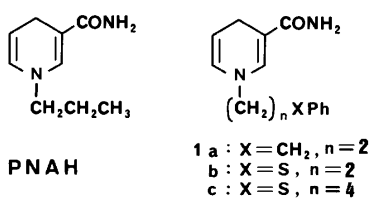
In order to understand the mechanism of enzymic oxidation-reduction with NAD(P$^+$)-NAD(P)H coenzyme, not only interactions between the coenzyme and a substrate but also the effect of environment in the pocket of enzyme should be taken into account. The pocket is entirely surrounded by hydrophobic moieties.[6] Thus, we synthesized NAD(P)H-models with a phenyl or phenylthio substituent. This paper will describe the effect of magnesium ion on the kinetics of reduction with the model of this type in acetonitrile.

Results

Models employed for the study were PNAH and **1**. Although the substrate, *m*-nitro-α,α,α-trifuoroacetophenone (**2**) exerted no evidence for the formation of a complex with magnesium ion in acetonitrile, the models formed finite complexes that were detectable spectrophotometrically. The results are listed in Table 1. Kinetics were studied at 323 K in the presence or absence of magnesium perchlorate. Kinetics with 4-deuterated models were also studied and primary kinetic isotope effects were calculated according to Steffens and Chipman equation.[7] Results are summarized in Table 2.



PNAH

It was already reported that water content in the solvent acetonitrile affects the rate of reduction.[8] In order to confirm the constancy of kinetic isotope effect on the variation of water content, we also studied kinetics for the reduction of **2** with PNAH and PNAH-4-*d* in acetonitriles containing 0.1 and 1.0% v/v of water, respectively. The kinetic isotope effect observed in these systems were the same as that listed in Table 2. Adduct-formation was not recognized. Thus, kinetic isotope effects listed in Table 2 can be definitely divided into two classes, small (≈2.3) and large (≈3.2).

Discussion

It is apparent from Table 2 that the phenyl group on the third atom of the substituent chain exerts small kinetic isotope effect in the coexistence of magnesium ion. The observation is in contrast with that from PNAH, where kinetic isotope effects are large both in the presence and absence of magnesium ion. Energy diagram for the reduction with PNAH has been proposed to be consisted of two energy barriers, one of which that corresponds to the initial electron transfer process is lower than the other that corresponds to the proton (or hydrogen atom) transfer process. Therefore, the rate-determining step of the reduction involves largely the movement of hydrogen nucleus exerting large kinetic isotope effect. Since magnesium ion catalyzes the process of electron transfer, the presence of magnesium ion does not affect the magnitude of kinetic isotope effect, although it accelerates the rate.

Table 1. Association constants and thermodynamic parameters for the complex between the model and magnesium ion in acetonitrile[a)]

	PNAH	**1a**	**1b**	**1c**

a) Errors are standard deviations. Errors in kinetic isotope effects are about 10% for each. [Substrate] = 2.20×10^{-2} mol dm^{-3}. [Model] = 1.00×10^{-3} mol dm^{-3}. b) dm^3 mol^{-1} min^{-1}. c) Data from ref. 2. d) [Substrate] = 4.50×10^{-2} mol dm^{-3}. [Model] = 2.30×10^{-3} mol dm^{-3}.

The present results indicate that **1a** and **1b** behave similarly to PNAH when magnesium ion is absent, whereas, in its presence, contribution of the initial electron transfer process to the rate-determining step becomes quite important in the reductions with **1a** and **1b**. It should be noted, however, that catalytic effect of magnesium ion in the reductions with **1a** and **1b** is as large as that in the reduction with PNAH. When the chain length becomes longer as seen in **1c**, the effect of phenyl group diminishes.

CPK-models for **1** suggest that the phenyl group in **1a** or **1b** locates very closely to the dihydropyridine ring. Thus, there is no doubt that a phenyl group closely situated to the dihydropyridine ring makes, by the assistance of magnesium ion, the movement of hydrogen nucleus easier. There are three possibilities to interpret the present result based on the reaction Scheme 1.

$$MH + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} MH^+S^- \xrightarrow{k_2} M\cdot HS\cdot \xrightarrow{k_3} M^+ + HS^-, \qquad (1)$$
$$\qquad\qquad\qquad

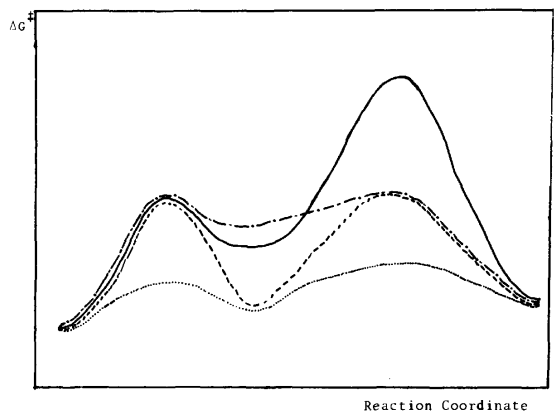

Fig. 1. Schematic energy diagram for the Reduction. The full line corresponds to the reduction without magnesium ion. Broken, dotted, and dashed lines correspond categories **1**, **2**, and **3** described in the text, respectively.

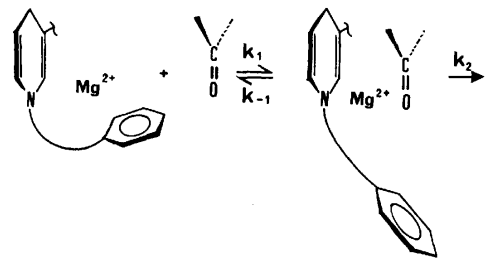

Scheme 1.

350 nm, there is no doubt that the magnesium ion primarily interacts with the dihydropyridine moiety. Nevertheless, the phenyl group in the model interrupts the approach of a substrate to form a composite ternary complex. The free-energy of transition state for the formation of initial intermediate, therefore, becomes higher than that with PNAH.

Once the intermediate is formed, on the other hand, competition takes place between the substrate and the phenyl group to ligate on the magnesium ion, and the free-energy level of the intermediate may be the same as that with PNAH (*cf.* Scheme 1). In other words, partition of the intermediate toward the reactants and products becomes less favored in the direction to the former. The energy level of the transition state for the k_2 (or k_2')-step, or migration of a hydrogen nucleus, is lowered and kinetic isotope effect becomes smaller.

Thermodynamic parameters listed in Table 1 indicate an interesting classification: although all models studied have equal free-energy of complexation, the enthalpy for **1a** is much smaller than those for others and the entropy compensates its minority. We do not have an appropriate explanation for this phenomenon. However, it seems probable that proximate phenyl group again interferes the approach of magnesium ion on complexation. The situation is improved in **1b** by the affinity of lone-pair electrons on sulfur.

Table 2 also shows that substitution of a methylene group in **1a** by a sulfur atom decreases the reactivity regardless the presence or absence of magnesium ion in the reaction system. The same trend was reported and the inhibitory effect of sulfur atom was attributed to the interference on the initial one-electron transfer process.[9] Characteristic absorption at around 350 nm from dihydropyridine moiety appears at shorter wavelength in **1b** than in other models (see Experimental), which suggests that **1b** is suffered from electronic distortion in its cyclic dienamine structure. Probably this is the reason of less ability to donate an electron to an acceptor. It is apparent, from Tables 1 and 2, that the sulfur substituent in the side-chain of model compound exerts different effects both in thermodynamics and kinetics from the corresponding methylene group. However, the proximity effect of the phenyl group is so large that present result alone is not sufficient to discuss on the effect of sulfur. Further and detailed discussion on the effect of sulfur substituent will be reserved for a forthcoming report from our laboratory.

Experimental

Melting and boiling points were not corrected.

Instruments. UV, NMR, and mass spectra were obtained on Union Giken SM-401, JEOL JNMFX-100, and Hewlett Packard 5992B GC/mass spectrometers, respectively. A Yanaco G-1800F was used for GLC analyses.

Materials. Acetonitrile was distilled over phosphorus pentaoxide five times and kept over potassium carbonate under argon atmosphere. The acetonitrile was refluxed over calcium hydride several hours, then distilled from the same pot under argon atmosphere prior to the use. Magnesium perchlorate was dried over phosphorus pentaoxide for a couple of days under reduced pressure at 400 K. The water content in a solution which was subjected to the kinetic or thermodynamic measurement was determined on GLC (30% bis(2-cyanoethyl) ether, 1 m, 313 K) prior and after the experiment and found to be less than 0.075% v/v.

1-Propyl-1,4-dihydronicotinamide (PNAH) and PNAH-4-*d* were prepared as described previously.[10] 1-(3-phenylpropyl)-1,4-dihydronicotinamide (**1a**), 1-(2-phenylthioethyl)-1,4-dihydronicotinamide (**1b**), and 1-(4-phenylthiobutyl)-1,4-dihydronicotinamide (**1c**) and their 4-deuterated analogs were prepared similarly. Deuterium contents were measured on GC/MS and NMR to be more than 99.5% for all deuterated compounds.

1a: λ_{max}=232 nm (ε=5.13×10³) and 352 nm (ε=5.36×10³) in acetonitrile at 303 K. Found: C, 74.05; H, 7.59; N, 11.42%. Calcd for $C_{15}H_{18}N_2O$: C, 74.35; H, 7.49; N, 11.56%.

1b: λ_{max}=254 nm (ε=8.48×10³) and 347 nm (ε=5.41×10³) in acetonitrile at 303 K. Found: C, 64.51; H, 6.26; N, 10.71%. Calcd for $C_{14}H_{16}N_2OS$: C, 64.59; H, 6.19; N, 10.76%.

1c: λ_{max}=256 nm (ε=1.01×10⁴) and 351 nm (ε=5.45×10³) in acetonitrile at 303 K. Found: C, 66.35; H, 7.00; N, 9.88%. Calcd for $C_{16}H_{20}N_2OS$: C, 66.63; H, 6.99; N, 9.71%.

m-Nitro-α,α,α-trifluoroacetophenone (**2**) was prepared according to a literature procedure.[11]

Kinetic Procedure. Solutions for kinetic studies were prepared under an atmosphere of argon and placed in a UV cell (0.1 dm) equipped with a silicon rubber stopper. The cell compartment of the spectrometer was also filled with dry argon and kept at 323±0.05 K. As a standard procedure, both sample and reference celles were filled with solutions of a substrate (and magnesium perchlorate, when necessary) in acetonitrile to obtain a difference spectrum. Then an acetonitrile solution of a model compound was injected into the sample cell by using a syringe to start the reaction.

The kinetics was followed by observing the decrease in the

intensity at 380 nm from a model. The spectrometer was attached by an NEC PC-8001 computor and absorptions at appropriate time intervals were monitored over 3 half-lives through the computer. One observed absorption was the avarage of 80 consecutive input. More than 50 points were monitored for a run. The data were automatically subjected to the least-squares treatment to give a pseudo-first order rate constant. Standard deviation and correlation coefficient for each run were better than ±1% (better than ±0.75% in most runs) and 0.9999, respectively. More than 5 runs were averaged to obtain rate constants listed in Table 2.

Thermodynamic Parameters. Equilibrium constants at appropriate temperatures were obtained by similar procedure as described above and according to the equation proposed by Creighton.[12]

Catalytic Activity of Highly Dispersed Palladium. III. The Effect of Added Zirconium Oxide upon Palladium Metal Surface Revealed by a Combined Infrared Spectroscopic and Thermal Desorption Study of Carbon Monoxide Adsorption

Bu Yong LEE, Yasunobu INOUE,*,† and Iwao YASUMORI

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

†*Analysis Center, Technological University of Nagaoka, Nagaoka, Niigata 949-54*

(Received August 11, 1983)

A combined infrared spectroscopic (IR) and thermal desorption (TD) study of CO adsorption was carried out to reveal the nature of Pd surface which is modified by the addition of ZrO_2. The TD spectra of CO from SiO_2- or α-Al_2O_3-supported Pd showed two broad peaks, α at 340 K and β at 530 K. The addition of ZrO_2 in a range of atomic ratios of Zr/Pd=0.5—3.0 produced a new broad peak δ at 390—420 K and the β peak shifted toward higher temperature by 16—19 K. The IR spectra of CO on Pd/SiO_2 catalysts, consisting of two broad bands: A (2030—2070 cm^{-1}) and B (1880—1920 cm^{-1}), were modified by the addition of ZrO_2 to give rise to a new sharp band, B_h (1970—1985 cm^{-1}) and to make the A band narrower. From the correspondence of the variation in intensities and position of the IR bands with those in the fraction of coverage of CO with temperature, the α peak was correlated to the A band, the δ peak to the B_h band, and the β peak to the B band. The changes in the TD peaks and the IR bands caused by added ZrO_2 were semiquantitatively compared and are discussed in terms of the electronic and geometric effects; a high electron density state of Pd surface atoms as well as the formation of adsorption sites with specific structure is proposed. A brief study was made for the role of the sites in the catalytic hydrogenation of ethylene and cyclohexene.

In this series of studies, which aims at clarifying the support effect in heterogeneous catalysis, the remarkable role of ZrO_2 in the catalytic behavior of dispersed palladium has been pointed out.[1,2] The Pd metal surfaces, in the presence of ZrO_2, exhibited an enhanced activity for the cyclohexene hydrogenation, causing a change in kinetic behavior. The XPS study showed that the Pd metal atoms were slightly negatively charged as a consequence of electron transfer from ZrO_2 to the metal and that this was mainly responsible for their prominent activities. It was also found that the ZrO_2 brought Pd metal to a highly dispersed state and increased the percentage exposed. These effects might be realted to the preferential fromation of the active sites with peculiar structures. Such ZrO_2-affected Pd metal surfaces may give rise to specific adsorptive properties as well, since the interaction with admolecules is much influenced by the changes in structure and electronic state. Therefore, a combined infrared spectroscopic (IR) and thermal desorption (TD) study of CO adsorption was undertaken to ascertain the adsorptive behavior and, further, to prove the advantage of using CO as a sensitive probe for investigating the details of characteristics of the surface.

In the present study, attention was paid to the following points. First, numerous IR measurements of adsorbed CO on metal surfaces have shown that the position of absorption band changed markedly according to the preparation methods of dispersed metals such as the procedures of metal loading, pretreatment, *etc.*[3] However, such disturbing influences can be avoided or, at least, minimized, when the samples to be measured are prepared with the same procedure. In the present study, thus, the silica- and α-alumina-supported Pd, ZrO_2-added Pd/SiO_2 and Pd/α-Al_2O_3, and the ZrO_2-supported Pd were prepared in the same way as exactly as possible. The produced catalysts were characterized by the X-ray diffraction and CO chemisorption methods.

Secondly, the IR band frequencies are also affected not only by the interaction between admolecule and surface, but also by the interactions such as dipole-dipole coupling and/or direct repulsion between admolecules[4] and, therefore, by the fraction of surface coverage. Thus, in order to reveal the contribution of the metal support interaction on adsorption, it is desirable to make the influence of the latter as low as possible; this situation will be attained in the case that the spectra obtained at similar low fractions of coverage are compared with each other for the similar adsorbed states. In this regard, the combination of IR spectroscopy with TD technique which is able to distinguish among the adsorbed states is indispensable. The catalytic activities of the prepared catalysts were briefly examined for the hydrogenation of ethylene and cyclohexene.

Experimental

The Pd/SiO_2 (2.1% in weight) and ZrO_2-added catalysts were prepared in a manner similar to those employed previously for the Pd/α-Al_2O_3 and ZrO_2-added catalysts.[1,2] The Aerosil silica 130, obtained from the Nihon Aerosil Co., was washed with 0.1 mol dm^{-3} nitric acid and then rinsed thoroughly with ion-exchanged water. The catalysts thus prepared were pretreated *in situ* in the TD or IR cell by oxidation, reduction and then evacuation at the same temperature of 723 K. This reduction temperature was higher than 523 K, *viz.*, a temperature employed in pretreatment of the catalysts for the previous kinetic studies,[1,2] since the TD experiments required Pd surfaces which are stable and resistive for heating up to 700 K. The supported catalysts were characterized by the X-ray diffraction and CO chemisorption methods.

The apparatus used for the TD and IR experiments were almost the same as those reported previously.[5] In the TD study, the catalysts were exposed to a CO atmosphere at room temperature, cooled down to 78 K, and then evacuated at the same temperature before a TD run. The temperature of the catalysts was raised at a rate of 13 K $min.^{-1}$ Under similar

Table 1. Characterization of the catalysts and ZrO_2 effects upon turn-over frequency of ethylene and cyclohexene hydrogenation

Support	Zr/Pd ratio	Amount of CO adsorbed (at 273 K) / molecule g-Pd^{-1}	$D_{CO}^{a)}$/%	$D_X^{b)}$/nm	Turn-over frequency(N_t)$^{c)}$	
					$C_2H_4+H_2$	$C_6H_{10}+H_2$
SiO_2	0	3.23×10^{20}	5.7	84	1.7	—$^{d)}$
	0.5	4.38	7.7	52	2.3	—
	1.0	5.21	9.2	20	3.3	—
	3.0	7.37	13.0	15	6.4	—
α-Al_2O_3	0	0.95×10^{20}	1.7(2.3)$^{e)}$	108	(1.4)	0.1(0.1)$^{e)}$
	0.5	1.07	1.9(3.0)	90	(6.1)	0.7(0.7)
	2.5	1.65	2.9(5.0)	55	(6.9)	0.8(0.7)
ZrO_2	—	3.5×10^{20}	6.2(10.1)	30	7.5	1.3(1.2)

The values in parentheses were for the catalysts pretreated at 523 K.
a) Percentage exposed (dispersion) evaluated by assuming one CO admolecule on each Pd atom. b) Particle size derived from X-ray line broadening. c) Partial pressure of each reactant: 40 Torr; reaction temperatures: 301 K for cyclohexene hydrogenation and 273 K for ethylene hydrogenation. d) Because of the take-up of cyclohexene by SiO_2 support, a direct comparison under the same conditions was difficult. e) See Ref. 2.

adsorption conditions, the ZrO_2 and SiO_2 supports themselves gave rise to a single peak of CO around 255 and 287 K, respectively, but no peak at all above 300 K. When the pressure of introduced CO was high, these peaks were superposed on a part of the CO peak desorbed from Pd metal. Such contribution of the interfering peak was compensated by extracting the peak-height which corresponds to that from the supports. In the IR study, CO was introduced at room temperature into the IR cell, and the spectra were recorded at the same temperature.

The catalytic hydrogenations of ethylene and cyclohexene were studied by using a closed circulation system up to 40 Torr (1 Torr=133.3 Pa) of partial pressure of each reactant and at temperatures between 273 and 301 K.

Results

Table 1 shows the observed characteristics of the supported Pd catalysts and ZrO_2-added catalysts. By the addition of ZrO_2, the particle size of Pd metals changed from 84 to 15 nm for Pd/SiO_2 and from 108 to 55 nm for Pd/α-Al_2O_3 catalysts. These changes were reflected in an increase in the percentage exposed. Table 1 also shows the turn-over frequency, N_t, of ethylene and cyclohexene hydrogenations; these values were evaluated on the assumption that the number of surface Pd atoms is equal to that of CO molecules adsorbed. With increasing Zr/Pd ratio, N_t's raised considerably for both reactions; at Zr/Pd=2.5—3, it increased by factors of 4—5 for the ethylene hydrogenation and 7—8 for the cyclohexene hydrogenation. As is shown by parentheses, the N_t's for the cyclohexene hydrogenation were the same within experimental error independent of pretreatment temperature: 523 or 723 K.

TD Spectra. Figure 1 shows the TD spectra of CO adsorbed on the Pd/SiO_2 catalysts. Two peaks were mainly observed, at 330—350 K (α peak) and at around 530 K (β peak); the latter peak had a shoulder γ around 600 K. Above 600 K, the spectra contained small peaks due to CO_2. The surface coverage, θ, was defined as the ratio of the amount of CO adsorbed to that at saturation. The β-peak was saturated at around θ=0.4, whereas the α-peak continued to increase with increasing θ. Figure 2 shows the TD spectra of CO desorbed from the ZrO_2-added Pd/SiO_2 catalysts. By the addition of ZrO_2 at a ratio of Zr/Pd=1, two main peaks were again observed but a peak appeared clearly at *ca.* 420 K (δ peak), and the β peak shifted toward high temperature by 16 K. With an increase in θ, the saturation of the β-peak occurred, followed by a considerable growth of the α, γ, and δ-peaks. Figure 3 shows the TD spectra at Zr/Pd=3. The δ-peak was more evidently observed, and the β-peak appeared at 547 K.

1. θ=0.13, 2. 0.26, 3. 0.35, 4. 0.49, 5. 0.59.

In continuation of the previous studies,[1,2] the α-alumina was employed as support, and the effects of added ZrO_2 were examined. As is shown in Fig. 4, the Pd metals on α-Al_2O_3 provided almost identical TD spectra of CO with those obtained by using the silica support. When ZrO_2 was loaded at a ratio of Zr/Pd=0.5 on this surface, a broad hump emerged at around 400 K,

and the β-peak shifted by 19 K toward higher temperature. It is to be noted that the ZrO_2 effect was analogous on both inert supports.

The relative intensity of the δ-peak was enhanced with an increase in the Zr/Pd ratio. As the other extreme, ZrO_2 was used as support; as is shown in Fig. 5, the corresponding δ-peak was clearly observed, and the β-peak appeared at 549 K.

IR Spectra. Figure 6 shows the IR spectra of CO adsorbed at room temperature on the silica-supported Pd surface and their changes upon subsequent heat treatment. As is reported elsewhere,[3] two broad bands, A and B, appeared; with an increase in the amount of CO adsorbed, the A-band at higher frequency shifted from 2029 to 2071 cm^{-1}, and the B band at lower frequency from 1880 to 1920 cm^{-1}. When gaseous CO was evacuated at room temperature, the A-band was remarkably attenuated with a shift to 2045 cm^{-1}, whereas the B-band was weakened to a lesser extent, giving a band at 1903 cm^{-1}. Further evacuation at 453 K caused almost complete disappearance of the A-band, but the B-band remained stable up to 533 K. The variations of IR spectra upon evacuation at elevated temperature occurred in a reverse way as the increase of the CO exposure.

The IR spectra for the ZrO_2-added catalysts are shown in Fig. 7. At Zr/Pd=0.1, the spectra below 2000 cm^{-1} exhibited a sharp band, B_H, centered at 1970 cm^{-1} and a shoulder tailing toward lower frequency, whereas the A-band appeared at 2097 cm^{-1} with narrow peak width. These spectral features became more distinct with

increasing Zr/Pd ratio; the addition of ZrO_2 at Zr/Pd=0.5—3.0 produced the B_H-band at 1970—1985 cm^{-1} and the A-band at 2090—2100 cm^{-1}. At the different exposures of CO, the spectral changes caused by added ZrO_2 were clearly observed, which indicated that the above-mentioned features are not coverage-dependent but are due to the intrinsic effect of added ZrO_2 oxide.

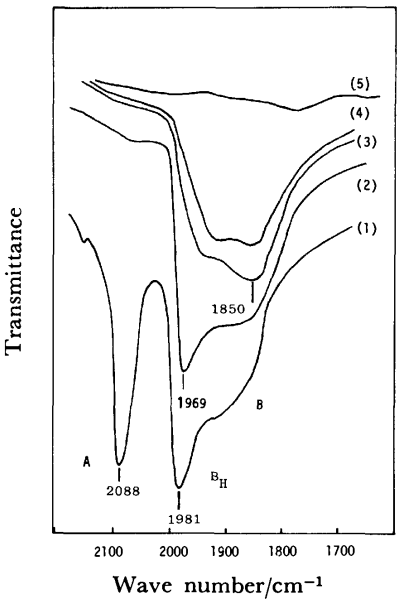

Fig. 9. Variations in IR spectra with evacuation temperature.
ZrO_2-added catalyst (Zr/Pd=0.5)
1. before evacuation ($P_{CO}=1$ Torr), 2. evacuated at 298 K for 40 min, 3. at 423 K for 20 min, 4, at 573 K for 30 min, 5. at 673 K for 20 min.

The IR spectra of the ZrO_2-added catalyst as a function of the CO exposure are shown in Fig. 8. The catalysts with the Zr/Pd ratio greater than 1.0 clearly exhibited ZrO_2-affected spectra even at low CO exposure, and, with increasing CO exposure, both A- and B_H-bands shifted to a lesser extent, in contrast to a large shift in the ZrO_2-absent catalysts. It is to be noted that the behavior of the band developments with CO exposure were different. Figure 9 shows the spectral variation upon heat treatment at different temperatures after CO adsorption at room temperature. For the catalyst with

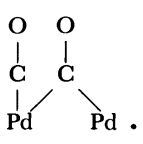
Zr/Pd=0.5, evacuation at 298 K caused the preferential and complete removal of the A-band, and further evacuation at 423 K resulted in the almost complete disappearance of the B_H band. Thanks to this evacuation, the remaining band, B, clearly manifested itself at an absorption frequency of 1850 cm^{-1}. Evacuation at 673 K annihilated completely the IR spectra in this region but produced a band around 1500 cm^{-1}, probably ascribable to the carbon dioxide species formed by disproportionation; such a result is in agreement with the TD results.

Discussion

In the absence of ZrO_2, the IR and TD spectra each provided two broad bands and peaks; these exhibited the corresponding changes upon increasing the amount of adsorbed CO as well as upon evacuation at different temperatures. The intensity of the A band in the IR spectra continued to increase above θ=0.4 and was easily removed by evacuation at 300 K; this seems to have a common base with the TD α-peak which is present only at high surface coverage and in lower temperature. Since the B-band was produced first and resisted heating up to 550 K, it is evident that this band is associated with the TD β and γ-peaks appearing at low coverage and in higher temperature. The remarkable effects of the added ZrO_2 upon the CO adsorption on the Pd surfaces were well reflected by the generation of the sharp B_H band at 1980 cm^{-1} and the clearer appearance of the δ-peak desorbed at an intermediate temperature region.

In the Pd carbonyl complexes, a linearly-coordinated CO[6] was found to have a stretching frequency at 2050—2169 cm^{-1}, whereas the three-fold coordinated CO produced the frequency at 1800 cm^{-1} or below.[7] Furthermore, many studies of CO adsorbed on Pd metals have shown that the absorption band of CO in the 2050—2100 cm^{-1} range is the stretching vibration of a linearly-bonded CO, whereas the band of a range 2000—1800 cm^{-1} is associated with the multiply-bonded CO such as a bridged one.[8-18] This classification allows us to assign the B_H- and B-bands to the C-O stretching frequency of CO coordinated on multiple Pd atoms and the A-band to that coordinated linearly.

Kokes *et al.*[15] suggested that a stretching frequency of 1970 cm^{-1}, corresponding to the characteristic B_H band, is due to the bridge-bonded CO which shares one of two Pd atoms with a linearly bonded CO, *viz.*,



This assignment, however, does not seem to hold for in the present case, since the B_H-band still remained after the linear CO was completely removed by evacuation. Boudart *et al.*[16] obtained a band of 1980 cm^{-1} as a shoulder at CO pressure of as high as 300 Torr on the silica-supported Pd, suggesting that the band is ascribable to intermolecular interaction as a result of the compression of the admolecule and is favored for the larger Pd particles. However, the present results showed that the spectral features could be distinguished depending on the absence or presence of ZrO_2 component, irrespective of the CO coverage. Furthermore, Table 1 indicates the opposite trend as to the particle-size effect; the B_H-band became intensive with the decrease in size.

In a recent combined IR-reflection absorption and LEED study using single crystals of Pd which expose the (100), (111), or (210) surface, Bradshaw and Hoffmann[19] showed that the C-O stretching vibrational frequency in the region 1880—1970 cm^{-1} was observed for θ<0.5 and CO is adsorbed on the two-fold coordination sites, which exist as bridge-site on the (100) plane as well as the (210) surface as the stepped (100) plane, whereas the frequency in the region 1800—1880 cm^{-1} was only observed for θ<0.3 and CO is adsorbed on the three-fold coordination sites on the (111) surface. They also showed that, on the (100) surface, the band associated with a linear-bonded CO appeared at 2096 cm^{-1} even for $\theta \cong 0.5$ in the case of the CO adlayer of poor ordering. The present IR spectra show that the IR band below 2000 cm^{-1} for Pd/SiO_2 catalyst covered broadly the range of the band for the ZrO_2-added catalysts, and the B-band still existed even in the presence of ZrO_2 (as a shoulder around 1880 cm^{-1}), thereby suggesting that the ZrO_2 effect can be related to the remarkable development of the narrow B_H-band. Thus, the consolidation of the above assignment and the fact that the B_H-band grew with increasing Zr/Pd ratio for similar CO coverage, as is shown in Fig. 7, lead to the consideration that the ZrO_2-affected Pd metal surfaces possess two-fold coordination sites of high density. This might be expected in case that the (100) plane and/or high index planes such as (210) were preferentially exposed, for instance, relative to the (111) plane. However, the extraordinarily narrow B_H band seems to reflect the existence of more specific dual sites such as isolated ones. The previous study showed that Pd metal atoms are able to interact strongly with ZrO_2 through the oxygen atoms.[2] When such incorporation of the metal with the oxide is taken into account, it is not unreasonable to consider that the ZrO_2 addition promoted the formation of the sites which have arrangements distinguishable from the usual largely-extended flat planes, *e.g.*, those like facets confined partially by ZrO_2 or a pair of protruded Pd atoms.

In the TD spectra, the position of the β-CO desorption peak remained almost unchanged as the CO coverage increased. This invariance is in agreement with the view that the CO desorption obeys the first-order kinetics.[20] Therefore, the shift of CO-desorption peak to higher temperature side by the presence of ZrO_2 component is indicative of the formation of stronger bonds between Pd metal and CO, since the adsorption of CO on Pd surfaces takes place *via* a nonactivated process.[21]

The β-CO corresponds to the CO remaining after evacuation at around 423 K, and the IR spectra gave rise to the absorption band at 1890 cm^{-1} for the Pd/SiO_2 catalysts and the band at 1850 cm^{-1} for the ZrO_2-added Pd/SiO_2 (Zr/Pd=0.5—3.0) catalysts. The presence of ZrO_2 actually caused a shift of the absorption band to

lower frequency, at least by 40 cm^{-1}. The direction of respective variation in the TD and IR spectra is in line with the generally accepted view in which the weakening of bonds between C and O atoms resulted in the strenghtening of the admolecule-surface bonding, as is accounted for in terms of a back-donation of a metal electron into the $2\pi^*$ orbital of the molecule.

Since the β-state corresponds to that of CO at a small coverage, it is considered that the effects of intermolecular interaction upon the IR-band frequency and TD-peak position are safely minimized. Thus, the above-mentioned shift appears to reflect the changes in an intrinsic metal-admolecule interaction in the absence or presence of ZrO_2. Thus, the enhancement of back-donating electrons arises from a high electron density of Pd metal atoms, which is indicative of electron transfer from ZrO_2 to the metal. This finding gives support to the previous conclusion obtained by using X-ray photoelectron spectroscopy.[2]

The variation in the heat of adsorption, ΔE, usually accompanies the shift of the C-O stretching vibrational frequency of the admolecule, ΔW. The experimental data on the CO-Pd systems[19,22,23] show that the energetic ratio of $\Delta W/\Delta E$ is retained in the range 1.5×10^{-2}—15×10^{-2}. The calculation for the present ZrO_2-caused shifts of the β-peak and B band showed that this ratio was about 7×10^{-2}, which falls within the region described above. From the shifts of the δ-peak and the B_H band, relative to the β-peak and B band respectively, the ratio was roughly estimated to be 3×10^{-2}. Such agreement gives support to the assignments for the TD peaks and IR bands. As to the α-peak, we need some caution, since the α-state present at low temperature is somewhat a function of evacuation time prior to the TD run as well depending on the validity of the correction in elimiating a contribution of interfering peaks which originate from the supports.

With CO exposure, the broad A-band due to a linearly-bonded CO moved to higher frequency for the Pd/SiO_2 catalysts, in agreement with the well-established view,[3] whereas the sharp A band for the ZrO_2-added catalysts showed a little shift. This invariance and narrowing of the peak seem to be an indication of ZrO_2 effects, suggesting that the CO accepts a compensative back-donation from the ZrO_2-affected Pd metal atoms or that it is adsorbed on the confined sites which make the molecule free from the neighbouring ones.

Thus, the ZrO_2 component exerts not only electronic influence but also some geometric effects, in the sense that the surface sites with specific structures are preferentially produced on the ZrO_2-added Pd metal. The previous study found that with increasing addition of ZrO_2 to Pd/α-Al_2O_3 catalysts the change in the kinetic parameters of the cyclohexene hydrogenation became negligibly small near a ratio of Zr/Pd=0.5, whereas the turn-over frequency continued to increase. It is likely that this can be correlated with the increase in the number of the specific sites. It is of interest to see that the ZrO_2 effects appear in the hydrogenation of unsaturated hydrocarbons such as ethylene, *cis*-2-butene and cyclohexene. The relative catalytic activities of the ZrO_2-added Pd/α-Al_2O_3 catalysts with reference to Pd/α-Al_2O_3 catalysts were increased with increasing dispersion (percentage exposed) in similar way for the hydrogenation of these olefines.[24]

Finally, in a recent IR study in connection with the catalytic hydrogenation of CO, Vannice *et al.*[25] showed that Pd metals on TiO_2 behave as in the case of the metal in Pt/TiO_2 catalysts; the strong metal-support interaction (SMSI) effect was generated after heating at 773 K such that the catalytic activity as well as the adsorptive properties was drastically reduced in spite of the presence of Pd metal particles with considerable surface area. In the present system, however, we observed little SMSI effect. The N_t for the cyclohexene hydrogenation was almost the same, independent of pretreatment temperature, *i.e.*, 1.2 for the 523 K-reduced Pd/ZrO_2 and 1.3 for the 723 K-treated one. Although a detailed comparison is needed, this fact seems to reflect a moderate interaction of the Zr cation through oxygen atoms with the metal, leading to a favorable catalytic effect, compared with an overly strong interaction of the Ti cation.

Physicochemical Studies of an Activated Europium Ion-exchanged Mordenite

Tsuyoshi ARAKAWA,* Midori TAKAKUWA, Gin-ya ADACHI, and Jiro SHIOKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, 2-1, Yamadaoka, Suita, Osaka 565

(Received September 5, 1983)

The physicochemical properties of an activated Eu(III) ion-exchanged mordenite (Eu-M) have been studied by the measurement of the fluorescence of the europium ion. When Eu-M (the exchanged level; 3.7%) was degassed only above 300 °C, a band emission which peaked at 488 nm appeared. This band emission was associated with the Eu^{2+} 5d-4f transition. The peak of the band emission shifted linearly to a shorter wavelength with the increase in the exchanged level of the Eu ions. For the Eu-M sample, which was reduced by H_2 at 500 °C, the peak position of the band emission was almost 499 nm in all cases, and the quantum yield for a reduced sample was larger than that for a dehydrated sample. The quantum yield for a reduced sample fell off extremely above the exchanged level of 6%. Moreover, the Eu^{2+}–Eu^{2+} energy transfer in the reduced samples was discussed.

Several attempts have been made to identify the structures and chemical properties of europium-exchanged zeolites. The presence of Eu^{4+} in zeolite A has been postulated by X-ray analysis.[1] Electron-paramagnetic resonance has been applied to study the ligand coordinations of europium-exchanged mordenite, zeolite Y, and zeolite A.[2,3] A Mössbauer study of europium-exchanged zeolite has been reported.[4,5] These techniques are, however, of restricted applicability. On the other hand, fluorescence spectroscopy can be helpful for rare-earth ion-exchanged zeolites, though the rare-earth mordenites have rarely been studied by the use of fluorescence techniques.[6] We ourselves have previously studied the physicochemical properties of rare-earth ion-exchanged zeolites from the measurement of the fluorescence of the rare-earth ions in an attempt to clarify the catalytic properties of these compounds.[7] Especially, it has been found that a part of the Eu^{3+} ion in zeolite Y and mordenite is reduced to the Eu^{2+} ion by dehydration in a vacuum or inert gases. That is, on Eu^{3+} ion-exchanged zeolites, the emission band for Eu^{3+} decreased and the band emission due to Eu^{2+} appeared as Eu^{3+} ion-exchanged zeolites were degassed above 300 °C. The fluorescence of Eu^{2+} has been studied, and a number of Eu^{2+}-containing phosphors emitting in the blue or ultraviolet region have been described.[8-10] In general, the Eu^{2+}-doped phosphors are made by the reduction of the Eu^{3+}-doped samples at higher temperatures (800 °C$<T$) in an hydrogen atmosphere. Therefore, it is noteworthy that the reduction of Eu^{3+} to Eu^{2+} in zeolites takes place easily upon degassing at low temperatures.

In this paper, the fluorescence properties of Eu^{2+} for an activated Eu ion-exchanged mordenite (Eu-M) will be reported in more detail.

Experimental

Materials. The Eu-M samples were prepared starting from Na-mordenite which had been supplied by the Norton Company. The parent mordenite had the following composition: $Na_8(AlO_2)_8\cdot(SiO_2)_{40}\cdot 24H_2O$. The mordenite was ion-exchanged in solutions containing $EuCl_3$, washed, dried at 100 °C, and calcined in air at 450 °C. The close correspondence between the decrease in the sodium content and the increase in the europium content indicated that a simple ion-exchanged process had occurred. The exchanged mordenites were analyzed for europium by means of X-ray fluorometry and for sodium by means of flame photometry. Thus, the exchanged levels (100x (%); $Na_{8(1-x)}\cdot Eu_{8\cdot x}(AlO_2)_8\cdot(SiO_2)_{40}\cdot 24H_2O$) of the europium ion were found to be 0.1, 0.5, 1.4, 3.7, 5.8, 6.7, and 8.0%.

Methods and Procedures. The emission and excitation spectra were measured using a Shimadzu Recording Absolute Spectrofluorophotometer (RF-502) at room temperature. The UV spectra were taken with a Shimadzu UV-180 apparatus, using MgO as the reference. The particle size of the Eu-M samples was made to fall in the range of 10^{-5}—10^{-4} m so that the light-scattering would be as uniform as possible. The UV spectra in the region from 200 to 400 nm were recorded using a glass filter (UV-D25), since the UV spectra in the region of 250—400 nm were affected by the fluorescence of the divalent europium ion as will be described below, Prior to the measurement, the samples in a quartz cell were dehydrated at the desired temperature for 4 h under a pressure of 10^{-5} Torr (1 Torr=133.322 Pa) and then cooled at room temperature. The reduced samples were obtained by treatment at 500 °C for 1 h in a hydrogen atmosphere. The quantum yield (Q_0) of fluorescence was derived from the following equation:[11]

$$Q_0 = \frac{Q_{\text{sample}}}{Q_{\text{CaWO}_4:\text{Pb}}} \times \frac{I_{\text{CaWO}_4:\text{Pb}}}{I_{\text{sample}}}, \qquad (1)$$

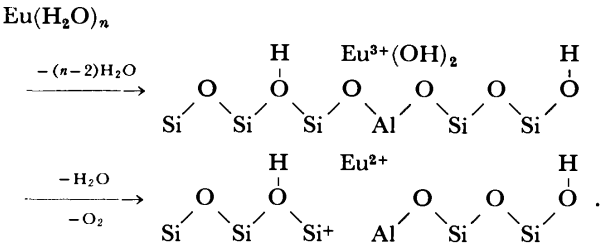
where Q_{sample} and $Q_{\text{CaWO}_4:\text{Pb}}$ are the photoluminescence outputs where, therefore, I_{sample} and $I_{\text{CaWO}_4:\text{Pb}}$ are the numbers of absorbed photons, as obtained from the UV spectra.

Gas-consumption Experiments. When the Eu-M sample was reduced by hydrogen, the amount of hydrogen consumption was accurately determined as a function of the time by measuring the pressure drop. Reoxidation was also investigated by measuring the oxygen-pressure drop in the same apparatus, which consisted of a closed circuit containing a circulation pump in series with a quartz tube reactor and a cold trap. The volume of the system was 180 cm^3; the rate of circulation of the gas was 1000 $cm^3\ min^{-1}$. The pressure drop was monitored on a digital manometer (Validyne CD-23). The accuracy of the gas-uptake measurements was better than ±0.002 mmol.

Lifetime Measurement. The fluorescence lifetimes were measured using a Nitrogen Laser (337 nm) with a lifetime of less than 5 ns. Also, for the measurement of the lifetimes a monochrometer was used to enable us to select the emission wavelength. The lifetimes were determined from the oscilloscope trace as the slope of log I *vs.* t.

Results and Discussion

Europium Spectra for the Dehydrated Samples. When the Eu-M sample (exchanged level: 3.7%) was degassed above 300 °C, the band-emission (Curve 1), peak at 488 nm newly appeared, as is shown in Fig. 1. The optimum excitation wavelength was 315 nm. The quantum yield was 4.3%. A new band emission in the short-wavelength UV region must be due to the $4f^65d$-$4f^7$ transition for the Eu^{2+} ion, as has been described elsewhere.[9] In the dehydrated Eu-M samples, the emission band for the Eu^{3+} ion under excitation with 300-nm radiation, which has its peaks at around 572 ($^5D_0$-$^7F_0$), 580 ($^5D_0$-$^7F_1$), and 624 nm ($^5D_0$-$^7F_2$), was observed (*cf.* Fig. 2). When Eu-M was dehydrated at 500 °C, the emission lines were observed on the foot of the band emission for the Eu^{2+} ion. No position of the emission lines changed between before and after the dehydration. However, the relative intensity of the $^5D_0$-$^7F_0$, $^5D_0$-$^7F_1$, and $^5D_0$-$^7F_2$ emissions varied with an elevation of the temperature. This fact is mainly attributable to the change in the local environment of the Eu^{3+} ion, with a loss of coordinated water molecules, as has been described elsewhere.[12] The mass-spectroscopic analysis of the noncondensable gaseous material evolved during the evacuation above 300 °C for Eu-M revealed that the gas was oxygen. The amount of oxygen evolved from Na-M was negligibly small. The evolved oxygen for Eu-M samples increased, though, with the increase in the exchange level of Eu ions. The degree of reduction for Eu^{3+} to Eu^{2+} in mordenite during the evacuation at 500 °C for 4 h was about 30%, judging from the measurement of the magnetic susceptibility, as has been described elsewhere.[12] Moreover, the total evolved oxygen amounted to one oxygen molecule desorbing per Eu^{2+} ion. Although we no clear data of the dissociation of adsorbed water,[12] it is probable that the dissociation of adsorbed water occurs as follows, in a manner similar to that occurring on the other rare-earth ion-exchanged zeolites; $Ln(OH_2)_2^{+3} \rightarrow Ln(OH)_2^+ + 2H^+$.[13] Thus, it can be considered that the reduction of Eu^{3+} in mordenite proceeds mainly according to Eq. (2):



(2)

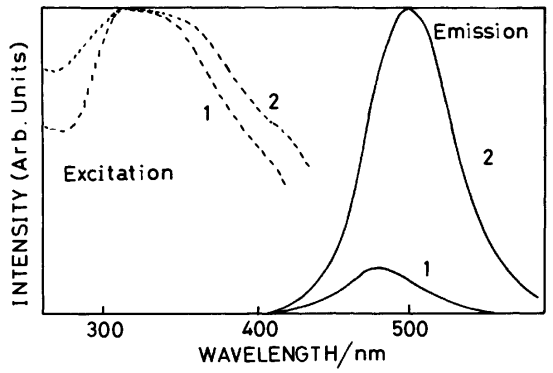


Fig. 1. Fluorescence spectra of Eu-M (3.7%) after degassing at 500 °C for 4 h (1) and reducing at 500 °C for 2 h (2).

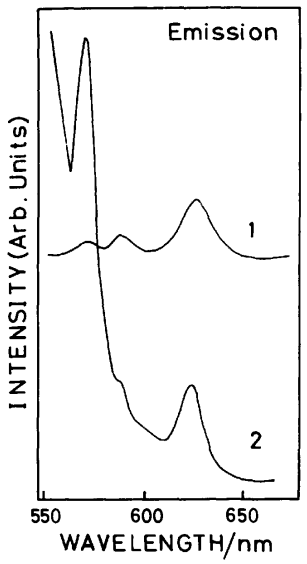

Fig. 2. Emission spectra of the Eu^{3+} ion in Eu-M (3.7 %). Excitation with 300 nm radiation. (1) After degassing at 25 °C for 2 h. (2) After degassing at 500 °C for 4 h.

The peak position of the band emission of Eu^{2+} in dehydrated samples changed with the concentration of europium ions in mordenite. However, the optimum excitation wavelength was 315 nm in all cases. Therefore, the excitation process of Eu-M may be thought to be relatively unimportant. Figure 3 gives the relationship between the wavelength of the peak position and the exchanged level of the europium ion. The peak position of the band emission shifts linearly to a shorter wavelength as the exchanged level increases. Similar behavior has been observed for the system of $SrMgP_2O_7$: Eu^{2+} or $Sr_{1-x}Ba_xAlF_5$:Eu^{2+}.[14] The wavelength for the band emission in Eu^{2+} ions is determined by two factors: on the one hand, the splitting of the 5d levels by the crystal field of the surrounding oxygen ions, and, on the other hand, the energy gap between the 4f ground state and the center of gravity of the 5d excited levels. The UV spectra of dehydrated samples with different exchanged levels are shown in Fig. 4. The peak of the absorption spectra in the UV region was about 300 nm in all cases. The split of the absorption bands attributable to the allowed electric dipole transitions between the 4f and 5d states was not clearly observed. Therefore, it

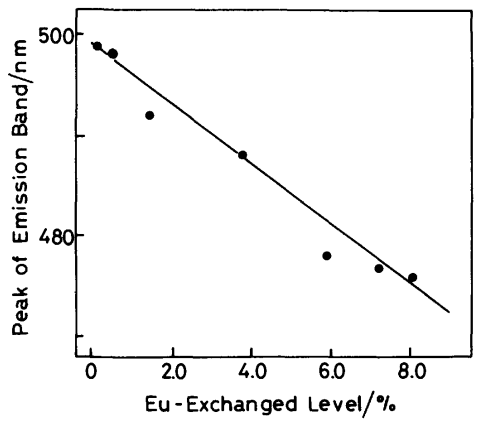

Fig. 3. The relationship between the peak position of the emission band for Eu^{2+} and the exchanged level of europium ion.

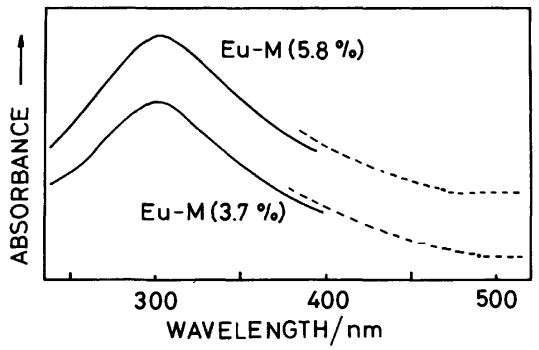

Fig. 4. The absorption spectra of the dehydrated samples. The solid lines are the spectra with a glass filter (UV-D25). The dotted lines are the spectra without the filter.

can be anticipated that the possibility of the peak shift is rarely present. The absorption edge, however, shifted to a shorter wavelength with the increase in the exchanged level of the europium ion. These results were consistent with the results for the shift of the band emission. The peak shift may be attributed to an increase in the fraction of Eu^{2+} ions which interact with each other in dipolar coupled pairs.[3] In this case, the exchanged sites will play an important part in the formation of dipolar coupled pairs.

The structure of Na mordenite has the space group Pbcn, a=17.92 (1), b=20.31 (1), and c=7.48 (7) Å.[15] Only the I′, IV, and VI sites are occupied by Na cations in a dehydrated Na mordenite. The percentages of occupancy for the sites are 43% (I′), 36% (IV), and 21% (VI). Jacobs *et al.*[16] have pointed out that, in Cu-Y, a small number of supercage oxygen ions were capable of causing a rupture or considerable weakening of the Si(Al)-O bond under evacuation at 623 K. In Na-M, the VI site faces the large channel, much like the supercage in the Y-type zeolite. Thus, it appears that the Eu^{3+} ions which occupy the VI site are easily reduced to Eu^{2+} ions during the dehydration, according to Eq. (2). The VI site is a wall site in the large channel, and the cation on the VI site sticks out of the wall somewhat. That is, the Eu^{2+} ions on the VI site are able to interact directly with each other. Also, the fraction of Eu^{3+} ions for the VI site is 21% if the Eu^{3+} ions are ion-exchanged according to the percentage of occupancy for each site. Since the degree of the reduction of the Eu^{3+} ions was about 30% under the evacuation, it is thought that the Eu^{3+} ions are slightly localized to the VI site. Therefore, the fraction of the Eu^{2+} ions which interact with each other in dipolar coupled pairs will be enhanced as the concentration of the Eu ions increases. Thus, in dehydrated Eu-M samples, a shift of the peak position would be observed as the Eu^{2+} concentration increased. Further physicochemical evidence should be collected to support the phenomena of the peak shift.

Europium Spectra for the Reduced Sample. The emission spectrum after the treatment at 500 °C in a hydrogen atmosphere is shown in Fig. 1 (Curve 2). The emission spectrum of Eu^{2+} for the reduced sample was distinct from that for the dehydrated sample. For Eu-M (3.7%), the peak position of the band emission is 499 nm under the optimum excitation of 315 nm, and the quantum yield (27.2%) is larger than that for the dehydrated sample (4.3%).

The stoichiometry of the reduction-reoxidation of dehydrated and reduced Eu-M samples at 500 °C can be derived from the data of Table 1. For Na-M, an oxygen or hydrogen pressure drop was rarely observed. After the dehydration of Eu-M, the small amount of oxygen was consumed. The amount of oxygen corresponds to 30% of the total Eu ions. The degree of reduction for Eu^{3+} to Eu^{2+} in mordenite was about 30%, as has been described elsewhere.[12] Also, we have concluded from the experiments of the thermal-programmed desorption (TPD) of oxygen that one oxygen molecule is adsorbed to an Eu^{2+} ion in mordenite.[17] Thus, the amount of oxygen estimated from the pressure drop is consitent with the amount of oxygen needed to reoxidize. On the other hand, the amount of oxygen needed to reoxidize after the reduction of hydrogen is consistent with the total number of Eu ions. The amount of hydrogen consumed, however, was 1.4 times the total amount of Eu ions in all cases. After the reduction at 500 °C, the sample was degassed and then exposed to oxygen at the same temperature. It was subsequently cooled to 25 °C under an oxygen atmosphere and then degassed for 1 h at the same temperature. After these operation, the TPD spectroscopy was done; the results

Table 1. Gas consumption (mmol g^{-1}) at 500 °C

Exchanged level (%)	Eu^{3+} ion (mmol g^{-1})	Cycle No.	H_2	O_2
5.8	0.044	1		0.013[a]
		2	0.058	0.043[b]
		3	0.060	0.044[b]
7.2	0.055	1		0.016[a]
		2	0.075	0.050[b]
		3	0.078	0.052[b]

a) Oxygen uptake at 500 °C for 2 h after dehydration. b) After the reduction of H_2, the circular system was evacuated for 1 h and then the reduced sample was reoxidized by O_2; reoxidation time: 0.5 h.

will be described elsewhere.[17] Thus, it was clear from the TPD experiment that the amount of desorbed oxygen from the reduced sample was almost consistent with that for the dehydrated sample described above. Also, the degree of reduction was about 100%, judging from the measurement of magnetic susceptibility, as has been described elsewhere.[12] Therefore, the amount of hydrogen consumed should be twice the amount of oxygen needed to reoxidize if oxygen does not desorb under the evacuation at 500 °C after oxygen exposure. As has been described above, it appears that the Eu^{3+} ions which occupy the VI site are easily reduced to Eu^{2+} ions during the dehydration, while other Eu^{3+} ions which exist on the I′ or IV site are reduced only under the reducing atmosphere. Since the I′ and IV sites are shaded by the (Si, Al)O_4 network,[15] the increase in the quantum yield for the reduced sample may be attributed to the increase in the isolated Eu^{2+} ions. That is, it is considered that, in the emission spectrum for the reduced sample, the emission band with a peak at 488 nm is concealed in the foot of the emission band with a peak at 499 nm.

Concentration Dependence. In Fig. 5, we plot the quantum yield *vs.* the exchanged-Eu-ion concentration for the reduced samples in comparison with that for the dehydrated samples. The quantum yield stays relatively constant up to almost 6%, but above that point it decreases abruptly. This phenomenon may be recorded in terms of the concentration-quenching effect. In order to discuss the concentration-quenching phenomenon in more detail, we have considered the Eu^{2+}—Eu^{2+} energy transfer in an reduced Eu-M. Since the transfer occurs mainly *via* dipole-dipole interaction,[18] the probability, $P_{Eu^{2+}-Eu^{2+}}$, of energy tranfer between Eu^{2+} ions by means of this interaction has been given as;

$$P_{Eu^{2+}-Eu^{2+}} = 6.3\times10^{27}\frac{Q_A}{R^6\tau_{Eu}}\frac{1}{E^4}\int f_{Eu}(E)F_{Eu}(E)dE, \quad (3)$$

where Q_A is the absorption cross-section of the Eu^{2+} ions (in cm^2 eV); R, the distance between the Eu^{2+} ions (Å); τ_{Eu}, the decay time of the fluorescence (in s); E the energy transferred (in ev), and $\int f_{Eu}(E)F_{Eu}(E)dE$, the overlap between emission and excitation bands. Blasse defined a critical distance, R_c, between two luminescent centers, S and A, as the distance for which the probability of transfer from S to A equals the probability of the radiative emission of S. This means that $P_{Eu^{2+}-Eu^{2+}}\cdot\tau_{Eu^{2+}}=1$ in terms of Eq. (3). Thus, R_c can be found from this equation;

$$R_c^6 = 6.3\times10^{27}\frac{Q_A}{E^4}\int f_{Eu}(E)F_{Eu}(E)dE. \quad (4)$$

Also, the critical distance R_c (in Å) can be estimated by geometrical considerations as follows:

$$R_c \simeq 2\left(\frac{3V}{4\pi x_c N}\right)^{1/3}, \quad (5)$$

where V is the volume of the unit cell (in $Å^3$); x_c the activator atom fraction (the concentration) at which the quenching starts, and N, the number of sites per unit cell at which the activator atoms enter. In this paper, we assume that, for the critical concentration, the average shortest distance between nearest activator ions is equal to the critical distance, R_c. Thus, the R_c value for the reduced sample, 22 Å, is derived from Eq. (5), as V is 2.72×10^3 $Å^3$, x_c is 0.06, and N is 8. This value is the same as that in the system of $BaBPO_5$; Eu^{2+} (22 Å).[18] 22 Å is the distance separating one Eu^{2+} ion and another Eu^{2+} ion when the quenching starts in Eu-M. If the Eu^{2+}-Eu^{2+} distance is expressed in terms of 3.4 Å×n, where 3.4 Å is the mean interatomic distance between Na nearest neighbors in Na mordenite, as has been described above and n is the number of exchanged sites, n is 6.5. $P_{Eu^{2+}-Eu^{2+}}$ is varied by the factor of $\left(\frac{R_c}{R}\right)^6\frac{1}{\tau_{Eu}}$, which is derived from Eqs. (3) and (4). Since τ_{Eu} is$\simeq10^{-6}$ s, as is shown in Table 2, in the reduced Eu-M the transfer probability for the separation of 3.4 Å is $\simeq10^{10}$ s^{-1}.

The concentration-quenching effect was also observed at a low concentration of Eu^{2+} ions in the dehydrated Eu-M, as is shown in Fig. 5. If Eu^{2+} ions disperse statistically, R_c is 46 Å, as x_c is 0.006 (the effective Eu^{2+} fraction is 0.02×0.3, since the degree of reduction is about 30%). The R_c value of 46 Å is much larger than the maximum R_c (27 Å).[10,19] Since the concentration-quenching effect is observed at a low concentration, it is probable that a Eu^{2+} ion, which is easily produced by the dehydration, is present at the specific site and in the neighborhood of another Eu^{2+} ion to be able to affect the concentration quenching as has been described above.

Since the fluorescence is a phenomenon depending on many variables, such as the concentration of the luminescent activator, its coordination, and the host lattice, the interpretation of results is not always easy. However, it is specific in the sence that it can solve certain problems which are very difficult to solve with

Table 2. Decay time of the reduced Eu-M samples at room temperature

Exchanged level (%)	Pretreatment	$\tau/10^{-6}$ s
3.7	500 °C, Reduced	3.5
5.8	500 °C, Reduced	3.5

other techniques, *e.g.*, the prediction of dipole-dipole interaction. Thus, it is considered that the results in this paper lead to a method of investigating the physicochemical properties of rare-earth ion-exchanged zeolites, although fluorescence spectroscopy is by no means a new technique. Further detailed studies to investigate these problems are now in progress.

We are grateful to Professor H. Mikawa and Dr. Y. Shirota of Osaka University for their support in the measurement of the decay time.

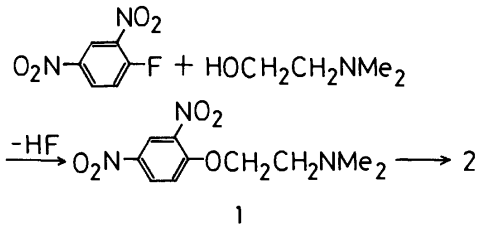
(Received September 8, 1983)

The crystal structure of *N,N,N',N'*-tetramethylpiperazinediium bis(2,4-dinitrophenolate) dihydrate has been determined by the X-ray method. The crystals are triclinic, space group $P\bar{1}$, a=11.504(2), b=8.239(2), c=7.119(2) Å, α=106.22(2), β=99.67(2), γ=92.31(2)°, Z=1. The final R is 0.067 for 2743 reflections. Two dinitrophenolate anions are connected by hydrogen bonds, *via* the water molecules, forming a dimeric unit related by the center of symmetry. *N,N,N',N'*-Tetramethylpiperazinediium ion has a chair conformation.

Reaction of 2,4-dinitrofluorobenzene with 2-(dimethylamino)ethanol gave 2,4-dinitrophenyl 2-(dimethylamino)ethyl ether (**1**) as a viscous liquid. On standing long at room temperature or heating in DMF, **1** gave yellow precipitates (**2**), whose NMR spectrum showed only three broad singlets at 3.3—4.0 ppm in addition to an AMX pattern in the aromatic region. In order to elucidate the character of **2** an X-ray structure analysis was undertaken.



1

Experimetal

Yellow crystals were grown from an EtOH-H_2O mixed solution. Intensity data were collected on a Rigaku automatic diffractometer AFC4 using graphite-monochromated Mo $K\alpha$ radiation. A specimen with approximate dimensions 0.4×0.4×0.2 mm was used. Reflections within the range 2θ<60° were measured by the ω-2θ scan technique with a scanning speed of 4°/min in 2θ and scan widths of $\Delta\omega$=1.1°+0.5°tanθ. At both ends of the scan range 10 s background counts were taken for each reflection. 2743 reflections had $|F_o| \geq 3\sigma(F_o)$ and were considered as observed. No absorption correction was applied.

Structure Determination

Crystals belong to the triclinic system, and the centrosymmetric space group $P\bar{1}$ was assumed on the basis of the intensity statistics. Unsuccessful attempts were made to solve the structure with MULTAN78.[1] E-maps obtained from the four sets of signs showed honeycomb-like arrays of peaks from which unambiguous recognition of molecules was impossible.

The space group was assumed to be $P\bar{1}$ and attempts to solve the structure with MULTAN78 gave two fragments of 2,4-dinitrophenolate anion (2,4-DNP$^-$). Examination of the structure showed that one fragment related to the other with the center of symmetry. Reassuming the space group to be $P\bar{1}$, the parameters were refined by a block-diagonal least-squares method to R value of 0.49. A Fourier map showed two other fragments; one was assigned to the water oxygen and the other to NC_4 of the tetramethylammonium group. All non-hydrogen atoms were refined with anisotopic temperature factors. A difference synthesis was calculated from which the positions of the hydrogen atoms in 2,4-DNP$^-$, H_2O, and $(CH_2)_2N(CH_3)_2$ were found. Examination of the structure revealed that the cation was not a tetramethylammonium, but an *N,N,N',N'*-tetramethylpiperazinediium whose center of inversion was coincident with that of the crystal symmetry. All the atoms were then refined with several cycles of block-diagonal least-squares using anisotropic temperature factors for the non-hydrogen atoms and isotropic ones for the H atoms. The quantity minimized was $w(|F_o|-k^{-1}|F_c|)^2$ where w=0.8 if $|F_o|$<2.0, w=1.0 if $2.0 \leq |F_o| \leq 8.0$ and $w=(8.0/|F_o|)^2$ if $|F_o|$>8.0. The final R value was 0.067 for all observed reflections. Scattering factors were taken from "International Tables for X-Ray Crystallography".[2] All computations were performed on a HITAC M180 computer of the Data Processing Center of the University of Electro-Communications, using the programs UNICS III,[3] MULTAN78 and ORTEP.[4] The final atomic parameters are given in Table 1.[5]

Discussion

Crystal data: $(C_8H_{20}N_2)^{2+} \cdot 2(C_6H_3N_2O_5^- \cdot H_2O)$.†† Triclinic, space group $P\bar{1}$, a=11.504 (2), b=8.239 (2), c=7.119 (2) Å, α=106.22 (2), β=99.67 (2), γ=92.31 (2)°, V=636.0 (2) Å^3, D_x=1.427 g cm^{-3}, Z=1.

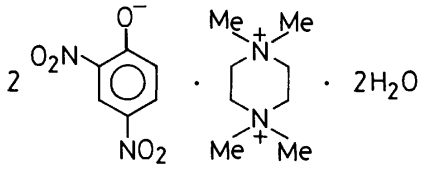


Figure 1 shows the atomic numbering of the crystal-chemical unit. Stereoscopic view of the structure and the projection along the b axis are shown in Figs. 2 and 3 respectively. The structure analysis established that the compound consists of two 2,4-dinitrophenolate

†† From the structure analysis.

anion (2,4-DNP$^-$), one *N,N,N′,N′*-tetramethylpiperazinediium (TMP^{2+}) ion and two water molecules. Thus the substance is a salt of 2DNP$^-$ and TMP^{2+}. Many picrate compounds have been known,[6] but this is the first example of the existence of 2,4-DNP$^-$ in the crystal. Two 2,4-DNP$^-$ anions are connected by the hydrogen bonds, *via* the water molecules, forming a dimeric unit related by the center of symmetry at (0,0,0) as shown in Fig. 3.

The result of the structure analysis suggests that 2,4-dinitrophenyl(dimethylamino)ethyl ether (**1**) cleaved between -O- and -CH_2- in the course of the reaction, and two -$CH_2CH_2NMe_2$ associated to form a TMP^{2+} ring. Thus the formation of **2** is nucleophilic cleavage of either C-O bond in Ar-O-CH_2 moiety intramolecularly or intermolecularly by the dimethylamino group. Primary and secondary amines usually displace the OCH_2 group through the Meisenheimer complexes, while tertiary amines can also cleave the O-CH_2 bond.[7]

Bond lengths and bond angles are listed in Table 2. The dimensions of 2,4-DNP$^-$ anion are close to those in the picrate anion. The C=O length (1.254 Å) is shorter than that of C-O (1,343 Å) in 2,4-dinitrophenol[8] and only slightly longer than the corresponding ones in the picrates. The angle at C(1) is typically low at 114.3° and the C-C bonds show characteristic variations in length. The C(1)-C(2) and C(1)-C(6) distances show some single-bonded character and the C(5)-C(6) length is shorter than the normal C-C aromatic length. The

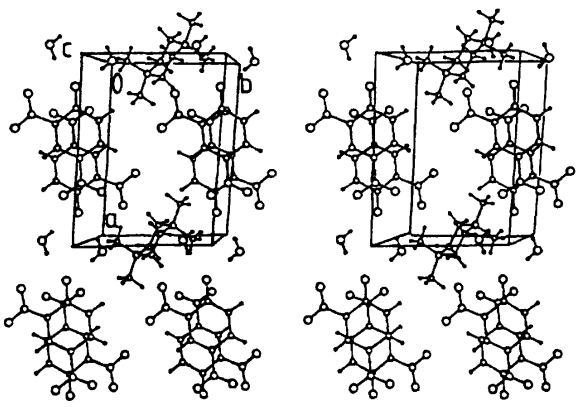

Fig. 2. Stereoscopic view of the crystal structure.

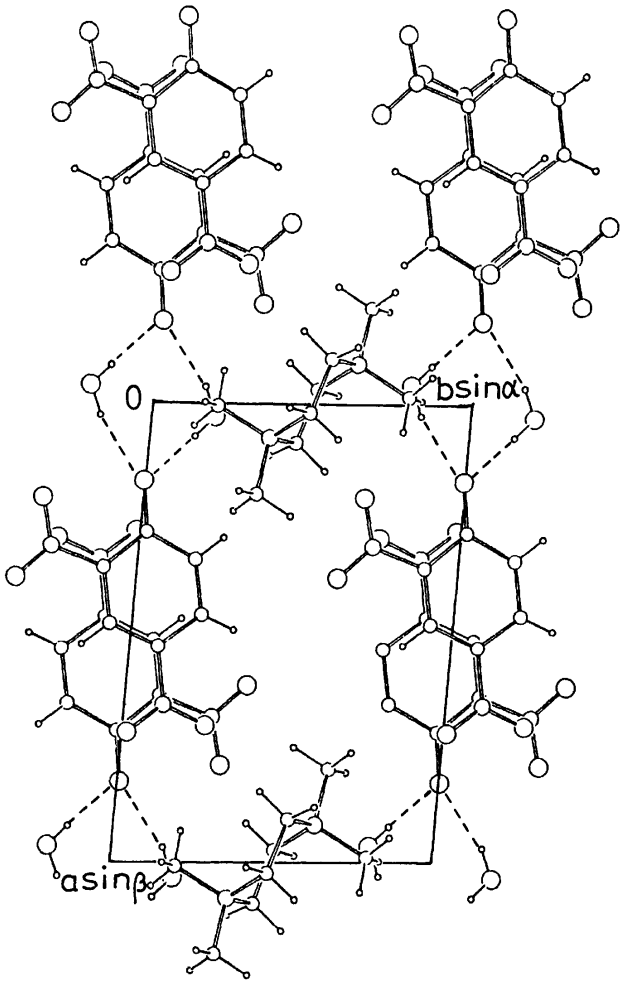

Fig. 3. Projection of the structure along the c axis.

benzene ring is planar, deviations being within 0.002 Å. Deviations of O(1), N(2), and N(4) from this plane are 0.006, 0.02, and 0.03 Å respectively. The two nitro groups are tilted only slightly from the mean plane of the benzene ring by 4.5 and 6.1° for the groups of N(2) and N(4) respectively. Some shortenings for the N-C lengths are found; N(2)-C(2) (1.444 Å) has the same value of the corresponding N-C bond in 2,4-DNP. The N(4)-C(4) length (1.436 Å) is significantly shorter than that of 2,4-DNP, but close to those in picrates. These shortenings of N-C bonds are due to the quinonoidal character of the anion.

The dimensions of O⁻···H-O hydrogen bonds between 2,4-DNP⁻ and H_2O are also listed in Table 2. The normal to the mean plane of the benzene ring of 2,4-DNP⁻ is almost parallel to the c axis and the average length between the ring planes of two 2,4-DNP⁻ related by the center of symmtry at (1/2,0,0) is 3.351 Å.

The piperazinediium ring exhibits the space-group imposed $\bar{1}$ (Ci) symmetry, and also shows the 2/m symmetry with a good approximation. The endocyclic C-N length is 1.505 Å and exocyclic C-N bonds are 1.507 and 1.498 Å. These values are longer than those usually found in C-N single bonds (1.47—1.49 Å), but similar values are reported for $C(sp_3)$-N^+(alkyl)$_3$ bonds in 1,1-dimethyl-4-phenylpiperazinium iodide,[9] (+)-*N*-2-(benzylmethylamino)propyl propionanilide hydrobromide,[10] and *trans*-2,5-dimethylpiperazine dihydrochloride.[11] The C-C length is 1.502 Å, which is significantly shorter than that in cyclohexane (1.520 Å). One of the reasons for the long C-N bond may be a nonbonding repulsion between ring hydrogens and methyl hydrogens. There are some short contacts between the axial hydrogens and the axial methyl

group; H(12)···H(43) and H(22)···H(43) are 2.29 and 2.27 Å respectively. The mean endocyclic CCN angle is 112.4° and the CNC angle is 108.5°. The exocyclic CNC angles average to 109.6°. The mean value of the ring torsion angle is 55.7° (min. 55.0—max. 57.2°). For cyclohexane derivatives and heterocyclic compounds in the chair conformation a correlation exists between the average torsion angle, ϕ, and the average ring bond angle, θ: $\cos\phi=-\cos\theta/(1+\cos\theta)$.[11] In the present case $\phi_{calcd}=55.8°$ for $\theta_{obsd}=111.1°$, which is compared with the observed value of 55.7°. This value shows that the ring in TMP^{2+} is more flat than the perfect chair model of cyclohexane with tetrahedral bond angles and torsion angles of 60°.

Some of the shorter intermolecular contacts are listed in Table 3. There are distinctly short C-H···O contacts between O(42)···CP(1), O(42)···CP(4), CP(4)···O^{iii}(41), CP(2)···OW^{iv}, OW···CP^{v}(2), and O(21)···CP^{vi}(1).

Association between Polar Molecules. III. ^1H and ^{13}C NMR Studies on the Dipole Association of Acetonitrile Derivatives with Tetramethylurea and Dibutyl Sulfoxide in Nonpolar Solvents

Tatsuya TAKAGI,* Hideaki FUJIWARA, and Yoshio SASAKI
Faculty of Pharmaceutical Sciences, Osaka University, 1-6 Yamadaoka, Suita, Osaka 565
(Received September 24, 1983)

Dipole association between acetonitrile derivatives and polar substances such as tetramethylurea and dibutyl sulfoxide is investigated in nonpolar solvents. Association parameters and thermodynamic parameters are derived and discussed in relation to the substituent constants. ^1H and ^{13}C NMR chemical shifts show that the major structures of the associate are antiparallel. Association energies are also determined using semiempirical MNDO MO method, which supports the experimental results for energies as well as structures.

It is important to study the association between polar molecules in order to elucidate the structure of polar liquids, various solvent effects, *etc.* Hitherto, few studies have been reported[1-3] about major structures of super systems for dipolar association; Saito *et al.*[1] and Frurip *et al.*[2] indicated that a partial dipole was more important than a classical one for dipolar association, using ^{13}C NMR and *ab initio* SCF MO method respectively. However, more exhaustive studies are surely necessary to understand the factors governing the strength of association and the structre of the associate.

In previous reports,[4] we have investigated the intermolecular interactions between *p*-substituted benzonitriles or *p*-substituted nitrobenzenes and hexamethylphosphoric triamide (HMPA), dibutyl sulfone (DBSN), dibutyl sulfoxide (DBSX), and tetramethylurea (TMU) by analyzing the NMR concentration dependence. One conclusion of the study is that the association is governed mainly by electrostatic interactions. It also indicated that the association takes place around the CN group in the case of the association of *p*-substituted benzonitriles with HMPA, as evidenced by the correlation between the association parameters and the substituent constants (σ_I, σ_π)[5] or dipole moments, and by the ^{32}P chemical shift in HMPA.

In the present study, we have investigated the association of aliphatic nitriles, in which the electric charges are less delocalized than in aromatic ones and the local dipole moments are expected to play an important role in the association. ^1H and ^{13}C NMR measurements and MO calculations are utilized to obtain more detailed information about the association, especialy the equilibrium structure of such super systems.

Experimental

(Dimethylamino)acetonitrile was synthesized from dimethylamine and formaldehyde according to the literature.[6] Other nitriles were of commercial grade; they were distilled under reduced pressure and stored over Molecular Sieve 4A. Cyclohexane for solvent was washed with mixed acid, alkaline solution and water succesively; and dried over calcium chloride. It was stored over Molecular Sieve 4A after distilling three times over calcium hydride. Carbon tetrachloride was similarly washed with alkaline solution and water, distilled over calcium hydride, and finally stored over Molecular Sieve 4A. TMU and DBSX were prepared in the same way as in the previous report.[4b]

^{13}C NMR spectra were observed with a HITACHI R-900M FT NMR spectrometer operating at 22.36 MHz and at 35 °C with 16k data points, using the peak of CCl_4 as internal references. Errors in the shift measurements were less than ±0.05 ppm. ^1H NMR measurements were made as in the previous report[4b] using cyclohexane as solvent.

The sample solution for T_1 measurements was sealed under nitrogen atmosphere and the height of the solution was adjusted to 20 mm. The spin-lattice relaxation times were measured by the fast inversion-recovery method[7] which uses the (180°-τ-90°-5″-HS) pulse sequence. T_1 values were obtained from the regression coefficients for 17 data points of τ and such measurements were repeated more than twice to test the reproducibility of the experiment. Errors in the measurements of T_1 were estimated to be ±10%.

The association parameters were determined in the same way as in the previous report.[4b] Molecular orbital calculations using semiempirical CNDO/2,[8a] INDO,[8b] and MNDO[8c] MO methods were performed by the programs[8d,e] after slight modifications by the authors. The molecular geometries used for the MO calculations were experimental ones from microwave spectra and calculated ones from MNDO MO method *i.e.*, TMU.

All numerical calculations were performed on an NEAC S-900 model II computer at the Computer Center, Osaka University and HITAC M-200H computer at the Computer Center, Institute of Molecular Sciences.

Results and Discussion

Changes in ^1H and ^{13}C NMR Shift. Estimated Structure of the Associate: Variations of ^1H NMR Shifts in CH_3OCH_2CN and $(CH_3)_2NCH_2CN$ on addition of TMU or DBSX are shown in Fig. 1. In contrast to the shifts of the methylene group, those of the methyl group show only small concentration dependences. Also the change was very small for the ^1H shift of TMU when these nitriles were added to the solution. These facts suggest that the association takes place near the CN and C=O groups.

^{13}C NMR shift also changes on addition of the partner molecule (Tables 1 and 2). The changes of shifts are evident at 1-C of each nitrile (Table 1) and at the carbonyl carbon (Table 2). These facts are also consistent with the above results for the ^1H shift.[9]

^{13}C Spin-Lattice Relaxation Times: It is well known that in monosubstituted benzenes ^{13}C spin-lattice relaxation times at the ortho or the meta positions are smaller than those at the para position. Levy *et al.*[10]

a) Equimolar (0.7 mol dm^{-3}) solutes is added.

interpreted this is due to anisotropic tumbling, *i.e.*, superior rotation around the symmetry axis. This superiority in rotation is expected to be reduced on addition of another polar molecule if they associate side by side. In the present case, the effect of the association on the relaxation time is investigated with nitrobenzene and TMU, adding 0—2.8 mol dm^{-3} of TMU to the 0.7 mol dm^{-3} solution of nitrobenzene in CCl_4. Nitrobenzene is chosen for the reason of higher solubility here. The results are given in Table 3. The higher the concentration of TMU, the more the r-value (Eq. 1)

$$r = \frac{T_1(\text{ortho}) + T_1(\text{meta})}{2T_1(\text{para})}, \quad (1)$$

approaches to 1. This is consistent with the loss of superiority in molecular rotation around the symmetry axis on addition of polar molecules indicating the increased moment of inertia around the axis.

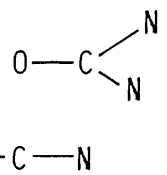

Fig. 2. Association models for the acetonitrile derivatives plus TMU systems.

All above experimental results support the idea that the polar molecules associate in the way shown in Fig. 2. For the compound treated here, electric charges are mainly distributed near the CN, C=O, and S=O groups, as calculated by CNDO/2 MO method or as reported by others.[11]

Determination of Association Parameters. The concentration dependence of the shifts at 2-C of the nitriles were measured and analyzed by nonlinear regression analsis and the equilibrium constant K and

the association shift Δ_{AB} were obtained (Table 4). 1:1 associates were assumed, similarly to the previous reports,[4] considering the results of Job plots. Plots of the association constants for the two systems containing TMU and DBSX show a linear relationship (Fig. 3), indicating similarity in the governing factor and the mode of the association in both systems. Regression analyses of the data according to the relation $y=ax$ result in

$$\ln K(\text{DBSX}) = 1.39 \ln K(\text{TMU}) \quad (2)$$
$$(n=6,\ R=0.987),^{12)}$$
$$\Delta_{AB}(\text{DBSX}) = 0.92\Delta_{AB}(\text{TMU}) \quad (3)$$
$$(n=6,\ R=0.996).$$

In *p*-substituted benzonitriles plus DBSX or TMU system, similar regression analyses result in

$$\ln K(\text{DBSX}) = 1.56 \ln K(\text{TMU}) \quad (4)$$
$$(n=6,\ R=0.943),$$
$$\Delta_{AB}(\text{DBSX}) = 0.87\Delta_{AB}(\text{TMU}) \quad (5)$$
$$(n=12,\ R=0.939).$$

As the coefficients are almost the same in both systems, the factor of association in the system containing aliphatic nitriles is similar to the one containing aromatic nitriles. Plots of $\ln K$ or Δ_{AB} against σ_i[5] show a significant correlation and the regression analyses in the system with TMU result in

$$\ln K = 4.11\sigma_i + 0.10 \quad (6)$$
$$(n=6,\ R=0.921,\ t=4.71),^{13)}$$
$$\Delta_{AB} = 11.08\sigma_i + 0.34 \quad (7)$$
$$(n=6,\ R=0.895,\ t=4.01),$$

and those in the system with DBSX result in

$$\ln K = 3.43\sigma_i + 0.72 \quad (8)$$
$$(n=6,\ R=0.958,\ t=6.68),$$
$$\Delta_{AB} = 11.11\sigma_i + 0.29 \quad (9)$$
$$(n=6,\ R=0.880,\ t=3.70).$$

Polar substituent effect for aliphatic compounds could be divided into two parts, *i.e.*, field effect and σ-inductive effect.[14] Tsuno[15] claimed that σ_i represent the former mainly. If this is also the case here, the association of the nitriles with TMU or DBSX is seen to be induced by the electric field effect.

Enthalpies ($\Delta H°$), entropies ($\Delta S°$), and Gibbs' free energies ($\Delta G°$) can be determined from van't Hoff plots after measuring the temperature dependence of the association constants (Fig. 4). These plots are obtained from the dependence of the shift on concentration as well as on temperature (Fig. 5). The results are given in Table 5. The $\Delta H°$ values derived amount to -8—-13 kJ mol^{-1}, which are about the same as those for the association of aromatic nitro or cyano compounds with HMPA and for weak hydrogen bonding. For this system, an enthalpy-entropy compensation relation, which held approximately for the aromatic nitro or cyano compounds plus HMPA systems, is not appropriate here (R=0.621). This may he due to larger steric effects for the aliphatic systems than that for the aromatic ones.

The orders of $\Delta G°$ or $\Delta H°$ are not the same as those of the dipole moments of nitriles, or more correctly, they gave a negative correlation, as was pointed out in the previous reports[4b] with aromatic systems. These facts indicate that multipole-multipole interaction, therefore, partial dipole is more important for the association of the nitriles with other polar molecules.

TABLE 6. ASSOCIATION PARAMETERS FOR THE CH_3CN PLUS TMU SYSTEM CALCULATED BY MNDO MO METHOD

	ΔE / kJ mol^{-1}	R / nm
I	−2.12	0.458
II	−3.40	0.471
III	−1.43	0.433

ΔE=−241 kJ mol^{-1} on the model II. Apparently, the energy is overestimated and the distance is underestimated. Similar results are reached by the INDO MO method. This tendency is well known as typical of the

CNDO/2 or INDO MO method. On the other hand, the MNDO MO calculation gives more practical results (Table 6), which accord well with the order of the experimental values. This method also supports model II as the most stable disposition, where the changes in formal charges induced at atoms when association occurs can be calculated against the association distance under model II (Fig. 7). The changes in ^{13}C chemical shifts are in the same order with the experimental ones, when they are estimated from the changes in formal charges on the basis of ≃200 ppm/electron.

The authors thank the Institute for Molecular Science for allotment of CPU time of the HITAC M-200H computer.

Conductivity and Ion Association of Some Diastereoisomeric Salts in Water. I. Δ-[Co(NO$_2$)$_2$(en)$_2$]Δ-[Co(edta)] and Λ-[Co(NO$_2$)$_2$(en)$_2$]Δ-[Co(edta)] at 15, 25, and 35 °C

Haruhiko YOKOYAMA

Department of Chemistry, Yokohama City University, 22-2 Seto, Kanazawa-ku, Yokohama 236

(Received October 4, 1983)

Electric conductivities of the diastereoisomeric salts, Δ(−)$_{589}$-[Co(NO$_2$)$_2$(en)$_2$]Δ(+)$_{546}$-[Co(edta)] and Λ-(+)$_{589}$-[Co(NO$_2$)$_2$(en)$_2$]Δ(+)$_{546}$-[Co(edta)], were measured in water at 15, 25, and 35 °C. Results were analyzed in terms of the conductivity equations of Fuoss-Hsia and Pitts. The obtained values of the ion-association constant are large and decrease with increasing temperature. The results can not be entirely explained by the electrostatic theories of ion association and suggest the formation of contact ion pairs, attributable to the existence of interactions other than simple electrostatic ones between the complex ions. No appreciable difference is found in the obtained thermodynamic parameters of ion association between the two salts. Ion-solvent interactions and effective sizes of the dissolved complex ions are also discussed in connection with the estimation of the closest distance of approach of the ions.

In recent years, many studies have been made on the stereoselectivity in ion association between optically active ions.[1-8] In particular, the association of L-tartrate ion with Δ- and Λ-[Co(en)$_3$]$^{3+}$ was widely investigated. Appearance of the stereoselectivity is attributed to the differences in structure and stability of ion pairs, and suggests the existence of ion-ion interactions other than simple electrostatic ones such as the Bjerrum-type ion association.[9,10] The hydrogen-bonding has often been presumed to be the most probable extra interaction for the association of [Co(en)$_3$]$^{3+}$ with dicarboxylate ions or other anions.[4-8,11,12] Such extra interactions are of importance for studies of ion-ion and ion-solvent interactions in the vicinity of dissolved complex ions. However, they are not necessarily investigated well.

Optically active *cis*-bis(ethylenediammine)dinitrocobalt(III) ion and (ethylenediaminetetraacetato)cobaltate(III) ion are frequently used as agents for resolution of optical isomers of complex ions.[13] The absolute configurations for (−)$_{589}$-enantiomer of *cis*-[Co(NO$_2$)$_2$(en)$_2$]$^+$ and (+)$_{546}$-enantiomer of [Co(edta)]$^-$ have been determined to be Δ-form by X-ray diffraction studies.[14,15] With respect to the solubilities of the diastereoisomeric salts, Δ-[Co(NO$_2$)$_2$(en)$_2$]Δ-[Co(edta)] and Λ-[Co(NO$_2$)$_2$(en)$_2$]Δ-[Co(edta)], the former is less soluble than the latter in water. The stereoselectivity has been observed on the rate of amino-hydrogen exchange of Δ- and Λ-[Co(NO$_2$)$_2$(en)$_2$]$^+$ in aqueous mixed electrolyte solutions containing Λ-[Co(edta)]$^-$.[16] However, no detailed information has been provided about the nature of the interactions between the complex ions. In the present study, conductivities of the above diastereoisomeric salts in water were observed at 15, 25, and 35 °C. From the analysis of conductivity data, we examined whether extra interactions are present between the complex ions or not, and whether these interactions, if present, are stereoselective or not.

The reason why such 1:1-type salts were chosen is given below. Strong 1:1 electrolytes such as sodium chloride have been usually thought to dissociate almost completely into ions in aqueous solutions.[17a] This is consistent with the prediction from the electrostatic theories of ion association.[9,10] Both ions, *cis*-[Co(NO$_2$)$_2$(en)$_2$]$^+$ and [Co(edta)]$^-$, are monovalent ones of large size. Simple electrostatic interactions may therefore be considered to be almost absent. This makes it easy to discuss the experimental results. The conductivity measurements were made with solutions of single salts alone. Consequently, the analysis of experimental data is very simple compared to the case for mixed electrolyte solutions with which most of the above studies on stereoselectivity have been carried out. The coexistence of other ions complicates not only the analysis but the explanation of results, owing to competitions or cooperative phenomena on ion association.[18]

The conductivity method is very effective to investigate ion association of 1:1 electrolytes, because it is very sensitive to a lowering of the conductivity due to the formation of noncharged ion pairs. Moreover, conductivity data obtained for 1:1 electrolytes can be precisely analyzed by using the excellent theoretical conductivity equations of Fuoss-Hsia and Pitts for a symmetrical electrolyte.[19,20] Pethybridge and Spiers have measured conductivities of the following 1:1 salts in water at 25 °C: *trans*-[Co(NO$_2$)$_2$(en)$_2$]X (X$^-$=Cl$^-$, Br$^-$, I$^-$, NO$_3^-$, ClO$_4^-$, and [Co(edta)]$^-$), *cis*-[Co(NO$_2$)$_2$(en)$_2$]X (X$^-$=I$^-$ and NO$_3^-$), and M[Co(edta)] (M$^+$=Li$^+$, Na$^+$, K$^+$, and Et$_4$N$^+$).[21,22] They analyzed their experimental data by use of the equations of Fuoss-Hsia and Pitts and found out that each electrolyte is slightly associated in water. The results obtained in the present study will be compared to theirs.

The measurements of conductivity were made by employing the linear-bridge conductometer developed by Katayama *et al.*[23] This apparatus is very favorable to examine a temperature dependence of conductivity since the temperature of the solution can be detected simultaneously with the observation of conductivity. The enthalpy and entropy of ion association will be estimated from the temperature dependence of the ion-association constant and will be used to discuss the nature of interactions between the complex ions.

Experimental

Materials. Δ- *and* Λ-*[Co(NO$_2$)$_2$(en)$_2$]X (X$^-$=Br$^-$ and*

I^-): The optically active bromide salts were prepared following the method of Dwyer and Garvan[24] from the nitrite of the racemic complex,[25] and were recrystallized from warm water (*ca.* 60 °C) by cooling in ice immediately after filtration. The recrystallization was repeated until a constant rotation result was obtained. The iodide salts were obtained by adding potassium iodide to aqueous solutions of the purified bromide salts, and recrystallized in the same manner as the bromide salts. Each salt was air-dried at room temperature. The $[\alpha]_{589}$ values of Δ- and Λ-$[Co(NO_2)_2(en)_2]Br$ were $-44°\pm1°$ and $+44°\pm1°$, respectively. Those of the iodides of Δ- and Λ-complexes were $-39°\pm1°$ and $+39°\pm1°$, respectively.

KΔ-*[Co(edta)]·2H₂O*: The optically active potassium salt was prepared following the method of Dwyer and Garvan.[26] The obtained salt was purified by fractional crystallization and air-dried at room temperature. The value of $[\alpha]_{546}$ was $+1010°\pm5°$.

Δ-*[Co(NO₂)₂(en)₂]*Δ-*[Co(edta)]·3H₂O*: This less soluble diastereoisomeric salt was prepared by adding KΔ-[Co(edta)]·$2H_2O$ to an aqueous solution of Δ-$[Co(NO_2)_2(en)_2]$-Cl, which was prepared by the double decomposition of the iodide of the complex and silver chloride in warm water (*ca.* 60°C). The obtained salt was recrystallized from warm water (*ca.* 45 °C) by the addition of ethanol. The absence of potassium and chloride ions was ascertained by adding sodium tetraphenylborate and silver nitrate, respectively, to an aqueous solution of the salt. After air-drying at room temperature, the number of molecules of the crystal water was confirmed to be three by the dehydration under vaccum by the use of a Cahn electrobalance.[27] The value of $[\alpha]_{546}$ was $+574°\pm5°$. The density of the crystal was 1.74 g cm^{-3} at 25 °C.

Λ-*[Co(NO₂)₂(en)₂]*Δ-*[Co(edta)]·H₂O*: This more soluble diastereoisomeric salt was prepared by adding ethanol to a warm aqueous solution (*ca.* 60 °C) containing equimolar proportions of the salts: Λ-$[Co(NO_2)_2(en)_2]I$ and KΔ-[Co(edta)]·$2H_2O$. The obtained salt was recrystallized twice from warm water (*ca.* 40 °C) by adding ethanol and was air-dried at room temperature. The check for potassium and iodide ions and the confirmation of the number of molecules of the crystal water were performed in the manner described above. The value of $[\alpha]_{546}$ was $+735°\pm5°$. The density of the crystal was 1.79 g cm^{-3} at 25 °C.

ORD and Electronic Absorption Spectra of the Diastereoisomeric Salts in Dilute Aqueous Solutions. The measurements of ORD and absorption spectra were carried out with a JASCO ORD/UV-5 spectropolarimeter and a Hitachi 139 spectrophotometer. The molar rotation of Δ-$[Co(NO_2)_2(en)_2]\Delta$-[Co(edta)] in water was identical with the sum of those of Δ-$[Co(NO_2)_2(en)_2]Br$ and KΔ-[Co(edta)] at any wave length from about 340 to 700 nm within the experimental error. A similar additivity was observed for Λ-$[Co(NO_2)_2(en)_2]\Delta$-[Co(edta)]. The absorption spectra of both diastereoisomeric salts in the wave length region of about 280 to 700 nm agreed with each other and with the prediction from those of *cis*-$[Co(NO_2)_2(en)_2]Br$ and K[Co(edta)] within the experimental error.

Conductivity Measurements. All solutions were made up by weight just before conductivity measurements. The conductivity of water used for the preparation was lower than 2.0×10^{-7} S cm^{-1} at 25 °C. The concentration of solutions on the molar scale at each temperature was determined by density measurements.

The conductivity measurements were made at 1000 Hz with a Fuso 360 linear-bridge conductometer according to the procedure described by Katayama *et al.*[23] The conductivity cell used was a four-necked flask with a 250 cm^3 capacity which was equipped with a thermistor, a nitrogen inlet, a magnetic stirrer, and two platinized platinum electrodes. The cell constant was 0.13702 cm^{-1}.

The conductivities of solutions were measured at 15.0, 25.0, and 35.0 °C in an atmosphere of purified nitrogen gas. Before the beginning of the measurements, dissolved carbon dioxide was removed by bubbling moistened nitrogen gas through the solution in the cell for about 50 min. During the bubbling, the solution was cooled to a temperature a little below 15 °C. The measurement was started from this temperature. The solution was warmed slowly at a speed of 0.02—0.03 °C/min to a temperature a little above 15 °C, while the change of resistance of the solution was recorded together with that of resistance of the thermistor inserted in the cell. Immediately after the recording, the solution was warmed at a high speed of 0.5—0.8 °C/min to a temperature a little below 25 °C. Subsequent procedures were made in a similar manner. A set of runs was accomplished in every case within about 2.5 h after the preparation of the solution. Throughout the measurements, the solution was protected from light.

The resistance readings of the linear bridge were calibrated by the substitution method with a precision decade resistance box (Dekabox DB62, Electro Scientific Industries; accuracy ±0.02%). The observed conductivity data were corrected for the conductivity of the solvent and for the minor conductivity change considered to be due to the aquation of *cis*-$[Co(NO_2)_2(en)_2]^+$.[28] The reproducibility of the conductivity measurements was about ±0.1%. The precision of the temperature measurements was ±0.003 °C.

Density Measurements. The density measurements were performed at (25.00±0.02) °C with all solutions used for the conductivity measurements, employing an Ostwald-type pycnometer of 10 cm^3 capacity. An approximately linear relationship was found between concentrations and densities for solutions of each diastereoisomeric salt. The density of the most concentrated solution was also measured at 15.0 and 35.0 °C to determine its molar concentration; these values were used to estimate that of the other solutions where a similar linear relationship was assumed to hold at these temperatures. The density measurements for solutions of *cis*-$[Co(NO_2)_2(en)_2]Br$ and K[Co(edta)] were carried out at 25.0 °C by using an Ostwald-type pycnometer of 50 cm^3 capacity, in order to estimate the partial molar volumes of the complex ions.

Results

Hereafter, the diastereoisomeric salts, $\Delta(-)_{589}$-$[Co(NO_2)_2(en)_2]\Delta(+)_{546}$-[Co(edta)] and $\Lambda(+)_{589}$-$[Co(NO_2)_2(en)_2]\Delta(+)_{546}$-[Co(edta)], will be often expressed by the abbreviations, Δ-Δ and Λ-Δ salts, respectively.

The observed values of molar conductivity, Λ (obsd), are summarized in Tables 1 and 2, where c is the molar concentration of a salt. In Fig. 1, the values of Λ (obsd) for each salt are plotted against those of $\sqrt{c}$. No appreciable difference in the plot is present between the Δ-Δ and Λ-Δ salts at any temperature.

The data of the density, d, obtained for aqueous solutions of the diastereoisomeric salts can be reproduced as a function of c:

$$d(\Delta\text{-}\Delta \text{ salt, } 25\,°C)/\text{g cm}^{-3} = (0.99704\pm0.00002) + (0.301\pm0.003)c$$

and

$$d(\Lambda\text{-}\Delta \text{ salt, } 25\,°C)/\text{g cm}^{-3} = (0.99705\pm0.00002) + (0.299\pm0.003)c.$$

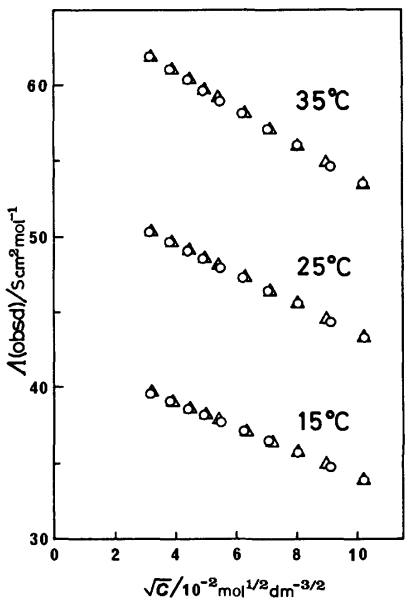

Fig. 1. Plot of Λ(obsd) against $\sqrt{c}$.
○, Λ(obsd) values for the Δ-Δ salt; △, Λ(obsd) values for the Λ-Λ salt.

From these data, the values of the partial molar volume of a salt at infinite dilution, V^∞(salt), were evaluated to be 318±4 cm^3 mol^{-1} for the Δ-Δ salt and 320±4 cm^3 mol^{-1} for the Λ-Λ salt according to the conventional manner.[29]

The values of V^∞(salt) for *cis*-$[Co(NO_2)_2(en)_2]$Br and K[Co(edta)] were estimated to be 175±2 and 181±2 cm^3 mol^{-1}, respectively, from the density data of their solutions: d(*cis*-$[Co(NO_2)_2(en)_2]$Br, 0.009972 mol dm^{-3}, 25 °C)=0.99880 g cm^{-3} and d(K[Co(edta)], 0.009161 mol dm^{-3}, 25 °C)=0.99893 g cm^{-3}. From these results, the values of the partial molar volume of an ion, V^∞(ion), can be estimated to be 145±2 and 177±2 cm^3 mol^{-1} for *cis*-$[Co(NO_2)_2(en)_2]^+$ and $[Co(edta)]^-$, respectively, using $V^\infty(Br^-, 25\ °C)$=30.1 cm^3 mol^{-1} and $V^\infty(K^+, 25\ °C)$=3.6 cm^3 mol^{-1}.[29,30] The sum of the partial molar volumes of the complex ions, 322±3 cm^3 mol^{-1}, agreeds closely with the above values of V^∞(salt) obtained for the diastereoisomeric salts.

Discussion

Analysis of Conductivity Data. The plot of Λ(obsd) against $\sqrt{c}$ gives a straight line in each case, but

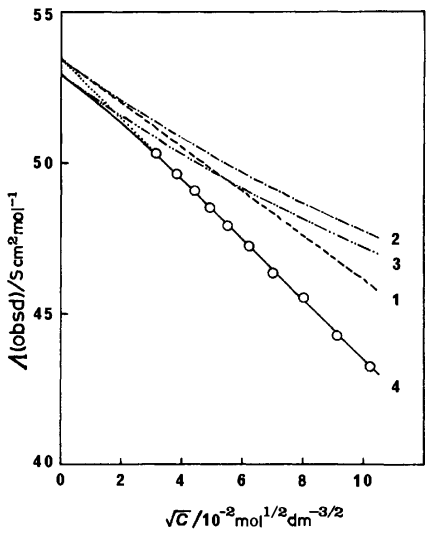

Fig. 2. Λ(obsd) values and theoretical curves for the Δ-Λ salt at 25 °C.
O, Λ(obsd) values.
Curve 1 (----) is the Onsager limiting slope drawn with a value of 53.45 S cm² mol⁻¹ for the limiting molar conductivity, Λ^∞, obtained by extrapolation of Λ(obsd) to $\sqrt{c}=0$. Curves 2 (—·—) and 3 (—··—) are Fuoss-Hsia's theoretical curves for a completely dissociated electrolyte with Λ^∞=53.45 and 52.93 S cm² mol⁻¹, respectively, on the assumption of a value of 7.0 Å for the closest distance of approach of ions. Curve 4 (——) is the theoretical curve of Fuoss-Hsia or Pitts with a set of a, K, and Λ^∞ values given in Table 3 (each set ranging a=1—9 Å gives almost the same curve).

does not obey the Onsager limiting law,[17b] as illustrated in Fig. 2. Further, the Λ (obsd) values lie considerably below the theoretical curves predicted for a completely dissociated electrolyte by the conductivity equation of Fuoss-Hsia.[19] Such negative deviations from the theoretical curves are considered to be due to the ion association. In this study, the conductivity data were analyzed by assuming the following ion association between the complex ions:

$$M^+ + A^- \rightleftharpoons M^+A^-, \quad (1)$$

where the symbol M^+ refers to the complex cation, Δ-$[Co(NO_2)_2(en)_2]^+$ or Λ-$[Co(NO_2)_2(en)_2]^+$, and the symbol A^- to the complex anion, Δ-$[Co(edta)]^-$. The analysis was made by using the Fuoss-Hsia equation[19] and the Pitts equation[20] for a symmetrical electrolyte.

The Fuoss-Hsia equation can be written symbolically as

$$\Lambda=\alpha(\Lambda^\infty-\Delta\Lambda_e)[1+(\Delta X/X)]/(1+1.5\phi), \quad (2)$$

where α is the degree of dissociation, Λ^∞ is the limiting molar conductivity, $\Delta\Lambda_e$ is the electrophoretic term, $\Delta X/X$ is the relaxation term, and 1.5ϕ corresponds to the term related to the obstruction effect.[17c] The symbol ϕ denotes the volume fraction occupied by the obstructions, approximated by $(4\pi N_A c/3000)(a/2)^3$ where N_A is the Avogadro number and a is the closest distance of approach of ions. The expressions for the electrophoretic and relaxation terms have been given by Fuoss and Hsia. The electrophoretic term is a function of αc, a, T, z, η_0, and, ε, where T is the absolute temperature, z is the absolute value of charge number of ions, and η_0 and ε are the viscosity and the dielectric constant of the solvent, respectively. The relaxation term is a function of these parameters and Λ^∞.

The Pitts equation for an incompletely dissociated electrolyte can be written symbolically as

$$\Lambda^\infty-(\Lambda/\alpha)=\Lambda^\infty P_1+P_2-P_3, \quad (3)$$

where P_1 is a function of αc, a, T, z, and ε, and where P_2 and P_3 are functions of these parameters as well as η_0. In practice, however, the following modified equation was used for the analysis instead of Eq. 3:

$$\Lambda=\alpha[\Lambda^\infty(1-P_1)-P_2+P_3]/(1+1.5\phi), \quad (4)$$

This obtained by rearranging Eq. 3 and introducing an obstruction term identical with that involved in Eq. 2.

The ion-association constant, K, was estimated for a given value of a in the following way. With an assumed value of Λ^∞, the degree of dissociation, α, was calculated by usig Eq. 2 or 4 through a successive approximation. The result was inserted in the following equation to obtain the value of K:

$$K=\frac{1-\alpha}{\alpha^2 c y_M y_A}, \quad (5)$$

where y_M and y_A are the activity coefficients of the free ions, expressed by the Debye-Hückel equation:

$$\log y_M=\log y_A=-A_{DH}\sqrt{\alpha c}/(1+B_{DH}a\sqrt{\alpha c}), \quad (6)$$

where A_{DH} and B_{DH} represent the theoretical coefficients.[17d] In these calculations, the values of η_0 and ε of water were taken from the monograph of Robinson and Stokes.[17e] The best-fit values of Λ^∞ and K for a given a value were determined by the least-squares method with the molar conductivity, Λ.

In Table 3, the results obtained on the assumption of several values for a are summarized, together with the values of the standard deviation, σ.[31] The obtained values of Λ^∞ are not much dependent on a, whereas those of K are somewhat changed by the choice of the value of a. The best values of Λ^∞ and K as well as of a are usually determined by the minimization of σ. However, this is not necessarily a good criterion for the determination of the best parameter values, because, as can be seen from Table 3, the variation of σ with a is only slight over a rather wide range of a and the value of a giving the minimum value of σ depends on the conductivity equation used for the analysis. The former reason is substantiated by the fact that the Λ(obsd) values can be theoretically reproduced well with any set of the values of Λ^∞ and K for a=1—9 Å as illustrated in Fig. 2. Further details have been described in the earlier papers.[31] We shall discuss what value of a should be taken as the best value after considering the effective sizes of the dissolved complex ions.

Ionic Radii of the Complex Ions and Ion-Solvent Interactions. From the results of the conductivity measurements, we can obtain the information concerning

Table 3. Λ^{∞} and K values at 25 °C for the Δ-Δ and Λ-Δ salts obtained with the Fuoss-Hsia equation (Eq. 2) and the Pitts equation (Eq. 4) by assuming several values for a

the ionic radii of the complex ions in the following way. From the values of Λ^{∞}(25 °C) for a=1—9 Å, the sum of the limiting molar conductivities of *cis*-[Co(NO$_2$)$_2$(en)$_2$]$^+$ and [Co(edta)]$^-$ is considered to be 52.9 to 53.0 S cm^2 mol^{-1}. For Λ^{∞}([Co(edta)]$^-$, 25 °C), a value of 26.17±0.10 S cm^2 mol^{-1} has been reported by Pethybridge and Spiers.[22] The use of this value leads to Λ^{∞}(*cis*-[Co(NO$_2$)$_2$(en)$_2$]$^+$, 25 °C)=26.8±0.1 S cm^2 mol^{-1}.[32] By employing these Λ^{∞}(ion) values, the Stokes radii, r_s,[33] are evaluated to be 3.4$_4$ Å for *cis*-[Co(NO$_2$)$_2$(en)$_2$]$^+$ and 3.5$_2$ Å for [Co(edta)]$^-$.

The ionic radii of the complex ions can also be estimated from their partial molar volumes, V^{∞}(ion). According to Glueckauf's study,[34] V^{∞}(ion) of a univalent ion of large size is expressed by

$$V^{\infty}(\text{ion}) = 2.52(r+0.55)^3 - 33/(r+1.38), \quad (7)$$

where r corresponds to the crystallographic radius of the ion. The first term refers to the intrinsic volume of the ion and the second term to the electrostriction volume loss. Equation 7 was employed for the estimation of the ionic radii of the complex ions by regarding these ions as spherical. Substituting V^{∞}(ion)= 145±2 cm^3 mol^{-1} for *cis*-[Co(NO$_2$)$_2$(en)$_2$]$^+$ and V^{∞}(ion)=177±2 cm^3 mol^{-1} for [Co(edta)]$^-$ in Eq. 7, we obtain r=3.3$_7$ Å and 3.6$_3$ Å, respectively. The r value is in fair agreement with the r_s value for each complex ion. This suggests that both complex ions are not appreciably hydrated.

Information relating to the ion-solvent interaction can be provided from the temperature dependence of the Walden products: Λ^{∞}(salt)η_0/10^{-4} S N s mol^{-1}= 0.474 (15 °C), 0.471 (25 °C), and 0.468 (35 °C) which are calculated from the averaged values of Λ^{∞} (salt) obtained for the Δ-Δ and Λ-Δ salts. These Λ^{∞}(salt)η_0 values decrease slightly as the temperature increases. The temperature coefficient, d ln {Λ^{∞}(salt)η_0}/dT, is evaluated to be -6×10^{-4} K^{-1} close to that of Me$_4$N$^+$.[35] This implies that at least one of *cis*-[Co(NO$_2$)$_2$(en)$_2$]$^+$ and [Co(edta)]$^-$ is a structure-breaker. The latter ion may be classified as a structure-breaker from the fact that the viscosity B{[Co(edta)]$^-$} coefficient in the Jones-Dole equation increases with increasing temperature.[36] For *cis*-[Co(NO$_2$)$_2$(en)$_2$]$^+$, there is no available information about the temperature dependence of the B coefficient. However, it is interesting that the values of V^{∞}(ion) and Λ^{∞}(ion) for *cis*-[Co(NO$_2$)$_2$(en)$_2$]$^+$ are very closely similar to those for tetrakis(2-hydroxyethyl)ammonium ion, (HOCH$_2$CH$_2$)$_4$N$^+$: V^{∞}(ion)=146.8 cm^3 mol^{-1} [37] and Λ^{∞}(ion)=27.0 S cm^2 mol^{-1} at 25 °C.[38] Both the Walden product Λ^{∞}(ion)η_0 and the B(ion) coefficient for (HOCH$_2$CH$_2$)$_4$N$^+$ are known to be nearly independent of temperature.[35,38]

From the above consideration, the complex ions, *cis*-[Co(NO$_2$)$_2$(en)$_2$]$^+$ and [Co(edta)]$^-$, are presumed to have no hydration shell and to be able to come into contact to each other. Therefore, it seems reasonable that the value of a is taken to be equal to the sum of the values of r or r_s obtained for the complex ions: a=7.0$_0$ Å from the r values or a=6.9$_6$ Å from the r_s values. These values of a are considered to be moderate values because the prediction from the distance between the central cobalt(III) atoms of the two complex ions ranges from about 5 to 9 Å dependent on the direction of approach of the ions. Such a range arises from the unsymmetrical shape of the complex ions and the complexity of their surface. For these reasons, the best value of a was assumed to be equal to 7.0 Å for the diastereoisomeric salts in water.

Ion-Ion Interactions. The results obtained by assuming 7.0 Å as the best value of a are shown in Table 4. The K values for each salt are considerably larger than those predicted by the electrostatic theories of ion association.[9,10,39] According to the Bjerrum theory,[9] the values of K are expected to be equal to zero since the Bjerrum critical distance q (=3.58 Å at 25 °C for a 1:1 electrolyte)[17g] is smaller than 7.0 Å. From the theoretical equation presented by Yokoyama and Yamatera,[40] the values of K/dm^3 mol^{-1} are estimated to be 0.23 (15 °C), 0.24 (25 °C), and 0.25 (35 °C). The Fuoss theory[39] predicts 2.38 (15 °C), 2.41 (25 °C), and 2.44 (35 °C)

Table 4. Λ^{∞} and K values at 15, 25, and 35 °C for the Δ-Δ and Λ-Λ salts obtained by assuming a=7.0 Å with the Fuoss-Hsia equation (Eq. 2) and the Pitts equation (Eq. 4)

Salt	Temp °C	With Eq. 2 (Fuoss-Hsia)		With Eq. 4 (Pitts)

by Fuoss[39]		−2.18	0.93	10.4

for K/dm³ mol⁻¹.

The K value for each salt decreases as the temperature is raised, contrary to the prediction from the electrostatic theories. This tendency means that the ion association is an exothermic reaction. The standard enthalpy and entropy of ion association, $\Delta H°$ and $\Delta S°$, were estimated from the temperature dependence of the ion-association constant. The $\Delta H°$ value was derived from the slope of a linear plot of log K against T^{-1}, while the $\Delta S°$ value was calculated from the equation, $\Delta S°=(\Delta H°-\Delta S°)/T$, where $\Delta G°$ is the standard Gibbs free energy of ion association. The obtained values of $\Delta G°$, $\Delta H°$, and $\Delta S°$ are shown in Table 5 and are compared with those predicted by the electrostatic theories of ion association.[39,40]

Table 5 shows that the relation, $\Delta H°<T\Delta S°\approx 0$, is valid for the observed values of $\Delta H°$ and $\Delta S°$. This relation is distinct from $T\Delta S°>\Delta H°>0$ obtained for the ion association of 2:2 electrolytes such as $MgSO_4$.[23,41] The negative $\Delta H°$ values can not be predicted from the ion-association theories.[39,40] Such values of $\Delta H°$ will be attributed to the existence of short-range forces almost independent of the dielectric constant of the medium. The $\Delta S°$ values nearly equal to zero may suggest that the ion association occurs without the release of the hydration water molecules of the complex ions. This is consistent with the presumption that the complex ions, *cis*-$[Co(NO_2)_2(en)_2]^+$ and $[Co(edta)]^-$, are not appreciably hydrated. Consequently, the comparatively large values of K for each salt are considered to imply the formation of contact ion pairs resulting from interactions other than simple electrostatic ones between the complex ions.

It has been found that tetraalkylammonium halides, R_4NX, are slightly associated in water and the K values of the salts decrease with increasing temperature in a similar manner as observed in the present study.[42] Pethybridge and Spiers have reported the fact that the K values in water for 1:1 electrolytes including R_4NX increase with increasing the sum of the crystallographic radii, $\sum r$(cryst).[21,22,43] Such a trend is the reverse of that predicted by the ion-association theories of Bjerrum[9] and Yokoyama-Yamatera.[10] The Fuoss theory predicts that the ion-association constant increases with increasing the a value at $a>2q/3$ ($a>2.39$ Å at 25 °C).[17h] However, his theory can not also give the negative $\Delta H°$ value for any ion association in water. Therefore, the phenomenon of ion association of 1:1 electrolytes is considered to be due to existence of ion-ion interactions other than the simple electrostatic ones.

Pethybridge and Spiers have expressed graphically the relationship between K and $\sum r$ (cryst).[21,22,43] If we estimate the value of K for the diastereoisomeric salts from this relationship, a value of 4—5 dm³ mol⁻¹ can be obtained.[44] However, this value of K is much smaller than the experimental ones given in Table 4. This implies that different kinds of extra interactions exist between the complex ions. The most effective interaction among them may be the hydrogen-bonding between the hydrogen atoms of amino groups of *cis*-$[Co(NO_2)_2(en)_2]^+$ and the oxygen atoms of calboxyl

groups of $[Co(edta)]^-$. The ion-association constants of the Δ-Δ and Λ-Δ salts are somewhat larger than that of *trans*-$[Co(NO_2)_2(en)_2][Co(edta)]$: $K \approx 9\ dm^3\ mol^{-1}$.[45] This may be mainly attributed to the difference not only in the magnitude of the dipole moment of the complex cations, but in the ease of the formation of the hydrogen bonds. In the case of the *trans*-isomer, the nitro groups are considered to be more unfavorably located for the hydrogen-bonding than in the case of the *cis*-isomer.

Stereoselectivity. The ion pairs, Δ-$[Co(NO_2)_2(en)_2]^+\Delta$-$[Co(edta)]^-$ and Λ-$[Co(NO_2)_2(en)_2]^+\Delta$-$[Co(edta)]^-$, can not be stereochemically the same. However, as shown in Table 5, no appreciable difference between the two ion pairs is found in the thermodynamic properties of ion-pair formation. Although the ΔH° value of the Δ-Δ salt seems to be slightly smaller than that of the Λ-Δ salt, it is indefinite because of the experimental error. The difference in solubilities of the Δ-Δ and Λ-Δ salts would have to be interpreted from that in their crystal structures.

Yamatera and Fujita have observed the rate of amino-hydrogen exchange of Δ- and Λ-$[Co(NO_2)_2(en)_2]^+$ ($0.039\ mol\ dm^{-3}$) under the presence of Λ-$[Co(edta)]^-$ ($0.035\ mol\ dm^{-3}$) in D_2O and found out that the rate constant for the Λ-complex cation is 0.86 times that for the Δ-complex cation.[16] The hydrogen-deutrium exchange rate is thought to be slowed down by means of the ion association. If the hydrogen-deutrium exchange rate of the associated complex cations were negligibly small compared with that of the free ion, the degree of dissociation for the Λ-complex cation should be 0.86 times that for the Δ-complex cation. However, such a large difference in the degree of dissociation can not be derived from the present results. Therefore, in order to explain the difference in the observed rate constant, the associated complex cations should be supposed to contribute to the hydrogen-deutrium exchange rate. In addition, the extent of the contribution of the associated Δ-complex cation should be greater than that of the associated Λ-complex cation. The hydrogen-deutrium exchange of $[Co(en)_3]^{3+}$ has been considered to be assisted by the OD^- ion.[5] If a similar mechanism is assumed also in the case of Δ- and Λ-$[Co(NO_2)_2(en)_2]^+$, the difference in the extent of the contribution to the exchange rate between the two associated complex cations may be attributed to the difference in the ease of N-H bond breaking caused by the association with Λ-$[Co(edta)]^-$ as well as the difference in the affinity of the associated complex cations with the OD^- ion.

The author is gratefully indebted to Professor Nobuyoshi Shinohara of Yokohama City University for his helpful discussion, Dr. Masataka Ozaki for the use of a Cahn electrobalance, and Dr. Shunzo Katayama of the Institute of Physical and Chemical Research for his helpful advice and suggestions on the conductivity measurements. I would also like to thank Mr. Michio Nishimura for his asistance. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 354227 from the Ministry of Education, Science and Culture.

27) Two water molecules of *Δ*-[$Co(NO_2)_2(en)_2$]*Δ*-[Co(edta)]·$3H_2O$ and the water molecule of *Λ*-[$Co(NO_2)_2$-$(en)_2$]*Δ*-[Co(edta)]·H_2O were dehydrated at room temperature *in vacuo*, while the third water molecule of the former salt was dehydrated by heating above *ca.* 90 °C *in vacuo*.
28) Pethybridge and Spiers have observed the increase with time in the conductivity for *trans*-[$Co(NO_2)_2(en)_2$]X (X^-= Cl^-, Br^-, I^-, NO_3^-, ClO_4^-, and $[Co(edta)]^-$) and *cis*-[Co-$(NO_2)_2(en)_2$]X (X^-=I^- and NO_3^-): about 0.01% per hour except for *trans*-[$Co(NO_2)_2(en)_2$][Co(edta)].[21] In the present study, the rate of increase in the conductivity for the diastereoisomeric salts was about 0.02% per hour at 25 °C. This value is consistent with the above value, since the increase per the molar conductivity of the complex cation can be estimated to be equal to about 0.04% per hour in both cases. For *trans*-[$Co(NO_2)_2(en)_2$][Co(edta)], the rate of increase in the conductivity has been reported to be about 0.1% per hour at 25 °C, much greater than that obtained for the other salts.[21] This abnormal value was explained by suggesting that the aquation of the complex cation is catalyzed by the hydrogen ion liberated as a result of hydrolysis of $[Co(edta)]^-$. If such a phenomenon occurred actually, the rate of increase in the conductivity would have to be accelerated with increase of concentration of the salt. However, no dependence of the rate on the concentration has been found in their study.[21]

44) From the K-$\sum r$ (cryst) graph given in Refs. 21, 22, and 43, a value of 2—3 dm^3 mol^{-1} for K can be read at $\sum r$ (cryst)=7.0 Å. However, this value can not be directly used for comparison with that obtained in the present study for the following reason. All the K values shown in the K-$\sum r$ (cryst) graph correspond to those obtained by the analysis with the assumption of a value of 3.58 Å for a. Further, the $\sum r$ (cryst) values for several electrolytes in this graph seem to be somewhat overestimated, as exemplified by the ionic radius of *trans*- or *cis*-[$Co(NO_2)_2(en)_2]^+$ which is assumed to be 4.3 Å, larger than 3.4 Å assumed in the present study. Considering these differences in the treatment, the value of K read at $\sum r$ (cryst)=7.0 Å is thought to have to be raised by about 2 dm^3 mol^{-1}.
45) In Ref. 21, K=8 dm^3 mol^{-1} is given for this salt. However, this value corresponds to that obtained by the analysis with the assumption of a=3.58 Å. If a=7.0 Å is assumed, a value of about 9 dm^3 mol^{-1} is obtained for K.

NMR Study of Protonated Halothiophenes. II. An *ab Initio* Self-consistent Field Calculation of the Protonation of Chlorothiophenes

Yukihide YAMASHITA, Hiroyuki KOBAYASHI, Akihiro YOSHINO,

(Received October 17, 1983)

The STO-3G method was applied to the protonation of thiophene and chlorothiophenes. The optimized structures and charge densities thus obtained are consistent with the experimental results obtained from the ^{1}H NMR spectral data. In the neutral molecule, the β-chloro substituent lowers the total energy more than the α-one; however, the latter stabilizes the protonated state more than the former.

We have observed the halothiophenium ions produced from halothiophenes at rather low temperatures.[1-4] The NMR parameters thus obtained are useful in discussing the properties of such ions. Molecular orbital calculations are also done as supplements to the experimental results. Such calculations have previously been done by many researchers.[4-6] The system of thiophenes has the problem of whether the calculations should be carried out with or without the d-orbitals on the sulfur atom.[7]

This study has been performed by using the minimal basis set, the so-called STO-3G method.[8] The method is a very simple *ab initio* calculation and has a problem as to the quantitative determination of the properties.[9] However, the results are good enough to discuss the problems qualitatively.

Procedure

The calculation was carried out by using the HITAC M-200H computer and the Library Program (IMSPAK) installed in the Computer Center, Institute of Molecular Science, at Okazaki. The basis wave functions used were the STO-3G minimal basis set.[10] For the optimization of the structure, an initial structure was taken from that obtained by Bak *et al.*,[11] while the distance of the C-Cl bond was taken from that of Harshbarger *et al.* (1.7095 Å).[12] The structure of the thiophenium ion was assumed to be on a plane except for the atoms bonded to the protonated sp^3-carbon, which has an initial bonding angle with two out-of-plane atoms of 109.5°.

For chlorothiophenium cations, the SCF initial molecular orbitals were composed from those of the anionic ones because, when they were composed from the cationic ones, the SCF calculations did not converge with the optimized structures.

Results and Discussion

Structure of Thiophene, Chlorothiophenes, and Their Cations. The optimized structures of thiophene are given in Table 1, along with its experimental results and other calculated values. The values obtained by the STO-3G method are shorter in the double bond and longer in the single bond than those calculated by Amato *et al.*[13]

Table 1. Comparison of structure determinations of thiophene

Bond length	Bak *et al.* (1961) *l*/Å	Amato *et al.* (1982) *l*/Å	This work *l*/Å
S-C	1.7140±0.0014	1.726	1.732
C=C	1.3696±0.0017	1.348	1.335
C-C	1.4232±0.0023	1.432	1.454

∠CCC	112.45±0.2	112.6	112.1

The optimized structures of chlorothiophenes and their cations are summarized in Figs. 1 and 2. The ring-interior-angle of the substituted carbons of chlorothiophenes increases, while the bond lengths concerned with the carbons generally increase, as compared with those calculated for thiophene. Further, the bond-lengths of the C_β-H and the C_β-Cl bonds are longer than those corresponding to the C_α-H and the C_α-Cl bonds. As would be expected, the bond angles of the protonated carbons approach the tetrahedral angle. Since only one 3*H*-thiophenium ion has been calculated, the discussion of the cations will hereafter be limited to the 2*H*-thiophenium ions. In the protonated state, the bond lengths of the C_2-C_3, the C_4-C_5, and the S-C_2 bonds increase, while the reverse shortening appears in the C_3-C_4 and the S-C_5 bonds. These features are expressed schematically in Scheme 1. The C-H bond length increases in the order of the 4-, 3-, and 5-positions in the thiophene ring of the cationic state as compared with that in the neutral molecule; however, conversely, the C-Cl bond lengths decrease in the same order. On the other

hand, the 3- and 5-(C-H) bonds are longer than those of the neutral molecules, although the situation is reversed with the 3- and 5-(C-Cl) bonds. This shows that the resonance effect of the chlorine atom plays a role in the cationic state. The expected structural model shown in Scheme 1 is consistent with the experimental finding that the values of J_{34} (*ca.* 5.5 Hz) are larger than those of J_{45} (*ca.* 4.0 Hz) in halogeno-substituted 2*H*-thiophenium ions.[2,3]

Charge Distributions. The total and π electronic charges of thiophene, chlorothiophenes, and their cations are tabulated in Tables 2 and 3. The protonations of these molecules occurred at the most negative carbons expected from the present calcula-

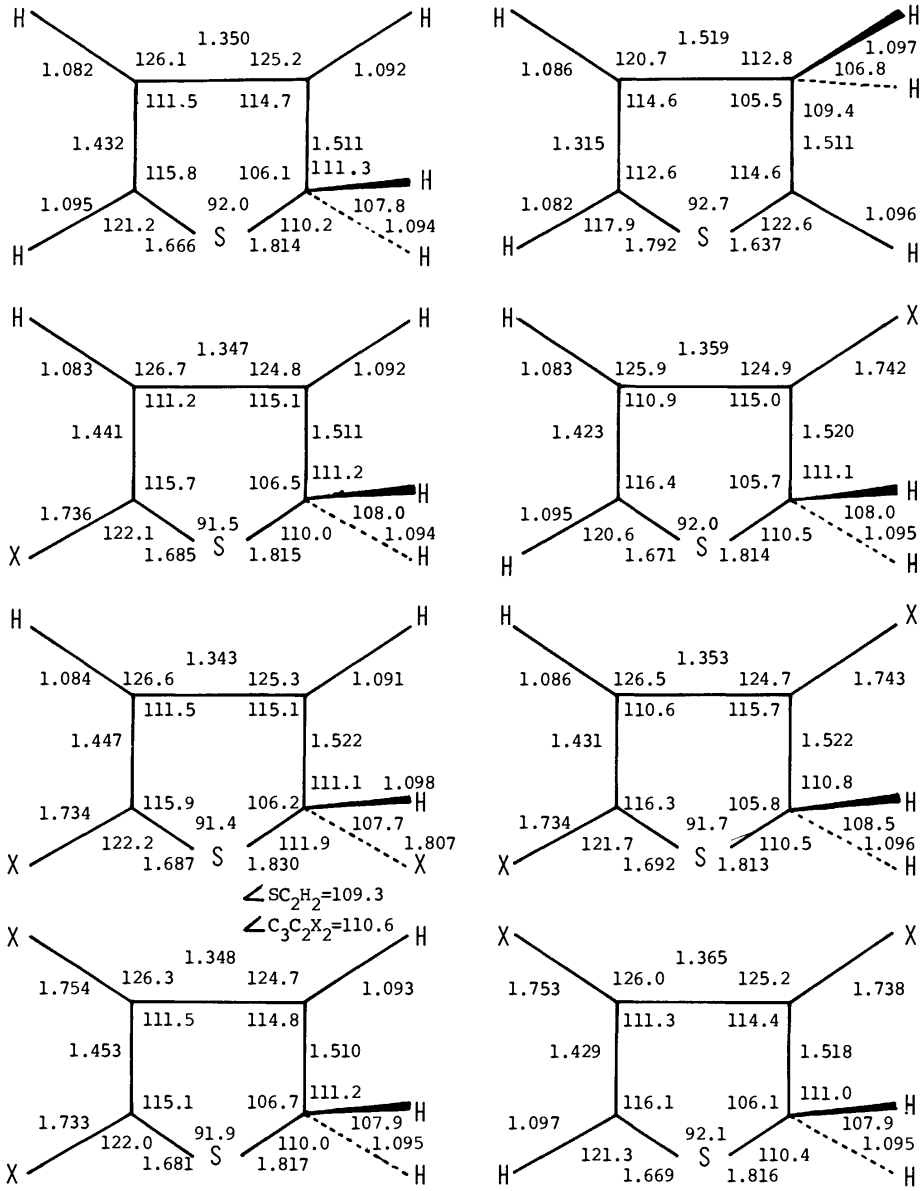

Fig. 2. Comparison of optimized geometries for thiophenium ions.
Bond lengths in Å and angles in degrees. X denotes chlorine atom.

tions. However, the ^{1}H NMR chemical shifts are not directly proportional to the calculated charge densities on the hydrogen atoms for the neutral molecules.

In the cationic states, the chlorine atoms all have a positive charge except for the atoms bonded to the sp^3-hybridized carbon. This shows that the resonance effect of the chlorine atom is important in the cationic state. Table 3 shows that the positive charges on the thiophenium ions are localized more at the 5-carbon than at the 3-carbon. Table 4 summarizes the π-charge-density differences between the neutral molecules and the corresponding cations. From the table, the excess π-charge densities can be seen to be located more at the 5-carbon than at the 3-carbon. For the thiophenium ions, the calculated electronic densities of the hydrogens bonded to the sp^2-hybridized carbons are proportional to the observed ^{1}H chemical shifts, as is shown in Fig. 3. The proportional coefficient is about 100 ppm/electron. The dotted lines in the figure show that the chlorine substituents cause a shielding effect in spite of attracting the electron from the hydrogens. The coefficients of the dotted lines are −25, −35, and −58 ppm/electron, from the bottom to the top in the figure. These values show the effects of the charge on the 4-, the 3-, and the 5-hydrogens respectively.

Energies. The total calculated energies of thiophene, chlorothiophenes, and their protonated species are given in Table 5. The total energies of the molecules are dependent upon the methods used. The values for thiophene obtained with several methods are shown in the table. The β-chloro substituent lowers the energy more than does the α-one. The α-protonation lowers the energy more than does the β-one in thiophene; the difference is about 48 kJ mol^{-1} (0.01877 a.u.). This result is consistent with the experimental result

reported in the previous study, in which only the α-protonation products have been observed, but not the β-ones.[2)]

The following schemes can be considered from the total-energy consideration of Table 5. In each case, the right system is more stable than the left system. Therefore, the protonation of thiophene is easier than that of

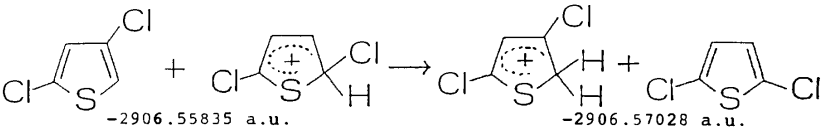
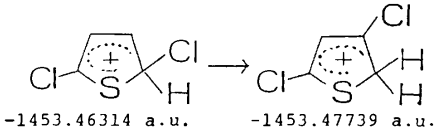


Scheme 5.

chlorothiophene. Scheme 4 is essentially interesting, for the chlorine substituent stabilizes the neutral molecule at the β-position more than at the α-position. However, Scheme 4 shows that the α-substituent is more effective than the β-one for the protonation. In other words, the resonance stabilization effect is stronger in the α-chlorine than in the β-one in the protonated state. Other interesting schemes appear below. The 2,4-dichlorothiophenium ion is more stable than the 2,5-one. However, the rearrangement has not occurred from the 2,5-dichlorothiophenium ion to the 2,4-one in the experiments,[1,2] though such a rearrangement has been observed in the dibromothiophenium ions.[3]



Scheme 6.

Conclusion

The STO-3G method was applied to the protonation of thiophene and chlorothiophenes. The optimized structures and charge densities thus obtained are consistent with those expected from the ^{1}H NMR spectral observations. The β-chlorine atom lowers the total energy more than the α-one in the neutral molecules; however, the latter substituent is more effective than the former in the resonance stabilization of the cationic state of the molecules.

An Analysis of the $E(0_g^+)$ Ion-pair State of Bromine through Stepwise Excitation Technique

Takashi Ishiwata, Atsuto Tokunaga, Tsutomu Shinzawa, and Ikuzo Tanaka*
Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152
(Received November 16, 1983)

The pulses of the fundamental and its frequency doubled outputs from a tunable dye laser are used to promote a stepwise exciation of the $E(0_g^+)$-$X^1\Sigma_g^+$ transition through the $B^3\Pi(0_u^+)$ state in molecular bromine. The double resonance is detected by the associated UV emission which originates from the $E(0_g^+)$ state radiating back to the $B^3\Pi(0_u^+)$ state. The $E(0_g^+)$ state is analyzed in detail on the basis of the selection rules of two transition components and the E-B fluorescence spectrum. The molecular parameters are derived as T_e= 49778.5 cm^{-1}, ω_e=150.8 cm^{-1}, $\omega_e x_e$=0.41 cm^{-1}, and r_e=3.197 Å for the $^{79}Br_2$ isotope species.

The electronic structure of diatomic halogens has been studied many times both theoretically and experimentally, and yet several important problems remain unsolved with regard to the existence and positions of certain electronic states.[1] In particular, the high-lying excited states of the ion-pair type are the subjects of recent interest and curiosity, because of their recent use in the development of the laser emissions in the ultraviolet and vacuum ultraviolet regions.[2-5] Designing a halogen laser system requires detailed spectroscopic and kinetic data on the emitting state itself as well as the surrounding electronic states.

It is well-known that the ion-pair states of Br_2 correlate with $Br^-(^1S)+Br^+(^3P, ^1D, ^1S)$ at the dissociation limit and the dominant attractive term in their potential function is simply $-e^2/r$. Therefore, all the ion-pair states are empirically taken to have relatively large internuclear distances (3.2 Å) and dissociation energies (35000 cm^{-1}) with small vibrational frequencies (150 cm^{-1}), and to group in accordance with the energies of the various Br^+ states.[6] Thus the 6 states ($0_u^+(D)$[7], $0_g^+(E)$[8], 1_u, 1_g, 2_u, and $2_g(D')$)[9] from $Br^+(^3P_2)$ would belong to the lowest group lying at around 49000 cm^{-1}, the 2 states ($0_u^+(F)$[10] and $0_g^+(f)$[11]) from $Br^+(^3P_0)$ and the 4 (0_u^-, 0_g^-, 1_u, and 1_g) from $Br^+(^3P_1)$ would locate near 53000 cm^{-1}. The 6 states (0_u^+, 0_g^+, 1_u, 1_g, 2_u, and 2_g) from $Br^+(^1D)$ would be expected at around 60000 cm^{-1}, and 2(0_u^+ and 0_g^+) from $Br^+(^1S)$, very considerably higher.

This work is part of a series[7,10,11] where the spectroscopic properties of the ion-pair states are examined for the Br_2 molecule. Since its optical pumping from the ground state requires large Franck-Condon shifts due to the large internuclear separation of the ion-pair states, our method involves a stepwise excitation through the $B^3\Pi_{0_u^+}$ state as an intermediate. The g or u ion-pair states can be proved if one or virtual two-photon transitions originate from the B state. In the experiment described here, the Br_2 molecules are pumped to the B state by the output of a tunable dye laser operated in the visible region and subsequently excited into the $E(0_g^+)$ ion-pair state by its second harmonics in the ultraviolet. It is obvious that the excitation proceeds only if the double resonance condition is satisfied for the two transition components. We can detect the resonances by the E-B emission and the stepwise processes are analyzed.

Experimental

The experimental apparatus is similar to that used in previous experiments.[11] Briefly, a nitrogen laser pumped dye laser provided 8 ns pulses with an energy of 1 mJ/pulse and 0.1 Å resolution, and a KDP crystal was installed for frequency doubling (conversion efficiency 5%). Both the fundamental laser light and its frequency doubled output passed through a UV fluorescence cell to excite the Br_2 molecules in a stepwise process. The fluorescence was dispersed by a 50 cm monochrometer in the second order and detected by a photomultiplier. The output signals were amplified ten times and averaged by a boxcar integrator.

To exclude the spectral congestion problem, monoisotopic $^{79}Br_2$ was used in the experiments. A sample pressure was 3.1 Torr (1 Torr=133.3 Pa). The emission spectra were recorded with a spectral resolution of 0.2 Å and studied as a function of excitation wavelength.

Results and Discussion

When the $^{79}Br_2$ molecules were excited both by the fundamental and its second harmonic outputs of the dye laser operated in the wavelength region between 595 and 621 nm, several series of fluorescent progressions were observed at around 310 nm. These closely resemble the $f(0_g^+)$—$B^3\Pi_{0_u^+}$ system of Br_2 (265—285 nm) which we have recently analyzed.[11] The emission bands consisted of the P and R doublets, and the vibrational spacing observed at the shortest wavelength was about 155 cm^{-1}, close to the vibrational frequency of the B state (ω_e=167.6 cm^{-1}).[12] From its position in the spectrum, the emission under study appears to be the $E(0_g^+)$—$B^3\Pi_{0_u^+}$ system observed by Tellinghuisen and co-workers[8] in conventional discharge experiments. In our case, the pumping to the E state was obviously achieved by a stepwise excitation through the B state. As a matter of fact, the emission vanished by blocking either the visible or the ultraviolet laser light with a suitable glass filter.

Table 1 summarizes the strong double resonance signals observed in the experiment. The laser frequencies noted here correspond to the positions of the rotational lines of the B-X absorption involved in the excitation process. Under our experimental conditions, the relaxations in the intermediate B state are negligible, so that the assignments of the following E-B transitions were straightforward. The rotational quantum number (J)

a) Excitation was performed by the second harmonics of the laser light used for the B-X transition ($h\nu_{UV}=2h\nu_{VIS}$). b) Definition of the final level in the E state. c) Assignment to the E-B transition. d) Assignment to the B-X transition. e) Term values of the final (v, J) level in the E state relative to the potential minimum of the ground state.

of the ion-pair state was derived from the emission spectrum depending on whether the P or R line was in resonance with the UV laser wavelength. The absolute v' numbering was established by the characteristic intensity pattern of the fluorescent progression. The internuclear distance of the ion-pair states (typically r_e=3.2 Å) is much longer than that of the B state (r_e=2.68 Å). The low-v level of the ion-pair state will display in emission a band system whose intensity distribution is modulated according to the probability distribution of the upper wavefunction. For example, the fluorescence spectra in Fig. 1 show (a) a double and (b) a single peak in emission envelope, and can be assigned to originate from the vibrational level of (a) v'=1 and (b) v'=0, respectively. The interpretation is confirmed by the energy level analyses and Franck-Condon calculations as described below.

The term energies $T^E_{v,J}$ of the ion-pair state in Table 1 were calculated relative to the potential minimum of the ground state. They were determined by adding the fundamental ($h\nu_{VIS}$) and its second harmonic ($h\nu_{UV}$) frequencies to the vibrational and rotational terms of the ground state levels (G''_v and $F''_v(J)$) from which the stepwise transitions originate (Eq. 1).

$$T^E_{v,J} = h\nu_{VIS} + h\nu_{UV}(=2h\nu_{VIS}) + G''_v + F''_v(J) \quad (1)$$

Based on these derived term energies, we calculated the absolute wavelength positions of the expected P and R doublets in the emission spectra of the $E(0_g^+)$—$B^3\Pi_{0_u^+}$ transition using the known molecular constants of the B state.[12] The calculated values agreed with the experimentally derived ones within our experimental accuracy (±0.2 Å) and the transition from the E state terminates on the high vibrational levels of the B state as shown in Fig. 1.

The molecular constants of the $E(0_g^+)$ state were

calculated to fit the term values to the form;

$$T^E_{v,J} = T_e + \omega_e\left(v+\frac{1}{2}\right) - \omega_e x_e\left(v+\frac{1}{2}\right)^2 + \left\{B_e - \alpha_e\left(v+\frac{1}{2}\right)\right\}J(J+1) - DJ^2(J+1)^2. \quad (2)$$

where the values of α_e and D were estimated from the following relations[13] in order to reduce the parameter of the higher order.

$$\alpha_e = 6B_e(\sqrt{\omega_e x_e \cdot B_e} - B_e)/\omega_e, \quad (3)$$

$$D = 4B_e^3/\omega_e^2. \quad (4)$$

The B_e values were calculated based on r_e values at around 3.2 Å at intervals of 0.001 Å and the equations fitted by the least squares method iteratively. Using sets of the derived constants, we have calculated the Franck-Condon factors for the E-B system.[14] The potential curve of the B state was constructed by the RKR method, while we approximated the potential curve of the E state by a Morse function using a set r_e value, and ω_e and $\omega_e x_e$ values determined from Eqs. 2, 3, and 4. Since the fluorescence intensity distribution shows a strong J dependence, the effective potential curve, $U_J(r)$, for the corresponding J level was used in the Franck-Condon calculations,

$$U_J(r) = V_0(r) + J(J+1)\hbar^2/2\mu r, \quad (5)$$

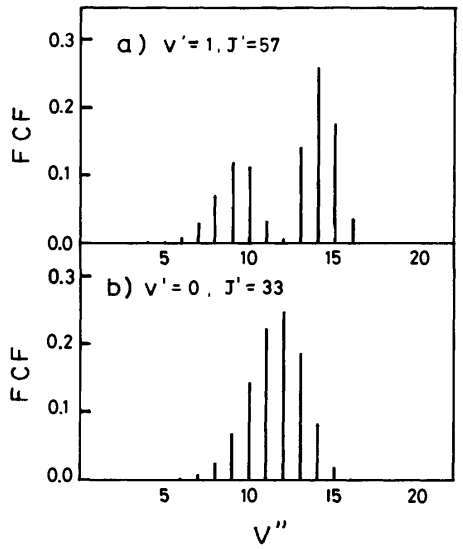

Fig. 2. Calculated Franck-Condon factors of the E $(0_g^+) \rightarrow B^3\Pi_{0_u^+}$ transition.

Table 2. Molecular parameters of the E(0_g^+) state for $^{79}Br_2$

Parameter	Value
T_e/cm^{-1}	49778.53(52)[a]
ω_e/cm^{-1}	150.78(27)
$\omega_e x_e/cm^{-1}$	0.41(3)
B_e/cm^{-1}	0.04180[c]
α_e/cm^{-1}	1.47×10^{-4}
D/cm^{-1}	1.28×10^{-7}
$r_e/Å$	3.197

a) Values in parentheses denote twice the standard deviation (2σ) and apply to the last digits of the constants. b) Calculated value corresponding to $r_e=3.197$ Å. c) From the Franck-Condon factor analysis. The accuracy is estimated to be ±0.003 Å assuming that the emission intensities fluctuate by 10%.

where $V_0(r)$ denotes the potential curve for $J=0$.

We found that the intensity distributions were fairly consistent with the results of the FCF calculations with setting $r_e=3.197$ Å. Typical examples of the agreements are shown in Fig. 2 for the fluorescence series from (a) $v'=1$, $J'=57$ and (b) $v'=0$, $J'=33$, corresponding to the results in Fig. 1 (a) and (b). Measured intensities are not corrected for instrumental sensitivity because this was essentially constant in the wavelength region under experiment. The derived spectroscopic parameters of the E(0_g^+) ion-pair state are listed in Table 2.

With the completion of this work, the E(0_g^+) ion-pair state of Br_2 correlating with $Br^-(^1S)+Br^+(^3P_2)$ has been spectroscopically characterizd in detail. The 310 nm emission system observed in the spectrum of discharge experiments can be definitely attributed to the E(0_g^+)—$B^3\Pi_{0_u^+}$ transition. This system was first studied by Venkateswarlu and Verma,[15] who deduced that the lower state was the $B^3\Pi_{0_u^+}$ state. Berwanger, Viswanathan, and Tellinghuisen[8] recently re-analyzed the spectrum based on a completely different vibrational numbering, but still using the B state as the terminating state. The set of molecular constants of the E state given here are in very good agreement with the values reported by Tellinghuisen and coworkers and obviously support their analyses.[8]

Finally, it should be pointed out that the selective excitation technique for ion-pair states of diatomic halogens is now available through stepwise processes. Efforts are being made in this laboratory to elucidate the relaxation processes involving these high-lying electronic states, especially for the inert gas-halide excimer formation mechanism in the reaction between inert gases and halogen molecules.

The authors acknowledge the assistance of Dr. J. T. Hougen of the National Bureau of Standards for supplying them with the RKR and Franck-Condon factor computer program.

The Adsorption of Dodecyldimethylammonium Bromide on Aqueous Surfaces of Sodium Bromide Solutions

Hideshi Okuda,† Sumio Ozeki, and Shoichi Ikeda*
†*Nagoya Municipal Industrial Research Institute, Atsuta, Nagoya 456*
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464
(Received November 18, 1983)

The surface tension of aqueous NaBr solutions of dodecyldimethylammonium bromide has been measured by the drop weight method at different surfactant and NaBr concentrations. By applying the Gibbs adsorption isotherm, surface excess densities of surfactant cation, Na^+ and Br^- are derived as functions of surfactant concentration at different NaBr concentrations. The rational mean activity coefficients of surfactant and NaBr are both approximated by a common expression satisfying the Brønsted principle for mixed electrolytes and containing the ionic strength as a variable. Surface excess density of surfactant cation increases with increasing surfactant concentration and has a general tendency still increasing even at the critical micelle concentration. Some comparison of the behavior of surface excess densities of ions between the present bromide system and the previous chloride system is made. The Corrin-Harkins plot for the critical micelle concentration consists of two straight lines intersecting at 0.015 mol dm^{-3} NaBr.

We have recently established the thermodynamic method for estimating surface excess densities of ionic species or solute components on aqueous surfaces of electrolyte solutions from measurements of their surface tension as functions of solute concentrations.[1-3] This method is based on the Gibbs adsorption isotherm for plane surfaces of dilute solutions and has been applied for aqueous solutions of mixed electrolytes having a common counterion, such as aqueous NaCl solutions of dodecyldimethylammonium chloride (DDAC).[4,5]

In the present work we briefly review the thermodynamic method, measure the surface tension of aqueous NaBr solutions of dodecyldimethylammonium bromide (DDAB), and apply the method to the experimental data. We will be concerned with the Gibbs adsorption isotherm for aqueous NaBr solutions of DDAB, in which no micelles are yet formed. Then we can derive the surface excess densities of three ionic species. We will further examine the effects of counterion species on the adsorption isotherms of ionic species and the critical micelle concentration (cmc) and standard free energy of micellization of dodecyldimethylammonium ions, by comparing the present results with those previously obtained for aqueous NaCl solutions of DDAC.[5]

Theoretical

Let us denote a cationic surfactant and sodium halide by DX and NaX, respectively, which have a common halide anion X^-. As we have already derived the Gibbs adsorption isotherm for aqueous solutions of DDAC-NaCl system,[5] we will here present brief derivation of the Gibbs adsorption isotherm.

In terms of species present in solution, H_2O, D^+, Na^+, and X^-, we can represent the Gibbs adsorption isotherm in the form

$$-d\gamma = \Gamma_{H_2O}d\mu_{H_2O} + \Gamma_{D^+}d\mu_{D^+} + \Gamma_{Na^+}d\mu_{Na^+} + \Gamma_{X^-}d\mu_{X^-}, \quad (1)$$

where γ is the surface tension of solution, Γ_i and μ_i are the surface excess density and chemical potential of species, i, respectively. Introducing the Gibbs convention, $\Gamma_{H_2O}=0$, the surface excess densities of ions have definite values. Then, by means of the condition of electroneutrality on aqueous surfaces

$$\Gamma_{D^+} + \Gamma_{Na^+} = \Gamma_{X^-}, \quad (2)$$

we have the Gibbs adsorption isotherm in terms of components

$$-d\gamma = \Gamma_D \cdot d\mu_{DX} + \Gamma_{Na} \cdot d\mu_{NaX}. \quad (3)$$

The chemical potentials of solute components, DX and NaX, can be expressed by their molar concentrations, C and C_s, and from these expressions we obtain

$$-d\gamma = RT\left[\left\{\left(1+\frac{C}{C+C_s}\right)\Gamma_{D^+}+\frac{C}{C+C_s}\Gamma_{Na^+}\right\}d\ln C + \left\{\frac{C_s}{C+C_s}\Gamma_{D^+}+\left(1+\frac{C_s}{C+C_s}\right)\Gamma_{Na^+}\right\}d\ln C_s + \Gamma_{D^+}\,d\ln y_{\pm}^2+\Gamma_{Na^+}\,d\ln y_{s\pm}^2\right], \quad (4)$$

where R is the gas constant, T the temperature, and $y_\pm$ and $y_{s\pm}$ are the molar mean activity coefficients of DX and NaX, respectively.

The molar mean activity coefficients of DX and NaX, $y_\pm$ and $y_{s\pm}$, can be related to their rational mean activity coefficients, $f_\pm$ and $f_{s\pm}$, by[6a]

$$\frac{y_\pm}{f_\pm} = \frac{y_{s\pm}}{f_{s\pm}} = \frac{\rho_w}{\rho - \frac{M-2M_w}{1000}C - \frac{M_s-2M_w}{1000}C_s}, \quad (5)$$

where M_w, M, and M_s are the molecular weights of H_2O, DX, and NaX, respectively, and ρ_w and ρ are the densities of water and solution, respectively.

