni couple. We may also note that the pH of the electrolyte solutions in this battery should be carefully controlled in view of two restrictions: the photodissolution of *n*-GaP and the passivity of Ni.

We could thus establish the photochemical charging of the storage battery with an *n*-GaP photoelectrode. An energy-level diagram of the battery during irradiation is shown in Fig. 6. In this battery, the storage of light energy is possible because of the existence of both the space-charge layer at the semiconductor surface and the separator between the cell compartments. The former assures the occurrence of charging reactions according to Eqs. 1—3, while the latter avoids the mixing of the $Fe(CN)_6]^{3-}$ and $[Fe(CN)_6]^{4-}$ in the compartment of the P- and C-electrodes and the Ni^{2+} in the compartment of the A-electrode. We could not dispense with the three-membrane system of the separator, as it was difficult to assemble a useful battery having only either an ACH-45T or CSV membrane. It seems that the existence of these three membranes has some effect upon the output voltage of the battery, as

the open-circuit voltage was slightly dependent on the combination of the membranes. We may try to define the power efficiency of the storage battery, η, in the following way:

$$\eta = \Phi_i \Phi_m \frac{q|E(\mathrm{Ox/Red}) - E(\mathrm{N}^{n+}/\mathrm{N})|}{E_g}, \quad (4)$$

where Φ_i and Φ_m denote the apparent quantum efficiency of the charging current and the efficiency of conversion from Q_{ch} to Q_{dis} respectively. E_g is the band-gap energy of the photoelectrode; $E(\mathrm{Ox/Red})$ and $E(\mathrm{N}^{n+}/\mathrm{N})$ are the standard electrode potentials of the redox couple and metal ion/metal respectively. q is the electron charge. As Φ_i and Φ_m are 13 and 55% respectively in this battery, η amounts to 1.9%. This value is considerably larger than the $\eta = 0.14\%$ evaluated for the storage battery with the n-TiO_2 photoelectrode.[1]

Hodes *et al.*[2] and Ang and Sammells[3] have used n-CdSe, n-GaAs, and n-$MoSe_2$ as the photoelectrodes of the photoelectrochemical systems with energy storage. In their cells, they have chosen various kinds of half-cells which demonstrate a good electrochemical cyclic performance in conventional batteries. However, the exact amount of light energy stored in the form of solid materials seems to be ambiguous in their cells, such as n-CdSe|S/S^{2-}|Ag_2S–Ag[2] and n-GaAs|Se/Se^{2-}|Cd[3], because they have employed metal electrodes themselves as the storage electrodes, *i.e.*, the Ag electrode in the former cell and the Cd electrode in the latter cell.

Of all the photoelectrolysis cells which can store light energy as chemical energy, light-energy storage as solid materials on the electrode surface seems to have two striking features; it enables the cell size to be compact, and the electrical energy can easily by drawn out of the cell by switching the junction of the electrodes.

This work was carried out with financial support from the Ministry of Education, Science and Culture (Grant-in-Aid for Scientific Research, No. 57040014).

Ab Initio SCF-SDCI Prediction of Type II Spectra and Geometry of $(ClHCl)^-$ Hydrogen Bond Complex. I. One Dimensional Vibrational Analysis

Toshikazu SAITOH,* Kazuhide MORI, Kotoku SASAGANE, and Reikichi ITOH
Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160
(Received January 17, 1983)

Ab initio SCF(self-consistent field)-SDCI(single and double configuration interaction) calculations are presented on HCl_2^-. Applied basis sets are 4-31G, 4-31G(**) (no 3d-polarization functions on Cl atoms and 2p-polarization functions on H atom), 4-31G** (addition of polarization functions both on Cl and H atoms) and the split basis by Dunning (Cl/12s9p)(H/4s)→[Cl/6s5p][H/2s] with the addition of diffuse functions and/or polarization functions. Vibrational and geometrical analyses are performed on the Cl–Cl potential surface under symmetry conservation, and then on the proton potential surface at optimized R_{Cl-Cl} position. After potential interpolation by the continuous quadratic functions which reconstruct the calculated potential values on all mesh points, the quantal vibrational analysis is perfomed by the Störmer-Levy difference method. Discussion is made on the experimental confusion about the assignment of type II spectra of HCl_2^- as ν_3 mode in an argon matrix by the selection of basis set and of CI matrix expansion. Whereas the calculations in a primitive size proposes the double minimum potential surface of proton and type II spectra in $\approx$700 cm^{-1} region as ν_3 (which corresponds to the experimental data by Evans and Lo (1966) and Ault (1975)), the extended calculations (*i.e.* the large basis sets and the great number of CI matrix expansion) reduce the central barrier of the proton potential and then conclude the IR absorption in 1000—1100 cm^{-1} region as ν_3 in the type II spectra (which corresponds to the experimental results of $CsCl \cdot 1/3\ [H_3O^+HCl_2^-]$ by Schröder (1970) and Smith (1973)).

It is the well known fact that the hydrogen bonded hydrogen dihalide ions $(XHX)^-$ and $(XHY)^-$ provide the useful informations about the symmetric and the asymmetric hydrogen bonds. Earlier investigations on this kind of molecules are focusd on $(FHF)^-$, which is one of the strongest hydrogen bonds (Hydrogen bond energy is 58 ± 5 kcal mol^{-1}).[1,2] Neutron diffraction,[3,4] neutron inelastic scattering,[5] and IR-Raman studies[6-8] predicted that HF_2^- ions in $NaHF_2$ and KHF_2 crystals have symmetric linear triatomic structure ($D_{\infty h}$ symmetry) with single minimum proton potential. Singh ans Wood (1968, 1969)[9] estimated the vibrational structure of this ion using the variational method for the empirical potential surface. Almlöf (1972)[10] calculated the *ab initio* SCF-MO potential surface of linear $(FHF)^-$ ion in the two vibrational degrees of freedom and succeeded in the assignment of the vibrational spectra with high accuracy. Jiang and Anderson (1973)[11] and Barton and Thorson (1979)[12] also performed the vibrational studies on $(FHF)^-$ by one-dimensional approach and adiabatic approximation respectively on the semi-empirical (Lippincott-Schröder) potential which was fitted to the MO potential by Almlöf. They also gave supports to the experimental accounts on the structure and properties of $(FHF)^-$ ion. Though the anions in KHF_2 and $NaHF_2$ have symmetric structures, $(FHF)^-$ in *p-toluidinium hydrogen difluoride* has an asymmetric structure affected by an enviroment. R_{F-F} is 2.26 Å in both symmetric salts and asymmetric salt. R_{H-F} distances in asymmetric $(FHF)^-$ ion are 1.025 and 1.235 Å.[13]

The hydrogen bond energies of $(ClHCl)^-$, $(BrHBr)^-$, $(IHI)^-$, and $(ClHBr)^-$ are 18.9,[14] 11.6, 7.3, and 9.1[15] kcal mol^{-1} respectively. This implies that the structures and spectra of those ions are readily influenced by the molecular enviroment. Waddington (1958)[16] reported the IR spectra of $(CH_3)_4N^+HCl_2^-$ and suggested that $(ClHCl)^-$ has the linear symmetric structure on the basis of the similarity of the spectra with that of $(FHF)^-$. Evans and Lo (1966)[17] obtained two different types of spectra for salts of HCl_2^- and $(ClHBr)^-$. They reported the IR spectra of $Cs^+HCl_2^-$ in solid phase and a series of $R_4N^+HCl_2^-$ type solutions. Type I spectra are observed for $Cs^+HCl_2^-$, $(CH_3)_4N^+HCl_2^-$, and n-$(C_3H_7)_4N^+HCl_2^-$. There are two intense broad peaks at 1520—1670 cm^{-1} and near 1200 cm^{-1} and weak band near 220 cm^{-1} in the type I spectra. Type II spectra are obtained for $(C_2H_5)_4N^+HCl_2^-$, n-$(C_3H_7)_4N^+HCl_2^-$, and n-$(C_5H_{11})_4N^+HCl_2^-$. Type II salts indicate intense and broad band at 700—800 cm^{-1} which is extending from 600 to 1300 cm^{-1} region and consecuted to another weak and broad peak at 1000—1050 cm^{-1}. Evans and Lo predicted that $(ClHCl)^-$ ions in type I salts are in the asymmetric ($C_{\infty h}$ or C_s) structures and type II salts are in the symmetric ($D_{\infty h}$ or C_{2v}) structures. Isotope frequency ratio of ν_3 suggests that the proton potentials are single minimum both in type I and type II salts. Nibler and Pimentel (1967)[18] also predicted that type I HCl_2^- ion in $Cs^+HCl_2^-$ salt is not in the symmetric structure by the group theory consideration on the infrared activities and by the analogy of IR spectra between Cs^+ClHBr^- and $Cs^+HCl_2^-$. Neutron scattering studies on $Cs^+HCl_2^-$ by Stirling *et al.* (1970),[19] Smith *et al.* (1973),[20] and Howard *et al.* (1979)[21] also gave supports to the prediction of the noncentrosymmetric structure of type I salts. The definitive structural data on a dichloride salt is obtained for $CsCl \cdot 1/3\ [H_3O^+HCl_2^-]$ by X-ray diffraction experiment (Schröder and Ibers (1966)[22]). The dichloride ions occur as strings$\cdots(ClHCl)^-\cdots(ClHCl)^-\cdots$, parallel to the hexagonal axis in the structure. R_{Cl-Cl} distance is 3.14 ± 0.02 Å. Schröder (1970)[23] also obtained type II spectra of this crystal. IR and Raman data predict the centrosymmetric structure for $(ClHCl)^-$ ion. ^{35}Cl Neutron Quadrupole Resonance (NQR) spectroscopy of $(ClHCl)^-$ salts show two different ^{35}Cl frequencies for

type I and type II salts. Ludman *et al.* (1970)[24] obtained ^{35}Cl NQR spectra on $(CH_3)_4N^+HCl_2^-$, $Cs^+HCl_2^-$ (type I salts) and on $(C_2H_5)_4N^+HCl_2^-$, $CsCl\cdot 1/3\,[H_3O^+HCl_2^-]$ (type II salts). ^{35}Cl frequencies of type I salt are classified into the group which indicate about 20 MHz and type II are about 12 MHz. Dixon *et al.* (1975)[25] obtained the theoretical value of ^{35}Cl NQR frequency by *ab initio* SCF-MO calculation with the use of minimal STO basis functions. Calculated values are 12.6 MHz for $(FHCl)^-$ and 37.5 MHz for $(ClHCl)^-$. Thomson *et al.* (1975)[14] also calculated the potential surface and ^{35}Cl NQR frequency for $(ClHCl)^-$ by *ab initio* SCF-MO applying STO double zeta+polarization basis functions. Their results are that;

(i) proton potential surface is flat (nearly single minimum) at $R_{Cl-Cl}=3.14$ Å (which corresponds to the experimental R_{Cl-Cl} distance of $CsCl\cdot 1/3\,[H_3O^+HCl_2^-]$), the proton localizes in the center of mass and then ^{35}Cl NQR frequency is 13.11 MHz,

(ii) proton potential has two equivalent minima at $R_{Cl-Cl}=3.22$ Å (which corresponds to the experimental R_{Cl-Cl} distance in $Cs^+HCl_2^-$), the proton localizes in either minimum and ^{35}Cl NQR frequency is 21.0 MHz in the two equivalent minima at $R_{HCl}=1.365$ Å.

It is assured by these experimental and theoretical results that HCl_2^- ions in type I salts are in the noncentrosymmetric structures and type II are in the centrosymmetric ones.

However on the assignments of ν_2 and ν_3 modes in type II spectra there are some disagreements among the experimental results. Evans and Lo assigned the ν_2 and ν_3 modes of $n\text{-}(C_5H_{11})_4N^+HCl_2^-$ as 1050 and 780 cm^{-1} respectively. Whereas Schröder (1970)[23] predicted $\nu_2=500$—$1200\ cm^{-1}$ and $\nu_3=1050$—$1200\ cm^{-1}$ for $CsCl\cdot 1/3\,[H_3O^+HCl_2^-]$. (The overlap with the ν_2 mode of H_3O^+, 1150 cm^{-1}, prevented the detailed assignments of ν_2 and ν_3 modes of $(ClHCl)^-$.) Neutroninelastic scattering studies of types II salts[20] predicted $\nu_2=795\ cm^{-1}$, $\nu_3=1275\ cm^{-1}$ for $(C_2D_5)N^+(CD_3)_3HCl_2^-$ and $\nu_2=795\ cm^{-1}$ for $CsCl\cdot 1/3\,[H_3O^+HCl_2^-]$. The ν_1 mode of centrosymmetric anion should be Raman active and IR inactive. Though type II spectra by Evans and Lo indicate the weak ν_1 absorption peak in the far-IR region (250 cm^{-1}), Schröder observed ν_1 mode as Raman active and far-IR inactive. The ν_1 mode by neutron inelastic scattering spectra[20] were 218 cm^{-1} for $(C_2D_5)N^+(CD_3)_3HCl_2^-$ and 275 cm^{-1} for $CsCl\cdot 1/3\,[H_3O^+HCl_2^-]$. Recently Ault and Andrews (1975)[26] reported a series of IR and Raman spectra of $M^+HCl_2^-$ (M=alkali metal) in the argon matrix. For example the results for $Rb^+HCl_2^-$ are $\nu_1=250\ cm^{-1}$ (Raman), $\nu_2=600\ cm^{-1}$ (IR), and $\nu_3=729\ cm^{-1}$ (IR). This encourage the assignments by Evans and Lo. ν_3 spectra of this type had been explained as those of HCl_2^- radical. Noble and Pimentel (1968)[27] obtained the IR spectra of $HCl/Cl_2/Ar$ matrix which indicate absorption peaks at 696.4 cm^{-1} (ν_3) and 955.6 cm^{-1} ($\nu_1+\nu_3$). However the later study (Milligan and Jacox (1970)[20]) by vacuum ultraviolet photolysis of HCl/Ar matrix provided the same spectra; $\nu_3=696\ cm^{-1}$ and $\nu_1+\nu_3=956\ cm^{-1}$, which were accounted as those of HCl_2^- ion. Type II spectra of alkali halide salts are consistent with those by Milligan and Jacox, and by Evans and Lo. The isotope frequency ratios ν_3^H/ν_3^D by Ault are almost the same those of harmonic oscillators. This is indicative of the single minimum potential for the vibration of proton. Since ν_1 is only Raman active, the structure of $ClHCl^-$ line is expected to have $D_{\infty h}$ symmetry.

The purpose of this paper is to determine the assignments of type II spectra of $(ClHCl)^-$ ion in the centrosymmetric structure by the theoretical consideration. We calculate the vibrational potential surfaces of Cl–Cl and proton by the *ab initio* SCF-SDCI method applying Gaussian basis sets. We still calculated the quantal vibrational eigenvalues for ν_1 and ν_3 modes by one dimensional Störmer-Levy difference method. In the next section we review the computational details, *i.e.* the selection of the basis sets, single and double excitations from the single reference state configuration interaction (SDCI) method, interpolation method of potential surface and quantal vibrational analysis (Störmer-Levy method). In the result section the calculated results are presented. In the final section we shall consider in the level of discussion the assignment of ν_3 in the type II spectra of centrosymmetric $(ClHCl)^-$ anion.

Computational Details

The AO basis sets employed in the present calculation are seven types of split valence ones. To clarify the types of basis sets we employ the following expressions,

(i) the well known 4-31G basis sets,[29]

(ii) 4-31G(**) *i.e.* we denote the addition of 2p polarization functions on H atom to 4-31G basis sets,

(iii) 4-31G** *i.e.* the addition of 3d polarization functions on Cl atoms and of 2p polarization functions on H atom,

(iv) [6s5p](**) basis for chlorine in a (6,3,1,1,1,1/5,1,1,1,1) contraction (*i.e.* [Cl/6s5p])[30] and hydrogen in a (3,1/1) contraction (*i.e.* [H/2slp]),[31]

(v) [6s5p](**)+diff basis sets with the addition of diffuse functions on Cl atoms to [6s5p](**) basis sets,

(vi) [6s5p]** basis sets with the addition of 3d polarization functions on Cl atoms to [6s5p](**) basis sets, and

(vii) [6s5p]**+diff basis sets with the addition of 3d polarization functions and diffuse functions on Cl atoms to [6s5p](**) basis sets.

The orbital exponents of 2p polarization functions of hydrogen are $\zeta_p=1.0$ (in 4-31G(**) and 4-31G**),[32] $\zeta_p=0.75$ (in Dunning basis sets)[33] which is optimized for HCl molecule. The exponents of 3d polarization functions are $\zeta_d=0.6$ for all basis sets, which is optimized for [Cl/6s4p] basis sets of HCl molecule.[33] Literature cited ζ_d value for Cl atom is 0.619 which is obtained by Ahlrichs equation, $\zeta_d=0.77\cdot Z-0.69$ (for $11\leqq Z\leqq 18$).[34] The employed ζ_d value will be a reasonable selection. The exponent of 3p diffuse function has the value $\zeta_{3p}=0.049$ for all Cl atoms.[35] SCF calculations are carried out with the use of GAUSSIAN 70 program[36] for 4-31G basis set calculations and with GAUSSIAN 76 program[32] for other basis sets in a double precision on IMS HITAC M-200H computers.

The CI calculations are in a single and double excitations from single reference state configuration interaction (SDCI) type[37] for 4-31G and 4-31G(**) calculations and in a direct SDCI (CIMI) type[38] for other calculations. All configuration state functions (CSF's)are treated with a common sets of MO's from the SCF solution. The valence occupied MO's of the SCF solution consist of $(\sigma_g)^2(\sigma_u)^2(\sigma'_g)^2(\pi_g)^4(\pi_u)^4(\sigma'_u)^2$ MO's. CSF's are generated from the pair of single and double excitations from the occupied MO's to the virtual MO's. For all calculations the size of CI matrix is selected so that the occupied MO's are restricted to the valence MO's only and the virtual MO's are from the lower state to a required state in consideration of the results. Another corrections to the CI energies are generated using Davidson's formula[39] for estimating the contribution of quadrupole excitations. Standard SDCI program is linked both to GAUSSIAN 70 and 76 SCF program and direct SDCI program is linked only to the latter.

The coordinates of the system are taken as to make two dimensional potential surface in which the vibration of Cl–Cl and proton on Cl–Cl axis occur. The origin of the potential is taken at the center of Cl–Cl. The interpolation of the MO potential is inevitable for the quantal vibrational analysis for the lack of mesh points. We employed the continuous quadratic functions interpolation method that is to interpolate the required potential values for the difference method. The procedure of the calculation starts with the computation of the MO potential value P_n at $N+1$ points S_n $(0 \leqq n \leqq N)$. Three pairs of potential data (S_{n-1}, P_{n-1}), (S_n, P_n), and (S_{n+1}, P_{n+1}) in a series provide one approximate potential function $f_n(x)=a_nx^2+b_nx+c_n$ which generates a series of mesh point values in a region $S_n \leqq x \leqq S_{n+1}$. The coefficients a_n, b_n, and c_n are given by,

$$a_n = \frac{P_{n-1}(S_{n+1}-S_n)-P_n(S_{n+1}-S_{n-1})+P_{n+1}(S_n-S_{n-1})}{(S_{n+1}-S_n)(S_{n+1}-S_{n-1})(S_n-S_{n-1})}, \quad (1)$$

$$b_n = \frac{P_n-P_{n-1}}{S_n-S_{n-1}} + a_n(S_{n-1}+S_n), \quad (2)$$

and

$$c_n = \frac{P_nS_{n-1}-P_{n-1}S_n}{S_{n-1}-S_n} + a_nS_{n-1}S_n (\text{for } 1 \leqq n \leqq N-1). \quad (3)$$

The potential value $h(x)$ (where $S_n \leqq x \leqq S_{n+1}$) are evaluated by the average of $f_n(x)$ and $f_{n+1}(x)$, which are generated succesively by the following equation,

$$h(x) = \frac{(S_{n+1}-x)f_n(x)+(x-S_n)f_{n+1}(x)}{S_{n+1}-S_n}$$
$$(\text{for } S_n \leqq x \leqq S_{n+1} \text{ and } 1 \leqq n \leqq N-1). \quad (4)$$

The potential values for $x<S_1$ and $x>S_{N-1}$ are extrapolated by the start and the final functions $f_1(x)$ and $f_N(x)$ respectively. The coordinates of the system are taken as the same ones by Almlöf[10] and Janoschek *et al.*[40] That is, the origin is centered on the $(Cl(1)–H–Cl(2))^-$ ion and the symmetry coordinates $R_{Cl-Cl}=R_{Cl(1)-H}+R_{Cl(2)-H}$ and $r_H=1/2\ (R_{Cl(1)-H}-R_{Cl(2)-H})$ are employed. This is one of the molecular Jacobi coordinates for symmetric linear triatomic system and is called as "molecular coordinates".[12] The reduced masses of two vibrational degrees of freedom are taken as $\mu_1=M_{Cl}/2$ and $\mu_3=2M_HM_{Cl}/(2M_{Cl}+M_H)$.

The quantal vibrational analysis is given by the Störmer–Levy difference method.[43] This method gives an accurate solution even in the case of discrete potential values in a numerical form with the great number of mesh points and with the proper selection of the position to start the initial guess at outside enough of the potential well. Vibrational analysis is performed on R_{Cl-Cl} surface and r_H surface. Initial point, final point, and the mesh width ΔR are taken as (2.7 Å, 3.8 Å, 0.001 Å) in R_{Cl-Cl} direction and (−0.914 Å, +0.886 Å, 0.001 Å) in r_H direction. The number of calculated MO potential values are 8 points in R_{Cl-Cl} direction and 11 points (21 points up to total by the symmetry) in r_H direction at optimized R_{Cl-Cl} distance.

Results

Figure 1 illustrates the correction energy variation in R_{Cl-Cl} direction. The effect of basis set extension is in the order 4-31G**>4-31G(**) both in magnitude and in R_{Cl-Cl} dependence of the shift value. This implies that the "steepness" of Cl–Cl potential curve is in the order 4-31G>4-31G**>4-31G(**) and the equilibrium

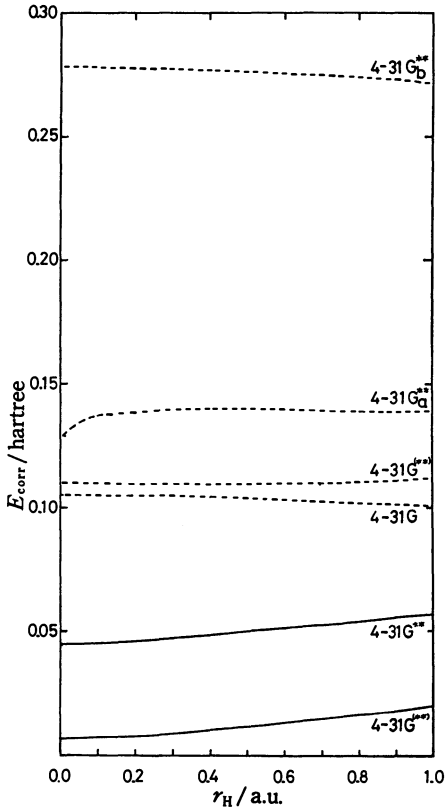

Fig. 3. Correction energy values on proton displacement from the symmetric position. $E_{corr}=E_T$(4-31G SCF)$-E_T$ for SCF calculations and $E_{corr}=E_T$(SCF)$-E_T$(CI) for CI calculations (in the same basis set). ——: SCF calculation and ------: CI calculation. 4-31G$_a^{**}$ denotes that the number of CI matrix expansion is 4005 and 4-31G$_b^{**}$ denotes that the expansion is 13041.

distance for Cl-Cl is in the order 4-31G>4-31G$^{(**)}$>4-31G**. Though the effect of CI is greater than that of basis set extension, R_{Cl-Cl} dependence of CI correction energy for the same basis set is rather small and in increase with the increase of R_{Cl-Cl}. This also implies that R_{Cl-Cl} potential become "gentle-sloping" in the long Cl–Cl distance and then lengthen the equilibrium Cl—Cl distance. The slope of CI potential curve is expected to be in the order 4-31G**>4-31G>4-31G$^{(**)}$. The effect of basis set extension cancel the effect of CI on the sloping of the potential. Thus the

basis set extension is expected to play an important role on the spacing of the vibrational energy to the extent of CI expansion terms.

Figure 2 shows the correction energies on Dunning basis sets. SCF results suggest that Dunning basis sets make the Cl–Cl potential "steeper" and make the equilibrium distance shorter in comparison with 4-31G SCF potential. The relation between SCF and CI among the SCF results for different basis sets are the same in 4-31G system. The CI correction value in the same number of CI expansion terms become smaller for the basis set extension from [6s5p]$^{(**)}$ to [6s5p]$^{(**)+diff}$. This indicates that the greater number of CI matrix expansion for the smaller basis set is the better selection to obtain the potential surface which involves the greater CI correction energy. Since R_{Cl-Cl} dependence of CI correction energy is relatively small, it is expected that the greater ν_1 value and shorter R_{Cl-Cl} distance appear in every calculation on Dunning basis sets in comparison with 4-31G results.

Tables 1 and 2 show calculated vibrational frequencies and optimized geometry of HCl_2^- for the basis sets (i)—(iii) and (iv)—(vii). In Tables 1 and 2 the above-mentioned tendencies are veirfied numerically. In Table 1 ν_1 values are in the order 4-31G** >4-31G $\gtrsim$4-31G$^{(**)}$ in SCF calculation. Since ν_1 values from CI potential are the sum of basis set contribution and CI contribution to the potential curvature around the equilibrium distance, the ν_1 variation become the complicated order. ν_1 values by CI are greater than those by SCF in 4-31G and 4-31G** CI(2). But the reverse relations are detected in 4-31G$^{(**)}$ and 4-31G** CI(1). In every calculation SDQ potentials provide no considerable shift in ν_1 values. R_{Cl-Cl} distances are also in the order 4-31G>4-31G$^{(**)}$>4-31G** in SCF calculations. In all basis sets in Table 1 R_{Cl-Cl} distances are in the order SCF>CI>SDQ. The competing contributions from basis set extension and CI and/or SDQ are indicated characteristically in Table 1. In Table 2 the effect of basis set extension makes ν_1 value greater The addition of diffuse function gives no significant shift on ν_1 value. Whereas the addition of 3d polarization functions on Cl atoms provides the greater ν_1 values. ν_1 values in all calculations correspond with the results for 4-31G**. Even in the case of [6s5p]$^{(**)}$ basis set ν_1 value is 37% greater than the experimental value 250 cm^{-1}. Whereas ν_1 values by 4-31G and 4-31G$^{(**)}$ SCF are only about 10% greater than the experimental value. Thus the basis set extension in every calculation seems to make the poorer fits of calculated ν_1 values to the experimental ones. Calculated equilibrium R_{Cl-Cl} distances show the same tendency as in 4-31G in the basis set extension. R_{Cl-Cl} distances are in the order [6s5p]$^{**+diff}$<[6s5p]**< [6s5p]$^{(**)+diff}$<[6s5p]$^{(**)}$ in SCF calculation. And the order SDQ>CI>SCF are detected for the R_{Cl-Cl} equilibrium distances by [6s5p]$^{(**)}$ and [6s5p]$^{(**)+}$< basis sets. Diffuse functions also make no significant effect on the equilibrium R_{Cl-Cl} distance. The competing relations between basis set extension and CI are also recognized in the calculations by Dunning basis sets. Both 4-31G**SDQ(2) and [6s5p]$^{**+diff}$ SCF calculations provide the best fits to the experimental R_{Cl-Cl} distance for CsCl·1/3 [$H_3O^+HCl_2^-$]. These results imply that the best calculation may be attained either by the small basis set and large scale CI calculation or by the large basis SCF calculation.

Figure 3 indicates the variation of correction energy in the direction of r_H. In the central region the potential is mainly depressed by CI correction energy in comparison with the SCF potential. Thus CI reduces the central barrier. But the 4-31G$_a$** result shows the anomalous depression of correction energy around the central position. This increases the anomalous barrier

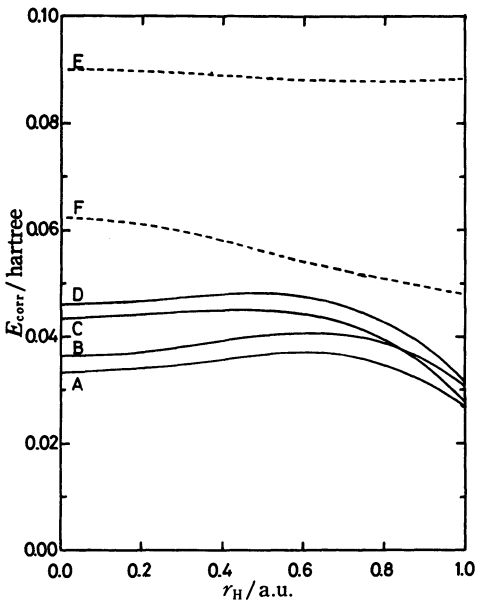

Fig. 4. Correction energy values (for Dunning's basis sets) on proton displacement from the central position. $E_{corr}=E_T(\text{4-31G SCF})-E_T$ for SCF calculation and $E_{corr}=E_T(\text{SCF})-E_T(\text{CI})$ for CI calculation (in the same basis set). The effects of basis set expansion are shown by —— and those of CI are shown by -------. A: [6s5p]$^{(**)}$ SCF, B: [6s5p]$^{(**)+diff}$ SCF, C: [6s5p]** SCF, D: [6s5p]$^{**+diff}$ SCF, E: [6s5p]$^{(**)}$ CI (the number of CI matrix expansion is 5565), F: [6s5p]$^{(**)+diff}$ CI (CI expans.=5565).

height. The reason for this will be discussed in the next section. In comparison with the relatively small change of CI correction energies on proton displacement, the correction to 4-31G SCF potential by the introduction of polarization function indicate the greater change on proton displacement. Slope of SCF correction curve is in the order 4-31G$^{(**)}$>4-31G**. Since the correction values by polarization functions are in the minimum at the symmetric position, SCF potentials for 4-31G$^{(**)}$ and 4-31G** are lowered in the asymmetric regions. This makes the central barrier greater and then makes ν_1 value smaller. Table 1 shows the numerical supports of these tendencies. The barriers come to be 404.4 and 88.6 cm^{-1} at 4-31G$^{(**)}$ SCF and 4-31G** SCF potentials respectively. The barrier height of 4-31G$^{(**)}$ SCF potential is reduced to be 205.5 and 115.9 cm^{-1} by introducing CI and SDQ respectively. In 4-31G calculation the barrier vanishes by CI(2) and SDQ(2) calculations. Though ν_3 values are about 1050 cm^{-1} in cases of single minimum potential, they decreased to be 550—870 cm^{-1} in double minimum potentials. The shift of ν_3 value for the basis set extension is in the order 4-31G>4-31G**>4-31G$^{(**)}$ and for the methods is in the order SDQ>CI>SCF. Exception is detected in the calculation of 4-31G** CI(1) and SDQ(1), in which the anomalous central barriers exist because of small number of CI matrix expansion.

Figure 4 shows the correction energy values on proton displacement from the symmetric position for the group of Dunning basis sets. The contribution from 3d polarization functions on the correction energy show the maximum at $r_H=0.5$ a.u. and is reduced in the highly asymmetric region. Whereas the contribution from the diffuse functions seems to be in nearly constant value in all regions. CI correction values are diminished in the asymmetric region and the value for [6s5p]$^{(**)+diff}$ (curve F) is smaller than that for [6s5p]$^{(**)}$ (curve E) in the same number of CI expansion terms and the curve E decreases in the asymmetric region. This implies the size of CI is not sufficient in [6s5p]$^{(**)+diff}$ CI calculation. These trends are also verified by the numerical results in Table 2. All of SCF potentials indicate double minimum shapes. The barrier heights by the SCF calculations are in the order [6s5p]$^{(**)+diff}\gtrsim$[6s5p]$^{(**)}$ >[6s5p]$^{**+diff}\gtrsim$[6s5p]**. The barrier heights for the methods are in the order SCF>CI>SDQ for [6s5p]$^{(**)}$ calculation. The barrier height for [6s5p]** or [6s5p]$^{**+diff}$ is nearly the same for 4-31G**.

ν_3 varies from 688.3 cm^{-1} to 892.4 cm^{-1} in SCF calculations. The contribution of 3d polarization functions adds about 100 cm^{-1} to the ν_3 values without 3d polarization functions. Single minimum potentials for [6s5p]$^{(**)+diff}$ CI and SDQ make ν_3 greater than 1100 cm^{-1}. The effect of diffuse functions on ν_3 is not significant. Whereas CI and SDQ contributions make ν_3 slightly greater than that by SCF value in [6s5p]$^{(**)}$ calculation. The experimental ν_3 values for $M^+HCl_2^-$ (M=alkali metal) varies from 658 to 736 cm^{-1}. Theoretical results by Jiang and Anderson[11] are $\nu_3=762$ cm^{-1} and $R_{Cl-Cl}=3.133$ Å, which are well corresponding with the experimental results. The value of barrier height 81 cm^{-1} by Jiang and Anderson corresponds well with our results by 4-31G** SDQ, 4-31G** SCF [6s5p]$^{(**)}$ CI, [6s5p]** SCF, and [6s5p]$^{**+diff}$ SCF. R_{Cl-Cl} value by 4-31G$^{(**)}$ is greater than the experimental ones. Results by above-mentioned basis sets except for 4-31G$^{(**)}$ seem to show good agreements with the experimental values not only in R_{Cl-Cl} but also in ν_3 value and the barrier height. However the isotope frequency ratios ν_3^H/ν_3^D are in poorer agreements with the experimental values. The experimental ones show nearly the harmonic values. But the above-mentioned values show the greater isotope frequency ratios about 1.7—1.9. Though the values for the single minimum potential show better fits to the experimental ν_3^H/ν_3^D values, ν_3^H is about 300 cm^{-1} greater than the experimental ones. The calculated results have lead us to the complicated situation in which the alternative relations exist between the small ν_3 value and the fit of ν_3^H/ν_3^D. This is the critical point for the explanation of the state of isolated HCl_2^- ion; *i.e.* whether isolated HCl_2^- has double minimum potential or single minimum one along r_H axis. Experimental R_{Cl-Cl} values of HCl_2^- are obtained for $(CH_3)_4N^+HCl_2^-$ and CsCl·1/3 [H_3O^+ HCl_2^-] crystals. The longer experimental R_{Cl-Cl} value is 3.22 Å for $(CH_3)_4N^+HCl_2^-$ which corresponds with the asymmetric bond. And the shorter experimental R_{Cl-Cl} value is 3.14 Å for CsCl·1/3 [$H_3O^+HCl_2^-$], which agrees well with the results by 4-31G**, [6s5p]**, and [6s5p]$^{**+diff}$. Experimental ν_3 value of type II spectra for n-$(C_5H_{11})_4N^+HCl_2^-$ is obtained by Evans and Lo as 780 cm^{-1} and for CsCl·1/3 [$H_3O^+HCl_2^-$] is predicted as 1050—1200 cm^{-1} by Schröder. Calculated

a) Numbers in parentheses denote CI matrix expansion. b) E_{400} denotes the total energy at R_{Cl-H} = 2.4087 a.u. and R_{H-Cl^-} = 400 a.u. c) The total energy at R_{Cl-H} = 2.4087 a.u. and R_{H-Cl^-} = 20 a.u.

