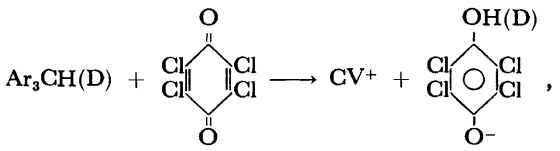
Kinetic Isotope and Pressure Effects in the Reaction of Leucocrystal Violet with Tetracyanoethylene and Chloranil

Norio NISHIMURA* and Takushi MOTOYAMA
Department of Chemistry, School of Science, Okayama University, Tsushima, Okayama 700
(Received March 25, 1983)

The rates of reaction of Leucocrystal Violet (LCV) with chloranil (CA) and tetracyanoethylene (TCNE) were measured, and the kinetic isotope and pressure effects were examined. In the LCV-CA system, a very large isotope effect ($k_H/k_D \approx 11$) was observed, while in the LCV-TCNE system, it was not so large ($k_H/k_D = 5$—6) suggesting the tunnel effect is not substantial. For both systems, the formation of a CT complex in equilibrium with the reactants was observed at low temperatures (<−50 °C). From the rate law, the isotope effect, the electronic and ESR spectra observed during the reaction, and their time dependence, possible reaction processes are proposed.

When hydrogen(H·, H^+, or H^-) undergoes transfer in a rate-determining step, it is sometimes observed that the kinetic isotope effects are larger than those expected from differences in the zero-point energy of the isotopic bonds undergoing fission ($k_H/k_D > 7$). This has been regarded as evidence for the occurrence of quantum-mechanical tunneling, a highly mass-dependent property. Besides abnormally large kinetic isotope effects, isotopic dependence of the Arrhenius pre-exponential factor and curved Arrhenius plots are believed to be criteria of tunneling.

In 1977, Isaacs *et al.*[1] found abnormally large isotope effect ($k_H/k_D = 11.2$) in the reaction between Leucocrystal Violet (LCV) and chloranil (CA), but it levels off at a value near the maximum normal ratio of about 7.5 when the external pressure is raised to 2 kbar. According to them, the external pressure serves to lower the free energy barrier, thus the relative importance of tunneling diminishes with increasing pressure. They considered that the rate-determining step of the reaction involves a direct hydride ion transfer to produce a Crystal Violet cation and a tetrachlorohydroquinone anion(one-step process):



Ar = *p*-NMe_2-C_6H_4-

Indeed, reactions of *N*-benzyl-1,4-dihydronicotinamide and related compounds, recognized as models of dihydronicotinamide coenzymes for biological redox reactions, were believed to involve direct hydride transfer.[2,3] However, Steffens and Chipman[4] presumed, based on the kinetic isotope effects, that these reactions involve a two-step process and the intermediate may be a CT complex. Ohno and Kito,[5] and Fukuzumi and Tanaka[6] demonstrated that a CT complex is really formed as an intermediate product in these reactions.

This study has been undertaken to reexamine the direct hydride transfer mechanism in the LCV-CA system in the hope that similar pressure dependence of the kinetic isotope effect might be observed also in the reaction between LCV and tetracyanoethylene (TCNE).

Experimental

Reagents. LCV(H) was prepared as follows: dried Crystal Violet chloride was mortared in dry tetrahydrofuran and then lithium aluminium hydride powder was added slowly until the purple color of the solution diminished. The preparation was carried out under nitrogen in a dry-box. The product was poured into deoxygenated water and the precipitated Leucocrystal Violet was collected and dried. The LCV was recrystallized from benzene-ethanol mixture to give colorless needles. The same method was used with lithium aluminium deuteride to obtain LCV(D). Deuteration was ascertained by NMR. Commercial TCNE was purified by repeated sublimations. Chloroform of the reagent grade which contains *ca.* 1% ethanol for stabilization, was used as received, since no appreciable kinetic effect was observed compared with freshly distilled chloroform. Other solvents were purified as usual.

Procedures. A high-pressure reaction vessel, which is made of 17-4PH stainless steel and equipped with a water-circulating jacket and a stop-valve, was used. The vessel consists of two compartments, one for sample solutions and the other for reference solvents, with optical windows.

After a solution containing LCV and TCNE, and the solvent had been charged, same pressure was applied on them by a hand-pump through liquid separation pistons. After reading the pressure by a Heise Bourdon gauge, the stop-valve was closed and the vessel was separated from the pump system, and placed in a cell compartment of a Hitachi 105 double-beam spectrophotometer. The reaction was followed by monitoring the Crystal Violet cation (CV^+, $\lambda_{max} = 586$ nm), and the absorbance was recorded. Most of the runs were carried out under the conditions that the pseudo first-order plots could be realized. All runs were carried out in air. The kinetic data were checked by duplicate or triplicate runs.

In order to estimate the partial molar volumes of LCV and Crystal Violet chloride, and the molar volume of bulk Crystal Violet chloride, Ostwald-Sprengel and Weld types of pycnometers were used. By measuring the density of their chloroform solutions at various concentrations, the partial molar volumes at infinite dilution were estimated. Liquid paraffin was used for the determination of the molar volume of bulk Crystal Violet chloride.

Product Analysis. An equimolar mixture of LCV and TCNE in dichloromethane was allowed to stand at room temperature overnight, and the solution was chromato-

graphed on silica gel(Wakogel C-200). Two kinds of Crystal Violet salts (F_1 and F_2) were obtained. F_1: mp 225—227 °C, golden metallic flakes, λ_{max}/nm (ε) in $CHCl_3$, 305(30000), 398(22000), 416(21800), 586(140000); IR(Nujol) 2196 cm^{-1} (C≡N str). F_2: mp 164—166 °C, dark blue powder, λ_{max}/nm in $CHCl_3$: 305, 586; IR (Nujol) 2200 cm^{-1} (C≡N str).

Results

The reaction between LCV and CA in acetonitrile was carried out in a thermostated cell and the spectral change with time in the visible region is shown in Fig. 1. By means of the initial-rate method, the reaction order was confirmed to be first-order with respect to each reactant (Fig. 2). The reaction proceeds, in the initial stage, in accordance with the second-order rate law strictly. Figure 3 shows the Arrhenius plots based on the data of Isaacs *et al.*[1] and ours. The spectral change with time for the reaction between LCV and TCNE in chloroform is shown in Fig. 4. The absorption maxima at 305 and 586 nm are attributed to CV^+. These absorption bands increase with time at the expense of the bands due to TCNE (λ_{max}=266 and 276 nm), the isosbestic point being at 277 nm. Most of the reactions were carried out in excess of TCNE. Under such condition, the plot of $\ln(A_\infty - A_t)$ *versus* time t, where A_∞ and A_t are the absorbance at λ=586 nm at t=∞ and t, gave a straight line. The slope of the line was then plotted against the initial concentration of TCNE as shown in Fig. 5, giving a straight line passing the origin. We can therefore conclude that the overall order of reaction is second order. Similar pseudo-first-order plots were made for the reaction under various pressures (Fig. 6). As seen in Fig. 6, the external pressure accelerates the rate remarkably. In Table 1, the second-order rate constants for the reaction between LCV (H and D) and TCNE at various temperatures and under various pressures are listed. On the basis of the data in the table, the Arrhenius parameters were evaluated and they are given in Table 2. In Fig. 7, the rate constants in the logarithmic scale are plotted against

the external pressures. The solid lines represent the following quadratic regression equation:

$$\ln k_p = a + bp + cp^2. \quad (1)$$

The activation volumes at the atmospheric pressure were estimated according to the following equation:

$$\left(\frac{\partial \ln k_p}{\partial p}\right)_T = -\frac{\Delta V^*}{RT} + \Delta n\kappa_0 \approx b, \quad (2)$$

where Δn is the difference in the number of species between the activated complex and reactants, and κ_0 is the isothermal compressibility of the system ($\kappa_0=1.54\times10^{-9}$ Pa^{-1} for chloroform). In Table 3, the volumes of activation are given. Auxiliary kinetic data in benzene, benzene-toluene and benzene-*p*-xylene binary mixtures are given in Table 4.

Discussion

Reacion of LCV with CA. The maximum absorption at 586 nm (Fig. 1) is assigned to Crystal Violet cations, since the band and its shape agree with

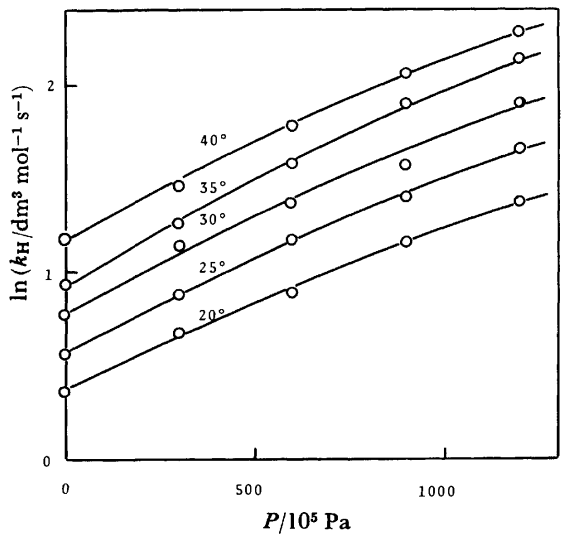

Fig. 7. Pressure dependence of k_H.

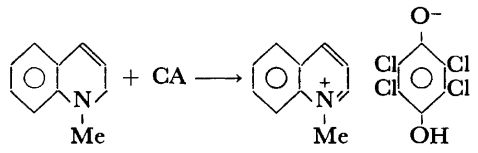
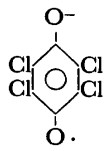
those of an authentic sample. As for the assignment of the band system in the region 400—500 nm with maxima at 448 and 20 nm in acetonitile, there has been a confusion. Braude *et al.*[7] reported that the reaction of 1,2-dihydro-1-methylquinoline with CA can occur only by removal of a hydride ion from the position next to the nitrogen atom, followed by quaternization,



1 **2**

and the salt (**1**+**2**) in an acidic solution has one of its absorption maxima at 452 nm. Hajdu and Sigman[8] followed the rate of reaction between CA and a series of dihydronicotinamides by monitoring the absorption maximum at 448 nm in acetonitrile. They considered that tetrachlorohydroquinone anion **2** is responsible for the band. Very recently, Fukuzumi and Tanaka[6] also reported that in the same system a 1 : 1 CT complex is formed at first as an intermediate product, followed by a hydride transfer to afford **2** which is characterized by the absorption spectrum (λ_{max}=448 nm in acetonitrile).

On the other hand, Kainar and Überle[9] demonstrated that a mixture of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) and CA acetonitrile solutions exhibits spectrum similar to that of CA-Na system in the range 400—500 nm. They considered that the complete transfer of an electron from TMPD to CA takes place to produce radical ions as ascertained by magnetic susceptibility measurements. Foster and Thomson[10] reported the visible absorption spectra for systems of TMPD-halobenzoquinones and considered that the band in question is due to CA semiquinone anion (**3**)



3

Iida[11] and Tsubomura *et al.*[12] also reported that the band can be assigned to **3**. The *g*-value of **3** is reported as 2.0058[13] and 2.0056±0.0002.[14]

When a mixture of LCV and CA acetonitrile solutions was subjected to ESR spectroscopy at room temperature, signals shown in Fig. 8 were recorded. The signal centered at 3337 G† has the *g*-value of 2.0058 in agreement with the reported one. From the above discussion and findings, the band system in the range 400—500 nm can unequivocally be assigned to **3**. The time dependence of the radical concentration is shown in Fig. 9. The radical concentration increases in parallel with the concentration of CV^+ at first, reaches a maximum and then decreases gradually. Therefore we regard **3** as the main product of the reaction.

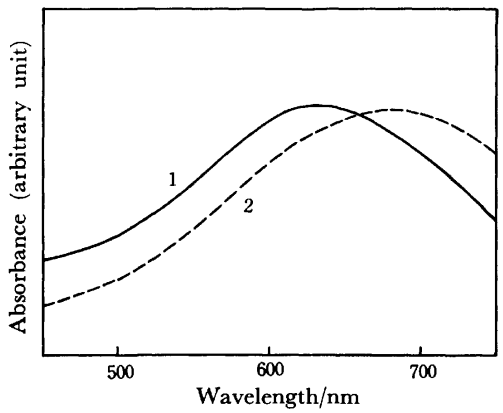

Fig. 10. Absorption spectra appeared when the mixture of LCV and TCNE (1) and LCV and CA (2) in EPA are cooled to ≈77 K.

There is a number of reports on the formation of CT complexes between CA and TCNE as electron acceptors, and bases. Since LCV may be regarded as a base, we expected the formation of CT complexes in our reaction systems. At room temperatures, there was no indication of the formation. However, when the reaction mixtures were cooled to below −50 °C, the solution turned deep blue. The color faded when warmed, and appeared again when cooled. The absorption spectra at ≈77 K are shown in Fig. 10. Judging from the position and the shape these absorption bands could be assigned to outer CT complexes in equilibrium with their components.

Nagakura *et al.*[15] found that an outer complex which is characterized by the absorption band at λ_{max}=560 nm (ε=1250) exists as a stable species in equilibrium with component CA and aniline below 200 K. On the basis of the time delay between the decay of the outer complex and the formation of a product, they further postulated the existence of an inner complex which is a precursor of the product.

Taking these situations into account, together with the substantial isotope effect and the kinetic law, the following alternative reaction schemes may be proposed.

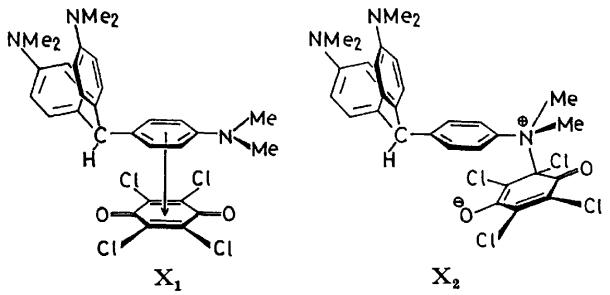
$$LCV + CA \rightleftharpoons X_1 \rightleftharpoons X_2$$
$$X_1 \text{ or } X_2 \xrightarrow{\text{slow}} CV^+ + \mathbf{2}$$

Scheme 1.

$$LCV + CA \rightleftharpoons X_1 \rightleftharpoons X_2$$
$$\searrow^{\text{slow}}$$
$$CV^+ + \mathbf{2}$$

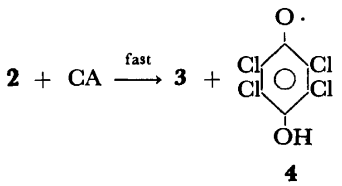
Scheme 2.

where X_1 and X_2 represent outer and inner complexes, respectively and their structures may be as follows:



We have not ascertained the existence of X_2 yet.

If X_1 or X_2 is a precursor of CV^+, the transfer of an electron from the LCV-moiety to the CA-moiety, followed by the hydrogen atom transfer, is more likely than the direct hydride transfer. In Scheme 2, a highly polarized partial bond formation of the type $\equiv C^{\delta+}\cdots H\cdots^{\delta-}O=$ in the transition state may be involved. The remarkable kinetic pressure effect[1] could better be accounted for by this scheme rather than Scheme 1. In any way, the preference and detailed discussion for the reaction mechanism are open to future investigations. Steady-state assumption for **2** could explain the simultaneous formation of CV^+ and **3**.



4

4 ⟶ dimerization, disproportionation

Reaction of LCV with TCNE. As seen in Fig. 4, a very weak band appears in the region λ=350—500 nm.

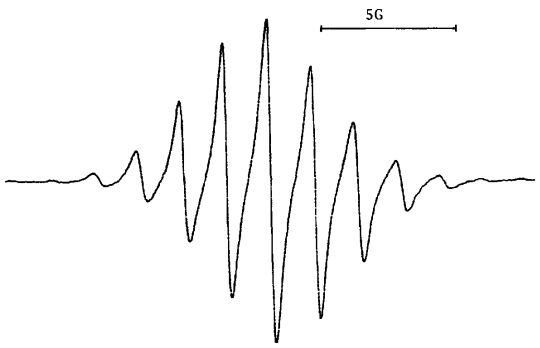


Fig. 11. ESR spectrum of TCNE anion radical.

The band spectrum becomes well-characterized in acetonitrile, and is assigned to TCNE anion radical, since the spectrum coincides with the reported one.[16] This is supported by the appearance of ESR signals when a mixture of LCV and TCNE solutions was subjected to ESR spectroscopy at room temperature (Fig. 11). The spectrum consists of nine lines (and two ^{13}C satellites) with a spacing of 1.6 G, and is assigned to TCNE anion radical, since the spectrum and the splitting constant agree with those reported.[17,18]

As seen in Table 3, the pressure effect on the rate of reaction is remarkable, suggesting also a large polarity change on going from the initial to the transition state in this system.

However, the ratios k_H/k_D in the LCV-TCNE system under various pressures are considerably smaller than those in the LCV-CA system,[1] and no systematic change in the ratio with increasing pressure was observed. The Arrhenius plots are not curved and the isotopic dependences of $\Delta S^{\ddagger}$ and $\Delta V^{\ddagger}$ (Tables 2 and 3) are not substantial. Therefore, we can conclude that the isotopic tunnel effect is, if any, immaterial in this system. As far as we inspected our data and those of Isaacs *et al.*, the reason why the tunnel effect is observed in the LCV-CA system alone has not been clarified.

When the reaction was carried out in benzene, the rate decreased a great deal (Table 4), while the isotope effect is similar to that in $CHCl_3$. The formation of CT complexes involving TCNE and various aromatic compounds are well known. Therefore, the very small rate constants in benzene compared with those in $CHCl_3$ may be attributed to the complex formation rather than the kinetic solvent effects. This is supported by the fact that the rate further decreased in the binary benzene-toluene and benzene-xylene systems in which more stable complexes are formed.[19]

The final electronic spectrum in the visible region for both the LCV-CA and LCV-TCNE systems agreed with the spectrum of authentic Crystal Violet in the case of kinetic runs. Under much more concentrated conditions, two kinds of salts (F_1 and F_2) were obtained (see Experimental section). The spectrum of F_1 involves extra maxima at 398 and 416 nm. Middleton *et al.*[20] reported that 1,1,2,3,3-pentacyano-2-propenide anion (PCP) in aqueous solutions is characterized by the absorption maxima at 393 nm (ε=22600) and 412 nm (ε=22100). Since our data for F_1 coincide with these values, the counter anion of the Crystal Violet cation may be PCP. The structure of F_2 has not been clarified yet.

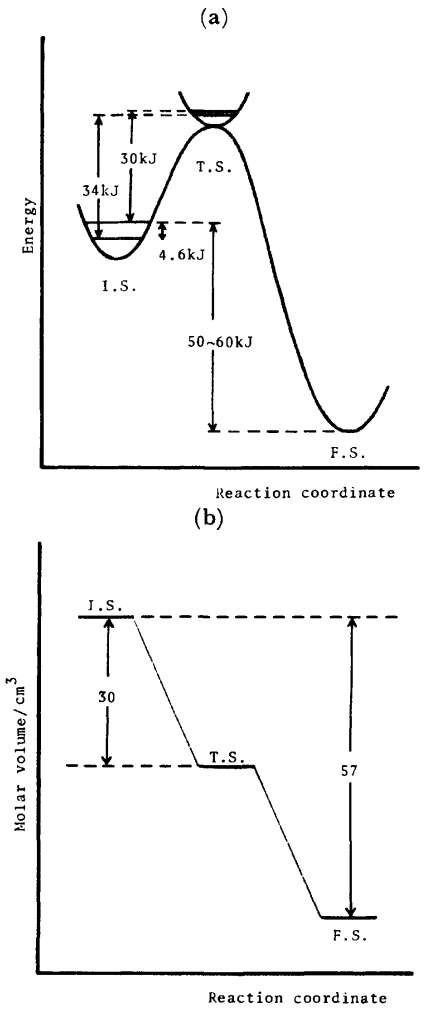

Fig. 12. (a) Energy profile. (b) Volume profile.

Potential and Volume Profiles. We finally wish to draw approximate potential and volume profiles. The zero point energy difference between C-H and C-D stretching vibrations of LCV was estimated to be *ca.* 4.6 kJ on the basis of the data for $CHCl_3$ (ν_{C-H}=3019 cm^{-1}, ν_{C-D}=2256 cm^{-1}). This might be responsible for the difference in the activation energy between the isotopic species (Table 2). Blanch *et al.*[22] studied the proton transfer reaction of 4-nitrophenylnitromethane with pentamethylguanidine to give an ion pair. According to them, the heat of reaction is -59.8 kJ mol^{-1} in acetonitrile and -54.0 kJ mol^{-1} in toluene. From the difference in the activation energy for the forward and backward reactions of *N*-ethyl-*N*-methylaniline with methyl iodide in nitrobenzene, Stewart and Weale[22] estimated the heat of forward reaction as -64.0 kJ mol^{-1}. If the overall heat of reaction in LCV-TCNE system is similar to those observed in perfect charge transfer reactions, it would be -50—-60 kJ mol^{-1}. In Fig. 12 (a), the potential profile for the reaction of LCV with TCNE is shown.

On the other hand, the partial molar volumes of LCV and CV^+ Cl^- in chloroform were estimated to be 349±6 and 320±10 cm^3 mol^{-1}, respectively. These values may be compared with the molar volume of bulk Crystal

Violet, 344.9 cm^3 mol^{-1}. The van der Waals volume of Cl_2 was estimated as 25.7 cm^3 mol^{-1}. The molar volume of Cl_2 may be twice as large as its van der Waals volume.[23] From the density data,[24] the partial molar volume of HCl in 40% aqueous solution was estimated as 23 cm^3 mol^{-1}. If we tentatively use these values, the volume change for the following reaction can be estimated as $\Delta V = -57$ cm^3.

$$\text{LCV} + \text{Cl}_2 \xrightarrow{\Delta\overline{V}} \text{CV}^+\text{Cl}^- + \text{HCl}$$

It is noted that the estimated volume change is similar to those observed in Menschutkin reactions (50—60 cm^3).[25] The volume of activation for the LCV-TCNE reaction are about -30 cm^3 mol^{-1} for both isotopic species (Table 3), indicating that the transition state is considerably polar. It was reported that in the LCV(H or D)-CA system, the volumes of activation in acetonitrile are -25(H) and -35(D) cm^3 mol^{-1}, respectively, the difference having been ascribed to the tunnel effect.[1] By using the above values, we can draw the volume profile for a reaction involving the nominal transfer of a hydride ion from LCV to a base, as shown in Fig. 12(b).

The authors wish to express their thanks to Mr. M. Kohno (JEOL) for the ESR measurements.

Lithium Salt Effects on Extractions of 15-Crown-5, 18-Crown-6, or Their Silver(I) Complexes as Picrates

Yuko HASEGAWA,* Takahisa NAKANO, Yoshihiro ODORI, and Yūkō ISHIKAWA
Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received May 18, 1983)

The extractions of 15-crown-5, 18-crown-6, or their silver(I) or lithium(I) complexes as picrates from lithium salt solutions into chloroform have been studied at 25 °C. The extractions of these crown ethers were impaired by an increase in the lithium perchlorate or nitrate concentration. A small salting-out effect was observed in the presence of lithium chloride. The extraction of silver(I) was also impaired by the addition of lithium perchlorate or nitrate. In the lower-concentration region of the lithium salts, the extraction of silver(I) was affected more markedly than that of crown ether itself.

The extraction of metal ions with crown ethers and anions has been measured under uncontrolled ionic media, although the extraction from constant ionic media should be useful in keeping the activity coefficients of all species constant. This fact is mainly caused by the facts that the extraction with crown ethers has been measured in rather dilute solutions, and that such suitable background salts as sodium perchlorate, which is employed in most extraction systems, can not be used because any cations may interact with the crown ethers.

However, information on the effects of salt on the extraction is necessary to treat the data quantitatively or to attempt the extraction and separation of trace elements such as the uranyl ion from seawater or concentrated salt solutions.

Recently, Kolthoff has made a preliminary report on the effect of salt on the extraction into dichloromethane of 18C6 (18-crown-6) and of the ion pair between the potassium ion complexed with the ether and the picrate anion.[1] According to his report, the extraction of 18C6 increased in the presence of lithium chloride, while the extraction of the complexed potassium ion decreased.

The present paper will describe the effect of lithium nitrate on the extraction of 15C5(15-crown-5), B15C5 (benzo-15-crown-5), 18C6, and DB18C6 (dibenzo-18-crown-6) and will extend to the effects of such anions as chloride and perchlorate ions on the extraction of 15C5 and 18C6. The effects of salt on the extraction of crown ether itself will be compared with the effect on the extraction of an ion pair consisting of silver(I) or lithium(I), a crown ether, and a picrate ion.

Experimental

Reagents. The lithium chloride and nitrate were recrystallized from water. The lithium perchlorate was prepared from lithium carbonate and perchloric acid and was then recrystallized from water. The concentration of the stock solutions, prepared by dissolving the salts in deionized water, was determined from the balance between the weight of an aliquot of each stock solution and that after it had dried up. The chloroform was washed with deionized water just before use. The benzo-15-crown-5 and DB18C6 were recrystallized from heptane and benzene respectively. The other reagents were used without further purification. The concentration of 15C5 or 18C6 was checked from the balance between the weight of the solution and that after it had dried up.

Procedures. Distribution constants of crown ethers: a portion of a salt stock solution at a certain concentration between 0 and 3 M (M=mol dm^{-3}) and a certain amount of a 15C5 or 18C6 aqueous solution were placed in a stoppered glass tube, together with chloroform, agitated mechanically for 1 h, and centrifuged. Then, a portion of each phase was transferred into another glass tube containing lithium dipicrylamide (7×10^{-4} M), a potassium chloride aqueous solution for 18C6 or a sodium chloride solution for 15C5, and a given volume of chloroform. After both phases had attained distribution equilibria, the absorbance of each chloroform phase was measured at 460 nm. Lambert-Beer's law holds to at least 2×10^{-5} M for 18C6 and 4×10^{-5} M for 15C5.

The distribution constant of a crown ether was calculated from the ratio of the total concentration between the two phases:

$$K_D = [E]_o/[E], \quad (1)$$

where E denotes crown ethers and where the subscript "o" and the lack of a subscript denote the organic phase and the aqueous phase respectively.

The distribution constant of B15C5 or DB18C6 was determined in a similar way except that we then employed the chloroform solution and the concentrations in the two phases were determined by measuring the absorption at 275 nm directly.

Distribution ratio of Ag^I or Li^I: Silver nitrate, lithium picrate, 15C5, or 18C6, and various amounts of lithium nitrate or perchlorate were placed in a stoppered glass tube together with an equal volume of chloroform. The two phases were then agitated vigorously. The concentration of silver(I) distributed between the two phases was determined by means of atomic absorption spectrometry. The extraction with DB18C6 was measured in a similar way except that we then used a chloroform solution containing DB18C6. The amount of lithium(I) extracted into the organic phases was measured by means of emission spectrometry. The distribution ratio of silver(I) or lithium(I), D, was defined as:

$$D = [M(I)]_o/[M(I)]. \quad (2)$$

Results and Discussion

Effect of Lithium Salts on the Distribution Constants of Crown Ethers. The distribution constants of crown ethers between water and chloroform, K_{D0}, are listed in Table 1. Figure 1 shows the change in the distribution constants (K_D) of 15C5, B15C5, 18C6, and DB18C6 as a function of the lithium nitrate concentration when the distribution constant (K_{D0}) between water and chloroform was employed as a reference (K_D/K_{D0}). The introduction of a benzene ring into crown

DB18C6	3.9[a)]	3.3[a)]
15C5	0.9	4.4
B15C5	2.4	3.5[b)]

a) Taken from Ref. 2. b) Taken from Ref. 3.

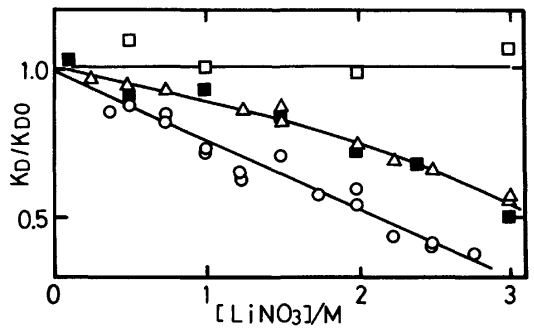

Fig. 1. The influence of $LiNO_3$ on the change in the distribution constant of 15C5 (○), 18C6 (△), DB18C6 (□), and B15C5 (■) when the distribution constant of each crown ether obtained from water was employed as a reference.
The total concentration of crown ether employed: 3.8×10^{-4} M (15C5), 1×10^{-4} M (18C6), 3×10^{-2} M (B15C5), and 1.8×10^{-2} M (DB18C6).

ether seems to lessen the salt effect. The different basicity of each crown ether would be one of the reasons why the effects of salt on the extraction of different crown ethers are not similar, as was suggested by Long and McDevit[4] with reference to the salt effect on simple molecules in aqueous solutions. Actually, the fact that the distribution constant of 15C5 changes more than that of B15C5 may be explained simply in terms of the higher basicity of 15C5. However, the extraction of 15C5 seems to be affected more markedly by the salt than that of 18C6, although 18C6 should be a little more basic than 15C5. If the difference in the effects of salt on different crown ethers is caused by the complexation of the ethers with the lithium ion in the background salt, the use of a more hydrophobic anion as a counter ion should improve the extraction. Figure 2-a shows the ratio of the distribution constants of 15C5 and 18C6 obtained from a salt solution to that of one obtained from water as a function of the lithium salt concentration. As may be seen from the figure, the anion effect does not seem to support the above expectation; *e.g.*, the value of the distribution ratio of 15C5 in the presence of 1 M lithium perchlorate is smaller than one-half the value of the distribution ratio in the absence of the salt, and in 2 M lithium perchlorate the value of the distribution ratio is only 20% of the value without the salt, while the presence of lithium chloride does not change the constant, although a rather large salting-out effect with lithium chloride was reported[1] (*e.g.*, the

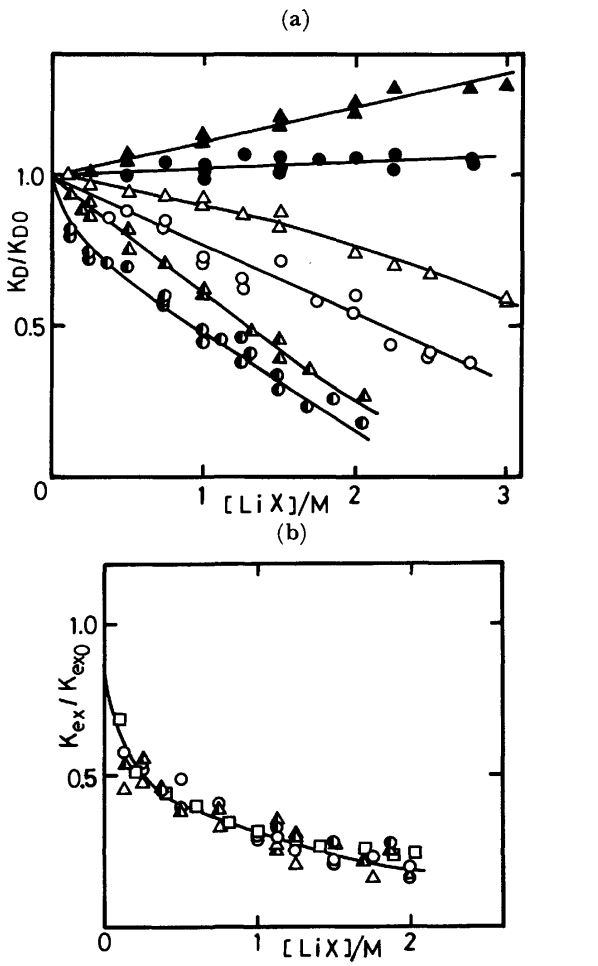

Fig. 2. Change in the distribution constant of crown ethers (denoted in Eq. 1) and the extraction constant of Ag^I with picrate ion and the crown ether (Eq. 5) by an addition of lithium chloride (closed symbols), nitrate (open symbols), or perchlorate (semiclosed symbols).
The K_{D0} and K_{ex_0} are listed in Table 1.

Aq phase: lithium salt solutions containing Ag^I of 5×10^{-5} M, 15C5 (circles) or 18C6 (triangles) of 1.1×10^{-3} M and 9.4×10^{-3} M lithium picrate. Org phase: $CHCl_3$ for 15C5 and 18C6 or $CHCl_3$ containing DB18C6 (squares) of 2.5×10^{-3} M.

distribution constant of 18C6 between water and dichloromethane, 4.5, increased to 7.4 even upon the addition of lithium chloride of only 0.4 M).

The tendency of the anion effect on the distribution constants of crown ethers is similar to that on the aqueous solutions of many nonelectrolytes, which was comprehensively reviewed by Long and McDevit.[4] The anion effect may not, however, be quantitatively explained by their theory, since they indicated that the theory is essentially valid only for nonpolar nonelectrolytes. They reported that the order of anions which exert greater salting-out effects on nonelectrolytes in aqueous solutions is in the sequence of $Cl^->NO_3^->ClO_4^-$.

The order of destroying the water structure by salt anions was also reported to be $ClO_4^->NO_3^->Cl^-$ on the basis of the IR measurements of various aqueous solutions.[5] Therefore, the order of anions whose presence leads to greater salting-in effects in the present extraction system, $ClO_4^->NO_3^->Cl^-$, seems reasonable.

Furthermore, it was confirmed by measuring the lithium(I) concentration in the organic phases that the increase in the extraction of the crown ethers is not caused by the extraction of the lithium ion complexed with crown ethers: when the concentrations of lithium(I) extracted with 15C5 or 18C6 into chloroform from lithium salt solutions were measured, it was observed that the concentrations increased with the increase in the salt concentration in the sequence of $ClO_4^->NO_3^->Cl^-$, as is generally observed in the extraction system of ion pairs. On the other hand, lithium(I) was not extracted without crown ether. Therefore, strictly speaking, the concentration ratio of crown ethers between organic and aqueous phases should be described as $D_E=([E]_o+[LiEX]_o)/[E]$ instead of Eq. 1. However, since even the concentration of lithium(I) in chloroform extracted from a 2 M lithium perchlorate solution containing 2.5×10^{-2} M 18C6 was less than 2×10^{-3} M, the proportion of $(LiE)^+ClO_4^-$ to the total crown ether in the organic phase would be 10% at a maximum under the present experimental conditions. Accordingly, the concentration ratio of the crown ether may be substantially represented as Eq. 1, and it may be concluded that the change in the distribution ratio of crown ether with the increase in the salt concentration is due to the change in the activity coefficients of crown ether, but not to the extraction of the lithium(I) complexed with crown ethers.

A simple method to determine activity coefficients using the solvent extraction method has previously been reported;[4,6] that is, the distribution constants of crown ethers, as represented by activity units, are always identical, as obtained either from water or from a salt solution:

$$\frac{\{E\}_o}{\{E\}}=\frac{\gamma_o[E]_o}{\gamma[E]}=\frac{\gamma_{0,o}[E]_{0,o}}{\gamma_0[E]_0}, \quad (3)$$

where γ or [E] denotes a value obtained from a lithium salt solution and where the subscript "0" denotes a value obtained from water. Since γ_o can be essentially regarded as $\gamma_{0,o}$ when the crown ether concentration in the organic phases is not high, $\gamma/\gamma_0=K_D/K_{D0}$. Therefore, the ratio of K_D to K_{D0} in Fig. 2-a should be nothing but the change in the activity coefficients of crown ether in lithium salt solutions at various concentrations.

Effect of the Salts on Extraction of the Ion Pair of Ag^I or Li^I with the Crown Ethers and the Picrate Ion. When silver(I) is distributed between aqueous solutions containing a crown ether and a picrate ion and chloroform, the extraction equilibrium and the extraction constant can be described as:

$$M^+ + E_{(o)} + A^- \rightleftarrows ME^+A^-_{(o)},$$

$$K_{ex}=\frac{[ME^+A^-]_o}{[M^+][E]_o[A^-]}, \quad (4)$$

$$=D[E]_o^{-1}[A^-]^{-1}, \quad (5)$$

where $[E]_o=[E]_{total}/(1+1/K_D)$ and the values of K_D at the different salt concentrations were obtained from Fig. 2-a.

Figure 2-b shows the change in the extraction constant of silver(I) as a function of the concentration of the background lithium salt when the extraction constant obtained from an aqueous solution containing no lithium salt was employed as the reference. The extraction of silver(I) also lessens upon the addition of lithium salts. It does not seem that there is a big difference with the sort of salt added or the sort of crown ether used as an extractant, although the extraction of the crown ether itself is affected by them, as may be seen in Fig. 2-a. Moreover, it is also observed that the addition of a small amount of the salt leads to a larger change in the extraction of silver(I) than in the extraction of the crown ethers. For example, the rate of the change in the extraction of the crown ethers to the extraction from a no-salt aqueous solution is only 5—20% upon the addition of the salts of 0.3 M, while that of silver(I) may be more than 50%.

The extraction constants of lithium(I) are plotted as a function of the salt concentration in Fig. 3. The extraction constants were calculated by using Eq. 5. The extraction constants of lithium(I) do not seem to change greatly with an increase in the salt concentration or with the sort of salt. The extraction with 18C6 would, though, be a little better than that with 15C5. The distribution ratio in the absence of a lithium salt such as nitrate or perchlorate could not be determined, because the amount of lithium(I) extracted into chloroform was too small to be determined.

As has been mentioned above, the salting-in effect with background salts on the extraction of the ion pairs can not be explained in terms of the decrease in the crown ether concentration which is effective in forming extractable complexes in aqueous phases. The different salt effect on the extraction of silver(I) from that of lithium(I) may suggest that cations may be affected by

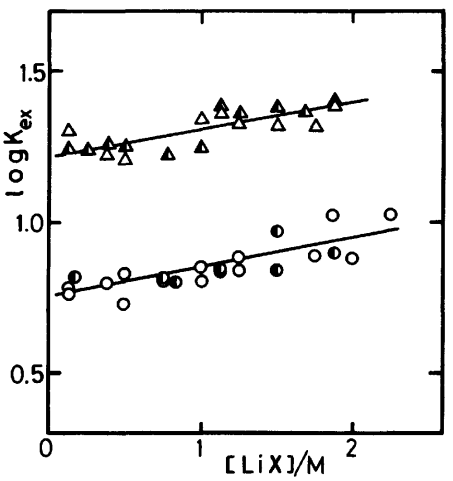

Fig. 3. The influence of lithium nitrate or perchlorate on the extraction constant of Li^I with 18C6 or 15C5 and picrate ion as a function of lithium salt concentration.
All symbols are the same in Fig. 2. The log D was around −4.

the background salt, because picrate ion is common to these systems. Besides, a metal ion trapped in a crown ether would not be as greatly affected as an untrapped metal ion. Salt effects on the extraction of an ion pair would thus be caused by a complex combination of many factors. Further information will be necessary before a detailed discussion of the salt effects on the ion pair extraction will become possible.

The authors wish to thank Professor Tatsuya Sekine of Science University of Tokyo for his valuable discussion. They would also like to thank Mr. Mitsuhiko Kase for his experimental aid.

Decrease in the Quantum Efficiency of a Cadmium Sulfide Photoanode Due to Sulfur Deposition. Determination of Quantum Efficiency by Temperature Measurement

Akira FUJISHIMA,* Tian-kai LI,† Yau-ning ZHU,† Guo-ding ZHOU,† and Xue-ping LI†

(Received June 23, 1983)

CdS photoelectrodes dissolve during photoanode reactions in a supporting electrolyte solution, and the quantum efficiency changes due to sulfur deposition. Temperature measurement technique has been used in this work to determine the quantum efficiency of the CdS photoelectrode. It has been found that decreases in the quantum efficiency can be monitored easily by this method.

A number of photoelectrochemical cells based on semiconductor electrodes for the purpose of converting solar energy either to chemical energy (*e.g.* the photodecomposition of water) or to electrical energy have been reported.[1-3] Most investigations to date have focused on the more familiar semiconductor compounds, *e.g.* Si, GaAs, GaP, ZnO, CdS, and TiO_2. Stable electrodes, such as TiO_2, have a large bandgap $Eg \geqslant 3$ eV, while materials with a smaller bandgap, such as CdS, tend to be unstable.

In the case of a CdS photocell, the electrode itself can be oxidized by photogenerated positive holes, so that the Cd^{2+} ions dissolve into the solution and atomic sulfur is deposited onto the electrode surface.[4] Hence, the photocurrent and the quantum efficiency of the electrochemical photocell dacay rapidly with time due to the filtering effect of the deposited sulfur.

The energy conversion efficiencies and quantum effiiencies of electrochemical photocells are very important factors in the effective utilization of solar energy. Recently Fujishima *et al.*[5] used a new method to measure the temperature change on a semiconductor electrode during photoelectrochemical reaction for determining the intrinsic quantum efficiency of the photoelectrochemical cell. When the semiconductor electrode is illuminated with a monochromatic light pulse having an energy E, with an average absorbed intensity I for a time t, consideration of the energy balance within the semiconductor photoelectrode in the limiting photocurrent region will result in the equation:

$$E\frac{\Delta T}{\Delta T^\circ} = \frac{Q_{sc}+T\Delta S}{It} + \eta e(V-V_{fb}), \qquad (1)$$

where ΔT is temperature change of the semiconductor surface; ΔT°, temperature change of the semiconductor surface in the open circuit; ΔS, entropy change for the semiconductor electrode reaction; Q_{sc}, heat evolved in the semiconductor *via* recombination and radiationless processes; η, quantum efficiency of photoelectrode reaction; V, applied potential *vs.* reference electrode; V_{fb}, flatband potential *vs.* reference electrode.

Therefore, under constant conditions of illumination (*i.e.* EIt held constant) a plot of $E\frac{\Delta T}{\Delta T^\circ}$ against $(V-V_{fb})$[5,6] yields the quantum efficiency η from the slope of the straight line and the loss term, $(Q_{sc}+T\Delta S)/It$, is obtained from the intercept of the $E\frac{\Delta T}{\Delta T^\circ}$ axis at $V=V_{fb}$.

To understand the quantum efficiency obtained from the relationship between temperature change and applied potential, two model cases are shown in Fig. 1. When $\eta=1.0$ the slope of $E\frac{\Delta T}{\Delta T^\circ}$ against V should be 1.0, since all the electrons excited into the conduction band by light irradiation move from the surface into the bulk of the semiconductor through the space charge layer generating heat. When $\eta=0.5$, the slope should be 0.5, since half of the excited electrons are recombined with the holes in the surface region.

In this study we used this method for measuring the change in the quantum efficiency of the photoelectrochemical reaction of the CdS photocell because of its great simplicity and the fact that there is no need to count the number of photons irradiated and/or absorbed.

Experimental

Electrode Preparation. The resistivity of the *n*-CdS single crystal used was 0.4 Ω cm, and the carrier concentration was 6×10^{16} cm^{-3}. The ohmic contact was made by rubbing In-Ga alloy on the back surface of the crystal and then attaching a copper wire to the contact with conducting Ag epoxy. The back and sides of the crystal were insulated and mounted on a flat piece of glass attached to a glass rod with epoxy resin.

Thermistors (Shibaura Electronics, Model BSB4-41A; nominal resistance 4 kΩ, sensitivity 0.052 °C/Ω), having a time constant 0.4 s when immersed in still water were used in matched pairs, in a differential arrangement with one held against the front surface of the semiconductor electrode and the other placed behind the electrode but not touching it.[5] The cell was carefully positioned so that the monochromatic light beam struck the electrode but none of the thermistors.

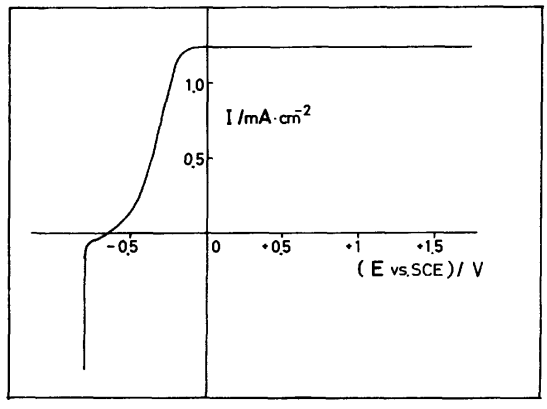

Fig. 4. Photocurrent *vs.* potential of CdS single crystal electrode in 0.1 M Na_2SO_3–0.2 M Na_2SO_4.

The CdS electrode was polished with sandpaper and etched for 10 s in concentrated HCl prior to use.

Apparatus. Figure 2 shows a block diagram of the experimental apparatus. The light source used was a 500 W Xenon lamp (Type SQ500) in an Ushio Model UI-501C lamp housing. Other apparatus included a lens to focus the light beam, a shutter to fix the irradiation period, and an interference filter (Koshin Kogaku) to select the wavelength of the exciting light.

Current-potential and current-time curves were measured under potentiostatic conditions with a Type HDV-7 potentiostat and Type KS-1 single scanner. These curves were displayed on an X-Y recorder (Type L23-24).

The electrochemical cell was a conventional three-electrode cell with a saturated calomel electrode (SCE) as the reference electrode and a Pt plate counter electrode.

All chemicals were of reagent grade and used without further purification.

Procedure. Figure 3 shows the experimental procedure. A photothermal experiment on surface-fresh *n*-CdS photoelectrode in 0.1 M Na_2SO_3–0.2 M Na_2SO_4 (1 M=

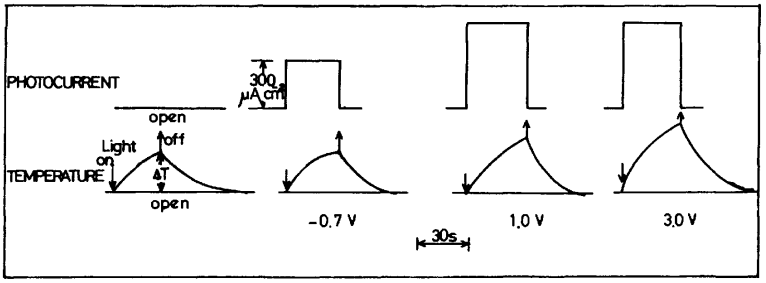

Fig. 5. Change in temperature *vs.* time (bottom) and anodic photocurrent *vs.* time (top) of the CdS anode in 0.1 M Na_2SO_3–0.2 M Na_2SO_4.

1 mol dm^{-3}) was first carried out according to the method reported.[5] The photothermal response and the saturated photocurrent, 1.15 mA/cm^2, were obtained. Then the electrode was put in 0.2 M Na_2SO_4 and the current-time was measured. The photocurrent gradually decreased because of sulfur deposition on the surface of the photoelectrode, and when it had decreased to a certain value (*e.g.* 1.0 mA/cm^2), the experiment was stopped. The electrode was immediately replaced in the 0.1 M Na_2SO_3–0.2 M Na_2SO_4 and the corresponding photothermal response was obtained. After that, the experiment was carried out alternately in the two solutions until the saturated photocurrent decreased to the lowest value in the experiment (*e.g.* 0.55 mA/cm^2).

Results are given for monochromatic irradiation at wavelengths shorter than that corresponding to the bandgap energy (*e.g.* 480 nm for CdS). Photothermal responses were obtained for the photoelectrode during anodic polarization, and under open circuit conditions in the electrolyte solutions. A change in temperature of the electrode caused a resistive change in the thermistor and produced a voltage imbalance in the DC bridge. The corresponding current and temperature changes were then plotted as a function of applied potential.

Results and Discussion

Figure 4 shows the current-potential characteristics of the CdS single crystal photoanode by using the 480 nm interference filter in 0.1 M Na_2SO_3–0.2 M Na_2SO_4 solution. In the dark, anodic photocurrent does not appear, but under illumination it does. The onset potential of the anodic photocurrent corresponds to the flatband potential of the photoanode, −0.75 V. The saturated photocurrent is stabilized at about 1.2 mA/cm^2.

The quantum efficiency of the CdS electrode was determined by temperature measurement in 0.1 M Na_2SO_3–0.2 M Na_2SO_4. Figure 5 shows the time dependency of changes in photocurrent and temperature of the CdS photoanode at each applied potential. Temperature increased when the light was turned on, and decreased when it was turned off. The relationship of temperature changes to applied potential is given in Fig. 6. The slope for CdS without deposited sulfur in the saturated photocurrent regions was approximately 1, nearly the same as reported by Maeda *et al.*,[6] but the slope decreased as sulfur was deposited on the electrode surface. In the absence of the reducing agent (Na_2SO_3) in the electrolyte solution (0.2 M Na_2SO_4), the photocurrent at the CdS photo-

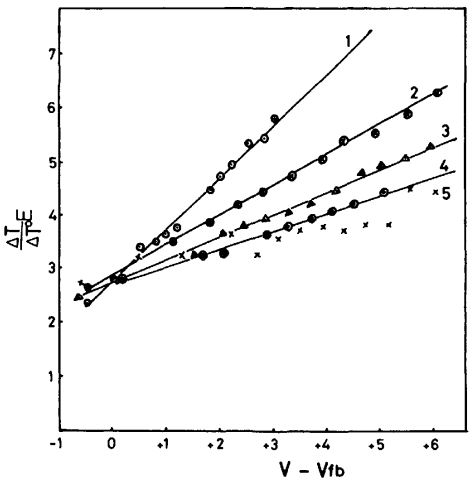

Fig. 6. Temperature change *vs.* potential of CdS single crystal electrode.
1: On fresh surface, 2—5: On surfaces with varying amounts of sulfur deposition. The photocurrents were observed in Na_2SO_3 solution. Therefore their values were almost constant as shown in dotted lines in Fig. 3; 1: 1.29(mA/cm^2), 2: 0.77, 3: 0.49, 4: 0.46, 5: 0.2—0.3

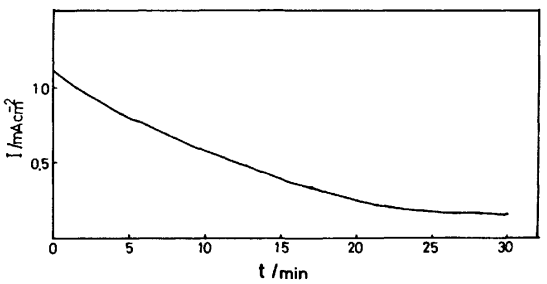

Fig. 7. Photocurrent *vs.* time of exposure of CdS single crystal electrode in 0.2 M Na_2SO_4.

anode resulted in the decomposition of the CdS according to the equation,[7]

$$CdS + 2p^+ \longrightarrow Cd^{2+} + S$$

and sulfur was deposited on the surface of the photoanode. Because the sulfur layer absorbed light, the intensity of the light penetrating it to impinge on the CdS single crystal decreased, so that the saturated photocurrent was reduced. The photocurrent decreased with the amount of sulfur, and with the time of

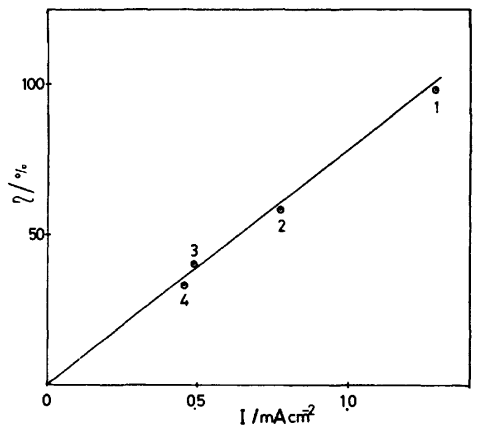

Fig. 8. Quantum efficiency *vs.* photocurrent of the CdS single crystal electrode. Number 1—4 was the same as Fig. 6.

exposure as shown in Fig. 7. Thus the saturated photocurrent corresponds to the amount of deposited sulfur. As the CdS photoanode decomposed in 0.2 M Na_2SO_4 to produce varying amounts of sulfur, a family of $E\frac{\Delta T}{\Delta T^\circ}$ *vs.* potential curves may be plotted (see Fig. 6). These lines corresponding to the amounts of sulfur deposited, remained linear in the saturated photocurrent regions, but their slopes varied with photocurrent. However, it was found at curve 5 in Fig. 6 that points at 0.35 mA did not form a straight line. Moreover, the saturated photocurrent increased during temperature measurement from 0.35 mA to 0.50 mA. It is suggested that in this case the deposited sulfur may not have adhered so strongly to the CdS surface, or may have broken off in part. A plot was made of slope, *i.e.*, quantum efficiency η, *vs.* photocurrent i, and it was found that η was also linear with i, as shown in Fig. 8. We assumed that it was the absorption of light by the deposited sulfur that resulted in the change of slope, since if the deposition layer was reflective, as for the reason of decrease of photocurrent, the slope would have been constant.

If the deposition layer adheres fully to the electrode surface, the amount of deposited sulfur, and presumably the average thickness of deposition layer will, in accordance with Faraday's law, be proportional to the number of coulombs. Therefore, the quantum efficiency of photocurrent will decreare with the number of coulombs flowed for surfur deposition. Actually we observed the decrease of quantum efficiency with the charge flowed for sulfur deposition.

This experiment indicates that the temperature measurement is also applicable to CdS photoanode on which sulfur is deposited.

The authors wish to express their thanks to Academia Sinica, People's Republic of China.

Infrared Intensities in Methyl Chloride. II. Binary Overtone and Combination Bands

Shigeo KONDO,* Yoshinori KOGA, Taisuke NAKANAGA, and Shinnosuke SAËKI
National Chemical Laboratory for Industry, Tsukuba Research Center, Yatabe, Ibaraki 305
(Received June 25, 1983)

Infrared intensities of binary overtones and combinations of CH_3Cl and CD_3Cl molecules have been measured by the pressure broadening technique. Simplified formulas for the intensities of binary overtone and combination bands of symmetric top molecules were given. Contribution from the mechanical anharmonicity was calculated by use of these equations. Contribution from the electric anharmonicity was estimated by *ab initio* MO method (4-31 G*). The calculated intensities were compared with the observed values and discussed.

In Part I, we have analyzed the fundamental band intensities of CH_3Cl and CD_3Cl molecules to determine the values of the first derivatives of the dipole moment with respect to the normal coordinates ($\partial \boldsymbol{P}/\partial Q_i$).[1] The result of Part I is applied in the present study to analyze the intensities of binary overtone and combination bands of this molecule. The general expressions have been developed for the absorption intensities of two quantumn transitions in polyatomic molecules using the contact transformation method.[2-4] Up to the second order of approximation, the transition moments of the binary overtone and combination bands can be calculated if both the first and second partial derivatives of the molecular dipole moment with respect to the normal coordinates together with the cubic normal coordinate force constants are known. In Part I, we have determined the values of the first derivatives of the dipole moment including their signs. Furthermore the cubic force constants have also been obtained by the present authors[5] through the analysis of the vibration-rotation interaction constants. Therefore, it may be possible to gain some information on the values of the second derivatives of the dipole moment from the intensities of the two quantumn transitions.

The present paper reports the result of such analysis for methyl chloride molecule.

Theoretical

The dipole moment function of a molecule is expanded as a Taylor series in the dimensionless normal coordinates and is written as,

$$\boldsymbol{P} = \boldsymbol{P}_0 + \sum_r \boldsymbol{P}_r q_r + (1/2)\sum_{rs} \boldsymbol{P}_{rs} q_r q_s + \cdots, \quad (1)$$

where $\boldsymbol{P}_r$ stands for $(\partial \boldsymbol{P}/\partial q_r)$, $\boldsymbol{P}_{rs}$ for $(\partial^2 \boldsymbol{P}/\partial q_r \partial q_s)$, *etc.*[3] On the other hand, the potential function may also be expanded in dimensionless normal coordinates to give:

$$V/hc = (1/2)\sum_r \omega_r q_r^2 + (1/6)\sum_{rst} \varphi_{rst} q_r q_s q_t + \cdots, \quad (2)$$

where ω_r is rth normal frequency and φ_{rst} is a cubic force constant.[6]

In order to evaluate matrix elements of the dipole moment operator for anharmonic vibrational wave functions, we may use a contact transformation, T, to obtain,

$$\boldsymbol{P}' = T\boldsymbol{P}T^{-1}, \quad (3)$$

where

$$T = \exp(i\lambda S). \quad (4)$$

All details of the contact transformation calculations are given in Refs. 2, 3, and 4, and are not repeated here.

Then, according to Overend,[4] the integrated intensities of binary combination bands may be expressed by the following equation:

$$A_{ss'} = (8\pi^3 N/3hc)(\omega_s + \omega_{s'}) d_f (Q_{ss'})^2 \times Z_s Z_{s'} [1 - \exp\{-\beta(\omega_s + \omega_{s'})\}], \quad (5a)$$

where

$$Q_{ss'} = |\langle v_s = v_{s'} = 0 | \boldsymbol{P}' | v_s = v_{s'} = 1 \rangle|. \quad (5b)$$

Similarly, for binary overtone bands,

$$A_{ss} = (8\pi^3 N/3hc)(2\omega_s) d_f (Q_{ss})^2 Z_s^2 \{1 - \exp(-2\beta\omega_s)\}, \quad (6a)$$

where

$$Q_{ss} = |\langle v_s = 0 | \boldsymbol{P}' | v_s = 2 \rangle|. \quad (6b)$$

Here, N is Avogadro's number, c is the velocity of light, h is Plank's constant, ω_s is the sth normal frequency, d_f is the degeneracy of the upper vibrational state, β is $1/kT$, Z_s is the partition function for the sth normal vibration, $Z_s = 1/\{1 - \exp(-\beta\omega_s)\}$, and $\boldsymbol{P}'$ is the transformed molecular dipole moment.

By substituting appropriate expressions for the transition moments, Q_{ss} and $Q_{ss'}$, we can also use these equations for the absorption intensities of different kind of two quantumn transitions of symmetric top molecules. The method of evaluating the transition moments was shown by Overend.[7] The result is as follows:

$$Q_{ss}^z = (1/2\sqrt{2})[P_{ss}^z + \sum_{s'} P_{s'}^z \varphi_{sss'} \omega_{s'}/(4\omega_s^2 - \omega_{s'}^2)], \quad (7)$$

$$Q_{ss'}^z = (1/2)[P_{ss'}^z + \sum_{s''} P_{s''}^z \varphi_{ss's''} \omega_{s''}/\{(\omega_s + \omega_{s'})^2 - \omega_{s''}^2\}], \quad (8)$$

$$Q_{st}^x = (1/2)[P_{st}^x + \sum_{t'} P_{t'}^x \varphi_{stt'} \omega_{t'}/\{(\omega_s + \omega_t)^2 - \omega_{t'}^2\}], \quad (9)$$

$$Q_{tt}^z = (1/2)[P_{tt}^z + \sum_s P_s^z \varphi_{tts} \omega_s/(4\omega_t^2 - \omega_s^2)], \quad (10)$$

$$Q_{tt}^x = (1/2)[P_{tt}^x + \sum_{t'} P_{t'}^x \varphi_{ttt'} \omega_{t'}/(4\omega_t^2 - \omega_{t'}^2)], \quad (11)$$

$$Q_{tt'}^z = (1/\sqrt{2})[P_{tt'}^z + \sum_s P_s^z \varphi_{tt's} \omega_s/\{(\omega_t + \omega_{t'})^2 - \omega_s^2\}], \quad (12)$$

$$Q^{x}_{tt'} = (1/\sqrt{2})[P^{x}_{tt'} + \sum_{t''} P^{x}_{t''}\varphi_{tt't''}\omega_{t''}/ \{(\omega_t+\omega_{t'})^2-\omega_{t''}^2\}]. \quad (13)$$

In these equations, all of the summations are unrestricted, so that $\Sigma_{s'}$ includes the term with $s'=s$ and $\Sigma_{t'}$ includes the term with $t'=t$, *etc.* However, the index s runs only over nondegenerate modes and the index t runs only over degenerate modes. The numerical subscripts on t for the other dipole moment expansion coefficients are as follows; $P^{x}_{t}=P^{x}_{ta}=P^{y}_{tb}$, $P^{x}_{tt'}=P^{z}_{tat'a}=P^{z}_{tbt'b}$, and $P^{x}_{tt'}=P^{x}_{tat'a}=-P^{x}_{tbt'b}=-P^{y}_{tat'b}=-P^{y}_{tbt'a}$.[7] Similarly, the numerical subscripts on t for the other cubic anharmonic force constants are as follows; $\varphi_{stt'}=\varphi_{stat'a}=\varphi_{stbt'b}$; $\varphi_{tt't''}=\varphi_{tat'at''a}=-\varphi_{tat'bt''b}=-\varphi_{tbt'at''b}=-\varphi_{tbt'bt''a}$.[8]

These equations are by no means new but have a definite advantage over the previous ones[7] in that the expressions are given for the individual cases in much simpler forms.

Experimental Results

The sample gases of CH_3Cl and CD_3Cl are the same as those used in Part I which were purchased from Takachiho Chemical Co. and Merck Sharp & Dohme Co. Canada, respectively. The purity of CH_3Cl was stated as 99.5% and that of CD_3Cl was 99 atom%. As will be described later inspection of full region of the infrared spectra of these gases well guaranteed the stated sample purities.

Spectra were all observed with a Nicolet model 7199 FT-IR spectrophotometer accomodated with a mercury-cadmium telluride detector. Optical resolution of 0.25 cm^{-1} was used (maximum path difference of 4 cm, with Happ-Genzel apodization). For intensity measurements, a 6 cm high pressure cell with KBr windows was used under a total pressure of 1.11×10^6 Pa. In order to investigate rotational fine structure of the bands, a conventional 10 cm glass body cell was used. The sample pressure was measured with an MKS baratron type 220, which covers a pressure range of 1.333×10^5 to 1.333×10^2 Pa with a stated accuracy of 0.25% of reading.

Integration of the "isolated" band area were carried out in a manner similar to the one described in Ref. 9 according to the following equation:

$$B_l = (1/nl)\int_{\text{band } l} \ln (T_0/T)d\nu, \quad (14)$$

where n is the sample concentration (mol m^{-3}), l is the optical path length (m), T and T_0 are the transmittance values of the cell with and without the sample gas, respectively. The band intensity is given by units of km $mol.^{-1}$

In many places in the spectra of both CH_3Cl and CD_3Cl, overtone and combination bands were observed to be overlapping with each other. Therefore, whenever possible use was made of a simulation technique to obtain individual band intensities. As usual, the simulation calculation was carried out for the spectra taken under the pressurized sample condition.[1,9] In the calculations, the ground state values of the rotational constants A and B were assumed for the excited vibrational states unless otherwise described. On the other hand, the values of the band centers ν^0 and Coriolis zeta constants ζ^z were obtained from the analysis of the spectra when they were not available in the literature.

For CH_3Cl molecule, the spectral region from 6300 through 500 cm^{-1} has been investigated. There are several things to be noticed in the spectrum. One is a fact that strongly absorbing bands are all due to the fundamentals. Only exception is a parallel component of the $2\nu_5$ band. The fact that the intensity of this particular band is by far the largest among the (binary) overtones and combinations strongly suggests that it is due to the Fermi resonance with the neighboring ν_1 band. This is in accord with the conclusion obtained by Bensari-Zizi and Alamichel.[10] Secondly, as regards the remaining bands, the large majority of them can be assigned to binary overtones and combinations. Also we can find a few of the ternary combinations such as $(\nu_2+2\nu_5^0)$, $(2\nu_2+\nu_5)$, $(\nu_6+2\nu_5^0)$, and $(\nu_3+2\nu_5^0)$.[11] It is most probable that their intensities are borrowed from the neighboring binary combinations through the Fermi resonances. Almost nothing is left to be assigned to impurity bands.

In the 6200—5800 cm^{-1} region, $2\nu_4$, $(\nu_1+\nu_4)$, and $2\nu_1$ bands are expected. The parallel component of the $2\nu_4$ band is clearly observed at 6015.1 cm^{-1}. The band center of the perpendicular component, $2\nu_4(\perp)$, was tentatively located at 6062 cm^{-1}. Since the $2\nu_4(\perp)$ band is strongly perturbed by the Fermi resonance with $(\nu_4+3\nu_6)$ band, the intensity of the $2\nu_4(//)$ was first determined by a simulation calculation for the spectral region of 6050—5980 cm^{-1}. And then the $2\nu_4(\perp)$ intensity was determined by subtracting the parallel component from the total area for these two bands. On the other hand, $(\nu_1+\nu_4)$ band is distributed over obscured $2\nu_1$ band, and the intensities for these two bands were not determined separately.

In a large bush observed between 4600 and 4300 cm^{-1}, $(\nu_4+\nu_5)$, $(\nu_1+\nu_5)$, $(\nu_2+\nu_4)$, and $(\nu_1+\nu_2)$ bands are expected. Since the spectrum of this region is so complicated that their individual intensities were not obtained separately. Towards the lower frequency skirts of this complicated structure, $(\nu_2+2\nu_5^0)$ band is observed.[11]

$(\nu_4+\nu_6)(\perp)$ and $(\nu_4+\nu_6)(//)$ bands are distributed over a region of 4120—4000 cm^{-1}. For these bands, since peaks of the $(\nu_4+\nu_6)(\perp)$ band are not apparent, only the total absorption area was determined from the spectrum. On the other hand, $(\nu_1+\nu_6)$ band appears with a neat band contour at 3979.66 cm^{-1}.[12] The $(\nu_1+\nu_6)$ intensity was obtained through simulating the spectrum from 3990 to 3910 cm^{-1}, by use of the molecular parameters reported in Ref. 12. Also the intensity of $(\nu_3+\nu_4)$ band was obtained through simulation calculation for the spectrum from 3830 to 3730 cm^{-1}. $(\nu_1+\nu_3)$ band is located at 3700.67 cm^{-1}.[12] The intensity of this band was obtained through calculation of the spectrum between 3730 and 3650 cm^{-1}.

The strong $2\nu_5^0$ band is located at 2879.25 cm^{-1},[10] and $(\nu_2+\nu_5)$ band is found at 2803.39 cm^{-1}.[13] Separation of the $(\nu_2+\nu_5)$ intensity from the $2\nu_5^0$ absorption was car-

ried out through comparison of the observed and calculated areas for both 2920—2820 and 2820—2720 cm^{-1} regions.

For the $(\nu_5+\nu_6)$ and $(\nu_2+\nu_6)$ region, a rotational analysis has been carried out by DiLauro and Alamichel.[14] Therefore, the molecular constants determined by them have been utilized to make simulation analysis of the spectrum. $(\nu_2+\nu_3)$ band was observed independently from other bands,[15] and its intensity was obtained in a straightforward manner. Due to the weakness of the absorptions, none of the intensities of the $(\nu_3+\nu_5)$,[15] $(\nu_3+\nu_6)$, and $2\nu_6$ bands were determined accurately. The observed intensities for CH_3Cl are summarized in Table 1.

For CD_3Cl molecule, the spectral region from 4800 through 500 cm^{-1} has been investigated. The general feature of the spectrum is very similar to that for CH_3Cl. However, in this case, we have observed three distinct bands at 3012,1300, and 1250 cm^{-1}, respectively. These bands seems to be due to CHD_2Cl species. From their intensities, the concentration of CHD_2Cl can be considered to be less than 1%.

The perpendicular component of $2\nu_4$ band is located at 4550.9 cm^{-1}, and the parallel one at 4515.5 cm^{-1}. The

a): Calculated from the cubic symmetry force constants in Ref. 5. b): See Ref. 5 for the classification of the force constants.

individual intensities of these two bands were easily obtained by the simulation method. The feature of the $(\nu_1+\nu_4)$ and $2\nu_1$ band region is quite similar to that in CH_3Cl, and the intensities of these bands were not separately determined. Also the spectral region for $(\nu_4+\nu_5)$, $(\nu_2+\nu_4)$, and $(\nu_1+\nu_5)$ shows a very complicated appearance, and the individual intensities were not determined either.

Althogh $(\nu_4+\nu_6)(//)$ band appears with an appreciable intensity,peaks due to the perpendicular component were not identified, as in the case of CH_3Cl. Instead, there was an extra parallel type band at 3011.6 cm^{-1}, presumably due to CHD_2Cl molecule. In fact, we have also observed a structure which seemed to be due to the "perpendicular" component of the same band. Due to the weakness, neither of $(\nu_3+\nu_4)$ and $(\nu_1+\nu_6)$ bands were clearly identified.

The parallel band of $(\nu_1+\nu_3)$ is clearly observed at 2861.6 cm^{-1}, which is accompanied by $(2\nu_2+\nu_3)$ and $(\nu_3+2\nu_5^0)$ bands. Intensities for $2\nu_5(//)$ and $2\nu_2$ have already been determined in Part I.[1] In this case however the intensity value for the $2\nu_5$ band should be considered as to include contributions both from $2\nu_5^0$ and $2\nu_5^2$.

Peaks due to the perpendicular component of $(\nu_5+\nu_6)$ band are apparent in the region between 1900 and 1750 cm^{-1}. However, the individual band intensities contributing to this region can not separately be obtained because of the spectral complexity. The $(\nu_2+\nu_3)$ band is clearly seen at 1725.7 cm^{-1}. Also $2\nu_3$ band is apparent at 1394.9 cm^{-1}, although we did not find clearly the $2\nu_6$ band anywhere. As mentioned above, a pair of parallel and perpendicular type bands appear at 1300 and 1250 cm^{-1}, respectively, which may

be due to CHD_2Cl.

The observed band intensities for the CD_3Cl molecule are summarized in Table 2.

Numerical Calculations and Discussion

As is apparent in the equations shown in a previous section, the intensities of binary overtone and combination bands contain contributions both from electrical and mechanical anharmonicities. If the second derivatives of the dipole moment are neglected, we can calculate the intensities of these bands by using the values of $(\partial P/\partial Q_r)$ and cubic force constants. The former has been determined in Part I, and the latter can be calculated from the cubic symmetry force field determined in Ref. 5. The cubic force constants obtained from the symmetry force constants are shown in Table 3. Calcd I in Tables 4 and 5 shows thus derived mechanical anharmonicity correction to the second derivatives of the dipole moment. Calcd I in Tables 6 and 7 shows the calculated intensities from these values. However, comparison of these values with the observed ones reveals that the agreement is not so good. Indeed, this is not surprising because we did not consider the second derivatives themselves to obtain the calculated intensities.

In order to obtain some estimates of the dipole moment derivatives, *ab initio* calculations may be useful. In fact, Scanlon *et al.* have calculated the second derivatives of the dipole moment for CH_4[16] and SF_6[17] with some success. In the following, a similar calculation will be carried out to obtain the values of the second derivatives of the dipole moment for methyl chloride.

The calculations were carried out by using the HONDO program[18] (IMS version) with the 4-31 G* basis set, where d-functions with $\alpha=0.80$ were used for both C and Cl atoms. The dipole moment derivatives were calculated with the experimental normal coordinates[19,21] for the optimized molecular geometry: CH=1.0775 Å, CCl=1.7775 Å, and ∠HCH=110.29°. The displacements for the second derivatives were obtained by addition of the simple harmonic motion of the two normal coordinates involved. Distorsions of 0.02 $u^{1/2}$ Å were employed in each case.

Calcd II in Tables 4 and 5 shows the resulting *ab initio* values of the second derivatives of the dipole moment. The numbers for Calcd III in the same tables are the sums of the numbers for Calcd I and II. On the other hand, Calcd II in Tables 6 and 7 shows the calculated intensities for the overtones and combinations using

a): Contribution from mechanical anharmonicity only was taken into account. b): The second derivatives of the dipole moment estimated by 4-31 G* were also taken into consideration. c): See footnote c) Table 2.

these estimated values of the dipole derivatives. On the whole, agreement of the calculated intensities with the observed ones improved much by the inclusion of the *ab initio* values of the second derivatives. The agreement is almost semi-quantitative for all bands expect $2\nu_2$, $(\nu_5+\nu_6)(//)$, and $(\nu_3+\nu_6)$ of CH_3Cl molecule. Therefore, the *ab initio* values of the second derivatives should at least be of correct orders of magnitude.

However, the discrepancies are still much larger than we expected. In this concern, it should be noted that the effect of Fermi resonance has not been taken into account exactly in the expressions given in this paper. The intensity values calculated from these equations may contain large errors when there are close resonances. For example, in the case of $2\nu_5(//)$ band of CH_3Cl and CD_3Cl, a part of discrepancy between the observed and calculated intensities must be due to Fermi resonance with the respective ν_1 band. Discrepancies are, however, also noted for some of those which are free from such resonances. It is possible that a considerable part of the discrepancy is due to the errors in the normal coordinate force constants used here. In fact, in order to determine the force constants through the least-squares calculation, we were forced to constrain some of the 38 independent force constants.[5] Moreover, the resulting errors for many of the force constants were more or less of the same magnitudes as or even larger than the derived values of the constants themselves.[5]

At any rate, it is clear that a further effort to refine the cubic force field is required before definite values are obtained for the second derivatives of the dipole moment of this molecule.

The *ab initio* calculations of the dipole moment derivatives were carried out by the HONDO program from Institute for Molecular Science through the courtesy of Professor Keiji Morokuma and Dr. Shigeki Kato.

Electrical Conductivities of the Complexes of Naphthaceno[5,6-*cd*:11,12-*c'd'*]-bis[1,2]dithiole and Its Analogs Obtained by Electrochemical Crystallization and Diffusion Method

Takashi NOGAMI,* Hidekazu TANAKA, Shigeo OHNISHI, Yoshihiko TASAKA, and Hiroshi MIKAWA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-oka, Suita, Osaka 565
(Received July 8, 1983)

Electrochemical crystallizations of the complexes of naphthaceno[5,6-*cd*:11,12-*c'd'*]bis[1,2]dithiole (TTT), anthra[1,9-*cd*:4,10-*c'd'*]bis[1,2]dithiole (TTA), anthra[1,9-*cd*:4,10-*c'd'*]bis[1,2]diselenole (TSA), and naphtho[1,8-*cd*:4,5-*c'd'*]bis[1,2]dithiole (TTN) were made in 1,1,2-trichloroethane or tetrahydrofuran as a solvent. Most of the crystals were obtained with non-stoichiometric compositions, and they included the solvent. Some charge-transfer complexes including the above donors were also made by a diffusion method. The electrical conductivities of the crystals were measured by a two-probe or four-probe method. TTT-$(PF_6)_{0.61}$ was found to be the most conductive materials in the complexes studied. Its electrical conductivity was 762 $(\Omega\,cm)^{-1}$ at room temperature, and it showed metallic behavior above 220 K. The conductivities of the other complexes varied widely in the range 10^2—10^{-7} $(\Omega\,cm)^{-1}$

The studies on the highly conductive organic materials have progressed greatly in the past few years.[1] The first organic superconductors were discovered for complexes of tetramethyltetraselenafulvalene (TMTSF).[2] Another organic superconductor has recently been reported for the complex of bis(ethylenedithio)tetrathiafulvalene (BEDT-TTF), (BEDT-TTF)$_4$(ReO_4)$_2$.[3] The crystals of these organic superconductors were grown by an electrochemical method.[4] However, most of the electrochemical crystallizations have been conducted on the complexes of tetrathiafulvalene (TTF) and its analogs. Naphthaceno[5,6-*cd*:11,12-*c'd'*]bis[1,2]dithiole (TTT) is known to give highly conductive organic complexes.[5] The TTT analogs are planar molecules with four chalcogen atoms stretched out from the aromatic ring. Interchain coupling through chalcogen atoms is expected for the complexes of TTT analogs; this might suppress Peierls transitions. Thus, these complexes are expected to be highly conductive down to low temperatures. We have made electrochemical crystallizations of TTT, anthra[1,9-*cd*:4,10-*c'd'*]bis[1,2]diselenole (TSA), anthra[1,9-*cd*:4,10-*c'd'*]bis[1,2]dithiole (TTA), and naphtho[1,8-*cd*:4,5-*c'd'*]bis[1,2]dithiole (TTN). We have also made some charge-transfer complexes by use of these donor molecules by diffusion method. Their electrical conductivities were measured by a two-probe or four-probe method. We have also measured the half-wave oxidation potentials and electronic absorption spectra of the above donor molecules to get their basic data.

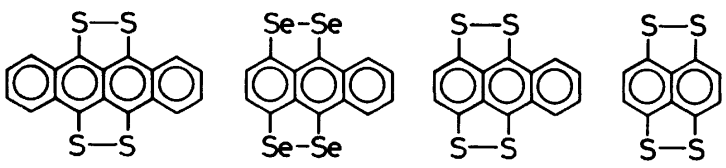
Experimental

Materials. TTT,[6] TSA,[7] TTA,[8] and TTN[9] were synthesized by the procedures reported. Tetrabutylammonium perchlorate was recrystallized from ethanol. Tetrabutylammonium hexafluorophosphate was synthesized according to the reported procedures.[10] Tetrabutylammonium hexafluoroarsenate was synthesized by mixing equimolar amounts of aqueous solutions of tetrabutylammonium bromide with potassium hexafluoroarsenate. The white powder was filtered, dried in vacuum, and recrystallized twice from the mixed solution of ethyl acetate and hexane (7:3). Tetrabutylammonium hexafluoroantimonate was synthesized by the reported procedures.[11] Tetrabutylammonium tetrafluoroborate was obtained by mixing equimolar amounts of aqueous tetrabutylammonium bromide with tetrafluoroboric acid (40%) at 0 °C in a polyethylene vessel. The crude product was recrystallized from ethyl acetate in the polyethylene vessel. Tetrabutylammonium triiodide was synthesized by the procedures reported.[12] 1,1,2-Trichloroethane was purified by refluxing it over phosphorus pentaoxide, followed by distillation. Tetrahydrofuran was purified by refluxing it over calcium hydride, followed by distillation. Benzonitrile was steam distilled, the organic layer was shaken with aqueous sodium carbonate, and the solution was mixed with diethyl ether. The organic solution was shaken with water, and the resulting mixture was dried over calcium chloride overnight. Diethyl ether was then distilled out, and the remaining liquid was distilled in vacuum.

Electrochemical Crystallization. Electrochemical crystallization was conducted under galvanostatic conditions (1—5 μA). The detailed procedures were described before.[13]

Crystal Growth by Diffusion Method. The single crystals of TCNQ complexes and iodine complexes of TTT and its analogs were grown by diffusion method in organic solvents. For the crystal growths of iodine complexes, tetrabutylammonium triiodide was used instead of iodine. The detailed procedures are similar to those of the literature.[14]

Cyclic Voltammetry. Cyclic voltammetry was made by a Potentiostat/Galvanostat (Hokuto Denko, HA-501), and by



a Function Generator (Hokuto Denko, HB-104).

Measurement of Electrical Conductivity. Electrical conductivities of the crystals were measured by a two-probe or four-probe method. Temperature dependence of the electrical conductivity was measured by a Type D Cryo Mini (Osaka Sanso Co. Ltd).

Results and Discussion

Cyclic Voltammetries of Donor Molecules. The electrochemical half-wave potentials were measured *vs.* SCE at a platinum electrode in benzonitrile-Bu_4NAsF_6 (0.1 mol dm^{-3}). Table 1 summarizes the first and second half-wave oxidation potentials and their differences ($E_{1/2}(2)-E_{1/2}(1)$) of TTT, TTA, and TSA, together with the reported values of TTN, TSN, TTF, TMTTF, TMTSF, and HMTTeF for comparison.[15] Here, TSN, TMTTF, and HMTTeF denote naphtho-[1,8-*cd*:4,5-*c'd'*]bis[1,2]diselenole,[16] tetramethyltetrathiafulvalene, and bis(trimethylene)tetratellurafulvalene, respectively. The first oxidation potentials increase in the order: TTT≃TMTTF<TTF<TSA≃TTA≃TMTSF≃HMTTeF<TSN<TTN.

Electronic Absorption Spectra of Donor Molecules. The electronic absorption spectra of a series of TTT analogs were measured in several solvents at room temperature. Figure 1 shows the electronic absorption spectra of TTT, TSA, TTA, TTN, and TSN.[16] Table 2 summarizes the absorption peak positions and logarithms of extinction coefficients. The absorption peak positions of the lowest energy transition of selenium derivatives showed bathochromic shifts relative to the corresponding sulfur derivatives.

Electrochemical Crystallization. Electrochemical crystallization was conducted for the donor molecules TTT, TSA, TTA, and TTN. The counter anions were Cl^-, Br^-, I^-, ClO_4^-, BF_4^-, PF_6^-, AsF_6^-, and SbF_6^-. Table 3 summarizes the complexes obtained, their decomposition temperatures, elemental analyses, solvents, appearances, and electrical conductivities at room temperature. Since the elemental analyses of chalcogen atoms and halogen atoms could not be made when they coexist in the same sample, elemental analyses were made only for carbon and hydrogen. The content of the solvent was estimated from the analyses by the least-squares method. Most of the complexes contained the solvent in non-stoichiometric ratios. The solvent could not be removed merely by drying the complex *in vacuo* at room temperature. The ratio of the donor molecule and the counter anion was also non-stoichiometric. The reason why $TTT(ClO_4)_{0.56}$, $TTT(PF_6)_{0.61}$, and $TTT(SbF_6)_{0.64}$ do not contain the solvent, 1,1,2-trichloethane, is not clear.

Electrical Conductivities of the Complexes. Electrical conductivities of the complexes were measured by a two-probe or four-probe method. Table 3 summarizes

Table 1. Electrochemical half-wave oxidation potentials of donor molecules in benzonitrile

the observed results. Roughly speaking, the order of the electrical conductivities obtained by electrochemical method is as follows: TTT complexes (10^{-3}—$10^{3}(\Omega\ cm)^{-1}$)>TTA complexes ($10^{-4}(\Omega\ cm)^{-1}$)>TSA complexes ($10^{-5}(\Omega\ cm)^{-1}$)>TTN complexes (10^{-6}—$10^{-7}(\Omega\ cm)^{-1}$). That is to say, the larger the aromatic ring is, the higher is the conductivity. The charge carrier in these complexes is considered to be a hole. The above orders of the conductivities arise partly from the weaker on-site Coulomb repulsion energy between holes for large aromatic systems than that for small aromatic systems, because the average distance between the holes becomes larger in going from TTN to TTT.[17] The electrical conductivities of the complexes which do not

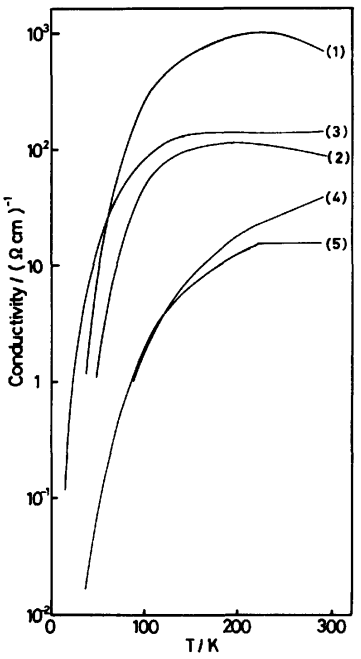

Fig. 2. Temperature dependences of the electrical conductivities of the complexes.
(1) $TTT(PF_6)_{0.61}$ (crystal 1), (2) $TTT(PF_6)_{0.61}$ (crystal 2), (3) $TTT\ I_{0.90}(TCE)_{0.20}$, (4) $TTT(SbF_6)_{0.64}$, (5) TSA·TCNQ

contain the solvents were high in general. The steric effect of the solvent prevents the overlap of the π-electron clouds between adjacent donor molecules; this leads to the low conductivity. Thus, we must select a proper solvent or a special condition of electrocrystallization in order to prevent the coordination of the solvent to the complex. Electrochemical crystallizations of TTT complexes were conducted both in 1,1,2-trichloroethane (TCE) and in tetrahydrofuran (THF). Most of the TTT complexes obtained in the former solvent were more conductive than those obtained in the latter solvent. Temperature dependences of the electrical conductivities of $TTT(PF_6)_{0.61}$, $TTT{\cdot}I_{0.90}(TCE)_{0.20}$, and $TTT(SbF_6)_{0.64}$ are shown in Fig. 2. $TTT(PF_6)_{0.61}$ gave two kinds of crystals, which could be distinguished from the appearances. The thin crystal (crystal 1 in Fig. 2) was more conductive than the thick one (crystal 2 in Fig. 2). $TTT(PF_6)_{0.61}$ (crystal 1) was the most conductive material, and its electrical conductivity was $762(\Omega\ cm)^{-1}$ at room temperature. The conductivity increased gradually with lowering the temperature which is a characteristic behavior of metallic conductivity, and showed the maximum value of $1050(\Omega\ cm)^{-1}$ at 220 K. $TTT(PF_6)_{0.61}$ (crystal 2) also showed metallic behavior above 190 K. $TTT{\cdot}I_{0.90}(TCE)_{0.20}$ showed almost no activation energy of the conductivity above 160 K. The conductivities of $TTT(PF_6)_{0.61}$ and $TTT{\cdot}I_{0.90}(TCE)_{0.20}$ decreased gradually at the lower temperature range due to a phase transition, like many low-dimensional conductors.

The complexes obtained by the diffusion method showed higher conductivities than those obtained by the electrochemical method, especially in TTA-, TSA-, and TTN-complexes; *e.g.*, $TTA{\cdot}I_{1.2}$, $4.2(\Omega\ cm)^{-1}$; TSA·TCNQ, $15(\Omega\ cm)^{-1}$; $TTN{\cdot}I_{2.4}$, $1.45\times10^{-2}(\Omega\ cm)^{-1}$. Temperature dependence of the electrical conductivity of TSA·TCNQ is shown in Fig. 2. The conductivity was almost constant above 220 K, at which temperature the phase transition gave rise to a low conductive phase. In view of the high electrical conductivities of the following complexes,[18] we can get highly conductive complexes more easily by the diffusion method than by the electrochemical method if we use TTT and its analogs as donor molecules: TTT_2I_3, $10^3(\Omega\ cm)^{-1}$; $TTT(TCNQ)_2$, $10^2(\Omega\ cm)^{-1}$; TTN·TCNQ, $40(\Omega\ cm)^{-1}$.

We are grateful to Prof. F. Wudl, University of California at Santa Barbara, for teaching us the detailed synthetic procedures of TTN.

Temperature Dependence of Magnetic Susceptibilities of (TTT)(TCNQ) and (TTT)(TCNQ)$_2$

Masashi TAKAHASHI, Tadashi SUGANO, and Minoru KINOSHITA*
The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106
(Received July 19, 1983)

Static magnetic susceptibility and ESR studies of 1:1 and 1:2 charge-transfer complexes of naphthaceno-[5,6-*cd*:11,12-*c'd'*]bis[1,2]dithiole and 2,2'-(2,5-cyclohexadiene-1,4-diylidene)bis(propanedinitrile) [(TTT)-(TCNQ) and (TTT)(TCNQ)$_2$] in the temperature region of 2—310 K are described. (TTT)(TCNQ)$_2$ exhibits a temperature dependent spin susceptibility, while the spin susceptibility of (TTT)(TCNQ) is almost independent of temperature. Spin susceptibilities of the TTT and TCNQ chains, which are evaluated with a *g*-value decomposition technique, are interpreted in terms of a one-dimensional Hubbard model. In both complexes, the on-site Coulomb repulsion is comparable with or larger than the band width on the TCNQ chains and is smaller on the TTT chains. Two magnetic phase transitions are observed in (TTT)(TCNQ)$_2$. The transition is driven in each chain independently by the Peierls instability. The amount of charge transfer in (TTT)-(TCNQ) is determined to be 0.73±0.05 from an X-ray photoelectron spectroscopic study.

Naphthaceno[5,6-*cd*: 11,12-*c'd'*]bis[1,2]dithiole [tetrathiotetracene; abbreviated as TTT hereafter] is known to be a powerful donor and forms many highly conductive low dimensional organic solids with some organic acceptors and inorganic anions.[1-7] TTT forms two distinct charge-transfer complexes with 2,2'-(2,5-cyclohexadiene-1,4-diylidene)bis(propanedinitrile) [tetracyanoquinodimethan; abbreviated as TCNQ]. One is (TTT)(TCNQ)[3,4] and the other is (TTT)(TCNQ)$_2$.[2,4] Electrical conductivity of a single crystal of (TTT)-(TCNQ)$_2$ has been found to be about 100 Ω^{-1} cm^{-1} at room temperature and shows metallic temperature dependence down to about 90 K, but becomes semiconductive below 90 K.[2] Room temperature conductivity of a powdered sample of (TTT)(TCNQ) has been found to be 0.1—1 Ω^{-1} cm^{-1},[2,4] and is comparable with that of (TTT)(TCNQ)$_2$. Therefore (TTT)(TCNQ) is also regarded as a highly conductive compound, though its single crystal conductivity has not yet been reported.

The temperature dependence of magnetic susceptibility is an important physical property for an organic conductor because it provides information on the band width and the on-site Coulomb correlation effects. The temperature dependences of magnetic susceptibilities of (TTT)(TCNQ) and (TTT)(TCNQ)$_2$ have been reported previously by two groups.[2,3] In these reports, a large contribution ((2—8)×10^{-2} spins per molecule) of paramagnetism described by Curie law inhibits an accurate evaluation of intrinsic paramagnetism. Furthermore, it is necessary to decompose total spin susceptibilities into individual contributions from the two chains in order to discuss quantitatively the band width and the Coulomb correlation effects. For this purpose, a decomposition technique has been developed which uses the *g*-value observed in electron spin resonance.[8] Therefore, we have reexamined the temperature dependence of the magnetic susceptibilities and, for the first time, measured ESR of (TTT)(TCNQ) and (TTT)-(TCNQ)$_2$ in the temperature range of 2—310 K.

In this report we describe the relation between the band width and the on-site Coulomb correlation in detail using the results of magnetic susceptibility and ESR measurements. Insight into magnetic phase transition is also provided. Moreover to evaluate the band width, the amount of charge transfer in (TTT)-(TCNQ) is estimated from the results of X-ray photoelectron spectroscopy.

Experimental

Materials. TTT was synthesized by using the procedures described in the literature[5,9] with a slight modification and purified by repeated vacuum sublimation.

TCNQ (Aldrich) was purified twice by recrystallization from an acetonitrile solution and for several times by sublimation under reduced pressure.

(TTT)(TCNQ) was obtained by the following procedures. A 50 cm^3 of hot toluene solution containing 20 mg (0.1 mmol) of TCNQ was added to a boiling solution of 35 mg (0.1 mmol) of TTT in 350 cm^3 of toluene and refluxed for 30 min. The solution stood for overnight and the precipitated crystals were collected, washed with ethanol, and dried in atmosphere. Yield; 48 mg. Found: C, 65.70; H, 2.09; N, 10.16; S, 20.92%. Calcd for $C_{30}H_{12}N_4S_4$: C, 64.72; H, 2.18; N, 10.67; S, 23.04%. Room temperature resistivity on a compressed powder sample was 1.8 Ω cm.

(TTT)(TCNQ)$_2$ was obtained in the same manner as (TTT)(TCNQ) except for using twice amount of TCNQ. Yield; 71 mg. Found: C, 65.98; H, 2.11; N, 13.54; S, 16.14%. Calcd for $C_{42}H_{16}N_8S_4$: C, 66.29; H, 2.12; N, 14.73; S, 16.85%. Resistivity at room temperature on a compressed powder sample was 4.5 Ω cm.

M(TCNQ) (M=Na, K, Rb) and (tetraethylammonium)-(TCNQ)$_2$ were prepared by the method in the literature.[10] The complex of 2,2'-bi(1,3-dithiolylidene), [tetrathiafulvalene; abbreviated as TTF], and TCNQ was prepared by direct reaction of equimolar amounts of TTF and TCNQ in purified hot acetonitrile solutions.

Magnetic Susceptibility. Static magnetic susceptibility of powder samples was measured with a Faraday susceptometer described below. The construction of the susceptometer system is schematically illustrated in Fig. 1. The susceptometer is composed of three main parts; a cryostat in combination with superconducting magnets (Oxford Instruments Limited), an electric microbalance (Cahn model 2000), and a temperature control unit.

The superconducting magnets consist of a main solenoid coil which produces homogeneous field up to 50 kOe[11] and a couple of quadrupole-type gradient coils which produces

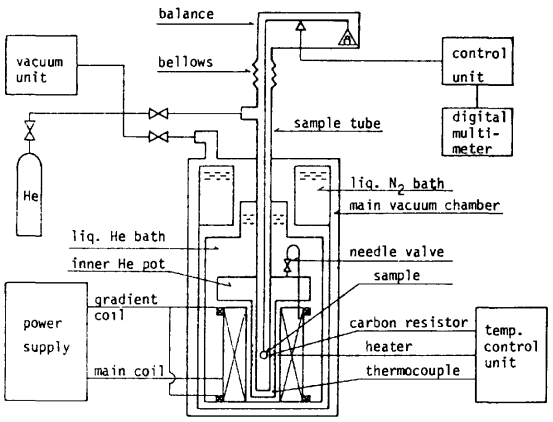

Fig. 1. Construction of the Faraday magnetosusceptometer system.

field gradient up to 1 kOe cm^{-1}. The solenoid and gradient coils are wound from NbTi filamentary wire. The magnets allow the field and field gradient to be set at desired values independently. The two magnets are used in superconducting state; in paticular, the main coil is used in a persistent current state for susceptibility measurements, and consequently fluctuation of the field strength is almost completely suppressed. The relation between a loading current and generated field was calibrated by measuring the susceptibility of sodium chloride.

The maximum loading capacity of the balance is 1 g and the magnetic force is reproducible within 1 μg, giving a maximum precision of the present system of 1×10^{-8} erg Oe^{-1} g^{-1} [11] for magnetization and 2×10^{-11} emu g^{-1} [11] for magnetic susceptibility.

A compressed powder sample of about 50 mg was contained in a quartz bucket and suspended from the balance beam with tungsten wire 30 μm in diameter. The output from the balance was read with a digital multimeter (Takeda Riken TR 6840). The sample and balance were pumped to less than 2×10^{-3} Pa to remove adsorbed oxygen and water. Typically evacuation for 90 h was necessary for (TTT)(TCNQ) to be free from paramagnetism of adsorbed oxygen. During the measurement, the sample tube was filled with purified helium gas at about 3 Pa to keep thermal contact between the sample and a copper heat sink.

Temperature below 20 K was measured with a carbon resistor and from 20 to 300 K with a 0.03% Fe-Au/chromel thermocouple. Temperature was controlled with an Oxford DTC2 temperature controller and calibrated by measuring the magnetic susceptibility of *N,N,N',N'*-tetramethyl-1,2-ethanediammonium tetrachlorocuprate(II).[12] The accuracy of temperature was to ±0.2 and ±0.5 K at 10 and 100 K, respectively.

Electron Spin Resonance. Temperature dependence of X-band electron spin resonance (ESR) spectra from 120 to 310 K were recorded on a JES-FX-1 equipped with a cryostat of cold gas nitrogen flow type. Spectra in the temperature region of 7—260 K were measured using a JES-FX-3AX with an Oxford ESR 900 continuous flow cryostat. In every measurement the modulation width was kept to be within 0.05 Oe in order to prevent a distortion of lineshape due to overmodulation.

X-Ray Photoelectron Spectroscopy (XPS). X-Ray photoelectron spectra of (TTT)(TCNQ) were measured by means of a McPherson ESCA 36 electron spectrometer on powder samples pressed onto aluminum plates employing Mg *Kα* (1253.6 eV) as the stimulating radiation. The binding energy was calibrated against the Au4f$_{7/2}$ peak (83.8 eV) of a thin film deposited on the sample surface in the spectrometer. Data for neutral TTT and (TTT)ClO$_4$ measured under the same conditions were kindly supplied by Professor Ikemoto.

Infrared Spectra. Infrared (IR) spectra were recorded using KBr disks of powdered samples with a Perkin-Elmer PE684 spectrometer.

Evaluation of the Amount of Charge Transfer

The amount of charge transfer, ρ, is one of the important quantities to consider physical properties of organic conductors, because it is related to the filling of electrons in an electron energy band. Several methods are proposed for estimation of ρ; X-ray[13,14] and neutron[15] scattering techniques, Raman[16] and IR[17] spectroscopies and XPS[18-21] method. Ikemoto *et al.*[20] have already evaluated ρ of (TTT)(TCNQ)$_2$ to be 0.93±0.05 with XPS. However, since ρ of (TTT)(TCNQ) has been left unknown, we have estimated it by means of XPS method.

The Nls core level peak of (TTT)(TCNQ) observed in this measurement has a broadened and asymmetric shape which is evidence for the presence of two kinds of TCNQ (*i.e.*, TCNQ^0 and TCNQ$^-$) in this solid as observed in (TTF)(TCNQ) and related compounds.[18-21] Since (TTT)(TCNQ) has the stoichiometry of 1 : 1, this observaton suggests that an incomplete charge transfer from TTT to TCNQ occurs in this complex.

Ikemoto *et al.* have suggested that the S2p peak is suitable for estimation of ρ for sulfur containing charge transfer complexes, because this peak is not accompanied with any strong satellite and is free from radiation damage in contrast to the Nls peak.[19,20] Our analysis is carried out by following the method proposed by them. We use the S2p peak profiles of TTT and (TTT)ClO$_4$ as standards for TTT^0 and TTT$^+$, respectively. ρ is estimated by trying to reproduce the observed (TTT)(TCNQ) peak as a sum of the TTT$^+$ and TTT^0 peaks by varying the relative intensities and separation of the two component peaks. The best fit profile is shown in Fig. 2. From the ratio of the cation peak area to the total one, ρ is estimated to be 0.73±0.05.

Chappell *et al.* have proposed an alternative method for estimation of ρ from IR spectra.[17] According to their result, wavenumber, ω, of the highest frequency vibration among those of the nitrile stretching bands has a linear relation to ρ.

We have measured the IR spectra of neutral TCNQ, alkali metal(Na, K, and Rb)-TCNQ, (TTF)(TCNQ) and tetraethylammonium(TCNQ)$_2$. The observed spectra for Na-, K-, and Rb(TCNQ) are in good agreement with the reported ones.[22-24] However, agreement with those of Chappell *et al.* is not satisfactory: For example, our results for the nitrile stretching mode are 2202 cm^{-1} for Na(TCNQ) and 2196 cm^{-1} for K-(TCNQ), while the values reported by Chappell *et al.* are 2185 and 2183 cm^{-1}, respectively. Our plot of ρ *versus* ω in several TCNQ salts shows a poor linearlity so that the evaluation of ρ from this plot would include larger error.

The value of ω=2183 cm^{-1} for K(TCNQ), which has been used as the standard for TCNQ$^-$ by them, seems to

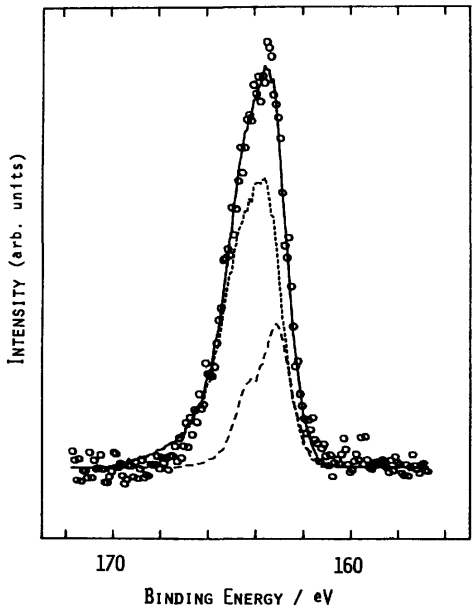

Fig. 2. Observed and calculated S2p peak profiles of X-ray photoelectron spectrum of (TTT)(TCNQ). ○: Observed data; ----: TTT^+ component; — — —: TTT^0 component; ——: superimposed peak.

correspond to the middle band among the three observed bands in the nitrile stretching band region. This band becomes allowed by vibronic coupling on the TCNQ chain[25,26] and the frequency is influenced by the strength of the coupling. Thus this band seems to be unsuitable for a reference.

For the reasons mentioned above, we employ the values of 0.73±0.05 derived from the XPS measurement as the amount of charge transfer. It has been shown that careful applicaton of the XPS method provides the ρ values in good agreement with those derived from other methods.[19-21]

Magnetic Susceptibilities

Temperature dependences of the total paramagnetic susceptibilities (χ_P) of (TTT)(TCNQ) and (TTT)-$(TCNQ)_2$ obtained by subtracting the diamagnetic contribution are shown in Fig. 3. The contribution of core diamagnetism to the observed susceptibility is estimated from the reported values of 2.15×10^{-4} emu mol^{-1} [11] for TTT[7] and 1.21×10^{-4} emu mol^{-1} for TCNQ.[27]

The temperature dependences of the susceptibilities of both complexes are different above 20 K and similar below there. To clarify the behavior in the low temperature region, $\log(\chi_P/\text{emu mol}^{-1})$ is plotted against $\log(T/\text{K})$ in Fig. 4. Below 20 K, the susceptibilities increase steadily with decreasing temperature according to the equation,

$$\chi_P = AT^{-\alpha}, \quad (1)$$

where A and α are constants. The values of $\alpha = 0.64$ and $A=1.37\times10^{-2}$ emu K mol^{-1} for (TTT)(TCNQ) and $\alpha=0.82$ and $A=4.35\times10^{-3}$ emu K mol^{-1} for $(TTT)(TCNQ)_2$ are obtained from the plots of Fig. 4. Either value of

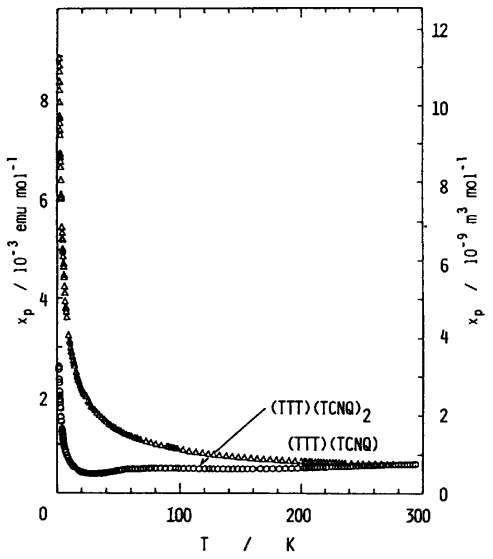

Fig. 3. Temperature dependence of total paramagnetic susceptibility. △: (TTT)(TCNQ); ○: (TTT)-$(TCNQ)_2$.

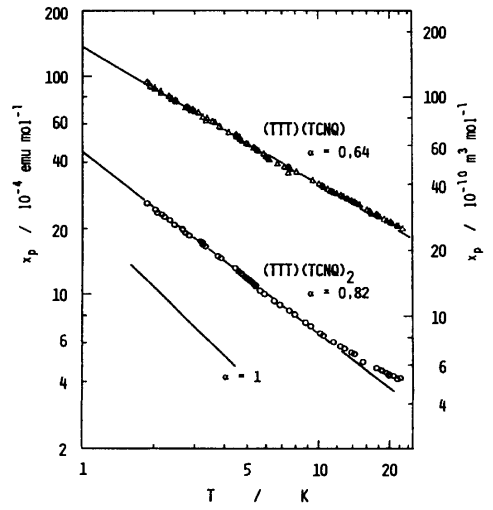

Fig. 4. Total paramagnetic susceptibility at low temperature. △: (TTT)(TCNQ); ○: $(TTT)(TCNQ)_2$; solid lines represent the least squares fit susceptibilities with T-power law.

α is unexpectedly less than unity, indicating that neither of the complexes obeys the Curie law in the low temperature region.

Some groups of organic conductors have been shown recently to exhibit the susceptibility obeying the power law expressed by Eq. 1 at low temperatures. This behavior has been interpreted in terms of a random exchange Heisenberg antiferromagnetic chain with $S=1/2$ spins.[28-32] One of the groups is represented by TCNQ complexes with asymmetric donors such as N-methylphenazinium(TCNQ),[29,33] acridinium $(TCNQ)_2$,[29] and quinolinium$(TCNQ)_2$.[29,33-36] The other group is comprised of complexes involving disorders additionally introduced by chemical doping or X-ray or neutron irradiation. Typical examples are $(HMTTF)_x$-

(HMTSF)$_{1-x}$(TCNQ), $x<1$,[35] and irradiated (TTF)-(TCNQ),[34,35] where HMTTF and HMTSF stand for 2,2′-bi(5,6-dihydro-4*H*-cyclopenta[1,3]dithiolylidene) and its selenium derivative.

Our samples seem to belong to the latter group because of the symmetric shape of TTT and TCNQ molecules. Disorder may be introduced by solvent molecules randomly included or by deviation from ideal stoichiometry. Our mass spectroscopic measurements have shown that (TTT)(TCNQ) and (TTT)(TCNQ)$_2$ include toluene, used as the solvent, in the crystals. The molar ratios of TCNQ to TTT are 1.1 for (TTT)-(TCNQ) and 1.9 for (TTT)(TCNQ)$_2$ with slight deviations among batches. This nonstoichiometry makes up kinks and missfits of the array of molecules in the molecular stacks to violate the periodic potential of the lattice and thus spins are trapped near the kinks or defects. In a similar way randomly included solvent molecules would also create the randomly trapped spins.

The reproducibility of α is good and the values of 0.63±0.05 for (TTT)(TCNQ) and 0.82±0.05 for (TTT)(TCNQ)$_2$ are obtained from the several measurements for each complex, while the magnitude of A, which corresponds to the Curie constant when $\alpha=1$, varies from sample to sample.

Regarding A as the Curie constant, though $\alpha\neq1$, we may estimate the spin concentration contributing to the susceptibility at low temperature. In spite of careful preparations of the samples, the spin concentrations estimated range from 1×10^{-2} to 4×10^{-2} spins per molecule for several batches of the both complexes. These values are comparable with or slightly less than those reported previously (about (2—8)$\times10^{-2}$ spins per molecule[4,5]). Therefore, we believe that the low temperature paramagnetism is inherent nature to the two complexes and is ascribed to the disorder mentioned above.

The spin susceptibilities (χ_s) of the two complexes in the higher temperature region are obtained by subtracting the low-temperature disorder paramagnetism discribed by Eq. 1 from the total paramagnetism. They are shown in Fig. 5. It will be shown later from the results of ESR study on powdered samples that this separation of susceptibility is appropriate for these complexes.

The χ_s values of the two complexes are quite different in temperature dependence and magnitude from each other. In (TTT)(TCNQ), χ_s is almost independent of temperature above 30 K, suggesting that no magnetic phase transition occurs in this temperature range. The value of about 2×10^{-4} emu mol^{-1} is rather smaller than that of various TCNQ complexes.

On the other hand, χ_s of (TTT)(TCNQ)$_2$ is similar to that of (TTF)(TCNQ) in temperature dependence and magnitude. The feature of temperature dependence of the observed spin susceptibility is in good agreement with the reported one in the whole temperature range, though the magnitude of our result is larger by about 30% than that.[2] The spin susceptibility increases rapidly with increase of temperature in the semiconducting region ($T\leq55$ K). Two sudden changes in χ_s are observed at about 55 and 85 K, implying occurrence

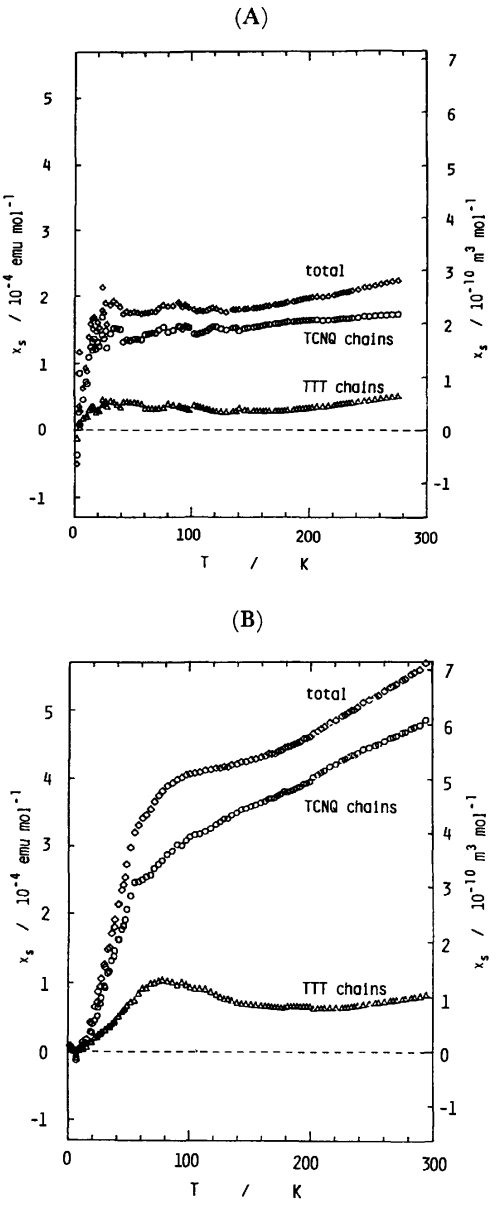

Fig. 5. Temperature dependence of total and individual spin susceptibilities. (A): (TTT)(TCNQ); (B): (TTT)(TCNQ)$_2$. ◇: Total susceptibilities; △: TTT chains; ○: TCNQ chains.

of magnetic phase transitions like those found in (TTF)-(TCNQ).[27,37] In the metallic region above 90 K, χ_s increases rather slowly with increasing temperature as observed with other organic conductors in their metallic region. We would be able to regard (TTT)(TCNQ)$_2$ as a characteristic organic conductor which is subject to a phase transition into semiconducting state at low temperature.

Decomposition of Total Spin Susceptibility into Contributions from Individual Chains

The observed spin susceptibilities of (TTT)(TCNQ) and (TTT)(TCNQ)$_2$ are total ones, namely the sums of spin susceptibilities of the TTT and TCNQ chains.

Both of the TTT and TCNQ chains are expected to exhibit finite magnetic susceptibilities almost independently. Thus separation of total susceptibilities into the individual components becomes important for further discussion. Two techniques for such separation have been proposed. One is the technique to use the g-values of ESR spectra.[8] The other is the method to make use of Knight-shift in ^{13}C-NMR spectra[38] The former technique is readily available to us and is employed here.

The observed ESR spectra at various temperatures are shown in Fig. 6. The structure appearing in the spectrum at high temperature is attributed to a g-value anisotropy for both complexes, because the lineshape cannot be reproduced by a superposition of absorption lines of TTT^+ and $TCNQ^-$ radicals. Indeed, a preliminary ESR measurement on a single crystal of (TTT)-(TCNQ)$_2$ shows a single narrow absorption.

Lineshapes of the spectra of the two complexes are clearly different and their temperature dependence reflects the presence or absence of magnetic phase transition. In (TTT)(TCNQ), the lineshape varies continuously from 300 K down to 7.8 K. There is no indication of magnetic phase transition in this temperature range. This behavior is consistent with the result of magnetic susceptibility in the preceding section. The low field line additionally appears below 200 K with $g'=2.0073$ and seems to be arising from the spins mainly localized on TTT, because the observed value of g' is close to the g-value of the TTT cation radical.[39] Since the intensity of this line increases rapidly on cooling, this line is likely caused by the localized paramagnetic centers introduced by disordered nature of the solid observed in the static susceptibility.

In (TTT)(TCNQ)$_2$, the lineshape varies suddenly at some temperatures. On cooling, the depth of the dip near g_1 increases and the width narrows gradually. Sud-

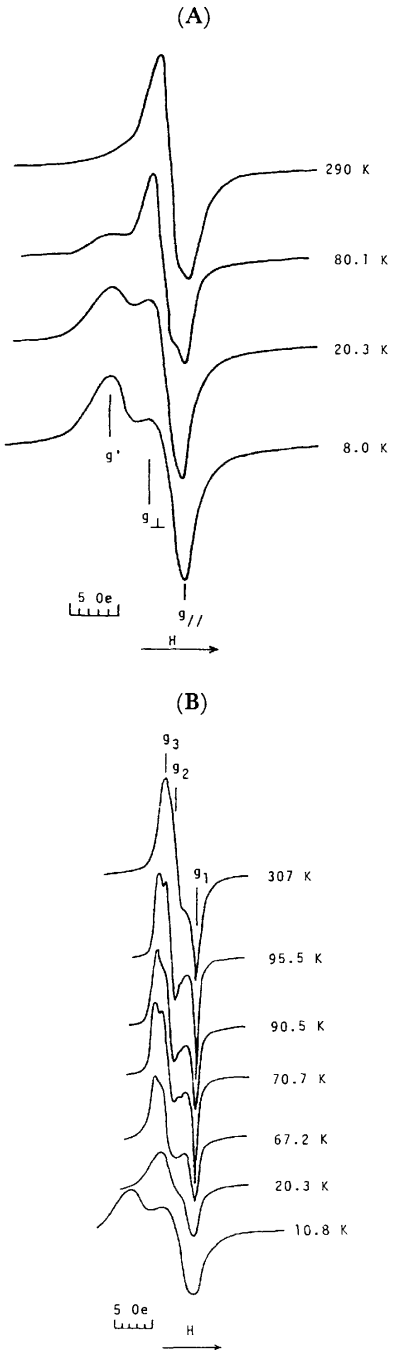

Fig. 6. ESR signals on powdered samples at various temperatures. (A): (TTT)(TCNQ); (B): (TTT)-(TCNQ)$_2$. Assignment of anisotorpic g-values is tentative.

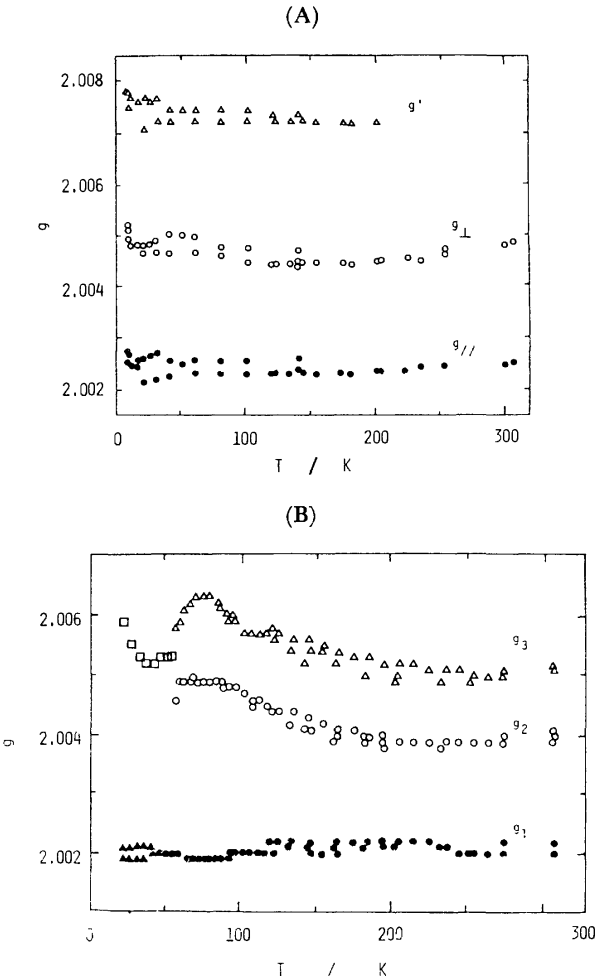

Fig. 7. Temperature dependence of g-values. (A): (TTT)(TCNQ); (B): (TTT)(TCNQ)$_2$.

den decrease in depth and increase in width are observed near 90 and 67 K, indicating the presence of phase transitions. The variation below 55 K is rather continuous, though the linewidth becomes broadened with decreasing temperature. A new line appearing below 15 K at the lower magnetic field would also be attributed to the signal due to the spin on disordered TTT site as discussed for (TTT)(TCNQ).

The temperature dependences of g-values shown in Fig. 7 support the results of the measurements of the temperature dependences of lineshape and magnetic susceptibility. Variation is continuous in (TTT)(TCNQ), while two irreguralities are found at 65 and 90 K in the temperature dependence of g_2 and g_3 in (TTT)(TCNQ)$_2$.

Since the main structures of the ESR spectra of (TTT)(TCNQ) and (TTT)(TCNQ)$_2$ are only due to the g-value anisotropy, the magnetic exchange interaction between TTT and TCNQ chains is expected to exceed the difference in the Larmor frequency, and averages out the g-values of the component radicals. Tomkiewicz *et al.* have shown that the observed g-value of such a complex is determined by a weighted average of the g-values of the component radicals,[8] where weight is proportional to χ_s of the donor and acceptor chains. Thus we may expect the following relationship to our complexes.

$$\bar{g} = \frac{\chi_{s,T}\bar{g}_T + \chi_{s,Q}\bar{g}_Q}{(\chi_{s,T} + \chi_{s,Q})}, \tag{2}$$

where $\bar{g}$, $\bar{g}_T$, and $\bar{g}_Q$ are the averaged g-values of the complex, the TTT^+ radical, and the $TCNQ^-$ radical, respectively, and $\chi_{s,T}$ and $\chi_{s,Q}$ are the spin susceptibility of the TTT and TCNQ chains. The value of 2.0029 is known as the average g-value of tetraethylammonium $(TCNQ)_2$.[40] The value of $\bar{g}_T$ is presently determined to be 2.0083 for $(TTT^+)(CH_3CO_2^-)$.[39] Using the relation of Eq. 2, we may estimate $\chi_{s,T}$ and $\chi_{s,Q}$ from these g-values. In this estimation, we have assumed that the $\bar{g}_T$ and $\bar{g}_Q$ are independent of temperature. The results are shown in Fig. 5 together with total χ_s.

In both complexes, $\chi_{s,Q}$ is larger than $\chi_{s,T}$. In particular the temperature dependence of χ_s of (TTT)(TCNQ)$_2$ is primarily dominated by the susceptibility of the TCNQ chains. It is clearly seen from Fig. 5 that the phase transition near 90 K is related to the TTT chains and that near 60 K is to the TCNQ chains, and moreover each phase transition does not seem to influence the other.

Estimation of Band Width and On-site Coulomb Repulsive Energy

Spin susceptibilities of organic conductors have often been explained in terms of a one-dimensional Hubbard model,[41] which takes into account of transfer of electron between neighboring sites and on-site Coulomb repulsion between two electrons on the same site. The magnetic properties on this model are known for the following three limiting cases which are characterized by the relation between the band width ($4t$) and the on-site Coulomb repulsive energy (U), where t is the transfer integral between neighboring sites; (a) non-interacting case ($U=0$), (b) small U limit ($U \ll 4t$), and (c) large U limit ($U \gg 4t$).

In the non-interacting case, the system is in metallic state and the magnetic susceptibility would be given by the Pauli paramagnetism. Assuming a tight-binding approximation, the Pauli susceptibility at $T=0$ K is given by[42]

$$\chi_{Pauli}(0) = \frac{N_A\mu_B^2}{t\pi \sin(\pi\rho/2)}, \tag{3}$$

where N_A is the Avogadro constant, μ_B is the Bohr magneton and ρ is the electron-to-site ratio. The temperature dependence of Pauli paramagnetism, $\chi_{Pauli}(T)$, has been calculatd only for $\rho=1$ by Shiba.[43] Therefore we have to assume that the temperature dependence of Pauli susceptibility for arbitrary ρ is given by dividing $\chi_{Pauli}(T)$ by filling factor, $\sin(\pi\rho/2)$.

In the small U limit ($U \ll 4t$), the spin susceptibility due to the Pauli paramagnetism would be enhanced by the on-site Coulomb repulsion and is given by[44]

$$\chi_s = \frac{\chi_{Pauli}(T)}{(1-U/4\pi t)\sin(\pi\rho/2)}. \tag{4}$$

As the on-site Coulomb repulsion increases, electrons tend to be scattered with each other and localized character of them gradually increases. In the large U limit ($U \gg 4t$), electrons are strongly localized on each site and this situation just coincides with the one-dimensional Heisenberg antiferromagnetic chain. In this case, the exchange coupling constant, J, is related to U, $4t$, and ρ by the equation,[45]

$$J = \frac{2t^2}{U + (4t/\pi)\sin\pi\rho}\left(1 - \frac{\sin 2\pi\rho}{2\pi\rho}\right). \tag{5}$$

The band width and the Coulomb repulsion energy may be estimated from these equations by examining the susceptibilities at various temperatures. Representative results of such fittings are shown in Fig. 8 for the spin susceptibilities of TTT and TCNQ chains in (TTT)(TCNQ) and (TTT)(TCNQ)$_2$, performed by using the values of ρ derived from the XPS study. Unfortunately, however, the agreement between the calculated and observed susceptibilities are not satisfactory in the whole temperature region in either case. In (TTF)(TCNQ), Torrance *et al.*[44] have also found lack of agreement in the temperature dependence of calculated susceptibilities with those observed. We concentrate then our attention on getting agreement in the magnitude of χ_s only at room temperature in order to see what is the most reasonable case as discussed by Torrance *et al.*

We examine the TCNQ chains at first. For the non-interacting case, agreements are obtained when we choose $4t$ to be 0.3 eV for (TTT)(TCNQ) and 0.15 eV for (TTT)(TCNQ)$_2$. Since most of the band widths of organic conductors have been estimated to be 0.4—1.5 eV from different experiments and calculations,[46,47] these obtained values seem to be too small. If we intend to apply the reasonable band width, we have to take into account of enhancement of χ_s by introducing a finite on-site Coulomb repulsive interaction.

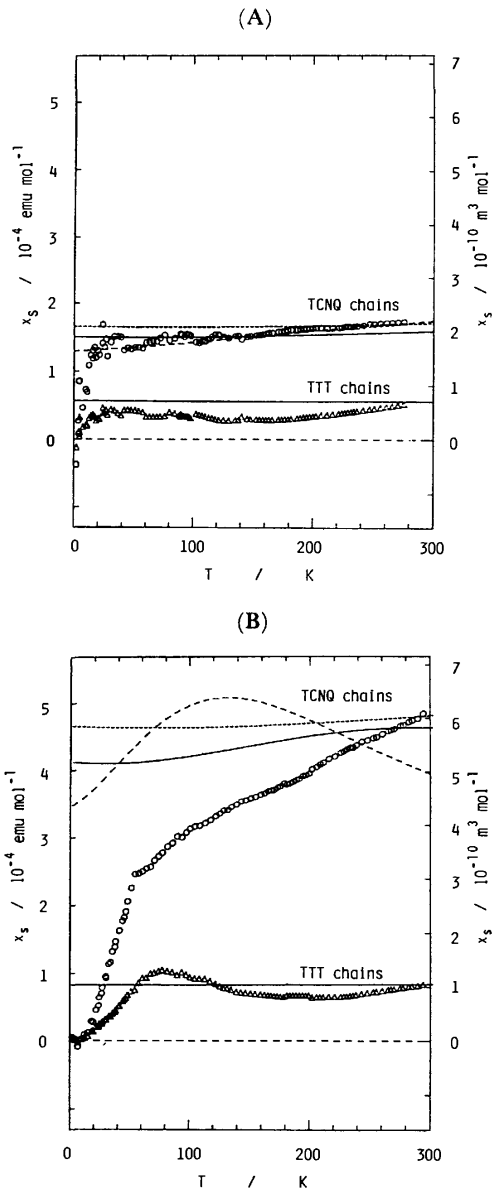

Fig. 8. Estimated spin susceptibilities with the one-dimensional Hubbard model for three limits. (A): (TTT)(TCNQ): △; $\chi_{s,T}$ observed, ——; non-interacting case (U=0, $4t$=0.8 eV), ○; $\chi_{s,Q}$ observed, ——; non-interacting case (U=0, $4t$=0.3 eV), ----; small U limit ($4t$=0.4 eV, $U/4t$=1.0), — — —; large U limit (J=420 K, $U/4t$=1.2), (B) (TTT)(TCNQ)$_2$: △; $\chi_{s,T}$ observed, ——; non-interacting case (U=0, $4t$=0.5 eV), ○; $\chi_{s,Q}$ observed, ——; non-interacting case (U=0, $4t$=0.15 eV), ----; small U limit ($4t$=0.4 eV, $U/4t$=2.1), — — —; large U limit (J=100 K, $U/4t$=2.1).

Berlinsky *et al.*[47] have estimated $4t$ of TCNQ chains in (TTF)(TCNQ) to be 0.44 eV based on extended Hückel MO calculation. The X-ray analysis of (TTT)(TCNQ)$_2$[2,48] shows that the manner of overlap of the TCNQ molecules is similar to that of (TTF)(TCNQ),[49] *i.e.*, so called ring-external bond type. The interplanar spacing between TCNQ molecules (318 pm) is nearly the same as that of (TTF)(TCNQ)(317 pm). By expecting that a value of $4t$ is not much influenced by the change in the manner of stacking, the band width of the TCNQ chains of the two complexes may be assumed to be 0.4 eV. On this assumption, the best fit is obtained when $U/4t$ is 1.0 for (TTT)(TCNQ) and 2.1 for (TTT)(TCNQ)$_2$ in the small U limit.

For the large U limit, fitting with Bonner-Fisher susceptibility[50] gives the J value of 420 K for (TTT)(TCNQ) and 100 K for (TTT)(TCNQ)$_2$. From these J, the values of $U/4t$ is estimated to be 1.2 for (TTT)(TCNQ) and 2.5 for (TTT)(TCNQ)$_2$.

In each limit, the estimated $U/4t$ falls into the range of 1—2.5 and contradicts the initially assumed condition, that is, small or large U. This fact suggests that the magnitude of U is comparable with that of $4t$; *i.e.*, the relation between U and $4t$ is in an intermediate case, since the behavior of susceptibility for intermediate U is simply intermediate between the behavior calculated for small U and that for large U. Torrance *et al.* have suggested that the intermediate U can be expected for (TTF)(TCNQ) and the role of the on-site Coulomb repulsion is important in magnetic properties of one-dimensional organic conductors.[44] Similar findings on χ_s have also been reported for organic conductors such as (TSF)(TCNQ) and (HMTTF)(TCNQ).[51]

For the TTT chains, the situation seems to be different. In the non-interacting limit, $4t$ of the TTT chains are evaluated to be 0.8 eV for (TTT)(TCNQ) and 0.5 eV for (TTT)(TCNQ)$_2$. These values seem to be in agreement with the reported values of 0.6—1.5 eV for (TTT)$_2$I$_3$.[5,6,52] Therefore, the on-site Coulomb repulsion seems to be very small on the TTT chains in both complexes.

It is of interest to compare the evaluated spin susceptibilities with those of other two-chains organic conductors. The spin susceptibilities of donor ($\chi_{s,d}$) and acceptor chains ($\chi_{s,a}$) of some two-chains conductors at 300 K are listed in Table 1 together with those of (TTT)(TCNQ) and (TTT)(TCNQ)$_2$. Table 1 indicates that the variation of $\chi_{s,d}$ among these complexes is larger than that of $\chi_{s,a}$. Since the TCNQ molecules in these complexes make stacking in the similar manner,[49,57-60] it is reasonably expected that $\chi_{s,Q}$ does not differ too much, though the interplanar spacings are varied from 317 to 331 pm. For the donor stacks, on

Table 1. Total ($\chi_{s,t}$), donor ($\chi_{s,d}$), and acceptor ($\chi_{s,a}$) spin susceptibilities of two-chains organic conductors at 300 K. Susceptibilities are given in 10^{-4} emu mol^{-1}

	$\chi_{s,t}$	$\chi_{s,d}$	$\chi_{s,a}$	Reference

(TTT)(TCNQ)	2.3	0.5	4.9	This work

a) TMTTF=2,2′-Bi(4,5-dimethyl-1,3-dithiolylidene). b) TMTSF=2,2′-Bi(4,5-dimethyl-1,3-diselenolylidene). c) DMTCNQ=2,2′-(2,5-Dimethyl-2,5-cyclohexadiene-1,4-diylidene)bis(propanedinitrile).

the other hand, the large variation of $\chi_{s,d}$ may be ascribed to the large difference in molecular structure and chemical properties of the donors.

Among these compounds, the susceptibility of donor chains in (HMTTF)(TCNQ) exhibits behavior similar to that in (TTT)(TCNQ) and (TTT)(TCNQ)$_2$ in temperature dependence and magnitude. The spin susceptibility of HMTTF chains in (HMTTF)(TCNQ) is almost independent of temperature above the transition temperature of 50 K and its magnitude is 0.75×10^{-4} emu mol^{-1}, which corresponds to the Pauli paramagnetism with $4t$=0.57 eV. Tomkiewicz *et al.* have explained this finding in terms of reduction of U arising from the following two possible ways;[51] (1) reduction of bare U, caused by chemical modification of donor molecule and (2) effective reduction of U, arising from a screening effect of counter ions which has been first proposed by LeBlanc.[61]

Since the interplanar distance of the donor in (TTT)(TCNQ)$_2$ (352 pm) is larger to a small extent than that in (TTF)(TCNQ) (347 pm), the band width of TTT is expected to be comparable with or slightly narrower than that of TTF. Therefore the flat temperature dependence of the small magnitude of susceptibility would have to be attributed to the reduction of the on-site Coulomb repulsion as discussed in the case of (HMTTF)(TCNQ). It is plausible to assume that the reduction of U arises from the chemical modification of donor molecule, because it is rather difficult to see that the screening effect of TCNQ as a counter ion contributes markedly to reduction of U from its molecular and crystal structure.

Spin density distribution calculations[62] on sulfur containing organic cation radicals would support this idea. The calculation on the TTT$^+$ radical has revealed that more than 70% of unpaired electron spins are distributed on the 5-, 6-, 11-, and 12-carbon atoms and the four sulfur atoms of the TTT molecule. In the TTF$^+$ radical, most of the spins are located on the 2- and 2′-carbon atoms and the four sulfur atoms. A comparison of the spin distributions allows us to regard TTT as a molecule similar to TTF, but the four sulfur atoms in TTF are pulled apart from 1,1′,3,3′-positions to 4,4′,5,5′-positions. Since the sulfur-sulfur distance between different five-membered rings is prolonged in TTT in comparison with that of TTF, U is expected to be reduced. At the same time, the four benzene rings in TTT also contribute to reduction of U as a result of the delocalization of electrons

Phase Transitions and Low-temperature Spin Susceptibility

As discussed in previous sections, the presence of the magnetic phase transition becomes apparent in (TTT)(TCNQ)$_2$ by the measurements of magnetic susceptibility and ESR. In (TTT)(TCNQ), however, no evidence for a phase transition has been found at least above 20 K. Thus our discussion about the phase transition is limited only to (TTT)(TCNQ)$_2$.

The temperature-dependent $\chi_{s,T}$ and $\chi_{s,Q}$ are shown in Fig. 9. On lowering the temperature below

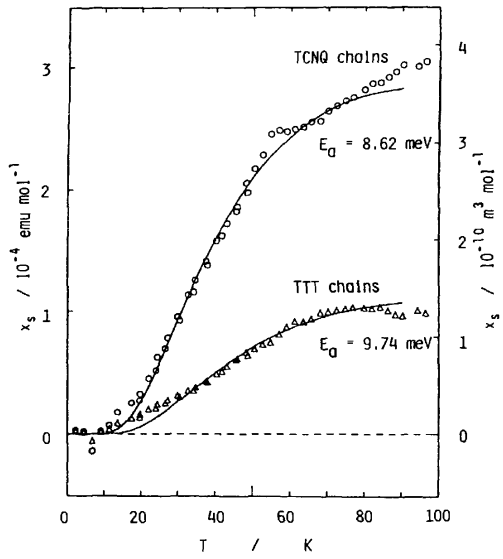

Fig. 9. Spin susceptibilities of TTT and TCNQ chains in (TTT)(TCNQ)$_2$ below the transition temperature. Solid lines are calculated susceptibilities with $\chi_s = (C/T)\exp(-E_a/k_BT)$, E_a=9.74 meV for TTT chains and 8.62 meV for TCNQ chains.

the transition temperature, the spin susceptibilities of both chains decrease monotonously with the activation-type equation,

$$\chi_s = (C/T)\exp(-E_a/k_BT), \quad (6)$$

where C is a constant and E_a is an activation energy. The values of C and E_a are found to be 0.034 emu K mol^{-1} and 9.74 meV for the TTT chains and 0.077 emu K mol^{-1} and 8.62 meV for the TCNQ chains. The temperature dependence of the susceptibilities arises from the spins which are thermally excited across a gap that is formed by a phase transition. This type of temperature dependence of susceptibility has often been found in the low temperature region of organic conductors which become semiconductive by the Peierls transition.[53,63] Indeed, the conductivity measurement carried out by Buravov *et al.* has shown that (TTT)(TCNQ)$_2$ is semiconductive below the transition temperature of about 90 K.[2] Thus the phase transition may be attributed to a metal-semiconductor transition driven by the Peierls instability.

The activation energies of paramagnetism of the TCNQ chains for (TTF)(TCNQ)[63] and (HMTTF)(TCNQ)[53] are known to be 36 and 21.5 meV, respectively, in the semiconductive region. The observed E_a of 8.62 meV for the TCNQ chains of (TTT)(TCNQ)$_2$ is smaller than these values. Since a magnetic activation energy is related to the strength of electron-phonon coupling,[64] the small value for (TTT)(TCNQ)$_2$ suggests a weaker electron-phonon coupling on the TCNQ chains in (TTT)(TCNQ)$_2$. The activation energies of the donor chains for (TTF)(TCNQ) and (TMTTF)(TCNQ) have been estimated to be 10.8 and 13.8 meV, respectively, and are slightly larger than those for the TTT chains of (TTT)(TCNQ)$_2$ (9.74 meV). Thus the magnitude of electron-phonon coupling on the TTT

chains in(TTT)(TCNQ)$_2$ seems to be close to that on TTF in (TTF)(TCNQ), whose donor chains are distorted at 49 K.[38,63]

The transition temperature of the TTT chains in (TTT)(TCNQ)$_2$ is rather high compared with that of the donor chains in other two-chains complexes, while that of the TCNQ chains is not so different from that of (TTF)(TCNQ). A transition temperature driven by the Peierls instability is associated with the strength of the electron-phonon coupling and the dimensionality, namely the strength of interchain interactions. The stronger the electron-phonon coupling and the weaker the interchain interaction, the higher phase transition temperature is expected. The crystal structure analysis suggests that the interchain interaction is weak in (TTT)(TCNQ)$_2$. The shortest interchain distances are 344 and 348 pm, and are considerably longer than those of (TTF)(TCNQ) (320 and 325 pm)[49] and (HMTTF)(TCNQ) (325 pm).[55] The weak interchain interaction is also suggested by our preliminary ESR measurements on a single crystal of this complex. The peak-to-peak linewidth of ESR signal at room temperature is quite narrow (1.1 Oe) among the sulfur containing organic conductors.[53,55] This finding indicates that the spin relaxation is suppressed, because if interchain interaction is too weak to transfer effectively the magnetic energy three-dimensionally, the correlation among spins is generally kept for rather long time.

Therefore high transition temperature of TTT chains reflects the low-dimensional character of this complex. For the TCNQ chains, the observed weak electron-phonon coupling would lower the transition temperature, whereas weak interchain interaction would raise the transition temperature. The two effects on the TCNQ chains counteract each other and consequently, the transition temperature of the TCNQ chains would not change much from that of (TTF)-(TCNQ).

Summary

The susceptibilities of both of the donor and acceptor chains extracted by the manipulation of the data indicate that, in the metallic region, the susceptibility of the TCNQ chains is considerably enhanced by the on-site Coulomb repulsion and dominates the magnitude of the total susceptibility, while the susceptibility of the TTT chains is explained by the Pauli paramagnetism.

The discontinuities in the temperature dependence of the spin susceptibility in (TTT)(TCNQ)$_2$ are driven by the Peierls instability, resulting in the thermally activated paramagnetism below the transition temperature. The susceptibility of (TTT)(TCNQ) is almost temperature independent above 20 K. Although some insight into electronic state is given in the latter complex, further experiments such as conductivity measurement on a single crystal and structure analysis are indispensable for detailed discussion.

The authors are thankful to Professor Kazuo Morigaki and Dr. Izumi Hirabayashi of the Institute for Solid State Physics and Drs. Mikio Hoshino and Hisaharu Hayashi of the Institute of Physical and Chemical Research for the kindness in putting the ESR spectrometers at their disposal. Thanks are also due to Professors Haruo Kuroda and Isao Ikemoto of the Department of Chemistry for their support in XPS measurements. The authors are grateful to Dr. Gunji Saito of the Institute for Molecular Science for measurements of mass spectra and Mr. Kenji Suzuki for his help in synthesis of TTT. A part of this work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture (No. 57740230).

Dinuclear Cobalt(II) Complexes with Various Dinucleating Ligands and Their Dioxygen Complexes

Masatatsu SUZUKI,*,† Hajime KANATOMI, and Ichiro MURASE
Laboratory of Chemistry, College of General Education, Kyushu University, Ropponmatsu, Chuo-ku, Fukuoka 810
(Received July 21, 1983)

Various types of dinuclear cobalt(II) complexes, $[Co_2L(CH_3COO)_2]ClO_4$, $[Co_2L(CH_3COO)](ClO_4)_2$, $[Co_2L(OH)](ClO_4)_2$, $[Co_2L(C_3H_3N_2)](ClO_4)_2$($C_3H_3N_2^-$=pyrazolate), and $[Co_2LX_2](ClO_4)_n$, were prepared, where HL represents 2,6-bis[bis(2-pyridylmethyl)aminomethyl]-4-methylphenol(Hbpmp), 2,6-bis[*N*-(2-pyridylmethyl)-2-(2-pyridyl)ethylaminomethyl]-4-methylphenol(Hbpmep), 2,6-bis[bis[2-(2-pyridyl)ethyl]aminomethyl]-4-methylphenol(Hbpep), and 2,6-bis[bis(2-benzimidazolylmethyl)aminomethyl]-4-methylphenol(Hbbimp), and X is N_3^-, NCS^-, Cl^-, Br^-, H_2O, or py(pyridine). The electronic spectra and magnetic moments of the complexes revealed that $[Co_2L(CH_3COO)_2]ClO_4$ (L=bpmp, bpmep, or bpep) are high-spin octahedral, whereas the other complexes have five-coordinate structure of high-spin configuration. Some of the bpmp and the bpmep complexes reacted reversibly with molecular oxygen more or less. The $P_{1/2}$ of some complexes were determined spectrometrically. The oxygen affinities of the complexes are highly dependent on the natures of the dinucleating ligands and additional bridging or unidentate ligands.

It has been demonstrated that a number of metal complexes with sterically and electronically controlled ligand environment reversibly bind molecular oxygen. Dinuclear metal complexes in which two metal ions are in suitable positions can bind molecular oxygen to form 2:1 (metal:O_2) dioxygen adducts.[1,2]

In biological system, hemocyanine and hemerythrin contain two metal ions (copper for hemocyanine and iron for hemerythrin) at each oxygen binding site and form 2:1 dioxygen adducts. For those complexes, it has been postulated that two metal ions are linked by such bridging ligands as phenolate, carboxylate, hydroxide, or oxide.[3,4]

In the previous studies,[5,6] we demonstrated that dinuclear cobalt(II) complexes having phenolate and carboxylate bridges, $[Co_2(bpmp)(CH_3COO)_2]ClO_4$ and $[Co_2(bpmp)(CH_3COO)](ClO_4)_2$, react with molecular oxygen to form 2:1 dioxygen adduct, $[Co_2(bpmp)(CH_3COO)(O_2)](ClO_4)_2\cdot 2H_2O$. The X-ray analysis of $[Co_2(bpmp)(benzoato)(O_2)](BF_4)_2\cdot 2H_2O$ showed that two cobalt ions are linked by three bridging ligands, *viz.* dioxygen, phenolate, and benzoate, and the O-O bond distance is 1.43 Å which is in the range of those of the μ-peroxo complexes.[6]

As an extension of the above studies, we have synthesized various types of dinuclear cobalt(II) complexes with the dinucleating ligands shown in Fig. 1, and their reactivities toward molecular oxygen have been investigated spectrometrically.

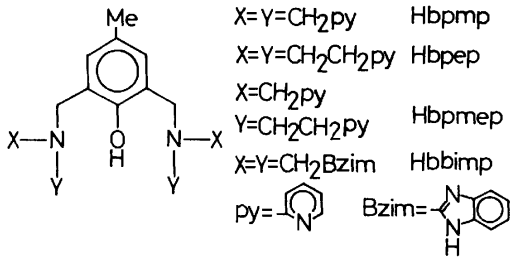

Fig. 1. Dinucleating ligands.

Experimental

Preparation of Ligands. Bis[2-(2-pyridyl)ethyl]amine was prepared according to the literature.[7] Bis(2-benzimidazolylmethyl)amine was synthesized by heating a mixture of iminodiacetic acid and *o*-phenylenediamine at 200 °C. *N*-(2-pyridylmethyl)-2-(2-pyridyl)ethylamine was prepared as follows. An ethanol solution of 2-(2-pyridyl)ethylamine (0.1 mol) and 2-pyridinecarbaldehyde (0.1 mmol) was refluxed for 30 min. The resulting Schiff base was hydrogenated under 4 atm pressure (1 atm=1.013×10^5 Pa) at room temperature using 1 g of 5% Pd-C catalyst. Approximately one molar equivalent of hydrogen was absorbed during 2 h. The filtered solution was distilled and fraction, bp 155—160 °C (133 pa), was collected. This was used for the preparation of Hbpmep without further purifications.

Hbpmep and Hbpep were prepared in the same way as that of Hbpmp.[5] Those ligands were used without further purifications. Hbbimp was prepared as follows. To a dimethylformamide solution (200 cm^3) of bis(2-benzimidazolylmethyl)amine (0.1 mol) and triethylamine (0.1 mol) was added 2,6-bis(chloromethyl)-4-methylphenol (0.05 mol) with stirring in small portions during 1 h at −30 °C. The solution was stirred for 1 h at 0 °C and then dimethylformamide was removed under reduced pressure. The residue was dissolved in 200 cm^3 of hot methanol and after cooling, white powder was obtained.

Preparation of Complexes. For the preparation of the bpmp and the bpmep cobalt(II) complexes, all the manipulations were carried out under argon atmosphere.

$[Co_2L(CH_3COO)_2]ClO_4$ (L=bpmp, bpmep, bpep, or bbimp). The complexes were prepared by the same method as that of $[Co_2(bpmp)(CH_3COO)_2]ClO_4$.[5]

$[Co_2L(CH_3COO)](ClO_4)_2$ (L=bpmp or bpep). Sodium acetate (0.5 mmol) was mixed with a methanol solution (30 cm^3) containing HL (0.5 mmol) and $Co(ClO_4)_2\cdot 6H_2O$ (1 mmol). Pink crystals deposited were collected by filtration, washed with methanol, and dried *in vacuo*. The bpmp complex was air-sensitive and exposure to air caused a color change from pink to brown. The elemental analysis was carried out for the brown compound.

$[Co_2L(OH)](ClO_4)_2$ (L=bpmp or bbimp). The prepar-

† Present address: Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920.

ation of the bpmp complex is exemplified. To a methanol solution (30 cm^3) containing Hbpmp (0.5 mmol) and $Co(ClO_4)_2 \cdot 6H_2O$ (1 mmol) was added a methanol solution (20 cm^3) of CH_3ONa (1 mmol) with stirring. The complex was obtained as green powder, which was filtered, washed with methanol, and dried *in vacuo*.

$[Co_2(bpmp)X_2]ClO_4$ ($X=N_3^-$, NCS^-, Cl^-, or Br^-). The complexes were prepared in a similar way. The typical procedure of the preparation is as follows. To a methanol solution (30 cm^3) of Hbpmp (0.5 mmol) and NaBr (1 mmol) was added a methanol solution (20 cm^3) of $Co(ClO_4)_2 \cdot 6H_2O$ (1 mmol). Violet crystals deposited were collected by filtration, washed with methanol, and dried *in vacuo*.

$[Co_2L(C_3H_3N_2)]ClO_4)_2$ (L=bpmp or bpmep). To a mixture of HL (0.5 mmol), $Co(ClO_4)_2 \cdot 6H_2O$ (1 mmol), and pyrazole (0.5 mmol) in hot ethanol was added dropwise a methanol solution (20 cm^3) of CH_3ONa (1 mmol) with stirring and then the solution was concentrated to 20 cm^3 under reduced pressure. Reddish brown powder deposited was collected by filtration, washed with cold ethanol, and dried *in vacuo*. The complexes were air-sensitive and exposure to air caused a color change from reddish brown to brown. The elemental analysis of the bpmp complex was carried out for the brown compound. For the bpmp complex, the elemetal analysis was carried out for the dioxygen complex (*vide infra*).

$[Co_2(bbimp)(OH_2)_2](ClO_4)_3$. Addition of Hbbimp (0.5 mmol) to 30 cm^3 of ethanol solution of $Co(ClO_4)_2 \cdot 6H_2O$ (1 mmol) gave violet crystals, which were filtered, washed with ethanol, and dried *in vacuo*.

$[Co_2(bbimp)(py)_2](ClO_4)_3 \cdot 2H_2O$. Addition of ethanol (50 cm^3) to a methanol solution (20 cm^3) containing Hbbimp (0.5 mmol), $Co(ClO_4)_2 \cdot 6H_2O$ (1 mmol), and 500 mg of pyridine afforded violet crystals, which were filtered, washd with ethanol, and dried *in vacuo*.

$[Co_2L(CH_3COO)(O_2)](ClO_4)_2$ (L=bpmp or bpmep). A brown methanol solution (100 cm^3) containing HL (0.5 mmol), $Co(ClO_4)_2 \cdot 6H_2O$ (1 mmol), and CH_3COONa (0.5 mmol) was left to stand overnight in air atmosphere. Brown crystals deposited were filtered, washed with ethanol, and dried.

$[Co_2(bpmp)(C_3H_3N_2)(O_2)](ClO_4)_2 \cdot 2H_2O$. To a methanol solution (50 cm^3) containing Hbpmp (0.5 mmol), $Co(ClO_4)_2 \cdot 6H_2O$ (1 mmol), and pyrazole (0.5 mmol) was added dropwise a methanol solution of CH_3ONa (1 mmol) with stirring. The resulting solution was exposed to air and allowed to stand overnight. The brown powder deposited was filtered, washed with ethanol, and dried.

$[Co_2(bpmp)(OH)(O_2)](Bph_4)_2 \cdot CH_3CN \cdot H_2O$. Sodium tetraphenylborate ($NaBph_4$)(1.5 mmol) was added to an acetonitrile solution of $[Co_2(bpmp)(OH)](ClO_4)_2 \cdot 0.5H_2O$ (0.5 mmol) in air atmosphere. The resulting brown solution was allowed to stand overnight to give brown crystals, which were filtered, washed with methanol, and dired.

Measurements. The electronic spectra of solutions and of solids were obtained with a Hitachi EPS-3T recording spectrophotometer and infrared spectra were recorded with a Hitachi 295 infrared spectrophotometer by means of KBr disks. Electrolytic conductivities at 25 °C on approximately 10^{-3} M (1 M=1 mol dm^{-3}) acetonitrile and methanol solutions were obtained using Yokogawa-Hawlett-Packard 4261 LCR meter. Magnetic susceptibilities were measured by Faraday method in a temperature range from liquid nitrogen temperature to room temperature. Magnetic moments were calculated by the expression, $\mu_{eff}=2.828\sqrt{\chi_a \times T}$, where χ_a is the magnetic susceptibility per one cobalt ion corrected for diamagnetism using Pascal's constants.

Oxygen Uptake Measurement. The equilibrium constants (K) for the reaction

$$[Co_2] + O_2 \rightleftharpoons [Co_2 \cdot O_2] \quad (1)$$

were determined at 25 °C(±0.5) in acetonitrile or methanol using visible spectroscopy. In a typical measurement, 7×10^{-6} mol of $[Co_2(bpmp)(N_3)_2]^+$ was dissolved in 50 cm^3 of acetonitrile in a specially designed reaction cell equipped with a quartz cell (1 cm path length). The reaction cell was evacuated and filled with argon gas, and heated at 70 °C until almost colorless solution was obtained. Then the reaction cell was evacuated for a while. Subsequently, after temperature equilibration, various pressures of oxygen were added to the reaction cell, and the contents were stirred until the constant absorbance was obtained. In the case of $[Co_2(bpmp)(CH_3COO)]^{2+}$, $[Co_2(bpmp)(C_3H_3N_2)]^{2+}$, $[Co_2(bpmp)(OH)]^{2+}$, and $[Co_2(bpmp)(CH_3COO)_2]^+$, various pressures of argon gas containing known oxygen partial pressure were added. Equilibrium constants were calculated by the method of Collman *et al.*[8] using the following equation,

$$P_{O_2} = [Co_2]_T \cdot l \cdot \Delta\varepsilon \cdot P_{O_2}/(A-A_0) - K^{-1},$$

where P_{O_2} is the partial pressure of O_2, $[Co_2]_T$ is the total complex concentraton, l is the path length of the cell, A is the absorbance of the solution at the oxygen pressure P_{O_2} and A_0 is the absorbance of the solution in the absence of oxygen, $\Delta\varepsilon$ is the difference between molar extinction coefficients of the oxy and the deoxy complexes. A plot of P_{O_2} *vs.* $P_{O_2}/(A-A_0)$ should be a straight line with slope of $[Co_2]_T \cdot l \cdot \Delta\varepsilon$ (constant) and intercept of $-K^{-1}$. Straight lines were then computor fit and the equilibrium constants (K) were determined from the intercepts.

The slopes of the plots of $\log((A-A_0)/(A_\infty-A))$ *vs.* $\log(P_{O_2})$ were 1.0—1.2, indicating a 1:1 stoichiometry for the oxygenation reaction (1). In the cases where complete oxygenation was not obtained at O_2 pressure of *ca.* 700 Torr (1 Torr=133.322 Pa), the values of A_∞ were determined by extrapolating a plot of A *vs.* P_{O_2} to infinite pressure.[9]

In the case of $[Co_2(bpmp)(CH_3COO)]^{2+}$, $[Co_2(bpmp)(C_3H_3N_2)]^{2+}$, and $[Co_2(bpmp)(OH)]^{2+}$ the values for K could not be obtained because of very small amount of O_2 involved for those measurements and $P_{1/2}$ values are only roughly estimated numbers, where $P_{1/2}$ represents a partial oxygen pressure at which 50% of the complex is oxygenated.

Results and Discussion

Dinuclear Cobalt(II) Complexes. The magnetic moments of the dinuclear cobalt(II) complexes are given in Table 1 (4.1—4.8 BM, 1 BM=9.274×10^{-24} J T^{-1}). Those values indicate that all the complexes have the high-spin configuration.

The electronic spectral data of the dinuclear cobalt(II) complexes are summarized in Table 2 and the representative electronic spectra are shown in Fig. 2. The electronic spectra of the complexes indicate that $[Co_2L(CH_3COO)_2]^+$ (L=bpmp, bpmep, or bpep) are six-coordinate, whereas all the other complexes are five-coordinate.

The complexes, $[Co_2L(CH_3COO)_2]^+$, show two d-d bands at *ca.* 9000 and 21000 cm^{-1}, except for $[Co_2(bbimp)(CH_3COO)_2]^+$ (Table 2 and Fig. 2). The spectra are closely similar to that of octahedral hexaaquacobalt(II).[10] In these six-coordinate complexes, two acetate ions can coordinate to cobalt ions in two way, *viz.* as chelating ligands or as bridging ligands in syn-syn configuration.[11] An examination of a Dreiding model suggested that the two acetate ions function as

a): In acetonitrile. b): Broad band. s: Shoulder.

bridging ligands. Therefore, we assumed that the six-coordinate complexes possess the structure given in Fig. 3a, where two cobalt ions are linked by three bridging ligands, *viz.* two acetates and one phenolate.

In contrast to the above complexes, $[Co_2(bbimp)(CH_3COO)_2]^+$ shows several d-d bands in the visible and the near infrared regions (Fig. 2). In general, five-coordinate cobalt(II) complexes exhibit several d-d bands in 5000—25000 cm^{-1}.[12] Thus the electronic spectrum of the complex indicates the presence of a five-coordinate cobalt(II) chromophere. The two acetate ions in this complex, therefore, coordinate to cobalt ions as unidentate ligands. A possible structure of the complex is given in Fig. 3e. Of particular interest is that bbimp forms five-coordinate bis(acetato) complex, whereas the other dinucleating ligands form six-coordinate bis(acetato) complexes. Such structural change in the bbimp complex seems to be attributed to a steric requirement in the bbimp complex; a steric interaction between bulky benzimidazolyl groups and methyl groups of the acetate ions may enforce five-coordinate structure.

The electronic spectra of $[Co_2(bpmp)X_2]$ ($X=N_3^-$, NCS^-, Cl^-, or Br^-) show that the complexes have five-

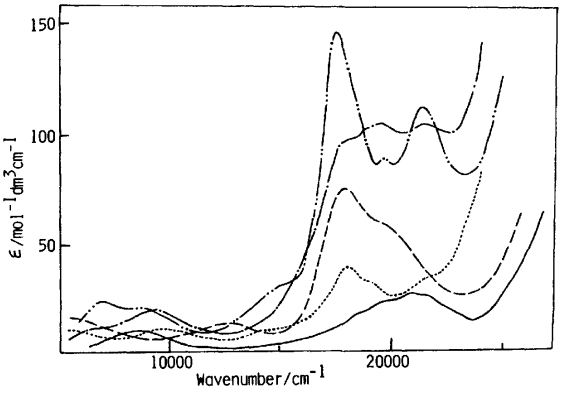

Fig. 2. Absorption spectra of $[Co_2(bpep)(CH_3COO)_2]^+$ (——), $[Co_2(bbimp)(CH_3COO)_2]^+$ (----), $[Co_2(bpep)(CH_3COO)]^{2+}$ (·····), $[Co_2(bpmp)(N_3)_2]^+$ (—·—), and $[Co_2(bpmp)Br_2]^+$ (—··—) in acetonitrile.

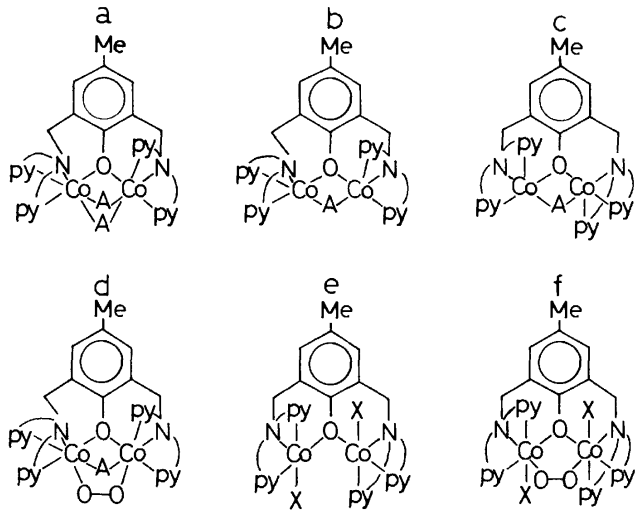

Fig. 3. Proposed structures of dinuclear complexes. A is CH_3COO^-, $C_3H_3N_2^-$, or OH^-, and X is N_3^-, NCS^-, Cl^-, or Br^-.

coordinate structure. The molar conductivities of the complexes in acetonitrile are 134—139 Ω^{-1} cm^2 mol^{-1}, which are typical for 1 : 1 electrolytes in acetonitrile,[13] supporting the above formula, $[Co_2(bpmp)X_2]^+$. The structure of the complexes seem to be essentially identical to that of $[Co_2(bbimp)(CH_3COO)_2]^+$ (Fig. 3e), where the two cobalt(II) ions are bridged by only phenolate.

The electronic spectra of the mono(acetato), mono(pyrazolato), mono(hydroxo) complexes also revealed that all the complexes are five-coordinate. In these complexes, the acetate, pyrazolate, and hydroxide ions seem to function as bridging ligands as found in the dinuclear copper(II) complexes containing such ions.[14]

For those complexes, there are two possible structures shown in Fig. 3b and c. Judging from the reactivities of the mono(acetato) and mono(pyrazolato) complexes with molecular oxygen in the solid state (*vide infra*), the structure b seems to be preferable. On the other hand, the structure (c) seems to be preferable for the hydroxo complex (*vide infra*).

In general, the magnetic moments of six-coordinate complexes are larger than those of five-coordinate complexes because of an extensive contribution from an orbital angular momentum in $^4T_{1g}$ ground state in octahedral symmetry. Such tendency can be observed for the present complexes (Table 1).

Table 3. Magnetic data

Complex	μ_{eff} BM		θ K
	82 K	291 K	
$[Co_2(bpmp)(CH_3COO)_2]ClO_4$	4.37	4.61	−15
$[Co_2(bpmp)(OH)](ClO_4)_2\cdot 0.5H_2O$	3.75	4.12	−27
$[Co_2(bpmp)(NCS)_2]ClO_4\cdot H_2O$	3.73	4.37	−51
$[Co_2(bbimp)(OH_2)_2](ClO_4)_3$	3.73	4.28	−36
$[Co_2(bbimp)(OH)](ClO_4)_2\cdot 3H_2O$	4.16	4.40	−12

The magnetic susceptibilities of the complexes listed in Table 3 were measured in the temperature range 80—300 K. The magnetic moment of the six-coordinate complex, $[Co_2(bpmp)(CH_3COO)_2]ClO_4$, decreases with temperature. However, this does not necessarily imply antiferromagnetic interaction between the cobalt(II) ions, since monomeric six-coordinate cobalt(II) complexes show such a decrease of magnetic moments because of an extensive contribution from an angular orbital momentum in $^4T_{1g}$ ground state in octahedral symmetry.[15] The magnetism of the complex obeys the Curie-Weiss law in the temperature range 80—300 K and the Weiss constant is −15 K. The Weiss constants of the monomeric cobalt(II) complexes have been shown to be in the range −10—−40 K.[15] Thus the magnetic interaction between the cobalt(II) ions must be negligibly small. The magnetisms of the five-coordinate complexes also obey the Curie-Weiss law. The Weiss constants are −10—−50 K. These values suggest that the antiferromagnetic interactions in the complexes are weak.

Oxygenation Reactions. Since all the oxygenated complexes showed intense brown color, the oxygenation can be easily followed spectrometrically. Brown color of the oxygenated complexes may be attributable to the charge transfer transitions from dioxygen and/or phenolic oxygen to the cobalt centers. The representative spectral change upon oxygenation is given in Fig. 4. The dioxygen complexes isolated are essentially diamagnetic (Table 1). The X-ray structure determination of $[Co_2(bpmp)(benzoato)(O_2)](BF_4)_2\cdot 2H_2O$ has shown that the O-O bond distance is 1.43 Å and the two cobalt ions are bridged by three ligands, dioxygen, phenolate, and benzoate (see Fig. 3d). These observations suggest that the dioxygen complexes are of μ-peroxo type.

The six-coordinate complex, $[Co_2(bpmp)(CH_3COO)_2]ClO_4$, was stable on exposure to air in the solid state, whereas the complex underwent oxygenation in methanol. The molar conductivity of the complex in methanol gradually increased by bubbling O_2 (90 → 150 Ω^{-1} cm^2 mol^{-1}), indicating the formation of a 2 : 1 electrolyte upon oxygenation.[13] The addition of sodium perchlorate in methanol solution in air atmosphere afforded brown crystals, $[Co_2(bpmp)(CH_3COO)(O_2)]$-

Table 4. Equilibrium constants for the reaction $[Co_2]+O_2 \rightleftarrows [Co_2 \cdot O_2]$[a] at 20 °C

Complex 7×10^{-6} mol	Solvent	$\log(K/\mathrm{Torr}^{-1})$	$P_{1/2}$/Torr
$[Co_2(bpmp)(CH_3COO)_2]^+$	CH_3OH	-0.8 ± 0.1[b]	6
$[Co_2(bpmp)(CH_3COO)]^{2+}$	CH_3CN		≈ 0.1[c]
$[Co_2(bpmp)(C_3H_3N_2)]^{2+}$	CH_3CN		≈ 0.1[c]
$[Co_2(bpmp)(N_3)_2]^+$	CH_3CN	-1.70 ± 0.02	50
$[Co_2(bpmep)(CH_3COO)]^{2+}$	CH_3CN	-1.39 ± 0.03	24

a): Standard state of 1 Torr. b): For the reaction, $[Co_2(bpmp)(CH_3COO)_2]^+ + O_2 \rightleftarrows [Co_2(bpmp)(CH_3COO)(O_2)]^{2+} + CH_3COO^-$, K is calculated by the following equation, $K=[Co_2 \cdot O_2]/[Co_2] \cdot P_{O_2}$, where the concentration of the acetate ion dissociated is omitted. c): Only roughly estimated number.

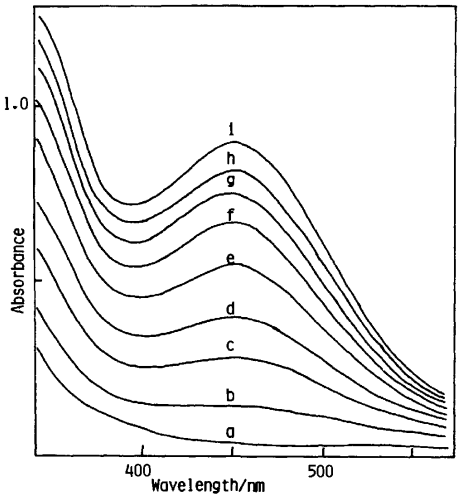

Fig. 4. Spectral change as a function of oxygen pressure for the reversible oxygenation of $[Co_2(bpmp)(N_3)_2]^+$ in acetonitrile at 20 °C. Spectra of a—i are at partial pressure of oxygen: 0, 6, 19, 32, 60, 104, 172, 284, and 692 Torr, respectively.

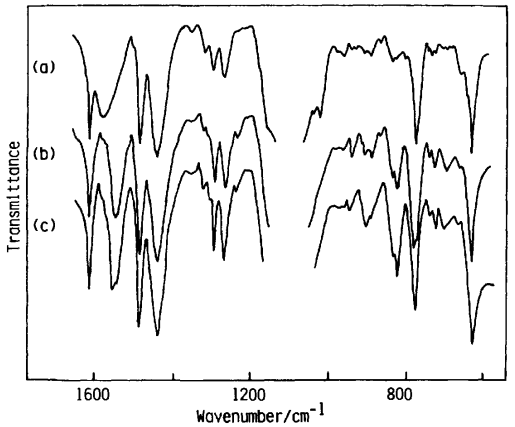

Fig. 5. Infrared spectra of $[Co_2(bpmp)(CH_3COO)](ClO_4)_2$ (a and b), and $[Co_2(bpmp)(CH_3COO)(O_2)](ClO_4)_2 \cdot 2H_2O$(c). a, freshly prepared; b, after 24 h.

$(ClO_4)_2 \cdot 2H_2O$, the structure of which is given in Fig. 3d. It is noteworthy that no oxygenation was observed in acetonitrile and dichloromethane. In addition, the oxygenation in a methanol solution was suppressed by the addition of sodium acetate. Those observations suggest that the oxygenation proceeds *via* the five-coordinate complex, $[Co_2(bpmp)(CH_3COO)]^{2+}$, and the dissociation of the acetate ion from $[Co_2(bpmp)(CH_3COO)_2]^+$ is suppressed in acetonitrile and dichloromethane. Therefore, it is likely that the oxygenation of the complex proceeds as follows,

$$[Co_2(bpmp)(CH_3COO)_2]^+ \rightleftharpoons [Co_2(bpmp)(CH_3COO)]^{2+} + CH_3COO^-$$

$$[Co_2(bpmp)(CH_3COO)]^{2+} + O_2 \rightleftharpoons [Co_2(bpmp)(CH_3COO)(O_2)]^{2+}.$$

$P_{1/2}$ for the complex is 6 Torr in methanol at 20 °C and may be controlled by the addition of sodium acetate. $[Co_2(bpmep)(CH_3COO)_2]^+$ also reacted reversibly with molecular oxygen in methanol. However, the oxygen affinity is too low to determine $P_{1/2}$ at 20 °C. For $[Co_2(bpep)(CH_3COO)_2]^+$, no oxygenation was observed in methanol even at −40 °C.

In contrast to the above six-coordinate complex with bpmp, the five-coordinate complex, $[Co_2(bpmp)(CH_3COO)]^{2+}(ClO_4)_2$, is air-sensitive in the solid state. Finely powdered compound gradually changed its color from pink to brown in the presence of O_2. The magnetic moment of the pink compound gradually decreased from 4.3 to 1.4 BM with color change at room temperature in air atmosphere. The pink compound also showed an infrared spectral change (Fig. 5). The brown compound resulted on exposure to air for 24 h shows a spectrum almost identical to that of $[Co_2(bpmp)(CH_3COO)(O_2)](ClO_4)_2 \cdot 2H_2O$. Heating the brown compound at *ca.* 140 °C *in vacuo* regenerated pink compound. Thus $[Co_2(bpmp)(CH_3COO)](ClO_4)_2$ reacts reversibly with molecular oxygen in the solid state. Such reversible O_2 binding in the solid state suggests that the coordination sites of the two cobalt ions should be close enough to bind O_2 in μ-peroxo fashion without extensive rearrangement of the structure. A possible structure of the five-coordinate complex is sketched in Fig. 3b.

The complex also underwent reversible oxygenation in acetonitrile. The deoxygenation by bubbling of argon gas was extremely slow at room temperature, whereas it was much accelerated by heating a solution at about 70 °C. No decomposition was observed after ten oxygenation-deoxygenation cycles. The $P_{1/2}$ of the complex is ≈0.1 Torr at 20 °C in acetonitrile. The dioxygen complex with bpmep, $[Co_2(bpmep)(CH_3COO)(O_2)](ClO_4)_2 \cdot 2H_2O$, also underwent reversible

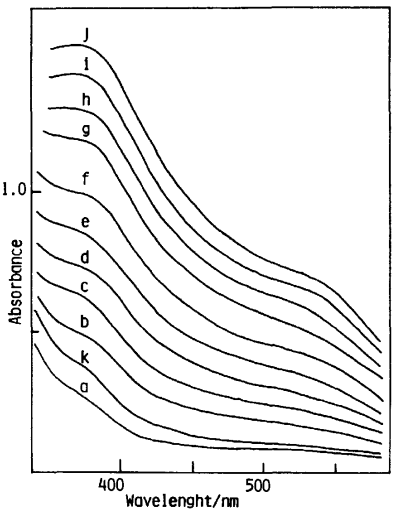

Fig. 6. Spectral change as a function of oxygen pressure for the oxygenation of $[Co_2(bpmep)(C_3H_3N_2)]^{2+}$ in acetonitrile at 20 °C. The spectra of a—j are at partial pressure of oxygen: 0, 10, 22, 42, 74, 119, 201, 301, 483, and 655 Torr, respectively. The spectrum k is at 0 Torr O_2 after oxygenation-deoxygenation cycle.

deoxygenation-oxygenations in acetonitrile. The $P_{1/2}$ is 25 Torr at 20 °C, which is considerably larger than that of the corresponding bpmp complex. In contrast to the above complexes, $[Co_2(bpep)(CH_3COO)]^{2+}$ did not react with molecular oxygen even at −40 °C in acetonitrile.

The pyrazolato-bridged complexes with bpmp and bpmep were also air-sensitive in the solid state. Reddish brown compounds turned brown upon exposure to air. For the bpmep complex, heating the brown compound at 140 °C regenerated the reddish brown compound, whereas the bpmp complex decomposed without the color change to reddish brown by heating. However, the reversible O_2 binding was observed for the bpmp complex in acetonitrile. The $P_{1/2}$ is ≈0.1 Torr at 20 °C, which is comparable to that of the mono(acetato) complex, with bpmp. On the other hand, for the bpmep complex, the oxygenation was not completely reversible in acetonitrile at 20 °C (Fig. 6) and a plot of P_{O_2} *vs.* $P_{O_2}/(A-A_0)$ did not give a straight line. Under such conditions, the $P_{1/2}$ was roughly estimated as ≈80 Torr.

In contrast to the above five-coordinate acetato- and pyrazolato-bridged complexes, $[Co_2(bpmp)(OH)](ClO_4)_2 \cdot 0.5H_2O$ was stable on exposure to air in the solid state. The complex reacted with molecular oxygen in acetonitrile to give brown solution and heating the brown solution at about 70 °C under argon atmosphere regenerated green solution. The addition of sodium tetraphenylborate to an acetonitrile solution in air atmosphere afforded brown crystals, $[Co_2(bpmp)(OH)(O_2)](Bph_4)_2 \cdot CH_3CN \cdot H_2O$. A possible structure of the oxygenated complex is given in Fig. 3d, which is essentially identical to those of the corresponding acetato and pyrazolato complexes.

An attempt to determine the $P_{1/2}$ was made in acetonitrile at 20 °C. The oxygenation was very slow as compared with those of the acetato and pyrazolato complexes at low oxygen pressure (0.2 Torr) and some decomposition was observed during the measurement. Under such conditions, the $P_{1/2}$ was roughly estimated as smaller than 0.2 Torr which is comparable to those of the acetato and pyrazolato complexes with bpmp.

There are two possible structures for $[Co_2(bpmp)(OH)]^{2+}$ as shown in Fig. 3b and c. The structure (b) is essentially identical to those of the acetato and pyrazolato complexes and the oxygen binding sites are close to each other. Therefore, the complex having the structure (b) would be expected to react with molecular oxygen in the solid state. On the other hand, for the structure (c), an extensive rearrangement of the structure is necessary for O_2 binding. Since the complex did not react with molecular oxygen in the solid state and the oxygenation was extremely slow as compared with those of the acetato and pyrazolato complexes in acetonitrile, the structure (c) seems to be plausible.

The complexes, $[Co_2(bpmp)X_2]^+$ ($X=N_3^-$ or NCS^-), reversibly reacted with molecular oxygen in acetonitrile. However, the oxygenated complexes could not be isolated. Conductivity measurement of the azido complex showed that the oxygenated complex is a 1:1 electrolyte in acetonitrile (135 Ω^{-1} cm^2 mol^{-1}) and can be formulated as $[Co_2(bpmp)(N_3)_2(O_2)]^+$. A possible structure is given in Fig. 3f. The $P_{1/2}$ of the complex is 50 Torr at 20 °C, whereas that of the isothiocyanato complex could not be determined because of its low oxygen affinity. The chloro and bromo complexes did not react with molecular oxygen even at −40 °C. Thus, in a series of $[Co_2(bpmp)X_2]^+$, the order of the oxygen affinity is $N_3^- > NCS^- > Cl^-$, Br^-. This order reflects the differences in the electron donor abilities of the unidentate ligands to the cobalt centers; the stronger the electron donor ability of the ligand, the greater the amount of the electron density on the cobalt centers, and the greater the oxygen affinity.

The oxygen affinities of the complexes studied are highly dependent on the nature of the dinucleating ligand. The order of the oxygen affinities for changes in the dinucleating ligands is bpmp>bpmep>bpep. The order can be explained by considering the effect of the chelate ring size of the dinucleating ligand. Martell *et al.*[16] demonstrated that, in a series of the cobalt(II) complexes with various quinquedentate ligands, the nitrogen donor atoms in the six-membered chelate rings are weaker electron donors than those in the corresponding five-membered chelate rings. This is also the case for the present complexes. In addition, it is likely that the observed differences in the oxygen affinities of the present complexes are also attributed to the steric requirement of the dinucleating ligand. The oxygen binding sites of the two cobalt ions must be held in suitable positions for the O_2 binding in μ-peroxo fashion and such a steric requirement which is governed by the nature of the dinucleating ligand would be also responsible to the stability of the dioxygen complex.

Martell *et al.*[17] also suggested that the total basicities of the ligands are important in determining whether a cobalt(II) complex will form a dioxygen adduct, and the presence of three aliphatic nitrogen donors is suffi-

cient but not necessary for dioxygen adduct formation. It should be noted that all the bbimp complexes (even $[Co_2(bbimp)(py)_2]^{3+}$ which has N_4O donor set for each cobalt ion) did not react with molecular oxygen even at −40 °C. Although the total basicities of Hbbimp and Hbpmp are not known, it is reasonable to assume that the total basicity of Hbbimp is larger than that of Hbpmp, because benzimidazole (pK_a=5.4) is stronger base than pyridine (pK_a=5.2). Stynes *et al.*[18] demonstrated that in 1 : 1 dioxygen adduct formation of LCoP (P=protoporphyrin IX dimethyl ester and L=various bases), pyridine is a better base than benzimidazole. In the above system, therefore, the lower oxygen affinity of the benzimidazole complex is ascribed not to the electronic effect but to the steric effect between benzimidazole and the porphyrine ring, which prevents close approach of benzimidazole to the cobalt center. It is likely that no reactivity of the bbimp complexes with molecular oxygen is also due to such a steric effect of benzimidazolyl groups.

It is interesting that the oxygen affinities of $[Co_2L(C_3H_3N_2)]^{2+}$ are comparable to or smaller than those of $[Co_2L(CH_3COO)]^{2+}$ (L=bpmp or bpmep). It is well known that the nitrogen donors tend to promote oxygenation, whereas the oxygen donors such as carboxylates tend to retard the dioxygen adduct formation.[17] Pyrazolate is a moderately strong base (pK_a's of the following equilibria, pyrazolium $\rightleftharpoons$ pyrazole+H^+ and pyrazole $\rightleftharpoons$ pyrazolate+H^+, are 2.5 and 14.2, respectively)[19] and therefore pyrazolate must be a more effective σ donor than acetate. However,the observed oxygen affinities of the pyrazolato complexes seem to be much weaker than those expected from the above general concept and the basicity argument. It is possible that pyrazolate plays a role as a strong π acceptor and/or pyrazolate-bridge prevents optimum binding of O_2 in μ-peroxo fashion.

Our thanks are due to Prof. S. Kida, Prof. H. Okawa, and Dr. Y. Nishida for their helpful discussions, and to Prof. A. Matsubara and Dr. K. Nomura for conductivity measurement.

Ylide-Metal Complexes. VIII.[1] The Preparation and Properties of Metal (Cu, Ag, Au, Zn, Cd, Hg, Ge, Sn, Pb, Pd, and Pt) Complexes with Methylenetris(dimethylamino)phosphorane

Yoshihisa YAMAMOTO
Faculty of Pharmaceutical Sciences, Higashi Nippon Gakuen University, Ishikari-Tobetsu, Hokkaido 061-02
(Received March 15, 1983)

Bis[methylenetris(dimethylamino)phosphorane]metal chlorides, $[(Me_2N)_3PCH_2\text{-}M\text{-}CH_2P(NMe_2)_3]Cl_n$ (M: Cu, Ag, Au, Zn, Cd, Hg; n: 1 or 2), have been isolated from a reaction mixture of methylenetris(dimethylamino)phosphorane $(Me_2N)_3P{=}CH_2$ (**L**) and CuCl, AgCl, $(C_6H_5)_3PAuCl$, $ZnCl_2$, $CdCl_2$, or $HgCl_2$ in the mole ratio of 2:1 or 3:1. The reactions of **L** with R_3MCl (M: Sn, Pb; R: Me, C_6H_5) in the mole ratio 1:1 yield new monomeric compounds of [methylenetris(dimethylamino)phosphorane]trimethyl(or triphenyl)-metal chloride, $[(Me_2N)_3PCH_2\text{-}MR_3]Cl$. The reactions of **L** with $PdCl_2$ or PtI_4 in the mole ratio of 2:1 or 4:1 yield $[(Me_2N)_3PCH_2]_2PdCl_2$ and $[(Me_2N)_3PCH_2]_4PtI_4$, respectively. The Ag, Au, Sn, and Pb complexes are stable. Their properties are compared with those of the metal complexes with methylenetriphenylphosphorane, $(C_6H_5)_3P{=}CH_2$.

Many investigations of the metal complexes[2-4] with phosphonium ylides, *e.g.*, with methylenetrimethyl- or methylenetriphenylphosphorane, have been reported. Their complexes have the $\begin{matrix}C\\ \diagdown\\ C\text{-}\overset{+}{P}\text{-}C\text{-}M\text{-}\\ \diagup\\ C\end{matrix}$ structure. However, few investigations of the ylide-metal complexes which have the $\begin{matrix}N\\ \diagdown\\ N\text{-}\overset{+}{P}\text{-}C\text{-}M\text{-}\\ \diagup\\ N\end{matrix}$ structure have been described: only the nitridobis(methylenedimethylphosphorane)metal complexes[5] and bis[methylenetris(dimethylamino)phosphorane]gold chloride.[6]

The present paper deals with the preparation and properties of group IB, IIB, IVA, and VIII metal complexes with methylenetris(dimethylamino)phosphorane, $(Me_2N)_3P{=}CH_2$ (**L**). Their properties are compared with those of the metal complexes,[4,7-9] with methylenetriphenylphosphorane, $(C_6H_5)_3P{=}CH_2$. In the previous paper[2] of this series, we have reported the preparation and properties of group IIA (Be, Mg) and IIIA (Al, Ga, In) complexes with methylenetriphenylphosphorane.

Results and Discussion

Bis[methylenetris(dimethylamino)phosphorane]group IB and IIB metal complexes (**1—6**) have been isolated from a reaction mixture of methylenetris(dimethylamino)phosphorane (**L**) and CuCl, AgCl, $(C_6H_5)_3PAuCl$, $ZnCl_2$, $CdCl_2$, or $HgCl_2$ in the mole ratio of 2:1 or 3:1. Complex **2** is stable in dichloromethane, though unstable in chloroform, and is sensitive to light.

$$\underset{\textbf{L}}{m(Me_2N)_3P{=}CH_2} + MCl_n \longrightarrow [(Me_2N)_3PCH_2\text{-}M\text{-}CH_2P(NMe_2)_3]Cl_n$$

m: 2 or 3 ; n: 1 or 2

1—6

No.	1	2	3	4	5	6
M	Cu	Ag	Au	Zn	Cd	Hg

Complex **3**[6] is highly hygroscopic. It is soluble in water and organic solvents, and is stable in air and solution.

The ^1H NMR spectra of **2** and **3** showed a doublet signal for the methylene group at 1.3 ppm for **2** (0.99 ppm for **3**) and a doublet signal for the methyl group at 2.6 ppm in a ratio of 4:36 at room temperature (r.t.) in dichloromethane-d_2. The chemical shifts of the methylene group are at a lower field than that[10] (0.1 ppm) of **L**. In the ^{13}C NMR spectra of **2** and **3**, the chemical shifts (+9 ppm) of the methylene carbon are at a lower field than that (−9 ppm) of **L**. Their coupling constants ($^1J_{CP}$: 97 for **2** and 89 Hz for **3**) are much smaller than that (176 Hz) of **L**. These spectral properties are similar to those[4,7,8] of bis(methylenetriphenylphosphorane)metal chloride, $[(C_6H_5)_3P\overset{R}{\overset{|}{C}}H\text{-}M\text{-}\overset{R}{\overset{|}{C}}HP(C_6H_5)_3]Cl_n$ (**7**) (M: group IB and IIB; R: H; n: 1, 2). Thus, the ylide is bonded to the metal atom through the carbanionic donor atom.

The following differences between **3** and **7** (M: Au; R: H) are significant: i) the chemical shift (δCH_2P) of **3** is at a higher field than that[7] of **7** as shown in Fig. 1; ii) the coupling constant ($^2J_{HCP}$) of **3** is similar to that of **L**, but that[7] (14 Hz) of **7** is larger than that[11] (7.5 Hz) of methylenetriphenylphosphorane, $(C_6H_5)_3P{=}CH_2$ (**L'**); iii) the coupling constant (J_{CP}) of **3** is much larger than that[7] (39 Hz) of **7**. The coupling constants ($^3J_{HCNP}$, $^2J_{CNP}$) and chemical shifts ($\delta PNCH_3$) of the methyl groups in **2** and **3** are similar to those of **L**, as shown in Table 1. Complexes **1** and **4—6** are unstable in dichloromethane and chloroform at r.t.; they give a methyltris(dimethylamino)phosphonium chloride, $[(Me_2N)_3PCH_3]Cl$ (**8**).

[Methylenetris(dimethylamino)phosphorane]silver chloride (**9**) and the corresponding zinc dichloride (**10**) have been prepared from the reaction mixture of **L** with AgCl or $ZnCl_2$ in the mole ratio of 1:1. Complexes **9** and **10** are also unstable in dichloromethane and chloroform at r.t.; they give the corresponding phosphonium chloride (**8**). Though their structures are un-

certain, they should not be polymers because they are soluble in dichloromethane. The elemental analyses of **9** and **10** agree with that of $[(Me_2N)_3PCH_2{-}MCl_n]_m$ (n: 1 or 2). Thus they can be a oligomer.[4a)]

[Methylenetris(dimethylamino)phosphorane]triphenyltin chloride (**11**) and [methylenetris(dimethylamino)phosphorane]triphenyltin (**12**) or -lead (**13**) chloride have been isolated from the reaction mixture of **L** and trimethyltin chloride or triphenyltin (or lead) chloride. They are stable in dichloromethane and air at r.t. The ^1H NMR spectra of **11**—**13** showed the dou-

$$(Me_2N)_3P{=}CH_2 + R_3MCl \longrightarrow [(Me_2N)_3PCH_2{-}MR_3]Cl$$

blet signals for the methylene group at 1.6—1.9 ppm and the doublet signals for the methyl group ($PNCH_3$) at 2.5—2.7 ppm in a ratio of 2:18 at r.t. in dichloromethane-d_2. The methyl protons (MCH_3) of **11** and the phenyl protons of **12** and **13** are assigned to a singlet signal at 0.69 ppm (9H) and the multiplet signals at 7.2—8.2 ppm (15H), respectively. The chemical shifts of the methylene group of **11**—**13** are at a lower field than that of **L**. This is similar to that[9)] of (methylenetriphenylphosphorane)triphenyllead chloride, $[(C_6H_5)_3PCH_2{-}MPh_3]Cl$ (**14**) M: Pb. The chemical shift of the methylene group of **12** is at a higher field than that of **11**. This difference is ascribed to the methyl (MCH_3) and phenyl groups. The chemical shift (δCH_2-P) of **13** is at a higher field than that[9)] of **14** (M: Pb), as shown in Fig. 1.

Tetrakis[methylenetris(dimethylamino)phosphorane]-germanium tetrachloride (**15**), tris[methylenetris-(dimethylamino)phosphorane]tin dichloride (**16**), bis-[methylenetris(dimethylamino)phosphorane]lead dichloride (**17**), bis[methylenetris(dimethylamino)phosphorane]paradium dichloride (**18**) and tetrakis[methylene-

tris(dimethylamino)phosphorane]platinum tetraiodide (**19**) have been isolated from the reaction mixture of **L** and $GeCl_4$, $SnCl_2$, $PbCl_2$, $PdCl_2$, or PtI_4. They are unstable in dichloromethane or chloroform at r.t., and give the corresponding phosphonium salt (**8**). Complexes **17** and **19** are stable in air. The melting points or decomposition temperatures of both the complexes differ from those of the ylide and **8**. They are thermally stable in the solid state. These properties resemble those[4,7,8] of **7** (M: group IB, IIB metal; R: Me, *i*-Pr) and **14**[9] (M: Ge, Sn). Thus, the ylide seems to be

$$m(Me_2N)_3P{=}CH_2 + MCl_n \longrightarrow [(Me_2N)_3PCH_2]_mMCl_n \quad (n: 2, 4;\ \mathbf{15}\text{—}\mathbf{18})$$

$$\downarrow PtI_4$$

n	4	2	2	2

bonded to the metal atom in the solid state,[9] though the structures are uncertain. Complexes **16** and **17** are not so stable as complexes **11**—**13** in dichloromethane. This property is similar to those[9] of other lead complexes such as $[Ph_3PCH_2PbPh_3]Cl$ and $[Ph_3PCH_2]_2PbCl_2$.

In the complexes of the methylenetris(dimethylamino)phosphorane and methylenetriphenylphosphorane, the most remarkable difference between them is solubility in water: *i.e.*, the gold complex (**3**) is soluble but complex (**7**) is insoluble.

The feature of the stable metal complexes with methylenetris(dimethylamino)phosphorane and alkylidenetriphenylphosphorane is ascribed to three factors of metals, ylides, and structures as follows. i) Metals: the metals of stable complexes are Cu(I), Ag(I), Au(I), Zn(II), Cd(II), Be(II), Mg(II), Al(III), Ga(III), In(III), Sn(IV), and Pb(IV). ii) Ylides: *e.g.*, the zinc complex with methylenetriphenylphosphorane is stable, though the complex with methylenetris(dimethylamino)phosphorane is unstable. iii) Structures: the silver complex (**2**) with the composition ratio 2:1 is stable, though the complex (**7**) with the composition ratio 1:1 is unstable; the tin and lead complexes (**11** and **13**) with the coexisting methyl and phenyl ligands are stable, though those complexes (**16** and **17**) with the coexisting chloride ion are unstable.

Experimental

Measurements. The NMR spectra were recorded with an R-40 spectrometer (Hitachi) for ^1H NMR and an FX-60 (JEOL) for ^{13}C NMR.

Starting Materials. Methylenetris(dimethylamino)-phosphorane (**L**) was prepared from methyltris(dimethylamino)phosphonium bromide and sodium in liquid ammonia by Issleib's method.[12] Methyltris(dimethylamino)-phosphonium bromide was prepared from the reaction mixture of tris(dimethylamino)phosphine[13] and methyl bromide.

Ylide-Metal Complexes. Bis[methylenetris(dimethylamino)phosphorane]copper Chloride (1): The ylide of 0.22 g (1.24 mmol) was added to dry THF (10 cm^3) under nitrogen. To the solution was added CuCl of 0.045 g (0.455 mmol). The mixture was stirred for 1 d at room temperature. The white complex which formed was filtered and dried under vacuum. Yield: 0.15 g (72.8%). Found: C, 36.73; H, 9.07%. Calcd for $C_{14}H_{40}N_6P_2CuCl$ (MW 453.46) C, 37.08; H, 8.89%.

Bis[methylenetris(dimethylamino)phosphorane]silver Chloride (2): The ylide of 0.56 g (3.16 mmol) was added to dry THF (5 cm^3) under nitrogen. To the solution was added AgCl (0.15 g, 1.05 mmol). The mixture was stirred for 1 d at r.t. The white complex which formed was filtered and dried under vacuum. Yield: 0.40 g (76.8%). Found: C, 34.02; H, 8.08%. Calcd for $C_{14}H_{40}N_6P_2AgCl$ (MW 497.78) C, 33.78; H, 8.10%.

Bis[methylenetris(dimethylamino)phosphorane]gold Chloride (3): Triphenylphosphinegold chloride of 0.36 g (0.727 mmol) and ylide of 0.39 g (2.2 mmol) were added to dry benzene of 20 cm^3 under nitrogen. The mixture was stirred for approximately 1 d at room temperature. The white complex which precipitated was filtered, washed with dry benzene and dried under vacuum. Yield: 0.33 g (77.3%). Found: C, 29.00; H, 6.86%. Calcd for $C_{14}H_{40}N_6P_2AuCl$ (MW 586.88) C, 28.65; H, 6.87%.

Bis[methylenetris(dimethylamino)phosphorane]zinc Dichloride (4): Zinc chloride of 0.15 g (1.10 mmol) was added to the dry THF (20 cm^3) solution of ylide (0.40 g, 2.26 mmol). The mixture was stirred at r.t. under nitrogen. After 1 d, the solution was filtered and ether was added to the filtrate at −60 °C. The white complex which formed was filtered and dried. Yield: 0.11 g (20.4%). Found: C, 33.62; H, 8.38%. Calcd for $C_{14}H_{40}N_6P_2ZnCl_2$ (MW 490.74) C, 34.26; H, 8.22%.

Bis[methylenetris(dimethylamino)phosphorane]cadmium Dichloride (5): Cadmium chloride of 0.17 g (0.93 mmol) was added to the dry THF (20 cm^3) solution of ylide (0.51 g, 2.88 mmol). The mixture was stirred for 3 d. Pentane was added to the solution and the resulting white precipitated complex was filtered and dried. Yield: 0.1 g (20.1%). Found: C, 31.48; H, 7.29%. Calcd for $C_{14}H_{40}N_6P_2CdCl_2$ (MW 537.76) C, 31.27; H, 7.50%.

Bis[methylenetris(dimethylamino)phosphorane]mercury Dichloride (6): Mercury(II) chloride of 0.2 g (0.74 mmol) was added to the dry THF (9 cm^3) solution of ylide of 0.34 g (1.92 mmol) and the mixture was stirred for 3 d. The white precipitated complex was filtered, washed with dry pentane and dried under vacuum. Yield: 0.43 g (93.3%). Found: C, 27.10; H, 6.21%. Calcd for $C_{14}H_{40}N_6P_2HgCl_2$ (MW 625.95) C, 26.86; H, 6.44%. This complex is hygroscopic. Decomp 188 °C under nitrogen.

[Methylenetris(dimethylamino)phosphorane]silver Chloride (9): Silver chloride of 0.17 g (1.19 mmol) was added to the dry THF solution (5 cm^3) of ylide 0.23 g (1.30 mmol) and the mixture was stirred for 16 h under nitrogen at r.t. The white complex which formed was filtered and dried under vacuum. Yield: 0.31 g (81.5%). Found: C, 26.40; H, 6.75%. Calcd for $C_7H_{20}N_3PAgCl$ (MW 320.55) C, 26.23; H, 6.29%. Complex **9** was sensitive to light.

[Methylenetris(dimethylamino)phosphorane]zinc Dichloride (10): Zinc chloride of 0.15 g (1.10 mmol) was added to the dry THF (8 cm^3) solution of ylide (0.20 g, 1.13 mmol) and the mixture was stirred 1 d under nitrogen. Ether was added to the solution and the white complex which precipitated was filtered and dried under vacuum. Yield: 0.15 g (43.5%). Found: C, 26.73; H, 6.43%. Calcd for $C_7H_{20}N_3PZnCl_2$ (MW 313.51) C, 26.82; H, 6.43%.

[Methylenetris(dimethylamino)phosphorane]trimethyltin Chloride (11): Trimethyltin chloride of 0.53 g (2.66 mmol) was added to the dry THF (7 cm^3) solution of ylide of 0.48 g (2.71 mmol) at 0 °C. The mixture was stirred for 1 d at r.t. The white complex which precipitated was filtered, washed with pentane and dried. Yield: 0.5 g (50.0%). Found: C, 30.93; H, 7.57%. Calcd for $C_{10}H_{29}N_3PSnCl$ (MW 376.48) C, 31.90; H,

7.76%. Mp 215—218 °C.

[Methylenetris(dimethylamino)phosphorane]triphenyltin Chloride (12): The ylide (0.10 g, 0.56 mmol) and triphenyltin chloride (0.21 g, 0.54 mmol) were added to dry THF (10 cm^3) and the resulting mixture was stirred 1 d at 0 °C. The white complex which precipitated was filtered and washed with pentane of 10 cm^3. Yield: 0.16 g (52.2%). Found: C, 52.94; H, 6.70%. Calcd for $C_{25}H_{35}N_3PSnCl$ (MW 562.69) C, 53.36; H, 6.27%. Mp 267—270 °C.

[Methylenetris(dimethylamino)phosphorane]triphenyllead Chloride (13): The mixture of the ylide (0.34 g, 1.92 mmol) and triphenyllead chloride (0.89 g, 1.88 mmol) in dry THF (8 cm^3) were stirred for 1 d at r.t. The white precipitate was filtered, washed with pentane and dried. Yield: 0.55 g (45.0%). Found: C, 46.40; H, 5.87%. Calcd for $C_{25}H_{35}N_3PPbCl$ (MW 651.12) C, 46.12; H, 5.42%. Mp 258—261 °C.

Tetrakis[methylenetris(dimethylamino)phosphorane]germanium Tetrachloride (15): Germanium tetrachloride (0.051 g, 0.24 mmol) was added to the dry THF (8 cm^3) solution of ylide of 0.17 g (0.96 mmol) at 0 °C, and the mixture was stirred 1 d at r.t. The white complex which precipitated was filtered and dried under vacuum. Yield: 0.14 g (63.7%). Found: C, 35.79; H, 8.89%. Calcd for $C_{28}H_{80}N_{12}P_4GeCl$ (MW 923.32) C, 36.42; H. 8.73%.

Tris[methylenetris(dimethylamino)phosphorane]tin Dichloride (16): Tin(II) chloride of 0.14 g (0.73 mmol) was added to the dry THF (8 cm^3) solution of ylide (0.4 g, 2.26 mmol). The mixture was stirred for 3 d at r.t. The white precipitate was filtered, washed with dry pentane and dried. Yield: 0.23 g (60.5%). Found: C, 34.80; H, 8.15%. Calcd for $C_{21}H_{60}N_9P_3SnCl_2$ (MW 721.28) C, 34.97; H, 8.38%.

Bis[methylenetris(dimethylamino)phosphorane]lead Dichloride (17): To the dry THF (18 cm^3) solution of ylide of 0.27 g (1.52 mmol) was added $PbCl_2$ (0.21 g, 0.76 mmol) at 0 °C and the mixture was stirred 1 d at r.t. The white complex which formed was filtered and dried. Yield: 0.36 g (75.0%). Found: C, 25.86; H, 6.18%. Calcd for $C_{14}H_{40}N_6P_2PbCl_2$ (MW 632.48) C, 26.59; H, 6.37%. Decomp 248 °C.

Bis[methylenetris(dimethylamino)phosphorane]paradium Dichloride (18): To the dry THF (12 cm^3) solution of ylide of 0.46 g (2.60 mmol) was added $PdCl_2$ (0.18 g, 1.02 mmol) at r.t. and the mixture was stirred 1 d. The precipitated complex was filtered, washed with pentane and dried. Yield: 0.42 g (77.8%). Found: C, 32.00; H, 8.06%. Calcd for $C_{14}H_{40}N_6P_2PdCl_2$ (MW 531.76) C, 31.62; H, 7.58%.

Tetrakis[methylenetris(dimethylamino)phosphorane]platinum Tetraiodide (19): Platinum(IV) iodide of 0.30 g (0.43 mmol) was added to the dry THF (10 cm^3) solution of ylide (0.35 g, 1.97 mmol) and the mixture was stirred 1 d at r.t. The yellow precipitate which formed was filtered, washed with dry ether and dried. Yield: 0.46 g (75.8%). Found: C, 24.23; H, 6.15%. Calcd for $C_{28}H_{80}N_{12}P_4PtI_4$ (MW 1411.62) C, 23.82; H, 5.71%. Mp 189—191 °C.

All complexes are soluble in dichloromethane and chloroform. Complexes **2**, **3**, **6**, **11**, and **16** are soluble in water and organic solvents such as acetone, alcohols, DMF, and DMSO. Complexes **12** and **13** are soluble in the organic solvents and insoluble in water. Complex **17** is slightly soluble in dichloromethane-chloroform (1 : 1) and insoluble in water and the organic solvents. Complex **19** is soluble in DMSO and MeOH, but insoluble in water, acetone, and DMF.

The authors thank Professor Hubert Schmidbaur of the Technical University of Munich, West Germany for his encouragement. The present work was partially supported by Grant-in-Aid for Scientific Research No. 554190 from the Ministry of Education, Science and Culture.

The Preparation and Properties of Ethylenediamine(2-methyl-8-quinolinolato)cobalt(III) Complexes†

Yoshihisa YAMAMOTO* and Eiko TOYOTA
Faculty of Pharmaceutical Sciences, Higashi Nippon Gakuen University, Ishikari-Tobetsu, Hokkaido 061-02
(Received May 14, 1983)

Ethylenediaminebis(2-methyl-8-quinolinolato)cobalt(III) complexes and bis(ethylenediamine)(2-methyl-8-quinolinolato)cobalt(III) complexes have been isolated and characterized by analytical and spectroscopic methods. In the former complexes, the NMR spectra indicate that the two nitrogen atoms of the coordinated 2-methyl-8-quinolinolato ligands are in the *trans* positions, whereas the two oxygen atoms are in the *cis* positions.

A few investigations of the stereochemistry of bis(8-quinolinolato)metal complexes, $[M(oxine)_2X_2]$, in an octahedral configuration have been reported by some authors.[1-6] The configuration of the coordinated 8-quinolinolato ligands in their complexes is in the *trans* positions for two oxygen atoms and in the *cis* positions for two nitrogen atoms except for the dicarbonyl complex[6] which is in the *cis* positions for both the two oxygen atoms and the two nitrogen atoms. However, a complex of the configurations in the *cis* positions for two oxygen atoms and in the *trans* positions for two nitrogen atoms of the coordinated 8-quinolinolato ligands has not yet been reported.

Previously, we have been concerned with ethylenediaminebis(8-quinolinolato)cobalt(III) complexes,[7] which are in the *cis* positions for the two oxygen atoms of the coordinated 8-quinolinolato ligands. However, it has not been resolved whether the two nitrogen atoms of the coordinated 8-quinolinolato ligands are in the *trans* or the *cis* positions. An X-ray study of the complexes has not yet been made, because the crystals could not be obtained. We have found that the two methyl groups of the coordinated 2-methyl-8-quinolinolato ligands in the complexes have a steric hindrance against the amine protons of the coordinated ethylenediamine ligand. Thus, the present paper describes the preparation and properties of the ethylenediaminebis(2-methyl-8-quinolinolato)cobalt(III) complexes and bis(ethylenediamine)(2-methyl-8-quinolinolato)cobalt(III) complexes, and deals with the identification of the configuration of the former complexes.

Results and Discussion

Ethylenediaminebis(2-methyl-8-quinolinolato)cobalt(III) chloride hydrate, $[Co(\text{  }-CH_3)(en)_2]Cl\cdot H_2O$ (**1**) has three isomers A, B, and C as is shown in Fig. 1. The isomers of A and C have C_2 symmetry, while that of B has C_1 symmetry. In isomer A, the two methyl groups of the coordinated 2-methyl-8-quinolinolato ligands are far from both the *N*-Ha and *N*-Hb amine protons of the coordinated ethylenediamine ligand. Thus, in the ^1H NMR spectrum of isomer A, the amine proton signals of the coordinated ethylenediamine ligand can differ little from those of the corresponding 8-quinolinolato chloride dihydrate $[Co(oxine)_2en]Cl\cdot 2H_2O$ (**2**), previous reported.[7] While, in the isomer C, the two methyl groups of the coordinated 2-methyl-8-quinolinolato ligands are very near both the *N*-Ha and *N*-Hb amine protons of the coordinated ethylenediamine ligand, *i.e.*, the amine proton signals of the ^1H NMR spectrum should be different from those of **2**. The two methyl groups in the isomer B are at different positions from those of A and C. Accordingly, the distinction between isomers A, B, or C should be evident in the NMR spectrum.

Complex **1** has been isolated by chromatographic separation from a reaction mixture of *trans*-$[CoCl_2en_2]Cl$,[8] Ag_2O, and 2-methyl-8-quinolinol. The corresponding nitrate (**3**) or picrate (**4**) has been prepared from the reaction mixture of **1** and silver nitrate or picric acid, respectively. The color of **1** in the solid state is brown, **3** is dark brown and **4** is yellowish green. Complexes **1** and **3** are soluble in alcohols, DMSO, CF_3COOH and water, though complex **4** is soluble in DMSO, and somewhat soluble in acetone and methanol.

^1H NMR and ^{13}C NMR spectra of **1** are suggestive of the present of C_2 symmetry[5,9] from Figs. 2 and 3, *i.e.*, the isomer of **1** can be suggested to be either A or C. In the ^1H NMR spectrum of **1**, the signals at 6.9—8.2 ppm (10H) are assigned to the protons of the coordinated 2-methyl-8-quinolinolato ligand. The signals (10H) at 2.55 ppm and 2.54—2.70 ppm are assigned to the methyl and methylene protons of the coordinated ligands. The amine protons of the coordinated ethylenediamine ligand showed two singlet signals at 4.88 ppm (2H) and 5.87 ppm (2H). A clear distinction of **1** and **2** was found in the amine proton signals of their ^1H NMR spectra as is shown in Fig. 2. The amine proton signals at 4.88 and 5.87 ppm of **1** shift to 5.27 and 5.79 ppm of **2**, respectively in the same conditions ($6.2\pm0.05\times10^{-2}$ mol dm^{-3} DMSO-d_6 solution). Also, this behavior occurs in 50% ($CF_3COOH+D_2O$) solution as is shown in Table 1. The shift of signal at 4.88 ppm is larger than that of 5.87 ppm. This behavior can be based on the steric effect of the methyl groups upon the amine protons. Then, the signal at 4.88 ppm is assigned to the *N*-Ha amine protons, because they are near both methyl groups. The signal at 5.87 ppm is assigned to *N*-Hb amine protons. Thus, complex **1** has been assigned to isomer C, which has been in the *trans* position for the two nitrogen atoms and in the *cis* position for the two oxygen atoms

of the coordinated 2-methyl-8-quinolinolato ligands. In the ^{13}C NMR spectrum of **1** as is shown in Fig. 3, the chemical shifts of the coordinated 2-methyl-8-quinolinolato ligands were assigned on the basis of the results of the complex **2**;[7] they are collected in Table 1.

Bis(ethylenediamine)(2-methyl-8-quinolinolato)cobalt(III) chloride dihydrate, $[Co(\text{  })(en)_2]Cl\cdot 2H_2O$ (**5**) has been isolated from a reaction mixture of *trans*-$[CoCl_2en_2]Cl$, Ag_2O, and 2-methyl-8-quinolinol. The corresponding nitrate (**6**) or picrate (**7**) has been prepared from the reaction mixture of **5** and silver nitrate or picric acid, respectively. The color of **5** in the solid state is russet brown, **6** is brown, and **7** is yellowish brown. Complexes **5** and **6** are soluble in DMSO, methanol and water, and they are somewhat soluble in ethanol, though complex **7** is soluble in acetone and DMSO and somewhat soluble in methanol. The signals of the methyl, metyhlene, and 8-quinolinolato

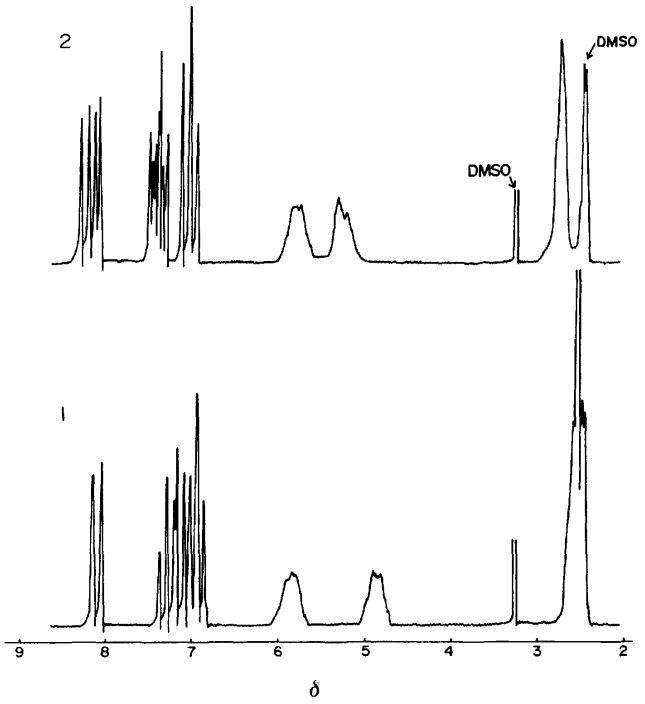

Fig. 2. The ^{1}H NMR spectra of [Co(2-Me-oxine)$_2$en]Cl·H_2O (**1**) and [Co(oxine)$_2$en]Cl·$2H_2O$ (**2**) in DMSO-d_6.

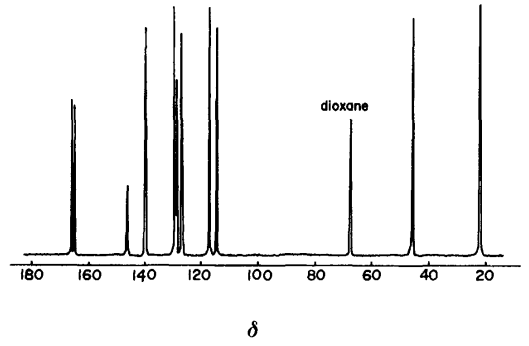

Fig. 3. The ^{13}C NMR spectrum of [Co(2-Me-oxine)$_2$-en]Cl·H_2O in D_2O.

protons and carbons and of amine protons of the coordinated ligands in **5**—**7** were assigned on the basis of the results of the bis(ethylenediamine)(8-quinolinolato)-cobalt(III) chloride dihydrate, [Co(oxine)en$_2$]Cl·$2H_2O$ (**8**), in the previous paper,[7] and collected in Table 1.

Absorption spectra of **1**—**3**, **5**, **6**, and **8** show three absorption bands at around 325, 340, and 400 nm in methanol as is shown in Table 1. The absorption bands at 340 nm of **1**—**3** complexes are stronger than those at 325 nm, though those at 325 nm of **5** and **6** are stronger than those at 340 nm. The ε's of three bands of **1** or **3** and **5** or **6** are smaller than those of **2** and **8**, respectively because it can be based on the inductive effect of the methly group of the chelate ligand. The absorption bands at around 400 nm are charge transfer band.[5] All complexes are diamagnetic. Their electric conductivities in an aqueous solution were collected in Table 1.

Experimental

Measurements. The NMR spectra were recorded with an FX-60 spectrometer (JEOL) for ^{13}C NMR and R-40 (Hitachi) for ^{1}H NMR. The visible absorption spectra were recorded with a Shimadzu MPS-5000 recording spectrophotometer. The electric conductivities of an aqueous solution were determined by the use of a conductometric meter CM-30 (Shimadzu) at room temperature. The magnetic susceptibilities were measured by Faraday's method using a magnetic balance (Shimadzu) at room temperature.

Preparation of Complexes. Ethylenediaminebis(2-methyl-8-quinolinolato)cobalt(III) Chloride Hydrate (1) and Bis(ethylenediamine)(2-methyl-8-quinolinolato)cobalt(III) Chloride Dihydrate (5): To 100 cm^3 of an aqueous solution of [CoCl(OH)en$_2$]$^+$ which was prepared from *trans*-[CoCl$_2$en$_2$]-Cl (10.0 g, 35.0 mmol) and Ag_2O (4.05 g, 17.5 mmol), a methanol solution (120 cm^3) of 2-methyl-8-quinolinol (5.5 g, 34.5 mmol) was added dropwise. The liquid was stirred for 45 h at 60 °C. The reaction mixtures were concentrated on a rotary evaporator and dried over silica gel. Complexes **1** and **5** were extracted with methanol from the dried mixture. The methanol extract was concentrated, and the solution was chromatography on a column of alumina. On elution with ethanol, the first band (complex **1**) was collected and the solution concentrated. The precipitated complex was recrystallized from ethanol-ether twice. The second band (complex **5**) was eluted with methanol and the solution was concentrated. This complex was recrystllized from methanol-ethanol (1:2) twice. Yields: 7.72 g (45.1%) for **1**, 0.62 g (4.0%) for **5**. Found **1**: C, 54.59; H, 5.27; N, 11.05; Cl, 7.76%. **5**: C, 37.80; H, 6.39; N, 16.06; Cl, 16.40%. Calcd for **1**: $CoC_{22}H_{26}N_4O_3Cl$ (MW 488.86) C, 54.05; H, 5.36; N, 11.46; Cl, 7.25%. **5**: $CoC_{14}H_{28}N_5O_3Cl_2$ (MW 444.25) C, 37.85; H, 6.35; N, 15.76; Cl, 15.96%.

Ethylenediaminebis(2-methyl-8-quinolinolato)cobalt(III) Nitrate (3): To an aqueous solution of **1** (0.5 g, 1.0 mmol) was added an aqueous solution silver nitrate (0.17 g, 1.0 mmol). The mixture was stirred, and the silver chloride precipitated was filtered. The filtrate was concentrated on a rotary evaporator. A small amount of silver complex in the filtrate was removed by column chromatography on alumina. The elution band of methanol was collected and the solution was concentrated. Complex **3**, thus precipitated, was recrystallized from ethanol-ether twice. Yield: 0.35 g (70.4%). Found: C, 52.69; H, 5.15; N, 14.12%. Calcd for $CoC_{22}H_{24}N_5O_5$ (MW 497.40) C, 53.12; H, 4.86; N, 14.08%.

Ethylenediaminebis(2-methyl-8-quinolinolato)cobalt(III) Picrate (4): An aqueous solution of **1** (0.5 g, 1.0 mmol) was added to a solution of picric acid (0.23 g, 1.0 mmol); the mixture was stirred, and the separated yellowish green complex was filtered and recrystallized from methanol. Yield: 0.60 g (90.4%). Found: C, 50.01; H, 3.99; N, 15.25%. Calcd for $CoC_{28}H_{26}N_7O_9$ (MW 663.50) C, 50.69; H, 3.95; N, 14.78%.

Bis(ethylenediamine)(2-methyl-8-quinolinolato)cobalt(III) Nitrate Hydrate (6): This complex was prepared from the reaction mixture of **5** (0.5 g, 1.1 mmol) and silver nitrate (0.38 g, 2.2 mmol) by the method of complex **3**, and recrystallized from water-ethanol twice. Yield: 0.31 g (58.8%). Found: C, 34.90; H, 5.58; N, 20.64%. Calcd for $CoC_{14}H_{26}N_7O_8$ (MW 479.35) C, 35.08; H, 5.47; N, 20.45%.

Bis(ethylenediamine)(2-methyl-8-quinolinolato)cobalt(III) Picrate (7): An aqueous solution of **5** (0.5 g, 1.1 mmol) was added to a solution of picric acid (0.51 g, 2.2 mmol), the mixture was stirred, and the separated russet brown complex was filtered and recrystallized from methanol. Yield: 0.59 g (67.6%). Found: C, 39.54; H, 4.17; N, 19.14%. Calcd for $CoC_{26}H_{28}N_{11}O_{15}$ (MW 793.52) C, 39.35; H, 3.56; N, 19.42%.

Mössbauer Effect of ^{119}Sn in Tin Sulfides Produced through Thermal Decomposition of SnS_2

Sumio ICHIBA* and Kazushi KUNITA
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received May 9, 1983)

The intermediate tin sulfides produced through thermal decomposition of SnS_2 were studied by quenching and Mössbauer spectroscopy. The thermal decomposition of SnS_2 in a nitrogen gas flow proceeded to SnS *via* Sn_2S_3. The existing phases of the decomposition products in the range of the S/Sn ratio less than 1.50 were Sn_2S_3 and $Sn_{1-x}S$. A new peak observed in the Mössbauer spectrum of tin sulfides with the S/Sn ratio less than 1.04 was assigned to Sn^{4+} in the nonstoichiometric compound $Sn_{1-x}S$.

The tin-sulfur system was studied by many workers.[1-8] Albers *et al.* gave a phase diagram (Fig. 1).[1] In the diagram, the existence of the compounds SnS_2 and SnS is clearly indicated. The intermediates Sn_2S_3, Sn_3S_4, Sn_4S_5, and $Sn_{1-x}S$ have been reported so far, but there are inconsistencies. G. H. Moh identified Sn_2S_3 and $Sn_{1-x}S$ as the intermediate compounds on the basis of his detailed studies by quenching, high-temperature X-ray powder diffraction, and differential thermal analysis; however he refuted the existence of Sn_3S_4 and Sn_4S_5.[7] Bartenov *et al.* studied the Sn–S system by Mössbauer spectroscopy and reported that the intermediate compound such as Sn_2S_3 and Sn_3S_4 did not exist.[8] On the other hand, P. I. Seregin *et al.* asserted the existence of Sn_2S_3 and Sn_3S_4 with intrinsic crystal lattice structures by Mössbauer spectroscopy.[9]

Previously the authors have examined the tin sulfides produced through thermal decomposition of SnS_2 and identified Sn_2S_3 as an intermediate by quenching, Mössbauer spectroscopy, thermogravimetry, differential thermal analysis, and X-ray powder diffraction.[10,11] In this study, the existing phases of tin sulfides in the range S/Sn=1.5 to 1.0 produced through thermal decomposition of SnS_2 in a nitrogen gas flow are examined by Mössbauer spectroscopy.

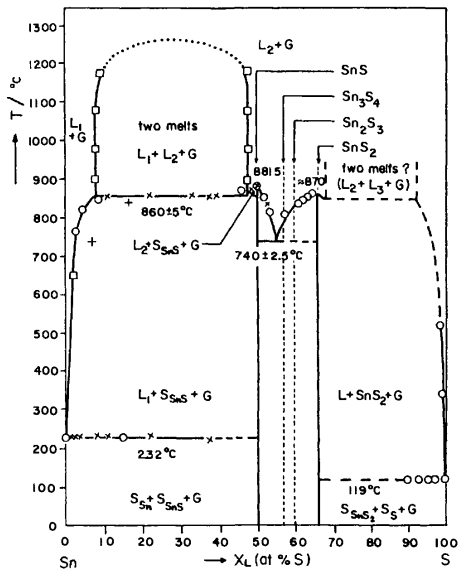

Fig. 1. The phase diagram of Sn–S system. (From Ref. 1)

Experimental

Preparation of the Tin Sulfide Sample. The tin sulfide samples were prepared by thermal decomposition of tin(IV) sulfide. The tin(IV) sulfide to be decomposed was prepared by the addition of 2 mol dm^{-3} -HCl to an aqueous solution of $Na_4SnS_4 \cdot 14H_2O$. To remove the reaction products NaCl and S throughly the crystals were washed with distilled water several times, then with methanol and carbon disulfide alternately. The thermal decomposition of SnS_2 was carried out by heating SnS_2 to 878 K at a rate of 3 K/min in a nitrogen gas flow and maintaining it at this temperature from 2 min to 60 min. After heating the decomposition products were quenched to room temperature without breaking the inert atmosphere. The S/Sn ratio of the sulfides was determined by analysing the tin in the sample gravimetrically in which the sample was calcined at 1173 K for 5 h in air.

Measurements. The Mössbauer spectra were measured using a constant acceleration type spectrometer with an accuracy within 0.05 mm s^{-1}. The γ-ray source of calcium stannate was used at room temperature and the absorber was cooled at 93 K in a liquid nitrogen cryostat. The velocity scale was calibrated against the spectra of $BaSnO_3$ and β-tin at room temperature. All isomer shifts are reported relative to $BaSnO_3$. Mössbauer parameters were deduced from Lorentzian curves computer-fitted to the spectra by a least-squares method.

Results and Discussion

The Mössbauer spectra of tin sulfides in the ranges S/Sn=1.50 to 1.07 and less than 1.04 are shown in Figs. 2 and 3, respectively. The spectra are apparently superposition of two spectra, *i.e.* the spectrum characteristic of SnS and the spectrum characteristic of SnS_2. Mössbauer parameters deduced from the spectra are shown in Table 1 along with the area ratio of Sn^{IV} to total. In Table 1, Sn_2S_3 with intrinsic lattice are distinguished from the other for the reason that the isomer shift and quadrupole splitting for Sn^{II} at S/Sn=1.50 are larger than those of SnS as reported previously.[10] Sn_2S_3 was decomposed further by heating the sulfide at 878 K for various times. The heating durations and the S/Sn ratios of the sulfides obtained are also shown in Table 1. The absorption peak for Sn^{IV} at about 1.1 mm s^{-1} decreased with the decreasing S/Sn ratio and disappeared at S/Sn=1.04. On the other hand, the peak for Sn^{II} increased with the decreasing S/Sn ratio. The value of the isomer shift for Sn^{IV} was almost the same in the range

Table 1. Mössbauer parameters for tin sulfides produced through thermal decomposition or SnS_2

Duration of heating at 878 K (min)	Atomic ratio (S/Sn)	Sn^{IV}		Sn^{II}			$\frac{Sn^{IV}}{Sn(total)}$
		δ / mm s^{-1}	Γ / mm s^{-1}	δ / mm s^{-1}	Δ / mm s^{-1}	Γ / mm s^{-1}	
0	1.50±0.02	1.12	1.20	3.55	1.01	1.12	0.50
2	1.38±0.02	1.17	1.23	3.45	0.95	1.15	0.37

27	1.02±0.03	−0.24	2.05	3.38	0.96	1.16	0.06
32	1.01±0.02	−0.44	1.54	3.36	0.90	1.15	0.05
57	1.01±0.02	—	—	3.38	0.93	1.17	—

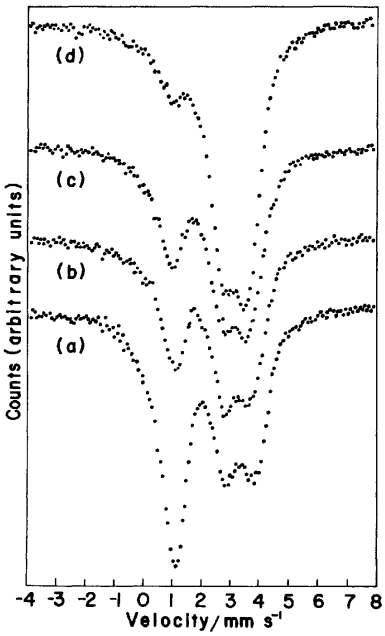

Fig. 2. Mössbauer spectra for tin sulfides produced through thermal decomposition of SnS_2. S/Sn ratio, (a) 1.50; (b) 1.33; (c) 1.24; (d) 1.07.

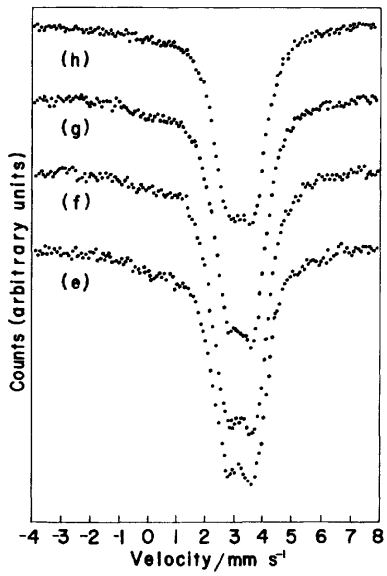

Fig. 3. Mössbauer spectra for tin sulfides produced through thermal decomposition of SnS_2. S/Sn ratio, (e) 1.04; (f) 1.03; (g) 1.02; (h) 1.0.

S/Sn=1.50 to 1.07, but the values of the shift and quadrupole splitting for Sn^{II} decreased with decreasing S/Sn ratio and approached the values for SnS. The area ratio coincided with the corresponding S/Sn ratio in the range S/Sn=1.50 to 1.33, however, in the range less than 1.24 the area ratio exceeded the corresponding S/Sn ratio.

Gerasimov *et al.* reported the existence of Sn_2S_3 and Sn_4S_5 as the intermediate products through thermal decomposition of higher sulfides, *viz.* $SnS_2 \rightarrow Sn_2S_3 \rightarrow Sn_4S_5 \rightarrow SnS$.[2] G. H. Moh synthesized the sulfides in evacuated, sealed silica tubes in which weighed amounts of tin and sulfur were heated at a predetermined temperature and the reaction products examined by X-ray powder diffraction and optical reflectivity. All the reaction products in the range of S/Sn ratio smaller than 1.50 were Sn_2S_3 and $Sn_{1-x}S$; but Sn_3S_4 and Sn_4S_5 did not exist.[7] P. I. Seregin *et al.* synthesized tin sulfides by melting initial components of tin and sulfur in evacuated quartz capsules and investigated the reaction products by Mössbauer spectroscopy. They assert the existence of Sn_3S_4 and Sn_2S_3, because the spectra of Sn_3S_4 and Sn_2S_3, obtained by different methods, have the same isomer shifts and quadrupole splittings, but the ratio of the area below the spectra of Sn^{II} and Sn^{IV} depends on the method of synthesis.[9]

In the present work, it seems likely that the existing phases of the decomposition products in the range of S/Sn less than 1.50 are Sn_2S_3 and $Sn_{1-x}S$, because the parameters were not anomalous at S/Sn=1.33 and 1.24, and the peak for nonstoichiometric $Sn_{1-x}S$ manifested itself in the range of S/Sn less than 1.04. The peak for Sn^{IV} characteristic of $Sn_{1-x}S$ becomes distinct at about 0

mm s^{-1} as the peak for Sn^{IV} characteristic of Sn_2S_3 disappeared and it diminished as the S/Sn ratio approached to the stoichiometric value, as shown in Fig. 3. The excess value of the area ratio to the corresponding S/Sn ratio in the range of S/Sn less than 1.24 may be caused by superposition of the peak in the spectrum characteristic of $Sn_{1-x}S$ to the spectrum of Sn_2S_3 if the recoilless fraction of Sn^{II} is equal in both $Sn_{1-x}S$ and Sn_2S_3.

Albers *et al.* showed that the existence region of solid SnS probably lies entirely on the excess sulfur side on the basis of their Hall effect measurements.[1] Rau also reported the sulfur rich boundary of the homogeneity region of SnS as the result of their measurement of the variation of sulfur pressure by a chemical method and that the doubly negatively charged tin vacancy is probably the prevailing imperfection at equilibrium.[12]

The lower thermal decomposition product of Sn_2S_3 can justifiably be refered to the formula $Sn_{1-x}S$. In $Sn_{1-x}S$ metal vacancies exist. The single metal vacancies act as acceptors with a level near the valence band and leave positive holes in the valence band. Trapping holes give rise to Sn^{4+} in $Sn_{1-x}S$. Besides this, association of the neutral vacancies will take place.

The pertinent quasi-chemical equations by the use of the Kröger's notation[13] are

$$V_{Sn}^{x} \rightleftarrows V_{Sn}'' + 2h\cdot, \quad (1)$$

$$2V_{Sn}^{x} \rightleftarrows (V_{Sn})_i^{x}, \quad (2)$$

with neutrality condition $[h\cdot]=2[V_{Sn}'']$.

The deviation from stoichiometry, x, is

$$x = [V_{Sn}^{x}] + [V_{Sn}''] + 2[(V_{Sn})_i^{x}]. \quad (3)$$

At high temperature, 878 K, where $Sn_{1-x}S$ was formed the association will be relatively unimportant and Eq. 3 may be approximated by $x \approx [V_{Sn}''] = [Sn^{4+}]$. Thus, the concentration of Sn^{4+} will be defined by the deviation from stoichiometry. In Table 1, the excess area ratio to the corresponding S/Sn ratio in the lower range may also be caused by still existing Sn_2S_3 as shown in the large line width of the peak.

Studies of the Selective Adsorption of Anions by Metal Ion Loaded Ion-exchange Resin. VI.[1] The Adsorption Behavior of the Phosphate Ion on the Iron(III) Loaded Ion-exchange Resin

Isao YOSHIDA,* Ryoichi TAKESHITA, and Keihei UENO
Department of Industrial Chemistry, Kumamoto Institute of Technology, Ikeda 4-22-1, Kumamoto 860
(Received June 6, 1983)

Adsorption isotherms for the phosphate ion by various iron(III)-loaded ion-exchange resins(IRC-Fe(III)), which are different in iron(III)-ion concentrations, were prepared at 5—35 °C in aqueous systems with pH values of 3 and 4.6 by means of the batch method. These isotherms could be represented by the $C_p = Q_\infty(C_p/Q) - 1/K$ equation in the phosphate-ion-concentration range from 3.23×10^{-4} to 3.23×10^{-2} mol dm^{-3} (10 ppm to 1000 ppm as P), where C_p and Q are the phosphate-ion concentrations of the aqueous phase and the adsorbent respectively; Q_∞ is the saturated phosphate concentration of the adsorbent, and K is the equilibrium constant. From the analysis of adsorption isotherms, the values for Q_∞ and K were determined on each adsorbent, and the nature of the adsorbent IRC-Fe(III) was discussed, with consideration paid to these two parameters and the pH-dependency of the distribution ratio of the phosphate ion between the aqueous phase and the adsorbent.

In a previous paper,[2] we reported on the adsorption behavior of the phosphate ion on the iron(III)-loaded chelating resin(UR 10-Fe(III)) and on the evidence that the resin-bound iron(III) was the site for phosphate adsorption. While iron(III) is tightly held on UR 10 resin through the chelate formation with the *N*-(*o*-hydroxybenzyl)iminodiacetate moiety, our investigation was extended to find a better phosphate adsorbent using other types of chelating resins or cation-exchange resins. We finally found that the iron(III)-loaded weakly acidic carboxylate-type cation-exchange resins, such as Amberlite IRC-50 or diaion WK, were the most advantageous adsorbents for phosphate with regards to their adsorption capacity, thermal stability, iron-binding property, and recycling perfomances.[3] This paper describes the results of our detailed investigation of the adsorption behavior of the phosphate ion on the iron(III)-loaded Amberlite IRC-50.

Experimental

Materials. The weakly acidic carboxylate-type cation-exchange resin, Amberlite IRC-50(30 to 50 mesh; proton-exchange capacity, 10.62 mequiv g^{-1}), was washed with 2 mol dm^{-3} of sodium hydroxide and hydrochloric acid alternatively three times, and finally converted to the sodium form. Fifteen grams of the sodium-form resin was suspended for 24 h in 200 cm^3 of a 0.03 mol dm^{-3} sodium acetate–acetic acid buffer solution of pH 3.0 containing from 0.7 to 5 g of iron(III) chloride hexahydrate. The resulting iron(III)-loaded Amberlite IRC-50(hereafter abbreviated as IRC-Fe(III)) was washed with deionized water until the washing became free from iron(III); it was then sucked and centrifuged. The IRC-Fe(III) adsorbent was sealed in a bottle and stored in a refrigerator.

The iron(III) content in the resin was determined spectrophotometrically on the acid eluate as has been described in a previous paper;[3] it was expressed in terms of C_{Fe}(mmol g^{-1} of the dry adsorbent). The iron(III) contents ranged from 0.323 to 1.97 mmol g^{-1}, as is shown in Table 1. The water content of IRC-Fe(III) was determined on each batch by measuring the weight loss after drying to a constant weight at 110 °C immediately before the adsorption study.

A stock solution of phosphate was prepared from potassium dihydrogenphosphate. All the other reagents were of an analytical grade.

Procedure for Adsorption Study. An exactly weighed amount of IRC-Fe(III)(*ca.* 0.5 g) was shaken with 50 cm^3 of a buffered solution containing phosphate at a constant temperature for 48 h. This shaking time was found to be sufficient to attain an approximate equilibrium. For the observation of the adsorption isotherms, the pH of the aqueous phase was adjusted to 3.0 or 4.6 with 0.09 mol dm^{-3} sodium sulfate or with 0.1 mol dm^{-3} acetic acid–sodium acetate respectively. However, in the experiment at pH 3.0, the pH of the solution after equilibration deviated over the range from 2.5 to 3.3 because of the poor buffering capacity of the reagent. For the measurements of the distribution ratio, D, at various pHs, the pHs of the aqueous phases were adjusted with the use of 2 mol dm^{-3} sodium hydroxide and 1 mol dm^{-3} hydrochloric acid. The ionic strength of the aqueous phase was maintained at 0.3 and 0.15 with sodium chloride for the study of the adsorption isotherm and the distribution ratio respectively. After equilibration, the phoshate concentrations were determined spectrophotometrically by the molybdenum blue method on both aqueous and resin phases, the latter being analyzed on the eluate with 2 mol dm^{-3} sodium hydroxide.[3] The percentages of the recovery of phosphate found in the adsorbent and in the aqueous phase against the initial phosphate concentration were 97.0 to 103%, with an average of 99.72±1.27% for 170 measurements.

The distribution ratio, D, of phosphate between the aqueous phase and the adsorbent is expressed as $D=Q/C_p$, where C_p and Q represent the phosphate-ion concentrations in the aqueous phase(mol dm^{-3}) and in the adsorbent(mmol g^{-1} of dry adsorbent) respectively. While the wet adsorbent was used throughout the experiment, the corrections were made for the dry-adsorbent base by taking into account the water content of each wet adsorbent.

Instruments. A TOA HM-5A pH meter was used for the pH measurements, while a Shimadzu MPS-50L spectrophotometer was used for the absorbance measurements.

Results and Discussion

Adsorption Isotherms. The effect of the iron(III) concentration of the resin, C_{Fe}, on the adsorption isotherms of phosphate at 35 °C is shown in Figs. 1(at pH

3) and 2(at pH 4.6). The adsorbed phosphate concentration, Q, increased with an increase in the concentration of iron in the resin, C_{Fe}, and of the phosphate ion in the aqueous phase, C_P, approaching the saturation point at higher phosphate concentrations. The value of Q also increased with a rize in the temperature in the range from 5 to 35 °C as is shown in Figs. 1 to 3.

Thus, the adsorption of phosphate is attributable to

tion isotherms can be treated by the linearized adsorption equation 1(in this equation, Q_∞ and K are the concentration of the saturated adsorbed phosphate and the equilibrium constant for the adsorption reaction respectively):

$$C_p = Q_\infty(C_p/Q) - 1/K. \quad (1)$$

Thus, the plots of C_P against C_P/Q should give a straight line with an intercept of $-1/K$ and a slop of Q_∞. Such plots, corresponding to Figs. 1 to 3, are shown in Figs. 4 to 6 respectively. The values of K and Q_∞ were evaluated from these plots by the least-squares method; the results are summarized in Table 1.

In the experiment at pH 3, the concentration, Q_∞, increased with the increase in the iron(III) concentration, C_{Fe}, while the molar ratio Q_∞/C_{Fe} was nearly equal to unity over the range from C_{Fe}=0.726 to 1.97, indicating that the resin-bound iron(III) is the adsorption site for phosphate. The adsorption equilibrium constant, K, was found to be from 400 to 618 at 35 °C, irrespective of the value of C_{Fe}.

In the experiment at pH 4.6, the value of Q_∞ also increased with the increase in C_{Fe}, but the molar ratio of Q_∞/C_{Fe} was smaller than unity at lower iron concentrations and approached unity with the increase in the iron concentration. The value of K was, in this case, evaluated as from 265 to 309 at 35 °C, irrespective of the value of C_{Fe}.

If one considers the molecular structure of Amberlite IRC-50, which is a cross-linked poly(acrylic acid), the different behavior of the adsorbent at pH 3 and 4.6 may be explained by the presence of free carboxyl groups in the adsorbent of a lower iron concentration. In the pH 3 region, these carboxyl groups remained undissociated, having little interaction with the resin-bound iron. At pH 4.6, however, the carboxyl groups, after deprotonation, became available for coordination to the resin-bound iron, giving the negatively charged tetracoordinated iron sites, which are not capable of ligand exchange with phosphate. The lower the iron concentration in the resin, the larger the fraction of inactivated adsorption sites in this pH region.

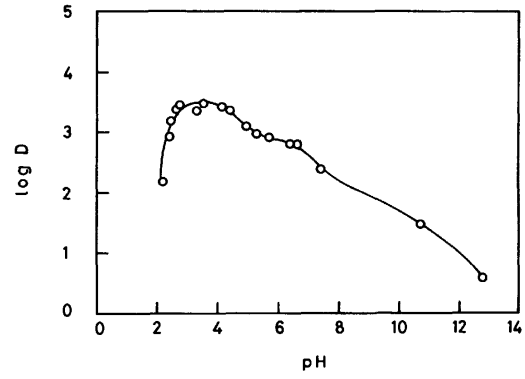

Fig. 7. pH profile of distribution ratio, D, of phosphate ion by IRC-Fe(III)(C_{Fe}=1.97 mmol g^{-1}) at 35 °C. I=0.15.

Effect of Temperature. It may be seen from Figs. 1 to 3 that the Q value increases with the rize in the temperature, while the Q_∞ value remains almost constant over the temperature range from 5 to 35 °C, as shown in Table 1. Thus, the increase in the Q value may be said to be due to the increase in the K value in this temperature range.

Effect of pH on the Distribution Ratio. The distribution ratio of phosphate, D, at 35 °C on IRC-Fe(III)(C_{Fe}=1.97 mmol g^{-1}) was markedly dependent upon the pH of the aqueous phase, as is illustrated in Fig. 7. In this experiment, the pH of the aqueous phase was adjusted with hydrochloric acid and sodium hydroxide, while the concentration of the phosphate ion in the aqueous phase, C_p, was kept in the range from 9.04×10^{-5} to 1.90×10^{-3} mol dm^{-3} (2.8 to 59 ppm) after equilibration to make Q considerably less than Q_∞.

It may be seen from Fig. 7 that the adsorption of the phosphate ion is most appreciable in the pH range from 2.5 to 4.0. The D value rapidly decreases beyond this optimum pH range. The pH profile of the distri-

bution ratio is similar to that of UR10-Fe(III) reported previously,[2] whereas the D values of IRC-Fe(III) are about twenty times larger than those of UR10-Fe(III).

The decrease in the D value in the pH region below 2.5 may be ascribed to the increasing concentration of phosphoric acid(H_3PO_4, pK_{a1}=2.1), which is not adsorbed on the resin, while that in the pH range above 4.0 may be due to the protolysis of hydrated water on the resin-bound iron.

Comparison of Adsorption Behavior of IRC-Fe(III) with That of UR10-Fe(III). In both adsorbents, the Q_∞ value increased with an increase in the C_{Fe} value, indicating that the resin-bound iron is the adsorption site of the phosphate ion. However, in the case of UR10-Fe(III), Q_∞/C_{Fe} decreased from 1.08 to 0.61 when C_{Fe} increased from 0.12 to 1.34 mmol g^{-1} at pH 6; this behavior was explained by the electrostatic and spatial interaction of the phosphate ion in the adsorbent with high C_{Fe} value. On the other hand, Q_∞/C_{Fe} remained unity regardless of the C_{Fe} value(0.726 to 1.97 mmol g^{-1}) at pH 3, while it increased from 0.381 to 0.949 with an increase in the C_{Fe} value from 0.323 to 1.97 mmol g^{-1} at pH 4.6. This behavior is opposite to that of UR10-Fe(III) at pH 6. The different behavior of IRC-Fe(III) in comparison with that of UR10-Fe(III) is presumably caused by the different nature of the resin matrices; that of the former and that of the latter being MR-type and gel-type respectively.