As was demonstrated previously,[5] the rational mean activity coefficients of DX and NaX can both be approximately represented as a function of ionic strength, $C+C_s$,

$$\log f_\pm = \log f_{s\pm} = -\frac{P\sqrt{C+C_s}}{1+Qa\sqrt{C+C_s}} + B_s(C+C_s), \quad (6)$$

where the constants, P and Q, of the Debye-Hückel electrostatic term are determined by the temperature

and the dielectric constant, and the ionic radius, a, serves as an adjustable parameter.[6b] The salting-out constant, B_s, is characteristic of NaX.

Then we have following identities, which are abbreviated by η and η_s, respectively:

$$\eta = \left(\frac{\partial \ln y_{\pm}^2}{\partial C}\right)_{C_s} = \left(\frac{\partial \ln y_{s\pm}^2}{\partial C}\right)_{C_s}, \quad (7)$$

$$\eta_s = \left(\frac{\partial \ln y_{\pm}^2}{\partial C_s}\right)_{C} = \left(\frac{\partial \ln y_{s\pm}^2}{\partial C_s}\right)_{C}. \quad (8)$$

The change of surface tension of solution can be formally related to the changes in concentrations of DX and NaX by

$$-\mathrm{d}\gamma = RT(\Gamma' \,\mathrm{d}\ln C + \Gamma'_s \,\mathrm{d}\ln C_s), \quad (9)$$

where Γ' and Γ'_s are given by

$$\Gamma' = \left(1+\frac{C}{C+C_s}+\eta C\right)\Gamma_{D^+} + \left(\frac{C}{C+C_s}+\eta C\right)\Gamma_{Na^+}, \quad (10)$$

$$\Gamma'_s = \left(\frac{C_s}{C+C_s}+\eta_s C_s\right)\Gamma_{D^+} + \left(1+\frac{C_s}{C+C_s}+\eta_s C_s\right)\Gamma_{Na^+}. \quad (11)$$

Solving equations 10 and 11, we obtain the surface excess densities of two cations as

$$\Gamma_{D^+} = \frac{1}{2+\eta C+\eta_s C_s}\left\{\left(1+\frac{C_s}{C+C_s}+\eta_s C_s\right)\Gamma' - \left(\frac{C}{C+C_s}+\eta C\right)\Gamma'_s\right\}, \quad (12)$$

$$\Gamma_{Na^+} = \frac{1}{2+\eta C+\eta_s C_s}\left\{-\left(\frac{C_s}{C+C_s}+\eta_s C_s\right)\Gamma' + \left(1+\frac{C}{C+C_s}+\eta C\right)\Gamma'_s\right\}, \quad (13)$$

and that of an anion as

$$\Gamma_{X^-} = \frac{1}{2+\eta C+\eta_s C_s}(\Gamma'+\Gamma'_s), \quad (14)$$

From Eqs. 5 and 6, we obtain

$$\eta = \eta_0 - \frac{2\left\{\left(\frac{\partial \rho}{\partial C}\right)_{C_s} - \frac{M-2M_w}{1000}\right\}}{\rho - \frac{M-2M_w}{1000}C - \frac{M_s-2M_w}{1000}C_s}, \quad (15)$$

$$\eta_s = \eta_0 - \frac{2\left\{\left(\frac{\partial \rho}{\partial C_s}\right)_{C} - \frac{M_s-2M_w}{1000}\right\}}{\rho - \frac{M-2M_w}{1000}C - \frac{M_s-2M_w}{1000}C_s}, \quad (16)$$

where

$$\eta_0 = \frac{2.303P}{(1+Qa\sqrt{C+C_s})^2\sqrt{C+C_s}} - 4.606B_s. \quad (17)$$

The density of aqueous NaX solution of DX is given by

$$\rho = \rho_s + (1-\bar{v}\rho_s)c, \quad (18)$$

where c (g cm^{-3})$=MC/1000$ is the weight concentration of solution, ρ_s is the density of solvent or aqueous NaX solution, and $\bar{v}$ is the partial specific volume of surfactant, DX. At surfactant concentrations lower than the critical micelle concentration

$$\left(\frac{\partial \rho}{\partial C}\right)_{C_s} = \frac{(1-\bar{v}\rho_s)M}{1000}, \quad (19)$$

$$\left(\frac{\partial \rho}{\partial C_s}\right)_{C} = \left(1-\frac{\bar{v}MC}{1000}\right)\left(\frac{\partial \rho_s}{\partial C_s}\right)_{C}. \quad (20)$$

Experimental

Materials. Dodecyldimethylammonium bromide (DDAB) was prepared from pure *N,N*-dimethyldodecylamine by passing dry HBr gas through its ethanolic solution and recrystallizing the resulting crystals from 1:1 acetone-diethyl ether mixtures three times. Commercial *N,N*-dimethyldodecylamine was purchased from Tokyo Kasei Kogyo Co., Inc., and purified by fractional distillation.

NaBr was of reagent grade from Wako Pure Chemical Industries, Inc., and was ignited on an evaporating dish and stored in a desiccator.

Methods. The surface tension of aqueous solutions was determined at 25±0.01 °C by means of the drop weight method, using a capillary tip of outer radius, r. The capillary was kept perpendicular, and its upper end was connected through rubber tubing to a burette, half-filled with water, so that the drop formed on the capillary tip could be kept at a desired size or released to fall at a desired instant by manipulating the burette. The capillary tip was kept in a glass bottle dipped in a water thermostat. Each drop was suspended on the tip for over 3 min before being allowed to fall, and five to ten drops of each solution were collected in a weighing bottle for weighing.

Surface tension, γ (mN m^{-1}), of solution was calculated from the weight, m, of a drop by the Harkins-Brown equation[7a]

$$\gamma = (mg/r)F, \quad (21)$$

where g is the gravitational acceleration (980 cm s^{-2}) and F is the correction factor, defined by V/r^3, V being the drop volume. The effective outer radius, r, of the capillary tip was determined by measuring the drop weight of distilled water, by assuming its surface tension to be 71.96 mN m^{-1},[7b] and it was found to be 0.3484 cm.

Density measurements of aqueous solutions were performed on an Anton Paar Precision Density Meter, DMA 02D. The temperature was kept at 25±0.01 °C by circulating water of constant temperature around the cell housing. The density meter was calibrated by using distilled water and air as standards, by assuming their densities to be 0.99704 g cm^{-3} and 0.00119 g cm^{-3}, respectively.

Results

Figure 1 shows the relation of surface tension, γ, with the logarithm of molar concentration of DDAB, log C, at different NaBr concentrations, C_s. Surface tension decreases with increasing surfactant concentration at concentrations up to the cmc, C_0, and also with increasing NaBr concentration. Values of Γ' can be obtained from the slope of the surface tension curves by

$$\Gamma' = -\frac{1}{RT}\left(\frac{\partial \gamma}{\partial \ln C}\right)_{C_s}. \quad (22)$$

At concentrations up to the cmc, we can apply the expression of the Gibbs adsorption isotherm developed above. At concentrations higher than the cmc, surface tension always remains constant, which is designated as γ_0, and it is clear that $\Gamma'=0$ for $C \geqq C_0$.

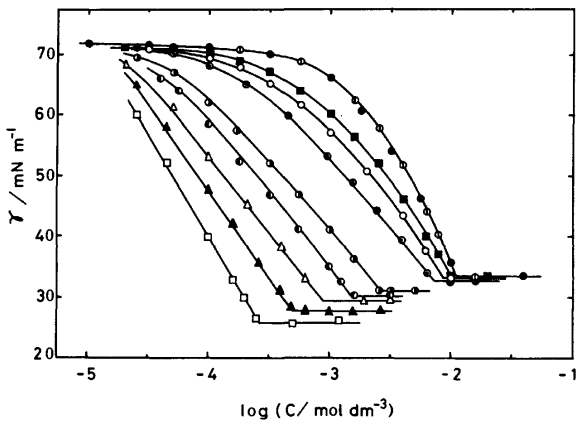

Fig. 1. Variation of surface tension with the logarithm of surfactant concentration at different NaBr concentrations.
C_s/mol dm^{-3}: ●; 0, ⦶; 1×10^{-4}, ■; 5×10^{-3}, ○; 0.01, ⊙; 0.02, ◑; 0.10, ◐; 0.20, △; 0.50, ▲; 1.00, □; 2.00.

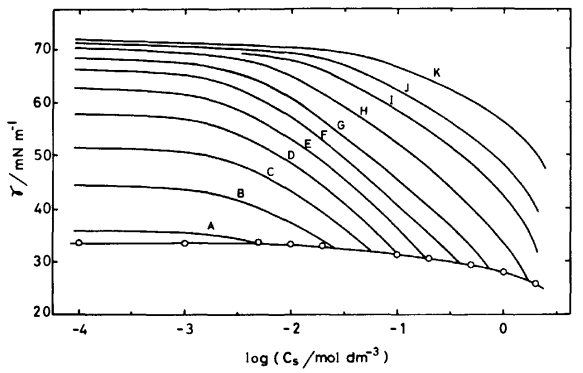

Fig. 2. Variation of surface tension with the logarithm of NaBr concentration at different surfactant concentrations. ○: Constant surface tension, γ_o, at a given NaBr concentration, obtained at surfactant concentrations higher than the critical micelle concentration.
$-\log C$/mol dm^{-3}: A; 2.0, B; 2.2, C; 2.4, D; 2.6, E; 2.8, F; 3.0, G; 3.2, H; 3.5, I; 3.8, J; 4.0, K; 4.3.

In Fig. 2 surface tension is replotted against the logarithm of molar concentration of NaBr at different surfactant concentrations. The lowest curve gives dependence of the constant surface tension on NaBr concentration, the constancy being observed at surfactant concentrations higher than the cmc. From the slope of surface tension curves we can obtain values of Γ'_s by

$$\Gamma'_s = -\frac{1}{RT}\left(\frac{\partial\gamma}{\partial \ln C_s}\right)_C. \tag{23}$$

Table 1 summarizes relevant numerical data at the cmc derived from Figs. 1 and 2. With increasing NaBr concentration, values of Γ' at the cmc decreases in the range of NaBr concentrations up to 0.10 mol dm^{-3}, and then increases at higher NaBr concentrations. On the other hand, values of Γ'_s at the cmc increases monotonously with increasing NaBr concentrations.

Figure 3 shows the density of aqueous NaBr solutions of DDAB as a function of surfactant concentration. It is

C_s/mol dm^{-3}: A; 0, B; 1×10^{-4}, C; 1×10^{-3}, D; 5×10^{-3}, E; 0.01, F; 0.02, G; 0.10, H; 0.20, I; 0.50, J; 1.00, K; 2.00.

seen that Eq. 18 holds well for the relation between the density and surfactant concentration below the cmc, and, as shown in Table 2, the partial specific volume of DDAB is found to be 0.93 cm^3 g^{-1} at surfactant concentrations lower than the cmc, irrespective of NaBr concentration. Above the cmc, the slope of the density curves becomes less steep, indicating that the partial specific volume of DDAB abruptly increases beyond the cmc, as shown in Table 2.

In applying Eqs. 12, 13, and 14 we use the values

$$P = 0.5115, \quad Qa = 1.316, \quad B_s = 0.075, \qquad (24)$$

where the value of B_s has been determined by adapting the tabulated activity data of NaBr up to 4.0 mol dm^{-3} [6c] to Eq. 6. Then we can derive the surface excess densities of surfactant cation, Na^+ and Br^-. Figure 4 shows the surface excess densities of ions plotted against the surfactant concentration. It is seen in Fig. 4(a) that the value of Γ_{D^+} increases more rapidly and approaches the saturated value at a low surfactant concentration, as the NaBr concentration is 5×10^{-3}, 0.01, or 0.02 mol dm^{-3} or it is higher than 0.20 mol dm^{-3}. When the NaBr concentration is 0.10 mol dm^{-3} or it is lower than 1×10^{-3} mol dm^{-3}, Γ_{D^+} appears to increase without reaching their saturation even at the cmc. It is seen in Fig. 4(b) that the value of Γ_{Br^-} increases without reaching its saturated value except that the NaBr concentration is 0.01 or 0.02 mol dm^{-3}. The value of Γ_{Na^+} is very low in its absolute value and is almost zero for all NaBr concntrations.

Recently, it was found that the surface tension-concentration curves of aqueous solutions of decylammonium chloride or dodecylammonium chloride show a break point at a low surfactant concentration.[8,9] Such a break point can be more clearly observed when the mixed adsorbed film is present.[9] The presence of the break point gives the discontinuity to the surface excess density of surfactant ion, indicating the establishment of equilibrium between two kinds of "surface phases." In the present data such a break point is not detectable at all NaBr concentrations and there is no discontinuity in the surface excess density curves.

Table 3 gives the values of Γ_{D^+}, Γ_{Na^+}, and Γ_{Br^-} at the cmc for different NaBr concentrations, and Fig. 5 shows these values as functions of the square root of NaBr concentration. With increasing NaBr concentration up to 0.01 mol dm^{-3}, the value of Γ_{D^+} at the cmc decreases. After passing the minimum, it increases gradually with increasing NaBr concentration.

Discussion

Surface Excess Densities of Ions. As shown in Fig. 4(a), the surface excess density of surfactant cation, Γ_{D^+}, at several NaBr concentrations still increases without reaching its saturation even at the cmc. Such behavior was not observed in the DDAC-NaCl system.[4,5] As shown in Fig. 4(b), the surface excess density of Br^-, Γ_{Br^-}, also increases even at the cmc at several NaBr concentrations. In the DDAC-NaCl system Γ_{Cl^-} behaves in the same way only at high NaCl concentrations.

Table 3. Surface excess densities of surfactant cation, Na^+ and Br^- at the critical micelle concentration

C_s	Γ_{D^+} at C_o	Γ_{Na^+} at C_o	Γ_{Br^-} at C_o
mol dm^{-3}	10^{-10} mol cm^{-2}	10^{-10} mol cm^{-2}	10^{-10} mol cm^{-2}
0	4.68		4.68
1×10^{-4}	4.68	0.04	4.73
1×10^{-3}	4.55	−0.11	4.44

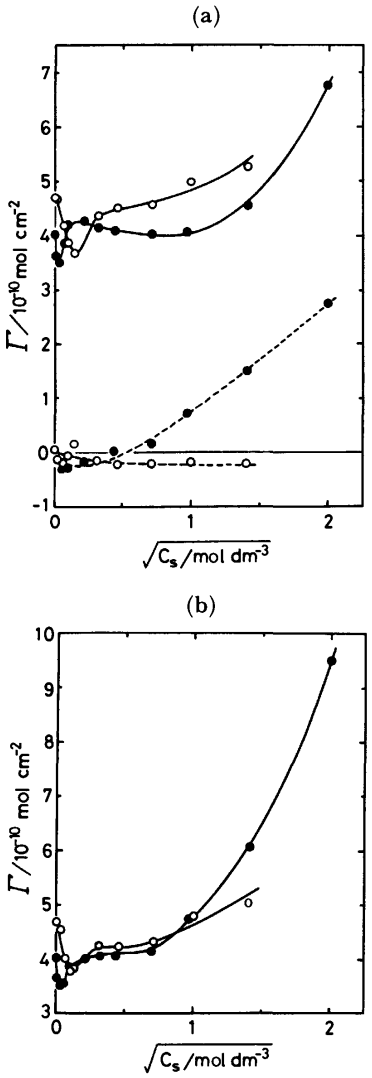

Fig. 5. The change of surface excess densities of ions at the critical micelle concentration.
(a) Γ_{D^+} (——) and Γ_{Na^+} (----) *vs.* $\sqrt{C_s}$, (b) Γ_{X^-} *vs.* $\sqrt{C_s}$. X^-: Br^- or Cl^-.
○: DDAB-NaBr, ●: DDAC-NaCl.

The values of Γ_{D^+} and Γ_{Br^-} at the cmc in the DDAB-NaBr system are essentially equal to their saturated values, respectively, at a given NaBr concentration. In Fig. 5 the values of Γ_{D^+}, Γ_{Na^+} and Γ_{Br^-} at the cmc are plotted against the square root of NaBr concentration, together with the saturated values of Γ_{D^+}, Γ_{Na^+}, and Γ_{Cl^-} in the DDAC-NaCl system.[4,5]

It is clear in Fig. 5(a) that the value of Γ_{D^+} at the cmc for the DDAB-NaBr system is higher than that for the DDAC-NaCl system at the same concentrations of sodium salts except at 0.01 and 0.02 mol dm^{-3}. This means that the effect of salting-out of Br^- is stronger than that of Cl^-, which is apparently exhibited in the values of B_s in Eq. 6, *i.e.*, 0.075 for NaBr and 0.055 for NaCl.[5,6b] It is also seen that the value of Γ_{Na^+} at the cmc for the DDAB-NaBr system is almost constant at NaBr concentrations higher than 0.20 mol dm^{-3}. For the DDAC-NaCl system the value of Γ_{Na^+} at the cmc increases rapidly and becomes positive at NaCl concentrations higher than 0.20 mol dm^{-3}. The reason for the large difference in Γ_{Na^+} at high salt concentrations is not clear, but it is certain that the difference between the two systems arises from the surface tension data themselves, since the treatment based on the ideal solution approximation also leads to such a difference in Γ_{Na^+}.

In Fig. 5(b) it is seen that the value of Γ_{Br^-} at the cmc for the DDAB-NaBr system is of the same order of magnitude as that of Γ_{Cl^-} at the cmc for the DDAC-NaCl system, as long as the concentrations of sodium salts are lower than 1.0 mol dm^{-3}. At concentrations higher than 1.0 mol dm^{-3}, the value of Γ_{Cl^-} at the cmc for the DDAC-NaCl system increases rapidly. This is because the value of Γ_{Na^+} for the DDAC-NaCl system, *i.e.*, the adsorption of NaCl, increases more rapidly.

The Corrin-Harkins Relation. Figure 6 shows the Corrin-Harkins plot for the cmc of the DDAB-NaBr system together with that of the DDAC-NaCl system. For the DDAB-NaBr system a linear relation holds at low and high counterion concentrations, respectively:

$$\log C_o = -0.452 \log (C_o + C_s) - 2.83, \quad C_s \leqq 0.015, \qquad (25)$$

$$\log C_o = -0.758 \log (C_o + C_s) - 3.33, \quad C_s \geqq 0.015. \qquad (26)$$

The threshold concentration of NaBr for the two linear plots at low and high counterion concentrations, 0.015 mol dm^{-3}, is lower than that obtained by light scattering measurement,[10] 0.095 mol dm^{-3}.

For the DDAC-NaCl system the Corrin-Harkins plot of the cmc is linear at NaCl concentrations up to 0.50 mol dm^{-3}:

$$\log C_o = -0.621 \log (C_o + C_s) - 2.98, \quad C_s \leqq 0.50, \qquad (27)$$

and at higher NaCl concentrations than 0.50 mol dm^{-3}, a linear relation no longer holds between the logarithm of the cmc and the logarithm of the concentration of Cl^-.[5]

As the cmc is a good measure of stability of the micellar state relative to the monomeric state, the lower value of the cmc for the DDAB-NaBr system than that for the DDAC-NaCl system clearly indicates the stabili-

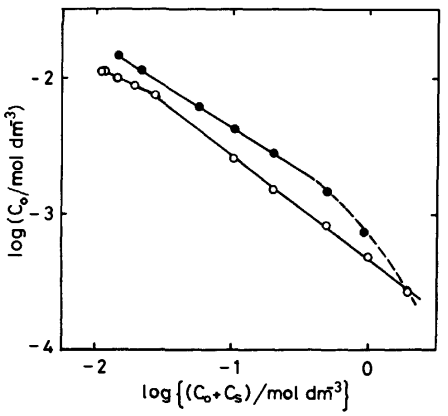

Fig. 6. Relation of the logarithm of the critical micelle concentration with the logarithm of ionic strength. ○: DDAB-NaBr, ●: DDAC-NaCl.

zation of dodecyldimethylammonium micelle by binding of Br^- stronger than binding of Cl^-. Similar relations of the lower value of the cmc of the bromide system than that of the chloride system were observed for surfactants having a dodecyl group[11,12] and surfactants having an octadecyl group.[13]

Standard Free Energy of Micellization. In terms of the pseudo-phase model for the micelle,[14] in which the solution of surfactant monomer is an ideal solution and the micelle is a separated phase, the standard free energy of micellization per mole of surfactant is given by

$$\Delta G_m^\circ = RT \ln X_o, \tag{28}$$

where X_o is the mole fraction of surfactant at the cmc. When expressed by the molar concentration of surfactant at the cmc, C_o, we have

$$\Delta G_m^\circ = RT \ln \frac{M_w C_o}{1000\rho_o - (M_s - M_w)C_s}, \tag{29}$$

where ρ_o denotes the density of solution at the cmc.

Table 4 gives the values of $-\Delta G_m^\circ$ for the DDAB-NaBr system, together with those for the DDAC-NaCl system. The micelles are both stabilized more as the ionic strength is increased. The stabilization of micelle is 0.7 kJ mol^{-1} more effective for the DDAB-NaBr system compared with that for the DDAC-NaCl system, as long as the ionic strength is lower than 0.05 mol dm^{-3}.

Surface Tension. We had originally attempted to measure the surface tension of solution by means of the Wilhelmy hanging plate method, but the downward shift of the plate was not reproducible at all. Thus we decided to employ the drop weight method for surface tension measurements.

For the surface tension measurements of aqueous solutions of a cationic surfactant, either in the presence or absence of added salt, we have found that the hanging plate method does not give any reproducible results, owing to the built-up of the cationic on the glass plate (and also possibly on the platinum plate) and the resulting change in contact angle. For the surface tension measurements of aqueous solutions by means of Wilhelmy hanging plate method, the contact angle of solution on the plate must be nearly zero. But in the case of cationic surfactants such as the derivatives of long-chain alkylammonium, this condition is never satisfied generally.

Table 4. Standard free energy of micellization of dodecyldimethylammonium bromide in aqueous NaBr solutions and dodecyldimethylammonium chloride in aqueous NaCl solutions at 25 °C

C_s / mol dm^{-3}	DDAB−NaBr $-\Delta G_m^\circ$ / kJ mol^{-1}	DDAC−NaCl $-\Delta G_m^\circ$ / kJ mol^{-1}
0	21.1	20.4
1×10^{-4}	21.1	20.4
1×10^{-3}	21.2	20.5
5×10^{-3}	21.3	20.6
0.01	21.7	21.0
0.02	22.1	
0.05		22.5
0.10	24.8	23.5
0.20	26.0	24.5
0.50	27.4	26.1
1.00	28.7	27.9[a]
2.00	30.3	30.3
4.00		34.1

a) $C_s = 0.94$ mol dm^{-3}.

The drop weight method is universally applicable for the measurements of surface tension of aqueous solutions of any surfactant. It permits to measure even the time change of surface tension, as referred to above.

The tendency of the relations between surface tension and surfactant concentration and between surface tension and the concentration of sodium salt in the present DDAB-NaBr system is analogous to those of the previous DDAC-NaCl system.[5] As it is seen in Fig. 1, the surface tension of the DDAB-NaBr system decreases with increasing the surfactant concentration up to the cmc and also with increasing the NaBr concentration, as was observed for the DDAC-NaCl system. At surfactant concentrations higher than the cmc, the surface tension remains constant in both of these systems.

Comparing the surface tension of two systems at the same concentration of the sodium salt, the surface tension of the DDAB-NaBr system is lower than that of the DDAC-NaCl system at all surfactant concentrations and also at all concentrations of sodium salt.

Partial Molar Volume. Table 2 gives the values of the cmc identified as the break point of the density curves of solution. These values are in agreement with those derived from the surface tension measurements.

The partial molar volume, $\bar{V}=M\bar{v}$, of DDAB changes abruptly at the cmc, and their values above and below the cmc are given in Table 2. The change in partial molar volume of DDAB by the micellization is 5—8 cm^3 mol^{-1}, depending on the NaBr concentration. The observed values for DDAB are comparable with that for DDAC in water, 8.4 cm^3 mol^{-1}. They are also roughly of the same order of magnitude or smaller than those for surfactants having a dodecyl group.[15,16]

One of the authors (H. O.) wishes to thank Dr. Kōichi Mase and Mr. Yoshikazu Terada for generous support and encouragement during this work.

The Preparation of DL-Isoleucine by Asymmetric Transformation

Chikara HONGO,* Ryuzo YOSHIOKA, Masanori TOHYAMA, Shigeki YAMADA,† and Ichiro CHIBATA††

Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd., 16-89, Kashima-3-chome, Yodogawa-ku, Osaka 532

(Received December 2, 1983)

The chemical synthesis of isoleucine leads to a mixture of DL-isoleucine and DL-alloisoleucine. The preparation of DL-isoleucine from the mixture was studied. When the mixture was reacted with 1,5-naphthalenedisulfonic acid in water, DL-isoleucine formed the less soluble 1,5-naphthalenedisulfonate and could be separated in the form of the salt from the mixture. The soluble DL-alloisoleucine salt was easily epimerized by heating in acetic acid in the presence of salicylaldehyde and free isoleucine mixture. Asymmetric transformation between the two diastereoisomeric racemates was carried out by the simultaneous combination of the fractional crystallization of the less soluble DL-isoleucine salt and the epimerization of the soluble DL-alloisoleucine salt. DL-Isoleucine salt was obtained in a yield of up to 95% from a DL-isoleucine–DL-alloisoleucine mixture or even from DL-alloisoleucine.

L-Isoleucine (L-Ile) is an essential amino acid useful as a nutrient or a food additive. The chemical synthesis of isoleucine leads to a mixture (Ile-mixture) of DL-Ile and DL-alloisoleucine (DL-allo-Ile), since the amino acid has two asymmetric carbon atoms. In order to obtain L-Ile from the mixture by a conventional optical-resolution method, such as the asymmetric hydrolysis of *N*-acyl-DL-amino acids by aminoacylase, it is necessary to separate DL-Ile from the Ile-mixture before the optical resolution.[1,2] Several methods for the separation of DL-Ile from the Ile-mixture are known. For example, DL-Ile or the sodium salt can be separated from the mixture by fractional crystallization with an appropriate solvent in which DL-Ile or the salt is less soluble than DL-allo-Ile or its sodium salt.[3,4] Also, *N*-acetyl-DL-Ile may be obtained as the more soluble fraction in a similar way.[2,5,6] In these methods, however, the crystallization must be systematically repeated several times to isolate the pure product; this results in low yields and is time-consuming.[7] Generally, the separation of the diastereoisomers of isoleucine is so difficult and tedious that no method to meet industrial demands is found in literatures. To develop practical and convenient methods for the production of DL-Ile, we have studied the separation of DL-Ile from the Ile-mixture by fractional crystallization and the preparation of DL-Ile by asymmetric transformation, *i.e.*, by a combination of fractional crystallization and simultaneous epimerization.

It has been well known that some aromatic sulfonic acids have been used as specific precipitating reagents for the separation of amino acids.[8] We have ourselves previously developed a technique using aromatic sulfonic acids for the optical resolution of DL-amino acid by means of a preferential crystallization procedure.[9-12] Aromatic sulfonic acids were chosen because they vary greatly in properties and easily form salts with any kind of amino acid; also, their salts tend to form racemic mixtures suitable for optical resolution by means of the preferential crystallization procedure. In the present study, with a similar idea, the separation of DL-Ile from the Ile-mixture was investigated using aromatic sulfonic acids. We prepared a wide variety of aromatic sulfonates of the Ile-mixture and screened the salts suitable for the separation. As a result, the salt of DL-Ile with 1,5-naphthalenedisulfonic acid (NDS) was found to form easy handling crystals from water in a good yield and to be very suitable for the separation of the two diastereoisomeric racemates. When the Ile-mixture was reacted with NDS in water, DL-Ile selectively crystallized as the less soluble salt, which was composed of two moles of DL-Ile and one mole of NDS, while soluble DL-allo-Ile·NDS remained almost quantitatively in the mother liquor. The DL-Ile·NDS obtained by the above procedure was contaminated with approx. 7% of DL-allo-Ile·NDS, but the sulfonate once recrystallized from water had an allo-Ile content as low as 0.3%.

From an economic point of view, it is wasteful to discard the DL-allo-Ile remaining in the mother liquor because the epimerization of DL-allo-Ile leads to a mixture of DL-Ile and DL-allo-Ile, from which DL-Ile can be separated in the form of the salt with NDS, as has been described above. Therefore, we investigated the epimerization of the DL-allo-Ile·NDS remaining in the filtrate after the separation of the DL-Ile·

Table 1. Effects of salicylaldehyde and Ile-mixture on the epimerization of L-Ile·NDS[a]

NDS. Our previous report[13] showed that various optically active α-amino acids were easily racemized by heating them moderately in an acetic acid solution in the presence of a catalytic amount of aldehyde. Although the NDS salt of DL-allo-Ile was epimerized only a little in the same way, the epimerization of DL-allo-Ile·NDS was found to be greatly accelerated by heating it in an acetic acid solution in the presence of large amounts (one molar equivalent or above) of salicylaldehyde and free Ile-mixture. The effects of salicylaldehyde and the free Ile-mixture on the epimerization of L-Ile·NDS are shown in Table 1.

Then, using the epimerization method described above, we studied the asymmetric transformation between two diastereoisomeric racemates by the simultaneous combination of the fractional crystallization of the less soluble DL-Ile·NDS and the epimerization of the soluble DL-allo-Ile·NDS. DL-Ile·NDS was fractionally precipitated even under the epimerizing conditions, while the precipitated crystals were nevermore epimerized. In the liquid phase, the epimerization of DL-allo-Ile·NDS proceeded simultaneously, and the equilibrium shifted in favor of DL-Ile·NDS as a whole by the continuous precipitation of DL-Ile·NDS from the epimerizing solution, so that a direct conversion of DL-allo-Ile·NDS into DL-Ile·NDS could be achieved by a so-called second-order asymmetric transformation. Starting with the Ile-mixture (Ile/allo-Ile ratio=56.4/43.6), DL-Ile·NDS (Ile/allo-Ile ratio=89.8/10.2) was obtained in a yield of 90% based on the original weight of the Ile-mixture by means of a reaction at 100 °C for 16 h. Also, starting with DL-allo-Ile, crystals of DL-Ile·NDS (Ile/allo-Ile ratio=93.1/6.9) were precipitated in a yield of up to 94.5% based on the original weight of DL-allo-Ile·NDS by means of a reaction at 100 °C for 30 h. The change in the composition of both diastereoisomeric racemates during the reaction is shown in Fig. 1. When the DL-Ile·NDS obtained above was once recrystallized from water, the ratio of Ile/allo-Ile was larger than 1000/2.

Although second-order asymmetric transformation has been reported for numerous examples of the diastereoisomeric salt of a racemic modification, including some amino acids with an optically active resolving agent,[14-16] no report has described the asymmetric transformation between two optically stable diastereoisomeric racemates in the absence of any auxiliary chiral agent. The present one-step asymmetric transformation method for the preparation of DL-Ile from a synthetic mixture of DL-Ile and DL-allo-Ile has a definite advantage and is suitable for industrial application.

Experimental

Materials. The diastereoisomeric mixture (Ile-mixture), consisting of 56.4% DL-Ile and 43.6% DL-allo-Ile, and L-Ile manufactured by our company, Tanabe Seiyaku Co., Ltd., were used. The DL-allo-Ile was prepared by the method of Greenstein *et al.*[2] The 1,5-naphthalenedisulfonic acid, salicylaldehyde, and other chemicals were obtained from the Tokyo Kasei Kogyo Co., Ltd.

Analyses. All samples were air-dried overnight at 50 °C. Elemental analyses were performed with a Perkin-Elmer 240 elemental analyzer. Amino acid analyses were performed by means of a Hitachi high-speed amino-acid analyzer, Model 835 [resin, Hitachi Custom Resin 2619; eluting buffer, 0.2 M sodium citrate buffer (1 M=1 mol dm^{-3}, pH 4.25); column temperature, 55 °C]. Under the conditions employed, the lower limit of the detection of allo-Ile was approximately 0.05%. The optical rotation was measured with a Perkin-Elmer 141 automatic polarimeter.

Separation of DL-Ile·NDS by Fractional Crystallization. A mixture of the Ile-mixture (10.0 g) and NDS (13.6 g; water content, 19.3%) was dissolved in water (120 ml) by heating at 80 °C and then allowed to stand in a refrigerator overnight. The crystals thus precipitated were collected by filtration, washed with a small amount of cold water, and dried to give crude DL-Ile·NDS (10.8 g); apparent yield, 91.3% (based on the DL-Ile in the starting Ile-mixture); DL-Ile/DL-allo-Ile ratio=93.5/6.5. The crude DL-Ile·NDS (10.8 g) was recrystallized twice from water (110 ml) to give pure DL-Ile·NDS (6.3 g); yield, 53.2% (based on the DL-Ile in the starting Ile-mixture); DL-allo-Ile, undetected; mp 240—241 °C (decomp). Found: C, 48.07; H, 6.27; N, 4.85; S, 11.71%. Calcd for $C_{22}H_{34}N_2O_{10}S_2$: C, 47.99; H, 6.22; N, 5.09; S, 11.64%. Solubility in water (g/100 ml): 1.84 (20 °C), 2.22 (30 °C).

Epimerization of Ile·NDS. The experiments aimed at the epimerization of Ile·NDS were carried out by using L-Ile·NDS,** since the optical rotations of L-Ile and D-allo-Ile are nearly equal in magnitude and opposite in sign. A mixture of L-Ile·NDS (0.1 g), salicylaldehyde (0.018 ml, 1.0 mol per 1.0 mol of L-Ile·NDS), an Ile-mixture (0.023—0.23 g, 1.0—10.0 mol per 1.0 mol of L-Ile·NDS), and 95% acetic acid*** (10 ml) was heated in a sealed tube at 100 °C for 3 h. The reaction mixture was diluted with 1 M-hydrochloric acid (5 ml), and the optical rotation was measured. The epimeriza-

** L-Ile·NDS was prepared as follows. A mixture of L-Ile (13.1 g) and NDS (14.5 g) was dissolved in water (50 ml) at an elevated temperature, and then the solution was allowed to stand in a refrigerator overnight. The resulting precipitates were collected, washed with cold water, and air-dried at 50 °C to give L-Ile·NDS (22.5 g); mp 253—254 °C (decomp), $[\alpha]_D^{25}$ +13.4° (c=1, water). The product was composed of 2 mol of L-Ile, 1 mol of NDS, and 1 mol of water.

*** Although the extent of epimerization decreased with the increase in the water content of acetic acid, as has been described in our previous report,[13] acetic acid containing 5% water was used in order to dissolve the L-Ile·NDS.

tion degree was calculated as follows:

$$\frac{\text{initial optical rotation} - \text{final optical rotation}}{\text{initial optical rotation}} \times 100.$$

The effects of the salicylaldehyde and the Ile-mixture on the epimerization of L-Ile·NDS are shown in Table 1.

Production of DL-*Ile·NDS by Asymmetric Transformation. From Ile-Mixture*: An Ile-mixture (13.1 g), NDS (17.9 g, water content, 19.3%; equivalent amount with Ile-mixture, 13.1 g), acetic anhydride (18.0 ml; equimolar amount with water contained in NDS, 17.9 g), and a combination of an Ile-mixture (2.2 g) and salicylaldehyde (0.22 ml) to accelerate the epimerization of DL-allo-Ile·NDS were added to glacial acetic acid (30 ml). The mixture once completely dissolved, and soon most of the Ile·NDS precipitated. The mixture was then stirred at 100 °C for 16 h. The crystals thus precipitated were quickly collected by filtration, washed with a small amount of acetic acid, and dried to give crude DL-Ile·NDS (24.8 g); yield, 90.1% (based on Ile-mixture·NDS), Ile/allo-Ile=89.8/10.2. The Ile/allo-Ile ratio of the mother liquor was 41.5/58.5. The crude DL-Ile·NDS (24.8 g) was recrystallized from water (300 ml) to give DL-Ile·NDS (17.6 g); Ile/allo-Ile ratio=1000/2.

From DL-*Allo-Ile*: DL-Allo-Ile (13.1 g, 100 mmol), NDS (14.3 g, water content 19.3%, 40 mmol), salicylaldehyde (0.26 ml, 2.5 mmol), and acetic anhydride (14.4 ml; equimolar amount with water contained in NDS, 14.3 g) were added to glacial acetic acid (60 ml). The mixture was stirred at 100 °C, seeded with finely pulverized crystals of DL-Ile·NDS (0.01 g) after 3 h, and further stirred for 30 h at the same temperature. The reaction mixture was then cooled to room temperature and stirred for 1 h. The crystals thus precipitated were collected by filtration, washed with a small amount of acetic acid, and dried to give DL-Ile·NDS (20.8 g); yield, 94.5% (based on DL-allo-Ile·NDS); Ile/allo-Ile=93.1/6.9. The Ile/allo-Ile ratio of the mother liquor was 40.7/59.3. The change in the composition of both diastereoisomeric racemates during the reaction is shown in Fig. 1.

Preparation of Pure DL-*Ile*. Recrystallized DL-Ile·NDS (16.0 g) was dissolved in water (800 ml). The solution was passed through a column of Amberlite IR-45 (70 ml, OH-form), and the column was washed with water. The effluent and washed water were concentrated, and methanol (45 ml) was added to the concentrated solution. The crystals thus precipitated were collected by filtration, washed with a small amount of cold water, and dried to give DL-Ile (7.3 g); DL-allo-Ile, undetected.

Sorption of Ammonia/Ammonium Ion on Crystalline Hydrous Titanium Dioxide Fibers

Takayoshi SASAKI,* Yū KOMATSU, and Yoshinori FUJIKI
National Institute for Research in Inorganic Materials
1-1 Namiki, Sakura-mura, Niihari-gun, Ibaraki 305
(Received August 5, 1983)

The sorption of ammonia/ammonium ion has been studied on crystalline hydrous titanium dioxide fibers with a layer structure, which are prepared from potassium tetratitanate ($K_2Ti_4O_9$). From the measurement of the distribution coefficient, it was found that this material strongly preferred ammonium ion to sodium ion. The results of the pH titration curves indicated that this material showed a wide range of acidities toward ammonia/ammonium ion and had 2.63 mequiv/g of an apparent capacity which was about a half of the theoretical ion-exchange capacity. The characterizations of the ammonium adsorbed solid phase at various loading levels were carried out by measuring the X-ray powder diffractograms and the water contents. From these studies, it was concluded that the sorption-desorption reaction of ammonia/ammonium ion on this material took place almost reversibly in three stages.

Recently Fujiki *et al.* have prepared a crystalline hydrous titanium dioxide with a fibrous form from potassium tetratitanate ($K_2Ti_4O_9$).[1,2] This material, which was named "crystalline hydrous titanium dioxide fibers," has been attractive because it has a layer structure and is supposed to be highly selective for some metal ions. We have studied the sorption of the microquantities of alkali metals, alkaline earth metals and divalent transition metals and determined their order of selectivity.[3-5] Considerably large differences of the affinities were observed between these metal ions, and some mutual separations of these metals were achieved on the column of this material.[4,5] We have also proposed that this material can be used advantageously to immobilize the dangerous nuclides such as cesium and strontium in a high-level radioactive waste solution.[6,7]

On the other hand, much attention has been paid to the problem of removal of ammonia/ammonium ion from an aqueous solution during the last decade. Some kinds of ion-exchangers such as zirconium phosphate are being employed to remove ammonia/ammonium ion from human blood, *e.g.* artificial kidney machine.[8,9] The sorption of ammonia/ammonium ion on crystalline hydrous titanium dioxide fibers, however, has not been studied yet, although they are promising for such a practical use because they are suitable for column operations because of their fibrous form. The sorption on this material is expected to be different from that on zirconium phosphate because there are some differences in the layer arrangement or the characteristics of the exchangeable protons. Thus it is interesting and important, from both fundamental and practical viewpoints, to study the sorption of ammonia/ammonium ion on crystalline hydrous titanium dioxide fibers.

In this paper, the sorption of ammonia/ammonium ion on crystalline hydrous titanium dioxide fibers is studied and the mechanism and characteristics of the sorption are also discussed.

Experimental

Reagents. Titanium dioxide used was of 99.98% purity. All the other chemicals were of analytical grade. Distilled, deionized water was used throughout the experiments.

Preparation of Crystalline Hydrous Titanium Dioxide Fibers. Crystalline hydrous titanium dioxide fibers were prepared as described previously;[5] potassium tetratitanate ($K_2Ti_4O_9$) fibers were grown by slow-cooling a K_2MoO_4 flux melt containing a mixture of K_2CO_3 and TiO_2 (1:3 molar ratio). The obtained fibers were placed in a column and converted into a hydrogen form by passing through 1 mol dm^{-3} hydrochloric acid as given by Eq. 1.

$$K_2Ti_4O_9 + 2H^+ + nH_2O \longrightarrow H_2Ti_4O_9 \cdot nH_2O + 2K^+. \quad (1)$$

After the concentration of potassium ion in the effluent became negligible, the resulting product was washed with water and dried in the air to a constant weight. The chemical formula of this material can be written as $H_2Ti_4O_9 \cdot 1.3H_2O$ taking into account the fact that the weight loss at 800 °C was 11.49%. The theoretical ion-exchange capacity is calculated to be 5.53 mequiv/g.

Distribution Coefficients. Distribution coefficients of ammonium ion were obtained by shaking 0.2 g of the material with 0.02 dm^3 of 1×10^{-3} mol dm^{-3} NH_4Cl solution at 25±0.5 °C. The pH value of the solution was controlled with hydrochloric acid. After the equilibrium was attained, the supernatant solutions were analyzed for their pH values and ammonium ion contents. The ammonium ion contents were determined by means of a TOA AE-235 ammonium ion selective electrode. The distribution coefficients were calculated by using

$$K_d = \frac{\text{moles of ammonium ion per 1 g of the material}}{\text{moles of ammonium ion per 1 cm}^3 \text{ of the solution}} \ (\text{cm}^3/\text{g}).$$

The concentrations of ammonium ion in the material were calculated from the differences between initial and final concentrations of solutions.

pH Titration Curve. The titrations for ammonia/ammonium ion were carried out batchwise; in the forward titration, 0.5 g of the material was shaken with 0.05 dm^3 of 0.1 mol dm^{-3} ($NH_4Cl+NH_3H_2O$) solution at 25±0.5 °C until the equilibrium was attained. The ratio of NH_4Cl/NH_3H_2O was varied from 0.1 M/0.0 M to 0.0 M/0.1 M (1 M= 1 mol dm^{-3}). After the pH value at equilibrium was measured, the ammonium content in the solution was determined by the standard acidimetric titration in the presence of formaldehyde. The solid was filtered off, washed and dried in the air at room temperature. The ammonium content in the solid was determined by the Kjeldahl method.

In the backward titration, 0.5032 g of the end product in the forward titration was treated with 0.05 dm^3 of 0.1 mol dm^{-3} (NH_4Cl+HCl) solution. Other procedures were similar to those in the forward titration. The pH titration curve for potassium ion was obtained in a similar way by using 0.1 mol dm^{-3} (KCl+KOH) solution.

Apparatus. The pH values of the solution were measured by a TOA HM-20E digital pH meter. X-Ray powder diffractograms were obtained by a Philips X-ray diffractometer with Cu $K\alpha$ radiation.

Results and Discussion

Distribution Coefficients. In order to determine the equilibration time, 0.2 g of the material was shaken with 0.02 dm^3 of 1×10^{-3} mol dm^{-3} NH_4Cl solution (pH=2.0) at 25±0.5 °C. Figure 1 shows the percent uptake of ammonium ion as a function of time. It was confirmed that 2 d shaking was enough to attain the equilibrium. Thus all the experiments were carried out by shaking the fibers with solutions for 3 d.

Figure 2 shows the pH dependence of distribution coefficients (K_d) of ammonium ion. The dashed lines denote the data of alkali metals obtained previously under similar experimental conditions.[3] The linear relationship was observed between log K_d and pH with a slope of +1. This fact indicated that the sorption of ammonium ion took place by an ideal ion-exchange reaction as given by Eq. 2.

$$x\mathrm{NH_4^+(aq)} + \mathrm{H_2Ti_4O_9\cdot}n\mathrm{H_2O(s)} \rightleftharpoons (\mathrm{NH_4})_x\mathrm{H_{2-}}_x\mathrm{Ti_4O_9\cdot}n'\mathrm{H_2O(s)} + x\mathrm{H^+(aq)} \quad (0<x<0.04), \tag{2}$$

where the subscripts "aq" and "s" represent aqueous and solid phases, respectively.

The order of selectivity was found to be Cs>Rb>K>NH_4>Na>Li. In the case of alkali metals, this order was parallel to their ionic radii. Since the ionic size of ammonium ion is almost the same as that of potassium ion, the affinities of these two ions are expected to be almost equal with each other, which is actually true from Fig. 2.

Table 1 gives the distribution coefficients and separation factors of ammonium ion and alkali metal ions at a pH value of 2.0. A large value of separation factor was observed between ammonium ion and sodium ion. This fact will be one of advantages when this material is employed to remove ammonium ion from a solution which contains a large amount of sodium ion.

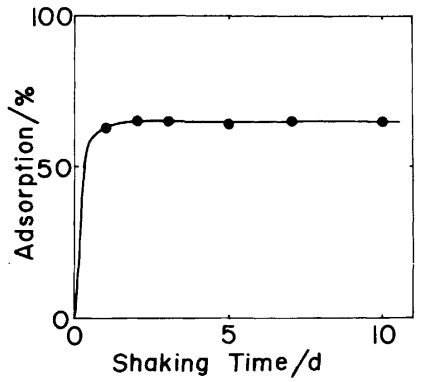

Fig. 1. Time dependence of the sorption of ammonium ion.
Exchanger: 0.2 g, solution: 0.02 dm^3 of 1×10^{-3} mol dm^{-3} NH_4Cl (pH=2.0).

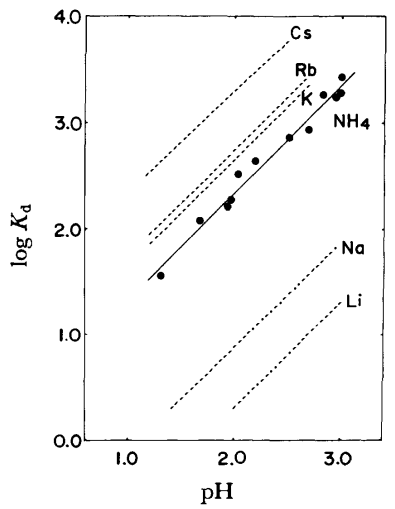

Fig. 2. pH dependence of distribution coefficients of ammonium ion.
Exchanger: 0.2 g, solution: 0.02 dm^3 of 1×10^{-3} mol dm^{-3} NH_4Cl.

Table 1. Distribution coefficients (K_d) and separation factors (α_A^B) of ammonium ion and alkali metal ions at pH=2.0

Ion	Cs	Rb	K	NH_4	Na	Li
K_d	2460	563	458	225	8.0	2.1
α_A^B	4.4	1.2	2.0	28.1	3.8	

$\alpha_A^B = K_d^B/K_d^A$ for neighboring ions. Data for alkali metal ions are from Ref. 3.

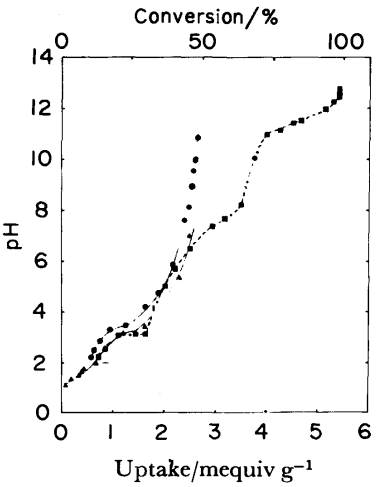

Fig. 3. pH titration curve.
—●— Ammonia/ammonium ion (forward); exchanger: 0.5 g, solution: 0.05 dm^3 of 0.1 mol dm^{-3} (NH_4Cl+NH_3H_2O), —▲— ammonia/ammonium ion (backward); exchanger (ammonium form): 0.5032 g, solution: 0.05 dm^3 of 0.1 mol dm^{-3} (NH_4Cl+HCl), —■— potassium ion (forward); exchanger: 0.2 g, solution: 0.02 dm^3 of 0.1 mol dm^{-3} (KCl+KOH).

pH Titration Curve. pH titration curves for ammonia/ammonium ion (forward and backward) are shown in Fig. 3. pH titration curve for potassium ion is also shown for comparison. The exchangeable protons in crystalline hydrous titanium dioxide fibers had a wide range of acidities toward ammonia/ammonium ion. The inflection point was observed at 25—30% conversion, which indicated that 25—30% of the exchangeable protons were more acidic than the others. The backward titration curve had a similar curvature to the forward one except for a slight difference. The apparent capacity for ammonia/ammonium ion was 2.63 mequiv/g which was about a half of the theoretical ion-exchange capacity of this material, whereas almost complete exchange was achieved with potassium ion.

Characterization of Ammonium-Adsorbed Solid Phase. Figure 4 shows the X-ray powder diffractograms of the material at various loading levels of ammonium in the forward titration. In most of the ion-exchange processes of inorganic ion-exchangers with a layer structure, two immiscible phases are observed; one is an unexchanged phase and the other is an exchanged phase with a different interlayer distance from that of the unexchanged phase.[10,11] In this work, however, X-ray diffractograms changed continuously, which indicated that ammonia/ammonium ion is taken into crystalline hydrous titanium dioxide fibers without phase transition.

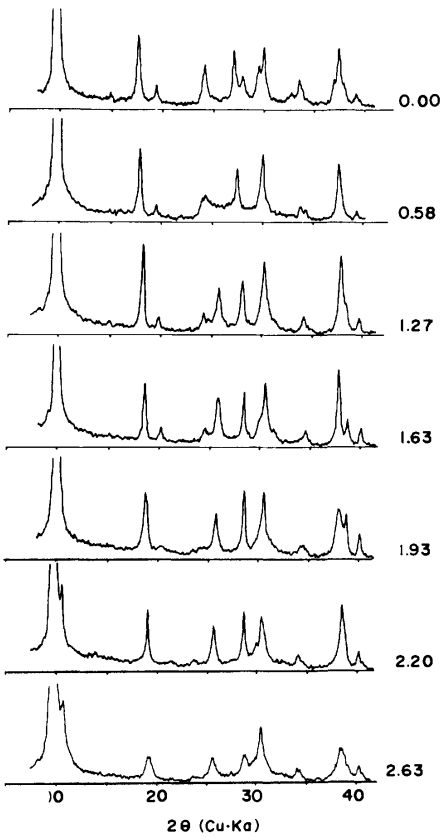

Fig. 4. Schematic diagrams of X-ray powder diffractograms of the ammonium adsorbed phase in forward titration. Numerals represent the uptake of ammonia/ammonium ion (mequiv/g).

Figure 5 shows the *d*-spacing of the strongest reflection, which appeared near the 2θ value of 10° in the X-ray diffractograms, as a function of ammonium loading. This reflection is from (200) plane and is attributable to the interlayer of the material.[12] Its spacing was determined by using potassium hexatitanate ($K_2Ti_6O_{13}$) as an internal standard.

Figure 6 shows the water content of the ammonium-adsorbed solid phase as a function of loading. The weight loss was determined by heating the ammonium-adsorbed solid phase at 800 °C for 1 h. The water content was calculated from the weight loss by assuming the decomposition given by Eq. 3.

$$(NH_4)_xH_{2-x}Ti_4O_9\cdot nH_2O(s) \longrightarrow 4TiO_2(s) + xNH_3(g) + (n+1)H_2O(g) \quad (3)$$

where subscripts "s" and "g" represent solid and gas phases, respectively.

Figure 7 shows the *d*-spacing of the (200) reflection at various loadings of ammonium in the backward titration. The *d*-spacings coincided roughly with those of

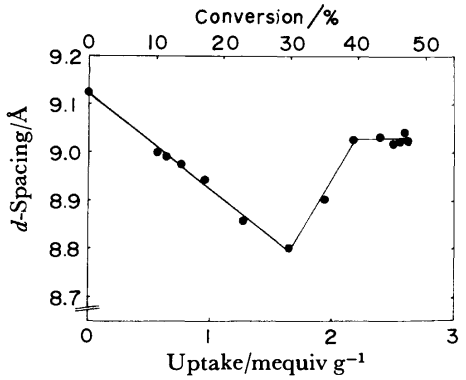

Fig. 5. *d*-Spacing of the (200) reflection as a function of loading in forward titration.

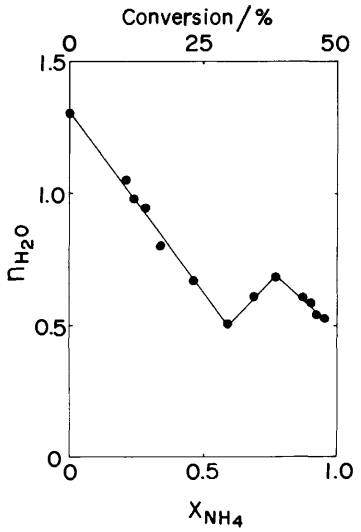

Fig. 6. Water content of the ammonium adsorbed solid phase in forward titration.
x_{NH_4} and n_{H_2O} correspond to the subscripts in the chemical formula of the ammonium adsorbed solid phase, $(NH_4)_xH_{2-x}Ti_4O_9\cdot nH_2O$.

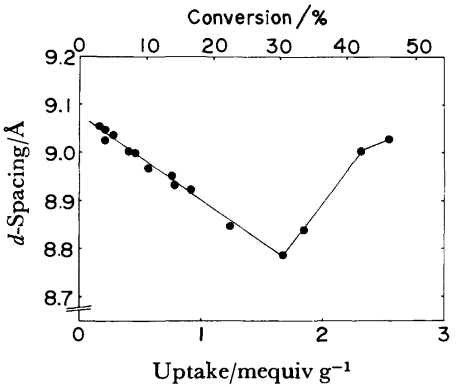

Fig. 7. *d*-Spacing of the (200) reflection as a function of loading in backward titration.

the material in the forward titration, which indicated that the sorption-desorption reaction took place almost reversibly. A slight difference between the forward and backward titration curves may be due to the loss of crystallinity of the material used in the backward titration which was the end product in the forward titration.

Mechanism of the Sorption of Ammonia/Ammonium Ion. There are two possible explanations for the sorption of ammonia/ammonium ion; one is an NH_4^+/H^+ exchange reaction and the other is a direct addition of NH_3 to the protons in the exchanger giving ammonium ion. Alberti and his co-workers have reached a conclusion after detailed investigations that the sorption on crystalline zirconium phosphate took place by the direct addition of NH_3.[12] In the case of crystalline hydrous titanium dioxide fibers, the sorption can be explained by the NH_4^+/H^+ exchange in the pH range of 1.0 to 3.0 from distribution coefficients shown in Fig. 2. However it is difficult to determine which way of the sorption process was predominant in the higher pH region from the result of pH titration curve.

As described above, about a half of the exchangable protons was replaced by ammonia/ammonium ion. The plots of the interlayer distance and the water content of the ammonium-adsorbed solid phase showed two distinct turning points at 30 and 40% conversion. These facts suggested that the ammonia/ammonium ion uptake took place in three stages; stage I [0—30% conversion], stage II [30—40% conversion] and stage III [40—48% conversion].

In stage I, ammonia/ammonium ion uptake proceeded accompanying the continuous decrease in interlayer distance and water content. This phenomenon can be explained as follows; the ammonium ion adsorbed between the layers can make a hydrogen-bond with an unexchanged hydroxyl group in an adjacent layer. As the ammonium loading increased, the number of hydrogen-bond increased, which induced the continuous decrease in interlayer distance. The water content also decreased linearly. The value of $d\,n_{H_2O}/d\,x_{NH_4}$ was 1.33 which was approximately equal to the number of water molecules per formula weight of the material. From these facts, it is suggested that the ammonia/ammonium ion was taken into the lattice by forming a hydrogen-bond and expelling the water around the sorption site.

In stage II, the ammonia/ammonium ion uptake gave rise to increase in interlayer distance and water content. In the X-ray powder diffractograms, a new tiny shoulder appeared beside the (200) reflection as seen in Fig. 4. It seems that ammonia/ammonium ion uptake beyond 30% of the conversion caused a slight distortion of the lattice of the material. If this is true, the sorption in this stage will require more energy than in stage I and the sorption will proceed in the higher pH region. This expectation is actually the case as shown in Fig. 3.

In stage III, no definite change was observed in the X-ray powder diffractograms, which suggested that the ammonium ion already adsorbed between the layers may act like a "pillar" and the material can accomodate additional ammonia/ammonium ion without an appreciable change in interlayer distance.

In conclusion, the sorption process can be summarized by the following three equation:

stage I
$$H_2Ti_4O_9\cdot 1.3H_2O + 0.6NH_3(NH_4^+) \quad [9.1\ \text{Å}]$$
$$\longrightarrow (NH_4)_{0.6}H_{1.4}Ti_4O_9\cdot 0.5H_2O + 0.8H_2O \quad [8.8\ \text{Å}] + (0.6H^+)$$

stage II
$$(NH_4)_{0.6}H_{1.4}Ti_4O_9\cdot 0.5H_2O + 0.2NH_3(NH_4^+) \quad [8.8\ \text{Å}]$$
$$+ 0.2H_2O \longrightarrow (NH_4)_{0.8}H_{1.2}Ti_4O_9\cdot 0.7H_2O \quad [9.0\ \text{Å}] + (0.2H^+)$$

stage III
$$(NH_4)_{0.8}H_{1.2}Ti_4O_9\cdot 0.7H_2O + 0.15NH_3(NH_4^+) \quad [9.0\ \text{Å}]$$
$$\longrightarrow (NH_4)_{0.95}H_{1.05}Ti_4O_9\cdot 0.5H_2O + 0.2H_2O \quad [9.0\ \text{Å}] + (0.15H^+),$$

where numerals in brackets correspond to the *d*-spacings of the (200) reflection.

Only a half of the exchangeable protons can be replaced by ammonia/ammonium ion. This phenomenon cannot be attributed to the steric effect, because almost all of the exchangeable protons were exchanged by potassium ions whose size is approximately equal to that of ammonium ion. This fact can also be explained by the hydrogen-bond formation of the ammonium ion between the layers. The stable pair of ammonium ion and an unexchanged hydroxyl group, which is hydrogen-bonded with each other, may be a good explanation for the fact that the apparent capacity was about a half of the theoretical ion-exchange capacity.

Electronic Absorption, Magnetic Circular Dichroism, and Circular Dichroism Spectra of *cis*- and *trans*-[Pd(Cl)$_2$(N)$_2$]-type Complexes and Their Electronic Structures

Kazuhiko NAKAYAMA,* Takashi KOMORITA, and Yoichi SHIMURA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received September 26, 1983)

The electronic absorption and MCD spectra of [PdCl$_2$L] (L=ethylenediamine(en), 1,3-propanediamine, *N,N*-dimethylethylenediamine, *N,N'*-dimethylethylenediamine, *N,N*-diethylethylenediamine, and *N,N*-dimethyl-1,3-propanediamine) and *trans*-[PdCl$_2$(L)$_2$] (L=EtNH$_2$, Me$_2$NH, Me$_3$N, *n*-BuNH$_2$, *i*-BuNH$_2$, *s*-BuNH$_2$, *t*-BuNH$_2$, and *rac*-pea (pea=1-phenylethylamine)), and CD spectra of [PdCl$_2$L] (L=(*S*)-1,2-propanediamine-(*S*-pn) and (2*S*)-*N*^{1},*N*^{1}-diethyl-1,2-propanediamine) and *trans*-[PdCl$_2$(*S*-pea)$_2$] have been measured over the visible-near UV region, together with the corresponding spectra of [PtCl$_2$L] (L=en and *S*-pn). The examination of the three kinds of spectra as well as their Gaussian analyses indicates that the splitting pattern of metal d orbitals for the cis type complexes is similar to that for [PdCl$_4$]$^{2-}$, and that as to the trans complexes the $d_{x^2-y^2}\leftarrow d_{xz}$ and d_{yz} transitions split largely to give apparent two spin-allowed d-d bands characteristic of the trans complexes. The average energy of the $d_{x^2-z^2}\leftarrow d_{xz}$ and d_{yz} transitions for the trans complexes is approximately equal to the energy of the $d_{x^2-y^2}\leftarrow d_{xz,yz}$ (D_{4h}) ones for the cis complexes. The transition energies of $d_{x^2-z^2}\leftarrow d_{xy}$ and d_{z^2} do not differ largely between both types of complexes. The assignments of high-intensity bands have also been made tentatively.

Palladium(II) complexes generally exhibit a less informative d-d absorption spectrum than the platinum analogs because of a small splitting of the metal d orbitals. Although three spin-allowed d-d bands are expected in a D_{4h} symmetry (or four in D_{2h}), most of palladium(II) complexes exhibit only a single unsymmetrical band. This situation makes assignment difficult for the d-d spectra of palladium(II) complexes. In the case of [PdCl$_4$]$^{2-}$,[1] the difficulty could be overcome by a concurrent examination of the MCD and absorption spectra and by a comparison with the corresponding spectra of [PtCl$_4$]$^{2-}$.

There have been known a few rare examples exhibiting a distinct splitting of spin-allowed d-d bands.[2,3] The typical examples are *trans*-[Pd(Cl)$_2$(N)$_2$]-type complexes,[2] but there has been no detailed investigation of them. Although the electronic and CD spectra of some complexes of *cis*-[M(Cl)$_2$(N)$_2$]-type (M=Pt and Pd) were reported by Ito *et al.*,[4] the discussion of electronic structure was almost limited to the platinum complexes. The concurrent study of *cis*- and *trans*- [Pd(Cl)$_2$(N)$_2$]-type complexes is desirable to understand systematically the electronic structure of square-planar palladium (II) complexes.

This paper presents new spectral assignment for *cis*- and *trans*-[Pd(Cl)$_2$(N)$_2$]-type complexes on the basis of the absorption, MCD, and CD spectra and their Gaussian analysis. These spectral and analytical data have been compared with those of [PdCl$_4$]$^{2-}$ [1] and [PtCl$_2$(en)]; a similarity of spectra and electronic structure such as noted between [PtCl$_4$]$^{2-}$ and [PdCl$_4$]$^{2-}$ [1] is also found between [PtCl$_2$(en)] and [PdCl$_2$(en)]. Although every *cis*-[Pd(Cl)$_2$(N)$_2$]-type complex gives MCD with a nearly ideal A-term pattern in the spin-allowed d-d region, the MCD is based not only on a transition to a degenerate excited state but on all the spin-allowed d-d transitions. Each of four transitions of the trans complexes proves to exhibit either CD or MCD selectively. In addition, the relationship between the electronic structures of the cis and the trans complexes has been discussed in detail.

Experimental

trans-[PdCl$_2$(L)$_2$] Complexes. *1) L=MeNH$_2$*: Palladium chloride (350 mg) was mixed with an aqueous solution of methylamine (20%, 10 cm^3). The mixture was heated at *ca.* 50 °C with stirring to give an almost colorless solution. After filtration the filtrate cooled was treated with concentrated hydrochloric acid (430 mg), giving yellow needles, which were collected, washed with water, ethanol, and ether; and dried *in vacuo*. Yield: 415 mg. Found: C, 10.13; H, 4.20; N, 11.71%. Calcd for *trans*-[PdCl$_2$(MeNH$_2$)$_2$]=C$_2$H$_{10}$N$_2$Cl$_2$Pd: C, 10.03; H, 4.21; N, 11.70%.

2) L=Me$_2$NH, EtNH$_2$, and n-*PrNH$_2$, and* n-*BuNH$_2$*: Each of these complexes was obtained in good yield by a method similar to that in *1)*. Found: C, 18.05; H, 5.27; N, 10.55%. Calcd for *trans*-[PdCl$_2$(Me$_2$NH)$_2$]=C$_4$H$_{14}$N$_2$Cl$_2$Pd: C, 17.96; H, 5.28; N, 10.47%. Found: C, 17.99; H, 5.25; N, 10.52%. Calcd for *trans*-[PdCl$_2$(EtNH$_2$)$_2$]=C$_4$H$_{14}$N$_2$Cl$_2$Pd: C, 17.96; H, 5.28; N, 10.47%. Found: C, 24.51; H, 6.10; N, 9.50%. Calcd for *trans*-[PdCl$_2$(*n*-PrNH$_2$)$_2$]=C$_6$H$_{18}$N$_2$Cl$_2$Pd: C, 24.38; H, 6.14; N, 9.48%. Found: C, 29.58; H, 6.82; N, 8.64%. Calcd for *trans*-[PdCl$_2$(*n*-BuNH$_2$)$_2$]=C$_8$H$_{22}$N$_2$Cl$_2$Pd: C, 29.69; H, 6.85; N, 8.66%.

3) L=Me$_3$N: After bis(benzonitrile)dichloropalladium(II)[5] (400 mg) had been dissolved in 2 cm^3 of acetone at 50 °C, a small amount of undissolved solid was filtered off and washed with a minimum volume of acetone. An aqueous solution of trimethylamine (30%, 450 mg) was added dropwise to the combined filtrate and washings, with stirring at room temperature. Continuous stirring and cooling gave orange-brown crystals, which were collected, washed with cold acetone, and dried *in vacuo*. Yield: 150 mg. Found: C, 24.50; H, 6.10; N, 9.41%. Calcd for *trans*-[PdCl$_2$(Me$_3$N)$_2$]=C$_6$H$_{18}$N$_2$Cl$_2$Pd: C, 24.38; H, 6.14; N, 9.48%.

4) L=Et$_2$NH: Diethylamine (99%, 160 mg) diluted with acetone (1 cm^3) was added dropwise to a solution (filtered if necessary) of bis(benzonitrile)dichloropalladium(II) (400 mg) in acetone (8 cm^3), with stirring at room temperature. After 1.5 hours of stirring, the desired orange-yellow product was filtered off, washed with water, ethanol, and ether;

and dried *in vacuo*. Yield: 220 mg. Found: C, 29.99; H, 6.87; N, 8.56%. Calcd for *trans*-[PdCl$_2$(Et$_2$NH)$_2$]=C$_8$H$_{22}$N$_2$Cl$_2$Pd: C, 29.69; H, 6.85; N, 8.66%.

5) L=i-*PrNH$_2$*: This was prepared by a method similar to that in *4)*. The crude product was recrystallized from *N,N*-dimethylformamide at *ca.* 80 °C. Found: C, 24.56; H, 6.19; N, 9.51%. Calcd for *trans*-[PdCl$_2$(*i*-PrNH$_2$)$_2$]=C$_6$H$_{18}$N$_2$Cl$_2$Pd: C, 24.38; H, 6.14; N, 9.48%.

6) L=s-*BuNH$_2$*: An acetone solution (1 cm^3) of *s*-butylamine (153 mg) was added dropwise with stirring to a solution of bis(benzonitrile)dichloropalladium(II) (400 mg) in acetone (4.5 cm^3). The mixture was stirred for half an hour and then concentrated to about one-fourth of its original volume. Yellow crystals were obtained from the concentrate by addition of ether followed by stirring for 2 h in an ice-bath. Yield: 230 mg. Found: C, 29.83; H, 6.89; N, 8.67%. Calcd for *trans*-[PdCl$_2$(*s*-BuNH$_2$)$_2$]=C$_8$H$_{22}$N$_2$Cl$_2$Pd: C, 29.69; H, 6.85; N, 8.66%.

7) L=i-*BuNH$_2$ and* rac-*pea*: These were prepared in the same way as in *6)*. In the case of the *rac*-pea complex, the crude product was recrystallized from carbon tetrachloride at *ca.* 70 °C. Found: C, 29.78; H, 6.81; N, 8.71%. Calcd for *trans*-[PdCl$_2$(*i*-BuNH$_2$)$_2$]=C$_8$H$_{22}$N$_2$Cl$_2$Pd: C, 29.69; H, 6.85; N, 8.66%. Found: C, 35.65; H, 3.87; N, 4.84%. Calcd for *trans*-[PdCl$_2$(*rac*-pea)$_2$]·CCl$_4$=C$_{17}$H$_{22}$N$_2$Cl$_6$Pd: C, 35.60; H, 3.87; N, 4.88%.

8) L=t-*BuNH$_2$*: This was prepared in the same manner as in *4)*, but a twofold concentration was adopted for the reaction mixture. The crude product was recrystallized from *N,N*-dimethylformamide at 70—75 °C. Found: C, 29.86; H, 6.85; N, 8.67%. Calcd for *trans*-[PdCl$_2$(*t*-BuNH$_2$)$_2$]=C$_8$H$_{22}$N$_2$Cl$_2$Pd: C, 29.69; H, 6.85; N, 8.66%.

9) L=S-*pea*: This complex was obtained by a method similar to that of Bosnich.[2] Found: C, 40.89; H, 4.61; N, 5.77%. Calcd for *trans*-[PdCl$_2$(*S*-pea)$_2$]·0.4CCl$_4$=C$_{16.4}$H$_{22}$N$_2$Cl$_{3.6}$Pd: C, 40.93; H, 4.61; N, 5.82%.

[PdCl$_2$L] Complexes. L=en, S-*pn, tn,* N,N-*Me$_2$en,* N,N′-*Me$_2$en,* N,N-*Et$_2$en,* N^1,N^1-*Et$_2$-(S)-pn, and* N,N-*Me$_2$tn*: These complexes were prepared according to the methods described in the literature[6] or ones similar to them.

[PtCl$_2$L] Complexes. L=en and S-*pn*: These were obtained by a method similar to that reported[7] (K$_2$PtCl$_4$: ligand=1:1).

Measurements. Electronic absorption, MCD, and CD spectra were recorded with the same apparatus and in the same manner as described elsewhere.[1,6] Spectral measurements of *trans*-[Pd(Cl)$_2$(N)$_2$]-type complexes were made in DCE (1,2-dichloroethane) and in methanol, and *cis*-[Pd(Cl)$_2$(N)$_2$]- and *cis*-[Pt(Cl)$_2$(N)$_2$]-type ones in 0.20 M KCl and 0.50 M HCl aqueous solutions, respectively, all at room temperature (1 M=1 mol dm^{-3}). No spectra of *trans*-[PdCl$_2$L$_2$] (L=MeNH$_2$, Et$_2$NH, *n*-PrNH$_2$, and *i*-PrNH$_2$) could be obtained because of their virtual insolubility in both DCE and methanol, and the spectrum of *trans*-[PdCl$_2$(Me$_3$N)$_2$] in methanol could not be obtained because of its decomposition in the solvent.

Gaussian Analyses. Gaussian analyses of absorption, MCD, and CD spectra were carried out in the same way as described previously.[1] Standard deviations given in Tables 2, 6, 7, 12, and 13 are from the observed values of ε, $\Delta\varepsilon$, or $\Delta\varepsilon_M$ for the corresponding calculated values.

Results and Discussion

Ligand-field Absorption Bands. The typical electronic absorption spectra of *cis*- and *trans*-[Pd(Cl)$_2$(N)$_2$]-type complexes[8] are shown in Fig. 1. The absorption curves of the cis complexes are composed

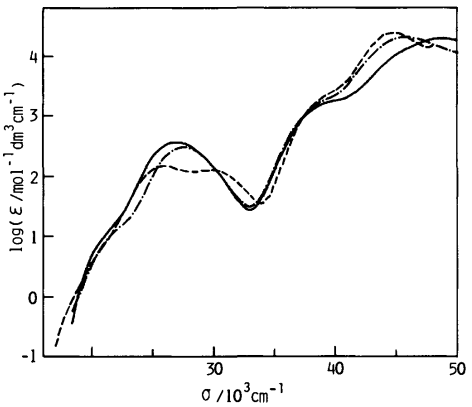

Fig. 1. A comparison of the absorption spectra of typical *cis*- and *trans*-[Pd(Cl)$_2$(N)$_2$]-type complexes. ——: [PdCl$_2$(en)] in 0.20 M KCl. —·—: [PdCl$_2$(tn)] in 0.20 M KCl. ----: *trans*-[PdCl$_2$(EtNH$_2$)$_2$] in DCE.

of an unsymmetrical main band (spin-allowed d-d band) and a lower-lying shoulder (spin-forbidden d-d band) in the ligand field transition region, being similar to that of [PdCl$_4$]$^{2-}$.[1] On the other hand, the spin-allowed d-d band of the trans complex, spreads toward both high and low energies as compared with those of the cis complexes to split into two bands (Fig. 1). Although such a distinct splitting has not been found in the ligand field absorption spectra of *trans*-[Pd(*S*-ala)$_2$][9] and *trans*-[Pd(*N*-Megly)$_2$],[10] one shoulder and one peak have been observed corresponding to the split bands. Therefore, it is reasonable to consider that the difference in ligand-field strength between two kinds of ligating atoms mainly determines the magnitude of the splitting.

For simplicity, we discuss the electronic structure of *cis*- and *trans*-[Pd(Cl)$_2$(N)$_2$]-type complexes under holohedrized symmetries.[11] Namely, the cis and trans complexes are approximately described by D_{4h} and D_{2h} symmetries, respectively. Then, the cis complexes should give rise to three spin-allowed d-d transitions ($^1A_{2g}$, $^1B_{1g}$, and $^1E_g \leftarrow {}^1A_{1g}$) similarly to [PdCl$_4$]$^{2-}$; and the trans complexes four (^1A_g, $^1B_{1g}$, $^1B_{2g}$, and $^1B_{3g} \leftarrow {}^1A_g$).

In the preceding paper,[1] we demonstrated that the absorption and MCD spectra of [PdCl$_4$]$^{2-}$ can be easily correlated with those of the platinum analog, [PtCl$_4$]$^{2-}$, by taking into account two points: firstly the energy separation of the $\Gamma_2(^1A_{2g})$ and $\Gamma_5(^1E_g)$ excited states is considerably large in the latter complex in comparison with the former; and secondly, in [PtCl$_4$]$^{2-}$ singlet-triplet transitions remarkably increase in absorption and MCD intensities and give more complicated spectra. Such a spectral resemblance between palladium and platinum complexes has been also found in [MCl$_n$(OH$_2$)$_{4-n}$]$^{2-n}$ (M=Pd and Pt; n=0—4).[12] Thus, it is helpful to examine first the spectra of [PtCl$_2$(en or *S*-pn)], which is expected to exhibit larger energy separations between d-d excited states than the palladium analog.

with the absorption and MCD spectra of $[PtCl_4]^{2-}$, and the numerical data in Table 1. Although the splitting of the d-d absorption band of $[PtCl_2(en)]$ is not so pronounced as observed for $[PtCl_4]^{2-}$, these two spectra can be easily correlated to each other. Such a correlation is also observed between their MCD spectra, except that the band corresponding to a negative band at 25.2×10^3 cm^{-1} of $[PtCl_4]^{2-}$ disappears in $[PtCl_2(en)]$ (Fig. 2). The dispersion of MCD at *ca.* 36×10^3 cm^{-1} is considered to be primarily composed of a negative A term, and assigned to the $\Gamma_5(^1E_g)\leftarrow\Gamma_1(^1A_{1g})$ transition. The dispersion changes sign around the middle of the whole spin-allowed d-d absorption band. From this fact and the similarities to $[PtCl_4]^{2-}$ as described above, the $\Gamma_2(^1A_{2g})$ and $\Gamma_3(^1B_{1g})\leftarrow\Gamma_1(^1A_{1g})$ transition components are reasonably considered to lie in the lower and higher energy side of the $\Gamma_5(^1E_g)\leftarrow\Gamma_1(^1A_{1g})$ transition, respectively. The results of Gaussian analysis on the basis of this deduction are tabulated in Table 2, together with

38.89	53.3	3.60	205	$\Gamma_3(^1B_{1g})$
	SD[e] = 0.43			

a) S(band area) = 1.0645 × (ε_{max}/mol^{-1} dm^3 cm^{-1}) × ($\Delta\sigma_{1/2}$/10^3 cm^{-1}). b) On the basis of holohedrized symmetry. c) f: fixed value. d) Spin-forbidden d-d transitions. e) Standard deviation (See Experimental).

the assignment. The three spin-allowed d-d transitions are blue-shifted by 6.8×10^3 cm^{-1} on the average from $[PtCl_4]^{2-}$.[1] The blue shift of the $\Gamma_2\leftarrow\Gamma_1$ transition is larger than the average shift by 0.6×10^3 cm^{-1}, and on the contrary that of the $\Gamma_5\leftarrow\Gamma_1$ transition is smaller by the same amount; thus the proximity of the Γ_2 and Γ_5 excited states relative to the case of $[PtCl_4]^{2-}$ makes the splitting of the spin-allowed d-d band less distinct.

The dispersion of MCD at *ca.* 36×10^3 cm^{-1} deviates from an ideal A-term pattern even by assuming such a positive B term as in $[PtCl_4]^{2-}$ for the $\Gamma_3(^1B_{1g})\leftarrow\Gamma_1(^1A_{1g})$ transition, which may be due to the reduction of symmetry from D_{4h}. The deformed dispersion pattern further suggests that the $\Gamma_5(^1E_g)\leftarrow\Gamma_1(^1A_{1g})$ transition exhibits a positive B term in addition to a negative A term because the zero point of the dispersion lies at lower energy than the corresponding absorption component obtained by Gaussian analysis. The positive band at 30.6×10^3 cm^{-1} can be assigned to a positive lobe of the negative A term based on the $\Gamma_5(^3B_{1g})\leftarrow\Gamma_1(^1A_{1g})$ transition by analogy with $[PtCl_4]^{2-}$.[1] Then a negative B term is required for the $\Gamma_2(^1A_{2g})\leftarrow\Gamma_1(^1A_{1g})$ transition in order to reproduce the observed curve because the negative lobe of the negative A term for $\Gamma_5(^3B_{1g})\leftarrow\Gamma_1(^1A_{1g})$ is expected to be overlapping the band based on $\Gamma_2(^1A_{2g})\leftarrow\Gamma_1(^1A_{1g})$.

As for the CD spectrum of $[PtCl_2(S\text{-pn})]$, the shoul-

der around 33×10^3 cm^{-1} and the main band at 36.7×10^3 cm^{-1} were assigned to $\Gamma_2(^1A_{2g})$ and $\Gamma_5(^1E_g)\leftarrow\Gamma_1(^1A_{1g})$, respectively, by Ito *et al.*[13] However, the latter band lies in somewhat higher energy than the $\Gamma_5(^1E_g)\leftarrow\Gamma_1(^1A_{1g})$ component obtained by the Gaussian analysis of the absorption spectrum. This fact can be rationalized by considering that the $\Gamma_3(^1B_{1g})\leftarrow\Gamma_1(^1A_{1g})$ ($d_{x^2-y^2}\leftarrow d_{z^2}$) transition at 38.9×10^3 cm^{-1} is exhibiting a weak negative CD band,[14] which is due to the magnetic moment aquired through the reduction of symmetry (C_{2v} from D_{4h}). This will be demonstrated in the case of [$PdCl_2$(*S*-pn)] (*vide infra*).

2) [PdCl$_2$(en or S-pn)] Complex: The absorption, MCD, and CD data are given in Fig. 3 and Tables 3—5 together with those of the related complexes, and discussed on the basis of the results for [$PtCl_2$(en or *S*-pn)] described above. The spin-allowed d-d band exhibits a swelling in the higher energy side, which corresponds to the shoulder observed at *ca.* 37.5×10^3 cm^{-1} in [$PtCl_2$(en)]. The relative position of the zero point of the apparent A term (*ca.* 27.4×10^3 cm^{-1}) to the main CD band is also the same as that in [$PtCl_2$(en)]. On the basis of this resemblance, the Gaussian analysis of the absorption spectrum of [$PdCl_2$(en)] was carried out (Table 6). Three spin-allowed d-d components are assigned to $^1A_{2g}$, ^1E_g, and $^1B_{1g}\leftarrow{}^1A_{1g}$ from lower energy, which for convenience we denote bands I, II, and III, respectively (Table 6).

Although the MCD spectrum shows a nearly ideal A-term pattern, or dispersion, in the spin-allowed d-d region, the dispersion band is difficult to attribute only to the $^1E_g\leftarrow{}^1A_{1g}$ transition. A positive B term based on the $^1B_{1g}\leftarrow{}^1A_{1g}$ transition is expected to be included in the negative lobe of the dis-

persion by analogy with $[PtCl_4]^{2-}$ and $[PdCl_4]^{2-}$.[1] Moreover, a positive B term in addition to a negative A term is assigned to $^1E_g\leftarrow{}^1A_{1g}$ because the dispersion changes sign at lower energy than the corresponding absorption component (band II) obtained by Gaussian analysis; the situation resembles that in $[PtCl_2(en)]$. A negative B term is consequently predicted for band I in order to reproduce the observed MCD curve. The prediction is parallel with that made on a different basis in the case of $[PtCl_2(en)]$. As the MCD spectra of *cis*-$[M(Cl)_2(N)_2]$-type complexes (M=Pt and Pd) are of a poor precision because of low solubility of the complexes, their Gaussian analyses were not performed. However, it was found that the MCD as well as the absorption spectra of $[PtCl_2(en)]$ and $[PdCl_2(en)]$ nicely corresponded to each other.

The CD spectrum of $[PdCl_2(S\text{-pn})]$ was analyzed by assuming two or three components in the spin-allowed d-d region (Table 7.) The component corresponding to the $^1B_{1g}\leftarrow{}^1A_{1g}$ transition (which is magnetic dipole forbidden in a D_{4h} symmetry) is neglected in the former case, where the half-value width of the negative band became rather wide relative to that of the positive band. The two-component case is further inferior to the three-component one with respect to coincidence between the positions of the CD and absorption components for band II and to standard deviation. Thus, it seems reasonable to assign a weak negative CD band to the $^1B_{1g}\leftarrow{}^1A_{1g}$ transition, as expected in the case of $[PtCl_2(S\text{-pn})]$.

3) Other cis-*[Pd(Cl)$_2$(N)$_2$]-type Complexes*: It is concluded that these complexes possess the same elec-

tronic structure with regard to metal d orbitals as [PdCl$_2$(en)] from the similarity of their absorption, MCD, and CD spectra. The spin-allowed d-d absorption bands are similarly unsymmetrical. We characterize the band shape by half-value width parameters[15] $\Delta\sigma^-$, $\Delta\sigma^+$, and $\Delta\sigma_{1/2}$ ($\varepsilon=\varepsilon_{max}/2$ at $\sigma=\sigma_{max}-\Delta\sigma^-$ and $\sigma_{max}+\Delta\sigma^+$; and $\Delta\sigma_{1/2}=\Delta\sigma^-+\Delta\sigma^+$) and unsymmetry parameter, $(\Delta\sigma^+-\Delta\sigma^-/\Delta\sigma_{1/2})\times100$. The parameters for the *cis*-[Pd(Cl)$_2$(N)$_2$]-type complexes are given in Table 8, which leads to the following findings. (1) $\Delta\sigma^+$ is larger than $\Delta\sigma^-$ for all the complexes. The bands of the complexes with a five-membered chelate ring are (2) more highly unsymmetrical and (3) wider than those of the complexes with a six-membered chelate ring. (4) An introduction of alkyl groups on amine nitrogen atom(s) makes the band widths smaller; this is more pronounced with tertiary amine than with secondary amine. It is interesting to interprete the findings in terms of the results of Gaussian analysis for the absorption spectra. Findings (1) and (2) can be explained primarily by the relative position of band II. The band II's of the en, *N*,*N*-Me$_2$en, tn, and *N*,*N*-Me$_2$tn complexes lie at energies higher than the observed absorption peaks by 1.14, 0.99, 0.77, and 0.67×10^3 cm^{-1}, respectively. The unsymmetry parameters decrease in this order. Findings (3) and (4) are attributable to a variation in the energy difference between the three bands, particularly between bands I and II. Accordingly, the transition energy of band I ($^1A_{2g}\leftarrow{}^1A_{1g}$) is affected by the variation of ligands in a different fashion from those of the other two bands (*i.e.* ^1E_g and $^1B_{1g}\leftarrow{}^1A_{1g}$). This result is compatible with the assignment of band I to an electronic transition in the coordination plane.

The MCD spectra in the d-d transition region are similar to one another and shifted together with the absorption spectra by the variation of ligands, which suggests that all the complexes possess a common electronic structure. A detailed examination of the MCD spectra shows that the intensity ratio of the positive to the negative lobe of the dispersion gives its larger absolute value for the complexes with a six-membered chelate ring than for those with a five-membered one.

The CD pattern of [PdCl$_2$(*N*^{1},*N*^{1}-Et$_2$-(*S*)-pn)] is similar to that of [PdCl$_2$(*S*-pn)] (Fig. 3). The negative band in the spin-forbidden d-d region becomes intense as compared with [PdCl$_2$ (*S*-pn)], whereas the main negative band in the spin-allowed d-d

a—d) As in Table 6.

region weak. This observation can be explained by considering that the spin-forbidden transition takes its intensity from the spin-allowed transition through an increased spin-orbit coupling and that substancial cancellation occurs between bands I and II which have a CD sign opposite to each other.

4) trans-[Pd(Cl)$_2$(N)$_2$]-type Complexes: The absorption, MCD, and CD data are given in Figs. 4—6 and Tables 9—11. Since absorption spectra in DCE show a more distinct splitting in the d-d transition region than those in methanol, the data in DCE will be primarily used in the following discussion on the d-d transitions. At first, we will examine *trans*-[PdCl$_2$(*rac*- or *S*-pea)$_2$] complex, for which all the

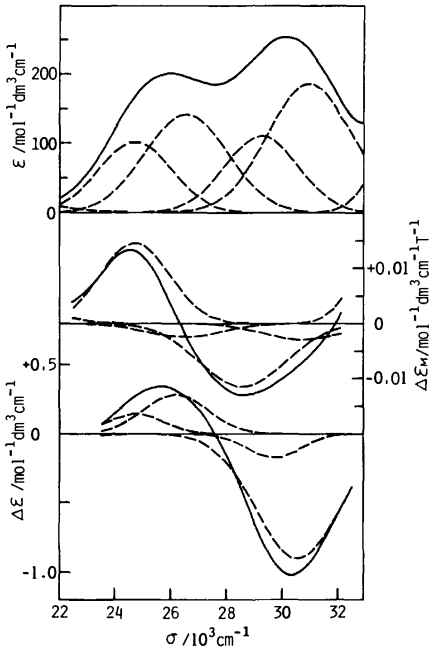

Fig. 7. Gaussian analysis curves for three spectra of *trans*-[PdCl$_2$(pea)$_2$] in DCE. ----: Gaussian components and ——: sum of them.

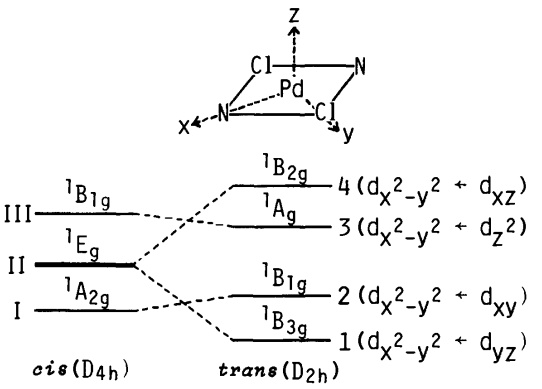

Fig. 8. The orderings of the singlet excited states arising from d-d transitions for *cis*- and *trans*-[Pd(Cl)$_2$(N)$_2$]-type complexes (on the basis of holohedrized symmetry) and the relation between them. I—III and 1—4 represent component band numbers of the cis and trans complexes, respectively (See also Tables 6, 12, and 13).

three kinds of spectra are available. The MCD and the CD spectrum each exhibit a positive and a negative band in the spin-allowed d-d region, and the positions of these four (two MCD and two CD) bands are different from one another. It is sufficient to take into account only B terms for an interpretation of the MCD because the complex has no degenerate excited state. Therefore, it is reasonable to consider that the four bands approximately correspond one by one to the four spin-allowed d-d transitions. On the basis of this consideration, the Gaussian analyses of the three spectra were carried out (Fig. 7 and Table 12). We denote the four components bands 1, 2, 3, and 4 from lower energy (Table 12). The assignment of the bands will be made in the following paragraph.

The Gaussian analyses of absorption spectra for the other trans complexes were performed by analogy with the case of the pea complex (Table 13). In assigning the spectra of the trans complexes, it is helpful to compare them with those of the cis analogs. It is *trans*-[PdCl$_2$(EtNH$_2$)$_2$] that is most suited for a comparison with [PdCl$_2$(en or tn)]. The transition energies for bands 2 and 3 of *trans*-[PdCl$_2$(EtNH$_2$)$_2$] are close to those for bands I and III of [PdCl$_2$(en or tn)], respectively, and the average energy of bands 1 and 4 of the trans complex to the energy of band II of the cis complex (Tables 6 and 13). From these facts, bands 1, 2, 3, and 4 can be assigned to $^1B_{3g}$, $^1B_{1g}$, ^1A_g, and $^1B_{2g}$←^1A_g transitions ($d_{x^2-y^2}$←d_{yz}, d_{xy}, d_{z^2}, and d_{xz}), respectively. The assignment is summarized in Fig. 8, together with that for the corresponding cis complex; the Cartesian coordinate axes are also shown. Figures 7 and 8 visuallize how the four spin-allowed d-d bands overlap to look like two bands in *trans*-[Pd(Cl)$_2$(N)$_2$]-type complexes.

The band area (or oscillator strength) of bands 3 and 4 increased with an introduction of alkyl groups on the nitrogen atoms (Fig. 5 and Table 13). The pronounced effect was found with the band 4 of *trans*-[PdCl$_2$(*rac*-pea)$_2$] complex, which exhibited a strong absorption based on pea ligands in the near-UV region (Table 12). On the other hand, the area of band 1 is hardly affected by the variation of ligands (Table 13). These results support the above assignment where bands 4 and 1 are attributed to transitions from the d_{xz} and d_{yz} orbitals, respectively, which lie in the planes containing only *N*-ligands and only chloro ligands, respectively. In the *S*-pea complex, the CD for band 4 is intense, whereas for bands 1 and 3 weak (Fig. 7). That is to say, high CD intensity is observed for the transition from the d_{xz} orbital lying in the plane containing only optically active ligands, and low for the transition from the d_{yz} orbital lying in the plane containing only optically inactive ligands (Cl) as well as for the transition magnetic dipole-forbidden. This description suggests a certain relation connecting vicinal CD and its intensity with electronic structure.

The replacement of EtNH$_2$ ligand by *n*-BuNH$_2$ caused scarcely any change in the position and intensity of every absorption component. On the other hand, the replacement by *t*-BuNH$_2$ caused shifts

to lower energies by *ca.* 1×10^3 cm^{-1} for bands 1, 2, and 4, and by *ca.* 2×10^3 cm^{-1} for band 3; in addition, the intensities of bands 3 and 4 were increased remarkably (Table 13). The anomalous behavior of band 3 was also observed in the MCD spectra (Fig. 6), and can be explained by considering that a repulsive interaction between the bulky *t*-butyl groups and the d_{z^2} electrons raised the energy of the d_{z^2} orbital. The energy shift caused by the repulsion is only 1×10^3 cm^{-1}, and the remaining shift by 1×10^3 cm^{-1} is attributed to the relative lowering of the $d_{x^2-y^2}$ orbital because this should lower all the d-d transition energies equally. The latter shift was also observed in the Me_3N complex (red shift of *ca.* 3×10^3 cm^{-1} relative to the $EtNH_2$ complex; Fig. 5 and Table 13).

It will be instructive to examine the energy separation of bands 1 and 4 in predicting the splitting for the other trans type complexes. We have empirically found that the transition energy of $^1E_g\leftarrow{}^1A_{1g}$ (D_{4h} approximation) for $[Pd(Cl)_n(N)_{4-n}]$- and $[Pd(N)_n(O)_{4-n}]$-type complexes is approximately given by $\sum_{i=1}^{4} e_i$, where e_i is an energy fraction assigned to each ligand. Because the average energy of $d_{x^2-y^2}\leftarrow d_{xz}$ and d_{yz} transitions for *trans*-$[Pd(Cl)_2(N)_2]$-type complexes is approximately equal to the transition energy of $d_{x^2-y^2}\leftarrow d_{xz,\,yz}$ for the cis analogs as described above, the empirical rule may be extended as follows: the average energy of $d_{x^2-y^2}\leftarrow d_{xz}$ and d_{yz} transitions for $[Pd(L_1)(L_2)(L_3)(L_4)]$ is approximately given by $\sum_{i=1}^{4} e_i$ ($\equiv E_{av}$). The typical values of e_i for chloro and amine ligands are 5.5 and 8.6×10^3 cm^{-1}, respectively. The former value was obtained from the transition energy of $^1E_g\leftarrow{}^1A_{1g}$ for $[PdCl_4]^{2-}$,[1] and the latter by averaging those for $[Pd(NH_3)_4]^{2+}$, $[Pd(en)_2]^{2+}$, and $[Pd(tn)_2]^{2+}$.[16] Using these values, E_{av} for $[Pd(Cl)_2(N)_2]$ can be calculated to be 28.2×10^3 cm^{-1}. The values obtained by Gaussian analyses are 28.07 and 28.32×10^3 cm^{-1} for band II's of $[PdCl_2(en)]$ and $[PdCl_2(tn)]$, respectively, and 28.10×10^3 cm^{-1} for the average energy of bands 1 and 4 of *trans*-$[PdCl_2(EtNH_2)_2]$. Thus, the empirical rule holds well for the complexes. The separation between bands 1 and 4 is about 6.2×10^3 cm^{-1} for all the *trans*-$[Pd(Cl)_2(N)_2]$-type complexes (Table 13). This value amounts to just twice as large as the difference between e_i's of chloro and amine ligands. Consequently, bands 1 and 4 possess the transition energies equal to E_{av}'s of $[Pd(Cl)_3(N)]$ and $[Pd(Cl)(N)_3]$ chromophores, respectively. The calculated values of E_{av} for the former and the latter type complexes are 25.1 and 31.3×10^3 cm^{-1}, which satisfactorily agree with the positions of the Gaussian components of the *trans*-$[Pd(Cl)_2(N)_2]$-type complexes except the Me_3N and *t*-$BuNH_2$ complexes (Table 13). The exceptions cannot be ascribed to the lowered ligand-field strength of only the amine ligands; because, if so, the splitting between bands 1 and 4 would be smaller. It must be considered that the ligand-field strength of the chloro ligand is simultaneously lowered in the two complexes.

MCD spectra in the d-d transition region are more intense in methanol than in DCE for all the trans complexes studied here (Figs. 4—6; Tables 9 and

a—d) As in Table 6. e) In methanol.

11). On the contrary, the CD spectrum of the *S*-pea complex is less intense in methanol. The Gaussian-analysis result of absorption spectra for the *n*-$BuNH_2$ complex indicates that the energy separations between four d-d components are reduced in methanol in comparison with those in DCE (Table 13). Therefore, the CD spectrum in methanol is partly explained by a cancellation between the positive and the negative band; whereas the MCD spectrum by a larger mixing between the d-d vibronic excited states in which $^1B_{3g}$ and ^1A_g are involved, because the magnitude of a contribution to a B term is inversely proportional to the energy difference between the states which are mixed. The overlapping B terms may be considered to form a pseudo A term.[18] The separation of bands 1 and 4 for the *n*-$BuNH_2$ complex is smaller by 0.5×10^3 cm^{-1} in methanol than in DCE, indicating that the difference between the ligand-field strengths of chloro and amine ligands decreases in methanol. This is conceivably ascribed to the relative weakening of the ligand-field strength of the amine ligand by hydrogen bondings with methanol, which is more polar than DCE.

High-intensity Bands. The high-intensity bands observed above 35×10^3 cm^{-1} of *cis*- and *trans*-$[Pd(Cl)_2(N)_2]$-type complexes are attributable to dipole allowed charge transfer transitions from their intensities, and moreover to ones with ligand-to-metal nature (LMCT) because the bands of the trans complexes are blue-shifted with replacing DCE solvent by methanol. There are three kinds of LMCT to be considered here: Pd(σ^*)←Cl(π), Cl(σ), and N(σ).

The shoulder located in $(35—40)\times10^3$ cm^{-1} for the cis complexes is assigned to Pd(σ^*)←Cl(π) transition, to which a negative B term corresponds. In $[PdCl_2(en)]$, another shoulder is observed at *ca.* 45.3×10^3 as well as the peak at 49.0×10^3 cm^{-1} (Fig. 3). The corresponding shoulder is barely appreciable in the *N,N*-Me$_2$en complex, but undetectable in the *N,N'*-Me$_2$en and *N,N*Et$_2$en complexes owing to the overlapping of the neighboring intense band. Their MCD spectra show a broad negative band above 40×10^3 cm^{-1}, supporting the presence of more than one component. Although the CD spectrum of the *S*-pn complex exhibits only a negative CD band corresponding to the absorption shoulder, that of the N^1,N^1-Et$_2$-(*S*)-pn complex shows an additional minor negative band in the higher energy side of the main band. Figure 9 shows the absorption spectra of $[PdCl_2(N,N'$-Me$_2$en$)]$ in 0.20 M KCl and in an aqueous solution. In the latter solution, the d-d absorption band is blue-shifted and the shoulder at *ca.* 38×10^3 cm^{-1} remarkably reduced. The observations are attributed to a significant degree of aquation of the complex, being consistent with the assignment of the shoulder to Pd(σ^*)←Cl(π). Since the band centered at 45.5×10^3 cm^{-1} still retains a considerable intensity (ε_{max}=15000), it seems to contain a Pd(σ^*)←N(σ) as well as a Pd(σ^*)←Cl(σ) transition. Then, the lower and the higher absorption (or CD) component in the en (or N^1,N^1-Et$_2$-(*S*)-pn) complex are assigned to Pd(σ^*)←N(σ) and Cl(σ) transitions, respectively. This assignment is based on the expectation that the CT transition from the nitrogen atoms will exhibit more intense vicinal CD than that from the chlorine atoms since the nitrogen atoms lie more close to the asymmetric carbon atom of an N^1,N^1-Et$_2$-(*S*)-pn or *S*-pn ligand than the chlorine atoms. The assignment then suggests that the molecular orbitals comprising mainly Cl(σ) orbitals lie below those comprising mainly N(σ) ones. The situation is the reverse of that having been accepted generally. In any case no definitive experimental evidence seems available for the point.

The spectra of the complexes with a six-membered chelate ring are likewise assigned. The MCD of the tn and the *N,N*-Me$_2$tn complex show a negative A-term pattern around the absorption bands occurring at 45.8 and 43.4×10^3 cm^{-1}, respectively. The sign of the "A" terms is the same as for a Pd(σ^*)←N(σ) transition in $[Pd(N)_4]$-type complexes with one or two tn ligands[16] but the reverse of the sign of the A term for a Pd(σ^*)←Cl(σ) transition in $[PdCl_4]^{2-}$.[1] Thus, it is likely that the MCD of the tn or *N,N*-Me$_2$tn complex is contributed mainly from the former kind of transition.

The absorption bands above 35×10^3 cm^{-1} of the trans type complexes are assigned in comparison with those of the cis type complexes discussed above. The shoulder around $(39—40)\times10^3$ cm^{-1}, which shows a negative B term, is assigned to a Pd(σ^*)←Cl(π) transition; and the band centered at *ca.* 45×10^3 cm^{-1}, which shows a positive and a negative B term in methanol, is to a composite of Pd(σ^*)←Cl(σ) and N(σ).

The absorption, MCD, and CD spectra above 40×10^3 cm^{-1} in $[PtCl_2$(en or *S*-pn)$]$ are quite different from those of $[PdCl_2$(en or *S*-pn)$]$ in the corresponding region (Figs. 2 and 3). Thus, it is irrational to assign the absorption band at *ca.* 48.8×10^3 cm^{-1} to the same set of transitions as in $[PdCl_2(en)]$. As the band exhibits a positive A-term pattern in the MCD spectrum it may be attributed to a d-p transition (p_z←$d_{xz,yz}$), because the corresponding transition in $[PtCl_4]^{2-}$ gives an A term with the same sign.[1] More data need to be accumulated on complexes with different chromophores containing nitrogen and/or chlorine for a more detailed assignment of all the above high-intensity bands.

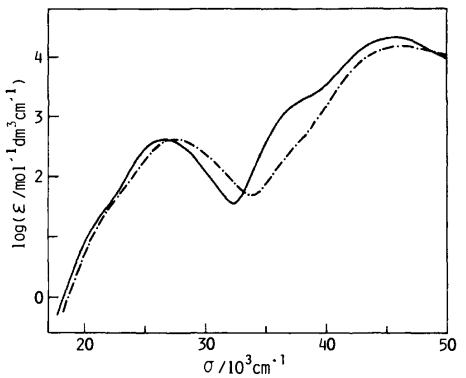

Fig. 9. Absorption spectra of $[PdCl_2(N,N'$-Me$_2$en$)]$ in 0.20 M KCl (——) and in H_2O (—·—).

Ion Exchange Studies of Zinc Chloride and/or Perchlorate in Ethylene Glycol

Tetsu KUMAGAI
Himeji Institute of Technology, Shosha, Himeji, Hyogo 671-22
(Received October 11, 1983)

The formation constants of zinc chloride and/or perchlorate in ethylene glycol were measured by a cation exchange method using the resin for forced-flow liquid chromatography in three systems: zinc chloride, zinc perchlorate, and zinc chloride and perchlorate together. The values obtained for the formation constants were: $\log \beta_1^{Cl}=3.03$, $\log \beta_2^{Cl}=4.80$, $\log \beta_1^{ClO_4}=2.34$, and $\log \beta_2^{ClO_4}=2.50$. The formation constant for the mixed complex of zinc, $\log k_m^{ClO_4}$, was 0.7 at the ionic strength of 0.1. The formation constants of zinc chloride in ethylene glycol containing 5 v/v% of water were 2.73 for $\log \beta_1^{Cl}$ and 4.18 for $\log \beta_2^{Cl}$, and those containing 10% of water were 2.32 for $\log \beta_1^{Cl}$ and 3.46 for $\log \beta_2^{Cl}$.

There are many methods to investigate the chemical equilibria of metal-ion complexes in aqueous solution, such as photometry, polarography, conductivity measurement, ion exchange method,[1-8] solvent extraction,[9-11] and potentiometric measurement.[12] However, the detailed studies in nonaqueous solution have been so far performed mainly by electrochemical methods. The cation exchange method using a radioactive tracer is expected to be available for studies of the chemical equilibria in nonaqueous systems. The method may be applicable to sparingly soluble compounds in nonaqueous solvents by the rise in specific activities of radio isotopes. The resins for the forced-flow liquid chromatography may withstand most of the organic solvents and attain equilibrium fairly rapidly with the ions in the solvents, compared with the ordinary ion exchangers. In the previous paper,[14] we investigated the distribution of zinc chloride and bromide complexes between the aqueous methanol solution and the cation exchange resin. The present work has extended the research to the distribution of zinc chloride and perchlorate between the cation exchange resin and ethylene glycol and has estimated the consecutive formation constants of zinc chloride and perchlorate by using a computer.

Data Treatment

The equilibria in the ethylene glycol solutions are expressed as follows:

$$Zn^{2+} + 2Cl^- = ZnCl_2 \qquad \beta_1^X,\ \beta_2^X, \qquad (1)$$

$$Zn^{2+} + 2ClO_4^- = Zn(ClO_4)_2 \qquad \beta_1^Y,\ \beta_2^Y, \qquad (2)$$

$$ZnCl^+ + ClO_4^- = ZnClClO_4 \qquad K_m^Y, \qquad (3)$$

$$ZnClO_4^+ + Cl^- = ZnClClO_4 \qquad K_m^X, \qquad (4)$$

$$Zn^{2+} + Na_2R = ZnR + 2Na^+ \qquad \beta_1^R,\ \beta_2^R, \qquad (5)$$

$$ZnCl^+ + Na_2R = ZnClNaR + Na^+ \qquad K_m^{RX}, \qquad (6)$$

$$ZnClO_4^+ + Na_2R = ZnClO_4NaR + Na^+ \qquad K_m^{RY}. \qquad (7)$$

Here the superscripts are X=Cl^- and Y=ClO_4^-. Concentrations of zinc in two phases are described as

$$\begin{aligned}(C_{Zn})_R &= C_{ZnR} + C_{ZnXNaR} + C_{ZnYNaR} \\ &= m_{ZnR} + m_{ZnXNaR} + m_{ZnYNaR}, \qquad (8)\\ (C_{Zn})_E &= C_{Zn} + C_{ZnX} + C_{ZnX_2} + C_{ZnY} \\ &\quad + C_{ZnY_2} + C_{ZnXY} \\ &= (m_{Zn} + m_{ZnX} + m_{ZnX_2} + m_{ZnY} + m_{ZnY_2} + m_{ZnXY})/\rho, \qquad (9)\end{aligned}$$

$$D = (C_{Zn})_R/(C_{Zn})_E. \qquad (10)$$

Here $(C_{Zn})_R$ is total zinc in the resin at equilibrium, $(C_{Zn})_E$ is total zinc in the solution at equilibrium, m_X is weight molarity and ρ is density. The distribution ratio, D, of zinc can be expressed as the ratio of $(C_{Zn})_R$ and $(C_{Zn})_E$. Equations 8—10 can be rewritten using equations 1—7 as follows:

$$\begin{aligned}(C_{Zn})_R = \Bigg(&\frac{\gamma_{Zn}m_{Zn}}{\gamma_{ZnR}\gamma_{Na}^2 m_{Na}^2}\cdot\beta_2^R + \frac{\gamma_{Zn}\gamma_X m_{Zn}m_X}{\gamma_{Na}\gamma_{ZnXNaR}m_{Na}}\cdot K_m^{RX}\beta_1^X \\ &+ \frac{\gamma_{Zn}\gamma_Y m_{Zn}m_Y}{\gamma_{Na}\gamma_{ZnYNaR}m_{Na}}\cdot K_m^{RY}\beta_1^Y\Bigg)\cdot\gamma_{Na_2R}m_{Na_2R}, \qquad (8')\end{aligned}$$

$$\begin{aligned}(C_{Zn})_E = \Bigg(&m_{Zn} + \frac{\gamma_{Zn}\gamma_X m_{Zn}m_X}{\gamma_{ZnX}}\cdot\beta_1^X + \frac{\gamma_{Zn}\gamma_X^2 m_{Zn}m_X^2}{\gamma_{ZnX_2}}\cdot\beta_2^X \\ &+ \frac{\gamma_{Zn}\gamma_Y m_{Zn}m_Y}{\gamma_{ZnY}}\cdot\beta_1^Y + \frac{\gamma_{Zn}\gamma_Y^2 m_{Zn}m_Y^2}{\gamma_{ZnY_2}}\cdot\beta_2^Y \\ &+ \frac{\gamma_{Zn}\gamma_X\gamma_Y m_{Zn}m_X m_Y}{\gamma_{ZnXY}}\cdot\beta_1^X K_m^Y\Bigg)\Big/\rho, \qquad (9')\end{aligned}$$

$$\begin{aligned}D = \gamma_{Zn}m_{Na_2R}\rho\cdot\Bigg\{&\frac{\beta_2^R}{\gamma_{Na}^2 m_{Na}^2} + \frac{\gamma_X m_X}{\gamma_{Na}m_{Na}}\cdot K_m^{RX}\beta_1^X \\ &+ \frac{\gamma_Y m_Y}{\gamma_{Na}m_{Na}}\cdot K_m^{RY}\beta_1^Y\Bigg\}\Bigg/ \\ &\{1 + \textstyle\sum\gamma_X^n m_X^n\beta_n^X + \sum\gamma_Y^n m_Y^n\beta_n^Y + \gamma_X\gamma_Y m_X m_Y\beta_1^X K_m^Y\}. \qquad (10')\end{aligned}$$

Here γ stands for the activity coefficient of each ion, γ_{Na_2R}, γ_{ZnR}, γ_{ZnXR}, and γ_{ZnYR} can be regarded as 1 and $\gamma_{ZnX}=\gamma_{ZnY}$, $\gamma_{ZnX_2}=\gamma_{ZnY_2}=\gamma_{ZnXY}\cdot\gamma_X$, γ_Y, γ_{Zn}, and γ_{Na} are calculated from Debye-Hückel's theory as

$$\gamma_X = \gamma_\pm^{1/2} = \left\{\frac{-A|Z^+Z^-|I^{1/2}}{1+BdI^{1/2}}\right\}^{1/2}, \qquad (11)$$

$$A = 8.1622\times\frac{\rho^{1/2}}{\varepsilon^{3/2}}\times 10^2 \quad B = 2.9127\times\left\{\frac{\rho}{\varepsilon}\right\}^{1/2}\times 10^8$$

at 25 °C. (12)

Here d denotes parameter of ionic radius, I represents ionic strength, m_{Na_2R} is expressed as g resin (Na-form)/dm^3 ethylene glycol, and ε is the dielectric constant of ethylene glycol. The constant of 5% aqueous ethylene glycol was obtained graphically by interpolation of the constants of 100, 90, and 80% ethylene glycol.[13]

In the Zn^{2+}-Cl^--ClO_4^- system, the distribution coefficient can be transformed as a function of chloride ion concentration, m_X, because m_X+m_Y=const. Sodium ions are originated from sodium chloride and sodium perchlorate, and these compounds are assumed to be completely dissociated in pure or aqueous ethylene glycol. Hence the relation that $m_{Na}=m_X+m_Y$ holds good. β_1^R is negligible, because it is expected that $\beta_2^R \gg \beta_1^R$. Equation 10 is arranged into fractional functions as follows:

1. (X=Cl or ClO_4)

$$D^* = \frac{P_{(1)}+P_{(2)}L^2}{1+P_{(3)}L+P_{(4)}L^2} \quad (13)$$

$L=\gamma_X m_X$, $D^*=D\gamma_{Na}^3 m_{Na}^3/\gamma_{Zn}$, $P_{(1)}=\beta_2^R m_{Na_2R}$,
$P_{(2)}=\beta_1^X K_m^{RX} m_{Na_2R}$, $P_{(3)}=\beta_1^Y$, and $P_{(4)}=\beta_2^R$.

2. (X=Cl and Y=ClO_4)

$$D^* = \frac{P_{(1)}+P_{(2)}m_X+P_{(3)}m_Y}{1+P_{(4)}m_X+P_{(5)}m_X^2+P_{(6)}m_Y+P_{(7)}m_Y^2+P_{(8)}m_Xm_Y} \quad (14)$$

$D^*=D\gamma_{Na}^3 m_{Na}^3/\gamma_{Zn}$, $P_{(1)}=m_{Na_2R}\beta_2^R$,
$P_{(2)}=m_{Na_2R}\beta_1^X K_m^{RX}\gamma_X\gamma_{Na}m_{Na}m_X$,
$P_{(3)}=m_{Na_2R}\beta_1^Y K_m^{RY}\gamma_{Na}\gamma_Y m_{Na}m_Y$, $P_{(4)}=\gamma_X\beta_1^X$,
$P_{(5)}=\gamma_X^2\beta_2^X$, $P_{(6)}=\gamma_Y\beta_1^Y$, $P_{(7)}=\gamma_Y^2\beta_2^Y$,
$P_{(8)}=\gamma_X\gamma_Y m_X m_Y \beta_1^X K_m^Y$.

γ_X, γ_Y, γ_{Na}, and γ_{Zn} were calculated from Eqs. 11 and 12 as a function of the ionic strength. These coefficients have constant values at constant ionic strenth. Parameters P_i were calculated by the nonliner least-squares method, a modified Gauss-Newton method, using a computer and were determined by enlisting the aid of a curve fitting method using computer graphics.

Experimental

Ethylene glycol was purified by distilling it under reduced pressure after drying over zeolite and was stored in closed bottles. Zinc-65 tracer was supplied as chloride by New England Nuclear, Boston, Mass., U.S.A. It was heated on a hot plate, adding perchloric acid to convert it into a zinc perchlorate form, and was dissolved in ethylene glycol. Sodium chloride and sodium perchlorate were dried at 110 °C and stored over phosphrous pentaoxide in a desiccator. Perchloric acid, sodium chloride, sodium perchlorate, and zinc perchlorate were guaranteed reagent grade. The cation exchange resin (mean radius, 15.5 μm), Hitachi custom ion exchange resin 2611 for the liquid chromatograph, was washed with hydrochloric acid and was transformed into the Na-form by sodium chloride solution. After washed with water to remove chloride ion, the resin was dried in vacuum and stored in a desiccator.

From 25 to 100 mg of the resin was taken in an Erlenmyer flask with a glass-stopper, and 20 ml of ethylene glycol solution containing sodium chloride and/or sodium perchlorate, zinc perchlorate, perchloric acid, and a radio-zinc tracer was added. Perchloric acid was added to minimize the loss of zinc that was caused by the adsorption on the vessel wall. The flask was set in the water bath with a thermostat at 25 °C and stirred by a teflon-coated bar. After the equilibrium was attained, both the solution and the resin were transferred to a centrifugal tube, and the two phases were separated centrifugally. Distribution coefficients were calculated from the ratio of radioactivity between the two phases. Two milliliters of solution phase were pipetted into a test tube and radioactivities were counted by a well-type scintillation counter (Metro Electronics Model PbW-6).

Results and Discussion

The attainment of the distribution equilibrium was checked by measuring the variation of the distribution coefficient of zinc *vs.* the stirring time. As shown in Fig. 1, little influence of the stirring time was observed upon the distribution of zinc between the glycol phase and the resin; the distribution attained equilibrium within 1 h at the latest and varied little within at least 48 h.

Stirring for 24 h was adopted in the experiment, because ethylene glycol has a somewhat higher viscosity than water, and then the resin was more difficult to disperse in the glycolic solution than in the aqueous one. The correct distribution coefficients can not be observed in high concentration range of zinc because of the comparatively low exchange capacity of the resin and in very low zinc concentration because of the adsorption on the resin. Figure 2 shows the influence of zinc perchlorate concentration on the distribution coefficients. The coefficients have a constant value for solutions ranging in concentration from 5×10^{-7} to 10^{-4} mol dm^{-3}. Therefore the initial zinc concentration was kept at 1×10^{-6} mol dm^{-3} throughout the experiment. It is expected from Eq. 10 that there exist a proportional relation between the distribution coeffi-

cient and the resin amount. The relation is shown in Fig. 3; plots of log D^* *vs.* the resin amount give straigth lines with the slope of about 1 in the various concentrations of sodium perchlorate and chloride.

Figures 4—7 show the plot of log D^* *vs.* a_{Cl} or a_{ClO_4} on the distribution of zinc chloride and perchlorate between the glycol phase and the ion exchanger; the concentrations of chloride and perchlorate ions in the figures are converted into the activities by using Debye-Hückel's theory. The curves in these figures are depicted by means of regression analysis on Eqs. 13—

14, and these show good accordance with the experimental data. The formation constants of zinc chloride and perchlorate are listed in Table 1.

In the zinc chloride and perchlorate system, the number of parameters in Eq. 14 are too many to get exact values. Consequently, the values of β_n^X and β_n^Y in Eq. 14 were calculated by substituting β_n^X and β_n^Y obtained in the zinc chloride and zinc perchlorate system in Eq. 13. The values of the formation constant obtained by the present ion exchange method are close to those determined by the nonaqueous liquid-liquid extraction method.[10]

The ion exchange method has a bright prospect for developing research on the chemical equilibria of metals in the nonaqueous system, especially in terms of the application to the sparing by soluble salts in nonaqueous solvent.

Equilibrium Solubilities of Iodine Vapor in Water

Isao SANEMASA,* Toyohisa KOBAYASHI, Cheng Yun PIAO, and Toshio DEGUCHI
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
(Received October 5, 1983)

Equilibrium solubilities of iodine vapor in water were measured by introducing iodine vapor, in equilibrium with solid iodine, into water and by circulating it in a closed system, and Henry's law constants were determined. Equilibrium distributions of iodine vapor between a gas phase and an aqueous phase were also measured by another method, and partition coefficients were determined. The solubilities of iodine vapor in water estimated from both the Henry's law constants and the partition coefficients are compared with those of solid iodine reported in the literature. Thermodynamic parameters for the hydration of iodine vapor are evaluated experimentally.

A large number of papers have been published on solubilities of iodine in water.[1] All of them are concerned with saturated solutions prepared through direct contact of solid iodine with water. On the other hand, in the field of nuclear power plant, there are some publications on the partition study of iodine vapor between air and water.[2,3,4] The experimentally determined partition coefficients, however, differ from literature to literature. Both the solubility of solid iodine in water and the iodine vapor pressure are known at a given temperature, so the partition coefficient can be predicted provided the iodine vapor behaves ideally.[5] However, the partition coefficients reported in the literature are not consistent with the prediction.

In our previous paper we reported a method of preparing solutions saturated with solute by use of solute vapor. The method has successfully been applied to determining Henry's law constants of metallic mercury and some liquid aromatic hydrocarbons.[6,7] The present paper is concerned with an extension of the method to such solutes as iodine which exists in the solid state at ordinary temperatures. Another technique was also employed for estimation of partition coefficients of iodine vapor between the gas phase and the aqueous phase.

Experimental

Materials. The iodine used as solute was of analytical reagent grade and used without further purification. Deionized-redistilled water was used as solvent. Analytical reagent grade carbon tetrachloride was used for solvent extraction and for the preparation of iodine standard solutions.

Apparatus and Procedures. The apparatus, used to prepare aqueous solutions saturated with iodine vapor, is shown in Fig. 1. It is composed of a separatory funnel (100 cm^3), A, two condensers, B and C, a bottle (300 cm^3), D, and a Viton diaphragm pump (Iwaki Type AP-32 Z), P. Gas inlet-type adaptors are mounted in A and D. Teflon and glass pipes, both of ϕ=8 mm, are used for connection. Solid iodine is packed in the upper condenser B (ϕ 8 mm×200 mm), the top end of which is equipped with a coarse sintered glass disk and the bottom part is plugged with glass wool. We will hereinafter refer to condenser B packed with solid iodine and separatory funnel A containing *ca.* 50 cm^3 water as the "solute reservoir" and "solubility flask," respectively. Lower condenser C and bottle D serve to trap water droplets and to keep the air and the solute reservoir in thermal equilibrium. The temperature of the solubility flask is held constant by circulating water through a surrounding jacket from a thermostated bath. The temperature of the solute reservoir is also maintained constant in the same way by using another thermostated bath. These thermostats are controlled within ±0.02 °C. The assembled apparatus was placed in a chamber, the temperature of which was kept higher than that of the solute reservoir in order to prevent the iodine vapor from condensing inside the apparatus. Aqueous solutions saturated with iodine vapor were prepared as follows: after the desired temperatures for the solubility flask and solute reservoir were attained, the pump was started, and the iodine vapor, which had been generated by allowing air to flow through the solute reservoir, was introduced into the solubility flask *via* a sintered glass ball, and circulated as indicated in Fig. 1. The iodine vapor pressure inside the solubility flask can be fixed at any desired value by controlling the temperature of solute reservoir. At the beginning of this study, iodine crystals purified by sublimation were packed in the solute reservoir. However, the fine crystals tended to pack together inside the column so tightly during the course of continuous air-circulation as to make the further aeration through the column difficult. Then, we used coarse iodine crystals. The circulation rate, which could be changed by means of a Variac, was set at 0.8 $dm^3\ min^{-1}$ in most instances. After the

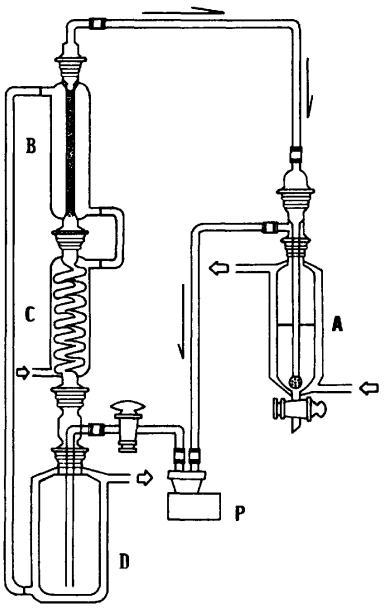

Fig. 1. Solubility apparatus.
The solid arrows indicate the direction of air-circulation.

solubility equilibrium was attained, a stopcock on the bottom of the solubility flask was opened. The first portion of *ca.* 10 cm^3 was discarded and the following 10 cm^3 portions were transferred successively into three cylindrical separatory funnels, in which 10 cm^3 CCl_4 had previously been placed. Each separatory funnel had been calibrated so that the volume of an aqueous solution poured into it might be read out. Mixtures in the separatory funnels were hand-shaken and allowed to stand for 30 min, and then, after dehydrating the CCl_4 phase with anhydrous sodium sulfate, absorbances were measured at 514 nm using a Hitachi Model 100-50 spectrophotometer against a blank extract as the reference. Standard solutions were prepared by weighing out of suitable quantities of solid iodine, followed by dilution with CCl_4 in volumetric flasks. Calibration curves were constructed by using iodine standard solutions of the order of 10^{-3} mol dm^{-3} in the same way as described in our previous paper.[7]

The apparatus, used to determine partition coefficients of iodine vapor between air and water, is shown in Fig. 2. A large separatory funnel of *ca.* 5 dm^3 capacity, to be called the "partition flask," was connected to a Viton diaphragm pump of the same type as pump P shown in Fig. 1 through Teflon tubes (ϕ=8 mm) and two glass adaptors, one of which was attached to a sintered glass ball and was long enough to reach nearly the bottom of the partition flask. The temperature inside the partition flask was kept constant by circulating water through a surrounding jacket from a thermostated bath. A particular attention was paid in assembling the apparatus so as to minimize the section exposed out of the jacket, down to a volume as small as 42.5 cm^3. Aqueous iodine solutions were prepared by using the apparatus shown in Fig. 1 with the solubility flask replaced by one of 300 cm^3 capacity. An aliquot of the iodine solution thus prepared was poured into the partition flask and another aliquot was used to determine the iodine concentration. The pump was operated at a flow rate less than 0.1 dm^3 min^{-1} and the air was circulated at least 10 min. The iodine concentration in the aqueous phase after this air-circulation was measured. The time required to attain the equilibrium partition was preliminarily investigated with a result that 10 min-circulation is sufficient. The air-circulation, however, needed to be made intermittently, lest the temperature of the aqueous phase should decrease owing to the heat of evaporation of the solvent water. From preliminary experiments the best way of the air-circulation was found to be as follows: the air was circulated for 1 min, then the solution was allowed to stand for another 1 min, and finally the operation was repeated at least 10 times.

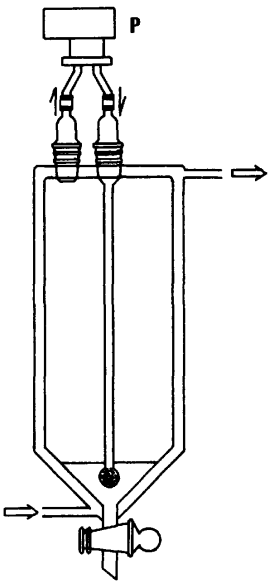

Fig. 2. Partition apparatus.
The solid arrows indicate the direction of air-circulation.

Results

The Time Required for Attaining the Solubility Equilibrium. The time required to attain the equilibrium solubility was checked by taking a small amount of aqueous solution from the bottom of the solubility flask directly into a cuvette and by measuring the absorbance at 460 nm without solvent extraction. The results are shown in Fig. 3. The absorbance readings begin to rise, reach a maximum after 30—90 min according to the rate of air-circulation, and thereafter remain constant. On the basis of this observation, subsequent experiments were carried out at a constant circulation rate of 0.8 dm^3 min^{-1} and iodine concentrations in sample solutions withdrawn after 60 min-circulation were measured.

Solubility as a Function of Iodine Vapor Pressure. It is an essential requirement, as we have emphasized in our previous paper,[7] to keep the temperature of solubility flask $\geqq$ the temperature of solute reservoir $<$ the room temperature. For this reason, the solubility runs were made by raising the temperature of solute reservoir up to that of solubility flask while the latter was maintained constant. The results are given in Table 1. The vapor pressure of iodine at a given temperature of solute reservoir was estimated from the equation $\log PT^{3/2}=16.945-3464/T$, where P is vapor pressure in Pa and T is absolute temperature. This equation was derived by reference to literature.[8,9] The equilibrium solubilities are plotted against iodine vapor pressure in Fig. 4, from which we can see that the solubility obeys Henry's law at respective temperatures of water. In Fig. 4 are also shown the results obtained under conditions such that the temperature of solute reservoir was set higher than that of solubility flask. Under such circum-

a) The vapor pressure of iodine, P (in Pa), was estimated by $\log PT^{3/2} = 16.945 - 3464/T$, where T is absolute temperature. b) A set of two or more solubility values indicates that experiments were carried out under the same conditions on different days.

stances, iodine vapor condenses inside the solubility flask, and the solid appears in the aqueous phase mostly in the bottom and a little on the surface. Solutions thus prepared were allowed to stand for at least 3 h without air-circulation, and aliquots were pipetted off from the middle part of the aqueous phase to measure iodine concentrations. The results varied widely and the reproducibility was poor as can be seen in Fig. 4.

Gas-Water Partition Coefficients of Iodine. The partition coefficient, K_P, is defined according to literature as follow:[3,4] K_P=(concentration of I_2 in aqueous phase in mol dm^{-3})/(concentration of I_2 in gaseous phase in mol dm^{-3}). In the present study, the concentration of iodine in the gaseous phase was not measured but estimated from the iodine concentrations in the aqueous phase before and after equilibrium, C_B and C_A (in mol dm^{-3}), respectively, by $K_P = C_A(10^3 \times V - v)/v(C_B - C_A)$, where v is the volume of aqueous phase (cm^3) and V is the volume of partition flask (V=4.9165 dm^3). The results are given in Table 2.

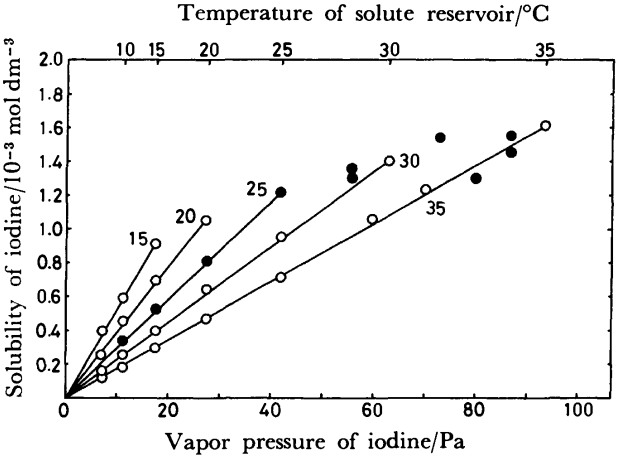

Fig. 4. Equilibrium solubility of iodine *vs.* iodine vapor pressure.
The figure near each solid line indicates the temperature of water. The solid circles are the results obtained under conditions such that the temperature of water was held constant at 25 °C while the temperature of solid iodine was raised beyond 25°C.

Discussion

Solubilities of Iodine in Aqueous Solutions. The primary purpose of the present study is to determine whether the method proposed here can be used for preparing aqueous solutions of desired iodine concentration. The most important problem is whether an aqueous solution is saturated with iodine vapor. It was experimentally confirmed that equilibrium solubilities obey Henry's law. However, this does not necessarily mean that solutions are saturated actually 100% with iodine vapor. Thus, solutions saturated, say, 90% can be expected to obey Henry's law in appearance provided the imperfect saturation is maintained constant throughout the range of iodine vapor pressure investigated. In this study, therefore, we employed the partition method, too, in which the problem of imperfect saturation need not be considered so long as the gas-water partition equiliblium is attained. The partition coefficients determined here are tabulated in Table 3, together with some available literature values. Though the data reported so far in the literature are scanty, our present results seem to be in reasonable agreement with those reported by Eguchi *et al.*[3]

The Henry's law constant, K_H, is expressed in the following well-known equation

$$K_H = P/X_2, \quad (1)$$

where P is the partial pressure of iodine vapor in Pa and X_2 is the mole fraction of dissolved iodine in water. Based on the definition of partition coefficient and on the assumption that the iodine vapor in the gaseous

phase is ideal, the partition coefficient can be written as

$$K_P = 55.51\, X_2/(PR^{-1}\, T^{-1}), \quad (2)$$

where the factor 55.51 is the mole number of 1 dm³ water and R and T have their usual significances, R being 8.3145×10^3 dm³ Pa K⁻¹ mol⁻¹. From Eqs. 1 and 2, we can derive the Henry's law constant from the partition coefficient as

$$K_H^* = 4.615 \times 10^5\, T/K_P. \quad (3)$$

We will specify as K_H^* the Henry's law constant as derived from the partition coefficient. In Table 4 are listed the values of K_H and K_H^*, the former being determined by applying the least-squares method to the data given in Table 1. The solubilities of iodine vapor in water were estimated from Eq. 1. Table 4 shows that the solubilities of iodine vapor are somewhat lower than those of solid iodine. Is there any essential difference between the solubilities of vapor and solid? They should both be equal to each other in principle if there is no possibility of any alteration, in physicochemical properties of the solid interface, to occur during the contact of the solid iodine with water, such as formation of hydrated iodine crystals (water molecule-included iodine crystals). It is supposed that an imperfect saturation with iodine vapor may give rise to the lower solubilities. However, this explanation seems to be unlikely since the values of K_H are lower than those of K_H^* over the temperature range studied. At present we cannot offer any satisfactory explanations for the difference observed between the solubilities of iodine vapor and solid iodine.

It should be mentioned that the present method for determining partition coefficients, though rapid and simple, suffers from three inherent disadvantages, and therefore the K_H^* values estimated seem to be less reliable than those of K_H. Firstly, iodine concentrations in the gaseous phase were estimated indirectly. Secondly, a part of the aqueous phase was caused to splash inside the partition flask during the course of air-bubbling. The partition equilibrium between the droplets and the gaseous phase might require much longer time, and therefore the volume of the aqueous phase initially taken, v, should be corrected for these droplets. Thirdly, in deriving Eq. 2, the iodine vapor in gase-

Table 5. Thermodynamic parameters of iodine corresponding to solution, vaporization, and hydration processes at 25 °C

	Solution process	Vaporization process	Hydration process		
			Calcd[a]	Exptl[b]	Lit[c]
ΔG / kJ mol^{-1}	26.40	19.360	7.040	7.20 (7.32)	6.987
ΔH / kJ mol^{-1}	22.70	62.421	−39.72	−41.7 (−38.3)	−39.52
ΔS / J K^{-1} mol^{-1}	−12.41	144.428	−156.8	−164 (−153)	−156.0

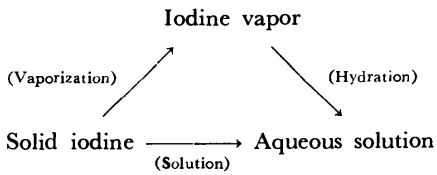
a) Calculated by subtracting the value for vaporization from that for solution process. b) Estimated from the temperature dependence of Henry's law constant. The values designated in parentheses were estimated from partition coefficients. In both cases the temperature dependence of ΔH was neglected. c) Taken from Ref. 12.

ous phase was postulated to be ideal. This assumption, however, may be permissible because of its low pressure. These disadvantages might lead to relatively large deviations for the measured K_P values and, therefore, for the estimated K_H* values, as compared with the K_H values. However, it is difficult to explain why, at respective temperatures of water, the value of K_H* is lower than that of K_H, the difference amounting to as much as *ca.* 10% in the extreme case.

In the beginning of this work, we used aqueous solutions acidified with perchloric acid, 10^{-4} mol dm^{-3}, as well as pure water. However, the difference in the two results could not be regarded as significant, and according to the literature,[10] the hydrolysis constant of the reaction $I_2+H_2O \rightarrow HIO+H^+ + I^-$ has been reported to be in the order of 10^{-13} at 25 °C. These facts, therefore, suggest that the hydrolysis may be neglected over the iodine concentration range concerned in the present study. Indeed, it has been pointed out from partition experiments that the hydrolysis of iodine does occur at very low iodine concentrations less than *ca.* 4×10^{-5} mol dm^{-3}.[11] This concentration range is much lower than those of solutions saturated with iodine.

The method described in this paper is considered to be useful to prepare aqueous solutions of desired iodine concentrations below saturation. The method is suitable for studying possible interactions between iodine and hydrophobic substances in aqueous environment by measuring solubility increments.

Thermodynamic Parameters of Hydration of Iodine Vapor. While it has previously been shown that thermodynamic parameters of hydration of iodine vapor can be evaluated from solubility data of solid iodine,[12] it is considered desirable to confirm them experimentally. The temperature dependence of Henry's law constants has led to an estimation of thermodynamic parameters which correspond to the hydration of iodine vapor. The results are given in Table 5, together with literature values. The solution of solid iodine in water can be divided into two processes: vaporization and hydration. This is shown in Scheme 1.



Scheme 1.

Thermodynamic parameters for each process are related to one another as follows:

$$\Delta G\,(\text{solution}) = \Delta G\,(\text{vaporization}) + \Delta G\,(\text{hydration}),$$
$$\Delta H\,(\text{solution}) = \Delta H\,(\text{vaporization}) + \Delta H\,(\text{hydration}),$$
$$\Delta S\,(\text{solution}) = \Delta S\,(\text{vaporization}) + \Delta S\,(\text{hydration}).$$

Values of ΔG, ΔH, and ΔS for the vaporization process are available from literature,[13] and those for the solution process are reported in literature.[14] Using these literature values, we have calculated the values of ΔG, ΔH, and ΔS for the hydration process. The results are given in Table 5. The agreement between the experimental and the calculated values is fairly good.

We wish to thank the Ministry of Education of people's Republic of China for the support offered to C. Y. Piao who was on leave from Yan Bian University.

Application of Gel Chromatography to Determining Formation Constants of Inclusion Compounds of Cyclodextrins

Isao SANEMASA,* Takemi MIZOGUCHI, and Toshio DEGUCHI
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
(Received October 27, 1983)

The gel filtration technique (Hummel and Dreyer method) was applied to determining formation constants of inclusion complexes of α- and β-cyclodextrins. As guest substances, *p*-nitrophenolate, *p*-nitrophenol, benzoate, and benzoic acid were used. Formation constants were determined at room temperature (25—30 °C) using Sephadex G-10 gel in aqueous buffered solutions of a constant ionic strength of 0.5 with NaCl or with phosphate buffer, and the results were compared with literature values. The method is applicable to such guest substances as exhibit strong adsorption onto the gel matrix.

It is generally accepted that cyclodextrins (CyDs) form inclusion complexes with a wide variety of inorganic and organic compounds in aqueous solutions. The CyD has a cavity, the interior side of which is considered to be hydrophobic, and some hydrophobic molecules can be accommodated in the cavity as guests. Thus, the CyD itself acts as a host. Several methods to determine formation constants of CyD inclusion complexes have been reported which utilize solubility,[1] kinetics,[2] pH potentiometry,[3] polarography,[4] calorimetry,[5,6] optical rotation,[7] NMR,[7,8] CD spectrum,[9,10] UV-visible spectrum,[2,4,5,7,11,12] positron annihilation,[13] and anion-exchange HPLC.[14]

A simple method of gel filtration chromatography has been successfully applied to studies on the association of macromolecules with low-molecular-weight ligands since it was first proposed by Hummel and Dreyer.[15] The method is based on the fact that associated complexes as well as free macromolecules are excluded from the gel phase, whereas small ligands are permeable into the gel, thus permitting the separation of the two. The method therefore makes use of a sieving effect of gel. In the gel chromatographic behavior, however, there have been observed some side-effects other than the sieving effect. Among them, adsorption of solute onto gel matrix is important, especially in such a case that the solute is a hydrophobic substance such as aromatic hydrocarbons.[16] The adsorption effect will be much more pronounced with the most tightly cross-linked Sephadex G-10. It was suggested, though not proved experimentally, that the interaction of ligands with gel matrix does not interfere with the determination of macromolecule-ligand association constants by the Hummel and Dreyer method.[17]

This paper is concerned with the application of gel chromatography to such a system that the ligand (guest) exhibits affinity to the gel matrix as well as to the macromolecule (host). We have chosen *p*-nitrophenolate, *p*-nitrophenol, benzoate, and benzoic acid as guests, because their formation constants with CyDs have abundantly been reported.

Experimental

Materials and Sample Preparations. Cyclodextrins (α- and β-CyDs from Wako) of reagent grade were recrystallized from water and dried over phosphorus pentaoxide. Benzoic acid and *p*-nitrophenol were of analytical reagent grade and used without further purification. Sephadex G-10 and Blue Dextran 2000 were obtained from Parmacia (Uppsala, Sweden). Phosphate buffer (Na_2HPO_4–NaOH for pH=11; NaH_2PO_4–H_3PO_4 for pH=3.5) and hydrochloric acid were used to adjust pH of eluents. Eluents, which contain guest molecules at various concentrations, $[guest]_0$, were prepared by dissolving *p*-nitrophenol or benzoic acid in buffered solutions and by applying a dilution with the same solutions. Ionic strength was adjusted to 0.5 with the buffer itself in the case of benzoate or with sodium chloride in the other cases. A suitable amount of the dried CyD was weighed out and dissolved in the eluent to prepare a CyD sample solution of known concentration.

Apparatus and Procedures. A 7.8 mm×19.5 cm glass-column packed with Sephadex G-10 gel was pre-equilibrated with the eluent. A 0.550 cm^3 aliquot of the CyD sample solution was applied to the pre-equilibrated column by using a sample injector (Kyowa Seimitsu Type KWM-4V-2) and then eluted with the eluent at a constant flow rate by means of a peristaltic pump (Atto Type SJ-1211). The absorbance of the eluant was monitored at the outlet of the column by a JASCO Type UVIDEC-100-III equipped with a flow-cell of 10 mm optical path length and recorded on a chart by a Hitachi Model 056. Both positive and negative peak areas were measured by cutting the chart and weighing the pieces.

Results

Experiments were carried out at room temperature (25—30 °C) under the conditions shown in Table 1. The formation constants of α- and β-CyDs inclusion complexes with *p*-nitrophenolate, *p*-nitrophenol, benzoate, or benzoic acid determined in this work are given in Table 2, together with literature values available. The data in Table 2 indicate that the present results are in reasonable agreement with the literature.

Discussion

Chromatograms were obtained by monitoring UV-visible absorbance of the guest in eluant, whose concentration, $[guest]_0$, is known. A typical chromatogram is shown in Fig. 1, which consists of a pair of positive and negative peaks. The negative peak reflects the guest lost by being incorporated into the CyD. It is desirable to assign the positive peak to a elution band of CyD, however this was not demonstrated in the present work because of the difficulty of detecting the eluted CyD.

a) The temperatures at which formation constants have been determined are indicated in parentheses when specified in the literature. b) Ref. 5. c) Ref. 11. d) Ref. 7. e) Ref. 4. f) Ref. 12. g) Ref. 13. h) Ref. 9. i) Ref. 6. j) Ref. 10. k) Ref. 3. l) Ref. 2. m) Ref. 8.

For all the CyD-guest combinations studied here, the elution volume of the positive peak was found to be nearly equal to the void volume. Based on this observation, α- and β-CyDs, with molecular weights 973 and 1135, respectively, are supposed to be completely excluded from the gel phase. Incidentally, the approximate exclusion limit of molecular weight is said to be 700, in general, for Sephadex G-10.

The formation constant, K, was determined for the reaction

$$\text{CyD} + \text{guest} \rightleftharpoons \text{CyD}\cdot\text{guest}. \quad (1)$$

In the calculation we assumed a stoichiometry of 1 : 1 for the CyD·guest based on the following two pieces of experimental evidence. Firstly, the UV-visible spectra

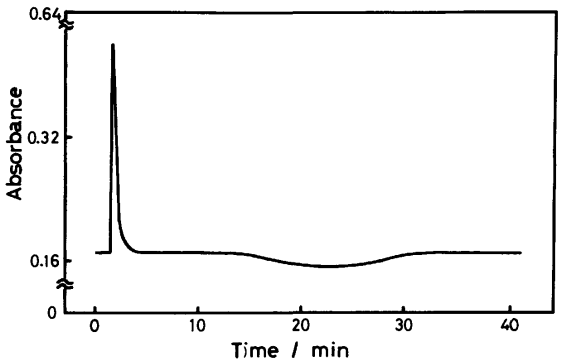

Fig. 1. Elution profile of β-cyclodextrin-*p*-nitrophenolate system.
Concentration of *p*-nitrophenolate anion in eluent: 1.03×10^{-5} mol dm^{-3}, concentration of β-CyD dissolved in eluent: 5.23×10^{-3} mol dm^{-3}, chart speed: 5 mm min^{-1}, AUFS: 0.64.

of all the CyD-guest combinations studied here were demonstrated to have isosbestic points. Secondly, ^{13}C NMR studies have revealed that benzoate anion form a 1:1 complex with α-CyD.[3] The formation constant can be expressed by using the amount of the CyD complex formed, $Q_{\text{CyD·guest}}$, the initial amount of CyD introduced to the column, $Q_{\text{CyD,o}}$, and the concentration of guest in the eluent, $[\text{guest}]_0$, as follows:[18]

$$K = Q_{\text{CyD·guest}}/[\text{guest}]_0(Q_{\text{CyD,o}} - Q_{\text{CyD·guest}}). \quad (2)$$

From the positive or negative peak area we can estimate the value of $Q_{\text{CyD·guest}}$. The negative peak area always leads to $Q_{\text{CyD·guest}}$, while this is not necessarily the case for the positive peak by the spectrophotometric measurement. Although CyDs have no absorbances in the UV-visible range investigated, the absorbance due to the guest changes with the concentration of the coexisting CyD. However, when the absorbance of the guest in the eluant is monitored at an isosbestic point, the positive and negative peak areas should be equal to each other. In Table 3 is shown such an example for *p*-nitrophenolate, from which formation constants have been determined.

The accuracy of the formation constant determined by the present method depends primarily on the con-

centration of the guest present in the eluent. That is, if $[\text{guest}]_0=K^{-1}$, a 50% of the total CyD molecules exists in the complexed form, and the most precise results are to be expected. The concentrations of CyD and guest have been fixed in this work so that the negative peak appearing on the chromatogram can be clearly recognized. The limit of Beer's law restricts the concentration of CyD as well as that of guest in the eluent. The positive peak is generally sharp, and the absorbance is apt to exceed the limit of Beer's law. The absorbance vs. concentration of guest was checked preliminarily by using the flow-cell. In the present work the product, $[\text{guest}]_0\cdot K$, falls in the order of 10^{-4} when the value of K is of the order of 10, for example, as with α-CyD-benzoate complex. This means that only 0.01% of the total CyD molecules is involved in association with the guest. Nevertheless, it is noticeable that the present results are in reasonable agreement with the literature.

Some of previous studies have suggested that several inorganic anions can form an adduct with CyDs, thereby affecting the formation of CyD inclusion complexes. In this work, we have studied effects of some electrolytes and their ionic strength on the formation of α-CyD complex with *p*-nitrophenolate. The results are shown in Table 4. As will be seen from Table 4, the formation constants measured decrease with increasing ionic strength and the effect is pronounced for NO_3^-. This is in accord with the literature.[6,11] The data of formation constants presented in this paper were obtained under the condition of ionic strength 0.5 adjusted with NaCl except for benzoate, in contrast to phosphate buffer in this case.

Table 4. Effects of electrolyte and ionic strength on the formation constant of α-cyclodextrin-*p*-nitrophenolate[a]

Electrolyte	Ionic strength	Formation constant / 10 mol^{-1} dm^3
KNO_3	0.5	119
	0.3	160
	0.1	195
$NaNO_3$	0.5	122
	0.1	176

	0.1	222
NaCl	0.5	227
	0.1	233
Na_2HPO_4	0.5	204
	0.3	189
	0.1	212
Phosphate buffer[b]		241

a) Concentration of *p*-nitrophenolate: 5.16×10^{-6} mol dm^{-3}; concentration of α-CyD: of the order of 5×10^{-3} mol dm^{-3}. b) Ionic strength was not adjusted. The ionic strength of buffer (Na_2HPO_4-NaOH) itself was less than 0.05.

Table 5. K_{av} values of guest substances in Sephadex G-10 gel column

Guest substance	Electrolyte used to adjust ionic strength[a]	K_{av}[b]
p-Nitrophenolate	$NaNO_3$	5.9
	NaCl	10.0
	Na_2HPO_4	20.3
p-Nitrophenol	NaCl	21.4
Benzoate	NaCl	1.2
	Na_2HPO_4	2.2
Benzoic acid	NaCl	11.7

a) The ionic strength was adjusted to 0.5. b) The K_{av} value is defined as $(V_e-V_o)/(V_t-V_o)$, where V_e, V_o, and V_t are the elution volume, the void volume, and the total bed volume, respectively.