ν_3 value for 4-31G(**) SDQ is 711.5 cm^{-1} and for 4-31G** SDQ (2) is 1094 cm^{-1}. Since SCF results for [6s5p](**), [6s5p]**, and [6s5p]**+diff give the counterpart of 4-31G** SCF results, 4-31G** represents the large basis sets. The shift of basis sets from 4-31G(**) to 4-31G** may represents the change from double minima to single minimum in the large CI and SDQ calculations. The experimental values of isotope frequency ratio ν_3^H/ν_3^D are near the harmonic value 1.42 for $(C_2H_5)_4N^+HCl_2^-$, 1.37 for n-$(C_3H_7)_4N^+HCl_2^-$, and 1.48 for n-$(C_5H_{11})_4N^+$-HCl_2^- in solution. In Table 2 the isotope frequency ratios for $M^+HCl_2^-$ (M=alkali metal) in argon matrix are given and ν_3^H/ν_3^D values vary from 1.42 to 1.51. The calculated results to provide lower ν_3 values (*i.e.* in the case of double minimum potential) show greater ν_3^H/ν_3^D values than the harmonic ones. ν_3^H/ν_3^D values close to harmonic ones are attained in the cases of single minimum potential. Introduction of CI reduces ν_3^H/ν_3^D value to the extent of the decrease of the central barrier in every case, but increase ν_3 value to be greater than 1000 cm^{-1}.

Tables 3 and 4 show the calculated hydrogen bond energies of HCl_2^- for SCF and CI calculations. Vibrationally corrected hydrogen bond energy ΔE_{corr} is obtained as follows;

$$\Delta E_{corr} = (E_{\infty}^{ClHCl^-} - E_{min}^{ClHCl^-}) + (E_{vib}^{HCl} - E_{vib}^{ClHCl^-}), \quad (5)$$

where $E_{\infty}^{ClHCl^-}$ denotes the total engy at $R_{H\cdots Cl}=\infty$ which is replaced by the value at R_{Cl-H}=2.4087 a.u. and $R_{H\cdots Cl}$=400 a.u., $E_{min}^{ClHCl^-}$ denotes the minimum energy in the total potential surface, E_{vib}^{HCl} denotes the vibrational zero point enrgy of HCl molecule and $E_{vib}^{ClHCl^-}$ denotes the vibrational ground state energy of $ClHCl^-$. The former parenthesis in Eq. 5 means the contribution of electronic energy difference between Cl–H···Cl^- and $ClHCl^-$. And the latter means the vibrational correction part. ΔE value is also estimated by the difference between the energies of HCl+Cl^- and $ClHCl^-$ (*i.e.* $\Delta E'=E_{Cl^-+HCl}-E_{min}^{ClHCl^-}$). In the case of 4-31G ΔE become 31.70 kcal mol^{-1} for SCF and 30.96 kcal mol^{-1} for CI, where the number of CI matrix expansion is employed the value 325 for HCl and 153 for Cl^-. Though ΔE values are greater than $\Delta E'$ in the case of 4-31G, we employ the ΔE value for simplicity of the estimation of CI energy. Orbital crossings to make significant change of CI correction value have not occured in every calculation between the equilibrium point and near dissociation limit. We also employed the correction by the experimental value of the vibrational zero point energy of HCl. The experimental vibrational constants of HCl are ω_e=2990.9 cm^{-1} and $\chi_e\omega_e$=52.8 cm^{-1}.[43] Thus the zero point energy of HCl is 1482.3 cm^{-1}. The vibrational correction terms are evaluated by the difference between the zero point energy of free HCl and the sum of zero point energy of ν_1 and ν_3. In comparison with the experimental value of hydrogen bond energy of HCl_2^- (18.9 kcal mol^{-1}), calculated values by 4-31G and its extended basis sets are fairly overestimated both in SCF and CI calculations. Though introduction of polarization functions reduce

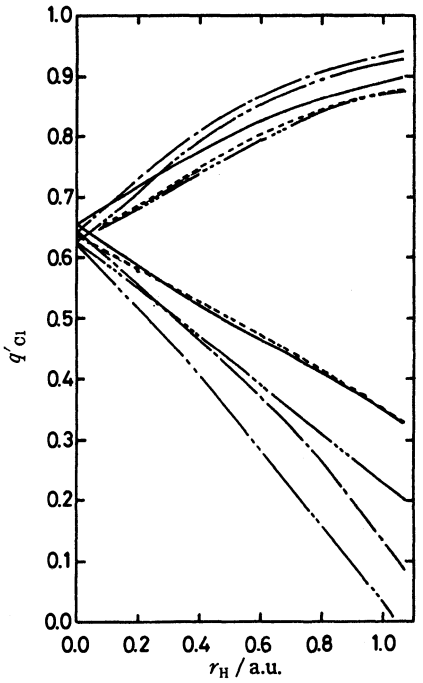

Fig. 5. Shift value of atomic charge on Cl ($q'_{Cl}=q_{Cl}-17.0$) with the proton displacement from the symmetric position at $R_{Cl-Cl}=3.228$ Å for 4-31G, 4-31G(**), and 4-31G**, at $R_{Cl-Cl}=3.157$ Å for [6s5p](**) and at $R_{Cl-Cl}=3.143$ Å for [6s5p]**. ------: 4-31G SCF, -----: 4-31G(**) SCF, ——: 4-31G** SCF, —·—: [6s5p](**) SCF, and ·—·—·: [6s5p]** SCF. CI results are not shown because the shifts on CI from SCF values are not so remarkable.

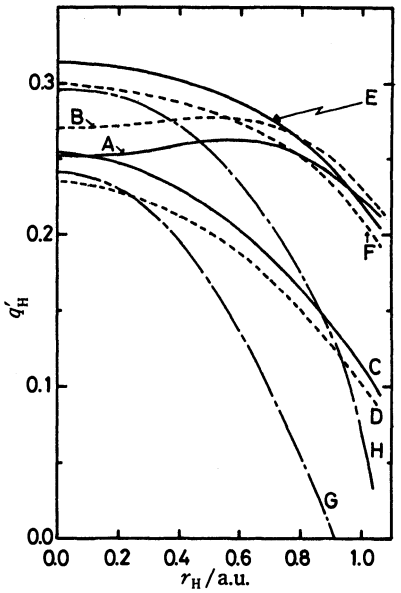

Fig. 6. Shift value of atomic charge on H ($q'_H=1.0-q_H$) with the proton displacement from the symmetric position at $R_{Cl-Cl}=3.228$ Å. R_{Cl-Cl} values are the same as that of Fig. 5. A: 4-31G SCF, B: 4-31G(**) CI (the number of CI matrix expansion is 3321), C: 4-31G(**) SCF, D: 4-31G(**) CI (CI expans.=5565), E: 4-31G** SCF, F: 4-31G** CI (CI expans.=13041), G: [6s5p](**) SCF, and H: [6s5p]** SCF.

both ΔE value and vibrational correction value and then reduce ΔE_{corr}, ΔE is rather greater than the experimental one in the best approximation. CI results are greater than SCF ones except for 4-31G. This is attributed to the difference of the weight of CI estimation in the total energy between $(Cl-H-Cl)^-$ and $Cl-H\cdots Cl^-$. Since SCF energy for 4-31G is obtained at $R_{H\cdots Cl^-}=20$ a.u. by the computational restriction, CI correction value is taken much more than in other cases. The SCF energy difference between the point at $R_{H\cdots Cl^-}=$ 200 a.u. and 400 a.u. is in the order 10^{-6} Hartree which approaches to the threshold of SCF convergence 10^{-7} hartree. The ΔE_{corr} values for [6s5p](**) and its extended basis sets are close to the experimental value. The extension of the basis set reduce the calculated hydrogen bond energy ΔE_{corr}. The effect by diffuse function is greater than that by 3d polarization functions. Though CI increase ΔE_{corr}, the weight of CI is greater in [6s5p](**) than in [6s5p](**)+diff. ΔE_{corr} value (SCF) for [6s5p]**+diff (19.33 kcal mol^{-1}) closes to the experimental one.[14] This is better than the SCF value, 28.96 kcal mol^{-1}, by Thomson *et al.*[14] $\Delta E'$ value for 4-31G SCF, 31.7 kcal mol^{-1}, is in agreement with the result by Alagona.[42] Our results give support to the experimental prediction of hydrogen bond energy of isolated HCl_2^- ion by Ault and Andrews[26] as 18—20 kcal mol^{-1}.

To verify the propriety of the basis sets we also estimated the shift of atomic charge on Cl and H with the proton displacement from the central position in Figs. 5 and 6 respectively. The shifts of atomic charge on Cl indicate no significant variation between SCF and CI, and among small basis set and extended ones. The curve for CI are not shown in Fig. 5. In Fig. 5 it is shown that there is little difference on the charge of Cl^- between the curves for 4-31G and 4-31G**, but significant difference on the charge of Cl at HCl side in the process $ClHCl^- \longrightarrow ClH+Cl^-$. The shift of Cl charge on HCl molecule is the same for 4-31G and 4-31G** and is also the same for [6s5p]** and 4-31G(**). The shift of Cl^- charge is in similar curves for [6s5p]** and [6s5p](**). These results provide the fact that the effect of 3d polarization function appears mainly on the HCl molecule rather than Cl^- and calculated hydrogen bond energy is fairly improved as the difference between the charges on Cl^- and Cl become greater with the extension of basis set. The improvement by the extension of basis sets appears considerably on Cl atom of HCl. Figure 6 shows the shift of atomic charge on H with the proton displacement from the central position. For every basis set SCF and CI curves are nearly in pararrel but slightly close with each other in an asymmetric region. The anomalous variations of q'_H are detected for 4-31G results. 4-31G(**) and [6s5p](**) curves are close to 4-31G curve at $r_H=0$ a.u. and q'_H decrease monotonically in asymmetric region. The reason of the anomalous shift of q'_H is attributed to the lack of 2p polarization functions on H atom. The q'_H values for extended basis sets (*i.e.* 4-31G** and [6s5p]**) are almost the same and are about 0.3 at $r_H=0$ a.u., but the shift along r_H is the greatest for [6s5p]**. The great variations of

q'_H are detected for Dunning basis sets. The shift values for 4-31G and its extended basis sets are rather small. It is summarized that,

(i) the effect of 3d polarization functions on Cl appears to be the increace of q'_H at $r_H=0$ a.u.,

(ii) the effect of 2p polarization functions on H atom reduces the anomalous change of q'_H,

(iii) the effect of basis set extension 4-31G→[6s5p] results in a great shift of q'_H along r_H.

The check on R_{Cl-Cl}, the hydrogen bond energy and (q'_{Cl}, q'_H) indicate that the addition of 2p polarization functions on the basis functions of hydrogen bonding H atom makes remarkable improvement for the calculation and that even in the calculation by small basis set such as 4-31G** the potential function around the equilibrium distance may provide the reliable vibrational constants of HCl_2^-.

Discussion

As mentioned in the previous section, in type II spectra of $ClHCl^-$ anion the experimental values of ν_3 are classified into the two series of data. One is predicted to take the value about 1050 cm^{-1} in $CsCl\cdot 1/3$ [H_3O^+-HCl_2^-] crystal.[23] And another is about 700 cm^{-1} in $M^+HCl_2^-$ (M=alkali metal) in argon matrix.[17,26] One of our results by the use of 4-31G** basis set and CI calculation seems to correspond to the experimental value. However the results by 4-31G(**) and [6s5p](**) seems to correspond to the latter experimental value. Our results of R_{Cl-Cl} by the use of 4-31G** CI correspond to the former experimental one ($R_{Cl-Cl}=3.14$ Å). Whereas the calculated results $R_{Cl-Cl}=3.22$ Å and $\nu_3=700$ cm^{-1} are obtained by the use of 4-31G(**) and [6s5p](**) basis sets. Since the SCF results for [6s5p] system are the counterparts of that for 4-31G system, we discuss only the case of the latter basis set system from now on. The value $\nu_1=257$ cm^{-1} by 4-31G(**) CI calculation is only 3% greater than the experimental value. The value $\nu_3=686.2$ cm^{-1} is also in the same agreement with the average experimental ν_3 value 712 cm^{-1} (4% smaller). The same vibrational constants are predicted by the use of two dimensional analysis[43] of Lippinocott-Schröder potential.[11] By the use of vibrational SCF calculation for two dimensional potential surface, the results $\nu_3^H=652$ cm^{-1} and $\nu_3^D=459$ cm^{-1} ($\nu_3^H/\nu_3^D=1.42$) are obtained.[44] Whereas the prediction of ν_3 by one dimensional vibrational analysis results in $\nu_3^H=762$ cm^{-1} and $\nu_3^D=455$ cm^{-1} ($\nu_3^H/\nu_3^D=1.67$).[11] That is, the vibrational interaction between ν_1 and ν_3 makes the harmonic value of isotope frequency ratio. But these will be a fortuitious results. The results by larger basis sets including 3d polarization functions on Cl atoms predict the larger vibrational frequencies and shorter R_{Cl-Cl} distance The value $\nu_1=352$ cm^{-1} by 4-31G** CI(2) calculation is 41% greater than the experimental values except for $Na^+HCl_2^-$, but is only 17% over estimation for $Na^+HCl_2^-$. If the calculated ν_3 value 1050 cm^{-1} is overestimated, the predicted ν_3 value by the same correction (41% or 17%) comes to be 620 cm^{-1} or 872 cm^{-1}. It is possible to predict that ν_3 value in type II salt is about 700 cm^{-1}. In comparison with the experimental ν_3 value for $CsCl\cdot 1/3$ [$H_3O^+HCl_2^-$] is 1050—1200 cm^{-1}, calculated value 1050 cm^{-1} is in underestimation, which is the same in the case of 4-31G(**). It is also possible to predict that the shorter hydrogen bond ($R_{Cl-Cl}=3.14$ Å) may have the ν_3 value about 1050 cm^{-1} and have a single minimum potential. Since Schröder have not obtained the IR spectra for $CsCl\cdot 1/3$ [$H_3O^+DCl_2^-$], we can not clarify which of the ν_3 values are reasonable from the view point of isotope effect. At least we can predict that HCl_2^- anion in the shorter R_{Cl-Cl} distance ($R_{Cl-Cl}=3.14$ Å) has a single minimum potential and that the symmetric HCl_2^- anion causes the type II spectra which is perfectly different from type I in smaller ν_3 value.

We have not calculated the potential surface of ν_2 mode. From the group theory consideration in centrosymmetric HCl_2^- anion ($D_{\infty h}$ symmetry) ν_1, ν_2, and ν_3 modes have the symmetry species Σ_g^+, Π_u, and Σ_u^+ respectively.[18] This implies that the inter-mode interaction is negligible between ν_2 and ν_3 and between ν_1 and ν_3. Experimentally ν_1 and ν_2 values indicate no significant shifts between type I and type II salts in comparison with the great shift of ν_3. Thus we concern mainly with the one dimesional potential surface along the D_∞ axis for the ion.

^{35}Cl Nuclear Quadrupole Resonance (NQR) spectroscopy provides the information about the position of H atom in HCl_2^- ion, *i.e.* whether the ion is centrosymmetric or not. Type I salts indicate ^{35}Cl NQR value near 20 MHz, *i.e.* 20.22 MHz for $(CH_3)_4N^+HCl_2^-$ (at 77 K),[24,45,46] 21.27 MHz for $Cs^+HCl_2^-$ (at 166 K).[24] Whereas type II show the value about 12 MHz, *i.e.* 11.89 MHz[24] or 12.48 MHz[47] for $(C_2H_5)_4N^+HCl_2^-$ (at 77K), 11.94 MHz for $CsCl\cdot 1/3$ [$H_3O^+HCl_2^-$] (at 203 K).[24] Townes-Dailey theory relates the ^{35}Cl quadrupole coupling constant e^2qQ/h with the charge δ_{Cl} on Cl by the following formula,

$$(e^2qQ/h)_{ion}(e^2qQ/h)_{atom} = 1 - \delta_{Cl}, \quad (6)$$

where δ_{Cl} is corresponding to q'_{Cl} in Fig. 5. Using this relation and the experimental NQR data, Evans and Lo estimated the net-charge density distribution of symmetric HCl_2^- anion.[47] The results are Cl(0.86)··· H(0.57)–Cl(0.57) for asymmetric anion and Cl(0.74)–H(0.52)–Cl(0.74) for symmetric one. This suggests that the large ^{35}Cl NQR frequency is attributed to the small net-charge density of Cl atom on HCl side of asymmetric ion and the low frequency to the relatively high density of the symmetric one. This picture is supported by Cousseau *et al.* (1973) on the same estimation for $[(C_2H_5)_3NH]^+HCl_2^-$ salt.[48] A priori accurate theoretical prediction of ^{35}Cl NQR frequency on HCl_2^- ion is given by Thomson *et al.*[14] ^{35}Cl NQR value by the use of Townes-Dailey theory and MO calculation is 21.0 and 6.3 MHz for asymmetric ion ($R_{Cl-Cl}=3.22$ Å and $R_{HCl}=1.365$ Å), 13.11 MHz for symmetric ion ($R_{Cl-Cl}=3.14$ Å and $R_{HCl}=1.57$ Å). We have the net charge distribution on HCl_2^- ion for the variation of basis set and the method (SCF and CI). (See Figs. 5 and 6.) From Fig. 5 we can see that the charge distribution on Cl split into Cl^- and Cl in HCl molecule with the variation of H position. The q'_{Cl} value at the symmetric

position is estimated about 0.62—0.65 which is in somewhat underestimation with the result by Evans and Lo.[47] In the asymmetric position of proton our result by 4-31G(**) predicts q'_{Cl} values as 0.52 and 0.70 (at r_H= 0.228 Å), which are in well agreements with the results by Evans and Lo.[47] The tendencies are same in larger basis sets. There are some discussions on the reliability of Mulliken population analysis.[51] But we can explain qualitatively the shift of charge density according to the equilibrium position of proton. These gross population on atoms are not so unrealistic. Cousseau *et al.* (1973)[49] also discussed the proton NMR shift on HCl_2^- ion. The proton NMR chemical shift values are 9.6 ppm for asymmetric ion and 13.9 ppm for symmetric ion. Martin and Fujiwara (1971)[50] suggested that in these cylindrically symmetric system all the significant contributions to the ^1H shielding increasing 1s orbital population of H atom. Estimated δ_H values by Cousseau *et al.* are 0.50 for asymmetric and 0.42 for symmetric ion. Thus the large ^1H shift is the corresponding with the low density on H atom of symmetric HCl_2^- ion. Figure 6 shows that our results on δ_H at symmetric position are scattered in region from 0.77 to 0.69, where δ_H is corresponding to $1.0-q'_H$ in Fig. 6. The result by 4-31G** SCF is 0.69 (at symmetric position). This result is relatively great in comparison with the results by Evans and Lo[47] and Cousseau *et al.*[49] But we can see from Fig. 6 that the increacing tendency of δ_H from the symmetric to asymmetric position seems to explain the difference of ^1H chemical shift between the symmetric position and the asymmetric position of H atom. The relatively low net-charge density on H atom is also explained by the spacing of MO in the occupied valence and virtual regions. Figures 7 and 8 show the orbital correlation diagrams of HCl_2^- ion for 4-31G(**) and 4-31G** basis sets. Both in HCl and HCl_2^- 1s orbital of hydrogen forms the LUMO and the orbital energy of LUMO is increasing in HCl_2^- in comparison with isolated HCl molecule. Whereas HOMO consists of σ_u orbital which is accompanied by the degenerate orbitals π_g and π_u with the slightly small energy differences. This is due to the long Cl—Cl distance which decrease the in phase overlapping of orbitals and minimize the out of phase overlapping. Then the anti-bonding orbitals σ_u and π_g become stable. As a result 1s orbital of H comes to be LUMO to decrease δ_H and σ_u become HOMO to increase the absolute value of δ_{Cl}. Estimated net-charge density of HCl (literature value) is H(0.62)–Cl(0.38), which turned out to be an opposite net-charge distribution both in symmetric and asymmetric HCl_2^- ions.[47] It is the same in our case that H(0.85)–Cl(0.15) turns out to be Cl(0.63)–H(0.74)–Cl(0.63) for 4-31G(**) SCF. Martin and Fujiwara note that, "As the halide ion, X^-, approaches the positive (H) region of the HX molecule, electronic charge is repelled out of the hydrogen orbital." The situation is well established not only by the shift of q'_{Cl} and q'_H (Figs. 5 and 6) but also by the orbital correlation diagram of HCl_2^- (Figs. 7 and 8).

Figure 8 also explains the anomalous CI potential surface of proton by 4-31G** CI(1) (*i.e.* CI expansion terms are 4005). CI correction energy is abnormally minimized at the center of HCl_2^-. CSF of CI(1) is

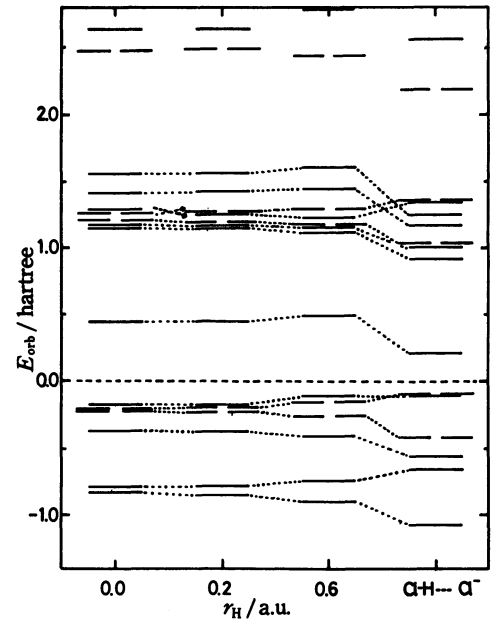

Fig. 7. Orbital correlation diagram of HCl_2^-(4-31G(**) basis set) on the proton displacement from the central position at R_{Cl-H}=3.228 Å. Cl–H···Cl⁻ denotes the position at r_{H-Cl}=1.257 Å and $r_{H\cdots Cl^-}$=211.7 Å, which corresponds to the dissociation limit. Only the orbitals numbered 10—18 (occupied) and 19—31 (unoccupied) are shown. Correlation among the polarization functions are not shown.

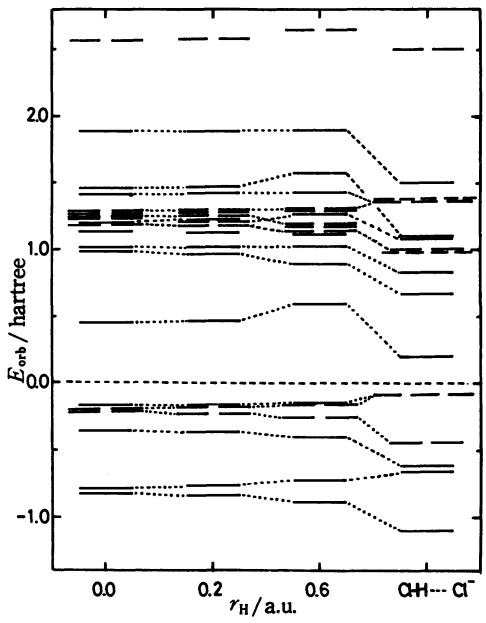

Fig. 8. Orbital correlation diagram of HCl_2^- (4-31G** basis set) on the proton displacement from the central position at R_{Cl-Cl}=3.140 Å. Cl–H···Cl⁻ denotes the position r_{H-Cl}=1.275 Å and $r_{H\cdots Cl^-}$=211.7 Å, which corresponds to the dissociation limit. Only the orbitals numbered 10—18 (occupied) and 19—38 (unoccupied) are shown. Correlation among the polarization functions are not shown.

constructed by the higher 8 occupied valence orbitals and lower 11 unoccupied orbitals. From Fig. 8 we can see eight doubly degenerate orbitals from 26th to 31st orbital, which correspond to 3d orbitals of Cl atoms. Since the crossing occurs between the lowest degenerate 3d orbitals (26th and 27th orbitals) and the 25th orbital in a region 0 a.u.$<r_H<$0.2 a.u., the contributions to the CI correction energy from these orbitals indicate significant change. Since CSF of CI(2) (CI expansion terms are 13041) consists of 8 occupied orbitals and 20 virtual orbitals, the anomalous potential surface is not formed. Though 4-31G(**) orbital correlation diagram (Fig. 7) indicates such crossings among the orbitals 24th, 25th (degenerate), and 26th, CSF consists of 8 occupied orbitals and 10 (CI expansion terms are 3321) or 13 (CI expansion terms are 5565) virtual orbitals. Thus the anomalous proton potential surface is not formed by any CI calculation for 4-31 G(**) basis set.

Now we have arrived at the conclusion summarized as follows:

(i) Symmetric HCl_2^- ions are formed in the salts which indicate ν_3 mode classified into type II IR spectra. But there is the possibility that the type II salts are classfied into the two types of molecules; *i. e.* one is the salts which indicate ν_3=700 cm^{-1} (*e.g.* $(C_2H_5)_4N^+HCl_2^-$ in aprotic solution or $Rb^+HCl_2^-$ in argon matrix), and another is the salts which possibly indicate ν_3=1050 cm^{-1} and has a single minimum potential of proton and the hydrogen bond length 3.14 Å (*e.g.* CsCl·1/3 [H_3O^+-HCl_2^-] in crystalline state).

(ii) At least we can predict by the largest CI calculation that the isolated linear symmetric HCl_2^- ion has the value R_{Cl-Cl}=3.14 Å and single minimum potential which causes the harmonic value of isotope frequency ratio. The SCF calculation by the largest basis set supports this prediction. (*i.e.* SCF barrier is very low and CI reduces the central barrier.) But we can hardly clarify which ν_3 values represents that of the linear symmetric HCl_2^- ion by the lack of accuracy of calculated potential curvature.

(iii) Calculated net-charge distribution also supports the conclusion (i)—(ii) in self consistent standpoint with the ^{35}Cl NQR spectra and ^1H NMR spectra which distinguish type II salts from type I salts. But the realistic structures of the former type II salts are not known. Thus we conclude with some reserve that type II HCl_2^- anion has symmetric structure of $D_{\infty h}$ symmetry.

The authors wish to express their thanks to Institute of Molecular Science (IMS) at Okazaki for the permission of the use of HITAC M-200H computer system for the MO calculation.

(Received February 5, 1983)

^{13}C-Chemical shifts and spin lattice relaxation times have been determined for dodecylammonium propionate/water/benzene or CCl_4 reversed micelles and for [^{13}C]glycine cosolubilized therein. Data obtained have been discussed in terms of the mobility of glycine molecules being effectively isolated from the surfactant headgroups by water molecules. The determined relaxation times of [^{13}C]glycine in glycerol-water mixtures correlated well with the macroscopic and microscopic viscosities of the reversed micellar solution. In a relatively small water pool, the apparent viscosity of water surrounding glycine in the micelle (microviscosity) was corresponding to that of 78% aqueous glycerol solution. Increasing the size of water pool resulted in decrased microviscosities.

Equilibria, rates, and pathways of inorganic and organic reactions are dramatically and specifically controlled by surfactant–water aggregates in apolar solvents, termed revesed micelles.[1] The reacting substrates are localized in a specific and restricted field provided by reversed micelles. In many respects, this water pool represents a unique and versatile reaction field. Depending on its water content, the microscopic polarity,[2,3] and viscosity[3-5] of the field and reactivity of water[6,7] can vary markedly, by which one can control chemical reactions as required. Therefore, detailed understanding of the nature of specific reaction field is not only inherently interesting, but is essential for the meaningful interpretation of the observed effects in controlling rate, equilibrium, and pathway.

As part of our overall program on the interactions and reactions in reversed micelles, we have investigated the microscopic viscosity of the water pool in the micelles using ^{13}C-NMR technique. The major advantage of this technique is that the use of probes which may perturb the system is avoided.[8] Additionally, ^{13}C-relaxation time measurements provide information on factors which determine molecular motions.[9] ^{13}C-NMR techniques have been applied to the investigations of aqueous micelles so far.[10] The present work reports data on ^{13}C-chemical shifts and spin lattice relaxation times for dodecylammonium propionate (DAP) aggregates in benzene or carbon tetrachloride and ^{13}C-labeled glycine cosolubilized therein. Glycine was chosen as the probe since it completely partitions into the water pool and the substantial rate enhancements have been observed in its ligand exchange reactions with vitamin B_{12}.[6a] The obtained data allows the elucidation of the apparent microscopic viscosity around glycine encapsulated in the restricted field provided by reversed micelles.

Experimental

DAP was prepared and purified by the established procedures.[11] Samples of [1-^{13}C]glycine and [2-^{13}C]glycine (90% enriched) were used as received from Merck, Sharp, and Dohm Co. Inc., N. J. Reagent grade benzene and carbon tetrachloride were distilled and stored over Linde 5A molecular sieve.

Special care was taken to eliminate paramagnetic impurities in sample preparations. The recommendations of Drs. Roberts[12a] and Smith[12b] were followed. Specifically, all glassware and NMR sample tubes were washed by caustic methanol (NaOH : MeOH : H_2O=1 : 4 : 1, w/w), soaked overnight in 0.35% EDTA (pH 8) and rinsed extensively by deionized and doubly distilled water. All NMR tubes were additionally steamed for 10—15 min prior to placing the sample solutions. Subsequent to introducing the sample into the NMR tubes, gaseous hydrogen sulfide was bubbled through them for approximately 10 min. Although any precipitate of metal sulfides was not discernible, the sample tubes were centrifuged just prior to commencing the measurements. Using these precautions, the observed spin lattice relaxation times for the carboxyl carbon of glycine agreed well with those reported.[12]

^{13}C-NMR chemical shifts and relaxation times (T_1) were determined at 25.0 MHz on a JEOL PFT-100 pulse-Fourier transform spectrometer connected to a Nicolet 1080 computer system. Wilmad coaxial NMR tubes were employed. First, a mixture of TMS and acetone-d_6 (1 : 1, by vol) in the coaxial tube was used to obtain the external standard and the NMR lock signal for 1.0 M (M=mol dm^{-1}) aqueous ammonium propionate as well as for the initial experiment in reversed micellar systems. Subsequently, solvent benzene was used as the second internal standard using external D_2O placed in a coaxial tube to obtain the lock signal. All the chemical shifts were given in ppm measured downfield form TMS. The inversion-recovery method was utilized for T_1-measurements under conditions of complete proton noise decoupling. FID signals for each spectrum were accumulated 8—32 times, depending on the glycine concentration. T_1-Values were computationally calculated employing either peak heights or areas. Differences between the two methods were less than the experimental error, ±10%. Viscosities of benzene solutions containing DAP–water aggregates, so-called macroscopic viscosities, were determined with use of an Ostwald viscometer at 27.0 °C (the temperature of the NMR probe). The viscometer was frequently calibrated with pure water.

Results and Discussion

Chemical shifts for the magnetically discrete carbon atoms of 1.0 M DAP in benzene with and without glycine ([1-^{13}C]glycine and [2-^{13}C]glycine) as a function

of water content are given in Table 1. Table 1 also contains values of the glycine carbon atoms cosolubilized in the micelles. The assignment for DAP carbon atoms was based on the known chemical shifts of alkyl amines and ammonium ions.[13,14)] The chemical shifts of C-1, C-2, and C-3 carbon atoms of DAP in benzene, 40.1, 28.8, and 27.5 ppm (Table 1), respectively, agree well with those of the corresponding carbon atoms of octylammonium trifluoroacetate in D_2O (40.2, 28.3, and 27.7 ppm). Although DAP is known to undergo polydispersion type association such as monomer$\rightleftharpoons$dimer $\rightleftharpoons$ trimer$\cdots\rightleftharpoons n$-mer,[15)] there were no observable distinct chemical shifts for monomers and aggregates. This implies, of course, that the equilibration between monomers and aggregates are rapid on the NMR time scale. Similar observations have been made for a variety of normal aqueous micelles.[10a)]

Addition of water alters the chemical shifts of only the carboxyl carbon (C-1′) and the carbon atom nearest to the cationic headgroup (C-1) of the surfactant. However, the magnitude of the change was modest (Table 1). This is not unexpected since the shielding of carbon nucleus is known to be less sensitive to medium change than that of hydrogen nucleus.[8b)] Even when propylammonium dodecanoate was employed instead of DAP, the effect of water content on the chemical shift of the C-1′ atom was larger than that of the C-1 atom. This may be explicable in terms of the difference in the type and strength of hydrogen bonding between the two headgroups and water: namely, $-\overset{\overset{O}{\|}}{C}-O^-\cdots H-OH$ and $-\overset{+}{N}H_2-H\cdots OH_2$.[16)] As expected, chemical shifts of the inner methylene carbon atoms (C-2 to C-12) of DAP are unaffected by solubilized water. These observations substantiate our proposal[1,3,16)] that water is solubilized upon interacting with the ionic headgroups of DAP and is isolated from the bulk apolar solvent by surfactant aggregates. Chemical shift of the C-1′ carbon atom of 1.0 M DAP shifts downfield from 181.6 ppm in the least amount (<6 ppm) of water to 183.4 ppm in the presence of 9.0 M water (Table 1). Chemical shifts of the methyl, methylene, and carboxyl carbon atoms of 1.0 M ammonium propionate in water at pH 7 were determined to be 11.7, 32.1, and 186.2 ppm, respectively. Chemical shifts of the methyl and methylene carbon atoms of propionate ion in the DAP/benzene reversed micellar system agreed well (Table 1) with those of ammonium propionate in water. Conversely, the chemical shift of the carboxyl carbon atom of 1.0 M ammonium propionate differs substantially from that of C-1′ of 1.0 M DAP in benzene. These results preclude the possibility of an experimental artifact in the observed chemical shift differences. Apparently, even at $R=9.0$ ($R=[H_2O]/[DAP]$), the environment of the surfactant headgroups is significantly different from that in bulk water. Chemical shifts of the surfactant carbon atoms are not altered by adding glycine. Magnetic resonances of the glycine carbon atoms in bulk water and reversed micellar core were found to be identical, implying that the amino acid, at least in the present series of experiments, is free enough from the direct interaction with headgroups of DAP.

^{13}C-Spin lattice relaxation times, T_1, of the carbon atoms of DAP are in Table 2. Since the exchange of DAP molecules between monomeric and aggregated environments is rapid with respect to $1/T_1$, the observed spin lattice relaxation times represent weighted averages of relaxation times in these environments:

$$1/T_1 = X_m/T_{1m} + X_d/T_{1d} + X_t/T_{1t} + \cdots X_i/T_{1i},$$

where suffixes, m, d, t, and i, stand for monomeric, dimeric, trimeric, and i-meric environments in the mole fraction, X, and relaxation time, T_1, respectively. Lack of information of the distribution of different sized aggregates in the 1.0 M DAP/benzene micelle precludes the dissection of T_1-values. Since ^{13}C-spin lattice relaxation times of micellar alkylammonium ions are considerably shorter than those of their monomers,[13)] the reported T_1-values are considered to represent upper limits in the environment of the aggregates. The relaxation times for the resolved carbon atoms of dodecylammonium ion in benzene (Tabel 2) are even longer than those reported for hexyl- and decylammonium ions in the same solvent,[13)] indicating further overall restriction in the motion of the ions.