Proton Chemical Shift Study of the Hydrophobic Interaction between Tris(1,10-phenanthroline)ruthenium(II) Ions in Aqueous Solutions

Yuichi MASUDA and Hideo YAMATERA*,†
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received June 18, 1983)

The proton NMR chemical shifts were measured in the D_2O solutions of $[Ru(phen)_3]SO_4$. The proton resonances of the phenanthroline ligand showed up-field shifts with increasing concentration of $[Ru(phen)_3]SO_4$, but they were not significantly affected by the addition of Na_2SO_4. The profile of the up-field shifts for the *Λ*-$[Ru(phen)_3]SO_4$ solution was different from that for the *rac*-$[Ru(phen)_3]SO_4$ solution. These results prove that the up-field shifts were caused by the interaction between $[Ru(phen)_3]^{2+}$ ions. Assuming the formation of the triple and quadrupole aggregates containing two $[Ru(phen)_3]^{2+}$ ions, the association constants of these aggregates and the up-field shifts of the proton signals in the aggregates were determined. A probable structure of the aggregates was deduced from the measured chemical shifts by attributing the up-field shift in the aggregates to the ring-current effect of the phenanthroline ligand. The importance of the hydrophobic interaction between $[Ru(phen)_3]^{2+}$ ions in aqueous solution was thus indicated.

Tris(1,10-phenanthroline) complex ions of bivalent metals, $[M(phen)_3]^{2+}$, are known to be hydrophobic with respect to their hydration[1,2] and also with respect to their interaction with hydrophobic anions in aqueous solutions.[3,4] The ion-pair between the complex cation and the alkanesulfonate anion shows an anomalously large ion-association constant[3] and has a structure which demonstrates the importance of the hydrophobic interaction between these ions.[4] Moreover, the $[Fe(phen)_3]^{2+}$ ions interact with alkyltrimethylammonium ions of a large alkyl group to form cation-cation pairs in aqueous solutions.[5] These findings suggest that the hydrophobic nature of the phenanthroline ligands might cause some mutual interaction between the ions of the $[M(phen)_3]^{2+}$type.

The object of the present study is to investigate how the $[M(phen)_3]^{2+}$ ions interact with each other. We observed the proton NMR of the 1,10-phenanthroline ligand of $[Ru(phen)_3]^{2+}$in aqueous solutions; evidence was obtained for a noticeable cation-cation interaction and information was gained about the structure of the aggregate containing two $[Ru(phen)_3]^{2+}$ ions.

Experimental

Materials. The preparation of tris(phenanthroline)-ruthenium(II)[6] and -cobalt(III)[7] chlorides and optical resolution for obtaining *Λ*-$[Ru(phen)_3]^{2+}$[8] were performed by the literature methods. The sulfate of each metal complex was obtained by double decomposition of Ag_2SO_4 and the chloride of the complex.

NMR Measurements. The ^1H NMR spectra were obtained on a JEOL FX-100 Fourier-transform spectrometer operating at 100 MHz with the D_2O and CD_3OD solutions of $[M(phen)_3](SO_4)_n$ (M=Ru(II) and Co(III)) at 28.0±0.5 °C. The chemical shifts, δ, were measured in ppm down-field from the central peak of the triplet resonance of the tetramethylammonium ion, which was added in the form of the nitrate as the internal reference. The concentration of the tetramethylammonium ion was 1/20 of that of the metal complex ion. The sample solutions for measuring NMR were prepared as follows. The sulfate of the metal complex was dissolved in D_2O and dried up by a rotary evaporator at room temperature. This procedure was repeated. The resulting complex salt was dissolved in D_2O. The methanol solutions were prepared in a similar manner, with CD_3OD in place of D_2O.

† Adjunct Professor of the Institute of Molecular Science, Okazaki (April 1981—March 1983).

Results and Discussion

Effect of the Ion-Ion Interaction on the Proton Chemical Shifts of the Ligands in $[Ru(phen)_3]^{2+}$. Figure 1 shows the representative examples of the proton NMR spectrum for the phenanthroline ligand of $[Ru(phen)_3]SO_4$ in D_2O. Different profiles of the spectra are found for different concentrations of the complex salt. The concentration dependence of the chemical shift was greatest for protons in the 5 and 6 positions. The dependences of the proton shifts on the concentration of $[Ru(phen)_3]SO_4$ in D_2O and CD_3OD are quantitatively shown in Fig. 2, where $\Delta\delta$ indicates the down-field shift with reference to each δ value at infinite dilution, $\delta(0)$. Each proton signal of the phenanthroline ligand of $[Ru(phen)_3]^{2+}$ in D_2O showed monotonous up-field shifts with increasing concentration of $[Ru(phen)_3]SO_4$. The magnitude of the up-field shifts increased in the order of the 2,9<3,8<4,7<5,6 positions of the protons.

If these up-field shifts were caused by the interaction with the sulfate ion, a similar change of the proton shifts of the phenanthroline ligands should be observed when Na_2SO_4 are added to the solution of $[Ru(phen)_3]SO_4$. However, only slight changes were observed in the proton shifts on the addition of Na_2SO_4 (up to about 0.25 mol dm^{-3}) to 0.0025 mol dm^{-3} $[Ru(phen)_3]SO_4$ solution in D_2O (Fig. 2, ◑). This indicates that the up-field shifts with the increase in the concentration of $[Ru(phen)]_3]SO_4$ (Fig. 2, ●) are not due to the interaction with the sulfate ion.

Then the change in the proton shifts may have arisen from interaction of $[Ru(phen)_3]^{2+}$ ions with each other.

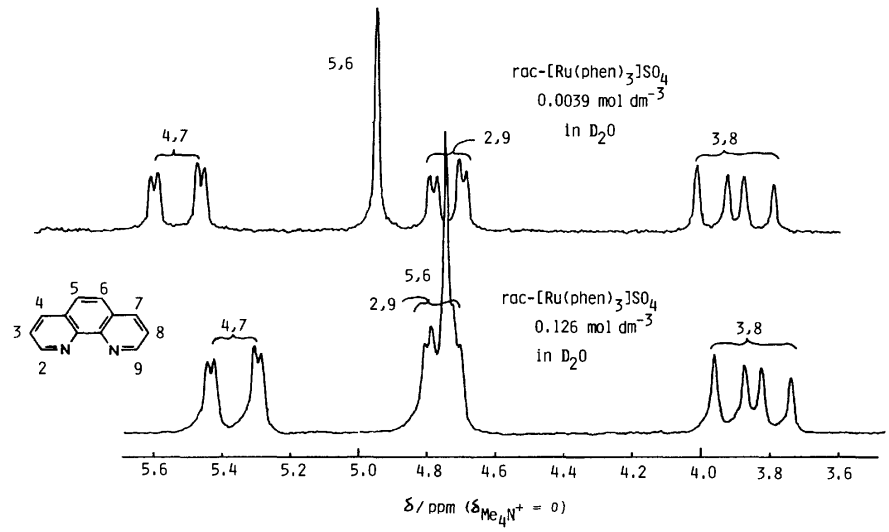

Fig. 1. ^1H NMR spectra of *rac*-$[Ru(phen)_3]SO_4$ in D_2O. (A) 0.0039 mol dm^{-3}. (B) 0.126 mol dm^{-3}. The chemical shift, δ, represents the down-field shift from the proton resonance of Me_4N^+.

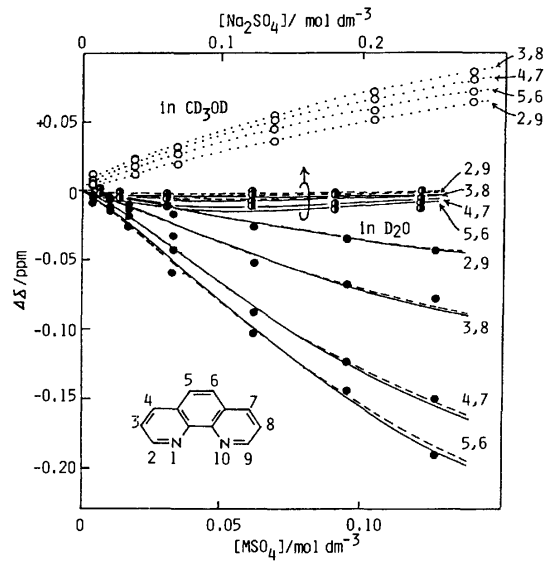

Fig. 2. Plots of the $\Delta\delta$ values *vs.* the concentration of *rac*-$[Ru(phen)_3]SO_4$ in D_2O (●) and in CD_3OD (○), and *vs.* the concentration of Na_2SO_4 added to 0.0025 mol dm^{-3} *rac*-$[Ru(phen)_3]SO_4$ in D_2O (◑). Broken and solid lines indicate the $\Delta\delta$ values calculated with the $\Delta\delta_{t,a}$ values for ion-size parameters, $a=10$ and 12 Å, respectively (Table 1).

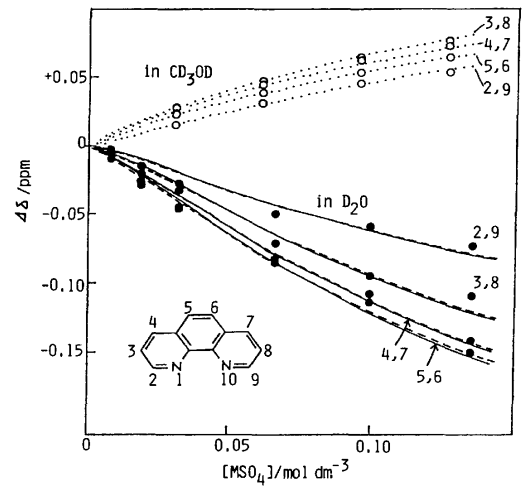

Fig. 3. Plots of the $\Delta\delta$ values *vs.* the concentration of *Λ*-$[Ru(phen)_3]SO_4$ in D_2O (●) and in CD_3OD (○). Broken and solid lines indicate the $\Delta\delta$ values calculated with the $\Delta\delta_{t,a}$ values for ion-size parameters, $a=10$ and 12 Å, respectively (Table 1).

Hydrophobic interaction between the ions may outweigh the coulombic repulsion between them. In order to confirm this, the proton shifts of the phenanthroline ligand were measured with optically active *Λ*-$[Ru(phen)_3]SO_4$ at various concentrations in D_2O (Fig. 3, ●). While the trend of the changes in the proton shifts of *Λ*-$[Ru(phen)_3]SO_4$ is similar to that for *rac*-$[Ru(phen)_3]SO_4$, the magnitudes of the changes are distinctly different. This difference between the racemate and the optical isomer indicates that these up-field shifts are caused by the interaction between two $[Ru(phen)_3]^{2+}$ ions. Either the manner of their interaction or the equilibrium constant for the aggregate formation may differ between the aggregate of a *Δ* and a *Λ*-$[Ru(phen)_3]^{2+}$ ion and that of two *Λ* ions. A further discussion of this problem will be given below.

In the CD_3OD solution of $[Ru(phen)_3]SO_4$, on the other hand, the proton resonances of the phenanthroline ligands (Fig. 2, ○) showed small down-field shifts with increasing concentration of the complex salt, and no meaningful differences were detected between the *Λ* isomer and the racemate. The D_2O solutions of $[Co(phen)_3](SO_4)_{3/2}$ showed only slight down-field shifts (within 0.02 ppm) when the concentration of the complex salt increased up to 0.1 mol dm^{-3} and when Na_2SO_4 was added up to 0.25 mol dm^{-3}. These results indicate that no significant short-range interaction exists

between the metal complex ions in these solutions. The stronger electrostatic repulsion between the complex cations in methanol solutions and that between the tripositive cations of the cobalt complex most probably prevented the complex ions from approaching each other.

Quantitative Treatment of the Proton Chemical Shifts. For the quantitative treatment of the proton shifts of $[Ru(phen)_3]SO_4$ in D_2O, the equilibria between chemical species existing in the solution are considered. The $[Ru(phen)_3]^{2+}$ ion forms the 1:1 ion-pair with the sulfate ion:

$$M + X \rightleftharpoons MX, \tag{1a}$$

where M, X, and MX indicate the $[Ru(phen)_3]^{2+}$ ion, the sulfate ion, and their ion-pair, respectively. The ion association constant at infinite dilution, K, is expressed by:

$$K = \frac{[MX]}{y_M y_X [M][X]}, \tag{1b}$$

where y_M and y_X represent the activity coefficient of each species. Among the species containing two $[Ru(phen)_3]^{2+}$ ions, the aggregate only of two $[Ru(phen)_3]^{2+}$ ions, M_2, is less probable than the triple ions, M_2X, and the quadrupole ions, M_2X_2, because of the large coulombic repulsion between the ions. Thus, the formation of the M_2 ion-pair is disregarded here. Equilibria and equilibrium constants for M_2X and M_2X_2 are:

$$MX + M \rightleftharpoons M_2X, \tag{2a}$$

$$K_t = \frac{y_{M_2X}[M_2X]}{y_M[MX][M]}, \tag{2b}$$

$$M_2X + X \rightleftharpoons M_2X_2, \tag{3a}$$

$$K' = \frac{[M_2X_2]}{y_X y_{M_2X}[M_2X][X]}, \tag{3b}$$

$$2MX \rightleftharpoons M_2X_2, \tag{4a}$$

$$K_q = \frac{[M_2X_2]}{[MX]^2}. \tag{4b}$$

The following relation exists between the four association constants:

$$\frac{K_q}{K_t} = \frac{K'}{K}. \tag{5}$$

For the sake of simplicity, we assume that the value of K' is equal to K. This assumption is justified as an approximation if the ion association in Eqs. 1a and 3a is caused by electrostatic interaction. Since both K and K' are association constants between dipositive and dinegative ions, it can be expected that their values are nearly equal. Substituting $K'=K$ in Eq. 5, we obtain $K_t=K_q$. This result is also reasonable even if hydrophobic interaction between two $[Ru(phen)_3]^{2+}$ ions is involved in the aggregation shown by Eqs. 2a and 4a. Similar results were obtained by Yokoyama and Yamatera by measuring the vapor pressure of aqueous $[Ru(phen)_3]SO_4$ solutions.[9]

Next, we consider the $\Delta\delta$ value for each aggregate. As shown in Fig. 2, the addition of sodium sulfate had only trivial effects on the proton shifts of $[Ru(phen)_3]^{2+}$. Therefore, we assume that the change in each proton chemical shift of the $[Ru(phen)_3]_2^{+}$ ion in D_2O is solely caused by the interaction between the $[Ru(phen)_3]^{2+}$ ions. We further assume for simplicity's sake that the $\Delta\delta$ values are the same for M_2X and M_2X_2 and denote them by $\Delta\delta_{t,q}$. This assumption is justified if the formation of these aggregates is essentially caused by the hydrophobic interaction between the $[Ru(phen)_3]^{2+}$ ions. Then, the observed $\Delta\delta$ value is represented by:

$$\Delta\delta = (x_t + x_q)\Delta\delta_{t,q}. \tag{6}$$

Here x_t and x_q denotes the mole fractions of $[Ru(phen)_3]^{2+}$ existing in the forms of the M_2X and M_2X_2 aggregates, respectively, defined by:

$$x_t = 2[M_2X]/c_M \text{ and } x_q = 2[M_2X_2]/c_M,$$

where c_M is the total concentration of $[Ru(phen)_3]^{2+}$.

If the K value (Eq. 1b) is known,[9] we have here two unknown parameters, $\Delta\delta_{t,q}$ and K_t ($=K_q$). (The activity coefficient, y, was calculated with the Debye-Hückel equation). The unknown parameters for the racemic solution, $K_t(rac)$ ($=K_q(rac)$) and $\Delta\delta_{t,q}(rac)$ and those for the Λ-isomer solution, $K_t(\Lambda)$ ($=K_q(\Lambda)$) and $\Delta\delta_{t,q}(\Lambda)$ were determined so as to give the best fit to the measured proton shifts for the racemic and the Λ-isomer solutions, respectively. The association constant obtained for the racemic solution, $K_t(rac)$ ($=K_q(rac)$), was practically identical with that for the Λ-isomer solution, $K_t(\Lambda)$ ($=K_q(\Lambda)$). The *rac*-$[Ru(phen)_3]SO_4$ solution contains two chemically different species of paired $[Ru(phen)_3]^{2+}$ ions, Λ-Λ and Λ-Λ (or Δ-Δ). The approximate equality of $K_t(rac)$ and $K_t(\Lambda)$ indicates that no significant difference exists between the values of the association constants for the Δ-Λ pair ($K_t(\Delta$-$\Lambda)$) and for the Λ-Λ pair ($K_t(\Lambda$-$\Lambda)$). This gives the relation:

$$\Delta\delta_{t,q}(rac) = (1/2)[\Delta\delta_{t,q}(\Delta\text{-}\Lambda) + \Delta\delta_{t,q}(\Lambda\text{-}\Lambda)]. \tag{7}$$

With Eq. 7, we obtained the $\Delta\delta_{t,q}(\Delta$-$\Lambda)$ value from the experimental values of $\Delta\delta_{t,q}(rac)$ and $\Delta\delta_{t,q}(\Lambda)$($=\Delta\delta_{t,q}$-$(\Lambda$-$\Lambda)$). Table 1 summarizes the association constants and the chemical-shift changes for M_2X and M_2X_2 in each case, where the ion-size parameter (a) in Debye-Hückel equation is assumed to be 10 or 12 Å[10] (1 Å= 10^{-10} m). The values in Table 1 were used to calculate the gross $\Delta\delta$ values for each solution (broken and solid lines in Figs. 2 and 3).

In the case of the Δ-Λ aggregate, the proton up-field shifts strongly depend on the position of the proton in the phenanthroline ligand; the magnitude of the up-field shifts increases in the order of 2,9<3,8<4,7<5,6. For the Λ-Λ aggregate, the up-field shifts were less strongly dependent on the position of the proton, although the order was the same as the Δ-Λ case. These results can be taken as the evidence for the operation of short-range interaction between the cations.

The Structure of the Aggregate Containing Two [Ru(phen)$_3$]$^{2+}$ Ions. The up-field shifts in the M_2X and M_2X_2 aggregates probably result from the ring-current effect[11] of the phenanthroline ligand. Such up-field shifts were previously observed for the ^{13}C chemical shifts of the hexanesulfonate ion in the ion-pair with the $[Fe(phen)_3]^{2+}$ ion,[4] and on the methyl proton shift of the amino acid with a large alkyl group in a mixed-ligand Zn(II) complex containing phenanthroline.[12] If

TABLE 1. THE UP-FIELD SHIFTS OF THE PROTONS IN THE M_2X AND M_2X_2 AGGREGATES AND THE ASSOCIATION CONSTANTS FOR THESE AGGREGATES (28 °C)

the ring-current effect is responsible for the up-field shifts, the proton of a $[Ru(phen)_3]^{2+}$ ion placed just above the aromatic rings of a phenanthroline ligand of another $[Ru(phen)_3]^{2+}$ ion will show the largest up-field shift, and increasing distance from this position will decrease the magnitude of the shift. Thus, the difference in the up-field shifts between the Δ-Δ and the Λ-Λ aggregate reflects the difference in the configuration between them. This result is similar to Yamagishi's recent report that the arrangement of the Λ-$[Fe(phen)_3]^{2+}$ ions adsorbed on soil from a solution of the Λ isomer is largely different from the alternate arrangement of the Δ and Λ ions adsorbed from a solution of the racemate.[13]

We first consider the aggregate containing the Λ and Δ complex ions. In the M_2X or M_2X_2 aggregate, the 5 and 6 protons with the largest up-field shifts are considered to be placed closest to the position just above the aromatic rings of a phenanthroline ligand of the other $[Ru(phen)_3]^{2+}$ ion and the other protons are farther from that position in the order of 5,6<4,7<3,8 <2,9. Figure 4 shows a probable configuration of two $[Ru(phen)_3]^{2+}$ ions in the aggregate, where the edge of a phenanthroline ligand (**A**) of one $[Ru(phen)_3]^{2+}$ ion is placed in an opening between two phenanthroline ligands of the other $[Ru(phen)_3]^{2+}$ ion. Then the 5 and 6 protons of the **A** phenanthroline ligand are considerably influenced by the ring-current of those two phenanthroline ligands. Either the 4 or the 7 proton of the **A** phenanthroline ligands is placed above one of those phenanthroline ligand and none of the 2, 3, 8, and 9 protons are placed above them. The same applies to the protons of the **B** phenanthroline ligand.

For estimating the up-field shifts of the 5 and 6 protons, we assumed that the ring-current effect of phenanthroline is approximated by that of phenanthrene. Then, Hazato's theory[14] predicts an up-field shift of 4.1—4.3 ppm for the 5 and 6 protons of the **A** and **B** ligands.[15] Since only a single signal was observed for the 5 and 6 protons (Fig. 1), the observed chemical shift corresponds to the average over six equivalent protons of $[Ru(phen)_3]^{2+}$. Then, assuming that the proton chemical shifts of the ligands other than the **A** or **B** ligand are not affected by the aggregate formation, the average up-field shift of the 5 and 6 protons was estimated to be about 1.4 ppm. The experimental value of about 1.1 ppm (Table 1) shows a reasonable agreement with this value; the small difference may be explained if the aggregate does not always take the optimum configuration. Such flexibility of the configuration will also explain the small but appreciable up-field shifts for the 2, 3, 8, and 9 protons in the aggregate.

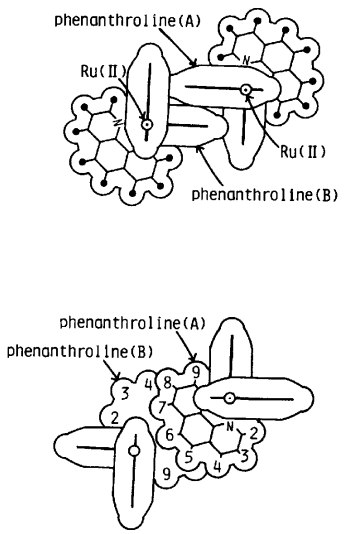

Fig. 4. Probable configuration of a pair of Λ- and Δ-$[Ru(phen)_3]^{2+}$ ions in the M_2X and M_2X_2 aggregates: the elevation (top) and the plan (bottom).

The up-field shifts of the protons of the Λ-Λ aggregate span an obviously narrower range than spanned by those of the Δ-Λ aggregate. This may indicate that the configuration of the Λ-Λ aggregate is more labile and/or more manifold than that of the Δ-Λ one. Actually, examinations with the CPK model demonstrated that a well-fitted structure like that shown in Fig. 4 is not possible for the Λ-Λ aggregate because of the steric hindrance between the phenanthroline ligands.

This work was carried out as a Cooperative Research (1982) of the Institute for Molecular Science. The authors thank the Ministry of Education, Science and Culture for the support of this work (Grant-in-Aid for Scientific Research No. 56470039).

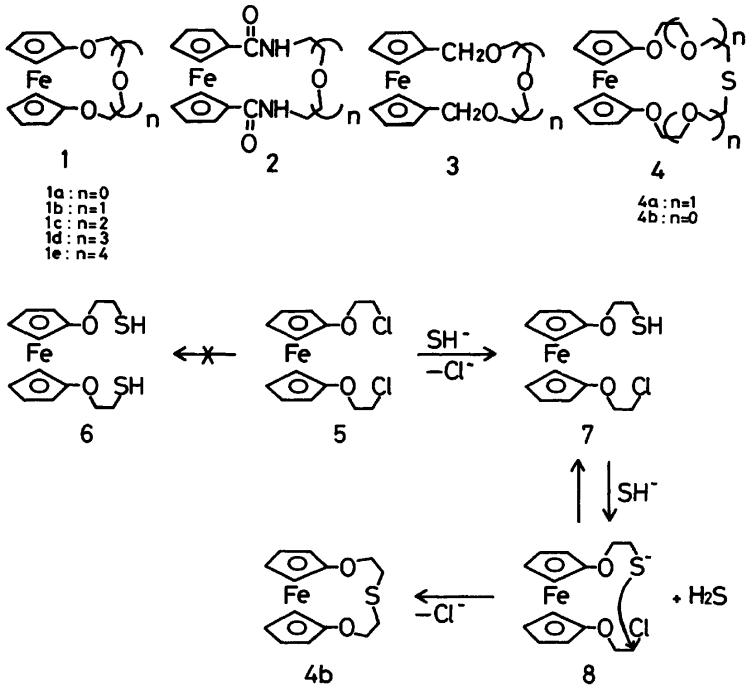
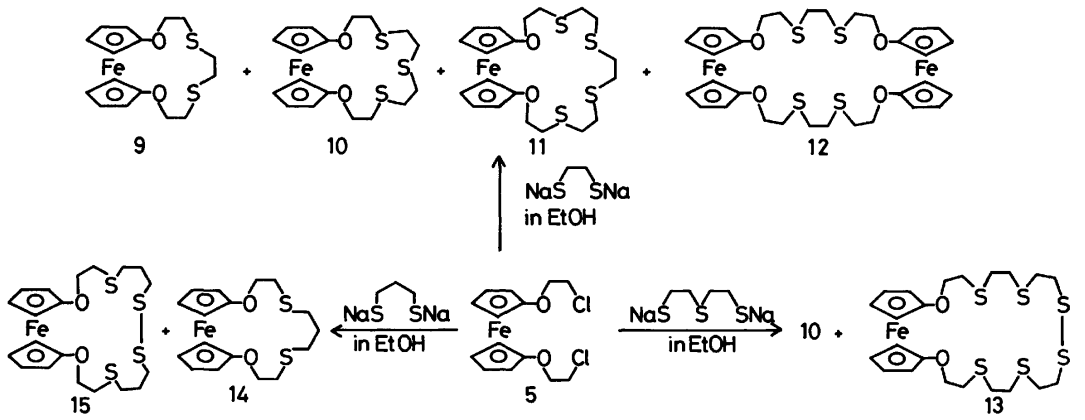
The reaction of 1,1′-bis(2-chloroethoxy)ferrocene with 1,2-ethanedithiolate in absolute ethanol gave mononuclear 1,10-dioxa-4,7-dithia[10]ferrocenophane and binuclear 1,10,21,30-tetraoxa-4,7,24,27-tetrathia-[10,10]ferrocenophane, along with a small amount of unexpected 1,13-dioxa-4,7,10-trithia[13]ferrocenophane and 1,16-dioxa-4,7,10,13-tetrathia[16]ferrocenophane. Extraction of aqueous metal picrates (M; alkali, alkaline earth, Ag^+, Tl^+, Cd^{2+}, Co^{2+}, Cu^{2+}, Ni^{2+}, and Hg^{2+}) with dioxathia[*n*]ferrocenophanes was examined and also with the corresponding ring membered polyoxa[*n*]ferrocenophanes. Dioxathiaferrocenophanes showed a highly selective extraction ability towards bivalent mercury and copper ions.

While investigations of crown ethers and their cation complexes have been steadily gaining interest during the past decade, most attention has been focused so far on the synthesis of a new type of ligand.[1] The preparation and physicochemical properties of several kinds of polyoxa- and polythia[*n*]ferrocenophanes (**1**—**4**) have been previously reported.[2-7] It was shown that some of these compounds, particularly those containing five and six heteroatoms in the macrocyclic ring, form complexes with alkali-metal, thallium, and silver cations. Many methods for the synthesis of polythiacrown ethers have been reported.[8-11] However, with the exception of thioformaldehyde polymerization,[12] all other methods of thioether ring closure were based on α-mercaptide displacement of ω-halide function. We wish here to report a novel finding concerning the synthesis and extraction ability of dioxathia[*n*]ferrocenophanes.

Synthesis and Structure. The following reactions were carried out in order to obtain 1,1′-bis(2-mercaptoethoxy)ferrocene (**6**) as a starting material. 1,1′-Bis(2-chloroethoxy)ferrocene (**5**) was readily synthesized by reaction of the disodium salt of 1,1′-ferrocenediol, which was prepared by the hydrolysis of 1,1′-diacetoxyferrocene, with large excess of 1-bromo-2-chloroethane. An attempt to convert **5** into the corresponding dithiol (**6**) by a reaction with sodium hydrogensulfide failed. Instead 1,7-dioxa-4-thia[7]ferrocenophane (**4b**) was obtained in 49% yield, doutless by incursion of the cyclization mechanism accompanying an intramolecular attack of the thiolate anion to the halogenated carbon atom.[11] Compound **4b** was found to be identical with an authentic sample[7] prepared by the reaction of **5** with sodium sulfide. Therefore, dioxathia[*n*]ferrocenophanes were prepared according to the following method.

A solution of 5 (1.0 molar equiv) in absolute ethanol was added at once to a solution of disodium 1,2-ethanedithiolate (3.0 molar equiv) in absolute ethanol and the resulting solution was stirred at refluxing temperature for 14 h. After the usual work-up, the reaction mixture was separated by silica-gel thinlayer chromatography. From the reaction mixture, mononuclear 1,10-dioxa-4,7-dithia[10]ferrocenophane (**9**) and





binuclear 1,10,22,31-tetraoxa-4,7,25,28-tetrathia[10.10]ferrocenophane (**12**) were obtained in 38 and 3.2% yields, respectively. Moreover, a small amount of unexpected 1,13-dioxa-4,7,10-trithia[13]ferrocenophane (**10**, 6.1%) and 1,16-dioxa-4,7,10,13-tetrathia-[16]ferrocenophane (**11**, 1.9%) were isolated.[13] When **5** was treated with equimolar of 1,2-ethanedithiol under similar conditions, compounds **9**, **10**, and **12** were obtained, although the yields of those were somewhat low and **11** could not be isolated. Interestingly, the reactions of **5** with bis(2-mercaptoethyl) sulfide did not yield the unexpected ring enlarged dioxathia[*n*]ferrocenophanes, but gave normal mononuclear ferrocenophane (**10**) and disulfide (**13**) in 51 and 2.9% yields, respectively. Such an abnormal reaction was not observed in the reaction of **5** with 1,3-propanedithiol. Isolation of the disulfide (**13** and **15**) suggest that the dithiolate, which was formed by a nucleophilic attack of two molar of 1,2-ethanedithiolate at the halogenated carbons of **5**, was easily oxidized by the trace amount of oxygen in an atmosphere of nitrogen to give the corresponding disulfide in low yield. The results obtained by the reactions of **5** with dithiols are listed in Table 1, along with the physical data of the products.

The possible mechanism of the unexpected formation of compounds **10** and **11** is shown in Scheme. The initial reaction may be a nucleophilic attack of two molar of 1,2-ethanedithiolate on the halogenated carbons of **5** to give the dithiolate **16**. The second step of the reaction is considered to be single proton elimination from the methylene next to the sulfur atom followed by elimination of S^{2-} to give the vinyl sulfide intermediate **17**. Thus, the formation of **10** can be interpreted by an intramolecular attack of $-S^-$ at the double bond followed by addition of a proton to the resulting sulfur-stabilized anion. Moreover, the addition of another disodium 1,2-ethanedithiolate to **17** would form the ferrocenophane **11** by the same mechanism. Support for this mechanism is provided by the following results. The reaction of **5** with disodium 1,3-propanedithiolate gave 1,11-dioxa-4,8-dithia[11]ferrocenophane (**14**) in 64% yield, but no abnormal product corresponding to **10** and **11**, because the dithiolate intermediate corresponding **17** in this reaction have no leaving group (S or SH) for forming a vinyl sulfide group. On the other hand, **5** reacted with the disodium salt of bis(2-mercaptoethyl) sulfide to afford

Table 1. Yield, Mp, mass spectral data of dioxapolythia[*n*]ferrocenophanes

Compd	Yield %	Mp θ_m/°C	Mass (M^+, *m/e*)
4a	49	104—106 (104—106)[7]

13	2.9	79—81	576
14	64	149—150	378
15	8.6	84—86	484

a) The value in parenthesis showed the yield obtained by the reaction of **5** with bis(2-mercaptoethyl) sulfide.

10 and **13**. This is probably due to the large ring size of the possible cyclization intermediate which would make the template effect impossible, and this can help the intramolecular nucleophilic attack to the cyclization to ferrocenophane. However, many attempts to isolate intermediates such as **17** and **18** from the reaction mixture failed. Thus, the resulting intermediates (**17** and **18**) must be unstable or too reactive and might react easily with an intermediate mercapto group.

Structural assignment of these ferrocenophanes **9**—**15** and **6** was achieved by their elemental analyses, spectral inspection, and partly on the basis of the unequivocal synthesis. In particular all of their elemental analyses were in good accord with the proposed compositions, and the IR spectra showed a cyclopentadienyl C-H absorption band at near 1485 cm^{-1}, an ether linkage band near 1015 cm^{-1} and a C-S stretching vibration band near 610 cm^{-1}. In addition to the above bands, the IR spectra of compounds **13** and **15** also showed an S-S stretching band near 490 cm^{-1}. In the ^{1}H-NMR spectra of **9**—**11**, the signal for methylene protons next to the oxygen atom appeared as a triplet (4H, J=*ca.* 6 Hz) near δ 4.10 and the signal for the methylene protons α to the sulfur atom appeared as a triplet (4H, J=*ca.* 6 Hz) near δ 2.9. The signals for the other methylene protons appeared at δ 3.03—2.62, respectively. Furthermore, ferrocene ring protons resonanced as a pair of triplets (each 4H, J=*ca.* 1.8 Hz)

at near δ 4.10 (Fc-H$_\alpha$) and 3.88 (Fc-H$_\beta$). The ^{1}H-NMR spectrum of binuclear ferrocenophane (**12**) and disulfide (**13** and **15**) are similar to those of mononuclear ferrocenophanes.

Extraction Ability. The extraction ability of ferrocenophanes (**4a**, **9**, and **10**) for alkali, alkaline-earth metals, and several other metal cations was measured by Pedersen's method.[15)] The data are summarized in Table 2, along with those of polyoxaferrocenophane (**1d**) and benzo-15-crown-5. The dioxathia[*n*]ferrocenophanes (**4a**, **9**, and **10**) showed little extraction ability toward alkali metal ions (hard cation), although benzo-15-crown-5 showed relatively high extraction ability. The extraction ability of the dioxathiaferrocenophanes toward alkaline-earth metal ions is also low and these result are similar to those of polyoxaferrocenophane (**1d**) and benzo-15-crown-5.

The extraction ability of dioxathiaferrocenophanes (**4a**, **9**, and **10**) toward transition metal cations was more complex. A soft mercury(II) ion was extracted by **9** and **10** very well. The extraction ability of the ferrocenophanes (**1d**, **4a**, and **10**) having the same ring member toward mercury(II) ion in the following order: **10**(76.1)>**4a**(30.4)>**1d**(11.7). The phenomenon may be explained by the HSAB rule.[16)] That is, the successive displacement of an oxygen atom in the macrocyclic ring of the ferrocenophanes by a sulfur atom, which is softer compared with an oxygen atom, increases the affinity to a soft mercury(II) ion. However, the extraction ability of a thallium(I) ion, which is classified in a soft ion, by the ferrocenophanes (**1d**, **4a**, and **10**) rather showed the reverse order: **1d**(25.2)>**4a**(8.3)> **10**(2.1). So, the extraction ability of metal ions by the ferrocenophanes must be influenced by other factors, such as the conformation of the macrocycles, the size of the hole in the macrocycles, and so on, as well as a soft-hard characterization of the metal ions. Interestingly, benzo-15-crown-5 extracted a thallium(I) ion more efficiently than **1d**, while it scarcely extracted a mercury(II) ion. These obsevations indicated that **10** has a specifically high extraction ability toward a mercury(II) ion. A similar trend was observed in the extraction ability of 18-crown-6 and its sulphur analog toward silver(I) ion.[10)] The extraction ability of **4a**, **9**, and **10** toward a silver(I) ion was then examined. However, their extraction ability could not be measured, because of a rapid decomposition, in which the iron atom of ferrocene might be oxidized by the incorporated silver(I) ion. A similar result was also observed in polyoxa[*n*]ferrocenophanes.[3)]

The extraction ability of these ferrocenophanes toward the borderline ions, nickel(II) and cobalt(II) ions,

was very low, while that of a copper(II) ion was relatively high. The remarkable extraction ability of **9** and **10** toward a copper(II) ion is noteworthy, since the extraction ability of a copper(II) ion by a crown-type compound has rarely been reported. In connection with this observation, it is interesting that cyclic polythiaethers formed the complex having a high stability constant with copper(II) ion.[18]

Experimental

The melting points are uncorrected. The mass spectra were taken on a Hitachi M-80 mass spectrometer. The ^{1}H-NMR spectra were obtained on a Hitachi R-90 spectrometer, with TMS as the internal standard. The optical spectra were obtained on a Hitachi Model 200-10 spectrometer. The IR spectra were measured on a JASCO IRA-2 Diffraction Grating Infrared Spectrometer.

Materials and Reagents. 1,1'-Bis(2-chloroethoxy)ferrocene (**5**) is prepared according to the previously reported method. The other reagents employed were commercial materials or were prepared by the usual methods.

Reaction of 5 with Sodium Hydrogensulfide. To a solution of **5** (0.243 g, 0.71 mmol) in *n*-butanol (150 ml) was added sodium hydrogensulfide hydrate (0.7 g, 7.1 mmol) and the mixture was stirred for 13 h at 120 °C under nitrogen. After the solution had been cooled to room temperature, the solvent was evaporated *in vacuo*. The residue was extracted with ether. The extracts were combined and filtered. The filtrate was concentrated and the residue chromatographed on silica gel TLC (hexane:acetone=3:1). The main fraction was extracted with acetone, followed by filtration and evaporation of the solvent, to give yellow crystals. Recrystallization of the crude material from hexane gave **4a** as yellow crystals, mp 104—106 °C (lit, 104—106 °C) in 49% yield. Compound **4b** was identified by direct comparison with the spectral data of an authentic sample.

Reaction of 5 with 1,2-Ethanedithiol. 1,2-Ethanedithiol (1.5 ml, 17 mmol) was added to 500 ml of absolute ethanol containing 0.53 g (13.3 mmol) of sodium hydroxide under nitrogen, and the mixture was stirred at room temperature. After 10 min, a solution of **5** (1.43 g, 4.17 mmol) in 100 ml of absolute ethanol was added all at once, and then the mixture was stirred for 13 h at refluxing temperature. After the solution had cooled to room temperature, the solvent was evaporated *in vacuo*. The residue was extracted with ether and chloroform. The extracts were combined, followed by filtration and evaporation of the solvent to give a yellow oil. The residue was chromatographed on silica gel TLC (hexane: acetone: chloroform=6:1:trace). The first fraction was extracted with acetone, followed by filtration and evaporation of the solvent, to give yellow crystals. Recrystallization of the crude material from hexane gave **9** as yellow crystals, mp 115—116 °C, in 38% yields. ^{1}H-NMR (in $CDCl_3$): δ 4.11 (t, J=1.8 Hz, H$_\alpha$, 4H), 3.89 (t, J=1.8 Hz, H$_\beta$, 4H), 4.12 (t, J=6.3 Hz, -OCH_2, 4H), 3.03 (s, -SCH_2CH_2S-, 4H), 2.91 (t, J=6.3 Hz, -SCH_2, 4H), MS (70 eV): m/e 364 (M^+). IR (KBr): 3100, 2930, 1485, 1275, 1080, and 610 cm^{-1}. Found: C, 52.72; H, 5.58%. Calcd for $C_{16}H_{20}O_2S_2Fe$: C, 52.75; H, 5.53%. The second fraction was extracted with acetone. Evaporation of the solvent gave yellow crystals. Recrystallization of the crude material from hexane gave pure **10**, mp 114—116 °C, in 6.1% yield. ^{1}H-NMR (in $CDCl_3$): δ 4.08 (t, J=2.0 Hz, H$_\alpha$, 4H), 3.88 (t, J=2.0 Hz, H$_\beta$, 4H), 4.05 (t, J=6.1 Hz, -OCH_2, 4H), 2.62—3.02 (t+m, -SCH_2, 12H). MS (70 eV): m/e 424 (M^+). IR (KBr): 3100, 2940, 1480, 1250, 1085, and 610 cm^{-1}. Found: C, 50.89; H, 5.75%. Calcd for $C_{18}H_{24}O_2S_3Fe$: C, 50,94; H, 5.70%. The third fraction was extracted with acetone. Evaporation of the solvent gave yellow crystals. Recrystallization of the crude material from ethanol gave pure **11**, mp 69—70 °C, in 1.9% yield. ^{1}H-NMR (in $CDCl_3$): δ 4.12 (t, J=1.8 Hz, H$_\alpha$, 4H), 3.88 (t, J=1.8 Hz, H$_\beta$, 4H), 4.05 (t, J=6.4 Hz, -OCH_2, 4H), 2.80—3.02 (s+m, -SCH_2, 16H). MS (70 eV): m/e 484 (M^+). IR (KBr): 3100, 2930, 1485, 1245, 1050, and 620 cm^{-1}. Found: C, 49.41; H, 5.99%. Calcd for $C_{20}H_{28}O_2S_4Fe$: C, 49.58; H, 5.82%. The fourth fraction was extracted with acetone. Evaporation of the solvent gave a yellow oil which was rechromatographed on silica gel TLC (hexane: acetone: chloroform=3:1:trace). The main band was extracted with acetone. Evaporation of the solvent gave a yellow oil. Recrystallization of the crude material from ethanol gave pure **12**, mp 129—131 °C, in 3.2% yield. ^{1}H-NMR (in $CDCl_3$): δ 4.07 (t, J=1.8 Hz, H$_\alpha$, 8H), 3.84 (t, J=1.8 Hz, H$_\beta$, 4H), 4.00 (t, J=6.5 Hz, -OCH_2, 8H), 2.77—2.97 (s+t, -SCH_2, 16H). MS (70 eV): m/e 728 (M^+). IR (KBr): 3100, 2920, 1480, 1245, 1085, and 610 cm^{-1}. Found: C, 52.91; H, 5.76%. Calcd for $C_{32}H_{40}O_4S_4Fe$: C, 52.75; H, 5.53%.

Reaction of 5 with Bis(2-mercaptoethyl) Sulfide. Bis(2-mercaptoethyl) sulfide (1.8 ml, 12.4 mmol) was added all at once to 240 ml of absolute ethanol containing sodium hydroxide (0.33 g, 8.2 mmol) under nitrogen and the mixture was stirred at room temperature. After 10 min, a solution of **5** (0.814 g, 2.4 mmol) in 60 ml of absolute ethanol was added all at once, then the mixture was stirred for 15 h at reflux temperature. After the solution had been cooled to room temperature, the solvent was evaporated *in vacuo*. The residue was extracted with chloroform. The extract was filtered off and the filtrate was concentrated *in vacuo*. The residue was chromatographed on silica gel (hexane: acetone: chloroform=6:1:trace). The first fraction was extracted with acetone. Evaporation of the solvent gave a yellow oil. Recrystallization of the crude material from hexane gave pure **10** as yellow crystals, mp 114—116 °C in 51% yield. The pure **10** was identified by direct comparison with the spectral data of an authentic sample obtained by reaction of 1,2-ethanedithiol with **5**. The second fraction was extracted with acetone. Evaporation of the solvent gave a yellow oil. The crude material was recrystallized from hexane to give **13** as yellow crystals, mp 79—81 °C, in 2.9% yield. ^{1}H-NMR (in $CDCl_3$): δ 4.10 (t, J=1.9 Hz, H$_\alpha$, 4H), 4.03 (t, J=6.5 Hz, 4H, -OCH_2), 3.87 (t, J=1.9 Hz, H$_\beta$, 4H), 2.78—3.00 (m, 20H). MS (70 eV): m/e 576 (M^+). IR (KBr): 3100, 2930, 1485, 1250, 1015, and 490 cm^{-1}. Found: C, 46.12; H, 5.70%. Calcd for $C_{22}H_{32}O_2S_6Fe$: C, 45.83; H, 5.56%.

Reaction of 5 with 1,3-Propanedithiol. 1,3-Propanedithiol (1.0 ml, 9.6 mmol) was added to 250 ml of absolute ethanol containing sodium hydroxide (0.277 g, 6.9 mmol) under nitrogen, and the mixture was stirred at room temperature. After 10 min, a solution of **5** (0.711 g, 2.07 mmol) in 100 ml of absolute ethanol was added all at once, and the mixture then stirred for 14 h at reflux temperature. The usual work-up gave a yellow oil, which was chromatographed on alumina using dichloromethane as eluent. The fraction gave yellow crystals. Recrystallization of the crude product from hexane gave pure **14**, mp 149—150 °C, in 64% yield. ^{1}H-NMR (in $CDCl_3$): δ 4.19 (t, J=2.0 Hz, H$_\alpha$, 4H), 3.91 (t, J=2.0 Hz, H$_\beta$, 4H), 4.10 (t, J=6.5 Hz, -OCH_2, 4H), 2.70—3.03 (m, -SCH_2, 8H), 2.08 (q, J=6.3 Hz, CH_2, 2H). MS (70 eV): m/e 378 (M^+). IR (KBr): 3080, 2910, 1485, 1245, 1075, and 610 cm^{-1}. Found: C, 53.69; H, 5.70%. Calcd for $C_{17}H_{22}O_2S_2Fe$: C, 53.97; H, 5.82%. The second fraction gave crude **15** as a yellow oil. Recrystallization of the crude material from hexane gave pure **15**, mp 84—86 °C, in 8.6% yield. ^{1}H-NMR (in $CDCl_3$): δ 4.07 (t, J=1.9 Hz, H$_\alpha$, 4H), 4.00 (t, J=6.4 Hz, -OCH_2 4H), 3.83 (t, J=1.9 Hz, H$_\beta$, 4H), 2.66—2.98 (m, 12H), 2.05 (q, J=6.2 Hz, CH_2, 4H). MS (70 eV): m/e 484 (M^+). IR (KBr): 3100, 2910, 1485, 1245, 1075, and 490 cm^{-1}.

Found: C, 49.77; H, 5.73%. Calcd for $C_{20}H_{28}O_2S_4Fe$: C, 49.58; H, 5.82%.

Extraction Ability. Extraction ability of the ferrocenophanes and benzo-15-crown-5 with metal picrate was examined by the method described in a previous paper.[3]

(Received June 17, 1983)

^{1}H- and ^{13}C-NMR spectra of free ligands and their alkali metal complexes with a new type of crown ethers containing a ferrocene unit have been recorded. The change of chemical shifts in ^{1}H- and ^{13}C-NMR spectra was attributed to an electronic field effect and a conformational change on the metal complexation, respectively. The crystal structure of the complex of 1,4,7,10,13-pentaoxa[13]ferrocenophane with sodium thiocyanate was determined by the X-ray method. The crystals are orthorhombic, space group Cccn, with a=20.579(4), b=25.622(8) c=7.606(1) Å, U=4010(2) Å^3, Z=8, D_c=1.48 g cm^{-3}. The distances between the iron atom of a ferrocene nucleus and the incorporated sodium cation and between the sodium cation and the nitrogen atom of a counter anion are 4.129 and 2.541 Å, respectively. The results suggest that the iron atom of the ferrocene does not take part directly in complex formation and that the sodium cation forms a contact ion pair with the nitrogen atom of a counter anion.

Polyoxa- and polythia[*n*]ferrocenophanes are a kind of crown ether-like compounds including a ferrocene subunit as a ring member; in it, the iron atom may act as a coordinatable heteroatom. Recently, several research groups have treated the interaction between the iron atom of ferrocene nucleus and the complexed cation,[1-3] and have synthesized polyoxa- and polythia[*n*]ferrocenophanes. Biernat *et al.* concluded that there is no interaction between the iron atom of **1a** and the complexed rubidium cation in methanol by only the UV spectral studies.[1] However, we ourselves previously observed a certain interaction between the iron atom of oxathia[*n*]ferrocenophane and the complexed silver cation.[4] In a previous paper,[5] we have reported the preparation and some spectroscopic and physicochemical properties of the polyoxa[*n*]ferrocenophanes and its alkali thiocyanate complexes. Polyoxa[*n*]ferrocenophanes (**1**) show a weak complexing ability to alkali, alkaline-earth cations (hard ions), and a higher complexing ability to silver and thallium cations (soft ions). It is of interest to know what kind of interaction can be expected between the iron atom of a ferrocene nucleus and the complexed cation. In continuation of our investigations about the complexes of polyoxaferrocenophanes with metal cations, we now report the ^{1}H-NMR, ^{13}C-NMR, and the crystal structure of the complexes of polyoxa[*n*]ferrocenophanes with alkali-metal thiocyanates.

Results and Discussion

Ligands (**1a** and **1b**) form complexes with various alkali metal thiocyanates.[5] Suitable crystals for the X-ray analysis of **4b** were obtained by slow addition of hexane to the chloroform solution containing the ligand and sodium thiocyanate.

^{1}H-NMR Spectra of the Complexes 3 and 4. In the ^{1}H-NMR spectrum of **1a**, the signals at δ 4.14 and 3.86 which appear as triplets (J=2.0 Hz) are attributable to α- and β-protons of cyclopentadienyl rings, respectively, while the two singlets at δ 3.70 and 3.78 and the two triplets at δ 3.86 and 4.05 (J=4.6 Hz) are attributable to the methylene protons of the macrocycle. The ^{1}H-NMR spectra of compounds **1** were compared with those of alkali metal thiocyanate complexes **3** and **4**. The chemical shift of the complexes are shown in Table 1, together with those of uncomplexed ligands (**1a** and **1b**). The differences in the chemical shifts between the free ligands and the complexes are also shown in parentheses in Table 1. The change of chemical shifts of the ferrocenophanes on complexation with alkali metals seems to be attributable to a) an electronic field effect caused by the metal cation and the counter anion, b) perturbation of the electron density on the carbon atom through M$^+$-Fe-cyclopentadienyl rings, and c) factors due to the conformational change on complexation. The downfield shift was observed not only on the methylene protons but also on all protons of the cyclopentadienyl rings of ferrocene nucleus. In **4a** and **4b**, the change of chemical shifts of the cyclopentadienyl ring protons seems to depend on the distance of each proton from the complexation site, that is, the downfield shift of α-protons is more enhanced than those of β-protons. By contrast, the chemical shift differences between α- and β-protons in **3a**—**c** were approximately the same. The cavity of the macrocyclic polyether ring of **1a** seems to be too large for Li$^+$ and Na$^+$, and the complexes may take a folded geometry as pictured by Poonia.[6] The above results are in good

Table 1. ^{1}H-NMR spectral data of compounds **1a** and **1b** and their alkali metal thiocyanate complexes[a, b]

Compd	Cp-ring protons		Methylene protons		
	H_α	H_β			
1a	4.09(t)	3.82(t)	3.66(s)	3.68(s)	3.93—4.04 (m)
3a(LiSCN)	4.17(t) (+0.08)	3.92(t) (+0.10)	3.75(s) (+0.09)	3.72(s) (+0.04)	4.04—3.78 (m)
3b(NaSCN)	4.13(t) (+0.04)	3.85(t) (+0.03)	3.66(s) (±0.0)	3.71(s) (+0.03)	4.06—3.77 (m)

a) Chemical shifts as δ values. A downfield shift is denoted as a positive value. b) Deuteriochloroform was used as solvent.

Table 2. ^{13}C-NMR spectral data of compounds **1a** and **1b** and their alkali metal thiocyanate complexes[a, b]

Compd	C_b	C_α	C_β	Methylene carbons			
1a	127.1	56.2	61.9	71.2	70.6	70.1	
3a(LiSCN)	126.6 (−0.5)	56.8 (+0.6)	62.3 (+0.4)	70.6	70.5 (−0.1—−0.6)	70.4	70.0
3b(NaSCN)	126.2 (−0.9)	56.9 (+0.7)	62.5 (+0.6)	69.5	69.4 (*ca.* −0.7)		
3c(KSCN)	126.2 (−0.9)	57.3 (+1.1)	62.4 (+0.5)	71.1	70.2 (−0.1—−0.6)	69.5	
1b	126.9	56.4	61.9	71.3	70.7	70.3	70.0
4a(LiSCN)	125.0 (−21.9)	58.4 (+2.0)	63.0 (+1.1)	71.1	69.1 (−0.2—−1.6)	68.4	
4b(NaSCN)	124.9 (−2.0)	59.9 (+3.5)	63.6 (+1.7)	73.4	69.1 (+2.1—−3.0)	68.7	

a) Chemical shifts as δ values. A downfield shift is denoted as a positive value. b) Deuteriochloroform was used as solvent. c) Shift changes are presented in parentheses.

agreement with the hole size estimated from Corey-Pauling-Koltum stereomolecular model (**1a**: 2.8—3.4 Å and **1b**: 2.2 Å) with the ionic diameters[7] of Li^+ (1.20 Å), Na^+ (1.90 Å), and K^+ (2.66 Å). It has already been reported[8] that in an 18-membered crown ether, such as dibenzo-18-crown-6, the addition of more than one equivalent of KSCN caused no further chemical shift change, although the resonances of all protons were successively shifted until done equivalent of the metal salt was added. The above results suggest that the electronic field effect of the counter anion, SCN^-, on all the protons of the host crown ether is small and negligible. Therefore, the chemical shifts of the complexes seems to be best interpreted in terms of an electronic field effect due to the incorporated metal cation and a perturbation of the electron density on the carbon atom through the C-O bond due to the coordination of an oxygen atom to the metal cation.

^{13}C-NMR Spectra. It is well known[9] that ^{13}C-NMR chemical shifts are sensitive to conformational changes, and relatively less sensitive to perturbation such as solvent effect than proton chemical shifts are. Therefore, the ^{13}C-NMR spectra of compounds **1a**, **1b**, and their alkali thiocyanate complexes (**3a—c** and **4a—b**) were recorded using deuteriochloroform as solvent. These results are listed in Table 2. The changes of the chemical shifts of the complexes are also shown in Table 2 in parentheses. The carbon resonances of cyclopentadienyl ring were assigned according to the literature.[10] Methylene carbon resonances were not rigorously assigned. In the ^{13}C-NMR spectra of **1b** the bridgehead carbon, α- and β-carbons of the cyclo-

pentadienyl rings showed their resonances at 126.9, 56.4, and 61.9 ppm, respectively, together with methylene carbons at 71.3, 70.7, 70.3, and 70.0 ppm. However, the ^{13}C-NMR spectrum of lithium thiocyanate complex (**4a**) showed resonances at 125.0, 58.4 (C_α), and 63.0 (C_β) ppm, together with the resonances of methylene carbons at 71.1. 69.1, and 68.4 ppm. Contrary to the upfield shifts of the bridgehead carbon of cyclopentadienyl rings, the α- and β-carbon resonances were shifted downfield on the metal complexation. The methylene carbon resonances were also shifted upfield on complexation except for the one methylene carbon of **4a**. In particular, the bridgehead carbon, C_b and methylene carbons at 2- and 12-positions showed a remarkable shift.

However, the spectral changes were slight for the alkali metal complexes containing six oxygen atoms, **3**, compared with the shift changes of **4**. The large shifts of bridgehead, C_α and methylene carbons at 2- and 12-position may be attributed to a special conformational change in which two oxygen lobes point inward. The upfield shifts of the bridgehead and methylene carbons and the downfield shifts of C_α- and C_β- resonances are in fair agreement with the results of alkali metal thiocyanate complexes of benzo-crown ethers.[8]

Crystal Structure of 4b. The molecular conformation and the coordinative aspects of the complex **4b** and the numbering are shown in Fig 1. Bond lengths and bond angles are summarized in Table 4. The complex can be divided into two parts: the roughly planar complexing unit containing O(1) through O(5) and the ferrocene unit. In the complexing unit, the bonding from the sodium ion to the ligand is directed to the five oxygen atoms and nitrogen atom of counter anion. The Na^+-O(1), -O(2), -O(3), -O(4), and -O(5) bond lengths are 2,439(10), 2.449(9), 2.474(10), 2.396(9), and 2.631(9) Å, respectively. These distances are in fair agreement with the sum of the ionic radius of Na^+ (0.95 Å) and the van der Waals radius of an oxygen atom (1.4 Å). Similar distances have found in the sodium complexes of dibenzo-18-crown-6[11] and 18-crown-6.[12] The distance between Na^+ and a nitrogen atom of a thiocyanate anion is 2.541(12) Å, which is slightly longer than the sum of the ionic radius of Na^+ (0.95 Å) and the van der Waals radius of a nitrogen atom (1.5 Å). Such results suggest that the sodium cation is coordinated by five coplanar oxygen atoms and a nitrogen atom of a thiocyanate anion, to give a contact ion pair. The interatomic O-O distances between adjacent oxygen atoms (mean, 2.73 Å) are appropriately equal to the sum (2.80 Å) of the van der Waals radius of an oxygen atom. Thus, the neighboring oxygen atoms are in contact with each other. The distance between the iron atom of a ferrocene nucleus and the incorporated sodium cation is 4.129(5) Å: this value is too long compared with the sum of the van der Waals radius of the iron atom and ionic radius of a sodium cation (0.95 Å). The result suggests that the iron atom of the ferrocene unit does not take part directly in complex formation, although we can not rule out some very weak interactions between the iron atom and the incorporated sodium cation.

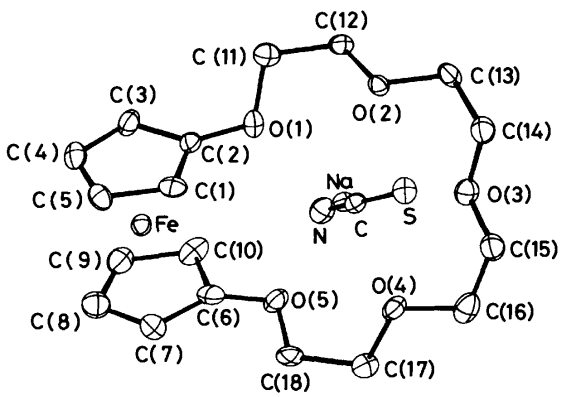

Fig. 1. Molecular structure of **4b** with atom numbering scheme.

Table 3. Fractional atomic coordinates ($\times 10^{-5}$), with estimated standard deviations in parentheses

a) Equivalent isotropic temperature factor as defined by W. C. Hamilton (*Acta Crystallogr.*, **12**, 609(1959)).

The C-C bond lengths of the cyclopentadienyl rings in the ferrocene unit were in the range of 1.410—1.444 Å in the A[C(1)-C(5)] ring and 1.409—1.465 Å in theB-[C(6)-C(10)] ring, with the average values of 1.432(48) Å and 1.437(47) Å, respectively. The valency angle in the A and B rings ranged over 107.0—110.3° and 104.2—111.2°, with the average values of 108.0(2)° and 108.0(2)°, respectively. The average length of the C-C bonds in the cyclopentadienyl rings is slightly longer than that found in ferrocene (1.40 Å)[13] but in good agreement with that of bridgehead ferrocenophanes.[14] The distance between the iron atom and the ring carbons ranged from 2.038 to 2.065 Å for the A ring and from 2.031 to 2.067 Å for the B ring; the average distance was 2.049 (30) Å for the A ring and 2.054(33) Å for the B ring. The perpendicular distances from the iron atom to the least square planes of the A and B rings, 1.647 and 1.651Å, respectively, are both slightly longer than that found in ferrocene itself but agree well with those of some bridged ferrocenophanes.[14]

TABLE 4. BOND LENGTHS AND ANGLES WITH ESTIMATED STANDARD DEVIATIONS IN PARENTHESES

Bond length	l/Å	Bond length	l/Å	Bond length	l/Å

It is well known[15] that the tilt angle between two cyclopentadienyl rings varies greatly with the number of bridging methylenes of the bridged ferrocenophanes. A deformation strain resulting from an interannular bridge shorter than four carbons in length can not be accomodated in the ferrocene nucleus without distortion of the prefered coplanar molecular geometry by the ring tilting. It is noteworthy that the cyclopentadienyl rings in the present complex (**4b**), containing thirteen atoms in an interannular bridge, deviates from planality, and its tilting angles are 3.30°. This may be because the crown ether part wrings the sodium cation. Finally it is also noteworthy that, although the nearest neighbor atoms between the intermolecules is C(11) and carbon atom of SCN^- and the distance (3.34(17) Å) is roughly equal to the sum of the appropriate van der Waals radii, the smallest distance in the host molecule is C(18) and O(5) and this distance (3.41(18) Å) is longer than the sum of the van der Waals radii. These results suggest that there is no strong interaction between the intermolecules.

Experimental

Polyoxa[n]ferrocenophanes (**1a** and **1b**) and their alkali metal complexes (**3a—c** and **4a, b**) were prepared by the procedures described previously.[5] ^{1}H-NMR spectra (90 MHz) and the ^{13}C-NMR spectra (22.5 MHz) were recorded in deuteriochloroform with tetramethylsilane as an internal standard on a JEOL-FX-90Q spectrometer.

X-Ray Crystallography. A crystal of dimensions 0.4×0.4×0.1 mm, obtained from hexane-chloroform, was used for the intensity measurements. Intensity data were obtained on a Rigaku four-circle automatic difractometer, equipped with graphite-monochromated Mo $K\alpha$ radiation, and using the θ-2θ scan technique ($2\theta \leq 60°$). 2539 independent reflections ($F_o \geq 3.0\sigma F_o$) were corrected for Lorentz and polarization factors but not for absorption. The crystal data are as follows: $C_{19}H_{14}O_5FeNSNa$, mol wt 457.3, orthorhombic, space group Cccn, a=20.579(4), b=25.622(8), c=7.606(1) Å, U=4010(2) Å^3, Z=8, D_c=1.48 g cm^{-3}. The structure was solved by the direct methods. The positional and thermal

parameters were refined by the block-diagonal least-squares methods. The final discrepancy index R is 0.10. The positional parameters for nonhydrogen atoms are listed in Table 3. Thermal parameters and observed and calculated structure factors are kept at the Chemical Society of Japan (Document No. 8352).

The authors wish to thank Professor Hayao Kobayashi, Department of Chemistry, Toho University, for the X-ray analyses.

Indole Syntheses Utilizing *o*-Methylphenyl Isocyanides

Yoshihiko Ito, Kazuhiro Kobayashi, Norihiko Seko, and Takeo Saegusa
Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received April 28, 1983)

New indole synthesis starting with *o*-methylphenyl isocyanides such as *o*-tolyl, 2,4-xylyl, and 2,6-xylyl isocyanide is described in full detail. Treatment of *o*-tolyl isocyanide with LDA in diglyme at −78 °C generated selectively *o*-(lithiomethyl)phenyl isocyanide in an almost quantitative yield, which on warming up to room temperature was cyclized to indole after aqueous workup. Similary, 2,4-xylyl and 2,6-xylyl isocyanides were cyclized to 5-methylindole and 7-methylindole quantitatively. The *o*-(lithiomethyl)phenyl isocyanides reacted with electrophiles such as alkyl halides and alkylene oxides to give *o*-alkylphenyl isocyanides, which were cyclized *via* the lithiation at the orthobenzylic carbon to afford 3-substituted indoles. On the other hand, the *o*-(lithiomethyl)phenyl isocyanides generated *in situ* at −78 °C was first warmed up to room temperature and then treated with electrophiles to furnish 1-substituted indoles. The *o*-(lithiomethyl)phenyl isocyanides were acylated in a fairly good yield with *N*-acylaziridines to give *o*-(acylmethyl)phenyl isocyanides, which were readily alkylated in the presence of sodium hydride to produce *o*-(1-acylalkyl)phenyl isocyanides. On acid hydrolysis followed by neutralization, *o*-(1-acylalkyl)phenyl isocyanides were converted to 2,3-disubstituted indoles.

Since Schöllkopf[1] discovered the lithiation of isocyanides at the α-carbon, isocyanides have been useful and versatile reagents in organic syntheses.[2] The carbon-carbon bond formation with the α-metalated isocyanides provides a new methodology for nucleophilic introduction of masked α-aminoalkyl groups because the resulting isocyanides are readily converted to primary amine derivatives by acid hydrolysis.

On the other hand, isocyanide functional group itself, which may be regarded formally as carbene, has reacted with various polar reagents in an α-addition manner.[3] Isocyanides, which have no α-hydrogen, react with organolithium to afford lithiated aldimines, which are able to be used as acyl anion equivalents.[4]

The reactions of electrophiles with α-metalated isocyanides coupled with intramolecular α-addition to isocyanide carbon lead to the formation of heterocycles. The heterocycle syntheses have permitted rapid and efficient preparation of a variety of heterocyclic ring systems, which are otherwise accessible with difficulty.

On the background of isocyanide chemistry mentioned above, we have attempted a selective lithiation at the ortho-methyl group of *o*-tolyl isocyanide with the expectation that the resulting *o*-(lithiomethyl)-phenyl isocyanide might be cyclized by the intramolecular α-addition. In the preliminary paper,[5] we reported a successful selective lithiation at the ortho-methyl group of *o*-tolyl isocyanide and its intramolecular cyclization leading to indole. This paper describes the full scope of syntheses of indole derivatives by elaboration of *o*-(lithiomethyl)phenyl isocyanides. The selective lithiation and nucleophilic elaboration of *o*-methylphenyl isocyanides such as *o*-tolyl isocyanide 2,4- and 2,6-xylyl isocyanides, which are readily prepared from commercially available toluidine derivatives, make the present indole syntheses more flexible. The indole syntheses have many advantages of simplicity, versatility and high yields over the reported synthetic methods.[6]

Selective Lithiation at the Benzylic Carbon of o-Alkylphenyl Isocyanides. Lithiation at the methyl group of *o*-tolyl isocyanide (**1a**) was achieved in an almost quantitative yield by treatment of **1a** with 2 equiv of lithium diisopropylamide (LDA) in diglyme at −78 °C. The deep-red *o*-(lithiomethyl)phenyl isocyanide (**2a**) thus generated was quenched at −78 °C with D_2O to yield *o*-tolyl isocyanide (>95% yield) with deuterium incorporation of >93%. The use of 2 equiv of LDA was required for the quantitative lithiation of **1a**. The silimar treatment of **1a** with 1 equiv of LDA followed by deuterolysis regenerated *o*-tolyl isocyanide (>95% yield) with deuterium incorporation of *ca.* 50%. The

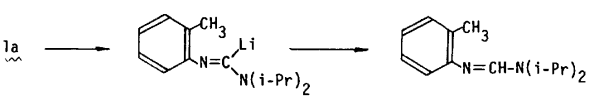
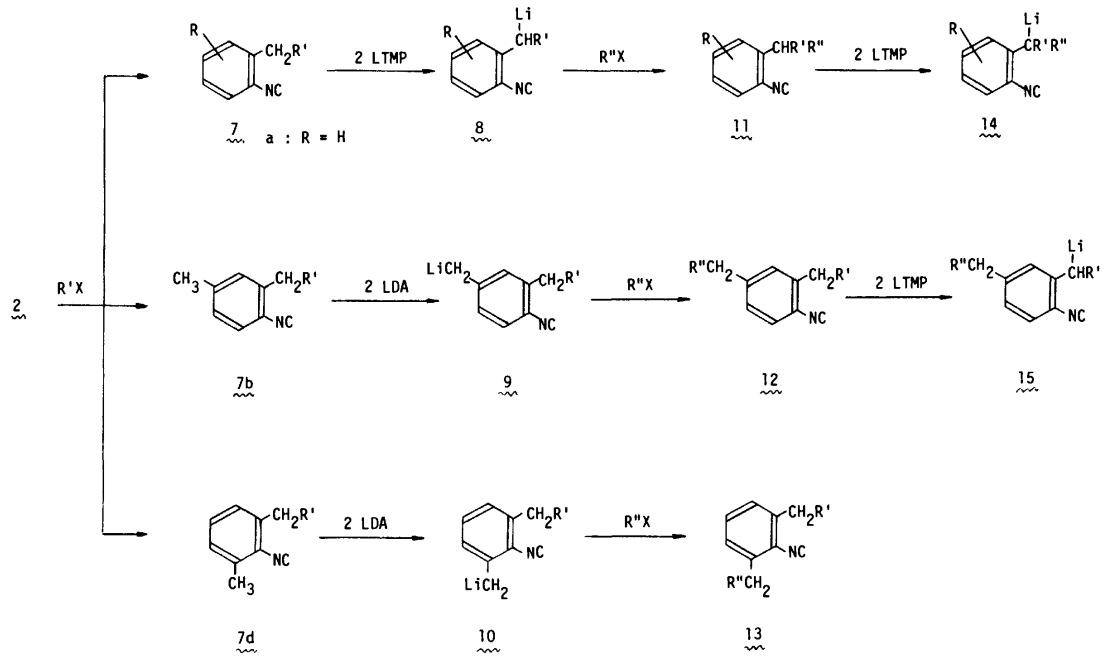
e : R = 4-MeO
f : R = 4-Cl

o-(lithiomethyl)phenyl isocyanide (**2a**) generated was stable at −78 °C under nitrogen in diglyme for several days. The selective lithiation of **1a** was solvent dependent. Use of monoglyme and heptane instead of diglyme gave **2a** but in somewhat decreased yields. In these solvents **2a** was slightly unstable and cyclized even at −78 °C within several hours, resulting in the formation of indole as mentioned later. The lithiation of **1a** in ether and THF solvents generated **2a** in a low yield, being substantially accompanied by an adduct (**3**) of LDA to the isocyano carbon of **1a**, of which hydrolysis furnished N^1,N^1-diisopropyl-N^2-(*o*-tolyl)formamidine (**4**). Similarly, the selective lithiation at the ortho-



3 4

methyl group of 2,4- (**1b**), 2,5- (**1c**), and 2,6-dimethylphenyl isocyanide (**1d**), 2-methyl-4-methoxyphenyl



Scheme 1.

isocyanide (**1e**), and 2-methyl-4-chlorophenyl isocyanide (**1f**) was performed with 2 equiv of LDA in diglyme at −78 °C. The selective lithiation at the ortho-methyl group of **1b** may suggest that the lithiation at the ortho-methyl group of *o*-methylphenyl isocyanide (**1**) is assisted to some extent by the neighboring isocyano function. But, the treatment of **1b** and **1d** with 4 equiv of LDA in diglyme at −78 °C generated the respective dianions (**5**) and (**6**). Lithiation at the

ortho-benzylic carbon of *o*-alkylphenyl isocyanides (**7**), which are readily prepared by alkylations of **2**, can be selectively achieved by means of 2 equiv of lithium 2,2,6,6-tetramethylpiperidide (LTMP). The benzylic lithiation of *o*-alkylphenyl isocyanides (**7**) with LDA was accompanied by an adduct of LDA onto the isocyano carbon of **7**. For instance, the treatment of *o*-pentylphenyl isocyanide (**7a-iii**) with LDA at −78 °C followed by warming up to room temperature produced, after aqueous workup, N^1, N^1-diisopropyl-N^2-(*o*-pentylphenyl)formamidine (60%) and 3-butylindole (30%), which is formed by the intramolecular cyclization of *o*-(α-lithiopentyl)phenyl isocyanide (**8a-iii**).

Noteworthy is that the lithiation of 2-alkyl-4-methylphenyl isocyanide (**7b**) and 2-alkyl-6-methylphenyl isocyanide (**7d**) with 2 equiv of LDA took place selectively at the 4-methyl and the 6-methyl groups, respectively, leading to 2,4-dialkylphenyl isocyanide (**12**) and 2,6-dialkylphenyl isocyanide (**13**) by alkylations (Scheme 1).

As expectedly, further lithiation of 2,4-dialkylphenyl isocyanides (**12**) with 2 equiv of LTMP occurred at the ortho-benzylic carbon with high selectivities.

Alkylations and Cyclizations of o-Alkylphenyl Isocyanides via the Selective Lithiation at the ortho-Benzylic Carbon. i) Syntheses of 3-Alkylindoles: *o*-(Lithiomethyl)phenyl isocyanide (**2a**), which is stable at −78 °C in diglyme, was cyclized on warming to give indole, after aqueous workup. Deep red characteristic of **2a** in diglyme at −78 °C gradually turned light brown as the temperature was raised up above −25 °C to room temperature. The light brown solution was quenched with H_2O at room temperature to produce indole in an almost quantitative yield. Similarly, the cyclizations of substituted *o*-methylphenyl isocyanides (**1b**—**f**) *via* the lithiation at the ortho-methyl group afforded indoles with substituents on the benzene ring in high yields.

The *o*-(lithiomethyl)phenyl isocyanides can be elaborated at −78 °C with electrophiles such as alkyl halides, aldehydes,[7] ketones,[7] epoxides, α, β-unsaturated carboxylic esters,[8] allyl carboxylates,[9] *N*-acylaziridines *etc.*, leading to a variety of *o*-substituted phenyl isocyanides. Some alkylations of *o*-(lithiomethyl)phenyl isocyanide (**2a**) including silylation and sulfenylation are summarized in Table 1.

The reactions of **2a** with alkyl halides are immedi-

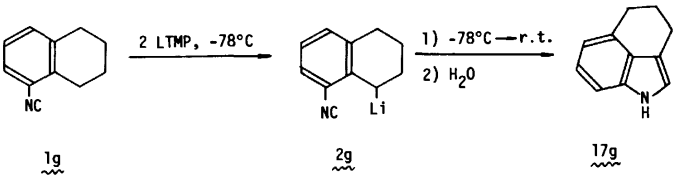
ately complete at −78 °C except for that **2a** reacted slowly with α-bromoacetaldehyde diethy acetal at −78 °C over 8—10 h. The reactions of **2a** with trimethylsilyl chloride and dimethyl disulfide permitted introductions of trimethylsilyl and methanesulfenyl groups on the methyl group of *o*-tolyl isocyanide (**1a**), both of which in turn are capable of stabilizing benzylic carbanion.

o-Alkylphenyl isocyanides (**7a-i**—**7a-iv** and **7a-vi**) thus prepared were cyclized to 3-substituted indoles in good yields by the selective lithiation at the ortho-benzylic carbon with 2 equiv of LTMP at −78 °C followed by raising the reaction temperature. Some syntheses of 3-alkylindoles (**17a**) are summarized in Table 1.

The cyclization of **7a-vi** presents a convenient synthesis of diethyl acetal (**17a-vi**) of indole-3-acetaldehyde, which is a metabolite from Helianthus Annuus. No cyclization of **7a-v** occurred on the similar treatment, because of the failure in the lithiation at the benzylic carbon with LTMP. Its cyclization was realized by successful lithiation at the ortho-benzylic carbon of **7a-v** with LTMP in the presence of HMPA. Cyclizations of **7a-vii** and **7a-viii**, of which the benzylic carbanions are stabilized by silicon and sulfur atoms, are readily accomplished *via* the lithiation with LDA.

All attempts to synthesize 3-alkylindoles (**17a**) in one-flask *via* alkylation and cyclization starting with *o*-methylphenyl isocyanide (**1a**) were, however, unsuccessful.

The present methodology also provides a convenient synthetic route to 1,3,4,5-tetrahydrobenz[*cd*]indole (**17g**), which constitutes the skeleton of ergot alkaloid, from 5,6,7,8-tetrahydro-1-naphthylamine *via* the lithiation of the corresponding isonitrile (**1g**) with LTMP as shown below.



The alkylation and cyclization using 2,4- and 2,6-dimethylphenyl isocyanides (**1b**) and (**1d**) make the present indole syntheses more applicable. 2,4-Dialkylphenyl isocyanides (**12**) were prepared *via* the stepwise selective lithiation (**2b** and **9**) or the direct lithiation (**5**) of **1b**, followed by alkylations. The 2,4-dialkylphenyl isocyanides (**12**) were cyclized *via* the selective lithiation at the ortho-benzylic carbon with 2 equiv of LTMP to 3,5-dialkylindoles (**18**) but in somewhat low yields.

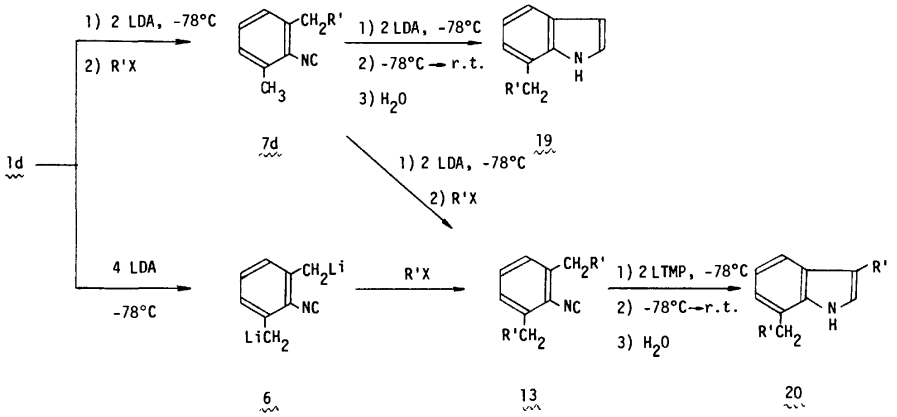
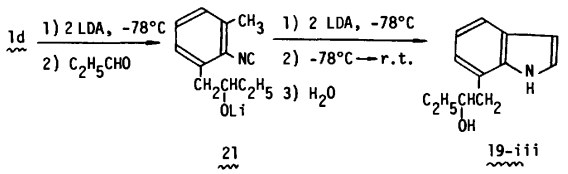


Scheme 2.

Similarly, mono- and dialkylations of 2,6-dimethylphenyl isocyanide (**1d**) were carried out *via* the stepwise selective lithiation (**2d** and **10**) or the direct lithiation (**6**). The monoalkylations of **1d** and subsequent cyclizations *via* the selective lithiation at the remaining methyl group provided a convenient synthesis of 7-alkylindoles (**19**) (Table 3).

2,6-Dialkylphenyl isocyanides (**13**) were also cyclized to 3,7-dialkylindoles (**20**) *via* the benzylic lithiation with LTMP (Table 3). But the cyclization of unsymmetrical 2,6-dialkylphenyl isocyanide was less significant from synthetic viewpoint, because of difficulty in the selective lithiation at either of two ortho-benzylic carbons. Another interesting elaboration of **1d** *via* **21** is illustrated in preparation of **19-iii**.



o-Alkylphenyl isocyanides **7a** were further alkylated by treatment with 2 equiv of lithium amide followed by addition of alkyl halides to afford *o*-(*s*-alkyl)phenyl isocyanides (**22**) in moderate to good yields (Table 4). Various attempts to cyclize *o*-(*s*-alkyl)phenyl isocyanides (**22**) to indolenine derivatives (**23**), however, failed, in spite of success of the benzylic lithiation.[10]

Table 4. Alkylations of **7a**[a]

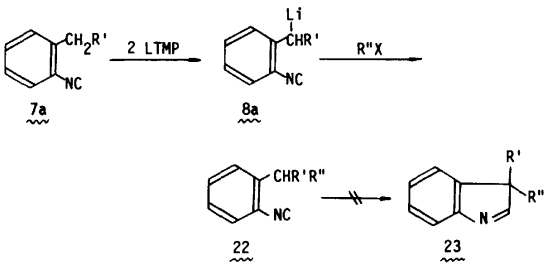
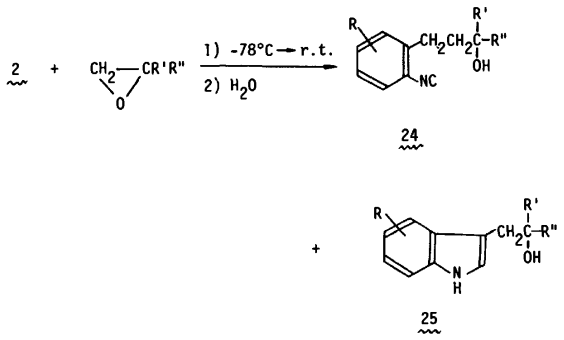
a) LTMP was used for the ortho-benzylic lithiation of **7a** unless otherwise noted. b) LDA was used for the ortho-benzylic lithiation.



ii) One-flask Synthesis of Tryptophol Derivatives: The carbon-carbon bond formation of *o*-(lithiomethyl)-phenyl isocyanides (**2**) with alkylene oxide and subsequent cyclization of the resultant *o*-(3-hydroxyalkyl)-phenyl isocyanide (**24**) *via* the ortho-benzylic lithiation provided a rapid synthetic route to tryptophol derivatives.

Unlike the synthesis of 3-alkylindoles by the alkylation and cyclization of **1** as mentioned above, the synthesis of tryptophol derivatives starting with *o*-methylphenyl isocyanides (**1**) was accomplished in one-flask without isolation of any intermediates. In the reaction of **2a** generated *in situ* from **la** and 2 equiv of LDA at −78 °C in diglyme with 2 equiv molar of alkylene oxide for 2 h, *o*-(3-hydroxyalkyl)phenyl isocyanide (**24**) was produced together with tryptophol derivatives (**25**) as a minor product, after aqueous workup at room temperature. The formation of **25** suggested



that lithium alkoxide of **24** initially formed from **2** and alkylene oxide underwent the ortho-benzylic lithiation with LDA during the reaction. Expectedly, *o*-(3-hydroxyalkyl)phenyl isocyanide (**24**) once isolated was converted to tryptophol derivative *via* the ortho-benzylic lithiation by 3 equiv of LDA. In this case, use of LTMP was not necessary. On the basis of these observations, one-flask synthesis of tryptophol derivatives was realized as follows. To the mixture of **1** and 2 equiv of LDA, which had been stirred at −78°C for 3 h, another 2 equiv of LDA was added at the same temperature and stirred for 2 h. The reaction mixture was warmed up to room temperature and quenched with water to furnish tryptophol derivative (**25**) in moderate yields. With unsymmetrical alkylene oxides, isomeric tryptophol derivatives, which may be derived by nucleophilic attack of **2** at the more substituted site of alkylene oxides, was produced in negligible yields as a by-product as judged by NMR analysis. Some syntheses of tryptophol derivatives starting with **1** are summarized in Table 5.

The tryptophol syntheses with 2,4- and 2,6-dimethylphenyl isocyanide (**1b**) and(**1d**) were accompanied by side reactions, which were caused from the lithiation at 4-methyl and 6-methyl of 2-(3-hydroxyalkyl)-4-methylphenyl isocyanide and 2-(3-hydroxyalkyl)-6-methylphenyl isocyanide. Accordingly, 2,4-bis(3-hydroxyalkyl)phenyl isocyanide (**26b**) and 7-(3-hydroxyalkyl)-indole (**27d**) were isolated with the desired tryptophol derivatives (**25b**) and (**25d**), respectively.

Table 5. One-flask synthesis of tryptophol derivatives (**25**)

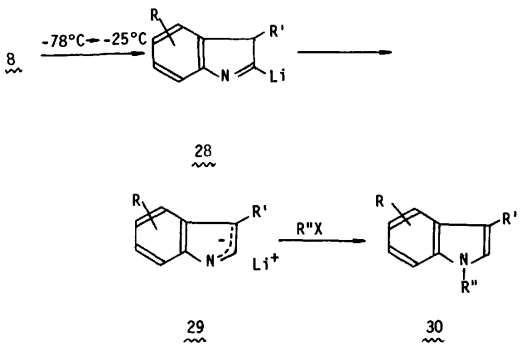
iii) Syntheses of 1-Alkylinodoles: The present indole synthesis presents an interesting example of a "5-*endo*-digonal" ring closure as classified by Baldwin,[11] in which the benzylic carbanion **8**, adds intramolecularly to the adjacent isocyano carbon, resulting in the formation of lithiated aldimine derivative (**28**). Attempts to



trap the lithiated aldimine **28** with electrophiles which could provide an entry to 2-substituted indoles, were, however, unsuccessful. When **8** generated *in situ* in diglyme at −78 °C was allowed to warm up to −25 °C, the characteristic color of **8** (R=H: deep red; R=alkyl: purple) gradually changed to light brown. The solution at −25 °C was treated with electrophiles such as alkyl halides, alkylene oxides, *etc.*, to afford the corresponding 1-substituted indoles (**30**) in good yields

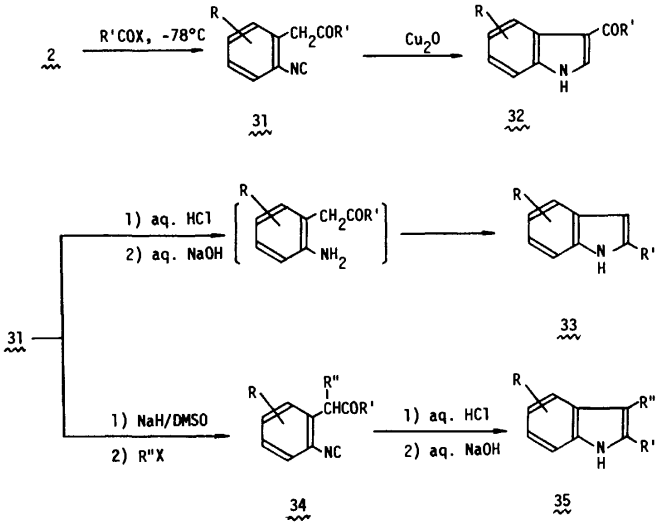
a) Ref. 9. b) The corresponding N-acylaziridine was used. c) Ethyl 4-chlorobutyrate was used. d) γ-Butyrolactone was also used.

(Table 6). The observation indicates that the lithiated aldimine **28** was rapidly converted to **29** even at −25 °C. Consequently, this procedure provided a convenient synthetic method of 1-substituted indoles starting with o-methylphenyl isocyanides (**1**).

Acylations and Cyclizations of o-Methylphenyl Isocyanides. Syntheses of 2,3-Disubstituted Indoles: Unlike the alkoxycarbonylation[4] of **2** with chloroformate, acylation of **2** was not successful with acyl halides. Carboxylic esters were conveniently employed for the acylations of **2** to afford o-(acylmethyl)-phenyl isocyanides (**31**). Allyl carboxylates gave better yields, but alkyl carboxylates including γ-butyrolactone were also usable. High-yielding acylations of **2** were accomplished with N-acylaziridines, as listed in Table 7.

As already reported,[9] 2-(acylmethyl)phenyl isocyanides (**31**) thus prepared were useful synthetic intermediates, which were cyclized to 3-acylindoles (**32**) by a Cu_2O catalyst and to 2-alkylindoles (**33**) on acid hydrolysis followed by neutralization. Usefulness of



31 was further demonstrated by cyclization coupled with alkylation of **31**, producing 2,3-disubstituted indoles (**35**). Alkylations of **31** having an active methylene group were conducted more easily by means of NaH, producing 2-(1-acylalkyl)phenyl isocyanides (**34**). (Table 8) The isocyanides **34** prepared were unexpectedly not cyclized by Cu_2O catalyst.[9] Moreover, **34-i** was treated with NaH at −78 °C followed by warming up to room temperature to give 3-methylindole and 1-acetyl-3-methylindole in good yield. But, **34** was cleanly converted to 2,3-disubstituted indole (Table 8) in good yield on treatment with aqueous HCl. This reaction presents an expedient and versatile preparative method of 2,3-disubstituted indoles.

Experimental

Measurements. The ^1H NMR spectra were recorded in $CDCl_3$ with tetramethylsilane as an internal standard, unless otherwise stated. The IR spectra were measured of neat samples, unless otherwise stated. Thin layer chromatography was performed using Merck Silica Gel 60 GF_{254}.

Materials. All solvents were dried over drying agents and distilled under nitrogen. Butyllithium (1.6 M† solution in hexane) was purchased from aldrich Inc. Alkyl halides and alkylene oxides were all purified by distillation under nitrogen. Starting o-methylphenyl isocyanides (**1a—f**) were prepared according to the Ugi's procedure[12] or the modified procedure (*vide infra*) from the corresponding formamides, which were prepared by formylation of commercially available o-toluidines with formic acid or acetic formic anhydrid.[13]

5-Isocyano-1,2,3,4-tetrahydronaphthalene (1g). To a solution of 6.0 g (34 mmol) of 5-formamido-1,2,3,4-tetra-

a) Isolated yield based on **31**. b) Isolated yield based on **34**.

hydronaphthalene, which was prepared from 5,6,7,8-tetrahydro-1-naphthylamine[14] and formic acid, and 14 mL of triethylamine in 40 mL of THF, was added dropwise 5.2 g (34 mmol) of phosphoryl chloride at 0 °C. After stirring at the same temperature for 30 min, the mixture was stirred for additional 30 min at room temperature, and poured into diluted aq $NaHCO_3$, extracted with ether and washed with water. The extract was dried over KOH pellet, filtered and evaporated. The residue was distilled to afford 4.7 g (88%) of 5-isocyano-1,2,3,4-tetrahydronaphthalene (**1g**), bp 86—87 °C (0.4 mmHg[††]). **1g**: IR 2110 cm^{-1}; NMR δ=1.55—2.10 (m, 4H), 2.46—3.10 (m, 4H), 6.75—7.30 (m, 3H). Found: C, 83.90; H, 7.21; N, 9.11%. Calcd for $C_{11}H_{11}N$: C, 84.04; H, 7.05; N, 8.91%.

*5-Methylindole (**16b**).* *General Procedure*: To a solution of 304 mg (3 mmol) of diisopropylamine in 4 mL of diglyme was added dropwise 3 mmol of butyllithium (1.6 M solution in hexane) at −78 °C, and stirred for 15 min at the same temperature. To the mixture, 197 mg (1.5 mmol) of 2,4-xylyl isocyanide (**1b**) was added and stirred for 30 min at −78 °C. The resultant red solution was allowed to warm up to room temperature, and quenched with aq NH_4Cl. The mixture was extracted with ether, washed with water three times and dried over anhydrous Na_2SO_4. After the ether extract was evaporated, the residual solid was recrystallized from hexane to furnish 5-methylindole in an almost quantitative yield, mp 57 °C (lit,[6d] 55.0—56.5 °C). IR (KBr disk) 3400 cm^{-1}; NMR(CCl_4 with Me_4Si) δ=2.36 (s, 3H), 6.22 (m, 1H), 6.61 (m, 1H), 6.83 (br s, 2H), 7.0 (br s, 1H), 7.22 (br s, 1H).

Indole (**16a**),[15a] 6-methylindole (**16c**),[16] 7-methylindole (**16d**),[15b] 5-methoxyindole (**16e**),[15c] and 5-chloroindole (**16f**)[15d] were synthesized according to the above procedure, and purified by recrystallization from hexane except for **16c** which was distilled, bp 60 °C (0.2 mmHg) [lit,[16] 148—155 °C (20 mmHg)]. Identities of **16a—f** were established by comparison of their spectral data with those reported. **16c**: IR 3400 cm^{-1}; NMR(CCl_4 with Me_4Si) δ=2.42 (s, 3H), 6.31 (m, 1H), 6.7—7.5 (m, 5H).

*o-Ethylphenyl Isocyanide (**7a-i**).* *General Procedure for Alkylations of o-Tolyl Isocyanide (**1a**)*: To a stirring solution of 3 mmol of LDA in 4 mL of diglyme at −78 °C was added dropwise 176 mg (1.5 mmol) of *o*-tolyl isocyanide (**1a**). After 30 min, 426 mg (3 mmol) of methyl iodide was added dropwise. The characteristic red color of *o*-(lithiomethyl)-phenyl isocyanide (**2a**) disappeared immediately. The reaction mixture was quenched with aq NH_4Cl at −78 °C, extracted with ether, washed with water three times and dried over anhydrous Na_2SO_4. The ether extract was evaporated and distilled using Kugelrohr apparatus to afford *o*-ethylphenyl isocyanide (**7a-i**) [bp 85 °C (10 mmHg)] in 95% yield. **7a-i**: IR 2115 cm^{-1}; NMR δ=1.28 (t, 3H), 2.77 (q, 2H), 7.20 (s, 4H). Found: C, 82.62; H, 7.09; N, 10.85%. Calcd for C_9H_9N: C, 82.40; H, 6.92; N, 10.68%. *o*-Alkylphenyl isocyanides (**7a-ii**)—(**7a-viii**) were prepared according to the above procedure.

*3-Methylindole (**17a-i**). General Procedure for Preparation of 3-Alkylindoles*: To a solution of 424 mg (3 mmol) of 2,2,6,6-tetramethylpiperidine in 4 mL of diglyme was added dropwise 3 mmol of butyllithium (1.6 M solution in hexane) at −78 °C, and stirred for 15 min at the same temperature. To the mixture, 197 mg (1.5 mmol) of *o*-ethylphenyl isocyanide (**7a-i**) was added and stirred for 30 min at −78 °C. The purple solution was then allowed to warm up to room temperature and quenched with aq NH_4Cl. The mixture was worked up in the same way mentioned for the preparation of **16b**. 3-Methylindole (**17a-i**) was recrystallized from hexane (95% yield) and identified by comparison of spectral data[15e] with those of the authentic sample.

3-Alkylindoles (**17a-ii**)—(**17a-vi**) and (**17g**) were prepared from the corresponding **7** according to the above procedure.

*3-Allylindole (**17a-ii**)*:[17] TLC(Silica gel, $CHCl_3$) R_f=0.79.

*3-Butylindole (**17a-viii**)*:[18] [Bp 130 °C (1 mmHg)]: IR 3400 cm^{-1}; NMR δ=0.93 (t, 3H), 1.1—1.8 (m, 4H), 2.72 (t, 2H), 6.9—7.6 (m, 5H), 7.9 (br 1H).

*3-Isobutylindole (**17a-iv**)*: [Mp 32 °C recrystallization from hexane (lit,[19] 31—32 °C)]: IR 3400 cm^{-1}; NMR(CCl_4 with Me_4Si) δ=0.96 (d, 6H), 1.96 (m, 1H), 2.61 (d, 2H), 6.86 (m, 1H), 7.0—7.3 (m, 3H), 7.5—7.7 (m, 1H), 7.9 (br 1H).

*Indole-3-acetaldehyde Diethyl Acetal (**17a-vi**)*: [Bp 140 °C (0.4 mmHg)]: IR 3400 cm^{-1}; NMR(CCl_4 with Me_4Si) δ= 1.09 (t, 6H), 2.90 (d, 2H), 3.39 (m, 4H), 4.63 (t, 1H), 6.7—6.9 (m, 4H), 7.2—7.5 (m, 1H), 8.0—8.2 (br 1H). Found: C, 72.33; H, 8.11; N, 6.23%. Calcd for $C_{14}H_{19}NO_2$: C, 72.07; H, 8.21; N, 6.00%.

*1,3,4,5-Tetrahydrobenz[cd]indole (**17g**)*: [Mp 53—54 °C, recrystallization from hexane (lit,[20] 50—52 °C)]: IR 3410 cm^{-1}; NMR δ=1.75 (m, 2H), 2.63—3.10 (m, 4H), 6.55—7.15 (m, 4H), 7.38—8.05 (br 1H).

*3-Isopropylindole (**17a-v**)*: To a solution of 3 mmol of LTMP in 4 mL of diglyme at −78 °C, 3 mL of hexamethylphosphoric triamide (HMPA) was added, and then 239 mg (1.5 mmol) of **17a-v** was dropwise added. After the mixture was stirred at −78 °C for 30 min, it was allowed to warm up to room temperature and quenched with aq NH_4Cl. 3-Isopropylindole (**17a-v**)[17] was isolated by preparative TLC [TLC(Silica gel, C_6H_6) R_f=0.85].

*3-Trimethylsilylindole (**17a-vii**)*: [Bp 104 °C (0.2 mmHg)] was prepared from **7a-vii** according to the procedure for the preparation of 3-methylindole (**17a-i**) except for that LDA was used in place of LTMP. IR 3410, 1252, 847 cm^{-1}; NMR (CCl_4 with Me_4Si) δ=−0.04 (s, 9H), 6.37 (m, 1H), 6.8—7.2 (m, 3H), 7.3—7.7 (m, 2H). Found: C, 69.54; H, 7.76; N, 7.18%. Calcd for $C_{11}H_{15}NSi$: C, 69.78; H, 7.99; N, 7.40%.

*3-(Methylthio)indole (**17a-viii**)*: [Bp 120 °C (0.1 mmHg)] [lit,[6d] bp 112—113 °C (0.15 mmHg)] was prepared from **7a-viii** according to the procedure for the preparation of **17a-vii**.

*2-Ethyl-4-methylphenyl Isocyanide (**7b-i**). General Procedure for Selective Alkylations at the ortho-Methyl Group of 2,4-Dimethylphenyl Isocyanide (**1b**)*: To a solution of 3 mmol of LDA in 4 mL of diglyme at −78 °C was added 197 mg of 2,4-dimethylphenyl isocyanide (**1b**). After 30 min, 426 mg (3 mmol) of methyl iodide was added to the mixture at −78 °C. The reaction mixture was worked up in the usual way and distilled to afford 2-ethyl-4-methylphenyl isocyanide (**7b-i**) [bp 70 °C (1 mmHg)] in 93% yield. IR 2125 cm^{-1}; NMR(CCl_4 with Me_4Si) δ=1.26 (t, 3H), 2.32 (s, 3H), 2.69 (q, 2H), 6.8—7.2 (m, 3H). Found: C, 82.66; H, 7.85; N, 9.88%. Calcd for $C_{10}H_{11}N$: C, 82.72; H, 7.64; N, 9.65%.

2-Alkyl-4-methylphenyl Isocyanide (**7b-ii**) and (**7b-iii**) were prepared according to the above procedure.

*2-Pentyl-4-methylphenyl Isocyanide (**7b-ii**)*: [Bp 80 °C (1 mmHg)]: IR 2120 cm^{-1}; NMR (CCl_4 with Me_4Si) δ=1.88 (t, 3H), 1.2—1.6 (m, 6H), 2.30 (s, 3H), 2.63 (t, 2H), 6.8—7.2 (m, 3H). Found: C, 83.51; H, 9.29; N, 7.62%. Calcd for $C_{13}H_{17}N$: C, 83.37; H, 9.15; N, 7.48%.

*2-(3-Butenyl)-4-methylphenyl Isocyanide (**7b-iii**)*: [Bp 54 °C (0.6 mmHg)]: IR 2115, 1638 cm^{-1}; NMR (CCl_4 with Me_4Si) δ=2.37 (s, 3H), 2.44 (m, 2H), 2.88 (m, 2H), 4.8—5.2 (m, 2H), 5.5—6.1 (m, 1H), 6.8—7.2 (m, 3H). Found: C, 84.36; H, 7.89; N, 8.00%. Calcd for $C_{12}H_{13}N$: C, 84.17; H, 7.65; N, 8.18%.

*2,4-Diethylphenyl Isocyanide (**12-i**). General Procedure for Selective Alkylations at the 4-Methyl Group of 2-Alkyl-4-methylphenyl Isocyanide (**7b**)*: To a solution of 3 mmol of LDA in 4 mL diglyme at −78 °C was added 218 m (1.5 mmol) of 2-ethyl-4-methylphenyl isocyanide (**7b-i**) and stirred for 30 min at the same temperature. To the red colored mixture, 426 mg (3 mmol) of methyl iodide was added. The usual work-up of the reaction mixture afforded 2,4-diethylphenyl isocyanide (**12-i**) [bp 57 °C (0.5 mmHg)] in 84% yield. IR 2120 cm^{-1}; NMR (CCl_4 with Me_4Si) δ= 1.20 (t, 3H), 1.28 (t, 3H), 2.56 (q, 2H), 2.68 (q, 2H), 6.8—7.2 (m, 3H). Found: C, 82.78; H, 8.43; N, 9.03%. Calcd for $C_{11}H_{13}N$: C, 82.97; H, 8.23; N, 8.80%.

Similarly, 2,4-dialkylphenyl isocyanides (**12-ii**), (**12-iii**), and (**12-iv**) were prepared by alkylations of **7b**

*2,4-Dipentylphenyl Isocyanide (**12-ii**)*: [Bp 120 °C (0.4 mmHg)]: IR 2120 cm^{-1}; NMR (CCl_4 with Me_4Si) δ=0.88 (t, 6H), 1.1—1.8 (m, 12H), 2.3—2.8 (m, 4H), 6.8—7.2 (m, 3H). Found: C, 83.69; H, 10.49; N, 5.95%. Calcd for $C_{17}H_{25}N$: C, 83.89; H, 10.35; N, 5.76%.

*2-Pentyl-4-(3-butenyl)phenyl Isocyanide (**12-iii**)*: [Bp 116 °C (0.4 mmHg)]: IR 2120, 1640 cm^{-1}; NMR (CCl_4 with Me_4Si) δ=0.92 (t, 3H), 1.2—1.6 (m, 6H), 2.1—2.8 (m, 6H), 4.7—5.0 (m, 2H), 5.3—5.8 (m, 1H), 6.7—7.2 (m, 3H). Found: C, 84.30; H, 9.08; N, 6.09%. Calcd for $C_{16}H_{21}N$: C, 84.53; H, 9.31; N, 6.16%.

*2-(3-Butenyl)-4-isobutylphenyl Isocyanide (**12-iv**)*: [Bp 115 °C (0.6 mmHg)]: IR 2120, 1638 cm^{-1}; NMR(CCl_4 with M_4eSi) δ=0.93 (d 6H), 1.85 (m, 1H), 2.2—2.8 (m, 6H), 4.8—5.1 (m, 2H), 5.4—5.9 (m, 1H), 6.8—7.2 (m, 3H). Found: C, 84.75; H, 8.70; N, 6.34%. Calcd for $C_{15}H_{19}N$: C, 84.45; H, 8.98; N, 6.57%.

*2,4-Diethylphenyl Isocyanide (**12-i**). General Procedure for Direct Dialkylations of 2,4-Dimethylphenyl Isocyanide (**1b**)*: To a solution of 6 mmol of LDA in 8 mL of diglyme at −78 °C was added 197 mg (1.5 mmol) of 2,4-dimethylphenyl isocyanide (**1b**) and stirred for 30 min at the same temperature. To the red solution was added 852 mg (6 mmol) of methyl iodide and worked up in the usual way. 2,4-Diethylphenyl isocyanide (**12-i**) was obtained in 64% yield.

*3-Methyl-5-ethylindole (**18-i**). General Procedure for Preparations of 3,5-Dialkylindoles (**18**)*: To a solution of 3 mmol of LTMP in 4 mL of diglyme at −78 °C was added dropwise 239 mg (1.5 mmol) of 2,4-diethylphenyl isocyanide (**12-i**), and stirred for 30 min at the same temperature. The reaction mixture was allowed to warm up to room temperature and quenched with aq NH_4Cl. After the usual work-up, 3-methyl-5-ethylindole (**18-i**) was isolated in 39% yield by preparative TLC [TLC (Silica gel, $CHCl_3$) R_f=0.63]. IR 3400 cm^{-1}; NMR (CCl_4 with Me_4Si) δ=1.27 (t, 3H), 2.25 (d,

3H), 2.69 (q, 2H), 6.62 (m, 1H), 6.85 (m, 2H), 7.16 (m, 1H), 7.8 (br 1H). Found: C, 83.01; H, 8.11; N, 8.99%. Calcd for $C_{11}H_{13}N$: C, 82.97; H, 8.23; N, 8.80%.

2,4-Dialkylindoles (**18-ii**)—(**18-iv**) were prepared according to the above procedure.

*3-Butyl-5-pentylindole (**18-ii**)*: [TLC (Silica gel, $CHCl_3$) R_f=0.84]: IR 3400 cm^{-1}; NMR δ=0.88 (t, 3H), 0.90 (t, 3H), 1.2—1.8 (m, 10H), 2.67 (t, 4H), 6.80 (m, 1H), 7.00 (m, 1H), 7.08 (m, 1H), 7.28 (m, 1H), 7.6 (br, 1H). Found: C, 83.78 H, 10.08; N, 5.49%. Calcd for $C_{17}H_{25}N$: C, 83.89; H, 10.35; N, 5.76%.

*3-Butyl-5-(3-butenyl)indole (**18-iii**)*: [TLC (Silica gel, C_6H_6-hexane (1:1)) R_f=0.65] IR 3400, 1638cm^{-1}; NMR δ=0.96 (t, 3H), 1.2—1.6 (m, 4H), 2.19 (m, 2H), 2.67 (m, 4H), 4.8—5.1 (m, 2H), 5.4—6.0 (m, 1H), 6.84 (m, 1H), 6.96 (m, 1H), 7.09 (m, 1H), 7.30 (m, 1H), 7.7 (br, 1H). Found: C, 84.82; H, 9.17; N, 6.00%. Calcd for $C_{16}H_{21}N$: C, 84.53; H, 9.31; N, 6.16%.

*3-Allyl-5-isobutylindole (**18-iv**)*: [TLC (Silica gel, $CHCl_3$) R_f= 0.82]: IR 3400, 1636 cm^{-1}; NMR (CCl_4 with Me_4Si) δ=0.85 (d, 6H), 1.85 (m, 1H), 2.45 (d, 2H), 3.34 (d, 2H), 4.8—5.1 (m, 2H), 5.6—6.1 (m, 1H), 6.54 (m, 1H), 6.79 (m, 2H), 7.09 (m, 1H), 7.3 (br, 1H). Found: C, 84.30; H, 8.72; N, 6.44%. Calcd for $C_{15}H_{19}N$: C, 84.45; H, 8.98; N, 6.57%.

*2-Methyl-6-pentylphenyl Isocyanide (**7d-i**). General Procedure for Monoalkylations of 2,6-Dimethylphenyl Isocyannide (**1d**)*: To a solution of 2.5 mmol[21] of LDA in 4 mL of diglyme at −78 °C was added dropwise 197 mg (1.5 mmol) of 2,6-dimethylphenyl isocyamide (**1d**) in 1 mL of diglyme and stirred for 30 min at the same temperature. 343 mg (2.5 mmol) of butyl bromide was added to the mixture, and then worked up in the usual way and distilled to give 2-methyl-6-pentylphenyl isocyanide (**7d-i**) [bp 95 °C (0.6 mmHg)] in 87% yield. IR 2110 cm^{-1}; NMR (CCl_4 with Me_4Si) δ=0.93 (t, 3H), 1.2—1.6 (m, 6H), 2.38 (s, 3H), 2.64 (m, 2H), 6.94 (m, 3H). Found: C, 83.11; H, 8.95; N, 7.32%. Calcd for $C_{13}H_{17}$-N: C, 83.37; H, 9.15; N, 7.48%.

2-Methyl-6-isobutylphenyl isocyanide (**7d-ii**) was prepared according to the above procedure. **7d-ii** [bp 62 °C (0.4 mmHg)] : IR 2110 cm^{-1}; NMR (CCl_4 with Me_4Si) δ=0.92 (d, 6H), 1.92 (m, 1H), 2.35 (s, 3H), 2.53 (d, 2H), 6.94 (m, 3H). Found: C, 83.09; H, 8.51; N, 7.85%. Calcd for $C_{12}H_{15}N$: C, 83.19; H, 8.73; N, 8.09%.

*2,6-Dipentylphenyl Isocyanide (**13-i**). General Procedure for Selective Alkylation at the 2-Methyl Group of 2-Methyl-6-alkylphenyl Isocyanide (**7d**)*: To a solution of 3 mmol of LDA in 4 mL of diglyme at −78 °C, 281 mg (1.5 mmol) of 2-methyl-6-pentylphenyl isocyanide (**7d-i**) was added dropwise, and stirred for 30 min at the same temperature. To the mixture, 411 mg (3 mmol) of butyl bromide was added then worked up in the usual way. 2,6-Dipentylphenyl isocyanide (**13-i**) [bp 112 °C (0.6 mmHg)] was distilled in 80% yield. IR 2110 cm^{-1}; NMR (CCl_4 with Me_4Si) δ=0.92 (t, 6H), 1.2—1.7 (m, 12H), 2.63 (m, 4H), 6.94 (m, 3H). Found: C, 83.74; H, 10.01; N, 5.48%. Calcd for $C_{17}H_{25}N$: C, 83.89; H, 10.35; N, 5.76%.

*2,6-Diethylphenyl Isocyanide (**13-ii**). General Procedure for Direct Dialkylations of 2,6-Dimethylphenyl Isocyanide (**1d**)*: To a solution of 6 mmol of LDA in 8 mL of diglyme at −78 °C was added 197 mg (1.5 mmol) of **1d** and stirred for 30 min at the same temperature. To the red colored solution of the dianion **6**, 852 mg (6 mmol) of methyl iodide was added, and worked up in the usual way. 2,6-Diethylphenyl isocyanide (**13-ii**) [bp 55 °C (0.4 mmHg)] was distilled in 75% yield. IR 2115 cm^{-1}; NMR (CCl_4 with Me_4Si) δ=1.27 (t, 6H), 2.70 (q, 4H), 6.99 (m, 3H). Found: C, 82.81; H, 8.01; N, 8.57%. Calcd for $C_{11}H_{13}N$: C, 82.97; H, 8.23; N, 8.80%.

2,6-Dipentylphenyl isocyanide (**13-i**) was prepared in 60% yield by the procedure for direct dialkylations.

*7-Pentylindole (**19-i**). General Procedure for Preparations of 7-Alkylindoles (**19**)*: To a solution of 3 mmol of LDA in 4 mL of diglyme at −78 °C was added 281 mg (1.5 mmol) of 2-methyl-6-pentylphenyl isocyanide (**7d-i**) and stirred for 30 min at the same temperature. The mixture was allowed to warm up to room temperature, quenched with aq NH_4Cl, and worked up in the usual way. 7-Pentylindole [TLC (Silica gel, $CHCl_3$) R_f=0.59] was isolated in 66% yield by preparative TLC. IR 3410 cm^{-1}; NMR (CCl_4 with Me_4Si) δ=0.85 (t, 3H), 1.1—1.7 (m, 6H), 2.52 (t, 2H), 6.25 (dd, 1H), 6.6—7.3 (m, 4H), 7.4 (br, 1H). Found: C, 83.55; H, 9.31; N, 7.35%. Calcd for $C_{13}H_{17}N$: C, 83.37; H, 9.15; N, 7.48%.

7-Isobutylindole (**19-ii**)[22] was similarly prepared and isolated by preparative TLC [TLC (Silica gel, $CHCl_3$) R_f= 0.68]. IR 3410 cm; NMR δ=0.98 (d, 6H), 2.03 (m, 1H), 2.64 (d, 2H), 6.42 (dd, 1H), 6.7—7.1 (m, 3H), 7.40 (m, 1H), 7.9 (br, 1H).

*3-Methyl-7-ethylindole (**20-ii**). General Procedure for Preparations of 3,7-Dialkylindoles (**20**)*: To a solution of 3 mmol of LTMP in 4 mL of digylme at −78 °C was added 239 mg (1.5 mmol) of 2,6-diethylphenyl isocyanide (**13-ii**) and stirred for 30 min at the same temperature. The purple solution was allowed to warm up to room temperature, and stirred for 30 min at room temperature. After the mixture was quenched with aq NH_4Cl, it was worked up in the usual way. 3-Methyl-7-ethylindole [bp 90 °C (0.6 mmHg)] was distilled in 63% yield. IR 3400 cm^{-1}; NMR δ=1.31 (t, 3H), 2.32 (d, 3H), 2.68 (q, 2H), 6.39 (q, 1H), 6.7—7.4 (m, 3H), 7.5 (br, 1H). Found: C, 82.77; H, 8.05; N, 8.95%. Calcd for $C_{11}H_{13}N$: C, 82.97; H, 8.23; N, 8.80%.

3-Butyl-7-pentylindole (**20-i**) was similarly prepared and isolated by preparative TLC [TLC (Silica gel, C_6H_6) R_f= 0.79]: IR 3400 cm^{-1}; NMR δ=0.91 (t, 3H), 0.96 (t, 3H), 1.2—1.7 (m, 10H), 2.76 (m, 4H), 6.50 (m, 1H), 6.8—7.5 (m, 3H), 7.6 (br, 1H). Found: C, 83.59; H, 10.30; N, 5.49%. Calcd for $C_{17}H_{25}N$: C, 83.89 ; H, 10.35; N, 5.76%.

*α-Ethylindole-7-ethanol (**19-iii**)*: To a solution of 3 mmol of LDA in 4 mL of diglyme at −78 °C, 197 mg (1.5 mmol) of 2,6-dimethylphenyl isocyanide (**1d**) was added and stirred at the same temperature for 30 min. To the red solution, 174 mg (3 mmol) of propionaldehyde was added at −78 °C. The red color of **2d** turned light yellow soon. Next, a solution of 3 mmol of LDA in 4 mL at −78 °C was added to the light yellow solution, and stirred for 30 min at −78 °C. The reaction mixture, which became red again, was allowed to warm up to room temperature and quenched with aq NH_4Cl. The usual work-up afforded α-ethylindole-7-ethanol in 57% yield [TLC (Silica gel, $CHCl_3$-AcOEt (1:4)) R_f= 0.36]: IR 3400, 3300 cm^{-1}; NMR (CCl_4 with Me_4Si) δ= 0.94 (t, 3H), 1.39 (m, 2H), 2.5 (br, 1H), 2.77 (d, 2H), 3.54 (m, 1H), 6.25 (m, 1H), 6.6—6.9 (m, 3H), 7.20 (m, 1H), 9.1 (br, 1H). Found: C, 76.41; H, 8.18; N, 7.26%. Calcd for C_{12}-$H_{15}NO$: C, 76.15; H, 7.99; N, 7.40%.

*o-(1-Methylpentyl)phenyl Isocyanide (**22-i**). General Procedure for Alkylations of o-Alkylphenyl Isocyanide(**7a**)*: To a solution of 3 mmol of LTMP in 4 mL of diglyme at −78 °C, was added 197 mg (1.5 mmol) of *o*-ethylphenyl iso cyanide (**7a-i**), and stirred for 30 min at the same temperature. To the purple solution, 322 mg (3 mmol) of butyl bromide was added at −78 °C and worked up in the usual way. *o*-(1-Methylpentyl)phenyl isocyanide (**22-i**) [bp 68 °C (2 mmHg)] was isolated in 72% yield by distillation. IR 2115 cm^{-1}; NMR (CCl_4 with Me_4Si) δ=0.88 (t, 3H), 1.1—1.8 (m, 9H), 2.5—3.3 (m, 1H), 6.9—7.4 (m, 4H). Found: C, 83.51; H, 9.00; N, 7.63%. Calcd for $C_{13}H_{17}N$: C, 83.37; H, 9.15; N, 7.48%.

o-(1-Methylpentyl)phenyl isocyanide (**22-i**) was also pre-

pared by methylation of *o*-pentylphenyl isocyanide (**7a-iii**). *o*-Alkylphenyl isocyanides (**22-ii**) and (**22-iii**) were prepared according to the above procedure.

o-Isopropylphenyl Isocyanide (22-ii): [Bp 50 °C (0.1 mmHg)]: IR 2120 cm^{-1}; NMR (CCl_4 with Me_4Si) δ=1.32 (d, 6H), 3.1—3.5 (m, 1H), 7.19 (m, 4H). Found: C, 82.60; H, 7.44; N, 9.37%. Calcd for $C_{10}H_{11}N$: C, 82.72; H, 7.64; N, 9.65%.

o-(1-Methylthioethyl)phenyl Isocyanide (22-iii): [Bp 86 °C (1 mmHg)]: IR 2110 cm^{-1}; NMR (CCl_4 with Me_4Si) δ=1.53 (d, 3H), 1.93 (s, 3H), 4.26 (q, 1H), 7.2—7.7 (m, 4H). Found: C, 67.93; H, 6.05; N, 7.71%. Calcd for $C_{10}H_{11}NS$: C, 67.76; H, 6.25; N, 7.90%.

o-(1-Methylthioethyl)phenyl Isocyanide (22-iii): To a solution of 3 mmol of LDA in 4 mL of diglyme at −78 °C was added 245 mg (1.5 mmol) of *o*-(methylthiomethyl)phenyl isocyanide (**7a-iii**), and stirred for 30 min at the same temperature. To the mixture, 426 mg (3 mmol) of methyl iodide was added at −78 °C and worked up in the usual way.

o-[Bis(methylthio)methyl]phenyl isocyanide (**22-iv**) and *o*-(1-trimethylsilylethyl)phenyl isocyanide (**22-v**) were prepared in the similar way.

o-[Bis(methylthio)methyl]phenyl Isocyanide (22-iv): [Bp 90 °C (0.4 mmHg)]: IR 2115 cm^{-1}; NMR (CCl_4 with Me_4Si) δ= 2.08 (s, 6H), 5.00 (s, 1H), 7.1—7.5 (m, 4H). Found: C, 57.19; H, 5.12; N, 7.01%. Calcd for $C_{10}H_{11}NS_2$: C, 57.38; H, 5.30; N, 6.69%.

o-(1-Trimethylsilylethyl)phenyl Isocyanide (22-v): [Bp 52 °C (0.6 mmHg)]: IR 2130, 1250, 835 cm^{-1}; NMR (CCl_4 with Me_4Si) δ=−0.06 (s, 9H), 1.30 (d, 3H), 2.71 (q, 1H), 6.7—7.2 (m, 4H). Found: C, 70.77; H, 8.40; N, 6.85%. Calcd for $C_{12}H_{17}NSi$: C, 70.87; H, 8.42; N, 6.89%.

α-α-Dimethylindole-3-ethanol (25a-i). General Procedure for One Pot Syntheses of Tryptophol Derivatrives (25): To a solution of 3 mmol of LDA in 4 mL of diglyme at −78 °C was added 176 mg (1.5 mmol) of *o*-tolyl isocyanide (**1a**) and stirred for 30 min at the same temperature. 216 mg (3 mmol) of 2,2-dimethyloxirane was added to the mixture at −78 °C and stirred. After 3 h, 3 mmol of LDA in 2 mL of diglyme was added to the mixture at −78 °C and stirred for additional 2 h. The resulting mixture was allowed to warm up to room temperature and worked up in the usual way. α,α-Dimethylindole-3-ethanol (**25a-i**) [bp 150 °C (0.5 mmHg); mp 92—93 °C (lit,[23] 93—94 °C)] was produced in 68% yield. IR 3400, 3300 cm^{-1}; NMR δ=1.24 (s, 6H), 1.51 (s, 1H), 2.80 (s, 2H), 6.8—7.6 (m, 5H), 8.20 (br, 1H). Tryptophol derivatives (**25a-ii**)[24]—(**25e-viii**) were prepared according to the above procedure.

α-Methylindole-3-ethanol (25a-iii): [Bp 155 °C (0.5 mmHg) (lit,[23] 140—145 °C (0.05 mmHg)); mp 129—133 °C]: IR 3400, 3300 cm^{-1}; NMR δ=1.26 (d, 3H), 2.2 (br, 1H), 2.85 (m, 2H), 4.03 (m, 1H), 7.0—7.7 (m, 5H), 8.0 (br, 1H).

2-(3-Indolyl)cyclohexanol (25a-iv):[25] [Bp 170 °C (0.1 mmHg); mp 168 °C]: IR 3450, 3220 cm^{-1}; NMR δ=1.0—2.0 (m, 9H), 2.5 (m, 1H), 3.8 (m, 1H), 6.9—7.7 (m, 5H), 8.1 (br, 1H). The reaction of *o*-(lithiomethyl)phenyl isocyanide (**2a**) and cyclohexene oxide was slow and took 5 h at −78 °C before the second addition of LDA.

α,α,5-Trimethylindole-3-ethanol (25b-v) (48% yield) was produced together with 2,4-bis(3-hydroxy-3-methylbutyl)-phenyl isocyanide (**26b-v**) (15% yield), which were separated and isolated by preparative TLC. **25b-v** [TLC (Silica gel, $CHCl_3$-AcOEt (5:2)) R_f=0.46]: IR 3400, 3300cm^{-1}; NMR δ=1.09 (s, 6H), 1.79 (br s, 1H), 2.32 (s, 3H), 2.65 (s, 2H), 6.57 (m, 1H), 6.80 (m, 2H), 7.17 (m, 1H), 8.2 (br, 1H). Found: C, 76.56; H, 8.20; N, 6.65%. Calcd for $C_{13}H_{17}NO$: C, 76.81; H, 8.43; N, 6.89%. **26b-v** [TLC (Silica gel, $CHCl_3$-AcOEt (5:2)) R_f=0.12]: IR 3350, 2121 cm^{-1}; NMR δ=1.17 (br s, 12H), 1.70 (m, 4H), 2.32 (br, 2H), 2.72 (m, 4H), 6.8—7.2 (m, 3H). Found: C, 73.96; H, 9.22; N, 5.28%. Calcd for $C_{17}H_{25}NO_2$: C, 74.14; H, 9.15; N, 5.09%.

α,5-Dimethylindole-3-ethanol (**25b-vi**) (48% yield) was produced with 2,4-bis(3-hydroxybutyl)phenyl isocyanide (**26b-vi**) (17% yield). **25b-vi** [Bp 160 °C (0.5 mmHg)]: IR 3400, 3300 cm^{-1}; NMR δ=1.25 (d, 3H), 1.85 (br s, 1H), 2.39 (s, 3H), 2.78 (m, 2H), 4.03 (m, 1H), 6.93 (d, 1H), 7.0—7.4 (m, 3H), 8.1 (br, 1H). Found: C, 75.94; H, 8.08; N, 7.57%. Calcd for $C_{12}H_{15}NO$: C, 76.15; H, 7.99; N, 7.40%. **26b-vi** [TLC (Silica gel, $CHCl_3$-AcOEt (5:2)) R_f=0.14]: IR 3350, 2120 cm^{-1}; NMR δ=1.18 (d, 3H), 1.21 (d, 3H), 1.77 (m, 4H), 2.4—2.9 (m, 6H), 3.6—4.0 (m, 2H), 6.8—7.2 (m, 3H). Found: C, 72.63; H, 8.34; N, 5.88%. Calcd for $C_{15}H_{21}NO_2$: C, 72.84; H, 8.56; N, 5.66%.

α,α,7-Trimethylindole-3-ethanol (**25d-vii**) (23% yield) was produced with 7-(3-hydroxy-3-methylbutyl)indole (**27d-vii**) (33% yield). **25d-ii** [TLC (Silica gel, $CHCl_3$-AcOEt (4:1)) R_f=0.49]: IR 3400, 3350 cm^{-1}; NMR δ=1.23 (s, 6H), 1.82 (s, 1H), 2.38 (s, 3H), 2.80 (s, 2H), 6.90 (m, 3H), 7.35 (m, 1H), 8.1 (br, 1H). Found: C, 76.55; H, 8.22; N, 6.51%. Calcd for $C_{13}H_{17}NO$: C, 76.81; H, 8.43; N, 6.89%. **27d-vii** [TLC (Silica gel, $CHCl_3$-AcOEt (4:1)) R_f=0.18]: IR 3400, 3300 cm^{-1}; NMR δ=1.27 (s, 6H), 1.94 (m, 2H), 2.42 (br s, 1H), 2.80 (m, 2H), 6.7—7.4 (m, 5H), 9.4 (br, 1H). Found: C, 76.64; H, 8.18; N, 6.66%. Calcd for $C_{13}H_{17}NO$: C, 76.81; H, 8.43; N, 6.89%.

1-Methylindole (30a-i). General Procedure for Preparations of 1-Substitued Indoles (30): To a solution of 3 mmol of LDA in 4 mL of diglyme at −78 °C was added 176 mg (1.5 mmol) of **1a**, and stirred for 30 min at the same temperature. After the reaction mixture was allowed to warm up to room temperature, 426 mg (3 mmol) of methyl iodide was added dropwise to the resulting light yellow solution, and stirred for 1 h at room temperature. The progress of the alkylation can be monitored by TLC or GLC. The mixture was worked up in the usual way to give 1-methylindole (**30a-i**) [bp 85 °C (1 mmHg) (lit,[26] 103—105 °C (2 mmHg))] in 82% yield. NMR δ=3.69 (s, 3H), 6.42 (d, 1H) 6.9—7.3 (m, 4H), 7.5—7.7 (m, 1H).

1-Substituted indoles (**30a-ii**)—(**30a-x**) were prepared according to the above procedure.

1-Butylindole (30-ii):[27] [Bp 114 °C (2 mmHg)]: NMR δ=0.93 (t, 3H), 1.0—2.0 (m, 4H), 4.02 (t, 2H), 6.31 (d, 1H), 6.8—7.2 (m, 4H), 7.4—7.6 (m, 1H).

1-(Methoxycarbonylmethyl)indole (30a-iii):[28] [Bp 119 °C (2 mmHg)]: IR 1733 cm^{-1}; NMR (CCl_4 with Me_4Si) δ= 3.56 (s, 3H), 4.66 (s, 2H), 6.32 (d, 1H), 6.82 (d, 1H), 6.9—7.1 (m, 2H), 7.3—7.5 (m, 1H).

1-(Trimethylsilyl)indole (30a-iv): [Bp 74 °C (0.4 mmHg) (lit,[29] 82—84 °C (0.4 mmHg))].

1-Propionylindole (30a-v): [Bp 93 °C (1 mmHg); mp 59—60 °C (lit,[30] 60.5—61 °C)]: IR 1697 cm^{-1}; NMR (CCl_4 with Me_4Si) δ=1.21 (t, 3H), 2.74 (q, 2H), 6.40 (d, 1H), 6.9—7.4 (m, 4H), 8.2—8.4 (m, 1H).

1-(Methoxycarbonyl)indole (30a-vi):[31] [Bp 100 °C (2 mmHg)]: IR 1736 cm^{-1}; NMR δ=3.96 (s, 3H), 6.55 (d, 1H), 7.1—7.6 (m, 4H), 8.0—8.2 (m, 1H).

α-Ethylindole-1-ethanol (30a-vii): [Bp 125 °C (1 mmHg)]: IR 3350 cm^{-1}; NMR δ=1.02 (t, 3H), 1.2—1.7 (m, 2H), 2.0 (br, 1H), 3.8—4.2 (m, 3H), 6.56 (d, 1H), 7.1—7.8 (m, 5H). Found: C, 75.95; H, 7.84; N, 7.15%. Calcd for $C_{12}H_{15}NO$: C, 76.15; H, 7.99; N, 7.40%.

α-Methylindole-1-ethanol (30a-viii): [Bp 117 °C (1 mmHg)]: IR 3350cm^{-1}; NMR δ=1.08 (d, 3H), 1.98 (s, 1H), 3.7—4.1 (m, 3H), 6.42 (d, 1H), 6.9—7.7 (m, 5H). Found: C, 75.19; H, 7.62; N, 7.77%. Calcd for $C_{11}H_{13}NO$: C, 75.40; H, 7.48; N, 7.99%.

α,α-Dimethylindole-1-ethanol (30a-ix): [TLC (Silica gel,

$CHCl_3$-AcOEt (4:1)) R_f=0.76]: IR 3400 cm^{-1}; NMR δ= 1.24 (s, 6H), 1.42 (s, 1H), 4.00 (s, 2H), 6.43 (d, 1H), 6.9—7.6 (m, 5H). Found: C, 76.01; H, 7.72; N, 7.58%. Calcd for $C_{12}H_{15}NO$: C, 76.15; H, 7.99; N, 7.40%.

*1-(2-Hydroxycyclohexyl)indole (**30a-x**)*: [TLC (Silica gel, $CHCl_3$) R_f=0.49]: IR 3400 cm^{-1}; NMR δ=1.0—2.1 (m 9H), 3.2—4.1 (m, 2H), 6.32 (d, 1H), 6.9—7.6 (m, 5H). Found: C, 78.27; H, 8.12; N, 6.37%. Calcd for $C_{14}H_{17}NO$: C, 78.10; H, 7.96; N, 6.51%.

*1-Butyl-3-methylindole (**30a-xi**)*: To a solution of 3 mmol of LTMP in 4 mL of diglyme at −78 °C was added 197 mg (1.5 mmol) of *o*-ethylphenyl isocyanide (**7a-i**) and stirred for 30 min at the same temperature. After the mixture was allowed to warm up to room temperature, 322 mg (3 mmol) of butyl bromide was added dropwise and stirred for 1 h. The usual work-up of the reaction mixture afforded 1-butyl-3-methylindole (**30a-xi**)[31] [bp 170 °C (1 mmHg)] in 65% yield.

*o-(Acetylmethyl)phenyl Isocyanide (**31**). General Procedure for Acylations of **2** with N-Acylaziridines*: To a stirring solution of **2a** (7.5 mmol) in 20 mL of diglyme at −78 °C was added dropwise 1.28 g (15 mmol) of *N*-acetylaziridine. After the reaction mixture was stirred at the same temperature for 10 min, it was worked up in the usual way. *o*-(Acetylmethyl)phenyl isocyanide (**31-i**) (92%) was distilled at bp 105 °C (1 mmHg).[9]

o-[(4-Chlorobutyryl)methyl]phenyl isocyanide (**31-iii**) and *o*-[(4-hydroxybutyryl)methyl]phenyl isocyanide (**31-iv**) were prepared by the reaction of **2a** with ethyl 4-chlorobutyrate and γ-butyrolactone according to the procedure reported.[9]

31-iii [TLC (Silica gel, $CHCl_3$-AcOEt (100:1)) R_f=0.44]: IR 2110, 1718 cm^{-1}; NMR (CCl_4 with Me_4Si) δ=2.15 (m, 2H), 2.80 (t, 2H), 3.61 (t, 2H), 3.91 (s, 2H), 7.0—7.8 (m, 4H). Found: C, 64.84; H, 5.59; N, 6.48%. Calcd for $C_{12}H_{12}NOCl$: C, 65.02; H, 5.46; N, 6.32%.

31-iv [TLC (Silica gel, $CHCl_3$-AcOEt (1:1)) R_f=0.43]: IR 3400, 2120, 1713 cm^{-1};NMR δ=1.83 (quintet, 2H), 2.2 (br, 1H), 2.67 (t, 2H), 3.59 (t, 2H), 3.87 (s, 2H), 7.27 (m, 4H). Found: C, 71.19; H, 6.70; N, 6.75%. Calcd for $C_{12}H_{13}NO_2$: C, 70.91; H, 6.45; N, 6.89%.

*o-(1-Acetylethyl)phenyl Isocyanide (**34-i**). General Procedure for Alkylations of o-(Acylmethyl)phenyl Isocyanide (**31**)*: To a stirring suspension of 48 mg (1 mmol, 50% in Oil) of NaH in 3 mL of DMSO-THF (1:1) at −20 °C was added 159 mg (1 mmol) of *o*-(acetylmethyl)phenyl isocyanide (**31-i**) in 1 mL of THF. After stirring for 15 min, the mixture was treated with 142 mg (1 mmol) of methyl iodide for 30 min. An extractive work-up gave 146 mg (84%) of *o*-(1-acetylethyl)phenyl isocyanide (**34-i**), bp 95 °C (0.4 mmHg). **34-i**: IR 2105, 1718 cm^{-1}; NMR δ=1.42 (d, 3H), 2.13 (s, 3H), 4.15 (q, 1H), 7.1—7.5 (m, 4H). Found: C, 76.44; H, 6.70; N, 8.22%. Calcd for $C_{11}H_{11}NO$: C, 76.27; H, 6.40; N, 8.09%.

*o-(1-Isovalerylethyl)phenyl Isocyanide (**34-ii**)*: [Bp 109 °C 0.2 mmHg)]: IR 2105, 1722 cm^{-1}; NMR δ=0.85 (d, 6H), 1.35 (d, 3H), 2.00—2.45 (m, 3H), 4.05 (q, 1H), 7.0—7.4 (m, 4H). Found: C, 78.03; H, 8.12; N, 6.68%. Calcd for $C_{14}H_{17}NO$: C, 78.10; H, 7.96; N, 6.51%.

*o-(1-Pivaloylethyl)phenyl Isocyanide (**34-iii**)*: [Bp 120 °C (0.6 mmHg)]: IR 2105, 1710 cm^{-1}; NMR δ=1.05 (s, 9H), 1.44 (d, 3H), 4.57 (q, 1H), 7.1—7.5 (m, 4H). Found: C, 77.91; H, 8.15; N, 6.68%. Calcd for $C_{14}H_{17}NO$: C, 78.10; H, 7.96; N, 6.51%.

*o-(1-Pivaloyl-2-methylpropyl)phenyl Isocyanide (**34-iv**)*: [Bp 105 °C (0.3 mmHg)]: IR 2105, 1703 cm^{-1}; NMR (CCl_4 with Me_4Si) δ=0.91 (d, 6H), 1.00 (s, 9H), 2.0—2.5 (m, 1H), 4.11 (d, 1H), 7.0—7.5 (m, 4H). Found: C, 79.03; H, 8.98; N, 5.54%. Calcd for $C_{16}H_{21}NO$: C, 78.97; H, 8.70; N, 5.76%.

*o-(1-Pivaloyl-3-oxobutyl)phenyl Isocyanide (**34-v**)*: [TLC (Silica gel, $CHCl_3$) R_f=0.62]: IR 2105, 1720, 1705 cm^{-1}; NMR δ= 1.13 (s, 9H), 2.15 (s, 3H), 2.56 (dd, 1H), 3.36 (dd, 1H), 5.03 (dd, 1H), 7.1—7.5 (m, 4H). Found: C, 74.44; H, 7.30; N, 5.66%. Calcd for $C_{16}H_{19}NO_2$: C, 74.68; H, 7.44; N, 5.44%.

*2-(1-Pivaloyl-2-cyanoethyl)phenyl Isocyanide (**34-vi**)*: [TLC (Silica gel, $CHCl_3$-AcOEt (40:1)) R_f=0.47]: IR 2238, 2115, 1700 cm^{-1}; NMR δ=1.09 (s, 9H), 2.56 (dd, 2H), 4.94 (t, 1H), 7.2—7.7 (m, 4H). Found: C, 74.81; H, 6.52; N, 11.85%. Calcd for $C_{15}H_{16}N_2O$: C, 74.97; H, 6.71; N, 11.66%.

*o-(1-Benzoyl-3-butenyl)phenyl Isocyanide (**34-vii**)*: [TLC (Silica gel, hexane-C_6H_6 (1:1)) R_f=0.80]: IR 2110, 1725, 1645 cm^{-1};NMR δ=2.4—2.9 (m, 2H), 4.6—5.5 (m, 3H), 5.5—6.4 (m, 1H), 7.1—7.6 (m, 6H), 7.8—8.1 (m, 3H). Found: C, 82.89; H, 5.55; N, 5.58%. Calcd for $C_{18}H_{15}NO$: C, 82.73; H, 5.79; N, 5.36%.

*2-[1-Pivaloyl-2-(ethoxycarbonyl)ethyl]-4-methylphenyl Isocyanide (**34-viii**)*: [TLC (Silica gel, $CHCl_3$-AcOEt (10:1)) R_f=0.54]: IR 2110, 1730, 1715 cm^{-1}; NMR δ=1.10 (s, 9H), 1.28 (t, 3H), 2.26 (s, 3H), 2.43 (dd, 1H), 3.02 (dd, 1H), 4.03 (q, 2H), 4.90 (dd, 1H), 6.8—7.9 (m, 3H). Found: C, 71.63; H, 7.88; N, 4.50%. Calcd for $C_{18}H_{23}NO_3$: C, 71.73; H, 7.69; N, 4.65%.

*2-(1-Pivaloyl-3-butenyl)-6-methylphenyl Isocyanide (**34-ix**)*: [Bp 130 °C (0.4 mmHg)]: IR 2105, 1709, 1640 cm^{-1}; NMR δ=1.06 (s, 9H), 2.45 (s, 3H), 2.4—3.0 (m, 2H), 4.5—5.2 (m, 3H), 5.4—6.0 (m, 1H), 7.1—7.6 (m, 3H). Found: C, 80.09; H, 8.38; N, 5.72%. Calcd for $C_{17}H_{21}NO$: C, 79.96; H, 8.29; N, 5.49%.

*2,3-Dimethylindole (**35-i**). General Procedure for Preparations of 2,3-Disubstituted Indole (**35**)*: A mixture of 173 mg (1 mmol) of *o*-(1-acetylethyl)phenyl isocyanide (**34-i**) and 6 mL of *ca.* 6% HCl in 5:1 methanol-water was stirred for 30 min at room temperature. Then, the mixture was made alkaline by adding 10% aqueous NaOH and stirred for 30 min. An extractive work-up, followed by recrystallization from hexane afforded 90 mg (62%) of 2,3-dimethylindole (**35-i**), mp 106—107 °C (lit,[15b] 105—107 °C).

*2-Isobutyl-3-methylindole (**35-ii**)*: [TLC (Silica gel, $CHCl_3$) R_f=0.85]: IR 3400 cm^{-1}; NMR δ=0.99 (d, 6H), 2.20 (s, 3H), 2.54 (d, 2H), 1.95—2.62 (m, 1H), 7.1—8.1 (m, 5H). Found: C, 83.38; H, 9.30; N, 7.61%. Calcd for $C_{13}H_{17}N$: C, 83.37; H, 9.15; N, 7.48%.

*2-t-Butyl-3-methylindole (**35-iii**)*:[32] [TLC (Silica gel, hexane-C_6H_6 (1:1)) R_f=0.60]: IR 3420 cm^{-1}: NMR δ= 1.40 (s, 9H), 2.31 (s, 3H), 6.8—7.5 (m, 4H), 7.5—7.9 (br, 1H). Found: C, 83.52; H, 9.01; N, 7.30%. Calcd for $C_{13}H_{17}N$: C, 83.37; H, 9.15; N, 7.48%.

*2-t-Butyl-3-isopropylindole (**35-iv**)*: [TLC (Silica gel, hexane-C_6H_6 (1 : 1)) R_f=0.74] (mp 100—102.5 °C): IR (KBr disk) 3430 cm^{-1}; NMR δ=1.42 (s, 9H), 1.45 (d, 6H), 3.44 (m, 1H), 6.8—7.3 (m, 3H), 7.5—7.8 (m, 2H). Found: C, 83.83; H, 10.02; N, 6.73%. Calcd for $C_{15}H_{21}N$: C, 83.66; H, 9.83; N, 6.51%.

*2-t-Butyl-3-(2-oxopropyl)indole (**35-v**)*: [TLC (Silica gel, $CHCl_3$-AcOEt (10:1)) R_f=0.57]: IR 3380, 1697 cm^{-1}; NMR δ=1.40 (s, 9H), 2.05 (s, 3H), 3.84 (s, 2H), 6.9—7.5 (m, 4H), 8.1—8.5 (br, 1H). Found: C, 78.72; H, 8.18; N, 5.96%. Calcd for $C_{15}H_{19}NO$: C, 78.56; H, 8.35; N, 6.11%.

*2-t-Butyl-3-(cyanomethyl)indole (**35-vi**)*: [TLC (Silica gel, $CHCl_3$-AcOEt (40:1)) R_f=0.53]: IR 3375, 2235 cm^{-1}: NMR δ=1.41 (s, 9H), 3.90 (s, 2H), 7.0—7.6 (m, 4H), 7.8—8.5 (br, 1H). Found: C, 79.50; H, 7.81; N, 13.32%. Calcd for $C_{14}H_{16}N_2$: C, 79.21; H, 7.60; N, 13.20%.

*2-Phenyl-3-allylindole (**35-vii**)*: [TLC (Silica gel, hexane-C_6H_6 (1:1)) R_f=0.53]: IR 3390, 1635 cm^{-1}; NMR δ=3.5—3.8 (m, 2H), 4.8—5.3 (m, 2H), 5.8—6.5 (m, 1H), 6.9—8.8

(m, 10H). Found: C, 87.35; H, 6.71; N, 5.98%. Calcd for $C_{17}H_{15}N$: C, 87.51; H, 6.48; N, 6.00%.

*2-t-Butyl-3-(ethoxycarbonylmethyl)-5-methylindole (**35-viii**)*: [TLC (Silica gel, $CHCl_3$) R_f=0.22]: IR 3390, 1725 cm^{-1}; NMR δ=1.29 (t, 3H),1.41 (s, 9H), 2.42 (s, 3H), 3.90 (s, 2H), 4.15 (q, 2H), 6.9—7.5 (m, 3H), 8.0 (br, 1H). Found: C, 74.85; H, 8.58; N, 5.01%. Calcd for $C_{17}H_{23}NO_2$: C, 74.69; H, 8.48; N, 5.12%.

*2-t-Butyl-3-allyl-7-methylindole (**35-ix**)*: [TLC (Silica gel, hexane-C_6H_6 (1:1)) R_f=0.63]: IR 3470, 1638 cm^{-1}; NMR δ= 1.43 (s, 9H), 2.47 (s, 3H), 3.61 (m, 2H), 4.7—5.2 (m, 2H), 5.6— 6.4 (m, 1H), 6.8—7.5 (m, 3H), 7.7 (br 1H). Found: C, 84.28; H, 9.11; N, 6.01%. Calcd for $C_{16}H_{21}N$: C, 84.53; H, 9.31; N, 6.16%.

*2-(3-Chloropropyl)indole (**33-i**)*: [TLC (Silica gel, $CHCl_3$) R_f=0.64]: IR 3375 cm^{-1}; NMR δ=2.11 (quintet, 2H), 2.88 (t, 2H), 3.58 (t, 2H), 6.30 (m, 1H), 7.1—7.7 (m, 4H), 7.8 (br, 1H). Found: C, 68.44; H, 6.40; N, 7.29%. Calcd for $C_{11}H_{12}NCl$: C, 68.22; H, 6.25; N, 7.23%.

*2-(3-Hydroxypropyl)indole (**33-ii**)*: [TLC (Silica gel. $CHCl_3$-AcOEt (10:1)] R_f=0.24] (mp 53—55 °C): IR (KBr disk) 3390, 3300 cm^{-1}; NMR δ=1.6—2.1 (m, 3H), 2.65 (t, 2H), 3.54 (t, 2H), 6.14 (m, 1H), 6.9—7.6 (m, 4H), 8.2 (br, 1H). Found: C, 75.59; H, 7.31; N, 8.10%. Calcd for $C_{11}H_{13}NO$: C, 75.40; H, 7.48; N, 7.99%.

N,N'-Carbonyldi[2(3*H*)-benzoxazolethione]: New, Reactive Condensing Agent for the Synthesis of Amides, Esters, Peptides, and Polyamides

Mitsuru UEDA,* Naomi KAWAHARASAKI, and Yoshio IMAI†
Department of Polymer Chemistry, Faculty of Engineering, Yamagata Universtiy, Yonezawa, Yamagata 992
†*Department of Textile and Polymeric Materials, Tokyo Institute of Technology, Meguro-ku, Tokyo 152*
(Received June 7, 1983)

A new condensing agent, *N,N'*-carbonyldi[2(3*H*)-benzoxazolethione] (**3**), was readily prepared by the reaction of 2-benzoxazolethiol and trichloromethyl chloroformate in benzene. The condensing agent **3** is shown to be useful for the preparation of amides, esters, and dipeptides under mild conditions. A successful polyamide synthesis by the polycondensation of isophthalic acid with diamines using **3** is also described.

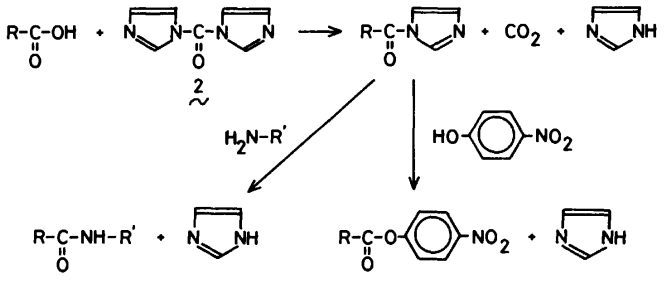
Dicyclohexylcarbodiimide (DCC) (**1**) and *N,N'*-carbonyldiimidazole (**2**) are useful and popular condensing agents. However, they have some disadvantages in acylation reactions; **1** is accompanied by the formation of *N*-acylurea which causes a purification problem as well as reducing the yield, and **2** is very sensitive to moisture, and must be handled with care. To overcome these problems, many condensing agents have been reported.[1]

As a part of our continuing research program on the preparation of amides, esters, and polyamides under mild conditions,[2] our group has recently initiated the synthesis of new active condensing agents. One requirement for an improved condensing agent is that the conversion of carboxylic acids to the active intermediates should occur readily under mild conditions. In the preceding paper, we showed that 3-substituted 1,2-benzisothiazole 1,1-dioxides and *N,N'*-carbonyldi[1,2-benzisoxazol-3(2*H*)-one] are new reactive condensing agents for the synthesis of amides and esters.[3,4]

We now report that amides, esters, dipeptides, and polyamides can be easily obtained from carboxylic acids and nucleophiles by a one-pot procedure using the new condensing agent, *N,N'*-carbonyldi[2(3*H*)-benzoxazolethione] (**3**).

Results and Discussion

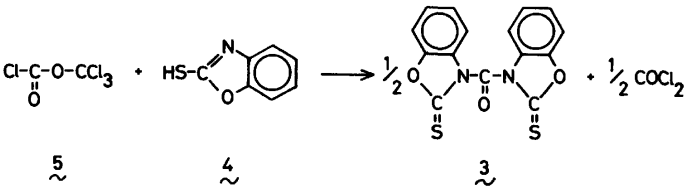
Synthesis of N,N'-*Carbonyldi[2(3H)-benzoxazolethione] (3).* *N*-Acyl derivatives of imidazoles, pyrazoles, and triazoles are highly reactive acylating agent which are involved in numerous condensing methods.[5] For example, carbonyldiimidazole (**2**) has been used for direct condensing method as in Scheme 1. The actual acylating agent is an *N*-acyl imidazole.



Scheme 1.

Recently we reported that *N*- or *S*-acyl derivatives of 2-benzoxazolethiol (**4**) is a new highly reactive acylating agent for amines and alcohols.[6] This finding prompted us to develop further new condensing agent, *N,N'*-carbonyldi[2(3*H*)-benzoxazolethione] (**3**) for the synthesis of amides and esters *via* *N*- or *S*-acyl derivatives of **4** as an active intermediate.

The condensing agent **3** was conveniently prepared from trichloromethyl chloroformate (**5**) and **4** in a 1:1 molar ratio in benzene (Scheme 2). Recrystallization from cyclohexane gave white needles melting point at 160—161 °C. It is stable even if exposed to atmospheric moisture for a long time. Acylation of **4** might be expected to yield the *S*- or *N*-acyl product, because of the tautomerism of **4**. The more thermodynamically stable isomers (*N*-acyl products) were obtained under a variety of reaction conditions,[7] but *S*-acyl products were obtained with a careful control of the reaction conditions.[6] The reaction of **4** and **5** in benzene under reflux conditions gave preferentially the more thermodynamically stable *N*-acyl product **3**. The structure of **3** was assigned on the basis of IR spectroscopy and elemental analysis. The IR spectrum exhibited a strong carbonyl absorptin at 1680 cm^{-1} and a C=S stretching absorption at 1350 cm^{-1}.



Scheme 2.

Reaction of 3 with Benzoic Acid (6a). In order to clarify the reaction pathway, the reaction of **3** with benzoic acid (**6a**) was carried out in *N*-methyl-2-pyrrolidone (NMP) at room temperature for 2 h in the presence of pyridine as a tertiary base. **3** reacted rapidly with **6a** with liberation of CO_2, and gave 3-benzoyl-2(3*H*)-benzoxazolethione (**7**) together with a

Table 1. Preparation of amides **10** and esters **11** using condensing agent **3**[a]

Carboxylic acid R-COOH, **6** R-	Amine or Alcohol	Reaction time (Step 2)	Product	Yield[b] %

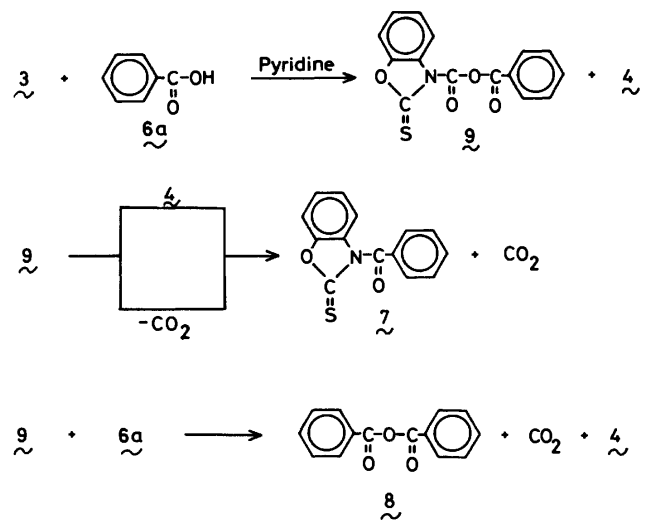
C_6H_5	1/2 *p*-Aminophenol	1 h/1 d	4′-Benzoyloxybenzanilide	88

a) Reaction was carried out with 2 mmol of the reactants in 4 ml of NMP at room temperature. Pyridine was used as a tertiary base at step 1. Reaction time: Step 1, 2 h. b) Isolated yields. c) Triethylamine as a tertiary base was used at the step 1.

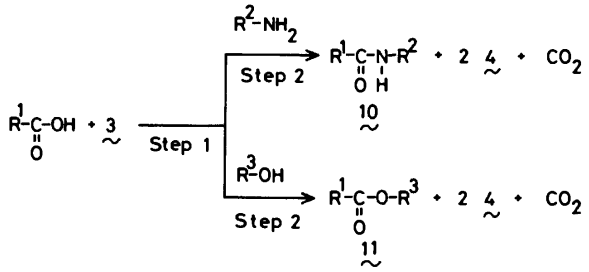
small amount of benzoic anhydride (**8**). The intermediate **7** has been characterized by high reactivity toward aminolysis. The above observations point to the following pathway (Scheme 3). **3** reacts first with



Scheme 3.

6a to form the mixed anhydride **9**, a highly activated acylating agent. The product **9** was less stable and it's enhanced reactivity causes it to react more rapidly with available nucleophiles, **4** and **6a**. These reactions yield the active intermediates **7** and **8**.

Synthesis of Amides (10) and Esters (11). The conversions of carboxylic acids into amides **10** or esters **11** using new condensing agent **3** were carried out by a one-pot procedure at room temperature in the presence of a tertiary base. Equimolar amounts of carboxylic acids, nucleophiles, and the condensing agent **3** are used. This efficient procedure involves two separate steps; (1) "activation" of the carbonyl component, *i.e.* generation of active intermediate **7** and **8** described above; and (2) "condensing" with the nucleophilic reagent (Scheme 4). The rections proceeded smoothly to give the corresponding amides **10**



Scheme 4.

and esters **11** in good yields. Pyridine as a base was more favorable than triethylamine (TEA) in step 1. The alcoholysis required an equimolar amount of TEA at step 2.

The amines, as expected from their generally greater reactivity in nucleophilic reactions, react more rapidly than the alcohols with the active intermediates **7** and **8**. With this different reactivity cited above between the reactions of the active intermediates with amines and alcohols, next, the selective *N*-acylation and *N,O*-diacylation of *p*-aminophenol (**12**) were performed either in the absence or in the presence of TEA, respectively. The corresponding amide **13** or amide ester **14** were obtained in good yields (Scheme 5). These results are summarized in Table 1.

Synthesis of Dipeptides (15). Futher it was found that the present reaction was applicable to the preparation of dipeptides **15**. Thus, the reaction of an *N*-protected α-amino acid (**16**) with an α-amino acid ester hydrochloride (**17**) was carried out with **3** in the presence of TEA. The *N*-protected α-amino acid **16** reacted with an equimolar amount of **3** in dichloromethane in the presence of TEA at room temperature. After several hours, the α-amino acid ester hydrochloride **17** and TEA, an acid acceptor, were added. The dipeptide product **15** was isolated in the ordinary manner. The optical purity of the dipeptides was estimated by comparison with the specific rotation of the reported values. *N*-Protected dipeptide esters **15** were prepared in good yields with the suppressed racemization (Table 2), (Scheme 6).

Table 2. Preparation of dipeptide esters **15** using condensing agent **3**[a)]

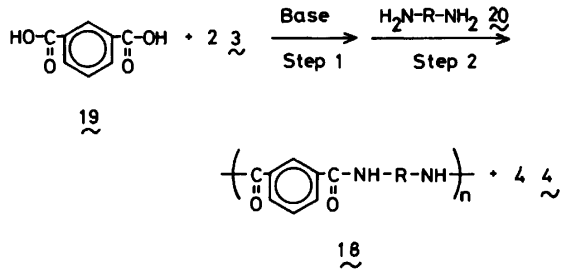

Scheme 7.

Synthesis of Polyamides (18). The direct polycondensation of diamines with dicarboxylic acids to form polyamides under mild conditions has received considerable attention. Most of them are based on phosphorylation reactions. Facile one-pot amide synthesis using the condensing agent **3** provides a promising route to polyamides. The polycondensation of isophthalic acid (**19**) with aromatic diamines (**20**) using **3** was investigated by the two methods, the one-pot polycondensation and the direct polycondensation. The one-pot polycondensation was carried out in solution at low temperature using 4,4′-oxydianiline and 4,4′-methylenedianiline as diamines **20**. The polar aprotic solvents, NMP and hexamethylphosphoric triamide (HMPA), were used as polymerization media (Scheme 7). The activation of isophthalic acid **19** (step 1) was carried out by the addition of the condensing agent **3** to a cold solution of **19** in a polar solvent in the presence of tertiary base. After several hours, the diamine was added. The solution was stirred at room temperature for a specified time. Although the polymers were isolated in excellent yields the molecular weights remained low. In order to determine the influence of base strength in these polymerizations, tertiary amines with a wide range of pK_a values were tested. But, there is no correlation between base strength and the resulting viscosity of the polymer. These results are summarized in Table 3.

To prevent the formation of a small amount of anhydride, the direct polycondensation of **19** with **20** was carried out at temperatures of 0—25 °C in the presence of the condensing agent **3** (Scheme 8). As

Scheme 8.

can be seen from the inherent viscosities in Table 4, the polymers were produced in quantitative yields with inherent viscosities up to 0.5 dl g^{-1}. The polymers were identified as polyamides by comparison of their IR spectra with those of the authentic polyamides.

In summary, our studies indicate that the condensing agent **3** is very useful reagent for the formation of amides, esters, peptides, and polyamides. The new condensing agent **3** is a crystalline solid having excellent hydrolytic stability and therefore it is handled more easily than conventional agents. Futhermore 2-benzoxazolethiol **4**, a leaving group, is readily removed from the reaction products by washing the reaction mixture with cold 1% aqueous sodium hydrogencarbonate.

Experimental

Melting points were uncorrected. Infrared spectra were obtained using potassium bromide pellets with a JASCO IRA-1 spectrophotometer. 4,4'-Oxydianiline, and 4,4'-methylenedianiline were recrystallized from tetrahydrofuran and benzene respectively. *N*-Methyl-2-pyrrolidone (supplied by Mitsubishi Chemical Industries Ltd.), hexamethylphosphoric triamides were purified by vacuum distillation and stored 4-Å Molecular Sieves. *N*-Protected α-amino acids and α-amino acid ester hydrochlorides were prepared by usual procedures. Trichloromethyl chloroformate was purchased from Hodogaya Chemical Industries Ltd. The other reagents were used without futher purification.

N,N'-Carbonyldi[2(3H)-benzoxazolethione] (3). A mixture of **4** (15 g, 0.1 mol) and trichloromethyl chloroformate (**5**) (12 ml, 0.1 mol) in benzene (100 ml) was refluxed with stirring for 3 h. Then the solvent was removed *in vacuo*, and the residue was allowed to stand overnight. Purification by recrystallization from cyclohexane gave white needles. Yield: 7.4 g (45%). Mp 160—161 °C; IR (KBr), 1680 and 1350 cm^{-1}.

Found: C, 55.0; H, 2.7; N, 8.6%. Calcd for $C_{15}H_8O_3N_2S_2$: C, 54.87; H, 2.46; N, 8.53.

Reaction of 3 with Benzoic Acid (6a). To a stirred solution of **6a** (0.244 g, 2.0 mmol), pyridine (0.18 ml, 2.0 mmol) in NMP (4 ml) was added **3** (0.657 g, 2.0 mmol), followed by stirring at room temperature for 2 h. The reaction mixture was poured into water (100 ml). The precipitate formed was collected by filtration, washed with water,

and dried *in vacuo*. 3-Benzoyl-2(3*H*)-benzoxazolethione (**7**) was the major product, and a small amount of benzoic anhydride (less than 5%) was formed. The crude product was recrystallized from ethanol to give yellow needles (**7**). Yield: 0.45 g (88%), mp 117—118 °C (lit,[6] 117 °C); IR (KBr), 1695 and 1340 cm^{-1}.

Amide (10). *General Procedure*: The condensing agent **3** (2 mmol) was added to a stirred solution of the carboxylic acid (2 mmol) and pyridine (2 mmol) in NMP (4 ml) at room temperature. After 2 or 3 h, the amine (2 mmol) was added. Stirring was continued for 1 h. The mixture was poured into 1% aqueous sodium hydrogencarbonate. The precipitate was filtered and washed with water and dried.

Ester (11). *General Procedure*: A mixture of **3** (2 mmol), benzoic acid (2 mmol), and pyridine (2 mmol) in NMP (4 ml) was stirred at room temperature for 2 h. To this mixture, the alcohol (2 mmol) and TEA (2 mmol) were added. Stirring was continued for several hours. The reaction mixture was worked up as described above.

Amide Ester (14). The condensing agent **3** (2 mmol) was added with stirring to a solution of benzoic acid (2 mmol) and pyridine (2 mmol) in NMP (4 ml) at room temperature. After 2 h, *p*-aminophenol (**12**) (1 mmol) was added to this mixture. After stirring 2 h, TEA (1 mmol) was added, the mixture was stirred for 4 d, and worked up as described. The compound (**13**) was obtained when TEA was omitted.

N-*Protected Dipepide Ester (15).* *General Procedure*: To a solution of the *N*-protected α-amino acid (1 mmol) and TEA (1 mmol) in dichloromethane (5 ml), **3** (1 mmol) was added under nitrogen. The solution was stirred for 3 h at 0 °C, then the α-amino acid ester hydrochloride (1 mmol) and TEA (1 mmol) were added. The solution was stirred for 12 h at room temperature. After removal of the solvent *in vacuo*, the residue was dissolved in ethyl acetate, and the organic solution was successively with 5% aqueous sodium hydrogencarbonate, 1 M hydrochloric acid and saturated brine, and then dried ($MgSO_4$). After evaporation of ethyl acetate, the dipeptide ester was purified by recrystallization.

Polyamide (18). *One-pot Polycondensation*: The condensing agent **3** was added to a stirred solution of isophthalic acid (**19**) (1 mmol) and pyridine (2 mmol) in NMP (2 ml). The mixture was stirred for a defined time at room temperature, then diamine (1 mmol) was added at room temperature. Stirring was continued for several hours. The resulting solution was poured into 1% aqueous sodium hydrogencarbonate (200 ml) and the precipitated polymer was collected and dried *in vacuo* at 60 °C for 2 d. The inherent viscosity was measured at a concentration of 0.5 g dl^{-1} in concentrated sulfuric acid at 30 °C.

Direct Polycondensation. To a solution of **19** (1 mmol) and diamine (1 mmol) in HMPA (2 ml), the condensing agent **3** (2 mmol) was added at 0 °C. The mixture was stirred for 10 h at 0 °C, and then for 14 h at room temperature. The polymer solution was worked up as described above.

We are indebted to Mr. Sadao Kato for the performance of the elemental analyses.

Studies of Bitter Peptides from Casein Hydrolyzate. IV.[1] Relationship between Bitterness and Hydrophobic Amino Acids Moiety in the C-Terminal of BPIa (Arg-Gly-Pro-Pro-Phe-Ile-Val)[2]

Ken OTAGIRI, Toshiaki SHIGENAGA, Hidenori KANEHISA, and Hideo OKAI*
Department of Fermentation Technology, Faculty of Engineering, Hiroshima University, Shitami, Saijo-cho, Higashihiroshima 724
(Received June 15, 1983)

In the synthetic studies of bitter peptide BPIa (Arg-Gly-Pro-Pro-Phe-Ile-Val), we synthesized several BPIa analogs to elucidate the participation of the hydrophobic amino acids moiety in the C-terminal in the bitter taste exhibited by BPIa. The syntheses of the peptides were performed by the usual MA (mixed anhydride) and DCC (dicyclohexylcarbodiimide)-HOBt (1-hydroxybenzotriazole) method,[3] and the bitterness of the peptides was organoleptically determined. The BPIa analogs in which more than two hydrophobic amino acids were located in the C-terminal exhibited a bitter taste as strong as that of BPIa.

In 1972, Minamiura *et al.*[4] isolated a bitter heptapeptide named BPIa from casein hydrolyzate by alkaline proteinase of *Bacillus subtilis*. They decided its amino acid sequence as follows: Arg-Gly-Pro-Pro-Phe-Ile-Val. In our laboratory, the authors have investigated the relationship between the bitterness and the chemical structure of BPIa. In a previous paper,[5] we explained that at least two hydrophobic amino acid residues in the C-terminal group are necessary for the intense bitter taste exhibited by BPIa. However, we did not deal with the relationship between the bitterness and the position of the hydrophobic amino acids in the C-terminal group of BPIa in that paper. In order to elucidate this, we synthesized several C-terminal analogs of BPIa, as shown in the Table.

Figure 1 indicates the route for the synthesis of the compound **1** (Arg-Gly-Pro-Pro-Gly-Gly-Val). *N*-(*t*-Butoxycarbonyl)glycylglycylvaline benzyl ester (**12**) was prepared by the reaction of *N*-(*t*-butoxycarbonyl)glycylglycine with valine benzyl ester by means of a mixed anhydride method. The subsequent treatment of **12** with hydrogen chloride in dioxane gave the tripeptide benzyl ester hydrochloride (**13**). *N*-(*t*-Butoxycarbonyl)prolylproline and **13** were coupled by the mixed anhydride method to yield *N*-(*t*-butoxycarbonyl)prolylprolylglycylglycylvaline benzyl ester (**14**). After treatment of **14** with hydrogen chloride, the pentapeptide benzyl ester hydrochloride (**15**) and N^{α}-benzyloxycarbonyl-N^{G}-nitroarginylglycine were coupled by the mixed anhydride method to yield N^{α}-benzyloxycarbonyl-N^{G}-nitroarginylglycylprolylprolylglycylglycylvaline benzyl ester (**16**). The protected heptapeptide was hydrogenated in the presence of palladium black to give the desired heptapeptide (H-Arg-Gly-Pro-Pro-Gly-Gly-Val-OH) (**1**).

Figure 2 indicates the route for the synthesis of the compound **2** (Arg-Gly-Pro-Pro-Gly-Ile-Gly). *N*-(*t*-Butoxycarbonyl)isoleucine and glycine benzyl ester were coupled by the mixed anhydride method to

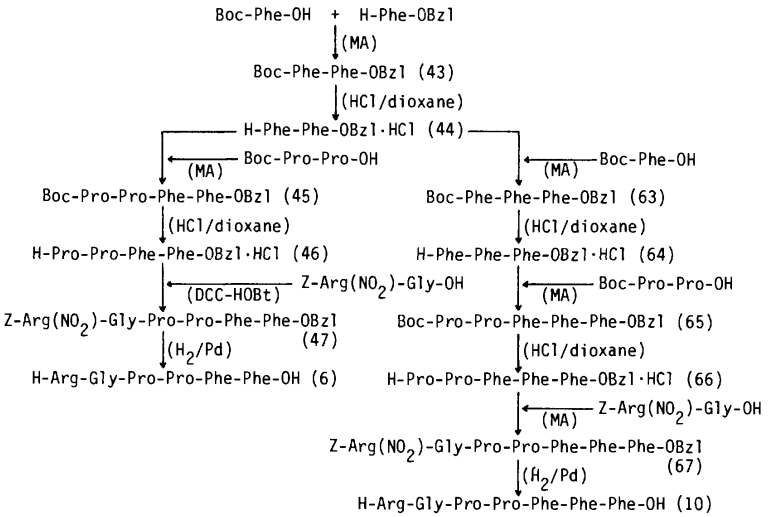

Fig. 4. Syntheses of compounds **6** and **10**.

yield *N*-(*t*-butoxycabonyl)isoleucylglycine benzyl ester (**17**). The subsequent treatment of **17** with hydrogen chloride in dioxane gave the dipeptide ester hydrochloride (**18**). The reaction of *N*-(*t*-butoxycarbonyl)glycine and **18** gave the tripeptide derivative (**19**). After treatment of **19** with hydrogen chloride in dioxane, the tripeptide benzyl ester hydrochloride (**20**) and *N*-(*t*-butoxycarbonyl)prolylproline were coupled by the mixed anhydride method to yield *N*-(*t*-butoxycarbonyl)prolylprolylglycylisoleucylglycine benzyl ester (**21**). The removal of the *t*-butoxycarbonyl group from **21** with hydrogen chloride in dioxane afforded the corresponding pentapeptide benzyl ester hydrochloride (**22**). N^{α}-Benzyloxycarbonyl-N^{G}-nitroarginylglycine and **22** were coupled by the mixed anhydride method to yield N^{α}-benzyloxycarbonyl-N^{G}-nitroarginylglycylprolylprolylglycylisoleucylglycine benzyl ester (**23**). The protected heptapeptide was hydrogenated in the presence of palladium black to give the desired compound (H–Arg–Gly–Pro–Pro–Gly–Ile–Gly–OH) (**2**).

The details of the synthetic routes to other peptides (compounds **3**—**10**) are shown in Figs. 3—5, and are described in the Experimental part. The purity of the synthetic peptides and their intermediates was confirmed by thin-layer examinations in two solvent systems, elemental analyses, and amino acid analyses.

The bitterness of the synthetic peptides was organoleptically determined by a panel evaluation of five people (see Table). Compounds **1**—**3** were synthesized to confirm the participation of the hydrophobic moiety in the bitter taste exhibition; bitterness of these compounds was weaker than that of BPIa. Compounds **3**, **4**, and **5** in which an L-phenylalanine residue is located at 5, 6, and 7 position[6] respectively, also exhibited a weak bitter taste. On the other hand, the bitterness of compounds **6**—**9**, in which two L-phenylalanine residues are located in the C-terminal, was on the same level as that of BPIa.

We treated the relationship between bitterness and the position of the hydrophobic amino acid residue. The bitterness of compound **4**, in which an L-phenylalanine residue locates at 6 position, was stronger than that of compounds **3** and **5**, which contain the hydrophobic amino acid residue at 5 and 7 posi-

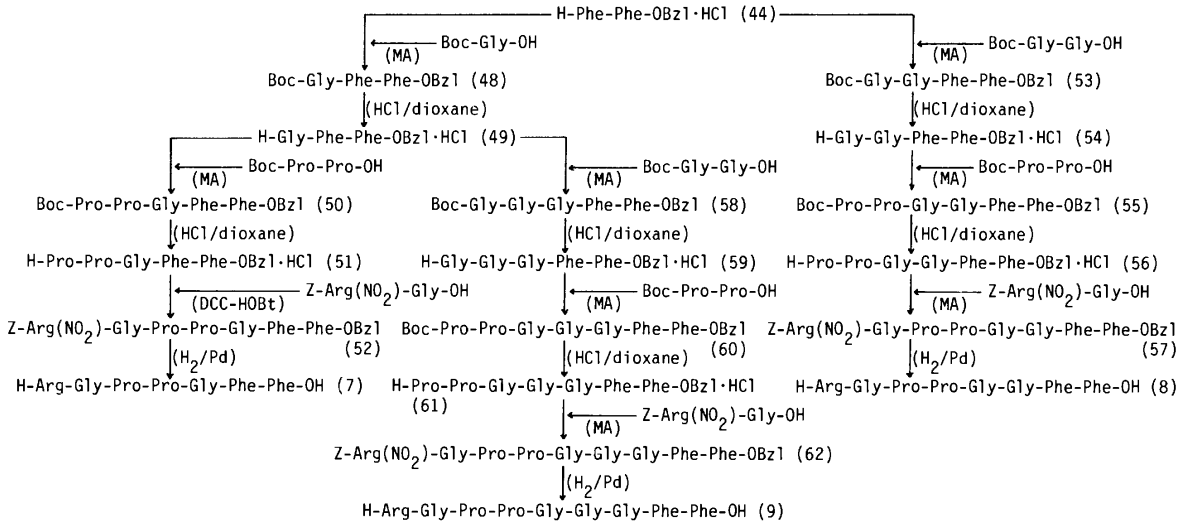

Fig. 5. Syntheses of compounds **7**, **8**, and **9**.

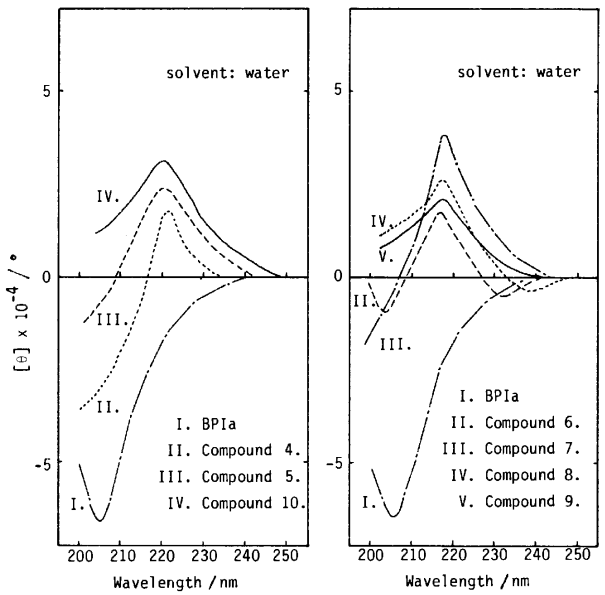

Fig. 6. CD curves of BPIa and its C-terminal analogs.

tion respectively. For compounds **6**—**9**, similar results obtained. In the previous paper,[5] we reported that the des-Gly[2]-BPIa, des-Pro[4]-BPIa, and des-Val[7]-BPIa, in which an L-hydrophobic amino acid residue is located at 6-position, exhibited a bitter taste as strong as that of BPIa.

The bitterness of compound **10**, in which three L-phenylalanine residues are located in the C-terminal, was five times stronger than that of BPIa. The result indicated that the strength of the bitterness increased with an increase of the hydrophobicity in the C-terminal. In conclusion, the presented data suggest that the hydrophobicity of the C-terminal moiety and the L-hydrophobic amino acid at 6-position were necessary for an intense bitter taste to be exhibited by BPIa.

The authors measured the circular dichroism (CD) of the synthetic peptides in this study, as shown in Fig. 6. In the previous papers,[1,5] the BPIa analogs that exhibited as strong and bitter a taste as BPIa have similarly shaped CD curves, with a negative trough at about 205 nm just as BPIa possesses. However, both the BPIa analogs in this study, the one which exhibited a strong bitter taste and the one with a weak bitter taste, have CD curves shaped oppositely to those of the BPIa analogs in the previous papers.[1,5] Further studies of this question are now in progress.

Experimental

All the melting points are uncorrected. Thin-layer chromatography (TLC) was carried out on Merck silica gel G with the following solvent systems: R_f^1, 1-butanol–acetic acid–pyridine–water (4:1:1:2, v/v); R_f^2, chloroform–methanol (5:1, v/v). Materials possessing a free amino group on a thin-layer plate were detected by spraying with ninhydrin. Compounds with blocked amino groups were detected by spraying with 25% hydrogen bromide in acetic acid and then with ninhydrin. The optical rotations were measured on a Union PM-101 polarimeter. Amino acid analyses were performed on a Hitachi amino acid analyzer KLA-5 type, after hydrolysis in a mixture of 6 M HCl (1 M=1 mol dm^{-3}) and propionic acid (1:1) at 110 °C for 72 h.

Boc-Gly-Gly-Val-OBzl (12). To a solution of Boc-Gly-Gly-OH[1] (2.32 g, 10 mmol) in DMF (20 ml) and NMM (1.1 ml, 10 mmol), ECF (1.0 ml, 10 mmol) was added at −5 °C. After 10 min, a solution of H-Val-OBzl·TsOH[7,8] (3.80 g, 10 mmol) and NMM (1.1 ml, 10 mmol) in chloroform (20 ml) was added. The reaction mixture was stirred in an ice bath for 1 h, then at room temperature overnight. The mixture was evaporated *in vacuo*, and the oily residue was dissolved in ethyl acetate. The solution was washed with water, 4% citric acid, 4% sodium hydrogencarbonate, and water successively, then dried over anhydrous sodium sulfate. Sodium sulfate was removed by filtration, and the filtrate was evaporated *in vacuo*. The oily residue was crystallized with ether–petroleum ether: yield 2.82 g (84%); mp 127—130 °C; $[\alpha]_D^{20}$ −21.0° (*c* 1, methanol); R_f^1 0.93 and R_f^2 0.67.

Found: C, 59.50; H, 7.43; N, 9.95%. Calcd for $C_{21}H_{31}O_6N_3$: C, 59.84; H, 7.41; N, 9.97%.

H-Gly-Gly-Val-OBzl·HCl (13). To a solution of compound **12** (2.40 g, 5.7 mmol) in dioxane (10 ml), 4 M HCl/dioxane (20 ml) was added. The reaction mixture was allowed to stand at room temperature. After 1.5 h, the solution was evaporated *in vacuo*. The residual oil was crystallized with ether: yield 1.82 g (89%); mp 205—206 °C; $[\alpha]_D^{20}$ −32.0° (*c* 1, methanol); R_f^1 0.80 and R_f^2 0.25.

Found: C, 53.16; H, 6.74; N, 11.63%. Calcd for $C_{16}H_{23}O_4N_3 \cdot HCl \cdot 1/4\ H_2O$: C, 53.03; H, 6.82; N, 11.60%.

Boc-Pro-Pro-Gly-Gly-Val-OBzl (14). Boc-Pro-Pro-OH[7,9] (1.25 g, 4 mmol) and compound **13** (1.43 g, 4 mmol) were coupled by the same method as described for the preparation of **12**: yield 2.12 g (86%); mp 73—76 °C; $[\alpha]_D^{20}$ −67.5° (*c* 1, methanol): R_f^1 0.82 and R_f^2 0.52.

Found: C, 59.16; H, 7.21; N, 10.72%. Calcd for $C_{31}H_{45}O_8N_5 \cdot H_2O$: C, 58.75; H, 7.47; N, 11.05%.

H-Pro-Pro-Gly-Gly-Val-OBzl·HCl (15). Compound **14** (2.11 g, 3.4 mmol) was treated as described in the case of **13**: yield 1.93 g (99%); mp 97—101 °C; $[\alpha]_D^{20}$ −50.0° (*c* 1, methanol); R_f^1 0.71 and R_f^2 0.55.

Found: C, 54.96; H, 6.87; N, 12.29%. Calcd for $C_{26}H_{37}O_6N_5 \cdot HCl \cdot H_2O$: C, 54.77; H, 7.07; N, 11.73%.

Z-Arg(NO$_2$)-Gly-Pro-Pro-Gly-Gly-Val-OBzl (16). Z-Arg(NO$_2$)-Gly-OH[7,10] (0.82 g 2 mmol) and compound **15** (1.10 g 2 mmol) were coupled by the same method as described for the preparation of **12**: yield 1.52 g (84%); mp 114—117 °C; $[\alpha]_D^{20}$ −69.0° (*c* 1, methanol); R_f^1 0.71 and R_f^2 0.55.

Found: C, 54.40; H, 6.30; N, 16.46%. Calcd for $C_{42}H_{57}O_{12}N_{11} \cdot H_2O$: C, 54.47; H, 6.42; N, 16.64%.

H-Arg-Gly-Pro-Pro-Gly-Gly-Val-OH (1). A solution of **16** (0.79 g, 1 mmol) in methanol (2 ml) and acetic acid (2 ml) was hydrogenated in the presence of palladium black at room temperature for 24 h. The catalyst was removed by filtration, then the filtrate was evaporated *in vacuo*. The residue was crystallized with acetone: yield 0.39 g (94%); mp 176—178 °C $[\alpha]_D^{20}$ −83.5° (*c* 1, H_2O); R_f^1 0.26 and R_f^2 0.00.

Found: C, 48.70; H, 7.20; N, 19.36%. Calcd for $C_{27}H_{46}O_8N_{10} \cdot H_2O \cdot CH_3COOH$: C, 48.59; H, 7.33; N, 19.55%.

Amino acid ratios in acid hydrolyzate: Arg 0.95, Gly 2.89, Pro 2.08, Val 1.00.

Boc-Ile-Gly-OBzl (17). Boc-Ile-OH·DCHA,[7,11] (13.62 g, 33 mmol) and H-Gly-OBzl·TsOH[12] (10.12 g, 30 mmol) were coupled by the same method as described for the preparation of **12**: yield 9.28 g (82%); mp 99—100 °C; $[\alpha]_D^{20}$ −22.5° (*c* 1, methanol); R_f^1 0.98 and R_f^2 0.71.

Found: C, 63.63; H, 8.09; N, 7.40%. Calcd for $C_{20}H_{30}O_5N_2$: C, 63.47; H, 7.99; N, 7.40%.

H-Ile-Gly-OBzl·HCl (18). Compound **17** (3.78 g, 10 mmol) was treated as described in the case of **13**: yield 2.96 g (94%); mp 52—56 °C; $[\alpha]_D^{20}$ +4.0° (*c* 1, methanol); R_f^1 0.78 and R_f^2 0.62.

Found: C, 56.48; H, 7.48; N, 8.79%. Calcd for $C_{15}H_{22}O_3N_2 \cdot HCl \cdot 1/4\ H_2O$: C, 56.42; H, 7.42; N, 8.77%.

Boc-Gly-Ile-Gly-OBzl (19). Boc-Gly-OH[13] (1.75 g, 10 mmol) and compound **18** (3.20 g, 10 mmol) were coupled by the same method as described for the preparation of **12**: yield 3.47 g (87%); mp 97—99 °C; $[\alpha]_D^{20}$ −28.5° (*c* 1, methanol); R_f^1 0.98 and R_f^2 0.43.

Found: C, 60.61; H, 7.69; N, 9.61%. Calcd for $C_{22}H_{33}O_6N_3$: C, 60.67; H, 7.64; N, 9.65%.

H-Gly-Ile-Gly-OBzl·HCl (20). Compound **19** (2.62 g, 6 mmol) was treated as described in the case of **13**: yield 2.21 g (99%); mp 185—187 °C; $[\alpha]_D^{20}$ −33.0° (*c* 1, methanol); R_f^1 0.77 and R_f^2 0.43.

Found: C, 53.25; H, 6.99; N, 11.19%. Calcd for $C_{17}H_{25}O_4N_3 \cdot HCl \cdot 2/3\ H_2O$: C, 53.18; H, 7.17; N, 10.95%.

Boc-Pro-Pro-Gly-Ile-Gly-OBzl (21). Boc-Pro-Pro-OH[7,9] (1.56 g, 5 mmol) and compound **20** (1.86 g, 5 mmol) were coupled by the same method as described for the preparation of **12**: yield 2.90 g (92%); 80—82 °C; $[\alpha]_D^{20}$ −63.0° (*c* 1, methanol); R_f^1 0.85 and R_f^2 0.50.

H-Phe-Gly-OBzl·HCl (32). Compound **31** (6.18 g, 15 mmol) was treated as described in the case of **13**. This product was obtained in a hygroscopic form: yield 5.37 g (98%); R_f^1 0.72 and R_f^2 0.61.

Boc-Gly-Phe-Gly-OBzl (33). Boc-Gly-OH[13] (1.75 g, 10 mmol) and compound **32** (3.65 g, 10 mmol) were coupled by the same method as described for the preparation of **12**. This product was obtained in an oily form: yield 4.51 g (96%); R_f^1 0.96 and R_f^2 0.77.

H-Gly-Phe-Gly-OBzl·HCl (34). Compound **33** (4.51 g, 9.6 mmol) was treated as described in the case of **13**. This product was obtained in an oily form: yield 3.76 g (97%); R_f^1 0.70 and R_f^2 0.41.

Boc-Pro-Pro-Gly-Phe-Gly-OBzl (35). Boc-Pro-Pro-OH[7,9] (2.91 g, 9.33 mmol) and compound **34** (3.76 g, 9.33 mmol) were coupled by the same method as described for the preparation of **12**. This product was obtained in an oily form: yield 4.70 g (76%); R_f^1 0.85 and R_f^2 0.69.

H-Pro-Pro-Gly-Phe-Gly-OBzl·HCl (36). Compound **35** (4.71 g, 7.09 mmol) was treated as described in the case of **13**: yield 4.00 g (94%); mp 76—78 °C; $[\alpha]_D^{20}$ −36.5° (*c* 1, methanol); R_f^1 0.72 and R_f^2 0.33.

Found: C, 58.27; H, 6.60; N, 11.29%. Calcd for $C_{30}H_{37}O_6N_5\cdot HCl\cdot H_2O$: C, 58.28; H, 6.53; N, 11.33%.

Z-Arg(NO₂)-Gly-Pro-Pro-Gly-Phe-Gly-OBzl (37). Z-Arg(NO₂)-Gly-OH[7,10] (0.82 g, 2 mmol) and compound **36** (1.19 g, 2 mmol) were coupled by the same method as described for the preparation of **12**: yield 1.39 g (73%); mp 125—128 °C; $[\alpha]_D^{20}$ −77.0° (*c* 1, acetic acid); R_f^1 0.75 and R_f^2 0.53.

Found: C, 57.21; H, 6.11; N, 16.02%. Calcd for $C_{46}H_{57}O_{12}N_{11}\cdot 1/2\ H_2O$: C, 57.25; H, 6.07; N, 15.97%.

H-Arg-Gly-Pro-Pro-Gly-Phe-Gly-OH (4). Compound **37** (0.96 g, 1 mmol) was treated as described in the case of **1**: yield 0.59 g (79%); mp 87—89 °C; $[\alpha]_D^{20}$ −83.0° (*c* 1, H_2O); R_f^1 0.20 and R_f^2 0.00.

Found: C, 52.01; H, 6.89; N, 18.24%. Calcd for $C_{31}H_{46}O_8N_{10}\cdot H_2O\cdot CH_3COOH$: C, 51.82; H, 6.87; N, 18.32%.

Amino acid ratios in acid hydrolyzate: Arg 0.93, Gly 2.99, Pro 1.98, Phe 1.00.

Boc-Gly-Gly-Phe-OBzl (38). Boc-Gly-Gly-OH[1] (2.58 g, 8 mmol) and H-Phe-OBzl·TsOH[16,17] (3.42 g, 8 mmol) were coupled by the same method as described for the preparation of **12**. This product was obtained in an oily form: yield 2.59 g (69%); R_f^1 0.93 and R_f^2 0.69.

H-Gly-Gly-Phe-OBzl·HCl (39). Compound **38** (2.59 g, 5.49 mmol) was treated as described in the case of **13**: yield 2.15 g (97%); mp 122—123 °C; $[\alpha]_D^{20}$ −2.0° (*c* 1, methanol); R_f^1 0.67 and R_f^2 0.27.

Found: C, 56.61; H, 6.02; N, 9.87%. Calcd for $C_{20}H_{23}O_4N_3\cdot HCl\cdot H_2O$: C, 56.65; H, 5.96; N, 9.91%.

Boc-Pro-Pro-Gly-Gly-Phe-OBzl (40). Boc-Pro-Pro-OH[7,9] (1.56 g, 5 mmol) and compound **39** (2.02 g, 5 mmol) were coupled by the same method as described for the preparation of **12**. This product was obtained in a hygroscopic form: yield 2.13 g (64%); R_f^1 0.76 and R_f^2 0.65.

H-Pro-Pro-Gly-Gly-Phe-OBzl·HCl (41). Compound **40** (2.13 g, 3.2 mmol) was treated as described in the case of **13**: yield 1.80 g (94%); mp 94—97 °C; $[\alpha]_D^{20}$ −35.0° (*c* 1, methanol); R_f^1 0.68 and R_f^2 0.32.

Found: C, 59.08; H, 6.44; N, 11.59%. Calcd for $C_{30}H_{37}O_6N_5\cdot HCl\cdot 1/2\ H_2O$: C, 59.14; H, 6.47; N, 11.50%.

Z-Arg(NO₂)-Gly-Pro-Pro-Gly-Gly-Phe-OBzl (42). Z-Arg(NO₂)-Gly-OH[7,10] (0.82 g 2 mmol) and compound **41** (1.19 g, 2 mmol) were coupled by the same method as described for the preparation of **12**: yield 1.43 g (79%); mp 121—123 °C; $[\alpha]_D^{20}$ −63.0° (*c* 1, acetic acid); R_f^1 0.75 and R_f^2 0.53.

Found: C, 56.11; H, 6.13; N, 15.72%. Calcd for $C_{46}H_{57}O_{12}N_{11}\cdot 3/2\ H_2O$: C, 56.19; H, 6.16; N, 15.67%.

H-Arg-Gly-Pro-Pro-Gly-Gly-Phe-OH (5). Compound **42** (0.96 g, 1 mmol) was treated as described in the case of **1**: yield 0.63 g (84%); mp 124 °C; $[\alpha]_D^{20}$ −72.0° (*c* 1, H_2O); R_f^1 0.19 and R_f^2 0.00.

Found: C, 52.35; H, 6.85; N, 18.47%. Calcd for $C_{31}H_{46}O_8N_{10}\cdot 1/2\ H_2O\cdot CH_3COOH$: C, 52.43; H, 6.81; N, 18.53%.

Amino acid ratios in acid hydrolyzate: Arg 0.92, Gly 3.01, Pro 1.98, Phe 1.00.

Boc-Phe-Phe-OBzl (43). Boc-Phe-OH·DCHA[15] (14.74 g, 33 mmol) and H-Phe-OBzl·TsOH[16] (12.82 g, 30 mmol) were coupled by the same method as described for the preparation of **12**: yield 13.01 g (86%); mp 144—146 °C (lit,[17] 148—149 °C); $[\alpha]_D^{20}$ −6.0° (*c* 1, DMF); R_f^1 0.99 and R_f^2 0.95.

Found: C, 71.61; H, 6.87; N, 5.55%. Calcd for $C_{30}H_{34}O_5N_2$: C, 71.68; H, 6.83; N, 5.58%.

H-Phe-Phe-Bzl·HCl (44). Compound **43** (10.05 g, 20 mmol) was treated as described in the case of **13**: yield 7.89 g (83%); mp 155—157 °C; $[\alpha]_D^{20}$ +10° (*c* 1, DMF); R_f^1 0.87 and R_f^2 0.71.

Found: C, 63.15; H, 5.79; N, 6.01%. Calcd for $C_{25}H_{26}O_3N_2\cdot HCl$: C, 63.21; H, 5.74; N, 5.90%.

Boc-Pro-Pro-Phe-Phe-OBzl (45). Boc-Pro-Pro-OH[7,9] (1.56 g, 5 mmol) and compound **46** (2.37 g, 5 mmol) were coupled by the same method as described for the preparation of **12**: yield 3.03 g (87%); mp 130—131 °C; $[\alpha]_D^{20}$ −80.0° (*c* 1, methanol); R_f^1 0.98 and R_f^2 0.68.

Found: C, 69.20; H, 6.81; N, 7.99%. Calcd for $C_{40}H_{48}O_7N_4$: C, 68.93; H, 6.96; N, 8.04%.

H-Pro-Pro-Phe-Phe-OBzl·HCl (46). Compound **45** (2.09 g, 3 mmol) was treated as described in the case of **13**: yield 1.89 g (98%); mp 78—79 °C; $[\alpha]_D^{20}$ −79.0° (*c* 1, methanol); R_f^1 0.69 and R_f^2 0.35.

Found: C, 65.57; H, 6.71; N, 8.68%. Calcd for $C_{35}H_{40}O_5N_4\cdot HCl\cdot 1/2\ H_2O$: C, 65.46; H, 6.61; N, 8.73%.

Z-Arg(NO₂)-Gly-Pro-Pro-Phe-Phe-OBzl (47). To a solution of Z-Arg(NO₂)-Gly-OH[7,10] (0.82 g, 2 mmol) in DMF (10 ml), DCC (0.41 g, 2 mmol), and HOBt (0.27 g, 2 mmol) were added at 0 °C. After 20 min, a solution of compound **46** (1.27 g, 2 mmol) and NMM (0.22 ml, 2 mmol) in DMF (10 ml) was added to the mixture. The mixture was cooled at 0 °C for 1 h and allowed to stand overnight at room temperature. The DCUrea was removed by filtration, and the filtrate was evaporated *in vacuo*. The oily residue was dissolved in ethyl acetate and the solution was

washed with water, 2% hydrochloric acid, 4% sodium hydrogencarbonate, and water successively. The solution was dried over anhydrous sodium sulfate. Sodium sulfate was removed by filtration, and the filtrate was evaporated *in vacuo*. The residue was crystallized with ether–petroleum ether: yield 1.07 g (54%); mp 115—117 °C; $[\alpha]_D^{20}$ −64.0° (*c* 1, acetic acid); R_f^1 0.69 and R_f^2 0.42.

Found: C, 60.35; H, 6.21; N, 13.68%. Calcd for $C_{51}H_{60}O_{11}N_{10}\cdot 3/2\ H_2O$: C, 60.27; H, 6.26; N, 13.79%.

H-Arg-Gly-Pro-Pro-Phe-Phe-OH (6). Compound **47** (0.79 g, 0.8 mmol) was treated as described in the case of **1**: yield 0.50 g (80%); mp 108—111 °C; $[\alpha]_D^{20}$ −73.0° (*c* 1, H_2O); R_f^1 0.25 and R_f^2 0.00.

Found: C, 54.91; H, 6.98; N, 14.21%. Calcd for $C_{36}H_{49}O_7N_9\cdot 2CH_3COOH\cdot 2H_2O$: C, 54.83; H, 7.03; N, 14.39%.

Amino acid ratios in acid hydrolyzate: Arg 0.93, Gly 1.01, Pro 1.98, Phe 2.00.

Boc-Gly-Phe-Phe-OBzl (48). Boc-Gly-OH[13] (1.75 g, 10 mmol) and compound **44** (4.75 g, 10 mmol) were coupled by the same method as described for the preparation of **12**: yield 5.26 g (94%); mp 129—130 °C; $[\alpha]_D^{20}$ −11.0° (*c* 1, methanol); R_f^1 0.89 and R_f^2 0.63.

Found: C, 68.74; H, 6.62; N, 7.55%. Calcd for $C_{32}H_{37}O_6N_3$: C, 68.67; H, 6.68; N, 7.51%.

H-Gly-Phe-Phe-OBzl·HCl (49). Compound **48** (4.48 g, 8 mmol) was treated as described in the case of **13**: yield 3.56 g (90%); mp 143—145 °C; $[\alpha]_D^{20}$ −2.0° (*c* 1, methanol); R_f^1 0.70 and R_f^2 0.63.

Found: C, 63.37; H, 6.25; N, 8.24%. Calcd for $C_{27}H_{29}O_4N_3\cdot HCl\cdot H_2O$: C, 63.44; H, 6.32; N, 8.22%.

Boc-Pro-Pro-Gly-Phe-Phe-OBzl (50). Boc-Pro-Pro-OH[7,9] (1.56 g, 5 mmol) and compound **49** (2.47 g, 5 mmol) were coupled by the same method as described for the preparation of **12**: yield 3.17 g (84%); mp 75—76 °C; $[\alpha]_D^{20}$ −54.0° (*c* 1, methanol); R_f^1 0.77 and R_f^2 0.46.

Found: C, 66.97; H, 6.75; N, 9.33%. Calcd for $C_{42}H_{51}O_8N_5$: C, 66.91; H, 6.83; N, 9.29%.

H-Pro-Pro-Gly-Phe-Phe-OBzl·HCl (51). Compound **50** (2.26 g, 3 mmol) was treated as described in the case of **13**: yield 1.90 g (92%); mp 95—97 °C; $[\alpha]_D^{20}$ −44.0° (*c* 1, methanol); R_f^1 0.46 and R_f^2 0.30.

Found: C, 62.83; H, 6.42; N, 9.77%. Calcd for $C_{37}H_{43}O_6N_5\cdot HCl\cdot H_2O$: C, 62.74; H, 6.49; N, 9.81%.

Z-Arg(NO$_2$)-Gly-Pro-Pro-Gly-Phe-Phe-OBzl (52). Z-Arg(NO_2)-Gly-OH[7,10] (0.82 g, 2 mmol) and compound **51** (1.38 g, 2 mmol) were coupled by the same method as described for the preparation of **47**: yield 1.68 g (80%); mp 93—96 °C; $[\alpha]_D^{20}$ −54.0° (*c* 1, acetic acid); R_f^1 0.94 and R_f^2 0.50.

Found: C, 60.35; H, 6.13; N, 14.54%. Calcd for $C_{53}H_{63}O_{12}N_{11}\cdot 1/2\ H_2O$: C, 60.32; H, 6.13; N, 14.60%.

H-Arg-Gly-Pro-Pro-Gly-Phe-Phe-OH (7). Compound **52** (1.05 g, 1 mmol) was treated as described in the case of **1**: yield 0.74 g (88%); mp 110 °C; $[\alpha]_D^{20}$ −71.0° (*c* 1, H_2O); R_f^1 0.22 and R_f^2 0.00.

Found: C, 57.36; H, 6.80; N, 16.77%. Calcd for $C_{38}H_{52}O_8N_{10}\cdot CH_3COOH$: C, 57.40; H, 6.76; N, 16.74%.

Amino acid ratios in acid hydrolyzate: Arg 0.92, Gly 2.00, Pro 1.98, Phe 2.00.

Boc-Gly-Gly-Phe-Phe-OBzl (53). Boc-Gly-Gly-OH[1] (2.32 g, 10 mmol) and compound **44** (4.74 g, 10 mmol) were coupled by the same method as descried for the preparation of **12**: yield 5.24 g (85%); mp 81—82 °C; $[\alpha]_D^{20}$ −6.0° (*c* 1, methanol); R_f^1 0.93 and R_f^2 0.55.

Found: C, 63.39; H, 6.71; N, 8.74%. Calcd for $C_{34}H_{40}O_7N_4\cdot 3/2\ H_2O$: C, 63.43; H, 6.75; N, 8.71%.

H-Gly-Gly-Phe-Phe-OBzl·HCl (54). Compound **53** (4.32 g, 7 mmol) was treated as described in the case of **13**: yield 3.76 g (97%); mp 159—161 °C; $[\alpha]_D^{20}$ −13.0° (*c* 1, methanol); R_f^1 0.75 and R_f 0.43.

Found: C, 61.05; H, 6.14; N, 9.80%. Calcd for $C_{29}H_{32}O_5N_4\cdot HCl\cdot H_2O$: C, 60.98; H, 6.19; N, 9.81%.

Boc-Pro-Pro-Gly-Gly-Phe-Phe-OBzl (55). Boc-Pro-Pro-OH[7,9] (1.56 g, 5 mmol) and compound **54** (2.77 g, 5 mmol) were coupled by the same method as described for the preparation of **12**: yield 3.51 g (87%); mp 88—90 °C; $[\alpha]_D^{20}$ −53.0° (*c* 1, methanol); R_f^1 0.74 and R_f^2 0.41.

Found: C, 63.70; H, 6.79; N, 10.17%. Calcd for $C_{44}H_{54}O_9N_6\cdot H_2O$: C, 63.75; H, 6.82; N, 10.14%.

H-Pro-Pro-Gly-Gly-Phe-Phe-OBzl·HCl (56). Compound **55** (2.43 g, 3 mmol) was treated as described in the case of **13**: yield 2.09 g (93%); mp 101—103 °C; $[\alpha]_D^{20}$ −38.0° (*c* 1, methanol); R_f^1 0.58 and R_f^2 0.39.

Found: C, 61.17; H, 6.52; N, 10.95%. Calcd for $C_{39}H_{46}O_7N_6\cdot HCl\cdot H_2O$: C, 61.21; H, 6.47; N, 10.98%.

Z-Arg(NO$_2$)-Gly-Pro-Pro-Gly-Gly-Phe-Phe-OBzl (57). Z-Arg(NO_2)-Gly-OH[7,10] (0.82 g, 2 mmol) and compound **56** (1.49 g, 2 mmol) were coupled by the same method as described for the preparation of **12**: yield 1.79 g (81%); mp 116—119 °C; $[\alpha]_D^{20}$ −48.0° (*c* 0.5, acetic acid); R_f^1 0.90 and R_f^2 0.32.

Found: C, 59.30; H, 6.02; N, 15.17%. Calcd for $C_{55}H_{66}O_{13}N_{12}\cdot 1/2\ H_2O$: C, 59.39; H, 6.08; N, 15.12%.

H-Arg-Gly-Pro-Pro-Gly-Gly-Phe-Phe-OH (8). Compound **57** (1.10 g, 1 mmol) was treated as described in the case of **1**: yield 0.72 g (81%); mp 128—130 °C; $[\alpha]_D^{20}$ −61.0° (*c* 1, H_2O); R_f^1 0.19 and R_f^2 0.00.

Found: C, 54.81; H, 6.85; N, 16.70%. Calcd for $C_{40}H_{55}O_9N_{11}\cdot 3/2\ H_2O\cdot CH_3COOH$: C, 54.76; H, 6.80; N, 16.73%.

Amino acid ratios in acid hydrolyzate: Arg 0.93, Gly 2.99, Pro 2.02, Phe 2.00.

Boc-Gly-Gly-Gly-Phe-Phe-OBzl (58). Boc-Gly-Gly-OH[1] (2.32 g, 10 mmol) and compound **49** (4.93 g, 10 mmol) were coupled by the same method as described for the preparation of **12**: yield 5.46 g (81%); mp 175—176 °C; $[\alpha]_D^{20}$ −11.0° (*c* 1, methanol); R_f^1 0.93 and R_f^2 0.58.

Found: C, 64.15; H, 6.49; N, 10.39%. Calcd for $C_{36}H_{43}O_8N_5$: C, 64.17; H, 6.45; N, 10.40%.

H-Gly-Gly-Gly-Phe-Phe-OBzl·HCl (59). Compound **58** (4.72 g, 7 mmol) was treated as described in the case of **13**: yield 4.03 g (94%); mp 170—173 °C; $[\alpha]_D^{20}$ −12.0° (*c* 1, methanol); R_f^1 0.63 and R_f^2 0.34.

Found: C, 60.97; H, 5.99; N, 11.53%. Calcd for $C_{31}H_{35}O_6N_5\cdot HCl$: C, 61.02; H, 5.96; N, 11.50%.

Boc-Pro-Pro-Gly-Gly-Gly-Phe-Phe-OBzl (60). Boc-Pro-Pro-OH[7,9] (1.56 g, 5 mmol) and compound **59** (3.05 g, 5 mmol) were coupled by the same method as described for the preparation of **12**: yield 3.63 g (84%); mp 130—131 °C; $[\alpha]_D^{20}$ −52.0° (*c* 1, methanol) R_f^1 0.73 and R_f^2 0.54.

Found: C, 63.60; H, 6.81; N, 11.33%. Calcd for $C_{46}H_{57}O_{10}N_7\cdot H_2O$: C, 63.64; H, 6.86; N, 11.30%.

H-Pro-Pro-Gly-Gly-Gly-Phe-Phe-OBzl·HCl (61). Compound **60** (2.60 g, 3 mmol) was treated as described in the case of **13**: yield 2.34 g (97%); mp 137—140 °C; $[\alpha]_D^{20}$ −29.0° (*c* 1, methanol); R_f^1 0.58 and R_f^2 0.30.

Found: C, 59.93; H, 6.31; N, 11.90%. Calcd for $C_{41}H_{49}O_8N_7\cdot HCl\cdot H_2O$: C, 59.88; H, 6.37; N, 11.93%.

Z-Arg(NO$_2$)-Gly-Pro-Pro-Gly-Gly-Gly-Phe-Phe-OBzl (62). Z-Arg(NO_2)-Gly-OH[7,10] (0.82 g, 2 mmol) and compound **61** (1.61 g, 2 mmol) were coupled by the same method as described for the preparation of **12**. This product was obtained in a hygroscopic form: yield 1.72 g (74%); R_f^1 0.85 and R_f^2 0.52.

H-Arg-Gly-Pro-Pro-Gly-Gly-Gly-Phe-Phe-OH (9). Compound **62** (1.15 g, 1 mmol) was treated as described in the case of **1**: yield 0.67 g (70%); mp 137—140 °C; $[\alpha]_D^{20}$

$-50.0°$ (c 1, H_2O); R_f^1 0.21 and R_f^2 0.00.

Found: C, 54.55; H, 6.61; N, 17.33%. Calcd for $C_{42}H_{58}O_{10}N_{12}\cdot H_2O\cdot CH_3COOH$: C, 54.52; H, 6.67; N, 17.35%.

Amino acid ratios in acid hydrolyzate: Arg 0.93, Gly 3.98, Pro 1.99, Phe 2.00.

Boc-Phe-Phe-Phe-OBzl (63). Boc-Phe-OH·DCHA[15] (5.36 g, 12 mmol) and compound **49** (4.74 g, 10 mmol) were coupled by the same method as described for the preparation of **12**: yield 5.78 g (89%); mp 170—172 °C; $[\alpha]_D^{20}$ $-27.5°$ (c 1, methanol); R_f^1 0.99 and R_f^2 0.89.

Found: C, 72.13; H, 6.76; N, 6.49%. Calcd for $C_{39}H_{43}O_6N_3$: C, 72.09; H, 6.77; N, 6.46%.

H-Phe-Phe-Phe-OBzl·HCl (64). Compound **63** (5.30 g, 8.15 mmol) was treated as described in the case of **13**: yield 4.55 g (95%); mp 186 °C (decomp); $[\alpha]_D^{20}$ $-9.0°$ (c 1, methanol); R_f^1 0.91 and R_f^2 0.81.

Found: C, 69.70; H, 6.19; N, 7.15%. Calcd for $C_{34}H_{35}O_4N_3\cdot HCl$: C, 69.67; H, 6.19; N, 7.13%.

Boc-Pro-Pro-Phe-Phe-Phe-OBzl (65). Boc-Pro-Pro-OH[7,9] (1.56 g, 5 mmol) and compound **64** (2.93 g, 5 mmol) were coupled by the same method as described for the preparaton of **12**: yield 3.46 g (82%); mp 109—112 °C; $[\alpha]_D^{20}$ $-66.5°$ (c 1, methanol); R_f^1 0.99 and R_f^2 0.84.

Found: C, 69.80; H, 6.83; N, 8.26%. Calcd for $C_{49}H_{57}O_8N_5$: C, 69.76; H, 6.81; N, 8.30%.

H-Pro-Pro-Phe-Phe-Phe-OBzl·HCl (66). Compound **65** (2.53 g, 3 mmol) was treated as described in the case of **13**: yield 2.22 g (95%); mp 100—103 °C; $[\alpha]_D^{20}$ $-76.5°$ (c 1, methanol); R_f^1 0.82 and R_f^2 0.40.

Found: C, 66.92; H, 6.48; N, 8.88%. Calcd for $C_{44}H_{49}O_6N_5\cdot HCl\cdot 1/2\ H_2O$: C, 66.95; H, 6.51; N, 8.87%.

Z-Arg(NO$_2$)-Gly-Pro-Pro-Phe-Phe-Phe-OBzl (67). Z-Arg(NO_2)-Gly-OH[7,10] (0.82 g, 2 mmol) and compound **66** (1.56 g, 2 mmol) were coupled by the same method as described for the preparation of **12**: yield 1.75 g (77%); mp 114—117 °C; $[\alpha]_D^{20}$ $-69.5°$ (c 1, methanol); R_f^1 0.84 and R_f 0.55.

Found: C, 62.47; H, 6.27; N, 13.32%. Calcd for $C_{60}H_{70}O_{12}N_{11}\cdot H_2O$: C, 62.43; H, 6.30; N, 13.35%.

H-Arg-Gly-Pro-Pro-Phe-Phe-Phe-OH (10). Compound **67** (1.14 g, 1 mmol) was treated as described in the case of **1**: yield 0.74 g (76%); mp 127—130 °C; $[\alpha]_D^{20}$ $-64.0°$ (c 1, acetic acid); R_f^1 0.29 and R_f^2 0.00.

Found: C, 60.25; H, 6.79; N, 15.03%. Calcd for $C_{45}H_{58}O_8N_{10}\cdot 1/2\ H_2O\cdot CH_3COOH$: C, 60.29; H, 6.80; N, 14.96%.

Amino acid ratios in acid hydrolyzate: Arg 0.95, Gly 1.00, Pro 2.08, Phe 2.99.

CD Measurement. The measurements were performed with a JASCO J-20 Automatic Recording Spectropolarimeter over a wavelength range of 200 to 250 nm. A cell of path length 0.2 mm was used and the runs were made at ambient temperature. Patterns in a solvent of distilled water are shown in Fig. 6.

Sensory Test. The bitterness of the synthetic BPIa analogs was organoleptically determined *via* panel evaluation by five people. A series of solution of decreasing concentration was prepared in which each solution was half as strong as its proceeding one. Before testing the sample, the tester's month was thoroughly rinsed with distilled water. The sample size was usually 2—3 ml. The sample solution was held in the mouth for *ca.* 10 s and then spit out. The threshold values of synthetic BPIa analogs are shown in the Table.

The authors wish to express their thanks to Professor Sakuzo Fukui of Hiroshima University for his helpful discussion in the course of this study. Thanks are also due to Associate Professor Michio Kondo of Saga University for his help in the CD measurements, and to Dr. Shinji Okumura of Ajinomoto Co. Inc., for supplying some amino acids.

Studies of Bitter Peptides from Casein Hydrolyzate. VI.[1] Syntheses and Bitter Taste of BPIc (Val-Tyr-Pro-Phe-Pro-Pro-Gly-Ile-Asn-His) and Its Analogs and Fragments[2]

Hidenori KANEHISA
Research and Development Division, Sunstar Inc., Asahi-cho, Takatsuki, Osaka 569
(Received June 15, 1983)

In order to investigate the relationship between chemical structure and bitter taste, the bitter peptide BPIc (Val-Tyr-Pro-Phe-Pro-Pro-Gly-Ile-Asn-His) isolated from casein hydrolyzate by Minamiura *et al.* and its analogs and fragments were synthesized. BPIc, whose threshold value of bitter taste was 0.05 mM, was found to be one of the most bitter compounds, like quinine and phenylthiourea. However, [Gly^{5,6}]- and [Gly^{9,10}]-BPIc, and N-terminal octa- and heptapeptide fragments of BPIc possessed much weaker bitterness than BPIc. The results suggested that 5,6-proline and the basic nature of C-terminal are necessary for the strong bitterness exhibited by BPIc.

In a series of studies of bitter peptides, the first paper[3] described the synthesis of bitter peptide BPIa (H-Arg-Gly-Pro-Pro-Phe-Ile-Val-OH) isolated from enzymatic hydrolyzate of cow milk casein by Minamiura *et al.*[4] The peptide possessed an extremely bitter taste of the same level as well known bitter substances such as quinine and phenylthiourea. The threshold value of bitter taste of BPIa was found to be 0.05 mM (1 M=1 mol dm^{-3}). To elucidate the structure-taste relationship of BPIa, its numerous fragments and analogs were prepared and their tastes were measured.[1,5-7] All the fragments except N-terminal hexapeptide fragment exhibited a weaker bitterness than BPIa itself.[5] Des-Gly^2-BPIa was the same as BPIa,[5] whereas the analogs in which prolylproline residue was substituted for glycylglycine or D-prolyl-D-proline residues exhibited a weaker bitterness than BPIa.[6] The results of their CD examinations in water also suggested that at least six amino acid residues are necessary for the exhibition of strong bitterness and that the spatial structure of BPIa molecule attributed to L-proline residue at 3-position contributes to its bitter taste.[5,6] In order to clarify the nature of the N-terminal arginine residue, the strength of bitterness for Arg^1-substituted analogs were compared with that of des-Gly^2-BPIa.[1] When the position of arginine was filled by another basic amino acid, the analogs possessed a bitter taste. However, the strength of bitterness decreased with reducing of the side-chain length of the basic amino acid residues. On the other hand, the analogs in which the position of arginine was replaced by hydrophobic or bulky side chain amino acid still possessed a bitter taste. However its strength was slightly weaker than that of basic amino acid-substituted analogs. The C-terminal moiety in the sequence of BPIa was studied; the analog in which C-terminal tripeptide moiety of BPIa was substituted for triphenylalanine residue possessed the strongest bitterness in the series of BPIa analogs.[7] The results suggested that both basic amino acid residue in N-terminal position and hydrophobic amino acid residues in C-terminal moiety are necessary for an intense bitterness in BPIa. This finding is also supported from taste behavior results: that des-Arg^1-BPIa and the N-terminal pentapeptide fragment of BPIa exhibited a much weaker bitterness than BPIa.[5]

Minamiura *et al.* isolated a bitter decapeptide named BPIc from casein hydrolyzate in addition to BPIa and decided that its amino acid sequence was H-Val-Tyr-Pro-Phe-Pro-Pro-Gly-Ile-Asn-His-OH.[4] It is interesting to compare the structure of BPIc with that of BPIa. They have several characteristic features in common. These peptides include prolylproline residue in the center of the molecules. Also, they include a basic amino acid residue (histidine or arginine) and some hydrophobic amino acid residues (valine, phenylalanine, isoleucine, and/or tyrosine) on both terminal positions in these molecules. Although BPIc is extremely bitter according to Minamiura *et al.*,[4] no study has made on the synthesis of BPIc.

In order to elucidate the relationship between chemical structure and bitterness of peptides, the author prepared BPIc. The author also prepared [Gly^{5,6}]-BPIc, in which prolylproline residue at 5,6-position was replaced by glycylglycine, and [Gly^{9,10}]-BPIc and N-terminal octa- and heptapeptide fragments, based on the findings in the synthetic studies of BPIa. The present paper describes the syntheses and bitter taste of BPIc and its analogs and fragments.

The sequence of reactions employed for the synthesis of BPIc is shown in Fig. 1. Acyldipeptide acid (**2**), derived from the corresponding methyl ester (**1**), was condensed with H-Pro-Phe-OEt·HCl (**4**) to yield the protected N-terminal tetrapeptide derivative (**5**) by means of the dicyclohexylcarbodiimide-1-hydroxybenzotriazole (DCC-HOBt) method. It was converted to the corresponding acid (**6**) by saponification with sodium hydroxide. Acyltripeptide ester (**8**) was prepared from Boc-Pro-Pro-OH (**7**) and H-Gly-OBzl·TsOH by the mixed anhydride (MA) method, and then the N-terminal protected group of **8** was removed by the action of hydrogen chloride in dioxane to yield the tripeptide ester hydrochloride (**9**).

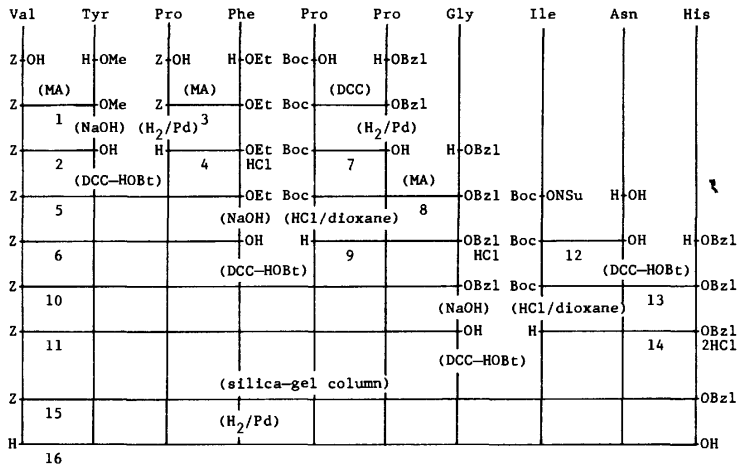

Fig. 1. Synthesis of BPIc.

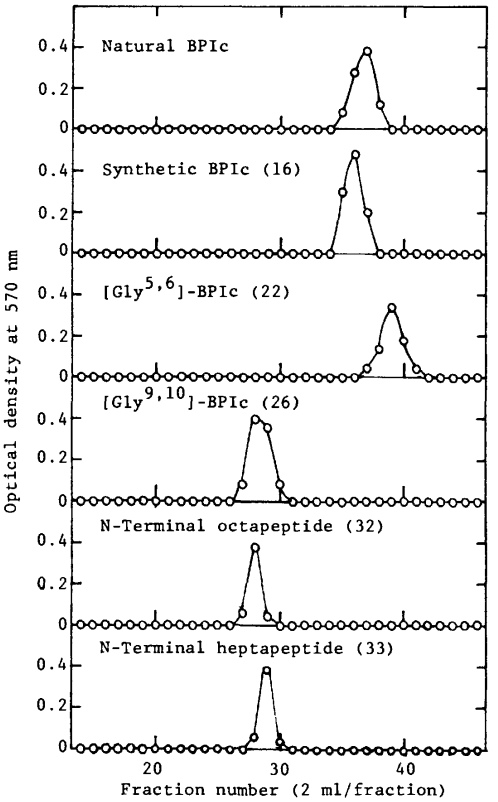

Fig. 2. Carboxymethylcellulose column chromatography of synthetic and natural BPIc. Solvent: 0.2 M pyridinium acetate, pH 5.0.

9 was coupled with **6** by the DCC-HOBt method and the resulting acylheptapeptide ester (**10**) was easily converted to the corresponding acid (**11**) by saponification. Asparagine was acylated to Boc-Ile-Asn-OH (**12**) with Boc-Ile-ONSu, then **12** and H-His-OBzl·2TsOH were coupled to yield acyltripeptide ester (**13**) by the DCC-HOBt method. The amino protection of **13** was removed by the action of hydrogen chloride in 98% formic acid. The compound **14** thus obtained and **11** were condensed by the DCC-HOBt method in DMF. The resulting acyldecapeptide ester (**15**) was purified with extraction of 1-butanol, and then the extract was placed on a silica-gel column and eluted with chloroform-methanol (5:1, v/v). The catalytic hydrogenation of pure **15** in methanol containing hydrogen chloride gave decapeptide BPIc (**16**).

The preparation of [Gly^{5,6}]-BPIc was described as follows. **6** was condensed with triglycine ethyl ester (**18**) by the DCC-HOBt method and the obtained heptapeptide (Z-Val-Tyr-Pro-Phe-Gly-Gly-Gly-OEt, **19**) was easily saponified to yield the corresponding acid (**20**), which was made to condense with **14** by the DCC-HOBt method. The Z-Val-Tyr-Pro-Phe-Gly-Gly-Gly-Ile-Asn-His-OBzl (**21**) thus obtained was hydrogenated in the presence of palladium black to give [Gly^{5,6}]-BPIc (**22**).

[Gly^{9,10}]-BPIc was prepared as described below. Boc-Ile-OH was coupled with H-Gly-Gly-OBzl·HCl by the MA method to give Boc-Ile-Gly-Gly-OBzl (**23**). It was converted to the corresponding tripeptide ester hydrochloride (**24**) by the treatment of hydrogen chloride in dioxane. Then **24** and **11** were condensed by the DCC-HOBt method to yield Z-Val-Tyr-Pro-Phe-Pro-Pro-Gly-Ile-Gly-Gly-OBzl (**25**). It was hydrogenated to give [Gly^{9,10}]-BPIc (**26**).

N-Terminal octapeptide fragment of BPIc was synthesized by the following procedures. Boc-Gly-OH and H-Ile-OBzl·TsOH were coupled by the MA method to give Boc-Gly-Ile-OBzl (**27**). This was converted to the corresponding dipeptide ester hydrochloride (**28**) by the action of hydrogen chloride in dioxane. **28** and **7** were condensed by the MA method to yield Boc-Pro-Pro-Gly-Ile-OBzl (**29**). This was converted to the corresponding tetrapeptide ester hydrochloride (**30**) by the action of hydrogen chloride in dioxane. **30** and **6** were then condensed by the DCC-HOBt method to give Z-Val-Tyr-Pro-Phe-Pro-Pro-Gly-Ile-OBzl (**31**). Catalytic hydrogenation of **31** gave N-terminal octapeptide fragment of BPIc (**32**). The N-terminal heptapeptide fragment of BPIc, H-Val-Tyr-Pro-Phe-Pro-Pro-Gly-OH (**33**), was obtained from **9** by hydrogenation.

The purity of synthetic BPIc, its analogs and fragments, and their intermediates was confirmed by thin-layer examinations on two solvent systems, and by elemental analyses. The homogeneity of the final products was also confirmed by paper electrophoresis, carboxymethylcellulose column chromatography, and amino acid analysis.

The taste of final products was organoleptically determined by panel evaluation employing several persons. The results are listed in the Table. All the synthetic peptides possessed a bitter taste. BPIc, whose threshold value of bitterness was 0.05 mM, was the same as BPIa. However, the strength of bitterness of BPIc analog **22** was *ca.* 1/5 of that of BPIc. This means that 5,6-proline residues are necessary

Table. The threshold values for bitter taste of BPIc and its analogs and fragments

Compound		Threshold values for bitter taste/mM
Val-Tyr-Pro-Phe-Pro-Pro-Gly-Ile-Asn-His	(BPIc, **16**)	0.05
Val-Tyr-Pro-Phe-Gly-Gly-Gly-Ile-Asn-His	(**22**)	0.23
Val-Tyr-Pro-Phe-Pro-Pro-Gly-Ile-Gly-Gly	(**26**)	0.30
Val-Tyr-Pro-Phe-Pro-Pro-Gly-Ile	(**32**)	0.15
Val-Tyr-Pro-Phe-Pro-Pro-Gly	(**33**)	0.30
Ile-Asn-His[8]		25.00
Asn-His[8]		100.00

for the strong bitterness of BPIc. The analog **26** was one-sixth as bitter as BPIc. Also, bitterness of BPIc fragments (**32** and **33**) was weaker than that of BPIc. Further, H-Ile-Asn-His-OH and H-Asn-His-OH were nearly tasteless. These results indicate that the basic nature of C-terminal position in BPIc, in addition to the hydrophobic nature of its N-terminal contributes to its bitter taste. The findings obtained from BPIc are equivalent to those from BPIa. Therefore, BPIc can be regarded as a retro form of BPIa possessing a reverse sequence of BPIa; in bitter peptides contain prolylproline residue in the center of the molecule and both basic and hydrophobic amino acid residues in N- and C-terminal positions respectively, it is possible for N- and C-terminal amino acid residues to change places with each other. Further studies of this problem are in progress.

Experimental

All melting points are uncorrected. Thin layer chromatography was carried out on Merck silica-gel G. Developing solvents commonly used were (1) 1-butanol-acetic acid-pyridine-water (4:1:1:2, v/v), and (2) chloroform-methanol (5:1, v/v). Materials possessing free amino groups on a thin layer plate were detected by spraying with ninhydrin. Compounds with blocked amino groups were detected by spraying with 25% hydrogen bromide in acetic acid and then with ninhydrin. Optical rotations were measured on a JASCO automatic polarimeter, DIR-SL type. Amino acid analyses were performed with a Hitachi amino acid analyzer, KLA-5 type. Prior to analysis, compounds were dried over phosphorus pentaoxide at 66 °C and 2 mmHg (1 mmHg≈133.332 Pa) for 2 h.

Synthesis of BPIc. *Z-Val-Tyr-OMe (1)*: A solution of Z-Val-OH[9] (10.05 g, 40 mmol) and NMM (4.4 ml, 40 mmol) in THF (100 ml) was chilled to −5 °C, then ECF (4 ml, 40 mmol) was added to it. After 10 min, a precooled solution of H-Tyr-OMe·HCl[10] (14.64 g, 40 mmol) and NMM (4.4 ml, 40 mmol) in DMF (100 ml) was added to it. The reaction mixture was refrigerated for 1 h and then allowed to stand overnight at room temperature. The mixture was evaporated *in vacuo*, and the oily residue was dissolved in ethyl acetate (400 ml). The solution was washed successively with 4% sodium hydrogencarbonate, 0.5 M hydrochloric acid and water, and then dried over anhydrous sodium sulfate. The solution was concentrated to an oily residue which was crystallized by addition of ether; yield 15.13 g (88%); mp 152—153 °C (lit,[11] 150 °C); $[\alpha]_D^{20}$ +14.0° (*c* 1, pyridine) (lit,[11] +12.1° (*c* 1, pyridine)); R_f^1 0.98 and R_f^2 0.69.

Found: C, 64.30; H, 6.74; N, 6.53%. Calcd for $C_{23}H_{28}O_6N_2$: C, 64.47; H, 6.59; N, 6.54%.

Z-Val-Tyr-OH (2): To a solution of **1** (12.9 g, 30 mmol) in methanol (40 ml), 2 M sodium hydroxide (31 ml) was added. The reaction mixture was allowed to stand for 1 h at room temperature and then diluted with water (40 ml). The mixture was then extracted with ether. The aqueous layer was acidified to pH 2 with 2 M hydrochloric acid. The oily product was extracted with ethyl acetate (400 ml). The organic layer was washed with water and dried with anhydrous sodium sulfate. The filtrate was evaporated *in vacuo*, the oily residue was crystallized by ether and petroleum ether; yield 8.60 g (69%); mp 163—164 °C (lit,[12] 161—163 °C); $[\alpha]_D^{20}$ +26.5° (*c* 1, pyridine) (lit,[12] +26.0° (*c* 1, pyridine)); R_f^1 0.85 and R_f^2 0.24.

Found: C, 63.91; H, 6.52; N, 6.73%. Calcd for $C_{22}H_{26}O_6N_2$: C, 63.75; H, 6.32; N, 6.76%.

Z-Pro-Phe-OEt (3): This compound was obtained from Z-Pro-OH[13] (9.95 g, 40 mmol) and H-Phe-OEt·TsOH[14] (16.45 g, 45 mmol), as described for the preparation of **1**; yield 12.68 g (75%) mp 67—68 °C (lit,[15] 65—68 °C); $[\alpha]_D^{20}$ −39.8° (*c* 1, methanol) (lit,[15] −33° (alcohol)); R_f^1 0.96 and R_f^2 0.92.

Found: C, 67.79; H, 6.65; N, 6.62%. Calcd for $C_{24}H_{28}O_5N_2$: C, 67.90; H, 6.65; N, 6.60%.

H-Pro-Phe-OEt·HCl (4): Compound **3** (11.46 g, 27 mmol) was hydrogenated in the presence of palladium black and 0.3 M methanolic hydrogen chloride (100 ml). The filtrate from catalyst was evaporated *in vacuo*, and the residue was crystallized from ether. It was recrystallized from ethanol-ether; yield 8.35 g (94%); 149—150 °C; $[\alpha]_D^{20}$ −41.5° (*c* 1, water) (lit,[16] −40.9° (*c* 2, water)); R_f^1 0.79 and R_f^2 0.66.

Found: C, 58.69; H, 7.16; N, 8.56%. Calcd for $C_{16}H_{23}O_3N_2Cl$: C, 58.77; H, 7.09; N, 8.56%.

Z-Val-Tyr-Pro-Phe-OEt (5): To a chilled solution of **2** (9.95 g, 24 mmol), **4** (8.17 g, 25 mmol), NMM (2.75 ml, 25 mmol) and HOBt (3.38 g, 25 mmol) in THF (100 ml), DCC (4.95 g, 24 mmol) was added. The reaction mixture was held overnight at 0 °C and the DCUrea which formed was filtered off. The filtrate was evaporated *in vacuo*, and the residual oil was dissolved in ethyl acetate. The solution was washed with 4% sodium hydrogencarbonate, 0.5 M hydrochloric acid and water, and dried over sodium sulfate. The filtrate was evaporated *in vacuo*, and the residue was crystallized by addition of ether and petroleum ether; yield 14.42 g (88%); mp 122—124 °C; $[\alpha]_D^{20}$ −67.0° (*c* 1, methanol); R_f^1 0.97 and R_f^2 0.64.

Found: C, 66.20; H, 6.73; N, 8.25%. Calcd for $C_{38}H_{46}O_8N_4$: C, 66.45; H, 6.75; N, 8.16%.

Z-Val-Tyr-Pro-Phe-OH (6): Compound **5** (13.73 g, 20 mmol) was saponified by 2 M sodium hydroxide (21 ml) and methanol (50 ml) for 1 h. Purification of the product

was done by the procedure used for the preparation of **2**; yield 9.17 g (70%); mp 121—124 °C; $[\alpha]_D^{20}$ −52.8° (*c* 1, methanol); R_f^1 0.88 and R_f^2 0.46.

Found: C, 65.81; H, 6.45; N, 8.47%. Calcd for $C_{36}H_{42}O_8N_4$: C, 65.64; H, 6.43; N, 8.51%.

Boc-Pro-Pro-OH (7): To a chilled solution of Boc-Pro-OH[17] (4.26 g, 20 mmol), H-Pro-OBzl·HCl[18] (5.06 g, 22 mmol) and NMM (2.4 ml, 22 mmol) in acetonitrile (50 ml), DCC (4.12 g, 20 mmol) was added. The reaction mixture was held overnight at 0 °C, then DCUrea was separated by filtration. The filtrate was evaporated *in vacuo*, the residue was dissolved in ethyl acetate and washed successively with 4% sodium hydrogencarbonate, 4% citric acid and water, and then dried over anhydrous sodium sulfate. The filtrate was evaporated *in vacuo*, and the residue was dissolved in methanol (100 ml). It was subjected to hydrogenolysis in the presence of palladium black. The filtrate from the catalyst was evaporated *in vacuo*, and the residue was crystallized with ether. It was recrystallized from hot ethyl acetate; yield 3.74 g (60%); mp 181—182 °C (lit,[19] 187—187.5 °C); $[\alpha]_D^{20}$ −118.0° (*c* 1, methanol); R_f^1 0.77 and R_f^2 0.40.

Found: C, 57.58; H, 7.90; N, 8.92%. Calcd for $C_{15}H_{24}O_5N_2$: C, 57.67; H, 7.74; N, 8.97%.

Boc-Pro-Pro-Gly-OBzl (8): This was prepared from **7** (4.69 g, 15 mmol) and H-Gly-OBzl·TsOH[20] (5.07 g, 15 mmol) as described for the preparation of **1**; yield 4.76 g (70%); mp 107—109 °C; $[\alpha]_D^{20}$ −127.8° (*c* 1, methanol); R_f^1 0.90 and R_f^2 0.74.

Found: C, 62.57; H, 7.28; N, 9.18%. Calcd for $C_{24}H_{33}O_6N_3$: C, 62.72; H, 7.24; N, 9.14%.

H-Pro-Pro-Gly-OBzl·HCl (9): Compound **8** (4.60 g, 10 mmol) was dissolved in 4 M hydrogen chloride in dioxane (25 ml) and held for 1 h at room temperature. The solution was evaporated *in vacuo*, dissolved in dioxane (20 ml), and evaporated again. A precipitate was obtained by the addition of ether. This precipitate was filtered off and dried over pellets of potassium hydroxide *in vacuo*; yield of hygroscopic powder was 3.96 g (98%); mp 65—67 °C; $[\alpha]_D^{20}$ −113.5° (*c* 1, methanol); R_f^1 0.65 and R_f^2 0.38.

Found: C, 57.38; H, 6.64; N, 10.43%. Calcd for $C_{19}H_{26}O_4N_3Cl$: C, 57.64; H, 6.62; N, 10.62%.

Z-Val-Tyr-Pro-Phe-Pro-Pro-Gly-OBzl (10): A solution of of DCC (2.06 g, 10 mmol) in THF was added to a chilled solution of **6** (6.59 g, 10 mmol), **9** (3.90 g, 10 mmol), NMM (1.1 ml, 10 mmol), and HOBt (1.48 g, 11 mmol) in THF (100 ml). The reaction mixture was held overnight at 0 °C. DCUrea was filtered off and the filtrate was evaporated *in vacuo*. The residue was dissolved in ethyl acetate. The solution was washed with 4% sodium hydrogencarbonate, 0.5 M hydrochloric acid and water, and dried over anhydrous sodium sulfate. The filtrate was evaporated *in vacuo*, and the product was obtained by addition of ether; yield 8.68 g (76%); mp 115—117 °C; $[\alpha]_D^{20}$ −118.5° (*c* 1, methanol); R_f^1 0.91 and R_f^2 0.63.

Found: C, 65.74; H, 6.62; N, 9.72%. Calcd for $C_{55}H_{65}O_{11}N_7$: C, 66.05; H, 6.55; N, 9.80%.

Z-Val-Tyr-Pro-Phe-Pro-Pro-Gly-OH (11): To a solution of **10** (8.00 g, 8 mmol) in methanol (70 ml), 2 M sodium hydroxide (9 ml) was added. The reaction mixture was held for 2 h at room temperature, then diluted with 150 ml water and extracted with ethyl acetate. The aqueous layer was acidified with 2 M hydrochloric acid and extraced with ethyl acetate. The organic layer was washed with water and then dried over anhydrous sodium sulfate. The filtrate was evaporated *in vacuo* and then was crystallized from ether; yield 5.79 g, (80%); mp 148—150 °C (decomp); $[\alpha]_D^{20}$ −128.0° (*c* 1, methanol); R_f^1 0.81 and R_f^2 0.36.

Found: C, 63.14; H, 6.46; N, 10.56%. Calcd for $C_{48}H_{59}O_{11}N_7$: C, 63.35; H, 6.54; N, 10.78%.

Boc-Ile-Asn-OH (12): Asparagine monohydrate (3.3 g, 22 mmol) and Et_3N (2.8 ml, 20 mmol) were dissolved in water (50 ml). Boc-Ile-ONSu[21] (6.65 g, 20 mmol) dissolved in dioxane (50 ml) was added at room temperature while the solution was being stirred. The mixture was stirred overnight, and then diluted with 5% sodium hydrogencarbonate (100 ml) and extracted with ether. The aqueous layer was acidified with citric acid and extracted with 1-butanol (300 ml). The butanol layer was washed with water and concentrated to 50 ml. The product was crystallized with ether and petroleum ether, then recrystallized from ethanol-ether; yield 4.69 g (68%); mp 159—161 °C; $[\alpha]_D^{20}$ −10.5° (*c* 1, methanol); R_f^1 0.86 and R_f^2 0.10.

Found: C, 52.34; H, 8.05; N, 11.88%. Calcd for $C_{15}H_{27}O_6N_3$: C, 52.16; H, 7.88; N, 12.17%.

Boc-Ile-Asn-His-OBzl (13): To a chilled solution of **12** (5.18 g, 15 mmol) and HOBt (2.44 g, 18 mmol) in THF (40 ml), DCC (3.09 g, 15 mmol) was added, then a solution of H-His-OBzl·2TsOH[22] (9.0 g, 15 mmol) and NMM (3.3 ml, 30 mmol) in DMF (20 ml) was added. The reaction mixture was held for 2 h at −5 °C and then refrigerated overnight at 0 °C. DCUrea was filtered off and washed with a small amount of DMF. The filtrate and the washing were combined and evaporated *in vacuo*, then dissolved in 1-butanol. The solution was washed successively with 4% sodium hydrogencarbonate and water, then dried over anhydrous sodium sulfate. The filtrate was evaporated *in vacuo*, the product was crystallized by the addition of ether and recrystallized from methanol-ether; yield 5.38 g (63%); mp 181—182 °C (decomp); $[\alpha]_D^{20}$ −9.5° (*c* 1, DMF); R_f^1 0.77 and R_f^2 0.57.

Found: C, 58.50; H, 7.12; N, 14.69%. Calcd for $C_{29}H_{40}O_7N_6$: C, 58.72; H, 7.04; N, 14.68%.

H-Ile-Asn-His-OBzl·2HCl (14): Compound **13** (5.15 g, 9 mmol) was dissolved in 98% formic acid (50 ml) and the solution was cooled in an ice bath. A solution of 4 M hydrogen chloride in dioxane (50 ml) was added to it, and the mixture was held for 1 h at 10 °C. The solution was then evaporated *in vacuo* below 25 °C. A residue was obtained by the aid of ether as a hygroscopic solid and was recrystallized from methanol-ether; yield 4.79 g (94%); mp 156—157 °C; $[\alpha]_D^{20}$ +8.5° (*c* 1, pyridine); R_f^1 0.67 and R_f^2 0.11.

Found: C, 50.55; H, 6.56; N, 15.67%. Calcd for $C_{23}H_{34}O_5N_6Cl_2$: C, 50.64; H, 6.28; N, 15.41%.

Z-Val-Tyr-Pro-Phe-Pro-Pro-Gly-Ile-Asn-His-OBzl (15): To a solution of **11** (3.64 g, 4 mmol), **14** (2.53 g, 4.5 mmol), HOBt (0.54 g, 4 mmol) and NMM (1.0 ml, 9 mmol) in DMF (40 ml), DCC (0.83 g, 4 mmol) was added. The reaction mixture was held overnight at 0 °C, then DCUrea was filtered off. The filtrate was dissolved in 1-butanol and washed with 4% sodium hydrogencarbonate and water. The solution was evaporated *in vacuo* and the crude product was precipitated with ether to give 4.43 g (81%, mp 135—140 °C). Two g of the crude product were dissolved in methanol (2 ml) and applied to a silica-gel column (Merck silica-gel G) (2×35 cm), then developed with a mixture of chloroform and methanol (5:1, v/v). The fractions (175—300 ml) which gave a single spot on thin-layer chromatography were collected and evaporated *in vacuo*. The residue was crystallized with ether; yield 1.15 g (57%); mp 144—145 °C; $[\alpha]_D^{20}$ −91.0° (*c* 1, methanol) R_f^1 0.79 and R_f^2 0.68.

Found: C, 62.77; H, 6.51; N, 13.06%. Calcd for $C_{71}H_{89}O_{15}N_{13}$: C, 62.49; H, 6.57; N, 13.35%.

H-Val-Tyr-Pro-Phe-Pro-Pro-Gly-Ile-Asn-His-OH·2HCl (16): Compound **15** (0.45 g, 0.33 mmol) in 0.035 M methanolic hydrogen chloride (20 ml) was hydrogenated in the presence of palladium black. The filtrate was evaporated

in vacuo and the residue was crystallized from acetone. It was reacrystallized from methanol-acetone; yield of the air-dried product was 0.39 g (95%); $[\alpha]_D^{20}$ −96.4° (*c* 1.3, water); R_f^1 0.51. Amino acid ratios in acid hydrolyzate:[23] Val 1.0; Tyr 1.0; Pro 3.1; Phe 1.0; Gly 1.0; Ile 1.1; Asp 1.1; His 1.1.