Cyclodextrins are cyclic oligosaccharides made up of α-1,4-linked D-glucopyranose units. On the other hand, Sephadex G-type gel is prepared by closs-linking polysaccharide dextran with epichlorohydrin. In view of the chemical similarity between these two, similar associations with hydrophobic solutes are probable. Indeed, the affinity of the dextran gel matrix for aromatic and pseudoaromatic substances is particularly striking.[16] In Table 5 are given K_{av} values measured under the same experimental conditions that have been used for formation constants. Table 5 clearly indicates that the guest substances are strongly adsorbed on Sephadex G-10 gel. The order of K_{av} for a given guest may be explained in terms of hydration of the electrolyte, that is, the larger the hydration of electrolyte, the more pronounced the adsorption of the guest onto the gel. In the case of benzoate with the smallest K_{av} value, the ionic strength was adjusted with phosphate buffer,

and thereby the negative peak was made to be retarded. In this case, the ionic strength being adjusted with NaCl, the negative peak appeared so closely to the positive one that no plateau between the two peaks was observed.

The Hummel and Dreyer method is principally based on the sieving function of the gel column, that is, small ligands can be separated from both macromolecules and their associated complexes. In the present chromatography, the separation is due to the adsorption onto the gel phase rather than the sieving. The interaction of small ligands with the gel matrix does not interfere at all with the evaluation of their association with macromolecules so long as the adsorption equilibrium of ligands between the gel phase and the eluent is maintained during the course of chromatography, or it is established rapidly compared with the flow rate of the eluent.

The gel filtration method will serve as a useful technique to determine the formation constant of inclusion compounds of CyDs with various hydrophobic guest substances. However, it should be mentioned that the hydrophobic guests give rise to very broad negative peaks and often make it difficult to measure the peak area. The positive peak is preferable to the negative one if CyDs are pure enough to exhibit no absorbance at the monitoring wavelength.

We wish to thank Mr. Yoshiyuki Nagai for his assistance to the present experiments.

(Received November 24, 1983)

New sydnone derivatives having heterocyclic substituents such as 4-thiazolyl, 3-thienyl, 2H-1,4-benzothiazin-3-yl, 2H-1,4-benzoxazin-3-yl, and 1,2-dihydro-3-quinoxalinyl groups at the 4-positions were prepared from 4-bromoacetyl-3-arylsydnones (**1**). Sydnone compounds substituted by a 1,2,3-triazol-4-yl group were prepared *via* new type phosphonium ylids derived from **1**. Electroreduction of **1** was also attempted in order to prepare a syndnone derivatives having a furyl group.

Although sydnone compounds are interesting in their chemical, physical, and biological properties,[1] their syntheses are limited[2] because a sydnone ring is unstable to acid, alkali, and heat.

As a part of a broad program to study on the synthesis of sydnone compounds and their properties,[3] we have investigated possible synthetic methods for sydnones having heterocyclic groups at their 4-positions: In earlier works, sydnone derivatives substituted directly by 4-thiazolyl,[4,5] 4-sydnonyl,[6,7] 1,2,4-thiadiazol-5-yl,[8] 1,2,4-oxadiazol-5-yl,[9] 3,4-dihydro-1,2,4-oxadiazol-3-yl,[9] 1,2,4-oxadiazol-5-yl,[8] and 1,2,4-triazol-3-yl[8] groups were successfully synthesized. In most of the above synthesis,[8,9] derivatives of sydnone-4-carboxylic acids were used as the starting materials and they were converted into the desired sydnone compounds having heterocyclic groups *via* acyclic intermediates.

Haloacetyl groups are known as good precursors to heterocyclic groups.[10] We have found that 4-bromoacetyl-3-arylsydnones (**1**) could be easily prepared *via* 4-acetyl-3-arylsydnones from the corresponding 4-unsubstituted 3-arylsydnones.[4,11] In this paper, we wish to report the synthesis of new sydnone compounds substituted directly by heterocyclic groups at the 4-positions from **1**.

Results and Discussion

*Reaction of 4-Bromoacetyl-3-phenylsydnone (**1a**) with Thioamides (**2a,b**) and Amidine (**2c**).* Only one synthetic reaction using **1** has been reported by us: It was found that **1a** reacted with thiourea to give 4-(2-amino-4-thiazolyl)-3-phenylsydnone.[4,5] This is the first synthesis of a sydnone having a heterocyclic group at the 4-position, except for 4,4′-bisydnone.[7]

At the first stage of investigation, an analogous reaction (Scheme 1) to the above was examined by using thioamides (**2a,b**) and benzamidine (**2c**) instead of thiourea.

Thiobenzamide (**2a**) reacted readily with **1a** suspended in ethanol at room temperature to form 3-phenyl-4-(2-phenyl-4-thiazolyl)sydnone (**3a**) in a good yield. 3-Phenyl-4-thiocarbamoylsydnone (**2b**) did not react with **1a** under the same conditions. When the reaction was carried out under reflux for a short time, 2,4-bis(3-phenyl-4-sydnonyl)thiazole (**3b**) was obtained in a good yield.

4-(2-Phenyl-4-imidazolyl)-3-phenylsydnone (**3c**) was expected to be formed from **1a** and benzamidine (**2c**), since it is known that α-bromoacetophenone reacts with **2c** to give the corresponding imidazole compound.[12] However, **3c** could not be obtained in ethanol at either room temperature or higher one and decomposition of **1a** and/or **3c** seemed to occur. The reaction in DMF instead of ethanol also gave a similar result. These unsuccessful results may be due to the decomposition of sydnone rings by a strong base of **2c**.

*Reaction of 4-Bromoacetyl-3-phenylsydnone (**1a**) with N,N-Disubstituted Thioamide (**4**).* It is known that the reaction of α-bromoacetophenone with *N,N*-disubstituted thioamides gives the corresponding thiophene

compounds.[13]

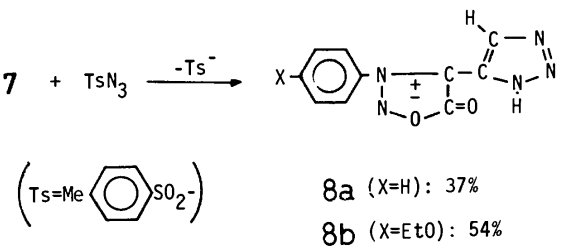
4-(Bromoacetyl)sydnone **1a** reacted with *N*-[benzyl-(thiocarbonyl)]piperidine (**4**) in dichloromethane at room temperature to form a salt (**5**) (Scheme 2). The structure of **5** was confirmed by IR and mass spectra and elemental analysis. A peak at *m/z* 403 (M^+—HBr—H_2O) was observed in the mass spectrum. The salt **5** decomposes gradually in the air.

The conversion of **5** into 3-phenyl-4-(4-phenyl-5-piperidino-3-thienyl)sydnone (**6**) was successfully carried out by heating **5** with triethylamine in ethanol. In the IR spectrum of **6**, absorption of the carbonyl group of the original **5** disappeared and the molecular ion peak at *m/z* 403 was observed in the mass spectrum.

Synthesis of Phosphonium Ylids (7) from 1 and Triphenylphosphine and their Conversion to 4-(1H-1,2,3-Triazol-4-yl)sydnones (8). It is known that phenacylidentriphenylphosphorane reacts with *p*-toluenesulfonyl azide to give 3-tosyl-4-phenyl-1,2,3-triazole.[14] Since the reaction proceeds under mild conditions, this method seems to be applicable to the synthesis of sydnone derivatives having a 1,2,3-triazol-4-yl group.

First, the synthesis of phosphonium ylid was attempted. Phosphonium bromide (**9**) was obtained by the reaction of **1** with triphenylphosphine in acetonitrile at room temperature. Treatment of **9** with aqueous sodium hydroxide provided phosphonium ylid **7** in a good yield. The structure of **7** was confirmed by comparison of IR spectra of **7** with those of **9**: The C=O stretching vibration band of **9** was at 1660—1670 cm^{-1}, while that of **7** was at 1530—1540 cm^{-1}. The shift was analogous to that of observed in the case of phenacylidenetriphenylphosphorane. The ylid **7** thus obtained melts around 200 °C and was found to be stable.

Next, the synthesis of 4-(1,2,3-triazol-4-yl)sydnone (**8**) from **7** was carried out. The reaction of **7** with



Scheme 4.

p-toluenesulfonyl azide took place in dichloromethane at room temperature, however **8** could not be obtained. The desired product **8** was obtained by the reaction in benzene under reflux for a long time. It is known that a tosyl group is easily eliminated from 4-aryl-3-tosyl-1,2,3-triazole under reflux in ethanol.[14] In a similar manner, **8** seems to be formed by hydrolysis of 3-aryl-4-[3-(*p*-tolylsulfonyl)-1*H*-1,2,3-triazol-4-yl]sydnone formed initially under the reaction conditions used.

Electroreduction of 4-Bromoacetyl-3-phenylsydnone (1a). Barba *et al.*[15] have recently reported an interesting electroreduction of α-bromoacetophenone to 2,4-diphenylfuran. Using the electrochemical method, the synthesis of a sydnone having a furyl group from 4-(bromoacetyl)sydnone (**1a**) was attempted.

The electroreduction of **1a** was carried out by means of controlled potential electrolysis at a mercury pool cathode in a DMF solution containing lithium perchlorate as a supporting electrolyte in a divided cell. One Faraday (96480 C)/mol of charge was coulometrically passed at −0.15 V *vs.* Ag/$AgNO_3$ (saturated in DMF). Products separated by a column chromatograph were not the expected furan compound but 4-acetyl-3-phenylsydnone (22% yield and 44% current efficiency) and the corresponding reduction dimer, 1,4-bis(3-phenyl-4-sydnonyl)-1,4-butanedi-

one (**10**) (7% yield and 7% current efficiency) whose structure was assigned from IR and mass spectra and analytical data.

Although a few papers deal with electrooxidation[16-18] and polarography[2b] of sydnones, no report of the electroreduction of sydnone compounds by means of preparative electrolysis has been published.[19] In this situation, it is interesting to note that the electroreduction of **1a** proceeded without any decomposition of the sydnone ring.

*Synthesis of Sydnone Compounds Having Six-membered Heterocyclic Groups (**11**, **12**, **13**).* The synthesis of sydnones substituted by six-membered heterocyclic groups at the 4-position has not been reported. In this work, the synthesis of such sydnone compounds was attempted using the reaction of **1** with *o*-aminophenol, *o*-aminobenzenethiol, and *o*-phenylenediamine.

o-Aminobenzenethiol reacted readily with **1** in ethanol at room temperature to give 4-(2*H*-1,4-benzothiazin-3-yl)sydnone (**11**) in a good yield, while *o*-aminophenol did not give the corresponding 4-(2*H*-1,4-benzoxazin-3-yl)sydnone (**12**) under the same conditions. Recently, Schrider *et al.*[20] prepared 2*H*-1,4-benzoxazines by heating α-bromoacetophenones and *o*-aminophenol in acetone in the presence of excess potassium carbonate. Using their procedure the reaction of **1a** with *o*-aminophenol was attempted. However, only decomposition took place even when the reaction was carried out at room temperature and no desired **12** was formed. After several trials, **12** could be synthesyzed by changing the solvent and base to DMF and 1 equiv. of sodium hydroxide, respectively. The compound **12** was very sensitive to base and the use of excess amount of the base caused the decomposition of **12**.

In the reaction with *o*-phenylenediamine, as shown in Table 1, the yield of 4-(3,4-dihydro-2-quinoxalinyl)-sydnone (**13**) strongly depended on the reaction conditions. When 2 equiv. of the diamine was used, the expected product **13** was obtained in satisfactory yields.

The new types of sydnone compounds thus prepared are expected to be pharmacologically active and screening tests of several biological activities of these sydnones are currently under investigation.

Experimental

^{1}H NMR spectra were recorded at 60 MHz on a Varian EM360 NMR spectrometer using DMSO-d_6 and Me_4Si as solvent and an internal standard, respectively. IR spectra were obtained on a Hitachi 295 infrared spectrometer. Electron impact mass spectra were determined at 30 eV on a JEOL JMS-D100 mass spectrometer by direct introduction *via* probe.

*4-Bromoacetyl-3-(p-ethoxyphenyl)sydnone (**1b**).* Using the procedure similar to preparation of **1a**,[4] the crude product was obtained. Recrystallization from ethanol provided pure **1b** as a yellow solid. Yield, 71%. Mp 133—134 °C. IR (KBr) 3000, 2950, 2900 (ν_{C-H}), 1770, and 1690 cm^{-1} ($\nu_{C=O}$). MS: *m/z* (rel intensity) 298 (M^++2−NO, 2), 296 (M^+−NO, 2), 270 (M^++2−NO−CO, 24), 268 (M^+−NO−CO, 24), and 148 (100). Found: C, 44.00; H, 3.20; N, 8.41; Br, 24.24%. Calcd for $C_{12}H_{11}N_2O_3Br$: C, 44.06; H, 3.39; N, 8.56; Br, 24.43%.

*3-Phenyl-4-(2-phenyl-4-thiazolyl)sydnone (**3a**).* To a stirred solution of 0.39 g (2.84 mmol) of thiobenzamide in 10 ml of ethanol was added 0.80 g (2.83 mmol) of **1a** and the mixture was stirred at room temperature for 10 min. The yellow precipitates were collected by filtration and washed with ethanol; 0.73 g, 80%. Recrystallization from ethanol provided 0.68 g (75%) of pure **2a** as pale yellow needles. Mp 183—183.5 °C. IR (KBr) 1770 cm^{-1} ($\nu_{C=O}$). ^{1}H NMR δ=7.47 (s, 5H, $C_6\underline{H}_5$), 7.80 (s, 5H, $C_6\underline{H}_5$), and 8.15 (s, 1H, thiazol C-$\underline{H}$). MS: *m/z* (rel intensity) 321 (M^+, 30) and 263 (M^+−NO−CO, 100). Found: C, 63.50; H, 3.23; N, 13.12; S, 10.26%. Calcd for $C_{17}H_{11}N_3O_2S$: C, 63.54; H, 3.45; N, 13.08; S, 9.98%.

*2,4-Bis(3-phenyl-4-sydnonyl)thiazole (**3b**).* After a mixture of 0.39 g (1.39 mmol) of **1a** and 0.30 g (1.36 mmol) of 3-phenyl-4-thiocarbamoylsydnone in 2 ml of ethanol was refluxed for 15 min, yellow precipitates appeared. After cooling, the precipitates were collected by filtration and washed with ethanol; 0.47 g, 86%. Mp 241—242.5 °C (de-

comp). Recrystallization from dichloromethane-hexane provided pure 0.37 g (66%) of **2b** as yellow needles. Mp 242—243 °C (decomp). IR (KBr) 1775 and 1765 cm^{-1} ($\nu_{C=O}$). ^1H NMR δ=7.45—7.83 (m, 10H, $C_6\underline{H}_5$), 8.21 (s, 1H, thiazol C-$\underline{H}$). MS: *m/z* (rel intensity) 405 (M^+, 5), 347 (M^+—NO—CO, 10), 289 (M^+—2NO—2CO, 5), and 147 (100). Found: C, 56.26; H, 2.63; N, 17.24; S, 8.04%. Calcd for $C_{19}H_{11}N_5O_4S$: C, 56.29; H, 2.74; N, 17.28; S, 7.91%.

1-[2-Phenyl-1-[(3-phenyl-4-sydnonyl)carbonylmethylthio]ethylidene]piperidinium Bromide (5). A mixture of 0.78 g (3.56 mmol) of *N*-[benzyl(thiocarbonyl)]piperidine (**4**)[21] and 1.00 g (3.53 mmol) of **1a** in 15 ml of dichloromethane was allowed to stand for 40 h at room temperature. The resulting precipitates were collected by filtration and pale pink prisms (0.95 g, 54%) were obtained. The filtrate was concentrated under reduced pressure and 0.14 g (8%) of a precipitating solid was obtained. Recrystallization from dichloromethane-ether provided 0.72 g (41%) of pure **5** as a pale pink solid. Mp 183—185 °C (decomp). IR (KBr) 1780 and 1720 cm^{-1} ($\nu_{C=O}$). MS: *m/z* (rel intensity) 403 (M^+—HBr—H_2O, 45) and 345 (M^+—HBr—H_2O—NO—CO, 100). Found: C, 55.20; H, 4.86; N, 8.21; S, 6.32; Br, 16.09%. Calcd for $C_{23}H_{24}N_3O_3SBr$: C, 54.98; H, 4.82; N, 8.46; S, 6.38; Br, 15.90%.

3-Phenyl-4-(4-phenyl-5-piperidino-3-thienyl)sydnone (6). A mixture of 0.60 g (1.19 mmol) of **5** and 0.13 g (1.29 mmol) of triethylamine in 20 ml of ethanol was refluxed for 30 min. After concentration, the residue was mixed with *ca.* 50 ml of water. A precipitating solid was collected by filtration, washed with water, and 0.47 g (97%) of a yellow solid was obtained. Mp 129.5—133 °C (decomp). Recrystallization from aq ethanol provided 0.29 g (59%) of pure **6** as a yellow solid. Mp 131—133 °C (decomp). IR (KBr) 1760 cm^{-1} ($\nu_{C=O}$). ^1H NMR δ=1.43 (br. S, 8H, $C\underline{H}_2$), 4.55 (s, 2H, $C\underline{H}_2$), 6.39 (s, 1H, thiophene C-$\underline{H}$), 7.23 (s, 5H, $C_6\underline{H}_5$), and 7.64 (s, 5H, $C_6\underline{H}_5$). MS: *m/z* (rel intensity) 403 (M^+, 7), 345 (M^+—NO—CO, 13), and 64 (100). Found: C, 68.51; H, 5.50; N, 10.04%. Calcd for $C_{23}H_{21}N_3O_2S$: C, 68.46; H, 5.25; N, 10.41%.

(3-Phenyl-4-sydnonylcarbonylmethyl)triphenylphosphonium Bromide (9a). To a stirred solution of 4.00 g (14.9 mmol) of triphenylphosphine in 60 ml of acetonitrile was added a solution of 4.00 g (14.1 mmol) of **1a** in 20 ml of acetonitrile and the mixture was stirred for 2 h. After concentration of the solution, ether was added and 5.45 g of insoluble material was collected by filtration. Mp 208—210 °C (decomp). Recrystallization from dichloromethane-hexane provided 2.70 g (50%) of pure **9a** as pale yellow crystals. Mp 209—211 °C (decomp). IR (KBr) 1775 and 1670 cm^{-1} ($\nu_{C=O}$). ^1H NMR δ=5.65 (s, 1H, C$\underline{H}$), 5.85 (s, 1H, C$\underline{H}$), 7.63, 7.75, and 7.88 (s, 20H, $C_6\underline{H}_5$). Found: C, 61.96; H, 4.10; N, 5.38%. Calcd for $C_{28}H_{22}N_2O_3BrP$: C, 61.67; H, 4.07; N, 5.14%.

(3-Phenyl-4-sydnonylcarbonylmethylene)triphenylphosphorane (7a). To a stirred solution of 1.96 g (9.94 mmol) of **9a** in 40 ml of dichloromethane was added 10 ml of 10% sodium hydroxide at room temperature. After the dichloromethane layer had been separated and dried over sodium sulfate, concentration of the solution provided 1.40 g (84%) of **7a**. Mp 222—224 °C (decomp). IR (KBr) 1760 and 1530 cm^{-1} ($\nu_{C=O}$). ^1H NMR δ=4.56, 4.96 (s, 1H, C$\underline{H}$), 7.60, 7.62, and 7.71 (s, 20H, C_6H_5). Found: C, 72.61; H, 4.49; N, 5.97%. Calcd for $C_{28}H_{21}N_2O_3P$: C, 72.41; H, 4.56; N, 6.03%.

[3-(p-Ethoxyphenyl)-4-sydnonylcarbonylmethylene]triphenylphosphorane (7b). Phosphonium bromide (**9b**) was prepared from **1b** and triphenylphosphine. IR (KBr) 1780 and 1660 cm^{-1} ($\nu_{C=O}$). Without purification, crude **9b** was used for the preparation of **7b**. By the procedure similar to the preparation of **7a**, crude **7b** was obtained from **9b**. Mp 196—197 °C. Recrystallization from dichloromethane-hexane provided pure **7b** as yellow crystals. Mp 196—197 °C. IR (KBr) 1750 and 1540 cm^{-1} ($\nu_{C=O}$). MS: *m/z* (rel intensity) 508 (M^+, 3) and 262 (PPh_3, 100). Found: C, 70.67; H, 4.89; N, 5.37%. Calcd for $C_{30}H_{25}N_2O_4P$: C, 70.86; H, 4.96; N, 5.51%.

3-Phenyl-4-(1H-1,2,3-triazol-4-yl)sydnone (8a). A mixture of 1.00 g (2.15 mmol) of **7a** and 0.50 g (2.54 mmol) of *p*-toluenesulfonyl azide in 80 ml of benzene was refluxed for 44 h. Black oily material was obtained after concentration of the solution. A solution of the oil in a small amount of ethyl acetate was allowed to stand for one week and crystals precipitated. Colorless needles were collected by filtration and washed with ethyl acetate, 0.18 g (37%). Mp 215—217 °C. Recrystallization from dichloromethane-hexane provided pure 0.12 g (24%) of **8a** as colorless needles. Mp 215—217 °C. IR (KBr) 3160 (ν_{NH}), 1715 ($\nu_{C=O}$), and 1605 cm^{-1} ($\nu_{C=N}$). ^1H NMR δ=7.79 (s, 5H,$C_6\underline{H}_5$), 8.13 (br. s, 1H, triazole C-$\underline{H}$), and 15.49 (br. s, 1H, N$\underline{H}$). MS: *m/z* (rel intensity) 229 (M^+, 12), 171 (M^+—NO—CO, 87), and 77 (C_6H_5, 100). Found: C, 52.20; H, 2.87; N, 30.58%. Calcd for $C_{10}H_7N_5O_2$: C, 52.40; H, 3.08; N, 30.56%.

3-(p-Ethoxyphenyl)-4-(1H-1,2,3-triazol-4-yl)sydnone (8b). In a similar manner, the reaction of **7b** with *p*-toluenesulfonyl azide was carried out. After the reaction, benzene was removed by evaporation and black oily material remained. The oil was dissolved in dichloromethane and the solution was treated with active charcoal. Concentration of the solution to dryness provided a solid. Recrystallization from dichloromethane-hexane (4:1) provided pure **8b** as colorless needles (54%). Mp 241—242 °C. IR (KBr) 3130 (ν_{NH}), 3000, 2920, 2860 (ν_{C-H}), and 1740 cm^{-1} ($\nu_{C=O}$). ^1H NMR δ=1.38 (t, 3H, C$\underline{H}_3$), 4.14 (q, 2H, C$\underline{H}_2$), 7.16 (d, 2H, *p*-EtOC$_6\underline{H}_4$), 7.70 (d, 2H, *p*-EtOC$_6\underline{H}_4$), 8.04 (s, 1H, triazole C-$\underline{H}$), 15.30 (br. s, 1H, N$\underline{H}$). MS: *m/z* (rel intensity) 273 (M^+, 18) and 215 (M^+—NO—CO, 100). Found: C, 52.70; H, 3.85; N, 25.28%. Calcd for $C_{12}H_{11}N_5O_3$: C, 52.75; H, 4.06; N, 25.63%.

Electroreduction of 4-Bromoacetyl-3-phenylsydnone (1a). An H-type cell divided with a sintered glass diaphragm was used. The cathode and anode were a mercury pool (7.07 cm^2) and a platinum plate (2.5×2.5 cm^2), respectively. 50 ml and 30 ml of 0.2 M $LiClO_4$/MeCN solution were used as catholyte and anolyte, respectively. To the catholyte was added 1.42 g (5 mmol) of **1a** and electricity was supplied. The cathode potential and temperature were maintained at −0.15 V *vs.* Ag/$AgNO_3$ (sat. in DMF) (an initial cathodic current density, 1.13 A/dm^2) and at 20 °C, respectively, during electrolysis. When 495 C (1.03F/mol) was passed, the cathodic current decreased to the background level. After electrolysis, the brown catholyte was concentrated under reduced pressure below 60 °C and 50 ml of water was added. The mixture was extracted respeatedly with dichloromethane and the extracts were washed with water, and then dried over anhydrous sodium sulfate. After the extract solution had been concentrated, the remaining reddish oily material was subjected to TLC (silica gel). Elution with dichloromethane provided 0.22 g (22%) of 4-acetyl-3-phenylsydnone (first elution component) and 0.15 g (7%) of 1,4-bis(3-phenyl-4-sydnonyl)-1,4-butandione (**10**) (second component). Product **10**: mp 237—238 °C (decomp). IR (KBr) 3080 (ν_{CH}), 2930 (ν_{CH_2}), 1780 ($\nu_{C=O}$ of sydnone ring), and 1660 cm^{-1} ($\nu_{C=O}$). *m/z* 406 (M^+). Found: C, 58.87; H, 3.20; N, 13.71%. Calcd for $C_{20}H_{14}N_4O_6$: C, 59.12; H, 3.47; N, 13.79%.

4-(2H-1,4-Benzothiazin-3-yl)-3-phenylsydnone (11a). To a stirred solution of 0.30 g (1.06 mmol) of **1a** in 2 ml of ethanol was added a solution of 0.14 g (1.08 mmol) of *o*-

aminobenzenethiol in 2 ml of ethanol at room temperature. After stirring for 5 min, *ca.* 10 ml of water was added to the reaction mixture and a resulting solid was collected by filtration. Washing with ethanol provided 0.28 g (85%) of an orange yellow solid. Mp 166—168 °C (decomp). Recrystallization from ethanol provided 0.25 g (76%) of pure **11a** as orange yellow needles. Mp 166—168 °C (decomp). IR (KBr) 3060, 2990 (ν_{C-H}), 1770 ($\nu_{C=O}$), and 1590 cm^{-1} ($\nu_{C=N}$). ^1H NMR δ=3.84 (s, 2H, $C\underline{H}_2$), 6.56—7.26 (m, 4H, aromatic C-$\underline{H}$), and 7.93 (s, 5H, $C_6\underline{H}_5$). MS: *m/z* (rel intensity) 309 (M^+, 53) and 251 (M^+—NO—CO, 100). Found: C, 62.35; H, 3.89; N, 13.49; S, 10.36%. Calcd for $C_{16}H_{11}N_3O_2S$: C, 62.12; H, 3.58; N, 13.58; S, 10.37%.

4-(2H-1,4-Benzothiazin-3-yl)-3-(p-ethoxyphenyl)sydnone (11b). By the same procedure, the pure product **11b** was directly obtained without purification. Mp 132—134 °C. IR (KBr) 3000, 2950, 2900 (ν_{C-H}), 1775 ($\nu_{C=O}$), and 1600 cm^{-1} ($\nu_{C=N}$). ^1H NMR δ=1.38 (t, 3H, $C\underline{H}_3CH_2O$), 3.80 (s, 2H, $C\underline{H}_2$), 4.17 (q, 2H, $CH_3C\underline{H}_2O$), 6.56—7.30 (m, 4H, aromatic C-$\underline{H}$), 7.12 (d, 2H, *p*-$EtOC_6\underline{H}_4$), and 7.68 (d, 2H, *p*-$EtOC_6\underline{H}_4$). MS: *m/z* (rel intensity) 353 (M^+, 11), 295 (M^+—NO—CO, 17), and 44 (100). Found: C, 61.33; H, 4.21; N, 11.80; S, 8.91%. Calcd for $C_{18}H_{15}N_3O_3S$: C, 61.15; H, 4.28; N, 11.89; S, 9.07%.

4-(2H-1,4-Benzoxazin-3-yl)-3-phenylsydnone (12). To a mixture of 0.40 g (3.67 mmol) of *o*-aminophenol, 3.9 ml of 1M† sodium hydroxide and 20 ml of DMF was added a solution of 1.00 g (3.53 mmol) of **1a** in 5 ml of DMF. The mixture was allowed to stand for 30 h. To the brown reaction mixture was added *ca.* 100 ml of water and a precipitating solid was collected, and then washed with water. The solid was chromatographed on silica gel (70—230 mesh). Elution with benzene provided 0.15 g (15%) of almost pure **12**. Mp 162.5—163.5 °C (decomp). Recrystallization from dichloromethane-hexane provided **12** as yellow needles. Mp 162.5—163.5 °C (decomp). IR (KBr) 3070 (ν_{C-H}), 1770 ($\nu_{C=O}$), and 1605 cm^{-1} ($\nu_{C=N}$). ^1H NMR δ=5.05 (s, 2H, $C\underline{H}_2$), 6.70—7.10 (m, 4H, aromatic C-$\underline{H}$), and 7.93 (s, 5H, $C_6\underline{H}_5$). MS: *m/z* (rel intensity) 293 (M^+, 57) and 235 (M^+—NO-CO, 100). Found: C, 65.60; H, 3.61; N, 14.24%. Calcd for $C_{16}H_{11}N_3O_3$: C, 65.53; H, 3.78; N, 14.33%.

4-(3,4-Dihydro-2-quinoxalinyl)-3-phenylsydnone (13a). To a hot solution of 0.16 g (1.45 mmol) of *o*-phenylenediamine in 2 ml of ethanol was added 0.20 g of **1a** and the mixture was refluxed for *ca.* 5 min. After cooling, 0.17 g (80%) of resulting reddish precipitate were collected by filtration. Recrystallization from dichloromethane-hexane provided pure **13a** as reddish crystals. Mp 143—146 °C (decomp). IR (KBr) 3430 (ν_{NH}), 1775 ($\nu_{C=O}$), and 1610 cm^{-1} ($\nu_{C=N}$). ^1H NMR δ=4.23 (d, 2H, *J*=1.8 Hz, $C\underline{H}_2$), 6.08 (d, 1H, *J*=1.8 Hz, N$\underline{H}$), 6.31—7.01 (m, 4H, aromatic C-$\underline{H}$), and 7.69 (s, 5H, $C_6\underline{H}_5$). MS: *m/z* (rel intensity) 292 (M^+, 18), 248 (M^+—CO_2, 27), 234 (M^+—NO—CO, 45), and 44 (100). Found: C, 65.62; H, 4.21; N, 19.14%. Calcd for $C_{16}H_{12}N_4O$: C, 65.75; H, 4.14; N, 19.17%.

When DMF was used as a solvent, the reaction was carried out at room temperature. After the reaction, addition of water to the reaction mixture provided the crude product of **13a**.

4-(3,4-Dihydro-2-quinoxalinyl)-3-(p-ethoxyphenyl)sydnone (13b). By the same procedure, pure **13b** was obtained without purification by the reaction of **1b** in ethanol. Mp 162.5—163 °C. IR (KBr) 3380 (ν_{NH}), 3000, 2950, 2900 (ν_{C-H}), 1780, 1760 ($\nu_{C=O}$), and 1610 cm^{-1} ($\nu_{C=N}$). ^1H NMR δ=1.40 (t, 3H, $C\underline{H}_3$), 4.00—4.36 (m, 4H, $CH_3C\underline{H}_2$, and $C\underline{H}_2NH$), 6.12 (s, 1H, N$\underline{H}$), 6.40—7.18 (m, 4H, aromatic C-$\underline{H}$), 7.22 (d, 2H, *p*-$EtOC_6\underline{H}_4$), and 7.73 (d, 2H, *p*-$EtOC_6\underline{H}_4$). MS: *m/z* (rel intensity), 336 (M^+, 26), 278 (M^+—NO—CO, 81), and 276 (100). Found: C, 64.07; H, 4.60; N, 16.54%. Calcd for $C_{18}H_{16}N_4O_3$: C, 64.28; H, 4.79; N, 16.66%.

Asymmetric Hydrogenation of Schiff Base Prepared from α-Keto Ester with Aliphatic Amino Acid Ester

Kaoru HARADA and Shozo SHIONO
Department of Chemistry, The University of Tsukuba, Sakura-Mura, Niihari, Ibaraki 305
(Received November 29, 1983)

Catalytic hydrogenation of Schiff bases prepared from α-keto esters with amino acid esters was carried out under various conditions. A significant substituent effect of the alkyl group of the ester moiety of amino acid on the stereoselectivity was observed in the hydrogenation of the Schiff bases prepared from methyl pyruvate with (*S*)-alanine ester. Higher asymmetric yields were obtained as the ester residue of amino acid ester became bulkier. A clear temperature effect on the asymmetric hydrogenation was also observed. These results could be explained by the chelation mechanism.

Several studies on the asymmetric hydrogenation of carbon-nitrogen double bonds have been performed.[1-3] In the previous study, hydrogenolytic asymmetric transamination of Schiff bases, prepared from α-keto ester with optically active benzylic amine and optically active aromatic amino acid ester, has been carried out.[4-7] The steric course of the catalytic hydrogenation was explained by the chelation mechanism assuming that the substrate forms a five-membered chelated intermediate with the catalyst and then hydrogenation reaction takes place from the less bulky side of the chelated substrate. The chelation mechanism was supported by the infrared absorption spectrum of ethyl 2-hydroxyimino-3-oxo-3-phenylpropionate on palladium metal which was measured by using the high-sensitivity reflection method.[8] Recently, asymmetric synthesis of amino acid by hydrogenation of the Schiff bases prepared from aliphatic amino acid *t*-butyl esters and methyl pyruvate, followed by oxidative cleavage of carbon-nitrogen single bond was reported by Yamada *et al.*[9] In the present study, the catalytic hydrogenation of Schiff bases prepared from α-keto ester with several aliphatic amino acid esters was carried out in order to examine the steric course of this kind of asymmetric hydrogenation.

Results and Discussion

Schiff bases prepared from α-keto esters with several aliphatic amino acid esters were hydrogenated with 5% palladium on charcoal in several solvents and at various temperatures. The solvents used are methanol, ethanol, 2-propanol, and ethyl acetate, and the reaction temperatures used are in a range −10—+30 °C. The diastereomeric ratio of the resulting iminodicarboxylic acid was determined by gas chromatographic analysis after derivatization of the hydrogenated product to *N*-(trifluoroacetyl)iminodicarboxylic acid diisopropyl ester.

Hydrogenation of the Schiff bases prepared from methyl pyruvate with four kinds of amino acid ester (methyl, ethyl, isopropyl, and *t*-butyl) was carried out in order to examine the substituent effect of the ester group of the chiral moieties on the asymmetric yield. The results were shown in Fig. 1 and Tables 1 and 2. When (*S*)-alanine ester was used as a chiral moiety, (2*S*,2′*S*)-2,2′-iminodipropionic acid was produced dominantly in all cases, and higher asymmetric yield was obtained as the ester group of the amino acid ester became larger as shown in Fig. 1. When (*R*)-2-aminobutyric acid ester was used as a chiral moiety, (*R*)-2-[(*R*)-1-carboxyethylamino]butyric acid was produced dominantly, and similar substituent effect in the ester group of the amino acid ester on the asymmetric yield was observed as shown in Table 2. These results indicate that the asymmetric yield of the newly formed iminodicarboxylic acid depends strongly on the bulkiness of the ester group of the chiral amino acid ester, but depends little on the bulkiness of the alkyl group of the amino acid used as the chiral moiety.

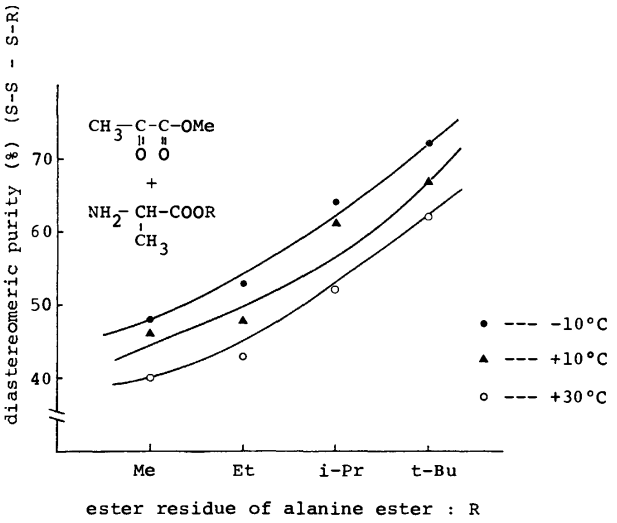

Fig. 1. Substituent effect on the asymmetric yield.

Hydrogenation of the Schiff bases prepared from methyl 2-oxobutyrate with (*S*)-alanine ester was carried out in order to examine the substituent effect of the alkyl group attached to the carbonyl group of the α-keto ester. The results were summarized in Table 3. (*S*)-2-[(*S*)-1-Carboxyethylamino]butyric acid was obtained dominantly in all cases and higher asymmetric yields were obtained as the ester residue of the amino acid ester became bulkier. An interesting result obtained is that lower asymmetric yield was obtained by using methyl 2-oxobutyrate rather than methyl pyruvate.

Hydrogenation of Schiff bases prepared from (*S*)-alanine with ethyl pyruvate instead of methyl pyruvate was carried out. The results were summarized in Table

Table 1. Hydrogenation of Schiff bases prepared from (*S*)-alanine ester and methyl pyruvate

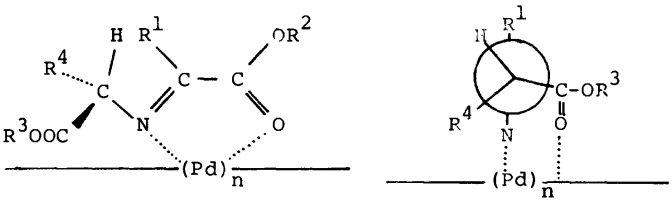

Fig. 2. Palladium-substrate complex.

are much bulkier than methyl or ethyl groups attached to the α-carbon of α-keto esters. If this is the case, the substrate-catalyst complex could be expected to form prior to catalytic hydrogenation as expected by the chelation mechanism. This five-membered chelated intermediate of the Schiff base used in the present study could be depicted as shown in Fig. 2. Considering the steric interaction between the alkyl substituent at the α-carbon of the α-keto ester and amino acid residue and the adsorption of the ester carbonyl oxygen of amino acid ester to catalyst, the conformation of the chiral moiety of the Schiff base with the catalyst could be that as shown in Fig. 2. The existence of the five-membered chelated structure could be supported by the following experimental results listed in Table 1—4 and Fig. 1. 1) The stereoselectivity in the hydrogenation of the Schiff base depends strongly on the bulkiness of the ester group of the amino acid ester. 2) Lower asymmetric yields were obtained by the use of α-keto esters with larger alkyl groups. 3) The use of ethyl pyruvate instead of methyl pyruvate gave practically no effect on the stereoselectivity in the hydrogenation of Schiff base.

Hydrogenation of Schiff base was carried out in several solvents at various temperatures. A clear temperature effect on the stereoselectivity was observed (Tables 1 and 2). Higher asymmetric yields were obtained at

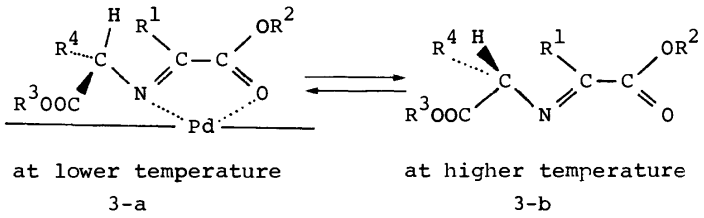

Fig. 3. Conformation of substrate at lower and at higer temperature.

lower temperature than at higher temperature. The Schiff base could form an intermediate chelated complex prior to the hydrogenation at lower temperature. On the other hand, the chelated complex might be liberated from the palladium surface to form a structure as shown in Fig. 3-b at higher temperature. Therefore, the proportion of nonchelated structure increases at higher temperature and this would result in the decrease in the stereoselectivity.

The stereoselectivity in the hydrogenation depends little on the solvent employed. In most cases, higher asymmetric yields were obtained in alcohols than in ethyl acetate. These effects might be explained by a hydrogen bonding between the solvent molecule and the ester group of the amino acid ester in the Schiff base. If the ester group of the amino acid ester in the chelated substrate forms a hydrogen bonding with alcohol, the relative steric bulkiness increases at the diastereomeric face, and this could make the stereoselectivity increase in the alcohols.

The results obtained above are summarized as follows. The stereoselectivity in the hydrogenation depends strongly on the bulkiness of the ester group of the amino acid ester and the alkyl group attached to α-carbon of α-keto ester. The use of bulkier ester group of amino acid ester afforded iminodicarboxylic acid in higher stereoselectivity. Lower asymmetric yields were obtained by the use of methyl 2-oxobutyrate than methyl pyruvate. The hydrogenation at lower temperature afforded iminodicarboxylic acid in higher stereoselectivity.

Considering the overall results, it could be concluded that the hydrogenation of the substrate used in this study proceed via the five-membered chelated intermediate.

Experimental

All the gas chromatographic analyses were carried out with a Hitachi 163 chromatograph, and the peaks on the chromatogram were integrated with a Hitachi 834-30 chromatogrocessor. 5% Palladium on charcoal was purchased from Nippon Engelhald.

General Procedure of Preparation and Hydrogenation of Schiff Base. To a suspension of methyl alaninate hydrochloride (279 mg, 2×10^{-3} mol) in 4 ml of benzene was added a solution of triethylamine (202 mg, 2×10^{-3} mol) in 1 ml of benzene and then a solution of methyl pyruvate (204 mg, 2×10^{-3} mol) in 1 ml of benzene was added to the mixture. After stirring for 1 h at 30 °C, 1 g of anhydrous magnesium sulfate was added to the mixture and the stirring was continued for 22 h at 30 °C. The mixture was filtered and the filtrate was concentrated *in vacuo*. The residue was dissolved in 6 ml of methanol and the solution was stirred with 50 mg of 5% palladium on charcoal for 9 h at 10 °C under hydrogen atmosphere. Catalyst was filtered off and the filtrate was concentrated *in vacuo*. The residue was dissolved in 20 ml of 6M-HCl[†] and the solution was refluxed for 12 h and the hydrolyzate was concentrated *in vacuo*. The residue was dissolved in a small volume of water and charged on a Dowex 50-X8 (H^+ form) column. The column was washed thoroughly with water and then eluted with 2 M-aqueous ammonia. The eluate containing iminodicarboxylic acid was concentrated *in vacuo*. One twentieth of the evaporated residue was treated with 2-propanol saturated with hydrogen chloride gas and then with trifluoroacetic anhydride in order to obtain the derivative of iminodicarboxylic acid for gas chromatographic analysis. Three quarter of the evaporated residue was dissolved in a small volume of water and charged on a column of Dowex 1-X8 (HCOOH form). The column was washed thoroughly with water and then eluted with 2 M-HCOOH. The eluate was concentrated *in vacuo* and obtained iminodicarboxylic acid, yield 178 mg (74%, based on methyl alaninate hydrochloride).

Determination of diastereomeric purity of hydrogenated product. To the residue obtained above was added 1 ml of 2-propanol saturated with hydrogen chloride gas and the mixture was heated for 1 h at 110 °C in a screw capped vial and was concentrated *in vacuo*. To the residue were added 0.5 ml of CH_2Cl_2 and 0.5 ml of trifluoroacetic anhydride and the mixture was heated for 2 h at 110 °C in a screw capped vial. The reaction mixture was concentrated *in vacuo* and the residue was extracted with ethyl acetate. The extract was washed with 10% citric acid, saturated $NaHCO_3$ and dried over magnesium sulfate, and was concentrated *in vacuo*. The residue was dissolved in ethyl acetate and the solution was injected into a gas chromatograph equipped with a glass capillary column (25 m×0.3 mm i.d.) coated with a chiral stationary phase (Chirasil-Val). The column temperature was raised from 80 °C to 180 °C at a rate of 3 °C per minute for the analysis of the diastereomeric ratio of 2,2′-iminodipropionic acid. The column temperature was raised from 80 °C to 180 °C at a rate of 0.25 °C per minute for the analysis of the diastereomeric ratio of 2-(1-carboxyethylamino)-butyric acid.

Authentic iminodicarboxylic acid, (2*S*,2′*S*)- and (2*S*,2′*R*)-2,2′-iminodipropionic acid and (*R*)-2-[(*R*)-1-carboxyethylamino]butyric acid and (*R*)-2-[(*S*)-1-carboxyethylamino]-butyric acid, were derivatized under same conditions. In each analysis of authentic derivatized samples, only a derivatized original diastereomer was detected. These results indicate that the epimerization during the derivatization would be none.

Aggregate Morphology and Hydrogenation Reactivity of Functionalized Bilayer Membrane Composed of Peptide Lipid Having NADH Activity†

Yukito MURAKAMI,* Jun-ichi KIKUCHI, Koji NISHIDA, and Akio NAKANO††
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received December 19, 1983)

A peptide lipid bearing the 1,4-dihydronicotinamide moiety, *N,N*-dihexadecyl-N^{α}-[1-(6-trimethylammoniohexyl)-1,4-dihydro-3-pyridylcarbonyl]-L-alaninamide bromide [N^+C_6(NAH)Ala2C_{16}], and its dehydrogenated form, *N,N*-dihexadecyl-N^{α}-[1-(6-trimethylammoniohexyl)pyridinium-3-ylcarbonyl]-L-alaninamide chloride bromide [N^+C_6(NA^+)Ala2C_{16}], were prepared. Both lipids formed bilayer membranes when they were dispersed in aqueous media, and the 1,4-dihydronicotinamide and nicotinamide moieties of the respective lipid molecules were placed in the so-called hydrogen-belt domain upon membrane formation. In an aqueous dispersion of the latter dicationic lipid, relatively small multilayered vesicles were predominantly formed while the related monocationic lipids bearing the same double alkyl chain composed much larger vesicles and/or lamellae. Formation of the charge-transfer (CT) complex of the nicotinamide moiety of N^+C_6(NA^+)Ala2C_{16} with 3-indolylacetic acid was much enhanced in the membrane through tight electrostatic interaction. The bilayer membrane composed of N^+C_6(NAH)Ala2C_{16} acted as a potential reductant toward anionic substrates in aqueous media. The high reactivity is gained primarily by the effective incorporation of the substrates into the hydrogen-belt domain through electrostatic, hydrogen bonding, and CT interactions and partly by the proximity effect which becomes valid between the 1,4-dihydronicotinamide moiety and the bound substrate molecule.

Currently, there is growing attention to the physical properties and aggregation behavior of synthetic lipids in aqueous media.[1] Since synthetic bilayer membranes provide hydrophobic and organized microenvironments to various extents, it is of much interest to carry out various organic reactions in such organic media. Coenzyme NAD(P)H is one of the most frequently occurring cofactors for electron-transfer reactions in biological systems, and the activity of integral enzymes is often sensitive to the change in lipid composition of membranes where such enzymes are bound.[2] Meanwhile, synthetic membranes may simulate the functions of apoproteins by providing hydrophobic and organized microenvironments for NAD(P)H.

We have previously clarified that peptide lipids compose stable bilayer vesicles having a tripartite structure: a hydrophobic zone formed with aliphatic double chains, a hydrophilic zone with ionic head groups, and a hydrogen-belt domain with amino acid residues interposed between the former two zones.[3,4] In addition, we have found that the hydrogen-belt domain serves as effective sites for hydrolysis and transamination reactions which simulate the functions of esterase and vitamin B_6-dependent transaminase, respectively.[5] In the present work, we prepared a peptide lipid bearing the 1,4-dihydronicotinamide moiety, N^+C_6(NAH)-Ala2C_{16}. The lipid was so designed as to place the dihydronicotinamide moiety in the hydrogen-belt domain when the membrane is formed. In the light of the aggregate morphology of N^+C_6(NAH)Ala2C_{16} examined herein, we studied the reduction of various substrates with the single-compartment bilayer vesicles in aqueous media.

N^+C_6(NA^+)Ala2C_{16}

Experimental

General Analyses and Measurements. Elemental analyses were performed at the Microanalysis Center of Kyushu University. Melting points were measured with a Yanagimoto MP-S1 apparatus (hot-plate type). ^{1}H-NMR spectra were taken on either a Hitachi R-24B or a Hitachi Perkin-Elmer R-20 spectrometer. pH-Measurements were carried out with a Beckman expandomatic SS-2 pH meter equipped with a Metrohm EA-125 combined electrode after calibration with a combination of appropriate standard aqueous buffers. Fluorescence and electronic absorption spectra were obtained with a Hitachi 650-60 spectrofluorometer and a Union Giken SM-401 high-sensitivity spectrophotometer, repsectively. Rapid reactions between the 1,4-dihydronicotinamide moiety and substrates were monitored with a Union Giken RA-401 stopped-flow spectrophotometer. The fluorescence polarization measurements were made on a Union Giken FS-501A fluorescence polarization spectrophotometer equipped with a Sord microcomputer M200 Mark II; the emission at 449 nm was monitored upon excitation at 360 nm with a slit width of 3.5 nm for both excitation and emission sides. The fluorescence polarization (P) was calculated by Eq. 1, where I is the fluorescence intensity, and

† Contribution No. 719 from this Department.

the subscripts v and h refer to the orientations, vertical and horizontal, respectively, for the excitation and analyzer polarizers in this sequence; *e.g.*, I_{vh} indicates the fluorescence intensity measured with a vertical excitation polarizer and a horizontal analyzer polarizer.[6]

$$P = (I_{vv} - C_f I_{vh})/(I_{vv} + C_f I_{vh}). \quad (1)$$

C_f is the grating correction factor, given by I_{hv}/I_{hh}. A JEOL JEM-200B electron microscope, installed at the Research Laboratory for High Voltage Electron Microscopy of Kyushu University, was used for morphological measurements. The detail of sample preparation for electron microscopy has been described elsewhere.[4]

Differential Scanning Calorimetry (DSC). The phase transition temperature (T_m, temperature at a peak maximum of DSC thermogram) for an amphiphile was measured with a differential scanning calorimeter (Daini Seikosha SSC-560U): heating rate, 2 °C/min; chart speed, 0.5 cm/min; sensitivity, 0.025 mcal/s/(full scale); temperature and transition heat being calibrated with benzophenone (48 °C) and/or water (0 °C). Each 50-μl sample of an aqueous dispersion [2.0 (w/w)%] in redistilled and deionized water was weighed and sealed into a silver capsule. The enthalpy change for phase transition (ΔH) was determined by measuring the peak area of DSC thermogram.

Materials. Sodium 2,4,6-trinitrobenzenesulfonate (TNBS), 2,6-dichloroindophenol (DCIP) (both from Wako Pure Chemical Industries), and Malachite Green (Merck) were obtained from commercial sources as guaranteed reagents and used without further purification. *N*-Methylacridinium chloride[7] and trifluoroacetophenone[8] were prepared according to the procedures reported in literature, and the products were identified by various spectroscopic measurements.

N,N-*Dihexadecyl*-N$^{\alpha}$-*nicotinoyl*-L-*alaninamide [(NA)Ala-2C$_{16}$].* Trifluoroacetic acid (25 g, 220 mmol) was added to a dry dichloromethane solution (20 ml) of *N,N*-dihexadecyl-N$^{\alpha}$-(*t*-butoxycarbonyl)-L-alaninamide[9] (6.0 g, 9.4 mmol), and the mixture was stirred for 30 min at room temperature. Evaporation of an excess amount of trifluoroacetic acid *in vacuo* gave a pale brown oil. Elimination of the *t*-butoxycarbonyl group was confirmed by ^{1}H-NMR spectroscopy. The amine thus formed was dissolved in dry benzene (20 ml), and the solution was cooled to 0 °C. Triethylamine (6.0 g, 60 mmol) was added dropwise to the solution, and then nicotinoyl chloride (3.7 g, 26 mmol) dissolved in dry benzene (20 ml) was added dropwise to the mixture in 20 min at 0 °C with stirring. The resulting mixture was stirred for 30 min at 0 °C and then washed with saturated aqueous sodium chloride (3×50 ml). After being dried over Na_2SO_4, the solution was evaporated to dryness *in vacuo*. The residue was chromatographed on a column of silica gel (Wako gel C-100) with ethyl acetate as an eluant. Evaporation of the solvent gave a pale brown solid: yield 4.5 g (75%): ^{1}H-NMR ($CDCl_3$, TMS) δ=0.88 [6H, t, $(CH_2)_{15}C\underline{H}_3$], 1.25 [56H, m, $CH_2(C\underline{H}_2)_{14}CH_3$], ≈1.8 [3H, m, $CH(C\underline{H}_3)$], 3.32 [4H, t, NCH_2], 5.03 [1H, m, $C\underline{H}(CH_3)$], 7.30 [2H, m, CONH and pyridine-5H], 7.99 [1H, d, pyridine-4H], 8.60 [1H, d, pyridine-6H], and 9.00 [1H, s, pyridine-2H].

6-Chlorohexyltrimethylammonium Bromide. A mixture of 30% aqueous trimethylamine (5.6 g, 28 mmol), 1-bromo-6-chlorohexane[10] (5.7 g, 29 mmol), and methanol (20 ml) was stirred for 40 h at room temperature. After evaporation of the solvent *in vacuo*, the residue was dissolved in water (20 ml) and washed with ether (2×20 ml). Evaporation to dryness gave a white solid: yield 5.0 g (68%), mp 113—114 °C; ^{1}H-NMR (D_2O, DSS) δ=1.0—2.1 [8H, m, $CH_2(C\underline{H}_2)_4CH_2$], 3.07 [9H, s, $(CH_3)_3N^+$], 3.33 [2H, t, N^+CH_2], and 3.58 [2H, t, CH_2Cl].

N,N-*Dihexadecyl*-N$^{\alpha}$-*[1-(6-trimethylammoniohexyl)pyridinium-3-ylcarbonyl]*-L-*alaninamide Chloride Bromide [N$^+$C$_6$(NA$^+$)Ala2C$_{16}$].* A mixture of (NA)Ala2C$_{16}$ (4.5 g, 6.9 mmol) and 6-chlorohexyltrimethylammonium bromide (3.5 g, 14 mmol) in dry *N,N*-dimethylformamide (10 ml) was stirred for 17 h at 120 °C under nitrogen. After the mixture was cooled to room temperature, the solvent was removed *in vacuo*, and the crude product was purified by gel-filtration chromatography on columns of Sephadex LH-20 and Toyopearl HW-40 fine in this sequence with methanol as an eluant: a pale brown glassy solid, yield 3.0 g (47%); ^{1}H-NMR ($CDCl_3$, TMS) δ=0.88 [6H, t, $(CH_2)_{15}C\underline{H}_3$], 1.26 [64H, m, $CH_2(C\underline{H}_2)_{14}CH_3$ and $N^+CH_2(C\underline{H}_2)_4CH_2$], ≈1.6 [3H, m, $CH(C\underline{H}_3)$], 2.8—3.7 [6H, m, NCH_2 and $(CH_3)_3N^+C\underline{H}_2$], 3.34 [9H, s, $(CH_3)_3N^+$], 4.90 [3H, m, $N^+(CH_2)_5C\underline{H}_2$ and $C\underline{H}(CH_3)$], 8.23 [1H, t, pyridine-5H], 8.95 [1H, d, pyridine-4H], 9.50 [1H, m, CONH], 9.90 [1H, d, pyridine-6H], and 10.38 [1H, s, pyridine-2H].

Found: C, 67.00; H, 10.37; N, 6.34%. Calcd for $C_{50}H_{96}BrClN_4O_2$: C, 66.68; H, 10.72; N, 6.22%.

N,N-*Dihexadecyl*-N$^{\alpha}$-*[1-(6-trimethylammoniohexyl)-1,4-dihydro-3-pyridylcarbonyl]*-L-*alaninamide Bromide [N$^+$C$_6$(NAH)-Ala2C$_{16}$].* A solution of N$^+$C$_6$(NA$^+$)Ala2C$_{16}$ (140 mg, 0.16 mmol) and 1-benzyl-1,4-dihydronicotinamide[11] (280 mg, 1.3 mmol) in dry methanol (2 ml) was placed in an ice bath, protected from room light, and stirred for 1 h under nitrogen atmosphere. The product was purified by gel-filtration chromatography on a column of Toyopearl HW-40 superfine with dry methanol as an eluant: a yellow solid, yield 40 mg (31%); λ_{max} (methanol) 356 nm (ε 6000); ^{1}H-NMR ($CDCl_3$, TMS) δ=0.88 [3H, t, $(CH_2)_{15}C\underline{H}_3$], 1.26 [64H, m, $CH_2(C\underline{H}_2)_{14}CH_3$ and $N^+CH_2(C\underline{H}_2)_4CH_2$], ≈1.8 [3H, m, $CH(C\underline{H}_3)$], 2.8—3.7 [10H, m, NCH_2, $N^+C\underline{H}_2(CH_2)_4C\underline{H}_2$, and pyridine-4H], 3.38 [9H, s, $(CH_3)_3N^+$], 4.80 [2H, m, $C\underline{H}(CH_3)$ and pyridine-5H], 5.65 [1H, d, pyridine-6H], 6.25 [1H, d, CONH], and 6.88 [1H, s, pyridine-2H].

Found: C, 70.26; H, 11.59; N, 6.48%. Calcd for $C_{50}H_{97}BrN_4O_2$: C, 69.33; H, 11.29; N, 6.47%.

The absence of chloride ion in the purified product was

confirmed by qualitative analysis.[12] The product decomposed gradually in the air at room temperature. Therefore, freshly prepared samples were used for all the measurements. A 1,6-dihydronicotinamide isomer was obtained as a by-product in the hydrogen transfer reaction between a 1,4-dihydronicotinamide and its dehydrogenated species.[13] However, the 1,6-isomer of N^+C_6(NAH)Ala2C_{16} was not detected in the purified product by NMR analysis.

Kinetic Measurements. For the reduction of 2,6-dichloroindophenol (DCIP) and sodium 2,4,6-trinitrobenzenesulfonate (TNBS) with N^+C_6(NAH)Ala2C_{16} in aqueous media, the reaction rate was measured with the stopped-flow spectrophotometer. Single-compartment vesicles of the lipid (4.0×10^{-4} mol dm^{-3}) were prepared by injecting 50 μl of an ethanol solution of the lipid into 5 ml of an aqueous phosphate buffer (0.01 mol dm^{-3}, pH 7.1), while ethanol solutions of the substrates were mixed with the same buffer to give final substrate concentrations of 4.0×10^{-5} mol dm^{-3} with the 1 (v/v)% ethanol content. Equal volumes of both vesicle and substrate solutions were rapidly mixed to initiate the reaction. The reaction was followed by monitoring the absorbance change at 600 nm (the absorption maximum for DCIP)[14] or 462 nm (the absorption maximum for the reduced form of TNBS).[15] As for the reduction of the substrates with 1-propyl-1,4-dihydronicotinamide (PNAH)[16] in the phosphate buffer (0.01 mol dm^{-3}, pH 7.1, 50 (v/v)% ethanol), the reaction was relatively slow and the rate was measured with the ordinary spectrophotometer. The reduction of *N*-methylacridinium chloride, Malachite Green, and trifluoroacetophenone was monitored by the ordinary spectrophotometric method: the absorbance changes at 357 (the absorption maximum for *N*-methylacridinium chloride),[17] 617 (the absorption maximum for Malachite Green),[18] and 370 nm (the absorption due to the 1,4-dihydronicotinamide moiety)[19] were measured, respectively.

Results and Discussion

Morphology of Aggregates. The peptide lipid bearing the 1,4-dihydronicotinamide moiety, N^+C_6(NAH)Ala2C_{16}, forms bilayer membranes in aqueous media. The phase transition parameters evaluated by differential scanning calorimetry (DSC) for its aqueous dispersion are as follows: T_m, 19.5 °C; ΔH, 33 kJ mol^{-1} (Fig. 1a). This is consistent with the formation of multi-walled vesicles and/or lamellae. In the light of our previous study, these parameters are primarily manipulated by the size of the double alkyl-chain segment of peptide lipids. The parameters obtained for N^+C_6(NAH)Ala2C_{16} are in good agreement with those observed for peptide lipids having the same double chain segment such as N^+C_nAla2C_{16} (n=2, 5, 7, and 10).[20]

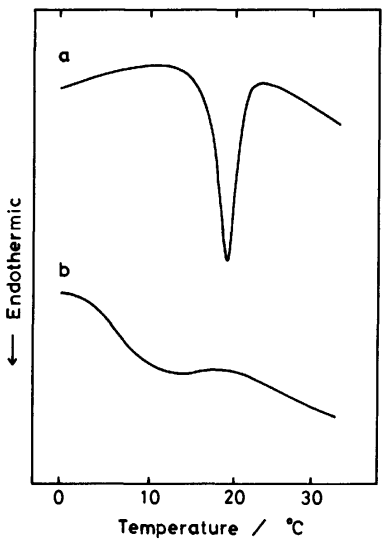

Fig. 1. DSC thermograms for aqueous dispersions of peptide lipids: a, N^+C_6(NAH)Ala2C_{16}; b, N^+C_6-(NA^+)Ala2C_{16}.

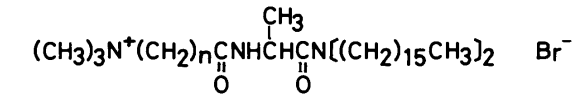

N^+C_nAla2C_{16}

In order to prepare single-walled bilayer vesicles of N^+C_6(NAH)Ala2C_{16}, the injection method which was originally employed for the formation of single-walled liposomes[21] was adopted in this work to avoid degradation of the 1,4-dihydronicotinamide group, which was detected to occur spectrophotometrically under ordinary sonication conditions. The solution thus obtained was sufficiently clear for the following various measurements in contrast to the slightly turbid dispersion of the lipid.

The electronic absorption and fluorescence maxima of N^+C_6(NAH)Ala2C_{16} in ethanol at 15 °C were observed at 353 and 448 nm, respectively, and identical with those of 1-propyl-1,4-dihydronicotinamide (PNAH). Since these spectroscopic maxima for the 1,4-dihydronicotinamide moiety are much sensitive to the microenvironmental polarity, such polarity in the so-called hydrogen-belt domain of the single-walled vesicle was evaluated by referring to the corresponding spectra of PNAH in various media. As a result, the present hydrogen-belt domain with absorption and fluorescence maxima at 359.5 and 455 nm, respectively, provides a microenvironment equivalent to that provided by ethanol-water (1:1 v/v) (solvent polarity Y-parameter, 1.665).[22] In addition, the fluorescence polarization (P=0.317) for the 1,4-dihydronicotinamide moiety of N^+C_6(NAH)Ala2C_{16} in the single-walled aggregate at 15 °C is larger than that measured in ethanol (0.114). This must be attributed to the tight side-by-side arrangement of the amphiphile molecules in the aggregated state.

An aqueous dispersion of N^+C_6(NA^+)Ala2C_{16}, the dehydrogenated counterpart of N^+C_6(NAH)Ala2C_{16}, shows a broad endothermic peak in the 5—20 °C range as shown in Fig. 1b. The morphological transformation of multi-walled bilayer aggregates, composed of natural and/or synthetic lipids, into smaller vesicles are reflected on the phase transition behavior between the gel and liquid-crystalline states; decrease in ΔH along with peak-broadening and shift of T_m to lower temperature.[20,23] The DSC thermogram for an aqueous dispersion of N^+C_6(NA^+)Ala2C_{16} is almost comparable to that for a sonicated solution of N^+C_5Ala2C_{16}. This implies that dicationic amphi-

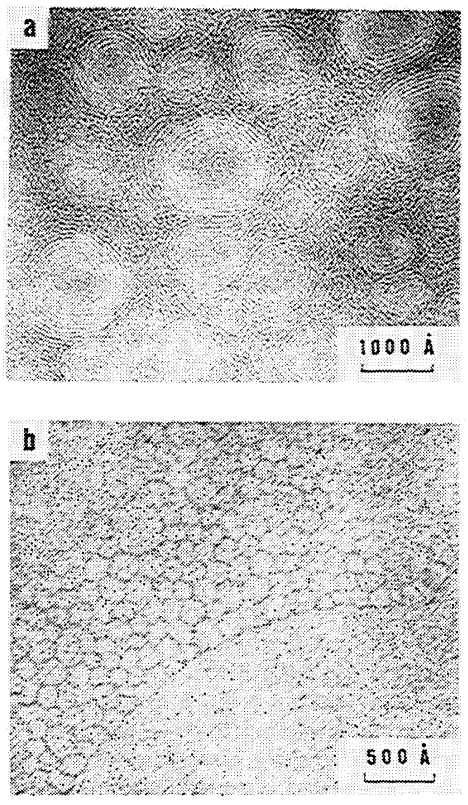

Fig. 2. Electron micrographs negatively stained with uranyl acetate: a, 10 mmol dm^{-3} aqueous dispersion of $N^+C_6(NA^+)Ala2C_{16}$; b, 10 mmol dm^{-3} aqueous solution of $N^+C_6(NA^+)Ala2C_{16}$ sonicated for 2 min at 30 W.

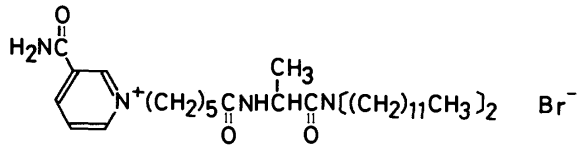
philes are inclined to form smaller aggregates compared with those of the corresponding monocationic ones having the same double alkyl chains when they are dispersed in water. Indeed, the electron micrograph of an aqueous dispersion of $N^+C_6(NA^+)Ala2C_{16}$ shows the presence of multi-walled vesicles with 500—1500 Å diameter (Fig. 2a) without forming straight or bent lamellae observed for aqueous dispersions of $N^+C_nAla2C_{16}$ (n=2, 5, 7, and 10).[20] The difference in aggregate morphology is apparently due to the extensive electrostatic repulsion among the $N^+C_6(NA^+)Ala2C_{16}$ molecules in the aggregated state. Sonication of an aqueous dispersion of $N^+C_6(NA^+)Ala2C_{16}$ with a probe-type sonicator for 2 min at 30 W resulted in a clear solution state which gave an electron micrograph indicating the presence of small particles in a manner as observed for sonicated solutions of $N^+C_nAla2C_{16}$[20] (Fig. 2b).

We have reported previously that an amphiphile involving the nicotinamide moiety as a polar head group, *N,N*-didodecyl-N^{α}-[6-(3-carbamoylpyridinio)-hexanoyl]-L-alaninamide bromide [$(NA^+)C_5Ala2C_{12}$], forms sngle-compartment vesicles in aqueous media upon sonication and provides molecular organization much favorable for the formation of charge-transfer (CT) complexes with electron donors such as 3-indolylacetic acid.[24] The CT interaction of $N^+C_6(NA^+)Ala2C_{16}$ (sonicated in water) with 3-indol-



$(NA^+)C_5Ala2C_{12}$

ylacetic acid was quite effective and showed the biphasic CT complex formation in a manner as observed with the vesicular system composed of $(NA^+)C_5Ala2C_{12}$. The formation constant for the CT complex thus obtained on a 2:1 (nicotinamide *vs.* 3-indolylacetic acid) stoichiometry is 7.3×10^3 mol^{-1} dm^3 at 25 °C in water.[25] Thus, it is reasonable to consider that such CT interaction is also effective for the vesicular system composed of $N^+C_6(NAH)Ala2C_{16}$, the 1,4-dihydronicotinamide moiety being the CT donor. Hence, the highly organized molecular aggregates formed with $N^+C_6(NAH)Ala2C_{16}$ and its dehydrogenated counterpart are expected to be utilized as effective reaction sites capable of promoting redox reactions due to the so-called proximity effect when substrate species, acting as CT-acceptors or -donors, are incorporated into them.

Reactivity of $N^+C_6(NAH)Ala2C_{16}$ Membrane in the Reduction of Various Substrates. In order to evaluate the reactivity of $N^+C_6(NAH)Ala2C_{16}$ membrane prepared by the injection method, the following substrates were used: cationic, *N*-methylacridinium chloride and Malachite Green; nonionic trifluoroacetophenone; anionic, 2,6-dichloroindophenol (DCIP) and sodium 2,4,6-trinitrobenzenesulfonate (TNBS). The reactions were carried out in an aqueous phosphate buffer (0.01 mol dm^{-3}, pH 7.1) containing 1 (v/v)% ethanol. In general, the reaction rate for reduction with NAD(P)H models is much influenced by the nature of microenvironment where the reaction takes place.[17,26] Prior to the kinetic analysis of the substrate-binding process with the membrane and the subsequent reduction, a reference reaction was examined in a homogeneous solution which provides the polarity equivalent to that in the $N^+C_6(NAH)Ala2C_{16}$ membrane: the hydrogenation with PNAH was investigated in ethanol-water (1:1 v/v).

As for the reduction of the cationic and neutral substrates, each substrate underwent reaction at an identical rate regardless of the nature of media, ethanol-water or membrane. This implies that the electrostatic repulsion on the positively charged surface of the membrane toward the cationic substrates inhibits the effective incorporation of the substrates into the membrane while the hydrophobic interaction between the hydrophobic domain of the membrane and the neutral substrate disturbs to attain the effective substrate concentration in the hydrogen-belt domain.

As for the reduction of the anionic substrates, however, the marked rate acceleration was observed in the membrane system. As shown in Table 1, the reaction rates for the reduction of DCIP and TNBS in the bilayer membrane were enhanced by 72- and 1.1×10^5-fold, respectively, relative to those in ethanol-water

Table 1. Apparent first-order rate constants for the reduction of 2,6-dichloroindophenol (DCIP) and sodium 2,4,6-trinitrobenzenesulfonate (TNBS) with 1,4-dihydronicotinamide derivatives at 15.0 °C[a)]

Substrate	1,4-Dihydronicotinamide	Medium[b)]	k_{obsd}/s^{-1}
DCIP	N^+C_6(NAH)Ala2C_{16}[c)]	A	9.4×10^{-1}
DCIP	PNAH	B	1.3×10^{-2}
TNBS	N^+C_6(NAH)Ala2C_{16}[c)]	A	2.5
TNBS	PNAH	B	2.3×10^{-5}

a) Initial concentrations: 1,4-dihydronicotinamide derivatives, 2.0×10^{-4} mol dm^{-3}; substrates, 2.0×10^{-5} mol dm^{-3}. b) A, phosphate buffer (0.01 mol dm^{-3}, pH 7.1) containing 1 (v/v)% ethanol; B, phosphate buffer (0.01 mol dm^{-3}, pH 7.1) containing 50 (v/v)% ethanol. c) Single-walled vesicles.

(1:1 v/v). Although the high reactivity of both of the anionic substrates in the membrane is undoubtedly due to the favorable electrostatic interaction which takes the substrates in the membrane surface, other interaction modes, which take the substrates into the hydrogen-belt domain, must be operative. Before such effects are discussed, the kinetic analysis needs to be carried out on the basis of the pseudo-phase concept[27,28] which was originally adopted for the analysis of micellar reactions.

According to the Berezin's concept which quantitatively explain the micellar effect on a bimolecular reaction,[27] the pseudo-first-order rate constant, k_{obsd}, is given by the following equation:

$$k_{obsd} = \frac{k_m P_{TNBS} P_{NAH} C\bar{V} + k_w(1-C\bar{V})}{[1+(P_{TNBS}-1)C\bar{V}][1+(P_{NAH}-1)C\bar{V}]}[NAH]_0. \quad (2)$$

Here, k_m and k_w represent the second-order rate constants in the bilayer membrane and in water, respectively; P_{TNBS} and P_{NAH} denote the partition coefficients of TNBS and N^+C_6(NAH)Ala2C_{16}, respectively, between the membrane and water, *e.g.*, $P_{TNBS}=[TNBS]_m/[TNBS]_w$ where the subscripts, m and w, stand for the membrane and water phases, respectively; $\bar{V}$ is the partial molar volume of the lipid in the membrane; C designates the stoichiometric lipid concentration minus its critical aggregate concentration (CAC); and $[NAH]_0$ is the total lipid concentration. Under the present kinetic conditions, the following assumptions are valid: (i) the rate of reaction in water is neglected, *i.e.*, $k_m P_{TNBS} P_{NAH} C\bar{V} \gg k_w(1-C\bar{V})$; (ii) the $(1-C\bar{V})$ term approximately equals 1 because of the low lipid concentration; (iii) C is nearly equals $[NAH]_0$ and $P_{NAH}C\bar{V} \gg 1$ because of the extremely low CAC;[29] (iv) the binding constant for incorporation of TNBS into the N^+C_6(NAH)Ala2C_{16} membrane, defined by $K_{TNBS}=(P_{TNBS}-1)\bar{V}$, nearly equals $P_{TNBS}\bar{V}$ because of $P_{TNBS} \gg 1$. Thus, Eq. 2 may be simplified to Eq. 3, which is subsequently rearranged to give Eq. 4.

$$k_{obsd} = \frac{k_m K_{TNBS}[NAH]_0}{\bar{V}(1+K_{TNBS}[NAH]_0)}, \quad (3)$$

$$\frac{1}{k_{obsd}} = \frac{\bar{V}}{k_m K_{TNBS}[NAH]_0} + \frac{\bar{V}}{k_m}. \quad (4)$$

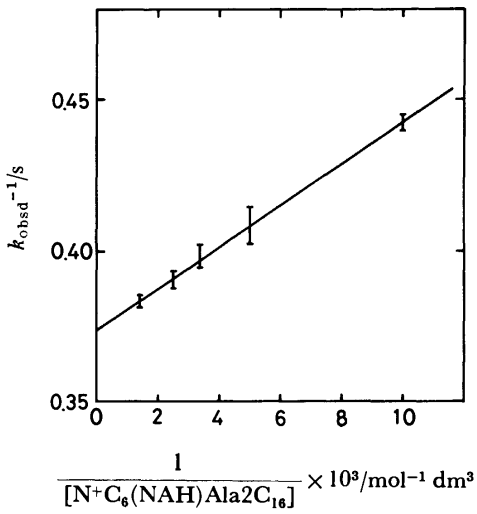


Fig. 3. Kinetic analysis on the basis of Eq. 4 for the reduction of TNBS with N^+C_6(NAH)Ala2C_{16} membrane in a phosphate buffer (0.01 mol dm^{-3}, pH 7.1) containing 1 (v/v)% ethanol at 15.0°C.

The plot of $1/k_{obsd}$ *vs.* $1/[NAH]_0$ gave a straight line correlation as illustrated in Fig. 3, and the K_{TNBS} value determined from its intercept and slope is 5.5×10^4 mol^{-1} dm^3. If one may employ 0.75 mol^{-1} dm^3 for the $\bar{V}$ value, which is calculated from the volume per lipid molecule for egg yolk phosphatidylcholine vesicles,[30] the second-order rate constant in the membrane is 2.0 mol^{-1} dm^3 s^{-1}. This assumption for $\bar{V}$ is reasonable since all the average vesicle parameters for single-walled vesicles of N^+C_5Ala2C_{16} and egg lecithin are comparable to each other as reported previously.[20] The second-order rate constant in the present membrane is 17-fold greater than the corresponding value in the homogeneous solution (0.115 mol^{-1} dm^3 s^{-1}). Consequently, the marked overall rate enhancement observed for the reduction of TNBS primarily originates in the effective substrate incorporation into the hydrogen-belt domain of the membrane. Such efficient binding behavior may come from the three interaction modes: (i) the electrostatic attraction which takes the substrate molecules in the membrane surface, (ii) the CT interaction between the 1,4-dihydronicotinamide and the substrate, and (iii) the hydrogen bonding interaction between the substrate and the hydrogen-belt domain. The latter two interactions may act to translocate the substrate molecules from the membrane surface to the hydrogen-belt domain.

In conclusion, the bilayer membrane formed with the cationic peptide lipid bearing the 1,4-dihydronicotinamide moiety, N^+C_6(NAH)Ala2C_{16}, acts as a potential reductant toward anionic substrates in aqueous media. The high reactivity primarily originates in the effective binding of such substrates to the lipid membrane, which is brought about by the three different interaction modes as stated above. The side-by-side arrangement of the 1,4-dihydronicotinamide moieties in the hydrogen-belt domain of the membrane may contribute in part to the overall

rate enhancement due to the proximity effect brought about by the CT and hydrogen-bonding interactions.

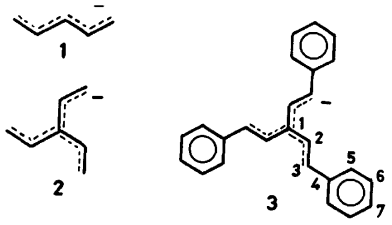
Synthesis and Properties of the Tristyrylmethyl Anion

Koichi KOMATSU, Shuzo SHIRAI, Isao TOMIOKA, and Kunio OKAMOTO*
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received December 20, 1983)

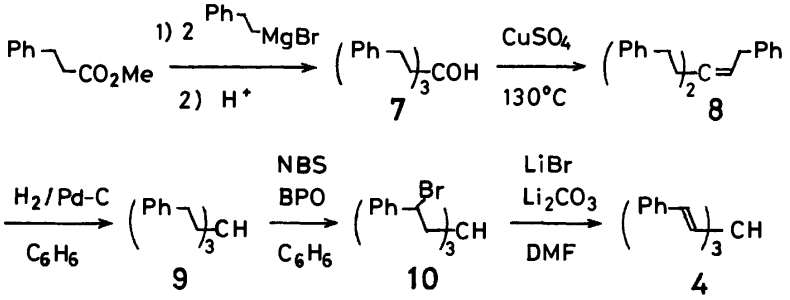
The title anion (**3**) having a C_{3v} symmetric structure was generated from newly synthesized tristyrylmethane (**4**) and was characterized by means of ^1H and ^{13}C NMR spectroscopy. The pK_a value of **4** was determined as 20.1 in DMSO-EtOH (9:1), indicating considerable conjugative stabilization of the anion **3**. The cyclic voltammetry of **3** in acetonitrile exhibited only irreversible one-electron oxidation peak corresponding to the formation of a chemically unstable radical species. Whereas quenching the anion **3** with H_2O or Me_3SiCl quantitatively afforded the cross-conjugated triene **6** (R=H or Me_3Si), the reaction of **3** with the tropylium ion yielded 1,1'-bicycloheptatrienyl (29%), as well as the triene **6** ($R=C_7H_7$) (66%), demonstrating that **3** can also acat as a one electron reductant.

Although linearly-conjugated open-chain pentadienyl anions (**1**) have been extensively studied by means of ^1H and ^{13}C NMR spectroscopy[1] and shown to be generally predominated by the "W" conformation, the NMR study on its cross-conjugated derivative, the 3-vinylpentadienyl anion (**2**), seems to be quite limited. For example, **2** and some of its alkylated derivatives were observed by NMR[1c,2] but no NMR data was reported for a variety of cross-conjugated carbanions with aryl substituents prepared by Kuhn *et al.*[3] Here we wish to report on the properties of the newly synthesized tristyrylmethyl anion (**3**), which can also be looked upon as a tri-vinylog of the long-known triphenylmethyl (trityl) anion.



The parent hydrocarbon, tristyrylmethane (**4**), was synthesized in 53% overall yield from methyl 3-phenylpropanoate as shown in Scheme 1. Upon treatment with an equimolar amount of *n*-BuLi or *t*-BuOK in THF, the hydrocarbon **4** afforded a deep blue solution of the anion **3**, which was quite sensitive to air but could be stored unchanged for more than a year when sealed under vacuum.

The ^1H and ^{13}C NMR data for the anion **3** are shown in Table 1 together with those for the parent hydrocar-



Scheme 1.

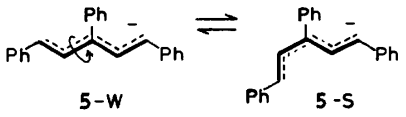
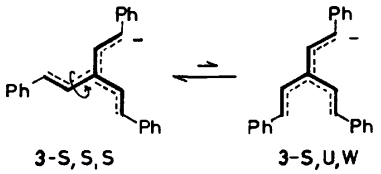
a) In $CDCl_3$. b) In THF-THF-d_8 (9:1). c) Estimated from δ_{13C} of **3**·K^+ according to the ρ-δ relationship obtained for K^+ salts of open-chain carbanions: $\rho=(289.5-\delta)/156.3$ (Ref. 1e). d) Calculated by simple HMO ($\beta_{1,2}=\beta_{3,4}=0.9$). e) q ($J=6.6$ Hz). f) dd ($J=16.2$, 6.6 Hz). g) d ($J=16.2$ Hz). h) d ($J=15.0$ Hz).

bon **4**. Close similarity of the ^1H and ^{13}C chemical shifts for **3**·K^+ to those for **3**·Li^+ suggests that these salts exist as "loose" or "solvent-separated" ion pairs with little interaction between the cation and the anion. Remarkable upfield shifts noted for the ^{13}C NMR signals of C-1 and C-3 in **3**, as well as of C-5 and C-7 although in lesser amounts, indicate the presence of high electron densities on these carbons in agreement with the results of MO calculations (Table 1).



Scheme 2.



Scheme 3.

1,3,5-Triphenylpentadienyl anion **5** was reported to be in a rapid equilibrium between the "W" and "S" forms having comparable stability (Scheme 2) and to exhibit ^{13}C NMR line broadening at −5 °C.[10] For the present anion **3**, the corresponding rotation of the inner bond inevitably results in the formation of the sterically unfavorable "U" shape for one of the pentadienyl moieties (Scheme 3). Thus, the ^{13}C NMR line broadening of the C-3 and C-2 signals was observed at −45 °C for **3**·Li^+ in THF, but at lower temperatures the C-3 signal reappeared at δ 103.7 as a sharp singlet with the relative intensity comparable to the original one, while the C-1 signal remained almost unchanged. This observation may be taken as evidence that the equilibrium shown in Scheme 3 lies far to the left favoring the symmetric structure, although at the low temperatures the C-2 signal was obscured by overlapping with the more slowly broadening phenyl signals and observation of the signals for **3**-S,U,W, if any, was precluded by the low S/N ratio resulting from decreased solubility of **3**·Li^+ itself.

The electronic spectrum of the anion **3** in DMSO exhibited the longest-wavelength absorption at 585 nm (log ε 4.75) with a shoulder at 540 nm (log ε 4.72). The acidity of the hydrocarbon **4**, which measures the stability of the anion **3**, was then determined on the basis of this absorption in DMSO-EtOH (9:1) by the spectrophotometric method of Kuhn and Rewicki[3b] using the H_- function corrected with 9-phenylfluorene (pK_a 18.5)[4,5] as a standard. The pK_a of **4** was found to be 20.1±0.2, indicating that **4** is about 10^{12} times more acidic than triphenylmethane (pK_a 32.5)[5] owing to the great conjugative stabilization of the anion **3**.

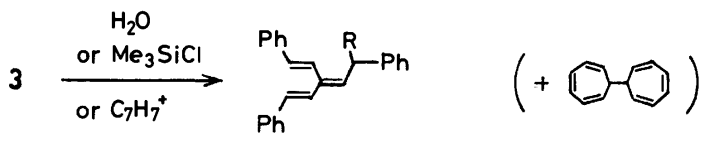
In order to compare the redox behavior of the anion **3** with that of the trityl anion, which exhibits two successive oxidation steps leading to the radical and to the cation,[6] cyclic voltammetry was conducted on the anion **3** generated with *t*-BuOK in acetonitrile. The voltammogram obtained at the scan rate of 0.1 V/s exhibited an irreversible anodic peak corresponding to the oxidation of **3** to the radical at −1.33 V *vs.* Ag/Ag^+, from which was estimated the $E_{1/2}$ value[7] as −1.38 V *vs.* Ag/Ag^+ (−1.09 V *vs.* SCE),[8] 0.11 V less negative than $E_{1/2}$ for the trityl anion (−1.20 V *vs.* SCE).[6] No peak corresponding to further oxidation of the radical was observable nor did the peak at −1.33 V become reversible upon increasing the scan rate up to 1 V/s, indicating that the radical species is chemically unstable and decomposes during measurement.

Finally, quenching reactions of the anion **3** were conducted with excessive H_2O and Me_3SiCl, and were found to give the cross-conjugated triene **6** (R=H and Me_3Si) in 100 and 79% yields, respectively (Scheme 4). In contrast, the reaction of **3**·Li^+ with an equimolar amount of the tropylium ion afforded 1,1′-bicycloheptatrienyl, the one-electron reduction product of the tropylium ion,[9] in 29% yield in addition to the triene **6** (R=C_7H_7) (66%). This result clearly demonstrates that the anion **3** can act not only as a nucleophile but also as a one-electron donor towards a stable carbocation.

Experimental

General. Melting points are uncorrected. The elemental analyses were performed by the Microanalytical Center, Kyoto University, Kyoto. The IR and visible spectra were recorded on Hitachi 215 and Hitachi 200-10 spectrometers, respectively. The ^1H NMR spectra were taken with a Hitachi R-24 (60 MHz) or, when specified, with a Nicolet NP-300 NB (300 MHz) spectrometer with Me_4Si as the internal standard. The ^{13}C NMR spectra were recorded on a JEOL FX-100 (25 MHz) spectrometer operated in the Fourier transform mode.

Tris(2-phenylethyl)methanol (7). A solution of methyl 3-phenylpropanoate (16.4 g; 0.100 mol) in ether (50 ml) was added dropwise over 0.5 h to a stirred solution of 2-phenylethylmagnesium bromide, prepared from 2-phenylethyl bromide (40.7 g; 0.220 mol) and Mg (5.35 g; 0.220 mol) in ether (100 ml). After refluxing for 3 h, the reaction mixture was hydrolyzed with saturated NH_4Cl and worked up in the usual way to give **7** (32.9 g; 95.5%) as white needles: mp 68.8—70.0 °C; IR (KBr) ν 3500 cm^{-1} (OH); NMR



6 (R=H, $SiMe_3$, C_7H_7)

Scheme 4.

($CDCl_3$) δ=7.20 (s, 15H), 2.67 (m, 6H), 1.86 (m, 6H), and 1.33 (s, 1H). Found: C, 86.97; H, 8.10%. Calcd for $C_{25}H_{28}O$: C, 87.16; H, 8.19%.

1,5-Diphenyl-3-(2-phenylethyl)-2-pentene (8). A stirred mixture of **7** (15.3 g; 44.3 mmol) and anhydrous $CuSO_4$ (5.39 g; 33.8 mmol) was heated at 130 °C for 0.5 h and then extracted with ether to give **8** (14.6 g; 100%) as a colorless viscous oil; IR (neat) ν 1660 cm^{-1} (C=C); NMR (CCl_4) δ=7.11 (s, 15H), 5.28 (t, 1H), 3.17 (d, 2H), and 2.9—2.2 (m, 8H).

Tris(2-phenylethyl)methane (9). A solution of **8** (15.4 g; 47.2 mmol) in benzene (50 ml) was catalytically hydrogenated over 5% Pd-C (2 g) for 2 d to give **9** (16.0 g; 100%) as a colorless viscous oil; NMR (CCl_4) δ=7.01 (s, 15H), 2.45 (m, 7H), and 1.58 (m, 6H).

Tris(2-bromo-2-phenylethyl)methane (10). A mixture of **9** (11.3 g; 34.3 mmol), *N*-bromosuccinimide (17.9 g; 101 mmol), and benzoyl peroxide (1.0 g; 4.1 mmol) in CCl_4 (60 ml) was stirred at room temperature for 1 h and at 80 °C for 1 h. The cooled mixture was filtered, evaporated, and crystallized from hexane to give **10** (11.9 g; 61.4%) as yellow crystals: NMR (CCl_4) δ=7.21 (s, 15H), 4.82 (t, 3H), and 2.15 (m, 7H).

Tristyrylmethane (4). A dried mixture of Li_2CO_3 (4.12 g; 55.8 mmol) and LiBr (4.14 g; 47.7 mmol) was added portionwise over 15 min to a stirred solution of **10** (6.00 g; 10.6 mmol) in DMF (50 ml) at 10 °C. After heating the stirred mixture at 100 °C for 1.7 h, the mixture was treated with water and worked up to give **4** (3.10 g; 90.6%) as pale brown powder. Recrystallization from hexane-benzene (1:1) afforded 2.70 g of off-white prisms: mp 110.0—111.0 °C; IR (KBr) ν 1650 cm^{-1} (C=C). Found: C, 93.00; H, 6.80%. Calcd for $C_{25}H_{22}$: C, 93.12; H, 6.88%.

The Tristyrylmethyl Anion (3). Method A (Preparation under Vacuum): The NMR Spectra; Under a stream of argon, the hydrocarbon **4** was added to an equimolar amount of *t*-BuOK or neat *n*-BuLi (obtained by evaporation of the hexane solution) in an NMR tube connected to a vacuum line. An appropriate amount of dry THF-THF-d_8 (9:1) was vacuum distilled into this mixture to give a 0.1 M solution. The tube was then sealed under vacuum and subjected to NMR measurements.

The Electronic Spectrum; A diluted solution (2.79×10^{-5} M[1]) of **4** in DMSO (5.00 ml) was placed in a 1-cm cell connected to a vacuum line. The cell was equipped with a mixing compartment containing *t*-BuOK (1 mg; 0.009 mmol). After the DMSO solution was degassed by three freeze-pump-thaw cycles, the whole assembly was sealed under vacuum, and the solution mixed with *t*-BuOK and subjected to the measurement.

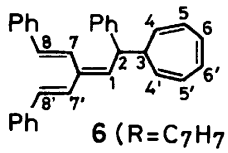
Quenching with H_2O; Water (1 ml) was vacuum distilled into a solution of **3**·K^+, prepared as described above from **4** (0.0405 g; 0.126 mmol) and *t*-BuOK (0.020 g; 0.18 mmol) in THF (3 ml). The resultant pale yellow solution was worked up and purified by PTLC over SiO_2 developed with hexane-benzene (2:1) to give **6** (R=H) (0.0400 g; 100%) as a colorless viscous oil; NMR (300 MHz) ($CDCl_3$) δ=7.44—7.14 (m, 15H), 7.10 (d, J=16.4 Hz, 1H), 6.95 (d, J=15.9 Hz, 1H), 6.73 (d, J=16.4 Hz, 1H), 6.69 (d, J=15.9 Hz, 1H), 5.97 (t, J=7.8 Hz, 1H), and 3.69 (d, J=7.8 Hz, 2H).

Method B (Preparation under Nitrogen): Quenching with Me_3SiCl; *n*-BuLi (1.4 M in hexane) (5.0 ml; 7.0 mmol) was added to a stirred and deaerated solution of **4** (0.471 g; 1.46 mmol) in dry THF (10 ml) under dry nitrogen. To the resultant deep blue solution was immediately added Me_3SiCl (2.6 g; 24 mmol) to give a pale yellow suspension, which was evaporated, hydrolyzed, and extracted with ether. The crude product was purified by PTLC over SiO_2 developed with hexane-benzene (2:1), affording **6** (R=Me_3Si) (0.449 g; 79.0%) as a pale yellow viscous oil: NMR (300 MHz) ($CDCl_3$) δ=7.40—7.05 (m, 15H), 6.94 (d, J=16.2 Hz, 1H), 6.90 (d, J=16.2 Hz, 1H), 6.52 (d, J=16.2 Hz, 1H), 6.31 (d, J=16.2 Hz, 1H), 6.21 (d, J=12.0 Hz, 1H), 3.52 (d, J=12.0 Hz, 1H), and −0.06 (s, 9H).

The pK_a Measurements. The pK_a value was determined by the method of Kuhn and Rewicki,[3b] using the H_ function reported by Bowden and Stewart and corrected with the known pK_a of 9-phenylfluorene (18.59).[4] The visible spectra were measured under vacuum as described above in 5.00 ml of DMSO-EtOH (90:10 by mol, also used were mixtures of 85:15 and 80:20 by mol) using NaOEt (0.05 mmol, obtained by evaporation of 0.500 ml of a 0.1 M ethanolic solution) as a base.

Cyclic Voltammetry. The measurements were performed by the method and apparatus previously reported,[10] on a sample solution freshly prepared by adding *t*-BuOK (0.0202 g; 0.180 mmol) to a stirred solution of **4** (0.0502 g; 0.156 mmol) and dried Bu_4NClO_4 (0.513 g; 1.50 mmol) in dry acetonitrile (15 ml) under an atmosphere of nitrogen.

Reaction of 3·Li^+ with Tropylium Tetrafluoroborate. A solution of 3·Li^+ was prepared as described above by vacuum distillation of dry THF (100 ml) into a 200 ml flask containing a stirring bar, **4** (2.90 g; 9.00 mmol), and *n*-BuLi (9.18 mmol, obtained by evaporation of 6.7 ml of 1.37 M solution in hexane). The flask was equipped with a side-arm containing tropylium tetrafluoroborate (1.60 g; 9.00 mmol). After sealing the whole equipment under vacuum, the tropylium salt was added from the side-arm into the stirred solution of 3·Li^+. The mixture was stirred for 16 h, hydrolyzed, and worked up to give the crude product, which was then separated by PTLC over SiO_2 developed with hexane-benzene (3:1). From the fraction with R_f 0.75 was obtained 1,1′-bicycloheptatrienyl (0.233 g; 28.5%) identified by spectral comparison with an authentic sample, while the fraction with R_f 0.52 afforded **6** (R=C_7H_7) (2.43 g; 65.6%) as a colorless viscous oil; ^1H NMR (300 MHz) ($CDCl_3$) δ=7.44—7.12 (m, 15), 7.06 (d, J=16.2 Hz, 1H, H-8), 6.87 (d, J=15.9 Hz, 1H, H-8′), 6.67 (d, J=16.2 Hz, 1H, H-7), 6.63 (d, J=15.9 Hz, 1H, H-7′), 6.62 (t, J=4.8 Hz, 2H, H-6,6′), 6.19 (dd, J=9.3, 4.8 Hz, 1H, H-5), 6.04 (dd, J=9.3, 4.8 Hz, 1H, H-5′), 5.89 (d, J=10.2 Hz, 1H, H-1), 5.30 (dd, J=9.3, 5.7 Hz, 1H, H-4), 5.07 (dd, J=9.3, 5.7 Hz, 1H, H-4′), 4.12 (dd, J=10.7, 10.2 Hz, 1H, H-2), and 2.08 (dt, J=10.7, 5.7 Hz, 1H, H-3); ^{13}C NMR



6 (R=C_7H_7)

($CDCl_3$) δ=142.9—124.2 (24 peaks), 46.7 (d, C-2), and 44.7 (d, C-3). From the fraction with R_f 0.29 was obtained a pale yellow viscous oil (0.856 g), which is supposed to be a polymeric material having structural units derived from the tristyrylmethyl radical based on its ^1H NMR exhibiting very broad signals corresponding to phenyl and olefinic protons in a ratio of about 15:5.

[1] 1 M=1 mol dm^{-3}.

(Received December 20, 1983)

Two shorter peptides of a heat-stable enterotoxin (ST_p), which is produced by enterotoxigenic *Escherichia coli* strain 18D, were prepared by two different procedures; i) chemical synthesis and ii) Edman-degradation of ST_p. These peptides (designated as $ST_p(4—18)$ and $ST_p(5—18)$) corresponded to 15 and 14 amino acid residues in the sequence of ST_p without three and four residues, respectively, of the N-terminus. Peptides $ST_p(4—18)$ and $ST_p(5—18)$ prepared by chemical synthesis had the same biological and physicochemical properties as the peptides obtained by the Edman method. Furthermore, they showed almost the same toxicity as native and synthetic ST_p, and their toxicity was neutralized by anti-native ST_p antisera. Synthetic $ST_p(4—18)$ had similar heat-stability to ST_p, but synthetic $ST_p(5—18)$ was much more heat-stable. These findings suggest that the sequence from the Cys residue near the N-terminus to the C-terminal residue is extremely important for the unique characters of toxicity and heat-stability of the toxin.

Various strains of enterotoxigenic *Escherichia coli* (ETEC) from animal hosts produce heterologous low-molecular-weight, heat-stable enterotoxins (ST's), which are responsible for acute diarrhea in man and various domestic animals. Burgess *et al.*[1] reported two distinct ST's, one (ST_a) being methanol-soluble and active in neonatal piglets and infant mice but inactive in weaned pigs, and the other (ST_b) being methanol-insoluble and active in weaned pigs but inactive in infant mice. Recently, we[2-4] isolated two kinds of ST_a (designated as ST_h and ST_p) in pure form from human strains SK-1 and 18D of ETEC, respectively. These ST_a's, which were active in suckling mouse assay, were found to have the amino acid sequences shown in Fig. 1. Slightly before our description,[4] Chan and Giannella[5] reported the amino acid sequence of an ST from ETEC strain 18D to be as shown in Fig. 1. The amino acid sequence of ST_p determined by us was very similar to that of ST proposed by Chan and Giannella,[5] but differed in two residues at positions 11 and 18 from the N-terminus, although we[4] isolated and purified ST_p from the same strain, ETEC 18D, that Chan and Giannella[5] used. To elucidate these discrepancy, we[6] synthesized ST_p and ST with the amino acid sequences proposed by us[4] and Chan and Giannella,[5] respectively, and confirmed that the former had the same biological and physicochemical properties as native ST_p isolated from ETEC strain 18D. Lallier *et al.*[7,8] and Ronnberg *et al.*[9] also purified ST produced by a porcine strain F11 (P155) and human strain C57/26C2 of ETEC, respectively, and reported their amino acid sequences to be as illustrated in Fig. 1. Their amino acid sequences were identical with that of ST_p from ETEC strain 18D determined by us.[4]

These toxins have great structural similarity, although the sequences of their N-terminal regions differ. The sequences from the Tyr residue near the N-terminus to the Tyr residue at the C-terminus are identical, except at the 4th residue from the C-terminus, although the sequence of toxin proposed by Chan and Giannella[5] also differs at the 11th and 18th residues. Six half-cystine residues are conserved in the same positions and intramolecularly linked by disulfide bonds, suggesting that these toxins have similar molecular conformations, although the

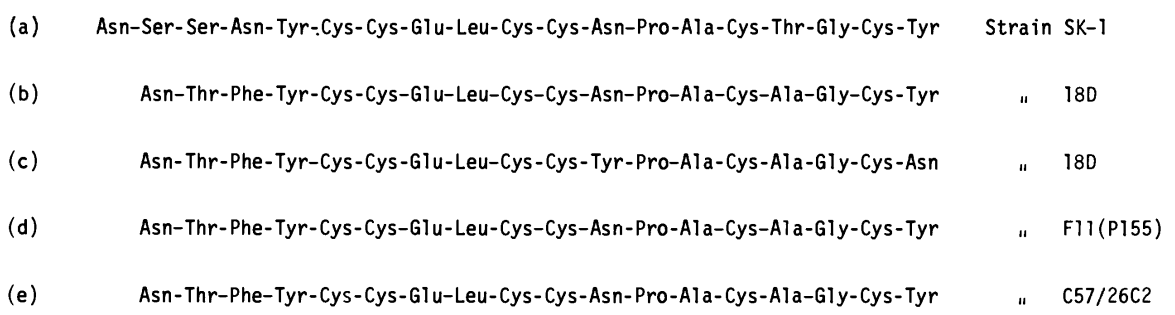

Fig. 1. Comparison of amino acid sequences of ST: (a) ST_h isolated from ETEC strain SK-1, reported in Ref. 3); (b) ST_p isolated from ETEC strain 18D by us;[4] (c) an ST isolated from ETEC strain 18D by Chan and Giannella;[5] (d) an ST isolated from a porcine strain (F11(P155)) of ETEC, reported in Ref. 8); (e) an ST isolated from ETEC strain C57/26C2, reported in Ref. 9).

positions of the disulfide linkages have not yet been determined. Moreover, ST_h and ST_p have the same activities in suckling mouse assay[3,4] and their activity is neutralized by homologous and heterologous *anti*-ST_p and *anti*-ST_h antisera.[10] These findings imply that the common region of the primary structures of these toxin molecules is important for their biological activity and heat-stability.

This paper reports the chemical syntheses of shorter peptides of ST_p, which constitute the common primary sequence of these toxins, but without N-terminal 3 and 4 amino acid residues, respectively, of the N-terminal sequence of ST_p. The preparation of shorter peptides of ST_p by stepwise Edman-degradation of ST_p is also described. Synthetic shorter peptides of ST_p (ST_p (4—18) and ST_p (5—18)) were confirmed to have the same properties as the peptides derived from ST_p by Edman-degradation and to have almost the same biological activities as native and synthetic ST_p. Interestingly, synthetic ST_p (5—18) was more heat-stable than native ST_p.

Experimental

The general experimental and analytical methods used were described in the preceding paper.[6] The abbreviations used in this paper are those recommended by the IUPAC-IUB: *J. Biol. Chem.*, **247**, 977 (1972). Additional abbreviations are: MBzl, *p*-methylbenzyl; TFA, trifluoroacetic acid; DMF, *N,N*-dimethylformamide; TEA, triethylamine.

Boc-Tyr-Cys(MBzl)-Cys(MBzl)-OMe (1). Boc-Cys(MBzl)-Cys(MBzl)-OMe[11] (21.9 g, 40 mmol) was dissolved in TFA (40 ml), stirred at room temperature for 30 min and concentrated to a syrup under reduced pressure. The syrup was mixed with dioxane containing 1 equiv of HCl and concentrated under reduced pressure to a syrup, which was dissolved in DMF (80 ml). Meanwhile, Boc-Tyr-N_2H_3 (13.0 g, 44 mmol) was dissolved in DMF (80 ml), cooled below −20 °C and mixed with 4.39 M HCl (1M=1 mol dm^{-3}) in dioxane (9.1 ml). The solution was stirred with isopentyl nitrite (6.5 ml, 50 mmol) at the same temperature for 35 min and then mixed with the above DMF solution and TEA (20.1 ml). The mixture was stirred at 0 °C for 2 d in a refrigerator. The resulting precipitate was filtered off and the filtrate was concentrated to an oil under reduced pressure. The oil was dissolved in AcOEt and washed successively with 0.1 M HCl, 5% aq $NaHCO_3$ and water. The washed solution was dried over anhydrous Na_2SO_4 and concentrated to a solid under reduced pressure. The solid was crystallized from a mixture of AcOEt, MeOH and hexane; wt 26.0 g (91.6%), mp 160—161 °C, $[\alpha]_D^{23}$ −39.2° (*c* 1.0, DMF).

Found: C, 62.45; H, 6.59; N, 5.72; S, 9.05%. Calcd for $C_{37}H_{47}O_7N_3S_2$: C, 62.61; H, 6.68; N, 5.92; S, 9.02%.

Boc-Tyr-Cys(MBzl)-Cys(MBzl)-N_2H_3 (2). Compound **1** (17.8 g, 25 mmol) was dissolved in a mixture of DMF (50 ml) and MeOH (300 ml). The solution was cooled in an ice-bath, mixed with 100% hydrazine hydrate (50 ml), and then stirred at room temperature for 2 h. The solution was concentrated under reduced pressure and the residue was mixed with water. The solid formed was collected and recrystallized from MeOH and ether; wt 17.0 g (95.5%), mp 194—195 °C, $[\alpha]_D^{23}$ −16.2° (*c* 1.0, DMF).

Found: C, 60.68; H, 6.53; N, 9.76; S, 8.95%. Calcd for $C_{36}H_{47}O_6N_5S_2$: C, 60.91; H, 6.68; N, 9.87; S, 9.02%.

Boc-Tyr-Cys(MBzl)-Cys(MBzl)-Glu(OBu^t)-Leu-OEt (3). Compound **2** (14.2 g, 20 mmol) was dissolved in DMF (100 ml), cooled to −20 °C, and mixed with 4.39 M HCl in dioxane (2.95 ml). The solution was stirred with isopentyl nitrite (2.86 ml, 22 mmol) at the same temperature for 20 min and then mixed with H-Glu(OBu^t)-Leu-OEt·HCl[11] (8.4 g, 22 mmol) and TEA (21.2 ml). The mixture was stirred at 0 °C for 4 d in a refrigerator. The precipitate formed was filtered off and the filtrate was concentrated to an oil under reduced pressure. The oil was dissolved in AcOEt and washed successively with 0.1 M HCl, 5% aq $NaHCO_3$ and water. The washed solution was dried over anhydrous Na_2SO_4 and concentrated under reduced pressure. The residue was crystallized from AcOEt and hexane; wt 19.0 g (93.1%), mp 153 °C (sintered) and 173 °C (melted), $[\alpha]_D^{23}$ −21.2° (*c* 0.5, DMF).

Found: C, 62.27; H, 7.49; N, 6.83; S, 6.20%. Calcd for $C_{53}H_{75}O_{11}N_5S_2$: C, 62.27; H, 7.40; N, 6.85; S, 6.26%.

Boc-Tyr-Cys(MBzl)-Cys(MBzl)-Glu(OBu^t)-Leu-N_2H_3 (4). Compound **3** (18.4 g, 18 mmol) was dissolved in EtOH (200 ml) and mixed with 100% hydrazine hydrate (40 ml) in an ice-bath. The mixture was stirred at room temperature for 4.5 h. The solution was concentrated under reduced pressure to a solid, which was collected with water. The crude material was crystallized from DMF and ether; wt 15.3 g (83.1%), mp 223 °C (decomp), $[\alpha]_D^{23}$ −11.6° (*c* 0.5, DMF).

Found: C, 59.38; H, 6.89; N, 9.46; S, 6.37%. Calcd for $C_{51}H_{73}O_{10}N_7S_2 \cdot H_2O$: C, 59.69; H, 7.37; N, 9.56; S, 6.24%.

Boc-Tyr-Cys(MBzl)-Cys(MBzl)-Glu(OBu^t)-Leu-Cys(MBzl)-Cys(MBzl)-Asn-Pro-Ala-Cys(MBzl)-Ala-Gly-Cys(MBzl)-Tyr-OBzl (5). Boc-Cys(MBzl)-Cys(MBzl)-Asn-Pro-Ala-Cys(MBzl)-Ala-Gly-Cys(MBzl)-Tyr-OBzl[6] (3.22 g, 2.0 mmol) was dissolved in TFA (40 ml), stirred at room temperature for 50 min, and then concentrated under reduced pressure. Meanwhile, compound **4** (2.42 g, 2.4 mmol) was dissolved in DMF 14 ml, cooled below −20 °C, and mixed with 4.39 M HCl in dioxane (4.2 ml). The mixture was stirred with isopentyl nitrite (0.35 ml, 2.7 mmol) at the same temperature for 20 min and then mixed with the above residue and TEA (2.87 ml). The mixture was stirred at 0 °C for 2 d in a refrigerator. The precipitate formed was filtered off and the filtrate was concentrated to a solid under reduced pressure. The solid was washed with 0.1 M HCl and water and crystallized first from DMF and ether and then from DMF and EtOH; wt 4.40 g (88.5%), mp 231 °C (decomp), $[\alpha]_D^{23}$ −37.5° (*c* 0.32, DMF). Amino acid ratio in the acid hydrolysate: Asp, 1.05 (1); Glu, 1.05 (1); Pro, 1.00 (1); Gly, 0.98 (1); Ala, 2.00 (2); Leu, 1.02 (1); Tyr, 2.18 (2).

Found: C, 61.54; H, 6.85; N, 9.10; S, 7.60%. Calcd for $C_{128}H_{164}O_{23}N_{16}S_6$: C, 61.82; H, 6.65; N, 9.01; S, 7.72%.

Boc-Cys(MBzl)-Cys(MBzl)-Glu(OBu^t)-Leu-Cys(MBzl)-Cys-MBzl)-Asn-Pro-Ala-Cys(MBzl)-Ala-Gly-Cys(MBzl)-Tyr-OBzl (6). This compound was synthesized as described previously.[6] Amino acid ratio in the acid hydrolysate: Asp, 1.06 (1); Glu, 1.00 (1); Pro, 1.07 (1); Gly, 1.00 (1); Ala, 2.02 (2); Leu, 1.01 (1); Tyr, 0.97 (1).

Removal of Protecting Groups and Air-oxidation: Protecting groups of compounds **5** and **6** were removed by treatment with anhydrous liquid hydrogen fluoride[12] and the deprotected peptides in dilute solution (5×10^{-5} M) were air-oxidized at pH 8.0, as described previously.[6]

Edman-degradation: Synthetic ST_p (1-18)[6] (1.4 mg, 0.7 μmol) was dissolved in 50% aq pyridine (300 μl). The solution was adjusted to pH 9.5 by the addition of *N*-methylmorpholine and mixed with phenyl isothiocyanate (30 μl). The mixture was kept at 40 °C for 1 h under a stream of nitrogen. The excess reagent used was removed by three washings with benzene (1 ml) and the aqueous layer was lyophilized. The residue was treated with a few drops of TFA at 40 °C for 20 min. TFA was removed under a stream of nitrogen and the residue was dissolved in water

(200 μl) and washed three times with AcOEt (0.5 ml). The aqueous layer was lyophilized. The lyophilized material was purified by HPLC, as described below, and the purified material was degraded by the Edman method under similar conditions to those described above.

Ion-exchange Chromatography: Ion-exchange chromatography of synthetic peptides was performed on a column (2×33 cm or 1.6×25 cm) of DEAE-Sephadex A-25 (acetate form). The material adsorbed on the ion-exchanger was eluted with a linear-gradient of 0 to 0.5 M acetic acid.

High-performance Liquid Chromatography (HPLC): HPLC was performed on a hand-made column (8×300 mm) packed with LiChrosorb RP-8 (Merck, 5 μm particle size) and on a YMC packed column ODS AM-312 (6×150 mm) (Yamamura Chemical Laboratory Co. Ltd., Kyoto, 5 μm particle size) for semipreparative separation and for analysis, respectively. LiChrosorb RP-8 was equilibrated with 0.01 M ammonium acetate (pH 5.7) containing 10% acetonitrile as an organic modifier. YMC packed column was equilibrated with 0.05% TFA (pH 2.2) containing 10% acetonitrile. Both columns were developed at a flow rate of 1 ml/min with a linear-gradient of 10% to 30% acetonitrile.

Biological Assay: ST activity was assayed in suckling mice of 2—4 d old, as described previously.[2] The minimum toxic activity, designated as 1 mouse unit, was the amount of peptide causing sufficient fluid accumulation in the intestine of the test animal to give a weight ratio of the entire intestine to that of the rest of the body of over 0.09.

Heat-stability: Synthetic peptides were tested for heat-stability with analysis by HPLC as described previously.[6]

Results and Discussion

Syntheses of ST_p (4–18) and ST_p (5–18). Two kinds of heat-stable enterotoxins (ST_h and ST_p) active in suckling mouse were isolated from various strains of ETEC and their amino acid sequences were determined by us[2-4] and others.[5,7-9] These toxins have the same sequence from the Tyr residue near the N-terminus to the C-terminal Tyr residue, except for the 4th residue from the C-terminus, as illustrated in Fig. 1, suggesting that this common sequence is important for their biological activity. On the other hand, we[6] recently obtained ST_p from a chemically synthesized linear peptide with the whole amino acid sequence proposed by us.[4] Since this synthetic ST_p had the same biological and physicochemical properties as native ST_p, it seemed to have the same structure, including disulfide linkages, as native ST_p, although the positions of the three disulfide linkages in ST_p have not yet been determined. Because of the structural similarities of ST_h and ST_p, we attempted to synthesize shorter peptides of ST_p covering the common sequence of the toxin, by the same procedure as that used for synthesis of ST_p. Protected pentadeca- and tetradecapeptides (**5** and **6**) were synthesized by similar procedures to those described previously[6] and then treated with anhydrous liquid hydrogen fluoride[12] to remove all the protecting groups. Then dilute solutions (5×10^{-5} M) of the linear peptides with free thiol groups were air-oxidized at pH 8.0 under similar conditions to those described previously.[6] Toxic peptides were isolated from the air-oxidized solution by successive ion-exchange chromatography (Figs. 2 and 3) and HPLC (Figs. 4 and 5). The purified peptides, ST_p (4—18) and ST_p (5—18), were ob-

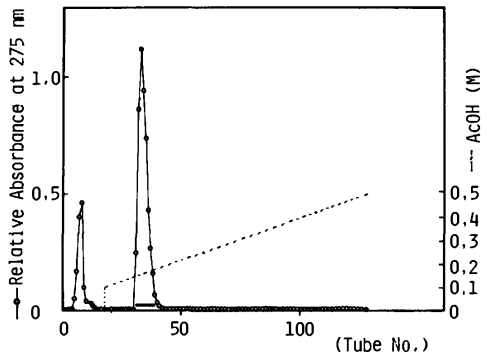

Fig. 2. Chromatography on DEAE-Sephadex A-25 of deprotected and air-oxidized material from compound **5**. Fractions indicated by a horizontal bar showed toxicity and were collected. Column size: 1.3×16.5 cm; fractionation size: 4.5 ml/tube; flow rate: 45 ml/h.

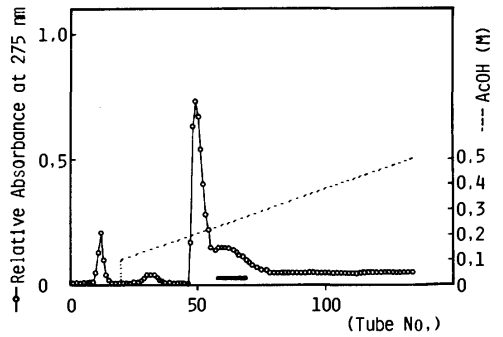

Fig. 3. Chromatography on DEAE-Sephadex A-25 of deprotected and air-oxidized material from compound **6**. The toxic fractions shown by a horizontal bar were collected. Column size: 1.6×25 cm; fractionation size: 4.5 ml/tube; flow rate: 20 ml/h.

tained in about 6.0% and 10.9% yield from the protected peptides **5** and **6**, respectively.

Preparation of Shorter Peptides of ST_p by Stepwise Edman-degradation. To examine whether synthetic shorter peptides of ST_p (ST_p(4—18) and ST_p(5—18)) were intramolecularly linked by the disulfide bonds in the same way as in native ST_p, we degraded synthetic ST_p (1—18),[6] which has the same biological and physicochemical properties as native ST_p and therefore seems to have the same disulfide linkages as the latter, by the Edman method. Peptides lacking one to four amino acid residues from the N-terminus of ST_p-(1—18) were purified on a semipreparative column of HPLC. The purities of the isolated peptides was confirmed by analytical HPLC, as illustrated in Figs. 6b—e. Removal of N-terminal hydrophilic amino acid residues Asn and Thr from the 1st and 2nd positions of ST_p increased the retention times of the degraded peptides ST_p (2—18) and ST_p (3—18) on HPLC. Further removal of the hydrophobic amino acid residues Phe and Tyr from the 3rd and 4th positions of ST_p gave shorter peptides, ST_p (4—18) and ST_p (5—18), which were eluted earlier than ST_p (1—18). ST_p (1—18) and the degraded peptides were eluted separately from a YMC ODS-column, as shown in Fig. 6f. The recoveries of the degraded peptides in Edman-degradation were 52—56%.

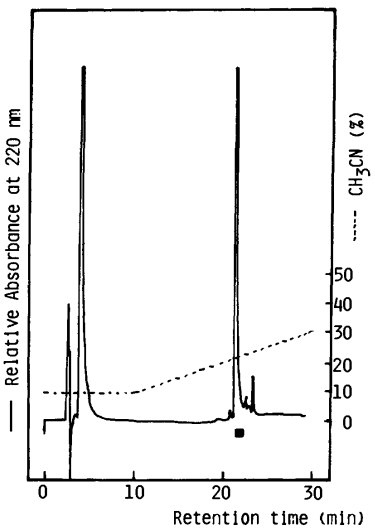

Fig. 5. Semipreparative HPLC on a LiChrosorb RP-8 (5 μm, 8×300 mm) of the fraction shown by a horizontal bar in Fig. 3.

Identification of Synthetic and Edman-degraded Peptides. *i) Amino Acid Analyses*: The amino acid compositions of synthetic peptides (ST_p (4—18) and ST_p (5—18)) and the Edman-degraded peptides (ST_p-(2—18) to ST_p (5—18)) are summarized in Table 1. The results indicate that the N-terminal amino acid residues of ST_p (1—18) were removed stepwise by Edman-degradation.

ii) Mass Spectra: Synthetic and Edman-degraded peptides were subjected to FAB mass spectrometry. As shown in Fig. 7, synthetic ST_p (4—18) and ST_p (5—18), like the Edman-degraded peptides (ST_p(4—18) and ST_p-(5—18)), gave intense signals at m/z=1609 and 1446. The results indicated that the molecular weights of synthetic ST_p (4—18) and ST_p (5—18) were 1608 and 1445, respectively, and hence that these synthetic peptides were intramolecularly linked by three disulfide bonds.

iii) HPLC: The synthetic peptides (ST_p (4—18) and ST_p (5—18)) were coeluted with the respective peptides prepared by the Edman method from LiChrosorb RP-8,

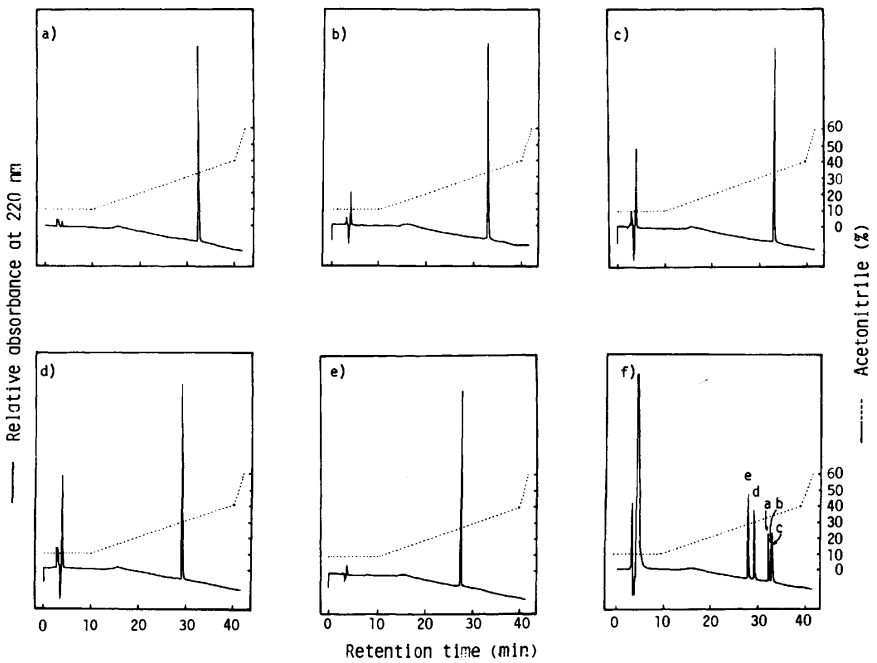

Fig. 6. HPLC profiles on a YMC ODS-column (6×150 mm) of shorter peptides of ST_p prepared by Edman-degradation: a) The starting peptide ST_p (1-18), b) ST_p(2-18), c) ST_p(3-18), d) ST_p(4-18), e) ST_p(5-18), and f) a mixture of a), b), c), d), and e).

Table 1. Amino acid compositions of synthetic peptides and Edman-degraded peptides of ST_p

	Synthetic peptides			Edman-degraded peptides			
	ST_p	ST_p[4-18]	ST_p[5-18]	ST_p[2-18]	ST_p[3-18]	ST_p[4-18]	ST_p[5-18]
Asp	2.00(2)	1.08(1)	1.08(1)	1.03(1)	1.02(1)	1.03(1)	1.04(1)
Thr	1.00(1)			0.95(1)			
Glu	1.11(1)	1.03(1)	1.05(1)	1.01(1)	1.01(1)	1.02(1)	1.06(1)
Pro	1.07(1)	1.22(1)	1.25(1)	0.93(1)	1.09(1)	1.06(1)	0.97(1)
Gly	0.99(1)	1.02(1)	1.02(1)	1.02(1)	0.99(1)	1.04(1)	1.03(1)
Ala	2.00(2)	2.00(2)	2.00(2)	2.00(2)	2.00(2)	2.00(2)	2.00(2)
1/2 Cys	5.25(6)	5.44(6)	5.05(6)	5.16(6)	5.16(6)	5.26(6)	5.18(6)

Tyr	1.86(2)	2.05(2)	0.91(1)	1.95(2)	1.95(2)	1.95(2)	0.98(1)
Phe	0.98(1)			0.97(1)	0.94(1)		

Values were calculated as mol/mol of Ala; numbers in parentheses indicate theoretical values.

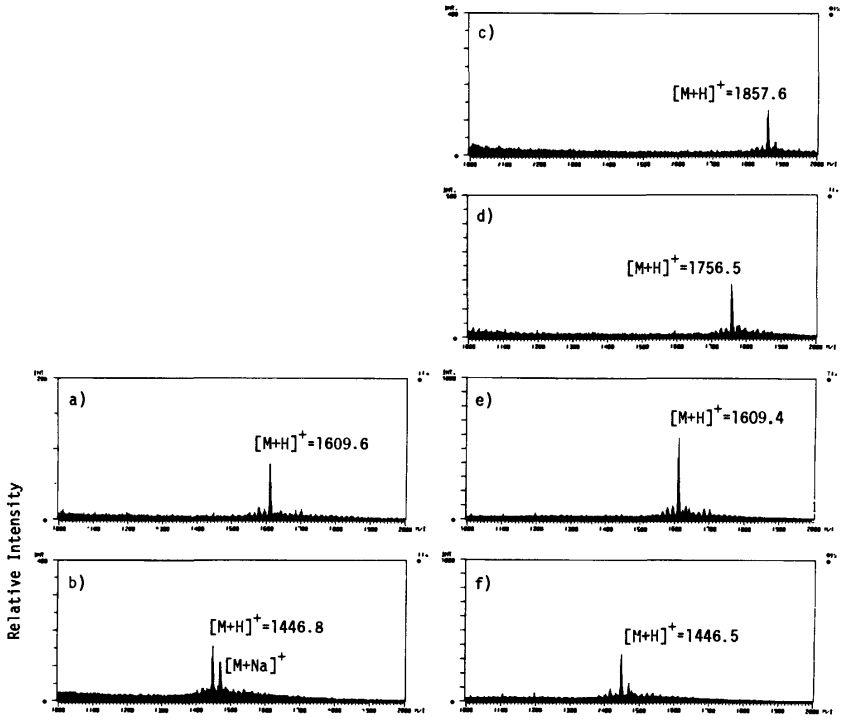

Fig. 7. Positive FAB mass spectra: (first column) synthetic peptides a) ST_p(4–18), b) ST_p(5–18); (second column) Edman degraded peptides c) ST_p(2–18), d) ST_p(3–18), e) ST_p(4–18), and f) ST_p(5–18).

as shown in Fig. 8. These results indicated that the synthetic ST_p (4—18) and ST_p (5—18) were intramolecularly linked by three disulfide bonds in the same positions as in native ST_p.

Biological Activities of Synthetic and Edman-degraded Peptides. The synthetic peptides (ST_p (4—18) and ST_p (5—18)) and Edman-degraded peptides (ST_p (2—18), ST_p (3—18), ST_p (4—18), and ST_p (5—18)) were assayed by the fluid accumulation test using suckling mice.[2] As seen in Table 2, these shorter peptides of ST_p all showed toxicity at a dose of about 1.5—2 ng, which was almost the same value as that of native and synthetic ST_p. Thus the sequence from the Tyr residue near the N-terminus to the C-terminal Tyr residue, which is the same in ST_h and ST_p, except for the 4th residue from the C-terminus, had the same biological

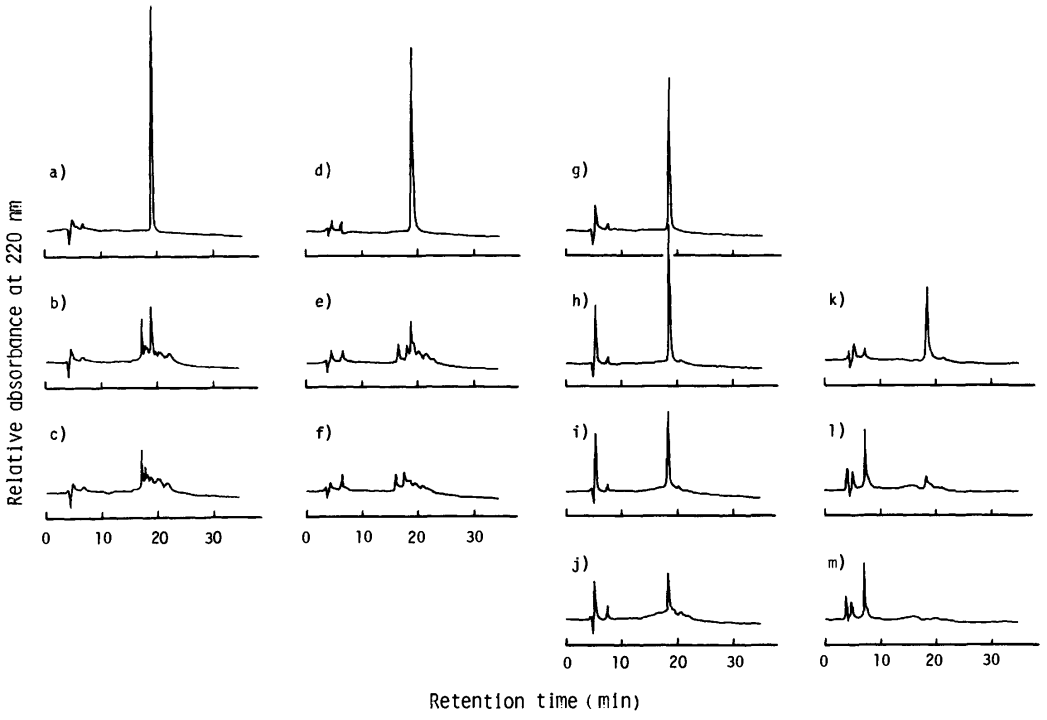

Fig. 9. Comparison of heat-stabilities of synthetic ST_p(1-18) and its shorter peptides: (first column) synthetic peptide ST_p(1-18) a) untreated, b) after 10 min at 100 °C, c) after 30 min at 100 °C; (second column) synthetic ST_p(4–18) d) untreated, e) after 10 min at 100 °C, f) after 30 min at 100 °C; (third and fourth columns) synthetic ST_p(5–18) g) untreated, h) after 10 min at 100 °C, i) after 30 min at 100 °C, j) after 60 min at 100 °C, k) after 10 min at 120 °C, l) after 30 min at 120 °C, and m) after 60 min at 120°C.

activity as that of the whole sequence in ST_p. The results also show that the Tyr residue at the 4th position of ST_p was not necessary for expression of toxicity.

Furthermore, the toxicity of the synthetic and Edman-degraded peptides was found to be neutralized by anti-native ST_p antisera,[10] as shown in Table 2. These results suggest that the three dimensional structure from the Cys residue near the N-terminus to the C-terminal Tyr residue, including the three disulfide linkages, is extremely important for the expression of the toxicity of ST_p, because the reductive cleavage of disulfide linkages destroys the toxicity of the toxin. If the receptor for ST_p is on the epithelial cell membrane in the intestine, the site for binding of ST_p to the receptor may be located in this three dimensional structure. Studies on this possibility are now in progress.

Heat-stabilities of Synthetic Peptides ST_p (4—18) and ST_p (5—18). The name "heat-stable" is based on

the observation[14,15] that the toxicity of this toxin is not lost on heating the toxin for 30 min in boiling water. Recently we[6,13] found that the heat-stability of the toxin can be examined by HPLC. By this HPLC procedure, we compared the heat-stabilities of synthetic ST_p-(4—18) and ST_p (5—18) with that of synthetic ST_p (1—18). ST_p (4—18) showed similar stability to ST_p (1—18) under the conditions examined, as illustrated in Figs. 9a—f. On the other hand, ST_p (5—18) was found to be more stable than ST_p (4—18) and ST_p (1—18) and after heating in boiling water for 60 min, about half its peak height was retained, as shown in Figs. 9g—j, whereas on similar treatment synthetic ST_p (1—18) and ST_p-(4—18) were almost completely destroyed. The HPLC profiles of ST_p (5—18) treated at 120 °C (Figs. 9k—m) were similar to those of ST_p (1—18) and ST_p (4—18) boiled at 100 °C. ST_p (5—18) was completely destroyed by treatment for 60 min at 120 °C. Thus, removal of the four N-terminal amino acid residues, especially the 4th Tyr residue, increased the heat-stability of the toxin. The enhanced structural stability of ST_p (5—18) may be due to decreased perturbation of the molecule on heating as a result of the absence of the N-terminal sequence.

This work was partly supported by a Grant-in-Aid for Scientific Research No. 58122002 from the Ministry of Education, Science and Culture.

Manufacture of Pure Titanium(IV) Oxide by the Chloride Process. III. Precipitation of Hydrous Titanium(IV) Oxide in Hydrochloric Acid Solution at Elevated Temperatures

Eiichi NARITA,* Hitoshi TAKEUCHI, Naoto HORIGUCHI, and Taijiro OKABE
Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980
(Received June 10, 1983)

Thermal hydrolysis of titanium(IV) in hydrochloric acid solutions (0.2 mol dm^{-3} in Ti(IV); 2 mol dm^{-3} in HCl) was carried out at temperatures up to 110 °C to investigate the effects of heating rate, heating temperature, aging time, and coexisting ions on the particle shape, size, crystal form, crystalline size, and content of water of the hydrous titanium(IV) oxide precipitated. The resulting polycrystalline particles having rutile structure were all distorted ellipsoids at the beginning of the hydrolysis, and gradually changed to spheres with rising temperature or with the duration of time. However, no effects of heating rate on the particle shape and size distribution were observed at the beginning of the hydrolysis. On the other hand, the precipitation rate of titanium(IV) measured at a constant temperature remarkably depended on the temperature; marked changes in the particle size distribution and mean particle size were observed during the reaction. The precipitation rate was well expressed by the rate equation based on the rate-determining step of the surface chemical reaction. The apparent activation energy was 111 kJ mol^{-1}. Although no effects of coexisting cations such as iron(III) and aluminium(III) were recognized, the presence of sulfate and fluoride ions significantly affected the particle shape and size of such precipitates. Anatase-type hydrous titanium(IV) oxide consisting of spherical particles of narrow size distribution was also obtained in the presence of fluoride ion.

As a new manufacturing process of titanium(IV) oxide, the authors previously proposed the Chloride Process,[1,2] in which both production of titanium(IV) oxide and recovery of iron compounds in higher state of purity were expected. This process is based on the leaching of ilmenite ore in concentrated hydrochloric acid solutions and on the selective recovery of titanium(IV) and iron(III) from the resulting leach liquor by solvent extraction with tributyl phosphate (TBP). In this process, ilmenite ore, which occurs abundantly in nature, can be used. The other important feature is that using hydrochloric acid as the leachant allows easier recovery of useful free acid from its waste solution than using sulfuric acid does.[3-5] The kinetics of leaching of ilmenite ore[1] and the solvent extraction of titanium(IV) and iron(III) using TBP[2] have been already studied. As the third unit process for producing hydrous titanium(IV) oxide from the back-extracted solution containing titanium(IV), the thermal decomposition[5,6] or the thermal hydrolysis[7,8] can be useful. In the conventional manufacturing process, *i.e.*, the sulfate process, thermal hydrolysis is extensively used.[9]

It is generally known that the rutile-type hydrous titanium(IV) oxide is produced in hydrochloric acid solutions by the thermal hydrolysis.[10] Recently Matijević *et al.*[11,12] also studied the thermal hydrolysis of titanium(IV) in hydrochloric acid solutions to clarify the optimum conditions for the preparation of titanium(IV) oxide hydrosol of narrow size distribution. On the other hand, the effect of various additives such as NO_3^-, Cl^-, SO_4^{2-}, and F^- ions on the crystal structure of the resulting hydrous titanium(IV) oxide was also investigated in the hydrolysis of titanium(IV) chloride,[7,10] in the aerial oxidation of titanium(III) chloride,[13] and in the hydrothermal treatment of amorphous titanic acid.[14] In addition, from the viewpoint of the kinetics of the hydrolysis[8] and of the mechanism of the particle growth,[15] the thermal hydrolysis of titanium(IV) chloride has been investigated. However, in the course of our development of the Chloride Process, further information about the factors influencing the particle properties of the hydrous titanium(IV) oxide precipitated by the thermal hydrolysis of titanium(IV) in hydrochloric acid solutions was necessary. This study will deal with the effect of process variables such as heating rate, heating temperature, aging time, and coexisting ions on the particle shape, size, crystal form, crystalline size, and content of water of the precipitates. The relation between the particle growth behavior and the precipitation rate of titanium(IV) was also investigated.

Experimental

Reagents. Commercial extra-pure titanium(IV) chloride (Wako Pure Chem. Ind., Ltd.) was purified by distillation at 61 °C and 64 mmHg (1 mmHg≈133.322 Pa) before being used. The titanium(IV) chloride stock solution was prepared by dissolving a 25 cm^3 portion of the distillate in 200 cm^3 analytical grade concentrated hydrochloric acid (Wako Pure Chem. Ind., Ltd.) and then by filtrating through a 0.66 μm teflon millipore filter to remove insoluble materials as impurities. The reaction solution used in the experiment was prepared by diluting the stock solution with hydrochloric acid solution. Additive ions were previously added as sodium salts in the case of anion and as chloride in the case of cation to the hydrochloric acid solution. All other reagents were of the highest purity grade available.

Procedure. Hydrochloric acid solution containing titanium(IV) (0.2 mol dm^{-3} in Ti(IV); 2 mol dm^{-3} in HCl) was transferred in a Vitro Dynamics rectangular parallelepiped microslide (inner size: 0.3 mm×3.0 mm×50 mm) and then both ends of the slide were sealed using epoxy resin adhesive. After this procedure, the slide was heated in the small-sized silicone oil bath equipped with a Sinku Riko HPC-5000 thermal program controller for the hydrolysis of titanium(IV). The oil bath was designed to allow us to observe the precipitation behavior of titanium(IV) in the

slide. After the lapse of a fixed time, the slide was taken out and rapidly quenched to room temperature. Subsequently, the slide was destroyed and the precipitate which had formed on the inner side of the slide was washed with 2 mol dm^{-3} hydrochloric acid and distilled water, and then dried over diphosphorus pentaoxide under reduced pressure. As an experiment to measure the precipitation rate of titanium(IV), the thermal hydrolysis was similarly carried out using a cylindrical glass sealed tube (36 cm^3 in volume). The resulting suspension was first quenched and then centrifuged. The supernatant solution was withdrawn to analyze for titanium ion. The percentage precipitation of titanium(IV) was calculated from the titanium ion concentrations in solution before and after the hydrolysis. The precipitate was washed and dried by the procedures described above.

Analysis. The observation of the particle shape and the measurement of the particle size distribution of the precipitate were performed using a Hitachi-Akashi MSM 4C-102 Scanning Electron Microscope. The X-ray diffraction patterns were obtained using a Rigaku Denki Geigerflex 2013 with Ni filtered Cu $K\alpha$ radiation, with 30 kV and 10 mA. The crystalline size of the precipitate was obtained by the line-broadening method,[16] based on the half-value width of X-ray diffraction peaks of 2θ=27.42° (110) for the rutile and of 2θ=25.28° (101) for the anatase, respectively. DTA and TG were obtained using a Rigaku Denki Thermoflex over the range from room temperature to 1200 °C. The rate of temperature rise was 10 °C min^{-1}. The concentrations of titanium ion and hydrochloric acid were analyzed by colorimetric method[17] and neutralization, respectively.

Results and Discussion

Effect of Heating Rate. Hydrochloric acid solution containing titanium(IV) was heated from room temperature with the heating rates of 0.2, 1.0, and 2.0 °C min^{-1}. The turbidity point is defined here as the temperature at which turbidity was observed in the solution by the hydrolysis of titanium(IV). The turbidity points observed were 77, 87, and 97 °C, respectively. Scanning electron micrographs of the precipitated particles obtained at the turbidity point or above under the heating rate of 1.0 °C min^{-1} are shown in Fig. 1. The particle shape of the precipitate obtained at the turbidity point was that of a distorted ellipsoid, an aggregate of two or three small particles. As the temperature was raised further, the shape changed to sphericity with an increase in the particle size. A similar result was obtained under the heating rate of 0.2 °C min^{-1}. X-Ray diffraction revealed that all these precipitates were rutile-type hydrous titanium(IV) oxide.

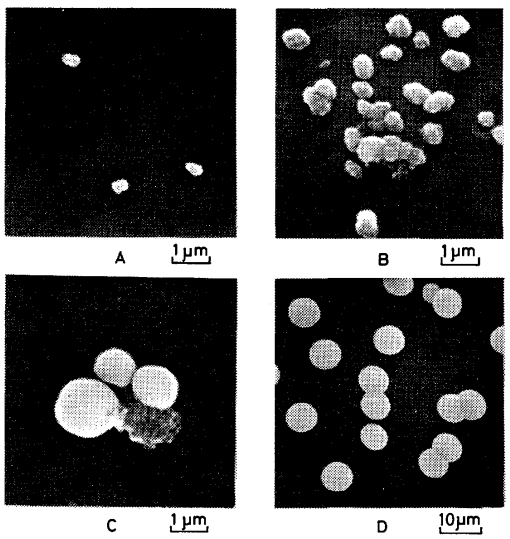

Fig. 1. Scanning electron micrographs of the precipitated particles obtained at different temperatures.
HCl: 2.10 mol dm^{-3}, Ti(IV): 0.230 mol dm^{-3}, heating rate (°C min^{-1})—1.0(A: 87 °C (turbidity point), B: 95 °C, C: 105 °C), 0.2(D: 105°C).

Figure 2 shows the effect of the heating rate on the particle size distribution of the precipitates obtained at the turbidity points. No marked differences can be detected in the distribution histogram and mean particle size, δ. Therefore, it was concluded that the particle shape and size of the hydrous titanium(IV) oxide were not affected by the heating rate. In the experiments conducted in 4 mol dm^{-3} hydrochloric acid, the same results were obtained, except for a rise in the turbidity point of about 10 °C.

Effect of Aging Time. Hydrochloric acid solution containing titanium(IV) was heated at a rate of 1.0 °C min^{-1}, and then maintained at the desired temperatures in all subsequent experiments. Figure 3 shows the effect of the aging time on the particle size distribution at 95 °C. The mean particle size increased with the duration of the aging. The other impressive feature was that the tailing phenomenon was recognized in the distribution histograms after the lapse of 1—3 h and then disappeared after the lapse of 6 h. These precipitates were all spherical in shape, having the rutile structure. The results obtained in the experiments conducted at 88 °C were approximately the same as those described above.

The precipitation rate of titanium(IV) measured at 88, 91, and 95 °C are shown in Fig. 4. A rapid precipitation step was found at 2—4 h for 88 °C, and also at 1—3 h for 95 °C. It is noticeable here that these rapid precipitation steps correspond to the time at which the tailing phenomenon shown in Fig. 3 appeared. The disappearance of the tailing phenomenon at 6 h also seemed

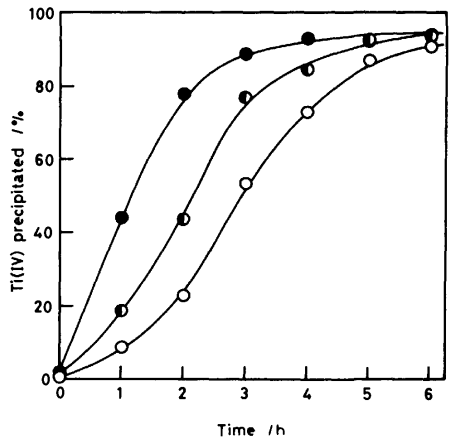

Fig. 4. Effect of temperature on the precipitation rate of Ti(IV) in HCl solution.
HCl: 2.16 mol dm^{-3}, Ti(IV): 0.219 mol dm^{-3}, temperature (°C)—○: 88, ◐: 91, ●: 95.

to be due to the growth of the particles by the dissolution-reprecipitation or by the annexation of small particles on the bigger ones.

Analysis of Particle Growth Rate. The analysis of the particle growth was carried out using the crystal growth theory. This analysis is based on the assumption that nucleation is finished at once in the beginning step of the crystal growth. In the case that the particle growth is limited by the surface chemical reaction, the precipitation rate is written as follows:[18]

$$\frac{dX}{dt} = \alpha X^{2/3}(1-X). \quad (1)$$

Here

$$\alpha = \{36\pi V^2(C_o - C_e)^2 N\}^{1/3} G, \quad (2)$$

where X is the molar fraction of precipitation (−), t the time (h), V the volume per unit molar of precipitate (m^3 kg mol^{-1}), Co the initial solute concentration in bulk solution (kg mol m^{-3}), C_e the solubility of the precipitate (kg mol m^{-3}), N the particle number per unit volume (m^{-3}), and G the transfer coefficient (m h^{-1}). By integration of Eq. 1, Eq. 3 was obtained:

$$\alpha t = \int_0^{X^{1/3}} \frac{3}{1-y^3} dy = I. \quad (3)$$

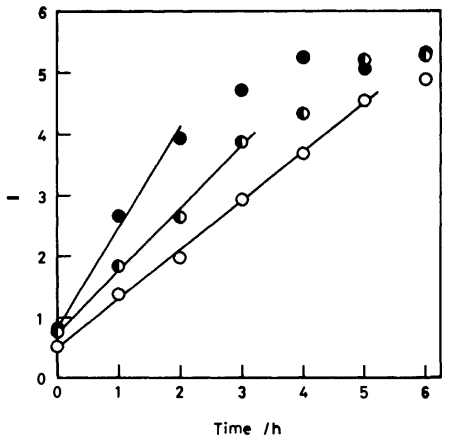

Fig. 5. Effect of temperature on the precipitation rate of Ti(IV) in HCl solution—I *versus* t.
HCl: 2.16 mol dm^{-3}, Ti(IV): 0.219 mol dm^{-3}, temperature (°C)—○: 88, ◐: 91, ●: 95.

Figure 5 shows the relationship between I and t. At 88 °C a good linear dependence of I on t was observed. This means that the precipitation rate of titanium(IV) is well expressed by Eq. 1. The linear dependence was also observed at early steps at 91 and 95 °C. However, there was not a linear relationship between I and t in the precipitation curves after 3 h at 91 °C or after 2 h at 95 °C. This deviation from the rate equation was thought to be dependent on the change in the rate-determining step from the surface chemical reaction process to the diffusion process of titanium(IV). The apparent activation energy calculated from the Arrhenius plots of α, which was given from the slope of the straight lines in Fig. 5, was 111 kJ mol^{-1}. This value indicates the reasonability of the assumption used in this analysis that the particle growth is limited by the surface chemical reaction.

Effect of Coexisting Ions. The effect of sulfate and fluoride ions, both which have stronger complexing ability for titanium(IV) than chloride ion does, on the particle shape, size, crystal form, crystalline size, and content of water of the precipitate was investigated in detail. Scanning electron micrographs of the precipitated particles obtained in the presence of these anions at 95 °C after 6 h are shown in Fig. 6, together with that obtained in the absence of these anions. The precipitated particles were perfectly spherical in shape; X-ray diffraction revealed that crystal form corresponded to rutile-type hydrous titanium(IV) oxide. On the other hand, the particle shape of the precipitate was irregular plate-like in the presence of sulfate ion and slightly distorted spherical in the presence of fluoride ion. The reason for this difference is as yet unclear. The other important feature was that both precipitates were ana-

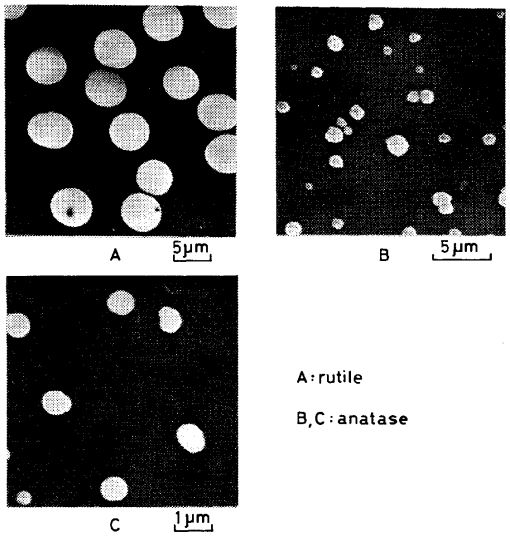

Fig. 6. Scanning electron micrographs of the precipitated particles obtained in the presence of sulfate and fluoride ions.

HCl: 2.13 mol dm^{-3}, Ti(IV): 0.220 mol dm^{-3}, temperature: 95°C, anion added—A: none, B: 0.480 mol dm^{-3} Na_2SO_4, C: 0.112 mol dm^{-3} NaF.