T_1-Values for carbon atoms of the dodecylammonium ion increase along with the carbon chain on going from C-1 to C-12 (Table 2), indicating an increase in the segmental motion of methylene units.[13)] The segmental motion of a molecule can be expressed in terms of its ω/α-value, defined as the ratio of the spin lattice relaxa-

tion time of the terminal methyl carbon (ω) to that on or the nearest one to the ionic headgroup (α).[13] The higher the ω/α-value is, the more the segmental motion is pronounced. In the absence of glycine, ω/α for 1.0 M dodecylammonium ion in DAP/benzene micelle was 20.0. This value should be compared to 19.5 which was determined for 1.2 M decylammonium ion in benzene-d_6.[13] Solubilizing 0.01 M glycine in 1.3 and 9.0 M water/DAP/benzene micellar systems results in ω/α-values of 18.7 and 12.9 respectively. It should be pointed out that changes in ω/α-values is predominantly the consequence of changes in the relaxation times of the

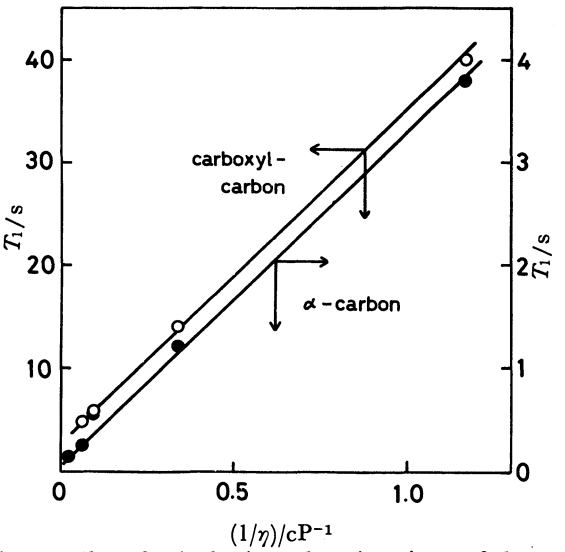

Fig. 1. Plot of spin lattice relaxation times of the carboxyl and α-carbon atoms of glycine in aqueous glycerol against the reciprocal viscosity of the solvent.

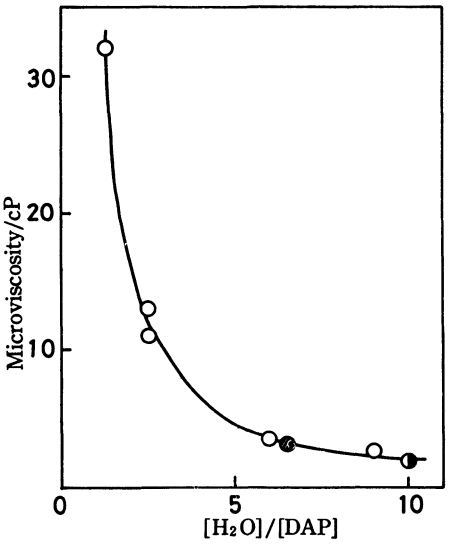

Fig. 2. Microscopic viscosity of the water pool estimated from T_1-values of glycine solubilized in DAP reversed micells as a function of R (=[H_2O]/[DAP])-value: ○, 1.0 M DAP/benzene micelle; ●, 0.2 M DAP/benzene micelle, and ◑, 0.2 M DAP/CCl_4 micelle, respectively.

C-1 carbon atoms (Table 2). A decrease in the segmental motion is brought about by an increase in the hydration at the site of the ionic headgroups. Increased hydration reduces the dipole-dipole interactions between surfactant headgroups and increases in the overall molecular motion.

Using ^{13}C-enriched glycine allowed the determination of spin lattice relaxation times of the carboxyl and α-carbon atoms of glycine (Table 3). Taking appropriate precautions, the determined T_1-values for the carboxyl carbon atom agree well with those cited.[12] The most significant fact emerged from Table 3 is the dramatic reduction in the relaxation times of both α and carboxyl carbon atoms in the water pool of DAP reversed micelles compared with those in bulk water. Evidently, the molecular motion of glycine is considerablly restricted in the micellar core. Macroscopic viscosities of the DAP/benzene reversed micellar system, the viscosity of the whole solution, were determined as a function of water content (Table 4). Increasing the water content results in an increase in the macroscopic viscosity of the whole system, which is ascribed to an increase in the size of water pool and the aggregation number. Consideration of the microenvironment of glycine in the DAP reversed micelle is more meaningful. Microscopic viscosities of the water pool of micelles have been assesed from the ruler obtained by the determined viscosities and ^{13}C-spin lattice relaxation times of glycine in aqueous glycerol solutions. A linear relationship has been obtained between the T_1-values of both the carboxyl and α-carbon atoms of glycine in glycerol–water mixtures and the reciprocal viscosities of the corresponding solution (Fig. 1). Using this correlation as a ruler, microviscosities of the water pool of DAP micelles have been read off (Table 4). Surprisingly, the apparent viscosity of the water pool of 1.0 M DAP/1.3 M water/benzene micelle containing 1.0×10^{-2} M glycine resembles that of approximately 78% aqueous glycerol solution. Conversely to the observed trend in the macroscopic viscosity, increasing the size of water pool resulted in a decreased microviscosity (Fig. 2). Figure 2 shows that the microscopic viscosity is determined predominantly by the R-value irrespective of the bulk organic solvent and the surfactant concentration, and that the microviscosity drastically decreases at the lower R-value region. Similar trends are seen in the relaxation time of water proton in ^{1}H-NMR[5b] and in the fluorescence polarization of pyranine[3] as a function of R-value. It is of interest to observe that changes of glycine concentration in a given DAP reversed micelle do not alter the microviscosity (Table 4). This is in accord with the above postulate that glycine may be appreciably isolated from the surfactant headgroup by water in the present systems. This means also that glycine must be localized in the "type II phase"[3] of water pool of reversed micelles.

This work had been carried out mostly in Texas A & M University when Janos H. Fendler was Professor of Chemistry in Department of Chemistry, Texas A & M University.

(Received February 7, 1983)

The crystal structure of (TMTSF)(ReO_4)($C_2H_3Cl_3$)$_{2.25}$ was determined. The crystals are monoclinic P2/c, $a=18.573(3)$, $b=7.418(2)$, $c=26.210(6)$Å, $\beta=107.85(2)°$, $Z=8$. TMTSF molecules are stacked to form diadic columns along the b axis. The mode of intermolecular overlapping between adjacent TMTSF molecules shows a new mode of overlapping. The strong alternation of the intermolecular Se–Se distances along the TMTSF columns indicates that this compound is a Peierls insulator, which is consistent with the semiconducting behavior. The Peierls instability is accompanied by a bending distortion of the planar TMTSF molecules. The room-temperature conductivity is 3×10^{-4} $(\Omega\,cm)^{-1}$, and the activation energy is 0.18 eV. There are some short Se–O contacts between ReO_4 anions and TMTSF stacks. The solvent molecnles ($C_2H_3Cl_3$) are located in the channel formed along the b axis.

Since the discovery of the organic superconductors, (TMTSF)$_2$X(X=ClO_4, PF_6···), a number of works have been undertaken to elucidate various aspects of the organic metal systems (TMTSF: tetramethyltetraselenafulvalene). The crystal structure analyses of (TMTSF)$_2$X compounds have revealed that these compounds have both one-dimensional (1-D) and two-dimensional (2-D) characters.[1] The TMTSF molecules are stacked face-to-face to form columns typically observed in 1-D organic metal systems. The interstack Se–Se contacts indicate the two-dimensionality of the crystals. Unlike the complex 2 : 1 salts of TMTSF, though no crystal-structure determination has been made on the simple 1 : 1 salts. In this paper, we report on the crystal structure of (TMTSF) (ReO_4) ($C_2H_3Cl_3$)$_{0.25}$.

Experimental

The black needle crystals were grown electrochemically from 1,1,2-trichloroethane by using twice-crystallized Bu_4NReO_4 as the electrolyte. The crystal data are: ($C_{10}H_{12}Se_4$) (ReO_4) ($C_2H_3Cl_3$)$_{0.25}$, $a=18.573(3)$, $b=7.418(2)$, $c=26.210(6)$ Å, $\beta=107.85(2)°$, $V=3489.7$ Å^3; monoclinic, space group P2/c, $Z=8$. The intensities were measured on a Rigaku automated four-circle diffractometer with Mo $K\alpha$ radiation ($\lambda=0.7107$ Å). The size of the crystal used was $0.04\times0.10\times0.30$ mm. The structure was solved by the direct method and has been refined to $R=0.089$, using 2742 independent reflections for which $|F|>3\sigma(|F|)$. The hydrogen atoms were not included in the calculations. The atomic coordinates are given in Table 1.[2]**

Result and Discussion

The crystal structure is shown in Fig. 1. There are three crystallographically independent TMTSF molecules. One is on the general position, and the others, on the two-fold axis. They will hereafter be named molecules A, B, and B′ respectively (see Fig. 1). The crystal has channels along the b axis. The structure refinements have revealed the existence of solvent molecules in the channels. A similar inclusion of the $C_2H_3Cl_3$ solvent molecules has been observed in (BEDT–TTF)$_2$-ClO_4($C_2H_3Cl_3$)$_{0.5}$.[3] The volume of the channel indicates that two solvent molecules can be accommodated in the unit cell. However, the atoms of the solvent molecules are highly disordered and could not be located definitely. Fourier maps gave four large and four small peaks around (1/2, 1/2, 1/2), which were assumed to be the positions of the Cl and C atoms of $C_2H_3Cl_3$.

** A list of the observed and calculated structure amplitudes and a table of the thermal parameters are kept at the Chemical Society of Japan as Document No. 8339.

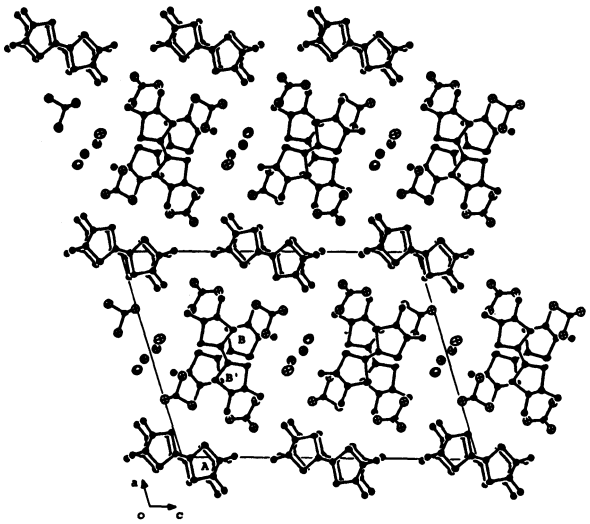

Fig. 1. The b axis projection of the structure of (TMTSF)(ReO_4) ($C_2H_3Cl_3$)$_{0.25}$.

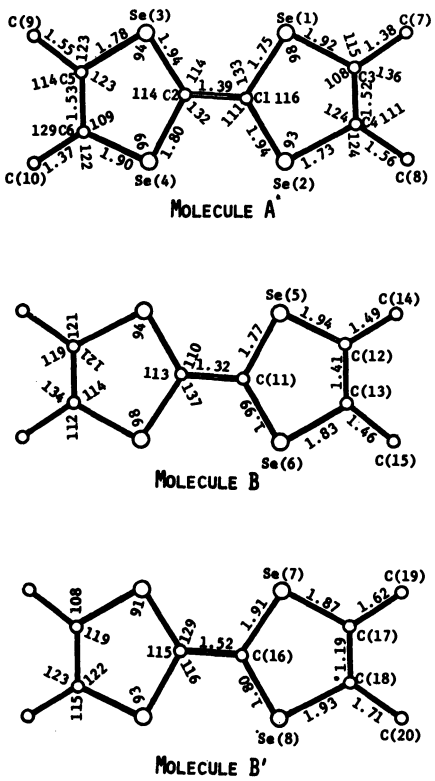

Fig. 2. Bond lengths (Å) and angles (°) of TMTSF. The standard deviations are: 0.06—0.07 Å (Se–C), 0.09—0.10 Å (C–C), 2—3° (C–Se–C), and 5—6° (C–C–Se and C–C–C).

In the least-squares refinements, the atomic populations of Cl and C atoms were taken to be 0.75 and 0.5 respectively.

Unlike (TMTSF)$_2ReO_4$,[4] (TMTSF)(ReO_4)($C_2H_3Cl_3$)$_{0.25}$ does not show the orientational disorder of ReO_4. However, the large temperature factors of some oxygen atoms of the ReO_4 anions indicate a large thermal motion. The isotropic thermal parameters (B/Å^2) are: O(1), 5.6; O(2), 6.1; O(3), 6.4; O(4), 6.7; O(5), 7.8; O(6), 6.5; O(7), 10.7; O(8), 7.7; Re(1), 4.6; Re(2), 5.1.[5] It is natural that the ReO_4 anion, with its relatively large thermal parameters (Re(2), O(5), O(6), O(7), and O(8)), shows a loose contact with

Molecule B 7.8
Molecule B′ 8.2

surrounding molecules: the (Se(6)···O(5)) contact is the only contact which is slightly shorter than the van der Waals distance (Table 4).

The bond lengths and angles are given in Fig. 2 and Table 2. As a result of the relatively small number of reflections, the standard deviations are fairly large. The least-squares planes of TMTSF molecules are listed in Table 3.

The TMTSF molecules are stacked face-to-face to form diadic columns. The modes of intermolecular overlapping are shown in Fig. 3. The A(x, y, z), A($\bar{x}, \bar{y}, \bar{z}$), and A($\bar{x}$, $1-y$, $\bar{z}$) molecules are stacked in a manner similar to that found in usual organic conductors, where A(u, v, w) indicates the molecule related to the A(=A(x, y, z)) molecule, by the symmetry operation (u, v, w). The mode of overlapping between A(x, y, z) and A($\bar{x}, \bar{y}, \bar{z}$) is similar to that observed in $(TMTSF)_2X$.[1] However, the mode between A(x, y, z) and A($\bar{x}$, $1-y$, $\bar{z}$) is that of a slightly modified direct overlap. The B and B′ molecules have C_2 symmetry, and the mode of intermolecular overlapping is of a new type. The longest axis of the B molecule is approximately perpendicular to that of the B′ molecule. This new overlapping mode appears to be natural, because this structure indicates a large intermolecular Se–Se interaction and a small intermolecular C–C repulsion. Since the symmetry of the highest occupied molecular orbital(HOMO) of TMTSF

a) The standard deviations are: 0.008 Å (Se···Se), 0.07 (Se···O), and 0.10 (C···O).

with ideal D_{2h} symmetry is b_{1u} (the coefficients of the atomic orbitals of the four Se atoms are identical), the magnitude of the intermolecular overlap integral of HOMO for this configulation will be almost equal to that for the direct overlapping. The short intermolecular Se–Se distances are given in Table 4 and Fig. 3. The average Se–Se distance between the A(x, y, z) and A($\bar{x}$, $1-y$, $\bar{z}$) molecules is 3.55 Å, but that between A(x, y, z) and A($\bar{x}$, $\bar{y}$, $\bar{z}$) is 3.93 Å. Similarly, the Se–Se separation between B(x, y, z) and B′(x, y, z) is 3.55 Å, and that between B(x, y, z) and B′(x, $y-1$, z) is 3.96 Å. Thus, the positions of the Se atoms are shifted alternately along the b axis from the positions of the regular arrangement, which makes the molecules nonplanar (see Fig. 3 and Table 3). The shortest Se–Se distance of 3.51 Å is much shorter than the van der Waals distance (4.0 Å). In (TMTSF)$_2$X, the Se–Se distance in the TMTSF stack is longer than 3.85 Å.[1,3] Unlike the case in (TMTSF)$_2$$ReO_4$, the TMTSF columns in (TMTSF)(ReO_4)($C_2H_3Cl_3$)$_{0.25}$ have no short Se–Se contact between adjacent columns (see Table 4). The only significantly short contact between TMTSF column can be seen between methyl carbons (C(9)–C(20), 3.31 Å). Thus, the TMTSF columns can be regarded as 1-D systems.

The temperature depence of the electrical conductivity shows that this compound is a semiconductor with the room-temperature conductivity of 3×10^{-4} $(\Omega\,cm)^{-1}$ and the activation energy of 0.18 eV (see Fig. 4).[6] Contrary to the semiconductive behavior of (TMTSF)(ReO_4)($C_2H_3Cl_3$)$_{0.25}$, (TMTSF)$_2$$ReO_4$ is metallic above 180 K(T_c), where a metal-insulator transition occurs.[7] The superconductivity appears above 9.5 kbar at 1.3 K.[8]

Since the stoichiometry of TMTSF to ReO_4 is 1 : 1, the diadic column of TMTSF indicates that the 1-D band formed along the TMTSF column is filled. Thus, the semiconductive nature of this salt is quite reasonable. The strong alternation of the intermolecular Se–Se distance is consistent with the Peierls instability of the 1-D metallic system. The intermolecular repulsion between the adjacent molecules in the same stack will tend to make the intermolecular spacings regular. On the other hand, the $2k_F$-(Peierls) instability of the 1-D chain tends to produce a diadic distortion in order to to gain the electronic stabilization energy. Since the 1-D band is considered to be made up of atomic orbitals of the Se atoms,[9] the periodical displacements of the other atoms do not contribute to the stabilization of the 1-D electronic system. Therefore, as a result of the Peierls instability, the intermolecular repulsion will make TMTSF molecules nonplanar. Besides the intra-stack interaction, the interaction between TMTSF molecules and ReO_4 anions may also be important. Since only a few short contacts can be seen between oxygen atoms and methyl carbons (Table 4), the steric repulsion between methyl carbons and ReO_4 is not important. However, significantly short contacts can be seen between the Se atoms of TMTSF and the O atoms of ReO_4. Consequently, some interaction must exist between these atoms. Similar short Se–O (or F) contacts have been observed in (TMTSF)$_2$X.[1]

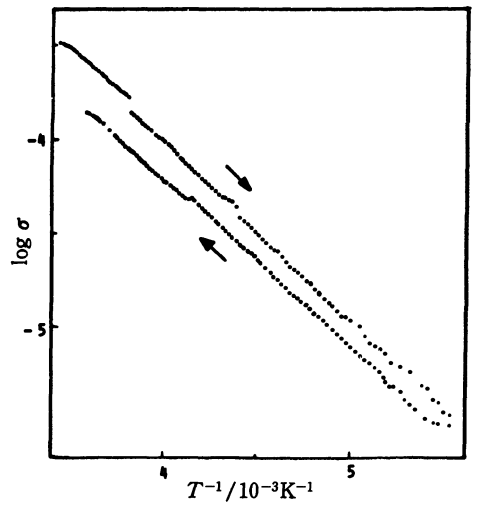

Fig. 4. The electrical conductivity of (TMTSF) (ReO_4) ($C_2H_3Cl_3$)$_{0.25}$.

A recent X-ray study by Moret, Pouget, Comes, and Bechgaard[10] has revealed that TMTSF columns in (TMTSF)$_2$$ReO_4$ are strongly modulated by the $2k_F$-wave below T_c(=180 K), where (TMTSF)$_2$$ReO_4$ is an insulator. They suggested that the correlation between the TMTSF molecules and the anion displacements can be analyzed as a cooperative phenomenon. The activation energy of about 0.20 eV in (TMTSF)$_2$$ReO_4$ is approximately equal to that of (TMTSF)(ReO_4)($C_2H_3Cl_3$)$_{0.25}$ (0.18 eV).

Since the elctron-phonon coupling in the commensurate system is considered to be strong, the large distortion must be related to that period of the $2k_F$-wave in (TMTSF)(ReO_4)($C_2H_3Cl_3$)$_{0.25}$, which is strongly commensurate with the lattice spacing.[11] The structure of this compound shows that the $2k_F$-wave is accompanied by molecular deformation. The bending deformation of the planar molecule has also been found in the partially oxidized platinum compound, $Rb_{1.67}[Pt(C_2O_4)_2]\cdot1.5H_2O$ (RbDOX), which has six-fold commensurate $2k_F$-structure.[14]

The average intermolecular Se–Se distance in the TMTSF stack is much smaller than that of (TMTSF)$_2$X ($\approx$3.9 Å). Therefore, if the TMTSF stack of (TMTSF)(ReO_4)($C_2H_3Cl_3$)$_{0.25}$ were regular, it would be a 1-D metal with a sufficiently large band width. However, the interstack interaction is not large enough to prevent the Peierls instability.

2) Adopting anisotropic temperature factors for the Se and Cl atoms and isotropic ones for C and O atoms, the block-

diagonal least-squares refinements gave the R value of 0.093. The subsequent anisotropic refinements of all the non-hydrogen atoms produced only a little improvement ($R=0.089$), but the temperature factor of C(3) became singular. Therefore, the isotropic temperature factors are adopted for C and O atoms (Table 1).

Demonstration of Electrostatic Field Effect Working on Dipolar Liquids with Correlation to Their Structures

Goro WADA,* Yasuko TERUTA, Takako KATO, and Naoko BITOH
Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630
(Received February 7, 1983)

When an electrically charged body is allowed to come close to a fine water stream falling down from the tip of a capillary, the vertical stream is bent a little towards the charged body by an attractive force due to the electricity-water dipole interaction. We constructed a simple equipment for the purpose of quantitative determination of the attractive force by defining a quantity P to search the correlation between the permittivity ε and the dipole momemt μ of polar liquids. For various pure polar liquids and mixtures at various mole fractions x of the components, we found a proportional correlationship $P\bar{\varepsilon}=k\bar{\mu}$ with a common constant k, when the electric potential applied on an electrode, temperature, and flow velocity are fixed. In the cases of mixtures, $\bar{\varepsilon}=\sum x_i\varepsilon_i$ and $\bar{\mu}=\sum x_i\mu_i$ are used. Pure liquids, such as methanol, ethanol, 1-propanol, acetic acid, acetone, acetonitrile, tetrahydrofuran, 1,4-dioxane, nitromethane, dimethyl sulfoxide, and nitrobenzene and mixtures, such as benzene–ethanol and benzene–nitrobenzene obey the proportionality rule approximately. On the other hand, water and some mixtures such as benzene–acetic acid and benzene–tetrahydrofran fail the rule, suggesting the possibility that molecular association occurs due to their mutual interactions in the liquids. Thus, this method may be considered as a simple demonstration illustrating the states of molecular aggregation in polar liquids.

We often experience a phenomenon even in our daily life that when something electrically charged such as mechanically rubbed plastics is brought close to a fine and smooth water current falling down from an end of a tap, the vertical pillar of water is forced to bend considerably towards the electrically charged body. This is caused by the interaction between the electricity on the charged body and the electric dipoles of water molecules. An idea that this may be caused, instead, by the frictional electricity produced on water surface when it is made to flow down off the end of the tap is easily denied by the facts that the phenomenon is not observed at all if water is replaced by nonpolar liquids such as benzene or 1,4-dioxane and that the interaction force occurs always to be attractive but never repulsive indifferent to whether the sign of the electricity on the rubbed body is positive or negative.

Some effects of electric[1,2] or magnetic[3] fields have ever been found and investigated on the viscosities of water and other several liquids. But the attractive force itself working on polar liquids in electric fields have never been quantitatively measured yet. In the present investigation, we constructed an equipment suitable for quantitative determinations of the forces applied to a variety of dipolar liquids; pure water, some organic substances, their mixtures, and various aqueous solutions of electrolytes. It was necessary to set up a device for reproducing the desired electric fields of constant strength and maintaining the stationary flow of liquids for the purpose. Then, the correlations of the dipole moments of liquids with their permittivities (dielectric constants) will be discussed as a convenient clue for the molecular association in liquids.

Experimental

Equipment. In order to apply a stable and reproducible electric field, a Hamamatsu Regulated DC Power Supply Model HTV-C752 was used as a high voltage source. The electrode of high voltage was made of a copper plate of 2 cm width and 4 cm length. The apparatus for the observation was constructed by wholly connected glass for the use of organic substances, as is shown in Fig. 1. The notations in the figure indicate as follows; A: sample liquid reservoir, B: overflow branch for keeping constant liquid level, C: reservoir bottle for waste liquid, D: capillary tip, E: electrode, F: thermostat, S: high-voltage source, and T: telescope with micrometer. Among the numbered stopcocks 1—6, only cock 1 is of three-way. The electrode and the capillary are settled vertically, and the vertical center line on the electrode surface was arranged to face just in paralled to the liquid current which was steadily flowing down from the end of the capillary tip. The distance between the electrode and the

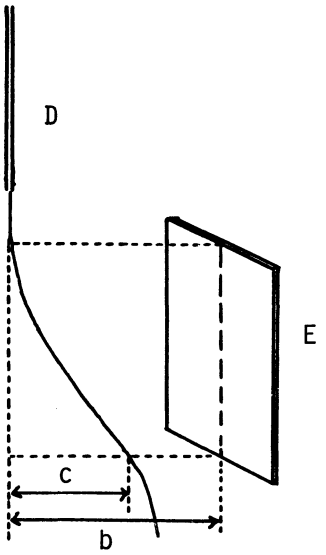

Fig. 2. Arrangement of capillary tip and electrode.

liquid stream was easily varied. The overflow branch B was deviced to make the pressure of the liquid at the capillary tip unchanged and reproducible in order to allow the liquid to flow down steadily during the cource of the observation. The telescope was used to measure the distance between the stream and the electrode to see how far the liquid stream was forced to displace horizontally towards the electrode.

Procedure. After an appropriate portion of the sample liquid in the reservoir C is pumped up to the reservoir A by use of an aspirator, slightly compressed air is applied on the liquid in A through the cock 1 to let the liquid flow down towards the overflow branch B *via* the cock 4. The main flow goes as far as to the capillary tip D through the thermostat F and the cocks 5 and 6 on the way as a steady current, while the overflowed liquid returns directly to the reservoir bottle C. The liquid in C can be used repeatedly. The regulation of the current was carried out at the cock 6. Cock 5 was used only for the interuption of the liquid current. The temperature of the liquid was 25 °C, except otherwise noted. The voltage on the electrode was variable 0—2.5 kV by the DC power supply and was generally kept at 2.5 kV.

In Fig. 2, the arrangement of the capillary tip and the electrode is shown. The distance b denotes the initial separation between the liquid and the electrode with no electric charge, while c is the distance of displacement caused by attraction when the electrode is charged. The distances b and c are measured horizontally at the bottom height of the electrode. Many conples of b and c were determined for the respective sample liquds.

Since the viscosities and the densities of the liquids differ from one another, it is necessary to regulate the flow velocity fixed for the purpose of comparison; the flow velocity was adjusted according to the amount of the liquid fallen during a definite time. The densities of the respective liquids were measured by use of a small pycnometer.

Materials. Water was purified by double distillation after being deionized through ion-exchange resin. Organic substances used were methanol, ethanol, 1-propanol, acetone, acetonitrile, nitromethane, 1,4-dioxane, tetrahydrofuran, acetic acid, dimethyl sulfoxide (DMSO), benzene, nitrobenzene, phenol, and pyridine, and electrolytes used were LiCl, NaCl, KCl, RbCl, $MgCl_2$, $(CH_3)_3NHCl$, and $(C_2H_5)_3$-NHCl, all of which were of the special reagent grade, being further purified by distillation or recrystallization for the use.

Results and Discussion

Evaluation of Magnitude of Attractive Force. The distances b and c have been defined above in Fig. 2. In general, the smaller the value of b, the larger becomes that of c; finally the liquid stream may touch the bottom edge of the electrode, where a length A is defined at the extreme distance, as $A \equiv b = c$. Figure 3 shows the relationships of c with b in the case of pure water, in which $\log(b/c)$ is found to be linear with respect to $\log b$ with an empirical formula,

$$\log \frac{b}{c} = m + n \log b.$$

Accordingly, the value of A is obtained by the linear extrapolation of $\log(b/c)$ to zero as equal to $A = 10^{-(m/n)}$. Thus, A is characteristic of the dipolar property of the liquid so far as the temperature and flow velocity are given in a definite electric field.

Since A is an integrated distance of horizontal displacement of liquid attracted towards the electrode with the lapse of time during which the falling liquid stream passes just the vertical length of the electrode. Therefore, the value of A multiplied by the liquid density d may be proportional to the attractive force f wrought on the dipolar liquid ($f \propto Ad$). If it is hypothesized for the sake of simplicity that the electricity on the electrode is a point charge (q) and that the dipolar liquid is fixed at the distance of $b-c$ apart from the point charge, the dipoles of the liquid are attracted by a force f as expressed below:

$$f = -\frac{2\mu q}{\varepsilon(b-c)^3},$$

where μ and ε are the dipole moment and the permittivity of the liquid, respectively. This correlation may hold approximately under the more complicated circum-

stances like the present experimental conditions, as $f \propto \mu/\varepsilon$. Combining the former proportionality with this, the following equation can be derived, if Ad is denoted by P and k is put as a proportional constant.

$$P \equiv Ad = k\frac{\mu}{\varepsilon} \quad (1)$$

After all, the proportionality of $P\varepsilon$ to μ will be confirmed by measuring A and d for various polar substances, and the obedience to and violation against the proportionality rule may lead us to the discussion on the problems on their molecular structures in liquidous state, as in the followings.

Dependence of P upon Electric Potential of Electrode. Figure 4 shows the correlation of P with the electric potentials of the electrode in the case of water at the flow velocity 0.810 cm^3 s^{-1} and 25 °C. The value of P increases with the increasing potential. In the following observations, the potential will be always fixed at 2.5 kV.

Dependence of P upon Temperature. P exhibited no significant variation with temperature within the range of 10—40 °C, $P=0.39\pm0.03$ g cm^{-2} in the case of water. Nevertheless, the orientation of dipoles in an electric field may be more perturbed by thermal agitation, and therefore P is expected to be smaller at higher temperatures. In the following observations, the temperature will be fixed at 25 °C.

Dependence of A upon Flow Velocity of Liquids. The flow velocity of a liquid current falling down from the tip of the capillary is expressed by $\pi r^2 u$ in cm^3 s^{-1}, where r and u represent the internal radius of the capillary and the current velocity of liquid stream, respectively. On the other hand, since the current velocity u is approximately equal to l/t where l and t are vertical length of the front of the electrode and the time of passing as far as l for the liquid, respectively, the flow velocity is given by $\pi r^2 l/t$. Since A is affected by t, t as well as both r and l should be fixed constant by adjusting the current by use of cock 6, for the purpose of relative comparisons of A with one another among various polar liquids. The flow velocity used throughout the investigation was 0.735 cm^3 s^{-1}. In the cases of different velocities from this value, A was corrected to the standard velocity by virtue of a calibration curve.

Proportional Correlation of Pε vs. μ for Pure Liquids. Figure 5 represents the proportionality between $P\varepsilon$ and μ for 13 pure substances:[4-6] water ($\varepsilon=78.5$, $\mu=1.80$), methanol (32.63, 2.87), ethanol (24.30, 2.89), 1-propanol (20.1, 1.66), acetic acid (6.15, 1.92), acetone (20.7, 3.11), acetonitrile (37.5, 3.45), tetrahydrofuran (7.39, 1.63), 1,4-dioxane (2.21, 0), nitromethane (35.87, 3.23), dimethyl sulfoxide (48.9, 4.30), benzene (2.274, 0), and nitrobenzene (34.82, 3.97). The proportional relationship due to Eq. 1 is well recognized to be approximately established with only one exception of water. When ε, instead of $P\varepsilon$, is plotted against μ for many polar substances, no proportionality is seen but ε grows up more rapidly as μ increases.[7] The reason why only water deviates severely from the proportionality of Eq. 1 is supposed because the used value of dipole moment 1.85 D. U. for water is that in gas phase and the essential value in liquid phase is probably as high as 7, estimated from the proportionality rule, due to the molecular association between themselves forming so-called clusters or icebergs.

Aqueous Mixtures of Some Organic Liquids. The variations of P with the mole fraction x of organic liquids in water are plotted in Fig. 6, where no linearity holds between P and x. But when $P\bar{\varepsilon}$'s are plotted against the

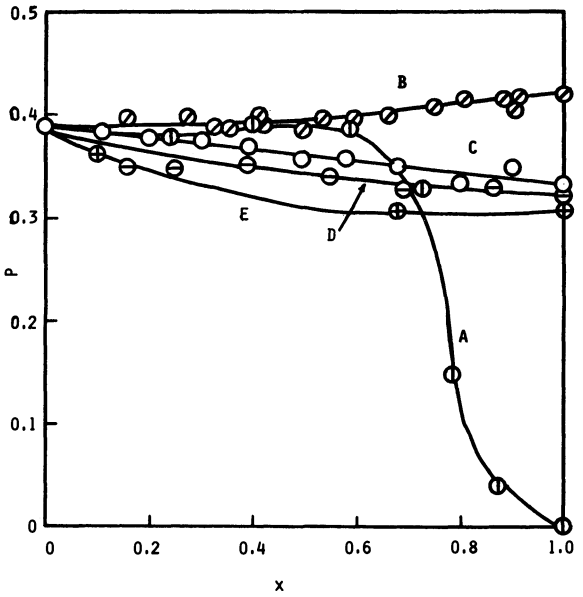

Fig. 6. Variations of P with mole fraction x of organic liquids in aqueous mixtures.

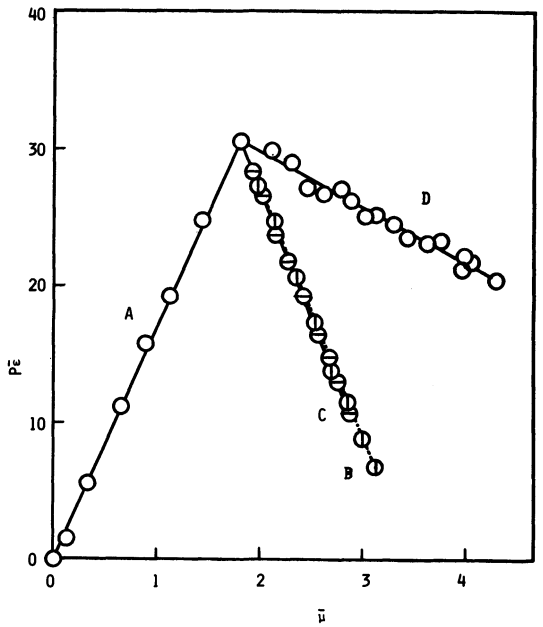

Fig. 7. Linear relationships between $P\bar{\varepsilon}$ and $\bar{\mu}$ for aqueous mixtures of organic substances.
A: 1,4-Dioxane, B: acetone, C: methanol, D: dimethyl sulfoxide.

individual apparent dipole moments of the mixed liquids, $\bar{\mu}$, as shown in Fig. 7, there appear straight lines connecting two limiting points for individual pure liquids respectively. The apparent permittivity $\bar{\varepsilon}$ and dipole moment $\bar{\mu}$ of mixture of two substances 1 and 2 are represented by

$$\bar{\varepsilon} = x_1\varepsilon_1 + x_2\varepsilon_2, \tag{2}$$

$$\bar{\mu} = x_1\mu_1 + x_2\mu_2, \tag{3}$$

at mole fraction x, respectively. The linearities appearing in Fig. 7 indicate that the mixtures behave like pure substances with $\bar{\varepsilon}$ and $\bar{\mu}$ exhibiting their dielectric and dipolar properties proportional to the concentrations of components, although the more delicate and fine properties have been noticed as stoichiometric and structured association of molecules at characteristic mole ratios in the mixtures of water with dimethyl sulfoxide,[8-10] 1,4-dioxane,[10,11] 1-propanol,[12,13] and tetrahydrofuran,[14,15] for instances.

As noticed above, Eq. 1 is valid to normal mixtures as well as pure substances, only if it is modified to be $P=k\bar{\mu}/\bar{\varepsilon}$. Therefore, the variation of P with x_1 may be expressed by the following equation:

$$\frac{dP}{dx_1} = k\frac{\mu_1\varepsilon_2-\mu_2\varepsilon_1}{(\varepsilon_1x_1+\varepsilon_2x_2)^2}. \tag{4}$$

Consequently, the increasing trend at $x_1\to 0$ can be presumed by

$$\left(\frac{dP}{dx_1}\right)_{x_1\to 0} = k\frac{\mu_1\varepsilon_2-\mu_2\varepsilon_1}{\varepsilon_2^2}, \tag{5}$$

where the suffixes 1 and 2 correspond to an organic substance and water, respectively. Then, the calculated values of $(dP/dx_1)_{x_1\to 0}$ are in a sequence: dimethyl sulfoxide>acetone>methanol>1, 4-dioxane, which coincides qualitatively with the observed one except for acetone: dimethyl sulfoxide>methanol>1,4-dioxane>acetone, this discrepancy being not interpreted at the present stage.