Found: C, 50.13; H, 7.26; N, 13.31%. Calcd $C_{56}H_{79}O_{13}N_{13}Cl_2 \cdot 7H_2O$: C, 50.29; H, 7.01; N, 13.47%. The air-dried product lost 8.7% of its weight after drying for 2 h at 110 °C and 2 mmHg. Calcd for $7H_2O$: 8.8%.

Syntheses of BPIc Analogs and Fragments. Z-Gly-Gly-Gly-OEt (17): A solution of Z-Gly-OH[24] (1.88 g, 9 mmol) and NMM (0.99 ml, 9 mmol) in THF (20 ml) was chilled to −5 °C, and ECF (0.9 ml, 9 mmol) was added under stirring. After 10 min, the precooled solution of H-Gly-Gly-OEt·HCl[25] (1.77 g, 9 mmol) and NMM (0.99 ml, 9 mmol) in DMF (20 ml) was added to it. The reaction mixture was kept for 1 h in a refrigerator and then kept overnight at room temperature. The mixture was added to 4% sodium hydrogencarbonate (100 ml) and the precipitate was collected by filtration, then washed with 4% sodium hydrogencarbonate, 0.5 M hydrochloric acid and water. It was recrystallized ethanol-ether; yield 2.11 g (67%); mp 166 °C (lit,[26] 167 °C); R_f^1 0.91 and R_f^2 0.64.

Found: C, 54.76; H, 6.04; N, 11.92%. Calcd for $C_{16}H_{21}O_6N_3$: C, 54.69; H, 6.02; N, 11.96%.

H-Gly-Gly-Gly-OEt·HCl (18): A solution of **17** (2.0 g, 5.7 mmol) dissolved in 0.3 M methanolic hydrogen chloride (30 ml) was hydrogenated in the presence of palladium black. The filtrate from the catalyst was evaporated *in vacuo* and the residue was crystallized by addition of ether; yield 1.25 g (87%); mp 219—220 °C (decomp) (lit, [27] 214—217 °C (decomp)); R_f^1 0.64 and R_f^2 0.08.

Found: C, 37.98; H, 6.43; N, 16.79%. Calcd for $C_8H_{16}O_4N_3Cl$: C, 37.87; H, 6.36; N, 16.56%.

Z-Val-Tyr-Pro-Phe-Gly-Gly-Gly-OEt (19): To a chilled solution of **6** (2.64 g, 4 mmol) and HOBt (0.57 g, 4.2 mmol) in THF (20 ml), DCC (0.83 g, 4 mmol) was added. After 20 min, the precooled solution of **18** (1.01 g, 4 mmol) and NMM (0.44 ml, 4 mmol) in DMF (20 ml) was added and the mixture was kept for 5 h at 0 °C, then stood overnight at room temperature. DCUrea was filtered off and the filtrate was evaporated *in vacuo* and then dissolved in ethyl acetate. The solution was washed successively with 4% sodium hydrogencarbonate, 0.5 M hydrochloric acid and water, then dried over anhydrous sodium sulfate. The filtrate was evaporated *in vacuo* and the residue was solidified by addition of petroleum ether. It was recrystallized from ethanol and petroleum ether; yield 2.78 g (81%); mp 96 °C; $[\alpha]_D^{20}$ −59.0° (*c* 1, methanol); R_f^1 0.92 and R_f^2 0.63.

Found: C, 61.07; H, 6.73; N, 11.11%. Calcd for $C_{34}H_{55}O_{11}N_7 \cdot 1/2\,H_2O$: C, 60.95; H, 6.51; N, 11.31%.

Z-Val-Tyr-Pro-Phe-Gly-Gly-Gly-OH (20): Compound **19** (2.53 g, 3 mmol) was subjected to the saponification in the mixture of methanol (10 ml) and 2 M sodium hydroxide (3.3 ml) for 1 h. The following procedure was employed for the preparation of **11**; yield 2.07 g (83%); mp 114—116 °C; $[\alpha]_D^{20}$ −65.0° (*c* 1, methanol); R_f^1 0.73 and R_f^1 0.29.

Found: C, 59.76; H, 6.22; N, 11.43%. Calcd for $C_{32}H_{51}O_{11}N_7 \cdot H_2O$: C, 59.45; H, 6.30; N, 11.55%.

Z-Val-Tyr-Pro-Phe-Gly-Gly-Gly-Ile-Asn-His-OBzl (21): This compound was prepared from **20** (1.25 g, 1.5 mmol) and **14** (0.98 g, 1.8 mmol) as described for the preparation of **15**; yield 1.36 g (71%); mp 153—155 °C; $[\alpha]_D^{20}$ −58.5° (*c* 1, methanol); R_f^1 0.84 and R_f^2 0.48.

Found: C, 60.92; H, 6.29; N, 14.13%. Calcd for $C_{65}H_{81}O_{15}N_{13}$: C, 60.78; H, 6.36; N, 14.18%.

H-Val-Tyr-Pro-Phe-Gly-Gly-Gly-Ile-Asn-His-OH·HCl (22): A solution of **20** (1.0 g, 0.78 mmol) in 0.3 M methanolic hydrogen chloride (4 ml) was subjected to the hydrogenation as described for **16**; yield 0.75 g (79%); mp 184—187 °C; $[\alpha]_D^{20}$ −39.5° (*c* 1, methanol); R_f^1 0.60. Amino acid ratios in acid hydrolyzate:[23] Val 1.1; Tyr 1.0; Pro 1.1; Phe 1.0; Gly 3.1; Ile 1.0; Asp 1.0; His 1.0.

Found: C, 51.43; H, 6.53; N, 15.45%. Calcd for $C_{50}H_{70}O_{13}N_{13}Cl \cdot 4H_2O$: C, 51.38; H, 6.73; N, 15.58%.

Boc-Ile-Gly-Gly-OBzl (23): This compound was prepared from Boc-Ile-OH·DCHA[28] (4.14 g, 10 mmol) and H-Gly-Gly-OBzl·HCl[29] (2.60 g, 10 mmol) as described for the preparation of **1**; yield 3.70 g (85%); mp 93—94 °C; $[\alpha]_D^{20}$ +3.0° (*c* 1, methanol); R_f^1 0.95 and R_f^2 0.67.

Found: C, 60.68; H, 7.73; N, 9.67%. Calcd for $C_{22}H_{33}O_6N_3$: C, 60.67; H, 7.64; N, 9.65%.

H-Ile-Gly-Gly-OBzl·HCl (24): This was prepared from **23** (1.74 g, 4 mmol) as described for the preparation of **9**; yield 1.40 g (94%); mp 186—187 °C; $[\alpha]_D^{20}$ +29.0° (*c* 1, methanol); R_f^1 0.80 and R_f^2 0.50.

Found: C, 54.58; H, 7.23; N, 11.49%. Calcd for $C_{17}H_{26}O_4N_3Cl$: C, 54.90; H, 7.31; N, 11.30%.

Z-Val-Tyr-Pro-Phe-Pro-Pro-Gly-Ile-Gly-Gly-OBzl (25): This was prepared from **11** (1.86 g, 2 mmol) and **24** (0.78 g, 2.2 mmol) as described for the preparation of **15**. Purification of the product was done by the recrystallization from ethanol-ether; yield 2.06 g (84%); mp 115—118 °C; $[\alpha]_D^{20}$ −91.0° (*c* 1, methanol); R_f^1 0.92 and R_f^2 0.57.

Found: C, 62.43; H, 6.90; N, 11.15%. Calcd for $C_{65}H_{82}O_{14}N_{10} \cdot H_2O$: C, 62.53; H, 7.02; N, 11.22%.

H-Val-Tyr-Pro-Phe-Pro-Pro-Gly-Ile-Gly-Gly-OH (26): Compound **25** (1.23 g, 1 mmol) was hydrogenated as described for the preparation of **16**; yield 0.95 g (85%); mp 168—171 °C; $[\alpha]_D^{20}$ −89.0° (*c* 1, methanol); R_f^1 0.71 and R_f^2 0.31. Amino acid ratios in acid hydrolyzate:[23] Val 1.0; Tyr 1.0; Pro 2.9; Phe 1.0; Gly 3.2; Ile 1.0.

Found: C, 56.77; H, 6.95; N, 13.05%. Calcd for $C_{50}H_{70}O_{12}N_{10} \cdot 3H_2O$: C, 56.80; H, 7.25; N, 13.25%.

Boc-Gly-Ile-OBzl (27): This was prepared from Boc-Gly-OH[30] (3.50 g, 20 mmol) and H-Ile-OBzl·TsOH[31] (9.00 g, 22 mmol) as described for the preparation of **1**. The product was obtained as an oily form; yield 7.50 g (100%); R_f^1 0.97 and R_f^2 0.81.

H-Gly-Ile-OBzl·HCl (28): Compound **27** (7.50 g, 20 mmol (oily form)) was treated with hydrogen chloride as described for the preparation of **9**; yield 5.10 g (81%); mp 108—110 °C; $[\alpha]_D^{20}$ −19.5° (*c* 1, methanol); R_f^1 0.81 and R_f^2 0.47.

Found: C, 55.52; H, 7.66; N, 8.95%. Calcd for $C_{15}H_{23}O_3N_2Cl \cdot 1/2\,H_2O$: C, 55.64; H, 7.47; N, 8.65%.

Boc-Pro-Pro-Gly-Ile-OBzl (29): This was prepared from **7** (1.87 g, 6 mmol) and **28** (1.88 g, 6 mmol) as described for the preparation of **1**. The product was obtained as an oily form; yield 3.43 g (100%) R_f^1 0.91 and R_f^2 0.63.

H-Pro-Pro-Gly-Ile-OBzl·HCl (30): Compound **29** (3.43 g, 6 mmol (oily form)) was treated with hydrogen chloride as described for the preparation of **9**; yield 2.54 g (83%); mp 68—70 °C; $[\alpha]_D^{20}$ −99.0° (*c* 1, methanol); R_f^1 0.77 and R_f^2 0.35.

Found: C, 58.08; H, 7.42; N, 10.59%. Calcd for $C_{25}H_{37}O_5N_4Cl \cdot 1/2\,H_2O$: C, 57.96; H, 7.39; N, 10.82%.

Z-Val-Tyr-Pro-Phe-Pro-Pro-Gly-Ile-OBzl (31): This compound was prepared from **6** (3.29 g, 5 mmol) and **30** (2.40 g, 5 mmol) as described for the preparation of **10**; yield 4.21 g (76%); mp 114—116 °C; $[\alpha]_D^{20}$ −104.0° (*c* 1, methanol); R_f^1 0.86 and R_f^2 0.71.

Found: C, 65.29; H, 7.01; N, 9.98%. Calcd for $C_{61}H_{76}O_{12}N_8 \cdot 1/2\,H_2O$: C, 65.28; H, 6.92; N, 9.98%.

H-Val-Tyr-Pro-Phe-Pro-Pro-Gly-Ile-OH (32): A solution of **31** (3.34 g, 3 mmol) in methanol (8 ml) and acetic acid (8 ml) was hydrogenated in the presence of palladium black. The filtrate from the catalyst was evaporated *in vacuo* and

the residue was crystallized from ether; yield 2.54 g (92%); mp 164—168 °C (decomp); $[\alpha]_D^{20}$ −124.5° (*c* 0.92, water); R_f^1 0.76 and R_f^2 0.40. Amino acid ratios in acid hydrolyzate:[23] Val 0.9; Tyr 1.0; Pro 3.1; Phe 1.0; Gly 1.0; Ile 1.0.

Found: C, 60.06; H, 7.10; N, 12.21%. Calcd for $C_{46}H_{64}O_{10}N_8 \cdot 3/2\ H_2O$: C,60.31; H, 7.37; N, 12.23%.

H-Val-Tyr-Pro-Phe-Pro-Pro-Gly-OH (33): Compound **11** (1.36 g, 1.5 mmol) was hydrogenated as described for the preparation of **32**; yield 1.15 g (91%); mp 172—174 °C (decomp); $[\alpha]_D^{20}$ −125.9° (*c* 0.84, water); R_f^1 0.67 and R_f^2 0.28. Amino acid ratios in acid hydrolyzate:[23] Val 1.0; Tyr 1.0; Pro 2.9; Phe 1.0; Gly 0.9.

Found: C, 58.63; H, 6.65; N, 11.93%. Calcd for $C_{40}H_{53}O_9N_7 \cdot 1/2\ CH_3COOH \cdot 2H_2O$: C, 58.49; H, 7.06; N, 11.65%.

A Comparison of Synthetic and Natural BPIc.[32] *Thin Layer Chromatography*: Both compounds gave a single spot and identical R_f values. R_f^1 values of both are 0.51.

Paper Electrophoresis: This was carried out under the following conditions. Paper, Toyo Roshi No. 51A chromatography paper; solvent, pyridine–acetic acid–water (10:0.4:90, v/v) (pH 6.4); voltage gradient, 15 V/cm; charge period, 2 h. Electrophoretic mobilities were recorded as R_{His}, the ratio of the distance the compounds moved to that which a standard histidine spot moved on the same electrophoreogram. BPIc migrated toward the cathode and gave a single spot. The R_{His} value of both natural and synthetic BPIc was 0.82. The R_{His} values of **22**, **26**, **32**, and **33** were 0.83, 0.70, 0.70, and 0.69 respectively.

Carboxymethylcellulose Column Chromatography: A portion (*ca.* 1 mg) of synthetic or natural BPIc was dissolved in 0.3 ml of 0.2 M pyridinium acetate (pH 5.0). The solution was applied to a column (1.0×60 cm) of carboxymethylcellulose. Elution was carried out with the same solvent and 2 ml fractions were collected at a flow rate of 8 ml h^{-1}. The peptide content was determined by the method described by Yemm and Cocking.[33] The results shown in Fig. 2 indicate that the pattern of the chromatogram of synthetic BPIc is indistinguishable from that of the natural material. The cochromatography of synthetic and natural BPIc was carried out under the same conditions and a single peak was obtained. The chromatographic patterns of other synthetic peptides are also presented in Fig. 2.

Sensory Test. Bitterness of the synthetic peptides was organoleptically determined by panel evaluation employing four people. A series of solutions of decreasing concentration, each half as strong as the proceeding one, were prepared. Before tasting the sample, the mouth was thoroughly rinsed with deionized water. The sample solution was held in the mouth for *ca.* 10 s and then spit out and the threshold value was determined. The results are listed in the Table.

The author wishes to express his thanks to Professor Nobuo Izumiya of Kyushu University and Associate Professor Hideo Okai of Hiroshima University for their helpful discussions. The author would like to thank Dr. Noshi Minamiura of Osaka City University for his kind offer of the natural sample of BPIc. Thanks are also due to Dr. Shinji Okumura of Ajinomoto Co. Inc., for supplying some amino acids.

(Received August 1, 1983)

To explain the bitter taste exhibited by BPIa (Arg-Gly-Pro-Pro-Phe-Ile-Val) which was isolated from casein hydrolyzate, we have proposed the following requirement: its characteristic spatial structure: the basic moiety in the N-terminal and the hydrophobic moiety in the C-terminal were affected to each other by prolylprolyl residue, is necessary for the bitterness to be exhibited. As for BPIc (Val-Tyr-Pro-Phe-Pro-Pro-Gly-Ile-Asn-His), which is the other fraction, although it exhibited as strong and bitter a taste as BPIa, the basic moiety of BPIc is located in the C-terminal and its hydrophobic moiety is located in the N-terminal. The authors synthesized retro-BPIa with the reverse peptide sequence and its fragments. The retro-BPIa exhibited as strong and bitter a taste as BPIa. However, the bitterness of the fragments of retro-BPIa was far weaker than that of retro-BPIa.

In studies of the relationship between bitterness and chemical structure of BPIa (Arg-Gly-Pro-Pro-Phe-Ile-Val) which was isolated by Minamiura *et al.*,[3] the authors reported that the basic amino acid residue in the N-terminal, the hydrophobic amino acid residues in the C-terminal, and its characteristic spatial structure, which may derive from prolylprolyl residues at 3 and 4 positions of BPIa, are necessary for an intense bitter taste to be exhibited by BPIa.[4-7] In the previous paper,[1] we reported that a decapeptide BPIc (Val-Tyr-Pro-Phe-Pro-Pro-Gly-Ile-Asn-His) in which basic moiety is located in the C-terminal and hydrophoic moiety is located in the N-terminal exhibited an extremely bitter taste on the same level as that of BPIa. From those results, it was expected that the retro-BPIa (Val-Ile-Phe-Pro-Pro-Gly-Arg) possessing the reverse amino acid sequence of BPIa would exhibit as bitter a taste as BPIa. Thus the authors synthesized retro-BPIa and its fragments, as shown in the Table, and investigated their bitterness.

The synthetic route to compound **1** (retro-BPIa) is shown in Fig. 1. *N*-(Benzyloxycarbonyl)isoleucine and phenylalanine benzyl ester were coupled by the mixed anhydride method to yield *N*-(benzyloxycarbonyl)-isoleucylphenylalanine benzyl ester (**12**). The free dipeptide (**5**) was given by the catalytic hydrogenation of **12**. *N*-(Benzyloxycarbonyl)valine *N*-hydroxysuccinimide ester and **5** were coupled to yield *N*-(benzyloxycarbonyl)valylisoleucylphenylalanine (**13**). *N*-(*t*-Butoxycarbonyl)prolylproline and glycine benzyl ester were coupled by the mixed anhydride method to yield *N*-(*t*-butoxycarbonyl)prolylprolylglycine benzyl ester (**14**). After treatment of **14** with hydrogen chloride in dioxane, the tripeptide benzyl ester hydrochloride (**15**) and **13** were coupled by the DCC-HONSu method to yield *N*-(benzyloxycarbonyl)valylisoleucylphenylalanylprolylprolylglycine benzyl ester (**16**). *N*-(Benzyloxycarbonyl)valylisoleucylphenylalanylprolylprolylglycine (**17**) was obtained by the saponification of **16**. **17** and N^G-nitroarginine benzyl ester were coupled by the DCC-HOBt method to yield *N*-(benzyloxycarbonyl)valylisoleucylphenylalanylprolylprolylglycyl-N^G-nitroarginine benzyl ester (**18**). The protected heptapeptide was hydrogenated in the presence of palladium black to give the retro-BPIa (**1**).

The synthetic route to compounds **2** and **3** is shown in Fig. 2. These compounds were obtained by the catalytic hydrogenation of **16** and **13**, which are the intermediates in the synthesis of retro-BPIa. The details

TABLE. THE THRESHOLD VALUE FOR BITTER TASTE OF THE SYNTHETIC PEPTIDES

	Compound	Taste	T.V./mM	$R_{caf.}$[a]
1.	Val-Ile-Phe-Pro-Pro-Gly-Arg	Bitter	0.08	12.50
2.	Val-Ile-Phe-Pro-Pro-Gly	Bitter	2.10	0.48
3.	Val-Ile-Phe	Bitter	1.30	0.77
4.	Val-Ile	Bitter	6.00	0.17
5.	Ile-Phe	Bitter	1.50	0.67
6.	Pro-Pro	Bitter	4.50	0.22
7.	Pro-Pro-Gly	Bitter	9.50	0.11
8.	Pro-Gly	Sweet	—	—
9.	Pro-Gly-Arg	Bitter	25.00	0.04
10.	Gly-Arg	Bitter	75.00	0.01
11.	Arg-Gly-Pro-Pro-Phe-Ile-Val	Bitter	0.05	20.00

a) Ratio of caffeine.

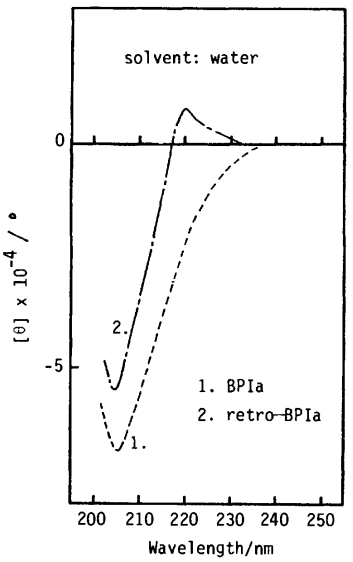

Fig. 5. CD curves of BPIa and retro-BPIa.

of the synthetic route to other peptides (compounds **4**—**10**) are shown in Figs. 3 and 4, and are described in the Experimental part. The purity of the synthetic peptides and their intermediates was confirmed by thin-layer chromatography in two solvent systems, elemental analyses, and amino acid analyses.

The bitterness of the synthetic peptides were organoleptically determined by panel evaluation of five people (see Table). The threshold value of retro-BPIa (compound **1**) was 0.08 mM (1 M=1 mol dm^{-3}). The value is about the same as that of BPIa. On the other hand, the bitterness of des-Arg^7-retro-BPIa (**2**) was far weaker than that of retro-BPIa. In the previous paper,[4] we reported that des-Arg^1-BPIa also exhibited a weakly bitter taste. The result indicated that the arginine residue plays an important role for the bitter taste exhibited by BPIa and retro-BPIa, as has been described in the previous papers.[4,7] As for the other fragments (**4**—**10**), they did not exhibit as strong and bitter a taste as BPIa.

We have reported that the strong bitter taste exhibited by BPIa may derive from its characteristic spatial structure.[4,5] In order to investigate that requirement, we measured the circular dichroism (CD) of the retro-BPIa, and compared its CD curves with that of BPIa, as shown in Fig. 5. The CD curves of BPIa and retro-BPIa were similar in shape.

The results described above suggest that the spatial structure of retro-BPIa possessing the reverse amino acid sequence may be similar to that of BPIa. Thus, in order for the bitter taste to be exhibited by BPIa, the spatial structure of the molecule is more important than the position of the basic and hydrophobic moieties.

Experimental

All the melting points are uncorrected. Thin-layer chromatography (TLC) was carried out on Merck silica gel G with the following solvent systems: R_f^1, 1-butanol-acetic acid-pyridine-water (4:1:1:2, v/v); R_f^2, chloroform-methanol (5:1, v/v). Materials possessing a free amino group on a thin-layer plate were detected by spraying with ninhydrin. Compounds with blocked amino groups were detected by spraying with 25% hydrogen bromide in acetic acid and then with ninhydrin. The optical rotations were measured on a Union PM-101 polarimeter. Amino acid analyses were performed on a Hitachi amino acid analyzer KLA-5 type, after hydrolysis in a mixture of 6 M hydrochloric acid and propionic acid (1:1) at 110 °C for 72 h.

Z-Ile-Phe-OBzl (12). Z-Ile-OH·DCHA (14.74 g, 33 mmol) was dissolved in ethyl acetate (100 ml), and 0.5 M sulfic acid (50 ml) was added to the mixture during stirring. The organic layer was washed with water and dried over anhydrous sodium sulfate. The solution was con-

centrated to dryness *in vacuo*, and the oily residue was dissolved in THF (50 ml) and NMM (3.3 ml, 30 mmol). ECF (3.0 ml, 30 mmol) was added to the mixture at −5 °C. After 10 min, a solution of H-Phe-OBzl·TsOH[8] (12.80 g, 30 mmol) in chloroform (50 ml) was added to the mixture. The reaction mixture was stirred in an ice bath for 1 h, then at room temperature overnight. The reaction mixture was evaporated *in vacuo*, and the oily residue was dissolved in ethyl acetate. The solution was washed with water, 0.5 M hydrochloric acid, 4% sodium hydrogencarbonate, and water successively, then dried over anhydrous sodium sulfate. Sodium sulfate was removed by filtration, and the filtrate was evaporated *in vacuo*. The oily residue was crystallized with ether-petroleum ether: yield 11.88 g (71%); mp 158 °C; $[\alpha]_D^{15}$ −15.5° (*c* 1, *N,N*-dimethylformamide); R_f^1 0.99 and R_f^2 0.97.

Found: C, 71.63; H, 7.01; N, 5.50%. Calcd for $C_{30}H_{34}O_5N_2$: C, 71.69; H, 6.82; N, 5.57%.

H-Ile-Phe-OH (5). A solution of compound **12** (10.05 g, 20 mmol) in methanol (20 ml) and acetic acid (5 ml) was hydrogenated in the presence of palladium black at room temperature overnight. The catalyst was removed by filtration, and the filtrate was evaporated *in vacuo*. The residue was crystallized by the aid of acetone: yield 4.96 g (90%); mp 250 °C (decomp); $[\alpha]_D^{15}$ +68.0° (*c* 1, acetic acid); R_f^1 0.83 and R_f^2 0.06.

Found: C, 65.16; H, 7.87; N, 10.11%. Calcd for $C_{15}H_{22}O_3N_2$: C, 64.72; H, 7.97; N, 10.07%.

Z-Val-Ile-Phe-OH (13). To a solution of Z-Val-ONSu[9] (4.20 g, 12 mmol) in THF (20 ml), a solution of compound **5** (2.78 g, 10 mmol) and Et_3N (1.4 ml, 10 mmol) in water (20 ml) was added. The reaction mixture was allowed to stand at room temperature for 24 h, and then suspended by the aid of water (200 ml). The insoluble product was collected by filtration and recrystallized from hot ethanol and ether: yield 3.58 g (70%); mp 208—210 °C; $[\alpha]_D^{15}$ +7.5° (*c* 1, *N,N*-dimethylformamide); R_f^1 0.89 and R_f^2 0.74.

Found: C, 65.10; H, 7.63; N, 8.40%. Calcd for $C_{28}H_{37}O_6N_3 \cdot 1/3\ H_2O$: C, 64.97; H, 7.34; N, 8.12%.

Boc-Pro-Pro-Gly-OBzl (14). Boc-Pro-Pro-OH[10] (6.24 g, 20 mmol) and H-Gly-OBzl·TsOH[11,12] (6.74 g, 20 mmol) were coupled by the same method as described for the preparation of **12**: yield 6.95 g (76%); mp 108—109 °C; $[\alpha]_D^{15}$ −122.5° (*c* 1, methanol); R_f^1 0.85 and R_f^2 0.67.

Found: C, 62.71; H, 7.36; N, 9.04%. Calcd for $C_{24}H_{33}O_6N_3$: C, 62.72; H, 7.24; N, 9.14%.

H-Pro-Pro-Gly-OBzl·HCl (15). To a solution of compound **14** (4.60 g, 10 mmol) in dioxane (20 ml), 4 M HCl/dioxane (50 ml) was added. The solution was allowed to stand at room temperature. After 2 h, the solution was evaporated *in vacuo*. The residual oil was solidified with ether: yield 3.92 g (99%); mp 65—67 °C; $[\alpha]_D^{15}$ −115.0° (*c* 1, methanol); R_f^1 0.62 and R_f^2 0.13.

Found: C, 56.74; H, 6.83; N, 10.38%. Calcd for $C_{19}H_{25}O_4N_3 \cdot HCl \cdot 1/3\ H_2O$: C, 56.78; H, 6.68; N, 10.45%.

Z-Val-Ile-Phe-Pro-Pro-Gly-OBzl (16). To a solution of compound **13** (2.56 g, 5 mmol) and compound **15** (1.98 g, 5 mmol) and NMM (0.55 ml, 5 mmol) and DMF (20 ml), DCC (1.55 g, 7.5 mmol) and HONSu (0.86 g, 7.5 mmol) were added to the mixture. The reaction mixture was cooled at −10 °C for 1 h and allowed to stand at room temperature for 48 h. The DCUrea was removed by filtration, and the filtrate was evaporated *in vacuo*. The oily residue was dissolved in ethyl acetate and the solution was washed with water, 0.5 M hydrochloric acid, 4% sodium hydrogencarbonate, and water successively. The solution was dried over anhydrous sodium sulfate. Sodium sulfate was removed by filtration and the filtrate was evaporated *in vacuo*. The residue was crystallized with ether-petroleum ether: yield 4.12 g (97%); mp 108—109 °C; $[\alpha]_D^{15}$ −54.5° (*c* 1, *N,N*-dimethylformamide); R_f^1 0.94 and R_f^2 0.60.

Found: C, 66.00; H, 7.33; N, 10.02%. Calcd for $C_{47}H_{60}O_9N_6$: C, 66.17; H, 7.09; N, 9.85%.

Z-Val-Ile-Phe-Pro-Pro-Gly-OH (17). To a solution of compound **16** (2.56 g, 3 mmol) in methanol (15 ml), 2 M sodium hydroxide (1.8 ml, 3.6 mmol) was added under stirring. The solution was allowed to stand at room temperature. After 2 h, the solution was evaporated *in vacuo*, and then diluted with water. The solution was washed with ethyl acetate. The aqueous layer was acidified to pH 4 with 2 M hydrochloric acid. The precipitate thus obtained was collected and washed with water. It was recrystallized from hot ethanol-ether: yield 2.16 g (92%); mp 130—134 °C; $[\alpha]_D^{15}$ −56.0° (*c* 1, *N,N*-dimethylformamide); R_f^1 0.78 and R_f^2 0.35.

Found: C, 62.01; H, 7.19; N, 10.84%. Calcd for $C_{40}H_{54}O_9N_6 \cdot 1/3\ H_2O$: C, 62.08; H, 7.12; N, 10.86%.

Z-Val-Ile-Phe-Pro-Pro-Gly-Arg(NO$_2$)-OBzl (18). To a solution of compound **17** (0.77 g, 1 mmol) and H-Arg(NO$_2$)-OBzl·2TsOH[13] (0.65 g, 1 mmol) in NMM (0.22 ml, 2 mmol) and DMF (10 ml), DCC (0.31 g, 1.5 mmol) and HOBt (0.20 g, 1.5 mmol) were added. The reaction mixture was cooled in an ice bath for an hour and allowed to stand at room temperature overnight. The DCUrea was removed by filtration, and the filtrate was evaporatd *in vacuo*. The oily residue was dissolved in ethyl acetate and the solution was washed with water, 0.5 M hydrochloric acid, 4% sodium hydrogencarbonate, and water successively. The solution was dried over anhydrous sodium sulfate. Sodium sulfate was removed by filtration, and the filtrate was evaporated *in vacuo*. The oily residue was crystallized with ether-petroleum ether: yield 0.75 g (71%); mp 130—133 °C; $[\alpha]_D^{15}$ −39.5° (*c* 1, *N,N*-dimethylformamide); R_f^1 0.98 and R_f^2 0.57.

Found: C, 59.93; H, 7.00; N, 14.17%. Calcd for $C_{53}H_{71}O_{12}N_{11} \cdot 1/2\ H_2O$: C, 59.87; H, 6.82; N, 14.49%.

H-Val-Ile-Phe-Pro-Pro-Gly-Arg-OH (1). Compound **18** (0.53 g, 0.5 mmol) was treated as described for the preparation of **5**: yield 0.37 g (87%); mp 180 °C (decomp); $[\alpha]_D^{15}$ −124.5° (*c* 1, H_2O); R_f^1 0.47 and R_f^2 0.00.

Found: C, 56.32; H, 7.82; N, 16.15%. Calcd for $C_{38}H_{60}O_8N_{10} \cdot CH_3COOH \cdot 1/2\ H_2O$: C, 56.25; H, 7.75; N, 16.40%.

Amino acid ratios in acid hydrolyzate: Val 1.03, Ile 1.00, Phe 1.01, Pro 2.02, Gly 1.00, Arg 0.96.

H-Val-Ile-Phe-Pro-Pro-Gly-OH (2). Compound **16** (0.85 g, 1 mmol) was treated as described in the case of **5**: yield 0.48 g (77%); mp 162—164 °C; $[\alpha]_D^{15}$ −86.5° (*c* 1, acetic acid); R_f^1 0.62 and R_f^2 0.03.

Found: C, 57.30; H, 7.75; N, 12.39%. Calcd for $C_{32}H_{48}O_7N_6 \cdot 7/3\ H_2O$: C, 57.29; H, 7.91; N, 12.53%.

Amino acid ratios in acid hydrolyzate: Val 1.02, Ile 1.00, Phe 0.99, Pro 2.01, Gly 1.01.

H-Val-Ile-Phe-OH (3). Compound **13** (0.51 g, 1 mmol) was treated as described in the case of **5**: yield 0.30 g (80%); mp 233 °C (decomp); $[\alpha]_D^{15}$ +9.0° (*c* 1, acetic acid); R_f^1 0.80 and R_f^2 0.13.

Found: C, 62.53; H, 8.23; N, 10.88%. Calcd for $C_{20}H_{31}O_4N_3 \cdot 1/3\ H_2O$: C, 62.63; H, 8.32; N, 10.95%.

Amino acid ratios in acid hydrolyzate: Val 1.01, Ile 1.00, Phe 0.99.

Z-Val-Ile-OBzl (19). Z-Val-ONSu[9] (2.10 g, 6 mmol) and H-Ile-OBzl·TsOH[8] (1.97 g, 5 mmol) were coupled by the same method as described for the preparation of **13**: yield 1.38 g (61%); mp 108—109 °; $[\alpha]_D^{15}$ −14.0° (*c* 1, methanol); R_f^1 0.98 and R_f^2 0.95.

O_5N_2: C, 68.70; H, 7.63; N, 6.14%.

H-Val-Ile-OH (4). Compound **19** (0.91 g, 2 mmol) was treated as described in the case of **5**: yield 0.44 g (96%); melting point above 250 °C; $[\alpha]_D^{15}$ +17.0° (*c* 1, H_2O); R_f^1 0.71 and R_f^2 0.21.

Found: C, 57.28; H, 9.68; N, 12.14%. Calcd for $C_{11}H_{22}O_3N_2$: C, 57.36; H, 9.65; N, 12.21%.

Amino acid ratios in acid hydrolyzate: Val 1.02, Ile 1.00.

Z-Pro-Pro-OBzl (20). To a solution of Z-Pro-OH[14-16] (2.49 g, 10 mmol) in CH_3CN (10 ml), DCC (2.48 g, 12 mmol) was added to the mixture at 0 °C. After 20 min, a solution of H-Pro-OBzl·HCl[17,18] (2.42 g, 10 mmol) and NMM (1.1ml, 10 mmol) in CH_3CN (10 ml) was added to the mixture. The resulting mixture was cooled at 0 °C for 1 h and allowed to stand overnight at room temperature. The DCUrea was removed by filtration, and the filtrate was evaporated *in vacuo*. The oily residue was dissolved in ethyl acetate and the solution was washed with water, 0.5 M hydrochloric acid, 4% sodium hydrogencarbonate, and water successively. The solution was dried over anhydrous sodium sulfate. Sodium sulfate as removed by filtration, and the filtrate was evaporated *in vacuo*. This compound was obtained in an oily form, while Appel *et al.*[19] reported that they obtained this compound as a crystalline form: yield 3.93 g (90%); R_f^1 0.89 and R_f^2 0.94.

H-Pro-Pro-OH (6). Compound **20** (3.93 g, 9 mmol) was treated as described in the case of **5**: yield 1.70 g (89%); mp 130—132 °C (lit, 125—127 °C,[19] 144—145 °C,[20] and 220—222 °C[21]); $[\alpha]_D^{15}$ −167.5° (*c* 1, H_2O) (lit, −166° (H_2O),[19] −169° (H_2O),[20] and −87° (H_2O)[21]); R_f^1 0.33 and R_f^2 0.10.

Found: C, 56.63; H, 7.58; N, 13.15%. Calcd for $C_{10}H_{16}O_3N_2$: C, 56.59; H, 7.63; 13.23%.

Z-Pro-Pro-OH (21). Compound **20** (5.13 g, 11.75 mmol) was treated as described for the preparation of **17**: yield 3.30 g (81%); mp 186 °C (lit, 187—190 °C[22] and 191.5—193.5 °C[23]); $[\alpha]_D^{15}$ −84.5° (*c* 1, *N,N*-dimethylformamide) (lit, −83° (*N,N*-dimethylformamide[23])); R_f^1 0.69 and R_f^2 0.17.

Found: C, 59.47; H, 6.58; N, 7.77%. Calcd for $C_{18}H_{22}O_5N_2 \cdot H_2O$: C, 59.32; H, 6.65; N, 7.69%.

Z-Pro-Pro-Gly-OBzl (22). Compound **21** (1.73 g, 5 mmol) and H-Gly-OBzl·TsOH[11,12] (1.69 g, 5 mmol) were coupled by the same method as described for the preparation of **12**: yield 2.42 g (98%); mp 121—124 °C (lit, 120—122 °C[24]); $[\alpha]_D^{15}$ −113.0° (*c* 1, methanol) (lit, −115° (methanol)[24]); R_f^1 0.87 and R_f^2 0.71.

Found: C, 65.82; H, 6.31; N, 8.61%. Calcd for $C_{27}H_{31}O_6N_3$: C, 65.70; H, 6.34; N, 8.52%.

H-Pro-Pro-Gly-OH (7). Compound **22** (0.99 g, 2 mmol) was treated as described for the preparation of **5**: yield 0.50 g (93%); mp 108—111 °C (lit, 112—114 °C[24]); $[\alpha]_D^{15}$ −97.0° (*c* 1, H_2O); R_f^1 0.27 and R_f^2 0.07.

Found: C, 51.89; H, 7.13; N, 14.98%. Calcd for $C_{12}H_{19}O_4N_3 \cdot 1/2\ H_2O$: C, 51.79; H, 7.26; N, 15.10%.

Amino acid ratios in acid hydrolyzate: Pro 2.10, Gly 1.00.

Z-Pro-Gly-OBzl (23). Z-Pro-OH[14-16] (4.99 g, 20 mmol) H-Gly-OBzl·TsOH[11,12] (6.75 g, 20 mmol) were coupled by the same method as described for the preparation of **12**: yield 6.99 g (88%); mp 81—83 °C (lit, 88—89 °C[19]); $[\alpha]_D^{15}$ −65.0° (*c* 1, methanol); R_f^1 0.90 and R_f^2 0.74.

Found: C, 66.58; H, 6.02; N, 7.18%. Calcd for $C_{22}H_{24}O_5N_2$: C, 66.65; H, 6.11; N, 7.07%.

H-Pro-Gly-OH (8). Compound **23** (0.79 g, 2 mmol) was treated as described in the case of **5**: yield 0.30 g (87%); mp 225—228 °C (lit, 230—232 °C[25]); $[\alpha]_D^{15}$ −23.5° (*c* 1, H_2O) (lit, −23° (H_2O[26])); R_f^1 0.23 and R_f^2 0.07.

Found: C, 46.27; H, 7.21; N, 15.38%. Calcd for $C_7H_{12}O_3N_2 \cdot 1/2\ H_2O$: C, 46.39; H, 7.25; N, 15.46%.

Amino acid ratios in acid hydrolyzate: Pro 1.07, Gly 1.00.

Z-Pro-Gly-OH (24). Compound **23** (5.95 g, 15 mmol) was treated as described in the case of **17**. This compound was obtained in an oily form:[27] yield 2.48 g (54%); R_f^1 0.77 and R_f^2 0.34.

Z-Pro-Gly-Arg(NO$_2$)-OBzl (25). Compound **24** (2.48 g, 8.1 mmol) and H-Arg(NO_2)-OBzl·TsOH[13] (5.29 g, 8.1 mmol) were coupled by the same method as described for the preparation of **12**: yield 4.02 g (83%); mp 75—79 °C; $[\alpha]_D^{15}$ −30.5° (*c* 2, methanol); R_f^1 0.90 and R_f^2 0.50.

Found: C, 53.70; H, 6.08; N, 15.83%. Calcd for $C_{28}H_{35}O_8N_7 \cdot 3/2\ H_2O$: C, 53.84; H, 6.14; N, 15.70%.

H-Pro-Gly-Arg-OH (9). Compound **25** (1.20 g, 2 mmol) was treated as described for the preparation of **5**. This compound was obtained in a hygroscopic form: yield 0.58 g (89%); R_f^1 0.23 and R_f^2 0.00.

Z-Gly-Arg(NO$_2$)-OBzl (26). Z-Gly-OH[28-30] (1.15 g, 5.5 mmol) and H-Arg(NO_2)-OBzl·2TsOH[13] (3.60 g, 5.5 mmol) were coupled by the same method as described for the preparation of **12**: yield 1.84 g (67%); mp 117—119 °C; $[\alpha]_D^{15}$ −14.0° (*c* 1, methanol); R_f^1 0.95 and R_f^2 0.53.

Found: C, 55.11; H, 5.68; N, 16.74%. Calcd for $C_{23}H_{28}O_7N_6$: C, 55.19; H, 5.65; N, 16.80%.

H-Gly-Arg-OH (10). Compound **26** (1.00 g, 2 mmol) was treated as described in the case of **5**: yeld 0.47 g (80%); mp 68—72 °C; $[\alpha]_D^{15}$ +4.0° (*c* 1, H_2O); R_f^1 0.19 and R_f^2 0.00.

Found: C, 38.71; H, 8.07; N, 22.74%. Calcd for $C_8H_{19}O_3N_5 \cdot CH_3COOH \cdot H_2O$: C, 38.83; H, 8.16; N, 22.65%.

Amino acid ratios in acid hydrolyzate: Pro 1.05, Gly 1.00, Arg 0.97.

CD Measurement. The measurements were performed with JASCO J-20 Automatic Recording Spectropolarimeter over a wavelength range of 200 to 250 nm. A cell of path length 0.2 mm was used and the runs were made at ambient temperature. Patterns in solvent of distilled water are shown in Fig. 5.

Sensory Test. The bitterness of the synthetic peptide was organoleptically determined *via* panel evaluation by five people. A series of solutions of decreasing concentration was prepared in which each solution was half as strong as its proceeding one. Before testing the sample, the panelist's mouth was thoroughly rinsed with distilled water. The sample size was usually 2—3 ml. The sample solution was held in the mouth for *ca.* 10 seconds and then spit out. The threshold value and the $R_{caf.}$ (ratio of caffeine) value, which expresses the extent of the strength of bitterness of the synthetic peptides, are shown in the Table.

The authors wish to express their thanks to Professor Sakuzo Fukui of Hiroshima University for his helpful discussion in the course of this study. Thanks are also due to Associate Professor Michio Kondo of Saga University for his help in the CD measurements, and to Dr. Shinji Okumura of Ajinomoto Co. Inc., for supplying some amino acids.

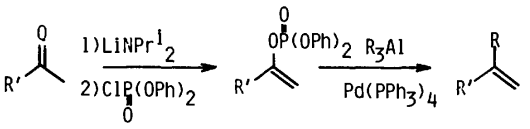
Cross-coupling Reaction between Enol Phosphates and Organoaluminium Compounds in the Presence of Palladium(0) Catalyst

Kazuhiko TAKAI, Mitsuyoshi SATO, Koichiro OSHIMA,* and Hitosi NOZAKI
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606
(Received June 25, 1983)

The title reaction in the presence of a catalytic amount of tetrakis(triphenylphosphine)palladium(0) affords alkylative coupling products in good to excellent yields in 1,2-dichloroethane at room temperature. This coupling reaction under C(sp^2)-O cleavage proceeds stereospecifically. The reaction does not affect a coexisting vinyl sulfide group. This feature enables 1,2- and 1,3-carbonyl transposition with or without alkylation *via* phenylthio-substituted enol phosphates.

The regioselective transformation of ketones into alkyl-substituted olefins is an important process in organic synthesis. The classical Grignard addition to ketones or organolithium version, followed by dehydration of the resultant alcohols, generally gives isomeric olefins and/or skeletal rearrangement products.[1] We report here (1) regioselective olefin formation[2] and (2) keto carbonyl 1,2- and 1,3-transposition[3] by palladium(0)-promoted cross-coupling of enol diphenyl phosphates and organoaluminium compounds.

(1) Regioselective Olefin Formation from Ketones. During the past decade, cross-coupling of alkenyl halides with organolithium and organomagnesium compounds has been achieved in the presence of Pd(0) or Ni(0) catalyst.[4,5] However there are few examples of the replacement of an enolate oxygen by an alkyl substituent.[6] We have found that organoaluminium compounds cause alkylation of enol phosphates under the C(sp^2)-O bond fission in the presence of a catalytic amount of $Pd(PPh_3)_4$ (Scheme 1). The results are summarized in Table 1.



Scheme 1.

Alkynyl (Runs, 3, 4, 8, and 10) and alkenyl group (Run 5) were introduced selectively in preference to the ubiquitous alkyl substituents on aluminium. The reaction of (*E*)-1-heptenyldiisobutylaluminium (Run 5) prepared *in situ* from 1-heptyne and Bu^i_2AlH in hexane,[7] gave a diene having and (*E*) olefinic linkage as the sole product.

Organolithium and magnesium compounds were not suitable for this reaction, as these organometallics caused nucleophilic attack on phosphorus atom of 1-phenylethenyl diphenyl phosphate (**1**), produc-

TABLE 1. COUPLING REACTION BETWEEN ENOL DIPHENYL PHOSPHATES AND ORGANOALUMINIUM REAGENTS CATALYZED BY $Pd(PPh_3)_4$[a]

Run	Enol phosphate	Aluminium reagent	Reaction time / h	Yield[b] of coupling product / %
1	$CH_3(CH_2)_9C(OP(O)(OPh)_2)=CH_2$	Me_3Al	2	91

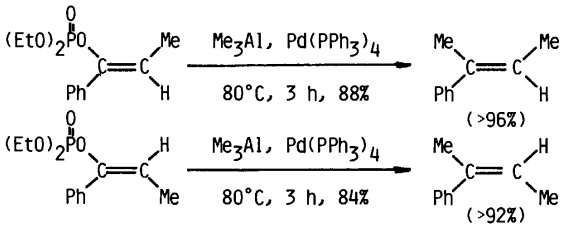
a) Reactions were performed on 2.0 mmol scale at 25 °C. Four mmol of aluminium reagent and 0.2 mmol of $Pd(PPh_3)_4$ were employed. b) Yields are based on isolated, purified products. c) Ethylated products were not detected. The sole product was the respective 2-substituted ethynylation product. d) GLPC yield.

ing acetophenone upon workup. In contrast, the less nucleophilic organoaluminium compounds effectively induce the desired replacement of diphenyl phosphate group under new C-C bond formation.[8]

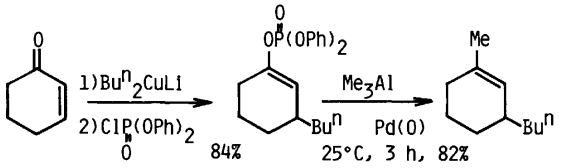
The reaction did not occur in the absence of the Pd(0) catalyst. Yields in the reaction between enol phosphate **2** and trimethylaluminium in the presence of various kinds of catalysts are given below: [Ni(acac)$_2$] (80 °C, 6 h, 12%), [Ni(acac)$_2$]-PPh$_3$-Bu$^i_2$AlH (80 °C, 6 h, 18%), [NiBr$_2$(PPh$_3$)$_2$] (80 °C, 6 h, <5%), [PdCl$_2$(PhCN)$_2$] (80 °C, 8 h, <5%), [Pd(acac)$_2$] (80 °C, 8 h, <5%).

The cross-coupling reactions proceed stereospecifically, analogously as those of alkenyl halides and organolithium compounds (or Grignard reagents).[5a] For example, methylation of (*Z*)- and (*E*)-1-phenyl-1-propenyl diethyl phosphates[9] afforded (*E*)- and (*Z*)-2-phenyl-2-butene in 88 and 84% yield; their isomeric purities are over 96 and 92% respectively (Scheme 2). The diethyl phosphate group is less effective than diphenyl phosphate as a leaving group. The reaction between diethyl phosphates and Me$_3$Al did not proceed at 25 °C but required heating at reflux in 1,2-dichloroethane.



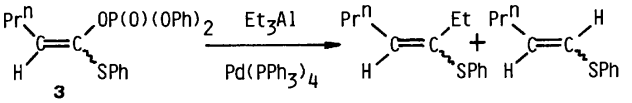
Scheme 2.

An enol phosphate was prepared alternatively by 1,4-addition of lithium dialkylcuprate(I) to an α,β-unsaturated carbonyl compound, followed by trapping of the resulting enolate with diphenyl phosphorochloridate.[10] Treatment of the enol phosphate furnished selective 1,3-dialkylation of the original conjugated enone (Scheme 3).



Scheme 3.

(2) 1,2- and 1,3- Transposition of a Keto Group. Scheme 4 shows that the present procedure does not affect the coexisting vinyl sulfide group, in sharp contrast to the Takei's analogous sp^2 carbon alkylation with Ni(0) catalyst.[11] Since alkenyl sulfides are valuable synthetic precursors of carbonyl compounds,[12,13] further extension of this reaction has been explored.



Scheme 4.

Treatment of phenylthio-substituted enol phosphate with organoaluminium compounds bearing a β-hydrogen, such as triethylaluminium, has afforded a mixture of the alkylated product and the hydrogenated one (Scheme 4). The ratios of these two products heavily depended on the solvents used. The reaction of the enol phosphate **3** and Et$_3$Al gave the following ratios of ethylated and hydrogenated products in solvents given in parentheses: 29:71 (hexane), 48:52 (1,2-dichloroethane), 62:38 (benzene), 71:29 (ether), 60:40 (THF), 71:29 (THF-HMPA, 9:1). The ethylated product was favored by using more

Table 2. Coupling reaction between enol phosphates derived from thiocarboxylic *S*-esters and organoaluminium reagents catalyzed by Pd(PPh$_3$)$_4$[a]

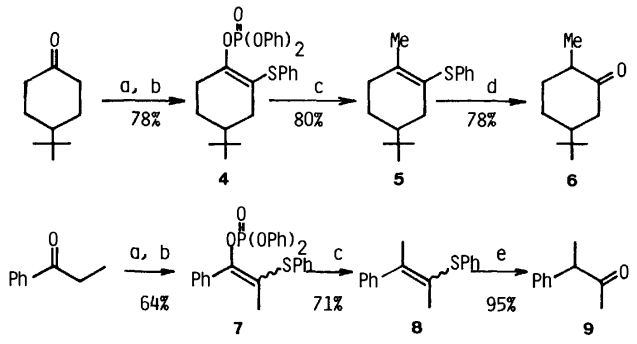
a) Reactions were performed on 2.0 mmol scale at 25 °C in benzene. Four mmol of aluminium reagent and 0.2 mmol of Pd(PPh$_3$)$_4$ were employed. b) Hydrolysis with TiCl$_4$. See Ref. 13. c) Mixture of ethylated and hydrogenated products in 3:2 ratio. d) Ethynylation or ethenylation product was obtained exclusively. e) Hydrolysis with HgCl$_2$. See Ref. 14.

polar solvents.

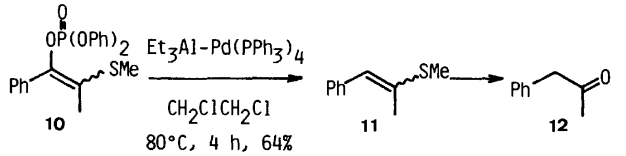
Coupling reactions between enol phosphates derived from thiocarboxylic *S*-esters and organoaluminium reagents are shown in Table 2. Hydrolysis of the resulting vinyl sulfides with $TiCl_4$[13] or $HgCl_2$[14] proceeded easily to give the corresponding ketones.

Scheme 5 provides 1,2-transposition[15] of a carbonyl group, accompanied by alkylation. Treatment of the enol phosphate **4** derived from α-phenylthio ketone with Me_3Al and a catalytic amount of $Pd(PPh_3)_4$ afforded the methylated alkenyl sulfide **5** in 80% yield. Hydrolysis with $TiCl_4$ gave the ketone **6**, which completed its 1,2-carbonyl transposition under methylation. The enol phosphate **10** was converted into benzyl methyl ketone in nearly 60% overall yield upon treatment with Et_3Al-$Pd(PPh_3)_4$ reagent and hydrolysis of the simple reduction product **11** isolated in 64% yield (Scheme 6). The ethylated sulfide, PhC(Et)=C(SMe)Me, was isolated in less than 4% yield.

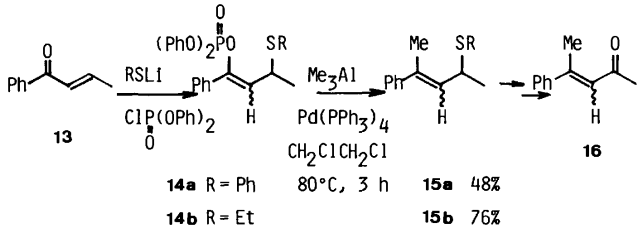


(a) $LiNPr^i_2$, PhSSPh (b) NaH, $ClP(O)(OPh)_2$ (c) Me_3Al, $Pd(PPh_3)_4$, CH_2ClCH_2Cl, 80 °C (d) $TiCl_4$-H_2O, CH_2Cl_2 (e) $TiCl_4$-H_2O, CH_3COOH

Scheme 5.



Scheme 6.



Scheme 7.

Alkylative 1,3-transposition[16] of a carbonyl group could be also achieved (Scheme 7). Enol phosphates **14a, b** prepared by 1,4-addition of RSLi (R=Ph, Et) to an enone **13** and successive phosphorylation were submitted to alkylation with the Me_3Al-$Pd(PPh_3)_4$ system. The alkylated product **15a** was transformed into an enone **16** by the procedures previously reported.[16a]

Experimental

The IR spectra were determined on Shimadzu IR-27-G spectrometer, the mass spectra, on a Hitachi M-80 machine, and the NMR spectra, on a Varian EM-360 spectrometer. The chemical shifts are given in δ, with TMS as the internal standard. The analyses were carried out by the staff at the Elemental Analyses Center of Kyoto University. 1,2-dichloroethane was dried on P_2O_5 and distilled. All the experiments were carried out under an argon atmosphere. Purification of product were performed by preparative thin layer chromatography (TLC) or column chromatography on silica gel (Merck Kieselgel 60). Analytical GLPC was performed with a Yanagimoto GCG-550-F or Shimadzu GC-4CPT. Preparative GLPC was performed with a JEOL-JGC-20K apparatus.

Preparation of Enol Diphenyl Phosphates. A solution of a ketone (5.0 mmol) in THF (30 ml) was treated with lithium diisopropylamide (5.5 mmol) at −78 °C for 30 min. To this was added at −78 °C a THF solution of diphenyl phosphorochloridate (1.3 g, 5.5 mmol) and the solution was allowed to warm to 0 °C. After being stirred for 20 min, the mixture was diluted with ether (20 ml), poured into ice-cold water (50 ml), and extracted with ether. The separated organic layer was washed with brine (2×20 ml), dried (Na_2SO_4), and concentrated. The crude product was purified by silica-gel column chromatography(hexane-ethyl acetate).

General Procedure for the Reaction between Enol Diphenyl Phosphates and Organoaluminium Compounds in the Presence of $Pd(PPh_3)_4$. Palladium tetrakis(triphenylphosphine) was prepared according to the literature.[17] To a solution of an enol diphenyl phosphate (2.0 mmol) and a catalytic amount of $Pd(PPh_3)_4$ (0.23 g, 0.2 mmol) in 1,2-dichloroethane (10 ml) was added at 25 °C a hexane solution of an organoaluminium compound (4.0 mmol) under an argon atmosphere. The yellow color of the solution turned red immediately in the case of trialkylaluminium. After being stirred for an appropriate time as listed in Table 1, the resulting mixture was diluted with ether (20 ml), poured into 1 M† hydrochloric acid (20 ml), and extracted with

† 1 M=1 mol dm^{-3}

ether. The separated organic layer was washed with brine (2×20 ml), dried over anhydrous sodium sulfate, and concentrated under reduced pressure. The crude product was purified by column chromatography or preparative TLC on silica gel using hexane as an eluent.

2-Methyl-1-dodecene: Bp 82 °C (bath temp, 5 Torr); IR (neat): 2930, 2850, 1654, 1470, 1460, 1374, 882 cm^{-1}; NMR (CCl_4): δ 0.89 (bt, J=7 Hz, 3H), 1.10—1.45 (m, 16H), 1.69 (s, 3H), 1.96 (t, J=7 Hz, 2H), 4.61 (s, 2H); MS m/e (%): 183 (M^++1, 2), 182 (M^+, 10), 126 (5), 97 (11), 83 (14), 69 (41), 56 (100), 41 (61); Found: C, 85.39; H, 14.37%. Calcd for $C_{13}H_{26}$: C, 85.63; H, 14.37%.

2-Ethyl-1-dodecene: Bp 86 °C (bath temp, 4 Torr); IR (neat): 2925, 2860, 1648, 1468, 1375, 960, 884 cm^{-1}; NMR (CCl_4): δ 0.87 (m, 3H), 1.00 (t, J=7 Hz, 3H), 1.15—1.45 (m, 16H), 1.70—2.15 (m, 4H), 4.62 (s, 2H); MS m/e (%): 196 (M^+, 4), 168 (5), 167 (5), 111 (9), 97 (15), 83 (25), 70 (100), 55 (70); Found: C, 85.55; H, 14.55%. Calcd for $C_{14}H_{28}$: C, 85.63; H, 14.37%.

2-Decyl-4-phenyl-1-buten-3-yne: Bp 176 °C (bath temp, 2 Torr); IR (neat): 2920, 2850, 1610, 1490, 1468, 1442, 890, 750, 686 cm^{-1}; NMR (CCl_4): δ 0.88 (bt, J=6 Hz, 3H), 1.15 1.80 (m, 16H), 2.22 (bt, J=6 Hz, 2H), 5.23 (s, 1H), 5.35 (s, 1H), 7.20—7.53 (m, 5H); MS m/e (%): 268 (M^+, 4), 210 (4), 168 (9), 154 (14), 142 (15), 141 (100), 140 (29); Found: C, 89.61; H, 10.74%. Calcd for $C_{20}H_{28}$: C, 89.49; H, 10.51%.

2-Decyl-1-octen-3-yne: Bp 128 °C (bath temp, 2 Torr); IR (neat): 2940, 2860, 1614, 1468, 1375, 885 cm^{-1}; NMR (CCl_4): δ 0.75—1.05 (m, 6H), 1.15—1.75 (m, 20H), 2.05 (t, J=7 Hz, 2H), 2.24 (t, J=6 Hz, 2H), 5.04 (s, 1H), 5.08 (s, 1H); MS m/e (%): 248 (M^+, 2), 191 (11), 149 (11), 135 (11), 122 (63), 108 (33), 107 (100), 93 (88), 79 (52); Found: C, 87.17; H, 13.20%. Calcd for $C_{18}H_{32}$: C, 87.02; H, 12.98%.

(E)-*2-Decyl-1,3-nonadiene*: Bp 175 °C (bath temp, 2 Torr); IR (neat): 2970, 2925, 2855, 1608, 1468, 1460, 962, 880 cm^{-1}; NMR (CCl_4): δ 0.73—1.07 (m, 6H), 1.07—1.73 (m, 22H), 1.73—2.27 (m, 4H), 4.77 (s, 2H), 5.57 (dt, J=15, 6 Hz, 1H), 5.97 (d, J=15 Hz, 1H); MS m/e (%): 264 (M^+, 8), 193 (14), 138 (82), 95 (91), 82 (72), 81 (100), 55 (58); Found: C, 86.57; H, 13.74%. Calcd for $C_{19}H_{36}$: C, 86.28; H, 13.72%.

2-Phenyl-1-butene: Bp 104 °C (bath temp, 15 Torr); IR (neat): 3090, 2960, 2930, 1630, 1498, 1465, 1445, 890, 770, 698 cm^{-1}; NMR (CCl_4): δ 1.01 (t, J=7.5 Hz, 3H), 2.47 (q, J= 7.5 Hz, 2H), 4.98 (s 1H), 5.18 (s, 1H), 7.00—7.40 (m, 5H); MS m/e (%): 132 (M^+, 66), 117 (100), 115 (28), 103 (53), 91 (33), 78 (36), 77 (46), 51 (62). The compound was identical with the authentic sample.[18]

2,4-Diphenyl-1-buten-3-yne: This compound (clear liquid) polymerized easily at 0 °C to give a pale yellow viscous liquid. IR (neat): 3070, 1604, 1576, 1494, 1448, 1335, 892, 753, 688 cm^{-1}; NMR (CCl_4): δ 5.64 (s, 1H), 5.86 (s, 1H), 7.15—7.75 (m, 10H); MS m/e (%): 205 (M^++1, 31), 204 (M^+, 100), 203 (54), 202 (54), 126 (23), 77 (39); Found: m/e 204.0895. Calcd for $C_{16}H_{12}$: M, 204.0940.

4-t-Butyl-1-methyl-1-cyclohexene: Bp 60 °C (bath temp, 9 Torr); IR (neat): 2975, 1675, 1390, 1360, 1242, 1175, 800 cm^{-1}; NMR (CCl_4): δ 0.86 (s, 9H), 1.00—1.43 (m, 3H), 1.60 (s, 3H), 1.67—1.98 (m, 4H), 5.29 (bs, 1H); MS m/e (%): 152 (M^+, 14), 137 (7), 123 (5), 109 (17), 95 (59), 81 (40), 57 (100); Found: C, 86.95; H, 13.00%. Calcd for $C_{11}H_{20}$: C, 86.76; H, 13.24%.

4-t-Butyl-1-(phenylethynyl)-1-cyclohexene: Bp 152 °C (bath temp, 2 Torr); IR (neat): 2950, 1598, 1492, 1364, 750, 688 cm^{-1}; NMR (CCl_4): δ 0.89 (s, 9H), 1.04—1.50 (m, 3H), 1.65—2.37 (m, 4H), 6.06 (bs, 1H), 7.12—7.50 (m, 5H); MS m/e (%): 238 (M^+, 23), 181 (18), 167 (27), 166 (21), 154 (66), 153 (26), 57 (100); Found: C, 90.89; H, 9.51%. Calcd for $C_{18}H_{22}$: C, 90.70; H, 9.30%.

(E)- *and (Z)-1-Phenyl-1-prophenyl Diethyl Phosphate*.[9] A mixture of α-bromopropiophenone (4.26 g, 20 mmol) and triethyl phosphite (4.15 g, 25 mmol) was heated at 100 °C for 24 h and washed with water (2×50 ml) to give a crude mixture containing two isomeric enol phosphates and *O,O'*-diethyl 1-benzoylethyl phosphonate in a ratio of *ca.* 3:1:1. The product was carefully separated by column chromatography (benzene–diethyl ether, 20:1) on silica gel (500 g). (*E*)-Isomer: Minor product (8% isolated yield); bp 96 °C (bath temp, 0.1 Torr); IR (neat): 3000, 1670, 1450, 1368, 1270, 1200, 1020, 884, 765, 698 cm^{-1}; NMR (CCl_4): δ 1.27 (t, J= 6 Hz, 6H), 1.75 (dd, J_{H-H}=7 Hz, J_{P-H}=3 Hz, 3H), 4.00 (dt, J_{H-H}=6 Hz, J_{P-H}=6 Hz, 4H), 5.68 (dq, J_{P-H}=2 Hz, J_{H-H}=7 Hz, 1H), 7.15—7.53 (m, 5H); MS m/e (%): 270 (M^+, 34), 155 (100), 127 (45), 116 (50), 115 (34), 99 (46). (*Z*)-Isomer: Major product (48% isolated yield); bp 94 °C (bath temp, 0.1 Torr); IR (neat): 2980, 1668, 1495, 1446, 1390, 1268, 1160, 1020, 882, 760, 690 cm^{-1}; NMR (CCl_4): δ 1.23 (t, J=6 Hz, 6H), 1.85 (dd, J_{H-H}=7 Hz, J_{P-H}=3 Hz, 3H), 4.00 (dt, J_{P-H}=6 Hz, J_{H-H}=6 Hz, 4H), 5.57 (dq, J_{P-H}=1.5 Hz, J_{H-H}=7 Hz, 1H), 7.05—7.55 (m, 5H); MS m/e(%): 270 (M^+, 32), 155 (100), 127 (45), 116 (55), 115 (34), 99 (50).

(E)-*2-Phenyl-2-butene*:[19] A hexane solution of trimethylaluminium (1.0 M, 40 ml, 4.0 mmol) was added at 25 °C to a stirred solution of (Z)-1-phenyl-1-propenyl diethyl phosphate (0.54 g, 2.0 mmol) and a catalytic amount of $Pd(PPh_3)_4$ (0.23 g, 0.2 mmol) in 1,2-dichloroethane (15 ml). The resulting mixture was heated at 80 °C for 3 h. After a usual workup, the crude product was purified by silica-gel column chromatography using hexane as an eluent to give (*E*)-2-phenyl-2-butene in 88% yield (0.23 g) as a colorless liquid: Bp 98 °C (bath temp, 20 Torr); IR (neat): 3040, 2930, 1650, 1600, 1500, 1448, 1382, 1022, 826, 750, 694 cm^{-1}; NMR (CCl_4): δ 1.79 (d, J=7 Hz, 3H), 2.02 (s, 3H), 5.76 (q, J=7 Hz, 1H), 7.03—7.37 (m, 5H); MS m/e (%): 132 (M^+, 86), 117 (100), 115 (20), 91 (18).

The isomeric purity of the crude product was determined by GLPC analysis (10% PEG 20 M, 2 m, 100 °C). (*E*)-Isomer: T_r=8.5 min. (*Z*)-Isomer: T_r=4.1 min.

(Z)-*2-Phenyl-2-butene*:[19] Treatment of (*E*)-1-phenyl-1-propenyl diethyl phosphate (0.54 g, 2.0 mmol) dissolved in 1,2-dichloroethane (15 ml) with trimethylaluminium (1.0 M of a hexane solution, 4.0 ml, 4.0 mmol) and a catalytic amount of $Pd(PPh_3)_4$ (0.23 g, 0.2 mmol) at 80 °C for 3 h gave the title (*Z*)-olefin in 84% yield (0.22 g). Bp 100 °C (bath temp, 20 Torr); IR (neat): 3040, 2930, 1650, 1602, 1500, 1450, 1380, 1260, 1024, 785, 750 cm^{-1}; NMR (CCl_4): δ 1.53 (d, J=7 Hz, 3H), 2.00 (s, 3H), 5.49 (q, J=7 Hz, 1H), 6.95—7.40 (m, 5H); MS m/e (%): 132 (M^+, 100), 117 (77), 91 (22).

3-Butyl-1-cyclohexenyl Diphenyl Phosphate. Butyllithium (2.5 ml of a 1.6 M hexane solution, 4.0 mmol) was added to a suspension of copper(I) iodide (0.19 g, 2.0 mmol) in ether (20 ml) at −23 °C under an argon atmosphere. After stirring at −23 °C for 20 min, the reaction mixture was cooled to −78 °C. A solution of 2-cyclohexen-1-one (0.19 g, 2.0 mmol) in ether (3.0 ml) was added and the resulting mixture was kept there for 1 h. A solution of diphenyl phosphorochloridate (0.59 g, 2.2 mmol) in ether (3.0 ml) was added and the mixture was stirred at −78 °C for 1 h, then warmed to 25 °C. Water (5.0 ml) was added and the mixture was filtered through a pad of Celite 545. The filtrate was washed with water (2×10 ml), dried over anhydrous sodium sulfate, and concentrated to give a pale yellow oil. Purification by column chromatography on silica gel (50 g) with hexane–ethyl acetate (10:1) as an eluent afforded a milky oil (0.61 g, 78%): Bp 162 °C (bath temp, 0.15 Torr); IR (neat): 2950, 1682, 1595, 1495, 1296, 1190, 950, 770, 750, 688 cm^{-1}; NMR (CCl_4): δ 0.87 (bt, J=6

Hz, 3H), 1.03—1.42 (m, 6H), 1.50—1.90 (m, 4H), 1.97—2.30 (m, 3H), 5.37 (bs, 1H), 7.04—7.42 (m, 10H); MS *m/e* (%): 386 (M^+, 27), 330 (20), 329 (100), 251 (71), 136 (23), 94 (17), 79 (32), 77 (61); Found: C, 68.50; H, 7.12%. Calcd for $C_{22}H_{27}O_4P$: C, 68.38; H, 7.04%.

3-Butyl-1-methyl-1-cyclohexene: Bp 127 °C (bath temp, 1 atm); IR (neat): 2950, 2860, 1460, 1380, 810 cm^{-1}; NMR (CCl_4): δ 0.91 (t, J=5 Hz, 3H), 1.05—1.46 (bm, 6H), 1.50—2.04 (m, 10H), 5.21 (bs 1H); MS *m/e* (%): 152 (M^+, 54), 96, (53), 95 (100), 81 (43), 79 (33), 67 (77), 55 (47); Found: C, 86.81; H, 13.30%. Calcd for $C_{11}H_{20}$: C, 86.76; H, 13.24%.

1-Phenylthio-1-pentenyl Diphenyl Phosphate (3). *S*-Phenyl pentanethioate was prepared by the reaction of the acid chloride with an excess of benezenethiol in pyridine. *S*-Phenyl pentanethioate (0.97 g, 5.0 mmol) dissolved in THF (25 ml) was treated with lithium diisopropylamide (5.5 mmol) at −78 °C. The resulting lithium enolate was trapped by diphenyl phosphorochloridate (1.48 g, 5.5 mmol) at 0 °C. The mixture was diluted with ether (20 ml) and poured into ice-cold water. The separated organic layer was washed with brine (2×20 ml), dried (Na_2SO_4), and concentrated. Purification of the crude product by silica-gel column chromatography (hexane-ethyl acetate, 10:1) gave the desired phosphate **3** in 89% yield (1.89 g). This compound decomposes at 140 °C (0.05 Torr). IR (neat): 3080, 2975, 1640, 1596, 1499, 1302, 1192, 960 cm^{-1}; NMR (CCl_4): δ 0.92 (t, J=7 Hz, 3H), 1.10—1.67 (m, 2H), 1.90—2.44 (m, 2H), 5.89 (dt, J=3, 7 Hz, 1H), 6.90—7.35 (m, 15H); MS *m/e* (%): 426 (M^+, 12), 251 (89), 177 (96), 176 (100), 147 (90), 143 (74), 110 (90), 99 (79), 77 (87); Found: C, 64.74; H, 5.46%. Calcd for $C_{23}H_{23}O_4PS$: C, 64.78; H, 5.44%.

2-Phenyl-1-(phenylthio)ethenyl Diphenyl Phosphate: This compound was prepared by treating *S*-phenyl 2-phenylethanethioate first with lithium diisopropylamide and then with diphenyl phosphorochloridate in THF. This phosphate decomposes at 150 °C (0.05 Torr). IR (neat): 3080, 1620, 1595, 1498, 1280, 1188, 945 cm^{-1}; NMR (CCl_4): δ 6.80—7.60 (m, 20H), 6.86 (d, J=2 Hz, 1H); MS *m/e* (%): 460 (M^+, 0.2), 342 (73), 306 (51), 250 (71), 109 (80), 94 (77), 86 (100), 77 (88), 65 (92); Found: *m/e* 460.0861. Calcd for $C_{26}H_{21}O_4PS$: M, 460.0899.

Cross-coupling Reactions between Organoaluminium Reagents and Enol Phosphates Derived from Thiocarboxylic S-Esters. A hexane solution of trimethylaluminium (1.0 M, 4.0 ml, 4.0 mmol) was added at 25 °C to a benzene (15 ml) solution of enol phosphate (2.0 mmol) derived from thiocarboxylic *S*-ester containing a catalytic amount of $Pd(PPh_3)_4$ (0.23 g, 0.2 mmol) under an argon atmosphere. After being stirred at 25 °C for an appropriate time, as listed in Table 2, the mixture was diluted with ether (20 ml) and poured into 1 M hydrochloric acid (20 ml). The separated organic layer was washed with brine (2×20 ml), dried over sodium sulfate, and concentrated. The crude product was purified by silica-gel column chromatography (hexane-ethyl acetate).

(E)- *and* (Z)-*1-Methyl-1-pentenyl Phenyl Sulfide.* TLC (hexane) showed two UV active bands, R_f=0.50 (23%, isolated yield) and R_f=0.40 (60%, isolated yield). Faster moving band: Bp 75 °C (bath temp, 0.08 Torr); IR (neat): 2970, 1634, 1588, 1484, 1442, 1380, 1056, 1025, 736, 686 cm^{-1}; NMR (CCl_4): δ 0.95 (t, J=7 Hz, 3H), 1.42 (tq, J=7, 7 Hz 2H), 1.87 (s, 3H), 2.27 (dt, J=7, 7 Hz, 2H), 5.71 (bt, J=7 Hz, 1H); MS *m/e* (%): 192 (M^+, 96), 163 (100), 136 (52), 130 (42), 110 (24); Found: C, 75.19; H, 8.43%. Calcd for $C_{12}H_{16}S$: C, 74.94; H, 8.39%. Slower moving band: Bp 72 °C (bath temp, 0.08 Torr); IR (neat): 2970, 1636, 1588, 1482, 1442, 1380, 1150, 1070, 1026, 896, 736, 686 cm^{-1}; NMR (CCl_4): δ 0.94 (t, J=7 Hz, 3H), 1.43 (tq, J=7, 7 Hz, 2H). 1.84 (s, 3H), 2.24 (dt, J=7, 7 Hz, 1H), 5.74 (bt, J=7 Hz, 1H), 6.94—7.30 (m, 5H); MS *m/e* (%): 192 (M^+, 99), 163 (100), 136 (57), 130 (41), 110 (26); Found: C, 74.89; H, 8.44%. Calcd for $C_{12}H_{16}S$: C, 74,94; H, 8.39%.

1-Pentenyl Phenyl Sulfide. GLPC analysis Silicone OV-17, 2 m, 140 °C) of the product generated by the reaction of enol phosphate **3** and triethylaluminium indicated two peaks, T_r=5.5 min (1-pentenyl phenyl sulfide) and T_r=7.3 min (1-ethyl-1-pentenyl phenyl sulfide). The analytically pure samples of both compounds were prepared by preparative GLPC (3% Silicone OV-17, 2 m). Bp 100 °C (bath temp, 1 Torr); IR (neat): 2970, 1612, 1590, 1488, 1444, 1092, 1026, 952, 734, 684 cm^{-1}; NMR (CCl_4): δ 0.94 (bt, 3H), 1.18—1.72 (m, 2H), 1.93—2.35 (m, 2H), 5.55—6.22 (m, 2H), 6.98—7.33 (m, 5H); MS *m/e* (%): 178 (M^+, 87), 149 (100), 110 (27); Found: C, 74.16; H, 8.01%. Calcd for $C_{15}H_{14}S$: 79.60; H, 6.23%.

1-Phenyl-2-(phenylthio)ethene and 1-Phenyl-2-phenylthio-1-butene. These compounds could not be separated well by GLPC (PEG 20M, PEG 6000, Silicone OV-17, or SE-30). The ratio of ethylated and hydrogenated products was determined by NMR analysis. Spectral data of the mixture are as follows. NMR (CCl_4): δ 1.13 (t, J=7 Hz, $C{=}C(SPh)CH_2C\underline{H}_3$), 2.27 (q, J=7 Hz, $C{=}C(SPh)C\underline{H}_2CH_3$), 6.3, 6.45 (d, J=11 Hz, $C{=}C\begin{matrix}\diagup\underline{H}\\ \underline{H}\diagdown\end{matrix}$), 6.68 (s, $PhC\underline{H}{=}C(SPh)$-Et), 6.61, 6.74 (d, J=15 Hz, $C{=}C\begin{matrix}\underline{H}\diagup & \diagdown\underline{H}\end{matrix}$), 7.03—7.54 (m, 10H); MS *m/e* (%): 240 (M^+ of ethylated compound, 64), 212 (M^+ of hydrogenated product 100). Hydrogenated product, 1-phenyl-2-(phenylthio)ethene ((*E*)- and (*Z*)-isomeric mixture), was prepared independently according to the literature.[20] NMR (CCl_4): δ 6.35 and 6.45 (d, J=11 Hz, 2H of (*Z*)-isomr), 6.61 and 6.74 (d, J=15 Hz, 2H of (*E*)-isomer), 6.99—7.53 (m, 10H); MS *m/e* (%): 212 (M^+, 100, 178 (29), 167 (29), 121 (39), 77 (50).

Hydrolysis of Vinyl Sulfide Derivatives with $TiCl_4$-H_2O System.[13] To a stirred dichloromethane (5 ml) solution of vinyl sulfide substrate (1.0 mmol) was added at 25 °C a

dichloromethane solution of titanium tetrachloride (1.0 M, 2.0 ml, 2.0 mmol) and water (72 mg, 4.0 mmol) successively. The mixture was stirred at 25 °C for several hours. Then ether (10 ml) was added to the reaction mixture and the whole was poured into water (10 ml). The separated organic layer was washed with brine (2×10 ml), dried (Na_2SO_4), and concentrated. Purification was carried out by preparative TLC (hexane-ether).

2-Hexanone and benzyl methyl ketone were identical with the authentic samples.

(E)-6-Dodecen-5-one: Mercury(II) chloride (0.54 g, 2.0 mmol) was added to a solution of (*E*)-1-butylidene-2-heptenyl phenyl sulfide (0.14 g, 0.5 mmol) in CH_3CN-H_2O (3:1, 8 ml) at 25 °C. The resulting mixture was heated at 100 °C for 8 h with rapid stirring. The cold mixture was filtered and the residue was washed with ethyl acetate (2×10 ml). The separated organic layer was washed with water (10 ml) and brine (2×10 ml), dried over magnesium sulfate, and concentrated. Purification by preparative TLC (hexane-ethyl acetate, 10:1) afforded the enone in 65% yield (59 mg). Bp 89 °C (bath temp, 1.5 Torr); IR (neat): 2975, 2950, 1700, 1680, 1635, 1472, 982, 726 cm^{-1}; NMR (CCl_4): δ 0.93 (bt, J=7 Hz, 6H), 1.07—1.80 (m, 10H), 2.00—2.51 (m, 4H) 5.92 (d, J=16 Hz, 1H), 6.65 (dt, J=16, 7 Hz, 1H); MS *m/e* (%): 182 (M^+, 1), 153 (1), 140 (15), 125 (40), 111 (17), 55 (100); Found: C, 78.95; H, 12.39%. Calcd for $C_{12}H_{22}O$: C, 79.06; 12.16%.

4-t-Butyl-2-phenylthio-1-cyclohexenyl Diphenyl Phosphate (4). Treatment of 4-*t*-butyl-2-phenylthiocyclohexanone (0.79 g, 3.0 mmol) with sodium hydride (60%, 0.13 g, 3.3 mmol) and diphenyl phosphorochloridate (0.89 g, 3.3 mmol) in THF (15 ml) at 0 °C afforded the title phosphate **4** (78% yield from 4-*t*-butylcyclohexanone) as a pale yellow liquid: Bp 175 °C (bath temp, 0.05 Torr); IR (neat): 3080, 2980, 1666, 1595, 1492, 1365, 1290, 1185, 950, 770, 750 cm^{-1}; NMR (CCl_4): δ 0.84 (s, 9H), 1.20—2.00 (m, 2H), 2.00—2.50 (m, 3H), 2.68—3.00 (m, 2H), 7.00—7.50 (m, 15H); MS *m/e* (%): 494 (M^+, 100), 329 (52), 251 (42), 187 (58), 160 (71), 57 (59); Found: C, 68.07; H, 6.31%. Calcd for $C_{28}H_{31}O_4PS$: C, 68.00; H, 6.32%.

1-Phenyl-2-phenylthio-1-propenyl Diphenyl Phosphate (7). Treatment of 2-phenylthiopropiophenone (0.73 g, 3.0 mmol) dissolved in THF with lithium diisopropylamide (3.3 mmol) and diphenyl phosphorochloridate (0.89 g, 3.3 mmol) at °C gave title phosphate **7** (64% yield from propiophenone) as a pale yellow liquid: Bp 176 °C (bath temp, 0.05 Torr); IR (neat): 3070, 1592, 1492, 1442, 1298, 1186, 1060, 955, 686 cm^{-1}; NMR (CCl_4): δ 1.78 and 2.00 (d, J=3 and 2 Hz respectively, 3H, (*E*)- and (*Z*)-isomeric mixture), 6.95—7.60 (m, 20H); MS *m/e* (%): 474 (M^+, 4), 326 (100), 325 (67), 251 (18), 233 (18), 170 (28), 94 (29); Found: C, 68.47; H, 5.15%. Calcd for $C_{27}H_{23}O_4PS$: C, 68.34; H, 4.89%.

5-t-Butyl-2-methyl-1-cyclohexenyl Phenyl Sulfide (5). To a solution of enol diphenyl phosphate **4** (0.99 g, 2.0 mmol) and $Pd(PPh_3)_4$ (0.23 g, 0.2 mmol) in 1,2-dichloroethane (10 ml) was added at 25 °C a hexane solution of trimethylaluminium (1.0 M, 5.0 ml, 5.0 mmol). The resulting mixture was heated at 80 °C for 4 h. After the usual workup, as described above, the crude product was purified by silica-gel column chromatography (hexane-ethyl acetate, 10:1) to give the sulfide **5** (0.42 g, 80%) as a colorless liquid: Bp 132 °C (bath temp, 2 Torr); IR (neat): 2960, 1752, 1588, 1482, 1442, 1364, 1220, 1020, 735, 688 cm^{-1}; NMR (CCl_4): δ 0.83(s, 9H), 1.13—1.46 (m, 3H), 1.92 (s, 3H), 1.46—2.35 (m, 4H), 7.00—7.40 (m, 5H); MS *m/e* (%): 260 (M^+, 100), 203 (8), 95 (44), 93 (42), 57 (78); Found: *m/e* 260.1582. Calcd for $C_{17}H_{24}S$: M, 260.1600.

2-Phenyl-3-phenylthio-2-butene (8): Bp 138 °C (bath temp, 2 Torr); IR (neat): 3080, 2940, 1590, 1484, 1445, 1024, 738, 700, 690 cm^{-1} NMR (CCl_4): δ 1.80, 2.03, 2.16, 2.30 (s, total 6H, (*E*)- and (*Z*)-isomeric mixture), 7.00—7.50 (m, 10H); MS *m/e* (%): 240 (M^+, 60), 132 (23), 131 (100), 91 (76); Found: C, 79.90; H, 6.75%. Calcd for $C_{16}H_{16}S$: C, 79.95; H, 6.71%.

2-Methyl-5-t-butylcyclohexanone (6).[21] Alkenyl sulfide **5** was subjected to hydrolysis with titanium tetrachloride according to the literature.[13] Bp 108 ° (bath temp, 3 Torr); IR (neat): 2970, 1708, 1448, 1364, 1220, 1052 cm^{-1}; NMR (CCl_4): δ 0.95 (s, 9H), 0.82—2.55 (m, 11H); MS *m/e* (%): 168 (M^+, 17), 112 (55), 111 (40), 57 (100), 55 (72).

3-Phenyl-2-butanone (9):[22] Bp 98 °C (bath temp, 5 Torr); IR neat): 3030, 2975, 2935, 1715, 1492. 1358, 1195, 950, 765, 702 cm^{-1}; NMR (CCl_4): δ 1.34 (d, J=7 Hz, 3H), 1.96 (s, 3H), 3.64 (q, J=7 Hz, 1H), 7.00—7.45 (m, 5H); MS *m/e* (%): 148 (M^+, 11), 133 (5), 105 (100), 79 (10), 77 (10), 43 (16).

2-Methylthio-1-phenyl-1-propenyl Diphenyl Phosphate (10). The enol phosphate **10** was prepared by treating α-(methylthio)propiophenone with lithium diisopropylamide and diphenyl phosphorochloridate in THF. TLC analysis (hexane-ethyl acetatea, 2:1) of the crude product showed two UV active bands, R_f=0.61 (49%, isolated yield) and R_f=0.51 (36%, isolated yield). The two isomers were separated by silica-gel column chromatography (hexane-ethyl acetate, 10:1). Faster moving band (**10a**): Bp 160 °C (bath temp, 0.15 Torr); IR (neat): 1590, 1488, 1294, 1184, 1055, 945, 684 cm^{-1}; NMR (CCl_4): δ 2.02 (d, J=2 Hz, 3H), 2.06 (s, 3H), 6.80—7.42 (m, 15H); MS *m/e* (%): 412 (M^+, 12), 306 (56), 251 (83), 250 (89), 170 (37), 147 (25), 94 (100); Found: *m/e* 412.0871. Calcd for $C_{22}H_{21}O_4PS$: M, 412.0899. Slower moving band (**10b**): Bp 160 °C (bath temp, 0.15 Torr); IR (neat): 1600, 1500, 1304, 1200, 1092, 955, 688 cm^{-1}; NMR (CCl_4): δ 1.92 (d, J=3 Hz, 3H), 2.22 (s, 3H), 6.80—7.40 (m, 15H); MS *m/e* (%): 412 (M^+, 50), 251 (19), 162 (46), 147 (100), 115 (26); Found: *m/e* 412.0882. Calcd for $C_{22}H_{21}O_4PS$: M, 412.0899.

(E)- and (Z)-1-Methyl-2-phenylethenyl Methyl Sulfide (11).[23] Treatment of enol phosphate **10a** dissolved in 1,2-dichloroethane with triethylaluminium (2.0 equiv) and a catalytic amount of $Pd(PPh_3)_4$ (0.1 equiv) at 80 °C for 4 h gave the hydrogenated sulfide **11** in 59% yield (*E*/*Z*=68/32). Meanwhile enol phosphate **10b** afforded (*E*)-isomer in 72% yield as the sole product under the same conditions. (*E*)-Isomer: Bp 94 °C (bath temp, 4 Torr); R_f=0.21 (hexane): IR (neat): 2920, 1618, 1500, 1440, 1376, 1002, 764, 692 cm^{-1}; NMR (CCl_4): δ 2.06 (s, 3H), 2.30 (s, 3H), 6.10 (s, 1H), 7.10—7.45 (m, 5H); MS *m/e* (%): 164 (M^+, 100), 149 (69), 134 (42), 115 (29), 91 (21). (*Z*)-Isomer: Bp 96 °C (bath temp, 4 Torr); R_f=0.17 (hexane); IR (neat): 2940, 1600, 1500, 1448, 1118, 746, 688 cm^{-1}; NMR (CCl_4): δ 2.17 (s, 3H), 2.24 (s, 3H), 6.33 (s, 1H), 6.95—7.42 (m, 5H); MS; *m/e* (%): 164 (M^+, 100), 149 (68), 134 (59), 115 (69), 91 (27).

1-Phenyl-3-phenylthio-1-butenyl Diphenyl Phosphate (14a). A solution of 1-phenyl-2-buten-1-one (**13**, 0.73 g, 5.0 mmol) in THF (20 ml) was added at −78 °C to a THF solution of lithium benzenethiolate (5.0 mmol) and the whole was stirred at 0 °C for 15 min. To this mixture was added a THF solution of diphenyl phosphorochloridate (5.0 mmol). After being stirred at 0 °C for 20 min, the mixture was diluted with ether (20 ml) and poured into ice-cold water (30 ml). The separated organic layer was washed with brine (2×20 ml), dried (Na_2SO_4), and concentrated. Purification of the crude product gave the desired phosphate **14a** in 74% yield (1.80 g). Bp 166 °C (bath temp, 0.05 Torr); IR (neat): 3075, 1662, 1595, 1498, 1302, 1188, 950 cm^{-1}; NMR (CCl_4): δ 1.36 (d. J=7 Hz, 3H), 4.30 (dq, J=10, 7 Hz, 1H), 5.44 (dd, J=2, 10 Hz, 1H), 6.84—7.50 (m, 20H); MS *m/e* (%): 488 (M^+, 1), 380 (33), 379 (100), 342 (35), 252 (49), 251 (98), 129 (99), 128 (97), 109 (95), 77 (93), 65 (95); Found: C, 68.60; H, 5.33%. Calcd for $C_{28}H_{25}O_4PS$: C, 68.84; H, 5.16%.

1-Phenyl-3-ethylthio-1-butenyl Diphenyl Phosphate (14b). This compound was prepared by using lithium ethanethiolate instead of lithium benzenethiolate in a manner similar to that described above. Bp 160 °C (bath temp, 0.05 Torr); IR (neat): 3070, 2975, 1660, 1592, 1495, 1186, 950 cm^{-1}; NMR (CCl_4): δ 1.16 (t, J=7 Hz, 3H), 1.27 (d, J=7 Hz,3H), 2.38 (q, J=7 Hz, 2H), 3.95 (dq, J=10, 7 Hz, 1H), 5.46 (dd, J=2, 10 Hz, 1H), 6.83—7.57 (m, 15H); MS m/e (%): 440 (M^+, 6), 379 (15), 251 (100), 190 (47), 175 (37), 129 (66), 77 (58); Found: C, 65.17; H, 5.68%. Calcd for $C_{24}H_{25}O_4PS$: C, 65.44; H, 5.72%.

2-Phenyl-4-phenylthio-2-pentene (15a). Enol diphenyl phosphate **14a** (0.97 g, 2.0 mmol) dissolved in benzene (15 ml) was treated with trimethylaluminium (1.0 M of a hexane solution, 5.0 ml, 5.0 mmol) and a catalytic amount of $Pd(PPh_3)_4$ (0.23 g, 0.2 mmol) at 80 °C for 3 h. After a usual workup,the crude product was purified by preparative TLC (hexane-ethyl acetate, 5:1) to afford the title coupling product **15a** in 48% yield (0.24 g). Bp 117 °C (bath temp, 0.09 Torr); IR (neat): 3080, 2985, 1606, 1592, 1502, 1445, 1200, 1024, 872 cm^{-1}; NMR (CCl_4): δ 1.27, 1.38 (d, J=7 Hz each, 3H, (*E*)- and (*Z*)-isomeric mixture), 1.68, 1.93 (s, 3H), 3.70, 4.00 (dq, J=11, 7 Hz each, 1H), 5.29, 5.53 (bd, J=10 Hz each, 1H), 7.01—7.46 (m, 10H); MS m/e (%): 254 (M^+, 1), 145 (100), 129 (9), 117 (12), 91 (8); Found: m/e 254.1128. Calcd for $C_{17}H_{18}S$: M, 254.1130.

2-Phenyl-4-ethylthio-2-pentene (15b): Bp 95 °C (bath temp, 0.1 Torr); IR (neat): 2980, 2940, 1605, 1503, 1452, 1385, 1272, 1213, 874, 758, 693 cm^{-1}; NMR (CCl_4): δ 1.22 (t, J=7 Hz, 3H), 1.31 (d, J=7 Hz, 3H), 2.05 (s, 3H), 2.41 (q, J=7 Hz, 2H), 3.75 (dq, J=10, 7 Hz, 1H), 5.54 (bd, J=10 Hz, 1H), 7.05—7.43 (m, 5H); MS m/e (%): 206 (M^+, 3), 145 (100), 128 (28), 117 (24), 91 (11); Found: C, 75.69; H, 8.92%. Calcd for $C_{13}H_{18}S$: C, 75.67; H, 8.79%.

(E)-*4-Phenyl-3-penten-2-one (16).* Treatment of allyl sulfide **15a** dissolved in methanol-water with sodium periodate (1.05 equiv) at 0 °C for 4 h afforded the corresponding sulfoxide (**17**, UV active, R_f=0.32 (hexane-ethyl acetate, 1:1)) in 74% yield. The sulfoxide **17** was treated with lithium diisopropylamide (1.5 equiv) and diphenyl disulfide (1.5 equiv) in THF at −78—0 °C for 1 h to give 2-phenyl-4-phenylthio-3-penten-2-ol (**18**, UV active, R_f=0.30 (hexane-ethyl acetate, 5:1). Hydrolysis of the crude sulfide **18** with mercury(II) chloride (1.05 equiv) in acetonitrile-water at 50 °C for 6 h gave the title enone **16** (E/Z=95/5) in 68% yield from **17**. Bp 85 °C (bath temp, 1 Torr); IR (neat): 1730, 1675, 1597, 1490, 1370, 1352, 1240, 1035, 955 cm^{-1}; NMR (CCl_4): δ 2.17 (s, 3H), 2.47 (s, 3H), 6.34 (s, 1H), 7.10—7.52 (m, 5H); MS m/e (%): 160 (M^+, 66), 159 (100), 145 (87), 117 (45), 115 (36), 91 (24). The compound was identical with the authentic sample.[24]

Financial support by the Ministry of Education, Science and Culture (Grant-in-Aid Nos. 403022, 530706) is gratefully acknowledged.

(Received July 11, 1983)

Entirely new type sydnones having alternating carbon-nitrogen chain groups such as 3-aryl-4-(arylcarbonimidoylcarbamoyl)sydnones, 3-aryl-4-(dimethylaminomethylenecarbamoyl)sydnones, and 4-(dimethylaminomethylenethiocarbamoyl)-3-phenylsydnone were prepared in high yields from 3-aryl-4-chloroformylsydnone, 3-aryl-4-carbamoylsydnone, and 3-phenyl-4-thiocarbamoylsydnone, respectively. The cyclization of the alternating carbon-nitrogen chain groups provided new sydnone derivatives having heterocyclic substituents such as 1,2,4-oxadiazol-5-yl, 1,2,4-triazol-3-yl, and 1,2,4-thiadiazol-5-yl groups in good yields.

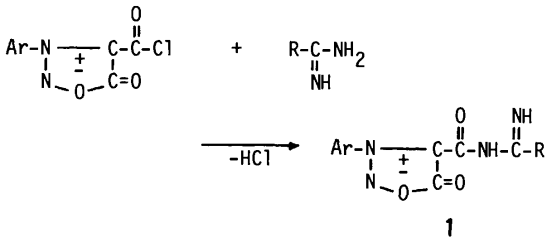
Sydnone is a typical mesoionic compound and its chemical and physical properties are very unique.[2,3)] Recently, many sydnone derivatives have been found to have biological and pharmacological activities.[2,4)] In addition, alternating carbon-nitrogen chain and nitrogen-containing heterocyclic compounds are also well known to show similar activities.

It therefore should be significant to establish some methods for synthesizing sydnone compounds having alternating carbon-nitrogen chain and heterocyclic groups as their substituents. However, a sydnone ring is so sensitive to acids, alkalies, and heat that reaction conditions for the preparation of sydnone compounds seem to be limited in cases. One of excellent methods for preparing alternating carbon-nitrogen chain compounds is to start from amino compounds but 4-aminosydnone compounds have been unknown, though some attempts had been done.[5)] Both amidines and imidates are also useful as precusors for the alternating carbon-nitrogen chain compounds, but their preparations have been unsuccesfully tried in the case of sydnone compounds.[6)]

In this work, the synthesis of sydnones attached to a carbon atom of the alternating carbon-nitrogen groups was aimed.

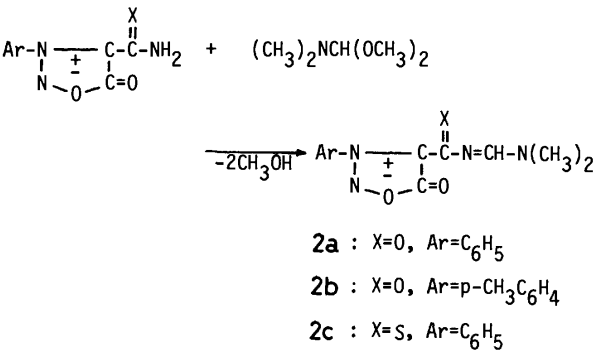
Results and Discussion

Synthesis of Sydnone Compounds Having Alternating Carbon-Nitrogen Chain Groups. 3-Aryl-4-(arylcarbonimidoylcarbamoyl)sydnones (1): Using a method similar to the preparation of *N*-acylamidines,[7,8)] the reaction of amidine hydrochloride with 3-aryl-4-chloroformylsydnone was carried out in aqueous solution in the presence of sodium hydroxide at room temperature. However, the yield was very low because of low solubility of the chloride and its instability in an alkaline solution. It was found that **1** could be prepared in good yields by changing the solvent and base into DMF and two equiv of triethylamine, respectively. Table 1 summarizes synthetic results of **1**.



Scheme 1.

*3-Aryl-4-(dimethylaminomethylenecarbamoyl)sydnones (**2a**, **2b**) and 3-Aryl-4-(dimethylaminomethylenethiocarbamoyl)sydnone (**2c**)*: Recently Lin *et al.*[8)] found that amides reacted readily with *N*,*N*-dimethylalkanamide dimethyl acetal to give N^2-acyl-N^1,N^1-dimethylamidines in good yields. Using this new amination method, **2a** and **2b** were prepared quantitatively by heating 3-aryl-4-carbamoylsydnone in large excess amount of *N*,*N*-dimethylformamide dimethyl acetal. In a similar manner, **2c** was also obtained quantitatively from 3-phenyl-4-thiocarbamolsydnone at room temperature. Physical properties and spectral data of **2** are summarized in Table 2.



Scheme 2.

Cyclization of Sydnone Compounds Having Alternating Carbon-Nitrogen Chain Groups. The alternating carbon-nitrogen chains of the sydnone compounds synthesized above could be converted into the corresponding heterocyclic groups without any decomposition of their sydnone rings.

*Synthesis of Sydnone Derivatives Having 1,2,4-Oxadiazol-5-yl Groups (**3**) from 1*: We previously developed a novel synthesis of 1,2,4-oxadiazoles from *N*-haloamidino compounds.[7,8)] In this work, this synthetic reaction could be successfully extended to the

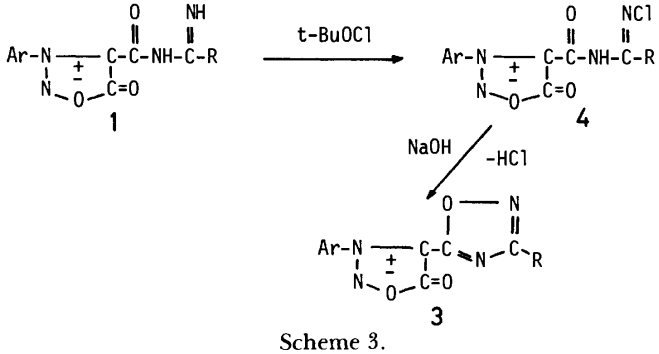
conversion of **1** into **3**, as shown in Scheme 3. The cyclization was found to proceed in DMF only when accurately equivalent amounts of both *t*-butyl hypochlorite and sodium hydroxide were used. When either reagent was used in excess, no sydnone derivatives having 1,2,4-oxadiazol-5-yl group (**3**) were obtained because the sydnone ring is very unstable to oxidation and alkali. In this reaction, attempts to isolate *N*-chloro intermediate (**4**) failed because of its instability. As shown in Table 3, **3** was thus prepared from **1** in excellent yields except for **3e**.



Scheme 3.

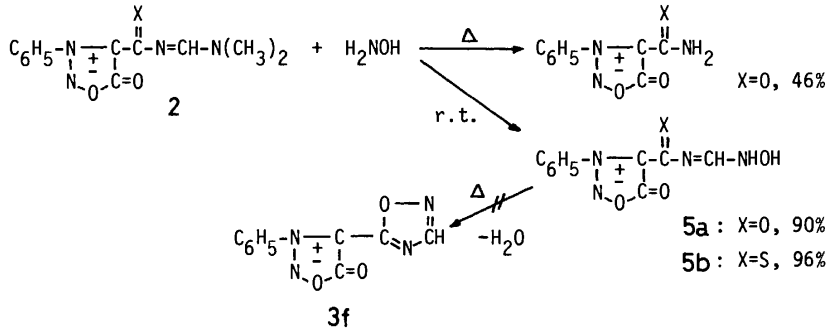
The cyclization seems to proceed *via* a nitrene intermediate as proposed previously by us.[7,8,10]

Attempts to Synthesize Sydnone Derivatives (3) Having 1,2,4-Oxadiazol-5-yl Group from 2: Recently Lin *et al.*[9] have reported a facile synthesis of 1,2,4-oxadiazoles and 1,2,4-triazoles by the reaction of N^2-acyl-N^1,N^1-dimethylamidines with hydroxylamine and hydrazine. Using their procedure, the cyclization of **2** to the corresponding (1,2,4-oxadiazol-5-yl)sydnone was attempted. However, when heated **2a** with hydroxylamine in an aq acetic acid solution, 4-carbamoylsydnone was formed instead of desired **3f**.

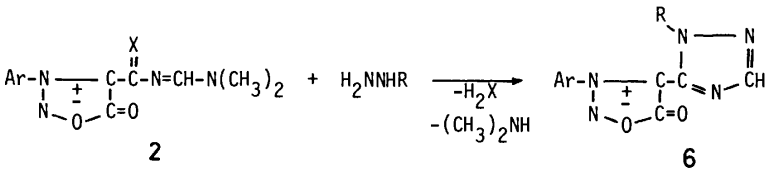
On the other hand this reaction was carried out at room temperature to give an open-chain intermediate (**5a**) in 90% yield. The cyclization was attempted by heating **5a** at 100 °C for 1 h in acetic acid, at 90 °C for 1 h in a mixed solution of acetic acid and dioxane (1 : 1), and for 2 h in boiling toluene, respectively. However all our

attempts failed and the starting material was recovered. The reaction seemed quite different from that of ordinary *N*-acylamidines with hydroxylamine. In a manner similar to the preparation of **5a**, **5b** was obtained in a high yield. When **5b** was heated in acetic acid at 90 °C, evolution of hydrogen sulfide was observed. However, **3b** expected could not be isolated.

Synthesis of Sydnone Derivatives (6) Having 1,2,4-Triazol-5-yl Groups from 2: Sydnone compounds (**6**) could be obtained in good yields by heating **2** and hydrazine hydrate in acetic acid at 90—100 °C for 1 h, as shown in Table 4.



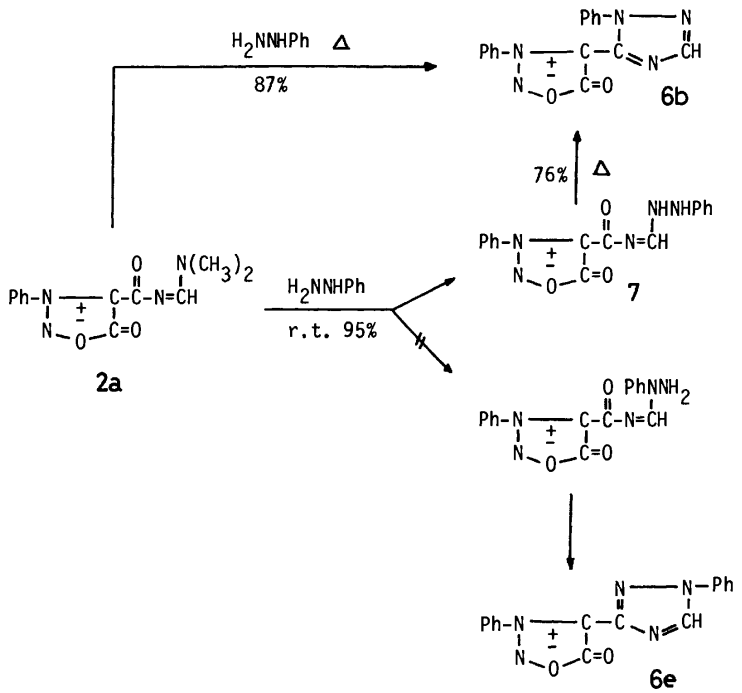
Scheme 4.



Scheme 5.

Table 4. Synthesis of sydnone compounds (**6**) from **2**

	Sydnone		Hydrazine	Product	Yield	Mp	IR (KBr)
	Ar	X	R		%	θ_m/°C	$\nu_{C=N}$/cm^{-1}
2a	C_6H_5	O	H	**6a**	85	268—269	1565
2c	C_6H_5	S	H	**6a**	88	268—269	1565
2a	C_6H_5	O	C_6H_5	**6b**	87	161—162.5	1560
2b	*p*-$CH_3C_6H_4$	O	H	**6c**	88	278—279	1570
2b	*p*-$CH_3C_6H_4$	O	C_6H_5	**6d**	82	193—194	1570

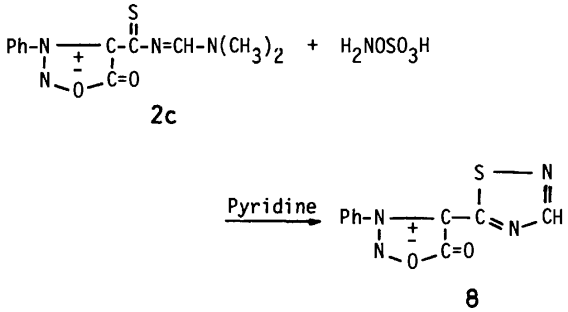


Scheme 6.

Since **2c** provided **6a** in an approximately same yield as **2a**, no remarkable difference in the reactivity was observed between the carbonyl and thiocarbonyl groups of **2**.

A sole product, **6b** was obtained in a good yield by heating **2** and phenylhydrazine although two possible products (**6b** and **6e**) were expected to be formed as shown in Scheme 6. The structure of **6b** was established by the NMR spectral study of an open-chain intermediate (**7**) which was obtained by the same reaction at room temperature. The proton NMR spectrum (DMSO-d_6) of the intermediate shows two doublets (C<u>H</u> and N<u>H</u>) at 8.25 and 9.55 ppm and one singlet (N<u>H</u>C_6H_5) at 9.81 ppm. The latter two signals disappeared while the former did not and changed to singlet by addition of deuterium oxide. On this bases, the structure of the open-chain intermediate was identified as **7**. When heated, **7** cyclized to give **6b**.

Synthesis of a Sydnone Derivative (8) Having 1,2,4-Thiadiazol-5-yl Group from 4-(Dimethylaminomethylenethiocarbonyl)-3-phenylsydnone (2c). Most recently, N^2-arylthiocarbonyl-N^1,N^1-dimethylamidines have been found to be transformed to 1,2,4-thiadiazoles by treatment with hydroxylamine-*O*-sulfonic acid in the presence of pyridine.[11] Using this new cyclization method, the transformation of **2c** to **8** was attempted. According to recommendation of the literature,[11] the reaction of **2c** was first run in a dichloromethane-ethanol mixture at room temperature, but the desired **8** was not formed and the starting **2c** was almost completely recovered. The reaction then was run under refluxing conditions to afford the formation **8** in a low yield as 35%. In this case, the starting **2c** still remained unreacted and 3-phenyl-4-thiocarbamoylsydnone was found to be formed. These results indicate that the thiocarbonyl group of **2c** is fairly less reactive than that of ordinary aromatic compounds.



Scheme 7.

The new types of sydnone compounds thus prepared are expected to be pharmacologically active and screening tests of several biological activities of these sydnones are currently under investigation.

Experimental

^{1}H NMR spectra were recorded at 60 MHz on a Hitachi R24B spectrometer using DMSO-d_6 and Me_4Si as solvent and an internal standard, respectively. IR spectra were obtained on a Hitachi 295 infrared spectrometer. Electron impact mass spectra were determined at 30 eV on a JEOL JMS-D100 mass spectrometer by direct introduction *via* solid probe.

3-Phenyl-4-*thio*carbamoylsydnone was prepared as follows: Hydrogen sulfide was passed into the solution of 4-cyano-3-phenylsydnone (2.20 g, 11.8 mmol) and triethylamine (1.44 g, 14.3 mmol) in 50 ml of ethanol at 0 °C for 1 h. The precipitating yellow solid was collected by filtration and washed with ether. The yield was 1.23 g (47%); mp 161 °C. Recrystallization from ethanol provided 0.96 g (37%) of the pure thiocarbamoylsydnone as orange-yellow needles; mp 161 °C (decomp). (Ref,[12] 133 °C).

4-Benzimidoylcarbamoyl-3-phenylsydnone (1a). To a stirred solution of benzamidine hydrochloride (0.44 g, 2.3 mmol) and triethylamine (0.73 g, 7.2 mmol) in 10 ml of DMF, gradually added a solution of 4-chloroformyl-3-phenylsydnone[13] (0.50 g 2.2 mmol) in 2 ml of DMF at 0 °C. After addition, the reaction mixture was stirred for 1.5 h at room temperature and was poured into about 100 ml of ice-water. The precipitates were collected by filtration. The yield was 0.51 g; mp 192—194 °C (decomp). Recrystallization from methanol provided 0.40 g (58%) of pure **1a** as a white solid. ^{1}H NMR δ=7.12—7.97 (m, 10H, C_6<u>H</u>$_5$), 9.36 (br s, 1H, N<u>H</u>), and 9.89 (br s, 1H, N<u>H</u>). Found: C, 62.28; H, 3.65; N, 18.04%. Calcd for $C_{16}H_{12}N_4O_3$: C, 62.34; H, 3.92; N, 18.17%.

4-(p-Nitrobenzimidoyl)-3-phenylsydnone (1b). Using the same procedure, the crude product was obtained; mp 169.5 —171.5 °C (decomp). Recrystallization from methanol provided pure **1b** (38%) as white needles. ^{1}H NMR δ=7.78—8.65 (m, 9H, Ar-<u>H</u>) and 10.05 (br s, 2H, N<u>H</u>). Found: C, 54.24; H, 3.49; N, 19.68%. Calcd for $C_{16}H_{11}N_5O_5$: C, 54.40; H, 3.14: N, 19.82%.

4-Benzimidoylcarbamoyl-3-(p-tolyl)sydhone (1c). Using the same procedure, the crude product was obtained from benzamidine and 4-chloroformyl-3-(*p*-tolyl)sydnone:[3e] mp 184—185 °C (decomp). Recrystallization from methanol provided pure **1c** (45%) as white needles. ^{1}H NMR δ=2.48 (s, 3H, C<u>H</u>$_3$), 7.40—7.80 (m, 9H, Ar-<u>H</u>), 9.42 (br s, 1H, N<u>H</u>), and 9.85 (br s, 1H, N<u>H</u>). Found: C, 63.13; H, 4.44; N, 17.08%. Calcd for $C_{17}H_{14}N_4O_3$: C, 63.35; H, 4.38; N, 17.38%.

4-(p-Nitrobenzimidoylcarbamoyl)-3-(p-tolyl)sydnone (1d). By the similar procedure, pure **1d** was obtained as white needles after recrystallization from methanol. ^{1}H NMR δ=2.30 (s, 3H, C<u>H</u>$_3$), 7.36 (d, 2H, J=8.4 Hz, Ar-<u>H</u>), 7.72 (d, 2H, J=8.4 Hz, Ar-<u>H</u>), 7.95 (d, 2H, J=11.4 Hz, Ar-<u>H</u>), 8.28 (d, 2H, J=11.4 Hz, Ar-<u>H</u>), and 9.75 (br s, 2H, N<u>H</u>). Found: C, 55.90; H, 3.46; N, 19.08%. Calcd for $C_{17}H_{13}N_5O_5$: C, 55.59; H, 3.57; N, 19.07%.

3-Phenyl-4-(piperidinocarbonimidoylcarbamoyl)sydnone (1e). By the similar method, pure **1e** was obtained as white needles after recrystallization from aq methanol. ^{1}H NMR δ=1.38 (br s, 6H, C<u>H</u>$_2$), 3.13 (br s, 4H, C<u>H</u>$_2$), 7.62 (s, 5H, C_6<u>H</u>$_5$), and 8.27 (br s, 2H, N<u>H</u>). Found: C, 57.27; H, 5.37; N, 22.30%. Calcd for $C_{15}H_{17}N_5O_3$: C, 57.14; H, 5.43; N, 22.21%.

4-(Dimethylaminomethylenecarbamoyl)-3-phenylsydnone (2a). A suspension of 4-carbamoyl-3-phenylsydnone[13] (4.07 g, 19.9 mmol) in *N*,*N*-dimethylformamide dimethyl acetal (4.68 g, 37.3 mmol) was heated at 110—120 °C for 1 h. After evaporation under reduced pressure, 5.16 g of a white solid was obtained. Recrystallization from ethanol provided 4.08 g (79%) of pure **2a** as white prisms. Found: C, 55.43; H, 4.49; N, 21.76%. Calcd for $C_{12}H_{12}N_4O_3$: C, 55.38; H, 4.65; N, 21.53%.

4-(Dimethylaminomethylenecarbamoyl)-3-(p-tolyl)sydnone (2b). Using the same procedure, the crude product was obtained; mp 175—176 °C. Recrystallization from ethanol provided pure **2b** as white prisms. Found: C, 56.67; H, 4.78; N, 20.15%. Calcd for $C_{13}H_{14}N_4O_3$: C, 56.93; H, 5.15; N, 20.43%.

4-(Dimethylaminomethylenethiocarbamoyl)-3-phenylsydnone (2c). A suspension of 3-phenyl-4-thiocarbamoylsydnone (1.00 g, 4.52 mmol) in *N*,*N*-dimethylformamide dimethyl acetal (0.68 g, 5.4 mmol) was allowed to stand at room

temperature for 1 h. Evaporation under reduced pressure provided 1.25 g of a reddish solid, mp 147 °C (decomp). Recrystallization from methanol gave 0.94 g (75%) of pure **2c** as reddish prisms. Found: C, 52.49; H, 4.45; N, 20.36; S, 11.56%. Calcd for $C_{12}H_{12}N_4O_2S$: C, 52.16; H, 4.38; N, 20.28; S, 11.60%.

*3-Phenyl-4-(3-phenyl-1,2,4-oxadiazol-5-yl)sydnone (**3a**).* To a stirred solution of **1a** (0.50 g, 1.61 mmol) in 20 ml of DMF was gradually added a solution of *t*-butyl hypochlorite (0.17 g, 1.60 mmol) in 5 ml of DMF at 0 °C. The color of the solution gradually changed to yellow. After the mixture had been stirred at the same temperature for 1 h, 1.6 ml of 1 M sodium hydroxide was added and the solution was stirred for additional 1 h. After the mixture had been warmed at 70—80 °C for 30 min, it was poured into about 100 ml of ice-water. After cooling the precipitates were separated by filtration and washed with water. The yield was 0.37 g, mp 163—166 °C (decomp). Recrystallization from dichloromethane-hexane provided pure **3a** as white needles. ^{1}H NMR δ=7.78—8.33 (m, 10H, C_6H_5). *m/e* 306 (M^+) and 248 (M^+—NO—CO). Found: C, 62.73; H, 3.02; N, 18.12%. Calcd for $C_{16}H_{10}N_4O_3$: C, 62.75; H, 3.29; N, 18.29%.

*4-[3-(p-Nitrophenyl)-1,2,4-oxadiazol-5-yl]-3-phenylsydnone (**3b**).* By the same procedure, the crude product was obtained; mp 205—206 °C (decomp). Recrystallization from dichloromethane-ether provided pure **3b** as white needles. ^{1}H NMR δ=7.85—8.53 (m, 9H, Ar-H). *m/e* 351 (M^+) and 293 (M^+—NO—CO). Found: C, 54.61; H, 2.47; N, 19.89%. Calcd for $C_{16}H_9N_5O_5$: C, 54.71; H, 2.58; N, 19.94%.

*4-(3-Phenyl-1,2,4-oxadiazol-5-yl)-3-(p-tolyl)sydnone (**3c**).* By the same procedure, the crude product was obtained; mp 159—163 °C (decomp). Recrystallization from dichloromethane-hexane provided pure **3c** as white needles in 60% yield. ^{1}H NMR δ=2.53 (s, 3H, CH_3), 7.52—7.95 (m, 9H, Ar-H). *m/e* 320 (M^+) and 262 (M^+—NO—CO). Found: C, 63.49; H, 3.68; N, 17.23%. Calcd for $C_{17}H_{12}N_4O_3$: C, 63.75; H, 3.78; N, 17.49%.

*4-[3-(p-Nitrophenyl)-1,2,4-oxadiazol-5-yl]-3-(p-tolyl)sydnone (**3d**).* By the same procedure, the crude product was obtained; mp 186—186.5 °C (decomp). Recrystallization from dichloromethane-ether provided pure **3d** as white needles. ^{1}H NMR δ=2.30 (s, 3H, CH_3), 7.63 (d, 2H, J=9.0 Hz, Ar-H), 7.93 (d, 2H, J=9.0 Hz, Ar-H), 8.15 (d, 2H, J=9.0 Hz, Ar-H), and 8.48 (d, 2H, J=9.0 Hz, Ar-H). *m/e* 365 (M^+) and 307 (M^+—NO—CO). Found: C, 55.82; H, 2.79; N, 19.04%. Calcd for $C_{17}H_{11}N_5O_5$: C, 55.90; H, 3.04; N, 19.17%.

*4-Hydroxyaminomethylenecarbamoyl-3-phenylsydnone (**5a**).* To a stirred solution of 0.30 g (4.3 mmol) of hydroxylamine hydrochloride, 10 ml of acetic acid, and 4.4 ml of 1 M sodium hydroxide was added **2a** (1.10 g, 4.2 mmol) and the mixture was stirred at room temperature for 1 h. The yellow precipitates were separated by filtration and washed with water. The yield was 0.94 g (90%), mp 180.5—182 °C (decomp). Recrystallization from ethanol provided pure **5a**; mp 180.5—182 °C (decomp). IR (KBr) 1775, 1695 (C=O), and 1660 cm^{-1} (C=N). ^{1}H NMR δ=7.61 (d, 1H, J=10.2 Hz, Ar-CH), and 7.75 (s, 5H, C_6H_5), 10.14 (d, 1H, J=10.2 Hz, NH), and 11.11 (s, 1H, OH). *m/e* 248 (M^+) and 190 (M^+—NO—CO). Found: C, 48.65; H, 3.18; N, 22.32%. Calcd for $C_{10}H_8N_4O_4$: C, 48.39; H, 3.25; N, 22.57%.

*4-Hydroxyaminomethylenethiocarbamoyl-3-phenylsydnone (**5b**).* The mixture of hydroxylamine hydrochloride (0.27 g, 3.9 mmol) and **2c** (1.00 g, 3.6 mmol) in 10 ml of acetic acid and 3.6 ml of 1 M sodium hydroxide was stirred at room temperature for 1 h. The resulting solid was separated by filtration and washed with ethanol to provide 0.79 g (83%) of a crude product, mp 142—145 °C (decomp). After addition of about 100 ml of water to the filtrate, the resulting precipitates were collected by filtration and washed with ethanol to provide the additional product, 0.12 g (13%); mp 141—143 °C (decomp). Recrystallization from aq acetone provided pure **5b** as orange needles; mp 142—144 °C (decomp). IR (KBr) 1755 (C=O), and 1655 cm^{-1} (C=N). ^{1}H NMR δ=7.68 (s, 5H, C_6H_5), 8.14 (d, 1H, J=8.4 Hz, CH), 11.55 (s, 1H, OH), and 11.78 (d, 1H, J=8.4 Hz, NH). *m/e* 264 (M^+), 246 (M^+—H_2S—NO—CO). Found: C, 45.85; H, 3.20; N, 21.02%; S, 12.15%. Calcd for $C_{10}H_8N_4O_3S$: C, 45.45; H, 3.05; N, 21.20; S, 12.13%.

*3-Phenyl-4-(1,2,4-triazol-3-yl)sydnone (**6a**).* *Synthesis of **6a** from **2a**:* The mixture of **2a** (1.00 g, 3.8 mmol) and hydrazine hydrate (0.20 g, 3.9 mmol) in 10 ml of acetic acid was heated at 90—100 °C for 1 h. After cooling, water was added to the reaction mixture. The precipitates were separated by filtration and washed with water. The yield was 0.75 g; mp 269—269.5 °C (decomp). Recrystallization from ethanol provided pure **6a** as white needles. IR (KBr) 1760 cm^{-1} (C=O). ^{1}H NMR δ=7.71 (s, 5H, C_6H_5), 8.52 (s, 1H, triazole C-H), and 14.36 (br s, 1H, NH). *m/e* 229 (M^+) and 171 (M^+—NO—CO). Found: C, 52.62; H, 2.85; N, 30.42%. Calcd for $C_{10}H_7N_5O_2$: C, 52.40; H, 3.80; N, 30.56%.

*Synthesis of **6a** from **2c***: The mixture of hydrazine hydrate (0.60 g, 1.1 mmol) and **2c** (0.30 g, 1.1 mmol) in 2 ml of acetic acid was heated at 90—100 °C for 1 h. After cooling about 50 ml of water was added to the reaction mixture. The needle precipitates were separated by filtration and washed with ethanol. The yield of **6a** was 0.22 g

*3-Phenyl-4-(1-phenyl-1,2,4-triazol-5-yl)sydnone (**6b**).* To a stirred solution of phenylhydrazine (0.13 g, 1.2 mmol) in 3 ml of acetic acid was added **2a** (0.30 g, 1.2 mmol). The color of the mixture changed to red and precipitates began to appear. Then, the mixture was heated at 90—100 °C for 1 h. The color gradually changed to yellow. About 100 ml of water was added to the reaction mixture and the resulting precipitates were separated and washed with ethanol. The yield was 0.31 g; mp 160.5—162 °C. Recrystallization from ethanol provided pure **6b** as pale yellow needles. IR (KBr) 1790 and 1780 cm^{-1} (C=O). ^{1}H NMR δ=7.56 (s, 5H, C_6H_5), 7.66 (s, 5H, C_6H_5), and 8.39 (s, 1H, triazole C-H). *m/e* 305 (M^+) and 247 (M^+—NO—CO). Found:, 63.20; H, 3.50; N, 23.20%. Calcd for $C_{16}H_{11}N_5O_2$: C, 62.95; H, 3.63; N, 22.94%.

*3-(p-Tolyl)-4-(1,2,4-triazol-3-yl)sydnone (**6c**).* Using the same procedure, the crude product was obtained; mp 278—279.5 °C (decomp). Recrystallization from ethanol provided pure **6c** as white needles. IR (KBr) 1775 cm^{-1} (C=O). ^{1}H NMR δ=2.45 (s, 3H, CH_3), 7.51 (d, 2H, J=9.0 Hz, tolyl CH), 7.74 (d, 2H, J=9.0 Hz, tolyl C-H), 8.70 (s, 1H, CH), and 14.74 (br s, 1H, NH). Found: C, 54.37; H, 3.57; N, 28.77%. Calcd for $C_{11}H_9N_5O_2$: C, 54.32; H, 3.73; N, 28.79%.

*4-(1-Phenyl-1,2,4-triazol-5-yl)-3-(p-tolyl)sydnone (**6d**).* Using the same prcedure, the crude product was obtained; mp 185—187 °C. Recrystallization from ethanol provided pure **6d** as white needles. IR (KBr) 1785 cm^{-1} (C=O). ^{1}H NMR δ=2.43 (s, 3H, CH_3), 7.48, 7.58 (two s, 9H, Ar-H), and 8.41 (s, 1H, triazol C-H). *m/e* 319 (M^+) and 261 (M^+—NO—CO) Found: C, 64.16; H, 3.98; N, 21.76%. Calcd for $C_{17}H_{13}N_5O_2$: C, 63.94; H, 4.10; N, 21.93%.

*3-Phenyl-4-(phenylhydrazinomethylenecarbamoyl)sydnone (**7**).* The mixture of phenylhydrazine (0.13 g, 1.2 mmol) and **2a** (0.30 g, 1.2 mmol) in 3 ml of acetic acid was allowed to stand at room temperature for 5 min. The resulting precipitates were separated by filtration and washed with ethanol. The yield was 0.34 g (90%); mp 182.5—184.5 °C. Recrystallization from acetone-hexane provided pure **7** as orange needles; mp 183—184.5 °C. IR (KBr) 1760 and 1675 cm^{-1} (C=O). ^{1}H NMR δ=6.56—7.30 (m, 5H, C_6H_5), 7.75 (s, 5H, C_6H_5) 8.25 (d, 1H, J=8.4 Hz, CH), 9.55 (d, 1H, J=8.4 Hz, NH), and 9.81 (s, 1H, NHC_6H_5). *m/e* 323 (M^+), 305 (M^+—H_2O) and 247 (M^+—H_2O—NO—CO). Found: C, 59.43; H, 3.99; N, 21.81%.

Calcd for $C_{16}H_{13}N_5O_3$: C, 59.44; H, 4.05; N, 21.66%.

Cyclization of **7** *to* **6b**. A mixture of **7** (84 mg, 0.26 mmol) in 1 ml of acetic acid was heated at 90—100 °C for 20 min. After cooling, about 100 ml of water was added to the reaction mixture. The resulting pale yellow precipitatees (60 mg, 76%) were separated by filtration. The product was identified as **6b** by comparison with IR spectrum.

3-Penyl-4-(1,2,4-thiadiazol-5-yl)sydnone (8). To a solution of **2c** (0.76 g, 2.8 mmol) and pyridine (0.49 g, 6.1 mmol) in 15 ml of dry dichloromethane was added a solution of hydroxylamine-*O*-sulfonic acid (0.35 g, 3.1 mmol) in 5 ml of absolute methanol. The reaction mixture was refluxed for 5 h. After cooling, about 30 ml of dichloromethane was added and the dichloromethane solution was washed with 2 M hydrochloric acid (50 ml×2), and water (50 ml), and then dried over sodium sulfate. After removal of the dichloromethane, the residue was chromatographed on silica gel (70—230 mesh). Elution with dichloromethane provided 0.24 g (35%) of the crude product. Recrystallization from dichloromethane-hexane provided 0.13 g (19%) of pure **8** as white needles, mp 144—145 °C. IR (KBr) 1775 cm^{-1} (C=O). ^1H NMR δ=7.73 (s, 5H, $C_6\underline{H}_5$) and 8.17 (s, 1H, thiazole C-$\underline{H}$). *m/e* 246 (M^+) and 188 ($M^+ -NO-CO$). Found: C, 48.68; H, 2.25; N, 22.57; S, 13.02%. Calcd for $C_{10}H_6N_4O_2S$: C, 48.78; H, 2.46; N, 22.75; S, 13.02%.

Infrared Spectroscopic Studies on the Resilium of a Surf Clam, *Spisula (Pseudocardium) sachalinensis*

Yasuo KIKUCHI* and Nobuo TAMIYA
Department of Chemistry, Faculty of Science, Tohoku University, Aobayama, Sendai, Miyagi 980
(Received July 11, 1983)

Sulfinyl group was detected in the resilium (internal hinge-ligament) of surf clam by IR spectrometry. The results reconfirm the previous reports on the presence of methionine *S*-oxide in the intact resilium protein. Aragonite structure was deduced for $CaCO_3$ in the resilium because the IR spectrum of the resilium was reproduced from those of decalcified resilium and aragonite ($CaCO_3$). The IR spectrum of intact protein component in the resilium was simulated from those of the resilium and aragonite ($CaCO_3$).

The hinge-ligaments of molluscan bivalves are elastic and function to open the shells. The resilium (internal hinge-ligament) of surf clam species (Mactridae family) consists of protein (40% of the dry weight) and calcium carbonate ($CaCO_3$). The resilium protein contains 50 mol% of glycine and 20 mol% of methionine of total amino acids.[1,2] Methionine in the resilium protein was suggested to be in an oxidized form, methionine *S*-oxide, by amino acid analysis of the alkaline hydrolysate of the resilium[1] and by solid-state ^{13}C-NMR spectroscopy on powdered resilium preparation without any chemical treatment.[2] It was the first solid evidence for the presence of methionine *S*-oxide in the intact natural proteins.

In the present study, an additional evidence for the presense of methionine *S*-oxide was obtained by infrared (IR) spectrometry and the aragonite structure of $CaCO_3$ was deduced by simulation method applied on IR spectra.

Experimental

Materials *Resilium*: Sakhalin surf clams, *Spisula (Pseudocardium) sachalinensis*, were collected at the north east coast of the main island of Japan. The resiliums were removed from the shells, dried *in vacuo* and stored at −20 °C.

Reduced Resilium: The powdered resilium (8.9 g) was stirred in 50% (v/v) aqueous *N*-methylmercaptoacetamide[3] (100 ml) at room temperature for 7 d, washed successively with water (50 ml×5), 50% (v/v) methanol (50 ml×5), methanol (50 ml×5) and acetone (50 ml×5) and dried *in vacuo* (7.1 g). The amino acid compositions of the resilium before and after the reduction are shown in Table 1.

TABLE 1. AMINO ACID COMPOSITION OF THE RESILIUM[a] BEFORE AND AFTER THE REDUCTION WITH *N*-METHYLMERCAPTOACETAMIDE

Amino acid[12]	Composition/mol%	
	Resilium	Reduced resilium
Met (O)	16	1
Met	0	19
Gly	53	52
Others	31	28

a) The resilium (about 2 mg) was hydrolyzed with 2.5 mol dm^{-3} NaOH at 105 °C for 15h. Amino acids were analyzed on JLC 10-D amino acid analyzer (JEOL Co. Ltd., Tokyo). No correction was made for hydrolytic losses.

Decalcified Resilium: The powdered resilium (2g) was stirred in 10% acetic acid (20 ml) for 15 h, washed with water (20 ml×5) and dried *in vacuo* (0.8 g).

Calcite and Aragonite: The authentic specimens of $CaCO_3$, calcite and aragonite, were provided by Dr. M. Akizuki of the Geology Department of this faculty.

Infrared Spectra. Infrared spectra were measured on a Hitachi 260-10 IR spectrophotometer (Hitachi Co. Ltd., Tokyo, Japan) by KBr disk method.

Combination of IR Spectra. The spectral data were digitized into absorbance values at every 50 cm^{-1} between 4000 cm^{-1} and 2000 cm^{-1} and at every 10 cm^{-1} between 2000 cm^{-1} and 650 cm^{-1}. The combination of the spectra was accomplished according to the additivity of absorbance values. The combination ratio was determined to give the smallest squared deviation of the differences between the resilium spectrum and the artificially prepared spectrum.

Results and Discussion

Methionine S-Oxide. While only 20 amino acids are involved as monomer building blocks in the protein synthesis, more than 140 amino acids have been identified in natural proteins because some amino acids are modified after they are incorporated into the peptide chain of proteins.[4] Methionine *S*-oxide had been detected in some proteins,[5-7] but it was not included in the list of post-translational modification products[4] because its contents were low and methionine can be oxidized *in vitro* during the isolation procedures of proteins.[8] Therefore, the presence of methionine *S*-oxide in an intact protein should be demonstrated excluding the possibility of formation as an artifact or, preferably, without any chemical treatment. In the previous studies, about 90% of methionine in the resilium protein was detected in sulfoxide form after alkaline hydrolysis of the resilium.[1] To exclude the posibility that methionine was oxidized during the alkaline hydrolysis, the presence of methyl group attached to sulfinyl group was demonstrated by solid-state ^{13}C-NMR using cross-polarization and magic angle spinnig techniques.[2]

In the IR spectrum (Fig. 1-a) of the resilium of a surf clam, *S.* (*Ps.*) *sachalinensis*, the absorption band at 1020 cm^{-1} was assigned to S-O stretching vibration of sulfinyl group. The corresponding band was not observed in the spectrum (Fig.1-b) of the reduced resilium, in which methionine *S*-oxide had been converted into methionine with reducing reagent (Table 1). The S-O stretching vibration band of authentic methionine *S*-oxide appeared at 1030 cm^{-1} and 1020 cm^{-1} as splitted

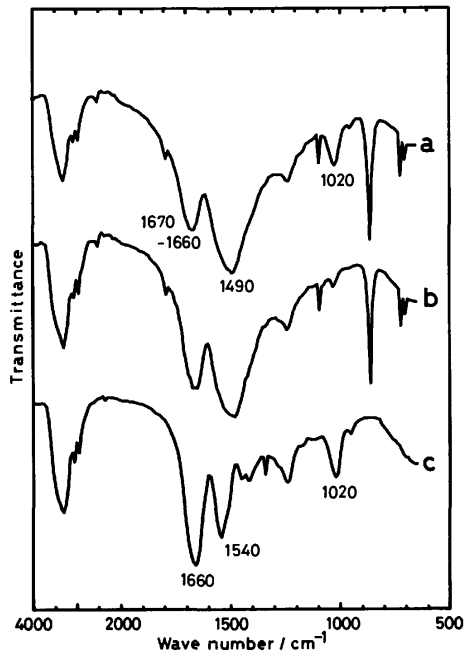

Fig. 1. IR spectra of (a) resilium, (b) reduced resilium, and (c) decalcified resilium.

peaks (not shown). These results indicate the presence of sulfinyl group in the resilium and recomfirm the presence of methionine *S*-oxide in the intact resilium protein.

Aragonite Structure of $CaCO_3$. In Fig.1-a, the absorption band at 1670—1660 cm^{-1} is assigned to amide I band of the resilium protein, but that at 1490 cm^{-1} is unusual as a typical amide II band because it is more intense than amide I band and it is at lower wave number than 1500 cm^{-1}. When the resilium was decalcified with 10% acetic acid, most of the protein remained insoluble. The decalcified resilium showed a typical amide II band at 1540 cm^{-1} (Fig.1-c). Therefore, the unusual band at 1490 cm^{-1} in Fig. 1-a was concluded to contain amide II band of protein and C-O stretching band of $CaCO_3$. Calcite and aragonite are the major crystal types of polymorphic $CaCO_3$ and they are distinguishable by IR spectrometry (Fig. 2-a and b) as reported by Adler and Kerr.[9] If a mixture containing the decalcified resilium and one of the $CaCO_3$ polymorphs could afford the IR spectrum of the resilium (Fig. 1-a), that type of $CaCO_3$ would be the one present in the resilium. In the present study, the spectra of decalcified resilium (Fig. 1-c) and $CaCO_3$ (Fig. 2-a or b) were combined to simulate the spectrum of the mixture. The combination ratio was determined to give the closest spectrum to that of the resilium (Fig. 1-a). Figure 3-a shows the spectrum prepared artificially from those of the decalcified resilium (Fig. 1-c) and calcite ($CaCO_3$) (Fig. 2-a). The amide II band of protein (1540 cm^{-1}) and C-O stretching band of $CaCO_3$ (1430 cm^{-1}) were observed separately. On the other hand, the combination of the spectra of the decalcified resilium (Fig. 1-c) and aragonite ($CaCO_3$) (Fig. 2-b) gave a single absorption band (1490 cm^{-1}) which contained amide II band and C-O band (Fig. 3-b). The IR spectrum of the resilium (Fig. 1-a) was reproduced with the spectra of the decalcified resilium and aragonite ($CaCO_3$). Calcite is the most stable form of $CaCO_3$ at normal temperature, but aragonite is more popular than calcite in the biologically derived structures such

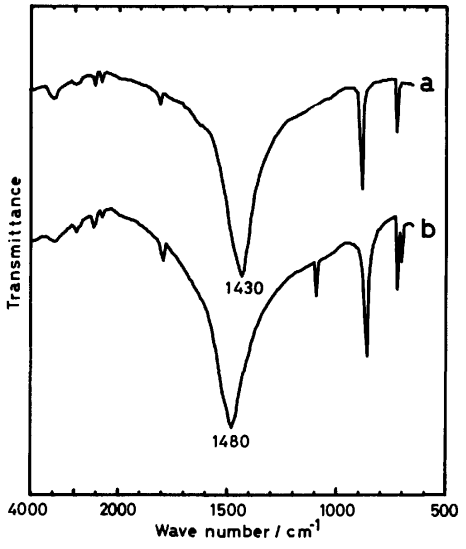

Fig. 2. IR spectra of (a) calcite and (b) aragonite.

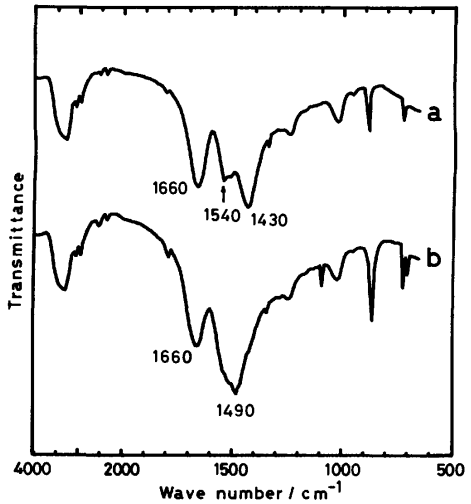

Fig. 3. IR spectra of resilium simulated with (a) decalcified resilium (Fig. 1-c) and calcite (Fig. 2-a) and (b) decalcified resilium (Fig. 1-c) and aragonite (Fig. 2-b).

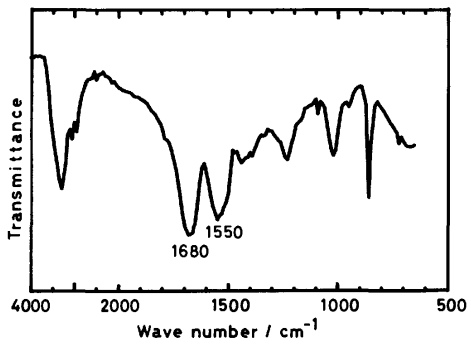

Fig. 4. Simulated spectrum of the protein component in the resilium. The spectrum of aragonite (Fig. 2-b) was subtracted from that of the resilium (Fig. 1-a).

as coral reefs and shells of molluscus.[10] Calcium carbonate in the resilium of surf clams appeared to be in the aragonite form as shown above.

The spectrum of aragonite ($CaCO_3$) (Fig. 2-b) was subtracted from that of the resilium (Fig. 1-a) to simulate the spectrum of the protein component in the resilium (Fig. 4). In Fig. 4, amide I and II bands are observed at 1680 cm^{-1} and 1550 cm^{-1}, while the corresponding bands of the decalcified resilium are at 1660 cm^{-1} and 1540 cm^{-1}, respectively (Fig 1-c). As the amide I and II vibrations are affected by the protein conformation,[11] the small shifts observed above might result from the conformational change of protein caused by decalcification. The amide I and II bands of the decalcified resilium (Fig. 1-c) are close to those assigned to the random-structured protein. The bands in the simulated spectrum of protein component of the resilim (Fig. 4) do not coincide with those proposed for α-helical or β-sheet structure. The protein conformation in the resilium is supposed to be stabilized with calcium ions and contribute to the elasticity of the resilium.

We thank Dr. Mizuhiko Akizuki of Geology Department for providing the specimens of calcite and aragonite. We also thank Professor Satoshi Kanisawa of College of General Education, Dr. Kei Mori of Geology Department and Dr. Yoshiyuki Morioka of this department for helpful discussions.

Chemical Synthesis of a Heat-stable Enterotoxin Produced by Enterotoxigenic *Escherichia coli* Strain 18D

Shoko YOSHIMURA, Makoto MIKI, Haruo IKEMURA, Saburo AIMOTO, Yasutsugu SHIMONISHI,*
Tae TAKEDA,† Yoshifumi TAKEDA,† and Toshio MIWATANI†
Institute for Protein Research, Osaka University, Suita, Osaka 565
†*Research Institute for Microbial Diseases, Osaka University, Suita, Osaka 565*
(Received July 26, 1983)

Two peptides with the two primary structures of 18 amino acid residues proposed for a heat-stable enterotoxin from enterotoxigenic *Escherichia coli* strain 18D were synthesized by solution methods and their physicochemical and biological properties were compared with those of native toxin. One of these peptides (Asn-Thr-Phe-Tyr-Cys-Cys-Glu-Leu-Cys-Cys-Asn-Pro-Ala-Cys-Ala-Gly-Cys-Tyr) showed the same heat-stability and ^{1}H-NMR spectrum as those of the native toxin and evoked fluid secretion in suckling mice at a dose of 1.5—2.0 ng, which is similar to the effective dose of native toxin. Moreover, its toxicity was neutralized by antisera against the native toxin. The other peptide (Asn-Thr-Phe-Tyr-Cys-Cys-Glu-Leu-Cys-Cys-Tyr-Pro-Ala-Cys-Ala-Gly-Cys-Asn) showed different physicochemical and biological behaviors from those of the native toxin and exhibited toxic activity at a dose of 50—80 ng, which is about thirty times the effective dose of the native toxin. Moreover, its toxicity was not neutralized by antisera against the native toxin. These observations indicate that the former peptide is identical to native toxin but that the latter peptide differs in properties from the native toxin.

Enterotoxigenic *Escherichia coli* (ETEC) produces two types of enterotoxin, singly or together, which cause acute diarrhea in man and various domestic animals: a high-molecular-weight, heat-labile enterotoxin (LT) and a low-molecular-weight, heat-stable enterotoxin (ST).[1] There are several reports[2,3] that LT shows similar immunological properties to those of cholera toxin and exerts its effect by stimulating adenylate cyclase in the epithelial cells of the small intestine. However, little is known about ST, except that it may affect the guanylate cyclase-cyclic GMP system.[4-7] This absence of information is mainly because the large quantities of pure ST necessary for biological studies cannot be obtained from a natural source.

In 1981, Chan and Giannella[8] reported that the amino acid sequence of an ST isolated from the culture supernatant of ETEC strain 18D was as illustrated in Fig. 1. Slightly before their report, So and McCarthy[9] determined the nucleotide sequence of DNA encoding an ST produced by a bovine strain of ETEC and hence deduced the amino acid sequence of the ST. The amino acid sequence reported by Chan and Giannella[8] was very similar to that of the C-terminal 18 residues in the amino acid sequence deduced from the nucleotide sequence by So and McCarthy,[9] but differed in two residues at positions 11 and 18 from the N-terminus. To examine this difference in the two sequences, we[10] reinvestigated the amino acid sequence of an ST (named ST_p in this paper) produced by the strain of ETEC used by Chan and Giannella.[8] We found that the sequence of ST_p was different from that proposed by Chan and Giannella,[8] but identical to that deduced from the nucleotide sequence of DNA by So and McCarthy,[9] as illustrated in Fig. 1. Recently, Lazure *et al.*[11] purified an ST produced by a porcine strain F11 (P155) of ETEC and reported the amino acid sequence (Fig. 1). Their sequence was identical to that for ST_p determined by us. Thus, the amino acid sequence of ST_p produced by ETEC strain 18D was established. However, it seemed interesting to confirm the structure of ST_p by chemical synthesis and also to study the effect of amino acid substitution in the sequence of ST_p on its biological properties. Since it is difficult to obtain much toxin by cultivation of bacteria, chemical synthesis of ST_p also seemed useful in providing a way to obtain the large amounts of toxin necessary for biological studies.

In this paper, we describe the chemical syntheses of two peptides with the amino acid sequences proposed by Chan and Giannella[8] (designated as ST_p[Tyr,[11] Asn[18]]) and by us[10] (designated as ST_p) for an ST isolated from strain 18D of ETEC. We also report some physicochemical and biological properties of the synthetic peptides.

Experimental

All chemicals used for preparative experiments were of reagent grade. Chemicals used for analysis were of special grade and solvents were redistilled before use. All amino acids used were of the L-configuration except glycine. DEAE-Sephadex ion-exchanger was purchased from Pharmacia Japan. LiChrosorb RP-8 was obtained from Merck Japan. Melting points were measured by the capillary method and are given as uncorrected values. Optical rotations were determined with a Perkin-Elmer Model 241 polarimeter. Peptide samples were hydrolyzed in 6 M HCl†† in evacuated sealed tubes at 105 °C for 24 or 48 h, and amino acids in the hydrolysates were analyzed in a Hitachi KLA-5 analyzer. Proton NMR spectra were recorded with a JEOL GX-500 spectrometer. Samples were dissolved in 0.3 ml of dimethyl-d_6 sulfoxide containing 15% acetonitrile-d_3 at a concentration of 1—3 mM and measurements were made at 10 °C after addition of 33 μl of D_2O. Chemical shifts were measured from tetramethylsilane added as an internal standard. A large peak caused by remaining H_2O was saturated by the ^{1}H-homo gated decoupling method. Fast atom bombardment (FAB) mass spectra were recorded with a JEOL double-focusing mass spectrometer JMS-HX100 equipped with an FAB ion source, as described previously.[10] Native ST_p was isolated from the culture supernatant of ETEC strain 18D and purified by high-performance liquid chromatography, as described previously.[10] The abbreviations used in this paper are those recommended by the IUPAC-IUB: *J. Biol. Chem.*, **247**, 977 (1972). Additional abbrevitions: MBzl, *p*-methylbenzyl; TFA, trifluoroacetic acid; TEA, triethylamine; DMF, *N,N*-dimethylformamide; DMSO, dimethyl

sulfoxide.

*Boc-Cys(MBzl)-Asn-OBzl (**Ia-1**).* Boc-Asn-OBzl[12] (32.2 g, 0.1 mol) was dissolved in TFA (150 ml) and stirred at room temperature for 30 min. The solution was concentrated under reduced pressure to a syrup, which was mixed with dioxane containing 1 equiv of HCl. The mixture was treated with ether and the resulting precipitate was redissolved with TEA (14.0 ml, 0.1 mol) in DMF (200 ml) and mixed with Boc-Cys(MBzl)-ONSu (46.5 g, 0.11 mol) in DMF (100 ml). The solution was stirred at room temperature for 1 d and then concentrated to a syrup under reduced pressure. The syrup was dissolved in AcOEt and washed successively with 0.1 M HCl, 5% aq $NaHCO_3$ and water. The washed solution was dried over anhydrous Na_2SO_4 and concentrated under reduced pressure to a solid, which was crystallized from a mixture of AcOEt, ether and hexane; wt 50.8 g (96.0 %), mp 124—125 °C, $[\alpha]_D^{23}$ −28.0° (*c* 1.0, DMF).

Found: C, 60.99; H, 6.74; N, 7.82; S, 5.98%. Calcd for $C_{27}H_{35}O_6N_3S$: C, 61.23; H, 6.66; N, 7.93; S, 6.04%.

*Boc-Gly-Cys(MBzl)-Asn-OBzl (**Ia-2**).* Compound **Ia-1** (42.4 g, 80 mmol) was treated with TFA (150 ml) at room temperature for 30 min. The solution was concentrated to dryness under reduced pressure and the residue was mixed with dioxane containing 1 equiv of HCl. The mixture was concentrated under reduced pressure to a syrup, which was solidified in ether. The solid was dissolved in DMF (200 ml) and mixed with TEA (11.2 ml) and Boc-Gly-ONSu (24.0 g, 88 mmol). After 1 d at room temperature, the solution was concentrated to a syrup under reduced pressure. The syrup was dissolved in AcOEt, washed successively with 0.1 M HCl, 5% aq $NaHCO_3$ and water, and dried over anhydrous Na_2SO_4. The dried solution was concentrated under reduced pressure to a solid, which was recrystallized from a mixture of AcOEt, ether and hexane; wt 40.5 g (86.4%), mp 119.5—120.5 °C, $[\alpha]_D^{23}$ −26.8° (*c* 1.0, DMF). Found: C, 59.17; H, 6.48; N, 9.38; S, 5.38%. Calcd for $C_{29}H_{38}O_7N_4S$: C, 59.37; H, 6.53; N, 9.55; S, 5.45%.

*Boc-Ala-Gly-Cys(MBzl)-Asn-OBzl (**Ia-3**).* Compound **Ia-2** (38.1 g, 65 mmol) was treated with TFA (150 ml) at room temperature for 25 min and then concentrated to dryness under reduced pressure. The residue was dissolved with dioxane containing 1 equiv of HCl and precipitated by adding ether. The precipitate was redissolved in DMF (150 ml), mixed with TEA (9.1 ml) and Boc-Ala-ONSu (20.0 g, 70 mmol) and stirred at room temperature for 1 d. The solution was concentrated to dryness under reduced pressure, redissoved in AcOEt, and then washed with 0.1 M HCl, 5% aq $NaHCO_3$ and water. The washed solution was dried over anhydrous Na_2SO_4 and then concentrated under reduced pressure to a solid, which was recrystallized from AcOEt, ether and hexane; wt 41.5 g (97.0%), mp 148—149 °C, $[\alpha]_D^{23}$ −33.8° (*c* 1.0, DMF).

Found: C, 57.84; H, 6.59; N, 10.65; S, 4.75%. Calcd for $C_{32}H_{43}O_8N_5S \cdot 0.5H_2O$: C, 57.65; H, 6.65; N, 10.51; S, 4.80%.

*Boc-Ala-Gly-Cys(MBzl)-Tyr-OBzl (**Ib-3**).* Boc-Gly-Cys(MBzl)-Tyr-OBzl[13] (41.3 g, 65 mmol) was dissolved in TFA (160 ml) and stirred at room temperature for 35 min. The solution was concentrated under reduced pressure to a syrup, which was treated with 1 equiv of HCl in dioxane and then with ether. The precipitate formed was dissolved in DMF (100 ml) and mixed with TEA (9.1 ml) and Boc-Ala-ONSu (21.0 g, 72 mmol). The solution was stirred at room temperature for 2 h and then concentrated to a syrup under reduced pressure. The syrup was redissolved in AcOEt and washed successively with 0.2 M HCl, 5% aq $NaHCO_3$ and water. The washed solution was dried over anhydrous Na_2SO_4 and then concentrated under reduced pressure to a semisolid material, which was recrystallized from AcOEt and ether; wt 34.5 g (75.2%), mp 126—128 °C, $[\alpha]_D^{18}$ −31.3° (*c* 1.0, DMF).

Found: C, 62.04; H, 6.53; N, 7.91; S, 4.39%. Calcd for $C_{37}H_{46}O_8N_4S \cdot 0.5H_2O$: C, 62.08; H, 6.62; N, 7.83; S, 4.47%.

*Boc-Cys(MBzl)-Ala-Gly-Cys(MBzl)-Asn-OBzl (**Ia**).* Compound **Ia-3** (30.0 g, 45 mmol) was dissolved in TFA (150 ml), stirred at room temperature for 20 min, and concentrated to a syrup under reduced pressure. The syrup was treated with dioxane containing 1 equiv of HCl and material was precipitated with ether. The precipitate was dissolved in DMF (150 ml) and mixed with TEA (6.3 ml) and Boc-Cys(MBzl)-ONSu (21.2 g, 50 mmol). The solution was stirred at room temperature for 1 d and then concentrated to dryness under reduced pressure. The residue was dissolved in AcOEt, washed with 0.1 M HCl, 5% aq $NaHCO_3$ and water, and then dried over anhydrous Na_2SO_4. The dried solution was concentrated under reduced pressure to a gelatinous solid, which was recrystallized from a mixture of MeOH and ether; wt 32.5 g (83.6 %), mp 187—188 °C, $[\alpha]_D^{23}$ −24.6° (*c* 1.0, DMF).

Found: C, 59.32; H, 6.56; N, 9.42; S, 7.29%. Calcd for $C_{43}H_{56}O_9N_6S_2 \cdot 0.5H_2O$: C, 59.09; H, 6.57; N, 9.62; S, 7.32%.

*Boc-Cys(MBzl)-Ala-Gly-Cys(MBzl)-Tyr-OBzl (**Ib**).* Compound **Ib-3** (31.8 g, 45 mmol) was dissolved in TFA (100 ml) and stirred at room temperature for 40 min. The solution was concentrated under reduced pressure to a syrup, which was solidified in ether. The solid was dissolved with TEA (6.3 ml) and Boc-Cys(MBzl)-ONSu (21.1 g, 50 mmol) in DMF (200 ml) and stirred at room temperature for 1 d. The solution was concentrated under reduced pressure to a syrup, which was redissolved in AcOEt and washed with 0.3 M HCl, 5% aq $NaHCO_3$ and water. The washed solution was dried over anhydrous Na_2SO_4 and concentrated to a syrup under reduced pressure. The material was crystallized from $CHCl_3$ and ether; wt 39.0 g (94.9 %), mp 89—91 °C (decomp), $[\alpha]_D^{14}$ −19.6° (*c* 1.0, DMF).

Found: C, 61.72; H, 6.71; N, 7.60; S, 6.67%. Calcd for $C_{48}H_{59}O_9N_5S_2 \cdot H_2O$: C, 61.85; H, 6.60; N, 7.52; S, 6.87%.

*Boc-Tyr-Pro-Ala-OMe (**IIa-1**).* Z-Pro-Ala-OMe[14] (16.7 g, 50 mmol) was dissolved in MeOH (300 ml) containing 1 equiv of HCl and hydrogenated over 5% palladium-charcoal catalyst under atmospheric pressure. The catalyst was filtered off and the filtrate was concentrated to dryness under reduced pressure. The residue was dissolved in DMF (20 ml). Meanwhile, Boc-Tyr-N_2H_3 (16.2 g, 55 mmol) was dissolved in DMF (100 ml), cooled below −20 °C and mixed with 4.39 M HCl in dioxane (29.5 ml). The solution was stirred with isopentyl nitrite (7.8 ml, 60 mmol) at the same temperature for 20 min and mixed with the above DMF solution and TEA (25.2 ml). The solution was stirred at 0 °C for 4 d in a refrigerator. The precipitate formed was removed by filtration and the filtrate was concentrated under reduced pressure to an oil, which was redissolved in AcOEt. The solution was washed successively with 0.5 M HCl, 5% aq $NaHCO_3$ and water. Then it was dried over anhydrous Na_2SO_4 and concentrated under reduced pressure to a syrup, which was crystallized from ether and hexane; wt 21.2 g (91.4%), mp 74—76 °C, $[\alpha]_D^{23}$ −33.5° (*c* 1.0, DMF).

Found: C, 59.89; H, 7.66; N, 8.76%. Calcd for $C_{23}H_{33}O_7N_3$: C, 59.60; H, 7.18; N, 9.07%.

*Boc-Cys(MBzl)-Cys(MBzl)-Tyr-Pro-Ala-OMe (**IIa-2**).* Compound **IIa-1** (18.5 g, 40 mmol) was treated with TFA (80 ml) at room temperature for 25 min and concentrated to dryness under reduced pressure. The residue was dissolved in DMF (80 ml). Meanwhile, Boc-Cys(MBzl)-Cys(MBzl)-N_2H_3[13] (24.1 g, 44 mmol) was dissolved in DMF (80 ml) and cooled below −20 °C. The solution was mixed with 4.39 M HCl in dioxane (23.6 ml) and isopentyl nitrite (6.5 ml, 50 mmol) and stirred at −20 °C for 35 min. The solution was mixed with the above solution and TEA (20.1 ml) and then stirred at 0 °C for 3 d in a refrigerator. The precipitate formed

was removed by filtration and the filtrate was concentrated to an oil under reduced pressure. The oil was dissolved in AcOEt and washed successively with 0.1 M HCl, 5% aq $NaHCO_3$ and water. The washed solution was dried over anhydrous Na_2SO_4 and then concentrated to an oil under reduced pressure. The oil was purified by chromatography on a column of silica gel using a mixture of AcOEt: benzene (v/v, 1/1) as eluent. The purified material was crystallized from AcOEt and hexane; wt 28.1 g (80.0%) mp 102—103 °C, $[\alpha]_D^{23}$ −52.4° (*c* 0.5, DMF).

Found: C, 61.38; H, 6.95; N, 7.73; S, 7.15%. Calcd for $C_{45}H_{59}O_9N_5S_2$: C, 61.56; H, 6.77; N, 7.98; S, 7.29%.

*Boc-Cys(MBzl)-Cys(MBzl)-Tyr-Pro-Ala-N_2H_3 (**IIa**).* Compound **IIa-2** (26.3 g, 30 mmol) was dissolved in MeOH (300 ml), mixed with 100% hydrazine hydrate (60 ml), and then stirred at room temperature for 1 d. The solution was concentrated to dryness under reduced pressure and mixed with water. The precipitate formed was collected and crystallized from MeOH and ether; wt 21.3 g (81.0%), mp 122—123 °C, $[\alpha]_D^{23}$ −42.8° (*c* 0.5, DMF).

Found: C, 59.06; H, 6.46; N, 10.80; S, 7.05%. Calcd for $C_{44}H_{59}O_8N_7S_2 \cdot H_2O$: C, 58.98; H, 6.86; N, 10.94; S, 7.14%.

*Boc-Cys(MBzl)-Cys(MBzl)-Tyr-Pro-Ala-Cys(MBzl)-Ala-Gly-Cys(MBzl)-Asn-OBzl (**IIIa**).* Compound **Ia** (8.65 g, 10.0 mmol) was dissolved in TFA (100 ml) in an ice-bath. The solution was stirred at room temperature for 20 min and concentrated under reduced pressure to a syrup, which was solidified in ether. The solid was dissolved in DMF (30 ml). Meanwhile, compound **IIa-3** (10.52 g, 12.0 mmol) was dissolved in DMF (50 ml), cooled below −20 °C and mixed with 4.39 M HCl in dioxane (14.7 ml) and isopentyl nitrite (1.82 ml, 14.0 mmol). The solution was stirred below −20 °C for 30 min, and then mixed with TEA (10.4 ml) and the solution described above. The mixture was stirred at 0 °C for 2 d in a refrigerator. The precipitate formed was removed by filtration and the filtrate was concentrated to a syrup under reduced pressure. The syrup was dissolved in hot AcOEt and kept at room temperature. The precipitate formed was collected and recrystallized from MeOH, DMF and ether; wt 15.1 g (93.8%), mp 173—175 °C, $[\alpha]_D^{19}$ −57.6° (*c* 0.5, DMSO).

Found: C, 60.00; H, 6.06; N, 9.24; S, 7.86%. Calcd for $C_{82}H_{103}O_{15}N_{11}S_4 \cdot 2H_2O$: C, 59.79; H, 6.55; N, 9.36; S, 7.79%.

*Boc-Cys(MBzl)-Cys(MBzl)-Asn-Pro-Ala-Cys(MBzl)-Ala-Gly-Cys(MBzl)-Tyr-OBzl (**IIIb**).* Boc-Cys(MBzl)-Cys(MBzl)-Asn-Pro-Ala-N_2H_3[13] (14.1 g, 17 mmol) was dissolved in DMF (50 ml), cooled below −20 °C and mixed with 4.39 M HCl in dioxane (14.7 ml) and then with isopentyl nitrite (2.5 ml, 19 mmol). The solution was stirred at −20 °C for 30 min. Meanwhile, compound **Ib** (13.7 g, 15 mmol) was dissolved in TFA (100 ml), stirred at room temperature for 40 min and then concentrated under reduced pressure to a syrup, which was solidified in ether. The solid and TEA (11.2 ml) were added to the azide solution described above and stirred at 0 °C for 1 d in a refrigerator. The precipitate was removed by filtration and the filtrate was concentrated to an oil under reduced pressure. The oil was solidified in a mixture of AcOEt and ether and recrystallized repeatedly from EtOH; wt 19.0 g (78.5%), mp 213—214 °C, $[\alpha]_D^{14}$ −41.6° (*c* 0.5, DMSO)

Found: C, 61.18; H, 6.66; N, 9.78; S, 8.09%. Calcd for $C_{82}H_{103}O_{15}N_{11}S_4$: C, 61.14; H, 6.45; N, 9.57; S, 7.95%.

*Boc-Cys(MBzl)-Cys(MBzl)-Glu(OBu^t)-Leu-Cys(MBzl)-Cys(MBzl)-Tyr-Pro-Ala-Cys(MBzl)-Ala-Gly-Cys(MBzl)-Asn-OBzl (**IVa**).* Compound **IIIa** (6.44 g, 4.00 mmol) was dissolved with anisole (2.5 ml) in TFA (75 ml) and stirred at room temperature for 60 min. The solution was concentrated under reduced pressure to a syrup, which was solidified in ether. The solid was dissolved in DMF (50 ml). Meanwhile, Boc-Cys(MBzl)-Cys(MBzl)-Glu(OBu^t)-Leu-N_2H_3[13] (4.06 g, 4.80 mmol) was dissolved in DMF (50 ml), cooled below −20 °C, and mixed with 4.39 M HCl in dioxane (5.5 ml) and isopentyl nitrite (0.62 g, 5.28 mmol). The solution was stirred at −20—−30 °C for 30 min and mixed with TEA (4.0 ml) and the solution described above. The mixture was stirred at 2—3 °C for 3 d in a refrigerator. The precipitate formed was collected with MeOH, boiled repeatedly in hot EtOH and collected; wt 7.60 g (81.7%), mp 225—227 °C, $[\alpha]_D^{19}$ −39.2° (*c* 0.5, DMF).

Found: C, 60.69; H, 6.82; N, 8.69; S, 8.26%. Calcd for $C_{119}H_{155}O_{21}N_{15}S_6 \cdot 3H_2O$: C, 60.61; H, 6.88; N, 8.91; S, 8.16%.

*Boc-Cys(MBzl)-Cys(MBzl)-Glu(OBu^t)-Leu-Cys(MBzl)-Cys(MBzl)-Asn-Pro-Ala-Cys(MBzl)-Ala-Gly-Cys(MBzl)-Tyr-OBzl (**IVb**).* Compound **IIIb** (8.05 g, 5.0 mmol) was dissolved in TFA (100 ml). The solution was stirred at room temperature for 30 min and concentrated under reduced pressure to a syrup, which was solidified in ether. The solid was dissolved in DMSO (40 ml). Meanwhile, Boc-Cys(MBzl)-Cys(MBzl)-Glu(OBu^t)-Leu-N_2H_3[13] (5.07 g, 6 mmol) was dissolved in DMF (30 ml), cooled below −20 °C, and mixed with 4.39 M HCl in dioxane (8.85 ml) and isopentyl nitrite (0.91 ml, 7 mmol). The solution was stirred at −20—−30 °C for 35 min and mixed with the solution described above and TEA (6.2 ml). The mixture was stirred at 0 °C for 2 d in a refrigerator. The precipitate formed was removed by filtration and the filtrate was concentrated to a syrup. The syrup was mixed with 0.2 M HCl and the precipitate formed was collected and recrystallized from EtOH; wt 11.0 g (94.8%), mp 236 °C (decomp), $[\alpha]_D^{18}$ −51.3° (*c* 0.32, DMSO).

Found: C, 61.01; H, 6.89; N, 8.90; S, 8.28%. Calcd for $C_{119}H_{155}O_{21}N_{15}S_6 \cdot H_2O$: C, 61.04; H, 6.76; N, 8.97; S, 8.20%.

*Z(OMe)-Phe-Tyr-OEt (**V-1**).* H-Tyr-OEt·HCl (8.1 g, 33 mmol) was dissolved with TEA (4.6 ml) in DMF (70 ml) and mixed with Z(OMe)-Phe-ONp (13.5 g, 30 mmol) in DMF (30 ml). The solution was stirred at room temperature for 6 d and concentrated to dryness under reduced pressure. The residue was dissolved in AcOEt and washed successively with 5% aq $NaHCO_3$, 0.5 M HCl and water. The washed solution was dried over anhydrous Na_2SO_4 and then concentrated under reduced pressure to a syrup, which was crystallized from AcOEt, EtOH and hexane; wt 15.5 g (99.4%), mp 139.5—140.5 °C, $[\alpha]_D^{19}$ −9.0° (*c* 1.0, DMF).

Found: C, 66.36; H, 6.24; N, 5.32%. Calcd for $C_{29}H_{32}O_7N_2$: C, 66.91; H, 6.20; N, 5.38%.

*Boc-Asn-Thr-OEt (**V-2**).* H-Thr-OEt·HCl (7.34 g, 40 mmol) was dissolved with TEA (5.6 ml) and Boc-Asn-ONp (12.4 g, 35 mmol) in DMF (30 ml). The solution was stirred at room temperature for 1 d and concentrated to dryness under reduced pressure. The residue was dissolved in 1-butanol and washed with 5% aq $NaHCO_3$, 0.1 M HCl and water. The washed solution was dried over anhydrous Na_2SO_4 and concentrated to a syrup under reduced pressure. The syrup was crystallized from AcOEt, hexane and ether: wt 8.70 g (69.0%), mp 150—151 °C, $[\alpha]_D^{23}$ −15.6° (*c* 1.0, DMF).

Found: C, 49.85; H, 7.68; N, 11.57%. Calcd for $C_{15}H_{27}O_7N_3$: C, 49.85; H, 7.53; N, 11.63%.

*Boc-Asn-Thr-N_2H_3 (**V-3**).* Compound **V-2** (8.67 g, 24.0 mmol) was dissolved in MeOH (100 ml) and mixed with 100% hydrazine hydrate (30 ml). The solution was stirred at room temperature for 1 d and then concentrated to an oil under reduced pressure. The oil was crystallized from MeOH and ether; wt 7.90 g (94.8%), mp 186—188 °C (decomp), $[\alpha]_D^{23}$ −25.2° (*c* 1.0, DMF).

Found: C, 44.10; H, 7.22; N, 20.33%. Calcd for $C_{13}H_{25}O_6N_5 \cdot 0.5H_2O$: C, 44.18; H, 7.30; N, 19.82%.

*Boc-Asn-Thr-Phe-Tyr-OEt (**V-4**).* Compound **V-1** (10.4 g, 20.0 mmol) was dissolved with anisole (5 ml) in TFA (30 ml), stirred at room temperature for 30 min and then

concentrated to a syrup under reduced pressure. The syrup was dissolved in DMF (60 ml). Meanwhile, compound **V-3** (7.63 g, 22.0 mmol) was dissolved in DMF (50 ml) and cooled below −20 °C. The solution was mixed with 4.39 M HCl in dioxane (14.8 ml) and isopentyl nitrite (3.25 ml, 25 mmol). The solution was stirred below −20 °C for 30 min and mixed with the solution described above and TEA (11.9 ml). The mixture was stirred at 0 °C for 6 d in a refrigerator. The precipitate formed was removed by filtration and the filtrate was concentrated to a syrup under reduced pressure. The syrup was dissolved in AcOEt and washed successively with 0.5 M HCl, 5% aq $NaHCO_3$ and water. The washed solution was dried over anhydrous Na_2SO_4 and concentrated to a gelatinous solid under reduced pressure. The solid was crystallized from EtOH and ether; wt 11.3 g (84.3%), mp 139.5—140.5 °C, $[\alpha]_D^{23}$ −27.5° (*c* 1.0, DMF).

Found: C, 58.03; H, 6.94; N, 10.19%. Calcd for $C_{33}H_{45}O_{10}N_5 \cdot 0.5H_2O$: C, 58.22; H, 6.81; N, 10.29%.

Boc-Asn-Thr-Phe-Tyr-N_2H_3 (V). Compound **V-4** (10.1 g, 15.0 mmol) was dissolved in MeOH (150 ml) and mixed with 100% hydrazine hydrate (20 ml). The solution was stirred at room temperature for 1 d and then concentrated to a crystalline solid under reduced pressure. The solid was collected with water and recrystallized from DMF and ether; wt 9.0 g (91.8%), mp 204—205 °C, $[\alpha]_D^{23}$ −42.3° (*c* 1.0, DMF).

Found: C, 54.80; H, 6.74; N, 14.25%. Calcd for $C_{31}H_{43}O_9N_7 \cdot H_2O$: C, 55.10; H, 6.71; N, 14.51%.

*Boc-Asn-Thr-Phe-Tyr-Cys(MBzl)-Cys(MBzl)-Glu-Leu-Cys(MBzl)-Cys(MBzl)-Tyr-Pro-Ala-Cys(MBzl)-Ala-Gly-Cys-(MBzl)-Asn-OBzl (**VIa**).* Compound **IVa** (2.3 g, 1.0 mmol) was dissolved in TFA (20 ml) and stirred at room temperature for 60 min. The solution was concentrated to dryness under reduced pressure and the residue was dissolved in DMF (10 ml). Meanwhile, compound **V** (0.79 g, 1.2 mmol) was dissolved in DMF (5 ml) and cooled below −20 °C. The solution was mixed with 4.39 M HCl in dioxane (1.5 ml) and isopentyl nitrite (0.18 ml, 1.4 mmol) and stirred below −20 °C for 30 min. The solution was mixed with the solution described above and TEA (1.1 ml) and stirred at 0 °C for 5 d in a refrigerator. The precipitate formed was removed by filtration and the filtrate was concentrated to an oil under reduced pressure. The oil was mixed with 0.1 M HCl and the resulting precipitate was collected with water. The precipitate was crystallized from DMF and ether; wt 2.50 g (89.6%), mp 225 °C (decomp), $[\alpha]_D^{23}$ −34.7° (*c* 0.34, DMSO). Amino acid ratio in the acid hydrolysate: Asp, 1.96 (2); Thr, 0.84 (1); Glu, 0.91 (1); Pro, 1.03 (1); Gly, 1.00 (1); Ala, 2.03 (2); Leu, 0.92 (1); Tyr, 1.75 (2); Phe, 0.93 (1).

Found: C, 60.09; H, 6.62; N, 9.77; S, 6.60%. Calcd for $C_{141}H_{178}O_{28}N_{20}S_6 \cdot H_2O$: C, 60.24; H, 6.45; N, 9.97; S, 6.83%.

*Boc-Asn-Thr-Phe-Tyr-Cys(MBzl)-Cys(MBzl)-Glu-Leu-Cys(MBzl)-Cys(MBzl)-Asn-Pro-Ala-Cys(MBzl)-Ala-Gly-Cys(MBzl)-Tyr-OBzl (**VIb**).* Compound **IVb** (4.65 g, 2 mmol) was dissolved in TFA (100 ml) and stirred at room temperature for 45 min. The solution was concentrated under reduced pressure to a syrup, which was solidified in ether. Meanwhile, compound **V** (1.58 g, 2.4 mmol) was dissolved in DMF (20 ml) and cooled below −20 °C. The solution was mixed with 6.72 M HCl in dioxane (1.75 ml) and isopentyl nitrite (0.37 ml) and stirred below −20 °C for 35 min. Then, the mixture was stirred at 0 °C for 4 d in a refrigerator with TEA (2.0 ml) and the solid prepared as described above and dissolved in DMSO (5 ml). The precipitate was removed by filtration and the filtrate was concentrated to a syrup under reduced pressure. The syrup was precipitated from EtOH and ether; wt 5.0 g (89.6%), mp 243 °C (decomp), $[\alpha]_D^{18}$ −39.4° (*c* 0.35, DMF). Amino acid ratio in the acid hydrolysate: Asp, 1.95 (2); Thr, 0.89 (1); Glu, 0.99 (1); Pro, 1.02 (1); Gly, 1.00 (1); Ala, 1.95 (2); Leu, 0.95 (1); Tyr, 1.85 (2); Phe, 0.97 (1).

Found: C, 60.14; H, 6.74; N, 9.77; S, 6.99%. Calcd for $C_{141}H_{178}O_{28}N_{20}S_6 \cdot H_2O$: C, 60.24; H, 6.45; N, 9.97; S, 6.83%.

HF-treatment and Air-oxidation: Compound **VIa** or **VIb** (69.8 mg, 25 μmol) was treated in the presence of anisole (0.1 ml) with anhydrous liquid hydrogen fluoride (3 ml) at 0 °C for 60 min. The HF-reagent was evaporated under reduced pressure. The residue was dissolved in 99% formic acid (1 ml) and washed three times with hexane. The solution was diluted to 5×10^{-5} M with distilled water and rapidly adjusted to pH 8.0 with aqueous ammonia. The solution was kept at room temperature for 4 d with occasional stirring. Free thiol became undetectable during this period. The solution was freeze-dried to a powder. The powder was dissolved in a small amount of water, applied to a column (2×90 cm) of Sephadex G-25, and eluted with 0.01 M NH_4HCO_3. The toxic fractions were collected and lyophilized. The lyophilized material was dissolved in water, applied to a column (2×33 cm or 1.6×25 cm) of DEAE-Sephadex A-25 (acetate form), and washed sufficiently with water. The adsorbed material was eluted with a linear-gradient of 0 to 0.5 M acetic acid. The toxic fractions were collected, lyophilized and purified on a reversed-phase column of HPLC, as described below.

High-performance Liquid Chromatography (HPLC): HPLC was performed on LiChrosorb RP-8 (Merck, 5 μm). Two columns (8×300 mm and 4×250 mm) were packed in our laboratory for semipreparative separation and for analysis, respectively. Both columns were equilibrated with 0.01 M ammonium acetate (pH 5.7) containing 10% acetonitrile and the sample solution was injected onto one of these columns. The column was developed at a flow rate of 1 ml/min with a linear-gradient of 10—30% acetonitrile in 0.01 M ammonium acetate (pH 5.7) with increase in the acetonitrile concentration at a rate of 1%/min.

Biological Assay: ST activity was assayed in suckling mice of 2—4 d old, as described previously.[16] The fluid accumulation ratio of each animal was calculated as the ratio of the weight of the entire intestine to that of the rest of the body. The minimal amount of ST giving a fluid accumulation ratio of over 0.09 was designated as 1 mouse unit, as described previously.[16]

Results and Discussion

Isolation of Biologically Active Synthetic Peptides. We recently determined the amino acid sequence of an ST (named ST_h in this paper) isolated from a human strain SK-1 of ETEC.[16,17] The sequence was identical with that of ST_p except for the N-terminal three residues and the fourth residue from the C-terminus, as shown in Fig. 1. Interestingly, six half-cystine residues were found at common positions and joined intramolecularly. The disruption of the disulfide bonds in ST_p by reduction destroyed the biological activity of ST.[8] Furthermore, we found that native ST_p and ST_h have the same potency in a fluid accumulation test using suckling mice[10,17] and their toxicity is neutralized by homologous and heterologous *anti*-ST_p and *anti*-ST_h antisera.[22] These findings suggested that ST_p and ST_h have the similar secondary structures including disulfide linkages, which play an important part for expression of the toxicity of ST, although the mode of disulfide bond formation has not yet been determined. Moreover, we recently prepared the protected peptide with the amino acid sequence of ST_h and deprotected all the protecting groups from the peptide followed by air-oxidation. We found that the crude air-oxidized product is highly toxic and that the purified

Fig. 1. Comparison of amino acid sequences proposed for ST: (a) Data reported for an ST isolated from ETEC strain 18D in Ref. 8; (b) deduced from the nucleotide sequence encoding an ST of bovine origin;[9] (c) data proposed for an ST (=ST_p) isolated from ETEC strain 18D by us;[10] (d) data proposed for an ST isolated from a porcine strain F11(P155) of ETEC in Ref. 11; (e) data proposed for an ST (=ST_h) isolated from a human strain SK-1 of ETEC by us.[17]

peptide shows the same biological and physicochemical properties as native ST_h.[18] Hence, we considered that two peptides with the amino acid sequences proposed for ST_p, which have similar amino acid sequences to that of ST_h, can be synthesized by a similar method to that used for synthesis of ST_h. The sequences were first divided into four segments and the protected derivatives of these fragments were prepared separately by conventional solution methods. Then, the segments were coupled sequentially from the C-terminus to the N-terminus by an azide method[19] to reduce undesirable racemization, as illustrated in Fig. 2. The protected fragments Boc-Cys(MBzl)-Cys(MBzl)-Glu(OBu^t)-Leu-N_2H_3[13] and **V** were used for the syntheses of both the two protected peptides **VIa** and **VIb**.

Then, all the protecting groups were removed by the HF-method[15] and free peptides were air-oxidized under similar conditions to those described previously.[18] The air-oxidized solutions of peptides were directly applied to a reversed-phase column of HPLC, as illustrated in

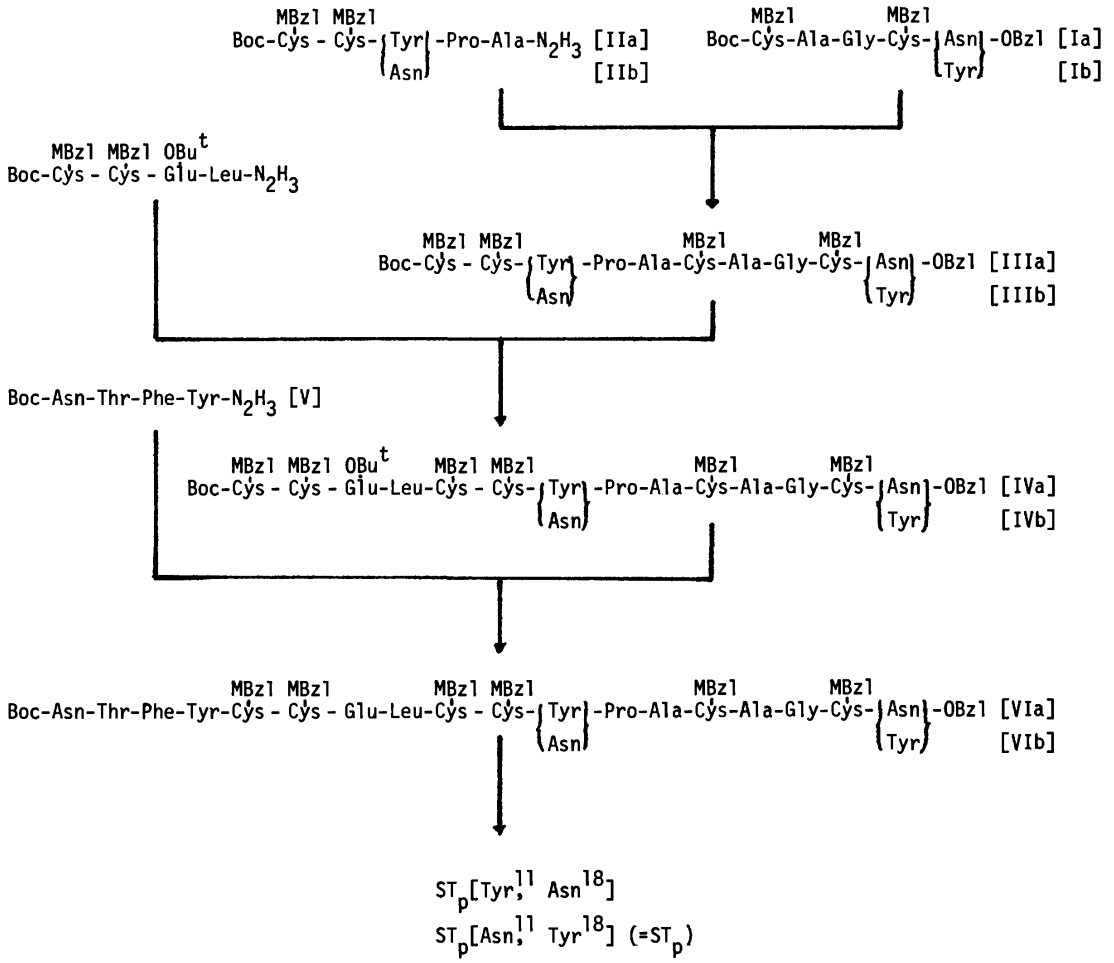

Fig. 2. Scheme for syntheses of $ST_p[Tyr^{11}, Asn^{18}]$ and ST_p.

Figs. 3A and 4A. Materials in the peaks obtained by HPLC were fractionated and subjected to biological assay. Toxic materials were mainly recovered in the peaks shown by bars in Figs. 3A and 4A, respectively, and the materials in these peaks were compared with native ST_p,[10] isolated from ETEC strain 18D,[8] as illustrated in Figs. 3B and 3C, and 4B and 4C, respec-

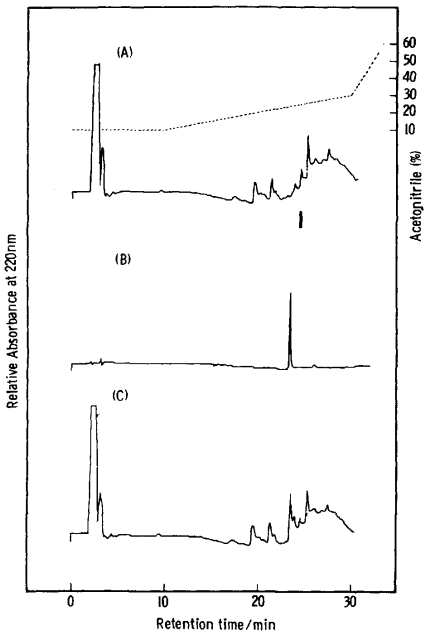

Fig. 3. HPLC profiles on a LiChrosorb RP-8 column (5 μm, 4×250 mm) of: (A) HF-treated and air-oxidized solution of **VIa**; (B) purified native ST_p;[10] (C) a mixture of (A) and (B). The toxic activity was found in the peak marked by a bar in (A).

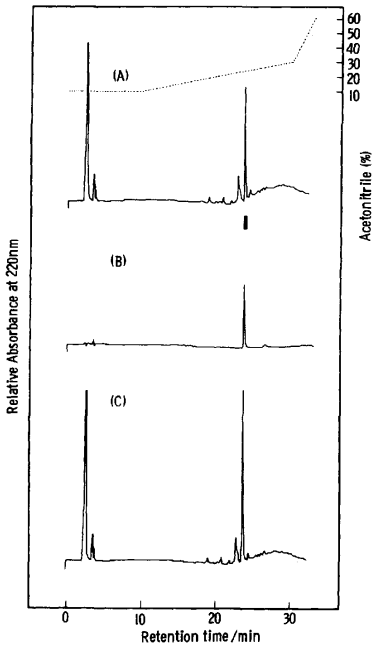

Fig. 4. HPLC profiles on a LiChrosorb RP-8 column (5 μm, 4×250 mm) of: (A) HF-treated and air-oxidized solution of **VIb**; (B) purified native ST_p;[10] (C) a mixture of (A) and (B). The main toxic activity was observed in the peak marked by a bar in (A).

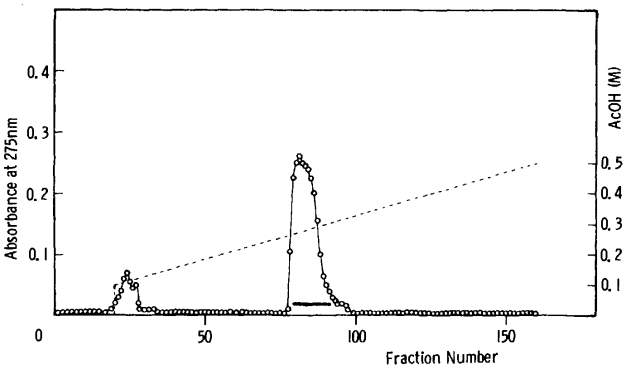

Fig. 5. Chromatography on DEAE-Sephadex A-25 of HF-treated and air-oxidized solution of compound **VIa**. The toxic fraction is shown by a horizontal bar. Column size: 2×33 cm; fractionation size: 10 ml/tube; flow rate: 100 ml/h.

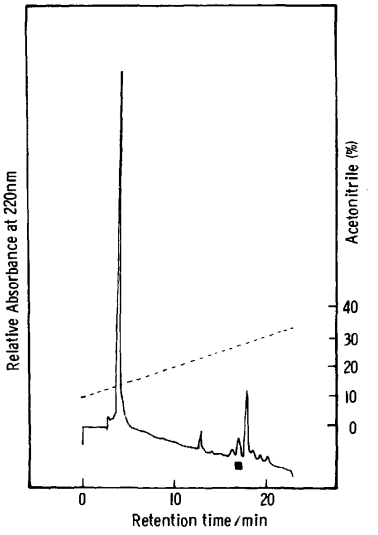

Fig. 6. Semipreparative HPLC of the toxic fraction shown by a horizontal bar in Fig. 5 on a LiChrosorb RP-8 column (5 μm, 8×300 mm). The toxicity was observed in the peak fraction shown by a horizontal bar.

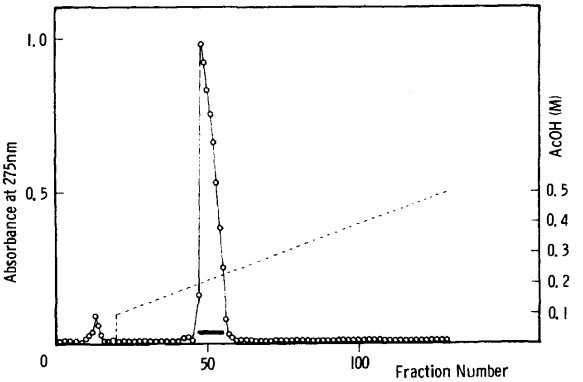

Fig. 7. Chromatography on DEAE-Sephadex A-25 of HF-treated and air-oxidized solution of compound **VIa**. The toxic fraction shown by a horizontal bar was collected. Column size: 1.6×25 cm; fractionation size: 5 ml/tube; flow rate: 35 ml/h.

tively. In Fig. 3A, the toxic fraction was eluted later than native ST_p; the peak fraction eluted at the same retention time as that of native ST_p showed no toxic activity. On the contrary, the toxic peak was eluted with the same retention time as that of native ST_p, in Fig. 4A. Furthermore, the total toxic activity of the air-oxidized solution of compound **VIa** was only one-hundredth of that of compound **VIb**.

The HF-treated and air-oxidized solution of **VIa** was purified on DEAE-Sephadex A-25 and toxic fractions were collected, as shown in Fig. 5. The toxic fractions shown by a horizontal bar were collected and purified further on a semipreparative HPLC column by the reversed-phase mode, as illustrated in Fig. 6. The purity of the separated fraction shown by a bar was also confirmed by analytial HPLC, as shown in Fig. 9A. The toxic peptide $ST_p[Tyr^{11}, Asn^{18}]$ was obtained in about 1—2% yield from compound **VIa**.

The HF-treated and air-oxidized solution of compound **VIb** was also purified on DEAE-Sephadex A-25, as illustrated in Fig. 7. The toxic fractions shown by a horizontal bar were combined, lyophilized and purified further on a semipreparative column of reversed-phase HPLC, as shown in Fig. 8. The purity of the toxic fraction was examined by analytical HPLC, as illustrated in Fig. 9B. The yield of purified synthetic peptide ST_p was about 13%, based on the amount of compound **VIb**. As illustrated in Fig. 9C, definite differences were observed between the retention times of the two synthetic peptides $ST_p[Tyr^{11}, Asn^{18}]$ and ST_p on a reversed-phase column of HPLC. The amino acid compositions of purified synthetic $ST_p[Tyr^{11}, Asn^{18}]$ and ST_p are summarized in Table 1.

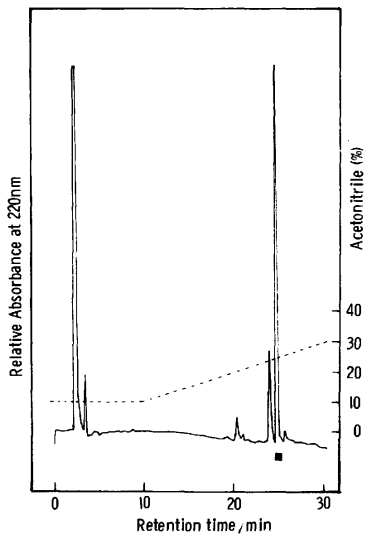

Fig. 8. HPLC profile on a LiChrosorb RP-8 (5 μm, 8×300 mm) of the fraction shown by a horizontal bar. The toxicity was observed in the peak fraction shown by a horizontal bar.

Physicochemical Properties of Synthetic Peptides $STp[Tyr^{11}, Asn^{18}]$ and STp. *i) Mass Spectra*: Purified synthetic peptides $STp[Tyr^{11}, Asn^{18}]$ and STp were subjected to mass measurement by FAB mass spectrometry[20] and the mass spectra were compared with that of native toxin as shown in Fig. 10. Like native STp, both $STp[Tyr^{11}, Asn^{18}]$ and STp gave strong signals at $m/z=1971$ (m/z means the ratio of the mass number of an ion m to the number of charges of ion z). The results indicate that the two synthetic $STp[Tyr^{11}, Asn^{18}]$ and STp both have the same molecular weight (M_r: 1970) as native STp and are intramolecularly linked by three disulfide bonds, although the positions of the disulfide linkages were not determined.

ii) Proton NMR Spectra: To determine whether either of the synthetic peptides had the same steric features as the native toxin, we compared the ^{1}H-NMR spectra of the two synthetic preparations ($STp[Tyr^{11}, Asn^{18}]$ and STp) with that of the native toxin. As illustrated in Fig. 11, proton chemical shifts of synthetic STp were superimposable on those of the native toxin, but the spectrum of synthetic $STp[Tyr^{11}, Asn^{18}]$ was different from that of the native toxin. The results strongly indicate that synthetic STp has the same three dimensional structure, including three disulfide linkages, as native toxin.

Comparison of Heat-stabilities by High-performance Liquid Chromatography (HPLC). Recently we reported a method for testing the heat-stability of ST by HPLC.[18] We found that synthetic STh had the same heat-stability as native STh and the peak heights on HPLC of synthetic and native STh were greatly decreased, although not abolished completely, by heating the compounds at 100°C for 30 min. Using this procedure, we compared the heat-stabilities of synthetic $STp[Tyr^{11}, Asn^{18}]$ and STp with that of native STp. Figure 12 shows HPLC profiles of synthetic and native peptides heated at 100°C for various periods. Both synthetic peptides showed similar heat-stability to that of native toxin, although synthetic $STp[Tyr^{11}, Asn^{18}]$ had lower toxic activity than native STp and its toxicity could not be neutralized by antiserum raised against native STp, as described below.

Biological Activities of Synthetic Peptides. Synthetic peptides $STp[Tyr^{11}, Asn^{18}]$ and STp were examined by the fluid accumulation test in suckling mice.[16] The minimum effective dose of synthetic peptide $STp[Tyr^{11}, Asn^{18}]$ was 50—80 ng, which was about 30 times that of native STp. On the other hand, the minimum effective dose of synthetic peptide STp was 1.5—2 ng, which was almost the same as that of native STp.

The immunological properties of synthetic peptides $STp[Tyr^{11}, Asn^{18}]$ and STp were tested by measuring neutralization of their ST activities with antisera against purified native STh[21] and STp.[22] The toxic activity of synthetic $STp[Tyr^{11}, Asn^{18}]$ was not neutralized by either of these antisera, but those of native STp and synthetic STp were both neutralized by these antisera.

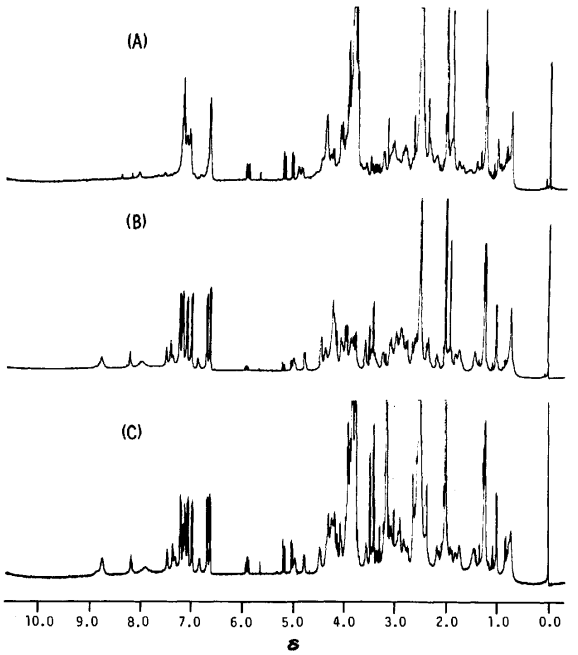

Fig. 11. 500 MHz ^{1}H-NMR spectra of (A) synthetic $STp[Tyr^{11}, Asn^{18}]$, (B) synthetic STp, (C) native STp, measured under the conditions described in the text.

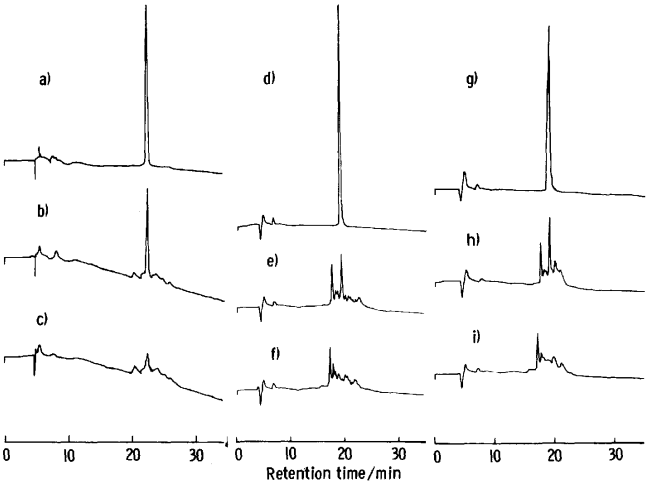

Fig. 12. Comparison of heat-stabilities of synthetic and native ST: (first column) synthetic $STp[Tyr^{11}, Asn^{18}]$ a) untreated, b) after 10 min at 100°C, c) after 30 min at 100°C; (second column) synthetic STp d) untreated, e) after 10 min at 100°C, f) after 30 min at 100°C; (third column) native STp g) untreated, h) after 10 min at 100°C, i) after 30 min at 100°C.

TABLE 2. SUMMARY OF BIOLOGICAL PROPERTIES OF SYNTHETIC PEPTIDES $STp[Tyr^{11}, Asn^{18}]$ AND STp

	MED[a]	Neutralization of ST Activity	
	ng	*anti*-STh Antiserum[b]	*anti*-STp Antiserum[c]
Native STp	2.5	+	+
Synthetic $STp[Tyr^{11}, Asn^{18}]$	50—80	−	−
Synthetic STp	1.5—2.0	+	+

a) Minimum effective dose. b) Antiserum against native STh raised in rabbits [21] was used. c) Antiserum against native STp raised in rabbits [22] was used.

The results, summarized in Table 2, strongly suggest that ST_p[Tyr^{11}, Asn^{18}] with the amino acid sequence proposed by Chan and Giannella[8] did not have the same biological and immunological activities as those of native ST_p, whereas ST_p with the sequence proposed by us[10] had similar biological and immunological properties indistinguishable from those of native toxin. The biologial and immunological properties of these synthetic peptides will be reported in detail elsewhere.

In this work, two peptides (ST_p[Tyr^{11}, Asn^{18}] and ST_p) with the amino acid sequences proposed in Ref. 8 and 10 for an ST produced by ETEC strain 18D were synthesized. Analyses of these synthetic peptides gave the following interesting results: 1) Synthetic ST_p was indistinguishable from native ST_p in all physicochemical and biological properties examined, 2) Synthetic ST_p[Tyr^{11}, Asn^{18}] differed in properties from native ST_p, although Klipstein *et al.*[24] recently reported that synthetic ST_p[Tyr^{11}, Asn^{18}] had similar properties to those of native ST_p, 3) In spite of its difference from native ST_p, synthetic ST_p[Tyr^{11}, Asn^{18}] had ST activity, although its toxicity was lower than that of native ST_p and could not be neutralized by antiserum against native ST_p. Using the synthetic preparation, it will be possible to examine the structure-activity relationship and the biological and immunological properties of the toxin.

This work was partly supported by a Grant-in-Aid for Scientific Research No. 58122002 from the Ministry of Education, Science and Culture.

Intra- and Intermolecular [3⁺+2] Cycloadditions of Aldehyde or Ketohydrazones[1)]

Tomio SHIMIZU,* Yoshiyuki HAYASHI, Mineo NAKANO, and Kazuhiro TERAMURA
Department of Color Chemistry and Technology, Faculty of Industrial Arts, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto 606
(Received August 1, 1983)

The reaction of several 2-(alkenyloxy)benzaldehydes (or 1-naphthaldehydes) (**1**) with arylhydrazine hydrochlorides leads to intramolecular [3⁺+2] cycloadducts, 3-substituted 2-aryl-1,2,3,3a,4,9b(or 1,2,3,3a,4,11c)hexahydro[1]benzopyrano (or naphtho[1′,2′:5,6]pyrano)[4,3-*c*]pyrazole hydrochlorides (**4**), in good yields. Free bases (**5**) were obtained in high yields after the treatment of **4** with triethylamine. The thermal treatment of **5** at 150 °C gave 3-substituted 2-aryl-2,3,3a,4-tetrahydro[1]benzopyrano (or naphtho[1′,2′:5,6]pyrano)[4,3-*c*]pyrazoles. The reaction of **1** with methylhydrazine sulfate gave the corresponding 2-methyl derivatives. Analogous intramolecular [3⁺+2] cycloadducts were obtained from the reaction of 2′-(alkenyloxy)acetophenones with arylhydrazine hydrochlorides. Intermolecular [3⁺+2] cycloadducts were also obtained from a reaction mixture of 1-naphthaldehyde, arylhydrazine hydrochlorides, and styrene.

Many heterocyclic compounds containing nitrogen atoms show a broad range of phermacological activities and industrially useful chemical properties. Several studies aimed at the synthesis of biologically important [1]benzopyrano[4,3-*c*]pyrazoles have been done by a number of investigators.[2-4)] In a series of investigations of the intramolecular 1,3-dipolar cycloaddition reactions of 2-(alkenyloxy)benzaldehyde arylhydrazones,[5)] we ourselves have prepared several [1]benzopyranopyrazoles in relatively good yields, but some desirable cycloadducts could not be brought about because of the weak reactivity of some substrates. (see Routes a and b in Scheme 1)

The acid-catalyzed [3⁺+2] 1,3-dipolar cycloaddition of hydrazones with olefins reported recently by Hamelin *et al.*[6)] is a fruitful alternative for the prepatation of the cycloadducts *via* an interesting type of dipole bearing a cationic center. However, their method, using an excess amount of sulfuric acid as a catalyst, is unsuitable for substrates bearing substituents which are labile in a strong acid. In the course of the application of their method to the synthesis of benzopyranopyrazoles, we have found that hydrochloride or sulfate of aryl(or alkyl)hydrazines itself acts as an acid-catalyst and that cycloadducts were obtained very easily from the reaction in good yields. (Route c in Scheme 1)

Results and Discussion

The reaction of 2-(alkenyloxy)benzaldehydes(or 1-naphthaldehydes) (**1**) with an equimolar amount of arylhydrazine hydrochlorides was carried out in ethanol for several hours at room temperature. 3-Substituted 2-aryl-1,2,3,3a,4,9b (or 1,2,3,3a,4,11c)hexahydro[1]benzopyrano(or naphtho[1′,2′:5,6]pyrano)[4,3-*c*]pyrazole hydrochlorides (**4**) were obtained from the reaction mixture in the yields shown in Table 1. The structure of **4** was established on the basis of elemental analyses and spectral data; the IR spectra show an NH-streching vibration of quarternary ammonium salts around 2500 cm^{-1} and no carbonyl-streching vibration of the formyl group observed at **1**. The NMR spectra show saturated methine and methylene protons at δ 3.0—5.0 and no alkenyl protons. The assignment of the structure was further supported by the transformation to known compounds, 3-substituted 2-aryl-2,3,3a,4-tetrahydro[1]benzopyrano(or 1-naphtho[1′,2′:5,6]-pyrano)[4,3-*c*]pyrazoles (**6**).[5c,d)] The treatment of **4** with triethylamine in chloroform at room temperature afforded the free bases (**5**) and/or further dehydrogenated compounds (**6**). Refluxing a xylene solution of pyrazolidines (**5**) at 150 °C for several hours resulted in pyrazolines (**6**) and/or further dehy-

a) The melting-point range was very broad because of the contamination of a small amount of **5** and/or **6**.

drogenated pyrazoles (**7**). (Table 3) The structure of **5** was established on the basis of elemental analyses and spectral data. (Table 2) Some of the **4** and **5** are so hygroscopic or easily oxidized to **5** or **6** that they are difficult to isolate in a pure state; thus, the range of the melting points of those compounds is relatively broad. **4** could also be obtained after the treatment of hydrazones (**2**) with ethanolic hydrogen chloride. The formation of **4** can not be accounted for in terms of the [3+2] 1,3-dipolar cycloaddition reaction after the thermal isomerization of hydrazones (**2**) to azomethine imine tautomers, for such isomerization can not be observed under the thermal conditions up to 100 °C.[5c] In fact, **2** are infinitely stable in refluxing ethanol. From these results, it is most plausible to explain the formation of **4** in terms of a [3⁺+2] 1,3-dipolar

a) Satisfactory analytical data were obtained for the new compounds. b) **6b, r,** and **7q** were obtained in these yields from **1** without the isolation of any precursors; **6c, j, k, l, m, n, o, t,** and **6x** were obtained in these yields from **4**; the yields of the other substances were based on **5**. c) Recrystallized from ethanol. d) Lit, 5c. e) Lit, 5d.

cycloaddition reaction of the cationic intermediate (**3**) (see Scheme 2). No remarkable substituent effects in these cycloaddition were observed except for the few examples described below. In the cases of $R^1=R^2=H$ and $R^3=CN$, hydrazones (**2**) were the only isolable products, and no cycloadducts were detected. However, the cycloadducts (**4**) could be obtained in good yields after the treatment of the hydrazones (**2**) in ethanol containing 8% hydrogen chloride. While the quantitative formation of hydrazones was also observed in the case of $R^4=NO_2$, these hydrazones were stable even in refluxing ethanol containing 8% hydrogen chloride. This result may be explained in terms of the electronic effect of the nitro group; the same effect was observed in the relatively poor 1,3-dipolar reactivity of *N*-(*p*-nitrophenyl)nitrilimines.[7]

A 1,3-dipolar cycloaddition reaction can generally be explained in terms of the frontier molecular orbital (FMO) theory,[8] but so far the FMO of the cationic dipole **3** has not been calculated accurately. The observed good reactivity toward both the electron-rich and electron-poor alkenes is consistent with the interactions of a relatively low LUMO and a high HOMO in the 1,3-dipole and alkenes, and Sustmann, Type-II behavior.[9] An alternative explanation for the reactivity of **3** may be proposed on the basis of the entropically favoured intramolecular reaction, while previous studies of an intramolecular 1,3-dipolar cycloaddition[5c,d] with analogous compounds showed a substantial rate dependence on substituents.

The method described here can readily be effected with olefins and hydrazones bearing many types of functional groups, thus greatly extending the usefulness of the cycloaddition. Much better yields of **6** were obtained after consecutive treatment with the base and the thermal treatment of the reaction mixture without the isolation of **4** and **5**.

It is now shown that the [3+2] cycloaddition is not restricted to some aldohydrazones but also to a variety of hydrazones, derived from ketones and alkylhydrazines. Some of the results are shown below.

The reaction of a suspension of methylhydrazine sulfate

in ethanol with **1** proceed to completion within a few hours at room temperature. A subsequent work-up of the reaction mixtures gave the expected salts (**10**) and/or free bases (**11**) (Scheme 3). The same procedure in the case of **4** also gave **11**,**12**, and/or **13** (Table 4).

The reaction of 2′-(alkenyloxy)acetophenones(**14**) with arylhydrazine hydrochlorides in ethanol proceeded sluggishly at room temperature, but occurred smoothly at 80°C to give cycloadducts (**17**) in the yields shown in Table 5. The structure of **17** was

a) Satisfactory analytical data were obtained for **20a, c, 22a, b,** and **22c**. b) The compounds **20** were recystallized from benzene; the compounds **22** were recrystallized from ethanol. c) **20a, c,** and **20d** were dissolved in DMSO-d_6; the other compounds were dissolved in $CDCl_3$. d) The melting points of **20d** and **22d** were very broad because a contamination of alcohol, which could not be removed completely by recrystallization from other solvents or by drying under reduced pressure at 80 °C.

assigned on the basis of the results of elemental analyses and the spectral data. Although some of the **17** gave crystalline free bases (**18**) upon treatment of triethylamine, some of the oily free bases (**18**) gave air-oxidation products (**19**) after the reaction mixture had been allowed to stand at room temperature for several days. The structure of **19** was assigned on the basis of the results of elemental analyses and the spectral data (see Table 5). The methylene at the 3-position of **18** is labile to air-oxidation. Thus, **18a**—**c** gave the 3-oxo products, while **18d** (with methyl substituted for one hydrogen) was stable for the oxidation under the same conditions.

While an intermolecular [3^++2] cycloaddition proceeds well in the presence of an excess of sulfuric acid,[6] our procedure under much milder conditions also gave the intermolecular cycloadducts (**20**) in higher yields (see Scheme 5 and Table 6). 1-Aryl-3-(1-naphthyl)-5-phenyl-2-pyrazolines (**22**) were obtained after the treatment of **20** with triethylamine. The intermediate, 1-aryl-3-(1-naphthyl)-5-phenylpyrazolidines (**21**), would be unstable and oxidized to **22** under the reaction conditions. The assignment of the structure was supported by a comparison of the physical properties of **22** with those of authentic specimens prepared according to the previously published procedures.[10] The cycloaddition with such dipolarophiles as acrylonitrile, methyl methacrylate, dimethyl maleate, dimethyl fumarate, *N*-phenylmaleimide, norbornene, dimethyl acethylenedicarboxylate, and phenylacetylene afforded cycloadducts in poor yields. The cycloadducts (**20**) were also obtained in good yields after the treatment of 1-naphthaldehyde arylhydrazones with olefins in ethanol containing 8% hydrogen chloride at room temperature.

Experimental

All the melting points are uncorrected. The IR spectra were recorded on a Hitachi 215 Infrared Spectrophotometer. The NMR spectra were measured on a Varian T-60A instrument, using suitable solvents and TMS as an internal standard.

Materials. The 2-(alkenyloxy)benzaldehydes(or 1-naphthaldehydes) (**1**) and their arylhydrazones were prepared according to the method previously reported.[5] The arylhydrazine hydrochlorides and methylhydrazine sulfate were commercially available (Nakarai Chem. Co.) and were used without further purification. The 2′-(alkenyloxy)-acetophenones (**14**) were prepared by the reaction of 2′-hydroxyacetophenone and ω-bromoalkenes in acetone in the presence of an equimolar amount of anhydrous potassium carbonate at 60°C for 20h. The 2′-allyloxyacetophenone (**14a**) was obtained in an 83% yield; bp 125—126°C (7mmHg), IR (neat): 1670cm^{-1} (C=O) and NMR ($CDCl_3$): δ 2.6 (s, 3H), 4.6 (d, 2H, J=5Hz), 5.1—5.6 (m, 2H), 5.75—6.4 (m, 1H), and 6.75—7.85 (m, 4H). The 2′-(2-butenyloxy)acetophenone(**14b**) was obtained in an 81% yield; bp 136—138°C (7mmHg), IR (neat): 1670cm^{-1} and NMR ($CDCl_3$) δ 1.7 (d, 3H, J=5Hz), 2.6 (s, 3H), 4.5 (d, 2H, J=4Hz), 5.6—5.95 (m, 2H), and 6.75—7.85 (m, 4H).

Reaction of 1 with Arylhydrazine Hydrochlorides. General Procedure: An equimolar mixture (5 mmol) of **1** and arylhydrazine hydrochlorides was stirred in ethanol (50ml) for several hours at room temperature. The crystals of arylhydrazine hydrochlorides are only slightly soluble in the solvent at this temperature, but the mixture became homogenous after 1 h, and then a crystalline precipitate of 3-substituted 2-aryl-1,2,3,3a,4,9b(or 1,2,3,3a,4,11c)hexahydro[1]-benzopyrano(or naphtho[1′,2′:5,6]pyrano)[4,3-*c*]pyrazole hydrochlorides (**4**) appeared within additional few hours. The evaporation of the solvent gave another corp of **4** or an oily residue. Scratching a benzene solution of the oily residue gave **4**. The yields, melting points, and spectral data are shown in Table 1. Almost all the **4** which could be recrystallized from ethanol gave correct elemental analyses. A solution of **1** and arylhydrazine hydrochlorides in warm ethanol (50—60°C) gave results similar to those described above.

The Treatment of 2-(Alkenyloxy)benzaldehyde(or 1-naphthaldehyde) Arylhydrazones in Ethanol Containing 8% HCl. 2-(Alkenyloxy)benzaldehyde (or 1-naphthaldehyde) arylhydrazones (**2**)[5c,d] was added to an ethanol containing 8% HCl at room temperature and the mixture was stirred for an additional hour after the complete dissolution of **2**. The subsequent evaporation of the solvent and the hydrogen chloride at 70°C in a rotary evaporator gave an oily residue. The residue was recrystallized from benzene to afford **4** in 90—100% yields.

The Treatment of 4 with Triethylamine. Into a suspension of **4** in chloroform we added an excess mol of triethylamine, after which the mixture was stirred for 30min. The reaction mixture was then washed with water several times, and the organic layer was dried over anhydrous sodium sulfate. The subsequent evaporation of the solvent yielded 3-substituted 2-aryl-1,2,3,3a,4,9b(or 1,2,3,3a,4,11c) hexahydro[1]benzopyrano(or naphtho[1′,2′,:5,6]pyrano)[4,3-*c*]pyrazoles (**5**) in the yields shown in Table 2.

Preparation of 3-Substituted 2-Aryl-2,3,3a,4-tetrahydro(or -2,4-dihydro)[1]benzopyrano(or naphtho[1′,2′:5,6]pyrano)[4,3-c] pyrazoles (6 and/or 7). A xylene solution (50ml) of **5** (1mmol) was refluxed for 4h. After the evaporation of the solvent, the residue was mixed with a small amount of ehtanol (10ml) and allowed to stand for several hours, and the precipitate (**6**) that thus formed was filtered off. The filtrate was chromatographed (silica gel) with chloroform to give another crop of **6** and/or **7**.

The Reaction of 1 with Methylhydrazine Sulfate. Into a suspension of methylhydrazine sulfate (10mmol) in ethanol (50ml) we added **1** (10mmol), after which the mixture was stirred at room temperature. After the complete dissolution of the methylhydrazine sulfate, the mixture was stirred for an additional 4 h. The subsequent work-up of the reaction mixture gave 3-substituted 2-methyl-1,2,3,3a,4,9b (or 1,2,3,3a,4,11c)hexahydro[1]benzopyrano(or naphtho[1′2′:5,6]-pyrano)[4,3-*c*]pyrazole sulfates (**10**) in a rather impure crystalline or oily state because of the contamination of a small amount of **11** and/or **12**. Free bases (**11**) and dehydrogenated products (**12** and **13**) were prepared following procedures similar to those described in the cases of **4**→**7**.

The Reaction of 14 with Arylhydrazine Hydrochlorides. A mixture of **14** (10mmol) and arylhydrazine hydrochloride (10mmol) in ethanol (70ml) was refluxed for 20h. After the evaporation of the solvent, benzene was added (30ml) to the residue; crystalline **17** was then precipitated immediately from the benzene solution. Recrystallization from benzene gave pure **17**. 2′-(3-Phenyl-2-propenyloxy)acetophenone arylhydrazones were the only isolable products from the reaction of 2′-(3-phenyl-2-propenyloxy)acetophenone (**14c**) with arylhydrazine hydrochlorides; no cycloadducts were detected.

The Treatment of 17 with Triethylamine. To a solution of **17b** (1.8g) in chloroform (70ml) we added triethylamine (1ml), after which the mixture was stirred for 30 min at room temperature. The reaction mixture was then washed with water several times, and the organic layer was dried over

anhydrous sodium sulfate. The subsequent evaporation of the solvent yielded crystals of 9b-methyl-2-phenyl-1,2,3,3a,4,9b-hexahydro[1]benzopyrano[4,3-*c*]pyrazole (**18b**) in a 77% yield (1.22 g). Recrystallization from ethanol gave pure **18b**. On the other hand, an oily mass was obtained after the similar treatment of **17a** (or **17c**) with triethylamine. The exposure of the ethanol solution of the oily mass to the atmosphere for several days yielded white crystals of 2-aryl-9b-methyl-1,2,3,3a,4,9b-hexahydro[1]benzopyrano[4,3-*c*]pyrazol-3-ones (**19a** or **19c**) in the yields shown in Table 5.

The Reaction of 1-Naphthaldehyde with Arylhydrazine Hydrochlorides in the Presence of Dipolarophiles. An ethanol solution (80 ml) of an equimolar (10 mmol) mixture of 1-naphthaldehyde and arylhydrazine hydrochlorides was stirred for 20 h at room temperature in the presence of dipolarophile (4 ml of dipolarophiles which exhibit boiling points less than 150 °C, and an equimolar amount (10 mmol) of other high-boiling dipolarophiles). After the evaporation of the solvent, the residue was mixed with hot benzene (20 ml) and the mixture was cooled to room temperature. The 5-substituted 1-aryl-3-(1-naphtyl)pyrazolidine hydrochlorides (**20**) thus precipitated filtered and were recrystallized from benzene. The yields and melting points are shown in Table 6.

The Reaction of 1-Naphthaldehyde p-*Chlorophenylhydrazone and Styrene in Ethanol Containing 8% HCl.* The reaction of 0.3 g (2 mmol) of 1-naphthaldehyde *p*-chlorophenylhydrazone and 1.0 g (10 mmol) of styrene was carried out in ethanol (30 ml) containing 8% HCl at toom temperature for 20 h. After the evaporation of the solvent and the excess amount of HCl and styrene, the residue was mixed with benzene (10 ml) to give white crystals (0.34 g, 82% yield) which shows the same physical properties as those of **20c**.

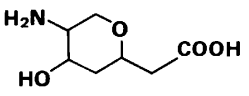
Structural and Stereochemical Study of Galantinic Acid, a New Amino Acid from Peptide Antibiotic Galantin I

Tateaki WAKAMIYA, Toshihiko ANDO, Tadashi TESHIMA, and Tetsuo SHIBA*
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received August 3, 1983)

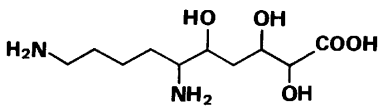
A new amino acid, galantinic acid, was found as one of the constituent amino acids in a peptide antibiotic galantin I. The structure of galantinic acid was determined to be (2*S*,4*S*,5*S*)-5-amino-2-carboxymethyl-4-hydroxytetrahydropyran on the basis of NMR and CD studies.

A peptide antibiotic galantin I effective against both Gram positive and Gram negative bacteria was isolated from the culture broth of *Bacillus pulvifaciensis* by Shoji and his co-workers.[1] Recently, we succeeded to determine the chemical structure of galantin I as shown in Fig. 1.[2]

From the hydrolyzate of galantin I, two new amino acids named galantinic acid (**1**) and galantinamic acid (**2**), were isolated and their primary structures had been preliminarily reported.[2] In the present paper, we describe the details about the structural determination as well as the assignment of steric configuration of galantinic acid.



1 galantinic acid



2 galantinamic acid

The isolation of galantinic acid from galantin I hydrolyzate was carried out by the use of ion-exchange chromatography and preparative paper electrophoresis. Galantinic acid was assumed to be a neutral amino acid taking into account the mobility on paper electropherogram and the retention time in amino acid analysis. However, its faster mobility or longer retention time compared with those of Gly or Ala indicated that galantinic acid would not be α-amino acid.

Characterization of galantinic acid was first achieved by NMR analyses. (Table 1) ^{13}C-NMR of this amino acid showed seven carbon signals which are of one carbonyl and six alkane carbons. Four of six alkane carbons were expected to carry heteroatoms such as *N* or *O* being classified into one carbon at higher field (51.8ppm) and three ones at lower field (64.7—73.6ppm). In general, the substitution of oxygen atom causes larger deshielding effect to the chemical shift of carbon atom than that of nitrogen atom. Therefore, we could deduce that amino group is attached on carbon atom at 51.8ppm and other three carbons are presumably bound to oxygen atoms.

^{1}H-NMR of galantinic acid revealed the presence of at least nine protons which are unexchangeable with deuterium. No protons were observed in olefinic or aromatic region. Of these protons, simple doublet centering at 2.39ppm (J=5Hz) was assumed to be methylene protons such as -X-C<u>H$_2$</u>-CH- (X=CO, NR$_2$, SR, *etc*). On the other hand, another seven protons appeared in complex multiplets which were expected from a ring structure. The correlations between carbon and proton signals were determined by the measurement of ^{13}C-NMR using selective decoupling method as summarized in Table 1.

Table 1. Correlations between ^{13}C and ^{1}H signals

δ		Supposed partial structure
^{13}C	Related ^{1}H	
37.6	1.43, 2.14	-C-<u>CH$_2$</u>-C-
41.6	2.39 (2H)	-C-<u>CH$_2$</u>-CO-
51.8	3.10	-C-<u>CH</u>-N-
64.7	3.44	-C-<u>CH$_2$</u>-O-, -C-<u>CH</u>-O- (×2)
67.2	3.82 (2H)	
73.6	4.11	
177.1	—	-C-<u>C</u>OOH

FD-MS spectrum of galantinic acid gave two peaks at m/z 175 and 176 which correspond to M^+ and $(M+H)^+$, respectively. When galantinic acid was *N*-benzoylated, the product gave two peaks at m/z 279 (M^+) and 280 ($(M+H)^+$) in FD-MS spectrum. This result clearly showed the introduction of one residue of benzoyl group indicating that galantinic acid is an aliphatic monoamino monocarboxylic acid.

From considerations of the molecular weight, carbon and proton numbers as well as the number of amino group, we could deduce unequivocally the molecular formula of galantinic acid to be $C_7H_{13}NO_4$. Therefore,

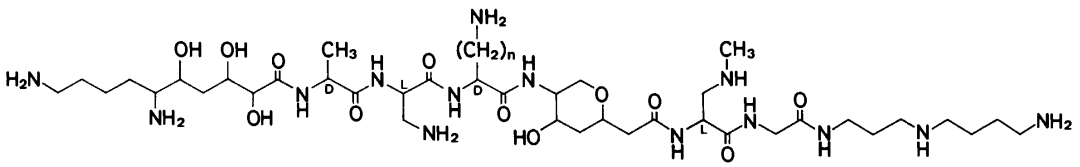


Fig. 1. The structure of galantin I. Galantin I is a mixture of two congeners differing at the fourth amino acid residue from N-terminal. Lysine (n=4) and ornithine (n=3) are found in a ratio of 9:1.

TABLE 2. ASSIGNMENTS OF PROTON SIGNALS AND THEIR SPIN COUPLING CONSTANTS (J/Hz)

δ	Multiplicity	Assignment	Coupled with

3.82	m	H_{2a} [a]	—	(11)	(2 or 5)	—	—	—	—	(7)
3.82	m	H_{4a} [a]	—	(11)	(5 or 2)	—	(11)	—	—	—
4.11	dd	H_{6e}	—	—	—	—	4	11	—	—

a) The analyses of multiplicity of H_{2a} and H_{4a} were impossible because of their complete overlapping. Therefore, the coupling constants only deducible from those of the related protons are shown in parentheses.

the degree of unsaturation of galantinic acid is two. Namely, one is of carboxylic acid and another one is of cyclic structure. The molecular formula also suggested that galantinic acid would be a hydroxyamino acid. When galantinic acid was oxidized with periodate and permanganate, no positive product to ninhydrin reaction was observed in amino acid analysis and on paper electropherogram. This result proposed the presence of vicinal amino alcohol moiety in galantinic acid.

Based on the facts mentioned above, a structure having tetrahydropyran skeletone was proposed for galantinic acid. The presence of three carbon atoms carrying oxygen atom, the multiplicity of proton signals, and their large coupling constants could be explained from the structure **1**. The assignments of proton signals in ^{1}H-NMR (Fig. 2) were achieved by use of the decoupling method as summarized in Table 2. The position of each proton was exactly determined and the relative configuration of galantinic acid was then estimated by

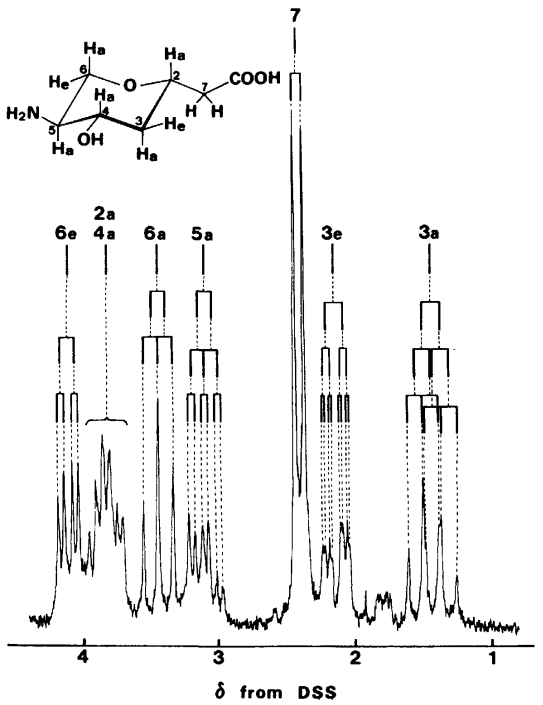

Fig. 2. ^{1}H-NMR of galantinic acid in D_2O (100 MHz).

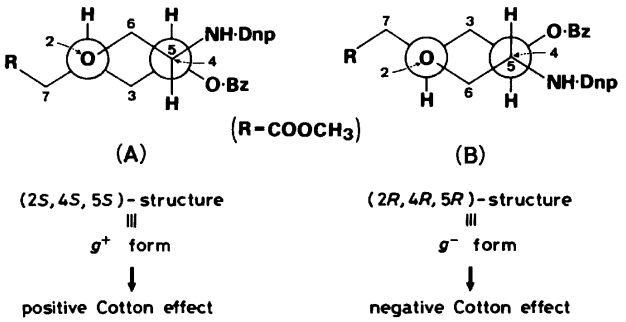

Fig. 3. Plausible stereo structures of galantinic acid and expected sign of Cotton effect of *N*-Dnp-*O*-Bz derivative. Dnp=2,4-dinitrophenyl; Bz=benzoyl.

precise analysis of the coupling constant of each proton. The fact that all the methine protons on C_2, C_4, and C_5 showed at least one large coupling constant over 10 Hz due to 1,2-diaxial protons might be elucidated from the steric structure mentioned in Fig. 2. For the purpose of determination of the absolute configuration of galantinic acid, Dnp-aromatic rule developed by Kawai and his co-workers was effectively applied.[3] The absolute configuration of vicinal amino alcohol part is thus deducible from the sign of CD spectrum of *N*-Dnp and *O*-Bz derivative. According to this rule, the structure **A** (g^+ form) of the two plausible stereo structures (Fig. 3), would show a positive Cotton effect, while the

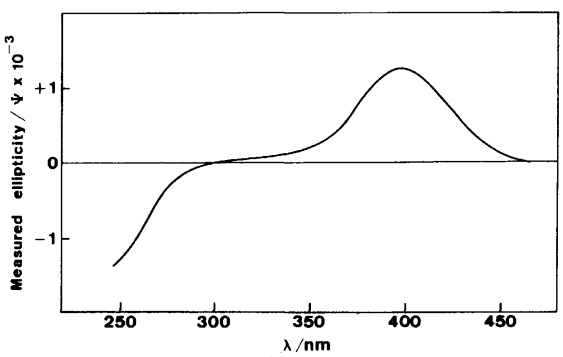

Fig. 4. CD spectrum of *N*-Dnp-*O*-Bz-galantinic acid methyl ester obtained in $CHCl_3$. The Cotton effect around 240 nm was not observed because of the disturbance due to solvent absorption.

structure **B** (g^- form) which corresponds to an enantiomeric form of the structure **A** would be expected to show a negative Cotton effect around 400 nm in CD spectrum.[4] *N*-Dnp-*O*-Bz-galantinic acid methyl ester prepared from the natural sample gave clearly a positive Cotton effect suggesting the g^+ form. (Fig. 4) As a result, the absolute structure of galantinic acid was defined to be (2*S*,4*S*,5*S*)-5-amino-2-carboxymethyl-4-hydroxytetrahydropyran.[5]

Experimental

The NMR spectra were obtained with Varian XL-100-15 and JEOL JNM-FX-90Q spectrometers for ^1H and ^{13}C in D_2O, respectively. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as the external standard and the chemical shift were given in δ value (ppm) from the standard. FD and EI mass spectra were measured with a JEOL JMS-O1SG-2 mass spectrometer. CD spectra were recorded with a JASCO ORD/UV-5 spectrometer in $CHCl_3$.

Isolation of Galantinic Acid. Crude galantin I (0.44 g) was hydrolyzed for 5 h at 110 °C with 10 ml of constant boiling 6 M† hydrochloric acid in a sealed tube after deaeration. The hydrolyzate obtained from 1.76 g of galantin I was concentrated *in vacuo* and the residue was applied to Amberlite IRCG-50 column (type I, NH_4^+ form, 1.5×140 cm). The elution was carried out with a gradient method from 0.1% to 1.5% aqueous ammonia. Thus, a mixture of neutral amino acids was obtained in a yield of 0.21 g.

The mixture of neutral amino acids (1.4 g) obtained by the above procedure was dissolved in a small amount of 1 M HCl and 95% ethanol was added to the solution. The precipitate was deposited by centrifugation and the supernatant was concentrated *in vacuo*. A powdery residue obtained was applied to Amberlite IRCG-120 column (type I, pyridine form, 1.8×50 cm) which was eluted with a linear gradient method from 0.125 M to 0.50 M pyridine-acetate buffer (pH 3.5). The fractions containing galantinic acid were pooled and concentrated *in vacuo*. The residue was dissolved in a small amount of 1 M HCl and ethanol was added. The supernatant after centrifugation was concentrated *in vacuo* and the residue was purified by preparative paper electrophoresis (pyridine-acetic acid-water=1:10:89, pH 3.5, 13 V/cm, 2 h, Toyo Roshi No. 50 filter paper). Galantinic acid was extracted from the paper with 0.1 M acetic acid. The extract was lyophilized and the lyophilization was repeated twice after dissolving the residue in a small amount of water. Pure galantinic acid (26 mg) was obtained as hygroscopic powder which showed a single spot on paper electropherogram and TLC (cellulose plate, developing solvent: *n*-BuOH-pyridine-AcOH-H_2O=15:5:8:12, R_f 0.68).

N-Benzoylgalantinic Acid for FD-MS Measurement. To a solution of galantinic acid (1.0 mg, 5.7 μmol) in 0.1 ml of water were added benzoyl chrolide (2.1 mg, 15 μmol) and 4.8% Na_2CO_3 solution (0.05 ml, 22.5 μmol). The reaction mixture was stirred overnight at room temperature and then once extracted with ether to remove exess benzoyl chloride. The aqueous layer was acidified with hydrochloric acid and extracted with ethyl acetate. The extract was washed with water, dried over $MgSO_4$ and then concentrated *in vacuo*. A solution of the residue in 0.1 ml of DMSO was subjected to FD-MS measurement: *m/z* 279 (M^+) and 280 ($(M+H)^+$).

N-(2,4-Dinitrophenyl)-O-benzoylgalantinic Acid Methyl Ester. To a solution of galantinic acid (1.0 mg, 5.7 μmol) in 50 μl of H_2O were added $NaHCO_3$ (1.4 mg, 17 μmol) and 0.5 mM 2,4-dinitrofluorobenzene (DNFB) in acetone (34 μl, 17 μmol). The mixture was stirred for 4 h at room temperature in the dark. The reaction was followed by TLC (silica gel plate, developing solvent: $CHCl_3$-MeOH-AcOH=6:2:1). Extra reagents (0.4 mg of $NaHCO_3$; 10 μl of DNFB in acetone) were added every a few hours until the starting material disappeared.

After the completion of the reaction, the mixture was extracted with ether several times and the aqueous layer acidified with 2 M HCl was concentrated *in vacuo*. The residue in ethyl acetate was washed with saturated NaCl solution several times and organic layer was dried over $MgSO_4$. To the solution was added an excess of CH_2N_2 in ether. The mixture was allowed to stand for 1 h and then concentrated *in vacuo*.

To the residue in CH_2Cl_2 (0.2 ml) were added benzoic anhydride (10 mg, 44 μmol), triethylamine (6.1 μl, 44 μmol), and 4-dimethylaminopyridine (0.3 mg, 2.5 μmol). The mixture was stirred overnight at room temperature in the dark and then subjected to preparative TLC. The reaction mixture was applied to silica gel plate (Merck, 0.25 mm thickness, 20×20 cm) which was developed with benzene-ethyl acetate (4:1). Yellow band corresponding to the desired product was extracted with $CHCl_3$ and the extract was concentrated *in vacuo*. The crystalline residue thus obtained gave a peak at *m/z* 459 (M^+) in both FD and EI mass spectra. This sample was used for the measurement of CD spectrum.

Periodate-permanganate Oxidation of Galantinic Acid. Galantinic acid (0.43 mg) was dissolved in 0.05 M sodium acetate buffer (pH 7.7, 200 μl). To the solution was added 0.1 M sodium periodate solution (100 μl). The mixture was allowed to stand for 2 d at 4 °C in the dark and then 0.2% potassium permanganate solution was slowly added until a pale purple color remained. MnO_2 formed was removed off by centrifugation. The supernatant was subjected to an amino acid analysis and a paper electrophoresis.

The authors wish to express their thanks to Dr. Junichi Shoji, Shionogi Research Laboratory, Shionogi & Co. Ltd., for his kind supply of galantin I. We are grateful to Dr. Masao Kawai, Nagoya Institute of Technology, for the valuable suggestions and discussions about Dnp-aromatic rule. We also appreciate to Dr. Yasufumi Ohfune, Suntory Institute for Bioorganic Research, for his information of the results obtained from his synthetic work of galantinic acid.

(Received April 13, 1983)

The photoionization mechanism of *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine (TMPD) in an acetonitrile solution was investigated by means of the fluorescence lifetime measurement, picosecond and nanosecond laser photolyses, and photocurrent measurement. The temperature dependence of the fluorescence lifetime was interpreted in terms of the thermally activated monophotonic ionization or the ion-pair-formation mechanism from the $S_{1,0}$ excited level. Picosecond laser photolysis clearly showed that a direct ionization from higher S_1 levels took place before relaxation into the $S_{1,0}$ level. The relative yields of triplet, ion-pair, and cation formation were estimated from analyses of the transient spectra and the photocurrent.

Considerable efforts have been devoted to the study of the photoionization mechanism of *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine (TMPD) in nonpolar and polar solvents. Tsubomura and his co-workers[1,2] have found a biphotonic ionization process in a nonpolar solvent by means of microsecond flash photolysis, and have suggested a monophotonic process in an acetonitrile solution on the basis of photocurrent measurements.[3] Ottolenghi[4-6] and his group performed an extended spectral study indicating the importance of the singlet-intermediate state. Richards and Thomas[7] have used microsecond and nanosecond flash photolysis techniques for studying the photoionization in cyclohexane, ethanol, and water; they established the characters of the triplet and ion-pair states and discussed a possible mechanism of photoionization in water. Ottolenghi[8] suggested a charge transfer to the solvent (CTTS) state as an intermediate in the photoionization of several organic molecules. The importance of the CTTS state has been shown in the decay and photoionization of sodium 8-anilino-1-naphthalenesulfonate.[9,10] In spite of many investigations so far performed, however, no fast method of analyzing the monophotonic ionization process in a polar solvent has yet appeared.

In this paper we present a combined investigation of the photoionization mechanism of TMPD in an acetonitrile solution by using the results of picosecond and nanosecond laser photolyses and photocurrent and fluorescence-lifetime measurements.

Experimental

Materials. The TMPD was obtained from the Aldrich Chem. Co., and was purified by vacuum sublimation in a furnace with a temperature gradient. The acetonitrile was refluxed over P_2O_5 and distilled. The hexane was a spectrograde product of Merck. The 1,3-pentadiene, a mixture of cis and trans isomers from Wako Pure Chem., was purified, while a zone-refined naphthalene from Tokyo Kasei was used without further purification.

Fluorescence-lifetime Measurements. The fluorescence-lifetime measurements were performed by two methods. One was a photon-counting technique employing a discriminator and a TAC (Canberra 1443A) combined with a MCA system. The light source was a free-running lamp in air at 1 atm; the 337-nm light was selected after passing it through a Nikon G250 monochromator. The half-band width of the pulse duration was 2.5 ns. Picosecond laser (a mode-locked Nd-YAG laser) excitation, followed by recording the fluorescence decay with a streak camera (HTV C-1000), was also used for the lifetime measurements in the range of a few nanoseconds. The temperature dependence of the fluorescence lifetimes was measured by circulating cooled nitrogen gas around the sample cell, while the temperature was kept constant with an accuracy of ±0.5 °C. The results obtained with the photon-countig method are tabulated in Table 1.

Nanosecond Laser-flash Photolysis. The transient absorption in the nanosecond and microsecond time domain was measured by means of nanosecond laser-flash-photolysis apparatus. The nitrogen laser was a home-made TEA type with a peak power of 500 kW and a time duration of 2 ns. All the solutions used for the fluorescence-lifetime and laser-photolysis experiments were degassed at least five times by means of a freeze-pump-and-thaw method. The temporal changes in the absorbance were recorded with an oscilloscope (Tektronix 485) at twenty points of significant absorbance; these data were then used to obtain the time-resolved transient absorption spectra.

Picosecond Laser-flash Photolysis. The transient absorption in the picosecond time region was measured by

TABLE 1. FLUORESCENCE LIFETIMES IN VARIOUS SOLVENTS AT DIFFERENT TEMPERATURES, AND ACTIVATION ENERGY FOR THE DECAY RATE OF THE TMPD $S_{1,0}$ STATE

Temperature	Lifetime/ns										Activation energy
K / Solvent	313	298	274	260	246	232	217	202	186	168	kJ mol^{-1}
Acetonitrile	0.8	1.3	3.5	6.9	9.5	12.4					33.9
Methanol	3.0	4.0	7.2	10.1	11.6	12.1	13.1	13.2	13.0		30.1
Ethanol	6.9	7.8	9.0	9.6	9.8	10.2	11.0	11.5	12.1	12.3	5.0
Hexane	4.9	4.9	4.9								—

means of a laser excitation of a third harmonics of a mode-locked Nd:YAG laser (355 nm) with a 20-ps pulse width. The laser light from the YAG oscillator was amplified and used for excitation and for recording transient absorption by means of multichannel photo-diode system with a pulsed-continuum light source (D_2O+2-propanol) or a fast-photomultiplier tube system (HTV R1294U), with a Xe arc lamp as a monitoring light. The Xe lamp was fired by a strong laser pulse focussed onto the arc electrode.[11]

Photocurrent Measurements. The photocurrents induced in irradiated solutions were measured in order to determine the decay of the transient carrier. The induced current in the solution was measured with Pt-electrodes separated by 0.3 mm after excitation from a YAG laser. The transient current was amplified through a preampifier (model 115, PAR) and recorded by means of an oscilloscope (Hewlett-Packard, 1744A). Between the electrodes, a constant voltage of 20 V was applied during the photocurrent measurements. All solutions were bubbled with nitrogen gas at least for 30 min or longer, because otherwise the dissolved oxygen would quench the photocurrent.