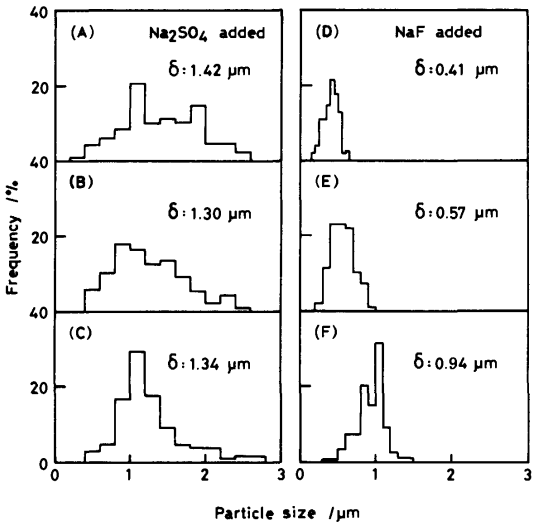

Fig. 7. Effect of coexisting anions on the particle size distribution of the precipitates.
HCl: 2.13 mol dm^{-3}, Ti(IV): 0.220 mol dm^{-3}, temperature: 95 °C, anion added—A—C: 0.480 mol dm^{-3} Na_2SO_4, D—F: 0.112 mol dm^{-3} NaF, Aging time (h)—A,D: 1, B,E: 3, C,F: 6.

tase-type hydrous titanium(IV) oxide; this result agrees with those reported by earlier workers.[7,10,13,14]

The effect of both anions on the particle size distribution is shown in Fig. 7. In the presence of sulfate ion, the distribution was broadened, although the mean particle size became smaller. However, in the presence of fluoride ion, the range of the distribution was extremely narrow, so that the particles can be regarded as monodispersed, whereas the mean particle size became even smaller. Although Matijević *et al.*[11,12] had reported the preparation method of rutile-type titanium(IV) oxide consisting of spherical particles of narrow size distribution, it was found here that a similar result on the formation of anatase-type titanium(IV) oxide could be obtained by the addition of fluoride ion.

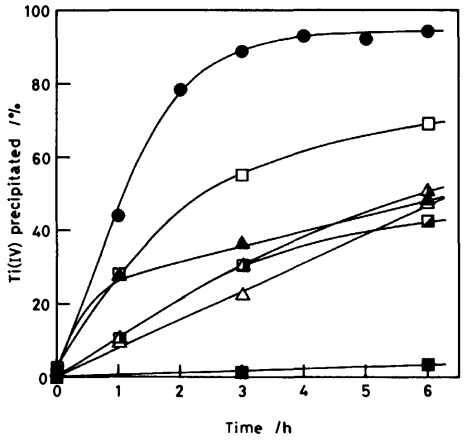

Fig. 8. Effect of coexisting anions on the precipitation rate of Ti(IV) in HCl solution.
HCl: 2.12 mol dm^{-3}, Ti(IV): 0.219 mol dm^{-3}, temperature: 95°C, anion added—None: ● Na_2SO_4 (mol dm^{-3}): △ 0.10, ▲ 0.20, ▲ 0.46, NaF (mol dm^{-3}): □ 0.10, ◪ 0.20, ■ 0.44.

Figure 8 also shows the effect of both anions on the precipitation rate of titanium(IV). In general, the precipitation rate decreased in the presence of these anions. The degree of the decrease in the precipitation rate was correlative with the stability constant of each titanium(IV) complex, as shown below (25 °C):

$$\frac{[TiOCl^+]}{[TiO^{2+}][Cl^-]} = 3.55,^{19} \quad (4)$$

$$\frac{[TiOSO_4]}{[TiO^{2+}][SO_4^{2-}]} = 1.69\times10^2,^{20} \quad (5)$$

$$\frac{[TiOF^+]}{[TiO^{2+}][F^-]} = 2.75\times10^6.^{21} \quad (6)$$

The precipitation rate decreased with increasing the concentration of fluoride ion. The initial precipitation rate oppositely increased with increasing the concentration of sulfate ion. This conflicting result can be explained by the phenomenon that sulfate ion exists mostly as HSO_4^- under the conditions of 90 °C and 2 mol dm^{-3} hydrochloric acid, as can be estimated from the following equation:

$$\frac{[SO_4^{2-}]}{[HSO_4^-]} = 3.97\times10^{-4}.^{23} \quad (7)$$

Namely, the increase in the initial precipitation rate seemed to be due to the actual decrease in acid concentration.

The time changes in the mean particle size of the precipitate obtained at different temperatures in the presence or absence of these anions are shown in Fig. 9. In general, the mean particle sizes increase with the duration of the aging, except in the case of the presence of sulfate ion, and decreased with an increase in the complexing ability of these anions for titanium(IV). It

was also found that the mean particle size increased with an increase in the heating temperature, as shown in Fig. 3, whereas no changes was observed in the case of the presence of sulfate ion.

The effect of coexisting cations such as iron(III) and aluminium(III), which would be contained in the hydrochloric acid leach liquor of ilmenite ore, was also investigated here. With regard to the coprecipitation behavior, about 5% of the initial concentration of iron(III) was incorporated in the hydrous titanium(IV) oxide precipitate, whereas no aluminium(III) was incorporated. Therefore, it is necessary to remove iron(III) from the leach liquor containing titanium(IV) by solvent extraction using TBP before the thermal hydrolysis.[2)]

Figure 10 shows the effect of the coexisting ions on the crystalline size of the precipitates. No changes in the crystalline size were observed in the presence of these cations, although it varied drastically in the presence of anions. Especially in the presence of fluoride ion, the crystalline size became extremely large, and increased with increasing the concentration of fluoride ion. The enlargement in the crystalline size was observed in the fluoride ion concentration of 0.05 mol dm^{-3} or above, whereas time dependences were generally not recognized. On the contrary, the crystalline size became slightly smaller in the presence of sulfate ion.

TG curves of the precipitated particles obtained in the presence or absence of various additional ions are shown in Fig. 11. The rutile-type hydrous titanium(IV) oxides obtained in pure hydrochloric acid solution or in the presence of such cations were found to contain 5—7% of water. The anatase-type hydrous titanium(IV) oxides obtained in the presence of sulfate and fluoride ions indicated that a large weight loss occurred in the heating process. Since the sulfate ion decomposes at temperature higher than 700 °C, most of this weight loss (16—17%) of Sample B can be regarded as the release of water. However, the rapid weight loss of Sample C at about 285 °C corresponded with the close-neighboring peaks of sharp exothermic peak (293 °C) and endothermic peak (300 °C) on the DTA curve. Therefore, this rapid weight loss seemed to be dependent on the formation and sublimation of TiF_4. From these results, the content of F^- ion in the precipitate was calculated as 0.82%. It can be said that the anatase-type hydrous titanium(IV) oxide contains a larger amount of water than the rutile-type one.

The results show that the particle shape, size, crystal form, crystalline size, and content of water of the hydrous titanium(IV) oxide precipitated in hydrochloric acid solution can be controlled in the limited range by varying the heating temperature, aging time, and addition of such anions.

Kinetics and Mechanism of Bromine Addition to Derivatives of Unsaturated Aliphatic Carboxylic Acids in Aqueous Solution

Syed Ahamed Mohamed Farook,† Seshaiyer Viswanathan, and (the late) Ramachandran Ganesan

Department of Physical Chemistry, University of Madras, Madras-600 025, India

(Received December 23, 1982)

This paper deals with the kinetics of bromine addition to unsaturated compounds in presence of added bromide ions at 22, 30, 38, 46, and 54 °C. The substrates used were acrylamide (AAm), methyl acrylate (MA), ethyl acrylate (EA), butyl acrylate (BA), *t*-butyl acrylate (*t*BA), methacrylamide (MAAm), methyl methacrylate (MMA), ethyl methacrylate (EMA), methyl crotonate (MC), and ethyl crotonate (EC). The kinetics was followed potentiometrically. The activation parameters ($\Delta H^{\neq}$, $\Delta S^{\neq}$, and $\Delta G^{\neq}$) were calculated and compared. Estimation of product ratio of bromohydrin to dibromide showed the absence of any correlation of the product formation with reactivity of the substrates. The observed parameters are discussed in relation to the proposed reaction mechanisms.

Although a number of mechanisms have been proposed for the bromination in presence of bromide ions,[1-3] controversy still persists regarding the electrophilic activity of the tribromide species.[2-8] We reinvestigated these mechanisms with the help of kinetic experiments, product analysis and salt effects.

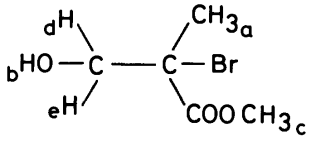
Experimental

Materials. Acrylamide,[9] methacrylamide,[10] and esters[11] were purified. Crotonates were prepared according to the reported procedures.[12] Sodium bromide was recrystallised three times from distilled water, and dehydrated at 120 °C for 5 d and kept in a vacuum desiccator over sodium hydroxide. All other inorganic chemicals used were of guaranteed reagents.

Kinetic Procedures. All the kinetic experiments were carried out by potentiometric method using Pt, Br_2/Br^-, and glass electrodes fitted into a specially fabricated reaction vessel.[13,14]

Analysis of Products. To study the regioselectivity factor mainly by ^1H NMR technique for the substrates, MMA and EMA a slight excess of bromine at various bromide concentrations was employed. After completion of the reaction potassium iodide and then sodium thiosulfate were added to remove unreacted bromine. After saturation with NaCl the products were ether extracted, dried over anhydrous sodium sulfate and then distilled off ether. The remaining liquid was used for analysis by TLC, GC, IR, and ^1H NMR studies, as the case may be.

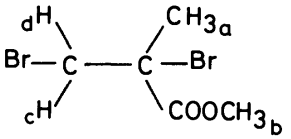
Authentic bromohydrins were prepared[15] and separated by column chromatography. The ^1H NMR spectrum of methyl 2-bromo-3-hydroxy-2-methylpropionate (CCl_4/TMS) showed a singlet (3H, H_a) at δ 1.90, a singlet (1H, H_b) at δ 3.31,



(exchangeable with D_2O), a singlet (3H, H_c) at δ 3.85, and a pair of doublets (2H, $H_{d,e}$) one pair at δ 3.72 and another pair at δ 4.90 resulting from the diastereotropic and hence anisochronous hydrogens on the carbon bearing the hydroxyl group (J_{gem}, 11 Hz). Similarly, the ^1H NMR spectrum of methyl 3-bromo-2-hydroxy-2-methylpropionate (CCl_4/TMS) showed a characteristic singlet at δ 1.49 for 2-methyl group.

† Present address: Department of Cemistry, A. G. C. W., Karaikal, Pondicherry State 609 602, India.

The ^1H NMR spectrum of methyl 2,3-dibromo-2-methylpropionate (CCl_4/TMS) showed a singlet (3H, H_a) at δ 2.0, a singlet (3H, H_b) at δ 3.8 and a pair of doublets (2H, $H_{c,d}$) situated at δ 3.66 and δ 4.19 resulting from the diastereotropic and hence anisochronous hydrogens on the carbon bearing the bromine (J_{gem}, 10 Hz).



Results and Discussion

In each reaction, the emf falls linearly with time (Fig. 1) showing first-order in bromine. The pseudo-first-order rate constants (k_1) were obtained from the slope of the plots.[16] The second-order rate constant, k_2(obsd),

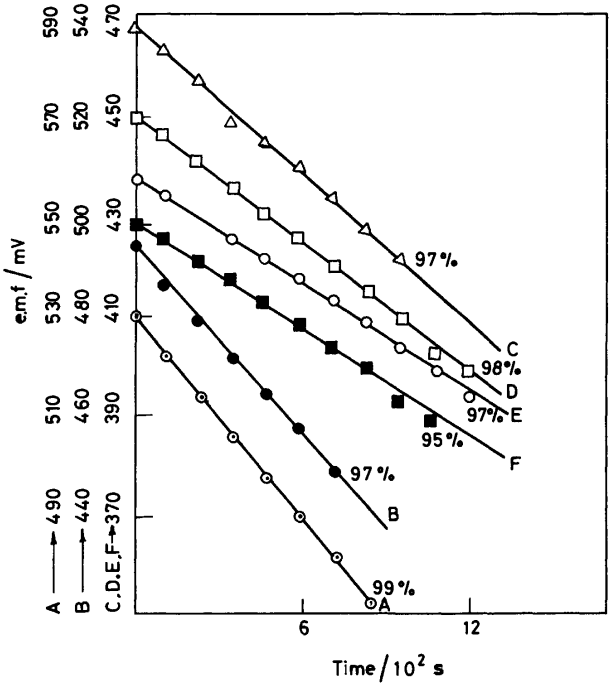


Fig. 1. Pseudo first-order plots for AAm-Br_2 reaction in water at 22 °C. The various $[Br^-]$'s/mol dm^{-3} used are A: 0.01, B: 0.05, C: 0.10, D: 0.20, E: 0.3, F: 0.40. $[AAm]=8.0\times10^{-3}$ mol dm^{-3}, $[Br_2]=6.0\times10^{-5}$ mol dm^{-3}, $[HClO_4]=1.0\times10^{-2}$ mol dm^{-3}.

can be obtained by dividing k_1 by the substrate concentration (S). The constancy in k_2(obsd) values for AAm and MAAm for a variation of the substrate concentration by a factor of 6 indicates the first-order in substrate.

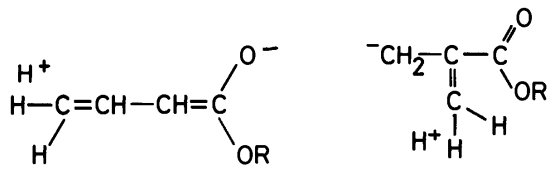
The acids like $HClO_4$, HNO_3, and H_2SO_4 had no effect on the rate constant even for a 100 times variation in concentration thus excluding the contribution of hypobromous acid to reaction. Further, the possibility of the reaction by bromine cation can be neglected in presence of such a high concentration of bromide used. It is therefore reasonable to assume that the reaction may proceed mainly by Br_2 and Br_3^- species. Hence, k_2(obsd), a composite parameter, is given by the equation:[2]

$$k_2(\text{obsd}) = (k_{Br_2} + k_{Br_3^-} K[Br^-])/(1 + K[Br^-]), \quad (1)$$

where k_{Br_2} is the rate constant for the attack by Br_2 species and $k_{Br_2^-}$ for the Br_3^- species; and K, the tribromide formation constant for $Br_2 + Br^- \rightleftharpoons Br_3^-$. Employing least square method for the K values of Scaife and Tyrrell,[17] the values at other required temperatures have been evaluated. Values of k_{Br_2} and $k_{Br_3^-}$ were calculated from the plots of k_2(obsd) $(1 + K[Br^-])$ *vs.* $[Br^-]$ (Fig. 2). Activation parameters were calculated by employing k_{Br_2} and $k_{Br_3^-}$ (Table 1). The values of ΔH^*, ΔS^*, and ΔG^* (at 303 K) are given in Tables 2 and 3.

It is clear from the Table 2 that the ΔH^* values for the methyl-substituted alkenic compounds are lower than that of the corresponding unsubstituted ones. It is evident that the introduction of a methyl group, which causes electron accession to the alkenic linkage by both inductive (+I) and hyperconjugative effects, brings down the activation enthalpy and correspondingly the reaction rate of the methyl-substituted compound increases.

The methacrylic esters react faster than their isomeric crotonates (Table 2). In MMA and EMA, resonance structure-**2** facilitates the retention of the negative charge on the alkenic carbon atom whereas in alkyl crotonates, where the methyl group is present on β-carbon, resonance structure-**1** reduces the electron density on the alkenic carbon atom,



1 2

where R = $-CH_3$ or $-C_2H_5$

When ΔH^* values of all these substrates were compared, it was observed that the activation enthalpy remains almost constant in each of the following sets of

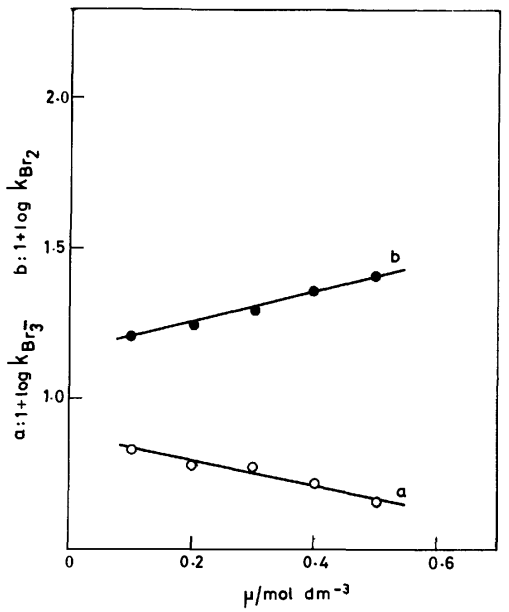

Fig. 3. Effect of ionic strength on k_{Br_2} and $k_{Br_3^-}$ for AAm-Br_2 reaction in water at 30°C.

compounds:
(i) CH_2=CHCOR$_1$; R$_1$=-NH_2, -OBu^t, -OBu, -OEt, -OMe, (ii) CH_2=C(Me)COR$_2$; R$_2$=-NH_2, -OEt, -OMe, and (iii) CHMe=CHCOR$_3$; R$_3$=-OEt, -OMe. In spite of constancy in ΔH^*, the variations in the rate constant for the compounds in each set are reflected in their ΔS^* values (Table 2). That the values of ΔG^* remain more or less constant indicates a similar reaction mechanism operating in these cases.

It was observed that the value of k_{Br_2} increases in much the same manner as does k_2(obsd) with increasing ionic strength (Fig. 3). The observed increase in rate is in accord with Hughes-Ingold theory of solvent action for a reaction in which the transition state is stabilised more than the initial state.[18] While k_{Br_2} increased with increasing ionic strength $k_{Br_3^-}$ decreased (Fig. 3). This trend was observed at all the experimental temperatures in the bromination of substrates such as AAm, MA, and MMA. However, the added $NaNO_3$ does not affect the activation enthalpy of the reaction (Table 2).

It was observed that the ratio (Q) of k_{Br_2} to $k_{Br_3^-}$ is greater for the extra methyl-substituted compounds. For each substrate, Q remains constant at all the experimental temperatures. In the present investigation, a comparison was, therefore, made between the reactivity of the substrate and the mean value of the ratio of k_{Br_2} to $k_{Br_3^-}$ obtained at all temperatures. It was observed that Q varied regularly in a set of compounds. For example, in compounds having the common structure CH_2=CHCOR (R= -OMe, -OEt, -OBu, -OBu^t, -NH_2), CH_2=C(Me)COR R=-OMe, -OEt, -NH_2) and CHMe=CHCOR R= -OMe, -OEt), Q increased with the increasing order of the reactivity of the substrate in each set.

Both by potentiometry and by titrimetry, the stoichiometry of alkene-bromine reactions was found to be 1:1. The values of product ratio, (P_r= [Bromohydrin]/[Dibromide]) were determined in order to find out the relation, if any, between the two reaction paths namely the attack by Br_2 and Br_3^- species, on the one hand, and the different products (bromohydrin and dibromide), on the other. When 1 mol of bromohydrin was formed by the attack of water, 1 mol of HBr will be liberated. The estimation of the liberated acid gave directly the amount of bromohydrin formed. The difference between the amount of bromine initially taken and the bromohydrin formed gave the amount of dibromide formed during the reaction. The product ratio of bromohydrin to dibromide did not agree with that calculated on the basis of Kanyaev's view[1] (Table 4).

When the observed product ratio values of all the substrates studied were compared at any particular bromide concentration, it did not fall under any correlation. The values of P_r neither follow the reactivities of the substrates[1] nor the relative reactivity ratio of Br_2 and Br_3^-.[2] Instead of comparing different substrates for the correlation of reaction rate and the product composition, an attempt was made in the present investigation to study such effect on a single substrate itself. According to Kanyaev[1] and Atkinson[2]

a) The calculated values of [bromohydrin]/[dibromide] based on Kanyaev's view.[1)]

the ratio of bromohydrin to dibromide should increase with k_{Br_2}. To examine this fact P_r was determined by carrying out the acrylamide-bromine reaction at various concentrations of added salts like $NaNO_3$ and Na_2SO_4. Though the ratio $k_{Br_2}/k_{Br_3^-}$ increases with the increase of ionic strength by adding $NaNO_3$, P_r decreased; and the product analysis in presence of nitrate revealed that this is due to the incorporation of NO_3^- in the product. In presence of added Na_2SO_4 P_r remained almost constant (Table 5). The present investigation reveals therefore, the following facts: i) the effect of ionic strength on the ratio in presence of non-participating radicals like SO_4^{2-} clearly indicates that there exists no relation between reaction rates and product distribution; ii) P_r was unaffected much by temperature and iii) the increase of acid concentration even by 100 fold did not alter P_r.

TABLE 5. EFFECT OF [$NaNO_3$], [Na_2SO_4], AND TEMPERATURE ON THE PRODUCT RATIO, P_r=[BROMOHYDRIN]/[DIBROMIDE] AT [Br^-]=0.1 mol dm^{-3} FOR AAm-BROMINE REACTION

0.6	2.65	0.6	3.80	46	4.18
1.0	2.53	—	—		

Contrary to the earlier observations[7,15)] the present investigation shows the formation of a small amount of bromohydrin (2.3%) even at [Br^-]=2 mol dm^{-3} and an appreciable amount of bromohydrin at [Br^-]=0.5 mol dm^{-3} (Tables 4 and 6). The products are, therefore, formed by the competitive attack by bromide, water, *etc.*

The aspect of regioselectivity was considered for the bromination of MMA and EMA. The product analysis by GC has shown the formation of three products and they were identified as a dibromide and two isomeric bromohydrins by comparing the retention time with those of authentic samples. Further, NMR spectrum showed three singlets at δ 2.00, δ 1.90, and δ 1.49 for C-2 methyl protons of 2,3-dibromo-, 2-bromo-3-hydroxy-, and 3-bromo-2-hydroxy- compounds as identified by the spectra of authentic samples. The nucleophilic attack by Br^-, Br_3^-, solvent molecule, *etc.*, may be on either of the two carbon atoms of the alkenic linkage giving rise to a dibromide and isomeric bromohydrins. The results also show that the bromonium ion formed in these cases did not favour any unsymmetrical bromonium structure. The regioselectivity value[19)] is fluctuating around 0.5. In spite of unsymmetrical nature of the substrate, the intermediate behaves almost like a symmetrical one. This may probably be due to the fact that in methyl acrylates a Me(+I) group on C-2 partially compensates for the influence of ester group

TABLE 6. THE PERCENT OF VARIOUS PRODUCTS (BY NMR SPECTRAL ANALYSIS) AT DIFFERENT [Br_r^-]'S FOR MMA, EMA-BRONINE REACTION IN AQUEOUS MEDIUM

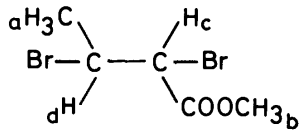
A: 2,3-dibromo-, B: 2-bromo-3-hydroxy-, C: 3-bromo-2-hydroxy-compounds.

R: Regioselectivity factor, $R(B)=\frac{B}{B+C}$.

(—I) on the same C-2 position. Thus the occurrence of isomeric compounds almost in equal proportion gives evidence for non-regiospecificity or non-regioselectivity in its product formation.

In order to find out the possibility of any cis-addition (*via* the addition of Br_3^- whose structure is slightly bent in the solid state[20] which may be favourable for a cis-addition) the study of stereochemistry was extended to methyl crotonate-bromine reaction in water in presence of bromide ions. The reaction mixture was fractionated by silica-gel column chromatography and a number of small fractions were collected and ^1H NMR spectra were taken for the first, the middle and the last fractions. The ^1H NMR spectrum of the dibromo compound namely the methyl 2,3-dibromobutanoate (CCl_4/TMS) showed a doublet at δ 1.92 (3H, $J=6$ Hz, H_a) a singlet at



δ 3.82 (3H, H_b) and a multiplet centered at δ 4.42 (2H, $H_{c,d}$); the methyl-decoupled spectrum showed a doublet at δ 4.36 ($J=5.2$ Hz) instead of a complex multiplet present in the original spectrum. This is compared with similarly methyl-decoupled spectrum of an authentic sample of erythro-dibromo product of methyl crotonate prepared, where bromination occurs only by trans addition.[21] Comparison shows that the dibromo compound obtained in the bromination in aqueous medium in the present case is also an erythro isomer (trans addition). Spectra for other fractions of dibromo compounds were also found to be similar for protons at C-2 and C-3 positions ($J=5.2$ Hz).[22] Absence of threo isomer completely rules out a cis-addition. The attempts to detect the presence of π-complex, if any, in water by UV spectrophotometric method were not successful. However, interactions between alkene and bromine leading to a π-complex cannot be ruled out and π-complex may be small to be detected spectrophotometrically. From a kinetic point of view, however, such a small concentration is quite sufficient, as the π-complex is formed in a fast equilibrium step. The absence of spectrophotometric evidence for alkene-bromine π-complex could not be considered as a total negative evidence for its formation. Dewar *et al.*[23] have also stressed this point.

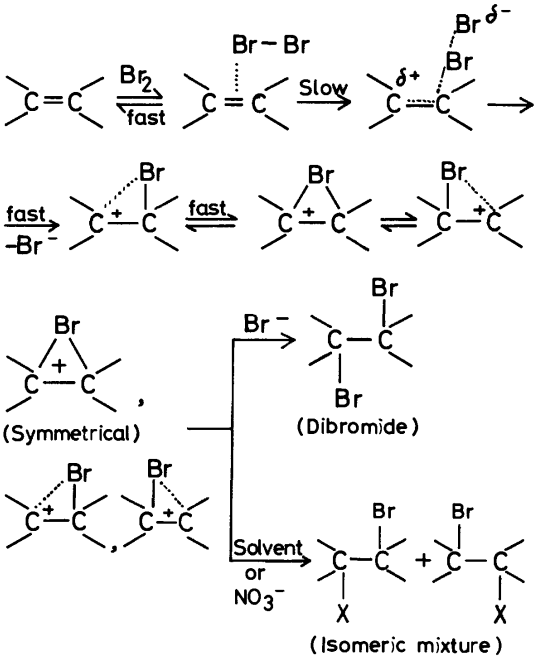
Reaction Mechanism. The experimental results show that the contribution to the reaction by Br_2 and Br_3^-, species is quite appreciable. The fact that the experimental values of k_2(obsd) $(1+K[Br^-])$ and the calculated values, $(k_{Br_2}+k_{Br_3^-}K[Br^-])$ are in total agreement with each other indicates that bromination, under the experimental conditions, occurs mainly by Br_2 and Br_3^- species. As a representative example, the observed and calculated values of k_2(obsd) $(1+K[Br^-])$ for the bromination of AAm in water at 22 °C are provided in Table 7. In the following two sections are discussed two mechanisms one for the reaction between alkene and Br_2 species and the other for alkene and Br_3^- species.

Mechanism of the Bromination of Alkenes by Br_2 Species. Based on the effect of ionic strength on

Table 7. The observed and calculated values of k_2(obsd) $(1+K[Br^-])$ for the bromination of AAm in water at 22 °C

$[Br^-]$/mol dm^{-3}	0.01	0.05	0.10	0.20	0.30	0.40	0.50
Obsd	1.73	2.15	2.64	3.30	4.44	5.15	6.15
Calcd	1.76	2.13	2.59	3.52	4.43	5.37	6.06

k_{Br_2} and on the formation of exclusive stereospecific but non-regiospecific, anti-addition products and in the light of the points discussed, the kinetic scheme for the bromination of alkene by Br_2 species in aqueous medium may be represented as follows:

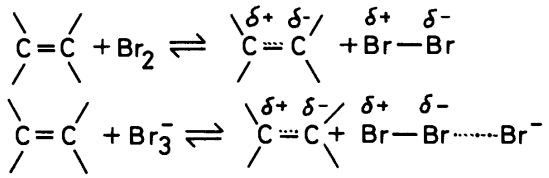


Thus it may be formulated that molecular bromine first attaches to double bond of alkenic compounds in a fast equilibrium step to form an intermediate complex, which then decomposes to give a carbonium ion. The carbonium ion rearranges to a bromonium ion which by subsequent fast steps readily forms dibromide, bromohydrin or bromo nitrates by the reaction with bromide, water molecule or with nitrate ions, respectively.

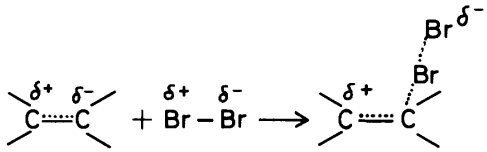
Mechanism of the Bromination of Alkenes by Br_3^-, Species. A number of mechanisms for the bromination of alkenes by Br_3^- species have been proposed by earlier workers.[2-8] The data collected on the rate constants correspond well with the following rate expression: rate $=k_{Br_3}[S][Br_3^-]$. Alternatively, the rate expression can also be represented as, rate $=k_{Br^-}[S][Br_2][Br^-]$. These two rate expressions cannot be distinguished kinetically. While the former represents the addition of Br_3^- by a bimolecular mechanism, the latter represents Br^- catalysed termolecular mechanism.

A possible mechanism for Br_3^- addition is envisaged in the present investigation for the first time on the basis of experimental kinetic parameters and the product analysis. Irrespective of whether the bromination is between alkene and Br_2 or between alkene and Br_3^-, the value of ΔH^* is observed to be the

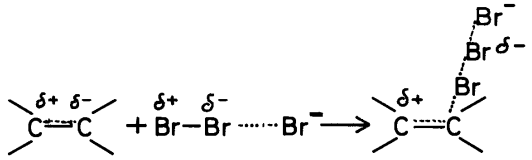
same in either case for a given substrate. There is thus every reason to believe that the approach of Br_2 or Br_3^- towards alkene should be quite similar. Since the structure of Br_3^- species even in solid state was predicted to be linear[20] and unsymmetrical[24] and carrying a single negative charge and since the Br_3^- structure in solution is even more uncertain, the approach to alkene by both Br_2 and Br_3^- species (in keeping with more or less same ΔH^* obtained in either case) can be unequivocally depicted as



It should be stressed at this point that the ionic strength effect is to increase the rate (k_{Br_2}) of alkene-Br_2 species reaction while decreasing that of alkene-Br_3^- species. As already stated the rate enhancement in the former case is due to the formation of polar or ionic intermediate from neutral molecules and can be represented in all probability as

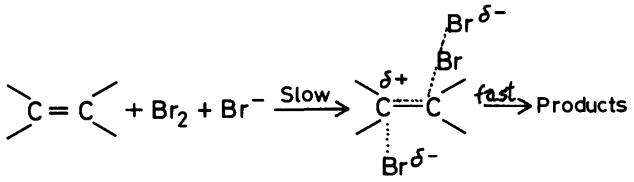


On the other hand, the decrease in rate ($k_{Br_3^-}$) with μ found in the reaction between alkene and Br_3^- species may be attributed to the less polar character of the transition state as compared to the reactants, a neutral molecule and an ionic species, and may be represented as follows:

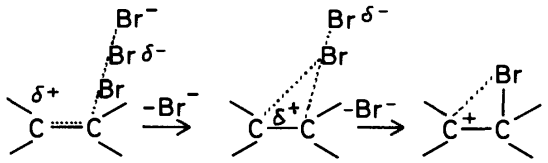


3

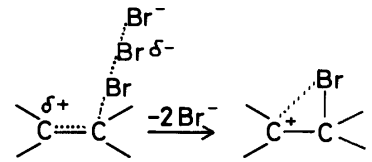
Similarly, a less-charged activated complex can be equivally possible in Br^--catalysed mechanism too, as shown below



Further, the Br^--catalysed reaction is stereospecific whereas structure **3** formed by Br_3^- can still lead to non-stereospecific products. However, in the present study, the product analysis made on the reaction between methyl crotonate and bromine showed a nil contribution of threo product. To account for this stereospecificity it is necessary to propose bromonium ion structure in Br_3^--addition also. Hence the activated complex (Structure **3**) giving rise to a bromonium ion should involve breakage of two Br-Br bonds in contrast to the addition by Br_2 species where only one bond needs to be broken. Thus the breakage of two Br-Br bonds may take place one at a time as in



or the two Br-Br bonds may break simultaneously as in



Futhermore, this bromonium ion must be either symmetrical or equilibrium mixture of two unsymmetrical forms in accordance with regioselectivity factor around 0.5. Otherwise, a single unsymmetrical structure formed by Br_3^- alone (and not by Br_2) might result in a regioselective products. The participation by Br_3^- as an electrophile is proved further in the present study as follows.

Substitution of a methyl group at the alkenic carbon increases both k_{Br_2} and $k_{Br_3^-}$. The methyl substitution accordingly, decreases activation enthalpy in either case. If we assume that $k_{Br_3^-}$ is especially due to Br^--catalysed reaction, then the product formed by this step should be only dibromide. And the solvent incorporated and salt (NO_3^-) incorporated products should then result from bromonium ion formed due to addition of Br_2 species. It is evident that if Kanyaev's view[1] namely bromohydrines are exclusively formed by the addition to alkene by Br_2 species and dibromide by Br_3^- species, is correct, then one can expect that both the observed and calculated product ratios, [bromohydrin]/[dibromide], should agree with each other. As already pointed out, the bromonium ion formation during the course of the reaction seems inevitable to explain the observed 'stereospecific *cum* non-regioselective' products. Also the dibromide formation in this situation is warranted. If this were so, the amount of bromohydrin formed should be actually lower than that predicted by calculation. This means that the observed ratio of bromohydrin to dibromide should be less than the calculated value. This expectation arises from the assumption that $k_{Br_3^-}$ is due to Br^- catalysis. However, the experimental P_r has been found to be greater than the calculated one (Table 4). It is quite clear that the formation of more of bromohydrin than the expected amount should have resulted only from Br_3^--addition. So the observation that bromohydrin is formed in rather large quantity than dibromide, cannot be explained by Br^--catalysed mechanism alone. All the foregoing arguments strongly suggest that Br_3^- species acts as an electrophile. Otherwise either nucleophilic attack by Br_3^- or bromide-catalysed reaction should have resulted only in a dibromide compound, which is not found to be the case.

In conclusion, the addition of bromine to alkenes in aqueous medium in presence of bromide in the present investigation is stereospecific and non-regioselective antiaddition. Though $k_{Br_3^-}$ is a composite term, in the

present set of substrates, electrophilic-bimolecular addition by Br_3^- species is more favourable. The activated complex formed by Br_3^- species is less polar than the one formed from the alkene-Br_2 species. The formation of activated complex is the slow step of the bromination. Besides dibromide, other products such as bromohydrins and bromonitrates too are formed due to incorporation of solvent and added salts like nitrates.

We thank the University Grants Commission of India for a teacher fellowship to one of us (S.M.F.).

A New Version of Inclusion of Overlap Charges in ω-Technique. π-Bond Energies, Heats of Formation, and Resonance Energies of Conjugated Hydrocarbons

Vindhya Prasad TEWARI, Krishna Behari LAL, and Arun Kumar SRIVASTAVA*
Department of Chemistry, University of Allahabad, Allahabad 211002, India
(Received March 31, 1983)

With systematic approximations to Roothaan equation it has been possible to deduce the IOC-ω-technique (inclusion of overlap charges in ω-technique) which apparently approximates the SCF-equations by bringing in an approximate correction for the two center-two electron repulsion integrals and represents a better version of PPP (Pariser-Parr-Pople) method by involving the hybrid integrals which have been completely neglected in PPP-approximations. In the present communication a new version of IOC-ω-Technique has been used for evaluating the π-bond energies, heats of formation and resonance energies of some conjugated hydrocarbons. The calculated values are found to be in excellent agreement with the experimental data and with some previously calculated values.

In the framework of LCAO-MO approximations Roothaan[1] has given $F_{\mu\nu}$ as,

$$F_{\mu\nu} = H^C_{\mu\nu} + \sum_{\lambda}\sum_{\sigma} P_{\lambda\sigma}\{(\mu\nu, \lambda\sigma) - 1/2(\mu\lambda, \nu\sigma)\}, \quad (1)$$

where $H^C_{\mu\nu}$ is the matrix element involving core Hamiltonian such that,

$$H^C_{\mu\nu} = \int \phi_\mu \left(-\frac{h^2}{8\pi^2 m}\right)\nabla^2 - \sum_{\sigma} V_\sigma \phi_\nu \mathrm{d}\tau, \quad (2)$$

and $(\mu\nu, \lambda\sigma)$ the electron repulsion integral represented as,

$$(\mu\nu, \lambda\sigma) = \iint \phi_\mu(1)\,\phi_\nu(1)\frac{e^2}{r_{12}}\phi_\lambda(2)\,\phi_\sigma(2)\,\mathrm{d}\tau_1\,\mathrm{d}\tau_2. \quad (3)$$

It has been shown[2] that if all electron repulsion integrals are neglected except for one centre integrals $(\mu\mu, \mu\mu)$, two centre integrals $(\mu\mu, \sigma\sigma)$ and the hybrid integrals $(\mu\mu, \mu\sigma)$, since the other integrals are of very small magnitude, then the diagonal matrix elements of Eq. 1 reduces to,

$$\begin{aligned} F_{\mu\mu} &= H^C_{\mu\mu} + 1/2\,p_{\mu\mu}(\mu\mu, \mu\mu) + 1/2\sum_{\sigma\neq\mu} p_{\mu\sigma}(\mu\mu, \mu\sigma) \\ &\quad + \sum_{\mu\neq\sigma} q_\sigma\,(\mu\mu, \sigma\sigma) \\ &= H^C_{\mu\mu} + 1/2\sum p_{\mu\sigma}(\mu\mu, \mu\sigma) + \sum_{\mu\neq\sigma} q_\sigma(\mu\mu, \sigma\sigma). \end{aligned} \quad (4)$$

However, the coulomb integral, $H^C_{\mu\mu}$, neglecting the penetration integral, is approximated as,[3]

$$H^C_{\mu\mu} = I_\mu - \sum_{\mu\neq\sigma}(\mu\mu, \sigma\sigma)$$

where I_μ is the valence state ionization potential of an electron associated with atom μ. Equation 4 therefore leads to,

$$F_{\mu\mu} = I_\mu + 1/2\sum_{\sigma} p_{\mu\sigma}(\mu\mu, \mu\sigma) + \sum_{\sigma\neq\mu}(q_\sigma - 1)(\mu\mu, \sigma\sigma). \quad (5)$$

Since the integral $(\mu\mu, \mu\sigma)$ obviously depends upon the charge distribution $\phi_\mu\,\phi_\sigma$ so that it can be made proportional to the overlap integral $S_{\mu\sigma}$,

$$(\mu\mu, \mu\sigma) = 2\omega_\mu\, s_{\mu\sigma} \quad (6)$$

where ω_μ is a proportionality constant which may be written as,

$$\omega_\mu = 1/2(\mu\mu, \mu\mu), \quad (7)$$

in case of $\mu = \sigma$.

However, ω_μ is treated as an empirical parameter in order to cover up the deficiencies in the method due to several approximations involved. Inserting Eq. 6 in Eq. 5,

$$F_{\mu\mu} = I_\mu + \omega_\mu \sum p_{\mu\sigma}\, s_{\mu\sigma} + \sum_{\sigma\neq\mu}(q_\sigma - 1)\,(\mu\mu, \sigma\sigma). \quad (8)$$

At this stage a new parameter α_μ has been defined as,

$$\alpha_\mu = I_\mu + \omega_\mu.$$

In terms of this parameter Eq. 8 will assume the following form,

$$\begin{aligned} F_{\mu\mu} &= \alpha_\mu + \omega_\mu\left(\sum_{\sigma} p_{\mu\sigma}\, s_{\mu\sigma} - 1\right) \\ &\quad + \sum_{\sigma\neq\mu}(q_\sigma - 1)\,(\mu\mu, \sigma\sigma). \end{aligned} \quad (9)$$

For most of the molecules last term of Eq. 9 would be very small and in fact will be equal to zero for alternant hydrocarbons. Therefore, this last term may be neglected and consequently Eq. 9 will assume the following form,

$$\begin{aligned} F_{\mu\mu} &= \alpha_\mu + \omega_\mu\left(\sum_{\sigma} p_{\mu\sigma}\, s_{\mu\sigma} - 1\right) \\ &= \alpha_\mu + \omega_\mu\{1/2\sum_{\sigma}(p_{\mu\sigma}\, s_{\mu\sigma} + p_{\sigma\mu}\, s_{\sigma\mu}) - 1\}. \end{aligned} \quad (10)$$

The last line of Eq. 10 follows from the fact that in the expansion of Eq. 1 both $(\mu\mu, \mu\sigma)$ and $(\mu\mu, \sigma\mu)$ type integrals will occur but since there is no difference between them the factor 1/2 has been included to avoid the counting of them twice. If ω_μ is treated as a negative parameter Eq. 10 will become,

$$F_{\mu\mu} = \alpha_\mu + \omega_\mu\{1 - 1/2\sum_{\sigma}(p_{\mu\sigma}\, s_{\mu\sigma} + p_{\sigma\mu}\, s_{\sigma\mu})\}, \quad (11)$$

which has been used in our calculation as diagonal matrix element. $F_{\mu\mu}$ as derived in Eq. 1 approximates the SCF equations by bringing in an approximate correction for the two centre-two electron repulsion integral and represents a better version of PPP-method since it involves hybrid integrals which have been completely neglected in PPP-metod and which are in no way negligible as they can be as large as 3.5 eV.[4] The success of the technique can also be attributed to the fact that the inclusion of overlap charges permits the ω-technique to make use of orthogonal atomic orbitals (OAO's) rather than usual nonorthogonal slater type

atomic orbitals (STAO's). The ω-technique, which has been put to successful use by Aihara,[5] can be said to be a simplified version of PPP-method (for example see Doggett[6]) which is based on zero differential overlap (ZDO) approximations of Pariser, Parr and Pople[3,7] and since these approximations are valid only over OAO's and not over usual non-orthogonal STAO's, the use of OAO's is essentially warranted in it. It has been shown by Gupta[8] that this necessity in ω-technique is fulfilled by inclusion of overlap charges. This is arrived at by deducing the IOC-ω-technique (inclusion of overlap charges in ω-technique) in the framework of Lowdin's OAO's. In the present communication the following form of the off diagonal matrix element has been used for the first time in the framework of IOC-ω-technique,

$$F_{\mu\nu} = K S_{\mu\nu} (F_{\mu\mu} \cdot F_{\nu\nu})^{1/2}, \tag{12}$$

where K is a dimensionless constant and $S_{\mu\nu}$ are the overlap integrals. Since $F_{\mu\nu}$ represents the energy of interaction between atomic orbitals μ and ν, the simple arithmatic mean, an approximation used by Wolfsberg and Helmholtz,[9] evidently takes into account only an average interaction between atomic orbitals whereas a use of geometric mean[10] will incorporate all the possible interactions between different atomic orbitals.

In most of the semiempirical π-electron calculations, using variant of the Pariser-Parr-Pople[3,7] (PPP-method), the choice of parameters required to give optimum agreement with experiment is specific for a particular property, or is valid for a specific class of compounds, and cannot therefore, generally be extended to other molecular properties or to different class of molecules. In the present work a set of parameters has been developed which when applied to a given molecular property, *e.g.* ionization potential produces good results and also give satisfactory results when used to calculate other properties, *e.g.* electron affinity, π-bond energies, heats of formation and resonance energies of different class of compounds.

π-Bond Energy. In molecular orbital theory the π-electronic energy of a molecule is given by,

$$E_\pi = \text{Total molecular orbital energy} = \sum_\mu \sum_\nu p_{\mu\nu} F_{\mu\nu}. \tag{13}$$

Substituting the values of $F_{\mu\mu}$ and $F_{\mu\nu}$ from Eqs. 11 and 12 into Eq. 13, we shall get the following expression for the total π-elecronic energy,

$$E_\pi = \sum_\mu q_\mu \alpha + \omega \sum_\mu q_\mu (1-q_\mu) - \omega S \sum_\mu \sum_{\sigma \neq \mu} q_\mu p_{\mu\sigma} + KS \sum_\mu \sum_\nu p_{\mu\nu} \{(\alpha + \omega(1-q_\mu) - \omega S \sum_\sigma p_{\mu\sigma})(\alpha + \omega(1-q_\nu) - \omega S \sum_\sigma p_{\nu\sigma})\}^{1/2}. \tag{14}$$

Now, consider the energy liberated when n carbon atoms with p-electrons combine to form π-bonds, *i.e.* energy ($E_{\pi b}$). The total π-electronic energy of a molecule is given by the algebraic sum of the energy of electrons in p-orbital of widely separated carbon atoms and the π-bond energy ($E_{\pi b}$). The former may be equated to $\sum q_\mu \alpha$. Hence, the remaining terms of Eq. 14 give π-bond energy. For alternant hydrocarbons with $q_\mu = 1$, we have,

$$E_{\pi b} = -\omega S \sum_\mu \sum_{\sigma \neq \mu} q_\mu p_{\mu\sigma} + 2KS \sum_{\mu<\nu} \sum p_{\mu\nu} \{(\alpha - \omega S \sum p_{\mu\sigma})(\alpha - \omega S \sum p_{\nu\sigma})\}^{1/2}. \tag{15}$$

Heat of Formation. The heat of formation of a molecule in its equilibrium configuration is the additive sum of the bond energies. The total bond energy of a molecule is given by the sum of the total σ-bond energy, $E_{\sigma b}$ and total π-bond energy, $E_{\pi b}$. The following expression provides a simple route to calculate heats of formation of hydrocarbons.

$$\Delta H_f = E_{\sigma b} + E_{\pi b} = N_C E_{CC} + N_H E_{CH} + E_{\pi b}, \tag{16}$$

where E_{CC} and E_{CH} are the bond energies of C-C and C-H bonds respectively and N_C and N_H are the number of C-C and C-H bonds respectively.

Resonance Energy. If a compound possesses more than one structure, the resonance energy is regarded as a physical measure of the most stable structure relative to other possible structure. Among the various possible definitions of the term resonance energy, the most important is one due to Mulliken and Parr[11] (empirical resonance energy), which is taken as the differences between the bond energies of structure I and II,

$$E_R = E_{b(I)} - E_{b(II)}, \tag{17}$$

where I represents an aromatic structure with all bonds equal to 1.40Å and II represents a structure with alternating C-C bond length and C=C bond length. The bond energies may be calculated with the help of the following equations,

$$E_{b(I)} = NE_C + N_H E_H + E_{\pi b(I)}, \tag{18}$$

and

$$E_{b(II)} = N_1 E_1 + N_2 E_2 + N_H F_H. \tag{19}$$

In which $E_{\pi b(I)}$ is the π-bonding energy of structure I and $N = N_1 + N_2$. E_1 and E_2 are the energies of a C-C bond of length 1.48 Å and C=C bond of length 1.34 Å respectively. N_1, N_2, N_H, and E_H represent the number of single and double bonds and number of C-H bonds and energy of carbon-hydrogen bonds respectively.

Now, since the values of E_1 and E_2 are very uncertain, we shall use the following scheme instead of using them directly,

$$E_R = NA_0 + (N_1 - N_2) A_1 + E_{\pi b(I)} \tag{20}$$

where,

$$A_0 = E_C - \frac{E_1 + E_2}{2}, \tag{21}$$

$$A_1 = \frac{E_2 - E_1}{2}. \tag{22}$$

However, A_0 and A_1 are to be treated as empirical parameters.

Values of Parameters. In the present communication, it has been assumed that the overlap integral $S_{\mu\nu}$ vanishes for non-neighbouring μ, ν and it

TABLE 1. π-BOND ENERGIES AND HEATS OF FORMATION OF ALTERNANT HYDROCARBONS

Compound	$E_{\pi b}$/eV	Present work	Ref. 16	Ref. 17	Experimetal Ref. 18

a) Ref. 22.

has a constant value S for μ, and ν directly bonded. S has been assigned a value of 0.25. ω has been taken to 1.4. Both the values have been extensively used by several workers.[12,13] K has been assigned a value of 1.634, which is very close to its value quoted in literature.[14] E_{CC} and E_{CH} are taken as 3.80 and 4.43 respectively, as proposed by Dewar and Gleicher.[15] A_0 and A_1 have been assigned values as −1.06 and 0.84 respectively. α has been taken to be 7.00.

Results and Discussion

In Table 1, we have listed the values of heat of formation obtained with Eqs. 15 and 16 along with some previously calculated values[16,17] and with available experimental values.[18] A close study of Table 1, shows that our calculated values are generally in excellent agreement with the experimental values. The values calculated by the present method (av.dev. = 0.12) are also in good agreement with Dellano[17] (av.dev. = 0.11) and are better than those calculated by Srivastava[16] (av.dev. = 0.765). Table 2, enlists the empirical resonance energy calculated by the present method along with some previously calculated values[19,20] and the relevant experimental data.[21,22] From Table 2, it is amply clear that the values obtained by the present method are in excellent agreement with the observed experimental values. The values calculated by the present technique (av. dev. = 0.09) are better than those calculated by Srivastava[20] (av. dev. = 0.286) and Dewar[19] (av. dev. = 0.246) PPP-method.

It is worth mentioning that the same set of parameters have been used for the calculation of different ground state properties of various class of compounds. Thus the values obtained are in good agreement with experimental values.

A Novel Synthesis of Azophenines

J. R. MERCHANT,* Gail MARTYRES, and N. M. SHINDE

[1]*D. G. Reparel College, Bombay-400016,India*
(Received March 7, 1983)

Aarylamines react with polyhaloalkanes in the presence of copper bronze to yield azophenines.

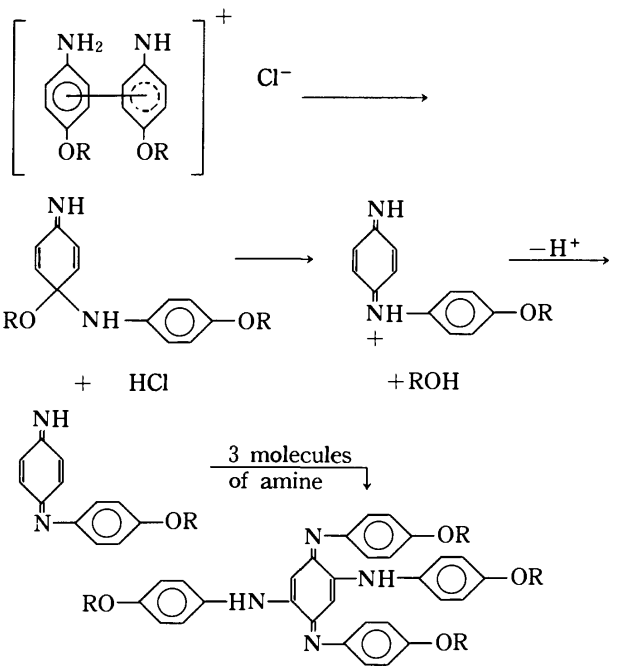
In the course of our work on the reactions of arylamines with polyhaloalkanes we investigated the reaction of aniline and some substituted anilines with 1,1,2,2-tetrachloroethane and hexachloroethane in the presence of copper bronze. Heating the arylamines with the alkyl halide in the presence of a catalytic quantity of copper bronze for 2—4 h afforded bright red compounds, isolated as single substances (TLC, chloroform-methanol) in 25—35% yield. The latter dissolved in concentrated sulfuric acid, giving a deep violet solution, which on dilution gave back the red colour. The sulfuric acid solution on heating at about 300 °C turned blue and when alkali was added to it a red coloration was observed. This property as well as the spectral and analytical data indicated that these compounds were probably *N,N'*-diphenyl-2,5-dianilino-*p*-benzoquinone diimines or azophenines.[1] This assumption was confirmed since azophenine (**1a**)[1] on heating with zinc and hydrochloric acid gave back aniline and *p*-phenylenediamine. The known azophenines were synthesized by previously reported methods and were found to be identical with our compounds. The literature methods reported so far are tedious, involve separation of mixtures and afford extremely low yields of the azophenines. These include the condensation of quinone with *N*-ethylideneaniline or *N*-benzylideneaniline in dry toluene[2] under anhydrous conditions to yield azophenine along with a dark red amorphous residue which does not melt up to 360 °C. Azophenines have also been obtained (in about 1% yield) by the peroxidase oxidation of a mixture of amines[3] as well as by the periodic acid oxidation of aniline.[4] γ-Irradiation of a mixture of aniline and bromobenzene afforded azophenine in a mixture of other products.[5] Benzofurazan-1-oxide, not an easily accessible starting material, on heating with aniline hydrochloride in aniline is reported to furnish azophenine.[6]

Azophenine (**1a**) has been prepared[3] by oxidizing *N,N'*-diphenyl-*p*-phenylenediamine with mercury(II) oxide to *p*-benzoquinone dianil and heating the latter with aniline.

Most of the above methods cannot be used to prepare substituted azophenines. The method described by us constitutes a simple and novel synthesis of azophenines (especially the *p*-substituted compounds) which are reported to be important intermediates in the synthesis of dyes,[7] such as Induline 3B and 6B and Nigrosine CF New. Indulines are blue basic dyes which could be prepared by heating azophenines with the arylamine concerned.

Mechanistically, it is indicated that polyhaloalkanes and copper bronze react to generate a sufficient amount of copper(II) chloride *in situ* which acts as an oxidising agent in the presence of the amine to yield an *N*-phenyl-*p*-benzoquinone diimine as an intermediate. The latter reacts with an excess of the amine to give the azophenine. The intermediacy of *N*-phenyl-*p*-benzoquinone diimine was established by preparing it as described by Goldschmidt[8] by oxidation of an ethereal solution of aniline with lead oxide. In the case of *p*-alkoxy substituted anilines the corresponding diimines were obtained by the method of Willstätter and Kubli[9] involving the silver oxide oxidation of *N*-phenyl-*p*-alkoxy-*p*-phenylenediamines. The diimines so obtained were allowed to react with excess of the corresponding amines to afford the expected azophenines. To confirm our assumptions, *p*-phenetidine (6.85 g) was heated with dry copper(II) chloride (0.135 g) on a steam bath for 4 h when the corresponding azophenine (**1c**) was isolated in about 1.8 g yield.

It is pertinent to mention here that the oxidation of *p*-anisidine with peroxidase in presence of acetic acid has been reported[10] to yield the corresponding azophenine in about 5% yield. The mechanism for the formation of azophenines in our reaction can be depicted as follows.



The formation of free radicals during the reaction could be ruled out since no 4-alkoxyazobenzene could be isolated during the reaction. Also *p*-benzoquinone, a known product of the oxidation of amines, is not an intermediate since its reaction with amines under mild conditions affords only 2,5-dianilino-*p*-benzoquinones.[11] Further, it is well known that quinones do not

TABLE 1. AZOPHENINES

Compound	Formula	Mp θ_m/°C	Found (Calcd) (%)		
			C	H	N
1a	$C_{30}H_{24}N_4$	242—244	82.0 (81.8	5.6 5.4	12.5 12.7)
1b	$C_{34}H_{32}N_4O_4$	230—232	72.6 (72.8	5.4 5.7	10.4 10.2)
1c	$C_{38}H_{40}N_4O_4$	237—239	74.3 (74.0	6.8 6.5	9.2 9.0)
1d	$C_{46}H_{56}N_4O_4$	220—222	75.0 (75.1	7.4 7.3	8.3 8.3)
1e	$C_{50}H_{64}N_4O_4$	155—157	75.8 (75.6	7.6 7.5	7.6 7.7)

easily form anils with amines.

Amines with strongly electron-donating groups like the alkoxyl in the *p*-position were found to take part in the reaction while amines with electron-withdrawing groups like a nitro group or a halogen atom in this position failed to yield the azophenine. The above reaction with *N,N*-dimethyl-*p*-phenylenediamine was also unsuccessful. When amines substituted at the *o*- or *m*-positions were employed, the reaction failed to occur probably due to steric hindrance.

Experimental

General Procedure. For Azophenine (1a), Tetra-p-methoxyazophenine (1b),[10] *and Tetra-p-ethoxyazophenine (1c)*: The amine (10 g), (aniline, *p*-anisidine or *p*-phenetidine) hexachloroethane or 1,1,2,2-tetrachloroethane (6 g) and copper bronze (40 mg) were heated on a boiling water bath for 2 h to give a black mass which was decomposed and washed with dilute hydrochloric acid and the residue refluxed with ethanol and filtered to afford a reddish brown solid. The latter was crystallized from pyridine and then from dioxane in dark red needles.

The spectral data of **1b** are as follows: UV $\lambda_{max}^{dioxane}$: nm (log ε): 305 (4.37), 420 (4.25); IR (KBr): 3350 (N-H), 1600, 1580, 1540, 1490, and 1450 (aromatic), 1050 (C-O-C) cm^{-1}; MS: *m/z* 560 (M^+). The NMR spectrum of **1b** could not be taken due to its insolubility in the usual solvents.

The IR and mass spectral data of **1c** are as follows: IR (KBr): 3360 (N-H), 1600, 1580, 1540, 1490, 1450 (aromatic), 1040 (C-O-C) cm^{-1}; MS: *m/z* 616 (M^+).

Tetra-p-propoxyazophenine (1d): The reaction was carried out as above with *p*-propoxyaniline. The black mass obtained was repeatedly recrystallized from ethanol to afford a reddish-violet solid. IR (KBr): 3360 (N-H), 1600, 1580, 1540, 1480, 1450 (aromatic), 1050 (C-O-C) cm^{-1}.

Tetra-p-butoxyazophenine (1e): The procedure used was similar to the general procedure. The black mass obtained was chromatographed over a silica-gel column. Elution with hexane-acetone (70:30) afforded a deep reddish-violet solid which was crystallized from ethanol. The NMR spectrum of compound **1e** is as follows: NMR ($CDCl_3$) δ=0.8—1.2 (12H, m, four $-CH_3$), 1.26—2.0 (16H, m, eight $-CH_2$), 3.76—4.19 (8H, q, four $-OCH_2$), 5.63 (2H, s, two =CH-), 6.66—7.76 (16H, m, aromatic protons).

We are grateful to the Ciba-Geigy Research Centre, Bombay, for the spectra recorded and the UGC for the award of a fellowship to GM.

Vibrational Energy Levels and Infrared Absorption Intensities of Carbon Monoxide

Tomoo MIYAZAKI,* Azuma MATSUURA, and Hisao TAKEUCHI

Department of Applied Chemistry, Faculty of Science and Engineering, Waseda University, Ohkubo, Shinjuku-ku, Tokyo 160

(Received July 14, 1983)

Synopsis. The vibrational energy levels and infrared absorption intensities of carbon monoxide have been calculated with due consideration for the mechanical and electrical anharmonicities of vibration by the use of ab initio molecular orbital calculation in which the C-I treatment and polarization functions were introduced.

The dipole moment of carbon monoxide, as a function of the interatomic distance, is a problem of absorbing interest not only in itself but in relation to the infrared absorption intensity. In this paper, the potential energy of the CO vibration and the dipole moment function have been studied by comparison between theoretical values and observations about the wave number and intensity in the infrared absorption spectrum of carbon monoxide. One of the remarkable features of this work is that the infrared absorption intensities are calculated by the use of a dipole moment function involving the higher order terms and by vibrational wave functions obtained from the variation method in which the potential energy function involving the higher order terms are adopted. Another feature is that the atomic polarizations of the C and O atoms which bring about the unexpected dipole moment of the CO molecule are determined. The calculations have been performed by employing the GAUSSIAN 76 and 80 programs provided by the QCPE and HITAC M-280H/M-200H system of the Computer Center in The University of Tokyo.

In the first step of this work, the results of several ab initio calculations on the dipole moment (μ), gross atomic population (P_{AA}), force constant (K), and total energy (E) at the theoretical equilibrium distance (R_{eq}) of the CO molecule were compared with observations.

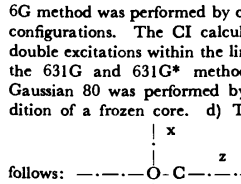
a) The Gaussian 76 was employed on all cases except for 6311G and 6311G* methods with or without CI treatment. b) The CI calculation for the STO-6G method was performed by considering all possible singly and doubly excited configurations. The CI calculations were performed by considering single and double excitations within the limits of orbital number 3 to 14 and 3 to 15 for the 631G and 631G* methods respectively. c) The CI calculation with Gaussian 80 was performed by considering all double excitations under condition of a frozen core. d) The Cartesian axis used in this calculation is as follows:



e) 1 D = 10^{-18} g$^{1/2}$ cm$^{5/2}$ s^{-1}, 1 mdyn Å^{-1} = 10^5 g s^{-2}, 1 a.u. = 4.35981×10^{-11} g cm^2 s^{-2}.

These values are listed in Table 1. Generally, the application of CI treatment leads to a slight increase of the theoretical bond distance and to a slight decrease of the theoretical force constant. On the basis of these results, we chose the STO-6G-CI and 6311G*-CI meth-

ods which differ from each other in adoption of the basis set. In the next step, the detailed calculation have been performed using these two methods. According to the method of least squares, the potential energy and dipole moment functions were obtained carefully from sufficient data for distorted molecules as the higher order equations with respect to the internal coordinate (R_{CO}). These equations have been transformed to the functions with the normal coordinate (Q) by the use of the L term which relates the internal coordinate to the normal coordinate. In order to obtain the appropriate final results, these functions have been rewritten by multiplying the coordinate term by an adjusting constant (α) determined in comparison with the observed frequency of fundamental band. Table 2 records the coefficients of these potential energy and dipole moment functions. The variation method has been used to calculate the energy levels of vibration in view of the mechanical anharmonicity and the wave function (ψ) of the molecular vibration has been described by the linear combination of harmonic oscillator wave functions(ϕ°). Further details of the treatment were reported in previous papers.[1,2] The calculated energy levles and wave functions are listed in Table 3. By the use of these anharmonic wave functions and dipole moment function indicated in Table 2, the absolute infrared absorption intensities of fundamental and overtone bands have been calculated in view of the mechanical and electrical anharmonicities.[1,2] The results are summarized in Table 4 in which reference data are also included. Since the potential energy function is modified by the use of the adjusting constant (α), the calculated wave number of the fundamental band agrees well with the observed value. The calculated wave numbers of overtone bands, too, almost coincide with the observed values. From these results, we may reasonably conclude that the potential energy function obtained in this work is adequate. Furthermore, according to the perturbation treatment,[9] the rotational constants α_e, γ_e, and δ_e have been determined by the use of anharmonic wave functions as indicated in Table 3. The calculated constants are listed in the footnote of Table 4.

When the higher approximate treatment of molecular orbital calculation was adopted, the appropriate value of the dipole moment could not always be obtained. However from Table 4, in which theoretical values of infrared absorption intensities are compared with experimental values, it has been definitely recognized that the values of M_1, M_2, and M_3 in dipole moment function are improved by employing the higher approximate 6311G* calculation than STO-6G, while Amore-Bonapasta[10] reported as follows: the agreement between experimental result and theoretical function from the STO-6G method is satisfactory and better than that between experimental and 631G functions.

The last point to which special attention should be paid is the change of the direction of the dipole moment in the vicinity of the equilibrium CO distance. The values of the atomic polarization resulting from the mixing of the S and P type orbitals or the P and D type orbitals are indicated in Table 5 in which gross atomic populations are also indicated. It is notable that the absolute value of the atomic polarization, μ^{c}_{AP}, of carbon is about double that, μ^{o}_{AP}, of oxygen. The sign of μ^{c}_{AP} is negative and that of μ^{o}_{AP} is positive when the CO molecule is fixed in the coordinate indicated in the footnote of Table 1. From these results, it is evident that the unexpected sign of the CO dipole moment is caused by atomic polarizations. In the results from different methods, there are opposite tendencies as to the increase in gross atomic population with the variation of CO distance. The same tendencies are seen in the value of the dipole moment with the exception of the atomic polarization term. In view of the above facts, it is found that the theoretical result for the electronic property of carbon monoxide is highly sensitive to the difference of approximation in the method of calculation.

The Number of Water Molecules Bound to Insulin

Nobuya NAGASHIMA,* Ei-ichiro SUZUKI, and Masamichi TSUBOI†

†*Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*
(Received September 10, 1983)

Synopsis. On cooling an aqueous solution of zinc pig-insulin to −40 °C, 108 water molecules per insulin molecule have been found (by NMR) unfrozen. This number is nearly equal to what was found crystallographically of the water molecules located within 4.7 Å of the protein molecule.

It is now well known that every globular protein is biologically active only when it is hydrated. Thus, the water molecules bound to a protein molecule are considered to play an essential role in its biological function. Their molecular structures as found in the crystal also involve a great amount of water, and these structures has been supposed to be kept on going from crystals to aqueous solutions. As a powerful tool for characterizing such protein-bound water, we have recently developed[1] a full computerized apparatus, whose main part is a broad-line pulsed NMR spectrometer with a Lamor frequency of 20 MHz, for the observation of a proton (Bruker, minispec p20). In this apparatus, the in-put is an aqueous solution of the sample protein now in question, while the out-put is the unfrozen-water content *versus* the temperature curve, where unfrozen water is defined as water molecules with protons of $T_2 > 70\ \mu s$ (here, T_2 is the spin-spin relaxation time). At any temperature below 0 °C, the usual solvent water is frozen, and the T_2 values for such water molecules are much shorter than 10 μs. Only some H_2O molecules in a special environment, such as hydrating water of a protein molecule, may be kept unfrozen, may keep a long T_2, and may be detected (as unfrozen water) by the present apparatus. The purpose of this paper is to compare what is found with this apparatus and what is found by an X-ray crystallographic study with regard to the hydration of insulin.

The sample of Zn pig-insulin powder was kindly provided by Dr. Noriyoshi Sakabe, Nagoya University; it is the same as what was subjected to his and his collaborators' crystallographic study.[2-4] Elementary analyses for this powder gave: C, 47.24; H, 6.80; N, 13.93%. This is consistent with the chemical formula of $C_{256}H_{383}N_{66}O_{76}S_6 \cdot (1/3)Zn \cdot 28H_2O$, so the water content of this powder was estimated to be 8.0 ±1.0%. This means that dry matter (DM) content=92.0 ±1.0%. The water content was also determined by measuring the weight decrease on keeping the powder sample at 115 °C for 8 h. This gave a value of H_2O content=9.4±1.0% (dry matter content=90.6 ±1.0%). A 29.2-mg portion of this powder (which should involve 26.9 mg of dry matter) was dissolved into 0.22 ml of distilled water, and this solution was then placed at the proper position in our apparatus. The out-put is illustrated in Figs. 1 and 2. As may be seen in Fig. 1, the unfrozen-water content drops suddenly at −1.5 °C (after some supercooling) in the process of cooling; this corresponds to the freezing of the solvent water. On further cooling, the unfrozen-water content is gradually lowered from 1.3 to 0.4 gH_2O/gDM. After it reaches 0.33_8 gH_2O/gDM at −25 °C, it remains nearly constant until −50 °C. In the course of warming, this unfrozen-water content is kept till the temperature becomes −10 °C, whereupon it suddenly increases. Thus, the unfrozen-water content 0.33_8 gH_2O/gDM at −40 °C seems to have some special significance; this unfrozen-water content corresponds to 108 H_2O molecules/insulin molecule, and to 216 H_2O molecules/two insulin molecules (see Table 1).

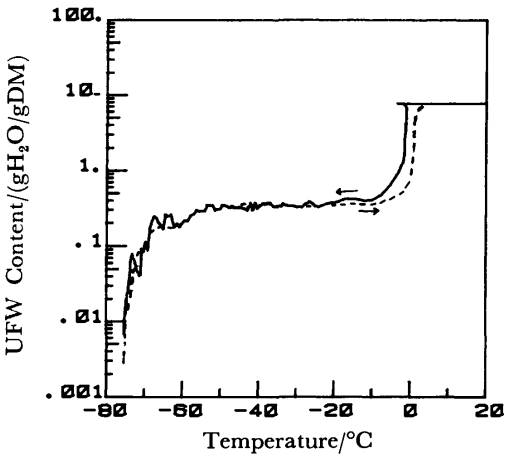

Fig. 1. Unfrozen water content *versus* temperature curves for zinc pig-insulin solution. The unfrozen water (UFW) content is given by g H_2O per g DM (dry matter). Solid line was obtained in the process of cooling (freezing curve), and dashed line was obtained in the process of warming (thawing curve).

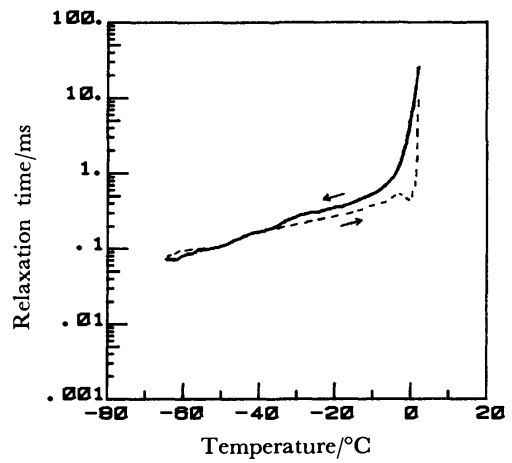

Fig. 2. T_2 (spin-spin relaxation time) *versus* temperature curves for zinc pig-insulin solution. Solid line was obtained in the process of cooling, and dashed line was obtained in the process of warming.

C	4.7—5.0	6					
				66	−25——8	0.3—0.5	0.10_0	64
Not found			55[b]				

a) Refs. 2—4. b) This may be greater than 55, because the total number of water molecules in the crystal was determined by chemical analysis, while the located molecules may have occupancy factors with values slightly less than 1.0 (private communication from Dr. N. Sakabe).

For the rhombohedral two-zinc porcine insulin crystal, a high-resolution (1.2 Å) X-ray diffraction analysis has been made.[2-4] A chemical analysis indicated that its asymmetric unit involves 2/3 Zn+2 insulin molecules+280 H_2O. Of these 280 H_2O, 225 were crystallographically determined. Among them, 214 H_2O molecules were found within the distance of 4.7 Å from the nearest atoms of insulin, and 11 H_2O molecules at distances of 4.7—5.0 Å from the nearest atoms. The remaining 55 H_2O molecules were not found because of their disorder and the larger temperature factors (see Table 1). Therefore, the water molecules remaining unfrozen in the −50——25 °C range (or in the −50——10 °C range in the thawing curve; see Fig. 1) may be correlated with the water of hydration located within 4.7 Å of the protein molecule. This may be called "tightly bound" water. The remaining 66 H_2O molecules were found in the crystallographic work to be less strongly bound to the insulin molecules. This number corresponds to the amount of water kept unfrozen in the temperature range of −8——25 °C on the freezing curve (or −15——3 °C on the thawing curve) in our NMR study. This may be called "weakly bound" water. In view of the errors (about ±5%) in our unfrozen-water content estimation, it is also possible that all the crystallographically located (at 4 °C) H_2O molecules (225 in number) correspond to unfrozen water at −40 °C ("tightly bound" water). If so, all the 55 water molecules that do not appear clearly in the crystal correspond to the "weakly bound" water.

The above-mentioned apparatus can also provide an average T_2 value of the unfrozen water at every temperature.[1] As is shown in Fig. 2, the "tightly bound" water was found to have a T_2 value of 0.1—0.3 ms, and the "weakly bound" water, one of 0.3—0.5 ms. It should also be pointed out here that a hysteresis loop in the freezing-thawing curves is found not only for the unfrozen water content (see Fig. 1), but also for the unfrozen water mobility (Fig. 2). By thermal analysis with a differential scanning calorimeter (Daini Seikosha, SSC 560U), an inflection was observed in the thawing process at −32.8 °C; this means an increase in the specific heat.

In conclusion, it may be suggested that the tightly-bound water molecules (and possibly the weakly-bound water molecules also) are nearly intrinsic on the surface of the insulin molecule, and that even in its aqueous solution their sites and orientations are similar to those in the crystal. This suggestion is based merely upon a coincidence in the numbers. If it is valid, however, it may be generalized to globular proteins other than insulin.

We wish to express our thanks to Dr. Noriyoshi Sakabe, Nagoya University, for his kindness in providing the sample and for his valuable advice.

Liquid Crystal Formation in Binary Systems. IX.[1] Effects of Branching of Ester Alkyl Group on the Induction of Liquid Crystals in the Alkyl 4-[4-(Dimethylamino)benzylideneamino]benzoate-4,4'-Dinitroazoxybenzene Systems

Yoshio MATSUNAGA* and Izumi SUZUKI
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received October 5, 1983)

Synopsis. Smectic A liquid crystals are formed not only in systems with normal alkyl esters but also with esters of branched alkyl groups such as *t*-butyl, 1,2-dimethylpropyl, and 1-ethylpropyl.

Branching of a terminal alkyl group has been shown to decrease nematic and smectic thermal stabilities relative to those of the unbranched chain compounds by Gray and Harrison.[2,3] However, the effects of branching on the liquid crystals induced in electron-donor-acceptor systems may not be the same as those found with single mesogenic compounds. Consequently, we decided to examine the effects employing binary systems consisting of nonmesogenic alkyl 4-[4-dimethylamino)benzylideneamino] benzoates as electron donors and nonmesogenic 4,4'-dinitroazoxybenzene as an electron acceptor.

The donor compounds were obtained by fusing equimolar mixtures of *p*-(dimethylamino)benzaldehyde and an appropriate alkyl *p*-aminobenzoate and purifying by repeated recrystallization from ethanol. The methyl, ethyl, two isomeric propyl, four isomeric butyl, five isomeric pentyl, and hexyl esters were prepared for this work. The acceptor compound, hereafter abbreviated as DNAO, is known to be able to produce liquid crystals when it is mixed with *N*-[4-(dimethylamino)benzylidene]-4-ethoxyaniline and related compounds.[4] The measurements were carried out as described in our earlier papers.[1,4]

A 2:1 solid molecular complex melting congruently at 179 °C is formed in the methyl ester–DNAO system. The smectic A phase induced in the composition range from 10 to 40 mol% of DNAO is metastable. The isotropic-smectic A (I-S_A) transition point at the former composition is 138 °C and that at the latter is 156 °C. The broad maximum lies at 173 °C and around 25 mol%.

As is shown in Fig. 1a, a phase diagram of the eutectic type is produced when the ethyl ester is mixed with DNAO. The I-S_A transition point curve is markedly convex upwards and appears near the eutectic point at 114 °C and 10 mol% and terminates at the intersection with the freezing point curve of DNAO at 147 °C and about 55 mol%. The effects of branching of this alkyl group are demonstrated by the phase diagrams of the isopropyl ester- and the *t*-butyl ester–DNAO systems (see Figs. 1b and 1c). The induced smectic A phases in these two systems are metastable and the maximum temperatures are 132 and 131 °C respectively. A decrease in the transition temperature by the introduction of the first methyl group to the ester ethyl group meets our expectation but, to our surprise, the effect of the second methyl group is essentially nil.

In the propyl ester–DNAO system, a smectic A phase is observable from 15 to 50 mol% (see Fig. 2a). The I-S_A transition point curve is less convex than that in the ethyl ester–DNAO system, and the maximum is found at 129 °C and around 34 mol%. By 1-methylation, the smectic A phase remains stable only in a small area. The I-S_A transition point curve reaches its maximum at 111 °C and 29 mol% (see Fig. 2b). The methylation on the penultimate carbon further reduces the thermal stability of the induced mesophase. As is shown in Fig. 2c, the smectic A phase is metastable in this binary system and a nematic phase is also induced on the acceptor-rich side. The maximum temperature of the smectic phase is 103 °C. These observations are in contrast to those made by Gray and Harrison for several series of mesogenic compounds: that is, 1-methylation generally produces the largest decrease in the thermal stability of the smectic A phase, and as the methyl group is moved to the end of the chain, the effect becomes less marked. The anomalous results described

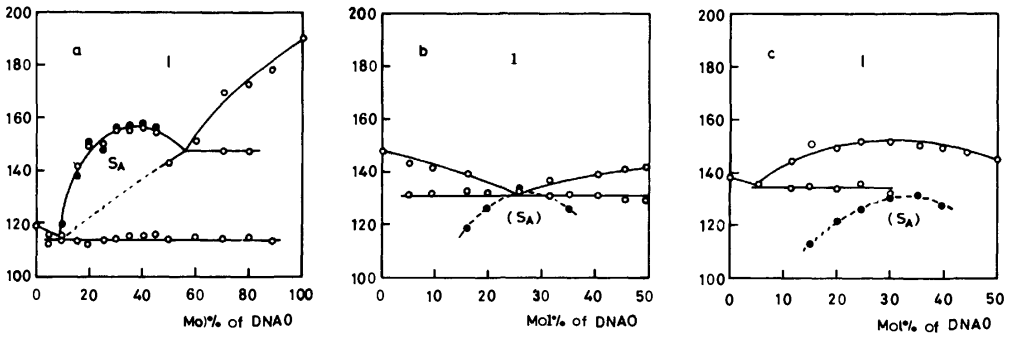

Fig. 1. Phase diagrams of the systems of DNAO with (a) the ethyl ester, (b) the isopropyl ester, and (c) the *t*-butyl ester. The open and shaded circles are transitions observed in the processes of heating and cooling respectively.

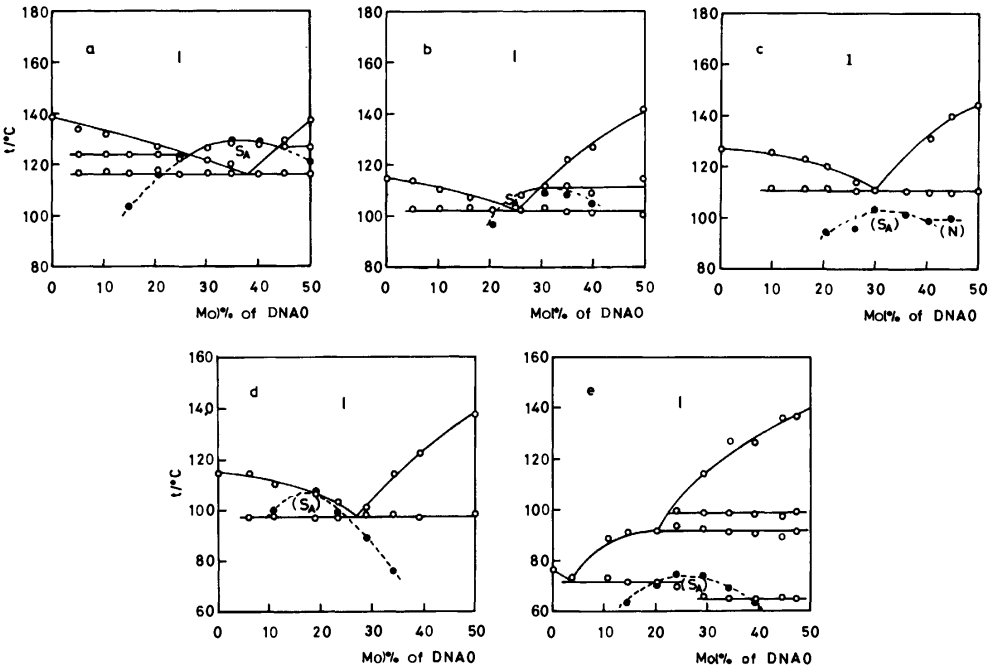

Fig. 2. Phase diagrams of the systems of DNAO with (a) the propyl ester, (b) the 1-methylpropyl ester, (c) the 2-methylpropyl ester, (d) the 1,2-dimethylpropyl ester, and (e) the 1-ethylpropyl ester. As to the open and shaded circles, see the caption of Fig. 1.

above appear to be characteristic of the present binary systems, and are in accord with the effects of the methyl substitution at both the 1 and 2 positions of the ester propyl group (see Fig. 2d). If one considers a 1-methyl group to be added to the isobutyl ester, the substitution raises the maximum I-S_A transition temperature by 3 °C, whereas if the 2-methyl group is regarded as an extra substituent, the temperature is lowered by 5 °C. Moreover, no mesophase could be observed in the neopentyl ester-DNAO system. Figure 2e presents the phase diagram of the 1-ethylpropyl ester-DNAO system. The transition temperature change by 1-ethylation to 74 °C is double that by 1-methylation.

Contrary to the above cases, the effects of methylation on the induced smectic A phase in the butyl ester-DNAO system is normal. The butyl ester and its 2-methyl and 3-methyl derivatives all produce stable smectic A phases when they are mixed with DNAO. The maximum I-S_A transition temperatures are 120, 90, and 111 °C respectively. Finally, it must be noted that the longer the unbranched alkyl group, the maximum I-S_A transition temperature becomes lower: namely, 110 °C with the pentyl ester and 108 °C with the hexyl ester. In the former case, the induced mesophase is metastable in the whole composition range. Thus, even numbers of carbon atoms in the ester alkyl group in the present binary systems tend to produce larger regions of stable existence of induced smectic A phase. This behavior may be, at least partly, ascribed to the marked odd-even alternation of the melting point of the ester as the mesophase is induced in the donor-rich composition range (compare Figs. 1a and 2a).

Although the mechanism of the transition temperature change by chain branching is not well understood even in single mesogenic compounds, branching certainly disturbs smectic order because of a steric interference with neighboring molecules. The anomalous effects observed with the ethyl and propyl esters may be tentatively explained by the difference in molecular length between the donor and acceptor. As the donor and acceptor molecules are arranged side by side in the mesophase, the 1-methyl group may be accommodated, partially at least, within room produced by the acceptor molecule which is shorter than the ester molecules. If the ester molecules are still longer and/or the point of branching is near the end of the chain, the flexible alkyl group is surrounded increasingly by like molecules and may behave as if it is in a single mesogenic compound.

The present work was partly supported by a Grant-in-Aid for Scientific Research No. 543001 from the Ministry of Education, Science and Culture.

Emergence of Nematic Phase in Purely Smectogenic Alkyl 4-(4-Substituted Benzylideneamino)benzoates by Chain Branching of the Ester Alkyl Group

Yoshio MATSUNAGA* and Nobuhiko MIYAJIMA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received November 4, 1983)

Synopsis. 2-Methylation of the ester butyl and pentyl groups in the phenyl-substituted compounds and also of the ester propyl, butyl, and pentyl groups in a number of the alkoxy-substituted compounds resulted in the production of nematic liquid crystals.

Gray and Harrison systematically studied the effects of branching of alkyl chain on the liquid crystalline behavior of 4-(4-substituted benzylideneamino)-cinnamates.[1,2] Methylation at any carbon of the ester alkyl chain was found to decrease liquid crystal stability. They noted that branching has a greater effect on nematic than on smectic thermal stability. However, there may be cases where nematic liquid crystals arise by partial destruction of smectic ordered arrangement due to methylation of the alkyl chain as subtle changes in molecular structure can strongly influence the liquid crystalline behavior. Thus, we began a study of the effects of chain branching specifically paying attention to such a possibility. In this note, we wish to report the formation of nematic liquid crystals by 2-methylation of alkyl chains (R′) in fourteen purely smectogenic compounds of the following type.

The mesogenic compounds first studied by us were alkyl 4-(4-phenylbenzylideneamino)benzoates (X=Ph) which are closely related in molecular structure to the compounds studied by Gray and Harrison. The ethyl and isopropyl esters are purely smectic in behavior. Stable nematic and smectic A phases are given by the propyl ester. As the butyl and pentyl esters exhibit only smectic properties, search for nematic phases was undertaken with all the possible methylbutyl and methylpentyl esters. The emergence is limited to the 2-methyl derivatives. The transition temperatures determined by differential scanning calorimetry are presented in Table 1 together with those of the unbranched alkyl esters. The mesophases were identified by examination of their textures with the aid of a polarizing microscope in conjunction with a heated stage.

Further examples were provided by some alkyl 4-(4-alkoxybenzylideneamino)benzoate (X=RO) series. The alkoxyl group includes all the members from methoxyl to decyloxyl. Among the propyl esters, the first two members are nematogenic, whereas the higher members are purely smectogenic (see Table 2).

We have found that five members from the propoxy to heptyloxy derivatives in the isobutyl esters exhibit nematic behavior. As in shown in Table 2, the nematic phase in the propoxy derivative is monotropic. Nevertheless, the temperature range of existence is as wide as 12 °C in this compound, and progressively decreases with lengthening of the alkoxyl group. Above octyloxy derivative a smectic A phase becomes the only observable mesophase. Thus, none of the isobutyl esters gives smectic B phase found with most of the propyl esters.

The butyl 4-(4-alkoxybenzylideneamino)benzoate series has been examined by Fishel and Patel.[3] The methoxy derivative gives no mesophase but a metastable smectic A phase is observable with the ethoxy derivative. All the higher members were reported to be purely smectic in behavior. The methoxy and ethoxy derivatives of the racemic 2-methylbutyl esters examined by us form nematic liquid crystals (see Table 3); however, the higher members give only smectic A

Table 1. Transition temperatures (°C) for alkyl 4-(4-phenylbenzylideneamino)benzoates

phase. These results contrast greatly with those described for the isobutyl ester series and also the findings with the 2-methylpentyl esters to be presented in next paragraph.

In the series of pentyl esters, the methoxy and ethoxy derivatives were found to be nonmesogenic and nematogenic respectively. All the other members give smectic A phase. Upon 2-methylation, the members from the propoxy to heptyloxy derivatives exhibit nematic properties (see Table 4). In this series too, the metastable phase in the propoxy derivative appears over the widest temperature range. The phase is enantiotropic in the next three members but monotropic again in the heptyloxy derivative and the range is as narrow as 1 °C in the last. Finally we add that neither the 3-methylpentyl nor 4-methylpentyl ester exhibits nematic behavior except for the methoxy derivative in the latter series. A monotropic isotropic-nematic transition occurs at 16 °C for this compound.

In conclusion, we wish to emphasize that methylation of the ester alkyl chain not only diminishes the thermal stability of smectic A mesophase, as confirmed by the ample examples presented in the four tables, but also gives rise to the appearance of nematic phase in a number of smectogens by partial destruction of the molecular order, the magnitude of which seems to be just right, in general, when the methyl group is located at the 2 position.

Determination of the Vapor Pressures of Lithium Chloride and Sodium Bromide by a Molecular Effusion-Surface Ionization Method

Hiroyuki KAWANO,* and Tsutomu KENPŌ
Department of Chemistry, Faculty of Science, Ehime University, 2-5, Bunkyō-chō, Matsuyama 790
(Received December 7, 1983)

Synopsis. By means of molecular effusion from a Knudsen cell and of thermal positive ionization on a glowing polycrystalline rhenium filament, the vapor pressure P (in atm) of LiCl or NaBr was measured as a function of cell temperature T (in K). The following equations were established empirically.

$$\log_{10} P(\mathrm{LiCl}) = (7.948\pm0.102) - (10954\pm76)/T \quad \text{for 662—848 K,}$$

$$\log_{10} P(\mathrm{NaBr}) = (7.716\pm0.072) - (11138\pm55)/T \quad \text{for 669—882 K.}$$

In order to study the chemical reactions in the gas phase or on solid surfaces, many workers have recently employed a molecular beam technique, where the beam intensity of molecules (MX) effusing from a Knudsen cell is usually evaluated thermodynamically from published data on the vapor pressure (P(MX)) of MX. Literature values of P(MX), however, scatter widely in general, thereby suggesting that reliable data on P(MX) should be obtained by precise measurements of both effusion rate and cell temperature.

From the above point of view, the present authors already tried a precise determination of the vapor pressures of CsF and CsCl, and obtained fruitful results in a previous work.[1] Therefore, the same method of thermal positive ionization was employed in this work, too, in order to detect a molecular beam of LiCl or NaBr.

In this paper the experimental data on the vapor pressure and on the entropy and enthalpy changes due to sublimation are summarized briefly and also compared with data published to date.

Experimental

Experimental apparatus and method employed in this work were the same as in the previous work.[1] A molecular beam of MX (LiCl or NaBr) effusing from a Knudsen cell heated to a temperature (T) was directed onto a polycrystalline rhenium filament (F) kept at a high temperature (T_F), and the total ion current ($I^+(M^+)$) of M^+ (Li^+ or Na^+) emitted from F was measured as a function of T or T_F. The samples (LiCl and NaBr) of optical grade were obtained from Wako Pure Chem. Ind., Ltd.

Results and Discussion

At first, the Knudsen cell was kept at a constant temperature higher than 800 K, and $I^+(M^+)$ was measured as a function of T_F in order to find a filament temperature suitable for detecting a beam of MX. In consequence, $I^+(Li^+)$ and $I^+(Na^+)$ corresponding to the cell temperatures T=840 and 885 K, for example, were constant at 38.4±1.8 and 35.6±0.6 nA in the ranges $T_F\simeq$1430—1520 and 1100—1500 K, respectively, indicating that the ionization efficiencies of LiCl and NaBr incident upon F were essentially unity in the respective ranges.

Next, $I^+(M^+)$ was measured as a function of T at T_F=constant in either of the above ranges.

Finally, the vapor pressure was evaluated from

$$P(\mathrm{MX}) = 1.27[M(\mathrm{MX})\cdot T]^{1/2}\, I^+(M^+), \qquad (1)$$

where P(MX) and $I^+(M^+)$ are expressed in atm and ampere, respectively, and M(MX) is the molecular weight of MX. This equation is the same as Eq. 3 in the previous paper.[1]

Temperature dependence of P(MX) determined by the present and other workers is illustrated in Figs. 1 and 2, which indicate that the following equation holds in general.

$$\log_{10} P(\mathrm{MX}) = A - B/T. \qquad (2)$$

The values of A and B determined empirically and of P(MX) evaluated from Eq. 2 for three selected temperatures are shown together with literature values in Table 1. The entropy and enthalpy changes ($\Delta S(\bar{T})$ and $\Delta H(\bar{T})$) due to sublimation at the mean temperature ($\bar{T}$) in the range (T_R) covered in each measurement were calculated from Eqs. 3 and 4, respectively.

† 1 cal=4.184 J.

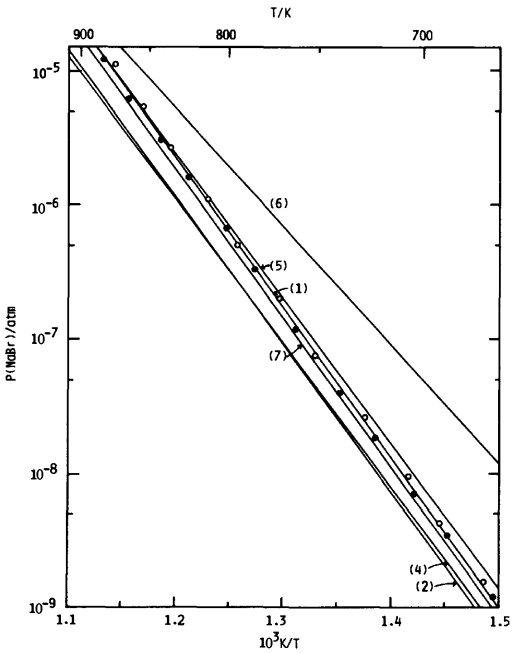

Fig. 2. Temperature depenednce of the vapor pressure of NaBr.
(1): This work at T_F=1360 K (open circle) or 1400 K (solid circle), (2): Ref. 2, (4): Ref. 4, (5): Ref. 5, (6): Ref. 6, and (7): Ref. 7.

$$\Delta S(\overline{T}) = (\ln 10)RA \equiv 4.575\,A \text{ cal mol}^{-1}\text{ K}^{-1}, \quad (3)$$

$$\Delta H(\overline{T}) = (\ln 10)RB \equiv 4.575\times10^{-3}\,B \text{ kcal mol}^{-1}, \quad (4)$$

where 1 cal is equal to 4.184 J. In a similar way as in the previous work,[1] the heat of sublimation at 300 K was calculated from

$$\Delta H(300) \simeq \Delta H(\overline{T}) + aR(\overline{T}-300). \quad (5)$$

According to the data on specific heats of MX,[2] the values of a in the range 300—800 K were taken as 2.27 and 2.16 for LiCl and NaBr, respectively, in this work.

The values of T_F in the present works (a)—(d) given in the last column in Table 1 were 1480, 1510, 1360, and 1400 K, respectively. The present works (A) and (B) indicate the average values of those (a) and (b) and those (c) and (d), respectively. As may be seen in Fig. 1 and Table 1, the values of P(LiCl) cited from Refs. 3, 4, and 5 and from Refs. 2 and 6 are close to and apart from those determined in this work, respectively. Figure 2 and Table 1 indicate that the data on P(NaBr) obtained in this work lie in the region between those quoted from Ref. 5 and those from Ref. 7, and also that the data in Ref. 6 have the largest deviation from the other data cited therein.

The above results may lead to the conclusions that the data on LiCl in Refs. 3, 4, and 5 are more reliable than those in Refs. 2 and 6, and that the data on NaBr in Refs. 5 and 7 are more accurate than those in Refs. 2, 4, and 6, and also that the data in Ref. 6 are not available for a precise evaluation of P(LiCl) or P(NaBr) in the temperature range lower than the melting point (887 K for LiCl or 1028 K for NaBr).

Crystal Structure of Dimethyltin Molybdenum Tetraoxide, $(CH_3)_2SnMoO_4$

Yukiyoshi SASAKI,* Hideo IMOTO, and Osamu NAGANO†

Department of Chemstry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received October 25, 1983)

Synopsis. Single-crystal X-ray analysis has shown that the title compound is tetragonal, $P4_2/mbc$, with a= 13.705(2), c=7.271(1) Å. The structure is made of octahedra of *trans*-$Sn(CH_3)_2O_4$ and tetrahedra of MoO_4. These polyhedra share apices to form a three-dimensional structure.

In 1953, Rochow *et al.* reported the synthesis of dimethyltin molybdenum tetraoxide. They treated dimethyltin dichloride with sodium molybdate in aqueous solution, and obtained the compound as a flocculent precipitate.[1] Later, ^{119}Sn Mössbauer spectroscopy of the compound showed that the asymmetry parameter of the tin atom was nearly zero, which indicated the trans-octahedral coordination.[2] Recently we have succeeded in preparing large single crystals of the compound by using isopolymolybdate as the molybdate source, and determined the structure by the single-crystal X-ray analysis.

Experimental

Dimethyltin dichloride (1 g) was added to the aqueous solution of ammonium heptamolybdate $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ (6 g in 60 cm^3 water). Immediately after the addition, pH of the solution decreased to *ca.* 2. After several hours, colorless rectangular crystals of dimethyltin molybdenum tetraoxide $(CH_3)_2SnMoO_4$ were obtained (Found: C, 7.86; H, 2.01%). The largest crystals were *ca.* 10 mm long.

Weissenberg photographs showed that the space group of the crystal was $P4_2/mbc$ (centrosymmetric) or $P4_2bc$ (noncentrosymmetric). The cell parameters were determined by least-squares refinements from 21 reflections ($45°<2\theta<60°$). X-Ray reflection data were collected with a Rigaku automated four-circle diffractometer (crystal, cubic in shape and *ca.* 0.2 mm long; radiation, Mo $K\alpha$ monochromatized by a graphite plate; scan method, ω-2θ, $2\theta\leq 60°$).[3] Intensities of three standard reflections were monitored for every 50 reflections and found to be constant. The structure was solved by the heavy atom method with the space group $P4_2/mbc$, and refined both in $P4_2/mbc$ and $P4_2bc$ by the block-diagonal least-squares method, where 879 independent reflections were used. The function minimized was $\sum w(|F_o|-|F_c|)^2$ where w=0.2 for $|F_o|<10$ and w=1 otherwise. Atomic scattering factors were taken from "International Tables for X-Ray Crystallography" (1974). The refinement in the space group $P4_2bc$ included the anomalous dispersions for heavy atoms. Computations were performed with a local version of *UNICS* at the Computer Center of the University of Tokyo.

The comparision of the results of the refinements in the space group $P4_2/mbc$ and $P4_2bc$ were summarized as follows:

(a) The final R-values were almost equal (0.031 for $P4_2/mbc$ and 0.030 for $P4_2bc$), though the number of parameters in $P4_2/mbc$ is much smaller than in $P4_2bc$ (46 for $P4_2/mbc$ and 73 for $P4_2bc$).

(b) Both refinements yielded substantially the same x and y values. Their standard deviations in $P4_2bc$ were 1—2 times larger than the corresponding values in $P4_2/mbc$.

(c) The standard deviations of the z values were very large in $P4_2bc$ (0.0006 for heavy atoms and 0.0011—0.0082 for light atoms), while in $P4_2/mbc$ they were small or zero due to the crystallographic symmetry. The z values of heavy atoms were significantly different in the two refinements, because the differences were 10 times of their standard deviations. However, for light atoms the differences of the z values were not very significant (1—3 times of their standard deviations). From these results we concluded that the space group $P4_2bc$ was very improbable.

Results and Discussion

The cell, positional, and thermal parameters are listed in Table 1, and bond lengths and angles are shown in Fig. 1.

The tin atom has the *trans*-octahedral coordination, *trans*-$Sn(CH_3)_2O_4$. This is consistent with the result of previous Mössbauer studies.[2] The molybdenum atom is tetrahedrally coordinated by four oxygen atoms. All oxygen atoms are bridging tin and molybdenum atoms (Fig. 1).

The structure extends three-dimensionally. It has zig-zag chains of $(-Sn-O-Mo-O-)_\infty$ along the a axis exactly on the plane at z=0, and identical chains along the b axis at z=1/2. These chains are not connected with other chains on the same plane, but with those on the neighboring planes through O(3) atoms (Fig. 2). The location of the tin atoms can be approximately described as a body-centered cubic arrangement as shown in Fig. 3. A unit cell contains four body-centered cells of the tin atoms. The body-centered cells are elongated 6% along the c axis, and the tin atoms are shifted on the xy plane 0.21 Å from the ideal positions. The molybdenum atoms are in the tetrahedral holes of this body-centered packing of the tin atoms, and oxygen atoms are placed between the metal atoms.

The structure of $(CH_3)_2SnMoO_4$ consists of octahedra and tetrahedra in the ratio of 1:1, and

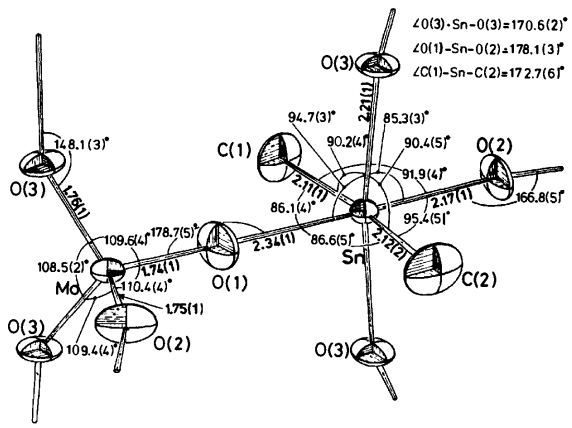

Fig. 1. ORTEP drawing of $(CH_3)_2SnMoO_4$ with bond lengths (in Å) and angles. The estimated standard deviations are in parentheses. The atoms, Sn, Mo, O(1), and O(2), are on a crystallographic mirror plane.

these polyhedra share only apices. Compounds with these structural features are rare, and we have found only two examples. Neither of them is isostructural with $(CH_3)_2SnMoO_4$. The first example is a series of compounds $A(H_2O)_2BO_4$ (A=Al, In, Tl, or Fe; B= P or As).[4] These compounds have a cis coordination of aqua ligands around the A atoms in contrast with a trans coordination of methyl groups in $(CH_3)_2SnMoO_4$. The second example is the clathrate compound $Cd(NH_3)_2Hg(CN)_4\cdot 2C_6H_6$ which has octahedra of *trans*-$Cd(NH_3)_2(NC)_4$ and tetrahedra of $Hg(CN)_4$.[5] The metal atoms of this clathrate compound are arranged in the same way as the platinum and sulfur atoms in the PtS structure. This compound and $(CH_3)_2SnMoO_4$ are structurally very similar because both have approximately body-centered arrangement of the metal atoms with the *trans*-octahedral coordination. Furthermore, in the three-dimensional networks of both structures, the smallest rings are 8-membered when the CN ligand is regarded as one unit. However, the two structures are definitely different. In $(CH_3)_2SnMoO_4$ three atoms, Sn, O(2), and Mo, are shared by neighboring 8-memberd rings, while in the clathrate compound only one atom, Cd or Hg, is shared.

The authors wish to express their thanks to Akiko Kobayashi, the University of Tokyo, for X-ray data collection and for helping with the structural determination.

Preparation and Characterization of the Diastereoisomers of the (*S*)- or (*R*)-1,2-Propanediaminebis(1,10-phenanthroline)cobalt(III) Ion

Akira TATEHATA* and Shigeru NATSUME
Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422
(Received November 19, 1983)

Synopsis. Four diastereoisomers of the type $[Co(S- or R-pn)(phen)_2]^{3+}$ (pn=1,2-propanediamine; phen=1,10-phenanthroline) were prepared and characterized by absorption, circular dichroism (CD), and ^1H NMR spectra. High stereoselectivity in the formation of the diastereoisomers was observed and the Λ-isomer of $[Co(S-pn)(phen)_2]^{3+}$ was formed in preference to the Δ-isomer.

Although some complexes of the type $[Co(aa)(phen)_2]^{n+}$ (aa=chiral α-hydroxy carboxylate ion[1] and α-amino acidate ion[2]) have been prepared and studied on the absorption and circular dichroism (CD) spectra, there is no report for this type of complex containing a chiral diamine. This Note describes the preparation and the spectroscopic properties of the optically active complexes $[Co(S- or R-pn)(phen)_2]^{3+}$ and compares the formation ratio between the diastereoisomers with that of the corresponding ethylenediamine complexes $[Co(S- or R-pn)(en)_2]^{3+}$. It is shown on the basis of ^1H NMR spectra that interligand interactions between 1,2-propanediamine and bis(1,10-phenanthroline) moiety lead to high stereoselectivity in this systems.

Experimental

1,2-propanediamine was resolved as described in the literature,[3] $[\alpha]_D^{25}$ +10.2° for *S*-(+)-pn and $[\alpha]_D^{25}$ −10.6° for *R*-(−)-pn (free diamine, 3—5% aqueous solution).

Preparation and Separation of Isomers. To a suspension of *cis*-$[CoCl_2(phen)_2]Cl\cdot 3H_2O$[4] (1 g, 1.7 mmol) in 50 cm³ of methanol, 1.5 cm³ of methanol solution of (*S*)- or (*R*)-1,2-propanediamine (10% v/v) was added with stirring. The solution was kept in a water bath (40 °C) for 3 h. The resulting yellow-orange solution was diluted with water and poured on a column of SP-Sephadex C-25 (φ2.7×50 cm) in the sodium form. Three bands were developed on the column during the elution with a 0.3 mol dm⁻³ NaCl solution. Their bands, identified as the $[Co(phen)_3]^{3+}$, $[Co(pn)(phen)_2]^{3+}$, and $[Co(pn)_2(phen)]^{3+}$, were eluted in this order from bottom of the column. The second band containing the desired complex was transfered to another SP-Sephadex column (φ2.7×90 cm) and was eluted with a 0.15 mol dm⁻³ $Na_2[Sb_2(d\text{-tart})_2]$ to separate into the diastereoisomers. The formation ratio between the diastereoisomers was calculated from the areas of the elution curve. In both cases of the *S*- and the *R*-pn complexes, Λ-isomer was always eluted earlier than Δ-isomer. The fractions for each band were combined and passed through an SP-Sephadex column (φ2.0×3 cm) after dilution with water and the adsorbed complex was eluted with a 0.5 mol dm⁻³ $NaClO_4$ solution. The solution was concentrated with a rotary evaporator under reduced pressure and was kept in a refrigerator. The specific rotations and analytical results are given in Table 1.

Measurements. Absorption and CD spectra were obtained on a Shimadzu MPS-50L recording spectrophotometer and a JASCO J-40 spectropolarimeter, respectively. ^1H NMR spectra (90 MHz) were measured on a Varian EM-390 spectrometer in D_2O solution using sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) as an internal standard reference. For the measurement of ^1H NMR spectra, the perchlorate salts were converted into the chloride salts with an anion exchange resin (Dowex 1-X8, Cl^- form).

Results and Discussion

The absorption and the CD spectra of $[Co(S-pn)(phen)_2]^{3+}$ are shown in Fig. 1, and their numerical data are given in Table 2. The absolute configurations of the isomers were assigned on the basis of the sign of dominant CD peak in the T_{1g} region and the CD spectra in the region of the phen ligand π-π^* transition. The configurational and vicinal effect curves under the T_{1g} band evaluated from the CD spectra of the diastereomeric pair of *R*-pn complexes are shown in Fig. 2. The configurational effect curve for Λ-$[Co(R-pn)(phen)_2]^{3+}$ is quite similar to the CD[5] for Λ-$[Co(en)(phen)_2]^{3+}$, where there is no vicinal effect. The contribution from vicinal effect exhibits a −, + CD sign pattern similar in shape to that reported for *R*-pn in Co (III) complexes containing *R*-pn and en,[6] but the relative intensities differ considerably. It is well known that the coordinated *R*-pn exists predominantly in the more stable conformation (λ gauche form) with an equatorial methyl group.[7] The above finding for the vicinal effect of the Λ-$[Co(R-pn)(phen)_2]^{3+}$ may indicate that although the coordinated *R*-pn ligand keeps the λ gauche form with an equatorial methyl group, it is subjected to different degrees of distortion because of the significant difference of the interligand interactions between the pn-en systems and the pn-phen systems. This may be also reflected on the formation ratios (Λ/Δ) of the diastereoisomers in both systems. The diastereoisomeric Λ/Δ ratio was 4.8±0.2 for the $[Co(S-pn)(phen)_2]^{3+}$, indicating that this stereoselectivity occurred in the phenanthroline complex is very higher than that for the corresponding ethylenedi-

amine complex [Co(*S*-pn)(en)$_2$]$^{3+}$, for which the value of Λ/Δ=2.1 had been reported.[8] This remarkable stereoselectivity in the pn-phen systems may be attributed to intramolecular ligand-ligand interactions between the aromatic ring of the phenanthroline ligands and the *S*-pn ligand. Molecular model reveals that the methyl group of *S*-pn in the Λ-isomer is located above the aromatic ring of one phenanthroline and thus lies under the influence of the ring current (Fig. 3). Such a hydrophobic interaction (CH$\cdots\pi$ interaction) is known to function as a stabilization effect of the complexes.[9] On the other hand, the methyl group of *S*-pn in the Δ-isomer takes a position by the side of the phenanthroline plane, and therefore may cause some repulsive interactions with α-proton of the phenanthroline (Fig. 3), resulting in the less favored Δ-isomer. These situations were confirmed by the ^{1}H NMR spectra of the diastereoisomers (Fig. 4). The methyl protons in the Λ-*S* isomer (1.49 ppm) resonate at higher field than in the Δ-*S* isomer (1.62 ppm), as has been observed for the methyl protons in [Co(*S*-ala)(phen)$_2$]$^{2+}$ complexes.[2] These chemical shifts observed imply that the methyl protons in the Λ-*S* isomer are shielded by one phenanthroline ring to resonate at a high field and those in the Δ-*S* isomer are in a deshielding region near the phenanthroline plane, being in agreement with considerations from the molecular model.

Reactions of Arenesulfonyl Chlorides with *cis*- or *trans*-β-Methylstyrene Catalyzed by Ruthenium(II) Complex

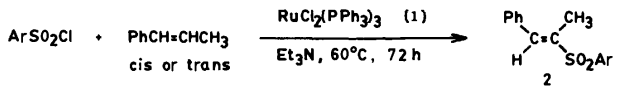
Nobumasa KAMIGATA,* Tomoo NARUSHIMA, Hideo SAWADA, and Michio KOBAYASHI
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158
(Received June 16, 1983)

Synopsis. The reactions of arenesulfonyl chlorides with *cis*- or *trans*-β-methylstyrene catalyzed by dichlorotris(triphenylphosphine)ruthenium(II) in the presence of triethylamine proceeded smoothly to give only (*E*)-2-arylsulfonyl-1-phenylpropene. The recovered *cis*-β-methylstyrene was isomerized to trans form, while *trans*-β-methylstyrene did not isomerize to the cis one.

Recently, much attention has been paid to the radical reactions formed from halides treated with transition metal complexes.[1] We have reported the reactions of arenesulfonyl chlorides with vinylarenes catalyzed by dichlorotris(triphenylphosphine)ruthenium(II) (**1**) in the presence of triethylamine to give α,β-unsaturated sulfones.[2] We report here the reactions of arenesulfonyl chlorides with *cis*- or *trans*-β-methylstyrene catalyzed by ruthenium(II) complex.

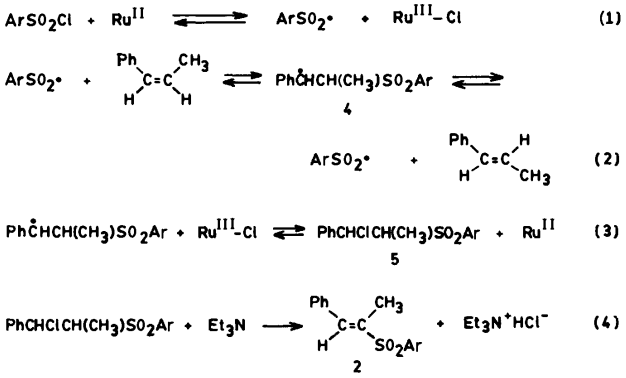
The reaction of *p*-toluenesulfonyl chloride with *trans*-β-methylstyrene was carried out in benzene, using ruthenium(II) complex **1** as catalyst in the presence of a molar equivalent of triethylamine at 60 °C for 72 h in a degassed sealed tube. The reaction mixture was chromatographed on Florisil column using benzene as an eluent to give (*E*)-1-phenyl-2-(*p*-tolylsulfonyl)propene (**2a**) as colorless crystals, mp 122.5—123.0 °C (from ethanol). The stereochemistry of **2a** was confirmed by its spectral data (see Experimental section). Its stereoisomer, (*Z*)-1-phenyl-2-(*p*-tolylsulfonyl)propene (**3a**), mp 54—55 °C, prepared by oxidation of 1-phenyl-1-phenylseleno-2-(*p*-tolylsulfonyl)propane exhibited different spectral properties.

The reaction of *p*-toluenesulfonyl chloride with *cis*-β-methylstyrene was carried out under similar conditions to give also **2a**; none of its (*Z*)-isomer **3a** was detected. Similarly, reactions of several arenesulfonyl chlorides with *cis*- and *trans*-β-methylstyrene catalyzed by **1** were studied and only (*E*)-2-arylsulfonyl-1-phenylpropene (**2**) were obtained in all the cases. The results are summarized in Table 1.



No isomerization of (*Z*)-1-phenyl-2-(*p*-tolylsulfonyl)-propene (**3a**) to its (*E*)-isomer **2a** was observed when **3a** was treated with ruthenium(II) catalyst **1** in benzene at 60 °C. This excluded the possibility that **3a** is first formed in the reaction of *p*-toluenesulfonyl chloride with *cis*- or *trans*-β-methylstyrene and then isomerized to **2a** during the reaction period. The formation of **2** may be explained by the base-catalyzed elimination of hydrogen chloride from the adduct 2-arylsulfonyl-1-chloro-1-phenylpropane (**5**) shown in Scheme 1 as one plausible mechanism. Accordingly, even though the adduct **5** formed is a mixture of threo and erythro isomers, the formation of **2** as a sole product may be accounted for by assuming that the elimination proceeded by E2 mechanism, the formation of *Z*-isomer **3** is very slow, and also the Eqs. 1—3 are equilibrium ones.

The stereochemistry of the β-methylstyrene which was recovered was examined by HPLC. No isomerization of *trans*-β-methylstyrene to *cis*-isomer was ob-



Scheme 1.

p-$CH_3OC_6H_4SO_2Cl$	cis	46	**2b**	70	4/96
$C_6H_5SO_2Cl$	cis	26	**2c**	73	42/58
p-$ClC_6H_4SO_2Cl$	cis	32	**2d**	69	37/63

a) The yields are based on the β-methylstyrene (cis or trans) consumed.

served, while a large part of *cis*-β-methylstyrene was found to be converted to trans form (see Table 1). The isomerization of *cis*-β-methylstyrene was not observed when a mixture of *cis*-β-methylstyrene, ruthenium(II) catalyst **1**, and triethylamine in benzene was heated at 60 °C for 72 h. This means that *cis*-β-methylstyrene does not isomerize to trans in the absence of arenesulfonyl chloride. The fact that *cis*-β-methylstyrene isomerized to trans only when a solution of *cis*-β-methylstyrene, ruthenium(II) catalyst, and arenesulfonyl chloride in benzene was heated in the presence or absence of triethylamine means that Eq. 2 in Scheme 1 is reversible and that thermodynamically stable *trans*-β-methylstyrene is preferably formed from the radical **4**.

Experimental

Measurement. Melting points and boiling points are uncorrected. The infrared absorption spectra were determined on a Hitachi Model EPI-G2 spectrophotometer using samples as KBr disks. The proton magnetic resonance spectra were recorded at 60 MHz using a Hitachi R-20B spectrometer with Me_4Si as an internal standard in $CDCl_3$. Mass spectra were determined with a JEOL JMS-07 mass spectrometer at an ionizing voltage of 30—75 eV. Elemental analyses were operated with a Perkin-Elmer 240 elemental analyzer. HPLC was carried out on a Water's ALC-204 HPLC using a silica-gel column using benzene as an eluent.

Materials. Dichlorotris(triphenylphosphine)ruthenium(II) (**1**) was prepared by the methods described in the literature.[3] *p*-Toluenesulfonyl chloride and *p*-chlorobenzenesulfonyl chloride of Tokyo Kasei Chemicals were recrystallized prior to use. Benzenesulfonyl chloride of Wako Chemicals, *cis*-β-methylstyrene of ICN Pharmaceuticals, and *trans*-β-methylstyrene of Tokyo Kasei Chemicals were purified by distillation under nitrogen prior to use. *p*-Methoxybenzenesulfonyl chloride was prepared by the methods described in the literature.[4]

General Procedures in the Reaction of Arenesulfonyl Chloride with cis- *or* trans-*β-Methylstyrene Catalyzed by 1.* A solution containing 2.0 mmol of arenesulfonyl chloride, 2.0 mmol of *cis*- or *trans*-β-methylstyrene, 2.0 mmol of triethylamine, and 0.16 mmol of **1** in 3.0 cm^3 of benzene was heated at 60 °C in a degassed sealed tube for 72 h. The remaining β-methylstyrene (cis and trans) was quantitatively analyzed by HPLC using an internal standard. The reaction mixture was chromatographed on Florisil using benzene as an eluent to give (*E*)-arylsulfonyl-1-phenylpropene **2** which were characterized by IR, ^1H NMR, and mass spectra, and elemental analyses.

*(E)-1-Phenyl-2-(p-tolylsulfonyl)propene (**2a**)*: Mp 122.5—123.0 °C. IR (KBr): 1150 and 1310 cm^{-1}. ^1H NMR ($CDCl_3$): δ=2.10 (3H, d, *J*=1.8 Hz), 2.44 (3H, s), 7.34 (2H, d, *J*=8.4 Hz), 7.38 (5H, s), 7.80 (1H, q, *J*=1.8 Hz), and 7.82 (2H, d, *J*=8.4 Hz). Mass: *m/z* 272 (M^+). Found: C, 70.26; H, 6.01%. Calcd for $C_{16}H_{16}O_2S$: C, 70.56, H, 5.92%.

*2-(p-Methoxyphenylsulfonyl)-1-phenylpropene (**2b**)*: Mp 82—83 °C. IR (KBr): 1147 and 1300 cm^{-1}. ^1H NMR ($CDCl_3$): δ=2.10 (3H, d, *J*=1.8 Hz), 3.87 (3H, s), 7.02 (2H, d, *J*=8.4 Hz), 7.39 (5H, s), 7.81 (1H, q, *J*=1.8 Hz), and 7.89 (2H, d, *J*=8.4 Hz). Mass: *m/z* 288 (M^+). Found: C, 66.70; H, 5.58%. Calcd for $C_{16}H_{16}O_3S$: C, 66.64; H, 5.59%.

*1-Phenyl-2-(phenylsulfonyl)propene (**2c**)*: Mp 88.5—89.0 °C. IR (KBr): 1152 and 1305 cm^{-1}. ^1H NMR ($CDCl_3$): δ= 2.10 (3H, d, *J*=1.8 Hz), 7.42 (5H, s), 7.86 (1H, q, *J*= 1.8 Hz), and 7.5—8.1 (5H, m). Mass: *m/z* 258 (M^+). Found: C, 69.80; H, 5.48%. Calcd for $C_{15}H_{14}O_2S$: C, 69.74; H, 5.46%.

*2-(p-Chlorophenylsulfonyl)-1-phenylpropene (**2d**)*: Mp 104—105 °C. IR (KBr): 1158 and 1310 cm^{-1}. ^1H NMR ($CDCl_3$): δ=2.13 (3H, d, *J*=1.8 Hz), 7.50 (5H, s), 7.62 (2H, d, *J*=8.4 Hz), 7.95 (1H, q, *J*=1.8 Hz), and 8.01 (2H, d, *J*=8.4 Hz). Mass: *m/z* 294 and 292 (M^+). Found: C, 61.51; H, 4.51%. Calcd for $C_{15}H_{13}ClO_2S$: C, 61.53; H, 4.48%.

*Preparation of (Z)-1-Phenyl-2-(p-tolylsulfonyl)propene (**3a**).* A solution containing 3.2 g (10.3 mmol) of *Se*-phenyl *p*-tolueneselenosulfonate and 1.46 g (12.3 mmol) of *trans*-β-methylstyrene in 11 cm^3 of benzene was heated at 80 °C in a degassed sealed tube for 20 h. Removal of the solvent left a light yellow solid, which when recrystallized from ethanol afforded 2.4 g (54%) of a colorless crystalline solid, whose structure was assigned as 1-phenylseleno-1-phenyl-2-(*p*-tolylsulfonyl)propane on the basis of its physical and spectral properties: Mp 118—119 °C. IR (KBr): 1190, 1295, and 1305 cm^{-1}. Found: C, 61.56; H, 5.19%. Calcd for $C_{22}H_{22}O_2SSe$: C, 61.53; H, 5.16%. To a solution containing of 1-phenylseleno-1-phenyl-2-(*p*-tolylsulfonyl)propane 1.0 g (2.3 mmol) in 10 cm^3 of THF, 2.0 cm^3 of 30% hydrogen peroxide was added slowly at room temperature and the mixture was stirred for an additional hour. The organic layer was extracted with ether, and the extract was dried over with anhydrous magnesium sulfate. After evaporation of the solvent, the residual oil was subjected to preparative thick-layer chromatography. The component isolated from the plate contained 0.35 g (55%) of a white solid, mp 54—55 °C (from ethanol), whose structure was assigned as (*Z*)-1-phenyl-2-(*p*-tolylsulfonyl)propene (**3a**) on the basis of its physical and spectroscopic data: Mp 54—55 °C. IR (KBr): 1150 and 1315 cm^{-1}. ^1H NMR ($CDCl_3$): δ=2.16 (3H, d, *J*=1.2 Hz), 2.33 (3H, s), 7.03 (1H, q, *J*= 1.2 Hz), 7.14 (2H, d, *J*=8.4 Hz), 7.27 (5H, s), and 7.53 (2H, d, *J*=8.4 Hz). Mass: *m/z* 272 (M^+). Found: C 70.62; H, 6.00%. Calcd for $C_{16}H_{16}O_2S$: C, 70.56; H, 5.92%.

*Attempt at the Isomerization of **3a** to **2a**.* A solution containing 102 mg (0.38 mmol) of **3a** and 84 mg (0.03 mmol) of **1** in 1.5 cm^3 of benzene was heated at 60 °C in a degassed sealed tube for 72 h. The reaction mixture was subjected to preparative thick-layer chromatography. The only one component isolated from the plate (98 mg) consisted of 100% of recovered **3a** and no **2a** was detected by its mp, IR, and ^1H NMR spectra.

Attempt at the Isomerization of cis- *or* trans-*β-Methylstyrene in the Absence of Arenesulfonyl Chloride.* A solution containing 236 mg (2.0 mmol) of *cis*- or *trans*-β-methylstyrene and 153 mg (0.16 mmol) of **1** in 3.0 cm^3 of benzene in the presence or absence of 202 mg (2.0 mmol) of triethylamine was heated at 60 °C in a degassed sealed tube for 72 h. After removal of the solvent, the residue was subjected to the elution chromatography on a short column of silica gel, using hexane as the eluent to remove the catalyst. The component concentrated by evaporation of the solvent was subjected to the HPLC. In every case, neither *cis*- to *trans*- nor *trans*- to *cis*-isomerization of β-methylstyrene was observed under these conditions.

The Formation of 1,2-Bis(alkylthio)-1,2-diphenylethanes by the Lithium Diisopropylamide-induced Fragmentation of Dibenzyl Disulfide Followed by the Trapping with Some Alkyl Halides

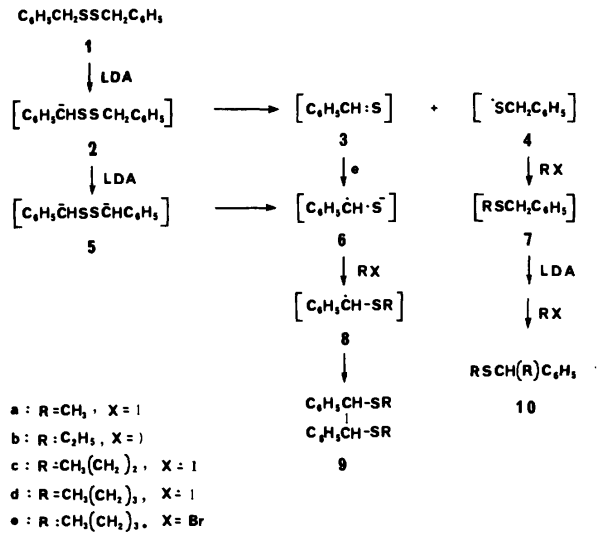
Hideyuki IKEHIRA* and Shigeo TANIMOTO*

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received October 14, 1983)

Synopsis. It was found that dibenzyl disulfide undergoes lithium diisopropylamide-induced fragmentation to afford several intermediate species which, on trapping with alkyl halides, lead to the formation of 1,2-bis(alkylthio)-1,2-diphenylethanes and α-alkylbenzyl alkyl sulfides.

The use of carbanions stabilized by the presence of one or more adjacent thioether groups has become an established technique in organic synthesis.[1-12] In some related works, we were interested in utilizing a carbanion that could be easily generated by the action of a strong base on disulfide possessing α-hydrogens. We chose dibenzyl disulfide (**1**) as a starting substrate in this research since it is easily available and relatively nontoxic. Since most of the reaction products from it are nonvolatile, it thus has advantages for small scale work. The removal of the α-hydrogens of **1** could be achieved by the addition of an easily available metalating agent such as lithium diisopropylamide (LDA). Presumably, the initially formed anionic species undergoes fragmentation followed by further conversion to the other intermediate species. These species were trapped by the addition of some alkyl halides to the reaction mixture. In this way a series of 1,2-bis(alkylthio)-1,2-diphenylethanes (**9**) were produced in fairly good yields, along with α-alkylbenzyl alkyl sulfides (**10**) (see Table 1). The structures of **9** and **10** were established from satisfactory analytical and spectral data. Table 2 shows the physical properties and analytical data of the isolated products.



Possible routes for the formation of **9** and **10** are shown by the accompanying equations. Presumably, the initially formed anion (**2**) undergoes fragmentation to afford thiobenzaldehyde (**3**) and α-toluenethiolate anion (**4**). This type of fragmentation may be certain from the fact that, in a preliminary experiment in which **1** was treated with equimolar amounts of LDA in tetrahydrofuran at −78 °C followed by addition of ethyl iodide, the formation of benzyl ethyl sulfide was observed (76% yield) together with small amounts of **9b**, **10b**, and tarry substance. Thus, the anion (**4**) which would be formed similarly in the present reaction undergoes trapping by alkyl halides and subsequent deprotonation-alkylation sequence to afford **10**. Although the deprotonation of **4** by butyllithium leading to a dianion such as $^{-}\overline{S}CHC_6H_5$ has already been recognized by Seebach and Geiss,[14] the possibility that **4** is further deprotonated by LDA to give the same dianionic species seems to be less reasonable, since LDA is less basic than butyllithium and also, in all runs, the formation of alkyl benzyl sulfides was observed, albeit in very low yields. Hiskey and Dennis[15] have previously proposed a mechanism for the alkoxide cleavage of bis(2-oxo-2-phenylethyl) disulfide. If such a mechanism also prevails in the LDA cleavage of **1**, **3** would be attacked by **4** to afford an anion of the hemidithioacetal which undergoes deprotonation with LDA and the subsequent intramolecular rearrangement leading to dianion of 1,2-diphenyl-1,2-ethanedithiol. However, this mechanism is incompatible with the fact that, in all runs of Table 1, the sum of the yield of **9** and that of **10** is beyond 100%. Thus, it seems reasonable that there is no occurrence of any recombination of **4** with **3**. On the basis of these considerations, the source of **9** could hardly be anything else than **3**. Concerning the trapping of thioaldehydes such as thiobenzaldehyde, one or two papers[16,17] have appeared in the literature. However, the isolation of **3** by the application of a similar method failed, presumably because it is immediately converted to the radical anion (**6**) by one-electron transfer from LDA. Such one-electron transfer has already been observed[12,18,19] in the reaction of several thioketones. The formation of **6** was also evident from the appearance of its characteristic color (blue-black). Thus, **6** undergoes charge neutralization by the applied alkyl halide to

generate the radical species (**8**), which on subsequent dimerization of itself leads to **9**. This explanation would mean that only half of the dibenzyl disulfide molecule is utilized in the formation of **9**. However, it is not tenable since it does not accommodate the experimental fact that the yields of **9**, which are calculated provided that 1 mol of **1** produce 1 mol of **9**, are beyond 50%. This problem could be solved by postulating that another process involving a further deprotonation of **2** followed by the S-S bond fission of the resulting dianion (**5**) to afford **6** is competitively operative. Such an assumption is also compatible with the facts that, in all runs of Table 1, **9** has been produced in more excess than **10** and that the employment of a fourfold excess or more of LDA under otherwise identical conditions results in increased yields of **9** and slightly decreased yields of **10**. For example, with propyl iodide as the trapping agent, the yield of **9c** was 75% and that of **10c** was 34%. However, there has not been any direct evidence for the occurrence of the conversion of **5** to **6**.

Experimental

Lithium Diisopropylamide(LDA)-induced Fragmentation of Dibenzyl Disulfide (1) Followed by the Trapping with Some Alkyl Halides. General Procedure: To LDA, prepared from diisopropylamine (0.36 g, 3.6 mmol) in tetrahydrofuran (7 ml) and 1.56 molar solution (2.18 ml, 3.4 mmol) of butyllithium in hexane, was added at −78 °C 0.27 g (1.1 mmol) of **1** in tetrahydrofuran (4 ml). The reaction mixture was allowed to warm to −15 °C and the stirring was continued for 1 h at that temperature. The mixture was cooled again to −78 °C, and an appropriate alkyl halide (3.3 mmol) was added with stirring. The stirring was continued for 1 h at −10—−5 °C and then for 24 h at room temperature. The mixture was quenched with water (100 ml) and a saturated aqueous solution (20 ml) of ammonium chloride, and then extracted with ether (3×60 ml). The combined ethereal extract was dried over magnesium sulfate and concentrated under reduced pressure to give a residue, which was sujected to preparative TLC on silica gel using ethyl acetate-hexane as the eluent. In Runs 1 and 2, however, the R_f values of **9a** and **9b** were almost same with those of **10a** and **10b**, respectively. Thus, the obtained mixture, which is composed of **9a** and **10a**, was distilled under vacuum to remove **10a** from the mixture, and the residue was again subjected to preparative TLC on silica gel using the same eluent. In the similar manner, only **9b** was isolated in Run 2.

(Received October 18, 1983)

Synopsis. The acid-catalyzed isomerization of 24-methylenecycloartanol with sulfuric acid afforded cyclosadol (23*E*-Δ^{23}), isocyclosadol (23*Z*-Δ^{23}), and other isomers, including lanostane- and cucurbitane-type isomers with (23*E*)- and (23*Z*)-Δ^{23}- and Δ^{24}-unsaturated side chains. The phytochemical significance of the isomers is discussed.

Our recent study of the acid-catalyzed isomerization of cycloartane (9β,19-cyclolanostane) triterpene alcohols has shown that this isomerization is quite useful in obtaining several lanostane- and cucurbitane [19(10→9β)*abeo*-lanostane]-type isomers.[1] In this study we undertook the isomerization of 24-methylenecycloartanol (24-methylene-9β,19-cyclo-5α-lanostan-3β-ol, **1a**), a cycloartane triterpene alcohol widely distributed in plants,[2,3] in order to prepare several isomers of **1a**. Since **1a** is considered to be the key intermediate of sterol biosynthesis in some plants,[2] the isomerization products which have a structural similarity to **1a** are also considered to be especially worthwhile from the points of view of phytochemistry and sterol biogenesis.

The isomerization of **1a** with sulfuric acid was performed in isopropyl alcohol at 80 °C for 12 h.[1] The compositions of the isomerized products were, after acetylation, carefully determined by GLC to be as follows: Cyclosadol[4-6] [(23*E*)-24-methyl-9β,19-cyclo-5α-lanost-23-en-3β-ol, **1b**, 24%], isocyclosadol [(23*Z*)-24-methyl-9β,19-cyclo-5α-lanost-23-en-3β-ol, **1c**, 7%], cyclobranol[7] (24-methyl-9β,19-cyclo-5α-lanost-24-en-3β-ol, **1d**, 30%), (23*E*)- (**2b**, 2%) and (23*Z*)-24-methyl-5α-lanosta-8,23-dien-3β-ol (**2c**, 1%), 24-methyl-5α-lanosta-8,24-dien-3β-ol (**2d**, 3%), (23*E*)- (**3b**, 12%) and (23*Z*)-24-methyl-5α-lanosta-9(11),23-dien-3β-ol (**3c**, 3%), 24-methyl-5α-lanosta-9(11),24-dien-3β-ol (**3d**, 14%), (23*E*)-24-methyl-10α-cucurbita-5,23-dien-3β-ol (**4b**, 0.5%), 24-methyl-10α-cucurbita-5,24-dien-3β-ol (**4d**, 0.5%), (23*E*)-24-methylcucurbita-5(10),23-dien-3β-ol (**5b**, 2%), and 24-methylcucurbita-5(10),24-dien-3β-ol (**5d**, 1%).

The carbon skeletons of **1**—**5** were established by comparing their ^{1}H NMR spectra with those of **1a** and the relevant compounds described previously.[1] The double bond of the side chains **b** and **c** was found to be located at C-23 by the observation of a mass-fragmentation ion at *m/z* 325 ($M^+-C_7H_{13}-HOAc$) for the acetyl derivatives.[5,6] The configurations of 23*E* (**b**) and 23*Z* (**c**) were established on the basis of the ^{1}H NMR spectra as compared with those of two model olefins, (2*E*)- (**6**) and (2*Z*)-3,4-dimethyl-2-pentene (**7**).[5] The acetyl derivatives with the side chain **d** were established to have a C-24(25) double bond by the ^{1}H NMR, which showed three overlapping olefinic methyl singlets due to the 26-H$_3$, 27-H$_3$, and 28-H$_3$ protons.[7]

Thirteen isomers were obtained by the acid-catalyzed isomerization of **1a**. Among them, two cycloartane isomers, a (23*E*)-Δ^{23}-isomer (**1b**) in *Zea mays*[4-6] and Δ^{24}-isomer (**1d**), have been detected as natural products in several seed-bearing plants,[3] and their possible intermediacy in sterol biosynthesis has been suggested.[2,6] Although the occurrence of the other eleven isomers has not yet been reported, these isomers are also considered to be of significance from the phytochemical and sterol biogenetic points of view. In particular, taking into account the fact that the (23*E*)- and (23*Z*)-isomers of 24-ethylcholesta-5,23-dien-3β-ol both occur as natural products,[8] the occurrence of (23*Z*)-Δ^{23}-compounds such as **1c** can be expected in seed-bearing plants, especially in *Z. mays*. On the other hand, since some 24-methylenated lanostenes, such as **2a** and **3a**, have been detected in some plants,[3] the natural occurrence of several of the lanostane-type isomers prepared in this study can be expected. Some Cucurbitaceae plants have recently been shown to contain 10α-cucurbita-5,24-dien-3β-ol;[9] hence, the occurrence of its higher homologs, such as **4b** and **4d**, is highly probable in these plants.

Experimental

The melting points are uncorrected. The argentic TLC (silica gel-$AgNO_3$, 4:1) was developed 4 times with

a) Given as δ values. Figures in parentheses denote J values in Hz. b) Singlet unless otherwise specified. c) Cyclopropyl methylene signal as for **1c**. d) Doublet if not otherwise specified. e) Assigned with the aid of the lanthanoid-induced-shift techniques.[11] f) Triplet. g) Septet. h) and i) The assignment in each row may be inverted, although that given here is preferred.

CCl_4-CH_2Cl_2 (5:1). The HPLC was carried out on a Partisil 5 ODS-2 column (25 cm×10 mm i.d.) using an UV detector and monitoring at 212 nm (mobile phase, MeOH-H_2O, 98:2). The GLC was performed with a 30 m×0.3 mm i.d. SCOT OV-17 glass capillary column at 260 °C. The R_c-values (relative mobilities) in the argentic TLC and the RRTs (relative retention times) in the HPLC and GLC were expressed relative to cholesteryl acetate (1.00). The MS spectra (70 ev) were taken by means of a probe injection. The ^{1}H NMR spectra (100 MHz) were obtained in a $CDCl_3$ solution, with Me_4Si as the internal standard. The 24-methylenecycloartanol (**1a**)[10] was kindly donated by the Riken Vitamin Co. (Tokyo). The isomerization of **1a** (500 mg) was carried out with conc H_2SO_4 (4 cm^3) in isopropyl alcohol (40 cm^3) while the mixture was being stirred at 80 °C for 12 h. The separation of the isomerization products was performed by the same way as has been described in the previous paper,[1] but the eventual isolation of each product was achieved by HPLC in this study. All of the other techniques used in this study[1] and the full ^{1}H NMR data[5] of **6** (4-H, *septet*, δ= 2.22, J=6.9 Hz; 6-H_3, *s*, δ=1.56) and **7** (4-H, *septet*, δ=2.83, J=6.9 Hz; 6-H_3, *s*, δ=1.59) have been described previously.

The High-resolution MS Data of New Triterpene Alcohols. The molecular ions (M^+) observed in the high-resolution MS for the acetates of the eleven new triterpene alcohols may be described as follows: The acetates of **1c** (m/z 482.4104; the molecular formulas of this and the subsequent compounds are $C_{33}H_{54}O_2$, calcd 482.4121), **2b** (m/z 482.4085), **2c** (m/z 482.4109), **2d** (m/z 482.4087), **3b** (m/z 482.4096), **3c** (m/z 482.4102), **3d** (m/z 482.4084), **4b** (m/z 482.4146), **4d** (m/z 482.4112), **5b** (m/z 482.4146), and **5d** (m/z 482.4160). The molecular formulas for the fragment ions described in Table 1 were taken from the MS data of the relevant compounds and may be summarized as follows; m/z 467 ($C_{32}H_{51}O_2$), 439 ($C_{30}H_{47}O_2$), 422 ($C_{31}H_{50}$), 407 ($C_{30}H_{47}$), 398 ($C_{27}H_{42}O_2$), 379 ($C_{28}H_{43}$), 355 ($C_{24}H_{35}O_2$), 353 ($C_{26}H_{41}$), 339 ($C_{25}H_{39}$), 325 ($C_{24}H_{37}$), 300 ($C_{22}H_{36}$), 297 ($C_{22}H_{33}$), 295 ($C_{22}H_{31}$), 288 ($C_{21}H_{36}$), and 273 ($C_{20}H_{33}$).

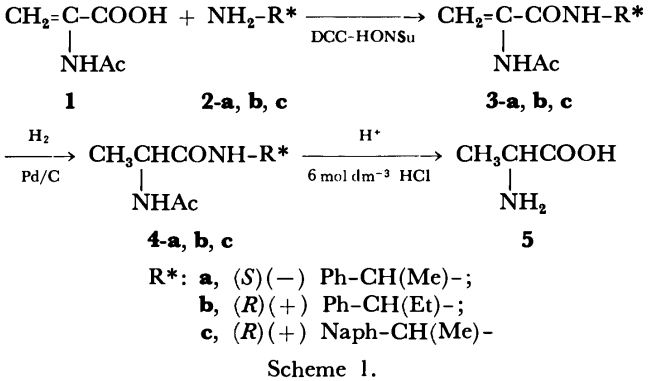
Asymmetric Synthesis of Alanine by Catalytic Hydrogenation of Chiral N^{α}-Acetyldehydroalaninamides

Kaoru HARADA* and Michiaki TAKASAKI
Department of Chemistry, University of Tsukuba, Niihari, Ibaraki 305
(Received December 12, 1983)

Synopsis. Asymmetric hydrogenation of chiral N^{α}-acetyldehydroalaninamides was studied. The asymmetric yield of the resulting alanine was in the range 0—24%. The effects of reaction temperature, solvent polarity and asymmetric moieties on the asymmetric yields were examined.

Several studies[1-7] have been performed on asymmetric reduction of α,β-dehydroamino acid derivatives yielding amino acids. Among these studies, heterogeneous hydrogenations of optically active linear derivatives of dehydroamino acids were reported,[1,2] and the steric course of the asymmetric hydrogenation was explained by the application of the Prelog rule.[8] However, no detailed studies on the effects of temperature and solvent polarity on asymmetric hydrogenation have been reported. In the present study, asymmetric catalytic hydrogenation of chiral N^{α}-acetyldehydroalaninamides was carried out and the temperature dependence on the asymmetric hydrogenation was studied using various solvents.

The chiral N^{α}-acetyldehydroalaninamides used were N^{α}-acetyl-*N*-[(*S*)-methylbenzyl]dehydroalaninamide (**3-a**), *N*-[(*R*)-α-ethylbenzyl]amide (**3-b**), and *N*-[(*R*)-1-(1-naphthyl)ethyl]amide (**3-c**). The compounds **3-a**, **b**, and **c** were prepared by the coupling of *N*-acetyldehydroalanine (**1**) and the corresponding chiral amines (**2-a**, **b**, and **c**) with dicyclohexylcarbodiimide in the presence



Scheme 1.

of *N*-hydroxysuccinimide. The hydrogenation reactions were carried out at 1 atm of hydrogen by using palladium on charcoal suspended in several solvents (methanol, ethanol, 2-propanol, and ethyl acetate). The reaction temperature was in the range of −50 °C to 50 °C. After the hydrogenation, the resulting N^{α}-acetylalaninamides (**4-a**, **b**, and **c**) were hydrolyzed to form alanine. The chemical yield of alanine was in the range of 78—98% as determined by an amino acid analyzer. The asymmetric yield of alanine was determined by gas chromatographic analysis employing a chiral stationary phase (Chirasil-Val[9]).

The results are summarized in Figs. 1, 2, and 3. In the reaction of compound **3-a**, a clear temperature effect on the asymmetric yield was observed. With the decrease in solvent polarity, the asymmetric yield of (*R*)-alanine increased at lower temperature. The effect observed could not be explained by the application of the Prelog rule,[8] which was employed in the previous reports.[1,2] Since a similar temperature effect was observed in the reaction of compound **3-b**, the same reaction mechanism would prevail in the hydrogenation of these two compounds.

In the reaction of compound **3-c**, the temperature effect was not so large. With the decrease in solvent polarity, the asymmetric yield of (*R*)-alanine increased except in the reaction using ethyl acetate as the solvent. This result was definitely different from the results

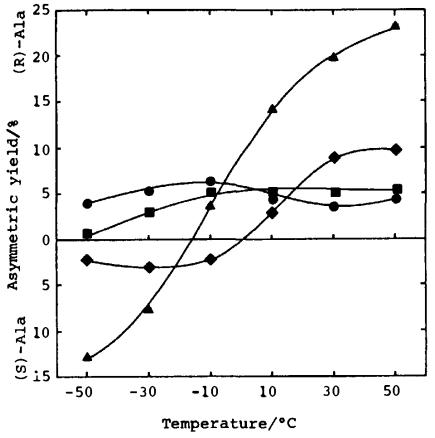


Fig. 1. Temperature effect in asymmetric hydrogenation of compound **3-a**. ●: In methanol, ■: in ethanol, ◆: in 2-propanol, ▲: in ethyl acetate.

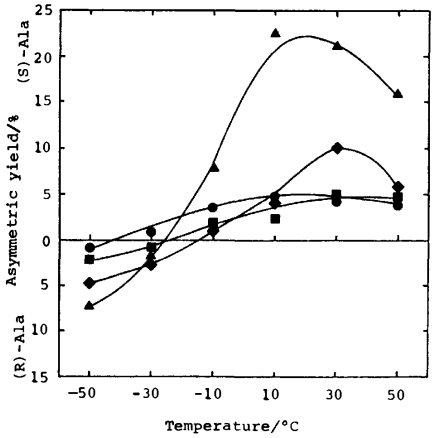

Fig. 2. Temperature effect in asymmetric hydrogenation of compound **3-b**. ●: In methanol, ■: in ethanol, ◆: in 2-propanol, ▲: in ethyl acetate.

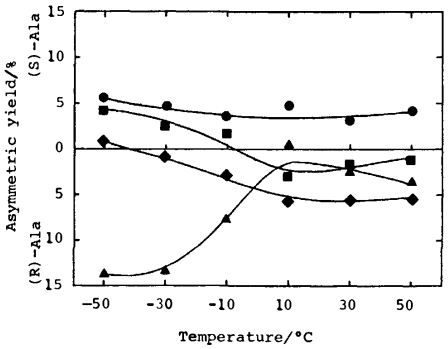

Fig. 3. Temperature effect in asymmetric hydrogenation of compound **3-c**. ●: In methanol, ■: in ethanol, ◆: in 2-propanol, ▲: in ethyl acetate.

obtained in the reactions of compounds **3-a** and **b**. Therefore, mechanisms prevailed in the reaction of compound **3-c** could be distinct from those of compounds **3-a** and **b**.

The results obtained could indicate the participation of several reaction mechanisms in the asymmetric synthesis. The mechanisms in these reactions could be changed by the reaction temperature, solvent polarity and asymmetric moieties.

Experimental

All the melting points were uncorrected. Optical rotations were measured with a JASCO DIP-181 Digital Polarimeter. The gas chromatographic analysis were carried out with a Hitachi 163 gas chromatograph and the peaks on the chromatogram were integrated with a Hitachi 834-30 chromatoprocessor. Amino acid analysis were carried out with a Yanagimoto LC-5S instrument.

N$^{\alpha}$-Acetyl-N-[(S)-methylbenzyl]dehydroalaninamide (3-a). *N*-Acetyldehydroalanine[10] (**1**) (3.25 g, 25 mmol) was dissolved in ethyl acetate (60 ml) together with (*S*)-methylbenzylamine (**2-a**) (3.00 g, 25 mmol), *N*-hydroxysuccinimide (2.9 g, 25 mmol) and dicyclohexylcarbodiimide (6.18 g, 25 mmol) at −15 °C. Stirring was continued at −15 °C for 1 h and at room temperatue for 10 h. The solution was filtered and the filtrate was washed with 10% aqueous citric acid, saturated aqueous sodium hydrogencarbonate and brine and dried over magnesium sulfate, and was concentrated *in vacuo*. The resulting crude product was purified by column chromatography (silica-gel column, 4 mm i.d.×350 mm). From the eluate with benzene–ethyl acetate (3:1), white solid was obtained, yield, 1.48 g (26.3%). It was recrystallyzed from methanol for elemental analysis, mp 119—121 °C, $[\alpha]_D^{15}$ −21.2° (*c* 0.523, methanol), Found: C, 67.19; H, 7.05; N, 11.97%. Calcd for $C_{13}H_{16}N_2O_2$: C, 67.22; H, 6.79; N, 12.06%.

Other *N$^{\alpha}$*-acetyldehydroalaninamides (**3-b** and **c**) were prepared in a similar way. The physical properties were as follows: **3-b**; mp 135—137 °C, $[\alpha]_D^{15}$ +20.2 (*c* 0.523, methanol), Found: C, 68.02; H, 7.57; N, 11.18%. Calcd for $C_{14}H_{18}N_2O_2$; C, 68.27; H, 7.37; N, 11.37%. **3-c**; mp 111—113 °C, $[\alpha]_D^{15}$ −61.8 (*c* 0.964, methanol), Found: C, 72.30; H, 6.59; N, 9.82%. Calcd for $C_{17}H_{18}N_2O_2$: C, 72.32; H, 6.43; N, 9.92%.

Alanine (5). The compound **3-a** (23 mg, 0.1 mmol) was dissolved in 5 ml of methanol and hydrogenated with 5% palladium on charcoal (100 mg) for 24 h at 30 °C under hydrogen (1 atm). After the reaction was over, the catalyst was removed by filtration, and the filtrate was evaporated to dryness. The resulting *N$^{\alpha}$*-acetylalaninamide (**4-a**) was hydrolyzed with 6 mol dm^{-3} HCl at 110 °C in a sealed tube with refluxing in a toluene bath for 10 h. A part of the solution was diluted appropriately and analyzed with an amino acid analyzer to determine the chemical yield of alanine (96.3%). A part of the resulting alanine was converted to *N*-(trifluoroacetyl)alanine isopropyl ester in the usual mammer and then subjected to gas chromatographic analysis employing a chiral stationary phase (Chirasil-Val[9]). The peaks due to (*R*)- and (*S*)-alanine on the chromatogram were in baseline separation.