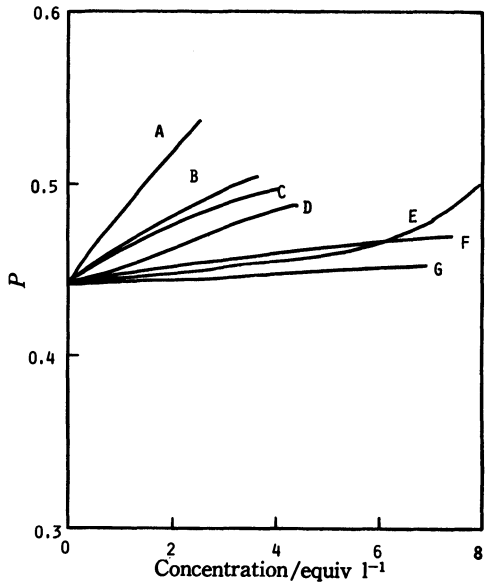

Fig. 8. Variations of P with concentrations of electrolytes in water.
A: RbCl, B: KCl, C: NaCl, D: $MgCl_2$, E: LiCl, F: $(C_2H_5)_3NHCl$, G: $(CH_3)_3NHCl$.
Observations were performed so many times that only smoothed curves are shown as general tendencies in order to avoid the complexity, in the figure.

Aqueous Solutions of Electrolytes. Figure 8 presents the variations of P with respect to the concentrations c/equiv dm^{-3} of electrolytes. The values of $(dP/dc)_{c\to 0}$ are all positive in a sequence: RbCl>KCl>NaCl>$MgCl_2$>LiCl>$(C_2H_5)_3NHCl\approx(CH_3)_3NHCl$. Concern-

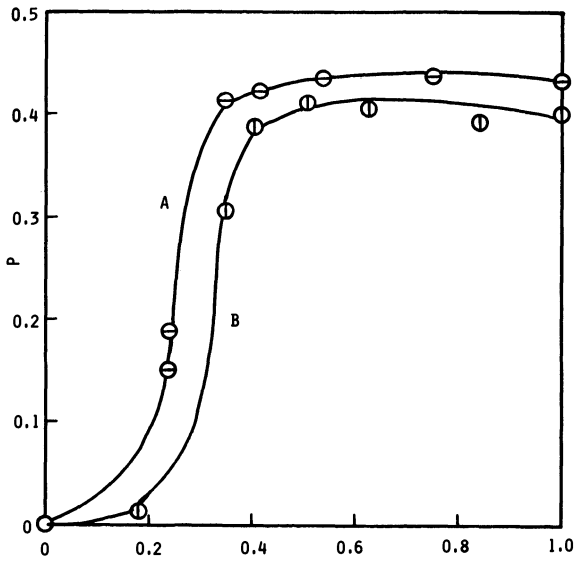

Fig. 9. Variations of P with mole fractions of polar substances in benzene.

A: Nitrobenzene, B: ethanol.

ing the cases of alkali chlorides, the observed order coincides with the nature of alkali ions changing from structure breakers to structure formers. Water molecules surrounding ions are classified into three categories, A, B, and C; water molecules in A layer are firmly attached to the central ions by the Coulombic interactions between ion and dipole, and water molecules in C range are bulk water having the ordinary nature as pure water, while water molecules in B layer are located intermediate between A and C and therefore are free from the restrictions due to both the Coulombic attraction as in A and the hydrogen bondings between themselves as in C. Accordingly, the electric dipoles of water molecules in B layer may be enabled to take proper orientations towards the outer electric field more easily than those in A or C area.[16] The structure-breaking

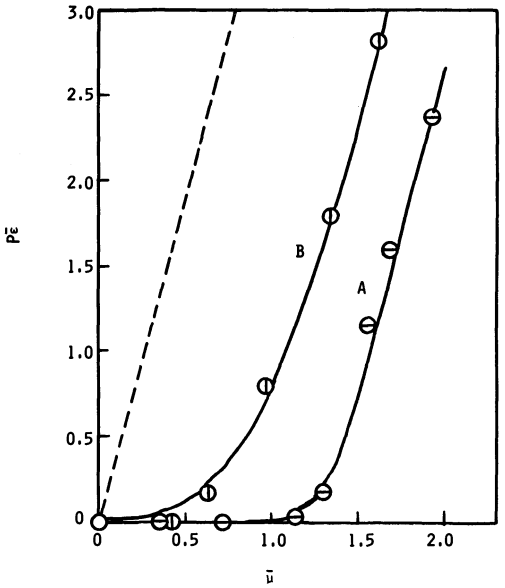

Fig. 11. Variations of $P\bar{\varepsilon}$ with $\bar{\mu}$ for benzene solutions.
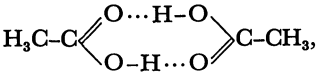
A: Acetic acid, B: tetrahydrofuran.

ions have more water molecules in B layer and therefore aqueous solutions of structure breakers may exhibit larger P value than the structure making ions. The observed order of the values of $(dP/dc)_{c\to 0}$ is thus well understood.

Although $(C_2H_5)_3NH^+$ and $(CH_3)_3NH^+$ ions have large ionic radii, they are not structure breakers but structure makers, because the hydrophobicity of CH_3 and C_2H_5 groups promotes the icelike hydrogen-bonded structure around ions.[17] This is the reason why alkyl ammonium ions exhibit smaller value of $(dP/dc)_{c\to 0}$ than Li^+ ion.

Benzene Solutions with Polar Substances. In order to make the matter simpler, we used mixtures of polar substances with nonpolar liquid: benzene with $\mu_2=0$ and $\varepsilon_2=2.274$. In this case, Eq. 5 becomes $(dP/dx_1)_{x_1\to 0}=k\mu_1/\varepsilon_2$. Although Fig. 9 shows that the correlationship between P and x_1 do not explicitly exhibit the expected slopes at the limiting concentration $x_1\to 0$ in mixtures of nitrobenzene or ethanol in benzene, respectively, the proportionality of $P\bar{\varepsilon}$ *vs.* $\bar{\mu}$ is approximately established over the whole concentration range for both mixtures, as shown in Fig. 10. This fact may indicate that individual molecules of both nitrobenzene and ethanol exist independently and freely in benzene without occurrence of any molecular association, respectively.

On the other hand, Fig. 11 shows the cases of benzene solutions of acetic acid and tetrahydrofuran, in which no proportionality is recognized between $P\bar{\varepsilon}$ and $\bar{\mu}$. Therefore, it seems that they are not simple mixtures but there probably happen mutual interactions between polar molecules of themselves in benzene solutions. Acetic acid is known to dimerize by hydrogen bondings in benzene, giving



which has a nonpolar structure and therefore may dimi-

TABLE 1. EXAMINATION FOR ADDITIVITY OF $P\bar{\varepsilon}$ BETWEEN PHENOL AND PYRIDINE IN BENZENE SOLUTIONS

Solute	x	$\bar{\varepsilon}$	$\bar{\mu}$	$P\bar{\varepsilon}$
Phenol	0.4	5.276	0.588	0.280
Pyridine	0.4	6.284	0.972	0.798
Mixture of phenol and pyridine	0.4 0.4	9.287	1.560	3.752

nish the apparent dipole moment, making the solutions to disobey the proportionality correlation in the result. Tetrahydrofuran also fails to obey the proportionality rule to the similar direction to acetic acid. But the reason for the depression of its apparent dipole moment in benzene is not understood at the present stage of the investigation.

As has been indicated in Fig. 5, the observed point for water appears far above the straight line of the proportionality between $P\varepsilon$ and μ. The apparent increment of μ is supposed to be caused by the molecular association of the type head to tail $(+-)(+-)\cdots$, while the apparent depression of μ as experienced in the case of acetic acid and presumably that of tetrahydrofuran in benzene solutions may be attributed to the formation of dimers of the type head to head $(+-)(-+)$.

Ternary Mixtures of Phenol, Pyridine, and Benzene. If two solutes S_1 and S_2 are independently dissolved in benzene without mutual interaction between molecules of the same species as well as between the different ones, an additivity correlation with respect to $P\bar{\varepsilon}$ values should hold in solutions of the both solutes. Table 1 gives data proving whether the additivity holds in the cases of phenol ($\varepsilon=9.78$, $\mu=1.47$) and pyridine (12.3, 2.43) or not. According to the table, the observed $P\bar{\varepsilon}$ for the ternary mixture of phenol ($x=0.4$), pyridine ($x=0.4$), and benzene ($x=0.2$) is 3.752, which is much larger than the value of the sum of the respective solutions in benzene of the same mole fraction, $0.280+0.798=1.078$. This discrepancy may suggest that there occurs molecular association between phenol and pyridine, forming a molecular complex with apparently large dipole moment as compared with those for respective species. Although the detailed structure of the molecular complex is not clear, the bonding between the two species would be a hydrogen bond of the type O–H···N and the resultant electron density at benzene ring may be larger than that at pyridine ring. Thus, the point for the observed $P\bar{\varepsilon}$ should appear above the simply expected one from the additivity as a normal mixture, in a $P\bar{\varepsilon}$-$\bar{\mu}$ diagram.

Conclusion. The attractive force wrought on polar substances in an outer electric field has been found to be proportional to the observable quantity P as defined above. The value of P offers a simple means to detect the structures of pure liquids or mixtures in liquids. $P\varepsilon$ *vs.* μ for various pure liquids and $P\bar{\varepsilon}$ *vs.* $\bar{\mu}$ for mixtures of some components give a straight line with a common proportional constant k, if no molecular association occurs, although ε *vs.* μ for various polar substances is not linear.

When $P\bar{\varepsilon}$ value *vs.* $\bar{\mu}$ fails to come on the straight line with the slope k, there probably happens to take place molecular association. The association to cause an apparently larger dipole moment makes the point locate above the straight line, and *vice versa.* The former instances are seen in the cases of water and mixture of phenol–pyridine–benzene, and the latters in those of mixtures of acetic acid–benzene and of tetrahydrofuran–benzene.

Free Energy, Enthalpy, and Entropy Changes of Mixing of Aqueous Solutions of D-Glucose and Tetraalkylammonium Bromide at 25 °C

Koichiro MIYAJIMA,* Masahiro SAWADA, and Masayuki NAKAGAKI
Faculty of Pharmaceutical Sciences, Kyoto University, Yoshida Shimoadachi-cho, Sakyo-ku, Kyoto 606
(Received March 16, 1983)

Changes of free energy and enthalpy of mixing of aqueous solutions of D-glucose and tetraalkylammonium bromide were measured at 25 °C by isopiestic method and calorimetry, and excess thermodynamic quantities and transfer functions were calculated. All transfer functions were positive and mutual salting-out was observed. The positive value of free energy of transfer of tetrabutylammoniun bromide from water to aqueous D-glucose solution comes from the predominance of enthalpic term over entropic term. These results are interpreted in terms of the structural incompatibility of hydration cospheres around these two kinds of solutes.

The tetraalkylammonium salt (TAAB) is known to enhance the structure of water by formation of a cage-like structure around itself. Judging from the results of x-ray analysis of the tetrabutylammonium fluoride,[1] the hydrogen bond network of clathrate compound is different from that of tridymite structure of ice, though the hydrogen bond length and the bond angle are similar.

Various monosaccharides, such as D-glucose, also promote the water structure by directly forming hydrogen bonds with water molecules. Kabayama and Patterson[2] postulated that the spacing of the equatorial oxygen atoms of the hexopyranose of the chair conformation nearly fits the spacing of oxygen atoms in the tridymite-like structure of water. In a previous paper,[3] we reported the excess thermodynamic quantities of aqueous monosaccharide solutions, and concluded D-glucose to be a structure maker from the negative value of excess partial molar entropy of water. Therefore, the water structure around D-glucose and that around the tetraalkylammonium bromide must be different from each other.

On the other hand, various saccharides and polyalcohols are reported to be an anti-denaturating agents of proteins in aqueous solutions,[4] and the mechanism is considered to be related to the strengthening of hydrophobic interaction in protein molecule by the presence of these compounds. Therefore, the study on the structural interaction of these two kinds of solutes, one is hydrophobic solute and the other hydrophilic, in aqueous solutions seems to be important as a model system of such a protein denaturation in aqueous solutions.

From these points of view, we measured the activity coefficients and heat of dilution on the ternary system D-glucose–tetrabutylammonium bromide (TBAB)–water at 25 °C, and discussed the interaction of these solutes through the structural change of water on the basis of the thermodynamic excess quantities and the transfer functions.

Theory

Activity Coefficient. Activity coefficients of solutes 1 (D-glucose) and 2 (TAAB) are determined from the isopiestic data by the Ellerton-Dunlop method.[5] Assume that the activity coefficient of solute 1 (γ_1) is expressed by Eq. 1.

$$\ln \gamma_1 = \sum_{i=0}^{4}\sum_{j=0}^{4} g_{ij} m_1^i m_2^j \quad (A_{00}=0,\ i+j\leq 4), \tag{1}$$

where g_{ij}'s are the interaction parameters and m_1 and m_2 the molalities of solutes 1 and 2, respectively. In Eq. 1, the four terms $g_{10}m_1$, $g_{20}m_1^2$, $g_{30}m_1^3$, and $g_{40}m_1^4$ correspond to the contributions of activity coefficient of binary system (γ_1°). Therefore, Eq. 1 is rewritten as

$$\begin{aligned}\ln \gamma_1 = \ln \gamma_1^\circ &+ g_{01}m_2 + g_{11}m_1m_2 + g_{02}m_2^2 + g_{21}m_1^2m_2 \\ &+ g_{12}m_1m_2^2 + g_{03}m_2^3 + g_{31}m_1^3m_2 + g_{22}m_1^2m_2^2 \\ &+ g_{13}m_1m_2^3 + g_{04}m_2^4.\end{aligned} \tag{2}$$

Here the cross differential relation holds between two solutes.

$$\left(\frac{\partial \ln \gamma_1}{\partial m_2}\right)_{m_1} = \nu \left(\frac{\partial \ln \gamma_2}{\partial m_1}\right)_{m_2}, \tag{3}$$

where ν is the number of moles of ions formed from 1 mole of solute 2 (TAAB). Introducing Eq. 2 to Eq. 3, we obtain Eq. 4 as an expression of activity coefficient for solute 2.

$$\begin{aligned}\nu \ln \gamma_2 = \nu \ln \gamma_2^\circ &+ g_{01}m_1 + \frac{1}{2}g_{11}m_1^2 + 2g_{02}m_1m_2 \\ &+ \frac{1}{3}g_{21}m_1^3 + g_{12}m_1^2m_2 + 3g_{03}m_1m_2^2 + \frac{1}{4}g_{31}m_1^4 \\ &+ \frac{2}{3}g_{22}m_1^3m_2 + \frac{3}{2}g_{13}m_1^2m_2^2 + 4g_{04}m_1m_2^3.\end{aligned} \tag{4}$$

Combining Eqs. 2 and 4 with Gibbs-Duhem relation, experimental quantity defined by Eq. 5 is expressed by Eq. 6 using g_{ji}'s.

$$\Delta = \nu_R m_R \phi_R - m_1\phi_1^\circ - \nu m_2 \phi_2^\circ, \tag{5}$$

and

$$\begin{aligned}\Delta/m_1m_2 = g_{01} &+ g_{11}m_1 + 2g_{02}m_2 + g_{21}m_1^2 + \frac{3}{2}g_{12}m_1m_2 \\ &+ 3g_{03}m_2^2 + g_{31}m_1^3 + \frac{4}{3}g_{22}m_1^2m_2 + 2g_{13}m_1m_2^2 \\ &+ 4g_{04}m_2^3.\end{aligned} \tag{6}$$

In these equations, ν_R is the number of moles of ions produced by the dissociation of 1 mol of reference salt, and m_R and ϕ_R are the molality and the osmotic coefficient of reference salt, respectively. ϕ_1° and ϕ_2° are osmotic coefficients of solutes 1 and 2 in binary aqueous solutions, respectively. The activity coefficients of solutes 1 and 2 can be calculated from g_{ij}'s obtained by the application of the least squares method to Eq. 6.

Heat of Dilution. Assume that the excess enthalpy of ternary system is expressed by the polynomials involving terms up to quartic.

$$H^{ex} = (m_1\phi_{L,1}^{ex,0} + m_2\phi_{L,2}^{ex,0}) + h_{11}m_1m_2 + h_{21}m_1^2m_2 + h_{12}m_1m_2^2 + h_{31}m_1^3m_2 + h_{22}m_1^2m_2^2 + h_{13}m_1m_2^3, \quad (7)$$

where $\phi_{L,1}^{ex,0}$ and $\phi_{L,2}^{ex,0}$ are the apparent molar excess enthalpies in aqueous binary solutions, and h_{ij}'s are interaction parameters. M and x being the total molality and the mole fraction of solute 1, respectively, excess mean apparent molar enthalpy (ϕ_L^{ex}) is expressed by Eq. 8.

$$\phi_L^{ex} = H^{ex}/M = [x\phi_{L,1}^{ex,0} + (1-x)\phi_{L,2}^{ex,0}] + h_{11}x(1-x)M + h_{21}x^2(1-x)M^2 + h_{12}x(1-x)^2M^2 + h_{31}x^3(1-x)M^3 + h_{22}x^2(1-x)^2M^3 + h_{13}x(1-x)^3M^3. \quad (8)$$
$$(M=m_1+m_2,\ x=m_1/M)$$

Q_D is defined as mean molar heat evolved on dilution from M to M', then Q_D is expressed by

$$-Q_D(M \to M') = \phi_L^{ex}(x, M) - \phi_L^{ex}(x, M'). \quad (9)$$

Introducing Eq. 8 to Eq. 9, we obtain

$$\begin{aligned} Q_D(M \to M') &- x[\phi_{L,1}^{ex,0}(xM) - \phi_{L,1}^{ex,0}(xM')] \\ &- (1-x)\{\phi_{L,2}^{ex,0}[(1-x)M] - \phi_{L,2}^{ex,0}[(1-x)M']\} \\ &= h_{11}x(1-x)(M-M') + h_{21}x^2(1-x)(M^2-M'^2) \\ &+ h_{12}x(1-x)^2(M^2-M'^2) + h_{31}x^3(1-x)(M^3-M'^3) \\ &+ h_{22}x^2(1-x)^2(M^3-M'^3) + h_{13}x(1-x)^3(M^3-M'^3). \quad (10) \end{aligned}$$

The left hand terms of Eq. 10 can be experimentally measurable quantities, because the first term corresponds to the enthalpy of dilution of ternary system and the second and the third terms correspond to the enthalpy of dilution of each binary system. Therefore, Q_D was measured with variations of total molarities and degree of dilution, and the interaction parameters were determined by the least squares method. H^{ex} and ϕ_L^{ex} were calculated from these h_{ij}'s using Eqs. 7 and 8.

Excess Thermodynamic Quantities of Mixing. Excess free energy change of mixing of each component is expressed by the Eqs. 11, 12, and 13.[6,8]

$$\Delta_m G_1^{ex} = RTm_1 \ln(\gamma_1/\gamma_1^\circ), \quad (11)$$

$$\Delta_m G_2^{ex} = \nu RTm_2 \ln(\gamma_2/\gamma_2^\circ), \quad (12)$$

and

$$\Delta_m G_w^{ex} = -RT\Delta, \quad (13)$$

where subscripts 1, 2, and w denote D-glucose, TAAB, and water, respectively. Total excess free energy change of mixing is the sum of three components.

$$\Delta_m G^{ex} = \Delta_m G_1^{ex} + \Delta_m G_2^{ex} + \Delta_m G_w^{ex}. \quad (14)$$

Excess enthalpy change of mixing is expressed by Eq. 15.

$$\Delta_m H^{ex} = H^{ex} - m_1\phi_{L,1}^{ex} - m_2\phi_{L,2}^{ex}. \quad (15)$$

Therefore, excess entropy change of mixing is obtained from $\Delta_m G^{ex}$ and $\Delta_m H^{ex}$,

$$\Delta_m S^{ex} = (\Delta_m H^{ex} - \Delta_m G^{ex})/T. \quad (16)$$

Change of the Partial Molar Thermodynamic Quantities of Transfer of the Solute from Water to Aqueous Solution; Thermodynamic Transfer Functions. Free energy change on transferring 1 mol of solute 1 from water to aqueous solution ($\Delta\bar{G}_1^{tr}$) is expressed by Eq. 17.

$$\Delta\bar{G}_1^{tr} = RT\ln(\gamma_1/\gamma_1^\circ). \quad (17)$$

Similarly in the case of solute 2 $\Delta\bar{G}_2^{tr}$ is expressed by Eq. 18.

$$\Delta\bar{G}_2^{tr} = \nu RT\ln(\gamma_2/\gamma_2^\circ). \quad (18)$$

Partial molar enthalpy change on transferring 1 mol of solute 1 or solute 2 from water to aqueous solution is expressed by Eq. 19 or Eq. 20.

$$\begin{aligned} \Delta\bar{H}_1^{tr} &= \left(\frac{\partial\Delta_m H^{ex}}{\partial m_1}\right)_{m_2} \\ &= h_{11}m_2 + 2h_{21}m_1m_2 + h_{12}m_2^2 + 3h_{31}m_1^2m_2 \\ &\quad + 2h_{22}m_1m_2^2 + h_{13}m_2^3, \quad (19) \end{aligned}$$

or

$$\begin{aligned} \Delta\bar{H}_2^{tr} &= \left(\frac{\partial\Delta_m H^{ex}}{\partial m_2}\right)_{m_1} \\ &= h_{11}m_1 + h_{21}m_1^2 + 2h_{12}m_1m_2 + h_{31}m_1^3 \\ &\quad + 2h_{22}m_1^2m_2 + 3h_{13}m_1m_2^2. \quad (20) \end{aligned}$$

Therefore, partial molar entropy change on transferring 1 mol of solute 1 or solute 2 from water to aqueous solution is written by Eq. 21.

$$\Delta\bar{S}_k^{tr} = (\Delta\bar{H}_k^{tr} - \Delta\bar{G}_k^{tr})/T. \quad (k=1 \text{ or } 2) \quad (21)$$

Experimental

Materials. Reagent grade D-glucose obtained from Nakarai Chemical Co. Ltd., was dried *in vacuo* for several days at room temperature over P_2O_5 before use. TBAB and TMAB purchased from Nakarai Chemical Co. Ltd. were recrystallized twice from appropriate solvent described elsewhere,[7] and dried *in vacuo* for 2 d at 80 °C before use. Reagent grade sodium chloride was obtained from Matsunaga Chemical Co. Ltd., and dried *in vacuo* for a day at 100 °C. Solutions were prepared with water purified by distillations and deionization.

Methods. Osmotic coefficients were measured at 25±0.2 °C by isopiestic comparison method described elsewhere.[8] Sodium chloride and TBAB were used as reference solutes. Measurement of heat of dilution was carried out by using a flow microcalorimeter (LKB 10700-1) at 25±0.001 °C. Experimental procedure and accuracy were the same as those reported elsewhere.[9] The least squares fittings were carried out by using FACOM OSIV/F4 in Data Processing Center of Kyoto university.

Results

Activity Coefficient. Isopiestic molalities of solutes 1 (D-glucose) and 2 (TAAB) in the ternary systems and of the reference solutes are shown in Table 1 together with the experimental quantity Δ/m_1m_2 and percentage errors (Diff. %) defined by Kelly *et al.*[10] The osmotic coefficients of aqueous binary solutions were taken from the literatures given by Robinson and Stokes[11] for NaCl, Lindenbaum and Boyd[12] and Wen *et al.*[13] for TBAB, Levien[14] for TMAB, and authors[3] for D-glucose. Parameters in Eq. 6 calculated from the data in Table 1 by the least squares method were shown in Table 2. The activity coefficient *vs.* molality curves for D-glucose and TBAB in binary and ternary solutions are shown in Figs. 1 and 2, respectively. The activity coefficient of

each solute increases in the presence of the other solute. Similar tendency was observed in the ternary system D-glucose–TMAB–water.

Heat of Dilution. Figure 3 shows the mean molar heat of dilution as a function of total concentration difference before and after dilution ($M-M'$). The values of molar heat of dilution for the binary systems, D-glucose–water and TBAB–water, obtained from this work agree with those of literatures.[15-17] Using the least squares method, interaction parameters in Eq. 10 are calculated and are shown in Table 3.

Discussion

As seen in Figs. 1 and 2, activity coefficient of each solute in ternary system increases in the presence of the other solute, showing mutual salting-out. Therefore, the repulsive force is working between these two solutes. Similar result, except for small in magnitude, was observed in the D-glucose–TMAB–water system. Taking into account the both solutes being strongly hydrated, the mutual salting-out observed in the D-glucose–TBAB–water system should be due to the structural salting-out arising from the structural difference of hydration cospheres around these two kinds of solutes.

Figures 4-(a) and -(b) show the relations between the changes of the excess thermodynamic quantities of mixing and the mole fraction of D-glucose at total molalities 1 and 2 mol kg^{-1}, repsectively. In these figures, the solid lines with star sign denote the excess free energy change of mixing for the D-glucose–TMAB–water system. The values of $\Delta_m G^{ex}$ for the both systems are positive, but the magnitude for the D-glucose–TBAB–water system is larger than that for the D-glucose–TMAB–water system. This result indicates that the hydrophobic hydration plays an important role on the magnitude of $\Delta_m G^{ex}$. The positive value of $\Delta_m G^{ex}$ implies that the system becomes unstable by mixing.

On the D-glucose–TBAB–water system, the positive value of $\Delta_m G^{ex}$ comes from the difference between large positive excess enthalpy change and entropy change, that is, the predominance of excess enthalpy term over excess entropy term makes $\Delta_m G^{ex}$ positive. Thus the unstableness of the system caused by mixing is due to the large positive excess enthalpy change.

Let us consider the mechanism of interaction between two kinds of solutes on the basis of the thermodynamic results obtained in this work. As stated in the introduction of this paper, both solutes are strongly hydrated but their structures of hydration cospheres are different each other. Accordingly the structural incompatibility causes the destruction of water structure around each solute, resulting in the increase of positive $\Delta_m S^{ex}$. The destruction of water structure accompanies the cleavage of hydrogen bonds among water molecules and makes the $\Delta_m H^{ex}$ value positive.

In order to compare the thermodynamic quantities of this system with those of the urea–TBAB–water system, thermodynamic transfer quantities were calculated by Eqs. 20, 21, and 22, and shown in Figs. 5 and 6 together with those for the urea–TBAB–water system reported by Wen *et al.*[18] As seen in Fig. 5, free energy ($\Delta\bar{G}_1^{tr}$), enthalpy ($\Delta\bar{H}_1^{tr}$), and entropy ($\Delta\bar{S}_1^{tr}$) of transfer of D-glucose from water to aqueous TBAB solution at infinite dilution are all positive, indicating the transfer process is disfavoured in enthalpic sence. The positive values of ΔH_1^{tr} and ΔS_1^{tr} mean the decrease of water structure around D-glucose in the transfer process. It is striking that the $T\Delta\bar{S}_1^{tr}$ *vs.* m_2 and $\Delta\bar{H}_1^{tr}$ *vs.* m_2 curves have maximum points around $m_2=1.5$, although the $\Delta\bar{G}_1^{tr}$ *vs.* m_2 curve gradually increases with m_2. The concentration of TBAB showing the maximum values of $\Delta\bar{H}_1^{tr}$ and $\Delta\bar{S}_1^{tr}$ nearly corresponds to the concentration at the minimum point observed in partial molar volume *vs.* concentration curve in aqueous TBAB solution.[19] At the concentration showing the minimum point, clusters around TBAB arrive at maximum cooperation in constructing a clathrate-like structure.[20] Therefore, this fact indicates that the water structure around D-glucose is destructed most strongly by TBAB at this concentration.

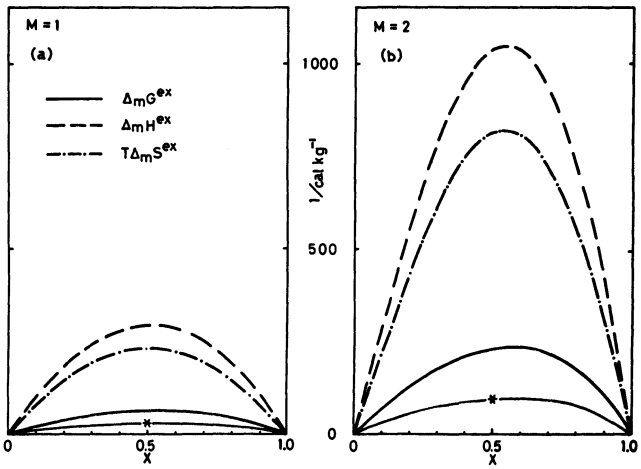

Fig. 4. Changes of excess thermodynamic quantities of mixing for the D-glucose–TBAB–water system at total molality (a) 1 or (b) 2 mol kg^{-1} at 25 °C. x; Mole fraction of D-glucose.
The solid lines with star sign denote change of excess free energy of mixing for the D-glucose–TMAB–water system.

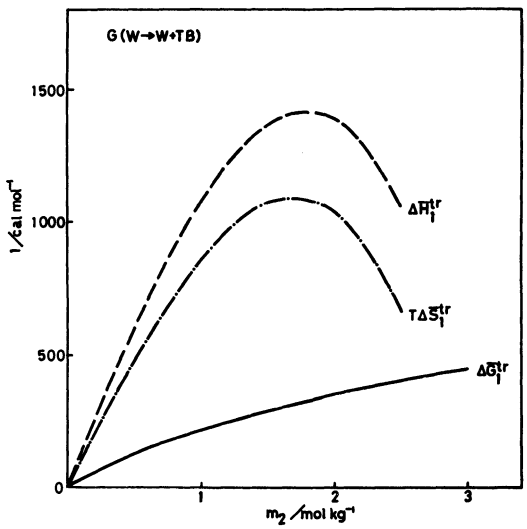

Fig. 5. Thermodynamic transfer functions of D-glucose from water to aqueous TBAB solution at infinite dilution at 25 °C.
m_2; Molality of TBAB.

Thermodynamic transfer functions of TBAB from water to aqueous D-glucose solution at infinite dilution are shown in Fig. 6-(a) as a function of the concentration of D-glucose. Similarly to Fig. 5, signs of all transfer functions are positive indicating that salting-out are caused by the large enthalpic contribution. Both positive $\Delta\bar{H}_2^{tr}$ and $\Delta\bar{S}_2^{tr}$ mean that the clathrate-like

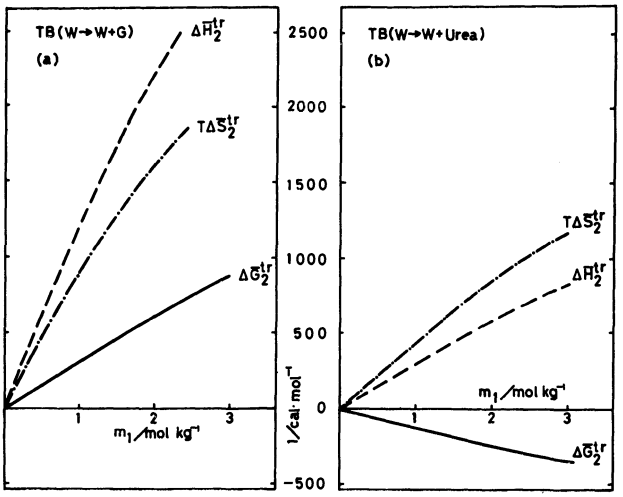

Fig. 6. Thermodynamic transfer functions of TBAB from water to (a) aqueous D-glucose solution or (b) aqueous urea solution[18] at infinite dilution at 25 °C.
m_1; Molality of D-glucose or urea.

structure of water around TBAB decreases in the presence of D-glucose. Figure 6-(b) shows the thermodynamic transfer functions of TBAB from water to various concentrations of aqueous urea solutions.[18] Comparing Fig. 6-(a) with Fig. 6-(b), one can find that both $\Delta\bar{H}_2^{tr}$ and $\Delta\bar{S}_2^{tr}$ are positive in each system but their relative magnitudes are different, that is, $\Delta\bar{H}_2^{tr} > T\Delta\bar{S}_2^{tr}$ for the D-glucose–TBAB–water system while $\Delta\bar{H}_2^{tr} < T\Delta\bar{S}_2^{tr}$ for the urea–TBAB–water system. Thus $\Delta\bar{G}_2^{tr}$ for the urea–TBAB–water system is negative, indicating salting-in. The positive value of $\Delta\bar{S}_2^{tr}$ in these two systems indicate that both D-glucose and urea decrease the clathrate-like structure of water around TBAB, but D-glucose needs more energy to break down the hydrogen bonds in clathrate-like structure than urea does. We can not explain the detail mechanism of destruction of clathrate-like structure by D-glucose at the present stage. However, it is plausible that the incompatibility of structure of hydration cosphere around D-glucose and that around TBAB enforces the mutual structure breaking action, because both solutes are known to be structure makers.

The conclusion drawn from the comparison of our results with Wen's results is that hydrophobic hydration is destabilized in the presence of both D-glucose (hydrophilic structure maker) and urea (hydrophilic structure breaker).

Saccharides and polyalcols are known to stabilize the native conformation of protein in aqueous solution, while urea destabilizes it. Hydrophobic interactions are considered to play an important role for the maintenance of the native conformation of protein.[21] The positive value of $\Delta\bar{G}_2^{tr}$ in aqueous D-glucose solution suggests that the hydrophobic moieties of protein may be more unstable in aqueous D-glucose solution than in water. Therefore, the salting-out effect of D-glucose for the hydrophobic TBAB may be related to the stabilization of native conformation of protein in aqueous D-glucose solution.

In conclusion, the excess enthalpy change ($\Delta_m H^{ex}$) and the excess entropy change ($\Delta_m S^{ex}$) of mixing for the ternary system D-glucose–TBAB–water are positive, showing that the degree of hydration of each solute in ternary solution decreases as compared with that in binary solution. The positive value of $\Delta_m G^{ex}$ which originates from the difference between $\Delta_m H^{ex}$ and $T\Delta_m S^{ex}$ indicates that each binary solution is more stable than the mixed ternary solution. Enthalpy and entropy changes of transfer of TBAB from water to D-glucose solution are positive similarly to those from water to urea solution. However, free energy of transfer of TBAB from water to D-glucose solution is positive in contrast to the case of urea–TBAB–water system. These differences seem to reflect the difference of structural effect between D-glucose and urea.

The authors express the sincere gratitude to Professor Sachio Murakami of Osaka City University for the permission and guidance of calorimetric measurements.

Thermodynamics of the Electrocapillarity of Oil-Water Interfaces

Takashi KAKIUCHI and Mitsugi SENDA*
Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606
(Received March 26, 1983)

General electrocapillary equations for the interfaces between two immiscible or partially miscible electrolyte solutions have been derived. The theory includes both nonpolarized and ideal polarized interfaces. The electrocapillary equation for the latter has been derived from the equation for the former as a special case where no common ionic species are distributed between the two phases. Implications of the general electrocapillary equation for oil–water interfaces are indicated.

Recent advances[1-3] in electrochemistry of the interfaces between two immiscible or partially miscible electrolyte solutions allow us to obtain various thermodynamic quantities characterizing the interface from the electrocapillary measurements. Koryta *et al.* have first interpreted the polarizability of the interfaces in terms of the transfer free energies of ions from one solvent to the other.[4] Kakiuchi and Senda have shown that the interface between a nitrobenzene solution of tetrabutylammonium tetraphenylborate and an aqueous solution of lithium chloride has a certain polarized potential region, where the ion transfer current across the interface is negligibly small, and gives an electrocapillary curve of parabolic shape.[5,6] The electrocapillary curves of nonpolarized nitrobenzene–water interfaces have been measured by Gros *et al.*[7] To analyze these electrocapillary data at full length, exact thermodynamic treatment of these interfaces is indispensable. Several thermodynamic treatments so far reported[7-10] suffer from limited applicability due to simplifications and various assumptions introduced.