Results and Discussions

Fluorescence Lifetime. As is shown in Table 1, a temperature dependence of fluorescence lifetimes was found in ethanol, methanol, and acetonitrile; however, it was not observed in hexane. This observation might be correlated with the temperature independence of the intersystem crossing and the absence of monophotonic ionization in hexane. Richards and Thomas[7] reported that the triplet yield of TMPD in cyclohexane was 0.96± 0.10 and that the fluorescence yield was 0.09. Since hexane is as inert as cyclohexane, all excited species may decay either into the triplet state through intersystem crossing at the rate k_{ISC} or to the ground state at the fluorescence rate k_f in hexane. Then the fluorescence lifetime in hexane, τ_h, is given as:

$$\tau_h = 1/(k_{ISC} + k_f) = 4.9 \text{ ns},$$

where $k_{ISC}=\phi_T/\tau_h=1.96\times10^8$ s^{-1}, $k_f=\phi_f/\tau_h=0.18\times10^8$ s^{-1}, and other radiationless processes are ignored. In a polar solvent such as acetonitrile, the monophotonic ionization process with the rate k_{ion} is involved, as will be discussed later, and the fluorescence lifetime, τ_f, will be shrunk as is described by:

$$\tau_f = 1/(k_{ion} + k_{ISC} + k_f) = 1.0 \text{ ns}.$$

k_{ion} is estimated as 8×10^8 s^{-1} at 300 K if k_{ISC} and k_f are assumed to be independent of the solvent and the temperature (Here the value of τ_f is obtained with a streak camera after picosecond excitation.). If we assume that the temperature dependence of the fluorescence lifetime is to be ascribed to the activation of the ionization process, then k_{ion} will be represented as $k_{ion}=k_0\exp(-\Delta E/RT)$, where other processes are considered to be temperature-independent. These assumptions are supported by the variation in the activation energies for acetonitrile, methanol, and ethanol (Table 1).

From the slope of $\ln(1/\tau_f-1/\tau_0)$ shown in Fig. 1, the activation energies for the temperature-dependent

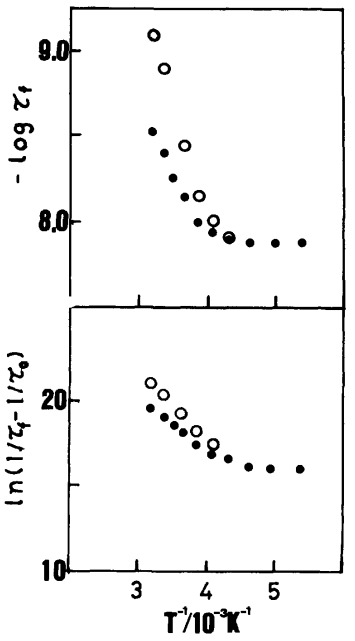

Fig. 1. Temperature dependence of fluorescence lifetime (τ_f) and $\ln(\tau_f^{-1}-\tau_0^{-1})$. ○: Acetonotrile and ●: methanol solutions.

ionization process are determined to be as is shown in Table 1. Here, τ_0 is the fluorescence lifetime obtained at a lower temperature, where the thermal process can be neglected. In an acetonitrile solution, the thermally activated decay process is most evident; below it will be connected with thermally activated monophotonic ionization process found by means of picosecond laser photolysis.

Picosecond Laser-flash Photolysis. Hexane Solution: The transient absorption spectra after picosecond-laser excitation are illustrated in Fig. 2. In a

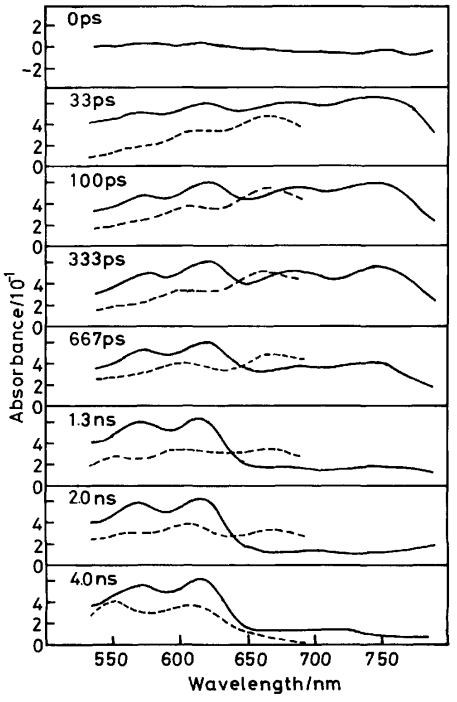

Fig. 2. Transient spectra of photolyzed TMPD measured with MCPD system in acetonitrile (——) and hexane (------) solutions.

hexane solution, the $S_n \leftarrow S_1$ absorption bands were observed immediately after excitation to have peaks at 670, 610, and 560 nm (the 700-nm region was not recorded); all these bands decayed with a time constant of 5 ns. The fluorescence lifetime (Table 1) in hexane was 4.9 ns; therefore, these bands were assigned to the $S_n \leftarrow S_1$ absorption. In the transient spectra in the 610—520 nm region, new bands grew with a time constant of $\simeq$5 ns, and the spectral shape was coincident with the previously reported $T_n \leftarrow T_1$ absorption.[1)]

In a hexane solution, the biphotonic ionization may occur via the siglet- or triplet-excited states under a high-intensity light, but the present laser has not enough power and has the very short duration of 20 ps; therefore, the biphotonic process can be neglected.

When the temporal changes in the transient spectra are superposed, an isosbestic point of the $S_n \leftarrow S_1$ and $T_n \leftarrow T_1$ absorptions is found at 620 nm. The molar-extinction coefficient of the $T_n \leftarrow T_1$ at 570 nm was determined by Richards and Thomas[7)] to be 11900. The molar absorption coefficient of the $S_n \leftarrow S_1$ absorption at 670 nm could be determined as 18000 by using the data at a time delay of 100 ps and the above-mentioned value for the $T_n \leftarrow T_1$ absorption. Thus, the picosecond laser photolysis in hexane showed the band shapes of the $S_n \leftarrow S_1$ and $T_n \leftarrow T_1$ absorptions and their molar-absorption coefficients.

Acetonitile Solution: In an acetonitrile solution, the spectra immediately after the excitation show peaks at 750, 680, 620, and 570 nm. The longer-wavelength peaks at 750 and 680 nm decayed with a lifetime of 1 ns, which indicated that these bands were due to the $S_n \leftarrow S_1$ absorption since the lifetime of the fluorescence was determined as 1 ns. The peaks at 620 and 570 nm should be assigned to the absorption bands of the photoionized product, either the cation or the ion-pair or the CTTS state, because these band positions coincide with those reported for cations.[1)] No distinction between the spectra of the ion-pair and the CTTS states with a cation is discernible, but we consider that the ion-pair state is the only singlet intermediate before the ionization because the CTTS state may have a similar electronic structure. Moreover, we can not say simply at this moment that the product is a cation, because there are several decay processes for this transient absorption. In the spectrum at 33 ps after the excitation, these peaks were already found, implying that a direct ionization or ion-pair formation took place before relaxation to the $S_{1,0}$ state. In the spectrum of the 4-ns time lag, some contribution of the triplet state might overlap. As is well known,[1)] the cation spectra and the $T_n \leftarrow T_1$ absorption bands are very close to each other, and so the separation of the transient spectra into these components is rather difficult without the aid of other means. The results of nanosecond flash photolysis and the photocurrent measurements were used for this analysis. In the picosecond photolysis spectra, the cation-like species were found immediately after the excitation; in addition to this, another process to produce this species was indicated because the cation-like band increased in intensity with a time constant of 1.2 ns. This temporal change in the spectra was also confirmed by the measurement of the transient absorbance with a fast photomultiplier tube, as is shown in Fig. 3. The analysis of the growth of the absorbance at 610 and 540 nm showed the rise time of 1.1 ns, which is in perfect agreement with the fluorescence lifetime in acetonitrile. After subtracting the contributions of the $S_n \leftarrow S_1$ and $T_n \leftarrow T_1$ transitions and the direct ionization from the transient spectra, the second process was found to have a yield twice that of the first direct ionization process. Thus, the cation-like band grows accompanied by the decay of the $S_{1,0}$ state. As has been discussed in the fluorescence-lifetime section, this decay process is thermally activated. Thus, the monophotonic ionization occurred by means of the 355-nm excitation, either from the higher S_1 level or from the bottom of the S_1 state ($S_{1,0}$), with the aid of thermal activation.

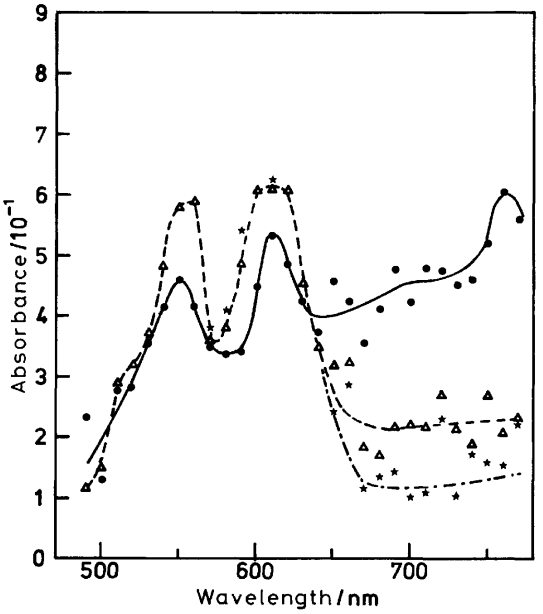

Fig. 3. Transient spectra measured by a fast photomultipler system at zero (●), 3 ns (△), and 10 ns (*) time delay.

Another important experiment to find the overall reaction scheme is that of the power dependence of the transient absorption. The intensity of the transient absorption at 620 nm was measured by varying the laser power in the range of 0.3—2 mJ; the absorbance was shown to be linear with the excitation energy as is shown in Fig. 4. This measurement was made with a photomultiplier tube with a rise time of 2 ns (RU928); therefore, the results showed that the overall ionization process is monotonic rather than the biphotonic process which was considered to occur in ethanol.[1)]

In the photolysis spectra above the 700-nm region, there remained a broad, residual transient absorption with a lifetime longer than the $S_n \leftarrow S_1$ transition; its lifetime was estimated as about 50 ns. In the literature, the spectra of CH_3CN^- is reported to have a maximum at 1.45 μm;[12)] therefore, we may observe the tail of the absorption band of CH_3CN^- in the 700-nm range. The short lifetime as compared with the literature value ($\simeq$900 ns) might be due to the presence of an efficient scavenger or a fast reaction with the cation produced.

Nanosecond Laser-flash Photolysis. The transient

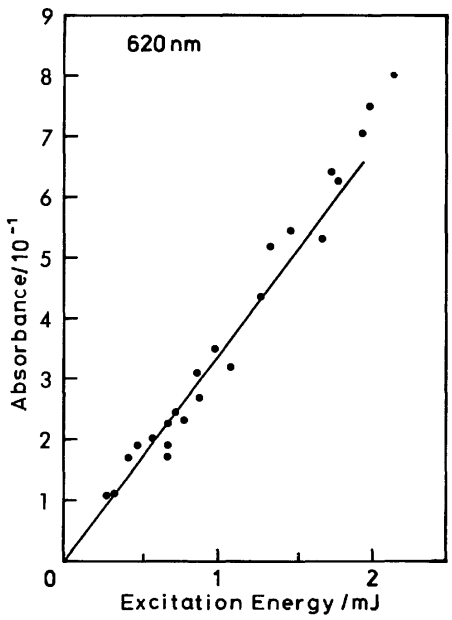

Fig. 4. Laser power dependence of transient absorption measured at 620 nm.

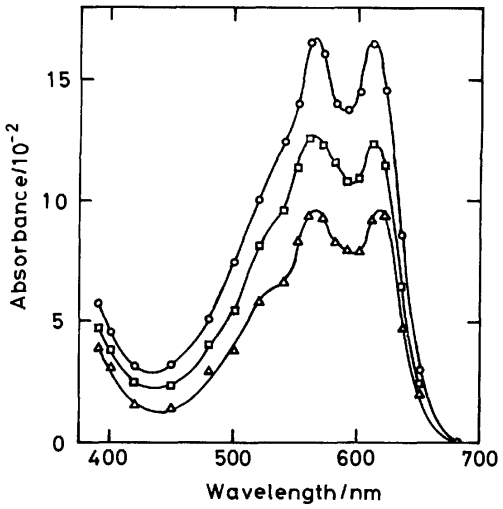

Fig. 5. Transient spectra obtained by nanosecond laser photolysis at 0.1 μs (—O—O—), 1.0 μs (—□—□—) and 4.0 μs (—△—△—) time delay.

absorption spectra as determined by nanosecond laser-flash photolysis, are shown in Fig. 5. The time-resolved absorption spectra after time delays of 100 ns, 1 μs, and 4 μs are illustrated. The decay of the absorbance at each wavelength was analyzed by a linear combination of several first-order decay curves, and at least three or four components were confirmed. The extrapolation to $t=0$ after the excitation gave three different absorption curves, as is shown in Fig. 6, where the height of the absorption represents the relative quantities of the photoproducts. The spectrum of the longest-lifetime component ($\tau>1$ s) is exactly the same as that of the cation; the medium-lifetime ones ($\tau\simeq2$ μs and $\simeq50$ μs) also resemble the cation spectrum.

The shortest-lifetime component ($\tau\simeq500$ ns) has a slightly different spectral shape; it is very close to the $T_n\leftarrow T_1$ absorption reported in the literature.[1]

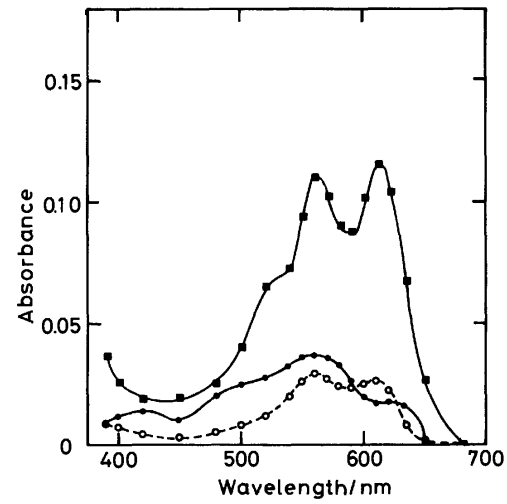

Fig. 6. Absorption spectra of the stable cation (—O—O—), the long lived component ($\tau=2$ and 50 μs (—■—■—), and the short lived component ($\tau=0.5$ μs) (—●—●—).

Therefore, this shortest component in the nanosecond flash photolysis is ascribed to the triplet state. Quite recently, Tokumura *et al.*[13] reported the decay of the T_1 state in acetonitrile to have a lifetime of 660 ns, thereby confirming our finding that the shortest-lifetime component of $\tau\simeq$ 500 ns is ^{3}TMPD. The relative yields of these three components have been estimated by an extrapolation to $t=0$; the yields and lifetimes are summarized in Table 2.

TABLE 2. LIFETIMES AND YIELDS OF LASER-PHOTOLYSIS PRODUCTS IN MICROSECOND TIME RANGE

Species	Lifetime	τ	Yield/%
^{3}TMPD	Shortest	0.5 μs	0.22±0.07
Cation and ion-pair or CTTS state	Medium	14 μs (2 and 50)	0.60±0.06
Stable cation	Longest	> 1 s	0.18±0.07

In this table the medium-lifetime components are represented as having a common decay time of 14 μs, but the detailed analysis showed that these are at least two components with 2 and 50 μs. It is apparent, therefore, that there are several decay processes of the cation and ion-pair state. However, the lifetimes of these intermediates are independent of the laser power; accordingly, these decays might be first-order processes. It is conceivable that a geminate recombination of the ion pair is a major decay process.

Photocurrent. In order to determine the mechanism of transient phenomena in detail, the photocurrent produced after the YAG laser excitation was measured with a time resolution of $\simeq$ 10 ns. The current was found to be linear with the intensity of the exciting light, which is in good agreement with the results of an earlier study.[3] The transient current was analyzed with a linear combination of several components with different lifetimes; it may be described as:

$$I_p(t) = \sum_j A_j e^{-t/\tau_j},$$

where A_j is a preexponential factor for the j-th decay component of the lifetime τ_j and where numerical values are as follow:

τ_j	0.08	0.7	1.6	40	240	(μs)	$>$1 ms
A_j	0.24	0.26	0.18	0.08	0.07		0.18

These lifetimes are independent of the power of the laser light. The shortest lifetime coincides with those of CH_3CN^- in transient spectra. The origin of the second component is not clear, but it may be due to the free cation produced immediately after the excitation. The third and fourth components have decay times similar to that found by nanosecond laser photolysis; therefore, they may be related to the ion-pair state. Although no report has yet been presented on the current originating from the ion-pair without a rise time, the present coincidence of the decay of the transient-cation spectra with that of the current might indicate that the ion-pair gives a current under an electric field near the electrode surface. The independence of the decay times of the power intensity may indicate that most of the ejected electrons are still bound close to the cation, forming an ion-pair or a CTTS state, and that they exhibit a photocurrent under the applied field by dissociation. The presence of several decay times may mean the existence of inhomogeneous electron-trapped states, in which electrons are loosely bound to the cation but give a transient current under the applied electric field. Although all these measurements were carried out with nitrogen-bubbled samples, the effect of oxygen on the photocurrent was also examined. The shortest- and the medium-lifetime transient currents were significantly quenched, the former being reduced to one-tenth, and the latter, to about one-fifth. Therefore, both the CH_3CN^- and the ion-pair were shown to be quenched by oxygen.

Conclusion

The photoionization mechanism of TMPD in an acetonitrile solution was investigated by means of picosecond and nanosecond laser photolyses and photocurrent and fluorescence-lifetime measurements. Although the monophotonic ionization from the higher S_2 state has been studied by several groups,[14,15] little attention has been given to that from the higher S_1 level except for the work by Siomos *et al.*[16] They showed the photocurrent in a heptane solution excited by a two-photon process, but the photoionization from the $S_{1,0}$ level was not indicated. In this study, however, both the monophotonic direct ionization from the higher S_1 level and the thermally activated process from the $S_{1,0}$ is confirmed by picosecond laser photolysis. However, not all the cation-like species in the transient spectra may be due to the free cation, since the final yield after the photolysis is $\simeq$0.18. In the initial stage of photolysis, the yield of the cation-like species is $\simeq$0.77 as a whole; the direct ionization is estimated as $\simeq$0.25, and the second thermal process is $\simeq$0.52, as is shown in Fig. 7. The yield of the triplet state was estimated by nanosecond laser photolysis to be $\simeq$0.21. The fluorescence yield was evaluated as 0.02 by comparing the fluorescence lifetimes in acetonitrile and cyclohexane and the quantum yield in cyclohexane.

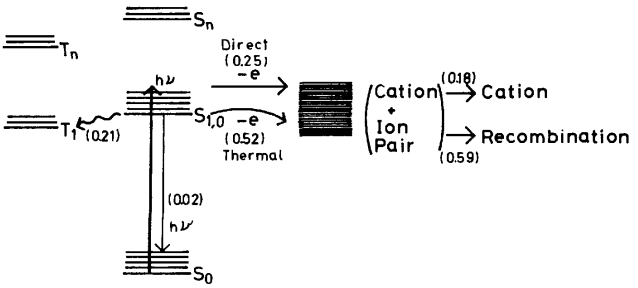

Fig. 7. Monophotonic ionization scheme of TMPD in acetonitrile solution.

In order to estimate the relative yields of the decay processes, quenching experiments with 1,3-pentadiene (1.0×10^{-3} M), naphthalene (1.2×10^{-3} M), and an air-saturated solution were performed. About one-third of the transient absorptions were quenched, indicating that most of the triplet absorption and some of the cation-like absorptions disappeared upon the use of the quenchers. The triplet yield of TMPD was found to be $\simeq$0.20 by means of the $T_n\leftarrow T_1$ absorption of naphthalene. This value was consistent with the value estimated by the nanosecond laser photolysis. Summarizing the whole photoionization scheme, the overall processes are illustrated in Fig. 7. The relative yields for each process might have uncertainties of $\pm$0.05.

In the initial statge of photolysis, two independent pathways leading to the ionization or the ion-pair formation were indicated, but 80% of the cation-like absorption decayed through the recombination process. The photo-ejected electrons in an acetonitrile solution may exist in several different environmental conditions, which means that some of them are bound to acetonitrile molecules; some are closely connected with $TMPD^+$, forming an ion-pair; some are free, and some decay rapidly by reacting with scavengers. The monophotonic ionization process from the S_1 state of TMPD in a polar solvent is thus found to be the main process, and the present analysis may throw light on the unsolved problems regarding the photoionization mechanism of TMPD in polar media.

The authors are grateful to Mr. Toshiaki Noda for making the photocurrent cell and to Mr. Atsuo Kawai for his contribution in the initial statge of this work. They also wish to thank Professor Michiya Itoh of Kanazawa University for his kind comments on this manuscript.

The Electronic Structure of the Fulvalene Trication Radical. A Localization of the Unpaired Electron

Azumao TOYOTA*,† and Takeshi NAKAJIMA

†*Department of Chemistry, Faculty of General Education, Yamagata University, Yamagata 990*
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980
(Received April 15, 1983)

The restricted Hartree-Fock (RHF) solution for the trication radical of fulvalene, obtained by using the open-shell SCF formalism of the Pariser-Parr-Pople-type MO method, is found to be doublet unstable at the conventional D_{2h} nuclear arrangement. We calculate the broken-symmetry charge-density wave solution lower in energy than the usual symmetry-adapted RHF solution and examine its properties. It is predicted that the unpaired electron should be localized on the single five-membered ring having a smaller positive charge. Finally, on the basis of the second-order Jahn-Teller effect, we examine the molecular-symmetry reduction of the trication radical from the fully-symmetrical D_{2h} to the C_{2v} nuclear arrangement.

On the basis of the doublet instability of the restricted Hartree-Fock (RHF) solution,[1,2] we have examined the origin of the anomalous phenomena that in the monoanion and trianion radicals of heptafulvalene the unpaired electron is localized on a single seven-membered ring.[3,4] It has been shown that the RHF solutions for the anion radicals, obtained by using the open-shell SCF formalism of the Pariser-Parr-Pople (PPP) type MO method, are doublet unstable at the conventional D_{2h} nuclear arrangement and the spin-density distributions obtained from the resulting broken-symmetry charge-density wave (CDW) solutions are in good agreement with the experimental ones.[5,6]

The monoanion radical of fulvalene has recently been prepared by Davies *et al.*[7,8] The spin-density distribution of this radical is of interest in connection with that of the heptafulvalene monoanion radical. In order to obtain information about the behavior of unpaired electron, they have made the ESR studies of the radical and it is revealed that the unpaired electron is delocalized over the entire molecule, showing a sharp contrast to the situation observed with the heptafulvalene monoanon radical.[3]

Although neither the monocation nor the trication radical of fulvalene has so far been prepared, both of the radicals are of great interest from theoretical and experimental points of view, because our previous research suggests that the localization of unpaired electron similar to those in the heptafulvalene monoanion and trianion radicals should occur: As to the monocation radical, we have partly studied the problem in view of the doublet instability of the RHF solution at the conventional D_{2h} nuclear arrangement.[5]

In this paper, we investigate the behavior of unpaired electron and the distribution of charge density in the trication radical of fulvalene by examining the instability of the RHF solution and by using the second-order Jahn-Teller theory. On the basis of the results obtained, we point out a distinct difference with regard to the distributions of the unpaired spin density and the ring charge density between the monocation and trication radicals.

Theoretical

The Stability Conditions of the RHF Solution. The stability conditions of the RHF solution for the open-shell case were formulated by Paldus and Cizek.[1,2] Since the conditions are well discussed in several literatures, we give here only the outline of the theory.

Using the usual real molecular orbitals, the question of whether the RHF solution is doublet stable or not resolves itself into the solution of the lowest-lying eigenvalue of the following two eigenvalue problems:

$$(A+B)D_+ = \lambda_+ D_+,$$
$$(A-B)D_- = \lambda_- D_-. \quad (1)$$

That is, if $\lambda_+ < 0$ or $\lambda_- < 0$, a doublet instability occurs in the usual symmetry-adapted RHF solution and a new RHF solution becomes a real CDW solution or a complex CDW solution, respectively.

In Eq. 1, elements of the square matrices, A and B, represent the configuration interactions between spin unflip singly excited configurations and those between the RHF ground state and spin unflip bi-excited states, respectively. The elements of the column matrix D_+ or D_- are the mixing coefficients which give the weights with which the virtual RHF molecular orbitals are admixed to the occupied ones. If the occupied and virtual orbitals belong to different irreducible representations, the symmetry properties of the new orbitals are broken (see Eq. 2): The molecular orbitals do not transform according to the irreducible representations of the molecular point group and, as a result, the new HF solution becomes the so-called broken-symmetry CDW solution.

Results and Discussion

The Broken-symmetry CDW Solution and Its Properties. The optimum nuclear arrangement of the trication radical with the D_{2h} symmetry was

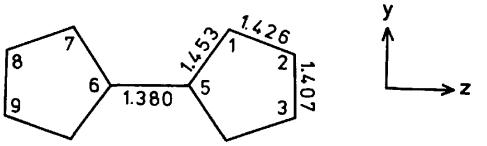

Fig. 1. The optimized bond lengths (in Å) of the fulvalene trication radical at the D_{2h} nuclear arrangement, the numberings of atomic positions, and the choice of molecular axes.

calculated by using Longuet-Higgins and Pople's MO method[9] in conjunction with the variable bond-length technique.[10] The RHF solution to which the stability conditions will be applied is the one corresponding to the molecular geometry thus optimized with respect to carbon nuclear arrangement (Fig. 1).

It turns out that the lowest-lying eigenvalue λ_{min}, obtained from the λ_+ subproblem of Eq. 1, is -1.227 eV and the electronic configurations that play an important role in the RHF instability are those including the orbital jumps from the highest doubly occupied orbital ϕ_3 (b_{3u}) to the next lowest vacant orbital ϕ_6 (b_{2g}) and from the singly occupied orbital ϕ_4 (a_u) to the lowest vacant orbital ϕ_5 (b_{1g}). As noted above, since the eigenvector d_{min} is of b_{1u} symmetry, a new HF solution becomes a real CDW solution having the C_{2v} spatial symmetry.

Let us now treat the CDW solution according to the same procedure as used in a previous paper.[5] For obtaining the CDW solution we take into account only the two orbital jumps above. This approximate procedure is justified, for the eigenvalue λ'_{min} (-1.130 eV) thus obtained reproduces well the eigenvalue λ_{min}(-1.227 eV) obtained by including all the singly excited configurations. By using the mixing coefficients of the eigenvector d'_{min} corresponding to the eigenvalue λ'_{min} the new occupied orbitals are formed as:

$$\begin{aligned}\phi_i &= \phi_i \ (i=1,2),\\ \phi_3 &= \mu_1\phi_3 + \mu_2\phi_6,\\ \phi_4 &= \nu_1\phi_4 + \nu_2\phi_5,\end{aligned} \tag{2}$$

and

$$\begin{aligned}\mu_1 &= \{1-(0.3135k)^2\}^{1/2},\ \mu_2 = -0.3135\,k\\ \nu_1 &= \{1-(0.9496k)^2\}^{1/2},\ \nu_2 = 0.9496\,k\end{aligned} \tag{3}$$

where k is the dimensionless mixing parameter, which indicates the degree of deformation of the CDW solution from the symmetry-adapted RHF solution. Using the molecular orbitals above, we can write the CDW solution as:

$$\begin{aligned}{}^2\Psi_{CDW}(k) &= \mu_1^2\nu_1^2\Psi_{RHF}(A_u) + \mu_1^2\nu_2^2\Psi_1(B_{1g}: 4\rightarrow5)\\ &+\sqrt{2}\,\mu_1\mu_2\nu_1^2\Psi_1(B_{1g}: 3\rightarrow6) + \mu_2^2\nu_1^2\Psi_2(A_u: 3,3\rightarrow6,6)\\ &+\sqrt{2}\,\mu_1\mu_2\nu_2^2\Psi_2(A_u: 3,4\rightarrow6,5)\\ &+ \mu_2^2\nu_2^2\Psi_3(B_{1g}: 3,3,4\rightarrow6,6,5),\end{aligned} \tag{4}$$

where notations used are the same as those in a previous paper.[5] It is seen that the CDW solution comprises the configurations of A_u and B_{1g} symmetries. Evidently, the symmetry-breaking components are the configurations of B_{1g} symmetry, for the RHF ground state is of A_u symmetry.

We now examine the dependence of the energy expectation value of the broken-symmetry CDW solution on the mixing parameter k. The result shows that the energy minimum point, *i.e.*, the stable CDW solution, is found at $k=0.66$, the energy lowering from the symmetry-adapted RHF solution being calculated to be 0.249 eV.

In Fig. 2 are shown the dependence of the electron densities and bond orders of the CDW solution on k. It is seen that the electron densities at 1 and 7, 2 and 8, and 5 and 6 and the bond orders between 1—5 and 6—7, 1—2 and 7—8, and 2—3 and 8—9 become separated as k increases. Included in Table 1 are the detailed values of electron density and bond order of the symmetry-adapted RHF and stable CDW solutions. It is found that there is a notable difference in the distribution of the density matrix elements between the two solutions: If we take the electron densities of the RHF solution as the reference values, a charge-density alternation can be seen along the longer molecular axis(z) in the electron-density distribution of the CDW solution. As to the

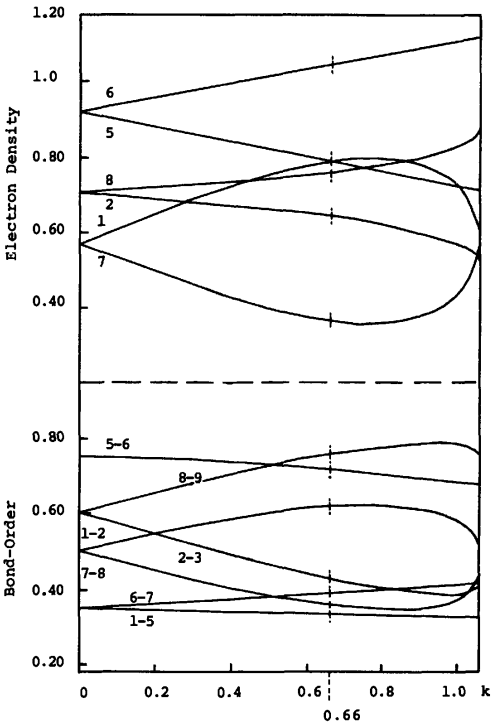

Fig. 2. The dependence of the electron densities and bond orders of the broken-symmetry CDW solution on the mixing parameter k.

2-3	0.424	0.438	0.607
8-9	0.752	0.763	
1-5	0.351	0.347	0.361
6-7	0.434	0.396	
5-6	0.693	0.726	0.753

distribution of bond orders, a similar behavior can be seen.[11] It is noted that the positive ring charges of the broken-symmetry CDW solution are unequal: The charge of the left-hand ring is 1.676(e) and that of the other ring is 1.324.

In Fig. 3 is depicted the dependence of the unpaired spin densities of the broken-symmetry CDW solution on k. This shows that the unpaired spin densities of the stable CDW solution ($k=0.66$) are localized essentially on a single five-membered ring. It is remarked that such a localization of the unpaired electron has also been found out theoretically in the monocation radical of fulvalene.[5] However there is a distinct difference with regard to the distributions of the unpaired spin density and the ring charge density between the trication and monocation radicals. In the latter, the unpaired spin density is localized in the five-membered ring having a larger positive charge, while in the former it is localized in the ring having a smaller positive charge. This difference will be explained by using Eq. 2 as follows. In the trication radical, the occupied orbital that is affected greatly by the appearance of the doublet instability is the singly occupied orbital ψ_4, whereas in the monocation radical such orbitals are the doubly occupied orbital ψ_4 and the singly occupied orbital $\psi_5(=\nu_1\phi_5-\nu_2\phi_4)$. As shown in Fig. 4, the atomic-orbital coefficients for the symmetry-adapted RHF orbitals, ϕ_4 and ϕ_5, are almost equal in absolute value and opposite on the respective carbon atoms. Thus, as k increases, orbitals ψ_4 and ψ_5 will be localized in the different five-membered rings. Consequently, in the trication radical the unpaired electron is localized in the ring having a smaller positive charge, while in the monocation radical it is localized in the ring having a larger positive charge.

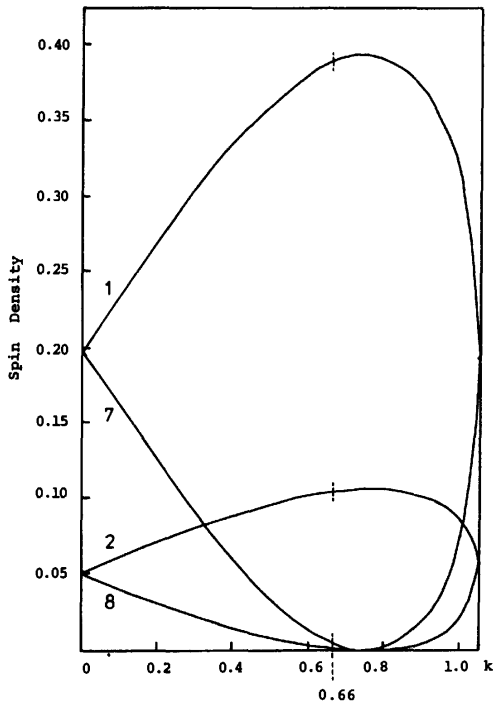

Fig. 3. The dependence of the unpaired spin densities of the broken-symmetry CDW solution on the mixing parameter k. The spin densities on the carbon atoms 5 and 6 are zero by symmetry.

2	0.1054	2.21	0.1235	2.59
5	0	0	0	0
6	0	0	0	0
7	0.0050	0.11	0.0174	0.36
8	0.0009	0.02	0.0032	0.07

a) 1 G=10^{-4} T.

The detailed spin densities of the stable CDW solution are listed in Table 2, together with the proton hyperfine splittings calculated by using McConnell's relationship[12] with $|Q|=21$ G (1G=10^{-4}T). It is predicted that the proton hfs constant on the carbon atom 1 is greater than that on the carbon atom 2.

It has thus been shown that the distribution of the density matrix elements inherent in the stable CDW solution is lower in symmetry than that of the nuclear arrangement used. Such an effect has been recognized in the theory of chemical reaction as the electron-cloud preceding.[13] Since it is known that such a preceding behavior of electron cloud brings about the change in nuclear configuration from unstable to stable one, we may expect that the broken-symmetry CDW solution is further stabilized by relaxation of the nuclear framework such that it may match up with the symmetry of the CDW solution.[14] This implies that a lattice instability similar to the second-order Jahn-Teller effect[15] may occur, as is very often the case.

The Second-order Jahn-Teller Effect. From the above argument, it is suggested that the trication radical may undergo the second-order Jahn-Teller distortion.[15] In order to elucidate this problem, we examine the lower electronic states of the trication

radical by assuming the optimized D_{2h} molecular geometry (Fig. 1). It turns out that the ground state is of A_u symmetry and the lowest excited doublet state corresponding to a single MO transition $\phi_4(a_u)\rightarrow\phi_5(b_{1g})$ is of B_{1g} symmetry, the energy separation between the two states being only 0.03 eV. Since both the states are nearly degenerate, the nuclear deformation of $B_{1u}(A_u\times B_{1g})$ symmetry should cause a strong vibronic interaction between them. Accordingly, we can expect that the ground state of the trication radical would undergo the second-order Jahn-Teller distortion from the D_{2h} to the C_{2v} nuclear arrangement. Of the three types of C-C bond distortion belonging to the B_{1u} symmetry, the one actually effective for the molecular-symmetry reduction can be given by examining the distribution of the transition density ρ between the ground and the lowest excited doublet state.[16-18] The nearest two-center components of the transition density, $\phi_4\phi_5$, are shown in Fig. 5.

We now calculate the geometrical structure with respect to C-C bond lengths of the trication radical as follows: As a starting geometry for iterative PPP-type SCF MO calculation, we adopt a nuclear configuration in which C-C bond lengths are distorted so that the set of displacement vectors may match up with the distribution of the transition density shown in Fig. 5. Then, self-consistency has been achieved at a set of C-C bond lengths corresponding to a lower symmetrical nuclear arrangement (C_{2v}). The obtained bond lengths and ring charges for the C_{2v} nuclear arrangement are shown in Fig. 5. Here, the stabilization energy, defined as the difference in total energy between the fully-symmetrical D_{2h} and the reduced C_{2v} molecular geometry,[16,17,19] is calculated to be 0.403 eV. In Table 1 are summarized the electron densities and bond orders for comparision with those of the broken-symmetry CDW solution. Moreover, the unpaired spin densities and the associated proton hfs constants calculated by assuming the C_{2v} nuclear arrangement are listed in Table 2. It is clear from Tables 1 and 2 that the density matrix elements of the symmetry-adapted RHF solution corresponding to the C_{2v} nuclear arrangement show a striking resemblance to those of the stable

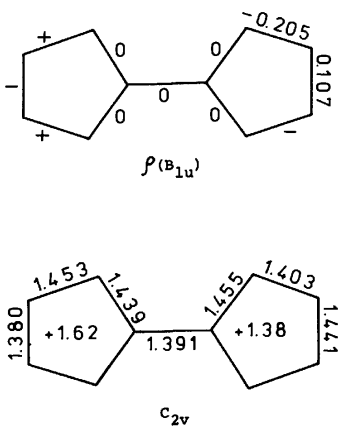

Fig. 5. The distribution of the nearest two-center components of transition density ρ and the optimized bond lengths (in Å) and ring charges at the C_{2v} nuclear arrangement.

broken-symmetry CDW solution and the unpaired electron is confined to the single five-membered ring having a ring charge of 1.38 (see Fig. 5). It is further proved that the present symmetry-adapted RHF solution (C_{2v}) is lower in energy than the stable CDW solution by 0.154 eV. From these aspects, it can be said that the broken-symmetry CDW solution is realized in the C_{2v} nuclear arrangement, becoming to be symmetry adapted.

The Ion Radicals of Fulvalene and Heptafulvalene. In connection with the fulvalene trication radical, it is noted that the RHF solution for the trianion radical, as well as that for the monoanion radical, is doublet stable ($\lambda_{min}=0.619$ eV) at the optimum nuclear arrangement with the D_{2h} symmetry. This shows a sharp contrast to the cases of the trication and monocation radicals. The explanation for this distinct difference between the anion radicals and the cation radicals of fulvalene can be given qualitatively as follows. From the stability conditions of the RHF solution, it is seen that the occurrence of the RHF instability depends on the magnitudes of energy separation between the RHF ground state and the singly excited doublet configurations. In fulvalene with the D_{2h} symmetry, the highest two occupied orbitals are nearly degenerate (in the HMO approximation those orbitals are accidentally degenerate). For the monocation and trication radicals, which are formed respectively by taking off one and three electrons from those orbitals, the RHF ground states are nearly degenerate with the respective lowest singly excited configurations. For this reason, the RHF solutions turn out to be doublet unstable. While, for the monoanion and trianion radicals the lowest singly excited configurations are well separated from the respective RHF ground states, so that the RHF solutions turn out to be doublet stable. In this connection, we also refer to the characteristic features of the RHF instabilities found in the ion radicals of heptafulvalene.[5,6] In heptafulvalene, the situation of the orbital pattern is quite different from that in fulvalene: The molecular orbitals that are accidentally degenerate in the HMO approximation are the lowest two unoccupied orbitals. Hence, for the monoanion and trianion radicals, which are formed respectively by adding the extra one and three electrons to those orbitals, the RHF ground states turn out to be nearly degenerate with the respective lowest singly excited configurations, resulting in the occurrence of the doublet instabilities in the RHF solutions. In cases of the monocation and trication radicals, the RHF solutions turn out to be double stable since the lowest singly excited configurations in question are well separated from the respective RHF ground states. Therefore, the origin of the instabilities of the RHF solutions and related phenomena, especially the anomalies in the spin-density distributions in the ion radicals of fulvalene systems, can be ascribed to the near degeneracy of the highest two occupied or the lowest two unoccupied orbitals inherent in the respective fulvalene systems.

Concluding Remarks. In the framework of the HF approximation, we have been concerned with the problem of the localization of unpaired electron in the

fulvalene trication radical. The results of the present calculations based on the RHF instability and the second-order Jahn-Teller theory show that the ground-state geometrical structure of the trication should be of C_{2v} symmetry and in the stable nuclear arrangement the unpaired electron is localized essentially on the single five-membered ring having a smaller positive charge. It has also been demonstrated that the occurrence of the RHF instability provides useful information about the type of wave function and the symmetry of nuclear framework. Especially, the resulting broken-symmetry CDW solution is shown to give a good account of the mechanism how the localization of unpaired electron occurs.

It is noted that the trication radical of 2,5-bis(2,4-cyclopentadien-1-ylidene)-1,4-cyclohexadiene, [5.6.5]quinarene, is expected to undergo a molecular symmetry reduction ($D_{2h} \rightarrow C_{2v}$) and exhibit an anomalous spin-density distribution similar to that of the fulvalene trication radical.

Water Photolysis by Means of Visible Light with a System Composed of Prussian Blue and the Tris(2,2′-bipyridine)ruthenium(II) Complex

Masao KANEKO,* Naoki TAKABAYASHI, Yukio YAMAUCHI, and Akira YAMADA*
The Institute of Physical and Chemical Research,
Hirosawa, Wako, Saitama 351
(Received May 2, 1983)

A water-photolysis system composed of Prussian Blue (PB) and the tris(2 2′-bipyridine)ruthenium(II) complex([Ru(bpy)$_3$]$^{2+}$)which evolves hydrogen and oxygen simultaneously was studied. Both the components worked catalytically in the photolysis. PB provides active sites for both H_2 and O_2 evolution. The dependence on the pH showed optimum conditions at pH 2. The photolysis required the presence of a cation, and only such cations as K^+ and Rb^+ whose hydrated ions are smaller than the pore size of the PB lattice were active for the reaction. The dependene on the KCl concentraition showed an optimum point at 0.5 mol dm^{-3}. The oxidative quenching of [Ru(bpy)$_3$]$^{2+*}$ by PB was suggested, but its ratio in the total quenching process was estimated to be only 8.5%. The static quenching of [Ru(bpy)$_3$]$^{2+*}$ by PB was demonstrated, and an interaction between the two components was shown by NMR spectroscopy. The effect of oxygen on the photolysis suggested that the reduction sites are located inside the PB lattice. A mechanism for the photolysis was proposed.

Water photolysis by visible light is attracting much attention in the chemical conversion of solar energy. Many studies of solar-energy conversion have been related to this subject.[1,2] The tris(2,2′-bipyridine)-ruthenium(II) complex ([Ru(bpy)$_3$]$^{2+}$) is the most promising photocatalyst for decomposing water photochemically.[1,3,4] Water photolysis with this complex requires, though, both electron mediator and catalysts. Methylviologen (MV^{2+}; 1,1′-dimethyl-4,4′-bipyridinium dichloride) has been studied as a promising electron mediator; however, the cation radical formed in its reaction system is too sensitive to oxygen oxidation for it to be used in a system evolving oxygen simultaneously. Moreover, the rather complicated system composed of [Ru(bpy)$_3$]$^{2+}$, MV^{2+}, and two kinds of catalysts for hydrogen and oxygen evolution (*e.g.*, Ref. 5) involves the problem of getting reproducible results.

It was found by the present authors[6] that Prussian Blue (PB) induces water photolysis to give hydrogen and oxygen simultaneously with the combination of [Ru(bpy)$_3$]$^{2+}$. PB is a polynuclear mixed-valent iron complex whose composition has been proposed to be $Fe^{III}_4[Fe(CN)_6]_3$;[7] it forms a colloidal aqueous solution. The studies of this simple photolysis system have shown that the PB works as a kind of electron mediator as well as a catalyst for both hydrogen and oxygen evolution.[6] Such multifunctionalities of PB must be due to its polynuclear and mixed-valent sturcture. In this paper the factors affecting the photochemical reaction as well as the reaction mechanism are reported.

Experimental

Materials. The potassium hexacyanoferrate(III), $K_3[Fe(CN)_6]$, and iron(II) chloride, $FeCl_2 \cdot 3.8\ H_2O$, were the purest commercially available grade. The PB was prepared by mixing aqueous solutions of both the iron salts at an equimolar ratio. The molar concentration (M=mol dm^{-3}) of PB in the text represents the concentration of each of the iron salts contained in the solution. The colloidal solution of PB thus prepared was stirred continuously before use in order to prevent the aggregation of the colloids, and used within 1 d. The [Ru(bpy)$_3$]$^{2+}$Cl$_2$ was prepared by the reaction of ruthenium(III) chloride and 2, 2′-bipyridine in methyl alcohol, and recrystallized twice from methyl alcohol.

Photochemical Reaction. A 10-ml aqueous solution of 5 mM PB and 10 μM [Ru(bpy)$_3$]$^{2+}$ containing 0.5 M KCl at pH 2 (HCl-KCl buffer) was stirred and irradiated with visible light under argon atmosphere in a sealed vessel with a volume of about 20 ml equipped with a silicone stopper for the gas sampling. The irradiation was made with a 500-W Xenon lamp through UV and IR cutoff filters (Toshiba VY-42 and IRQ-80). The light intensity at the illuminated surface was 78 mW cm^{-2}.

Measurements. The gases formed were analyzed mainly by gas chromatography with a column consisting of a Molecular Sieve 5 A, using argon as the carrier gas. The O_2 evolved by the photochemical reaction was calculated by subtracting the content of O_2 coming from the air. For this calculation, the blank O_2/N_2 ratio was obtained by measuring the ratio (O_2/N_2) in the same vessel containing the same solution without irradiation. The errors in the determinations were ±0.01 μl for H_2 and ±0.02 μl for O_2. The lifetime was measured by a single-photon-counting method, with an exciting light pulse of about 1 ns from a 12-atm hydrogen lamp. The particle size of the PB colloids was studied by means of transmission electron microscope (Hitachi H-3000), using phosphotungstic acid as the negative staining agent.

Results and Discussion

The mass spectrum of the gases evolved by the reaction of water containing D_2O and $H_2{}^{18}O$ in the presence of PB, [Ru(bpy)$_3$]$^{2+}$, and KCl showed that hydrogen and oxygen came from water.[6] The ratio of H_2 to O_2 was almost 2 to 1, corresponding to the theoretical value of water decomposition.[6] The time dependencies of the water photolysis, as represented by the amount of H_2 evolved at various concentrations of PB and [Ru(bpy)$_3$]$^{2+}$, are shown in Fig. 1. The photolysis occurs almost linearly with the time. The turnover number of [Ru(bpy)$_3$]$^{2+}$ in the photolysis with 1 μM [Ru(bpy)$_3$]$^{2+}$ and 500 μM PB is calculated to be 11 after 90 h. The visible spectrum of the solution after that reaction showed no actual change in the absorptions of either PB or [Ru(bpy)$_3$]$^{2+}$ indicating that both the reactants work as catalysts.

As has been described in the previour paper[6] the excitations of both the complexes were required for the water photolysis to occur. The irradiation of an aque-

ous solution containing EDTA, $[Ru(bpy)_3]^{2+}$, and PB gave H_2[6], suggesting that PB works as the H_2-evolving catalyst. The irradiation of an aqueous solution containing 10 μM ascorbic acid and 5 mM PB gave a small amount of H_2 (0.03 μl), while no H_2 was formed in the dark. An excess ascorbic acid brought about the formation of Prussian White, which is a Fe^{2+}-Fe^{2+}-type polynuclear cyanide complex, but H_2 was not formed even under irradiation. These results lead to the conclusion that H_2 is formed only by the irradiation of partially reduced PB. As will be shown later (Fig. 7), the ground state of Prussian White (entirely reduced PB) can not reduce protons because of its redox potential, but the excited state of a partially reduced PB must induce proton reduction to give H_2. The excitation of PB at the λ_{max} of 700 nm is known to be due to an intervalent charge transfer (ICT) between the adjacent Fe^{2+} and Fe^{3+} ions through the antibonding π orbitals of the bridging CN ligand.[8] Since the Fe^{2+} ion itself can not reduce protons, the reduction of the protons must occur through the antibonding π orbitals of CN groups under excited conditions. The partially reduced PB would bring about the excitation of the adjacent CN ligands under ICT conditions, and such activated states of the adjacent CN groups would reduce two near-by protons to give H_2.

It has been shown that the $[Ru(bpy)_3]^{3+}$ complex alone can not oxidize water in the absence of a catalyst.[9] The oxidation of water to give O_2 by $[Ru(bpy)_3]^{3+}$ in the presence of PB has led to the conclusion that PB works also as a catalyst for water oxidation.[6] Table 1 shows that a small amount of $[Ru(bpy)_3]^{3+}$ with respect to PB produces a high yield of O_2 when PB is used as the catalyst. The use of a higher concentration of

Table 1. Oxygen evolution by $[Ru(bpy)_3]^{3+}(ClO_4^-)_3$ with PB as the catalyst

PB: 5 mM, pH 2 (HCl-KCl buffer); solution: 10 ml; reaction for 1 h at 21 °C. a) Based on $[Ru(bpy)_3]^{3+}$.

$[Ru(bpy)_3]^{3+}$ increased the amount of O_2 evolved; however, its yield rather decreased. This is due to the oxidative degradation of PB, *i.e.*, the formation of a Fe^{3+}-Fe^{3+}-type complex (so-called Berlin Green), which was observed to form upon adding an excess of $[Ru(bpy)_3]^{3+}$ to PB. When a small amount of $[Ru(bpy)_3]^{3+}$ is used PB works as a good catalyst for O_2 formation by means of water oxidation. Considering the redox potential of $[Ru(bpy)_3]^{3+/2+}$ (1.27 V at pH 7), it can oxidize water to give O_2 only in the presence of a 4-electron oxidation catalyst.[10] Therefore, PB would work as a 4-electron oxidation catalyst to oxidize two molecules of water to form one molecule of O_2 through its polynuclear structure. The 4-electron catalytic reduction of O_2 by means of electrode reaction with PB-coated glassy carbon[11] supports the occurrence of a multi-electron process in the polynuclear PB lattice.

For the water photolysis, an excess of PB with respect to $[Ru(bpy)_3]^{2+}$ is required. Table 2 shows that at least a

KCl: 0.5 M, pH 2 (HCl-KCl buffer); solution: 10 ml; reaction for 15 h at 21 °C.

50-fold excess of PB is needed. As will be shown later (Fig. 5), a low concentration of PB can efficiently quench the excited state of the Ru complex. It can, therefore, be concluded that a large excess of PB is necessary not for the quenching process, but for the catalytic redox reactions.

Colloidal particles of PB were studied by means of an electron micrograph. The average diameter of the particles was about 23 nm. Studies by means of optical and electron microscopes showed that the particles aggregate to *ca.* 1 μm in the presence of KCl, even when stirred. The standing of the colloidal solution in the presence of KCl induced the growth of the aggregates to tens of μm, and at last caused the sedimentation of almost 90% of the PB. The rates of aggregation and sedimentation depend on the KCl concentration. The aggregation and sedimentation of PB lower its activity markedly. The presence of KCl in the solution hinders the study by means of microscope; however, since PB

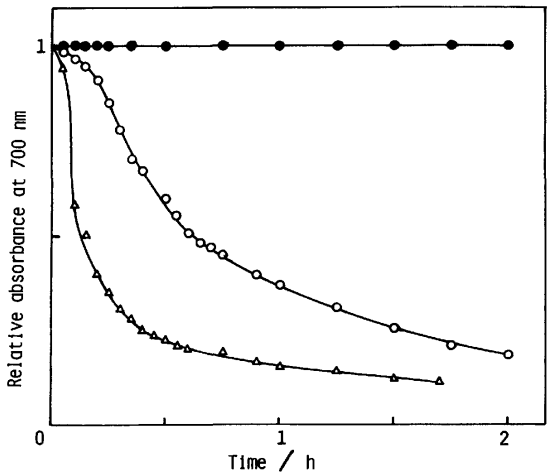

Fig. 2. Decrease of absorbance at 700 nm induced by aggregation and sedimentation of PB at pH 2. PB; 0.5 mM, $[Ru(bpy)_3]^{2+}$; 10 μM. KCl concentration (M): ●; 0, ○; 0.5, △; 0.9.

aggregation brings about a decrease of its absorbance at 700 nm, the aggregation can be followed by means of visible spectroscopy. The decrease in the absorbance at 700 nm on standing is shown in Fig. 2. No absorbance change was observed in the absence of KCl, while the addition of KCl remarkably enhanced the absorbance decrease; *i.e.*, the aggregation becomes very rapid on the addition of KCl when there is no stirring. During a photochemical reaction, no spectrum change is observed, since the reaction mixture is stirred vigorously. However, the results of Fig. 2 reflect at least the effect of KCl on the aggregation of PB, which is not observed as a spectrum change under stirring.

The pH dependency of the H_2 formation is shown in Fig. 3. No photochemical reaction was observed below pH 1.5 or above 3.5. Since H_2 is formed by the reduction of protons, a lower pH should give a higher H_2 yield. However, the O_2 evolution by the $[Ru(bpy)_3]^{3+}$ oxidation of water showed its optimum point at pH values from 2 to 3, and no O_2 was formed at pH 1.[9] If O_2 is not evolved efficiently, the back-electron transfer shown

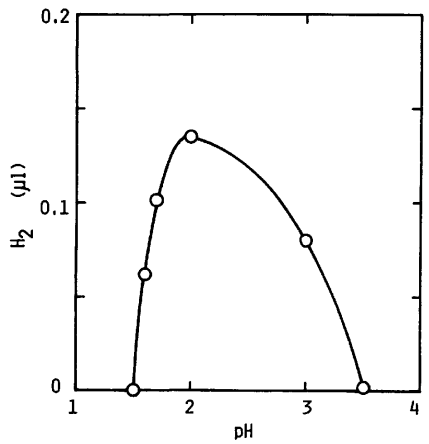

Fig. 3. pH dependency of H_2 formation. PB; 1 mM, $[Ru(bpy)_3]^{2+}$; 10 μM, KCl; 0.5 M, Buffer solution: pH 1.5—2 (HCl-KCl), pH 2.5—3 (CH_3COONa-HCl), pH 3.5 (CH_3COONa-CH_3COOH). Irradiated under argon for 15 h. Solution; 4 ml.

later as Eq. 4 lowers the efficiency of the photolysis. Thus, the low efficiency of O_2 evolution would be one of the reasons for the low activity below pH 2 in Fig. 3. Since the redox potential of PB^+/PB is only slightly more positive than that of H_2O/O_2 at pH 2 as shown later in Fig. 7, the shift of the latter potential to more positive value at lower pH than 2 (*e.g.*, 1.17 V for H_2O/O_2 at pH 1) might be the reason for the lower activity at the pH lower than 2.

In the present water-photolysis system, the addition of KCl enhances the reaction rate. The effect of a neutral salt on the photolysis is shown in Table 3. RbCl and KCl were effective, but NaCl, LiCl, and $BaCl_2$ did not induce photolysis. For the reduction of PB, a cation (Cat^+) must enter into the PB lattice in order to compensate the negative charge of the electron (Eq. 1):

Table 3. Effect of neutral salt on water photolysis with PB and $[Ru(bpy)_3]^{2+}$

Neutral salt	Diameter (nm) of hydrated cation	H_2(μl)
RbCl	0.24	0.2
KCl	0.25	0.2
NaCl	0.37	0
LiCl	0.47	0
$BaCl_2$	0.58	0

$$(Cat^+)Fe^{III}[Fe^{II}(CN)_6]^{4-} + e^- + Cat^+ \longrightarrow (Cat^+)_2Fe^{II}[Fe^{II}(CN)_6]^{4-} \quad (1)$$

Itaya *et al.* recently studied the electrochemical reduction of PB coated on a platinum electrode in the presence of various neutral salts.[12] They found that neutral salts composed of cations whose hydrated ions are smaller than the pore size of the PB lattice (0.35 nm) can induce PB reduction, but neutral salts composed of larger cations are entirely ineffective. The results in Table 3 also shows that only the cations whose hydrated ions are smaller than the PB pore size are effective for the water photolysis.

The dependence of the photochemical reaction on the concentration of KCl is shown in Fig. 4. It has an optimum point at about 0.5 M. As has been described above, the present photolysis system demands the presence of a neutral salt such as KCl. On the other hand, neutral salt makes colloidal dispersions aggregate (see Fig. 2), because colloids are stabilized by an electrostatic repulsion of the charged particles. The decrease in photolysis at the higher concentration of KCl in Fig. 4 is thus explained by the easy aggregation of PB.

The excited state of the $[Ru(bpy)_3]^{2+}$ is efficiently quenched by PB. The formation of H_2 by the irradiation of the mixture of EDTA, $[Ru(bpy)_3]^{2+}$, and PB in water[6] indicated that the oxidative quenching of $[Ru(bpy)_3]^{2+*}$ by PB is involved. The Stern-Volmer plots of the $[Ru(bpy)_3]^{2+*}$ quenching by PB in the presence of 0.5 M KCl are shown in Fig. 5 (a). The quenching-rate constant is calculated to be 1.99×10^{10} ($M^{-1}\,s^{-1}$), using the lifetime (528 ns) of the $[Ru(bpy)_3]^{2+*}$ under these conditions. If the quenching is entirely due

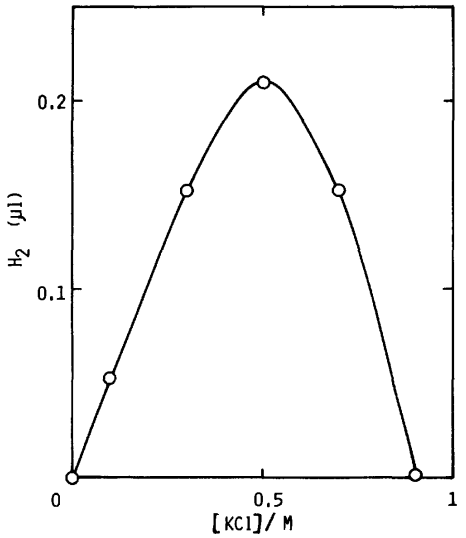

Fig. 4. Dependency of H_2 formation on KCl concentration. PB; 5 μM, $[Ru(bpy)_3]^{2+}$; 10 μM, pH 2. Irradiated under argon for 15 h. Solution; 10 ml.

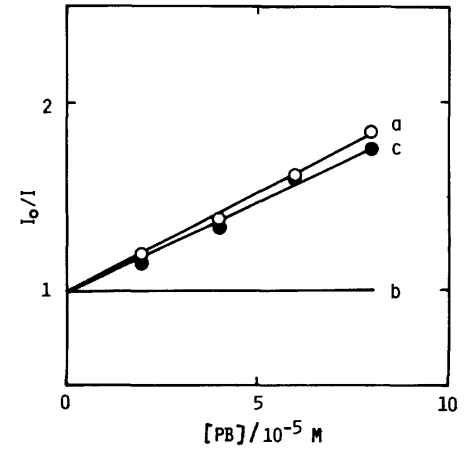

Fig. 5. Stern-Volmer plots for the quenching of $[Ru(bpy)_3]^{2+}$ by PB measured by emission intensity at 600 nm. $[Ru(bpy)_3]^{2+}$; 20 μM, pH 2, under argon, excited at 450 nm. (a) KCl; 0.5 M, (b) Theoretical line when no quenching occurs, (c) NaCl; 0.5 M.

to electron transfer from $[Ru(bpy)_3]^{2+*}$ to PB, it would not occur in the presence of NaCl instead of KCl, because PB can not be reduced in the presence of NaCl.[12] The plots must fall on the (b) line of Fig. 5 in this case. If the quenching is only partly due to the electron transfer, the Stern-Volmer plots measured in the presence of NaCl would fall between (a) and (b) lines. The quenching of $[Ru(bpy)_3]^{2+*}$ in the presence of NaCl without KCl was measured; it is shown in Fig. 5(c). The (c) line lies between (a) and (b), indicating that the quenching is partly due to electron transfer. The ratio of the electron-transfer quenching is estimated to be 8.5% from the ratio of the difference in the (a) and (c) slopes to the slope of (a), assuming that the other quenching process of the $[Ru(bpy)_3]^{2+*}$ by PB is not affected by the cation species of the neutral salt present.

The Stern-Volmer plots, as measured by means of emmision quenching and the lifetime, are shown in Fig. 6. The two plots fall on quite different lines,

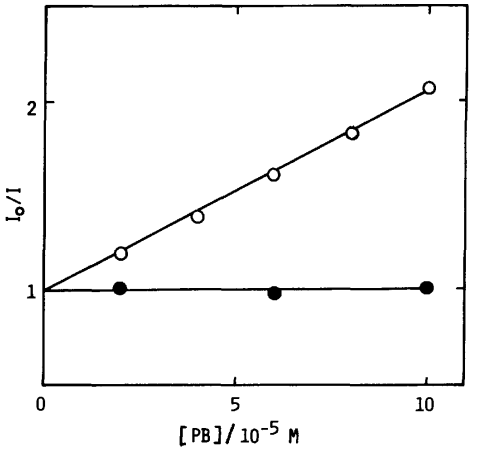

Fig. 6. Stern-Volmer plots measured by emission quenching (○) and lifetime (●) of $[Ru(bpy)_3]^{2+}$ with PB as a quencher. $[Ru(bpy)_3]^{2+}$; 20 μM, KCl; 0.5 M, pH 2, under argon, at 25 °C, excited at 450 nm.

indicating that static quenching occurs. It is suggested that there is an interaction between PB and $[Ru(bpy)_3]^{2+}$. No such interaction was observed in the visible spectrum, but the ^1H NMR spectrum showed an evidence of it. The proton signals of the bpy rings of the Ru complex shown in Table 4, that were observed at the δ values of 7—9, did not appear in the presence of PB at δ=0—15. It was observed that the proton signals of benzoic acid, which does not form any complex with PB, are not affected by the presence of PB. These results indicate some strong interaction, probably complex formation, between $[Ru(bpy)_3]^{2+}$ and PB. Such an interaction must cause the static quenching of $[Ru(bpy)_3]^{2+*}$ by PB.

Table 4. ^1H NMR of $[Ru(bpy)_3]^{2+}$ in the absence and presence of PB

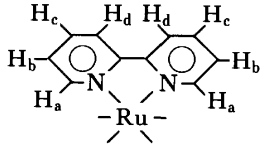
Measured in D_2O:



In a photochemical conversion system using MV^{2+} as an electron mediator, the presence of even a trace of oxygen inhibits the photochemical reaction, because O_2 very rapidly oxidizes the cation radical of MV^{2+} formed as an internediate. For the same reason, MV^{2+} is not suited as an electron mediator for a system that aims at simultaneous O_2 and H_2 evolution. The effect of O_2 on the water photolysis by PB and $[Ru(bpy)_3]^{2+}$ is shown in Table 5. It is interesting that H_2 was evolved even in the presence of O_2, although the efficiency decreased to one-third that of the system containing no O_2. The shape of the O_2 molecule can be approximated as a cylinder which has a diameter of about 0.28 nm and a length of 0.4 nm. The O_2 molecule can, therefore,

TABLE 5. EFFECT OF O_2 ON THE WATER PHOTOLYSIS WITH PB AND $[Ru(bpy)_3]^{2+}$

Atmosphere	H_2(μl)
Argon	0.27
Air	0.09

PB: 5 mM, $[Ru(bpy)_3]^{2+}$; 10 μM; KCl: 0.5 M, pH 2 (HCl-KCl buffer); reaction: 15 h.

enter into the PB lattice only from the direction of its axis, the inside of the lattice being fairly protected against O_2 attack. From a thermodynamic point of view, the active site of H_2 evolution must be sensitive to O_2 oxidation, leading to inactivation. The fact of H_2 evolution in spite of the presence of O_2 shown in Table 5 suggests, then, that the active reduction sites are located inside the PB lattice, allowing the water photolysis even under air.

The mechanism of the present water-photolysis system can be summarized as follows:

$$[Ru(bpy)_3]^{2+} \xrightarrow{450\ nm} [Ru(bpy)_3]^{2+*}, \quad (2)$$

$$[Ru(bpy)_3]^{2+*} + PB \longrightarrow [Ru(bpy)_3]^{3+} + PB^-, \quad (3)$$

$$[Ru(bpy)_3]^{3+} + PB^- \longrightarrow [Ru(bpy)_3]^{2+} + PB, \quad (4)$$

$$[Ru(bpy)_3]^{2+*} + PB^- \longrightarrow [Ru(bpy)_3]^{3+} + PB^{2-}, \quad (5)$$

$$PB^{2-} + 2H^+ \xrightarrow{700\ nm} PB + H_2, \quad (6)$$

$$2[Ru(pby)_3]^{3+} + H_2O \xrightarrow{PB} 2[Ru(bpy)_3]^{2+} + 1/2\ O_2 + 2\ H^+. \quad (7)$$

The excited state of $[Ru(bpy)_3]^{2+}$ is quenched by PB by means of a static process. A part of the quenching occurs by means of electron transfer from $[Ru(bpy)_3]^{2+*}$ to PB in the presence of cation such as K^+ or Rb^+, thus giving $[Ru(bpy)_3]^{3+}$ and PB^- (Eq. 3). Although back-electron transfer (Eq. 4) might prevail, the electron-transfer quenching of $[Ru(bpy)_3]^{3+*}$ by PB^- would also occur to form $[Ru(bpy)_3]^{3+}$ and PB^{2-} (Eq. 5). The PB^{2-} thus formed would reduce two protons under excited ICT-conditions to give H_2 (Eq. 6). The active site for this reduction process would be located inside the lattice, protected against O_2 attack. When four molecules of $[Ru(bpy)_3]^{3+}$ are accumulated, they oxidize water with the PB catalyst to give O_2 (Eq. 7).

As has been shown before (Fig. 6), strong static quenching occurs in the present photolysis system. In addition, the entire shift of the $[Ru(bpy)_3]^{2+}$ proton peaks of the NMR spectrum in the presence of PB (shown in Table 3), and the almost complete quenching of the excited state of $[Ru(bpy)_3]^{2+}$ by PB under usual reaction conditions, show that almost all the Ru complexes are interacting with PB. Assuming that PB has a spherical form, one particle 23 nm in diameter contains about 6×10^3 unit cells. One PB particle then interacts with 2.4×10^2 $[Ru(bpy)_3]^{2+}$ molecules under the usual conditions of a 10 μM Ru complex and 1 mM PB. Since $[Ru(bpy)_3]^{2+*}$ is entirely quenched by PB under these conditions, the occurrence of the multi-electron reduction of PB shown in Eq. 5 is possible. The mixing of $[Ru(bpy)_3]^{2+}$ with PB before or after the formation of the latter complex did not affect the catalysis. Considering this result and the fact that the Ru Complex is too large to be included in the PB lattice, the Ru complex must be present on the surface of the PB particle. The location of the oxidation sites has not been elucidated by the experiments so far; however, it might be located on or near the PB surface, considering that the oxidation and reduction sites must be located separately.

The presence of Pt colloids and/or RuO_2 (powders or sol) in the reaction mixture did not increase the rate of water photolysis. These results would support the above-mentioned mechanism, the idea that the inner or surface structure of PB colloids plays an important role in the H_2 and O_2 evolution.

The potential diagram of the present photolysis system (at pH 2) is shown in Fig. 7. The redox

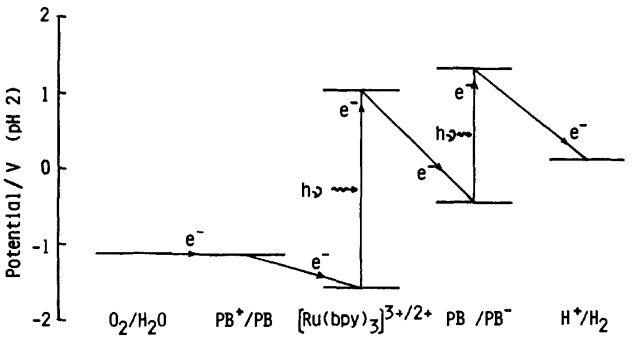


Fig. 7. Potential diagram of the water photolysis system with PB and $[Ru(bpy)_3]^{2+}$.

potentials of PB are the values at pH 4 reported by Itaya *et al.*[12] It could be assumed that the potentials of PB are almost pH-independent. Since the ground state of PB^- can not reduce protons potentially, the excitation of the partially reduced PB is necessary in order to reduce H^+ to give H_2. Such a diagram is regarded as a model for the photoinduced electron flow of the photosyntesis, where two steps of excitation brings about an endoergic electron transfer from water to CO_2.

PB thus works as a kind of electron mediator and also as a catalyst for both H_2 and O_2 evolution. These multifunctionalities of PB are due to its polynuclear and mixed-valent structure.

The authors are grateful to Prof. Y. Inoue and Dr. M. Ikeuchi for the measurements using the electron microscope.

Polarized Absorption Spectra of Aromatic Radicals in Stretched Polymer Film. V. The Benzophenone Radicals

Tsuneyuki MINEGISHI, Hiroshi HIRATSUKA,* Yoshie TANIZAKI,† and Yuji MORI
Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152
(Received May 25, 1983)

Benzophenone radical anions and ketyl radicals have been prepared in poly(vinyl alcohol) [PVA] films by means of γ-ray irradiation at 77 K. The polarized absorption spectra have been measured and used to determine the resolved spectra of these radicals. The spectrum of radical anions in the PVA film is very similar to that of ketyl radicals and can also be well explained by the calculated results for the hydrogen-bonding model of radical anions. The intense near-UV and visible absorption bands of radical anions in the PVA film are both correlated with those of ketyl radicals.

In previous papers we have reported the polarized absorption spectra of some aromatic radicals, determined by the stretched polymer film technique combined with γ-irradiation.[1-4] It was shown that the information on the direction of transition moments is useful for the assignment of the electronic transitions of these radicals.

A number of investigations have been reported on the preparation and the electronic structure of benzophenone radicals.[5-18] Porter and Wilkinson studied the visible absorption spectra of benzophenone ketyl radicals and radical anions prepared in an acidic or alkaline solution by means of flash photolysis.[5] They also studied the equilibrium between these radicals and determined the pK_a value of this equilibrium. The molar-extinction coefficients of these radicals in an acidic or alkaline solution have been determined by Hayon *et al.*, using the technique of pulse radiolysis-absorption spectroscopy.[11] McCelland investigated the electronic spectra of metal ion-paired ketyls by taking into account the effect of alkali metal ions as the perturbing electrostatic potential and semiquantitatively showed the spectroscopic blue shift of the visible absorption band.[7] Shida *et al.* measured the electronic absorption spectra of benzophenone radicals prepared by γ-irradiation in rigid glassy matrices and discussed the visible and near-UV bands in comparison with the results of MO calculations.[14] They suggested that the near-UV absorption bands of benzophenone radical anions and ketyl radicals have different polarization directions, though their spectra are quite similar in appearance. The polarization study of the electronic transition, however, has not been carried out for these radicals. It is desirable to determine experimentally the assignments of these absorption bands from the point of view of the direction of the transition moment.

In this study we investigate the polarized absorption spectra of benzophenone ketyl radicals and radical anions, prepared by the γ-irradiation of benzophenone in poly(vinyl alcohol) [PVA] films. The results are discussed in comparison with the results of MO calculations.

Experimental

Guaranteed reagent-grade benzophenone and methanol from Tokyo Kasei Co. Ltd., were used as received. PVA films were prepared by the method described previously.[2] Benzopheone was introduced into PVA films with the aid of methanol. The acidic sample film was prepared by immersing a PVA film into an acidic methanol solution of benzophenone containig 2 vol% of concd hydrochloric acid. The alkaline sample film was prepared by immersing a PVA film into an alkaline methanol solution of benzophenone containing 0.05 mol dm^{-3} of sodium hydroxide. These sample films were irradiated by ^{60}Co γ-ray for 2 h at a dose rate of 1.0×10^6 rad/h in liquid nitrogen. To control the concentrations of the ketyl radicals and radical anions of benzophenone, the irradiated films were taken out from liquid nitrogen and kept for tens of seconds. After this warming at room temperature, the films were again immersed in liquid nitrogen. The absorption spectrum of the radicals produced in the film was determined as the difference in the absorbances of the film before and after irradiation. In this experiment, the error introduced by the decrease of the parent molecule by the formation of radicals is less than 2% in absorbances below 360 nm because of the small molar-extinction coefficient ($\varepsilon\approx300$)[19] of the parent molecule. The absorption spectra from 300 to 850 nm were measured with a spectrophotometer (JASCO SS-50) equipped with a Rochon polarizer. For the polarization measurements, the sample films were stretched about 4 times before irradiation.[2]

Roothaan's restricted Hartree-Fock open-shell calculations were carried out in the pi-electron approximation for benzophenone ketyl radicals and radical anions. The configuration interaction calculations were limited to all the singly excited and ground configurations. In order to take into account the effects of the hydrogen bond, the point charge, Z_{eff} e, was located at the distance of 1.72 Å from the oxygen atom. The value of Z_{eff} was changed from 0 to 0.8. The valence-state ionization potentials (I_p), electron affinities (E_a), and resonance integrals (β) used were as follows; $I_p(C)=11.22$, $E_a(C)=0.62$, $I_p(=O)=11.76$, $E_a(=O)=3.87$, $I_p(-OH)=33.00$, $E_a(-OH)=11.47$, $\beta_{C-C}=-2.318$, $\beta_{C=O}=-2.70$, and $\beta_{C-OH}=-2.30$ in eV.

Results and Discussion

Curve a in Fig. 1 shows the absorption spectrum of the benzophenone radicals at 77 K produced by the γ-irradiation of the sample PVA films. By making reference to the spectra of benzophenone radical anions [$BP^{-\cdot}$] and ketyl radicals [$BPH^{\cdot}$] reported by Porter and

Wilkinson,[5] this is ascribed to the mixture of $BP^{-\cdot}$ and BPH$^{\cdot}$. The absorption maxima appearing at about 18×10^3 cm^{-1} and 16×10^3 cm^{-1} are assigned to BPH$^{\cdot}$ and $BP^{-\cdot}$ respectively. Assuming the values of the molar-extinction coefficients reported by Hayon *et al.* for these peaks,[11] the concentrations of $BP^{-\cdot}$ and BPH$^{\cdot}$ are estimated to be $(2.8\pm0.2)\times10^{-3}$ mol dm^{-3} and 1.1 ± 0.1 mol dm^{-3} respectively. Curve a′ in Fig. 1 is the spectrum measured at 77 K after a slight warming. The concentrations of $BP^{-\cdot}$ and BPH$^{\cdot}$ are estimated to be $(1.3\pm0.1)\times10^{-3}$ mol dm^{-3} and $(1.9\pm0.2)\times10^{-3}$ mol dm^{-3} respectively. It should be noted here that $BP^{-\cdot}$ was converted to BPH$^{\cdot}$ by warming, though some of the radicals disappeared. This change has been attributed to the acid-base equilibrium between benzophenone radicals.[5]

Curve b in Fig. 1 shows the spectrum of the γ-irradiated benzophenone in the PVA film containing methanol and hydrochloric acid. It is similar to curve a′ in appearance. The concentrations of $BP^{-\cdot}$ and BPH$^{\cdot}$ are estimated to be $(3.0\pm0.3)\times10^{-3}$ mol dm^{-3} and $(2.8\pm0.3)\times10^{-3}$ mol dm^{-3} respectively. After a slight warming, the spectrum of curve b′ was also observed. This is similar to that of BPH$^{\cdot}$ in an ethanol glass reported by Shida *et al.*[14] The peak of $BP^{-\cdot}$ disappeared. The concentration of BPH$^{\cdot}$ is $(6.0\pm0.5)\times10^{-3}$ mol dm^{-3}. Curve c in Fig. 1 shows the spectrum of the γ-irradiated benzophenone in the PVA film containing methanol and sodium hydroxide. After a slight warming, the spectrum of curve c′ was observed. Though there remains a shoulder at about 18×10^3 cm^{-1} which is assigned to BPH$^{\cdot}$, $BP^{-\cdot}$ is predominant after this warming. The concentrations of $BP^{-\cdot}$ and BPH$^{\cdot}$ are estimated to be $(2.2\pm0.2)\times10^{-3}$ mol dm^{-3} and $(0.2\pm0.1)\times10^{-3}$ mol dm^{-3} respectively. It should be noted that only 5% of the absorbance of the intense near-UV band at 29.5×10^3 cm^{-1} (curve c′) is due to BPH$^{\cdot}$.

Thus, under acidic or alkaline conditions benzophenone ketyl radicals or radical anions are predominantly prepared in the PVA films. The sample films for the polarization measurements of BPH$^{\cdot}$ and $BP^{-\cdot}$ were prepared in the same manner as those of b′ and c′ in Fig. 1.

Figure 2 shows the polarized absorption spectra of BPH$^{\cdot}$ (a) and $BP^{-\cdot}$ (b) in the stretched PVA films. The sample films (a) and (b) contain hydrochloric acid and sodium hydroxide respectively, as in curves 1b and 1c. In Fig. 2b there remains the absorption due to BPH$^{\cdot}$ and the molar ratio of BPH$^{\cdot}$ to $BP^{-\cdot}$ is about 0.13. The behavior of the dichroic ratio ($R_d=A_{/\!/}/A_{\perp}$) of these spectra is similar; the R_d values in the regions of the intense near-UV and visible bands are large. It is usually admitted that the molecular long axis is preferentially inclined to the stretching direction of the film. This has been confirmed by the analysis of the polarized absorption spectra for the radicals produced in the PVA films by γ-irradiation and for the parent molecule, benzophenone.[1-4,19] This means that the transition moments of these bands are polarized parallel to the molecular long axis. In order to show this situation more clearly, the resolved spectra were determined by making use of the polarized absorption spectra, according to a method described in a previous paper.[4] Figure 3 shows the resolved spectra of BPH$^{\cdot}$ (a) and $BP^{-\cdot}$ (b). The extreme values used to determine the resolved spectra were as follows; $R_d^1=1.86$ and

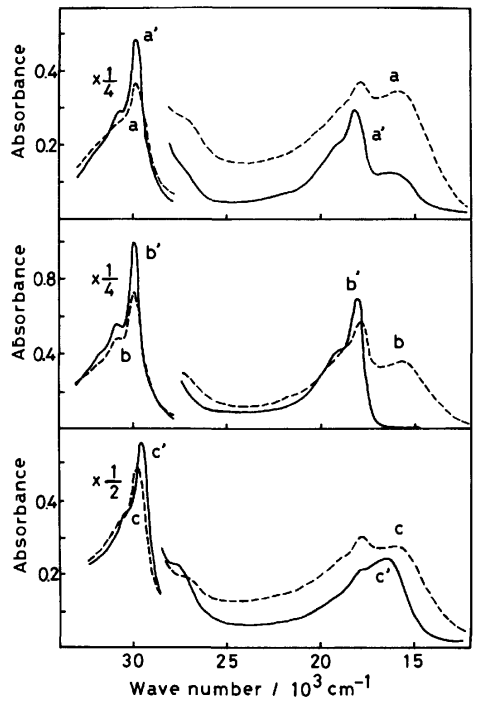

Fig. 1. Absorption spectra of the γ-irradiated benzophenone in the neutral (curve a), acidic (b) and alkaline (c) PVA films. Curves a′, b′, and c′ are the spectra observed after slight warming at room temperature.

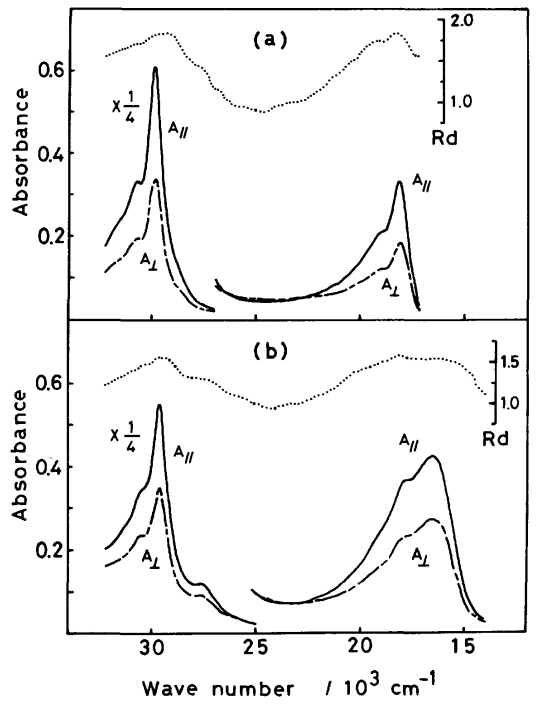

Fig. 2. Polarized absorption spectra of benzophenone ketyl radicals (a) and radical anions (b) in the stretched PVA films.

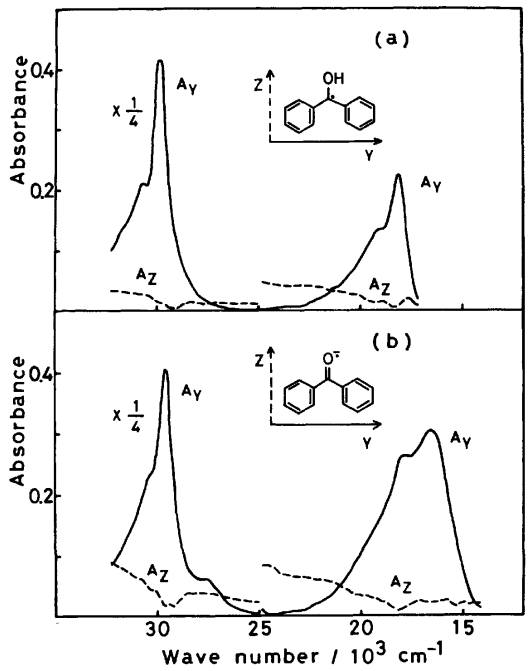

Fig. 3. Resolved spectra of benzophenone ketyl radicals (a) and radical anions (b). A_Y and A_Z curves are the molecular long- and short-axis polarized components, respectively.

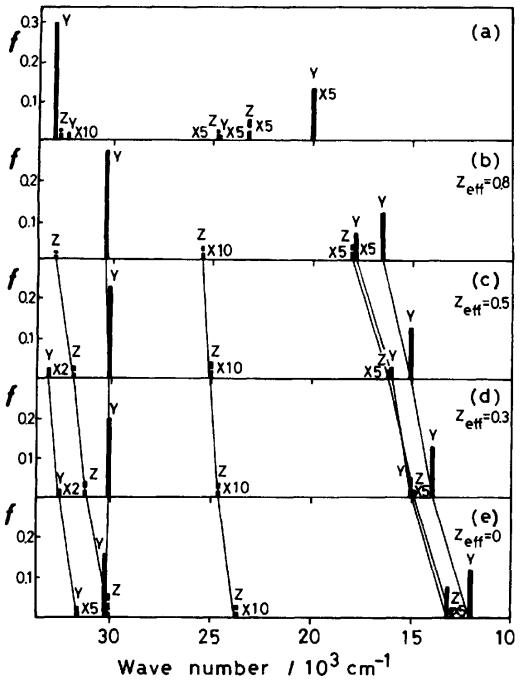

Fig. 4. Calculated results for benzophenone ketyl radicals (a) and radical anions (b)—(e). A point charge, Z_{eff} e, was set at the distance of 1.72 Å from the oxygen atom in order to take into accounts the effects of hydrogen bond.

R_d^s=0.87 for BPH·, and R_d^1=1.60 and R_d^s=0.94 for $BP^{-\cdot}$. As may be seen in Fig. 3, the main parts of the intense UV and visible bands of both radicals are long-axis (Y-) polarized components. No intense peak is found for the short-axis (Z-) polarized component.

The calculated results for BPH· are shown in Fig. 4a. The results are similar to those obtained by the Longuet-Higgins and Pople type MO calculation.[10,14] By comparison of Figs. 3a with 4a, it may be seen that the calculated transition energies are greater than the experimental values by $(2—3)\times10^3$ cm^{-1}, but the correspondence of the intense bands is fairly good. The Y-polarized bands at 18×10^3 cm^{-1} and 30×10^3 cm^{-1} are assigned to the first and seventh transitions respectively. The upper-state wave functions of these electronic transitions are represented by the following two main configurations; $\Psi_I=0.638\,\Phi_{8\to9}-0.383\,\Phi_{6\to8}+\cdots$ and $\Psi_{VII}=0.504\,\Phi_{8\to9}+0.424\,\Phi_{6\to8}+\cdots$, where the subscripts 6, 7, and 8 refer to the number of MO's and where MO ϕ_8 is the singly occupied orbital. Thus, these transitions originate mainly from two configurations, $\Phi_{8\to9}$ and $\Phi_{6\to8}$, and are similar to each other in characteristics. This assignment agrees well with those of other authors.[10,14]

The calculated results for $BP^{-\cdot}$ are shown in Fig. 4e. As $BP^{-\cdot}$ is considered to form a hydrogen bond in the PVA film, model calculations were carried out by locating a point charge, Z_{eff} e, at a distance of 1.72 Å from the oxygen atom of radical anions. These results are shown in Fig. 4b—d (Z_{eff}=0.8 to 0.3). On going from Z_{eff}=0 (Fig. 4e) to Z_{eff}=0.8, the first four transitions shift to blue, whereas the intense UV transition does not. The results for Z_{eff}=0.8 explain well the resolved spectra of Fig. 3b. The intense Y-polarized visible and near-UV bands at about 16.5×10^3 cm^{-1} and 29.5×10^3 cm^{-1} are, respectively, assigned to the first and the fifth transitons, the excited states of which are represented by the following two charge-resonance configurations; $\Psi_I=0.837\,\Phi_{8\to9}-0.278\,\Phi_{7\to8}+\cdots$ and $\Psi_V=0.402\,\Phi_{8\to9}+0.637\,\Phi_{7\to8}+\cdots$, where MO ϕ_8 is the singly occupied orbital.

The coefficients of the atomic orbitals of MO's, ϕ_6, ϕ_8, and ϕ_9 of BPH·, and ϕ_7, ϕ_8, and ϕ_9 of $BP^{-\cdot}$, are shown schematically in Fig. 5. As can be seen in Fig. 5, the

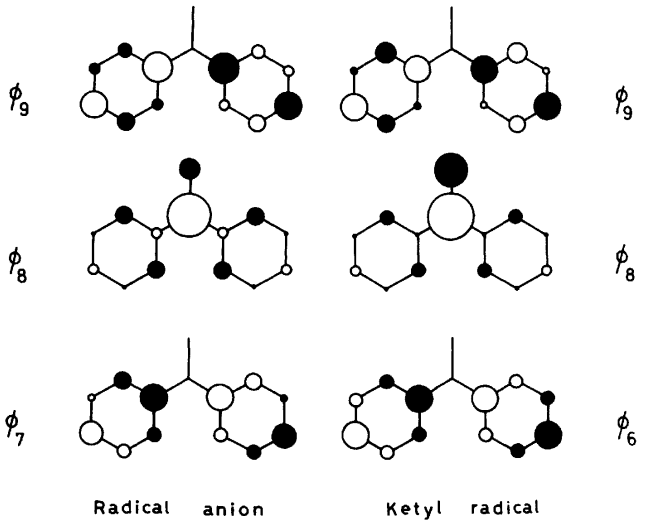

Fig. 5. Correlations of MO's ϕ_6, ϕ_8, and ϕ_9 of benzophenone ketyl radicals with the corresponding ones of radical anions (Z_{eff}=0.8). MO ϕ_8 is the singly occupied orbital. The size of the circle represents the relative value of the coefficient of the atomic orbitals. Open circles indicate positive sign and full circles negative sign.

MO's ϕ_6, ϕ_8, and ϕ_9, of $BPH^{\cdot}$ are similar to the ϕ_7, ϕ_8, and ϕ_9 of $BP^{-\cdot}$ respectively. Therefore, the $\Phi_{8\to9}$ and $\Phi_{7\to8}$ configurations of $BP^{-\cdot}$ are correlated with the $\Phi_{8\to9}$ and $\Phi_{6\to8}$ of $BPH^{\cdot}$ respectively. As a result,the Ψ_I and Ψ_V of $BPH^{\cdot}$ are correlated with the Ψ_I and Ψ_{VII} of $BPH^{\cdot}$. According to the results of the polarization measurement and the above discussion, the near-UV and visible bands of $BPH^{\cdot}$ in the PVA films can be said to be similar to those of $BP^{-\cdot}$ not only in spectral appearance, but also in the direction of the transition moments.

According to the Longuet-Higgins and Pople type MO calculation on $BP^{-\cdot}$, two transitions with large oscillator strengths are calculated to be located in the near-UV region.[14,20] The intense near-UV band observed in an MTHF glass was assigned to the Z-polarized transition by Shida *et al.*[14] However, in our caluclation (Fig. 4e, $Z_{eff}=0$) the Y-polarized transition is calculated to appear in this region with an oscillator strength larger than that of the Z-polarized one by a factor of 3. On going from $Z_{eff}=0$ to 0.8, this Z-polarized transition shifts to blue, while the Y-polarized one remains. Furthermore, the direction of the transition moment of the near-UV band of $BP^{-\cdot}$ in the PVA film is parallel to the molecular long axis (Y). Therefore, the main part of the intense near-UV band in an MTHF glass may be assigned to the Y-polarized transition.

Carbon Monoxide Absorption by Aqueous CuCl–$MgCl_2$ Absorbent

Masayuki KATSUMOTO,* Keiichi KANEHORI, and Taiji KAMIGUCHI†
Central Research Laboratory, Hitachi Ltd., Kokubunji, Tokyo 185
†*Kure Research Laboratory, Babcock-Hitachi K. K., Kure, Hiroshima 737*
(Received June 1, 1983)

Carbon monoxide absorption characteristics of an aqueous CuCl–$MgCl_2$ solution system are clarified. A CuCl 3.7 mol/l-$MgCl_2$ 4.7 mol/l solution is found to absorb 2.2 mol of CO per liter at 30 °C and $P_{CO}=2\times10^4$ Pa. This is 8 times greater than a CuCl 3.2 mol/l-HCl 8.2 mol/l solution and 16 times greater than a CuCl 4.8 mol/l-KCl 5.9 mol/l solution. The CO absorption of the concentrated aqueous solution of CuCl–$MgCl_2$ is accompanied with fine particle precipitation. This precipitate, which consists of CO, Cu^+, Mg^{2+}, Cl^-, and H_2O, is estimated to be $CO\cdot CuMgCl_3\cdot nH_2O$. The complex completely releases CO at 70 °C or above. Chloride ion influence on the formation of $CO\cdot CuMgCl_3\cdot nH_2O$ is discussed.

The carbon monoxide absorption properties of an aqueous copper(I) chloro-complex solution and aqueous CuCl–MCl_n (M=H^+, NH_4^+, metal ion and $n=1-3$) suspension systems have long been known.[1,2] Among these systems, the CuCl–$MgCl_2$ suspension was reported by Deringer[3] as absorbing a larger amount of CO at relativey low CO partial pressure region (above 20 kPa) than the aqueous solution of copper(I) chloro-complex. Decomposition pressure of the CO complex was said to be lowered only in the CuCl–$MgCl_2$ suspension absorbent, which contains solid $MgCl_2\cdot 6H_2O$.[3,4] The solid CO complex thus formed may contain $MgCl_2$, since the appearance of solid $MgCl_2\cdot 6H_2O$ changes after CO absorption.[3] However, neither the details of these phenomena nor the absorption behavior of CuCl–$MgCl_2$ solution has been clarified.

Aqueous absorbent that does not contain an acid or alkali, is quite promising for industrial use in recovering carbon monoxide from gas mixtures containing H_2O and CO_2. It includes no inflammable organic solvent and requires no pre-dehydration or pre-decarbonation of gas mixtures.[5,6]

The present work clarifies the CO absorption phenomena of the aqueous CuCl–$MgCl_2$ solution system.

Experimental

Materials. Copper(I) chloride and other chloride salts listed in Table 1 were purchased as reagent grade (Kanto Chemical Co., Inc.) and used as received. Carbon monoxide gas (99% pure) was used without further purification.

Copper(I) solutions were prepared by the following procedure. The desired amounts of chloride salts were weighed and transferred into a flask in a nitrogen box. Oxygen-free deionized water was added to the flask. Then, the flask was sealed and stirred. The flask was permitted to stand at 30 °C overnight to settle either the excess chloride or the impurities. The upper portion was used as a solution absorbent.

Metal ion concentration of the solution was determined by atomic absorption analysis. Chloride ion concentration was determined by spectrophotometry using mercury(II) thiocyanate and iron(III) ion,[7] after eliminating the metal ion as hydroxide precipitates.

The copper(II) ion content was checked by redox titration, using $TiCl_3$ standard solution as the reductant and monitoring the redox potential, for several solutions prepared as described above. Copper(II) ion content was always below 1% of the total copper ion concentration. Copper(II) ion does not form a compound with CO, and was ignored in the following discussion.

CO Absorption Measurement. Carbon monoxide absorption was measured using a constant pressure apparatus. The absorption vessel was connected to the apparatus *via* a tapered joint and immersed in temperature regulated water. The solution or suspension was rigorously stirred with a magnetic stirrer.

The amount of CO absorbed at $P_{CO}=1.01\times10^5$ Pa was determined as follows. Twenty ml of copper(I) solution or suspension was transferred to an absorption vessel. The apparatus was degassed quickly to the vapor pressure of the solution, and then CO gas was introduced to the apparatus. Pressure decrease due to absorption was detected by manometric pressure sensor and more CO gas was fed automatically to keep the pressure constant.

Dependence of the amount of CO absorbed on the CO pressure was determined as follows. After evacuation to a vapor pressure, measured quantities of CO were added. After each addition of CO, the equilibrium pressure and amount of CO absorbed were determined. The absorption equilibrium was attained within 1 h when the amount of CO absorbed was below 1.5 mol/l, after the precipitation occurred. It was considered that the maximum CO absorption under given conditions was obtained when the pressure change was less than 133 Pa within 30 min. No precipitation was observed before the CO absorption occurred.

To separate fine particles or a flake precipitate formed by

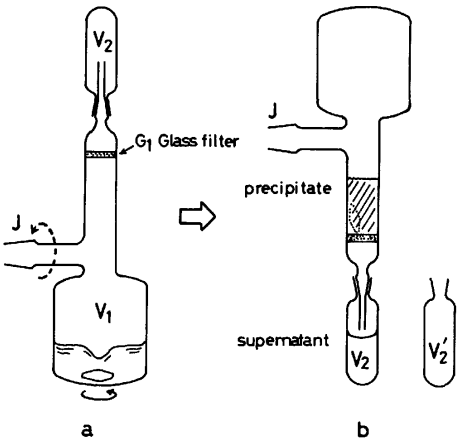

Fig. 1. Apparatus and procedure for precipitate separation from supernatant liquid.
V_1: Absorption vessel, V_2 and V_2': vessel for recuperation of liquid obtained after CO release, J: ground glass joint, a: CO absorption, b: separation of precipitate.

CO absorption in some cases, a vessel V_1, equipped with a glass filter (Fig. 1) was used. After CO absorption, V_1 was rotated around joint J. The supernatant portion dropped to vessel V_2, leaving the fine particles or flakes on the glass filter. Then, V_2 was replaced by V_2', previously filled with CO. The fine particles or the flakes remained on the glass filter were warmed and the quantity of CO released was measured with a gas buret. The liquid, obtained after CO release from the fine particles, dropped into vessel V_2'. During these procedures, the supernatant liquid and the precipitate were kept under an atmosphere of CO ($P_{CO}=1.01\times10^5$ Pa). This was done because the CO complex formed in the liquid phase as well as in the solid phase releases CO when the partial pressure of CO decreases. The white solid remained after CO release from the flake was dissolved in HCl solution. The total amount of CO released from the supernatant liquid and the precipitate corresponds to the amount of CO absorbed within the experimental errors.

Results and Discussion

Comparison of CO Absorption Behavior. The characteristics of CO absorption by aqueous CuCl-$MgCl_2$ solution (not including solid $MgCl_2\cdot6H_2O$) are compared with those of other CuCl-MCl_n solutions in terms of the maximum amount of CO absorbed, the molar ratio of CO absorbed to Cu^+, CO/Cu^+, and the appearance of precipitate. Results are summarized in Table 1.

Maximum Amount of CO Absorbed: The maximum amount of CO absorbed under given conditions increases with the dissolved CuCl concentration. It is noteworthy that the maximum amount of CO absorbed by the concentrated CuCl-$MgCl_2$ solution is larger than that by CuCl-MCl_n solution which contain nearly the same amount of dissolved CuCl as the CuCl-$MgCl_2$ solution.

CO/Cu^+ Ratio: The CO/Cu^+ ratio decreases as the dissolved CuCl concentration increases in the CuCl-HCl system.[1] All systems, except CuCl-$MgCl_2$, show the same tendency at 30 °C, regardless of whether flakes of CuCl-CO complex are formed.[1,8] The CO/Cu^+ ratio of the CuCl-$MgCl_2$ system decreases in the low concentration region. In high concentration region, the ratio increases with the dissolved CuCl concentration.

Appearance of Precipitate: When the concentration of CuCl and $MgCl_2$ was high, the precipitation of fine particles, which were considered as the CO complex, was observed. This kind of precipitate with a fine particle form has not been previously reported. This precipitate differs from the flake of CuCl-CO solid complex in both size and shape. The former is much smaller (about one-tenth that of the latter). It is also more spherical as opposed to flaky.

These observations clearly indicate that the CO absorption characteristics of the CuCl-$MgCl_2$ system are quite different from other CuCl-MCl_n systems.

Composition of the Precipitate with Fine Particle Form: The composition of supernatant solution, the content of precipitates, and the amount of CO released from the supernatant solution and the precipitate are summarized in Table 2.

Table 1. Maximum amount of CO absorbed by CuCl-MCl_n solutions (30 °C, $P_{CO}=1.01\times105$ Pa)

For the CuCl-$MgCl_2$ and CuCl-$MgCl_2$-MCl_n solutions, the following results were obtained.

(1) About 80% of CO absorbed, was released from the fine particles.

(2) CO/Cu^+ ratio was about 0.8 for the precipitate and 0.2 for the supernatant solution.

TABLE 2. COMPOSITION OF SUPERNATANT LIQUID AND FINE PARTICLE PRECIPITATE

a) Amount of Cl^- could not be determined because the solid remaining after CO release was dissolved in HCl solution.

(3) The amount of chloride ion A_{Cl^-}, was expressed as $A_{Cl^-}=A_{Cu^+}+2A_{Mg^{2+}}+n\,A_{M^{n+}}$ where A_{Cu^+}, $A_{Mg^{2+}}$, and $A_{M^{n+}}$ are Cu^+, Mg^{2+}, and M^{n+} content in mol/l, respectively.

(4) As much Mg^{2+} as Cu^+ was contained in the precipitate.

(5) The Mg^{2+} concentration of the supernatant solution was always lower than that of the absorbent before CO absorption, while the M^{n+} concentration was always higher despite the rough separation process.

These results indicate that the precipitate with fine particle form consists of CO, Cu^+, Mg^{2+}, Cl^-, and H_2O. Since the M^{n+} distribution between a supernatant and a precipitate is opposite that of Mg^{2+}, M^{n+} is not considered as a precipitate compounent.

This precipitate might be expressed as the rational formula: $CO{\cdot}CuMgCl_3{\cdot}nH_2O$.

Flake formed when CO is absorbed by a concentrated CuCl–KCl solution, was analyzed in a simillar way. In this case, residue remained after release of CO from the flake was dissolved in HCl solution and the ratio of K^+ to Cu^+, K^+/Cu^+, was determined. As this ratio is much smaller than unity (0.58), the flake appears to be composed essentially of CuCl-CO as previously reported.[2,8]

Partial Pressure Dependence of CO Absorption. Pressure dependene of CO absorption by CuCl 3 mol/l-$MgCl_2$ 4.8 mol/l solution is shown in Fig. 2 (curve A). The amount of CO absorbed, A_{CO}, increases abruptly when CO partial pressure surpasses the threshold pressure, P^*_{CO}; and CO absorption above P^*_{CO} is accompanied with fine particle precipitation.

The pressure dependence of CO absorption by CuCl-$MgCl_2$ suspension and that by CuCl-KCl solution are also shown in Fig. 2. Curves C and D show the results obtained by Deringer.[3] This figure clearly shows that the dependence of the amount of CO absorbed on CO partial pressure is substantially the same for each CuCl-$MgCl_2$ system, regardless of whether it is a solution or a suspension. Furthermore, when CO was absorbed by CuCl 3 mol/l-$MgCl_2$ 5 mol/l suspension absorbent above P^*_{CO}, precipitate with fine particle form was also observed at the wall of the absorption vessel, in the vicinity of gas-liquid interface. Therefore, the CO complex pointed out by Deringer, which might contain $MgCl_2{\cdot}6H_2O$, is considered to be $CO{\cdot}CuMgCl_3{\cdot}nH_2O$.

The amount of CO absorbed by the concentrated CuCl-KCl system changes gradually with increasing CO partial pressure (curve E) in quite a different

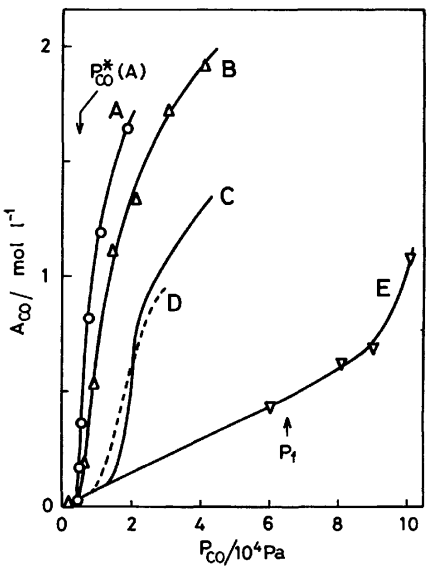

Fig. 2. Pressure dependence of CO amount absorbed, A_{CO}, by CuCl-$MgCl_2$ and CuCl-KCl (30 °C).
A: CuCl 3 mol/l-$MgCl_2$ 4.8 mol/l, B: CuCl 3 mol/l-$MgCl_2$ 5 mol/l (suspension), C: CuCl 1 g+3 ml of $MgCl_2$ suspension (Deringer[3]), D: CuCl 1 g+3 ml of Carnallite suspension (Deringer[3]), E: CuCl 4.8-KCl 5.9 mol/l.
P^*_{CO} (A): Threshold pressure for absorbent A above the amount of CO absorbed increases remarkably with increased CO partial pressure. CO absorption above P^*_{CO} is accompanied with fine particle precipitation. P^f_{CO}: Flake formation pressure for absorbent E. CO absorption above P^f_{CO} is accompanied with flake formation.

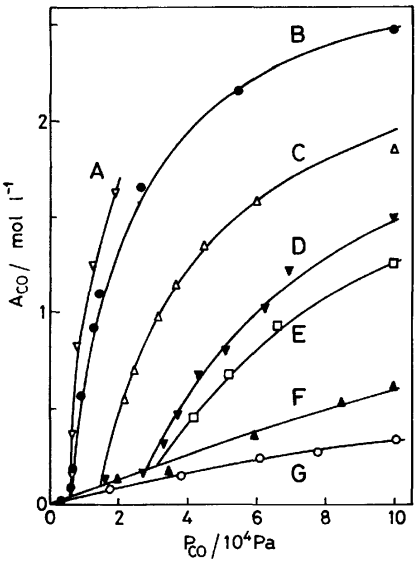

Fig. 3. Pressure dependence of CO amount absorbed, A_{CO}, for several CuCl-$MgCl_2$ solutions and suspensions (30°C).
A: CuCl 3 mol/l-$MgCl_2$ 4.8 mol/l, B: CuCl 3 mol/l-$MgCl_2$ 5 mol/l (suspension), C: CuCl 2.8 mol/l-$MgCl_2$ 3.9 mol/l, D: CuCl 3 mol/l-$MgCl_2$ 4 mol/l (suspension), E: CuCl 2.7 mol/l-$MgCl_2$ 3.7 mol/l, F:CuCl 2.2 mol/l-$MgCl_2$ 3.3 mol/l, G: CuCl 0.8 mol/l-$MgCl_2$ 2.0 mol/l.
Solid lines A to E were calculated using Eq. 4 with $K_2=8.86\times10^{-5}$ Pa^{-1} and $P^*_{CO}=5\times10^3$ Pa for A, $K_2=5.196\times10^{-5}$ Pa^{-1} and $P^*_{CO}=5\times10^3$ Pa for B, $K_2=2.625\times10^{-5}Pa^{-1}$ and $P^*_{CO}=1.16\times10^4$Pa for C, $K_2=1.26\times10^{-5}$ Pa^{-1} and $P^*_{CO}=2.33\times10^4$ Pa for D, and $K_2=1.191\times10^{-5}$ Pa^{-1} and $P^*_{CO}=2.43\times10^4$ Pa for E. Solid lines F and G were calculated using Eq. 2 with $K_1=3.725\times10^{-6}$ Pa^{-1} for F and $K_1=6.771\times10^{-6}$ Pa^{-1} for G.

manner than with CuCl-$MgCl_2$ system.

The partial pressure dependence of CO absorption by several CuCl-$MgCl_2$ solutions and suspensions are summarized in Fig. 3. There, P^*_{CO} increases as either CuCl or $MgCl_2$ content decrease, in either solution or suspension. Furthermore, the change in amount of CO absorbed with the CO pressure above P^*_{CO}, is smaller for more dilute absorbents.

These phenomena can be explained as follows. In solutions F and G, CO absorption proceeds *via* Reaction 1 as previously reported.[1,8]

$$\text{Cu(I)·chloro-complex(dissolved)} + \text{CO} \longrightarrow \text{CO·Cu(I)·chloro-complex(dissolved)} \quad (1)$$

The physical solubility of CO in this system is expected to be very low as in the case of the CuCl–HCl system.[8] Thus, the amount of CO absorbed, *i.e.* amount of CO·Cu(I)·chloro-complex dissolved, α in mol/l, is expressed by Eq. 2:

$$\alpha = \frac{K_1 P_{CO} A^\circ_{Cu^+}}{(1+K_1 P_{CO})}, \quad (2)$$

where K_1 denotes the absorption coefficient in Pa^{-1}, which depends on the absorbent composition and the temperature, and $A^\circ_{Cu^+}$, the total concentration of Cu^+ in mol/l.

The solid lines, F and G in Fig. 3, calculated using Eq. 2 and K_1, agree with the experimental results (K_1 was determined with the amount of CO absorbed at $P_{CO}=1.01\times10^5$ Pa).

For absorbents A to E, the amount of CO absorbed increases gradually with CO partial pressure below P^*_{CO}, in the same manner as for solutions F and G. Therefore, CO absorption in this region also proceeds *via* Reaction 1 .

Above P^*_{CO}, fine particle precipitation might occur *via* Reaction 3:

$$\text{CO·Cu(I)·chloro-complex(dissolved)} + Mg^{2+} + m\text{Cl}^- + n\text{H}_2\text{O} \longrightarrow \text{CO·CuMgCl}_3\cdot n\text{H}_2\text{O}\downarrow. \quad (3)$$

The pressure dependence of CO absorption in this region is expressed by Eq. 4:

$$A_{CO} = \frac{K_2(P_{CO}-P^*_{CO})A^\circ_{Cu^+}}{1+K_2(P_{CO}-P^*_{CO})}, \quad (4)$$

where K_2 is the absorption coefficient above P^*_{CO}, which depends on absorbent composition and temperature. Solid lines A to E of Fig. 3 calculated using Eq. 4, agree with the experimetal results. Values for K_2 and P^*_{CO}, used in the calculation are summarized in the figure caption.

To precipitate CO·$CuMgCl_3\cdot n\text{H}_2\text{O}$ a certain concentration of CO·Cu(I)·chloro-complex (dissolved) as well as Mg^{2+} and/or Cl^-, may be required. Once CO·$CuMgCl_3\cdot n\text{H}_2\text{O}$ precipitation occurs, the concentration of CO·Cu(I)·chloro-complex (dissolved), Mg^{2+} and Cl^- decrease. When CO partial pressure increases, the concentration of CO·Cu(I)·chloro-complex increases *via* Reaction 1. Then, precipitation occurs again *via* Reaction 3.

Temperatre Dependence of CO Absorption. The changes in the amount of CO absorbed, A_{CO}, by the CuCl 3 mol/l-$MgCl_2$ 5 mol/l suspension absorbent at $P_{CO}=4\times10^4$ Pa and at 1.01×10^5 Pa are shown in Fig. 4. The amount of CO absorbed decreases especially above

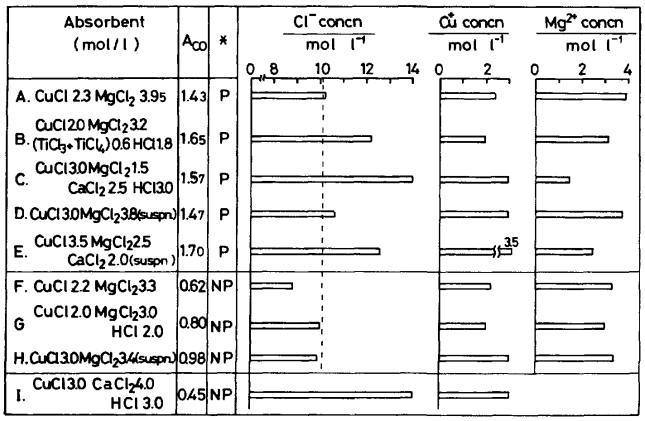

Fig. 5. Dependence of CO absorption behavior on ion concentration of solutions (30 °C: $P_{CO}=1.01\times10^5$ Pa).
* P: Precipitation was observed. NP: No precipitation was observed.

50 °C, becoming nearly zero at 70 °C. This means that the decomposition temperatre of the CO·$CuMgCl_3$·nH_2O complex at $P_{CO}=1.01\times10^5$ Pa is around 70 °C.

Influences of Chloride Ion Concentration on CO·CuMgCl₃·nH₂O Formation. Deringer claimed that only CuCl–$MgCl_2$ suspension absorbent containing solid $MgCl_2\cdot6H_2O$ absorbs a large amount of CO in the relatively low CO partial pressure range. As mentioned above, the amount of CO absorbed increases drastically above P^*_{CO} for both the CuCl–$MgCl_2$ solution and suspension absorbents. Therefore, the conditions proposed by Deringer are not always necessary for absorption of large amounts of CO by the CuCl–$MgCl_2$ system. Furthermore, this absorption of CO above P^*_{CO} closely relates to the formation of CO·$CuMgCl_3$·nH_2O.

The dependence of the absorption behavior of the CuCl-$MgCl_2$ system on the concentration of Cu^+, Mg^{2+}, and Cl^- is shown in Fig. 5. There is no threshold value for Cu^+ and Mg^{2+}, above that CO absorption accompanied with CO·$CuMgCl_3$·nH_2O precipitation.

On the contrary, absorbents containing more than 10 mol/l chloride ions manifest the CO absorption characteristic that is accompanied with the precipitation of CO·$CuMgCl_3$·nH_2O. Solution I, which contains 14 mol/l of chloride ion but no Mg^{2+}, absorbs only 0.45 mol/l of CO and no precipitation is observed.

Summary

The CO absorption by the concentrated aqueous CuCl-$MgCl_2$ solution system is characterized by (i) a large amount of CO absorbed per unit volume of absorbent, and (ii) precipitation of fine particles different from the flake complex of CuCl-CO. A chloride ion concentration of more than 10 mol/l in the CuCl-$MgCl_2$ system results in the formation of fine particles estimated to be CO·$CuMgCl_3$·nH_2O.

Hydrates of Organic Compounds. VIII. The Effect of Carboxylate Anions on the Formation of Clathrate Hydrates of Tetrabutylammonium Carboxylates

Haruo NAKAYAMA* and Shigeru TORIGATA

Department of Chemistry, Faculty of Engineering, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240

(Received June 28, 1983)

The solid-liquid phase diagrams of binary mixtures of tetrabutylammonium carboxylates, $(n\text{-}C_4H_9)_4$ NOOCR (R=H-n-$C_{10}H_{21}$ including various alkyl groups replaced by either methyl or ethyl group), with water were examined in order to confirm the formation of clathrate-like hydrates. The results can be summarized as follows: (1) for 14 carboxylates the formation of a clathrate-like hydrate is newly confirmed; (2) judging from melting points and hydration numbers, the hydrates can be classified into three groups: I, II, and III; (3) the group I hydrates, formed by the carboxylates with R=H, CH_3, C_2H_5, n-C_3H_7, i-C_3H_7, and t-C_4H_9, have hydration numbers around 30 and are the most stable hydrates among those examined in this experiment, with the exceptions of 2-methylpropionate and 2,2-dimethylpropionate hydrates; (4) the group II hydrates, with hydration numbers around 39, are formed by the salts with R=n-C_4H_9, s-C_4H_9, i-C_4H_9, and all the C_5H_{11}, and are relatively unstable (mp=5—11 °C); (5) the group III hydrates, with hydration numbers around 30 like the group I hydrates, are formed by the carboxylates with long alkyl chains from n-C_6H_{13} to n-$C_{10}H_{21}$ and are generally unstable; and (6) judging from the hydration number, the crystal structure of the group I and III hydrates seems to be isomorphous with a tetrabutylammonium fluoride hydrate, and that of the group II hydrates with a tetrabutylammonium benzoate hydrate.

As early as 1940, the formation of unusual hydrates of tetrabutylammonium carboxylates like formate and benzoate, which had a large number of water molecules per one salt molecule, was reported by Kraus *et al.*[1] In the subsequent crystallographic studies made by Jeffrey and his coworkers, it was concluded that hydrates of tetrabutylammonium acetate[2] and of tetrabutylammonium benzoate[3] had a clathrate-like structure similar in general character to the gas hydrates: the structure of the acetate hydrate is isomorphous with tetrabutylammonium fluoride hydrate,[4] in which each butyl group of the ammonium cation is located in a hydrogen-bonded framework of water molecules; and in the tetragonal benzoate hydrate, not only four butyl groups of the cation but also one benzyl group of the anion is surrounded by a hydrogen-bonded water framework.

Thus, there are at least two types of tetrabutylammonium carboxylate hydrates. However, we have no sufficient data to draw any conclusion as to the influence of an alkyl chain of a carboxylate anion on both the stability and the structure of the tetrabutylammonium carboxylate hydrates. In this paper, from the solid-liquid phase diagrams for 19 binary mixtures of tetrabutylammonium carboxylate-water, the effect of the shape and/or length of the alkyl group of a carboxylate anion on the stability (*i.e.*, melting point) and the crystal structure (*i.e.*, hydration number) of their clathrate hydrates has been systematically examined. These fundamental data would also offer a guiding principle, for example, for highly selective separation of a specific carboxylate anion from an aqueous solution containing several kinds of carboxylate anions by means of the formation of a mixed clathlate hydrate of tetrabutylammonium carboxylates.[5]

Experimental

Aqueous solutions of tetrabutylammonium carboxylates, except for formate, were prepared by a reaction between tetrabutylammonium iodide and the corresponding silver carboxyates in water, followed by filtration of AgI precipiate. Tetrabutylammonium iodide was synthesized by reacting tributylamine with butyl iodide in ethyl acetate and purifie by recrystallization from ethyl acetate-acetone mixture. Each silver carboxylate was obtained by mixing an aqueous solution of silver nitrate with an aqueous carboxylic acid solution after neutralization with NaOH, followed by repeated washing with water in order to remove the resultant sodium nitrate. An aqueous solution of tetrabutylammonium formate was prepared by neutralizing tetrabutylammonium hydroxide solution with formic acid solution. The hydroxide solution was obtained by treating tetrabutylammonium iodide with freshly prepared silver hydroxide in water. The silver hydroxide was obtained by reacting silver nitrate solution with sodium hydroxide solution, followed by filtration and by repeated washing with water. All the carboxylic acids were purchased from Tokyo Kasei Kogyo Co. Ltd. and were used without further purification. Some impurities contained in the carboxylic acid could be removed during the precipitation procedure of the silver salt of the carboxylic acid.

Solid-liquid phase diagrams for the binary systems of water-tetrabutylammonium carboxylate were determined in the same manner as described in the previous paper[6] (an ampoule method). The concentration of each mother solution was determined by a titration method using a standard sodium tetraphenylborate solution.[6]

Results and Discussion

The solid-liquid phase diagrams for tetrabutylammonium carboxylate-water binary systems are shown in Figs. 1, 2, and 3. The logarithm of the concentration expressed in mole fraction (X) is plotted against the reciprocal of the absolute temperature. The temperature expressed in ordinary Celsius units is shown on the upper side of each figure. For comparison, Fig. 1 includes the phase diagram of the tetrabutylammonium fluoride-water system reported earlier.[6,7] Because of the similarity of the data with each other, some of the results

are either excluded from these figures or represented by a dotted or a broken line only in the vicinity of each congruent point. These figures clearly show that all the salts examined in this experiment can form clathrate-like hydrates similar to that of the fluoride, although their congruent melting points are considerably lower than that of the fluoride hydrate (Fig. 1). All the melting points and the hydration numbers, determined from each congruent melting point and congruent composition, are summarized in Table 1, together with those previously reported by other authors.[2,8] Among these hydrates, 14 hydrates which have not been reported earlier are confirmed in this experiment.

In Fig. 4, the melting point of the clathrate hydrate is plotted against the number of carbon atom in the main alkyl chain of each carboxylate anion. The points corresponding to the hydrates of a series of normal alkanoates are connected by a solid line. A filled circle indicates a hydrate with hydration number around 30 and an open circle indicates one with hydration number around 39. From this figure it is clear that the effect of an alkyl chain in the carboxylate anion on the formation of the clathrate hydrate of the tetrabutylammonium carboxylates is fairly complicated and also that all the

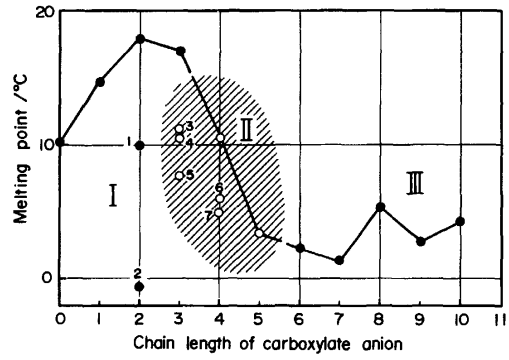

Fig. 4. Relatioship between the melting points of the tetrabutylammonium carboxylate, $(n\text{-}C_4H_9)_4NOOCR$, hydrates and the chain length of R in the carboxylate anion. Filled circle indicates the hydrate with hydration number of 30 and open circle indicates the one with hydration number of 39. All points not numbered indicate that R is normal alkyl group. Numbered point means as follows:
1: $R=CH_3CH(CH_3)$; 2: $R=(CH_3)_3C$; 3: $R=CH_3CH(CH_3)CH_2$; 4: $R=CH_3CH_2C(C_2H_5)$; 5: $R=CH_3CH_2CH(CH_3)$; 6: $R=CH_3CH(CH_3)CH_2CH_2$; 7: $R=CH_3(CH_2)_2CH(CH_3)$ and $R=CH_3CH_2CH(CH_3)CH_2$. Three groups shown by I, II, and III are explained in the text.

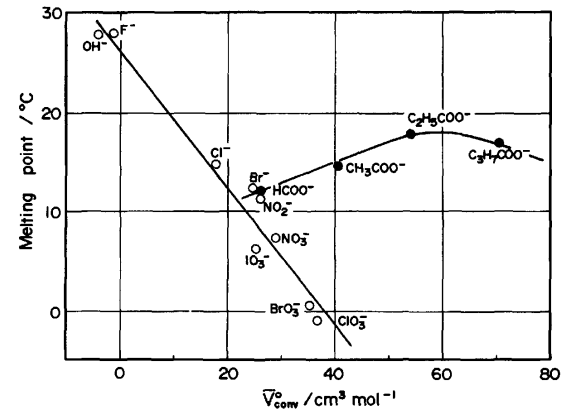

Fig. 5. Relationship between the melting points of the hydrates of tetrabutylammonium salt, $(n\text{-}C_4H_9)_4NX$, and the conventional partial molal ionic volumes of the anion X.

points corresponding to the hydrates of hydration number 39 (open circles) gather in a limited region (shown by the hatched area). Thus, we analyze these results by classifying, tentatively, these hydrates into three groups: I, II, and III, as also indicated in Fig. 4.

The group I hydrates include the hydrates formed by the carboxylates with R=H, CH_3, C_2H_5, $n\text{-}C_3H_7$, $i\text{-}C_3H_7$, and $t\text{-}C_4H_9$. These hydrates, except for the 2,2-dimethylpropionate hydrate, are fairly stable as compared with hydrates in the other groups. The fact that the hydration number of these hydrates is around 30, just as the fluoride hydrate, suggests that the crystal structue of the group I hydrate is isomorphous with that of the fluoride hydrate.[4] In fact McMullan and Jeffrey[2] have reported that the tetrabutylammonium acetate hydrate forms the same tetragonal crystal as those of such salts as fluoride, chloride, and bromide. Very recently, in the course of our investigation Dyadin *et al.*[8] have also reported that four tetrabutylammonium carboxylates having $HCOO^-$, CH_3COO^-, $C_2H_5COO^-$, and $n\text{-}C_3H_7OO^-$ anion can form a clathrate-like hydrate which is tetragonal and has 32 mol of water per one mole of the salt.

However, the effect of carboxylate anions on the stability of these group I hydrates cannot be explained by the same consideration as that applied to the hydrates of ordinary tetrabutylammonium inorganic salts.[6] In the previous paper,[6] we pointed out that the stability of the ordinary $(n\text{-}C_4H_9)_4NX$ (X=monovalent inorganic anion) hydrates approximately decreased with increasing the ionic volume of the X. This relationship is represented in Fig. 5, in which the melting point of each hydrate is plotted against the conventional partial molal anionic volume ($\bar{V}^\circ_{conv}$) at 25 °C as an indication of the effective volume of an anion within the hydrate solid. This nearly linear relationship between the melting point (*i.e.*, the stability) of the hydrate and $\bar{V}^\circ_{conv}$ of its anion[9] indicates that the stability of the hydrate is mainly governed by the distortion effect of the anion on the hydrogen-bonded water framework in the hydrate. In Fig. 5, similar plots are also given for the group I hydrates. The conventional partial molal volume of each carboxylate anion was obtained from the partial molal volumes of each sodium salt[10–12] at infinite dilution using the relation that $\bar{V}^\circ_{conv}$ for Na^+ is equal to -1.21 cm³/mol at 25 °C.[9] As is obvious from this figure, these plots, except for the formate hydrate, appreciably deviate from the simple, linear relationship found for the ordinary inorganic salt hydrate. This indicates that the stability of the group I hydrate, except for the formate hydrate, cannot be explained by a simple distortion effect caused by the presence of the carboxylate anion within the hydrate lattice.

A reasonable explanation for this behavior will be that such alkyl groups as CH_3, C_2H_5, and C_3H_7 are located in a pentagonal dodecahedron, which exists in a gap between the arrangement of larger polyhedra (tetrakaidecahedra and/or pentakaidecahedra filled by one of the butyl group of the tetrabutylammonium cation) and is believed to be either vacant or partially filled by a small molecule such as free water, oxygen, and nitrogen. Very recently, a similar consideration has been proposed by Dyadin *et al.*[8] on the basis of X-ray diffraction characteristics.

Our reasons derived from this investigation are summarized as follows: (1) the occupation of a pentagonal dodecahedron by an akyl group of a carboxylate anion will not cause any change in the crystal structure or the hydration number of the hydrate since the fundamental network of the hydrogen-bonded water molecules has nothing to do with the occupation of a pentagonal dodecahedron; (2) the best fitness of $CH_3CH_2COO^-$ anion to a pentagonal dodecahedron, as revealed by the highest melting point of the propionate hydrate, can be reasonably explained since the mean free diameter of a pentagonal dodecahedron is about 5.0 Å[13] and the van der Waals diameter of $CH_3CH_2COO^-$ anion is estimated to be 4.7Å if we take into account the fact that the oxygen atoms of the carboxylate anion are hydrogen-bonded to the water framework and form part of the polyhedral structure;[3] and (3) low stability of both 2-

methylpropionate and, especially, 2,2-dimethylpropionate hydrates can be interpreted by a distortion of pentagonal dodecahedron due to the presence of these bulky, methyl-substituted anions.

The group II hydrates include all the hydrates with the hydration number of 39. They are formed exclusively by all the carboxylates with R=C_4H_9 and C_5H_{11} except for *t*-C_4H_9, and are newly confirmed in this experiment except for the pentanoate hydrate.[8] The large hydration number, 39, as compared with that of the group I hydrate, 30, indicates that one more hydrogen-bonded water cage will be present in order to enclathrate such a fairly large carboxylate anion as $C_4H_9COO^-$ or $C_5H_{11}COO^-$, which is too large to be accommodated in a pentagonal dodecahedron just as considered for the group I hydrate. Although there is no more evidence about the crystal structure of the group II hydrate than the hydration number, the crystal structure seems to be essentially the same as that of the tetrabutylammonium benzoate hydrate, which is tetragonal and has an ideal composition of $(n\text{-}C_4H_9)_4NOOCC_6H_5 \cdot 39.5H_2O$.[3]

The effect of the length and/or shape of an alkyl chain of a carboxylate anion on the stability of the group II hydrates are summarized as follows:

(1) Among the hydrates with R=C_4H_9, except for *t*-C_4H_9, the melting points of the pentanoate and the 3-methylbutanoate hydrate are approximately equal and higher than that of the 2-methylbutanoate hydrate (7.7 °C). This suggests that the methyl group attached to the carbon atom of 2-position causes a considerable distortion in the hydrogen-bonded water framework.

(2) The hydrates of the salt with $C_5H_{11}COO^-$ anion are generally unstable, as compared with those of the salt with $C_4H_9COO^-$ anion, presumably because the alkyl chain is a little too long to be accommodated stably within a water framework structure and, in addition, because of a distortion effect caused by the substituted methyl group. However, the 2-ethylbutanoate hydrate is exceptionally stable (mp=10.6 °C). This would partly be due to the fact that the main alkyl chain is shorter by either one or two carbon atoms than in the rest of the salts. Another interesting reason is that the distortion effect caused by a ethyl group attached to the carbon atom of 2-position is expected to be smaller than that caused by a methyl group, since the carbon atom of 2-position is connected with the small and flexible methylene group and not with the bulky methyl group.

(3) As is seen from Table 1, the pentanoate hydrate (mp=10.6 °C) is more stable than the 4-methylpentanoate hydrate (mp=6.0 °C). This indicates that the *n*-$C_4H_9COO^-$ ion can be more suitably enclathrated by the hydrogen-bonded water framework than the *i*-$C_5H_{11}COO^-$ ion, in striking contrast to the fact that, in the hydrates of ordinary tetraalkylammonium salts with the same inorganic anion like F^- tetraisopentylammonium salt hydrate is more stable than tetrabutylammonium salt hydrate.[7]

The formation of a clathrate-like hydrate for the tetrabutylammonium carboxylates with such long alkyl chains as *n*-$C_6H_{13}COO$-*n*-$C_{10}H_{21}COO^-$ is clearly confirmed from the phase diagrams shown in Fig. 3. The existence of these hydrates has never been known before. They are classified as the group III hydrates. The characteristic features of the group III hydrates are summarized as follows: (1) the hydration number is around 30; (2) the melting points are low; and (3) there is no simple relationship between the melting point and the alkyl chain length of the carboxylate anion. From the fact that the hydration number is around 30, the possible crystal structure of these hydrates would be isomorphous with a distorted $(n\text{-}C_4H_9)_4NF$ hydrate just as the group I hydrate. The main difference between the structure of the group I hydrate and that of the group III hydrate would be the existence of the interpenetration of a long alkyl chain into two or three pentagonal dodecahedra, which are face-sharing with each other, in the group III hydrate crystal.

Pressure Effects on the Hydrolysis of Acetanilide Catalyzed by Cyclodextrins

Syoichi MAKIMOTO, Keizo SUZUKI, and Yoshihiro TANIGUCHI*

Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto 603

(Received July 18, 1983)

The rates of the hydrolysis of *p*-nitrotrifluoroacetanilide (pNFA) catalyzed by α- and β-cyclodextrins (α-, β-CD) were measured at pressures up to 2 kbar at 25 °C and at pH 6.9 in a 0.05 M† Tris buffer solution. The substrate binding constants, K, and the rate constants of the acylation process, k_{acyl}, increased monotonically up to 2 kbar. From the pressure dependence of K, the volume changes (ΔV) accompanying the formation of the inclusion complexes at 1 bar were -3 ± 2 cm^3/mol for α-CD-pNFA and -2 ± 2 cm^3/mol for β-CD-pNFA. The activation volumes (ΔV) for the cleavage of the anilide molecule in the acylation process were -25 ± 2 cm^3/mol for α-CD-pNFA and -18 ± 2 cm^3/mol for β-CD-pNFA. The reaction mechanisms of the cleavage of the anilide substrte by CDs were discussed on the basis of the volume parameters (ΔV and ΔV^*).

Cyclodextrins have served as a good model of a serine protease, as has been reviewed by Bender *et al.*[1] The reactions of the CD-acceleated cleavage of the phenyl ester and anilide proceed *via* the three steps of the substrate binding, the acylation of CD, and the deacylation of acyl-CD as well as by means of the chymotrypsin reaction. The first reason for the great interest in these reactions is that the rate determining step of anilide hydrolysis is acylation, whereas that of ester hydrolysis is deacylation.[2—4] Secondly, the general acid catalysis in the acylation step has been observed only in the anilide substrate.[4] Therefore, the CD-catalyzed hydrolysis of anilide can be a means to discuss the reaction mechanism of the hydrolysis of amide compounds catalyzed by hydrolytic enzymes. In order to consider such a mechanism of the acylation of CD related to general acid catalysis, the volume changes and activation volumes (ΔV and ΔV^*) given by the pressure dependence of the rate process are useful, because a proton transfer in the general-acid catalysis is accompanied by a volume decrease of 5 cm^3/mol with one hydrogen-bonding formation[5,6] Thirdly, the difference in the reaction mechanism between meta and para substrates is reflected in the stereospecificity. It is well known that meta-substituted compounds are cleaved much faster than the corresponding para-substituted ones in the ester substrates.[2] In the anilide substrates, the reverse results have been reported.[4]

In the previous reports,[7,8] the most important difference in the stereospecific cleavage of the phenyl ester catalyzed by CDs between para- and meta-substrates has been regarded as the solvation effect; the para type is solvated, while the meta type is hardly solvated at all, in the activation state from the point of view of the ΔV^* values.

In this paper, the hydrolysis rates of pNFA catalyzed by α- and β-CDs were measured at pressures up to 2 kbar at 25 °C in order to obtain the ΔV value for the formation of the inclusion complex and the ΔV^* value for the acylation process. The difference in the reaction mechanism between an ester and an anilide is discussed in terms of the ΔV and ΔV^* values for the two kinds of substrates by comparing them with the findings of previous studies.[7,8]

† 1 M=1 mol dm^{-3}.

Experimental

Materials. The purification of the α- and β-CDs has been described previously.[7] The pNFA was synthesized from trifluoroacetic anhydride and *p*-nitroaniline and recrystallized 4 times from hexane-acetone; mp 149—150 °C (lit,[4] 150 °C). The ionized water was distilled. The acetonitrile was distilled over phosphorus pentaoxide before use.

Apparatus and Procedure. The method of measuring the rate of hydrolysis reactions under a high pressure has been described in a previous report.[9] The rate was measured at pH 6.9 in a 0.05 M Tris buffer solution up to 2 kbar at 25± 0.5 °C. The pressure dependence of the pH value is negligible, as the volume change of the dissociation process is −1 cm^3/mol.[10] By the use of a Hitachi 340-type spectrophotometer, the hydrolysis was monitored by means of the optical density at 390 nm attributable to the *p*-nitroaniline formed as a product. The initial concentrations of the cyclodextrins varied from 4.0×10^{-3} M to 2.0×10^{-2} M for α-CD and from 2.0×10^{-3} M to 1.0×10^{-2} M for β-CD respectively. The concentration of pNFA was 1.0×10^{-4} M.

Results and Discussion

At 1 bar, the apparent rate constant, k_{app} increased with an increase in the concentrations of the α- and β-CDs. The hydrolysis of pNFA catalyzed by CD has been shown by VanEtten *et al.*[2] to proceed *via* the scheme of Eq. 1, where S, P, K, and

$$\begin{array}{ccccccc} \mathrm{CD} + \mathrm{S} & \overset{K}{\rightleftharpoons} & \mathrm{CD{\cdot}S} & \xrightarrow{k_{acyl}} & \text{acyl-CD} & \xrightarrow{k_{deacyl}} & \mathrm{CD} + \mathrm{P_2} \\ \downarrow k_w & & & & + & & \\ \mathrm{P_1} + \mathrm{P_2} & & & & \mathrm{P_1} & & \end{array} \quad (1)$$

ks′ denote the anilide, the products, the binding constant, and the rate constants of each process respectively. K and k_{acyl} values at various pressures and at 25 °C, as determined by means of the Lineweaver-Burk plots[7] in Fig. 1 (pNFA, α-CD), are shown in Table 1. From the linear relations of log K and log k_{acyl} *vs.* the pressure established for each system in Figs. 2 and 3, the ΔV values for the formation of the CD complexes and ΔV^* values for the process of the product formation at 1 bar were determined to be as shown in Table 2, along with the previous data on the α-CD- and β-CD-*p*-

nitrophenyl acetate (pNPA) systems.[7]

Substrate Binding. The ΔV values in the anilide substrate, as shown in Table 2, are −3 cm³/mol for α-CD and −2 cm³/mol for β-CD; those values are slightly more negative than those of the ester substrate (0 cm³/mol for α- and β-CDs).[7] This volume difference is

probably attributable to the differences in the inclusion mechanism between the NH group of anilide and the ether oxygen atom of the ester.

The X-ray analysis[11] of the β-CD-inclusion complex of *p*-nitroaniline (pNA) as a model for the β-CD·pNFA complex has shown that the pNA molecule is wholly included in the cavity of β-CD. If the *p*-nitrophenol (pNP) part of pNPA is wholly included in the cavity of CD, the ΔV value of pNFA for the inclusion process decreases to be 2.5 cm³/mol larger than that of pNPA, because the value of 2.5 cm³/mol is the difference in the molar volumes between the NH_2 group (10.54 cm³/mol) and the OH group (8.04 cm³/mol).[12] The estimated value is in good agreement with the experimental value of the volume difference of 2 cm³/mol.

From the X-ray analysis of the α-CD-inclusion complexes of *p*-iodoaniline (pIA)[13] and pNP[14] as models for the pNFA- and pNPA-α-CD complexes, both the NH_2 group of pIA and the OH group of pNP molecules are seen to stick out from the cavity of α-CD. Since both groups exist in the aqueous media before and after the complexation, the volume differences between the NH_2 and OH groups must be cancel each other out. The difference in the electron-donating power in the NH_2 and OH groups related to the hydrogen-bonding formation may be estimated from the bond-dissociation energy of the charge-transfer (CT) complex between I_2 and an electron-donor molecule. The energy of I_2-diethyl ether as the model for the ether oxygen of pNPA is 2.1 kcal/mol,[††] and that

†† 1 cal=4.184 J.

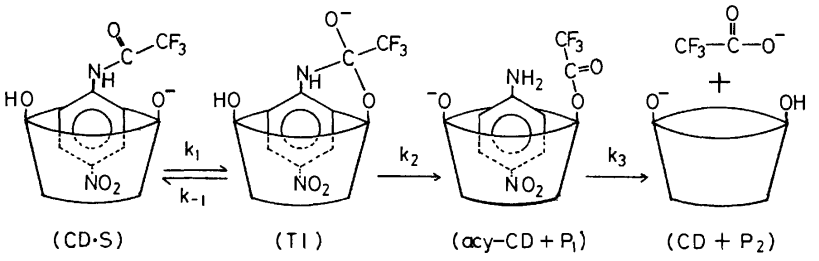

Fig. 4. Schematic drawing of the proposed reaction scheme of α-CD-catalyzed hydrolysis of pNFA after the complexation.

of I_2-*N*,*N*-dimethylaniline for the NH group of pNFA is 8.2 kcal/mol.[16] The amino nitrogen atom of the NH_2 group is more than 0.4 nm apart from any atom in α-CD.[13] After the complexation with pNFA, a hydrogen-bonding bridge among the NH group of pNFA, a water molecule, and the OH group of α-CD may be formed by the strong electron-donating power of the NH group. As the O···O distance between the water molecule and its second neighboring water molecue in an aqueous solution is approximately 0.4—0.5 nm,[15] the hydrogen-bonding system can form between the NH group of pNFA and the OH group of the α-CD through the bridge of a water molecule. Such a hydrogen-bonding system is supported by the X-ray analysis of the α-CD·pIA complex.[13] On the other hand, the ether oxygen atom of pNPA probably can not form such a hydrogn bond because of the lower power of its hydrogen-bonding formation than that of the NH group of pNFA. The volume change for a hydrogen-bonding formation is −5 cm^3/mol.[5,6] This value is in agreement with the value of −3 cm^3/mol for the volume difference between the ester and anilide substrates.

Acylation Process. The mechanism of the α-CD-catalyzed hydrolysis of pNFA after the complexation, as proposed by Komiyama and Bender,[4] is shown in Fig. 4 (Scheme 1). Here, TI is the tetrahedral intermediate produced as a result of the nucleophillic attack by the oxide ion from the secondary hydroxyl group of CD on the carbonyl carbon atom of pNFA. Then, the rate constant of the acylation step is given by Eq. 2, where $K_1=k_1/k_{-1}$:

$$k_{acyl} = K_1 \cdot k_2. \quad (2)$$

The activation volume in the acylation step is given by Eq. 3:

$$\Delta V^* = \Delta V_1 + \Delta V_2^*. \quad (3)$$

Since there is no difference in the volume change on the K_1 process between the ester and the anilide, the ΔV_1 values were estimated to be −16 cm^3/mol for α-CD and −13 cm^3/mol for β-CD in a previous report.[7] From these values and Eq. 3, we can determine that the ΔV_2^* values in the process of k_2 are −9 (=−25—(−16)) cm^3/mol for α-CD and −5(=−18—(−13)) cm^3/mol for β-CD.

From the isotope effects in the acylation step, Komiyama and Bender reported[4] that, in the breakdown of the TI (k_2 process), an un-ionized secondary hydroxyl (OH) group functions as an intracomplex general acid catalyst, either directly or *via* water molecules. From the discussion of the substrate

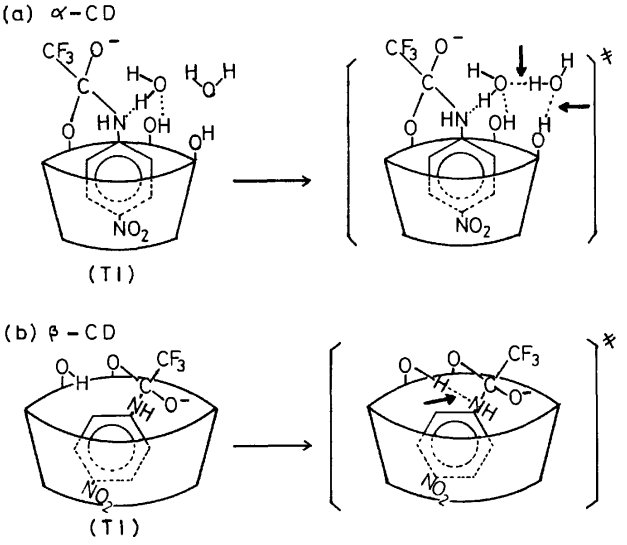

Fig. 5. Schematic drawing of the reaction mechanism of CD on the process of TI cleavage.

binding, the formation of the hydrogen-bonding bridge [(α-CD)-OH···O(H)-H···NH-(pNFA)] in the TI for α-CD has already been expected, but for β-CD, the NH group of pNFA located in the hydrophobic cavity of β-CD has already been dehydrated. If the proposed general acid catalyst functions *via* water molecules except for the hydrated water molecules, the formation of a hydrogen bond between the hydrated water molecule and the secondary water molecule can be expected to be related to the general acid catalysis on the basis of the value of −5 cm^3/mol.[5,6] The value of ΔV_2^*=−9 cm^3/mol for α-CD suggests the formation of two hydrogen bonds, while the value of −5 cm^3/mol for β-CD suggests one hydrogen bond. Following the discussion of the substrate-binding and acylation process, we can propose the reaction mechanism shown in Fig. 5 (Scheme 2). That is, an OH group of α-CD in the activation state is expected to function *via* a free (not hydrated) water molecule through the oxygen atom of a water molecule in the hydrogen-bonding system in TI. Accordingly, it is considered that two water molecules may exist between the OH group of α-CD and the NH group of pNFA. On the other hand, the OH group of β-CD functions directly as a intracomplex general acid catalyst.

We are grateful to Mr. Yoshio Yamaguchi of Ritsumeikan University for the synthesis of the anilide

and for his experimental assistance.

(Received August 31, 1983)

Proton spin-lattice relaxation times (T_1 and $T_{1\rho}$) were measured in solid and liquid phases of 2-methyl-2-nitropropane. In the lowest temperature solid phase (Phase III) a broad, asymmetric minimum in T_1 as well as a large reduction in the second moment was observed due to the coupled reorientations of methyl and *t*-butyl groups. The analyses of the T_1 and $T_{1\rho}$ in Phase III gave the activation parameters E_a=14.6±0.2 kJ mol^{-1} and τ_0=(6.45±0.10)×10^{-14} s for the methyl reorientation and E_a=15.1±0.3 kJ mol^{-1} and τ_0=(1.35±0.10)×10^{-13} s for *t*-butyl reorientation. In Phase II, the T_1 is governed by the *t*-butyl reorientation with the activation parameters E_a=15.3±0.1 kJ mol^{-1} and τ_0=(5.85±0.10)×10^{-14} s. In the low temperature region of the highest temperature plastic phase (Phase I) the molecular overall reorientation governs the T_1 and the molecular translational self-diffusion becomes the dominant relaxation mechanism near melting point. The $T_{1\rho}$ results were analyzed with the isotropic translational diffusion model and the activation parameters were determined to be E_a=46.5±0.9 kJ mol^{-1} and τ_0=(4.6±1.8)×10^{-15} s. The mean jump time of the molecule at the melting point, 6×10^{-7} s, is slightly longer than those in other plastic crystals. The activation energy for the translational diffusion is 9.7±1.5 kJ mol^{-1} in the liquid phase.

t-Butyl compounds ($(CH_3)_3CX$ (where X=Cl, Br, NO_2, and CN) are globular molecules with relatively large electric dipole moments[1,2] and they commonly exist in three solid phases which are named Phase I, Phase II, and Phase III in the decreasing order of temperature. The highest temperature phase, Phase I, of these compounds except $(CH_3)_3CCN$ is a plastic crystal. Although the unit cell of the most plastic crystals has a high symmetry like fcc, hcp, and bcc, Phase I of 2-methyl-2-nitropropane ($(CH_3)_3CNO_2$) belongs to an orthorhombic system with two molecules in the unit cell. This phase exists between the melting point (299.2 K) and 260.1 K. The intermediate phase, Phase II, that appears between 260.1 and 215.3 K and the lowest temperature phase (Phase III) below 215.3 K are both triclinic.[3] Structure and properties of solid $(CH_3)_3CNO_2$ have been studied by many experimental methods.[2-13] The molecular motions in solid $(CH_3)_3CNO_2$ were examined by dielectric measurement,[9-11] pulsed NMR method[12] and quasi-elastic neutron scattering method.[13] Mazur and Nosel[12] measured the proton T_1 at 25.5 MHz from about 150 K to the melting point and derived the activaion energy for methyl reorientation about its C_3 axis, 15.5±0.3 kJ mol^{-1}.

We measured proton magnetic resonance and relaxation (T_1 and $T_{1\rho}$) on the liquid and crystalline phases of $(CH_3)_3CNO_2$. The present paper reports its results and their interpretation in relation to the molecular motion and the phase transitions.

Experimental

2-Methyl-2-nitropropane obtained from Aldrich Chemical Co., Inc. was purified by a preparative gas chromatograph, followed by dehydration using Molecular Sieve 4A, vacuum distillation, and degassing by usual freeze-pump-thaw technique. The specimen was sealed under vacuum in a glass ampule of the outside diameter of 10 mm. The purity of the specimen was estimated to be higher than 99.87 mol per cent by a gas chromatographic analysis.

The melting point and the two transition points of this specimen were determined to be 298.7±0.3, 260.1±0.3, and 216.1±0.3 K, respectively by differential thermal analysis (DTA).

The line-shape of ^{1}H-NMR was measured as a function of temperature between 77 and 260.1 K at 12.1 MHz using a Robinson-type spectrometer. The proton relaxation times in the laboratory frame, T_1, and in the rotating frame, $T_{1\rho}$, were measured by the use of Bruker CXP 4—60 MHz pulsed NMR spectrometer. T_1 was measured at 10.0 MHz and 15.0 MHz by the saturation recovery method {$(\pi/2)_{comb}-\tau-\pi/2$ pulse sequences} for the liquid and the plastic phase (Phase I), and by the inversion recovery method ($\pi-\tau-\pi/2$ pulse sequences) for Phase II and Phase III.

The magnetization recovered exponentially in the whole temperature range of the measurements. $T_{1\rho}$ was measured at 15.0 MHz with a rotating rf magnetic field (H_1) of 7.0 and 3.0 G†† (also with H_1=2.0 and H_1=10.0 G for Phase I) by the spin-locking method. Generally, T_1 and $T_{1\rho}$ measurements were carried out between 100 K and the melting point but T_1 at 10 MHz was measured up to 320 K.

The temperature was measured with a Chromel-P/Constantan thermocouple** and was controlled to within 0.1 K.

Experimental Results and Their Analysis

Line-shape. The derivative of the proton resonance line together with its integrated line-shape in the solid phases at a few selected temperatures are shown in Fig. 1. The line-shape at 84 K corresponds to a typical three proton system in the rigid lattice indicating that rotational motion of the methyl and the *t*-butyl groups are frozen at this temperature, whereas those at 173.2 and 225.5 K show that some large amplitude motions of molecules are excited at these temperatures.

The second moment of the absorption line at each temperature was calculated, corrected for the modulation width, and given in Fig. 2. One sees in this figure that the second moment decreases sharply

†† 1 G=10^{-4} T.

** This thermocouple with its temperature scale was kindly donated by Chemical Thermodynamics Laboratory, Faculty of Science, Osaka University.

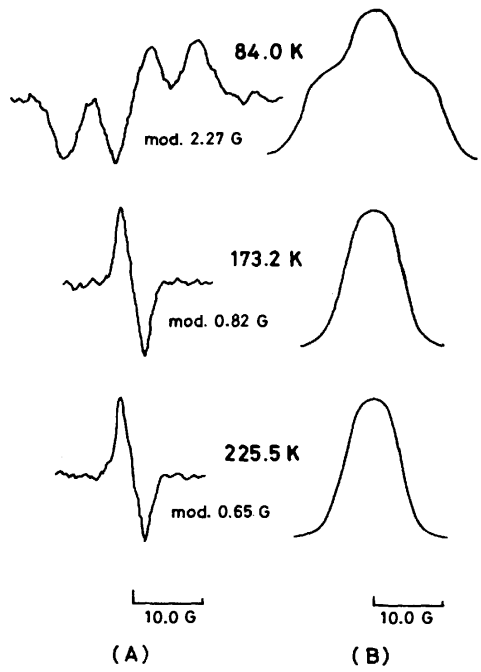

Fig. 1. Observed line shapes (A) and its integrated line shapes (B) at selected temperatures. The 'mod.' denotes modulation width of magnetic field.

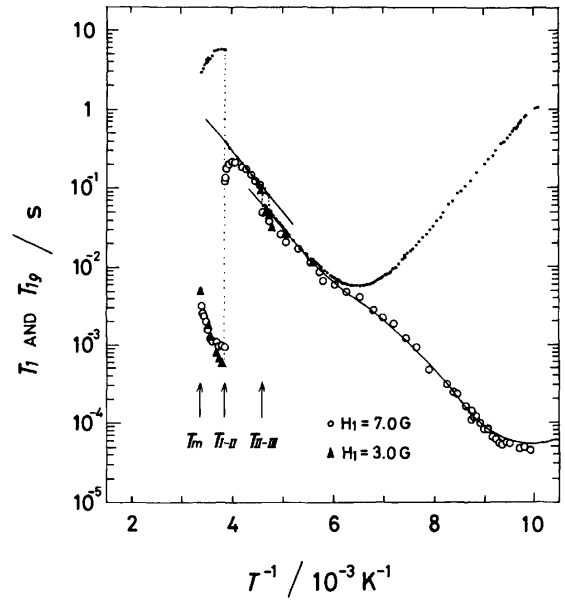

Fig. 4. Temperature dependences of the T_1(●) and the $T_{1\rho}$ at 15 MHz for rotating magnetic rf field of 7.0 G (○) and 3.0 G (▲).

between 80 and 110 K from 21 G^2 to 1.9 G^2. The intramethyl second moment calculated for a rigid lattice in a polycrystalline sample is 22.4 G^2, if the usual interproton distance, 0.178 nm, is used. The dipolar interaction between the methyl groups within one molecule contributes to the second moment by 1.8 G^2 which is based upon the tetrahedral and the staggered conformation of methyl groups in the molecule. Therefore, we obtain a value of 24.2 G^2 for the limiting low-temperature second moment without including the intermolecuar contribution.

If the methyl and the *t*-butyl groups rotate simultaneously, the intramethyl group second moment is reduced to 0.6 G^2 corresponding to the reduction factor 0.026.[14] The intermethyl second moment in one molecule becomes a quarter of 1.8 G^2. Therefore the concurrent reorientation of methyl groups about its C_3 axis and about the C_3' axis (C(Me)-C bond) causes the motional narrowing below 100 K in Phase III. Second moments of similar magnitude have been reported for a number of other compounds[15–19] containing *t*-butyl groups. Above 216 K, which is the phase transition point from Phase III to Phase II, the second moment further decreases gradually until the transition into Phase I occurs at 260.1 K, beyond which temperature the resonance line becomes narrower than the modulation width.

Spin-lattice Relaxation Times (T_2 and $T_{1\rho}$). Figure 3 shows the temperature dependence of the T_1 at 10 and 15 MHz in different phases of $(CH_3)_3CNO_2$. Discontinuities in the T_1 were observed at 298, 260, and 216 K due to the first order phase transitions. Among these discontinuities only the T_1 at the phase transition between Phase III and Phase II (216 K) showed a significant thermal hysteresis. The dielectric permitivity[9] in solid $(CH_3)_3CNO$ also showed a similar hysteresis at this phase transition.

The rotating frame relaxation times, $T_{1\rho}$, at the spin-locking field intensity (H_1) of 7.0 and 3.0 G

together with the T_1 at 15 MHz are shown in Fig. 4. Discontinuity is also seen in the $T_{1\rho}$ at each transition point.

Relaxation in Phase III: In Phase III, a broad, slightly asymmetric minimum in the T_1 was observed. The minimum value was 4.2±0.2 ms at 149.3 K and 10 MHz, and 5.6±0.2 ms at 153.8 K and 15 MHz. These values are consistent with the results by Mazur and Nosel[12] at 25.5 MHz, *i.e.* 11.5 ms at 170.9 K. As was discussed in the preceding section, we infer that the motion responsible for the relaxation in Phase III is the simultaneous excitation of the C_3- and the C_3'-rotations. In this case we obtain the expression for T_1 as follows,

$$1/T_1 = (1/T_1)_{\text{intra}} + (1/T_1)_{\text{inter}} + (1/T_1)_{\text{intermol}}, \quad (1)$$

where 'intra' and 'inter' denote intramethyl and intermethyl (intramolecular) contributions to the T_1, respectively, and 'intermol' denotes intermolecular contribution to the T_1. However, since the intermolecular contribution to the T_1 is very difficult to estimate accurately when the molecular motion involves different types of reorientations and since this contribution is expected to be small compared with other contributions, we ignore it in the following analysis. The relaxation rate for dipolar interaction within the molecule undergoing C_3- and C_3'-rotations is given by

$$(1/T_1)_{\text{intra}} = (\gamma^4\hbar^2/60r^6)\{8B(\tau_m) + 8B(\tau_M) + 19B(\tau_c)\}, \quad (2)$$

where r is the interproton distance in a methyl group, γ is the gyromagnetic ratio, τ_m and τ_M are the correlation times for C_3- and C_3'-rotations, respectively, and τ_c is defined by

$$1/\tau_c = 1/\tau_m + 1/\tau_M. \quad (3)$$

Here we used an approximation that C_3- and C_3'-rotations are mutually independent and ignored any correlation between these motions.[20,21]. The spectral density function $B(\tau)$ has the form

$$B(\tau) = \tau/(1+\omega^2\tau^2) + 4\tau/(1+4\omega^2\tau^2), \quad (4)$$

where ω is the Larmor frequency. The intermethyl contribution to the T_1 in the presence of the t-butyl reorientation is significantly large. In order to calculate this contribution, we assumed that the three protons in each methyl group reside at the center of the three proton system set. We can then calculate the relaxation rate due to the dipolar interaction between these hypothetical methyl groups as

$$(1/T_1)_{\text{inter}} = (27\,\gamma^4\hbar^2/20\,l^6)B(\tau_M), \quad (5)$$

where l is the distance between the centers of the methyl groups in a t-butyl group. The relaxation rate; $1/T_1$, is the sum of Eqs. 2 and 5;

$$1/T_1 = (2\,\gamma^4\hbar^2/15\,r^6)\{B(\tau_m) + B(\tau_M)\} + (19\,\gamma^4\hbar^2/60\,r^6)B(\tau_c) + (27\,\gamma^4\hbar^2/20\,l^6)B(\tau_M). \quad (6)$$

Under the same assumption for the molecular motion as in the calculation of T_1 we calculated the $T_{1\rho}$ in the weak collision limit[22] as

$$1/T_{1\rho} = (\gamma^4\hbar^2/15\,r^6)\{G(\tau_m) + G(\tau_M)\} + (19\,\gamma_4\hbar^2/120\,r^6)G(\tau_c) + (27\,\gamma^4\hbar^2/40\,l^6)G(\tau_M), \quad (7)$$

where $G(\tau)$ is the spectral density function,

$$G(\tau) = 5\,\tau/(1+\omega^2\tau^2) + 2\,\tau/(1+4\omega^2\tau^2) + 3\,\tau/(1+4\omega_1^2\tau^2), \quad (8)$$

and $\omega_1=\gamma H_1$.

Activation parameters for these two types of motions were obtaind by fitting the data of Fig. 3 to Eq. 7 using r=0.178 nm and l=0.310 nm, and by assuming the Arrhenius equation for the temperature dependence of the correlation time for each of C_3-rotation and C_3'-rotation,

$$\tau = \tau_0 \exp(E_a/RT),$$

where τ_0 is the pre-exponential factor and E_a the activation energy. Here we used a following assumption: The straight line portion of the T_1 curve in the temperature region below the temperature of T_1(min) is mainly governed by the methyl reorientation and T_1 on the high temperature side of the T_1(min) by the t-butyl reorientation. The activation parameters thus obtained for the methyl reorientation and the t-butyl reorientation are tabulated in Table 1 and the T_1 reproduced with these parameters is shown in Fig. 3 by the solid line. The minimum value (6.7 ms at 154 K at 15 MHz) of the theoretical T_1 is somewhat larger than that of the observed T_1. The descrepancy is due to the simple nature of our theoretical model in which cross correlation effect of methyl and t-butyl group reorientation as well as intermolecular dipolar contribution to the T_1 were ignored. The solid line in Fig. 4 is the calculated $T_{1\rho}$ using Eq. 7 and the activation parameters obtained from the analysis of the T_1, data. The theoretical $T_{1\rho}$ in Fig. 4 is in reasonable agreement with the experimental $T_{1\rho}$. The minimum value of the calculated $T_{1\rho}$ is 54 μs which occurs at 100 K.

Similarity in the activation parameters for the two motions gives the broad minimum instead of a reported double minimum of the T_1 responsible for each of these motions.

Relaxation in Phase II: The T_1 jumps from 65 ms to 95 ms at the transition point, T_{II-III}, and then increases

Table 1. Activation parameters (E_a and τ_0) obtained in this study for the various motions in $(CH_3)_3CNO_2$

	Motion	E_a/kJ mol^{-1}	τ_0/s
Phase III	Methyl reorientation	14.6±0.2	$(6.45\pm0.10)\times10^{-14}$
	t-Butyl reorientation	15.1±0.3	$(1.35\pm0.10)\times10^{-13}$
Phase II	t-Butyl reorientation	15.3±0.1	$(5.85\pm0.10)\times10^{-14}$
Phase I	Translational diffusion	46.5±0.9	$(4.6\pm1.8)\times10^{-15}$
Liquid	Translational diffusion	9.7±1.5	

monotonously in Phase II with increasing temperature as is seen in Fig. 3. The $T_{1\rho}$ shows a similar jump in T_1 at T_{II-III} but assumes a maximum value of 200 ± 20 ms at 250 K, and then decreases with increasing temperature in Phase II. The decrease in the $T_{1\rho}$ above 250 K is due to the onset of an additional mode of molecular motion, probably the overall molecular tumbling. The activation energy obtained from the slope of log T_1 against reciprocal temperature below 250 K in Phase II is 15.3 ± 0.1 kJ mol^{-1}. It agrees well with the E_a for the *t*-butyl reorientation in Phase III and gives support to the interpretation that the molecular motion governing the T_1 below 250 K is C_3'-rotation. As the change in the unit cell volume on going from Phase III to Phase II must be very small, considering the change of the second moment value (0.5 G^2), we can infer that the magnitude of intermolecular dipolar interaction does not change significantly. Hence we fitted the T_1 data in Phase II to Eq. 6 using the same E_a and the same molecular constants as in Phase III to estimate τ_0 for C_3'-rotation in Phase II. We obtained the τ_0 value of $(5.85\pm0.10)\times10^{-14}$ s which is shown in Table 1. At the transition point, T_{II-III} (216.1 K), the correlation time for the *t*-butyl reorientation is changed discontinuously from 6.1×10^{-10} s to 3.0×10^{-10} s. It is interesting to see that the rate of C_3'-rotation increases by a factor of two at the transition from Phase III to Phase II, whereas the activation energy controlling this mode does not undergo any significant change. For Phase II, a study[13] of quasi-elastic broadening in neutron scattering (QENS) led to the correlation time of about 1.6×10^{-12} s at 237 K for the 120° jump model for *t*-butyl group, which is larger than $\tau_c=1.4\times10^{-10}$ s at the same temperature deduced by using E_a and τ_0 in Table 1 by a factor of 100. It is hardly conceivable that the τ_c from NMR has such a large error since our value is consistent also with the narrowing condition. Thus, in Phase III, the *t*-butyl rotation has $\tau_c=1.0\times10^{-5}$ s at 100 K where the motional narrowing occurs. A difference by a factor of 100 means that the narrowing would occur when τ_c is as small as 10^{-7} s, which does not seem plausible. A similar discrepancy has been recognized in the solid phase of $(CH_3)_3CCl$: NMR measurements[23] reported the correlation time of the order of 10^{-8} s for *t*-butyl reorientation, whereas QENS measurements[24] reported the correlation time of the order of 10^{-12} s.

At the transition point, T_{I-II} (260.1 K), a jump in $T_{1\rho}$ by a factor of 100 and the corresponding jump in T_1 by a factor of 10 were observed as seen in Figs. 3 and 4. The correlation time of C_3'-rotation in Phase II is 6.9×10^{-11} s at T_{I-II}. This value is much smaller than that (4.3×10^{-9} s)[23] at the corresponding transition point of $(CH_3)_3CCl$. It was pointed out by Boden[25] that the correlation time of reorientational jumps between equivalent sites (*e.g.* for *t*-butyl compounds it is the C_3'-rotation.) in the ordered phase of some plastic crystals tends to converge into the value of 5×10^{-9} s at the brittle-plastic phase transition. The deviation in the case of $(CH_3)_3CNO_2$ is probably related to the non-cubic structure in its Phase I.

Relaxation in Phase I: In the plastic crystal phase, Phase I, the T_1 has a maximum which is frequency-dependent as can be seen in Fig. 3. On the low temperature side of this

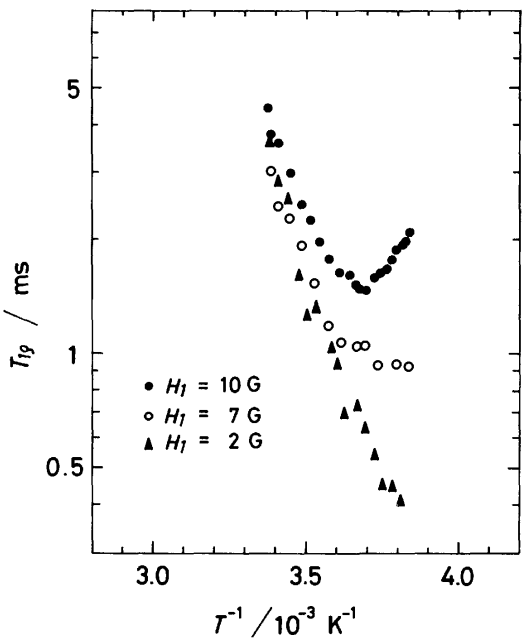

Fig. 5. Temperature dependence of the $T_{1\rho}$ (at 15 MHz) for three different rotating magnetic rf fields (H_1) in Phase I.

maximum the dominant relaxation mechanism is the overall molecular reorientation while the translational diffusion (self-diffusion) is responsible for the relaxation on the high temperature side as revealed by a study[26] of the pressure dependence of the T_1. This assignment of motion was also put forward by Mazur and Nosel.[12] When such two different relaxation mechanisms work, the experimental relaxation rate $1/T_{1\,obsd}$ can be written as

$$1/T_{1\,obsd} = 1/T_{1\,trans} + 1/T_{1\,rot}, \tag{9}$$

where $1/T_{1\,trans}$ and $1/T_{1\,rot}$ are the relaxation rate due to the translational diffusion and the overall molecular reorientation, respectively. According to Torrey's isotropic diffusion model,[27]

$$1/T_{1\,trans} = 2.67\,\gamma^2\delta\langle\Delta H^2\rangle/\omega^2\tau, \tag{10}$$

when $\omega\tau\gg1$, where τ is the mean time between successive diffusional jumps and $\delta\langle\Delta H^2\rangle$ is the change in second moment due to the translational diffusion. The activation energy for the translational diffusion was determined to be 47 ± 8 kJ mol^{-1} from the slope of the semilog plot of the $T_{1\,trans}$ against the inverse temperature. The temperature dependence of the $T_{1\rho}$ data at three different rotating rf fields is shown in Fig. 5. $T_{1\rho}$ measured at $H_1=10$ G assumes a minimum value of 1.50 ± 0.05 ms at 271 K and $T_{1\rho}$ measured at 7 G shows a less obvious minimum 0.94 ± 0.03 ms at 263 K. Isotropic diffusion model predicts that the minimum value of $T_{1\rho}$ is given by

$$1/T_{1\rho\,minimum} = 0.25\,\gamma^2\delta\langle\Delta H^2\rangle/\omega_1, \tag{11}$$

and on the high temperature side of the minimum, it is approximated by

$$1/T_{1\rho} = 0.5\,\gamma^2\delta\langle\Delta H^2\rangle\tau. \tag{12}$$

By substituting the experimental $T_{1\rho}$ minimum cited above and the appropriate value of $\omega_1=\gamma H_1$, $\delta<\Delta H^2>$ is estimated to be 1.0 ± 0.1 G^2 which agrees fairly well with the reduction of second moment 1.4 G^2 mentioned earlier. Activation parameters for the translational diffusion were determined by assuming the Arrhenius-type activation process (Eq. 8) for the correlation time τ and using $\delta<\Delta H^2>=1.0$ G^2 and are listed in Table 1. For this motion the result obtained from the $T_{1\rho}$ data is consistent with the result obtained from the T_1 data within the experimental error. The mean jump time at the melting point is about 6×10^{-7} s .

Relaxation in Liquid Phase: The T_1 in the liquid phase shows a monotonous increase on heating as shown in Fig. 3. The activation energy obtained from the slope of the T_1 was 9.7 ± 1.5 kJ mol^{-1} due to the translational motion (self-diffusion). Our result agreed with the result[7] of NMR spin echo method for the self-diffusion ($E_a=10.8$ kJ mol^{-1}) in the liquid phase of $(CH_3)_3CNO_2$.

Discussion

The result of analysis of the nuclear magnetic relaxation is summarized in Table 1. In Phase II, the relaxation due probably to the overall molecular tumbling is also seen although it was not possible to derive a value of its activation energy. Whether or not the *t*-butyl reorientation is accompanied by the reorientation of the NO_2 group was difficult to determine by experiment.

The large electric dipole moment (12.35 C m) is responsible for the unique properties of 2-methyl-2-nitropropane among *t*-butyl compounds which form a plastic phase. The fact that the Phase I is not of cubic symmetry indicates that the molecular reorientation in this phase is not rapid enough to eliminate the effect of anisotropy of intermolecular forces.

Such an anisotropy in molecular interaction is even more prominent in Phase II, where the structure is reported to be triclinic.[3] If the NO_2 group is also reorienting or even the molecule undergoes reorientation about its C_3 axis very vigorously, the molecule would assume on the average a cylindrical symmetry which would in turn lead to a crystal structure of higher symmetry.

These properties are probably related to the small value of the correlation time for *t*-butyl reorientation at T_{I-II} as compared with many other plastic crystals. In other words, the molecular motion in 2-methyl-2-nitropropane is not as rapid as one would expect for a typical plastic crystal and as a result the lattice is a little harder.

The change in NMR properties at the III—II transition is much smaller than that at the II—I transition although the corresponding entropy changes are comparable (2.36*R* and 2.16*R*, respectively). The packing factor change is greater at T_{III-II} than at T_{II-I}.[11] To rationalize all these behaviors and even the existence of Phase II requires more elaborate studies including detailed crystal structures of all the solid phases.

(Received Februaty 21, 1983)

The arsenite transesterification reaction $As(OCH_3)_3 + HOR \rightleftharpoons As(OCH_3)_2OR + HOCH_3$ (with R equaling benzyl and *t*-butyl) has been studied in acetonitrile solvent. With benzyl alcohol, K, $\Delta H°$, and $\Delta S°$ are 3.6 (25 °C), 5.0 kJ mol^{-1} and 27 J mol^{-1} K^{-1} respectively; with *t*-butyl alcohol, the values are 0.36 (25 °C), 4.0 kJ mol^{-1}, and 5 J mol^{-1} K^{-1} respectively. The rate law for the approach to equilibrium in the case of benzyl alcohol is:

$$\frac{-d[As(OCH_3)_3]}{dt} = k_f'[As(OCH_3)_3][HOCH_2Ph]^2 - k_r'[As(OCH_3)_2(OCH_2Ph)][HOCH_3][HOCH_2Ph].$$

A mechanism which explains the unusual law has been postulated. The slower *t*-butyl alcohol reaction proceeds by a different mechanism which apparently involves catalysis by small amounts of water in the solvent. The steric effects are very significant.

Arsenious acid $As(OH)_3$ and related arsenic(III) compounds are potent inhibitors of enzymes which have a mercaptan function near the active site. Thus, understanding the rates and equilibria of these arsenic compounds is important.

A few studies of replacement rates in arsenic(III) compounds have been carried out. These include an ^{17}ONMR line-broadening investigation of the exchange between arsenite ions and water[1] and a quantitative study of the hydrolysis of arsenite triesters.[2] In both instances, the rates were too fast for classical rate techniques. Some less definitive studies of the glycol complexing of arsenite ions,[3] of the arsenite catalysis of arsenate-oxygen exchange with water,[4] and 2-mercaptoethanol complexing of arsenite ions[5] gave results also indicating rapid replacement in the arsenic coordination sphere.

In the present work, data on the arsenite transesterification reaction:

$$As(OCH_3)_3 + HOR \rightleftharpoons As(OCH_3)_2(OR) + HOCH_3, \quad (1)$$

with R equaling benzyl and *t*-butyl, have been obtained. With benzyl alcohol, the rates have been found to be rapid; on the other hand, with *t*-butyl alcohol, the reactions are much slower. The mechanisms are strikingly different.

Experimental

Chemicals. Trimethyl arsenite, also known as trimethoxyarsine, $As(OCH_3)_3$, was prepared by two methods,[6,7] both of which were found satisfactory. $AsCl_3$ (Aldrich, ultrapure) was used as obtained. All the other materials for the preparations (ether, hexane, triethylamine, and methanol) were dried according to standard procedures.[8] The product was characterized by NMR and chloride-ion analysis to see if any side products such as $As(OCH_3)_2Cl$ were present. The $As(OCH_3)_3$ was found to be at least 99.993% pure.

Benzyl alcohol and *t*-butyl alcohol were dried by the usual methods.[8] Acetonitrile, which was employed as the reaction solvent, was normally distilled twice from P_2O_5; drying is important because any significant amount of water in acetonitrile will cause cloudiness or turbidity when the arsenite ester is dissolved. In some experiments, we used acetonitrile vigorously dried by the following procedure: 1) The acetonitrile was distilled. 2) It was then stirred with P_2O_5 (about 0.04 g per 10 g of CH_3CN). 3) It was redistilled, collected over 4 Å Molecular Sieves (which had been previously dried by heating in a vacuum oven), and shaken occasionally for 2 h. 4) It was again distilled, and then stored over Molecular Sieves. The dried solvent was taken up just before use by means of a Pasteur pipet with a glass-wool filter.

Equipment. For the benzyl alcohol kinetic runs, a Bruker WP60 FT NMR apparatus was coupled to a specially constructed stopped-flow apparatus based on the design of Couch *et al.*[9] The glass tips of the syringes were constructed so that the two solutions were fed directly into the NMR tube. The equilibrium data and kinetic results for the slower *t*-butyl alcohol runs were obtained with the Bruker instrument or with a Varian EM-360 NMR apparatus.

Reaction Analyses. The concentration of the reactant and product species were determined by measuring their NMR peak heights and by comparing them with the known initial concentration of trimethyl arsenite. These peak heights correlated well with the integrated areas, and mass balance was also tested.

Results

Proton NMR. For both equilibrium and rate experiments, the analysis were based on the proton-NMR-line intensities. The chemical-shift assignments in acetonitrile are as follows: $C\underline{H}_3OH$, 3.31 ppm; $(C\underline{H}_3O)_3As$ and $(C\underline{H}_3O)_2AsOCH_2Ph$, both 3.53±0.03 as one line; $PhC\underline{H}_2OH$, 4.59 ppm; $PhC\underline{H}_2OAs(OCH_3)_2$, 4.87 ppm; $C_6\underline{H}_5CH_2OH$, 7.35 ppm; $(C\underline{H}_3)_3COH$, 1.19 ppm; and $(C\underline{H}_3)_3COAs(OCH_3)_2$, 1.37 ppm.

Equilibria. The transesterification reaction, Eq. 1, proceeds rapidly to a convenient degree when trimethyl arsenite and the alcohol are in the concentration range from 1 to 3 M.†

Some results for the benzyl-alcohol reaction are given in Table 1. At 25 °C, the average value or K from these data is 3.59±0.08 (standard deviation), while from the results in Table 3 it is 3.49±0.04. The temperature dependence of K gives $\Delta H°=5.0\pm0.3$ kJ mol^{-1} and $\Delta S°=27\pm1$ J mol^{-1} K^{-1}. It is important to mention that the evidence for the formation of some $(PhCH_2O)_2As(OCH_3)$ was indicated by a significant increase in the apparent binding constant when there was an excess of benzyl alcohol, therefore, all of the present results are given for the condition, $[PhCH_2OH]_0<[As(OCH_3)_3]_0$ so as to minimize this complication.

Some results with t-butyl alcohol are presented in Table 2. The average of the first three values of K therein is 0.364±0.010. Under the kinetics conditions (see below), the observed value was 0.29±0.03. The thermodynamic quantities based on the Table 2 data are $\Delta H°=4.0\pm0.4$ kJ mol^{-1} and $\Delta S°=5.2\pm1.1$ J mol^{-1} K^{-1}. From the equilibrium constant based on the kinetic data in Table 5, the values of $\Delta H°$ and $\Delta S°$ were found to be 4.2±0.5 kJ mol^{-1} and 6±2 J mol^{-1} K^{-1} respectively; these values are considered somewhat less accurate than those based on the Table 2 data.

Kinetics with Benzyl Alcohol. The stoichiometry of the reaction may be represented as:

$$A + B \underset{k_r}{\overset{k_f}{\rightleftharpoons}} 2C \qquad (2)$$

with C standing for each product (since they are present in equal concentrations). For purposes of calculation and plotting, it is initially assumed that the orders match the stoichiometry; this assumption can be checked in order to obtain the correct rate law. Thus, the tentative law;

$$\frac{-d[A]}{dt} = k_f[A][B] - k_r[C]^2 \qquad (3)$$

is employed. This is converted to the integrated form:

$$\frac{1}{Q}\ln\left\{\frac{([A]_0-[A]_e)([A]-[A]_e+Q)}{([A]-[A]_e)([A]_0-[A]_e+Q)}\right\} = (k_f-k_r)t, \qquad (4)$$

where $Q=[1/(K-1)]\{K^2([B]_0-[A]_0)^2+4[A]_0[B]_0K\}^{1/2}$, where the subscripts 0 and e designate the initial and equilibrium states, and where K is obtained for each run separately. If the left-hand side is plotted *versus* the time t, (k_f-k_r) is obtained from the slope; with $K=k_f/k_r$ on the basis of microscopic reversibility, k_f and k_r can be evaluated.

Table 2. Equilibrium constants with t-butyl alcohol

t/°C	$[As(OCH_3)_3]_0$/M	$[HOC(CH_3)_3]_0$/M	K
25	3.10	1.65	0.362

66	2.82	2.74	0.448

† 1 M=1 mol dm^{-3}.

As may be seen in Fig. 1a, the plots are linear, with the results from experiments at variable concentrations given in Table 3. The values of k_f and k_r at variable $[As(OCH_3)_3]$ and constant $[PhCH_2OH]$ are essentially constant. On the other hand, when the benzyl alcohol concentration is varied, k_f and k_r both increase in proportion to the concentration; this indicates that the true order is larger by one than the assumed order. Furthermore, the fact the rate plots shown in Fig. 1a are linear over the measured course of reaction suggests that both forward and reverse reactions involve the initial concentration of benzyl alcohol, $[PhCH_2OH]_0$, which may be equated the total alcohol concentration at any time t, $\{[PhCH_2OH]_t+[CH_3OH]_t\}$.

Employing the corrected rate law consistent with the observed results:

$$\frac{-d[As(OCH_3)_3]}{dt} = k_1[As(OCH_3)_3][HOCH_2Ph][HOCH_2Ph]_0 - k_2[As(OCH_3)_2(OCH_2Ph)][HOCH_3][HOCH_2Ph]_0, \qquad (5)$$

and the preliminary data in Table 3, the average values of k_1 and k_2 obtained are 0.349±0.008 M^{-2} s^{-1} and 0.100±0.002 M^{-2} s^{-1}. The values of k_1 and k_2 are calculated by using the relations, $k_1=k_f/[HOCH_2Ph]_0$

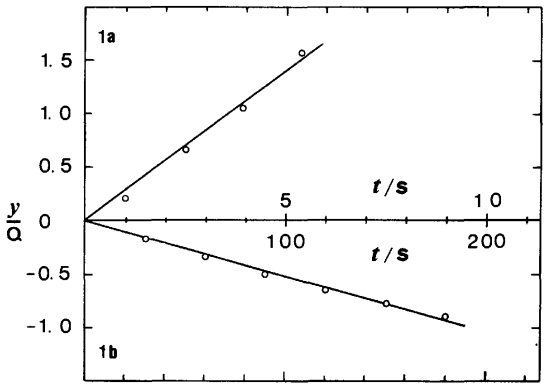

Fig. 1. Rate plots for arsenite transesterification reactions with (a) $[As(OCH_3)_3]=2.02$ M, $[HOCH_2Ph]=1.16$ M, and (b) $[As(OCH_3)_3]=1.69$ M, $[HOC(CH_3)_3]=1.07$ M. The ordinate is the left side of Eq. 4.

1.25	1.07	1.95	7.11	0.28	2.09	7.61

a) At 25 °C in acetonitrile. b) $K=k_f/k_r$. c) $k_3=k_f[HOC(CH_3)_3]_0$. d) $k_4=k_r[HOC(CH_3)_3]_0$.

and $k_2=k_r/[HOCH_2Ph]_0$ respectively.

It was not possible to obtain the activation parameters because the stopped-flow injector did not have a temperature-control attachment.

The catalysis of the transesterification reaction is important. 1-Pentanethiol, *p*-toluenesulfonic acid, and 2,4-dimethylpyridine, all at concentrations near 10^{-2} M, accelerated the reaction to such an extent that equilibrium was reached in times comparable to or less than the time necessary for getting the first data point.

Kinetics with t-*Butyl Alcohol.* It is possible to treat the initial rate data for this alcohol in a manner (*i.e.*, Eq. 4) identical with that used for benzyl alcohol. However, the slope is now negative (as would be expected for $K<1$), and the alcohol concentration effect on the slope was in the opposite direction.

A typical plot is shown in Fig. 1b, and the data are presented in Table 4. As the *t*-butyl alcohol concentration increased, the preliminary rate constants decreased. This change in the rate constant indicates that the order assumed in the derivation is too large; these constants vary in such a manner as to indicate that the correct order in *t*-butyl alcohol is zero. This surprising conclusion can be visualized in the plots of the concentration of the product against the time shown in Fig. 2. The initial slopes must be essentially identical because the 30-second points for all three alcohol concentrations are the same, within the limits of experimental error.

The recalculation of the k_f and k_r data in Table 4 on the basis of the corrected rate law:

$$\frac{-d[As(OCH_3)_3]}{dt} = k_3\frac{[As(OCH_3)_3][HOC(CH_3)_3]}{[HOC(CH_3)_3]_0} - k_4\frac{[As(OCH_3)_2(OC(CH_3)_3][HOCH_3]}{[HOC(CH_3)_3]_0} \quad (6)$$

was then carried out. The two constants, k_3 and k_4, from Table 4 have values of $(2.20\pm0.22)\times10^{-3}$ s^{-1} and $(7.59\pm0.10)\times10^{-3}$ s^{-1} respectively.

The rates for the *t*-butyl alcohol reaction were measured at five temperatures from 30 to 60 °C; these are given in Table 5. The values of ΔH^* and ΔS^* for k_3 are 15 ± 1 kJ mol^{-1} and -253 ± 4 J mol^{-1} K^{-1}; for k_4, the corresponding numbers are 10 ± 1 kJ mol^{-1} and -258 ± 5 J mol^{-1} K^{-1} respectively.

Table 5. Dependence of *t*-butyl alcohol rate constant on temperature[a)]

t/°C	10^3k_3/s^{-1}	10^3k_4/s^{-1}	K[b)]
30.0	1.20	3.24	0.369
36.5	1.41	3.59	0.392
45.0	1.77	4.45	0.397
53.0	1.98	4.78	0.414
61.0	2.25	5.15	0.438

a) In acetonitrile, $[As(OCH_3)_3]=2.025$ M, and $[HOC(CH_3)_3]=1.073$ M. b) $K=k_3/k_4$.

The *t*-butyl alcohol reaction with $As(OCH_3)_3$ was found not to be catalyzed by 2,4-dimethylpyridine, *p*-toluenesulfonic acid, or 1-pentanethiol.

The rate law (Eq. 6) in the forward direction shows a dependence on only a single species: this might suggest a unimolecular reaction. However, the activation parameters give evidence that such a suggestion can not be correct. A low ΔH^* value and a very negative ΔS^* value can only be explained if considerable bond formation between several species is taking place in the transition state and in equilibria prior to the transition state. A further piece of evidence that other species are present in the transition state is the slight difference in rate constants in Tables 4 and 5, the data for which were obtained using different batches of a solvent. It seems possible that the rate-limiting step in the transesterification reaction was the reaction of $As(OCH_3)_3$ with a trace amount of water in the acetonitrile. This hypothesis was tested by treating the solvent so as to dry it beyond the normal purification procedure. The rate decreased greatly, by about three powers of ten; the resulting halftime was about one week at room temperature. Because of other complications, however, the further study of this very slow transesterification was not possible.

Discussion

General. From prior arsenite-rate studies,[1-5] it

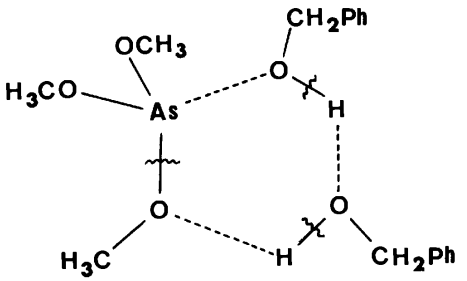
was expected that the transesterification reaction would be rapid, with a cleavage of the arsenic-oxygen bond. The observed rates with benzyl alcohol are indeed rapid, although slightly slower than the oxygen-exchange process[1] and the ester hydrolysis.[2] Low values of $\Delta H^{\ddagger}$ and negative values of $\Delta S^{\ddagger}$ are found for all three reactions; presumably this is a characteristic of replacements in the arsenite-coordination sphere.

Equilibria. The K value found for benzyl alcohol is 3.6. This can be converted (using the appropriate statistical factor of 3) to the corrected value of 1.2. The reaction is slightly endothermic (5.0 kJ mol^{-1}). The entropy is (after correction for the statistical factor) $+18$ J mol^{-1} K^{-1}.

For t-butyl alcohol, the value of K is near 0.3; after statistical correction, it is 0.1. An enthalpy (4.0 kJ mol^{-1}) comparable to the case of benzyl alcohol was found. The decrease of a power of ten in the equilibrium constant shows up as a lower entropy ($\Delta S°=+5$ J mol^{-1} K^{-1}; after correction, -4).

The difference in the equilibrium constants can be traced completely to the entropy contribution. It seems probable that As–O free rotations, which are probably active in $As(OCH_3)_3$, may be shut down in $As(OCH_3)_2OC(CH_3)_3$ because of the large t-butyl group. For one carbon-carbon free rotation, the entropy contribution is about 16 J mol^{-1} K^{-1};[10] even if the rotation about the arsenic-oxygen bond is less important, three such rotations could easily be sufficiently active to explain a loss of 22 J mol^{-1} K^{-1}.

Kinetics with Benzyl Alcohol. The rate of this transesterification was rapid as expected; on the other hand, the rate law was somewhat of a surprise. Nevertheless, it is readily explicable in terms of a mechanism. The second benzyl alcohol molecule is presumably present in order to accomplish the necessary proton transfer (without an energy-costly charge-separation process) in a transition state of this type:



The dashed lines indicate bonds being formed; bonds being cleaved are denoted by a bond line crossed by a wavy line. A recent study of the arsenate ester/alcohol transesterification reaction indicated hydrogen-bonding, and a transition state similar to the above had to be considered.[11]

The energetic basis for additional (over stoichiometry) molecules has been discussed in some detail in relation to the peroxide oxidation of neutral nucleophiles.[12] Two examples of reactions which are catalyzed by extra protic molecules and involve proton transfer in the transition state are the oxidation of dialkyl sulfides by hydrogen peroxide[13] and the hydration of carbonyl compounds in mixed solvents.[14]

In the present case, at least two proton transfers are involved; these could take place synchronously or in a stepwise fashion. One arsenic-oxygen bond is being broken, while another is being formed, at essentially the same time. Since the rate plots as shown in Fig. 1a are linear over the measured course of the reaction, it appears that benzyl alcohol and methanol have similar proton-transrer capabilities.

Kinetics with t-Butyl Alcohol. For this alcohol, the half-time for the reaction is about one power of ten longer (in a normally purified solvent) than for benzyl alcohol; this slower rate makes it possible to follow the process using normal NMR line-intensity techniques. Now, however, the initial rate is independent of the entering alcohol concentration, and the experimental rate law given in Eq. 6 which was found to give a quantitative fit of the data most certainly cannot be complete. The activation parameters show that other particles must be present in the transition state, and evidence has been presented that the trace of water in the acetonitrile solvent acts as a catalyst. This leads to the following mechanism:

$$As(OCH_3)_3 + H_2O \underset{k_2'}{\overset{k_1'}{\rightleftharpoons}} As(OCH_3)_2OH + HOCH_3,$$

$$As(OCH_3)_2OH + HOC(CH_3)_3 \underset{k_4'}{\overset{k_3'}{\rightleftharpoons}} As(OCH_3)_2OC(CH_3)_3 + H_2O. \quad (7)$$

The steady-state rate law derived from Eq. 7 is:

$$-\frac{d[As(OCH_3)_3]}{dt} = k_1'[H_2O][As(OCH_3)_3]R/(1+R) - k_4'[H_2O][As(OCH_3)_2OC(CH_3)_3]/(1+R), \quad (8)$$

where $R=k_3'[HOC(CH_3)_3]/k_2'[HOCH_3]$. Equation 8 reduces to Eq. 6 if $R \gg 1$ to give $k_3=k_1'[H_2O]$ and $k_4=k_2'k_4'[H_2O]/k_3'$.

The fit to Eq. 6 was, in fact, not perfect (notice the slight curvature of the points in Fig. 1b). A three-parameter fit to Eq. 8 is considerably better. The results of a nonlinear least-squares fit are:[15] $k_1'[H_2O]=3.5\times10^{-3}$ s^{-1}, $k_4'[H_2O]=1.5\times10^{-3}$ s^{-1} and $k_3'/k_2'=0.15$. Since k_1' is just the rate constant for hydrolysis, we can use the known value, 4.4 M^{-1} s^{-1},[2] to obtain an estimate of the water concentration in the acetonitrile solvent, 8×10^{-4} M, which is not an unreasonable value.

For this transesterification study, t-butyl alcohol was chosen because the bulk of the large alkyl group was expected to bring about interesting effects; such turned out to be the case. Compared to the benzyl-alcohol results, the K value is very low and this is reflected in the fact that k_4 is larger than k_3. The binding difference of a factor of ten is due wholly to the lower value of ΔS, and this may be related to the loss of internal rotations in the product, the mixed ester.

The direct reaction of t-butyl alcohol with trimethyl arsenite is exceedingly slow, if it occurs at all, and this allows the entry of a mechanism which seems to be based on catalysis by very small concentrations of water in the solvent. Finally, the discrimination constant, k_3'/k_2', reflects the fact that t-butyl alcohol (in spite of

its probably larger nucleophilicity) is larger than the competing methanol.

(Received May 23, 1983)

A highly selective solvent extraction and spectrophotometric determination of copper and/or silver is proposed; it is based on the extraction of the ion-pair formed by the copper(I)- or silver(I)-thiocrown ether complex cation and the appropriate dye anion. A comparative study of Bromocresol Green (BCG), Thymol Blue (TB), and picrate ions as the pairing ions for the extraction of copper using a 1,4,8,11-tetrathiacyclotetradecane (TTCT) solution of 1,2-dichloroethane is described. The use of BCG gave the highest sensitivity among these three kinds of anions and made it possible to determine copper in the range of 0.6—3.2 $\mu g\,ml^{-1}$. The interferences of six kinds of cations and four kinds of anions were examined; only Ni^{2+} and ClO_4^- interfered, and they slightly. The separation by the extraction of silver and/or copper with TTCT solution of 1,2-dichloroethane from an aqueous solution containing seven kinds of metal ions (Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, and Ag^+) in the presence of picrate ion (Pic^-) was also examined. Silver was first extracted quantitatively as the ion-pair compound, $[Ag(ttct)_2]^+Pic^-$, and then copper as $[Cu(ttct)]^+Pic^-$ after having been reduced to copper(I). The absorption maximum of both extracted species lies at 378 nm (ε: 1.8×10^4), and the spectrophotometric determination of these metals is possible. This method was successfully applied to the determination of copper and silver in standard samples of steel.

Although the solvent extraction of alkali metals using crown-ether compounds has been widely studied,[1-7] there have been few studies of metals using thiocrown ether compounds.[8-10] We tried to examine the solvent extraction of various metal ions with TTCT, which is a typical thiocrown ether.[11] Consequently, it was found that the Class *b* metals classified by Ahrland,[12] in particular copper(I) and silver(I), are extracted; on the other hand, the Class *a* metals are not extracted at all, and the Class *ab* metals are practically not extracted at all.

In the present study, the extraction-spectrophotometric determination of copper and silver using TTCT as the ligand, the dye anion(BCG or picrate) as the pairing anion, and 1,2-dichoroethane as the extracting solvent, was examined. Therefore, it was confirmed that TTCT is a useful selective reagent to separate the Class *b* metals, especially copper and silver, from other metals. It was also found that the use of the dye anion makes the spectrophotometric determination of copper and/or silver possible. Hitherto,such reagents as neocuproine, diethyldithiocarbamic acid (DDTC), and dithizone for copper and those such as *p*-dimethylaminobenzidinerhodanine and dithizone for silver have usually been employed as the spectrophotometric reagents in the routine analysis of these metals. By comparing the proposed method with conventional methods, it was found that the proposed method is more sensitive than the neocuproine method and more selective than the DDTC and dithizone methods for copper, and is more reproducible than the *p*-dimethylaminobenzidinerhodanine method and more selective than the dithizone method for silver.

Experimental

Reagents. The TTCT was synthesized by the method described by Rosen and Bush[13] and recrystallized three times from ethanol. A 5×10^{-5} M (1 M=1 mol dm^{-3}) TTCT 1,2-dichloroethane solution was prepared; it was stable for a week at least. After we had prepared the 1×10^{-2} M copper(II) and silver(I) sulfate solutions, we determined their concentrations by EDTA titration and by potentiometric titration with sodium chloride respectively. The 1,2-dichloroethane was shaken three times with 2 M potassium hydroxide and then with distilled water. After drying with calcium chloride anhydride, it was distilled. The other reagents used were of analytical-reagent grade.

Apparatus. A Taiyo M incubator was used for shaking a 50-ml glass cylindrical tube equipped with a glass stopper. An Iwaki KM-shaker was used for shaking a 100-ml separatory funnel. A Seiko SAS-725 atomic absorption spectrophotometer was used for the determination of the copper and silver concentrations. The absorption spectra were measured with a Hitachi 124 double-beam spectrophotometer and a Shimadzu UV-240 self-recording spectrophotometer. The pH of the aqueous phase was measured with a Hitachi-Horiba H-5 PH meter.

Solvent Extraction of Copper(I). An aqueous solution containing 5×10^{-5} M copper(II) sulfate, the 5×10^{-5} M dye anion(BCG, TB or picrate), a 1×10^{-2} M buffer, and 0.1 M hydroxylammonium sulfate was prepared; its ionic strength was kept at 0.1 with sodium sulfate. The buffer solutions were prepared with acetic acid–sodium acetate in the weak acidic region and sodium tetraborate and sodium hydroxide in the weak basic region. Ten ml of this aqueous solution was placed in a 50-ml glass cylindrical tube equipped with a glass stopper. After the addition of 10 ml of the 5×10^{-3} M TTCT solution of 1,2-dichloroethane, the mixture was shaken for 30 min at 200 strokes/min at 25±0.1 °C and then centrifuged for 5 min at 2000 min^{-1}. The absorption spectra of the 1,2-dichloroethane phase were measured against a reagent blank in the range from 250 to 550 nm. The pH of the aqueous phase was measured, and the copper concentration of the aqueous phase was measured by means of atomic-absorption spectrophotometry. The copper concentration of the 1,2-dichloroethane phase was determined as follows: a five ml portion of the organic phase was placed in a beaker and allowed to evaporate. The residue was dissolved in concentrated nitric acid and diluted to 25 ml or 10 ml with water. The copper concentration was determined by means of atomic-absorption spectrophotometry.

Separation of Silver and Copper from a Mixed Solution Containing Various Metal Ions. An aqueous solution

containing various metal ions(Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, and Ag^{+}), a picrate (1×10^{-3} M), and an acetic acid-sodium acetate buffer (1×10^{-2}M, pH 5.4) was prepared. Ten ml of this aqueous solution was introduced into a 50-ml glass cylindrical tube equipped with a glass stopper, and then 10 ml of the 5×10^{-3} M TTCT solution of 1,2-dichloroethane was added. The mixture was shaken for 30 min at 200 strokes/min at 25±0.1 °C and then centrifuged for 5 min at 2000 min^{-1}. A 5 ml portion of the aqueous phase was introduced into a 50-ml glass cylindrical tube equipped with a glass stopper, and then 5-ml of an aqueous solution containing 0.2 M hydroxylammonium sulfate,the 1×10^{-3} M picrate, and the 1×10^{-2} M acetic acid-sodium acetate buffer were added. After the addition of 10 ml of the 5×10^{-3} M TTCT solution of 1,2-dichloroethane, the mixture was shaken for 30 min at 200 strokes/min at 25±0.1 °C and then centrifuged for 5 min at 2000 min^{-1}. All the metals were determined by means of atomic-absorption spectrophotometry. The concentration of the metal ion in the organic phase was determined as has been described above.

Preparation of a Standard Sample Solution of Steel. A standard sample of steel (0.1 g) was dissolved in 20 ml of (1+4) nitric acid by heating. After the addition of 10 ml of (1+9) sulfuric acid, the solution was heated gently until fumes of sulfuric acid had been evolved. The residue was cooled to room temperature, and then the walls of the beaker were washed with a small portion of water. After the addition of several drops of a hydrogen-peroxide solution (30%), the solution was heated gently until fumes of sulfuric acid had been evolved. The residue was cooled and then dissolved in water. Finally the solution was diluted to 100 ml with water.

Recommended Procedure for the Determination of Copper and Silver. (I) Determination of Copper in a Standard Sample of Steel in the Absence of Silver: Pipette an aliquot of a sample solution containing up to 32 μg of copper(II) into a 100-ml separatory funnel. Add 5 ml of 1 M hydroxylammonium sulfate and 5 ml of a 1×10^{-2} M picric acid or 2.5×10^{-3} M BCG solution. Adjust the pH in the range of pH 4—5 with a 1.5 M sodium acetate solution, and then dilute with water to 50 ml. After the addition of 10 ml of the TTCT solution of 1,2-dichloroethane, shake for 10 min. Allow it to stand and the layers to separate, and then place the yellow extract in a 1-cm cell. Measure the absorbance at 378 nm for picrate or at 408 nm for BCG against the reagent blank as the reference solution.

(II) Determination of Silver and Copper in a Standard Sample of Steel in the Presence of Silver and Copper: Pipette an aliquot of a sample solution containing up to 54 μg of silver(I) into a 100-ml separatory funnel. Add 5 ml of 1×10^{-2} M picric acid, and then adjust the pH in the range of pH 4—6 with 1.5 M sodium acetate. Dilute it with water to 50 ml, and then shake with 10 ml of the TTCT solution of 1,2-dichloroethane for 10 min. Allow it to stand and the layers to separate, and then place the yellow extract in a 1-cm cell. Measure the absorbance at 378 nm against the reagent blank. Pipette an aliquot of the aqueous phase containing up to 32 μg of copper(II) into a 100-ml separatory funnel. Finally, add 5 ml of 1 M hydroxylammonium sulfate and the 1×10^{-2} M picric acid solution to make a 1×10^{-3} M. The subsequent procedure was the same as that used for the determination of copper in a standard sample of steel in the absence of silver.

Results and Discussion

Extraction Behavior of Copper(I) with TTCT in the Presence of BCG, TB, or Picrate. The extraction of copper(I) with TTCT from the aqueous solution in the presence of BCG, TB, or picrate ions into 1,2-dichloroethane was examined in the pH range from 3—8. Plots of the logarithm of the distribution ratio of copper(I) (log D) *vs.* the pH of the aqueous solution are shown in Fig. 1. For the extraction of copper(I) in the presence of BCG, TB, or picrate ions, almost the same pH dependence was observed. Each extractability is kept constant at a value of more than 99% (log D>2) in the pH range from 4 to 6, but it decreases with the decrease in pH value below 4 and with the increase above 6. It is considered that the decrease in the extraction on the acidic side is due to the decrease in the amount of copper(I), accompanied by the decrease in the reducing power of hydroxylammonium sulfate; on the other hand, the decrease in the extraction on the basic side is considered to be due to the hydrolysis of copper(I).

It was found in the previous study[11] that copper(I) was extracted with TTCT into organic solvents by forming an ion-pair compound, $[Cu(ttct)]^{+}Pic^{-}$, in the presence of picrate. In the present study, the composition of the extracted species in the presence of BCG or TB was checked. The logarithmic plot of the distribution ratio of copper(I) *vs.* the concentration of TB in the aqueous phase, which was determined by means of the absorbance at 431 nm, is shown in Fig. 2.

-○-; $[Cu^{+}]_i=5\times10^{-5}$M, $[BCG]_i=5\times10^{-4}$M. -●-; $[Cu^{+}]_i=5\times10^{-5}$M, $[TB]_i=5\times10^{-4}$M. -Φ-; $[Cu^{+}]_i=5\times10^{-5}$M, $[Pic]_i=5\times10^{-4}$M. -◑-; $[Cu^{2+}]_i=5\times10^{-5}$M, $[BCG]_i=5\times10^{-4}$M.

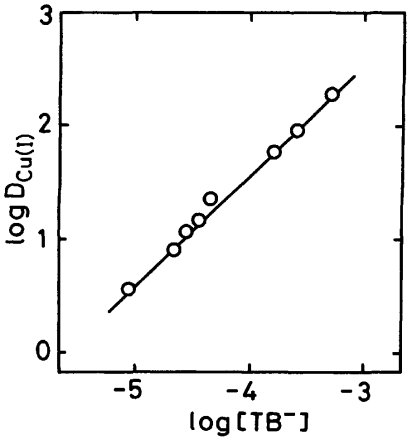

Fig. 2. Plot of log $D_{Cu(I)}$ *vs.* log $[TB^{-}]$. pH 4.5. Initial concentration; copper(I): 5×10^{-5}M, TTCT: 5×10^{-3}M.

The straight line with the slope of +1 thus obtained, indicates the 1 : 1 ratio of copper to TB. The molar ratio of copper to BCG was examined by the continuous-variation method; the results are shown in Fig. 3. As may be seen in Fig. 3, the maximum absorbance is found at the 1 : 1 molar ratio of copper to BCG. These results suggest that the species extracted into 1,2-dichloroethane are $[Cu(ttct)]^+A^-$, where A^- is the TB or BCG anion.

Absorption Spectra. The absorption spectra of the organic extracts, as measured against a reagent blank, are shown in Fig. 4. It was found that the absorption maxima lie at 408, 391,and 378 nm for BCG, TB, and picrate ions respectively. BCG exhibited the maximum absorbance among these three kinds of pairing ions. Although the extracted complexes are stable, the absorbance of the organic phase was measured within 4 h after the extraction.

Effect of pH. The effect of the pH of the aqueous phase was also examined. Plots of the absorbance at the maximum wavelength of the organic phase *vs.* the pH of the aqueous phase are shown in Fig. 5. As is shown in Fig. 5, the absorbance is constant over the pH range from 4.0 to 5.0 for BCG, from 3.8 to 7.0 for TB, and from 4.0 to 5.5 for picrate in the examined pH. It seems that the decreases in absorbance in the range of pH 5—6 for BCG is related to the pH range of color change interval of BCG from pH 3.7 to 5.4. Figure 5 also shows that among the three kinds of pairing ions, BCG is most favorable for the spectrophotometric determintion of copper.

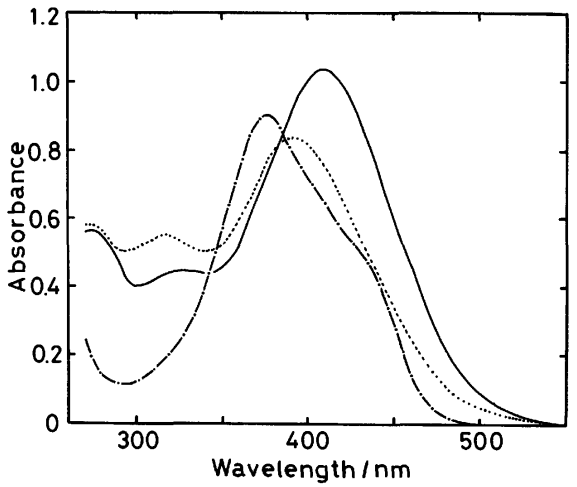

Fig. 4. Absorption spectra of 1,2-dichloroethane extracts from aqueous solution containing 5×10^{-4}M BCG^- (—), TB^-(····), or Pic^-(– –). Initial concentration; copper(I): 5×10^{-5} M, TTCT: 5×10^{-3} M.

Calibration, Sensitivity, and Precision. When the procedure described for the solvent extraction of copper(I) (Experimental section) was used, Beer's law was followed in the range of 0.6—3.2 μg Cu ml^{-1}. When BCG or picrate ions were used, the molar absorptivity was 2.01×10^4 or 1.80×10^4 l $mol^{-1}cm^{-1}$ respectively. These values are higher than the molar absorptivity for the neocuproine method; 7.95×10^3 at 454 nm in isoamyl alcohol, bathocuproine method; 1.42×10^4 at 479 nm in *n*-hexyl alcohol and diethyldithiocarbamic acid method; 1.42×10^4 at 432 nm in chloroform. The sensitivity for the 0.001 absorbance was 3.16 or 3.53 ng cm^{-2} respectively. When 10 solutions containing 15.9 μg of copper were deter-

Table 1. Effects of diverse ions

Ion	Concentration/M	Absorbance at 408 nm
None	—	0.505
Mn^{2+}	2.5×10^{-2}	0.050
Fe^{2+}	2.5×10^{-2}	0.504
Co^{2+}	2.5×10^{-2}	0.510
Ni^{2+}	2.5×10^{-2}	0.535
	2.5×10^{-3}	0.507
Zn^{2+}	2.5×10^{-2}	0.504
Cd^{2+}	2.5×10^{-2}	0.510
ClO_4^-	5.0×10^{-2}	0.482
	2.5×10^{-2}	0.491
	5.0×10^{-3}	0.495
NO_3^-	0.1	0.493
Cl^-	0.1	0.502
SO_4^{2-}	0.1	0.508

Concentration of copper(I) in each case: 2.5×10^{-5} M.
Reference: reagent blank.

mined using the BCG or the picrate as the pairing ion, the relative standard deviation was 1.5% or 0.6% respectively.

Effect of Foreign Ions. The interference from the following metal ions and anions were examined by using BCG; Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+}, and Cd^{2+}, ClO_4^-, NO_3^-, Cl^-, and SO_4^{2-}. All the metal ions were added as sulfates, while all the anions were added as their sodium salts. The results are shown in Table 1. Mn^{2+}, Fe^{2+}, Co^{2+}, Zn^{2+}, and Cd^{2+} in a 1000-fold excess over the copper concentration did not interfere, whereas Ni^{2+} in a 1000-fold excess serves to increase the absorbance by 5.9%. However, Ni^{2+} in a 100-fold excess did not interfere with the determination of copper. The presence of 0.1 M sulfate, chloride, and nitrate ions did not affect the determination of copper significantly, whereas the perchlorate ion when present in a quantity of more than 2.5×10^{-3} M gave a negative error.

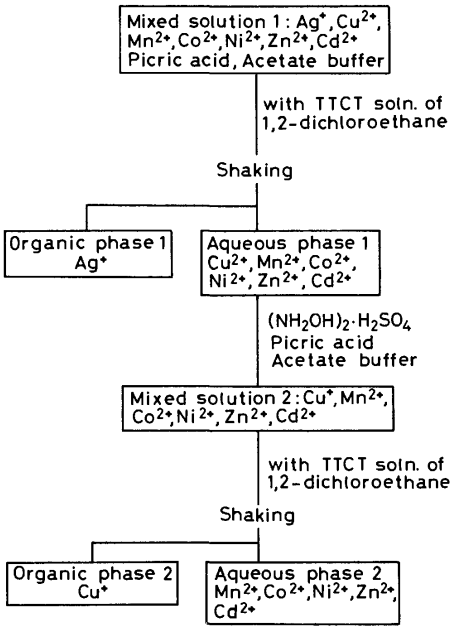

Fig. 6. Procedure of separation for silver and copper.

Separation of Silver and Copper from Aqueous Solution Containing Various Metal Ions. As has been mentioned above, it seems that among the dye anions examined, the BCG is most advantageous for both the ion-pair extraction and the spectrophotometric determination. However, from the fact that about 50% of the copper(II) was extracted when the BCG was used as the pairing ion (Fig. 1), it seems that the selectivity for silver(I) toward copper(II) decrease. Little copper(II) is extracted with TTCT in the presence of the picrate, whereas silver(I) is completely extracted.[11] Consequently a procedure was devised for separating silver and copper from an aqueous solution containing various metal ions using the picrate as the pairing ion. This separation scheme is shown in Fig. 6. Silver was first extracted as the ion-pair compound, $[Ag(ttct)_2]^+Pic^-$, the composition of which will be clarified in another paper, and then copper was extracted as $[Cu(ttct)]^+Pic^-$ after reducing the copper(II) to copper(I) with hydroxylammonium sulfate. The results are shown in Table 2. Silver(I) in a mixed solution containig Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, and Ag^+ (each metal ion concentration: 5×10^{-5} M) was more than 99% extracted by a single extraction. The other metal ions remained in the aqueous phase. In the case of the extraction from an aqueous solution containing 5×10^{-5} M Ag^+ and 1×10^{-2} M of other metal ions, almost the same results were obtained except that only a little copper(II) was extracted (3.8×10^{-6} M). The ion-pair compound, $[Ag(ttct)_2]^+Pic^-$, was completely back-extracted with 3 M HCl into the aqueous phase. In order to reduce copper(II) to copper(I), a hydroxylammonium sulfate solution was added to an aqueous phase into which silver(I) was extracted into the 1,2-dichloroethane phase, and then the extraction of copper(I) with TTCT was carried out. Ninety-nine percent of the copper(I) in the mixed solution was extracted by the single extraction in this procedure. All the other metal ions remained in the aqueous phase.

Table 2. Results of the separation of Ag^+ and Cu^+

Mixed solution 1		Organic phase 1		Recovery of Ag
Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}	Ag^+	Cu^{2+}	Ag^+	%
5×10^{-5} M	5×10^{-5} M		4.98×10^{-5} M	99.6
1×10^{-2} M	5×10^{-5} M	3.8×10^{-6}	4.99×10^{-5} M	99.8
Mixed solution 2		**Organic phase 2**		**Recovery of Cu**
Mn^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+}, Cd^{2+}	Cu^+	Cu^+		%
2.5×10^{-5} M	2.5×10^{-5} M	2.48×10^{-5} M		99.2
5×10^{-3} M	2.5×10^{-5} M	2.46×10^{-5} M		98.4

TABLE 4. ANALYSIS OF STANDARD STEEL SAMPLES FOR COPPER AND SILVER

Sample	Cu(wt%)			Ag(wt%)	
	Standard value	Present work		Standard value	Present work
		BCG	Pic		Pic
No. 1	0.30	0.30	0.31	—	—
No. 2	0.181	—	0.181	0.090	0.093

The absorption spectrum of the extracted species of silver(I) was almost the same as that of copper(I) in Fig. 4, and the absorption maximum lay at 378 nm.

These results show that the selective extraction-spectrophotometric determination of silver and copper from an aqueous solution containing first-transition metal ions (Mn^{2+}, Fe^{2+}, Ni^{2+}, Co^{2+}) and post-transition metal ions (Zn^{2+}, Cd^{2+}) is possible.

Practical Application. Two kinds of standard samples (No. 1 and 2) of steel were used in this study. Sample No. 1 contains copper, but no silver, while sample No. 2 contains both copper and silver. The chemical compositions of these samples are shown in Table 3. Sample No. 1 was analysed for copper using the BCG or picrate as the pairing anion (Table 4). The values in Table 4 are the averages of five measurements. The results show a reasonable agreement with the standard values. This sample contains a relatively large percentage of copper, so that 5 ml of the sample solution is sufficient for the determination of the copper. Therefore, the determination of copper is possible according to the procedure described in the solvent extraction of copper(I) (Experimental section), in which the volume of the aqueous phase is 10 ml. However, in the case of a sample containing a small percentage of copper, we adopted the recommended procedure for the determination of copper and silver, in which the volume of the aqueous phase was 50 ml. The absorbance of the organic phase did not change, although the volume of the aqueous phase increased from 10 to 50 ml.

Sample No. 2 was analyzed for copper and silver according to the procedure described for the separation of silver and copper from a mixed solution containing various metal ions (Table 4). The values in Table 4 are the averages for five measurements. The copper and silver contents (0.181% and 0.093% respectively) obtained by proposed method compare reasonably well with the standard values of 0.181 and 0.090% for copper and silver respectively.

The proposed method is so selective that the determinations of copper(I) and silver(I) are not interfered with the first-transition metal ions even when no masking reagent is present.

The authors are grateful to the Central Research Laboratory, Sumitomo Metal Industries, Ltd., for the supply of the standard samples of steel.

Mechanism of the Reactions of Oxomolybdenum(V) Tetraphenylporphyrin Complex with Alcohols in the Presence of Superoxide

Taira IMAMURA,* Koichi HASEGAWA, Tetsuya TANAKA, Wataru NAKAJIMA, and Masatoshi FUJIMOTO*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received June 6, 1983)

The successive addition of ROH (R=CH_3 and C_2H_5) to the dichloromethane solution of Mo^VO(tpp)Br (tpp=*meso*-tetraphenylporphinato) causes two-step reactions at 25 °C. The products of the first and the second step of the reactions are alcohol complex, [Mo^VO(tpp)(ROH)]Br, and alkoxo complex, Mo^VO(tpp)OR, respectively. In the presence of superoxide ion, O_2^-, in the dichloromethane solution of Mo^VO(tpp)X (X=Br and NCS) containing alcohol, Mo^VO(tpp)OR is formed through competitive two reaction paths where O_2^- acts as a proton acceptor and a reducing agent. The reaction steps of the two paths were confirmed by optical and ESR studies.

Much attention has been given to the studies of the reactions of metal complexes with superoxide to elucidate the mechanisms of the formation reaction and the electronic structure of dioxygen complex and of disproportionation reactions of superoxide by superoxide dismutases.[1,2] Superoxide possesses versatile reactivities as a ligand, a reductant, an oxidant, and a base depending on the reaction conditions such as solvents and temperature.[2,3]

Recently, the authors reported that Mo^VO(tpp)Br was reduced to $Mo^{IV}O$(tpp) by superoxide ion in aprotic solvents *via* an intermediate which was suggested to be a dioxygen complex.[4] When the reaction system contained a small amount of alcohol, alkoxo complex, Mo^VO(tpp)OR, was finally formed.[5,6] The present paper reports the mechanism of the reaction of Mo^VO(tpp)X with alcohols (CH_3OH and C_2H_5OH) in the presence of superoxide ion. In this reaction system, superoxide ion acts as a base to remove a proton from alcohol and a reducing agent for Mo^VO(tpp)X.

Experimental

The syntheses of the complexes, Mo^VO(tpp)X,[5] Mo^VO(tpp)OC_2H_5,[5] Mo^VO(tpp)OCH_3,[7] and $Mo^{IV}O$(tpp),[4] were reported previously. Dichloromethane was distilled, passed through a column of basic alumina to remove stabilizer,[8] and again distilled immediately before use. Methanol and ethanol were purified by the usual methods.[9] Dimethyl sulfoxide was kept with calcium hydride for several days, distilled at 37 °C under reduced pressure, and stored under Ar atmosphere. Potassium superoxide (ICN Pharmaceuticals) and 18-crown-6 (Nippon Soda) were used without further purification. The solution of superoxide was prepared from potassium superoxide solubilized by 18-crown-6 in dimethyl sulfoxide under Ar atmosphere.[10] The concentration of superoxide in dimethyl sulfoxide was determined by photometric titration with iodine.[6]

Visible absorption spectra were measured at 25.0±0.1 °C with a Hitachi 808 spectrophotometer. ESR spectra were recorded with a JEOL JES-FE1X spectrometer at 25 °C.

Results and Discussion

Reactions of Mo^VO(tpp)X with Alcohols. The successive addition of methanol to the dichloromethane solution of Mo^VO(tpp)Br at 25 °C causes two-step reactions. In the first step, the absorbance of the Soret band of Mo^VO(tpp)Br at 508 nm is decreased with increasing absorbance of a new Soret band at 478 nm (spectra 1—4 in Fig. 1). This spectral change has isosbestic points. Asmus plot[11] for this spectral change indicates that the reaction is the type of A+B⇄C, where A and B denote the reactants (Fig. 2). By the further addition of a large excess of methanol, the Soret band at 478 nm diminishes with appearance of a new absorption band at 454 nm (spectrum 5 in Fig. 1). The absorption spectrum of the final product agrees with that of the complex, Mo^VO(tpp)OCH_3, synthesized and isolated independently.[7] The product of the first step of the reaction is assigned to the alcohol complex, [Mo^VO(tpp)(CH_3OH)]Br, which is namely formed by the substitution of Br^- in Mo^VO(tpp)Br with methanol.[12] The spectral change shown in Fig. 1 suggests that the second step reaction is the deprotonation

Table 1. Absorption peaks in UV and visible regions

Complex	λ_{max}/nm ($\varepsilon/10^4$ mol^{-1} dm^3 cm^{-1}) in CH_2Cl_2 at 25 °C

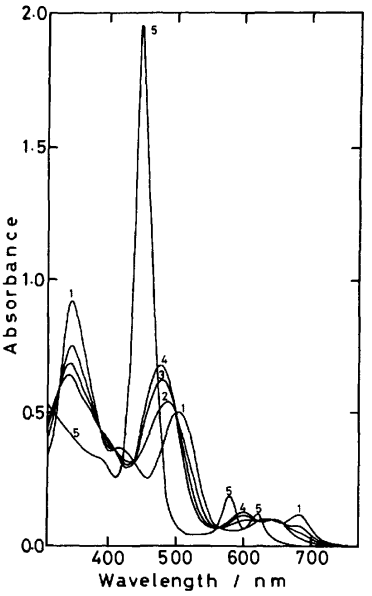

Fig. 1. The spectral change in the reaction of $Mo^{V}(tpp)Br$ with methanol in dichloromethane at 25 °C. The initial concentrations are $[Mo^{V}O(tpp)Br]_0=1.44\times10^{-5}$ mol dm^{-3} and $[CH_3OH]_0$=0 (0) (1); 0.2 (0.049) (2); 0.5 (0.12) (3); 0.9 (0.22) (4); 5.0%(v/v) (1.24 mol dm^{-3}) (5).

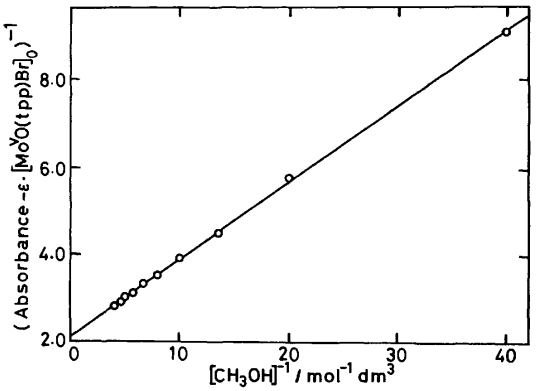

Fig. 2. Asmus plot at 478nm for the reaction of $Mo^{V}O(tpp)Br$ with methanol at 25 °C.

reaction of $[Mo^{V}O(tpp)(CH_3OH)]Br$ enhanced by the presence of a large amount of alcohol in the reaction system. This deprotonation reaction could be resulted from the change in the dielectric constant of the solution or the role of alcohol as a base.

The formation constant, K_s, of the first step of the reaction,

$$Mo^{V}O(tpp)Br + CH_3OH \overset{K_s}{\rightleftharpoons} [Mo^{V}O(tpp)(CH_3OH)]Br$$
$$\lambda_{Soret} = 508\ nm \qquad \lambda_{Soret} = 478\ nm$$
$$\overset{+CH_3OH}{\rightleftharpoons} Mo^{V}O(tpp)OCH_3 + HBr \qquad (1)$$
$$\lambda_{Soret} = 454\ nm$$

and the molar absorption coefficient at 478 nm of $[Mo^{V}O(tpp)(CH_3OH)]Br$ were determined to be K_s= 12.5 mol^{-1} dm^3 and $\varepsilon_{478\,nm}=5.4\times10^4$ mol^{-1} dm^3 cm^{-1} from Asmus plot at 25 °C.

By the reaction of $Mo^{V}O(tpp)Br$ with ethanol, $Mo^{V}O(tpp)OC_2H_5$ is also formed *via* the formation of $[Mo^{V}O(tpp)(C_2H_5OH)]Br$. The formation constant of the $[Mo^{V}O(tpp)(C_2H_5OH)]Br$ is $K_s=2.8\pm0.2$ mol^{-1} dm^3 at 25 °C. The spectral change of the reaction does not show any isosbestic points since the first step of the reaction is not discriminated from the second step owing to the small value of the formation constant, K_s.

The solution of the complex, $[MoO(tpp)(CH_3OH)]Br$, resulted from the reaction of $Mo^{V}O(tpp)Br$ with methanol shows ESR signals due to molybdenum which indicates that the oxidation state of the central molybdenum atom of the complex is 5+ as that of the complexes, MoO(tpp)Br and MoO(tpp)OR.[13]

The successive addition of methanol to the dichloromethane solution of $Mo^{V}O(tpp)NCS$ causes the shift of absorption peak from 493 to 480 nm followed by the appearance of a new band at 454 nm. The bands at 480 and 454 nm are ascribed to $[Mo^{V}O(tpp)(CH_3OH)]NCS$ and $Mo^{V}O(tpp)OCH_3$, respectively. The amount of the alcohol complex, $[Mo^{V}O(tpp)(CH_3OH)]NCS$, formed in the course of the reaction is relatively small compared to that of the reaction system of $Mo^{V}O(tpp)Br$, which is due to the small value of the formation constant, $K_s<1.0$ at 25 °C. The order of the magnitude of the formation constant of the dimethyl sulfoxide complexes, $[Mo^{V}O(tpp)(dmso)]X$, was also found to be $K^{DMSO}_{X=NCS} \ll K^{DMSO}_{X=Br}$.[12]

Mechanisms of the Reactions between $Mo^{V}O(tpp)X$, Alcohols, and Superoxide. The complex, $Mo^{V}O(tpp)X$, is present as the reaction species, $Mo^{V}O(tpp)X$, $[Mo^{V}O(tpp)(ROH)]X$, and $Mo^{V}O(tpp)OR$, in dichloromethane solutions containing 10^{-3}—2% (v/v) alcohol at 25 °C. By the addition of dimethyl sulfoxide solution of superoxide to the solution, the absorption peak of the alkoxo complex, $Mo^{V}O(tpp)OR$, is rapidly increased (Fig. 3).[5,6] The formation reaction of $Mo^{V}O(tpp)OR$ proceeds through competitive two

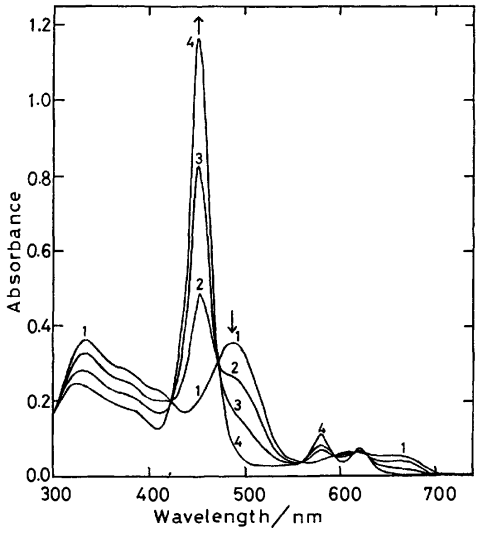

Fig. 3. The spectral change in the reaction between $Mo^{V}O(tpp)NCS$, methanol, and superoxide in dichloromethane at 25 °C. The initial concentrations are $[Mo^{V}O(tpp)NCS]_0=7.54\times10^{-6}$ mol dm^{-3}, $[CH_3OH]_0$=2%(v/v) (0.49 mol dm^{-3}), $[DMSO]_0$=1% (v/v) (0.14 mol dm^{-3}), and $[O_2^-]_0$=0 (1); 3.05×10^{-6} (2); 5.59×10^{-6} (3); 1.12×10^{-5} mol dm^{-3} (4).

reaction paths, A and B.

Reaction path A

$$ROH + O_2^- \rightleftarrows RO^- + HO_2 \quad (2)$$

$$Mo^VO(tpp)X + DMSO \rightleftarrows [Mo^VO(tpp)(dmso)]X \quad (3)$$

$$Mo^VO(tpp)X + ROH \rightleftarrows [Mo^VO(tpp)(ROH)]X \quad (4)$$

$$[Mo^VO(tpp)(ROH)]X \rightleftarrows Mo^VO(tpp)OR + HX \quad (5)$$

$$Mo^VO(tpp)X + RO^- \rightleftarrows Mo^VO(tpp)OR + X^- \quad (6)$$

$$[Mo^VO(tpp)(dmso)]X + RO^- \rightleftarrows Mo^VO(tpp)OR + X^- + DMSO \quad (7)$$

$$[Mo^VO(tpp)(ROH)]X + RO^- \rightleftarrows Mo^VO(tpp)OR + X^- + ROH \quad (8)$$

$$[Mo^VO(tpp)(ROH)]X + O_2^- \rightleftarrows Mo^VO(tpp)OR + X^- + HO_2 \quad (9)$$

Reaction path B

$$Mo^VO(tpp)X + O_2^- \rightleftarrows Mo^{IV}O(tpp) + O_2 + X^- \quad (10)$$

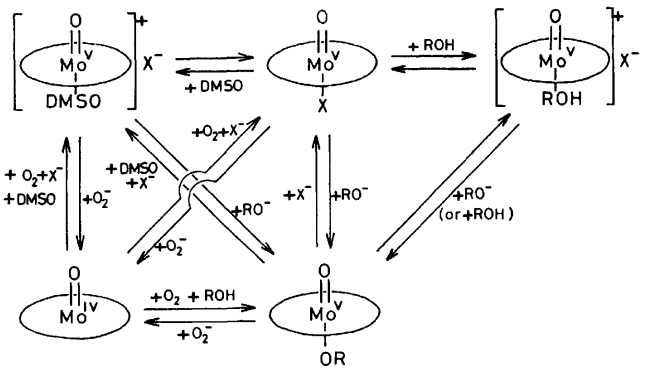
$$[Mo^VO(tpp)(dmso)]X + O_2^- \rightleftarrows Mo^{IV}O(tpp) + O_2 + X^- + DMSO \quad (11)$$

$$Mo^{IV}O(tpp) + O_2 + ROH \rightleftarrows Mo^VO(tpp)OR + HO_2 \quad (12)$$

The reaction path A starts with the formation of alkoxide ion, RO^-. The RO^- is first formed by the reaction of alcohol with superoxide (Eq. 2).[14,15] The formation of the dimethyl sulfoxide complex, $[Mo^VO(tpp)(dmso)]X$, is confirmed by adding dimethyl sulfoxide to the dichloromethane solution of $Mo^VO(tpp)X$ (Eq. 3).[12] The spectral change of the reaction of the complex, $Mo^VO(tpp)X$ or $[Mo^VO(tpp)(dmso)]X$, with $C_2H_5O^-$ derived from C_2H_5ONa solubilized by 18-crown-6 to dichloromethane reveals the occurrence of the reactions 6 and 7.[13] Reaction 8 was also confirmed by the spectral change in the reaction of $[Mo^VO(tpp)(CH_3OH)]Br$ with $C_2H_5O^-$ ion. The reaction of alcohol with superoxide (Eq. 2) suggests the presence of the reaction 9 in which superoxide directly reacts with the coordinated alcohol in $[Mo^VO(tpp)(ROH)]X$ to form $Mo^VO(tpp)OR$.

The reaction path B is started by the direct reduction of the complex, $Mo^VO(tpp)X$ and $[Mo^VO(tpp)(dmso)]X$, by an excess of superoxide to $Mo^{IV}O(tpp)$ (Eqs. 10 and 11); the reaction was confirmed by spectral and ESR measurements.[4] The ESR spectrum of the dichloromethane solution of $Mo^VO(tpp)X$ consists of a strong central line ($\bar{g}$=1.967) due to $^{94,96,98,100}Mo$ nuclei (I=0)(natural abundance *ca.* 75%) which is split to nine lines by coordinated four nitrogens of the ligand.[13] By the addition of an excess of superoxide to the solution of $Mo^VO(tpp)X$, ESR signal due to $Mo^V(d^1)$ diminished, owing to the formation of $Mo^{IV}O(tpp)$ which is ESR silent. Equation 12[16] was also confirmed by adding alcohol to the dichloromethane solution of $Mo^{IV}O(tpp)$ synthesized and isolated independently.[4]

The reaction ratio of the paths A to B to form $Mo^VO(tpp)OR$ largely depends on the concentrations of alcohol and superoxide ion. The reaction path through A is of greater advantage than that through B and completes within 1 min under the conditions of high alcohol concentration, *e.g.* 2%(v/v) methanol (0.49 mol dm^{-3}).



Scheme 1.

The stoichiometry of the $Mo^VO(tpp)OCH_3$ formation reaction in 2%(v/v) methanol–dichloromethane was determined to be $Mo^VO(tpp)NCS: O_2^- = 1:1$ by the molar ratio method.[6] Equations 10 and 11 which reveal respectively the reduction reactions of $Mo^VO(tpp)X$ and $[Mo^VO(tpp)(dmso)]X$ with superoxide lie on the left. More than tenfold excess of superoxide over the complex is required to complete the reduction. It takes more than 20 min at 25 °C to complete the reactions 10 and 11 with the initial concentrations of $[O_2^-]_0 = 2.2\times10^{-4}$ and $[Mo^VO(tpp)Br]_0 = 7.9\times10^{-6}$ mol dm^{-3}.[4] Thus, under the conditions of 2%(v/v) methanol and $[CH_3OH]_0 \gg [O_2^-]_0$, the formation reaction of $Mo^VO(tpp)OCH_3$ proceeds almost (>90%) through the reaction path A. The lower the concentration of methanol becomes, the more the reaction through the path B increases. The complex, $Mo^VO(tpp)OR$, formed finally is relatively stable in the solution but is reduced by a very large excess, *e.g.* 10^{-1}—10^{-2} mol dm^{-3}, of superoxide over the initial concentrations of $[Mo^VO(tpp)X]_0$ and $[ROH]_0$ (Eq. 13).

$$Mo^VO(tpp)OR + O_2^- \rightleftarrows Mo^{IV}O(tpp) + RO^- + O_2 \quad (13)$$

Under the experimental conditions such as in Fig. 3, this equilibrium lies far on the left, which is supported by the large differences of the oxidation-reduction potentials between the O_2/O_2^- couple (−0.5—−0.65 V *vs.* NHE in aprotic solvents)[17] and $Mo^VO(tpp)OCH_3/Mo^{IV}O(tpp)$ couple (−0.74—−0.89 V *vs.* SCE in dichloromethane).[18] All reactions among $Mo^VO(tpp)X$, ROH, and superoxide and the absorption spectral data are shown in Scheme 1 and Table 1, respectively.

Addition of an excess of superoxide to the dichloromethane solution of $Mo^VO(tpp)X$ containing a trace amount of water gives the hydroxo complex, $Mo^VO(tpp)OH$, which has the Soret peak at 464 nm.[19] The equilibrium of the reaction 15 also depends on the concentration of superoxide.

$$Mo^VO(tpp)X + H_2O + O_2^- \rightleftarrows Mo^VO(tpp)OH + X^- + HO_2 \quad (14)$$

$$Mo^VO(tpp)OH + O_2^- \rightleftarrows Mo^{IV}O(tpp) + OH^- + O_2 \quad (15)$$

The hydroxo complex, $Mo^VO(tpp)OH$, should be formed through the same competitive two reaction paths of A and B as in the formation reaction of the alkoxo complex, $Mo^VO(tpp)OR$. The slow reaction of superoxide ion with dichloromethane[20] does not affect the mechanism of the reaction between $Mo^VO(tpp)X$, alcohol, and superoxide.

A Study of the Mechanism for the Extraction of Uranium, Water, and Nitric Acid with Trioctylphosphine Oxide Using a Binary Molten Mixture of Biphenyl and Naphthalene as the Solvent

Takehiro KOJIMA

Department of Chemistry, Okayama College of Science, 1-1, Ridai-chō, Okayama 700

(Received June 23, 1983)

Liquid-liquid distribution with trioctylphosphine oxide (TOPO) and a binary molten mixture of biphenyl and naphthalene (weight ratio=3:1) has been examined for the extraction of uranium from a 0.1 mol kg^{-1} nitric acid solution. The stoichiometry of the TOPO complex of uranyl nitrate in the molten biphenyl-naphthalene phase was established to be $UO_2(NO_3)_2(TOPO)_2$. The extracted species of water and nitric acid are $H_2O \cdot TOPO$ and $H_3O^+ \cdot TOPO \cdot NO_3^-$ at concentrations of TOPO of less than 0.1 mol kg^{-1}. The thermodynamic quantities ($\Delta H°$, $\Delta G°$, and $\Delta S°$) were obtained for the extraction of uranyl nitrate, nitric acid, and water into TOPO-biphenyl-naphthalene and TOPO-cyclohexane solutions from the temperature dependence of the extraction constants. More exothermic enthalpy and smaller entropy changes were observed for the binary molten mixture; these differences were attributed to the aromatic and viscous properties of the solvent.

Solvent extraction systems with organophosphorus compounds, such as trioctylphosphine oxide (TOPO) and tributylphosphate (TBP), have been reported in many papers[1–5] and have been documented in books.[6–7] Furthermore, to clarify the mechanism of the selective extraction many fundamental investigations have been done: the competitive extraction of uranium complexes and acid,[8–9] the extraction of water and acids,[10–16] and the thermodynamic quantities of the free energy, enthalpy, and entropy changes in the extraction process.[17–21]

A method involving solid-liquid separation after liquid-liquid extraction has been developed by Fujinaga *et al.*[22] The method has been applied to the spectrophotometric determination of micro amounts of metals by using a molten organic compound, such as biphenyl (mp 70 °C)[22] or naphthalene (mp 80 °C),[23–25] combined with appropriate chelating agents such as 8-quinolinol. The extraction method with molten solvents has some advantages: metal ions can be efficiently concentrated, since only an organic/aqueous volume ratio of 1/1000 is available, the phase separation is easily facilitated by cooling without a separatory funnel, and high distribution ratios are obtained.

Recently we have studied the process of capturing uranium from sea water by adsorption on adsorbents made of polyacrylamide and hydrous titanium oxide.[26–27] Although the solvent extraction with TOPO and ordinary liquid solvents such as toluene has been carried out by others,[4–5] we ourselves have efficiently applied solvent extraction with a molten solvent to the concentration of uranium in the eluent in order to determine uranium or zirconium spectrophotometrically.[28–32]

However, the molten-solvent method suffers from two disadvantages: the volatilization of naphthalene and the adhesion of the extractants to the walls of vessels. It is desirable to do extraction at as low a temperature as possible to minimize volatilization. Therefore, the mixed molten solvent of molten biphenyl and naphthalene was chosen because the melting point of the extraction phase become lower, reaching a minimum temperature of 52 °C at a biphenyl-naphthalene weight ratio of 3/1. There have, however, been few reports on the mechanism of the extraction with molten solvents, especially with the binary molten solvent.

The present paper investigates the separation of uranium as the TOPO complex by solvent extraction with a binary molten mixture of biphenyl and naphthalene and elucidates the mechanism of the extraction more thermodynamically than the extraction by cyclohexane. There is an appreciable difference in the enthalpy and entropy changes of extraction between the binary molten-mixture solvent and cyclohexane. The enthalpy and entropy changes for the extraction process indicate that the extracted species, $UO_2(NO_3)_2(TOPO)_2$, is more stable in the binary molten solvent than in cyclohexane.

Experimental

Reagents. TOPO (Doindo Co., Ltd.) of a reagents grade was used without further purification. A standard uranium solution (10^{-2} mol kg^{-1}) was prepared by dissolving 0.502 g of uranyl nitrate hexahydrate ($UO_2(NO_3)_2 \cdot 6H_2O$, Yokozawa Chemical Co., Ltd.) in deionized water and then diluting it to 100 cm^3. The binary molten mixture solvent with a melting point of 52 °C was prepared by mixing 100 g of naphthalene (mp 80 °C) and 300 g of biphenyl (mp 70 °C). The other reagents used were of an analytical grade.

Procedure

Extraction of Uranium(VI). Twenty cm^3 of 10^{-3} mol kg^{-1} uranium in a 0.1 mol kg^{-1} nitric acid solution was transferred to a 50-cm^3 glass-stoppered flask. Then 5 g of the mixture of biphenyl-naphthalene containing TOPO(0.01—0.3 mol kg^{-1}) was added to it, and the flask was heated on a water bath at 60 °C until the TOPO-biphenyl-naphthalene had melted completely. The mixture was stirred for 3 h with a magnetic stirrer (Toyo Kagaku Sangyo Co., Ltd., Model SS-5) and then allowed to stand for 3 h for the phase-separation.

Determinaton of Distribution Ratio of Uranium. The determination of the uranium(VI) remaining in the aqueous phase was carried out spectrophotometrically with 1-(2-pyridylazo)-2-naphthol (PAN).[33] After the phase-separation, an aliquot

of the aqueous phase was transferred into a 100-cm^3 separatory funnel by means of a pipet. A 100 mg part in sulphamic acid was then added, followed by appropriate amounts of concentrated nitric acid and water to give 2 mol kg^{-1} nitric acid in a final volume of 20 cm^3. Five cm^3 of the 0.05 mol dm^{-3} TOPO cyclohexane solution was then added, and the funnels were vigorously shaken for 1 min. After phase-separation, the aqueous phase was removed and the organic phase was transferred to a 10-cm^3 volumetric flask containing 1 cm^3 of the 0.1% PAN solution and 2 cm^3 of a 10% triethanolamine ehtanol solution. The solution was adjusted to 10 cm^3 with ethanol. After mixing well, the absorbance of the solution at 555 nm was measured against a reagent blank. The distribution ratio was calculated according to this relation: $D=$ (concentration of uranium(VI) in the organic phase)/(concentration of uranium(VI) in the aqueous phase) × (weight of aqueous phase)/(weight of organic phase).