The Reaction of Fluorenethione *S*-Tosylimide with Grignard Reagents

Takao SAITO, Michio NAKANE, and Shinichi MOTOKI*

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka 1-3, Shinjuku-ku, Tokyo 162

(Received December 26, 1983)

Synopsis. Fluorenethione *S*-tosylimide reacted with Grignard reagents to afford both the thiophilic and carbophilic products depending on the solvent used.

Thione *S*-imides have three potential reactive sites (carbon, sulfur, nitrogen atoms) on the cumulated system, and hence reactions with nucleophiles, *e.g.* Grignard reagents include interesting possible modes of the site selectivity, *viz.* carbophilic, thiophilic, and azophilic reactions.

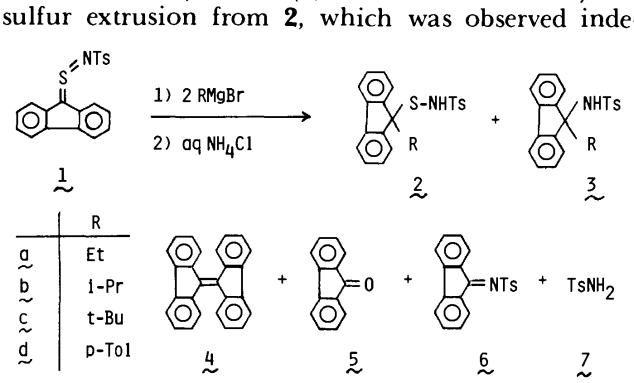
Only one example has been reported first by Senning *et al.*[1] on the reaction of thione *S*-imide (*S,S'*-diphenyl trithiocarbonate *S,S*-dioxide *S''*-*t*-butylimide) with organometallic reagents (phenyllithium) giving carbophilic adduct.[2]

In this paper we will describe the reaction of fluorenethione *S*-tosylimide (**1**) with some Grignard reagents.

Results

The reactions were carried out by adding a twofold excess of a Grignard reagent to thione *S*-imide (**1**) at low temperature in diethyl ether or THF (method A), or *vice versa* (method B).[3]

The reactions in diethyl ether (0.06 mol/l of **1**) afforded products **2—7** (Scheme 1, Table 1). It is unambiguous that sulfenamide **2** was produced by the attack of the nucleophile R of the Grignard reagent to the 9-carbon of the fluorenylidene ring in **1**. *N*-Substituted tosylamide (**3**) would be formed by the sulfur extrusion from **2**, which was observed independently, and/or by the reaction of **6** with a Grignard reagent.



Scheme 1.

d	THF (B)	1.0	0	0	87	6	5	64

a) Trace amount, checked by TLC.

In contrast, the reactions in THF gave 9,9'-bifluorenylidene (**4**) as a major product, and the formation of **2** and **3** was not detected (Table 1).

Discussion

Probable mechanisms of the reaction are shown in Scheme 2 on the basis of polar and single electron transfer (SET) mechanisms in general Grignard reactions.[4] The negatively charged nitrogen of **1** coordinates the positive magnesium of the reagent (**8**), followed by the slow SET giving **9** and **10**.[5] The intermediary **8** (**9**) and **10** are key species giving thiophilic and carbophilic adducts, respectively. The carbophilic attack of R· to the 9-carbon of the fluorenylidene ring in **10** gives **2** *via* **15**. The new Grignard reagent (**11**) formed by the thiophilic attack of R in **8** (**9**) further reacts with another molecule of **1** on the sulfur atom to afford **4** *via* **12—14**.

Similar reaction mechanisms have been reported in the reaction of fluorenethione *S*-oxide (sulfine) with organolithium reagents,[6] where no carbophilic reaction product was obtained.[7] On the contrary, sulfilimine **16** which corresponds to sulfoxide formed by the thiophilic reaction of the sulfine was not detected. The sulfilimine **16** or **11** might produce **5** and **7** by hydrolysis.

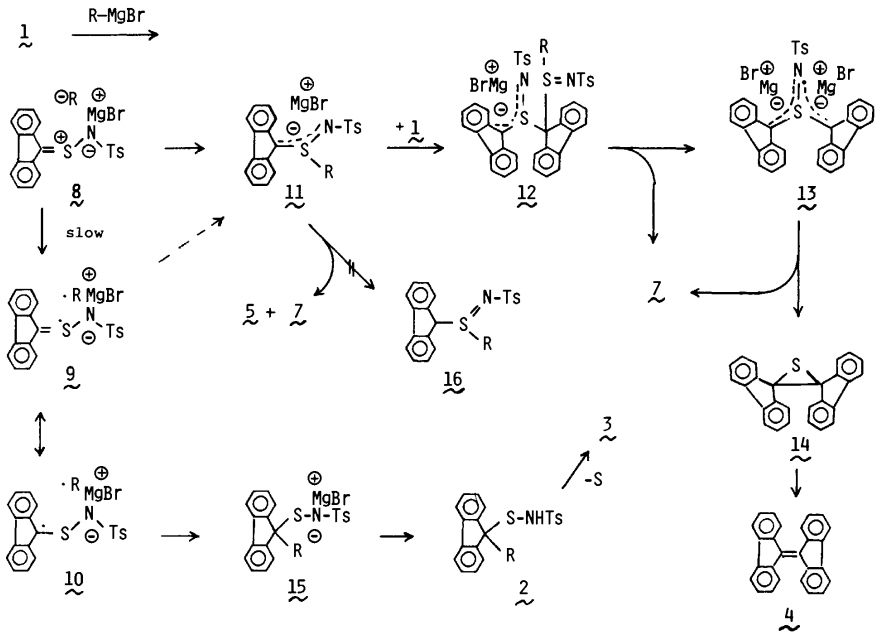
In the reactions in diethyl ether, the yields of the carbophilic adducts (**2**, **3**) are in the order of **c**(R=*t*-Bu) ≥**b**(R=*i*-Pr)>**a**(R=Et), and the yields of the thiophilic adducts (**4**) are in the order of **a**(R=Et)>**b**(R=*i*-Pr)> **c**(R=*t*-Bu). This result is consistent with the view that the more radical property of tertiary alkyl (*t*-Bu) stabilized preferentially attacks the carbon atom in **10** whereas the less radical property of primary alkyl (Et) instantly forms the thiophilic adduct **11**.[8] On the other hand, the reaction in THF implies that the solvent effect (higher solubility for **1**: concentration dependence, polarity) of THF makes the route to thiophilic adduct **4** favorable.

Experimental

All the melting points are uncorrected. IR spectra were measured on a Hitachi Model 260-10 spectrometer. Mass spectra were recorded on a Hitachi double-focusing mass spectrometer RMU-7M operating at an ioninzing potential of 70 eV. ^{1}H- and ^{13}C-NMR spectra were measured on a JEOL-FX 100 spectrometer in $CDCl_3$ using TMS as an internal standard.

Fluorenethione *S*-tosylimide (**1**) was prepared by the method reported previously.[9]

Reaction of 1 with Grignard Reagents. General Procedure: 1) A diethyl ether solution (7 cm^3) of a Grignard reagent (7.0 mmol) was added with stirring to a suspension of **1** (1.21 g, 3.32 mmol) in 48 cm^3 of diethyl ether at −15 °C (0 °C in THF) under nitrogen atmosphere (method A). 2) A suspension of **1** (1.47 g, 4.02 mmol) in



Scheme 2.

ether (30 cm³) was added to *p*-tolylmagnesium bromide ethereal solution (37 cm³) under the same conditions as described for method A (method B). After being stirred for 1—3.5 h at −15 °C (0 °C in THF), the reaction mixture was rinsed with aq NH_4Cl and water, dried over Na_2SO_4, and concentrated *in vacuo*. The residue was column-chromatographed on silica gel (Wako C-200) using hexane, benzene, dichloromethane, and methanol as eluents to give the products **2—7**. The products **4—7** were identified by comparison of the spectral data with those of authentic samples.

2a: Mp 150—151 °C; IR (Nujol) 3320 cm^{-1} (NH), 1160, 1100 (SO_2); MS *m/z* 395 (3%, M^+), 193 (100, M^+—SNHTs); ^{1}H-NMR ($CDCl_3$) δ 0.44 (t, *J*=8 Hz, 3H, CH_3), 2.34 (s, 3H, CH_3(Ts)), 2.60 (q, *J*=8 Hz, 2H, CH_2), 5.70 (s, 1H, NH), 7.13—7.70 (m, 12H, Ar-H); ^{13}C-NMR ($CDCl_3$) δ 65.0 (9-C), 28.7 (CH_2), 21.5 (CH_3(Ts)), 8.8 (CH_3). An Easy Preparation of Triphenylmethyl Carboxylates

Shun-ichi HASHIMOTO, Masahiko HAYASHI, and Ryoji NOYORI*
Department of Chemistry, Nagoya University, Chikusa, Nagoya 464
(Received December 27, 1983)

Synopsis. A new recipe for triphenylmethylation of carboxylic acids and phenol is disclosed.

Triphenylmethylation of carboxylic acids has been conventionally achieved by heating triphenylmethyl bromide and metal carboxylates in nonpolar solvents.[1] Sensitive, polymerizable acrylic acids, however, can be esterified only using the expensive silver salts.[2] We found that condensation of economically accessible trimethylsilyl carboxylates (**1**) and triphenylmethyl fluoride (**2**) proceeds smoothly at room temperature in acetonitrile containing a catalytic amount of tetrafluorosilane (**3**). This facile procedure allows the easy synthesis of triphenylmethyl methacrylate (**4a**),[3] an important material for the preparation of the chiral liquid chromatographic stationary phases.[4,5]

$$\underset{\mathbf{1}}{RCOOSi(CH_3)_3} + \underset{\mathbf{2}}{(C_6H_5)_3CF} \xrightarrow{SiF_4} \underset{\mathbf{4}}{RCOOC(C_6H_5)_3} + (CH_3)_3SiF$$

a: R=CH_2=C(CH_3), **b**: R=*n*-C_9H_{19}, **c**: R=C_6H_5

In a like manner, the tetrafluorosilane-catalyzed reaction of phenyl trimethylsilyl ether and the fluoride **2** gave phenyl triphenylmethyl ether in a high yield.

Experimental

All melting points were uncorrected. IR spectra were recorded on a JASCO IRA-1 spectrometer. ^{1}H NMR spectra were measured with a JEOL JNM FX-90Q (90 MHz) spectrometer using tetramethylsilane as an internal standard. Mass spectra were determined with a Hitachi RMU-6C mass spectrometer, operating with an ionization energy of 70 eV. Tetrafluorosilane (**3**) was purchased form Matheson Co. Triphenylmethyl fluoride (**2**) was prepared by the reported method.[6] Acetonitrile was distilled from CaH_2 before use. All products are known compounds and gave consistent spectral data.

*Triphenylmethyl Methacrylate(**4a**).* To a solution of **1a** (1.25 g, 7.91 mmol) and **2** (2.07 g, 7.91 mmol) in dry acetonitrile (2 cm^3) was added a 0.08 mol dm^{-3} solution of **3** in acetonitrile (4.9 cm^3, 0.396 mmol) at 14 °C under argon atmosphere. After 6-h stirring at this temperature, the resulting yellow mixture was poured into a vigorously stirred, pH 7.4 phosphate buffer (80 cm^3) containing KF (8.0 g) which was kept at 0 °C. The whole mixture was extracted with a 2:1 mixture of ether and hexane (50 cm^3×2), and the combined organic layers were washed with aq $NaHCO_3$ and brine, dried over anhydrous Na_2SO_4, and evaporated *in vacuo*. The residual solid was recrystallized from hexane to give **4a** (2.42 g, 94% yield) as colorless prisms: Mp 98—99 °C (lit,[7] 101—102 °C); IR (CCl_4) 1725, 1490, 1140 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.99 (3H, dd, J=1.0, 1.4 Hz), 5.60 (1H, m), 6.23 (1H, m), 7.2—7.5 (15H, m); MS *m/z* 328 (M$^+$), 260, 259, 243, 183, 165, 105, 85, 83, 77.

The above reaction was carried out in acetonitrile-d_3 for 6 h, and the reaction mixture was subjected to ^{1}H NMR analysis, which indicated the production of the theoretical amount of trimethylfluorosilane[8] (δ=0.21, d, $J_{CH_3,F}$=7.5 Hz) in addition to **4a**.[9]

*Triphenylmethyl Decanoate (**4b**).* A mixture of **1b** (232 mg, 0.95 mmol), **2** (249 mg, 0.95 mmol), and **3** (0.08 mol dm^{-3} in acetonitrile, 0.62 cm^3, 0.05 mmol) in acetonitrile (2.5 cm^3) was stirred at 16 °C for 6 h. The reaction mixture was worked up as described above, and the oily residue was chromatographed on silica gel, which had been treated with triethylamine (2%), using a 5:1 mixture of hexane and ether as an eluent. Pure **4b** was obtained as a colorless oil (361 mg, 88%): IR (CCl_4) 1760, 1500, 1150 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.87 (3H, br t, J=6.0 Hz), 1.07—1.73 (14H, m) 2.43 (2H, t, J=6.8 Hz) 7.1—7.4 (15H, m); MS *m/z* 414 (M$^+$), 260, 259, 244, 243, 165, 78, 77.

*Triphenylmethyl Benzoate (**4c**).* A mixture of **1c** (372 mg, 1.92 mmol), **2** (503 mg, 1.92 mmol), and **3** (0.08 mol dm^{-3} in acetonitrile, 1.2 cm^3, 0.1 mmol) in acetonitrile (4 cm^3) was stirred at 16 °C for 4 h. Workup followed by recrystallization from a 10:1 mixture of hexane and benzene afforded **4c** (671 mg, 96%) as colorless plates: Mp 170—171 °C (lit,[1] 168—170 °C); IR (CCl_4) 1740, 1600, 1500, 1270 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=7.1—7.6 (18H, m), 8.13 (2H, J=1.5, 7.8 Hz); MS *m/z* 364 (M$^+$), 260, 259, 244, 243, 85, 83.

Phenyl Triphenylmethyl Ether. A mixture of phenyl trimethylsilyl ether (166 mg, 1.0 mmol), **2** (262 mg, 1.0 mmol), and **3** (0.08 mol dm^{-3} in acetonitrile, 0.63 cm^3, 0.05 mmol) in acetonitrile (2 cm^3) was stirred at 15 °C for 24 h. Aqueous workup followed by column chromatography on 2% triethylamine-treated silica gel using a 30:1 mixture of hexane and ether as an eluent, afforded the product (286 mg, 85%) as a colorless oil. This oil crystallized as colorless prisms from ethanol solution: Mp 103—104 °C (lit,[10] 103 °C); IR (CCl_4) 1600, 1500, 1450, 1220 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=6.6—7.1 (5H, m) 7.1—7.5 (15H, m); MS *m/z* 244, 243, 165, 94.

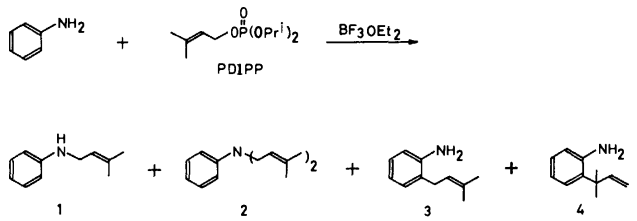
Prenylation of Aromatic Amines and Nitrogen-containing Aromatic Heterocycles by Prenyl Diisopropyl Phosphate

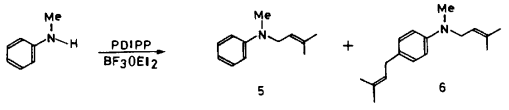
Shuki ARAKI, Shin-ichi MANABE, and Yasuo BUTSUGAN*
Department of Synthetic Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received January 5, 1984)

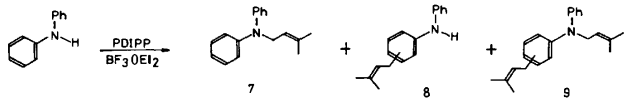
Synopsis. Lewis-acid catalyzed prenylation of aromatic amines with prenyl diisopropyl phosphate gave *N*-prenylated amines, whereas nitrogen-containing aromatic heretocycles gave nucleus prenylated products.

N-Alkylation of amines by trialkyl phosphates is well documented. For example, Billman *et al.* reported that trimethyl and triethyl phosphates readily alkylate various anilines to *N,N*-dialkylanilines in good yields.[1] Recently, Kinoshita and his coworkers described the methylation and ethylation of nucleic acid-bases by means of trimethyl and triethyl phosphates.[2] Moreover, they succeeded the allylation of nucleic acid-bases by triallyl phosphate.[3] *N*-Prenylation of amines by prenyl phosphates is a biogenetically important process, because naturally occurring amines such as cytkinin[4] and acrophylline,[5] which bear a prenyl group on the nitrogen atom, are proposed to be biosynthesized *via* *N*-prenylation with prenyl pyrophosphate. However, there have been no studies describing the prenylation of amines by the use of prenyl phosphate. Here we wish to report the reaction of prenyl diisopropyl phosphate (PDIPP) with aromatic amines and nitrogen-containing aromatic heterocycles in an attempt to have insight into the nature of the prenylation of amines by prenyl phosphate.

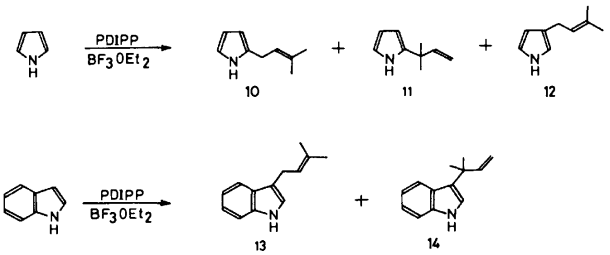
When a mixture of aniline and PDIPP was treated with boron trifluoride etherate in dimethyl sulfoxide (DMSO) at room temperature, the reaction proceeded and *N*-prenylaniline (**1**) and *N,N*-diprenylaniline (**2**) were obtained in 12 and 10% yields, respectively, after column chromatography on silica gel. As minor products, trace amounts of 2-prenylaniline (**3**) and 2-(1,1-dimethyl-2-propenyl)aniline (**4**) were also isolated from the reaction mixture. The formation of **3** and **4** may be rationalized in terms of the Lewis acid-catalyzed amino-Claisen rearrangement[6] of the initially formed *N*-prenylaniline (**1**). In the absence of the Lewis acid, the reaction did not occur. The use of polar aprotic solvents such as DMSO and *N,N*-dimethylformamide (DMF) was essential for the present reaction. In other solvent such as ether, dichloromethane, and benzene, no characterized products were obtained. Under the similar conditions, *N*-methylaniline gave 56% yield of *N*-methyl-*N*-prenylaniline (**5**) accompanied by a small amount (1.2% yield) of *N*-methyl-*N*,4-diprenylaniline (**6**). For the latter, the position of the prenyl group on the benzene ring was determined by the ^{13}C NMR spectral analysis. The prenylation of diphenylamine gave *N,N*-diphenylprenylamine (**7**) (24% yield) as the main product. Nucleus-prenylated products, 4-(or 2-)prenyldiphenylamine (**8**) (7%) and *N*-phenyl-*N*,4-(or 2)diprenylaniline (**9**) (3%) were also formed, but the prenylated position remained uncertain. Aliphatic amines such as diisopropylamine and pyrrolidine could not be prenylated by the present method.







Nitrogen-containing aromatic heterocycles, pyrrole and indole, are also susceptible to prenylation by PDIPP. Pyrrole gave a mixture of 2-prenylpyrrole (**10**) (34% yield), 2-(1,1-dimethyl-2-propenyl)pyrrole (**11**) (10%), and 3-prenylpyrrole (**12**) (6%), and indole gave 3-prenylindole (**13**) (21% yield) and 3-(1,1-dimethyl-2-propenyl)indole (**14**) (5%). Unlike the cases of aromatic amines described above, *N*-prenylated products could not be found in the reaction mixtures. This result contrasts to the fact that the methylation of indole with trimethyl phosphate gives only 1-methylindole.[7]



Experimental

General. Infrared spectra were recorded on a JASCO IRA-1 spectrometer. ^1H NMR spectra were determined with a Hitachi R-24A spectrometer (60 MHz). Chemical shifts (δ) are recorded in ppm downfield from Me_4Si. Mass spectra were measured on a Hitachi M-52 mass spectrometer, operating with an ionization energy of 20 eV. GLPC analyses and preparative GLPC were performed on a Yanaco G1800 gas chromatograph. Elemental analyses were performed at the Elemental Analysis Center of Kyoto University.

Reaction of Aniline with Prenyl Diisopropyl Phosphate. To a solution of aniline (470 mg, 5 mmol) and prenyl diisopropyl phosphate (1.27 g, 5.1 mmol) in DMSO (10 ml) was added boron trifluoride etherate (1.99 g, 14 mmol) at

room temperature and the mixture was stirred for 16 h. Saturated aqueous sodium hydrogencarbonate was added and the products were extracted with light petroleum. The extracts were washed with water and brine, dried over anhydrous magnesium sulfate, and concentrated. The residue was column chromatographed on silica gel with benzene as an eluent to give *N*-prenylaniline (**1**)[6] (92 mg, 12% yield), *N,N*-diprenylaniline (**2**)[6] (118 mg, 10%), and trace amounts of 2-prenylaniline (**3**)[6] (5 mg) and 2-(1,1-dimethyl-2-propenyl)aniline (**4**) (1 mg).

4: ^{1}H NMR (CCl_4) δ=6.40—7.00 (m, 5H, ring), 5.00—5.90 (m, 3H, olefin), 3.20 (br s, 2H, NH_2), 1.35 (s, 6H, CH_3).

Reaction of N-*Methylaniline with Prenyl Diisopropyl Phosphate.* To a solution of *N*-methylaniline (550 mg, 5.1 mmol) and prenyl diisopropyl phosphate (2.02 g, 8.1 mmol) in DMF (10 ml) was added boron trifluoride etherate (1.26 ml, 10 mmol) under nitrogen at room temperature and the mixture was stirred for 15 h. The reaction mixture was treated as above. Silica-gel column chromatography (benzene as an eluent) gave *N*-methyl-*N*-prenylaniline (**5**) (499 mg, 56%) and *N*-methyl-*N*,4-diprenylaniline (**6**) (15 mg, 1.2%).

6: IR (neat) 2960, 2920, 1670, 1590, 1510, 1440, 1245, and 693 cm^{-1}; ^{1}H NMR (CCl_4) δ=6.40—7.30 (m, 4H, ring), 5.10 (br t, 2H, olefin), 3.80 (d, J=6 Hz, 2H, CH_2), 3.35 (d, J=6 Hz, 2H, CH_2), 2.80 (s, 3H, CH_3), 1.65 (br s, 12H, CH_3); ^{13}C NMR ($CDCl_3$) 151.2 (s), 136.8 (s), 132.5 (s), 121.3 (s), 129.8 (d), 126.3 (d), 123.5 (d), 120.3 (d), 55.2 (t, N-CH_2), 41.5 (t, Ph$\underline{C}H_2$), 29.2 (q, N-CH_3), 25.9 (q), 25.8 (q), 18.0 (q), 17.9 (q); MS *m/z* (rel intensity) 243 (M^+; 13) and 174 (100); Found: C, 84.17; H, 10.60%. Calcd for $C_{17}H_{25}N$: C, 83.89; H, 10.35%.

Reaction of Diphenylamine with Prenyl Diisopropyl Phosphate. To a solution of diphenylamine (852 mg, 5.0 mmol) and prenyl diisopropyl phosphate (2.00 g, 8.0 mmol) in DMF (10 ml) was added boron trifluoride etherate (1.26 ml, 10 mmol) under nitrogen at room temperature and the mixture was stirred for 15 h. Work-up and column chromatography on silica gel with benzene-light petroleum (1:3) gave *N,N*-diphenylprenylamine (**7**)[9] (280 mg, 24%), 4(or 2-)prenyldiphenylamine (**8**) (85 mg, 7%), and *N*-phenyl-*N*,4(or 2)-diprenylaniline (**9**) (40 mg, 3%).

8: IR(neat) 3400, 2980, 2930, 1595, 1500, 1450, 1310, 750, and 695 cm^{-1}; ^{1}H NMR (CCl_4) δ=6.40—7.50 (m, 9H, ring), 5.15 (t, J=6 Hz, 1H, olefin), 5.05 (br s, 1H, NH), 3.24 (d, J=6 Hz, 2H, CH_2), 1.73 (s, 6H, CH_3); MS *m/z* (rel intensity) 237 (M^+; 100); Found: C, 86.09; H, 8.15%. Calcd for $C_{17}H_{19}N$: C, 86.03; H, 8.07%.

9: IR (neat) 2980, 2930, 1595, 1500, 1450, 1355, 1260, 750, and 695 cm^{-1}; ^{1}H NMR (CCl_4) δ=6.20—7.20 (m, 9H, ring), 5.20 (m, 2H, olefin), 4.03 (d, J=6 Hz, 2H, N-CH_2), 3.10 (d, J=6 Hz, 2H, CH_2), 1.62 (s, 6H, CH_3), 1.50 (s, 6H, CH_3); MS *m/z* (rel intensity) 305 (M^+; 35) and 236 (100); Found; C, 86.53; H, 9.21%. Calcd for $C_{22}H_{27}N$: C, 86.51; H, 8.91%.

Reaction of Pyrrole with Prenyl Diisopropyl Phosphate. To a solution of pyrrole (680 mg, 10.1 mmol) and prenyl diisopropyl phosphate (4.01 g, 16 mmol) in DMF (20 ml) was added boron trifluoride etherate (2.52 ml, 20 mmol) under nitrogen at room temperature and the mixture was stirred for 15 h. Work-up and column chromatography on silica gel (benzene-light petroleum=1:1) gave a mixture (679 mg, 50% yield) of 2-prenylpyrrole (**10**), 2-(1,1-dimethyl-2-propenyl)pyrrole (**11**), and 3-prenylpyrrole (**12**). GLPC analysis (Apiezon Grease L on Uniport B (15%), 1 m×3 mm, temp 130 °C, He 90 ml/min) revealed that the ratio of **10**:**11**:**12** was 68:20:12. They were separated by preparative GLPC.

10: IR (neat) 3400, 2970, 1678, 1568, 1440, 1378, 1022, 768, and 710 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=6.60 (m, 1H, pyrrole H^5), 5.75—6.20 (m, 2H, pyrrole H^3 and H^4), 5.30 (t, J=7 Hz, 1H, olefin), 3.30 (d, J=7 Hz, 2H, CH_2), 1.70 (s, 6H, CH_3); MS *m/z* (rel intensity) 135 (M^+; 100). Found: C, 80.16; H, 9.79%. Calcd for $C_9H_{13}N$: C, 79.95; H, 9.69%.

11: IR (neat) 3400, 2980, 1700, 1455, 1378, 1020, and 764 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=6.65 (m, 1H, pyrrole H^5), 5.75—6.25 (m, 3H, olefin and pyrrole H^3 and H^4), 4.85—5.20 (m, 2H, olefin), 1.35 (s, 6H, CH_3); MS *m/z* (rel intensity) 135 (M^+; 100); Found: C, 80.24; H, 9.89%. Calcd for $C_9H_{13}N$: C, 79.95; H, 9.69%.

12: IR (neat) 3400, 2910, 1680, 1550, 1436, 1372, 1052, 760 and 705 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=6.45—6.80 (m, 2H, pyrrole H^2 and H^5), 6.10 (m, 1H, pyrrole H^4), 5.35 (t, J=7 Hz, 1H, olefin), 3.20 (d, J=7 Hz, 2H, CH_2), 1.69 (s, 6H, CH_3); MS *m/z* (rel intensity) 135 (M^+; 100); Found: C, 79.97; H, 9.98%. Calcd for $C_9H_{13}N$: C, 79.95; H, 9.69%.

Reaction of Indole with Prenyl Diisopropyl Phosphate. To a solution of indole (586 mg, 5.0 mmol) and prenyl diisopropyl phosphate (2.00 g, 8.0 mmol) in DMF (10 ml) was added boron trifluoride etherate (1.26 ml, 10 mmol) under nitrogen at room temperature. The reaction mixture was stirred for 13 h and treated as above. Column chromatography on silica gel (benzene-light petroleum=1:1) gave a mixture (242 mg, 26% yield) of 3-prenylindole (**13**) and 3-(1,1-dimethyl-2-propenyl)indole (**14**) as a yellow oil. GLPC (Apiezon Grease L on Uniport B (15%), 1 m×3 mm, temp 200 °C, He 90 ml/min) of the oil showed two peaks of **13** and **14** in the ratio of 82:18. They were separated by preparative GLPC.

13:[10] IR (neat) 3420, 2960, 1640, 1450, 1360, and 740 cm^{-1}; ^{1}H NMR (CCl_4) δ=6.90—7.70 (m, 5H, benzene ring and NH), 6.70 (br s, 1H, H^2), 5.40 (t, J=7 Hz, 1H, olefin), 3.40 (d, J=7 Hz, 2H, CH_2), 1.73 (s, 6H, CH_3); MS *m/z* (rel intensity) 185 (M^+; 100).

14: IR (neat) 3420, 2960, 1640, 1450, 1360, and 740 cm^{-1}, ^{1}H NMR (CCl_4) δ=6.70—8.00 (m, 6H, benzene ring and NH), 4.75—6.50 (m, 3H, olefin), 1.49 (s, 6H, CH_3); MS *m/z* (rel intensity) 185 (M^+; 51) and 170 (100).

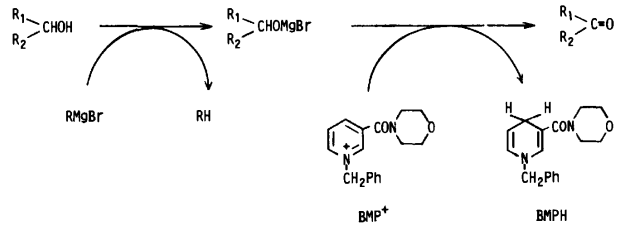
Oxidation of Alcohols *via* Alkoxymagnesium Halides by an NAD$^+$ Model Compound[1)]

Seiji SHINKAI,* Hiroyuki ERA, Takaharu TSUNO, and Osamu MANABE
Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852
(Received January 25, 1984)

Synopsis. Alkoxymagnesium bromides prepared from phenylmagnesium bromide and alcohols are capable of reducing an NAD$^+$ model compound to the 1,4-dihydronicotinamide in good yields. The carbonyl products were detected in quantitative yields from diphenylmethanol and 1-phenylethanol but in low yields from benzyl alcohol and aliphatic alcohols. This is a new route to 1,4-dihydronicotinamides with alcohols although it remains uncertainty whether or not the route has relevance as a model process for NAD$^+$ oxidaiton of alcohols.

In alcohol dehydrogenases, the interconversion of aldehydes (or ketones) and alcohols occurs in conjunction with that of NADH and NAD$^+$ coenzymes. In contrast to a number of investigations on the NADH model reduction of carbonyl substrates, there are only a few examples for the NAD$^+$ model oxidation of alcoholic substrates.[2-5)] The contrast suggests the difficulty to mimick the NAD$^+$-dependent oxidations in model systems. Interestingly, it is well established that 5-deazaflavin and its analogs which have the isoelectronic structure to NAD$^+$ can oxidize alcohols,[6-8)] but the mechanistic difference between 5-deazaflavin and NAD$^+$ is not well understood. One important information to exploit NAD$^+$ model oxidation would be the fact that protic or acidic media are very favorable to reduction of carbonyls by NADH,[9,10)] whereas oxidation of alcohols by 5-deazaflavin proceeds favorably in basic media.[11)] The findings are quite understandable from a viewpoint of the principle of the microscopic reversibility. Meanwhile, some metal ions such as Mg^{2+} and Zn^{2+} play a crucial role not only in the dehydrogenase reduction but also in the NADH model reduction.[12)] The principle suggests, therefore, that alcohols would be oxidized by an NAD$^+$ model compound through the metal (Mg^{2+} or Zn^{2+}) alkoxide intermediates. We here report that alkoxymagnesium halides prepared from a Grignard reagent and alcohols are capable of reducing an NAD$^+$ model compound to the 1,4-dihydronicotinamide in good yields, although the yields of the carbonyl products are in some cases unstatisfactory.



We used 1-benzyl-3-morpholinocarbonylpyridinium bromie (BMP$^+$) as an NAD$^+$ model compound. BMP$^+$ was prepared by the reaction of 3-morpholinocarbonylpyridine[2)] and benzyl bromide in benzene at reflux temperature for 4 h; mp 117—120 °C, yield 80.8%. Found: C, 55.63; H, 5.33; N, 7.49%. Calcd for $C_{17}H_{19}N_2O_2Br$: C, 56.21; H, 5.27; N, 7.71%.

1-Benzyl-3-morpholinocarbonyl-1,4-dihydropyridine (BMPH) was prepared from BMP$^+$ and $Na_2S_2O_4$ according to the method of Kim and Chaykin[13)]; oil, one spot on TLC, yield 64%. NMR (Me_2SO-d_6): 4-CH_2, δ= 3.00, 2H; morpholine protons, 3.35 (4H) an 3.52 (4H); 5- and 6-H, 4.2—4.4, 2H; N-CH_2, 5.97, 2H; 2-H and benzene protons, 7.3—7.4, 6H. The mixture of BMPH and 1-benzyl-3-morpholinocarbonyl-1,6-dihydropyridine was prepared by the reduction of BMP$^+$ by $NaBH_4$ in methanol. The ratio of 1,4- *vs.* 1,6-isomer determined on the basis of NMR[14)] was 57/43.

A typical experimental procedure is as follows: phenylmagnesium bromide (3.5 mmol) was prepared in 10 ml of anhydrous tetrahydrofuran (THF). Alcohol (3.5 mmol) was added and the reaction mixture was stirred for 3 h at room temperature under a nitrogen stream. Then, BMP$^+$ (2.8 mmol) in a mixed solvent of 20 ml THF and 20 ml *N*,*N*-dimethylformamide was added. The progress of the reaction (25 °C) was monitored analyzing the aliquot withdrawn from the reaction mixture. The yield of the dihydronicotinamide was directly determined by HPLC analysis: Shimadzu LC-3, Lichroprep RP-18, acetonitrile: water=8:2 v/v. To determine the yields of the oxidized carbonyl products the sample was once mixed with aqueous solution (pH 4) and extracted with chloroform. The chloroform solution was analyzed on GLC. Both methods had been certified by making the calibration curves using the authentic samples.

In the HPLC analysis we could detect BMPH, but

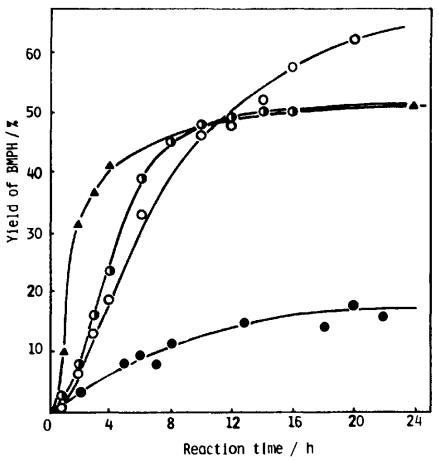


Fig. 1. Time-dependence of the yield of BMPH (1,4-isomer). ▲: Diphenylmethanol, ●: benzyl alcohol, ◑: 1-octanol, ○: cyclohexanol. The plot for 1-phenylethanol is essentially identical to that for diphenylmethanol.

Table 1. Product analysis for the reaction of BMP^+ and alkoxymagnesium bromides

Alcohol	Reaction time / h	Yield/%[a] BMPH	Yield/%[a] Carbonyl compound
Diphenylmethanol	24	51.2	100
1-Phenylethanol	24	52.0	100
Benzyl alcohol	5	8.8	0.2
	22	15.8	0.2
1-Octanol	4	24.1	0.9
	16	50.8	0.8
Cyclohexanol	8	40.3	trace ($\approx$0.1)
	20	61.9	trace ($\approx$0.1)

a) Yield based on BMP^+.

neither the 1,6-isomer nor the 4,4'-dimer[15] was detected. Speculating from the accuracy of the HPLC analysis, the yield of the 1,6-isomer (even if it was produced) would be less than 3%. The time-dependence of the BMPH yield is illustrated in Fig. 1 and the typical results are summarized in Table 1.

The oxidation of alcohols by 5-deazaflavin and its analogs affords the oxidized carbonyl products in good yields and in some cases the yields under aerobic conditions exceed 100% because of the autorecycling nature.[6-8] In the previous experiments of NAD^+ model oxidation, however, the analysis of the oxidized products was rather incomplete or unsuccessful: For example, the analysis of acetaldehyde was not carried out in the reaction with lithium ethoxide[3] and the oxidized product could not be detected in spite of the authors' best efforts in the reaction with glyceraldehyde.[4] We found that the reaction with diphenylmethanol and 1-phenyethanol affords the corresponding ketones in quantitative yields, whereas benzaldehyde expected for the oxidation of benzyl alcohol could be detected only in 0.2% yield. We first considered that the difference might be attributed to the steric difference between primary and secondary alcohols, because the unfavorable adduct formation between alkoxides and BMP^+ would be relatively suppressed in sterically crowded secondary alcohols. In fact, it was suggested in the oxidation by 5-deazaflavin analogs that to suppress the adduct formation leads to the efficient oxidation of alcohols.[8] This may be true for aromatic alcohols but is not the case for aliphatic alcohols, because the oxidation of cyclohexanol, as well as that of 1-octanol, gave only a trace amount of cyclohexanone. Two possibilities come to mind as a general scheme to explain the reaction. First, these reaction products may undergo further reaction in the strongly basic reaction solution. In relation to this, we observed that the yields increase up to 3—4% in the initial stage and then decrease. The second possibility is associated with the adduct formation proposed by Ohno *et al.*[4] In the HPLC analysis we sometimes detected a few unknown peaks (absorbing at around 350 nm) other than the 4,4'-dimer, but these peaks were not found for the oxidation of diphenylmethanol and 1-phenylethanol. Hence, the whole story of this reaction may be more complex than described by a single scheme. Further extensive studies are thus necessitated to answer this question.

It is known that 1,4-dihydronicotinamides result selectively from the oxidation of lithium ethoxide or glyceraldehyde.[3,4] Also in our reaction with alkoxymagnesium bromides, the 1,4-isomer of BMPH was produced selectively. As seen in Fig. 1, the reactions with diphenylmethanol and 1-phenylethanol ($t_{1/2}$ 1,4-2 h) was much faster than those with benzyl alcohol (6 h), 1-octanol (4 h), and cycloloxanol (7 h). It may be of some significance that the reactions yielding the corresponding carbonyl products are faster than others.

In the previous examples the yields of 1,4-dihydronicotinamides obtained from the 1:1 molar ratio reaction are not high (21—28%).[2,3] On the other hands, the yields of BMPH in the present system are much higher (50.8—61.9%) except benzyl alcohol. In particular, one can expect not only the high yield of BMPH but also the quantitative production of the ketones for the oxidation of diphenylmethanol and 1-phenethyl alcohol. We believe, therefore, that although it is still equivocal mechanistically whether or not the present reaction has direct relevance to NAD^+-dependent oxidations, the method is undoubtedly useful as a convenient route to 1,4-dihydronicotinamides with "alcohols."

Resistance to Alkali of the Nascent Fibril Produced by *Acetobacter xylinum*

Akira KAI* and Tomoki KOSEKI
Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158
(Receivd October 31, 1983)

Synopsis. The resistance of the nascent fibril produced by *Acetobacter xylinum* to alkali is lower than that of the crystalline cellulose I and higher than that of the amorphous cellulose. In the nascent fibril the cellulose chains are thougth to be in the form of cellulose sheets corresponding to the (1$\bar{1}$0) plane of cellulose I.

Investigation of the structure of the nascent fibril produced by *Acetobacter xylinum (A. xylinum)* is very important for the clarification of the biogenesis and the structure of bacterial cellulose. We have studied the structure of cellulose fibril after production by *A. xylinum*, in particular its staining behavior toward heavy metal salts[1] and its resistance to alkali.[2,3] However, the structure of nascent fibril is not yet clear enough. In this paper, therefore, the structure of nascent fibril produced by *A. xylinum* was examined from the aspects of the resistance to alkali of the never-air-dried fibrils. These were formed by glucose incubation for 3 h at 28 °C; they did not contain any crystalline microscopic fibril but were composed of 15 wt% of the amorphous fibril and 85 wt% of the fibril having the uneven staining behavior.[2]

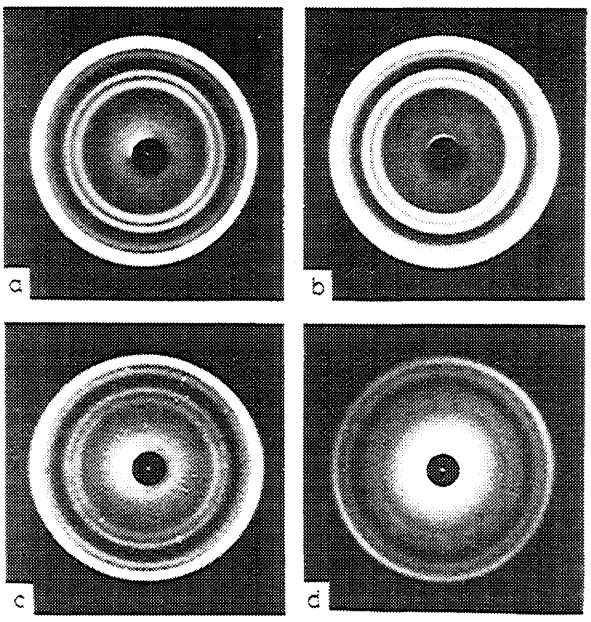

Fig. 1. X-Ray photographs of alkali-treated samples. a: Purified and dried sapmle obtained from the complex incubation for 2d at 28 °C, b: 10.8 wt% alkali-treated sample made from purified and dried sample a, c: 9.0 wt% alkali-treated never-air-dried cellulose obtained from the glucose incubation for 3 h at 28 °C, d: 10.8 wt% alkali-treated never air-dried cellulose obtained from the incubation of the same conditions as sample c.

The never-air-dried cellulose samples from the 3 h incubation were treated with 9.0 or 10.8 wt% aqueous NaOH solution. The X-ray diffraction diagram of 9.0 wt% alkali-treated sample showed only the diffraction of cellulose I, but not that of cellulose II (Fig. 1c). On the other hand, very little diffraction of the (1$\bar{1}$0) plane of cellulose II was found in the X-ray diffraction diagram of 10.8 wt% alkali-treated sample (Fig. 1d). In the diffraction diagram of the 10.8 wt% alkali-treated purified and dried sample, of course, the diffraction of cellulose II does not occur (Fig. 1b).

As described in the previous paper,[2] from the relationship between the change in the morphology of an amorphous fibril after production and the increase in the yield of cellulose with the incubation time, it is presumed that in the never-air-dried cellulose from the 3 h incubation some amorphous fibrils (about 15 wt%) are contained. However, it is considered that such amorphous fibril (15 wt%) will not shown up on the X-ray diffraction diagram of the 10.8 wt% alkali-treated sample. If the cellulose chains are arranged at random in the cross-section of an amorphous fibril, some cellulose chains in the low order region may be dissolved by alkali-treatment with 9.0—10.8 wt% aqueous NaOH solution. But, as shown in Table 1, the values for each weight of alkali-treated samples coincides with the values of each untreated sample, within the experimental errors. This result shows that the cellulose chains are not rejected by alkali-treatment. Accordingly, the X-ray test shows that the resistance of an amorphous fibril to alkali is close to that of the crystalline cellulose I.

The results shown above suggest that in the cross-section of amorphous fibril, as one of the authors described previously,[3] the cellulose chains are in the form of monomolecular layers corresponding to the (1$\bar{1}$0) plane of cellulose I. The amorphous fibril may include staining agent, water and culture substrates between (1$\bar{1}$0) planes.[3] This idea is supported by the studies on the alkali-treatment of cotton,[4,5] which conclude that the structure of a cellulose sheet formed by hydrophobic bond does not easily change by alkali-treatment.

TABLE 1. COMPARISON OF WEIGHTS OF ALKALI-TREATED AND UNTREATED NEVER-AIR-DRIED CELLULOSE FROM THE 3 h GLUCOSE INCUBATION

Concn of NaOH/wt%	Untreated	9.0	Untreated	10.8
Weight (mg/720 ml)	0.18	0.19	0.15	0.17

a) 720 ml is the volume of the culture medium.

Experimental

The culture of *A. xylinum* and the alkali-treatment of the never-air-dried cellulose were as described previously.[2,3] 40 ml of 3 wt% glucose medium (pH 6.8) was added to 200 ml of cellulose-free cell suspension and the mixture was then incubated at 28 °C for 3 h. To the incubated medium was gradually added dropwise an equal volume of aqueous NaOH, two times as dense as the given concentration. After gently making a homogeneous alkali solution, we kept the solution at 20 °C for 1 h and then added 30 vol% aqueous acetic acid solution to neutralize it. The solution was dialyzed through Cellulose Dialyzer Tubing (Nakarai Chemical Ltd, through M. W. cut-off: 8000, diameter: 90 mm, thickness: 0.09 mm) until it became sodium acetate free. The requisite quantity of cellulose for the X-ray photographing was obtained from preparing many times over (1 cycle/week). The dialyzed solution from many times preparations was boiled to collect cellulose. This collected cellulose was boiled in 1 wt% aqueous NaOH solution for 10 h under a nitrogen atmosphere, then neutralized with 1 vol% aqueous acetic acid solution and washed with distilled water until sodium acetate free. The wet cellulose was formed into a disk with the diameter of 1.5 mm and the thickness of about 1 mm for the X-ray photographing. The X-ray diffraction diagram of cellulose was taken with a flat-film camera with Ni filtered Cu $K\alpha$ radiation (35 kV, 15 mA, time of exposure: about 35 min) at specimen film distance of 50 mm.

Kinetics and Mechanism of Oxidation of Pyridoxine by Sodium *N*-Chlorobenzenesulfonamidate

Beby JAYARAM and Sarabaghatta Mayanna MAYANNA*

Department of Chemistry, Central College, Bangalore University, Bangalore-560 001, India

(Received May 16, 1983)

Synopsis. Oxidation of pyridoxine (PRX) by chloramine-B (CAB) in HCl medium at 313 K shows first order dependence each on oxidant, substrate and Cl^- ion concentrations, but is independent of $[H^+]$. A first-order retardation of rate is observed by the addition of reaction product, benzenesulfonamide. Suitable mechanism is proposed.

Aromatic *N*-halosulfonamides are compounds containing positive halogen and they act as both chlorinating and oxidising agents. The important members of this class of compounds are chloramine-T (CAT) and chloramine-B (sodium *N*-chlorobenzenesulfonamidate, CAB). Although sufficient reports are available about the mechanism of oxidation of substrates by CAT[1], information about CAB is scanty. Pyridoxine (PRX) find extensive application in pharmaceutical industries but mechanistic studies of its oxidation are meagre. It has been oxidised to pyridoxal by MnO_2[2] and $KMnO_4$[3] in acidic and alkaline media respectively. We report here the kinetics and mechanism of pyridoxine by CAB in HCl medium at 313 K.

Experimental

Chloramine-B was prepared and purified by standard procedures.[4] Pyridoxine (Fluka) was used without further purification. Aqueous solutions of the compounds were prepared in double distilled water. Heavy water (99.8%) was obtained from BARC, Bombay, India. All other reagents used were of AR grade. The reactions were followed under pseudo-first order conditions by estimating the unreacted CAB iodometrically. Experimental details are described elsewhere.[1]

Stoichiometry. Varying proportions of CAB and pyridoxine solutions in presence of HCl (0.04—0.14 M, 1M = 1 mol dm^{-3}) were mixed and the unreacted CAB was estimated. Values of $\Delta[CAB]/\Delta[PRX]$ and $\Delta[\text{pyridoxal}]/\Delta[CAB]$ in Table 1 suggest the overall reaction:

$$C_8H_{11}NO_3 + RNClNa \longrightarrow C_8H_9NO_3 + RNH_2 + NaCl.$$
$$(R = C_6H_5SO_2)$$

Benzenesulfonamide among the reaction product was detected by TLC technique.[5] Pyridoxal was identified and estimated as semicarbazone[6] (mp 509 K).

Table 1. Stoichiometry of oxidation of pyridoxine by CAB at 313 K

[HCl]/M	Δ[CAB]/Δ[PRX]	Δ[Pyridoxal]/Δ[CAB]
0.02	0.89	0.86
0.04	0.92	0.90
0.06	0.94	0.93
0.08	0.99	1.01
0.10	1.01	1.01
0.12	1.02	0.99
0.14	0.99	1.00

Results and Discussion

Oxidation of PRX by CAB was carried out at 313 K in the presence of various concentrations of HCl, H_2SO_4, and $HClO_4$ (0.04—0.14 M) but the reaction was found to be facile only in the presence of chloride ion in the solution. Hence, a detailed study was made on the kinetics of oxidation of PRX by CAB in HCl medium.

At constant [HCl] and [PRX], plots of log $(a-x)$ *vs.* time were linear indicating a first-order dependence of rate on [CAB]. The value of first-order rate constant k was independent of [CAB] (Table 2). Values of k increase with increase in [PRX] (Table 2) and a plot of log k *vs.* log [PRX], gives a straight line of slope unity, indicating first order dependence of rate on [PRX].

The rate also increases with increase in [HCl]. A plot of log k *vs.* log [HCl], shows a first-order dependent of rate on [HCl]. At constant $[H^+]$, addition of NaCl increased the rate. Plot of log k *vs.* log $[Cl^-]$ was linear with unit slope, showing first-order dependence of rate on $[Cl^-]$. The effect of $[H^+]$ at constant $[Cl^-]$ was studied. It was observed that the rate is independent of $[H^+]$ (Table 3).

Table 2. Effect of concentration of reactants on the rate

0.08	0.02	5.10±0.14
0.08	0.04	5.96±0.10
0.08	0.06	7.20±0.16
0.08	0.08	7.71±0.16

[CAB]=5×10^{-4} M; [PRX]=5×10^{-3} M.

The effect of temperature on the rate of oxidation of PRX by CAB in HCl medium was studied. The values of k at various temperatures (K) -303, 308, 313, 318, 323 are 1.77 ± 0.03, 3.11 ± 0.08, 4.64 ± 0.09, 7.90 ± 0.15, and 13.51 ± 0.24, ($\times10^4\,s^{-1}$) respectively. From the Arrhenius plot of log k *vs.* $1/T$ ($r=-0.9984$) values of E_a (82.6 kJ mol^{-1}), ΔS^* (-45.5 J K^{-1}), ΔG^* (94.0 kJ mol^{-1}), ΔH^* (80.0 kJ mol^{-1}), and A ($2.8\times10^{10}\,s^{-1}$) were computed.

The effect of the dielectric constant of the medium was studied by adding methanol to the reaction system. A plot of log k *vs.* $1/D$, where D is dielectric constant of the medium, gives a straight line with a positive slope of value 0.8642 ($r=0.9976$).

Change in the ionic strength of the medium (0.1—0.5 M) (with $NaClO_4$) had no effect on the rate of reaction (Table 2). The effect of reaction product was studied by adding benzenesulfonamide (BSA). The rate of reaction decreased with increase in BSA, showing a first-order retardation of rate by [BSA] (Fig. 1). The reaction was also studied in D_2O medium. The solvent isotope effect was found to be 0.907.

Eqilibria present in acidified CAT solution has been clearly established.[7] No detailed information is available about the oxidative species present in acidic solution of CAB. Zilberg[8] has shown that acidification of CAB gives dichloramine-T ($RNCl_2$) and RNH_2. Mogilevski *et al.*[9] have reported the presence of HOCl in acidic CAB solution. It is likely that equilibria similar to those of CAT exist in acidified CAB solution.

Hence the probable oxidizing species are RNHCl, $RNCl_2$ and HOCl. A strict first-order dependence of rate on [CAB] (Table 2) rules out $RNCl_2$ as the oxidizing species. In acidic chloride solution, HOCl forms Cl_2 while RNHCl can be further protonated to give RN^+H_2Cl.[10] Kinetic data obtained with Cl_2 water were found to be identical with those of CAB under comparable experimental conditions. First order retardation of rate by the addition of BSA further supports the involvement of Cl_2 in the reaction sequence. Hence free chlorine can be assumed to be the reactive species, which oxidizes PRX present in the protonated form, SH^+ in acid solution.[11] Based on

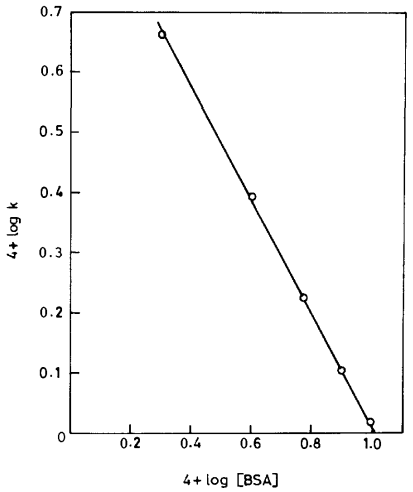

Fig. 1. Plots of log k *vs.* log [BSA].
[PRX]$=5\times10^{-3}$ M; [CAB]$=5\times10^{-4}$ M; [HCl]$=$ 0.1 M; temp$=$313 K.

these facts, the following reaction scheme may be proposed:

$$RN^+H_2Cl + Cl^- \overset{K}{\rightleftharpoons} RNH_2 + Cl_2, \quad (1)$$

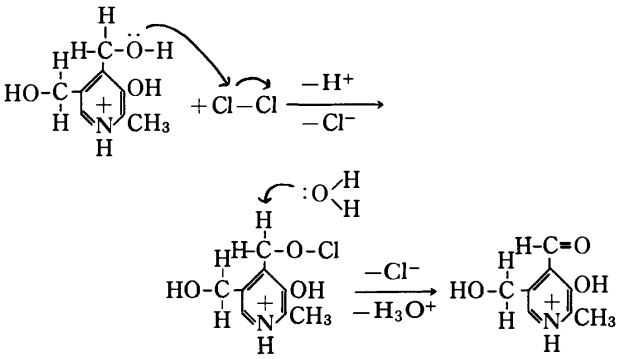
$$Cl_2 + SH^+ \xrightarrow{k} \text{products}. \quad (2)$$

Scheme

From Eqs. 1 and 2, the rate law becomes,

$$\text{Rate} = \frac{kK[SH^+][CAB][Cl^-]}{[RNH_2]}. \quad (3)$$

The mechanism of oxidation of primary alcohol usually involves the hydride transfer which accounts for the high solvent isotope effect[12] ($k_{D_2O}/k_{H_2O}\approx4$ to 7). In the present system hydride transfer is unlikely in view of the observed low solvent isotope effect (0.907). Therefore a mechanism involving the formation of hypochlorite is suggested. The electron flow during oxidation is depicted as follows:



The negative entropy of activation indicates the formation of the compact hypochlorite species at the determining step. The observed neutral salt effect and slight positive dielectric constant effect on the rate support the proposed mechanism.

Ferromagnetic Interactions in Formazanyl-Copper Complexes

Yoshiko KAWAMURA, Hiroaki OHYA-NISHIGUCHI,† Jun YAMAUCHI, and Yasuo DEGUCHI*

Department of Chemistry, College of Liberal Arts and Sciences, Kyoto University, Sakyo-ku, Kyoto 606

†*Department of Chemistry, Faculty of Sciences, Kyoto University, Sakyo-ku, Kyoto 606*

(Received April 26, 1983)

The magnetic susceptibility of four formazanyl-copper complexes have been measured by the use of a torsion balance in the range from 2 K to room temperature. Their ESR parameters have been measured on powdered samples at room temperature and the temperature of liquid nitrogen, and in solution at room temperature in order to elucidate the electronic structures of the complexes. The complexes which have shown the exchange-narrowed pattern in the spectra of powdered samples have been paramagnetic as low as 2 K. Nitro and carboxy derivatives characterized by a single, broad ESR absoption line have positive Weiss constants, indicating ferromagnetic interaction. Especially, the magnetic behavior of the carboxy derivative has been well interpreted in terms of a ground triplet-excited singlet model with the exchange parameter of 24 K. The nitro derivative showed an abnormally low magnetic moment. It has been concluded that the magnetic properties of formazanyl-copper complexes are very sensitive to substitution at the phenyl rings.

Formazans are compounds which contain a characteristic chain of atoms: -N=N-C=N-NH- and which yield tetrazolium salts upon oxidation. Since Kuhn and Jerchel drew attention to their valuable applications to biological research in 1941,[1] formazans and their tetrazolium salts have been studied extensively from various points of views.[2] In addition, it has been learned that formazans react with compounds of Cu^{2+}, Co^{2+}, and Ni^{2+} to give complexes which have two or four nitrogen atoms as ligands.[3,4] The magnetic susceptibilities of several complexes have been measured at room temperature or at three points between the temperature of liquid nitrogen and room temperature in order to ascertain the effective magnetic moments.[5,6] However, although quite a few papers have referred to the magnetic interaction among copper ions, only a few have made mention of the structures.[7] The fact that 1-(*o*-hydroxyphenyl)-3,5-diphenylformazanyl copper showed an abnormally low magnetic susceptibility was attributed to its having a binuclear form, not to its mixing of Cu^{+} and Cu^{2+}.[8] 1-(*o*-carboxyphenyl)-3,5-diphenylformazanyl copper has also been presumed to be a dimer, but it showed normal magnetic susceptibility down to the temperature of liquid nitrogen.[5,8] Therefore, the dimer structure has been proposed on the basis only of the elemental analyses and the hypothetical molecular arrangement. Though it is clear from the elemental analyses that 1-(*o*-carboxyphenyl)-3,5-diphenylformazan reacts with a divalent transition-metal ion with 1:1 stoichiometry,[3,4] the structure of the complex has been an open question for a long time.

In order to clarify the problems mentioned above, four formazanyl-copper complexes have been prepared, and ESR and magnetic-susceptibility measurements have been carried out. In this paper we will report first the results of the ESR and magnetic susceptibility measurements. Second, the magnetic properties will be discussed; they will be classified into two groups, the paramagnetic species and the ferromagnetic species. Especially, the latter will be discussed theoretically based on a ferromagnetic dimer model.

Experimental

The formazans were prepared by a method described elsewhere.[1] Bis(1,3,5-triphenylformazanyl)copper as (**1**) was prepared following the method by Hunter *et al.*, but using a different solvent. Bis[1-(*p*-chlorophenyl)-3,5-diphenylformazanyl]copper (**2**), 1-(*o*-carboxyphenyl)-3,5-diphenylformazanyl copper (**3**), and the copper complex of 1-(*p*-nitrophenyl)-3,5-diphenylformazan (**4**), were prepared by a similar method. **1**, **2**, and **4** all consisted of a fine, almost black powder, while **3** was a fine, purple powder. The elemental analyses of **1** and **2** agreed well with the calculated values; those of **4** also agreed well with the calculated values assuming the 2:1 stoichiometry of formazan and copper. The hypothetical molecular structure of **4** is shown as **4'** in Fig. 1. An amount of **3** large enough for the measurements was too difficult to obtain. The **3'** used for the measurements was a sample containing some solvent molecules. In Table 1, the

values calculated based on the 1:1 and 1:2 stoichiometries of copper and 1-(*o*-carboxyphenyl)-3,5-diphenylformazan are also listed for comparison. It was found that **3'** has basically the 1:1 stoichiometry.

The ESR spectra were observed at room temperature and at the temperature of liquid nitrogen by using an X-band ESR spectrometer(JEOL ME-3X) equipped with 100 kHz field modulation. The molar magnetic susceptibility χ_M was measured with powdered samples of about 50—70 mg in the temperature range from 2 K to room temperature by using a magnetic torsion balance described elsewhere.[10] All the data were corrected for the diamagnetic contribution calculated by the Pascal method: -341.2×10^{-6}, -331.3×10^{-6}, -288.7×10^{-6}, and -331.6×10^{-6} emu/mol for Compounds **1**, **2**, **3'**, and **4** respectively.**

Results

ESR in Solution. In order to obtain information about the isolated paramagnetic species, the ESR spectra in benzene solutions were measured at room temperature. The isotropic hyperfine structures due to the copper nuclear spin with $I=3/2$ have been observed in **1**, **2**, and **4**. Their hyperfine coupling constants are listed in Table 2. Their spectra showed a linewidth-variation effect; the linewidth in the higher field was sharper than that in the lower field. In the case of **4**, the superhyperfine splittings due to the four ligand-nitrogen nuclei(a_N) could be further observed in the absorption line of Cu^{2+} at the highest field, as is shown in Fig. 2, and a_N was equal to 5.4 G.*** On the contrary, in the benzene solution of **3**, only a single broad line with a linewidth of about 120 G was observed at room temperature, without any hyperfine splitting due to the copper nucleus. At the temperature of liquid nitrogen the ESR spectrum of **3** showed a tendency to split further into seven components. These results can be reasonably interpreted by assuming that the two copper nuclei are coupled with each other, with a strong exchange interaction. It should be noted in Table 2 that the Cu-hyperfine coupling constants (a_{Cu}) of about 41 G are abnormally small compared with those in the Cu-complexes with a planar structure. The a_N in **4**, is also much smaller than those of the usual planar complexes. These are the characteristic features of formazanyl copper complexes.

Magnetic Properties of 1 and 2. The ESR spectra of powdered samples of four compounds are shown in Fig. 3, while their *g*-values are listed in Table 2. The hyperfine splitting of copper in **1** could not be observed.

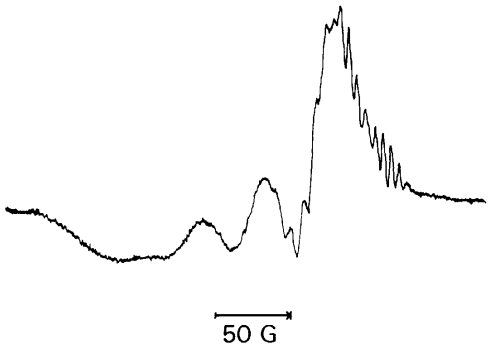

Fig. 2. ESR spectrum of **4** in benzene solution at room temperature. Note that the group at the highest field shows additional superhyperfine structure.

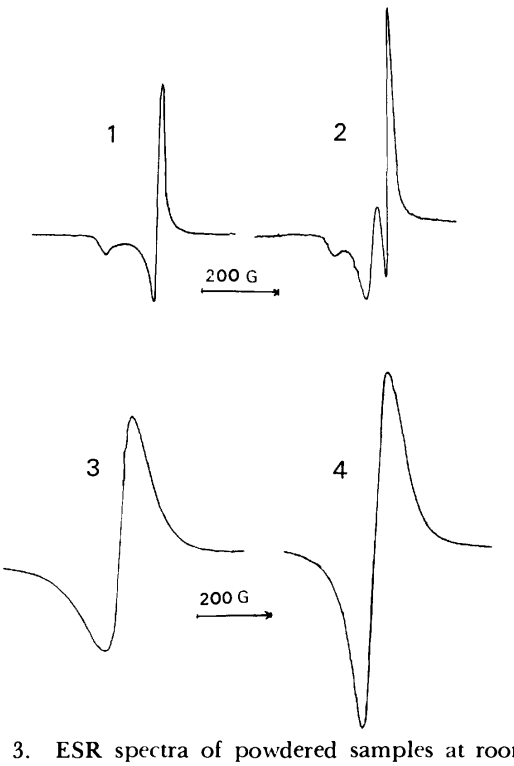

Fig. 3. ESR spectra of powdered samples at room temperature.

** The diamagnetic contribution was calculated for **4'**.
*** $1\,G=10^{-4}\,T$.

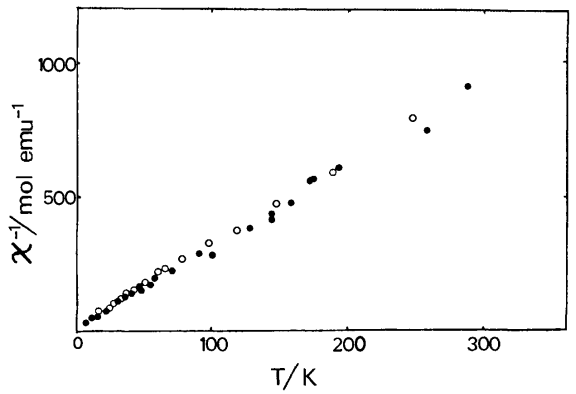

Fig. 4. The reciprocals of molar magnetic susceptibility of **1** (full circle) and **2** (open circle).

The linewidth between the halves of the absorption intensity of the parallel component, $\Delta H_{//}$, and the peak-to- peak width of that of the perpendicular component, $\Delta H_{\perp}$, were 26 and 15 G respectively. The results clearly show an exchange-narrowing effect. In Compound **2**, three components of the g-value, g_1, g_2, and g_3, were obtained. The difference in the g_{ave}-values between that at room temperature and that at the temperature of liquid nitrogen was quite small in **1** and **2**.

The reciprocal plots of χ_M of Compounds **1** and **2** *versus* the temperature are shown in Fig. 4. The most remarkable feature of these compounds is that both χ_M values follow the Curie-Weiss law described by Eq.(1):

$$\chi_M = C/(T-\theta), \quad C = Ng^2\beta^2 S(S+1)/3k, \tag{1}$$

$$\mu_{eff}/\beta = g\sqrt{S(S+1)}, \tag{2}$$

with the negative Weiss constant of -4 K. Here, the other notations have the usual meanings. This negative θ value indicates the existence of weak antiferromagnetic interaction among the magnetic species under consideration. The effective magnetic moment, μ_{eff} of **1** and **2** was estimated as 1.9β from the slopes of the $1/\chi_M - T$ (temperature) curves. This agrees well with the μ_{eff} value (1.78β) calculated with $g=2.06$ and $S=1/2$ in Eq. (2). This can be attributed to the fact that each molecule in the system possesses an isolated magnetic moment with $S=1/2$.

Magnetic Properties of **3**. The average g-value was 2.09. The ESR spectra of powdered samples of **3** and **3'** consisted of almost symmetrical broad lines without any hyperfine structure. The line shape and the g-value were almost temperature-independent.

The full circles in Fig. 5 show the experimental results of **3'**. The $1/\chi_M$ value obeys the Curie-Weiss law in the higher-temperature region (I) above 30 K. The Weiss constant in (I) was $+12$ K, indicating ferromagnetic interaction. On the other hand, the $1/\chi_M$ value in the lower-temperature region (II) deviates from the Curie-Weiss law in (I) at around 30 degrees and follows the Curie-Weiss law with a different θ value. The θ value estimated in the (II) region was almost zero. This behavior can be well interpreted in terms of the ground triplet-excited singlet model (referred to as the T-S mode),[13] as will be described later.

Magnetic Properties of **4**. The ESR spectrum observed in the powdered sample of **4** is also a single

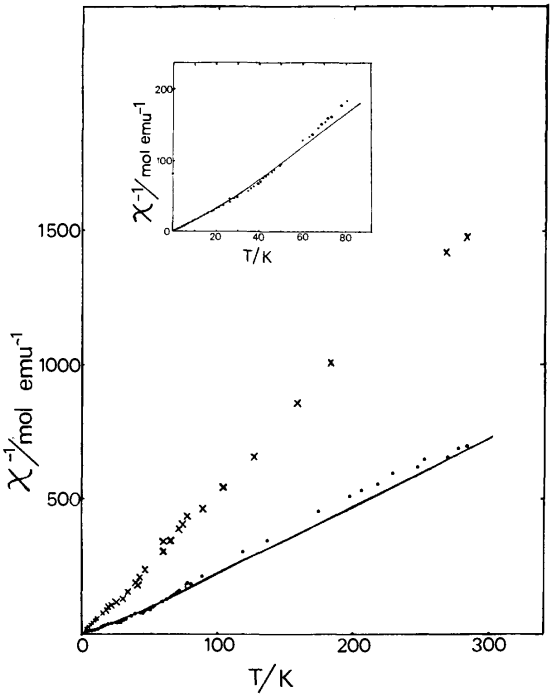

Fig. 5. The reciprocals of molar magnetic susceptibility of **3'** (full circle) and **4** (cross).
The inset shows the susceptibility of **3'** in the lower temperature region; the experimental results (full circle) and theoretical curve (solid line) based on the T-S model (see text).

broad line which is almost symmetrical and which gives an average g-value of 2.06. This is not so much different from that of **3**. However, the stoichiometry of formazan and copper of **4** was 2:1, in contrast with that of **3**, 1:1, as is seen in the elemental analyses.

The ESR in solution and stoichiometry indicate that **4** is of a monomer type, similar to **1** and **2**. On the contrary, the ESR of the powdered sample suggests a strong interaction among the copper ions, because neither the g anisotropy nor the hyperfine splitting could be observed.

A plot of the $1/\chi_M$ of **4** *versus* the T is also shown in Fig. 5. The Weiss constant extrapolated in the higher-temperature region(I) was $+11$ K, indicating that the exchange interaction in **4** is also ferromagnetic. The $1/\chi_M$ value in the lower-temperature region(II) obeys a Curie-Weiss law, with $\theta=0$ K.

Discussion

The $g_{//}$ and $g_{\perp}$ values of **1** were similar to those of Cu-tetraphenylporphyrine ($g_{//}=2.12$, $g_{\perp}=2.07$).[11] This fact indicates that the environment of the nitrogen-bonded copper ion in the present compound is square-planar. On the other hand, the three components of the g-value in **2** demonstrate that the planarity around the copper ion is no longer kept. However, the average g-value of **2**, $g_{ave}=(g_1+g_2+g_3)/3$, is not so much different from that of **1**. The slight deviation from the square-planar configulation is probably caused by the introduction of chlorine into the phenyl rings. In spite of this difference, both Compound **1** and Compound **2** showed an exchange-

Table 2. Results of ESR and magnetic susceptibility measurements

Compound	Magnetism	Weiss constant θ/K	μeff BM	g-value Room temp.	g-value Liq. nitrogen	a_{Cu}(iso) G
1	Curie-Weiss	−4	1.9	g=2.120 g=2.031 g_{ave}=2.061	g=2.121 g=2.031 g_{ave}=2.061	41.3
2	Curie-Weiss	−4	1.9	g_1=2.032 g_2=2.061 g_3=2.123 g_{ave}=2.072	g_1=2.033 g_2=2.065 g_3=2.125 g_{ave}=2.074	41.0
3′	Ferromagnetic (T-S model)	+12	1.8	g_{ave}=2.094	g_{ave}=2.100

(I) and (II) mean the higher- and the lower-temperature regions respectively.

narrowed pattern in ESR and obeyed the Curie-Weiss law. These results indicate that these compounds are typical paramagnetic species with small exchange interactions among the mononuclear units. On the other hand,the g_{ave} of **3**, 2.09, is the largest among the four compounds; the others have almost identical g_{ave} value, about 2.06.

The g-anisotropy of the copper ion in the powdered sample of **4** could not be seen because of the single broad line, but the copper hyperfine coupling constant of **4** in solution was almost the same as those of **1** and **2**, about 41 G, and the stoichiometry was also the same. The most remarkable difference between Compound **4** and Compounds **1** and **2** was that the χ_M of **4** at 288 K, 670×10^{-6} emu/mol, is abnormally small compared with the values of the others, 1200×10^{-6} emu/mol. The χ_M value of the isolated spin system with $S=1/2$ is calculated as 1300×10^{-6} emu/mol at 288 K on a spin-only basis. Therefore, the experimental value of χ_M of **4** at 288 K is about one half of the calculated value. In order to interpret these results quantitatively, we need the crystal structure of **4**. Further experiments such as ESR measurements below the temperature of liquid nitrogen and X-ray analysis are now in progress.

In conclusion, it is characteristic in formazanyl copper complexes that a subtle perturbation such as the introduction of a substituent into the phenyl rings far from the central copper ion results in changes in the symmetry of the ligand field and the magnetic properties.

Ground Triplet-excited Singlet Model. Recently, the ferromagnetic behavior in several copper complexes has been reported and discussed in relation to their molecular structures.[12] In the present case, the ferromagnetic behavior of **3′** can be well explained on the basis of the T-S model.[13] The molar magnetic susceptibility of this model is expressed by the Bleaney-Bowers equation (3):[14]

$$\chi_M = \frac{Ng^2\beta^2}{kT}\frac{1}{3+\exp(-2J/kT)}, \quad (3)$$

where $2J$ is the energy separation between the ground triplet and the excited singlet states, and where N is the number of monomer complexes. Equation (3) indicates that the $1/\chi_M$ ratio approaches linearly to zero with a lowing of the temperature. In the higher-temperature region, χ_M can be approximated by Eq. (1), with $\theta=J/2k$. Therefore, the theoretical ratio of the slope of the $1/\chi_M$-T curve in the lower-temperature region to that in the higher-temperature region, R, can be calculated; it is equal to 0.75. The R of **3′** was found to be 0.7 ± 0.05. The θ in the higher-temperature region clearly indicates the ferromagnetic-exchange interaction. These results indicate that the ferromagnetically coupled dimeric model is adequate for **3′**. The exchange energy, J, could be estimated from the relation: $J/k=2\theta$, based on the high-temperature approximation of Eq. (3). J was equal to 24 k erg**** in this case. In conformance with the above mentioned T-S model and the estimated J value, the theoretical curve of the temperature dependence of the magnetic-susceptibility behavior was drawn with the solid line in Fig. 5; it agreed with the experimental results within the limits of experimental error. Thus, the T-S model accounts well for the susceptibility behavior of **3′**. We have carried out the magnetic-susceptibility calculations based on Cubane-type models.[15,16] The experimental data fit well at the limit of the interdimer-interaction, $J'=0$. This establishes the appropriateness of the T-S model.

It is well known that the coupling of the copper ions can be ferromagnetic when the bonding angle of Cu-O-Cu is about 90°.[17] The construction of the molecular model of **3** shows that the angle of Cu-O-Cu can be about 90°. The results of the magnetic measurement give circumstantial evidence for the molecular structure of **3** shown in Fig. 1, which had been proposed only on the basis of the elemental analyses.[5]

Thus, it can be concluded that the most possible structure of **3** is the magnetic dimer, in which the triplet state is the ground state, the energy separation $2J/k$ being 48 K. Finally, it is of interest to point out that the copper complexes having such large ligands as formazan derivatives show comparatively large ferromagnetic interactions, as is visualized in **3′** and **4**. The central chain structure of formazan has a high flexibility on complexation with metal ions. This results in a variety of magnetic properties in these

**** 1 erg = 10^{-7} J.

complexes. We are now planning to investigate such features in the other formazanyl-transition metal complexes.

The authors would like to acknowledge the helpful advice of Professor Yutaka Takaki of Osaka Kyoiku University in the preparation of formazans. They are also much obliged to Professor Mamoru Mekata for the susceptibility measurements and his helpful discussion.

Optically Active and Racemic Glycerides. I. The Thermodynamic and Structural Relationship between Optically Active and the Corresponding Racemic α-Monostearins in Their Crystalline, Molten, and Dissolved States

Makio IWAHASHI,* Yasutoshi WATANABE,† Toshihiko WATANABE,†† and Mitsuo MURAMATSU†††
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158
(Received June 8, 1983)

The thermodynamic and spectrographic properties, such as the melting temperature, the latent heat of fusion, the solubility, the heat of solution, and the infrared and NMR spectra, were studied for the stable β-forms of the optically active (*S*)- and the corresponding racemic (*RS*)-α-monostearin crystals. The phase diagram for the binary mixture and the IR spectra of (*S*)- and (*RS*)-crystals indicate that the (*RS*)- form is a racemic molecular compound consisting of (*R*)- and (*S*)-α-monostearin molecules. The latent heats of fusion for the (*S*)- and (*RS*)-α-monostearin crystals were 82.4 kJ mol^{-1} and 75.4 kJ mol^{-1} respectively. The heats of solution in benzene for the (*S*)- and the (*RS*)-crystals were 86.3 and 99.9 kJ mol^{-1} respectively. The difference in the heat of solution between the (*S*)- and the (*RS*)-crystals, $\Delta(\Delta H_S)$, was 13.6 kJ mol^{-1}, which may be attributable to the difference in the extent of hydrogen bonding. These results suggest that (*R*)- and (*S*)-molecules in the (*RS*)-form strongly interact to form a racemic pair not only in the crystalline state, but also in the molten state. Such a racemic pair dissociates into the free molecules when it is dissolved in a nonpolar solvent. The conclusion is supported by the IR and NMR spectra for both the glycerides in dissolved states.

The properties of α-monoglycerides, harmless detergents, have been studied by many investigators.[1-6] Little has yet been reported on the thermodynamic difference between optically active and (*RS*)-forms, however. The (*RS*)-form can, in general, be classified, in terms of the interaction of (*R*)- and (*S*)-molecules in the crystal, into three types of modification:[7,8] a racemic compound, a solid solution, or a mixture of (*R*)- and (*S*)-crystals. (*RS*)-α-Monoglycerides containing even carbon-chain lengths from C-12 to C-18 seem to be racemic compounds, as they appear at higher melting points than do their optically active (*S*)-forms.[9] The crystalline properties of the racemic compounds can be expected to differ from those of the optically active species. A comparative study has thus been made of the properties of these crystals: the thermodynamic and structural properties of the crystals of (*RS*)-α-monostearin were compared with those of (*S*)-α-monostearin in an effort to obtain knowledge of the interaction between (*R*)- and (*S*)-molecules in the racemic α-monostearin crystal.

Experimental

Materials. Pure (≫99%) samples of optically active (*S*)- and racemic (*RS*)-α-monostearins obtained from Fluka AG (Switzerland) were further purified by repeated recrystallizations from hexane. The melting points of these samples were 349.3 and 355.6 K respectively, in good agreement with the previously reported values[9] (349.2 K for (*S*)- and 355.2 K for (*RS*)-) for the β-form crystals. The polymorphic forms of the (*S*)- and (*RS*)-α-monostearins are the β, β′, α, and sub-α forms. The first one obtainable by slow crystallization from a solvent is the most stable[2,4,10] under ordinary conditions.

Apparatus and Procedures. The latent heat of fusion and the melting point were determined by the use of a differential scanning calorimeter (Shimadzu Model DSC-30) in the temperature range of 300—373 K at a constant rate of 5 K min^{-1} to rise the temperature. In order to obtain melting temperature-composition diagrams for mixtures of (*S*)- and (*RS*)-α-monostearins, they were mixed in benzene and allowed to stand overnight *in vacuo* to evaporate the solvent.** A standard sample of KNO_3[11] was used for calibration to obtain the latent heat of fusion. The solubility in benzene was determined at a constant temperature (±0.02 K) in the range of 281—298 K by the method of an asymptotic approach to the concentration-time curves for under- and super-saturated solutions.[12,13] About 10 h after the addition of a monostearin to the solvent, a 2.00 ml portion of a saturated solution was pipeted out through a glass tip covered with a piece of filter paper (Toyoroshi No. 5) which had been soaked in the solvent for 24 h prior to pipeting.[13] The pipeted solution was then evaporated to dryness *in vacuo* for weighing. The infrared spectra of the monostearins in crystalline state (in the KBr disks) and in the molten state (on the NaCl plate) were obtained with a Hitachi Model 260-10 spectrometer (resolving power of 0.5 cm^{-1}); those in CCl_4 solutions were obtained with a JASCO IR-A3 spectrometer (Japan Spectroscopic Co., Ltd.; resolving power of 0.7 cm^{-1}). The NMR spectra for those monostearins in benzene-d_6 (C_6D_6) were obtained with a JEOL-FX 60 NMR spectrometer.

Results and Discussion

The values of the melting point, the latent heat, ΔH_f, and the entropy, ΔS_f, of the fusion of (*S*)- and (*RS*)-α-monostearin crystals are listed on the second to fourth lines respectively in Table 1. The value of ΔH_f (75.4 kJ mol^{-1}) for the (*RS*)-form is in good agreement with that (75.4 kJ mol^{-1}) reported by T. Maruyama *et al.*[3]

Figure 1 shows the temperature dependences of the solubilities for the (*S*)- and (*RS*)-compounds in

** Simple mixing of the two in a mortar always resulted in the appearance of two peaks on the DSC chart, the two giving a molar ratio exactly the same as that of the initial mixture. The peak positions also corresponded to the melting points for the mixture components.

benzene. The following van't Hoff equation was used to calculate the heat of solution, ΔH_s;

$$\ln C = \Delta H_s/RT + K, \quad (1)$$

where C is a solubility; R, the gas constant; T, the absolute temperature, and K, an integration constant. The activity coefficient was always assumed to be unity because of the low solubilities. The ΔH_s values are tabulated on the last line of Table 1.

In Fig. 2 the melting point is plotted against the mole fraction of (*RS*)-α-monostearin in the mixture of (*S*)- and (*RS*)-α-monostearins. The figure indicates that the (*RS*)-form is a typical racemic compound, giving an eutectic mixture at a molar ratio of 3:7. If there were a crystal of (*R*)-α-monostearin, it would have been of the same melting point as that for the crystal of the (*S*)-α-monostearin because enantiomers in general possess the same physical and chemical properties except in optical rotations and biological actions. The mp for the (*RS*)-form should thus give a maximum at an equilmolar mixture of the (*R*)- and (*S*)-compounds, implying that a racemic pair exists in the (*RS*)-crystal, as has been suggested by Larsson.[5,6] Such an implication leads to a more ordered arrangement of the molecules in the (*RS*)-crystal compared to the (*S*)-crystal, reflecting a kind of contradiction of the results on the third and fourth lines of Table 1: if we assume enthalpic and entropic identities between the liquid form (*S*)-crystal and (*RS*)-crystal, the former crystal should be in a more ordered state, with a lower enthalpy, than the latter. On the other hand, the ΔH_s values in Table 1 reveal a lower enthalpy for the (*RS*)-crystal, than that for the (*S*)-crystal, if we assume an identical state for a benzene solution of α-monostearin, whether it is (*S*) or (*RS*). In fact, the NMR pattern for a solution of the (*S*)-glyceride in benzene-d_6 (C_6D_6) was exactly the same as that of the (*RS*)-compound. The contradiction between the heat of fusion and that of solution can be clarified by assuming that the molten states of the (*S*)-form and the (*RS*)-form are different from each other. McGinn[14] has reported that "a liquid" of (*RS*)-octanol differs considerably from that of the (*R*)- or (*S*)-compound in its physical properties, such as density, boiling point, and refractive index.

The difference in the heat of solution between (*S*)- and (*RS*)-α-monostearin crystals, $\Delta(\Delta H_s)$, was 13.6 kJ mol^{-1}, which may be attributable to the difference mainly in the extent of hydrogen bonding. In fact, the OH-stretching vibration in the former crystal was different from that for the latter crystal, as shown in Fig. 3.

From the identity between (*S*)- and (*RS*)-compounds in the dissolved state and the assumption that their

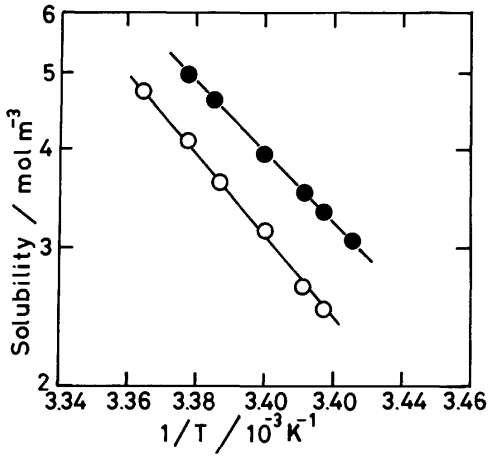

Fig. 1. Relationship between the solubilities and (1/*T*) for (*S*)- (filled symbols) and (*RS*)-α-monostearin (open) crystals.

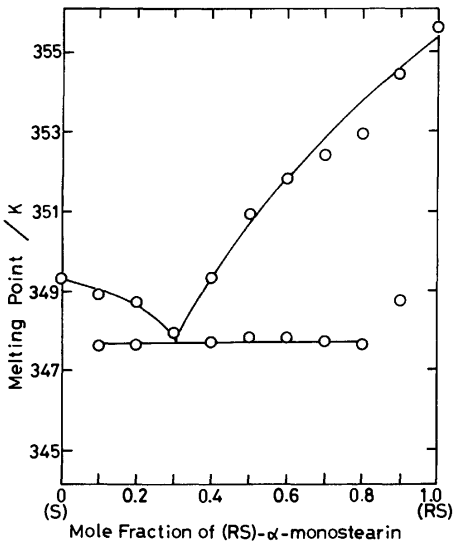

Fig. 2. Melting point of the mixture of (*S*)- and (*RS*)-α-monostearins as a function of the mole fraction of the (*RS*)-species.

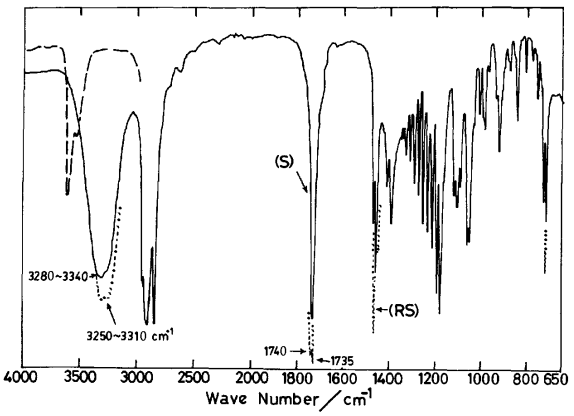

Fig. 3. Infrared spectra of α-monostearins:
Solid line expresses (*S*)-crystal in KBr disk, dotted one (*RS*)-, and dashed one (*S*)- or (*RS*)-forms in CCl_4.

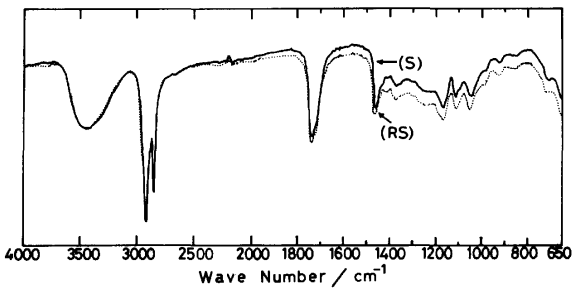

Fig. 4. Infrared spectra of α-monostearins in molten state at 358 K:
Solid line expresses (*S*)-form and dotted one (*RS*)-form on NaCl plate, respectively.

liquid states for (*S*)- and (*RS*)-crystals differ from each other, 20.6 [=(99.9−75.4)−(86.3−82.4)] kJ mol^{-1} can be calculated for the enthalpic difference between the molten (*S*)- and (*RS*)-forms, if we ignore the temperature difference between the solubility and the melting data. The enthalpic difference probably due to the difference in the intensities of the hydrogen bonding forces, the cohesive forces, and so on, between (*S*)- and (*S*)-molecules, and (*R*)- and (*S*)-molecules in their molten states. However, the IR spectra for their molten samples at 358 K did not show a remarkable difference between them, as shown in Fig. 4. The reason for that is uncertain at present.

Larsson[6] described that a unit cell of the (*S*)-α-monostearin contains eight molecules and is orthorhombic, with these dimensions; a=4.94 Å, b=8.97 Å, and c=100.4 Å, while in the (*RS*)-form, its unit cell contains also eight molecules, but gives monoclinic system with these dimensions; a=9.20 Å, b=100.5 Å, c=5.04 Å, and β=100.2°, giving a denser packing for the former as a whole. The racemic pair in the latter crystal should thus be arranged so as to give a lower density. Such a difference in the packing mode may contribute to the entropy difference $\Delta(\Delta S_f)$ between (*S*)-crystal→(*S*)-liquid (235.9 J K^{-1} mol^{-1}) and (*RS*)-crystal →(*RS*)-liquid (212.0 J K^{-1} mol^{-1}). Whatever the case, it must be stated that the $\Delta(\Delta H_f)$ difference is overwhelmed by the $\Delta(\Delta H_s)$ difference, so that the thermodynamic difference between (*S*)-crystal→(*S*)-liquid and (*RS*)-crystal→(*RS*)-liquid is much less than the thermodynamic difference between (*S*)-crystal→solution and (*RS*)-crystal→solution. This, in turn, implies that (*S*)-liquid is more different from (*RS*)-liquid than (*S*)-crystal is different from (*RS*)-crystal.

Catalytic Activities of 12-Molybdophosphoric Acid and Its Salts Supported on Silicon Dioxide for the Reduction of Nitrogen Monoxide

Isao MOCHIDA,* Toshihiro NAKASHIMA,† and Hiroshi FUJITSU

Research Institute of Industrial Science,

†*Department of Molecular Technology, Graduate School of Industrial Sciences, Kyushu University, Kasuga 816*

(Received July 25, 1983)

12-Molybdophosphoric acid and its metal salts, supported on SiO_2 (H_3PA and MPA/SiO_2), were found to exhibit significant activities for the catalytic reduction of nitrogen monoxide with hydrogen or ammonia, the latter reductant being more reactive. The activity orders of the catalysts were as follows, depending on the reductant: $Cu^{2+}>Ag^+>Ni^{2+}>Cs^+\simeq Co^{2+}\simeq H^+$ (hydrogen), $Cu^{2+}>Co^{2+}>H^+>Ag^+>Ni^{2+}>Cs^+$ (ammonia). It is of value to mention also that H_3PA/SiO_2 exhibited ten times many activity when ammonia was applied. The extent of the cation exchange (X) of $Cu_XH_{3-2X}PA/SiO_2$ influenced the catalytic activity differently, depending again on the reductant, although the maximum activity was obtained with both reductants when X was 1.1. Nitrogen monoxide was decomposed by a stoichiometric reaction with the reduced site on $Cu_{1.1}H_{0.8}PA/SiO_2$, especially when the catalyst was reduced with hydrogen, although no oxygen was detected in the product, the initial rate being comparable to that of the reduction with hydrogen. The following rate-equations were obtained with the respective reductants on $Cu_{1.1}H_{0.8}PA/SiO_2$ at 300 °C over the partial pressure range of NO (3.0—10.1 kPa) and reductants (3.0—35.5 kPa): $V=k_{H_2}P_{NO}^{0.8}P_{H_2}^{0.04}$, $V=k_{NH_3}P_{NO}^{0.6}P_{NH_3}^{0.4-0.7}$. The wide range in the magnitude of powers with respect to the ammonia partial pressure in the latter equation implies the strong adsorption of ammonia on the catalyst. These results suggest that the redox and Langmuir mechanisms are plausible for the reactions with hydrogen and ammonia respectively. An ESR study of the copper and molybdenum ions of the catalyst supports the above mechanisms.

The practical removal or reduction of NO_x in the flue gas has been widely carried out in various industries.[1] Nevertheless, techniques with higher efficiency are still extensively explored for using various catalytic reactions. The recent increase in coal firing, which tends to exhaust highly contaminated flue gas,[2] may also force the acceleration of technical development.

In the present study, the catalytic activities of heteropolyphosphoric acid and its metal salts were examined for the reactions of NO-H_2 and NO-NH_3. Since they are well known catalysts for acid-catalyzed and oxidation reactions,[3] the simultaneons activation of ammonia and nitrogen monoxide can be expected to provide an excellent activity. They are soluble in water or methanol, and can easily be recovered and regenerated when the catalyst is poisoned by fly ashes exhausted from coal. The salt forms may be durable against the alkali metal compounds which are known to poison some metal oxide catalysts severely.[4]

Experimental

Catalysts. The 12-molybdophosphoric acid ($H_3PMo_{12}O_{40}$) was purchased from the Nippon Inorganic Colour and Chemical Co. The metal salts were prepared using their corresponding metal carbonates according to the method described in the literature.[5] The salts or the acid were supported on silica gel (Merck, Kiesel gel 60HR, 350 m^2/g) from their methanol solution. The loading level of the salts or the acid was 33.3 wt%. Granules of 28—40 mesh, prepared by molding and crushing, were used for the catalytic reaction.

Reaction Procedure. The reduction of nitrogen monoxide was carried out in a fixed-bed flow reactor (8 mmϕ, Pyrex glass tube) and in a closed-circuration reactor (vol. 800 ml). The reactant gas contained 5 vol% (5.07 kPa) of nitrogen monoxide (Seitetsu Kagaku Co.), plus 10 vol% (10.1 kPa) of ammonia or hydrogen as the reductant. The catalyst weight and the total flow rate in a typical case of the flow reactor were 500 mg and 100 $cm^3\,min^{-1}$ (SV: 9200/h) respectively. The same reactant gas was supplied to the circulation reactor, where the circulation rate was 500 ml min^{-1} at a total pressure of 15.2 kPa. The rate dependence on their partial pressures was measured under partial pressures of nitrogen monoxide and reductants varying from 3.0 to 10.1 kPa (3 to 10 vol%) and from 3.0 to 35.5 kPa (3 to 35 vol%) respectively by means of a flow reactor under differential reactor conditions (conversions less than 10%). The gas composition was analyzed before and after the reaction by means of a gas chromatograph with columns packed with Porapak Q (1 m) and Molecular Sieve 13X (2 m).

Adsorption Measurements. The adsorption of NO and NH_3 was measured volumetrically with a fixed volume apparatus.

ESR Measurements. The ESR measurements were carried out at room temperature with a JEOL JES-FEIX spectrometer at a modulation frequency of 100 kHz. Mn^{2+} doped in MgO was used as the external standard to determine the g values of the paramagnetic species.

Results

Catalytic Activity for NO Reduction with Hydrogen and Ammonia. The catalytic activities of 12-molybdophosphoric acid and its stoichiometric metal salts supported on silica gel are summarized in Table 1; the reduction of NO was examined with hydrogen as a reductant. All the catalysts showed activity stable enough for more than 12 h and commonly produced nitrogen and dinitrogen monoxide, without any ammonia. The activity and selectivity varied considerably, depending on the kind of metal cation; the following activity order was deduced:

$$Cu^{2+}>Ag^+>Ni^{2+}>Cs^+\simeq Co^{2+}\simeq H^+.$$

The three active catalysts produced considerable amounts of dinitrogen monoxide; its selectivity on the nickel salt was as high as 60%, whereas no dinitrogen monoxide was found over the catalysts of much less

Ag_3PA	11.2	74.2	25.8
Cs_3PA	6.0	67.9	32.1

Reaction temp: 300°C, pretreatment: 300°C-3 h (in He), catalyst weight: 0.5 g, NO: 5.0%, NH_3: 10.0%, He: Carrier: 100 $cm^3 min^{-1}$.

activity except for the cobalt salt.

The catalytic activities using NH_3 as a reductant are shown in Table 2, where the conversion and selectivity were observed 3 h after the reaction had started. Although all the catalysts showed activities higher than those with hydrogen, their activities decreased to *ca.* 80% of the initial value within 3 h and then further gradually to give *ca.* 50% after 20 h. The selectivities, however, stayed constant. The catalytic activities depended considerably on the exchanged cations, although N_2 was always the principal product over all the catalysts, regardless of the cation. The activity order was deduced to be as follows:

$$Cu^{2+}>Co^{2+}>H^{+}>Ag^{+}>Ni^{2+}\simeq Cs^{+}.$$

It must be noted that H^+ and Co^{2+} catalysts showed activities over ten times larger than those observed in the reaction with hydrogen.

The Effects of the Extents of Cation Exchange on the Catalytic Activity. The catalytic activities of the acid exchanged with Cu^{2+} at variable levels (defined as $M_XH_{3-2X}PA$, where the exchange levels of X were 0.5, 1.1, and 1.5), with hydrogen and ammonia as the reductants, are shown in Fig. 1. When hydrogen was used, the conversion of NO increased proportionally with the increase in X until X was 1.1. The acid and $Cu_{0.5}H_2PA$ produced nitrogen almost exclusively, whereas the more copper(II)-ion-exchanged one produced dinitrogen monoxide with about a 30% selectivity, in addition to the principal product of nitrogen.

The activity in the reduction with NH_3 depended more markedly on the exchange level, showing a bell-shaped correlation against X where $Cu_{1.1}H_{0.8}PA$ showed the highest activity, whereas the selectivity

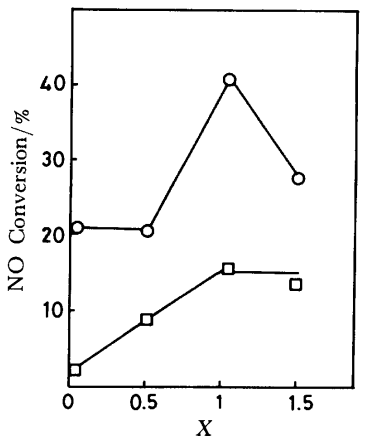

Fig. 1. The effects of the extent of cation exchange (X) on the catalytic activity of $Cu_XH_{3-2X}PA/SiO_2$. Catalyst: 0.5 g, NO and reductant: 5% and 10% in He, total flow rate: 100 $cm^3 min^{-1}$, reaction temp: 300°C, □: $NO-H_2$, ○: $NO-NH_3$.

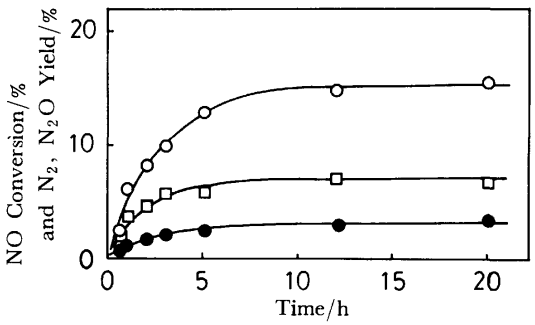

Fig. 2. Decomposition reaction of NO over $Cu_{1.1}H_{0.8}PA/SiO_2$ using a closed circulation reactor. Catalyst: 1.0 g, P_{NO}=40.3 kPa, reaction temp: 300°C. ○: NO conversion, ●: N_2 yield, □: N_2O yield.

was almost constant at all exchange levels.

Decomposition Reaction of NO over $Cu_{1.1}H_{0.8}PA/SiO_2$. The decomposition of NO was found to proceed over $Cu_{1.1}H_{0.8}PA/SiO_2$ at 300°C. Its reaction profile, as observed in a closed circulation reactor (P_{NO} = 40.3 kPa, catalyst = 1 g), is shown in Fig. 2. The reaction proceeded slowly but steadily to produce nitrogen and dinitrogen monoxide, and terminated at 10 h after the reaction started. At the end of the reaction, the reacted NO amounted to one molecule per Keggin unit of the catalyst. It must be noted that no oxygen was detected in the gas phase throughout the reaction.

The activity of reduced $Cu_{1.1}H_{0.8}PA/SiO_2$ (under a hydrogen flow at 300 °C for 20 h) observed with a flow reactor is shown in Fig. 3, where the reaction temperature, the amounts of catalyst, the partial pressure of NO, and the total flow rate were 300 °C, 0.5 g, 1.057% (1.1 kPa) in helium, and 50 $cm^3 min^{-1}$ (SV 4600/h) respectively. Although the conversion was very high at the early stage of the reaction (70% at 30 min), it decreased sharply to *ca.* 2% after 5 h and terminated after 10 h. The total amounts of decomposed NO reached 12 molecules per Keggin unit. Nitrogen was the principal product at the early stage of the reaction; however, the amount of dinitrogen monoxide increased, reaching *ca.* 40% at 1 h and then gradually decreasing with the reaction time. The reaction in the later stage was very similar to that over the unreduced catalyst.

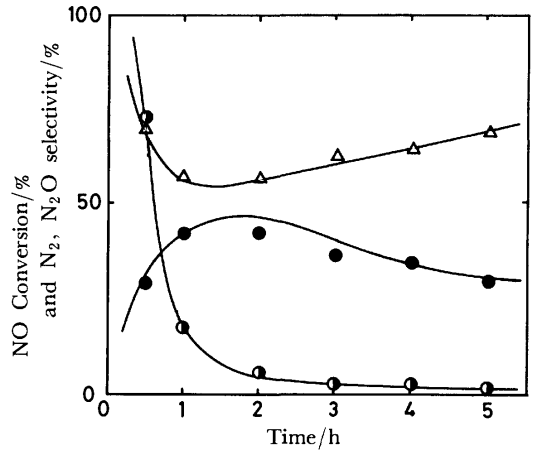

Fig. 3. Time on stream of NO decomposition over $Cu_{1.1}H_{0.8}PA/SiO_2$ reduced with hydrogen.
Catalyst: 0.5 g (reduction conditions: 300 °C, 20 h in H_2), NO: 1.06% in He, total flow rate: 50 $cm^3 min^{-1}$, reaction temp: 300 °C, ◑: NO conversion, △: N_2 yield, ●: N_2O yield.

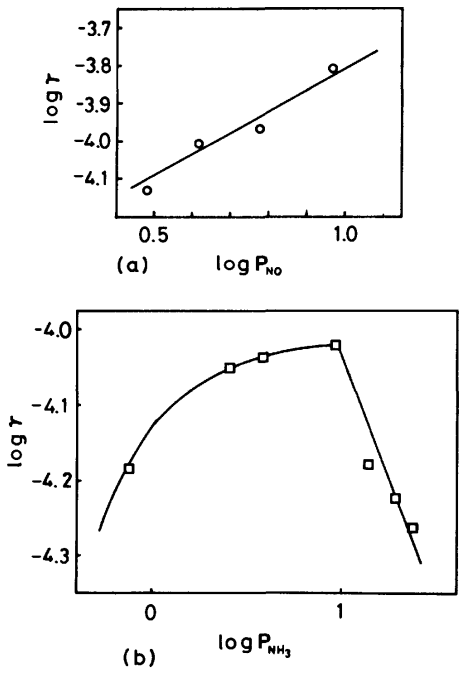

Fig. 4. The partial pressure dependence of $NO-NH_3$ reaction over $Cu_{1.1}H_{0.8}PA/SiO_2$.
a) Dependence on the partial pressure of NO, b) dependence on the partial pressure of NH_3.

Kinetic Measurements. Some kinetic studies were carried out for the reaction over $Cu_{1.1}H_{0.8}PA/SiO_2$. The logarithmic rates of the $NO-H_2$ reaction varied linearly with the partial pressures (Fig. 4), providing the following rate equation (Eq. 1):

$$r = k_{H_2} P_{NO}^{0.8} P_{H_2}^{0.04}. \quad (1)$$

For the $NO-NH_3$ reaction, a good linear correlation was obtained with NO, providing the order of 0.6 (Fig. 4a). On the other hand, a complex dependence on NH_3 was observed (Fig. 4b). The rate increased rather sharply first while the pressure was below 1.3 kPa, leveling off at *ca.* 5.3 kPa, the order being 0.4 at first and decreasing to zero. Above 10.1 kPa of NH_3 the rate decreased very sharply, providing the order of −0.7. Thus, the rate equation is described by Eq. 2 with a variable order of ammonia:

$$r = k_{NH_3} P_{NO}^{0.6} P_{NH_3}^{0.4 \sim -0.7}. \quad (2)$$

The activation energy for NO disappearance in the $NO-NH_3$ reaction was calculated to be 91.6 kJ mol^{-1}. The selectivity for N_2 was slightly decreased (85% at 300 °C to 80% at 350 °C); instead, that of N_2O increased.

The adsorption of NO and NH_3 on the H_3PA, $Cu_{0.5}H_2PA$, $Cu_{1.1}H_{0.8}PA$, and $Cu_{1.5}PA$ after pretreatment at 300 °C in He was observed at room temperature and 300 °C respectively. H_3PA adsorbed 0.5 molecule of NO per Keggin unit, whereas the cupric ion exchanged PA adsorbed one molecule per Keggin unit. *Ca.* six molecules of NH_3 were adsorbed at 300 °C on both the acid and the salts, a half of those adsorbed being subsequently desorbed by evacuation at the same temperature.

ESR Spectra of $Cu_xH_{3-2x}PA/SiO_2$. The ESR spectra of the orignal $Cu_{1.1}H_{0.8}PA/SiO_2$ and that after the heat-treatment at 300 °C *in vacuo* are illustrated in Fig. 5. The original salt exhibited only an anisotropic signal due to the cupric ion ($g_\perp = 2.222$, $g = 2.071$); however, the heat-treatment decreased its intensity very much, to one-eighth of the original value, because of the formation of Cu^+, and provided an intense signal of Mo^{5+} ($g_\perp = 1.945$, $g = 1.894$). These facts suggest that a considerable reduction takes place during the heat-treatment. The extent of reduction for $Cu_xH_{3-2x}PA/SiO_2$, based on the decrease of Cu^{2+} and the appearance of Mo^{5+}, were estimated thus: $Cu_{1.1}H_{0.8}PA$ (1.8 electron/Keggin unit) > $Cu_{0.5}H_2PA$ (1.4 electron/Keggin unit) ≃ $Cu_{1.5}PA$ (1.3 electron/Keggin unit) > H_3PA (0.7 electron/Keggin unit).

A similar spectrum was observed in the $Cu_{1.1}H_{0.8}PA$ after the reaction of $NO-H_2$. The extent of reduction did not change after the NH_3 treatment at 300 °C; however it decreased samewhat after the reaction of $NO-NH_3$, Mo^{5+} decreasing by *ca.* 10% with the increase in Cu^{2+} (twice the intensity) compared to their respective intensities after the heat-treatment.

Mechanistic Consideration. The heteropoly acid and its transition-metal salts have been well documented to exhibit significant activities in the acid-catalyzed and oxidation reactions.[3] The reduction of

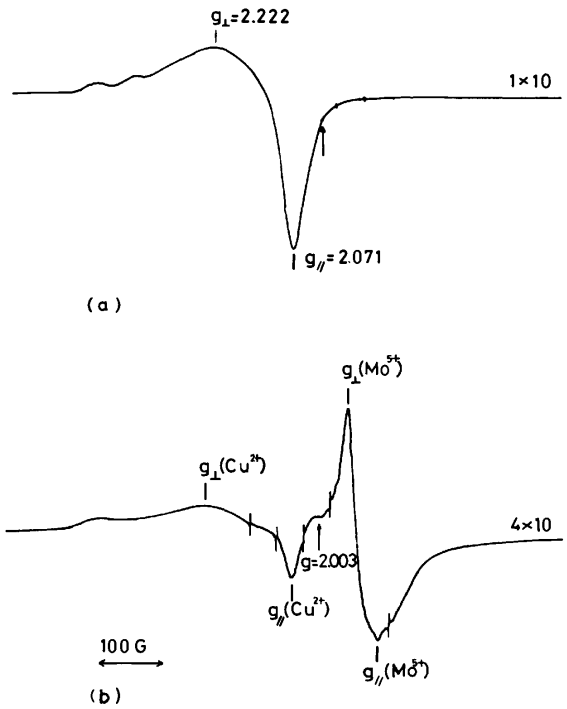

Fig. 5. ESR specra of $Cu_{1.1}H_{0.8}PA/SiO_2$.
a) Original, b) after evacuation at 300°C.

NO can be listed for one of them, although its activity is not remarkably high. Copper(II) salt supported on silica gel showed the highest activities for the reactions of both NO-H_2 and NO-NH_3: however, some different features of the catalytic reactions suggest different mechanisms.

As is shown in Fig. 6, the redox-cycle mechanism, which is similar to that for the oxidation of methacrolein,[6] is assumed in the NO-H_2 reaction over $Cu_{1.1}H_{0.8}PA/SiO_2$, where the reduction of NO by copper(I) or molybdenum(V) ions of the reduced catalyst is rate-determining, judging from the kinetic equation. The rate of NO decomposition over the catalyst reduced by hydrogen at 300°C is similar to that of NO reduction with hydrogen on the same catalyst when the rates are compared at similar reduction extents of the catalyst (as estimated by ESR measurements after the reaction). The catalytic activity is, thus, influenced by the number of reduced sites[7] and by the activation degree of NO, both of which are themseleves influenced by the cations, the transition metal ions probably being favorable for both factors since they can activate NO as well as hydrogen, the latter of which reduces the catalyst. It may be of value to mention that the most active $Cu_{1.1}H_{0.8}PA$ was revealed by ESR to be the most easily reduced by the heat-treatment. Eguchi *et al.* have also reported that the reduction of the heteropoly acid occurred upon evacuation at 300°C[8].

$$r = kP_{NO}^{0.8} P_{H_2}^{0.04}$$

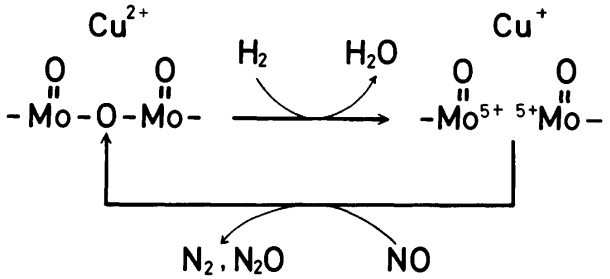

Fig. 6. Mechanism of NO-H_2 reaction over $Cu_{1.1}H_{0.8}PA/SiO_2$.

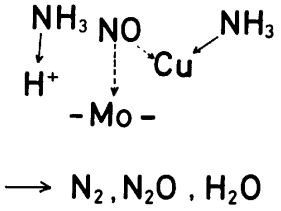
$$r = kP_{NO}^{0.6} P_{NH_3}^{0.4 \sim -0.7}$$



$\longrightarrow N_2, N_2O, H_2O$

Fig. 7. Mechanism of NO-NH_3 reaction over $Cu_{1.1}H_{0.8}PA/SiO_2$.

The ESR measurements suggest that the decomposition reaction of NO on the $Cu_{1.1}H_{0.8}PA/SiO_2$ may proceed by means of the stoichiometric oxidation of the reduced sites which may be produced during the heat-treatment (*ca.* 1 sites/Keggin unit). The reduction of the catalyst by hydrogen before the reaction enhances the activity; however, the reaction also terminates when the reduced sites are consumed. In the latter case, the possibility that the adsorbed hydrogen atoms[9] contribute the high activity at the early stage of the reaction cannot be excluded. No generation of a reduced site takes place during the reaction under the present conditions.

The NO-NH_3 reaction provides some contrasting mechanistic features to the NO-H_2 reaction. A plausible mechanism is illustrated in Fig. 7. The acid itself showed a significant activity, but $Cu_{1.5}PA$ was much inferior to $Cu_{1.1}H_{0.8}PA$. The ammonia treatment of $Cu_{1.1}H_{0.8}PA$ after the evacuation at 300°C causes no change in the ESR spectrum, suggesting that ammonia did not produce the reduced sites. Such results as well as the kinetic equation suggest the participation of NH_3 activation. Thus, the surface reaction between the NO adsorbed on the metal-ion sites and the NH_3 on the acidic sites seems to be rate-determining. $Cu_{1.1}H_{0.8}PA$, which contains proton as well as copper sites suitable for activating both reactants, naturally exhibits the highest activity. In contrast, the lack of any proton site on $Cu_{1.5}PA$ may lose the advantages of NH_3 activation. Excess NH_3 decreases the rate, covering the active sites for NO.

In conclusion, the heteropoly acid and its transition-metal salts were found to exhibit significant activities for the reduction of nitrogen monoxide with hydrogen and ammonia, according to their redox and acidic properties. Although the activities were not markedly high, such origins of activity may be suggestive for the catalyst design.

Single-crystal ESR and X-Ray Crystallographical Studies of a Binuclear Copper(II) Complex with a Coaxially Stacked Square-pyramidal Geometry

Yuji KAJIKAWA, Tosio SAKURAI,[I] Nagao AZUMA,[II] Shizue KOHNO, Sei TSUBOYAMA,[I] Kimiko KOBAYASHI,[I] Kazuo MUKAI, and Kazuhiko ISHIZU*

(Received October 3, 1983)

A binuclear complex of bis(μ-*N*,*N*′-dipicolinoyl-1,3-propanediamine)-bis(sulfato)dicopper(II) has been isolated as a blue single crystal tridecahydrate, $[\{Cu(SO_4)(ppda)\}_2]\cdot 13H_2O$, from an aqueous solution. The crystals are orthorhombic, $C222_1$, with $a=15.42(1)$, $b=24.92(2)$, $c=25.73(2)$ Å, and $Z=8$. Each copper(II) ion is in a square-pyramidal coordination with two pyridine nitrogen atoms, two carbonyl oxygen atoms, and a sulfate oxygen atom at the apex. The two equivalent copper(II) ions, about 3.9 Å apart from each other, are aligned coaxially. The eight Cu-Cu vectors are approximately parallel to one another along the c axis. The most important feature of the crystal structure is the presence of the bulky ligands and of many water molecules, which magnetically isolate the Cu-Cu coupled pair from one another. This facilitates the ESR study of the molecular anisotropies by using the single crystal, even at room temperature. The ESR parameters determined are as follows: $g_{//}=2.280(2)$, $g_{\perp}=2.067(1)$, $|D|=422.4(8)$, $|A_{//}|=170(2)$, and $|A_{\perp}|=14(1)$ in 10^{-4} cm^{-1}. Bleaney and Bowers treatments of the exchange coupling contribution in the *D* parameter indicated a ground singlet state about 7 cm^{-1} below a triplet state for the coupled copper(II) ions. A comparison of the ESR parameters measured for the single crystal with those in the aqueous solution enabled us to conclude that the molecular structure in the solution was very similar to that in the crystalline phase, apart from the coordination of sulfate ions.

The imidazole ring, as a histidine moiety, derives a function as a ligand towards transition-metal ions in a variety of biologically important metalloprotein and peptides.[1] As one simple model ligand, *N*,*N*′-dipicolinoyl-1,3-propanediamine (abbreviated as ppda, Fig. 1), which is a dipeptide with pyridyl groups in place of the imidazolyl groups, was employed to mimic the structure of the metal-active site involving the histidine ligand of related metalloproteins. In an aqueous solution, the coordination chemistry of ppda containing a copper(II) ion has been much altered as the solution is varied from an alkaline one to an acidic one.[2,3] The complex prepared in the alkaline solution has been isolated in the form of trihydrate, and it has been characterized by Ojima[2] by means of visible and IR spectroscopies. This complex is electrically neutral and is composed of mononuclear copper(II) ion. Its coordination geometry is to be ascribed to deprotonation from the amide groups. The acidified solution of this complex showed a sharp red-shift, implying protonation to the anionic nitrogen atoms.[2] ESR measurements in solution have given critical knowledge about the molecular structures: we ourselves have previously reported that the copper(II) complex

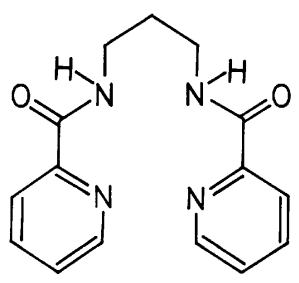

Fig. 1. The chemical structure of *N*,*N*′-dipicolinoyl-1,3-propanediamine (ppda) ligand.

stable in an alkaline solution takes a square-planar ligand geometry, while the one stable in an acidic solution behaves as an axially symmetric binuclear copper(II) complex ion.[3]

The ESR studies of the binuclear complex ion in an aqueous solution have suggested that the square-planar chromophores bearing the two equivalent copper(II) ions stack so as to possess a common *Z* axis; thus, the respective unique axes of the *g* and *D* tensors of axial symmetry coincide with the molecular unique axis.[3] This structure is quite exceptional as compared with the structures reported for a great many of copper(II) binuclear complexes.[4] In many cases, the unique axes of the two square basal planes are inclined to each other, and the observed ESR parameters are usually described in terms of a spin Hamiltonian, with a rhombic symmetry. In order to reveal the absolute molecular geometry of the ppda-copper(II) binuclear complex ion, X-ray crystallographic studies have been undertaken of those of its crystals which contain sulfate or chloride ions. The former, bis(μ-*N*,*N*′-dipicolinoyl-1,3-propanediamine)-bis(sulfato)dicopper(II) tridecahydrate, $[\{Cu(SO_4)(ppda)\}_2]\cdot 13H_2O$, has been successfully obtained as a blue single crystal in a concentrated aqueous solution. However, the crystal is easily cracked as soon as it is taken from the solution or as soon as the solution is warmed beyond room temperature. Since the crystals show such disorder, the model structure has not been refined beyond an *R* factor of 17%. In so far as we have examined, the latter crystal, $[\{CuCl_x(H_2O)_y(ppda)\}_2]\text{-}Cl_{4-2x}\cdot(2-2y)H_2O$, gave no Bragg reflection.

Although the ppda-copper(II) binuclear complex has been of interest to us as a model for active sites in metalloproteins[5] and as a bimetallic catalyst,[6] the ESR feature in the aqueous solution and the crystal and molecular structure of this complex have caused us to pay much attention to its magnetic properties. The

structure around the copper(II) ions revealed by the X-ray analysis is consistent with the structure indicated by the ESR study in the aqueous solution; this is an example of an investigation in which the crystallographic study assisted by ESR study plays a decisive role in establishing the molecular structure in solution. The prominency of this example is due to the question of whether the ESR parameters for the single molecule in the crystal are the same as those for one in the solution. Even at room temperature, the ESR spectrum of the crystal has exhibited a resolved hyperfine structure as well as a fine structure similar to that in a glassy aqueous solution, which is a very rare case. In order to compare the single-crystal ESR parameters with those obtained from the solution spectrum, therefore, the results of the single-crystal ESR and crystallographic studies of $[\{Cu(SO_4)(ppda)\}_2]\cdot 13H_2O$ are reported in the present paper.

Experimental

Materials. The ppda ligand was prepared from methyl picolinate and 1,3-propanediamine by the method of Ojima.[2] The complex was isolated by the slow evaporation of an aqueous solution containing an equimolar mixture of ppda and $CuSO_4$. Recrystallization from the aqueous solution gave deep blue rhombic-plate crystals with the plate normally along the c axis and diagonals along the a and b axes. The analogous procedure gave a solid containing chloride ions.

Exactly 200 mg of the chloride, dried in the air at room temperature, was reduced to 191.86 mg by further drying in a vacuum for 12 h at 110 °C; this indicated a formula of $[\{CuCl_x(H_2O)_y(ppda)\}_2]Cl_{4-2x}\cdot(2-2y)H_2O$. Anal. calcd for this formula: C, 39.61; H, 4.33; N, 12.32%. Found: C, 39.55; H, 4.32; N, 12.31%. $\lambda_{max}(H_2O)=680$ nm with $\varepsilon=60$. Based on this ε value, $[\{Cu(SO_4)(ppda)\}_2]\cdot 13H_2O$ was assumed for the present compound. Anal. calcd for this formula: C, 32.11; H, 5.21; N, 9.99%. Found: C, 31.97; H, 5.49; N, 10.19%.

ESR Measurements. The ESR spectra from the single crystal were observed at room temperature through the rotation of the three crystallographic axes. The spectrum from the aqueous solution was recorded at 77 K by the use of a glassy solvent containing 30% ethylene glycol. All the measurements were carried out on a JES-ME-3X X-band spectrometer equipped with a 100 kHz field modulation for the first derivative. The magnetic field was calibrated by the splitting of Mn^{II} in MgO, which had previously been corrected by the splitting of Fremy's salt ($a_N=1.300$ mT and $g=2.0054$[7]). The microwave frequency was measured with a Takeda-Riken frequency counter. The resonant-field intensities were estimated based on the spacings between the respective spectral lines and the line from Li-TCNQ taken as a secondary standard.

X-Ray Analysis. Some of the crystals recrystallized a few times were coated with a manicure while the others were sealed in glass capillaries. They were all then tested on a Rigaku automated diffractometer AFC or on a Weissenberg camera. The preliminary measurements showed that the crystals belonged to the orthorhombic system, but some of them lost their orthorhombic symmetry.

After many trials, the diffraction data were obtained for the best crystal examined. Crystal data: $C_{30}H_{58}N_8O_{25}S_2Cu_2$, F.W.=1194.1, orthorhombic, space group=$C222_1$, $a=15.42(1)$, $b=24.92(2)$, $c=25.73(2)$ Å, $V=9885(13)$ Å^3, $D_x=1.51(Z=8)$, $D_m=1.52$ g cm^{-3}. The intensity data were collected on the same diffractometer up to $2\theta=40°$. The observed data numbered 910, about 40% of the possible reflections. The intensity data were corrected for the Lorentz and polarization factors.

The intensity distribution showed some special features:

(a) only $k+l=4n$ are observed for $0kl$, with a few exceptions,

(b) only $h+k=4n$ are observed for $hk0$ at lower angles, while only $h+k=4n+2$ are observed for $hk0$ at higher angles, and

(c) 008 is extraordinary strong.

Based on these feature, the reasonable positions of the heavy atoms were obtained after several attempts.

Successive Fourier syntheses revealed the planar atomic groups around the Cu atoms, and also SO_4 groups above and below the planes. R index was reduced to about 23% by the block-diagonal least-squares method. Although the R index could be further reduced by additional cycles, the molecular shape became poor. Therefore, a constrained refinement was applied in order to keep a reasonable molecular shape. The bases for the constraint were the picolinoyl and SO_4 groups. Many residual peaks corresponding to the crystalline water molecules were added from the difference Fourier syntheses. Without the constraint, the R index could be reduced to 17%, but it was about 21% with the constraint. The atomic scattering factors were taken from the "International Tables for X-Ray Crystallography."[8]

Results and Discussion

Crystal Structure. In the asymmetric unit there are two crystallographically independent molecules, each with a two-fold axis through the central methylene carbon atoms in the bridging propane groups. One of them has two pairs of pyridyl rings, upper and lower, which overlap each other almost completely, while the other has two pairs in which the overlapping is partial. The other differences between the two geometries are not very great, so the sketch of only the latter molecule is shown in Fig. 2.

The copper(II) ion is ligated by two pyridine nitrogen atoms and by two carbonyl oxygen atoms to give a square-planar coordination geometry, and that ion is about 0.3 Å above the basal plane. The apical ligand is the oxygen atom of the sulfate ion as a proximal group (Cu-O≃2.3 Å) and the copper ion in the alternative moiety as a distal one (Cu···Cu≃3.9 Å). The two major planes of the pairs of the picolinamido

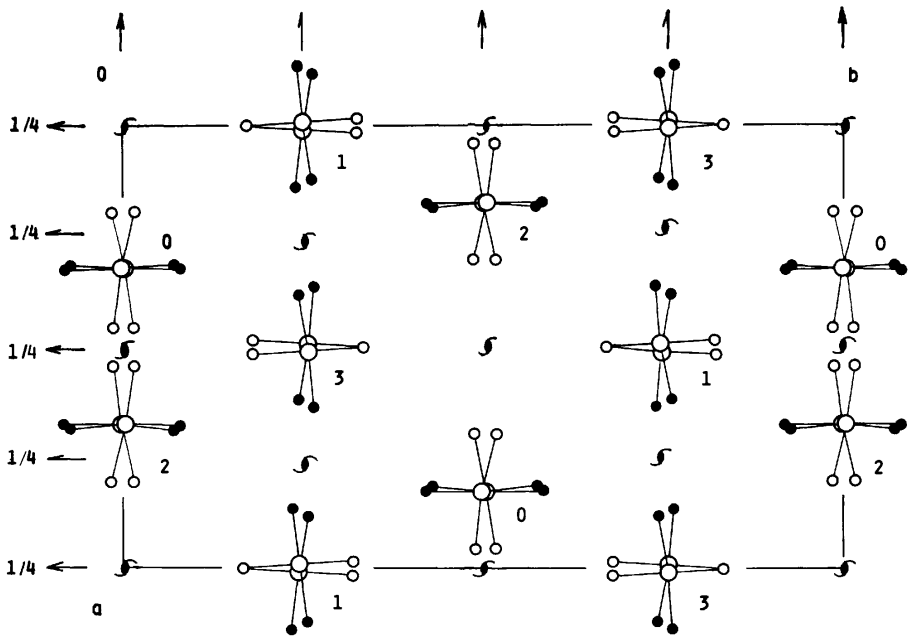

Fig. 3. The arrangement of the [{Cu(N_2O_2)}2] chromophore in the unit cell viewed along the c axis.
The large open circle stands for copper atom, the small open circle oxygen atom, and the solid circle nitrogen atom. The n figure shows the z-component of $z=n/4$ for the center of indicated Cu-Cu pair.

groups are approximately perpendicular to the Cu-Cu distance vector. The two square-planar chromophores bearing two equivalent Cu(II) ions are stacked together so that their local axes approximately coincide to form two sets of x, y, and z axes; this can be seen better in Fig. 3 than for Fig. 2.

Figure 3 shows how the pairs of the copper ions and the metal-binding sites of ppda ligands are packed in the unit cell. The crystal structure consists of a parallel array of the biplanar molecules. The directions of the two-fold axes are parallel to the a and b axes respectively. Therefore, the orientations of the molecules in the c-axis projection are perpendicular to each other. This arrangement is consistent with the extra extinction (b) mentioned in the last section.

The temperature factors of some atoms, especially those at the end of the pyridine rings, are unreasonably high. Therefore, it can not be completely denied that the result might be biased by the proposed model or by the shape of the constrained base. However, the general agreement of the F_o's with the F_c's is good, and the results are at least generally satisfactory within the limits of the quality of the diffraction data.

Magnetic Aspect of the Structure. One can concisely discuss the magnetic aspect of this crystal structure by taking each copper(II) ion to be in an identical coordination geometry of an ideal square pyramid and by taking all the *intramolecular* Cu-Cu distance vectors to be parallel to the c axis.

Then, any single copper ion shows a magnetic anisotropy of a nearly axial symmetry, and the unique axis of the anisotropy is parallel to the c axis. Because the difference between the two kinds of intramolecular Cu-Cu distances can be neglected, the binuclear paramagnetic clusters occupy identical sites of the axial symmetry. On the other hand, the small overlapping between the ligands of the molecules packed discretely indicates a very weak *intermolecular* spin-spin exchange interaction. Moreover, the shortest intermolecular Cu-Cu distance is about 8.3 Å, which is sufficiently large to take the magnitude of the *intermolecular*

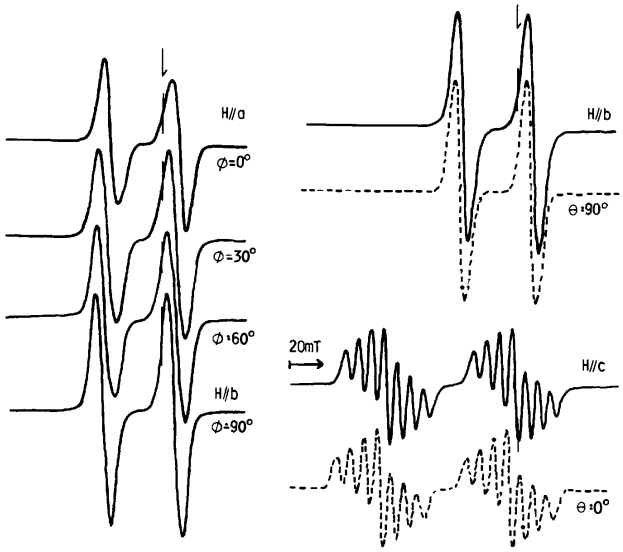

Fig 4. The ESR spectra observed (solid line) and simulated (broken line).
The spectra at left side were obtained when the applied field, $\boldsymbol{H}$, was rotated around the c axis, from $\boldsymbol{H}$//a (uppermost) to $\boldsymbol{H}$//b (lowest) at intervals of 30°. The spectra upper and below at alternative side were recorded when $\boldsymbol{H}$//b and $\boldsymbol{H}$//c, respectively. The arrow shows the resonant field of Li-TCNQ. The simulation was carried out approximating the transition probability to be $g_\perp^2(1+g_{/\!/}^2/g^2)$, where $g^2=g_{/\!/}^2\cos^2\theta+g_\perp^2\sin^2\theta$, and the line-shape function to be Gaussian, with $\sigma_{/\!/}=\sigma_\perp=4.0$ mT ($\boldsymbol{H}$//b) and $\sigma_{/\!/}=\sigma_\perp=3.2$ mT ($\boldsymbol{H}$//c).

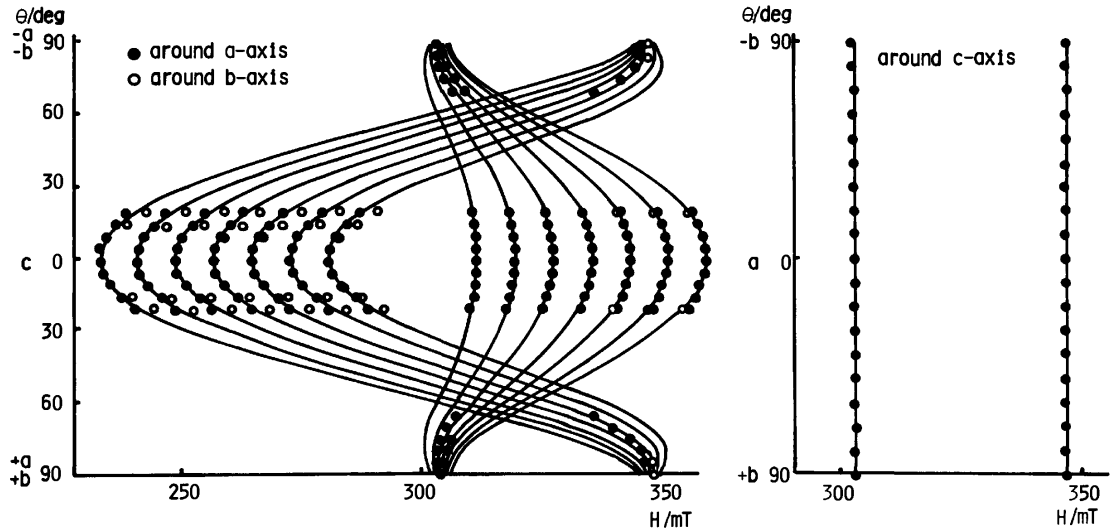

Fig. 5. The angular variation of the resonant fields observed (circles) and calculated (solid lines) when the applied field was rotated around the a and b axes (left side) and the c axis (right side).

magnetic dipolar interaction down one place from that of the *intramolecular* one. Therefore, we can take the crystal anisotropy to be the molecular anisotropy within the limits of the present approximation.

Magnetic Anisotropy. Within the limits of the approximation mentioned above, the axial symmetry of the coordination geometry places restrictions on the principal direction of the molecular coordinate system; therefore, an *a priori* deduction of the magnetic axes can be made. This contrasts with the case of the low symmetric copper binuclear complexes, for example, the $[Cu_2Cl_8]^{4-}$ anion,[9] the low symmetry of which precluded any *a priori* determination of the magnetic principal axes. Figure 4 shows the ESR spectra of the present copper binuclear complex, obtained by applying the external field parallel to the respective principal axes, which coincide with the crystallographic axes. The spectra show a fine structure from the system of $S=1$ and a hyperfine structure due to the exchange-coupled copper atoms. Some investigators have observed fine structures from authentic single crystals of copper binuclear complexes at room temperature.[10] However, they could not record any hyperfine structure from those crystals.

The angular variations of the fine and hyperfine structures are shown in Fig. 5. The error in the setting of the a, b, and c axes is believed to be less than 3°. Figure 5 indicates that the anisotropies in the g factor, the spin-spin dipolar interaction, and the hyperfine interaction are all of an axial symmetry and that the paramagnetic clusters are in equivalent sites. These results are consistent to the approximation made in this text.

In order to obtain the g tensor components ($g_{/\!/}$, $g_{\perp}$), the zero-field splitting parameter (D), and the components of the hyperfine coupling tensor ($A_{/\!/}$, $A_{\perp}$), the following spin Hamiltonian is employed:

$$\begin{aligned}\mathcal{H} &= \beta[g_{/\!/}H_zS_z+g_{\perp}(H_xS_x+H_yS_y)] \\ &+D[S_z^2-S(S+1)/3]+2J\boldsymbol{S}_1\cdot\boldsymbol{S}_2 \\ &+A_{/\!/}S_zI_z+A_{\perp}(S_xI_x+S_yI_y),\end{aligned} \tag{1}$$

where $S=S_1+S_2$, $I=I_1+I_2$, while the other symbols have their usual meanings. The simulation of the ESR spectrum from the glassy solution suggested that the exchange-coupling energy, $|J|$, is much greater than the micro-wave quantum, $W=h\nu=g\beta H_0\cong 0.3\,\mathrm{cm}^{-1}$. Under such conditions, Lund and Hatfield[11] calculated the allowed transitions:

$$\begin{aligned}&H_{1,2}/H_0 \\ &=1-[\pm 3D_1+K(m_1+m_2)/2]/W \\ &-[D_3^2/2+D_4^2/2+R^2(m_1+m_2)^2/8\pm 3D_4R(m_1+m_2)/2]/W^2 \\ &-(B_1\mp B_2)/W^2,\end{aligned} \tag{2}$$

where the meanings of the symbols are as given in their paper. Using this equation, the spin Hamiltonian parameters were determined by the nonlinear least-squares method for the data shown in Fig. 5. The starting parameters were obtained by the conventional method. The hamiltonian parameters thus obtained are as follows: $g_{/\!/}=2.280(2)$, $g_{\perp}=2.067(1)$, $|D|=422.4(8)$, $|A_{/\!/}|=170(2)$, and $|A_{\perp}|=14(1)$, in $10^{-4}\,\mathrm{cm}^{-1}$. The unique principal axis, Z, of the axial symmetry is parallel to the c axis. Based on these parameters, the angular variations of the fine and hyperfine structures are calculated to be as shown by the solid lines in Fig. 5. The spectra simulated for the $\boldsymbol{H}$//a and $\boldsymbol{H}$//c cases are presented in Fig. 4 by broken lines. The agreement of the simulated spectra with those observed is good in view of the approximation employed. The observed zero-field splitting parameter, D, is the sum of the magnetic dipolar and exchange coupling contributions:

$$D=D_{ex}-(g_{/\!/}^2+g_{\perp}^2/2)\beta^2/r^3. \tag{3}$$

Here, the second term results from the dipolar interaction and is appropriate in this particular form only if both ions occupy identical sites of axial symmetry.[12,14] The observed g components and r(Cu-Cu)=3.86 Å indicate the approximate value of $-55\times 10^{-3}\,\mathrm{cm}^{-1}$ for the dipolar contribution. On the other hand, D_{ex} depends on the sign of D. When D is negative, $D_{ex}=13\times 10^{-3}\,\mathrm{cm}^{-1}$ is obtained; hence, the

dipolar coupling rules over the zero-field splitting. If D is regarded as positive, $D_{ex}=97\times10^{-3}\,cm^{-1}$ is derived. The negative D value can be inferred in view of the long distance between the two copper ions in the binuclear complex. When one uses the simplest expression for D_{ex} given by Bleaney and Bowers:[13]

$$D_{ex}=-2J[(g_{//}-2)^2-4(g_{\perp}-2)^2]/32, \quad (4)$$

the exchange-coupling parameter, J, or a half of the energy separation between the singlet and triplet levels can be estimated to be about $-3.5\,cm^{-1}$, based on the negative D value. If D is positive, the calculated J is $-26\,cm^{-1}$. The negative J values indicate antiferromagnetic exchange-coupling between the two copper ions. In order to determine which of the J's is adequate, we measured the magnetic susceptibility of this complex by using liquid nitrogen as a coolant; we thus obtained the Weiss constant of $\theta=-4$ K. Since the binuclear complex molecules are isolated from one another in the present crystal, the J parameter obtained from the susceptibility data can be attributed to the exchange-coupled pair of the copper ions in the binuclear complex. The Weiss constant corresponds to $J=2k\theta\simeq-5.5\,cm^{-1}$, which is much closer to the value of $-3.5\,cm^{-1}$ based on the negative D value than to that of $-26\,cm^{-1}$ estimated from the positive D value. Thus, the separation between the ground-singlet and excited-triplet energy levels is estimated from the ESR parameters to be about $-7\,cm^{-1}$. The copper hypefine interaction causes a slight breakdown of the pure singlet and triplet character.[14]

In order to know how the coordination geometry is perturbed by the dissolution of the crystal in a water medium, the ESR parameters obtained for the aqueous solution are compared with those for the single crystal. The observed spectrum, shown with a solid line in Fig. 6, has been simulated with a broken line in the same figure by means of the following parameters: $g_{//}=2.280$, $g_{\perp}=2.072$, $|D|=453$, $|A_{//}|=168$, and $|A_{\perp}|=14$, in $10^{-4}\,cm^{-1}$. The values other than D are in good agreement with those for the crystal. The disagreement between the two D parameters corresponds to the shortening of the Cu-Cu distance by 2.5%, within the limits of the point-dipole approximation.[15] Therefore, one can take it for granted that the molecular structure of the present binuclear complex is retained throughout both the crystalline and solution states, apart from the coordination of the sulfate ions. We suppose that the water molecules play an important role in bringing the molecular structure in the solution into the crystalline phase as it stands, as well as in stabilizing the binuclear complex, since the ppda and the copper(II) ion in common organic solvents do not form any binuclear complex.

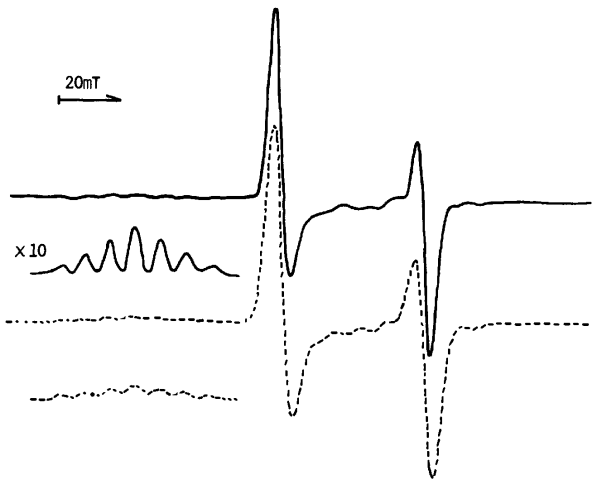

Fig. 6. The ESR spectrum of $[\{Cu(SO_4)(ppda)\}_2]\cdot13H_2O$ dissolved in 30% ethylene glycol aqueous solution at 77 K (solid line) and its simulated spectrum (broken line). The following parameters were employed in the simulation: $g_{//}=2.280$, $g_{\perp}=2.072$, $|D|=0.0453$, $|A_{//}|=0.0168$, $|A_{\perp}|=0.0014\,cm^{-1}$, and $\sigma_{//}=\sigma_{\perp}=2.5$ mT. The transition probability and the line-shape function were the same as those applied in the simulation in Fig. 4.

The authors are grateful to Professor Heijiro Ojima of Aichi Kyoiku University for his encouragement throughout this work. The crystallographic calculations were performed on a FACOM M-200 computer at this Institute using the UNICS III program system.[16] The magnetic data were processed at the Computer Center of this University.

X-Ray Structural Elucidation of a Novel Steric Effect of *o*-Methoxyl Substituents in 2,6-Dimethoxyphenylnickel(II) Complexes Mediated by *m*-Bromo Substitution

Duanjun Xu,[†] Yasushi Kai, Kunio Miki, Nobutami Kasai,* Koichi Nishiwaki, and Masanori Wada
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565
(Received October 19, 1983)

Molecular structures of novel *trans*-[NiR_2L_2] complexes, *trans*-[$Ni\{C_6H_3(OMe)_2$-2,6$\}_2(PR_3)_2$] [PR_3=PMe_3 (**1a**), PMe_2Ph (**1b**)], and their *m*-brominated derivatives, *trans*-[$Ni\{C_6H(OMe)_2$-2,6-Br_2-3,5$\}_2(PR_3)_2$] [PR_3=PMe_3 (**2a**), PMe_2Ph (**2b**)], were determined by X-ray crystal structure analysis. A remarkable effect of *m*-substitution on the conformation of the *o*-methoxyl groups was found. This correlated well with the reactivity difference toward carbon monoxide. Crystal data: **1a**: monoclinic, space group $P2_1/c$, a=8.737(2), b=18.282(3), c=16.319(4) Å, β=105.06(2)°, Z=4, R=0.062; **1b**: triclinic, space group $P\bar{1}$, a=16.993(5), b=10.180(3), c=17.177(5) Å, α=112.44(2), β=117.59(2), γ=66.25(2)°, Z=3, R=0.060; **2a**: monoclinic, space group $P2_1/c$, a=9.294(2), b=14.091(3), c=10.770(2) Å, β=92.06(3)°, Z=2, R=0.067; **2b**: triclinic, space group $P\bar{1}$, a=9.370(1), b=11.387(2), c=9.013(1) Å, α=94.52(2), β=107.24(2), γ=77.35(2)°, Z=1, R=0.058.

Several 2,6-dimethoxyphenyl derivatives of transition metals are known. There seem to be at least three characteristic features caused by the *o*-methoxyl substituents. First, the steric effect allows the facile preparation of derivatives for Ni^{II},[1] Cu^{I},[2] Ag^{I},[3] and Au^{I},[4] which display greatly increased thermal and/or chemical stabilities, making their manipulation more facile than that of common phenyl derivatives. Secondly, the coordination properties through the oxygen lone-pair electrons have been demonstrated by the X-ray molecular structures of V_2R_4·2THF[5] and Cr_2R_4,[6] [R = $C_6H_3(OMe)_2$-2,6]. This functionality also explains the facile lithiation of the phosphine methyl groups in *trans*-[$NiR_2(PR'_3)_2$] [R = $C_6H_3(OMe)_2$-2,6; PR'_3 = PMe_3 (**1a**), PMe_2Ph (**1b**)].[1] Thirdly, the mesomeric effect caused by the methoxyl oxygen atom affects the facile and stereospecific bromination (electrophilic substitution) on the 2,6-dimethoxyphenyl group, as observed for **1a** and **1b**.[1] Interestingly, some of the resulting bromophenyl complexes *trans*-[$Ni\{C_6H(OMe)_2$-2,6-Br_2-3,5$\}_2(PR'_3)_2$] [PR'_3=PMe_3 (**2a**), PMe_2Ph (**2b**)] remarkably differed from the parent complexes **1a** and **1b** in the reactivity toward carbon monoxide, which catalyzes the intermolecular exchange of the PR'_3 ligands between **1a** and **1b** but not between **2a** and **2b**.[1] In order to obtain more structural information to aid in understanding the difference, the detailed molecular structures of these complexes have now been determined by the X-ray crystal structure analysis.[7] The results revealed the additional feature caused by the *o*-methoxyl substituents: their steric effect is highly influenced by the *m*-substituents and is associated with the rotational flexibility of the methoxyl group around the C(phenyl)-O bond.

Experimental

Crystallographic Data. Complexes **1a**, **1b**, **2a**, and **2b** were prepared by the procedures previously described.[1] Single crystals were obtained by recrystallization from ethanol (**1a**, **1b**), ethyl methyl ketone (**2a**), or acetone (**2b**). Crystals of **1a**, **1b**, **2a**, and **2b** are all pale yellow in color with regular prismatic shapes. Preliminary oscillation and Weissenberg photographs taken with Cu$K\alpha$ radiation showed that crystals of **1a** and **2a** are monoclinic, whereas those of **1b** and **2b** are triclinic. Accurate unit-cell parameters were determined at room temperature by the least-squares fit of 2θ values of 30, 25, 24, and 25 strong, higher angle reflections for **1a**, **1b**, **2a**, and **2b**, respectively. The density of each crystal was measured at room temperature by a flotation method in an aqueous solution of zinc bromide. Crystal data are summarized in Table 1.

Collection and Reduction of Intensity Data. Integrated intensities were measured on an Rigaku four-circle diffractometer by the θ-2θ scan technique at a 2θ scan rate of 4° min^{-1} and a scan width of $\Delta 2\theta=(2.0+0.70\tan\theta)°$. The background intensities were measured for 7.5 s at both ends of a scan. Four standard reflections were measured after every 60 reflections in order to monitor the radiation damage and the change of the crystal orientations. No significant intensity decay of the standard reflections was observed for any of the crystals. The reflection intensities collected up to 2θ=54° ($\sin\theta/\lambda$=0.639 $Å^{-1}$) were 5492, 3885, and 3904 for **1a**, **2a**, and **2b**, among which the observed reflections ($|F_o|>3\sigma(F_o)$) were 4138, 2284, and 3206, respectively. A total of 3394 (2397 non-zero) intensities for **1b** was first measured by adopting the small unit cell, which was later found to be a subcell of the true one. Reflections for **1b** based on the true unit cell were later collected up to 2θ=50°, and among the reflections measured 6006 were classed as observed ($|F_o|>3\sigma(F_o)$). The usual Lorentz and polarization effects were corrected for the intensity data, but no absorption correction was applied.

Determination and Refinement of the Structure. The crystal data of **2a** (space group $P2_1/c$ and Z=2) and **2b** (space group $P\bar{1}$ and Z=1) show that the **2a** and **2b** molecules must lie on a crystallographic center of symmetry. The crystal structures of **1a** and **2a** were solved by the heavy atom method. The heavy atoms located from the three-dimensional Patterson maps are: a nickel atom on a general position for **1a**, two bromine atoms on general positions in addition to a nickel atom on (0,0,0) for **2a**, respectively. The crystal structure of **2b** was solved by a combined use of the Patterson function and the direct method (*MULTAN*-78),[8] and two bromine atoms were located on general positions in addition to a nickel atom on (0,0,0).