The purpose of this study is to present a general thermodynamic theory of electrocapillarity for the planar interface between two immiscible or partially miscible electrolyte solutions, which we hereafter call the oil–water interface. In this paper, we first establish the basic electrocapillary equations for a nonpolarized oil–water interface at equilibrium, where some of the ions as well as some of the neutral components can pass through the interface and are distributed between the two phases in equilibrium. Then the electrocapillary equation for an ideal polarized oil–water interface, which is defined as the interface where no ionic species is common in both phases or where each charged species is present in appreciable amounts in only one of the two phases,[11] is derived from the equation for the nonpolarized interface by eliminating the terms involving the common ionic species.

Theoretical

Nonpolarized Oil–Water Interface. The System: We shall consider the following cell:

$$\mathrm{M}\,|\mathrm{R1}|\,\mathrm{O}\,|\,\mathrm{W}\,|\,\mathrm{R2}|\,\mathrm{M}', \qquad \text{(I)}$$

where M and M′ are two pieces of the same metal between which we measure the potential difference, and R1 and R2 are the appropriate reference electrodes, each of which is reversible to one of the ions in the adjoining solution phase. We assume a planar interface between the oil phase (O) and the water phase(W). The oil phase contains i cations, j anions, and k uncharged nondissociating components, which we hereafter simply call neutral components, while the water phase contains p cations, q anions, and h neutral components. These sets of the components are also designated by i, j, k, p, q, and h, respectively, so that these symbols are used to indicate both the set and the number of the components. Suppose that α cations, β anions and l neutral components are able to pass through the interface and are commonly distributed over the two phases; the interface is nonpolarizable with respect to these common ions. In other words, i-α cations, j-β anions, and k-l neutral components stay solely within the oil phase, while p-α cations, q-β anions, and h-l neutral components stay within the water phase. Let the sets of these common cations, anions, and neutral components also be denoted by α, β, and l, respectively.

The number of the intensive variables for this system is $i+j+k+p+q+h+2$ including temperature and pressure, but not all of them are independent. Since $\alpha+\beta+l$ components are common in both phases, there are $\alpha+\beta+l$ equations relating the chemical potentials of the common components in the two phases with each other. In addition, there are two Gibbs-Duhem equations: one for the oil phase and one for the water phase. Moreover, the potential difference between the two terminals of the cell (I) correlates the two electrochemical potentials of the two ions which are reversible to the reference electrodes R1 and R2. The number of the independent intensive variables which define the present system is, therefore, $i+j+k+p+q+h-(\alpha+\beta+l)-1$.

The Electrocapillary Equation: We adopt the concept of a surface phase[12,13] to describe the interface. An exact definition of the surface phase which the present treatment rests on has been given by Eriksson.[14] The analogue of the Gibbs-Duhem equation for the surface phase with a planar interface is[14]

$$-\mathrm{d}\gamma = \eta\,\mathrm{d}T - \tau\,\mathrm{d}P + \sum_x \Gamma_x \mathrm{d}\mu_x, \qquad (1)$$

where γ is the interfacial tension, η is the entropy of the surface phase per unit area of the interface, T is the temperature, τ is the thickness of the surface phase, P is the pressure, and Γ_x is the number of moles of the x component per unit area of the interface, which may be called the surface concentration of the x component.

The summation in the right hand side of Eq. 1 includes all the components in the system including ionic species. In Eq. 1 μ_x represents the electrochemical potential for a charged component and the chemical potential for a neutral component. For the present system Eq. 1 takes the form

$$-\mathrm{d}\gamma = \eta\,\mathrm{d}T - \tau dP + \sum_{i\neq\alpha}\Gamma_i\mathrm{d}\tilde{\mu}_i + \sum_{j\neq\beta}\Gamma_j\mathrm{d}\tilde{\mu}_j + \sum_{k\neq l}\Gamma_k\mathrm{d}\mu_k + \sum_{p\neq\alpha}\Gamma_p\mathrm{d}\tilde{\mu}_p + \sum_{q\neq\beta}\Gamma_q\mathrm{d}\tilde{\mu}_q + \sum_{h\neq l}\Gamma_h\mathrm{d}\mu_h + \sum_{\alpha}\Gamma_\alpha\mathrm{d}\tilde{\mu}_\alpha + \sum_{\beta}\Gamma_\beta\mathrm{d}\tilde{\mu}_\beta + \sum_{l}\Gamma_l d\mu_l. \quad (2)$$

In Eq. 2, we have made a distinction between the electrochemical potential, $\tilde{\mu}_x$, for a charged component $x(x=i, j, p, q, \alpha, \beta)$, and the chemical potential, μ_y, for a neutral component $y(y=h, k, l)$. The symbol $\sum_{f\neq g}$ means that the summation covers all the f components except g. There are $i+j+k+p+q+h-(\alpha+\beta+l)+2$ intensive variables and hence three of them are dependent variables as described above.

Suppose that the reference electrodes R1 and R2 are reversible to a cation i' among the cations $i\neq\alpha(i$ except $\alpha)$ and an anion q' among the anions $q\neq\beta(q$ except $\beta)$. Furthermore, we choose the anion j' out of $j\neq\beta$ anions as a counter anion of the cation i' to make up an indicator salt[15] $i'j'$ and the cation p' out of the $p\neq\alpha$ cations as a counter cation of the anion q' to make up an indicator salt $p'q'$. Then the electrochemical potentials of the ionic components can be related to the chemical potentials of the salt containing one of the ions: i', j', p', or q'.

In many practical cases, the ions constituting the indicator salts may also be commonly distributed in the two phases. To make the present treatment general enough to include these cases, we further suppose here that, in addition to the common ions, α and β, the ions consituting the indicator salts also are commonly distributed in the two phases. There are then $\alpha+2$ common cations and $\beta+2$ common anions in the system. Although these newly added four ions could be included in the sets α and β, we retain in the following treatment a distinction between these ions and the sets of ions α and β for later convenience when deriving the electrocapillary equation for an ideal polarized oil–water interface. Obviously, this extension does not change the number of independent variables. Then we have the following equations relating the electrochemical potentials of the ionic components with the chemical potential of their salt:

$$\mathrm{d}\mu_{i'j'} = \nu^+_{i'j'}\mathrm{d}\tilde{\mu}_{i'} + \nu^-_{i'j'}\mathrm{d}\tilde{\mu}_{j'} \quad (3\text{-}1)$$

$$\mathrm{d}\mu_{ij'} = \nu^+_{ij'}\mathrm{d}\tilde{\mu}_i + \nu^-_{ij'}\mathrm{d}\tilde{\mu}_{j'} \quad (i\neq i', \alpha) \quad (3\text{-}2)$$

$$\mathrm{d}\mu_{i'j} = \nu^+_{i'j}\mathrm{d}\tilde{\mu}_{i'} + \nu^-_{i'j}\mathrm{d}\tilde{\mu}_j \quad (j\neq j', \beta) \quad (3\text{-}3)$$

$$\mathrm{d}\mu_{\alpha j'} = \nu^+_{\alpha j'}\mathrm{d}\tilde{\mu}_\alpha + \nu^-_{\alpha j'}\mathrm{d}\tilde{\mu}_{j'} \quad (3\text{-}4)$$

$$\mathrm{d}\mu_{i'\beta} = \nu^+_{i'\beta}\mathrm{d}\tilde{\mu}_{i'} + \nu^-_{i'\beta}\mathrm{d}\tilde{\mu}_\beta \quad (3\text{-}5)$$

$$\mathrm{d}\mu_{p'q'} = \nu^+_{p'q'}\mathrm{d}\tilde{\mu}_{p'} + \nu^-_{p'q'}\mathrm{d}\tilde{\mu}_{q'} \quad (3\text{-}6)$$

$$\mathrm{d}\mu_{pq'} = \nu^+_{pq'}\mathrm{d}\tilde{\mu}_p + \nu^-_{pq'}\mathrm{d}\tilde{\mu}_{q'} \quad (p\neq p', \alpha) \quad (3\text{-}7)$$

$$\mathrm{d}\mu_{p'q} = \nu^+_{p'q}\mathrm{d}\tilde{\mu}_{p'} + \nu^-_{p'q}\mathrm{d}\tilde{\mu}_q \quad (q\neq q', \beta) \quad (3\text{-}8)$$

$$\mathrm{d}\mu_{\alpha q'} = \nu^+_{\alpha q'}\mathrm{d}\tilde{\mu}_\alpha + \nu^-_{\alpha q'}\mathrm{d}\tilde{\mu}_{q'} \quad (3\text{-}9)$$

$$\mathrm{d}\mu_{p'\beta} = \nu^+_{p'\beta}\mathrm{d}\tilde{\mu}_{p'} + \nu^-_{p'\beta}\mathrm{d}\tilde{\mu}_\beta \quad (3\text{-}10)$$

$$\mathrm{d}\mu_{i'q'} = \nu^+_{i'q'}\mathrm{d}\tilde{\mu}_{i'} + \nu^-_{i'q'}\mathrm{d}\tilde{\mu}_{q'} \quad (3\text{-}11)$$

$$\mathrm{d}\mu_{p'j'} = \nu^+_{p'j'}\mathrm{d}\tilde{\mu}_{p'} + \nu^-_{p'j'}\mathrm{d}\tilde{\mu}_{j'}, \quad (3\text{-}12)$$

where μ_{CA} is the chemical potential of a salt $(C)_{\nu^+_{CA}}(A)_{\nu^-_{CA}}$, and ν^+_{CA} and ν^-_{CA} are the stoichiometric numbers for the dissociation of the salt:

$$(C)_{\nu^+_{CA}}(A)_{\nu^-_{CA}} = \nu^+_{CA}C^{z_C} + \nu^-_{CA}A^{z_A}, \quad (4)$$

where C and A represent a cation and an anion and z_C and z_A are their ionic charges. By using the Gibbs-Duhem equations for the oil and water phases, we can eliminate any two of the intensive variables in Eq. 1. Usually, it is convenient to eliminate the chemical potentials of the two neutral components, which may be identified as the solvents in each phase, *e.g.*, water in the water phase and an oil in the oil phase. These two components are called the reference components. Since most organic solvents used in electrochemistry of oil–water interfaces have a certain solubility in water and *vice versa*, let l' and l'' out of l neutral components be chosen as the reference components.

The Gibbs-Duhem equations for the oil and water phases may then be written in the form

$$\bar{s}^{O}\mathrm{d}T - \bar{v}^{O}\mathrm{d}P + \sum_{i\neq i',\alpha}x^{O}_{ij'}\mathrm{d}\mu_{ij'} + \sum_{\alpha}x^{O}_{\alpha j'}\mathrm{d}\mu_{\alpha j'} + \sum_{j\neq j',\beta}x^{O}_{i'j}\mathrm{d}\mu_{i'j} + \sum_{\beta}x^{O}_{i'\beta}\mathrm{d}\mu_{i'\beta} + x^{O}_{i'j'}\mathrm{d}\mu_{i'j'} + x^{O}_{i'q'}\mathrm{d}\mu_{i'q'} + x^{O}_{p'j'}\mathrm{d}\mu_{p'j'} + \sum_{k\neq l}x^{O}_{k}\mathrm{d}\mu_k + \sum_{l\neq l',l''}x^{O}_{l}\mathrm{d}\mu_l + x^{O}_{l'}\mathrm{d}\mu_{l'} + x^{O}_{l''}\mathrm{d}\mu_{l''} = 0, \quad (5)$$

and

$$\bar{s}^{W}\mathrm{d}T - \bar{v}^{W}\mathrm{d}P + \sum_{p\neq p',\alpha}x^{W}_{pq'}\mathrm{d}\mu_{pq'} + \sum_{\alpha}x^{W}_{\alpha q'}\mathrm{d}\mu_{\alpha q'} + \sum_{q\neq q',\beta}x^{W}_{p'q}\mathrm{d}\mu_{p'q} + \sum_{\beta}x^{W}_{p'\beta}\mathrm{d}\mu_{p'\beta} + x^{W}_{p'q'}\mathrm{d}\mu_{p'q'} + x^{W}_{i'q'}\mathrm{d}\mu_{i'q'} + x^{W}_{p'j'}\mathrm{d}\mu_{p'j'} + \sum_{h\neq l}x^{W}_{h}\mathrm{d}\mu_h + \sum_{l\neq l',l''}x^{W}_{l}\mathrm{d}\mu_l + x^{W}_{l'}\mathrm{d}\mu_{l'} + x^{W}_{l''}\mathrm{d}\mu_{l''} = 0, \quad (6)$$

where $\bar{s}$ and $\bar{v}$ are the mean molar entropy and the mean molar volume of the bulk phase and x is the mole fraction. The superscript O and W denote the oil phase and the water phase, respectively. Substituting Eqs. 3, 5, and 6 into Eq. 2 to eliminate the chemical potential terms for l' and l'' and for all the ionic components except i' and q', we obtain

$$-\mathrm{d}\gamma = (\eta - J\bar{s}^{o} - K\bar{s}^{W})\mathrm{d}T - (\tau - J\bar{v}^{o} - K\bar{v}^{W})\,\mathrm{d}P + \sum_{k\neq l}(\Gamma_k - Jx^{O}_{k})\mathrm{d}\mu_k + \sum_{h\neq l}(\Gamma_h - Kx^{W}_{h})\,\mathrm{d}\mu_h + \sum_{l\neq l',l''}(\Gamma_l - Jx^{O}_{l} - Kx^{W}_{l})\,\mathrm{d}\mu_l + \sum_{i\neq i',\alpha}\left(\frac{\Gamma_i}{\nu^+_{ij'}} - Jx^{O}_{ij'}\right)\mathrm{d}\mu_{ij'} + \sum_{j\neq j',\beta}\left(\frac{\Gamma_j}{\nu^-_{i'j}} - Jx^{O}_{i'j}\right)\mathrm{d}\mu_{i'j} + \sum_{p\neq p',\alpha}\left(\frac{\Gamma_p}{\nu^+_{pq'}} - Kx^{W}_{pq'}\right)\mathrm{d}\mu_{pq'} + \sum_{q\neq q',\beta}\left(\frac{\Gamma_q}{\nu^-_{p'q}} - Kx^{W}_{p'q}\right)\mathrm{d}\mu_{p'q} + \sum_{\alpha}\left(\frac{\Gamma_\alpha}{\nu^+_{\alpha q'}} - Jx^{O}_{\alpha j'}\frac{\nu^+_{\alpha j'}}{\nu^+_{\alpha q'}} - Kx^{W}_{\alpha q'}\right)\mathrm{d}\mu_{\alpha q'} + \sum_{\beta}\left(\frac{\Gamma_\beta}{\nu^-_{p'\beta}} - Jx^{O}_{i'\beta}\frac{\nu^-_{i'\beta}}{\nu^-_{p'\beta}} - Kx^{W}_{p'\beta}\right)\mathrm{d}\mu_{p'\beta} + \frac{1}{\nu^-_{i'j'}}\Big(\Gamma_{j'} - \sum_{i\neq i',\alpha}\frac{z_i}{|z_{j'}|}\Gamma_i - J\sum_{\alpha}\nu^-_{\alpha j'}x^{O}_{\alpha j'} - J\nu^-_{p'j'}x^{O}_{p'j'} - K\nu^-_{p'j'}x^{W}_{p'j'} - J\nu^-_{i'j'}x^{O}_{i'j'}\Big)\mathrm{d}\mu_{i'j'}$$

$$+\frac{1}{\nu^{+}_{p'q'}}\Big(\Gamma_{p'}-\sum_{q\neq q'}\frac{|z_q|}{z_{p'}}\Gamma_q+J\sum_{\beta}\frac{|z_\beta|}{z_{p'}}\nu^{-}_{i'\beta}x^{0}_{i'\beta}$$
$$-J\nu^{+}_{p'j'}x^{0}_{p'j'}-K\nu^{+}_{p'j'}x^{W}_{p'j'}-K\nu^{+}_{p'q'}x^{W}_{p'q'}\Big)\mathrm{d}\mu_{p'q'}$$
$$-\frac{Q^{W}}{z_{i'}F}\mathrm{d}\tilde{\mu}_{i'}+\frac{Q^{0}}{|z_{q'}|F}\mathrm{d}\tilde{\mu}_{q'}, \tag{7}$$

where F is the Faraday and Q^{W}, Q^{0}, J, and K are given by

$$\frac{Q^{W}}{F}=\sum_{p}z_p\Gamma_p-\sum_{q}|z_q|\Gamma_q-J\sum_{\alpha}|z_{j'}|\nu^{-}_{\alpha j'}x^{0}_{\alpha j'}$$
$$+J\sum_{\beta}z_{i'}\nu^{+}_{i'\beta}x^{0}_{i'\beta}+J(z_{i'}\nu^{+}_{i'q'}x^{0}_{i'q'}-|z_{j'}|\nu^{-}_{p'j'}x^{0}_{p'j'})$$
$$+K(z_{i'}\nu^{+}_{i'q'}x^{W}_{i'q'}-|z_{j'}|\nu^{-}_{p'j'}x^{W}_{p'j'}), \tag{8}$$
$$\frac{Q^{0}}{F}=\sum_{i\neq\alpha}z_i\Gamma_i-\sum_{j\neq\beta}|z_j|\Gamma_j+J\sum_{\alpha}z_\alpha\nu^{+}_{\alpha j'}x^{0}_{\alpha j'}$$
$$-J\sum_{\beta}|z_\beta|\nu^{-}_{i'\beta}x^{0}_{i'\beta}-J(z_{j'}\nu^{+}_{i'q'}x^{0}_{i'q'}-|z_{j'}|\nu^{-}_{p'j'}x^{0}_{p'j'})$$
$$-K(z_{i'}\nu^{+}_{i'q'}x^{W}_{i'q'}-|z_{j'}|\nu^{-}_{p'j'}x^{W}_{p'j'}), \tag{9}$$
$$J=\frac{\Gamma_{l'}x^{W}_{l''}-\Gamma_{l''}x^{W}_{l'}}{x^{W}_{l'}x^{0}_{l''}-x^{0}_{l'}x^{W}_{l''}}, \tag{10}$$
$$K=\frac{\Gamma_{l'}x^{0}_{l''}-\Gamma_{l''}x^{0}_{l'}}{x^{W}_{l'}x^{0}_{l''}-x^{0}_{l'}x^{W}_{l''}}. \tag{11}$$

The electroneutrality condition of the interface can be written in the form

$$\sum_{i\neq\alpha}z_i\Gamma_i+\sum_{p\neq\alpha}z_p\Gamma_p+\sum_{\alpha}z_\alpha\Gamma_\alpha-\sum_{j\neq\beta}|z_j|\Gamma_j$$
$$-\sum_{q\neq\beta}|z_q|\Gamma_q-\sum_{\beta}|z_\beta|\Gamma_\beta=0, \tag{12}$$

from which it can be shown that $Q^{W}=-Q^{0}$. Then the last two terms in the right hand side of Eq. 7 become

$$\frac{Q^{0}}{F}\Big(\frac{1}{z_{i'}}\mathrm{d}\mu_{i'}+\frac{1}{|z_{q'}|}\mathrm{d}\mu_{q'}\Big)=$$
$$-\frac{Q^{W}}{F}\Big(\frac{1}{z_{i'}}\mathrm{d}\mu_{i'}+\frac{1}{|z_{q'}|}\mathrm{d}\mu_{q'}\Big). \tag{13}$$

Since the reference electrodes R1 and R2 in the cell (I) are reversible to i' and q' ions, respectively, we may write[15]

$$\mathrm{d}\tilde{\mu}_{i'}=-z_i\mathrm{d}\tilde{\mu}^{M}_{e}+\mathrm{d}\mu^{\cdot,R1}_{+}$$
$$=-z_i\mathrm{d}\tilde{\mu}^{M}_{e}+s^{\cdot}_{R1}\mathrm{d}T-v^{\cdot}_{R1}\mathrm{d}P, \tag{14}$$

and

$$\mathrm{d}\tilde{\mu}_{q'}=|z_{q'}|\mathrm{d}\tilde{\mu}^{M'}_{e}+\mathrm{d}\mu^{\cdot,R2}_{-}$$
$$=|z_{q'}|\mathrm{d}\tilde{\mu}^{M'}_{e}+s^{\cdot}_{R2}\mathrm{d}T-v^{\cdot}_{R2}\mathrm{d}P, \tag{15}$$

where $\tilde{\mu}^{M}_{e}$ and $\tilde{\mu}^{M'}_{e}$ are the electrochemical potentials of electron in M and M′, and $\mu^{\cdot}$, $s^{\cdot}$, and $v^{\cdot}$ are linear combinations of the chemical potentials, the molar entropies and the molar volumes of the neutral substances involved in the electrochemical reactions at the reference electrodes[15] and hence are dependent only on the nature of the reference electrodes. Substitution of Eqs. 13, 14, and 15 into Eq. 7 yields the basic electrocapillary equation for the cell (I),

$$-\mathrm{d}\gamma=\Big[\eta-J\bar{s}^{0}-K\bar{s}^{W}-\frac{Q^{W}}{F}\Big(\frac{s^{\cdot}_{R1}}{z_{i'}}+\frac{s^{\cdot}_{R2}}{|z_{q'}|}\Big)\Big]\mathrm{d}T$$
$$-\Big[\tau-J\bar{v}^{0}-K\bar{v}^{W}-\frac{Q^{W}}{F}\Big(\frac{v^{\cdot}_{R1}}{z_{i'}}+\frac{v^{\cdot}_{R2}}{|z_{q'}|}\Big)\Big]\mathrm{d}P$$
$$+\sum_{k\neq l}(\Gamma_k-Jx^{0}_{k}-Kx^{W}_{k})\mathrm{d}\mu_k+\sum_{h\neq l}(\Gamma_h-Kx^{W}_{h})\mathrm{d}\mu_h$$
$$+\sum_{l\neq l',l''}(\Gamma_l-Jx^{0}_{l}-Kx^{W}_{l})\mathrm{d}\mu_l$$
$$+\sum_{i\neq i',\alpha}\Big(\frac{\Gamma_i}{\nu^{+}_{ij'}}-Jx^{0}_{ij'}\Big)\mathrm{d}\mu_{ij'}+\sum_{j\neq j'\beta}\Big(\frac{\Gamma_j}{\nu^{-}_{i'j}}-Jx^{0}_{i'j}\Big)\mathrm{d}\mu_{i'j}$$
$$+\sum_{p\neq p',\alpha}\Big(\frac{\Gamma_p}{\nu^{+}_{pq'}}-Kx^{W}_{pq'}\Big)\mathrm{d}\mu_{pq'}+\sum_{q\neq q',\beta}\Big(\frac{\Gamma_q}{\nu^{-}_{p'q}}-Kx^{W}_{p'q}\Big)\mathrm{d}\mu_{p'q}$$
$$+\sum_{\alpha}\Big(\frac{\Gamma_\alpha}{\nu^{+}_{\alpha q'}}-J\frac{\nu^{+}_{\alpha j'}}{\nu^{+}_{\alpha q'}}x^{0}_{\alpha j'}-Kx^{W}_{\alpha q'}\Big)\mathrm{d}\mu_{\alpha q'}$$
$$+\sum_{\beta}\Big(\frac{\Gamma_\beta}{\nu^{-}_{p'\beta}}-J\frac{\nu^{-}_{i'\beta}}{\nu^{-}_{p'\beta}}x^{0}_{i'\beta}-Kx^{W}_{p'\beta}\Big)\mathrm{d}\mu_{p'\beta}$$
$$+\frac{1}{\nu^{-}_{i'j'}}\Big(\Gamma_{j'}-\sum_{i\neq i',\alpha}\frac{z_i}{|z_{j'}|}\Gamma_i-J\sum_{\alpha}\nu^{-}_{\alpha j'}x^{0}_{\alpha j'}-J\nu^{-}_{p'j'}x^{0}_{p'j'}$$
$$-K\nu^{-}_{p'j'}x^{W}_{p'j'}-J\nu^{-}_{i'j'}x^{0}_{i'j'}\Big)\mathrm{d}\mu_{i'j'}+\frac{1}{\nu^{+}_{p'q'}}\Big(\Gamma_{p'}-\sum_{q\neq q'}\frac{|z_q|}{z_{p'}}\Gamma_q$$
$$+J\sum_{\beta}\frac{|z_\beta|}{z_{p'}}\nu^{-}_{i'\beta}x^{0}_{i'\beta}-J\nu^{+}_{p'j'}x^{0}_{p'j'}-K\nu^{+}_{p'j'}x^{W}_{p'j'}-K\nu^{+}_{p'q'}x^{W}_{p'q'}\Big)\mathrm{d}\mu_{p'q'}$$
$$+Q^{W}\mathrm{d}E^{W-}_{O+}, \tag{16}$$

where $\mathrm{d}E^{W-}_{O+}=(\mathrm{d}\tilde{\mu}^{M}_{e}-\mathrm{d}\tilde{\mu}^{M'}_{e})/F$ is the change in the potential of the right hand side terminal, M′, in the cell (I) with respect to the left, M. The superscript W− and the subscript O+ indicate that the reference electrodes are reversible to the anion in the water phase and the cation in the oil phase, respectively. In Eq. 16 there are $k+h+i+p+q-(\alpha+\beta+l)-1$ intensive variables, and hence all of them are independent variables.

Generalization of the Electrocapillary Equation: In the derivations of Eq. 16 we have chosen the chemical potentials of the salts of $\alpha q'$ and $p'\beta$ types as the independent variables for all the salts containing the commonly distributed ions α and β. In principle, we can choose as the independent variables either one of $\mu_{\alpha q'}$, and $\mu_{\alpha j'}$ for each of α and either one of $\mu_{p'\beta}$ and $\mu_{i'\beta}$ for each of β. In the present treatment we consider only the simple cases where all the chemical potentials of the salts of the same type are either simultaneously dependent variables or simultaneously independent variables. There are then four possible cases to choose the sets of the independent variables involving the commonly distributed ions α and β: ($\alpha q'$ and $p'\beta$), ($\alpha q'$ and $i'\beta$), ($\alpha j'$ and $p'\beta$), and ($\alpha j'$ and $i'\beta$). The change of the independent variables among these variables results in the corresponding changes in the coefficients of $\mathrm{d}E^{W-}_{O+}$, $\mathrm{d}\mu_{i'j'}$, and $\mathrm{d}\mu_{p'q'}$ in Eq. 16 as well as those of the terms involving the chosen independent variables. Furthermore, the expressions of the coefficients of $\mathrm{d}\mu_{i'j'}$ and $\mathrm{d}\mu_{p'q'}$ depend upon the set of the ions reversible to the reference electrodes R1 and R2. There are four possible cases for the choice of the set of the ions among the ions i', j', p', and q': (i' and p'), (i' and q'), (j' and p'), and (j' and q'). The coefficients of the $\mathrm{d}T$ and $\mathrm{d}P$ terms also depend upon the choice of the set of these ions.

Taking account of these possible cases, we have a general formula for the basic electrocapillary equation for the non-polarized interface:

$$-\mathrm{d}\gamma=\Big\{\eta-J\bar{s}^{0}-K\bar{s}^{W}-\frac{Q^{W}}{F}(\mathrm{A}+\mathrm{A}')\Big\}\mathrm{d}T$$
$$-\Big\{\tau-J\bar{v}^{0}-K\bar{v}^{W}-\frac{Q^{W}}{F}(\mathrm{B}+\mathrm{B}')\Big\}\mathrm{d}P$$

$$+ Cd\mu_{i'j'} + Dd\mu_{p'q'} + Gd\mu_{\alpha x} + Hd\mu_{y\beta} + Q^{W}dE^{W\pm}_{0\pm}$$
$$+ \sum_{k\neq l}(\Gamma_k - Jx^{O}_k)d\mu_k + \sum_{h\neq l}(\Gamma_h - Kx^{W}_h)d\mu_h$$
$$+ \sum_{l\neq l',l''}(\Gamma_l - Jx^{O}_l - Kx^{W}_l)d\mu_l$$
$$+ \sum_{i\neq i',\alpha}\left(\frac{\Gamma_i}{\nu^{+}_{ij'}} - Jx^{O}_{ij'}\right)d\mu_{ij'} + \sum_{j\neq j',\beta}\left(\frac{\Gamma_i}{\nu^{-}_{i'j}} - Jx^{O}_{i'j}\right)d\mu_{i'j}$$
$$+ \sum_{p\neq q',\alpha}\left(\frac{\Gamma_p}{\nu^{+}_{\alpha q'}} - Kx^{W}_{pq'}\right)d\mu_{pq'} + \sum_{q\neq q',\beta}\left(\frac{\Gamma_q}{\nu^{-}_{p'q}} - Kx^{W}_{p'q}\right)d\mu_{p'q}, \quad (17)$$

where G, H, and Q^{W} are given in Tables 1 and 2, and A, A′, B, B′, C, and D are in Tables 3 and 4. In Eq. 17 $\mu_{\alpha x}(x=j' \text{ or } q')$ and $\mu_{y\beta}(y=i' \text{ or } p')$ are the chemical potentials of the salts containing α and β, respectively, and $E^{W\pm}_{0\pm}$ is the potential of M′ with respect to M in the cell (I), where the plus(minus) sign is taken when the reference electrode is reversible to a cation(anion).

Ideal Polarized Oil–Water Interfaces: When no common ionic species is present between the oil and the water phases the interface may be called an ideal polarized oil–water interface. In general, the ideal polarized oil–water interface permits the equilibrium distribution of neutral compounds between the two phases. In this case the terms involving the common ionic species α and β in Eqs. 8, 9, 16, and 17 vanish. The terms involving the mole fractions of $p'j'$ and $i'q'$ in the two phases also reduce to zero. We then obtain for the ideal polarized oil–water interface corresponding to Eq. 16:

$$-d\gamma = \left[\eta - J\bar{s}^{O} - K\bar{s}^{W} - \frac{Q^{W}}{F}\left(\frac{s^{*}_{R1}}{z_{i'}} + \frac{s^{*}_{R2}}{|z_{q'}|}\right)\right]dT$$
$$-\left[\tau - J\bar{v}^{O} - K\bar{v}^{W} - \frac{Q^{W}}{F}\left(\frac{v^{*}_{R1}}{z_{i'}} + \frac{v^{*}_{R2}}{|z_{q'}|}\right)\right]dP$$
$$+ \sum_{k\neq l}(\Gamma_k - Jx^{O}_k)d\mu_k + \sum_{h\neq l}(\Gamma_h - Kx_h)d\mu_h$$
$$+ \sum_{l\neq l',l''}(\Gamma_l - Jx^{O}_l - Kx^{W}_l)d\mu_l$$
$$+ \sum_{i\neq i'}\left(\frac{\Gamma_i}{\nu^{+}_{ij'}} - Jx^{O}_{ij'}\right)d\mu_{ij'} + \sum_{j\neq j'}\left(\frac{\Gamma_i}{\nu^{-}_{i'j}} - Jx^{O}_{i'j}\right)d\mu_{i'j}$$
$$+ \sum_{p\neq p'}\left(\frac{\Gamma_p}{\nu^{+}_{pq'}} - Kx^{W}_{pq'}\right)d\mu_{pq'} + \sum_{q\neq q'}\left(\frac{\Gamma_q}{\nu^{-}_{p'q}} - Kx^{W}_{p'q}\right)d\mu_{p'q}$$
$$+ \frac{1}{\nu^{-}_{i'j'}}\left(\Gamma_{j'} - \sum_{i\neq i'}\frac{z_i}{|z_{j'}|}\Gamma_i - J\nu^{-}_{i'j'}x^{O}_{i'j'}\right)d\mu_{i'j'}$$
$$+ \frac{1}{\nu^{+}_{p'q'}}\left(\Gamma_{p'} - \sum_{q\neq q'}\frac{|z_q|}{z_{p'}}\Gamma_q - K\nu^{+}_{p'q'}x^{W}_{p'q'}\right)d\mu_{p'q'}$$
$$+ q^{W}dE^{W-}_{0+}, \quad (18)$$

where $q^{W}(=-q^{O})$ is the surface charge density due to the components in the water phase (q^{O} is the surface charge density due to the components in the oil phase) and is defined by

$$q^{W} = F\left(\sum_{p} z_p\Gamma_p - \sum_{q}|z_q|\Gamma_q\right)$$
$$= F\left(\sum_{j}|z_j|\Gamma_j - \sum_{i} z_i\Gamma_i\right) = -q^{O}. \quad (19)$$

The degree of freedom of Eq. 18 is $k+h+i+j+p+q-l-1$ and, hence, all the intensive variables are independent. When the pair of the ions reversible to the reference electrodes R1 and R2 is not the $i'q'$ pair, one can easily find a corresponding electrocapillary equation using Eq. 17 and Tables 1, 3, and 4 if we omit the terms involving the common ionic species α and β and the mole fractions of $p'j'$ and $i'q'$.

Discussion

Ideal non-polarized interface is characterized by the lack of the degree of freedom concerning the electrical state of the interface; it is not possible to change the electrical potential difference between the interface or the surface charge density if we keep all other intensive variables constant. In the basic electrocapillary equation for the ideal nonpolarized interface represented by Eq. 16, or in more general terms in Eq. 17, there appears the potential difference between the two terminals of the cell (I) as an independent variable. This does not mean that one can apply a voltage to the interface without changing the equilibrium state of the interface. The potential difference between the two terminals can of course be measured, but the change of this potential can be achieved only through the change of the chemical potential of at least one of the salts containing α and β. In fact, the dE^{W-}_{0+} term in Eq. 16 can be rewitten in terms of the chemical potential of one of these salts which has been taken as a dependent variable in Eq. 16.

Let $\mu_{p'\beta'}$ instead of E^{W-}_{0+} be the independent variable, where β' is any one of β common anions. By using Eq. 3 the last two terms in the right hand side of Eq. 7 become

$$-\frac{Q^{W}}{z_{i'}F}d\mu_{i'} + \frac{Q^{O}}{|z_{q'}|F}d\mu_{q'} =$$
$$-\frac{Q^{W}}{F}\left(\frac{1}{z_i\nu^{+}_{i'\beta'}}d\mu_{i'\beta'} - \frac{1}{|z_\beta|\nu^{-}_{p'\beta'}}d\mu_{p'\beta'} + \frac{1}{z_{p'}\nu^{+}_{p'q'}}d\mu_{p'q'}\right).$$

Therefore, dE^{W-}_{0+} may be rewritten as

$$dE^{W-}_{0+} = \frac{1}{|z_{\beta'}|\nu^{-}_{p'\beta'}}d\mu_{p'\beta'} - \frac{1}{z_{i'}\nu^{+}_{i'\beta'}}d\mu_{i'\beta'} - \frac{1}{z_{p'}\nu^{+}_{p'q'}}d\mu_{p'q'}.$$

Necessary changes in Eq. 16 accompanied by the change of the independent variable from E^{W-}_{0+} to $\mu_{p'\beta'}$ are given in Table 5. Thus, in ideal nonpolarized oil–water interfaces one can always replace the electromotive force of the cell with the chemical potential of one of the salts containing a common ion. Namely, a change of the chemical potential is always accompanied by a change of the chemical potential and is achieved only through the change of the chemical potential of the salt, as described above. When the interface is ideally polarized, there is no salt whose constituent ion is commonly distributed in both phases. In this case, one can arbitrarily change E^{W-}_{0+} by applying a voltage between the two reference electrodes.