Determination of Water Content in the Organic Phases. After phase-separation, an aliquot of the molten organic phase (TOPO–biphenyl–naphthalene) was transferred into a 10-cm^3 Erlenmyer flask with a heated pipet, because the molten organic phase is solidified at room temperature. The amount of the organic phase was weighed. Then the solidified organic phase was dissolved in a constant amount of cyclohexane. The water content in the organic phase was measured coulometrically by using a Hiranum AQ-3C aquacounter. In the case of the binary molten solvent, the water content was corrected for the amount of water contained in cyclohexane alone.

Determination of Acid Content in the Organic Phase. The content of acid in the organic phase was determined by back-titration with the standard nitric acid solution (0.1 mol dm^{-3}) after the addition of a constant excess of 0.1 mol dm^{-3} potassium hydroxide solution. Phenolphthalein was used as the indicator.

Results and Discussion

Extraction of Acid and Water. The uranium nitrate and acid are extracted competitively from an aqueous solution.[8-9] It is well known that a trace amount of water is also extracted with an organophosphorus compound.[10-16] Therefore, it is necessary to examine the extraction behavior of acid and water into the binary molten solvent prior to the extraction of uranium(VI). The total concentration of water in the organic phase is written as:

$$[H_2O]_{org} = [H_2O]_{org,blank} + [H_2O]_{org,ext}, \quad (1)$$

where $[H_2O]_{org,blank}$ and $[H_2O]_{org,ext}$ are the concentrations of the water in the binary molten solvent and of the water extracted with TOPO. The relation of the concentration of extracted water to that of TOPO in the organic phase is shown in Fig. 1. The extraction equilibrium is:

$$m\text{TOPO}_{org} + nH_2O_{aq} \rightleftharpoons m\text{TOPO}\cdot nH_2O_{org}, \quad (2)$$

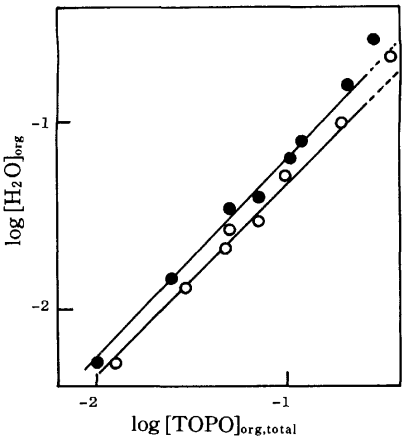

Fig. 1. Variation of water content of the organic phase with total TOPO concentration in cyclohexane or biphenyl-naphthalene, after correction for the dissolved water by the diluent.
Aqueous phase: 10 g, organic phase: 5 g, -●- cyclohexane, at 50 °C, -O- biphenyl-naphthalene, at 55 °C.

with the corresponding extraction constant K_{H_2O}:

$$K_{H_2O} = [m\text{TOPO}\cdot nH_2O]_{org}/[\text{TOPO}]^m_{org}[H_2O]^n_{aq}. \quad (3)$$

In view of the low solubility of the studied TOPO in water and its relatively low initial concentration in the organic phase, the water activity of the aqueous phase may be assumed to be unity; the plot of $\log[H_2O]_{org,ext}$ *vs.* $\log[\text{TOPO}]_{org}$ thus reflects the number of water molecules per TOPO molecule. In Fig. 1 the free TOPO concentration is calculated on the basis of its initial concentration in the organic phase and the amount of the water extracted. It can be seen that the log-log plot is linear from 0.01 to 0.1 mol kg^{-1} TOPO, with a slope of 1.0 corresponding to $m=n$. From the dependence of the amount of coextracted water on that of TOPO and from the IR studies,[15] we can say that the 1-1 species TOPO · H_2O is the predominant species in various solvents, such as cyclohexane and carbon tetrachloride.[14] From Eqs. 1 and 3 with $m=n=1$, we get the following relation:

$$[H_2O]_{org,ext} = [K_{H_2O}/(1+K_{H_2O})][\text{TOPO}]_{org}. \quad (4)$$

The K_{H_2O} values at various temperatures were evaluated by using the log-log plot of Eq 4, the results obtained are given in Table 1. The K_{H_2O} value of 3.13 for cyclohexane is comparable with the value reported

Table 1. Extraction constants of water and nitric acid with TOPO at various temperatures

t/°C	Cyclohexane			
	25	30	40	50
K_{H_2O}	2.12	1.80	1.89	1.64
K_{HNO_3}	42.0	38.7	35.0	31.8
t/°C	Biphenyl-naphthalene			
	55	60	65	
K_{H_2O}	0.73	0.70	0.61	
K_{HNO_3}	24.9	12.3	—	

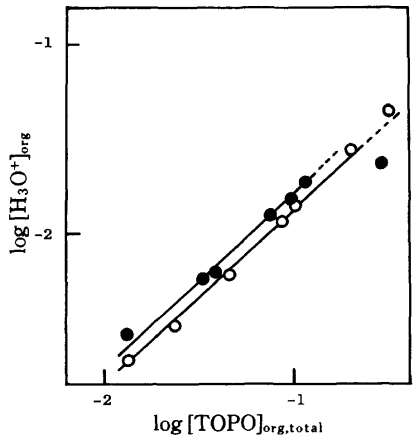

Fig. 2. Variation of organic phase acid with TOPO ncentration in cyclohexane or biphenyl-naphthale.
-●- Cyclohexane, at 50°C, -O- biphenyl-naphthalene, at 55°C.

(3.57) at 25°C[14]: the slightly smaller K_{H2O} values for TOPO in the binary solvent system have also been reported for carbon tetrachloride (0.85,[10] 0.56,[10] 0.68,[11] at 25°C). Binary molten biphenyl-naphthalene or cyclohexane containing quantities of TOPO ranging from 0.01 to 0.3 mol kg^{-1} was equilibrated with the 0.1 mol kg^{-1} nitric acid solution. The results are shown in Fig. 2. The amount of nitric acid extracted into the binary molten solvent and cyclohexane without TOPO was confirmed to be negligibly small. The 1:1 stoichiometry for nitric acid-TOPO extraction has been well established,[15] and the above results in the binary solvent are compatible with the 1:1 stoichiometry. Therefore, the extraction equilibrium for nitric acid is written by Eq 5:

$$H^+_{aq} + NO_3^-{}_{aq} + TOPO_{org} \rightleftharpoons HNO_3 \cdot TOPO_{org}, \quad (5)$$

and the extraction constant is:

$$K_{HNO_3} = [HNO_3 \cdot TOPO]_{org} / [H^+]_{aq}[NO_3^-]_{aq}[TOPO]_{org} f_{H^+} f_{NO_3^-}. \quad (6)$$

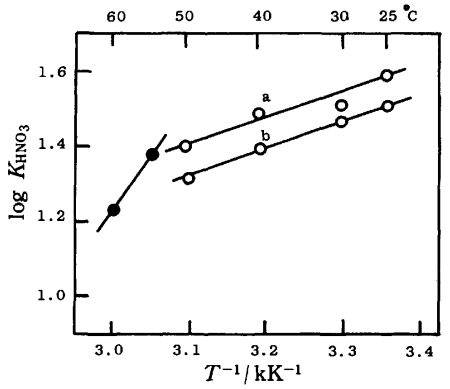

Fig. 3. Effect of varying temperature on extraction of nitric acid by TOPO in cyclohexane or biphenyl-naphthalene.
-●- Biphenyl-naphthalene, TOPO concentration in mol kg^{-1}: 0.013 to 0.3, -O- cyclohexane, TOPO concentration in mol kg^{-1}: a, 0.12; b, 0.09.

In a way similar to that for water extraction, the K_{HNO_3} values were estimated; they are given in Table 1. The mean activity coefficients of nitric acid were estimated by the extrapolation of values at concentrations of more than 0.1 mol kg^{-1} at 25°C;[34] their temperature dependences were neglected.

Figure 3 shows the temperature dependence of nitric-acid extraction; the thermodynamic quantities ($\Delta H°$, $\Delta G°$, and $\Delta S°$) for extracton were calculated by means of the following equations:

$$\Delta G° = -2.303\,RT \log K_{ex}, \quad (7)$$

$$\Delta H° = -2.303\,R(\mathrm{d} \log K_{ex}/\mathrm{d}(1/T)), \quad (8)$$

$$\Delta S° = (\Delta H° - \Delta G°)/T, \quad (9)$$

where R is the gas constant and T is the absolute temperature. The results obtained are given, together with those for the water extraction, in Table 4. It should be noted that the enthalpy and entropy changes for the binary system are much larger han those for cyclohexane. The extraordinarily large enthalpy changes accompanying the large entropy loss for nitric acid should be attributed to the solvation of the TOPO nitrate complex by the molten solvent of an aromatic character. Similar aspects were observed for the uranium extraction, as will be described later.

Extraction of Uranium(VI). The distribution ratios of the uranium-TOPO complex at a uranium concentration of 1×10^{-3} mol kg^{-1} from a 0.1 mol kg^{-1} nitric acid solution were determined as a function of the TOPO concentrations, ranging from 0.01 to 0.3 mol kg^{-1}. The results are shown in Fig. 4. The slope of the line in Fig. 4 is 2.1, indicating the composition of the extracted species to be $UO_2(TOPO)_2(NO_3)_2$, just as in cyclohexane.[35]

The distribution ratio for the extraction of uranium(Vl) from a 0.1 mol kg^{-1} nitric acid solution was obtained as a function of the TOPO concentration at different temperatures. The results are given in Tables 2 and 3. The D value decreases with an increase in the temperature under all sets of conditions examined. The equilibrium expression for the extrac-

Table 3. Variation in the distribution ratio of U(VI) for molten biphenyl–naphthalene with the TOPO concentration at different temperatures

TOPO(mol kg^{-1})	0.010	0.018	0.032	0.054
D, at 55 °C	3.2	12	53	1.8×10^2
60	2.3	7.4	44	1.7×10^2
65	2.0	6.7	32	1.3×10^2

U(VI): 10^{-3} mol kg^{-1}, HNO_3: 10^{-1} mol kg^{-1}, organic phase/aqueous phase: 5/20, solvent: molten biphenyl-napthalene (weight ratio=3:1).

tion of uranium is given by Eq. 10:

$$UO_2^{2+}{}_{aq} + 2NO_3^-{}_{aq} + 2TOPO_{org} \rightleftharpoons UO_2(NO_3)_2(TOPO)_{2\,org}. \quad (10)$$

Thus, the corresponding extraction constant can be expressed by Eq.11:

$$K_{ex} = [UO_2(NO_3)_2(TOPO)_2]_{org}/[UO_2]_{aq}[NO_3^-]^2_{aq}\,[TOPO]^2_{org}\,f_{UO_2^{2+}}f^2_{NO_3^-} \quad (11)$$

where the square brackets refer to the concentrations and where f is the activity coefficient of the respective species. The extraction constant was estimated from the distribution ratio D by Eq.12:

$$K_{ex} = D(1+\sum_1^n \beta_n[NO_3^-]^n_{aq})/[NO_3^-]^n_{aq}[TOPO]^2_{org}\,f_{UO_2^{2+}}f^2_{NO_3^-}, \quad (12)$$

where the $(1+\sum_1^n\beta_n[NO_3^-]^n_{aq})$ term takes into account the formation of uranyl nitrate complexes with the formation constant for $UO_2(NO_3)_n^{(2-n)+}$ in the aqueous phase. Thus, $D(1+\sum_1^n\beta_n[NO_3^-]^n_{aq})$ is equal to the ratio of the concentration of $UO_2(NO_3)_2(TOPO)_2$ in the organic phase (assuming that this is the only species extracted) to that of free UO_2^{2+} in the aqueous phase.

From the temperature dependence of the extractability of 0.1 mol kg^{-1} nitric acid, it was found that, at a TOPO concentation of 0.05 mol kg^{-1} the aqueous nitric acid concentration in mol kg^{-1} varies from 0.0982 at 25 °C to 0.0984 at 50 °C for cyclohexane and from 0.0981 at 55 °C to 0.0982 at 60 °C for the molten mixed solvent.

Therefore, it is reasonable to assume that the equilibrium concentrations of the nitrate ion in the aqueous phase and of free TOPO in the organic phase would remain practically constant over the temperature range studied. A value of 0.02 for $(1+\sum_1^n\beta_n[NO_3^-]^n_{aq})$ in a 0.1 mol kg^{-1} nitric acid solution was reported at 25 °C by Patil *et al.*[19] The values of $(1+\sum_1^n\beta_n[NO_3^-]^n_{aq})$ for uranium(VI) were estimated by using the method of cation exchange: 1.02 (25 °C) in a 0.1 mol dm^{-3} nitric acid solution,[19] and 2.1 (25 °C) and 2.3 (40 °C) in a 3 mol dm^{-3} nitric acid solution.[36] If the correction term $(1+\sum_1^n\beta_n[NO_3^-]^n_{aq})$ and activity coefficients do not change significantly over the temperature range investigated, the enthalpy change, $\Delta H°$, associated with the extraction of uranium can be calculated from Eq. 8.

The logarithms of the distribution ratio at different concentrations of TOPO were plotted against the reciprocal temperature. Some typical plots for the extraction of nitric acid and uranium with cyclohexane and the molten mixture solvent are shown in Figs. 3 and 5 respectively. All the plots were linear. The $\Delta H°$ values obtained from these plots by using a least-square procedure are given in Table 4. It was found that the $\Delta H°$ values are independent of the concentration of TOPO, supporting the above assumptions. The $\Delta H°$ values for uranium in the binary molten solvent are two times higher than that in cyclohexane.

The Gibbs-free-energy and entropy changes for uranium extraction obtained by using Eq. 7 are given in Table 4. A mean activity coefficient of 0.60 for the UO_2^{2+} ions in *ca.* 0.1 mol kg^{-1} nitric acid, which was

calculated by means of the modified Debye-Hückel equation,[34] was used over the temperature range studied.

From Table 3 it may be seen that uranium is a little more extractable in the binary molten solvent, with a more negative enthalpy and smaller entropy changes, than in cyclohexane. As has been stated earlier, a more exothermic enthalpy change is also observed for the nitric acid–molten solvent system; it may be due to the stronger solvation of the extracted TOPO complex by aromatic solvents, with additional interactions of π-electrons, compared with the case for alicylic cyclohexane.

In addition to the strong solvation effect, the viscous characteristics of the binary molten solvent can also be responsible for the smaller entropy changes. However, in the cyclohexane phase the extracted species disperse easily, resulting in larger entropy changes.

In conclusion, the extraction behavior of uranium(VI), water, and nitric acid for the molten biphenyl–naphthalene solvent is similar to that for cyclohexane. However, the metal UO_2^{2+} ion is extracted in the molten solvent with more exothermic enthalpy and smaller entropy changes than those for the cyclohexane system.

The author is deeply indebted to professor Y. Yamamoto and Dr. E. Iwamoto, Hiroshima University, for their helpful discussions and suggestions, and to professor Y. Shigetomi, Okayama College of Science, for his helpful suggestions and warm encouragement.

Kinetics and Mechanism of Copper(II), Zinc(II), and Cadmium(II) Incorporation into 5,10,15,20-Tetraphenylporphine and *N*-Methyl-5,10,15,20-tetraphenylporphine in *N,N*-Dimethylformamide

Shigenobu FUNAHASHI, Yūshi YAMAGUCHI, and Motoharu TANAKA*
Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received August 4, 1983)

The kinetics of reactions of 5,10,15,20-tetraphenylporphine (H_2(tpp)) and *N*-methyl-5,10,15,20-tetraphenylporphine (H(metpp)) with Cu^{II}, Zn^{II}, and Cd^{II} ions was studied spectrophotometrically in *N,N*-dimethylformamide. The rate of incorporation of metal ions (M^{2+}: Cu^{2+}, Zn^{2+}, Cd^{2+}) into H(metpp) is first order with respect to both H(metpp) and metal ion: $d[M(metpp)^+]/dt=k[H(metpp)][M^{2+}]$ with k(25 °C)=11.5±0.5 mol^{-1} dm^3 s^{-1} for Zn^{2+} and (5.8±0.8)×10^2 mol^{-1} dm^3 s^{-1} for Cd^{2+}. The rate of incorporation of copper and zinc into H_2(tpp) is first order in H_2(tpp) and the conditional first-order rate constants are expressed as follows: $k_{0(M)}=K[M^{2+}](1+K[M^{2+}])^{-1}(k_1+k_2[M^{2+}])$ where for Cu^{2+} and Zn^{2+} K/mol^{-1} dm^3, k_1/s^{-1}, and k_2/$mol^{-1}dm^3$ s^{-1} at 25 °C are (1.6±0.2)×10^4 and (7.2±1.5)×10^2, (1.2±0.1)×10^{-4} and (3.5±0.7)×10^{-5}, and (5.2±0.2)×10^{-2} and (8.6±0.2)×10^{-4}, respectively. Metal ion incorporation into H_2(tpp) proceeds through the formation of intermediates prior the rate-limiting step. For the H(metpp) system, the methyl group on the pyrrole in H(metpp) prevents the formation of such an intermediate. On the other hand, the rate of cadmium incorporation into H_2(tpp) is first order with respect to Cd^{2+} and H_2(tpp) and its second order rate constant k is (6.5±1.0)×10^{-3} mol^{-1} dm^3 s^{-1}. The large cadmium(II) ion can not fit into the porphyrin nucleus and its reaction proceeds through a pathway involving a mononuclear activated complex.

The mechanisms of complexation of labile metal ions have attracted a good deal of attention. Now one can make a reasonable accurate assessment of the rate constant for the reaction of a particular metal ion–ligand system.[1,2] More recently attention has been directed to the more unusual ligands such as macrocycles,[3,4] cryptands,[5–7] and porphyrins.[8–12] Their steric restrictions are likely to slow down the "normal" rates and introduce mechanistic novelties.

A number of kinetic studies of metalloporphyrin formation have been published and the work has been reviewed by Schneider,[13] Hambright,[14] and Longo.[15] A classification of kinetics of metalloporphyrin formation has been presented recently.[16] Since the solvents, metal salts, porphyrins, and other conditions are different in these kinetic studies, a quantitative comparison of the available data is difficult. A number of studies have been addressed to the question of how metal ions are incorporated into porphyrin molecules to form metalloporphyrins. A particularly attractive idea was that of "sitting-atop" (SAT) complexes, produced by reaction of metal ions with free base porphyrins prior to metal ion incorporation.[17] Evidence for SAT complexes has been presented in various types of systems.[18–20] On the other hand, there are some papers to show evidence for the nonexistence of SAT complexes.[21,22]

Previously we have investigated the rate of reaction of 5,10,15,20-tetra(4-pyridyl)porphine with cobalt(II) in acetic acid and demonstrated the variation of the reaction order in metal ion with varying metal ion concentration.[8] We have emphasized that it is indispensable to conduct experiments over as wide a concentration range as possible. In order to elucidate the origin of previously reported differences in mechanisms of metalation, reactions of copper(II), zinc(II), and cadmium(II) ions with 5,10,15,20-tetraphenylporphine (H_2(tpp)) and *N*-methyl-5,10,15,20-tetraphenylporphine (H(metpp)) have been studied over a wide range of metal ion concentrations in *N,N*-dimethylformamide (DMF).

X = H, H_2(tpp)
X = CH_3, H (metpp)

Two of the most significant studies which we will refer to are those of Bain-Ackerman and Lavallee,[9] who have provided data for complexation of H(metpp) by Cu^{II}, Zn^{II}, Co^{II}, Mn^{II}, and Ni^{II} and Longo *et al.*,[23] who have provided activation parameters for reactions of H_2(tpp) and its derivatives with metal chloride in DMF.

Experimental

Reagents. In order to prepare sample solutions as dry as possible, extreme care was taken in purification and preparation of all reagents and solutions.

DMF: Reagent grade DMF was dried over calcium hydride and distilled twice under reduced pressure. The water content in DMF was determined to be less than 3×10^{-3} mol dm^{-3} by the Karl-Fisher titration.

Porphyrins: H_2(tpp) (Strem Chemicals) was chromatographed on an alumina column by elution with chloroform. H(metpp) was prepared from methylation of H_2(tpp) by methylfluorosulfonate (Aldrich Chemical Co., "Magic methyl") according to literature procedures.[24] H(metpp) was isolated and purified by a thin-layer chromatograph twice. H(metpp) is characterized by ^{1}H NMR spectrum and electronic spectra. The distinctive NMR spectrum shows a sharp singlet due to *N*-methyl group at 4.1 ppm upfield from

$SiMe_4$ in $CDCl_3$.

Copper(II) Perchlorate DMF Solution: Crystals of hydrated copper(II) perchlorate were obtained by treating copper metal (99.999%) and perchloric acid of special purity (Wakojunyaku) The crystals were dissolved in DMF in the presence of 3A Molecular Sieves and allowed to stand for 1 d under reduced pressure. Then the Molecular Sieves were removed by filtration.

Calcium(II) Perchlorate DMF Solution: Crystals of hydrated calcium(II) perchlorate were obtained from reagent grade calcium(II) carbonate and perchloric acid, and recrystallized twice from distilled water. The crystals were placed in an oven at 110 °C for 1 h and then at 240 °C at least for 24 h. The anhydrous calcium(II) perchlorate was dissolved in DMF.

DMF Solutions of Zinc(II), Cadmium(II), and Calcium(II) Nitrates: Reagent grade zinc(II) nitrate was recrystallized twice from distilled water. Crystals of hydrated zinc(II) nitrate were dissolved in DMF. The water involved was removed by 3A Molecular Sieves under vacuum line. The DMF solutions of cadmium(II) nitrate and calcium(II) nitrate were prepared by the same procedure as above.

The amounts of water involved in the DMF solutions were determined to be less than 5×10^{-3} mol dm^{-3}. The concentrations of copper(II), zinc(II), cadmium(II), and calcium(II) solutions were determined complexometrically by EDTA.

The purification of DMF and the preparation of DMF solutions were carried out just before kinetic measurements.

Measurements. The slow reactions were monitored spectrophotometrically by a Union Giken (Type SM401) spectrophotometer or a Hitachi (Type 124) spectrophotometer with a thermostated cell compartment maintained within $\pm$0.1 °C. The formation of metalloporphyrins was carried out in 1 cm cells by mixing a porphyrin solution and a metal ion solution preequilibrated at the reaction temperature. The absorption spectra change as a function of time with distinct isosbestic points until completion of the reaction. The faster reactions in the H(metpp) system were followed by a Union Giken (Type RA1100) stopped-flow spectrophotometer. Addition of calcium(II) nitrate or perchlorate as an electrolyte did not affect visible spectra and rates.

The kinetics were run under pseudo-first-order conditions at 25 °C with the metal ion concentration at a large excess over the free base porphyrin concentration (10^{-6}—10^{-5} mol dm^{-3}). Pseudo-first-order plots showed good linearity untill three half-lives. Conditional first-order rate constants were obtained from the slope of such plots. The half-life times for the fastest and slowest reaction in the present reaction systems were 1 s and 120 h, respectively.

Results

Kinetics of Metal Ion Incorporation into H_2(tpp). The kinetics of reactions of H_2(tpp) with copper(II) perchlorate and zinc(II) nitrate in DMF at 25 °C was studied. The rate for the formation of metalloporphyrin is first order in porphyrin:

$$\frac{d[M(tpp)]}{dt} = -\frac{d[H_2(tpp)']}{dt} = k_{o(M)}[H_2(tpp)'], \qquad (1)$$

where $k_{o(M)}$ is the conditional first-order rate constant involving the metal concentration and $[H_2(tpp)']$ is the total concentration of porphyrin (C_P) minus the concentration of metalloporphyrin. The values of $k_{o(Cu)}$ are plotted against total concentration of copper C_{Cu} and its square root $C_{Cu}^{1/2}$(Fig. 1). As apparent from Fig. 1 the rate is proportional to neither the concentration of metal ion nor its half power.

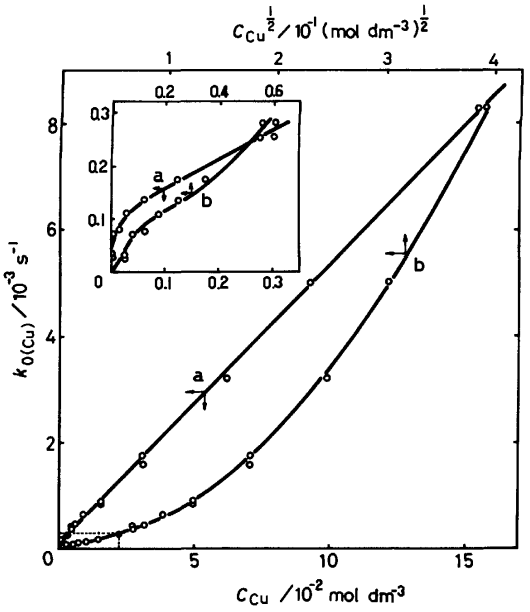

Fig. 1. Relationship between $k_{o(Cu)}$ and copper(II) ion concentration. (a): Plot of $k_{o(Cu)}$ *vs.* C_{Cu}; (b) Plot of $k_{o(Cu)}$ *vs.* $C_{Cu}^{1/2}$. The solid curves are calculated with the rate constants and formation constants obtained. The inset shows the plots in the range of lower concentration.

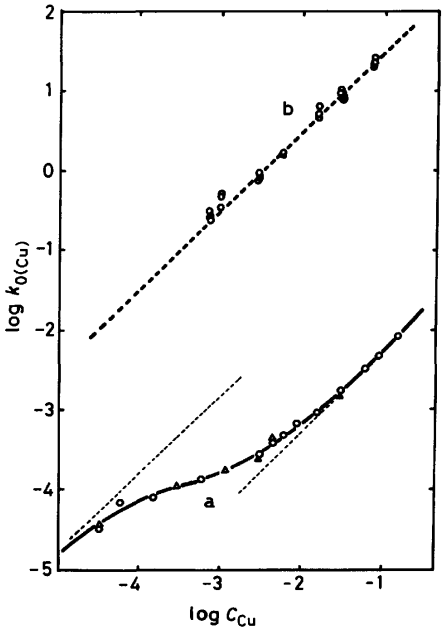

Fig. 2. Plots of log $k_{o(Cu)}$ *vs.* log C_{Cu} for the H_2(tpp) system (a) and the H(metpp) system (b). (a): The data at 25.0 °C in the absence (○) and in the presence (△) of 0.0924 mol dm^{-3} calcium(II) perchlorate; (b): the data given in ref 9.

The logarithmic relationship between rate constants and copper concentrations is shown in Fig. 2a. At lower and higher copper concentration, the reaction tends to be first order in C_{Cu}, while at the intermediate copper concentration $k_{o(Cu)}$ changes with C_{Cu} to a lesser extent. This concentration dependence of the rate constants indicates a mechanism involving a rapid preequilibrium between copper(II) ion and H_2(tpp) prior to metal insertion and proton release:[8]

$$H_2(tpp) + Cu^{2+} \overset{K}{\rightleftharpoons} Cu^{2+}\cdots H_2(tpp), \quad (2)$$

$$Cu^{2+}\cdots H_2(tpp) \xrightarrow{k_1} Cu(tpp) + 2H^+, \quad (3)$$

$$Cu^{2+}\cdots H_2(tpp) + Cu^{2+} \xrightarrow{k_2} Cu(tpp) + Cu^{2+} + 2H^+, \quad (4)$$

where $Cu^{2+}\cdots H_2(tpp)$ is an intermediate. DMF is sufficiently basic to absorb the low concentration of protons released from the free-base porphyrins as the complexation reaction proceeds. In addition, DMF should strongly solvate metal ions and compete well against trace levels of water for coordination sites on the metal ions. Assuming a rapid preequilibrium step of Eq. 2 and two parallel rate-determining steps of Eqs. 3 and 4, Eq. 5 can be readily derived.

$$k_{0(Cu)} = \frac{K[Cu^{2+}]}{1+K[Cu^{2+}]}(k_1 + k_2[Cu^{2+}]) \quad (5)$$

This equation reproduces very nicely the experimental rate data as illustrated in Fig. 2.

The important role of water in the formation of metalloporphyrins has been demonstrated in some systems.[11] We checked the effect of water on the rate in the present systems. An introduction of small amounts of water ($[H_2O]$/mol dm^{-3}=0.0608, 0.151, 0.209, 0.453, 0.867) into the copper(II)-H_2(tpp) system did not appreciably affect the rate constants. Since the water concentration of our systems is at most *ca.* 5×10^{-3} mol dm^{-3}, we believe with confidence that the presence of water, if any, did not affect our results.

Since there are some reports about effects of ionic strength on the rate of metalloporphyrin formation, we studied the effect of added salt on the rate in the present systems. The addition of 0.0924 mol dm^{-3} calcium(II) perchlorate has no effect on the reaction rate (see Fig. 2a). The absence of salt effect on the rate is consistent with the porphyrin reacting as the free-base porphyrin H_2(tpp).

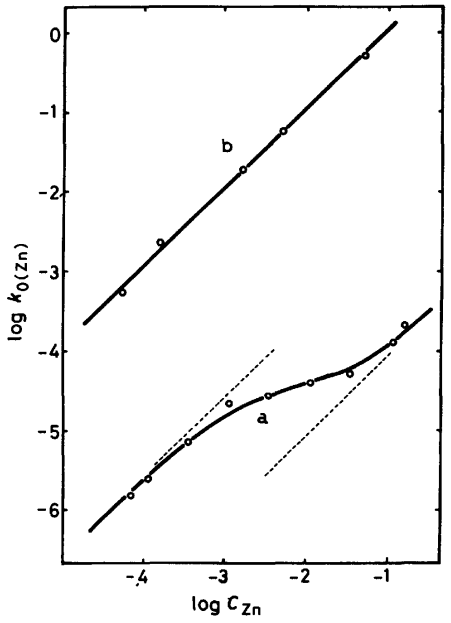

Fig. 3. Plots of log $k_{0(Zn)}$ *vs.* log C_{Zn} for the H_2(tpp) system (a) and the H(metpp) system (b). (a): At 25.0 °C in the presence of 0.30 mol dm^{-3} calcium(II) nitrate; (b): at 25.0 °C in the presence of 0.34 mol dm^{-3} calcium(II) nitrate.

a) At 30 °C. b) For D_2(tpp) the same rate constant was obtained (no kinetic effect).

As shown in Fig. 3a, the dependence of $k_{0(Zn)}$ on zinc(II) concentration is the same as for the Cu(II)-H_2(tpp) system. On the other hand, the cadmium(II)-concentration dependene of $k_{0(Cd)}$ is clearly linear over a wide range of cadmium concentrations, as illustrated in Fig. 4a.

Rate constants were determined by a nonlinear least-squares fitting with weight. The constants obtained are summarized in Table 1.

Kinetics of Metal(II) Ion Incorporation into H(metpp). The kinetics of reaction of H(metpp) with an excess of zinc(II) nitrate was studied in DMF solution containing 0.34 mol dm^{-3} calcium(II) nitrate. The rate for formation of metalloporphyrin is first order in porphyrin:

$$\frac{d[Zn(metpp)^+]}{dt} = -\frac{d[H(metpp)]}{dt} = k_{0(Zn)}[H(metpp)]. \quad (6)$$

The values of $k_{0(Zn)}$ determined in the wide range from 10^{-1} mol dm^{-3} to 10^{-5} mol dm^{-3} of zinc nitrate are proportional to the total concentration of zinc nitrate C_{Zn} (Fig. 3b).

For the Cd^{II}-H(metpp) system the dependence of $k_{0(Cd)}$ on cadmium nitrate concentration is clearly linear (see Fig. 4b) as in the case of the Cd^{II}-H_2(tpp) system. In Fig. 2b, the values of $k_{0(Cu)}$ obtained by Bain-Ackerman and Lavallee[9] are plotted against C_{Cu}. All the reactions for the H(metpp) system obey a second-order rate law: first order in porphyrin and first order in metal ion. The rate constants obtained are listed in Table 1.

Discussion

Results obtained in the present system are summarized in Table 1 together with data reported previously.[9,11,23,25,26] In the Zn^{II}-H(metpp) system the rate constant in the perchlorate medium[9] is in good agreement with ours in the nitrate medium. It has been reported that the reaction order of metal ion in the metalation of porphyrins is not always unity.[8] The earlier workers, working over a narrow range of metal ion concentration, may have deduced the first order or half order in metal ion as obvious from Fig. 1. The second-order rate constant k obtained previously in the Cu^{II}- and Zn^{II}-H_2(tpp) systems should be regarded as k_2 in the present work. In fact, as apparent from figures in Table 1, the reported k values are in good agreement with the corresponding k_2 values.

In the Cu^{II}- and Zn^{II}-H_2(tpp) systems, the formation constants (K) of intermediates given by Eq. 2 are considerably large and the K for copper(II) is greater than that for zinc(II). The intermediate may be regarded as a kinetically detected SAT complex. In the k_2 path (Eq. 4), a second metal should be inserted from the opposite side of the metal in the SAT complex with a homodinuclear activated complex. On the other hand, in the k_1 path, the metal ion in the SAT complex just drops into the porphyrin ring. Such a mechanism has been proposed previously for the cobalt incorporation into 5,10,15,20-tetra(4-pyridyl)porphine in acetic acid.[8]

In the H(metpp) systems the rate is first order with respect to metal ion over a wide range of metal ion concentrations. Recent study[27] on the crystal structures of mono-chloro-*N*-methyl metalloporphyrins of Mn, Fe, Co, and Zn shows the out-of-plane displacement of metal ion and deviation of *N*-methylated pyrrole ring from the plane of reminder of the porphyrin core. Judging from these structures, in the metalation of H(metpp) a second metal can not attack from the opposite side due to steric hindrance of the methyl group. Therefore the reaction does not involve a homodinuclear activated complex as observed in the Cu^{II}- and Zn^{II}-H_2(tpp) system: the rate of metal ion incorporation into H(metpp) is invariably first order in metal ion.

The rate of cadmium incorporation into H_2(tpp) is first order in Cd^{2+} and H_2(tpp). A large metal ion such as Cd^{2+} ion (its crystal ionic radius is 97 pm[28]) can not fit into the porphyrin nucleus because the N-N distance in H_2(tpp) is 408 pm[29] and its reaction proceeds through a pathway involving a mononuclear activated complex.

In the H(metpp) systems the rate of cadmium incorporation is faster than in the H_2(tpp) systems, whereas the rate is much slower than that for the solvent exchange at this cation.[30] In common to all mechanisms, the porphyrins form an outer-sphere complex with the metal ions (K_{os}) and then the porphyrin nucleus deforms to provide a suitable configuration to complex the metal ion (K_D). The rapid K_{os} and K_D preequilibria should be followed by the rate-determining step involving a mono-nuclear activated complex.

K_{os} for porphyrins should be smaller than those for small ligands as estimated by the Fuoss theory,[31] because the outer-sphere interaction of solvated metal ions with porphyrins occurs effectively only in the vicinity of the central part of porphyrins.

The *N*-methylated porphyrin is largely deformed in comparison with the non-methylated porphyrin. This deformation enhances both the coordinating ability of the lone pairs by directing them away from the central porphyrin cavity and the acidity of the central protons by destroying the N-H tautomerism.[32] The predeformed *N*-methylated porphyrin incorporates metal ions up to five orders of magnitude faster than the corresponding non-*N*-methylated analogue, pointing to the importance of porphyrin deformation in the metal ion incorporation into porphyrins.

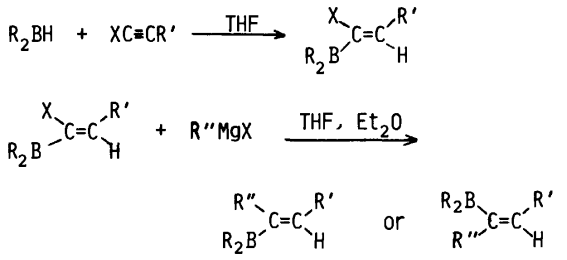
A Novel Synthesis of Internal Alkenyldialkylborane by the Reaction of 1-Halo-1-alkenyldialkylborane with Grignard Reagent

Akira ARASE,* Masayuki HOSHI, and Yuzuru MASUDA
Department of Applied Chemistry, Kitami Institute of Technology, Kitami 090
(Received December 11, 1982)

To synthesize internal alkenyldialkylboranes, coupling reactions were carried out by using 1-halo-1-alkenyldialkylboranes and Grignard reagents. Hydrogen peroxide oxidation and protonolysis with acetic acid of the reaction product revealed that internal (*E*)-alkenyldialkylborane was formed in 60—90% yield.

Organoborane is readily prepared by hydroboration, in which borane adds to a carbon-carbon double or triple bond in a regio- and stereoselective manner.[1] The skeleton of the alkyl or alkenyl group of organoborane formed by hydroboration is specified by the starting unsaturated compound. If the structure of the alkyl or alkenyl group of organoborane could be transformed to a desired one, the synthetic utility of organoborane would be greatly enhanced, although it is presently unavailable *via* hydroboration.

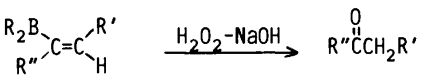
By the coupling reaction of 1-bromoalkyldialkoxyborane with alkylmagnesiumhalides, substitution of bromine with alkyl group has been reported,[2,3] and the application of this reaction to 1-halo-1-alkenylborane seems to be a successful route to regio- and stereoselective synthesis of internal alkenylboranes.[4] In this paper, we wish to report a synthesis of internal alkenyldialkylboranes by the coupling reaction of 1-halo-1-alkenylborane with a Grignard reagent (Scheme 1).



Scheme 1.

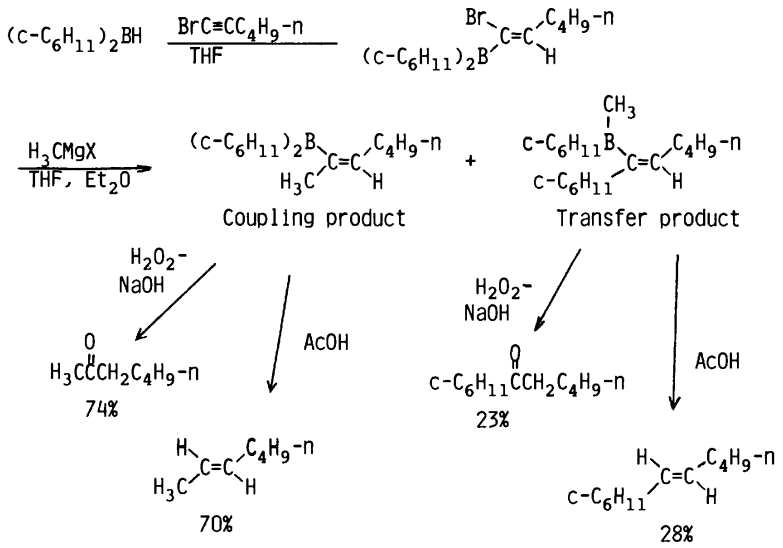
Results and Discussion

We have no suitable means to estimate directly the formation of internal alkenyldialkylborane at present. Fortunately, however, the internal alkenyl group of organoborane can be almost quntitatively transformed to the corresponding ketone by alkaline hydrogen peroxide oxidation.[5,6] Thus the yield of the internal alkenyldialkylborane was estimated indirectly from the amount of ketone formed by the above oxidation of the reaction product.



The reaction was carried out in the following way. To a THF solution of 2 mmol of 1-halo-1-alkenyldialkylborane, prepared from dialkylborane and 1-halo-1-alkyne,[7] diethyl ether solution of 2 mmol of alkylmagnesium halide was added at −50 °C and the solution was stirred at this temperature for 1 h. Then the reaction mixture was treated with alkaline hydrogen peroxide, and the product was analyzed by GLC.

In the reaction of 1-bromo-1-hexenyldicyclohexylborane with methylmagnesium iodide, 2-heptanone was obtained in 74% yield based on dicyclohexylborane employed. This result indicated that the expected 1-methyl-1-hexenyldicyclohexylborane was formed at least in this yield by the coupling reaction depicted in Scheme 2. In addition to 2-heptanone, cyclohexyl-



Scheme 2.

pentylketone was formed in 23% yield. This fact suggests that the transfer of the cyclohexyl group from the boron atom to the hexenyl carbon atom competed with the coupling reaction, to give 1-cyclohexyl-1-hexenylmethylcyclohexylborane (Transfer product in Scheme 2).

Brown *et al.* reported that the protonolysis of internal alkenylborane with carboxylic acid provided corresponding alkenes in retention of the configuration.[8] Thus to obtain further evidence for the formation of 1-methyl-1-hexenyldicyclohexylborane and to reveal the configuration of the alkenyl moiety of this com-

pound, the reaction mixture was treated with acetic acid at room temperature for 3 h, and the products were analyzed by GLC.

In this case (*E*)-2-heptene was formed in 70% yield based on dicyclohexylborane employed. The above fact supported the formation of (*E*)-1-methyl-1-hexenyldialkylborane. Thus, inversion of the configuration must be involved in the coupling reaction because 1-bromo-1-hexenyldicyclohexylborane has the *Z*-configuration as depicted in Scheme 2.[7]

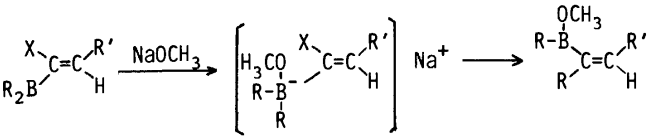
Several coupling reactions of 1-bromo-1-alkenyldialkylboranes with some Grignard reagents were examined. The results are shown in Table 1.

In most cases, two (*E*)-1-alkyl-1-alkenyldialkylboranes were formed. One was the expected coupling product and the other was the transfer product. The size of the alkyl group of the Grignard reagent had an appreciable influence on the distribution of these products. Thus in the case of small groups, such as methyl, propyl and allyl, the coupling reaction proceeded predominantly, while in the case of bulky groups, such as cyclohexyl, phenyl and benzyl, the transfer reaction proceeded predominantly.

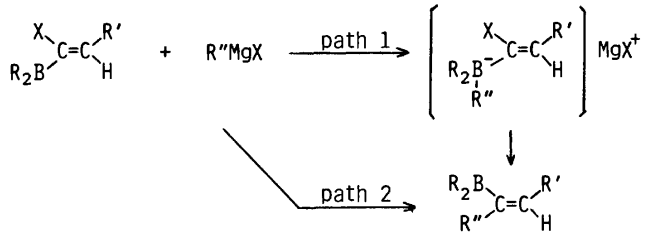
Much better results were obtained when 1-iodo-1-alkenyldialkylboranes were employed instead of 1-bromo-1-alkenyldialkylboranes. 1-Alkyl-1-alkenyldialkylborane formed in these reactions and their yields estimated in a similar manner as described above are presented in Table 2.

To clarify the configuration of the alkenyl moiety of these internal alkenylboranes, the reaction mixtures were protonolyzed with acetic acid and the resulting alkenes are presented in Table 3. In all cases examined, (*E*)-alkenes were formed, indicating that these internal alkenyldialkylboranes have the *E*-configuration.

Campbell *et al.* reported that in the reaction of (*Z*)-1-halo-1-alkenyldialkylborane with *t*-butyllithium, an inversion of the configuration occured *via* an ate-complex with hydride.[9] On the other hand, Zweifel *et al.* revealed that an internal (*E*)-alkenylborinate, having one alkyl group and one methoxl group on the boron atom, was formed in the reaction of 1-halo-1-alkenyldialkylborane with sodium methoxide.[10] In this reaction one of the two alkyl groups on the boron atom is transfered to the α-carbon atom of the alkenyl group *via* an ate-complex.



In the present reaction, it seems probable that a similar ate-complex of 1-halo-1-alkenyldialkylborane with the carbanion from the Grignard reagent would be formed at the first stage of the reaction, and then R'and R" may be transfered to the alkenyl carbon atom in a competitive manner, path 1 in Scheme 3. Initially, we attempted to couple directly 1-halo-1-alkenyldialkylborane and the Grignard reagent, path 2 in Scheme 3. However, we have no clear evidence for such a coupling reaction at the moment. In any event, it was revealed that (*E*)-1-alkyl-1-alkenyldialkylborane was formed in the present reaction.



Scheme 3.

Internal alkenyldialkylborane can be synthesized by hydroboration of internal alkyne with sterically hindered dialkylborane.[7] However, in this reaction the regioselective addition of the boron atom to the triple bond is impossible for an internal alkyne whose two alkyl groups are of a similar structure. Thus the reac-

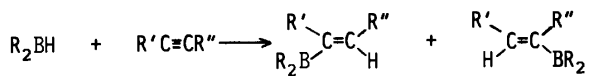
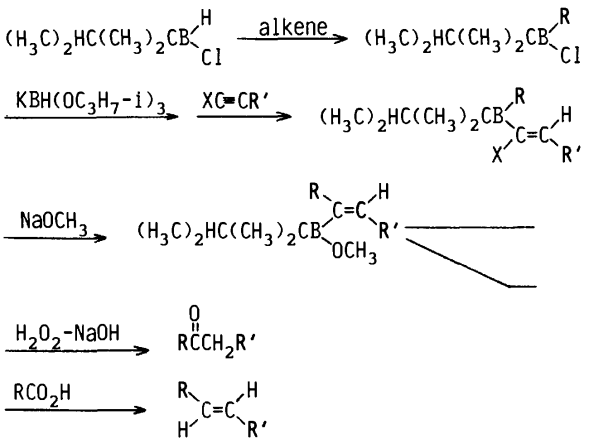
a) Protonolyzed at room temperature for 3 h. b) Based on dialkylborane used. c) 1,2-Dimethylpropyl. d) Diethyl ether was used as the solvent for the Grignard reagent. e) 1-Bromo-alkenyldialkylborane was used. f) 1-Iodo-alkenyldialkylborane was used.



tion can be successfully applied only for alkynes in which the steric hindrance and/or electronic character of the two alkyl groups differ largely from each other, or for completely symmetrical alkynes. Further, internal alkenyldialkylborane, thus obtained has the *Z*-configuration. The present reaction has the feature that two alkyl groups on the alkenyl double bond can be chosen arbitrarily. One is from relatively unhindered Grignard reagent and the other is from 1-halo-1-alkyne. In addition, the resulting internal alkenyldialkylborane has the *E*-configuration.

Several attempts were made to increase the yield of the internal alkenyldialkylborane. For, example, metal-triphenylphosphine compounds $NiCl_2(PPh_3)$[11] and $Pd(PPh_3)_4$,[12] known to have a remarkable promoting effect on the coupling reaction of alkenyl halide with the Grignard reagent, were added to the reaction mixture. Also 9-BBN was used as the hydroborating agent instead of dicyclohexylborane and bis(1,2-dimethylpropyl)borane. However, these failed to give satisfactory results.

Although the purpose of the present work is to synthesize internal alkenyldialkylborane, the regioselective formation of ketones and the regio- and stereoselective formation of internal alkenes observed in the examination of 1-alkyl-1-alkenyldialkylborane is also of interest to organic synthesis. Brown *et al.* obtained ketones or internal (*E*)-alkenes by the successive treatment of (1,1,2-trimethylpropyl)chloroborane with alkene, potassium triisopropoxyborohydride, 1-halo-1-alkyne and alkaline hydrogen peroxide or a carboxylic acid.[7,13] In this reaction the alkyl group introduced into the alkenyl double bond is derived from alkene *via* hydroboration.



However, in the present reaction such an alkyl group is derived from the Grignard reagent. Accordingly the reaction is applicable to the introduction of such alkyl groups as methyl and allyl, which cannot be introduced *via* hydroboration. For example, in the preparative scale experiment using 1-bromo-1-hexenyldicyclohexylborane and methyl magnesium iodide 2-heptanone was obtained in 68% yield by distillation of the oxidized products. Similarly (*E*)-2-heptene was also obtained in 65% yield by distillation of the protonolyzed products.

Experimental

Instruments. IR spectra (film) were recorded by using a Hitachi 285 spectrometer. ^1H NMR (CCl_4, TMS) spectra were run on a Hitachi R-20A spectrometer. Mass spectra were recorded by using a Hitachi M-52 mass spectrometer.

Reagents. Cyclohexene and 2-methyl-2-butene were distilled under argon stream after drying over lithium aluminium hydride. 1-Bromo-1-hexyne,[14] 1-bromo-1-octyne,[14] 1-iodo-1-hexyne,[15] and 1-iodo-1-octyne[16] were prepared by the methods described in the literatures. Dicyclohexylborane and bis(1,2-dimethylpropyl)borane[17] in THF were prepared as described in the literature. Alkyl halides were dried over Molecular Sieve 5A and distilled before use.

Representative Procedure. A 100-ml round bottomed flask, equipped with a gas inlet for argon, a septum inlet with a serum cap and a magnetic stirring bar, was flushed with argon. 1-Bromo-1-hexenyldicyclohexylborane was prepared by the addition of cyclohexene (0.82 g, 10 mmol) to BH_3 (5 mmol) in THF. 1-Bromo-1-hexyne (0.81 g, 5 mmol) was added slowly to the solution at −10 °C and the solution was stirred for 3 h at 0 °C. To this stirred solution, a diethyl ether solution of methylmagnesium iodide (5 mmol), prepared separately, was transfered with the aid of a syringe at −50 °C and the stirring was continued at this temperature for 1 h. Then the solution was allowed to warm to room temperature and oxidized with alkaline hydrogen peroxide, neutralized with hydrochloric acid, washed three times with NaCl-saturated water and dried over anhydrous magnesium sulfate. The solution was analyzed by GLC (10% PEG-20M, Diasolid M) using the internal standard method.

In the preparative reaction, the amounts of reagents and solvents used were four times those in the analytical reaction. After work-up diethyl ether and THF were evaporated, and the residue was put on a silica-gel column (Wako Q-50). From a mixture of two ketones, eluted by a mixture of benzene and diethyl ether (95:5), 1.55 g of 2-heptanone was distilled at 147 °C/753 Torr (68% yield) nearly free from cyclohexylpentyl ketone. ^1H NMR δ=0.88 (3H, t), 1.08—1.90 (6H, m), 2.05 (3H, s) and 2.31 (2H, t); IR 1712 cm^{-1}; MS *m/e* 142 (M^+).

The protonolysis was performed in the following way. To the reaction mixture, obtained as described above, 5 ml of acetic acid was added and the solution was stirred at room temperature for 3 h. Then the solution was washed three times with NaCl-saturated water and dried over anhydrous calcium chloride. The solution was analyzed by GLC (10% PEG-20M, Diasolid M) using the internal standard method. The preparative reaction was carried out by using four times the amounts of reagents and solvents used in the analytical reaction. After work-up 1.27 g of (*E*)-2-heptene was distilled at 97 °C/754 Torr (65% yield) uncontaminated by (*E*)-1-cyclohexyl-1-hexene. ^1H NMR δ=0.88 (3H, t), 1.00—1.50 (4H, m), 1.59 (3H, d), 1.70—2.25 (2H, m) and 5.00—5.72 (2H, m); IR 964 cm^{-1} (HC=CH); MS *m/e* 98 (M^+).

Analytical data of ketones and alkenes obtained in the examination of internal alkenyldialkylboranes are as follows.

2-Nonanone: ^1H NMR δ=0.88 (3H, t), 1.08—1.90 (10H, m), 2.05 (3H, s) and 2.30 (2H, t); IR 1713 cm^{-1}; MS *m/e* 142 (M^+).

4-Nonanone: ^1H NMR δ=0.83 (6H, t), 1.05—2.00 (8H, m) and 2.28 (4H, t); IR 1718 cm^{-1}; MS *m/e* 142 (M^+). Found: C, 76.01; H, 12.74%. Calcd for $C_9H_{18}O$: C, 75.99; H, 12.76%.

6-Undeuanone: ^1H NMR δ=0.83 (6H, t), 1.05—2.00 (12H,

m) and 2.28 (4H, t); IR 1718 cm^{-1}; MS *m/e* 170 (M^+). Found: C, 77.55; H, 13.00%. Calcd for $C_{11}H_{22}O$: C, 77.58; H, 13.02%

1-Nonen-4-one: ^1H NMR δ=0.83 (3H, t), 1.00—2.00 (6H, m), 2.30 (2H, m), 3.00 (2H, d) and 4.65—6.20 (3H, m); IR 1720 and 915 cm^{-1} (-CH=CH_2); MS *m/e* 140 (M^+). Found: C, 77.12; H, 11.50%. Calcd for $C_9H_{16}O$: C, 77.09; H, 11.50%.

1-Undecen-4-one: ^1H NMR δ=0.87 (3H, t), 1.00—2.00 (10H, m), 2.30 (2H, m), 3.00 (2H, d) and 4.65—6.20 (3H, m); IR 1719 and 916 cm^{-1} (-CH=CH_2); MS *m/e* 168 (M^+). Found: C, 78.48; H, 11.97%. Calcd for $C_{11}H_{20}O$: C, 78.51; H, 11.98%.

(E)-*5-Undecene*: ^1H NMR δ=0.81 (6H, t), 1.00—1.70 (10H, m), 1.70—2.20 (4H, m) and 5.18—5.40 (2H, m); IR 965 cm^{-1} (CH=CH): MS *m/e* 154 (M^+). Found: C, 85.66; H, 14.33%. Calcd for $C_{11}H_{22}$: C, 85.63; H, 14.33%.

(E)-*5-Tetradecene*: ^1H NMR δ=0.85 (6H, t), 1.00—1.70 (16H, m), 1.70—2.30 (4H, m) and 5.20—5.40 (2H, m); IR 964 cm^{-1} (HC=CH); MS *m/e* 196 (M^+). Found: C, 85.60; H, 14.34%. Calcd for $C_{14}H_{28}$: C, 85.63; H, 14.34%.

(E)-*1,4-Undecadiene*: ^1H NMR δ=0.84 (3H, t), 1.10—1.70 (8H, m), 1.70—2.20 (2H, m), 2.50—2.75 (2H, m) and 4.60—6.10 (5H, m); IR 914 (-CH=CH_2) and 965 cm^{-1} (CH=CH); MS *m/e* 152 (M^+). Found: C, 86.80; H, 13.21%. Calcd for $C_{11}H_{20}$: C, 86.76; H, 13.24%.

Enantioselectivity Enhancement in the Deacylation of *N*-Acyl Amino Acid Esters by Vesicular Systems of Long Chain Dipeptide Nucleophiles and a Cationic Double Chain Surfactant

Katsutoshi OHKUBO,* Noriko MATSUMOTO, Masaru NAGASAKI, Kazuhiro YAMAKI, and Harumi OGATA
Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860
(Received April 25, 1983)

The enantioselective deacylation of short chain and long chain *N*-acyl amino acid *p*-nitrophenyl esters, $CH_3(CH_2)_nCONH\overset{*}{C}H(R)\text{-}CO_2C_6H_4NO_2\text{-}p$ (R=$C_6H_5CH_2$, $(CH_3)_2CHCH_2$, CH_3; n=0, 8, 12), was carried out at 4—25 °C (pH 7.68) with the vesicular systems composed of *N,N*-didodecyl-*N,N*-dimethylammonium bromide and long chain nucleophiles, N^{α}-dodecanoyl-L-histidine, N^{α}-(*N*-dodecanoyl-L-leucyl)-L-histidine (**3a**), N^{α}-(*N*-dodecanoyl-L-phenylalanyl)-L-histidine (**3b**), and *N*-(N^{α}-dodecanoyl-L-histidyl)-L-leucine (**3c**). Both the deacylation rate and the enantioselectivity were the largest in the deacylation of the substrates possessing a long *N*-acyl chain (n=8) with the efficient dipeptide nucleophiles (**3a** and **3b**) including the L-histidine moiety in their terminal position, and the neighboring amino acid binding to the L-histidine in **3a**, **3b**, and/or **3c** was found to play an important role in the enhancement of enantioselectivity. The lowering of the reaction temperature decreased the deacylation rate and increased the enantioselectivity. The maximum enantiomer rate ratio of 24.5 was obtained in the deacylation of *p*-nitrophenyl *N*-dodecanoylphenylalaninates with the dipeptide nucleophile **3b**. The characteristic features of the present reaction are discussed on the basis of kinetic parameters (binding constants and activation parameters) and isokinetic relationships.

The enantioselective hydrolysis of ester substrates by chiral bilayer membranes has recently received considerable attention in the biomimetic chemistry. There are four reports dealing with the following reactions: (a) the deacylation of *p*-nitrophenyl *N*-benzyloxycarbonylphenylalaninates by a synthetic functionalized membrane including L-histidine moiety with a maximum enantiomer rate ratio (k_L/k_D) of 4.4 (4 °C),[1] (b) the deacylation of *p*-nitrophenyl *N*-acylphenylalaninates by the vesicles including N^{α}-palmitoyl-L-histidine with a maximum rate ratio of 5.6 (25 °C),[2] (c) the deacylation of di- or tripeptide type amino acid *p*-nitrophenyl esters by the mixed vesicles of *N,N*-dihexadecyl-*N,N*-dimethylammonium bromide and 1-hexadecanethiol surfactant with a maximum ratio of 4.53 (25 °C),[3] and (d) the deacylation of *p*-nitrophenyl *N*-acylphenylalaninates by the vesicular systems of N^{α}-(*N*-benzyloxycarbonyl-L-leucyl)-L-histidine and a cationic double chain surfactant with maximum rate ratios of 29.6 (25 °C) and 83.6 (10 °C).[4] In this paper, we wish to report the enantioselective deacylation of *N*-acyl amino acid esters by vesicular systems composed of long chain dipeptide nucleophiles and *N,N*-didodecyl-*N,N*-dimethylammonium bromide.

chain. The suitably long hydrophobic chain of **1a** (n=8), **1b** (n=8), or **1c** (n=8) contributes to the incorporation of **1a** (n=8), **1b** (n=8), or **1c** (n=8) *per se* into the vesicles and intensifies the approximation between the nucleophile and the substrate. However, the substrate **1a** (n=12) has an excessively long *N*-acyl chain which might refuse the close approach of the susceptible carbonyl group in **1a** (n=12) to the imidazolyl moiety in the nucleophile; thus **1a** showed a decreased rate and lower enantioselectivity. It is unlikely that all parts of the substrate and the nucleophile are incorporated into the vesicle layer out of the aqueous phase. Thus such an interaction between the hydrophobic benzyl group (substrate) and imidazolyl moiety (nucleophile) seems important for making the reacting positions of the nucleophile and the substrate come closer together. In this sense, the order of the deacylation rate and of the enantioselectivity in the deacylation of **1a** (n=8), **1b** (n=8), and **1c** (n=8) with **2**, **1a** (n=8)>**1b** (n=8)>**1c** (n=8), might reflect the extent of the magnitude of the interaction between the hydrophobic imidazolyl part (nucleophile) and the apolar R (R=$C_6H_5CH_2$, $(CH_3)_2CHCH_2$, or CH_3) substituent (substrate).

We studied the structural effects of the nucleophiles. The dipeptide nucleophiles (**3a** and **3b**) including the L-histidine moiety in their terminal position resulted in the large deacylation rate and the high enantioselectivity as compared with those of the nucleophile (**2**). The L-leucine or L-phenylalanine moiety, which is adjacent to the L-histidine part, might intensify the hydrophobic interaction between **3a** or **3b** and the substrate so as to enhance the deacylation rate and the enantioselectivity, even in the deacylation of the short chain substrate **1a** (n=0) which is condensed or partly incorporated by the vesicles. The chirality of the neighboring group of L-leucine or L-phenylalanine in **3a** or **3b** is also important, because the use of the D-isomer instead of the above neighboring group decreases both the deacylation rate and the enantioselectivity considerably.

The dipeptide nucleophile **3c**, which includes a L-leucine unit in its terminal position, showed low hydrolyzing activity in the deacylation of the present substrates and resulted in little or no enantioselectivity for the short chain substrate **1a** (n=0). Presumably the

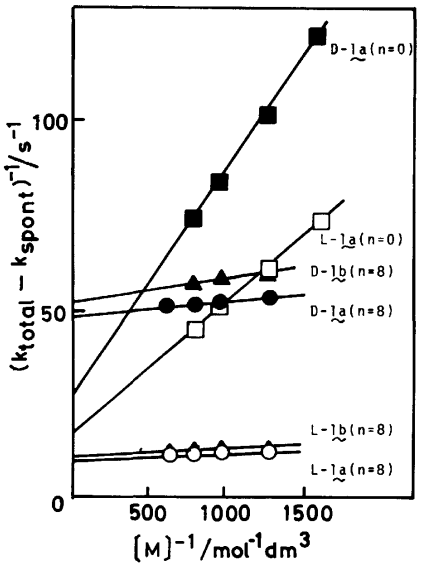

Fig. 1. Typical examples of the linear relationships between the reciprocal values of (k_{total}—k_{spont}) and [M] ([M]=[surfactant]+[nucleophile]—[surfactant]$_{cmc}$). The deacylation of 1 (1×10^{-3} mol dm^{-3}) with **2** ((3.0—7.5×10^{-5} mol dm^{-3}) and **4** ((0.6—1.5)×10^{-3} mol dm^{-3}; [**4**]/[**2**]=20) at 25 °C (pH 7.68).

steric hindrance of the terminal L-leucine part in **3c** against the reaction of **3c** itself with the substrates decreased the deacylation rate (and/or enantioselectivity), especially in the case of the deacylation of the weakly hydrophobic short-chain substrate **1a** (n=0). However, the relatively high enantioselection of the hydrophobic, long-chain substrates (**1a** (n=8, 12) and **1b** (n=8)) by **3c** suggested the contribution of the L-leucine part to the enhancement of enantioselectivity for the long chain substrates which bind strongly to the vesicles. The deacylation rate and enantioselectivity were also influenced by the reaction temperature, which affects the mobility of the substrate and the nucleophile and the liquid crystal-gel equilibrium of the vesicles. As can be seen from Table 1, the lowering of the reaction temperature decreased the deacylation rate and increased the enantioselectivity. These reaction circumstances were well reflected in the binding

Table 2. Kinetic parameters[a]

a) The reaction conditions are the same as in Table 1 except [2 or 3]=(3—7.5)×10^{-5} mol dm^{-3}, [4]=(0.6—1.5)×10^{-3} mol dm^{-3}, and [4]/[2 or 3]=20. b) The binding parameters (K_b/N and k_v) are given for the reactions at 25 °C, and the units of parameters are K_b/N (dm^3 mol^{-1}), and k_v (s^{-1}).

constant K_b/N (N is the aggregation number) and the rate constant k_v; these kinetic parameters were obtained in the usual way,[5] as indicated in Fig. 1, by taking the deacylation of **1a** (n=0, 8) and **1b** (n=8) with **2** as an example. They are listed in Table 2. The fast deacylation rate and high selectivity of the long-chain substrates are well reflected in the large values of K_b/N and k_v^L/k_v^D obtained in the deacylation of **1a** (n=8) and **1b** (n=8) with **2** or **3c**. The dipeptide nucleophile **3a** which possesses a higher enantioselective activity than that of **2** or **3c**, showed large values of K_b/N and k_v^L/k_v^D in the deacylation of short chain substrate **1a** (n=0). Furthermore, the relatively small K_b/N values of the dipeptide nucleophile **3c**, as compared with those of **2**, are in harmony with the low deacylation ability of **3c**, and the negligibly small enantioselection of the short chain substrate **1a** (n=0) by **3c** is also reflected in the markedly small K_b/N and k_v values.

The change of deacylation rate due to the temperature decrease from 25 to 4 °C was expressed by closely linear Arrhenius plots in which all the plots obtained at 4 °C deviated from linear Arrhenius plots (Fig. 2). Such a deviation of the plots at 4 °C from the Arrhenius relation might be related to the liquid crystal-gel phase transition.[6] The temperature decrease from 10 to 4 °C remarkably increased the enantioselectivity with the maximum enantiomer rate ratio 24.5 in the hydrolysis of **1a** (n=8) by the efficient dipeptide nucleophile **3b**. The characteristic features of the present reaction were also reflected in the activation parameters (ΔH^* and ΔS^*) for the reaction at 10—25 °C (Table 3); that is, the smaller (or negatively larger) ΔH^* (or ΔS^*) values of the L-substrates, as compared with those of the D-substrates, indicate the preferential attack of the nucleophile on the L-substrate, and the small ΔH^* (or ΔS^*) values for the deacylation of **1a** (n=8) or **1b** (n=8) supported the intensified interaction between the efficient dipeptide nucleophile and the substrates possessing the N-acyl chain of appropriate length (n=8). In this respect, the relatively low deacylation rate of **1a** (n=12) was reflected in the relatively large ΔH^* or ΔS^* values of **1a** (n=12). These aspects of the present reaction were also deduced from the isokinetic relation between the ΔH^* and ΔS^* values (Fig. 3). The extent of enantioselectivity can be seen in the difference of the

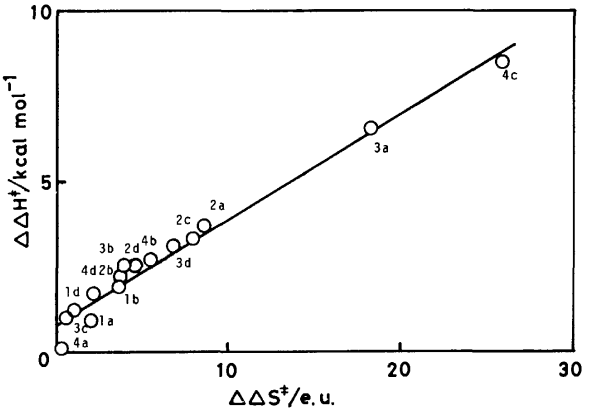

Fig. 4. A linear correlation between $\Delta\Delta H^{\ddagger}$ and $\Delta\Delta S^{\ddagger}$ values.
(Notations are the same in Fig. 3).

activation parameters between the enantiomers ($\Delta\Delta H^{\ddagger}=\Delta H^{\ddagger}_{D}-\Delta H^{\ddagger}_{L}$ or $\Delta\Delta S^{\ddagger}=\Delta S^{\ddagger}_{D}-\Delta S^{\ddagger}_{L}$). The high enantioselectivity was well reflected in the large $\Delta\Delta H^{\ddagger}$ (or $\Delta\Delta S^{\ddagger}$) values, and there is an approximately linear correlation between the $\Delta\Delta H^{\ddagger}$ and $\Delta\Delta S^{\ddagger}$ values (Fig. 4).

The present vesicular system including the dipeptide nucleophile exhibited a relatively high enantioselectivity through the efficient interaction between the L-phenylalanyl(or L-leucyl)-L-histidine moiety in the nucleophile and the hydrophobic substrates incorporated (or condensed) by the vesicles.

Experimental

Materials. N^{α}-dodecanoyl-L-histidine (**2**) and *N*-(N^{α}-dodecanoyl-L-histidyl)-L-leucine (**3c**) were obtained by the acylation of commercially available L-histidine and L-histidyl-L-leucine with dodecanoyl chloride.[7,8] N^{α}-(*N*-dodecanoyl-L-leucyl)-L-histidine (**3a**) and N^{α}-(*N*-dodecanoyl-L-phenylalanyl)-L-histidine (**3b**) were prepared from *N*-hydroxysuccinimide ester of *N*-benzyloxycarbonyl-L-leucine and *N*-benzyloxycarbonyl-L-phenylalanine by the coupling with L-histidine, the hydrobromination of the *N*-benzyloxycarbonyl group, and then the acylation of the NH_2HBr group with dodecanoic anhydride. Satisfactory elemental analyses were obtained for the nucleophiles, and those for new compounds are shown below. **3a**: Found: C, 63.18; H, 9.39; N, 12.30%. Calcd for $C_{24}H_{42}N_4O_4$: C, 63.97; H, 9.39; N, 12.43%. **3b**: Found: C, 66.32; H, 8.74; N, 10.50%. Calcd for $C_{27}H_{40}N_4O_4$: C, 66.91; H, 8.32; N, 11.56%. **3c**: Found: C, 63.81; H, 9.17; N, 12.33%. Calcd for $C_{24}H_{42}N_4O_4$: C, 63.97; H, 9.39; N, 12.43%.

The ester substrates (**1**) were prepared by the method described previously,[9] and the double chain surfactant **4** was obtained by the reaction of *N*,*N*-dimethyldodecylamine and dodecyl bromide.[9] Satisfactory elemental analyses were also obtained for **1** and **4** (C, H, N).

Hydrolysis and Kinetic Measurements. The hydrolysis of 1×10^{-5} mol dm^{-3} substrates (**1**) by the vesicles of 5×10^{-5} mol dm^{-3} nucleophile (**2** or **3**) and 1×10^{-3} mol dm^{-3} surfactant (**4**) were carried out at 4—25°C, pH 7.68 in 0.083 mol dm^{-3} tris(hydroxymethyl)aminomethane buffer involving 0.083 mol dm^{-3} KCl (μ=0.083) in H_2O including 3 vol% CH_3CN, where the stock solutions were prepared by dissolving **2** (or **3**) and **4** in the buffer by sonication at 45°C for 1 h.

The hydrolysis rate, which obeyed a good pseudo-first-order rate law (up to *ca.* 80% conversion), was followed by the spectrophotometric determination of *p*-nitrophenolate (400 nm). The second-order catalytic rate constant k was evaluated from the pseudo-first-order rate constants k_{total} (obtained with the nucleophile) and k_{spont} (obtained without the nucleophile) in the usual way ($k=(k_{total}-k_{spont})/[\text{nucleophile}]$). The binding constant K_b/N and the rate constant k_v were obtained (correlation coefficient>0.990) in the deacylation of 1×10^{-5} mol dm^{-3} substrate (**1**) by the vesicles of $(3-7.5)\times10^{-5}$ mol dm^{-3} nucleophile (**2** or **3**) and $(0.6-1.5)\times10^{-3}$ mol dm^{-3} surfactant (**4**) ([**4**]/[**2** or **3**]=20) at 25°C (pH 7.68) in the usual way with the following simplified reactions.[5]

$$S + V \underset{}{\overset{K_b}{\rightleftharpoons}} SV \xrightarrow{k_v} V + P$$

$$S \xrightarrow{k'} P,$$

where S=substrate, V=vesicles, SV=substrate-vesicle complex, and P=*p*-nitrophenolate.

The Addition Reaction of Substituted Benzenesulfinic Acids to *N*-Phenylmaleimide

Itsuo MATSUDA,* Keiichi AKIYAMA, Hiroyuki FURUTA,† and Masateru MIZUTA†

Developing and Engineering Group, Toshiba Chemical Products Co., Ltd., Chidori-cho, Kawasaki, Kanagawa 210

†*Department of Industrial Chemistry, Faculty of Engineering, Gifu University, Yanagido, Gifu 500*

(Received May 10, 1983)

The reaction of substituted benzenesulfinic acids with *N*-phenymaleimide has been carried out, and the products obtained have been identified as sulfones from analyses of their IR, UV, and NMR spectra. From the kinetic investigation, a linear Hammett relationship between the σ-value and log K_2/K_0 has been confirmed. It is concluded that the nucleophilic attack of the sulfinic acid sulfur atom on the carbon of the C=C bond of *N*-phenylmaleimide is the rate-determining step.

The addition reaction of benzenesulfinic acid to seven *N*-substituted phenylmaleimides was studied in the preceding paper.[1] A U-shaped Hammett plot was reported, but the reaction mechanism was not clearly confirmed. It was assumed that the substituent effect was not directly transferred toward the carbon atom of the C=C bond of *N*-(substituted phenyl)maleimide.

In order to pursue this point by using substituted benzenesulfinic acids, in which the substituent effect is directly conveyed toward the sulfur atom, the reaction of five substituted benzenesulfinic acids with *N*-phenylmaleimide has been studied.

The present paper will deal with the kinetic investigation of the addition reaction of *p*-substituted benzenesulfinic acids with *N*-phenylmaleimide. By measuring the unreacted sulfinic acid by means of neutralization titration, the rate constants of the reaction have been determined in the same manner as in the preceding paper.[1]

The Hammett plot, the ρ-value, and the correlation coefficient (r) have also been studied, and the activation parameters for the reaction have been calculated.

Experimental

Materials. The *N*-phenylmaleimide has been prepared by the literature method[2] and recrystallized from ethanol; mp 89.5—90.3 °C (88.0—88.5 °C[2]). The five substituted benzenesulfinic acids have been prepared in the same manner as in the literature. The following materials have been used; benzenesulfinic acid, mp 74.0—76.0 °C (74.0—76.0 °C[1]); *p*-methylbenzenesulfinic acid, mp 82.3—83.5 °C (84—85 °C[3]); *p*-methoxybenzenesulfinic acid, mp 95.5—99.0 °C (97—98 °C[4]); *p*-chlorobenzenesulfinic acid, mp 92.0—94.0 °C (93—94 °C[4]); *p*-bromobenzenesulfinic acid, mp 94.0—97.0 °C (94.0—97.0 °C[5]).

The Confirmation and Analysis of Adducts of Five Substituted Benzenesulfinic Acids with N*-Phenylmaleimide.* The adducts have been prepared in the same manner as in the preceding paper[1] and recrystallized from dichloromethane/hexane. The structural formulas have been confirmed by means of IR, UV, NMR, and elemental analyses. The yields, mps, results of elemental analyses, and NMR are summarized in Table 1.

Measurement of the Rate Constant for the Reaction The rate constants have been determined in the same way as in the preceding paper[1] by the measurement of the remaining

unreacted substituted benzenesulfinic acid *via* neutralization titration with a 0.025 M alcholic KOH solution (1 M= 1 mol dm^{-3}), using phenolphthalein as the indicator. All the kinetic runs have been conducted in the same way as in the preceding paper.[1] All the rate constants have been calculated from the second-rate equation as follows:

$$k_2 t = \frac{1}{A_0}\left(\frac{a}{a_0 - a}\right) = \frac{1}{A_0}\left(\frac{a_0}{a_0 - a} - 1\right).$$

$a_0 - a$: The titre of the 0.025 M alcoholic KOH solution at time (t).
a_0 : The initial titre of the 0.025 M alcoholic KOH solution.
A_0 : The initial concentration (mol/l) of N-substituted maleimide.

The second-order plots of the reaction of substituted benzenesulfinic acids with N-phenylmaleimide are obtained. All the rate constants, ρ-values, and r-values are noted in Table 2.

Results and Discussion

The Structural Identification of Adducts. The structural formulas of the adducts have been identified from the IR, UV, NMR, and elemental analyses, as noted in Table 1. The absorption peak at 1719—1716 cm^{-1}, assigned to C=O vibrations, and the absorption peaks at 1159—1144 cm^{-1} and at 1329—1326 cm^{-1}, assigned to S=O vibrations of the sulfones,[6], have been confirmed in the infrared spectra of all the adducts. As far as the ultraviolet spectra are concerned, λ_{max} (log ε 3.4—4.09) was observed at 218—245 nm in the UV spectra of sulfinic acids and sulfinates,[7,8] whereas λ_{max} (log ε 2.8—2.9) was observed at 266—273 nm in those of sulfones.[7,8] The values of the molar-extinction coefficients are nearly 1000 (log ε=3.00), and λ_{max} has been observed at 260—278 nm in the UV spectra of all the adducts. These data prove that the adducts are sulfones.

In the NMR spectra, the observed values agree well with the theoretical values as to the number of protons of all the adducts. The results obtained indicate that the adducts are sulfones.

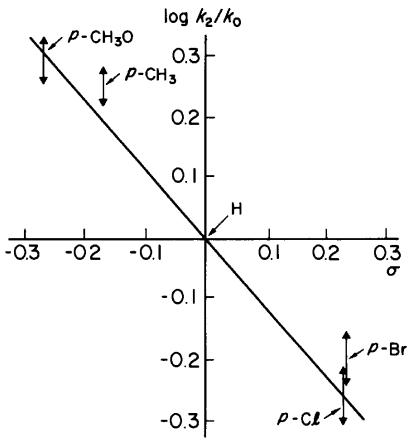

Fig. 1. Hammett plots with σ at 15 °C.

The Investigation of the Hammett Plot. The Hammett plot (log k_2/k_0 *vs.* σ-value) has been examined from the rate constants of the reactions of the five substituted benzenesulfinic acids with N-phenylmaleimide.

As be shown in Fig. 1, a plot of log k_2/k_0 against the σ-value gives a straight line. The linear Hammett relationship has been confirmed from the calculation of the ρ-value and the correlation coefficient (r). As a result, it is evident that the reaction rate is accelerated by an electron-donating group on the benzene nucleus of benzenesulfinic acid, whereas it is retarded by an electron-withdrawing group.

The Calculation of the Activation Entropy. The Arrehenius equation is as follows:

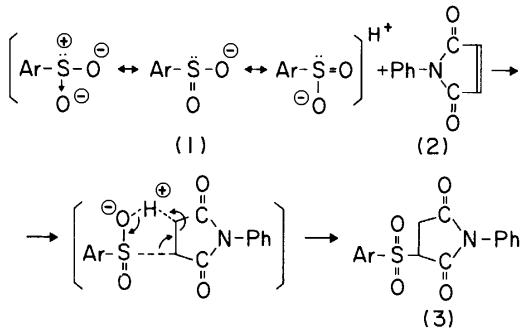
$$k = A \exp(-E_A/\mathbf{R}T),$$
$$\log k = -E_A/4.576\,T + \log A.$$

The activation energy, E_A(kcal/mol, 1 cal=4.184 J), and the logarithm of the fequency factor, log A(s^{-1}), have been obtained by plotting log$k$ against $1/T$. The activation entropy, ΔS^*(e.u.) has been calculated from the following equation:

Table 3. Activation parameters

X	E_A/kcal mol^{-1}	log(A/s^{-1})	ΔS^{*}/e.u.^{288K}
p-CH_3O	9.15±0.57	5.7±0.4	−33±2
	[8.63]	(5.2)	(−35)
p-CH_3	8.90±0.51	5.4±0.3	−34±2
	[8.17]	(4.8)	(−37)
H	8.48±0.47	4.8±0.3	−37±2
	[8.12]	(4.5)	(−38)
p-Cl	8.94±0.22	4.9±0.2	−36±1
	[8.70]	(4.7)	(−37)
p-BR	9.42±0.27	5.3±0.2	−34±1
	[8.86]	(4.9)	(−36)

The values in brackets have been calculated by the least-squares method.



Scheme 1.

$$\Delta S^{*} = 2.303\,\mathbf{R}\,(\log A - \log \mathbf{K}T/\mathbf{h}).$$

The results obtained are shown in Table 3.

The Reaction Mechanism. In the preceding paper[1] it was presumed that the nucleophilic addition of benzenesulfinic acid takes place only at the carbon-carbon double bond of *N*-substituted maleimide. However the reaction mechanism was not clearly confirmed from the substituent effect of *N*-(substituted phenyl)maleimide.

From the investigation of the Hammett plot in the present paper, it is evident that the nucleophilic attack of the sulfur atom of the sulfinic acid on the carbon atom of the ethylene linkage of *N*-substituted maleimide is the rate-determining step. As be noted in Table 3, all the activation entropies have large negative values.[9,10] It can be presumed that the degree of freedom of the transition state is smaller than that of the initial state and that the intermediate is cyclic.[5] It may be concluded that, as be shown in Scheme 1, the reaction of the substituted benzenesulfinic acid with *N*-(substituted phenyl)maleimide proceeds *via* the ionic process, and that the nucleophilic attack of the sulfur atom of sulfinic acid on the carbon atom of the ethylene linkage of *N*-substituted maleimide forms sulfone *via* a cyclic transition state.

Kinetic Studies of the Oxidation of 2,3-Dihydroxy-2-propenal (Triose Reductone) by the Peroxodisulfate Ion

Yasuo Abe,* Hideo Horii, and Setsuo Taniguchi
Radation Center of Osaka Prefecture, Shinke-cho, Sakai 593
(Received May 13, 1983)

Kinetic studies of the oxidation of 2,3-dihydroxy-2-propenal (triose reductone) by the peroxodisulfate ion ($S_2O_8^{2-}$) were carried out between pH 4.1 and 5.9 at various temperatures (10—30 °C) and for ionic strengths (I) (0.07 to 1.07 M (1 M=1 mol dm^{-3})) which were adjusted using $NaClO_4$. The pH dependence of the reaction rates revealed that the singly-charged anion (RH^-) was chiefly responsible for the reaction, while undissociated reductone was inactive to peroxodisulfate ion. The rate constant (k_2) of RH^- with $S_2O_8^{2-}$ was 0.79 $M^{-1}s^{-1}$ at 25 °C and I=1.07 M (ΔH^*=37 kJ mol^{-1}, ΔS^*=−123 J deg^{-1} mol^{-1}). A relationship of $\log k_2 = -0.95 + 1.88I^{1/2}/(1+I^{1/2})$ was found at 30 °C.

The 2,3-dihydroxy-2-propenal produced from dextrose by alkaline hydrolysis is called triose reductone because of its strong reducing ability. The reductone is the simplest in structure of the compounds having an enediol group; the physiologically important L-ascorbic acid is a typical compound of this structure. Thus kinetic studies on the reaction of triose reductone would help to clarify the mechanisms of the physiological activities of enediol compounds. Previously, we studied the kinetics of the autoxidation of triose reductone in an aqueous solution and compared the rate constants with those of L-ascorbic acid.[1] The peroxodisulfate ion is known as a powerful two-electron oxidizing agent which employes an electron-transfer mechanism. The reaction with alcohol gives alcohol radicals and sulfate anion radicals.[2] In an effort to resolve whether the sulfate anion radicals work as an oxidizing species in the present experiment, we have studied the kinetics of the oxidation of triose reductone by aqueous peroxodisulfate ion in the pH range 4.1—5.9 and have compared the kinetic parameters with those for the reaction of L-ascorbic acid.[3]

Experimental

Materials. Triose reductone was prepared and purified by the method described in the literature.[4] Potassium peroxodisulfate and sodium perchlorate of analytical grade of E. Merck were used without further purification. All the other chemicals used were guaranteed reagents of the Wako Pure Chemicals Co. Ltd.

Reaction Solution. The triose reductone solution was prepared by dissolving 2 mg of the compound in 0.5 dm^3 of the aqueous solution saturated with argon (a high-purity argon gas was bubbled through the solution to remove the dissolved oxygen) and containing 50 mM of acetate buffer, 5 mM of disodium dihydrogen ethylenediaminetetraacetate (EDTA), and a given weight of sodium perchlorate; the bubbling of an argon gas was continued to avoid oxygen contamination. The potassium peroxodisulfate solution was prepared by dissolving 0.9 g of the solid in 0.25 dm^3 of water and then the dissolved oxygen was removed by the bubbling of argon through the solution.

Kinetic Method. Since the triose reductone is sensitive to oxygen, the reductone solution was transferred into a quartz cell under replacement with argon gas. The reaction was started by mixing the peroxodisulfate solution with the reductone solution. The pH value, ionic strength, and temperature of the reaction solution were kept constant during the reaction. Kinetic data were obtained spectrophotometrically by using a Hitachi 323 Recording Spectrophotometer. The temperature was controlled by circulating thermostated water around the cell housing. The reaction were followed by measuring the decreasing absorption of triose reductone at a wavelength between 268 and 293 nm. The pH values of the reaction solutions were measured with a Toa Dempa HM-20E digital pH meter immediately after the measurement of the absorption. The activity coefficients f_i for protons at varying ionic strengths (I) were obtained by using $\log f_i = -0.358 z_i^2 I^{1/2}/(1+10^8 a_i \times 0.2325 I^{1/2})$ with a_i=900 pm and z_i=1.[5] The activity coefficients used in this paper were 0.83 (0.17), 0.79 (0.57), and 0.76 (1.07): the ionic strength is given in parentheses.

Results and Discussion

Dissociation Constant of Triose Reductone. The first dissociation constants (pK_1) of triose reductone (RH_2) for the equilibrium, $RH_2 \rightleftharpoons RH^- + H^+$, were determined by the spectrophotometric method reported previously[1] at an ionic strength of 1.07 M (with the temperature (°C) in parentheses): 4.83 (10), 4.83 (15), 4.78 (20), 4.74 (25), and 4.70 (30), and at 30 °C (with the I in parentheses): 4.78 (0.57) and 4.88 (0.17).

Kinetics of the Reactions. The kinetic runs were carried out over the pH range from 4.1 to 5.9. In this pH range, the thermal decomposition of either peroxodisulfate or triose reductone was so slow under 30 °C that the decomposition could be neglected.[2] When pseudo-first-order conditions ($[TR]_0 \ll [S_2O_8^{2-}]_0$) were adopted, plots of $\ln A_t$ *vs.* t were linear for at least 60% of the whole reaction; here $[TR]_0$ indicates the initial concentrations of all the forms of triose reductone ($[TR]_0$ can be put as $[RH_2]_0 + [RH^-]_0$ in the present pH range), $[S_2O_8^{2-}]_0$ indicates the initial concentration of peroxodisulfate ion, and A_t indicates the absorbance of triose reductone at time t. The observed first-order rate constants were proportional to the concentration of peroxodisulfate ion. When second-order conditions ($[TR]_0 = [S_2O_8^{2-}]_0$) were employed, the second-order plots were also linear; *i.e.* the plots of $[TR]^{-1}$ *vs.* t were rectilinear. Thus, the empirical rate equation may be written as follows:

$$-\frac{d[TR]}{dt} = k_0[TR][S_2O_8^{2-}], \quad (1)$$

where k_0 is the observed second-order rate constant. The conventional treatment of the reaction involving the acid dissociation equilibrium gives k_0 as in Eq. 2.

$$k_0 = k_1 + (k_2 - k_1)\frac{K_1}{[H^+] + K_1}, \quad (2)$$

$$RH_2 \overset{K_1}{\rightleftharpoons} RH^- + H^+, \quad (3)$$

where K_1 is the first dissociation constant of triose reductone, and k_1 and k_2 are rate constants of the reaction of RH_2 and RH^- with $S_2O_8^{2-}$, respectively. The plots of k_0 *vs.* $K_1/(K_1+[H^+])$ showed a proportional relationship; the plots are given in Figs. 1 and 2. The k_1 values calculated from the experimental data are considered to be zero within the experimental errors. Hence, the rate equation becomes:

$$-\frac{d[TR]}{dt} = \frac{k_2K_1[TR][S_2O_8^{2-}]}{[H^+] + K_1}. \quad (4)$$

The k_2 values are listed in Table 1. The rate equation 4 can be simplified to Eq. 5:

$$-\frac{d[TR]}{dt} = k_2[RH^-][S_2O_8^{2-}]. \quad (5)$$

Equation 5 shows that the reactive species of triose reductone against peroxodisulfate is the monoanion of the reductone in the present pH range.

Mechanism of the Reaction. The presence of $RH^{\cdot}$ radical in the autoxidation of triose reductone catalyzed by peroxidase has been confirmed by ESR measurements.[6] For the purpose of examining whether the present reaction occurs *via* successive one-electron transfers involving the $RH^{\cdot}$ radical, the acrylonitrile (2×10^{-4} dm^3) was added as a radical scavenger to the reaction solution (3×10^{-3} dm^3) at the start of the reaction. The observed second-order rate constant decreased to only 90% of the value in the absence of acrylonitrile. No observable white sediment of polyacrylonitriles was found in the reaction solution in the course of reaction. Although there are some possibilities that the sulfate anion radicals produced in Eq. 6 oxidize triose reductone by chain reactions, the effect of the radical scavenger is not so strong as to indicate the importance of $RH^{\cdot}$ radical. This fact suggests that the reaction occurs *via* a two-electron oxidation instead of successive one-electron oxidations. But it is reasonable to suppose that triose reductone radical and sulfate anion radical are produced by a one-electron oxidation once in a cage, then they react rapidly to consume the radicals. The following scheme can be written to account for the experimental results:

$$RH^- + S_2O_8^{2-} \xrightarrow{k_2} (RH^{\cdot} + SO_4^{-\cdot} + SO_4^{2-}), \quad (6)$$

$$\xrightarrow[\text{very fast}]{} 2SO_4^{2-} + DR + H^+, \quad (7)$$

where DR represents dehydroreductone hydrate, 2,2-dihydroxypropane-1,3-dial. Dehydroreductone is known as an unstable product in the oxidation of triose reductone by many oxidizing agents to give formic acid,

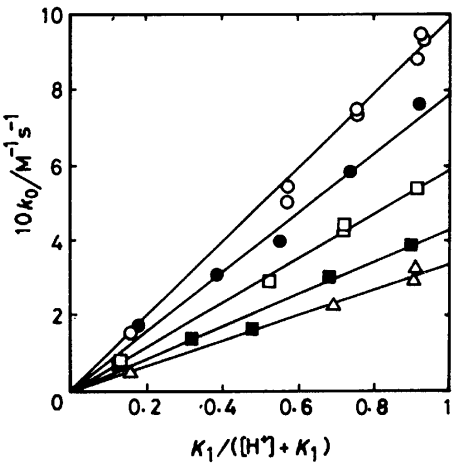

Fig. 1. Relation between k_0 and $K_1/([H^+]+K_1)$ for the oxidation of triose reductone with peroxodisulfate at ionic strength 1.07 M and various temperatures. ○: 30°C, ●: 25°C, □: 20°C, ■: 15°C, △: 10°C.

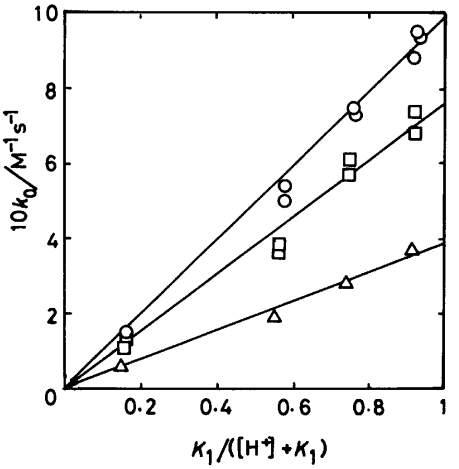

Fig. 2. Relation between k_0 and $K_1/([H^+]+K_1)$ for the oxidation of triose reductone with peroxodisulfate at 30°C and various ionic strengths. ○: 1.07 M, □: 0.57 M, △: 0.17 M.

Table 1. The second-order rate constant, k_2 in Eq. 2, and the kinetic parameters[a]

Temp	Ionic strength	$10k_2$
°C	M	$M^{-1}\,s^{-1}$
10	1.07	3.4±0.1
15	1.07	4.3±0.2
20	1.07	5.9±0.1
25	1.07	7.9±0.3
30	1.07	9.9±0.2
30	0.57	7.6±0.2
30	0.17	3.9±0.2
$\Delta H_2^{\ddagger}$	37±1 kJ mol^{-1}	
$\Delta S_2^{\ddagger}$	−123±5 J deg^{-1} mol^{-1}	

a) The initial concentrations are 6.0×10^{-5} M for triose reductone and 4.5×10^{-4} M for potassium peroxodisulfate, 5×10^{-3} M in EDTA, 0.05 M in sodium acetate, and the given concentrations of acetic acid and sodium perchlorate.

glyoxylic acid, and carbon dioxide.[7-9] Therefore, DR produced in this reaction may also be decomposed by the following equations.

$$DR + 2H_2O + S_2O_8^{2-} \xrightarrow{\text{very slow}} HCOCOOH + 2SO_4^{2-} + HCOOH + 2H^+, \quad (8)$$

$$HCOCOOH + H_2O + S_2O_8^{2-} \xrightarrow{\text{very slow}} HCOOH + 2SO_4^{2-} + CO_2 + 2H^+. \quad (9)$$

Although the reaction of triose reductone with peroxodisulfate is complicated by competitive and successive reactions with the peroxodisulfate, it is reasonably supposed that the decomposition reactions of DR, Eqs. 8 and 9, occur very slowly compared with Eq. 6, since the experimental rate law for the reaction scheme (Eqs. 6—9) is in agreement with Eq. 5.

Temperature Dependence. The activation parameters correspnding to the specific rate constants are shown in Table 1. Both ΔH_2^* and ΔS_2^* values in the reaction of triose reductone (37 ± 1 kJ mol^{-1} and -123 ± 5 J deg^{-1} mol^{-1}) are smaller than those (45 ± 1 kJ mol^{-1} and -102 ± 4 J deg^{-1} mol^{-1}, respectively) obtained in the reaction of L-ascorbic acid with peroxodisulfate ion.[3] The k_2 values in the reaction of triose reductone are larger than those obtained in the reaction of L-ascorbic acid over the temperature range of 10—30 °C. Although it has no practical significance, it is worth mentioning that the k_2 for triose reductone should become smaller than the k_2 for L-ascorbic acid at temperatures higher than 108 °C.

Ionic-strength Dependence. Although the ionic-strength values employed in this work lie outside the Debye-Hückel region, the plots of $\log k_2$ *vs.* $I^{1/2}/(1+I^{1/2})$ showed a straight line, with a relationship of $\log k_2 = -(0.95 \pm 0.07) + (1.88 \pm 0.17) I^{1/2}/(1+I^{1/2})$. This dependence is of a kind which is expected for the reaction between two ions of the same sign; the positive value of 1.88 is in good agreement with that of 2.04 which is obtained from the theoretical term of $1.02 z_a z_b \times I^{1/2}/(1+I^{1/2})$ with $z_a = -1$ for RH^- and $z_b = -2$ for $S_2O_8^{2-}$. The ionic-strength dependence suggests that the reaction between RH^- and $S_2O_8^{2-}$ (Eq. 6) is the rate-determining step.

The authors wish to express their thanks to Professor Masaru Kimura of Nara Women's University and to Dr. Takaaki Dohmaru for their helpful discussions and to Dr. Shin-ichi Fujita for kindly offering his data processing system.

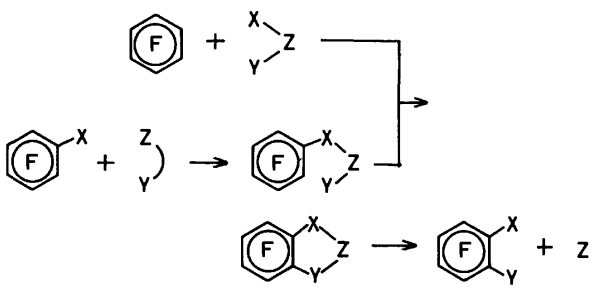
ortho-Disubstituted *F*-Benzenes. V. Intramolecular Heteroatom-facilitated ortho-Substitution of *F*-Benzene Derivatives with Oxazolinyl and Oxazinyl Groups

Yoshinari INUKAI,† Keisuke TAKUMA, Koji TORITANI,††
Takaaki SONODA, and Hiroshi KOBAYASHI*
Research Institute of Industrial Science, Kyushu University 86, Kasuga, Fukuoka 816
††*Department of Molecular Science and Technology, Interdisciplinary Graduate School of Engineering Sciences, Kyushu University 39, Kasuga, Fukuoka 816*
(Received June 6, 1983)

The oxazinyl and oxazolinyl substituents on an *F*-benzene ring facilitated the substitution of fluorine ortho to the heterocyclic functional groups by carbon and nitrogen nucleophiles. Alkylmagnesium halides and alkyllithium compounds were employed as the carbon nucleophile, and lithium *N*-methylanilide and *N*-methylanilinomagnesium halide as the nitrogen nucleophile. The selective ortho-substitution was accomplished by the complexing interaction between the ring-membered nitrogen on the functional substituents and the anionic nucleophile through the interposing metal cation. Effects of the substituents in the orientations and rates of the reactions depended upon the polarity of the reaction solvent and the kinds of anionic nucleophile and counter metal cation.

The reaction of monosubstituted *F*-benzene[1] with nucleophiles affords predominantly para-disubstituted derivatives, except for a few cases of the formation of meta-disubstituted products.[2] Some attempts at the specific formation of ortho-disubstituted *F*-benzenes are available in the literature. Most of them can be classified as intramolecular cyclization followed by cleavage of the resulting (*F*-benzo)-heterocyclic ring, as shown in Scheme 1.[3-16] Such heterocyclic rings, however, sometimes have been difficult to cleave.

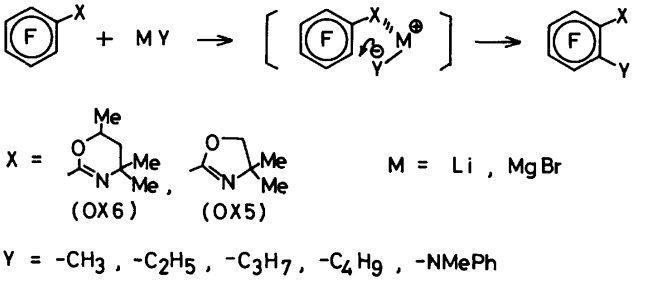


Scheme 1.

There are also some exceptional cases where the ortho-substitution dominates. Actually nitro, carbonyl, sulfone, and amine oxide substituents direct the ortho-substitution in nonpolar solvents.[2c,17] This anomalous behavior was interpreted in terms of a particular affinity of such substituents for the counter cation paired with an anionic nucleophile at the transition stage; namely, the cation is pulled towards the close neighborhood of such a substituent, so that the anionic nucleophile is oriented to attack preferentially the sterically favorable ortho-position.

Meyers and Gschwend showed that an oxazolinyl substituent on an aromatic ring was highly efficient in directing the lithiodeprotonation at the ortho-position,[18,19] and accelerated the nucleopuhilic displacement of a methoxyl group or fluorine ortho to the oxazolinyl substituent.[18,20] The ortho-activation by the oxazolinyl group in deprotonation and nucleophilic displacement was attributable to the strong ion-dipole interaction between the oxazolinyl group and lithium cation.

In the present study, 2-oxazolin-2-yl (OX5) and 1,3-oxazin-2-yl (OX6) groups on an *F*-benzene ring were examined as to how well they promoted nucleophilic attack of carbon and nitrogen nucleophiles on the ortho-position prior to the para-one (Scheme 2).



Scheme 2.

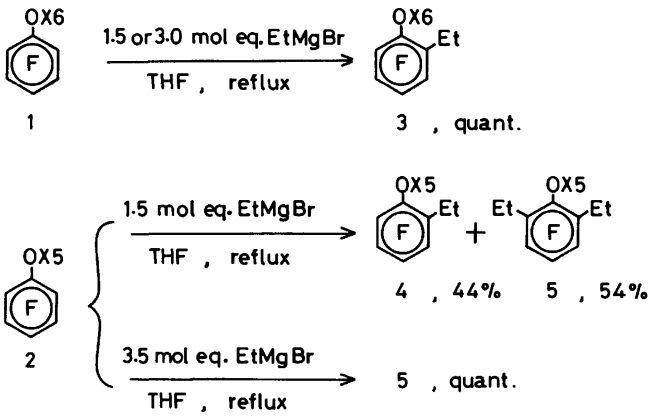
Results

The starting 2-(*F*-phenyl)-4,4,6-trimethyl-5,6-dihydro-4*H*-oxazine (**1**) and 2-(*F*-phenyl)-4,4-dimethyl-2-oxazoline (**2**) were obtained according to the methods for the preparation of the corresponding hydrocarbon analogues.[21]

Reaction with C-Nucleophile. Lithium and magnesium ions were favorable for the complex formation with the oxazoline and oxazine groups.[18] Organolithium and Grignard reagents were therefore employed as carbon nucleophiles.

Both Grignard and lithio reagents attacked exclusively the aromatic carbon ortho to the oxazolinyl and oxazinyl groups. The efficacies in the ortho-orientation caused by these functional substituents are evident in the formation of 2′-alkyl-*F*-phenyl derivatives (locations on the *F*-phenyl ring are primed) and 2′,6′-dialkyl-*F*-phenyl ones, while no 4′-monoalkylated products nor 2′,4′-dialkylated ones form at all.

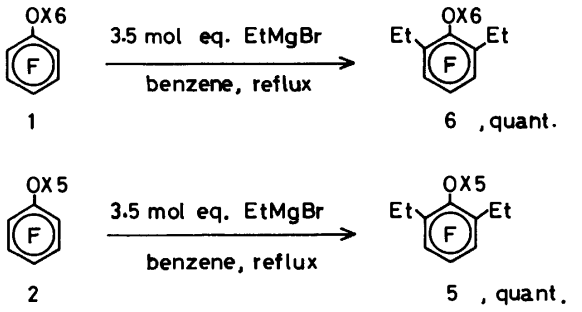
† Present address: Government Industrial Research Institute in Kyushu, Shukumachi, Tosu, Saga 841.



Scheme 3.

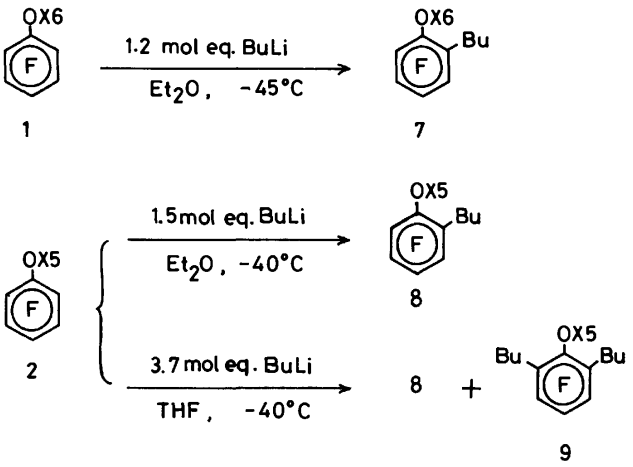
In the reaction of the oxazine **1** and the oxazoline **2** with 1.5 times molar amounts of ethylmagnesium bromide in THF, the corresponding ortho-substituted *F*-phenyl derivatives, **3**, **4**, and **5**, were exclusively afforded, as shown in Scheme 3. The ethyl derivatives **3** and **4** each show four ^{19}F-NMR signals of equal intensity. Even if an excess of ethylmagnesium bromide was added, the oxazine **1** in THF gave only the 2′-monoalkylated product **3** quantitatively, while the oxazoline **2** gave the 2′,6′-dialkylated product **5** also in quantitative yield by use of an excess of ethylmagnesium bromide. The latter product exhibits two ^{19}F-NMR signals with relative intensities of one to two. These results indicate that the oxazine **1** and the oxazoline **2** are both highly ortho-directing, no para-substituted products being formed at all.

When an excess amount of ethylmagnesium bromide was used in benzene, which is less polar and has a higher boiling point than THF, the oxazine **1** and oxazoline **2** both afforded only the 2′,6′-disubstituted products, **5** and **6**, quantitatively (Scheme 4).



Scheme 4.

These substrates **1** and **2** reacted with butyllithium to give the corresponding ortho-substituted products, as shown in Scheme 5. The reactions with butyllithium, however, could be controlled only with some difficulty, so that the selectivity and yield of the products were less reproducible than those with the Grignard reagent.



Scheme 5.

a) Molar ratio of lithium *N*-methylanilide to the subtrate. b) IPE, for diisoproryl ether.

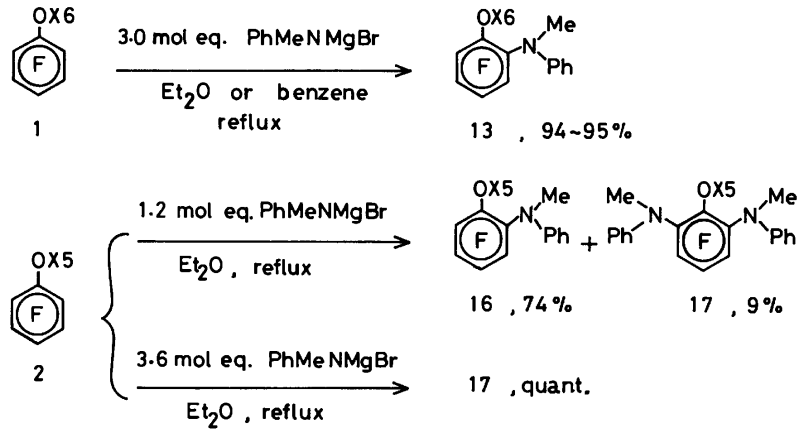
These difficulties would be due to the reactivity of alkyllithium being higher than that of the alkylmagnesium halide.

Methyl and propyl groups could be also introduced to the ortho-position on the *F*-phenyl group of the oxazine **1** and the oxazoline **2** by use of their lithio and Grignard reagent to give 2'-alkyl derivatives **10**, **11**, and **12**.[22)]

Comparisons of ^{19}F-NMR spectra of the present (2'-alkyl-*F*-phenyl)oxazines, **3**, **7**, and **10**, and -oxazolines **4**, **8**, **11**, and **12**, indicated that the chemical shifts of one fluorine varied with the alteration of the alkyl substituents, while those of the other fluorines remained within a range of 0.2 ppm, as shown in Table 1. Thus, the former signals could be assigned tentatively to the 3'-fluorine adjacent to such alkyl substituents. The assignment of fluorine chemical shifts was compatible with the relatively large downfield shifts at the adjacent 3'-fluorine caused by the monoalkylation and at the 3'- and 5'-fluorines by the dialkylation, and also the presence of the long-range coupling between 3'-fluorine and 2'-methyl hydrogens of **11** in its ^{19}F-NMR spectrum.

Reaction with N-*Nucleophile.* In the reactions with lithium *N*-methylanilide as a nitrogen nucleophile, the oxazine **1** and the oxazoline **2** gave the corresponding ortho-substituted *F*-phenyl derivatives in diisopropyl ether and THF solutions, as shown in Scheme 6.

The monoanilino derivatives, **13** and **16**, each show four ^{19}F-NMR signals of equal intensity. Their structures were interpreted on the basis of the ^{19}F-NMR chemical shifts which were assigned in an analogous manner with those of the ortho-alkylated *F*-phenyloxazines and -oxazolines. The mass spectra of **14**, **15**, and **17** indicate that the dianilino substitutions also occurred in the above reactions. ^{19}F-NMR spectra of **14** and **17**, which showed two signals of one to two in intensity ratio indicated that the disubstituted *F*-phenyloxazine and -oxazoline were of the vicinal 1',2',6'-trisubstituted *F*-benzene structure. On the other hand, three ^{19}F-signals of equal intensity of **15** indicated



Scheme 7.

that the disubstituted *F*-phenyloxazine structure was the unsymmetrical 1′,2′,4′-trisubstituted *F*-benzene structure. Lithium *N*-methylanilide in a THF solution attacked the oxazine **1** on the 2′- and 4′-positions (Run 3 in Table 2), while in diisopropyl ether, which is less polar than THF, it attacked the 2′- and 6′-positions (Run 2 in Table 2). The oxazoline **2** did not afford any 4′-substituted product, even in a THF solution (Compare Run 6 with Run 3 in Table 2), and was superior in the regioselectivity than was the oxazine **1**.

With *N*-methylanilinomagnesium bromide, on the other hand, both the reaction of the oxazine **1** and that of the oxazoline **2** proceeded, in analogy with those with alkylmagnesium bromide, to give 2′-mono- and 2′,6′-disubstituted products, **13**, **16**, and **17**, predominantly, in both diethyl ether and benzene solutions (Scheme 7).

Discussion

The oxazinyl and oxazolinyl groups on an *F*-benzene ring are effective to facilitate the carbon-carbon and carbon-nitrogen bond formation exclusively at the ortho-position on the *F*-benzene ring relative to those heterocyclic functional groups. Such ortho-directing effects, however, seemed to be remarkable among the carbon and nitrogen nucleophiles studied so far, since the reaction with other nucleophilic reagents such as lithium aluminum hydride and lithium phenoxide took a longer reaction period and afforded an appreciable yield of the para-substituted product, though the ortho-substituted one was major.[23]

The ring-membered nitrogens of the oxazinyl and the oxazolinyl groups seem to play the indispensable role in the interacion with the metal cation, since the oxolanyl group in 2-methyl-2-(*F*-phenyl)-1,3-dioxolane (**18**) is less effective not only in the regioselectivity but also in the acceleration of reactions, as shown in Scheme 8, where the dioxolane **18** were not alkylated with ethylmagnesium bromide under reflux in benzene.

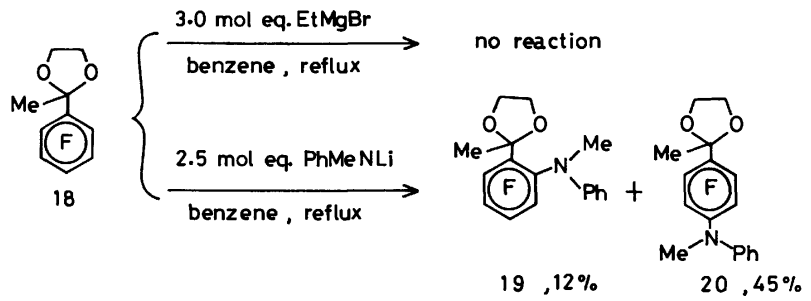
Complexation of the metal cation at the ring-membered nitrogen would lead the nucleophilic agent, which was tightly paired with the metal cation, to attack the ortho-position nearest to the heterocyclic substituent. The coordination of the nitrogen to metal cation would also induce the mesomeric polarization of the C–N double bond of the heterocyclic substituents. The effect would promote not only the nucleophilicity of the anionic agent at the beginning stage of the attack, but also the mesomeric stabilization of an intermediary anionic σ-complex at the subsequent stage, and facilitate the bond formation between the ortho-carbon and nucleophiles as illustrated in Scheme 9.

The oxazolinyl group of a smaller ring size seemed more effective in promoting the reaction than the larger oxazinyl group; once the substitution occurred on an ortho-position, the former allowed the successive substitution on the opposite ortho-position even under milder conditions, in contrast to the latter in which no additional ortho-substitution occurred.

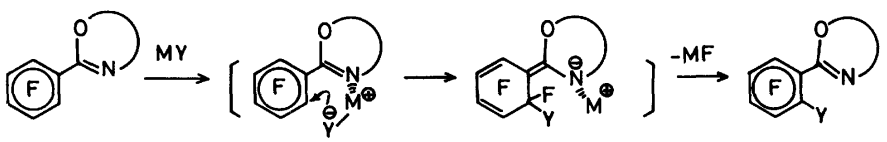
Such differences in the reactivity and selectivity might be due to the restricted rotation about the bond between the heterocyclic ring and the ortho-monosubstituted *F*-phenyl ring; *i.e.*, a coplanar conformation which would be required for mesomeric stabilization upon the subsequent substitution might be hindered by the ortho-substituent on the *F*-phenyl ring, and such a steric hindrance would be more pronounced with a larger ring size than a smaller one.

Polarity of the reaction solvent also affected the reaction path. In a less polar solvent such as benzene, the substitution proceeded to a higher extent. Such increased reactivity was understandable as follows: The less polar was the reaction solvent, the more tightly the metal cation would be coordinated with the substrate molecule at the donating nitrogen atom, so that the anionic nucleophile attacked preferably the nearest ortho-position.

The participation of the oxazinyl and oxazolinyl substituents depended also upon the kind of anionic nucleophiles; lithium amide, hydroxide, and bromide in benzene solutions caused no reactions; the starting compounds remaining intact, presumably due to very low solubility of these lithium salts in the reaction solvent.



Scheme 8.



Scheme 9.

Experimental

Melting points were uncorrected. IR spectra were measured with a JASCO DS-403G spectrometer. ^{1}H- and ^{19}F-NMR chemical shifts were recorded on a HITACHI 24-B against the internal TMS reference, and on JEOL FX-100 and HITACHI 24-F as the positive values downfield from the internal *F*-benzene reference, respectively. Mass spectra were obtained with JEOL JMS-07 and 01SG spectrometers. Electronic spectra were measured with a HITACHI 200-20 instrument. *F*-Benzonitrile[24] and *F*-benzoyl chloride[25] were prepared according to the literature methods.

2-(F-Phenyl)-4,4,6-trimethyl-5,6-dihydro-4H-oxazine (1). *F*-Benzonitrile (5.79 g, 30 mmol) was added dropwise to concentrated sulfuric acid (15 g, 220 mmol) over a 5-min period at 0 °C. To the mixture was added 2-methyl-2,4-pentanediol (3.54 g, 30 mmol) over a 15-min period at 0 °C. The resulting mixture was stirred at 0 °C for an additional 30 min, then at room temperature for another additional 30 min, and poured into ice-water. The aqueous mixture was basified by sodium hydroxide and extracted with diethyl ether. The ethereal extract was washed with water and dried over sodium sulfate. The dried extract was distilled, and the fraction boiling at 113 °C/1200 Pa gave 2-(*F*-phenyl)-4,4,6-trimethyl-5,6-dihydro-4*H*-oxazine (**1**) (4.48 g, 51%) in colorless oil. ^{1}H-NMR (neat): δ=1.05—2.10 (m, 11H, CH_3, CH_2) and 4.00—4.60 (m, 1H, CH)). ^{19}F-NMR (CCl_4): —0.7 (m, 2F, F$^{3'}$ and F$^{5'}$), 7.6 (tt, 1F, F$^{4'}$), and 20.4 ppm (m, 2F, F$^{2'}$, and F$^{6'}$), ($J_{2'4'}$=3.4 and $J_{3'4'}$=21.2 Hz). UV (EtOH): λ_{max} (log ε); 207 (2.94) and 263 nm (2.16). Found: C, 53.12; H, 4.20; N, 4.50%; M$^+$, 293. Calcd for $C_{13}H_{12}NF_5O$: C, 53.25; H, 4.13; N, 4.78%; M, 293.

2-(F-Benzoylamino)-2-methyl-1-propanol (21). A solution of *F*-benzoyl chloride (1.74 g, 7.6 mmol) in anhydrous dichloromethane (5 cm^3) was added dropwise to a stirred solution of 2-amino-2-methyl-1-propanol (1.35 g, 15 mmol) in anhydrous dichloromethane (10 cm^3) over a 30-min period at 0 °C. The mixture was kept stirred at room temperature for an additional 12 h, and then evaporated to dryness *in vacuo*. The residue was washed with water, and recrystallization from benzene gave 2-(*F*-benzoylamino)-2-methyl-1-propanol (**21**) (1.86 g, 87%) in colorless plates, mp 126 °C. IR (KBr): 3350 and 3200 (OH, NH), and 1660 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$–DMSO-d_6): δ=1.34 (s, 6H, CH_3), 3.54 (d, J=5.3 Hz, 2H, CH_2), 4.28 (br. t, J=5.3 Hz, 1H, OH), and 7.25 (br. s, 1H, NH). Found: M$^+$, 283. Cacld for $C_{11}H_{10}NF_5O_2$: M, 283.

2-(F-Phenyl)-4,4-dimethyl-2-oxazoline Hydrochloride (22). A mixture of the propanol **21** (9.52 g, 33.7 mmol) and thionyl chloride (7.1 cm^3, 100 mmol) was stirred at room temperature for 1 d. The mixture was poured into diethyl ether, and evaporated to dryness *in vacuo*. The residue was 2-(*F*-phenyl)-4,4-dimethyl-2-oxazoline hydrochloride (**22**) (7.47 g, 72%) in a colorless solid, mp 119—120 °C. ^{1}H-NMR ($CDCl_3$): δ=1.45 (s, 6H, CH_3), 3.85 (s, 2H, CH_2), and 6.15 (br. s, 1H, HCl). Found: M$^+$, 303 and 301. Calcd for $C_{11}H_9NClF_5O$: M, 303 and 301.

2-(F-Phenyl)-4,4-dimethyl-2-oxazoline (2). A solution of the hydrochloride **22** (3.35 g, 11.1 mmol) in anhydrous THF (10 cm^3) was added dropwise to a stirred mixture of sodium hydride (17.7 mmol) and anhydrous THF (10 cm^3) over a 5-min period at room temperature under a dry nitrogen atmosphere. The mixture was stirred at room temperature for an additional 10 min and poured into diethyl ether. The ethereal solution was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue was distilled, and the fraction boiling at 96—97 °C/1600 Pa gave 2-(*F*-phenyl)-4,4-dimethyl-2-oxazoline (**2**) (2.68 g, 91%) in colorless oil. ^{1}H-NMR (CCl_4): δ=1.32 (s, 6H, CH_3), and 4.03 (s, 2H, CH_2). ^{19}F-NMR (CCl_4): 0.3 (m, 2F, F$^{3'}$ and F$^{5'}$), 10.5 (tt, 1F, F$^{4'}$), and 24.6 ppm (m, 2F, F$^{2'}$ and F$^{6'}$), ($J_{2'4'}$=2.1 and $J_{3'4'}$=21.1 Hz). UV (EtOH): λ_{max} (log ε); 211 nm (2.92). Found: C, 49.66; H, 3.06; N, 5.26%; M$^+$, 265. Calcd for $C_{11}H_8NF_5O$: C, 49.82; H, 3.04; N, 5.28%; M, 265. Isolation of the free oxazoline **2** from the hydrochloride **22** failed with aqueous and methanolic alkalis.

Reaction of the Oxazine 1 with Ethylmagnesium Bromide. The Reaction in THF: A solution of the oxazine **1** (1.17 g, 4.0 mmol) in anhydrous THF (10 cm^3) was added dropwise to a stirred mixture of ethylmagnesium bromide (6.0 mmol) and anhydrous THF (20 cm^3) over a 5-min period at room temperature under a dry nitrogen atomosphere. The mixture was refluxed for 10 h with stirring, poured into water after being cooled, and extracted with dichloromethane. The extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue was developed on a silica-gel TLC plate with dichloromethane. The fraction of R_f=0.15—0.20 afforded 2-(2-ethyl-*F*-phenyl)-4,4,6-trimethyl-5,6-dihydro-4*H*-oxazine (**3**) (1.16 g, 93%) in colorless oil. Found: M$^+$, 303. Calcd for $C_{15}H_{17}NF_4O$: M, 303. Elemental analysis was carried out in the form of its hydrochloride monohydrate. Found: C, 50.34; H, 5.63; N, 3.91%. Calcd for $C_{15}H_{18}NClF_4O \cdot H_2O$: C, 50.36; H, 5.63; N, 3.92%.

The Reaction in Benzene: A solution of the oxazine **1** (1.17 g, 4.0 mmol) in dry benzene (20 cm^3) was added dropwise to a stirred mixture of ethylmagnesium bromide (14 mmol) and anhydrous diethyl ether (30 cm^3) over a 10-min period at room temperature under a dry nitrogen atmosphere. Diethyl ether was distilled out of the mixture by adding portions of dry benzene. The resulting benzene solution was refluxed for an additional 10 h and worked up in a similar manner. 2-(2,6-Diethyl-*F*-phenyl)-4,4,6-trimethyl-5,6-dihydro-4*H*-oxazine (**6**) was obtained quantitatively, in colorless oil. ^{19}F-NMR (CCl_4): 1.1 (t, 1F, F$^{4'}$) and 18.9 ppm (d, 2F, F$^{3'}$ and F$^{5'}$), ($J_{3'4'}$=21.2 Hz). Found: M$^+$, 313. Calcd for $C_{17}H_{22}NF_3O$: M, 313. Found: (Hydrochloride monohydrate): C, 55.41; H, 6.83; N, 3.77%. Calcd for $C_{17}H_{23}NClF_3O \cdot H_2O$: C, 55.51; H, 6.85; N, 3.81%.

Reaction of the Oxazoline 2 with Ethylmagnesium Bromide. The Reaction in THF: The oxazoline **2** (1.06 g, 4 mmol) reacted with ethylmagnesium bromide (6 mmol) in anhydrous THF (30 cm^3) like the oxazine **1** did. The reaction mixture was distilled, and the fraction boiling at 95—96 °C/1200 Pa gave colorless oily 2-(2-ethyl-*F*-phenyl)-4,4-dimethyl-2-oxazoline (**4**) in 44% yield. Found: C, 56.85; H, 4.91; N, 4.94%; M$^+$, 275. Calcd for $C_{13}H_{13}NF_4O$: C, 56.73; H, 4.76; N, 5.09%; M, 275. The residue was developed on a silica-gel TLC plate with dichloromethane. The fraction of R_f=0.2—0.3 afforded 2-(2,6-diethyl-*F*-phenyl)-4,4-dimethyl-2-oxazoline (**5**) in 54% yield, colorless oil. ^{19}F-NMR (CCl_4): 3.5 (t, 1F, F$^{4'}$) and 19.7 ppm (d, 2F, F$^{3'}$ and F$^{5'}$), ($J_{3'4'}$=21.6 Hz). Found: M$^+$, 285. Calcd for $C_{15}H_{18}NF_3O$: M, 285. Found (Hydrochloride): C, 56.06; H, 6.02; N, 4.26%. Calcd for $C_{15}H_{19}NClF_3O$: C, 55.99; H, 5.95; N, 4.35%.

The Reaction in Benzene: The reaction in dry benzene was carried out in a similar manner to that in diethyl ether. The residue was purified by TLC on a silica-gel plate. The fraction of R_f=0.2—0.3 gave the diethyl derivative **5** quantitatively.

Reaction of the Oxazine 1 with Butyllithium. A mixture of butyllithium (1.17 mmol, *ca.* 15% hexane solution) and anhydrous diethyl ether (3 cm^3) was added dropwise to a stirred solution of the oxazine **1** (298 mg, 1 mmol) in anhydrous diethyl ether (5 cm^3) over a 5-min period at —45 °C under a dry nitrogen atmosphere. The mixture was kept stirred at —45 °C for 21 h and at room temperature for an additional 3 h, and poured into diethyl ether. The ethereal solution was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue was purified by TLC to give 2-(2-butyl-*F*-phenyl)-4,4,6-trimethyl-5,6-dihydro-4*H*-oxazine (**7**) in 65%

yield, a colorless oil. Found: M+ 331. Calcd for $C_{17}H_{21}NF_4O$: M, 331. Found (Hydrochloride): C, 55.41; H, 6.05; N, 3.76%. Calcd for $C_{17}H_{22}NClF_4O$: C, 55.51; H, 6.03; N, 3.81%.

Reaction of the Oxazoline **2** *with Butyllithium.* A mixture of butyllithium (2.3 mmol, *ca.* 15% hexane solution) and anhydrous diethyl ether (5 cm³) was added dropwise to a stirred mixture of the oxazoline **2** (396 mg, 1.5 mmol) and anhydrous diethyl ether (5 cm³) over a 25-min period at −40 °C under a dry nitrogen atmosphere. The mixture was stirred at −40 °C for 6.5 h and then at room temperature for an additional 3 h, and then was worked up as above. The residue was chromatographed on a silica-gel column. The earlier fraction eluted with dichloromethane gave 2-(2-butyl-*F*-phenyl)-4,4-dimethyl-2-oxazoline (**8**) (49 mg, 11%) in colorless oil. Found: C, 59.33; H, 5.69; N, 4.50%; M+, 303. Calcd for $C_{15}H_{17}NF_4O$: C, 59.40; H, 5.65; N, 4.62%; M, 303. The later fraction eluted with dichloromethane was the starting compound **2** (266 mg, 67%).

When treated with 3.7 times molar amounts of butyllithium, the compound **8** (40%) and 2-(2,6-dibutyl-*F*-phenyl)-4,4-dimethyl-2-oxazoline (**9**) (15%) was obtained. ^{19}F-NMR (CCl_4): 3.1 (t, 1F, F$^{4'}$) and 19.4 ppm (d, 2F, F$^{3'}$ and F$^{5'}$), ($J_{3'4'}$ = 21.5 Hz). Found: C, 66.86; H, 7.63; N, 4.11%; M+, 341. Calcd for $C_{19}H_{26}NF_3O$: C, 66.84; H, 7.68; N, 4.10 %; M, 341.

Reaction of the Oxazine **1** *with Lithium* N-*Methylanilide.* A solution of the oxazine **1** (0.1 g, 0.36 mmol) in anhydrous diisopropyl ether (6 cm³) was added dropwise over a 10-min period at room temperature under a dry nitrogen atmosphre to a stirred mixture of lithium *N*-methylanilide (0.72 mmol), which was prepared from *N*-methylaniline and lithium amide in anhydrous diisopropyl ether (7 cm³). The mixture was stirred at 50 °C for an additional 19.5 h, and poured into diethyl ether after being cooled. The ethereal solution was washed with water. The aqueous washings were acidified and again extracted with diethyl ether. The ethereal extract and the original ethereal solution were combined, washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on a silica-gel column. The fraction eluted with dichloromethane gave 2-[2-(*N*-methylanlino)-*F*-phenyl]-4,4,6-trimethyl-5,6-dihydro-4*H*-oxazine (**13**) (73%) in pale yellow oil. ^{19}F-NMR ($CDCl_3$): 3.89 (ddd, 1F, F$^{5'}$), 7.59 (ddd, 1F, F$^{4'}$), 15.79 (ddd, 1F, F$^{3'}$), and 20.44 ppm (ddd, 1F, F$^{6'}$) ($J_{3'4'} = J_{4'5'} =$ 22.59, $J_{3'6'} = 10.99$, and $J_{4'6'} = J_{3'5'} = 2.44$ Hz). Found: C, 63.30; H, 5.45; N, 7.29%; M+, 380. Calcd for $C_{20}H_{20}N_2F_4O$: C, 63.14; H, 5.31; N, 7.37%; M, 380.

When 3.0 times molar amounts of the reagent were used in the same solvent, a mixture of the monoanilino derivative **13** and 2-[2,6-bis(*N*-methylanilino)-*F*-phenyl]-4,4,6-trimethyl-5,6-dihydro-4*H*-oxazine (**14**) was obtained in the yields of 13 and 86%, respectively. The latter was a yellow oil. ^{19}F-NMR ($CDCl_3$): 6.79 (t, 1F, F$^{4'}$) and 20.28 ppm (d, 2F, F$^{3'}$ and F$^{5'}$), ($J_{3'4'}$=21.97 Hz). Found M+, 467. Calcd for $C_{27}H_{28}N_3F_3O$; M, 467. Found (Hydrochloride): C, 64.41; H, 5.84; N, 8.42%. Calcd for $C_{27}H_{29}N_3ClF_3O$: C, 64.35; H, 5.80; N, 8,34%.

When the reaction was carried out in anhydrous THF with 1.5 times molar amounts of the reagent, the mixture of the monoanilino derivative **13** and 2-[2,4-bis(*N*-methylanilino)-*F*-phenyl]-4,4,6-trimethyl-5,6-dihydro-4*H*-oxazine (**15**) was afforded in the yields of 12 and 36%, respectively. ^{19}F-NMR (CCl_4) of the latter **15**: 20.6 (dd, 1F, F$^{6'}$), 21.0 (d, 1F, F$^{5'}$), and 33.9 ppm (d, 1F, F$^{3'}$), ($J_{3'6'} = 13.0$, $J_{5'6'} = 24.0$ Hz). Found: M+ 467. Calcd for $C_{27}H_{28}N_3F_3O$: M, 467.

Reaction of the Oxazoline **2** *with Lithium* N-*Methylanilide.* The reaction was carried out in anhydrous diisopropyl ether with 2.0 times molar amounts of the reagent as described above. The reaction mixture was chromatographed on a silica-gel column, then eluted with dichloromethane. The earlier fraction gave 2-(2-*N*-methylanilino-*F*-phenyl)-4,4-dimethyl-2-oxazoline (**16**) (87%), which was isolated in the form of the yellow picrate, mp 149—150 °C (decomp). ^{19}F-NMR ($CDCl_3$): 4.17 (ddd, 1F, F$^{5'}$), 12.15 (ddd, 1F, F$^{4'}$), 17.27 (ddd, 1F, F$^{3'}$) and 24.43 ppm (ddd, 1F, F$^{6'}$), ($J_{3'4'} = J_{4'5'} = J_{5'6'} = 21.97$, $J_{3'6'} = 10.98$, $J_{3'5'} = 4.88$, and $J_{4'6'} = 2.44$ Hz). Found (Picrate): C, 49.71; H, 3.31; N, 12.02%. Calcd for $C_{24}H_{19}N_5F_4O_8$: C, 49.58; H, 3.29; N, 12.05%. The later fraction afforded 2-[2,6-bis(*N*-methylanilino)-*F*-phenyl]-4,4-dimethyl-2-oxazoline (**17**) (10%) in pale yellow powder, mp 102—103.5 °C. ^{19}F-NMR ($CDCl_3$): 9.41 (t, 1F, F$^{4'}$) and 21.16 ppm (d, 2F, F$^{3'}$ and F$^{5'}$, ($J_{3'4'}$ = 21.97 Hz). Found: C, 68.26; H, 5.66; N, 9.32%; M+, 439. Calcd for $C_{25}H_{24}N_3F_3O$: C, 68.31; H, 5.52; N, 9.56%; M, 439.

When 3.0 times molar amounts of the reagent were used in the same reaction solvent, a mixture of the same products, **16** and **17**, was obtained, while the yields varied to 49 and 46%, respectively; these values were determined by GLC peak areas and ^{19}F-NMR signal intensities. The reaction which was carried out in anhydrous THF with 1.5 times molar amounts of the reagent, also afforded the same products, **16** and **17**, in the yields of 17 and 40%, respectively.

Reaction of the Oxazine **1** *with* N-*Methylanilinomagnesium Bromide.* A solution of the oxazine **1** (0.3 g, 1.19 mmol) in anhydrous diethyl ether (8 cm³) was added dropwise to the solution of *N*-methylanilinomagnesium bromide (3.57 mmol), which was prepared by adding ethereal *N*-methylaniline into ethylmagnesium bromide in diethyl ether over a 10-min period under a dry nitrogen atmosphere. The mixture was refluxed for 14.5 h, and the formation of the product **13** was determined by GLC to be in 96% yield. When the reaction solvent was altered into dry benzene, the same product **13** was formed in 95% yield.

Reaction of the Oxazoline **2** *with* N-*Methylanilinomagnesium Bromide.* The reaction was carried out in anhydrous diethyl ether with 1.2 times molar amounts of the reagent, and the resulting mixture was worked up as above. The yields of ortho-substituted products, **16** and **17**, were 74 and 9%, respectively, and the starting oxazoline **2** was recovered in 17% yield; the yields were determined by the ^{19}F-NMR signal ratio of the reaction mixture.

When 3.0 times molar amounts of the reagent was used, 2′,6′-disubstituted product **17** was obtained quantitatively.

2-Methyl-2-(F-phenyl)-1,3-dioxolane (18). A solution of 2,3,4,5,6-pentafluoroacetophenone (4.62 g, 22 mmol), ethylene glycol (1.24 g, 20 mmol), and *p*-toluenesulfonic acid (0.1 g, 1 mmol) in anhydrous methanol (50 cm³) was refluxed for 22 h under a nitrogen atmosphere. Cyclohexane (230 cm³) was added to the resulting mixture, which was distilled to remove water as an azeotropic mixture. The residue was then distilled and the fraction boiling at 113 °C/6300 Pa gave 2-methyl-2-(*F*-phenyl)-1,3-dioxolane (**18**) (1.85 g, 36%). IR (neat): 1208 and 1168 cm^{-1} (C-O-C). ^{1}H-NMR (neat): δ = 1.7 (s, 3H, CH_3) and 3.8—4.4 (m, 4H, CH_2). ^{19}F-NMR (neat): —0.3 (m, 2F, F$^{3'}$ and F$^{5'}$), 6.7 (tt, 1F, F$^{4'}$), and 21.4 ppm (m, 2F, F$^{2'}$ and F$^{4'}$), ($J_{2'4'} = 3.7$, $J_{3'4'} = 20.8$ Hz). Found: C, 47.25; H, 2.79%; M+, 254. Calcd for $C_{10}H_7F_5O_2$: C, 47.26; H, 2.77%; M, 254.

Reaction of the Dioxolane **18** *with Ethylmagnesium Bromide.* The dioxolane **18** (0.4 g, 1.6 mmol) reacted with ethylmanesium bromide (4.8 mmol) in anhydrous benzene like the oxazine **1** did. The starting dioxolane **18** was confirmed by GLC to remain intact under such conditions.

Reaction of the Dioxolane **18** *with Lithium* N-*Methylanilide.* A solution of the dioxolane **18** (0.3 g, 1.2 mmol) in dry benzene (5 cm³) was added dropwise to a stirred mixture of lithium *N*-methylanilide (3.0 mmol) and anhydrous benzene (5 cm³) over a 10-min period at room temperaure under a nitrogen atmosphere. The mixture was refluxed for 29 h, and poured into diethyl ether (50 cm³) after being cooled. The ethereal solution was washed with water, dried over

magnesium sulfate, and evaporated *in vacuo*. An addition of a small amount of heptane into the residue afforded the precipitates of 2-methyl-2-(4-*N*-methylanilino-*F*-phenyl)-1,3-dioxolane (**20**), mp 113—115 °C. ^{19}F-NMR ($CDCl_3$): 16.89 dd, 2F, $F^{2'}$ and $F^{6'}$) and 18.72 ppm (dd, 2F, $F^{3'}$ and $F^{5'}$), ($J_{2'3'}$ = 21.97 and $J_{2'5'}$ = 10.99 Hz). Found: C, 59.94; H, 4.51; N, 4.18%. Calcd for $C_{17}H_{15}NF_4O_2$: C, 59.82; H, 4.44; N, 4.10%. The residue after separating the dioxolane **20** contained 2-methyl-2-(2-*N*-methylanilino-*F*-phenyl)-1,3-dioxolane (**19**), which could not be isolated in its pure form; the structure was assigned by its ^{19}F-NMR spectrum. ^{19}F-NMR ($CDCl_3$): 3.99 (dd, 1F, $F^{5'}$), 10.43 (ddd, 1F, $F^{4'}$), 16.80 (dd, 1F, $F^{3'}$), and 23.89 ppm (ddd, 1F, $F^{6'}$), ($J_{3'4'} = J_{4'5'} = J_{5'6'} = 21.97$, $J_{3'6'} = 10.79$, and $J_{3'5'} = 4.89$ Hz). Overall yields of **19** and **20** were 12 and 45%, respectively.

This study was supported by the Grant-in-Aid for Developmental Scientific Research (Project No. 00585221) from the Ministry of Education, Science and Culture, to whom the authors are grateful.

Reduction of Sulfonic Acids with Triphenylphosphine–Diaryl Disulfide System

Shigeru OAE*,† and Hideo TOGO
Department of Chemistry, The University of Tsukuba, Sakura, Niihari, Ibaraki 305
(Received, July 18, 1983)

Diaryl disulfides are effective catalysts to reduce arenesulfonic acids with triphenylphosphine to the corresponding arenethiols in good yields, while alkanesulfonic acids are transferred into the corresponding alkyl aryl sulfides. Arenesulfonic acids bearing electron-donating substituents can be reduced more readily than those having electron-withdrawing substituents, while diaryl disulfides bearing electron-withdrawing substituents are more effective catalysts than diaryl disulfides with electron-donating ring substituents.

The first example of one-pot reduction of sulfonic acids to thiols was recently reported from this laboratory, by using $(CF_3CO)_2O/(n\text{-}Bu)_4N^+I^-$. This method is the first break through in the direct deoxygenative reduction of sulfonic acids to thiols and thiol derivatives. However, it not only requires a large excess of expensive reagents but also affords a mixture of reduction products, *i.e.* thiols and thiol trifluoroacetates.[1] G. A. Olah *et al.* reported recently a second successful one-pot reduction of sulfonic acids to the corresponding disulfides with BX_3 (X=Cl, Br, I)/KI.[2] In the previous paper, we reported another facile and quantitative deoxygenative reduction of sulfonic acids and its derivatives by a new reducing system, *i.e.* triphenylphosphine-iodine system.[3] This paper deals with another facile and attractive reduction of sulfonic acids with triphenylphosphine–diaryl disulfide system. Although triphenyphosphine is known to be a relatively strong reducing agent, it does not react directly with sulfonic acids. Meanwhile, the mixture of triphenylphosphine with halogen[4] and that of triphenylphosphine with disulfide[5] respectively are known to give phosphonium salts. Several reactions are known to utilize such phosphonium salts *e.g.* the conversion of alcohol and phenol derivatives to the corresponding halides by treatment with the phosphine and halogen,[6] the desulfurization of disulfides to the corresponding sulfides with the phosphine,[7] the condensation of carboxylic acids and alcohols or amines to the corresponding esters or amides by treatment of the phosphine and diaryl disulfide[8] or diselenide,[9] and the conversion of alcohols to the corresponding sulfides by treatment with a mixture of the phosphine and the disulfide.[10] Thus a mixture of triphenylphosphine and a catalytic amount of diaryl disulfide or diaryl diselenide was our choice system for the reduction of sulfonic acids.

Results and Discussion

Reduction of Arenesulfonic Acids and Alkanesulfonic Acids to the Corresponding Arenethiols and Alkyl Aryl Sulfides with Triphenylphosphine and Diaryl Disulfide. Arenesulfeyltriphenylphosphonium arenethiolate is known to be formed upon treatment of diaryl disulfide with triphenylphosphine and has been utilized for the synthetic organic chemistry, *e.g.* syntheses of alkyl aryl sulfides,[10] peptide synthesis, *etc.*[8] This reagent system was found to reduce also arenesulfonic acids. The reducing ability of the system appears to depend on the choice of the disulfide used for the reduction. Some disulfides showed nearly the same activity as iodine, while others were found to be much weaker reducing catalysts than iodine.[3] In this reducing system, the amount of the disulfide did not affect the yield (Table 2) of the thiol, the reduction product, but changed the time to complete the reaction, suggesting that the disulfide acts as a catalyst. GLC analysis after the completion of reaction showed two kinds of thiols and three kinds of disulfides. These disulfides were then heated with an enough amount of triphenylphosphine and water, to be reduced to the thiols of which the yields were determined by GLC or isolation (Eq. 1).

$$ArSO_3H + \left(3+\frac{1}{2}\right)Ph_3P + \frac{1}{2}(Ar'S)_2 \xrightarrow[2)\ H_2O]{1)\ \text{reflux in benzene}} ArSH + Ar'SH + \left(3+\frac{1}{2}\right)Ph_3PO \quad (1)$$

The reaction is considered to be resulted by the following consecutive reactions (Eqs. 2—7) as postulated in the reaction of triphenylphosphine/iodine system.[3]

$$Ar'SSAr' + Ph_3P \rightleftharpoons Ar'S\text{–}\overset{+}{P}Ph_3\ Ar'S^- \quad (2)$$

$$ArSO_3H + Ar'S\text{–}\overset{+}{P}Ph_3\ Ar'S^- \overset{K_3}{\rightleftharpoons} ArSO_3^-\ Ar'S\text{–}\overset{+}{P}Ph_3 + Ar'SH \quad (3)$$

$$ArSO_3^-\ Ar'S\text{–}\overset{+}{P}Ph_3 \overset{K_4}{\rightleftharpoons} ArSO_2\text{–}O\text{–}\overset{+}{P}Ph_3\ Ar'S^- \quad (4)$$

$$ArSO_2\text{–}O\text{–}\overset{+}{P}Ph_3\ Ar'S^- \longrightarrow ArSO_2SAr' + Ph_3PO \quad (5)$$

$$ArSO_2SAr' + 2\,Ph_3P \longrightarrow \frac{1}{3}[ArSSAr + ArSSAr' + Ar'SSAr'] + 2\,Ph_3PO \quad (6)$$

$$ArSSAr + ArSSAr' + Ar'SSAr' + 3\,Ph_3P + 3\,H_2O \longrightarrow 3\,ArSH + 3\,Ar'SH + 3\,Ph_3PO \quad (7)$$

The reaction of alkanesulfonic acid such as 1-phentanesulfonic acid with triphenylphosphine/di-2-pyridyl disulfide gave the alkyl pyridyl sulfide.

$$CH_3(CH_2)_4SO_3H + (PyS)_2 + 4\,Ph_3P \longrightarrow CH_3(CH_2)_4\text{–}S\text{–}Py + 3\,Ph_3PO + Ph_3PS + PySH \quad (8)$$

a) After this reaction, the mixture of 300 mg of water and 2 ml of dioxane was added and refluxed for 0.5—1.0 h. GLC yield (20% OV-1, 10 m glass column). c) Isolated yield. d) Pentyl 2-pyridyl sulfide was obtained, and Ph_3PS was also obtained in 83% isolated yield. e) Di-2-pyridyl disulfide. f) Bis(2,4,5-trichlorophenyl) disulfide.

When dialkyl disulfide, such as lipoic acid or dibutyl disulfide was used, the following known desulfurization reaction took place rather than the reduction to the thiol.[11]

$$RSSR + Ph_3P \longrightarrow RSR + Ph_3PS \quad (9)$$

Thus, diaryl disulfides had to be used for this purpose. Inspection of the data in Tables 1, 2, and Fig. 1 reveals that the diaryl disulfide which bears a stronger electron-withdrawing aryl group is a better catalyst in the reduction of sulfonic acids with triphenylphosphine; *e.g.* unsubstituted diphenyl disulfide exhibits only a trivial catalytic activity, however, the catalytic ability of bis(2,4,5-trichlorophenyl) disulfide is nearly as strong as that of iodine.[3] Di-2-pyridyl disulfide was found to be the best among several disulfides tested (Tables 1 and 2), while 1,2-dithiaacenaphthene was not a good catalyst, probably due to the unfavorable equilibrium (Eq. 2) because of its unusually high stability of the stereoelectronic arrangement, or due to the formation of a very stable phosphorane intermediate by the reaction between triphenylphosphine and 1,2-dithiaacenaphthene. Diphenyl diselenide displayed only a weak catalytic

activity. The use of tributylphosphine instead of triphenylphosphine led to a sluggish reaction even when it was used in combination with di-2-pyridyl disulfide.

Inspection of the data in Tables 1, 2, and Fig. 2, reveals that the introduction of an electron-releasing substituent on the aromatic ring of arenesulfonic acid accelerates the reduction with $Ph_3P/(Ar'S)_2$ system. Typical examples are shown in Fig. 2. In contrast to the reaction with triphenylphosphine/iodine system, addition of tertiaryl amine in the reaction of the arenesulfonic acid with triphenylphosphine/diaryl disulfide system did not accelerate the reaction but slightly retarded the reaction (Table 2). The rate of the reaction of sodium arenesulfonate in the presence of crown ether was found to be much lower than that of the corresponding acid. This opposite behavior with bases in the reaction of $Ph_3P/(Ar'S)_2$ system to that with Ph_3P/I_2 system suggests that since arenethiolate anion is a much stronger base than sulfonate anion in the reduction with $Ph_3P/(Ar'S)_2$ system, K_3 is quite large and hence a higher concentration of the sulfonate anion can be maintained, however K_4 is very small. Whereas in the case of Ph_3P/I_2 system, since hydrogen iodide would be a strong acid comparable to the sulfonic acid in an aprotic solvent, K_{10} would not be sufficiently large

$$ArSO_3H + Ph_3\overset{+}{P}\text{–}I\ I^- \overset{K_{10}}{\rightleftharpoons} ArSO_3^-\ Ph_3\overset{+}{P}\text{–}I + HI \quad (10)$$

$$ArSO_3^-\ Ph_3\overset{+}{P}\text{–}I \overset{K_{11}}{\rightleftharpoons} ArSO_2\text{–}O\text{–}\overset{+}{P}Ph_3\ I^- \quad (11)$$

enough to maintain a high concentration of the sulfonate anion in the absence of any base catalyst, however, K_{11} is larger than K_4.[3] These considerations along with the actual observations would suggest that the rate-determining step involves the nucleophilic substitution on the phosphorus atom of the arenesulfenyltriphenylphosphonium ion by the sulfonate anion. This hypothesis is also in accordance with the observation that a diaryl disulfide bearing an electron-withdrawing group is a better catalyst than that which bears an electron-donating substituent in the reduction of arenesulfonic acids with triphenylphosphine as shown in Figs. 1 and 2; *i.e.* the better leaving ability of $Ar'S^-$ and the stronger nucleophilicity of $ArSO_3^-$ facilitate the reactions Eqs. 2 and 4. If the following elemental reaction, Eq. 5, is the rate-determining step of this reaction, the observed electronic demand should be the opposite, since the nucleophilicity of $Ar'S^-$ increases with the decrease of electronegativity of Ar' group and any electron-withdrawing substituent on Ar group should accelerate the nucleophilic displacement on the sulfonyl sulfur. The retardation of the rate of the reaction, Eq. 3, by addition of any base can be rationalized in terms of our postulate that the rate-determining step is the reaction shown by Eq. 4. If the reaction shown by Eq. 5 would be the rate-determining step, the addition of a base would have to accelerate the reaction, since the base ionizes the thiol, generating the thiolate anion which is a much stronger nucleophile than the thiol, toward the sulfonyl sulfur. Once the thiosulfonic S-ester is formed, this can be very readily reduced by either triphenylphosphine[3] or thiol.

Alkyl arenesulfonate, sodium arenesulfonate, and tetraethylammonium benzenesulfonate, however, could not be reduced to the corresponding thiols even with triphenylphosphine/dipyridyl disulfide which was the best catalyst.

Experimental

Preparation of Disulfide. Disulfides, which are not commercially available, were synthesized by a known method.[12] To a benzene solution (150 ml) of a thiol (0.05 mol) and pyridine (0.055 mol), was added dropwise iodine (0.025 mol) dissolved in benzene (50 ml). When the color of the solution changed to brown by excess iodine, the addition was stopped. The reaction mixture was washed with water, 5% HCl solution, $Na_2S_2O_3$ solution, and then water again, and the organic layer was dried over $MgSO_4$. After evaporation of benzene, the residual disulfide was purified by

recrystallization usually from hexane. Yields were nearly quantitative. Di-*p*-tolyl disulfide mp 44—45 °C (lit,[13] 46 °C). Bis(*p*-chorophenyl) disulfide mp 70—71 °C (lit,[14] 73 °C). 1,2-Dithiaacenaphthene was prepared according to the method of Zweig and Hoffmann, starting with commercial 8-amino-1-naphthalenesulfonic acid *via* initial formation of yellow crystals of 1,8-naphthalenedithiol[7.1%, NMR ($CDCl_3$) δ= 4.11 (2H, s), 7.0—7.8 (6H, m)] and subsequent autoxidation of the dithiol (84%). The product was recrystallized from ethanol. Mp 116—117 °C (lit,[15] 116 °C).

Competitive Reduction of p-*Substituted Benzenesulfonic Acids with $Ph_3P/(PyS)_2$ System.* A mixture of 190.2 mg (1 mmol) of *p*-toluenesulfonic acid, 176 mg (1 mmol) of benzenesulfonic acid, and 192.5 mg (1 mmol) of *p*-chlorobenzenesulfonic acid was dissolved in 5 ml of benzene, and the mixture was refluxed in a reactor which was equipped with a condenser and a calcium chloride tube. These sulfonic acids were dehydrated to nearly completely dry prior to the reaction by way of azeotropic distillation with benzene. After 3406 mg (13 mmol) of triphenylphosphine and 154 mg (1 mmol) of biphenyl (standard) were added to the mixture of these sulfonic acids, this reactor was equipped with another condenser and a nitrogen balloon and then substituted with this inert gas with a vacuum pump. Then, 330 mg (1.5 mmol) of di-2-pyridyl disulfide which was dissolved in 5 ml of dry benzene was added into the mixture which was stirred at 75 °C. A small portion, 0.1 ml, of the reaction mixture was picked up by a microsyringe and quenched with a mixture of water–dioxane–benzene (v=1/1/2) at every fixed time (2, 6, 15, 30, 60, and 120 min from initial reaction time respectively). The yields of three thiols obtained by this method were determined by comparison of the GLC curve with the predetermined calibration curve by gas chromatography (SE-30, using biphenyl as the standard).

Relative Catalytic Effects of Various $(Ar'S)_2$ Catalysts in the Reduction of p-*Toluenesulfonic Acid with $Ph_3P/(Ar'S)_2$ System.* *p*-Toluenesulfonic acid monohydrate 381 mg (2 mmol) was dissolved in 5 ml of benzene, refluxed, and dehydrated to nearly completely dry by the same procedure. After 2100 mg (8 mmol) of triphenylphosphine and 300 mg (2 mmol) of biphenyl were added to this dried sulfonic acid, this reactor was equipped with another condenser and a nitrogen balloon, and was substituted with this inert gas with a vacuum pump. Then, 3 ml of dry benzene was added to this mixture and 1 mmol of a chosen diaryl disulfide (di-2-pyridyl disulfide, bis(2,4,5-trichlorophenyl) disulfide, or bis(*p*-chlorophenyl) disulfide) which was dissolved in 5 ml of dry benzene was added to this mixture (total benzene 8 ml) and the whole mixture was stirred, and refluxed (bath temperature 112 °C). A small portion, 0.1 ml, of reaction mixture was picked up by a microsyringe and quenched with a mixture of water–dioxane–benzene (v=1/1/2) at fixed time intervals. The yields of thiols obtained by this procedure were determined by comparison of the GLC curve with the predetermined calibration curve by gas chromatography (SE-30, using biphenyl as the standard).

Reductive Conversion of Alkanesulfonic Acid with $Ph_3P/(PyS)_2$ System. 1-Pentanesulfonic acid, 304 mg (2 mmol) of which was dried completely by a vacuum pump and 2620 mg (10 mmol) of triphenylphosphine were added into a reactor which was equipped with a condenser and a nitrogen balloon. Then, 440 mg (2 mmol) of di-2-pyridyl disulfide which was dissolved in 5 ml of dry benzene was added to this mixture which was then stirred for 3.5 h at room temperature; the reaction was monitored by GLC. After the reaction, the yields of triphenylphosphine sulfide, pentyl 2-pyridyl sulfide were determined by GLC (SE-30). Pentyl 2-pyridyl sulfide 60% IR (NaCl) 750, 1120, 1400, 1440, 1570 cm^{-3}. GC-MS: m/e 181, TLC (benzene) R_f=0.4, bp 104—106 °C/5.5 mmHg (1 mmHg=133.322 Pa). Found: C, 66.33; H, 8.35; N, 7.77. Calcd for $C_{10}H_{15}NS$: C, 66.25; H, 8.33; N, 7.72. NMR (CCl_4) δ=8.3 (m, 1H), 6.7—7.5 (m, 3H), 0.9 (t, 3H, J=6 Hz), 1.1—2.9 (m, 6H), 3.15 (t, 2H, J=6 Hz).

Triphenyphosphine sulfide 83%. The yield of triphenylphosphine oxide was determined through a silica-gel column chromatography with benzene as eluent (85%).

Preparation of Diphenyl Diselenide. Diphenyl diselenide was prepared according to a known procedure[16,17] by autoxidation of benzeneselenol which was prepared by treating phenyl Grignard reagent with black selenium in an excellent yield. Mp 57—58 °C (lit,[17] 61—63 °C).

Reduction of Arenesulfonic Acid with $Ph_3P/(PyS)_2$/Amine System. To a carefully dehydrated mixture of 352 mg (2 mmol) of benzenesulfonic acid and 371 mg (2 mmol) of tributylamine, 2360 mg (9 mmol) of triphenylphosphine was added into a reactor which was equipped with a condenser and a nitrogen balloon and substitued thoroughly with this inert gas with a vacuum pump. Then, 220 mg (2 mmol) of di-2-pyridyl disulfide which was dissolved in 5 ml of dry benzene was added to this mixture. The reaction mixture was stirred and refluxed for 2 h, following the reaction by GLC. Then a mixture of 3 ml of water and 3 ml of dioxane was added to this reaction mixture which was refluxed for 0.5 h. Benzenethiol was obtained in 18% yield by GLC.

Optical Resolution of Pyridoxal-like Pyridinophanes

Yoji TACHIBANA,† Toshihiko KOMATSU,†† Makoto ANDO, and Hiroyoshi KUZUHARA*
The Institute of Physical and Chemical Research, Wako, Saitama 351
(Received July 22, 1983)

Racemic modifications of the pyridoxal-like ansa compounds such as 15-formyl-14-hydroxy-2,8-dithia-[9](2,5)pyridinophanes prepared as a pontential catalyst for stereospecific nonenzymatic reactions were optically resolved through formation of Schiff bases by treatment with amino sugar derivatives or amino acids. Resolutions with the amino sugar derivatives were ascribable to the difference of the solubilities of the diastereomeric Schiff bases, whereas those with the amino acids resulted from the difference of the reaction rates for the formation of the diastereomeric Schiff bases. As the amino sugar resolving agents, 3-amino-3-deoxy-1,2:5,6-di-*O*-isopropylidene-β-D-idofuranose and the corresponding α-D-glucofuranose isomer were employed and gave (*R*)- and (*S*)-pyridoxal-like pyridinophanes, respectively. On the other hand, chiral valine was the most efficient resolving agent among the amino acid tested and the presence of half equimolar Fe^{3+} markedly increased the optical purities of the products. Employment of (*S*)-valine gave (*R*)-pyridinophanes in excess and *vice versa*.

In a series of studies pursuing systems mimicking vitamin B_6-dependent enzymes capable of enantio-face differentiation, we have reported the synthesis of pyridoxal-like pyridinophanes with planar chirality due to restricted rotation; *i.e.*, (*S*)-15-formyl-14-hydroxy-2,8-dithia[9](2,5)pyridinophane ((*S*)-**1**)[1] and (*S*)-15-formyl-14-hydroxy-5,5-dimethyl-2,8-dithia-[9](2,5)-pyridinophane ((*S*)-**2**).[2] Compound (*S*)-**1** was an active catalyst for the stereospecific racemization of a chiral amino acid[1] and both (*S*)-**1** and (*S*)-**2** were important precursors of the corresponding chiral pyridoxamine-like pyridinophanes,[2,3] which played a main role in the stereoselective transamination reactions.[4]

We now wish to describe some interesting additional findings concerning the optical resolutions of the racemate of these pyridoxal-like pyridinophanes. Amino sugar derivatives or amino acids could be employed as the resolving agents but their resolution mechanisms were completely different.

Results and Discussion

Resolution with Amino Sugar Derivatives. As described in the previous paper,[1] the attempt to resolve racemic **1** *via* formation of a Schiff base by treatment with commercial chiral α-methylbenzylamine failed because the Schiff base resisted crystallization; whereas 3-amino-3-deoxy-1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**3**) served as an efficient resolving agent for racemic **1**[1] or **2**[2] because it gave a crystalline Schiff base mixture (**4**), from which one diastereomer could be readily isolated in a pure state by recrystallization. Acidic hydrolysis of the less soluble diastereomer gave levorotatory **1** or **2** that was later assigned as the *S*-enantiomer on the basis of X-ray analyses[5] and other data on ORD and CD spectra.[2]

One of the disadvantages of using the amino sugar derivatives such as **3** as the resolving agent was the inaccessibility to its antipode, L-glucofuranose derivative (**5**). This meant that the *R*-enantiomer of the pyridinophanes could not be readily obtainable in a pure state. This situtation prompted us to develop more readily accessible resolving agent in the place of **5**. As a result, 3-amino-3-deoxy-1,2:5,6-di-*O*-isopropylidene-D-idofuranose (**6**) proved to be a good candidate. The only difference between **5** and **6** is the configuration of the substituent at C-5 and, therefore, their approximate molecular shapes are quite similar. The preparation of **6** was performed *via* the corresponding 3-azido-3-deoxy derivative (**7**) from the known 1,2:5,6-di-*O*-isopropylidene-β-D-talofuranose (**8**).[6] Thus, **8** was methylsulfonylated at 0 °C to the syrupy 3-*O*-mesylate (**9**), which was treated with sodium azide in hexamethylphosphoric triamide to give the crystalline 3-azido-3-deoxy-D-idofuranose derivative (**7**). The azido sugar derivative was catalytically hydrogenated with Raney Ni, giving **6**. Optical resolution of racemic **1** using **6** was conducted in a similar way to the resolution using **3** reported previously. A mixture of racemic **1** and **6** was refluxed in benzene with azeotropic removal of the water produced, giving a Schiff base mixture (**10**) as crystals. Recrystallization of **10** from a benzene–cyclohexane mixture was conducted twice, giving the less soluble diastereomer (**10a**) of sharp melting

point (150 °C). There was a couple of doublets around δ 6.17 assignable to the anomeric proton of the sugar moiety in the ^{1}H NMR spectrum of **10** as shown in Fig. 1, whereas one doublet at δ 6.18 completely disappeared in the spectrum of **10a**, suggesting that separation between the two diastereomers had been attained. In contrast to the Schiff base isolatable in a homogeneous state from the diastereomeric mixture (**4**, R=H)[1] prepared from **1** and **3**, the crystals of **10a** incorporated 2/3 equimolar benzene and 1/2 equimolar cyclohexane; this was suggested by the results of elemental analyses and the ^{1}H NMR spectra. After acidic hydrolysis of **10a**, the regenerated pyridinophane was extracted with an organic solvent and purified by chromatography, giving the dextrorotary species ((*R*)-**1**) as expected. The absolute value of the specific rotation of this specimen was a little lower than that of the alternative enantiomer previously obtained by using **3** as the resolving agent. This was probably because the *gluco* configuration was superior to the *ido* configuration for the resolution of racemic **1** and since the solubility of **10** was too low to provide smooth fractional crystallization. However, it was interesting that the D-idose derivative (**6**) could substitute the antipode of **3** having the L-*gluco* configuration (**5**). This suggests that optical resolution of atropisomers might depend on the approximate molecular shape of the resolving agent.

Althouth both enantiomers of pyridoxal-like pyridinophanes could be obtained by employing the **3** and **6** pair as the resolving agents, there was still a problem; *i.e.*, acidic hydrolysis of the Schiff base including the moieties of **3** or **6** for reproduction of the pyridoxal-like pyridinophanes accompanied hydrolysis of the isopropylidene groups in **3** or **6**, making their recovery difficult. These facts further prompted us to develop other type of resolution method.

Resolution with Amino Acids. Generally, pyridoxal and its analogs can condense with free amino acids owing to their great tendency to form Schiff bases.[7,8] As amino acids belong to the most readily obtainable chiral compounds, it would be convenient if they could be utilized for the optical resolu-

11 R=Me$_2$CH- 12 13

tion of racemic **1** or **2**. The problem is that racemization of the amino acid moieties may proceed within such Schiff bases, especially when some heavy metal ions are coexisting and the media is basic.[9,10] Therefore, we first examined the capability of the resolution of racemic **1** and **2** with chiral amino acids in the absence of metal ions in neutral media. Racemic **1** was condensed with (*R*)-valine[11] in methanol, changing the molar ratio of both reactants. Figure 2 shows 400 MHz ^{1}H NMR spectra of the C_6D_6 solution of the resulted mixture. Two pairs of signals, (a), (b) and (c), (d), were assigned to the azomethine and pyridine ring protons of the Schiff bases (**11** and **12**) derived from (*S*)-**1** and (*R*)-**1** respectively by referring them to those in the spectra of the Schiff bases derived from the authentic chiral pyridoxal-like pyr-

Table 1. Optical resolution of **1** and **2** with chiral amino acids in the absence of Fe^{3+}

a) Major enantiomer. b) The optical purities were determined on the basis of the specific rotations observed by reference to the values of the authentic samples.[1,2] c) The chemical yields were calculated on the basis of the amount of the amino acids used.

idinophanes. As the molar ratio of **1**/(*R*)-valine was increased, the apparent predominance of the intensity of the signals (a), (b) over (c), (d) was observed. These data sugested that (*R*)-valine coupled with (*S*)-**1** more preferentially than with (*R*)-**1**. In fact, the acidic hydrolysis of the Schiff base obtained through the reaction between (*R*)-valine and excess of racemic **1** and the subsequent removal of the unreacted **1** gave partially resolved **1** containing the (*S*)-enantiomer in excess. In the same way, employment of (*S*)-valine gave (*R*)-**1** in excess and employment of other chiral amino acids also resulted in the partial resolution of racemic **1**. The racemate of **2** was similarly resolved. The optical purities of the pyridinophanes isolated were determined by measuring their optical rotations. These results are shown in Table 1. The highest optical purities achieved by using valine indicated that the bulkiness of the α-substituents of the amino acids was important factor[12,13] dominating the optical purity of the products resolved. Throughout all runs, the efficiency of the resolution with amino acids seemed not so high.

In expectation of the enhancement of the optical purities of the resolution products, our attention was next directed towards addition of heavy metal ions to the reaction mixture for the Schiff base formation. It is known that some metal ions accelerate the formation of such Schiff bases, finally producing the chelate compounds of the Schiff bases.[14-17] Following preliminary experiments changing the metal ions employed, addition of iron(III) salt half equimolar to the amino acids served most effectively for the resolution of **1**. Furthermore, we found no racemization of the amino acid moiety in the Schiff base chelate complex (**13**) in the experiment using the system composed of **1**, chiral amino acid, and Fe^{3+} (4:1:0.5 in the molar ratio) under neutral conditions. On the basis of these preliminary results, the resolutions of racemic **1** and **2** were attempted in the presence of Fe^{3+} under neutral conditions, varying the kind and amount of the amino acid employed. The results are tabulated in Table 2. Again, the optical purity of the resolved pyridinophane (**1**) increased as the ratio of **1**/chiral amino acid increased, suggesting that this resolution is also ascribable to a kinetic asymmetric transformation.[18] The optical purities of **1** so obtained were almost twice obtained under similar conditions in the absence of Fe^{3+} (Table 1). In both cases, use of (*S*)-amino acids gave (*R*)-**1** in excess and *vice versa*. Use of a ratio larger than 4/1 for **1**/chiral amino acid resulted in no appreciable improvement in the optical purity of the product. Therefore, a combination of racemic pyridinophane–chiral valine–Fe^{3+} (4:1:0.5 in molar ratio) was regarded as the practical resolution system. Two treatments by this system were enough to give pure enantiomers of **1** and **2**.

The foregoing two types of resolution procedures using amino sugars and amino acids as the resolving agents differ from each other in several aspects. Concerning the resolution mechanisms, the former is based on the difference of the solubilities between the diastereomeric Schiff bases; whereas the later owes its specificity to the preferencial formation of one diastereomer; *i.e.*, to a difference in the reaction rate. In contrast to the readily available chiral amino acids, amino sugar derivatives are difficult to prepare. However, the efficiency of the optical resolution was much higher with the amino sugars than with amino acids.

Experimental

Solutions were evaporated under reduced pressure. Melting points are uncorrected. ^1H NMR spectra were recorded with a JEOL HA-100 spectrometer for amino sugar derivatives and with a JEOL JNM-FX 400 spectrometer for amino acid derivatives, using tetramethylsilane as the internal standard. Optical rotations were determined with a Perkin-Elmer Model 241 MC polarimeter. The racemic specimens of the pyridoxal-like pyridinophanes (**1** and **2**) were prepared according to our previous papers.[1,2]

3-Azido-3-deoxy-1,2:5,6-di-O-isopropylidene-β-D-idofuranose (7). Methanesulfonyl chloride (3.5 g) was added in portions at 0 °C to a solution of **8** (5.8 g) in dry pyridine (20 ml). The mixture was kept at the ambient temperature overnight, poured into ice-water, and extracted with chloroform. The extract was washed with 3% H_2SO_4, water, dried (Na_2SO_4) and evaporated to give **9** (6.4 g) as a yellow syrup: IR (film) 1185 cm^{-1}. To the solution of **9** in HMPA (35 ml) was added sodium azide (4.0 g). The mixture was heated at 100 °C with stirring for 11 h, cooled, diluted with ice-water (500 ml), and extracted with diethyl ether. The extract was washed with water, dried (Na_2SO_4) and evaporated to give a syrup (4.0 g). The syrup was chromatographed on silica gel with 5:1 (v/v) benzene–diethyl ether as the eluent to give **7** (3.3 g, 52% on the basis of **8**) as colorless crystals: mp 66—66.5 °C; $[\alpha]_D^{23}$ +74° (*c* 0.9, $CHCl_3$); IR(KBr) 2100 cm^{-1}. Found: C, 50.49; H, 6.76; N, 14.70%. Calcd for $C_{12}H_{19}O_5N_3$: C, 50.52; H, 6.71; N, 14.73%.

3-Amino-3-deoxy-1,2:5,6-di-O-isopropylidene-β-D-idofuranose (6). A solution of **7** (400 mg) in ethanol (20 ml) was stirred with Raney Ni (W-IV) in hydrogen atmosphere for 2 h. After filtration, the filtrate was evaporated to give crystalline **6** which was recrystallized from cyclohexane: yield 360 mg (99%); mp 98—98.5 °C; $[\alpha]_D^{22}$ +40° (*c* 0.26, $CHCl_3$); IR (KBr) 3380, 3330, and 1630 cm^{-1}; ^1H NMR ($CDCl_3$) δ= 1.24 (2H, s, NH_2), 3.35 (1H, d, $J_{3,4}$=4.0 Hz, H-3), and 5.93 (1H, d, $J_{1,2}$=3.5 Hz, H-1). Found: C, 55.68; H, 8.18; N, 5.24%. Calcd for $C_{12}H_{21}NO_5$: C, 55.58; H, 8.16; N, 5.40%.

Preparation of Schiff Base Mixture (10) and Isolation of Less Soluble Diastereomer (10a). A solution of racemic **1** (100 mg) and **6** (100 mg) in benzene (10 ml) was placed in an open flask and heated for 1 h under gentle boiling. Evaporation of the residual solvent gave **10** as yellow powder: ^1H NMR ($CDCl_3$) δ=6.16 (0.5H, d, $J_{1',2'}$=4.0 Hz, H-1'), and 6.18 (0.5H, d, $J_{1',2'}$=4.0 Hz, H-1'). This powder was dissolved in a hot mixture of benzene (10 ml) and cyclohexane (6 ml) and then cooled, giving yellow crystals (78 mg): mp 139—140 °C. The crystals were recrystallized from a mixture of benzene (3.5 ml) and cyclohexane (3.5 ml) to give **10a**: yield 60 mg (65% on the basis of half of **1** used); mp 149—150 °C; $[\alpha]_D^{26}$ +236° (*c* 0.064, $CHCl_3$); IR (KBr) 3470 and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.16 (1H, d, $J_{1',2'}$= 4.0 Hz, H-1'), the doublet at 6.18 completely disappeared, 8.01 (1H, s, H-6 of the pyridine ring), 8.79 (1H, s, -CH= N-), and signals due to the solvent: 1.42 (6H, s, cyclohexane), and 7.32 (4H, s, benzene). Found: C, 62.31; H, 7.50; N, 4.17; S, 10.23%. Calcd for $C_{25}H_{36}O_6N_2S_2 \cdot 2/3\ C_6H_6 \cdot 1/2\ C_6H_{12}$: C, 62.11; H, 7.49; N, 4.53; S, 10.36%.

Acidic Hydrolysis of 10a to (R)-*1.* The Schiff base **10a** (400 mg) was dissolved in hot 1,4-dioxane (40 ml) and cool-

ed. After addition of 1 M (1 M=1 mol dm^{-3}) HCl (10 ml), the mixture was kept at room temperature for 40 min, diluted with water (250 ml), and extracted with ethyl acetate (300 ml). The extract was washed with aq $NaHCO_3$ and water successively, dried (Na_2SO_4), and evaporated to give (*R*)-**1** as a syrup, which was chromatographed on silica gel with 6:1 (v/v) benzene–diethyl ether as the eluent: yield 169 mg (92%); $[\alpha]_D^{17}$ +347° (*c* 1.05, $CHCl_3$) (lit[1]) for the antipode $[\alpha]_D^{24}$ −366°); IR (film) 3100 and 1660 cm^{-1}. Found: C, 55.64; H, 5.92; N, 4.86; S, 22.30%. Calcd for $C_{13}H_{17}O_2NS_2$: C, 55.09; H, 6.05; N, 4.94, S, 22.63%.

^1H NMR Measurement of the Schiff Bases Derived from **1** *and* (R)-*Valine.* A methanol solution (5 ml) of **1** (20.4 mg) and (*R*)-valine (4.1 mg) was stirred at room temperature overnight and evaporated. The resulting residue was dissolved in C_6D_6 (1 ml) and the NMR spectrum of the solution was recorded at 400 MHz.

Attempt for the Resolution of **1** *and* **2** *with Amino Acids in the Absence of Fe^{3+}.* A typical procedure for the resolution of **1** is exemplified in the following. A methanol solution (100 ml) containing (*S*)-valine (59 mg) and **1** (283 mg) was stirred at room temperature overnight. The methanol was evaporated and the residue was washed with 1:1 (v/v) benzene–hexane to remove the unreacted **1**, which was recycled. After addition of ethyl acetate (200 ml), the mixture was adjusted to pH 1 with 1 M HCl. The ethyl acetate solution was washed with water, dried ($MgSO_4$), and evaporated to give a yellow syrup, which was chromatographed on silica gel with 5:1 (v/v) benzene–diethyl ether as the eluent to give (*R*)-rich **1**: yield 100 mg (71% on the basis of valine); $[\alpha]_D^{23}$ +76° (*c* 0.16, $CHCl_3$); optical purity 21%.

Resolution of **1** *and* **2** *with Amino Acids in the Presence of Fe^{3+}.* A typical procedure is exemplified in the following. To a stirred solution of (*S*)-valine (47 mg), 0.1 M methanolic sodium methoxide (4 ml), and **1** (453 mg) in methanol (200 ml) was added dropwise a solution of $Fe(ClO_4)_3 \cdot 8H_2O$ (100 mg) in methanol (50 ml). The mixture was stirred at room temperature overnight. The pH value of the media was around 7 during the reaction. Methanol was evaporated and the resulting residue was washed with chloroform. Ethyl acetate was added to the residue and the mixture was adjusted to pH 1 with 1 M HCl. The ethyl acetate solution was washed with water, dried ($MgSO_4$), and evaporated to dryness. The resulting residue was chromatographed on silica gel with 5:1 (v/v) benzene–diethyl ether as the eluent to give (*R*)-rich **1**: yield 86 mg (76% on the basis of valine), $[\alpha]_D^{24}$ +256° (*c* 0.12, $CHCl_3$); optical purity 70%. The aqueous layer underwent ion-exchange chromatography as described in the previous paper[3] to give 38 mg of valine; $[\alpha]_D^{23}$ +27.6° (*c* 0.90, 6 M HCl) (authentic (*S*)-valine $[\alpha]_D^{23}$ +28.8° (*c* 1.10, 6 M HCl)). The 70% optically pure (*R*)-**1** (80 mg), (*S*)-valine (28 mg), 0.1 M methanolic sodium methoxide (2.4 ml), and $Fe(ClO_4)_3 \cdot 8H_2O$ (60 mg) were treated again in methanol (200 ml). After a similar work up to the first resolution, almost pure (*R*)-**1** was obtained: yield 46 mg (68% on the basis of valine); $[\alpha]_D^{23}$ +360° (*c* 0.13, $CHCl_3$).

The authors express their gratitude to Dr. Jun Uzawa and Mrs. Tamiko Chijimatsu for recording and measuring the ^1H NMR spectra. Also, they are indebted to Dr. Haruo Homma and his collaborators for elemental analyses.

Arylation and 1-Alkenylation on α-Position of Ketones *via* Tributyltin Enolates Catalyzed by Palladium Complex

Masanori KOSUGI, Isao HAGIWARA, Takao SUMIYA, and Toshihiko MIGITA*
Department of Chemistry, Faculty of Technology, Gunma University, Kiryu, Gunma 376
(Received August 8, 1983)

The reaction of tributyltin enolates, prepared from tributyltin methoxide and enol acetates *in situ*, with aryl and 1-alkenyl bromides in the presence of dichlorobis(tri-*o*-tolylphosphine)palladium was found to give α-aryl and α-(1-alkenyl) ketones, respectively, in good yields with essentially complete retention of the enol acetate regiochemistry.

Aryl and 1-alkenyl halides, except those bearing electron-withdrawing groups at the ortho and/or para positions, are usually unreactive toward nucleophilic displacement reactions, and thus fail to react with metal enolates under usual conditions.[1] Various methods of α-phenylation[2] and α-vinylation[3] of metal enolates are now developed. However, these require the strong basic conditions or multistep operations.

While organotin enolates have been shown to react both with carbonyl compounds to give addition products[4] and with alkyl halides to give coupling products,[4,5] there is no example of the reaction with aryl and 1-alkenyl halides. In our previous communications, we briefly reported that tributyltin enolates, irrespective of their tautomeric structures, α-stannyl ketones or enol stannyl ethers, reacted with aryl and 1-alkenyl halides in the presence of a catalytic amount of dichlorobis(tri-*o*-tolylphosphine)palladium to give α-aryl and α-(1-alkenyl) ketones in good yields.[6] Trial for similar coupling reaction with enol silyl ether *via* tin enolates was also reported by Kuwajima *et al.*[7] This paper describes the details of our results. The reaction is thought to proceed through the oxidative-adduct of the halides to palladium, followed by metathesis with tin compounds, and then reductive elimination.

Results and Discussion

Acetonylation of Aryl Bromides. Initial studies were focused on the palladium-catalyzed acetonylation of aryl bromides with the isolated acetonyltributyltin. The yield of phenylacetone, however, is rather low and substantial amounts of acetone are produced. These imply that the desired coupling competes with thermal decomposition of acetonyltributyltin under the prolonged heating conditions. Then, it may be desirable that relative concentration of acetonyltributyltin to organic halides is kept as small as possible. Indeed the best procedure was found to be the method in which acetonyltributyltin was prepared *in situ*.

$$Bu_3SnOMe + AcOCMe{=}CH_2 \longrightarrow [Bu_3SnCH_2COMe] + AcOMe$$

$$[Bu_3SnCH_2COMe] + ArBr \xrightarrow{[Pd]} ArCH_2COMe + Bu_3SnBr$$

a) Isolated yield based on bromide, GLC yield in parenthesis. b) Reaction with PhI. c) Reaction with PhCl.

The procedure is quite simple. Thus, just heating of a stirred solution of tributyltin methoxide (15 mmol), isopropenyl acetate (15 mmol), aryl bromide (10 mmol), and palladium complex (0.1 mmol) in toluene (5 ml) under argon at 100 °C for 5 h, followed by usual work up gave arylacetone. The results are shown in Table 1.

The reaction was fairly sensitive to the nature of the ligand on the dichloropalladium catalyst. The best ligand was tri-*o*-tolylphosphine. The reaction using dichlorobis(tri-*p*-tolylphosphine)palladium as a catalyst, gave only poor yield, although tri-*p*-tolylphosphine may have an electronic effect resembling to that of tri-*o*-tolylphosphine. Tris(*o*-chlorophenyl)phosphine ligand providing almost the same steric situation around palladium with that of tri-*o*-tolylphosphine was the next better ligand, but more bulkier trimesitylphosphine was not proper as ligands. Tri-*o*-tolylphosphine was previously demonstrated by Heck *et al.* to be more suitable ligand than triphenylphosphine for the palladium-catalyzed vinylation of aryl halides.[8] They explained this in terms of difference in easiness of phosphonium salt formation between the two ligands. However, even with triphen-

ylphosphine, it was found that aryl bromide did not form phosphonium salt effectively although aryl iodide did.[9] Then, phosphonium salt formation seems not to be an essential factor influencing the efficiency of the catalyst. Although the reason why tri-*o*-tolylphosphine was effective for the present reaction is not made clear comprehensively, we feel that steric situation around palladium provided by ligand is responsible.

As shown in Table 1, among halobenzenes, bromobenzene was the best substrate. Chlorobenzene did not react with this reagent, and iodobenzene which was considered to be more reactive, gave the product in poor yields. The isolated yields were reasonably high irrespective of the substituent (Me_2N–, MeO–, Me–, Cl–, or Ac–) in aryl bromide, indicating that the reaction can be used for the preparation of arylacetone. However, there were some limitations, that is, the reaction cannot be applied to the bromide having *p*-NO_2, *p*-CN, and *o*-Ac. The presence of nitrobenzene in the reaction mixture for the acetonylation of bromobenzene did not affect the yield of phenylacetone. This means that the presence of nitro group in reacting systems does not disturb the catalytic cycle. Since the aryl bromide bearing electron-withdrawing substituent easily reacts with palladium to form the oxidative-adduct,[10] these substituent groups seem to retard subsequent steps, metathesis or reductive-elimination.

The reaction can be carried out with the substrates bearing Me–, MeO–, and Cl– at an ortho position, and even with mesityl bromide. Thus, the reaction is not sensitive to the steric effect of ortho substituents, except *o*-Ac– group, in aryl bromides.

Stepwise acetonylation of *p*- and *m*-dibromobenzene could be attained by changing the molar ratio of the reactants. Usage of three molar excess of the tin enolates gave the diacetonylbenzene in 81 and 84% yield based on the corresponding dibromobenzene, respectively, while usage of three molar excess of dibromobenzenes gave *p*- and *m*-acetonylbromobenzenes in 65 and 57% yields based on the reagent, respectively. The reaction of *o*-dibromobenzene was rather complicated. Under the conditions of monoacetonylation, *o*-acetonylbromobenzene was obtained in 56% yield, but under the conditions of double acetonylation the sole isolated product was phenylacetone (13%), indicating that *o*-acetonylbromobenzene once formed was reduced under the conditions.

α-Phenylation of Ketones. Even though the α-arylation of ketones has received much attention,[2] there is still a need for a simple and regio-controlled procedure for this conversion. Since arylated acetone was effectively produced by palladium-catalyzed reaction between α-stannylacetone and aryl bromide, we tried to extend the reaction to various stannyl ketones, and to utilize the reaction for α-phenylation of ketones by the following two steps.

$$R^1COCHR^2R^3 \longrightarrow R^1\overset{OAc}{\overset{|}{C}}{=}CR^2R^3 \xrightarrow[[Pd],\ PhBr]{Bu_3SnOMe} R^1COCPhR^2R^3 + Bu_3SnBr + AcOMe$$

a) Isolated yield, GLC yield in parenthesis.

The first step has been investigated thoroughly, including its regiochemistry.[11] The following method was particularly useful to prepare enol acetates used here: (A) treatment of ketone with ketene and (B) treatment of ketone with acetic anhydride and perchloric acid. Enol acetates thus prepared are shown in Table 2.

The second step is a one-pot reaction involving tributyltin enolates prepared *in situ* from the enol acetates and tributyltin methoxide as cited above. The tin enolate which would be formed *in situ* have been known to exist in either or both of tautomeric structures, α-stannyl ketones or enol stannyl ethers.[12] α-Phenyl ketones, irrespective of the tautomeric structure of the tin reagents, were obtained in reasonably high yields with complete retention of the acetate regiochemistry.

Thus, as shown in Table 3, the reaction with 2-acetoxy-1-butene and -2-butene gave exclusively 1-phenyl and 2-phenyl-butanone, respectively. Low yields from enol acetates bearing methyl substituents on the reaction site (particularly 3-methyl-2-acetoxy-2-butene) may be due to the steric hindrance. The enol ester of aldehyde cannot be used, because the produced α-phenyl aldehyde adds tributyltin methoxide.

Thus, α-arylation of ketones with complete retention of the acetate regiochemistry could be attained by two steps starting from ketones.

success of α-arylation of ketones *via* tin enolates catalyzed by palladium complex suggests that similar reaction can be applied to the reaction between tin enolates and 1-alkenyl bromides, which may give allylic ketones. We found that various allylic ketones were obtained in good yields under the conditions similar to those for the reaction of aryl bromide. Results are shown in Table 4.

The reaction seems sensitive to steric hindrance caused by substituent on enol acetate. The reaction of enol acetates bearing terminal methylene gave the 1-alkenylated ketones generally in high yields, while lower yields were obtained for the substrates having substituents on the reaction site. Number and position of substituents on 1-alkenyl bromide seem not to give the serious effect on the product yield. The configuration of 1-alkenyl bromide was completely retained. Thus from (*E*)- and (*Z*)-2-bromo-2-butene, (*E*)- and (*Z*)-2,2,5-trimethyl-5-hepten-3-one were obtained exclusively, respectively.

Experimental

Materials. Tributyltin methoxide was prepared by the reaction of tributyltin chloride with sodium methoxide.[13] *o*-Bromotoluene,[14] *o*-chlorobromobenzene,[15] *o*-bromoanisole,[15] mesityl bromide,[16] 2-bromopropene,[17] 3-methyl-2-bromo-2-butene,[18] 2-methyl-1-bromo-2-propene,[18] (*E*)-2-bromo-2-butene,[18] (*Z*)-2-bromo-2-butene,[17] triarylphosphines,[19] tetrakis(triphenylphosphine)palladium,[20] and dichlorobis(triarylphosphine)palladium[21] were prepared from the method described in literatures. 3,3-Dimethyl-2-acetoxy-1-butene, α-acetoxystyrene, 1-cyclohexenyl acetate, 4-methyl-2-acetoxy-1,3-pentadiene, 2-acetoxy-2-butene, and 3-methyl-2-acetoxy-1-butene were prepared by treatment of the corresponding ketones with ketene in the presence of small amounts of sulfuric acid.[11a] 3-Methyl-2-acetoxy-2-butene was prepared by treatment of the ketone with acetic anhydride and perchloric acid.[11b] 2-Acetoxy-1-butene which could be prepared by treatment of the ketone with triphenylmethyllithium followed by acetic anhydride was not obtained by the method.[11c,d] Then it was prepared by the addition of acetic acid to 1-butyne in the presence of mercury(II) acetate.[11e] Other substrates were available commercially and used after distillation or recrystallization.

Reaction Procedures. A stirred solution of tributyltin methoxide (15 mmol), a particular enol acetate (15 mmol), bromobenzene or 1-alkenyl bromide (10 mmol), and $PdCl_2$-[(*o*-$MeC_6H_4)_3P]_2$ (0.1 mmol) in toluene (5 ml) was heated under argon at 100 °C for 5 h. After evaporation of the solvent and methyl acetate, column chromatograph of the residue (silica gel; cyclohexane followed by diethyl ether as eluants) provided the α-phenyl or α-(1-alkenyl) ketone in the ethereal elute, from which the products were isolated by distillation under reduced pressure. Some α-(1-alkenyl) ketones were obtained by distilling the reaction mixture directly under reduced pressure.

Products. The structure of the products were deduced based on the analytical and spectroscopic data recorded here. Boiling points were uncorrected.

Phenylacetone: Bp 88—92 °C/15 mmHg (1 mmHg= 133.322 Pa). IR Aldrich 742A.[22] ^{1}H NMR (CCl_4) δ=2.00 (s, 3H), 3.50 (s, 2H), and 7.30 (s, 5H).

p-Methoxyphenylacetone: Bp 88—90 °C/3 mmHg. IR (neat) 1710 (C=O), 1610 (C=C), 1512 (C=C), and 1248 cm^{-1} (C-O-C). ^{1}H NMR (CCl_4) δ=2.02 (s, 3H), 3.49 (s, 2H), 3.80 (s, 3H), and 6.61, 6.94 (ABq, *J*=9 Hz, 4H). MS

(20 eV) *m/e* (rel intensity) 164 (M^+, 7) 149 (10), 121 (33), and 43 (100). Found: C, 72,77; H, 7.43%. Calcd for $C_{10}H_{12}O_2$: C, 73.15; H, 7.37%.

o-*Methoxyphenylacetone*: Bp 118 °C/15 mmHg. IR (neat) 1718 (C=O), 1603 (C=C), 1498 (C=C), and 1250 cm^{-1} (C-O-C). ^1H NMR (CCl_4) δ=2.00 (s, 3H), 3.55 (s, 2H), 3.80 (s, 3H), and 6.67—7.35 (m, 4H). MS (20 eV) *m/e* (rel intensity) 164 (M^+, 100), 122 (100), 121 (100), and 43 (100).

p-*Chlorophenylacetone*: Bp 115—117 °C/15 mmHg. IR (neat) 1717 (C=O), 1598 (C=C), and 1491 cm^{-1} (C=C). ^1H NMR (CCl_4) δ=2.05 (s, 3H), 3.51 (s, 2H), and 6.97, 7.20 (ABq, *J*=8 Hz, 4H). MS (20 eV) *m/e* (rel intensity) 170 (M^+, 3), 168 (10), 127 (9), 125 (30), and 43 (100). Found: C, 64.15; H, 5.56%. Calcd for C_9H_9OCl: C, 64.11; H, 5.38%.

o-*Chlorophenylacetone*: Bp 119 °C/18 mmHg. IR (neat) 1726 (C=O), 1573 (C=C), and 1473 cm^{-1} (C=C). ^1H NMR (CCl_4) δ=2.09 (s, 3H), 3.71 (s, 2H), and 7.05—7.60 (m, 4H). MS (20 eV) *m/e* (rel intensity) 168 (1), 127 (9), 125 (27), and 43 (100).

p-*(Dimethylamino)phenylacetone*: Bp 103—104 °C/2.5 mmHg. IR (neat) 1710 (C=O), 1610 (C=C), 1520 (C=C), and 1350 cm^{-1} (C-N). ^1H NMR (CCl_4) δ=1.95 (s, 3H), 2.95 (s, 6H), 3.44 (s, 2H), and 6.61, 7.01 (ABq, *J*=9 Hz, 4H). MS (20 eV) *m/e* (rel intensity) 177 (M^+, 13), 134 (100), and 43 (7).

p-*Acetylphenylacetone*: Bp 128—130 °C/2.5 mmHg, mp 43—44 °C. IR (neat) 1718 (C=O), 1680 (C=O), 1603 (C=C), and 1508 cm^{-1} (C=C). ^1H NMR (CCl_4) δ=2.01 (s, 3H), 3.45 (s, 3H),3.59 (s, 2H), and 7.16, 7.79 (ABq, *J*=8 Hz, 4H). MS (30 eV) *m/e* (rel intensity) 176 (M^+, 2), 161 (9), 134 (100), 133 (10), 119 (20), 91 (49), and 43 (100). Found: C, 75.17; H, 6.85%. Calcd for $C_{11}H_{12}O_2$: C, 74.98; H 6.86%.

Mesitylacetone: Bp 130 °C/10 mmHg, mp 60 °C. IR (neat) 1720 (C=O), 1611 (C=C), and 1487 cm^{-1} (C=C). ^1H NMR (CCl_4) δ=1.98 (s, 3H), 2.20 (s, 9H), 3.53 (s, 2H), and 6.75 (s, 2H). MS (20 eV) *m/e* (rel intensity) 176 (M^+, 24), 134 (16), 133 (100), and 43 (18). Found: C, 81.81; H, 9.54%. Calcd for $C_{12}H_{16}O$: C, 81.77; H, 9.15%.

p-*Diacetonylbenzene*: Bp 118 °C/0.5 mmHg, mp 46—47 °C. IR (neat) 1715 (C=O), 1610 (C=C), and 1511 cm^{-1} (C=C). ^1H NMR (CCl_4) δ=2.07 (s, 6H), 3.58 (s, 4H), and 7.10 (s, 4H). MS (20 eV) *m/e* (rel intensity) 190 (M^+, 13), 148 (78), 147 (13), 105 (40), and 43 (100). Found: C, 75.75; H, 7.65%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%.

m-*Diacetonylbenzene*: Bp 127 °C/2 mmHg. IR (neat) 1712 (C=O), 1602 (C=C), and 1487 cm^{-1} (C=C). ^1H NMR (CCl_4) δ=2.08 (s, 6H), 3.59 (s, 4H), and 6.93—7.28 (m, 4H). MS (20 eV) *m/e* (rel intensity) 190 (M^+, 9), 148 (18), 147 (21), 105 (21), and 43 (100). Found: C, 75.57; H, 7.24%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%.

p-*Bromophenylacetone*: Bp 91—92 °C/1 mmHg. IR (neat) 1718 (C=O), 1592 (C=C), and 1488 cm^{-1} (C=C). ^1H NMR (CCl_4) δ=2.10 (s, 3H), 3.58 (s, 2H), and 7.05, 7.47 (ABq, *J*=9 Hz, 4H). MS (20 eV) *m/e* (rel intensity) 214 (M^+, 27), 212 (28), 171 (32), 169 (30), and 43 (100). Found: C, 50.62; H, 4.71%. Calcd for C_9H_9OBr: C, 50.73; H, 4.26%.

m-*Bromophenylacetone*: Bp 83 °C/0.3 mmHg. IR (neat) 1718 (C=O), 1591 (C=C), and 1471 cm^{-1} (C=C). ^1H NMR (CCl_4) δ=2.10 (s, 3H), 3.59 (s, 2H), and 7.05—7.50 (m, 4H). MS (20 eV) *m/e* (rel intensity) 214 (M^+, 63), 212 (64), 171 (14), 169 (14), and 43 (100).

o-*Bromophenylacetone*: Bp 88—92 °C/0.6 mmHg. IR (neat) 1722 (C=O), 1597 (C=C), and 1472 cm^{-1} (C=C). ^1H NMR (CCl_4) δ=2.11 (s, 3H), 3.73 (s, 2H), and 6.90—7.70 (m, 4H). MS (20 eV) *m/e* (rel intensity) 171 (100), 169 (100), and 43 (100).

1-Phenyl-2-butanone: Bp 102—103 °C/15 mmHg. IR Aldrich 742C.[22] ^1H NMR (CCl_4) δ=0.96 (t, *J*=7 Hz, 3H), 2.35 (q, *J*=7 Hz, 2H), 3.55 (s, 2H), and 7.19 (s, 5H).

3-Phenyl-2-butanome: Bp 94—95 °C/14 mmHg. (107 °C/22 mmHg)[23] IR (neat) 1718 (C=O), 1600 (C=C), and 1496 cm^{-1}(C=C). ^1H NMR (CCl_4) δ=1.35 (d, *J*=7 Hz, 3H), 1.97 (s, 3H), 3.68 (q, *J*=7 Hz, 1H), and 7.25 (s, 5H). MS (20 eV) *m/e* (rel intensity) 148 (M^+, 29), 133 (9), 106 (25), 105 (100), and 43 (100). Found: C, 80.62; H, 8.25%. Calcd for $C_{10}H_{12}O$: C, 81.04; H, 8.16%.

1-Phenyl-3-methyl-2-butanone: Bp 114—115 °C/25 mmHg. IR (neat) 1712 (C=O), 1602 (C=C), and 1496 cm^{-1} (C=C). ^1H NMR (CCl_4) δ=1.05 (d, *J*=7 Hz, 6H), 2.61 (h, *J*=7 Hz, 1H), 3.61 (s, 2H), and 7.18 (s, 5H). MS (20 eV) *m/e* (rel intensity) 162 (M^+, 27), 119 (5), 92 (22), 91 (100), 71 (100), 44 (19), and 43 (100). Found: C, 81.79; H, 8.45%. Calcd for $C_{11}H_{14}O$: C, 81.44; H, 8.70%.

3-Phenyl-3-methyl-2-butanone: Mp 99—101 °C/16.5 mmHg, Ir, (neat) 1710 (C=O), 1599 (C=C), and 1495 cm^{-1} (C=C). ^1H NMR (CCl_4) δ=1.43 (s, 6H), 1.81 (s, 3H), and 7.19 (s, 5H). MS (20 eV) *m/e* (rel intensity) 162 (M^+, 6), 120 (36), 119 (100), 43 (25), and 15 (9). Found C, 80.86; H, 8.78%. Calcd for $C_{11}H_{14}O$: C, 81.44; H, 8.70%.

1-Phenyl-3,3-dimethyl-2-butanone: Bp 110—111 °C/18 mmHg. IR (neat) 1710 (C=O), 1600 (C=C), and 1493 cm^{-1} (C=C). ^1H NMR (CCl_4) δ=1.15 (s, 9H), 3.70 (s, 2H), and 7.20 (s, 5H). MS (20 eV) *m/e* (rel intensity) 176 (M^+, 2), 119 (1), 92 (26), 91 (28), 85 (100), 58 (25), and 57 (100). Found: C, 82.14; H, 9.00%. Calcd for $C_{12}H_{16}O$: C, 81.77; H, 9.15%.

2-Phenylcyclohexanone: Bp 143—145 °C/14 mmHg, mp 58—59 °C (155 °C/13 mmHg, 60 °C)[24] IR Aldrich 742E.[22]

1-Phenyl-4-methyl-3-penten-2-one: Bp 80—81 °C/1.5 mmHg. IR (neat) 1685 (C=O), 1618 (C=C), and 1496 cm^{-1} (C=C). ^1H NMR (CCl_4) δ=1.79 (s, 3H), 2.07 (s, 3H), 3.52 (s, 2H), 5.88 (s, 1H), and 7.19 (s, 5H). MS (20 eV) *m/e* (rel intensity) 174 (M^+, 14), 119 (3), 92 (3), 91 (34), 83 (100), 56 (5), and 55 (69). Found: C, 82.37; H, 8.26%. Calcd for $C_{12}H_{14}O$: C, 82.77; H, 8.10%.

Phenylacetophenone: Bp 115—117 °C/1 mmHg, mp 54—55 °C (160 °C/5 mmHg, 56 °C)[25] IR Aldrich 748E.[22]

5-Methyl-4-hexen-2-one: Bp 43—45 °C/17 mmHg. IR (neat) 1720 cm^{-1} (C=O). ^1H NMR (CCl_4) δ=1.65 (s, 3H), 1.73 (s, 3H), 2.06 (s, 3H), 2.98 (d, *J*=7 Hz, 2H), and 5.23 (t, *J*=7 Hz, 1H). MS (20 eV) *m/e* (rel intensity) 112 (M^+, 100), 97 (100), 70 (100), 69 (100), 43 (100), and 15 (13). Found: C, 75.31; H, 11.12%. Calcd for $C_7H_{12}O$: C, 74.95; H, 10.78%.

4,5-Dimethyl-4-hexen-2-one: Bp 53 °C/21 mmHg. IR (neat) 1712 cm^{-1} (C=O). ^1H NMR (CCl_4) δ=1.69 (s, 9H), 2.01 (s, 3H), and 3.01 (s, 2H). MS (20 eV) *m/e* (rel intensity) 126 (M^+, 93), 111 (100), 84 (100), 83 (100), 43 (100), and 15 (8). Found: C, 75.83; H, 11.18%. Calcd for $C_8H_{14}O$: C, 76.14; H, 11.18%.

6-Methyl-5-hepten-3-one: IR (neat) 1718 cm^{-1}(C=O). ^1H NMR (CCl_4) δ=1.03 (t, *J*=7 Hz, 3H), 1.67 (s, 3H), 1.79 (s, 3H), 2.38 (q, *J*=7 Hz, 2H), 3.01 (d, *J*=7 Hz, 2H), and 5.30 (t, *J*=7 Hz, 1H). MS (20 eV) *m/e* (rel intensity) 126 (M^+, 10), 97 (7), 70 (2), 69 (23), 57 (100), and 29 (74). Found: C, 75.63; H, 11.20%. Calcd for $C_8H_{14}O$: C, 76.14; H, 11.18%.

3,5-Dimethyl-4-hexen-2-one: Bp 56—58 °C/20 mmHg. IR (neat) 1715 cm^{-1} (C=O). ^1H NMR (CCl_4) δ=1.05 (d, *J*=7 Hz, 3H), 1.73 (s, 6H), 3.29 (d of q, *J*=10 and 7 Hz, 1H), and 4.98 (d, *J*=10 Hz, 1H). Found: C, 76.34; H, 11.51%. Calcd for $C_8H_{14}O$: C, 76.14; H, 11.18%.

2,6-Dimethyl-5-hepten-3-one: Bp 69—70 °C/20 mmHg. IR (neat) 1712 cm^{-1} (C=O). ^1H NMR (CCl_4) δ=1.09 (d, *J*=7 Hz, 6H), 1.62 (s, 3H), 1.74 (s, 3H), 2.55 (h, *J*=7 Hz, 1H), 3.05 (d, *J*=7 Hz, 2H), and 5.27 (t, *J*=7 Hz, 1H). MS (20 eV) *m/e* (rel intensity) 140 (M^+, 69), 97 (59), 71 (100), 70 (63), 69 (100), 44 (93), and 43 (100). Found: C, 76.85; H, 11.44%. Calcd

for $C_9H_{16}O$: C, 77.09; H, 11.50%.

3,3,5-Trimethyl-4-hexen-2-one: IR (neat) 1709 cm^{-1} (C=O). ^1H NMR (CCl_4) δ=1.17 (s, 6H), 1.49 (s, 3H), 1.71 (s, 3H), 2.02 (s, 3H), and 5.27 (s, 1H). MS (20 eV) *m/e* (rel intensity) 140 (M^+, 37), 95 (100), and 43 (62). Found: C, 76.65; H, 11.70%. Calcd for $C_9H_{16}O$: C, 77.09; H, 11.50%.

2,2,5-Trimethyl-5-hexen-3-one: Bp 62—63 °C/34 mmHg. IR (neat) 1713 cm^{-1} (C=O). ^1H NMR (CCl_4) δ=1.15 (s, 9H), 1.71 (s, 3H), 3.11 (s, 2H), 4.67 (s, 1H), and 4.81 (s, 1H). MS (20 eV) *m/e* (rel intensity) 140 (M^+, 53), 85 (100), 83 (100), 58 (38), 57 (100), 56 (38), and 55 (68). Found: C, 76.81; H, 11.63%. Calcd for $C_9H_{16}O$: C, 77.09; H, 11.50%.

2,2,6-Trimethyl-5-hepten-3-one: Bp 72—73 °C/19 mmHg. IR (neat) 1710 cm^{-1} (C=O). ^1H NMR (CCl_4) δ=1.10 (s, 9H), 1.60 (s, 3H), 1.73 (s, 3H), 3.11 (d, J=7 Hz, 2H), and 5.24 (t, J=7 Hz, 1H). MS (20 eV) *m/e* (rel intensity) 154 (M^+, 4), 97 (19), 85 (77), 70 (18), 69 (46), 58 (18), and 57 (100). Found: C, 77.93; H, 11.95%. Calcd for $C_{10}H_{18}O$: C, 77.87; H, 11.76%.

2,2,5,6-Tetramethyl-5-hepten-3-one: Bp 79—80 °C/16 mmHg. IR (neat) 1715 cm^{-1} (C=C). ^1H NMR (CCl_4) δ=1.17 (s, 9H), 1.58 (s, 6H), and 1.70 (s, 3H). MS (20 eV) *m/e* (rel intensity) 168 (M^+, 19), 111 (29), 85 (99), 84 (28), 83 (64), 58 (28), and 57 (100). Found: C,78.42; H, 11.97%. Calcd for $C_{11}H_{20}O$: C, 78.51; H, 11.98%.

(E)-*2,2,5-Trimethyl-5-hepten-3-one*: Bp 70—71 °C/15 mmHg. IR (neat) 1710 cm^{-1} (C=O). ^1H NMR (CCl_4) δ= 1.15 (s, 9H), 1.58 (s, 3H), 1.60 (d, J=7 Hz, 3H), 3.08 (s, 2H), and 5.15 (t, J=7 Hz, 1H). ^{13}C NMR 26.4 (q), 214 (s), 47 (t), 130 (s), 123 (d), 13.5 (q), 16.1 (q), and 44.4 (s), MS (20 eV) *m/e* (rel intensity) 154 (M^+, 20), 97 (64), 85 (100), 70 (82), 69 (100), 58 (79), and 57 (100). Found: C, 77.72; H, 11.79%. Calcd for $C_{10}H_{18}O$: C, 77.87; H, 11.76%.

(Z)-*2,2,5-Trimethyl-5-hepten-3-one*: Bp 67—69 °C/14 mmHg. IR (neat) 1711 cm^{-1} (C=O). ^1H NMR (CCl_4) δ= 1.16 (s, 9H), 1.50 (d, J=7 Hz, 3H), 1.60 (s, 3H), 3.12 (s, 2H), and 5.30 (q, J=7 Hz, 1H). ^{13}C NMR 26.4 (q), 44.5 (s), 213 (s), 39.3 (t), 129.9 (s), 123.0 (d), 13.5 (q), and 24.1 (q). MS (20 eV) *m/e* (rel intensity) 154 (M^+, 15), 97 (61), 85 (100), 70 (75), 69 (97), 58 (71), and 57 (100). Found: C, 77.62; H, 11.78%. Calcd for $C_{10}H_{18}O$: C, 77.87; H, 11.76%.

2-(2-methyl-1-propenyl)cyclohexanone: Bp 95—97 °C/15 mmHg. IR (neat) 1710 cm^{-1} (C=O). ^1H NMR (CCl_4) δ=1.60 (s, 3H), 1.75 (s, 3H), 1.50—2.15 (m, 6H), 2.15—2.50 (m, 2H), and 2.70—3.55 (m, 1H). MS (20 eV) *m/e* (rel intensity) 152 (M^+, 15), 137 (26), 109 (36), 95 (37), 93 (30), 81 (57), 67 (100), and 43 (36).

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 56540291 from the Ministry of Education, Science and Culture.

Effect of the Base Stacking Association on the Phosphate Ionization of 2′-Deoxyguanosine 5′-Monophosphate

Kazumi HIROTA, Yoshio INOUE, and Riichirô CHÛJÔ*
Department of Polymer Chemistry, Tokyo Institute of Technology, O-okayama 2, Meguro-ku, Tokyo 152
(Received August 16, 1983)

The concentration dependence of ^{31}P chemical shifts at neutral pH has been measured for 2′-deoxyguanosine 5′-monophosphate and deoxyribose 5-monophosphate. The chemical shifts are sensitive to the variation of concentration, and are affected by the presence or absence of the base. The variations of ^{31}P chemical shifts correspond to those of $pK_{a'}$ values. The concentration dependence of ^{31}P chemical shift of deoxyribose 5-monophosphate can be explained by the ionic strength change accompanied by the concentration change, whereas that of the nucleotide can not be interpreted with the aid of it alone. The phosphate group of the nucleotide ionizes more readily at higher concentration. There is an additional effect other than ionic strength on the $pK_{a'}$ eand it is caused by the presence of the base. The appearance of the concentration effect owing to the base is attributable to the base stacking association. The measurements at different temperatures support this conclusion.

The association of naturally occurring nucleotides in aqueous solution has been studied by various experimental techniques such as microcalorimetry[1] and UV[2-4] and NMR[5-12] spectroscopy. It is now generally accepted that base stacking is a possible mode of self-association of nucleotides and it proceeds beyond dimer stages.[6,7,9] It is also well established that the stacking affinity of the nucleobases contributes greatly to the free energy sustaining the nucleic acid secondary structure.[13,14] The majority of studies have based on the concentration dependence of ^1H NMR chemical shift. A change of concentration should, however, affect the phosphate ionization of nucleotides through a change of ionic strength of solutions. The base stacking is also expected to affect the phosphate ionization through the formation of new molecular assemblies, since assembly of electrolytes in solution affects the pK_a value.[15] It seems that an understanding of the effect of the base stacking association on the phosphate ionization and on the conformation of nucleotides would promote the understanding of the secondary structure of DNA. In this work, we will focus on the phosphate ionization.

^{31}P NMR is a useful technique for studying an ionization state of phosphate group, since the chemical shift is a very sensitive function of pH.[16,17] The effect of pH on ^{31}P chemical shifts of mononucleotides has been studied by Cozzone and Jardetzky,[17] where the nucleotides were 0.5×10^{-2} M or less to avoid possible effects of self-associations.

In order to clarify the effect of the base stacking on the phosphate ionization of nucleotides, it is necessary to differentiate the effect of ionic strength from that of self-association both of which are included in the concentration dependence of ^{31}P chemical shifts. For the purpose of this subject, we will study, based on ^{31}P and ^1H NMR, the effect of concentration, ionic strength, and temperature on the phosphate ionization of 2′-deoxyguanosine 5′-monophosphate (5′-dGMP) and deoxyribose 5-monophosphate (5-dRP).

Experimental

Sample Preparation. Sodium salts of 5′-dGMP and 5-dRP were purchased from Sigma Chemical Co. Deuterium oxide (isotope purity >99.7%) was from Merck Sharp& Dohme, Canada Ltd.. Paramagnetic contaminants were removed from NMR samples by chromatography on Chelex-100 (Bio-Rad Laboratory), followed by lyophilization. All NMR sample tubes were soaked in 40% nitric acid prior to use. NMR samples were prepared in D_2O, containing 0.5×10^{-2} M† ethylenediaminetetraacetic acid (EDTA). The addition of EDTA did not affect the ^{31}P and ^1H chemical shifts. The pH of solution was adjusted to a desired value by an addition of very small amount of concentrated DCl and/or NaOD solutions in D_2O. The pH was measured with an accuracy of ±0.01 pH unit, both before and after the NMR experiments, using a Toko TP-101 pH meter with a combination electrode of Type CE-103 which can be directly used for NMR sample tube. No correction was made for the deuterium isotope effect on pH value. Concentrations were determined by dry weight and then adjusted to desired values, typically from 0.5×10^{-2} M to 0.2 M, by dilution using a volumetrically variable pipette 4710 (Eppendolf).

NMR Measurements. ^{31}P NMR spectra were obtained in the Fourier transform mode on a JEOL PS-100 NMR spectrometer operating at 40.5 MHz, equipped with a PFT-100 Fourier transform system and a JEOL EC-100 computer. Heteronuclear proton noise decoupling was achieved with a JEOL JNM HD-SC. The spectrometer was field-frequency locked on the deuterium resonance of deuterium oxide used as a solvent. ^{31}P chemical shifts were measured in Hz from 85% H_3PO_4 as an external reference, without any correction of bulk susceptibility. Digital resolution was 0.2 Hz.

Fourier transformed ^1H NMR spectra were taken at 100 MHz on the same spectrometer. All ^1H chemical shifts were measured from 2-methyl-2-propanol as an internal reference. Although this reference is known to be shifted upfield in the presence of high concentration of aromatic solute,[18] the shift is negligibly small in the concentration range of our experiments (up to 0.2 M).

All spectra were recorded at 27 °C, unless specified other-

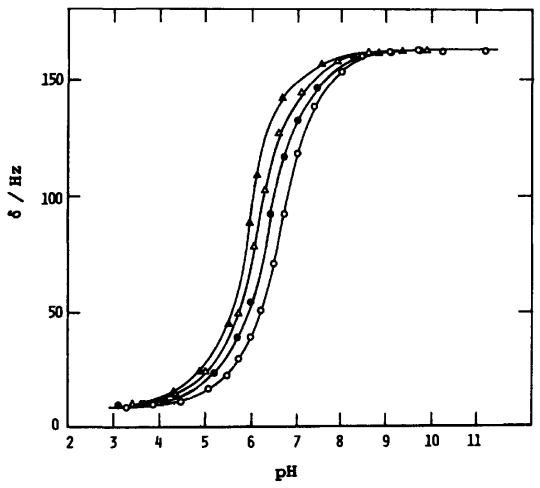

Fig. 2. ^{31}P chemical shift(δ) of 5'-dGMP as a function of pH at various 5'-dGMP concentrations, 0.5×10^{-2} M(○), 4×10^{-2} M(●), 0.1 M(△), and 0.2 M (▲).

wise. A JES VT-3 temperature controller was used for the stabilization, with an accuracy of ±2 °C.

Results and Discussion

Concentration dependence of ^{31}P chemical shifts of 5'-dGMP and 5-dRP was measured at a constant pH (6.60) near the pK_a for secondary ionization of phosphate groups (Fig.1). The ^{31}P resonances of these compounds show remarkable downfield shifts with increasing concentration. ^{31}P chemical shifts of these compounds are identical with each other at lower concentration (<0.02 M), but they are differentiated at higher concentration and the difference increases with increasing concentration. The magnitude of shift is larger for 5'-dGMP than for 5-dRP.

In order to clarify whether the concentration dependence of the chemical shift of each compound is owing to a change of pK_a value or not, titration curves were measured for 5'-dGMP at various concentrations (Fig. 2). The pK_a value decreased with increasing concentration. The ^{31}P resonance at pH 6.60 undergoes a remarkable downfield shift with a small decrease of the pK_a value. At an alkaline pH (>9), the ^{31}P chemical shift is independent of the concentration. It was found that 5'-dGMP and 5-dRP have the same thermodynamic pK_a (6.87±0.01) and chemical shift at an infinite dilution (65±0.5 Hz). The variation of chemical shifts of these compounds with concentration corresponds to the change of pK_a value. The concentration dependence of ^{31}P chemical shifts in Fig. 1, therefore, shows that the phosphate group of 5'-dGMP ionizes more readily than that of 5-dRP. The presence of base moiety may influence on the ^{31}P chemical shift.

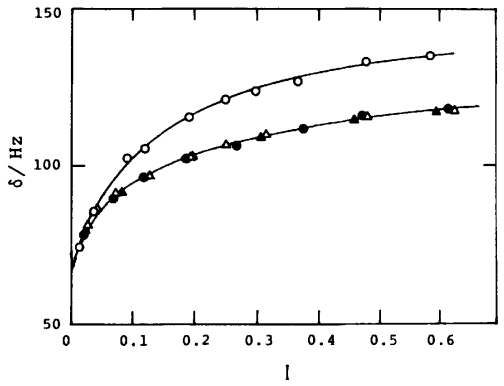

Fig. 3. Dependence of ^{31}P chemical shifts(δ) of 5'-dGMP (circle) and 5-dRP(triangle) on ionic strength (I) at pH 6.60. Open symbols, the ionic strengths calculated from the concentration of each compound in Fig. 1; filled symbols, those adjusted by adding NaCl to 0.5×10^{-2} M solution of each compound.

The conditional pK_a($pK_{a'}$) changes with concentration by the change in the activity coefficient induced by that of the ionic strength.[15,19] To estimate the extent of this effect, the dependence of ^{31}P chemical shift on the ionic strength is observed at pH 6.60 by adding neutral salt (NaCl) to the 0.5×10^{-2} M solution of each compound (Fig. 3, all of filled symbols). At this concentration, the degree of self-association of nucleotides is negligibly small. The ionic strength dependence of ^{31}P chemical shift in this case is little affected by the presence of the base. In Fig. 3 is also shown the dependence of ^{31}P chemical shifts of both compounds on the ionic strength in which the ionic strength is changed with its own concentration (open symbols). As can be seen in Fig. 3, ^{31}P chemical shift change of 5-dRP lacking the base moiety depend only on the ionic strength, while those of 5'-dGMP can not be interpreted by the ionic strength alone. This also indicates that the concentration dependence of ^{31}P chemical shift of 5-dRP represents an concentration effect on the phosphate ionization of the nucleotide in the case where any self-association does not occur. There is an additional effect other than ionic strength in the concentration effect on the phosphate ionization of the nucleotide, which should be owing to the existence of base moiety of the nucleotide.

Above results suggest that the additional effect is

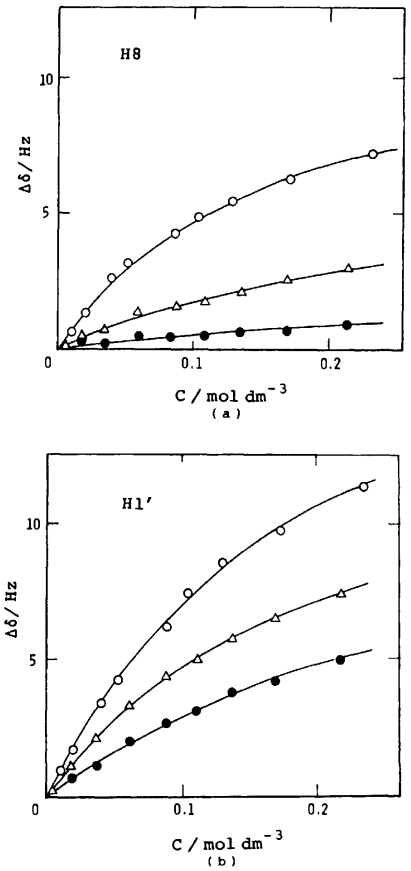

Fig. 4. Effect of temperature on the concentration(C) dependence of H-8(a) and H-1′(b) ^{1}H chemical shift differences($\Delta\delta$) of 5′-dGMP at pH 6.60. 27 °C(○); 45 °C(△); 60 °C(●). $\Delta\delta$ is the difference between the chemical shift of a particular proton at each concentration and that at an infinite dilution.

owing to the formation of the base stacking aggregates. Effects of temperature on the phosphate ionization of the nucleotide were studied to confirm this view. It is known that base stacking aggregates break down with increasing temperature.[11] First the concentration dependence was measured for H-8 and H-1′ chemical shifts of 5′-dGMP at three temperature, 27, 45, and 60 °C (Fig. 4). These resonances shift upfield with increasing concentration. The chemical shift changes are consistent with the isodesmic model of indefinite non-cooperative stacking.[20] The magnitude of shift decreases with increasing temperature. From the concentration dependence of ^{1}H chemical shifts at each temperature, the association constants (K) for the base stacking were estimated with the aid of the isodesmic model (Table 1). The K values derived from both ^{1}H chemical shifts decrease with increasing temperature, indicating the decrease of the stacking affinity.

If the additional reduction of p$K_{a'}$ value for the phosphate group of 5′-dGMP with increasing concentration is owing to the base stacking association, the magnitude of ^{31}P shift at pH 6.60 should decrease with increasing temperature. To verify this idea, the concentration dependence of ^{31}P chemical shift of 5′-dGMP was observed at different temperatures, 27, 45, 60 °C (Fig. 5). With increasing temperature, a reduction of induced shift is observed and the variation of shift with concentration at 60 °C agrees well with that of 5-dRP at 27 °C, indicating a validity of the interpretation based on the base stacking association. An essential effect of temperature on the p$K_{a'}$ value of 5′dGMP must be considered, but it was very small (d pK_a/ d T=0.5×10^{-3}).[21] Previous ^{1}H NMR studies have demonstrated that temperature variation has little effect on the nucleotide conformation.[22-24] There is, therefore, little contribution of conformational changes to the temperature variation of ^{31}P chemical shift.

Table 1. Effect of temperature on the association constant K[a] for the base stacking of 5′-dGMP at pH 6.60

T/°C	K/M^{-1}		K_{av}/M^{-1} [b]
	H-8	H-1′	
27	2.6	2.8	2.7
45	2.0	2.2	2.1
60	1.2	1.4	1.3

a) Estimated errors for these association constants are 10—15%. b) K_{av} is the mean of the individual results. (1 M = 1 mol dm^{-3})

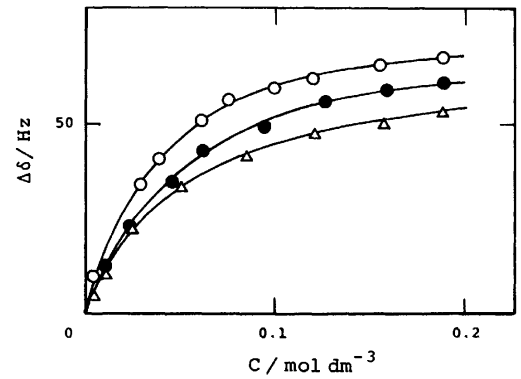

Fig. 5. Effect of temperature on the concentration(C) dependence of the ^{31}P chemical shift differences($\Delta\delta$) of 5′-dGMP at pH 6.60. 27 °C(○); 45 °C(●); 60 °C(△). $\Delta\delta$ is defined as in Fig. 2.

Base stacking should cause a change of nucleotide conformation: the ribose-phosphate backbone,[24-26] the ribose ring[25,26] and the ribose-base torsion.[26-29] One can postulate that ^{31}P chemical shift could be affected by these changes. However, the influence of these conformational changes is not large enough to affect significantly ionization of the phosphate groups, since the same pK_a value can be obtained from the titration curves for various nucleoside 5′-monophosphates with different conformation.[17,24] Identical percentages of the preferred "gauche-gauche" rotamers around C$_{5'}$–O$_{5'}$ and C$_{4'}$–C$_{5'}$ bonds are found for various nucleoside-5′-monophosphates.[24] Although a change of the rotamer populations around the C$_{5'}$–O$_{5'}$ and C$_{4'}$–C$_{5'}$ bonds, determining

the statistically preferred orientation of the 5′-phosphate group, should affect the chemical shift of the corresponding ^{31}P signal, constancy of conformer populations was found from the measurements of coupling constants $^{3}J_{PH}$ (*ca.* 4.8 Hz) and $^{4}J_{PH}$ (*ca.* 1.5 Hz) for 5′-dGMP over the range of experimental concentration at pH 6.60.

The effects on the ^{31}P shift of the ring current fields, as well as the diamagnetic and paramagnetic components of the atomic magnetic anisotropy, seem also insignificant, since ^{31}P chemical shifts are independent of concentration at alkaline pH (>9) (Fig. 2). Even in this pH region, base stacking can also occur.[7]

The effect of concentration on the 5′-phosphate ionization of 5′-dGMP should be attributed to the molecular condensation effect owing to the base stacking association.

Oxidative Carbonylation of Piperidine in the Presence of Palladium(II)-Copper(II) Catalytic System

Yuri L. Sheludyakov and Valentin A. Golodov*
Institute of Organic Catalysis and Electrochemistry 480100, Alma-Ata, K. Marx str., 142, USSR
(Received January 14, 1982)

A kinetic study on oxidative carbonylation of piperidine to give 1,1'-carbonyldipiperidine in the presence of Pd(II) and Cu(II) complexes at 40 °C has been investigated.

Carbonylation of amines depending on the conditions of the reaction and the catalyst nature produces various oxygen-containing derivatives.[1-4] Thermodynamic characteristics of the reaction are most favorable in case of the oxidative carbonylation.[3] A new catalytic system of the oxidative carbonylation of amines, based on Pd(II) and Cu(II) complexes in mild conditions, was reported previously.[5] Its high activity is due to the development of the synergistic effect of the mixed catalyst.

This paper is aimed at the elucidation of the reaction mechanism and causes of the synergistic effect by studying in detail the kinetics of the oxidative carbonylation of piperidine to give 1,1'-carbonyldipiperidine in the same catalytic system.

A static system under volumetric and potentiometric control was adopted. During the kinetic study, the reactor was energetically shaked up to provide good mixing of gas and liquid. In the study of the mechanism of separate stages, the solution of the complexes from the reactor was periodically fed to the cell of UR-20 spectrometer.

Results and Discussion

The rate of the reaction (1)

$$2C_5H_{10}NH + CO + 2Cu\,(II) \xrightarrow{Pd(II)} 2Cu(I) + (C_5H_{10}N)_2CO + 2H^+ \quad (1)$$

increased linearly with both Pd(II) concentration and CO partial pressure (Fig. 1a, c) and nonlinearly with Cu(II) concentration (Fig. 1b). At the ratio of Cu(II) : Pd(II) = 2 the reaction order was 1, but it approached to zero at the ratio >40. It was found that the reaction rate was independent of the piperidine concentration in the 4.2×10^{-3}—1.4×10^{-1} mol l^{-1} range. The kinetic equation is thus represented in the following form:

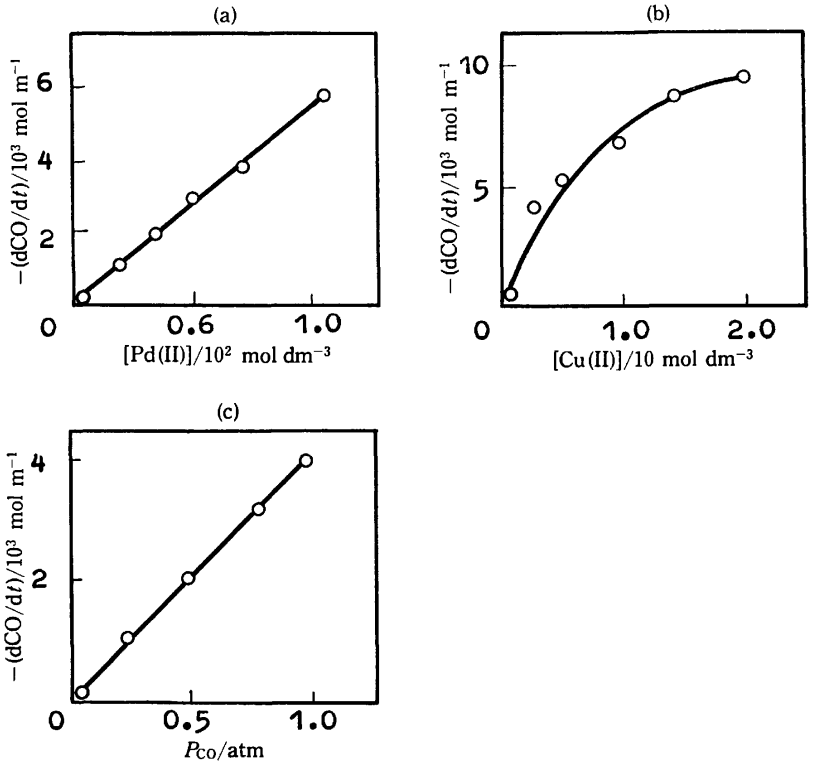

Fig. 1. Dependences of oxidative carbonylation rate of piperidine on Pd(II) (a), Cu(II) (b) concentrations and CO partial pressure (c). Pyridine, 40 °C, $[Pd(II)]=7.2\times10^{-3}$ mol dm^{-3}, $[Cu(II)]=7.2\times10^{-2}$ mol dm^{-3}, $P_{CO}=1$ atm.

$$-\frac{dCO}{dt} = k_{ef}\cdot[Cu(II)]^n\cdot[Pd(II)]\cdot[CO], \quad (2)$$

$n = 0—1$

Our data and those cited in the paper of Brakman[6] on piperidine carbonylation in the Cu(II)–Cu(I) catalyst system can be described by the kinetic Eq. 3:

$$-\frac{dCO}{dt} = k_{ef}\cdot[Cu(I)CO]\cdot[C_5H_{10}NH], \quad (3)$$

which shows that autocatalysis is carried out in the reaction till the complete consumption of Cu(II) with accumulation of 1,1′-carbonyldipiperidine and copper-(I) carbonyl in the solution (bands in the IR spectrum at 1650 and 1970 cm^{-1}).

In the absence of copper(II), $PdCl_2(C_5H_{10}NH)_2$ in the excess of piperidine with CO gives a product having a number of bands in the "carbonyl" region, *i.e.* 1595, 1895, 2010, and 2045 cm^{-1}.

If the excess of piperidine was replaced by two equivalents of triphenylphosphine, then the IR spectrum would show only one intensive band at 1590 cm^{-1} which, on the basis of literature data,[7] may be attributed to the carbamoyl complex. The band at 1595 cm^{-1} in the above-mentioned group is attributed to the same complex. The relation of other bands is not quite clear.

Literature[8] and our experimental data show that the key-complex of palladium in the catalytic reaction is represented by the carbamoyl complex which is stable to the action of the excess of amine and air oxygen at a room temperature but is easily decomposed by water forming metallic palladium and by piperidine complex of copper(II) forming 1,1′-carbonyldipiperidine (ν_{CO}= 1650 cm^{-1}).

$$Pd(II)(CONC_5H_{10}) + 2Cu(II) \xrightarrow{k_4} 2Cu(I) + Pd(II) + (C_5H_{10}N)_2CO \quad (4)$$

(Cl^- and amine ligands are omited for Simplicity) Presynthesized carbamoyl complex of palladium(II) can be titrated potentiometrically by copper(II) chloride in the excess of piperidine and in the absence of CO (Fig. 2).

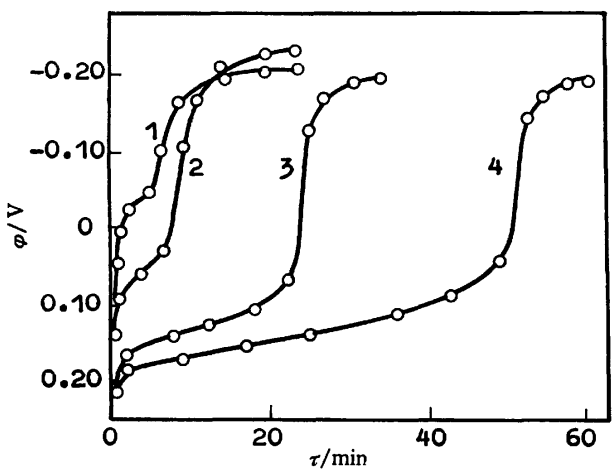

Fig. 2. Potentiometric curves of the interaction of carbamoyl complex of palladium with copper(II) amine complex. Pyridine, 25 °C, $[Pd(II)]=4.0\times10^{-2}$ mol dm^{-3}, $[Cu(II)]=0.8\times10^{-2}$ (1), 1.6×10^{-2} (2), 2.4×10^{-2} (3), 4.0×10^{-2} mol dm^{-3} (4).

According to the stoichiometric Eq. 4, 2 mol Cu(II) are necessary for the formation of 1,1′-carbonyldipiperidine. However, the first order for copper(II) obtained experimentally, indicates that the reaction (4) consists of minimum two stages where the interaction with the second complex of copper(II) proceeds, probably, fast and does not affect the rate of the process as a whole.

When the reaction is carried out directly in the IR spectrometer, palladium carbonyl preceding the carbamoyl complex is not observed. The formation of carbamoyl can be supposed to be carried out by CO incorporation into Pd–N bond despite the fact that in a similar Cu(I)–Cu(II) system the reaction proceeds through the stage of the formation of carbonyl; this reaction route is considered as a key reaction for the synthesis of carbamoyl complex.[9]

$$Pd(II)(C_5H_{10}NH) + CO \underset{k_5}{\overset{k_{-5}}{\rightleftharpoons}} Pd(II)(CONC_5H_{10}) + H^+ \quad (5)$$

The kinetic Eq. 6 corresponding to the stages (5) and (4) qualitatively agrees with the experimental one (2).

$$-\frac{dCO}{dt} = \frac{k_5\cdot k_4\cdot[Pd(II)]\cdot[CO]\cdot[Cu(II)]}{k_{-5}[H^+]+k_4\cdot[Cu(II)]} \quad (6)$$

By the graphic method the constants of the Eq. 6 have been determined as $k_5=117$ dm^3 mol^{-1} min^{-1} and $k_{-5}/k_4=1.82\times10^{-3}$. The k_4 can be determined independently by the initial rate of the reaction product of Pd(II) with carbon monoxide and copper(II). The constant k_4 thus obtained is 17 dm^3 mol^{-1} min^{-1}, which gives the value of $K_5=k_5/k_{-5}=3.8\times10^3$.

As the values of k_5 and k_4 are similar the change of the reaction order of Cu(II) from 0 to 1 in a relatively narrow range of copper(II) concentrations would be accounted for. In fact at low Cu(II) concentrations the reaction rate is limited by the reaction (4) and we find the first order for copper, while at high Cu(II) concentrations the products of Pd(II) and CO interaction are quickly transformed to urea derivatives and the process is limited by the reaction (5).

The synergistic effect in Pd(II)–Cu(II) system (Fig. 3) can be accounted for the fact that in the presence of Pd(II) the stage of the formation of the carbamoyl

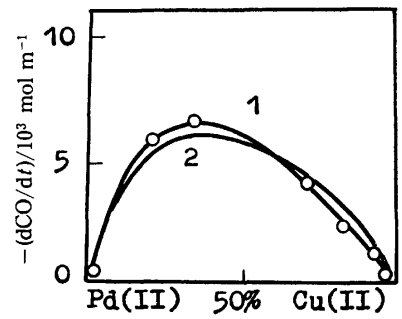

Fig. 3. Dependence of the initial rate of the oxidative carbonylation of piperidine on the ratio of palladium and copper complexes. $Pd(II)+Cu(II)=5.0\times10^{-4}$ mol CO, $C_5H_{10}NH$: $(Pd(II)+Cu(II))=20$. 1: Experimental points, 2: calculated curve.

complex is accelerated while Cu(II) additions accelerate its redox decomposition, *i.e.* an oxidizer is necessary for the stage of redox decomposition of the carbamoyl complex. In the classification offered,[10] this is a third type of synergism.

Hence, by the present study we managed to confirm the scheme of the process of piperidine carbonylation using a new mixed Pd(II)–Cu(II) catalyst for this reaction; to determine a key intermediate species *i.e.* the carbamoyl complex of palladium and to show that an oxidizer is necessary for the stage of redox decomposition of this complex which leads to the synergism in the system.

On the Physicomagnetic Properties of Some Nitro Compounds

Mohamed M. Abdel-Kader* and Safia M. Salem
Physics Department, Faculty of Science, University of Cairo Giza, Egypt
(Received January 12, 1983)

The mean molar susceptibilities of nine aromatic nitro compounds namely, *o*-, *m*-, *p*-dinitrobenzene; *o*-, *m*-, *p*-nitrobenzoic acid and *o*-, *m*-, *p*-nitrophenol have been measured. The semiexperimental anisotropies of these molecules have been calculated. The magnetic data are correlated with the positional isomerism of the nitro groups and the crystal structures of these molecules as well as their hydrogen bonding.

Introduction of a large group like that of the nitro group (NO_2) for hydrogen atom in a benzene ring generally resulted in a detectable change in various physical constants of the molecule. But the nature of the effect depends much on the position of the group in the ring. The mean molar susceptibilities of the nitro group and nitro compounds have been extensively considered theoretically or experimentally. Cabrena and Fahlenbrach[1] found that, in nitrotoluene, the *m*-compound had a higher value of the observed molar susceptibility (χ_M^{obsd}) than the other two isomers. French[2] after studying a large number of compounds, noticed an anomalous effect in the case of nitro-substituted compounds. This anomaly was explained by Badder and Mikhail[3] and later by Mikail,[4] as arising from the contribution of the quinonoid structures of the nitro group to the normal structure. From their measurements of the χ_M^{obsd} of seventeen aromatic nitro compounds, Sriraman *et al.*[5] found that the contribution of the nitro group to the mean susceptibilities depends on its position on the benzene ring.

We felt that, it is of interest to study the contribution of the nitro group to the magnetic anisotropies of some benzenoid molecules semiexperimentally. The large anisotropies of the diamagnetic susceptibilities of benzenoid molecules are usually interpreted in terms of ring currents[6–10] despite some criticism.[11,12] A recent paper on the use of the ring current concept has been given by Gomes.[13]

If K_1, K_2, and K_3 are the principal molecular susceptibilities, (K_1, K_2) are the in-plane susceptibility and K_3 is the out-of-plane susceptibility, then the magnetic anisotropy of a molecule is defined as:

$$\Delta K = K_3 - \frac{1}{2}(K_1+K_2) \qquad (1)$$

In general, the molecular susceptibilities (and hence the magnetic anisotropy) can be estimated by measuring the principal crystal susceptibilities (χ_1, χ_2, χ_3) combined with the information about the orientation of the molecules in it. The mathematical relations concerning the transition from crystalline to molecular susceptibilities were previously given by Lonsdale and Krishnan.[14]

In the present work, the magnetic anisotropies of these molecules have been calculated semiexperimentally. The details of this method have been discussed before by one of the present authors.[15] The equation used is

$$\Delta K_{semi} = 3[\chi_M^{obsd} - \frac{1}{2}(K_1+K_2)]. \qquad (2)$$

Experimental

The molecules studied in this paper can be classified into three groups:

1) Dinitro Benzenes: a) *o*-Dinitrobenzene.[16] b) *m*-Dinitrobenzene.[17] c) *p*-Dinitrobenzene.[18]

2) Nitrobenzoic Acids: a) *o*-Nitrobenzoic acid.[19] b) *m*-Nitrobenzoic acid.[20] c) *p*-Nitrobenzoic acid.[21]

3) Nitrophenols: a) *o*-Nitrophenol.[22] b) *m*-Nitrophenol. c) *p*-Nitrophenol.[23]

The crystal structure of these compounds are known except for *m*-nitrophenol. The purity of each compound was tested by measuring its melting point. Purification by recrystallization from solvents was carried out when the melting point of the compound is slightly different from that given in the literatures. The melting point (mp) of each compound has been given in Table 1.

The Gouy method was employed for the measurements of the susceptibility of each compound. Details of this method has been given elsewhere.[15]

Results and Discussion

In Table 1, the specific susceptibility χ_S, the observed

p-Nitrophenol	−68.14	−45.34	−107.86	−39.72	−62.46

a) The calculated values of $\Delta K'$ and/or ΔK_{semi} for the benzene ring and/or the acid molecule were given in Ref. 15.

molar susceptibility χ_M^{obsd} and the calculated molar susceptibility χ_M^{calcd} of each compound are presented.

The method used for the calculation of χ_M (in 10^{-6} emu mol^{-1}) is as follows:

a) The mean molar susceptibility of the benzene ring is −55.20.[10]

b) The drop in diamagnetism of the benzene ring due to the replacement of one hydrogen atom by another atom or group is 2.00.

c) The mean molar susceptibility of the $(NO_2)^{1+}$ group is −6.7,[5] using Yung method,[24] we get for the neutral NO_2 group the value $-(6.7+2.44)=-9.14$.

d) The mean molar susceptibility of the COOH group is −17.20[25] and of the OH group is 6.7.[25]

Thus the calculated molar susceptibility of any molecule of the compounds of the first series is $(-55.20+2.00\times2-9.14\times2)=-69.48$.

The most important fact emerging from the data shown in Table 1 is that, the *m*-compound has a markedly higher diamagnetic susceptibility than the other two isomers. Such a result is normally expected. According to French,[2] Sriraman *et al.*,[5,26] and Baliah *et al.*,[27] the nitro group is strong meta-directing. When such group is substituted in the benzene ring, it tends to withdraw electrons from the ring and the displacement of electrons is mainly from the *o*- and *p*-positions. As a result, the *m*-position is the point of relatively high electron density which will mean a higher χ_M^{obsd} value for the *m*-isomer. It can also be seen from Table 1 that, the order of χ_M^{obsd} for the members of the first and second series is:

meta>para>ortho,

as suggested by Baliah *et al.*[27] in a similar work. For the compounds of the third series, the OH group is *o*, *p*-directing and the NO_2 group is strong *m*-directing, so the order of χ_M^{obsd} is

meta>ortho>para.

Recently,[28] a different theoretical approach, where the susceptibility is represented as a sum of bond contributions and bond-bond interaction is capable of explaining difference between isomers.

The values of $\frac{1}{2}(K_1+K_2)$, K_3 or $K^{\perp}$, and ΔK_{semi} for each compound are listed in Table 2. The values of the atomic susceptibilities used in the calculations of $\sum\chi_{atomic}$ are:

$\chi_C = -7.4$,[29] $\chi_H = -2.0$,[29] $\chi_O = -4.6$.[30]

For the NO_2 group, its magnetic susceptibility depends on its position in the benzene ring,[5] its value is taken as −9.14.