Non-hydrogen atoms for **1a**, **2a**, and **2b** were located on the subsequent Fourier maps based on the positions of the heavy atoms. These crystal structures were refined by the block-diagonal least-squares procedure (*HBLS*-V),[9] the function minimized being $\sum w(|F_o|-|F_c|)^2$. All the hydrogen atoms

a) $|F_o|>3\sigma(|F_o|)$. b) Weighting scheme used: $w=(\sigma^2_{cs}+a|F_o|+b|F_o|^2)^{-1}$, where σ_{cs} is the standard deviation obtained from counting statistics. c) Used in the final refinement. d) Goodness of fit, $\Sigma w(|F_o|-|F_c|)^2/(n-m)$, where n and m are the number of reflections used and number of parameters refined, respectively. e) $R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$. f) $R_w=\{\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2\}^{1/2}$

could be located on the difference Fourier maps, which were included in the successive refinement with isotropic temperature factors. At this stage of the refinement, the weighting schemes of the form $w=(\sigma^2_{cs}+a|F_o|+b|F_o|^2)^{-1}$ for $|F_o|>3\sigma(F_o)$ were applied. σ_{cs} is the standard deviation obtained from the counting statistics. The final weighted R values are (**1a**): 0.068; (**2a**): 0.077; (**2b**): 0.073. The values of a and b used in the final refinement are given in Table 2.

The structure analysis of **1b** was first carried out in a similar way to that for **1a**, **2a**, and **2b**, by adopting the subcell. Through the process of conventional refinement, a rather curious disordered structure was found: one of the methoxyl oxygen atoms takes two positions more than 1 Å apart from each other with half occupancy probability. After the anisotropic refinement of non-hydrogen atoms (R=0.103), hydrogen atoms were included in the refinement, but the convergence was not satisfactory. At this stage, a well-exposed Weissenberg photograph was taken around the b axis; additional reflections were thus found. This fact strongly indicated the possibility of a larger unit-cell for this crystal. The unit cell dimensions were redetermined, and reflection intensities were remeasured based on the true cell. Two interesting crystallographic features were found: (i) 2/3 of the total reflections measured based on the true cell are systematically weaker than the remaining 1/3 of the reflections, (ii) the subcell had been determined by using the stronger 1/3 reflections only. These two unit cells are related by these equations:

$$a=a_S-c_S,$$
$$b=b_S,$$
$$c=a_S+2c_S,$$

where the subscript shows the cell parameters of the subcell.

The crystal structure obtained by adopting the subcell, therefore, gives only the average structure. The true cell contains three molecules, and the space group is $P\bar{1}$. Therefore, one centrosymmetric molecule [**1b-1**] must lie on (0,0,0) and the other two molecules [**1b-2**] must lie on general positions. These two molecules [**1b-1** and **1b-2**] are crystallographically equivalent in the subcell. For the redetermination of the structure, the initial position of the **1b-2** could be easily deduced from the relationship between the true cell and the subcell. The coordinates of the nickel atom on the general position were refined by introducing an artificial bias of ±0.01 (in fraction) to the y parameter. The isotropic temperature factor of 3.0 Å^2 was applied for the nickel atom as the starting parameter. After two cycles of refinement, the temperature factors of the nickel atoms with the initial positions of (0,0,0) and (2/3, +0.01, 1/3) changed to large values of 10.1 and 3.2 Å^2 respectively and those with initial positions of (0,0,0) and (2/3, −0.01, 1/3) to 2.5 and 3.5 Å^2; the resulting atomic coordinates were (0.6657, 0.0209, 0.3258) from (2/3, +0.01, 1/3) and (0.6672, −0.0268, 0.3426)

a) Positional parameters are in fraction of cell edges and B_{eq} is the equivalent isotropic temperature factor calculated from the corresponding anisotropic factors.[11)]

from (2/3, −0.01, 1/3), respectively. The Fourier map based on phases of the former set of nickel positions includes many unreasonable supurious peaks especially around the methoxyl group, whereas the Fourier map calculated from the latter set of nickel positions could easily locate all the non-hydrogen atoms except two. The latter structure was then refined isotropically, and the next Fourier synthesis revealed the remaining two atoms. Refinement was then carried out in the same manner as those of **1a**, **2a**, and **2b**; it converged to a reasonable R value.

The details of the refinements for all the crystals are summarized in Table 2. The atomic scattering factors were taken from the International Tables for X-Ray Crystallography.[10)] Final atomic coordinates of four crystals, together with equivalent isotropic temperature factors B_{eq}[11)] for non-hydrogen atoms are listed in Table 3.[‖]

Computation. All the calculations were carried

[‖] Tables of anisotropic temperature factors for non-hydrogen atoms, the atomic coordinates and isotropic temperature factors for hydrogen atoms, and the observed and the calculated structure factors are deposited as Document No. 8415 at the Office of the Editor of the Bulletin of the Chemical Society of Japan.

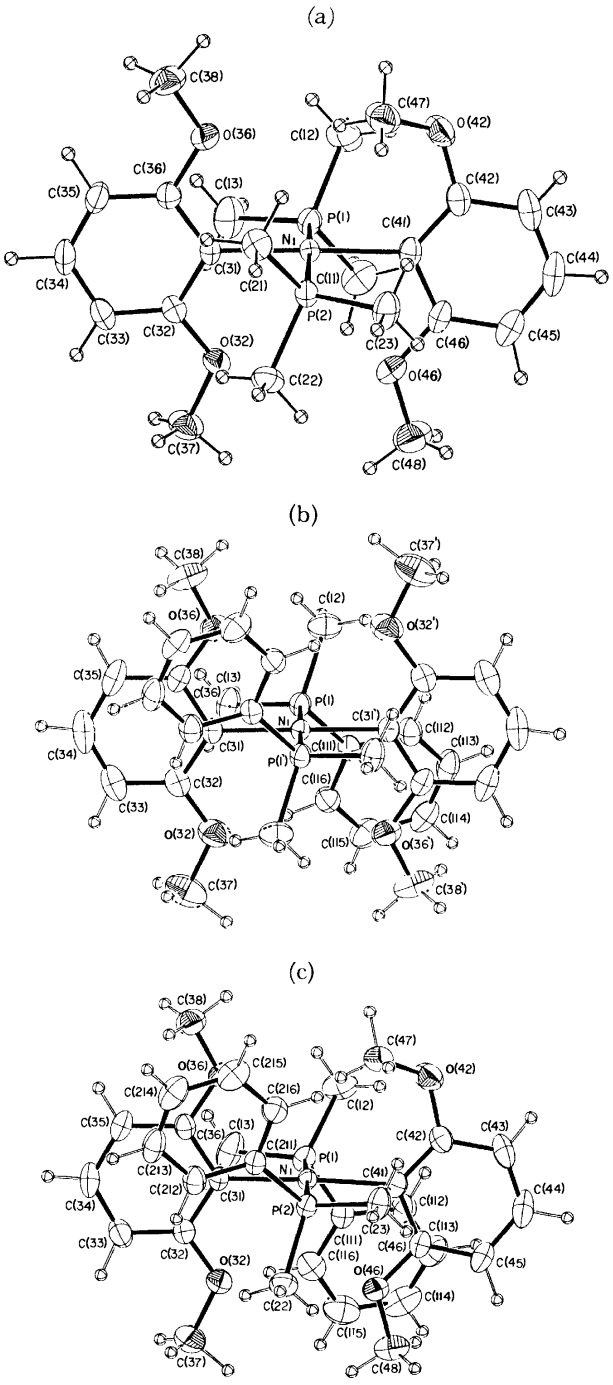
Results and Discussion

Molecular Structure. The molecular structures of **1a**, **1b-1**, **1b-2**, **2a**, and **2b** are shown in Fig. 1 by the *ORTEP* drawings,[12] together with the atomic numberings. The crystallographic molecular symmetries of **1b-1**, **2a**, and **2b** are C_i. The **1a** and **1b-2** molecules have no crystallographic symmetry, but the local center of symmetry is found in these structures when the conformations of methoxyl groups are ignored. The interatomic bond distances and angles observed in these complexes are summarized in Table 4.

Coordination Geometry of Nickel Atom: The important structural parameters needed to describe the coordination geometry of nickel atom are summarized in Table 5. The first structural feature commonly observed in these complexes is that the nickel atom takes a square-planar coordination with two phenyl and two phosphine ligands on *trans*-positions. As the **1b-1**, **2a**, and **2b** molecules occur on the center of symmetry, the five atoms defining the coordination plane of nickel atom are exactly coplanar. The least-squares planes of the coordination planes in **1a** and **1b-2** are listed in Table 6. The coplanality of the five atoms in **1a** is slightly lower than that of those in **1b-2**. However, the deformation geometry of the coordination planes is the same in both structures; that is, all the four atoms bonding to the nickel atom deviate toward the same direction from nickel atom, bending away from the C(47) atom, which is the only methoxyl methyl group approaching near to nickel atom in these complexes. It is noteworthy that the P(1)-Ni-P(2) bond angle [172.5(1)°] in **1a** shows an angular deviation of



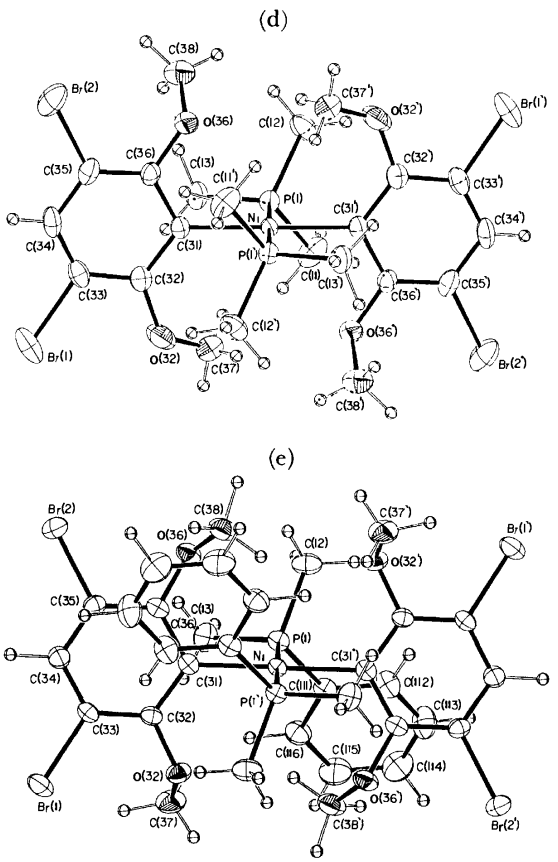


Fig. 1. Molecular structures of *trans*-[NiR_2L_2] complexes drawn by *ORTEP*-II,[12] together with the atomic numberings. Thermal ellipsoids for non-hydrogen atoms are drawn at the 30% probability level. The hydrogen atoms are shown as spheres with arbitrary temperature factor of 1.0 Å^2. a) **1a**; R=$C_6H_3(OMe)_2$-2,6, L=PMe_3, b) **1b-1**; R=$C_6H_3(OMe)_2$-2,6, L=PMe_2Ph, c) **1b-2**; R and L are same as those in **1b-1**, d) **2a**; R=$C_6H(OMe)_2$-2,6-Br_2-3,5, L=PMe_3, e) **2b**; R=$C_6H(OMe)_2$-2,6-Br_2-3,5, L=PMe_2Ph.

7.5° from the exact *trans* coordination, while the other P-Ni-C and P-Ni-P bond angles in Table 5 take the value near to 90° and 180°, respectively. The second structural feature to note is that the ring planes of phenyl ligands are nearly perpendicular to the coordination plane of nickel atom. The dihedral angles between these planes in Table 5 show that almost all the phenyl ligands are normal to the coordination plane within several degrees, with one exception having the relatively large deviation of 13.9° from the right angle in the **2b** molecule. The third interesting feature is that the phosphine ligands take a very characteristic conformation, with one methyl group located roughly on the coordination plane of nickel atom regardless of the types of phosphine ligands, PMe_3 or PMe_2Ph. The torsional angles ϕ_1 and ϕ_2 in Table 5 are the measure to

a) Torsional angles around C(phenyl)-O(methoxyl) bonds: $\phi_1=\phi_{C(31)\text{-}C(32)\text{-}O(32)\text{-}C(37)}$, $\phi_2=\phi_{C(31)\text{-}C(36)\text{-}O(36)\text{-}C(38)}$, $\phi_3=\phi_{C(41)\text{-}C(42)\text{-}O(42)\text{-}C(47)}$, and $\phi_4=\phi_{C(41)\text{-}C(46)\text{-}O(46)\text{-}C(48)}$. b) Distances from methoxyl methyl carbons to the normal of the coordination plane through Ni atom: d_1, d_2, d_3, and d_4 correspond with the C(37), C(38), C(47), and C(48) atoms, respectively. c) These parameters are not crystallographically unique but are listed for the sake of better understanding.

estimate the angular deviation of the unique methyl group of each phosphine ligand from the coordination plane; the maximum angular deviation observed is 14.4° of ϕ_2 in **1b-2** molecule.

Conformation of Methoxyl Group: The selected structural parameters for the conformations of methoxyl groups are listed in Table 7. The most interesting and important difference in the molecular structures of this series of complexes is the difference in the conformations of methoxyl groups, which are influenced very sensitively by the steric and/or electrostatic effect in the different types of phosphine ligands and/or the different substituents on *m*-positions.

The torsional angles around the O(methoxyl)-C(phenyl) bond (ϕ's in Table 7) were calculated as the measure to describe the conformation of methoxyl groups. When the methoxyl methyl groups are near the nickel atom, the ϕ angles become smaller, and when the methoxyl

methyl groups are far from the nickel atom and near the substituents on *m*-positions, the ϕ angles become larger. Five independent molecules in Table 7 are divided into three conformers according to the conformations of methoxyl groups. The **1b-1** molecule gives one extreme case (Conformer A), in which all of the four methoxyl groups (only two are crystallographically independent) take the ϕ values near to 180°, indicating that all the methoxyl groups are located far from the nickel atom and near the *m*-substituents (H atoms). The molecules **1a** and **1b-2** have similar structures (Conformer B): one of the four methoxyl groups has the angle of 36.0° in **1a** and 34.3° in **1b-2** respectively, and the remaining three methoxyl groups have ϕ angles between 164.1° and 176.4°; this shows that only one methoxyl methyl is located near the nickel atom. The *m*-brominated derivatives, **2a** and **2b**, give the third conformer (Conformer C), in which all the ϕ angles are much smaller than 180°, the maximum value being 111.7° in the **2a** molecule.

The distances from the methoxyl carbons to the normal of the coordination plane passing through the nickel atom are calculated (*d*'s in Table 7) to estimate the free space of the 5th and/or 6th coordination sites of nickel atom. The average values of these distances on each coordination site of nickel atom are devided clearly into three types corresponding to the three types of conformers found in these complexes. The Conformer A [**1b-1**] gives the longest *d* distance of 2.492 Å on both sites of the coordination plane of nickel atom. Conformer B [**1a** and **1b-2**] takes a little shorter *d* distances, between 2.077 and 2.217 Å, than the Conformer A. On the other hand, Conformer C [the *m*-substituted derivatives **2a** and **2b**] takes the shortest *d* distances of 1.794 and 1.799 Å.

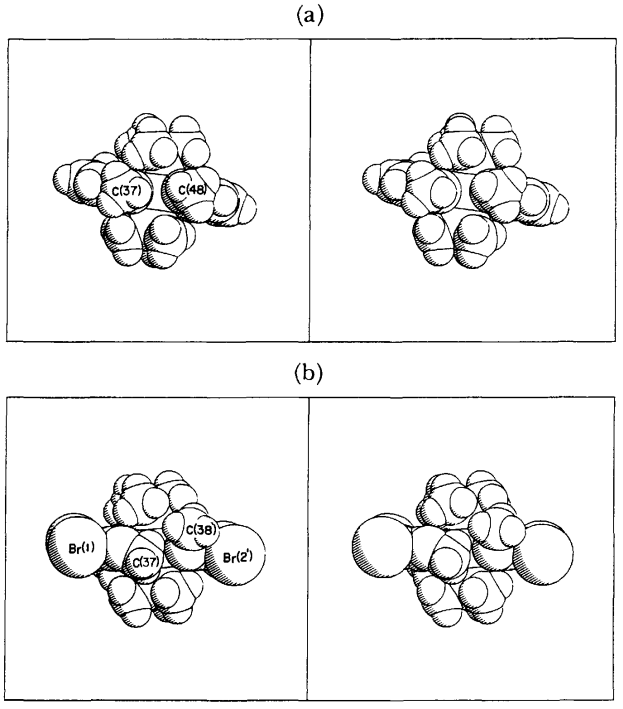

Fig. 3. Stereoscopic views of the molecular structures of **1a** and **2a** complexes shown by the space filling models drawn by *PLUTO*-78.[13] a) **1a**, b) **2a**.

The bond distances and angles included in the coordination plane of nickel atom show some interesting deformations which are correlated to the conformational differences of *o*-methoxyl groups and *m*-substituents. The Ni-C(phenyl) distances are divided into two types. The shorter ones are the Ni-C(31) bonds in *m*-unsubstituted molecules with two methoxyl groups near to the *m*-substituents: from 1.928(5) to 1.933(5) Å. The longer ones are the the Ni-C(phenyl) bonds in *m*-unsubstituted molecules with one methoxyl group near to the nickel atom, and those in *m*-brominated molecules with two methoxyl groups near to the nickel atom: from 1.945(5) to 1.962(8) Å. Similar structural deformations are also found in Ni-P distances. The Ni-P distances in *m*-brominated molecules [**2a** and **2b**: 2.220(2) and 2.224(1) Å] are significantly longer than those in *m*-unsubstituted ones [**1a**, **1b-1**, and **1b-2**: from 2.168(2) to 2.188(2) Å]. The Ni-C(phenyl)-C(phenyl) angles also reflect the steric effect of methoxyl groups. The corresponding angles associated with the phenyl ligand with different conformations of methoxyl groups, one near to the *m*-substituent and another near to the nickel atom, show a remarkable difference: Ni-C(41)-C(42) angles [130.2(4) and 130.5(5)°] are much larger than the Ni-C(41)-C(46) ones [115.3(4) and 115.5(4)°] in **1a** and **1b-2**. These structural deformations are the causes of the slightly shorter *d* distances [$(d_1+d_4)/2$] in **1a** and **1b-2** molecules (2.217 Å in **1a** and 2.206 Å in **2b**) compared to that in **1b-1** (2.492 Å); this occurs in spite of the similar conformations of the methoxyl groups on the corresponding sites of the coordination plane. The structural deformations found in these molecules show that the Ni-C(phenyl), Ni-P distances and Ni-C(phenyl)-C(phenyl) angles are very flexible and sensitive to the steric effect of the methoxyl groups onto the nickel atom and its ligand molecules.

Crystal Structures. The crystal structures of **1a**, **1b**, **2a**, and **2b** complexes are shown in Fig. 2. No intermolecular distance shorter than the normal van der Waals contact is found in these structures. The molecular packing in **1b** crystal is projected the b* axis [Fig. 2(b)], which shows surprisingly identical molecular arrangement of crystallographically independent two molecules [**1b-1** and **1b-2**] in the unit cell. The only difference in these molecules is found in the conformation of the methoxyl group [O(42)-C(47)]. This specific packing structure in **1b** resulted in the systematically weak diffraction intensities of 2/3 of the total reflections observed from this crystal.

Concluding Remarks. The intermolecular exchange of the *t*-phosphine ligands are catalyzed by carbon monoxide between **1a** and **1b** but not between **2a** and **2b**.[1] The X-ray structure determinations of these complexes seem now to have revealed the structural evidence needed to understand the reactivity differences. We observed the largest structural difference between these complexes in spatial locations of methoxyl methyl group on *o*-positions, as shown by the space filling models of **1a** and **2a** complexes in Fig. 3.[13] Probably due to the relative lack of spatial restriction, the methoxyl methyl groups in **1a** and **1b** can adopt a variety of directions around the

C(phenyl)-O bond, both in the solid state as observed and in solution, too. It then can yield spatial free coordination sites on nickel atom both above and below the four-coordination plane by taking the conformations of methoxyl groups directed toward the *m*-substituents. Both such 5th and 6th coordination sites of nickel atom in *m*-brominated complexes **2a** and **2b** are completely confined by the four methoxyl methyl groups, at least in the solid state. Due to the spatial restriction caused by the large *m*-substituents, the rotational flexibility of the methoxyl groups must be highly restricted even in solution to the direction apart from the *m*-position, toward the phosphine ligands and closer to the nickel atom. The nickel atom there must be well protected from the attack of carbon monoxide.

Another structural feature related to the reactivity difference seems to exist in the flexibilities of C-Ni-C and P-Ni-P bond angles. The observed coplanality of these five atoms in **1a** and **1b** is poorer in the crystals than that in **2a** and **2b**, which suggests the flexibility of these bond angles in **1a** and **1b** in solution. If so, this flexibility enables the coordination of the fifth ligand such as carbon monoxide on the nickel to be more facile by bending one of these bonds (C-Ni-C and P-Ni-P) toward the opposite side of the fifth ligand. The observed coplanality for **2a** and **2b** are higher in the crystals. The deviational motions of these bonds in solution must be restricted by the steric interaction between the methoxyl methyl groups locating over and below the coordination plane.

An analogous effect may be expected from the observed deviations of Ni-C-C bond angles from 120° in **1a** and **1b**.

An Optical-optical Double Resonance Excitation of Bromine to a New D(0_u^+) Ion-pair State

Takashi Ishiwata,* Atsuto Tokunaga, Tsutomu Shinzawa, and Ikuzo Tanaka
Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152
(Received January 5, 1984)

An optical-optical double resonance (OODR) technique utilizing a sequential three-photon absorption has been applied to study the electronic structure of Br_2. Two pulsed dye lasers were used to excite the molecules to appropriate rovibronic levels of the $B^3\Pi(0_u^+)$ state and subsequently into an ion-pair state by simultaneous two-photon transition. The OODR excitation spectra showed a number of transitions consisting of closely-spaced O, Q, and S branches which combine the $B^3\Pi(0_u^+)$ state with a new ion-pair state designated D(0_u^+). The following spectroscopic constants of the D(0_u^+) state were determined for the $^{79}Br_2$ isotope species: T_e=49925.4(6), ω_e=135.7(3), $\omega_e x_e$=0.27(3), B_e=0.04190(14), and α_e=5.9(23)×10^{-5} cm^{-1}.

It has been demonstrated that an optical-optical double resonance (OODR) method is very promising to study the spectroscopic details of high-lying electronic states in atoms and molecules.[1] In particular, this technique is attractive in the spectroscopy of diatomic halogens to explore their excited states of the ion-pair type whose precious information is normally inaccessible by the conventional single-photon spectroscopy.[2] Recently we have reported a series of ion-pair states observed in the two or three photon transitions through the $B^3\Pi_{0_u^+}$ state.[3-5] In this report, we present the analysis of a new D(0_u^+) state of Br_2 which might belong to the lowest group of ion-pair states correlating with $Br^-(^1S)+Br^+(^3P_2)$.

In our experiments the output pulses from two synchronously pumped dye lasers are focused inside a fluorescence cell containing $^{79}Br_2$ vapor from opposite directions and are aligned to overlap with each other at the focusing point. One laser, refered as the pump laser, is operated at a fixed wavelength to pump the molecules to appropriate rovibronic levels of the $B^3\Pi_{0_u^+}$ state through a visible B-X transition at around 583 nm. The setting was performed by monitoring the near-infrared B-X fluorescence. The second dye laser, the probe laser, is scanned in the wavelength region of 600—660 nm to promote two-photon transitions from the pumped levels of the B state to an ion-pair state. The OODR signals are detected by the UV emission between 240 and 290 nm.

The outputs of the dye lasers are horizontally polarized in the normal experiments. Polarization studies to examine anisotropic characters of the two-photon transitions from the B state are carried out for several of the strong transitions by changing the polarization angles of the probe laser light.

Results and Discussion

Figure 1 presents a part of a typical OODR excitation spectrum observed in the experiments on the $^{79}Br_2$ molecule. The pump laser (ν_1) was adjusted to a photon energy of 17155.9 cm^{-1} which is in resonance with the three rotational lines of the $B^3\Pi_{0_u^+}$ -$X^1\Sigma_g^+$ transition within our laser bandwidth; (9-0) P_{25} and R_{29}, and (10-0) P_{71}. The spectrum was recorded by scanning the probe laser (ν_2) using a sample pressure of 1.1 Torr (1 Torr≈133.322 Pa). There is no time delay between the pump and probe laser pulses. Under the conditions, the relaxations in the intermediate B levels are negligible, so that the OODR spectrum is very simple and the assignment is straightforward.

First of all, we found that the probe laser induced three types of transitions to form an ion-pair state by overall three-photon processes.

Type (I)	$\nu_1+(2\nu_2)$
Type (II)	$\nu_1+(\nu_1+\nu_2)$
Type (III)	$\nu_2+(2\nu_2)$

The type (I) transition denotes the (1+2) process, which corresponds to the excitation of the Br_2 molecules to the specific rovibronic levels of the B state by pump frequency (ν_1) and thence to an ion-pair state in the virtual two-photon transition by probe frequency ($2\nu_2$). On the other hand, the two-photon process in the type (II) transition proceeds by a combination of pump and probe lasers ($\nu_1+\nu_2$). The type (II) transitions appear because of temporal overlap of pump and probe laser pulses. They can be distinguished from the type (I) transitions by the dependence of the line intensities on the time delay of the two laser pulses and more easily by the polarization effects on their transition strengths. For example, when the polarization of the probe laser light is changed from horizontal to vertical, the anisotropic change of line intensities is predicted in the type (II) transitions. Because randomly oriented molecules cannot distinguish the vertically polarized photons from the horizontally polarized ones in the type (I) transitions. In the spectrum, typical results of the polarization effects for the type (II) transitions are shown in Fig. 1. These bands disappeared under the conditions of a 15 ns time delay between laser pulses, as being expected. The type (III) transitions produced by the probe laser alone appear only if the double resonance condition of two transition components is satisfied at a given frequency. They are obviously not suitable for a systematic analysis of an ion-pair state.

Secondly, the type (I) and (II) transitions clearly show the closely-spaced rotational lines, which should correspond to the O, Q, and S branches in the 0_u^+-0_u^+ transition from the following considerations. Molecular bromine belongs to the symmetry of $D_{\infty h}$ and its ion-pair states are known to be described in Hund's case c due to large multiplet splittings. From the dipole matrix elements of two-photon absorption, the symmetry species of the upper state which combine with the $B^3\Pi_{0_u^+}$ state by identical photons in the type (I)

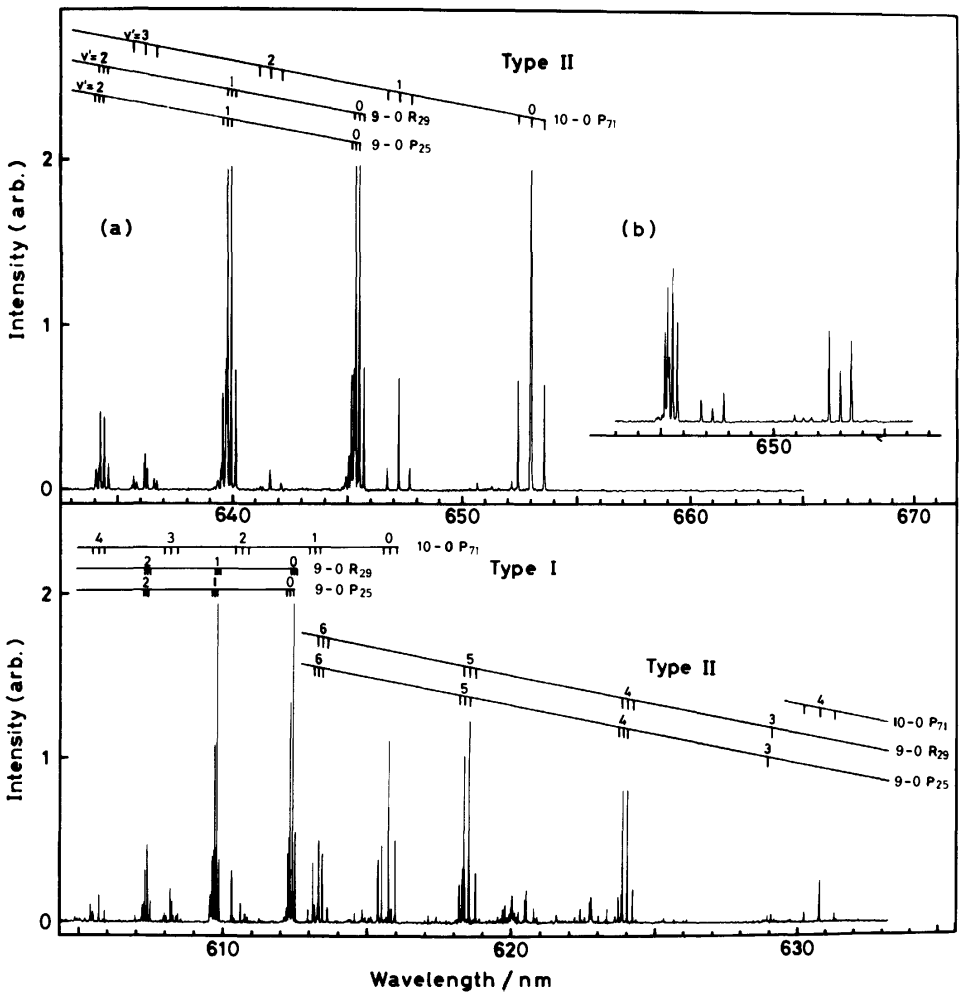

Fig. 1. A portion of the OODR excitation spectrum of $^{79}Br_2$. The pump frequency (ν_1) is in resonance with (9-0) P_{25} and R_{29}, and (10-0)P_{71} of the B-X transition within laser bandwidth. The probe laser (ν_2) was scanned in the wavelength region of 605—655 nm using dyes, Rh-610 and Rh-640. Two-photon transition from the B state proceeds according to the selection rule of $\Delta J=0, \pm2$ by the probe laser alone (type I, $2\nu_2$) and by the probe and pump lasers (type II, $\nu_1+\nu_2$). The pump laser is polarized horizontally, while the probe laser is polarized (a) horizontally and (b) vertically. No correction is made for signal intensities with the variation of laser power.

transition are 0_u^+, 1_u, and 2_u. According to the treatment of McClain and Harris,[6] their rotational selection rules are

$$\Delta J=0, \pm2 \quad \text{for the } 0^+\text{-}0^+ \text{ transition,} \tag{I}$$

$$\Delta J=0, \pm1, \pm2 \quad \text{for the } 1\text{-}0^+ \text{ and } 2\text{-}0^+ \text{ transitions,} \tag{II}$$

and also the large anisotropic behavior of the Q branch as shown in Fig. 1(b) is only expected for that of the 0^+-0^+ transition as discussed in the previous publication.[3b] The progression in the spectrum can be assigned from the splittings of the O and S branches ($\Delta\nu_{OS}$).

$$\Delta\nu_{OS}=(8J+4)B_v' \quad \text{for type (II).} \tag{III}$$

B_v' denotes the rotational constant of a v' ion-pair state (typically $B_v' \simeq 0.04\,cm^{-1}$ for lower v' levels) and J is the rotational quantum number of the $B^3\Pi_{0_u^+}$ state from which the two-photon transition originates. The type (II) transitions show a series of the progressions with intervals of around $135\,cm^{-1}$. The rotational splittings and vibrational intervals in the type (I) transitions are equal to half of the corresponding values in the type (II) transitions.

Thirdly, the intensity distribution of each progression in Fig. 1(a) shows the characteristic profiles inherent to the pumped vibrational levels of the B state. The progressions increase their intensities at the longer wavelength ends and suddenly break off. As discussed later on the basis of their Franck-Condon factors, the first levels observed at the lowest energies are assigned to the transition terminating on a $v'=0$ level of the ion-pair state.

Finally, it should be pointed out that the strong perturbation was observed in the ion-pair state. For example, the O, Q, and S branches in the $v'=3$ levels in Fig. 1 (see (10-0) P_{71}) split into two with comparable intensities. They are excluded in the following analysis of the energy level. A high resolution study utilizing etalon tuning dye lasers is in progress from which the detailed information about the perturbation by the

surrounding electronic states will be obtained.

The term energies of the ion-pair state, $T(v', J')$, relative to the potential minimum of the ground state are obtained by

$$T(v', J') = \nu_1 + 2\nu_2 + G_v'' + F_v''(J) \quad \text{for type (I),} \quad \text{(IV)}$$
$$= 2\nu_1 + \nu_2 + G_v'' + F_v''(J) \quad \text{for type (II),} \quad \text{(V)}$$

where G_v'' and $F_v''(J)$ are the vibrational and rotational energies of the $X^1\Sigma_g^+$ level, respectively. The G_v'' and $F_v''(J)$ values were determined from the constants of the Barrow, Clark, Coxon, and Yee.[7] The pump frequency (ν_1) corresponded to the position of either a P(J) or R(J) line in the B-X system. The probe frequency (ν_2) had three values in accord with the $\Delta J = 0, \pm 2$ transitions from a pumped level.

We have measured 117 rovibronic levels of a 0_u^+ ion-pair state corresponding to $0 \leqq v' \leqq 8$ and $6 \leqq J' \leqq 78$ pumped through the B-X transitions of (9-0) P_{25}, R_{29}; (10-0) P_{71}, R_{75}; (12-1) P_{51}, R_{55}; (14-2) R_5; (15-2) P_{51}. They were fitted by a least-squares method to the limited expansions;

$$T(v', J') = T_e + \omega_e\left(v' + \frac{1}{2}\right) - \omega_e x_e\left(v' + \frac{1}{2}\right)^2 + \left\{B_e - \alpha_e\left(v' + \frac{1}{2}\right)\right\} J'(J' + 1). \quad \text{(VI)}$$

The derived molecular constants are summarized in Table I.

Table 1. Molecular parameters of the D(0_u^+) state for $^{79}Br_2$

Parameter	Value
T_e/cm^{-1}	49925.4(6)[a]
ω_e/cm^{-1}	135.7(3)
$\omega_e x_e/cm^{-1}$	0.27(3)
B_e/cm^{-1}	0.04190(14)
α_e/cm^{-1}	$5.9(23)\times10^{-5}$

a) Values in parentheses denote twice the standard deviation (2σ) and apply to the last digits of the constants.

In order to confirm the absolute v' numbering of the ion-pair state, we have compared the intensity distribution of the OODR spectra with the calculated Franck-Condon factors. In the FCF calculations we used the version from Hougen of the RKR and FCF programs which were originally written by Zare, Schmeltekopf, Harrop, and Albritton for use.[8] The potential curve of the B state was constructed by using the constants of Barrow *et al.*,[7] while that of the ion-pair state was approximated by a Morse function defined by three parameters (ω_e, $\omega_e x_e$, and B_e) in Table 1. The patterns of observed vibrational progressions are reproduced in the FCF calculations as shown in Fig. 2. The calculated intensities using the different v' numbering have never fitted the observed intensities, since our spectrum includes the transition to a $v' = 0$ level of the ion-pair state. For example, the calculations by shifting the v' numbering upward have always predicted significantly strong bands at longer wavelengths which were not observed.

According to our preliminary results, the UV

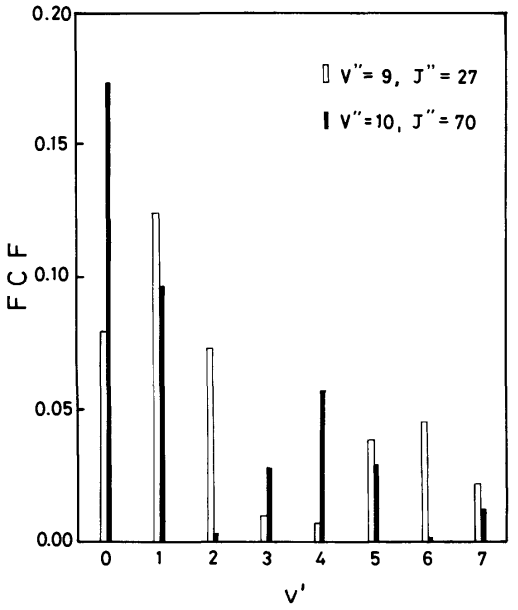

Fig. 2. Calculated Franck-Condon factors for the transitions shown in Fig. 1.

fluorescence spectrum of Br_2 observed in the experiment closely resembles that of the F(0_u^+)-$X^1\Sigma_g^+$ system analyzed recently.[5] The strong parallel bands were observed at around 269 nm. The emission system showed the vibrational structure which we could assign to a transition originating from a $v' = 0$ level of the ion-pair state and terminating on the $X^1\Sigma_g^+$ ground state at the high vibrational levels around $v'' = 48$. Other fluorescence terminating on the low valence states was present at the longer wavelengths (≈310 nm) in the spectra.

To summarize the results, a new 0_u^+ ion-pair state of Br_2 has been observed by the OODR excitation technique utilizing a sequential three-photon absorption through the B state. The new state is the third ion-pair state spectroscopically characterized in any detail among the 6 states (0_u^+, 0_g^+(E), 1_u, 1_g, 2_u, 2_g (D')) arising from $Br^-(^1S) + Br^+(^3P_2)$, and could be labelled as D(0_u^+) in the analogy of I_2. The D state lies about 1000 and 150 cm^{-1} higher than the D' and E states, respectively, with a similar equilibrium internuclear distance of 3.19 Å but with a smaller vibrational frequency of 135.7 cm^{-1}; $T_e = 48930 \pm 100\ cm^{-1}$ [12]. $\omega_e = 150.86\ cm^{-1}$, and $r_e = 3.170$ Å for D' (2_g),[9] and $T_e = 49777.96\ cm^{-1}$, $\omega_e = 150.83\ cm^{-1}$, and $r_e = 3.194$ Å for E(0_g^+).[11]

We plan further investigations on the D(0_u^+) ion-pair state of Br_2. Macdonald, Donovan, and Gower[13] have recently studied the fluorescence spectrum of Br_2 directly excited at 158 nm (F_2 laser) and reported three bound-free transitions originating from the D(0_u^+) state in the region of 210—440 nm. It is obvious that they excite the molecules to the high vibrational levels of ion-pair state more than $v' = 100$. By extending the probe frequency to analyze these high levels, we can provide the accurate potential curve of the D state which might not only answer the correct numbering of D levels in the VUV absorption but also explain the spectrum observed by Macdonald *et al.*[13]

Experimental

Experimental details were described previously.[3b] Briefly, a nitrogen laser pumped dye lasers (Molectron UV-24 and DL-14) provided 10 ns pulses with an energy of around 0.5 mJ/pulse and 0.4 cm^{-1} linewidth. The experiments were performed at 10 Hz. The signals from a solar blind photomultiplier (Hamamatsu TV R-166) were processed by a boxcar integrator (PAR 162/164) through a preamplifier (PAR 115).

The authors are grateful to Dr. J. T. Hougen of the National Bureau of Standards for supplying them the RKR and Franck-Condon factor program.

Effects of $Hg(ClO_4)_2$, $HgCl_2$, and $AgClO_4$ on the Conformations of Poly(*S*-carboxymethyl-L-cysteine) and Poly[*S*-(2-carboxyethyl)-L-cysteine] in Solution

Kazuki Oka, Hiroshi Maeda,* and Shoichi Ikeda*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received January 5, 1984)

The effects of $Hg(ClO_4)_2$, $HgCl_2$, and $AgClO_4$ on the conformations of fully neutralized poly(*S*-carboxymethyl-L-cysteine) and poly[*S*-(2-carboxyethyl)-L-cysteine] in the absence of supporting electrolytes were examined by circular dichroism (CD) spectra. The induction of the β-form was suggested by the addition of $Hg(ClO_4)_2$ and $AgClO_4$, while it could not be concluded in the case of $HgCl_2$. Spectroscopic evidence for the coordination of metals with the two polypeptides was provided in the case of $Hg(ClO_4)_2$ and $HgCl_2$ by the appearance of a new CD band around 250—260 nm as well as the distortion of the polymer CD spectra in the region of 200—230 nm, while it was not obtained in the case of $AgClO_4$. The decrease of pH observed on addition of the three metal compounds also suggested the conformational change. Extraordinary lowering of pH and enhanced solubility were observed on addition of $HgCl_2$.

Recently, the effects of various bivalent metal ions on the conformations of poly(*S*-carboxymethyl-L-cysteine) (poly[Cys(CH_2COOH)])[1] and poly[*S*-(2-carboxyethyl)-L-cysteine](poly[Cys(CH_2CH_2COOH)])[2] were studied. Transition metal ions, such as Cu^{2+}, Cd^{2+}, Zn^{2+}, and Ni^{2+} ions, effectively induced the β-form of these two polypeptides, while alkaline earth ions such as Mg^{2+}, Ca^{2+}, and Ba^{2+} ions were not effective inducers. Based on these results, it is likely that the β-form of these polypeptides is induced *in solution* only when their negative charges are annihilated by a kind of complex formation with counterions. In other words, shielding of the charged sites on the polypeptides by condensed counterions is not effective at all, even in the case of bivalent counterions, in the induction of the β-form of these two polypeptides. The complex formation with counterions is shown by ultraviolet absorption spectra and circular dichroism (CD) in the interactions of Cu^{2+} ions with these two polypeptides.[3] These two polypeptides have carboxyl and thioether groups in the side chains, which readily react with mercury and silver. According to the suggested mechanism of the β-form induction, these two metal species are expected to induce the β-form of the two polypeptides in solution.

In the present study, the effects of $Hg(ClO_4)_2$, $HgCl_2$, and $AgClO_4$ on the conformations of the two polypeptides are examined in their fully neutralized states mainly by CD.

Experimental

Poly[Cys(CH_2COOH)] (Lot No. KO125W; M_w=12000, DP=75) and poly[Cys(CH_2CH_2COOH)] (Lot No. H920WR; M_w=16000, DP=92) are the same samples as used in the previous studies.[1-3] Here M_w and DP denote, respectively, the weight average molecular weight and degree of polymerization. Reagent grade $HgCl_2$ and $AgClO_4 \cdot H_2O$ and $Hg(ClO_4)_2$ (99%) were purchased from Nakarai Chemicals Ltd. and were used without further purification. Doubly distilled water was used to prepare the solutions.

Circular dichroism (CD) spectra were taken on a Jasco J-40 A circular dichrograph using cells of 1 and 5 mm light paths. Measurements of pH were carried out on a Hitachi-Horiba F-7 ss pH meter. These measurements were carried out at 25±2 °C.

The polymer concentration C_p is expressed in residue molarity, mol dm^{-3} (M) and is kept constant at 1×10^{-3} M in the present study. Metal concentrations C_M are expressed in molarity, mol dm^{-3} (M). The CD data are expressed in terms of the residue ellipticity $[\theta]$ based on the polymer concentration. To ascertain the time independent results, the solutions were kept at ambient temperature (25±2 °C) at least 20 h before the measurements were made.

In the present study, the two polymers were examined invariably in their fully neutralized states. Hence, they are abbreviated as poly[Cys(CH_2COONa)] and poly[Cys(CH_2CH_2-COONa)], except for the case that these abbreviations are confusing.

Results

1. $Hg(ClO_4)_2$ and $HgCl_2$. The CD spectra of poly[Cys(CH_2COONa)] in the presence of different amounts of $Hg(ClO_4)_2$ and $HgCl_2$ are shown in Figs. 1(a) and (b), respectively. In the absence of the mercury compounds, the CD spectrum of random coils at low ionic strengths is seen (curves A).[5] The CD spectra at large values of the mixing ratio C_M/C_p are different from those found on the mixtures of the β-form and random coils in the respect that a small positive CD band appears around 255 nm. This CD band is observed for both $Hg(ClO_4)_2$ and $HgCl_2$, and hence probably originates as a result of the coordination of Hg atoms to the side chains of the polypeptides. It is likely that the CD spectra in the wavelength region shorter than 230 nm are also modified. Nevertheless, the change of CD spectra by the addition of $Hg(ClO_4)_2$ can be ascribed mostly, if not all, to the induction of the β-form. The spectra of the β-forms of the two polypeptides are characterized by a negative band around 224 nm ($[\theta]\simeq-10^4$) and a positive band around 200 nm ($[\theta]\simeq3.5\times10^4$ for poly[Cys(CH_2COOH)][4] and $\simeq2\times10^4$ for poly[Cys(CH_2CH_2COOH)][5]). In the case of $HgCl_2$, definite conclusions cannot be obtained.

Residue ellipticities at 205 nm and 255 nm, $[\theta]_{205}$ and $[\theta]_{255}$, are plotted against the mixing ratio C_M/C_p in Fig. 2. The value of $[\theta]_{205}$ is tentatively chosen as a measure of the extent of the β-form induction, since the measurements at 200 nm was not always reliable due to the absorption of $HgCl_2$. The values of $[\theta]_{255}$ were mostly obtained using a cell of 5 mm light path. The

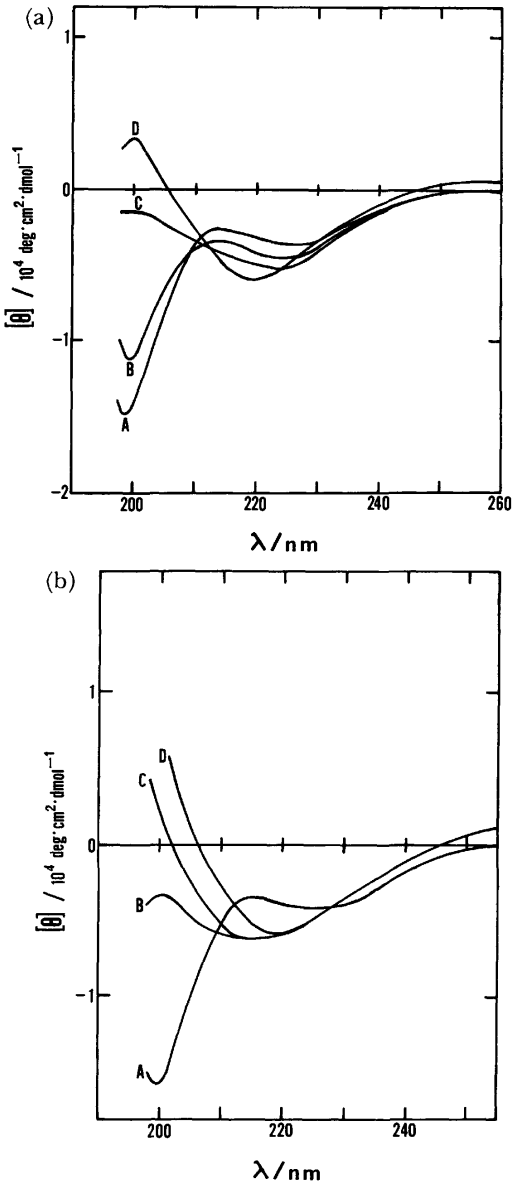

Fig. 1. CD spectra of poly[Cys(CH_2COONa)] in the presence of (a) $Hg(ClO_4)_2$ and (b) $HgCl_2$. Polymer concentration (C_P) is 1×10^{-3} M. Mixing ratios (C_M/C_P). (a); 0(A), 0.052(B), 0.156(C), and 0.259(D). (b); 0(A), 0.201(B), 0.402(C), and 1.005(D).

induction of the β-form is suggested for $Hg(ClO_4)_2$ also from the comparison with the previous results on $CuCl_2$,[1] which is given by a dashed curve in Fig. 2.

In Figs. 3(a) and (b), the CD spectra of poly[Cys(CH_2CH_2COONa)] in the presence of different amounts of $Hg(ClO_4)_2$ and $HgCl_2$ are shown, respectively. In the case of $Hg(ClO_4)_2$, the spectrum at $C_M/C_P=0.415$ resembles, in shape, that of the β-form except for the wavelength region larger than 240 nm. In the intermediate region of the mixing ratio, $0.15<C_M/C_P<0.26$, a characteristic CD pattern appears (curves C and D), which is different from the spectrum found on the mixtures of the β-form and random coils. The CD pattern found in the presence of $HgCl_2$ differs considerably from the spectrum characterizing the β-form of poly[Cys(CH_2CH_2COOH)] induced either by protonation or by the addition of bivalent metal

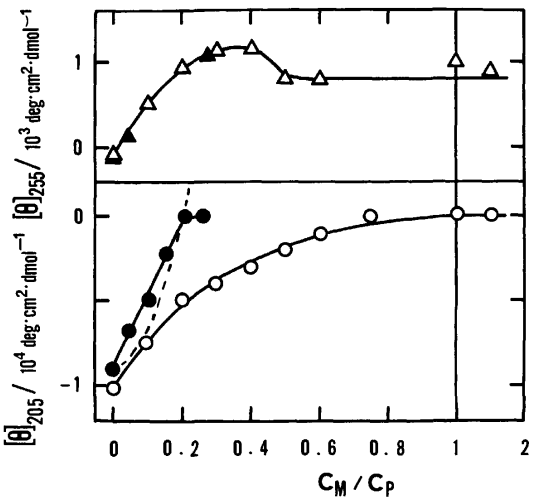

Fig. 2. Dependences of the residue ellipticities of poly[Cys(CH_2COONa)] at 205 nm ($[\theta]_{205}$) and 255 nm ($[\theta]_{255}$) on the mixing ratio (C_M/C_P). Open symbols (○, △) refer to $HgCl_2$ and filled symbols (●, ▲) refer to $Hg(ClO_4)_2$. A dashed curve represents the result on $CuCl_2$.

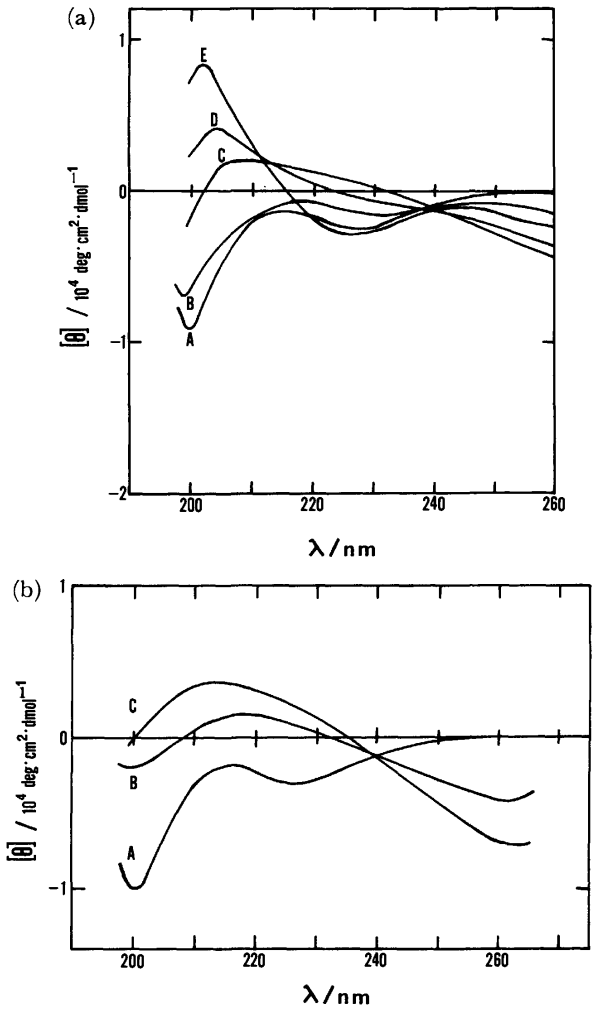

Fig. 3. CD spectra of poly[Cys(CH_2CH_2COONa)] in the presence of (a) $Hg(ClO_4)_2$ and (b) $HgCl_2$. Polymer concentration (C_P) is 1×10^{-3} M. Mixing ratios (C_M/C_P). (a); 0(A), 0.052(B), 0.156(C), 0.259(D), and 0.415(E). (b); 0(A), 0.100(B), and 0.200(C).

210 nm (○, ●) and 260 nm (△, ▲). Open and filled symbols refer to $HgCl_2$ and $Hg(ClO_4)_2$, respectively. A dashed curve represents $[\theta]_{210}$ obtained on $CdCl_2$.

cations.[2] The CD spectra at the mixing ratios larger than about 0.2 fall between curves B and C. It is difficult to infer the induction of the β-form in the case of $HgCl_2$.

A large negative CD band appears around 260 nm for both $Hg(ClO_4)_2$ and $HgCl_2$, which becomes negligible at the wavelengths larger than 320nm. The residue ellipticities at 210 nm and 260 nm, $[\theta]_{210}$ and $[\theta]_{260}$, obtained at different mixing ratios are shown in Fig. 4 together with the previous results on $CdCl_2$[2] for 210 nm. The wavelength 210 nm is chosen partly because the characteristic CD pattern in the case of $HgCl_2$ shows the maximum around 210 nm and partly because reliable measurements of CD were hampered at 205 nm by strong absorption of $HgCl_2$. At 205 nm, CD spectra were obtained up to $C_M/C_P=0.2$ in the case of $HgCl_2$. The values of $[\theta]_{205}$ were very similar for both $Hg(ClO_4)_2$ and $HgCl_2$. Comparison of the present results with the results on $CdCl_2$ suggests the distortion of the polymer CD spectra as well as the induction of the β-form. It is likely that the β-form of poly[Cys(CH_2CH_2COOH)] is induced by the coordination of Hg atoms, at least, in the case of $Hg(ClO_4)_2$. The dependences of $[\theta]_{210}$ and $[\theta]_{260}$ on C_M/C_P are well correlated to each other, especially in the case of $HgCl_2$. This correlation also suggests that the induction of the β-form parallels the coordination of Hg atoms.

When the effects of $Hg(ClO_4)_2$ and $HgCl_2$ are compared between the two polypeptides, the characteristic CD patterns inherent to the coordination of Hg atoms are more evident in poly[Cys(CH_2CH_2COONa)] than in poly[Cys(CH_2COONa)]; a new CD band around 260 nm is more intense and the distortion of the CD spectra in the range 200—230 nm is more significant in poly[Cys(CH_2CH_2COONa)].

In Fig. 5, the dependences of pH on $Hg(ClO_4)_2$ and $HgCl_2$ concentrations (C_M) are shown in logarithmic scale for the two polypeptides. There is no appreciable difference between the effects of $Hg(ClO_4)_2$ (filled circles) and $HgCl_2$ (open circles). The profiles of pH change are very similar for the two polypeptides. The change of pH on log C_M is almost identical between the two polypeptides, when the pH values are corrected

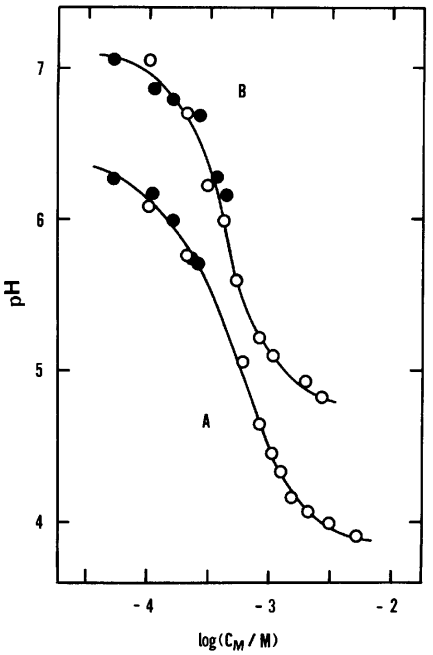

Fig. 5. Dependence of pH on the logarithm of the salt concentration (C_M).
Polymer concentration (C_P) is 1×10^{-3} M. (A) poly[Cys(CH_2COONa)] and (B) poly[Cys(CH_2CH_2COONa)]. Open and filled circles refer to $HgCl_2$ and $Hg(ClO_4)_2$, respectively.

for the difference in the intrinsic dissociation constants K_0; $pK_0=3.2$ for poly[Cys(CH_2COOH)][6] and 4.0 for poly[Cys(CH_2CH_2COOH)].[7] The correction is made in such a way that one of the two curves, either A or B, is shifted vertically by about 0.8 pH unit, which corresponds to the difference between the two values of pK_0. After the correction, these two curves are nearly identical to each other in the whole range of C_M examined. This profile of the pH change is, however, different from that expected for the effect of added salt on random coil polyelectrolytes.[8] The pH change thus suggests the conformational change. In the previous studies, pH decreased to about 4.5 on addition of the most effective species (Cu^{2+} ions) to poly[Cys(CH_2COONa)][1] while pH decreased to about 6.0 in the case of poly[Cys(CH_2CH_2COONa)][2]. In the present study, the extents of pH decrease by the addition of $HgCl_2$ are much larger than those found in previous studies, while the effects of $Hg(ClO_4)_2$ are consistent with previous data. The extraordinary lowering of pH on addition of $HgCl_2$ may suggest the coordination of $HgCl_2$ to peptide nitrogens, which releases hydrogen ions and converts the partially formed β-form to random coils.

A marked difference between $Hg(ClO_4)_2$ and $HgCl_2$ is found in Figs. 2, 4, and 5 concerning the solubilities of the two polypeptides. Precipitation of the two polypeptides did not occur at the mixing ratio of 5 in the case of $HgCl_2$. Precipitation occurred at the mixing ratios of about 0.3 for poly[Cys(CH_2COONa)] and about 0.4 for poly[Cys(CH_2CH_2COONa)] in the case of $Hg(ClO_4)_2$. The solubilities found in the case of $Hg(ClO_4)_2$ are consistent with the previous results on other bivalent metal cations, although they are the least or nearly the least among the solubilities in the

presence of bivalent cations.[1,2] It is interesting to note that the solubility in the presence of $Hg(ClO_4)_2$ is larger for poly[Cys(CH_2CH_2COONa)] than for poly[Cys(CH_2COONa)].

In conclusion, the induction of the β-form occurs on addition of $Hg(ClO_4)_2$ to the solutions of poly[Cys(CH_2COONa)] or poly[Cys(CH_2CH_2COONa)] due to the formation of a complex between them, as suggested by the appearance of a new CD band around 250—260 nm. In the case of $HgCl_2$, on the other hand, the induction of the β-form cannot be concluded, although evidence for the complex formation is obtained.

II. $AgClO_4$. In Figs. 6(a) and (b), the CD spectra of poly[Cys(CH_2COONa)] and poly[Cys(CH_2CH_2COONa)] are shown respectively in the presence of different amounts of $AgClO_4$. The change of CD spectra indicates the formation of the β-form by the addition of $AgClO_4$. This result is the first example of the β-form of these two polypeptides induced *in solution* by a univalent metal cation. Based on the mechanism suggested for the induction of the β-form of these two polypeptides deduced from previous studies, silver ions are supposed to be covalently bound to the side chains of the polypeptides. However, there is no new CD band in the whole wavelength region examined nor anomalous pattern around 200—230 nm, contrary to the case found on the addition of the mercury compounds.

In Fig. 7, the residue ellipticities at 200 nm, $[\theta]_{200}$, are shown as functions of the mixing ratio. The results on

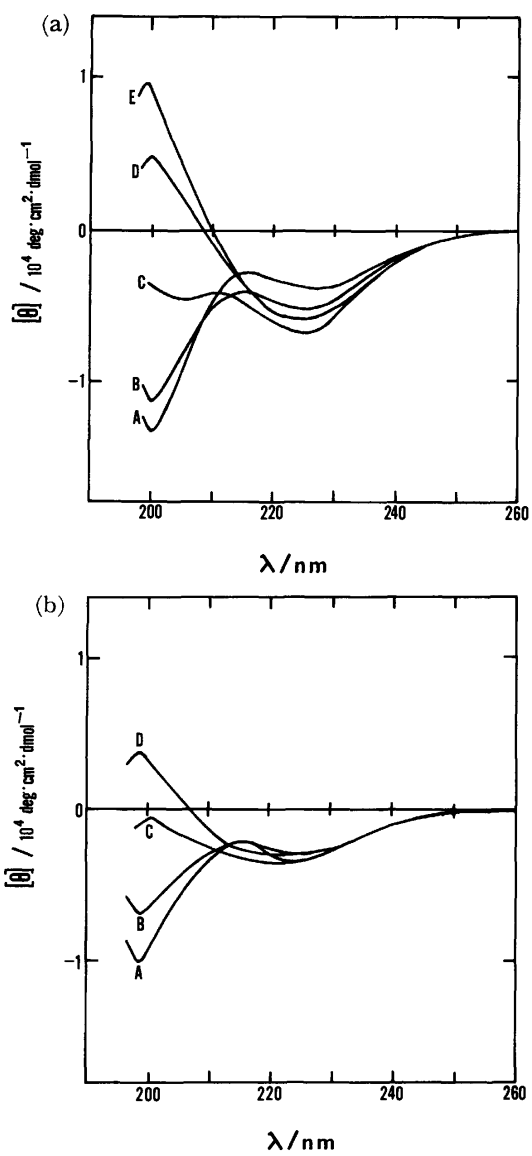

Fig. 6. CD spectra of (a) poly[Cys(CH_2COONa)] and (b) poly[Cys(CH_2CH_2COONa)] in the presence of $AgClO_4$.
Mixing ratios (C_M/C_P). (a); 0(A), 0.101(B), 0.402(C), 0.503(D), and 0.754(E). (b); 0(A), 0.102(B), 0.409(C), and 0.512(D).

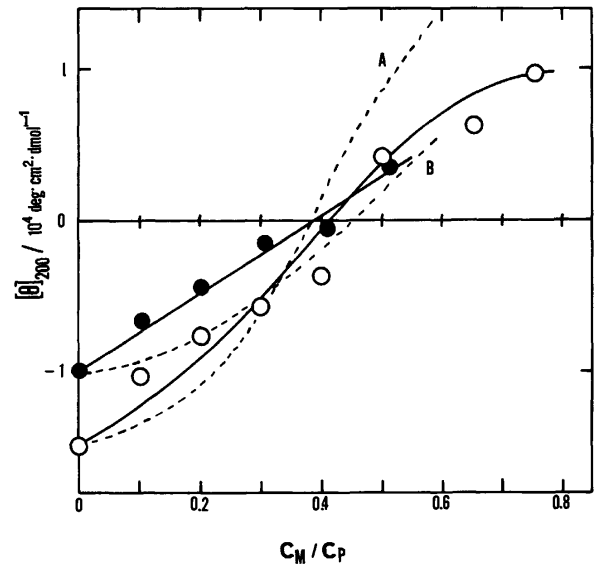

Fig. 7. Dependence of the residue ellipticity at 200 nm, $[\theta]_{200}$, on the mixing ratio (C_M/C_P).
(○) Poly[Cys(CH_2COONa)] and (●) Poly[Cys(CH_2CH_2COONa)].
Polymer concentration (C_P) is 1×10^{-3}M. Dashed curves represent the results on (A) $CuCl_2$-poly[Cys(CH_2COONa)] and (B) $CdCl_2$-poly[Cys(CH_2CH_2COONa)]. The scale of abscissa is doubly enlarged for these dashed curves.

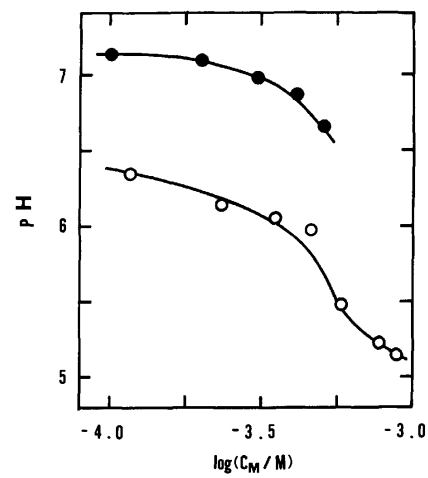

Fig. 8. Dependence of pH on the logarithm of $AgClO_4$ concentration (C_M).
(○) Poly[Cys(CH_2COONa)] and (●) poly[Cys(CH_2CH_2COONa)]. Polymer concentration (C_P) is 1×10^{-3}M.

$CuCl_2$ for poly[Cys(CH_2COONa)] (curve A)[1] and on $CdCl_2$ for poly[Cys(CH_2CH_2COONa)] (curve B)[2] are also shown. These are the most effective inducers of the β-forms of respective polypeptides in the previous studies. To facilitate the comparison, the scale of the abscissa for these bivalent cations is doubly enlarged. The induction of the β-form by $AgClO_4$ is comparable with $CdCl_2$ in the case of poly[Cys(CH_2CH_2COONa)], while it is less effective than $CuCl_2$ in the case of poly[Cys(CH_2COONa)].

In Fig. 8, values of pH of the solutions of the two polypeptides are given as functions of $AgClO_4$ concentration (C_M) in the logarithmic scale. As in the case of the mercury compounds shown in Fig. 5, the changes are nearly identical for the two polypeptides, when either of the two curves is shifted vertically by about 0.8 pH unit, the correction for the difference in the intrinsic dissociation constants. The decrease of pH is much larger than that expected for the effect of added salt on random coil polyions and hence confirms the coordination of Ag^+ ions, probably, to the side chains.

Precipitation occurred at the mixing ratios of about 0.8 for poly[Cys(CH_2COONa)] and 0.5 for poly[Cys(CH_2CH_2COONa)], which correspond to 0.4 and 0.25 in the case of bivalent ions, respectively. They are comparable with those found on $Hg(ClO_4)_2$, 0.3 and 0.4 given above. The solubility of poly[Cys(CH_2CH_2COONa)] in the presence of $AgClO_4$ is lower than that of poly[Cys(CH_2COONa)], which is consistent with the general trend found for the β-forms of these two polypeptides induced by bivalent metal cations and hydrogen ions.[1,2]

Discussion

In the present study, new CD band appears in the region of 240—260 nm and distortion of the CD spectra occurs in the region of 200—220 nm on addition of $Hg(ClO_4)_2$ or $HgCl_2$ to the solutions of poly[Cys(CH_2COONa)] and poly[Cys(CH_2CH_2COONa)]. These changes can be ascribed to the electronic transition involving Hg atoms. The absorption of $HgCl_2$ is more intense than that of $Hg(ClO_4)_2$ in the region of 200—260 nm; the molar absorption coefficients differ by about one order around 230 nm.[9] The absorption maxima are about 205 nm for $HgCl_2$ and below 190 nm for $Hg(ClO_4)_2$.[9] This can explain why the anomaly was observed more clearly for $HgCl_2$ than for $Hg(ClO_4)_2$. In the case of $AgClO_4$, which has absorption bands around 225, 210, and 194 nm,[10] neither distortion of the CD spectra occurs nor new CD band appears appreciably, although the β-form is induced.

The different solubilities of the two polypeptides are seen from Figs. 2, 4, and 5 between the solutions containing $Hg(ClO_4)_2$ or $HgCl_2$. The difference may be related to the different extents of the covalent nature of these two compounds. While $Hg(ClO_4)_2$ readily dissociates, $HgCl_2$ remains mostly undissociated in aqueous solutions. The induction of the β-form, the low solubility, and the characteristic decrease of pH are reasonably understood in the case of $Hg(ClO_4)_2$ in terms of the interactions of ionic species Hg^{2+} with the polypeptides. Contrary to the expected behavior for neutral species, the complex formation is indicated from the CD spectra in the case of $HgCl_2$. [Figs. 1(b) and 3(b)]. It is difficult, however, to infer the induction of the β-form from the CD spectra.

All the obtained data (CD spectra, pH change, and solubility) in the case of $HgCl_2$ cannot be consistently explained by assuming for the bound species either neutral species or bivalent ionic species. Explanations in terms of various possible bound species could be developed. However, it is not pertinent to present highly speculative discussions here.

The Formation of Metastable Potassium Trivanadate from Melts

Yoshiya KERA
Department of Applied Chemistry, Faculty of Science and Engineering, Kinki University, Higashi-Osaka 577
(Received May 16, 1983)

Potassium vanadates, which were prepared from melts by rapid quenching and slow cooling over the composition range of K_2O-contents of $C=(K)/(V)=0$—0.50, were examined by means of IR spectrometry and X-ray powder diffraction. In the composition range of $C\leq 0.17$, mixtures of V_2O_5, $K_2V_{18}O_{45}$, and $K_2V_8O_{21}$ were produced by the slow cooling. At the composition of $C=0.33$, however, an unknown compound and $K_2V_8O_{21}$ were the main products upon rapid quenching from melts, while at $C=0.50$ the main products were $K_3V_5O_{14}$ and an additional unknown compound. The unknown compound was confirmed to be metastable and was formed as a single compound only by a rapid quenching from melts of K_2O and V_2O_5 especially at $C=0.37$. The X-ray diffractions for the compound were characterized as $d=8.2$ (very strong), 4.05, and 3.27 Å, and the V=O stretching frequencies, as 995, 968, and 955 cm^{-1}. By comparing these characteristic data with those of lithium trivanadate and sodium trivanadate (γ-phase), it was suggested that the unknown compound was isomorphous with trivanadate ($M_{1+x}V_3O_8$).

In the previous paper, it was examined how alkali tri- and/or hexavanadates could be produced or not by the procedures of the rapid quenching and slow cooling of the melts which had been prepared from mixtures of M_2CO_3 and NH_4VO_3 or V_2O_5 as the starting materials with the composition of $C=(M)/(V)=0.33$.[1] Only in the case of K_2O-containing samples, however, was neither the trivanadate nor the hexavanadate formed by those procedures,while the mixtures of $K_2V_8O_{21}$, an unknown compound, and $K_3V_5O_{14}$ were formed. The reasons why the tri- or hexavanadate could not be formed only in the K_2O-V_2O_5 binary system, and also what the unknown compound was, have remained to be investigated. With a potassium oxide-vanadium oxide binary system, five stable compound have been reported by Holtzberg *et al.*,[2] corresponding to these five formulas: $K_2V_8O_{21}$, KVO_3, $K_{32}V_{18}O_{61}$, $K_4V_2O_7$, and K_3VO_4. Kelmers[3] also found $K_3V_5O_{14}$ as a high-temperature phase; he further suggested the existence of $K_2V_{12}O_{30}$ and metastable $K_2V_{18}O_{45}$. However, no such compounds, the composition of which is near 0.33 ($C=0.33$), have yet been reported to be formed from high-temperature melts.

On the other hand, potassium hexavanadate ($K_2V_6O_{16}$) has been prepared by Kelmers[4] from V_2O_5 solution with alkali dissolved in it. Evans and Block called the potassium vanadate prepared by this procedure potassium trivanadate(KV_3O_8) based on an exact X-ray analysis.[5] The potassium trivanadate is monoclinic; its X-ray powder data has also been shown on an ASTM-card.[6] However, any diffraction peaks are inconsistent with the unknown compound formed from high-temperature melts in a previous experiment.[1]

In the present experiment IR spectrometry and X-ray powder diffraction were used for analysing in detail the potassium vanadates formed by slow cooling and/or rapid quenching from the melts of K_2O and V_2O_5 over the composition range of $C=0$—0.50. Especially, in order to characterize the unknown compound, many samples formed in the region near $C=0.33$ were investigated.

Experimental

1) Materials and Preparations. Potassium vanadates in the composition range of $C=(K)/(V)=0$—0.17 (in atomic ratio) were prepared from K_2CO_3 (Wako Pure Chem. Co., Ltd.; guaranteed grade) and NH_4VO_3,which had been purified cautiously,[7] by the following procedures. The NH_4VO_3 was immersed into a K_2CO_3 aq soln, dried at 120 °C, and calcined in a quartz tube with opening to the air at 600 °C for 20 h. After the heating, they were cooled slowly in the furnace. The samples will be called K-1—6. Sample K-7, with the composition of $C=0.33$, was prepared by the same procedures except for the final cooling procedures; it was rapidly quenched in ice-water. For preparing Sample K-8, K_2CO_3 and V_2O_5 (both Kanto Chem. Co., Ltd.; guaranteed grade) were well mixed in the composition of $C=0.33$ in an agate mortar and then heated in a quartz tube (outer diameter, $d_o=10$ mm) with an opening to the air at 530 °C for 14 h.

TABLE 1. K-CONTENTS OF POTASSIUM VANADATES PREPARED BY MELTS AND THEIR V=O STRETCHING FREQUENCIES, AS ESTIMATED FROM Figs. 1 AND 2

Sample	C/[M]/[V]	V=O Stretching ν/cm^{-1}					
K-1	0.020(s)[a]	1022	—	—	960	—	940
K-2	0.040(s)	1022	—	—	970	—	942
K-3	0.063(s)	1020	1005	—	—	—	942
K-4	0.087(s)	1023	1000	—	972	—	941
K-5	0.119(s)	1020	1000	—	972	—	942
K-6	0.171(s)	1021	1001	—	972	—	942
K-7	0.33 (r)	—	995	985	967	955	940
K-8	0.33 (s)	—	995	—	970	955	937
K-9	0.33 (r)	—	995	985	967	955	938
K-10	0.50 (r)	—	995	980	—	955	935

a) The letters of s and r in parentheses denote the procedures of the slow cooling and the rapid quenching respectively.

Table 2. The K_2O-contents of samples V-1—7

Sample	C/(K)/(V)
V-1	0.261
V-2	0.285
V-3	0.310
V-4	0.334
V-5	0.350
V-6	0.374
V-7	0.399

After further heat-treatment at 590 °C for 8 h, it was cooled slowly in the furnace. For preparing Samples K-9 and 10, the compositions of which were $C=0.33$ and 0.50 respectively, given amounts of K_2CO_3 and NH_4VO_3 were well mixed in an agate mortar and then heated in a quartz tube ($d_o=10$ mm) with an opening to the air at 620 °C for 72 h. Finally they were quenched rapidly in ice-water. The compositions of the samples thus prepared are summarized in Table 1. In order to investigate the unknown compound in detail, K_2CO_3 and V_2O_5 were mixed well in the composition of $C=0.26$—0.40 and then heated in a quartz tube ($d_o=6$ mm) with an opening to the air at 750 °C for 22 h. After the heat-treatment they were quenched in ice-water. The compositions of the samples, V-1—7, are summarized in Table 2.

2) IR and X-Ray Measurements. The IR spectra of Samples K-1—10 were measured in the frequency range from 650 to 1200 cm^{-1} by using the normal KBr-disk method. The IR spectrometer used was JASCO, model DS-402 G. The IR spectrum for Sample V-6 was measured in the range of 400—1100 cm^{-1} by the use of a JASCO model A-202 spectrometer. The X-ray powder diffraction was carried out on all the samples in the range of $2\theta=4$—60 °. The X-ray diffractometer used was a Rigaku-Denki model; GF-Rad-γA; Cu $K\alpha$-radiation (at 40 kV, 120 mA) and a Ni-filter were used.

Results

The IR spectra of Samples K-1—7 are shown in Fig. 1, in which the spectrum of pure-V_2O_5 is also given for the sake of comparison. The 1022 cm^{-1} band appearing in pure-V_2O_5 has already been assigned to the V=O stretching vibration.[8,9] It may be seen that sharp bands appear at 1000, 972, and 942 cm^{-1} in Samples K-1—7 and that the intensities of those bands increase with an increase in the K_2O-content. In the IR spectra of Samples K-7—9, which differ in their starting materials and with the procedures used to prepare them but whose are the same in the K_2O-content ($C=0.33$), the band peaks were seen at 995, 985, 955, and 940—937 cm^{-1}, a little different from those of Samples K-1—6. In Sample K-10 ($C=0.50$), the characteristic broad and sharp bands appeared at about 980 and 935 cm^{-1} respectively, while a shoulder band seemed to appear at 995 cm^{-1}. In Samples K-8 and 10, a very weak band was seen in the region of 905—908 cm^{-1}. The frequencies for the V=O stretching bands of Samples K-1—10 are summarized in the third colum of Table 1. The 967 cm^{-1} band seems to be more intensive than the 995 cm^{-1} band in Sample K-9, while the two intensities are similar in extent in Sample K-7. The broad 980 cm^{-1} and the sharp 935 cm^{-1} bands became relatively intensive in Sample K-10. With respect to Samples K-1—6, the peak intensities for the sharp band in the region of 930—1000 cm^{-1} were estimated by drawing a base line smoothly under the bands of the spectra according to the previous papers;[1,10] their relative intensities are given in Table 3. As the band separations were not good enough for us to estimate the intensities of each peak in the K-7 —10 samples, these values were excluded from the table.

Table 3. The relative intensities of the V=O stretching bands for samples K-1—6

Sample	C/[M]/[V]	Band Intensities			
		1022	1000	972	942 cm^{-1}
K-1	0.020	0.92	0.047	0.017	0.018
K-2	0.040	0.87	0.077	0.037	0.019
K-3	0.063	0.784	0.134	0.041	0.041
K-4	0.087	0.76	0.160	0.040	0.037
K-5	0.119	0.61	0.246	0.065	0.079
K-6	0.171	0.48	0.30	0.13	0.09

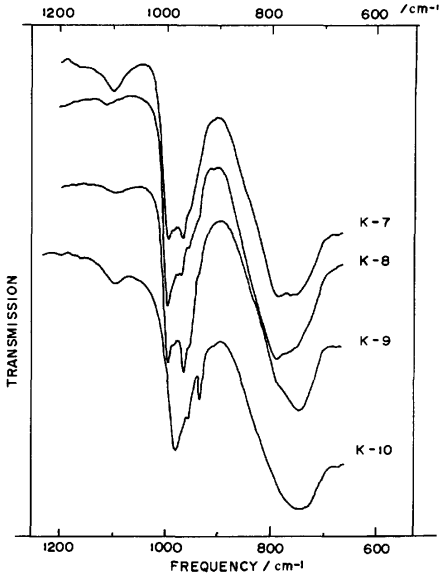

Fig. 2. IR-spectra of Samples K-7—10.

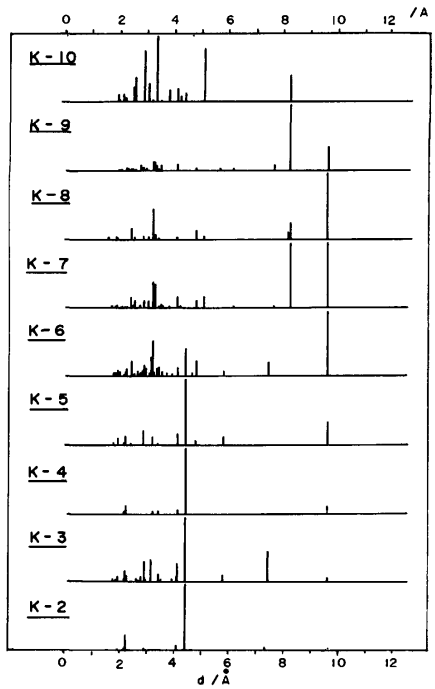

Fig. 3. The X-ray powder diffraction patterns for Samples K-2—10, recorded in the angles of 2θ =4—60° (d=22—1.54 Å).

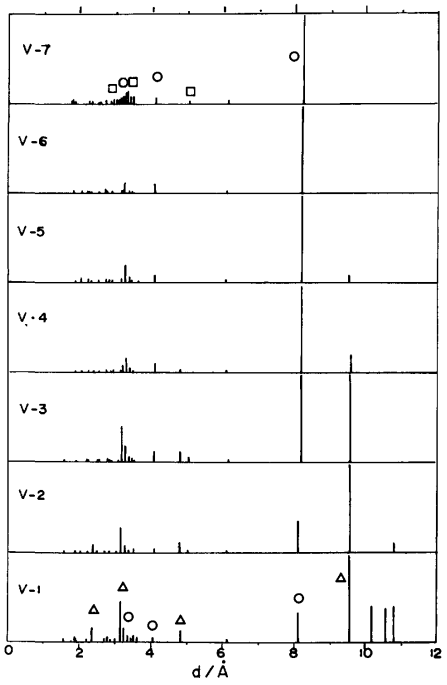

Fig. 4. The X-ray powder diffraction patterns for Samples V-1—7 recorded in the angles of 2θ=4—60° (d=22—1.54 Å). The signs, △, ○, and □, denote the lines for $K_2V_8O_{21}$,[12] the unknown compound, and $K_3V_5O_{14}$,[13] respectively. See also text.

The X-ray diffraction patterns of Samples K-2—10 are shown in Fig. 3. The diffraction peak corresponding to the interplanar spacing of d=4.38 Å, which has been characterized as V_2O_5,[11] was the highest in Samples K-2—5 (C=0.040— 0.12), but it completely disappeared in Samples K-7—10 (C=0.33—0.50). On the other hand, the peak for d= 9.60 A, characteristic of $K_2V_8O_{21}$,[12] appeared at first in the K-2 sample (C= 0.04), became intensive with an increase in the K_2O-content, and reached its highest point in the K-6—8 samples (C=0.17—0.33). In the K-10 sample (C= 0.50), the peak at d=3.28 Å, characteristic of the $K_3V_5O_{14}$ phase[13] became the highest.

At a rather low content, especially in the K-3 sample, the intensive diffraction peak appeared at d=7.4 Å, which was characteristic of the $K_2V_{18}O_{45}$ phase.[12] With respect to the highest peak at d=8.2 Å in the K-9 sample, the corresponding compound was not found out in any ASTM-cards for potassium vanadates; thus, it has been called an unknown compound. From the comparisons of the diffraction intensities at d=9.6, 8.2, and 3.28 Å, which are the highest of the compounds of $K_2V_8O_{21}$, the unknown compound, and $K_3V_5O_{14}$, respectively, $K_2V_8O_{21}$ seems to be a major component in the K-8 sample and the unknown compound seems to be the major in the K-9 sample. Similarly $K_3V_5O_{14}$ seems to be a major component in the K-10 sample.

The X-ray diffraction patterns of Samples V-1—7 are shown in Fig. 4. In the V-1 sample the most intensive peak is seen at 9.5 Å, and the second most intensive at 3.16 Å: they are characteristic of $K_2V_8O_{21}$.[12] With an increase in the potassium content (C=0.26→0.37), it may be seen in the figure that the peak at 8.2 Å, becomes intensive, while, on the contrary, that at 9.5 Å, decreases. Similarly, the intensities of the peaks at 4.05 and 3.27 Å, (marked with ○) increase relative to the peaks at 4.85, 3.15, and 2.12 Å (marked with △). Finally in the V-6 sample (C=0.374), those peaks assigned to $K_2V_8O_{21}$ disappear completely, while the very strong peak at d=8.2 Å and weak peaks at 4.05 and 3.27 Å which have been ascribed to the unknown compound remain. In Sample V-7 (C=0.399), the other peaks assigned to $K_3V_5O_{14}$[13] appear at d=5.01, 3.29, and 3.02 Å (marked with □). Therefore, it is clearly suggested that the unknown compound is formed as a single compound only by the rapid quenching from the melt at C=0.37. Furthermore, the characteristic X-ray peaks of the unknown compound may be regarded as corresponding to the interplanar distances of 8.2 (very strong), 4.05 and 3.27 Å. The IR spectrum of the

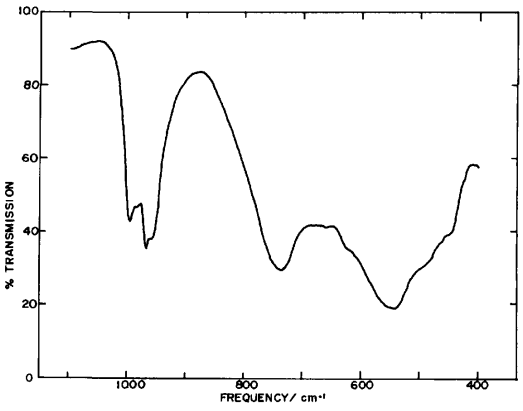

Fig. 5. IR-spectrum of Sample V-6, in which the unknown compound was regarded to be purely contained, recorded in the frequency range of 400—1100 cm^{-1}. See also text.

V-6 sample is shown in Fig. 5. The V=O stretching frequencies characteristic of this compound were determined exactly to be 995, 968, and 955 cm^{-1}.

Discussion

1) The V=O Stretching Frequencies of the Potassium Vanadates Formed from the Melts of K_2O-V_2O_5 in the Range of C=0—0.50. V_2O_5, $K_2V_{18}O_{45}$, and $K_2V_8O_{21}$ were the main components in the samples of $C=0.04$—0.17, as has been pointed out above. Furthermore, the content of the $K_2V_8O_{21}$ phase has been seen to increase with C, and simulteneously the 1000, 972, and 942 cm^{-1} bands have been seem to become intensive, while the 1022 cm^{-1} band weakens, as is shown in Fig. 1 and Table 3. The band intensities are plotted against C in Fig. 6, in which the plot for the 1022 cm^{-1} band can be linearly extrapolated toward the point at $C=0.33$ on the abscissa. As has already been noted above,the V_2O_5 phase is not contained in the samples of $C\geq0.33$. In fact, the X-ray diffraction peak for d=4.38 Å ascribed to V_2O_5 was not detected completely in Samples K-7—10. The intensities of the 1000, 972, and 942 cm^{-1} bands increase linearly with C, keeping approximntely a constant relation with one another, although the content ratio of $K_2V_8O_{21}$ and $K_2V_{18}O_{45}$ differs considerably among Samples K-2—6. Therefore, it can be suggested that the V=O stretching frequencies in $K_2V_8O_{21}$ are nearly the same as those in $K_2V_{18}O_{45}$.

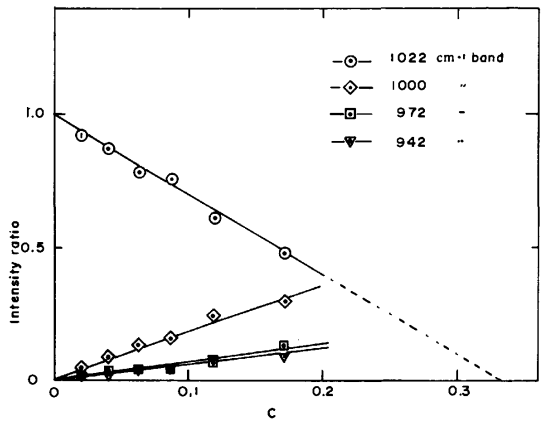

Fig. 6. Changes in the relative intensities of the V=O stretching bands (Intensity ratio) with increasing the K_2O-contents (C) for Samples K-1—6. The 1022 cm^{-1} band is ascribed to pure-V_2O_5 and the 1000, 972, and 942 cm^{-1} for $K_2V_8O_{21}$ (or $K_2V_{18}O_{45}$).

From comparisons of the IR spectra and X-ray diffraction lines between the K-8 and 9 samples, the 967 cm^{-1} band could be assigned to the unknown compound because the band in Sample K-9 was more intensive than that in Sample K-8, while, simultaneously, the existing ratio of the unknown compound to $K_2V_8O_{21}$ in K-9 was higher than that in K-8. It has been reported by Zurkova *et al.*[13] that the characteristic bands of $K_3V_5O_{14}$ were found at 985 and 940 cm^{-1}. The broad band at 980 cm^{-1} and the sharp band at 935 cm^{-1} in the K-10 sample seemed to correspond to these bands, although the frequencies deviated a little bit because of the overlapped spectrum with those of the unknown compound. Therefore, the bands at 995 and 955 cm^{-1} remaining in the spectrum of the K-10 sample could be regarded as having been caused by the unknown compound. Thus, the V=O stretching bands of the unknown compound were established as appearing at 995, 967, and 955 cm^{-1}. These values are in good agreement with those determined from the spectrum for the V-6 sample, $C=$ 0.37 (995, 968, and 955 cm^{-1} respectively).

2) Chemical Formula and Structural Features of the Unknown Compound. With the increase in C, the diffraction peaks at $d=8.2$, 4.05, and 3.27 Å, became intensive relative to those at $d=9.5$, 4.85, 3.15, and 2.12 Å, which are ascribed to the diffraction of $K_2V_8O_{21}$ ($C=0.25$)[12] untile finally, at $C=0.37$, only those lines remained, as is shown in Fig. 4. Therefore, those at $d=$ 8.2, 4.05, and 3.27 Å should be ascribed to the unknown compound. Thus, the unknown compound might be expressed by this formula: $K_{1+x}V_3O_8$ ($x=0.11$). If this $K_{1+x}V_3O_8$ is assumed to be isomorphous with lithium and sodium trivanadates ($K_{1+x}V_3O_8$, γ-phase), both the X-ray diffraction lines and the V=O stretching bands should correspond to one another. Furthermore, those values should be expected to vary more or less among themselves depending upon the alkali-metal-ion size. The strongest peak at $d=$ 8.2 Å for the $K_{1+x}V_3O_8$ compound seems to correspond to that at 6.4 Å, which has been assigned to the interplanar spacing of the (100) plane with $Li_{1+x}V_3O_{7.9}$ ($x=0.12$)[14] and that at $d=7.0$ Å with NaV_3O_8,[15] although it has not been assigned.

In order to compare the d-values of not only 8.2 Å but also 4.05 and 3.27 Å for $K_{1+x}V_3O_8$ with the the

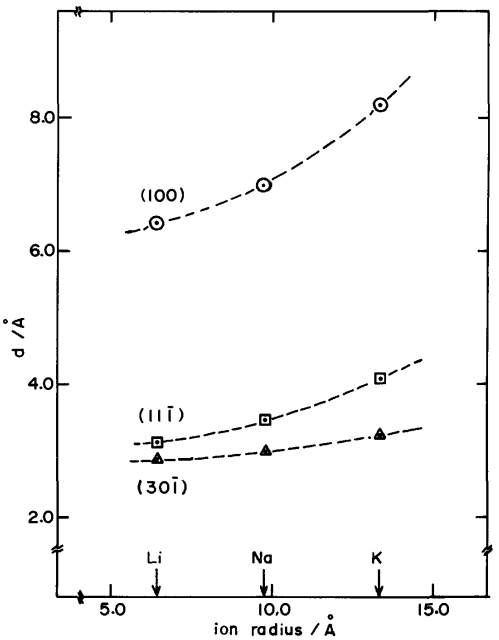

Fig. 7. Comparisons of the X-ray diffraction lines characterized to the compound $K_{1+x}V_3O_8$ (just assigned) with those referred to Li and Na-trivanadates (γ-phase) by use of the alkali metal ion radii as an parameter. The d-values for $Li_{1+x}V_8O_{7.9}$($x\leq0.12$)[14] 6.36, 3.15, and 2.216 Å has been assigned to the (100), (11$\bar{1}$), and (30$\bar{1}$), as were shown in the figure.

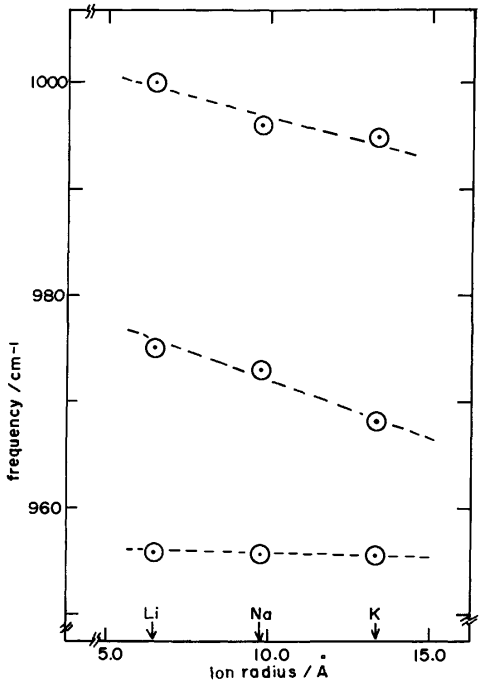

Fig. 8. Comparisons of the V=O stretching frequencies characterized to the compound $K_{1+x}V_3O_8$ (just assigned) with those reported previously for Li and Na-trivanadates[1] by use of the alkali metal ion radii as an parameter.

corresponding *d*-values for $Li_{1+x}V_3O_{7.9}$ and NaV_3O_8 respectively, the *d*- values were plotted against alkali ion radii;[16] they are shown in Fig. 7. Those values are known to correlate well with the alkali-metal-ion radii in the figure. Especially, such a large change in the *d*-value with the (100) can be understood reasonably because alkali-metal-ions are placed into the interplanar spacing along the a-axes in the monoclinic lattice. Thus, from the good coorelations, these three compounds might be concluded to be isomrphous with each other.

Such correlation is consistent with those found in the hexavanadates of potassium, ammonium, rubidium, and cesium, being isomorphous with each other, reported by Kelmers.[4] The V=O stretching bands, 995, 968, and 955 cm^{-1} for the $K_{1+x}V_3O_8$, seem to correspond to those of 1000, 975, and 957 cm^{-1} for LiV_3O_8 and those of 996 , 973, and 957 cm^{-1} for NaV_3O_8, respectively.[1] In fact, the V=O stretching frequencies also gave a good correlation to the alkali-metal-ion radii, as is shown in Fig. 8.

Therefore, throughout any discussions it should be emphasized that the metastable potassium trivanadate (KV_3O_8), being isomorphous with lithium and sodium trivanadates (γ-phase), was favorably formed, especially upon rapid quenching from high-temperature melts (≃750 °C). Furthermore, it should be noted that the present potassium trivanadate differs completely in its X-ray diffraction patterns from the potassium hexavanadate($K_2V_6O_{16}$) reported by Kelmers[4] and from the potassium trivanadates (KV_3O_8) reported by Evans and Block,[5] prepared from aq soln and regarded as isomorphous with $(NH_4)_2V_2O_{16}$, $Rb_2V_2O_{16}$ and $Cs_2V_2O_{16}$.

3) The V=O Bond Lengths of The Potassium Vanadates, $K_2V_8O_{21}$, $K_{1+x}V_3O_8$, and $K_3V_5O_{14}$. From the 1000, 972, and 942 cm^{-1} bands ascribed to the V=O stretching bands for $K_2V_8O_{21}$, the corresponding bond lengths were evaluated as 1.599, 1.618, and 1.630 Å respectively, according to the same procedure as was used in previous papers.[1,10] Similarly, the V=O bond lengths corresponding to the 995, 968, and 955 cm^{-1} bands of $K_{1+x}V_3O_8$ were evaluated as 1.603, 1.622, and 1.630 Å respectively, and those corresponding to the 980 and 935 cm^{-1} bands of $K_3V_5O_{14}$ as 1.613 and 1.645 Å respectively.

The author wishes to express his appreciation to Mr. Tetuo Yamamoto for his measurements of the IR spectra.

The Circular Dichroism Spectra of *cis*-$[Co(CN)_2(CO_3)_2]^{3-}$, *cis*-$[Co(NO_2)_2(CO_3)_2]^{3-}$, and Related Bis(dicarboxylato) Complexes

Shuhei Fujinami,* Akihide Shimoda, Toshihito Furukawa, and Muraji Shibata
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920
(Received September 5, 1983)

Five kinds of *cis*-$[Co(CN)_2(OO)_2]^{3-}$ and *cis*-$[Co(NO_2)_2(OO)_2]^{3-}$ complexes ($OO=CO_3^{2-}$, ox^{2-}, mal^{2-}) have been optically resolved. As to the dicarbonato complexes, one enantiomer has been obtained in a yield far exceeding 50% because of the rapid racemization. When the carbonato ligand is replaced with an oxalato or malonato ligand, the complex becomes inert for racemization and a new Cotton peak with an opposite sign appears at the lower frequency in the first-absorption-band region. The CD spectral change is different from the change observed in *cis*-$[Co(a)_2(OO)_2]^-$ complexes ($a=NH_3$, py, en/2), suggesting the intimate participation of the unidentate ligands in determining the signs of the Cotton peaks.

It is known that the variation in the size of a dicarboxylato chelate ring causes a marked change in the CD spectra.[1-6] For example, a $[Co(CO_3)_2(en)]^-$ complex exhibits a single Cotton peak in the first-absorption-band region, while $[Co(ox)_2(en)]^-$ and $[Co(mal)_2(en)]^-$ complexes exhibit two and three Cotton peaks respectively. Such a spectral change has been utilized to assign a single Cotton peak observed in the *cis*-$[Co(a)_2(CO_3)_2]^-$ complex ($a=NH_3$, py, or en/2).[6] When the carbonato ligand is replaced with an oxalato or malonato ligand, a new Cotton peak with an opposite sign appears at a higher frequency in the first-absorption-band region. Therefore, the single Cotton peaks in the dicarbonato complexes have been assigned to the $A_{1g}\rightarrow E_g$ transition component in a holohedrized[7] D_{4h} symmetry, since this component lies at a lower frequency in the *cis*-$[Co(N)_2(O)_4]$-type complexes.

This paper deals with the optical resolutions of *cis*-$[Co(CN)_2(OO)_2]^{3-}$ and *cis*-$[Co(NO_2)_2(OO)_2]^{3-}$ complexes ($OO=CO_3^{2-}$, ox^{2-}, and mal^{2-}). These dicyano and dinitro complexes have previously been synthesized, and only *cis*-$[Co(CN)_2(CO_3)(ox)]^{3-}$ and *cis*-$[Co(CN)_2(ox)_2]^{3-}$ complexes have been optically resolved.[8,9] The CD spectral changes in the *cis*-$[Co(CN)_2(OO)_2]^{3-}$ and *cis*-$[Co(NO_2)_2(OO)_2]^{3-}$ complexes will be investigated and compared with those in the *cis*-$[Co(a)_2(OO)_2]^-$ complexes ($a=NH_3$, py, and en/2).

Experimental

1) Optical Resolution of cis-*[Co(CN)$_2$(CO$_3$)$_2$]$^{3-}$.* This complex was prepared and crystallized by adding $(+)_{589}$-$[Co(en)_3]Br_3$ and an appropriate amount of ethanol according to the method in the literature.[8] Since the dicyano complex racemized rapidly in an aqueous solution, the CD spectrum was measured by the following procedure. The brown-violet crystals[8] were quickly dissolved into a cold 0.5 mol dm^{-3} $NaHCO_3$ solution. The solution was poured onto a column of Dowex 50W-X8 (ϕ 1 cm × 1 cm, in Na^+ form) and then discharged rapidly by air-pressing the top of the column. The effluent was submitted to the measurement of the CD spectrum within the range of 50—100 nm at 5 °C. The procedure should be done as fast as possible and repeated several times to cover the region of the d-d transition bands. Each time needed to separate the complex cation was recorded in order to correct the spectrum. The separation of the cation was carried out at *ca.* 10 s, and the spectrum was recorded at a speed of 100 nm min^{-1}. Since no change in the absorption spectrum was observed after the measurement of the CD spectrum, the metal concentration was evaluated from the absorption spectral data. The height of the Cotton peak at 459 nm decreased to half after *ca.* 27 s at 5 °C in a 0.5 mol dm^{-3} $NaHCO_3$ solution. The deposited brown-violet crystals contained the $(+)^{CD}_{589}$-dicyano isomer.

2) Preparation and Optical Resolution of cis-*[Co(CN)$_2$(mal)$_2$]$^{3-}$.* This complex was prepared by a literature method with only a slight modification.[8] Malonic acid (25 g, 0.35 mol) and potassium hydrogencarbonate (25 g, 0.25 mol) were dissolved in 30 cm^3 of warm water, and the solution was stirred vigorously until the evolution of CO_2 gas ceased. The resultant solution was added to a deep red solution of *cis*-$[Co(CN)_2(CO_3)_2]^{3-}$[8] which had been prepared by using a green solution of tricarbonatocobaltate(III) (0.05 mol scale).[10] The mixed solution was adjusted to pH 5 by acetic acid and stirred at room temperature for 3 h.

After filtration, the filtrate was poured onto a column of QAE Sephadex A-25 in the Cl^- form (ϕ3 cm × 15 cm). By elution with 0.6 mol dm^{-3} KCl, red and orange bands were discharged from the column, in that order. The effluent of the orange band was concentrated to a small volume (*ca.* 10 cm^3) with the simultaneous removal of the precipitated KCl. An appropriate amount of an acetone solution of $(+)_{589}$-$[Co(en)_3](ClO_4)_3$ was added to the concentrate. After the removal of the deposited $KClO_4$, small amount of ethanol was added to the filtrate. The precipitated resolving agent was repeatedly removed, and a red diastereoisomeric salt containing the $(+)^{CD}_{546}$-dicyano complex was finally obtained. The yield was very poor. The salt was dissolved in water, and the solution was passed through a short column of Dowex 50W-X8 (ϕ 1 cm × 2 cm, in Na^+ form). The absorption spectral data of the effluent were identical with those of the literature.[8] The CD spectrum was measured by using the effluent, and the metal concentration was estimated from the absorption spectral data. The enantiomer was enough inert for racemization for the CD spectrum to be measured.

3) Optical Resolution of cis-*[Co(NO$_2$)$_2$(CO$_3$)$_2$]$^{3-}$.* This complex was prepared according to the method in the literature.[9] Into a cold solution of $K_3[Co(NO_2)_2(CO_3)_2]\cdot H_2O$ (2 g, 5 mmol, in 200 cm^3 H_2O) we stirred, in turn, a solution of $(-)_{589}[Co(gly)(en)_2]Cl_2$[11] (1.6 g, 5 mmol, in 50 cm^3 H_2O) and acetone (20 cm^3) under iced conditions. The *cis*-$[Co(NO_2)_2(CO_3)_2]^{3-}$ complex was deposited as a less-soluble pink diastereoisomeric salt. Found: C, 18.17; H, 5.26; N, 18.63%. Calcd for $[Co(gly)(en)_2]_3\cdot[Co(NO_2)_2(CO_3)_2]_2\cdot 7.5H_2O$: 18.39; H, 5.26; N, 18.52%.

The dinitro complexes was also racemized rapidly in an aqueous solution, and the CD spectrum was measured by a method similar to that used for *cis*-$[Co(CN)_2(CO_3)_2]^{3-}$. The Cotton peak at 521 nm decreased in intensity to half after *ca.* 80 s at 5 °C in a 0.5 mol dm^{-3} $NaHCO_3$ solution. No change

in the absorption spectrum was observed after the measurement of the CD spectrum. The diastereoisomeric salt contained the $(-)^{CD}_{589}$-dinitro isomer.

4) Optical Resolution of cis-*[Co(NO$_2$)$_2$(CO$_3$)(ox)]$^{3-}$.* Into a solution of *cis*-$K_3[Co(NO_2)_2(CO_3)(ox)]$[9] (4 g, 0.01 mol, in 300 cm^3 H_2O) we stirred a solution of $(+)_{589}[Co(en)_3]Cl_3$ (2 g, 5 mmol, in 50 cm^3 H_2O) at room temperature. Red diastereoisomeric salt was soon deposited. The salt was sparingly soluble in water, but it could not be recrystallized. Purification was carried out by the following method. The salt and the ion-exchange resin (Dowex 50W-X8, Na^+ form) were mixed in water, and the mixture was stirred for 20 min. The resin was filtered out, and the filtrate containing the $(-)^{CD}_{589}$-isomer of the dinitro complex was mixed with a solution containing an equimolar amount of $(+)_{589}[Co(en)_3]Cl_3$. The red salt was soon obtained. This procedure was repeated until the $\Delta\varepsilon$ value at 490 nm became constant. The CD spectrum was measured by using the solution from which the resin had been removed by filtration; the metal concentration was evaluated from the absorption spectral data. The rate of the racemization of the enantiomer was very slow compared with that of *cis*-$[Co(NO_2)_2(CO_3)_2]^{3-}$.

5) Derivation of Optically Active cis-*[Co(NO$_2$)$_2$(ox)$_2$]$^{3-}$.* Into a solution of an optically active $[Co(NO_2)_2(CO_3)(ox)]^{3-}$ isomer (5 mmol in 100 cm^3 H_2O) we successively stirred potassium oxalate (35 g, 0.21 mol) and oxalic acid (1 g, 0.01 mol) under iced conditions; the pH of the solution thereupon became *ca.* 4. After stirring for 3 h, the solution was filtered and the filtrate was poured onto a column of QAE Sephadex A-25 (ϕ2.5 cm × 15 cm, in Cl^- form). The band containing a univalent species was discharged by elution with 0.6 mol dm^{-3} KCl, and then the desired tervalent complex species was eluted with 1 mol dm^{-3} KCl. The absorption spectrum of the eluate was identical with that in the literature.[9] The eluate was also subjected to the measurement of its CD spectrum, while the metal concentration was evaluated from the absorption spectral data. The enantiomer was enough inert for racemization for the CD spectrum to be measured. The $(-)^{CD}_{589}[Co(NO_2)_2(ox)_2]^{3-}$ isomer was derived from the $(-)^{CD}_{589}[Co(NO_2)_2(CO_3)(ox)]^{3-}$ isomer.

Measurement. The absorption and CD spectra were measured with a Hitachi 323 recording spectrophotometer and a JASCO J40-C automatic recording spectropolarimeter respectively.

The CD spectrum of $(-)^{CD}_{589}[Co(CN)_2(ox)(H_2O)_2]^-$ was measured by acidifying a solution of $(-)^{CD}_{589}[Co(CN)_2(CO_3)(ox)]^{3-}$ [8] to pH 2 with perchloric acid. The spectrum was reformed to that of the parent complex on the addition of $KHCO_3$.

Results and Discussion

Optical Resolution of the Labile Complex. A series of *cis*-$[Co(CN)_2(OO)_2]^{3-}$ complexes (OO = CO_3^{2-}, ox^{2-}, mal^{2-}) has been prepared, and the optical resolutions have been successfully done for the *cis*-$[Co(CN)_2(CO_3)(ox)]^{3-}$ and *cis*-$[Co(CN)_2(ox)_2]^{3-}$ complexes by using $(+)_{589}[Co(en)_3]Br_3$ as a resolving agent.[8] The attempt to measure the CD spectrum of *cis*-$[Co(CN)_2(CO_3)_2]^{3-}$ has resulted in failure, although the anion was easily crystallized with a $(+)_{589}[Co(en)_3]^{3+}$ cation. This failure is attributable to a rapid racemization of *cis*-$[Co(CN)_2(CO_3)_2]^{3-}$ in an aqueous solution. In this study, the separation of the complex cation from the solution of the diastereoisomeric salt was done as fast as possible. A CD spectral measurement was carried out within a narrow range of wavelengths and was repeated several times under the same conditions to cover the first-absorption-band region. Since the half-life of the optical activity (*ca.* 27 s at 5 °C) is shorter than the time needed to record a CD spectrum, the recorded curve does not afford a correct CD spectrum. The curves were corrected by extrapolating the ellipticity recorded at each wavelength to that at the time when the diastereoisomeric salt had been dissolved. The corrected spectrum was reproducible with a deviation of *ca.* 4%. A dominant positive extremum appeared at 21800 cm^{-1} and a weak positive plateau, at 17500 cm^{-1}, in the first-absorption-band region.

The *cis*-$[Co(NO_2)_2(OO)_2]^{3-}$ complexes (OO = CO_3^{2-}, ox^{2-}) have been prepared, but their optical resolutions have not been reported.[9] The *cis*-$[Co(NO_2)_2(CO_3)(ox)]^{3-}$ complex was optically resolved with $(+)_{589}[Co(en)_3]Br_3$, while the *cis*-$[Co(NO_2)_2(ox)_2]^{3-}$ complex was not resolved by using resolving agents. The optically active bis(oxalato) isomer was derived from the optically resolved $[Co(NO_2)_2(CO_3)(ox)]^{3-}$. The rates of the racemization of the two dinitro complexes were very slow, so the recorded CD spectra did not need to be corrected. The $[Co(NO_2)_2(CO_3)_2]^{3-}$ complex was rapidly racemized in an aqueous solution. The half-life of the optical activity was *ca.* 80 s at 5 °C. The recorded CD spectral curves were also corrected by the method described in the case of *cis*-$[Co(CN)_2(CO_3)_2]^{3-}$. The corrected spectrum exhibits two extrema, with opposite signs, at 16400 and 19200 cm^{-1}, the extremum at the lower frequency being extremely weak.

It is characteristic that almost the whole of the dicarbonato complex in a solution could be deposited as a less-soluble diastereoisomeric salt by adding excess amounts of a resolving agent and an organic solvent; the crop of the crystals and the rate of crystallization were controlled by the amount of organic solvent added, but the optical purity was independent of the conditions. Moreover, the $\Delta\varepsilon$ value of the dominant peak in each dicarbonato complex is comparable with that in the corresponding carbonatooxalato complex, as is shown in Table 1. The high-yield resolution of the dicarbonato complexes can be explained by a so-called second-order asymmetric process.[12,13]

As to the *cis*-$[Co(NH_3)_2(CO_3)_2]^-$ complex, $Li(-)_{589}$-$[Co(NH_3)_2(CO_3)_2]$ has been deposited in the presence of $(-)_{589}[Co(ox)(en)_2]^+$, with the yield far exceeding 50%.[14] However, the $[Co(CN)_2(CO_3)_2]^{3-}$ and $[Co(NO_2)_2(CO_3)_2]^{3-}$ complexes crystallized as diastereoisomeric salts. The present dicarbonato complexes racemize more rapidly than the $[Co(NH_3)_2(CO_3)_2]^-$ complex.

CD Spectra of Bis(dicarboxylato) Complexes. The CD spectral data for the enantiomers obtained from the less-soluble diastereoisomeric salts are listed in Table 1. The CD spectral changes in a series of *cis*-$[Co(CN)_2(OO)_2]^{3-}$ complexes are illustrated in Fig. 1. Except for the dicarbonato complex, the dicyano complexes exhibit two Cotton peaks, with opposite signs, in the first-absorption-band region. It is found that the peak observed on a lower-frequency side apparently increases in intensity as the member of the

chelate ring increases.

It is troublesome to decide whether the Cotton peaks of a complex with C_2 symmetry indicate three transition components or two transition components. Both interpretations have been applied to the *cis*-$[Co(a)_2(mal)_2]^-$ (a = NH_3, en/2, and tn/2) complexes which exhibit three Cotton peaks with alternating signs.[1,6] However, Gaussian analyses of both situations have given splittings of the transition components incompatible with the predictions from an angular overlap model.[15] Since the *cis*-$[Co(CN)_2(mal)_2]^{3-}$ complex, in which the transition components are considered to be well separated from one another, exhibits two extrema, we will analyze the CD spectra of the dicarboxylato complexes with two transition components.

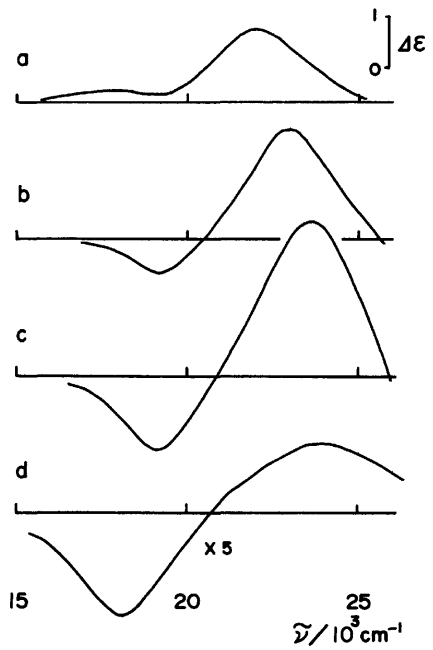

Fig. 1. CD Spectra of; a) $(+)^{CD}_{589}[Co(CN)_2(CO_3)_2]^{3-}$, b) $(-)^{CD}_{589}[Co(CN)_2(CO_3)(ox)]^{3-}$, c) $(-)^{CD}_{589}[Co(CN)_2(ox)_2]^{3-}$, d) $(-)^{CD}_{589}[Co(CN)_2(mal)_2]^{3-}$.

The angular overlap model also predicts that two of the three transition components in an octahedral parentage band will almost entirely degenerate in these dicarboxylato complexes with a holohedrized D_{4h} symmetry,[7] while the remaining one will separate well from the two components. In this situation, the Cotton peak, which increases in intensity on a lower-frequency side with the replacement of the OO chelate from CO_3^{2-} to ox^{2-} or mal^{2-}, can be assigned to the $A_{1g} \rightarrow E_g(D_{4h})$ component, while the dominant Cotton peak in *cis*-$[Co(CN)_2(CO_3)_2]^{3-}$ is attributed to $A_{1g} \rightarrow A_{2g}(D_{4h})$. Similar CD spectral changes were observed in the *cis*-$[Co(NO_2)_2(OO)_2]^{3-}$ complexes, as is shown in Fig. 2. The negative Cotton peak at a lower frequency also increases in intensity with the change from CO_3^{2-} to ox^{2-}.

These spectral changes are different from those in the *cis*-$[Co(a)_2(OO)_2]^-$ complexes (a = NH_3, py, and en/2), in which a new component has been observed on a

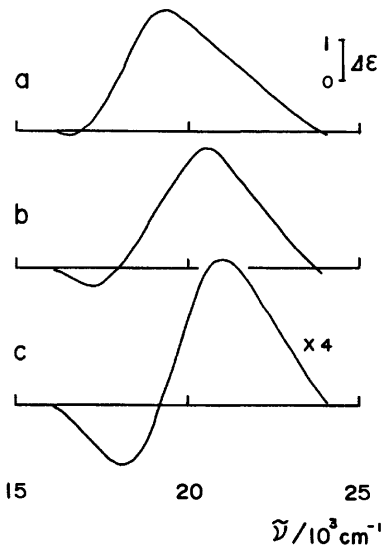

Fig. 2. CD spectra of; a) $(+)^{CD}_{589}[Co(NO_2)_2(CO_3)_2]^{3-}$, b) $(-)^{CD}_{589}[Co(NO_2)_2(CO_3)(ox)]^{3-}$, c) $(-)^{CD}_{589}[Co(NO_2)_2(ox)_2]^{3-}$.

higher-frequency side with the replacement from CO_3^{2-} to ox^{2-} or mal^{2-} and in which a single Cotton peak in each dicarbonato complex has been assigned to $A_{1g} \rightarrow E_g(D_{4h})$.[6] This difference is considered to be caused by the difference between the charges of the unidentate ligands. The unidentate a is neutral, while the cyano and nitro ligands are anionic.

Similar CD spectral changes with the ligand replacement from CO_3^{2-} to $2H_2O$ have been reported in *cis*-$[Co(N)_2(O)_4]$-[6] and *cis*-$[Co(N)_4(O)_2]$-type complexes.[16] The $(+)_{589}[Co(CO_3)(mal)(NH_3)_2]^-$ and $(-)_{589}[Co(CO_3)(NH_3)_2(py)_2]^+$ complexes exhibit (−) and (+) Cotton peaks from a lower frequency in the first-absorption-band region. When the $(-)_{589}$-$[Co(mal)(NH_3)_2(H_2O)_2]^+$ and $(-)_{589}[Co(NH_3)_2(py)_2$-$(H_2O)_2]^{3+}$ complexes are derived from these optically active carbonato complexes, two Cotton peaks, with (+) and (−) signs, from a lower frequency are observed. This phenomenon has been explained in terms of a crystal-field model of the rotatory strength in transition-metal complexes: the spectral change is ascribed to a change in the effective charge on donor atoms according to aquation.[17] Therefore, the CD spectral changes in the dicyano and dinitro complexes are regarded as the second piece of evidence indicating an intimate relation between the effective charge of donor atoms and the Cotton signs.

When a $(-)^{CD}_{589}[Co(CN)_2(ox)(H_2O)_2]^-$ complex was derived from the $(-)^{CD}_{589}[Co(CN)_2(CO_3)(ox)]^{3-}$ complex, no drastic change in the CD spectrum was observed. However, a decrease in the negative Cotton peak at a lower frequency, compared with that of the parent carbonato complex, was detected.

The Influence of Anions on the Distribution Coefficients of Hard Acid-Metals for Anion-exchange Resin in $HF-H_3BO_3$ Media

Takeo ADACHI,* Hideyo YOSHIDA, Kimie IZAWA, and Sorin KIHARA†
Analytical Chemistry Laboratory, Japan Atomic Energy Research Institute, Tokai, Ibaraki 319-11
(Received October 17, 1983)

The distribution coefficients, K_d, of eighteen hard acid-metal ions for a strongly basic anion-exchange resin were determined in $HF-H_3BO_3$ media in the presence of Cl^- or NO_3^-, SO_4^{2-}, and ClO_4^-, and the relation between the adsorbabilities of the coexisting anions and the K_d values of the metal ions was discussed. The fluoride-ion concentration is quite low in $HF-H_3BO_3$ media because of the complex formation of the fluoride ion with boric acid, and most of the hard acid-metal ions have lower K_d values in $HF-H_3BO_3$ media than those in a hydrofluoric acid solution. By varying the kinds of coexisting anions and their concentrations in $HF-H_3BO_3$ media containing less than 0.02 M (1 M = 1 mol dm^{-3}) of fluoroborate ions, the K_d values of metal ions can be controlled to allow the anion-exchange separations. As fluoroborate ions, *e.g.*, BF_4^- or BF_3OH^-, are strongly adsorbed on the resin, metal ions which are strongly held on the resin can be eluted by media including fluoroborate ions in higher concentrations. By using $HF-H_3BO_3$ media and selecting the coexisting anions, an effective mutual separation of titanium-zirconium, titanium-uranium, tin-niobium, and molybdenum-tungsten can be attined.

The highly fluorinated metal complexes in a hydrofluoric acid solution change their forms to poorly fluorinated complexes when boric acid is added to the solution, because the free fluoride-ion concentration is considerably reduced by the formation of such fluoroborate ions as BF_4^- or BF_3OH^-. The free fluoride-ion concentration in $HF-H_3BO_3$ mixed media is kept constant by the buffer action due to the dissociation of fluoroborate ions, even if the free fluoride ions are consumed by the complex formation with coexisting metal ions. As the fluoroborate ions in the mixed media are strongly adsorbed on the anion-exchange resin, metal-anion comlexes held on the resin can be eluted by the aid of fluoroborate ions in a increased concentration.

In the previous paper,[1] the usefulness of $HF-H_3BO_3$ media in the anion-exchange separation of hard acid-metals was reported and it was also pointed out that a more effective mutual separation of metals can be attained if nitrate ions coexist in the mixed media.

In the present paper, for the extensive application of the mixed media in the ion-exchange separation, the distribution coefficients of metal ions on the anion-exchange resin are determined in mixed media containing various anions, and the relation between the distribution coefficients and the adsorbabilities of anions on the resin is discussed.

Experimental

Chemicals and Apparatus. The standard solutions of the metal ions were prepared by the procedures described in previous papers.[1,2] The other chemicals and apparatus were the same as those used before.

Ion-exchange Resin. A strongly basic anion-exchange resin, Diaion SA#100, a product of Mitsubishi Chemical Ind. Ltd. (8% DVB, 75—150 μm, Cl^--form), was used. After washing the resin in a column with five times as much as the column volume of 3 M HCl or HNO_3, H_2SO_4, and $HClO_4$ and with a sufficient volume of distilled water, the resin was dried to a constant weight at 70 °C and stored in a vacuum desiccator.

† Present address: Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

Determination of Distribution Coefficient. Fifty ml of a definite concentration of a hydrofluoric-hydrochloric acid solution or a hydrofluoric-boric-hydrochloric acid solution containing 2×10^{-4} M of a metal ion was added to a 150-ml polyethylene bottle containing 0.5 g of the dried resin in the Cl^--form. The bottle was then shaken gently for 24 h at room temperature. After the filtration of the resin, the metal-ion concentration in the solution was determined by a suitable method, as has been described previously.[2]

The distribution coefficient, K_d, was determined by the following equation:

K_d = (Amount of metal ion in resin / Amount of metal ion in solution) × (ml of solution / g of resin).

The K_d was also determined in the media containing sulfuric, nitric, or perchloric acid instead of hydrochloric acid by the manner described above.

Column Operation. About 4 g of the dried resin, which had been swelled well with distilled water, was packed in a polyethylene column (8 mmϕ × 180 mm), and was conditioned with about 50 ml of 0.2 M HF. After the addition of a test solution containing 1—250 mg of a metal ion in 0.2 M HF, an eluent of a definite composition was passed through the column. The effluent was then collected with a fraction collector, and the concentration of the metal ion in each fraction was determined by a method described previously.[2] In the mutual-separation experiments, two kinds of metal ions were added together to the column.

Results and Discussion

In the present experiments, the coexisting anions are added as their acid forms in order to prevent the hydrolysis of the hard acid-metals.

In the following discussion, as a criterion for ion-exchange separation, we adopt Ringbom's suggestion for the column-filtration method (*i.e.*, the K_d of an adsorbed ion is larger than 10^2—$10^{2.5}$, method (*i.e.*, the K_d of an adsorbed ion is larger than 10^2—$10^{2.5}$, while that of the emerging ion is less than $10^{0.5}$—10^1).[3]

Distribution Coefficients. The distribution coefficients of the metal ion, K_d, on strongly basic anion-exchange resin were determined in hydrofluoric-boric acid media containing Cl^-, SO_4^{2-}, NO_3^-, or ClO_4^-; they are summarized in Tables 1—4. In the third column of these tables, the K_d values in the absence of boric acid are also tabulated.

V(V) is slightly adsorbed in HF-0.05 M H_2SO_4. Al(III), V(IV), and Fe(III) are not adsorbed in either $HF-H_2SO_4$ or $HF-H_3BO_3-H_2SO_4$.

The concentration of fluoride ions and fluoroborate ions in $HF-H_3BO_3$ media in the presence of 0.1 or 1 M of nitric acid was calculated using the dissociation constants given by Sillen *et al.*[4] and Mesmer *et al.*;[5] they are shown in Fig. 1 as a function of the hydrofluoric acid concentration, C_{HF}.

Qualitatively speaking, the K_d values of metals in $HF-H_3BO_3$ media are smaller than those in the absence of boric acid, and decrease with the increase in C_{HF}, though the K_d values in HF solutions increase or stay constant. The variation in K_d values may be explained as follows: (1) As the addition of boric acid to the hydrofluoric acid solution reduces the free fluoride-ion concentration, C_{F^-} to about one hundredth (Curves b and c in Fig. 1), the fraction of metal-anion complexes to be adsorbed onto the anion-exchange resin in $HF-H_3BO_3$ media becomes smaller than that in the absence of boric acid. (2) In a hydrofluoric acid solution, with the increase in C_{HF}, C_{F^-} and also the fraction of metal-fluoride complexes to be adsorbed onto the resin are increased. On the other hand, in $HF-H_3BO_3$ media, C_{F^-} does not increase when C_{HF} is larger than 0.1 M. (3) The concentration of fluoroborate ions in the mixed media increases with the increase in C_{HF}, and the increased fluoroborate ions which are strongly adsorbed on the resin lower the K_d values of the metals.

The influence of coexisting anions on the K_d can be interpreted by considering their adsorbabilities on the anion-exchange resin. The following selectivity

coefficients of anions for the anion-exchange resin, referred to the Cl^- ion, K_{Cl}^A, were calculated from the data presented in a previous paper[1] according to the method of Wheaton *et al.*:[6] $K_{Cl}^{BF_4}$ 30, $K_{Cl}^{ClO_4}$ 30, $K_{Cl}^{NO_3}$ 3.3, $K_{Cl}^{(SO_4)_{1/2}}$ 1.4, and K_{Cl}^F 0.04. As ClO_4^- and BF_4^- are strongly adsorbed on the resin, in a solution containing more than 0.1 M of $HClO_4$ or 0.5 M HF-0.5 M H_3BO_3, which contains 0.1 M of BF_4^- and 0.05 M of BF_3OH^-, the K_d values of metal ions are extremely small and none of the metal ions presented in Tables 1-4 are adsorbed on the resin except Ta(V). With more concentrated HF-H_3BO_3 media, as is indicated in Table 5, Ta(V) comes not to be absorbed on the resin.

In the media where the concentration of $C_{BF_4^-}$ or $C_{BF_3OH^-}$ is less than 0.02 M, the effect of coexisting anions becomes significant. In 0.1 M HF-0.5 M H_3BO_3 media, which contain 0.01 M of BF_4^- and 0.02 M of BF_3OH^-, only Ta(V) is retained on the resin in the presence of 0.1 M $HClO_4$, but in the presence of 0.1 M HNO_3 or 0.1 M HCl instead of $HClO_4$, Nb(V) and W(VI) or Nb(V), W(VI), and Mo(VI) are retained in addition to Ta(V). In the media where $C_{BF_4^-}$ or $C_{BF_3OH^-}$ is further reduced, the adsorbed elements increase in

(a) ——: 0.01 M HF-0.5 M H_3BO_3-0.1 M HCl, ----: 0.1 M HF-0.5 M H_3BO_3-0.05 M H_2SO_4, (b) 0.1 M HF-0.5 M H_3BO_3-1 M HCl, (c) 0.1 M HF-0.5 M H_3BO_3-0.1 M HCl, (d) 0.1 M HF-0.5 M H_3BO_3-0.05 M H_2SO_4, (e) 4 M HF-2 M H_3BO_3-1 M HNO_3. Amount of metal ion; ○: 1 mg, ●: 100 mg, △: 250 mg.

number; *i.e.*, Zr(IV) and Hf(IV), besides Ta(V), Nb(V), W(VI), and Mo(VI), become adsorbed on the resin in 0.01 M HF-0.1 M H_3BO_3-0.1 M HCl media.

Though the discussion above has been carried out from the viewpoint of the adsorbability of a coexisting anion, there are some exceptions which cannot be explained from this point of view. It is thought that the exceptions are due to the complex formation of metal ions with anions other than the fluoride ion and to the adsorption of non-fluorinated metal-oxoacid anions, such as MoO_4^{2-} or WO_4^{2-}, on the resin.

Mutual Separation of Hard Acid-Metals by the Column Method. Referring to the K_d values in Tables 1—4, the mutual separation of hard acid-metals that had been considered to be difficult was attempted by the column method according to the procedure described in the Experimental section. It is clear from Fig. 2 that the several mutual separations described below are possible. The elution curves of metal ions in Fig. 2 are shown in integrated forms.

(a) Ti-Zr: Only one pice of literature concerning the ion-exchange separation of Ti(IV) and Zr(IV) in a solution containing hydrofluoric acid was reported by one (T.A.) of the present authors, who used an anion-exchange resin in HF-H_3BO_3-HNO_3 media.[1] As is shown in Fig. 2 (a), an effective separation can also be attained by using HCl or H_2SO_4 instead of HNO_3.

(b) Mo-W: The anion-exchange separation of Mo(VI) and W(VI) in 3 M HF-10 M HCl[7] has been the most recommended method for these ions. The difficulty with this method is that acids of a high concentration are inevitable. In HF-H_3BO_3 media, it is possible to separate Mo(VI) from W(VI) in acid mixtures of a lower concentration, *i.e.*, 0.1 M HF-0.5 M H_3BO_3-1 M HCl, as is shown in Fig. 2 (b).

(c) Sn-Nb; Adopting the HF-H_3BO_3-HCl media, an effective separation can be attained in a less concentrated acid mixture, as is shown in Fig. 2 (c). The difference *in* K_d between Sn(IV) and Nb(V) is larger than that in the HF-HCl[8] or HF-HNO_3[9] media.

(d) Ti-U: In the general method for the anion-exchange separation of Ti(IV) and U(VI), Ti(IV) was adsorbed on the resin, whereas U(VI) was eluted. On the contrary, in the HF-H_3BO_3-H_2SO_4 media, U(VI) was adsorbed and Ti(IV) was eluted, as is shown in Fig. 2. Therefore, the media are useful for the separation of Ti(IV) in samples of a uranium matrix.

The media usually used for the elution of Ta(V) from the anion-exchange resin are composed of highly concentrated salts or acids, *e.g.*, 1 M NH_4F-4 M NH_4Cl[7] or 5 M HF-12 M HNO_3.[10] Using 4M HF-2M H_3BO_3-1 M HNO_3, as is shown in Fig. 2 (e), Ta(V) can be eluted from the column.

It is obvious from the above examples that the HF-H_3BO_3 media are useful for the effective mutual separation of hard acid-metal ions. In the practical mutual separation of two components, in order to reduce the volume of the effluents it is recommended that, after one metal ion is completely eluted from the column, the other ion should be then eluted by the use of a different composition of the eluent in which the other ion has a low K_d value. Zirconium(IV), W(VI), and U(VI) are quantitatively eluted by 100 ml of 0.1 M HF-0.5 M H_3BO_3-1 M HCl, 150 ml of 0.5 M HF-0.5 M H_3BO_3-1 M HCl, and 120 ml of 0.1 M HF-0.5 M H_3BO_3-0.5 M H_2SO_4 respectively.

In addition, the fluoroboric acids in the effluent can easily be evaporated prior to the subsequent determination. The elution behavior of metal ions are not affected by the amount of metal ions, as is demonstrated in Fig. 2, because the HF-H_3BO_3 media have a buffer action relating to C_{F^-}, as has already been mentioned.[1]

Because hydrofluoric acid is indispensable in the dissolution of most hard acid-metals, it should be stressed that the HF-H_3BO_3 media will be useful for the consecutive separation of metals in a matrix of hard acid-metals.

Alkali-free Magnesium Phosphate Glasses as Nitrate-ion-selective Materials for Solid-state Electrochemical Sensors

Tsuyoshi NOMURA* and Genkichi NAKAGAWA

Laboratory of Analytical Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466

(Received November 2, 1983)

Ion-selective electrochemical sensors which respond to nitrate-ion activities have been developed. The sensor material consists of alkali-free magnesium phosphate glasses containing CuO, Al_2O_3, and SiO_2. The response characteristics have been observed strongly on the glass composition. Studies of the selectivity coefficient and the electrode function of nitrate-ion activities have shown that the most suitable glass composition is $10CuO:55P_2O_5:15MgO:10Al_2O_3:10SiO_2$. The potential response is linear over the nitrate-ion activities of (10^{-1}—10^{-5}) mol/dm^3, and it has a sub-Nernstian response of about 54 mV/decade change at 20 °C. The order of the selectivity is $NO_3^->ClO_4^->I^->NO_2^->Cl^->SO_3^{2-}\gg SO_4^{2-}$. Therefore, its use to determine the nitrate-ion activities in a solution containing perchlorate ions is suggested. The physical and chemical properties, such as the glass transition temperature, the softening temperature, the thermal expansion, the membrane resistance, and the chemical durability, were measured and compared with those of other glasses.

Solid electrodes for the determination and monitoring of nitrate ion have not been commercially available. Liquid ion-exchanger electrodes have been made, and used for the determination of nitrate-ion activities in various sample solutions.[1,2] However, common anions such as iodide and perchlorate interfere seriously, and the loss of the liquid ion-exchanger in the liquid electrodes can be expected. Some investigations of selective nitrate-ion solid-type sensors have been made. One of the solid-type sensors was made of PVC film, which included the optimum proportion of the nitrate-selective liquid-ion-exchanger in the PVC matrix,[3] and another was made by the film of the nitron-nitrate precipitate in the araldite matrix.[4]

There have been relatively few studies of the ion-selective electrode behavior of phosphate glasses.[5,6] Phosphate glasses containing iron oxide[5] have been investigated as materials of the cation selective membrane electrode for alkaline-earth cations. On the other hand, it has been suggested that the replacement of aluminium in the sodium alumino silicate glass by phosphorus can be expected to lead to anion-exchanger properties.[7]

We have already investigated some phosphate glass membranes as materials of ammonia-selective electrodes[8] and that of the hydrogen-ion-selective electrode in the hydrofluoric acid solution.[9] However, it is an important fact that some anion-responsive glass electrodes have apparently not been reported on to date.

In this investigation, the physical and chemical properties of alkali-free magnesium phosphate glasses containing various metal oxides, such as CuO, Ag_2O, Al_2O_3, and SiO_2, were measured, and a systematic check of the response behavior of those glass electrode was made. After several modifications of the glass compositions, some promising results were obtained for the solid-state nitrate-ion-selective sensors.

Experimental

Preparation of the Glass Membrane. The materials used were the following reagents. Orthophosphoric acid (85%) and tetramagnesium tris(carbonate)dihydroxide were used in all the systems. Dicopper(II) carbonate dihydroxide, silver carbonate, aluminium hydroxide, and silicon dioxide were used in the composition of each glass. The sample were prepared by melting it in a platinum crucible at 1200 °C for an hour; after melting, the glasses were annealed at a temperature 20 °C higher than the respective glass transition temperature for 20 min and then cooled.

The preparation of the phosphate glasses and the glass membranes has been described previously.[8]

The chemical compositions of some of the tested glasses are listed in Table 1.

Measurements of Physical and Chemical Properties. The glass-transition temperature (T_g, °C), the softening temperature (T_s, °C), and the thermal expansion (α, cm °C^{-1}) were measured with a Shimadzu TM-30-type dilatometer. The chemical durability of glass against water and the membrane resistance were measured by the method previously described in the literature.[9] The physical and chemical properties of some of the magnesium phosphate glasses containing CuO, Ag_2O, Al_2O_3, and SiO_2 are summarized in Table 2.

Reagents and Solutions. All the reagents were of an analytical grade unless otherwise specified. Sodium, potassium, and ammonium nitrate were used as nitrate standard solutions. Chloride, iodide, perchlorate, sulfate, nitrite, and sulfite salts of sodium were used as the sources of interfering anions. The water was twice-distilled. The activities of various anions were calculated from the concentration by means of the activity coefficients tabulated by Kielland.[10]

Measurements of the Membrane Potentials. The sensor element is sealed in the end of a cylindrical plastic tube, with one surface of the disk exposed to the test solution and the other to the internal-reference solution (0.1 mol/dm^3 $NaNO_3$). A double-junction-type saturated calomel reference electrode makes contact with the internal-reference solution (0.1 mol/dm^3 $NaNO_3$). The responses of each sensor are investigated by measuring the potential *vs.* SCE with a DKK IOC-10 ion-meter connected with a Sekonic model SS-250F recorder.

The electrode potential is strongly affected by prior conditioning in regard to its electrical resistance and the response

Table 1. Composition of the glasses

Glass No.	CuO	Ag_2O	P_2O_5	MgO	Al_2O_3	SiO_2
1	10	—	55	35	—	—
2	10	—	55	25	10	—
3	—	—	55	25	10	10
4	5	—	55	20	10	10
5	10	—	55	15	10	10
6	20	—	55	5	10	10
7	5	—	47	28	10	10
8	—	5	55	20	10	10

time. Thus, each sensor disc was polished on both sides with silicon carbide paper and then preconditioned in twice-distilled water for one day before use.

The membrane potentials for nitrate-ion and other anions are measured in a solution containing a 10^{-4} mol/dm^3 sulfuric acid solution at 20°C. The steady state of the membrane electrode is defined as a potential stable to a drift of less than 1 mV in 2 min in the stirred solution (600 min^{-1}). With stirring, the electrode potentials are read the same within 2 mV. As a result of determining the effect of the potential response on the membrane thickness, it can be said that the response rate and the reproducibility of the electrode potential are absolutely not affected within a thickness of 1 mm.

Results and Discussion

Physical and Chemical Properties of Glasses. As shown in Table 2, with the addition of the Al_2O_3 and SiO_2, the values of T_g and T_s of the tested glasses are increased. On the contrary, the values of the thermal expansion decrease with an increase in their metal oxides in the glass compositions. On the other hand, it was observed that the chemical durability of the glass with a lower P_2O_5 content (No. 7 glass) was rather worse than that of the other ultra-phosphate glasses. This fact suggest that the ultraphosphate glass corresponding to the network-forming structure seems to stabilize structurally more than the metaphosphate glass corresponding to the straight-chain structure.[11] Moreover, the addition of silicon dioxide may also be conducive to the advancement of the chemical durability because of its tendency forms network-forming.

Potential Response of the Magnesium Phosphate Glass Membrane. The potential response curves of some of the alkali-free magnesium phosphate glass membranes for the nitrate ion activities are shown in Fig. 1. The response characteristics of a magnesium phosphate glass membrane depend strongly upon its glass composition. In particular, glasses not containing Ag_2O or CuO show a small electrode function of the nitrate-ion activities, and the electrode potentials show an unstable behavior.

As shown in Fig. 1, when we compare the electrode function of the metaphosphate glass membrane (No. 7 glass) and the other ultraphosphate glass membrane containing copper(II) oxide, the latter is better than the former. Threfore, the suitable quantity of the P_2O_5 contents in the glass membrane, determined by means of an analysis of the nitrate-ion activities, was fixed at 55 mol%, with varied quantities of the other metal oxides.

Among the glasses examined, the $10CuO:55P_2O_5:15MgO:10Al_2O_3:10SiO_2$ glass membrane is the best in terms of stability, reproducibility, rapidity of response, and magnitude of the electrode function with nitrate-ion activities.

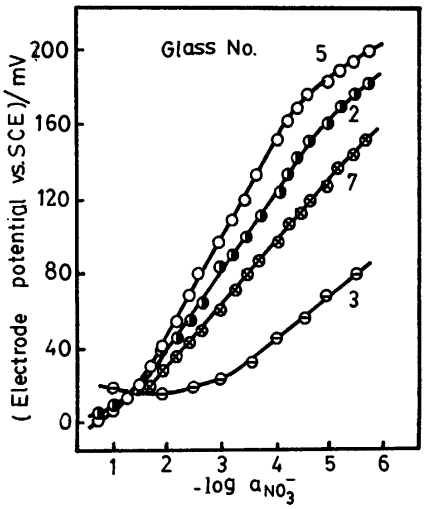

Fig. 1. Electrode response of some glasses as a function of the nitrate ion activities.
Glass compositions used in this figure were described in Table 1.

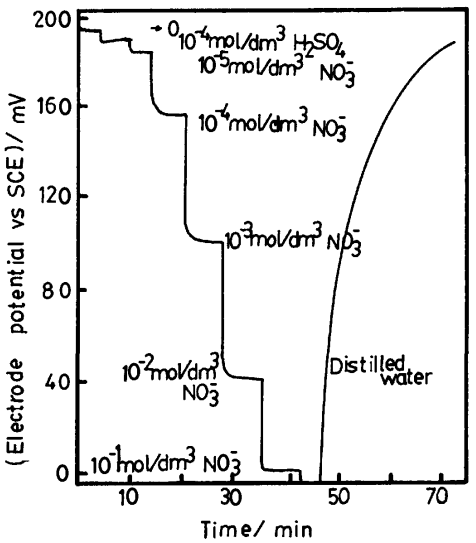

Fig. 2. Response characteristics of the No. 5 glass electrode with the nitrate ion concentration.

Table 2. Physical and Chemical Properties of the Glasses

Glass No.	Transition temperature T_g/°C	Softening temperature T_s/°C	Thermal expansion $\alpha\times10^7$/cm°C^{-1}	Chemical durability mg mm^{-2}	Memberane resistance MΩ cm^{-1}
1	508	552	125.7	2.04×10^{-2}	4.53
2	546	621	100.6	2.43×10^{-3}	6.31
3	637	717	91.2	8.87×10^{-3}	3.71
4	—	—	—	1.53×10^{-2}	6.68
5	589	678	99.7	8.51×10^{-3}	5.27
6	563	632	102.4	7.32×10^{-3}	3.79
7	568	628	91.7	4.73×10^{-2}	7.77
8	574	646	120.5	3.82×10^{-3}	8.93

The potential response of nitrate-ion activities for this glass membrane was linear over the range of (10^{-1}—$10^{-4.5}$) mol/dm^3, and the slope of the potential-concentration relationship shows a sub-Nernstian response of about 54 mV/decade change at 20 °C. However, when the range of the nitrate-ion activities is below $10^{-4.5}$ mol/dm^3 or above 10^{-1} mol/dm^3, the slope becomes small.

Figure 2 shows the response characteristics of the No. 5 glass electrode operated in the following manner. The electrode was first placed directly in twice-distilled water, to which a solution of 10^{-4} mol/dm^3 sulfuric acid was added, then the electrode was exposed to increasing concentrations of nitrate ions in the order of 10^{-5}, 10^{-4}, 10^{-3}, 10^{-2}, and 10^{-1} mol/dm^3 with the addition of the value-calculated sodium-nitrate solution. After recording the potential of the nitrate-ion activities to 10^{-1} mol/dm^3, the electrode was carefully washed with distilled water and then immersed in the twice-distilled water. The response rate with an increase in the concentration of nitrate-ion activities was observed to be somewhat faster than that with a decrease in the concentration of nitrate ions.

In solutions containing 10^{-1} and 10^{-4} mol/dm^3 of nitrate ions, equilibrium was reached within about 1 and 3 min respectively. However, after the electrode has been exposed to a nitrate concentration of 10^{-1} mol/dm^3, and then to concentrations decreasing to 10^{-5} mol/dm^3, the dynamic response time needed for reaching the equilibrium potential was more than 5 min. It is clear that 95% of the response times are about one minute expect in the case of nitrate-ion concentrations of less than 10^{-4} mol/dm^3.

Interferences of Diverse Anions and the Selectivity Coefficient of Nitrate Ion for the Other Anions. There were essentially no effects of the cations on the determination of nitrate ions when the magnesium phosphate glass electrode was used.

The effect of common anions on the determination of nitrate-ion activities was determined by means of the potential-concentration curve, and the order of magnitude of the selectivity, as regards all of the glass electrodes examined, was defined as: $NO_3^- > ClO_4^- > I^- > NO_2^- > Cl^- > SO_3^{2-} \gg SO_4^{2-}$. Therefore, sodium sulfate or sulfuric acid is used to adjust the ionic strength. The electrode function of the nitrate-ion activities and the selectivity coefficients of some of the coexisting anions for the magnesium phosphate glass electrodes are listed in Table 3. The selectivity coefficients were deternined by the mixed solution method.[12] The values of the selectivity coefficients are calculated by means of the electrode potential, with fixed quantities of the interfering ion (0.1 mol/dm^3) and a varied activity of the nitrate ions.

The selectivity coefficients of ClO_4^- and NO_2^- with the No. 5 glass electrode are smaller than that of the liquid ion-exchanger nitrate-ion selective electrode,

Table 3. Electrode function of nitrate-ion activities and selectivity coefficients of various anions

Glass No.	Electrode function mV/pa$_{NO_3^-}$	Selectivity coefficient×10^2				
		Cl^-	ClO_4^-	SO_4^{2-}	NO_2^-	SO_3^{2-}
1	31.1	—	—	—	—	—
2	42.0	3.98	15.8	0.63	1.26	2.09
3	21.3	—	—	—	—	—
4	41.6	4.57	11.7	0.59	11.2	8.73
5	54.2	3.36	7.52	0.67	3.98	1.84
6	38.5	6.31	3.16	1.58	9.32	5.25
7	35.3	16.5	21.9	5.25	10.7	7.41
8	42.6	12.6	63.1	5.01	25.1	14.5

and the electrode potentials of mixed nitrate-perchlorate solutions indicate that the effect of the perchlorate ion on a concentration of about 0.01 mol/dm^3 can be neglected for the determination of nitrate ions at concentrations above 7.5×10^{-4} mol/dm^3.

As is obvious from the results shown in Table 3, Nos. 1, 3, and 7 glasses can not be used as ion-selective electrodes because of their poor chemical durability and small electrode function. Moreover, No. 8 glass is also observed to have a poor selectivity for the other anions.

The selectivity coefficient and the electrode function show that the No. 5 glass is better for use as an ion-selective glass sensor for nitrate-ion activities than the other glasses.

We wish to thank Professor Yoshihiro Abe for his valuable advice.

Characterization of Cobalt(III) Complex with 2-Aminoethaneseleninate. Spontaneous Resolution and Crystal Structure of $(-)^{CD}_{500}$-(2-Aminoethaneseleninato)bis(ethylenediamine)cobalt(III) Nitrate

Ken-ichi Okamoto,* Takumi Konno, Masayo Nomoto, Hisahiko Einaga,† and Jinsai Hidaka

Department of Chemistry, University of Tsukuba, Sakura, Ibaraki 305

†*Institute of Materials Science, University of Tsukuba, Sakura, Ibaraki 305*

(Received December 3, 1983)

The crystal structure and the absolute configuration of the spontaneously resolved title complex cation, $(-)^{CD}_{500}$-$[Co(aesei)(en)_2]^{2+}$, has been determined by X-ray diffraction. The red crystalline needle was monoclinic, space group $P2_1$, $a=9.572(4)$, $b=10.410(3)$, $c=8.838(5)$ Å, $\beta=115.35(3)°$, $Z=2$, and the final R value was 0.035 for 2358 independent reflections with $|F_o|>3\sigma(|F_o|)$. The crystal used showed a negative CD value at 500 nm and had Δ configuration. The 2-aminoethaneseleninate is bound to the cobalt atom by the nitrogen and oxygen atoms, and the asymmetric selenium atom takes an S configuration. The value of the protonation constant (pKa) was determined to be 1.91 ± 0.05, on the basis of the major absorption spectral change at 304 nm of the title complex by spectrophotometric titration ($\mu=1.0$ mol dm^{-3} ($NaClO_4$) and 25 °C). The electronic absorption and CD spectral behavior were compared with those of the related sulfinato complexes, in which the *S*-bonded sulfinato complex, $(+)^{CD}_{500}$-$[Co(S(O)_2CH_2CH_2NH_2)(en)_2]^{2+}$, was resolved in this work.