Equations 16 and 17 show that the partial derivative of the interfacial tension with respect to the potential drop across the terminals of the cell (I) gives the quantity Q^{W}. This Q^{W} is different from the surface charge density in the water phase q^{W} defined by Eq. 19 for an ideal polarized oil–water interface. First, Q^{W} defined by Eq. 8 contains the terms of the surface concentrations of the ions commonly distributed in the two phases, and, second, in comparison with q^{W}, Q^{W} has four additional terms involving the mole fractions of the salts containing the common ions. Unlike the ideal polarized interfaces, the potential of the electrocapillary maximum of the electrocapillary curve for a nonpolarized oil–water

interface, therfore, does not generally correspond to the potential of zero charge, which, however, can be defined only through an assumption of a dividing surface in the case of nonpolarized interfaces. The difference between Q^W and q^W originates in the difference in thermodynamic polarizability of the interfaces and is free from any particular model which assumes a physical dividing surface.[16] The surface charge density due to the components in the water phase q^W defined by Eq. 19 is conventionally called the surface charge density in water phase and q^O the surface charge density in oil phase. Note that the surface charge density $q^W(=-q^O)$ is a thermodynamically defined quantity for an ideal polarized oil–water interface and may not correspond to the physical surface charge density.[11,16] For example, the ionic charge due to the hydrophilic group of an amphiphile which is present only in the oil phase and is adsorbed at an oil–water interface should be considered as a part of the "surface charge density in the oil phase" even when the hydrophilic ionic groups protrude into the water phase and are exposed to the aqueous medium, as is the case of the adsorption of phospholipids at the oil–water interface.[17]

In Eqs. 16, 17, and 18 the partial derivative of the interfacial tension with respect to the chemical potential of any one of the neutral components gives the relative surface concentration of the corresponding component, *i.e.*, the surface concentration relativised by the surface concentrations of the two reference components l' and l'', which enter into the measured quantity through J and K terms. Similarly, the partial derivative of the interfacial tension with respect to the chemical potential of any one of the salt components gives the relative surface concentration of the corresponding ionic component. When the mutual solubility between l' and l'' is considerably high, the denominators of Eqs. 10 and 11 become very small. This means that the relative surface concentrations can be significantly different from the actual surface concentrations. This is due to the fact that the relative surface concentrations in Eqs. 16–18 are relativised by the two reference components; hence, this is one of the features of the oil–water interfaces which distinguish them from the metal-solution interfaces.[15]

When there occurs an ion pair formation or an incomplete dissociation of a salt, which may be expected especially in the oil phase having lower dielectric constant, the surface concentration of an ion pair or an undissociated salt appears in the relevant terms in Eq. 17 (and also in Eqs. 16 and 18). Extension of the basic electrocapillary equation to meet these cases is feasible. For example, suppose that the cation $\bar{i}$ in the cations i (except i' and α) and the anion $\bar{j}$ in the anions j (except j' and β) form a neutral ion pair $\bar{i}\bar{j}$ in the oil phase. There then appears an additional term $\Gamma_{\bar{i}\bar{j}}\mathrm{d}\mu_{\bar{i}\bar{j}}$ in Eq. 2, where $\Gamma_{\bar{i}\bar{j}}$ and $\mu_{\bar{i}\bar{j}}$ are the surface concentration and the chemical potential of the ion pair $\bar{i}\bar{j}$. Since the differential of the chemical potential of $\bar{i}\bar{j}$, $\mathrm{d}\mu_{\bar{i}\bar{j}}$, can be written in terms of those of the electrochemical potentials of $\bar{i}$ and $\bar{j}$ ions, $\mathrm{d}\mu_{\bar{i}}$ and $\mathrm{d}\mu_{\bar{j}}$, as

$$\mathrm{d}\mu_{\bar{i}\bar{j}} = \nu^+_{\bar{i}\bar{j}}\mathrm{d}\mu_{\bar{i}} + \nu^-_{\bar{i}\bar{j}}\mathrm{d}\mu_{\bar{j}},$$

where $\nu^+_{\bar{i}\bar{j}}$ and $\nu^-_{\bar{i}\bar{j}}$ are the stoichiometric numbers of the ion pair formation reaction represented by the equation similar to Eq. 4, the term $\Gamma_{\bar{i}\bar{j}}\mathrm{d}\mu_{\bar{i}\bar{j}}$ can be rewritten in the form:

$$\Gamma_{\bar{i}\bar{j}}\mathrm{d}\mu_{\bar{i}\bar{j}} = \Gamma_{\bar{i}\bar{j}}(\nu^+_{\bar{i}\bar{j}}\mathrm{d}\mu_{\bar{i}} + \nu^-_{\bar{i}\bar{j}}\mathrm{d}\mu_{\bar{j}}).$$

Substituting Eqs. 3-1 to 3-3 into this equation, we obtain

$$\Gamma_{\bar{i}\bar{j}}\mathrm{d}\mu_{\bar{i}\bar{j}} = \Gamma_{\bar{i}\bar{j}}\left(\frac{\nu^+_{\bar{i}\bar{j}}}{\nu^+_{\bar{i}j'}}\mathrm{d}\mu_{\bar{i}j'} - \frac{\nu^-_{\bar{i}\bar{j}}}{\nu^-_{i'\bar{j}}}\mathrm{d}\mu_{i'\bar{j}} - \frac{z_{\bar{i}}}{\lvert z_{j'}\rvert}\cdot\frac{\nu^+_{\bar{i}\bar{j}}}{\nu^+_{i'j'}}\mathrm{d}\mu_{i'j'}\right).$$

Consequently, the ion pair formation between the ions $\bar{i}$ and $\bar{j}$ gives rise to additional terms involving the surface concentration of the ion pair, $(\nu^+_{\bar{i}\bar{j}}/\nu^+_{\bar{i}j})\Gamma_{\bar{i}\bar{j}}$, $(\nu^-_{\bar{i}\bar{j}}/\nu^-_{i'\bar{j}})\Gamma_{\bar{i}\bar{j}}$, and $(z_{\bar{i}}/\lvert z_{j'}\rvert)(\nu^+_{\bar{i}\bar{j}}/\nu^+_{i'j'})\Gamma_{\bar{i}\bar{j}}$, in the coefficients of $\mathrm{d}\mu_{\bar{i}j'}$, $\mathrm{d}\mu_{i'\bar{j}}$, and $\mathrm{d}\mu_{i'j'}$ terms, respectively, in Eq. 17 (and also in Eqs. 16 and 18). Thus the ion pair formation or incomplete dissociation of a salt is easily taken into account in the general electrocapillary equation. The case of the formation of a charged ion pair may be considered similarly.

If we introduce a new function defined by $\xi = Q^W E^{W\pm}_{0\pm} + \gamma$, which has been proposed by Parsons[18] for an ideal polarized metal-solution interface, we can replace the independent variable $E^{W\pm}_{0\pm}$ with Q^W in Eq. 17. Then several useful relationships can be obtained from the cross-differentiation relationship. For example, the Esin–Markov coefficient of a neutral component k, which is defined as the slope of a plot of $E^{W\pm}_{0\pm}$ *vs.* the chemical potential of component k at constant T, P, Q^W, and chemical potentials of all other components, is related to the rate of the change of the relative surface concentration of a component k with Q^W at constant T, P, and composition:

$$\left(\frac{\partial E^{w\pm}_{0\pm}}{\partial \mu_k}\right)_{T,P,Q^w,\mu\neq\mu_k} = -\left(\frac{\partial(\Gamma_k - Jx^{0}_{k})}{\partial Q^w}\right)_{T,P,\mu}$$

(for $k\neq l$).

Similar relations are easily obtained for the Esin–Markov coefficients of the neutral components $h(\neq l)$ and $l(\neq l', l'')$ and of the salts $i'j'$, $p'q'$, αx ($x=j'$ or q'), $y\beta$($y=i'$ or p'), ij'(for $i\neq i'$, α), $i'j$(for $j\neq j'$, β), pq'(for $p\neq p'$, α), and $p'q$(for $q\neq q'$, β). Such cross-differentiation relations have been employed to analyze the Esin-Markov coefficients at the interface between a nitrobenzene solution of tetrabutylammonium tetraphenylborate and an aqueous solution of lithium chloride to detect the specific adsorption of the ions.[6]

Homoconjugation in Bicyclo[2.2.1]hept-2-en-7-yl and 1,4-Dihydro-1,4-methanonaphthalen-9-yl Radicals

Takashi KAWAMURA,* Yoshio SUGIYAMA, and Teijiro YONEZAWA
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received March 28, 1983)

2,3-Dimethylbicyclo[2.2.1]hept-2-en-7-yl and 6-methyl-1,4-dihydro-1,4-methanonaphthalen-9-yl radicals are examined wiht ESR. Comparisons of their hyperfine splitting constants with those of bicyclo[2.2.1]hept-2-en-7-yl (**1a**) and 1,4-dihydro-1,4-methanonaphthalen-9-yl (**2a**) radicals show that the odd electron on the tervalent carbon atom is delocalized to the extent of 10% into the π system of the vinylene bridge in **1a**, and 5% at maximum into the π system of the phenylene bridge in **2a**, respectively. This odd eletron delocalization is accompanied by an increase of carbanion character of the tervalent carbon atom. The nonplanarity of their tervalent carbon atoms is discussed in relation to the carbanion character.

Molecules with bicyclo[2.2.1]hept-2-en-7-yl, 1,4-dihydro-1,4-methanonaphthalen-9-yl and related frameworks are of interest because of possible involvement of homoconjugation. In a previous communication,[1] the tervalent carbon atom of the bicyclo[2.2.1]hepta-2,5-dien-7-yl radical was shown to have a deep pyramidal geometry, which was proposed to arise mainly from intramolecular charge transfer interactions from the vinylene bridges onto the tervalent carbon atom. To estimate the extent of this type of charge transfer interaction, 2,3-dimethylbicyclo[2.2.1]hept-2-en-7-yl (**1b**) and 6-methyl-1,4-dihydro-1,4-methanonaphthalen-9-yl (**2b**) radicals are examined with ESR and compared with results of bicyclo[2.2.1]hept-2-en-7-yl (**1a**) and 1,4-dihydro-1,4-methanonaphthalen-9-yl (**2a**) radicals.

2
a : R = H
b : R = CH_3

Results

The ESR spectrum of **1b** (Fig. 1) was observed during photolysis of a cyclopropane solution of a mixture of 7-bromo-2,3-dimethylbicyclo[2.2.1]hept-2-ene, triethylsilane, and di-*t*-butyl peroxide at −127 °C. The hyperfine structure of the spectrum arises from a proton (0.992 mT), two pairs of equivalent protons (0.173 and 0.161 mT), and six equivalent protons (0.140 mT). The *g* factor is 2.00240. On the basis of the comparison of these hyperfine splitting constants (hfsc) with those of **1a**,[2,3] the formers are assigned as shown below:

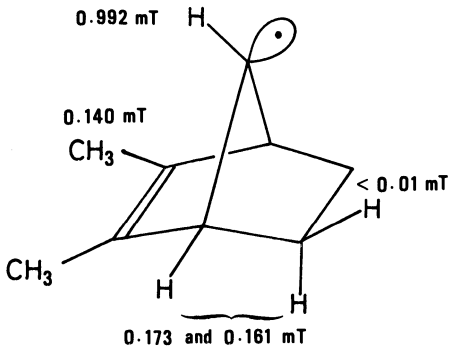

Figure 2 shows the ESR spectrum of **2b** generated similarly from 9-*anti*-bromo-6-methyl-1,4-dihydro-1,4-dihydro-1,4-methanonaphthalene. The spectrum consists of a doublet of 0.812 mT split into triplets of 0.166 mT further into quintets of 0.028 mT. By comparing these hfsc's with those of **2a**,[3] the formers can be most reasonably assigned as shown on the next page.

The hfsc's of phenylene protons and vinylene protons of **2a** could not be uniquely assigned in the previous communication[3] due to lack of sufficient data. The present assignment of phenylene proton hfsc of **2b** leads to following assignment of the observed hfsc's of **2a**:

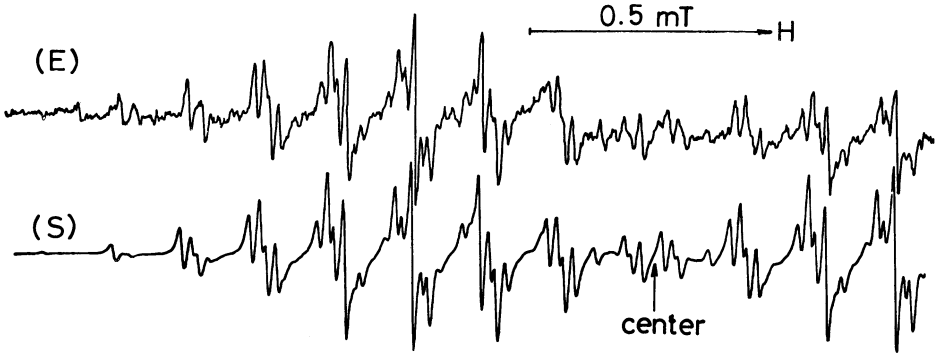

Fig. 1. Observed (E) and simulated (S) ESR spectra of **1b**.

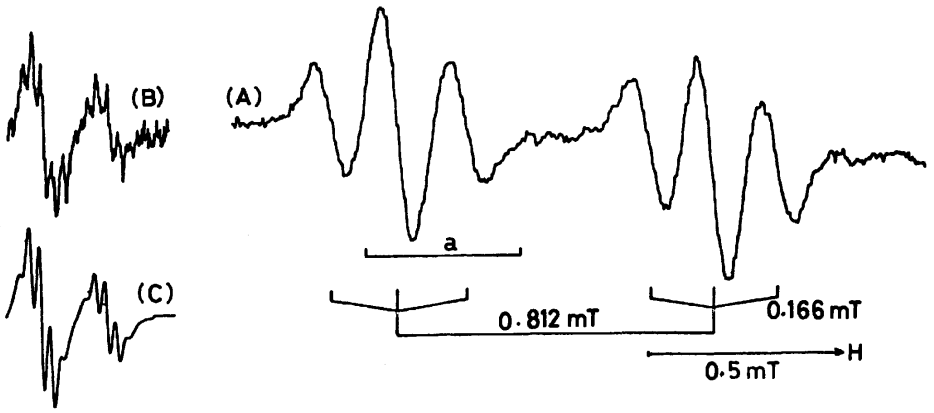

Fig. 2. (A) ESR spectrum of **2b**. (B) Underlined part a of (A) observed with higher resolution. (C) Simulated spectrum corresponding to (B).

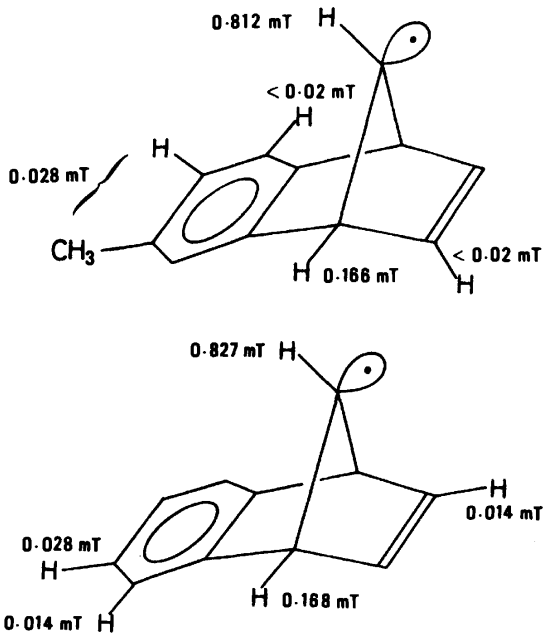

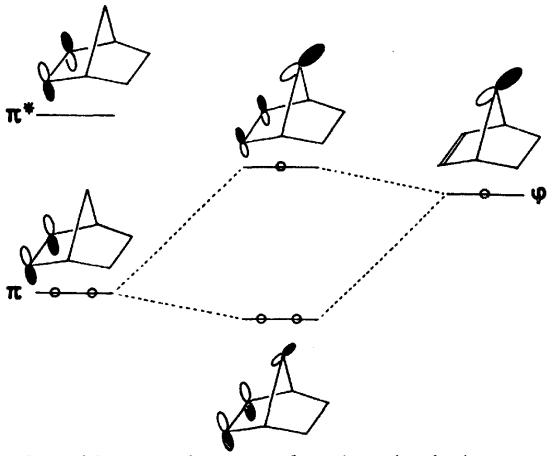

Fig. 3. Bishomocyclopropenyl conjugation in **1a** and **1b**. The mixing of π^* and φ is symmetry-forbidden.

Discussion

Homoconjugation in 1a and 1b. The bishomocyclopropenyl conjugation in **1a** and **1b** is the symmetry-allowed intramolecular charge transfer interaction from the vinylene π system to the tervalent carbon atom as shown in Fig. 3. This conjugation gives the tervalent carbon atom a carbanion character and delocalizes the odd electron onto a π atomic orbital of a vinylene carbon atom from the tervalent carbon atom. When the electron density of δ is transferred from the vinylene bridge onto the tervalent carbon atom, the odd electron density on a vinylene carbon atom is $\delta/2$ in the present simple model. If this mechanism is the major source of the hfsc of the vinylene proton of **1a** (0.12 mT),[2,3] this hfsc, $a(H_2)$, can be correlated with the odd electron density, $\delta/2$, as

$$a(H_2) = Q_\alpha\delta/2, \quad Q_\alpha = 2.3 \text{ mT},$$

and the methyl proton hfsc of **1b**, $a(CH_3)$, with $\delta/2$ as:

$$a(CH_3) = Q_\beta\delta/2, \quad Q_\beta = 2.7 \text{ mT}.$$

Both of the equations are satisfied when $\delta=0.10$, showing that both $a(H_2)$ of **1a** and $a(CH_3)$ of **1b** originate from the odd electron delocalization onto the vinylene π system from the tervalent carbon atom through the homoconjugation and that the extent of this delocalization is about 10%.

Homoconjugation in 2a and 2b. The bishomobenzocyclopropenyl conjugation in **2a** and **2b** is the symmetry-allowed mixing of the odd electron orbital on C_9 (φ) with phenylene orbitals of π_1, π_2, and π_3 shown in Fig. 4. Since the orbital energy difference between π_1 and φ is larger than those between φ and the other two π orbitals in Fig. 4, the mixing between π_1 and φ can be neglected for the present semiquantitative analysis of the homoconjugation.

Protons and/or those in the methyl moiety bonding to C_6 and C_7 of **2a** and **2b** have larger hfsc's than those of protons bonding to C_5 and C_8. This shows that the odd electron is delocalized onto π_2 rather than π_3. This mixing of the odd electron orbital on C_9, φ, with the doubly occupied π_2 orbital induces a carbanion character of the tervalent carbon atom. The extra electron density accumulated on the tervalent carbon atom by this bishomobenzocyclopropenyl conjugation is estimated from the phenylene proton hfsc's of **2a** and **2b** as 0.05 at maximum, which is smaller than that of the bishomocyclopropenyl conjugation in **1a** and **1b**.

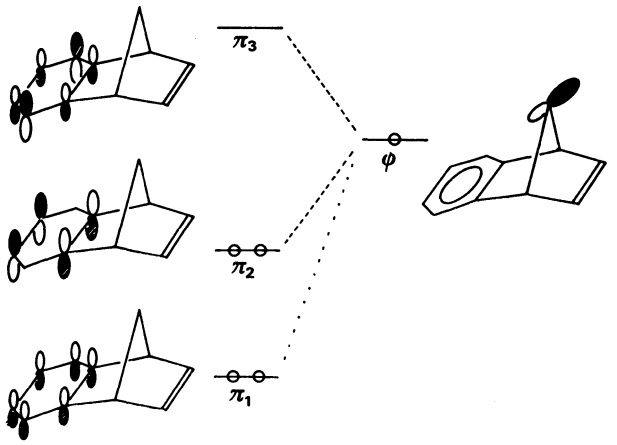

Fig. 4. Bishomobenzocyclopropenyl conjugation in **2a** and **2b**. The other three π molecular orbitals of the phenylene ring are symmetry-forbidden to interact with the odd electron orbital, φ.

The resolved small hyperfine splittings by H_5 and H_8 of **2a** indicate that there exists a minor mixing of π_3 into φ. This mode of interaction is stabilizing, but it transfers electron density from C_9 onto the phenylene π system. Therefore, even if the total electron density accumulated on the tervalent carbon atom by bishomobenzocyclopropenyl interaction is smaller than that by bishomocyclopropenyl interaction, the former can be more stabilizing than the latter.

Pyramidal Geometry of Tervalent Carbon Atom. The decrease of the α proton hfsc in the order of bicyclo[2.2.1]hept-7-yl radical (**3**) (1.678 mT),[2] 1,2,3,4-tetrahydro-1,4-methanonaphthalen-9-yl radical (**4**) (1.278 mT),[3] **1a** (1.087 mT),[2] **2a** (8.27 mT),[3] and bicyclo[2.2.1]hepta-2,5-dien-7-yl radical (**5**) (0.449 mT)[1] indicates the increase of the nonplanarity of the tervalent carbon atom, because these hfsc's have negative signs.[1,3] We suggested previously that the extent of the bending of the tervalent carbon atom of **3** and related radicals would correlate with the angle between C_1–C_7 and C_7–C_4 bonds.[3] However, the difference between C_1–C_7–C_4 angles of **3** and **5** is expected to be small, since the corresponding angle in bicyclo[2.2.1]heptane (93.2°) is only slightly larger than that of bicyclo[2.2.1]hepta-2,5-diene (92.0°).[4] It seems difficult to attribute the difference between the bendings of the tervalent carbon atoms of **3** and **4** entirely to the small difference between their C_1–C_7–C_4 bond angles.[1]

The introduction of methyl substituent(s) onto a bridging unsaturated moiety of **1a** or **2a** induces an increase of the nonplanarity of the tervalent carbon atom as shown by the decrease of their α proton hfsc's. Thus we propose that the increase of the nonplanarity of the tervalent carbon atom of **1a**, **1b**, **2a**, **2b**, **4**, and **5** from that of **3** would have been induced mainly by the increase of the carbanion character of their tervalent carbon atoms arising from homoconjugation(s). Indeed, the small bond angle of C_1–C_7–C_4 of **3** should be one of major factors inducing the pyramidal geometry of its tervalent carbon atom.

The geometry of the tervalent carbon atom of the radicals appearing in the present discussion suggests the following trends: (i) bishomocyclopropenyl interaction induces more carbanion character of the tervalent tarbon atom than bishomobenzocyclopropenyl interaction, but the latter is more stabilizing than the former; and (ii) a geometry in which the rear-lobe of the odd electron orbital on the tervalent carbon atom overlaps with the π orbital(s) of the bridging moiety is preferred than the geometry of the front-lobe overlap, but the extent of charge transfer by homoconjugation in the front-lobe overlap geometry is not negligibly small.

Experimental

The equipments and procedures for the photolysis-ESR experiments have been described earlier.[5]

7-anti-Bromo-2,3-dimethylbicyclo[2.2.1]hept-2-ene. 2,3-Dimethylbicyclo[2.2.1]hept-2-en-7-one (2.4 g, 0.18 mmol) was reduced to 7-hydroxybicyclo[2.2.1]hept-2-ene by $LiAlH_4$ in ether.[6] The alcohol, freed from ether, was dissolved into 20 ml of pentane without purification and shaken with 22 ml of 47% HBr aqueous solution for 10 min at room temperature. After evaporation of the pentane from the organic layer, *anti*-7-bromo-2,3-dimethylbicyclo[2.2.1]hept-2-ene (bp 95 °C/21 Torr)[7] was obtained in 42% yield based on the starting ketone. 60 MHz ^{1}H NMR (CCl_4): δ 1.10 (H_{5endo}, H_{6endo}). 1.63 (CH_3), 2.03 (H_{5exo}, H_{6exo}), 2.5 (H_1, H_4), 3.73 (H_{7syn}).

9-anti-Bromo-6-methyl-1,4-dihydro-1,4-methanonaphthalene. To a stirred solution of 6-methyl-1,4-dihydro-1,4-methanonaphthalene[8] (3.0 g, 19 mmol) in 11 ml of CCl_4 kept below 10 °C, bromine (3.4 g, 21 mmol) in 25 ml of CCl_4 was added dropwise in 10 min and stirred for 1 h at room temperature thenafter. After evaporation of the solvent and excess of the bromine, crude 2-*exo*,9-*anti*-dibromo-6-methyl-1,4-dihydro-1,4-methanonaphthalene was obtained as a viscous residue. The crude dibromide was reacted with potassium *t*-butoxide (2.2 g, 20 mmol) in dry dimethyl sulfoxide under nitrogen atmosphere at 70—80 °C for 1.5 h. The reaction mixture was poured into water and extracted with ether. After evaporation of the ether, the residue was recrystallized from ethanol to give 9-*anti*-bromo-6-methyl-1,4-dihydro-1,4-methanonaphthalene (1.1 g, 4.7 mmol) as white crystals. 220 MHz ^{1}H NMR (CCl_4) δ 2.25 (s, 3H), 3.95 (s, 2H), 4.28 (s, 1H), 6.58 (s, 2H), 6.67 (m, 1H), 6.95—7.00 (m, 2H). (s: singlet. m: multiplet.).

We are indebted to Drs H. Tanida and T. Tsushima (Shionogi Research Laboratory, Osaka) for the offer of 6-methyl-1,4-dihydro-1,4-methanonaphthalene.

(Received April 4, 1983)

The title compound crystallizes in the triclinic space group $P\bar{1}$ with two fomrula units in a unit cell of dimensions; $a=11.621(3)$, $b=15.177(3)$, $c=10.229(2)$ Å, $\alpha=95.63(2)$, $\beta=105.46(2)$, and $\gamma=76.43(2)°$. The crystal structure was solved by a conventional heavy-atom method and refined by block-diagonal least-squares procedures to give a final R value of 0.050 for 3428 reflections, with $F_o>2\sigma(F_o)$, collected on a four-circle diffractometer. The bond distance shared between the acenaphthene and the cyclopentane rings is unusually long at 1.596(6) Å, which may result from the additional strain induced by the fusion of these rings. The solvent molecules are disordered in the channel composed of the main molecules.

As a part of our studies of the reaction of enamines with triafulvenes, we have recently reported that 1-(1-pyrrolidinyl)acenaphthylene reacts with 2-phenyl-2-(2,3-diphenyl-2-cyclopropenylidene)acetonitrile to give two isomeric 1 : 1 adducts.[1] This reaction was regared as the first example in which a phenyl group on the three-membered ring of methylenecyclopene had taken part in a cyclization. On the basis of chemical and spectroscopic techniques alone, the stereochemical structures of the adducts could not be elucidated unambiguously. In order to confirm the structure as well as to explore the essential features of this reaction, we have undertaken an X-ray structural study of the title main molecule (abbreviated as ICPA) which was the major product from the reaction of 1-(1-pyrrolidinyl)acenaphthylene with 2-(*p*-bromophenyl)-2-(2,3-diphenyl-2-cyclopropenylidene)acetonitrile under the same reaction conditions. The X-ray structural study was not applied to the minor product because the crystals obtained were unsuitable.

Experimental

The title compound was obtained by recrystallization from acetone as colorless prisms elongated along the c axis. The crystal used for the X-ray work was approximately triclinic in shape, with dimensions of 0.2 mm × 0.3 mm × 0.4 mm, and it was coated with nail enamel to prevent deterioration in air. The density was measured by flotation in an aqueous KI solution. Preliminary X-ray photographs showed the crystal to be triclinic. The unit-cell parameters and intensity data were measured on a Rigaku automated four-circle diffractometer with monochromated Mo $K\alpha$ radiation ($\lambda=0.71073$ Å). The unit-cell parameters were determined by a least-squares procedure using 25 reflections within the range of $23<2\theta<27°$. The crystal data are given in Table 1.

TABLE 1. CRYSTAL DATA[a]

Formula unit	$C_{39}H_{29}N_2Br\cdot C_3H_6O$
Formula weight	663.66

$c=10.229$ (2) Å	$\gamma=76.43$ (2)°
$V=1689.1$ (6) Å^3	$Z=2$
$D_M=1.310$ g cm^{-3}	$D_X=1.305$ g cm^{-3}
$\mu=1.24$ mm^{-1} (for Mo $K\alpha$ radiation)	$F(000)=688$

a) The numbers in parentheses, here and elsewhere in this paper, are the e.s.d.'s in the last significant digits.

Intensity data of 4404 independent reflections within a range of $2\theta<45°$ were collected by an ω-2θ scanning technique. Of these, 3434 reflections with $F_o>2.0\sigma(F_o)$ were used for the structure analysis. The intensity data were corrected for Lorentz and polarization effects, but not for absorption or extinction. The statistical distribution of the normalized structure factors favoured the centrosymmetric space group, which was confirmed by the convergence of the structure at a later stage of the refinement.

Structure Determination and Refinement

The Br-atom position was easily deduced from a Patterson synthesis, and the remaining non-H atoms of ICPA molecule were located in a subsequent Fourier map. Refinement was carried out by the block-diagonal least-squares procedures, in which initially equal weights and later Cruickshank's weighting scheme were adopted.[2] After several cycles of refinements with isotropic and then anisotropic thermal parameters, the H atoms were located in difference Fourier maps, in which also eight peaks with three times the height of these H atoms were found between ICPA molecules. These peaks were interpreted as disordered acetone atoms with an occupancy factor of 0.5. After the removal of the five strong reflections affected by secondary extinction and of one reflection with a strong imbalance of the background intensities, refinement was terminated when all shift/e.s.d. for non-H atoms of ICPA became less than 0.3. The final difference Fourier synthesis showed two implausible peaks of *ca.* 0.6 eÅ^{-3} in the vicinity of the Br atom and eight peaks of 0.3—0.5 eÅ^{-3} distributed at random in the vicinities of the acetone atoms. This suggested that the model of the disordered acetone was yet ambiguous, but no attempt was made to clarify the disorder. Thus, the molecular dimensions of the acetone were omitted from the later table and discussion. The final conventional R index was 0.050 for 3428 measurable reflections. The

atomic scattering factors for Br, O, N, and C_{cov}, with correction factors for anomalous dispersion, were taken from International Tables for X-ray Crystallography.[3] Those for H were adopted from the table of Stewart *et al.*[4] All the calculations were carried out on a FACOM M-200 computer in the Computer Center of Kyushu University by the use of locally modified versions of the UNICS-III program system.[5,6] Figures. 1 and 3 were drawn by the use of the ORTEP program.[7] The final atomic parameters are listed in Table. 2, together with their e.s.d.'s. Lists of the structure factors and anisotropic thermal parameters have been deposited as Document No. 8341 at the Office of the Editor of the Bulletin of the Chemical Society of Japan.

Results and Discussion

The molecular structure of ICPA was confirmed by

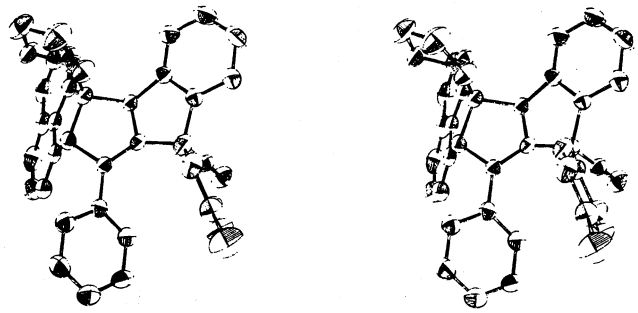

Fig. 1. Stereoscopic view of the molecular structure of ICPA. The thermal-motion ellipsoids are scaled to enclose 50% probability. The H atoms have been omitted for clarity, and likewise in the following figures.

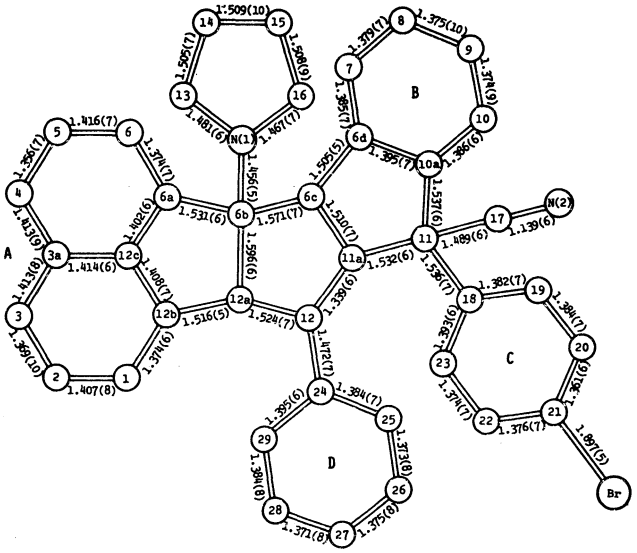

Fig. 2. Bond distances (l/Å) of the schematically drawn ICPA molecule with atomic-nomenclature scheme. The C atoms are shown by the position-numbers.

this X-ray structural study. A stereoscopic view of this molecular structure is shown in Fig. 1. The bond distances(l) are shown schematically in Fig. 2, together with the atomic-nomenclature scheme. The bond angles(θ) are listed in Table 3.

The naphthalene ring [A] deviates slightly from planarity, the maximum deviation being 0.04 Å, as shown in Table 4. C(6b) is shifted by 0.17 Å from this plane, whereas C(12a) is displaced 0.11 Å in the opposite direction, so that the acenaphthene ring has a somewhat twisted conformation. The distance of the C(6b)–C(12a) bond, which is shared between the acenaphthene and the central cyclopentane ring [C(6b), C(6c), C(11a), C(12), and C(12a)], is unusually long (1.596(6) Å). This may result from the additional strain induced on the bond by the fusion of these rings. A similar phenomenon has been observed in a series of fused acenaphthylenes, $C_{14}H_{10}$, $C_{18}H_{12}$, $C_{22}H_{14}$, and $C_{26}H_{14}N_2$.[9–12] The central cyclopentane ring is slightly puckered in an envelope-like conformation; the maximum torsion angle is 21.8(4)° about the C(6b)–C(6c) bond, and C(6b) is shifted by 0.38 Å from the plane through the other four atoms. The B ring [C(6d) through C(10a)] is planar within limits of the experimental error. C(6c) and C(11a) were found to lie almost equidistant from the plane on different sides, and so the indane ring has a

C(6c)-C(11a)-C(12)-C(12a)	−3.4(5)	C(13)-C(14)-C(15)-C(16)	−2.2(7)
C(11a)-C(12)-C(12a)-C(6b)	−11.6(5)	C(14)-C(15)-C(16)-N(1)	23.4(6)
C(12)-C(12a)-C(6b)-C(6c)	20.5(4)	C(15)-C(16)-N(1)-C(13)	−36.3(5)
C(12a)-C(6b)-C(6c)-C(11a)	−21.8(4)	C(16)-N(1)-C(13)-C(14)	35.0(5)
Around the C(6b)-N(1) bond			
C(6a)-C(6b)-N(1)-C(13)	48.4(5)		
C(6c)-C(6b)-N(1)-C(13)	173.1(4)		
C(12a)-C(6b)-N(1)-C(13)	−70.6(5)		

somewhat twisted conformation. The plane of the B ring makes an angle of 42.0° with the naphthalene ring. Thus, the body of the molecule has an uncomfortable chair form.

The pyrrolidine ring is in the normal envelope conformation, with N(1) out of the plane of the other four atoms. The torsion angles about the C(6b)–N(1) bond are close to 50, 170, and 290°, so that the lone pair of electrons of N(1) is *cis* to C(12a). The D ring [C(24) through C(29)] is planar within the limits of experimental error, and this plane is tuned from the plane through the four atoms [C(11a), C(12), C(12a), and C(24)] by an angle of 42.1° away from the naphthalene moiety. The bromophenyl group faces the D ring at an angle of *ca.* 60°. The bromophenyl group is *cis* to the pyrrolidine, so that the close contact between the two groups is 2.26(9) Å of the H(16)2···H(23) distance.