Perhaps the most striking fact emerging from the magnetic data of the compounds of the first series given in Table 2 is that the semiexperimental magnetic anisotropy of the *m*-dinitrobenzene is numerically too high. Fortunately, the observed magnetic data of this compound have been determined by Lasheen.[31] Accordingly,

$$K_L \equiv (K_1) = -50 \pm 6.9,\ K_M \equiv (K_2) = -41.7 \pm 2.1,$$
$$K_N \equiv K_3 = -119.8 \pm 6.7 \text{ and } \Delta K_{obsd} = -74 \pm 7.6.$$

Unfortunately Lasheen did not give any explanation for his results because he was interested only in the molecular susceptibilities. The semiexperimental magnetic anisotropy of *m*-dinitrobenzene agrees closely with Lasheen value. Furthermore, our results for $K^{//}$ and $K^{\perp}$ are also in agreement with Lasheen values. This can be considered as a check on the accuracy of the semiexperimental method.

Since the *m*-dinitrobenzene crystals are orthrhombic, therefore the crystallographic axes agree with the axes of the triaxial ellipsoid representing the crystal susceptibilities (χ_a, χ_b, and χ_c). Assuming $K_1 \simeq K_2$, the values of χ_a, χ_b, and χ_c have been calculated by the present authors from the set of equations given in Ref. 15. Our values for χ_a, χ_b and χ_c are

$$\chi_a = -48.34,\ \chi_b = -59.40,\ \chi_c = -105.84.$$

In a good agreement with Lasheen experimental values namely,

$$\chi_a = -45.1 \pm 2.3,\ \chi_b = -58.9 \pm 2.4,$$
$$\chi_c = -107.05 \pm 4.6.$$

In the opinion of the present authors, there are two possibilities for the interpretation of the high value of ΔK for this compound:

a) The NO_2 group is not magnetically isotropic and may have a certain value of anisotropy like for example the carbonate or nitrate groups.[32]

b) The second possibility which seems to us more likely to exist is the dipole moment of the molecule. Since we have two NO_2 groups, therefore the dipole moment of the molecule will depend largely on the positions of the two NO_2 groups relative to each other. From

their measurements of the dipole moment of the nitro-substituted compounds, Jalkar and Phansalker[33] confirmed that the *m*-directing inductive effect of the nitro group had a considerable influence on the dipole moment.

At this point, it is necessary to calculate the delocalization anisotropy or the π-electron susceptibility. The results of calculations are given in Table 2. The empirical equation used for these calculations is that given by Davies,[34] namely

$$\Delta K' = K^{\perp} - \sum \chi_{\text{atomic}}.$$

From Table 2, it is clear that the delocalization anisotropy of the *m*-isomer is numerically much higher than that of the benzene ring and of the other two isomers. In other words the effect of the NO_2 groups in the *m*-position to the magnetic properties of the molecule is much more pronounced than that of the other two isomers.

For the members of the second and third series it is of interest to correlate the magnetic properties of these molecules with their structures and their hydrogen bonding systems. Refinements of the crystal structures of the nitrobenzoic acid molecules have been carried out by the Indian group, Pant *et al.*[19-21] The general feature of the crystal structures of these molecules is that, the acid groups are dimerized across intermolecular hydrogen bonds. The O–H···O are 2.645 and 2.653 Å for *o*- and *p*-nitrobenzoic acids respectively. For the *m*-nitrobenzoic acid, each dimeric unit consisting of crystallographically independent molecules A and B. The O–H···O hydrogen bonds linking molecules A and B are 2.630 and 2.666 Å.[29]

The contribution of the hydrogen bonding to both the magnetic susceptibilities and anisotropies of some aromatic compounds containing a benzene ring has been discussed by the present authors,[15,35] We have showed that the effect of the hydrogen bonding is to increase the values of $\Delta K'$ and/or ΔK of the acid molecule by about 5×10^{-6} emu mol^{-1}. from the calculated one. Thus for the *o*- and/or *p*-nitrobenzoic acid the numerical increase in $\Delta K'$ and/or ΔK of the molecule can be ascribed to the additional magnetic anisotropy of the electron delocalization resulting from the hydrogen bonding as suggested by Mason.[29]

The case of *m*-nitrobenzoic acid is very intersting. For this compound, the values of $\Delta K'$ and/or ΔK are numerically much greater than that of the other two isomers. Since the hydrogen bonding scheme of the three nitrobenzoic acid molecules are similar,[19-21] therefore one cannot attribute this large anisotropy to the effect of the hydrogen bonding alone. In other words, the contribution of the NO_2 group in this case (*i.e.* in the *m*-position) to the anisotropy of the molecule is very clear.

For the compounds of the third series, the hydrogen bonds are due to the OH and/or NO_2 group. This type of hydrogen bonding is much weaker than that of the COOH group. Thus the slight increase in the anisotropies of the *o*- and/or *p*-nitrophenol can be explained as resulting from the contribution of the weak hydrogen bonding of these molecule. On the other hand, the anisotropy of the *m*-nitrophenol is numerically much greater than that of the *o*- and/or *p*-isomers and cannot be ascribed to the effect of hydrogen bonding alone.

In conclusion, the observed molar susceptibilities and the magnetic anisotropies of the *m*-nitro compounds are numerically much greater than that of the *o*- and/or *p*-isomers. These peculiar magnetic properties of the *m*-nitro compounds may be attributable to the large dipole moments of the *m*-isomers or probably to the anisotropy of the nitro group in the *m*-position. Certain anomalous effects which agree and support this conclusion were found by other workers. Abe[36] found that *m*-dinitrobenzene showed the maximum absorption band at shorter wavelengths than nitrobenzene, such a result was also confirmed by Semba.[37] He also measured the equilibrium constants of isomeric nitroanilines and nitrophenol, and found that the meta compound had a very high value compared with other two isomers.

Kinetics and Mechanism of the Oxidation of Alcohols by Pyridinium Fluorochromate

Manabendra N. BHATTACHARJEE, Mihir K. CHAUDHURI,* and Himadri S. DASGUPTA
Department of Chemistry, North-Eastern Hill University, Shillong 793003, India
(Received February 1, 1983)

Pyridinium fluorochromate, $C_5H_5NHCrO_3F$, oxidizes benzyl alcohol, ethanol, and cyclohexanol to benzaldehyde, acetaldehyde, and cyclohexanone, respectively. While each of the oxidation, studied in acetonitrile–nitrobenzene (1 : 1, v/v) medium, is first order with respect to the oxidant, the rate is almost independent of the substrate concentration. The reactions are catalyzed by acid, the acid-catalyzed reactions being very fast, precluded determination of their order in acid medium. The effects of temperatures and solvent compositions were studied and activation parameters evaluated. Probable mechanisms are discussed.

There has been a continued interest in the development of new chromium(VI) reagents[1–6] for the effective oxidation of organic substrates, particularly alcohols, under mild conditions, and significant improvements were achieved, in recent years, by the use of new oxidizing agents.[2–6] We have very recently developed[7] a new reagent pyridinium fluorochromate, $C_5H_5NHCrO_3F$ (PFC) and found several advantages of our reagent over similar oxidizing agents in respects of amounts of oxidant and solvent required, short reaction times, and high yields. The mechanism of oxidations involving this important reagent has not yet been reported. The present paper describes the kinetics of oxidation of three typical alcohols *viz.*, benzyl alcohol, ethanol, and cyclohexanol, studied in medium acetonitrile–nitrobenzene (1 : 1, v/v), evaluates the reaction constants and discusses the probable mechanism.

Experimental

All chemical used were reagent grade products. The solvents were purified and dried by the literature methods.[8] *p*-Toluenesulfonic acid (TsOH) and benzoic acid were used in the attempts to study the acid-catalyzed reactions. Pyridinium fluorochromate, PFC, was synthesized by the method originally described in our previous paper.[7]

The reaction products benzaldehyde, acetaldehyde and cyclohexanone were characterized by spectral analyses and estimated as their 2,4-dinitrophenylhydrazones.

For kinetic measurements, the reactions were performed under pseudo-first-order conditions by maintaining a large excess (×5 or greater) of alcohol over PFC. The reactions were carried out at constant temperature (±0.1 K) and progress of the reactions were followed by iodometric estimation of unreacted chromium(VI), after quenching the reaction. The medium of reactions was always 1 : 1 (v/v) acetonitrile: nitrobenzene, unless otherwise stated. Acetonitrile–nitrobenzene system was chosen as the solvent because it was observed in our previous studies[7] that acetonitrile did not react with PFC. The reaction mixtures were homogeneous for the total period of kinetic investigation.

Computations of the rate constants were made from the plot of log[oxidant] against time. The values reported are the mean of at least duplicate runs and are reproducible to within ±4%.

Dielectric constants for the varying proportions of acetonitrile–nitrobenzene mixtures were estmiated from the dielectric constants of the pure solvents[9] and are set out in Table 3. A constant ionic strength could not be maintained owing to the nonaqueous nature of the reaction medium. It may, however, be mentioned that the variation in ionic strength did not bring about any change[10] in the oxidation of benzyl alcohol by chromium(VI) oxide in aqueous acetic acid medium.

The uncatalyzed reactions were studied with varying temperatures of 303, 308, 313, and 318 K (error limit ±0.1 K) respectively for all the three alcohols (Table 4). The frequency factors were determined on the basis of the results obtained thereof. The activation parameters were evaluated by the standard procedure,[11] within allowable average error limit (at 303 K) (Table 5).

Results and Discussion

The oxidation of benzyl alcohol, ethanol and cyclohexanol by PFC in 1 : 1 (v/v) acetonitrile–nitrobenzene leads to the formation of benzaldehyde, acetaldehyde and cyclohexanone respectively in very high yields (>90%), showing no indication of further oxidation of the carbonyls conforming to our earlier synthetic studies involving PFC.[7]

The stoichiometry of various oxidations studied herein were estimated by the reaction of the respective alcohol with an excess of oxidant (PFC) followed by estimating the unreacted Cr^{VI}. In some runs, however, an excess of alcohols were used followed by the estimation of the carbonyl product. The stoichiometry of the reactions can be represented as follows:

$$3RCH_2OH + 2Cr^{VI} \longrightarrow 3RCHO + 6H^+ + 2Cr^{III}. \quad (1)$$

The stoichiometry of the reactions with cyclohexanol was determined in an analogous manner,

$$3C_6H_{11}OH + 2Cr^{VI} \longrightarrow 3C_5H_{10}CO + 6H^+ + 2Cr^{III}. \quad (2)$$

Like the analogous PCC[12–14] reactions, all the three alcohols studied herein were found to be first order with respect to time, because the first order rates were constant at different times. The reactions were also observed to be clearly first order with respect to the oxidant (PFC) as the rate constants were found to be practically unaltered for most of the reaction times (Table 1) with varying concentration of oxidant. The most prominent difference in the oxidations involving PCC[12–14] and those involving PFC is that the order of the reactions of the three alcohols with respect to the substrate concentrations was found to be practically constant enabling us to infer that the rates are almost independent of substrate concentrations. However, a small but steady increase in the rate constant values for all the three alcohols with increasing concentrations of the substrate

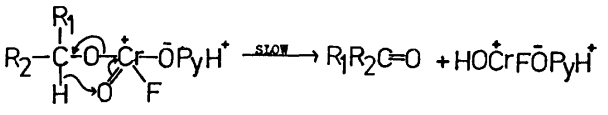
has been observed (Table 2) and a plot of log k_{obsd} against log [substrate] shows that the rates increase in very small fractions with the sequential increase in substrate concentration. This most probably implies that complex formation between the substrate and oxidant is taking place in present cases.

Our attempts to study the acid-catalyzed oxidations of the three alcohols were unsuccessful. Attempted acid-catalyzed reactions involving *p*-Toluenesulfonic acid or benzoic acid, and varying proportions of solvent compositions were observed to be too fast to measure the rate.

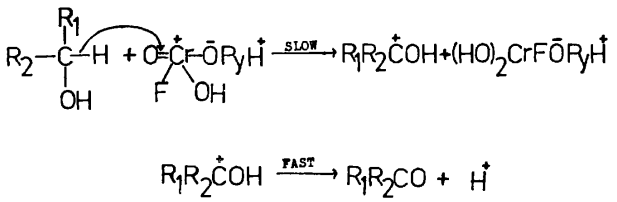
The results of uncatalyzed reactions with varying composition of the solvent components (Table 3) shows that the reaction rate decreases with increase in dielectric constant (though small) of the medium suggesting that the more polar solvents may require larger reaction times for the oxidation reactions. A plot of log k_1 against the inverse of dielectric constants of the media is a straight line with positive slope and implies the occurrence of an interaction between a dipole and a positive ion,[15] and also indicates the probable involvement of a protonated Cr^{VI} species, in the presence of an acid, in the rate determining step. However, since the range of dielectric constants varies between 35.6 and 36.7 showing a large increase in the rate, the observed change could as well be solvent specific rather than owing to the effect of change in dielectric constant.

The near constancy of the values of the free energies of activation of the three reactions (Table 5) suggest that a similar mechanism is operative in each of the three oxidations. Free energies of the acid-catalyzed reactions appear to be lower, as there has been a pronounced increase in the rate of catalyzed reactions suggesting thereby that a protonated Cr^{VI} species may be involved in the rate determining step in the presence of an acid. This is in accord with the involvement of such species well established in chromium(VI) oxide oxidations.[16]

The large negative entropy values obtained in the present studies, suggest that the solvent molecules are strongly oriented or 'frozen' around the ions thereby resulting in the loss of entropy,[17] the effect being larger in nonpolar solvents. This conforms to the contention that the decrease of polarity of the medium results in increase of the entropy value and the number of unbound molecules in the solution increases.[18] This also accounts for the lowering of rate coefficient values with increasing polarity of the medium. Comparatively greater reactivity of pyridinium fluorochromate (PFC) over that of the corresponding chlorochromate (PCC), as shown in our previous paper,[7] can now be understood from the relatively higher negative entropy values of the reactions. We believe that the bonding of F with chromium in PFC facilitates larger charge distribution in the transition state in the cases of PFC oxidation and correlates well with the observed entropy values.



Scheme 1.



Scheme 2.

In view of the above results it appears that a hydride transfer mechanism is involved in the rate determining step of the PFC oxidations. It is possible that the hydride transfer may take place either through the prior formation of chromate (Scheme 1), or directly (Scheme 2). The present data also suggest, like the similar oxidations involving chromic acid,[16] a chromate formation in the rate-determining step (Scheme 1) although the chances of Scheme 2 can not be totally ruled out. It is also expected that the chromate intermediate will be better stabilised in the less polar medium and will enhance the oxidation rate, thus conforming to the observations made by us.

The authors wish to thank the University for the award of a fellowship (U. G. C.) to one of them (M. N. B.) and also to Dr. A. K. Sil, for his interest in the work.

Vibrational Spectra and Thermodynamic Functions of 2-Methoxypyridine and 2-Methoxy-d_3-pyridine

Kanak C. Medhi

Department of Physics, Gauhati University, Gauhati-781014, India

(Received February 4, 1983)

The infrared spectra in the liquid state (4000—50 cm^{-1}) and in the vapor phase (4000—400 cm^{-1}) and the polarized laser Raman spectra in the liquid state have been measured for 2-methoxypyridine and 2-methoxy-d_3-pyridine. Essentially complete assignments of the observed frequencies are presented. Ideal gas state thermodynamic functions of the molecules are also calculated in the temperature range 200—1500 K.

In continuation of the earlier work on the vibrational analysis of a few substituted pyridine molecules,[1-4] the investigation has now been extended to 2-methoxypyridine and 2-methoxy-d_3-pyridine. The infrared spectrum of 2-methoxypyridine in solution or in the pure liquid state was reported by Katritzky and Hands,[5] Katritzky and Coats,[6] and Spinner and White[7] in a limited range, and a partial assignment of only a few bands was given. The earlier work on the simple Raman spectrum of 2-methoxypyridine relate to that of Spinner and White.[7] There is however no previous study on the vibrational spectra of the deuterated species, 2-methoxy-d_3-pyridine.

The present investigation was undertaken with a view to making a detailed study of the infrared spectra of 2-methoxypyridine and 2-methoxy-d_3-pyridine in the liquid and vapor phases and the polarized Raman spectra of the two molecules in the liquid state. Assignments of the observed frequencies based on the infrared band contours, state of polarization of the Raman lines and comparison with the assignments for related molecules[8-12] are given. The ideal gas state thermodynamic functions of the molecules are also calculated on the basis of these assignments.

Experimental

Chemically pure sample of 2-methoxypyridine, used in this experiment, was obtained from Aldrich Chemical Company, U. S. A. and purified by fractional distillation. A sample of 2-methoxy-d_3-pyridine of 98 at.% isotopic purity was supplied by Merck Sharp and Dohme, Canada Ltd., and used as received.

The infrared spectra of the samples in the liquid and vapor states in the range 4000—400 cm^{-1} were recorded on a Carl-Zeiss Specord IR 75 spectrophotometer. The calibration of the instrument was checked by a polystyrene film run immediately after each record. The gas-phase spectra were taken at different temperatures using a 9 cm heated gas cell equipped with KBr windows. A Perkin-Elmer model 180 spectrophotometer and a DIGILAB FTS-15B Fourier Transform interferometer were employed to scan the far infrared spectra of the pure liquid samples in the region 500—50 cm^{-1}. The Raman spectra were measured on a Cary 82 laser Raman spectrophotometer using 488.0 nm (200 mW) line of an argon ion laser as the excitation source. Polarization measurements were made by the method described elsewhere.[4]

Results and Discussion

The frequencies observed in the infrared and Raman spectra of the two molecules, their approximate intensities and probable assignments are given in Table 3. The calculated values of the thermodynamic functions are listed in Tables 4 and 5. Assuming C_s symmetry for both the molecules, the thirty-nine normal vibrations, which are active both in the infrared and Raman spectra, are divided over the irreducible representation as follows:

$$\Gamma = 26a' + 13a''$$

The a′ modes should give rise to polarized Raman lines, whilst the depolarized lines are associated with the a″ modes.

Taking the ring as a planar regular hexagon, the principal moments of inertia of 2-methoxypyridine and 2-methoxy-d_3-pyridine molecules and the asymmetry parameters $\kappa=(2B-A-C)/(A-C)$ and $\rho^*=(A-C)/B$, where A, B, and C are the rotational constants, have been calculated (Table 1) with the following geometry on the assumption that the 2-methoxypyridine molecules exist in the cis (synperiplanar) conformation (Fig. 1).

$$r(\text{C–C}) = r(\text{C–N}) = 1.397\ \text{Å},\ r(\text{C–H}) = 1.084\ \text{Å},$$
$$\angle\text{CCC} = \angle\text{CCN} = \angle\text{CCO} = 120°,$$

and for OCH_3 group : $r(\text{C–H})=1.0936$ Å, $r(\text{C–O})=1.426$ Å, $\angle\text{COC}=109.47°$, and all other angles are tetrahedral (109.47°). The values of relative atomic masses recommended by IUPAC[13] were used in the calculation.

Making use of the results given in Table 1, the PR separations of the vapor-phase band envelopes in the infrared spectra have been calculated at $T=323$ K by the method of Seth-Paul and Dijkstra[14] and compared with the observed values (Table 2). While the normal

modes of species a″ will have a contour of type-C with strong Q branch, the a′ modes will give rise to A- or B-contours or contours of the hybrid type-AB depending on the directions of the oscillating dipoles.

Species a′. The polarized Raman lines observed at 3013, 3062, 3072, and 3094 cm^{-1} in the case of 2-methoxypyridine and 3021, 3066, and 3078 cm^{-1} and the infrared band at 3088 cm^{-1} in 2-methoxy-d_3-pyridine are readily assigned to the C–H stretching vibrations. The Raman spectra of the two molecules show polarized lines at 1602 and 1572 cm^{-1}, and 1599 and 1571 cm^{-1} respectively; these are assigned to the C–C stretching modes of the highest energy. The infrared bands observed at 1481, 1419, and 1312 cm^{-1} and 1472, 1433, and 1316 cm^{-1} in 2-methoxypyridine and its deuterio analog respectively show type-A vapor-phase contours, and are attributed to the next ring stretching modes. The highly intense and polarized Raman shifts at 988 and 984 cm^{-1} observed in the spectra of the two molecules may be confidently assigned to the ring breathing mode.

The two components of the planar ring deformation mode are little affected by substitution in the present cases, and identified with the polarized Raman lines at 622 and 602 cm^{-1}, and 620 and 577 cm^{-1} in the case of the two molecules respectively. The three substituent-sensitive modes belonging to the a′ class may be represented by the polarized Raman lines at 1289, 811, and 254 cm^{-1} in 2-methoxypyridine and 1292, 786, and 232 cm^{-1} in 2-methoxy-d_3-pyridine. The remaining a′ modes that can be derived from pyridine may be assigned to the polarized Raman lines observed at 1256, 1143, 1098, and 1044 cm^{-1}, and 1257, 1144, 1075, and 1042 cm^{-1} in the case of the normal and deuterated molecules respectively.

Species a″. The infrared bands at 781, 738, and 526 cm^{-1} in 2-methoxypyridine and 779, 737, and 524 cm^{-1} in the deuterio analog show conclusively type-C vapor-phase contours, and are assigned as a″ fundamentals. Similarly, the infrared spectra of the two molecules show absorptions of medium strength at 862 and 861 cm^{-1} respectively which appear to have type-C structures with prominent central maxima in the gas-phase spectra. These are assigned to the a″ mode involving principally out-of-plane bending motions of the ring H atoms. The remaining fundamentals belonging to the a″ species may be identified with the weak or moderately intense infrared bands at 957, 827, 412, and 116 cm^{-1} in 2-methoxypyridine and 957, 837, 415, and 130 cm^{-1} in 2-methoxy-d_3-pyridine in agreement with the assignments proposed for other monosubstituted pyridines.[4,9,10]

The Internal Vibrations of the Methoxyl Group. There would appear twelve additional modes of vibration arising from the internal motions of the methoxyl group. The moderately intense infrared band at 2980 cm^{-1} appears to have type-C band contour in the gas-phase spectrum, while the Raman line at 2944 cm^{-1} is very strong and highly polarized. These are assigned to the a″ and a′ CH_3 asymmetric stretching modes respectively. Both of these frequencies are shifted to 2241 and 2263 cm^{-1} on OCH_3 deuteration. Again the infrared vapor-phase band contour of the 2241 cm^{-1} band shows a sharp central maximum characteristic of a type-C band, and its Raman counterpart is depolarized. It is, therefore, assigned to the a″ component of the CD_3 asymmetric stretching mode, while the a′ component may be identified with the polarized Raman line at 2263 cm^{-1}. The frequency at 2209 cm^{-1} appearing with comparable intensity both in the infrared and the Raman spectra may be explained as the overtone $2\times 1101=2202$ cm^{-1} (A′) enhanced by Fermi-resonance interaction with the fundamental at 2263 cm^{-1}. But the situation is complicated by the appearance of three polarized Raman lines of almost equal intensity at 2870, 2850, and 2828 cm^{-1} each having a counterpart in the infrared spectrum of 2-methoxypyridine. Since there occurs an infrared band at 2823 cm^{-1} in the deuterated species corresponding to the 2828 cm^{-1} frequency of the normal molecule, it must be assigned as a combination

band. Of the remaining two frequencies, the 2850 cm^{-1} band is taken as the CH_3 symmetric stretching fundamental on the basis of the observed fact that a sharp band is usually occurs at about 2835 cm^{-1} when a methoxyl group is attached to the aromatic ring,[8,15-17] while the 2870 cm^{-1} band may be explained as the overtone $2\times 1444=2888$ cm^{-1} (A′) in Fermi-resonance[18] with the fundamental at 2850 cm^{-1}. These are shifted to 2124, 2105, and 2075 cm^{-1} on OCH_3 deuteration. Of these, the 2105 cm^{-1} band being weak must be explained as a combination tone. The polarized Raman line at 2075 cm^{-1} and its infrared counterpart at the same frequency showing type-A contour in the gas-phase spectrum are more intense, and may be reasonably assigned to the CD_3 symmetric stretching mode, while the 2124 cm^{-1} frequency appearing with smaller intensity both in the infrared and Raman spectra may be interpreted as the overtone $2\times 1049=2098$ cm^{-1} (A′) or the combination band $1101+996=2097$ cm^{-1} (A′) in Fermi-resonance with the 2075 cm^{-1} fundamental.

A moderately intense polarized Raman line at 1444 cm^{-1} with a strong infrared counterpart at the same frequency is observed in 2-methoxypyridine, but it is absent in the Raman spectrum of the deuterio analog, though an infrared band with much reduced intensity appears at 1451 cm^{-1}. It is also known that the CH_3 symmetric deformation frequency being somewhat sensitive to the electronegativity of the attached oxygen atom in OCH_3 group, shifts to higher frequency[15] as a result of changes in the HCO bending force constant.[19] These observations lead the 1444 cm^{-1} band to be assigned to the CH_3 symmetric deformation mode, while the 1451 cm^{-1} band in 2-methoxy-d_3-pyridine may be attributed to the combination $802+642=1444$ cm^{-1} (A′). The Raman line at 1464 cm^{-1} with its infrared counterpart of medium intensity is assigned to both the components of the CH_3 asymmetric deformation mode.

There appear two polarized Raman lines of almost equal strength at 1100 and 1051 cm^{-1} on OCH_3 deuteration. The infrared band at 1101 cm^{-1} showing type-A contour is very strong, while the band at 1049 cm^{-1} is comparatively weak. The former is therefore assigned to the CD_3 symmetric bending vibration and the latter to the CD_3 asymmetric bending mode in agreement with the assignments proposed for similar molecules.[20-23]

It is found that the 1044 and 811 cm^{-1} bands observed in the infrared and Raman spectra of 2-methoxypyridine, which are already assigned to the a′ fundamentals, decrease appreciably in intensity showing a small shift to lower frequency on OCH_3 deuteration. This may be taken as an evidence that two different fundamentals are overlapping at each of these positions. This frequency range being appropriate for CH_3 rocking modes, the bands at 1044 and 811 cm^{-1} are again assigned to the out-of-plane and in-plane CH_3 rocking modes respectively in agreement with the assignments for other molecules.[9,20,23,24] There appear two additional bands at 894 and 642 cm^{-1} in the infrared spectrum of 2-methoxy-d_3-pyridine. The corresponding Raman shift at 897 cm^{-1} being completely depolarized, is assigned to the CD_3 out-of-plane rocking mode, while the frequency at 642 cm^{-1} may be identified with the CD_3 in-plane rocking mode. The fundamental associated with the torsional mode remains unidentified in the present cases.

The strong infrared band at 1022 cm^{-1} and the polarized Raman line at 457 cm^{-1} in 2-methoxypyridine shift to 996 and 440 cm^{-1} respectively on OCH_3 deuteration. The former is assigned to the O–CH_3 stretching mode in agreement with the previous assignments,[7,25,26] while the latter may arise from the O–CH_3 in-plane bending vibration.[11] The O–CH_3 out-of-plane bend-

ing mode may be represented by the depolarized Raman shift at 234 cm^{-1} in 2-methoxypyridine.

The Application of the Product Rule. When the Teller-Redlich product rule is applied to the assignments for the a′ species, it is found that the observed ratio is

$$\frac{\pi\nu^{\mathrm{I}}}{\pi\nu} = 0.192$$

and the calculated value of this ratio is 0.189.

Since the torsional frequencies are not identified, the product rule cannot be applied to the assignments for the a″ species.

Thermodynamic Functions

The thermodynamic functions of 2-methoxypyridine and 2-methoxy-d_3-pyridine were calculated at several temperatures assuming a rigid rotator, harmonic oscillator approximation and free internal rotation of the methyl group by utilising the fundamental frequencies given in Table 3. The reduced moments of inertia of the CH_3 and CD_3 groups were calculated to be 5.2627×10^{-47} kg m^2 and 10.4120×10^{-47} kg m^2 respectively.

The author wishes to thank Professor I. Haque and Professor J. R. Durig for their kind permission to use the infrared spectrophotometers. The author is also thankful to S. K. Barooah and K. K. Chatterjee for their assistance in recording some of the infrared spectra.

Extractive Separation of Osmium and Ruthenium from Thiocyanate Media

Sambamoorthy JAYA* and Tiruvesaloor V. RAMAKRISHNA
Department of Chemistry, Indian Institute of Technology, Madras-600 036, India
(Received January 25, 1983)

The sequential separation of osmium and ruthenium as thiocyanate complexes by extraction into mesityl oxide and cyclohexanone is described. The conditions for their re-extraction prior to determination from the respective organic layers have been established. Alternatively, the amounts of osmium and ruthenium were established spectrophotometrically from the coloured mesityl oxide and cyclohexanone layers respectively. The developed procedure has been applied to the separation of these metals present in synthetic samples of various minerals.

The reaction of thiocyanate with osmium and ruthenium has been extensively investigated for the spectrophotometric determination of these elements after extraction into diethyl ether, 2-octanone or isobutyl methyl ketone.[1-3] Though the extraction of osmium into diethyl ether or 2-octanone has been reported to be selective, the extraction behaviour of ruthenium has not been described.[1] In the extraction of ruthenium as tetraoxide into carbon tetrachloride,[2] osmium interferes demanding a separation prior to determination. Recently a method[3] has been described for the sequential separation of osmium and ruthenium when present together. This procedure is based on the extraction of the thiocyanate complex of osmium into peroxide containing ether and subsequently ruthenium into isobutyl methyl ketone. The extraction efficiency of osmium and ruthenium however are critically dependent on various experimental parameters such as acidity and duration of heating for complex formation in addition to peroxide content of ether. In the course of our study on the extraction behaviour of the thiocyanate complexes of osmium and ruthenium, it was found that osmium forms such complex at very low concentrations of thiocyanate and low acidities at room temperature itself while the formation of such extractable complex of ruthenium requires heating besides higher acidity and thiocyanate concentration. This formed the basis of the sequential solvent extractive separation procedure described here.

Experimental

Reagents. *Osmium(VIII) Solution*: Prepare by dissolving 1 g of osmium tetraoxide in 250 cm^3 of water as described elsewhere.[4] A working solution containing 100 $\mu g\ cm^{-3}$ of osmium is prepared by suitably diluting the stock solution with water.

Ruthenium(III) Solution: Dissolve 0.513 g of ruthenium trichloride (LOBA-CHEMIE-PURISS) in 25 cm^3 of concentrated hydrochloric acid and dilute with water to 250 cm^3 to get a solution 1000 ppm in ruthenium.

Potassium Thiocyanate Solutions (0.05 mol dm^{-3} and 4 mol dm^{-3}) Sulfuric Acid (3 and 10 mol dm^{-3}).

Solvents: Mesityl oxide, cyclohexanone and cyclohexane.

Apparatus: A carl Zeiss PMQ-II spectrophotometer with 10 mm quartz cells.

Recommended Procedure. *Separation*: Transfer a suitable aliquot of sample solution (upto 8 cm^3) into a 60 cm^3 separatory funnel, add 1 cm^3 each of 0.05 mol dm^{-3} potassium thiocyanate and 3.0 mol dm^{-3} sulfuric acid and dilute to 10 cm^3. Equilibrate the solution with 5 cm^3 of mesityl oxide for 5 min. Separate the organic layer and equilibrate the aqueous layer with 10 cm^3 of cyclohexanone to remov the traces of dissolved mesityl oxide. Drain the aqueous layer into a 25 cm^3 beaker. Add 1.5 cm^3 of 10 mol dm^{-3} sulfuric acid and 3 cm^3 of 4 mol dm^{-3} potassium thiocyanate and dilute to 15 cm^3. Heat the solution at 75 °C for 20 min. Transfer the cooled solution after diluting to 15 cm^3 with water into a 60 cm^3 separatory funnel and equilibrate with 5 cm^3 of cyclohexanone for 1 min.

Equilibrate the mesityl oxide layer with 10 cm^3 of 0.1 mol dm^{-3} sodium hydroxide for 5 min to re-extract osmium. Add 15 cm^3 of cyclohexane to cyclohexanone layer and equilibrate with 10 cm^3 of water for 5 min. Use suitable aliquots of the stripped layers, if necessary, after diluting to a known volume and proceed with the determination as follows:

Determination: Add with mixing 5% potassium thiocyanate solution (2.5 cm^3 for osmium[5] and 1 cm^3 for ruthenium[6]) and 2.5 cm^3 of 1 mol dm^{-3} sodium acetate. Adjust the pH to 3, dilute to about 15 cm^3 with water and heat on a boiling water bath for 20 min. Cool and transfer into 25 cm^3 volumetric flasks. Add 5 cm^3 of 0.005% Rhodamine 6G solution and 1 cm^3 of 1% gelatin. Make up the solutions to mark and measure the absorbance at 565 nm in 10 mm cells against the respective reagent blanks. Establish the concentration by reference to corresponding calibration graphs prepared by using 0 to 40 μg of osmium and 0 to 8 μg of ruthenium.

Results and Discussion

Extraction of Osmium: Preliminary studies were carried out by extracting 100 μg each of osmium or ruthenium into 5 cm^3 of mesityloxide from 10 cm^3 of weakly acidic and acidic solutions containing 0.05 mol dm^{-3} potassium thiocyanate. The per cent extraction was established by estimating the amounts of osmium and ruthenium left out in the aqueous phase using the procedures described under 'Determination.'

The effect of varying the potassium thiocyanate concentration on the extraction of osmium (curve A) and ruthenium (curve B) are shown in Fig. 1. It is evident that though a concentration of as low as 5×10^{-4} mol dm^{-3} potassium thiocyanate is sufficient for the quantitative extraction of osmium, higher concentrations upto 0.9 mol dm^{-3} do not affect the extraction. There is no extraction of ruthenium until the potassium thiocyanate concentration is raised to 0.4 mol dm^{-3}.

Curve A in Fig. 2 shows the effect of acidity on the extraction of osmium from which it is clear that the extraction of osmium is quantitative from 0.1 to 0.6 mol dm^{-3} sulfuric acid. Over the whole range of acidity studied, ruthenium is found to be not at all extracted

Diethyl ether	5.3	<0.01
Mesityl oxide	≫100	<0.01

(*cf.* curve B Fig. 2).

The extractability of osmium and ruthenium into a variety of solvents has been studied from a medium 0.005 mol dm^{-3} in potassium thiocyanate and 0.3 mol dm^{-3} in sulfuric acid. The results are summarised in Table 1 from which it is clear that only mesityl oxide extracted osmium quantitatively while none of the solvents extracted ruthenium under similar conditions. It is also established that a minimum of 3 min of equilibration is essential for the quantitative extraction of osmium into mesityl oxide and a ten-fold increase of the aqueous phase volume to that of the organic phase did not affect the extraction.

Extraction of Ruthenium. As ruthenium forms the extractable thiocyanate complex only on heating, extraction studies on ruthenium are carried out by heating 100 μg of ruthenium in a media which is 0.8 mol dm^{-3} in thiocyanate and 1 mol dm^{-3} in sulfuric acid to 70 °C in a water bath and equilibrating with 5 ml each of various solvents. As clear from Table 2, cyclohexanone alone extracts ruthenium quantitatively while mesityl oxide and cyclohexanol extract only partially. Other solvents like diethyl ether, benzene, cyclohexane, and pentyl acetate do not at all extract ruthenium. Cyclohexanone is preferred in further studies.

The effect of temperature on the formation of thiocyanate complex is established by heating the solution 0.8 mol dm^{-3} in potassium thiocyanate and 1 mol dm^{-3} in sulfuric acid for 20 min in a thermostat maintained at various temperatures and extracting into 5 cm^3 of cyclohexanone after cooling. The results indicate that for quantitative extraction the complex should be formed over the temperature range 70 to 85 °C. Higher temperatures are found to cause lower recoveries of ruthenium possibly due to the decomposition of the extractable species. It is also found that a minimum of 15 min of heating at 75 °C is essential for the complete formation of the complex while heating upto even one hour did not affect the extraction.

The effect of varying the concentration of thiocyanate (curve C, Fig. 1) indicates that a minimum of 0.6 mol dm^{-3} potassium thiocyanate is essential for the quantitative extraction of ruthenium. The effect of acidity on the extraction of ruthenium is studied using varying amounts of sulfuric acid in a medium 0.8 mol dm^{-3} in potassium thiocyanate. The results are indicated in

TABLE 2. CHOICE OF SOLVENT–RUTHENIUM STAGE

Solvent	Distribution ratio D_{Ru}
Carbon tetrachlride	0.286
Chloroform	0.174
Benzene	<0.01
Cyclohexane	<0.01
Isobutyl methyl ketone	0.667
Cyclohexanone	≫100
1-Butanol	1.704
Cyclohexanol	26.220
Pentyl acetate	<0.01
Diethyl ether	<0.01
Mesityl oxide	18.000

curve C, Fig. 2, from which it is clear that over the range of 0.75 to 2 mol dm^{-3} sulfuric acid, the extraction is quantitative. The extraction is found to be quantitative with equilibration times as low as 10 seconds and an aqueous to organic phase volume ratio of 3.5 : 1 does not affect the extraction.

Sequential Separation of Osmium and Ruthenium. From the studies on the individual extraction of osmium and ruthenium it is found that osmium forms a quantitatively extractable complex at concentrations of thiocyanate as low as 5×10^{-4} mol dm^{-3} from weakly acidic media at room temperature itself. Further, it is found that, under these conditions, increasing the thiocyanate concentration or acidity does not increase the extraction of ruthenium considerably. It has also been observed that ruthenium can form such extractable complex only on heating and the various parameters have been optimized for the quantitative extraction of ruthenium.

Hence the two individual extraction steps are combined and applied to the sequential separation of osmium and ruthenium from their mixtures in the following manner.

After the extraction of osmium, the thiocyanate concentration of the aqueous phase is increased to 0.8 mol dm^{-3} and acidity to 1 mol dm^{-3} in sulfuric acid, dilute to 15 cm^3 and heated in a boiling water bath at 75 °C for 20 min. The solution was then cooled, diluted to about 15 cm^3 and when equilibrated with 5 cm^3 of cyclohexanone gave lower recoveries of ruthenium. This can be attributed to the presence of dissolved mesityl oxide in the aqueous phase. Equilibration of the aqueous phase, after extracting off osmium, with 10 cm^3 of cyclohexanone renders it free of any dissolved mesityl oxide and in this instance the recoveries of ruthenium are found to be quantitative. The results of the extraction and re-extraction studies of binary mixtures of osmium and ruthenium over varying ratios are indicated in Table 3. From the table it is clear that the developed procedure works quite satisfactorily for the separation of osmium and ruthenium over a widely varying ratios and concentrations.

Estimation. Of the various stripping agents studied only sodium hydroxide (0.1 mol dm^{-3}) is found to re-extract osmium quantitatively while none of the reagents examined are effective for the quantitative stripping of ruthenium. Since hydrocarbons are found not to extract ruthenium (*cf.* Table 2), addition of such hydrocarbons to the organic phase is attempted to facilitate the quantitative re-extraction of ruthenium. Both benzene and cyclohexane are found to be effective. However, the latter is chosen, as in this instance, the phase separation is clean and rapid. A minimum ratio of 3 : 1 by volume of cyclohexane to cyclohexanone is found to be essential for the quantitative stripping of ruthenium into 10 cm^3 of water. The osmium and ruthenium contents are established by subjecting the respective strippings to 'Determination' as described earlier.

Further, it is observed that the organic extracts are coloured blue in the case of osmium and bluish violet in the case of ruthenium. Hence the amounts of osmium or ruthenium extracted are also determined by measuring the absorbance of these layers at 590 nm and 560 nm respectively after centrifuging. The Beer's law ranges are 0.4 to 24 ppm for osmium and 1 to 12 ppm for ruthenium. The molar absorptivities for the determination of osmium and ruthenium are 9.5×10^3 and 1.4×10^4 dm^{-3} mol^{-1} cm^{-1} respectively.

Analysis of Synthetic Samples. As no standard sample is available, the method developed is applied to synthetic samples of syserkite (osmiridium) and Nevjanskite (iridioosmium) containing both osmium and ruthenium, after oxidative fusion with potassium hydroxide and potassium nitrate.[7] The samples were prepared by mixing the respective metal solutions in proportions reported elsewhere.[8] To each sample 1 cm^3 of 5% hydrazine sulfate was added and heated gently almost to dryness to which about 1 g of 8 : 1 mixture of potassium hydroxide and potassium nitrate were added and heated at 800 °C for 30 min. The fused melt was leached with 5 cm^3 of 1 mol dm^{-3} hydrochloric acid and diluted to 50 cm^3. Aliquots of the made up solution are subjected to the separation and determination and the results are summarized in Table 4. The results show that the procedure developed can be directly applied to the analysis of osmium and ruthenium in these minerals.

The Two-phase Oxidation of Some Aromatic Compounds with Cerium Ammonium Nitrate in the Presence of Surfactants

Jacek SKRŻEWSKI* and Ewa CICHACZ
Institute of Organic and Physical Chemistry, Technical University of Wroclaw, 50-370 Wroclaw, Poland
(Received December 24, 1982)

The two-phase oxidations of 3,6-dimethoxydurene and xylenes in cyclohexane solutions with the aqueous solution of cerium ammonium nitrate were carried out in the presence of cationic, nonionic, and anionic surfactants. Both cationic (ammonium salt) and nonionic (Dipodand) surfactants inhibited the reaction. The anionic surfactant (sodium dodecyl sulfate, SDS) catalyzed these oxidations. From the product distribution it was concluded that the catalytic action of SDS is due to the binding of aromatic compounds and the Ce(IV) ions to the surface of the SDS micelles. The micellar oxidant has the high oxidation potential which should allow to oxidize the comparatively nonreactive substrates.

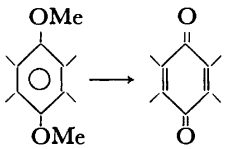
Although there have been many investigations of micellar effects on electron transfer reactions,[1] only very few studies have since appeared which consider a micellar catalysis in the oxidation of organic substrates by metal ions.[2] However, it seems obvious that the aggregates of amphiphilic molecules should help to bring together hydrophobic substrates and hydrophilic, highly charged metal ion oxidants. This is particularly important when the reaction is run under the two-phase conditions, so there is a gap of hydrophobic repulsions between the reagents.

Our interest in the oxidation of aromatic compounds by cerium ions[3] prompted us to examine the influence of the complexing surfactants on the two-phase oxidation reactions. In a previous paper we reported the catalytic effect of a lipophilic complexone **6** bringing the Ce(IV) species into an organic phase.[4] This report describes our study of the title reactions carried out in the presence of typical cationic, anionic, and nonionic surfactants.

Results and Discussion

In the case of the two-phase system with the micelle-forming catalyst the reaction can take place at the interface, or in the bulk aqueous, bulk organic or micellar phases. With the catalyst located in an aqueous layer, one can expect that the lipophilic substrate will be solubilized partially in the micellar phase and in this way will be brought to the oxidant. In an organic phase the reversed micelles can be formed thus takeing the oxidant to the substrate. The micelles can also affect the reactivity of both organic substrate and metal ion, changing their redox potentials by the electrostatic interactions. The high ionic strength of the oxidant solution should favour an increase of density of surface charge of the aqueous micelles as well as the higher solubility of organic substrate in this micellar phase.

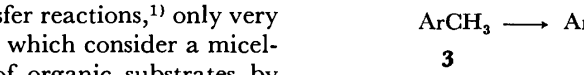
With these general considerations in mind we examined the catalytic activity of surfactants by determining the



(1)

1 **2**

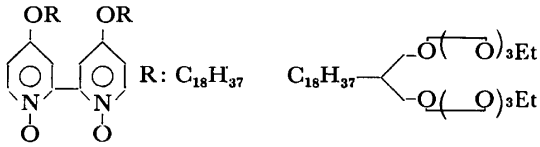
extent of reactions 1 and 2 with and without catalyst.



(2)

3 **4** **5**

Both reactions were carried out in cyclohexane–water system under mild, standard stirring at 20 °C and gave the same products as previously reported.[3-5] The following surfactants were tested: Dipodand **7**,[6] sodium dodecyl sulfate (SDS), and dodecyltriethylammonium nitrate (**8**). These compounds were compared with 4,4′ bis (octadecyloxy)-2,2′-bipyridine 1,1′-dioxide (**6**) which was used earlier.[4] The results are given in Table 1.



6 **7**

8

From Table 1 it can be seen that nonionic Podand **7** and cationic dodecyltriethylammonium nitrate (**8**) hinder the oxidation while lipophilic complexone **6** and SDS accelerate the reaction. The inhibitory effects are analogous to lowering of the rates of oxidation of phenothiazine by Fe^{3+} ions in the presence of both cationic (CTAB) and nonionic (Triton-X-100) surfactants reported by Pelizzetti and Pramauro.[2] They ascribed these effects to the difficulty of approach of the metal ion to the organic substrate in the micelle as well as to an increase of the apparent reduction potential of the substrate. The same effects can be responsible for the decrease of the reaction rate in our case. Additionally, the hampering effect of salt **8** on the oxidation in the presence of **6** (acting in the organic phase only[4]) suggests that some modification of the interface can take place as well. Such modification would prevent the reagents from reaching each other. In the presence of SDS, a remarkable increase of the oxidation rate was observed and this result was also in agreement with that of Pelizzetti and Pramauro.[2] In their case it was due to a concentration effect as well as to decrease of the reduction potential of substrate in the micelles.

Since only SDS showed the accelerating effect, this surfactant was used in all subsequent experiments. Thus,

TABLE 1. EFFECTS OF SURFACTANTS ON THE TWO-PHASE CAN OXIDATION OF 3,6-DIMETHOXYDURENE IN CYCLOHEXANE[a)]

Catalyst (10×No. of mol)	Consumption of CAN(%)	
	After 6 min	After 40 min
None	19.1	57
6(1.30)	41.3	—
7(5.84)	8.0	—
8(10.0)	10.2	42
6 and **8**(1.30, 10.0)	22.2	74
SDS(6.00)	57.0	—

a) A solution of **1** in cyclohexane (0.10 M, 2 ml) was oxidized with aqueous CAN (1.0 M, 1 ml) in the presence of catalyst at 20 °C. The consumptions of CAN based on organic substrate were determined by oxidimetry.

consumption of cerium ammonium nitrate (CAN) in the two-phase oxidation of **1** *vs.* SDS concentration was determined and shown in Fig. 1. This plot demonstrates that the rate enhancement was strongly affected by the concentration of surfactant in its CMC-range. Figure 2 presents the time dependent effects of SDS and SDS with **6** on the oxidation of *p*-xylene. The catalytic effects of SDS were higher than those of **6** and the competitive inhibition was observed when both catalysts were used together. The second effect can be due to the association of weaker oxidant [**6**. Ce(IV)][4] with the micelles.[8]

In order to learn about the new oxidant, we studied the oxidation of *p*-xylene (1 M† solution in cyclohexane) with aqueous CAN solution in the presence of SDS in various concentrations and under standard stirring conditions (magnetic stirrer, ellipsoid-like mixing bar, >300 min^{-1}). As in all experiments, so far described, if the stirring rate dropped below *ca.* 100 min^{-1}, the yields were much lower and hardly reproducible. The resulting mixture was analyzed (Ce^{4+}-by oxidimetry, organic products-by GLPC) and the reaction advancements were determined from the consumption of CAN and from the yields of **4** and **5**, respectively (Fig. 3). The yields of organic products *vs.* concentration of SDS are presented in Fig. 4. The experiments run under nitrogen gave the same results as those under air atmosphere.

From the results given in Fig. 3 it is apparent that the catalytic effect occurs at the concentration of surfactant which is much less (10^{-5} M) than the CMC value for diluted solution of SDS (8.1×10^{-3} M).[1] It seems to be caused by the extremelly high ionic strength of 1 M CAN solution (μ 12 M), thus "salting out" all the hydrophobic species and forming the micelles at very low concentration of surfactant. The discrepancy between CAN consumption and the yield of organic products observed for $c_{SDS}\approx10^{-4}$ M led us to check the possibility of the consecutive oxidation of *p*-tolualdehyde (**5**). This was the case and as can be seen from Table 2, the rate of this reaction increases sharply at higher concentration of SDS. Analysis of the product distribution (Fig. 4) shows that the micellar oxidant increases a contribution of aldehyde in the reaction mixture. The true increase

† 1 M=1 mol dm^{-3}.

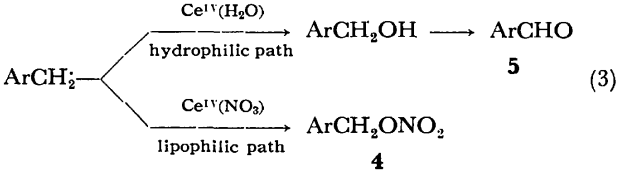
is even higher than this observed from the plot because of the consecutive oxidation of **5**. This result suggests that the catalyzed oxidation takes place in a hydrophilic medium (3).



(3)

It is well known that aromatic compounds are located at the surface of micelles.[9] On the other hand, the recently investigated association of metal ions to SDS

Conditions: as for Fig. 3.

micelles has revealed that the metal ions were bound to the micellar surface. The association constant has been rationalized by considering the chemistry of the specific ion.[10)] The Ce(IV) ions associate more strongly to the sulface than to nitrate ions and the reduced metal ions form the weaker complexes.[11)] The above arguments suggest that the catalytic reaction site is located at the hydrophilic surface of micelles.

In order to gain insight into the properties of the new oxidizing system, we studied, as previously for **6**,[4)] the yields of benzylic nitrates (**4**) and aldehydes (**5**) obtained in the two-phase oxidation of xylenes without diluent in the presence and absence of SDS. The ionization potentials of these substrates differ slightly so the effectiveness of catalyst in each case can test the oxidation potential of the oxidant. The corresponding benzoic acids were formed as by-products and this fact was responsible for the lack of material balance (Table 3). The results in Table 3 indicate that catalyst has almost the same effectiveness for *o*- and *m*-xylene. For *p*-xylene there was the relatively high oxidation yield without SDS, so the addition of catalyst led to the consecutive oxidation of aldehyde. The observed lack of selectivity of the oxidant action implies its high oxidation potential, perhaps related to the potential of Ce(IV) in an equilibrium with the sulfate ions (1.44 V[12)]). All these facts support the evidence that the reaction takes place at the micellar surface.

Summarizing, we conclude that the two-phase oxidation of aromatic compounds with the aqueous CAN solution is inhibited by cationic and nonionic surfactants and catalyzed by the anionic one.

The catalytic action of SDS is due to the binding of aromatic compounds and the Ce(IV) ions to the surface of micelles. The micellar oxidant has the high oxidation potential which should allow to oxidize the comparatively nonreactive substrates. The catalyst is effective at the very low concentration level, so it does not disturb the phase separation process during the work up.

Experimental

Reagents. The following surfactants were prepared and purified as described in the literature: 4,4′-bis(octadecyloxy)-2,2′-bipyridine 1,1′-dioxide,[7)] Dipodand **7**,[6)] and dodecyltriethylammonium nitrate.[13)] Sodium dodecyl sulfate (Merck) was recrystallized twice from ethanol and dried in vacuum desiccator over P_2O_5. Cyclohexane was shaken with aqueous $KMnO_4$, concd. H_2SO_4, water, and $NaHCO_3$ soln, dried over $CaCl_2$ and distilled. 3,6-Dimethoxydurene was prepared and purified according to the literature.[14)] Xylenes (GLPC standard grades) were used as purchased. Cerium ammonium nitrate and other inorganic reagents were of highest available purity. Doubly distilled water was used.

Procedure. All the reactions were carried out in Erlen-

meyer flasks (Quickfit, ₹ 14/23) in sizes 5 and 10-ml with a Teflon-coated ellypsoidal stirring bar (5 mm × 15 mm) or in sizes 25 and 50-ml with the (7 mm × 21 mm) bar.

In a typical experiment, 5 ml of a solution of *p*-xylene (1.00 M) in cyclohexane, an appropriate quantity of SDS, and 10.0 ml of CAN solution (1.00 M) in water were introduced *via* pipette into a 25-ml flask. The flask was sealed with a ground joint stopper, placed in a water bath maintained at the desired temperature (20 or 25 °C), and stirring was started. After appropriate time the phases were separated in a small separatory funnel. Samples of CAN solution were quenched with an excess of a standardized iron(II) sulfate solution and then titrated with 0.1 M CAN. The organic phase was washed with the $FeSO_4$ solution, water, $NaHCO_3$ soln., water, dried over $MgSO_4$ and subjected to the GLPC analysis (GCHF-18.3.6, Gide apparatus, 20% Carbowax on Chromosorb W, 1 m -long column at 120 °C, FID-detector). The identified products were the same as observed earlier.[4]

In the reaction under nitrogen, the water solution was bubbled with a stream of N_2 and then organic substrate solution was injected, the flask was sealed and the reaction started. The work up was the same as described above. Cyclohexane itself was found not to undergo any changes under the conditions used.

The reproducibility of the results obtained was within a few per cent when the same flask and stirring bar were applied.

This work was supported by Grant R. 1.9 from the Polish Ministry of Science, Education and Technology.

8) A Referee has pointed out that the reversed micelles in the organic phase can be responsible for the catalysis. In order to check this possibility we extracted a 1 M CAN solution (5×10^{-3} M in SDS) with an equal volume of cyclohexane. After the saturation a sample of cyclohexane was treated with the same volume of ferroin (1×10^{-5} M) solution in water which, in turn, did not lose its extinction at 510 nm. This experiment demonstrated that under the conditions used no appreciable amount of Ce(IV) was transferred to the organic phase so we belive that the reaction was catalyzed by the aqueous micelles, even if some aggregates of the surfactant were present in cyclohexane. The results of product distribution study support this conclusion (see the text).

The Crystal Structure of 4-Cyanoimino-3-methoxymethyl-perhydro-1,3,5-oxadiazine

Toichi EBISUNO,* Michiaki TAKIMOTO, and Ryuichi SHIBA†

Department of Chemistry, Faculty of Science, Toho University, Miyama 2-2-1, Funabashi, Chiba 274

†*Department of Applied Science, Faculty of Technology, Tokyo Denki University, Kanda, Chiyoda-ku, Tokyo 101*

(Received May 4, 1983)

Synopsis. The structure of 4-cyanoimino-3-methoxymethylperhydro-1,3,5-oxadiazine in the crystalline state was determined by X-ray crystal analysis. The crystal is triclinic, space group $P\bar{1}$, a=10.307(3), b=8.166(2), c=5.082(1) Å, α=97.34(2), β=91.98(2), γ=107.13(2)°, Z=2. The final R value was 0.061 for 1651 reflections.

In the reaction of cyanoguanidine (CG) with formaldehyde, only two hydroxymethylated CG have been isolated;[1] mono- and 1,3-bis(hydroxymethyl)-2-cyanoguanidine (CG-1F and CG-2F). No adducts of 3 mol or more of formaldehyde per mole of CG have been isolated. As reported in the previous paper,[2] the exhaustive hydroxymethylation of 1,3-bis(methoxymethyl)-2-cyanoguanidine (CG-2M), prepared by the methoxylation of CG-2F, was examined and two new products were isolated. They had the structure of a cyclic ether of perhydro-1,3,5-oxadiazine. One was assigned as 4-cyanoimino-3-methoxymethylperhydro-1,3,5-oxadiazine (CG-1Mcyc2F), an adduct of 3 mol of formaldehyde per mole of CG, and the other as 3,5-bis(methoxymethyl)-4-methoxymethyl (carbamoylimino)perhydro-1,3,5-oxadiazine (AU-3Mcyc2F) by the elemental analysis, FD-MS and ^{1}H- and ^{13}C-NMR spectrometry. The latter product was derived from the hydration of the cyano group in the former and further addition of 2 mol of formaldehyde, one by one, to the imino group and to the newly formed amino group. The former product was derived by the dehydration from two newly introduced hydroxymethyl groups in methoxylated CG-1F or by the MeOH elimination between a newly introduced hydroxymethyl group in one imino group and the methoxymethyl group in the other imino group in CG-2M.

In order to confirm the cyclic nature of CG-1Mcyc2F and to elucidate its structural characteristic, the crystal structure of CG-1Mcyc2F has been determined by the X-ray method. Intensity data were collected on a Rigaku automated four-circule diffractometer using Mo $K\alpha$ radiation (λ=0.7107 Å).

Results and Discussion

Crystal Data. $C_6H_{10}N_4O_2$, M.W.=170.17, triclinic, space group $P\bar{1}$, a=10.307(3), b=8.166(2), c=5.082(1) Å, α=97.34(2), β=91.98(2), γ=107.13(2)° U=404.3 Å^3, Z=2, D_C=1.40 g cm^{-3}, μ(Mo $K\alpha$)=1.0 cm^{-1}. The structure of CG-1Mcyc2F was solved by direct methods and refined to a final R value of 0.061 for 1651 unique reflections. All the scattering factors were taken from the International Tables for X-Ray Crystallography.[3] The final atomic parameters are listed in Table 1. The complete table of observed and calculated structure factors is kept as Document No. 8403 at the Office of the Editor of the Bulletin of the Chemical Society of Japan. A perspective drawing of the molecular structure of CG-1Mcyc2F is shown in Fig. 1, which is a view perpendicular to the plane of the guanidine moiety. The structure agrees with that deduced from the spectroscopic data.[2] The underscored numbers in Fig. 1 give the heights of the atoms above or below the plane in Å. The interatomic distances and bond angles are listed in Table 2. Figure 1 shows a plane char-

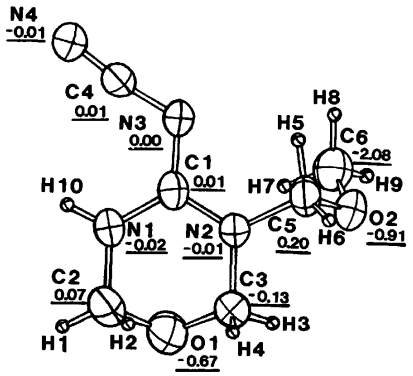

Fig. 1. The structure of CG-1Mcyc2F projected on the plane of the guanidine moiety composed of C_1, N_1, N_2, and N_3. Underscored numbers are heights in Å of the atoms above or below the plane.

acteristic of the structure which is composed of four nitrogen atoms (N_1, N_2, N_3, and N_4) and two carbon atoms (C_1 and C_4). Furthermore, two carbon atoms (C_2 and C_3) and one hydrogen atom (H_{10}) are placed near the plane. This planar structure is due to the triple bond character of the cyano group and to the resonated structure of the guanidine moiety and is similar to the molecular structure of CG.[4] The observed atomic distances for the cyanoimino group (1.308 Å (C_4–N_3) and 1.144 Å (C_4–N_4)) are in fair agreement with the previously predicted values,[5] 1.32 and 1.20 Å, but differ from those for the cyanoimino group in CG,[4] 1.28 and 1.22 Å. This difference in the atomic distances for the cyanoimino group between CG and CG-1Mcyc2F is probably due to the presence and absence of hydrogen bonds in CG and CG-1Mcyc2F, respectively. In CG, the terminal nitrogen of the cyanoimino group was reported to have three hydrogen bonds directed towards three amino groups in two adjacent molecules, while in CG-1Mcyc2F, most of the hydrogen atoms in the amino groups have already been substituted and the residual one hydrogen atom of H_{10} in the imino group is placed near the plane. The intra- and intermolecular distances and the bond angle of N_1–H_{10}– –X in CG-1Mcyc2F clearly indicate that there are no hydrogen bonds.

Determination of the Rate Constant for the Reaction $NH_3+O\rightarrow NH_2+OH$

Nobuyuki FUJII,* Hisaaki SATO, Shiro FUJIMOTO,† and Hajime MIYAMA
Department of Materials Science and Technology, The Technological University of Nagaoka, Kamitomioka, Nagaoka, Niigata 949-54
(Received May 13, 1983)

Synopsis. The rate constant for the reaction $NH_3+O\rightarrow NH_2+OH$ was determined by the comparison of the calculated ammonia consumption rates with those observed in shock tube experiments in the range of 1690—2310 K, for NH_3-N_2O-Ar mixtures. The rate constant can be represented by the expression $k=3.1\times10^{12}\exp(-25.5\ \mathrm{kJ}/RT)\ \mathrm{cm^3\ mol^{-1}\ s^{-1}}$.

The rate constants for the reaction $NH_3+O\rightarrow NH_2+OH$ were measured at low temperatures below 1000 K by several researchers,[1,2] but those at high temperatures have not been measured accurately. The rate constants at higher temperatures in the range of 1690—2310 K were determined using the shock tube technique in this experiment.

Experimental

The shock tube consisted of a 2 m driver section and a 3.6 m experimental section. These were made of 46 mm inside diameter precision-bore stainless steel tubing. The shock velocity was measured by two piezogauges with a time counter. An observation section was placed at a position of 3 m apart from the diaphragm. Here, the change of absorption of NH_3 at 220 nm behind the incident shock wave was monitored by using an optical system consisting of a D_2 lamp, a monochromator, and a photomultiplier. Simultaneously at the same location, the infra-red emission of N_2O at 4.52 μm was measured with an InSb detector through an infra-red filter (half width: 0.18 μm). These signals were displayed on an oscilloscope and photographed. The composition of the gas mixtures, the temperature and the pressure range of incident shock waves are shown in Table 1. The shock parameters were calculated from the incident shock velocities.

Results and Discussion

Typical profiles of NH_3 and N_2O concentration change with reaction time behind the incident shock wave are shown in Fig. 1. In order to compare the profiles with those obtained by computer simulation, elementary reactions shown in Table 2 were selected as the important ones in this reaction system. Among the rate constants of these reactions shown in Table 2. Those of Reactions 1, 3, 7, and 8 were well established. From the preliminary calculation, the dissociation reaction of NH_3 was eliminated from the scheme, because the rate constant of this reaction[3] was smaller than that of Reaction 1 by about 200 times at 2000 K, and the rate of NH_3 consumption was hardly affected by the former reaction.

In order to examine the contribution of other elementary reaction to the rate of NH_3 consumption, the sensitivity checks described previously[4] were applied as follows. The calculated reaction time required for 10% consumption of NH_3, τ in Fig. 1, was found to be very sensitive to the change in the rate constants of Reactions 1—4, but not sensitive to those of other elementary reactions. However, when the N_2O concentration was not smaller than that of NH_3 and the temperature was higher than 2000 K, the calculated reaction time τ was not sensitive to the rate constant of Reaction 4. The conditions were satisfied only by mixture II.

Therefore, only Reactions 1—3 were used in the simulation for mixture II and the rate constant of Reaction 2 was determined accurately by choosing the value to fit best the calculate τ value of NH_3 consumption to the experimental one. In this calculation, the heat of reaction and the correction for the nonideality of shocked flow caused by the boundary layer behind the incident shock front[5] were taken into account. The rate constants of Reaction 2 obtained are shown in Fig.

8) $N_2O + O \longrightarrow N_2 + O_2$	14.00	0	117.2	1

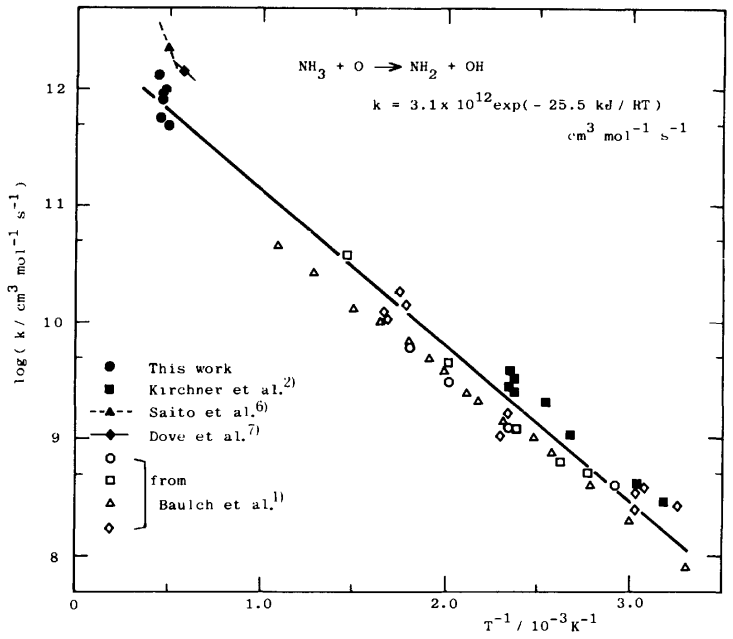

Fig. 2. Arrhenius plots of the rate constants for Reaction 2.

2. The values obtained recently by Satio and Bradley[6] and those obtained as the upper limit by Dove and Nip[7] are shown together in Fig. 2. Comparing the values obtained in the present work, both reported values are larger than the extrapolated value from those obtained in the lower temperature region.

A combination of our values with the mean values at low temperatures reported by Kirchner *et al.*[2] and by other researchers[1] yields the following Arrhenius expression for Reaction 2.

$$k_2 = 3.1 \times 10^{12} \exp(-25.5\ \text{kJ}/RT)\ \text{cm}^3\ \text{mol}^{-1}\ \text{s}^{-1}.$$

The NH_3 and N_2O consumption profiles calculated by using Reactions 1—3 are shown by the dotted lines in Fig. 1. The agreement between the calculated and experimental values at the initial stage of the reaction is good. In the figure, the deviations of the calculated curves from the experimental values after the reaction time τ were improved by adding subsequent Reactions 4—8 to the reaction scheme, as shown by the solid lines. The rate constants obtained for mixtures I and III, which did not satisfy the conditions, were also within the scattering of the above-obtained values.[8]

Adsorption of Oligomer Type Surfactants on Iron Oxide

Kunio ESUMI,* Kimihiko OGIHARA, and Kenjiro MEGURO
Department of Applied Chemistry and Institute of Colloid and Interface Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received June 14, 1983)

Synopsis. Adsorption of oligomer type surfactants synthesized from acrylic acid, acrylonitrile, and 1-dodecanethiol on α-Fe_2O_3 was examined by measuring adsorption isotherms and zeta potentials. It was found that the adsorption behavior of oligomer type surfactants on α-Fe_2O_3 was influenced by the pH of suspensions and further by the differences of composition of oligomer type surfactants.

Recently, from the standpoints of environment pollution and of conservation of resources, water-base paints[1] have been preferred instead of organic-base ones. The preparation of stable pigment dispersions requires the addition of dispersants. Many kind of surfactants[2-5] have been utilized for this purpose. Of these surfactants, oligomer type surfactants[6-10] have been developed and employed for dispersion of pigments due to suitable properties, such as improvement of film formation and resistance for water vapor.

In this work, to understand the interactions of oligomer type surfactant and pigment surface in aqueous solution, the adsorption of oligomer type surfactants synthesized from acrylic acid, acrylonitrile, and 1-dodecanethiol on α-Fe_2O_3 is examined by measuring adsorption isotherms and zeta potentials.

Experimental

Materials. The oligomer type surfactant used in this study was synthesized[10] by co-oligomerization of acrylic acid, acrylonitrile, and 1-dodecanethiol, followed by neutralization with potassium hydroxide. The chemical structure and analytical properties of the oligomers are given in Table 1. All the chemicals were of reagent grade. The water used was purified by passing through Milli-Q Reagent Grade Water Systems until its specific conductivity fell below 10^{-7} Ω^{-1} cm^{-1}.

As a pigment, α-Fe_2O_3 was supplied by Titan Chemicals; it was washed with water sufficiently to remove impurities and then dried. The specific surface area of this pigment was determined to be 6.35 m^2/g by nitrogen adsorption at its liquid temperature.

Measurements. A 20 ml portion of oligomer aqueous solution was placed in an L-shaped test tube and α-Fe_2O_3 (0.3 g) was added in; then the test tube was shaken at 25 °C. After at least 2 h, having reached adsorption equilibrium, the sample was separated by using a Milli-pore filter. The concentration of supernatant solution was determined with UV spectrophotometer by measuring the absorbancy at 215 nm.

The zeta potential of α-Fe_2O_3 after the adsorption was measured using a Pen Kem Laser 500.

The surface tensions of oligomer type surfactant aqueous solutions were determined by a modified Wilhelmy type surface tension meter (Shimadzu ST-1) at 25 °C.

Results and Discussion

Before a study of adsorption of oligomer type surfactant on pigments, it is important to characterize the surface properties of the oligomer type surfactant aqueous solution. The surface tension of oligomer type surfactant(I) as a function of the concentration in the absence and in the presence of HCl was measured.[10] In the absence of HCl, the surface tension curve of oligomer type surfactant(I) was similar to that of an ordinary surfactant like sodium dodecyl sulfate, while the surface tension value over a relative low concentration became lower in the presence of HCl, indicating that some $-COO^-K^+$ groups in oligomer(I) molecule are converted to -COOH groups by addition of HCl, resulting in enhancement of surface activity due to decrease of repulsion forces between $-COO^-K^+$ groups and of the hydrophilicity of oligomer(I) molecule. Thus, oligomer type surfactant exhibits an appreciable surface activity.

Figure 1 gives the adsorption isotherms of oligomer(I) on α-Fe_2O_3 in the absence and in the presence of HCl. All three isotherms were Langmuir type; furthermore, the amount adsorbed of oligomer(I) on α-Fe_2O_3 increased with an increase of the concentration of HCl added. Also, to elucidate the interaction of oligomer(I) and the surface of α-Fe_2O_3, the zeta potential of α-Fe_2O_3 corresponding the adsorp-

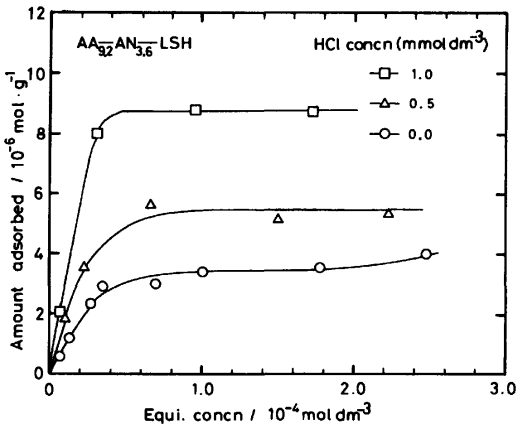

Fig. 1. Adsorption isotherms of oligomer type surfactant(I) on α-Fe_2O_3 in the absence and in the presence of HCl at 25 °C.

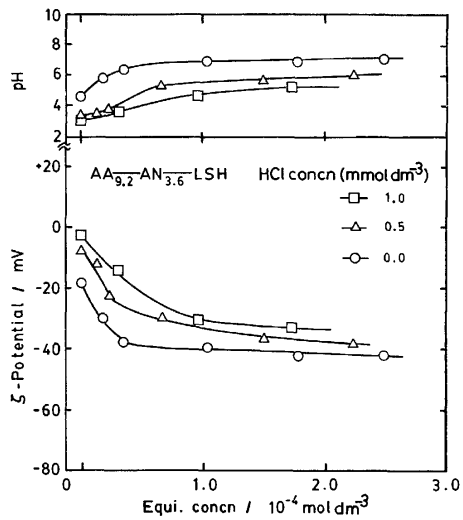

Fig. 2. Zeta potentials of α-Fe_2O_3 and pH values of suspension shown in Fig. 1.

tion isotherm was measured; the result is shown in Fig. 2. It can be seen that the zeta potential value decreases as a function of the equilibrium concentration of oligomer(I) in the absence and in the presence of HCl. The magnitude of zeta potential in the presence of higher concentrations of HCl was less negative than that in lower concentration of HCl. The above results can be interpreted as follows: since the pH of oligomer(I) aqueous solution without adding HCl is about 6, some $-COO^-K^+$ groups in oligomer(I) molecule are likely to dissociate easily. When such an oligomer is adsorbed on the surface of α-Fe_2O_3, an appreciable negative charge at the surface is provided in spite of the fact that less oligomer(I) is adsorbed; this may be due to repulsion of dissociable $-COO^-K^+$ groups in the molecule. On the other hand, with an increase of the concentration of HCl added, some $-COO^-K^+$ groups in oligomer(I) molecule are changed to undissociated -COOH groups, resulting in a decrease of negative charge density of the oligomer molecule. Accordingly, though the amount adsorbed with adding HCl is relatively large, the magnitude of zeta potential of α-Fe_2O_3 in the presence of HCl is less negative than that without HCl. Thus, the change in charge density of oligomer(I) molecule in the presence of various concentrations of HCl exhibits a different adsorption behavior. So, it seems interesting to study the adsorption behavior by different chemical structures of the oligomer.

Figure 3 demonstrates the adsorption isotherms of oligomer(II) containing no acrylonitrile groups on α-Fe_2O_3. This oligomer(II) has less surface active than oligomer(I). These isotherms are different from those of oligomer(I); the amount adsorbed of oligomer(II) in the presence of HCl increases with an increase of the concentration of oligomer(II), reaches a maximum, and then decreases. The isotherm is changed much remarkably in the presence of higher concentrations of HCl than in lower concentrations of HCl. This phenomenon might be explained by changes in the solubility of oligomer(II) with adding HCl and in the interaction between oligomer(II)

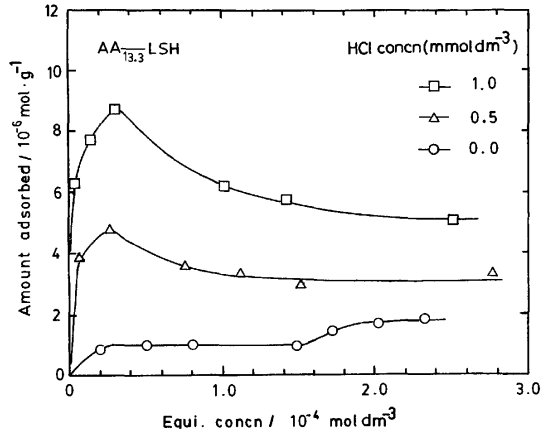

Fig. 3. Adsorption isotherms of oligomer type surfactant(II) on α-Fe_2O_3 in the absence and in the presence of HCl at 25 °C.

molecules and surface of α-Fe_2O_3. That is, some $-COO^-K^+$ groups in oligomer(II) molecule at lower concentration are converted by addition of HCl to -COOH groups, which reaction decreases the solubility of oligomer(II), resulting in an increase of amount adsorbed. Further, with an increase of the concentration of oligomer(II) in the presence of HCl, the conversion ratio from $-COO^-K^+$ to -COOH declines. As a result, the increment of solubility of oligomer(II) reduces the amount adsorbed. Also, as it is expected that repulsion forces between oligomer(II) molecule and surface of α-Fe_2O_3 charged negatively increase with an increase of the suspension's pH, so the amount adsorbed would decrease. Further, the zeta potential of α-Fe_2O_3 by the adsorption of oligomer(II) in the absence and in the presence of HCl was measured. These changes in zeta potential corresponded to those of the adsorption isotherms as shown in Fig. 3. The adsorption of oligomer(II) provided more negative charge on the surface of α-Fe_2O_3 than that of oligomer(I).

The occupied area per molecule at 2×10^{-4} mol dm^{-3} of the equilibrium concentration for two oligomers was calculated as a function of pH of the suspension. For both oligomers, the calculated area increases with an increase of pH of the suspension. The calculated area for oligomer(II) is larger than that for oligomer(I) in the region of above pH=6.

The Tricritical Point in the n-$C_8H_{17}SO_3Na$/n-C_4H_9OH/H_2O/n-$C_{14}H_{30}$ System

Hironobu KUNIEDA* and Tsutomu ARAI†

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Tokiwadai 156, Hodogaya-ku, Yokohama 240

(Received June 18, 1983)

Synopsis. The phase behavior of three coexisting liquid phases has been studied in the four-component system of n-$C_8H_{17}SO_3Na$/n-C_4H_9OH/H_2O/n-$C_{14}H_{30}$. With a rise in the temperature, the three-phase region shrinks to a tricritical point at which the three liquid phases become identical.

Since ultralow interfacial tensions are attained and a solubilizing power of a surfactant reaches its maximum around a three-phase region (water(W), surfactant(D), and oil(O) phases)[1,2] due to critical phenomena, it is very important to investigate the solution behavior of a surfactant around this region. In a three-liquid-phase system, two liquid phases (O-D or D-W phases) become identical in the presence of a third phase (W or O phase) at a critical end point which is located on the boundary between the two- and three-phase regions.[2] If the two critical end points of the O-D and D-W phases coincide with each other, the three coexisting phases become identical at a high-order critical point, the tricritical point.[3,4] This kind of critical phenomenon has been observed in some systems,[5] but not in a surfactant system.

We previously found a tricritical phenomenon in a bile-salt system.[4] In this paper, in order to find a tricritical point in an ordinary surfactant system, the phase behavior of the n-$C_8H_{17}SO_3Na$/n-C_4H_9OH/H_2O/n-$C_{14}H_{30}$ system has been investigated.

Experimental

Materials. Extra-pure-grade n-$C_8H_{17}SO_3Na$ and n-$C_{14}H_{30}$ were obtained from the Tokyo Kasei Kogyo Co., while extra-pure-grade n-C_4H_9OH was obtained from the Wako Chemicals Co. The procedures for the determination of the phase beoundaries have been described elsewhere.[4]

Results and Discussion

In the n-C_4H_9OH/H_2O/n-$C_{14}H_{30}$ system,[6] a three-phase region appears at a lower temperature in the absence of a surfactant, as is shown in Fig. 1 (●). In this case, a critical end point is an invariant point at a constant pressure (an atmospheric pressure).[2,7] By adding n-$C_8H_{17}SO_3Na$ to this three-component system, the maximum temperature of the three-phase region moves up to a higher temperature, as is also shown in Fig. 1 (○). This maximum temperature of a three-phase region is determined for a variety of over-all compositions; the maximum over all compositions of these maxima may be identified as the tricriti-

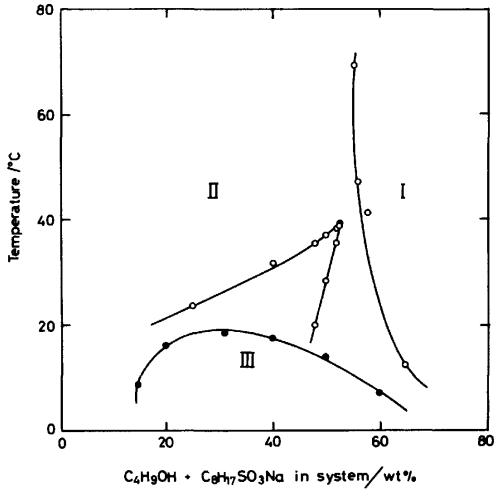

Fig. 1. Phase diagrams of equi-weight mixtures of H_2O–$C_{14}H_{30}$ containing C_4H_9OH (●) and 95 wt% C_4H_9OH+5 wt% $C_8H_{17}SO_3Na$ (○) as a function of temperature. I, II, and III denote one-, two-, and three-phase regions respectively.

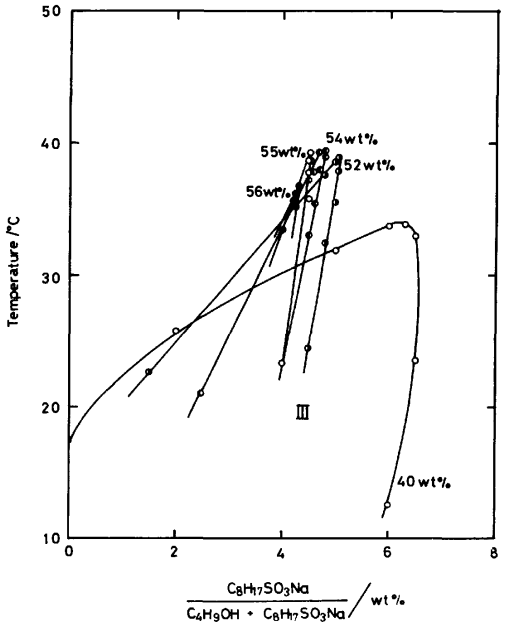

Fig. 2. The effect of concentration of $C_8H_{17}SO_3Na$ in $C_8H_{17}SO_3Na$+C_4H_9OH on the three-phase region of equi-weight mixture of H_2O–$C_{14}H_{30}$ containing $C_8H_{17}SO_3Na$+C_4H_9OH. Numerical number in the Figure indicates the concentration of $C_8H_{17}SO_3Na$+C_4H_9OH in system.

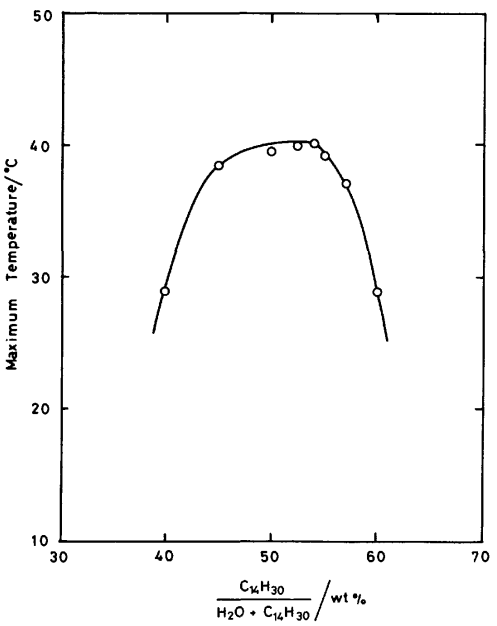

Fig. 3. The effect of $H_2O/C_{14}H_{30}$ ratio on the maximum temperature of the three-phase region.

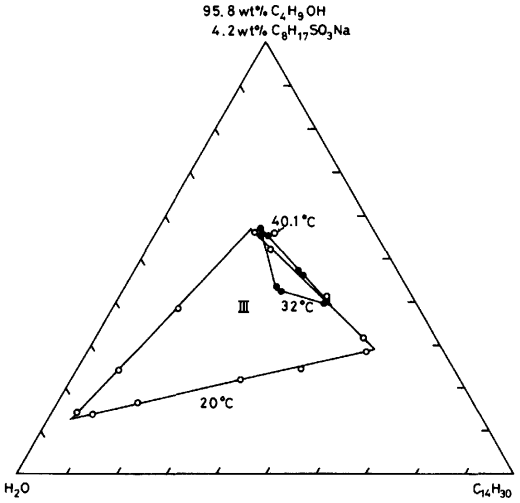

Fig. 4. The three-phase region of pseudo ternary system of (95.8 wt% $C_4H_9OH+C_8H_{17}SO_3Na)/H_2O/C_{14}H_{30}$. The three-phase region shrink to a tricritical point with the rise in temperature.

cal point.[3] This is because, in a four-component system, a line of critical end points exists in a certain space of temperature and compositions at a constant pressure, and the two critical end points of O-D and D-W exist at the respective temperatures as long as a three-phase region appears.[4] Since a three-phase region is a point in a composition tetrahedron at the maximum temperature, the two critical end points may coincide at this point, *i.e.*, the tricritical point. In Fig. 2, the three-phase region is determined as a function of n-$C_8H_{17}SO_3Na/(n$-$C_8H_{17}SO_3Na+n$-$C_4H_9OH)$ and the weight fraction of oil/water is unity. In this case, the maximum temperature of the three-phase region appears at the 54 wt%/system of (n-$C_8H_{17}SO_3Na+n$-C_4H_9OH). Similar maximum temperatures are determined for a variety of water/oil ratios and are plotted in Fig. 3. The maximum temperature of these maxima is 40.1 °C (n-$C_8H_{17}SO_3Na+n$-C_4H_9OH, 56 wt%/system. n-$C_{14}H_{30}/H_2O$, 0.54/0.46 (W/W). n-$C_8H_{17}SO_3Na/n$-C_4H_9OH, 0.042/0.958 (W/W)).

Therefore, at this temperature, the three-phase region is a point in this four-component system and is identified as the tricritical point. In fact, the critical opalescence is observed in all phases in the vicinity of this point. The three-phase region in the pseudo-three-component system of 95.8 wt% n-C_4H_9OH+4.2 wt% n-$C_8H_{17}SO_3Na)/H_2O/n$-$C_{14}H_{30}$ is shown at 20, 32, and 40.1 °C in Fig. 4. The three-phase region shrinks to a point on approaching 40.1 °C.

The authors wish to thank Prof. Kōzō Shinoda for his helpful discussion.

The Thermal Properties of (4-Substituted Cyclohexyl) 4-Substituted Cinnamates

Shigetsugu HAYASHI, Shunsuke TAKENAKA,* and Shigekazu KUSABAYASHI
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565
(Received July 13, 1983)

Synopsis. The thermal properties for a homologous series of 4-alkylcyclohexyl 4-alkoxy- and 4-cyanocinnamates are examined. They exhibit nematic phases with low melting points. The effect of the cyclohexyl group on the mesophase stability is discussed.

(4-Substituted phenyl) 4-substituted benzoates have been known to be good nematogens for devices employing a twisted nematic mode, as one of the substituents is a polar group, such as cyano, and the guest-host and dynamic scattering modes, as both substituents are the nonpolar groups, such as an alkyl and/or alkoxyl.[1] For practical purposes, (4-substituted cyclohexyl) 4-substituted benzoates are also good nematogens, because the cyclohexyl group tends to lower the melting point and increases the clearing point. In this paper, we will demonstrate the preparation and thermal properties of (4-substituted cyclohexyl) 4-substituted cinnamates; the effect of the cyclohexyl group on the thermal properties is also discussed.

Preparation

The 4-alkylcyclohexanols were obtained by the hydrogenation of the corresponding 4-alkylphenols in the presence of Ranney nickel under 150×10^5 Pa at 150 °C. The cis and trans mixtures of the cyclohexanols were reacted with benzoyl chloride, giving 4-alkylcyclohexyl benzoates. The esters were purified by column chromatography over silica gel, using a mixed solvent of hexane–ether (98:2—95:5). After repeating the chromatographic purification, the esters were hydrolyzed with methanol– 2 mol dm^{-3} potassium hydroxide (1:1), thus giving *trans*-4-alkylcyclohexanols. The purity was checked by means of the NMR spectrum. The NMR spectrum for *trans*-4-heptylcyclohexyl benzoate shows a multiplet at 4.7—5.1 ppm arising from the methine proton at the 1 position, and the cis form a broad singlet at 5.3 ppm (Δ) in $CDCl_3$. The yields of the materials with a purity of more than 99% were less than 20%. 4-Alkyl-, 4-alkoxy-, and 4-cyanocinnamoyl chlorides were reacted with *trans*-4-alkylcyclohexanols according to the usual method. The esters prepared here were purified by column chromatography over silicagel, using a mixed solvent of hexane–ether (98:2), followed by recrystallization from absolute ethanol. The data of elemental analysis are shown in Table 1.

Results and Discussion

The melting points and mesomorphic transition temperatures for the cinnamate esters are given in Table 2. Compounds **1**—**11** have melting points that lie between 53 and 99 °C, while compounds **12** and **13** have somewhat lower melting points. The nematic-isotropic transition temperatures for the homologous series of 4-heptylcyclohexyl cinnamates show a typical even-odd effect. Compounds **12** and **13** have low melting points and enthalpies, being good nematogens.

a) Parentheses indicate monotropic transition temperatures.

The transition temperatures were measured using a Nikon polarized microscope POH equipped with a Mettler FP 52 heating stage and a control unit. The transition enthalpies were measured by means of a Daini Seikosha SSC 560 differential scanning calorimeter, using indium (99.9%) as the calibration standard at a heating rate of 5 °C/min.

As the alkoxyl group is replaced by a cyano group, both melting and clearing points increase, showing monotropic nematic properties. These results may be compared with those of the corresponding phenyl cinnamates. It has been known that a cyclohexyl group is less favorable for the thermal stability of the mesophase than a phenyl, because the former is more flexible than the latter. For example, 4-alkylbenzoic acids have higher melting and clearing points than 4-alkylcyclohexanecarboxylic acids.

For compounds **1**—**13** having nonpolar substituents, the melting points are lower by 10—30 °C than those for the corresponding phenyl cinnamate esters.[3,4] On the other hand, the clearing points for the present series are also lower by 5—40 °C than those for the corresponding phenyl cinnamate esters. The difference tends to become larger with increase in the carbon number in the alkyl and alkoxyl chains. These trends are probably connected with the flexibility of the cyclohexyl group.

As the terminal group is replaced by a cyano group, the circumstances differ significantly. Usually, as the phenyl group with the alkyl chain in 4-cyano-4′-alkylbiphenyls and 4-cyanophenyl 4-alkylbenzoates is replaced by a cyclohexyl group, the clearing points increase by *ca.* 20 °C, whereas the melting points are almost unchanged. These trends have been interpreted in terms of the structural difference in the antiparallel dimer of the molecules in the mesophase.[5] Indeed, X-ray measurements indicate that the "overlapping core" formed by the 4-cyanobiphenyls and 4-cyanophenyl benzoates differs significantly from the "partially overlapping" one formed by the corresponding cyclohexyl compounds.[6] For the present series (**14**—**16**), by contrast, the melting points are higher by 30—40 °C, and the clearing points are lower by 10—20 °C than those for the corresponding 4-alkylphenyl 4-cyanocinnamates.[7,8] These facts indicate that the enhancement of the nematic stability upon the replacement of the phenyl group with the cyclohexyl one does not occur in this system. A possible explanation is that the "overlapping core" for the phenyl 4-cyanocinnamates differs from those for the 4-cyanobiphenyls and 4-cyanophenyl benzoates and is rather similar to those for the cyclohexyl compounds, while the flexibility of the cyclohexyl group decrease the stability of the nematic phase, as has been mentioned above.

In conclusion, the replacement of the phenyl ring by the cyclohexyl in the phenyl cinnamate core leads to a decrease in the thermal stability of the nematic phase, presumably because of an increase in the flexibility of the core, even though both terminal substituents are nonpolar alkyl and/or alkoxyl groups or a polar cyano.

The Volume Profile for the Aquation Reactions of *trans*-[CoBr(NO$_2$)(en)$_2$]$^+$ and *trans*-[CoCl(N$_3$)(en)$_2$]$^+$ †

Yoichi KITAMURA,* Shinji NARIYUKI, and Toshiaki KONDO††
Department of Chemistry, Faculty of Science, Ehime University, Matsuyama, Ehime 790
(Received January 27, 1983)

Synopsis. For the aquation of *trans*-[CoBr(NO$_2$)(en)$_2$]$^+$, the activation volume at atmospheric pressure ($\Delta V^{\neq}$) is 0.3±0.2 cm^3 mol^{-1} at 10 °C, and the reaction volume (ΔV) is −10.4±0.1 cm^3 mol^{-1} at 7.4 °C, both in pure water. For *trans*-[CoCl(N$_3$)(en)$_2$]$^+$, $\Delta V^{\neq}$ is 0.7±0.6 cm^3 mol^{-1} at 30 °C in 0.011 M HClO$_4$ (1 M=1 mol dm^{-3}) and ΔV is −11.0±0.6 and −11.4±0.3 cm^3 mol^{-1} at 25 °C in 0.008 M HClO$_4$, thus yielding the trans and the cis aqua products respectively.

In a recent report, one (Y. K.) of the present authors has examined the magnitudes of $\Delta V^{\neq}$ and ΔV of 14 aquation reactions of the Co^{III} complex ion, where the leaving ligand is a monovalent anion.[1] It has been indicated that the ΔV's for 10 such reactions lie in the relatively limited range from −7 to −13 cm^3 mol^{-1} and are typically −10 cm^3 mol^{-1}. A general feature that has also been pointed out is that the $\Delta V^{\neq}$ is large (*ca.* 14 cm^3 mol^{-1}) when the initial complex contains the strongly electron-donating NH_2^- nonlabile ligand; moderate when the initial complex contains a moderately electron-donating Cl^- or N_3^-, or moderately electron-withdrawing NO_2^-, nonlabile ligand, and small (*ca.* −9 cm^3 mol^{-1}) and close to the corresponding ΔV when the initial complex does not contain any nonlabile ligand with electron-donating or -withdrawing power.

In the present work, $\Delta V^{\neq}$ and ΔV are obtained for two additional reactions, where the initial complex contains a nonlabile NO_2^- or N_3^- ligand:

trans-[CoBr(NO$_2$)(en)$_2$]$^+$ + H$_2$O ⟶
trans-[Co(NO$_2$)(en)$_2$H$_2$O]$^{2+}$ + Br$^-$, (1)[2]

trans-[CoCl(N$_3$)(en)$_2$]$^+$ + H$_2$O ⟶
80% *trans*-, 20% *cis*-[Co(N$_3$)(en)$_2$H$_2$O]$^{2+}$ + Cl$^-$. (2)[3]

It is tested whether or not the volume profiles of Reactions 1 and 2 are pertinent to the general tendency and whether or not the previous interpretation of the $\Delta V^{\neq}$ is also applicable in these cases. In Reaction 2 the trans configuration of the reactant is not retained. On the basis of this, the geometry of the transition state in Reaction 2 should differ from those in analogous reactions, where the geometries are retained.[4] We are further interested in whether or not this feature of Reaction 2 is remarkable in its $\Delta V^{\neq}$. The isomerization velocity of *trans*-[Co(NO$_2$)(en)$_2$H$_2$O]$^{2+}$ to the cis-isomer is sufficiently slow, and the kinetic course of Reaction 1 is not interrupted by this isomerization.[5] The *trans*- and *cis*- [Co(N$_3$)(en)$_2$H$_2$O]$^{2+}$ have an isosbestic point at 533 nm, where the velocity of Reaction 2 can be followed spectrophotometrically.[3]

Experimental

Materials. The *trans*-[CoBr(NO$_2$)(en)$_2$]ClO$_4$ (**1**)[2] and *trans*-[CoCl(N$_3$)(en)$_2$]ClO$_4$ (**2**)[6] were obtained by the published methods and identified by means of elemental analysis (C, H, N).

Kinetic Measurements and Dilatometry. The procedures were the same as in the previous report except that a Heise high-pressure gauge was used.[1]

Results and Discussion

Kinetic Results. The rate constants at each pressure are shown in Table 1. The k-values at each pressure are fitted to $\ln(k/k_o)/P=a+bP$ by the least-squares method, where k_o is the average rate constant at atmospheric pressure. $\Delta V^{\neq}$ is obtained by the use of $\Delta V^{\neq}=-RT(\mathrm{d}\ln k/\mathrm{d}P)=-RTa$. The rate constants are rather independent of the pressure, and the resultant $\Delta V^{\neq}$'s are close to zero (Table 2). Reaction 1 was followed in pure water and in an 0.01 M HClO$_4$ aqueous solution. The rate constants at each pressure are essentially the same in both.

6[f]	*trans*$[CoCl_2(en)_2]^+$	65% trans, 35% cis	−1.7±1.1 (25, H_2O)	−13.9 (25, H_2O)

a) Configuration of the aqua product. b) This work. c) For the trans aqua product. d) For the cis aqua product. e) Ref. 1. f) Ref. 7. g) Ionic strength = 0.1 M ($NaClO_4$).

Dilatometric Results. Reaction 1 was followed at 7.4 °C in a 4.0 mM aqueous solution of **1** from a 52 to a 99% completion. ΔV was obtained from the intercept at t=0 of the $\ln(h_t-h_\infty)$ *vs.* t plot, where h_t is the meniscus height at the reaction time (t). The h_∞ value is calculated from h_t's, and k=40.7×10^{-5} s^{-1} is obtained from this plot. The volume change in a 4.0 mM solution of **2** in 0.008 M $HClO_4$ was followed at 25 °C from a 40 to a 90% completion. The total volume (V) of the solution is related to the partial molal volume ($\overline{V}_i$) and the mole number (n_i) of each component (i) in the solution as: $V=\sum n_i\overline{V}_i$. At several stages of Reaction 2, n_i's were calculated according to the following scheme, where the initial product of the aquation consists of 80% trans and 20% cis aqua complex:[3]

$$\begin{array}{l} \textit{trans}\text{-}[CoCl(N_3)(en)_2]^+ + H_2O \xrightarrow{k} \\ \qquad\qquad \textit{trans}\text{-}[Co(N_3)(en)_2H_2O]^{2+} + Cl^- \\ \qquad\qquad\qquad k_1 \downarrow \uparrow k_{-1} \\ \qquad\qquad \textit{cis}\text{-}[Co(N_3)(en)_2H_2O]^{2+} + Cl^-. \end{array}$$

We used the literature rate constants at 25 °C in an 0.01 M $HClO_4$ aqueous solution (k=22.0×10^{-5} s^{-1}, k_1=7.2×10^{-5} s^{-1}, k_{-1}=2.6×10^{-5} s^{-1}).[3] The ΔV's of Reaction 2 were obtained for the trans aqua and the cis aqua products respectively by solving a set of simultaneous equations for several reaction stages. Two independent runs were performed. ΔV is −10.7± 0.5 and −11.3±0.6 cm^3 mol^{-1} for the trans product, and −11.4±0.3 and −11.3±0.3 cm^3 mol^{-1} for the cis product. These results indicate that the difference between the $\overline{V}_i$'s of *trans*-$[Co(N_3)(en)_2H_2O]^{2+}$ and of *cis*-$[Co(N_3)(en)_2H_2O]^{2+}$ is small enough. Assuming this difference as zero, k=21.2×10^{-5} and 21.9×10^{-5} s^{-1} are obtained from the Guggenheim plots of the dilatometric data, which agree well with that in the literature.[3] The results are summarized in Table 2, along with four volume profiles of analogous reactions.

Discussion. It can be noticed that, in Reactions 1 and 2, the ΔV^*'s are close to zero and the ΔV's are close to −10 cm^3 mol^{-1}. Thus, the volume profiles of Reactions 1 and 2 are quite pertinent to the general tendency indicated in the previous report.[1] Therefore, these volume profiles can be interpreted along the previous line of arguments. The transition state is composed of an ion pair between the leaving ligand and the five-coordinate intermediate, $[Co(NO_2)(en)_2\cdots OH_2]^{2+}$ or $[Co(N_3)(en)_2\cdots OH_2]^{2+}$, where the entering water molecule is halfway between the vacant coordination site and the first solvation sphere. The volume profiles of Reactions 1—6 are quite similar to each other. The magnitudes of ΔV^* are not affected by the geometrical difference in the transition state between those for Reactions 2 and 6 and those for Reactions 1, 3, 4, and 5. This is further in accordance with the fact that the ΔV's of Reaction 2 are quite similar in both cases where cis and trans aqua products are formed. It seems that neither ΔV^* nor ΔV is sensitive to the stereochemical course of the reaction.

Cobalt(III) Complexes with Quadridentate Ligands. V.[1] The Preparation and Properties of Paramagnetic and Diamagnetic *cis*-β_2-Isomer of the 5-Nitrosalicylato(quadridentate amine)cobalt(III) Complexes

Yoshihisa YAMAMOTO* and Hiroko KUDO
Faculty of Pharmaceutical Sciences, Higashi Nippon Gakuen University, Ishikari-Tobetsu, Hokkaido 061-02
(Received April 15, 1983)

Synopsis. Several green paramagnetic 5-nitrosalicylato(quadridentate amine)cobalt(III) chloride nitrate hydrates, $[Co(5\text{-}NO_2sal)L]Cl\cdot NO_3\cdot nH_2O$ (L: 2,3,2-tet, 3,2,3-tet, and 3,3,3-tet) and the corresponding orange diamagnetic nitrate hydrates, $[Co(5\text{-}NO_2sal)L]NO_3\cdot nH_2O$, have been isolated and characterized by analytical, spectroscopic, and magnetic methods.

The preparation and properties of paramagnetic metal complexes with the quadridentate amine ligands such as 2,3,2-tet, 3,2,3-tet, and 3,3,3-tet, as is shown in Fig. 1, have not previously been described, except for iron(III) complexes[2] with sexadentate ligands derived from salicylaldehyde and 3,2,3-tet or 3,3,3-tet. The present paper deals with the preparation and properties of the green paramagnetic 5-nitrosalicylato(quadridentate amine)cobalt(III) complexes, $[Co(5\text{-}NO_2sal)L]^{n+}$ (L: 2,3,2-tet, 3,2,3-tet, and 3,3,3-tet; n=2) and of the corresponding orange diamagnetic cobalt(III) complexes (n=1).

Results and Discussion

The green paramagnetic *cis*-β_2-5-nitrosalicylato-(quadridentate amine)cobalt(III) chloride nitrate hydrates, $[Co(5\text{-}NO_2sal)L]Cl\cdot NO_3\cdot nH_2O$ (L: 2,3,2-tet (**1a**), 3,2,3-tet (**1b**), 3,3,3-tet (**1c**)), have been isolated from a reaction mixture of the diamagnetic *cis*-β_2-salicylato(quadridentate amine)cobalt(III) chloride hydrates,[3] $[Co(sal)L]Cl\cdot nH_2O$ (L: 2,3,2-tet (**2a**), 3,2,3-tet (**2b**), 3,3,3-tet (**2c**)), 60% HNO_3 and acetone. From the orange acetone filtrate, the orange diamagnetic *cis*-β_2-5-nitrosalicylato(quadridentate amine)-cobalt(III) nitrate hydrates, $[Co(5\text{-}NO_2sal)L]NO_3\cdot nH_2O$ (L: 2,3,2-tet (**3a**), 3,2,3-tet (**3b**), 3,3,3-tet (**3c**)) have been isolated. Their colors in the solid state are green (**1a—c**), organge (**3a** and **3b**), and pink-russet (**3c**). The effective magnetic moments of **1a—c** are 1.7—1.8 BM,† suggesting one unpaired electron. Complexes **3a—c** are diamagnetic. In the ^1H NMR spectra, the signals of the methylene protons, amine protons, and salicylato protons of **1a—c** and **3a—c** have been assigned by the comparison with those[3] of **2a—c**. Their form is *cis*-β_2-form from their ^1H NMR spectra, because both signals of the NH_2-side methylene protons (*cf.* Table 1) and the NH-side methylene protons (*cf.* Table 1) of the coordinated quadridentate ligands of **1a—c** and **3a—c** are distinguishable.[3,7]

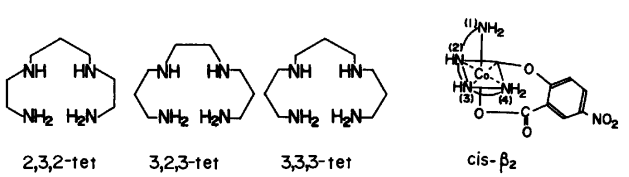

Fig. 1. The quadridentate amine ligands of 2,3,2-tet, 3,2,3-tet, and 3,3,3-tet, and the *cis*-β_2-form of complexes.

The properties of IR, ^1H-, ^{13}C NMR spectra, and magnetic moments of **1a—c** are similar to those of the green paramagnetic 5-nitrosalicylato(amine)cobalt(III) complexes, $[Co(5\text{-}NO_2sal)L]X_2\cdot nH_2O$ (L: trien (**4a**), en_2 (**4b**), $(bpy)_2$ (**4c**), and $(NH_3)_4$ (**4d**)), *i.e.*, an unpaired electron of **4a—d** is delocalized over the chelate ring containing the cobalt atom and the 5-nitrosalicylato ligand from the results of the IR spectra,[4] ^1H-, ^{13}C NMR spectra,[4] magnetic susceptibility,[5] the electric resistivity,[5] ESR,[5] and XPS.[6] Thus, an unpaired electron of **1a—c** is also delocalized over the chelate ring containing the cobalt atom and the 5-nitrosalicylato ligand.

A clear distinction between **1a—c** and **4a**[7] was found in the absorption spectra in 60% HNO_3. The ε's of the absorption bands at around 350 nm of **1a—c** are larger than those at 460 nm. The absorption bands at around 350 nm of **1a—c** show a hypsochromic shift from that (360 nm) of **4a** as is shown in Table 1. These properties have been ascribed to the coordinated quadridentate ligands.

The properties of **3a—c** are similar to those of the orange diamagnetic 5-nitrosalicylato(trien)cobalt-(III) complex,[7] $[Co(5\text{-}NO_2sal)trien]NO_3\cdot 3H_2O$ (**5**), in the IR, NMR spectra, and magnetic susceptibility. Both signals of the center methylene protons (*cf.* Table 1) and NH_2-side methylene protons of the coordinated quadridentate ligand in **3a—b** are distinguishable, but those of **1a—b** are indistinguishable, because of the paramagnetism. The first absorption bands of **3a—c** shift to 503 nm (**3a**) from 535 nm (**3c**). This shift is similar to that[3] of **2a—c**. Some physical properties of **1a—c**, **3a—c**, **4a**, and **5** are collected in Table 1.

Experimental

Measurements. The NMR spectra were recorded with an R-40 apparatus (Hitachi) for ^1H NMR. The IR spectra were recorded in potassium bromide disks with an IR-27G spectrophotometer (Shimadzu). The visible absorption spectra were recorded with a Shimadzu MPS-5000 recording spectrophotometer. The magnetic susceptibilities were measured by the Faraday method using a mag-

† 1 BM=9.274×10^{-24} A m^{-2}.

netic balance (Shimadzu) from liquid nitrogen to room temperature.

Materials. The quadridentate amine ligands of 2,3,2-tet, 3,2,3-tet, and 3,3,3-tet were purchased from Strem Chemicals Inc.

Preparation of Complexes. Diamagnetic *cis*-β_2-salicylato(quadridentate amine)cobalt(III) chloride hydrates, $[Co(sal)L]Cl \cdot nH_2O$ (L: 2,3,2-tet, n=2 (**2a**), L: 3,2,3-tet, n=3 (**2b**), and L: 3,3,3-tet, n=1 (**2c**)) were prepared from the reaction mixture of salicylic acid or sodium salicylate and $[CoCl_2L]Cl \cdot nH_2O$ (L: 2,3,2-tet, 3,2,3-tet, and 3,3,3-tet) according to the previous paper.[3]

*Paramagnetic β_2-5-Nitrosalicylato(3,7-diazanonane-1,9-diamine)cobalt(III) Chloride Nitrate Dihydrate (**1a**), Paramagnetic β_2-5-Nitrosalicylato(4,7-diazadecane-1,10-diamine)cobalt(III) Chloride Nitrate Dihydrate (**1b**), and Paramagnetic β_2-5-Nitrosalicylato(4,8-diazaundecane-1,11-diamine)cobalt(III) Chloride Nitrate Dihydrate (**1c**)*: One cubic centimeter of 60% nitric acid was added to **2a** (1.0 g, 2.34 mmol), **2b** (1.0 g, 2.18 mmol), and **2c** (1.0 g, 2.29 mmol), respectively. After the reaction, 60% nitric acid (1 cm^3) was added to the reaction mixture and stirred. Then the green solution was filtered using a glass filter (G-4), and the filtrate was added to acetone. The green complex thus precipitated was filtered off, washed with acetone, and dried. It was then precipitated twice more by dissolution in 60% nitric acid and by the addition of acetone. Complexes **1a—c** are soluble in water, DMSO, DMF, and acid solvents and slightly soluble in MeOH, though insoluble in common organic solvents. Yields: 0.28 g (22.4%) for **1a**, 0.15 g (12.6%) for **1b**, 0.29 g (22.5%) for **1c**. Found **1a**: C, 31.67; H, 5.42; N, 15.51; Cl, 6.61%. **1b**: C, 32.83; H, 5.23; N, 15.91; Cl, 6.79%. **1c**: C, 34.55; H, 5.95; N, 15.12; Cl, 6.69%. Calcd for **1a**: C, 31.50; H, 5.10; N, 15.74; Cl, 6.64%. **1b**: C, 32.89; H, 5.34; N, 15.34; Cl, 6.47%. **1c**: C, 34.20; H, 5.56; N, 14.96; Cl, 6.31%. Decomp 184 °C for **1a**, 183 °C for **1b** and 160 °C for **1c**. IR spectra, **1a**: 3050, 3080, and 3180 cm^{-1}; 1030(s), 1050(sh), 1055(s), and 1080(m) cm^{-1}. **1b**: 3050, 3100, and 3200 cm^{-1}; 1015(m), 1040(s), 1045(s), and 1080(m) cm^{-1}. **1c**: 3080, 3120, and 3200 cm^{-1}; 1025(sh), 1035(s), 1050(s), and 1080(s) cm^{-1}.

*β_2-5-Nitrosalicylato(3,7-diazanonane-1,9-diamine)cobalt(III) Nitrate (**3a**), β_2-5-Nitrosalicylato(4,7-diazadecane-1,10-diamine)cobalt(III) Nitrate Hydrate (**3b**), and β_2-5-Nitrosalicylato(4,8-diazaundecane-1,11-diamine)cobalt(III) Nitrate Hydrate (**3c**)*: The **1a**, **1b**, or **1c** complex was precipitated by the addition of acetone to a 60% nitric acid solution of the **2a**, **2b**, or **2c** (above section). From the orange acetone solution of the filtrate, complexes **3a**, **3b**, or **3c** crystallized directly on standing. Then, the orange complex thus separated was filtered off, washed with water and dried. Complexes **3a—c** isolated were recrystallized from water, twice and dried. Complexes **3a**, **3b** are soluble in DMSO and somewhat soluble in water, though complex **3c** is soluble in water, DMSO, DMF, and MeOH. Yields: 0.36 g (33.3%) for **3a**, 0.43 g (39.9%) for **3b**, 0.30 g (25.8%) for **3c**. Found **3a**: C, 36.27; H, 4.72; N, 18.65%. **3b**: C, 36.57; H, 5.54; N, 17.40%. **3c**: C, 38.16; H, 5.39; N, 17.05%. Determination of a Small Amount of a Biological Constituent by the Use of Chemiluminescence. II. Determination of Albumin as a Model Protein by Means of the Flow-injection Analysis Using a Cobalt(III) Complex Compound as a Catalyst

Tadashi HARA,* Motohiro TORIYAMA, and Kazuhiko TSUKAGOSHI
Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602
(Received April 15, 1983)

Synopsis. A new procedure for the determination of 8×10^{-9}—3×10^{-7} mol dm^{-3} bovine serum albumin as a model protein has been established on the basis of the fact that the catalytic activity of *cis*-tetraamminediaquacobalt(III) sulfate for the chemiluminescent reaction between luminol and hydrogen peroxide decreases in the presence of bovine serum albumin.

In the previous paper,[1] several proteins were determined by use of the fact that the catalytic activity of copper(II) for the chemiluminescent reaction between 5-amino-2,3-dihydro-1,4-phthalazinedione (luminol) and hydrogen peroxide (H_2O_2) decreased in the presence of those proteins. In the present work, *cis*-tetraamminediaquacobalt(III) sulfate which is known to give a longer luminescence time and more stable luminescence intensity than those in copper(II)[2,3] was used in place of copper(II) in the previous method. It was experimentally observed that the catalytic activity of the cobalt(III) complex compound for the chemiluminescent reaction between luminol and H_2O_2 decreased in the presence of bovine serum albumin (BSA), human serum albumin, bovine serum α-globulin, and bovine serum γ-globulin. BSA was chosen as a model protein. Though the present method is similar to the previous method in its detection limit and concentration range suitable for the determination, the standard curve of BSA in the present method is linear, and different from the non-linear one in the previous method. This means that the present method is superior to the previous method.

Experimental

All reagents were of commercially available special grade. Ion exchange water was distilled for use. A luminol solution, a H_2O_2 solution, and a buffer solution were prepared as in the previous paper. A 1.0×10^{-3} mol dm^{-3} cobalt(III) catalyst solution was prepared as a stock solution by dissolving *cis*-tetraamminediaquacobalt(III) sulfate[4] in water and it was diluted to 1.0×10^{-5} mol dm^{-3} with water, followed by the dilution with a buffer solution for use. BSA (Sigma Chemical Co., mol wt 66000) was used as a model protein.

The experiment was carried out as in the previous paper using the same apparatus. A sample solution containing BSA was dissolved and diluted with a buffer solution, and to it a cobalt(III) catalyst solution was added to give a definite concentration of cobalt(III) solution. After the solution was held at 30 °C for 50 min, an aliquot of the solution was subjected to the flow-injection analysis and the chemiluminescence (CL) intensity in the luminol-H_2O_2-cobalt(III) catalyst system was measured.

Results and Discussion

A calibration curve was obtained for the solution which contained only cobalt(III) catalyst (Fig. 1), and it is quite different from the non-linear calibration curve obtained for the copper(II) catalyst solution.

The relationship between reaction time and the CL intensity at 3.0×10^{-8}, 7.6×10^{-8}, and 3.0×10^{-7} mol dm^{-3} BSA was obtained (Fig. 2). Figure 2 shows that the reaction between cobalt(III) catalyst and BSA goes to completion in 50 min at 30 °C.

Initial BSA concn = 3.0×10^{-8} mol dm^{-3}. a) Estimated from Fig. 1.

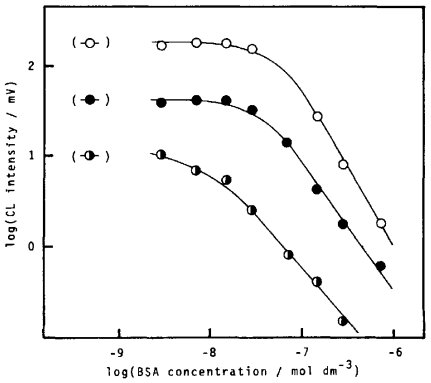

Fig. 3. Standard curves. ◑: 1.5×10^{-8} mol dm^{-3}-, ●: 5.0×10^{-8} mol dm^{-3}-, ○: 2.0×10^{-7} mol dm^{-3}-Co(III), and (○), (◑), (●): BSA free. Conditions: 1.0×10^{-3} mol dm^{-3} luminol and 2.5×10^{-3} mol dm^{-3} H_2O_2.

Standard curves were obtained by the reaction of BSA with 1.5×10^{-8}, 5.0×10^{-8}, and 2.0×10^{-7} mol dm^{-3} cobalt(III) catalyst solutions (Fig. 3). Lowering of the chemiluminescent activity of cobalt(III) catalyst solution in the presence of BSA seems to be due to the formation of cobalt(III)-polypeptide linkage similarly as in the copper(II) catalyst solution. As can be seen from Fig. 3, BSA in the concentration range of 8×10^{-9}—3×10^{-7} mol dm^{-3} could be determined, with a detection limit of 0.2 μg, by use of 1.5×10^{-8} mol dm^{-3} cobalt(III) catalyst solution. The present method is superior to the previous method since the standard curve in the present method is almost linear.

Lowry *et al.*[5] estimated an apparent dissociation constant between copper(II) and protein as 3×10^{-6} mol dm^{-3} on the assumption that they associated at the mole ratio 1:1 in the copper(II) concentration range of 8×10^{-6}—4×10^{-5} mol dm^{-3}. The authors also estimated an apparent association constant between cobalt(III) and BSA similarly as in the case of Lowry *et al.* The slope of the standard curve at 1.5×10^{-8} mol dm^{-3} cobalt(III) catalyst solution in Fig. 3 is approximately −1 and then the association between cobalt(III) and BSA is given by Eq. 1 as an equimolar reaction.

$$[\mathrm{Co}] + [\mathrm{BSA}] \rightleftharpoons [\mathrm{Co\cdot BSA}], \quad (1)$$

where [Co], [BSA], and [Co·BSA] are the concentrations of free cobalt(III), free BSA, and associated complex, respectively. An apparent association constant, K is defined by Eq. 2.

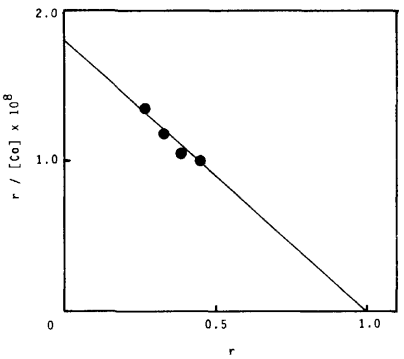

Fig. 4. Relationship between r and r/[Co]. Conditions: 1.0×10^{-3} mol dm^{-3} luminol and 2.5×10^{-3} mol dm^{-3} H_2O_2.

$$\frac{[\mathrm{Co\cdot BSA}]}{[\mathrm{Co}][\mathrm{BSA}]} = K. \quad (2)$$

From Eq. 2, Eq. 3 is derived.

$$r/[\mathrm{Co}] = K - rK, \quad (3)$$

where r means the mole ratio of bound cobalt(III) to total BSA. Figure 4 shows the plot of r/[Co] to r which was obtained by use of the data in Table 1. The straight line obtained by plotting r/[Co] against r on section paper passed through the point at r=1 in Fig. 4. This means that the derivation of Eqs. 1, 2, and 3 was reasonable. The value of K, 1.8×10^8 mol^{-1} dm^3 at 1.5×10^{-8} mol dm^{-3} cobalt(III) catalyst solution was found from the slope of the straight line in Fig. 4. The value of K thus obtained may be reasonable by considering the principle of the present method in which the concentration of a liberated cobalt(III) in the reaction between cobalt(III) and BSA is measured.

According to the present flow-injection analysis method, 8×10^{-9}—3×10^{-7} mol dm^{-3} BSA as a model protein can be determined at the rate of about 30 samples per hour after the reaction between cobalt(III) and BSA, with the detection limit of 0.2 μg BSA and with the standard curve which is almost linear in the range of 1×10^{-8}—3×10^{-7} mol dm^{-3} BSA.

The authors wish to thank Messrs. Masakatsu Imaki and Hirohumi Hashimoto for their help with the experiments.

(Received May 19, 1983)

Synopsis. The temperature dependence of the magnetic susceptibility of $Cu(CH_3COO)_2 \cdot 2NH_4Cl$ obeys the Bleaney-Bowers equation, indicating the existence of the anionic copper(II) acetate dinuclear unit. The exchange integral, J/k, is equal to -205 K. For $NH_4Cu(HCOO)Cl_2$, the structure containing copper(II) formate layers connected by tetrachlorocuprate(II) bridges is presumed on the basis of the value of the Weiss constant.

It has been suggested that, in dinuclear copper(II) carboxylate adducts, the axial ligand (apical ligand of the square pyramidal coordination polyhedron) plays a role in determining the extent of spin-exchange interaction or the singlet-triplet separation ($-2J$).[1] Goodgame *et al.* have reported the magnetic properties of several dinuclear anionic copper(II) acetate complexes, $(R_4N)_2[Cu(CH_3COO)_2X]_2$ (X=NCS, NO_2, or Br).[2,3] However, insufficient data have been available to draw any precise conclusions regarding the role of the axial ligand in anionic copper(II) acetate complexes. In this work, we prepared three copper(II) acetate complexes, $Cu(CH_3COO)_2 \cdot 2KCl$, $Cu(CH_3COO)_2 \cdot 2NH_4Cl$, and $Cu(CH_3COO)_2 \cdot 3/2C_4H_9NH_3Cl$, and two copper(II) formate complexes, $KCu(HCOO)Cl_2$ and $NH_4Cu(HCOO)Cl_2$, and measured their magnetic susceptibilities in order to study the effect of the chloride ions upon the magnetic properties.

The compound with the stoichiometry of $Cu(CH_3COO)_2 \cdot nACl$, where $n=2$ for A=NH_4 or K and $n=3/2$ for A=*n*-$C_4H_9NH_3$, was precipitated in large green crystals when an excess of ACl was added to a hot aqueous solution of copper(II) acetate monohydrate with a few drops of acetic acid and the mixture was allowed to stand overnight at *ca.* 5 °C in a refrigerator. The magnetic moments of these compounds were evaluated from their susceptibilities observed at room temperature and the relevant Pascal constants.[4] They are low and practically the same as that of copper(II) acetate monohydrate (Table 1).

The temperature dependence of the magnetic susceptibility of the $Cu(CH_3COO)_2 \cdot 2NH_4Cl$ complex over the range of 77—300 K (Fig. 1) was also found to correspond well with the known behavior of copper(II) acetate monohydrate. A reasonably good agreement was found between the experimental results and the theoretical curve calculated from the usual expression[5] for the susceptibility of the copper(II) ions in the copper(II) acetate dimer (Bleaney-Bowers equation), using the following parameters: $g=2.14$, $J/k=-205$ K, and $N\alpha=60\times10^{-6}$ emu/mol (1 emu/mol$=4\pi\times10^{-6}$ m^3/mol). The variation in the value of $-2J$ on the replacement of H_2O by Cl is too small to confirm the suggestion that the exent of spin-exchange interaction increases as the axial ligand becomes stronger as an electron donor.[6] However, the obtained result is consistent with the assumption that the anionic copper(II) acetate is constructed by replacing the water molecules in $[Cu(CH_3COO)_2 \cdot H_2O]_2$ with chloride ions.

We attempted to prepare the analogous formate complexes by the method described above. However, the compounds with the stoichiometry of $ACu(HCOO)Cl_2$, where A=NH_4 or K, were obtained as fine yellowish

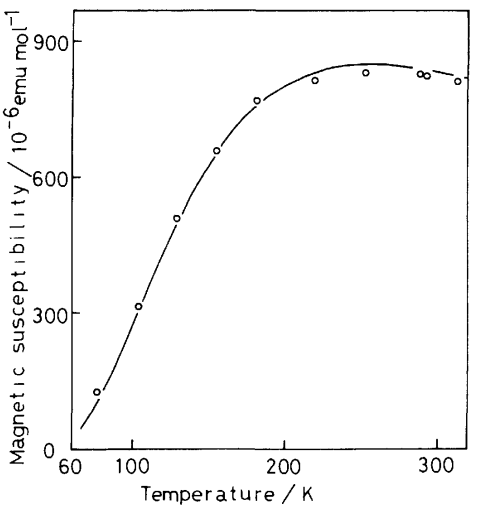

Fig. 1. Observed and calculated magnetic susceptibilities of $Cu(CH_3COO)_2 \cdot 2NH_4Cl$: experimental points and solid curve calculated by the Bleaney-Bowers equation.

TABLE 1. ANALYTICAL DATA AND EFFECTIVE MAGNETIC MOMENTS AT 17 °C

Compound	Cu (%)		Cl (%)		μ_{eff}/BM
	Calcd	Found	Calcd	Found	
$Cu(CH_3COO)_2 \cdot 2KCl$	19.21	19.16	21.44	21.29	1.38
$Cu(CH_3COO)_2 \cdot 2NH_4Cl$	22.02	22.05	24.57	24.76	1.39
$Cu(CH_3COO)_2 \cdot 3/2C_4H_9NH_3Cl$	18.34	18.45	15.35	15.17	1.41
$KCu(HCOO)Cl_2$	29.07	29.12	32.44	32.27	1.78
$NH_4Cu(HCOO)Cl_2$	32.46	32.17	35.90	35.81	1.77

green crystals. The room-temperature magnetic moments determined for these formates are slightly lower than those found for paramagnetic copper(II) compounds, indicating the existence of antiferromagnetic interactions among the copper(II) ions. Their values, however, are obviously different from those of dimeric copper(II) formate adducts with pyridine,[7,8] urea,[9] or thiocyanate ions.[2] The composition suggests that these compounds are 1 : 1 complexes between copper(II) formate and tetrachlorocuprates(II), $Cu(HCOO)_2 \cdot A_2CuCl_4$. This formulation is supported by the fact that these crystals can be obtained more efficiently by concentrating an aqueous solution of $Cu(HCOO)_2 \cdot 2H_2O$ and $A_2CuCl_4 \cdot 2H_2O$ on a water bath.

The temperature dependence of the magnetic susceptibility of the $NH_4Cu(HCOO)Cl_2$ complex over the range of 77—300 K (Fig. 2) obeys the Curie-Weiss law when the following parameters are used: g=2.21 and Θ=−52.8 K. The value of the weiss constant for this compound is almost half of the value for $Cu(HCOO)_2 \cdot 4H_2O$,[10] the X-ray crystal analysis of which has indicated that the metal ions are bridged in anti-anti-bonding arrangements of Cu-O-C-O-Cu links to form a two-dimensional lattice.[11] It is known that half of the water molecules interposed between the copper(II) formate layers can be replaced by urea[12] or pyridine,[8] and that the resultant compound has essentially the same configuration as does tetrahydrate. These facts suggest that the present formates are also formed by interposing A_2CuCl_4 between the copper(II) formate layers, because the paramagnetic ions between layers seem to diminish the value of the Weiss constant. Martin and Waterman[10] have suggested that the adduct ligands which most effectively reduce the residual charge on the copper(II) ion may favour a syn-syn-bonding arrangement of the Cu-O-C-O-Cu links, but the importance of the packing effects was also pointed out.[13] The above-mentioned structure can be explained by this packing effect.

(Received June 13, 1983)

Synopsis. A vacuum sublimation apparatus with a continuous temperature gradient (25—260 °C) along the tube (0—50 cm) at 2×10^{-2} Torr (1 Torr≈133.322 Pa) was used. STTA (1,1,1-trifluoro-4-(2-thienyl)-4-mercapto-3-buten-2-one) and its metal chelates of Mn^{II}, Fe^{III}, Co^{III}, Ni^{II}, Cu^{II}, Zn^{II}, and Pd^{II} sublimed quantitatively without thermal decomposition, while the chelates of Ag^{I} and Cd^{II} were accompanied by thermal decomposition.

The vacuum sublimation method is useful for the purification and separation of metal chelates.[1,2] Of the 14 chelating reagents other than β-thioxo ketones, diethyldithiocarbamates and oxine were found to offer the greatest promise for this purpose.[1] The present research aims to find suitable β-thioxo ketones for the purification of metals as their chelates by vacuum sublimator with continuous temperature gradient under low pressure. Some aspects of vacuum sublimation behavior of the chelate compounds will also be discussed.

Experimental

Materials. Various monothio analogs of β-diketones were synthesized by the reaction of hydrogen sulfide with β-diketones in an anhydrous ethanol in the presence of hydrogen chloride for 30—60 min, as described previously.[3,6] Nickel(II) chelate compounds with disulfur analogs of β-diketones were also prepared by the modification of the reaction of a corresponding β-diketone dissolved in an anhydrous ethanol with hydrogen sulfide in the presence of nickel(II) chloride and hydrogen chloride as a catalyst for 1—5 h.[7] Nickel(II) dithioacetylacetone was also prepared by the two electron reduction of 3,5-dimethyl-1,2-dithiolium cation with sodium tetrahydroborate in the presence of nickel(II) ion.[8] The chelating reagents and their nickel(II) chelates tested were as follows: SAA (4-mercapto-3-penten-2-one), SSAA (4-mercapto-3-penten-2-thione), SDBM (3-mercapto-1,3-diphenyl-2-propen-1-one), SBFA (1,1,1-trifluoro-4-mercapto-4-phenyl-3-buten-2-one), SSBFA (1,1,1-trifluoro-4-mercapto-4-phenyl-3-butene-2-thione), STTA (1,1,1-trifluoro-4-(2-thienyl)-4-mercapto-3-buten-2-one), SSTTA (1,1,1-trifluoro-4-(2-thienyl)-4-mercapto-3-butene-2-thione), and their parent β-diketones of AA (2,4-pentanedione), BA (1-phenyl-1,3-butanedione), DBM (1,3-diphenyl-1,3-propanedione), BFA (benzoyltrifluoroacetone), TTA (2-thenoyltrifluoroacetone). All other metal chelates were prepared by solvent extraction mentioned previously.[2] These materials were purified by recrystallization from carbon tetrachloride or by sublimation *in vacuo* before usage. The content of sulfur in the products was ascertained by using the Sn^{II}-strong phosphoric acid method;[9] the results were in good agreement with the theoretical values.

Sublimation Procedure. A vacuum sublimation apparatus providing a continuous temperature gradient (25—260 °C) along the tube (0—50 cm) at 2×10^{-2} Torr was used, as previously described.[1] The patterns of the rise in temperature along the sublimation tube are shown in Fig. 1. These patterns were obtained by supplying the following electric power through the mantle heaters; 50, 20, 10, and 4.2 V at 1.38 A. Metal chelates were placed inside the apparatus for 2 h after establishment of the thermal equilibrium. The temperature gradient along the sublimator is shown in Fig. 2; this was obtained after the thermal equilibrium. The temperature gradient in the region of 25 (room temperature) to 260 °C is about 4 °C/cm with the deviation of ±4 °C. The sublimate zone along the sublimation tube was decided from the color of the chelate and its position of deposition.

Results and Discussion

Effect of ligands on the sublimation-recrystallization temperatures for various nickel(II) chelates of β-thioxo ketones and their parent β-diketones are shown in Fig. 3. The temperature range of the deposited zones, the recovery, and the colors of the various nickel(II) chelates after sublimation are summarized in Table 1. The

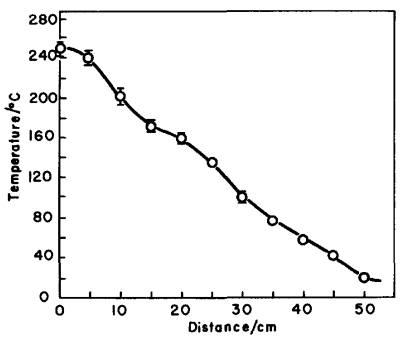

Fig. 2. Continuous temperature gradient along vacuum sublimator.

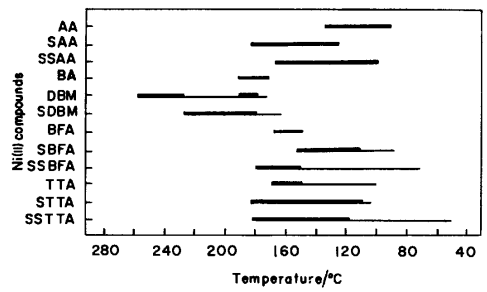

Fig. 3. Effect of ligands on the sublimation-recrystallization temperatures for nickel(II) chelates with various β-thioxo ketones and their parent β-diketones.

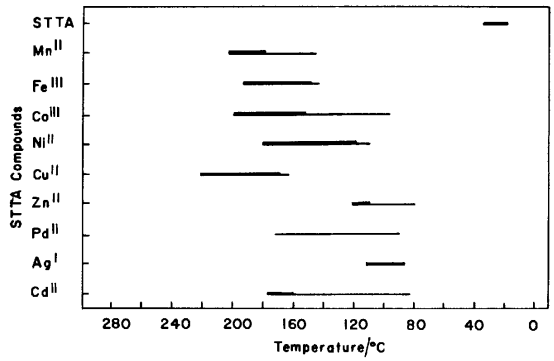

Fig. 4. Sublimation-recrystallization temperature for various metal STTA chelates.

sublimation-recrystallization temperature of nickel(II) chelates generally increased in the following order: AA<BFA, TTA<BA<DBM; SSAA, SBFA, SSBFA, STTA, SSTTA, SAA<SDBM. All of the chelates sublimed within 30 min to 2 h, and deposited inside the wall of the glass tube in the temperature range of 50 to 260 °C. The preliminary examination on the sublimation behavior of nickel(II) chelates of various β-thioxo ketones revealed that the STTA chelates were more volatile and stable on heating, so that a series of metal chelates of STTA was examined in detail. The results are schematically shown in Fig. 4, in which a thicker line indicates the deposited zone of uniformity with a large amount of metal chelate. The data are listed in Table 2. The STTA and its metal chelates of Mn^{II}, Fe^{III}, Co^{III}, Ni^{II}, Cu^{II}, Pd^{II}, and Zn^{II} sublimed quantitatively without thermal decomposition, while the chelates of Ag^{I} and Cd^{II} were accompanied by thermal decomposition. Berg and Reed reported that the STTA chelates of Cd^{II}, Co^{II}, Cu^{II}, Ni^{II}, Pb^{II}, Pd^{II}, and Zn^{II} partially sublimed with remarkable thermal decomposition at 1.3 Torr in a stream of air.[11] The thermal decomposition may be due to an air oxidation of STTA chelates under higher pressure. In the present investigation, it was found that the STTA chelates (1.6—53.5 mg) sublimed quantitatively without thermal decomposition at 2×10^{-2} Torr. The sublimation-recrystallization temperature of individual chelates increased in the following order: $Ag^{I}<Zn^{II}<Pd^{II}<Cd^{II}<Ni^{II}<Fe^{III}<Co^{III}<Mn^{II}<Cu^{II}$. In general, when a large amount of metal chelate (20—200 mg) sublimed, the deposited zone appeared at a temperature higher by about 50 °C than the ordinary position. Therefore the sublimation is useful for purification of each metal chelate, since highly pure crystals, especially large-sized pure crystals, can be obtained.

Table 1. Sublimation-recrystallization zone temperatures, amounts remaining, and colors of various nickel(II) chelates after sublimation at 2×10^{-2} Torr

The X-Ray Fluorescence Spectroscopy of Inorganic Solids. VI. The P $K\alpha$ Energy of Phosphate Glasses and Crystals

Takashi MAEKAWA,* Masakazu FURUKAWA, and Toshio YOKOKAWA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received June 29, 1983)

Synopsis. The P $K\alpha$ emission spectra of several phosphorus compounds and phosphate glasses were examined. The P $K\alpha$ energies decrease with an increase in the basicities of the matrices. The results also suggest that in order to interprete the chemical shift one must take into account the effects due to changes in the short range structure around the phosphorus atom in the PO_4 tetrahedron.

The present note reports an extension of our earlier studies concerning the X-ray fluorescence spectroscopy of inorganic glasses. Phosphorus is one of the most important constituents of oxide glasses and slags. However, in contrast with silicates, there have been few spectroscopic studies of the chemical state of phosphorus in phosphates. As to the X-ray spectroscopy, Fichter reported the $K\alpha$ energies of phosphorus in various compound.[1] Although he found a relation between the effective charges on phosphorus and the P $K\alpha$ energies, no chemical shifts of the P $K\alpha$ energy among phosphates were observed. In this work, the P $K\alpha$ energy shifts are obtained for several phosphate glasses and crystals. The results are discussed in connection with the effective positive charges on phosphorus and the basicity of the glasses.

Experimental

Apparatus. The P $K\alpha$ from crystals and glasses were measured by means of a high resolution 2-crystal spectrometer (Toshiba AFV 701). The analyzing crystals were ADP. A Cr X-ray tube was used for the primary excitation. Pulses from a gas-flow proportional counter were stored in a multichannel analyzer. The other details including the procedure for determining the chemical shifts were described in previous papers.[2-4]

Samples. The glassy samples were prepared by melting desired quantities of commercial $NaH_2PO_4 \cdot 2H_2O$, P_2O_5, H_3BO_3, and Na_2CO_3 in a platinum crucible and then pouring them onto a stainless steel plate. The sodium ion concentration in glasses with a high P_2O_5 content was determined by the ion-selective electrode method. SiP_2O_7 and BPO_4 were synthesized by direct reactions of phosphoric acid with silica or boric acid. The other anhydrous phosphates were obtained by the dehydration of commercial reagents in an electric furnace. All the crystalline samples were examined by means of an X-ray diffraction method.

Results and Discussion

In Table 1 are compiled the results of the P $K\alpha$ energy shifts of phosphates (crystals and glasses) referred to that of $NaPO_3$ glass. In contrast to the results of the previous author,[1] it could be detected that the P $K\alpha$ energy depends on the kind and the content of the metal ion, even among phosphates. This behavior may become clearer when looking at the relation between the energy shifts of the glassy samples and their composition. In Fig. 1 the composition dependence of the P $K\alpha$ energy of Na_2O–P_2O_5 and Na_2O–P_2O_5–B_2O_3 glasses is shown. In the binary glasses, the P $K\alpha$ energy decreases with an increase in the Na_2O contents, which is consistent with the previous results for Si $K\alpha$.[3] The addition of B_2O_3 to $NaPO_3$ glass results in smaller shifts than in binary glasses.

It has been shown that the $K\alpha$ energies of the third period elements increase with an increase in the partial positive charges on the corresponding elements.[5] Therefore, the P $K\alpha$ energy reflects the degree of polarity of the phosphorus–oxygen bond in the PO_4 tetrahedron. Around an one-to-one mole ratio of Na_2O to P_2O_5, *i.e.*, $NaPO_3$, phosphate changes its form with an increase in the Na_2O contant as follows:

$$PO_{2.5} \longrightarrow PO_3^- \longrightarrow PO_{3.5}^{1-} .$$

Because of the rather strong acidic character of P_2O_5,

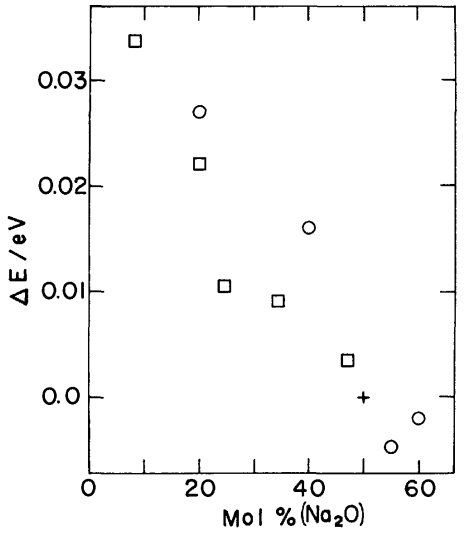

Fig. 1. Composition dependence of P $K\alpha$ energy shifts of Na_2O–P_2O_5 (○) and Na_2O–P_2O_5–B_2O_3 (□) glasses. The reference material is $NaPO_3$ (+).

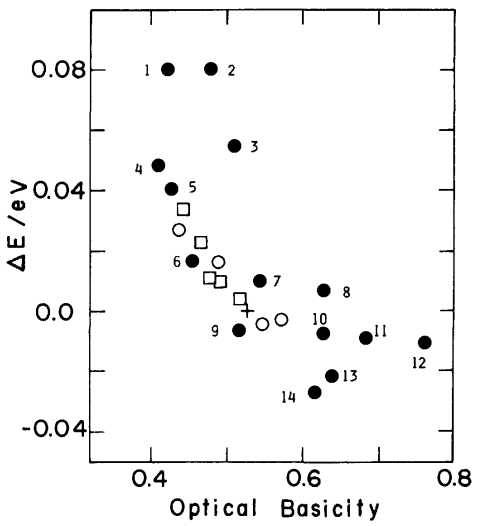

Fig. 2. The relation between P $K\alpha$ energy shifts and theoretical optical basicities of Na_2O–P_2O_5 (○), Na_2O–P_2O_5–B_2O_3 (□) and phosphates (●). The reference material is $NaPO_3$ (+). Numbers indicated in the figure correspond to the compounds in Table 1.

this sequential transformation is sensitive to the composition, especially at the equivalent points. This transformation naturally leads to the changes in the effective charge on the phosphorus atom. The effect of the B_2O_3 addition, therefore, is understandable, though B_2O_3 is a weak acid compared with P_2O_5.[6] Figure 2 shows the dependence of the P $K\alpha$ energy shifts on the theoretical optical basicity, as defined by Duffy and Ingram.[7] The P $K\alpha$ energy increases with a decrease in the optical basicities. However, the P $K\alpha$ energy shifts are larger in the Si and Al phosphates than in alkali phosphates, even with the same optical basicity.

The addition of alkali or alkaline earth metal oxides to a pure P_2O_5 causes the breakage of a P–O–P bond, giving rise to a non-bridging oxygen ion, accompanied by adjacent metal ions as charge compensators. In this case, the isostructural picture with the corresponding silicate can be expected. If more electronegative elements, such as silicon or aluminium, are located, they will form a linkage such as –P–O–Si–O– at the expence of the P=O double bond. The electrons which have been localized on a PO_4 tetrahedron as a double bond with oxygen then diffuse to adjacent polyhedra (SiO_6 in the above case). In other words, the effective positive charge on phosphorus should increase much more than would be expected from the average electronegativity or theoretical optical basicity. The $K\alpha$ energy increases in proportion to the increased positive charges on the phosphorus atom. A further quantitative discussion will be made after measuring the P $K\alpha$ spectra, which give direct information about the chemical bond in phosphates.

The present work was partially supported by a Grant-in-Aid for Foundamental Scientific Research from the Japan Society of Promotion Science. (T. Maekawa).

Studies of the Interaction of Isocyanides with Transition-metal Complexes.[1] XXVI. The Preparation of Octakis(aryl isocyanide)dirhodium

Yasuhiro YAMAMOTO* and Hiroshi YAMAZAKI
The Institute of Physical and Chemical Research, Wako, Saitama 351
(Received July 15, 1983)

Synopsis. The treatment of a mixture of $[Rh(cod)Cl]_2$ and aryl isocyanide with sodium amalgam afforded octakis(aryl isocyanide)dirhodium. A structure with two bridging and six terminal isocyanide ligands was deduced from the IR spectrum in comparison with that of the known cobalt analog. The temperature-dependent ^1H NMR spectrum of this complex suggested harder intramolecular and easier intermolecular ligand exchanges than those of the corresponding cobalt analog.

Previously Green *et al.*[2] and also the present authors[3] reported the synthesis of dinuclear zerovalent $Co_2(RNC)_8$ either by the reduction of alkyl and aryl isocanide complexes of cobalt(I) and cobalt(II) by the alkali metal amalgam, or by the substitution reaction of $Co_2(CO)_8$ or $Co_4(CO)_{12}$ with aryl isocyanide. Spectroscopic and X-ray crystallographic analyses showed that the molecule consists of two bridging and six terminal isocyanide ligands and that the molecule is fluxional in a solution. For comparison we attempted to prepare related rhodium complexes and to examine their structural features.

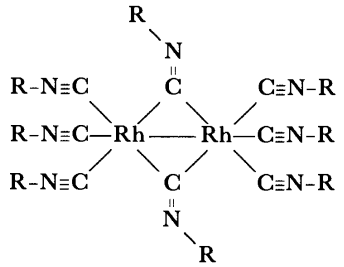
Results and Discussion

The treatment of dichloro-bis(η^4-1,5-cyclooctadiene)dirhodium(I) and 2,6-xylyl isocyanide with a sodium amalgam in THF at room temperature led to formation of zerovalent octakis(2,6-xylyl isocyanide)dirhodium (**1a**) in a moderate yield:

$$[Rh(cod)Cl]_2 + 8\,RNC \xrightarrow{Na/Hg} Rh_2(RNC)_8.$$
1a—c

Yellow crystals of **1a** which contain benzene as a solvate are fairly stable in the solid state and can be kept in a refrigerator under an inert-gas atmosphere. In contrast, $Rh_2(CO)_8$ has only been characterized spectroscopically under a high pressure of carbon monoxide[4] and also in a low-temperature matrix (*ca.* 35 K).[5] No isocyanide cluster complexes, such as $Rh_4(RNC)_{12}$ and $Rh_6(RNC)_{16}$ corresponding to the known binary carbonyl clusters were formed, probably for steric reasons. The use of mesityl or 2,6-dimethyl-4-bromophenyl isocyanide also afforded similar complexes (**1b**: 2,4,6-$Me_3C_6H_2NC$; **1c**: 2,6-Me_2-4-BrC_6H_2NC).

The IR spectrum of **1a** in nujol shows characteristic absorptions assignable to the terminal isocyanide groups [2125(sh), 2090(sh), 2070(s), and 1995(sh) cm^{-1}] and to the bridge-bonded isocyanide groups [1672(m) and 1653(s) cm^{-1}]. The IR spectrum in a solution also shows a similar absorption pattern. These spectra were similar to those of the known cobalt analog, $Co_2(2,6\text{-}Me_2C_6H_3NC)_8$, and suggest that **1a** has a dimeric structure consisting of two bridging and six terminal isocyanide ligands.



It has been known that binary rhodium carbonyl exists in the bridge-bonded form, and there is no evidene for the non-bridged form.[4,5]

The ^1H NMR spectrum of **1a** in PhCl at the ambient temperature shows only one sharp singlet, at δ 2.30, which is assigned to methyl protons. This simple spectrum implies a rapid intramolecular ligand exchange between bridging and terminal isocyanide ligands. Similar behavior has also been observed in the case of the cobalt analog. However, the sharp singlet at δ 2.30 broadened on cooling and at *ca.* −33 °C splitted into two signals in an intensity ratio of 3:1, showing slow intramolecular ligand exchange; this was in contrast to the case of the cobalt analog, which showed rapid ligand exchange even at −90 °C. The intermolecular ligand exchange with added 2,6-xylyl isocyanide was also observed. The spectrum at 14 °C showed two sharp, separated signals, at δ 2.30 and 2.17, due to coordinated and uncoordinated isocyanides respectively. No intermolecular ligand exchange occurs below this temperature, as is indicated by the sharpness of the two separated singlets. The two signals become broad on warming and coalesce to a broad singlet at 40 °C. The spectrum at 60 °C shows a sharp singlet, suggeting rapid intermolecular exchange. This temperature-dependent NMR behavior is reversible. The coalescence temperature of intermolecular exchange in the cobalt analog is 127 °C. Thus, the intramolecular ligand exchange is harder, and the intermolecular exchange is easier in **1a** than in the cobalt analog. The thermodynamic data for the ligand-exchange processes of **1a**, **1b**, and **1c** are listed in Table 1.

The electronic spectra of **1a** in cyclohexane, together with that of $Co_2(2,6\text{-}Me_2C_6H_3NC)_8$, are shown in Fig. 1. The band at 29670 cm^{-1} (337 nm) is assigned to the σ-σ^* transition by analogy with the electronic spectrum of $Co_2(2,6\text{-}Me_2C_6H_3NC)_8$. The energy of the σ-σ^* transition in **1a** is lower by 8790 cm^{-1} than that of $Rh_2(CO)_8$.[5] This difference can be associated with the weaker π-acid character of isocyanide than that of carbon monoxide. The

isocyanide ligand promotes the accumulation of d-electron density on the rhodium atoms and so increases the d-d repulsive energies. The σ-σ^* transition band in the isocyanide complex red-shifts on passing from $Co_2(2,6\text{-}Me_2C_6H_3NC)_8$ to $Rh_2(2,6\text{-}Me_2C_6H_3NC)_8$; this is the reverse of the trend observed in binary carbonyls of cobalt and rhodium.[5]

Experimental

The reactions were carried out under an atmosphere of nitrogen. The IR and electronic spectra were obtained on Shimadzu IR-27G and Shimadzu UV-180 spectrophotometers respectively. The ^1H NMR spectra were recorded on a Varian HA-100B spectrometer, using tetramethylsilane as a reference. The isocyanides[6] and $[Rh(cod)Cl]_2$[7] were prepared by procedures described in the literature. The tetrahydrofuran was distilled from sodium ketyl just before use.

*Octakis(2,6-xylyl isocyanide)dirhodium (**1a**).* A mixture of $[Rh(cod)Cl]_2$ (0.20 g) and 2,6-xylyl isocyanide (0.50 g) (mole ratio: *ca.* 1:9.4) in dry tetrahydrofuran (50 ml) was stirred at room temperature with an excess of the sodium amalgam (1%) for 0.5 h. The solution was then decanted, and the solvent was evaporated to dryness under reduced pressure. The residue was chromatographed on alumina (deactivated by H_2O (10%), 2 cm×5 cm), using benzene as the eluent. The concentration of the orange eluate and the addition of hexane gave yellow crystals of the title cmpound containing a benzene molecule (0.36 g, 68%); mp *ca.* 120 °C (decomposing in a nitrogen filled capillary tube). Found: C, 70.29; H, 5.29; N, 8.42%. Calcd for $Rh_2C_{78}H_{78}N_8$: C, 70.26; H, 5.95; N 8.40%.

Similarly, octakis(2,6-dimethyl-4-bromophenyl isocyanide)-dirhodium (**1c**) was obtained in a 24% yield; mp *ca.* 150 °C (decomposing in a nitrogen filled capillary tube). Found: C, 48.38; H, 3.75; N, 5.69%. Calcd for $Rh_2C_{78}H_{70}N_8Br_8$ (containing a benzene molecule): C, 47.69; H, 3.59; N, 5.70%.

For the preparation of the mesityl isocyanide analog (**1b**), the reaction mixture was chromatographed on alumina, using tetrahydrofuran as the eluent.

The subsequent concentration of the eluate gave yellow crystals of **1b** in a 60% yield; mp *ca.* 130 °C (decomposing in a nitrogen filled capillary tube). Found : C, 69.91; H 6.81; N 7.57%. Calcd for $Rh_2C_{84}H_{96}N_8O$ (containing a tetrahydrofuran molecule): C, 70.09; H,6.72;N,7.78%.

Variable-temperature NMR. A mixture of **1a** (388 mg) and 2,6-xylyl isocyanide (12 mg) was dissolved in chlorobenzene and sealed under a nitrogen atmosphere in a 5-mm NMR tube. The temperatures were calibrated using the chemical-shift separation obtained from an ethylene glycol solution at high temperatures and using that obtained from a methanol solution at low temperatures. Similar variable-temperature NMR spectra of **1b** and **1c** were also measured; the results are summarized in Table 1.

Theoretical Interpretation of the Mössbauer Parameter in [1]Ferrocenophanes

Shigeru IKUTA,* Izumi MOTOYAMA, and Hirotoshi SANO*
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158
(Received August 20, 1983)

Synopsis. The smaller quadrupole splitting values in [1]ferrocenophanes than that in ferrocene were accounted for by assuming a lesser quantity of the nuclear part in the electric-field gradient at the iron nucleus; smaller quadrupole splitting could not be explained by the electron distribution among Fe 3d orbitals.

Mössbauer spectroscopy has been used as a very useful tool for probing the changes in the electronic environment around the iron nucleus.

Quadrupole splitting values (qs=2.0 mm s^{-1}) about 15% smaller than that in ferrocene were observed in (1,1′-ferrocenediyl)diphenylgermane, (1,1′-ferrocenediyl)phenylphosphine, and (1,1′-ferrocenediyl)diphenylsilane.[1] Stoeckli-Evans *et al.*[2] performed a three-dimensional X-ray analysis of these compounds, and determined the distances between the Fe and Ge atoms and between the Fe and P atoms to be 2.744 Å and 2.774 Å, respectively. They pointed out that there is clearly no bonding between these atoms, since these interatomic distances are appreciably longer than the bond lengths calculated from the metallic covalent radii ($l_{Fe\text{-}Ge}$=2.47 Å and $l_{Fe\text{-}P}$=2.37 Å).

On the other hand, Clemance *et al.*[3] stated that the Fe–P length of 2.77 Å does not preclude the possibility of bonding interaction between the Fe and P atoms, and that the contribution of the phosphorus' d orbitals can be present in (1,1′-ferrocenediyl)phenylphosphine.

These discussions indicate a lack of clear understanding of the reason why smaller qs values are to be expected in these [1]ferrocenophanes.

In the present note, the electronic structures and the electric-field gradients around the iron nucleus in (1,1′-ferrocenediyl)diphenylgermane and (1,1′-ferrocenediyl)phenylphosphine were estimated based on calculations by means of an *ab initio* (coreless) MO method. The smaller qs values than that in ferrocene are explained in terms of the lesser quantity of the nuclear part in the electric-field gradient at the iron nucleus.

Calculation

The pseudo-potential method of Barthelat and Durand[4] was used for the *ab initio* (coreless) MO calculations in order to account for the electronic structures and electric-field gradients around the iron nucleus. A one-electron-property-package of the MONSTERGAUSS program[5] was installed in the PSHONDO program[6] which has been revised by Daudey in order to apply the pseudo-potential method to an original HONDO program.[7] The basis sets used for the Fe, C, and H atoms were the same as those in the previous communications;[8] only the basis set for the Fe 3d orbital was of a double-zeta quality. The contracted [2s2pld] basis sets[9] optimized by Daudey were used for the valence of the Ge and P atoms.

The geometrical structures determined by Stoeckli-Evans *et al.*[2] were used for the calculations, but the phenyl groups were replaced by hydrogen atoms because of their large systems. These simplifications can not be expected to affect the electron distributions, especially in the 3d orbitals of the iron atom, which lies far from the phenyl groups. The original structures determined by Stoeckli-Evans *et al.*[2] were used without any modifications in calculating the nuclear part of the electric-field gradient at the iron nucleus in (1,1′-ferrocenediyl)diphenylgermane.

The usefulness of the coreless MO calculations with the pseudo-potential method has already been reported by several authors,[8,10–15] and we ourselves have discussed the ferrocene derivatives.[8]

All the calculations were performed by the use of a FACOM M380 computer at the Institute of Physical and Chemical Research.

Results and Discussion

The quadrupole splitting (qs) can be theoretically calculated by means of the principal component of the electric-field gradient (q_{zz}) around the iron nucleus: $qs=1/2\cdot eQV_{zz}(1+1/3\cdot\eta^2)^{1/2}$, where V_{zz} equals $-q_{zz}$, where Q is the nuclear electric quadrupole moment, and where η is the asymmetry parameter.[8] The qs value is, then, directly proportional to the q_{zz} values. The principal electric-field gradient (q_{zz}) is composed of the nuclear (q_{zz}^{NUC}) and electronic (q_{zz}^{ELF}) ones.

The q_{zz}^{ELF} values are proportional to the following amount, which corresponds to the electron distribution among iron's 3d orbitals: $q_{zz}^{ELF}\propto[p(d_{x^2-y^2}+d_{xy})-\{p(d_{z^2}+1/2\cdot p(d_{xz}+d_{yz})\}]$. Therefore, the qs values are also related to the electron distribution among the iron's 3d orbitals.

In Table 1, the total energies, the electron populations among iron's 3d orbitals, the net atomic charges, the electric-field gradients around the iron nucleus, and the asymmetry parameters are summarized. In the present *ab initio* (coreless) MO calculations, the phenyl moiety was replaced by a hydrogen atom because of its large system. The values in ferrocene, as calculated by means of the *ab initio* coreless MO method, have already been found to be in agreement with them obtained by using the all-electron MO method.[8]

The q_{zz}^{ELF} values in (1,1′-ferrocenediyl)diphenylgermane and (1,1′-ferrocenediyl)phenylphosphine are quite similar to that in ferrocene. These results come from the fact that the electron distribution among iron's 3d orbitals (in these molecules) agrees well with that in ferrocene, as is shown in the table. The η values in these compounds are quite small.

Table 1. Total energies, electron populations, net atomic charges, electric-field gradients, and asymmetry parameters in [1]ferrocenophanes

η[i]	0.00	0.12	0.01	0.00

a) 3d Function was not added on the P atom. b) 3d Function was added on the P atom. c) Total energies in a.u. d) Electron populations among Fe 3d orbitals. e) Net atomic charges. f) Nuclear part of the electricfield gradient in a.u. g) We used the geometrical structures determined by Stoeckli-Evans *et al.*,[2] in which diphenyl was not replaced by hydrogen atoms. h) Electronic part of the electric-field gradient in a.u. The correction due to core electrons (shielding effect) was not performed. See Ref. 8. i) Asymmetry parameters.

The nuclear part of the electric-field gradient (q_{zz}^{NUC}) does not show a negligible value. It is worthwhile to note that the q_{zz}^{NUC} value in (1,1′-ferrocenediyl)diphenylgermane, in which the experimetal geometry determined by Stoeckli-Evans *et al.*[2] is used without any modifications, is lower by about 0.3 a.u. than that in ferrocene. This quite important result indicates that the total electric-field gradient in (1,1′-ferrocenediyl)diphenylgermane is also lower by 0.30 a.u. than that in ferrocene. (The overlap populations between the Fe and Ge atoms are −0.030, showing that there is no bonding between these two atoms.) Therefore, the smaller *qs* value in (1,1′-ferrocenediyl)diphenylgermane than that in ferrocene cannot be ascribed to the change in the electron distribution among iron's 3d orbitals caused by a direct bonding between the Fe and Ge atoms, but it can clearly be accounted for by the contribution of a smaller quantity of the nuclear part of the electric-field gradient around the iron nucleus in (1,1′-ferrocenediyl)diphenylgermane.

For the (1,1′-ferrocenediyl)phenylphosphine, two types of the calculations were performed; one (A) does not include the 3d polarization function for the phosphorus atom, while the other (B) does include it. As is shown in the table, the two sets of data are almost identical, indicating that the contribution of the phosphorus' 3d polarization function to the electron distribution among the iron's 3d orbitals does not exist in this system; the same q_{zz}^{ELF} values are obtained in these two types of calculations. The nuclear part of the electric-field gradient (q_{zz}^{NUC}) is smaller by 0.2 a.u. than that in ferrocene. (The q_{zz}^{NUC} value is estimated to become even smaller if the experimental geometry determined by Stoeckli-Evans *et al.*[2] is used, for in it the phenyl group is not replaced by a hydrogen atom.)

In (1,1′-ferrocenediyl)phenylphosphine, also the smaller experimental *qs* value can be accounted for by assuming a lesser contribution of the nuclear part to the electric-field gradient.

In conclusion, the smaller experimental *qs* values can be ascribed by the lesser q_{zz}^{NUC} values, without using any unreasonable supposition such as that reported by Clemance *et al.*[3]

The authors gratefully acknowledge the help of Dr. P. Daudey, who provided his PSHONDO program to one of them (S.I.). They also wish to thank Professor M. Imamura, the Institute of Physical and Chemical Research, who gave them the chance to use the FACOM M380 computer.

Studies of Bitter Peptides from Casein Hydrolyzate. V.[1] Bitterness of the Synthetic N-Terminal Analogs of des-Gly²-BPIa (Arg-Pro-Pro-Phe-Ile-Val)[2]

Hidenori KANEHISA† and Hideo OKAI*

Department of Fermentation Technology, Faculty of Engineering, Hiroshima University, Shitami, Saijo-cho, Higashihiroshima 724

(Received June 15, 1983)

Synopsis. In order to investigate how the basic amino acid residue in the N-terminal contributes to the bitter taste exhibited by BPIa (Arg-Gly-Pro-Pro-Phe-Ile-Val), we synthesized several kinds of N-terminal analogs of des-Gly²-BPIa (Arg-Pro-Pro-Phe-Ile-Val). The basic amino acid residue of BPIa was found to play an important role in its bitter taste.

In studies of the relationship between bitterness and chemical structure of BPIa (Arg-Gly-Pro-Pro-Phe-Ile-Val) which was isolated from casein hydrolyzate by Minamiura *et al.*,[3] BPIa and its various analogs and fragments have been synthesized in our laboratory.[1,4-6] In Previous papers,[1,5] we explained that the hydrophobic amino acids moiety in the C-terminal and the L-arginine residue in the N-terminal of BPIa are necessary for an intense bitter taste. However, the participation in the bitter taste of several basic amino acids other than L-arginine in the N-terminal of BPIa was not dealt with in those papers.[1,5] During the synthetic studies of BPIa, we found that des-Gly²-BPIa (Arg-Pro-Pro-Phe-Ile-Val) exhibited a strong bitter taste of the same level as BPIa.[5] We synthesized six kinds of des-Gly²-BPIa analogs, as shown in Table 1, and compared their bitterness with that of des-Gly²-BPIa.

The synthesis of compound **1** was as follows: Z-Lys(ε-Z)-OH·DCHA and H-Pro-Pro-Phe-Ile-Val-OBzl·HCl[4] that is an intermediate in the synthesis of BPIa were coupled by the mixed anhydride method to yield Z-Lys(ε-Z)-Pro-Pro-Phe-Ile-Val-OBzl. The protected hexapeptide was hydrogenated in the presence of palladium black to give H-Lys-Pro-Pro-Phe-Ile-Val-OH (**1**). Other peptides (compounds **2—6**) were prepared by the same procedures mentioned above, employing the corresponding acylamino acids instead of Z-Lys(ε-Z)-OH·DCHA. The purity of synthetic peptides and their intermediates was confirmed by thin-layer examinations on two solvent systems, elemental analyses, and amino acid analyses. The threshold value for bitter taste and the ratio of caffeine ($R_{caf.}$) value of the synthesized peptides were organoleptically determined by panel evaluation with five people, as shown in Table 1.

All the synthesized peptides possessed a bitter taste. However, their bitterness was weaker than that of des-Gly²-BPIa (**7**). By comparing the bitteness of compounds **1—3** and **7** with that of **4—6**, it is obvious that the basic nature in the N-terminal is important for showing the strong bitter taste in compound **7**. The strength of bitterness of compounds **1—3** decreased proportionally to the decreasing of the side chain length of the amino acid residue in the N-terminal. On the other hand, we found an interesting result for the bitter taste of compounds **5** and **6**. The bitter taste of compound **1** where L-lysine residue was located in the N-terminal was stronger than that of compound **2** in

which L-ornithine replaced L-lysine. However, N^{δ}-acetyl-L-orinithine N-terminal substituted analog (compound **6**) gave a stronger bitterness than N^{ε}-acetyl-L-lysine substituted one (compound **5**), which is due to the acetyl group introduction. From the results described above, the strong bitterness exhibited by BPIa depends on both basicity and side chain length of the amino acid in the N-terminal.

Experimental

All the melting points are uncorrected. Thin-layer chromatographies were performed on Merck silica gel G. Developing solvents commonly used were (1) 1-butanol-acetic acid-pyridine-water (4:1:1:2, v/v) and (2) chloroform-methanol (5:1, v/v). Materials possessing a free amino group on a thin-layer plate were detected by spraying with ninhydrin. Compounds with blocked amino groups were detected by spraying with 25% hydrogen bromide in acetic acid and then with ninhydrin. The optical rotations were measured on a Union PM-101 polarimeter. Amino acid analyses of peptides were carried out on samples that had been hydrolyzated with constant boiling hydrochloric acid for 65 h in evacuated, sealed tubes at 110 °C, and were recorded on a Hitachi amino acid analyzer KLA-5 type.

Syntheses of Protected Hexapeptides. Z-Lys(ε-Z)-Pro-Pro-Phe-Ile-Val-OBzl: A solution of Z-Lys(ε-Z)-OH·DCHA (0.89 g, 1.5 mmol) and *N*-methylmorpholine (0.16 ml, 1.5 mmol) in tetrahydrofuran (1.5 ml) was chilled to −5 °C. Ethyl chloroformate (0.15 ml, 1.5 mmol) was added, and then the mixture was kept for 15 min at −5 °C. A solution of H-Pro-Pro-Phe-Ile-Val-OBzl·HCl[4] (1.05 g, 1.5 mmol) and *N*-methylmorpholine (0.16 ml, 1.5 mmol) in *N*,*N*-dimethylformamide (10 ml) was added to the mixture and stirred for 1 h, then at room temperature overnight. The mixture was evaporated *in vacuo*, and the oily residue was dissolved in ethy acetate. The solution was washed with water, 0.5 M (1 M=1 mol dm^{-3}) hydrochloric acid, 4% sodium hydrogencarbonate, and water successively, then dried over anhydrous sodium sulfate. Sodium sulfate was removed by filtration, and the filtrate was evaporated *in vacuo*. The oily residue was crystallized with ether-petroleum ether; yield, physical constants, and elemetal analysis of this compound is given in Table 2. Other protected hexapeptides were prepared from the corresponding acylamino acids and H-Pro-Pro-Phe-Ile-Val-OBzl·HCl by the same method. Their yields and analytical data are also presented in Table 2.

Syntheses of Final Products. H-Lys-Pro-Pro-Phe-Ile-Val-OH (1): Z-Lys(ε-Z)-Pro-Pro-Phe-Ile-Val-OBzl (1.05 g, 1 mmol) was hydrogenated in methanol (2 ml) and acetic acid (2 ml) for 20 h by the aid of palladium black. The catalyst was filtered off, and the filtrate was evaporated *in vacuo*. The oily residue was crystallized from acetone-ether. It was recrystallized from methanol-acetone-ether; Compounds **2—6** were prepared from the corresponding hexapeptides by hydrogenation. Yields and analytical data of final products are given in Table 3.

Sensory Test. Taste of the peptides was organoleptically determined by the same manner as described in the previous papers.[1,4-6]

The authors wish to express thank to Dr. Shinji Okumura of Ajinomoto Co. Inc., for supplying some amino acids.

Monodebromination of *gem*-Dibromocyclopropanes by Sodium Hydrogentelluride

Atsuhiro OSUKA,* Keita TAKECHI, and Hitomi SUZUKI*
Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho 2-5, Matsuyama 790
(Received June 30, 1983)

Synopsis. *gem*-Dibromocyclopropanes were effectively reduced to monobromocyclopropanes by sodium hydrogentelluride.

Much attention has been focused in recent years on the application of tellurium in organic syntheses.[1] Among these, sodium hydrogentelluride (NaHTe),[2] which was prepared *in situ* from tellurium and sodium borohydride ($NaBH_4$), has been reported to possess considerable versatility as selective reagent for the reduction of a wide variety of organic molecules.[2-5] While NaHTe effects the hydrogenation of α,β-unsaturated carbonyl compounds, it does not reduce simple ketones or aldehydes.[3b,4] Several observations that anionic tellurium species have strong affinity toward activated halogen have led to the development of their uses for dehalogenation reactions.[3a,5,6,7] In this note, we wish to report an effective monodebromination of *gem*-dibromocyclopropanes by NaHTe.

Monobromocyclopropanes were obtained by treatment of *gem*-dibromocyclopropanes with 2.5 equiv. of NaHTe in refluxing ethanol. A further reduction of the resultant monobromides was not observed under the reaction conditions employed. For comparison, the reduction of *gem*-dibromocyclopropanes with $NaBH_4$ was also investigated. The yields and trans/cis ratios of the present reactions are given in the Table 1. Apparently, the reduction with NaHTe is faster and more selective than that with $NaBH_4$ in ethanol. A similar debromination may be expected in the reaction with NaHSe,[8] but neither 1,1-dibromo-2-phenylcyclopropane, nor 1,1-dibromo-2-methyl-2-phenylcyclopropane, nor 7,7-dibromobicyclo[4.1.0]heptane underwent reduction upon treatment with 2.5 equiv. of NaHSe in refluxing ethanol. It should be noted here that NaHTe has strong affinity for activated halogens, which property is not shared by NaHSe. 1,1-Dichloro-2-phenylcyclopropane and 7,7-dichlorobicyclo[4.1.0]heptane were quantitatively recovered after prolonged treatment with NaHTe, while dichlorodiphenylmethane was readily reduced by NaHTe to give tetraphenylethylene and diphenylmethane in 37 and 33% yields, respectively.

$$Ph_2CCl_2 \xrightarrow[EtOH]{NaHTe} Ph_2C{=}CPh_2 + Ph_2CH_2.$$

It was indeed true that numerous methods are availabe to bring about the monodebromination of *gem*-

dibromocyclopropanes[9] but the present method would be a simple and convenient addition to them.

Experimental

gem-Dibromocyclopropanes and *gem*-dichlorocyclopropanes were prepared according to the reported procedures.[10]

General Procedure for the Reduction of gem-*Dibromocyclopropanes with Sodium Hydrogentelluride.* To a hot solution of sodium hydrogentelluride, prepared in situ by reacting tellurium (1.30 g, 10 mmol) and sodium borohydride (0.90 g, 24 mmol) for 1 h in refluxing ethanol (40 ml) under argon atmosphere, *gem*-dibromocyclopropane (4 mmol) in 4 ml of ethanol was added. The resulting mixture was refluxed for a suitable time as indicated in the Table 1. The progress of the reaction was followed by GLPC (a Hitachi Model 163, using a 3 mm×2 m strainless steel column packed with 10% SE-30 on Celite 545 AW.) After completion of the reaction, the reaction mixture was cooled to room temperature, 50 ml of water was added, and the resulting mixture was left open to air with stirring. The solution became clear after about 3 h with the deposition of tellurium species as tellurium powder. It was then filtered through Celite 545 and the filtrate was extracted with three portions of hexane (30 ml). The extracts were washed with water, dried over Na_2SO_4, and evaporated to give the crude product, which was purified by Kugel-rohr distillation. The products were identified by comparison with authentic samples.

NaHSe was preprared by the method of Klayman[8] and used directly.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 58740233 from the Ministry of Education, Science and Culture.

The Alkylation of 1-Hydroxyanthraquinone with Visible-light Irradiation

Masahiro TAJIMA,* Haruo INOUE,† and Mitsuhiko HIDA†
General Education Course, Faculty of Engineering, Toyo University, Nakanodai Kujirai, Kawagoe 350
†*Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158*
(Received July 2, 1983)

Synopsis. The 2-position of 1-hydroxyanthraquinone was alkylated by the use of tertiary amine or methanol with visible-light irradiation (λ>400 nm).

Recently various new reactions of anthraquinones with visible-light irradiation have been reported and have attracte much attention.[1] We ourselves have now found a photochemical alkylation of 1-hydroxy-9, 10-anthraquinone (**1**) by the use of tertiary amine or methanol with visible-light irradiation.

When **1** in aerated methanol was irradiated with the light of λ>400 nm in the presence of triethylamine, 1-hydroxy-2-methyl-9,10-anthraquinone (**2**) was obtained in a 54% yield (Table 1). The photoproduct, **2**, was identified by means of elemental analysis, IR, ^{1}H NMR, UV, and visible-absorption spectra in comparison with those of an authentic sample.[2] In acetonitrile or 2-propanol, however, a 2-ethyl-substituted product (**3**) and its dimer (**4**) were obtained in the photoreaction with triethylamine. All the spectral data suggested that the structure of the dimer was **4**. A similar alkylation was also observed when trioctylamine was used as the tertiary amine (Table 1). Without a tertiary amine, the photoalkylation was not observed at all in any solvent. The alkyl group of the tertiary amine was transferred into the quinone nucleus except for the reaction in methanol, which gave the methylated product regardless of the amine used.

No alkylation occurred in the cases of 1-methoxyanthraquinone (**6**) and 1-acetylaminoanthraquinone (**7**) each of which has an absorption maximum (**6**: λ_{max}=380 nm; **7**: λ_{max}=398 nm in ethanol) similar to that of **1** (λ_{max}=403 nm in ethanol). 1-Hydroxyanthraquinones have been revealed to have tautomerism and acid-base equilibria in their excited states,[3] and their photochemical behavior has been expected to be different from that of the other derivatives, which are unable to be converted to the 1,10-quinonoid form. The alkylation may be connected with the tautomer of **1**, 9-hydroxy-1,10-anthraquinone. Although we have no substantial evidence for the reaction mechanism, the alkylation seems to be closely related to the reactions between the tertiary amine and the benzene derivertives[4] which are induced by an electron transfer from the amine to the excited aromatics, followed by proton transfer. In methanol, the methoxide ion presumably behaves as an electron donor, for no reaction occurs in the absence of the tertiary amine, which can cause a dissociation of the methanol.

Experimental

Light irradiation was carried out by means of a 500 W high-pressure mercury lamp (Eikosha) through a solution filter (saturated aqueous solution of $NaNO_2$ (5 mm path length)), until the **1** in aerated methanol, acetonitrile, or 2-propanol disappeared completely. The initial concentration were 5.0×10^{-4} (in methanol), 3.0×10^{-3} (in acetonitrile), and 1.0×10^{-3} mol dm^{-3} (in 2-propanol). After the solvent and amine had been evaporated from the irradiated solutions, the products were separated by silica-gel column chromatography, using benzene as the eluent, and then recrystallized from benzene.

The Dehydration of Ketohexoses into 5-Chloromethyl-2-furaldehyde. The Isolation of Diketohexose Dianhydrides

Kazuhiko HAMADA,* Hiroshi YOSHIHARA, Gohfu SUZUKAMO, and Osamu HIROAKI
Takatsuki Research Laboratory, Sumitomo Chemical Co., Ltd., Takatsuki, Osaka 569
(Received July 16, 1983)

Synopsis. The isolation of diketohexose dianhydrides, produced during the dehydration of D(−)-fructose and L(−)-sorbose with concentrated hydrochloric acid, in a mixture containing water, an organic solvent and a catalytic amount of a surface-active agent is described.

The chemistry of 2,5-disubstituted furan derivatives has attracted attention recently in connection with the transformation of carbohydrates into useful organic intermediates. We ourselves have previously reported an improved method for synthesizing 5-chloromethyl-2-furaldehyde (CFAL), a potent intermediate of synthetic pyrethroid, in a high yield from saccharides with mineral acids.[1] The present work will describe the isolation and structural determination of diketohexose dianhydrides produced during the early stage of the reaction.

Experimental

In a typical run, D(−)-fructose, 4 equiv. of concd hydrochloric acid, and a catalytic amount of a cationic surface-active agent ($C_{12}H_{25}N^+(CH_3)_3Cl^-$) were mixed and stirred at 15—20 °C for 2 h ("pre-reaction solution"). This "pre-reaction solution" was then added, drop by drop, to an inert organic solvent (benzene, toluene, or chlorobenzene), and maintained at 80 °C for about 30 min with stirring. After the temperature of the solution had been allowed to drop to room temperature under continuous stirring (1—2 h), a small amount of water and some active charcoal were added and the mixture was stirred further. The organic layer separated after filtration was washed with a saturated aqueous NaCl solution twice, dried over anhydrous sodium sulfate, and concentrated to obtain CFAL in a yield of 70%.[2]

Results and Discussion

The polarimetric analysis of the "pre-reaction solution" revealed that the addition of a catalytic amount of a surface-active agent accelerated the pyranose-furanose mutarotation rate of D(−)-fructose twice as much as in a solution containing D(−)-fructose and concd hydrochloric acid. The HPLC analysis of the "pre-reaction solution"[3] revealed that the two compounds, **1** and **2** (total 45%;[4] **1**/**2**=2.5/1) were equibrated with the remaining D(−)-fructose **3** (55%) at the end of the "pre-reaction." The isolation of these products using HPLC or cellulose-column chromatography[5] was carried out, and then they were studied spectroscopically. **1** and **2** were attributed to be difructose dianhydrides.[6] The D-fructose rings in **2** were found by periodate oxidation to be pyranoid moieties only; **1** possessed one pyranoid and one furanoid resudue. The proton signals of ^{1}H NMR[7] of the peracetylated difructose dianhydrides in benzene-d_6 were resolved to permit first-order analysis; each of these sugars was thus found to possess three rings, one substituted 1,4-dioxane and two D-fructose.[8] The conformations of the ring systems and the anomeric configurations were determined by means of ^{13}C NMR[7] (Table 1). The structures of **1** and **2** were found to be 1′,2-anhydro-1-*O*-α-fructopyranosyl-(1C)-β-D-fructofuranose-(E3) ($[\alpha]_D^{20}$ =−36°; *c* 3.5, H_2O) and 1′,2-anhydro-1-*O*-α-D-fructopyranosyl-(1C)-α-D-fructopyranose-(C1) ($[\alpha]_D^{20}$=−49°; *c* 3.1, H_2O) respectively, which coincided with the known difructose dianhydrides.[9] A ^{13}C NMR study[10] of the remaining D(−)-fructose fraction, **3** ($[\alpha]_D^{20}$=−41—−44°; *c* 2.6, H_2O, 2 h), by means of the measurement

of the integration of the peak intensities, clarified the equilibrium composition at 20 °C: α-D-fructofuranose 25%, β-D-fructofuranose 17%, β-D-fructopyranose 57%. It should be noted that the isolated **1** was converted into CFAL in a yield of only about 40%[2] under the present reaction conditions.

In the same way, the treatment of L(−)-sorbose with 4 equiv. of concd hydrochloric acid in the presence of a catalytic amount of a surface-active agent (*e.g.*, $C_{16}H_{33}N^+(CH_3)_3Cl^-$ or $C_{12}H_{25}N^+(CH_3)_3Cl^-$) under stirring at 20 °C for 4 h afforded two compounds, **4** and **5** (total 20%), equibrated with the remaining L(−)-sorbose (80%). The isolation of **4** and **5** using HPLC[3] was then carried, and the spectroscopic data were obtained. **4** and **5** were thus identified as disorbose dianhydrides.[11] The L-sorbose rings in **4** were found by periodate oxidation to be pyranoid moieties only; **5** possessed one furanoid and one pyranoid residue. A ^1H NMR[7] of the peracetylated disorbose dianhydrides (Table 2) showed the conformational structures of **4** and **5** to be 1′,2-anhydro-1-*O*-L-sorbopyranosyl-L-sorbopyranose and 1′,2-anhydro-1-*O*-L-sorbopyranosyl-L-sorbofuranose respectively. ^{13}C NMR was used to determine the anomeric configurations of the two compounds (Table 3). The structures of **4** and **5** were thus identified as new disorbose dianhydrides, 1′,2-anhydro-1-*O*-β-L-sorbopyranosyl-(1C)-β-L-sorbopyranose-(Cl) ($[\alpha]_D^{20}=-107°$; *c* 0.17, H_2O) and 1′,2-anhydro-1-*O*-α-L-sorbopyranosyl-(E3)-α-L-sorbopyranose-(1C) ($[\alpha]_D^{20}=-121°$; *c* 0.40, H_2O) respectively (Fig. 1).

The Formation and Solubility of Various Lead(II) Compounds Prepared by the Hydrolysis of Lead(II) Nitrate

Eiichi NARITA,* Hiroshi OKAYASU, and Hiroyuki NAITO†

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980

†Mizusawa Factory, Mizusawa Industrial Chemicals, Ltd., Nishime, Tsuruoka 999-75

(Received January 10, 1983)

Synopsis. Lead(II) nitrate was hydrolyzed by mixing with sodium hydroxide solutions at 25 and 50 °C. Four kinds of lead(II) hydroxide nitrates and two kinds of lead(II) oxides (massicot and litharge) were formed, depending on the pH, temperature, lead(II) nitrate concentration, and aging time of the suspension. The solubility of the products was also measured.

It is generally known that the kind of product obtained by the hydrolysis of lead(II) salts strongly affected by coexisting anions in the resulting suspension,[1,2] and that various basic lead(II) compounds are formed according to the formation conditions.[3-11] Among these studies, the hydrolysis of lead(II) chloride[3] and lead(II) acetate[4] have been investigated in detail. On the hydrolysis of lead(II) nitrate, the formation of various lead(II) hydroxide nitrates has been reported by earlier workers.[5-9] However, some of them have been thought to be ambiguous. Although recent results on the chemical composition of the products were reported by Kwestroo *et al.*[10] and Brusset *et al.*,[11] both results were partially different. Therefore, reliable information about the kind of the product from the hydrolysis of lead(II) ion in the presence of nitrate ion is needed, together with data about these particle characteristics and solubilities. This study will deal with the hydrolysis of lead(II) nitrate, especially with the effects of changes in pH, temperature, concentration of lead(II) nitrate and aging time on the kind, particle characteristic and solubility of the products.

Experimental

A 300 cm^3 acrylic resin cylindrical reactor was equipped with a reflux condenser, a dropping funnel, a nitrogen gas inlet tube, a glass electrode of a pH meter, a thermometer, and a magnetic stirrer. A 50 cm^3 portion of NaOH solutions was transferred to the reactor and maintained at 25±0.2 or 50±0.2 °C. Then, a 200 cm^3 portion of $Pb(NO_3)_2$ solution in the dropping funnel was added to the stirred NaOH solution. Total lead concentration in the suspension obtained after the mixing was set to be 0.05 and 0.5 M (1 M=1 mol dm^{-3}). Unless otherwise stated, the resulting suspension was stirred for a further 1 h. All procedures were carried out under nitrogen atmosphere. After measuring the pH of the suspension, the product was filtered off, washed with distilled water, and then dried at room temperature under reduced pressure. The identification of the product and the quantitative analysis of binary mixtures were made by X-ray diffractometry using a Rigaku Denki Geigerflex 2013 with Ni filtered Cu $K\alpha$ radiation, with 30 kV and 10 mA. The observation of the product was performed using a Hitachi-Akashi Scanning Electron Microscope MSM 4C-102. The solubility of the product was determined by analyzing the filtrate for lead ion with atomic absorption spectroscopy.

Results and Discussion

The kind and solubility of the products at various pH values of the suspension are shown in Fig. 1. On the hydrolysis of 0.5 M $Pb(NO_3)_2$ at 25 °C (A in Fig. 1), the basicity in the chemical composition of the precipitated lead(II) hydroxide nitrates increased with increasing pH of the suspension, namely $Pb(NO_3)_2 \cdot Pb(OH)_2$ (phase **a**, white), $2Pb(NO_3)_2 \cdot 5Pb(OH)_2$ (phase **b**, white), and $Pb(NO_3)_2 \cdot 5Pb(OH)_2$ (phase **d**, white), or a binary mixture of these three at pH range of 6—13. The pH range of the formation of binary mixtures was negligible. This tendency was the same as the results reported by earlier workers.[10,11] The X-ray diffraction patterns of these lead(II) hydroxide nitrates were identical with those reported by Kwestroo *et al.*[10] However, the formation of $Pb(NO_3)_2 \cdot 2Pb(OH)_2$ and $3Pb(NO_3)_2 \cdot 7Pb(OH)_2$ identified as an intermediate by Brusset *et al.*[11] from potentiometric and conductimetric measurements was not observed here after aging of 1 h, because of the unstability of these compounds. If the resulting suspension contains no anions, for example, in the case of the hydrolysis of lead(II) alkoxide,[12,13] massicot (orthorhombic), litharge (tetragonal), or hydrous lead(II) oxide ($3PbO \cdot H_2O$, tetragonal) should be formed over the same pH range. It was also found that the solubility of lead(II) hydroxide nitrates decreased with increasing basicity of products and was minimized at the pH range of 10—11. At the pH values higher than 11, the solubility gradually increased, and massicot (phase **M**, yellow) and litharge (phase **L**, red) were formed. Figure 2 shows the scanning electron micrographs of typical lead(II) hydroxide nitrates obtained here. The particle sizes were considerably smaller than those of massicot (10—20 μm) and litharge (5—10 μm).

On the hydrolysis of 0.05 M $Pb(NO_3)_2$ at 25 °C (B in Fig. 1), the pH range of the formation of these lead(II) hydroxide nitrates was shifted, on the whole, to the pH side lower than that of A in Fig. 1. It was also found that the pH range of the formation of massicot was broadened. This means that the stable phase is easily formed by decreasing the concentration of $Pb(NO_3)_2$. The particle sizes of these precipitates became progressively greater as the concentration of $Pb(NO_3)_2$ became lower, as shown in Fig. 2(e), whereas no changes in the particle shape were observed.

At a higher temperature (50 °C, C in Fig. 1), the pH range of the formation of these lead(II) hydroxide nitrates was further shifted to the lower pH side and the particle sizes of these precipitates further increased, as shown in Fig. 2(f).

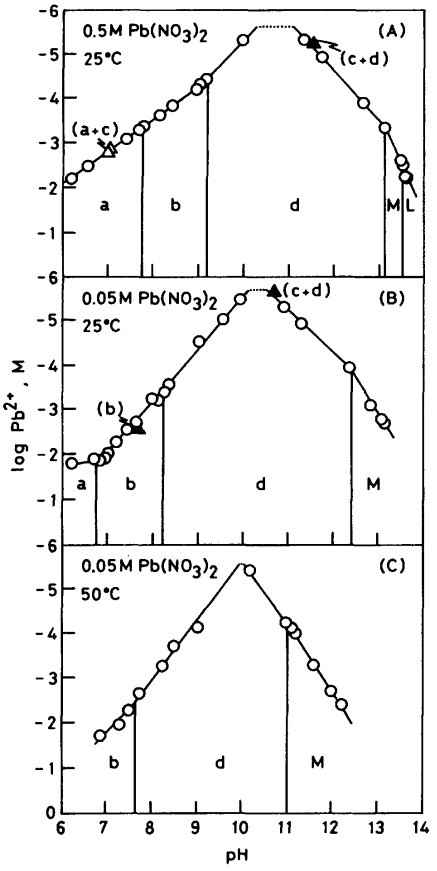

Fig. 1. Solubilities of lead(II) compounds at various pH values of the suspensions.
(a): $Pb(NO_3)_2 \cdot Pb(OH)_2$, (b): $2Pb(NO_3)_2 \cdot 5Pb(OH)_2$, (c): $Pb(NO_3)_2 \cdot 3Pb(OH)_2$, (d): $Pb(NO_3)_2 \cdot 5Pb(OH)_2$, (M): massicot, (L): litharge.
Aging time(h): ○ 1, △ 8, ▲ 24.

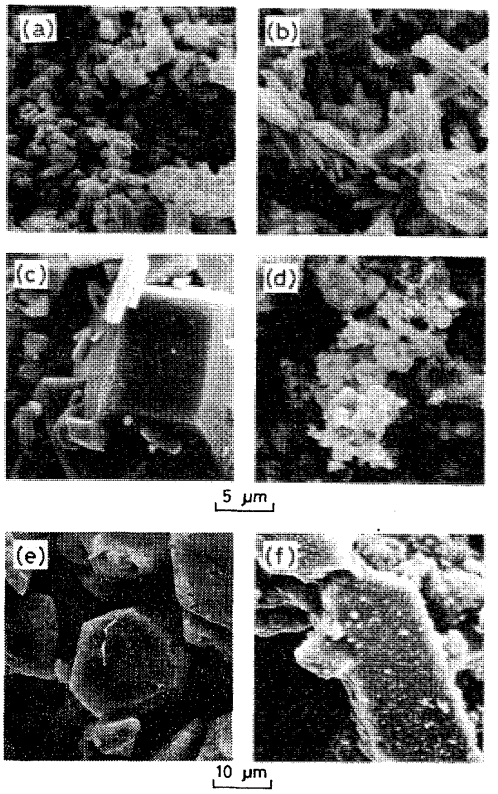

Fig. 2. Scanning electron micrographs of lead(II) hydroxide nitrates prepared by hydrolysis of lead(II) nitrate.
(a)—(d): samples in Fig. 1(A), (e): sample in Fig. 1(B), (f): sample in Fig. 1(C).
(a),(e): $Pb(NO_3)_2 \cdot Pb(OH)_2$, (b),(f): $2Pb(NO_3)_2 \cdot 5Pb(OH)_2$, (c): $Pb(NO_3)_2 \cdot 3Pb(OH)_2$, (d): $Pb(NO_3)_2 \cdot 5Pb(OH)_2$.

When the aging time was prolonged, the initial pH of the suspension of only 8—9 was occasionally changed; one of the reasons for this phenomenon is thought to be the occurrence of another phase during the aging. The kind and solubility of the products were changed with variation of pH. However, the solubility was found to change along with the solubility curves shown in Fig. 1 and there was no difference with the solubility values measured after 1 h. One other phase, $Pb(NO_3)_2 \cdot 3Pb(OH)_2$ (Phase c, white) was formed together with $Pb(NO_3)_2 \cdot 5Pb(OH)_2$, the formation ratio of c/d being as about 4 after 24 h. This phase was also formed together with $Pb(NO_3)_2 \cdot Pb(OH)_2$, the formation ratio of c/a being as about 6 after 8 h. Kwestroo *et al.*[10] identified it only in diluted reaction mixtures. In this experiment it was obtained by aging the resulting mixtures for a while. As can be seen in Fig. 2(c), the particle size of $Pb(NO_3)_2 \cdot 3Pb(OH)_2$ was larger than those of the coprecipitated $Pb(NO_3)_2 \cdot Pb(OH)_2$ and $Pb(NO_3)_2 \cdot 5Pb(OH)_2$.

The authors wish to thank Prof. Taijiro Okabe of the Department of Applied Chemistry, Tohoku University, for his helpful discussion.

Viscosity of the Quaternary Gaseous Mixture He-N_2-O_2-CO_2

Ali BOUSHEHRI* and Shahrbanoo RAHMANSETAYESH
Department of Chemistry, Shiraz University, Shiraz, Iran
(Received December 6, 1982)

Synopsis. The kinetic theory expressions for multicomponent gas mixtures are used in conjunction with the law of corresponding states formulated by Kestin, Ro and Wakeham to generate the viscosities of the quaternary gaseous mixture He-N_2-O_2-CO_2. The calculated viscosities are compared with direct measurements performed in a capillary flow apparatus.

The extended law of corresponding states of Kestin, Ro, and Wakeham[1-3] has provided the correlation of low-density equilibrium and transport properties of the monatomic gases and their mixtures with an uncertainty commensurate with the experimental accuracy. In an earlier paper[4] it has been established that the viscosity of the quaternary mixture N_2-O_2-CO_2-N_2O conforms to the extended law of corresponding states. In this work the kinetic-theory expressions for multicomponent gas mixture are used in conjunction with the law of corresponding states and the appropriate scaling parameters σ_{ij} and ε_{ij} to generate the viscosities of He-N_2-O_2-CO_2 mixture. The calculated viscosities are compared with direct measurements made by a capillary flow method at temperatures 0 and 40 °C. For the viscosity we can employ the known formula[5]

$$\mu(T) = (-1)\begin{vmatrix} H_{11} & H_{12}\cdots H_{1n} & X_1 \\ H_{21} & H_{22}\cdots H_{2n} & X_2 \\ H_{n1} & H_{n2}\cdots H_{nn} & X_n \\ X_1 & X_2\cdots X_n & 0 \end{vmatrix} \Bigg/ \begin{vmatrix} H_{11} & H_{12}\cdots H_{1n} \\ H_{21} & H_{22}\cdots H_{2n} \\ H_{n1} & H_{n2}\cdots H_{nn} \end{vmatrix}^{-1}, \quad (1)$$

where X_i is the fraction of component i, and the element H_{ij} are written as:

$$H_{ii} = \frac{X_i}{\mu_i} + \sum_{\substack{k=1 \\ k\neq i}}^{n} \frac{2X_iX_k}{\mu_{ik}} \frac{M_iM_k}{(M_i+M_k)^2}\left(\frac{5}{3A^*_{ik}} + \frac{M_k}{M_i}\right), \quad (1a)$$

$$H_{ij} = -\frac{2X_iX_j}{\mu_{ij}} \frac{M_iM_j}{(M_i+M_j)^2}\left(\frac{5}{3A^*_{ij}} - 1\right) i \neq j. \quad (1b)$$

Here M_i represents the molecular weight of species i in the mixture. The interaction viscosity μ_{ij} is determined from:

$$\mu_{ij} = 5/16(k\,M_{ij}\,T/\pi N)^{1/2}(1/\sigma_{ij}^2\Omega_{22}), \quad (2)$$

where $M_{ij}=2M_iM_j/(M_i+M_j)$ and σ_{ij} is a distance scaling parameter.

It should be mentioned that the recently determined scaling parameters for rare-gas pairs by Kestin and coworkers perform a discrepancy by a factor of 1.016 in the distance of zero potential.[6,7]

The best empirical expressions for the universal functions of the single parameter $T^*=k_BT/\varepsilon_{ij}$ determined by Kestin *et al.* are given as:

$$\Omega_{11} = \Omega^{(1,1)*} = \exp[0.347 - 0.444(\ln T^*) + 0.093(\ln T^*)^2 - 0.010(\ln T^*)^3], \quad 0.5<T^*<25, \quad (3)$$

$$\Omega_{22} = \Omega^{(2,2)*}/f_\mu = \exp[0.45667 - 0.53955(\ln T^*) + 0.18265(\ln T^*)^2 - 0.03629(\ln T^*)^3 + 0.00241(\ln T^*)^4], \quad 1<T^*<90, \quad (4)$$

where f_μ is higher-order correction to the viscosity and:

$$A^* = \Omega^{(2,2)*}/\Omega^{(1,1)*} \simeq \Omega_{22}/\Omega_{11}.$$

The quantities Ω_{22} and A^*_{ij} are functionals of the potential energy function describing the interaction of molecular pairs. Equations 1—4 together with a knowledge of the scaling parameters σ_{ij} and ε_{ij} characteristic of the i-j interaction permit the evaluation of the viscosity μ of He-N_2-O_2-CO_2 at any composition and any desired temperature.

With the aid of the scaling factors, the universal functions provide us with a sharp criterion which permits us to disqualify guessed analytic forms of the pair potential. The (11-6-8) potential proposed by Hanley and Klein[8] is acceptable as a correlator data (for $1\leq T^*\leq 20$), even this potential fails for helium at high reduced temperatures. For the temperature range considered here, we are able (within the precision of the experimental data) to neglect the quantum effects for the present gaseous mixtures.

Experimental

The measurements reported here were made with a constant-volume gas viscometer similar to that of McCoubrey and Singh.[9] The viscometer bulb and capillary were thermostated in a water bath except at 0 °C where an ice-slush was used. The bath was controlled to within ±0.1 °C. Pressures were measured with a travelling microscope reading to 0.05 mm and the times with a precision stopwatch (calibrated in tenths of a second). The apparatus constant at each temperature was determined from the wellknown Poiseuille equation modified for slip correction. The apparatus constant at each temperature was determined using nitrogen and checked with oxygen (whose viscosities are known). The pressure range in these measurements was 22—11 cm mercury.

Nitrogen was supplied by the Matheson Co. Oxygen and helium were obtained from Fluka Co. Carbon dioxide was

TABLE 1. VISCOSITY OF QUATERNARY MIXTURES

Compn (mole fraction)				Temp	Viscosity/μP		
He	N_2	O_2	CO_2	°C	Exptl	Calcd	Deviation(%)
0.10	0.50	0.25	0.15	0	178.5	176.3	1.25
				40	197.2	197.0	0.10
0.25	0.25	0.25	0.25	0	182.6	185.8	−1.72
				40	208.6	207.9	0.34

supplied by the Chemical Co., Shiraz, Iran. The minimum purities were 99%. For each mixture, viscosity results at each temperature were averaged from at least three runs.

Results and Discussion

The experimental results for He–N_2–O_2–CO_2 are given in Table 1. The viscosity of the two quaternary mixtures can be calculated with the aid of Eqs. 1—4 and scaling parameters, for the gases He, N_2, O_2, and CO_2, taken from Ref. 10. Evalution of the viscosity is made by using computer program developed by Kestin and co-workers. The scheme presented here may be used for the generation of viscosity for any mixtures of these same gases.

Concentration Dependence of Transport Properties of Glass-forming Melts

Sheik MAHIUDDIN and Kochi ISMAIL*
Department of Chemistry, North-Eastern Hill University, Bijni Campus, Laitumkhrah, Shillong 793003, India
(Received March 10, 1983)

Synopsis. The Vogel-Tammann-Fulcher (VTF) equation has been derived from the Adam-Gibbs (AG) model after accounting for the empirical nature of the temperature dependence of configurational heat capacity. An expression for describing the concentration dependence of the preexponential parameter of the VTF equation and another two-parameter isothermal equation for describing such dependences of transport properties are obtained. The applicability of the newly derived equations has been verified using the data available for several hydrate melts. The present study emphasizes the view that the glass transition temperature controls the concentration dependence of transport properties of glass-forming melts.

A large amount of literature[1-8] on the transport properties of binary molten systems containing at least one component as the hydrated salt has been accumulated. The temperature dependence of the transport properties of all such molten salt systems has been described in terms of the VTF equation

$$Y = A_y T^{-1/2} \exp[-B_y/(T-T_{oy})], \quad (1)$$

where Y is the transport property, either fluidity (ϕ) or equivalent conductance (Λ). T is the absolute temperature. A_y, B_y, and T_{oy} are the three constant parameters. Empirically these three parameters have been found to have dissimilar types of concentration dependence. B_y remains almost independent of concentration in binary molten systems containing either anhydrous or hydrated salts (or both). The ideal glass transition temperature, T_{oy} has been found to vary linearly with concentration in almost all the binary melts studied.

On the other hand, the dependence of A_y parameter on concentration is comparatively less understood and the nature of this dependence is found to be inconsistent in the various systems studied. For instance, studies made by Islam and coworkers[4-7] have revealed a linear dependence of A_y on concentration. Instead, Moynihan *et al.*[3] observed a linear variation of $\ln A_y$ with concentration in the molten mixture of calcium nitrate tetrahydrate and cadmium nitrate tetrahydrate and this trend was found to be contrary to the be havior expected from the free volume model.[9]

The objective of this paper is therefore to obtain an analytical expression to describe the observed trend in the variation of A_y with concentration and then to derive an isothermal equation for representing the concentration dependence of fluidity and conductance of binary mixture containing hydrate melt or melts. The approach adopted to achieve this is to insert the temperature dependence of heat capacity in the AG equation.[10]

Derivation of the New Isothermal Equation. As adopted by others,[11-13] in the absence of a rigorous theoretical description for the variation of heat capacity, C_p of molten salt systems with temperature, an alternative approach to account for the temperature dependence of configurational heat capacity, ΔC_p would be to take into cognizance the general trend in the empirical behavior of C_p with T. It is interesting to note from the reported heat capacity data for hydrate melts[14] and molecular liquids[12,15] that their C_p exhibits a linear dependence on T in the glassy as well as liquid regions. Accordingly, ΔC_p may be written as

$$\Delta C_p = \Delta C_o + \Delta C_1(T-T_o), \quad (2)$$

where $\Delta C_o = C_{ol} - C_{og}$ and $\Delta C_1 = C_{1l} - C_{1g}$. C_{ol} is the extrapolated heat capacity of the melt at T_o, C_{1l} is the slope of the linear variation of melt heat capacity with T, C_{og} is the heat capacity of the corresponding glass at T_o, C_{1g} is the slope of the linear variation of glass heat capacity with temperature. It may be noted that ΔC_1 becomes a negative, zero, or positive term depending upon the relative rates of change (linear) of C_p of mels and glass with T. For example, in $Ca(NO_3)_2 \cdot 4H_2O$,[14] $Cd(NO_3)_2 \cdot 4H_2O$,[14] $Mg(OAc)_2 \cdot 4H_2O$,[14] *o*-terphenyl,[12,15] *o*-benzylphenol,[12] and phenyl salicylate[12] ΔC_1 is found to be a negative quantity and Eq. 2 resembles with the function used for ΔC_p by Laughlin and Uhlmann[12] as well as with one of the probable functiont suggested by Privalko.[13] Substituting Eq. 2 in the AG equation[10] and then by making a few approximations, we get for Y an expression of the form

$$Y = A_{1y} T^{-1/2} \exp(B_{1y}/T_{oy}) \times \exp[-B_{1y}(1-\Delta C_1 T_{oy}/\Delta C_2)/(T-T_{oy})], \quad (3)$$

where A_{1y} and B_{1y} are constant parameters and $\Delta C_2 = \Delta C_o - \Delta C_1 T_o$. It is interesting to find that Eq. 3 is similar to the VTF equation and comparison of Eqs. 1 and 3 gives

$$A_y = A_{1y} \exp(B_{1y}/T_{oy}), \quad (4)$$

$$\text{and } B_y = B_{1y}[1-(\Delta C_1/\Delta C_2)T_{oy}]. \quad (5)$$

The empirical fact that B_y remains almost independent of concentration appears to imply that in molten salt systems the term $\Delta C_1/\Delta C_2$ is proportional to $1/T_{oy}$. By taking into account in Eq. 3 the constancy of B_y and the linear variation of T_{oy} with mole fraction of the solute, x, we obtain an isothermal expression for describing the concentration dependence of Y which approximates after neglecting the higher powers of x to

$$Y = A_y^* \exp(\pm Q_y^* X), \quad (6)$$

A_y^* and Q_y^* are empirical constants. The negative sign of the exponent in Eq. 6 is valid when T_o increases with x and the positive sign corresponds to the case of T_o decreasing with x.

On the Application of Eqs. 5 and 7. To justify the suitability of Eq. 4 for describing the variation of A_y parameter with concentration, exemplary plots of $\ln A_y$ *versus* $1/T_{oy}$ using their reported values are drawn in Fig. 1 for some of the molten mixtures.[3,4b,5,6] The linearity of these plots justifies the validity of Eq. 4. Furthermore, on substituting the linear concentration dependence of T_o (decrease or increase) in Eq. 4 it approximates to (after

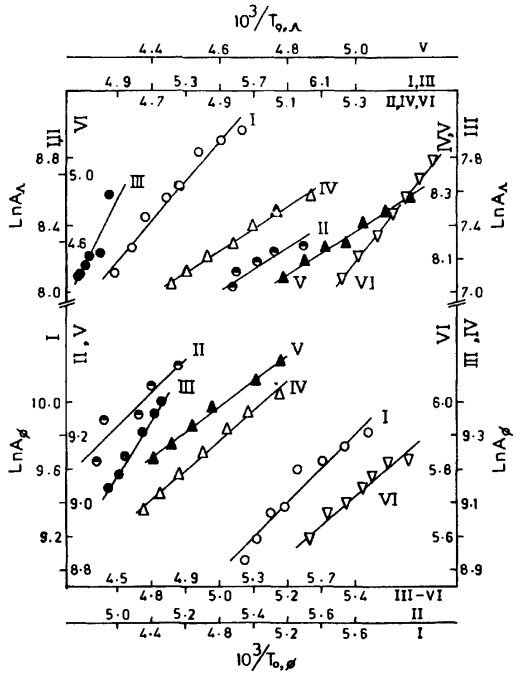

Fig. 1. Plots of $\ln A_y$ *versus* $1/T_{oy}$ for binary melts. The plots I to VI correspond to the six systems given in Table 1 and are in the same order.

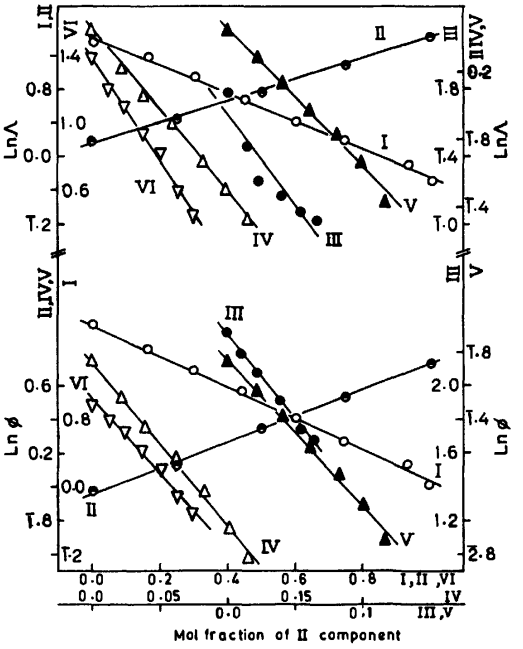

Fig. 2. Plots of $\ln Y$ *versus* mole fraction of the second component for binary melts. The plots I to VI correspond to the six systems given in Table 1 and are in the same order.

neglecting higher powers of x)

$$\ln A_y = A'_y \pm B'_y X, \qquad (7)$$

where A'_y and B'_y are another set of constant parameters. It is interesting to find that Eq. 7 explains the empirical behavior of A_y with concentration in molten $Ca(NO_3)_2 \cdot 4.09H_2O + Cd(NO_3)_2 \cdot 4.07H_2O$ mixture which could not be explained[3] on the basis of the free volume model[9] as mentioned above.

To verify the applicability of Eq. 6, the reported fluidity and equivalent conductance data at 313 K for the various molten mixtures cited above are least-squares fitted to Eq. 6. The values of A_y^* and Q_y^* so obtained are listed in Table 1. It is apparent from Table 1 and from the linearity of the plots of $\ln Y$ *versus* x (Fig. 2) that Eq. 6 describes satisfactorily the concentration dependences of transport properties of binary molten mixtures containing hydrate melts. It is worthwhile to note that the isothermal Eq. 6 has only two adjustable parameters unlike the cases with the expressions reported earlier.[4b,16,17] The applicability of Eqs. 4 and 6 also reinforces the view that the concentration dependence of transport properties of binary melts is completely governed by the behavior of the ideal glass transition temperature with concentration.

TABLE 1. BEST-FIT PARAMETERS FOR Eq. 6 FOR THE FLUIDITY AND EQUIVALENT CONDUCTANCE OF GLASS-FORMING MELTS

Melt	A_y^*	Q_y^*	Std. dev. in $\ln Y$
$Zn(NO_3)_2 \cdot 6.33H_2O + Ca(NO_3)_2 \cdot 4.1H_2O$	1.9401	−1.8714	0.029
	(1.4351)	(−1.6966)	(0.046)
$Ca(NO_3)_2 \cdot 4.09H_2O + Cd(NO_3)_2 \cdot 4.07H_2O$	−0.0498	0.7681	0.017
	(−0.2163)	(0.6215)	(0.012)
$Ca(NO_3)_2 \cdot 3.91H_2O + CoCl_2$	−0.1054	−9.8721	0.020
	(−0.3662)	(−10.6646)	(0.106)
$Cd(NO_3)_2 \cdot 4.1H_2O + NiCl_2$	0.7641	−10.0624	0.020
	(0.4589)	(−9.6243)	(0.016)
$Cd(NO_3)_2 \cdot 4.1H_2O + CoCl_2$	0.7797	−9.0010	0.036
	(0.4891)	(−8.4575)	(0.042)
$Zn(NO_3)_2 \cdot 6.27H_2O + CoCl_2$	1.9078	−2.1327	0.038
	(1.3715)	(−3.0096)	(0.033)

Parameters for equivalent conductance are within the parentheses.

Desulfurization of *N,N'*-Diarylthioureas by Lead Tetraacetate Oxidation

Abhijit DEBROY, Sujit NANDY MAZUMDAR, Parag D. BARUA, and Mahinder P. MAHAJAN*
Department of Chemistry, North-Eastern Hill University, Shillong 793003, India
(Received January 5, 1983)

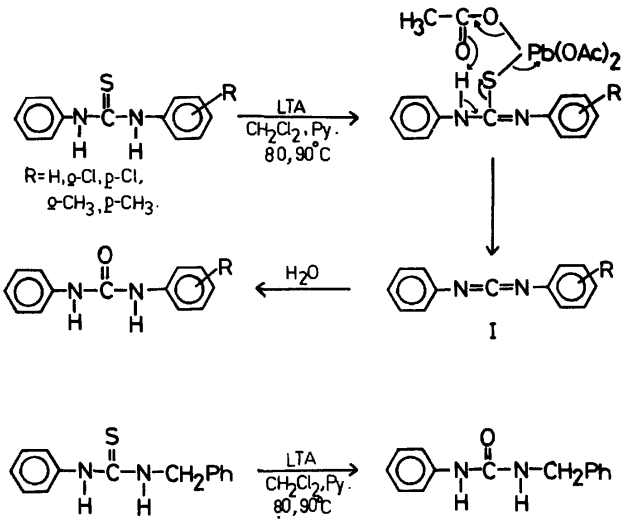
Synopsis. Lead tetraacetate oxidation of *N,N'*-diarylthioureas in refluxing dichloromethane and pyridine gave the corresponding *N,N'*-diarylureas. Sulfur was isolated during each oxidation reaction.

One of the interesting oxidation reactions in organic chemistry is the oxidation of thioureas. Depending on the substitution pattern of thioureas, the oxidizing agent, the polarity of the medium and reaction conditions, a variety of products have been isolated.[1-3]

Suitable synthetic methods are available for the chemical transformation of carbonyl into thiocarbonyl functions. In order to increase the synthetic versatility of this reaction investigation of the proper reagents for carrying out reverse conversion, *i.e.*, thiocarbonyl into carbonyl, is considered to be of great importance. Moreover, because of the discovery of 4-thiouridine in t-RNA of *E. Coli*,[4] it has recently inspired many groups to search for mild reagents for this transformation in order to elucidate the biochemical role of this minor component of t-RNA.[5] Apart from earlier reported reagents, a number of reagents have recently been discovered for conversion of thiocarbonyl compounds to carbonyl analogues. Almost all of them, having different limitations, have been used with varying degrees of success and include, DMSO–acids,[6,7] DMSO–iodine,[8] oxonium tetrafluoroborate,[9] manganese dioxide,[3] mesitylenecarbonitrile oxide,[10] diaryl selenooxides,[11,12] diaryl telluroxide,[13] benzeneseleninic anhydride,[14] thiophosgene,[15] potassium *t*-butoxide/Br_2 or I_2[16,17] and trimethyl phosphite or iron(O) pentacarbonyl.[18]

The oxidation of *N,N'*-diarylthioureas with lead tetraacetate/acetic acid has been reported to give disulfides.[19] Considering the significance of desulfurization reactions, *i.e.*, conversion of thiocarbonyl compounds into their carbonyl analogues, it was thought worthwhile to reinvestigate this reaction with the specific idea of carrying out this transformation. Also, keeping in mind the dependence of oxidation product on reaction conditions it was resolved to achieve this transformation by carrying out the oxidation in aprotic medium.

Thus in our laboratory we have carried out the oxidation of *N,N'*-diarylthioureas with lead tetraacetate in dichloromethane and pyridine at 80—90 °C. In every case, the corresponding urea and sulfur were isolated from the reaction mixture. The products were characterised with the help of IR spectra and melting points. The IR spectra of these compounds showed intense absorption in 1655—1700 cm^{-1} region due to carbonyl stretching. The desulfurization reaction and the formation of ureas is believed to proceed through carbodiimide intermediate(I) as shown in the Scheme 1.



Scheme 1.

Experimental

Starting Materials. Lead tetraacetate was prepared according to literature method.[20] All the *N,N'*-diarylthioureas were prepared by mixing phenyl isothiocyanate and corresponding amines in molecular ratio in ethanol and stirring the mixture at room temperature.

Oxidation of N,N'-*Diphenylthiourea.* To a stirred solution of *N,N'*-diphenylthiourea (2.28 g; 0.01 mol) in dichloromethane (25 cm^3) and pyridine (5 cm^3) was added lead tetraacetate (4.88 g; 0.011 mol) in small portions over a period of 20 min. After complete addition of lead tetraacetate, the reaction mixture was refluxed in an oil bath (80—90 °C) for 1.5 h. The solvent was then removed under reduced pressure and the residue so obtained was chromatographed over a silica-gel column. Elution of the column with hexane gave 0.2 g of sulfur, identified by its undepressed mixed mp. After removal of the sulfur, further elution of the column with a mixture (4 : 1) benzene and ethyl acetate gave 1.8 g (86%) of a solid, identified as *N,N'*-diphenylurea, which was recrystallized from a mixture (1 : 1) of benzene and ethanol, mp 235—236 °C. (Lit,[21] mp 237 °C). IR (Nujol): ν_{max}: 3400 (ν_{N-H}); 3060, 3020, 2970 (ν_{C-H}); 1655 ($\nu_{C=O}$) and 1610, 1580 ($\nu_{C=C}$). These IR bands are common in all the *N*-phenyl-*N'*-arylureas reported here.

Other *N*-phenyl-*N'*-arylureas (Table 1, 2—6) were obtained similarly by lead tetraacetate oxidation of the corresponding *N*-phenyl-*N'*-arylthioureas.

Table 1. *N*-Phenyl-*N'*-arylureas

Sl. No.	Name of the compound	Mp θ_m/°C (Lit)	Yield %
1	*N,N'*-Diphenylurea	235—236 (237)[21]	86
2	*N*-Phenyl-*N'*-(*o*-chlorophenyl)urea	225	65
3	*N*-Phenyl-*N'*-(*p*-chlorophenyl)urea	236 (238)[21]	73
4	*N*-Phenyl-*N'*-benzylurea	166	73
5	*N*-Phenyl-*N'*-(*o*-tolyl)urea	193 (195)[21]	68
6	*N*-Phenyl-*N'*-(*p*-tolyl)urea	220 (219)[3]	73

Studies on the Mechanism of Zeolite X Crystallization. II. Effect of Silica Sources of Starting Materials on the Gas-phase Adsorption at Solid Phases

Ryozi Hino,* Hiroyasu Aoi, and Kenzi Toki
Department of Chemistry, Faculty of Science, Shimane University, Nishikawatsu, Matsue 690
(Received January 31, 1983)

The mechanism of zeolite X crystallization was studied by using two kinds of silica sources, tetraethyl orthosilicate and silica sol. The adsorption of benzene and cyclohexane was subjected to a measurement to clarify the distribution of cation Na^+ and the change in the pore structure and surface of solid phases with reaction progress. The relation between specific surface area and reaction time has been revealed by means of adsorption of nitrogen gas, benzene, and cyclohexane as follows: 1) In the early stage of reaction or in the amorphous solid state, $N_2 \approx C_6H_6 \approx C_6H_{12}$ for tetraethyl orthosilicate and $N_2 \approx C_6H_6 > C_6H_{12}$ for silica sol; 2) for crystals in the early stage, $N_2 > C_6H_{12} > C_6H_6$ for tetraethyl orthosilicate and $N_2 > C_6H_{12} \approx C_6H_6$ for silica sol; 3) for crystals in a sufficiently developed stage, $N_2 \gg C_6H_{12} > C_6H_6$ for tetraethyl orthosilicate and $N_2 \approx C_6H_6 > C_6H_{12}$ for silica sol. In the case of silica sol, the crystallization mechanism is based on inhomogeneous nucleation; a number of critical nuclei may be generated but their dimension is small. In the case of tetraethyl orthosilicate critical nuclei are fewer in number and larger in size than in the case of silica sol; the mechanism of crystallization is based on homogeneous nucleation.

Zeolites are aluminosilicate crystals which are easily formed from gels composed of silica, alumina, soda, and water. However, because of the complexity of aluminosilicate gel in structure and reaction, the process of zeolite crystallization has not yet been made clear.

Many investigations concerning zeolite crystallization have been done in recent years.[1-10] Two representative hypotheses exist as follows: One is a zeolite crystallization which occurs in the solid phase in such a way that crystals are formed through interaction between the solid and liquid phases of a gel. This is supported by Breck and Flanigen,[5] McNicol *et al.*,[11] and Aiello *et al.*[12] The other is a crystallization which occurs in the liquid phase in such a way that an amorphous precursor is formed from a reaction mixture and then caused its constituents to be dissolved in the liquid phase prior to crystallization. This has been supported by Kerr,[1] Ciric,[7] Culfaz and Sand,[2] and Cournoyer *et al.*[13]

Some additional investigations in support of the latter hypothesis have recently been reported by Ueda and Koizumi[10] and Kageyama *et al.*[9] They pointed out that the presence of the solid-gel phase is not always needed in the crystallization process of zeolite Y, because crystals are grown in homogeneous solution. But, in general, the presence of solid phases as transient intermediates has been observed in many systems for zeolite synthesis.

The present authors[14,15] have reported that sources of silica remarkably influence the crystallization process. In this study, we made measurements on the adsorption of benzene or cyclohexane vapor to clarify the distribution of cation Na^+ and the change in pore and surface with reaction progress, and made an inference on the change in solid phases by considering both the interaction between the cation and the π-electrons of benzene and the physical adsorption of cyclohexane.

Experimental

The preparation of specimens, the chemical analysis of solid phases, and the adsorption of nitrogen gas were conducted as described in previous papers.[14,15] The absorption of benzene or cyclohexane vapor was subjected to volumetric measurements at 25 °C. The pretreatment of specimens was carried out in such a sequence that specimens were placed in a bath thermostated at 110 °C for 24 h, heated at 300 °C for 2 h, and finally degassed under a reduced pressure of 1×10^{-4} mmHg (1 mmHg≈133.322 Pa) at 300 °C. The adsorbates, benzene and cyclohexane, were obtained by purifying commercial guaranteed reagents by distillation.

Results and Discussion

The change in the chemical composition of solid phases with reaction time is shown in Fig. 1. Figure 1 indicates analytical values obtained for the solid phases during the process of aging with mechanical stirring at room temperature for 6—72 h followed by standing in the bath thermostated at 85 °C for 74—96 h. As can be seen from Fig. 1, the change in the analytical values for the solid phases derived from silica sol is abrupt as compared with those derived from tetraethyl orthosilicate.

The solid phases derived fom tetraethyl orthosilicate contain all constituents uniformly throughout the

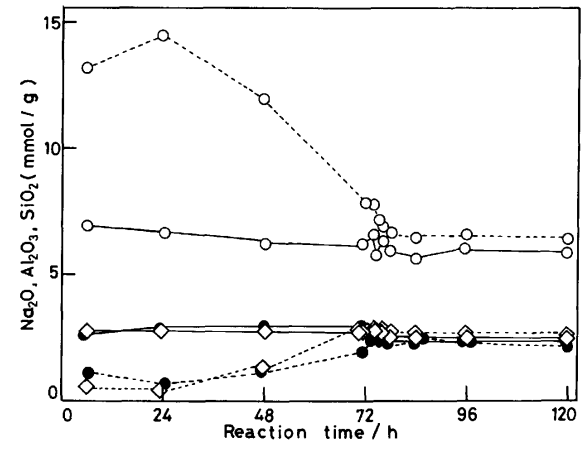

Fig. 1. Relation between reaction time and component concentrations in the solid phase.
——: Si $(OC_2H_5)_4$, ------: silica sol, ○: SiO_2, ◇: Al_2O_3, ●: Na_2O.

course of reaction. For example, the SiO_2/Al_2O_3 molar ratios of the solid phases obtained at 24, 72, and 96 h are 32.7, 2.89, and 2.60 in the case of silica sol in contrast to 2.34, 2.40, and 2.44 in the case of tetraethyl orthosilicate; thus the constituent concentration of the solid phases in the latter case changes little as compared with that in the former case.

Adsorption isotherms with benzene and cyclohexane vapors on the solid phases derived from tetraethyl orthosilicate are shown in Figs. 2 and 3, respectively. The adsorption isotherms in each figure are classified into three groups. The solid phases (24E-75E, where the figure denotes the reaction time and the symbol E indicates that the solid phase concerned has been obtained from tetraethyl orthosilicate) obtained in the early stage of reaction were amorphous and capable of adsorbing the vapors only in small quantities. The amount adsorbed increased greatly with the progress of crystallization.

The crystals obtained in the early stage (76E) and a sufficiently developed stage (84E-96E) gave the same adsorbed quantities at a relative pressure of 0.5 for benzene and at 0.25 for cyclohexane. Above these relative pressures, the former crystal caused no increased adsorption, whereas the latter ones resulted in adsorption in large quantities. This different behavior sug-

gests a difference in the developments of pore structure of the crystals.

The adsorption isotherms of benzene and cyclohexane on the solid phases derived from silica sol are shown in Figs. 4 and 5, respectively. The adsorption isotherms in each figure may be classified into three groups in the same way as in the case of tetraethyl orthosilicate. The solid phases in the early stage (6C-74C, where the figure denotes the reaction time and the symbol C indicates that the solid phase concerned has been derived from silica sol) adsorbed fairly large quantities of benzene and cyclohexane, as compared with the case of tetraethyl orthosilicate. In addition, the amount adsorbed increased steeply with increasing relative pressure. These features are consistent with the results obtained from a nitrogen-gas adsorption, that is, the measured quantities depend primarily on the particle size distribution of the amorphous solid phases.[15]

In Figs. 4 and 5, the crystal in the early stage (75C) and those in a sufficiently developed stage (78C-96C) exhibit somewhat similar patterns of isotherms, although the latter adsorb the adsorbates in larger quantities than the former. As mentioned in the case of tetraethyl orthosilicate, this difference is due primarily to the difference in pore-structure development.

By applying the BET method[16] to the adsorption isotherms, the monolayer capacity, V_m, for benzene or cyclohexane was calculated except the case of amorphous states (6E-48E). In this case (6E-48E), the BET method could not apply to the isotherms, because these solid phases adsorbed the vapors in too small a quantity. The monolayer capacity, specific surface area, and the constant C are listed in Table 1. The specific surface areas evaluated from the nitrogen-gas isotherms are tabulated in the same table.

For the calculation of the specific surface area for solid phases from the monolayer capacity, we used the molecular dimensions of 7.4 (l)×6.7 (b) for benzene and of 7.2 (l)×6.4 (b) for cyclohexane,[17,18] where the symbols (l) and (b) denote the length and breadth for the molecular dimensions in Å, respectively. We assumed that the molecules adsorbed are oriented nearly flat to the solid surface.[19-21]

In Table 1, the specific surface areas of the amorphous phases derived from tetraethyl orthosilicate are nearly equal for both the benzene and cyclohexane adsorptions. In addition, they are consistent with those as evaluated from the nitrogen adsorption. Therefore, the surface of the solid phases may be taken to be covered with these adsorbates in the same manner. In contrast, the crystal phases adsorb cyclohexane more than benzene. This different behavior suggests that the adsorption depends mainly on the molecular dimensions rather than the effect of the interaction between the cations and the π-electrons of benzene.

As seen from a comparison of data of the crystals formed in the early stage and those in a sufficiently developed stage, the specific surface area slightly decreases with reaction time. This seems due to the change in the particle size distribution with the development of crystal phase. The surface area as evaluated by the nitrogen-gas adsorption does not show any of the tendency mentioned above, because the degree of development of micro pores has a strong effect on the specific surface area, as compared with the change in the outer specific surface area. This agrees with the fact that the outer area of zeolite crystals is only about 1% of the total surface area.[22]

On the other hand, the solid phases derived from silica sol give larger specific surface areas by the benzene adsorption than by the cyclohexane adsorption. The degree of the difference in this case is somewhat smaller than that in the case of tetraethyl orthosilicate. But the amorphous phases (6C-74C) adsorb benzene in larger quantities than cyclohexane. Consequently, the interaction between adsorbates and cations has a somewhat

a) Evaluated by using the BET equation. b) Evaluated by means of nitrogen adsortion.

stronger effect than the molecular dimensions. This suggests that, as previously mentioned,[14,15] the crystal phase derived from silica sol includes an amorphous substance, and that the micro structure of crystals is not yet be developed sufficiently. Therefore, the large specific surface areas evaluated with benzene depend mainly on the amorphous substance included in crystals. This indicates that the surface of the solid phase can be covered with benzene, but that there is a portion on the surface that cannot be sufficiently covered with cyclohexane. On the whole, the amorphous phases prepared from silica sol give larger specific surface areas than those derived from tetraethyl orthosilicate. This depends on the interaction between adsorbates and cations in addition to the difference in the particle size distribution.

No regularity of constant C is found in the case of silica sol, in contrast to the case of tetraethyl orthosilicate. As previously pointed out,[14,15] the surface of the solid phase derived from tetraethyl orthosilicate is supposed to be made up of aluminosilicate with chemical and structural orderliness. On the contrary, the surface of the solid phase derived from silica sol is influenced by complex factors such as the heterogeneity of surface, the wide distribution of particle sizes, the presence of foreign substances, and the interaction between hydroxyl groups and adsorbate.

The relation between the monolayer capacity obtained with benzene, V_m, and the cation concentration is shown in Fig. 6. The monolayer capacity of the amorphous solid phases (72E–75E) derived from tetraethyl orthosilicate changes little with increase in cation concentration. But the monolayer capacity of the crystals in the early stage (76E) and those in a sufficiently developed stage (78E–96E) changes considerably in a steeply linear relationship with cation concentration.

In the case of the amorphous solid phases (6C–72C), the monolayer capacity somewhat decreases with change in cation concentration, and the crystal phases (75C–96C) exhibit an approximately linear relationship between the monolayer capacity and cation concentration. This result suggests that the interaction of π-electrons of benzene is stronger with cations existing in cavities of crystals than with those on the surface of solid phases.

The monolayer capacity obtained with cyclohexane shows none of such a relationship as that with benzene does. This result indicates the existence of a strong interaction between π-electrons of benzene and cations on the solid surface. It has been suggested that benzene is associated with a similarly strong interaction, whereas cyclohexane with some weak interaction.[23]

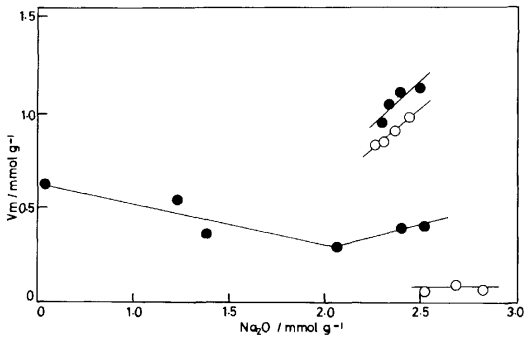

Fig. 6. Relation between monolayer capacity, V_m, and cation (Na_2O) concentration. —O—: $Si(OC_2H_5)_4$, —●—: silica sol.

On the basis of these results and discussions, the change in pores and channels of the solid phases and the mechanism of the crystallization of zeolite X are to be considered.

The schematic representation of the channel and pore formation is given in Fig. 7. The amorphous solid phases derived from tetraethyl orthosilicate are of the same chemical composition as the crystal phase, and therefore, Na^+ ions are contained in the solid phase in large quantities. These solids adsorb benzene and cyclohexane in rather small quantities.

The amorphous solid phases derived from silica sol contain Na^+ ions in small quantities but adsorb benzene more than the solid phases derived from tetraethyl orthosilicate; they adsorb benzene more than cyclohexane. In addition, taking into account the different particle size distribution and the relative specific surface areas $N_2 \approx C_6H_6 \approx C_6H_{12}$ for tetraethyl orthosiicate and $N_2 \approx C_6H_6 > C_6H_{12}$ for silica sol, we have given schematic representations of the surfaces of the amorphous solid states derived from silica sol and tetraethyl orthosilicate in A-1 and B-1, respectively. In the case of tetraethyl orthosilicate, the cations in the solid phase exist in a similar state as in the crystal phase or ordered aluminosilicate, whereas in the case of silica sol, a small quantity of cations are widely distributed on the

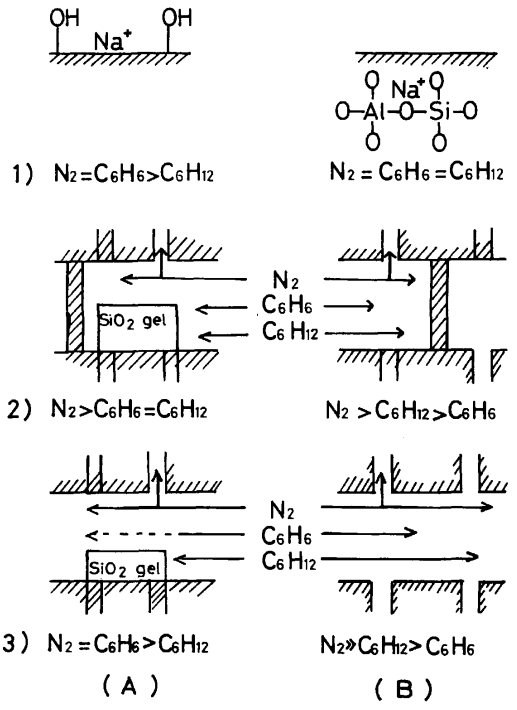

Fig. 7. Schematic diagram of channel and pore formations with reaction time. (A) and (B) are the solid phases derived from silica sol and tetraethyl orthosilicate respectively.

outer surface of the solid phase. Furthermore, there seem to exist no less than the hydroxyl groups on the heterogeneous surface of the solid phase.[15]

The crystal phase derived from silica sol in the early stage give the order of specific surface areas: $N_2 > C_6H_{12} \approx C_6H_6$. This order suggests that the channels and pores characteristic of the zeolite structure have already been formed but not yet so much developed as to be able to adsorb benzene and cyclohexane in large quantities. This is due to a contamination of silicic polymers in the channel and pore structures, as previouly pointed out.[14,15]

The crystals derived from tetraethyl orthosilicate give the order of specific surface areas: $N_2 \gg C_6H_{12} > C_6H_6$. This differece in specific surface area is due to the molecular dimensions. The crystal phases derived from tetraethyl orthosilicate may be supposed not to be contaminated with amorphous substances such as a silicic polymer which will not be incorporated in the aluminosilicate framework; thus, these solid phases are capable of adsorbing nitrogen gas and cyclohexane in larger quantities than can be expected from the degree of crystallinity. This crystal phase adsorbs nitrogen gas and cyclohexane in fairly larger quantities than benzene. Therefore, the crystals in the early stage may be considered to have had their structure developed to a considerable extent with respect to channel and pore.

The crystals derived from tetraethyl orthosilicate in a sufficiently developed stage give the order of specific surface areas: $N_2 \gg C_6H_{12} > C_6H_6$. An increase in crystallinity is accompanied by development of the internal structure of crystals. On the whole, channels and pores, which can adsorb nitrogen gas but not appreciably benzene or cyclohexane, have been formed considerably in the crystal phase. This is in accord with the abrupt increase in the specific surface areas, evaluated by the nitrogen adsorption, from 460 for 76E to 720 m^2/g for 96E.

The crystals derived from silica sol in a developed stage give the order of specific surface areas: $N_2 \approx C_6H_6 > C_6H_{12}$. The channels and pores have fairly been developed. But the existene of amorphous substances in the crystal phase prevents cyclohexane to a higher degree from being adsorbed than nitrogen gas and benzene vapor. Because of the interaction between π-electrons of benzene and surface hydroxyl groups or cations distributed on the outer surface, benzene is adsorbed in larger quantities than cyclohexane. These considerations are in conformity with experimental results on IR spectra, chemical analyses, and crystallinity previously described.[14,15]

The authors wish to express their thanks to Professor Ryohei Matuura of Kyushu University for many helpful discussions during the course of this work and to Shimadzu Co., Ltd. for the measurement of the particle size distributions with a SediGraph type 5000-01.

(Received May 30, 1983)

External magnetic field and magnetic isotope effects on the dynamic behavior of radical pairs in solutions have been studied theoretically, where the relaxation of their electron spins was taken into account. The decay observed with some radical pairs in micellar solutions under high magnetic fields is successfully interpreted in terms of the relaxation mechanism, and the magnetic field dependence of the relaxation rates is calculated for a model system.

Magnetic field effects on chemical reactions have been extensively studied during the last decade.[1-8] The effects observed for usual solvents are known to be classified and systematically explained in terms of the Δg, hyperfine coupling (HFC) and level-crossing (J) mechanisms[9] of the radical pair theory.[10,11]

Recently,we first succeeded in measuring the effect on photochemical reaction rates, taking the reactions of benzophenone (BP),[12-14] its derivatives,[15] and dibenzyl ketone (DBK)[14,16] in some micelles as examples. A similar effect was also observed in the reactions of 1,4-naphthoquinone (NQ) derivatives in a sodium dodecyl sulfate (SDS) micelle.[17] In these reactions, we have found some new external magnetic field and magnetic isotope effects on the decay of their intermediate radical pairs which cannot be explained in terms of only the Δg, HFC, and J mechanisms of the radical pair theory. The yields of their escaping radicals and reaction products were also found to show similar effects.

Among the new effects observed in the micellar solutions, the effects observed in the photodecomposition reaction of DBK[14] were explained in terms of the triplet (T) mechanism successfully applied to some chemically induced dynamic electron polarization (CIDEP).[18] On the other hand, the effects observed in the hydrogen abstraction reactions of BP's and NQ's could not be explained by this mechanism. In preceding papers,[14,15] we have suggested that the relaxation mechanism may explain these magnetic field effects. Brocklehurst studied theoretically the effect of the relaxation times (T_1 and T_2) of electron spins in a radical pair on the evolution of its singlet character.[19] However, it is not clear at present how the decay of the radical pair and the yields of escaping radicals and reaction products are influenced by a magnetic field when the relaxation mechanism is effective. Therefore, the purpose of the present study is to analyze theoretically the dynamic behavior of the radical pair through the relaxation mechanism and to explain the observed effects in micellar solutions with the developed theory.

Theoretical

Dynamic Behavior of Radical Pair. It has already been shown that a separated radical pair plays a very important role in the magnetic field effects on chemical reactions in solutions.[9,11,20] Thus, in the present paper, we also consider the dynamic behavior of the separated radical pair, in which the interaction between its component radicals (radicals a and b) is very small. In this paper, the separated radical pair is simply written as the radical pair.

The energy diagram of the radical pair is shown in Fig. 1. At the zero magnetic field, we assume that the energy (E_S) of its singlet state ($|S\rangle$) and that (E_{Ti}) of each sublevel (i=x, y, or z) of its triplet state are degenerate with each other. On this assumption, the singlet-triplet (S-T) separation ($2J$) of the radical pair and the energy splittings within the triplet sublevels are considered to be zero. This assumption is usually adopted for the theoretical studies of the above-mentioned mechanism except for the J one.

At a high field, where the high field approximation holds,[21,22] two of the triplet sublevels ($|T_{\pm1}\rangle$) are shifted from the central one ($|T_0\rangle$) through the Zeeman effect. In usual radical pairs, the magnetic flux density (B) of 0.04 T is enough for the high field approximation.[9,20]

In order to analyze exactly the dynamic behavior of the radical pair, a stochastic Liouville equation must be solved.[20] However, it cannot be solved analytically and a tedious calculation is necessary for its solution. On the other hand, many nuclear spin states of a radical pair can interfere with one another and the overall dynamics of its singlet and triplet states become very simple. Thus we can use the first order rate equations

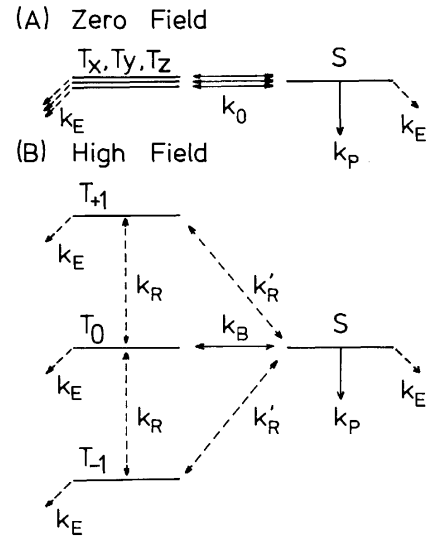

Fig. 1. Dynamic behavior of a radical pair at (A) the zero field and (B) a high field.

in order to understand the dynamics intuitively. In fact, all of the decay curves of radical pairs observed in micellar solutions with a laser-photolysis technique[13-17] have been expressed by combination of some exponential functions.

Therefore, we introduce rate equations for the populations of the singlet state and triplet sublevels ([S] and [T_i]) of a radical pair. At the zero field, they can be written as follows:

$$d[T]/dt = -(k_0+k_E)[T] + 3k_0[S], \quad (1)$$

$$d[S]/dt = k_0[T] - (k_P+3k_0+k_E)[S], \quad (2)$$

where $[T]=[T_x]+[T_y]+[T_z]$. Each rate constant (k_i) is shown in Fig. 1(A). The S-T conversion rate constant is written by k_0, which is determined by the HFC and has the order of 10^9—10^8 s^{-1}.[23] The reaction rate constant from the singlet state is written by k_P, which has the order of 10^{10}—10^7 s^{-1}.[23] The reaction from the triplet state is not considered in the present study for simplicity, although it is possible if necessary. The escaping rate constant of radicals from the radical pair, k_E, may have the order of 10^5 s^{-1} for the micellar solutions of BP's and NQ's. In usual solvents, it may be much larger.