The structure and bonding for the cobalt(III) complexes with selenium- or sulfur-containing bidentate ligands have been studied in some detail.[1-12] These complexes have only Co-Se or Co-S bonding, except for the (2-aminoethanesulfinato-N,O)bis(ethylenediamine)cobalt(III), $[Co(aesi\text{-}N,O)(en)_2]^{2+}$, obtained by photochemical preparation.[6,7] The (2-aminoethaneseleninato)bis(ethylenediamine)-cobalt(III), $[Co(aesei)(en)_2]^{2+}$, was obtained by treatment of the (2-aminoethaneselenolato)bis(ethylenediamine)cobalt(III), $[Co(aes)(en)_2]^{2+}$, with excess hydrogen peroxide. The aesei acts as a bidentate ligand and takes either of the two coordination modes, aesei-N,Se or aesei-N,O. The *S*-bonded sulfinato complex, which is obtained by a similar procedure to the aesei complex, takes up the nitrogen and sulfur coordinations, and the primary coordination sphere of the cobalt atom remains intact throughout the oxidation process.[2,10] Therefore, there has been no real evidence for the coordination mode of the seleninato complex except for the anticipation on the basis of the electronic absorption spectra of the related sulfinato complexes.[2,6,7]

The present paper deals with the preparation and spontaneous resolution of $[Co(aesei)(en)_2](NO_3)_2$. The crystal structure and absolute configuration of the $(-)^{CD}_{500}$ aesei isomer are established by X-ray diffraction studies and an investigation based on the CD spectra. The electronic absorption and CD spectra in solution of the aesei complex are discussed in comparison with the related sulfinato complexes, in which the $[Co(aesi\text{-}N,S)(en)_2]^{2+}$ isomer was resolved in this work. A preliminary report has been presented.[12]

Experimental

1) Preparation and Resolution of the Complexes. a) Spontaneous Resolution of $[Co(aesei)(en)_2](NO_3)_2$: An excess amount of 5% aqueous H_2O_2 (5 cm^3) was added to a solution containing 0.4 g of $[Co(aes)(en)_2](NO_3)_2$[9] in 7 cm^3 of water, followed by addition of 2 cm^3 of 15% HNO_3. The solution was stirred for 20 min and stood in a refrigerator for a day. The solution was adjusted to pH 7 by the addition of an queous solution of NaOH and concentrated with a rotary evaporator. The resultant seleninato complex was collected by filtration. The spontaneous resolution of the nitrate salt was observed for the needle crystals as follows; the racemic nitrate was dissolved in a small amount of water at room temperature and when the solution was kept in a refrigerator overnight, the spontaneously resolved red complex was obtained as fairly large needle crystals. A piece of one of these crystals was used for the X-ray diffraction study.

b) $(+)^{CD}_{500}$-$[Co(aesei)(en)_2](ClO_4)_2$: The $(+)^{CD}_{500}$ aesei isomer was obtained by the same procedure as that used in a), using the $(+)^{CD}_{500}$-$[Co(aes)(en)_2](ClO_4)_2$ isomer[11] instead of the racemic nitrate. This isomer shows the identical electronic absorption and CD spectra as the spontaneously resolved $(+)^{CD}_{500}$ isomer. Found: C, 13.21; H, 4.27; N, 12.94%. Calcd for $[Co(aesei)(en)_2](ClO_4)_2\cdot0.5H_2O=CoC_6H_{22}N_5O_{10}SeCl_2\cdot0.5H_2O$: C, 13.29; H, 4.28; N, 12.92%.

c) $(+)^{CD}_{500}$-$[Co(asei\text{-}N,S)(en)_2](ClO_4)_2$: This $(+)^{CD}_{500}$ aesi isomer was obtained by the same procedure as that used in b), using the $(+)^{CD}_{500}$-$[Co(SCH_2CH_2NH_2)(en)_2](ClO_4)_2$ isomer[9] instead of the $(+)^{CD}_{500}$-$[Co(aes)(en)_2](ClO_4)_2$ one. The analytical result was obtained from the racemic nitrate salt. Found: C, 16.71; H, 5.62; N, 22.91%. Calcd for $[Co(aesi\text{-}N,S)(en)_2](NO_3)_2\cdot H_2O=CoC_6H_{22}N_7O_8S\cdot H_2O$: C, 16.79; H, 5.63; N, 22.84%.

2) General Data. The electronic absorption spectra were recorded with a JASCO UVIDEC-1 spectrophotometer, and the CD spectra, with a JASCO J-20 spectropolarimeter. All measurements were carried out in aqueous solution at room temperature. The calculations were carried out on a FACOM M-200 computer at the University of Tsukuba. The protonation constant was determined by measuring the adsorbance at 304 nm in aqueous media at 25 °C and $\mu=1.0$ mol dm^{-3} ($NaClO_4$). The hydrogen ion concentration was measured with a HORIBA pH meter (F7-SS).

3) X-Ray Characterization. The unit cell parameters and intensity data were measured on a Rigaku-denki automated four-circle diffractometer (AFC-5) with a graphitemonochromatized Mo $K\alpha$ radiation ($\lambda=0.710690$ Å). A spontaneously resolved needle crystal with approximate dimensions of $0.03\times0.07\times0.7$ mm^3 was used for the intensity measurements. The unit cell parameters were determined by least-squares refinement based on 20 reflections. The systematic absence led to the space group $P2_1$. Crystal data: $CoC_6H_{22}N_7O_8Se$, $M.W.=458.2$, monoclinic, space group $P2_1$, $a=9.572(4)$, $b=10.410(3)$, $c=8.838(5)$ Å, $\beta=115.35(3)°$, $V=795.9(6)$ Å^3, $D_m=1.90$ g cm^{-3} (by the flotation), $D_x=1.91$ g cm^{-3}, and $Z=2$.

The intensity data were collected by the ω-2θ scan technique with a scan rate of 3 ° min^{-1}. During the course

of the data collection, three reflections were monitored every 40 reflections. The intensity data were converted to the Fo data in the usual manner. Absorption corrections were not applied. A total of 2603 reflections up to $2\theta=60°$ was collected, of which 2358 independent reflections with $|F_o|>3\sigma(|F_o|)$ were considered as 'observed' and used for the structure analysis.

Determination of the Crystal Structure

1) Solution and Refinement of Structure. The positions of the cobalt and selenium atoms were obtained from the three dimensional Patterson function. The difference-Fourier maps based on the cobalt and selenium positions revealed all non-hydrogen atoms. The structure was refined by a full-matrix least-squares refinement of the positional and anisotropic thermal parameters of all the non-hydrogen atoms (program RFINE by L. W. Finger, as modified by H. Horiuchi, was used). The neutral atomic scattering factors for all the non-hydrogen atoms were taken from the literature.[13] The final residual values were $R=0.036$ and $R_w=0.049$, respectively.

2) Determination of the Absolute Configuration. The absolute configuration was determined by the anomalous scattering technique. The anomalous dispersion corrections, $\Delta f'$ and $\Delta f''$, for all the non-hydrogen atoms were taken from the literature.[13] When the refinements were carried out by the use of a set of the atomic parameters containing the Δ configuration of the complex cation, the residual values converged to $R=0.035$ and $R_w=0.046$, respectively. On the contrary, the refinements in the enantiomeric atomic parameters (the Λ configuration) resulted in the residual values of $R=0.041$ and $R_w=0.055$, respectively. These facts indicate that the former is probably the correct choice, namely, the complex cation has the Δ configuration. A similar relationship between the residual values and the absolute configuration was observed for the determination of the crystal structure of cobalt(III) complexes with the *S*-(2-aminoethyl)-L-homocysteinate.[14,15] The crystal, which was used for this X-ray intensity measurement, showed the enantiomeric CD curve for that of the $(+)^{CD}_{500}$-[Co(aesei)$(en)_2]^{2+}$ isomer derived from the $(+)^{CD}_{500}$-[Co(aes)$(en)_2]^{2+}$ one. This is in line with the result that the $(+)^{CD}_{500}$ aesei isomer has been assigned to the Δ configuration from the comparison with the CD spectrum of the Δ-[Co(mea)$(en)_2]^{3+}$ isomer mea; 2-(methylthio)ethylamine).[9,11]

The final atomic parameters with their estimated standard deviations are given in Table 1. A list of structure factors and anisotropic thermal parameters of the non-hydrogen atoms is kept at the Chemical Society of Japan as Document No. 8416.

a) B_{eq} is the equivalent isotropic temperature factor defined by Hamilton.[24]

Results and Discussion

Description of the Structure. Perspective drawing of the complex cation obtained is given in Fig. 1 and its packing mode is illustrated in Fig. 2. The bond lengths and angles with their estimated standard deviations in the complex are summerized in Table 2. The coordination geometry around the cobalt atom is approximately octahedral. The 2-aminoethaneseleninate coordinates to cobalt atom with the nitrogen and oxygen atoms instead of the nitrogen and selenium ones in the starting complex, $[Co(SeCH_2CH_2NH_2)(en)_2]^{2+}$ [3] in contrast to the case of the related sulfinato complex whose coordinated atoms remain intact during the oxidation process.[2] This suggests that the treatment of the selenolato complex with excess hydrogen peroxide is accompanied by linkage isomerization and the *O*-bonded seleninato complex is obtained. The asymmetric selenium atom in the Δ-$(-)^{CD}_{500}$-[Co(aesei-N,O)$(en)_2]^{2+}$ takes the *S* configuration as shown in Fig. 1.

The bond lengths and angles are similar to those for the [Co$(en)_2$(L)] type complexes, where L denotes the selenium- or sulfur-containing bidentate ligands.[1-5,8,14,15] The selenium-oxygen bond lengths,

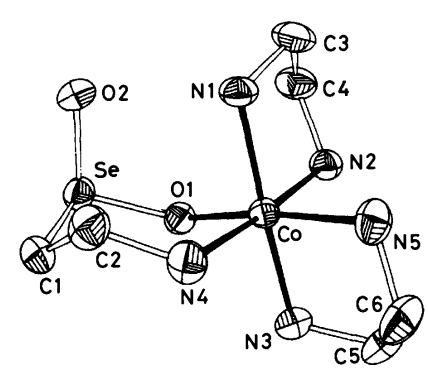

Fig. 1. A perspective drawing of Δ-$(-)^{CD}_{500}$-[Co(aesei-N,O)$(en)_2]^{2+}$ with the numbering scheme of atoms.

Se-O1 and Se-O2, are 1.698(4) and 1.680(4) Å, respectively. They are longer than those of the sulfur-oxygen ones (1.456 and 1.476 Å) in the [Co(aesi-N,S)-(en)$_2$](ClO$_4$)·(NO$_3$).[2] The bond angle of O1-Co-N4 for the six-membered chelate ring is 95.6(2)°, which is consistent with that of the cobalt(III) complexes containing amino carboxylate.[16,17] The bond angles around the selenium atom are about 100°, and this value seems tobe reasonable for the selenium atom whose tetragonal positions are occupied by the three bonding pairs and a lone pair.[18]

O21-N21-O23	120.4(7)	O22-N21-O23	122.2(7)

In the present complex cation, the two gauche conformations, δ and λ, are possible for each of the two ethylenediamine chelate rings.[1-5,8,17] As shown in Fig. 1 and Table 3, both of the ethylenediamine chelate rings in the Δ-$(-)^{CD}_{500}$-[Co(aesei-N,O)(en)$_2$]$^{2+}$ isomer take up the reasonable λ gauche conformation. The six-membered chelate ring (O1-Se-C1-C2-N4) of the coordinated aesei ligand takes up a chair conformation (Table 3) and dihedral angle for the two-planes, O1-Co-N4 and Se-C1-C2, is 24.5°. This suggests that the six-membered chelate ring is distorted from the normal chair conformation, because the bond lengths and angles around the selenium atom are larger than those around the carbon atom (Table 2).

The crystal structure consists of the complex cations and nitrate anions, and the distance between the two nitrate anions is 3.140(8) Å. The O2-N2 and O2-N3 distances between adjacent complex cations are

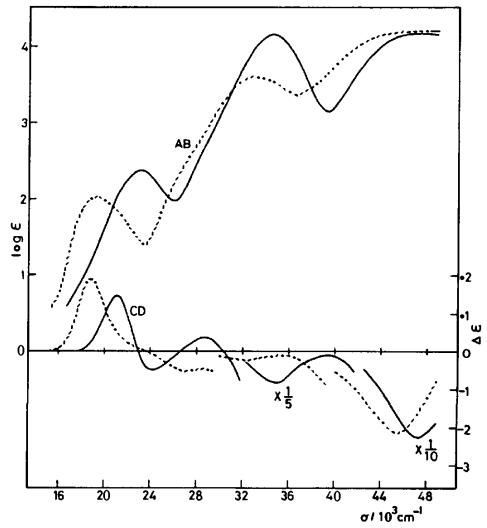

Fig. 4. Absorption and CD spectra of $(+)^{CD}_{500}$-[Co(aesei-N,S)$(en)_2]^{2+}$ (------) and $(+)^{CD}_{500}$-[Co(aesi-N,S)$(en)_2]^{2+}$ (——).

2.802(7) and 2.827(6) Å, respectively. In addition, the distances between the nitrogen atoms of the complex cation and the oxygen atoms of the nitrate anions are from 2.948 Å to 3.091 Å, as shown in Fig. 2. These distances suggest that they are hydrogen bonds.

Protonation Constant. The absorption spectral changes were reversible and an acid-base equilibrium is indicated. The value of the protonation constant (pK_a) is calculated from the following equation.

$$pK_a = -\log\gamma_H + pH_{meas} - \log\{(A_{HL}-A)/(A-A_{L^-})\},$$

where A_{HL} and A_{L^-} are the absorbances of acid and base, respectively, and A is the absorbance containing both of them. The γ_H is the activity coefficient of hydrogen ion and the value, $-\log\gamma_H = 0.13$, is calculated by the Debye-Hückel equation.[19] The value of pH_{meas} at $-\log\{(A_{HL}-A)/(A-A_{L^-})\}=0$ is determined to 1.78 ± 0.05 by least-squares treatment from Fig. 3. As a result, the value of pK_a can be determined to be 1.91 ± 0.05. The corresponding sulfinato complex, [Co(aesi-N,O)$(en)_2]^{2+}$, gave a pK_a of -0.7 (8 mol dm^{-3} ($NaClO_4$) uncorrected for H^+ activity coefficient changes).[6] This is consistent with the conclusion that the selenium atom is more "basic or soft" than the sulfur atom.[20]

Electronic Absorption and CD Spectra. The electronic absorption and CD spectra of the *A*-$(+)^{CD}_{500}$-[Co(aesei-N,O)$(en)_2]^{2+}$ isomer are shown in Fig. 4 and their data are summarized in Table 4, together with the related sulfinato complex, $(+)^{CD}_{500}$-[Co(aesi-N,S)$(en)_2]^{2+}$. This aesei isomer, which belongs to the [Co(O)$(N)_5$] type, exhibits a broad band with a vague shoulder on the higher energy side in the first absorption band region. This absorption behavior agrees well with those for the [Co(amino-carboxylato)$(en)_2$] type complexes.[21-23] The intense absorption band at *ca.* $33\times10^3\,cm^{-1}$ is weaker than that of the *Se*-bonded or *S*-bonded cobalt(III) complexes (Fig. 3 and Table 4) [2,3,5-11] Since the seleninate moiety can still interact with a cobalt center (Fig. 1), this absorption band seems to be a new charge transfer band from the seleninato chromophore to the cobalt atom. A similar absorption spectral trend was also observed for the photoproduct of the [Co(aesi-N,S)-$(en)_2]^{2+}$ complex.[6,7]

The CD spectrum shows a positive band in the first absorption band region (Fig. 4). This CD spectral behavior is consistent with those of the *A*-[Co(amino-carboxylato)$(en)_2$] type complexes.[21-23] These facts suggest that the asymmetric selenium atom contributes little to the CD band in this region. The $(+)^{CD}_{500}$-[Co(aesi-N,S)$(en)_2]^{2+}$ isomer exhibits a similar CD spectrum to that of *A*-$(+)^{CD}_{500}$-[Co(aesei-N,O)$(en)_2]^{2+}$ over the whole region, although the absorption and CD spectra of the latter shift to lower energy than those of the former. This seems to suggest that the $(+)^{CD}_{500}$ aesi isomer is also in the *A* configuration.

Pyrolytic Sulfurization Gas Chromatography. XVI. Pyrolytic Sulfurization Reaction at Atmospheric Pressure and Its Application to the Identification of Carbon, Hydrogen, Oxygen, and Nitrogen in Organic Components

Tadashi HARA* and Fujio OKUI

Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602

(Received December 5, 1983)

A new method by which the component elements: C, H, O, and N, in an organic compound can be simply, rapidly, and economically identified was established on the basis of the reaction of an organic compound with sulfur at atmospheric pressure. The apparatus for this method consists of two gas chromatographs and an original reactor for reacting an organic compound with sulfur vapor. One component separated from a given mixture by the use of one gas chromatograph was made to react with sulfur vapor in the original reactor and then the reaction products were analyzed by the use of the other gas chromatograph. The reaction products were restricted to seven kinds of compounds irrespective of the chemical structure of the target component. According to this method, the component elements: C, H, O, and N, in an organic compound could be easily identified by the reaction products within 20 min with a detection limit of a few pmol.

It is well known that gas chromatography-mass spectrometry(GC-MS) and atomic emission spectrometry(AES) using inductively coupled plasma (ICP) or microwave induced plasma(MIP) excitation are useful tools for identifying or determining component elements in a sample. However, the component elements in a sample cannot be easily identified or determined by means of GC-MS, though GC-MS can in principle clarify the chemical structure of a compound which can vaporize at relatively low temperature by its fragmentation. But complicated data analysis is required to clarify the chemical structure of the compound. On the other hand, though the component elements in a sample are easily identified by means of ICP- or MIP-AES, the applicable elements are restricted to heavy elements, such as metal elements. Few reports concerning the identification of light elements such as C, H, O, and N are available.[1-3] Moreover, both mass spectrometry and AES have the following disadvantages: 1) The apparatus is very expensive, 2) the system is very complicated, and 3) data analysis is very troublesome. Accordingly, it is now difficult to identify simply or to determine the component elements in an organic compound by means of instrumental analysis. Therefore, a new method by which the light elements such as C, H, O, and N in an organic compound can be simply, rapidly, and economically identified was investigated and successfully established. This method is based on the reaction of an organic compound with sulfur vapor at atmospheric pressure in the flow of sulfur vapor: A target component separated from a given mixture by gas chromatography is introduced to the reactor and is made to react with sulfur vapor, and then the resulting products are analyzed by gas chromatography. The apparatus used for this method consists of two gas chromatographs and an original reactor, in which a target component reacts with sulfur. The apparatus is set up by linking one gas chromatograph, the pyrolytic sulfurization reactor, and the other gas chromatograph in series in that order. This method will therefore be called "gas chromatograph-pyrolytic sulfurization reactor-gas chromatography (GC-PSR-GC)". By using GC-PSR-GC under the optimum conditions, carbon in an organic compound is mainly converted to carbon disulfide (CS_2) and/or carbonyl sulfide (COS), hydrogen to hydrogen sulfide (H_2S), oxygen to COS, and nitrogen to hydrogen cyanide (HCN). Therefore, the component elements, C, H, O, and N, in a target component can be successfully identified by observing four kinds of reaction products: CS_2, COS, H_2S, and HCN. The time necessary for an analysis by GC-PSR-GC is about 20 min.

Experimental

Reagents. The sulfur used as a reaction agant with a sample was obtained by purifying[4] commercially available sulfur (chemical pure). The organic compounds used as standard samples were of reagent grade; their purities were confirmed by gas chromatography. Helium as a carrier gas was purified in the present apparatus by passing through a stainless steel column(3 cm i.d. and 18 cm long) packed

with Molecular Sieve 5A (60—80 mesh) and a copper column (8 mm i.d. and 35 cm long) packed with sponge granular copper(12—25 mesh) heated at 380 °C.

Apparatus. The apparatus constructed for this study is schematically illustrated in Fig. 1. This apparatus consists of the following four sections: 1) Introduction section of a target component, 2) generation and condensation section of sulfur vapor as a reaction agent, 3) reaction section of the component with sulfur vapor, and 4) analysis section of the reaction products. The sections are constructed in the following detailed manners:

Section 1: A gas chromatograph(Shimadzu GC-4CPT)-I (GC-I) (C) mounted with a four-way cock(E) held at 180 °C was used for the introduction of a target component to the pyrolytic sulfurization. GC-I was operated under the optimum conditions for a sample, except that the flow rate of He as a carrier gas was set at 11 cm^3/min. All the stainless steel tubing (1.5 mm o.d. and 1.0 mm i.d.) (M) used to introduce a target component to the reactor were held at 180 °C, so as to prevent the condensation of the component in the tube.

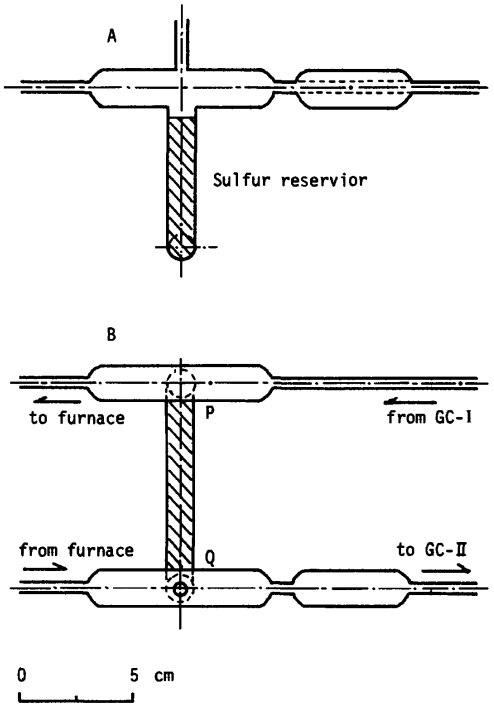

Fig. 2. The apparatus for supplying and recovering sulfur vapor.
A: Front view and B: plain.

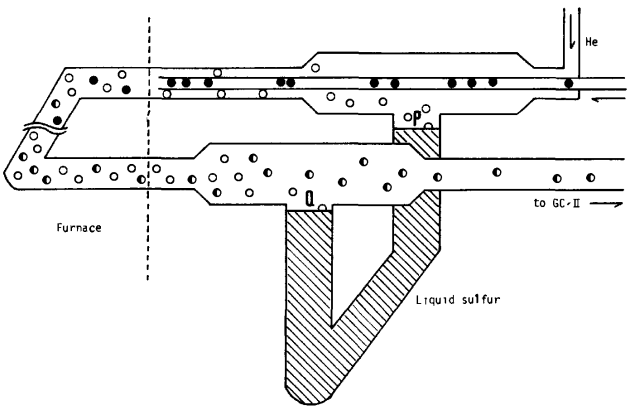

Fig. 3. The system of the pyrolytic sulfurization reaction.
○: Sulfur, ●: sample, and ◐: products.

Section 2: The quartz-made apparatus (J) by which sulfur vapor could be supplied and recovered was designed and constructed; this is shown in Fig. 2. Sulfur vapor was generated from the position P in Fig. 2 by heating it at 350 °C and was carried into the reaction section by He at a flow rate of 4 cm^3/min; then the sulfur vapor was condensed at the position Q held at 150 °C. Sulfur trap column (4 mm i.d., 6 mm o.d., and 10 cm long) (K) packed with quartz wool was connected with this apparatus for completely eliminating sulfur mist.

Section 3: A spiral quartz tube(2.5 mm i.d., 4 mm o.d., and 5 m long) (I) was used as a reaction tube by placing it in a electric furnace (Seiwa Riko Co. Ltd., FDH-15) heated at 900 °C.

Section 4: A gas chromatograph (Shimadzu GC-4CPT)-II (GC-II) (D) mounted with two six-way cocks (F and G) and a stainless steel column (3 mm i.d., 4 mm o.d., and 50 cm long) (L) for trapping the reaction products was used for analyzing the reaction products; the trap column was packed with Silica gel (60—80 mesh). The reaction products could be trapped in this column at room temperature and released from this column by heating it to 250 °C. GC-II was operated under the following conditions: A 0.25 m stainless steel column D_1 was packed with Chromosorb 104 (80—100 mesh), a 1.75 m stainless steel column D_2 with Porapak QS (80—100 mesh), and a 0.2 m stainless steel column D_3 with Deactigel (60—80 mesh) were used by linking them in series in that order. The column temperature was programmed between 80 and 185 °C at the rate of 20 °C/min. The flow rate of He carrier gas was 30 cm^3/min at room temperature.

The system for the pyrolytic sulfurization reaction between a target component and sulfur vapor by the use of the present apparatus is illustrated in Fig. 3. The component gas and sulfur vapor were mixed just before the entrance of the furnace and then the mixture components were made to react in the furnace. The reaction products thus obtained and the excessive sulfur over the pyrolytic sulfurization reaction were separated at the position of the condenser (Fig. 3, Q) by condensing the excessive sulfur vapor to liquid sulfur, and only the reaction products were introduced to the analysis system by GC-II. Therefore, this system for supplying and recovering sulfur makes it possible to minimize the sulfur consumption necessary for the analysis and allows the excessive sulfur to be reused for the next analyses.

Procedure. Several decimilligrams of a sample, either a single compound or a mixture, was injected into GC-I by the use of a microsyringe and the elution behavior of the sample was monitored by the thermal conductivity detector installed in GC-I. The target peak of the sample to be analyzed was introduced to the reactor of pyrolytic sulfurization by operating the four-way cock E, and other compounds, if present, were sent from the exit at the same time. The target component was mixed with sulfur vapor generated from a sulfur generator just before the furnace. Then their mixture were subjected to react for about 1 min during the passage through the reaction tube heated at 900 °C by the electric furnace. The products thus obtained were separated from the excessive sulfur and only the products were trapped by the trap column L at room temperature for 2.5 min after the elution from GC-I. The reaction products trapped were released from the trap column and introduced to GC-II by operating two six-way cocks (F and G) and by heating the trap column rapidly to 250 °C, followed by analysis by the use of GC-II. The peak areas of the products on the gas chromatogram of GC-II were read out by the use of

the integrator (Shimadzu digital integrator E1A). By the use of the chromatogram thus obtained, the component elements C, H, O, and N, in the target component were qualitatively identified.

Results and Discussion

Optimization of the Reaction Conditions between a Sample and Sulfur. Flow rate of carrier gas, He, for supplying a target component to the reactor was set at 11 cm^3/min, and that for supplying sulfur vapor was set at 4 cm^3/min, based on the design of the apparatus. In these experimental conditions, vaporizing temperature for supplying the sufficient sulfur necessary for the pyrolytic sulfurization of the component was examined by the use of 1 μl of toluene, which did not seem to be so reactive with sulfur (Fig. 4). Figure 4 indicates that vaporizing temperature of sulfur has to be held over about 350 °C. Therefore, the vaporizing temperature of sulfur was chosen at 350 °C as its optimum condition.

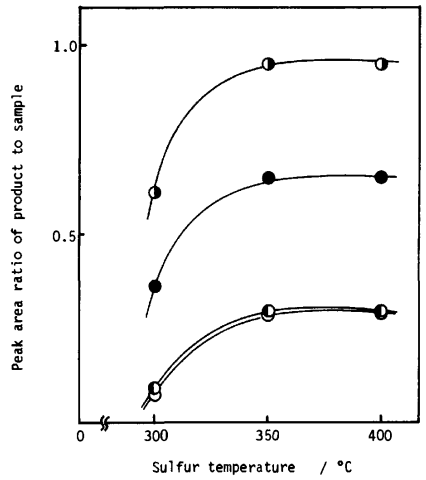

Fig. 4. Effect of the sulfur temperature on the amount of products.

Conditions: Furnace temperature 900 °C.

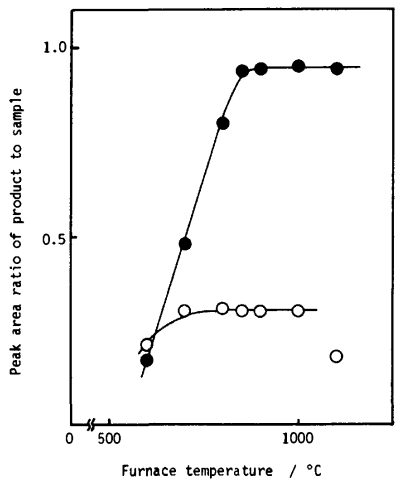

Fig. 5. Effect of furnace temperature on the amount of products.
○: H_2S and ●: CS_2. Conditions: Trap time 5 min.

The reaction temperature of the component with sulfur vapor in the electric furnace was also examined by the use of 1 μl of toluene as a standard sample; the effects of the furnace temperature on the amount of products are shown in Fig. 5. The reaction temperature has to be held over about 850 °C. Moreover, COS as a blank was produced at a temperature of over 1100 °C; this may be attributed to the fact that carbon in the component reacted with the internal surface of the reaction tube.[5] Therefore, the reaction temperature was chosen at 900 °C as its optimum condition.

Trap Time of the Reaction Products. The products from the reaction between a target component and sulfur were trapped by the stainless steel column packed with silica gel. The time necessary for trapping the products was examined; the effects of trap time on the amount of the products are shown in Fig. 6. Figure 6 indicates that a trap time over 15 min is required to trap quantitatively all the products from a target component. In the present conditions, a small

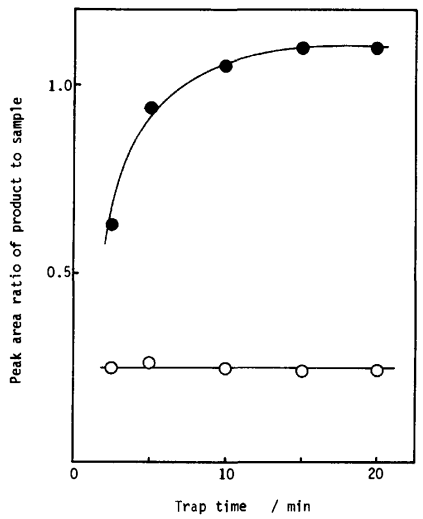

Fig. 6. Effect of trap time on the amount of products.

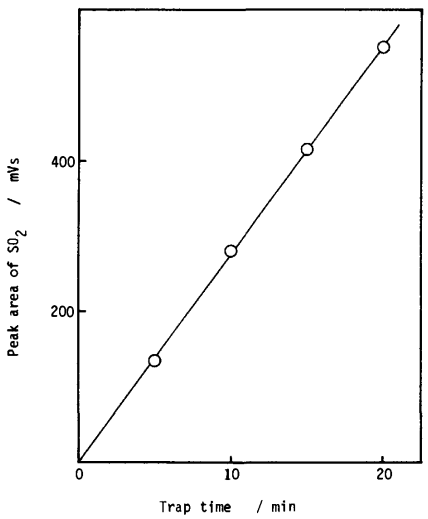

Fig. 7. Relationship between trap time and peak area of SO_2.

amount of sulfur dioxide (SO_2) was constantly produced from sulfur as its impurity, so the amount of SO_2 was measured in the range of 5—20 min of trap time by the use of the present system (Fig. 7). The amount of SO_2 is proportional to the trap time. It is generally better to minimize the analysis time and to simplify the data analysis in all qualitative identification. Therefore, the trap time for qualitative identification was chosen to 2.5 min after the elution of a target component from GC-I as its optimum condition by considering both the analysis time and the blank value of SO_2.

Reaction Products by Pyrolytic Sulfurization. The reaction products obtained by the pyrolytic sulfurization reaction under the above-mentioned conditions were investigated by subjecting several kinds of organic compounds to the GC-PSR-GC system. The reaction products were restricted to carbon dioxide (CO_2), COS, CS_2, H_2S, water (H_2O), SO_2, and HCN. Here each product was identified gas-chromatographically by analyzing a authentic sample. The results showed that carbon in an organic compound is converted to CO_2, COS, CS_2, and HCN, hydrogen to H_2S, H_2O, and HCN, oxygen to CO_2, COS, SO_2, and H_2O, and nitrogen to HCN, respectively, by the pyrolytic sulfurization reaction under the present conditions. In order to separate and determine the seven kinds of the products by gas chromatography, their optimum conditions were searched and obtained, as described in experimental term. A typical chromatogram of the products is shown in Fig. 8. This was obtained by analyzing nitromethane as a target component, from which seven kinds of products were produced by the use of GC-PSR-GC. As can be seen from Fig. 8, seven kinds of products

can be successfully separated one from another and can be eluted within 15 min.

Qualitative Indentification of C, H, O, and N in a Standard Sample. Many kinds of organic compounds were analyzed by GC-PSR-GC by the use of 0.4 μl of sample; the products from the sample are shown in Table 1. With regard to all samples, carbon in a sample was mainly converted to CS_2 and COS, where CS_2 became a main product in a carbon-rich compound and COS did in an oxygen-rich compound, hydrogen to H_2S, oxygen to COS, and nitrogen to HCN. Therefore, the component elements: C, H, O, and N in an organic compound could be easily identified by observing four kinds of products: CS_2, COS, H_2S, and HCN; all the samples are shown in Table 1. The component elements in the sample can be qualitatively identified without any exceptions.

Detection Limit of GC-PSR-GC. The detection limit of GC-PSR-GC was examined under the present conditions by the use of ethanol and acrylonitrile as standard samples. No products except SO_2 were observed by the blank test under the present conditions, and a small amount of COS produced by the reaction between carbon in a target component and SO_2 as an impurity of sulfur was observed when the component containing no oxygen was analyzed. Therefore, the detection limit of the present method for the products except COS was defined as the signal to noise ratio equal to two on a gas chromatogram, while that for COS was also defined as the signal to blank ratio equal to two. As a result of the investigation on the basis of above definition, the detection limit of GC-PSR-GC was a few pmol.

Identification of C, H, O, and N in a Component Separated from a Mixed Sample by Gas Chromatography. The mixed sample was artificially prepared by mixing four kinds of compounds: cyclohexene consisting of C and H, methanol consisting of C, H, and O, pyridine consisting of C, H, and N, and morpholine consisting of C, H, O, and N. This sample was subjected to GC-PSR-GC in the following manner. One μl of the sample was injected to GC-I(chromatogram of this sample is shown in Fig. 9) and the target peak of a sample was introduced to the pyrolytic sulfurization reactor by operating the four-way cock mounted with GC-I, followed by analysis by the present procedure. By repeating the above-mentioned procedure, four kinds of compounds in the mixed sample were analyzed. Each chromatogram is shown in Fig. 10. The component elements in each compound could be successfully and easily identified by the use of each chromatogram of the compound. These results indicate that all organic compounds which can be separated by gas chromatography can be subjected to GC-PSR-GC and can be qualitatively identified according to their component elements: C, H, O, and N. In other words, the present system can be expected to become a useful tool as a secondary

detector for gas chromatography.

Pyrolytic Sulfurization Reaction under the Present Conditions. Pyrolytic sulfurization reaction under the present conditions is discussed here on the basis of the results obtained in this study. Figure 4 indicates that the amount of CS_2 produced is influenced by the trap time, though that of H_2S is not, for each sulfur temperature. Figure 6 also indicates that the amount of CS_2 becomes constant by trapping it for over 15 min, while that of H_2S becomes constant within 2.5 min. These results can be explained by presuming the mechanism of pyrolytic sulfurization under the present conditions as follows: A target component is immediately decomposed in the furnace to gaseous compounds and carbon deposit. Then the gaseous compounds react with sulfur vapor during the passage through the reaction tube and the carbon deposit reacts with sulfur vapor at the position of the thermal decomposition until it is completely converted to CS_2. Therefore, the times necessary for the production of H_2S and CS_2 may be different. This was also experimentally proved by the use of other kinds of compounds.

Comparison of GC-PSR-GC with PSGC with Regard to Pyrolytic Sulfurization. Pyrolytic sulfurization gas chromatography(PSGC)[6-19] has been previously investigated and successfully established by the authors as a new elemental analysis method by which the atomic ratio between C, H, O, and N in an organic compound can be simultaneously determined. This method has been successfully applied to various organic compounds, such as an usual organic compound, a metal organic chelate, a polymer, and an organic halogen compound. In PSGC, a sample is made to react with sulfur in a sealed quartz tube for 1 min at 1500 °C or for 30 min at 950 °C. Therefore, a pyrolytic sulfurization reaction occurs at high pressure. On the contrary, pyrolytic sulfurization reaction by GC-PSR-GC occurs at atmospheric pressure, as described in this study. The reaction products obtained by GC-PSR-GC are the same as those obtained by PSGC, except for HCN. Nitrogen in a sample is converted to molecular nitrogen in PSGC. This suggests that the reaction conditions of PSGC are severer than those of GC-PSR-GC. The fact that pyrolytic sulfurization reaction by GC-PSR-GC is completed by reacting a sample with sulfur for 15 min at 900 °C, though the reaction by PSGC is done for 30 min at 950 °C may be explained as follows: Pyrolytic sulfurization reaction by PSGC may take a longer time to convert carbon in a sample to CS_2 at the end of the reaction. This suggests that a trace amount of carbon must react with a trace amount of sulfur at the end of the reaction since a stoichiometric amount of sulfur is present in the sealed tube, unlike the case of GC-PSR-GC.

On the basis of the above-mentioned investigation, a method for the qualitative identification of the component elements, C, H, O, and N, in an organic compound was newly established. This method, called GC-PSR-GC, is characterized by the following: 1) The component elements: C, H, O, and N, in an organic compound can be qualitatively identified, 2) data analysis is very simple, 3) this method is more simple and economical than earlier ones, and 4) this method is also useful as a secondary detector of gas chromatography. This method will contribute to progress in organic chemistry.

1,3-Dipolar Cycloaddition Reactions of 6-Methylenetricyclo-[3.2.1.$0^{2,7}$]oct-3-en-8-one and Its Related Compounds

Makoto NITTA,* Akihiko OMATA, and Shuji OKADA

Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160

(Received August 18, 1983)

The cycloaddition reactions of 1,5-dimethyl-6-methylenetricyclo[3.2.1.$0^{2,7}$]oct-3-en-8-one (**1a**), its corresponding -8-*endo*-ol (**1b**), 1,5,8-trimethyltricyclo[3.2.1.$0^{2,7}$]oct-3-en-8-*endo*-ol (**1c**), and 5,8-dimethyl-9-methylenetricyclo[3.3.1.$0^{2,8}$]non-3-en-7-one (**2**) were investigated in order to study the origin of its stereoselectivity or site selectivity. The reaction of 2,4,6-trimethylbenzonitrile oxide (mesitonitrile oxide, MNO) with **1a, b** occurs on the *exo*-mthylene group from the *exo*-side, but on the endocyclic double bond in the case of **1c**. The compound **2** undergoes the addition of MNO on both the exocyclic and endocyclic double bonds to give a corresponding bis-adduct. On the other hand, the reaction of phenyl azide (PA) with **1a—c** occurs on the endocyclic double bond from the endo-side to give a single adduct. The reaction of 6-*exo*-methoxy-1,5,6-trimethyltricyclo[3.2.1.$0^{2,7}$]oct-3-en-8-one with MNO or PA was also studied to prove the regioselectivity of the cycloadditions of constrained vinylcyclopropane moiety.

Recently the stereoselectivities and/or site selectivities of electrophilic reactions or cycloadditions of molecules containing proximal π-bonds, such as alkylidenenorbornene and alkylidenebenzonorbornadiene have been investigated.[1-5]

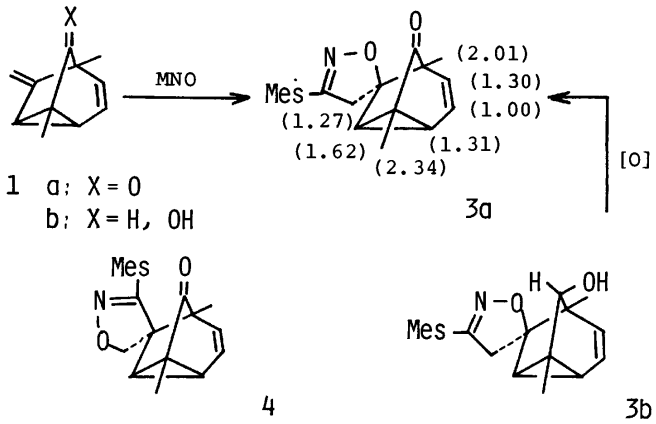
In previous papers, we reported that electrophilic reactions such as solvomercuration, bromination and its related reactions on the exocyclic double bond of 1,5-dimethyl-6-methylenetricyclo[3.2.1.$O^{2,7}$]oct-3-en-8-one (**1a**) and its related compounds of general structure (**A**) exhibit a remarkable stereoselectivity to give

n = 0 or 1 X = O or H, OH Z = Br or HgOAc

(**B**).[6,7] The stereoselectivity was explained by the steric and/or electronic factor of mercurinium or bromonium ion formation and the stereoelectronic control of the endocyclic double bond for the incorporating nucleophiles. In continuation of this study, the 1,3-dipolar cycloadditions of 2,4,6-trimethylbenzonitrile oxide or phenyl azide with **1a**, its corresponding-8-*endo*-ol (**1b**), 1,5,8-trimethyl-6-methylenetricyclo[3.2.1.$0^{2,7}$]oct-3-en-8-*endo*-ol (**1c**), 5,8-dimethyl-9-methylenetricyclo[3.3.1.$0^{2,8}$]non-3-en-7-one (**2**), and 6-*exo*-methoxy-1,5,6-trimethyltricyclo[3.2.1.$0^{2,7}$]-oct-3-en-8-one (**11**) were studied to probe the origin of stereoselectivity or site selectivity. The results are described in this paper.

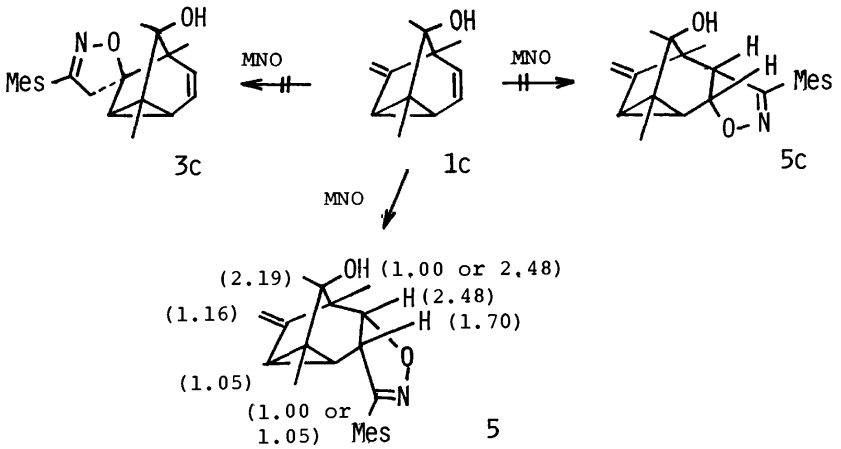
Results and Discussion

The reaction of 2,4,6-trimethylbenzonitrile oxide (mesitonitrile oxide, MNO) with **1a**[8] and **1b**[9] under reflux in benzene for 5 h gave 1 : 1 adducts **3a** and **3b** in 83 and 82% yields, respectively. The structural proof was based on the elemental analyses and spectroscopic data. The stereochemical arrangement of the MNO moiety of **3a** was deduced from the pseudo-contact NMR spectra obtained by using Eu(fod)$_3$. The relative down field shifts of δ's are given in parentheses in the structural formula.[10] The large values of 2.01 and 2.34 for the methyl groups as compared to the value of 1.27 for the methylene protons of the isoxazoline ring suggest the coordination of Eu(fod)$_3$ occurs on the carbonyl-oxygen and the MNO moiety is *exo* to the carbonyl group. On oxidation with pyridinium chlorochromate, **3b** was converted to **3a** in an 80%



yield, therefore the stereochemistry of **3a** and **3b** were assessed. Regarding the frontier orbital theory, the regioselectivity of the present cycloadditions is explained by LUMO (MNO)-HOMO (**1a, b**) interaction, since the unsubstituted terminus of the exomethylene group (possible large HOMO coefficient) was bound to the carbon terminus of MNO (large LUMO coefficient).[11,12] The regiochemistry of **3a, b** is also favorable for a steric reason. The van der Waals nonbonded interaction energies should be very large in such material as **4** as compared to the adduct **3a, b** (*vide infra*).

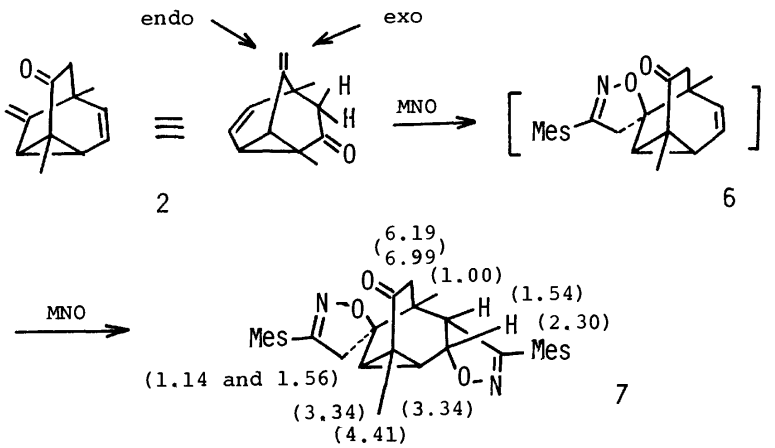
In order to probe the *exo*-selectivity of the present cycloadditions, the reaction of **1c**, which has a bulky methyl group at 8-position, was studied. The reaction of **1c**[13] with MNO under reflux in benzene for 7 h gave 1 : 1 adduct **5** in a 26% yield, the remainder being recovered starting material **1c** in a 53% yield. The structural proof including the regiochemistry and the stereochemistry of the MNO moiety was assessed on the basis of the spectral data and the pseudo-contact NMR spectra.[10] The relatively large values of 2.48 and 1.70 for the methine protons of the isoxazoline ring clearly indicate the *endo*-orientation of the MNO moiety of **5**. In the adduct **5**, the terminus of the

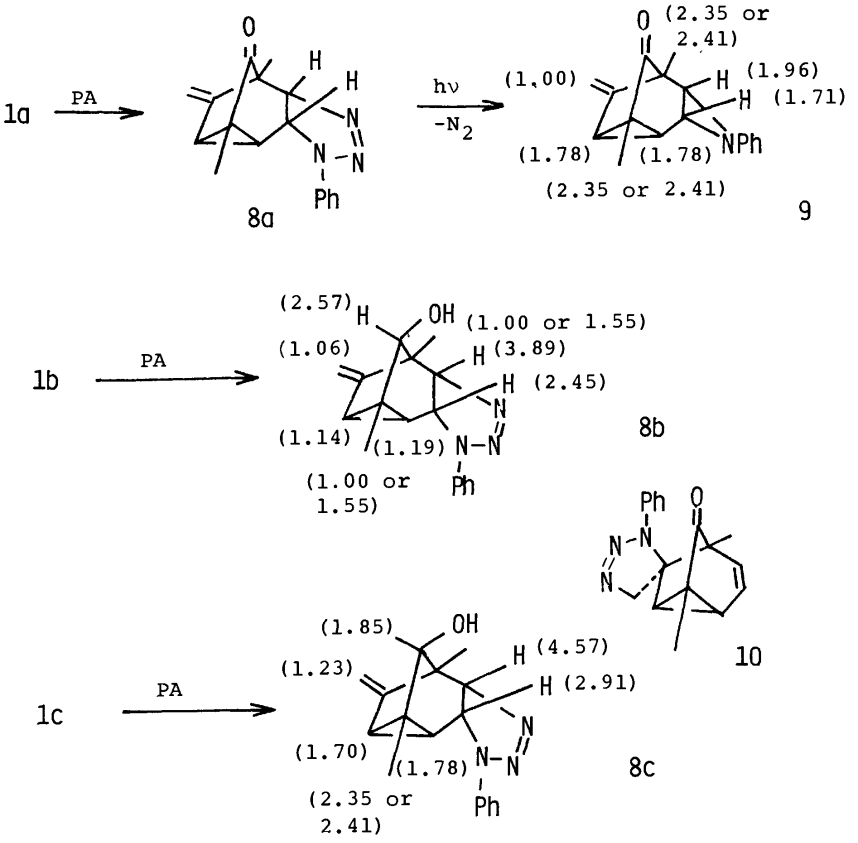


divinylcyclopropane moiety (possible large LUMO coefficient) was bound to the oxygen of MNO (large HOMO coefficient).[11,12] The bulky methyl group at 8-position of **1c** seems to prevent the *exo*-attack to give **3c**, which is expected from LUMO (MNO)-HOMO (**1c**) interaction as in the case of **1a**, **b**. The *endo*-arrangement of the MNO moiety of **5** is suggestive of the steric effect between the bulky mesityl group and two methyl groups at 1-and 5-positions. The blocked LUMO (MNO)-HOMO (**1c**) interaction to give **5c** stands in contrast to the cycloaddition of MNO with the vinylcyclopropane moiety of **11** (*vide infra*). The *endo*-attack of MNO on the *exo*-methylene group of **1c**, as well as **1a**, **b**, was prevented completely. This feature suggests a stereoelectronic effect of the endocyclic double bond[6] rather than a steric effect.

In order to probe this point, the reaction of **2**,[14] in which the *exo*-methylene group is located symmetrically with respect to the carbon skeleton, was investigated. The reaction of MNO with **2** under reflux in benzene for 20 h gave the bis-adduct **7** in a 48% yield, leaving 27% of **2**. Unfortunately the mono-adduct **6** was not isolated even in the presence of an excess amount of **2**. The structural proof and the stereochemical arrangement of the isoxazoline moiety were deduced from the spectral data.[10] The reaction of MNO with the *exo*-methylene gorup of **1a** or **1b** seemed to be faster than that with the endocyclic double bond of **1c** (*vide supra*), therefore it is suggested that the mono-adduct **6** might be the primary cycloadduct leading to **7**. An electrophilic reaction of sulfenyl chloride with **1a** could give a 1:1 adduct on the *exo*-methylene group, while that of **2** could give a 1:1 adduct on the *exo*-methylene group and a bis-adduct which can be derived from the former mono-adduct. Thus the endocyclic double bond of **2** seems to be more reactive than that of **1a**.[15] This fact may also suggest the intermediacy of **6** in the present cycloaddition. Regarding the steric hindrance of the hydrogen at the α-position of the carbonyl group, the *exo*-attack of MNO on the *exo*-methylene group of **2** seems unfavorable as compared to the endo-attack. However, MNO appeared to attack the *exo*-methylene group of **2** from the *exo*-side. Thus the *endo*-attack of **1a—c** or **2** may be prevented by the repulsive orbital interaction, which would be experienced with the endocyclic double bond.

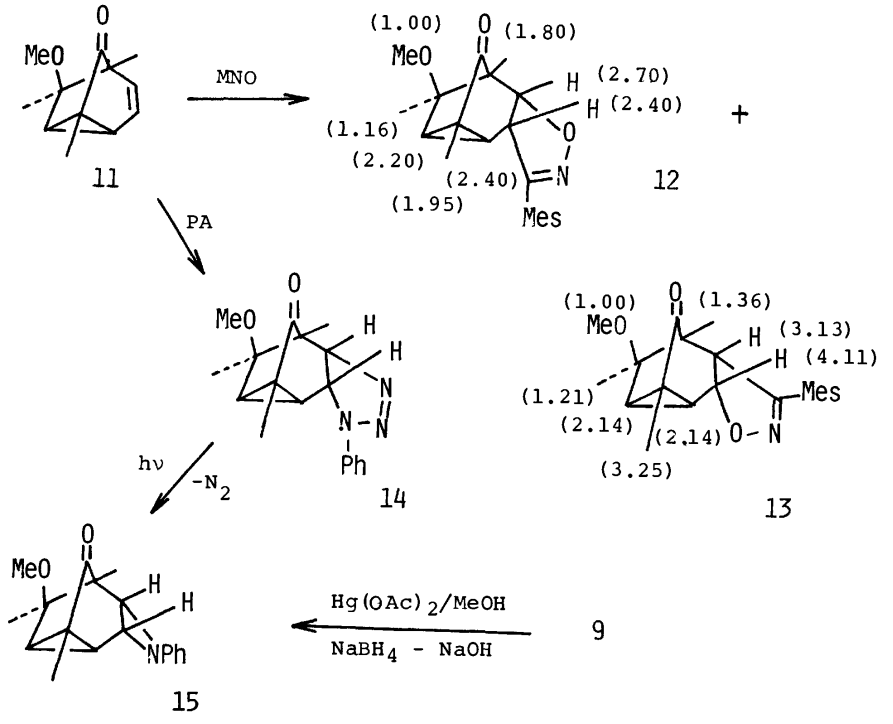
The cycloaddition of phenyl azide (PA) to the compounds **1a—c** was carried out under reflux in cyclohexane for 1 week to give 1:1 adducts **8a—c**. No adduct on the *exo*-methylene group was obtained. The structural proof including the stereochemistry and regiochemistry was based on the spectral data.[10] Photoirradiation of **8a** could undergo a clean elimination of a nitrogen molecule to give aziridine **9**, the structure of which including stereochemistry was also confirmed by the spectral data. Since the terminus of the divinylcyclopropane moiety (possibly with a large HOMO coefficient) was bound to the nitrogen bearing no phenyl group (large LUMO coefficient),[12] the regiochemistry of the adducts **8a—c** appears to be controlled by the LUMO (PA)-HOMO (**1a**, **b**, **c**) inter-





actions. The attack of PA on another terminus of the divinylcyclopropane moiety (*exo*-methylene group) to give **10** would be impossible because of the large steric hindrance. The attack of PA on the *exo*-methylene group from the *endo*-side would also be prevented because of the large steric effect and the stereoelectronic effect (*vide supra*).

The HOMO of MNO[16] and PA[12] are −8.3 and −9.5 eV, and LUMO have been estimated at +0.11 and −0.22 eV. Thus the low lying LUMO (PA), as compared to the high lying LUMO (MNO), appeared to control the regioselectivity of **8a—c**. On the other hand, the regiochemistry of **3c** or the second isoxazoline moiety of **7** seemed to be controled by HOMO



(MNO)-LUMO (**1c**) or LUMO (MNO)-HOMO (**6**) interactions, respectively.

Furthermore the cycloaddition of MNO or PA with constrained vinylcyclopropane was studied. The reaction of **11** with MNO under similar conditions gave the 1:1 adducts **12** and **13** in 13 and 10% yields, along with unreacted **11** in 70% yield. The structural proof is based on the spectroscopic data. On the other hand, the reaction of **11** with PA in cyclohexane under similar conditions described above gave single adduct **14** in 40% yield along with the unreacted **11** in 23% yield. The photoirradiation of **14** afforded 89% of aziridine **15**, which was also obtained by the methoxymercuration-demercuration of **9**. Thus the structure of **14** was established. Therefore both the high lying LUMO and HOMO of MNO, as compared to that of PA, can intervene in the cycloaddition of a constraiened vinylcyclopropane system such as **11**, while only low lying LUMO in the case of PA. In the adduct **12**, **13**, and **14**, 1,3-dipoles were incorporated from the *endo*-side to the carbonyl group. Regarding the steric effect of methyl groups at 1-and 5-positions, *endo*-orientation seems to be favorable.

In conclusion, the selective *exo*-attack on the *exo*-methylene group of **1a**, **b** and **2** giving **3a**, **b** and **6**, respectively, seems to be controlled by the stereoelectronic effect, which would prevent the *endo*-attack. The site selectivity giving **5** or **8a—c** would be caused by the sterically hindered *exo*-attack of 1,3-dipoles on the *exo*-methylene group and the stereoelectronically hindered *endo*-attack on the *exo*-methylene group. The stereochemistry and the regiochemistry of 1,3-dipolar cycloaddition of endocyclic double bond of **1a—c**, **6**, and **11** seemed to be controlled by the steric effect of the methyl groups at the ring junction and frontier orbital interaction, respectively.

Experimental

IR spectra were recorded on a Shimadzu IR-400 spectrometer. The mass spectral studies were conducted using a Hitachi RMU-60 spectrometer. All NMR spectra were recorded on a JEOL PS-100 high resolution spectrometer using tetramethylsilane as the internal standard. The shift data were obtained by adding small increments of Eu(fod)$_3$ to the sample and noting the extent to which each peak was shifted. The relative shift-slopes were obtained by dividing each of the slopes by the slope of the least shifted signal. The analyses were performed by the Science and Engineering Research Laboratory, Waseda University.

*Cycloaddition of **1a** with 2,4,6-Trimethylbenzonitrile Oxide (Mesitonitrile Oxide, MNO).* A solution of **1a** (160 mg, 1 mmol) and MNO (161 mg, 1 mmol) in 3 cm^3 of anhydrous benzene was refluxed for 5 h. After the solvent removal *in vacuo*, the residue was separated by TLC on silica gel using dichloromethane as the eluent. The first band from the TLC plates contained 20 mg (13%) of **1a**. The second band from the TLC plates gave 267 mg (83%) of the adduct **3a**: mp 150—151 °C (from hexane); IR ($CHCl_3$), 1607, 1336 cm^{-1}; NMR ($CDCl_3$), δ=1.21 (3H, s), 1.38 (3H, s), 2.12—2.33 (1H, m), 2.32 (6H, s), 2.35 (3H, s), 2.43 (1H, d, J=8.1 Hz), 3.02 (1H, d, J=18.6 Hz), 5.68 (1H, d×d, J=8.4, 3.0 Hz), 6.27 (1H, d×d, J=8.4, 5.1 Hz), 7.05—7.16 (2H, broad s); MS, m/z (rel intensity), 321 (M$^+$, 50), 159 (100). Found: C, 78.75; H, 7.21; N, 4.22%. Calcd for $C_{21}H_{23}O_2N$: C, 78.47; H, 7.21; N, 4.36%.

*Cycloaddition of **1b** with MNO.* A solution of **1b** (162 mg, 1 mmol) and MNO (161 mg, 1 mmol) in 3 cm^3 of anhydrous benzene was refluxed for 5 h. After the solvent removal *in vacuo*, the residue was separated by TLC on silica gel using dichloromethane as the eluent. The first band from the TLC plates contained 13 mg (8%) of **1b**. The second band from the TLC plates gave 265 mg (82%) of the adduct **3b**: mp 97—98 °C (from hexane); IR (CCl_4), 3561—3251, 1610, 1053 cm^{-1}; NMR (CCl_4), δ=1.41 (3H, s), 1.56—1.72 (2H, m), 2.22 (6H, s), 2.30 (3H, s), 2.57 (1H, d, J=18.6 Hz), 2.91 (1H, d, J=18.6 Hz), 3.79—3.93 (1H, broad s), 5.37 (1H, d×d, J=8.4, 1.2 Hz), 6.41 (1H, d×d, J=8.4, 5.4 Hz), 6.93—7.02 (2H, broad s). Found: C, 77.70; H, 7.47; N, 4.11%. Calcd for $C_{21}H_{25}O_2N$: C, 77.98; H, 7.79; N, 4.35%.

*Oxidation of **3b**.* To a stirred suspension of pyridinium chlorochromate (100 mg, 0.46 mmol) and anhydrous sodium acetate (20 mg, 0.24 mmol) in 0.5 cm^3 of dichloromethane, was added **3b** (100 mg, 0.31 mmol) in 0.5 cm^3 of dichloromethane under a nitrogen stream. After the reaction mixture was stirred for 5 h, it was chromatographed on Florisil using dichloromethane as the eluent to give 78 mg (80%) of the ketone **3a**, which was identified by mixed mp.

*Cycloaddition of **1c** with MNO.* A solution of **1c** (176 mg, 1 mmol) and MNO (161 mg, 1 mmol) in 3 cm^3 of benzene was refluxed for 7 h. After the solvent removal *in vacuo*, the residue was separated by TLC on silica gel using dichloromethane as the eluent. The first band from the TLC plates contained 93 mg (53%) of **1c**. The second band from the TLC plates gave 88 mg (26%) of the adduct **5**: mp 203—204 °C (from EtOH); IR ($CHCl_3$), 3694, 1608, 1070 cm^{-1}; NMR ($CDCl_3$), δ=1.08 (3H, s), 1.12 (6H, s), 1.55—1.80 (1H, m), 1.64 (1H, d, J=6.0 Hz), 2.24 (9H, s), 4.13 (1H, d×d, J=11.4, 2.4 Hz), 4.72 (1H, d, J=11.4 Hz), 4.77 (1H, s), 4.89 (1H, s), 6.81 (2H, broad s); MS, m/z (rel intensity), 337 (M$^+$, 100), 338 (100). Found: C, 77.95; H, 8.34; N, 3.92%. Calcd for $C_{22}H_{27}O_2N$: C, 78.30; H, 8.07; N, 4.15%.

*Cycloaddition of **2** with MNO.* A solution of **2** (140 mg, 0.8 mmol) and MNO (161 mg, 1 mmol) in 1.5 cm^3 of benzene was refluxed for 20 h. After the solvent removal *in vacuo*, the residue was separated by TLC on silica gel using benzene-ether (1/1) as the eluent. The first band from the TLC plates afforded 38 mg (27%) of **2**. The second band from the TLC plates contained 193 mg (48%) of the adduct **7**; mp above 250 °C (from EtOH); IR ($CHCl_3$), 2941, 1684, 1456, 1381, 1325, 891 cm^{-1}; NMR ($CDCl_3$), δ=1.22 (3H, s), 1.37 (3H, s), 1.40 (1H, d, J=7.5 Hz), 2.01 (1H, d, J=7.5 Hz), 2.23 (1H, d, J=18.3 Hz), 2.81 (18H, s), 2.84 (1H, d, J=18.3 Hz), 3.11 (1H, d, J=18.2 Hz), 3.83 (1H, d, J=10.2 Hz), 3.99 (1H, d, J=18.2 Hz), 4.54 (1H, d, J=10.2 Hz), 6.92 (4H, s); MS, m/z (rel intensity), 497 (M+1, 41), 496 (M$^+$, 100). Found: C, 77.45; H, 7.47; N, 5.33%. Calcd for $C_{32}H_{36}O_3N_2$: C, 77.39; H, 7.31; N, 5.64%.

*Cycloaddition of **1a** with Phenyl Azide (PA).* A solution of **1a** (100 mg, 0.63 mmol) and PA (150 mg, 1.27 mml) in 5 cm^3 of cyclohexane was refluxed for 7 d. After the removal of the solvent, the residue was recrystallized from carbon tetrachloride to give 104 mg (60%) of the adduct **8a**. The filtrate contained 8 mg (8 %) of **1a**. For **8a**: mp 143—145 °C (dec); IR ($CHCl_3$), 1738, 1667, 1600, 1493, 1108, 1091, 1067, 965 cm^{-1}; NMR (CCl_4), δ=1.10 (3H, s), 1.44 (3H, s), 2.45 (1H, d×d, J=7.5, 1.9 Hz), 2.67 (1H, d, J=7.5 Hz), 4.46 (1H, d×d, J=11.7, 1.9 Hz), 4.62 (1H, d, J=11.7 Hz), 4.87 (1H, s) 4.97 (1H, s), 6.86—7.47 (5H, m), MS, m/z (rel intensity), 279 (M$^+$, absent), 251 (25), 118 (100). Found: C, 72.54; H, 6.09; N, 14.15%. Calcd for $C_{17}H_{17}ON_3$: C, 73.19; H, 6.31; N, 14.04%.

*Photoirradiation of the Adduct **8a**.* A solution of **8a** (100 mg, 0.36 mmol) in 10 cm^3 of acetonitrile was irradiated with a high pressure mercury lamp (400 W) through a Pyrex filter for 24 h under a nitrogen atmosphere. After the removal

of the solvent, the residue was chromatographed on Florisil using dichloromethane as the eluent to give 80 mg (85%) of **9**: mp 128—129 °C (from hexane-benzene, 1/1); IR (CCl_4), 1751, 1664, 1601, 1492, 1407 cm^{-1}; NMR ($CDCl_3$), δ=1.29 (3H, s), 1.34 (3H, s), 2.28 (1H, d, J= 6.0 Hz), 2.36—2.55 (2H, m), 2.68 (1H, d×d, J=6.0, 3.0 Hz), 4.72 (1H, s), 4.83 (1H, s), 6.66—7.17 (5H, m). Found: C, 81.28; H, 6.66; N, 5.86%. Calcd for $C_{17}H_{17}ON$: C, 81.24; H, 6.82; N, 5.57%.

Cycloaddition of ***1b*** *with PA.* A solution of **1b** (100 mg, 0.62 mmol) and PA (147 mg, 1.24 mmol) in 5 cm^3 of cyclohexane was refluxed for 7 d. The reaction mixture was then recrystallized from hexane-CCl_4 to give 48 mg (28%) of the adduct **8b**. The filtrate contained 44 mg (44%) of **1b**. For **8b**: mp 172—174 °C (dec): IR ($CHCl_3$), 3625, 1601, 1491, 1113, 1096, 1065 cm^{-1}; NMR ($CDCl_3$), δ=1.32 (3H, s), 1.43 (3H, s), 1.58—1.79 (2H, m), 2.32—2.45 (1H, broad s), 3.76 (1H, broad s), 4.46 (1H, d×d, J=12.0, 2.4 Hz), 4.57 (1H, d, J=12.0 Hz), 4.57 (1H, s), 4.77 (1H, s). 6.86—7.40 (5H, m), MS, m/z (rel intensity), 281 (M^+, absent), 253 (28), 119 (100). Found: C, 72.99; H, 6.82; N, 14.68%. Calcd for $C_{17}H_{19}ON_3$. C, 72.57; H, 6.81; N, 14.94%.

Cycloaddition of ***1c*** *with PA.* A solution of **1c** (100 mg, 0.57 mmol) and PA (136 mg, 1.14 mmol) in 5 cm^3 of cyclohexane was refluxed for 7 d. After the removal of the solvent, the residue was recrystallized from hexane-benzene to give 50 mg (30%) of the adduct **8c**. The filtrate contained the recovered **1c** (30 mg, 30%). For **8c**: mp 145—146 °C (dec): IR ($CHCl_3$), 3549, 1600, 1494, 1110 cm^{-1}; NMR ($CDCl_3$), δ=1.20 (3H, s), 1.24 (3H, s), 1.33 (3H, s), 1.57—1.81 (2H, m), 4.51 (1H, d×d, J=12.0, 3.0 Hz), 4.55 (1H, s), 4.63 (1H, d, J=12.0 Hz), 4.73 (1H, s), 6.83—7.40 (5H, m); MS, m/z (rel intensity), 295 (M^+, absent), 267 (100). Found: C, 73.42; H, 7.17; N, 14.23%. Calcd for $C_{18}H_{21}ON_3$: C, 73.19; H, 7.17; N, 14.23%.

Cycloaddition of ***11*** *with MNO.* A solution of **11** (200 mg, 1.04 mmol) and MNO (168 mg, 1.04 mmol) in 8 cm^3 of benzene was refluxed for 6 h. After the removal of the solvent, the residue was separated by TLC on silica gel using benzene-ethyl acetate (4/1) as the eluent to give **11** (139 mg, 70%), the adduct **12** (47 mg, 13%), and the adduct **13** (36 mg, 10%). For **12**: mp 170—171 °C (from hexane-benzene); IR ($CHCl_3$), 2949, 1732, 869 cm^{-1}; NMR ($CDCl_3$), δ= 1.16 (3H, s), 1.22 (3H, s), 1.30 (3H, s), 1.53—1.68 (1H, m), 2.18—2.48 (1H, m), 2.28 (9H, s), 3.19 (3H, s), 4.04 (1H, d×d, J= 10.5, 3.0 Hz), 4.64 (1H, d, J=10.5 Hz), 6.84 (2H, broad s); MS, m/z (rel intensity), 353 (M^+, 82), 338 (32), 43 (100). Found: C, 74.76; H, 7.79; N, 3.87%. Calcd for $C_{22}H_{27}O_3N$: C, 74.75; H, 7.70; N, 3.96%. For **13**: mp 195—196 °C (from benzene); IR ($CHCl_3$), 2930, 1729, 875 cm^{-1}; NMR ($CDCl_3$), δ=0.50 (3H, s), 1.26 (3H, s), 1.35 (3H, s), 2.15 (3H, s), 2.19 (3H, s), 2.28 (3H, s), 2.28—2.38 (2H, m), 3.26 (3H, s), 3.84 (1H, d, J=10.2 Hz), 5.09 (1H, d×d, J=10.2, 3.0 Hz), 6.71 (1H, broad s), 6.84 (1H, broad s). MS, m/z (rel intensity), 353 (M^+, 68), 43 (100). Found: C, 74.68; H, 7.69; N, 3.40%. Calcd for $C_{22}H_{27}O_3N$: C, 74.75; H, 7.70; N, 3.96%.

Cycloaddition of ***11*** *with PA.* A solution of **11** (100 mg, 0.52 mmol) and PA (124 mg, 1.04 mmol) in 5 cm^3 of cyclohexane was refluxed for 7 d. After the removal of the solvent, the residue was recrystallized from hexane-benzene to give 65 mg (40%) of the adduct **14**. The filtrate contained 23 mg (23%) of **11**. For **14**: 178—179 °C (decomp); IR ($CHCl_3$), 1735, 1601, 1487, 1108, 1095 cm^{-1}; NMR (acetone-d_6), δ=1.00 (3H, s), 1.25 (3H, s), 1.44 (3H, s), 2.37—2.70 (2H, m), 3.26 (3H, s), 4.77 (2H, s), 6.87—7.50 (5H, m); MS, m/z (rel intensity), 311 (M^+, absent), 285 (85), 267 (100). Found: C, 69.07; H, 6.85; N, 13.77%. Calcd for $C_{18}H_{21}O_2N_3$: C, 69.43; H, 6.80; N, 13.50%.

Photoirradiation of ***14****.* A solution of **14** (100 mg, 0.32 mmol) in 10 cm^3 of acetonitrile was irradiated with a Rayonet Photoreactor (MGR-100) fitted with RPR-350 nm lamps through a Pyrex filter for 2 h under a nitrogen atmosphere. After the removal of the solvent, the residue was chromatographed on Florisil using dichloromethane as the eluent to give 81 mg (89%) of 15: mp 129—132 °C; IR ($CHCl_3$), 1733, 1592, 1482, 1448, 1111, 1047 cm^{-1}; NMR ($CDCl_3$), δ= 1.21 (3H, s), 1.27 (3H, s), 1.64 (3H, s), 2.03—2.57 (3H, m), 2.71 (1H, d×d, J=5.8, 3.6 Hz), 3.17 (3H, s), 6.58—7.27 (5H, m); MS, m/z (rel intensity), 283 (M^+, 12), 118 (100). Found: C, 75.43; H, 7.33; N, 5.23%. Calcd for $C_{18}H_{21}O_2N$: C, 76.29; H, 7.47; N, 4.94%.

Methoxymercuration of ***9****.* A suspension of **9** (502 mg, 2 mmol), mercury(II) acetate (638 mg, 2 mmol) in methanol (8 cm^3) was stirred for 30 min. To this reaction mixture, 8 cm^3 of 3 mol dm^{-3} sodium hydroxide solution was added and followed by reduction with 38 mg (1 mmol) of sodium borohydride in 2 cm^3 of 3 mol dm^{-3} aqueous sodium hydroxide. To this mixture, 10 cm^3 of brine and 10 cm^3 of benzene was added and then filtered. The filtrate was extracted with benzene, and the benzene extract was dried over sodium sulfate. After the removal of the solvent *in vacuo*, 439 mg (78%) of **15** was obtained.

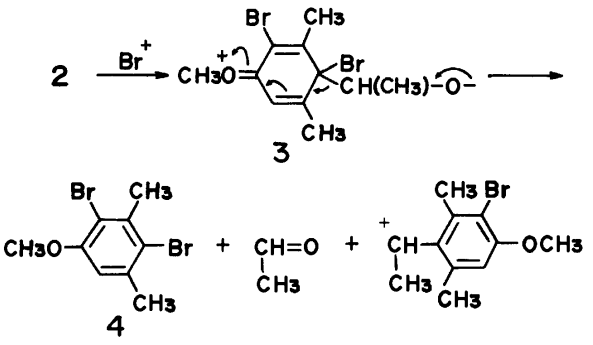
Bromination of 2,6-Dimethyl-4-methoxybenzyl Alcohol Derivatives

Munehiro NAKATANI,* Kimi TAKAHASHI, Sumie WATANABE, Atsuko SHINTOKU, and Tsunao HASE
Department of Chemistry, Faculty of Science, Kagoshima University, Koorimoto 1-Chome, Kagoshima 890
(Received August 26, 1983)

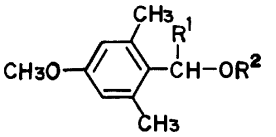
The reaction of 2,6-dimethyl-4-methoxybenzyl alcohols, ethyl ethers, and acetates, possessing electron-donating and -withdrawing groups at the benzylic position, with bromine water was studied at different temperatures. The reaction was strongly affected by the electronegativity of a benzyl substituent to afford bromination products of aromatic nuclei and 2,4-dibromo-3,5-dimethylmethoxybenzene along with 2,4,6-tribromo derivatives formed by the cleavage of C-C bond.

Bromination of bis[1-(2,6-dimethyl-4-methoxyphenyl)ethyl] ether (**1**) with bromine water in acetic acid has been reported to give acetaldehyde and 2,4-dibromo-3,5-dimethylmethoxybenzene (**4**) at 60 °C *via* bis[1-(3-bromo-2,6-dimethyl-4-methoxyphenyl)ethyl] ether (**2**).[1] A reaction mechanism involving the electrophilic displacement to **2** by bromine to give the oxonium intermediate **3**, which undergoes the cleavage of C-C bond to give the dibromide **4**, was proposed (Scheme 1). When the methoxyl group of **1** was displaced by



Scheme 1.

methyl group or hydrogen, the cleavage of C-C bond was not observed under the same conditions, whereas at room temperature, but not at 60 °C, 1-(2,6-dimethyl-4-methoxyphenyl)ethanol (**6a**) and 1-(2,4,6-trimethylphenyl)ethanol afforded **4** and 2,4-dibromo-1,3,5-trimethylbenzene along with acetaldehyde, respectively. These results supported that the cleavage reaction was influenced by the resonance effects of the methoxyl and methyl groups, and suggested that it should be further affected by the ease of formation of an aldehyde **5**. Similar cleavage of C-C bond have been observed in the bromination of some bromosalicylic acid and methylphenol derivatives.[2,3] We have devoted conciderable attention to the electrophilic reaction of bromine to 2,6-dimethyl-4-methoxybenzyl alcohols (**6**), ethyl ethers (**7**) and acetates (**8**), especially to the effects of R^1 and R^2 substituents (Fig. 1) on the cleavage of C-C bond. To compare the effect of substituent, a series of 2,6-dimethyl-4-methoxybenzyl alcohol derivatives, **6**, **7**, and **8**, possessing various electron-donating and -withdrawing substituents, CN, CO_2CH_3, $CONH_2$, CH_3, and H, at the benzylic position were synthesized from 3,5-xylenol *via* 2,6-dimethyl-4-methoxybenzaldehyde[4] and reaction with saturated bromine in water was studied in acetic acid at 10, 20, 30, 60 and 90 °C.



6a: R^1 = Me, R^2 = H

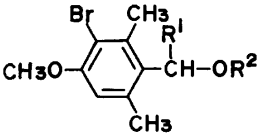
Fig. 1.

Results and Discussion

The results of the reaction with bromine water at 10, 20, 30, and 60 °C are summerized in Table 1. The alcohols, **6a—e**, mainly afforded the dibromide **4** at 20 °C derived from the cleavage of C-C bond, while at the same temperature, main products from the acetates, **8a—e**, possessing the electronegative acetyl group were 3-bromo derivatives, **11a—e**. On the other hand, in the reaction of the ethyl ethers at 20 °C, **7a** (R^1= Me) and **7b** (R^1=H) afforded **4**, but **7c** (R^1=$CONH_2$), **7d** (R^1=CO_2Me) and **7e** (R^1=CN) gave 3-bromo derivatives, **10c**, **10d**, and **10e**, as main products, respec-



9c: R^1 = $CONH_2$, R^2 = H
9d: R^1 = CO_2Me, R^2 = H
9e: R^1 = CN, R^2 = H

10c: R^1 = $CONH_2$, R^2 = Et
10d: R^1 = CO_2Me, R^2 = Et
10e: R^1 = CN, R^2 = Et

11a: R^1 = Me, R^2 = Ac
11b: R^1 = H, R^2 = Ac
11c: R^1 = $CONH_2$, R^2 = Ac
11d: R^1 = CO_2Me, R^2 = Ac
11e: R^1 = CN, R^2 = Ac

TABLE 1. BROMINATION OF ALCOHOLS **6**, ETHYL ETHERS **7**, AND ACETATES **8** AT 10, 20, 30, AND 60 °C

Compound			Products (yield/%)			
	R^1	R^2	at 10 °C	at 20 °C	at 30 °C	at 60 °C
6a	Me	H	**11a**(43) **4**(45)	**11a**(81) **4**(14)	**11a**(3) **4**(95)	**4**(87) **14**(7) **15**(4)

15: R = H

tively. These results indicate that the C-C bond cleavage is strongly affected by the R^1 and R^2 substituents, as clarified below. Although **6a** and **6b** yielded **4** even at low temperature (10 °C), **6c**, **6d** and **6e** afforded 3-bromo derivatives, **9c**, **9d**, and **9e**, in yields of 43, 49, and 85%, respectively, along with **4**. The reaction of **6a** alone afforded a bromo acetate **11a** at low temperature and all of the alcohols, **6a—e**, gave mixtures of **4**, 2,4,6-tribromo-3,5-dimethylmethoxybenzene (**14**) and the corresponding phenol **15** at 60 and 90 °C. The resulting aldehydes from the C-C bond cleavage afforded their 2,4-dinitrophenylhydrazones, but the corresponding benzyl bromides presumed from bromination with generating hydrobromic acid in the reaction systems could not be isolated. The reaction of the ethyl ethers, **7a—e**, at 10 °C showed a similar result to that of **6a—e**, that is, **7a** and **7b** afforded **4** and **7c—e** yielded monobromides, **10c—e**. The ethers **7c—e**, however, afforded 3,5-dibromo derivatives, **12c** and **12d**, at 30 °C and **12e** at 90 °C by the second bromination on the benzene nucleus, while the first formation of **4** was recognized at 20, 30, and 90 °C, respectively. Apparently, the bromo substituent suppresses the bond cleavage reaction so that **7c** afforded 20% of **12c** at high temperature (90 °C). Both compounds having $CONH_2$ and CO_2Me groups afforded similar reaction products, but the proportions of products from **6c** and **6d** at 10 °C, and from **7c** and **7d** at 20, 30, and 60 °C revealed that the methoxycarbonyl group suppressed the C-C bond cleavage more than the carbamoyl group. Although the acetates, **8a** and **8b**, afforded the monobromides, **11a** and **11b**, at low temperature, they showed no formation of the corresponding dibromides at higher temperature. On the other hand, **8c—e** first showed the formation of dibromides, **13c**, **13d** and **13e**, at 60, 60, and 90 °C in 13, 13, and 7% yields along with **11c** (73%), **11d** (75%), and **11e** (49%), respectively. These acetates, **8c—e**, yielded **4** in 4—5% yields at 60 °C from hydrolysis of the acetate group.

Some potent points derived from our studies on the substituent effects are listed as follows: (i) The electrophilic substitution on the benzene nucleus of the alcohols **6** by bromonium ion, being accompanied by C-C bond cleavage, proceeds according to the mechanism proposed previously and the bond cleavage reaction is largely governed by the R^1 substituent. But in the reaction of the ethyl ethers, **7c—e**, and the acetates, **8c—e**, possessing electronegative carbamoyl, methoxycarbonyl and cyano groups, the bond cleavage reaction is in competition with the second bromination on benzene nucleus to give the dibromides, **12c—e** and **13c—e**. (ii) The cleavage reaction is also largely regulated by the R^2 substituent and occurred most readily in the reaction of the alcohols **6** by the easy formation of aldehydes. (iii) In each R^1 series, this reaction becomes difficult in the order of R^1=CN, CO_2Me, $CONH_2$, H, CH_3.

Experimental

All of the melting and the boiling points are uncorrected. The IR spectra were recorded with a Shimadzu IR-27C spectrophotometer. The ^1H NMR spectra were measured with JEOL JNM 60 and JNM 100 apparatus. The HPLC separation was done with Waters M45 system and Whatman

Partisil M9 Semi-prep column.

*Preparation of **6a**, **7a**, and **8a**.* To an ether soln of MeMgI prepared from MeI (8.0 g) and Mg (1.5 g), a soln of 2,6-dimethyl-4-methoxybenzaldehyde (5.0 g) was added with stirring. After refluxing for a 1/2 h, the resulting complex was decomposed with aq NH_4Cl and the ether layer was washed with aq $Na_2S_2O_3$, aq $NaHCO_3$, and water. The crude product was chromatographed over silica gel to give **6a** (4.7 g; 85%), $C_{11}H_{16}O_2$, mp 51—52 °C; IR ($CHCl_3$) 3240, 1605, 853, 830 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.45 (3H, d, J=7.2), 1.84 (1H, s), 2.37 (6H, s), 3.71 (3H, s), 5.30 (1H, q, J=7.2), 6.52 (2H, s). Found: C, 73.56; H, 9.12%. Calcd for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95%. The alcohol **6a** was refluxed with a catalytic amount of TsOH in abs EtOH for 12 h and after removal of EtOH, the crude product was purified by column chromatography to give the ethyl ether **7a** (95%), $C_{13}H_{20}O_2$, bp 92—93 °C/7 mmHg (1 mmHg≈133.322 Pa); IR ($CHCl_3$) 1605, 850, 835 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.16 (3H, t, J=7.0), 1.44 (3H, d, J=7.0), 2.38 (6H, s), 3.28 (2H, q, J=7.0), 3.74 (3H, s), 4.88 (1H, q, J=7.0), 6.56 (2H, s). Found: C, 74.90; H, 9.58%. Calcd for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68%. The alcohol **6a** was acetylated with Ac_2O in pyridine followed by treatment in the usual way to give the acetate **8a** (97%), $C_{13}H_{18}O_3$, bp 134—137 °C/10 mmHg; IR (liq film) 1750, 848, 827 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.51 (3H, d, J=7.0), 2.01 (3H, s), 2.41 (6H, s), 3.71 (3H, s), 6.25 (1H, q, J=7.0), 6.56 (2H, s). Found: C, 70.11; H, 8.09%. Calcd for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16%.

*Preparation of **6b**, **7b**, and **8b**.* The reduction of 2,6-dimethyl-4-methoxybenzaldehyde with $LiAlH_4$ followed by the treatment with aq NaOH gave **6b** (92%), $C_{10}H_{14}O_2$, mp 70—71 °C; IR (Nujol) 3350, 1603, 853, 830 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.61 (1H, s), 2.37 (6H, s), 3.73 (3H, s), 4.60 (2H, s), 6.55 (2H, s). Found: C, 72.30; H, 8.50%. Calcd for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49%. The treatment of **6b** with a catalytic amount of TsOH in abs EtOH under reflux afforded **7b** (93%), $C_{12}H_{18}O_2$, bp 117—119 °C/7 mmHg; IR ($CHCl_3$) 1605, 850, 830 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.23 (3H, t, J=6.8), 2.36 (6H, s), 3.54 (2H, q, J=6.8), 3.76 (3H, s), 4.45 (2H, s), 6.56 (2H, s). Found: C, 74.30; H, 9.29%. Calcd for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34%. The acetylation of **6b** with Ac_2O in pyridine afforded **8b** (92%), $C_{12}H_{16}O_3$, mp 59—60 °C; IR ($CHCl_3$) 1745, 1603, 877, 835 cm^{-1}; ^1H NMR ($CDCl_3$) δ= 2.00 (3H, s), 2.34 (6H, s), 3.73 (3H, s), 5.15 (2H, s), 6.55 (2H, s). Found: C, 69.20; H, 7.71%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%.

*Preparation of **6e**, **7e**, and **8e**.* A mixture of 2,6-dimethyl-4-methoxybenzaldehyde (2 g) and anhydrous HCN (2 ml) was kept with CaO (400 mg) in a sealed tube at 50 °C for 2 h. The reaction mixture was acidified with dil H_2SO_4 followed by extraction with ether to give the cyanohydrin **6e**[5] (1.8 g; 77%), $C_{11}H_{13}NO_2$, mp 122—123 °C; IR ($CHCl_3$) 3470, 2280, 1610, 850, 834 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.47 (6H, s), 3.04 (1H, d, J=4.0), 3.77 (3H, s), 5.83 (1H, d, J= 4.0), 6.60 (2H, s). Found: C, 69.23; H, 6.91; N, 7.30%. Calcd for $C_{11}H_{13}NO_2$: C, 69.09; H, 6.85; N, 7.33%. The treatment of **6e** with a catalytic amount of TsOH in abs EtOH under reflux afforded **7e** (90%), $C_{13}H_{17}NO_2$, mp 49—59 °C; IR ($CHCl_3$) 1608, 850, 830 cm^{-1}; ^1H NMR($CDCl_3$) δ=1.41 (3H, t, J=7.0), 2.45 (6H, s), 3.67 (2H, m), 3.74 (3H, s), 5.46 (1H, s), 6.60 (2H, s). Found: C, 71.04; H, 7.90; N, 6.39%. Calcd for $C_{13}H_{17}NO_2$: C, 71.20, H, 7.82; N, 6.39%. The acetylation of **6e** with Ac_2O in pyridine afforded **8e** (98%), $C_{13}H_{15}NO_3$, mp 54—55 °C; IR (Nujol) 1770, 1610, 860, 840 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.08 (3H, s), 2.48 (6H, s), 3.73 (3H, s), 6.60 (2H, s), 6.80 (1H, s). Found: C, 66.91; H, 6.45; N, 6.11%. Calcd for $C_{13}H_{15}NO_3$: C, 66.93; H, 6.84; N, 6.01%.

*Preparation of **6c**, **7c**, and **8c**.* Into a soln of the cyanohydrin **6e** in abs EtOH, dry HCl gas was passed at 50 °C for 3 h. After removal of the solvent, the crude product was purified by column chromatography to give the glycolamide **6c** (76%), $C_{11}H_{15}NO_3$, mp 145.5—146 °C; IR (Nujol) 3500, 3350, 1670, 1585, 853, 830 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.33 (6H, s), 3.56 (1H, d, J=2.0), 3.74 (3H, s), 5.45 (1H, br), 5.75 (2H, br), 6.60 (2H, s). Found: C, 63.03; H, 7.03; N, 6.82%. Calcd for $C_{11}H_{15}NO_3$: C, 63.14; H, 7.23; N, 6.69%. The treatment of **6c** with a catalytic amount of TsOH in abs EtOH under reflux afforded **7c** (87%), $C_{13}H_{19}NO_3$, mp 121—122 °C; IR (Nujol) 3500, 3150, 1700, 1605, 875, 846, 820 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.18 (3H, t, J=6.8), 2.37 (6H, s), 3.40 (2H, q, 6.8), 3.77 (3H, s), 5.25 (1H, s), 6.20 (1H, br), 6.68 (2H, s), 6.93 (1H, br). Found: C, 65.93; H, 8.09; N, 5.89%. Calcd for $C_{13}H_{19}NO_3$: C, 65.80; H, 8.07; N, 5.90%. The acetylation of **6c** with Ac_2O in pyridine at room temperature afforded **8c** (78%), $C_{13}H_{17}NO_4$, mp 145 °C; IR (Nujol) 3490, 3200, 1755, 1700, 860, 845 cm^{-1}: ^1H NMR ($CDCl_3$) δ=2.17 (3H, s), 2.47 (6H, s), 3.80 (3H, s), 6.50—5.60 (2H), 6.60 (2H+1H, s). Found: C, 62.32; H, 6.97; N, 5.52%. Calcd for $C_{13}H_{17}NO_4$: C, 62.14; H, 6.82; N, 5.57%.

*Preparation of **6d**, **7d**, and **8d**.* The amide **6c** was hydrolyzed with 30% aq KOH and methylated with diazomethane to give the methyl glycolate **6d** (82%), $C_{12}H_{16}O_4$, mp 149—150 °C; IR (Nujol) 3480, 1750, 1605, 855, 835 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.34 (6H, s), 3.27 (1H, br s), 3.71 (6H, s), 5.46 (1H, br s), 6.56 (2H, s). Found: C, 64.26; H, 7.16%. Calcd for $C_{12}H_{16}O_4$: C, 64.27; H, 7.19%. The treatment of **6d** with a catalytic amount of TsOH in abs EtOH under reflux afforded **7d** (92%), $C_{14}H_{20}O_4$, bp 109—111 °C/7 mmHg; IR ($CHCl_3$) 1765, 1610, 845, 830 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.21 (3H, t, J=6.8), 2.41 (6H, s), 3.48 (2H, d quint, J=2.0, 6.8),[6] 3.65 (3H, s), 3.72 (3H, s), 5.29 (1H, s), 6.55 (2H, s). Found: C, 66.38; H, 8.14%. Calcd for $C_{14}H_{20}O_4$: C, 66.64; H, 7.99%. The acetylation of **7d** with Ac_2O in pyridine afforded **8d** (95%), $C_{14}H_{18}O_5$, mp 66—66.5 °C; IR (Nujol) 1750, 1735, 865, 835 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.12 (3H, s), 2.35 (6H, s), 3.66 (3H, s), 3.72 (3H, s), 6.61 (2H+1H, s). Found: C, 63.09; H, 6.77%. Calcd for $C_{14}H_{18}O_5$: C, 63.14; H, 6.81%.

*Reaction of the Alcohols **6**, the Ethyl Ethers **7**, and the Acetates **8** with Bromine Water.* To a soln of a material (100 mg) in acetic acid (15 ml), saturated bromine in water (10 ml) containing KBr (0.8 g) was added with stirring until a red colour persisted and the soln was stirred for 1 h, in which to keep the red colour, additional bromine water was sometimes added. After addition of aq $Na_2S_2O_3$, the reaction products at 10, 20, and 30 °C from **7** and **8** except for **7c** and **8c** were directly extracted with hexane from the resulting mixture, and the others were extracted with ether after neutralization with aq $NaHCO_3$. The crude product was chromatographed over silica gel and difficult congeners (**10** and **12**, and **11** and **13**) were separated by a use of HPLC with 1—2% MeOH in CH_2Cl_2.

*2,4-Dinitrophenylhydrazones of Aldehydes from **6a** and **6b**.* The reactions of **6a** and **6b** with bromine water were carried out under a N_2 stream at 90 °C and the each resulting vapour was bubbled through a soln of 2,4-dinitrophenylhydrazine in aq HCl. The precipitate was collected by filtration and recrystallized from EtOH. 2,4-Dinitrophenylhydrazone of acetaldehyde; mp 146—147 °C. 2,4-Dinitrophenylhydrazone of formaldehyde; mp 165—166 °C. They were identified by direct comparison with authentic samples.

*2,4-Dinitrophenylhydrazones of Aldehydes from **6c**, **6d** and **6e**.* Into reaction mixtures of **6c**, **6d**, and **6e** with bromine water at 60 °C, a soln of 2,4-dinitrophenylhydrazine was added and the solutions were left overnight. Each ether extract was purified by chromatography and recrystallization. 2,4-Dinitrophenylhydrazone of glyoxylamide; $C_9H_8O_6N_4$, mp 241.5—243.5 °C (decomp); IR (Nujol) 3400, 3250, 3150, 3070, 1675, 1615, 1590 cm^{-1}; MS, m/z (rel intensity) 253 (M^+, 65), 181 (28), 152 (29), 74 (100). 2,4-Dinitrophenylhydrazone of

methyl glyoxylate; $C_9H_8O_6N_4$, mp 200—202.5 °C (decomp); IR (Nujol) 3300, 3090, 1730, 1620, 1590 cm^{-1}; MS, *m/z* (rel intensity) 268 (M^+, 100), 237 (12), 180 (44), 181 (12), 152 (13). 2,4-Dinitrophenylhydrazone from **6e**; mp 126—127 °C; IR (Nujol) 3300, 1620, 1570 cm^{-1}; MS, *m/z* (rel intensity) 238 (M^+, 100), 181 (24), 152 (21).

Reaction products at 10, 20, 30, and 60 °C. **4**,[1] $C_9H_{10}OBr_2$, mp 107—110 °C; ^{1}H NMR ($CDCl_3$) δ=2.36 (3H, s), 2.58 (3H, s), 3.82 (3H, s), 6.61 (1H, s). **9c**, $C_{11}H_{14}NO_3Br$, mp 144—145 °C; IR (Nujol) 3470, 3230, 1690, 1640, 825 cm^{-1}; ^{1}H NMR (acetone-d_6) δ=2.37 (3H, s), 2.43 (3H, s), 3.82 (3H, s), 4.93 (1H, d, *J*=3.8), 5.48 (1H, d, *J*=3.8), 6.45—7.04 (2H), 6.77 (1H, s). Reaction of 6a with Bromine Water at 90 °C. The alcohol **6a** (100 mg) was stirred with saturated bromine water in acetic acid (15 ml) at 90 °C for 1 h. The crude product was isolated in the usual way to give **4** (87 mg; 66%), **14** (31 mg; 15%), and **15** (24 mg; 12%).

Reaction of 7c with Bromine Water at 90 °C. The ethyl ether **7c** (100 mg) was treated in a manner similar to the one descrived for **6a** at 90 °C and the crude product afforded **4** (46 mg; 37%), **12c** (33 mg; 20%), **14** (34 mg; 22%) and **15** (25 mg; 17%).

Reaction of 7e with Bromine Water at 90 °C. The ethyl ether **7e** (100 mg) was treated in a similar manner as above at 90 °C and the crude product afforded **4** (5 mg; 4%), **10e** (19 mg; 14%), **12e** (110 mg; 64%), **14** (3 mg; 2%) and **15** (2 mg; 2%). **12e**, $C_{13}H_{15}NO_2Br_2$, mp 101—102 °C; ^{1}H NMR ($CDCl_3$) δ=1.26 (3H, t, *J*=6.8). 2.55 (6H, s), 3.72 (2H, m), 3.83 (3H, s), 5.83 (1H, s). Found: C, 41.38; H, 4.06; N, 3.66%. Calcd for $C_{13}H_{15}NO_2Br_2$: C, 41.41; H, 4.01; N, 3.71%.

Reaction of 8e with Bromine Water at 90 °C. The acetate **8e** (100 mg) was worked up in a similar manner as above at 90 °C to give **4** (34 mg; 27%), **11e** (66 mg; 49%), **13e** (12 mg; 7%), **14** (11 mg; 7%) and **15** (9 mg; 6%). **13e**, $C_{13}H_{13}NO_3Br_2$, mp 137.5 °C; IR ($CHCl_3$) 1765 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ= 2.14 (3H, s), 2.63 (6H, s), 3.87 (3H, s), 7.03 (1H,s). Found: C, 40.06; H, 3.45; N, 3.51%. Calcd for $C_{13}H_{13}NO_3Br_2$: C, 39.92; H, 3.35; N, 3.58%.

2,4-Dinitrophenylhydrazones of Aldehydes from 8d. Into a reaction mixture of **8d** (100 mg) with bromine water at 90 °C, a soln of 2,4-dinitrophenylhydrazine was added and the reaction vessel was left overnight at room temperature. Ether extract of the reaction mixture was purified by chromatography and recrystallization to give 2,4-dinitrophenylhydrazones of methyl glyoxylate and glyoxylic acid; 18 mg and 23 mg. 2,4-Dinitrophenylhydrazone of glyoxylic acid, mp 185—188 °C; IR (Nujol) 3500—2500, 3280, 1705, 1618, 1577 cm^{-1}, afforded a methyl ester by methylation with diazomethane, which was identical with the 2,4-dinitrophenylhydrazone of methyl glyoxylate.

We wish to express our sincere gratitude to Dr. Shibata of Osaka City University for the elemental analysis.

Organic Photochemical Reactions. XXX. Photoreactions of *N,N*-Dimethylpyruvamide in Methanol and Ethanol[1,2]

Kensuke SHIMA,* Kimiko TANABE, Shinpei FURUKAWA, Jouji SAITO, and Kazuhiro SHIRAHASHI
Department of Industrial Chemistry, Faculty of Engineering, Miyazaki University, Kirishima, Miyazaki 880
(Received August 29, 1983)

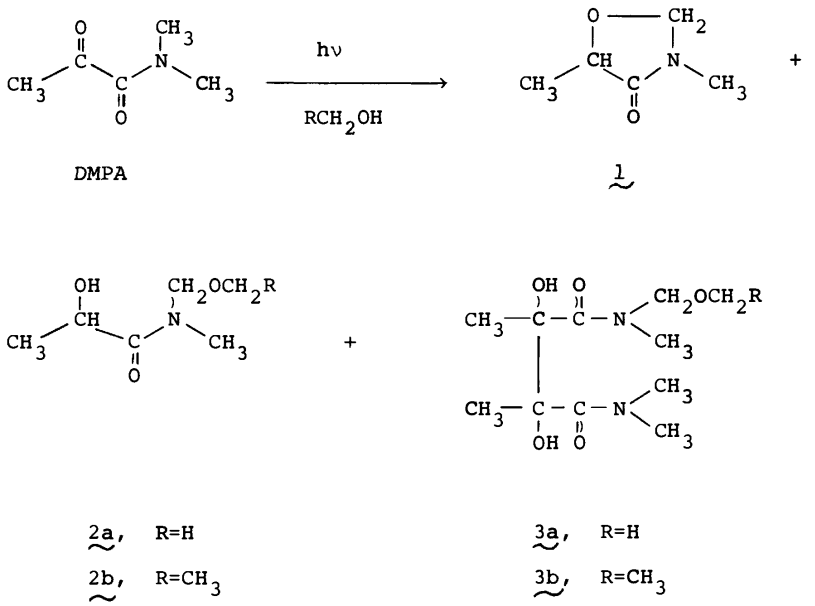
The photoreactions of *N,N*-dimethylpyruvamide (DMPA) in methanol and ethanol were investigated. Irradiation of DMPA in methanol gave three products (3,5-dimethyl-4-oxazolidinone, 2-hydroxy-*N*-methyl-*N*-(methoxymethyl)propanamide, and 2,3-dihydroxy-2,3-dimethyl-*N,N,N'*-trimethyl-*N'*-(methoxymethyl)-butanediamide) in good yields. The product distribution was dependent on the concentration of DMPA and methanol. Similarly, irradiation of DMPA in ethanol gave three products (3,5-dimethyl-4-oxazolidinone, 2-hydroxy-*N*-methyl-*N*-(ethoxymethyl)propanamide, and 2,3-dihydroxy-2,3-dimethyl-*N,N,N'*-trimethyl-*N'*-(ethoxymethyl)butanediamide). The mechanism for the formation of these products is discussed.

Extensive photochemical studies of α-oxo amides have recently been performed by Aoyama's group;[3-6] they considered both synthetic and mechanistic points. They reported that irradiation of *N,N*-dialkylpyruvamides in methanol gave 4-oxazolidinones as a sole product in quantitative yields.[3] In our recent study of the photoadditions of pyruvamides to alkenes,[7] we found that irradiation of *N,N*-dimethylpyruvamide (DMPA) in methanol gave not only 3,5-dimethyl-4-oxazolidinone (**1**), but also the adducts of DMPA with methanol (**2a** and **3a**) in good yields. In this paper we wish to report on the photochemical reactions of DMPA with methanol and ethanol, and to discuss the mechanism for the formation of the photoproducts.

Results and Discussion

Irradiation of DMPA in methanol resulted in the formation of three products (**1**, **2a**, and **3a**) in good yields. These products were separated by preparative GC or column chromatography on silica gel. Their structures were determined by IR, ^{1}H- and ^{13}C-NMR, mass spectra, and elemental analyses, as detailed in the experimental section. Product **1** was assigned as a derivative of 4-oxazolidinones.[3] Product **2a** was the 1:1 adduct of DMPA and methanol, whereas product **3a** was found to be 2:1 adduct of DMPA and methanol on the basis of the elemental analyses and mass spectra. **2a** was characterized as 2-hydroxy-*N*-methyl-*N*-(methoxymethyl)propanamide by IR, ^{1}H- and ^{13}C-NMR spectra.[2] **3a** was found to be the stereoisomeric mixtures of 2,3-dihydroxy-2,3-dimethyl-*N,N,N'*-trimethyl-*N'*-(methoxymethyl)butanediamide from the ^{1}H- and ^{13}C-NMR spectra. Similarly, irradiation of DMPA in ethanol gave three products (**1**, **2b**, and **3b**).

The produced amounts of **1**, **2a**, and **3a** in the irradiation of DMPA in methanol increased linearly with the irradiation time (see Fig. 1). Therefore, these products can be considered to be the primary products from DMPA. Furthermore, it was confirmed that each product remains unchanged under the irradiation in methanol. The product distribution in the photoreaction of DMPA in methanol was found to depend on the concentration of DMPA; as the concentration of DMPA increases, **3a** increases and **1** decreases (see Table 1). The effects of methanol concentration on product yields are shown in Fig. 2. In the irradiation of benzene solutions containing 0.1 mol dm^{-3} DMPA and 0—22 mol dm^{-3} methanol, the yield of **1** remains almost constant, and the yield of **2a** gradually increases



Scheme 1.

as the concentration of methanol increases. The yield of **3a** is highest at *ca.* 1.5 mol dm^{-3} of methanol and decreases at higher methanol concentration. Thus, at very high concentration of methanol, **2a** becomes the major product. The quantum yields for the formation of **1**, **2a**, and **3a** in methanol solution of 0.2 mol dm^{-3} DMPA were as follows: ϕ_1=0.098; ϕ_{2a}=0.34; ϕ_{3a}=0.065.

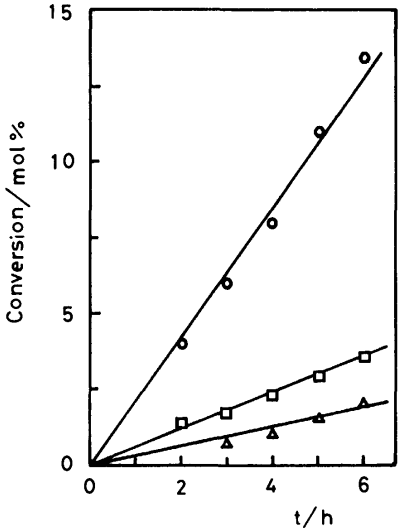


Fig. 1. Effects of irradiation time on product yields. □: **1**, ○: **2a**, △: **3a**. [DMPA]=0.2 mol dm^{-3} in methanol.

The formation of these products is most reasonably explained by a mechanism which involves a zwitterionic intermediate (**5**).[6] The formation of the oxazolidinone (**1**) and the methanol adducts (**2a** and **3a**) from the zwitterion (**5**) can be explained as shown in Scheme 2. Aoyama *et al.*[6] have proposed the mechanism in which the oxazolidinone and the methanol adduct are formed from the imminium ion (**6**), produced by the addition of proton to the zwitterion (**5**). However, it seems to be difficult to explain the formation of **3a** by the mechanism suggested by them.

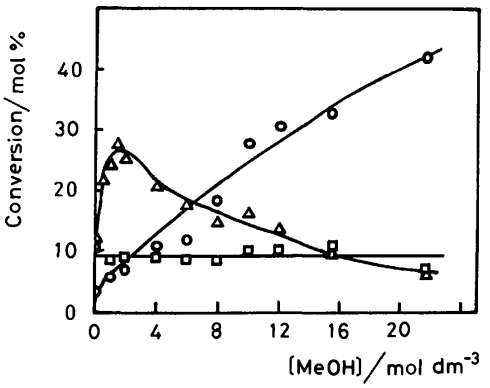

Fig. 2. Effects of methanol concentration on product yields. □: **1**, ○: **2a**, △: **3a**. [DMPA]=0.1 mol dm^{-3}.

Table 1. Concentration effects on products distribution in the photoreactions of DMPA in methanol

DMPA/g	MeOH/cm^3	Irradiation time/h	Products distribution/%		
			1	**2a**	**3a**
8.3	200	72	37	54	9
8.2	140	30	24	55	21
5.5	45	140	12	53	35

Experimental

General. ^{1}H-NMR spectra were recorded on a JEOL JNM-MH 100 machine, ^{13}C-NMR spectra on a JEOL FX 60 machine, IR spectra on a Hitachi IR 260-50 and a JASCO IRA-1 spectrometer, and mass spectra on a JEOL D-300 machine. GC were performed on a Shimadzu GC-6AM and a Hitachi 163 apparatus using a column of Si DC 550 or DEGS at 170 °C. *N,N*-Dimethylpyruvamide (bp 103—105 °C/25 mmHg[†]; lit, bp 53.8 °C/4.5 mmHg[8]) was prepared by the permanganate oxidation[9] of *N,N*-dimethyllactamide (bp 113—116 °C/14 mmHg), which in turn was prepared from the reaction of methyl lactate and anhydrous dimethylamine.[10]

Irradiation of DMPA in Methanol. A solution of DMPA (8.2 g) in 140 cm^3 of methanol was irradiated in a Pyrex doughnut-type vessel under nitrogen with a 300 W high pressure mercury lamp for 30 h. After removal of the solvent, the residue was distilled under reduced pressure to give a liquid (bp 63—130 °C/3 mmHg, 8.3 g) and a viscous oily residue (2.2 g). GC analysis of the distillate showed that it was composed of three products (**1**, **2a**, and **3a**) with the area ratio of 24:55:21. Products **1** and **2a** were isolated by preparative GC on Si DC 550 or DEGS column at 150 °C, and **3a** was isolated by column chromatography on silica gel.

3,5-Dimethyl-4-oxazolidinone (1): IR ($CHCl_3$) 1705, 1100, 1025 cm^{-1}; ^{1}H-NMR (CCl_4) δ=1.31 (3H, d, J=7 Hz, $C\underline{H}_3CH$), 2.83 (3H, s, NCH_3), 4.18 (1H, q, J=7 Hz, $CH_3C\underline{H}$), 4.92 (2H, s, OCH_2N); ^{13}C-NMR (C_6D_6) δ=17.4 (q, $\underline{C}H_3CH$), 26.5 (q, NCH_3), 74.5 (d, $CH_3\underline{C}H$), 81.5 (t, OCH_2N), 172.7 (s, C=O); MS m/z 115 (M^+). Found: C, 51.90; H, 7.97; N, 11.95%. Calcd for $C_5H_9NO_2$: C, 52.16; H, 7.88; N, 12.17%.

*2-Hydroxy-*N*-methyl-*N*-(methoxymethyl)propanamide (2a)*: IR ($CHCl_3$) 3420, 1650, 1100 cm^{-1}; ^{1}H-NMR (CCl_4) δ=1.28 (3H, d, J=7 Hz, $C\underline{H}_3CH$), 2.91 and 2.96 (3H, s, NCH_3), 3.17 and 3.26 (3H, s, OCH_3), 3.94 (1H, br. s, OH), 4.28—4.60 (1H, m, $CH_3C\underline{H}$), 4.64 —4.90 (2H, m, NCH_2O); ^{13}C-NMR (C_6D_6) δ=20.9 and 21.8 (q, $\underline{C}H_3CH$), 33.4 and 33.7 (q, NCH_3), 55.6 (q, OCH_3), 65.2 (d, $CH_3\underline{C}H$), 78.6 and 80.8 (t, NCH_2O), 174.7 (s, C=O); MS m/z 147 (M^+). Found: C, 48.74; H, 9.16; N, 9.47%. Calcd for $C_6H_{13}NO_3$: C, 48.97; H, 8.90; N, 9.52%.

*2,3-Dihydroxy-2,3-dimethyl-*N,N,N′*-trimethyl-*N′*-(methoxymethyl)butanediamide (3a)*: Bp 121—123 °C/2 mmHg; IR ($CHCl_3$) 3340, 1600, 1100 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.46 (6H, br. s, CH_3C), 2.91, 2.94, 3.30, 3.38, and 3.41 (s, 12H, NCH_3 and OCH_3), 4.69, 4.87, 5.14, and 5.30 (2H, d, J=10 Hz, NCH_2O), 5.89, 6.08, and 6.23 (2H, br. s, OH); ^{13}C-NMR (CCl_4) δ=18.2 and 19.1 (q, $\underline{C}H_3C$), 32.7, 34.0, 36.9, and 37.8 (q, NCH_3), 54.3 and 55.1 (q, OCH_3), 78.3 and 79.5 (t, NCH_2O), 79.5 (s, $CH_3\underline{C}OH$), 177.8 and 186.6 (s, C=O); MS m/z 263 (M^++1, by CI). Found: C, 50.48; H, 8.50; N, 10.65%. Calcd for $C_{11}H_{22}N_2O_5$: C, 50.37; H, 8.45; N, 10.68%.

Irradiation of DMPA in Ethanol. A solution of DMPA (5.9 g) in 140 cm^3 of ethanol was irradiated in a Pyrex vessel for 40 h. After removal of the solvent, the residue was distilled under reduced pressure to give a liquid (bp 45—105 °C/0.5 mmHg, 6.1 g) and a viscous oily residue (1.3 g). GC analysis of the distillate showed that three products (**1**, **2b**, and **3b**) with the area ratio of 57:18:25 were present. Products **1** and **2b** were isolated by preparative GC, and **3b** was isolated by column chromatography on silica gel.

*2-Hydroxy-*N*-methyl-*N*-(ethoxymethyl)propanamide (2b)*: IR ($CHCl_3$) 3420, 1650, 1080 cm^{-1}; ^{1}H-NMR (CCl_4) δ=1.12—1.38 (3H, m, $OCH_2C\underline{H}_3$), 1.27 (3H, d, J=7 Hz, $C\underline{H}_3CH$), 2.97 (3H, s, NCH_3), 3.41 (2H, q, J=7 Hz, $OC\underline{H}_2CH_3$), 3.60 (1H, br. s, OH), 4.24—4.56 (1H, m, $CH_3C\underline{H}$), 4.62—4.93 (2H, m, NCH_2O); ^{13}C-NMR ($CDCl_3$) δ= 15.1 (q, $OCH_2\underline{C}H_3$) 20.9 and 21.9 (q, $\underline{C}H_3CH$), 32.7 and 33.9 (q, NCH_3), 63.8 (t, $O\underline{C}H_2CH_3$), 64.6 (d, $CH_3\underline{C}H$), 76.8 and 78.7 (t, NCH_2O), 176.5 (s, C=O); MS m/z 161 (M^+). Found: C, 52.33; H, 9.15; N, 8.72%. Calcd for $C_7H_{15}NO_3$: C, 52.15; H, 9.38; N, 8.69%.

*2,3-Dihydroxy-2,3-dimethyl-*N,N,N′*-trimethyl-*N′*-(ethoxymethyl)butanediamide (3b)*: Bp 101—102 °C/0.5 mmHg; IR ($CHCl_3$) 3320, 1600, 1100 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.10—1.42 (3H, m, $OCH_2C\underline{H}_3$), 1.48 (6H, br. s, CH_3C), 2.91, 2.96, 3.38, and 3.42 (9H, s, NCH_3), 3.30—3.64 (2H, m, $OC\underline{H}_2CH_3$), 4.68, 4.87, 5.14, and 5.30 (2H, d, J=10 Hz, NCH_2O), 5.90, 6.07, and 6.23 (2H, br. s, OH); ^{13}C-NMR (C_6D_6) δ=16.0 (q, $OCH_2\underline{C}H_3$), 19.2 and 20.3 (q, $\underline{C}H_3C$), 34.3, 35.3, 37.9, and 38.8 (q, NCH_3), 63.9 (t, $O\underline{C}H_2CH_3$), 78.3 and 79.8 (t, NCH_2O), 81.2 (s, $CH_3\underline{C}OH$), 179.1 and 180.9 (s, C=O); MS m/z 277 (M^++1, by CI). Found: C, 51.91; H, 8.96; N, 10.05%. Calcd for $C_{12}H_{24}N_2O_5$: C, 52.16; H, 8.75; N, 10.14%.

The Ratio of 1: *2a*: *3a under Various Conditions.* In the experiments on the effects of irradiation time, solutions (4 cm^3) of DMPA (0.2 mol dm^{-3}) in methanol were placed in 10 mm Pyrex tubes. The samples were degassed by four freeze-pump-thaw cycles at $\approx 10^{-5}$ mmHg and sealed. The tubes were irradiated for 1—6 h with a merry-go-round apparatus using a Halos PIH 300 mercury lamp in a water bath. After the irradiation, an internal standard (vanilin) was added to each tube, and product yields were determined by GC analysis. The calibration factors were 0.69 for **1**, 3.22 for **2a**, and 2.06 for **3a**. In the experiments of the effects of methanol concentration, degassed benzene solutions (4 cm^3) containing 0.1 mol dm^{-3} of DMPA and 0—22 mol dm^{-3} of methanol were irradiated for 1 h. Light Intensities in quantum yield measurements were determined by tris(oxalato)ferrate(III) actinometry.[11]

The authors are grateful to the Research Center for Material Analysis in Miyazaki University for the use of NMR and MS spectrometers. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 154163 from the Ministry of Education, Science and Culture.

The Enantioface-differentiating Hydrogenation of the C=O Double Bond with Asymmetrically Modified Raney Nickel. XXXVIII. The Hydrogenation of Methyl Ketones to Optically Active Secondary Alcohols

Tsutomu OSAWA* and Tadao HARADA
Institute for Protein Research, Osaka University, Yamada-oka, Suita, Osaka 565
(Received September 22, 1983)

The enantioface-differentiating (asymmetric) hydrogenation of various methyl ketones ($R-COCH_3$) was carried out over the Raney nickel catalyst modified with (*R*,*R*)-tartaric acid and sodium bromide. The presence of an appreciable amount of carboxylic acid in the reaction system was indispensable for a high optical yield. The highest optical yield (74%) was obtained in the hydrogenation of 3,3-dimethyl-2-butanone in the presence of pivalic acid.

The development of a facile method for the preparation of optically active compounds is one of the important tasks in synthetic organic chemistry. Enantioface-differentiating (asymmetric) catalysts could be useful for a large-scale production of optically active compounds, because the reaction produces a large amount of optically active compounds from a catalytic amount of the optically active substance employed for the preparation of the catalyst.

Many attempts have been carried out to prepare optically active secondary alcohols *via* the hydrogenation of prochiral ketones over enantioface-differentiating catalysts. Several catalysts have been reported to give good optical yields in the enantioface-differentiating hydrogenation of ketones carrying polar groups or unsaturated groups.[1-4] However, no efficient catalysts have been reported for the enantioface-differentiating hydrogenation of alkyl ketones. As far as we know, the highest optical yield (43%) was attained in the hydrogenation of 3,3-dimethyl-2-butanone using an optically active phosphine-rhodium complex catalyst.[5]

As has been reported preliminarily, the Raney nickel modified with tartaric acid (TA) and sodium bromide (TA-NaBr-MRNi) is an excellent catalyst for the enantioface-differentiating hydrogenation of 2-octanone.[6] This paper will describe a successful attempt to obtain a high optical yield in the hydrogenation of 2-octanone and the application of MRNi to the hydrogenation of various methyl ketones.

Results and Discussion

It was well documented that the enantioface-differentiating hydrogenation of β-keto esters over TA-NaBr-MRNi proceeded to give an optical yield of more than 80%.[7] When the optimum conditions for the hydrogenation of β-keto esters were applied to the hydrogenation of 2-hexanone, about 30% of the optical yield was obtained.[8] This result strongly suggested that MRNi was a promising enantioface-differentiating catalyst for the hydrogenation of alklyl ketones as well as β-keto esters. However, under the same conditions as above, the hydrogenation of 2-octanone gave only a poor optical yield. Since the structural difference between 2-hexanone and 2-octanone is not significant, it was expected that the change in the reaction conditions would improve the optical yield of the hydrogenation of 2-octanone. The optical yield of the

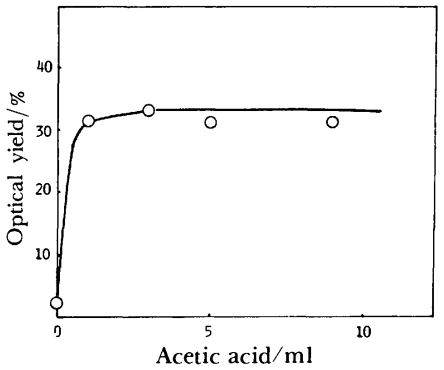

Fig. 1. The relation between the optical yield and the amount of acetic acid in the reaction system. Catalyst; RNi modified with TA (2 g) and NaBr (4 g).

hydrogenation of methyl acetoacetate (MAA) was known to be affected by the presence of carboxylic acid in the reaction system as an additive.[9,10] Thus, the effects of additives on the hydrogenation of 2-octanone were first examined. As is shown in Fig. 1, the addition of a small amount of acetic acid to the reaction system steeply increased the optical yield. Around 30% of the optical yield was obtained by the addition of 1 ml (0.02 mol) of acetic acid to 10 ml (0.064 mol) of the substrate. However, no further increase in the optical yield was observed when more than 1 ml of acetic acid was added. In order to find a more efficient substance than acetic acid, the reaction was carried out in the presence of various additives. The results are listed in Table 1. Among the compounds examined, α-branched carboxylic acids gave the best results. The best result was obtained by the use of pivalic acid. No other classes of compounds, such as hydroxy acid, alcohol, amine, and sulfonic acid, functioned as effective additives. Figure 2 shows the relationship between the amount of pivalic acid in the reaction system and the optical yield. The optical yield increased with the increase in the amount of pivalic acid until it reached a constant value. The maximum optical yield was obtained when more than 12 ml (0.11 mol) of pivalic acid was added to 10 ml (0.064 mol) of 2-octanone. The results showed that the use of a proper amount of α-branched carboxylic acid was important in obtaining a high optical yield.

In the second step, the effects of the modification variables of the nickel catalysts on the optical yields were examined, because the optical yield was also known to be affected significantly by the modification

Table 1. Effects of the additives on the optical yield

Additives	Amount	$[\alpha]_D^{20}$/°	Optical yield/%
None	—	+0.22	2
Acetic acid	3 ml	+3.2	33
Propionic acid	12 ml	+4.2	43

2, 2-Dimethyl-1-propanol	9 g	+0.26	3
Triethylamine	15 ml	+0.88	9
p-Toluenesulfonic acid	7 g	—[1]	—[1]

Modifying solution: (*R*, *R*)-TA (2 g) and NaBr (4 g) in 200 ml of H_2O. 1) No hydrogen uptake.

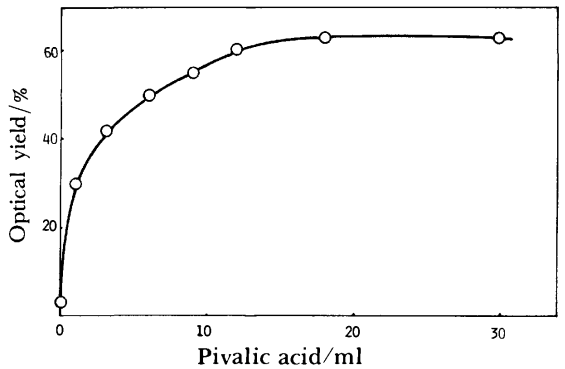

Fig. 2. The relation between the optical yield and the amount of pivalic acid in the reaction system. Catalyst; RNi modified with TA (2 g) and NaBr (4 g).

variables. Figure 3 shows the relationship between the amount of NaBr used for the preparation of MRNi and the optical yield. The optical yield increased with the increase in the amount of NaBr to reach a plateau. The constant value was obtained by the addition to TA of more than twice as much NaBr by weight.

Besides NaBr, various inorganic salts were used for the preparation of MRNi. None of the inorganic salts was found to be more effective than NaBr, as is shown in Table 2.

The modifying pH and the temperature were found to be important factors governing the optical yield of the reaction, like the hydrogenation of MAA.[7] The dependences of the optical yields on the modifying pH and the temperature are listed in Table 3. So far as we

Modifying solution: (*R*, *R*)-TA (2g) and NaBr (12g) in 200ml of H_2O. Additive: Pivalic acid (18ml). 1) MRNi was prepared from 19g of the RNi alloy.

examined, the modification at pH 3.2, and 100 °C gave the best result.

The enantioface-differentiating hydrogenations of various kinds of methyl ketones were carried out under the optimum reaction conditions for the hydrogenation of 2-octanone. The results are shown in Table 4. Unbranched methyl ketones, except for 2-butanone and 4-phenyl-2- butanone, were hydrogenated in an optical yield of around 65%. 2-Butanone and 4-phenyl-2-butanone were hydrogenated in rather low optical yields. From the comparison of the optical yields of the hydrogenation of 2-butanone, 3-methyl-2-butanone, and 3,3-dimethyl-2-butanone, it appears that there is a tendency for methyl ketones with α-alkyl substituents to be hydrogenated in higher optical yields than unbranched ones. The highest optical yield (74%) was obtained in the hydrogenation of 3,3-dimethyl-2-butanone.

Experimental

The analytical and preparative GLC of the products were carried out with a Shimadzu GC-6A gas chromatograph. The optical rotations were measured with a Perkin Elmer 241 polarimeter. The ^{1}H-NMR and IR spectra were taken with a JEOL-FX200 instrument and a Shimadzu IR 27G spectrometer respectively.

Materials. All the chemicals except for those described below were obtained from commercial sources and were used without further purification.

Tetrahydrofuran. Commercial tetrahydrofuran was dried over NaH overnight and then distilled.

Racemic 3-Hydroxybutyric Acid. This was prepared by the alkali hydrolysis of methyl 3-hydroxybutyrate which had been obtained by the hydrogenation of MAA.

2,2-Dimethylhexanoic Acid. This compound was prepared by the procedure of Pfeffer *et al.*[11]

Catalyst. Unless otherwise stated in the text, the catalyst was prepared in the following manner: a 3.8-g portion of the Raney nickel alloy (Ni:Al=42:58)was added, portion by portion,to 40 ml of a 20% aqueous NaOH solution, and then the mixture was allowed to stand at 100 °C for 1 h. After the subsequent removal of the alkaline solution by decantation, the catalyst was washed 30 times with a 30-ml portion of deionized water. The resulting catalyst was modified for 1 h at 100 °C with 200ml of an 1.0% aqueous solution of (*R*,*R*)-TA containing the stated amount of inorganic salt, the pH of which had been adjusted to 3.2 with 1 mol dm^{-3} NaOH. After the removal of the modifying solution, the catalyst was washed successively with a 20-ml portion of water, two 100-ml portions of methanol, and two 30-ml portions of anhydrous tetrahydrofuran.

Hydrogenation of Methyl Ketones. A mixture of methyl ketone (10ml) dissolved in anhydrous tetrahydrofuran (20 ml) and a stated amount of an additive was subjected to hydrogenation under an initial hydrogen pressure of 90 kg/cm^2. Hydrogenation was carried out in a 100ml autoclave at 100 °C. After the removal of the catalyst by decantation and the evaporation of the solvent, the product was dissolved in 100ml of ether and washed with a saturated aqueous solution of K_2CO_3 to remove the carboxylic acid. The ether solution was then dried over anhydrous Na_2SO_4 and concentrated *in vacuo*. As for 2-hexanol, 2-heptanol, 2-octanol, 2-decanol, 2-tridecanol, and 4-phenyl-2-butanol, simple distillations gave hydrogenated products with chemical purities of more than 98% (GLC analyses: at 130 °C, 5% Tween 80 on Shimalite W; at 100—220 °C, 2% OV-17 on Chromosorb W). In the cases of 2-butanol, 2-pentanol, 3-methyl-2-butanol, and 3,3-dimethyl-2-butanol, the products were contaminated by the solvent (tetrahydrofuran) through the simple distillation. Some of the products were further purified by preparative GLC (at 100 °C for 2-butanol, 130 °C for 2-pentanol and 3,3-dimethyl-2-butanol, 20% PEG-20M Chromosorb W; at 125 °C, 15% UCON 50HB-2000 on Chromosorb W for 3-methyl-2-butanol) and subjected to analyses of the chemical and optical purities. These products showed chemical purities of more than 98% in the GLC analyses (at 130 °C, 5% Tween 80 on Shimalite W; at 100—220 °C, 2% OV-17 on Chromosorb W). The ^{1}H-NMR spectra of the products were consistent with their structures; IR (neat) 3350—3400 cm^{-1} (OH).

Determination of Optical Yield. The optical yields of the hydrogenation of methyl ketones were estimated from the specific rotations of the pure enantiomers: (*S*)-2-butanol, $[\alpha]_D^{20}$+13.87 ° (neat);[12] (*S*)-2-pentanol, $[\alpha]_D^{20}$+13.70 ° (neat);[12] (*S*)-2-hexanol, $[\alpha]_D^{20}$+11.57 ° (neat);[12] (*S*)-2-heptanol, $[\alpha]_D^{20}$ +10.32 ° (neat);[12] (*S*)-2-octanol, $[\alpha]_D^{20}$+9.76 ° (neat):[12] (*S*)-2-decanol, $[\alpha]_D^{20}$+8.68 ° (neat);[12] (*S*)-2-tridecanol, $[\alpha]_D^{20}$+7.22 ° (neat);[12] (*S*)-3-methyl-2-butanol, $[\alpha]_D^{20}$+4.85 ° (neat);[13] (*S*)-3,3-dimethyl-2-butanol, $[\alpha]_D^{20}$+7.71 ° (neat);[14] (*S*)-4-phenyl-2-butanol, $[\alpha]_D^{20}$+14.23 ° (neat).[14]

The authors would like to thank Professor Yoshiharu Izumi, Dr. Akira Tai, and Dr. Hiroshi Ozaki, Osaka University, for their many helpful suggestions. The authors also wish to express their thanks to the Ajinomoto Co., Inc., for its financial support and to the Kawaken Fine Chemicals Co., Ltd., for providing the RNi alloy.

Studies of Liquid Water by Computer Simulations. III. Dynamical Properties of a 2-D Model

Yosuke KATAOKA
Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606
(Received December 2, 1983)

Molecular dynamics simulations of a water-like system are performed at many temperatures and densities. A 2-dimensional model of water is used for the system with 144 molecules in a square cell. The calculated self-diffusion coeffcient and the dipole direction relaxation time are in good agreement with the observed values in a wide temperature-pressure plane. Cross correlation function of displacement and local orientational order parameter are computed by the time-averaged configurations, where the average of period is several times longer than the velocity correlation time. The cross correlation is observed even in the third neighbor pairs, which proves the existence of hydrogen-bonded local structure. The lifetime of this local structure is about 2×10 ps at low temperatures and low density, where density maximum is known. The lifetime of the unstable species with a rather high energy is found to be about 0.5—2 ps at low temperatures and low density.

In the first paper of this series,[1] it was shown that a simple 2-D model of water can reproduce main features of the thermodynamical behavior observed in real water over a wide region of the liquid state. In the present article, we shall study dynamical properties of 2-D water by molecular dynamics (MD) simulations.

By MD method, Rahman and Stillinger and others[2] studied static and dynamic properties of liquid water. However, a systematic study is not yet performed on the density dependence of the dynamical properties of liquid water. For this reason, we are going to perform MD simulations at many temperatures and densities. The dipole direction relaxation time and the self-diffusion coefficient will be calculated as a function of temperature and density. The effects of compression on these quantities which are in good agreement with experimental data[3,4] will be discussed. The present paper also deals with the lifetime of the local structure in liquid water which is not examined so far. Because water molecules perform oscillatory motion within the framework of hydrogen-bonded local structure, the configuration is averaged over a period longer than the correlation time of velocity. The lifetime of the local structure will be calculated by two methods, the cross correlation function of displacement and the local orientational order parameter. The dynamics of the unstable molecule which is not well bound in the hydrogen-bonded cluster will be also studied. The concentration of the unstable species will be obtained as a function of temperature and pressure and will be compared with the results of the two-state model analysis of real water.[5]

Molecular Dynamics Method

Classical mechanics describes the time evolution of our 2-D water system. The Hamiltonian H for N rigid rotor molecules consists of kinetic energy for translational and rotational motions, plus interaction potential energy.

$$H = \frac{1}{2}\sum_{i=1}^{N}(m\boldsymbol{v}_i^2 + I\dot{\varphi}^2) + \sum_{(ij)} U(\boldsymbol{R}_{ij}, \varphi_i, \varphi_j). \quad (1)$$

The linear and angular velocities are denoted by $\boldsymbol{v}$ and $\dot{\varphi}$.

The pair potential U consists of a Lennard-Jones potential and an anisotropic potential U_{anis} multiplied by a switching function S:

$$U(\boldsymbol{R}_{12}, \varphi_1, \varphi_2) = 4\varepsilon\left[\left(\frac{\sigma}{R_{12}}\right)^{12} - \left(\frac{\sigma}{R_{12}}\right)^{6}\right] + S(R_{12}; R_1, R_2, R_3)\, U_{\text{anis}}(\boldsymbol{R}_{12}, \varphi_1, \varphi_2), \quad (2)$$

where R_{12} denotes the distance between two molecules 1 and 2 and φ_1 and φ_2 the orientations of the respective molecules. The switching function S cuts down the anisotropic potential for $R_{12}<R_1$ and for $R_{12}>R_3$. The details are shown in Ref. 1.

The mass of the molecule m is 18 in units of atomic weight and the moment of inertia I is 3.34×10^{-46} g m^2. For simplicity, the center of mass is assumed to be the center of the molecule (see Fig. 2 of Ref. 1).

We shall use the following reduced units.[1] The energy E is measured in units of ε_0=24.68 kJ/mol, ($-\varepsilon_0$ is the absolute minimum of the pair potential energy, *i.e.* ε_0 is the hydrogen bond energy), the length in units of R_0=27.6 nm and area per molecule A in units of R_0^2. Pressure P is measured in units of ε_0/R_0^2. (If we replace R_0^2 by R_0^3, new reduced units can be applied to the three-dimensional real water. Such reductions of units are of course only a convention, and therefore one should be satisfied with semiquantitative comparisons between the 2 D model and real water). Temperature T is measured in units of ε_0/R, where R is the gas constant which is not shown explicitly hereafter. As for the time units we use three kinds of units:

1) Time unit for rotation
$$t_0^{\text{ROT}} = (I/\varepsilon_0)^{1/2} = 2.86 \times 10^{-14}\,\text{s},$$
2) Time unit for translation (3)
$$t_0^{\text{TR}} = (mR_0^2/\varepsilon_0)^{1/2} = 2.37 \times 10^{-13}\,\text{s},$$
3) and real time scale s.

Our system consists of 144 molecules in a square unit cell with periodic boundary condition. The coupled dynamical equations are numerically integrated[6] with time increment

$$\Delta t = 0.870 \times 10^{-15}\,\text{s} = 0.304\, t_0^{\text{ROT}}. \quad (4)$$

The total energy is conserved within 0.01% after 24000 steps, or 21 ps. At low temperatures and low density, a long run (30000 steps or 78 ps) with time increment

2.6×10^{-15} s is performed to obtain the long (20 ps) lifetime of the local structure.

At a given density the 144 molecules are placed initially within the periodic cell at random positions, with random orientations, and with no translational or rotational velocities. After some steps, the kinetic energies are reduced to decrease the temperature. This reduction was repeatedly performed to obtain several low temperature samples. In our standard run, 3000 steps are spent for the aging of the system. After this interval, the subsequent period of 30000 steps, or 26 ps is the period over which the molecular dynamics' statistical averages are calculated. Simulations are performed at about 90 state points. The static properties (energy, pressure, radial distribution function and others) thus calculated are in good agreement with the results of our Monte Carlo simulations.[1]

Kinetic Properties

A couple of dynamical quantities are calculated in a way similar to Rahman and Stillinger's method.[2] As these results are only the 2-D version of their results, in the first place only a part of these will be shown briefly in the low density region (area per molecule $A=0.957\ R_0^2$), where thermodynamic quantities of 2-D water show interesting aspects like real liquid water under normal pressure. After that, the dipole direction relaxation time and the self-diffusion coefficient will be discussed.

The velocity autocorrelation function at temperature $T=0.18\ \varepsilon_0$, area per molecule $A=0.957\ R_0^2$ crosses the horizontal axis at 0.05 ps and shows several oscillations. The Fourier spectrum has a peak at $3\times10^{13}\ s^{-1}$ with half-full-width $6\times10^{13}\ s^{-1}$. The angular velocity correlation function crosses the horizontal axis at 0.02 ps. The Fourier spectrum has a peak at $9\times10^{13}\ s^{-1}$, with half-full-width $6\times10^{13}\ s^{-1}$. These frequencies correspond to the observed ν_L and ν_T.[7] These functions show clearly that there exists an oscillatory motion of water molecules at low temperatures.

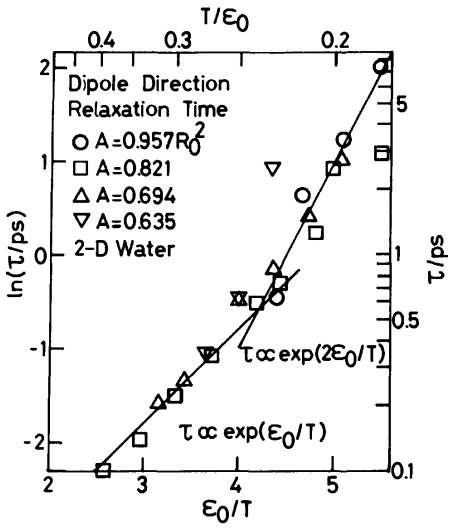

Fig. 1. The dipole direction relaxation time τ is plotted against the inverse of temperature $1/T$ at four densities.

The molecular dipole direction relaxation time τ is shown in Fig. 1 at four densities. This time constant at low densities and low temperatures has the comparable value to the measured dielectric relaxation time.[3,7] The relaxation time in the case where $A=0.821\ R_0^2$ is shorter than that in the case of low density ($A=0.957\ R_0^2$) at low temperatures $T\leq0.24\ \varepsilon_0$. This effect of compression is compared with the experiments on the dielectric relaxation under high pressure,[3] qualitatively. Figure 1 also shows that the temperature dependence of the dipole direction relaxation time τ is roughly written as $\tau\propto\exp(2\ \varepsilon_0/T)$ at low temperatures ($T\lesssim0.24\ \varepsilon_0$) and as $\tau\propto\exp(\varepsilon_0/T)$ at high temperatures ($T\gtrsim0.24\ \varepsilon_0$), where ε_0 is the hydrogen bond energy. The temperature dependence at low temperatures seems too steep, compared with the observed results on real water.[7]

The self-diffusion coefficient D is calculated from the mean-square displacement. In Fig. 2, D is shown as a function of T and P. The region between two dashed lines corresponds to liquid state. At low temperature ($T=0.18\varepsilon_0$), D is almost constant in spite of compression, thus D shows anomalous behavior similar to the observed one.[4] Figure 3 shows that the temperature dependence of D at constant density is well approximated to be $D\propto\exp(-\varepsilon_0/T)$. This depend-

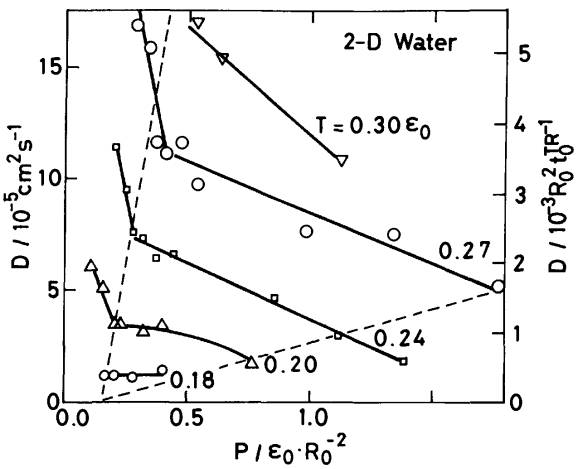

Fig 2. The self-diffusion coefficient D *vs.* pressure P plots are shown. Values of the temperature are indicated next to each curve. The region between two dashed lines corresponds to the liquid state.

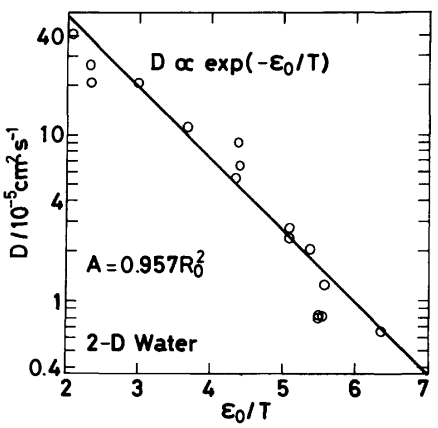

Fig. 3. Plot of D *vs.* $1/T$ at $A=0.957\ R_0^2$.

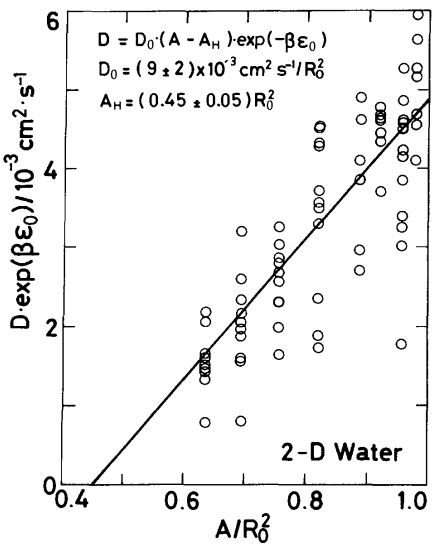

Fig. 4. Plot of $D\exp(\varepsilon_0/T)$ *vs.* area per molecule A.

ence is comparable with experimental results on real water.[7] The density dependence is shown in Fig. 4. From Figs. 3 and 4 the temperature-density dependence of D is summarized as follows;

$$\begin{aligned} D &= D_0\,(A-A_H)\exp\,(-\varepsilon_0/T), \\ D_0 &= (9\pm2)\times10^{-3}\,\mathrm{cm^2\,s^{-1}}\,R_0^{-2}, \\ A_H &= (0.45\pm0.05)\,R_0^2, \end{aligned} \tag{5}$$

although there are some deviations especially at low temperatures. It is worthwhile to notice that the value of constant A_H is close to the area of the high density ice ($0.50\ R_0^2$) and A-A_H means the area of hole in liquid water.

Thus it has been shown that the MD simulation of 2-D model can reproduce the main anomalous dynamical behavior of liquid water. On the basis of these results, the lifetime of the hydrogen-bonded cluster will be obtained in the next section.

Lifetime of Hydrogen-bonded Local Structure

Time Averaged Configuration. An oscillatory motion of water molecule is seen at low temperatures and densities as shown in the preceding section. Therefore, we use the time averaged configuration in this section in order to obtain the lifetime of hydrogen bonded local structure. The configuration is averaged over a period of 0.13 ps. This means that we study the vibrationally averaged structure (V-structure) of liquid water as discussed by Eisenberg and Kauzmann.[7,8]

Cross Correlation of Displacement. In the V-structure it is expected that the molecules in the same hydrogen-bonded cluster move to nearly the same direction on average. On the basis of this idea, we are going to calculate the cross correlation of displacement.

The position r_i of molecule i at time $t=0$ is denoted as r_i^0, and the displacement of molecule i is $r_i-r_i^0$. Figure 5 shows the cross correlation of displacement of molecule i and j $<(r_i-r_i^0)\cdot(r_j-r_j^0)>$ at low temperatures and low density with the following condition at $t=0$. As the low density ice type network of hydrogen bond is the square lattice in our model,[1] the molecular distance R_{ij} at $t=0$ is classified as follows;

$$\begin{aligned} &0.85\,R_0 < R_{ij} < 1.23\,R_0 \quad (i.e.\ R_{ij} \simeq R_0), \\ &1.23\,R_0 < R_{ij} < 1.71\,R_0 \quad (i.e.\ R_{ij} \simeq 2^{1/2}R_0), \\ &1.71\,R_0 < R_{ij} < 2.41\,R_0 \quad (i.e.\ R_{ij} \simeq 2R_0), \\ \text{or } &2.41\,R_0 < R_{ij} < 2.91\,R_0 \quad (i.e.\ R_{ij} \simeq 2^{3/2}R_0). \end{aligned} \tag{6}$$

It should be noticed that the linear part of cross correlation function ($R_{ij}-R_0$ at $t=0$) extends up to 2×10 ps. The value of tangent of this linear part is as large as about 30% of that in the

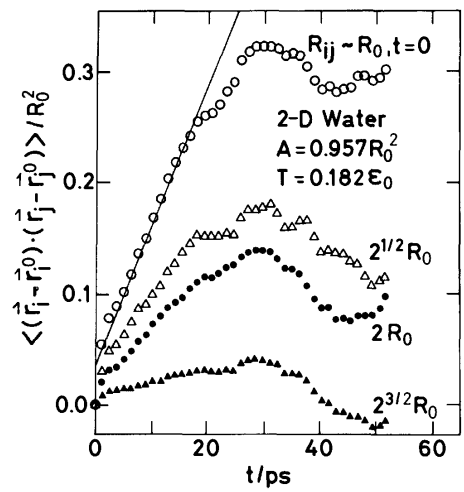

Fig. 5. The cross correlation functions $<(r_i-r_i^0)\cdot(r_j-r_j^0)>$. The initial conditions in the statistics are indicated in the figure.

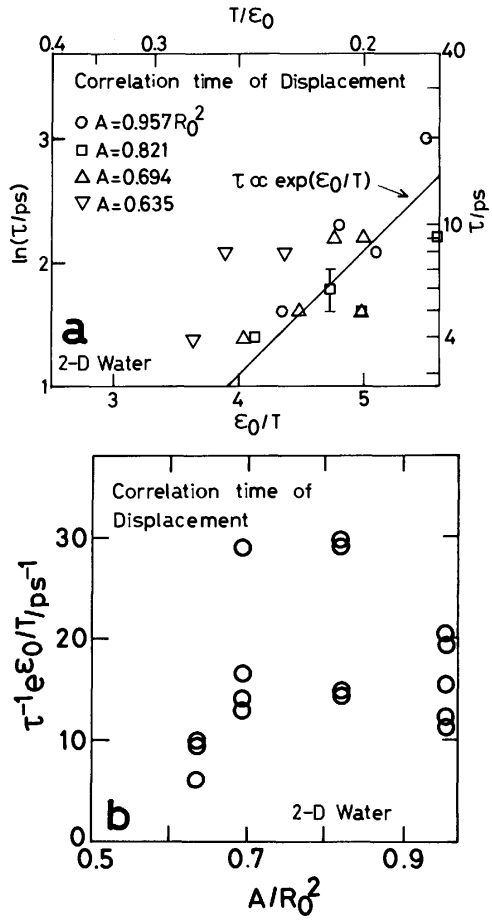

Fig. 6. a) The cross correlation time τ of displacement *vs.* the inverse of temperature $1/T$. b) Plot of $\tau^{-1}\exp(\varepsilon_0/T)$ *vs.* area per molecule A.

case of $i=j$. Thus this figure shows that molecules i and j with $R_{ij}-R_0$ at $t=0$ move collectively in a period of about 2×10 ps to nearly the same direction.

One can see cross correlation of the displacement in the cases of $R_{ij}-2^{1/2}R_0$ and $2R_0$ which is negligible in the case of more distant pair $R_{ij}-2^{3/2}R_0$. In other words cross correlation of displacement is seen even in the third neighbor pair. Figure 6 shows the temperature and density dependence of the cross correlation time τ of displacement. In Fig. 6(a), we see that the cross correlation time τ depends on temperature T as $\tau\propto\exp(\varepsilon_0/T)$ on average, where ε_0 is the energy of hydrogen bond. This temperature dependence seems reasonable (*cf.* Fig. 3). For this reason, a quantity $\tau^{-1}\exp(\varepsilon_0/T)$ is plotted against the area per molecule A in Fig. 6(b) in order to obtain the density dependence of τ. This figure shows that the cross correlation time τ at first becomes shorter due to compression from the normal density, then it becomes longer if 2-D water is compressed to the density close to that of high density ice.[1]

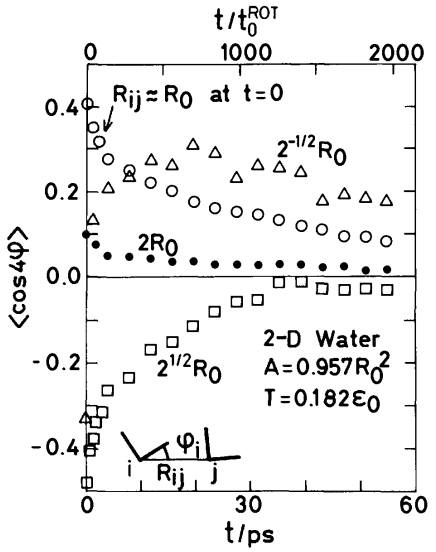

Fig. 7. Plot of $<\cos4\varphi>$ *vs.* time t. The initial conditions in the statistics are indicated in the figure.