The C–H bond distances are in the range from 0.84 to 1.09 Å, with an average of 0.96(6) Å, and the bond angles involving the H atoms are reasonable. These bond distances and angles have been omitted in Table 3, since the H atoms were unlikely to play a role except in crystal packing.

The crystal structure projected along the c axis is shown in Fig. 3. There is a channel parallel to the c axis extending throughout the entire crystal. Acetone molecule is contained in this channel, without close contact with the main molecule. This explains the easy loss of acetone from the crystal.

The structure of the minor product was presumed to be stereoisomer of the present compound, with a different configuration only at the C(11) atom.[1)]

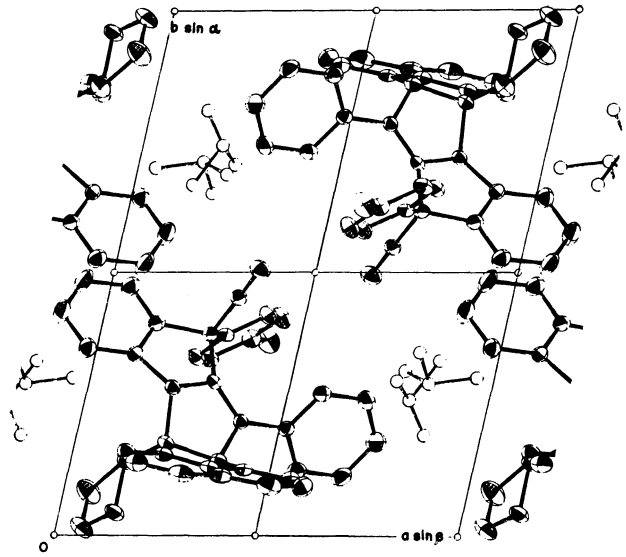

Fig. 3. The crystal structure projected along the c axis. The thermal-motion elliposids are scaled to enclose 30% probability, and acetone atoms are shown as open circles of arbitrary size.

The authors are grateful to Professor Shigeo Kida of the Faculty of Science, Kyushu University, for allowing us to use the automated diffractometer, and to Asst. Professor Shigeaki Kawano of the College of General Eduction of this University for his advice with regard to the computation process.

Acidic and Catalytic Properties of Niobium Pentaoxide

Tokio Iizuka,* Kazuharu Ogasawara, and Kozo Tanabe
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received April 30, 1983)

The surface acidic property of $Nb_2O_5 \cdot nH_2O$ and its catalytic activities for the isomerization of 1-butene, the polymerization of propylene and the dehydration of 2-butanol were examined. The activities were high on $Nb_2O_5 \cdot nH_2O$ evacuated at moderate temperatures (100—150 °C) in all of the reactions and decreased drastically on evacuation at higher temperatures (400—500 °C). The surface of $Nb_2O_5 \cdot nH_2O$ showed a strong acidic character ($H_0 \leqq -5.6$) even after heating in air at 100 °C, but the strong acid sites disappeared on heat treatment at higher temperatures. The active sites on the catalysts heat-treated at moderate temperatures were ascribed mainly to Brönsted acid sites on the basis of the IR study of adsorbed pyridine.

Although niobium oxides are reported in the patents to catalyze several reactions such as the oxidation of organic molecules,[1] oxidative dehydrogenation of olefins or paraffins,[2] and the decomposition of NO_x,[3] the details of surface property and catalytic activity are not known. On the other hand, catalysts containing molybdenum and vanadium, neighbors of niobium in the periodic table, are the most important industrial catalysts and their catalytic properties have been studied extensively by many workers. In this sense, it will be possible to use niobium oxides as a catalyst or an active component of catalysts for certain reaction. For this purpose, a fundamental knowledge about niobium oxides is required. Thus, we have studied the surface acid-base properties and the catalytic activities for the reactions of 1-butene, propylene, and 2-butanol as model reactions.

Experimental

Niobium oxide was prepared by heating $Nb_2O_5 \cdot nH_2O$ (CBMM AD-108) in a vacuum or in air at various temperatures. The $Nb_2O_5 \cdot nH_2O$ was used after washing with distilled water followed by drying at 100 °C. The content of Nb in $Nb_2O_5 \cdot nH_2O$ was 55.54% and no impurity of K or Na was detected.

The differential thermal analysis (DTA) and thermogravimetry (TG) were done by using a Rigaku TG-DTA apparatus with the heating program rate of 10 °C/min. The X-ray diffraction pattern was taken by a Shimadzu XRD spectrometer with Cu *Ka* source. The surface area of $Nb_2O_5 \cdot nH_2O$ was measured by using a conventional BET apparatus.

For the measurement of acidic and basic properties, Nb_2O_5 was suspended in a benzene solution, basic or acidic indicators were adsorbed and the color change of indicators was observed.[4] The indicators used were anthraquinone ($pK_a = -8.2$), benzylideneacetophenone (−5.6), dicinnamylideneacetone (−3.0), Crystal Violet (+0.8), 4-anilinoazobenzene (+1.5), 4-dimethylaminoazobenzene (+3.3), Methyl Red (+4.8), and Bromthymol Blue (+7.1).

Infrared spectra were recorded with a JASCO-701G spectrometer using an in situ cell. The sample was pressed into a thin wafer and placed in the cell. Pyridine was adsorbed on $Nb_2O_5 \cdot nH_2O$ which had been evacuated at various temperatures for 2 h and degassed at certain temperatures for 30 min. The IR spectra of adsorbed CO_2 was also measured by the same method as in pyridine adsorption.

For the reactions of 1-butene and 2-butanol, a closed recirculation reactor having a volume of 300 cm^3 was used. After the evacuation of $Nb_2O_5 \cdot nH_2O$ at various temperatures for 2 h, 6.7 kPa of 1-butene or 1.4 kPa of 2-butanol was introduced at the reaction temperature. The polymerization activity of propylene was measured by observing the pressure decrease in a static reactor. The activity was obtained by measuring the rate of decrease in reactant pressure (initial pressure = 13.3 kPa) at 5 min reaction time to avoid the pressure decrease due to the adsorption in the initial stage of the reaction.

Results

X-Ray and Thermal Analysis of $Nb_2O_5 \cdot nH_2O$. The results of DTA and TG of $Nb_2O_5 \cdot nH_2O$ are shown in Fig. 1(A). At around 90 and 180 °C, two endothermic peaks with the decrease of gravity were observed. These can be ascribed to the dehydration process of $Nb_2O_5 \cdot nH_2O$. The dehydration was completed by heating up to 300 °C and the gravity change of the sample was not observed at 300—700 °C. The exothermic peak at

about 550—570 °C with no gravity change might be due to a phase transformation.

X-Ray diffraction patterns of the samples which were heat-treated at different temperatures are shown in Fig. 1(B). After heating $Nb_2O_5 \cdot nH_2O$ at 400 °C in air, very broad peaks at $2\theta \simeq 30°$ and around 55° were

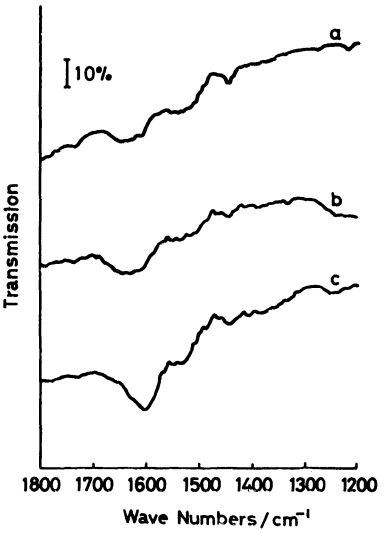

Fig. 4. IR spectra of CO_2 adsorbed on $Nb_2O_5 \cdot nH_2O$ evacuated at 300 °C, a: background, b: evacuated at room temperature after the adsorption for 15 min, c: adsorption for 15 h.

observed. Upon heating at 500 °C in air, those peaks sharpened slightly. A good crystallinity was observed by heating at 700 °C and the diffraction pattern corresponded well to the T–T phase Nb_2O_5.[5]

The surface areas of $Nb_2O_5 \cdot nH_2O$ were 164, 126, and 42 $m^2 g^{-1}$ after the evacuation at 100, 300, and 500 °C, respectively.

Acidic and Basic Character of $Nb_2O_5 \cdot nH_2O$. The acid strength of $Nb_2O_5 \cdot nH_2O$ examined by the indicator adsorption method is mentioned first. After drying at 100 °C, $Nb_2O_5 \cdot nH_2O$ changed the color of benzylideneacetophenone ($pK_a = -5.6$) indicator to its acidic color (yellow), but no color change of anthraquinone ($pK_a = -8.2$) was observed. After heat treatment at 300 °C, all the indicators of $pK_a \geqq -8.2$ also changed their colors to those of the acidic forms. Thus, $Nb_2O_5 \cdot nH_2O$ which was heated at 100—300 °C has an acid strength of $H_0 \leqq -5.6$. However, the strong acid sites disappeared and only an acid strength of $H_0 \leqq +3.3$ was observed by heating at 500 °C.

In order to obtain further information about the acidity of $Nb_2O_5 \cdot nH_2O$, the infrared spectroscopic study of the adsorbed pyridine was examined. The results are shown in Fig. 2. Upon the adsorption of pyridine over $Nb_2O_5 \cdot nH_2O$ which had been evacuated at various temperatures, the bands at 1610, 1540, 1480, and 1440 cm^{-1} were observed after degassing at 100—150 °C. The bands at 1610, 1480, and 1440 cm^{-1} are due to coordinated pyridine and the band at 1540 cm^{-1} is ascribed to pyridinium ion.[6] Thus, $Nb_2O_5 \cdot nH_2O$ has both Lewis and Brönsted acid sites on the surface. The pyridinium ion band almost disappeared after degassing at 300 °C, but the Lewis acid bands still remained. The band intensity changes with evacuation temperature on $Nb_2O_5 \cdot nH_2O$ which had been preheated in a vacuum at different temperatures are shown in Fig. 3. The Brönsted acid band intensity was strongest on the sample evacuated at 100 °C and decreased with the increase of

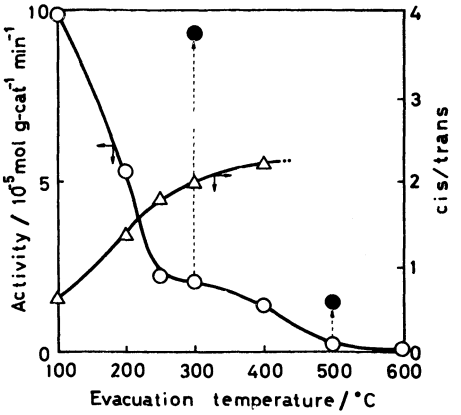

Fig. 5. Activity and selectivity of 1-butene isomerization.
●: H_2O added after pretreatment and evacuated at 100 °C.

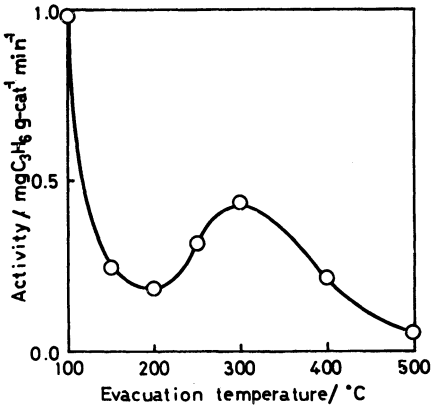

Fig. 6. Polymerization activity of propylene over $Nb_2O_5 \cdot nH_2O$.

pretreatment temperature. However, Lewis acid band intensity showed a maximum on the sample which had been evacuated at 300 °C. Upon preheating at 500 °C, both the acidic sites decreased remarkably.

The adsorption of CO_2 on $Nb_2O_5 \cdot nH_2O$ was examined to obtain an information about surface basic property. The spectra are shown in Fig. 4. After the introduction of CO_2 (2.7 kPa) on the sample which had been evacuated at 300 °C, no distinct change on the spectrum was observed. When the sample was contacted with CO_2 for 15 h, a slight increase of the bands at 1600 and 1390 cm^{-1} were noticed.

Isomerization of 1-Butene. The activity and selectivity changes of 1-butene isomerization with evacuation temperature are shown in Fig. 5. The $Nb_2O_5 \cdot nH_2O$ which was evacuated at 100 °C for 2 h showed a remarkable isomerization activity, the selectivity (the ratio of *cis*-2-butene to *trans*-2-butene) being less than unity. However, if the pretreatment temperature was increased to 200—250 °C, the activity decreased remarkably and the selectivity increased to about 2. In the range of evacuation temperature of 250—400 °C, the activity was not sensitive to the treatment temperature but diminished after the treatment at 500—600 °C. When $Nb_2O_5 \cdot nH_2O$ which had been evacuated at 300 °C was exposed to H_2O vapor at room temperature followed by

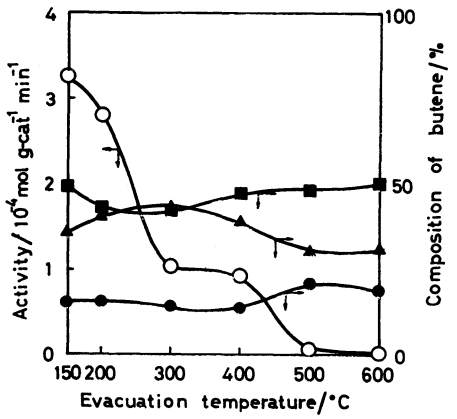

Fig. 7. Activity and selectivity changes of 2-butanol over $Nb_2O_5 \cdot nH_2O$ evacuated at various temperatures.
●: 1-Butene, ▲: *trans*-2-butene, ■: *cis*-2-butene

evacuation at 100 °C, almost the same activity as the catalyst originally evacuated at 100 °C was restored. On the other hand, after evacuation at 500 °C, the activity actually increased by the same treatment but the effect was far less compared to the case evacuated at 300 °C.

Polymerization of Propylene. The change of polymerization activity at 100 °C with evacuation temperature is shown in Fig. 6. The activity was highest on the sample evacuated at 100 °C and decreased remarkably after evacuation at 150—200 °C. However, upon evacuation at higher temperatures, the activity increased again and attained a maximum on treatment at 300 °C. After evacuation at the temperatures higher than 500 °C, the catalyst became almost inactive. The products of polymerization were not thoroughly analyzed due to the adsorption on the sample, but a considerable amount of butenes and pentenes along with the higher hydrocarbons desorbed at higher temperature (300 °C).

Dehydration of 2-Butanol. The changes of activity and selectivity of 2-butanol dehydration reaction with evacuation temperature are shown in Fig. 7. The activity gradually decreased with evacuation temperature. However, the activity was not changed by evacuation between 300—400 °C. The activity finally diminished on evacuation at 500—600 °C.

The formation of dehydrogenated product was not observed in the reaction at 150 °C over the whole catalysts. The ratio of formed *cis*- and *trans*-2-butenes was almost unity and the amount of 1-butene was less than 20% of the products over the catalysts evacuated at lower temperatures (150—300 °C), but the amount of 1-butene increased and that of *trans*-2-butene decreased after evacuation at 400—500 °C.

Discussion

The surface of $Nb_2O_5 \cdot nH_2O$ showed a considerable strong acidic character and rather weak basic property. After heat treatment at 100 °C, the strong acid sites of $H_0 \leqq -5.6$ were found to exist on the surface. Over the typical solid acid catalysts such as SiO_2–Al_2O_3 and SiO_2–TiO_2, the strong acid sites appear only after heat treatment at high temperature ($\simeq$500 °C)[7] along with the

removal of surface water. The acid sites on those catalyst surfaces are thought to be the isolated OH groups as Brönsted acid sites and the exposed metal ions as Lewis acid sites both of which appear after rigorous heat treatment.[7] However, $Nb_2O_5 \cdot nH_2O$ has acidic OH groups (Brönsted acid sites) as observed by IR experiment even after the mild heat treatment at 100 °C. Thus, the surface acidic property of $Nb_2O_5 \cdot nH_2O$ pretreated at mild temperatures is very peculiar and interesting because the residual water might cover almost the whole surface after the treatment. Upon pretreatment at 300 °C, H_2O was almost removed from $Nb_2O_5 \cdot nH_2O$ as observed in DTA experiment, and Lewis acidity increased along with the decrease of Brönsted acidity. However, after treatment at 500 °C, Nb_2O_5 became very inactive and the acidic property was very weak. This surface change is considered to be due to a phase transformation of amorphous $Nb_2O_5 \cdot nH_2O$ to T–T phase Nb_2O_5[5] at around 500—600 °C as observed by DTA and XRD. The catalytic activity of Nb_2O_5 was diminished by heat treatment at 500 °C or higher temperatures in the whole cases of 1-butene isomerization, propylene polymerization and 2-butanol dehydration reactions. In the case of 1-butene isomerization, $Nb_2O_5 \cdot nH_2O$ was very active on evacuation at 100 °C. The ratio of produced cis- and trans-isomers was around unity as observed in a typical case of acid-catalyzed reaction over SiO_2–Al_2O_3.[8] Though the activity decreased drastically after the sample was evacuated at 300 °C, almost the same activity as the sample evacuated at 100 °C was restored only by the introduction of H_2O vapor followed by evacuation at 100 °C. This fact indicates that the isomerization is catalyzed mainly by Brönsted acid sites whose amount decreases with the increase of evacuation temperature as shown in Fig. 3. However, after evacuation at 500 °C, only a slight increase of activity was observed by the introduction of H_2O vapor. The decrease of surface area due to the phase transformation at around 500 °C might prevent the regeneration of Brönsted acid sites on the surface.

In the reaction of 2-butanol dehydration, a high activity was achieved by evacuation at 150—200 °C. The activity on the catalyst evacuated at 150 °C was almost comparable to that on SiO_2–Al_2O_3 (3.7×10^{-4} mol min^{-1} g^{-1} at 200 °C).[9] Since the activity was reduced remarkably by evacuation at 300 °C, the activity would be also ascribed to Brönsted acidity, but Lewis acid sites might also act as active sites on evacuation at 300—400 °C. It is known that the selectivity of produced butenes from 2-butanol is very sensitive to the surface acidic and basic property.[10] The oxide catalysts which have both acidic and basic sites such as ThO_2 and ZrO_2 produce 1-butene dominantly.[11] However, over the strongly acidic catalysts such as SiO_2–Al_2O_3 produce less amount of 1-butene than 2-butene.[12] The $Nb_2O_5 \cdot nH_2O$ in this experiment is the latter case. It would be reasonable because the surface of $Nb_2O_5 \cdot nH_2O$ was mainly acidic and only very weak basic sites were observed in IR of CO_2 adsorption or indicator adsorption.

The polymerization of propylene is known as a model reaction catalyzed by Brönsted acid sites over SiO_2–Al_2O_3 or other acid catalysts.[13] In this work, $Nb_2O_5 \cdot nH_2O$ evacuated at 100 °C showed the highest activity for the polymerization, but the activity decreased remarkably when evacuated at 200—250 °C. In this case, it might be reasonable that the activity is ascribed to Brönsted acidity. However, the activity increased again on evacuation at 300—400 °C in contrast to the cases of 1-butene isomerization and dehydration of 2-butanol. This fact suggests the importance of Lewis acidity in the polymerization of propylene over Nb_2O_5 evacuated at higher temperatures. It is known that niobium compounds such as niobium trichloride distearate and niobium tetrachloride butanoate can polymerize ethylene, propylene, and 1,3-butadiene.[14] The promoting effect of niobium halide in the polymerization in Ziegler-Natta system is also known in the patent.[15] Since the importance of niobium ion as an active site for the polymerization is apparent in those cases, the Lewis acid site is thought to be an active site even on the oxide of niobium. Thus, we conclude that the polymerization of propylene proceeds on Brönsted acid sites on $Nb_2O_5 \cdot nH_2O$ pretreated at low temperatures ($\simeq$100 °C), but Lewis acid sites become main active sites after treatment at higher temperatures.

In conclusion, niobium oxide treated at 100 °C is characterized as a very strong Brönsted acid and can be used as a potential catalyst for Brönsted acid-catalyzed reactions at mild conditions. It should be emphasized that niobium oxide exhibits the highest acid strength among all of the metal oxides pretreated at 100 °C.

We are indebted to Dr. Hideshi Hattori for his valuable suggestion and kind cooperation and to CBMM LTDA for their kind supply of niobium samples and financial support.

The Effect of Surfactant on Formation of Calcium Carbonate

Tsuneo SUHARA, Kunio ESUMI,* and Kenjiro MEGURO
Department of Applied Chemistry and Institute of Colloid and Interface Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received May 23, 1983)

Calcium carbonate was precipitated by rapidly mixing calcium chloride solution, sodium carbonate solution, and aqueous surfactant solution at 25 °C in order to elucidate the effect of addition of surfactant on the formation. The samples obtained were examined by scanning electron microscopy, X-ray powder diffraction, and a specific surface area study. The sample without surfactant proved to be calcite crystals. When a cationic surfactant was added, the crystal structure was transferred from calcite and vaterite to calcite with an increase of the concentration of the cationic surfactant. On the other hand, the addition of a lower concentration of an anionic surfactant provided a mixture of calcite and vaterite, but in higher concentration, amorphous material was obtained. The samples with nonionic surfactant were vaterite crystals. It was found that the spherical particle ratio (N_{sp}) and the vaterite crystal ratio (F_v) in the sample depend on the concentration of the nonionic surfactant.

The preparation of the spherical particles of inorganic compounds has been the subject of many studies.[1-14] However, the spherical particles can be obtained only under limited synthesis conditions, depending on the concentration of solution, temperature, reaction rate, pH, and the ripening method.

Anhydrous calcium carbonate as an inorganic compound is known to exist in three crystalline modifications: calcite, aragonite, and vaterite. Calcite is a stable form at ordinary temperatures and pressures. Aragonite and vaterite are metastable modifications which transform to calcite on heating.[10-12]

Miyata and Nakahara[13] have reported that vaterite was prepared by an interfacial reaction method in which calcium carbonate was formed by the reaction of K_2CO_3 aqueous solution emulsified in benzene with $CaCl_2$ aqueous solution. Inoue and Kanaji[11] prepared vaterite by reacting the concentrated aqueous solution of $CaCl_2$ with Na_2CO_3 and the same process was also employed in the system of $Ca(NO_3)_2$ with Na_2CO_3. Enomoto *et al.*[14] obtained vaterite by mixing $CaCl_2$, $NaHCO_3$, and NH_3 at 45 °C to attain a final pH of 6.8.

In this work, calcium carbonate was precipitated by mixing $CaCl_2$–Na_2CO_3 solutions in the presence of aqueous surfactant solution at 25 °C. The effects of addition of aqueous surfactant solution on the morphology and polymorphism of calcium carbonate were examined.

Experimental

Preparation of Calcium Carbonate. Nonionic surfactants used in this experiment were supplied by Nikko Chemicals Co., Ltd.; other chemicals were of reagent grade.

Calcium carbonate was precipitated by rapidly mixing 2.5×10^{-2} mol dm^{-3} of $CaCl_2$ solution, 2.5×10^{-2} mol dm^{-3} of Na_2CO_3 solution, and aqueous surfactant solution at 25 °C. The concentrations of the surfactant added were 5.0×10^{-5}, 9.0×10^{-4}, and 5.0×10^{-3} mol dm^{-3} (cationic surfactant: hexadecyltrimethylammonium bromide, CTAB), 5.0×10^{-5}, 3.2×10^{-3}, and 8.0×10^{-3} mol dm^{-3} (anionic surfactant: sodium dodecyl sulfate, SDS), and 5.0×10^{-6}, 1.0×10^{-5}, 5.0×10^{-5}, 1.0×10^{-4}, 5.0×10^{-4}, and 1.0×10^{-3} mol dm^{-3} (nonionic surfactant: poly(oxyethylene) nonylphenyl ether, NP-n: n=10, 20). Each solution was mixed for 10 s and unstirred thereafter. Precipitation commenced less than 5 s after mixing, with a rapid onset of turbidity, and crystals gradually settled out of the solutions. In this experiment, the precipitate of calcium carbonate adhered tenaciously to the walls and bottom of the reaction cell after 3 h of aging. The precipitate obtained was washed with water to remove unreactive salts and by-products, washed again with methanol to remove the surfactant, then dried *in vacuo*. Each dried precipitate was used as a sample.

pH Measurement. The pH of the supernatant was measured by a Corning pH meter 130.

Scanning Electron Microsopy (SEM). The morphology and polymorphic composition of samples obtained were taken with a JEOL JSM-T20 SCANNING MICROSCOPE and a AKASHI ALPHA-10 after coating by the thick 30 nm of gold on each sample was carried out by a JEOL COAT ION SPUTTER JEC-1100. Further, the spherical particle ratio (N_{sp}) was determined by counting the number of spherical and unspherical particles on the microphotgraphs taken with different fields.

Specific Surface Area. The specific surface area of calcium carbonate was measured by a Shimadzu GAS CHROMATOGRAPH GC-7A connected with a Shimadzu SORPTOGRAPH ADS-1B. The area was determined by applying the BET method to the nitrogen adsorption at liquid nitrogen temperature.

X-Ray Powder Diffraction.[15] An X-ray powder diffraction was measured by a Rigaku Denki Geigerflex RAD-IIIA MJ 200 DX with nickel filtered copper $K\alpha$ radiation (35 kV and 10 mA). To evaluate the crystal transfer ratio in vaterite to calcite in the presence of surfactant, the following equations were employed:

$$F_c = \frac{I_{104(c)}}{I_{110(v)} + I_{104(c)} + I_{112(v)} + I_{114(v)}} \times 100, \quad (1)$$

$$F_c + F_v = 100. \quad (2)$$

Here diffraction intensities (I) of the (104) reflection of calcite and of the (110), (112), and (114) reflections of vaterite are obtained and the vaterite (F_v) and calcite (F_c) crystal ratios can be determined by the X-ray diffraction measurement using Eqs. 1 and 2.

Results and Discussion

The crystals obtained in the absence of surfactant had a characteristic calcite(rhombohedral) morphology, as shown in Fig. 1. Further, the X-ray powder diffraction

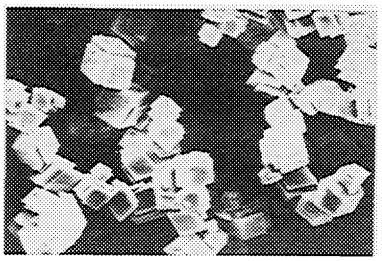

Fig. 1. SEM photomicrograph of calcium carbonate crystals precipitated in the absence of surfactant.

analysis showed the calcite (ASTM No. 5-586) diffraction peak. The pH values of each reacting solution, with and without the surfactant solutions, were 10.30, and 10.30—10.40, indicating that the effect of pH on the formation of calcium carbonate by the addition of surfactant will be negligibly small.

Figure 2 shows a scanning electron microphotograph of the powders prepared in the presence of CTAB, whose critical micelle concentration(cmc) is 9.0×10^{-4} mol dm^{-3}. The samples obtained in the presence of 5.0×10^{-5} mol dm^{-3} of CTAB were a mixture of characteristic calcite and vaterite(hexagonal) whose morphology is shown in Fig. 2(A). With an increase of the concentration of CTAB (9.0×10^{-4} and 5.0×10^{-3} mol dm^{-3}), the morphology became that characteristic of calcite, as shown in Figs. 2(B) and (C). The above results indicate that the vaterite fraction in the samples decreases with an increase of the concentration of CTAB added. Especially. in the concentration of 5.0×10^{-5} mol dm^{-3} of CTAB, the spherical particle ratio (N_{sp}), the vaterite crystal ratio (F_v), and the specific surface area were 82.5%, 47.0%, and 2.8 m^2/g, respectively. The decrease in the vaterite crystal ratio with an increase of the concentration of CTAB might be caused by the slow diffusion of water owing to the thick layer of CTAB adsorbed around the calcium carbonate particles.

Figure 3 gives the SEM pictures of the powders prepared in the presence of SDS, whose cmc is 8.0×10^{-3} mol dm^{-3}. The morphology of the samples obtained in the presence of 5.0×10^{-5} mol dm^{-3} of SDS exhibited a mixture of calcite and vaterite, as shown in Fig. 3(A). The addition of higher concentrations of SDS (3.2×10^{-3} and 8.0×10^{-3} mol dm^{-3}) provided amorphous precipitates, as shown in Figs. 3(B) and (C). Thus, vaterite and calcite crystals become amorphous with increasing the concentration of SDS added. In the concentration of 5.0×10^{-5} mol dm^{-3} of SDS, N_{sp}, F_v, and specific surface area were 70.0%, 32.0%, and 2.3 m^2/g, respectively.

The adsorption of SDS onto calcium carbonate powder has been studied by Chibowski.[16] According to his report, in the low concentration of SDS, the adsorption in the synthesis reaction step of calcium carbonate was appreciable, while in the highcon centration, this solution dissociated similarly to Eq. 3, and Ca^{2+} and $2DS^-$ in this solution produced $Ca(DS)_2$ after reacting like Eq. 4. Since this reaction affects significantly the reaction of calcium carbonate, it is considered that calcite and vaterite crystals become amorphous by the addition of SDS.

$$Na\text{–}Ds \longrightarrow Na^+ + DS^-, \quad (3)$$

$$Ca^{2+} + 2DS^- \longrightarrow Ca(DS)_2. \quad (4)$$

Thus, cationic and anionic species of the surfactant play important roles in the formation of calcium carbonate. As nonionic surfactants have no charge groups, the formation of calcium carbonate in the presence of nonionic surfactant proceeds without taking into consideration the charge effect.

Figure 4 gives the SEM pictures of the powders prepared in the presence of NP-10, whose cmc is $(7.5—9.0)\times10^{-5}$ mol dm^{-3}. The samples in the presence of NP-10 (5.0×10^{-6} and 1.0×10^{-4} mol dm^{-3}) had a characteristic calcite and vaterite morphology, as shown in Fig. 4(C). The vaterite crystal ratio (F_v) calculated

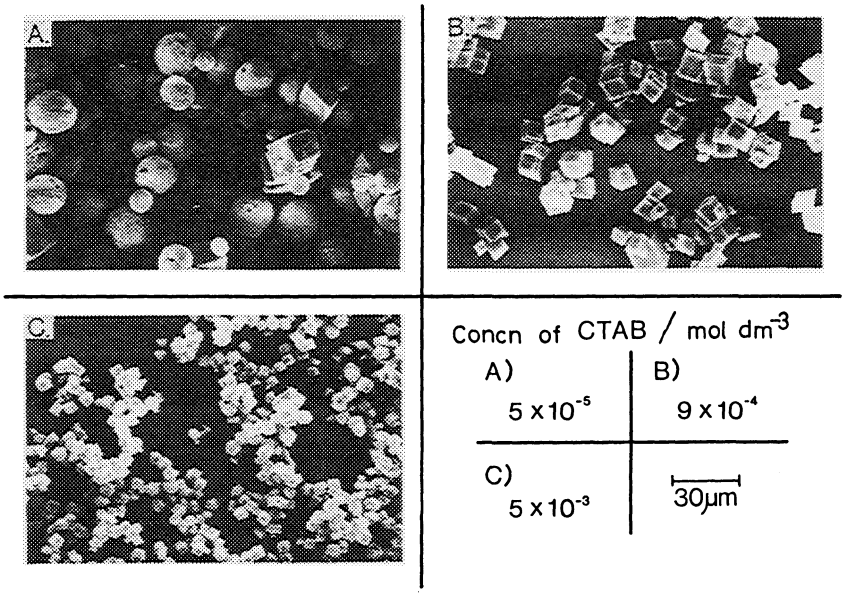

Fig. 2. SEM photomicrographs of calcium carbonate crystals precipitated in the presence of various concentrations of CTAB.

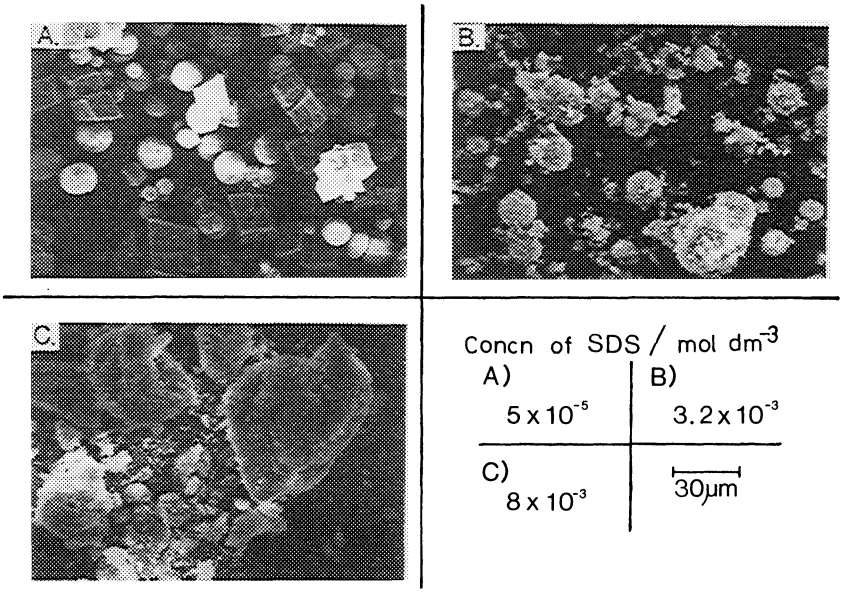

Fig. 3. SEM photomicrographs of calcium carbonate crystals precipitated in the presence of various concentrations of SDS.

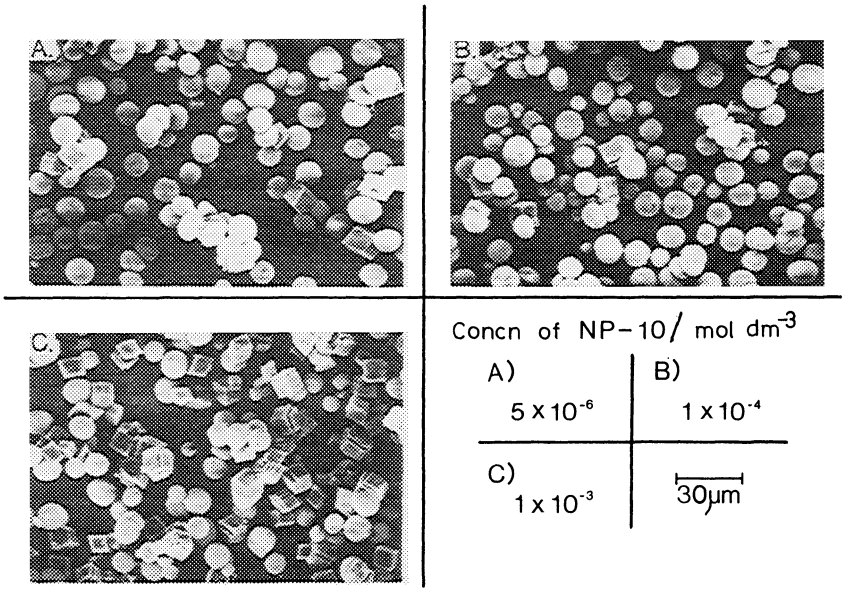

Fig. 4. SEM photomicrographs of calcium carbonate crystals precipitated in the presence of various concentrations of NP-10.

by Eqs. 1 and 2 is plotted against the concentration of surfactant shown in Fig. 5. In the case of NP-10, the F_v increased until the concentration of 5.0×10^{-5} mol dm^{-3}, then decreased slowly with an increase of the concentration until 1.0×10^{-4} mol dm^{-3}, and then decreased rapidly. In the case of NP-20, the F_v increased gradually with an increase of the concentration of surfactant. Thus, it is found that the vaterite crystal ratio depends on the concentration of the nonionic surfactant.