At a high field, the following equations are introduced.

$$d[T_i]/dt = -(\sum_{i\neq i}' k_{ij}+k_{iS}+k_E)[T_i] + \sum_{j\neq i} k_{ji}[T_j] + k_{Si}[S], \quad (3)$$

$$d[S]/dt = \sum_i k_{iS}[T_i] - (k_P+\sum_i k_{Si}+k_E)[S], \quad (4)$$

where i, j=0 or ±1, k_{ij} is the conversion rate constant from the i-triplet sublevel to the j-one, and k_{Si} and k_{iS} are the S-T converson rate constants between the singlet state and the i-triplet sublevel. Since $k_{ij}=k_{ji}$,[21,22] and $k_{Si}=k_{iS}$,[9] Eqs. 3 and 4 are summarized as follows:

$$d[T']/dt = -(k_R+k_R'+k_E)[T'] + 2k_R[T_0] + 2k_R'[S], \quad (5)$$

$$d[T_0]/dt = k_R[T'] - (k_B+2k_R+k_E)[T_0] + k_B[S], \quad (6)$$

$$d[S]/dt = k_R'[T'] + k_B[T_0] - (k_P+k_B+2k_R'+k_E)[S], \quad (7)$$

where $[T']=[T_1]+[T_{-1}]$, $k_B=k_{S0}$, $k_R=k_{\pm10}$, and $k_R'=k_{\pm1S}$. As shown in Appendix, k_{10} is equal to k_{-10} and k_{1S} is equal to k_{-1S}. Each rate constant is shown in Fig. 1(B). It is noteworthy that the relaxation from the ±1-triplet sublevel to the singlet state must be taken into account besides that to the 0-one (see Appendix). In usual radicals, T_1^{-1} is 10^6—10^4 s^{-1}.[23] Thus k_R and k_R' may have similar values. According to the radical pair theory, k_B is based on the HFC and $\Delta g\beta B$ of the radical pair, where Δg is the difference between the isotropic g-values (g^a and g^b) of the component radicals and β is the electric Bohr magneton. Usually, k_B is larger than k_0.

Solution of Rate Equations. Equations 1 and 2 and Eqs. 5—7 are solved approximately for $k_P \gg k_0$, k_B (case a) and k_0, $k_B \gg k_P$ (case b), respectively. As already explained, in micellar solutions k_P, k_0, and k_B can be considered to be much larger than the other rate constants. This condition is considered in the present calculation. For the reaction from an S-precursor, the initial population ([ ]$_0$) can be taken as follows: $[S]_0=1$, $[T]_0=0$, or $[T_i]_0=0$ (i=0 or ±1). For the reaction from a T-precursor, the initial population can be taken as follows:[24] $[S]_0=0$, $[T]_0=1$, or $[T_i]=1/3$.

After calculation of [S], [T], [T'], and [T_0], the total population of the radical pair ([R]) is obtained, where $[R]=[S]+[T]$ at the zero field and $[R]=[S]+[T']+[T_0]$ at a high field. The results are as follows:

S-precursor:

At the zero magnetic field:

$$\text{Case a } (k_P \gg k_0)\text{: } [R] = \exp[-(k_P+3k_0+k_E)t], \quad (8)$$

$$\text{Case b } (k_0 \gg k_P)\text{: } [R] = \exp[-(k_P/4+k_E)t]. \quad (9)$$

At a high magnetic field:

$$\text{Case a } (k_P \gg k_B)\text{: } [R] = \exp(-r_1t), \quad (10)$$

$$\text{Case b } (k_B \gg k_P)\text{: } [R] = \exp(-r_2't). \quad (11)$$

T-precursor:

At the zero magnetic field:

$$\text{Case a } (k_P \gg k_0)\text{: } [R] = \exp[-(k_0+k_E)t], \quad (12)$$

$$\text{Case b } (k_0 \gg k_P)\text{: } [R] = \exp[-(k_P/4+k_E)t]. \quad (13)$$

At a high magnetic field:

$$\text{Case a } (k_P \gg k_B)\text{: } [R] = (1/3)\exp(-r_2t) + (2/3)\exp(-r_3t), \quad (14)$$

$$\text{Case b } (k_B \gg k_P)\text{: } [R] = (1/3)\exp(-r_2't) + (2/3)\exp(-r_3't), \quad (15)$$

where r_1, r_2, r_3 r_2', and r_3' are given as follows:

$$r_1 = k_P + k_B + 2k_R' + k_E, \quad (16)$$

$$r_2 = k_B + 2k_R + k_E, \quad (17)$$

$$r_2' = k_P/2 + k_R + k_R' + k_E, \quad (18)$$

$$r_3 = r_3' = k_R + k_R' + k_E. \quad (19)$$

From these solutions, the following predictions can be given for the reaction from the S-precursor: (1) The decay of the radical pair can be expressed by a single exponential function for all the cases under consideration. (2) The decay rate constant at the zero field shows no or very little isotope effect because k_P and k_E usually show no magnetic isotope effect.[7] (3) For case a, the magnetically induced change of its decay rate constant is $k_B-3k_0+2k_R'$. This value is negative at a relatively low field and increases with increasing B. The magnetic field effect on the rate constant, however, is very small because the main component of r_1 is k_P. (4) For case b, the change is $k_P/4+k_R+k_R'$. This value is positive and the decay rate constant rapidly increases with increasing B in the low field region ($B<0.04$ T). On the other hand, in the high field region ($B>0.04$ T) its magnetically induced change becomes very small because k_P is a main term for the decay rate constant.

For the reactions from the T-precursor, the following predictions are made: (1) The decay of the radical pair can be expressed by a single exponential function at the zero field and by a combination of two eponential functions at a high field. (2) At the zero field, the decay rate constant can be represented by k_0+k_E for case a and by $k_P/4+k_E$ for case b. Therefore, its magnetic isotope effect can be expected for the former case but not for the latter. (3) For case a, the change from the decay rate constant at the zero field to the larger one in the high field region (r_2) is $k_B-k_0+2k_R$. Its magnetic field effect

at a relatively low field is small but increases with increasing B. The smaller one (r_3) in the high field region is much smaller than the rate constant at the zero field. (4) For case b, the change from the decay rate constant at the zero field to r_2' is $k_P/4+k_R+k_R'$. This value is the same as that is given in the reaction from the S-precursor. On the other hand, the second component appears in the high field region for the reaction from the T-precursor. Its rate constant (r_3') is much smaller than that at the zero field.

The populations of one of the escaping radicals ([E]) and the product from the singlet radical pair ([P]) can also be obtained from the following equations:

$$d[E]/dt = k_E[R], \quad (20)$$

$$d[P]/dt = k_P[S]. \quad (21)$$

Results and Discussion

Summaries of Experimental Results. In the reactions of BP's and NQ's in micelles at room temperature,[12-15,17] the following characteristics were found for their magnetic field effects:

(a) The decay curves of their radical pairs observed at the zero field are expressed by single exponential functions. Some of the decay rate constants observed in an SDS micelle are listed in Table 1. They are about 3×10^6 s^{-1} for BP's and about 5×10^6 s^{-1} for NQ's. For BP, the magnetic isotope effect on the decay rate constant can scarcely be observed at the zero field.

(b) In the presence of a magnetic field above 0.04 T, the decay curves of the radical pairs are expressed by combinations of two eponential functions. The rate constants of the slow decay component observed with BP's and NQ's in the SDS micelle are listed in Table 1. They decrease with increasing B until 1.34 T at which the magnetic field effects become almost constant. They are about 2×10^6 s^{-1} at 0.04 or 0.05 T but are as small as about 3×10^5 s^{-1} at 1.34 T.

(c) As shown in Table 1, the magnetic isotope effects on the rate constants appeared clearly between 0.04 and 0.5 T, but the effects became small above 0.5 T again. Similar magnetic isotope effects were also obtained more accurately for the yields of the escaping radicals in the BP reaction.[15]

(d) The yields of the escaping radicals in the reactions of BP's and NQ's increase with increasing B until 1.34 T.[15,17]

The external magnetic field and magnetic isotope effects summarized above cannot be interpreted by the Δg, HFC, and J mechanisms for the following reasons: According to the Δg mechanism,[9] the decay rate constant of the radical pair in the reactions from the T-precursor should increase with increasing B. From the HFC mechanism,[9,20] the rate constant is expected to decrease with increasing B, which is saturated at a low magnetic field ($B\ll0.1$ T).[20] According to the J mechanism,[9] the rate constant should increase at a level-crossing field. These predictions clearly contradict the observed results (see summary b).

The observed results cannot be explained also by the T mechanism for the following reason: The initial population of each sublevel of the triplet radical pair ($[T_i]_0$) can be influenced by a magnetic field through the T mechanism. However, this mechanism cannot explain appearance of the two decay components of the radical pair in the presence of a magnetic field and the magnetically induced changes of the slow decay component. The magnetic field effects on this component are the main problem of the present paper.

Application of Relaxation Mechanism. Now let us consider the observed magnetic field effects on the reactions of BP's and NQ's, taking account of the relaxation mechanism developed in the present paper. The observed numbers of the decay components of [R] in the absence (one) and presence (two) of a magnetic field agree well with the prediction for the reaction from the T-precursor. For case a, the observed decay rate constan at the zero magnetic field should correspond to k_0+k_E. As explained above, k_0 should have the order of 10^9—10^8 s^{-1} and should show a magnetic isotope effect. This prediction contradict the observed results (see summary a).

For case b, the rate constant at the zero magnetic field should correspond to $k_P/4+k_E$ and may not show any appreciable isotope effect. The magnitudes of k_P and k_E are also reasonable for explaining the observed rate constants. Thus we can conclude that case b is

a) Benzophenone; Refs. 13 and 15. b) Benzophenone-d_{10}; Ref. 13. c) Benzophenone-carbonyl-^{13}C; Refs. 13 and 15. d) 4,4'-Difluorobenzophenone; Ref. 15. e) 1,4-Naphtoquinone; Ref. 17. f) 2-Methyl-1,4-Naphtoquinone; Ref. 17. g) The values measured under a residual magnetic field (0.12 mT) are listed.

applicable to the reactions of BP's and NQ's in the micellar solutions and the rate constants of the fast and slow decay components are assigned to r_2' and r_3', respectively. This means that the magnetic field and magnetic isotope effects observed with the slow decay component are due to $r_3'=k_R+k_R'+k_E$ (see Eq. 19). Since k_E can be considered to be insensitive to a magnetic field below 1.34 T, the observed magnetic field and magnetic isotope effects are considered to be due to k_R and k_R'.

It is noteworthy that these effects are not due to such direct S-T conversion rate constant as k_0 and k_B. This is a new situation in the study of the magnetic field effects on chemical reactions through radical pairs. The effects through the other mechanisms have been shown to be due to k_0 and k_B.[9,20]

Analytical Forms of Relaxation Rate Constants. The external magnetic field and magnetic isotope effects on k_R and k_R' of the radical pair have not yet been studied well. Therefore, we have undertaken to analyze them theoretically. The internal motions of a radical pair against the direction of an external magnetic field are shown in Fig. 2. Here Ω^i and Ω^{ab} represent the sets of the angular coordinates of the molecular axes of the i-th radical (X^i, Y^i, and Z^i) and the vector (r_{ab}) from an odd electron on radical b to that on radical a, respectively.

We have obtained the analytical forms of k_R and k_R' for the following simple model of a radical pair: (1) Each of the component radicals has its HFC with only one nucleus having spin 1/2. The principal values of the HFC tensor (A^i tensor) are given by A_X^i, A_Y^i, and A_Z^i. The nuclear spin quantum number is written by M^i. (2) The principal axes of the g tensor of the i-th radical (g^i tensor) are supposed to coincide with those of the A^i one. (3) The axial symmetry is assumed for g^i and A^i tensors. Their isotropic parameters are given by $g^i=g_\parallel^i/3+2g_\perp^i/3$ and $A^i=A_\parallel^i/3+2A_\perp^i/3$, respectively. Their anisotropic parameters are given by $\Delta g^i=g_\parallel^i-g_\perp^i$ and $\Delta A^i=A_\parallel^i-A_\perp^i$, respectively. Here $\parallel$ and $\perp$ represent the parallel and perpendicular components against the axis of symmetry, respectively. (4) The dipole-dipole interaction between the odd electrons is assumed to be due to that between the two points which are separated with each other by the averaged distance (R) of r_{ab}.

For the above model, k_R and k_R' are given as follows:

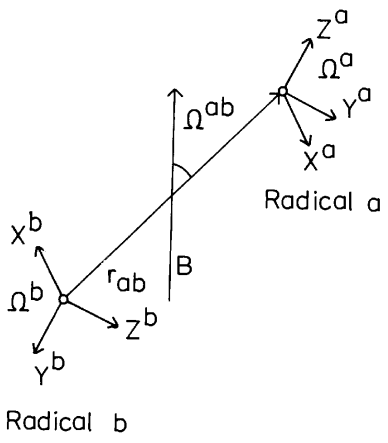

Fig. 2. Internal motions of a radical pair.

$$k_R=(1/4)\sum_{M^a}\sum_{M^{a'}}\sum_{M^b}\sum_{M^{b'}}P<T_{\pm1},M^a,M^b|T_0,M^{a'},M^{b'}>, \quad (22)$$

$$k_R'=(1/4)\sum_{M^a}\sum_{M^{a'}}\sum_{M^b}\sum_{M^{b'}}P<T_{\pm1},M^a,M^b|S,M^{a'},M^{b'}>, \quad (23)$$

where $P<m|l>$ is the transition probability from the m-th state to the l-th one. The derivations and analytical forms of the right sides of Eqs. 22 and 23 are given in Appendix.

Model Calculations of Relaxation Times. After hydrogen abstraction by the triplet state of BP or NQ from a micellar molecule, a radical pair of the ketyl or semiquinone radical with the alkyl one is produced. Thus the former and latter radicals can be written by radicals a and b, respectively.

Now let us calculate k_R+k_R' numerically with the aid of Eqs. 22 and 23. Since many parameters in these equations have not yet been measured, they are assumed adequately. The following parameters are fixed: $g^a=g^b=2.003$,[25] $\Delta g^b=0.002$,[25] $\tau_a=1\times10^{-10}$ s,[28] and $\tau_b=5\times10^{-9}$ s.[28] The others are changed. The calculated contributions of the motions of radicals a and b (V^a and V^b) and the relative motion of the two radicals (V^{ab}) to $\log(k_R+k_R')$ are plotted against B in Fig. 3.

From Fig. 3, the following characteristics are found: (1) Curves a—e show the contributions of V^a for some sets of parameters. From curve a which shows the contribution of Δg of 0.002, this contribution is proved to be neglibly small. The increases from curve a to curves b—d show the contributions of the increases in $\Delta A^a/g\beta$ from 0 to 0.002, 0.004, and 0.006 T, respectively, where g is $(g^a+g^b)/2$. This contribution is

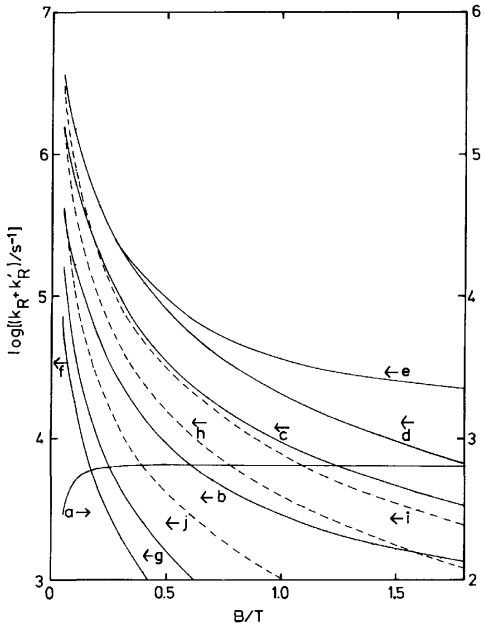

Fig. 3. Calculated contributions of V^a, V^b, and V^{ab} to k_R+k_R' with the following parameters: V^a: $g^a=2.003$ and $\tau_a=1\times10^{-10}$ s^{-1} (a) $\Delta g^a=0.002$ and $\Delta A^a/g\beta=0$ T; (b) $\Delta g^a=0.002$ and $\Delta A^a/g\beta=0.002$ T; (c) $\Delta g^a=0.002$ and $\Delta A^a/g\beta=0.004$ T; (d) $\Delta g^a=0.002$ and $\Delta A^a/g\beta=0.006$ T; (e) $\Delta g^a=0.01$ and $\Delta A^a/g\beta=0.006$ T. V^b: $g^b=2.003$, $\Delta g^b=0.002$, and $\tau_b=5\times10^{-9}$ (f) $\Delta A^b/g\beta=0.004$ T; (g) $\Delta A^b/B\beta=0.006$ T. V^{ab}: (h) $R=0.8$ nm and $\tau_{ab}=1\times10^{-9}$ s; (i) $R=0.8$ nm and $\tau_{ab}=5\times10^{-10}$ s; (j) $R=1.0$ nm and $\tau_{ab}=1\times10^{-9}$ s.

shown to be larger under low magnetic fields and to increase with increasing ΔA^a. This is the origin of the magnetic isotope effect on k_R+k_R' and the amount of the effect is also shown to decrease with increasing B because of the denominator $(1+\omega^2\tau_a^2)$ in Eqs. A7—A9. The differnce between curves e and d is the contribution of the increase of Δg from 0.002 to 0.01. This is also small.

(2) Curves f and g show the contribution of V^b. Thus the contribution of the alkyl radical is found to be negligibly small. This is due to the fact that its correlation time is assumed to be very long. Since this radical may take part in micellar formation, this assumption may be permitted.

(3) Curves h—j show the contribution of V^{ab}. This contribution is found to be comparable to that of V^a in magnitude. Thus this is also shown to play an important role in k_R. Figure 3 shows that this contribution decreases with inreasing B, R, and τ_{ab}. However, it is very difficult to determine the values of R and τ_{ab} from other experimental methods.

Comparison between the Observed and Calculated Rate Constants. In Fig. 4, the observed dependence of the decay rate constants on B is plotted for some typical reactions. In this figure, the rate constant values calculated for the adopted model are also shown. Here the contributions of V^a and V^{ab} are only taken into account because that of V^b has been shown to be much smaller than the former. The assumed parameters are as follows: $k_E=4\times10^5$ s^{-1}, $g^a=2.003$, $\Delta g^a=0.002$,[25] $\tau_a=1\times10^{-10}$ s, $R=0.8$ nm, and $\tau_{ab}=1\times10^{-9}$ s.[28] The value of ΔA^a is changed. The k_E, R, and τ_{ab} values are chosen in such a way as the calculated rate constant values agree with the observed ones. They seem to be reasonable for radical pairs considered in the present paper.

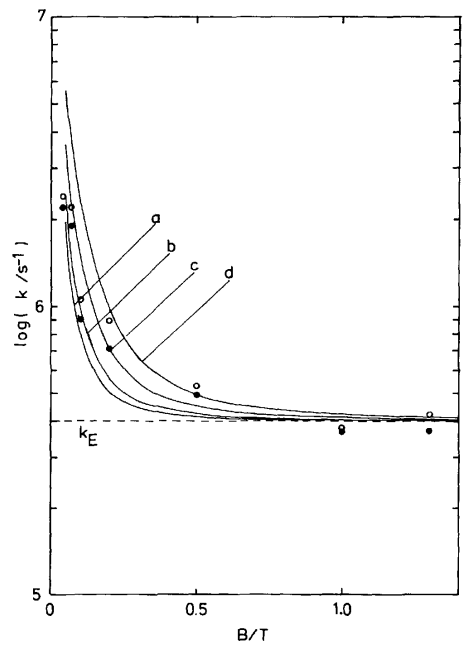

Fig. 4. The magnetic field dependences of the rate constants (k) of the slow decay components observed with the SDS solutions of (●) benzophenone and (○) benzophenone-carbonyl-^{13}C.[13,15] Calculated magnetic field dependences of the rate constants due to the combination of V^a and V^{ab} with the following parameters: (a) $\Delta A^a/g\beta=0$ T, (b) $\Delta A^a/g\beta=0.002$ T, (c) $\Delta A^a/g\beta=0.004$ T, and (d) $\Delta A^a/g\beta=0.006$ T. The other parameters are written in the text.

From the comparison among the results shown in Table 1 and Fig. 4, it is considered that this calculation can explain the observed characteristics of the decay rate constants in spite of the facts that the adopted model is very simple and that there are some ambiguities in assuming the parameters. The observed magnetic field dependence of the decay rate constant is well interpreted by the calculated k_R+k_R'. Its decrease with increasing B is due to the denominators in Eqs. A7—A9.

The observed magnitude of k_R+k_R' is also explained by this calculation. At magnetic fields below 0.1 T, the magnitude is calculated to be larger than 10^6 s^{-1}. At fields above 0.5 T, the magnitude is smaller than 10^5 s^{-1}. They agree well with the observed values if the observed decay rate constant at 1.34 T is nearly equal to k_E in each of the investigated reactions. The observed magnetic isotope effects on the decay rate constant in the BP reaction are also explained by the calculated curved in Fig. 4. They show that the decay rate constant increases with increasing ΔA^a and that the magnitude of the effects is appreciable at low magnetic fields and becomes small at high fields.

Thus the observed external magnetic field and magnetic isotope effects on the radical pair decay in each of the reactions of BP's and NQ's in micelles have been successfully interpreted in terms of the relaxation mechanism. At the zero magnetic field, the decay rate constant of the radical pair corresponds to $k_P/4+k_E$, which should not show any appreciable magnetic isotope effect. In the presence of a magnetic field where the high field approximation holds, the constant shows the external magnetic field and magnetic isotope effects which are due to the relaxations from the ±1-sublevel of the triplet radical pair to the 0-sublevel (k_R) and the singlet state (k_R'). The analytical forms for a model system are derived and numerical values of k_R and k_R' are calculated. The magnetic field effects on the yields of the escaping radicals and reaction products observed in these micellar solutions are also explained by the relaxation mechanism. Details of the effects on the yields will be published elsewhere.[15,17]

Appendix

The transition probability, $P<m|n>$, under a time dependent perturbation ($V(t)$) is given as follows:[21]

$$P<m|n> = \hbar^{-2}|V_{mn}|^2 2\tau_c/(1+\omega_{mn}^2\tau_c^2), \quad \text{(A1)}$$

where ω_{mn} is expressed by

$$\omega_{mn} = \hbar^{-1}(E_n-E_m), \quad \text{(A2)}$$

and $V(t)$ is supposed to take the form

$$V(t) = V\cdot f(t), \quad \text{(A3)}$$

where V is an operator which is independent of time and $f(t)$ is a fluctuating numerical factor. When the autocorrelation function ($G(\tau)$) of $f(t)$ decays exponentially with a correlation time of τ_c,

$$G(\tau) = \overline{f(t+\tau)f(t)} = \overline{f(t)^2} \exp(-|\tau|/\tau_c), \quad \text{(A4)}$$

Eq. A1 is obtained.

For a radical pair, various off-diagonal matrix elements among $|T_{\pm1}>$, $|T_0>$, and $|S>$ have been obtained previously (Eqs. 39 and 40 in Ref. 10b). They can be used for $V(t)$. In the presence of a magnetic field where the high field approximation holds, $P<T_{\pm1}|\Gamma>$ (Γ is T_0 or S) can be obtained as follows:

$$P<T_{\pm1}|\Gamma> = \sum_i \frac{|V^i|^2}{\hbar^2} \cdot \frac{2\tau_i}{1+\omega^2\tau_i^2} + \frac{|V^{ab}|^2}{\hbar^2} \cdot \frac{2\tau_{ab}\delta_{\Gamma T_0}}{1+\omega^2\tau_{ab}^2}, \quad \text{(A5)}$$

where $\delta_{T_0T_0}=1$ and $\delta_{ST_0}=0$. V^i (i=a or b) contains the contributions from the anisotropic terms of the g^i and A^i tensors and V^{ab} is due to the dipole-dipole interaction between radicals a and b. The correlation times of Ω^i and Ω^{ab} are given by τ_i and τ_{ab}, respectively. In this calculation, we consider the case where

$$\hbar\omega = |E_{T_{\pm1}} - E_{T_0}| = |E_{T_{\pm1}} - E_S| = (g^a+g^b)\beta B/2. \quad \text{(A6)}$$

From Eq. A5, the following equations can be derived: $k_{10}=k_{-10}$ and $k_{1S}=k_{-1S}$. It is shown that k_R' is comparable to k_R in magnitude. For the adopted model shown in the text, non-vanishing elements of P can be expressed as follows:

$$\hbar^2P<T_{\pm1},M^a,M^b|\Gamma,M^a,M^b> = \sum(\beta B\Delta g^i + M^i\Delta A^i)^2\tau_i/[30(1+\omega^2\tau_i^2)] + D^2\tau_{ab}\delta_{\Gamma T_0}/[7.5(1+\omega^2\tau_{ab}^2)], \quad \text{(A7)}$$

$$\hbar^2P<T_{\pm1},\pm 1/2,M^b|\Gamma,\mp 1/2,M^b> = (\Delta A^a)^2\tau_a/[30(1+\omega^2\tau_a^2)], \quad \text{(A8)}$$

$$\hbar^2P<T_{\pm1},\mp 1/2,M^b|\Gamma,\pm 1/2,M^b> = (\Delta A^a)^2\tau_a/[180(1+\omega^2\tau_a^2)]. \quad \text{(A9)}$$

$P<T_{\pm1}, M, M'|\Gamma, M, M''>$ has the same form as $P<T_{\pm1}, M', M|\Gamma, M'', M>$, where D is given as follow:[22]

$$D = -(3/2)(\mu_0/4\pi)(g^2\beta^2/R^3). \quad \text{(A10)}$$

Since k_R and k_R' are defined as the averaged transition probabilities about the nuclear spin states, they are given as shown in Eqs. 22 and 23.

We wish to thank Professor Koichi Itoh, Osaka City University, and Dr. Yoshio Sakaguchi, The Institute of Physical and Chemical Research, for their helpful discussions.

The Structure of Liquid Water by Neutron Scattering. III. Calculations of the Partial Structure Factors

Norio Ohtomo,† Kazuo Tokiwano,† and Kiyoshi Arakawa*
Research Institute of Applied Electricity, Hokkaido University, Sapporo 060
†*Faculty of Engineering, Hokkaido University, Sapporo 060*
(Received June 8, 1983)

A formula for obtaining partial structure factors for fluid systems composed of molecular clusters with various sizes was derived according to the theoretical procedure proposed in the preceding papers (N. Ohtomo, K. Tokiwano, and K. Arakawa, *Bull. Chem. Soc. Jpn.*, **54**, 1802 (1981): **55**, 2788 (1982)). The formula was applied to calculate partial structure factors of liquid water, and from the good agreement between the calculated and observed values the pentamer-monomer mixture model for liquid water was confirmed as reasonable.

As the result of neutron diffraction studies of liquid water reported in the preceding papers,[1,2]†† the pentamer–monomer mixture model turned out to be the best structure model of water, where the total neutron structure factors obtained were interpreted successfully by that model.

Quite recently, two partial structure factor data of liquid water at 25°C were reported by Thiessen and Narten[3] and by Soper and Silver[4] using an isotope substitution technique of neutron diffraction. A comparison between calculated and observed partial structure factors will offer a very sensitive test for the structure model of liquid. However, no useful theoretical procedure has been proposed for the calculation of partial structure factors for associated liquids like water.

In the present study, thus, we attempt to derive a formula useful for obtaining partial structure factors for the fluid system composed of molecular clusters with various sizes based on the theoretical procedure proposed in paper I and II.[1,2] Then the partial structure factors of liquid water for the pentamer–monomer mixture model are calculated by the use of the formula derived, and the results are compared with the observed data.[3,4]

Procedure of Calculations of Partial Structure Factors

Partial Structure Factors for Fluids Composed of Molecular Clusters. For a r-component system, the partial structure factors $S_{ss'}(Q)$ are connected with the total structure factor $S_m(Q)$ by

$$S_m(Q) = \sum^{-2} \sum_{s,s'}^{r} c_s c_{s'} b_s b_{s'} S_{ss'}(Q), \quad (1)$$

where $\sum \equiv \sum_s^r c_s b_s$, b_s the coherent scattering length for the nucleus species s, c_s the number of the nuclei per molecular unit, and $Q \equiv |\vec{Q}|$ ($\vec{Q}$: the scattering vector).

We consider here the case of a fluid system consisting of molecular clusters with various sizes including monomers and, then, begin with Eq. 12 for $S_m(Q)$ in paper II,

$$S_m(Q) = \sum_\nu \frac{x_\nu}{\nu} f_1^\nu(Q) + \sum_{\nu \geqq 2} \frac{x_\nu}{\nu} f_c^\nu(Q) + \bar{f}_{2U}(Q)[S_c(Q) - 1], \quad (2)$$

where x_ν is the fraction of ν-mer clusters in molecular number, the $f_1^\nu(Q)$ the intramolecular contribution within the clusters (Eq. 13 in II), $f_\ell^\nu(Q)$ the factor originating from the orientational correlation of molecules within the clusters (Eq. 14 in II), $S_c(Q)$ the molecular-centers structure factor of the liquid (Eq. 10 in II), and $\bar{f}_{2U}(Q)$ an extended form of a factor resulting from the completely uncorrelated orientational configuration between molecules in the liquid (Eq. 11 in II). We rewrite $f_\ell^\nu(Q)$ as

$$f_c^\nu(Q) = \nu f_1^c(Q) - f_1^\nu(Q) - \nu f_3^\nu(Q) \cdot f_{2U}^\nu(Q), \quad (3)$$

where

$$f_1^c(Q) = \sum^{-2} \frac{1}{\nu} \left[\left\langle \sum_{l,l'} \sum_{n_l, n_{l'}} b_{n_l} b_{n_{l'}} \exp(i\vec{Q} \cdot \vec{r}_{n_l n_{l'}}) \right\rangle \right]_\nu, \quad (4)$$

$$f_3^\nu(Q) = \frac{1}{\nu} \left[\left\langle \sum_{l \neq l'} \exp(i\vec{Q} \cdot \vec{r}_{cll'}) \right\rangle \right]_\nu \quad (\nu \geqq 2), \quad (5)$$

and

$$f_{2U}^\nu(Q) = \sum^{-2} \frac{1}{\nu} \left[\sum_l^\nu \left[\sum_{n_l} b_{n_l} \left\langle \exp(i\vec{Q} \cdot \vec{r}_{cn_l}) \right\rangle \right]^2 \right]_\nu. \quad (6)$$

Suffix l denotes the l-th molecule within the ν-mer cluster and n_l the n-th nucleus in the molecule l. $\vec{r}_{n_l n_{l'}}$ is the vector distance from the n_l-th nucleus to the $n_{l'}$-th one, $\vec{r}_{cll'}$ the vector distance from the center of the l-th molecule to that of the l'-th one, and $\vec{r}_{cn_l}$ the vector distance from the center of the molecule l to its n_l-th nucleus, within the ν-mer cluster. $f_1^c(Q)$ is the contribution of atom-pairs within the ν-mer cluster (Eq. 8 in I), $f_3^\nu(Q)$ a factor resulting from the molecular-center pairs within the cluster (Eq. 11 in I), and $f_{2U}^\nu(Q)$ an extended form of a factor resulting from the completely-uncorrelated orientational configuration between molecules within the cluster.

Introducing Eq. 3 into Eq. 2, we obtain

$$S_m(Q) = \sum_\nu x_\nu \left[\frac{1}{\nu} f_1^\nu(Q) \delta_{\nu 1} + f_1^c(Q)(1 - \delta_{\nu 1}) - f_3^\nu(Q) \cdot f_{2U}^\nu(Q) \right] + \bar{f}_{2U}(Q)[S_c(Q) - 1], \quad (7)$$

where δ_{ik} is Kronecker's δ.

From Eqs. 1 and 7, we can obtain the partial structure factors $S_{ss'}(Q)$ for the liquid composed of molecular clusters of various sizes including monomers. The Eq. 1 has a quadratic form on b_s as well as the Eq. 7, though in Eq. 7 the b_s are contained in an implicit form. And then, we can obtain the formula of $S_{ss'}(Q)$ by comparing these two equations, when an explicit form of the total $S_m(Q)$ is given. Thus, the formula of $S_{ss'}(Q)$ is obtained for the practical model of the liquid under consid-

†† We cite Refs. 1 and 2 as paper I and II, respectively, in the following.

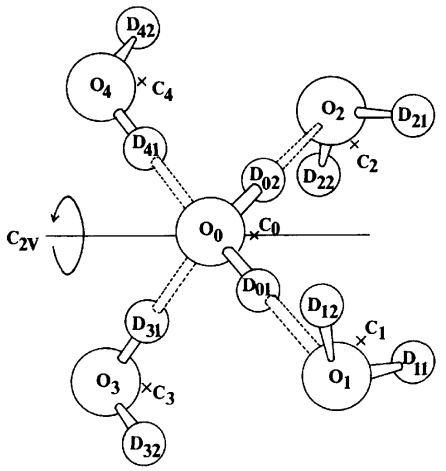

Fig. 1. The structure of the regular tetrahedral pentamer with the C_{2v} symmetrical coordination. The suffix O_i indicates oxygen in the i-th molecule within the pentamer, D_{ij} the j-th deuteron in the i-th molecule, and C_i the molecular center of the i-th molecule.

eration.

Partial Structure Factors for Pentamer-Monomer Mixture Model. For liquid water, using three partial structure factors $S_{OO}(Q)$, $S_{OD}(Q)$, and $S_{DD}(Q)$, Eq. 1 becomes

$$S_m(Q) = \sum^{-2}[b_O^2 S_{OO}(Q) + 4b_O b_D S_{OD}(Q) + 4b_D^2 S_{DD}(Q)], \quad (8)$$

where $\sum = b_O + 2b_D$.

In order to calculate the partial structure factors, we adopt the pentamer-monomer mixture model fully examined in paper II, which is composed of regular tetrahedral pentamers with the C_{2v} symmetrical coordination (Fig. 1) and monomers as its constituents. In this case, we put $x_1 \neq 0$ and $x_5 \neq 0$ (others=zero). Since $\bar{f}_{2U}(Q) = x_1 f_{2U}^1(Q) + x_5 f_{2U}^5(Q)$, Eq. 7 becomes

$$S_m(Q) = x_1\{f_1^1(Q) + f_{2U}^1(Q)[S_c(Q) - 1]\} + x_5\{S_m^p(Q) + f_{2U}^5(Q)[S_c(Q) - f_3^5(Q) - 1]\}. \quad (9)$$

The intra-pentamer contribution $S_m^p(Q)$ ($\equiv f_1^c(Q)$ for pentamer) is given from Eq. 13 in paper I as

$$S_m^p(Q) = \frac{1}{5} f_1^5(Q) + \sum^{-2}[b_O^2 S_{m,p}^{(OO)}(Q) + 4b_O b_D S_{m,p}^{(OD)}(Q) + 4b_D^2 S_{m,p}^{(DD)}(Q)]. \quad (10)$$

The factors $S_{m,p}^{(OO)}(Q)$, $S_{m,p}^{(OD)}(Q)$, and $S_{m,p}^{(DD)}(Q)$, are the intra-pentamer part of the contributions of the O-O, O-D, and D-D pairs, respectively, and the explicit expressions are written below when the orientational configuration of water molecules within the pentamer is specified. The intramolecular contribution $(1/\nu) f_1^\nu(Q)$ (ν=1 for monomer and ν=5 for pentamer) is

$$\frac{1}{\nu} f_1^\nu(Q) = \sum^{-2}[b_O^2 + 2b_D^2 + 4b_O b_D Y_{OD}^\nu(Q) + 2b_D^2 Y_{DD}^\nu(Q)], \quad (11)$$

and

$$Y_{nn'}^\nu(Q) = j_0(Q r_{nn'}^\nu) \exp(-\gamma_{nn'}^\nu Q^2), \quad (12)$$

where $j_0(x) = \sin x/x$, $r_{nn'}^\nu$ is the distance between two different nuclei n and n′ within a molecule and $2\gamma_{nn'}^\nu$ the mean-square variation to the distance $r_{nn'}^\nu$. The factor $f_{2U}^\nu(Q)$ is

$$f_{2U}^\nu(Q) = \sum^{-2}[b_O^2\{Y_{cO}^\nu(Q)\}^2 + 4b_O b_D Y_{cO}^\nu(Q) Y_{cD}^\nu(Q) + 4b_D^2\{Y_{cD}^\nu(Q)\}^2], \quad (13)$$

where the suffix c denotes the molecular center.

From Eqs. 8—13, the partial structure factors $S_{OO}(Q)$, $S_{OD}(Q)$, and $S_{DD}(Q)$ for liquid water are given explicitly as follows:

$$S_{OO}(Q) = x_1[1 + \{Y_{cO}^1(Q)\}^2[S_c(Q) - 1]] + x_5[1 + S_{m,p}^{(OO)}(Q) + \{Y_{cO}^5(Q)\}^2[S_c(Q) - f_3^5(Q) - 1]], \quad (14)$$

$$S_{OD}(Q) = x_1[Y_{OD}^1(Q) + Y_{cO}^1(Q) Y_{cD}^1(Q)[S_c(Q) - 1]] + x_5[Y_{OD}^5(Q) + S_{m,p}^{(OD)}(Q) + Y_{cO}^5(Q) Y_{cD}^5(Q)[S_c(Q) - f_3^5(Q) - 1]], \quad (15)$$

and

$$S_{DD}(Q) = x_1\left[\frac{1}{2}\{1 + Y_{DD}^1(Q)\} + \{Y_{cD}^1(Q)\}^2[S_c(Q) - 1]\right] + x_5\left[\frac{1}{2}\{1 + Y_{DD}^5(Q)\} + S_{m,p}^{(DD)}(Q) + \{Y_{cD}^5(Q)\}^2[S_c(Q) - f_3^5(Q) - 1]\right]. \quad (16)$$

For the C_{2v} symmetry pentamer (Fig. 1), $S_{m,p}^{(OO)}(Q)$, $S_{m,p}^{(OD)}(Q)$, and $S_{m,p}^{(DD)}(Q)$ are given as Eqs. 16, 17, and 18 in I, respectively, and the factor $f_3^5(Q)$ is

$$f_3^5(Q) = \frac{1}{5}[8Y_{c_0c_1}(Q) + 4\{Y_{c_1c_3}(Q) + Y_{c_1c_4}(Q)\} + 2\{Y_{c_1c_2}(Q) + Y_{c_3c_4}(Q)\}]. \quad (17)$$

For the $S_c(Q)$ required in the calculation of Eqs. 14—16, we can use the observed X-ray intensity data, considering from the fact that the first peak mainly expresses the averaged packing of water molecules in the liquid.

Parameters Used in the Present Calculation. According to the procedure described above, we can calculate the $S_{OO}(Q)$, $S_{OD}(Q)$, and $S_{DD}(Q)$ for the pentamer-monomer mixture model with an appropriate value of pentamer fraction x_5 and other several parameters (intramolecular distances, distances between molecular centers, mean-square variations, *etc*). The calculated curves are compared with the experimental data at 25 °C by Thiessen and Narten[3] and by Soper and Silver.[4]

According to the result in paper II the value of x_5 is 0.85 at 25 °C. Then, we use x_1=0.15 and x_5=0.85 in the present analysis.

The values of molecular parameters are identical with those in paper II: for pentamer, r_{OD}^5=0.98 Å, r_{DD}^5= 1.60 Å, and DOD angle=109.5° corresponding to the molecule in heavy ice-I, for monomer, r_{OD}^1=0.96 Å, r_{DD}^1 =1.52 Å, and DOD angle=104.5° corresponding to the molecule in the vapor, and for the hydrogen-bonding, $r_{O_1O_2}$ (=r_{OO} in paper II)=2.85 Å and the O-O-O angle=109.5°.

In performing calculations, the determination of molecular centers is required and there are three ways of defining the molecular center: the center of mass of the molecule $\vec{r}_G$, the definition as $\vec{r}_{c_1}=\Sigma b_n\vec{r}_n/\Sigma b_n$,[6] and

$$\vec{r}_{c_2}=\frac{\sum b_n^2\vec{r}_n}{\sum b_n^2}, \tag{18}$$

where n ranges over the nuclei in a molecule. Positions of the three types of molecular center in heavy water molecules ($b_O=0.58\times10^{-12}$ cm and $b_D=0.67\times10^{-12}$ cm)[7] are indicated in Fig. 2. As seen in the figure, $\vec{r}_{c_1}\simeq\vec{r}_{c_2}$ for heavy water molecule. Thus, we adopt here the two kinds of molecular centers, $\vec{r}_G$, and $\vec{r}_{c_2}$.

With respect to the magnitudes of Debye-Waller factors, assuming the mean-square variation $2\gamma_{nn'}^{\nu}\propto$ the inter-nucleus distance $r_{nn'}^{\nu}$,[8] we assign the following values to the rms variation $\{2\gamma_{nn}^{\nu}\}^{1/2}$ as: first, $D_1=0.06$ Å$^{1/2}$ per 1 Å for intramolecular distances (r_{OD}^1, r_{DD}^1, r_{OD}^5, r_{DD}^5, r_{cO}^1, r_{cD}^1, r_{cO}^5, and r_{cD}^5) and for hydrogen-bonded distances ($r_{O_0O_1}$, and $r_{O_1D_{01}}$); second, $D_2=0.07$ Å$^{1/2}$ per 1 Å for the seven intermolecular distances ($r_{O_1O_2}$, $r_{O_0D_{11}}$, $r_{O_1D_{31}}$, $r_{D_{01}D_{11}}$, $r_{D_{01}D_{21}}$, $r_{D_{01}D_{22}}$, and $r_{D_{31}D_{41}}$) and for five distances between molecular centers ($r_{c_0c_1}$, $r_{c_1c_2}$, $r_{c_1c_3}$, $r_{c_1c_4}$, and $r_{c_3c_4}$); third, $D_3=0.1$ Å$^{1/2}$ per 1 Å for four intermolecular (distances ($r_{O_1D_{21}}$, $r_{O_1D_{22}}$, $r_{D_{12}D_{41}}$, and $r_{D_{11}D_{31}}$); and, fourth, $D_4=0.2$ Å$^{1/2}$ per 1 Å for four intermolecular distances ($r_{D_{11}D_{21}}$, $r_{D_{11}D_{22}}$, $r_{D_{11}D_{42}}$, and $r_{D_{12}D_{22}}$).

Results and Discussion

Comparison between Calculated Partial Structure Factors $S_{OO}(Q)$, $S_{OD}(Q)$, and $S_{DD}(Q)$ and Observed Data. Now, we can calculate the $S_{OO}(Q)$, $S_{OD}(Q)$, and $S_{DD}(Q)$, using Eqs. 14—18 together with the observed X-ray intensity data at 25 °C[9] for the $S_c(Q)$. The calculated O-O, O-D, and D-D structure factors are shown in Figs. 3, 4, and 5, respectively, and compared with the corresponding observed data. All calculated curves essentially reproduce the observed data successfully on the whole. Detailed features observed in these figures are described in the following.

Two calculated curves, $S_{OO}^{c2}(Q)$ and $S_{OO}^{G}(Q)$, are indicated in Fig. 3, where upper suffixes c2 and G shows the factor for the case when $\vec{r}_{c_2}$ and $\vec{r}_G$ is taken as the molecular center respectively. The $S_{OO}^{c2}(Q)$ is in agreement with the observed data on the whole, except for the deviation in the first peak at 2.1 Å^{-1} and that near $Q\simeq5$ Å^{-1}. On the other hand, an over oscillatory behavior appears in the calculated $S_{OO}^{G}(Q)$ curve, though a good agreement in the first peak. On the whole, the $S_{OO}^{c2}(Q)$ curve is somewhat better than $S_{OO}^{G}(Q)$ and the small difference between $S_{OO}^{c2}(Q)$ and $S_{OO}^{G}(Q)$ is attributed to the different magnitudes of the factors $Y_{cO}^{c2}(Q)$ and $Y_{cO}^{G}(Q)$ mainly.

With respect to the $S_{OD}(Q)$ shown in Fig. 4(a), the main features of the observed data are seen as: the

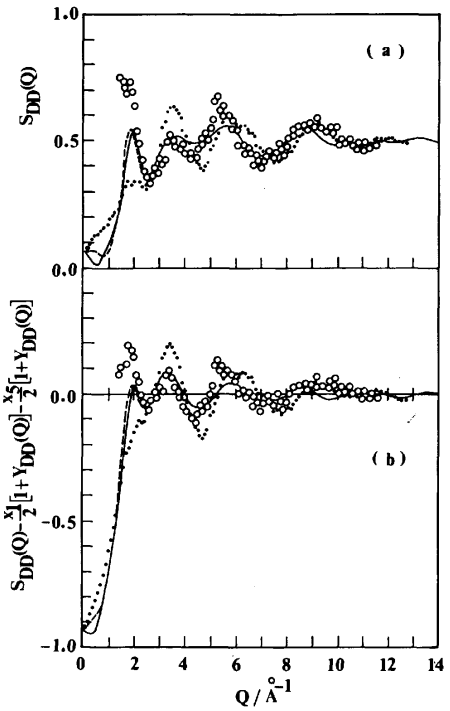

Fig. 5. Comparison between calculated D-D structure factors for the C_{2v} symmetry model and observed data.
(a) $S_{DD}(Q)$ (○: $S_{DD}(Q)$ observed by Soper and Silver,[4] ●: $S_{DD}(Q)$ observed by Thiessen and Narten[3]), (b) $S_{DD}(Q)-\frac{x_1}{2}[1+Y^1_{DD}(Q)]-\frac{x_5}{2}[1+Y^5_{DD}(Q)]$ (○: intermolecular part of $S_{DD}(Q)_{obsd}$ by Soper and Silver[4] from which the intramolecular contribution of the pentamer-monomer mixture model is subtracted, ●: intermolecular part of $S_{DD}(Q)_{obsd}$ by Thiessen and Narten[3] from which the intramolecular contribution of the pentamer-monomer mixture model is subtracted), ——: calculated curves ($\vec{r}_{c_2}$ as the molecular center), ------: calculated curves ($\vec{r}_G$ as the molecular center).

largest peak at 2 Å^{-1}, a bump at *ca.* 4 Å^{-1} a deep minimum at *ca.* 5 Å^{-1} and a broader peak ranging over 6—9 Å^{-1}. The calculated curve essentially reproduces these features of the $S_{OD}(Q)$ data. Especially, the agreement between the $S^{c_2}_{OD}(Q)$ and the observed data is excellent in the range of the first peak, 1—3 Å^{-1}. A large deviation of the calculated $S^{G}_{OD}(Q)$ curve from the data is seen in the lower Q range, like the case of O-O structure factor (Fig. 3). The same trend is found in the intermolecular part of the O-D structure factor, $S_{OD}(Q)-x_1Y^1_{OD}(Q)-x_5Y^5_{OD}(Q)$, shown in Fig. 4(b).

In Fig. 5, the calculated D-D structure factors are compared with the neutron diffraction data at reactor by Thiessen and Narten[3] and those at LINAC by Soper and Silver.[4] The two recent experimental data agree with each other on the whole. But, several noticeable deviations are observed. Taking account of the experimental difficulties in determining partial structure factors, we can see in Fig. 5(a) that the calculated $S^{c_2}_{DD}(Q)$ and $S^{G}_{DD}(Q)$ curves are in essential agreement with Soper and Silver's data on the whole. With respect to these features, the behavior of the intermolecular part of the $S_{DD}(Q)$ shown in Fig. 5(b) is quite similar to that of the $S_{DD}(Q)$ on the whole. Thus, we can state that the pentamer-monomer mixture model with the regular tetrahedral pentamer of the C_{2v} symmetrical structure reproduces the fundamental character of the D-D structure factors satisfactorily. In addition, the appearance of the first peak at 2 Å^{-1} in the calculated curves as well as in Soper and Silver's data is noticeable, though the magnitude of the calculated curves is only half that of their data.

Thus, the agreement between the calculated structure factor curves and observed data suggests the essential effectiveness of the pentamer-monomer mixture model with the regular tetrahedral pentamer as its dominant constituent.

We have taken so far the molecular center to be at the oxygen nucleus, similarly to the choice by Page and Powles,[5] and successfully interpreted the total structure factors of heavy water.[1,2] When the center is taken so, the $S_{OO}(Q)$ is reduced to $S_c(Q)$ resultantly as seen in Eq. 14, and then a reasonable estimation of the molecular center is required for the present calculation. As described in the preceding section, we have adopted two kinds of molecular centers for heavy water molecule, $\vec{r}_{c_2}$ and $\vec{r}_G$ (Fig. 2), and have calculated the partial structure factors (Figs. 3—5). The reasonable choice of the molecular center is practically important in obtaining successful results. Moreover, it is pointed out, as a noticeable feature, that the calculated curves are independent on the choice of molecular centers in this work, although only slight deviations of the $S^{G}_{ss}(Q)$ from $S^{c_2}_{ss}(Q)$ appear in lower Q region as seen in Figs. 3—5.

Freely Rotating Model. It is of much interesting whether the overall orientational configuration of water molecules in tetrahedral pentamer is the C_{2v} symmetry or the freely rotating, with respect to peripheral molecules. In paper I, we calculated the total structure factors for the freely rotating model in addition to the C_{2v} symmetry model. In the former model, the peripheral molecules are rotating freely around the axis on a straight line joining the central and peripheral oxygens. Here, we calculate the partial structure factors of the freely rotating model also. Then, for that model, we have assumed that the positions of outer six deuterons are reduced to those of peripheral oxygens on the average and also that the positions of all the molecular centers are reduced to those of oxygens within the molecule including its molecular center. Accordingly, the $S^{(OD)}_{m,p}(Q)$ and $S^{(DD)}_{m,p}(Q)$ are written as

$$S^{(OD)}_{m,p}(Q) = \frac{1}{5}[2Y_{O_1D_{01}}(Q) + 3Y_{O_1D_{31}}(Q) + 6Y_{O_0D_{11}}(Q) + 9Y_{O_1O_2}(Q)], \quad (19)$$

and

$$S^{(DD)}_{m,p}(Q) = \frac{1}{10}[Y_{D_{31}D_{41}}(Q) + 8Y_{O_0D_{11}}(Q) + 10Y_{O_1D_{31}}(Q) + 8Y_{O_1D_{01}}(Q) + 13Y_{O_1O_2}(Q)], \quad (20)$$

respectively, and $f^5_3(Q)$ (Eq. 20) is reduced to Eq. 17. Equations 19 and 20 are identical with Eqs. 19 and 20 in paper I, where a typographical error in Eq. 20 in paper I is corrected.[10] Then, for the freely rotating model, using Eqs. 14—20, we calculated the O-O, O-D, and

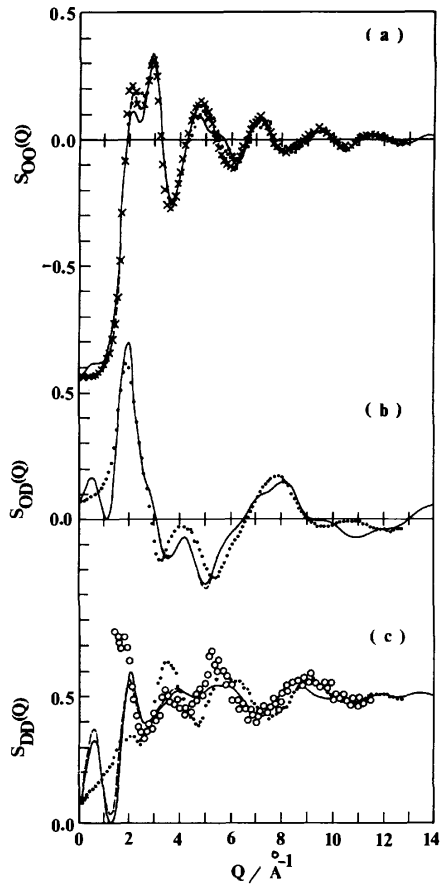

Fig. 6. Comparison between calculated partial structure factors for the freely rotating model and observed data.

D–D structure factors. The calculated curves are shown in Fig. 6.

Compared Figs. 6(a)—(c) with Figs. 3—5, respectively, it is found that the difference between the results for the freely rotating model and those for the C_{2v} symmetry model is very slight, except the D–D structure factors in lower Q region. As seen in Figs. 5 and 6(c), the calculated $S_{DD}(Q)$ curves for both models are fairly different from each other in lower Q region ($\lesssim 1.5$ Å^{-1}). This means the fact that the D–D structure factors in low Q region dominantly reflect the orientational configuration of water molecules in the liquid. Thus, the marked deviation of the calculated $S_{DD}(Q)$ curve for the freely rotating model from the observed data is considered to indicate that the model behaves only as an approximate one.

Studies of Polystyrene-based Ion Exchange Fiber. II. A Novel Fiber-form Catalyst for Sucrose Inversion and Methyl Acetate Hydrolysis†

Toshio YOSHIOKA* and Masaharu SHIMAMURA
Fibers Research Laboratories, Toray Industries, Inc., Sonoyama, Otsu 520
(Received June 9, 1983)

To obtain a novel acid-base catalyst of high activity and easy treatment, we have prepared polystyrene-based fibrous ion exchange catalysts which have large surface areas per unit of weight and which can be utilized in various forms. They are excellent in chemical stability and mechanical strength due to their composite structures, reinforced with polypropyrene. The reactions of sucrose inversion and methyl acetate hydrolysis were carried out by using these cation exchange fibers and ordinary cation exchange resins. The fiber has about sixteen times as high a catalytic activity per equivalent acid as the resin in the case of sucrose inversion. The intrinsic rate constant in the fiber phase is evaluated to be 2.4 times larger than that in the resin phase in terms of the solid-catalysis theory considering the catalytic effectiveness factor and the absorption coefficient. On the other hand, the catalytic activity per equivalent acid of the fiber is almost equal to that of the resin in the case of methyl acetate hydrolysis. It is suggested that this different behavior is attributable to the different molecular sizes of the reactants.

Polystyrene-based ion exchange resins have been intensively studied as solid acid-base catalysts in a number of organic reactions.[2] The use of ion exchange resins, however, has the disadvantage that their catalytic activities per equivalent acid or base are lower than those of free acids or bases in the case of a reaction controlled by intraparticle diffusion. Although catalytic activity is enhanced by using a fine or crushed resin, catalytic treatment becomes difficult.

In order to enhance the catalytic activity and to make catalytic treatment easier, we have undertaken an investigation of fibrous acid-base catalysts, which have large surface areas per unit of weight and which can be used in various forms. Polystyrene-based fibrous ion exchange catalysts have been prepared and used in the well-known reactions of sucrose inversion and methyl acetate hydrolysis.[3] These results will be discussed in terms of the solid-catalysis theory in this paper.

Experimental

Polystyrene (PSt; average molecular weight: 23×10^4) as the predominant *sea* ingredient and polypropylene (PP; average molecular weight: 20×10^4) as the *island* ingredient were spun into composite filaments having an *islands-in-a-sea* type sectional structure, as is shown in Fig. 1, in the conventional manner. Polystyrene-based ion exchange fibers, named IONEX, were prepared according to the process shown in Fig. 2 after spinning.[1] The crosslinking was performed by treating the fiber (10 g) with 100 ml of a solution consisting of 5 wt% paraformaldehyde, 25 wt% acetic acid, and 70 wt% concd. sulfuric acid at 80 °C for 2 h or at 90 °C for 4 h.[4] Fibrous acid or base catalysts were obtained by treating these fibers with an acid or a base in the usual manner.

These fibrous cation exchange catalysts were packed into a jacketed glass fixed-bed reactor with an inside diameter of 2 cm. The reactions of sucrose inversion and methyl acetate hydrolysis were carried out by pumping a 50 wt% sucrose aqueous solution at 60 °C and a 3.2 M (1 M=1 mol dm^{-3}) methyl acetate aqueous solution at 30 °C respectively through the reactor. For the purposes of comparison, the reactions were also carried out by using commercially available cation exchange resins (Amberlite IR-120B and IR-200) with radii of *ca.* 250 μm. The reaction ratio of sucrose was measured according to the usual polarimetric technique.[5] The acetic acid concentration was determined by the titration method.

† A preliminary report of this work was presented in *Shokubai*, **25**, 115 (1983).

Results and Discussion

Fibrous Acid-base Catalyst. The characteristic data of the filamentary IONEX are summarized in Table 1. Acid-base catalysts in various forms, such as cut fiber, knitted fabric, woven fabric, braid, felt, nonwoven fabric, and paper, can be obtained by processing the filaments before chemical reactions, as the filaments reinforced with polypropylene have high mechanical strengths. Figure 3 shows fibrous cation

exchange catalysts in various forms. The ion exchange capacities per unit of weight of IONEX are lower than those of ordinary ion exchange resins by the amount of polypropyrene used for reinforcement.

Sucrose Inversion. The results of sucrose inversion by various acid catalysts are shown in Fig. 4 and Table 2. On the assumption of first-order kinetics, the apparent rate constant, k, was determined from the following equation:

$$\ln(1-X) = -k\tau, \tag{1}$$

where X is a reaction ratio of sucrose and where τ is a contact time.

The effect of the packing density of the fibers was also examined. In the density range above 0.1 g ml^{-1} the rate constant is close to the value of 13.4×10^{-3} ml s^{-1} mequiv^{-1} determined by a batch method. However, below 0.1 g ml^{-1} it decreases slightly as the density is lowered, probably because of the effect of an irregular flow. It was found that the height of the fixed-bed and the crosslinking degree of the fiber do not affect the rate constant. The catalytic activity of the knitted IONEX is 30% lower than that of the filamentary IONEX. This result may be interpreted by assuming that the effective surface area per unit of weight decreases or an irregular flow takes place because of the knitted structure.

The apparent rate constant of the filamentary IONEX is about sixteen times as large as that of the gel-type resin, IR-120B. According to the solid-catalysis theory, the apparent rate constant, k, can be described by the following equation:[6,7]

$$k = \lambda k_0 \eta, \tag{2}$$

where λ, k_0, and η are an absorption coefficient, an intrinsic rate constant, and a catalytic effectiveness factor respectively. Here, the catalytic effectiveness factors in the two cases of spherical and fibrous catalysts with a given radius, R, are given by:[8]

$$\eta(\text{sphere}) = \frac{3(mR\coth mR-1)}{(mR)^2} \tag{3}$$

and

$$\eta(\text{fiber}) = \frac{2I_1(mR)}{I_0(mR)} \tag{4}$$

respectively, where I_0 and I_1 are modified Bessel functions of zero and first-order and where $m=\sqrt{k_0/D}$, in which D is an effective diffusion coefficient of a reactant in a catalyst. The relation between m and η in the two cases of the spherical catalyst with a radius of 250 μm and the fibrous catalyst with a radius of 15 μm is shown in Fig. 5.

The value of η for IR-120B is larger than 0.25, judging from the results studied by Gilliland *et al.*,[7] so that the value of η for the fiber can be roughly evaluated

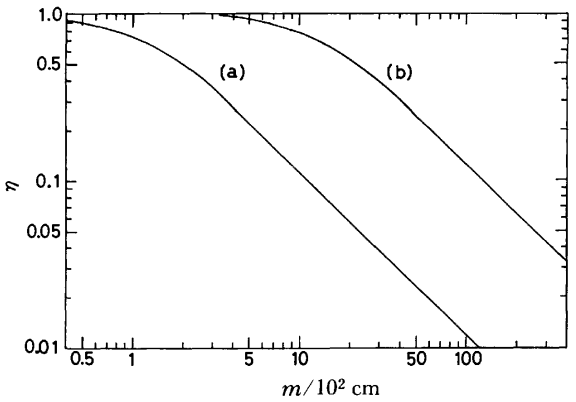

Fig. 5. Catalytic effectiveness factor η as a function of m (Eqs. 3 and 4).
(a) Spherical catalyst (R= 250 μm), and (b) fibrous catalyst (R=15 μm).

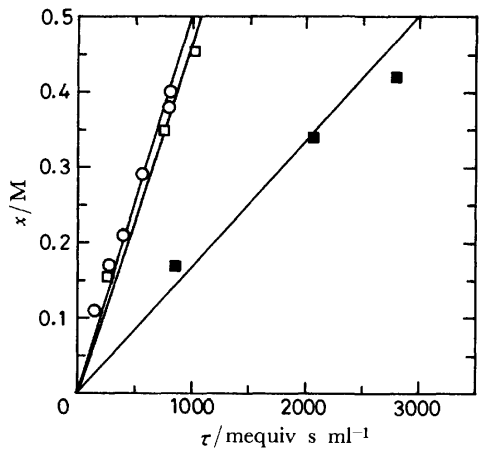

Fig. 6. Plots of x *vs.* τ in methyl acetate hydrolysis (Eq. 5).

to be almost equal to 1 at the corresponding m-value from Fig. 5. The sucrose-absorption coefficients for IR-120B and the fiber in a Na form were found to be 0.30±0.05 and 0.50±0.1 in a 50 wt% sucrose aqueous solution. The former value is much larger than that in a 20 wt/vol% sucrose aqueous solution determined by Gilliland *et al.*[7] It is, however, considered to be an adequate value, because the absorption coefficient generally increases as the concentration of sucrose in a solution increases. Probably the absorption coefficient of the fiber is larger than that of the resin because of the difference in water contents; that is, the fiber has a higher water content than the resin.[6]

In considering the results described above, the experimental data show that the intrinsic rate constant in the fiber phase is 2.4 times larger than that in the resin phase. It has been reported by Gilliland *et al.* that the intrinsic rate constants in the resin phase are only 60% as large as those determined in 3 M acid solutions.[7] The reason for the reduced effectiveness of the resin as a catalyst has been attributed to an irregular structure of the crosslinked resin and to steric hindrance due to a large reactant of the sucrose molecule. The fact that the fiber has a higher intrinsic rate constant than the resin may be explained by assuming that the fiber has such a crosslinked structure that the steric hindrance is relieved. That is, the fiber based on polystrene essentially has a less restricted one-dimensional structure although its chains are crosslinked by methylene bonds, while the resin based on a styrene–divinylbenzene polymer has a more restricted three-dimensional structure. The difference in the intrinsic rate constants may be enhanced by the high sucrose concentration of 50 wt%.

On the other hand, the catalytic effectiveness factor for IR-200 of the macroreticular type can be estimated to be 1 from its large surface area of 50 $m^2\ g^{-1}$. Its absorption coefficient for sucrose was measured as 0.40±0.05. Taking these facts into account, the intrinsic rate constant in the IR-200 phase is found to be only 20% as large as that in the IR-120B phase. This may be attributable to the large effect of the steric hindrance, which prevents a close approach of a sucrose molecule to an active site for inversion, because the macroreticular-type resin is three-dimensionally and tightly crosslinked.[7,9]

Methyl Acetate Hydrolysis. The reaction of methyl acetate hydrolysis was carried out by using the Nos. 1, 4, and 5 beds shown in Table 2. The acetic acid concentrations in effluent solutions as a function of the contact times are shown in Fig. 6. As this reaction is first-order, the apparent rate constant can be evaluated from the following equation:

$$\ln a/(a-x) = k\tau, \tag{5}$$

where x is an acetic acid concentration and a is its concentration in equilibrium. It is possible to evaluate the apparent rate constants directly from Fig. 6, since k is equal to $x/a\tau$ when x is sufficiently small.

No large difference in the apparent rate constants was observed between the fiber and IR-120B. This fact indicates that their catalytic effectiveness factors are both close to 1 because of the probable rapid diffusion of methyl acetate molecules in the catalysts, and that both the absorption coefficient and the intrinsic rate constant of the fiber are almost equal to those of the resin.[6,10] On the other hand, the apparent rate constant for IR-200 is only one third as large as that for IR-120B. This result can be interpreted by assuming that the former has a small absorption coefficient and also has a small intrinsic rate constant because of the steric hindrance in comparison with the latter, although their catalytic effectiveness factors are both close to 1.[11]

The fibrous catalyst is expected to be applicable to new reactors such as the reaction distiller of methyl acetate hydrolysis, since it can be used in various forms.[12,13]

Conclusion

1. Polystyrene-based fibrous ion exchange catalysts which are excellent in chemical stability and mechanical strength have been prepared. These fibrous acid-base catalysts have a large surface areas per unit of

weight and can be used in various forms.

2. These ion exchange fibers have not only much higher catalytic activities than ordinary ion exchange resins when the reactant is a large molecule such as sucrose, but also the advantage of easier catalytic treatment than a fine or crushed resin.

3. When the reactant is a small molecule such as methyl acetate, these ion exchange fiber show as high catalytic activities as ordinary ion exchange resins.

The authors would like to express their appreciation to Dr. Tatsuro Kawaguchi, Mr. Michihiko Tanaka, and Dr. Masaki Nishino for their continuous encouragement throughout this work. They are also much obliged to Mr. Kazuo Teramoto for his advice on the chemical treatments and to Mr. Seiichi Yoshikawa and other collaborators for the preparation of the composite fibers. The authors also wish to thank Toray Industries, Inc., for making this study possible.

The Mercury Volatilization Rate from Water to the Atmosphere

Shoichi Okouchi,* Sokichi Sasaki, and Yoshio Harano†
Chemical Laboratory, College of Engineering, Hosei University, Koganei, Tokyo 184
†*Department of Applied Chemistry, Osaka City University, Sumiyoshi-ku, Osaka 558*
(Received June 20, 1983)

The volatilization rate of mercury was studied, together with the oxygen reaeration rate, in a laboratory scale under various mixing conditions. The rates of both mercury and oxygen were controlled by mass transfer in the aqueous phase. The obtained ratio of the mercury-volatilization rate constant to the oxygen-reaeration rate constant was 0.94 at temperatures ranging from 283 to 303. If the oxygen-reaeration rate constant is available in a real-water body or in a wastewater-treatment facility, multiplying its value by the ratio of 0.94 permits the determination of the volatilization rate constant of mercury without the direct measurement of the mercury.

It is well known that contaminants such as mercury, DDT, and PCB have been transported widely throughout global environments. The volatilization of contaminants from natural water bodies to the atmosphere has been considered to be a very important step in the environmental-pollution process.

A mass balance for the volatilization of a contaminant, i, from well-mixed water into the atmosphere is given by Eq. 1:

$$-dC^{(i)}/dt = K_V^{(i)}(C^{(i)} - p^{(i)}/H^{(i)}), \quad (1)$$

where C is the concentration of the contaminant in the water; t is the time; K_v is the volatilization rate constant; p is the partial pressure of the contaminant in the atmosphere, and H is Henry's law constant. The subscript (i) denotes the component i. According to the two-film model, $K_V^{(i)}$ is given by Eq. 2:

$$K_V^{(i)} = K_L^{(i)}a = [1/k_L^{(i)} + (RT/H^{(i)})(1/k_G^{(i)})]^{-1}a, \quad (2)$$

where K_L is the overall mass-transfer coefficient based on the liquid-phase concentration; k_L and k_G are the mass-transfer coefficients in liquid and gas films respectively; a is the interfacial contact area per liquid volume; R is the gas constant, and T is the absolute temperature.

The actual environmental-water body generally comes in contact with the atmosphere on its free surface; therefore, a is given by the reciprocal of the depth of the water, L. Thus, the overall volatilization rate constant of a component, i, from an environmental-water body, $K_{V(env)}^{(i)}$, is expressed by:

$$K_{V(env)}^{(i)} = (1/L)[1/k_{L(env)}^{(i)} + (RT/H^{(i)})(1/k_{G(env)}^{(i)})]^{-1}. \quad (3)$$

The subscript (env) means the environmental-water body. Since the coefficients, $k_{L(env)}$ and $k_{G(env)}$, depend greatly on the hydrodynamic situation of both water and atmosphere, it is necessary, for the direct evaluation of $K_{V(env)}^{(i)}$, according to Eq. 3, to grasp the mixing situation of the system quantitatively. This is, however, a very difficult matter, except the oxygen-reaeration rate constant, $K_{V(env)}^{(O_2)}$,[1-3] of $i = O_2$.

From these circumstances, the volatilization rates of some contaminants on the actual water body can be estimated indirectly, according to Eq. 4, by using the data on $K_{V(env)}^{(O_2)}$:

$$K_{V(env)}^{(i)} = K_{V(env)}^{(O_2)} \times (K_V^{(i)}/K_V^{(O_2)}), \quad (4)$$

where $K_V^{(O_2)}$ is the oxygen-reaeration rate constant defined by Eq. 5 and where both $K_V^{(i)}$ and $K_V^{(O_2)}$ can be measured experimentally under well-defined conditions:

$$dC^{(O_2)}/dt = K_V^{(O_2)}(C_S^{(O_2)} - C^{(O_2)}), \quad (5)$$

where $C_S^{(O_2)}$ is the solubility of oxygen in water for a partial of oxygen in the atmosphere.

The volatilization rate of mercury in the actual water body has not been estimated, although mercury is one of the most important environmental contaminants and can be anticipated to volatilize readily to the atmosphere.[4] In this work, the $K_V^{(i)}/K_V^{(O_2)}$ ratio, which is the determining factor for the volatility of the contaminants, was determined experimentally for mercury.

Experimental

All the chemicals used were of an analytical reagent grade. A schematic diagram of the experimental apparatus is shown in Fig. 1. The volatilization rate constant of mercury was measured as follows. An aqueous solution of mercury(II) chloride at the concentration of the ppb level (below the value of elemental mercury solubility[17] in water) was prepared in the vessel (V in Fig. 1) and was then stirred at a constant agitation speed by means of a magnetic stirrer. The vessel was maintained at a constant temperature, and air was made to flow through the space above the aqueous solution in the vessel, the absorption cell(C), and the absorber(S),

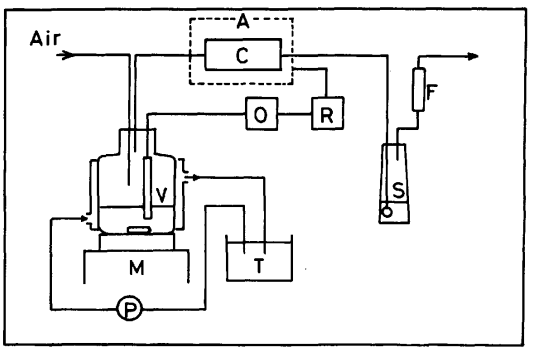

Fig. 1. Schematic diagram of apparatus.
A: Atomic absorption spectrophotometer, C: absorption cell, F: flow meter, M: magnetic stirrer, O: dissolved oxygen analyzer, P: pump, R: recorder, S: ($KMnO_4$+H_2SO_4) absorber, T: thermostat, V: volatilization vessel.

successively, at a constant flow rate throughout the measurements. By the addition of hydrazine hydrate to the aqueous solution as a reducing agent,[4] the mercury(II) species were reduced quickly and completely to elemental mercury. The elemental mercury thus formed began immidiately to volatilize into the flowing air. The concentration of mercury in air was continuously measured from the absorbance at 253.7 nm obtained by means of an absorption spectrophotometer(A). The volatilization rate constant of mercury was determined by fitting the concentration data to the integral form of Eq. 1.

As to the measurement of the oxygen-reaeration rate, the distilled water in the vessel(V) was purged with nitrogen to remove most of the dissolved oxygen. By agitating the water at a constant agitation speed, oxygen from the atmosphere was dissolved in the oxygen-deficient water. The oxygen-reaeration rate constant was determined by fitting the data of the oxygen concentration in the water, as measured by means of a dissolved oxygen analyzer, to the integral form of Eq. 5.

Results and Discussion

The volatilization rate constant of mercury, $K_v^{(Hg)}$, was unaffected by the mercury concentration over the range from 5×10^{-11} to 2.5×10^{-10} mol m^{-3}, as was to be expected from Eq. 2. The effect of turbulence in the gas phase on $K_v^{(Hg)}$ and on the oxygen-reaeration rate constant, $K_v^{(O_2)}$, was not observed over the air-flow rate range from 0.03 to 0.3 m^3 h^{-1} at 298 K, as shown in Fig.

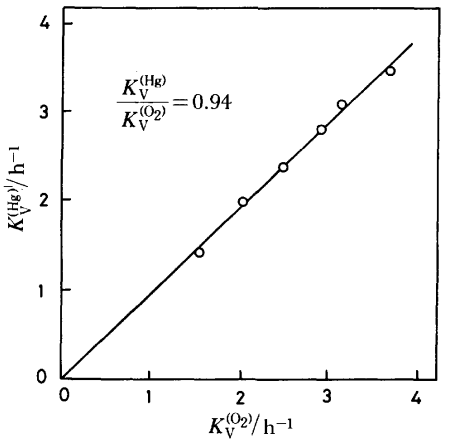

Fig. 4. Relation between $K_v^{(Hg)}$ and $K_v^{(O_2)}$ at 298 K.

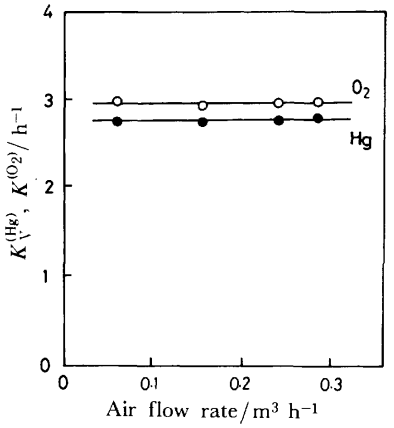

Fig. 2. Effect of air flow rate on $K_v^{(Hg)}$ and $K_v^{(O_2)}$ at 298 K.

Table 1. Volatilization rate constant and half-life of contaminants estimated as $K_{v(env)}^{(O_2)}=10^{-2}$ h^{-1}

Contaminant (i)	Molecular weight	$K_v^{(i)}/K_v^{(O_2)}$	$K_{v(env)}^{(i)}$/h^{-1}	$\tau^{(i)}$/d	Vapor pressure/Pa (at 298 K)
Mercury	200.59	0.94	9.4×10^{-3}	3.1	0.245
Benzene	78.11	0.56	5.6×10^{-3}	5.2	12700
Tetrachloroethylene	165.83	0.52	5.2×10^{-3}	5.6	2400

2. On the other hand, both the rate constants increased with an increase in the agitation rate in the aqueous phase, as shown in Fig. 3. From these data, the values of $K_v^{(Hg)}$ and $K_v^{(O_2)}$ at 298 K were related by a linear relationship with a slope of 0.94 ($=K_v^{(Hg)}/K_v^{(O_2)}$), as shown in Fig. 4. The $K_v^{(Hg)}/K_v^{(O_2)}$ ratio was observed to be independent of temperatures ranging from 283 to 303 K, as shown in Fig. 5, although both the rate constants increased with a rise in the temperatures. Figure 6 shows the effect of the depth of the solution on the rate constants, indicating that the greater the depth, the smaller the rate constants become at a constant agitation speed because of the smaller turbulence in the aqueous solution and the smaller interfacial area. However, the $K_v^{(Hg)}/K_v^{(O_2)}$ ratio did not change, regardless of the depth.

Mackay and Leinonen[5] have suggested that mass transfer in the liquid phase is rate-controlling when the value of Henry's law constant is greater than 500 m^3 Pa mol^{-1}. Henry's law constant of mercury and oxygen is 993[6] and 79240[7] m^3 Pa mol^{-1} respectively at 298 K. As has been mentioned above, the mercury-volatilization rate and the oxygen-reaeration rate were both much many affected by the turbulence in the liquid phase than by that in the gas phase; consequently, these results support the suggestion of Mackay and Leinonen. Therefore, most of the resistance to these mass-transfer rates is concluded to lie in the liquid-phase boundary layer; thus, the term of $(RT/H^{(i)})(1/k_G^{(i)})$ in Eq. 2 can be neglected.

Taking into account the fact that the mass-transfer coefficient is proportional to the n-th power of diffusivity,[8] together with the above consideration, Eq. 6 is obtained from Eq. 2:

$$K_V^{(Hg)}/K_V^{(O_2)} = K_L^{(Hg)}/K_L^{(O_2)} = (D_L^{(Hg)}/D_L^{(O_2)})^n, \quad (6)$$

where D_L is the diffusivity** in the liquid phase. The value of n is $0.5\leq n\leq 1$, where n becomes unity in the case based on the classical theory of the two-film mass-transfer model[9] and where n is equal to 0.5 according to the theories of the penetration model[10] or the surface-renewal model[11]. From Eq. 6, the value of $K_v^{(Hg)}/K_v^{(O_2)}$ is estimated to be 1.2 ($n=1$) or 1.1 ($n=0.5$) by using the Othmer-Thakar relation[12] of $D_L\propto V_b^{-0.6}$, where V_b is the molar volume at the boiling point, 0.83 ($n=1$) or 0.91 ($n=0.5$) by considering the inverse proportionality of D_L to the molecular diameter[13] and 1.3 ($m=-0.5$[14]) or 1.2 ($m=-0.31$[15]) by applying the relation of $K_v\propto V_c^m$, where V_c is the critical molar volume. Based on the Liss-Slater's relation[16] of $K_v\propto M^{-0.5}$, the value of 0.4 is obtained. Besides this, all the other estimated values are considered to support the value of 0.94 obtained experimentally in this work.

The values of the oxygen-reaeration rate constant in the representative environmental water bodies, $K_{v(env)}^{(O_2)}$ [h^{-1}], have been reported[1] to be 4.6×10^{-3}—9.6×10^{-3} for ponds, 4.2×10^{-3}—3.9×10^{-1} for rivers, and 4.2×10^{-3}—1.2×10^{-2} for lakes. Table 1 shows the $K_{v(env)}^{(i)}$ values calculated by Eq. 4 for some contaminants, taking the value of $K_{v(env)}^{(O_2)}$ to be 10^{-2} h^{-1} and the values of $K_v^{(i)}/K_v^{(O_2)}$ to be 0.94, 0.57,[7] and 0.52[7] for mercury (in this work), benzene, and tetrachloroethylene respectively. Table 1 also shows the half-life times of the contaminants, $\tau^{(i)}$, defined by Eq. 7:

$$\tau^{(i)} = \ln 2/K_{v(env)}^{(i)}. \quad (7)$$

As is apparent in Table 1, mercury volatilizes about 1.7—1.8 times more rapidly than benzene or tetrachloroethylene, although the latter has much higher vapor pressures and smaller molecular weights. In this work, it has been demonstrated that the volatiliation of mercury in a water body to the atmosphere occurs much faster than has generally been appreciated.

** The diffusivity of mercury has not been measured.

Magnetic Circular Dichroism Studies of Bipyridyls

Hiroyuki UCHIMURA, Akio TAJIRI, and Masahiro HATANO*
Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai 980
(Received June 21, 1983)

The magnetic circular dichroism (MCD) and UV absorption spectra of 2,2′- and 4,4′-bipyridyl in cyclohexane and sulfuric acid were measured at room temperature. The MCD spectrum of 2,2′-bipyridyl is different from that of 4,4′-bipyridyl, reflecting the difference in molecular symmetry between them. The absorption and MCD spectral profiles of 2,2′-bipyridyl in cyclohexane are different from those of 2,2′-bipyridyl in mineral acids, in this system protonation taking place on the nitrogen atoms to give a mono- or di-cation with low symmetry. On the contrary, the MCD spectra of 4,4′-bipyridyl in cyclohexane and in acidic media at pH 0.98 exhibit a similar spectral profile to each other due to the D_2 symmetry being retained in 4,4′-bipyridyl. Theoretical calculations were carried out on the basis of the PPP-SCF-CI method to get a reasonable explanation for the observed MCD spectra. The assignments of the MCD bands of these compounds are given and their dihedral angles are estimated.

According to Fisher-Hjalmars' consideration,[1] the repulsion among ortho-protons in biphenyl plays an important role in determining its stable conformation. The twisted angle around the central bond (see Fig. 1) is given on a balance between two effects, the conjugation between the two benzene rings and the repulsion among the nonbonded atoms, especially among the ortho-protons. Accordingly, on substitution with bulky groups at the ortho-positions the dihedral angle of biphenyl will increase due to an appreciable increase in the steric repulsion, giving rise to a hypsochromic effect on the transition energy and a hypochromic effect on the intensity of the conjugation band.[2]

It has been known from an X-ray diffraction study that 2,2′-bipyridyl has a trans-planar structure.[3] The molecular structure in solvents where the protonation of the bipyridyl moiety is prevented is expected to be planar because of the absence of the repulsion among the protonated protons. On the other hand, in 4,4′-bipyridyl there exists a repulsion among the ortho-protons as in biphenyl. Accordingly, the two pyridine rings of 4,4′-bipyridyl in solution are expected to be twisted around the central bond.

For bipyridyls, abbreviated to B hereafter, the equilibria are expected to be established in acidic media,

$$BH_2^{2+} \overset{K_2}{\rightleftharpoons} BH^+ + H^+ \overset{K_1}{\rightleftharpoons} B + 2H^+,$$

where K_1 and K_2 are the acid dissociation constants. There exist three species, a neutral species B and protonated species BH^+ and BH_2^{2+}, in acidic solutions. Nakamoto[4] investigated the equilibrium between the neutral molecule B and the mono-cation BH^+ of 2,2′-bipyridyl by observing UV absorption spectra at various pH values. According to this investigation 2,2′-bipyridyl exists mainly in a mono-cationic form at pH≃1.80 and in a neutral form at pH>9.15. Krumholz[5] determined pK_1 of 2,2′-bipyridyl to be 4.44 based on the potentiometric titration method. This value is in good agreement with that obtained by Nakamoto.[4]

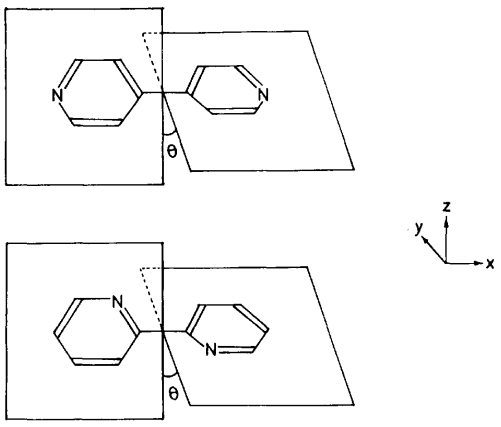

Fig. 1. Molecular skeletons and choice of axis for 4,4′-(top) and 2,2′-bipyridyl (bottom).

On the other hand, pK_1 and pK_2 for 4,4′-bipyridyl were evaluated to be 4.82 and 3.17, respectively.[5] Therefore, 4,4′-bipyridyl exists mainly as a di-cation at pH<2.0.

In 2,2′-bipyridyldium, two pyridinium rings seem to be twisted around the central bond due to the repulsion among the ortho-protons. However, Nakamoto[4] has suggested that the planar trans-configuration is preferable for 2,2′-bipyridyldium in view of the charge distribution. Borgen *et al.*[6] have drawn the same conclusion for the di-cation of 2,2′-bipyridyl on the basis of a CNDO calculation.

The 2,2′-bipyridylium cation was confirmed to have a cis-form by Nakamoto[4] based on a comparative absorption spectroscopic study between the mono-cation and the metal-chelate compound $[Ni(bypy)_3]Cl_2$ in which bipyridyl is forced to take a cis-form. In the mono-cation the two pyridine rings seem to be twisted to some extent around the central bond due to the repulsion among the ortho-protons.

In this work 2,2′- and 4,4′-bipyridyl in cyclohexane and acids were reexamined from the view point of MCD spectroscopy. A quantum mechanical calculation based on the PPP method was carried out to get a reasonable characterization and assignment of observed MCD bands. A comparison between experimental and theoretical results has led to an estimation of the dihedral angles of bipyridyls in solution.

Experimental

Commercially available 2,2′- and 4,4′-bipyridyl were purified by sublimation under reduced pressure. The cyclohexane and sulfuric acid were of spectro-grade and used

as solvents without further purification. The buffer solutions were $CH_3COOH+CH_3COOK$ with pH=3.0—6.0 and $NaOH+KH_2PO_4$ with pH=6.97.

MCD and UV spectra were measured with a JASCO-J500C recordig circular dichrometer equipped with a 1.14 T electromagnet and with a JASCO-UVIDEC-J510 recording spectrophotometer, respectively. All measurements were carried out at room temperature.

Theoretical

The electronic transition energies, oscillator strenghths, and Faraday B values of the bipyridyls and their cations were evaluatd by the use of the PPP method[7] together with configuration interaction among singly excited configurations with transition energies below 10 eV. One-center core and repulsion integrals were evaluated from valence state ionization potentials and electron affinities. Two-center core integrals, β_{pq}, were calculated by use of the Wolfsberg-Helmholz equation,[8] except β_{CN^+} for which the value of −2.74 eV was used.[9] Two-center repulsion integrals were evaluated by use of the Nishimoto-Mataga equation.[10] The repulsion integrals, γ_{pq}, within the pyridine ring, were evaluated according to the usual formula

$$\gamma_{pq} = \frac{14.397}{R_{pq} + a_{pq}}, \tag{1}$$

with

$$a_{pq} = \frac{28.794}{\gamma_{pp} + \gamma_{qq}}, \tag{2}$$

where R_{pq} is the distance between atoms p and q, and γ_{pp} stands for the one-center repulsion integral. The repulsion integral, γ_{pq}, in which atoms p and q belong to different pyridine rings was calculated using Eq. 1 with the following modification on a_{pq}:

$$a_{pq} = \frac{28.794}{(\gamma_{pp}+\gamma_{qq})\cos^2\theta + (\gamma'_{pp}+\gamma'_{qq})\sin^2\theta}, \tag{3}$$

$$\gamma'_{pp} = \gamma_{pp} - 6F_2, \tag{4}$$

where θ is the dihedral angle and F_2 is the Slater-Condon parameter. The bond distances and bond angles of 2,2′-bipyridyl were taken from X-ray diffraction data.[3] The molecular geometry for the pyridine ring in 4,4′-bipyridyl was taken from electron diffraction data for pyridine.[11] The molecular structure of the cation was assumed to be identical with that of the corresponding neutral molecule. The coordinate system is shown in Fig. 1. The x axis lies along the long molecular axis and the y axis bisects the dihedral angle, θ.

The theoretical Faraday B term associated with an electronic transition, $j \leftarrow a$, is expressed as[12]

$$\begin{aligned} B(j\leftarrow a) = \mathrm{Im}\Big[& \sum_{k\neq a} \{\langle k|\vec{\mu}|a\rangle/(E_k - E_a)\} \times \\ & \langle a|\vec{m}|j\rangle \times \langle j|\vec{m}|k\rangle \\ & + \sum_{k\neq j} \{\langle j|\vec{\mu}|k\rangle/(E_k - E_j)\} \times \\ & \langle a|\vec{m}|j\rangle \times \langle k|\vec{m}|a\rangle\Big], \end{aligned} \tag{5}$$

where $\vec{\mu}$ and $\vec{m}$ denote the magnetic and electric moment operators, respectively. The quantities in the denominator, *e.g.*, E_k, is the energy of the kth state. The transition dipole moments were estimated by the dipole length method using the Slater AO's. The atomic integrals of the electric and magnetic dipole moments were retained only for the nearest neighbor atoms, and were neglected for the distant atoms because they are too small to give any decisive effect on calculated results. The deorthogonalized set of atomic orbitals obtained by the inverse Löwdin procedure[13] was used for the calculation of these quantities. The calculation was carried out using an ACOS-700 computer at The Computer Center of Tohoku University.

Results and Discussion

2,2′-Bipyridyl and Its Cations. The UV absorption spectrum of 2,2′-bipyridyl in cyclohexane is illustrated in Fig. 2 (left), showing absorption maxima at 35400, 40800, and 42000 cm^{-1}. The MCD spectrum exhibits a negative peak at 36000 cm^{-1} and a positive extreme at 42300 cm^{-1}. Another MCD band appears in the wave number region higher than 47000 cm^{-1}. From a comparison of the 2nd MCD band with the corresponding absorption band, the fine structure of the latter is considered to be vibrational in origin. In fact, the UV absorption spectrum of 2,2′-bipyridyl in basic media shows a structureless single peak in the same region.

The calculated Faraday B values and oscillator strengths of 2,2′-bipyridyl are schematically represented in Fig. 2 (right). For convenience $-B$ is taken on the ordinate since the Faraday parameter B appears as $-B$ in the expression of the molar ellipticity, $[\theta]_M$. It is assumed in the present calculation that 2,2′-bipyridyl has the trans-planar structure (θ=0°). The 1st and 2nd MCD bands of 2,2′-bipyridyl are assigned to the 1st and 2nd $^1B_u \leftarrow {}^1A_g$ electronic transitions, respectively. The strong negative MCD band in the energy region higher than 47000 cm^{-1} is assigned to the predicted $^1B_u \leftarrow {}^1A_g$ (51100 cm^{-1}) transition.

The UV absorption spectra of 2,2′-bipyridyl in sulfuric acid of various concentrations between 0.102 and 3.87 M (1 M=1 mol dm^{-3}) are illustrated in Fig. 3, where three isosbestic points are observed, exhibiting the equilibrium $BH_2^{2+} \rightleftarrows BH^+ + H^+$. 2,2′-Bipyridyl in sulfuric acid of 0.102 M exists in a mono-cationic form, exhibiting the absorptions at 33300 and 41700 cm^{-1} (the dotted line in Fig. 3). Increasing the concentration of the acid causes the equilibrium to shift toward left so as to give the absorption at 35000 cm^{-1} characteristic of the di-cation (the solid line). No further change in spectral profile takes place at concentrations lower (higher) than 0.102 M (3.87 M). It is clear from these facts that 2,2′-bipyridyl in sulfuric acid with concentrations higher than 3.87 M exists as the di-cation, and that 2,2′-bipyridyl in sulfuric acid with pH's lower than 1.80 exists as the mono-cation.

The absorption spectrum of 2,2′-bipyridyl in sulfuric acid at pH 1.22 is included in Fig. 4, which reveals absorptions at 33300 and 41700 cm^{-1}, characteristic of the mono-cationic species. The intensity of the former

is twice as strong as that of the latter. The observed 1st and 2nd absorption bands are weak as compared with the corresponding bands of the neutral molecule on the whole.

The MCD spectrum of the mono-cation shows negative bands at 33700 and 37600 cm^{-1} and a positive band at 41700 cm^{-1}. The spectral profile of the mono-cation is much complicated as compared with that of the neutral molecule. This may be attributed to the increase in the dihedral angle and the reduction in the molecular symmetry on protonation.

In Table 2 the calculated transition energies, oscillator strengths, and Faraday B values for both the trans- and cis-form with a dihedral angle of 30° are listed and compared with experimental values. There appears an appreciable difference between the calculated Faraday B values of the cis- and trans-form. The evaluated MCD signs of the 3rd, 4th, and 6th transitions of the trans-form are opposite to those of the corresponding transitions of the cis-form. Since the

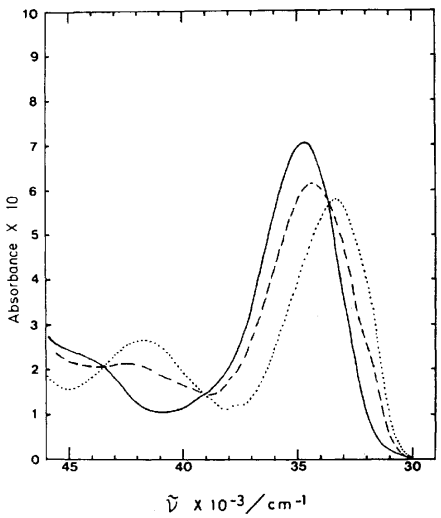

Fig. 3. The absorption spectra of 2,2′-bipyridyl (7.18×10^{-5} M) in sulfuric acid (3.87 M ——; 1.41 M -----; 0.102 M. ·····) at room temperature.

calculated result for the trans-structure is in better agreement with the observation than that for the cis-structure, the mono-cation of 2,2′-bipyridyl is considered to take the trans-configuration. The lowest transition energy of the mono-cation with the trans-structure is predicted to be 28400 cm^{-1}, which is considered to be assigned to the observed absorption band at 33300 cm^{-1} in view of the oscillator strengths.

The calculated Faraday B values and oscillator strengths of the mono-cation in the trans-form with the dihedral angle of 30° are included in Fig. 4 (right).

In Fig. 5 (left) the absorption and MCD spectra of 2,2′-bipyridyl in sulfuric acid of 7.04 M are represented. The absorption spectrum shows an intense band with its maximum at 34600 cm^{-1}. In the higher wave number region a discernible shoulder appears at *ca.* 43300 cm^{-1}. The MCD spectrum exhibits negative extrema at 34800 and 41800 cm^{-1} and a positive peak at 38700 cm^{-1}. The MCD spectral profile of the di-cation differs from that of the neutral molecule and also from that of the mono-cation. Especially, in the energy region of 41000—44000 cm^{-1} both the mono-cation and the neutral molecule exhibit positive MCD's, whereas the di-cation shows a negative band.

In Table 3 the calculated Faraday B values and oscillator strengths of the di-cation in a trans-structure are listed along with experimental values. It is clear from Table 3 that the transition energies increase with an increase in the dihedral angle. The 1st, 2nd, and 3rd transitions show characteristic behavior depending on the variation of the dihedral angle. Both the Faraday B value and oscillator strength associated with the 1st transition decrease with an increase in the dihedral angle. On the other hand, those of the 2nd and 5th transitions increase with an increase in the dihedral angle, and are close to zero when θ=0°. The sign of the Faraday B values associated with the 2nd (38700 cm^{-1}) MCD band is calculated to be positive and assigned to the 2nd transition.

From comparison of the theoretical with experimental results, it is concluded that the di-cation of 2,2′-bipyridyl takes a structure twisted by 30—40° around the central bond. The calculated results for the di-cation with a dihedral angle of θ=40° are schematically represented in Fig. 5 (right) and summarized in Table 1. They are considered to be in good agreement with the experimental results.

It seems clear from the above discussion that the di-cation has a comparatively large dihedral angle, and accordigly that the conjugation between two pyridinium rings must be small. This is in contradiction with the inference by Nakamoto[4] and Borgen *et al.*[6] that the di-cation of 2,2′-bipyridyl has a planar structure.

4,4′-Bipyridyl and Its Cations. The UV absorption spectra of 4,4′-bipyridyl in acidic media at

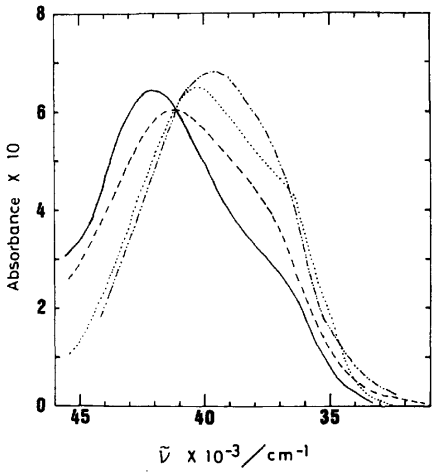

Fig. 6. The absorption spectra of 4,4′-bipyridyl (8.46×10^{-5} M) in sulfuric at pH 2.04 (·····), 3.20 (·····), 5.13 (-----), and 6.97 (——).

pH values between 2.06 and 6.97 are illustrated in Fig. 6. In basic conditions as well as in most organic solvents, 4,4′-bipyridyl exhibits an absorption at 42000 cm^{-1} characteristic of the neutral species.

On the other hand, in acidic solutions at pH<2.06, the UV absorption spectrum of 4,4′-bipyridyl exhibits the same spectral feature as the dotted line in Fig. 6 indicates. Accordingly, the UV absorption spectrum illustrated with the solid line in Fig. 6 is due to the neutral molecule and the one with the dotted line is ascribed to the di-cation.

The absorption and MCD spectra of 4,4′-bipyridyl in cyclohexane are represented in Fig. 7 (left). The negative MCD band at 42500 cm^{-1} corresponds to the absorption at 42500 cm^{-1}. The absorption shoulder at about 37500 cm^{-1} exhibits positive MCD. The MCD spectral profile of 4,4′-bipyridyl in cyclohexane is thus similar to that of substituted biphenyls with electron-attracting groups at the para-positions.

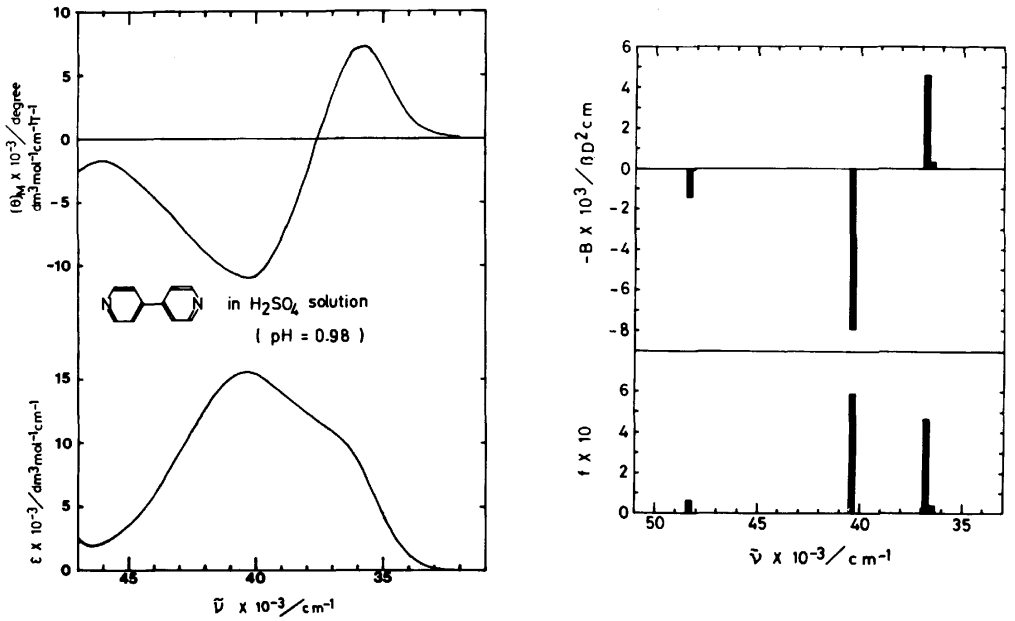

Fig. 8. The observed MCD (left top) and absorption (left bottom) spectra of 4,4′-bipyridyl in sulfuric acid at pH 0.98. Theoretical B values (right top) and oscillator strengths (right bottom) calculated at $\theta=30°$.

The Faraday B values and oscillator strengths of 4,4′-bipyridyl where the dihedral angle is assumed to be 30° are indicated in Fig. 7 (right). The agreement between experiment and theory is fairly good with respect to the sign, relative intensity, and transition energy. Accordingly, the dihedral angle of 4,4′-bipyridyl may be considered to be about 30°, larger than that of biphenyl in solution which has been found to be 20°.[15] The difference in dihedral angle between 4,4′-bipyridyl and biphenyl may be ascribed to the nitrogen atoms being incorporated in the biphenyl skeleton in the former so as to localize electrons on its para-positions. This leads to a less conjugation between the two rings. Then, 4,4′-bipyridyl exists in a more twisted form than biphenyl, although the repulsion among the ortho-protons seems to be nearly equal in both the cases.

The calculated result for 4,4′-bipyridyl is summarized in Table 4. The 1st and 2nd MCD bands of 4,4′-bipyridyl are assigned to the predicted $^1B_2\leftarrow{}^1A$ and $^1B_3\leftarrow{}^1A$ transitions, respectively. The assignment is identical with that for bipyridyl.[14] The absorption and MCD spectra of 4,4′-bipyridyl in sulfuric acid at pH 0.98 are represented in Fig. 8 (left). In the UV spectrum an absorption maximum is observed at 40300 cm^{-1} with a shoulder at about 36000 cm^{-1}. The MCD spectrum exhibits a positive band at 35700 cm^{-1} and a negative one at 40300 cm^{-1}. The intensity of the latter is greater than that of the former. Although the absorption and MCD extrema exhibit a red-shift in comparison with those of the neutral molecule, the di-cation of 4,4′-bipyridyl shows a similar spectral profile to the neutral molecule as a whole.

The calculated result for the di-cation of 4,4′-bipyridyl with $\theta=30°$ is included in Fig. 8 (right). It is found that the theoretical result is rather insensitive to the variation of the dihedral angle. The calculated result is summarized and listed in Table 4. The 1st, 2nd, and 3rd $\pi^*\leftarrow\pi$ transitions of the di-cation are calculated to be $^1B_1\leftarrow{}^1A$, $^1B_2\leftarrow{}^1A$, and $^1B_3\leftarrow{}^1A$, respectively, of which transitions $^1B_2\leftarrow A$ and $^1B_3\leftarrow{}^1A$ are assigned to the 1st and 2nd MCD bands.

Concluding Remarks

Bipyridyls exhibit characteristic spectra depending on the position of the nitrogen atoms and also on protonation. The observed absorption and MCD spectra are considered to have been reproduced fairly well by a theoretical calculation based on the PPP method, since the agreement between theory and experiment is acceptable in view of the approximation employed.

Calculated absorption and MCD spectra were compared with the observed spectra to get dihedral angles of 30—40° for di-cations of 2,2′- and 4,4′-bipyridyl. In the present work the dihedral angle of 2,2′- and 4,4′-bipyridyl have been estimated to be 0° and 30°, respectively.

Exponential Distribution of Aqueous 1-1 Electrolytes Due to Convective Thermal Diffusion in Vertical Columns

Naokata TAKEYAMA* and Kimie NAKASHIMA
Department of Industrial Chemistry, Faculty of Science and Engineering, Saga University, Saga 840
(Received July 11, 1983)

Using titanium columns of 10 cm length and glass columns of different lengths, the vertical exponential distribution of the concentration of aqueous 1-1 electrolytes in each column has been ascertained at the steady state of convective thermal diffusion. The value of $(a^4/L)\ln q$ is found to be characteristic of individual solutes, and possibly proportional to the thermal diffusion coefficients, where q is the quotient of the steady concentration of a solute at the bottom of column to that at the top, L is the effective column length, and a is the working column space. This fact has been also shown by jointed glass columns with and without top vessel, capable of multistep sampling from the top to the bottom through intermediate jointed parts along columns. The rate constants in processes to the steady state have been examined to be proportional to the square of temperature difference applied, and to decrease with increasing L. Although the enhancement of downward enrichment of solutes has been observed by attaching a large top vessel to the column top, the rate constants decrease inevitably and significantly thereby.

The thermal diffusion in liquid systems has been studied by measuring the Soret effect in a nonconvective cell,[1] and by using the Clusius-Dickel column settled vertically to utilize effectively natural convection induced by a temperature gradient applied horizontally.[2,3] The former is mainly directed to the determination of the Soret coefficient of solutes, while the latter is being examined to be applied to the separation of mixtures. Regarding aqueous ionic solutions, however, in spite of valuable efforts by several authors,[4-8] the basic principle of convective thermal diffusion in the column method is still unsolved in many respects. At present, various applications of the column method are being attempted by the present authors to seek a clue to effective utilization of thermal energy in a lower grade, concerning aqueous electrolytes.[9]

From a fundamental viewpoint, the thermal diffusion coefficient of aqueous electrolytes provides important information on the dissolved state of ions through the reduction rule in heats of transfer in connection with water structure-making and breaking properties of ions.[10] In the course of these applicative and basic studies, it grows as an important subject whether the thermal diffusion coefficient may be obtained by the column method in comparison with the Soret cell method established well.

Toward the subject, this paper describes basic experimental results by the column method to show the validity of exponential distribution of aqueous electrolytes along vertical columns, single and jointed, in a sedimentation-like way. From the exponential distribution of a solute at the steady state of convective thermal diffusion, a constant quantity having the dimension of volume, characteristic of the solute, may be obtained independently of column size to show a direct connection with the thermal diffusion coefficient from the Soret coefficient, in spite of large discrepancy in experimental conditions.

Experimental

Titanium Columns (Ti-I and Ti-II). Two columns made of titanium, Ti-I and Ti-II, were prepared by courtesy of the Nippon Kōgyo Co. and the Nikko Engineering Co., having a similar structure to that in Fig. 1 of a glass column. The outermost cylindrical wall was made by a poly (vinyl chloride) pipe equipped with two branches for circulation of cooling water, in which Ti made double annular part was fixed by sealing with poly(vinyl chloride) paste. The innermost Ti tube (1.00 mm thickness and 6.00 mm ϕ) and the outer Ti tube (1.00 mm thickness and 10.0 mm ϕ) were set to form the co-annular cylindrical space having 1.00 mm spacing for Ti-I and 0.97 mm for Ti-II,[11] in 10.0 cm length between the top and bottom reservoirs of 3.4 and 5.4 cm^3, respectively. Warm water at T_h°C was circulated into the innermost tube of column from a thermostatted bath. At the same time, colder water at T_c°C was circulated into the outermost space between the outer Ti tube and the outermost poly(vinyl chloride) pipe. Two by two branches were attached to the top and bottom reservoirs as an inlet of test solution and as an outlet of sample. As a reference column having 1.00mm spacing and 10.0cm length, Ti-I was selected. Both were individually used as single columns of total 10.5 ± 0.2 cm^3 volume.

Glass Columns. The structure of a Pyrex glass column, in Fig. 1, was composed of co-annular triple walls having 1 mm thickness in an outlook of Liebig condenser. Three main parts were the innermost tube, into which warm water was circulated, the co-annular cylindrical space between the top and bottom reservoirs of 6 cm^3, of which

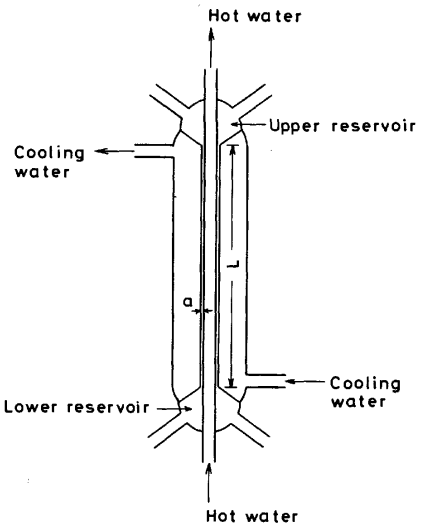

Fig. 1. Structure of a glass column. a; The spacing of working annular space, L: the effective length.

spacing a was kept at about 0.9 mm as constant as possible, and the outer space, in which cooling water was circulated. Two by two branches were attached to the top and bottom reservoirs for sampling outlets and for jointing branches. In some cases, a 500 cm^3 vessel was directly connected with one of two top branches to enhance downward enrichment of solutes. The working space was in the co-annular space of effective length L between the innermost (hotter) and outer (colder) walls. A unit column of L=10 cm was used to be jointed in series and in V-shape to lengthen total effective length as shown in Fig. 2, without and with top vessels. These jointed columns were very useful and effective for practical applications. In single column experiments, 4 glass columns

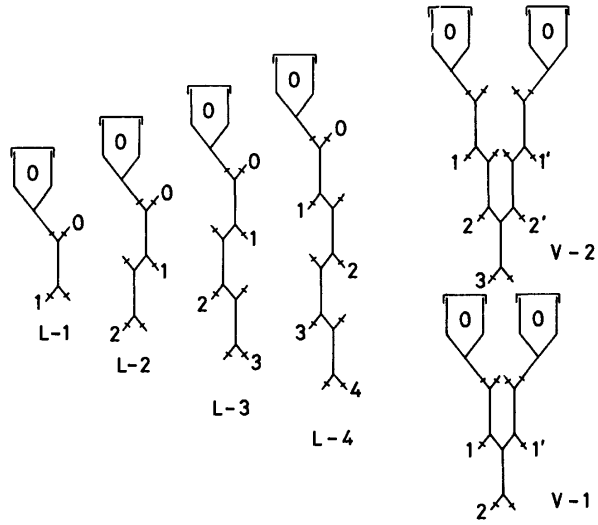

Fig. 2. Arrangement of jointed columns with and without top vessels.
The sampling outlets are denoted by 0, 1, ···, n for a column jointed linearly of n unit columns, and by 0, 1 and 1′, 2 and 2′, ···, n for a V-shape jointed column composed of $(2n-1)$ unit columns.

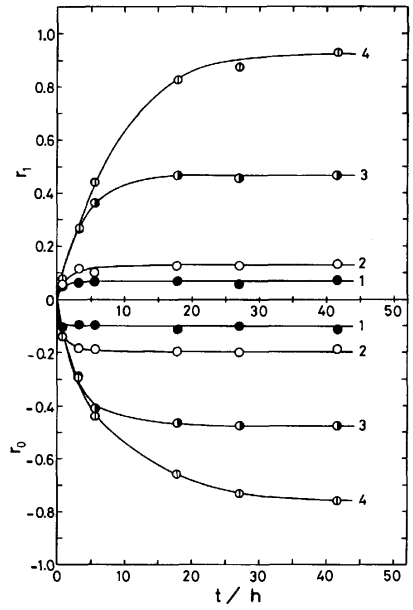

Fig. 3. Changes in the extents of dilution (r_0) at the top of column, and of enrichment (r_1) at the bottom with time, referring to 0.983 mol dm^{-3} HCl, at ΔT= 40.1, and T_m=54.0°C.
Column length L: 5.0 cm for (1), 10.0 cm for (2), 24.5 cm for (3), and 49.0 cm for (4).

of L=5.0, 10.0, 24.5, and 49.0 cm were used to examine the dependence of enrichment of solutes on the effective length. For the same purpose, jointed column experiments were successfully performed.

Sample Solutions. All of aqueous solutions were prepared from the purest available reagents using distilled and deionized water. Before and after a run of experiment, the concentration of a solute was volumetrically determined in each sample taken from the top and bottom outlets, including intermediate outlets in the case of jointed column experiments, shown in Fig. 2. Chemical analyses were performed according to the ordinary methods established well.

Procedure. A sample solution of the initial concentration C_i of an electrolyte was filled from the bottom inlet to the top of column using a leveler connected by a flexible tube with the inlet. After closing all stopcocks except one at the top, a run was started by circulating water at different temperatures from the bottom to the top. The top stopcock was closed after relaxation of thermal expansion of the solution filled. In a batch operation, test solutions were taken at a time t elapsed from the top outlet by a pipette, and then from the bottom outlet, after wasting a few drops to clean the part, by about 2 cm^3 in a dropping way. Such a sampling did not cause serious error. In a jointed column experiment, test solutions were taken from the top to the bottom through each intermediate outlet in order in a quite similar way.

When the concentration of the electrolyte under consideration was C_j at the j-th outlet, where j was numbered from the top j=0 to the bottom j=n as shown in Fig. 2, the result was expressed by the following relative deviation from the initial C_i at t:

$$r_j(t) = [C_j(t) - C_i]/C_i. \quad (1)$$

The duration of a run was changed in repetition of batch operations to be plotted $r_j(t)$ against t in a wide range. On a curve of $r_j(t)$ *versus* t, a time derivative $dr_j(t)/dt$ was evaluated by a graphical differentiation at t.[12] A linearity from plotting $dr_j(t)/dt$ against $r_j(t)$ showed

$$dr_j(t)/dt = A_j - k_j r_j(t), \quad (2.1)$$

which was characterized by constant A_j *and* k_j. The steady value $r_{j,st}$ was graphically determined as an intercept on the abscissa of $r_j(t)$, given by

$$r_{j,st} = A_j/k_j. \quad (2.2)$$

From Eqs. (2.1) and (2.2), the following equation was obtained:

$$dr_j(t)/dt = k_j[r_{j,st} - r_j(t)], \quad (2.3)$$

or

$$r_j(t) = r_{j,st}[1 - \exp(-k_j t)]. \quad (2.4)$$

Thus k_j was called the rate constant at the j-th outlet.

A set of experiments were specified by an average temperature difference $\Delta T = T_h - T_c$ applied and a mean temperature $T_m = (T_h + T_c)/2$ for the set of runs.

Results and Discussion

To clarify the nature of enrichment of solutes due to convective thermal diffusion in a vertical column, first of all, it is required to establish empirical relations from experimental results for the dependence of enrichment on column length and the working space. The subject is closely associated with the actual formulation of experimental results described below.

In the first place, the results from single column experiments are described, and then those by jointed columns without and with top vessels are reported.

Using 4 glass columns kept at $a \approx 0.9$ mm as constant as possible and having $L=5.0$, 10.0, 24.5, and 49.0 cm, the temporal changes of $r_j(t)$ for $j=0$ and 1 are studied to examine the dependence of $r_{j,st}$ on L, referring to aqueous 1-1 electrolytes, 4 alkalis, 3 acids, and 2 neutral salts, at *ca.* 1 mol dm^{-3}. In Fig. 3, the curves of $r_j(t)$ *versus* t for 0.983 mol dm^{-3} HCl are shown. In all columns used, the positive values of r_1 increase with time to individual steady values of $r_{1,st}$ to show the enrichment of HCl at the bottom of each column, while the negative values of r_0 decrease simultaneouly with time to individual steady values of $r_{0,st}$ to show the dilution of HCl at the top of individual columns. Such behavior is common to the cases of other species. Qualitatively, the extents of enrichment and dilution increase with increasing L. More quantitatively, firstly $r_{1,st}$ and $r_{0,st}$ are plotted in Fig. 4 against L for various electrolytes. Although $r_{1,st}$ increases with L almost linearly in all cases, $r_{0,st}$ decreases upward-concavely with L. Next, each pair of curves for an electrolyte in Fig. 4 may be transformed into one plait line, almost straight, by introducing

$$\ln q = \ln(C_{1,st}/C_{0,st}) = \ln[(r_{1,st}+1)/(r_{0,st}+1)], \quad (3)$$

as shown in Fig. 5, though the practical convenience of $r_{j,st}$ is inevitably lost. The values of ln q are individually proportional to L in all cases. The proportional constant for an electrolyte, given by $(\ln q)/L$, expresses an enriching power of column, still dependent on a, within experimental errors, partly due to slight difference in a. The values of $(\ln q)/L$ are tabulated in Table 1 as glass columns for 9 electrolytes at *ca.* 1 mol dm^{-3} and at $\Delta T=38.2\pm0.8$ °C and $T_m=55.1\pm0.8$ °C.

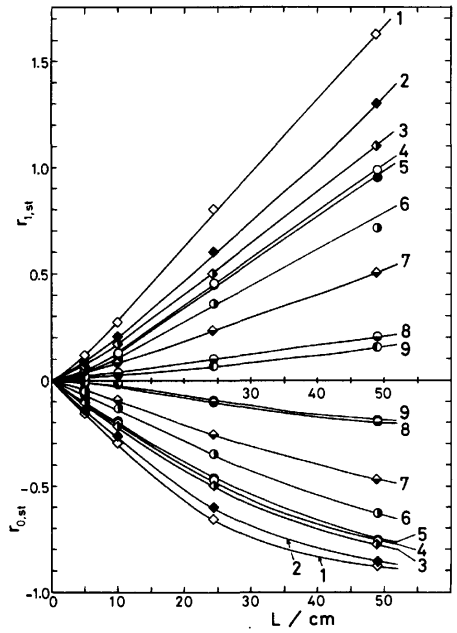

Fig. 4. Changes in the steady extents of dilution ($r_{0,st}$) at the column top, and of enrichment ($r_{1,st}$) at the bottom due to column length (L), at $\Delta T=38.2$, and $T_m=55.1$ °C.
1: 0.226 M CsOH, 2: 1.080 M KOH, 3: 1.044 M NaOH, 4: 1.530 M HBr, 5: 0.983 M HCl, 6: 0.999 M HNO_3, 7: 1.112 M LiOH, 8: 1.038 M KCl, and 9: 1.054 M NaCl (1M=1 mol dm^{-3}).

In Table 1, the data of $(\ln q)/L$ by Ti-I and Ti-II are shown for 12 electrolytes at *ca.* 1 mol dm^{-3} and at $\Delta T=49.7\pm0.5$ °C and $T_m=48.2\pm0.5$ °C. Moreover, for Ti-II and glass columns, the ratio of $(\ln q)/L$ to that of Ti-I is given in Table 1 to examine the constancy in the individual ratios by columns, because Ti-I is selected as a reference. The ratios are 1.14 ± 0.16 for Ti-II, and 1.91 ± 0.27 for glass columns as a whole, independently of the nature of electrolytes under consideration. According to the theoretical treatment of convective thermal diffusion in liquid mixtures,[2,3,13] the ratio may be mainly attributable to the difference in a in reference to a_0 of Ti-I as follows:

$$\frac{[(\ln q)/L]_{\text{for a column}}}{[(\ln q/L]_{\text{for Ti-I}}} = \left(\frac{a_0}{a}\right)^4 \quad (4)$$

This is valid in a crude approximation, at this stage, that other conceivable factors from differences in temperature, concentration, and column material do not seriously influence the ratio. The values of a, however, may be determined by Eq.(4) in reference to a_0; $a=0.97\pm0.03$ mm for Ti-II, and 0.85 ± 0.03 mm for glass columns on an average. These are reasonable values. Regarding the importance of this result, the dependence of ln q on ΔT and on the initial concentration of electrolytes is examined by using Ti-I. Figures 6 and 7 show that the values of ln q are independent of ΔT and initial concentrations, irrespectively of the nature of electrolytes investigated. Hence, the validity of Eq. (4) may be admitted.

Now, for a single column, the enriching power per unit length multiplied by a^4, $(a^4/L)\ln q$, represents an intrinsic quantity characteristic of an aqueous electrolyte solution, at least referring to single solutions, independently of experimental conditions and the column size a and L. Although the physicochemical content of characteristic volume $(a^4/L)\ln q$ at the steady state of convective thermal diffusion should be experimentally and theoretically clarified, it may be directly proportional to $(\eta/\beta\rho g)D'$ at the present status of theoretical treatment,[2,3,13] where

η is the viscosity, β the thermal expansion coefficient, ρ the density of a sample solution, g the acceleration of gravity, and D' the thermal diffusion coefficient of an aqueous electrolyte. These physical properties should be estimated at the mean temperature and at the experimental conditions. It remains to be solved, however, whether the above expression for the characteristic volume, $(a^4/L)\ln q$, is compatible with the insensitibity to the experimental conditions mentioned above. At present, unfortunately, we cannot directly examine the validity because of no available data. In comparison with the thermal diffusion coefficients of 14 electrolytes at 0.01 mol kg^{-1} and at the mean temperature 25 °C, which are calculated from the Soret coefficients measured by Snowdon and Turner,[14] the values of $(a^4/L)\ln q$ in cm^3 are summarized in Table 2, obtained from the data in Table 1 by using the values of a estimated. The values for individual electrolytes are in good agreement with each other among columns used. Moreover, in spite of large discrepancies in experimental conditions, a parallelism between $(a^4/L)\ln q$ and D' may be seen, apart from a few inversions in order. This fact suggests $(f\eta/\beta\rho g)$ to be the order of magnitude of 10 cm s K by introducing a non-dimentional f. In this respect, it may be commented that for pure water at T_m=50 °C $(\eta/\beta\rho g)$ is 1.23×10^{-2} cm s K, thereby f is of the order of magnitude of 10^3.

Concerning the difference in column material between titanium and Pyrex glass, titanium is a good thermal conductor appropriate for the column material, especially best for aqueous alkaline and salt solu-

TABLE 2. THE VALUES OF $(a^4/L)\ln q$ MEASURED BY TITANIUM AND GLASS COLUMNS IN COMPARISON WITH THERMAL DIFFUSION COEFFICIENTS D' FROM SORET COEFFICIENTS AT 0.01 mol kg^{-1} AND 25 °C[a)]

a) From the date of Soret coefficients, observed by Snowdon and Turner[14], D' may be calculated using the limiting diffusion coefficient in the Nernst-Hartley approximation.

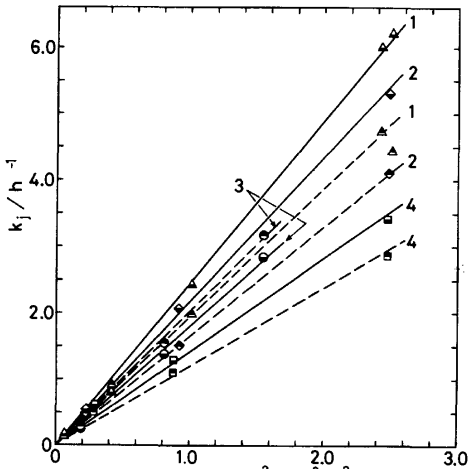

Fig. 8. Rate constants (k_j) *vs.* $(\Delta T)^2$, by Ti-I column. 1: 1.054 M HCl, 2: 0.830 M KOH, 3: 1.013 M NaOH, and 4: 1.114 M LiOH. k_0 at the top is denoted by broken lines, and k_1 at the bottom is by solid lines.

tions, capable of specifying $(\Delta T/a)$ for the gradient of temperature applied, while glass is a poorer one having the thermal conductivity comparable with that of aqueous solutions, and hence the effective temperature gradient may be $(1/3)(\Delta T/a)$, because in glass columns ΔT is applied to an aqueous layer in the working space of column between innermost and outer glass walls having the thickness comparable with a. Actually, the occurrence of convective thermal diffusion can be detected at $\Delta T \approx 1.5$ °C at the lowest in titanium columns, but at $\Delta T \approx 6$ °C at the lowest in glass columns.

The kinetic results by Ti-I are shown in Fig. 8. The rate constants k_0 at the top and k_1 at the bottom are proportional to $(\Delta T)^2$. This is true for glass columns, too, though the rate constants are smaller by 1/10 than

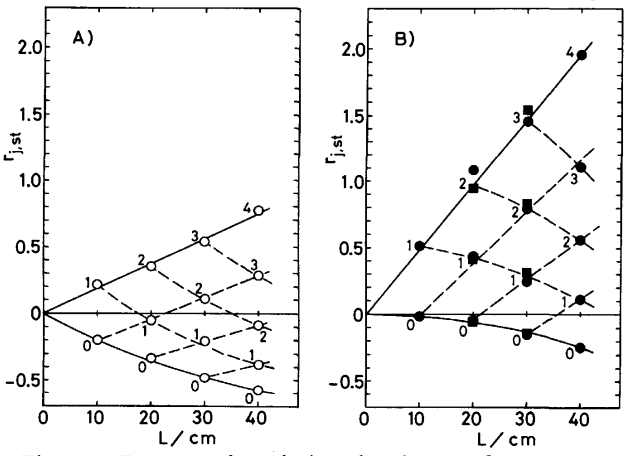

Fig. 9. Extents of variation in the steady concentration relative to the initial concentration ($r_{j,st}$) at the j-th outlet of jointed columns *vs.* total column length L, referring to 1.051 M HCl at $\Delta T=$ 49.8, and $T_m=49.0$ °C.
A): For the arrangements L-1, L-2, L-3, and L-4 without top vessel in Fig, 2, and B): for the same arrangements as in A) with top vessel (500 cm^3) denoted by solid circles and for V-shape arrangements V-1 and V-2 in Fig. 2 with two top vessels (each 500 cm^3) denoted by solid squares

those for Ti-I and Ti-II. Such a fact is consistent with the earlier theoretical prediction.[15]

In order to ascertain the relation of ln q proportional to L with jointed column experiments, the results for 1 mol dm^{-3} HCl are summarized in Fig. 9, in which $r_{j,st}$ in each jointed column of the number of jointed unit columns $n=1$ to 4 are plotted against total effective column length given by $L=10\times n$(cm) in A) referring to the cases without any top vessel, and B) for the cases with a top vessel (500 cm^3 volume) in the linear arrangements of L-1, L-2, L-3, and L-4 in Fig. 2, and also with two top vessels (each 500 cm^3) in the V-shape arrangements of V-1 and V-2 in Fig. 2.

In A) and B) in Fig. 9, curvilinear lattices are formed among the points of (L, $r_{j,st}$) in each jointed column. Connecting with the points of $r_{0,st}$ at the top in the cases of A), and in the top vessels for B), solid curves are drawn to show the changes in the extent of dilution. The extents of dilution in the top vessels in the cases of B) are lowered due to the presence of top vessels, while the extents of enrichment at the bottom are enhanced in each case in comparison with A). Such an enhancement of downward enrichment is clearly caused by the simple direct attachment of large vessels at the top of columns jointed. In the linear and V-shape arrangements of columns, L is taken as the effective height jointed column part except jointed parts and top vessels. Although the representation of $r_{j,st}$ is useful for the practical applicative purpose, the data in A) and B) are numerically examined in terms of ln q_j at the j-th outlet of jointed columns to compare with the results from single column experiments, where ln q_j has been defined by

$$\ln q_j = \ln[(r_{j,st}+1)/(r_{0,st}+1)] = \ln(C_{j,st}/C_{0,st}), \quad (5)$$

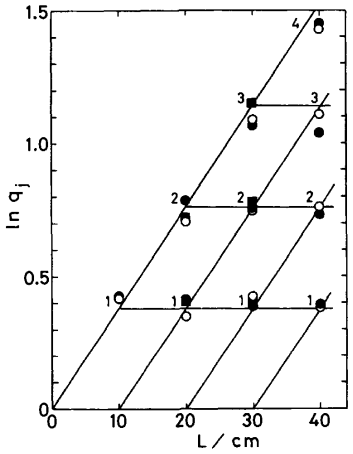

Fig. 10. Transformation of the data in Fig. 9, A) and B), into ln q_j for the j-th outlet of jointed columns against L.

in place of Eq. (3), for $j=1, 2, \cdots, n$, to investigate the vertical distribution of HCl from the top to the bottom through intermediate jointed parts. For jointed columns without any top vessel, the value of $(\ln q_j)/L_j$ is reduced to 0.0376 ± 0.0026 cm^{-1} averaged over 10 points, where L_j is the effective length from the top to the j-th outlet of an n-jointed column, $L_j=10\times j$(cm). For those with top vessels, it is 0.0380 ± 0.0024 cm^{-1} on average, in good agreement with the value mentioned above. As a whole, the average of $(\ln q_j)/L_j$ is 0.0379 ± 0.0025 cm^{-1} which is just equal to the value for HCl by single glass columns in Table 1. Using this average value, an inclined lattice is drawn in Fig. 10 by solid lines, in which the lattice points coincide satisfactorily with the observed points transformed from those in A) and B) in Fig. 9. Therefore, it may be mentioned that all of the points expressed by $r_{j,st}$ converge finally on one point averaged over those.

Regarding rate constants k_j at the j-th outlet of jointed columns, the dependence of k_j on L is numerically shown in Table 3. First, in the cases of jointed columns without and with top vessels, all k_j in each column are nearly constant independently of j, but k_0 in the top vessel is much smaller than other k_j at lower outlets presumably due to the large volume of top vessel, though such a trend vanishes gradually with increasing total L. Second, k_j for jointed columns with top vessel is smaller than that in the cases without top vessel by about 1/10 to 1/5. These facts show that, although the time required for one-half each $r_{j,st}$ to be attained are almost equal in a given total L except in top vessels, the rate constants decrease with increasing L, and the time required for each $r_{j,st}$ are prolonged with it.

TABLE 3. RATE CONSTANTS k_j OF CONVECTIVE THERMAL DIFFUSION FOR EACH OUTLET j NUMBERED FROM THE TOP TO THE BOTTOM OF JOINTED COLUMNS WITHOUT AND WITH A TOP VESSEL OF 500 cm^3 OPERATED AT $\Delta T=50.0\pm0.2$ °C AND $T_m=49\pm0.2$ °C, AND AT 1.0 mol dm^{-3} HCl

Total effective length L/cm	Number of outlet j	k/h^{-1} Without top vessel	k/h^{-1} With top vessel[a]

(Received July 16, 1983)

The photooxidation of iodide ions on n-type silicon electrodes highly doped with boron from the surface in hydrogen iodide or hydrogen iodide/iodine solutions was investigated. Two doping methods were employed: thermal diffusion and ion implantation. The electrode was remarkably stabilized by coating with a 2 to 3 nm-thick platinum layer, followed by heat-treatment at about 400 °C for *ca.* 10 min. The photocurrent was stable for more than 500 h at a density of the order of 10 mA cm^{-2}. The boron-doped and Pt-coated n-Si electrode also generated a photovoltage much higher than that for a Pt-coated n-Si electrode, showing an advantage of forming the p-n junction. Photoelectrochemical cells made of a boron-doped-Pt-coated n-Si electrode, a platinized Pt counter electrode, and a commercial cation exchange membrane were found to photoelectrolyze hydrogen iodide without externally applied voltage into hydrogen and iodine with a solar-to-chemical energy conversion efficiency (ϕ^{s}_{chem}) under simulated AM 1 solar radiation of 8.2%, probably the highest of the ϕ^{s}_{chem} values observed for the cells working without external voltage.

The semiconductor photoelectrochemical (PEC) cell is an interesting device for chemical conversion of solar energy. The basic idea of this device is to use the photovoltage generated in the semiconductor directly to drive electrochemical reactions at the semiconductor-solution interface. Extensive work has so far been made on such PEC cells,[1–7] but attention has been paid mostly to the photovoltaic effect at the Schottky junction formed at the semiconductor-solution (or semiconductor-overlayer) interface, and very little to the photovoltage arising from the p-n junction inside the semiconductor.

The use of semiconductors having the p-n junction in PEC cells is interesting because it has a merit in that the photovoltage is effectively generated irrespective of the presence of surface states often arising from surface defects, electrochemical reaction intermediates, *etc.* As is well known, the photovoltage at the p-n junction, together with that at the Schottky barrier, is widely used in the solid solar cells. The difference between the PEC cell and the solid cell lies in the fact that in the PEC cell the photogenerated holes (or electrons) arriving at the semiconductor surface directly react with the solution with little migration along the surface, while in the solid cell the holes (or electrons) have to travel along the surface for a macroscopic distance of a few mm until they reach the collecting grid on the cell surface. The PEC cell therefore has an advantage in that it has no restriction to have a conductive layer on the semiconductor surface so as to avoid the ohmic losses for the surface current. The photocurrent losses by electron-hole recombinations at crystal defects may also be minimized because the photogenerated holes (or electrons) coming to the surface mostly react with the solution before they drift along the surface and arrive at the defects. These advantages will be important when a polycrystalline or an amorphous material is used.

A problem, common to all semiconductor PEC cells, is that most of the available semiconductors having suitable band gaps are subject to photocorrosion in electrolyte solutions. Some trials have been made to stabilize the semiconductor electrodes. For example, an n-type silicon (n-Si) electrode was reported to be stabilized by coating with thin layers of noble metals,[8] metal oxides,[9,10] metal silicides,[11] or organic materials,[12–14] though the solar energy conversion efficiencies reported are in most cases unsatisfactory. Attempts to deposit metals on the surface for catalyzing desired electrode reactions have also been reported.[15–17]

In a recent letter[18] we reported that an n-Si electrode doped with boron from the surface and coated with a thin platinum (Pt) or palladium (Pd) layer was stable and a PEC cell with such an electrode efficiently decomposed hydrogen iodide into hydrogen and iodine under no external bias. A similar idea of photoelectrolyzing hydrogen iodide or bromide by use of electrodes composed of Si particles was proposed and high solar-to-chemical energy conversion efficiencies (6.3% in natural sunlight and *ca.* 10% by computer modelling) were reported at recent conferences by the Texas Instruments group.[19] In the present paper we will report on the electrochemical behavior of surface-boron-doped n-Si single crystal electrodes coated or not coated with a thin metal layer, together with their application to solar photoelectrolysis of hydrogen iodide.

Experimental

Two methods of boron-doping were employed: thermal diffusion and ion implantation. Thermally doped specimens were prepared from single crystal wafers of n-Si, cut perpendicular to the <111> axis and having the resistivity of 0.2 to 0.4 Ω cm and the donor (phosphorus) density of $(1-2)\times10^{16}$ *cm*$^{-3}$ *obtained from Shin-Etsu Handotai Co.* Chips of the n-Si wafer 0.5 to 1.0 cm^2 in area were cleaned ultrasonically in trichloroethylene, acetone, methanol, water, and 46% hydrofluoric acid, and doped with boron from the surface by coating with a saturated methanol solution of diboron trioxide (B_2O_3) and heating at 920 to 1000 °C for 0.5 to 2.0 h in the air. The chips thus doped were washed in water and etched in a 46% hydrogen fluoride (HF) solution for *ca.* 60 s.

† Central Research Laboratory, Mitsubishi Electric Corp., Amagasaki, Hyogo 661.

Specimens doped by ion implantation were obtained from Mitsubishi Electric Corp. Single crystal n-Si wafers cut perpendicular to the <100> axis and having the resistivity of 0.1 to 0.3 Ω cm were heated at 950°C in an atmosphere of water vapor in order to cover the surface with an oxide layer *ca.* 100 nm thick, then doped by irradiating a 50 keV $^{11}B^+$-ion beam at various doses from 10^{13} to 10^{16} cm^{-2}, annealed in vacuum at 1000°C for 20 min and etched in an HF solution.

The depth of the p-n junction formed was measured by employing the spherical drill method, namely, by slightly scraping the doped wafer with a rotating steel ball, staining by photoetching in a 46% HF solution, and inspecting the resultant concentric circles with a microscope. The p-n junction depth (x_j) was calculated from the radii of the concentric circles (R_1, R_2) and that of the steel ball (R) by using an equation $x_j=|R_1^2-R_2^2|/2R$. The sheet resistance (ρ_s) of the B-doped surface layer was measured with the four-point probe method. The surface density of boron was calculated from the above-obtained x_j and ρ_s values.[20]

A thin platinum or palladium layer was deposited by a method of thermal evaporation under $(1-2)\times10^{-5}$ Torr (1 Torr≈133.322 Pa). The Si wafer was etched in a 10% HF solution for *ca.* 60 s just before the metal evaporation. The average thickness of the metal layer was monitored with a quartz crystal oscillator. The Pt layers 2, 5, and 8 nm thick had the light transmittance at 700 nm of *ca.* 80, 50, and 30%, respectively.

ESCA spectra were obtained with a Shimadzu ESCA 750 spectrometer having a Mg *Kα* X-ray (1253.6 eV) source and a filter-type electron energy analyzer. The binding energies were corrected by taking the C1s peak as a standard, which always appeared due to sample contamination. The relative atomic concentrations were calculated from the integrated peak intensities, corrected for the relative ionization cross sections for the Si2p, O1s, B1s, N1s, $I3d_{5/2}$, Pd3d, and Pt4f peaks taken to be 0.86, 2.9, 0.49, 1.5, 19.3, 16.1, and 15.86, respectively. The depth profile was obtained by the ion etching technique using a 2.0 keV argon ion beam of a current density of 60 to 150 μA cm^{-2} under an argon pressure 5×10^{-6} Torr.

The p-n junction Si electrodes were prepared by making an ohmic contact on n-Si at the back face with indium-gallium alloy, attaching a copper wire with silver paste, and covering with epoxy resin. Current-potential curves were obtained with a commercial potentiostat and potential sweeper. The electrode not having a metal layer was in most cases etched in a 10% HF solution just before the experiment. A 120 V-300 W tungsten-halogen lamp was used as a light source, normally operated at 30 to 50 V and in some cases combined with glass filters transparent in wavelengths longer than 690 nm. Commercially available special grade chemicals were used without further purification.

Results

In the present paper, surface-boron-doped n-Si is abbreviated as p^+/n-Si. Similarly, surface-B-doped and Pt-deposited n-Si is abbreviated as Pt/p^+/n-Si, and Pt-deposited n-Si as Pt/n-Si. The depth of the p-n junction, x_j, for the thermally B-doped p^+/n-Si electrodes used in the present work was in a range from 0.3 to 1.5 μm. The surface boron concentration, c_s, determined from x_j and the sheet resistance of the doped layer took a nearly constant high value of *ca.* $(3-6)\times10^{20}$ cm^{-3}. The x_j for the B^+-ion implanted specimens ranged from 0.25 to 0.84 μm, and the c_s ranged from 10^{18} to 10^{21} cm^{-3}.

1. Photoelectrochemical Behavior of p^+/n-Si Electrodes in HI/I_2 Solutions. Figure 1A shows cyclic scanning of current density (j) *vs.* potential (U) curves for an n-Si electrode in a 7.6 M HI solution (M= mol/dm^3) under illumination. Although n-Si in this solution was more stable than in an HCl or H_2SO_4 solution, the j-U curve shifted with time toward the positive potential. The curve was restored to the initial state by dipping the electrode in an HF solution. These results suggest that the photocurrent in this case corresponds mostly to the oxidation of I^- ions and partly to the oxidation of the electrode surface.

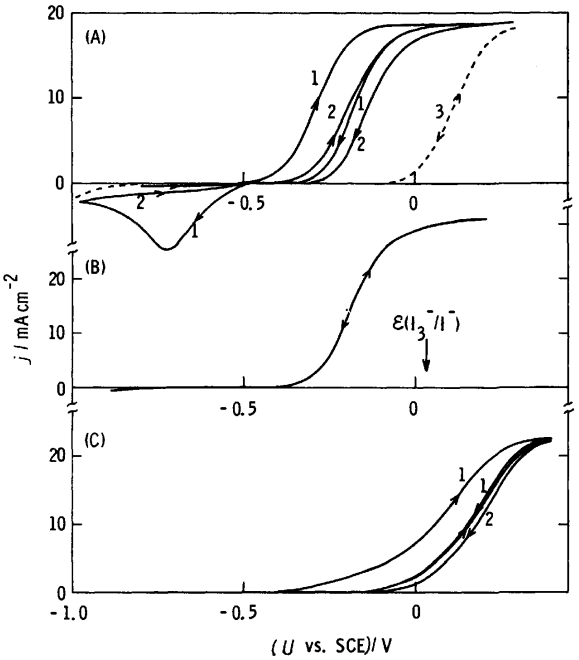

Fig. 1. Current density (j) *vs.* potential (U) curves: (A) for an n-Si electrode, 1; 1st scan, 2; 2nd scan, and 3; a curve after cyclic scanning for 60 min. (B) for a thermally B-doped p^+/n-Si electrode (x_j 0.9 μm and c_s 5×10^{20} cm^{-3}). (C) for a B^+-ion implanted p^+/n-Si electrode (x_j 0.8 μm and c_s 6×10^{20} cm^{-3}), 1 and 2 denote the 1st and 2nd scans, respectively. The electrolyte is a 7.6 M HI solution. The scan rate is 50 s/V. The illumination intensity is somewhat different in each case.

The j-U curve for a thermally B-doped p^+/n-Si electrode (Fig. 1B) was fairly stable during the repeated cyclic scans for more than 4h, the photoanodic current corresponding to the oxidation of the I^- ions,[18] while the j-U curve for an ion-implanted p^+/n-Si electrode changed at each scan (Fig. 1C). The surface of the thermally B-doped specimens showed the presence of a dark brown, lusterless, inhomogeneous thin layer, while the ion-implanted specimens gave no presence of such a layer. The layer could be removed by oxidizing the electrode surface either photoelectrochemically or by dipping in a concentrated HNO_3 solution or heating in the air at *ca.* 850°C followed by etching in a 46% HF solution and wiping. After such a treatment the electrode showed j-U curves similar to Fig. 1C. The x_j and c_s values were unchanged by removing the layer. The ESCA spectra of specimens having the brown layer showed that it was composed mainly of B, Si, and O atoms, the atomic ratio B/Si/O changing in a range

2/1/1 to 1/2/2 from specimen to specimen.

It is to be noted that the photocurrent for the p^+/n-Si electrode without the dark brown layer (Fig. 1C) shows very gradual increase with the potential even compared with that for the n-Si electrode (Fig. 1A). The ESCA studies of p^+/n-Si electrodes showed that they were easily oxidized only by immersing in an HI/I_2 solution in the dark for a few min, covered with a thin silicon oxide surface layer.

2. Photoelectrochemical Behavior of Pt (or Pd)/p^+/n-Si Electrodes in HI/I_2 Solutions. Figure 2 shows *j-U* curves for a Pt/p^+/n-Si electrode (ion-implanted specimen with a Pt layer *ca.* 3 nm thick) in a 7.5 M HI/0.01 M I_2 solution in the dark and under illumination, together with the curve for an illuminated Pt/n-Si electrode. The similar *j-U* curves were obtained for Pt/p^+/n-Si electrodes prepared from thermally B-doped specimens. The photocurrent for the Pt/p^+/n-Si electrode was quite stable, corresponding to the oxidation of the I^- ions.[18] The difference between the potential (U_0) at which the current under illumination is zero and the redox potential of an I_3^-/I^- couple, $\varepsilon(I_3^-/I^-)$, determined from a *j-U* curve at a Pt electrode was 0.55 to 0.59 V for the Pt/p^+/n-Si electrodes, much larger than that for the Pt/n-Si, as seen from Fig. 2. This means that the former electrode generates a photovoltage much higher than the latter, indicating an advantage of the p-n junction.

Nearly the same *j-U* curves were obtained when Pd was deposited on p^+/n-Si instead of Pt. The electrode in this case was stable during the cyclic scanning for several hours. Figure 3 shows the relative atomic concentrations (A) as well as the binding energy for a $Pd3d_{5/2}$ ESCA peak (B) as functions of the Ar^+-ion etching time for a Pd/p^+/n-Si electrode which was immersed in an HI/I_2 solution in the dark after the Pd deposition. Even though a thick Pd layer had been deposited, Fig. 3A shows that most of the Pd was dissolved. The binding energy for a $Pd3d_{5/2}$ peak lay *ca.* 1.5 to 1.9 eV higher than that for pure Pd metal (Fig. 3B). Based on the reported binding energies (336.8 to 337.0 eV) for silicide-forming Pd atoms,[21] these results indicate that most of the Pd atoms left without dissolving are penetrating into the Si crystal and form silicide bonds. It is interesting to note that such a small amount of Pd is effective to stabilize the electrode and catalyze the electron transfer reaction.

Figure 4 shows the photocurrent *vs.* time for three different Pt/p^+/n-Si electrodes which were prepared from the same ion-implanted p^+/n-Si wafer of x_j 0.6 μm and c_s 1×10^{20} cm^{-3}, obtained under continuous illumination in a 7.5 M HI/0.1 M I_2 stirred solution, with the Si electrode connected through a resistor of 80 to 100 Ω to a Pt counter electrode. Curve A stands for an electrode having a Pt layer *ca.* 7 nm thick. The photocurrent initially increased gradually, but in about 50 h decreased suddenly. The ESCA spectra of the degraded electrode showed almost complete disappearance of the deposited Pt metal and the growth of a considerable amount of silicon oxide.

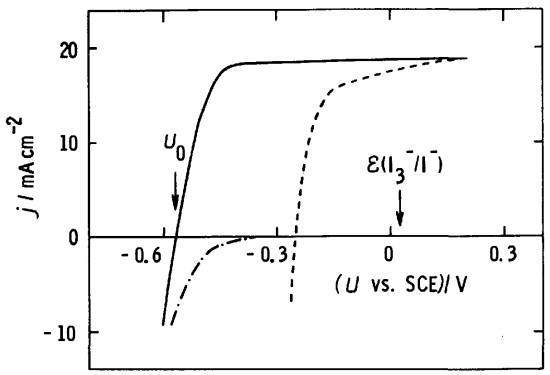

Fig. 2. Current density (*j*) *vs.* potential (*U*) curve for a Pt/p^+/n-Si electrode (B^+-ion implanted specimen, x_j 0.8 μm, c_s 6×10^{20} cm^{-3}, and the thickness of a Pt layer *ca.* 3 nm) in a 7.5 M HI/0.01 M I_2 solution in the dark (— · —) and under illumination (——), and the curve for an illuminated Pt/n-Si electrode (----).

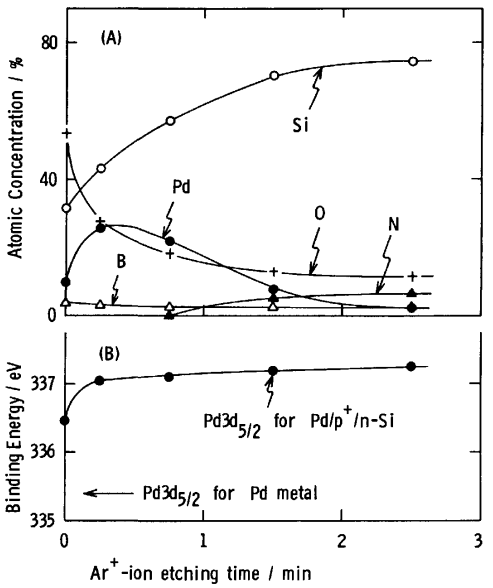

Fig. 3. Relative atomic concentrations (A) and the binding energy for a $Pd3d_{5/2}$ ESCA peak (B) as functions of the Ar^+-ion etching time for a Pd/p^+/n-Si electrode (thermally B-doped specimen) which was beforehand immersed in a 7.5 M HI/0.01 M I_2 solution in the dark for 40 s after the Pd deposition.

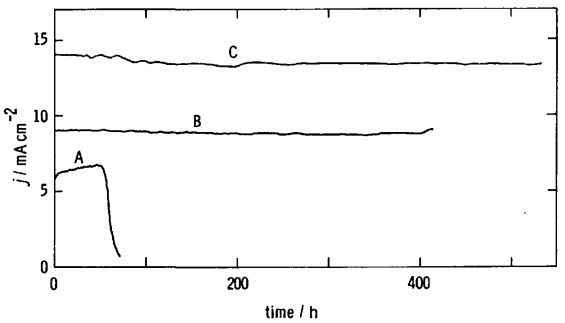

Fig. 4. Photocurrent *vs.* time curves for Pt/p^+/n-Si electrodes prepared from the same B^+-ion implanted p^+/n-Si wafer but coated with Pt in various ways: (A) A Pt layer *ca.* 7 nm thick as evaporated. (B) That *ca.* 7 nm thick heated at *ca.* 400 °C under $(2-5)\times10^{-5}$ Torr for 10 min. (C) Spotted Pt layers *ca.* 3 nm thick heated at *ca.* 400 °C under $(2-5)\times10^{-5}$ Torr for 6 min.

Curve B is for an electrode which was coated with a Pt layer *ca.* 7 nm thick and heated at about 400 °C under $(2-5)\times10^{-5}$ Torr for 10 min. The photocurrent in this case was steady for more than 400h. The *j-U* curves for this electrode (Fig. 5) observed before and after the stability test shows that the electrode is only slightly degraded by the prolonged illumination. The ESCA studies (Fig. 6) also show that a considerable amount of the deposited Pt still remains in this case after the prolonged illumination, though the oxygen concentration increases near the surfaces. These results indicate that the heat-treatment after the Pt deposition is effective for the electrode stabilization. It is also to be noted that the ESCA spectra of the heated and unheated specimens were almost the same, namely, the deposited Pt existed mostly in the form of pure metal, not silicide, even in the heated specimen, as seen from Fig. 6A.

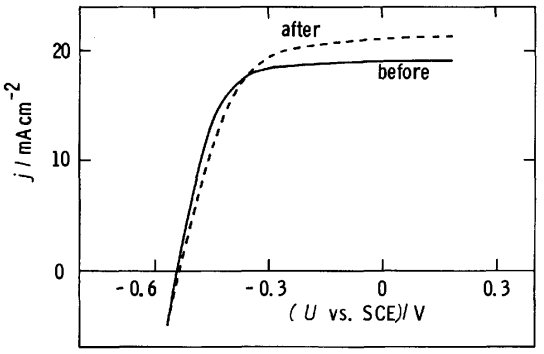

Fig. 5. Current density (j) *vs.* potential (U) curves for the Pt/p⁺/n-Si electrode observed before (——) and after (----) the stability test shown by curve B of Fig. 4.

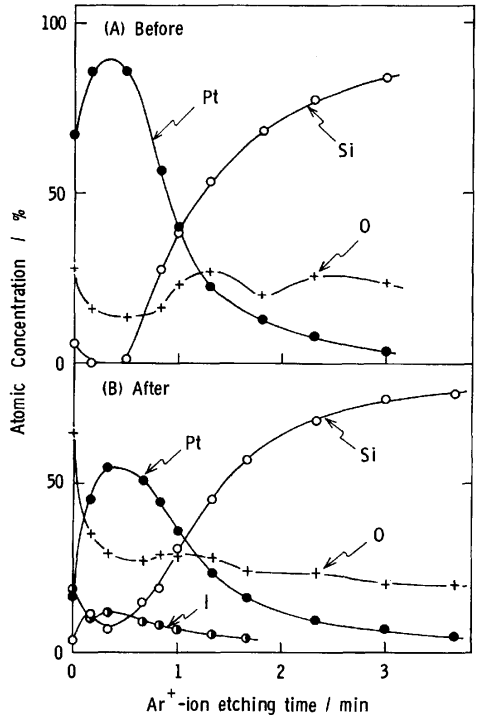

Fig. 6. Relative atomic concentrations as a function of the Ar⁺-ion etching time for the Pt/p⁺/n-Si electrode before (A) and after (B) the stability test shown by curve B of Fig. 4.

Curve C in Fig. 4 was obtained for a Pt/p⁺/n-Si electrode in which the Pt was deposited through a metal net so as to form metal layers in the form of small rectangles *ca.* 3 nm thick and *ca.* 0.3 mm² in area, spaced *ca.* 0.7 mm from each other, followed by heating at about 400 °C under $(2-5)\times10^{-5}$ Torr for 6 min. Although the Pt layer in this case did not cover the whole surface and was considerably thinner than the case of curve B, the photocurrent was stable for more than 500 h. It was also confirmed that the photocurrent was proportional to the averaged light transmittance of the Pt layer even in the case of spotted coating.

3. PEC Cells. A number of PEC cells of a photoelectric conversion type, consisting of a Pt/p⁺/n-Si electrode, a Pt counter electrode, and a 7.5 M HI/0.03 M I_2 stirred solution, were constructed by using various Pt/p⁺/n-Si electrodes. With the thermally B-doped electrodes, both the open-circuit voltage (V_{oc}) and the short-circuit current (I_{sc}) were almost independent of x_j in a range 0.3 to 0.9 μm. With the B⁺-ion implanted electrodes, nearly the same V_{oc} and I_{sc} were obtained, but the fill factor was in general somewhat better than that for the thermally doped electrodes. Under illumination of simulated AM 1 solar radiation at a power density of 100 mW cm⁻² by use of a Wacom Solar Simulator, the PEC cells having the B⁺-ion implanted electrodes generated the V_{oc} of 0.52 to 0.59 V, the I_{sc} of 21 to 29 mA

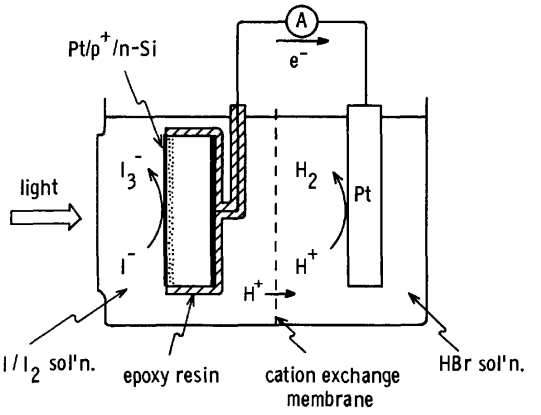

Fig. 7. A PEC cell for the HI photoelectrolysis.

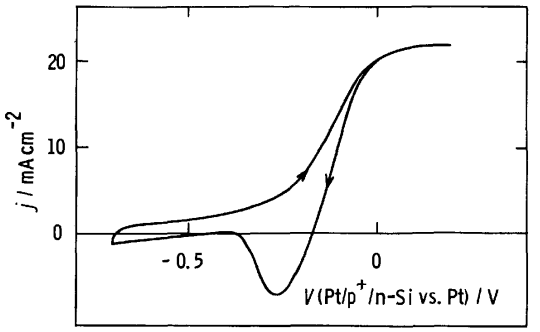

Fig. 8. Current density (j) for a Pt/p⁺/n-Si electrode in the PEC cell shown in Fig. 7 under illumination by a simulated 100 mW/cm² AM 1 solar radiation as a function of the voltage externally applied between the Si and the Pt counter electrode. The curve was obtained by cyclic scanning of the applied voltage at a rate 33 mV/s.

cm^{-2}, and the fill factor of 0.52 to 0.66. The solar-to-electric energy conversion efficiencies (ϕ^{s}_{elec}) calculated were 7.1 to 9.8%. These values are considerably high if we take account of the loss of incident light intensity due to the coloration of the HI/I_2 solution.

PEC cells for the photoelectrolysis of HI were also constructed using a $Pt/p^+/n$-Si electrode (ion-implanted specimen, x_j 0.6 μm, c_s 1×10^{20} cm^{-3}, and the thickness of a Pt layer *ca.* 2 nm) and a platinized Pt counter electrode (Fig. 7). 2 M HI/0.01 M I_2 and 2 M HBr solutions were used in the anode and the cathode compartment, respectively, by taking account of the overvoltage for the hydrogen evolution in the HBr solution smaller than that in the HI solution. The solutions were separated with a commercial cation exchange membrane (Asahi Glass Co., Selemion), both half cells stirred independently. Figure 8 shows the current density (j) for the $Pt/p^+/n$-Si electrode in the above cell under illumination by the Solar Simulator mentioned above as a function of the voltage (V) externally applied between the $Pt/p^+/n$-Si and the Pt electrode. The negative applied voltage implies that the PEC cell has an electrical output even in the photoelectrolysis of HI. The current at the zero applied voltage (*i.e.*, the short circuit current of the cell) was 20.0 mA cm^{-2}. During the current flow, the solution near the $Pt/p^+/n$-Si electrode became brown or red and gas evolved at the Pt counter electrode, showing that HI was photodecomposed into H_2 and I_2 (or I_3^-). The change in the Gibbs energy of this reaction was estimated both from current-potential curves for the two half-cell reactions at a platinized Pt electrode and from an open circuit voltage of a fuel cell operated with the same solutions as above and one atmosphere of hydrogen gas to be 0.41 eV/ion (or 79 kJ/mol). The chemical energy stored is then calculated to be 20 mA $cm^{-2}\times0.41$ V=8.2 mWcm^{-2}, and the solar-to-chemical energy conversion efficiency (ϕ^{s}_{chem}) to be 8.2%. When a 2 M HI/0.001 M I_2 solution was used in the anode compartment of the cell, the short circuit current increased to 21.7 mA cm^{-2} due to the better light transmittance of the solution.

Discussion

As mentioned before, the c_s values for the p^+/n-Si electrodes in the present work are so high, the order of 10^{20} cm^{-3} that the B-doped p^+-Si layer just beneath the surface should be degenerate at room temperature,[22] namely, the Fermi level of the layer (E^{p}_{F}) lies within the valence band. This implies that the surface p^+-Si layer behaves like a metal. Accordingly, when a p^+/n-Si electrode is in an HI/I_2 solution in the dark, the Fermi level (E^{p}_{F}) should coincide with the redox level of the I_3^-/I^- couple, $-e\varepsilon(I_3^-/I^-)$, with a negligibly thin Schottky barrier at an interface between the p^+-Si layer and the solution. It is therefore easily expected that the oxidation of the p^+-Si surface proceeds to some extent in an HI/I_2 solution even in the dark through the reaction of holes in the p^+-Si layer with water, followed by the hole injection by the I_3^- ions. This was really confirmed by the ESCA experiments, as described before. Very gradual increase of the photocurrent at the p^+/n-Si electrode with increasing the potential (Fig. 1C) can be understood on the basis of the presence of such an oxide layer at the surface.

The relatively stable j-U curve for the p^+/n-Si electrode prepared by the thermal diffusion method (Fig. 1B) was in a previous letter[18] explained by assuming the presence of a thin Schottky-type potential barrier at a p^+-Si-solution interface. It has been revealed in the present work that this stability is due to the presence of a dark brown overlayer consisting of the Si, B, and O atoms. It is interesting to note that such a brown layer plays a role in preventing further oxidation of the p^+-Si layer, contrary to the SiO_x layer which grows thicker and thicker with the passage of the photoanodic current (see Figs. 1A and C). This might suggest that the brown layer has a compact structure to be able to prevent the penetration of OH^- ions or H_2O molecules, though the holes may pass it by tunneling or thermal hopping. Unfortunately the brown layer-covered p^+/n-Si electrode is not sufficient both in the stability and the photocurrent efficiency in a potential

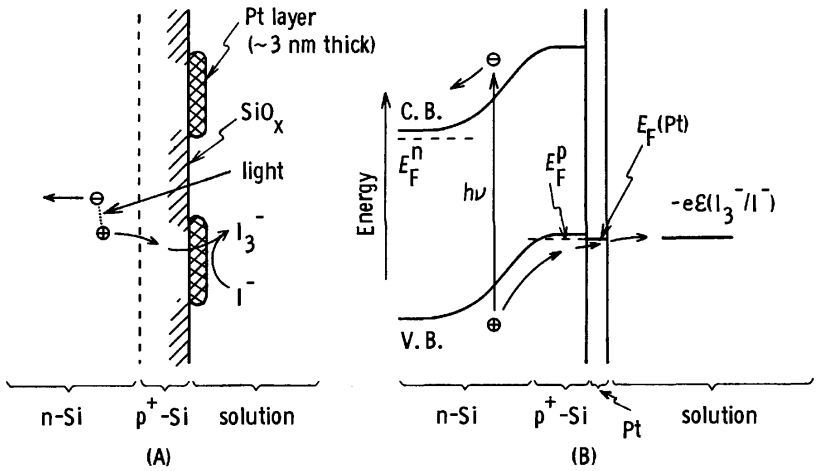

Fig. 9. Schematic cross section of a $Pt/p^+/n$-Si electrode (spotted Pt coating) in contact with an HI/I_2 solution (A) and energy band diagram under illumination (B). E^{n}_{F}: The Fermi level for the inside n-Si, E^{p}_{F}: that for the surface p^+-Si layer, and $E_F(Pt)$: that for the deposited Pt layer. ⊖ and ⊕: Photogenerated electron and hole, respectively.

range more negative than $\varepsilon(I_3^-/I^-)$.

The p^+/n-Si electrode coated with a Pt layer is very stable in an HI/I_2 solution (Fig. 4). This is true even for spotted coating with a relatively thin (2 to 3 nm thick) layer (curve C in Fig. 4). In such a case, the naked parts of the p^+-Si surface must be oxidized in the HI/I_2 solution, covered with insulating SiO_x layers, as mentioned above. Therefoe the photogenerated holes must be gathered into the Pt spots and react with the I^- ions, as shown in Fig. 9. Since the p^+-Si layer just beneath the surface is degenerate, as mentioned before, and is thought to be in ohmic contact with the Pt layer, the efficient photocurrent (Fig.2) can be explained by taking account of the effective photovoltage at the p-n junction and the low overvoltage for the I^- oxidation at the surface of the Pt layer.

As described before, the Pt layer as deposited by the vacuum evaporation is not sufficiently stable, disappearing during the prolonged flow of the photoanodic current in the HI/I_2, solution, and heat-treatment is necessary for stabilization. There was no difference between the heated and the unheated Pt layer in the ESCA spectra. Possibly, some change occurred in the structure of the Pt layer. This is contradictory to the results reporting the formation of Pt-silicide by heating.[11,23] In the present work a small amount of Pt-black on a boat-shaped tungsten heater was evaporated under 2×10^{-5} Torr quickly within several to 50 s. The Si wafer thus Pt-coated was then left in the air for, say, 1 d and heated at about 400 °C under $(2-5)\times10^{-5}$ Torr by use of an electric heater covered with mica plates. It was also confirmed that the silicide was really formed when Pt was deposited slowly by a method of electron-beam evaporation under 2×10^{-6} Torr, followed by heating of the Pt-deposited Si wafer at 350 to 450 °C without exposing to the air. Anyway, we can conclude from the results of Figs. 4 to 6 that the photocurrent of the Pt/p^+/n-Si electrode is stable as far as the deposited Pt is left at the electrode surface.

The solar-to-chemical energy conversion efficiency (ϕ^s_{chem}) obtained in the present work for the HI photoelectrolysis is encouragingly high, 8.2%. This value is, to our knowledge, the highest of the chemical conversion efficiencies ever obtained for the PEC cells working without external bias.[13,24-28] It will still be increased by optimizing various cell conditions. We can thus conclude that the use of the p-n junction semiconductors is an effective method for the solar energy conversion by use of PEC cells. Of course, there still lie many problems for the development of the presently proposed system to a practically feasible structure.

The authors express their thanks to Shin-Etsu Handotai Co. for offering n-Si single crystal wafers.

Variational Determination of Molecular Orbital Energies in Independent Particle Models

Makoto ISIHARA

Department of General Education, Shotoku-Gakuen Women's Junior College, Nakauzura 1-38, Gifu 500

(Received August 3, 1983)

A simple construction formalism of molecular orbitals is presented in the context of partitioning of the electronic Hamiltonian. As a consequence of the formalism, a variational method of determining molecular orbital energies is proposed. The method is illustrated with the numerical example for the helium atom, whose result is reasonably meaningful.

Success of molecular orbital (MO) theory strongly suggests that the electronic Hamiltonian of a molecular system is often well represented by an independent particle model (IPM) Hamiltonian. Although MO's and MO energies are not inherently physical quantities, they are allowed to describe the physics of the system as conceptual tools of definite physical meanings under an IPM Hamiltonian. The IPM Hamiltonian is, however, almost always implicit in MO theory; MO's, their energies, wave functions, and state energies are determined usually through variational procedure. One may be tempted to think that the IPM Hamiltonian is merely a simple sum of the one-particle Hamiltonians determining MO's, but without any justification by the physical meaning of the one-particle Hamiltonian itself, the thought is generally incorrect. It seems natural to regard the IPM Hamiltonian as the best unperturbed Hamiltonian in the perturbation theory for electron correlation.

On the other hand, various perturbation methods aiming to go beyond the Hartree-Fock (HF) method have been developed using the so-called HF Hamiltonian as an unperturbed Hamiltonian.[1-5] However, irrelevance of that choice to molecular problems has been revealed in spite of the physically sound nature of the HF wave function as the zeroth order wave function.[6-9]

There are many unperturbed Hamiltonians having an identical wave function as an eigenfunction; what is the best unperturbed Hamiltonian? After Epstein's suggestive work on this problem,[10] taking the unphysical nature of the virtual HF orbitals into account, Silverstone and Yin have exploited the non-HF unperturbed Hamiltonian, the zeroth order wave function still remaining the HF one.[11] Davidson has also investigated some related aspects extensivly.[12] From a rather different viewpoint, partitioning the wave function space with projection operators,[13] an elaborate choice of the unperturbed Hamiltonian has been achieved for the correlation energy calculation by Kutzelnigg.[14,15]

This paper has two purposes: One is to present a simple construction formalism of MO's in the context of partitioning of the electronic Hamiltonian. Another is, as a consequence of the formalism, to propose that MO energies are to be adjusted through certain stability condition related to the perturbation left over. The former can be regarded as giving a prescription to extract some practical possibilities from the "unlimited variability"[10] concerning selection of the unperturbed Hamiltonian along Silverstone and Yin's way of thinking.[11]

Construction of MO's and Partitioning of the Electronic Hamiltonian

Let us start with the electronic Hamiltonian in the second quantized form as

$$H = \sum_{pq} h_{pq} a_p^\dagger a_q + \frac{1}{4} \sum_{pqrs} v_{qs}^{pr} a_p^\dagger a_r^\dagger a_s a_q, \tag{1}$$

where $a_p^\dagger$ and a_p stand for the creation and annihilation operators for the one-electron quantum state p, respectively. Whether the one-electron quantum states form a complete set or not, we regard that the space to be considered is defined by this Hamiltonian.[16] The hermiticity is brought in as requirements on the matrix elements:

$$h_{pq} = h_{qp}^* \tag{2}$$

and

$$v_{qs}^{pr} = v_{pr}^{qs}{}^*. \tag{3}$$

Further we assume that the electron repulsion matrix elements are antisymmetrized in the sense that

$$v_{qs}^{pr} = v_{sq}^{rp} = -v_{sq}^{pr} = -v_{qs}^{rp}. \tag{4}$$

When we have a starting set $\{p\}$ of one-electron quantum states other than MO's, say, site states, the first step is to generate MO's through an eigenvalue problem

$$\sum_q (h_{pq} + x_{pq}) c_{qj} = c_{pj} \varepsilon_j^{(0)}, \tag{5}$$

where $\{x_{pq}\}$ is selected so as to give a topologically appropriate nature to the MO's, namely, to $\{c_{pj}\}$; almost exclusively one imposes hermiticity upon $\{x_{pq}\}$ to obtain orthogonal MO's with real eigenvalues. The crucial point in this MO generation step is to separate the space under consideration into two parts, occupied and unoccupied spaces. Denoting sets of the whole, occupied, and unoccupied orbitals, respectively, by M, M_1, and M_2, we have

$$M = M_1 \oplus M_2. \tag{6}$$

Though this expression looks rather trivial, it is just an essence of MO theory. The most typical and plausible choice of $\{x_{pq}\}$ is

$$x_{pq} = \sum_{j \in M_1} v_{qj}^{pj}, \tag{7}$$

which leads us to the canonical HF orbitals. Such a choice makes Eq. 5 a pseud-eigenvalue problem; to work out the problem includes self-consistency procedure in general. Through the MO generation step we arrive at the Hamiltonian in the "MO representation"

$$H = \sum_j \varepsilon_j^{(0)} a_j^{(0)\dagger} a_j^{(0)} + \frac{1}{4}\sum_{jklm} v_{km}^{jl(0)} a_j^{(0)\dagger} a_l^{(0)\dagger} a_m^{(0)} a_k^{(0)} - \sum_{jk} x_{jk}^{(0)} a_j^{(0)\dagger} a_k^{(0)} \quad (8)$$

and the Fermi sea state

$$|F\rangle = \prod_{j\in M_1} a_j^{(0)\dagger} |\text{ vacuum }\rangle. \quad (9)$$

We label MO's with the indices $\{j,k,\cdots\}$.

Since any unitary transformation within the occupied or unoccupied orbital manifold keeps the Fermi sea state invariant, we can modify MO's (and MO energies) through the following eigenvalue problems.

$$\sum_{k\in M_{\xi\eta}} (\delta_{jk}\varepsilon_j^{(0)} + y_{jk}^{(0)}) u_{kl}^{(1)} = u_{jl}^{(1)} \varepsilon_l^{(1)} \quad (l\in M_{\xi\eta})(\xi = 1,2;\ \eta = 1,2,\cdots) \quad (10)$$

with

$$M_\xi = M_{\xi 1} \oplus M_{\xi 2} \oplus \cdots \quad (\xi = 1,2). \quad (11)$$

Note that MO indices $\{j,k,\cdots\}$ here are used for both modified(new) and unmodified(old) orbitals. It should be understood that they do not indicate any concrete one-electron function but label MO's flexibly in each orbital manifold. Representatives of MO modifications include the hole potential,[17,18] the electron-hole potential,[19,20] and the localized orbital [21] methods. By using the notation

$$a_j^{(n+1)} = \sum_k a_k^{(n)} u_{kj}^{(n+1)*}, \quad (12)$$

$$x_{jk}^{(n+1)} = \sum_{lm} u_{lj}^{(n+1)*} x_{lm}^{(n)} u_{mk}^{(n+1)}, \quad (13)$$

and so on, the Hamiltonian is rewritten as

$$H = \sum_j \varepsilon_j^{(1)} a_j^{(1)\dagger} a_j^{(1)} + \frac{1}{4}\sum_{jklm} v_{km}^{jl(1)} a_j^{(1)\dagger} a_l^{(1)\dagger} a_m^{(1)} a_k^{(1)} - \sum_{jk} x_{jk}^{(1)} a_j^{(1)\dagger} a_k^{(1)} - \sum_{\xi\eta}\sum_{jk\in M_{\xi\eta}} y_{jk}^{(1)} a_j^{(1)\dagger} a_k^{(1)}. \quad (14)$$

Of course, successive modifications are possible and to be utilized. For example, putting

$$M_{\xi\eta} = M_{\xi\eta 1} \oplus M_{\xi\eta 2} \oplus \cdots \quad (\xi = 1,2;\ \eta = 1,2,\cdots) \quad (15)$$

and solving

$$\sum_{k\in M_{\xi\eta\zeta}} (\delta_{jk}\varepsilon_j^{(1)} + z_{jk}^{(1)}) u_{kl}^{(2)} = u_{jl}^{(2)} \varepsilon_l^{(2)} \quad (l\in M_{\xi\eta\zeta})(\xi = 1,2;\ \eta,\zeta = 1,2,\cdots), \quad (16)$$

we have

$$H = \sum_j \varepsilon_j^{(2)} a_j^{(2)\dagger} a_j^{(2)} + \frac{1}{4}\sum_{jklm} v_{km}^{jl(2)} a_j^{(2)\dagger} a_l^{(2)\dagger} a_m^{(2)} a_k^{(2)} - \sum_{jk} x_{jk}^{(2)} a_j^{(2)\dagger} a_k^{(2)} - \sum_{\xi\eta}\sum_{jk\in M_{\xi\eta}} y_{jk}^{(2)} a_j^{(2)\dagger} a_k^{(2)} - \sum_{\xi\eta\zeta}\sum_{jk\in M_{\xi\eta\zeta}} z_{jk}^{(2)} a_j^{(2)\dagger} a_k^{(2)}. \quad (17)$$

Presumably it is suitable to call the process of modifications as a whole the MO modification step.

The "smallest" modification is the one-dimensional transformation; the MO does not change but the MO energy does. This is nothing other than level-shifting[22-26] and should be discussed separately from the above mentioned MO modification step. After any MO modification step consisting of g stages we are always still allowed to transform MO's as

$$\varepsilon_j = \varepsilon_j^{(g)} + \theta_j \quad (18)$$

with

$$u_{jk} = \delta_{jk}. \quad (19)$$

To rewrite $a_j^{(g)}$ as a_j, $x_{jk}^{(g)}$ as x_{jk}, and so on leads us to the resultant expression for the partitioned Hamiltonian

$$H = K + V \quad (20)$$

with

$$K = \sum_j \varepsilon_j a_j^\dagger a_j \quad (21)$$

and

$$V = \frac{1}{4}\sum_{jklm} v_{km}^{jl} a_j^\dagger a_l^\dagger a_m a_k - \sum_{jk} x_{jk} a_j^\dagger a_k - \sum_{\xi\eta}\sum_{jk\in M_{\xi\eta}} y_{jk} a_j^\dagger a_k - \sum_{\xi\eta\zeta}\sum_{jk\in M_{\xi\eta\zeta}} z_{jk} a_j^\dagger a_k - \cdots - \sum_j \theta_j a_j^\dagger a_j. \quad (22)$$

Apart from the MO modification step, which is to be based on physical reasoning, we can and should always adjust the MO energies by shifting in order to let the unperturbed Hamiltonian be the "best"; it must be emphasized that this MO energy shift step has nothing to do with the topological nature of the MO at all, as is obviously shown in Eq. 19. In the field of molecular quantum mechanics, the level shifting has been introduced and utilized in connection with the convergence problem in self-consistency procedure from a rather technical standpoint.[23] Another utilization worth referring to is seen in the degenerate perturbation approach.[22,24]

A Variational Determination of the MO Energy Shift

It is not very obvious how to determine the MO energy shift. In this section we describe one possible way of determining the MO energy shift for the canonical HF orbitals (without modification, for brevity), based on the quantum-mechanical variation principle. Hereafter the indices $\{j,k,l,m\}$ and $\{a,b,c,d\}$ are, respectively, used to label the occupied and unoccupied MO's: $j,k,l,m\in M_1$ and $a,b,c,d\in M_2$. The index i labels both: $i\in M$.

Let $|\psi\rangle$ be a trial correlated state corresponding to

the Fermi sea state. To take the first order perturbative state correction into account leads us to

$$|\Psi> = (1+C^\dagger)|F> \tag{23}$$

with

$$C^\dagger = -\frac{1}{4}\sum_{abjk} v_{jk}^{ab} w_{jk}^{ab} a_a^\dagger a_b^\dagger a_k a_j, \tag{24}$$

where the notation

$$w_{jk}^{ab} = 1/(\varepsilon_a+\varepsilon_b-\varepsilon_k-\varepsilon_j) \tag{25}$$

is used; of course, we have

$$w_{jk}^{ab} = w_{kj}^{ab} = w_{jk}^{ba} = w_{kj}^{ba} \tag{26}$$

and

$$w_{jk}^{ab} = -w_{ab}^{jk}. \tag{27}$$

The HF choice (Eq. 7) prevents any singly excited configuration from appearing in the first order state correction.[1] Denoting the exact ground state energy of H by E and abbreviating $<F|\cdots|F>$ to $<\cdots>$, we see the quantum-mechanical variation principle assert that[27-29]

$$E_0 + E_1 + (E_2+E_3)/(1+s) \geqq E \tag{28}$$

with

$$E_0 + E_1 = <K+V> = \sum_j \varepsilon_j^{(0)} - \frac{1}{2}\sum_{jk} v_{jk}^{jk}, \tag{29}$$

$$E_2 = <[C,V]> = -\frac{1}{4}\sum_{abjk} |v_{jk}^{ab}|^2 w_{jk}^{ab}, \tag{30}$$

$$\begin{aligned} E_3 &= <[[C,V],C^\dagger]> \\ &= \frac{1}{8}\sum_{abjk} v_{jk}^{ab} w_{jk}^{ab} (-2(\theta_a+\theta_b-\theta_k-\theta_j) v_{ab}^{jk} w_{jk}^{ab} \\ &\quad + \sum_{cd} v_{ab}^{cd} v_{cd}^{jk} w_{jk}^{cd} + \sum_{lm} v_{lm}^{jk} v_{ab}^{lm} w_{lm}^{ab} + 8\sum_{cl} v_{bl}^{kc} v_{ca}^{lj} w_{lj}^{ca}), \end{aligned} \tag{31}$$

and

$$s = <[C,C^\dagger]> = \frac{1}{4}\sum_{abjk} |v_{jk}^{ab}|^2 w_{jk}^{ab\,2}. \tag{32}$$

Now since E_0+E_1 is independent of $\{\theta_i\}$, that is,

$$\frac{\partial}{\partial\theta_i}(E_0+E_1) = 0 \quad (\text{any } i), \tag{33}$$

we require the "best" $\{\theta_i\}$ to fulfil the necessary condition

$$\frac{\partial}{\partial\theta_i}\left(\frac{E_2+E_3}{1+s}\right) = 0 \quad (\text{any } i), \tag{34}$$

which gives inhomogeneous simultaneous equations of variation parameters $\{\theta_i\}$. Generally speaking, they are to be solved only numerically, say, with the Newton-Raphson method. Here it should be noted that Eq. 34's for all i are not independent of each other, for the following equation identically holds.

$$\sum_i \frac{\partial}{\partial\theta_i}\left(\frac{E_2+E_3}{1+s}\right) = 0. \tag{35}$$

We can and should set, at least, one of $\{\theta_i\}$ arbitrarily.

The quantities needed in the numerical solution are the derivatives of E_2+E_3 and s with respect to $\{\theta_i\}$, which have expression as

$$\begin{aligned} \frac{\partial}{\partial\theta_m}(E_2+E_3) &= \frac{1}{2}\sum_{abj} w_{jm}^{ab\,2}\{-2|v_{jm}^{ab}|^2(\theta_a+\theta_b-\theta_m-\theta_j)w_{jm}^{ab} \\ &\quad + \sum_{cd} \mathrm{Re}(v_{jm}^{ab} v_{ab}^{cd} v_{cd}^{jm}) w_{jm}^{cd} + \sum_{kl} \mathrm{Re}(v_{jm}^{ab} v_{kl}^{jm} v_{ab}^{kl}) w_{kl}^{ab} \\ &\quad + 4\sum_{ck}(\mathrm{Re}(v_{jm}^{ab} v_{bk}^{jc} v_{ca}^{mk}) w_{mk}^{ca} + \mathrm{Re}(v_{jm}^{ab} v_{bk}^{mc} v_{ca}^{kj}) w_{kj}^{ca})\}, \end{aligned} \tag{36}$$

$$\begin{aligned} \frac{\partial}{\partial\theta_d}(E_2+E_3) &= -\frac{1}{2}\sum_{ajk} w_{jk}^{ad\,2}\{-2|v_{jk}^{ad}|^2(\theta_a+\theta_d-\theta_k-\theta_j)w_{jk}^{ad} \\ &\quad + \sum_{cd} \mathrm{Re}(v_{jk}^{ad} v_{lm}^{jk} v_{ad}^{lm}) w_{lm}^{ad} + \sum_{bc} \mathrm{Re}(v_{jk}^{ad} v_{ad}^{bc} v_{bc}^{jk}) w_{jk}^{bc} \\ &\quad + 4\sum_{bl}(\mathrm{Re}(v_{jk}^{ad} v_{al}^{kb} v_{db}^{lj}) w_{lj}^{db} + \mathrm{Re}(v_{jk}^{ad} v_{al}^{kb} v_{ba}^{lj}) w_{lj}^{ba})\}, \end{aligned} \tag{37}$$

$$\frac{\partial s}{\partial\theta_m} = \sum_{abj} |v_{jm}^{ab}|^2 w_{jm}^{ab\,3}, \tag{38}$$

and

$$\frac{\partial s}{\partial\theta_d} = -\sum_{ajk} |v_{jk}^{ad}|^2 w_{jk}^{ad\,3}. \tag{39}$$

Note that the quantities dependent on $\{\theta_i\}$ are only $\{w_{jk}^{ab}\}$ besides $\{\theta_i\}$ themselves in the above derivatives. The condition given by Eq. 34 is, of course, not sufficient as the minimum condition, but we have to be contented with describing such stationary one because of practical difficulty; numerical "checking" is possible.

Simplifications by reducing the number of the variation parameters may be worth being investigated. One is to set

$$\begin{cases} \theta_j = \theta & (\text{any } j) \\ \theta_a = \theta' & (\text{any } a), \end{cases} \tag{40}$$

which is actually one-parametric because of Eq. 35; the "distance" between the occupied and unoccupied spaces is arranged as a whole. Another is to use θ_i's only for specific orbitals, say, the highest occupied, the lowest unoccupied, and so on; the number of the variation parameters ranges from one to several. For example,

$$\theta_i = \begin{cases} \theta & (\text{the highest occupied}) \\ \theta' & (\text{the lowest unoccupied}) \\ 0 & \text{otherwise.} \end{cases} \tag{41}$$

Numerical Example

As an illustration we have applied the spin restricted version of the above mentioned methods to the ground state of the helium atom. The result of calculation is summarized in Tables 1, 2, and 3. The canonical HF orbitals are calculated by Roothaan's method[30] using the Slater-type s orbitals

$$\chi = ((2n)!)^{-1/2}(2\zeta)^{n+1/2} r^{n-1} e^{-\zeta r} Y_{00} \tag{42}$$

as a basis. The $1s$ ζ's are taken from best double-ζ calculation by Clementi and Roetti.[31] To the other ζ's we assign $1/n$ without any attempt of optimization.[17]

Table 1. Orbital energy shifts

		Orbital coefficients					Orbital energies and shifts		
		1s	1s	2s	3s	4s	ε^{o} [a]	θ	ε [b]/a.u.

A4	−2.86168	−0.01347	−0.01393	−0.00046

a) $E_{HF}=E_0+E_1$. b) E_c and E_c° are $(E_2+E_3)/(1+s)$ with and without shifting, respectively. c) $\Delta E_c=E_c-E_c^{\circ}$.

Table 3. One-parameter cases

	θ	E_c [a]	ΔE_c [a]/a.u.
A1	−0.67749	−0.01329	−0.00045
B2	−0.42354	−0.01369	−0.00032
B3	−0.38584	−0.01373	−0.00030
B4	−0.37144	−0.01376	−0.00029

a) See the footnote of Table 2.

The unoccupied orbitals are designated as *a*, *b*, *c*, and *d* in accordance with the characteristic of the orbital coefficients, the occupied orbital being named *1*. In the cases A1—A4 all of the unoccupied orbital energies are allowed to be variationally shifted, whereas the cases B2—B4 have only one variation parameter common to all the unoccupied orbitals (see Eq. 40); the shift of the occupied orbital energy is set to be zero in every case. Fulfillment of the minimum condition is checked numerically after variational solution for the stationary one.

The values of the orbital energy shifts obtained are neither extraordinary nor negligible. In A1—A4 we have the shifts similar to each other for the corresponding orbitals (the orbitals of the same name), which is the most impressive feature observed from the present example. It is more or less interesting that all the unoccupied orbital energies are shifted low and that the orbital energies of *a* and *b* in A4 are put in the reverse order by shifting. Although these are, of course, to be ascribed to the "nature" of the present example, the inclination reminds us of the hole potential treatment.[17]

The HF energies in A2—A4 scarcely differ from that of the double-ζ calculation (the HF energy in A1), the changes being 0.00001 a.u.; the correlation corrections with and without shifting, E_c and E_c°, vary clearly as the basis orbitals are added, though by the small amount of 0.00004—0.00009 a.u. On the other hand, the changes of the correlation corrections by shifting are about 0.00046 a.u. in A1—A4 and about 0.00030 a.u. in B2—B4, which are significantly large in comparison with the changes of the HF energies and the correlation corrections by the addition of the basis orbitals. The cases B2—B4 may be said to give passable result, if we take it into account that the method is merely one-parametric.

In spite of poorness of the additional basis, the result obtained here seems rather encouraging. We cannot, however, give any conclusive remark as to how the method proposed in the preceding section work in general. They are to be examined through further numerical calculations on leading systems, which is another enormous story.

Supplementary Remarks

First, we refer to a non-variational way of setting $\{\theta_i\}$. Putting

$$\theta_j = \frac{1}{2}\sum_k v_{jk}^{jk} - x_{jj} - y_{jj} - z_{jj} - \cdots, \tag{43}$$

we have

$$E_0 + E_1 = \sum_j \varepsilon_j. \tag{44}$$

Namely the state energy to first order can be written in terms of a sum of the occupied MO energies without regard to MO coefficients. Thus the Hückel model

Hamiltonian is obtained in a natural way. Especially, under the HF choice with no modification, the HF energy is expressed as

$$E_{\mathrm{HF}} = \sum_j \varepsilon_j \tag{45}$$

by setting

$$\theta_j = -\frac{1}{2}\sum_k v_{jk}^{jk}, \tag{46}$$

MO coefficients continuing to be the HF ones. The state energy shifting to give the HF energy as the zeroth order state energy has been early devised.[32]

Next, let us consider approximate evaluations of physical quantities with few terms in the Rayleigh-Schrödinger perturbation expansion.[27,28] The perturbation terms contain the MO energy differences in thier energy denominators to second and higher orders, so that the ambiguity due to the MO energy shift is not negligible but may be often significant. We should rather make use of it. Above all, the distance between the occupied and unoccupied spaces is to be treated carefully.

(Received August 16, 1983)

The proton tunneling has been examined for the reaction between 2,4,6-trinitrotoluene and 1,8-diazabicyclo[5.4.0]undec-7-ene in benzonitrile in view of the solvent effect on the rate ratio k^H/k^D as well as on the various activation parameters. The reaction rate ratio k^H/k^D diminishes from 18.3 at 15 °C to 14.5 at 35 °C. The difference in the activation energies $E_a^D - E_a^H$ is 8.8 kJ mol^{-1} and the ratio of Arrhenius preexponential factors is 2.5. All these values are greater than the semiclassical limits of the primary kinetic isotope effects. According to Bell's equation the remarkable isotope effect is due to considerable contribution from tunneling in benzonitrile. The present results, being compared with those in other aprotic solvents, are discussed in relation with the effects of solvent polarity, specific acid-solvent interaction, and geometrical bulkiness in the vicinity of the reaction site.

Recently the primary kinetic isotope effect of the proton-transfer reaction in solution has been studied in detail from theoretical and phenomenological viewpoints.[1,2] The semiclassical theory of kinetic isotope effects, especially as applied to hydrogen and proton transfers, is well developed.[3-8] One of the recent topics is the quantum-mechanical tunneling phenomenon associated with a proton-transfer reaction.[9] The enormously large value of the kinetic isotope rate ratio has been almost explained on the basis of a tunneling contribution.[10-12]

In particular, the following proton/deuteron-transfers have attracted much interest because the experimental results of kinetic parameters and isotope effects are explained evidently by taking account of the appreciable tunneling effect; the reactions of (4-nitrophenyl)nitromethane (4NPNM) with tetramethylguanidine (TMG),[13-16] and pentamethylguanidine (PMG),[17] and the reactions of 2,4,6-trinitrotoluene (TNT) with TMG,[18-20] and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU).[21]

In the results of the reaction between 4NPNM and TMG[13] there appeared a sharp difference in the degree of kinetic isotope rate ratio k^H/k^D between the polar and nonpolar solvents: The larger was the dielectric constant, the smaller was the rate ratio. However, in the reaction of TNT with TMG,[18] a reverse tendency was found that k^H/k^D was 20.4 in acetonitrile (dielectric constant, $\varepsilon = 36$) and 13.7 in benzonitrile ($\varepsilon = 25.2$). It seems likely that a solvent character other than polarity also affects the degree of tunneling.

We reported previously proton tunneling of the reaction between TNT and DBU in acetonitrile (MeCN) and 1,2-dichloroethane (DCE).[21] In this paper we deal with the kinetics of the proton/deuteron-transfer reactions of the same system in benzonitrile (PhCN) for the purpose of investigating the steric effect of the medium. Benzonitrile is chosen as solvent because it is more bulky and less polar molecule than acetonitrile and so it might allow a greater contribution from tunneling.

Experimental

Materials. 2,4,6-Trinitrotoluene (TNT), 2,4,6-trinitrotoluene-α,α,α-d_3 (TNT-d_3), and 1,8-diazabicyclo[5.4.0]-undec-7-ene (DBU) were treated as described previously.[21] Benzonitrile (PhCN) was purified by the molecular sieves (type 5A), dried with phosphorus pentaoxide, then distilled several times. This treatment was repeated at frequent intervals.

Apparatus and Procedures. Absorption spectra were determined with a Shimadzu UV-200S spectrophotometer. Kinetic measurements were carried out with a Union Giken RA-401 stopped-flow apparatus. In all measurements the temperature was regulated within ±0.1 °C by circulating thermostated water. Solutions were freshly prepared before use and the following concentration of solutions were used: TNT, TNT-d_3, 0.02—0.08 mM; DBU, 1.3—14 mM. The apparent reaction rate was determined according to the same procedure as before.[21]

Results and Discussion

The reaction of TNT-d_3, as well as TNT, with DBU in PhCN gives a purple solution due to an ion pair. The absorption maxima of the product as a result of proton/deuteron-transfer from the methyl group of TNT to DBU are around 380, 535, and 645 nm in PhCN, and almost identical with those observed in other solvents.[21] The equilibrium constants K^H, K^D of the TNT, TNT-d_3+DBU reactions in PhCN were determined at 25 °C according to the Benesi-Hildebrand equation[22] (Fig. 1).

$$[AH]/a = 1/K\varepsilon[B] + 1/\varepsilon. \quad (1)$$

In this equation, [AH] is the initial concentration of TNT, [B] that of DBU, K the equilibrium constant, ε the molar absorption coefficient, and a the absorbance at 535 nm after equilibration. In kinetic measurement the stopped-flow trace fitted a first-order kinetic equation very well at each temperature when DBU existed in large excess over TNT or TNT-d_3. The plots of the observed first-order rate constant k_{obsd} against DBU concentration [B] are linear in agreement with Eqs. 2 and 3 (Figs. 2 and 3).

$$k_{obsd} = k_f^H[B] + k_b^H, \quad (2)$$

$$k_{obsd} = k_f^D[B] + k_b^D. \quad (3)$$

In these equations, k_f^H, k_f^D, k_b^H, and k_b^D denote the forward and backward rate constants of the proton- and deuteron-transfer reactions. The values of k_f^H, k_f^D, and k_f^H/k_f^D at each temperature are given in Table 1 together with those of K^H and K^D determined by equilibrium measurements at 25 °C. However, the values k_b^H and k_b^D are too small to be reliable and are not recorded. From the temperature dependence of the second-order rate constants (k_f^H and k_f^D), the activation parameters E_a, ΔH^*, ΔS^*, ΔG^*, and Arrhenius preexponential factors (A factors) were computed by a least-squares method (Table 2).

The result in Table 1 that K^H increases with solvent polarity suggests qualitatively that the ion pair is mainly stabilized by electrostatic interaction with the surrounding solvent molecules. On the other hand, increase of the activation energy E_a^H as well as the rate constant k_f^H is out of accord with increasing solvent polarity. E_a^H in PhCN is greater than those observed in MeCN and DCE by 8.0 and 18.4 kJ mol^{-1}, respectively, although solvent polarity increases in the order MeCN>PhCN>DCE. Contrary to ordinary cases, increasing solvent polarity tends to decrease k_f^H. These apparent differences in activation energy and rate constant between solvents originate from tunneling effect as described later.

The largely negative entropies of activation ΔS^*

indicate that the transition state is solvated more strongly than the initial one. For the TNT+DBU reaction, $-\Delta S^*$ (H) in PhCN is smaller by about 30 J K^{-1} mol^{-1} in comparison with that in MeCN. Such a tendency, which is also found in the 4NPNM+TMG[13] and TNT+TMG reactions,[18] will suggest that the initial state in PhCN is more strongly solvated than that in MeCN. The stronger solvation in PhCN seems to be a result of the interaction of π electrons of PhCN with TNT rings.[18]

Tunneling in a proton/deuteron-transfer reaction is revealed by the following characteristic features;[1,2,9] a kinetic isotope rate ratio $k^H/k^D>11$ at 25 °C, an activation energy difference $E_a^D-E_a^H>5.8$ kJ mol^{-1}, and a ratio of the Arrhenius preexponential factors $A^D/A^H>1.4$. As found in Tables 1 and 2, the present results conform to the above mentioned features of tunneling. We have evaluated quantitatively the tunneling correction factor Q to manifest tunneling contribution according to the procedure described previously.[21] The tunneling factor Q is, in general, defined as the ratio of the actual rate constant k to the semiclassical rate constant k_s:

$$Q = k/k_s. \tag{4}$$

Assuming that the preexponential factor A is the same for H and D in the absence of tunneling, we obtain Eq 5:

$$Q^H/Q^D = (k^H/k^D)\exp[-(E^D-E^H)/RT]. \tag{5}$$

Further, Q is expressed by assuming a symmetrical parabolic potential barrier:

$$Q = 0.5u/\sin(0.5u) - \sum_{n=1}^{\infty}(-1)^n \exp[(u-2n\pi)\alpha/u]/[(u-2n\pi)/u], \tag{6}$$

where $\alpha=E/kT$, $u=h\nu/kT$, and $\nu=(E/2m)^{1/2}/\pi b$; k is Boltzmann's constant, h Planck's constant, E the height of barrier, b the half width of the barrier at the base, m the mass of the particle transferred, and ν the frequency of oscillation of a particle in parabolic potential. We calculated Q^H and Q^D under the same conditions described previously.[21] The values of E^H, E^D, and $2b$ were adjusted in Eqs. 5 and 6 by trial and error until the calculated rate ratios $(k^H/k^D)_{calcd}$ reproduced the experimental ones of $(k^H/k^D)_{Arrh}$ taken from the Arrhenius plots over the whole range of experimental temperature. These calculations fix the values of E^H and E^D within ±0.2 kJ mol^{-1} and those of $2b$ within ±0.002 A. The results in PhCN are given in Table 3 together with those in MeCN and DCE.[21] As seen in Table 3, Q^H at 25 °C in all these solvents is larger than unity, that is, the reaction is subjected to tunneling.

Tunneling factor Q is closely related with the curvature at the top of the potential barrier, $2E/b^2$, and so it also gives a criterion of tunneling. If we take $m^H=1$ and $m^D=2$ amu in continuum medium irrespective of solvent, E will decrease with increasing solvent polarity, and so Q^H will be smaller in more polar solvent. The comparison between DCE and MeCN will conform to this case. The barrier width $2b$ is a little longer in MeCN perhaps because of the partial specific interaction of CN group with TNT. But the difference of tunneling factors is mainly due to that of E. Besides electrostatic or specific interaction, the solvent environment in the vicinity of reaction site must affect the degree of tunneling. When geometrical bulkiness of a solvent molecule is significant, we have to consider two effects: One is the steric hindrance which will work so as to separate the acid-base distance, and the other is to form a solvent cage in which reaction takes place under much less electrostatic effect of solvent. The former case will depress the tunneling degree, while the latter will enhance. The present results in PhCN suggest that the solvent PhCN molecule works so as not to form a cage-like environment around the reactive site but to separate the barrier width $2b$. For the case of PhCN the interposition of solvent molecule enlarges the distance between proton donor and acceptor, and brings about the smaller degree of tunneling, because there may be the stronger solvation due to π electron interaction between PhCN and TNT ring.

In this study we could not unfortunately discriminate the purely steric effect of solvent molecule. For that purpose an experiment in a bulky and nonpolar solvent is required, but within the preliminary experiments in various solvents we could not find any solvent

in which the reaction took place effectively.

A.c. Polarographic Study of Ion Transfer at the Water/Nitrobenzene Interface

Toshiyuki OSAKAI, Tadaaki KAKUTANI, and Mitsugi SENDA*
Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606
(Received August 22, 1983)

The transfer of tetramethylammonium (TMA^+) ion across the interface between a 0.1 mol dm^{-3} LiCl aqueous solution and a 0.1 mol dm^{-3} tetrabutylammonium tetraphenylborate nitrobenzene solution was investigated by means of phase-selective a.c. polarography. In recording the a.c. polarographic current a two-electrode cell system was used and the ohmic drop due to solution resistance in the cell was compensated for by positive feedback. The ion-transfer admittance *vs.* potential curves were determined in the a.c. frequency range between 10 and 100 Hz and the kinetic parameters of the TMA^+-ion transfer across the water/nitrobenzene interface were determined.

Kinetics of the charge (ion or electron) transfer at the interface between two immiscible electrolyte solutions has been studied by several authors using electrochemical techniques. Gavach and his coworkers have employed chronopotentiometry[1-3] and impedance measurement methods[1] to determine the kinetic parameters of the transfer of alkylammonium ions at the water/nitrobenzene interface. Recently, Koczorowsky and Geblewicz[4] have also applied chronopotentiometry to the kinetic study of the transfer of tetrabutylammonium ion at the water/1,2-dichloroethane interface. On the other hand, Samec *et al.* have employed cyclic voltammetry, with or without convolution analysis, for the kinetic studies of the transfer of Cs^+ ion at the water/nitrobenzene interface[5,6] and the transfer of alkaline earth metal cations facilitated by synthetic neutral carriers at the water/nitrobenzene interface,[7] and also the electron transfer between ferrocene in nitrobenzene and hexacyanoferrate(II) in water.[6]

In this work we have applied a phase-selective a.c. polarographic technique to the study of the kinetics of ion (tetramethylammonium ion) transfer at the water/nitrobenzene interface; an a.c. voltage of small amplitude was superimposed on a linear sweep voltage applied to the interface, and the real and imaginary components of the resulting alternating current were recorded against the applied linear sweep voltage in the frequency range between 10 and 100 Hz and in the concentration range of transferring ion between 0.15×10^{-3} and 0.50×10^{-3} mol dm^{-3}. In recording phase-selective a.c. polarographic curves we used a two-electrode cell system and the ohmic drop due to the solution resistance in the cell was compensated for by a positive feedback circuit. The recorded phase-selective a.c. polarographic currents were transformed into the admittance of the test interface and the latter was corrected for the admittance of the base aqueous solution/base nitrobenzene solution interface to give the admittance due to the ion transfer at the interface. The resulting ion-transfer admittance *vs.* potential curves were analysed using the conventional theory of a.c. polarography, and the kinetic parameters of the ion transfer at the water/nitrobenzene interface were determined.

Experimental

Chemicals. The tetramethylammonium chloride (TMACl) was analytical grade (Wako Pure Chemical Industries, Ltd.), and used as received. The tetrabutylammonium chloride (TBACl) was analytical grade (Nakarai Chemicals Co.), and was purified as previously described.[8] The concentrations of TMACl and TBACl were determined by potentiometric titration with a standard silver nitrate solution. The analytical grade nitrobenzene (Nakarai) was distilled under reduced pressure; the middle 60% of the distillate was collected and shaken with active alumina overnight; after filtration of the suspension, the filtrate was washed with triply distilled water. The nitrobenzene solution of tetrabutylammonium tetraphenylborate (TBATPB) was prepared in the dark immediately before use. The other chemicals and the preparation of the aqueous solution have been described elsewhere.[9]

Electrolytic Cell. The electrolytic cell assembly is shown in Fig. 1. A glass tube A, which was filled with a 0.1 mol dm^{-3} LiCl aqueous solution containing $(0.15-0.50)\times10^{-3}$ mol dm^{-3} TMACl, was dipped into a 0.1 mol dm^{-3} TBATPB nitrobenzene solution. The test interface was formed at the end of the glass tube A with an area of 0.159 cm^2. A reproducible, flat water/nitrobenzene interface was formed by treating the edge and the outer surface of the glass tube with dimethyldichlorosilane.[9,10] The test interface was

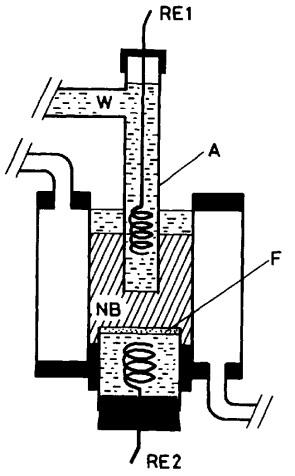

Fig. 1. Electrolytic cell. W, water phase; NB, nitrobenzene phase; A, glass tube; RE1 and RE2, reference electrodes; F, sintered glass.

renewed for each measurement of a single a.c. polarogram. The cell was water-jacketted at 25±0.1 °C.

The reference electrode for the nitrobenzene phase, RE2, was an Ag/AgCl/0.1 mol dm^{-3} TBACl (water) electrode with a large surface area (>6 cm^2), which was connected to the nitrobenzene phase through sintered glass. The other reference electrode for the aqueous phase, RE1, was an Ag/AgCl electrode with a large surface area (>4 cm^2), which was immersed in the aqueous phase. Accordingly, the cell to be studied can be expressed by:

$$\begin{array}{l} \qquad\qquad\qquad\qquad\quad \text{I} \qquad\qquad\quad \text{II} \\ \text{(RE2) Ag}\,|\,\text{AgCl}\,|\,0.1\ \text{mol dm}^{-3}\ \text{TBACl}\ \text{(W)}\,|\,0.1\ \text{mol dm}^{-3}\ \text{TBATPB}\ \text{(N)} \\ \qquad\qquad\qquad\quad \text{III} \\ |\,(0.15\text{—}0.50)\times 10^{-3}\ \text{mol dm}^{-3}\ \text{TMACl} + 0.1\ \text{mol dm}^{-3}\ \text{LiCl}\ \text{(W)} \\ |\,\text{AgCl}\,|\,\text{Ag (RE1)}, \qquad\qquad\qquad\qquad\qquad\qquad \text{(A)} \end{array}$$

where (W) and (N) represent the aqueous and the nitrobenzene phases. The interface between phases I and II is nonpolarizable and the potential difference across the interface is determined by the activities of TBA$^+$ ion in the two phases.[9,10]

Measurement of Solution Resistance. In a.c. polarographic measurements, we adopted a two-electrode cell system in which the ohmic drop due to the solution resistance between RE1 and RE2, R_u, was compensated for by means of positive feedback (see Fig. 3). For exact compensation of the ohmic drop, the value of R_u must be known accurately. We used a laboratory-made linear bridge[11] to determine R_u. Figure 2 shows the basic circuit of the bridge, which allowed accurate determination of resistance (a dummy cell resistance) using a 10 kHz a.c. generator with an error less than 10 Ω in the range between 0.5 and 5.0 kΩ. Determination of R_u was made every time the test interface was renewed. For a representative cell, as shown in Fig. 1, R_u was in the range between 1.41 and 1.54 kΩ.

A.c. Polarographic Measurement. The diagram of the basic electronic circuit for measurement of the interfacial impedance with a two-electrode cell system is shown in Fig. 3. The circuit bordered by broken lines is a conventional polarographic circuit (Yanako potentiostat PE21-TB2S). D.c. and a.c. voltages are generated by a sweep generator (Hokuto Denko HB-104) and an a.c. generator (YHP 3310B), respectively, and applied through R_1 to the summing point, e_s, of the inverting adder (OA1 and OA2), the output of which is applied to the terminal of RE1, while the terminal of RE2 is always held at virtual ground. The output voltage of OA3, E_o, is proportional to the current flowing through the cell, i, that is, $E_o=iR_i$. For the ohmic drop compensation, a part of this output voltage was fed back to the summing point. The feedback voltage was made equal to $\beta R_u i=\beta R_u E_o/R_i$ by adjusting a potentiometer, R_c, where β is the fraction of positive feedback and $\beta=1$ for 100% positive feedback. The real (in-phase) and imaginary (out-of-phase) components of the a.c. polarographic current flowing through the cell were determined by a lock-in amplifier (NF LI-574) and recorded against the linear sweep voltage applied to the test interface, usually at the voltage scan rate of $v=5$ mV s^{-1}, using an X-Y

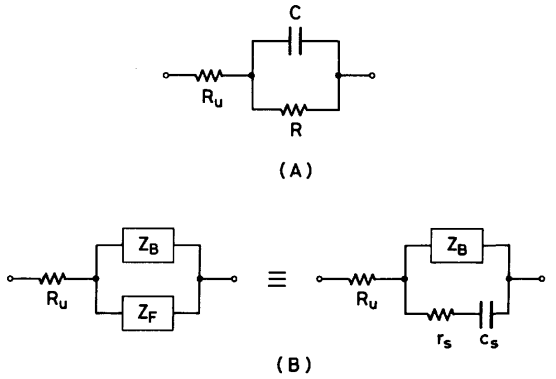

Fig. 4. (A) Dummy cell. R, C, and R_u correspond, respectively, to the resistance and capacitance of the test interface, and the solution resistance. (B) Equivalent circuit of the cell. R_u, solution resistance; Z_B, base impedance; $Z_F=r_s-j(1/\omega C_s)$, ion-transfer impedance.

recorder (Watanabe WX4302). The magnitude of the superimposed a.c. voltage (usually 5 mV peak to peak) was calibrated by replacing the cell with a known capacitor and measuring the a.c. current flowing through the capacitor by the lock-in amplifier.

The measuring circuit was calibrated by a dummy cell, which consists of R_u=1.5 kΩ, R=0.2 to 2 kΩ, and C=2 to 20 μF, as shown in Fig. 4(A), in the a.c. frequency range of 10 to 100 Hz. The error in measuring the dummy admittance ($1/R$ and ωC) with β being equal to 1 was not negligible, especially at high frequencies. Accordingly, the measured or apparent admittance was corrected for the non-ideal dynamic response of the measuring circuit, where the response was represented, in the first approximation, by the gain function of $G=K/(1+\tau_a s)$ of the control amplifier (OA1) with other amplifiers functioning ideally. The residual error in the corrected admittance was less than 1, 3, and 6% at 10, 50, and 100 Hz, respectively, in the calibrated range of R and C of the dummy cell.

Theoretical

In the following, the potential applied to cell A, E, is defined as the potential of RE1 against that of RE2, *i.e.*, $E=E_{RE1}-E_{RE2}$. The flow of the positive charge from the aqueous to the nitrobenzene phase is taken as the positive current.

Interfacial Admittance. The admittance of the test interface as determined by phase-selective a.c. polarography can be generally represented by:

$$Y_t = Y_t' + jY_t'', \tag{1}$$

where j is an operator $j=(-1)^{1/2}$. Let the base admittance, that is, the admittance of the base aqueous solution/base nitrobenzene solution interface, be $Y_B=Y_B'+jY_B''$. Then the admittance due to the ion transfer $Y_F=Y_F'+jY_F''$ can be estimated by:

$$Y_F' = Y_t' - Y_B', \tag{2}$$

$$Y_F'' = Y_t'' - Y_B''. \tag{3}$$

Finally, the ion-transfer admittance, Y_F, is related to a series combination of resistance and capacitance, r_s and c_s, due to the ion transfer (see Fig. 4(B)) by:

$$r_s = Y_F'/(Y_F'^2 + Y_F''^2), \tag{4}$$

$$1/\omega c_s = Y_F''/(Y_F'^2 + Y_F''^2), \tag{5}$$

where ω is the a.c. angular frequency ($\omega=2\pi f$, f being the a.c. frequency).

Ion-transfer Impedance. We suppose that the ion-transfer current I is a function of the surface concentrations of the ion in the aqueous and nitrobenzene phases, C^W and C^N, and of the interfacial potential difference, $\Delta_N^W\phi$, or the potential applied to the cell, $E=\Delta_N^W\phi+\Delta E_{ref}$, where ΔE_{ref} is determined by the reference electrode system:[9]

$$I = I(E,C^W,C^N). \tag{6}$$

In this and the following equations the terms containing activity coefficients of the ions are neglected for the sake of simplicity. When a small a.c. voltage is superimposed on the d.c. potential, E_{dc}, the ion-transfer impedance, $r_s-j(1/\omega c_s)$ (see Fig. 4(B)), can be generally expressed, by analogy with the faradaic impedance of an electrode reaction,[12-14] by:

$$r_s = r_{ct} + r^W + r^N, \tag{7}$$

$$1/\omega c_s = x^W + x^N, \tag{8}$$

with

$$r_{ct} = 1/\left(\frac{\partial I}{\partial E}\right)_{dc}, \tag{9}$$

$$r^\alpha = \pm\left[\left(\frac{\partial I}{\partial C^\alpha}\right)_{dc}\Big/\left(\frac{\partial I}{\partial E}\right)_{dc}\right](h_r)^\alpha(1/zFA), \tag{10}$$

$$x^\alpha = \pm\left[\left(\frac{\partial I}{\partial C^\alpha}\right)_{dc}\Big/\left(\frac{\partial I}{\partial E}\right)_{dc}\right](h_y)^\alpha(1/zFA), \tag{11}$$

where the superscript α (=W and N) stands for the aqueous (W) and nitrobenzene (N) phases, and the upper and lower signs in Eqs. 10 and 11 apply to W and N, respectively; z is the ionic valence, F the Faraday and A the surface area of the test interface. The expression $(\ )_{dc}$ means the partial differential coefficients with respect to the stated variable of Eq. 6 at $E=E_{dc}$, and $(h_r)^\alpha$ and $(h_y)^\alpha$ are the coefficients, which depend only on the mass transfer of the ion in the two phases and are given for semi-infinite linear diffusion by:

$$(h_r)^\alpha = (h_y)^\alpha = (2\omega D^\alpha)^{-1/2}, \tag{12}$$

where D^α is the diffusion coefficient of the ion in the α phase.

When the ion transfer is reversible or nernstian in d.c. cyclic voltammetry, the Nernst equation is valid for the d.c. components of surface concentration or the mean surface concentrations, $\bar{C}^W$ and $\bar{C}^N$:

$$E_{dc} = E^\circ + (RT/zF)\ln(\bar{C}^N/\bar{C}^W). \tag{13}$$

Here E° is the standard potential of the ion transfer at the test interface with respect to the reference electrode system in cell A and is defined by:

$$E^\circ = -\frac{\Delta G_{tr}^{\ominus,N\to W}}{zF} + \Delta E_{ref}, \tag{14}$$

where $\Delta G_{tr}^{\ominus,N\to W}$ is the standard Gibbs free energy of ion transfer from the nitrobenzene to the aqueous phase. Thus, we have $(\partial I/\partial C^W)_{dc}/(\partial I/\partial E)_{dc}=-(\partial E_{dc}/\partial \bar{C}^W)=(RT/zF)(1/\bar{C}^W)$ and $(\partial I/\partial C^N)_{dc}/(\partial I/\partial E)_{dc}=-(\partial E_{dc}/\partial \bar{C}^N)=-(RT/zF)(1/\bar{C}^N)$. For semi-infinite linear diffusion, we also have $(D^W)^{1/2}(C^{W,o}-\bar{C}^W)=(D^N)^{1/2}(\bar{C}^N-C^{N,o})$ where $C^{\alpha,o}$ is the bulk concentration of the ion in the α phase. Then we get from Eqs. 7 to 13, upon assuming that $C^{N,o}=0$:

$$r_s = (\sigma/\omega^{1/2})[1+(2\omega)^{1/2}\lambda^{-1}], \tag{15}$$

$$1/\omega c_s = \sigma/\omega^{1/2}, \tag{16}$$

where

$$\sigma = \frac{4RT\cosh^2(\xi/2)}{z^2F^2A(2D^W)^{1/2}C^{W,o}}, \tag{17}$$

$$\xi = zF(E_{dc} - E_{1/2}^r)/RT, \tag{18}$$

$$E_{1/2}^r = E^\circ + (RT/zF)\ln(D^W/D^N)^{1/2}, \tag{19}$$

and

$$\lambda = \frac{1}{zFA(D^W)^{1/2}}\left(\frac{\partial I}{\partial C^W}\right)_{dc} - \frac{1}{zFA(D^N)^{1/2}}\left(\frac{\partial I}{\partial C^N}\right)_{dc}. \tag{20}$$

Equations 15 and 16 can be rewritten as:

$$\lambda = (2\omega)^{1/2}/(r_s c_s \omega - 1). \quad (21)$$

For the sake of simplicity, we assume a simple linear kinetic equation:

$$I = zFA(\vec{k}C^W - \overleftarrow{k}C^N), \quad (22)$$

where $\vec{k}$ and $\overleftarrow{k}$ are the rate constants of the ion transfer from the aqueous to the nitrobenzene phase and from the nitrobenzene to the aqueous phase, respectively. We further assume Butler-Volmer type equations for $\vec{k}$ and $\overleftarrow{k}$:

$$\vec{k} = k_s \exp[\vec{\alpha}zF(E_{dc}-E^\circ)/RT], \quad (23)$$

$$\overleftarrow{k} = k_s \exp[-\overleftarrow{\alpha}zF(E_{dc}-E^\circ)/RT], \quad (24)$$

where k_s is the standard rate constant; $\vec{\alpha}$ and $\overleftarrow{\alpha}$ ($\vec{\alpha}+\overleftarrow{\alpha}=1$) are the transfer coefficients. Then Eq. 20 can be written as:

$$\lambda = \frac{\vec{k}}{(D^W)^{1/2}} + \frac{\overleftarrow{k}}{(D^N)^{1/2}}$$

$$= \Lambda[\exp(\vec{\alpha}\xi) + \exp(-\overleftarrow{\alpha}\xi)], \quad (25)$$

with

$$\Lambda = k_s\left(\frac{1}{(D^W)^{1/2}}\right)^{\overleftarrow{\alpha}}\left(\frac{1}{(D^N)^{1/2}}\right)^{\vec{\alpha}}, \quad (26)$$

Equation 25 can also be rewritten as:

$$\ln[\lambda/(1+\exp(-\xi))] = \ln\Lambda + \vec{\alpha}\xi. \quad (27)$$

Results and Discussion

Cyclic Voltammetry of TMA^+ Ion. Cyclic voltammograms for the transfer of TMA^+ ion across the interface between a 0.1 mol dm^{-3} LiCl aqueous solution and a 0.1 mol dm^{-3} TBATPB nitrobenzene solution were recorded, using the two-electrode cell system shown in Fig. 1, by means of the polarographic circuit shown in Fig. 3 with the ohmic drop compensation by positive feedback. Representative cyclic voltammograms are shown in Fig. 5. Reversible cyclic voltammograms were obtained when the solution resistance was compensated for by positive feedback of $\beta=1$; the positive and negative peak potentials were independent of the TMA^+-ion concentration between 0.15×10^{-3} and the 0.50×10^{-3} mol dm^{-3} and of the scan rate between 5 and 50 mV s^{-1}, and the peak separation was 60 ± 2 mV. The positive and negative peak currents, when corrected for the base current, were proportional to the TMA^+-ion concentration and to the square root of the voltage scan rate (data are not shown here). These results indicate that the two reference electrodes function as ideal non-polarized electrodes and that the ohmic drop compensation works correctly. The reversible half-wave potential, $E^r_{1/2,TMA}$ (or the midpoint potential between the positive and negative peak potentials) was determined to be 0.317 ± 0.001 V. This result agrees well with the previous result of $E^r_{1/2,TMA}=0.32$ V which was determined by potential-step chronoamperometry, cyclic voltammetry, and chronopotentiometry with a four-electrode electrochemical cell.[9]

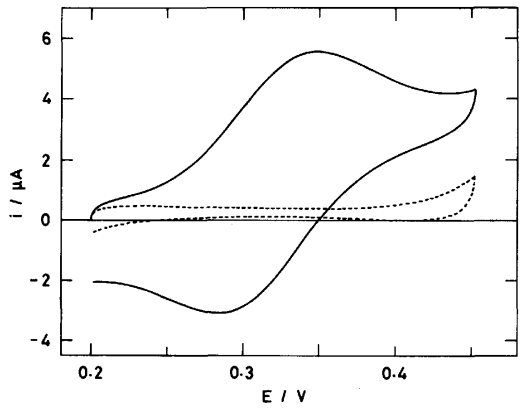

Fig. 5. Cyclic voltammogram obtained with the two-electrode cell system using the polarographic circuit as shown in Fig. 3 with positive feedback of $\beta=1$, for the transfer of 0.5×10^{-3} mol dm^{-3} TMA^+ ion from a 0.1 mol dm^{-3} LiCl aqueous solution to a 0.1 mol dm^{-3} TBATPB nitrobenzene solution at $v=5$ mV s^{-1}. Dashed line, cyclic voltammogram in the absence of TMA^+ ion.

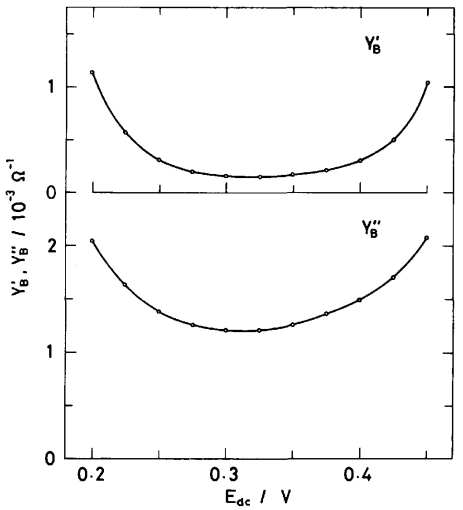

Fig. 6. Real (Y'_B) and imaginary (Y''_B) components of the base admittance at $f=50$ Hz for the interface between a 0.1 mol dm^{-3} LiCl aqueous solution and a 0.1 mol dm^{-3} TBATPB nitrobenzene solution.

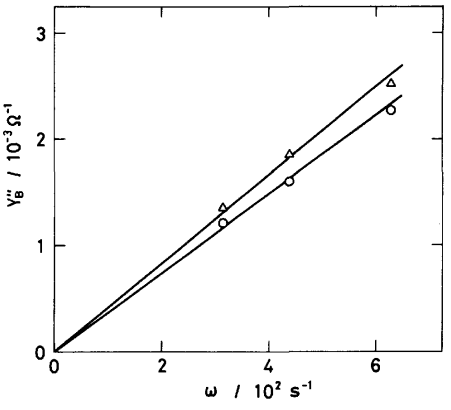

Fig. 7. Dependence of the imaginary components of the base admittance, Y''_B, on the angular frequency, ω, at $E_{dc}=0.300$ V (○) and 0.375 V (△).

Double-layer Capacity of Water/Nitrobenzene Interface. Figure 6 shows an example of Y'_B *vs.* E_{dc} and Y''_B *vs.* E_{dc} curves for the interface between a 0.1 mol dm^{-3} LiCl aqueous solution and a 0.1 mol dm^{-3} TBATPB nitrobenzene solution. Also, as seen in Fig. 7, Y''_B was proportional to ω in the frequency range between 50 and 100 Hz. From the slope of the plot of Y''_B *vs.* ω the double-layer capacity of the interface, C_{dl}, was determined by $Y''_B = A\omega C_{dl}$. The resultant C_{dl} *vs.* E curve is shown in Fig. 8. The potential of the capacity minimum, E_{min}, was about 0.30 V. This value is close to E_{min}=0.29 V reported by Samec *et al.*[15] The value of C_{dl} at E_{min}, $C_{dl,min}$, was 23.3 μF cm^{-2} , which is small compared with their 27 μF cm^{-2} (*cf.* Fig. 5 in Ref. 15).

Integration of the C_{dl} *vs.* E curve should yield the surface charge density on the water side of the interface,[8,16] q^W:

$$q^W = \int_{E_{pzc}}^{E} C_{dl}\, dE, \tag{28}$$

where E_{pzc} is the potential of zero charge. The value of E_{pzc} has been found to be 0.265 V in the present system by electrocapillary measurement.[8,16] The resultant q^W *vs.* E curve is shown in Fig. 9. Also plotted in Fig. 9 are the surface charge density data obtained from the electrocapillary measurement.[8,16] The two values of q^W obtained by the two different methods are in excellent agreement.

It has been shown that the residual current in the potential range between 0.20 and 0.45 V is mainly due to the transfer of TBA^+ and TPB^- ions across the interface.[8] However, the calculated values of Y'_B due to

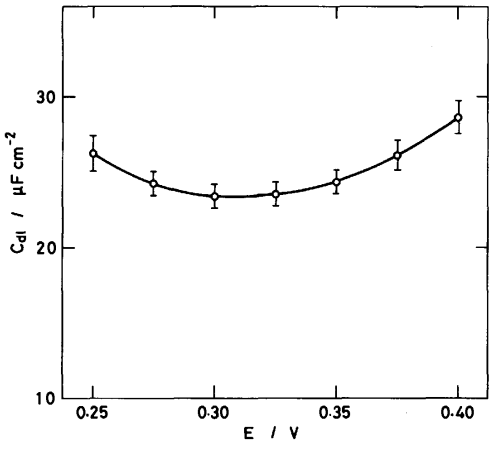

Fig. 8. Plot of the double-layer capacity, C_{dl}, against the potential, E, for the interface between a 0.1 mol dm^{-3} LiCl aqueous solution and a 0.1 mol dm^{-3} TBATPB nitrobenzene solution.

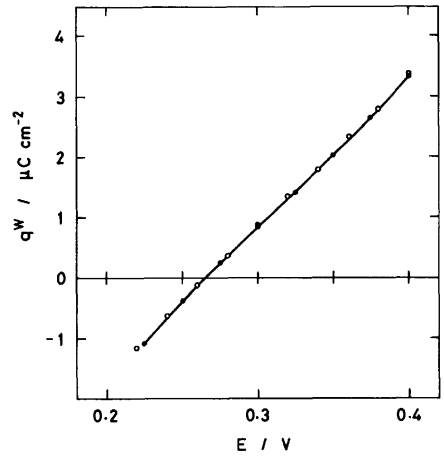

Fig. 9. Plot of the surface charge density on the water side of the interface, q^W, against the potential, E, for the interface between a 0.1 mol dm^{-3} LiCl aqueous solution and a 0.1 mol dm^{-3} TBATPB nitrobenzene solution, obtained by the integration of C_{dl} *vs.* E curve (●) and by the differentiation of the electrocapillary curve (○).[8]

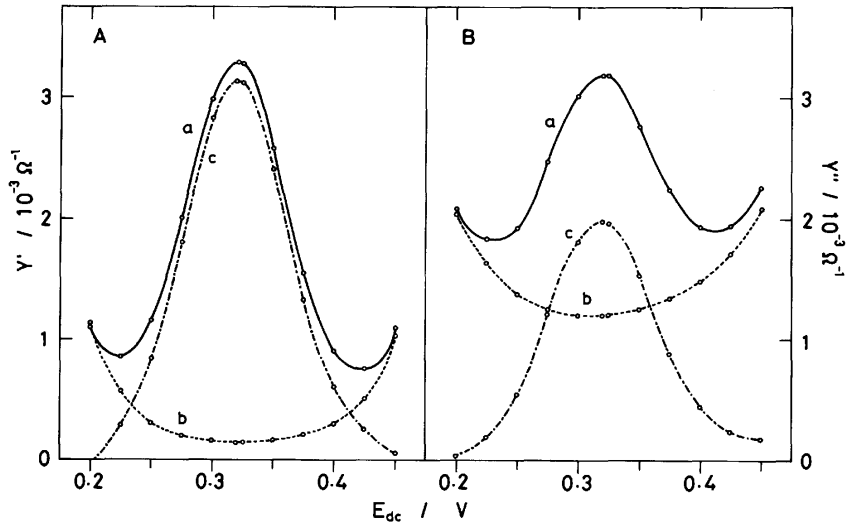

Fig. 10. Real (A) and imaginary (B) components of the admittance of the interface between a 0.1 mol dm^{-3} LiCl aqueous solution and a 0.1 mol dm^{-3} TBATPB nitrobenzene solution, at f=50 Hz, in the presence (a) and the absence (b) of 0.5×10^{-3} mol dm^{-3} TMA^+ ion in the aqueous phase. Curve c shows the ion-transfer admittance, Y'_F and Y''_F, for the TMA^+-ion transfer corrected for the base admittance.

the transfer of TBA^+ and TPB^- ion are too small to explain the observed values of Y'_B (Fig. 6); for example, the calculated value of Y'_B at 0.30 V and 50 Hz is 2.5×10^{-5} Ω^{-1}, while the observed value was 1.6×10^{-4} Ω^{-1} The reason for this discrepancy is left for further study.

Ion-transfer Impedance of TMA^+ Ion. In Fig. 10 the solid lines show representative plots of Y'_t and Y''_t *vs.* E_{dc} for the transfer of TMA^+ ion across the interface between a 0.1 mol dm^{-3} LiCl aqueous solution and a 0.1 mol dm^{-3} TBATPB nitrobenzene solution. Y'_F *vs.* E_{dc} and Y''_F *vs.* E_{dc} curves, obtained by Eqs. 2 and 3, are also shown in Fig. 10. The peak potentials of Y'_F and Y''_F coincided and were equal to 0.319 ± 0.002 V, irrespective of the frequency and the TMA^+-ion concentration, and agreed well with the reversible half-wave potential, $E^r_{1/2,TMA}=0.317\pm0.001$ V, obtained by cyclic voltammetry.

The real and imaginary components of the ion-transfer impedance, r_s and $1/\omega c_s$, at $E_{dc}=0.319$ V were calculated by Eqs. 4 and 5, and plotted against $\omega^{-1/2}$ in Fig. 11. Both plots are straight lines with a common slope, which gives $D^W_{TMA}=(1.46\pm0.05)\times10^{-5}$ cm^2 s^{-1} by Eqs. 17 and 18. This result agrees well with the previously reported value of 1.2×10^{-5} cm^2 s^{-1} determined by other electrochemical techniques.[9] Similar linear plots were also obtained for the ion-transfer impedances at several other d.c. potential in the range between 0.250 and 0.375 V.

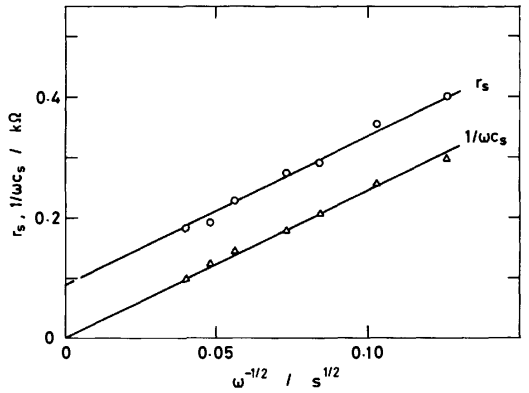

Fig. 11. Plot of the real (r_s) and imaginary ($1/\omega c_s$) components of the ion-transfer impedance against $\omega^{-1/2}$ for the transfer of 0.5×10^{-3} mol dm^{-3} TMA^+ ion at the interface between a 0.1 mol dm^{-3} LiCl aqueous solution and a 0.1 mol dm^{-3} TBATPB nitrobenzene solution at $E_{dc}=0.319$ V.

We calculated λ from r_s and $1/\omega c_s$ using Eq. 21. The results are shown in Table 1 for three different concentrations of TMA^+ ion. The figures are the average of the data obtained at seven different frequencies: 10, 15, 22.3, 30, 50, 70, and 100 Hz. As shown in this Table, λ is not very dependent on the TMA^+-ion concentration, indicating the approximate validity of the linear kinetic equation for the ion transfer (see Eq. 22).

In Fig. 12, $\ln[\lambda/(1+\exp(-\xi))]$ is plotted against ξ, giving an appreciably upward convex plot, instead of a linear or nearly linear one. Frumkin correction for the double-layer effect does not reform but rather intensifies the convex nature of the plot. Formally, this convex plot can be explained by the potential dependence of the transfer coefficients. Upon assuming that $\vec{\alpha}$ varies linearly with the potential: $\vec{\alpha}=\vec{\alpha}_0+\alpha'\xi$ so that $\overleftarrow{\alpha}=\overleftarrow{\alpha}_0-\alpha'\xi=(1-\vec{\alpha}_0)-\alpha'\xi$, where $\vec{\alpha}_0$ and $\overleftarrow{\alpha}_0$ are the transfer coefficients at $\xi=0$ and α' is the constant, the plot was fitted to Eq. 29, a modified form of Eq. 27, by adjusting three parameters, A', $\vec{\alpha}_0$ and α':

$$\ln[\lambda/(1+\exp(-\xi))] = \ln A' + \alpha'\xi \ln (D^W/D^N)^{1/2} + (\vec{\alpha}_0 + \alpha'\xi)\xi, \quad (29)$$

with

$$A' = k_s\left(\frac{1}{(D^W)^{1/2}}\right)^{\overleftarrow{\alpha}_0}\left(\frac{1}{(D^N)^{1/2}}\right)^{\vec{\alpha}_0}. \quad (30)$$

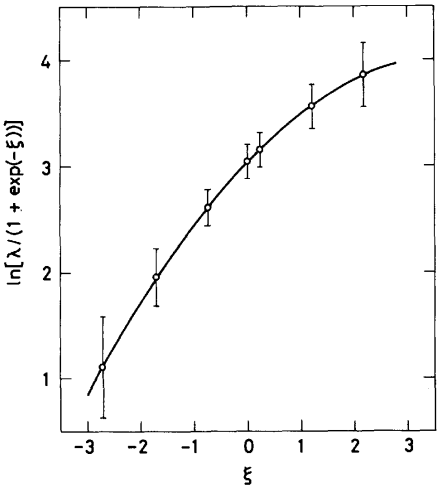

Fig. 12. Plot of $\ln[\lambda/(1+\exp(-\xi))]$ *vs.* ξ $(=zF(E_{dc}-E^r_{1/2})/RT)$. The solid line shows the regression line obtained by fitting the plot to Eq. 29. Vertical bars indicate the standard deviations.

Table 1. Dependence of λ ($s^{-1/2}$) values on the cell potential, E_{dc}, and the concentration of TMA^+ ion in the aqueous phase, $C^{W,o}_{TMA}$

E_{dc}	$C^{W,o}_{TMA}/10^{-3}$ mol dm^{-3}			
V	0.15	0.30	0.50	Mean
0.250	52.2(40.7)[a]	58.2(9.9)[a]	48.2(12.6)[a]	52.3(25.3)[a]
0.275	47.8(18.4)	50.7(5.4)	44.9(8.6)	47.8(12.2)
0.300	41.4(8.5)	45.8(3.6)	41.6(8.2)	42.9(7.1)
0.319[b]	41.2(8.6)	44.8(4.0)	40.6(7.3)	42.2(6.9)
0.325	40.4(9.1)	45.8(4.1)	40.4(7.8)	42.2(7.3)
0.350	46.9(16.0)	51.7(8.4)	43.5(6.1)	47.3(11.0)
0.375	50.6(18.5)	65.5(22.1)	50.6(7.8)	55.6(17.2)

a) The figures in parentheses are the standard deviations. b) The peak potentials: $E_p=0.319\pm0.002$ V.

Regression analysis was carried out using the SALS program[17] on the FACOM M-200 Computer in the Data Processing Center of Kyoto University. The result was $A'=20.8\pm2.1\ s^{-1/2}$, $\vec{\alpha}_0=0.55\pm0.08$, and $\alpha'=-0.067\pm0.047$ by taking $D^{W}_{TMA}=1.46\times10^{-5}\ cm^2\ s^{-1}$ and $D^{N}_{TMA}=D^{W}_{TMA}/2.07=7.05\times10^{-6}\ cm\ s^{-1}$.[18] Also k_s (the apparent standard rate constant) was tentatively determined to be 6.5×10^{-2} cm s^{-1} from A'. Further study is needed to find out whether the marked dependence of the transfer coefficents on the potential (as obtained here) is the common nature of the kinetic parameters of ion transfer at the interface of water and nitrobenzene (two immiscible electrolyte solutions), or a special case, indicating that the TMA^+-ion transfer at the 0.1 mol dm^{-3} LiCl(W)/0.1 mol dm^{-3} TBATPB(N) interface may involve complications which would require more complex equations of kinetics for the TMA^+-ion transfer in place of Eqs. 22 to 25.

In conclusion, phase-selective a.c. polarography is a promising technique for the kinetic study of the charge transfer at the interface between two immiscible electrolyte solutions.

This work was supported in part by a Grant-in-Aid from the Ministry of Education, Science and Culture.

Binding of 1-Decylpyridinium Bromide to Poly(vinyl sulfate)

Keishiro SHIRAHAMA* and Masatoshi TASHIRO
Department of Chemistry, Faculty of Science and Engineerig, Saga University, Saga 840
(Received September 12, 1983)

Binding of 1-decylpyridinium bromide onto poly(vinyl sulfate) in aqueous solution is measured by using a potentiometric titration method which employs propionyl-α-cyclodextrin as a neutral carrier in a 1-decylpyridinium selective electrode. Binding is highly cooperative and biphasic. The first step binding is reduced, while the second one increased on increasing added NaBr concentration. Temperaure dependence is very small giving an enthalpy of binding equal to −1.4 kJ mol^{-1}

Surfactants, a group of molecules possessing a large hydrophobic group as well as a strong hydrophilic group, show remarkable characters:[1,2] adsorption onto surfaces and aggregation into micelles. Furthermore surfactants are bound onto macromolecules, both natural and synthetic.[3,4] Recently relevant studies are being accumulated.[5–11] We also have reported binding isotherms for such systems as poly(ethylene oxide)-alkyl sulfates,[12,13] dodecyl sulfate-denatured proteins,[14] decyl sulfate-synthetic cationic polymer,[15] and DNA-1-dodecylpyridinium salt.[16] All the systems mentioned above are characterized by very marked cooperative binding: a sudden occurrence and completion of binding in a very narrow range of equilibrium concentration.

There are several methods in order to study surfactant–polymer interactions. We prefer a binding isotherm method which provides with a direct evidence of interaction and allows for thermodynamic interpretation by the aid of statistical mechanics. This kind of study can afford fundamental knowledges about interactions of various sorts of biomedical materials with biomacromolecules such as proteins and nucleic acids.

In the present study, binding of 1-decylpyridinium bromide (DePBr) to poly(vinyl sulfate) (PVS) was measured by a potentiometric titration method which employs a DeP-sensitive electrode to seek for a further understanding of the phenomena. A potentiometric method is superior to an equilibrium dialysis method in constructing a binding isotherm, because the former measures a thermodynamic activity directly and promptly, while the latter takes a very long time to reach an equilibrium followed by tedious analytical procedures, especially when a surfactant is used as a dialysate. A DeP-selective electrode prepared by using a hydrophobic cyclodextrin derivative dissolved in poly(vinyl chloride) (PVC) membrane was successfully used.[16]

Experimental

Materials. 1-Decylpyridinium bromide was synthesized by treating a fractionally distilled 1-bromodecane with dried pyridine and recrystallized from acetone three times followed by decolorization with active charcoal in a methanol solution. The critical micelle concentration as measured by an electric conductivity method is 51.6 mM† at 25 °C. Potassium poly(vinyl sulfate) (Wako Chemicals Co.) was converted into the sodium salt by dialysis in a concentrated sodium bromide solution (1 M) and then in pure water for days. The polymer solution was slightly acidic (pH 6). The sulfate content of the polymer solution was determined by a colloid titration method.[17]

Electrode. α-Cyclodextrin (Tokyo Kasei) was esterified with propionic anhydride in dried pyridine at room temperature for 1 d. Purification by precipitation with water followed by dissolution in acetone was repeated three times. The obtained white material is propionyl-α-cyclodextrin (prop-α-CD) working as a neutral carrier of the surfactant. Poly(vinyl chloride) (0.6 g), bis(2-ethylhexyl) phthalate (2.37 g), and the neutral carrier (0.03 g) are mixed well. Into the slurry mixture, 6 ml of tetrahydrofuran is added. The whole mixture is heated at 60 °C until it becomes a clear and viscous solution, which is then cast on a flat glass plate. After gradual evaporation of the solvent, the gel membrane (about 0.2 mm thick) is cut out and put on one end of a PVC tube (9 mm inner diameter and 11 cm long), where a 10% PVC tetrahydrofuran solution is a good adhesive. The electrode membrane is "annealed" at 40—50 °C under reduced pressure. A concentration cell is formed as follows:

$$\text{Calomel}\left|\begin{matrix}\text{1 M KCl}\\ \text{agar bridge}\end{matrix}\right|\begin{matrix}C_o\text{mM DePBr}\\ C_a\text{mM NaBr}\end{matrix}\Bigg|\mathbf{M}\Bigg|\begin{matrix}C_s\text{mM DePBr}\\ C_a\text{mM NaBr}\end{matrix}\left|\begin{matrix}\text{1 M KCl}\\ \text{agar bridge}\end{matrix}\right|\text{Calomel},$$

where **M** is the surfactant-selective membrane, C_S and C_O are the outer and inner surfactant concentrations respectively, and C_a is the added NaBr concentration. The polyelectrolyte concentation is usually about 1 mM residue. The potentiometric titration is carried out in a thermostated cocylindrical cell. The electromotive force (EMF) is measured with a digital voltmeter (Takeda Riken TR-6843). Asymmetric potential is usually less than ±2 mV and is not corrected for.

Results and Discussion

Figure 1 shows a relation between the EMF and logarithm of surfactant concentration. The electrode is excellently responsive from the cmc down to *ca.* 2×10^{-6} M with a slope of 58 mV per decade concentration difference at 20 °C. In the presence of 1 mM residue PVS, however, a deviation from the linearity is found suggesting that a part of surfactant is bound onto the polymer. Amount of binding, $\Delta C=C_s-C_f$ at an equilibrium concentration, C_f, is obtained by following the arrows shown. A degree of binding, X, is defined as ΔC/(total concentration of sulfate groups on polymer). A binding isotherm is constructed by plotting X against $\log C_f$.