The spherical particle ratio (N_{sp}) is also plotted against the concentration of nonionic surfactant in Fig. 6. In the range of concentration of NP-10 from 5.0×10^{-6} to 5.0×10^{-4} mol dm^{-3}, the crystals were spheres, cubes, and amorphous. Further, at concentrations above 5.0×10^{-4} mol dm^{-3}, the N_{sp} decreased with an increase of the concentration of NP-10. Similarly, in the range of concentration of NP-20 from 5.0×10^{-6} to 1.0×10^{-3} mol dm^{-3}, the N_{sp} increased with an increase of the concentration of NP-20. The magnitude of N_{sp} obtained by using NP-10 is larger than that of NP-20.

The adsorption of nonionic surfactant onto inorganic powders has been studied by several investigators.[17-20] Akers and Riley[19] and Hsiao and Dunning[20] examined the adsorption of nonionic surfactants onto calcium carbonate or sands. They reported that the adsorption increases with decrease in the length of oxyethylene chain of the surfactant. According to their results, as the film thickness of the surfactant adsorbed on the powder particle increases with an increase of the concen-

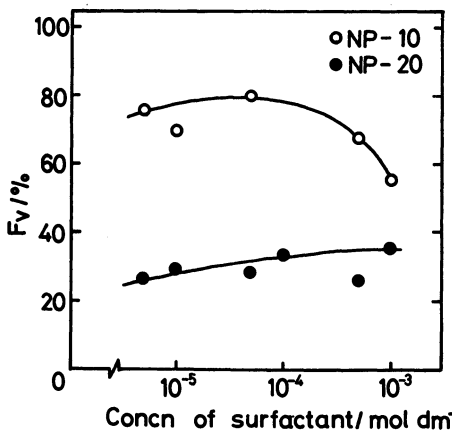

Fig. 5. Relation between vaterite ratio (F_v) in calcium carbonate and concentration of surfactant added.

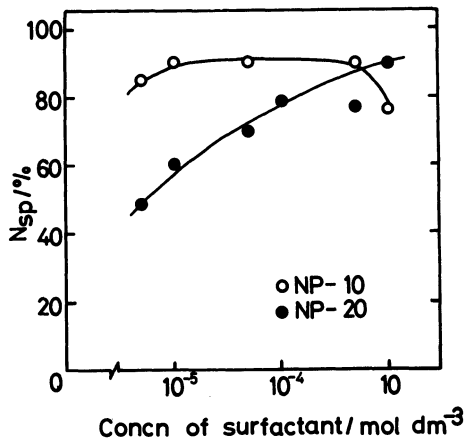

Fig. 6. Relation between spherical particle ratio (N_{sp}) in calcium carbonate and concentration of surfactant added.

tration of the surfactant, the film prevents the surface of the particle from contacting the water. Thus, the increase of the vaterite crystal ratio might be caused by preventing the vaterite particle from coming into contact with the water; this would result in stability of the vaterite crystal. On the other hand, at higher concentrations of the surfactant, the decrease in the vaterite crystal ratio is due to the slow diffusion of water through the thick film layer of the surfactant adsorbed around the particle. The above results show that the N_{sp} and F_v depend on the concentration of the surfactant and the length of their oxyethylene chain. Here, the N_{sp} in the case of NP-10 and NP-20 were 20—30% and 40—50% greater than those of their F_v, respectively. This difference might be interpreted if some of the sherical particles in the preparation of the above conditions are amorphous vaterite rather than vaterite crystals.

The mean particles size (arithmetic mean diameter, D) and specific surface area (S_N, S_D) of calcium carbonate are given in Table 1. The S_D value was determined by calculating from the mean particle size, employing Eq. 5:

$$S_D = 6/D \times \rho, \quad (5)$$

where D is an arithmetic mean diameter estimated from

Table 1. Mean particle size and surface area of calcium carbonate precipitated in the presence of surfactant

Surfactant mol dm^{-3}	Mean particle μm	S_N $m^2\,g^{-1}$	S_D $m^2\,g^{-1}$
None	10.50	1.48	0.22
NP-10			
1×10^{-5}	14.12	3.56	0.16
5×10^{-5}	12.32	3.02	0.18
1×10^{-4}	11.56	3.74	0.20
5×10^{-4}	10.56	4.81	0.21
NP-20			
5×10^{-6}	13.69	2.05	0.17
1×10^{-5}	12.57	2.80	0.18
5×10^{-4}	10.36	2.58	0.22
1×10^{-3}	12.44	4.59	0.18

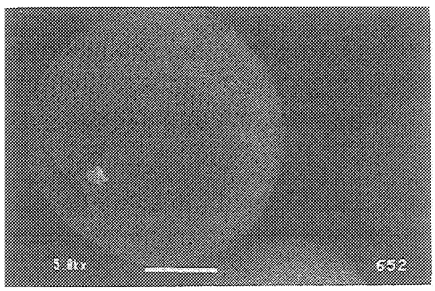

Fig. 7. SEM photomicrograph of a vaterite crystal enlarged.

the SEM pictures and ρ is the specific gravity, 2.65. The S_N value was also determined by the BET method from the nitrogen adsorption. From Table 1, it is seen that the S_N value is larger than that of the S_D, indicating that the calcium carbonate formed by the addition of nonionic surfactant is porous. Further, to elucidate the surface morphology of vaterite crystal, the SEM picture was taken and is shown in Fig. 7. It is found that, as predicted by the S_N/S_D value, the surface of vaterite seems to have many pores.

The Preparation and Some Properties of Potassium Tris(1,1′-ferrocenedicarboxylato)ferrate(III)

Tomoko NOMURA

Department of Chemistry, Faculty of Science and Engineering, The Aoyama Gakuin University, Shibuya, Shibuya-ku, Tokyo 150

(Received October 5, 1982)

The K_3[Fe(1,1′-ferrocenedicarboxylato)$_3$] complex was synthesized. The infrared absorption bands of the ligand (parent) acid, its potassium and barium salts, and the complex were assigned in studying the nature of the oxygen-to-metal bond in the complex. The electronic absorption spectra of the ligand acid and the complex were also measured. The techniques of thermogravimetry (TG) and differential thermal analysis (DTA) were used to establish the thermal decomposition of the complex.

There are some complexes in which ferrocenyl groups are introduced into the ligand,[1,7,9] but no complexes with 1,1′-ferrocenedicarboxylic acid (H_2fdc) as ligands have yet been reported. The K_3[Fe(1,1′-ferrocenedicarboxylate)$_3$] (K_3[Fe(fdc)$_3$]) complex was synthesized by using iron(III) sulfate and barium 1,1′-ferrocenedicarboxylate. Its properties was investigated in the present study.

Experimental

Preparation of Ligand. H_2fdc was prepared according to Rausch and Ciappenelli.[2] The product recrystallized from glacial acetic acid was orange and melted, with decomposition, at *ca.* 246 °C (lit: decomposition over 240 °C). The product was identified by means of IR[3] and NMR measurments. Calcd for $C_{12}H_{10}O_4Fe$: Fe, 20.38%. Found: Fe, 20.1%.

Preparation of the Complex. The K_3[Fe(fdc)$_3$] complex could not be synthesized by the following procedure:

$$2Fe(OH)_3 + 3H_2fdc \longrightarrow Fe_2(fdc)_3 + 6H_2O,$$

$$Fe_2(fdc)_3 + 3K_2fdc \longrightarrow 2K_3[Fe(fdc)_3].$$

However, the procedure of Bailar and Jones[4] could be successfully applied:

$$Fe_2(SO_4)_3 \cdot nH_2O + 3Bafdc \longrightarrow Fe_2(fdc)_3 + 3BaSO_4,$$

$$Fe_2(fdc)_3 + 3K_2fdc \longrightarrow 2K_3[Fe(fdc)_3].$$

$Fe_2(SO_4)_3$ (0.55 g), Bafdc (2.2 g) (prepared from $Ba(OH)_2 \cdot 8H_2O$ (3.15 g) and H_2fdc (2.74 g)), and K_2fdc (1.6 g) (prepared from K_2CO_3 (1.38 g) and H_2fdc (2.74 g)) were placed in water (400 cm^3) and digested for 3 h on a water bath. A crystalline substance then began to precipitate. After centrifugation, the filtrate was evaporated to *ca.* 70 cm^3, at which point crystals precipitated. The product, which formed after standing for 1 h, was filtered with suction and washed with 50% ethanol several times. Yellowish brown, flat crystals of K_3[Fe(fdc)$_3$] were thus prepared in a nearly quantitative yield . The complex was stable in air, decomposed at 284 °C, and was insoluble in most organic solvents. It was dried *in vacuo* over silica gel at room temperature. Found: C, 44.86; H, 2.95; Fe, 22.1%. Calcd for K_3[Fe(fdc)$_3$]: C, 43.70; H, 2.42; Fe, 22.6%. Attempted recrystallizations with water and *N,N*-dimethylformamide were unsuccessful. In the case of a protogenic solvent such as acetic acid or an amphiprotic solvent such as water, the K_3[Fe(fdc)$_3$] was changed to H_2fdc. In an organic solvent such as *N,N*-dimethylformamide, a slight decomposition was observed after one week.

Measurements. The electronic spectra were measured with a Shimadzu UV-200 spectrophotometer in cells with a 1-cm light path. The infrared spectra were measured with a JASCO IRA-1 spectrophotometer in the range of 650—4000 cm^{-1} on KBr pellets. The TG and DTA measurements were made with a Shimadzu DTA-20B differential thermal microbalance under two conditions, in static N_2 and air at the heating rate of 10 °C/min. The sample amounts taken in the TG runs were *ca.* 5 mg, and in the DTA runs, *ca.* 2 mg.

Results and Discussion

Composition of the Chelate. The K_3[Fe(fdc)$_3$] complex crystals obtained in a solid state could not be recrystallized, and they were too fine for any powder X-ray study. The complex was, however, homogeneous and was found to be composed of single crystals under a polarizing microscope. Therefore it was considered that the complex was pure enough for the structural study. DTA and TG measurements showed that no water molecules existed in the complex. Considering that the majority of Fe(III) complexes are octahedral, like the tris(oxalato) complex, the molar ratio of Fe : H_2fdc (1 : 3) seems to be natural. The molecular weight and conductivity of the complex were not measured, since no suitable solvent could be found.

IR Spectra. A) Assignment of the Observed Frequencies of 1,1′-Ferrocenedicarboxylic Acid and Its Potassium and Barium Salts: The main bands are listed in Table 1. Characteristic bands for the carboxylic acid[3] were observed at 2625, 2545, and 914 cm^{-1} in the spectrum of the H_2fdc, which could be assigned to the OH stretching and out-of-plane OH deformation vibrations. A very strong band at about 1680—1720 cm^{-1} in the H_2fdc spectrum was assigned to the C=O stretching vibrations. Bands at 1492 and 1300 cm^{-1} in the H_2fdc spectrum were assigned to the C–O vibrations, coupled with the in-plane OH deformation vibration. Very strong bands at about 1600 cm^{-1} and other strong band at about 1400 cm^{-1} observed in the spectra of K_2fdc and Bafdc were assigned to the antisymmetric and symmetric OCO stretching vibration respectively. Strong bands at 1465 cm^{-1} in the K_2fdc spectrum and at 1475 cm^{-1} in the Bafdc spectrum were also assigned to the symmetric OCO stretching vibrations.

B) Assignment of the Observed Frequencies of the Potassium Tris(1,1′-ferrocenedicarboxylato)ferrate(III) Complex: On the basis of the reported data on the bands of similar complexes, such as the oxalato,[5] malonato,[6] and 1,1′-diacetylferrocenato complexes,[7] the absorption bands

of $K_3[Fe(fdc)_3]$ were assigned; they are shown in Table 2 and Fig. 1 (——). The bands at 2860—3120, 2625, and 2545 cm^{-1} assignable to the OH stretching vibration were not observed. The very strong C=O stretching vibration at 1680—1720 cm^{-1} in the ligand was shifted to a lower frequency, 1677 cm^{-1}, in the complex. New bands were observed at 1586 and 1542 cm^{-1}; they were assigned to the antisymmetric OCO stretching vibrations corresponding to the bands at 1555 and 1525 cm^{-1} respectively present in the spectrum of Bafdc. The band at 1465 cm^{-1} corresponded to the bands of symmetric OCO stretching vibration in the K_2fdc and Bafdc spectra. The band at 1380 cm^{-1} and new weak bands at 1353 and 1325 cm^{-1} assigned to the symmetric OCO stretching vibrations corresponded to the bands at 1387, 1362, and 1340 cm^{-1} respectively in the K_2fdc spectrum and to the bands at 1388, 1358, and 1346 cm^{-1} in the Bafdc spectrum. The nature of the metal-to-ligand

bond (M–O) could thus be studied indirectly from the value of the CO stretching frequency, without determining the M–O stretching vibration, which appears at a much lower frequency. The structure deduced from these data is shown in Fig. 2.

Electronic Spectra. The electronic spectra of H_2fdc and its complex was measured in three solvents: 95% ethanol (EtOH), dimethyl sulfoxide (DMSO), and H_2O. The absorption bands in the $(12.5—33.5)\times10^3$ cm^{-1} region are given in Table 3. In these spectra, a broad low-intensity band around 440 nm, which is identified as a forbidden d-d transition localized on the iron atom, and another band at 325 nm, which is identified as a N–Q transition or as a symmetry-forbidden N–V transition, are characteristic. In comparison with the absorption bands of ferrocene (325 nm (ε, 49), 440(91)) and ferrocenemonocarboxylic acid (342^{sh}-(361), 445(223)) in 95% EtOH,[8] the spectrum of the H_2fdc showed a bathochromic shift. These bands shifted with substitution on the cyclopentadienyl ring, and the intensity increased in such derivatives where a ferrocene was conjugated with COOH. In the spectrum of the complex, the positions of the absorption bands were negligibly changed, while the intensities increased. Interestingly, the change in the electronic spectrum was not so pronounced as would be expected when COOH groups substituted on ferrocene are coordinated to Fe^{III}. The H_2fdc ligand has a strongly aromatic nature with π electrons. When such ligands are coordinated to a metal, the spectrum of the complex is almost the same as that of a free ligand. Therefore the electronic spectrum of the complex showed the absorption bands based on the ligand.

TG and DTA. The data for $K_3[Fe(fdc)_3]$ are shown in Fig. 3. They show that the thermal-decomposition process of $K_3[Fe(fdc)_3]$ proceeds in two stages, corresponding to the exothermic peaks at 284 and 339 °C in air and at 289 and 343 °C in N_2. The H_2fdc ligand is decomposed with an exothermic peak at 246 °C in air. In the investigation of the thermal decomposition of $K_3[Fe(fdc)_3]$ in N_2, the solid residue obtained at 290 °C (loss in weight 12%) was identified by means of its IR spectra. Figure 1 (------) shows that the strong absorption band at 1677 cm^{-1} assigned to the C=O stretching vibration and that at 1280 cm^{-1} assigned to the C=O stretching and the O–C=O deformation vibrations were both very much reduced. The weak absorption bands at 1586, 1325, and 730 cm^{-1} disappeared. These spectral changes show that the Fe–O bonds are partially dissociated by heating. After the extraction of this solid residue with *N,N*-dimethylformamide, ferrocene or its derivative was not found by studying IR spectra of the extract. It seems that such an organic compound is sublimed in the thermal decomposition process, as has been described in the literature.[9] The solid residue obtained at 360 °C (loss weight in 49.8%) was identified by means of its IR spectra; it was found to be potassium carbonate. A comparison of the thermal decomposition of the chelate of H_2fdc and that of the chelate of oxalic acid[10] shows that the thermal stability rises a little upon the introduction of the carboxyl groups into ferrocene, which is thermally stable.

The author wishes to express her deep gratitude to Professor Shoichiro Kawakubo of Aoyama Gakuin University.

Particle Size of Nickel in Nickel-Alumina Catalysts and Its Effects on Propene Hydrogenation

Yoriko TAKAI, Akifumi UENO,* and Yoshihide KOTERA
Department of Materials Science, Toyohashi University of Technology, Tempaku-cho, Toyohashi 440
(Received November 30, 1982)

The particle size of nickel in Ni/Al_2O_3 catalysts prepared by the alkoxide technique is well controlled by changing the metal concentration in the catalyst. The rate of propene hydrogenation over the catalyst increases with decrease in Ni particle size, and this phenomenon is explained on the assumption that nickel atoms located on edges and/or corners of crystallites may contribute predominantly to the hydrogenation of propene.

The relation between dispersion states and catalytic behavior of a metal has been of current interest in the field of catalysis, since it was reported that physical properties of a fine metal particle should be different from those of bulk metal when the particle size is smaller than 100 Å.[1] Boudart[2] proposed that there are two types of catalytic reactions, each called the structure sensitive reaction and the structure insensitive reaction. The hydrogenation of ethylene, cyclopropane, or benzene on Pt/Al_2O_3 is considered to be structure insensitive,[3] while the hydrocracking, isomerization, and dehydrocyclization of 2-methylpentane are likely to be structure sensitive.[4] For a structure sensitive reaction, Brunelle *et al.*[5] tried to explain the effect of metal particle size on reaction selectivity by assuming a simple geometrical arrangement of metal atoms exposed on the surface of crystallite. Otero-Schipper *et al.*[6] also applied the idea to the hydrogenation of propene or butadiene on Pt/Al_2O_3 catalyst. The idea of simple geometrical arrangement was first proposed by van Hardeveld and van Montfoort[7] and developed by Anderson.[8] On the contrary, Primet *et al.*[9] studied the influence of metal particle size on chemisorption properties of supported platinum by means of infrared spectroscopy. They discussed size effects on the basis of an idea that electronic properties of a metal would change with its particle size when it is less than 100 Å.

In the present work the hydrogenation of propene was studied on Ni/Al_2O_3 catalysts prepared by the alkoxide technique.[10] The nickel metal particle size was well controlled by adjusting the metal concentration in the catalyst. The rate of hydrogenation increased with decrease in the metal particle size and this was interpreted by an assumption that the reaction would take place preferentially on nickel atoms located on edges and/or corners of crystallites.

Experimental

Catalyst Preparation. The catalyst employed was Ni/Al_2O_3 prepared by hydrolysis of a mixed solution of aluminium isopropoxide dissolved in butyl alcohol and nickel nitrate dissolved in ethylene glycolate: The nickel nitrate was heated at 90 °C to remove water *via* $Ni(NO_3)_2 \cdot 6H_2O \longrightarrow Ni(NO_3)_2 \cdot H_2O$, and the butyl alcohol and ethylene glycolate were distilled before use; about 5.0 g of nickel nitrate was dissolved in ethylene glycolate at 80 °C. Depending upon the concentration of nickel in the designed catalyst, the corresponding amount of this solution was poured into the aluminium isopropoxide dissolved in butyl alcohol and stirred at 80 °C in an N_2 atmosphere. Water was then added to the mixed solution. The volume of water added was about 4 times the volume of aluminium isopropoxide employed. The solution was stirred at 80 °C for 4 h and then cooled to room temperature without stirring. A gel was obtained, filtered, and dried at 110 °C in an oven. The powder thus obtained was calcined at 500 °C for 4 h in air and then reduced with hydrogen at 500 °C for 4 h. The loading of Ni ions on the catalyst could be controlled by varying the concentration of nickel nitrate in the mixed solution employed. The Ni ions in the catalyst were extracted by heating the catalyst in an aqueous solution of nitric acid and the concentration of nickel ions was determined with a X-ray fluorescence spectrometer. In the present experiment the concentrations of nickel in the catalysts prepared were 0.39, 0.78, 3.96, and 13.9 wt%.

Measurement of Particle Size of Nickel Metal by Transmission Electron Micrography. The particle size of Ni in the catalyst was measured with a transmission electron microscope (TEM) operated at an accelerating voltage of 75 kV (Hitachi, H-300). The sample was first ground in an agate mortar and then suspended in water or ethyl alcohol by using supersonic waves. Some of the finest parts of the suspension was pipetted onto a microgrid covered with collodion film (400 mesh, Nisshin Film Co.). Micrographs were obtained with an instrumental magnification of $\times 50000$ and enlarged with $\times 2$ for print.

Measurement of Mean Particle Size by Hydrogen Chemisorption. After the reduction of catalyst samples at 500 °C, they were evacuated at the same temperature for 3 h and cooled to room temperature to be sebjected to hydrogen chemisorption measurement. The measurement was carried out by using an absolute pressure gauge (MKS Baratoron type 222B) in the hydrogen pressure range 5—50 mmHg (1 mmHg = 133.322 Pa) as registered at adsorption equilibrium. The volume adsorbed was determined by extrapolating the linear part of the isotherm to zero pressure as proposed by Hall and Wilson.[11] The specific surface area of Ni in the catalyst was estimated on the assumption that a nickel atom will occupy an area of 6.8 Å^2 [12] and the mean particle size was calculated by

$$d = 5/\rho S,$$

where ρ is the density of nickel metal and S is the specific surface area of nickel particle in the catalyst. In this calculation nickel particles were assumed to be in the f.c.c. packing.

Magnetic Measurement of Nickel Reduced to Metal. In order to obtain the specific surface area of nickel in a catalyst, the fraction of nickel reduced to metel should be estimated, because hydrogen adsorbs on metallic nickel but not on Ni cations in the catalyst. After the reduction of catalyst samples, they were loaded on a vibrating sample magnetometer (Toei Kogyo Co., Model VSM-2) at a vibration frequency of 80 kHz with a magnetic field strength up to 10 kOe†. The

† 1 Oe = $(1000/4\pi)$A m^{-1}.

Table 1. Measurement of saturation magnetization of catalysts and the fractions reduced to metal

Ni Concentration/wt%	Reduction temperature/°C	Time/h	Saturation magnetization[a)] of Ni in catalyst /emu cm^3 g^{-1}	Fraction of Ni metal/%
0.39	500	2	0.0671	23.6
0.78	500	2	0.1000	31.7
3.96	500	2	0.6850	31.9
3.96	500	4	0.7250	33.7
3.96	700	4	1.250	58.2
13.9	500	2	2.370	31.4

a) Saturation magnetization of Ni: 54.39 emu cm^3 g^{-1}.

magnetization was measured at room temperature. One problem in the measurement was the exposure of the reduced catalyst to air a few minutes while being packed into the sample holder.

Particle Size Effects on Reaction Rate. As a model reaction the hydrogenation of propene was selected since Ni catalysts are often employed for the hydrogenation of olefinic hydrocarbons. The reaction was carried out at 50 °C with a closed circulating reactor, made of glass, containing about 0.5 g of catalyst. Feed gases were usually composed of propene and hydrogen each of 20 cmHg pressure. Gas products were analyzed with a gas chromatograph equiped with columns packed with molecular sieves 13X and Polapak Q. The rate of propene hydrogenation was calculated from the amount of propane produced during the initial 5 min of reaction.

Results

Particle Size of Nickel Measured by TEM and H_2 Chemisorption. Typical photographs obtained by TEM are shown in Fig. 1 for the 0.78, 3.96, and 13.9 wt% Ni/Al_2O_3 catalysts. The particle size distributions were obtained by measuring 500—1000 particles in the photographs. Unfortunately, no qualified photographs were obtained for the 0.39 wt% Ni/Al_2O_3 catalyst so as to allow the determination of particle size distribution. It must be mentioned that small nickel particles often coagulated with each other when irradiated by an electron beam from the microscope.

The mean particle size obtained by hydrogen chemisorption measurements is given in Fig. 3. The mean particle size increases with increase in the concentration of nickel in the catalyst. To obtain the mean particle size, the specific surface area of Ni was calculated by

$$S/\text{Å} = 13.6\, VN_AR^{-1},$$

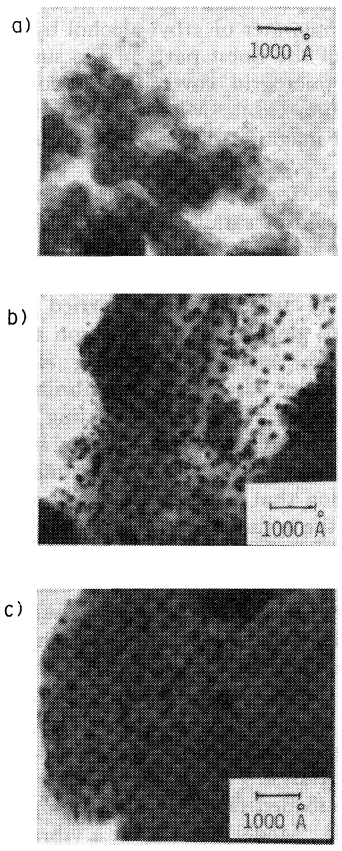

Fig. 1. Transmission electron micrographs ($\times 10^5$).

—●—: particle size measured by TEM.

where V is the mole of hydrogen adsorbed on the unit mass of Ni, N_A is Avogadro's number, and R is the fraction of nickel reduced to metal. For catalysts prepared by the usual impregnation method the fraction of metal reduced is almost 1.0, while for the present catalysts it was as low as 0.3 (Table 1).

Magnetic Measurements. Measurements were made for the saturated magnetization of Ni with catalysts reduced by hydrogen at 500 and/or 700 °C (Table 1). Since the saturated magnetization of Ni is 34.59 emu $cm^3\ g^{-1}$,[13] the fraction of nickel reduced to metal was calculated from the magnetization observed, the results being given in Table 1.

Effects of Ni Particle Size on the Rate of Propene Hydrogenation. The rate obtained for the initial 5 min of reaction was expressed in terms of (the number of the molecules of propane formed per min)/(the number of the nickel atoms exposed on the surface), which is the so-called turnover number. In Fig. 4, the turnover number increased with decrease in the particle size when the size was less than 50 Å, indicating that a size effect is involved in the propene hydrogenation on Ni/Al_2O_3 catalyst.

Discussion

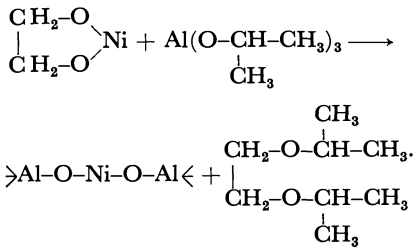
The most important factor for studying effects of particle size on catalytic activity is that the catalyst should be free from any impurities which will affect the activity. In the present work, the catalyst was prepared by the alkoxide technique, because one of the best methods of obtaining a pure metal oxide is hydrolysis of its alkoxide in a proper solvent. It has been reported that most metals form their alkoxides by the reaction between metal chloride and sodium alkoxide in the presence of an excess of alcohol and a hydrocarbon solvent.[14] The elimination of the chlorine and sodium ions from alkoxides thus prepared is difficult. It was reported that a well dispersed Ni/Al_2O_3 catalyst was prepared by using a mixture of aluminium *s*-butylate and nickel acetate.[15]

A highly dispersed Ni/SiO_2 was prepared[10] by hydrolysis of a mixture of nickel nitrate dissolved in ethylene glycolate and ethyl silicate. In this work aluminium isopropoxide dissolved in butyl alcohol was employed in place of ethyl silicate in hope of formation of the Ni–O–Al structure in the catalyst since the Ni–O–Si structure was observed by infrared spectroscopy in Ni/SiO_2 catalyst as mentioned in the previous paper.[10] Although the Ni–O–Al structure was not identified here by infrared spectroscopy, we believe the formation of the structure in the catalyst thus prepared. This will be discussed later.

Homogeneous dispersion of metal particles is also important to investigate the relation between particle size and activity. The particle size of Ni in the catalyst thus prepared was measured by use of hydrogen chemisorption, leading to a conclusion that the mean particle size is well controllable by varying the concentration of Ni in the catalyst. At a glance over the photographs shown in Fig. 1, it is clear that the size of the Ni particles are almost the same with each other. The size distribution of nickel shown in Fig. 2 also indicates that the nickel particles are controlled so as to be in an even size level, although the mean particle sizes calculated from the results by TEM are larger than those obtained by hydrogen chemisorption. The particles of Ni in the 0.39 wt% Ni/Al_2O_3 catalyst may be too small to be observed by TEM.

The nickel ions in the catalyst prepared by the usual impregnation method are ready to be reduced by hydrogen at 500 °C, while the nickel ions in the present catalyst prepared by the alkoxide technique are hard to be reduced under the same conditions. The fraction of the nickel reduced to metal was determined by measuring the saturation magnetization of Ni in the catalyst. The magnetization would be affected by the nickel particle size,[16] but this effect was ignored here in

calculating the fraction of nickel reduced. The low fraction of nickel metal in the present catalyst suggests that the nickel cations in the catalyst are strongly bound to the Al_2O_3 support. This interaction is due to formation of the Ni–O–Al structure possibly *via* the reaction between cyclic glycolate of nickel and aluminium isopropoxide



In this sense, Ni atoms may be atomically dispersed in the bulk of alumina and hence they are hardly reduced by hydrogen. The fraction of Ni reduced to metal increased gradually with increase in the reduction temperature (see Table 1).

Thus, it was confirmed that the particle size can be controlled by the concentration of Ni in the catalyst and that the particles are well dispersed in an even size level, when the catalyst is prepared by the alkoxide technique. Accordingly, a discussion on the relation between particle size and catalytic activity will be available. The hydrogenation of propene was employed as a model reaction since Ni catalysts are often used for hydrogenation processes. It is well known that catalytic hydrogenation of an olefin accompanies hydrocracking at higher temperatures, so the reaction was carried out at 50 °C where no hydrocracking takes place. The amount of propane formed is in a linear relation with reaction time during the initial 5 or 10 min of reaction. The rate of hydrogenation was estimated from the slope for the initial 5 min. The relation between the catalyst is shown in Fig. 4. It was found that the rate significantly increased when the particle size became smaller than 50 Å. Schwab[17] proposed that catalytic reactions might be divided into two groups; one consists of donor reactions in which the rate determining step involves an electron transfer from the reactant molecule to the catalyst and the other consists of acceptor reactions where the reactant must accept an electron from the catalyst. Hydrogenation belongs to the group of donor reactions so that an electron transfers to the catalyst from the reactant. Since it was reported that electrons in a metal particle will move to the carrier when the particle size is so small,[18] the observation is understandable that the rate of hydrogenation was enhanced when the size of nickel particle was less than 50 Å. Three kinds of nickel atoms may be considered to exist on the surface of particles; one is a nickel atom located on the surface plane of a crystallite and the other two are those on the edge and corner of a crystallite, respectively. The fraction of the atoms located on edges and corners of crystallites is a function of the dimension of the crystallite and the fraction is shown in Fig. 4 on an assumption that the Ni particles are f.c.c. crystallites.[7,8] The turnover number for nickel atom for the hydrogenation is also plotted against particle size in Fig. 4. Both the curves are similar to each other, suggesting that the hydrogenation might taken place over the nickel atoms located on edges and corners of crystallites. There will be a question why the atoms on edges and corners are more active for the hydrogenation. Mott and Davis[19] describe that atoms on edges and corners have two and three dangling bonds, respectively, whereas those located on surface planes have one such bond, and that the total energies (electron plus lattice) of a crystallite are lowered by the interaction of these dangling bonds: $2D^0 \rightarrow D^+ + D^-$, where D^0 is a dangling bond unperturbed, D^+ is a dangling bond from which an electron is released, and D^- is a dangling bond to which an electron has moved. In the present nickel particles, it might be possible that electrons in the dangling bonds of nickel atoms at the edges and corners will transfer to the dangling bonds of the nickel atoms located on surface planes. This will result in an enhancement of the positive character of nickel atoms located on edges and corners, hence the activity for olefin hydrogenation will also be enhanced.

The present authors would like to express their thanks to Drs. J. Tasaki, Y. Murase, and T. Mori at the Japanese Government Industrial Research Institute, Nagoya for the measurement of saturation magnetization and transmission electron micrograph.

(Received March 3, 1983)

The crystal structures of $(pyH)_4[Mo_2O_2S_2(NCS)_6]$ (**1**) (pyH=pyridinium ion) and $(pyH)_4[Mo_2O_3S(NCS)_6]\cdot 2H_2O$ (**2**) have been determined from the diffractometer data. The **1** and **2** structures were refined by the least-squares method to R 0.041 and 0.064 for 2728 and 2349 non-zero reflections respectively. The two structures are isomorphous. Each Mo(V) ion has a distorted octahedral coordination, and two coordination octahedra share a common edge to form a binuclear complex. The binuclear complex contains a mirror plane through two bridging atoms. The two terminal oxo ligands on each Mo(V) are *cis* to each other and *cis* to the bridging oxo or sulfido. The Mo–N(NCS) bond length *trans* to the Mo–O_t (terminal oxo) is *ca.* 0.1 Å longer than the other Mo–N(NCS) bond lengths, showing the large *trans* effect of the O_t ligand.

Although the preparation and X-ray structure of the $(pyH)_4[Mo_2O_4(NCS)_6]\cdot H_2O$ complex with the di-μ-oxo bridge have been reported,[1] no similar complex containing the di-μ-sulfido or μ-oxo-μ-sulfido bridge has yet been prepared. In this paper, we wish to describe the preparation and structures of $(pyH)_4[Mo_2O_2S_2(NCS)_6]$ (**1**) and $(pyH)_4[Mo_2O_3S(NCS)_6]\cdot 2H_2O$ (**2**) and to compare the structures of the two complexes with that of $(pyH)_4[Mo_2O_4(NCS)_6]\cdot H_2O$[1] in connection with the *trans* bond-weekening effects of the terminal oxo, bridging oxo, and bridging sulfido.

Experimental

Preparation of 1 and 2. Complex **1** was prepared by the addition of sodium thiocyanate about six times the molar quantity of the aqua-ion $[Mo_2O_2S_2(H_2O)_6]^{2+}$ in 1 mol dm^{-3} of HCl,[2] followed by the drop-by-drop addition of pyridine (*ca.* one thirtieth of the volume of the aqua-ion solution). After the solution had stood in a refrigerator a couple of days, the red crystals which had deposited were filtered by suction and air-dried. Yield, 85%. Found: N, 14.67; C, 32.51; H, 2.53%. Calcd for $(pyH)_4[Mo_2O_2S_2(NCS)_6]$: N, 14.64; C, 32.64; H, 2.53%.

Complex **2** was prepared similarly by the use of the aqua ion $[Mo_2O_3S(H_2O)_6]^{2+}$ in 1 mol dm^{-3} HCl[3] instead of the $[Mo_2O_2S_2(H_2O)_6]^{2+}$ used for the preparation of **1**. Yield, 70%. Found: N, 14.87; C, 33.29; H, 2.50%. Calcd for $(pyH)_4[Mo_2O_3S(NCS)_6]\cdot 2H_2O$: N, 14.34; C, 31.97; H, 2.89%.

X-Ray-data Collection. Complex **1** crystallizes in the form of red square-prisms. The crystal of **2** is thin red plate. The **1** and **2** crystals were mounted in an arbitrary orientation on a Philips PW1100 automated diffractometer. The PW1100 programs obtained 17 centered reflections for **1** and 15 for **2**, and an orientation matrix for each crystal, and then identified the monoclinic cells for the two crystals. The $P2_1/m$ space group for **1** and **2** was assumed throughout the structure analyses and was confirmed by the successful refinement of the structures. The unit-cell dimensions were refined by the least-squares analyses of the θ values of 36 reflections for **1** and of 38 for **2**. The crystal data and experimental details for **1** and **2** are given in Table 1. The intensity data were collected by the use of Mo $K\alpha$ radiation. During the data collection, three standard reflections were monitored every 4 h to check the stability and orientation of each crystal. Both compounds remained quite stable. Each data set was corrected for Lorenz-polarization effects,[4] but not for absorption.