NaBr concentration in mM: a; 20, b; 50, and c; 100.

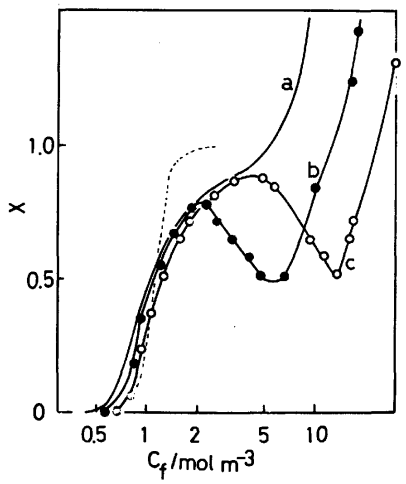

Fig. 3. Effect of temperature on binding isotherms in 50 mM NaBr.
Temperature in °C: a; 20, b; 40, and c; 50.

In Fig. 2, there are three binding isotherms in different NaBr concentrations at 20 °C. It is seen on an isotherm that there are two-step bindings: one occurring suddenly and sharply increasing until a shoulder around $X=1$, followed by another step binding. Titrated solution sometimes became turbid near $X=1$ due to neutralization of charges on the polymer and subsequent precipitation. The turbidity, however, soon disappears on further addition of surfactant. The hydrophobic precipitate is redispersed on further binding surfactants with their polar groups exposed to the bulk water phase, while their alkyl chains are in contact with the hydrophobic surfactant-polymer complex.

Now our analysis is mainly limited within the first step binding, since the second one is less reproducible probably because of the precipitation. The binding isotherm shifts right along the equilibrium concentration axis with increase in the added electrolyte concentration. This is the same tendency as we observed previously in the sodium decyl sulfate-cationic polymer system.[15] Added counterions suppress the electrostatic potential on a polyelectrolyte and reduce an affinity potential. It is a cooperative nature that the binding occurs suddenly and concludes within a very narrow range of equilibrium concentration: an already bound surfactant helps later coming surfactants bound through hydrophobic interaction between alkyl chains.

In Fig. 3, binding isotherms at three temperatures in the presence of 50 mM NaBr are shown. It is noted that isotherms slightly shift right on increasing temperature. Maxima and minima found at 40 and 50 °C: should be ascribed to precipitation mentioned above, which is apt to occur at higher temperature.

The following features are extracted from the binding isotherms semiquantitatively in accordance with the above discussion. According to the Ising's nearest neighbor interaction theory,[18] PVS may be viewed as one dimensional array of binding sites where surfactants are bound with mutual interaction. A partition function for such a system is explicitly expressed and yields a lot of important relations,[18] two of which are especially useful for the present purpose:

$$[dX/d\ln C_f]_{X=0.5} = \sqrt{u}/4, \tag{1}$$

$$K = [uC_f(0.5)]^{-1}, \tag{2}$$

where $C_f(0.5)$ is an equilibrium concentration corresponding to half binding ($X=0.5$), u the cooperative parameter, or an equilibrium constant for an aggregation process among bound surfactants, and K means a binding constant for a process that a surfactant ion is transferred from an aqueous solution phase onto an isolated binding site on a polyelectrolyte molecule. These thermodynamic parameters are obtained by fitting the lower half of the binding isotherms (actually $X<0.4$) to the theoretical formula (3), which is also derived from the original partition function.[15,18]

$$X = \frac{1}{2}\left[1 - \frac{1-s}{\sqrt{(1-s)^2+4s/u}}\right], \tag{3}$$

where $s=uKC_f$, or a kind of binding "pressure". Curve-fitting was carried out starting with an observed $C_f(0.5)$ and an assumed u, readjusting the two parameters until the best fit on a CRT display of a microprocessor was obtained. A small variation in the parameters (*ca.* 20% in u or 5% in K) results in appreciable deviation from the experimental points. Use of lower half of binding isotherm may be justified because the electrostatic potential of the polymer remains nearly constant there by the ion-condensaion effect as depicted by Manning.[19] So the Ising's theory may be applied. The calculated isotherms are plotted with dashed lines in Figs. 2 and 3. Deviation from the theoretical values at $X>0.5$ indicates a break down of the ion-condensation effect due to decreased ionization of the polyelectrolyte below a critical value predicted by the Manning's theory as a result of surfactant-binding. Electrostatic potential now is so much reduced on binding surfactants that a sort of negative cooperativity decreases actual binidng less than a theoretical one. The values of K and u are summarized in Table 1. It is a remarkable feature that u is insensitive to changes in added salt concentration as well as in temperature, albeit u contains substantial amount of uncertainty (some 30%). The insensitivity of u to added salt may be expected because a surfactant ion is discharged on binding and aggregation on polymer should be little influenced by changes in ionic atmosphere.[15] The aggregation is mainly promoted by hydrophobic interaction which usually accompanies very little thermal changes leading to a very small temperature-dependence of u values. If u is assumed to be constant then the observed variation in the binding isotherms is solely ascribed to the changes of K. The decrease in K with increasing C_a is evidently due to a diminished electrostatic potential at the polymer surface that is brought about by compression of electric double layer. Binding tendency is inversed, however, above $X=1$ where electric charges are accumulated on binding surfactant, while electric charges are reduced in the course of the first step binding. So the effect of added electrolyte on the second step binding is in the same direction as that for ordinary micelle formation in which electric charge is accumulated.

Table 1. Thermodynamic parameters

(1) Effect of added NaBr at 20 °C.

C_a/mM	20	50	100
u	200	150	150
K/M^{-1}	12	7.4	4.4

(2) Effect of temperature in 50 mM NaBr.

t/°C	20	40	50
u	150	150	150
K/M^{-1}	7.4	6.7	6.3

The values of K were calculated by using u and C_h instead of $C_f(0.5)$, where u and C_h are determined so that they give the best fit. C_h is usually about 10% smaller than $C_f(0.5)$.

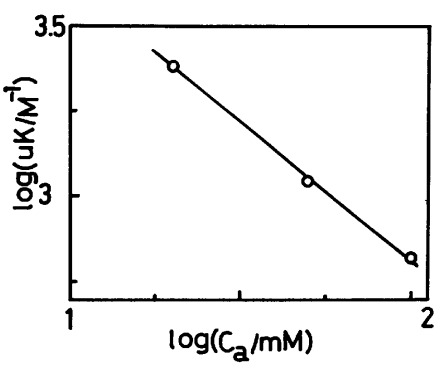

Fig. 4. Effect of added NaBr on binding affinity.

Temperature dependence of K is very small. van't Hoff plot gives an enthalpy change of the corresponding process -1.4 kJ mol^{-1} which may be a difference between exothermic discharging and endothermic rearrangement of hydration. The slightly negative enthalpy change suggests that some entropic effect also should contribute to promote the binding process.

Reciprocal of $K(K^{-1}=0.15$ M) is an equilibrium concentration that would be required to ensure a half-binding if the cooperativity were absent. In this context, it is easily understood why no binding is observed at such low C_f, *e.g.*, 0.1 mM. So it is stressed that the cooperativity is important for the binding process to appear in such a low equilibrium concentration.

A free energy of aggregation, or cooperativity, $\Delta G_u=-kT\ln(u)=-5kT$ is divided by a free energy of aggregation per methylene group, $\Delta\Delta G_u=-0.52$ kT/CH_2 which is half a difference of ΔG_u's between tetradecyltrimethylammonium and dodecyltrimethylammonium in their binding to DNA,[8] to result in 5/0.52=9.6. It is interpreted that almost all methylene groups are in action to gain cooperativity.

In Fig. 4, a $\ln(uK)$ *vs.* $\ln(C_a)$ plot shows a good linearity with a slope$=-0.81$, which is roughly interpreted as a fraction of released counterions (Na^+) having been condensed around charged sites on polyelectrolyte, when a surfactant cation is bound there. The condensed counterions are replaced with bound surfactant thus maintaining nearly constant electrostatic potential until the critical linear charge density is attained.[7,19]

The Thermal Intramolecular Redox Reaction of *N,N'*-Ethylenebis(salicylideneaminato)(2,4-alkanedionato)cobalt(III) in the Solid State**

Setsuko KINOSHITA,* Kikuo MIYOKAWA, Hisanobu WAKITA, and Isao MASUDA
Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Jonan-ku, Fukuoka 814-01
(Received April 1, 1983)

The title complexes with the $[Co^{III}(salen)L^2]$ formula, where salen denotes *N,N'*-ethylenebis(salicylideneaminato) dianion and L^2, bidentate 2,4-alkanedionato anions, like the pent, hex, hept, or non anions,† underwent thermally induced, intramolecular one-electron transfer reaction from L^2 to Co(III) in the solid state to give $[Co^{II}(salen)]$ in a stoichiometric amount. The gaseous products evolved on the pyrolysis included 1/2 mol of free 2,4-alkanedione, corresponding to the L^2 of the complexes, per mole of the complexes. The pyrolysis reaction process was described by the contracting-disk equation for all the complexes. The rate constants increased in the following order of L^2: pent<hex<hept<non. The activation enthalpy values were found to increase in the same order. These solid-state reactions are found to be predominantly controlled by the activation entropy.

The thermally induced intramolecular electron-transfer reaction, which occurs in solid transition-metal complexes, is of interest in connection with the physical and chemical properties of such complexes. Many Co(III) complexes seem to have the potential to undergo an electron-transfer reaction from a ligand to Co(III) on heating; however, this reaction tends to be followed by complicated decomposition reactions. Hence, there are very few examples in which the redox reaction can be demonstrated to proceed stoichiometrically. For such complexes as $[Co(NH_3)_6]X_3$ ($X=Cl^-$, Br^-, I^-), $K_3[Co(C_2O_4)_3]$, and *trans*-$[Co(CH_3NH_2)_2(phbgH)_2]Cl_3$,† it has been revealed by the thermoanalytical technique that they undergo a thermally induced electron-transfer reaction from the NH_3, X, or phbgH ligands to the central Co(III) ion.[1] For the thermal dissociation of NO or O_2 from the nitrosyl or dioxygen complexes with a unitary formula, Co(III)-NO^-, Co(III)-O_2^-, or Co(III)-O_2^{2-}-Co(III), it was considered that the electron-transfer occurred from these ligands to Co(III).[2]

Podder and Biswas first prepared the series of complexes with the $[Co^{III}(salen)L^2]$ (L^2=2,4-alkanedionato) formula.[3] Subsequent investigations provided the extended series of analogous Co(III) complexes.[4] The crystal X-ray diffraction analysis of $[Co^{III}(salen)(pent)]\cdot 0.7H_2O$† has elucidated its octahedral structure, in which pent is coordinated as a bidentate ligand at the cis-position, and salen, as a tetradentate one at the remaining four positions.[5] In the present paper, the solid $[Co^{III}(salen)L^2]$ complexes are shown to undergo the thermally induced, intramolecular one-electron transfer reaction of $L^2 \rightarrow Co(III)$, affording oxygen-active crystals of $[Co^{II}(salen)]$ complex in a stoichiometric amount. Moreover, the kinetic analyses will disclose that the reaction rate is apparently dominated by the factor included in the activation entropy term.

This work was partly reported previously in *Polyhedron*, **2, 125(1983).

† The following abbreviations are used: pent, 2,4-pentanedionato; hex, 2,4-hexanedionato; hept, 2,4-heptanedionato; non, 2,4-nonanedionato anions; phbgH, phenylbiguanide; and salam, salicylideneaminato anion.

Experimental

Preparation of Complexes. The 2,4-pentanedione ligand was commercially available. The other 2,4-alkanediones were synthesized according to the literature.[6] The series of $[Co^{III}(salen)L^2]$ complexes, including newly prepared ones with L^2=hept and non, were prepared as follows: $[Co^{II}(salen)]$, obtained by following the literature method,[7] was heated with the appropriate 2,4-alkanedione in a water-acetone (2 : 3) solution on a steam bath for a few minutes. When the solution was cooled, it separated crystals; these were purified by recrystallization from chloroform. The crystals thus obtained were anhydrous; this was confirmed by thermal and elemental analyses. The crystals were hygroscopic in ordinary air and showed diamagnetism at room temperature.

Elemental analysis for $[Co(salen)L^2]$. Found, (Calcd for anhydride). For L^2=pent: C, 59.10 (59.43); H, 5.02 (4.95); N, 6.52 (6.60); Co, 13.80% (13.90%). For L^2=hex: C, 60.22 (60.28); H, 5.16 (5.29); N, 6.38 (6.40); Co, 13.38% (13.46%). For L^2=hept: C, 60.88 (61.06); H, 5.53 (5.57); N, 6.10 (6.19); Co, 12.81% (13.04%). For L^2=non: C, 62.29 (62.50); H, 6.08 (6.08); N, 5.89 (5.83); Co, 12.25% (12.28%).

The ^{1}H-NMR spectral investigation showed that the complex with L^2=pent had a "cis-β" coordination,[8] δ/ppm values of -CH=N- in the $CDCl_3$ solution: 7.80, 7.57. As for the complexes with L^2=hex, hept and non, three peaks were observed for -CH=N- in the $CDCL_3$ solution; δ/ppm: 7.82, 7.59, and 7.55 for each complex, and the δ values were not different among the three complexes. This observation suggested the two geometrical isomers, such as cis-β_1 and cis-β_2, were present.

Measurements. The TG and DTA curves were recorded in a flowing nitrogen atmosphere at a heating rate of 10 °C/min on a Rigaku Denki thermal analyzer, Model 8002. The kinetic analysis under dynamic conditions was carried out on the TG curves recorded by the use of a Sinku Riko TGD-3000-RH apparatus at a heating rate of 1 °C/min. The particle size of the samples provided for the measurements was under 200 mesh.

The powder X-ray diffractions were recorded on a Rigaku Denki Geigerflex diffractometer, using Co $K\alpha$ radiation and an iron filter.

Pyrolysis gas chromatographic (PGC) measurements[9] were made under the conditions cited in the footnote of Table 1. The calibration curves were drawn by means of the direct injection of known amounts of an appropriate, purified 2,4-alkanedione into the separation column of the

TABLE 1. THERMAL PROPERTIES OF [Co^{III}(salen)L^2]

instrument; the peak area was recorded on an integrator.

Results

Pyrolysis. The TG-DTA curves for the [Co^{III}(salen)L^2] complexes are shown in Fig. 1. The complexes undergo an endothermic change in the 170—230 °C range, the decrease in the weight corresponding to the elimination of one mol of L^2 per mole of the complexes. In the case of [Co^{III}(salen)(pent)], the elementary analytical results of the solid, pyrolysis product agreed with the results calculated for [Co(salen)]: Found, (Calcd): C, 58.62 (59.08); H, 4.21 (4.31); N, 8.30 (8.62); Co, 18.07% (18.12%). The effective magnetic moment μ_{eff}= 2.51 μ_B (300 K), of the product was consistent with the value, μ_{eff}=2.51 μ_B (296 K), previously reported for the authentic [Co^{II}(salen)];[10] it indicates that one unpaired electron was in the complex molecule. Moreover, the powder X-ray diffraction pattern for the resultant product agreed with that of authentic [Co^{II}(salen)], as is shown in Fig. 2. Similarly, the pyrolyses of the complexes with L^2=hex, hept, and non left behind a product that could be shown to be [Co^{II}(salen)] from the elementary analytical results and from the measurements of the magnetism and the X-ray diffraction.

The PGC analytical results clearly indicated that the gaseous products evolved by the pyrolysis included 1/2 mol of the corresponding free HL^2 per mole of the starting [Co(salen)L^2]. The data are given in Table 1. The production of free HL^2 was also indicated by the ^{1}H-NMR spectra in the DMSO-d_6 solution in which the gaseous products were trapped. In addition, when L^2=pent, the NMR spectral inspection indicated that the gaseous products included indefinite amounts of acetone, methanol and ethanol, besides the principal amount of Hpent.

From the above facts, the thermal reaction can be described as follows:

$$[Co^{III}(salen)L^2] \longrightarrow [Co^{II}(salen)] + 1/2\,HL^2 + X. \quad (1)$$

In Eq. 1, X represents a mixture of such volatile compounds as have been cited above; the further identification of X has not been undertaken here.

Kinetic Analysis. The kinetic analysis was carried out in order to ascertain the kinetic character of the reaction. As has been mentioned, the ^{1}H-NMR spectra suggested that the complexes with L^2=hex,

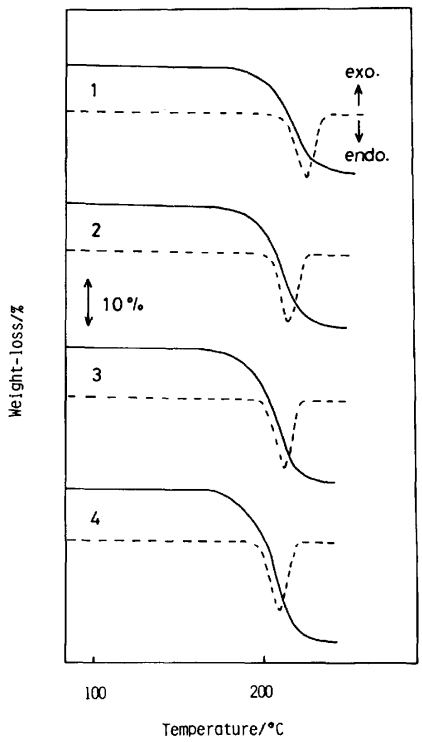

Fig. 1. TG (——) and DTA (----) curves of [Co^{III}(salen)L^2].
1: L^2=pent, 2: L^2=hex, 3: L^2=hept, 4: L^2=non.
No response appeared blow 100°C in the TG and DTA curves.

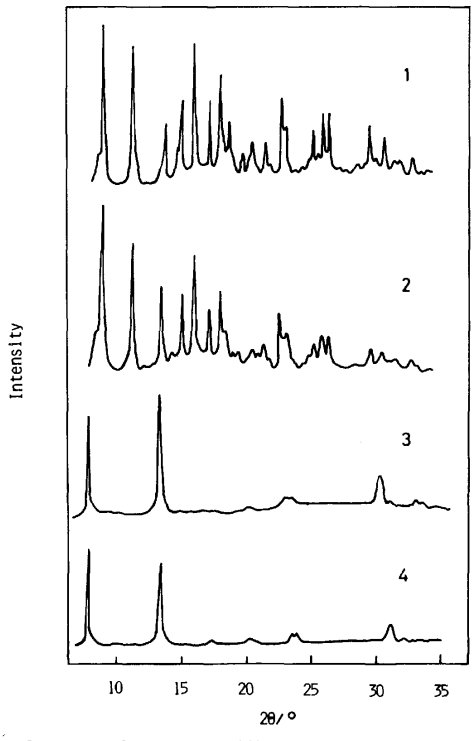

Fig. 2. Powder X-ray diffractograms.
1: [Co^{III}(salen)(pent)]·0.7H_2O, 2: [Co^{III}(salen)(pent)], 3: [Co^{II}(salen)] obtained by the pyrolysis of [Co^{III}-(salen)(pent)], 4: authentic [Co^{II}(salen)]; oxygen-active form crystal.

hept, and non in the solution existed in two isomeric forms. However, the TG and DTA curves showed only one-stage changes. Hence, it was assumed that these isomers were thermally indistinguishable in the solid state, if they were present there at all. Then, the rate plots under non-isothermal conditions were obtained by the use of Eq. 2, according to the method developed by Coats and Redfern:[11]

$$\log\{[1-(1-\alpha)^{1-n}]/T^2\} = \log\frac{AR(1-n)}{aE}\left[1-\frac{2RT}{E}\right]-\frac{E}{2.3RT}. \quad (2)$$

In Eq. 2, E is the activation energy; A, the pre-exponential factor; α, the molar fraction of [Co^{II}-(salen)]; T, the absolute temperature; R, the gas constant; a, the heating rate. Since, as is shown in Fig. 3, the rate plot of the reaction for [Co^{III}(salen)(pent)] under isothermal conditions was found to fit the contracting-disk equation, $1-(1-\alpha)^{1/2}=kt$ (k, the rate constant; t, the reaction time), n in Eq. 2 is replaced with a value of 1/2. Then, the rate plot, *i.e.*, the $\log\{[1-(1-\alpha)^{1/2}]/T^2\}$ *vs.* $1/T$ plot, gives a straight line, as is shown in Fig. 4. These facts indicate that the reaction fits the contracting-disk equation well for all the complexes investigated. The E and A values were calculated from, respectively, the slope and the intercept of these straight lines. For the sake of comparison, it is desirable to normalize the rate constants to those at a definite temperature. Therefore, the rate constants at 460 K were calculated from the Arrhenius equation, $k=A\exp(-E/RT)$, by using the above E and A values. The activation enthalpy ΔH^* value was calculated from the $\Delta H^*=E-RT$ relation; while the activation entropy ΔS^* value was obtained from Eq. 3, assuming the transmission coefficient κ to be 1;

$$\Delta S^* = R[\ln(Ah/\kappa kT) - 1]. \quad (3)$$

In Eq. 3, k is the Boltzman constant, and h, the Planck constant. The kinetic characteristics are tabulated in Table 2.

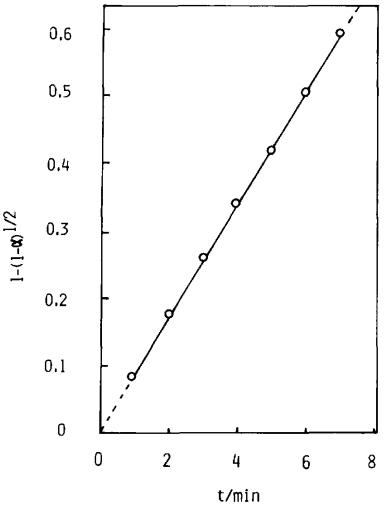

Fig. 3. Rate plots for thermal reaction of [Co^{III}-(salen)(pent)] under isothermal conditions. α; 0.17—0.84.

Discussion

It was shown by the mass spectrometric investigation that, upon pyrolysis, [$Co^{III}(pent)_3$] evolved gaseous products, including principally acetone and CO_2;[12] the redox process of the reaction was not elucidated, however. On the pyrolysis of the [Co^{III}(salen)L^2] complexes, the thermally induced one-electron transfer reaction, $L^2\rightarrow$Co(III), obviously occurred, producing [Co^{II}(salen)] and HL^2 in stoichiometric amounts, as is represented by Eq. 1. As may be seen in Fig. 2, the powder X-ray diffractogram of the anhydrous crystal of [Co^{III}(salen)(pent)], which was prepared here and subjected to pyrolysis, is almost entirely consistent with the diffractogram of the 0.7 hydrate crystal, for which crystal-structure analysis has been performed.[5] The other anhydrous crystals of the complexes investigated also showed well-defined diffractograms, although their crystal systems were not determined. For all the [Co^{III}(salen)L^2] complexes, the pyrolysis left behind [Co^{II}(salen)], which showed a diffraction pattern agreeing with that of authentic [Co^{II}(salen)]. Hence, it can be said that the thermal reaction described by Eq. 1 proceeds accompanied by a crystal-structure change in the pair of [Co^{II}(salen)] and respective [Co^{III}(salen)L^2].

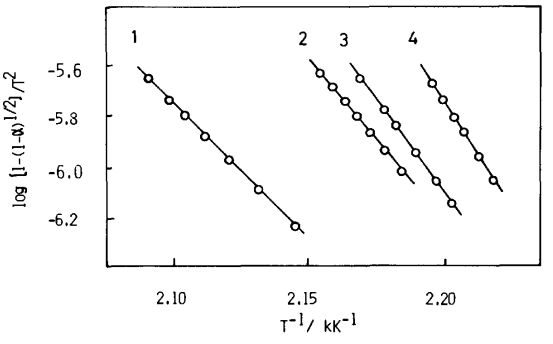

Fig. 4. Rate plots for thermal reactions of [Co^{III}-(salen)L^2] under non-isothermal conditions. 1: L^2=pent, 2: L^2=hex, 3: L^2=hept, 4: L^2=non.

Table 2. Kinetic data of thermal reactions of [Co^{III}(salen)L^2]

The volatile pyrolytic products consisting of HL^2 and other compounds are considered to diffuse through the system as rapidly as that the pyrolytic reaction can be described by only one equation, *i.e.*, the contraction-disk equation, over the range of α=0.17—0.84. In such cases as the thermal pyridine dissociation of Ni[*N*-(*p*-CH_3-C_6H_4)salam]$_2$(py)$_2$[†], the reaction proceeds, following the contracting-disk equation in the earlier stage of the reaction, α=0—0.35, and according to Jandar's equation in the later stage, α=0.35—0.75. This later stage of the reaction was interpreted as showing that the diffusion of the liberated pyridine was slow enough to be observed.[13]

The production of HL^2 can be explained as follows. The thermally induced, homolytic fission of the L^2-Co(III) bond causes a concomitant L^2→Co(III) one-electron transfer to form the $\cdot L^2$ radical; this derives a hydrogen atom from another $\cdot L^2$ radical to produce HL^2; the dehydrogenated $\cdot L^2$ radical decomposes into lower molecular compounds; these are represented by X in Eq. 1. It is noteworthy that HL^2 was produced quantitatively through such a reaction as occurs in the solid phase. The crystals of the [Co(salen)(pent)]$\cdot 0.7H_2O$ complex belong to the $P2_12_12_1$ space group, suggesting that, in these crystals, two complex molecules are packed as if they were a pair. In the anhydrous crystals, the molecular packing is considered not to be remarkably changed, as is indicated by the powder X-ray diffractograms shown in Fig. 2. Therefore, it may be speculated that this molecular arrangement, forming a pair as above, causes the reaction to proceed stoichiometrically, yielding one mole of Hpent from two moles of [Co(salen)(pent)]. Although the crystal structures for the other complexes have not yet been elucidated, a crystal structure analogous to that of [Co(salen)(pent)] might be suggested from their stoichiometric formation of HL^2.

As may be seen from the above discussion, the kinetic data apparently correspond to the change depicted by Eq. 4;

$$[Co^{III}(salen)L^2]\ (crystal) \rightarrow [Co^{II}(salen)]\ (crystal). \quad (4)$$

In Eq. 4 three processes are involved; i) the bond cleavage of L^2-Co(III), which occurs with a concomitant L^2→Co(III) electron-transfer, ii) the rearrangement in the coordination geometry from octahedron to square-plane, and iii) the change in the crystal packing from that of [Co^{III}(salen)L^2] to that of [Co^{II}-(salen)]. In the following argument, the effect on the kinetic data arising from the difference in the crystal packing of the starting complexes is assumed to be negligible among the complexes of the present series.

Generally speaking, the k value in most reactions decreases as the $\Delta H^{\ddagger}$ value increases. In the present complexes, the L^2-Co(III) bond can be expected to be more strengthened when the alkyl group substituted on L^2 has a longer chain; the electron-donating property (I-effect) of the alkyl group acts to increase the electron density on the O-atom in L^2 and hence, to strengthen the L^2- Co(III) coordination bond. Therefore, the complex with a longer chain alkyl group on L^2 can be expected to have larger $\Delta H^{\ddagger}$ values and smaller k values. Actually, however, the reaction

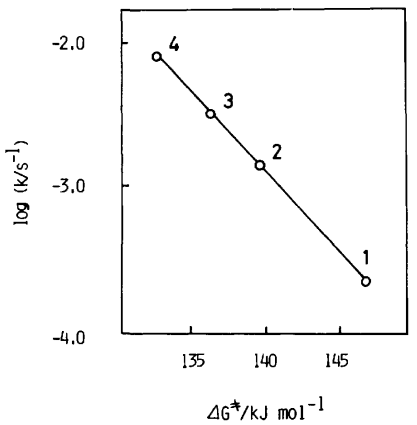

Fig. 5. Relation between log k and $\Delta G^{\ddagger}$ values at T= 460 K.
1: L^2=pent, 2: L^2=hex, 3: L^2=hept, 4: L^2=non.

examined here did not occur along these lines. That is, whereas the $\Delta H^{\ddagger}$ value increased in the order of L^2, pent<hex<hept<non, as predicted, the k value increased in the same order; this is numerically demonstrated in Table 2. This finding led us to consider that the activation entropy might involve a factor favoring the occurrence of these solid-state reactions. The $\Delta S^{\ddagger}$ value calculated in the case of a complex with L^2=non is *ca.* 3.5 times larger than that with L^2=pent. Therefore, for the complex with L^2=non, the $\Delta G^{\ddagger}$(=$\Delta H^{\ddagger}-T\Delta S^{\ddagger}$) value comes to be smallest and the k value, largest, among the complexes investigated; this relation between the $\Delta G^{\ddagger}$ value and the nature of L^2 is shown in Fig. 5.

As Table 2 shows, the $\Delta S^{\ddagger}$ value of the reaction is positive and rather large. This fact is not contrary to the assumption that the reaction rate is predominantly determined not by the electron-transfer, but by the L^2-Co(III) bond-cleavage reactions. In the transient structure, if the electrons participating in the L^2-Co(III) bonding were withdrawn toward the Co atom, this structure might have a lower entropy than usual. On the other hand, if the L^2-Co(III) bond were relaxed, this structure might have an increased entropy due to the increased freedom of L^2. By accepting the latter transient structure, it could be understood that the $\Delta S^{\ddagger}$ value of the reaction for the complex with L^2=non is larger than that for the complex with L^2=pent. In conclusion, L^2 ligands with longer alkyl chains cause the solid-state reaction of the complexes examined here to occur more easily through the entropic factor.

The crystalline [Co^{II}(salen)] complex obtained by the pyrolysis took up oxygen in a dry air or an oxygen atmosphere at room temperature. The O_2-adduct liberated oxygen endothermally at *ca.* 65 °C, thus decreasing the weight by 4.8%; this indicated that the composition of the adduct was [Co(salen)]$_2\cdot O_2$. There have appeared in the literatures two crystalline forms of the [Co^{II}(salen)] complex; one is active, and the other, inactive, toward oxygen-uptake;[7] the active form takes up oxygen reversibly in a molar ratio of Co(II) : O_2= 2 : 1. It has also been reported that the pyrolysis of the solid [Co^{II}(salen)(py)] or [Co^{II}-

(salen)($CHCl_3$)] leaves behind the oxygen-active complex of [Co^{II}(salen)].[14]

The Reactions of (Trichlorostannato)rhodates(III) with Trichlorostannate(II) in Hydrochloric Acid Solutions

Shigemi Iwasaki,* Takashi Nagai, Eiichi Miki, Kunihiko Mizumachi, and Tatsujiro Ishimori
Department of Chemistry, College of Science, Rikkyo University, Nishi Ikebukuro 3, Toshima-ku, Tokyo 171
(Received May 23, 1983)

(Trichlorostannato)rhodate(III) complexes, $[(CH_3)_4N]_3[RhCl_n(SnCl_3)_{6-n}]$ (n=2, 3, and 4), reacted with tin(II) in hydrochloric acid solutions to form a purple species. This purple species is assumed to be $[Rh^I(SnCl_3)_5]^{4-}$. The formation reaction of the purple species involved two independent paths, fast and slow paths. The main path was the fast one, in which the reactant mixture was in equilibria among $[RhCl_3(SnCl_3)_3]^{3-}$, $[RhCl_2(SnCl_3)_4]^{3-}$, $[RhCl(SnCl_3)_5]^{3-}$, and probably $[Rh(SnCl_3)_6]^{3-}$. The reaction orders in the formation of the purple species were 1, 2, and −2 with respect to the concentrations of the total rhodium(III) complexes, $SnCl_3^-$, and Cl^- respectively. The absorpton spectra of the reactant mixture showed an interaction absorption between $[RhCl_2(SnCl_3)_4]^{3-}$ and $SnCl_3^-$.

A series of six-coordinated (trichlorostannato)rhodate(III) complexes, $[(CH_3)_4N]_3[RhCl_n(SnCl_3)_{6-n}]$, where n=2, 3, and 4, have been prepared by Kimura.[1] The presence of $[RhCl(SnCl_3)_5]^{3-}$ (the pentakis complex) was confirmed in tin(II)–hydrochloric acid solutions by the use of Sn-119 NMR.[2] The complexes react with an excess of tin(II) in a hydrochloric acid solution to form a purple solution. In this paper, tentatively assuming the purple species in the solution to be $[Rh^I(SnCl_3)_5]^{4-}$, we will report an equilibrium mixture of the (trichlorostannato)rhodates(III) in tin(II)–hydrochloric acid solutions and the formation of the purple species from the equilibrium mixture.

Experimental

Materials. The rhodium(III)–trichlorostannato complexes (the rhodium(III) complexes), $[(CH_3)_4N]_3[RhCl_n(SnCl_3)_{6-n}]$, where n=2 and 3, were prepared by the methods of Kimura.[1] Reagents of a special grade were used.

Reaction Solution. The reaction solution was prepared by dissolving $[(CH_3)_4N]_3[RhCl_3(SnCl_3)_3]$ (the tris complex) or $[(CH_3)_4N]_3[RhCl_2(SnCl_3)_4]$ (the tetrakis complex) in a freshly prepared tin(II)–hydrochloric acid solution to give 2×10^{-4} mol dm^{-3}. The concentrations in the tin(II)–hydrochloric acid solution were adjusted to $[H^+]_{total}+[Li^+]_{total}$=3.0 mol dm^{-3}, $[Cl^-]_{total}+[ClO_4^-]_{total}$=3.4 mol dm^{-3}, and $[Sn^{II}]_{total}+[Zn^{II}]_{total}$=0.2 mol dm^{-3} by using zinc chloride, lithium chloride, and perchloric acid solutions respectively. In order to avoid the air oxidation of Sn^{II} in the reaction solution, a quartz cell was filled with the reaction solution and stoppered without any empty space, the stopper was then wrapped two-fold with polyethylene sheets. The concentration of Sn^{II} in the cell did not decrease more than a few per cent within 2 or 3 d. The total concentrations of Sn^{II} and Rh^{III} were determined in each run.

Measurements. The spectral change in the reaction solution was measured with a HITACHI 340 spectrophotometer equipped with a thermospacer cell compartment. The temperature of the reaction solution in the cell was thermostated at 25.0±0.3, 40.0±0.1, and 55.0±0.3 °C. A micro-computer was connected to the spectrophotometer to memorize the absorption curves at predetermined times and to calculate the rate constants by the method of least squares.

Kinetic Measurements. Figure 1 shows a typical example of the spectral change in the reaction solution. The absorptions at 402 and 560 nm were used independently for the kinetic analyses. Since Sn^{II}, Cl^-, and H^+ were in a large excess of the rhodium(III) complex, the pseudo-first-order method was used for the analyses. Because the absorption at 560 nm originated only from the product, the purple species, the change in the absorption at 560 nm(A_{560}) was used to determine the pseudo-first-order rate constant ($k_{obsd}(560)$) according to Eq. 1:

$$d(A_{560})/dt = k_{obsd}(560)\cdot(A_{560,\infty} - A_{560}). \quad (1)$$

When absorption curves during the reaction were corrected for the contribution of the purple species, the absorption curves showed a maximum around 402 nm. The corrected absorption at 402 nm(A_{402}) was assumed to be proportional to the total concentration of the rhodium(III) complexes, which were in rapid equilibria with each other; A_{402} was also used to determine the pseudo-first-order rate constant, $k_{obsd}(402)$, according to Eq. 2:

$$-d(A_{402})/dt = k_{obsd}(402)\cdot(A_{402}). \quad (2)$$

The spectral change at 402 nm was much greater than that at any other wavelength.

To determine the dependences of k_{obsd} on $[Sn^{II}]$ and $[H^+]$, $[Sn^{II}]_{total}$ was changed over the range of 0.02—0.06 mol dm^{-3} and $[H^+]_{total}$, over that of 0.25—3.0 mol dm^{-3}. The total concentration of Cl^- was changed over the range of 1.8—4.5 mol dm^{-3}. However, since the formation of the purple species was inhibited somewhat by the presence of perchloric acid, and since the reaction proceeded in a different way for $[HClO_4]$> 1.8 mol dm^{-3}, lithium chloride was added to the reaction solution, ignoring the increase in ionic strength in the cases of $[Cl^-]_{total}$>3.4 mol dm^{-3}.

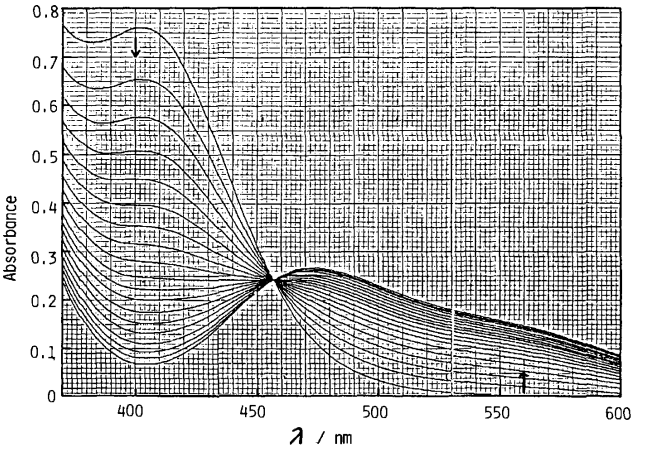

Fig. 1. An example of the spectral change of the reaction solution at 40.0 °C. $[Rh]_{total}=7.45\times10^{-5}$ mol dm^{-3}, $[Sn^{II}]_{total}$=0.0568 mol dm^{-3}

Results and Discussion

Reaction Product. The spectrum of the purple solution has been well established. The purple species can be assumed to be $[Rh(SnCl_3)_5]^{3-}$ (the rhodium(I) complex) on the basis of the complex salt obtained from the purple solution, $[Rh^{III}(NH_3)_6][Rh^{I}(SnCl_3)_4(SnCl_4)]\cdot[SnCl_6]\cdot 4H_2O$,[3] and on the basis of Sn-119 NMR studies of the Rh^{III}–Sn^{II} system in a hydrochloric acid solution.[2]

Reactants. Figure 2 shows an example of the conventional plots of the change in the absorptions at 402 and 560 nm. Two independent reaction paths, fast and slow ones, were generally observed under the conditions of $[Sn^{II}]_{total}>0.02$ mol dm^{-3}. The formation of the rhodium(I) complex through the slow path was only a few per cent, and its rate constant could not be determined accurately. Therefore, data on the slow path were used mainly for determining accurately the pseudo-first-order rate constant of the fast path.

Some of the kinetic results at 40.0 °C are listed in Table 1. In each run, $k_{obsd}(560)$ agrees with $k_{obsd}(402)$ within the limits of experimental error. This supports

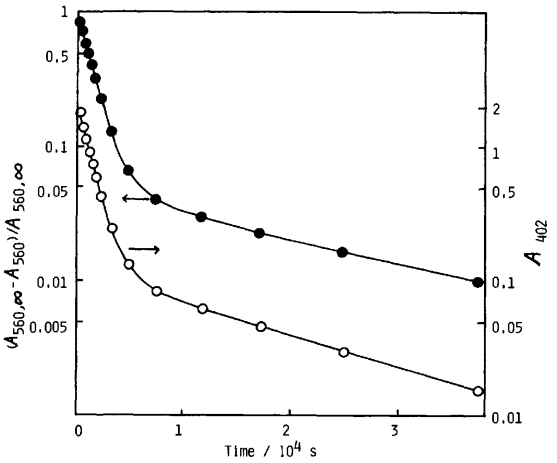

Fig. 2. The change in the absorptions at 402 and 560 nm.
log A_{402} *vs.* time(○), and log $(A_{560,\infty}-A_{560})/A_{560,\infty}$ *vs.* time(●). $[(CH_3)_4N]_3[RhCl_3(SnCl_3)_3]$ was dissolved at 55.0 °C. $[Rh]_{total}=1.96\times10^{-4}$ mol dm^{-3}, $[Sn^{II}]_{total}=0.0574$ mol dm^{-3}.

the assumption on the absorption at 402 nm in the Experimental section. When the absorption curves during the reaction were corrected for the contributions of the rhodium(I) complex and of the reaction mixture involved in the slow path and were expressed as the molar absorption curves with respect to the total rhodium(III) complexes involved in the fast path, all the absorption curves gave almost the same curve in a kinetic run except during the last period of the reaction. However, the curve did not agree with the absorption curves of the tris complex nor with that of the tetrakis complex, and it varied with such reaction conditions as $[Sn^{II}]_{total}$.

It is reasonable to consider that equilibria among the rhodium(III) complexes are present in relation to $[Sn^{II}]_{total}$, that one of the rhodium(III) complexes is the true reactant, and also that the equilibria are established rapidly enough for the rate of the reaction. The total rhodium(III) complexes in equilibria will hereafter be called "the yellow species" (Y); especially, the yellow species involved in the fast reaction path will be abbreviated as Y_I. The mean molar-absorption coefficients of Y_I, $\varepsilon(Y_I)$ were much greater than the molar-absorption coefficients of $[(CH_3)_4N]_3[RhCl_3(SnCl_3)_3]$ (the tris complex) or $[(CH_3)_4N]_3[RhCl_2(SnCl_3)_4]$ (the tetrakis complex), as is shown in Fig. 3. Furthermore, the absorptions of the pentakis and the hexakis complex are not expected to be large enough to explain the absorptions of Y_I. The molar-absorption coefficients of Y_I can be explained on the basis of the interaction absorption between $SnCl_3^-$ and the tetrakis complex, Y_4. The interaction absorption, IA, per mole of Y_4 can be defined as Eq. 3:

$$IA = \varepsilon(Y_I) - \varepsilon(Y_4), \quad (3)$$

where $\varepsilon(Y_I)$ is the mean molar-absorption coefficient of Y_I, and $\varepsilon(Y_4)$ is the molar-absorption coefficient of the tetrakis complex. Plots of IA at 402 nm *vs.* $[SnCl_3^-]$ are shown in Fig. 4. The values of $[SnCl_3^-]$ were calculated as will be described below. In Fig. 4, there is a linear relationship by which the straight line passes through the point of origin, the molar-absorption coefficient of Y_4. The relationship held at the other wavelengths as well. It is certain that these relationships are caused by the interaction absorption. It is also indicated that the tetrakis complex is the predominant species among the

rhodium(III) complexes in these reaction solutions.

The interaction absorption in Sn^{II}-Sn^{IV} in a hydrochloric acid solution[4] has been assumed to occur through a Cl^- bridge between Sn^{II} and Sn^{IV}.[5] The Mössbauer spectra of the rhodium(III) complexes suggested that the cooridnating Sn atoms were rather more similar to Sn^{IV} than to Sn^{II}.[1] Accordingly, the interaction absorption between $[RhCl_2(SnCl_3)_4]^{3-}$ and $SnCl_3^-$ in the reaction solution can be considered to occur with an associated species such as $[(SnCl_3)_3Cl_3RhSnCl_3{-}{-}SnCl_3]^{4-}$.

Rate Law. In Fig. 5, the logarithm of the means of k_{obsd}(560) and k_{obsd}(402), namely, k_{obsd}, are plotted against the total concentration of Sn^{II}. In the figure, the k_{obsd}'s for the reaction solutions prepared by dissolving the tris complex or the tetrakis complex are distributed on the same line. This also confirms the idea regarding the yellow species in the equilibria. The slopes of the

○: 25.0°C, the starting materials (s.m.)=the tris complex, ◑: 40.0°C, s.m.=the tris complex, ◐: 40.0°C, s.m.=the tetrakis complex, ●: 55.0°C, s.m.=the tris complex.

lines were 1.82±0.02 at 25.0°C, 2.03±0.06 at 40.0 °C, and 2.31±0.02 at 55.0°C. The slopes increased with an increase in the temperature.

The slope for the plot of log k_{obsd} *vs.* log $[Cl^-]_{total}$ at 40.0°C was −2.0. Since the total concentration of Sn^{II} could not be kept absolutely constant in the series of experiments, the rate constants, k_{obsd}'s, obtained were corrected according to the dependence on the concentration of Sn^{II} described above. As perchlorate ions inhibited the progress of the formation of the rhodium(I) complex, the concentration of Cl^- was not changed over a wide range; the ionic strengths of the reaction solutions used ranges from 3.60 to 4.68 mol dm^{-3}. In order to examine the effect of the ionic strength, the solutions with the following compositions were compared: Soln A; [LiCl]=2.75 mol dm^{-3}, [HCl]=0.25 mol dm^{-3}, $[Cl^-]_{total}$=3.4 mol dm^{-3}, $[Sn^{II}]_{total}$= 0.038 mol dm^{-3}, $[Zn^{II}]_{total}$=0.16 mol dm^{-3}, I(ionic strength)=3.6 mol dm^{-3}. Soln B; $[CaCl_2]$= 1.375 mol dm^{-3}, [HCl]=0.25 mol dm^{-3}, $[Cl^-]_{total}$= 3.4 mol dm^{-3}, $[Sn^{II}]_{total}$=0.038 mol dm^{-3}, $[Zn^{II}]_{total}$= 0.16 mol dm^{-3}, I=4.98 mol dm^{-3}. The A and B solutions had the same concentrations of Cl^- and Sn^{II}, but different ionic strengths. The k_{obsd} was 6.7×10^{-4} s^{-1} for the A solution and 7.0×10^{-4} s^{-1} for the B. Consequently, the variation in the ionic strength to such an extent had little effect on k_{obsd}. The dependence was −1.95±0.04 for $[Cl^-]_{total}$ in the range from 2.55 to 4.47 mol dm^{-3}.

The slope for the plot of log k_{obsd} *vs.* log $[H^+]_{total}$ at 40.0 °C was −0.40±0.03. The corrections for slight variations in $[Sn^{II}]_{total}$ were made similarly to the case of the $[Cl^-]$ dependency.

A kinetic run was carried out in the presence of 1600 times as much $[Sn^{IV}]$ as [Rh^{III} complex]$_{total}$. The observed rate constant for the fast reaction path, k_{obsd}, was not influenced by the presence of $[Sn^{IV}]$; this suggested that the redox equilibrium, Rh^{III}+

$Sn^{II} \rightleftarrows Rh^{I} + Sn^{IV}$, was not involved in the processes before the rate-determining step.

These results for the fast reaction path at 40.0 °C can be summarized as in Eq. 4:

$$k_{obsd} \propto [Sn^{II}]^{2.0}_{total}[Cl^-]^{-2.0}_{total}[H^+]^{-0.4}_{total}[Sn^{IV}]^{0}_{total}. \quad (4)$$

We attemped to express the rate law in terms of the concentrations of definite species instead of the total concentrations. Since $SnCl_3^-$ behaved as a ligand, the concentraion of $SnCl_3^-$ was used in place of the total concentraion of Sn^{II}. In the calculation, the formation constants of $ZnCl^+$, $ZnCl_2$, and $ZnCl_3^-$,[6] and of $SnCl^+$, $SnCl_2$ and $SnCl_3^-$,[7] and the acid-dissociation constants of $HZnCl_3$ and $HSnCl_3$ were taken into account. The present experiments were carried out at temperatures different from those in the literature; the differences were corrected by using the thermodynamic data in the literature to estimate the formation constants of the zinc-chloro and tin-chloro complexes. Although hydrogen trichlorostannate(II), $HSnCl_3$, has been reported to be a weak acid, [8] the dissociation constant, $K_a(HSnCl_3)$, has not been measured. Therefore, $K_a(HSnCl_3)$ was assumed to be 0.1, 1, 2, 5, 10, and ∞. On the other hand, since the value of $K_a(HZnCl_3)$ previously reported[9] was considered to be too small, $K_a(HZnCl_3)$ was measured at $[Cl^-]_{total}=3$ mol dm^{-3} and found to be 4.9 ± 1.5 at 40.0 °C ($I=3.0$ mol dm^{-3}) by the potentiometric-titration method. By the use of these values, the dependencies were expressed at 40.0 °C as follows:

$$\begin{aligned}
K_a(HSnCl_3) = 0.1 \quad & k_{obsd} \propto [SnCl_3^-]^{2.0}[Cl^-]^{-1.8}[H^+]^{1.2} \\
1 \quad & [SnCl_3^-]^{2.0}[Cl^-]^{-1.9}[H^+]^{0.3} \\
2 \quad & [SnCl_3^-]^{2.0}[Cl^-]^{-2.0}[H^+]^{0.1} \\
5 \quad & [SnCl_3^-]^{2.0}[Cl^-]^{-2.1}[H^+]^{-0.1} \\
10 \quad & [SnCl_3^-]^{2.0}[Cl^-]^{-2.1}[H^+]^{-0.2} \\
\infty \quad & [SnCl_3^-]^{2.0}[Cl^-]^{-2.2}[H^+]^{-0.3}.
\end{aligned} \quad (5)$$

In the range of $K_a(HSnCl_3)$ values described above, the rate of the fast reaction path was always second-order with respect to the concentration of $SnCl_3^-$. When $K_a(HSnCl_3)$ was set at 2, the rate constant, k_{obsd} was almost independent of the hydrogen concentration. It was possible that H^+ participated only in the acid-dissociation equilibrium of $HSnCl_3$. The kinetic order of the concentration of Cl^- was in the range from -1.8 to -2.2. In the experiments concerning the effect of the Cl^- concentration on the fast reaction path, the concentration of Cl^- was somewhat changed. In the case of $K_a(HSnCl_3)=2$, the reaction order of $[Cl^-]$ was an integer, -2.0. It is probable that $K_a(HSnCl_3)=2$.

Reaction Routes. Several reaction routes were possible and so were considered. However, none of them could be chosen as the most probable one, because the reactant involved in the rate-determining step was not identified. As examples, two possible reaction routes are shown in Scheme 1.

In Route (1), the yellow species involved in the fast reaction path, Y_I, are considered to be an equilibrium mixture of the tris (Y_3), the tetrakis (Y_4), the pentakis (Y_5), and the hexakis(Y_6) complex. The rate-determining step is assumed to be the reaction of Y_6; it is assumed not to involve $SnCl_3^-$. The construction of a model of the hexakis complex shows that six trichlorostannato(II) ligands can coordinate to the rhodium(III) atom when the Cl–Sn–Cl angles are small enough.

Yellow Species: $Y = Y_I + Y_{II}$

Fast path

Route (1) K_4 K_5 K_6

$$Y_I: Y_3 \underset{Cl^-}{\overset{L^-}{\rightleftharpoons}} Y_4 \underset{Cl^-}{\overset{L^-}{\rightleftharpoons}} Y_5 \underset{Cl^-}{\overset{L^-}{\rightleftharpoons}} Y_6; Y_6 \xrightarrow{\text{r.d.s.}} [Rh^{I}L_5]^{4-} + Sn^{IV}Cl_3^+$$

Route (2)

$$Y_I: Y_3 \underset{Cl^-}{\overset{L^-}{\rightleftharpoons}} Y_4 \underset{Cl^-}{\overset{L^-}{\rightleftharpoons}} Y_5 \underset{Cl^-}{\overset{L^-}{\rightleftharpoons}} [Rh^{III}L_5]^{2-} \overset{L^-}{\rightleftharpoons} [L_4RhSnCl_3- -SnCl_3]^{3-}; Y_5'\text{–}SnCl_3$$

$$Y_5'\text{–}SnCl_3 \xrightarrow{\text{r.d.s.}} [Rh^{I}L_5]^{4-} + Sn^{IV}Cl_3^+$$

Slow path $Y_{II} \longrightarrow [Rh^{I}L_5]^{4-}$

Scheme 1. Possible reaction routes. $L = SnCl_3$, $Y_3 = [RhCl_3L_3]^{3-}$, $Y_4 = [RhCl_2L_4]^{3-}$, $Y_5 = [RhClL_5]^{3-}$, $Y_6 = [RhL_6]^{3-}$. r.d.s. represents rate-determining step. $K_4 = [Y_4][Cl^-]/[Y_3][L^-]$, $K_5 = [Y_5][Cl^-]/[Y_4][L^-]$, $K_6 = [Y_6][Cl^-]/[Y_5][L^-]$.

On the basis of the reaction Route (1) (in Scheme 1), k_{obsd} is expressed as follows:

$$k_{obsd} = \frac{k_1K_4K_5K_6[SnCl_3^-]^3}{[Cl^-]^3 + K_4[SnCl_3^-][Cl^-]^2 + K_4K_5[SnCl_3^-]^2[Cl^-] + K_4K_5K_6[SnCl_3^-]^3}. \quad (6)$$

In Eq. 6, the first term of the denominator is attributed to the tris complex(Y_3); the second term, to the tetrakis complex(Y_4); the third term, to the pentakis complex (Y_5), and the fourth term, to the hexakis complex(Y_6). When the tetrakis complex is the predominant species in the equilibrium mixture(Y_I), the following relationship is derived:

$$k_{obsd} = k_1K_5K_6[SnCl_3^-]^2[Cl^-]^{-2}. \quad (7)$$

This is in agreement with the derived rate law when $K_a(HSnCl_3)$ is assumed to be 2 in Eq. 5. In Fig. 5, the k_{obsd}'s obtained at low $[SnCl_3^-]$ values are found somewhat below the line with a slope of 2, which suggests that, in the reaction solution with a low $[SnCl_3^-]$, small amounts of the tris complex are present together with the major species, the tetrakis complex.

Route (2) (in Scheme 1) also satisfies the observed rate law when the tetrakis complex is predominant in the reactant mixture. The intermediate, $Y_5'\text{–}SnCl_3$, can be assumed because it is similar to the intermediate[5] in the exchange reaction of Sn^{II} and Sn^{IV} in hydrochloric acid solutions.

As to the temperature effect on the reaction, the slope of log k_{obsd} *vs.* log $[Sn^{II}]_{total}$ increased with the increase in the temperature, as may be seen from Fig. 5. This is explained by the shift of the equilibria among the rhodium(III) complexes due to the temperature; that is, at a higher temperature the tetrakis complex dissociates to the tris complex, whereas at a lower temperature the pentakis complex comes to be formed.[10]

It was found that the formation of the purple species

was generally accelerated by light irradiation. When $[(CH_3)_4N]_3[RhCl_4(SnCl_3)_2]$ was used as the starting material, the reaction was complicated and was greatly accelerated by light irradiation.

From this study, it was found clearly that the equilibria concerning the rhodium(III)-trichlorostannato complexes were rapidly established in the process of the formation reaction of the rhodium(I) complex. The reduction of the rhodium(III) complexes was not involved in the equilibria. It has been stated that anionic complexes of Rh^{III} are kinetically labile.[11] Our results were consistent with this view.

Potentiometric and Calorimetric Studies on the Formation of Ethylenediamine Complexes of Copper(II) Ion in Water and Aqueous Dioxane Solutions

Shin-ichi Ishiguro, Yoshihiro Oka, and Hitoshi Ohtaki*
Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, 4259 Nagatsuta-cho, Midori-ku, Yokohama 227
(Received June 29, 1983)

Gibbs energies (or formation constants), enthalpies and entropies of formation of ethylenediamine complexes of copper(II) ions have been determined by means of potentiometric and calorimetric titrations at 25 °C in an aqueous solution and dioxane-water mixtures (dioxane contents are 0.1 and 0.2 mole fractions, which correspond to 35.2 and 55.0% w/w, respectively), all containing 3 mol dm^{-3} $LiClO_4$ as a constant ionic medium. The thermodynamic quantities of the reactions $CuL_{n-1}^{2+}+L=CuL_n^{2+}$ (L=ethylenediamine and n=1 and 2) determined in the solutions were as follows: ΔG_1°=−65.0 kJ mol^{-1} (dioxane content: 0.0 mole fraction), −66.8 kJ mol^{-1} (0.1 mole fraction), and −68.8 kJ mol^{-1} (0.2 mole fraction); ΔG_2°=−56.9 kJ mol^{-1} (0.0), −58.8 kJ mol^{-1} (0.1), and −61.1 kJ mol^{-1} (0.2); ΔH_1°=−67.7 kJ mol^{-1} (0.0), −68.6 kJ mol^{-1} (0.1), and −66.7 kJ mol^{-1} (0.2); ΔH_2°=−71.0 kJ mol^{-1} (0.0), −70.2 kJ mol^{-1} (0.1), and −68.8 kJ mol^{-1} (0.2); $T\Delta S_1^\circ$=−2.7 kJ mol^{-1} (0.0), −1.8 kJ mol^{-1} (0.1), and 2.1 kJ mol^{-1} (0.2); $T\Delta S_2^\circ$=−14.1 kJ mol^{-1} (0.0), −11.4 kJ mol^{-1} (0.1), and −7.7 kJ mol^{-1} (0.2). In any solvent examined the enthalpies contribute predominantly to the Gibbs energies. On the other hand, for a given complex with varying solvent compositions, the entropies mainly contribute to the change in the Gibbs energies of the complex formation reactions. With an increase in the dioxane content of the solvent, the Gibbs energies of the complex formation reactions become more negative, while the enthalpies of the reactions remain practically unchanged or even become less negative. Consequently, the entropies of the reactions increase with increasing dioxane content of the solvent, which is explained in terms of weakening of the hydrogen-bonded structure of water in the bulk solvent by the addition of dioxane.

In a previous paper,[1] we reported the solvent effect on the formation of ethylenediamine complexes of nickel(II) ions in an aqueous solution and in aqueous dioxane mixtures. The formation constants of the NiL^{2+}, NiL_2^{2+}, and NiL_3^{2+} complexes (L denotes ethylenediamine) increased with increasing dioxane content of the solvent, and the increment of the formation constants with varying solvent compositions was almost independent of the species. The solvent effect on the formation constants of the complexes was attributed mainly to the increase in the entropies of formation of the complexes. Enthalpies of the complex formation reactions became less negative at each stepwise reaction with the increase in the dioxane concentration in the solvents. The results have been explained in terms of the change in the hydrogen-bonded structure of water in the bulk solvent by the addition of dioxane.[1-3]

In the present study, we employed copper(II) ions in order to further examine solvent effects on the complex formation reaction of metal ions with neutral ligands in which the charges of the complexes remain unchanged in the course of the complex formation reaction. Ethylenediamine was used as the neutral ligand, as was demonstrated in the previous work.[1]

Experimental

Reagents. Copper(II) perchlorate was prepared from copper(II) oxide and perchloric acid of reagent grade. The copper(II) perchlorate thus prepared was recrystallized three times from water. A small amount of perchloric acid was added to the copper(II) perchlorate stock solution and pH of the stock solution was kept about 3. The concentration of free acid was determined coulometrically. The total concentration of copper(II) ions in the stock solution was determined electrogravimetrically.

Other chemicals used were prepared by the same methods as described previously.[1,4]

Method of Measurements and Analysis of Data. All potentiometric and calorimetric titrations were performed at 25 °C in a constant ionic medium of 3 mol dm^{-3} $LiClO_4$. The experimental method and the procedure of data analysis were described previously.[1]

Results and Discussion

Over the range of $-\log([H^+]/\text{mol dm}^{-3})$ from 3 to 10 in all the solvents examined, potentiometric titration curves of the copper(II)-ethylenediamine system could be well explained by assuming the formation of two mononuclear CuL^{2+} and CuL_2^{2+} complexes. The tris(ethylenediamine)copper(II) complex was not appreciably formed under the present experimental conditions. Typical titration curves obtained in the aqueous solution are shown in Fig. 1, where $-\log([H^+]/\text{mol dm}^{-3})$ values measured are plotted against X, the degree of neutralization of ethylenediammonium ions in the solution. The experimental points fitted well curves calculated (X_{calcd}) by using Eq. 1 over the whole range of the $-\log([H^+]/\text{mol dm}^{-3})$ values examined.

$$X_{calcd} = (2C_L - [H^+] + K_w[H^+]^{-1} - K_2^{-1}[H^+][L] - 2K_1^{-1}K_2^{-1}[H^+]^2[L])/C_L, \quad (1)$$

where K_1 and K_2 denote the dissociation constants of H_2L^{2+} and HL^+ ions, respectively. K_w represents the autoprotolysis constant of the solvent. Concentrations of free hydrogen ions and ethylenediamine molecules were calculated by using Eqs. 2 to 4.

$$C_M = [Cu^{2+}] + \beta_1[Cu^{2+}][L] + \beta_2[Cu^{2+}][L]^2, \quad (2)$$

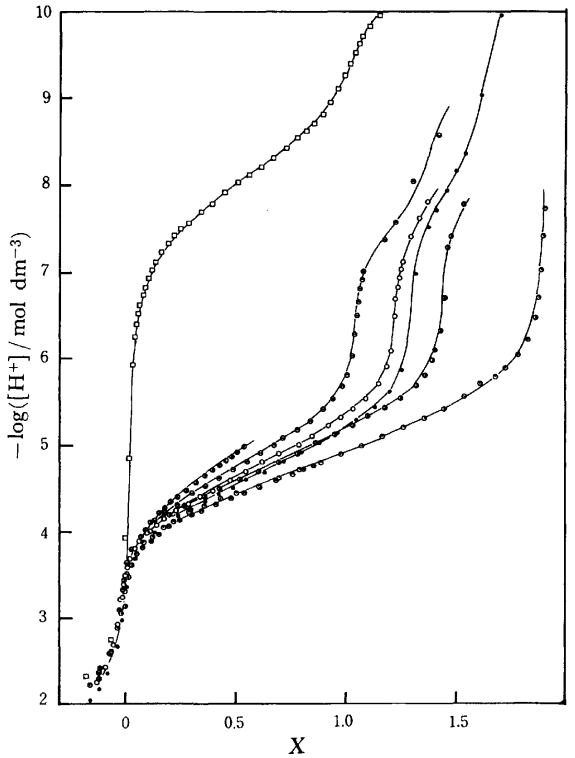

Fig. 1. Potentiometric titration curve of ethylenediamine and copper(II)-ethylenediamine aqueous solutions.
Curve □: C_M(mmol dm^{-3})=0.0, C_L(mmol dm^{-3})= 58.47; ○: 14.10, 45.75; ⊙: 16.53, 35.11; ⊖: 9.853, 37.46; ⊕: 22.96, 49.57; ●: 19.69, 61.06; ◑: 14.09, 38.57: ⓓ: 12.49, 59.60.
The concentrations of the metal ion and the ligand were changed by dilution during the titrations. The solid lines show calculated curves by using the constants in Table 1.

$$C_L = [L] + K_2^{-1}[H^+][L] + K_1^{-1}K_2^{-1}[H^+]^2[L] + \beta_1[Cu^{2+}][L] + 2\beta_2[Cu^{2+}][L]^2, \quad (3)$$

$$C_H = [H^+] - K_w[H^+]^{-1} + K_2^{-1}[H^+][L] + 2K_1^{-1}K_2^{-1}[H^+]^2[L]. \quad (4)$$

Here C_i denotes the total concentration of species i. β_1 and β_2 represent the overall formation constants of CuL^{2+} and CuL_2^{2+}, respectively. The values were optimized by using the least-squares method for searching the minimum error-square sum $U=\sum\{(C_M-C_{M,calcd})^2+(C_L-C_{L,calcd})^2+(C_H-C_{H,calcd})^2\}$, the program MINIQUAD[5] being employed for the calculation. The final values for the overall formation constants of the complexes are listed in Table 1.

In Fig. 2 typical results for the calorimetric titrations of aqueous copper(II)-ethylenediamine solutions are depicted, where heats evolved q_i at the addition of the i-th portion of a titrant are plotted against the average number $\bar{n}$ of ethylenediamine molecules bound per copper(II) ion in the solution. The solid lines are drawn by using the enthalpy values finally obtained with the aid of the least-squares program KALORI.[6] The results obtained are tabulated in Table 2.

Table 1. The formation constants, β_n, for the reactions, $Cu^{2+}+nL=CuL_n^{2+}$; $\beta_n=[CuL^{2+}]/[Cu^{2+}][L]^n$ (L=en) in aqueous dioxane containing 3 mol dm^{-3} $LiClO_4$ at 25 °C

Aqueous Solution. Since the stepwise formation constants of the mono- and bis(ethylenediamine)-copper(II) complexes decrease with the ligand number within the complexes, the Gibbs energies of the first complex is more negative than the second one. However, the stepwise enthalpy of formation of the mono(ethylenediamine)copper(II) complex is less negative than that of the bis-complex. Therefore, the stepwise entropy of formation of the former complex is larger than that of the latter, although the values are both negative (see Table 3). Thus, $\Delta G_1^\circ<\Delta G_2^\circ$, $\Delta H_1^\circ>\Delta H_2^\circ$ and $\Delta S_1^\circ>\Delta S_2^\circ$. Similar trends in the variations of ΔG_n°, ΔH_n° and ΔS_n° have been observed in the formation of nickel(II)-ethylenediamine complexes.[1]

It may be generally accepted that metal-water bonds within an aquametal ion weaken when a part of water molecules within the aquametal ion are replaced with a ligand which has an atom or atoms with a stronger donor property than water.[7] Thus, we can expect that the Cu-OH_2 bonds within the mono(ethylenediamine)-copper(II) complex is weaker than those within the aquacopper(II) ion. Therefore, when we introduce the second ethylenediamine molecule to the mono-(ethylenediamine)copper(II) complex, an energy (enthalpy) to expell two water molecules from the coordination sphere of the mono-complex may be less than that of the aquacopper(II) ion. Consequently, the stepwise enthalpy of formation of the CuL_2^{2+} complex becomes more negative than that of the CuL^{2+} complex. On the contrary, when water molecules within the mono(ethylenediamine)copper(II) complex in which the water molecules combine relatively weakly with the metal ion are removed from the coordination sphere, a less entropy gain may be resulted compared with that for releasing water molecules from the aquacopper(II) ion. The negative values of the entropies of formation of the CuL^{2+} and CuL_2^{2+} complexes indicate that the complex formation is accompanied by the loss of entropy due to the combination of ethylenediamine molecules with the copper(II) ion and also to the recombination of dehydrating water molecules from the metal ion with those in the bulk solvent by the formation of hydrogen bonds.

The Solvent Effect on the Complex Formation. The Gibbs energies of formation of each complex became more negative with increasing dioxane content of the solvent. The decrease in the Gibbs energy of a given complex with varying solvent compositions is attributable to the increase in the entropy of formation of the complex, the enthalpy contributing to the Gibbs energy less favorably with the solvent effect.

As has been pointed out in the previous paper,[1] the secondary solvation of the both aquametal ion and metal-ethylenediamine complexes is enhanced in dioxane-water mixture and the degree of enhancement of the solvation is larger in the aquametal ion than in the metal-ethylenediamine complexes. Moreover, the enhancement become less significant within a complex with a larger number of the ethylenediamine molecules coordinated to the metal ion.

Although we have no experimental data for the enthalpy of transfer of copper(II) ions from water to a dioxane-water mixture and, therefore, we cannot calculate the enthalpies of transfer of each complex between the two solvents, we can expect that the secondary solvation of the aquacopper(II) ion is enhanced more strongly than that of a copper(II)-ethylenediamine complex in a given solvent mixture. Consequently, the formation of the copper(II)-ethylenediamine complexes becomes less favorable in the enthalpic point of view in a solvent with a larger dioxane content.

On the other hand, water molecules liberated from the coordination sphere of a complex can behave more freely in a dioxane-water mixture in which the hydrogen-bonded structure of water is partially destroyed. Therefore, the increase in the entropy of any copper(II)-ethylenediamine complex in a dioxane-water mixture is attributable mainly to an entropy gain of water liberated.

Such trends in the changes of the Gibbs energies, enthalpies and entropies of formation of complexes have also been observed in the nickel(II)-ethylenediamine system.[1]

The decrements of the Gibbs energies of formation of the copper(II)-ethylenediamine complexes with varying dioxane contents in the solvent are practically the same as those of the nickel(II)-ethylenediamine ones. Moreover, the changes are essentially independent of the number of ethylenediamine molecules coordinated. Such results are predictable from a simple Born equation by assuming the same ionic radii of the CuL_n^{2+} and NiL_n^{2+} ions. However, it should be noted that the increments of the both enthalpy and entropy of formation of each copper(II)-ethylenediamine complex are smaller than those of the corresponding nickel(II)-ethylenediamine ones (2.5 kJ mol^{-1} and 4.0 kJ mol^{-1} for the enthalpies of NiL^{2+} and NiL_2^{2+} complexes, respectively, at the transfer from water to the aqueous dioxane of 0.2 mole fraction dioxane content and 21.1 J K^{-1} mol^{-1} and 26.6 J K^{-1} mol^{-1} for the corresponding entropies of the respective species). The reason why the solvent effects on the enthalpies and entropies of formation of the CuL_n^{2+} complexes are smaller than those of the NiL_n^{2+} ones is not clear at the present stage.

Five-coordinate Bis(1,1,1,5,5,5-hexafluoro-2,4-pentanedionato)(tertiary phosphine)palladium(II) and -platinum(II) Complexes. X-Ray Crystal and Molecular Structures and Fluxional Motions in Solution

Seichi Okeya,*,† Toshiko Miyamoto, Shun'ichiro Ooi,* Yukio Nakamura, and Shinichi Kawaguchi*
Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received July, 29, 1983)

Five-coordinate complexes [M(hfac)$_2$L] (M=Pd, Pt; hfac=1,1,1,5,5,5-hexafluoro-2,4-pentanedionate anion) were produced by the reactions of [M(hfac)$_2$] with equimolar amounts of tertiary phosphines, phosphites, and triphenylarsine. They were characterized by ^{1}H, ^{13}C, ^{19}F, and ^{31}P NMR spectra in solution and several complexes containing bulky phosphines as L were isolated, and structures of [Pd(hfac)$_2${P(*o*-tolyl)$_3$}] and [Pt(hfac)$_2${P(cyclohexyl)$_3$}] were determined by X-ray analysis. Both complexes have very distorted square-pyramidal structures, one of the two hfac anions in either of them spanning the apical and basal coordination sites. NMR spectra at various temperatures disclosed the fluxional behaviors of these complexes which retain the solid-state structures at such low temperatures as −60 °C. Two kinds of twist mechanisms were proposed.

By our extensive studies, the ligand substitution reactions of bis(β-diketonato)palladium(II) and -platinum(II) with various nitrogen bases[1] and tertiary phosphines[2] were found to afford many types of complexes depending on the natures of the central metals, β-diketonate ligands, attacking Lewis bases, and solvents employed. In either case, a molecule of Lewis base L was considered to transform one of the chelating β-diketonate ligands (β-dik) into the *O*-unidentate state (β-dik-*O*) in the first stage of the overall reaction (Eq. 1). In fact several palladium(II) and

$$[M(\beta\text{-dik})_2] + L \longrightarrow [M(\beta\text{-dik})(\beta\text{-dik-}O)L] \quad (1)$$

platinum(II) complexes containing an *O*-unidentate 1,1,1-trifluoro-2,4-pentanedionate (tfac) ligand were isolated.[2]

The ligand substitution reactions of square-planar complexes usually proceed according to the associative mechanism[3] but the five-coordinate intermediate can hardly be detected experimentally,[4] although rather many stable five-coordinate palladium(II) and platinum(II) complexes have been prepared (*vide infra*). When the reaction between [Pd(tfac)$_2$] and tri-*o*-tolylphosphine was studied spectrophotometrically, a distinct isosbestic point was recorded, indicating that no intermediate was accumulated to an appreciable concentration.[5]

On the contrary, the reactions of bis(1,1,1,5,5,5-hexafluoro-2,4-pentanedionato)palladium(II) and -platinum(II) with bulky tertiary phosphines were found to give stable adducts [M(hfac)$_2$(PR$_3$)]. This paper reports the characterization of these five-coordinate complexes and their fluxional behaviors in solution as well as the molecular structures of two of them which were determined by the X-ray diffraction method.[6]

Experimental

Preparation of Compounds. The starting chelates [Pd(hfac)$_2$] and [Pt(hfac)$_2$] were prepared according to the previously reported method.[7] Commercially supplied tertiary phosphines were used without further purification except P(*o*-tolyl)$_3$ which was recrystallized from ethanol.

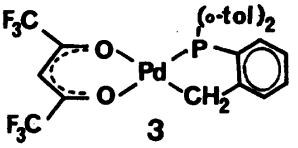
*Bis(1,1,1,5,5,5-hexafluoro-2,4-pentanedionato)(tri-o-tolylphosphine)palladium(II), [Pd(hfac)$_2${P(o-tolyl)$_3$}] (**1a**)*: After [Pd(hfac)$_2$] (494 mg, 0.949 mmol) and P(*o*-tolyl)$_3$ (293 mg, 0.963 mmol) were dissolved in hot hexane (10 cm^3), the mixture was kept at −5 °C in a refrigerator to precipitate dark red crystals, which were filtered, washed with a small amount of hexane, and dried *in vacuo* (530 mg). The filtrate was allowed to stand at room temperature to make the solvent evaporate spontaneously. Another crop of crystals was left on the wall of vessel. The combined yield was 669 mg (85%). Red plates obtained by recrystallization from hexane were subjected to X-ray analysis.

*Bis(1,1,1,5,5,5-hexafluoro-2,4-pentanedionato)(tri-o-tolylphosphine)platinum(II), [Pt(hfac)$_2${P(o-tolyl)$_3$}] (**2a**)*: A solution of [Pt(hfac)$_2$] (254 mg, 0.417 mmol) and P(*o*-tolyl)$_3$ (127 mg, 0.417 mmol) in diethyl ether (15 cm^3) was kept standing at ambient temperature to allow the solvent to vaporize spontaneously. Orange plates left on the wall of vessel were gathered, washed with a small amount of hexane, and dried *in vacuo*. The yield was 339 mg (89%).

*Bis(1,1,1,5,5,5-hexafluoro-2,4-pentanedionato)(phenyldi-o-tolylphosphine)palladium(II), [Pd(hfac)$_2${PPh(o-tolyl)$_2$}] (**1b**) and -platinum(II), [Pt(hfac)$_2${PPh(o-tolyl)$_2$}] (**2b**)*: Both compounds were prepared in a similar way and the yield was 70% in either case. Recrystallization from hexane gave red plates (**1b**) and yellow needles (**2b**), respectively.

*Bis(1,1,1,5,5,5-hexafluoro-2,4-pentanedionato)(tricyclohexylphosphine)platinum(II), [Pt(hfac)$_2$(PCy$_3$)] (**2g**)*: The complex was also prepared by the method similar to that for **2a** in a 93% yield. Orange columns obtained by recrystallization from hexane were used for X-ray analysis.

*(1,1,1,5,5,5-Hexafluoro-2,4-pentanedionato){2-(di-o-tolylphosphino)benzyl-C,P}palladium(II), [(hfac)PdCH$_2$(o-C$_6$H$_4$)P(o-tolyl)$_2$] (**3**)*: A solution of **1a** (350 mg, 0.424 mmol) in dichloromethane (5 cm^3) was left to stand at ambient temperature for 10 d and the solvent was then allowed to evaporate spontaneously to leave yellow oil. The crude product was dissolved in dichloromethane (0.5 cm^3). Petroleum ether (bp <60 °C) was added to the solution and the mixture was cooled to precipitate yellow plates, which were filtered and dried *in vacuo*. The yield was 124 mg (47%). When kept at ambient temperature for a long time, even the solid specimen of **1a** changed gradually to **3**. Anal. Found: C, 50.60; H, 3.40% M$^+$, 616 (^{106}Pd, 27%), 618 (^{108}Pd, 27%), 615 (^{105}Pd, 22%), and 614 (^{104}Pd, 11%). Calcd for $C_{26}H_{21}O_2PF_6Pd$: C, 50.63; H, 3.43%; M, 616.79. ^{1}H NMR in $CDCl_3$, δ(ppm from internal Me_4Si): 2.45 and 2.75 (6H, s, br, 2CH$_3$); 3.79 (2H, d,



3

J(P-H)=4 Hz, CH_2); 6.8—7.3 (≈12H, ring protons). ^{13}C NMR in $CDCl_3$, δ(ppm from internal Me_4Si): 22.4 (d, br, ^3J(C-P)=10 Hz, ^1J(C-H)=*ca.* 130 Hz, CH_3); 32.1 (s, ^1J(C-H)=136 Hz, CH_2); 89.2 (s, br, ^1J(C-H)=164 Hz, CH of hfac). Other carbon signals are not analyzed. The ^{31}P NMR signal is observed in $CDCl_3$ as a singlet at 35.6 ppm downfield from external H_3PO_4. The above-mentioned splitting and broadening of methyl proton signals and broadening of methyl carbon signal seem to be caused by the restricted free rotation of the two tolyl groups around the P-C bonds. These signals became a broad singlet and a doublet, respectively at 50 °C.

X-Ray Analysis. The crystal data for [Pd(hfac)$_2${P(*o*-tolyl)$_3$}] (**1a**) and [Pt(hfac)$_2$(PCy$_3$)] (**2g**) are given in Table 1. The Laue symmetries and the space groups were determined from Weisenberg and precession photographs. The unit cell dimensions were obtained from the least-squares treatment of 20 θ values of higher angle reflections (θ=7—15°) measured on an automated diffractometer by use of Mo$K\alpha$ radiation.

The intensities were measured on the diffractometer by using graphite-monochromated Mo$K\alpha$ radiation. The background was counted at each side of the scan range. The intensities of three standard reflections monitored every 4 h for each compound showed no appreciable variation during the data collection. The intensity data from compound **2g** were corrected for absorption.[8]

The crystal structures were solved by the heavy atom technique. The positional and thermal parameters were refined by block-diagonal-matrix least-squares. The minimized function was $\sum\omega(F_O-|F_C|)^2$, where $\omega=1/\sigma^2(F_O)$. All H atoms in **1a** could be found on the difference Fourier map but the refinement of their parameters was unsuccessful. They were included in the least-squares calculation but the parameters were fixed, the isotropic temperature factor $B_H=B+1.0$ being assigned for individual H atom, where B is the isotropic temperature factor of the C atom (obtained at the final cycle of isotropic refinement) to which the H atom is bound. No attempt was made to locate H atoms in **2g**. All parameter shifts in the final cycle of the refinement were less than 0.5σ in either case.

Table 1. Crystal data and experimental details

Compound	**1a**	**2g**
Crystal system	Monoclinic	Orthorhombic
Space group	$P2_1$	Pcab
a/Å	13.998(3)	25.652(3)

R	0.039	0.045
R'(=[$\sum\omega\Delta^2/\sum\omega F_o^2$]$^{1/2}$)	0.052	0.052

The atomic scattering factors, with correction for real part of anomalous dispersion of Pd^0 and Pt^0, were taken from Ref. 9. Compound **1a** crystallizes in a chiral space group, being resolved spontaneously on the way of crystallization. However, no attempt was made to determine the absolute crystal structure. The atomic coordinates are given in Table 2. The F_O–F_C tables, the anisotropic thermal parameters, and the H atom coordinates in **1a** are preserved at the Chemical Society of Japan (Document No. 8409). The computation was performed by a FACOM 230-60 computer at Osaka City University and ACOS-700 computer at Crystallographic Reserch Center of Osaka University by use of the program in the UNICS[10] and ORTEP.[11]

Other Measurements. Infrared spectra were obtained in Nujol mull with a Hitachi 295 spectrophotometer. Electronic spectra were measured in dichloromethane or hexane with a Hitachi 200-20 spectrophotometer. NMR spectra were recorded on JEOL-C60HL (in the case of ^1H), FX60Q (for ^1H, ^{13}C, and ^{31}P), FX90Q (for ^{13}C, ^{19}F, and ^{31}P), and FX100 (for ^{13}C and ^{195}Pt) instruments. A vapor-pressure osmometer manufactured by Knauer in West Berlin, West Germany, was used for molecular weight determination.

Results and Discussion

The reactions of [M(hfac)$_2$] (M=Pd^{II} and Pt^{II}) with equimolar amounts of bulky tertiary phosphines such as P(*o*-tolyl)$_3$ and PCy$_3$ in hexane or diethyl ether gave crystalline adducts [M(hfac)$_2$(PR$_3$)] (M=Pd (**1**) and Pt (**2**)) in high yields, of which decomposition temperatures and analytical data are listed in Table 3. Of these products, crystals of [Pd(hfac)$_2${P(*o*-tolyl)$_3$}] (**1a**) and [Pt(hfac)$_2$(PCy$_3$)] (**2g**) were suitable for X-ray analysis.

Molecular Structures in Crystals. Both crystals are composed of discrete complex molecules. Figures 1 and 2 show their perspective views and projections along the normal of the coordination plane for each molecule, respectively. Figure 3 gives the views of the phosphine ligands along the respective M-P vectors. As both complexes have similar ligands, common atom numbering is used as is seen in these Figures. Bond lengths and bond angles are summarized in Tables 4 and 5, respectively. Average values are given for the parameters of CF_3 groups, since these groups have large thermal parameters indicative of a disorder (Table 2) and hence individual structural parameter is of less importance.

The metal atom in either complex is five-coordinate and has a very distorted square-pyramidal coordination. The apical atom [O(11)] largely deviates from the ideal site for tetragonal symmetry as is seen in Fig. 2. The M-O(11) bond intersects the basal coordination plane defined by the O(12), O(21), O(22), and P atoms at 65.3(2)° and 66.9(3)° in **1a** and **2g**, respectively. The apical M-O bond is much longer than the basal one, indicating the weaker interaction between M and the apical O in either case. The basal donor atoms show slight but significant deviations from the mean plane, being displaced toward tetrahedral disposition. The magnitude is more than three times larger in **2g** than in **1a**. Although the O(12)-Pt-O(22) angle is 178.6(3)°, the P-Pt-O(21) angle is 173.1(2)° and the P and O(21) atoms are distant from the idealized apical site.

Such a very flattened tetrahedral arrangement of the

basal atoms has also been found in the pseudo tetragonal five-coordinate Pd^{II} and Pt^{II} complexes such as [MBr$_2$L$_3$] (M=Pd and Pt, L=5-ethyl(or methyl)-5*H*-dibenzophosphole;[12] M=Pd, L=2-phenylisophosphindoline[13]), [PdCl$_2$(PMe$_2$Ph)$_3$],[14] [PtCN(phen)$_2$]NO$_3$,[15] [Pd(hfac)(triphos)](hfac) (triphos =Ph$_2$PCH$_2$CH$_2$P(Ph)CH$_2$CH$_2$PPh$_2$),[16] and [Pd(hfac)$_2$(PPh$_3$)].[17] Furthermore, the metal atom is displaced from the basal plane toward the apical site, the deviation of Pd in **1a** being about twice as much as that of Pt in **2g**. Such deviation is characteristic of a square-pyramidal coordination of transition metals.

The Pt-P bond in **2g** is slightly but significantly shorter than Pd-P in **1a**. The M-O(21) bond, in which O(21) lies trans to the phosphine ligand, is somewhat longer than the other basal M-O bonds probably owing to the trans influence of the phosphine.

Table 2a. Fractional coordinates and temperature factors for [Pd(hfac)$_2${P(*o*-tolyl)$_3$}] (**1a**). Standard deviations of the least significant figures are given in parentheses

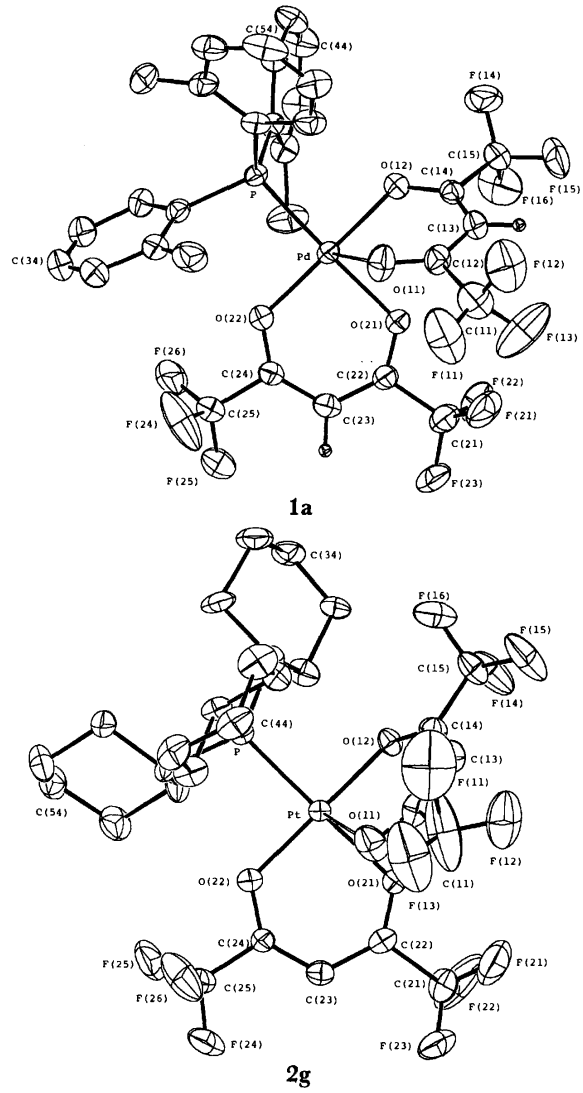

Fig. 2. Projection of each complex along the normal of coordination plane. Thermal ellipsoids are drawn at 30% probability level. The H atoms linked to the C(13) and C(23) atoms in **1a** are shown by spheres with arbitrary radius.

The hfac ligand lying on the basal plane in either complex forms a symmetrical planar chelate ring with the metal atom, and bond lengths indicate complete delocalization of π electrons within hfac. On the other hand, the hfac ligands which span the basal and apical sites in both complexes have structural parameters similar to each other. However, while the chelate ring in **2g** is totally planar, that in **1a** is folded along the line O(11)···O(12), the interplanar angle between the ligand plane (Plane 2 in Table 6) and the [Pd, O(11), O(12)] plane being 141.1(3)° as is seen in Fig. 2 and Table 6. Bond lengths clearly show the localization of π electrons in the latter ligand, indicating a greater contribution from the resonance structure $^{-}O\text{-}C(CF_3)=CH\text{-}C(CF_3)=O$. A detailed structural examination revealed that the two planar CF_3COC moieties are rotated with respect to each other through a dihedral angle of 9.2(4)°.

As stated already, the reactions of $[M(tfac)_2]$ with bulky tertiary phosphines afford four-coordinate

a) Mean value of six C-C-F angles. b) Mean value of six F-C-F angles.

square-planar complexes [M(tfac)(tfac-*O*)(PR$_3$)] containing an *O*-unidentate tfac ligand, which is bound to the metal atom through the acetyl oxygen and the oxygen atom of the dangling trifluoroacetyl group is far from the metal atom, showing no sign of interaction.[18] On the other hand, an oxygen atom of hfac in [M(hfac)$_2$(PR$_3$)], which is obtained by a similar reaction, lies near the apical position of a square-pyramidal structure. The structural difference between these two types of complexes of similar composition may stem from (i) a greater net positive charge on the metal atom in the hypothetical complex [M(hfac)-(hfac-*O*)(PR$_3$)] caused by the lower basicity of the hfac anion than that of tfac, and (ii) preference of the *Z,Z*-form by hfac over either *E,E*-, or *E,Z*-form because of repulsions between bulky CF$_3$ groups or between CF$_3$ and the carbonyl oxygen. Thus it seems reasonable that when an hfac anion is allowed to occupy a single basal site to link to a metal atom through one of the two oxygens, the other oxygen atom of the dangling CF$_3$CO group is positioned around the apical site. The lone-pair electrons of the apical donor atom can interact with a net positive charge on the metal which is effected by incomplete neutralization of the metal charge due to low basicities of σ donors and/or by back donation through the M-L π bonding, thus completing a five-coordination. It is worth noting that the reactions between [M(hfac)$_2$] and various nitrogen bases have never given rise to five-coordinate complexes.[1]

Structures and Dynamic Behaviors of the Five-coordinate Complexes in Solution. Electronic and Infrared Spectra: The electronic spectrum of complex **1a** exhibits absorption maxima at 302 nm (ε=18200) and 410 nm (ε=2500) in dichloromethane at room temperature, and shows no appreciable change in hexane at −90 °C, suggesting that the structure of **1a** in solution does not vary in this temperature range. The absorption maxima of **2a** in dichloromethane at room temperature were observed at 275 nm (ε=11600), 280 nm (ε=11500), and 308 nm (ε=9600).

On addition of increasing amounts of P(*o*-tolyl)$_3$ to a solution of [Pd(hfac)$_2$] in hexane, the absorption

spectrum changed stepwisely, exhibiting distinct isosbestic points at 341 and 369 nm (Fig. 4). Addition of the phosphine beyond the equimolar amount caused no further change in spectrum and the final spectrum closely resembles that of the authentic sample of **1a**. These results clearly indicate that the reaction between [Pd(hfac)$_2$] and P(o-tolyl)$_3$ affords no product other than **1a** and that the equilibrium constant of this addition reaction is very large. As is shown in Table 3, the molecular weight data for complexes **1a**, **2a**, and **2g** in dichloromethane at room temperature nearly coincide with the calculated values, indicating that these complexes are stable in solution and do not dissociate the phosphine to any appreciable extent.

Infrared spectrum of **1a** includes characteristic bands at 1690(s), 1633(vs), 1550(vs), and 1530(s) cm^{-1} and **2a** also absorbs at 1705(m), 1616(s), 1564(vs), and 1523(m) cm^{-1}. In either case, the highest-frequency band may be assigned to the ν(C=O) vibration of the CF_3CO group occupying the apical position. The other bands lie in the frequency region which is related with the ν(C=O)+ν(C=C) vibrations of the usually O,O'-chelated hfac ligand.

^{1}H NMR Spectra: The ^{1}H NMR data for the isolated complexes listed in Table 3 are given in Table 7. The ^{1}H NMR signals observed for reaction mixtures of [Pd(hfac)$_2$] with equimolar amounts of various tertiary phosphines, arsines, and phosphites are also included in Table 7. The spectra are quite similar to those of **1a** and **2g**, suggesting that the reaction products probably have the five-coordinate structures

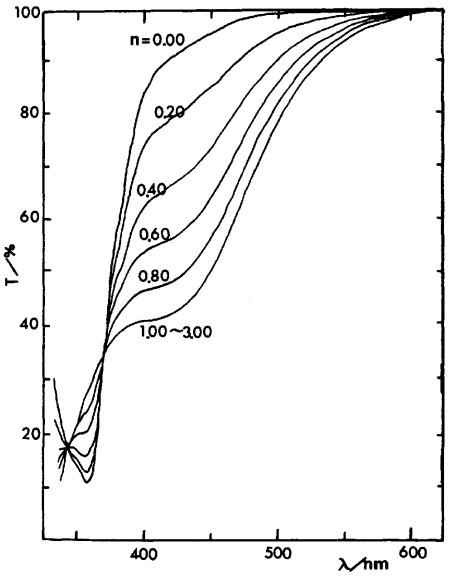

Fig. 4. Transmittance spectra of hexane solutions containing [Pd(hfac)$_2$] and n times molar amounts of P(o-tolyl)$_3$.
[complex]=1.50×10^{-4} mol dm^{-3}.

similar to those of **1a** and **2g**, although they were not isolated. Thus, in either case a single methine signal from the hfac ligands is observed at room temperature in the 5.8—6.1 ppm region except for **2i**, showing upfield shift by 0.3—0.6 ppm as compared with that from [M(hfac)$_2$]. Furthermore, the ^4J(Pt-H) values for the Pt^{II} complexes (**2**) are 5—7 Hz, about one half of 10.5 Hz for the parent bis-chelate, probably reflecting decrease in s-character of the platinum bonding with the change in structure from square to square-pyramid.

If the square-pyramidal structure in crystals is retained in solution, the two hfac ligands are not equivalent and should exhibit two methine proton

a) Chemical shifts in ppm from internal Me_4Si. Figures in parentheses, double parentheses, and braces are $^3J(CH_2$-$CH_3)$, J(P-H), and J(Pt-H) in Hz, respectively. d: Doublet, t: triplet, q: quartet, br: broad, c: complex. b) The ^{195}Pt satellites are indiscernible.

signals. In fact, at lower temperatures (−50 and −60 °C) either of complexes **1a** and **2a** shows two methine and three methyl signals, indicating that the stereochemically rigid five-coordinate structure is retained in solution at low temperatures. If free rotation of the phosphine ligand around the M-P bond is prohibited, the three methyl groups attached to the phenyl rings may have different environments from each other since there exists no plane of symmetry involving the M-P bond. Signals from the phenyl-ring protons also show splitting and a 1H doublet is observed for either of **1a** and **2a** at such a low field as 9.27 and 9.15 ppm, respectively. The α-proton of a phenyl ring attached to phosphorus might exist near the sixth coordination site around the metal and suffer its paramagnetic anisotropic effect. Although such a conformation is not reallized in the crystal of **1a**, the M···H-C interaction is rather frequently noticed in metal complexes[19] especially as a prerequisite for orthometallation.[20]

At room temperature, besides the free rotation of the phosphine ligand, the five-coordinate complex may undergo some fluxional motion to average environments of the two hfac ligands. In the case of complexes **1c** and **2c** containing triphenylphosphine probably as a basal ligand, the hfac-CH signal does not show splitting even at −50 °C. The smaller steric hindrance of PPh_3 than that of P(*o*-tolyl)$_3$ may enhance the stereochemical nonrigidity of the five-coordinate complex.

^{19}F NMR Spectra: Figure 5 shows the ^{19}F{^{1}H}NMR spectra of complexes **1a** and **2a** in CD_2Cl_2 at various temperatures. At −60 °C both complexes exhibit four signals at 73.8_3, 74.6_3, 75.7_1, and 76.5_4 ppm upfield from internal $CFCl_3$ in the case of **1a** and at 73.5_4, 74.3_9, 79.5_0, and 76.9_9 ppm upfield for **2a**. These spectra are consistent with the molecular structure of **1a** in the solid, indicating nonequivalence of the four CF_3 groups. The signals from **1a** become broad with increasing temperature, coalesce at around −40 °C and give rise to a sharp singlet at -75.8_5 ppm at 22 °C. On the other hand, complex **2a** exhibits a little different behavior. Two signals in the lower field merge at 22 °C to a sharp singlet at -74.4_2 ppm (half-height width=1.6 Hz) flanked by the ^{195}Pt satellites (J(Pt-F)= 15 Hz), whereas the remaining two signals in the

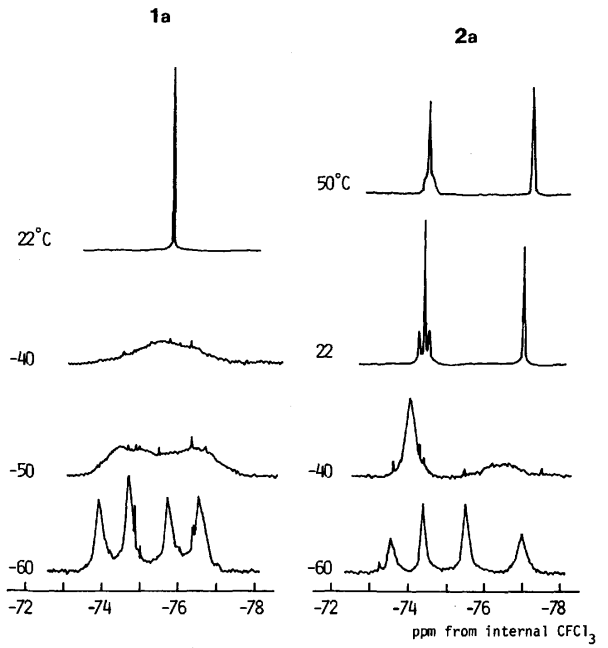

Fig. 5. ^{19}F{^{1}H} NMR spectra at 84.31 MHz of [Pd(hfac)$_2$-{P(*o*-tolyl)$_3$}] (**1a**) and [Pt(hfac)$_2${P(*o*-tolyl)$_3$}] (**2a**) in CD_2Cl_2 at several temperatures.

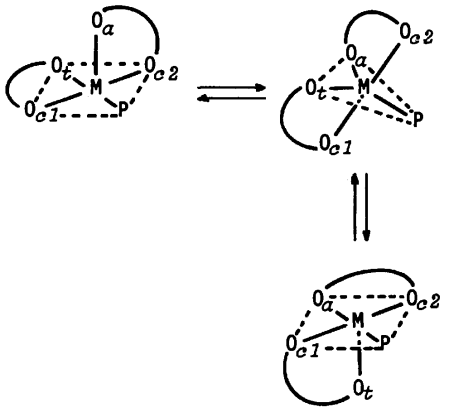
higher field are converted into a broader singlet at -77.0_1 ppm (half-height width=2.9 Hz). However, the two signals broaden at 50 °C, indicating that complex **2a** may behave in the same way as **1a** does but need much larger energy than **1a**.

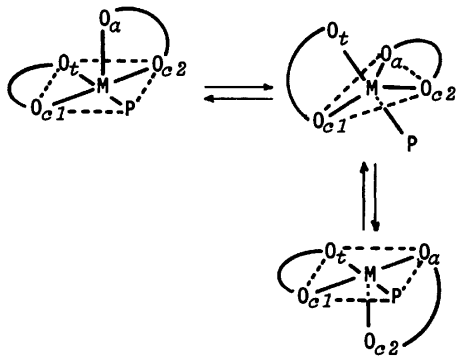
Exchange between the basal and apical hfac ligands may be achieved by a twist motion via a trigonal-bipyramidal transition state as depicted in Eq. 1.



(1)

However, two halves of each hfac anion are not yet equivalent under this rapid motion. One half of each hfac is always near the site cis to phosphorus, while the other lies trans to P or at the apical site, being averaged. The ^1H and ^{19}F NMR spectra of complex **2a** at 22 °C are satisfactorily interpreted by this rapid intramolecular transformation (Eq. 1). Of the two ^{19}F signals, the lower-field one flanked by the ^{195}Pt satellites may be assigned to the CF_3 groups positioned cis to the phosphine, and the other broader high-field one to the average of CF_3 groups at the apical and trans sites, since the ^{19}F atoms around the positions cis to phosphine will couple to platinum more strongly than those around the apical and trans positions.

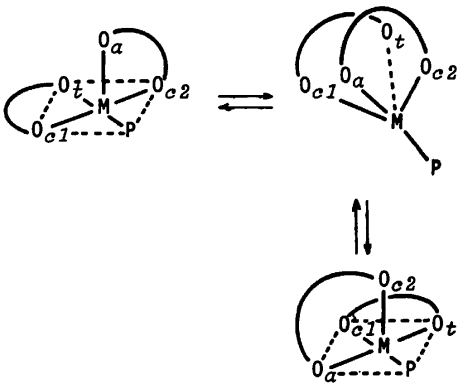
The ^{19}F NMR spectrum of **1a** at 22 °C can not be explained solely by Eq. 1, but needs another fluxional mode to average the cis and trans or apical positions. A simple oscillatory motion of the apical chelate ring as depicted in Eq. 2 may be sufficent to supplement mechanism (1) in averaging all four CF_3 groups.



(2)

The ^1H NMR spectrum of a quasi square-pyramidal complex *cis*-$[PtCl(PEt_3)_2(phen)]BF_4$[21] showed that the two halves of phen are environmentally averaged in solution even at −80 °C.[22] The mechanism of the fluxional motion can not be dissociative, since couplings between Pt and both P and α-H of phen are retained in the fast-exchange limit NMR spectra. The ^{31}P NMR spectra also certified retention of the mutually cis arrangement of the PEt_3 ligands. All these findings are consistent with mechanism (2).[22] The fluxional process by which the metal changes its point of attachment to the α-diimine ligand in some *trans*-$[MCl_2L(dim)]$ complexes (M=Pd, Pt; L=unidentate tertiary phosphine or arsine) was also interpreted based on the same mechanism, that is oscillatory motion of the chelated α-diimine in a five-coordinate square-pyramidal intermediate.[23]

The observed ^{19}F NMR spectra of **1a** in Fig. 5 are rationalized if the Pd^{II} complex undergoes both modes of intramolecular rearrangement (Eqs. 1 and 2) concurrently. Alternatively, either one of the twist motions analogous to those proposed by Ray and Dutt, Bailar, and Springer and Sievers as the intramolecular mechanism for racemization of octahedral complexes[24] will also be effective for averaging environments of some fluorine atoms in **1a**. For example Eq. 3 shows the Ray-Dutt twist, in which the (O_{c1}, O_t) chelate ring rotates by 90 ° on the basal plane and the (O_a, O_{c2}) chelate ring moves synchronously on the plane perpendicular to the P-M axis.



(3)

It should be noted that mechanism (3) does not exchange the basal and apical hfac ligands although both halves of each hfac are averaged. Therefore it is only supplementary to mechanism(1) in averaging all four CF_3 groups.

After we had completed this investigation,[6] Siedle and his collaborators[17] reported the X-ray structure of $[Pd(hfac)_2(PPh_3)]$ which is quite similar to that of **1a** and analyzed the dynamic ^{19}F NMR spectra of **1a** in CD_2Cl_2 to obtain the activation parameters, $\Delta H^{\ddagger}=7.7\pm1$ kcal mol^{-1} and $\Delta S^{\ddagger}=-20\pm5$ cal deg^{-1} mol^{-1} (1 cal=4.184 J). They preferred a transition state of the square-pyramidal structure with the phosphine ligand at the apical position which makes all CF_3 groups equivalent. However, this symmetrical transition state may need a much higher activation energy, since the five-coordinate $Pd^{II}$and Pt^{II} complexes cited above have the strongly-bonding ligands such as tertiary phosphines and the cyanide ion exclusively at the basal positions. Figure 5 clearly indicates that four CF_3 groups are averaged not simultaneously by a single process, but by two consecutive processes at least in the case of Pt^{II} complex **2a**. Wernberg and Hazell[15] found that $[PtCN(phen)_2]^+$ has a square-

pyramidal structure in the solid state with one of the phenanthroline nitrogens at the apical position, but its ^{13}C NMR spectrum showed no difference between the two phen ligands and furthermore both halves of each chelating molecule gave identical signals. They proposed the intramolecular transformation processes *via* trigonal bipyramids, denying a square-pyramidal transition state with the cyanide at the apical position because of the steric hindrance between the two phen molecules on the basal plane.[15]

^{13}C NMR Spectra: Table 8 lists the ^{13}C NMR data. Complex **1a** shows one set of signals. On the other hand, **2a**, **2b**, and **2g** exhibit two sets of signals from the CF_3 and CO carbons, although the CH signal is single in each case. These spectral features are quite similar to those observed for ^{1}H and ^{19}F NMR spectra and rationalized by mechanism (1) for the Pt^{II} complexes and combined (1) and (2) for the Pd^{II} complexes. The carbonyl-carbon signals from **2g** in $CDCl_3$ are composed of two quartets, of which only the higher-field set couples to platinum (^2J(Pt-C)=16 Hz) and is assigned to the two CO carbons positioned cis to the phosphine. The CF_3 carbons also exhibit two sets of signals. One is a quartet flanked by the ^{195}Pt satellites (J(Pt-C)=89 Hz) and assigned to the CF_3 groups positioned cis to the phosphine. The other is a doublet of quartets coupling to ^{31}P and is considered to be an averaged signal from the CF_3 groups at the trans and apical sites, of which the ^{195}Pt satellites are indiscernible.

The ^{13}C NMR spectrum of **2g** in C_6D_6 at room temperature is quite similar to that in $CDCl_3$, but the CF_3 carbon signal at 80 °C appears as a single doublet of quartets, indicating that environments of all four CF_3 groups are averaged at this temperature. The ^1J(F-C) (286 Hz) and ^4J(P-C) (2 Hz) values are also averaged. The fluxional motion is rapid at room temperature for all Pd^{II} complexes and [Pt(hfac)$_2$(PPh$_3$)] (**2c**), the averaged ^1J(C-F) value being 286 Hz in either case. The rate of fluxional motion decreases with increasing bulkiness of tertiary phosphines in the sequence $PPh_3 > PCy_3 > P(o\text{-tolyl})_3$. The ^{195}Pt NMR signal from **2a** in $CDCl_3$ was recorded as a doublet at 295.7 ppm upfield from external $K_2[PtCl_4]$, ^1J(Pt-P) being 448_5 Hz.

^{31}P NMR Spectra: The ^{31}P{^{1}H} NMR data are collected in Table 9. The ^1J(Pt-P) values are rather large lying in the range of 4130—4540 Hz. The δ_P and

a) Chemical shifts (δ_P) in ppm from external H_3PO_4 at 30 °C (downfield positive).

^1J(Pt-P) values show no appreciable change with temperature in the −50 to +30 °C region, indicating retention of the five-coordinate structure. When an equimolar amount of PMe_2Ph or PEt_3 was added to $[Pt(hfac)_2]$ in $CDCl_3$, signals assignable to $[Pt(hfac)(PR_3)_2](hfac)$ appeared besides those from **2e** and **2f**, respectively, and increased with time in the expense of the latters. The disproportionation reactions of **2e** and **2f** to produce $[Pt(hfac)(PR_3)_2](hfac)$ and $[Pt(hfac)_2]$ were completed in about 2 d. The tertiary phosphines in the square-planar complexes $[Pt(hfac)(PR_3)_2](hfac)$ give the ^{31}P NMR signals in the 5—10 ppm lower field than those in the corresponding five-coordinate complexes and their ^1J(Pt-P) values are appreciably lower lying in the region of 3670—4020 Hz. On the other hand, $[Pd(hfac)_2]$ reacts with equimolar amounts of PMe_2Ph and PEt_3 rapidly with heat evolution to afford $[Pd(hfac)(PR_3)_2](hfac)$ exclusively. NMR signals assignable to the five-coordinate complexes were not detected.

When an equimolar amount of PPh_3 is added to $[M(hfac)_2]$ (M=Pd and Pt) and PCy_3 to $[Pd(hfac)_2]$ in CD_2Cl_2, complexes **1c**, **2c**, and **1g** are formed in equilibrium with small amounts of the $[M(hfac)(PR_3)_2](hfac)$-type complexes, respectively. (In the case of **1c**, signals attributable to $[Pd(hfac)(hfac\text{-}C^3)(PPh_3)]$ are also observed.) When another equivalent of phosphines is added to the solution, only the signals from $[M(hfac)(PR_3)_2](hfac)$ are observed. On the other hand, complexes **1a**, **2a**, and **2g** are quite stable in $CDCl_3$ and do not react with excess amounts of phosphines. These observations indicate that the thermodynamic stability of the five-coordinate complex becomes higher with increase in the bulkiness (cone angle[25]) of tertiary phosphine in the sequence $PPhMe_2 \approx PEt_3 < PPh_3 < PCy_3 < P(o\text{-tolyl})_3$. Difference in behaviors of **1g** and **2g** suggests that the stability of the five-coordinate complex is higher for platinum(II) than for palladium(II).

We wish to thank Mr. Junichi Gohda and Dr. Isamu Kinoshita for elemental analysis and measurements of electronic spectra at low temperatures, respectively. We also are grateful to Mr. Tetsu Hinomoto of JEOL, Ltd. for measurements of the ^{19}F and ^{195}Pt NMR spectra.

Hydrophobic Vitamin B_{12}. II. Coordination Geometry and Redox Behavior of Heptamethyl Cobyrinate in Nonaqueous Media†

Yukito MURAKAMI,* Yoshio HISAEDA, Akiro KAJIHARA, and Teruhisa OHNO
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received August 12, 1983)

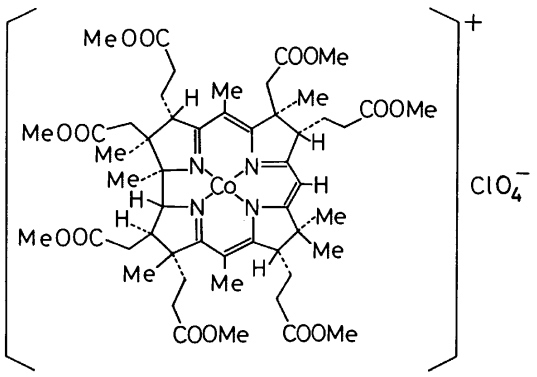
The nuclear cobalt(II) ion in heptamethyl cobyrinate iodide, Cob(II)ester·I, was found to assume a distorted square-planar geometry of $Co-N_4$ type with iodide as a counterion in a polar solvent (methanol) and a square-pyramidal one of $Co-N_4I$ type with the iodide ion coordinated at one of the axial positions in apolar solvents such as dichloromethane, benzene, and toluene. The redox chemistry of Cob(II)ester·I and heptamethyl cobyrinate perchlorate, [Cob(II)ester]ClO_4, was investigated in various organic solvents by means of cyclic voltammetry and controlled-potential electrolysis. The Co(II)/Co(I) and Co(III)/Co(II) redox potentials for [Cob(II)ester]ClO_4 exhibited cathodic shifts as either solvent basicity or polarity was raised, and were found to be in the anodic side relative to the corresponding potentials for Co^{II}(tpp) under identical conditions. The medium effect on the redox behavior of hydrophobic vitamin B_{12} was discussed in connection with the microenvironmental effect on vitamin B_{12} placed in the enzyme active sites.

We have been dealing with hydrophobic vitamin B_{12} derivatives in order to simulate various functions of vitamin B_{12} as exerted in the hydrophobic active sites of enzymes concerned. One of hydrophobic vitamin B_{12} derivatives involving a largely polarizable ion (iodide) shows different colors in solution as the solvent nature changes. Cob(II)ester·I has been prepared originally by Werthemann *et al.*,[1] and the X-ray diffraction analysis of its single crystal has shown that the complex is in a dimeric form which contains one bridging iodide per dimer complex and the second iodide ion is not coordinated.[2] However, any comprehensive structural clarification of the complex in solution has not been carried out yet. Thus, we studied firstly in this work the structures of Cob(II)ester·I in various organic solvents to clarify the origin of color change.

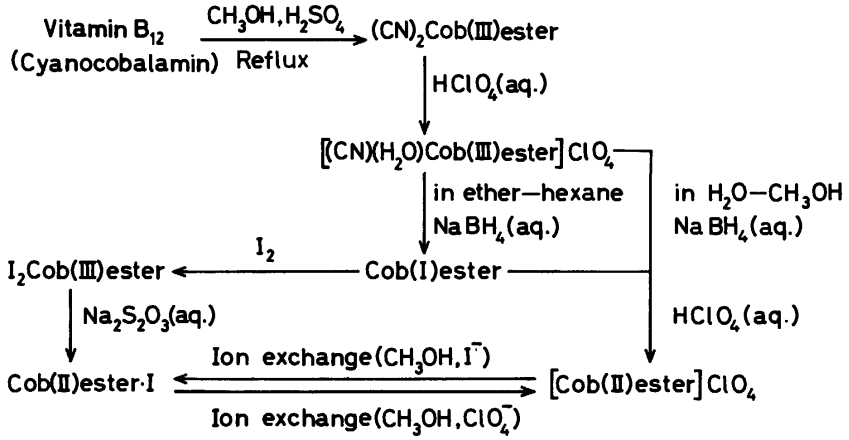
The redox behavior of vitamin B_{12} has recently been examined rather extensively,[3-9] and the studies on its catalytic reactions have been carried out by electrochemical means.[10-13] However, the redox chemistry of vitamin B_{12} in organic solvents has not been investigated because of its insolubility in most of such solvents. Thus, the redox behavior of hydrophobic vitamin B_{12} derivatives in various organic media was examined in this work by means of cyclic voltammetry in order to obtain useful information for the redox property of vitamin B_{12} under various microenvironmental conditions comparable to the enzyme active sites. In addition, the redox potentials of heptamethyl cobyrinate perchlorate, [Cob(II)ester]-ClO_4, were compared with those of (5,10,15,20-tetraphenylporphinato)cobalt(II), Co^{II}(tpp), evaluated under identical conditions, so that the intrinsic ligand effect on the redox behavior of vitamin B_{12} is to be characterized.

Experimental

Materials. Cob(II)ester·I was prepared by the



[Cob(II)ester] ClO_4



Scheme 1.

† Contribution No. 707 from this Department.

procedures outlined in Scheme 1 after the method of Werthemann *et al.*[1] [Cob(II)ester]ClO_4[14] and Co^{II}(tpp)[15] were synthesized according to the reported procedures. Tetrabutylammonium perchlorate (TBAP), tetrabutylammonium iodide (TBAI) of polarographic grade and ferrocene of guaranteed reagent grade were commercially obtained from Nakarai Chemicals. Organic solvents used for electrochemical measurements were purified and dried according to the standard procedures[16] and kept over 4-Å Molecular Sieves.

General Measurements. Electronic absorption spectra and diffuse reflectance spectra were recorded on a Hitachi 340 recording spectrophotometer. ESR spectra were obtained on a JEOL JES-ME 3 X-band spectrometer equipped with a 100-kHz field modulation unit; a standard MgO/Mn^{II} sample calibrated with a NMR magnetometer was employed for calibration of the magnetic field. Molecular weight measurements were carried out with a Hitachi Perkin-Elmer 115 vapor pressure osmometer by using benzene as a solvent.

Electrochemical Measurements. Cyclic voltammograms were obtained on a YANACO P-8 polarograph. An electrochemical cell similar to that reported in literature[17] was used and equipped with platinum wire of 0.5-mm diameter as working and auxiliary electrodes. A saturated calomel electrode (SCE) or an Ag/AgCl electrode was served as a reference which was separated from a bulk electrolyte solution by a salt bridge prepared with benzylidene-D-sorbitol[18] and a nonaqueous solution of TBAP (5.0×10^{-2} mol dm^{-3}). Nonaqueous solutions containing the cobalt complex (*ca.* 5×10^{-4} mol dm^{-3}) and TBAP (*ca.* 5×10^{-2} mol dm^{-3}) were deaerated prior to each measurement, and the inside of the cell was maintained under argon atmosphere throughout each measurement. All the measurements were carried out at 20 ± 2 °C. The scan rate was varied in a range from 10 through 200 mV s^{-1}. Half-wave potentials ($E_{1/2}$) and anodic and cathodic currents were evaluated according to the method described previously.[19]

Controlled-potential electrolysis was carried out in a three-electrode cell modified for electronic spectral measurements, as described previously.[19] An applied potential between the working and reference electrodes was maintained constant with a conventional potentiostat and monitored with a Takeda Riken TR-6656 digital multimeter.

Results and Discussion

Coordination Geometry of Cob(II)ester · I in Solution. Cob(II)ester · I shows two different kinds of electronic spectra in solution depending upon the nature of solvents (Figs. 1 and 2). The complex in methanol shows a spectral feature which is characteristic of the base-off vitamin B_{12r} in aqueous media and comparable to those of [Cob(II)ester]ClO_4 observed in methanol and dichloromethane. The diffuse reflectance spectrum of [Cob(II)ester]ClO_4 shown in Fig. 1 is apparently comparable to the spectrum of Cob(II)ester · I in methanol. Cob(II)ester · I has been known to be in a dimeric form with a single μ-iodo bridging between two cobalt atoms in the solid state as confirmed by the X-ray diffraction study.[2] The solution spectrum of Cob(II)ester · I in dichloromethane is apparently comparable to its diffuse reflectance spectrum as shown in Fig. 2. In order to identify the coordination geometry

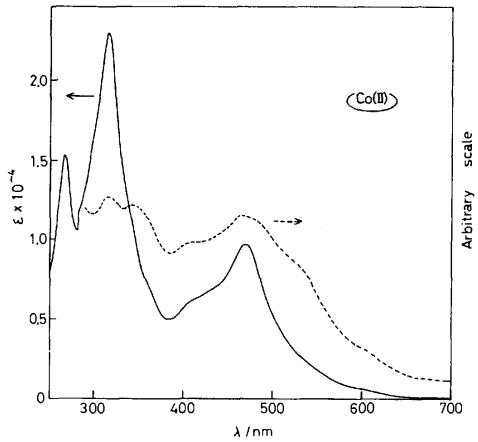


Fig. 1. Electronic absorption spectrum of Cob(II)ester · I (4.47×10^{-5} mol dm^{-3}) in methanol (solid line) and diffuse reflectance spectrum of [Cob(II)ester]ClO_4 (broken line) at room temperature.

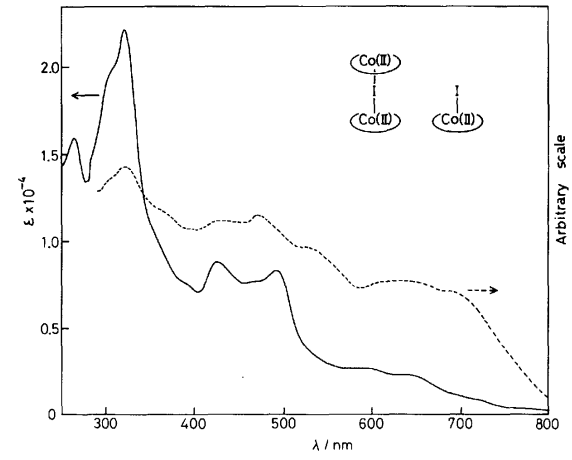

Fig. 2. Electronic absorption spectrum in dichloromethane (solid line; concentration of the complex, 4.90×10^{-5} mol dm^{-3}) and diffuse reflectance spectrum (broken line) of Cob(II)ester · I at room temperatue.

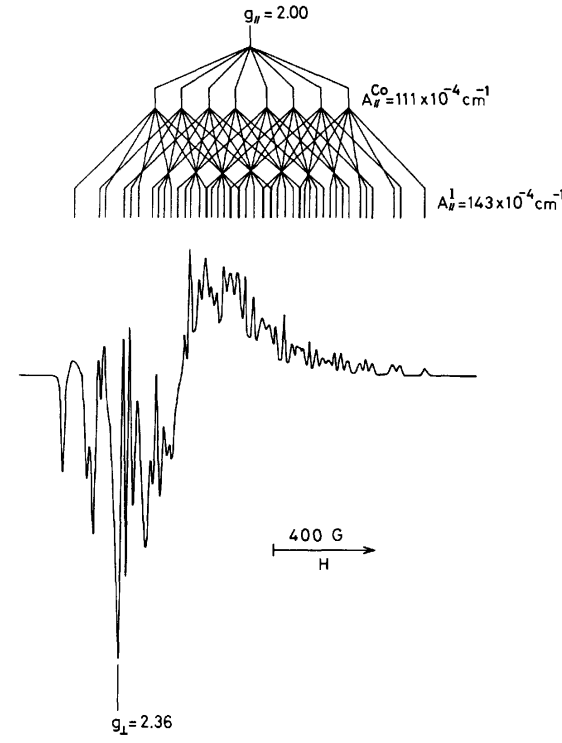

Fig. 3. ESR spectrum of Cob(II)ester · I (5.87×10^{-3} mol dm^{-3}) in toluene at 77 K.

of this complex in dichloromethane, another spectroscopic method was adopted in view of the advantageous property of Cob(II)ester · I in dichloromethane as being paramagnetic.

The ESR spectrum of Cob(II)ester · I in toluene at 77 K is shown in Fig. 3. Spin Hamiltonian parameters for the complex are as follows; $g_{\parallel}=2.00$, $g_{\perp}=2.36$, $A_{\parallel}^{Co}=11.1\times10^{-3}\,cm^{-1}$, and $A_{\parallel}^{I}=14.3\times10^{-3}\,cm^{-1}$. The superhyperfine structure observed in the $g_{\parallel}$ region is apparently due to the interaction between the iodine nucleus ($I=5/2$) and the cobalt nucleus ($I=7/2$). This indicates that one iodide ion is coordinated to the central cobalt at one of the axial positions of the latter. The spin Hamiltonian parameters thus evaluated are comparable to those for the same complex as measured by the Q-band ESR spectroscopy at 120 K in toluene; $g_{\parallel}=2.003$, $g_{\perp}=2.263$, $A_{\parallel}^{Co}=11.2\times10^{-3}\,cm^{-1}$, $A_{\parallel}^{I}=14.0\times10^{-3}\,cm^{-1}$, $A_{\perp}^{Co}\approx0$, and $A_{\perp}^{I}\approx0$.[20] An ESR signal due to forbidden transition, being characteristic of a dinuclear cobalt complex, was not observed for a wide scanning range of magnetic field. Consequently, the present complex is not associated with the interaction between cobalt-iodide-cobalt in dichloromethane. The ESR spectrum of Cob(II)ester · I measured in methanol at 77 K did not show such superhyperfine structure as caused by the interaction between the iodine and cobalt nuclei, but showed a spectral feature identical with that observed for [Cob(II)ester]ClO_4.[14] This again serves to confirm that the iodide ion is not coordinated to the cobalt atom at its axial position.

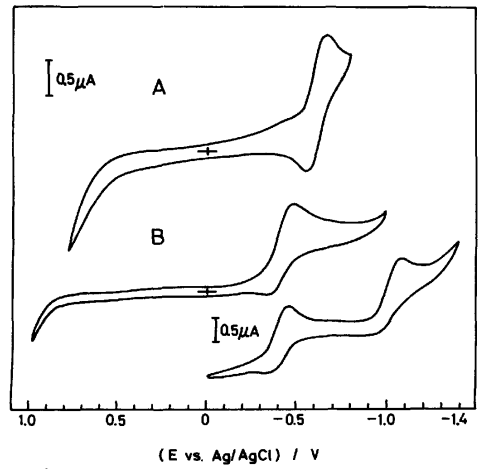

Fig. 4. Cyclic voltammograms of [Cob(II)ester]ClO_4 (5.0×10^{-4} mol dm^{-3}) containing 5.0×10^{-2} mol dm^{-3} TBAP in methanol (A) and dichloromethane (B) at 20±2 °C: scan rate, 100 mV s^{-1}.

Cob(II)ester · I in methanol was readily converted into [Cob(II)ester]ClO_4 by ion-exchange chromatography on a column of Amberlite IRA-401. This result also indicates that the iodide ion is acting only as a counteranion in methanol.

The molecular weight of Cob(II)ester · I was determined in benzene by vapor pressure osmometry: 1120±70; calcd for Cob(II)ester · I as monomer, 1164. This result further serves to confirm that Cob(II)ester · I is not dimeric but monomeric in apolar solvents.

In summarizing the above results, the coordination geometry around the nuclear cobalt of Cob(II)ester · I is subjected to change by the nature of solvents employed. In polar solvents such as methanol, the complex assumes a distorted square-planar geometry around the cobalt atom and the anion of weak coordination ability, iodide, simply acts as a counterion species even though solvent molecules would possibly occupy the axial positions of cobalt. In apolar solvents such as dichloromethane, benzene, and toluene, however, the complex assumes a square-pyramidal geometry around the nuclear cobalt having coordination number 5, the iodide ion being coordinated to the cobalt atom at its axial position, and exists as a mononuclear species in solution. Such coordination structures are closely correlated with the redox behavior of the complex as described below.

Electrochemical Behavior of Cob(II)ester Species. Cyclic voltammograms of [Cob(II)ester]ClO_4 and Cob(II)ester · I in methanol and dichloromethane are shown in Figs. 4 and 5. The Co(II)/Co(I) redox couple for [Cob(II)ester]ClO_4 is observed at −0.61 V *vs.* Ag/AgCl (−0.65 V *vs.* SCE) in methanol and at −0.41 V *vs.* Ag/AgCl (−0.45 V *vs.* SCE) in dichloromethane. The redox reversibility observed with [Cob(II)ester]ClO_4 and

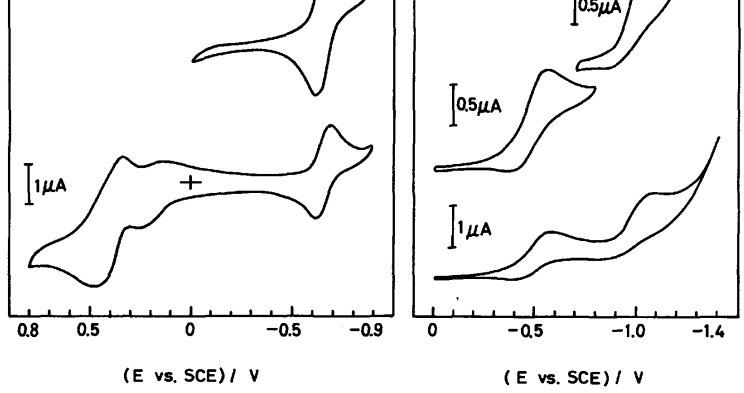

Fig. 5. Cyclic voltammograms of Cob(II)ester · I (7.0×10^{-4} mol dm^{-3}) containing 5.0×10^{-2} mol dm^{-3} TBAI in methanol (A) and dichloromethane (B) at 20±2 °C: scan rate, 100 mV s^{-1}.

Cob(II)ester·I in dichloromethane is less satisfactory as compared with that in methanol on the basis of relative potential peak intensities between the cathodic and anodic peaks; the redox process was irreversible in dichloromethane even at the scan rate as fast as 500 mV s^{-1} and the anodic peak disappeared at the slowest extreme. This is attributed to the fact that Cob(I)ester formed by electrochemical reduction undergoes reaction with dichloromethane to yield the corresponding alkylated complex [ClH_2C-Cob(III)ester] as confirmed independently by a preparative experiment. Scanning further to the cathodic side showed a one-electron reduction peak at −1.07 V *vs.* Ag/AgCl (−1.11 V *vs.* SCE). This reduction peak seems to be attributed to the alkyl complex derived from the reaction of Cob(I)ester with dichloromethane, ClH_2C-Cob(III)ester, in the light of the first reduction potential for [CH_3-Cob(III)ester]ClO_4 in dichloromethane (−1.23 V *vs.* SCE). The Co(III)/Co(II) redox peak was not observed under the above experimental conditions.

The cyclic voltammograms of Cob(II)ester·I in the presence of TBAI as a supporting electrolyte show redox peaks due to the iodide ion in the positive potential range (Fig. 5). The Co(II)/Co(I) redox peak for Cob(II)ester·I is observed at −0.65 V *vs.* SCE in methanol; comparable to that for [Cob(II)ester]ClO_4 in methanol. However, the same redox peak is observed at −0.52 V *vs.* SCE in dichloromethane; shifted by 70 mV to the cathodic side relative to the potential peak for [Cob(II)ester]ClO_4. Since the iodide ion acts as an axial ligand in dichloromethane, the reduction of Cob(II)ester·I requires greater cathodic potential relative to that of [Cob(II)ester]ClO_4. The Co(II)/Co(I) redox peak exhibits some anodic shift in dichloromethane relative to that in methanol even though the liquid junction potential difference between the two solvent systems is taken into consideration as described below. It is reasonable to expect that Cob(II)ester is more readily reduced in dichloromethane since this solvent is of noncoordinating nature and Cob(I)ester without charge on it is stabilized in highly apolar solvents.

Redox Potentials of [Cob(II)ester]ClO_4 in Various Solvents. The Co(II)/Co(I) and Co(III)/Co(II) redox potentials for [Cob(II)ester]ClO_4 in various organic solvents are summarized in Table 1. Cyclic voltammograms of the complex in dimethyl sulfoxide (DMSO) are shown in Fig. 6 as a typical example. The ratios between anodic and cathodic peak currents, i_{pa}/i_{pc}, were unity and independent of scan rate (from 10 to 200 mV s^{-1}) for the two redox couples in various organic solvents except dichloromethane. Plots of i_p ($=i_{pa}+i_{pc}$) *vs.* $v^{1/2}$(v for scan rate, mV s^{-1}) were linear, and potential separation between the anodic and cathodic peaks varied from 160 to 80 mV for the two redox couples, while $E_{1/2}$ values remained constant within an accuracy of ±3% regardless of scan rate variation. Thus, the present electrochemical redox reactions in various organic media except dichloromethane are consistent with reversible or quasi-reversible one-electron transfer processes.[21] In order to identify the complex species formed during each redox process, the controlled-potential electrolysis was performed at −1.20 and 0.80 V *vs.* SCE. The electrochemical reduction at −1.20 V *vs.* SCE was followed by electronic spectroscopy as shown in Fig. 7, where clear isosbestic points are observed at 308, 355, 417, and 547 nm. Since the developing absorption maximum at 394 nm during the reduction process is characteristic of Cob(I)ester, the redox potential at −0.64 V *vs.* SCE in DMSO is

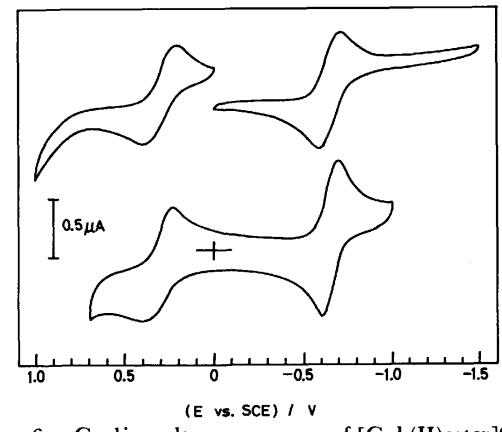

Fig. 6. Cyclic voltammograms of [Cob(II)ester]ClO_4 (5.2×10^{-4} mol dm^{-3}) in dimethyl sulfoxide containing 5.1×10^{-2} mol dm^{-3} TBAP at 20±2 °C: scan rate, 100 mV s^{-1}.

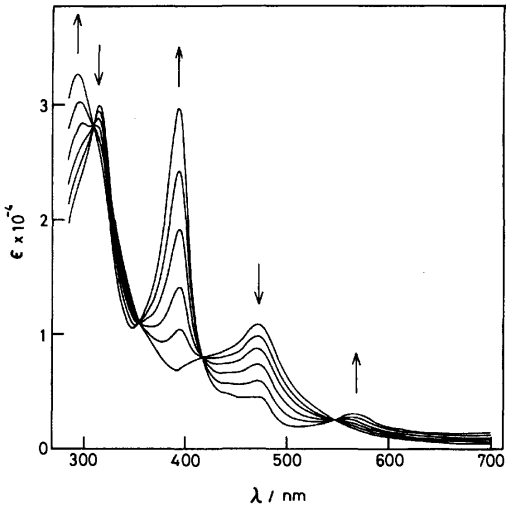

Fig. 7. Electrochemical reduction of [Cob(II)ester]ClO_4 (2.0×10^{-5} mol dm^{-3}) at −1.20 V *vs.* SCE in dimethyl sulfoxide containing 5.0×10^{-2} mol dm^{-3} TBAP at 20±2 °C: trends of spectral change with time are shown by arrows. About 80% of [Cob(II)ester]ClO_4 was reduced to Cob(I)ester after electrochemical reaction for 9 h.

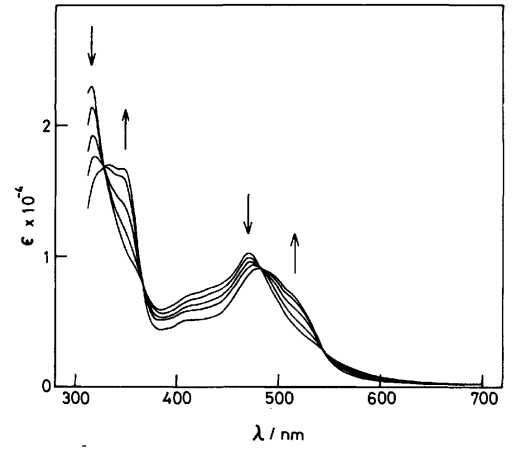

Fig. 8. Electrochemical oxidation of [Cob(II)ester]ClO_4 (2.0×10^{-5} mol dm^{-3}) at +0.80 V *vs.* SCE in dimethyl sulfoxide containing 5.0×10^{-2} mol dm^{-3} TBAP at 20±2 °C: trends of spectral change with time are shown by arrows. About 40% of [Cob(II)ester]$^+$ was oxidized to [Cob(III)ester]$^{2+}$ after electrochemical reaction for 3 h.

assigned to the Co(II)/Co(I) redox couple for the complex. Cob(I)ester thus produced was quantitatively reconverted into the original complex by oxidation at 0 V *vs.* SCE. The electronic spectral change during the electrochemical oxidation at 0.80 V *vs.* SCE in the same medium is shown in Fig. 8, and is accompanied with the increase in absorbance at 350, 490, and 520 nm. Since such absorption maxima are characteristic of Cob(III)ester, the redox potential at +0.30 V *vs.* SCE is assigned to the Co(III)/Co(II) redox couple.

Since the liquid junction potential is subjected to change by the nature of solvent system, the redox potentials observed in various solvents cannot be directly compared with each other among them. Though liquid junction potentials between electrolytic solutions in various solvents have been extensively investigated,[22] the most conventional and reliable means of eliminating the difference in liquid junction potential between various media is to adopt the observed redox potentials for the couple of ferrocene/ferricinium ion in various media as references. Because the true redox potential for the couple of ferrocene/ferricinium ion is considered to remain constant regardless of the nature of organic media,[23] the redox potentials corrected for the difference in liquid junction potential in the light of observed redox potentials for ferrocene/ferricinium ion are shown in Table 1. Gutmann investigated correlations between the half-wave potential of metal ion and the donor number of solvent (*DN*) for combination of various metal ions and solvents, and the half-wave potential for transition-metal ions was found to exhibit significant cathodic shift with the increase in solvent basicity (*DN*).[24] We claim here both polarity and basicity of solvents are primarily concerned with the redox potential after corrected for liquid junction potential. The solvent polarity is associated with the electrostatic stabilization of a metal complex; a polar solvent tends to favor the formation of a charged complex and such a solvent effect becomes more pronounced as the charge on a complex increases. On the other hand, the solvent basicity is concerned with the axial ligation behavior of solvent molecules; a sufficiently basic solvent tends to coordinate to the nuclear metal of a complex. Therefore, we discuss the Co(III)/Co(II) and Co(II)/Co(I) redox potentials for [Cob(II)ester]ClO_4 in correlation with both solvent polarity and basicity. Kosower's *Z*-value[25] and Gutmann's donor number (*DN*) are adopted here as polarity and basicity parameters, respectively. The correlations between the redox potential (Co(III)/Co(II) or Co(II)/Co(I)) and *DN* or *Z*-value are shown in Figs. 9 and 10. The Co(III)/Co(II) redox potential shows cathodic shift as the *DN* and *Z* parameters increase (Fig. 9); the higher the solvent basicity or polarity is, the more readily Cob(II)ester is oxidized. Such correlations are also observed for the Co(II)/Co(I) redox potential and level off beyond certain ranges of *DN* and *Z* parameters as shown in Fig. 10, but the extent of variation of the redox potential in various solvents is rather small as compared with that for the Co(III)/Co(II) couple. Since the overall charges on Cob(III)ester, Cob(II)ester, and Cob(I)ester are +2, +1, and 0, respectively, the tervalent cobalt complex is most stabilized in solvents of greater polarity. In addition, the tervalent cobalt in Cob(III)ester readily takes up the 5th and 6th ligand molecules at its axial sites while the univalent cobalt in Cob(I)ester has no tendency to interact with extra ligand molecules at its axial sites. Thus, the Co(III)/Co(II) redox potential is subjected to change by the variation of *DN* more effectively than the Co(II)/Co(I) couple. The correlations given in Figs. 9 and 10 apparently reflect such solvent effects. Similar solvent effects were observed on the Co(III)/Co(II) and Co(II)/Co(I) redox potentials for Co^{II}(tpp) (Table 1 and literature[26]). The Co(III)/Co(II) and Co(II)/Co(I) redox potentials for [Cob(II)ester]ClO_4 in various media appeared in the anodic side relative to the corresponding values for Co^{II}(tpp) as shown in Table 1. This must arise from the difference in ligand nature; the corrin and porphyrin

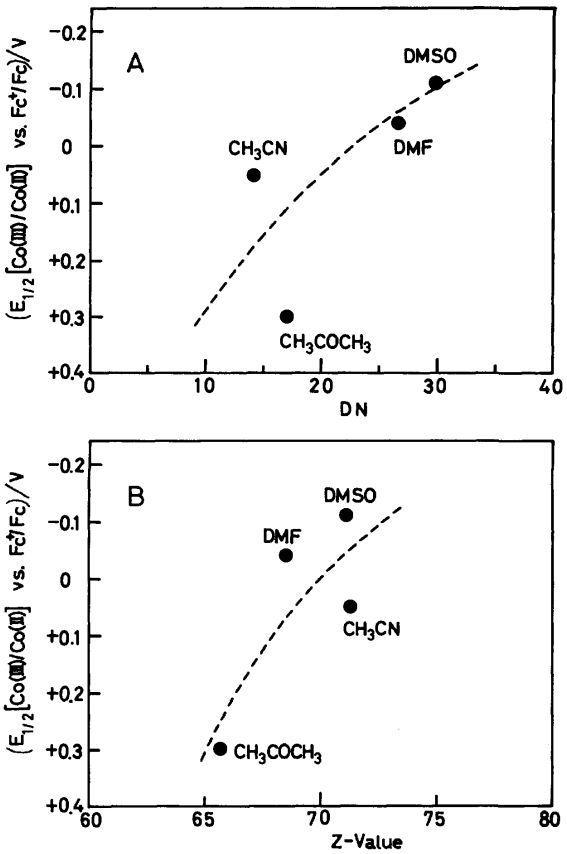

Fig. 9. Correlations of redox potential of [Cob(II)-ester]ClO_4 with solvent basicity and polarity: A, $E_{1/2}$[Co(III)/Co(II)] *vs. DN*; B, $E_{1/2}$[Co(III)/Co(II)] *vs. Z*-value.

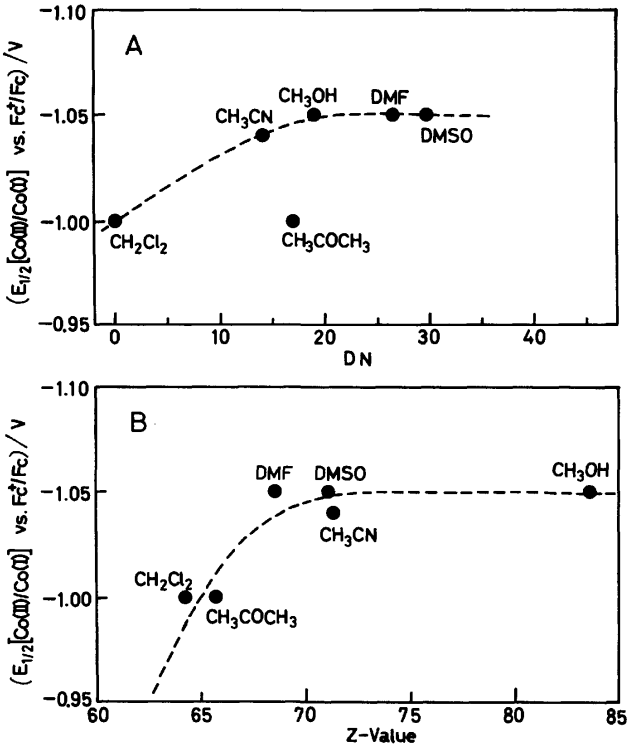

Fig. 10. Correlations of redox potential of [Cob(II)-ester]ClO_4 with solvent basicity and polarity: A, $E_{1/2}$[Co(II)/Co(I)] *vs. DN*; B, $E_{1/2}$[Co(II)/Co(I)] *vs. Z*-value.

ligands are mono- and dianionic, respectively, when coordinated to the cobalt ion. Thus, Co^{II}(tpp) is more readily oxidized and less readily reduced than Cob(II)ester. As reported in our previous paper,[14] the axial ligation behavior is subjected to change significantly by the nature of equatorial ligands, and the thermodynamic properties for the axial ligation of Cob(II)ester are much different from those observed for cobalt(II)-porphyrin. Such an equatorial ligand effect must be reflected on the redox behavior of cobalt.

The microenvironmental property effective on vitamin B_{12} in enzyme systems is considered to vary rather extensively by the nature of apoenzymes concerned. In the light of the present results, the redox behavior of the nuclear cobalt of vitamin B_{12} seems to be subjected to change from one enzyme to another depending upon the medium effects provided by the enzyme active sites. In particular, the Co(III)/Co(II) redox potential is sensitive to the nature of medium and the divalent cobalt state is more effectively stabilized in greater hydrophobic environments in the absence of coordinating ligands.

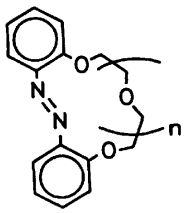
(Received September 1, 1983)

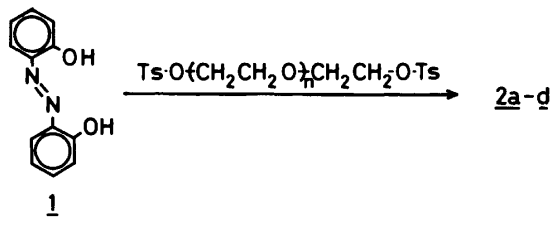
New crown ethers which have a benzeneazo group as a building block of a macrocyclic polyether ring. The complexation properties of these new azobenzo-crown ethers with alkali and alkaline earth metal iodide salts were investigated in acetonitrile solution spectrophotometrically. The complex formation constants were evaluated for alkali metal salts. The azo group is not particularly a favorable component of a crown ether macrocycle for stabilizing the metal complexes.

During the course of our investigation to develop the chromogenic crown ether reagents for the photometric determination of alkali and alkaline earth metal ions, a series of new crown ethers have been synthesized, in which 2,2′-positions of azobenzene were bridged by oligoethylene glycol to form a skeletal structure of crown ether. The crown ethers synthesized in this study are shown in structure **2**. They are conveniently named as azobenzo-crown ether or azobenzo-13-crown-4 for **2a** as an example, because the structure and hole size of **2a** is comparable with that of 13-crown-4 when azobenzene moiety takes trans-conformation.



2a n = 1
b n = 2
c n = 3
d n = 4

In our previous communication,[1] we reported the photoisomerization of azobenzo-crown ethers. The trans-isomer was more favorable for metal ion complexation. The complexation behavior of azobenzo-crown ethers was also evaluated semiquantitatively by the ion-pair extraction of metal complex with tetrabromophenolphthalein ethyl ester. Lithium was not extracted by any of these crown ethers, but sodium was extracted by **2a** preferentially over potassium. **2b** preferred the extraction of potassium. Recently, Shinkai, Manabe and co-workers described the 4,4′-(oligoethylene glycol-linked) azobenzene, which showed a marked photo-responsive metal extraction properties in relation to their trans-cis isomerization of azo linkage.[2]



1

Scheme 1.

As we have found that considerable spectral change was observed for these azobenzo-crown ethers upon complexation with metal ion in aprotic solvents such as acetonitrile, a detailed photometric investigation has been done to evaluate the interaction quantitatively.

Experimental

Synthesis of Azobenzo-crown Ethers. The synthetic reaction is shown below, and the procedure for azobenzo-13-crown-4 is described below as an example.

*Azobenzo-13-crown-4 (**2a**).* To a 200 ml round bottomed flask containing 1.0 g (4.7 mmol) of 2,2′-dihydroxyazobenzene (**1**)[3] was added 1.1 g (9.8 mmol) of potassium *t*-butoxide in 50 ml THF under a nitrogen atmosphere at room temperature, and the mixture was stirred for 30 min. To this mixture, 2.0 g (4.8 mmol) of diethylene glycol ditosylate was added dropwise in 1 h, and refluxed for 16 h. After cooling, the precipitate in the reaction mixture was filtered off, and the filtrate was evaporated under a reduced pressure. The residue was taken into chloroform, and washed with water. After evaporation, the residual mass was applied on a silica-gel column (WAKO-gel C-200, 20×100 mm), and eluted with benzene, followed by chloroform. The red colored fraction was collected, and evaporated to obtain crystalline mass, which was recrystallized from heptane. Yield 0.36 g (27%). Mp 69.5—71 °C. IR (KBr disk) 2920 (CH), 1590 cm^{-1} (N=N). ^1H NMR (δ ppm from TMS; $CDCl_3$); δ=3.8—4.0 (4H, m, $-CH_2OCH_2-$), 4.12—4.35 (4H, m, $ArOCH_2-$), 6.63—7.50 (8H, m, Ar-H). Ms (*m/z*); 284 (M^+). Found: C, 67.36; H, 5.82; N, 9.56%. Calcd for $C_{16}H_{16}N_2O_3$: C, 67.59; H, 5.67; N, 9.85%.

*Azobenzo-16-crown-5 (**2b**), -19-crown-6 (**2c**), and -22-crown-7 (**2d**).* The procedures were almost the same as that of **2a**, except for the use of tri-, tetra- and pentaethylene glycol ditosylates for **2b**, **2c**, and **2d**, respectively, in place of diethylene glycol ditopsylate.

2b. Yield 11% (red crystal). Mp 67.5—68.0 °C. IR (KBr disk) 2900 (CH), 1590 cm^{-1}(N=N). ^1H NMR ($CDCl_3$); δ=3.62—4.00 (8H, m, $-CH_2OCH_2-$), 4.10—4.32 (4H, m, $ArOCH_2-$), 6.71—7.75 (8H, m, Ar-H). MS (*m/z*); 328 (M^+). Found: C, 65.84; H, 6.18; N, 8.49%. Calcd for $C_{18}H_{20}N_2O_4$: C, 65.84; H, 6.04; N, 8.53%

2c. Yield 23% (red plates). Mp 111.0—113.5 °C. IR (KBr disk) 2960 (CH), 1580 cm^{-1} (N=N). ^1H NMR ($CDCl_3$); δ=3.32—3.95 (12H, m, $-CH_2OCH_2-$), 4.10—4.42 (4H, m, $ArOCH_2-$), 6.71—7.45 (8H, m, Ar-H). MS (*m/z*); 372 (M^+). Found: C, 64.52; H, 6.45; N, 7.53%. Calcd for $C_{20}H_{24}N_2O_5$: C, 64.50; H, 6.50; N, 7.52%.

2d. Yield 31% (red syrup). IR (neat) 2900 (CH), 1590 cm^{-1} (N=N). ^1H NMR ($CDCl_3$); δ=3.51—4.00 (16H, m,

-CH_2OCH_2-), 4.15—4.48 (4H, m, $ArOCH_2$-), 6.75—7.60 (8H, m, Ar-H). MS (*m/z*); 416 (M^+). Found: C, 63.45; H, 6.78; N, 6.73%. Calcd for $C_{22}H_{18}N_2O_6$: C, 64.21; H, 6.63; N, 7.35%.

Reagents. Other reagents were of analytical grade.

Apparatus. Absorption spectra were recorded using a Hitachi-556 double wavelength spectrophotometer. ^1H NMR and IR spectra were obtained by Hitachi R-24B ^1H NMR spectrometer and JASCO DS 403GR infrared spectrophotometer, respectively.

Measurement of Complex Formation Constants. To a 1.0×10^{-4} M (1 M=1 moldm^{-3}) acetonitrile solution of azobenzo-crown ether, various amount of alkali iodide, was added to give a final concentration of $(0—1.0)\times10^{-2}$ M, and the resulting spectral change was measured using a standard 1 cm quartz cell. The optical absorbances were treated in a standard manner, and the complexation constants were calculated according to the Marquardt's nonlinear least square method.[4]

Results and Discussion

Synthesis. The syntheses of azobezo-crown ethers proceeded in a usual manner[5] and proposed structures of azobenzo-crown ethers were fully supported by the elemental analyses and the spectral informations.

Spectral Change and Complexation Behavior. Absorption spectra of azobenzo-13-crown-4, -16-crown-5, -19-crown-6, and -22-crown-7 in acetonitrile in the absence and in the presence of metal iodide are shown in Figs. 1, 2, 3, and 4, respectively. Acetonitrile was chosen as a common solvent for azobenzo-crown ethers and metal iodides. Since no spectral change was observed in a system of 2,2′-dimethoxyazobenzene and metal iodide in acetonitrile under comparable reaction conditions, such spectral change was understood to be due to the complexation of metal ions with the crown ether rings.

It is seen from Figs. 1 and 2 that the spectral changes occurred mainly in the increase of absorption intensity, but not much in the shift of absorption maxi-

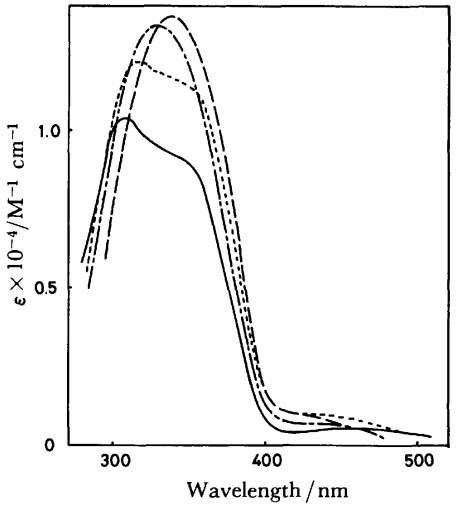


Fig. 1. Spectral change of azobenzo-13-crown-4 on the addition of metal salts. [L]=1×10^{-4} M, [MI]=1×10^{-3} M, [MI_2]=1×10^{-3} M, acetonitrile: ——, without salt; ----, LiI; ——, CaI_2; ——-, BaI_2.

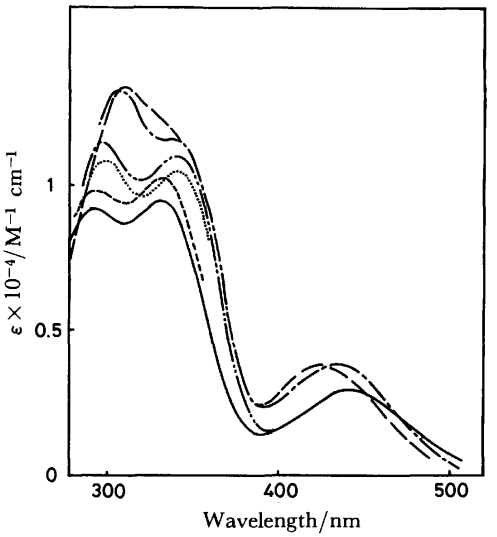

Fig. 3. Spectral change of azobenzo-19-crown-6 on the addition of metal salts. [L]=1×10^{-4} M, [MI]=1×10^{-3} M, [MI_2]=1×10^{-3} M, acetonitrile: ——, without salt; -----, LiI; —··—··—, NaI; ·····, KI; ——, CaI_2; ——, BaI_2.

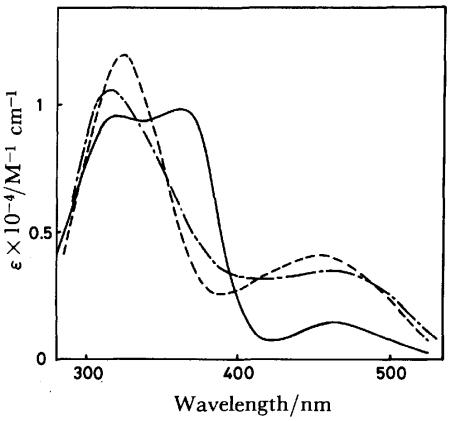

Fig. 4. Spectral change of azobenzo-22-crown-7 on the addition of metal salts. [L]=1×10^{-4} M, [MI]=1×10^{-3} M, acetonitrile: ——, without salt; ——, CaI_2; —·—·—, BaI_2.

mum. The change is more pronounced with divalent metal ions than with monovalent ions, indicating the importance of ion-dipole interaction between the metal and the chromophore group. Similar spectral changes have been also reported by Dix and Vögtle on monoaza-crown ethers with a pendent *p*-arylazophenyl group on the crown ether nitrogen.[6]

The extent of spectral changes depends on the nature of azobenzo-crown ethers and metal salts. It also depends on their concentrations. The association equilibrium constants of azobenzo-crown ethers with metal salts can be evaluated from these changes in absorption spectra. It should be recalled in the passing that the spectral shift widths on the rate of absorption enhancement can not be a measure of the energy of association between the crown ether and the metal salts. These may reflect the extent of interaction between the azo group and the metal, but not represent that between the crown ether entity and metal.

Spectrophotometrically, we have no way to differentiate metal ion (M^+) from metal iodide (MI), nor metal ion-crown ether complex (ML^+) from its iodide complex (MLI) in acetonitrile solution. Therefore the conditional association constant (K_{ML}) as defined by Eq. 1 was used to evaluate the extent of interaction between azobenzo-crown ether and metal iodide.

$$K_{ML}=\frac{[(MLI)_t]}{[L][(MI)_t]}, \quad (1)$$

where

$$[(MLI)_t]=[ML^+]+[MLI], \quad (2)$$

and

$$[(MI)_t]=[M^+]+[MI]. \quad (3)$$

The optical absorbance of the solution of this system can be expressed by Eq. 4,

$$A=\varepsilon_{MLI}[(MLI)_t]+\varepsilon_L[L], \quad (4)$$

where, ε_{MLI} and ε_L are molar absorption coefficients of metal complex and crown ether, respectively. The total concentrations of metal salt and crown ether are defined as follows:

$$C_M=[(MI)_t]+[(MLI)_t], \quad (5)$$

$$C_L=[L]+[(MLI)_t]. \quad (6)$$

By combining Eqs. 1—6, the mean molar absorption coefficient ε is derived as in Eq. 7.

$$\varepsilon = A/C_L = \{(\varepsilon_{MLI}-\varepsilon_L)((K_{ML}(C_M+C_L)+1) - \sqrt{(K_{ML}(C_M+C_L)+1)^2-4K_{ML}^2C_MC_L}\}/(2K_{ML}\cdot C_L) + \varepsilon_L. \quad (7)$$

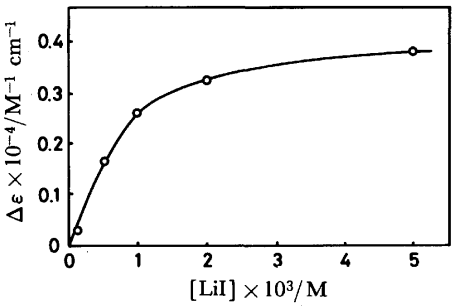

Fig. 5. Change of absorbance on the addition of lithium iodide to azobenzo-13-crown-4. 350 nm, [L]=1×10⁻³ M.

Experimentally, the value of $\varepsilon-\varepsilon_L$ ($\simeq\Delta\varepsilon$) is measured as a function of metal salt concentration as illustrated in Fig. 5. The values of K_{ML} and ε_{MLI} are then simultaneously determined from Eq. 7 by using Marquardt's non-linear least-squares method.

The constants obtained are summarized in Table 1. The spectral changes of **2a** on interaction with sodium iodide and potassium iodide and those of **2d** with alkali metal iodides were so small that the meaningful values of K_{ML} could not be obtained. As to the complexation with alkaline earth metal salts, the calculated values scattered and dependented on the wave lengths adopted for calculation. This indicates that the reactions can not be formulated in a simple manner as in Eqs. 1—6.

It is seen from the table that the association constant for lithium is highest with **2a** and decreases with increasing hole size of crown ether, indicating that (the trans form of) azobenzo-13-crown-4 (**2a**), whose hole size is approximately comparable with that of 12-crown-4, fits most well lithium ion. It is interesting to note that, among the alkali metal iodides investigated in this study, lithium ion forms about the most stable complexes with azobenzo-crown ethers, regardless of the hole size of crown ethers. Sodium then follows. This result does not agree with the generally accepted ion-cavity size fitness concept, suggesting that the energy of metal salt-crown ether interaction is primarily governed by a simple ion-dipole interaction (enthalpy contribution) rather than a macrocyclic encapsulating interaction (entropy contribution). The smallest lithium ion thus exercises the highest effective interaction with the crown ethers.

The complexation constants of **2b** and **2c** with sodium iodide or potassium iodide are unanimously lower than those of dibenzo-18-crown-6 (**3**) and "dicyclohexyl-18-crown-6" (**4**).[7] Even though **2c** has

almost the same hole size as **3**, the K_{ML} value of **2c** is 40 times lower than that of **3**. A relatively low complexation ability of azobenzo-crown ethers as compared with normal crown ethers has been previously noticed.[1] The conformational structure of azobenzo-crown ether is suggested from CPK model considerations to be slightly distorted and disordered from that of standard crown ethers, and it is likely that the azo group does not contribute much to the stabilization of complexes. In the case of the azobenzo-crown ether having larger ether ring such as **2c** and **2d**, metal ion should be readily accomodated in the crown ether ring, but the spectral change upon metal complexation is less than that of **2a** and **2b**.

Dix and Vögtle synthesized a variety of crown ether dyes and described the spectral change upon interaction with metal salts in acetonitrile.[6] Some of the crown ethers showed a drastic spectral shift as large as 100 nm. Unfortunately, they did not treat the data in terms of the association equilibrium constants; however, the spectral pictures they showed suggest that the association constants are in the similar order of magnitude to the present study.

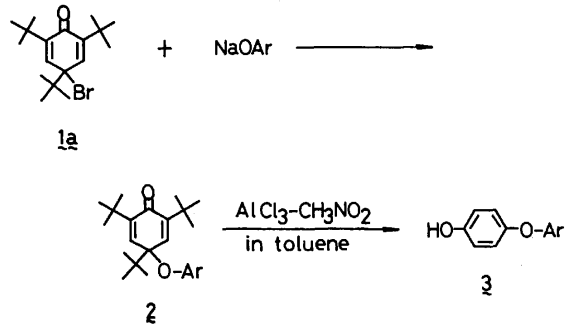
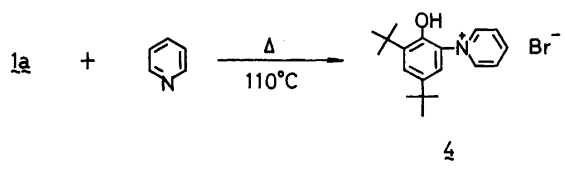
(Received March 3, 1983)

Reaction of 4-halocyclohexadienones such as 4-bromo-(**1a**), 4-chloro-2,4,6-tri-*t*-butyl-(**1b**), 2,4-dichloro-4,6-di-*t*-butyl-2,5-cyclohexadien-1-one, and 2,4-dichloro-2,6-di-*t*-butyl-3,5-cyclohexadien-1-one with phenols in the presence of α-picoline was carried out under various conditions. The reaction of **1a** and **1b** with phenols afforded the corresponding 2-aryloxy-4,6-di-*t*-butyl phenols together with various by-products. The $AlCl_3$-catalyzed *trans*-*t*-butylation of 2-aroxy-4,6-di-*t*-butyl-phenols, which were obtained by the above reaction, afforded the corresponding 2-hydroxyphenyl aryl ethers. The similar reaction of 4-aroxy-2,4,6-tri-*t*-butyl-2,5-cyclohexadien-1-ones also afforded the corresponding 4-hydroxyphenyl aryl ethers.

It has been previously reported that[2] 4-bromo-2,4,6-tri-*t*-butyl-2,5-cyclohexadien-1-one (**1a**) reacted with sodium phenoxides to give 4-phenoxy dienones (**2**), which were easily converted to the corresponding 4-hydroxyphenyl aryl ethers (**3a**) by treatment with $AlCl_3$-CH_3NO_2 catalyst in toluene.



Reaction of **1a** with pyridine at 110 °C afforded *N*-(2-hydroxyphenyl)pyridinium bromide (**4**), but α-picoline did not react with **1a**.[3]



These results suggest that the reaction of **1a** with phenols at 110 °C might afford the corresponding 2,4-di-*t*-butyl-6-aryloxyphenols which would be suitable for the preparation of 2-hydroxyphenyl aryl ethers.

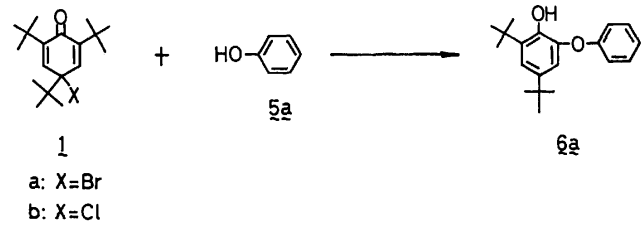
Results and Discussion

Reaction of Halocyclohexadienones with Phenols. Reaction of 4-bromo-(**1a**) and 4-chloro-2,4,6-tri-*t*-butyl-2,5-cyclohexadien-1-one (**1b**) with phenol (**5a**) was carried out at 110 °C under various conditions. The results are summarized in Table 1 and Scheme 1.

TABLE 1. REACTION OF 4-HALOCYCLOHEXADIENONES (**1a—b**) WITH PHENOL (**5a**) IN THE PRESENCE OF BASE[a)]

Run	Dienone	Base	Time/h	**6a** (%)
1	**1a**	α-Picoline	2	15
2	**1b**	α-Picoline	2	24
3	**1b**	α-Picoline	8	18
4	**1b**	2,6-Lutidine	2	23

a) A stirred mixture of **1** and **5a**, and base (molar ratio= 1:2:2) was heated at 110 °C (bath temperature). b) Isolated yields are shown.



Scheme 1.

The data of the Table 1 show that reaction of **1a** with **5a** in the presence of α-picoline afforded the expected 2,4-di-*t*-butyl-6-phenoxyphenol (**6a**) in 15% yield together with by-products shown in following Scheme 2.

Compound **1b** gave the same product **6a** in higher yield than that of **1a**. Even under prolonged reaction time, **6a** was obtained in only 18% yield. It was also found that 2,6-lutidine afforded the same yield of **6a** as that of α-picoline though the former has a higher basicity than the latter.

The results of the reaction of **1b** with several phenols in the presence of α-picoline are summarized in Table 2 and Scheme 2.

The data of Table 2 show that **5b—o** as well as **5a** gave the expected **6b—o** together with by-products such as **8—12** respectively. It was also found that the phenols having ortho substituents afforded poor yields of **6**. It should be noted that the reactions with phenols **5k—o** having nitro, cyano, formyl, and acetyl

10	**5j**	*p*-$CO_2C_2H_5$	**6j** (36), **8** (7), **9** (33), **10** (+)
11	**5k**	*p*-NO_2	**6k** (21), **7a** (16), **8** (6), **9** (21), **10** (5)
12	**5l**	*m*-NO_2	**6l** (28), **7b** (15), **8** (8), **9** (19), **10** (9)
13	**5m**	*p*-CN	**6m** (28), **7c** (12), **8** (7), **9** (31), **10** (9)
14	**5n**	*p*-CHO	**6n** (18), **7d** (6), **8** (16), **9** (11), **10** (2)
15	**5o**	*p*-$COCH_3$	**6o** (12), **7e** (9), **8** (10), **9** (20), **10** (5)

a) Reaction time: 2 h, molar ratio of **1b**, **5**, and α-picoline is 1:2:2. b) Isolated yields are shown.

group afforded besides the corresponding **6**, cyclohexadienone derivatives **7a—e**, which could not be obtained by the reported method[2] described above.

The yields of by-products such as **8** and **9** increased with decrease in the yield of **6**. However, the reason for the above phenomena is still not clear.

Reactions of **1c** and **1d** with **5a** and **5k** were carried out under similar conditions (Scheme 3). However, the expected compounds such as **13, 14, 16,** and **19** were not formed in any case. Formation of **6a** from **1c** and **20** from **1d** might suggest that the chloro substituents of **1c** and **1d** migrated and then reacted with the phenols. However, the detailed reaction pathways of the formation of these compounds are still obscure.

trans-t-*Butylation.* The $AlCl_3$-catalyzed *trans-t*-butylation of **6** was carried out in order to obtain the corresponding 2-hydroxyphenyl aryl ethers. The results are summarized in Table 3 and Scheme 4.

When **6a** was treated with $AlCl_3$-CH_3NO_2 catalyst in toluene at 80 °C for 30 min, a mixture of **21a** and **22a** was obtained together with **23**. However, similar reaction of **6h** or **6k** afforded selectively **21f** or **21h** in good yield. These results suggest that the *t*-butyl group ortho to the hydroxyl group of **6** might be more easily removed than that in the para position. The same phenomenon was previously observed in *trans-t*-butylation of 3,3′,5,5′-tetra-*t*-butylbiphenyl-2,2′-diol.[4]

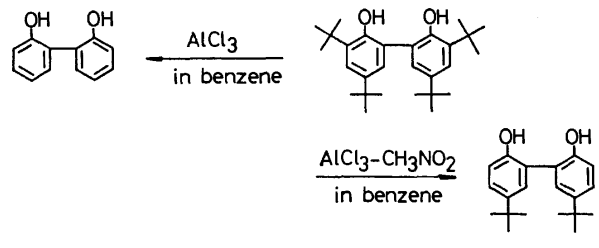

Table 3. *trans-t*-Butylation of **6** in toluene at 80 °C for 30 min[a]

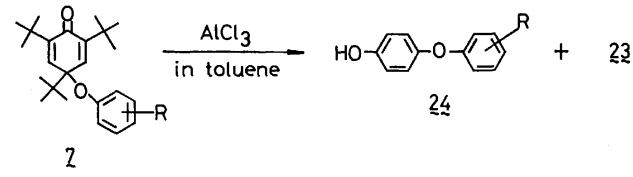
Run	6	Catalyst	Product (%)[b]
1	**6a**	$AlCl_3$-CH_3NO_2	**21a** (80), **22a** (20)[c]
2	**6a**	$AlCl_3$	**22a** (85)
3	**6c**	$AlCl_3$	**22b** (80)
4	**6e**	$AlCl_3$	**22c** (89)
5	**6f**	$AlCl_3$	**22d** (96)
6	**6g**	$AlCl_3$	**22e** (99)
7	**6h**	$AlCl_3$-CH_3NO_2	**21f** (80)
8	**6h**	$AlCl_3$	**22f** (78)
9	**6j**	$AlCl_3$	**22g** (87)
10	**6k**	$AlCl_3$-CH_3NO_2	**21h** (69)
11	**6k**	$AlCl_3$	**22h** (52)
12	**6m**	$AlCl_3$	**22i** (91)
13	**6n**	$AlCl_3$	**22j** (61)
14	**6o**	$AlCl_3$	**22k** (97)

a) A mixture of 1 mmol of **6** and 2.2 mmol of $AlCl_3$ in 20 ml of toluene was heated. b) Isolated yields are shown. c) The yields shown were obtained by GC analysis.

The $AlCl_3$-catalyzed *trans-t*-butylation of **6** afforded only the expected **21** in good yields in all cases. Compound **23** was formed in all cases.

The $AlCl_3$-catalyzed *trans-t*-butylation of **7** was also carried out in order to obtain the corresponding 4-hydroxyphenyl aryl ethers (**24**). The results are summarized in the Scheme 5.



a: R=p-NO_2 86% d: R=p-CHO 68%
b: R=m-NO_2 68% e: R=p-$COCH_3$ 91%
c: R=p-CN 97%

Scheme 5.

The desired products **24a—e** were obtained together with **23** in good yields.

Experimental

All melting points are uncorrected. NMR spectra were determined at 100 MHz with a JEOL FT-100 NMR spectrometer with Me_4Si as an internal reference, and IR spectra were measured as KBr pellets or as liquid films on NaCl plates in a JASCO IR-A-102 spectrometer. Mass spectra were obtained on a JEOL JMS-OISA-2 spectrometer at 75 eV by using a direct inlet system.

Materials. Compounds **1a**,[5] **1b**,[5] **1c**, and **1d** were obtained according to Person's procedure.[5] **1c**: Mp 77—79 °C, **1d**: Mp 56—59 °C.

Reaction of Halocyclohexadienones (1) with Phenols (5). General Procedure: After a stirred mixture of **1** (2.5 mmol), **5** (50 mmol), and 0.5 ml of α-picoline was heated on an oil bath (110 °C) for specified reaction time under a stream of nitrogen gas, 50 ml of benzene was added. The benzene solution was washed with 10% hydrochloric acid (10

ml×2), 2.5% NaOH solution (20 ml×2) and water (20 ml), dried with Na_2SO_4 and evaporated *in vacuo* to leave a residue which was chromatographed on silica gel using hexane and a mixture of hexane and benzene as eluents to give the products shown in Tables 1 and 2, and Scheme 3. The melting points, elemental analyses, and spectral data of the products are summarized below.

6a: Colorless prisms (MeOH-H_2O), mp 38.5—40 °C; ^{1}H-NMR ($CDCl_3$); δ=1.22, 1.43 (each s, 9H), 5.67 (s, 1H, disappeared with D_2O), 6.78 (d, J=2.3 Hz, 1H), and 6.86—7.38 (m, 6H); Mass m/z 298 (M^+). Found: C, 80.41; H, 8.88%. Calcd for $C_{20}H_{26}O_2$: C, 80.50; H, 8.78%.

6h: Colorless needles (MeOH), mp 110.5—111 °C; ^{1}H-NMR ($CDCl_3$); δ=1.22, 1.42 (each s, 9H), 5.60 (1H, s, disappeared with D_2O), 6.74, 7.05 (each d, J=2.5 Hz, 1H), and 6.85, 7.38 (each d, J=9.0 Hz, 1H); Mass m/z 378 (M^+), 376 (M^+). Found: C, 63.63; H, 6.71%. Calcd for $C_{20}H_{25}BrO_2$: C, 63.66; H, 6.68%.

6i: Colorless needles (MeOH-H_2O), mp 93—94.5 °C; ^{1}H-NMR ($CDCl_3$); δ=1.22, 1.43 (each s, 9H), 5.72 (s, 1H, disappeared with D_2O), 6.75 (d, J=2.3 Hz, 1H), and 6.84—7.38 (m, 10H); Mass m/z 390 (M^+). Found: C, 79.84; H, 7.84%. Calcd for $C_{26}H_{30}O_3$: C, 79.97; H, 7.74%.

6j: Colorless prisms (MeOH-H_2O), mp 100—101 °C; ^{1}H-NMR ($CDCl_3$); δ=1.24, 1.43 (each s, 9H), 1.34 (t, J=7.0 Hz, 3H), 4.32 (q, J=7.0 Hz, 2H) 5.62 (s, 1H, disappeared with D_2O), 6.80, 7.10 (each d, J=2.0 Hz, 1H), and 6.97, 7.97 (each d, J=9.0 Hz, 2H); Mass m/z 370 (M^+). Found: C, 74.77; H, 8.23%. Calcd for $C_{23}H_{30}O_4$: C, 74.56; H, 8.16%.

6k: Pale yellow prisms (hexane), mp 126—127.5 °C; ^{1}H-NMR ($CDCl_3$); δ=1.25, 1.43 (each s, 9H), 5.41 (s, 1H, disappeared with D_2O), 6.82, 7.15 (each d, J=2.1 Hz, 1H), and 7.02, 8.17 (each d, J=9.0 Hz, 2H); Mass m/z 343 (M^+). Found: C, 70.22; H, 7.36; N, 4.26%. Calcd for $C_{20}H_{25}NO_4$: C, 69.95; H, 7.34; N, 4.08%.

6l: Colorless plates (MeOH-H_2O), mp 95.5—96.5 °C; ^{1}H-NMR ($CDCl_3$); δ=1.23, 1.41 (each s, 9H), 5.50 (s, 1H, disappeared with D_2O), 6.78 (d, J=2.2 Hz, 1H), 7.11 (d, J=2.2 Hz, 1H), 7.19—7.32 (m, 1H), 7.44 (t, J=8.0 Hz, 1H), and 7.76—7.97 (m, 1H); Mass m/z 343 (M^+). Found: C, 70.08; H, 7.32; N, 4.28%. Calcd for $C_{20}H_{25}NO_4$: C, 69.95; H, 7.34; N, 4.08%.

6m: Colorless prisms (hexane), mp 169—171 °C; IR (KBr) ν_{OH} 3450 and ν_{CN} 2210 cm^{-1}; ^{1}H-NMR ($CDCl_3$); δ=1.24, 1.42 (each s, 9H), 5.44 (s, 1H, disappeared with D_2O), 6.79, 7.13 (each d, J=2.5 Hz, 1H), and 7.00, 7.57 (each d, J=9.0 Hz, 2H); Mass m/z 323 (M^+). Found: C, 78.09; H, 7.82; N, 4.60%. Calcd for $C_{21}H_{25}NO_2$: C, 77.99; H, 7.79; N, 4.33%.

6n: Colorless prisms (hexane), mp 131—133 °C; IR (KBr) ν_{OH} 3410 and ν_{CO} 1658 cm^{-1}; ^{1}H-NMR ($CDCl_3$); δ=1.25, 1.44 (each s, 9H), 5.52 (s, 1H, disappeared with D_2O), 6.83, 7.12 (each d, J=2.2 Hz, 1H), 7.06, 7.83 (each d, J=8.8 Hz, 2H), and 9.87 (s, 1H); Mass m/z 326 (M^+). Found: C, 77.65; H, 8.02%. Calcd for $C_{21}H_{26}O_3$: C, 77.27; H, 8.06%.

6o: Colorless needles (hexane), mp 135—136 °C; IR (KBr) ν_{OH} 3400 and ν_{CO}1658 cm^{-1}; ^{1}H-NMR ($CDCl_3$); δ=1.23, 1.42 (each s, 9H), 2.54 (s, 3H), 5.54 (s, 1H, disappeared with D_2O), 6.80, 7.10 (each d, J=2.2 Hz, 1H), and 6.97, 7.89 (each d, J=8.8 Hz, 2H); Mass m/z 340 (M^+). Found: C, 77.83; H, 8.37%. Calcd for $C_{22}H_{30}O_3$: C, 77.61; H, 8.29%.

7a: Pale yellow prisms (MeOH), mp 140.5—142 °C; IR (KBr) $\nu_{C=O}$ 1660 and 1640 cm^{-1}; ^{1}H-NMR ($CDCl_3$); δ=1.06 (s, 9H), 1.21 (s, 18H), 6.40 (s, 2H), and 6.89, 8.03 (each d, J=9.0 Hz, 2H); Mass m/z 399 (M^+). Found: C, 72.17; H, 8.30; N, 3.38%. Calcd for $C_{24}H_{33}NO_4$: C, 72.15; H, 8.32; N, 3.32%.

7b: Pale yellow prisms (MeOH-H_2O), mp 102—103 °C; IR (KBr) $\nu_{C=O}$ 1660 and 1640 cm^{-1}; ^{1}H-NMR ($CDCl_3$); δ=1.05 (s, 9H), 1.19 (s, 18H), 6.60 (s, 2H), 7.08—7.37 (m, 2H), and 7.65—7.80 (m, 2H); Mass m/z 399 (M^+). Found: C, 72.34; H, 8.34; N, 3.36%. Calcd for $C_{24}H_{33}NO_4$: C, 72.15; H, 8.32; N, 3.15%.

7c: Colorless prisms (MeOH-H_2O), mp 152.5—154 °C; IR (KBr) $\nu_{C=O}$ 1658, 1638 and ν_{CN} 2220 cm^{-1}; ^{1}H-NMR ($CDCl_3$); δ=1.04 (s, 9H), 1.20 (s, 18H), 6.60 (s, 2H), and 6.87, 7.41 (each d, J=9.0 Hz, 2H); Mass m/z 380 (M^++1). Found: C, 79.02; H, 8.78; N, 4.30%. Calcd for $C_{25}H_{33}NO_2$: C, 79.12; H, 8.78; N, 3.69%.

7d: Pale yellow prisms (MeOH-H_2O), mp 109.5—111 °C; IR (KBr) $\nu_{C=O}$ 1690, 1658 and 1638 cm^{-1}; ^{1}H-NMR ($CDCl_3$); δ=1.07 (s, 9H), 1.22 (s, 18H), 6.64 (s, 2H), 6.94, 7.67 (each d, J=9.0 Hz, 2H), and 9.79 (s, 1H); Mass m/z 383 (M^++1). Found: C, 78.52; H, 8.90%. Calcd for $C_{25}H_{34}O_3$: C, 78.49; H, 8.96%.

7e: Colorless prisms (MeOH-H_2O), mp 113—113.5 °C; IR (KBr) $\nu_{C=O}$ 1680, 1660 and 1640 cm^{-1}; ^{1}H-NMR ($CDCl_3$); δ=1.05 (s, 9H), 1.21 (s, 18H), 2.11 (s, 3H), 6.64 (s, 2H), and 6.86, 7.74 (each d, J=9.0 Hz, 2H); Mass m/z 394 (M^+). Found: C, 78.52; H, 9.01%. Calcd for $C_{26}H_{36}O_3$: C, 78.74; H, 9.15%.

20: Pale yellow prisms (MeOH-H_2O), mp 126—127.5 °C; ^{1}H-NMR ($CDCl_3$); δ=1.42 (s, 18H), 5.13 (s, 1H, disappeared with D_2O), 6.91, 8.15 (each d, J=9.5 Hz, 2H), and 7.22 (s, 2H); Mass m/z 343 (M^+). Found: C, 70.10; H, 7.56; N, 4.18%. Calcd for $C_{20}H_{25}NO_4$: C, 69.95; H, 7.33; N, 4.08%.

As the other products such as **7**,[6] **8**,[7] **9**,[8] **10**,[9] **11**,[10] **12**,[11] **13**,[12] and **14**[13] which were obtained in the reaction described above are known compounds, their identification was carried out by comparison with authentic spectral data.

The $AlCl_3$-CH_3NO_2 Catalyzed trans-t-*Butylation. Typical Procedure*: To a stirred solution of 343 mg of **6k** in 20 ml of toluene was added a solution of 300 mg of $AlCl_3$ in 10 ml of nitromethane at room temperature. After the reaction mixture was heated at 80 °C for 1 h, it was poured into 50 ml of ice-water and extracted with benzene (20 ml×3). The benzene solution was dried with sodium sulfate and evaporated *in vacuo* to leave a residue which was chromatographed on silica gel using benzene as an eluent to give **23** and 200 mg (69%) of **21h**. Compound **21f** was also obtained in 80% yield

by this method. However, the case of **6a** afforded a mixture of **21a** and **22a** which could not be separated by the usual methods.

21f: Colorless needles (MeOH-H_2O), mp 85.5—87 °C ; ^{1}H-NMR ($CDCl_3$); δ=1.22 (s, 9H), 4.72 (s, 1H, disappeared with D_2O), 6.68—7.12 (m, 5H), and 7.38 (d, J=9.0 Hz, 2H), Mass m/z 322 (M^+), 320 (M^+). Found: C, 59.71; H, 5.18%. Calcd for $C_{14}H_{17}BrO_2$: C, 59.83; H, 5.33%.

21h: Colorless needles (hexane), mp 95.5—97 °C;^{1}H-NMR ($CDCl_3$); δ=1.25 (s, 9H), 5.14 (s, 1H, disappeared with D_2O), 6.80—7.15 (m, 5H) and 8.16 (d, J=9.2 Hz, 2H); Mass m/z 287 (M^+). Found: C, 66.62; H, 5.96; N, 4.88%. Calcd for $C_{16}H_{17}NO_3$: C, 66.89; H, 5.96; N, 5.08%.

The $AlCl_3$ Catalyzed trans-t-*Butylation. General Procedure*: After a mixture of 10 mmol of **6** or **7**, 30 mmol of $AlCl_3$ and 100 mmol of toluene was heated at 80 °C for 30 min, it was treated and worked up as described above to give the products shown in Table 3.

22a: Colorless granules (hexane), mp 100.5—103 °C; ^{1}H-NMR ($CDCl_3$); δ=5.54 (s, 1H, disappeared with D_2O), and 6.70—7.41 (m, 9H); Mass m/z 186 (M^+). Found: C, 76.93; H, 5.58%. Calcd for $C_{12}H_{10}O_2$: C, 77.40; H, 5.41%.

22b: Colorless needles (hexane), mp 61.5—62 °C; ^{1}H-NMR ($CDCl_3$); δ=2.51 (s, 3H), 5.58 (s, 1H, disappeared with D_2O), and 6.62—7.22 (m, 8H). Found: C, 77.12; H, 6.23%. Calcd for $C_{13}H_{12}O_2$: C, 77.10; H, 6.00%.

22c: Colorless prisms (hexane), mp 77—78 °C; ^{1}H-NMR ($CDCl_3$); δ=5.50 (s, 1H, disappeared with D_2O), and 6.68—7.06 (m, 8H); Mass m/z 204 (M^+). Found: C, 70.60; H, 4.54%. Calcd for $C_{12}H_9FO_2$: C, 70.58; H, 4.44%.

22d: Colorless crystals, mp 46.5—48 °C; ^{1}H-NMR ($CDCl_3$); δ=5.64 (s, 1H, disappeared with D_2O), and 6.64—7.52 (m, 8H); Mass m/z 222 (M^+) 220 (M^+). Found: C, 65.61; H, 4.18%. Calcd for $C_{12}H_9ClO_2$: C, 65.32; H, 4.11%.

22e: Colorless needles (hexane), mp 82—84 °C; ^{1}H-NMR ($CDCl_3$); δ=5.50 (s, 1H, disappeared with D_2O), 6.62—7.08 (m, 6H), and 7.28 (d, J=9.0 Hz, 2H); Mass m/z 222 (M^+), 220 (M^+). Found: C, 65.49; H, 4.19%. Calcd for $C_{12}H_9ClO_2$: C, 65.32; H, 4.11%.

22f: Colorless prisms (hexane), mp 58—59.5 °C; ^{1}H-NMR ($CDCl_3$); δ=5.68 (s, 1H, disappeared with D_2O), and 6.46—7.50 (m, 8H); Mass m/z 266 (M^+), 264 (M^+). Found: C, 54.40; H, 3.63%. Calcd for $C_{12}H_9BrO_2$: C, 54.37; H, 3.42%.

22g: Colorless needles (hexane), 95.5—97 °C; IR (KBr) $\nu_{C=O}$ 1695 cm^{-1}; ^{1}H-NMR ($CDCl_3$); δ=1.37 (t, J=7.0 Hz, 3H), 4.33 (d, J=7.0 Hz, 3H), 5.59 (s, 1H, disappeared with D_2O), 6.62—7.13 (m, 6H), and 7.96 (d, J=9.0 Hz, 2H), Mass m/z 258 (M^+). Found: C, 69.87; H, 5.27%. Calcd for $C_{15}H_{14}O_4$: C, 69.75; H, 5.46%.

22h: Colorless needles (benzene-hexane), mp 111—112 °C; ^{1}H-NMR ($CDCl_3$); δ=5.32 (s, 1H, disappeared with D_2O), 6.76—7.25 (m, 6H), and 8.19 (d, J=9.5 Hz, 2H); Mass m/z 231 (M^+). Found: C, 62.33; H, 3.98; N, 6.23%. Calcd for $C_{12}H_9NO_4$: C, 62.34; H, 3.92; N, 6.06%.

22i: Colorless needles (benzene-hexane), mp 104—105 °C; IR (KBr) ν_{CN} 2240 cm^{-1}; ^{1}H-NMR ($CDCl_3$); δ=5.50 (s, 1H, disappeared with D_2O), 6.72—7.22 (m, 6H), and 7.36 (d, J=9.0 Hz, 2H); Mass m/z 211 (M^+). Found: C, 73.81; H, 4.36; N, 6.54%. Calcd for $C_{13}H_9NO_2$: C, 73.92; H, 4.30; N, 6.63%.

22j: Colorless needles (benzene-hexane), mp 90.5—92 °C; IR (KBr) $\nu_{C=O}$ 1680 cm^{-1}; ^{1}H-NMR ($CDCl_3$); δ=5.56 (s, 1H, disappeared with D_2O), 6.76—7.20 (m, 6H), 7.80 (d, J=9.0 Hz, 2H), and 9.86 (s, 1H); Mass m/z 214 (M^+). Found: C, 73.17; H, 4.80%. Calcd for $C_{12}H_{10}O_3$: C, 72.89; H, 4.70%.

22k: Colorless needles (benzene), mp 84—85 °C; IR (KBr) $\nu_{C=O}$ 1660 cm^{-1}; ^{1}H-NMR ($CDCl_3$); δ=2.55 (s, 3H), 5.80 (s, 1H, disappeared with D_2O), 6.82—7.14 (m, 6H), and 7.89 (d, J=9.0 Hz, 2H); Mass m/z 228 (M^+). Found: C, 73.91; H, 5.29%. Calcd for $C_{14}H_{12}O_3$: C, 73.67; H, 5.30%.

24a: Yellow needles (benzene), mp 173.5—175 °C; ^{1}H-NMR ($CDCl_3$); δ=4.96 (s, 1H, disappeared with D_2O), 6.70—7.04 (m, 6H), and 8.14 (d, J=9.3 Hz, 2H); Mass m/z 281 (M^+). Found: C, 62.30; H, 3.95; N, 6.10%. Calcd for $C_{12}H_9NO_4$: C, 62.34; H, 3.92; N, 6.06%.

24b: Pale yellow oil; IR (NaCl) ν_{OH} 3440 cm^{-1}; ^{1}H-NMR ($CDCl_3$); δ=4.83 (br, s, 1H, disappeared with D_2O), and 6.72—7.93 (m, 8H); Mass m/z 231 (M^+).

Acetate of **24b** was prepared by treatment with acetic anhydride in order to obtain a crystalline compound.

The acetate: Colorless plates (ether-benzene), mp 62—63 °C; Mass m/z 273 (M^+). Found: C, 61.25; H, 3.98; N, 5.18%. Calcd for $C_{14}H_{11}NO_5$: C, 61.54; H, 4.06; N. 5.13%.

24c: Colorless prisms (benzene), mp 147—148.5 °C; IR (KBr) ν_{CN} 2340 cm^{-1}; ^{1}H-NMR ($CDCl_3$); δ=5.18 (s, 1H, disappeared with D_2O), 6.70—7.02 (m, 6H), and 7.54 (d, J=9.0 Hz, 2H); Mass m/z 211 (M^+). Found: C, 74.07; H, 4.34; N, 6.73%. Calcd for $C_{13}H_9NO_2$: C, 73.92; H, 4.29; N, 6.63%.

24d: Colorless plates (benzene-hexane), mp 129—130.5 °C; IR (KBr) $\nu_{C=O}$ 1675 cm^{-1}; ^{1}H-NMR ($CDCl_3$); δ=5.08 (s, 1H, disappeared with D_2O), 6.75—7.07 (m, 6H), 7.79 (d, J=9.0 Hz, 2H), and 9.85 (s, 1H); Mass m/z 214 (M^+). Found: C, 72.89; H, 4.74%. Calcd for $C_{12}H_{10}O_3$: C, 72.89; H, 4.70%.

24e: Colorless plates (benzene), mp 164—166.5 °C; IR (KBr) $\nu_{C=O}$ 1660 cm^{-1}; ^{1}H-NMR ($CDCl_3$); δ=2.55 (s, 3H), 5.38 (s, 1H, disappeared with D_2O), 6.72—7.03 (m, 6H), and 7.88 (d, J=9.0 Hz, 2H); Mass m/z 228 (M^+). Found: C, 73.56; H, 5.31%. Calcd for $C_{14}H_{12}O_3$: C, 73.67; H, 5.30%.

(Received May 20, 1983)

Polyoxadithia[*n*]ferrocenophanes and polyoxatetrathia[*n.n*]ferrocenophanes were prepared by treatment of 1,1′-ferrocenedithiol with α,ω-dibromo polyethers. The ferrocenophanes formed efficiently a complex with a silver ion, but not with alkali and alkali-earth metal ions. The spectral data of the silver ion-complexed ferrocenophanes suggested the presence of a partial electron-transfer interaction between the iron atom and the complexed silver ion.

In order to develop a new functional ability, various attempts to prepare modified crown ethers have been made.[1] Incorporation of a certain heteroatom into a crown ether ring increases a complexing affinity with transition metals. For example, polythiamacrocycles are able to form a stable complex with silver(I),[2] nickel(II),[3] and copper(II) salts.[4] Polyoxathiaferrocenophane is a crown ether-like compound containing a ferrocene ring and a sulfur atom as ring members, in which the iron atom of the ferrocene may play a role of a coordinatable heteroatom to a complexed cation. A few were reported about this class of compounds. For example, 1,1′-ferrocenedicarbonyl dichloride reacted with a diazacrown ether and the product was reduced to give the ferrocene derivatives (**1**) of cryptand.[5] Polythia- (**2**)[6] and dithiaoxaferrocenophanes (**3**)[7] were prepared from 1,1′-ferrocenedimethanol and its derivatives. In these compounds, however, the distance between the iron atom of the ferrocene and the center of the macrocycle is too long to effect an interaction between the iron atom and the complexed metal ion. Polish workers[8] recently prepared polyoxaferrocenophanes (**4**) carrying oxygen atoms attached directly to a ferrocene nucleus, and suggested, from their electronic spectra, no interaction between the iron atom and the complexed rubidium cation. We also prepared polyoxaferrocenophanes and discussed their complexing ability and interaction between the iron atom and the complexed metal cations.[9] We now report the preparation and some complexing properties of polyoxadithiaferrocenophanes, carrying sulfur atoms attached to the ferrocene nucleus.[10]

Syntheses and Spectral Properties. Disodium 1,1′-ferrocenedithiolate, prepared from 1,1′-ferrocenedithiol[11] and aqueous sodium hydroxide in ethanol, reacted with α,ω-dibromo polyethers in ethanol at room temperature and the products were chromatographed by a silca-gel column to give two kinds of oxathiaferrocenophanes (**5**) and (**6**). The structures were determined by the elemental analyses and spectral data. For example, the molecular formula of **5c** was deduced to be $C_{18}H_{24}O_3S_2Fe$ by the elemental analysis and mass spectroscopy (M^+ 408). In the ^{1}H-NMR spectrum of **3d**, the α- and β-ring protons of the ferrocene nucleus appeared as a singlet (8H) at δ 4.24, while the methylene protons next to the oxygen atom appeared as a triplet (4H, J=6 Hz) at δ 3.74 and a singlet (8H) at 3.71, and those next to the sulfur atom resonated as a triplet (J=6.0 Hz) at δ 3.03. In the ^{13}C-NMR spectrum of **5c**, the bridgehead carbon (C_b), α- and β-carbons of the ferrocene nucleus resonated at δ 84.8, 72.7, and 68.8, respectively. In addition, the signal of the carbon next to the sulfur atom appeared at δ 35.8 and those next to the oxygen atoms appeared at δ 69.5, 70.5, and 70.7.

The yield of polyoxadithia[*n*]ferrocenophanes (**5**) amounted to maximum when n=3, but that of polyoxatetrathia[*n.n*]ferrocenophanes (**6**) decreased with the increase of the size of the macrocycle, which may indicate that a template effect of sodium cation plays a little role in the final cyclization step. As shown in the ^{1}H-NMR spectral data of Table 2, there is a remark-

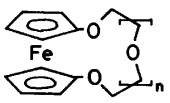
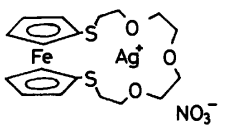
(3)



(4)



(7)

able difference in the pattern of ferrocene ring protones between mononuclear compounds **5** and dinuclear compounds **6**. In the former, the α- and β-ring protons of the ferrocene nucleus resonated as a singlet or a narrow multiplet, but in the latter the corresponding protons appeared as a pair of triplets. The methylene protons next to the sulfur atom in **5** resonated at lower field by 0.3 ppm than the corresponding ones in **6**. A similar trend was also observed in the methylene protons next to the oxygen atom. The low-field shift of the methylene protons in the mononuclear ferrocenophane **5** would be probably due to the fact that those protons exists in the deshielding zone of a ferrocene nucleus (an interannular area)[12] according to consideration of its stereomolecular model.

In the ^{1}H-NMR spectra of the ferrocene ring protons, **5a—d** have a similar chemical shift (δ *ca.* 4.2) to each other. In the ^{13}C-NMR spectra of the ferrocene ring carbons, however, **5a** showed a trend different from the other mononuclear ferrocenophanes **5b—d**, that is, the bridge-head carbon atom resonated at a lower field ($\Delta\delta$ *ca.* 6 ppm) and the α- and β-carbon atoms of **5a** resonated at a higher field ($\Delta\delta$ *ca.* 2 ppm) in **5a** than in the other **5b—d**. A similar specificity of **5a** was also observed in the electronic spectra of **5** (Table 1).

The absorption band near 440 nm of **5a**, assignable to a d-d transition of ferrocene nucleus,[13] shifted to a longer wavelength region ($\Delta\lambda$ *ca.* 10 nm) than that of **5b—d**, and its absorbance increased considerably (*ca.* 40%), the details of which will be discussed in another paper.[14]

Complexing Ability. The complexing ability of polyoxaferrocenophanes (**4**) with alkali metals was first reported to be conspicuous by the TLC method,[8] but was recently shown to be rather faint by the extraction method.[9] This trend is comparable with the fact that the complexing ability of benzocrown ether with alkali metal cations is smaller than that of crown ether itself, the reason of which has been rationalized by the HSAB principles.[15] On the basis of this principle, the displacement of some oxygen atoms of **4** by the sulfur atoms to **5** and **6** will results in a decrease in the affinity to hard cations and an increase in the affinity to soft heavy metal cations. The complexing ability of **5** and **6** with a variety of metals cation was examined by the extraction method described by Pedersen,[16] and the results were summarized in Table 3, alkali and alkali-earth metal cations being excluded because no extraction ability toward them was observed. This result is coincident with the expectation described above. The complexing ability of **5** and **6** was a little

or negligible with lithium, sodium, potassium, calcium, strontium, cadmium, and lead cations, while it was excellent with a silver cation and moderate with a thallium ion. The high complexing ability with a silver ion is comparable with that of benzooxathiacyclopolyethers.[2] It is also noteworthy that lead and thallium ions showed a remarkable dependence on the size of the macrocycle of **5** and **6**.

On addition of silver nitrate to **5** and **6** in acetonitrile, the absorption band near 440 nm showed a hypsochromic shift and a decrease in its absorbance, which are summarized in Table 4. There seems to be a parallel relationship between the hypsochromic shift and the decrease in absorbance in the mononuclear series **5b—d**, but not in the binuclear series **6a—c**. Both of the complexing ability and the electronic spectral change are large in **5c** and **5d**, but small in **5b**. This parallel relationship suggests an importance of the fitness of the macrocycles in **5** with a silver ion. The change of electronic spectra of a crown ether on addition of a metal cation is reported to be small.[17] So, a large electronic spectral change which depends on the complexing ability of those crown ether-type compounds presented here should be noticable.

In the ^{1}H-NMR spectrum of **5** in acetonitrile-d_3, the addition of silver nitrate causes a deshielding shift of the signals of methylene protons next to the sulfur atom and the ferrocene ring protons (Table 4). As shown in Fig. 2, the deshielding shift ($\Delta\delta$) increases almost linearly according to the increase of silver nitrate until the amount of the salt becomes equivalent to polyoxadithiaferrocenophanes **5**, but the addition of more silver ion results in little change of deshielding shift, which suggests the formation of a 1:1 complex of the ferrocenophanes 5 with silver nitrate in acetonitrile. The ferrocene ring protons of the complex of **5c** and **5d** with silver(I) nitrate appeared as a singlet just like those of free **5c** and **5d**, while the α- and β- protons of ferrocene ring protons of the complexed **5b** resonated as a separated pair of triplets. This is probably because the complex formation of **5b** with silver(I) nitrate demands the tilt-deformation of two cyclopentadienyl rings in order to put the silver(I) ion in the hole by spreading the macrocycle, because it is well known that the tilt-deformation of the cyclopentadienyl ring in ferrocenophanes causes the splitting of the α- and β-protons of ferrocene ring.[18] Since the tilting of two cyclopentadienyl rings results in some bathochromic shift,[18] the small change in the electronic spectrum of **5b** described above may reflect the difficulty on complexation of **5b** with a silver ion.

The deshielding of methylene protons on the complexation of **5** may be caused by the magnetic anisotropy of the silver ion. However, the large deshielding ($\Delta\delta$ *ca.* 0.2 ppm) of the ferrocene ring protons seems to be due to the electron density of the cyclopentadienyl rings decreased by a partial electron transfer from the iron atom to the complexed silver ion in **5**, since the α-and β-protons shifted to the same extent. If the deshielding shift is caused by the perturbation of the inductive and conjugative effect of the sulfur-substituent with coordination of a silver ion to a sulfur atom, the α-protons would be expected to resonate at a lower field than the β-protons. (The influence of an electron attracting substituent is well known to appear at the α-protons more remarkably.) Such a partial electron transfer has been observed in the complex of 1,1′-bis(diphenylphosphino)ferrocene with mercury(II) chloride.[19] An additional support was obtained from the ^{13}C-NMR spectra of **5b—d** and its benzene analog measured in the presence of silver(I) nitrate in acetonitrile-d_3 (Table 5).

Table 5. Low-field shift of ^{13}C-NMR spectra on additon of silver(I) nitrate to a solution of **5** in acetonitrile-d_3 (Δ, ppm)

Compd	C_b	C_α	C_β	SCH_2
5b	−3.2	1.1	2.0	1.3
5c	−8.2	4.2	2.8	3.9
5d	−6.4	3.5	2.2	3.2
8	−4.0	−1.5	1.5	2.7

a) C_b means the bridgehead carbon.

The signal of the α- and β-carbon of ferrocene ring in **5b—d** shifted down-field but those of the bridgehead carbon shifted up-field. The deshielding shift of methylene carbons next to a sulfur atom was similar to that of the ferrocene ring carbones, but the methylene carbons next to an oxygen atom showed only a little shift. In the benzene analog 4′-methyl-2,3-benzo-1,4-dithia-7,10,13-trioxa-2-cyclopentadecene (**8**),[2] on the other hand, the bridgehead carbon and methylene carbons next to sulfur atoms showed the same trend with in **5**, but the α-ring carbons showed some upfield shifts, suggesting a significant complexing of the silver ion with the sulfur atom. The fact that the ferrocene ring carbons (C_α and C_β) in **5** showed more deshielding shift than the corresponding benzene ring carbons in **8** suggest some electron transfer from the iron atom to the complexed silver ion on addition to the electron transfer *via* the sulfur atom from the cyclopentadienyl ring to the silver cation. Finally, the complexation of **5c**, among **5**, with silver(I) ion would be the strongest because the change of the carbon chemical shifts in the ^{13}C-NMR spectra was the largest in **5c**. The length of an oxyethylene chain in **5** would probably control the fitness of the macrocycle to a silver(I) ion.

Complex of 5c with Silver(I) Nitrate. A solution of **5c** and an equimolar silver(I) nitrate in acetonitrile was poured into anhydrous ether under nitrogen to give stable yellow crystalline precipitates of the 1:1 complex (7). However, **5b** and **5d** gave no crystalline complex. This result is coincident with suggestion described above that **5c** will form the most tight complex with silver(I) nitrate among **5**. The ^{1}H-NMR spectrum of **7** in $CDCl_3$ showed a pair of triplets corresponding to the H_α and H_β protons of a ferrocene nucleus at δ 4.50 and 4.33 (J=2.0 Hz), a pair of triplet assigned to the protons next to a sulfur atom and next to an oxygen atom at δ 3.04 and 3.74 (J=5.8 Hz) respectively, and a singlet at δ 3.77 (-OCH_2CH_2-). The difference in the chemical shift between free ligand **5c** and complex **7** is almost similar to that measured on

addition of silver(I) nitrate to a solution of **5c** in acetonitrile-d_6. The ferrocene ring protons appeared as a pair of triplet in the former but a broad singlet in the latter. This seems to be probably because in the latter, there is an equilibrium between the free ligand and the complex in acetonitrile and hence the signals of α- and β-protons are avaraged to an single signal. The fact that the splitting of the ferrocene ring protons was observed in the isolated silver-complex (**7**) indicates that the through-space electronic interaction between the iron atom of a ferrocene nucleus and the complexed silver ion in **7** described in the preceding section is too emphasized.

The ^{13}C-NMR spectrum of **7** in $CDCl_3$ showed the signals of bridge-head, α-, and β-carbons appeared at δ 77.7, 77.1, and 71.1 ppm, respectively. The carbons next to a sulfur atom appeared at δ 40.0 ppm, and those next to an oxygen atom appeared at δ 70.4, 69.7, and 67.2 ppm. The deshielding shifts of α- and β-carbons of ferrocene ring and the sulfur-attached carbons in **7** are almost similar to those measured on the addition of silver(I) nitrate to a solution of **5c** in acetonitrile-d_3. These NMR data of **7** indicate that **5c** and probably other polyoxadithiaferrocenophanes (**5b** and **5c**) also form a 1:1 complex in acetonitrile, and that the discussion about the nature of the complex of **5** with silver(I) nitrate described in the preceding and present section is reasonable enough.

Experimental

The melting points are uncorrected. The electronic spectra were measured on a Hitachi 340 Spectrometer. The IR spectra were measured on a JASCO IRA-2 Infrared Spectrometer. The ^{1}H-NMR and ^{13}C-NMR spectra were obtained on a JEOL FX-90Q Spectrometer, TMS being chosen as an internal standard. The mass spectra were taken by using a Hitachi M-80 Spectrometer.

Material. 1,1′-Ferrocenedithiol was prepared by reduction of 1,2,3-trithia[3]ferrocenophane with lithium aluminum hydride.[11] Bis(2-bromoethyl) ether,[20] 1,8-dibromo-3,6-dioxaoctane,[20] 1,11-dibromo-3,6,9-trioxaundecane,[21] and 1,14-dibromo-3,6,9,12-tetraoxatetradecane were prepared according to the literatures.

Polyoxadithia[n]*ferrocenophanes(5) and Polyoxatetrathia*-[n.n]*ferrocenophanes. General Procedure*: To a suspension of 1,1′-ferrocenedithiol (0.45 g, 1.8 mmol) in ethanol (90 ml) was added a solution of sodium hydroxide (0.18 ml of 20M** solution, 3.6 mmol) under stirring and bubbling of nitrogen. To the resulting red-orange solution was added a solution of the corresponding α,ω-dibromopolyether (1.8 mmol) in ethanol (3 ml). The solution was stirred for 4 h at room temperature under bubbling of nitrogen. After evaporating the solution, the residue was redissolved in benzene and filtered. The filtrate was condensed by an evaporator and charged on silica-gel column chromatography. Elution by toluene-ethyl acetate mixture gave **5** and **6**.

4-Oxa-1,7-dithia[7]ferrocenophane (5a). Red needles, 8%, mp 62—63 °C. Found: C, 52.70; H, 5.28%. Calcd for $C_{14}H_{16}OS_2Fe$: C, 52.51; H, 5.04%. MS (75 eV): *m/z* 320 (M^+, 100%). IR (KBr): 3100, 2940, 2850, 1420, 1120, 1035, and 807 cm^{-1}.

4,22-Dioxa-1,7,19,25-Tetrathia[7.7]ferrocenophane (6a). Orange needles, 30%, mp 112—113 °C. Found: C, 52.56; H, 5.09%. Calcd for $C_{28}H_{32}O_2S_4Fe_2$: C, 52.51; H, 5.04%. MS (75 eV): *m/z* 640 (M^+, 100%), 320 ($M^+/2$, 32%), and 304 (30%). IR (KBr): 3100, 2900, 2870, 1420, 1195, 1110, 1025, and 810 cm^{-1}.

4,7-Dioxa-1,10-dithia[10]ferrocenophane (5b). Orange oil, 26%. Found: C, 52.91; H, 5.44%. Calcd for $C_{16}H_{20}O_2S_2Fe$: C, 52.75; H, 5.53%. MS (75 eV): *m/z* 364 (M^+, 100%). IR (KBr): 3100, 2930, 2860, 1420, 1295, 1130, 1025, and 810 cm^{-1}.

4,7,25,28-Tetraoxa-1,10,22,31-tetrathia[10.10]ferrocenophane (6b). Orange oil, 12%. Found: C, 52.99; H, 5.60%. Calcd for $C_{32}H_{40}O_4S_4Fe_2$: C, 52.75; H, 5.53%. MS (75 eV): *m/z* 728 (M^+, 100%), 364 ($M^+/2$, 56%), and 304 (25%). IR (KBr): 3100, 2900, 2870, 1420, 1325, 1290, 1140, 1020, and 810 cm^{-1}.

4,7,10-Trioxa-1,13-dithia[13]ferrocenophane (5c). Orange oil, 63.8%. Found: C, 53.00; H, 6.42%. Calcd for $C_{18}H_{24}O_3S_2Fe$: C, 52.94; H, 5.92%. MS (75 eV): *m/z* 408 (M^+, 100%). IR (Neat): 3100, 2930, 2875, 1420, 1365, 1295, 1150—1100, 1030, 830, and 810 cm^{-1}.

4,7,10,28,31,34-Hexaoxa-1,13,25,37-tetrathia[13.13]ferrocenophane (6c). Orange cubes, mp 84—85 °C, 17.1%. Found: C, 53.10; H, 6.09%. Calcd for $C_{36}H_{48}O_6S_2Fe_2$: C, 52.94; H, 5.92%. MS (75 eV): *m/z* 816 (M^+, 100%) and 408 ($M^+/2$, 42%). IR (KBr): 3100, 2860, 1295, 1240, 1120, 835, and 820 cm^{-1}.

4,7,10,13-Tetraoxa-1,16-dithia[16]ferrocenophane (5d). Orange oil, 60.4%. Found: C, 52.81; H, 6.29%. Calcd for $C_{20}H_{28}O_4S_2Fe$: C, 53.10; H, 6.24%. MS (75 eV): *m/z* 452 (M^+, 100%). IR (Neat): 3100, 2925, 2870, 1420, 1360, 1295, 1150—1095, 1025, and 830 cm^{-1}.

The electronic, ^{1}H-NMR, and ^{13}C-NMR spectra of the compounds described above were summarized in Tables 1 and 2.

Method of Solvent Extraction. Extractability of polyoxathiaferrocenophanes **5** and **6** with metal cations was measured by the extraction method[9] which was the somewhat modified Pedersen method[16].

Measurement of the Electronic, ^{1}H- and ^{13}C-NMR Spectra in the Presence of Silver(I) Nitrate. The electronic spectra of **5b—d** (4.00×10^{-3}M) was recorded in the presence of silver(I) nitrate (2.00×10^{-3}M) in acetonitrile. The ^{1}H-NMR spectra of **5b—d** (0.08 mmol) was recorded in the presence of 0.25, 0.5, 1, 2, and 3 equivalents of silver(I) nitrate in acetonitrile-d_3 (*ca.* 0.3 ml). The results were summarized in Table 4 and Fig. 2. The ^{13}C-NMR spectra of **3b—d** and **8** (0.08 mmol) was recorded in the presence of silver(I) nitrate (0.1 mmol) in acetonitrile-d_3 (*ca.* 0.3 ml).

The Complex of 5c with Silver(I) Nitrate. **5c** (0.37 g, 0.9 mmol) and silver(I) nitrate (0.15 g, 0.9 mmol) were dissolved in acetonitrile (3 ml) under nitrogen. The resulting solution was heated for 3 min and then poured into anhydrous ether (40 ml). Yellow crystalline precipitates resulted.

Filtration and washing with anhydrous ether gave yellow crystals (0.43 g, 74%). The crystals were dissolved in chloroform and the resulting solution was filtered into anhydrous ether to give a pure complex. Mp 152 °C (decomp).

Found: C, 37.53; H, 4.32%. Calcd for $C_{18}H_{24}O_6NS_2FeAg$: C, 37.39; H, 4.18%. IR (KBr): 3090, 2870, 1390—1355, 1300, 1120, 1125, and 835 cm^{-1}.

**1 M=1 mol dm^{-3}.

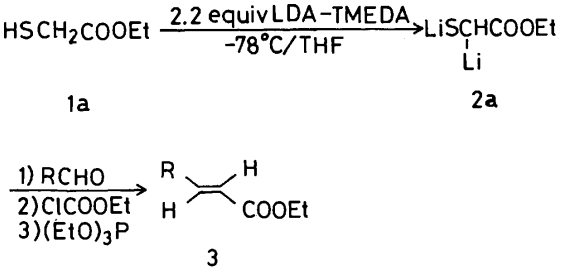
Mechanism of Formation of α,β-Unsaturated Esters in the Reaction of Ethyl Mercaptoacetate Dianion with Carbonyl Compounds

Syuichi MATSUI
Department of Industrial Chemistry, Fukui Technical College, Geshi, Saboe, Fukui 916
(Received May 28, 1983)

Dianion derived from ethyl mercaptoacetate undergoes aldol type reaction with a carbonyl compound to give an adduct, which exhibited low diastereoselectivity. However, the adducts obtained by the reaction with a variety of aldehydes were subsequently treated with ethyl chloroformate in the presence of trivalent phosphorus compound to give (*E*)-isomers of α,β-unsaturated esters in high yields with greater than 85% stereoselectivity regardless of the stereochemistry of the diastereomers of the adducts. The stereochemical mechanism and application of this reaction were studied in detail.

Recently, it has been reported in the communication[1] that, when trivalent phosphorus compound was used as a desulfurization agent, the (*E*)-products of α,β-unsaturated esters can be synthesized in high yields with high stereoselectivity by treating aldehydes with dianion derived from ethyl mercaptoacetate (**1a**). This finding would account for the mechanism of this reaction which involves the intramolecular cyclization to thiirane as an intermediate, followed by extrusion of sulfur to **3**.

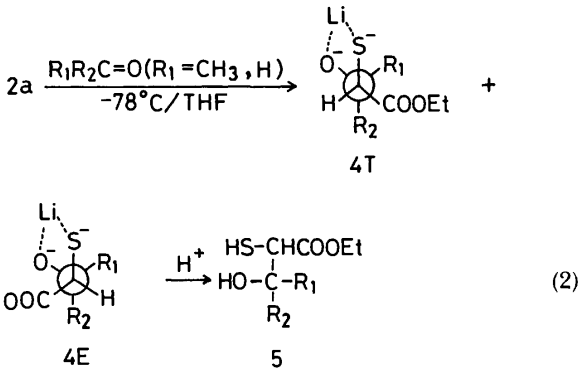


(1)

In the present study the author has observed that the aldol adducts were obtained in good yields by the reaction of **2a** with aldehydes, exhibiting consistently low diastereoselectivity. However, the reaction of the low diastereomeric mixture of the aldol products with 2.2 equiv of the base gave α,β-unsaturated esters of high stereoselectivity after treating with ethyl chloroformate and triethyl phosphite. In this paper the studies on the mechanism of the stereoselective formation of α,β-unsaturated esters and the application of this reaction to the synthesis of a component of royal jelly are described.

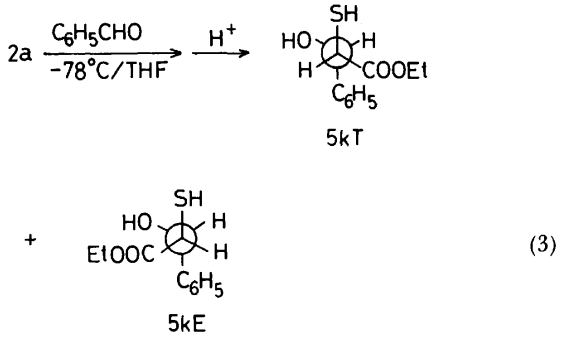
Results and Discussion

Aldol Condensation. Dianion (**2a**) undergoes aldol type reaction with a carbonyl compound to afford a mixture of diastereomers of an adduct (**4**). The conformations of aldol adduct, in which thiolate anion and alcoholate anion are gauche, are represented as **4T** and **4E** because of a chelation of lithium cation with both thiolate and alcoholate anion.[2] In order to determine the aldol diastereomer ratios (**4T** : **4E**), **2a** was treated with carbonyl compounds in THF at −78 °C for 2 h and quenched with saturated aqueous solution of ammonium chloride. The usual work-up and distillation afforded **5** in good yields.



(2)

Diastereomer ratios were determined by the ^{1}H-NMR spectra of the purified aldol product, using the well-established results that $J_{threo} > J_{erythro}$ and a chemical shift of threo isomer is higher than that of erythro isomer.[2a,3] For example, the ^{1}H-NMR spectrum of **5** derived from benzaldehyde shows the hydroxymethine proton at δ 4.70 (J=8.0 Hz) for threo isomer and at δ 4.82 (J=6.0 Hz) for erythro isomer. Integration of these protons showed that the ratio of threo isomer and erythro isomer was 60 : 40, being identical with the ratio obtained by capirally column GLC analysis (ratio=61 : 39). The stereochemical compositions of **5** prepared from various carbonyl compounds are summarized in Table 1. Next, the effect of reaction time of aldol condensation on the diastereomer ratio (**5kT** : **5kE**) of aldol adduct derived from benzaldehyde was investigated (Table 2).



(3)

Tables 1 (Entry 12) and 2 show that there is no obvious effect of reaction time and temperature on the diastereomer ratios. Thus, this aldol reaction was pre-

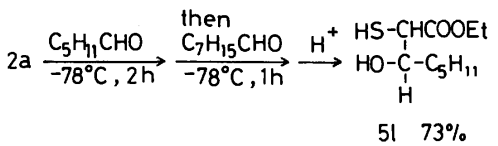
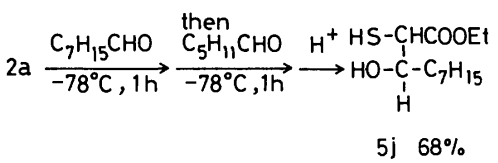
sumed to be kinetically controlled. Cross-over experiments which were attempted by adding another aldehydes to the reaction mixture produced no detectable cross-over product at −78 °C.



5l 73%

90%

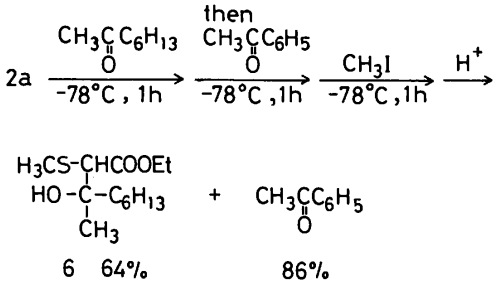
(4)



5j 68%

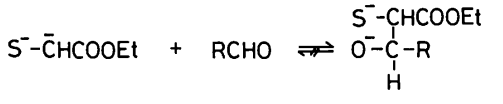
75%

(5)



(6)

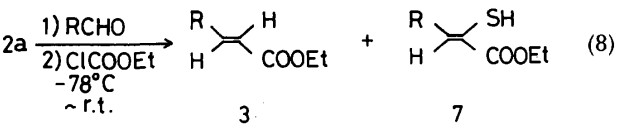
The carbonyl compound added first was always condensed with **2a** to afford **5l**, **5j**, and **6** in good yield, whereas the carbonyl compound added secondly was almost recovered. From these results, it is reasonable to consider that **4** is not in equilibrium with **2a** as follows (Eq. 7).



(7)

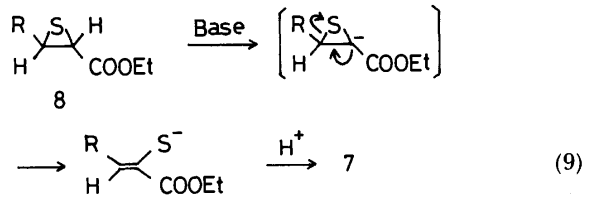
Generation of Thiirane Derivatives. It was found that a thioenol compound (**7**) could be isolated as a by-product in moderate yield in the reaction of **2a** with aldehydes, and that the formation of **7** was responsible for the low yield of **3** (Table 3). Yields of **7** were found to be strongly dependent on the reaction temperature after treating with ethyl chloroformate. For example, **7b** and **7d** were isolated in 41 and 68% yields respectively, by quenching the reaction at 10—15 °C after treating with ethyl chloroformate, whereas the yields of **7b** and **7d** were decreased to 22 and 53%, respectively, by quenching at 30—35 °C. On the other hand, **7** was not obtained by the reaction of **2a** with ketones. The structures of **7** were confirmed by their elemental analyses and spectral (IR, NMR) properties

(see Experimental). The *E*/*Z* ratio of **7** was determined by GLC and NMR analysis; *e.g.*, the ratio of (*E*)-isomer to (*Z*)-isomer of ethyl 2-mercapto-2-decenoate determined by integration of the olefinic proton at δ 6.59 and 5.83, respectively, is 93 : 7. Analysis of this material by GLC indicates a 94 : 6 mixture.



(8)

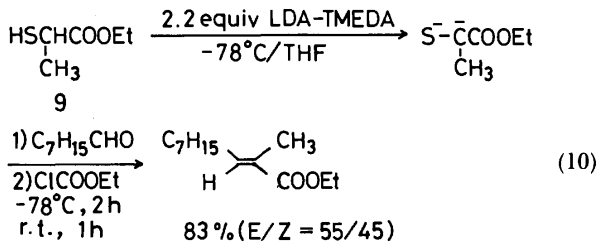
It is reasonable to assume that **7** is resulted from thiirane species (**8**) according to the following route (Eq. 9), since when trivalent phosphorus compound was added the formation of **7** was not observed and the yield of α, β-unsaturated ester (**3**) was increased.



(9)

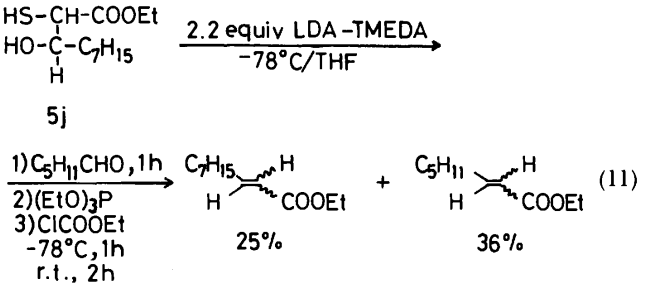
As anticipated, by the reaction of dianion derived from ethyl 2-mercaptopropionate (**9**) with aldehydes the thioenol compound was not obtained and α,β-unsaturated ester was isolated in high yield.

Attempts to isolate the thiirane species (**8**), however, were failed due to its unstability.



(10)

Retro-aldolization after Treating with ClCOOEt. When the adduct (**5j**) obtained by the reaction of **2a** with octanal was dilithiated with 2.2 equiv of LDA in the presence of TMEDA at −78 °C and followed by treating with hexanal and ethyl chloroformate in the presence of triethyl phosphite, ethyl 2-decenoate and ethyl 2-octenoate were obtained in 25 and 36% isolated yields, respectively. This scramble of carbonyl compound with **2a** demonstrates the retro-aldolization *after treating with ethyl chloroformate* (Eqs. 11, 12, 13, and 14).



(11)

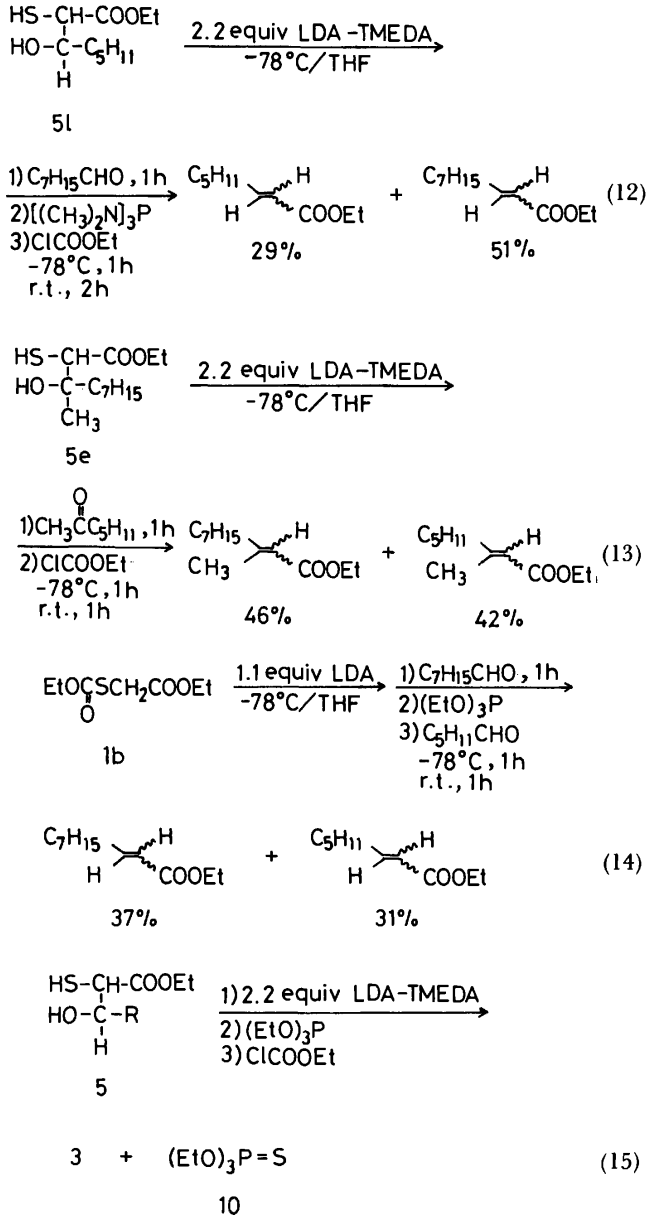
4	**5j**	58/42	**3b**	73	92/8
5	**5k**	40/60	**3f**	80	100/0

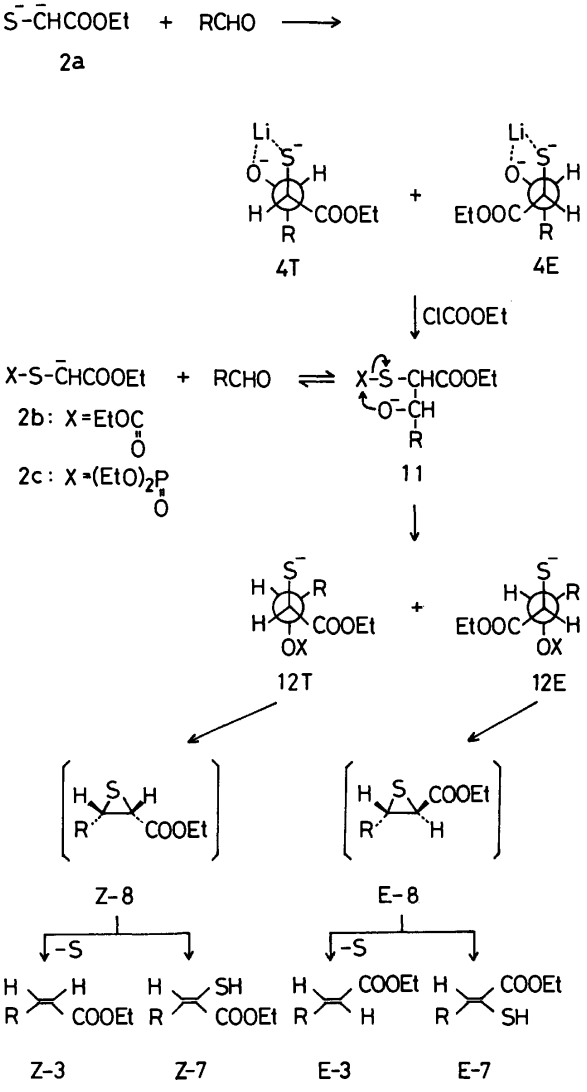
a) Determined by ^{1}H-NMR. b) Isolated yields. c) Determined by ^{1}H-NMR and GLC.



The aldol adducts (**5**) derived from carbonyl compounds afforded **3** in the following manner. These results were summarized in Table 4.

The substantial difference between the stereochemistry of **5** and the geometry of **3** was observed, that is, the predominant formation of (*E*)-α,β-unsaturated esters was observed.

Reaction Mechanism. It has been previously reported[4] that the mechanism of the reaction of **2a** with carbonyl compounds involves aldol type condensation, rearrangement of an adduct (**11**) to **12**, subsequent conversion of **12** to thiirane species (**8**), and elimination of sulfur to give α,β-unsaturated esters (**3**). The observations presented here would lead to the mechanism of the stereoselective formation of (*E*)-α,β-unsaturated esters.



Scheme 1.

The aldol type condensation of **2a** with aldehydes exhibited low diastereoselectivity due to the kinetically controlled process, whereas the reaction after treating with ethyl chloroformate proceeded with high stereoselectivity to give (*E*)-isomer of **3**. This result can be rationalized by considering that a retroaldolization of **11** to **2b** is in competition with rearrangement of **11** to **12**, that is, the reaction after treating with ethyl chloroformate is the thermodynamically controlled process. In two possible stereoisomeric precursors (**12T** and **12E**) leading to **3** as shown in Scheme 1, if the conformer, in which the $O\overset{O}{\overset{\|}{C}}OEt$ and S^- groups are antiperiplaner, is favorable one for the subsequent intramolecular attack of S^- group and elimination of the $O\overset{O}{\overset{\|}{C}}OEt$ species, the orientation of R group is thus represented as **12T** and **12E**. The equiliblium between the stereoisomers **12T** and **12E** would surely favor **12E**, since the steric interaction between a bulky R group and an ethoxycarbonyl group is minimized in **12E**. On the other hand, the stereoisomer **12T**, in which the alkyl and ethoxycarbonyl group are gauche, would exhibit serve interactions. Thus, even if **12T** and **12E** should convert to (*Z*)-**3** and (*E*)-**3** stereospecifically, respectively,[5] the (*E*)-isomers of monosubstituted α,β-unsaturated esters would be predominantly obtained regardless of the stereochemistry of the aldol adduct (**4**) in the reaction of **2a** with aldehydes. On the other hand, in the reaction of **2a** with ketones, almost 1 : 1 mixture of geometrical isomers of disubstituted analogue was obtained.[4] Since in the conformers **13T** and **13E** (Scheme 2), the difference in steric interaction would be diminished by an introduction of methyl group in the place of hydrogen atom.

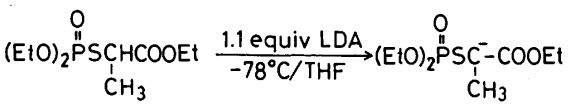
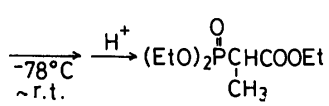
Scheme 2.

Reactivity of S-[1-(Ethoxycarbonyl)ethyl] Diethyl Phosphorothioate Carbanion. An already-published report described the efficient synthesis of trisubstituted α,β-unsaturated esters, starting from *S*-[1-(ethoxycarbonyl)ethyl] diethyl phosphorothioate (**14**).[6] To study the reactivity of **14**, the author treated *S*-[1-(ethoxycarbonyl)ethyl] diethyl phosphorothioate with 1.1 equiv of LDA in THF at −78 °C. The resulting



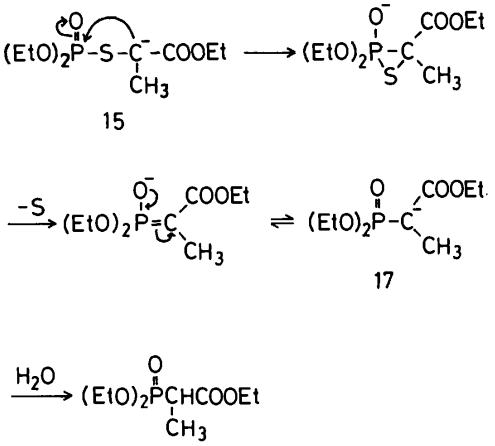
14 15



16 (16)

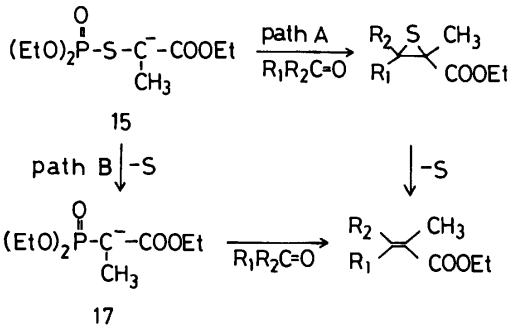
carbanion (**15**) afforded ethyl 2-(diethoxyphosphinyl)-propionate (**16**) in 88% yield upon quenching with saturated aqueous solution of ammonium chloride after warming to room temperature (Eq. 16).

The mechanism of the formation of **16** is proposed as follows (Scheme 3).



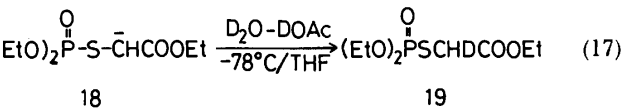
Scheme 3.

Therefore, two routes are taken into consideration for the reaction of **15** with carbonyl compounds to afford α,β-unsaturated esters (Scheme 4).



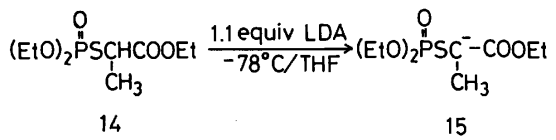
Scheme 4.

One is path A that proceeds *via* thiirane species as intermediate, another is path B where the product (**16**) acts as Emmons-Wadsworth reagent[7] and undergoes Wittig reaction.[8] In order to clarify the mechanism, the carbanion **18** was quenched with deuterium oxide and acetic acid-*d* at −78 °C, giving **19** in 89% yield (Eq. 17).

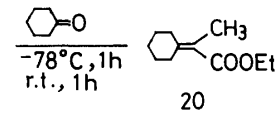


18 19 (17)

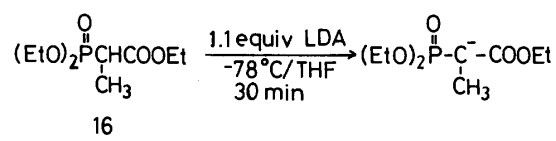
Furthermore, when **15** was treated with cyclohexanone at −78 °C for 1 h and at room temperature for 1 h, ethyl 2-cyclohexylidenepropionate (**20**) was isolated in 90% yield. Whereas **20** was obtained in only 33% yield from Emmons-Wadsworth reagent (**16**) under the same reaction conditions as those used for **14**.



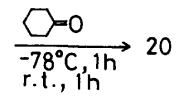
14 15



20 (18)



16



20 (19)

These results suggest that the reaction of *S*-[1-(ethoxycarbonyl)ethyl] diethyl phosphorothioate carbanion (**15**) with carbonyl compounds proceeds *via* path A.

Synthesis of (E)-*10-Hydroxy-2-decenoic Acid.* To demonstrate the utility of our novel methodology,[1] the author has carried out the synthesis of (*E*)-10-hydroxy-2-decenoic acid, a component of royal jelly from *Apis Melifica*.[9] Reaction of **2a** with **21** in the presence of triethyl phosphite gave pure **22** as a pale yellow oil in 63% isolated yield (*E*/*Z*=94/6). Acid hydrolysis of **22**[10] produced pure ethyl (*E*)-10-hydroxy-2-decenoate (**23**) as a viscous oil in 79% isolated yield after purification by silica-gel chromatography. Alkali hydrolysis of **23**[11] produced pure (*E*)-10-hydroxy-2-decenoic acid (**24**) in 73% isolated yield after recrystallization from ether.

Experimental

General. Boiling points were determined during distillation and are uncorrected. Infrared spectra were determined on a Hitachi Model 260-30 spectrophotometer. Nuclear magnetic resonance spectra were determined on a JEOLCO MH-100 spectrometer. Gas chromatograms were obtained using a Varian Aerograph Model 920 instrument with a 0.15 cm×120 cm glass column (20% Silicone DC-550 on Celite 545). Tetrahydrofuran (THF) was dried by distillation from calcium hydride and by subsequent distillation from lithium aluminum hydride under a nitrogen atmosphere. Diisopropylamine and *N,N,N′,N′*-tetramethylethylenediamine (TMEDA) were distilled from calcium hydride and stored over molecular sieves. Triethyl phosphite and carbonyl compounds were purified by distillation under a nitrogen atmosphere. All reactions were performed under a nitrogen atmosphere. The glassware was dried by flaming in a nitrogen stream.

Preparation of Aldol Adduct (5). To a mixture of lithium diisopropylamide (LDA) (44 mmol) and TMEDA (44 mmol) in 40 ml of THF was added a solution of 2.4 g (20 mmol) of ethyl mercaptoacetate (**1a**) in 5 ml of THF at −78 °C. After being stirred for 1 h, a solution of 22 mmol of a carbonyl compound in 5 ml of THF was added and the reaction mixture was stirred at −78 °C for 2 h. The cooling bath was removed and the reaction mixture was quenched with 10 ml of saturated aqueous solution of ammonium chloride, poured into dilute hydrochloric acid, and extracted with ether (50×4 ml). The combined organic layer was washed twice with brine, dried on anhydrous sodium sulfate, and concentrated under reduced pressure. Distillation of the resulting oil gave **5**.

Ethyl 3-Hydroxy-2-mercapto-3-methylheptanoate (5a): Bp 93—96 °C/1 Torr (1 Torr≈133.322 Pa). ^{1}H-NMR (CCl_4); δ=4.16 (q, J=7 Hz, 2H, CH_2), 3.22 (s, 0.38H, erythro CH), 3.10 (s, 0.62H, threo CH), 2.93 (brs, 1H, OH), 2.23 and 2.14 (each d, J=6 and 5 Hz, total 1H, SH), 1.00—1.60 (m, 12H, $3CH_2$ and $2CH_3$), 0.70—1.00 (m, 3H, CH_3). IR (neat); 3500 (OH), 2560 (SH), 1710 cm^{-1} (COO). Found: C, 54.27; H, 9.16%. Calcd for $C_{10}H_{20}O_3S$: C, 54.51; H, 9.15%.

Ethyl 3-Hydroxy-2-mercapto-3-methyloctanoate (5b): Bp 96—100 °C/1 Torr. ^{1}H-NMR (CCl_4); δ=4.02 (q, J=7 Hz, 2H, CH_2), 3.10 (s, 0.39H, erythro CH), 2.99 (s, 0.61H, threo CH), 2.90 (brs, 1H, OH), 2.22 and 2.06 (each d, J=5 and 5 Hz, total 1H, SH), 1.12—1.58 (m, 14H, $4CH_2$ and $2CH_3$), 0.72—1.06 (m, 3H, CH_3). IR (neat); 3500 (OH), 2560 (SH), 1720 cm^{-1} (COO). Found: C, 56.17; H, 9.53%. Calcd for $C_{11}H_{22}O_3S$: C, 56.38; H, 9.46%.

Ethyl 3-Hydroxy-2-mercapto-3-methylnonanoate (5c): Bp 108—112.5 °C/1Torr. ^{1}H-NMR (CCl_4); δ=4.16 (q, J=7 Hz, 2H, CH_2), 3.20 (s, 0.43H, erythro CH), 3.09 (s, 0.57H, threo CH), 2.96 (brs, 1H, OH), 2.30 and 2.18 (each d, J=6 and 5 Hz, total 1H, SH), 1.18—1.60 (m, 16H, $5CH_2$ and $2CH_3$), 0.80—0.96 (m, 3H, CH_3). IR (neat); 3500 (OH), 2560 (SH), 1720 cm^{-1} (COO). Found: C, 57.87; H, 9.69%. Calcd for $C_{12}H_{24}O_3S$: C, 58.03; H, 9.74%.