Local Orientational Order Parameter. We performed many calculations to confirm the above lifetime by other methods. One of them will be shown in this section. The rotational motion, too, will be studied here.

At low temperatures water molecule has local orientational order due to the hydrogen bond. The angle φ_i is the orientation of the molecule i measured from the vector $\boldsymbol{R}_{ij}$ (see Fig. 2 in Ref. 1). The average $<\cos4\varphi>$ is used to examine the local orientational order, as shown in Fig. 7. In the case of low density ice at OK (Fig. 5 in Ref. 1), this order parameter has the following values:

$$<\cos4\varphi> = 1, \qquad R_{ij} = R_0, 2R_0,$$
$$<\cos4\varphi> = -1, \qquad R_{ij} = 2^{1/2}R_0. \tag{7}$$

One can see the local orientational order in the first neighbor ($R_{ij}-R_0$) and the second neighbor pair ($R_{ij}-2^{1/2}R_0$). The half-life period of $<\cos4\varphi>$ (orientational relaxation time) is 15 ps in the case of $R_{ij}-R_0$. This value is in good agreement with that of the cross correlation time of displacement.

The density dependence of orientational relaxation time is shown in Fig. 8. Figure 8(a) shows that the temperature dependence of the orientational relaxation time τ is written as $\tau\propto\exp(2\varepsilon_0/T)$ at low temperatures ($T\lesssim0.24\varepsilon_0$) (*cf.* Fig. 1). As for the density dependence, the cross correlation time of displacement and the relaxation time of $<\cos4\varphi>$ has a

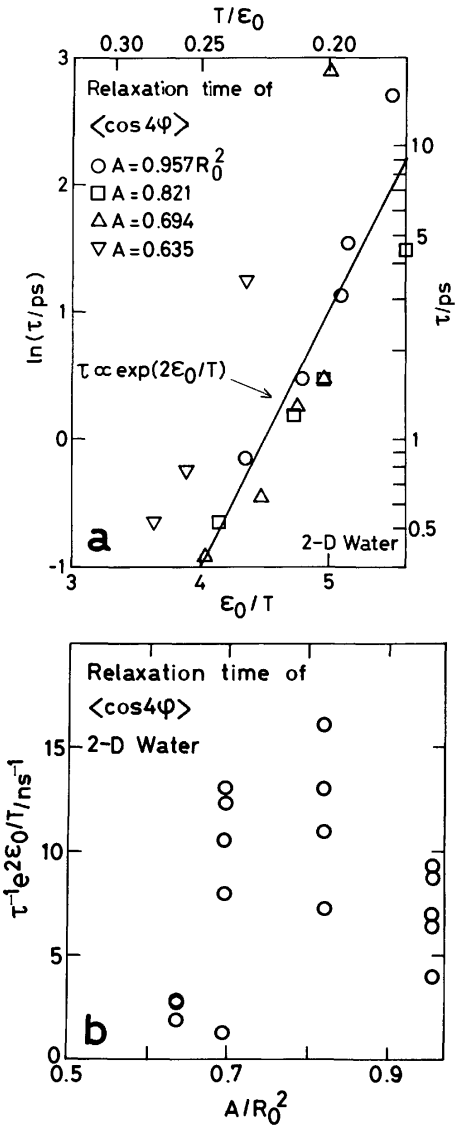

Fig. 8. a) The orientational relaxation time τ of $<\cos4\varphi>$ *vs.* the inverse of temperature $1/T$. b) Plot of $\tau^{-1}\exp(2\varepsilon_0/T)$ *vs.* area per molecule A.

similar behavior as that shown in Figs. 6(b) and 8(b). Figures 1, 6, and 8 indicate that the initial effect of pressure increase (at low temperatures and low pressure) leads to increased fluidity, known to be true in the case of real water.[3,4]

Dynamics of Unstable Species

In the preceding section it was described that molecules with the oscillatory motion are stable and are located in the hydrogen-bonded cluster. This section is devoted to the dynamics of the unstable species. On the contrary to the preceding section, the time averaged configuration is not used here.

The binding energy (BE) is defined as follows:

$$\mathrm{BE}_i = \frac{1}{2}\sum_j U_{ij} \tag{8}$$

In liquid water the distribution of BE is as wide as shown in Fig. 9 in Ref. 1.[9] The BE of the molecule with one hydrogen bond is about 0.5 ε_0. The molecule with more than one hydrogen bond may be called stable species. Thus, we call this molecule unstable species if the following condition is fulfilled:

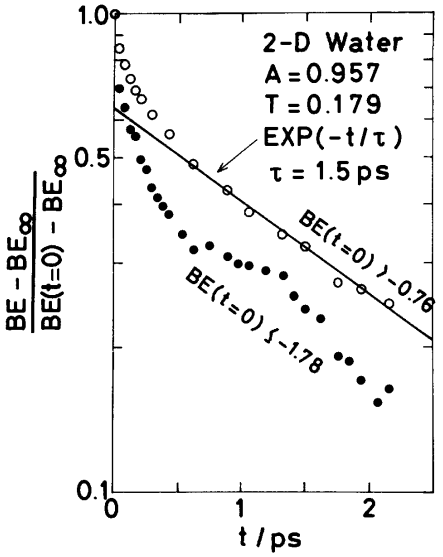

Fig. 9. The relaxation of the binding energy.

$$BE > -0.76\,\varepsilon_0. \tag{9}$$

The relaxation of BE for unstable species is shown in Fig. 9. Here, the molecules are classified according to Eq. (9), where BE is taken to be the value at $t=0$. The deviation of BE from its equilibrium value relaxes to 0.5 times the deviation at initial condition at about $t=0.5$ ps (short term) and then decays as a function $\exp(-t/\tau)$, $\tau=1.5$ ps (long term) ($A=0.957\,R_0^2$, $T=0.179\,\varepsilon_0$). The long term of relaxation time of BE is shown as a function of temperature and density in Fig. 10. It can be seen that this relaxation time τ does not depend strongly on density and that its temperature dependence is written as $\tau \propto \exp(\varepsilon_0/T)$.

The velocity autocorrelation functions

$$f^{TR}(t) = \frac{\langle \boldsymbol{v}(t)\cdot\boldsymbol{v}(0)\rangle}{\langle \boldsymbol{v}(0)\cdot\boldsymbol{v}(0)\rangle}, \tag{10}$$

of both species are shown in Fig. 11. Dynamical properties are different in two species. The behavior of $f^{TR}(t)$ for the unstable species is very similar to that of liquid Ar.[10] The unstable species has a larger self-diffusion coefficient than the stable one.

The concentration x of the unstable species is shown as a function of T and P in Fig.12. This figure is similar to the results of the mixture model by Konda and Yamamoto.[5]

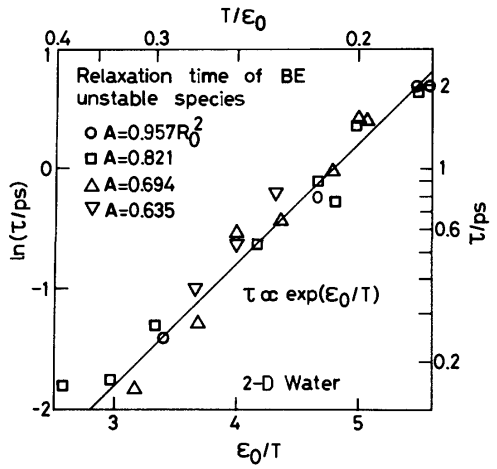

Fig. 10. The long term of the relaxation time τ of BE *vs.* the inverse of temperature $1/T$.

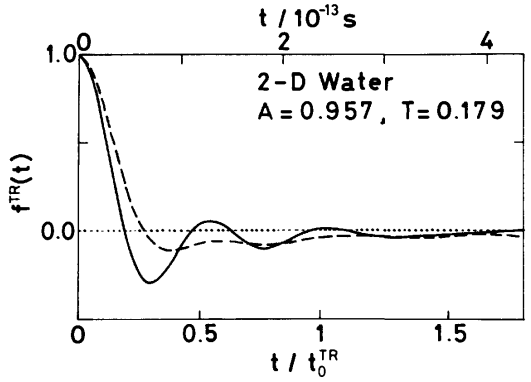

Fig. 11. The velocity autocorrelation functions. The dashed curve corresponds to the unstable species and the solid one corresponds to the stable species.

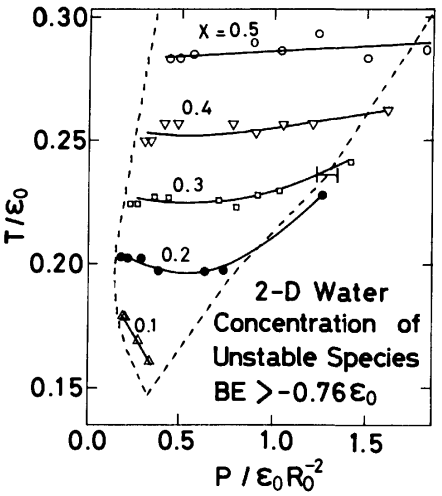

Fig. 12. The concentration of the unstable species is shown in P-T plane.

In this section, the relaxation of BE is calculated and it turned out that the short term of relaxation is about 0.5 ps and the long term one, about 1.5 ps. Therefore, classification like Eq. (9) is meaningfull in observations where the time scale in not longer than several ps. Such classification may be usefull in understanding of the anomalous behavior of liquid water, like the simple two-state model.

Concluding Remarks

The vibrationally-averaged structure (V-structure) of liquid water was discussed by Eisenberg and Kauzmann.[7,8] In the present article the size and lifetime of the vibrationally-averaged local structure in 2-D water are obtained to be about 13 molecules (as far as third neighbors) and about 2×10 ps by observing time scale of 0.13 ps at low temperatures and low density, where the density maximum is known.

The oscillatory motion of water molecule has a time constant of about 0.02—0.05 ps. The relaxation time of dipolemoment of the water molecule is about 5 ps. The binding energy relaxes with decay constants of about 0.5—1.5 ps.

The author would like to thank Professor Tsunenobu Yamamoto, Dr. Keiji Okazaki, Dr. Shuichi

Nosé, Dr. Kenkichi Okada and Dr. Kazuo Maki for kind discussions. A part of the computation was done at the Computer Center of the Institute for Molecular Science and at the Kyoto University Data Processing Center.

Yields of Electron Transfer Reactions in the Quenching of the Phosphorescent States (^{2}E) of Tris(2,2′-bipyridine)chromium(III) and Tris(4,7-diphenyl-1,10-phenanthroline)chromium(III) Compounds

Takeshi OHNO* and Shunji KATO
Chemistry Department, College of General Education, Osaka University, Toyonaka, Osaka 560
(Received December 21, 1983)

Molar absorption coefficients of the phosphorescent states (^{2}E) of $[Cr(2,2'\text{-bipyridine})_3]^{3+}$ and $[Cr(4,7\text{-diphenyl-1,10-phenanthroline})_3]^{3+}$ were determined. The ^{2}E state of $[Cr(2,2'\text{-bipyridine})_3]^{3+}$ was reduced to $[Cr(2,2'\text{-bipyridine})_3]^{2+}$ with the yield of less than 0.2 in the quenching by iron(II) compounds. The reduction yields of $[Cr(2,2'\text{-bipyridine})_3]^{3+}$ and $[Cr(4,7\text{-diphenyl-1,10-phenanthroline})_3]^{3+}$ in the quenching of ^{2}E by aromatic amines increase with the Gibbs energy change ($-\Delta G$) in the reverse electron-transfer process. The weak dependence of the yields on ΔG can not be interpreted in terms of adiabatic reverse electron transfer in the geminate pair, which is formed in the quenching process. The electron transfer from the chromium(II) compounds of triplet spin-multiplicity to the amine radical of doublet spin-multiplicity suffers from spin-restriction.

The bimolecular electron transfer reactions of photoexcited compounds are followed by two kinds of the reverse process. The one takes place in the lifetime of the geminate radical pair formed in the electron transfer quenching. The other can be observed to occur as the second order process with respect to the free radical formed in the bulk. Hoselton *et al.*[1] proposed that the small yield of the electron transfer products in the bulk was ascribed to the fast reverse electron transfer in the geminate pair. Ohno and Lichtin also found that the yield of free radical was reduced by the reverse electron transfer competing with the dissociation of the triplet geminate pair, though every bimolecular quenching of the phosphorescent state of a dye molecule, Methylene Blue, yielded the geminate radical pair.[2-4] Moreover, they found that the rates of the reverse electron transfer are slower than those estimated from the free energy changes and the rearrangement energies involved in the process. The slower rates of the reverse electron transfers were ascribed to the spin-restriction of the process.[4,5] In this work, the product yields in the electron transfer quenching of the phosphorescent states of $[Cr(2,2'\text{-bipyridine}^*)_3]^{3+}$ and $[Cr(4,7\text{-diphenyl-1,10-phenanthroline}^*)_3]^{3+}$ are investigated by means of laser photolysis kinetic spectroscopy. Nonadiabaticity due to spin-restriction on the electron transfer reactions will be discussed.

Experimental

Apparatus. An NEC SLG-2018 Q-switched ruby laser was used in most of the experiments. The second harmonics (347 nm) of the power less than 0.1 J was generated by using temperature matching nonlinear crystal of RDA supplied by Quantum Tecknology. The laser beam (ϕ=10 mm) is vertically converged and holizontally expanded to 3 mm ×12 mm on the sample cell (10 mm×10 mm) by using two cylindrical lenses. The monitoring beam from a 150 W xenon arc lamp was set in right angles to the laser beam. Increases in light intensity of 50—100 times can be obtained by the use of a transistor-switched discharging circuit. The converged monitoring beam passes through a small aperture on the sample cell, which is located at the depth of 1—2 mm from the cell window exposed to the laser. The laser intensity at 347 nm was attenuated by insertion of a filter solution of chromium alum. The details of the laser and the monitoring apparatuses have been described elsewhere.[4] The absoption change was recorded in a transient recorder, Kawasaki Electronica M-500T or a storagescope, Iwasaki-Tsushinki TS-8123, followed by computer analysis using a laboratory-constructed mini-computer.[6] A 5 cm long cell was used for an excitation by means of xenon flash apparatus. A Hitachi 323 Spectrophotometer was used for the measurement of absorption spectra and a Hitachi MPF-2A Spectrofluorophotometer was used for the measurement of phosphorescence.

Materials. $[Cr(bpy)_3](ClO_4)_3\cdot 1/2H_2O$ was prepared by a similar method as that reported by Baker and Mehta.[7] The crude sample of $[Cr(bpy)_3](ClO_4)_3$ was purified by repeated recrystalizations from the aqueous solution and the methanol solution. $[Cr(dp\text{-}phen)_3](ClO_4)_3\cdot H_2O$ was prepared by a method of Kane-Maguire *et al.*[8] All the aromatic amines- diphenylamine(DPA), triphenylamine (TPA), 3,3′-dimethylbenzidine(DMB), 1,2-phenylenediamine (1,2-DP), 1,4-phenylenediamine (1,4-DP), *N,N,N′,N′*-tetramethylbenzidine(TMB), *N,N,N′,N′*-tetramethyl-1,4-phenylenediamine(TMPD), supplied by Tokyo Kasei or Aldrich, were purified by vacuum sublimation. Ferrocene was recrystallized from the benzene solution and ferrocenecarboxylic acid was recrystallized from the ethanol solution. $Fe(NH_4)_2(SO_4)_2\cdot 6H_2O$ and acetonitrile (AN) of Wako Pure Chemical Co. were used as supplied. Water was purified by the passage through a Millipore deionizer and filter.

Procedure. All the sample solutions were deaerated by purging with nitrogen of 99.99% purity for 15 min. All the measurements were done at 15±2 °C.

Molar Absorption Coefficients. The molar absorption coefficients of ^{2}E states were obtained on the assumption that all the $[Cr(bpy)_3]^{3+}$ or $[Cr(dp\text{-}phen)_3]^{3+}$ of 40—50 μM[1] were excited to the ^{2}E state by the laser light of 347 nm. The complete excitation of the compound to ^{2}E state was ascertained by a constant production of the transient absorbance due to ^{2}E with an attenuation of the laser intensity.

Quenching Rate Constants. Decays of the excited state absorptions of the chromium compounds were spectroscopically monitored with or without a quencher. In order not to excite the quenchers of TMPD and TMB which are photoionized on the exposure to 347 nm light, a xenon flash for the photolysis was used with a 375 nm cut-off-filter. The quenching rate constants of the excited state by TMPD

* The following abbreviations will be used hereafter, 2,2′-bipyridine: bpy, and 4,7-diphenyl-1,10-phenanthroline: dp-phen.

[1] 1 M=1 mol dm^{-3}.

and TMB (k_q) were obtained from Stern-Volmer plots of the phosphorescence intensity of the chromium(III) chelate compounds ($[Cr(NN)_3]^{3+}$).

Fractions of Electron-transfer-product Formation in the Quenching. The production of $[Cr(N-N)_3]^{2+}$ ($[Cr(N-N)_3^{2+}]_0$) or the radical cation of amine in the quenching was calculated from the absorption change by using the molar absorption coefficients of $[Cr(bpy)_3]^{2+}$ ($4860\,M^{-1}cm^{-1}$ at 560 nm[9]), $[Cr(dp\text{-}phen)_3]^{2+}$($5500\,M^{-1}cm^{-1}$ at 460 nm[10]), $TPA^{\dagger}$ ($30500\,M^{-1}cm^{-1}$ at 660 nm in dichloromethane[11]), $TMB^{\dagger}$ ($41000\,M^{-1}\,cm^{-1}$ at 474 nm in AN[12]), and $TMPD^{\dagger}$ ($12000\,M^{-1}cm^{-1}$ in H_2O[13]). The production of $[Cr(N-N)_3]^{2+}$, which decayed in several hundred microseconds, was measured after the fast disappearance of ^2E in a few microseconds. The production of ^2E state ($[^2Cr(N-N)_3^{3+}]_0$) in the presence of the quencher was monitored to be constant. The fractions of $[Cr(N-N)_3]^{2+}$ production in the quenching, denoted by F_i, were calculated as a ratio of the reaction rate constant of $[Cr(N-N)_3]^{2+}$ production (k_{et}) to the quenching rate constant (k_q) or a ratio of $[Cr(N-N)_3^{2+}]_0$ to $[^2Cr(N-N)_3^{3+}]_0$ with the complete quenching. The rate constants of $[Cr(N-N)_3]^{2+}$ production (k_{et}) were determined by using a following equation,

$$\frac{[Cr(N-N)_3^{2+}]_0}{[^2Cr(N-N)_3^{3+}]_0} = k_{et}\frac{[Q]}{k_d}, \qquad (1)$$

where [Q] is the quencher concentration and k_d is the observed decay rate constant of $^2[Cr(N-N)_3]^{3+}$ in the presence of the quencher.

Results

Absorption Spectrum of Excited State of $[Cr(N-N)_3]^{3+}$. A transient species observed after laser excitation of $[Cr(N-N)_3]^{3+}$ exhibits an absorption spectrum as in Figs. 1 and 2. The lifetimes of the excited state were 60 μs for $[Cr(bpy)_3]^{3+}$ and 200 μs for $[Cr(dp\text{-}phen)_3]^{3+}$. The transient absorbances of $^2[Cr(bpy)_3]^{3+}$ at 390 nm and of $^2[Cr(dp\text{-}phen)_3]^{3+}$ at 520 nm were measured with attenuation of the laser intensity (see Fig. 3).

Electron Transfer Quenching of ^2E by Iron(II) Compounds. Ferrocene and ferrocenecarboxylic acid of less than 0.5 mM quenched the ^2E state of $[Cr(bpy)_3]^{3+}$ in a 70% AN aqueous solution. Iron(II) ions in a 1 M HCl or a 1 M $HClO_4$ aqueous solution also quenched the ^2E. The quenching were more effective in 1 M HCl than in 1 M $HClO_4$. The quenching rate constants are shown in Table 1. As the ^2E state decayed in the presence of ferrocene, another transient species was produced, whose absorption spectrum consists of bands at 480 and 560 nm as is shown in Fig. 4. This transient spectrum is almost identical to that of $[Cr(bpy)_3]^{2+}$ reported by König and Herzog,[9] and by Serpone *et al.*[10] The iron(III) compound formed, ferro-

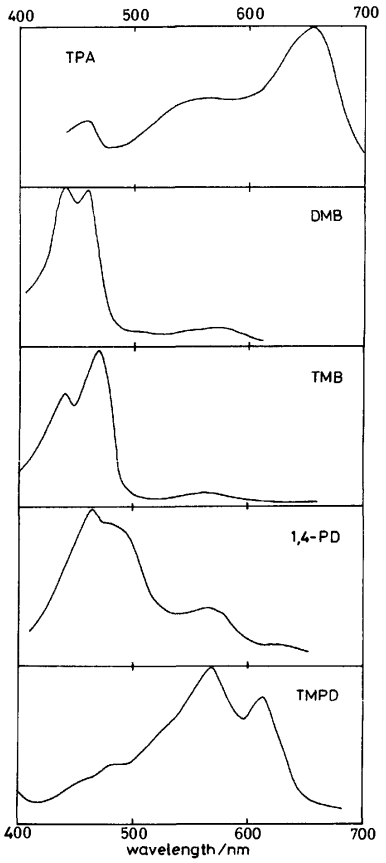

Fig. 5. Difference absorption spectra of the photolyzed solution of $[Cr(bpy)_3]^{3+}$ and the amine after the decay of ^2E. The intensity is arbitary.
a) triphenylamine, b) 3,3′-dimethylbenzidine, c) *N,N,N′,N′*-tetramethylbenzidine, d) 1,4-phenylenediamine, e) *N,N,N′,N′*-tetramethyl-1,4-phenylenediamine.

cenium ion, has a minor contribution to the transient spectrum, because ferrocenium ion which was obtained by the oxidation of ferrocene in a 1 M $HClO_4$ 70% AN aqueous solution with iron(III) ion, has a broad and weak absorption (the molar absorption coefficient is 800 $M^{-1}cm^{-1}$ at 560 nm).

The fraction of $[Cr(bpy)_3]^{2+}$ production in the quenching by the iron(II) compounds examined are less than 0.18 of the ^2E production. The values of k_{et} and F_1 are shown in Table 1.

Electron Transfer Quenching of ^2E by Aromatic Amines. Aromatic amines of DPA, TPA, DMB, 1,2-PD, 1,4-PD, TMB, and TMPD, quenched the ^2E of $[Cr(N\text{-}N)_3]^{3+}$ with the rate contants close to the diffusion-controlled

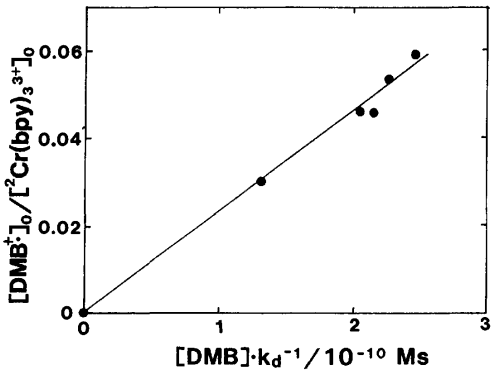

Fig. 6. Determination of k_{et} in the quenching of $^2[Cr(bpy)_3]^{3+}$ by DMB. $[DMB^+]_0$ is the production of one-electron oxidized 3,3-dimethylbenzidine in the quenching.

one (see Table 2). The quenching processes resulted in the production of the second transient species of $[Cr(N\text{-}N)_3]^{2+}$ and the radical cation of the amine. As Fig. 5 shows, transient absorption spectra were observed after the disappearance of ^2E except for the quenching by DPA. They are composed of the bands at 560 nm due to $[Cr(N\text{-}N)_3]^{2+}$ and the more intense band(s) which can be ascribed to the radical cation of the quencher, because these intense bands are in agreement with those of the radical cation reported[11-13]; the band at 660 nm is ascribed to TPA^+, the bands at 440 and 460 nm to DMB^+, the band at 465 nm to 1,4-PD^+, the band at 470 nm to TMB^+, and the bands at 580 and 615 nm to $TMPD^+$. The rate constants of the electron transfer reactions (k_{et}) are obtained by plotting Eq. 1 as is shown in Fig. 6. Most of the fractions of $[Cr(N\text{-}N)_3]^{2+}$ production measured in the quenching of $^2[Cr(bpy)_3]^{3+}$ were obtained as the ratio of k_{et} to k_q. As for $^2[Cr(dp\text{-}phen)_3]^{3+}$, all the fractions were obtained as the ratio of $[Cr(dp\text{-}phen)_3]^{2+}$ production to $^2[Cr(dp\text{-}phen)_3]^{3+}$ production with complete quenching of $^2[Cr(dp\text{-}phen)_3]^{3+}$. They are tabulated in Table 2. All the radical and $[Cr(bpy)_3]^{2+}$ formed in the quenching reactions were returned to the parent compounds via the second-order reaction, *e.g.* the reverse electron transfer.

Discussion

^2E States of $[Cr(N\text{-}N)_3]^{3+}$. The difference absorption spectra of photolyzed solution of $[Cr(N\text{-}N)_3]^{2+}$ are ascribed to the production of the excited state of $[Cr(N\text{-}N)_3]^{3+}$, ^2E which are identical to those reported by Maestri *et al.*[14] and by Serpone *et al.*[10]

TABLE 2. REDOX POTENTIALS OF AROMATIC AMINES AND RATE CONSTANTS OF ^2E WITH AROMATIC AMINES

Compound	$E°$/V	$Cr(bpy)_3^{3+}$ k_q / $10^9 M^{-1}s^{-1}$	F_1	$Cr(dp\text{-}phen)_3^{3+}$ k_q / $10^9 M^{-1}s^{-1}$	F_1

a) C. K. Mann and K. K. Barnes, "Electrochemical Reactions In Nonaqueous Systems," Marcel Deckker, N. Y. (1970). b) The value is estimated from the redox potential of 1, 4-PD assuming the difference in the redox potential between 1, 2-PD and 1, 4-PD to be equal to the difference in the redox potential between *N, N, N', N'*,-tetramethyl-1, 2-phenylenediamine and *N, N, N', N'*,-tetramethyl-1, 4-phenylenediamine.[c] c) A. Zweig, J. E. Lancaster, N. T. Neghia, and W. H. Jura, *J. Am. Chem. Soc.*, **86**, 4130(1964).

The complete conversion of $Cr(N\text{-}N)_3^{3+}$ to the ^2E state (see Fig. 3) allowed us to calculate the molar absorption coefficients of the excited states to be 3.1×10^3 M^{-1} cm^{-1} at 390 nm and to be 200 $M^{-1}cm^{-1}$ at 600 nm for $^2[Cr(bpy)_3]^{3+}$ and to be 6.0×10^3 $M^{-1}cm^{-1}$ at 520 nm for $^2[Cr(dp\text{-}phen)_3]^{3+}$ after the correction due to the depression of absorbance of the ground state. They agree in the order with the molar absorption coefficients of $^2[Cr(bpy)_3]^{3+}$ calcuated from the light absorption, which was roughly estimated from the absorbance of the sample solution in the wide wavelength region and the light intensity of non-monochromatic pumping xenon flash.[14] Since the absorption bands of ^2E except for the broad band of $^2[Cr(bpy)_3]^{3+}$ at 600 nm are too strong to be assigned as a d-d band,[15] they can be assigned to the transitions from ^2E at 13700 cm^{-1} to the doublet CT state. This assignment is in agreement with that proposed by Serpone *et al.*,[10] who studied the band shift in the absorption spectra of excited chromium(III) compounds of substituted 2,2′-bipyridine or 1,10-phenanthroline. Since strong CT transitions of ^2E states were also observed in the visible region for chromium(III) compounds, such as $[Cr(NCS)_6]^{3-}$, $[Cr(NCS)_4(NH_3)_2]^-$, Cr(acetylacetonato)$_3$, and so on,[16] an appearance of strong CT band in the visible region can be expected for the excited states of most chromium(III) compounds. Meanwhile, the weak and broad band in the visible region can be assigned to a d-d transition ($^2E\rightarrow{}^2A_2$).

The strong absorption bands of ^2E are useful to estimate the production of ^2E and to calculate the fractions (F_1) of $[Cr(N\text{-}N)_3]^{2+}$ production in the quenching process. It is parenthetically noted that a larger molar absorption coefficient of $^2[Cr(bpy)_3]^{3+}$ (7000 $M^{-1}cm^{-1}$) has been reported by Lilie and Waltz.[17] They obtained the value on an assumption made by Ferraudi *et al.*[18] that the production of $[Cr(bpy)_3]^{2+}$ in the complete quenching by Fe^{2+}_{aq} in 0.1 M $HClO_4$ might be equal to the production of $^2[Cr(bpy)_3]^{3+}$. However, since the efficiency of $[Cr(bpy)_3]^{2+}$ production in the quenching may not be unity (0.18 in 1 M $HClO_4$), this value of the molar absorption coefficient is assumed to be the possible maximum.

Electron Transfer Reaction of ^2E with Amines. The productions of $[Cr(bpy)_3]^{2+}$ and the radical cation of the aromatic amine indicate the quenching of ^2E *via* electron transfer mechanism by the amine, as has been reported by Ballardini *et al.*[19] The efficiencies (F_1) of $[Cr(N\text{-}N)_3]^{2+}$ production in the quenching reaction can be expressed as $F_1=k_{et}/k_q$ using the rate constants of electron transfer reaction (k_{et}) and quenching reaction (k_q). As Table 2 shows, the values of the F_1 increase with the decrease of the redox potential of the amine; F_1 is the largest with TMPD (0.25 V) and the smallest with DPA (1.08 V) or TPA (1.1 V). This trend in the change of F_1 can be understood by assuming the following reaction mechanism, in which a reaction intermediate, a geminate pair or a cage complex, is postulated.

$$^2[Cr(N\text{-}N)_3]^{3+}+D \longrightarrow {}^2({}^3[Cr(N\text{-}N)_3]^{2+}\text{—}{}^2D^+), \quad k_f \quad (2)$$

$$^2({}^3[Cr(N\text{-}N)_3]^{2+}\text{—}{}^2D^+) \longrightarrow {}^3[Cr(N\text{-}N)_3]^{2+}+{}^2D^+, \quad k_{dis} \quad (3)$$

$$^2({}^3[Cr(N\text{-}N)_3]^{2+}\text{—}{}^2D^+) \longrightarrow {}^4[Cr(N\text{-}N)_3]^{3+}+D. \quad k_r \quad (4)$$

The fraction of $[Cr(N\text{-}N)_3]^{2+}$ production in the quenching can be rewritten as,

$$F_1 = k_{dis}/(k_{dis}+k_r), \quad (5)$$

using the rate constants of elementary processes of the geminate pair. The dependence of k_r on the free energy change (ΔG) involved in the process is apparently reflected on the ratio of k_r to k_{dis}, which is expressed as the observable quantity, $1/F_1-1$, because the rate of electron transfer can be written as follows, provided that the electron transfer process is adiabatic,

$$k_r = (k_1k_2f_{12})^{1/2}\exp(-\Delta G/2RT), \quad (6)$$

where k_1 and k_2 are the rate constants of the self exchange electron transfer of reactants 1 and 2, respectively, and f_{12} is nearly constant.[20] Then, the final expression is as follows,

$$\ln(k_r/k_{dis}) = \ln(1/F_1-1) = -\Delta G/2RT + A', \quad (7)$$

for the adiabatic process on assuming the free energy change for the dissociation of the geminate pair to be constant. As shown in Figs. 7 and 8, the values of ln $(1/F_1-1)$ nearly fit the expected relation of Eq. 7, provided that the difference in the solvation energy and the electrostatic energy between the initial and the final states is neglected and ΔG is expressed as $E°(Cr^{III}/Cr^{II})-E°(D^+/D)$, where $E°(Cr^{III}/Cr^{II})$ and $E°(D^+/D)$ are the redox potentials of $[Cr(N\text{-}N)_3]^{3+}$

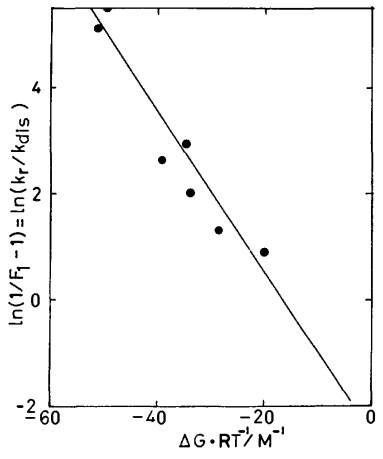

Fig. 7. The dependence of the fraction of $[Cr(bpy)_3]^{2+}$ production in the quenching reaction on the free energy change involved in the reverse electron transfer.

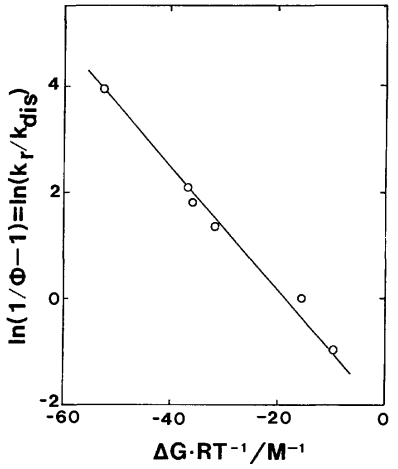

Fig. 8. The dependence of the fraction of $[Cr(dp\text{-}phen)_3]^{2+}$ production in the quenching on the free energy change involved in the reverse electron transfer.

(-0.26 V[10,21]) and the amine, respectively. However, the values (-0.14 for $[Cr(bpy)_3]^{3+}$ and -0.12 for $[Cr(dp\text{-}phen)_3]^{3+}$) of $\partial(\ln(k_r/k_{dis}))/\partial(\Delta G/RT)$ obtained from Figs. 7 and 8 are less negative compared to the ideal value (-0.5) estimated for an adiabatic electron transfer process. Since the reverse electron transfer is accompanied by spin conversion (doublet→quartet) as shown in Eq. 4, the nonadiabaticity in the process may retards the reaction rate. Actually, a less negative value(-0.07) of $\partial(\ln(k_r/k_{dis}))/\partial(\Delta G/RT)$ was obtained for the spin-inverted electron transfer between doublet organic radicals containing no heavy atom.[3,5] The larger dependence of k_r on ΔG was reported for the spin-inverted electron transfer reactions between doublet iron(III) compounds and the doublet radical of Methylene Blue,[3] and between the triplet excited state of $[Ru(bpy)_3]^{2+}$ and doublet $Cu^{+2}{}_{aq}$.[1]

An alternative explanation is that a part of the geminate pair may be converted to an exciplex in which the spin conversion more likely occurs and the reverse electron transfer occurs as a radiationless transition of the exciplex. Since the dependence of radiationless transition rate in the exciplex on ΔG is positive according to Mataga *et al.*,[22] $\partial(\ln k_r/k_{dis})/\partial(\Delta G/RT)$ is expected to be positive. This kind of switchover mechanism has been proposed to explain the radical yield in the bimolecular quenching of singlet excited state.[23]

Electron Transfer Reaction of ^2E with Iron(II) Compounds. Efficiencies of $[Cr(bpy)_3]^{2+}$ formation in the quenching by the iron(II) compounds are calculated to be 0.069—0.18 as shown in Table 1. The smaller values of the efficiencies with iron(II) ion in the 1 M hydrochloric acid than in the 1 M perchloric acid are essentially ascribed to the faster reverse electron transfer in the geminate pair because the reverse electron transfer from the bulk in the hydrochloric acid ($1.4\times10^9\,M^{-1}s^{-1}$) is faster than that in the perchloric acid ($1.0\times10^9\,M^{-1}s^{-1}$). However, since the efficiencies of net electron transfer in the quenching are much smaller than the fraction of collision complex undergoing no electron transfer in the bulk reverse process (0.53—0.67), which can be obtained from the rate constants of the reverse electron transfer (k_{ret}) and the collision complex formation (k_e) as $(k_e-k_{ret})/k_e$, other types of quenching, paramagnetic ion-induced intersystem crossing and energy transfer must be accompanied with electron transfer. It is probable that the iron(II) quenching of ^2E takes place *via* quintet iron-induced intersystem crossing,[15b] which was proposed in the iron(II) quenching of triplet excited molecule.[24] Meanwhile, the ΔG-dependence of k_q in the iron(II) quenching of ^2E led to conclusion that the principal process was not energy transfer but electron transfer.[25]

The larger rate of reverse electron transfer in the 1 M hydrochloric acid indicates the formation of $Fe^{III}Cl_{6-n}(H_2O)_n^{(3-n)+}(n=1—6)$. The larger quenching rate constant in 1 M HCl than in 1 M $HClO_4$ may sugggest the formation of the chloride complex of iron(II), which is responsible for the faster rate of reverse electron transfer in the geminate pair.

F_1 in the quenching by ferrocenecarboxylic acid is less than a half of the value by ferrocene. This reduction is ascribed to the fast reverse electron transfer in the geminate pair compared to ferrocene because $-\Delta G$ of the reverse process with ferrocenecarboxylic acid (1.06 ev) is larger than that (0.81 ev) with ferrocene.

Studies of the Hydrous Tin(IV) Oxide Ion-exchanger. II. Some Properties as a Cation-exchanger

Yasushi INOUE* and Hiromichi YAMAZAKI
Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980
(Received September 5, 1983)

In order to elucidate the fundamental properties of hydrous tin(IV) oxide as a cation-exchanger, the stoichiometry of cation exchange and its acid-base property were studied by means of the uptake curves for alkali-metal ions. The results are summarized as follows: 1) The equivalent exchange between the hydrogen ion and either alkali-metal or alkaline-earth-metal ions holds, irrespective of the ionic strength of the solution and the extent of exchange. 2) The water content in the exchanger depends on the ionic composition. 3) This material is an amphoteric ion-exchanger, with at least two kinds of weakly dissociable ion-exchange sites, and the conditional dissociation constant depends on the ionic composition of the exchanger. The stability to various reagents was also examined.

Several studies have been carried out on the ion-exchange property of hydrous tin(IV) oxide,[1-8] but different compositions and ion-exchange properties have been reported by different investigators. This may be due to the irreproducibility of the synthesis; hence, a detailed examination of the synthetic procedure is indispensable to undertaking any further study of this material. With this point in mind, the relation between the yield of hydrous tin(IV) oxide and the conditions of precipitation for various synthetic systems, and the ion-exchange properties relevant to the synthesis were investigated in a previous paper.[9] There is little choice between the $Na_2[Sn(OH)_6]$-H_2SO_4 and $SnCl_4$-NH_3 aq systems with respect to yield or physical and ion-exchange properties, but the former system is inferior to the latter in its very lengthy washing. The exchanger is semitransparent and consists of nearly amorphous particles which are hard to be ground into particles suitable for column operation, and can be converted to the pure hydrogen form by conditioning with 0.1 mol dm^{-3} HCl. The exchanger of the H^+ form prepared from the $SnCl_4$-NH_3 aq system has a composition of $SnO_2 \cdot 2.18H_2O$ and an ion-exchange capacity of 1.18 mmol Na^+ g^{-1} (at pH 11.3). This is stable for longer than 15 months after preparation when it is stored over a saturated NH_4Cl solution.

Of the many properties which have not been investigated in detail, the acid-base property and the mechanism of adsorption are very important in understanding the material as an ion-exchanger. This induced us to examine the validity of the equivalence of cation-exchange reactions on the exchanger prepared from the recommended $SnCl_4$-NH_3 aq system and the uptake curves for various alkali-metal ions, which are useful for understanding the acid-base property of the exchanger.

Experimental

Reagents and Apparatus. The hydroxide solutions of the alkali-metal and alkaline-earth-metal ions except those of the lithium and sodium ions were prepared by passing corresponding chloride solutions through a column packed with Dowex 1-x8 anion-exchange resin in the OH^- form. All the other chemicals used were of the highest-purity grade obtained from Wako Pure Chemical Industries, Ltd. All the apparatuses were the same as described previously.[9]

Preparation of the Ion-exchanger. The synthetic system No.5 described in the preceeding paper was chosen for the preparation of the ion-exchanger.[9] Into 0.5 dm^3 of a 1 mol dm^{-3} $SnCl_4$ solution prepared by diluting liquid $SnCl_4$ with water, 1.5 dm^3 of 2% NH_3 aq was added, drop by drop, at an average rate of 20—30 cm^3 min^{-1}. The precipitate thus formed was separated from the mother liquor by a combination of decantation and filtration through Toyo No.1 filter paper under suction, uniformly dispersed into distilled water, and filtered again after being completely sedimentated. This procedure was repeated until no chloride ion was detected in the filtrate. Then the precipitate was filtered and sufficiently air-dried at room temperature. The resulting product was then immersed in distilled water to break it down into fine particles. The grains were dried again at room temperature. Particles larger than desired, if any, were ground in a porcelain mortar and sieved to obtain the required particle sizes. The exchanger of a desired particle size (100—200 mesh) was converted to the H^+ form by treating it with a 0.1 mol dm^{-3} HCl solution by the procedure described previously.[9] Finally, the exchanger was air-dried and stored in a desiccator containing a saturated NH_4Cl solution(relative humidity: 79% at 25 °C).

Conversion to Na^+ Form. The exchanger in the H^+ form was immersed in an alkaline solution, prepared by the combination of 0.1 mol dm^{-3} NaCl and 0.1 mol dm^{-3} NaOH(ionic strength=0.10, pH=11.0). Then the slurry was poured into a glass column, through which the same solution was subsequently passed until the pH of the effluent approached that of the influent. The column was then washed with distilled water, followed by acetone. Then the exchanger was taken out of the column, air-dried for 30 min, and stored in a desiccator containing saturated NH_4Cl and 5 mol dm^{-3} NaOH solutions.

Analytical Methods. The Cl^- ions were determined by the Fajans method after the solution had been neutralized. The alkali-metal ions were converted to the corresponding pure chlorides and indirectly determined by titrating the Cl^- ions. The Sr^{2+} and Ba^{2+} ions were assayed by a complexometric titration: the Zn-EDTA displacement method, using eriochrome black T as an indicator. The OH^- and CO_3^{2-} ions were determined by differential titration. The water content in the exchanger was calculated from the weight loss when it was heated in air at 850 °C to a constant weight.

Chemical Stability. In 30 cm^3 of a suitable solution, 0.25 g of the exchanger in the H^+ form was immersed for 4 d at room temperature. The tin dissolved in the supernatant solution was determined spectrophotometrically.[10]

Ion-exchange Stoichiometry. The exchanger in the H^+ form was immersed in an alkaline solution of metal ions, of suitable concentrations(ionic strength=0.0024—0.022), in a nitrogen atmosphere for longer than 2 d at room temperature,

with intermittent shaking. This was followed by chemical analysis, and the ratio of the amount of metal ions taken up in the exchanger to that of the hydrogen ions released from the exchanger was evaluated from the difference between the initial and final concentrations of the respective ions present in the solution.

The other experimental procedures were the same as those previously described.[9]

Results and Discussion

Chemical Stability. To examine the chemical stability of the exchanger, the amount of tin dissolved in various reagents was measured. The results, shown in Table 1, indicate that, in neutral or alkaline solutions, the exchanger was unstable to NaOH and K_2CO_3, whereas it was fairly stable to NaCl, Na_2CO_3, and aqueous NH_3. In acid solutions, it was very stable to HNO_3 and H_2SO_4, but dissolved appreciably into HCl, $HClO_4$, and $H_2C_2O_4$, even at concentrations as low as 1 equivalent dm^{-3}. These results show that this exchanger is easily attacked by the acids having a strong tendency to complex tin(IV) and the bases which form soluble hexahydroxostannates. As it is known that α-stannic acid dissolves easily in K_2CO_3 and that β-stannic acid is stable to HNO_3 and H_2SO_4, the charscteristics of this exchanger are intermediate between those of α- and β-stannic acids. Because β-stannic acid is the dehydration product of α-stannic acid, this exchanger is considered to be more dehydrated and more condensed than α-stannic acid.

Table 1. Chemical stability[a]

Reagent	Solution Concentration	Amount of Sn dissolved
	mol dm^{-3}	wt%
NaOH	0.10	10
	0.94	19

Dependence of Exchange Capacity on Particle Size. The ion-exchange capacity for the Na^+ ion was measured as a function of the particle size, as is shown in Table 2. This table shows that the capacity was independent of the particle size. Hence, it can be concluded that the exchange sites are distributed uniformly in the particle.

Stoichiometry and Reversibility of Exchange Reaction. Table 3 presents the results concerning the stoichiometry of the exchange reaction between hydrogen ions on the exchanger and alkali-metal or alkaline-earth-metal ions in the solution. When the concentration of carbonate ions in a solution was decreased during contact, the amount of hydrogen ions released was determined from the difference in the sum of the carbonate and hydroxide ions before and after the equilibrium. As is shown in the last column of Table 3, the equivalent ratio of hydrogen ions released to metal ions absorbed became unity within the limits of experimental error. Therefore, the equivalent ion exchange holds irrespective of the ionic strength of the solutions, the extent of the exchange, and the kind of metal ion. From the stoichiometry of ion exchange and the dependence of the exchange capacity on the particle size, this material acts as an ideal cation-

Table 2. Dependence of cation-exchange capacity on particle size[a]

exchanger, possessing exchange sites distributed uniformly in the particle.

Figure 1 shows the forward and backward uptake curves for sodium ions. Since these curves agree with each other, the exchange reaction can be said to proceed reversibly, and it seems that no structural change would occur upon ion-exchange.

Change in Water Content of the Exchanger. The change in the water content of the exchanger with the amount of alkali-metal ions uptaken is shown in Table 4, where the amount of water and of metal ions uptaken is normalized to the value per mole of tin in the exchanger. If we compare this value with the water content in the H^+-form exchanger, 2.16 ± 0.01 mol H_2O (mol Sn)$^{-1}$, it is clear from Table 4 that the decrease in the water content is brought about by the uptake of alkali-metal ions. As part of water is removed from the exchanger by the release of H^+ ions from the OH group by ion-exchange, the water content, as estimated from the weight loss, should be corrected by adding half the amount of metal ions uptaken if the water content in the H^+ form is compared with that in the metal form. The corrected values are shown in the last column of Table 4, which shows that the water content decreased at first to a minimum and then increased gradually with the amount of alkali-metal ions in the exchanger. Furthermore, the water content is greater for larger hydrated cations, suggesting that these cations are uptaken as hydrated ions. As will be reported in a following paper, the order of selectivity for alkali-metal ions $Li^+ \gg Na^+ > K^+ > Rb^+ \approx Cs^+$, leads to the assumption that alkali-metal ions are present in the anhydrous state. This contradicts the foregoing suggestion. These results can be understood by considering that, at the early stage of exchange, the interstitial water is excluded by ingoing anhydrous cations, which have a larger volume than the proton. When the amount of cations uptaken exceeds a certain limit, the exchanger swells to relax the distortion produced in the structure of the matrix, so it can accommodate a larger ammount of water.

Acid-Base Properties. In order to study the acid-base property of the exchanger, the uptake curves for sodium and chloride ions were measured as a function of the pH, as is shown in Fig. 2. This figure reveals that this material is an amphoteric ion-exchanger

1) : Calcinated at 850°C. a) : Water content(II)=Water content(I)+1/2 (M^+ content). Exchanger: H^+ form, 100—200 mesh, $SnO_2 \cdot (2.16\pm0.01)H_2O$.

possessing a larger ion-exchage capacity for cations than for anions and having an isoelectric point close to pH 4. The inflection points at pH 7.6 and pH 2.0 for cation and anion exchanges respectively suggest that the exchanger has at least two kinds of dissociable ion-exchange sites.

The ion-exchange reaction and its equilibrium constant can be written:

$$\overline{H} + Na = \overline{Na} + H,$$

and:

$$K = K' \cdot \frac{\bar{f}_{Na}}{\bar{f}_H} = \frac{[\overline{Na}]\bar{f}_{Na}a_H}{[\overline{H}]\bar{f}_H a_{Na}},$$

where a superscript bar indicates the exchanger phase; [ ], the concentration; a, the activity of ions in the solutions; $\bar{f}$, the activity coefficient of ions in the exchanger, and K' ($\equiv[\overline{Na}]\cdot a_H/[\overline{H}]\cdot a_{Na}$), the conditional selectivity coefficient. By introducing the total specific ion-exchange capacity, $[\bar{S}]=[\overline{Na}]+[\overline{H}]$, we get:

$$\frac{1}{[\overline{Na}]} = \frac{1}{[\bar{S}]} + \frac{a_H}{K[\bar{S}]}\cdot\frac{\bar{f}_{Na}}{\bar{f}_H}\cdot\frac{1}{a_{Na}} = \frac{1}{[\bar{S}]} + \frac{a_H}{K'[\bar{S}]}\cdot\frac{1}{a_{Na}}.$$

If K' is assumed to be constant, the $1/[\overline{Na}]$ *vs.* $1/a_{Na}$ plot will show a linear relation, because $[\bar{S}]$ and a_H are constant in the present experiment. Table 5 shows the ion-exchange capacities of the exchanger for sodium ions, measured at a constant pH (11.00±0.03) as a function of the sodium-ion concentration in the solution. The plot of $1/[\overline{Na}]$ *vs.* $1/a_{Na}$, however, was not linear, as is shown in Fig. 3. In the calculation of a_{Na} for making this plot, the values of γ_{Na} given by Kielland[11] were used except in the case of the ionic strength, 0.5, where γ_{Na} was estimated by means of this relationship: $\gamma_{Na}=\gamma_{\pm NaCl}/\gamma_{\pm KCl}$. The non-linearity does not support the assumption that K' is constant, even in the pH region, where the same kind of acidic site takes part in the exchange reaction. Hence, either the $\bar{f}_{Na}/\bar{f}_H$ ratio or K changes as the exchange reaction proceeds. The change in the $\bar{f}_{Na}/\bar{f}_H$ ratio may be brought about by the variation in the electric field in the exchanger, which would be strongly affected by the ratio of dissociated to undissociated OH groups. The dissociation of an OH group may affect the electric distribution of other OH groups. This will result in a successive change in the dissociation constant with the change in the ionic composition of the exchanger, even in the same kind of exchange site. We can not decide which is more important, the ratio of the activity coefficients in the exchanger or the dissociation constant of the exchange site, as a reason for the non-constancy of K'. In any event, this material is an amphoteric ion-exchanger possessing at least two kinds of weakly dissociable ion-exchange sites. Furthermore, for the same functional group, the degree of dissociation depends on its ionic composition.

Table 5. Effect of Na^+ concentration on the ion-exchange capacity

Concentration of Na^+ $[Na^+]$ / mol dm^{-3}	Activity of Na^+ $\gamma^*_{Na}[Na^+]$	Ion-exchange capacity[a] $[Na]$ / mmol g^{-1}
1.0×10^{-2}	9.3×10^{-3}	0.974±0.006
5.0×10^{-2}	4.3×10^{-2}	1.094±0.006
1.0×10^{-2}	8.2×10^{-2}	1.160±0.006
5.0×10^{-1}	3.6×10^{-1}	1.29 ±0.01

a) : Column exchange capacity at pH 11.0. *: Activity coefficient of Na^+ ion; J. Kielland, *J. Am. Chem. Soc.*, **59**, 1675 (1937).

In order to compare the ion-exchange behavior for the Na^+ ion with that for other cations, uptake curves were obtained for other alkali-metal ions, as is shown in Fig. 4. The curve of the Li^+ ions was similar to that of the Na^+ ions, but the specific ion-exchange capacity was greater for Li^+ than for Na^+, by 0.2 and 0.3 mmol g^{-1} respectively, at the first and second stages. Because the hydrous tin(IV) oxide possesses a micropore structure and because its mean pore radius is as small as 0.5 nm, as was reported by Selim and Zeidan,[12] the difference between the ion-exchange capacity of

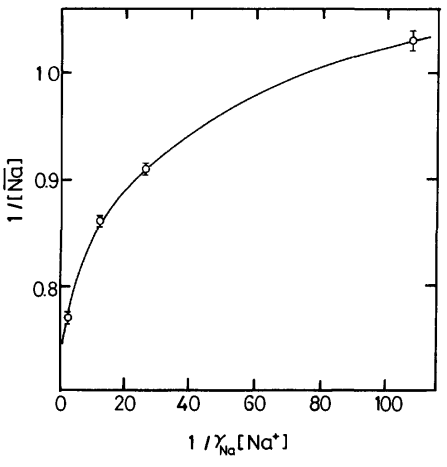

Fig. 3. $1/[\overline{Na}]$ *vs.* $1/\gamma_{Na}[Na^+]$ plot.
$[\overline{Na}]$: Column exchange capacity for Na^+ ion at pH 11.0 (mmol g^{-1}). $\gamma_{Na}[Na^+]$: Activity of Na^+ ion in the equilibrium solution.

these two ions may be attributable to an ion-sieving effect of this material. On the other hand, the uptake curves for the K^+, Rb^+, and Cs^+ ions agreed with that for the Na^+ ion in the lower pH region until the ion-exchange capacity reached around 0.45 mmol g^{-1}, whereupon it began to decrease steeply. This phenomenon can be ascribed to the dissolution of a part of the exchanger, which was verified by analyzing the amount of tin dissolved in the supernatant solution; the exchanger began to dissolve into the solution of K^+, Rb^+, and Cs^+ ions at a pH of around 7, in spite of the fact that no dissolution was observed in the solution of Na^+ and Li^+ ions. The unstability of the exchanger in alkaline solutions of heavy alkali-metal ions reflects the characteristics of α-stannic acid, which has a high solubility in K_2CO_3 and KOH. For α-stannic acid prepared by a similar method, the ion-exchange capacity for the K^+ ion was reported by Abe and Ito and by Sautereau *et al.* to be 0.54 and 0.75 mequiv. g^{-1} respectively at pH 10.[3,8] The reason for this contradiction may be the difference in the duration of immersion when the specific ion-exchange capacity was measured.

The Effects of Salts on the Solubilities of Benzene, Toluene, Ethylbenzene, and Propylbenzene in Water

Isao SANEMASA,* Seiji ARAKAWA, Masatake ARAKI, and Toshio DEGUCHI
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
(Received October 1, 1983)

Salt effects on the solubilities of benzene, toluene, ethylbenzene, and propylbenzene were studied by making use of the solute vapor. The salting coefficients were determined at 25 °C, and the results were compared with the literature values and with those estimated by means of theoretical equations. The McDevit-Long equation did not give satisfactory predictions until the equation was multiplied by a factor of 0.4. The scaled particle theory gave a favorable agreement with the observations in most cases if suitable pair-potential parameters of solutes were used in the calculations.

The solubility of a nonelectrolyte (solute) in aqueous electrolyte solution has been found to depend on the concentration and on the type of electrolyte present in the solution. In a sufficiently dilute nonelectrolyte solution, the activity coefficient, f, in the salt solution of a given molar concentration, C, is given by:

$$\log f=\log (S_0/S)=k_s C, \quad (1)$$

where S and S_0 denote the solubility of the nonelectrolyte in salt and salt-free solutions respectively, k_s being the salting coefficient.

In a previous paper, we reported a method of preparing aqueous solutions saturated with a solute such as benzene and the alkylbenzenes by means of a technique that made use of the solute vapor.[1] By means of this technique, the solubility equilibrium can be attained within quite a short time; moreover, we can determine the equilibrium solubility as a function of the vapor pressure of the solute. The present paper is an extension of the method to determining the salting coefficients of benzene, toluene, ethylbenzene, and propylbenzene. Many data on salt effects have been reported in the literature concerning benzene and, to less extent, toluene, but little is known about the alkylbenzenes of larger molecules. Almost all of the literature data have been obtained by putting "liquid" solute in direct contact with aqueous electrolyte solutions. Here we report salting coefficients determined by solubility measurements of the solute "vapor" in the presence of some typical electrolytes. The results obtained are compared below with the literature data and with those predicted by both the McDevit-Long equation and the scaled-particle theory.

Experimental

All the electrolytes and the nonelectrolytes used were of an analytical reagent grade. Deionized-redistilled water was used as a solvent. The concentrations of the electrolyte (stock) solutions were determined by either the argentometric or the gravimetric method.

The apparatus used and the procedures of the solubility measurements were the same as those described in the previous paper.[1] The apparatus was composed of two main parts: one was a separatory funnel (300 cm^3) in which an aqueous solution of from 100 to 200 cm^3 was placed, and the other was a pear-shaped flask (50 cm^3) in which a liquid solute of from 10 to 20 cm^3 was placed. We will call the former "solubility flask," and the latter, "solute reservoir." The solubility flask and the solute reservoir were connected to each other with Teflon and glass tubes. A Viton diaphragm pump was incorporated into the assembly. By means of the pump, the solute vapor was generated by bubbling air through the solute reservoir *via* a sintered glass ball and was then introduced into the solubility flask *via* another sintered ball. The solute vapor was thus circulated in a closed system. The total pressure inside the closed system was kept under atmospheric pressure. After the solubility equilibrium had been attained, an aliquot of the aqueous solution was taken out of the bottom of the solubility flask to determine the solute concentration by means of solvent extraction-spectrophotometry.

Results

The Time Required for Attaining the Solubility Equilibrium. An aqueous solution in the presence of an electrolyte has reached equilibrium with the solute vapor within 5 min at a circulation rate of 2 $dm^3 min^{-1}$. Some examples are shown in Fig. 1.

Solubility as a Function of the Solute-vapor Pressure. The aqueous phase in the solubility flask has come to be in equilibrium with the solute vapor, while in the solute reservoir the liquid solute has attained equilibrium with the vapor of water. From this point of view, the solute phase is no longer "pure"; hence, the vapor pressure of the solute inside the solubility flask differes from that of the pure solute. However, the solubilities of water in the liquid hy-

Circulation rate: 2.0 dm^3/min. Pure water (○), 0.408 mol dm^{-3} $(C_2H_5)_4NBr$ (●), 0.991 mol dm^{-3} $(CH_3)_4NBr$ (◑). Temperature of aqueous solution: 35.0 (○), 25.0 °C (●, ◑). Temperature of solute reservoir: 15.0 (○), 11.8 (●), 19.0 °C (◑).

drocarbons employed here are as small as 3×10^{-3} in the mole fraction.[2] Suppose that Raoult's law is valid; then, the difference in vapor pressure between the pure and actual solutes is only 0.3% or so. We have thus considered it permissible to employ the vapor pressure of the pure solute for the present purpose, the vapor-pressure data of benzene and the alkylbenzenes being taken from previously published tabulations.[3]

In order to check whether or not the solubilities are linearly dependent on the solute-vapor pressure, preliminary experiments were made on the following solute-electrolyte combinations: benzene-tetraalkylammonium bromides, toluene-(NaCl, KCl, $BaCl_2$, and NaSCN). The solubility runs were carried out under conditions such that, at a constant temperature of the aqueous electrolyte solution, the temperature of the solute reservoir was raised nearly up to that of the aqueous solution. Some typical results are shown in Figs. 2 and 3 for a given electrolyte concentration and in Fig. 4 for a constant temperature of the aqueous electrolyte solution, 25 °C. Strictly speaking, the solute-vapor pressure inside the solubility flask may differ from that inside the solute reservoir because of such factors as solute-water and solute-electrolyte interactions in the aqueous phase and the difference in temperature between the solute reservoir and the solubility flask. However, as can be seen from Figs. 2, 3, and 4, a plot of the solubility *vs.* the vapor pressure of the pure solute appears as a straight line for each solute-electrolyte combination investigated, regardless of the salting-in or -out nature of the electrolyte.

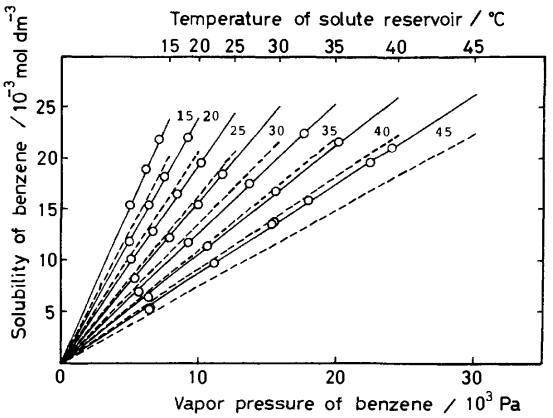

Fig. 2. Equilibrium solubility of benzene in $(CH_3)_4NBr$ aqueous solutions *vs.* vapor pressure.
Pure water (dotted line), 0.496 mol dm^{-3} $(CH_3)_4NBr$ solution (solid line). The figure near each line indicates the temperature of aqueous solution.

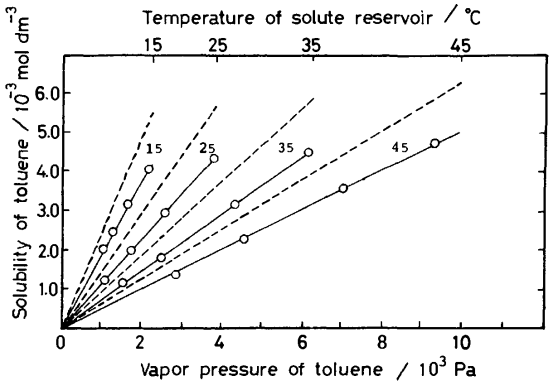

Fig. 3. Equilibrium solubility of toluene in NaCl aqueous solutions *vs.* vapor pressure.
Pure water (dotted line), 0.508 mol dm^{-3} NaCl solution (solid line). The figure near each line indicates the temperature of aqueous solution.

Experimental Salting Coefficients. The salting coefficients were all determined at 25 °C. In the beginning of this study, the solubilities were measured under conditions where the temperatures of both the solubility flask and the solute reservoir were the same. However, somewhat poor reproducibilities were then oberved. This is probably due to the fact that, because it is difficult to keep both temperatures exactly the same, the solute vapor condenses temporarily inside the solubility flask. Therefore, the solubility in each electrolyte solution, S, was estimated as follows: the equilibrium solubility was first measured keeping the solute reservoir at a temperature just below 25 °C, while the temperature of the solubility flask was maintained at 25 °C, and then the equilibrium solubility was extrapolated to find S on the assumption that the solubility obeys Henry's law. The solubility in pure water, S_0, was also estimated in the same way. The values thus determined are, at 25 °C: $10^3 \cdot S_0$ (in mol dm^{-3})=20.7 (benzene), 5.65 (toluene), 1.62 (ethylbenzene), 0.376 (propylbenzene). These values are in good agreement with those previously reported except for that of propylbenzene, which differs by *ca.* 10%.[1] In the present study, we will use as S_0 the values determined here. The salting coefficients, k_s, were determined by the least-squares method according to Eq. 1. The log (S_0/S) *vs.* C plots were almost proportional to the electrolyte concentrations up to 1 mol dm^{-3} for 1:1 electrolytes and 0.5 mol dm^{-3} for $BaCl_2$ and Na_2SO_4. The use of NaI as an electrolyte gave scattered plots and a poor reproducibility except in the case of benzene;

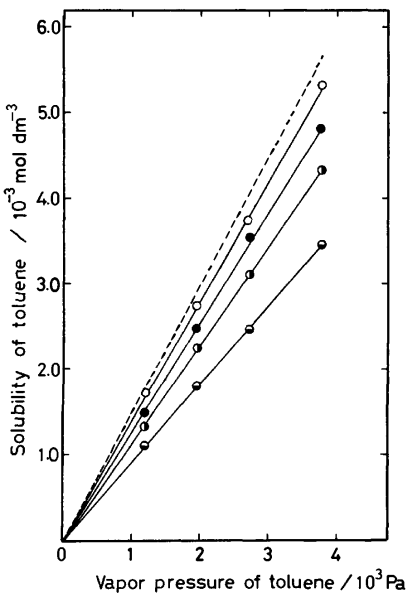

Fig. 4. Equilibrium solubility of toluene in KCl aqueous solutions *vs.* vapor pressure.
Pure water (dotted line), concentration of KCl: 0.101 (○), 0.253 (●), 0.505 (◑), 1.01 mol dm^{-3} (◒). The temperature of aqueous solution: 25.0 °C.

a) Observed and calculated at 25 °C. b) McDevit-Long equation (multiplied by a factor of 0.4). c) Scaled-particle theory. d) Ref. 4. e) Ref. 7. f) Z. Sir, L. Strnadova, and V. Rad, *Collect. Czech. Chem. Commun.*, **45**, 679(1980).

therefore, the results for the other solutes were omitted. The observed k_s values are listed in Table 1, together with the literature values. The present results are in good agreement with the literature. Comparisons for ethylbenzene and propylbenzene cannot be made, since no data are available for these solutes in the literature at the present time.

Salting Coefficients Calculated by Means of the McDevit-Long Equation. Based on the internal pressure theory (IPT), McDevit and Long have derived this equation[4]:

$$k_s=\overline{V}_i^\circ(V_s-\overline{V}_s^\circ)/2.3\,\beta_0 RT, \qquad (2)$$

where $\overline{V}_i^\circ$ is the partial molar volume of the solute at an infinite dilution, V_s is the molar volume of the pure electrolyte, $\overline{V}_s^\circ$ is the partial molar volume of the electrolyte at an infinite dilution, and β_0 is the compressibility of pure water. At 25 °C, $\overline{V}_i^\circ$ (in $cm^3\,mol^{-1}$)=89.4 (benzene), 106 (toluene), 123 (ethylbenzene), and 145 (propylbenzene).[5] All the other parameters were taken from the literature.[4,6-8] The values of k_s calculated by means of Eq. 2 are given in Table 1.

Salting Coefficients Calculated by Means of the Scaled-particle Theory. In order to predict the salting coefficients, equations have been derived based on the scaled-particle theory (SPT) by Masterton and Lee[9] and, more recently, by Miyajima *et al.*[10] We have calculated the salting coefficients according to the latter authors, since their equations are more definite and are

more widely applicable. In the present calculations, however, we neglected the self-interaction coefficient, k_2, in the equation given by Miyajima *et al.* since, in the present case, plots of $\log(S_0/S)$ *vs.* the electrolyte concentrations are almost linear through the zero intercept. Equations leading to k_0 are expressed as functions of the hard-sphere diameter, σ; the energy parameter, ε/κ; the polarizability, α; and the apparent molar volume of salt at an infinite dilution, ϕ_0. We adopted the same values of σ and ε/κ for water as those used in Ref. 10, and the same values of σ, α, and ϕ_0 for electrolytes as those used in Ref. 1, the parameter for I^- being taken from Ref. 9. The values of ε/κ for the electrolytes have been evaluated by means of Mavroyannis-Stephen equation:

$$\varepsilon/\kappa = 2.28\times10^{-8}\alpha^{3/2}Z^{1/2}\sigma^{-6}, \quad (3)$$

where Z is the total number of electrons of species. The necessary information on the parameters used for solutes is tabulated in Table 2.

Table 2. Parameters used for solutes in calculating salting coefficients by scaled-particle theory

Solute	$10^{24}\times\alpha$ [a]	$10^{8}\times\sigma$ [b]	ε/κ [c]
	$cm^3 mol^{-1}$	cm	K
Benzene	10.43	5.46	188
Toluene	12.26	5.93	159
Ethylbenzene	14.09	6.31	145
Propylbenzene	16.03	6.67	135

a) Estimated from molar refractivity. b) Evaluated by Eq. 4 in the text. c) Evaluated by Eq. 3 in the text.

Discussion

Table 1 shows that the absolute values of the salting coefficient as calculated by means of the McDevit-Long equation are generally larger than those observed and that, if the equation is multiplied by a factor of 0.4, the calculations give the closest prediction. The various k_s values observed for a number of hydrocarbons available in the literature enable us to compare the data with those estimated by the use of Eq. 2. The results are summarized in Table 3, from which it is noticable that most ratios, k_s(obsd)/k_s(calcd), are in the range of from 0.3 to 0.4. The McDevit-Long equation implies that the k_s is linearly dependent on the molar volume of the solute at a given electrolyte. Such plots are shown in Fig. 5 using the data obtained in the present study. The k_s appears for each electrolyte to be approximately proportional up to the molar volume corresponding to

Table 3. Comparison of salting coefficients reported in the literature with those calculated by McDevit-Long equation

ethylbenzene, but exhibits a poor proportionality in the vicinity of propylbenzene. According to the data shown in Table 3, the values of k_s observed for NaCl are plotted against the molar volume of each solute. The results are shown in Fig. 6, where the solid line and the dotted line indicate, respectively, the molar volume dependence of k_s expected from Eq. 2 and that of k_s multiplied the equation by a factor of 0.4. The plots in Fig. 6, though they seem to scatter around the dotted line, when inspected in more detail display a gently downward curve with an increase in the molar volume rather than a straight line.

The McDevit-Long equation gives satisfactory predictions of k_s for such solutes as H_2, N_2, O_2, CH_4, C_2H_4, and rare gases.[9,11] On the other hand, as was originally pointed out by McDevit and Long, the equation gives a k_s value for benzene consistently too high by a factor of from 2 to 3.[4] Deno and Spink also suggested that the equation must be multiplied by a factor of 0.3 to improve the agreement with the observed and the calculated k_s values of benzene.[7] It is noteworthy that the McDevit-Long equation predicts a high k_s not only for benzene, but also for such hydrocarbons as are shown in Table 3. The IPT explains the salt effect in terms of the electrostriction, $V_s - \overline{V}_s^o$ of the solvent caused by salt, and it does not take into account any interactions which may be possible between solute and solvent and between solute and electrolyte. The solute-solvent interaction should be an important factor, especially in the case of aromatic hydrocarbon solutes. Masterton *et al.* have emphasized that the solute-electrolyte interaction, especially with anions, plays a major role in the salting-in of some aromatic hydrocarbons.[12] We can see from Table 3 that the k_s(obsd)/k_s(calcd) ratio is definitely smaller for Br^- than for Cl^-. However, the solute-electrolyte interaction seems to be less important than the solute-solvent interaction, since the k_s(obsd)/k_s(calcd) ratios for various hydrocarbons are almost consistently in the range from 0.3 to 0.4. An empirical factor of from 0.3 to 0.4 cannot be explained quantitatively at present.

The SPT involves two steps: (1) the creation of a cavity in the solvent of a suitable size to accommodate a solute molecule, and (2) the interaction of a solute molecule with the solvent and electrolyte species. The theory would, therefore, reflect the characteristic interactions between solute and solvent and between solute and electrolyte. It is important in calculating k_s by means of SPT to select the most suitable values of σ and ε/κ for the solute in question. Lennard-Jones 6—12 pair potential parameters have been reported except for propylbenzene, but they differ from report to report.[13] At first we adopted the pair-potential parameters evaluated by the use of the following equations:

$$\sigma=(2.3454+0.2972\ \omega)\ (T_c/P_c)^{1/3}, \quad (4)$$

$$\varepsilon/\kappa=(0.8082-0.4504\ \omega)\ T_c, \quad (5)$$

where $\omega=-1+3\theta/7(1-\theta)\times\log P_c$, $\theta=T_b/T_c$ and where T_c, T_b, and P_c are the critical temperature, the boiling temperature, and the critical pressure of the solute respectively. These equations have been explained as being successful for nonpolar molecules.[14] We have taken the alkylbenzenes used in this study to be nearly nonpolar, with quite small dipole moments. The values of ε/κ estimated from Eq. 5 are: ε/κ (in K)=398 (benzene), 406 (toluene), 412 (ethylbenzene), and 415 (propylbenzene). The calculated k_s values, however, led to consistently lower results compared with the observations. Masterton and Lee found that Eq. 3 gave an appropriate ε/κ value in predicting the k_s of benzene.[9] Wilcox and Schrier also recommended the use of the ε/κ estimated from Eq. 3 in calculating the k_s values of polar solutes such as alcohols.[15] For the solutes considered in this work, the values of ε/κ have been determined by Eq. 3 using the corresponding σ values estimated from Eq. 4. These parameters are shown in Table 2. The calculated k_s values

are in reasonable agreements with the observations, as will be seen from Table 1, except for $NaNO_3$, NaSCN, $NaClO_4$ and tetraalkylammonium salts. The considerable discrepancies relating to NO_3^-, SCN^-, and ClO_4^- may be attributable to the uncertainty as to the true σ values for these polyatomic anions. In the case of tetraalkylammonium salts, however, the failure of SPT is inherent.

The present method to determine k_s, which makes use of solute vapor, has a potential usefulness when an anionic or cationic electrolyte is subject to being extracted into the liquid solute phase accompanying a counter ion; hence, it is difficult to determine k_s in the presence of a liquid solute.

Physicochemical Speciation of Trace Elements in River Water by Size Fractionation

Yoshiyuki TANIZAKI,* Masao YAMAZAKI, and Sumiko NAGATSUKA
Tokyo Metropolitan Isotope Research Center, Fukazawa, Setagaya-ku, Tokyo 158
(Received November 11, 1983)

Eight kinds of Millipore filters with different pore sizes (8—0.025 μm) were used for the filtration of two water samples taken from the Tama River. The filtrates were analyzed for 31 elements using a neutron activation analysis. Most alkali and alkaline earth elements were distributed in the smallest size fraction (<0.025 μm). The same fractionation pattern was also recognized for As, Se, Mo, Sb, and W, which tend to form oxoanions. But the major transition elements were concentrated in the larger size fractions (>0.45 μm). For the river water sample with higher concentration of total organic carbon, however, most of such elements were found in the smallest size fraction. The solubilities of rare earth elements bacame higher with increasing their ionic potentials.

The analysis of chemical species for various elements in natural water is of great importance not only to substantiate their geochemical behavior such as dissolution, fluidity, adsorption, and precipitation, but also to estimate the toxicity of the elements towards aquatic organisms.[1,2] For trace elements, however, it is very difficult to determine directly their chemical species hecause of their low concentrations and the complexity of their physical or chemical forms in natural water. Consequently, a physicochemical fractionation technique has been developed for an indirect speciation of the trace elements. Stumm and Bilinski first proposed that trace metal species could usefully be classified according to their size distribution.[3] Subsequently, a few workers studied the effect of filter pore size exerted on the analytical concentrations of some trace elements in filtrates of natural water.[4,5] Laxen and Harrison applied the fractionation technique to speciation of several trace elements in lake water,[6] and to effluents from sewage treatment plants and industrial processes and the river water which receives these effluents.[7,8] This fractionation technique was summarized together with other physicochemical speciation techniques such as centrifugation, ultrafiltration, dialysis and gel filtration chromatography, by Mora and Harrison.[9] But no one has applied the size fractionation technique to a systematic analysis of multielements. In this paper, therefore, we tried to clarify the size distribution of 31 elements found in river water, and to discuss their chemical species, by utilizing this technique and neutron activation analysis (NAA).

Experimental

Water Samples. The river water samples were taken from two points of the Tama River, which runs through the Metropolis of Tokyo, in November 1982 and February 1983. The two sampling points are shown in Fig. 1. They are located up-stream of the Hamura intake dam (A point) and near the Tamagawara bridge (B point). The water qualities are listed in Table 1 for the two points. The river water of B point (sample B) is more enriched in chlorine and total organic carbon (TOC) than those of the river water of A point (sample A) by a factor of 10 or above. This indicates that sample B is largely influenced by anthropogeneous pollutions. Chemical constituents in sample A, on the other hand, are mainly derived from rocks and their efflorescences in the drainage basin or by rainfall, as reported in a previous paper.[10]

Filtration. All-glass Millipore apparatus and eight kinds of Type HA millipore filters (mixed esters of cellulose) with diameter 142 mm, of average pore sizes 8, 3, 1.2, 0.45, 0.22, 0.1, 0.05, and 0.025 μm, were used for all filtrations. Decontamination of each filter was achieved by passing through 30 ml of dilute nitric acid (1:3), followed by 2-l of redistilled water under reduced pressure. The filtration of each water sample was performed in the following way. Forty liters of the water sample was pre-filtrated using the filter with pore size 8 μm, in order to remove large size particles. The filtrate was divided into eight 5-l portions. The seven portions of filtrate were filtrated once again using the other seven kinds of filters, one by one. The eight filtrates were transferred to clean 5-l polyethylene bottles, and then acidified immediately with 30 ml of nitric acid (Super Special Grade) in order to avoid any adsorption of trace elements on

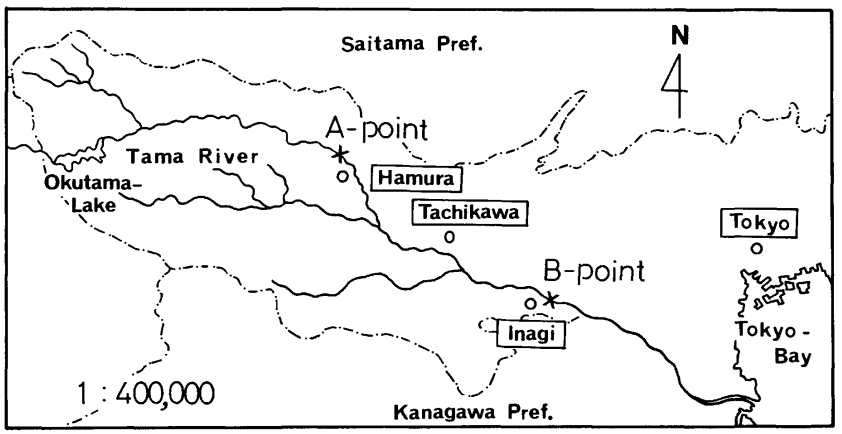

Fig. 1. Sampling locality.

a) Amount of evaporated residue. b) Total organic carbon.

the wall of the bottle.

Five-liter of the water sample was taken as the original material in another polyethylene bottle without filtration and was then acidified with 30 ml of the nitric scid.

Preparation of Irradiation Samples. For the NAA in this work, two kinds of irradiation samples, an evaporated residue sample and iron(III) hydroxide coprecipitated one, were prepared from each filtrate and the original (unfiltrated) water sample. The procedures were reported in detail in our previous papers.[10-12]

Irradiation and Gamma-ray Counting. The irradiation was performed by the TRIGA-Mark II Reactor of Rikkyo University, with a thermal neutron flux of 1.5×10^{12} n/cm^{2}s. The gamma ray spectrometer consists of a high pure germanium detector with 15% efficiency and 2.0 keV resolution, and a 2048 and 4096 channel pulse height analyzer.

The evaporated residue sample was first irradiated for 1 min to determine the elements that result the short life nuclides such as Al (^{28}Al), Ca (^{49}Ca), K (^{42}K), Mg (^{27}Mg), Mn (^{56}Mn), Na (^{24}Na), and V (^{52}V); these radioactivities were measured for 100 s by the spectrometer. One month later, the same sample was irradiated once more for 12 h to determine the elements that result the long life nuclides such as Ag (^{110m}Ag), Ba (^{131}Ba), Ce (^{141}Ce), Co (^{60}Co), Cr (^{51}Cr), Cs (^{134}Cs), Fe (^{59}Fe), Ni (^{58}Co), Rb (^{86}Rb), Sb (^{124}Sb), Sc (^{46}Sc), Se (^{75}Se), Sr (^{85}Sr), Tb (^{160}Tb), and Th (^{233}Pa). The measurement of these long life activities were carried out for 50000 s after a cooling time of 2—4 weeks to reduce the short or medium life nuclides.

The iron(III) hydroxide coprecipitated sample, on the other hand, was also irradiated for 12 h to determine the elements that result the medium life nuclides such as As (^{76}As), Eu (^{152m}Eu), La (^{140}La), Lu (^{177}Lu), Mo (^{99}Mo), Sm (^{153}Sm), U (^{239}Np), W (^{187}W), and Yb (^{175}Yb), and after the cooling time of 1 d, these activities were measured for 2000 s.

Results and Discussion

The concentrations of 31 elements were determined for the eight filtrates and the original water sample by NAA. The statistical errors based on the gamma ray counting were 5—30% for Ag, Ba, Ce, Cr, Eu, Fe, La, Mg, Mn, Mo, Ni, Se, Tb, Th, and U, and less than 5% for the other 16 elements.

The, size distribution of each element is calculated in the following way. When the analytical concentration of an element in the original water sample and the filtrates resulted from the filters with pore size of 8, 3, ···, 0.05, and 0.025 μm are represented by C_T and C_8, C_3, ···, $C_{0.05}$, and $C_{0.025}$, the size distribution (S) of the elements is given by

$$
\begin{aligned}
S(>8\,\mu m) &= C_T - C_8 && F(>8\,\mu m)\\
S(8-3\,\mu m) &= C_8 - C_3 \\
S(3-1.2\,\mu m) &= C_3 - C_{1.2} && F(8-0.45\,\mu m)\\
S(1.2-0.45\,\mu m) &= C_{1.2} - C_{0.45} \\
S(0.45-0.22\,\mu m) &= C_{0.45} - C_{0.22} \\
S(0.22-0.1\,\mu m) &= C_{0.22} - C_{0.1} && F(0.45-0.025\,\mu m)\\
S(0.1-0.05\,\mu m) &= C_{0.1} - C_{0.05} \\
S(0.05-0.025\,\mu m) &= C_{0.05} - C_{0.025} \\
S(<0.025\,\mu m) &= C_{0.025} && F(<0.025\,\mu m)
\end{aligned}
$$

The results are classified into four size fractions: F (>8 μm), F (8—0.45 μm), F (0.45—0.025 μm), and F (<0.025 μm); these results are shown in Tables 2—6.

In general, chemical constituents passing through the filter with pore size 0.45 μm are defined as "dissolved", and those retained on the filter are classified as "particulate".[13] However, the "dissolved" constituents need not be in true solution but can include "colloidals".[3,9] The boundary in size between "colloidals" and "true solution" probably lies in the range of 0.01—0.001 μm.[9,14] Consequently, it is difficult to fractionate perfectly chemical constituents in the river water samples between "colloidals" and "true solution" because the smallest pore size of the Millipore filter is 0.025 μm. For convenience, it is assumed in this paper that the constituents passing through the 0.025 μm filter (F (<0.025 μm)) are mostly "true solution", and the materials with size ranging from 0.45 μm to 0.025 μm (F (0.45—0.025 μm)) are "colloidals". The materials with size larger than 0.45 μm (F (>8 μm) and F (8—0.45 μm)) are classified as "particulate".

In order to discuss systematically the fractionation results, the 31 elements are divided into 5 groups in the following manner, as shown in Tables 2—6.

Alkali and Alkaline Earth Elements (Na, K, Rb, Cs, Mg, Ca, Sr, and Ba). The total concentrations are given in the concentrations for the original (unfiltrated) water sample. For alkali and alkaline earth elements in sample A, these concentrations were considerably lower than those in sample B, although the concentration of Cs in sample A was exceptionally high, as can be seen in Table 2. The very high enrichments in Na, K and Mg concentrations for sample B indicate that the B point of the Tama River is largely influenced by anthropogeneous pollutions.

Na, K, Mg, Ca, and Sr were found only in the smallest size fraction (< 0.025 μm) for both samples A and B. It is well known that these elements are dissolved in natural water as uni- or bivalent cations. Rb and Cs in sample A were divided mainly between the particulate (>8 μm and 8—0.45 μm) and the smallest size fractions, with few colloidals (0.45—0.025 μm), although in sample B all those elements were also found in the smallest size fraction. 47% of Ba were associated with the particulate, and the remaining 53% were distributed in the smallest size fraction for sample A. For sample B, on the other hand, 15 and 85% of Ba were found in the particulate and the smallest size fractions, respectively. It is supposed that considerable parts of Rb, Cs, and Ba

in sample A are held on ion exchange sites of inorganic suspended materials[15] such as clay minerals or iron(III) hydroxide, which will be explained in later discussion, by the fact that the contents of particulate Al and Fe for sample A are high.

Transition Elements (Sc, V, Cr, Mn, Fe, Co, and Ni). Sample A was more enriched in the total concentrations of Sc and Fe, and deficient in V, Cr, Mn, Co, and Ni in comparison with the concentrations in sample B, as can be seen in Table 3. This indicates that Sc and Fe in the Tama River water are mainly derived from rocks or their efflorescences, while the other five heavy metals are chiefly supplied by anthropogeneous sources.

The major parts (80% or more) of Sc, Mn, Fe, and Co in sample A were distributed in the particulate size fraction. In particular, Sc and Fe were mostly particulate (>97%), and only a few percent of those elements could be fractionated as dissolved species (<0.45 μm). It is known that Fe is the main component of suspended materials in most river water along with Al and SiO_2,[16,17] and it usually forms iron(III) hydroxide.[4,18] The concentration of Sc is very low for ordinary natural water.[10,12] It is supposed that the behavior of Sc in river water with poor TOC concentration is governed by coprecipitation with iron(III) hydroxide. For sample B, on the other hand, although approx. 80% of Sc and Fe were also associated in the particulate size fraction, the remaining 20% were fractionated as the dissolved species. For Mn and Co, 80—90% of them in sample A were found in the particulate size fraction. On the contrary, 80—90% of these elements in sample B were distributed in the smallest size fraction. In general, transition elements are known to have a strong complexing ability for organic substances such as humus.[19-21] Sample B has a

much higher TOC concentration than that of sample A, by a factor of ahout 14, as listed in Table 1. In sample B, therefore, the transition elements should be mostly present as soluble organic complexes, so that they are distributed in the smallest size fraction. However, it is very difficult to draw any quantitative conclusion about the extent of complexing of the transition elements by organic substances because we have no information on their chemical forms. This remains to be studied.

Even in sample A with poor TOC concentration, V and Cr were found in the smallest size fraction in substantial quantity (55 and 35%, respectively). This can be explained by assuming the existences of their soluble quinque- or sexivalent species such as $V_{10}O_{28}^{6-}$,[22,23] CrO_4^{2-}.[24]

Almost all Ni, which is distinct from the other six transition elements, was found in the smallest size fraction for both samples A and B. This indicates that Ni easily dissolves in natural water as a bivalent species, Ni^{2+}.[25]

The Elements Forming Oxoanions (As, Se, Mo, Sb, and W). The total concentrations of As, Se, Mo, Sb, and W in sample B were higher than those in sample A by a factor of about 2. However, the same fractionation result was observed for all of them, that they were detectable only in the smallest size fraction (<0.025 μm), as can be seen in Table 4. This result is consistent with the view that these elements tend to form soluble oxoanions such as AsO_4^{3-}, SeO_3^{2-}, MoO_4^{2-}, SbO_4^{3-}, WO_4^{2-}[12,26-31] in ordinary natural water.

Rare Earth Elements (REEs: La, Ce, Sm, Eu, Tb, Yb, and Lu). Major parts (86—94%) of La, Ce, and Sm were associated with the particulate size fraction (>8 μm and 8—0.45 μm) for both samples A and B, and those elements distributed in the colloidal (0.45—0.025 μm) and the smallest size fractions (<0.025 μm) were only several percent, as can be seen in Table 5. Europium in sample A was also found mainly in the particulate size fraction, whereas in sample B 10 and 14% of Eu were distributed in the colloidal and the smallest size fractions,respectively. Although Yb in sample A was also mostly the particulate, 33% of Tb and approx. 80% of Yb and Lu in sample B were fractionated as the dissolved species (0.45—0.025 μm and <0.025 μm). These findings suggest that the higher TOC concentration in sample B is largely contributed to the dissolution of the heavier REEs such as Tb, Yb, Lu. This conclusion is substantiated by the analytical data that the total concentrations of the heavier REEs for sample B are higher than those for sample A, even though for the light REEs, except La,

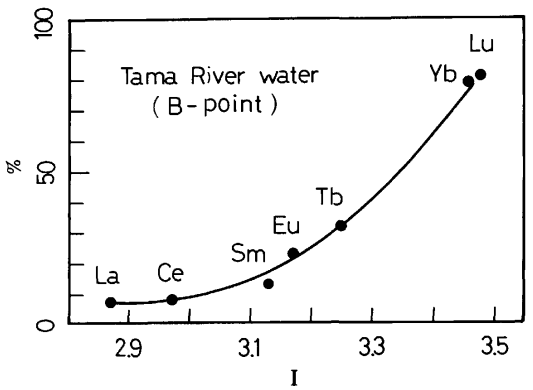

Fig. 2. Plot showing the relation between the solubilities (%) of REEs and their ionic potentials (*I*).

the higher total concentrations were found in sample A, as shown in Table 5.

The relation between the solubilities of the REEs in sample B and their ionic potentials is demonstrated by Fig.2, which is a plot of the proportions(%) of REEs fractionated as the dissolved species to their total concentrations *versus* ratios of the chemical valency to their ionic radii.[32] The diagram shows that the solubilities of the REEs increase with increasing ionic potentials. In other words, the heavier REEs with high ionic potentials tend to form the organic complexes in the river water with high TOC concentration. The monotonous increasing fashion of the solubilities for the heavier REEs illustrated in the diagram agrees with that reported by Goldberg *et al.*,[33] who have studied the behavior of REEs in marine environment.

For the light REEs, on the other hand, it is supposed that most of those elements may be coprecipitated with iron(III) hydroxide. This is explained by the following considerations. The total concentration ratios of La, Ce, and Sm to Fe in samples A and B are $(0.55—1.3)\times10^{-3}$, $(1.7—2.1)\times10^{-3}$, and $(0.96—1.0)\times10^{-4}$, and those in particulate matters in the Thames River water reported by Habib *et al.*[17] are 0.46×10^{-3}, 1.9×10^{-3}, and 0.86×10^{-4}, respectively. These values are close to the same ratios for the earth's crust presented by Taylor[34] and Wedepohl[35] $(0.53—1.2)\times10^{-3}$, $(1.2—2.1)\times10^{-3}$, and $(1.1—1.9)\times10^{-4}$. Therefore, it could be said that the behavior of light REEs in the river water is similer to that of Fe, on the process of dissolution or precipitation. Iron tends to form insoluble iron(III) hydroxide in ordinary natural water, as mentioned above, so that the light REEs also precipitate as the hydroxides.

Others (Al, Ag, Th, and U). Sample A was more enriched in the total concentrations of Al and U by a factor of about 2 in the comparison with those in sample B, as can be seen in Table 6. Silver in sample A and Th in sample B were less than the detection limits. Thorium in sample A could not be determined since no standard reference sample was prepared, so that the gamma ray counting ratio was utilized for the discussion. The higher total concentrations of Al, Th, and U in sample A indicate that those elements are mainly derived from the rocks or their efflorescences in the drainage basin, while the higher total concentration of Ag in sample B means that Ag is largely influenced by artificial pollution.

Table 6 notes that 87% of Al in sample A was associated with the particulate, and 11% was found in the smallest size fraction. For sample B, on the other hand, Al amounts distributed in the particulate and the smallest size fractions were 65 and 34%, respectively. The colloidal Al was only a few percent for both samples. Aluminium is one of the main components of suspended materials in most river water as well as Fe and SiO_2, as stated above. However, the proportion of Al fractionated as the dissolved species (0.45—0.025 μm and<0.025 μm) to the total concentration are 13 and 35% for samples A and B, and these values are much higher than those of Fe, 1.3 and 19% respectively. This can be explained in the following way. It is well known that Al in natural water not only precipitates as the hydroxide, but also forms clay minerals in the process of the rock weathering.[36] In general, clay minerals have a small size distribution (<5 μm), and a certain type of them has been found with size smaller than 0.45 μm.[37] Such materials pass through the filter with the corresponding pore size. In addition, Hem and Roberson showed that some finegrained Al compounds suspended in water may be passed through a 0.45 μm membrane filter.[38] Thus, a considerable part of Al can be fractionated as the dissolved species.

Eighty five percent of Ag was found in the particulate size fraction with 14% of the colloidal for sample B. Silver seems to be easily halogenated in the polluted river water, and is predominantly held on clay minerals or iron(III) hydroxide.

Thorium in sample A was also chiefly associated with the particulate size fraction; on the contrary, almost all U was distributed in the smallest size fraction, although approx. 20% of the particulate U was

Table 6. Fractionation results of aluminium, silver, thorium, and uranium in the river water

	B	0(0)	0(0)	0(0)	0.027(100)	0.027

found for sample A. The difference of the fractionation patterns between Th and U seems to arise from the differences of their chemical forms in the river water. It is well known that U tends to form the soluble sexivalent species UO_2^{2+} in most natural water.[39-41] But for Th, a quadrivalent species is the only stable form, which is probably coprecipitated with the hydroxides of Fe and Al in water.[42]

Conclusion

Using the size fractionation technique and NAA method, it was possible to obtain some knowledge about the chemical species of the trace elements existing in the Tama River water. One of the factors that governed the size distribution patterns of the trace elements was the TOC concentration in the river water. The high TOC concentration largely contributed to the dissolution of Rb, Cs, Ba, Al, U, the transition elements, and the heavier REEs. Fe, Sc, Th, and the light REEs, which tend to precipitate as the hydroxides, however, were predominantly distributed in the particulate size fraction. Na, K, Mg, Ca, Sr, Ni, As, Se, Mo, Sb, and W, which easily form the various soluble inorganic ions, on the other hand, were found only in the smallest size fraction, regardless of the TOC concentration in the river water.

Several tedious problems, however, still remain to be examined concerning the size fractionation technique. It must be kept in mind that adsorptive losses of trace elements onto the filter[43] and contamination from the filter materials[44] may occur during the filtration, which may lead to erroneous analytical results. Equilibrium conditions on chemical species of trace elements kept in the river water may be upset at the time of filtration, so that rapid treatments of the samples are required. Filters are not 100% efficient with respect to their size selectivety characteristics,[9] and the effective pore size decreases during the filtration because of filter clogging. Such problems are more insidious and require consideration in greater detail to minimize analytical errors. In order to determine exactly the chemical species of trace elements in river water, further studies will be necessary.

Determination of a Small Amount of Biological Constituent by Use of Chemiluminescence. III. The Flow-injection Analysis of Protein by Direct Injection

Tadashi HARA,* Motohiro TORIYAMA, and Kazuhiko TSUKAGOSHI
Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602
(Received November 29, 1983)

A flow-injection analysis method of protein by direct injection has been established by use of the luminol-hydrogen peroxide luminescence system. The determination of protein is based on the measurement of the decreasing catalytic activity of copper(II) for the chemiluminescent reaction between luminol and hydrogen peroxide. The present flow-injection analysis in which a protein solution is directly injected is quite different from the previous one in which a protein solution is injected after having been previously allowed to react with copper(II) outside the flow-through system. The optimum conditions for the determination of protein were determined with regard to reagent concentration, flow rate, reaction time, and reaction temperature. The present method is simple, rapid, and applicable to the determination of 2×10^{-4}—1×10^{-1} g dm^{-3} of protein with 40 ng of detection limit at a rate of about 30 samples per hour. The present method was also applied to the determination of the ratio of albumin to globulin in a sample. The present flow-injection system is expected to be a sensitive detector for the determination of small amounts of protein.

A new method for the determination of protein, in which use was made of the decreasing catalytic activity for the chemiluminescence (CL) reaction between 5-amino-2, 3-dihydro-1, 4-phthalazinedione(luminol) and hydrogen peroxide(H_2O_2) when copper(II) (Cu(II)) interacted with polypeptide linkage, was reported by the authors in the previous paper[1]. The method was more sensitive and applicable to a wider range of protein concentration than is available with the conventional methods. However the protein in a sample solution had to be made to react with Cu(II) at 30 °C for 50 min before its injection into a flow-injection system.

Here the flow-injection system in the previous paper has been modified to enable a protein solution to inject directly into the flow-injection system. In the previous paper,[2] protein was also determined by use of a cobalt(III) complex. However Cu(II) is used in the present work as a catalyst for the CL reaction because Cu(II) shows faster reaction with protein and smaller difference between CL responses of individual protein compared with those of cobalt(III). In the present method, the protein solution is directly injected into the flow-injection system without any pretreatment and the analytical results are obtained simply and rapidly because the reaction between Cu(II) and protein proceeds in the flow-path.

Experimental

Reagents. By diluting with the buffer solution (pH 10.15) consisting of boric acid and potassium hydroxide presented in the previous paper,[1] a 5.0×10^{-4} mol dm^{-3} luminol solution and a 2.0×10^{-6} mol dm^{-3} Cu(II) catalyst solution from a 2.0×10^{-2} mol dm^{-3} Cu(II) stock solution[1] were prepared. A 5.0×10^{-4} mol dm^{-3} H_2O_2 solution was prepared by diluting a 0.3 wt% H_2O_2 solution with water. The reagents used were of commercially available special grade.

Human serum albumin(HSA) and bovine serum α-globulin from ICN Pharmaceuticals, Inc., and human serum γ-globulin, bovine serum albumin(BSA), and bovine serum γ-globulin from Sigma Chemical Co., and control serum(Q-PAK-Chemistry Control Serum I) from HYLAND were used. All these proteins were dissolved in the buffer solution and diluted with it.

Ion exchange water was distilled for use.

Apparatus and Procedure. The schematic diagram of the apparatus used for the present flow-injection analysis is shown in Fig. 1. All the tubes and connectors used were made of Teflon. Each solution of luminol(a), H_2O_2(b), Cu(II) (c), and a buffer(d) was fed by means of 2.3×10^5 Pa gauge pressure of nitrogen gas; the flow rate was adjusted to 10 cm^3 min^{-1} by a needle valve. A 0.4 cm^3 of protein sample solution was injected into the buffer solution line through the sampling loop(k) and the six-way cook(j). The protein sample solution was first mixed with a Cu(II) catalyst solution and passed through 1.6 m of tube held at 0 °C in the cooling bath (n) *via* a 1.0 m of tube held at 95 °C in the heating bath(m). Then the solution was mixed with a H_2O_2 solution and a luminol solution in that order, and passed through the flow cell(o). The distances between T and S or U were 35 and 10 cm, respectively. The same flow cell as in the previous paper was used. The CL intensity of the solution passing through the cell was measured by a photomultiplier (p) (Hamamatsu TV Co. Ltd., R928), amplified with a amplifier(g) (Horiba Ltd., OPE-402), and recorded on a recorder(r) (Yokogawa Electric Works, Ltd., 3046). The CL intensity of the solution containing no sample was recorded

as a base line while the CL intensity of the solution containing protein was recorded as a negative peak because the catalytic activity of Cu(II) decreased because of the complex formation between Cu(II) and protein. The amount of protein was estimated from the peak area.

Results and Discussion

Determination of Analysis Conditions. Bovine serum albumin was used as a model protein.

The CL intensity was measured by using 0.5, 1.0, 2.0, and 3.0 m of tube held at 95 °C in the heating bath, but no difference between CL intensities was observed in all the tubes except the first one. Then a 1.0 m of tube was used for the heating bath in the following experiment.

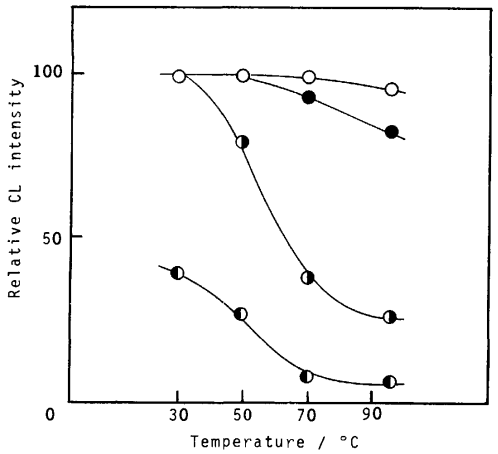

Fig. 2. Effect of heating bath temperature on relative CL intensity.[a)]

Conditions: 5.0×10^{-4} mol dm^{-3} H_2O_2 and 2.0×10^{-6} mol dm^{-3} Cu(II).
a) The CL intensity of the solution containing protein to the CL intensity of the solution containing no protein.

The effect of the temperature of the heating bath on the CL intensity is shown in Fig. 2. Each plot represents the CL intensity in the presence of BSA against the CL intensity 100 of a base line. Then the temperature of the heating bath was set at 95 °C because the CL intensity decreased with a rise of temperature.

The tube held at 0 °C in the cooling bath played two important roles: cooling the hot effluent so as not to affect the CL intensity and charging the back pressure so as not to produce a foam inside the tube in the heating bath. 1.6 m tube length was chosen to make the diffusion of the samples as small as possible.

The effect of the concentration of luminol, H_2O_2, and Cu(II) solutions on the CL intensity are shown in Figs. 3, 4, and 5. From these results, the optimum

concentrations corresponding to maximum decreases in the CL intensity were as follows: luminol solution 5.0×10^{-4} mol dm^{-3}; H_2O_2 solution 5.0×10^{-4} mol dm^{-3}; and Cu(II) catalyst solution 2.0×10^{-6} mol dm^{-3}.

Determination of Protein. The calibration curve of BSA obtained under the above-mentioned conditions is shown in Fig. 6. As can be seen from it, 1×10^{-4}—1×10^{-1} g dm^{-3} protein gave the CL response which corresponded to the peak area of the negative peak recorded in the addition of BSA solution. The decrease of the CL intensity in the presence of protein is attributed to the lowering of the catalytic activity of Cu(II) based on the formation of a Cu(II)-polypeptide complex. The fact that the ratio of the change of peak area to the change of protein concentration is rather small seemed to be based on the diffusion of a sample and the dilution of a sample solution by additions of reagent solutions. The flow chart obtained by injecting each 1.0×10^{-4}, 5.0×10^{-3}, and 5.0×10^{-2} g dm^{-3} BSA and that obtained at a blank experiment are shown in Fig. 7.

The CL responses of HSA, human serum γ-globulin, bovine serum α-globulin, and bovine serum γ-globulin by the present method were examined in the manner used in the preparation of the calibration curve of BSA (Fig. 8). Approximately similar responses were obtained for them. This suggests that the present flow-injection system will serve as a promising detector for the determination of protein.

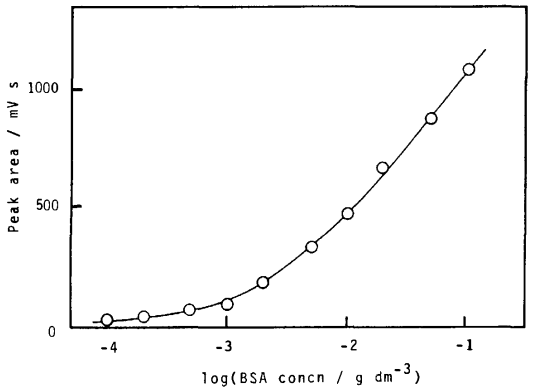

Fig. 6. Calibration curve of BSA by the present method.
Conditions: 5.0×10^{-4} mol dm^{-3} luminol, 5.0×10^{-4} mol dm^{-3} H_2O_2, and 2.0×10^{-6} mol dm^{-3} Cu(II).

Precision was not so good in the previous paper because each solution was delivered by means of a peristaltic pump, accompanied by fluctuating flow, while precision in the present work was drastically improved by means of the utilization of a gas pressure without any fluctuations in flow. Therefore the present method makes it possible to estimate a small amount of protein with the concentration range of 2×10^{-4}—1×10^{-1} g dm^{-3} and the detection limit of about 40 ng. The coefficients of variation of the present method for 10 analyses of 5.0×10^{-3} and 5.0×10^{-2} g dm^{-3} protein solutions were both 4.1%.

Estimation of the Ratio of Albumin to Globulin. The ratio of albumin to globulin(A/G) has been looked upon as an important parameter for diagnosis of the abnormal metabolism of protein in human body. Here the A/G ratio was estimated to examine whether or not the present method could be applied to a mixed protein sample.

To examine the effect of the coexisting constituents in a control serum on the CL intensity when a control serum was diluted to 2000 times of volume with a buffer solution and measured, the analytical values against HSA or a definite amount of control serum (containing 2.3×10^{-2} g dm^{-3} of protein) plus HSA were obtained by use of the calibration curve shown in Fig. 8. All the analytical values of the ordinate in Fig. 9 were represented as the amount of HSA. The difference between straight lines I and II in the analytical value was approximately equal to the protein amount of the added control serum. This means that the constituents other than protein in the serum do not significantly affect the CL intensity when a sample solution is diluted to 2000 times of volume with a buffer solution and measured. Then the present method was applied to the estimation of the A/G ratio.

Various A/G ratio of mixtures of HSA and human serum γ-globulin were subjected to the fractionation

using sodium sulfate as a salting-out agent, and the A/G ratio were determined on the basis of the albumin amount from the albumin fraction and of the globulin amount obtained by subtracting the albumin amount from the total amount obtained for the mixture. Neither sodium sulfite and ammonium sulfate were suitable as a salting-out agent, because the sulfite worked as a reducing agent and the ammonium salts produced a ammine complex in an alkaline solution. To 0.5 cm^3 of protein solution, the concentration of which is the same as that of protein in control serum, 0.5 cm^3 of water and 0.18 g sodium salfate were added and dissolved by shaking in a centrifugal tube. The contents was centrifuged at 10000 min^{-1} for 10 min. An aliquot volume of supernatant liquid was diluted to 1000 times of volume with the buffer solution, and the albumin amount in it and the A/G ratio were determined by the above-mentioned procedure. The relationship between theoretical and analytical values of A/G ratio is shown in Fig. 10. Though the present fractionation did not seem to give complete separation of albumin from globulin, there was a linear correlation,as shown in Fig. 10. The analytical value of the A/G ratio in a control serum was also determined similarly and is plotted in Fig. 10 against the A/G ratio of 1.71, which stood for the mean value of 1.47—2.00 estimated by different methods in eight laboratories as the A/G ratio for the same control serum. The result was almost satisfactory, but a better result would be obtained by the complete separation of albumin from globulin. The possibility of estimating the A/G ratio in human serum by the present method suggests that the combination of the present method with a continuous separation procedure for a mixed protein sample enables the system used in the present method to be a promising detector for the sensitive determination of protein.

On the basis of the results obtained, the flow-injection analysis method of protein by direct injection has been established by use of the luminol-H_2O_2 luminescence system. According to the present method, the previous reaction between Cu(II) and protein as in the previous paper is unnecessary and a protein sample solution can be directly injected into the flow system, followed by the reaction between Cu(II) and protein in the flow-path and the determination of protein. The measurement can be done at the rate of about 30 samples per hour with the concentration range of 2×10^{-4}—1×10^{-1} g dm^{-3} protein and the detection limit of about 40 ng. The present method is expected to serve as a promising detector in the near future because the method is simple, rapid, and applicable to the sensitive determination of a wide range of protein concentration.

The authors wish to thank Mr. Masakatsu Imaki (Horiba Ltd.,) for providing the apparatus necessary for the present study.

Correlation between Axial and In-Plane Coordination Bond Lengths in Tetragonal Six-coordinate Complexes of the *trans*-MX_2N_4 Type ($M=Co^{3+}$, Ni^{2+}, and Zn^{2+}). X-Ray Structural and *ab initio* Molecular Orbital Studies

Tasuku Ito,* Masako Kato, and Haruko Ito

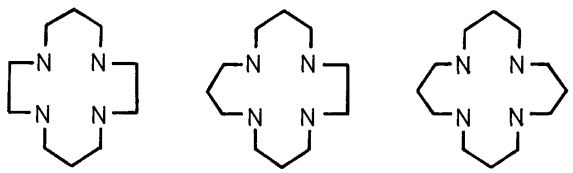
Department of Applied Molecular Science, Institute for Molecular Science, Okazaki National Research Institutes, Okazaki 444

(Received December 16, 1983)

X-Ray data of 16 structures having coordination geometry of the *trans*-MX_2N_4 type show that (i) an out-of-plane coordination bond length decreases as an in-plane distance increases, (ii) the degree of the correlation is metal ion dependent and varies in the order, $Zn^{2+}>Ni^{2+}>Co^{3+}$. In the Ni(II) systems, complexes having stronger ligands ($X=NCS^-$) at axial positions show the weaker correlation as compared with complexes with weaker axial ligands (Cl^-). Electronic origin that causes such negative correlations has been investigated in terms of the potential energy surfaces obtained from *ab initio* MO calculations for model compounds, *trans*-$[MCl_2(NH_3)_4]$. A section of the potential surface along the M-Cl and M-N bond axes is an ellipse and the ellipse has a tilt with respect to the metal-ligand bond axes. The dependence of the M-Cl distances on the M-N distances becomes stronger, as the tilt of the ellipse increases, and/or as the ratio of the length of long to short axes of the ellipse is increased. The degree of correlation expected from the potential energy surfaces are consistent, in all respect, with experimentally observed results. The interrelationships, found both experimentally and theoretically, are associated with softness of metal ions. Among the metal ions studied, Co(III) is the hardest, Zn(II) is the softest, and Ni(II) is intermediate.

Earlier studies of tetragonally distorted octahedral metal complexes suggest that, in complexes of this type, there exists an interaction between in-plane and out-of-plane ligands through a metal ion.[1] Hathaway[2] and Gažo[1] demonstrated, on the basis of available X-ray data of metal ion salts and simple coordination compounds, correlations between in-plane and out-of-plane coordination bond lengths for some Cu(II) and Ni(II) complexes of this type. Generally, an in-plane bond distance increases as an out-of-plane distance decreases. In our recent structural study of a series of Ni(II) complexes, a similar negative correlation of the coordination bond lengths was observed.[3] It has been also noted, in solution chemistry of some Co(III) complexes of this type, that equatorial ligands affect rates of hydrolyses of the axial ligands.[4] In an NMR spectral study of five-coordinate Cd(II) porphyrin complexes with substituted pyridines at the axial position, coupling constant between ^{111}Cd and porphyrin nitrogen(^{15}N) has been found to decrease with an increase in basicity of substituted pyridine.[5] Busch and coworkers observed a similar phenomenon in ligand field electronic spectra.[6] They showed that, in Ni(II) complexes of *trans*-NiX_2N_4 type, ligand field strength of an axial ligand (Dq^z) decreases as an in-plane ligand field (Dq^{xy}) increases, and they termed it the "electronic cis effect".[6] They also reported that a series of Co(III) complexes of the same type do not show a correlation between Dq^z and Dq^{xy}.[7]

These seem to arise from the same electronic origin. The occurrence of such an interaction between in-plane and out-of-plane ligands through a metal ion, as well as the degree of the interaction, should be metal ion dependent. The present series of the studies were undertaken in order to investigate the electronic effect in more systematic and quantitative way to elucidate the role and function of the metal ion in the observed phenomenon. We have carried out X-ray analyses and *ab initio* MO calculations for a series of complexes which have the same or very similar coordination environments. As metal ions, we chose Co(III), Ni(II), and Zn(II) because of the following reasons: (i) these metal ions form tetragonal octahedral complexes of this type; (ii) routine application of an *ab initio* MO method is in hand in this laboratory for complexes of first row transition metal ions. In the experimental approach, we have determined the structures of a series of complexes of *trans*-MX_2N_4 type, where X is halide or pseudo-halide ion. Tetraazacycloalkanes with different ring sizes, 1,4,8,11-tetraazacyclotetradecane ([14]aneN$_4$), 1,4,8,12-tetraazacyclopentadecane ([15]aneN$_4$), and 1,5,9,13-tetraazacyclohexadecane ([16]aneN$_4$), were used as in-plane ligands so as to vary the M-N distance systematically.



As axial ligands (X), we chose Cl^- and NCS^-, which have relatively weak and strong ligand field strengths, respectively, so that it is possible to investigate the effect of ligand field strength on the correlation between M-X and M-N distances. In the present paper, we summarize and discuss the experimental data on the coordination bond distances found in the series of studies. Structural details of Ni(II)[8] and Zn(II)[9] complexes have been described elsewhere. In the theoretical approach, we have carried out *ab initio* MO calculations on model systems, *trans*-$MCl_2(NH_3)_4$ ($M=Co^{3+}$, Fe^{2+}, Ni^{2+}, and Zn^{2+}).[10] We discuss electronic factors, or metal ion characteristics, which bring about the experimentally observed correlation of intramolecular coordination bond lengths in terms of potential en-

ergy surfaces along M-N and M-Cl bond axes.

We also showed, for the Ni(II) complexes, that the electronic cis effect is manifested in far infrared spectra due to coordination bond stretching vibrations.[8]

Results and Discussion

Correlation between Axial and In-plane Coordination Bond Lengths in trans-MX_2N_4 *Type Complexes.* Table 1 collates the average in-plane (M-N) and axial (M-X) coordination bond lengths of the complexes studied. As expected, with an increase in the number of ring members in macrocyclic ligands, the in-plane M-N distance increases. This increase amounts to 0.04—0.06 Å for each ring member added. They are not as large as expected from calculations of strain energy minimizations for free ligand molecules (0.10—0.15 Å).[11] Data reported previously for the same type of complexes with other similar tetraazamacrocyclic or diamine ligands are also included in Table 1. The correlations are shown in Fig. 1, in which the M-X distances are plotted on the vertical axis and the M-N distances horizontally. As is seen in Fig. 1, there exists a negative correlation between M-X and M-N distances for complexes of each metal ion with given axial ligands: axial coordination bond length decreases as in-plane distance increases, generally. Although there exist steric effects in the molecular and crystal structures of the compounds, that cause the large standard deviations in the average coordination bond lengths,[8,9] they are characteristic of each system and should not give rise to the correlation shown in Fig. 1. Thus, the nature of the phenomenon depicted in Fig. 1 must be electronic in origin.

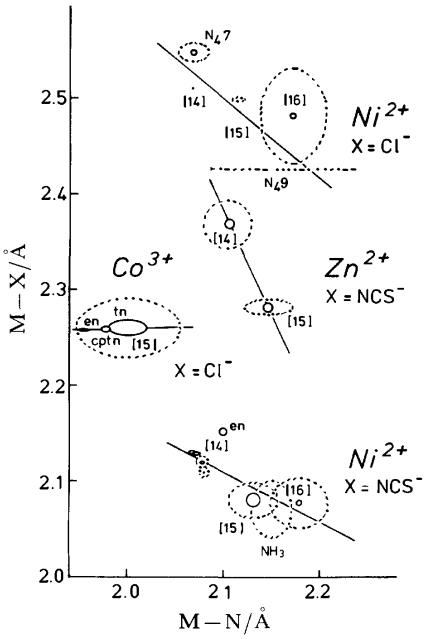


Fig. 1. Correlation between axial and in-plane coordination bond lengths in complexes of the *trans*-MX_2N_4 type. Size of a dashed ellipse or line illustrate an esd obtained upon averaging chemically or crystallographically inequivalent distances, while that of a full-line figure within the dashed one shows an arithmetic mean of esd's for individual metal-ligand distances (see footnote a) in Table 1). Ligand abbreviations: [14]=[14]aneN$_4$, [15]=[15]aneN$_4$, [16]=[16]aneN$_4$. See footnotes of Table 1 for others. For the en complex, no esd values were reported.

Table 1. Average in-plane and axial coordination bond lengths in complexes of *trans*-MX_2N_4 type[a]

a) A number in parentheses is an esd for a mean value of more than two chemically or crystallographically inequivalent bond lengths and is equal to $[\Sigma\Delta_i^2/(n-1)]^{1/2}$, where Δ_i is the deviation of i-th value in a set of n such values from arithmetic mean of the n values. In case of n=2, it is taken to be the largest of three values: the esd for one parameter (q_1), the esd for the other (q_2), or $|q_1-q_2|/2$. b) N_47=1,4,7,10-tetraazacyclotetradecane. c) N_49=1,4,7,10-tetraazacyclohexadecane. d) There are four crystallographically independent complexes in the unit cell.[8] e) Green form isomer. f) tn=1,3-Propanediamine. g) cptn=1,2-cyclopentanediamine. h) An average value of C_t-NCS distances, where C_t denotes a center of the cavity formed with four in-plane nitrogens(see Ref. 9).

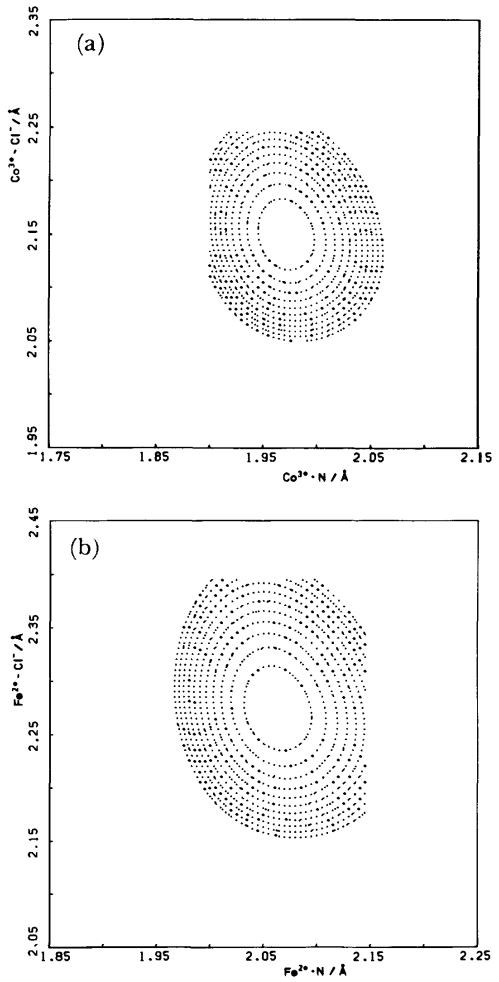
In the crystal structure of *trans*-[Ni(NCS)$_2$([14]aneN$_4$)], there are four crystallographically nonequivalent molecules.[8] Interestingly, data for these four molecules show clearly a trend for the negative correlation within the very limited range of metal-ligand distances (see Fig. 1).

Among the present three metal ions, the Zn^{2+} system shows the strongest correlation, the Co^{3+} system almost no correlation, and the Ni^{2+} system is intermediate.

When the $NiCl_2N_4$ and $Ni(NCS)_2N_4$ systems are compared, the slope for the chloro complexes is steeper than that for the isothiocyanato complexes. This indicates that the weaker the axial ligand field is, the stronger is the correlation (*vide infra*). It should be noted that the Zn system has a steep slope in spite of the fact that the data have been obtained with complexes with strong axial ligands NCS^-.[19]

For the Ni(II) system, it is possible to observe changes in the M-N distances of complexes having the same in-plane ligand by altering the axial ligand. Although the number of data for such comparisons are very limited and the changes in the M-N distances are very small, it is likely that there exist negative correlations between M-X and M-N distances in each of [NiX$_2$([14]aneN$_4$)], [NiX$_2$([15]aneN$_4$)], and [NiX$_2$([16]aneN$_4$)].

Coordination geometries found for Ni(II) complexes with the N$_4$7 ligand may provide further evidence for the occurrence of such an electronic cis effect. The structures of [NiCl$_2$(N$_4$7)][3] and [Ni(NCS)$_2$(N$_4$7)][20] have been found to be of trans and cis types, respectively. It is most reasonable to consider the observed cis and trans stereochemistries to be a result of the electronically controlled cis effect in view of the relative size between the cavity of the N$_4$7 ligand and a high spin octahedral Ni^{2+}, and the relative ligand field strength between Cl^- and NCS^- ligands.[8,20]



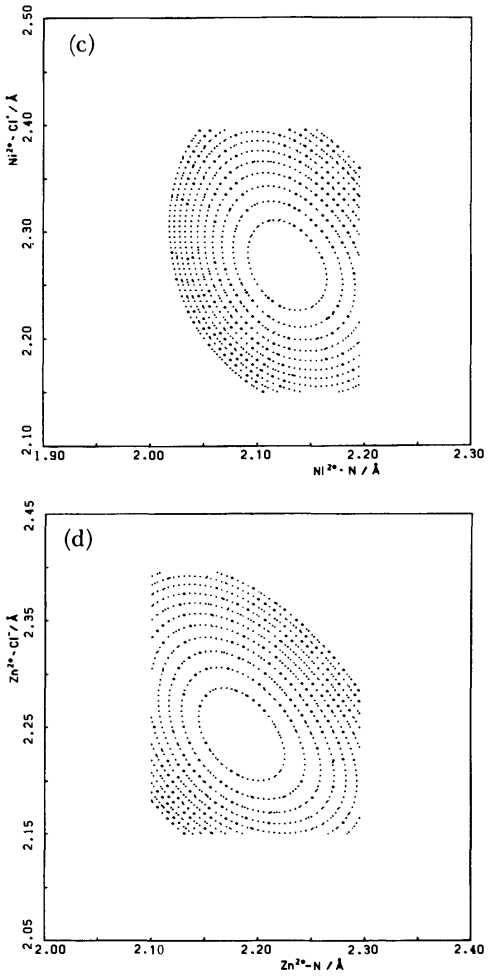


Fig. 2. Potential energy surfaces of *trans*-[MCl$_2$(NH$_3$)$_4$] along the M-Cl (vertical axis) and M-N (horizontal axis) coordination bonds: (a) *trans*-[CoCl$_2$(NH$_3$)$_4$]$^+$; (b) *trans*-[FeCl$_2$(NH$_3$)$_4$]; (c) *trans*-[NiCl$_2$(NH$_3$)$_4$]; (d) *trans*-[ZnCl$_2$(NH$_3$)$_4$]. Contours are at intervals of 0.5 kcal mol^{-1}.

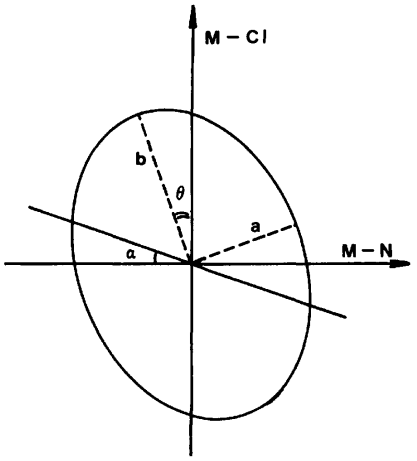
Potential Energy Surfaces of trans-*[MCl$_2$(NH$_3$)$_4$] (M= Co^{3+}, Fe^{2+}, Ni^{2+}, and Zn^{2+}) along Coordination Bond Axes.* Figure 2 shows the calculated potential energy surfaces for the Co^{3+}, Fe^{2+}, Ni^{2+}, and Zn^{2+} complexes, M-Cl distances being plotted on the vertical axis and M-N distances horizontally. The MO calculations for a hypothetical low spin Fe(II) complex, *trans*-[FeCl$_2$(NH$_3$)$_4$], have been carried out in order to investigate the effect of electric charge, since experimental data have been obtained with complexes of divalent metal ions except for the Co(III) system. The Fe(II) complex is isoelectronic with the Co(III) complex and its ground state was assumed to be closed-shell singlet.[21]

The calculated maps of the potential surfaces have the following common features: (i) each contour is an

ellipse elongated in the M-Cl direction; (ii) each ellipse has an anticlockwise tilt. When the maps shown in Fig. 2 are compared, the ellipse for Co^{3+} is the closest to a circle, the axis ratio of the Zn^{2+} ellipse is the largest, and the Ni^{2+} system is intermediate. The tilt of the ellipse is the smallest for Co^{3+}, intermediate for Ni^{2+}, and the largest for Zn^{2+}. Contour lines are the most congested for Co^{3+}, while they are the farthest apart for Zn^{2+}. These features are very important in the interpretation of the experimentally observed correlation between the axial and in-plane coordination bond distances.

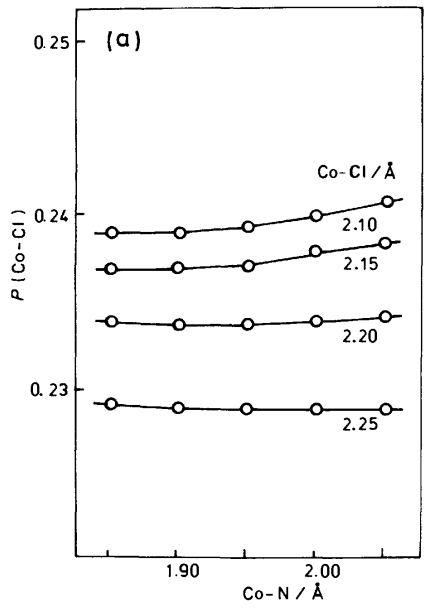
On the basis of the section map, we will discuss the case where the M-N distance is varied, as was done experimentally by use of the macrocyclic ligands with different ring sizes.



When energy minimum points at various M-N distances are connected, a line with a slope (α) is obtained. This line shows the interrelationship between the M-Cl and M-N distances under the electronically most stable circumstances. Thus, the larger the slope (α) is, the stronger is the correlation. Assuming that each contour is a perfect ellipse, α is given by the following equation,

$$\tan^{-1}\alpha=[\{1-(a/b)^2\}\sin\theta\cos\theta]/[\sin^2\theta+(a/b)^2\cos^2\theta], \quad (1)$$

where θ denotes a tilt of the ellipse and a/b represents an axis ratio of the ellipse ($b>a$). As is clear from Eq. 1, if the contour is not an ellipse but a circle ($a=b$), or if the longer axis of the ellipse is parallel to the vertical axis ($\theta=0$), α equals zero. Under such circumstances, the M-Cl distance does not change at all, even though the M-N distance is varied. The larger α value would be expected when the ellipse has a larger tilt[23] and the axis ratio of the ellipse is smaller.[24]



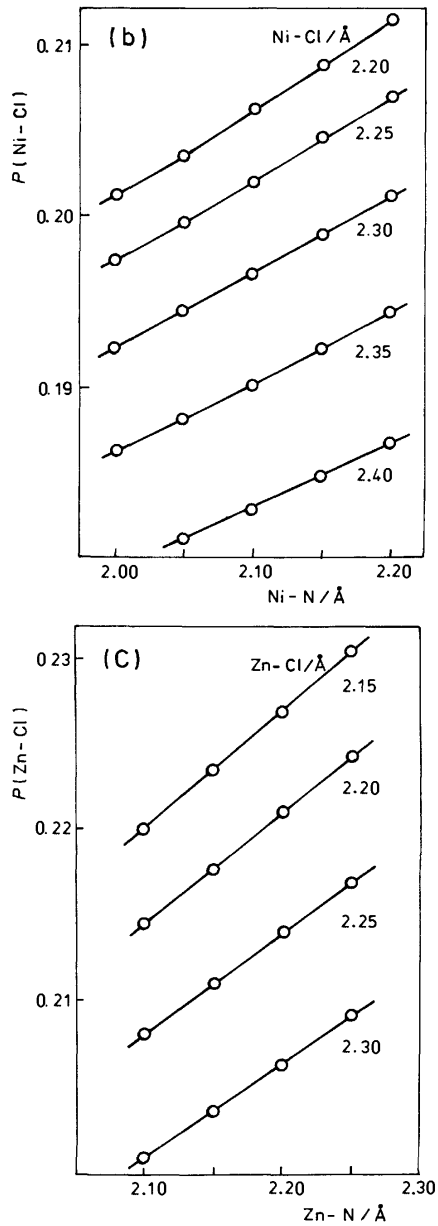


Fig. 3. M-Cl overlap population (P) as a function of M-N distances: (a) *trans*-$[CoCl_2(NH_3)_4]^+$; (b) *trans*-$[NiCl_2(NH_3)_4]$; (c) *trans*-$[ZnCl_2(NH_3)_4]$.

As the difference in the ligand field strengths between axial and in-plane ligands becomes larger, the ellipticity (a/b) decreases to give larger α. This is exemplified by the difference in the slopes for the chloro and isothiocyanato Ni(II) complexes, shown in Fig. 1 (*vide supra*). In the present systems, the ellipse becomes more nearly circular with an increase in the axial ligand field strength. The closer the ellipse is to a circle, the weaker is the correlation. The Co(III) system demonstrates such a situation (see Figs. 1 and 2(a)).

The tilt of the ellipse in Fig. 2 is 14° for Co(III), 18° for Fe(II), 31° for Ni(II), and 41° for Zn(II). The tilt reflects ease with which electrons move when the coordination bond lengths are forced to be varied. Thus, it seems that the tilt is associated with polarizability of the complex. Figure 3 shows overlap population on an M-Cl bond as a function of M-N distances. Generally, the M-Cl overlap population increases as the M-N distance increases. This arises from the fact that each metal atom tends to keep the electric charge neutral. In fact, within the computed range of M-N and M-Cl distances (the optimized distance $\pm$ *ca.* 0.25 Å, see Computational Procedures), total electron population on the metal atoms (Mulliken population) was constant within 2% for each metal atom. The values were 26.4 for Co(III), 25.5 for Fe(II), 27.5 for Ni(II), and 29.4 for Zn(II). The interrelationships depicted in Fig. 3, which are strongly metal ion dependent, are deeply related to the tilts of the ellipses of Fig. 2.

The congestion of the contour lines, *i.e.*, the slope of the potential surface, is also an important factor. If contour lines were less congested, the electronic cis effect would occur more easily. On the other hand, coordination bond lengths would not vary widely, if the slope of the potential surface were steep. It is manifested in the Co(III) system (see Figs. 1 and 2(a)). The most apparent difference in the feature of the potential surfaces between the Co(III) and Fe(II) complexes is the slopes. There is no doubt that the Co(III) surface becomes steeper by the effect of the electric charge. Higher electric charge on the metal brings about more congested contour lines.

The conclusions obtained from the features of the potential surfaces, such as the axis ratio, the tilt of the ellipse and the degree of the congestion of the contour lines, agree very well with the experimentally observed results shown in Fig. 1.

Pearson made the following statement in his paper describing the concept of Hard and Soft Acids and Bases: Softness in both the acid and base means that the repulsive part of the potential energy curve rises less sharply than for hard acids and bases.[25] According to this, it follows that the degree of the congestion of the contour lines in Fig. 2 shows hardness of the metal ions. Furthermore, softness (or hardness) is known to be directly associated with the polarizability,[25] which is correlated with the tilt of the ellipse in Fig. 2. In view of these, it is clear from Figs. 1 and 2 that, among the metal ions studied, Co(III) is the hardest, Zn(II) is the softest, and Ni(II) is intermediate. Although Pearson classifies both of Ni^{2+} and Zn^{2+} into borderline Lewis acids,[25] there is a clear difference in softness between them.

In the present MO calculations, we used a double ζ quality basis set for metal 3d orbitals and minimal basis sets for the others. The approximation might not be sufficient to describe detailed electronic structures and molecular dimensions. For example, M-Cl bond distances in the optimized structures (see below (Table 2)) are evidently shorter than the normal values.[26] However, we believe that the present calculations give sufficiently reliable results concerning the relative differences of the potential surfaces.

Both theoretically and experimentally, it has been found that the degree of correlation increases in the order, $Co^{3+}<Ni^{2+}<Zn^{2+}$. It should be pointed out that the number of d-electrons in e_g orbital in O_h symmetry increases in the same order: 0 for Co^{3+}, 2 for Ni^{2+}, and 4 for Zn^{2+}.

Computational Procedures

Geometries and Basis Set. Each ammonia ligand was assumed to have the N-H bond length of 1.00 Å and tetrahedral bond angles with its C_3 axis lying on the M-N bond. The ammonia molecules were arranged in such a manner that the entire molecule of *trans*-$[MCl_2(NH_3)_4]$ has D_{2d} symmetry.

The basis sets used were the STO-3G set for ligand atoms and the [4s3p2d] contracted set for central metal atoms, respectively.[27] For M=Co^{3+}, Fe^{2+}, and Zn^{2+}, the ground states are assumed to be closed-shell singlet, whereas, for M=Ni^{2+}, it is assumed to be triplet, and the restricted Hartree-Fock method was used in the SCF-MO calculations.

Section Maps of the Potential Surfaces along M-Cl and M-N Bond axes. In order to draw section maps of the potential energy surfaces along the coordination bond axes, we have calculated SCF MO's on 20—30 geometries for each model compound, M-N and M-Cl distances being varied by 0.05 Å near the minimized structures. Contours were drawn by means of two-dimensional spline fitting program at intervals of 0.5 kcal mol^{-1}. Coordinates for the optimum structure of each compound were obtained by smooth interpolation from the section map (Table 2).

Table 2. Optimized coordination geometries for *trans*-$[MCl_2(NH_3)_4]$.

M	M-N/Å	M-Cl/Å
Co^{3+},[a]	1.97	2.15
Fe^{2+}	2.06	2.27
Ni^{2+}	2.13	2.27
Zn^{2+}	2.18	2.25

a) For Co(III) complexes of *trans*-$CoCl_2N_4$ type, Co-N and Co-Cl distances have been found to be $\approx$1.98 Å and $\approx$2.26 Å, respectively.[18]

All the calculations were carried out by using the IMSPACK program system[28] on a HITAC M-200H computer at the Computer Center of IMS.

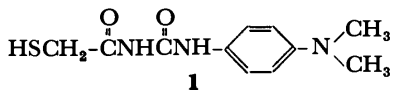
A Kinetic Study on Oxidation of a Pair of Associating Thiols Having Substituted Phenyl Groups with Oxygen

Tadashi Endo,* Masao Hashimoto, Toyohiko Orii, and Masato M. Ito
Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157
(Received May 31, 1983)

The rates of oxidation of 1:1 mixtures of associating thiols, each having the binding site (-CNHCNH-) and the recognition site [p-$(CH_3)_2NC_6H_4$ or R], with O_2 were measured in 80% (v/v) acetonitrile-20% water in the range of 20 to 50 °C. Oxidation of the thiol having the p-$(CH_3)_2NC_6H_4$ group proceeds about 100 times faster than that of the thiols with R. It has been found that oxidation of 1:1 mixtures of the thiols is first-order with respect to thiols and 0.7 th-order with respect to triethylamine by means of the method of initial rates. The $k_{1.7}$ values for R=C_6H_5, p-$CH_3C_6H_4$, and p-$C_2H_5C_6H_4$ were similar to one another; this makes a sharp contrast with our previous work that the selectivity (the logarithmeric ratio of the yield of the unsymmetrical disulfide to twice that of the symmetrical disulfide) changes greatly with the structures of R and temperature. It is concluded that the product ratio does not depend upon the $k_{1.7}$. The large negative activation entropies (−51 to −45 cal K^{-1} mol^{-1})† suggest that the oxidation would proceed through a highly ordered transition state.

The recognition of the methyl groups on nucleotide bases plays a significant role in living cells, whether prokaryotes or eukaryotes.[1] It is striking that highly complicated *in vivo* reactions are controlled by a rather simple modification, methylation, of the aromatic rings. Therefore, an approach to the problem of methylation from a chemical point of view would serve to elucidate the factors governing chemical reactions including those in biological systems.

As a continuing study on molecular recognition,[1-6] we examined the effect of methylation of the benzene ring on chemical selectivity.[1] A pair of thiols (**1** and **2**) were used as model compounds. Thiols **1** and **2** each

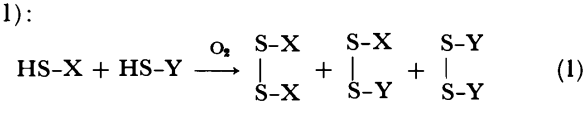


1

2a R =

2b R = 
2c R = 
2d R = $(CH_2)_2CH(CH_3)_2$

have the binding site (-CNHCNH-) participating in intermolecular hydrogen bonding and the recognition site (p-$Me_2NC_6H_4$ or R) participating in the specific discrimination. As a model reaction, we used oxidation of a 1:1 mixture of **1** and **2** with oxygen in the presence of a catalytic amount of triethylamine (Et_3N) (Eq. 1):



(1)

1 **2** **3** **4** **5**

The temperature dependence of the selectivity in the above oxidation has previously been reported as a function of the structures of R in 80% (v/v) acetonitrile-20% water (Fig. 1);[1,2] the selectivity (r) is represented here by the logarithmeric ratio of the yield of the unsymmetrical disulfide (**4**) to twice that of the symmetrical disulfide (**3**) {r=ln([**4**]/(2 [**3**]))}. The selectivity for R=p-MeC_6H_4 displayed a minimum (r= −0.86) at 35 °C, whereas for R=C_6H_5 the selectivity passed through a maximum (r=1.6) at 35 °C; for R=p-$C_2H_5C_6H_4$ a plot of the selectivity against temperature showed a sigmoid-like curve.

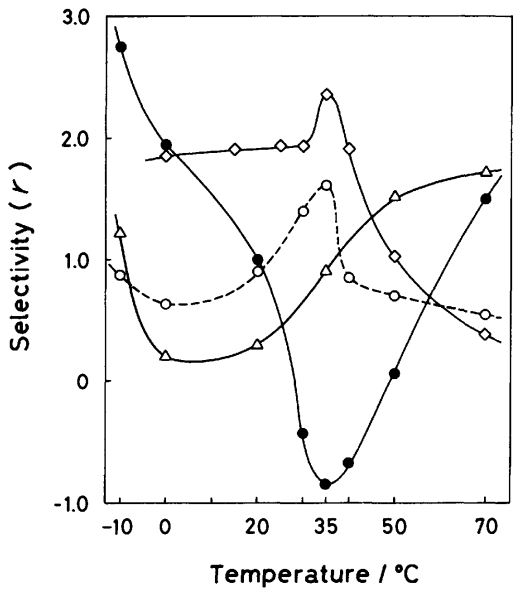


Fig. 1. Temperature dependence of the selectivity (r) in oxidation of 1:1 mixtures of **1** and **2** with O_2 in 80% (v/v) acetonitrile-20% water. ○, **1** and **2a**; ●, **1** and **2b**; △, **1** and **2c**; ◇, **1** and **2d**. We have previously represented the selectivity as the ratio of the yield of unsymmetrical disulfide **4** to that of symmetrical disulfide **3**.[1,2]

In order to elucidate the mechanism of the oxidation described above, we made a kinetic study on the oxidation under conditions similar to those where the selectivity was investigated. Measurements were performed on overall rates for 1:1 mixtures of thiols **1** and **2a**—**c** as well as on rates for the individual thiols,

† 1 cal=4.184 J.

by titration of remaining thiols with iodine. For comparison, the rates were also determined for **2d**—the thiol with an isopentyl group as the recognition site—and a 1:1 mixture of **1** and **2d**; for oxidation of the 1:1 mixture of **1** and **2d**, a plot of the selectivity against temperature showed a sharp peak of maximum selectivity (r=2.4) at 35 °C[2] under the same conditions as with oxidation of **1** and **2a—c** (Fig. 1).

Results

Kinetic Behavior of Catalytic Oxidation of Thiols. Oxidation of each thiol (**1** or **2**) was carried out in oxygen-saturated 80% (v/v) acetonitrile-20% water in the presence of Et_3N as a catalyst. Figure 2 summarizes the time course of thiol consumption where $[RSH]_0$ represents the initial concentration of thiols. Downward curvature was observed for **1** in a plot of log ($[RSH]/[RSH]_0$) against time in the presence of 0.1 equivalent of Et_3N. The use of 2.0 equivalents of Et_3N led to the pseudo first-order reaction, as might be expected from the results by Wallace *et al.*[7] that oxidation of thiols follows pseudo first-order kinetics in the presence of 2.0 equivalents of a base.

For oxidation of 1:1 mixtures of **1** and **2**, total concentration of thiols was measured. Remarkable downward curvatures were observed (Fig. 2) in the presence of 0.1 equivalent of Et_3N, the same concentration of Et_3N as in the oxidation whose selectivity is given in Fig. 1. However, on addition of 20 equivalents[8] of Et_3N, the oxidation has proved to follow

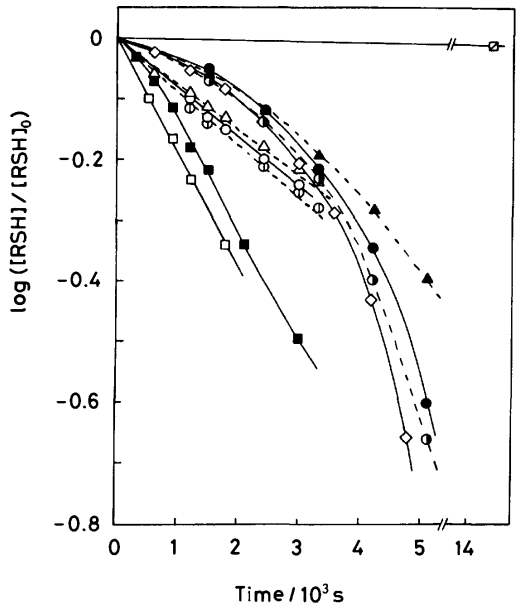

Fig. 2. Dependence of log ($[RSH]/[RSH]_0$) on time for oxidation of **1**, **2**, and their 1:1 mixtures at $[RSH]_0$=0.020 M in 80% (v/v) acetonitrile-20% water at 35.0 °C. The concentration of Et_3N as a catalyst was 0.0020 M, unless otherwise mentioned. ■, **1**; □, **1** ($[Et_3N]$=0.040 M); ⊠, **2b**; ◑, 1:1 mixture of **1** and **2a**; ●, 1:1 mixture of **1** and **2b**; ▲, 1:1 mixture of **1** and **2c**; ◇, 1:1 mixture of **1** and **2d**; ⊕, 1:1 mixture of **1** and **2a** ($[Et_3N]$=0.40 M); ○, 1:1 mixture of **1** and **2b** ($[Et_3N]$=0.40 M); △, 1:1 mixture of **1** and **2c** ($[Et_3N]$=0.40 M).

Table 1. Initial rates for oxidation of individual thiols (**1** and **2**) and overall initial rates for their 1:1 mixtures

Compd	$[Et_3N]\times10^3$/M	$v_0\times10^8$ [a]/mol l^{-1}s^{-1}
1	2.0	440
2a	2.0	3.3
2b	2.0	3.1
2c	2.0	3.3
2d	2.0	2.9
1+**2a**	2.0	200
1+**2b**	2.0	180
1+**2c**	2.0	180
1+**2d**	2.0	210
1+**2a**	400	610
1+**2b**	400	480
1+**2c**	400	450

a) Average rates until 10% consumption of thiols ($[RSH]_0$=0.020 M) (1 M=1 mol dm^{-3}) at 35.0 °C in oxygen saturated 80% (v/v) acetonitrile-20% water.

pseudo first-order kinetics.

Initial rates (v_0)—average rates until 10% consumption of thiols—for the oxidation are listed in Table 1. The thiol with the isopentyl group (**2d**) was similar to the thiols with the aromatic groups (**2a—c**) both in kinetic behavior (Fig. 2) and in the initial rates (Table 1).

Rate Equation for Oxidation of 1:1 Mixtures of Thiols. The observed downward curvatures for oxidation of 1:1 mixtures at $[Et_3N]=2.0\times10^{-3}$ M (1M=1 mol dm^{-3}) showed that rate equations were impossible to derive directly from the plots in Fig. 2. Thus we used the method of initial rates in order to determine the rate equation for the Et_3N-catalyzed oxidation. Since the concentration of oxygen is considered to be constant for low levels of conversion,[9] the rate equation becomes Eq. 2

$$v = k_n[RSH]^{n-m}[Et_3N]^m \quad (2)$$

where n represents the overall reaction order and k_n the n-th order overall rate constant for the oxidation. Putting Eq. 2 into logarithmeric form yields Eq. 3.

$$\log v = \log k_n + (n-m)\log[RSH] + m\log[Et_3N] \quad (3)$$

The v_0 values were measured at various $[RSH]_0$, with the molar ratio of **1**, **2b**, and Et_3N being fixed (1:1:0.2). Since $[Et_3N]$=0.1 $[RSH]_0$, Eq. 3 can be rewritten as Eq. 4.

$$\log v_0 = \log k_n + n\log[RSH]_0 - m \quad (4)$$

Figure 3 plots the logarithm of v_0 against log $[RSH]_0$. Linear relationship was found to exist between them. The slope of a log $[RSH]_0$—logv_0 plot for a 1:1 mixture of **1** and **2b** gave the n value of 1.7 for the oxidation.[10]

The initial rates were then measured at different Et_3N concentrations with $[RSH]_0$ fixed. In this case the first two terms on the right-hand side of Eq. 3 can be regarded as constant. Since a linear relationship exists between log v_0 and log $[Et_3N]$ (Fig. 4), the slope of the straight line gives m value in Eq. 3. The m value turned out to be 0.7, indicating that the reaction is first-order with respect to thiols.[11] Thus the rate follows the equation:

$$v = k_{1.7}[RSH][Et_3N]^{0.7} \quad (5)$$

The 1.7th-order rate constants for oxidation of 1:1 mixtures ($k_{1.7}$) were obtained at 20.0, 35.0, and 50.0 °C using Eq.5. The results are listed in Table 2. In all cases, the linear relationship existed between ln $k_{1.7}$ and $1/T$, demonstrating that Eq. 5 holds true for the temperature range described above. Activation parameters for the oxidation are also given in Table 2.

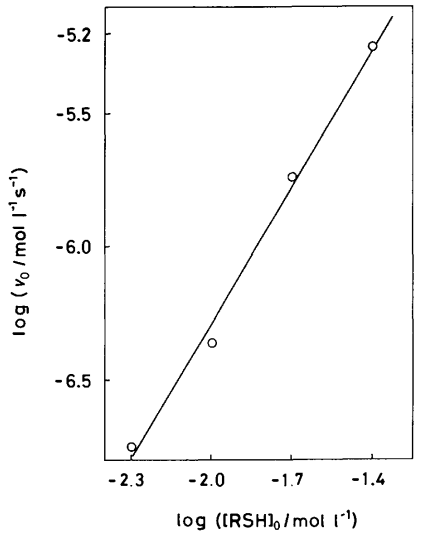

Fig. 3. Dependence of initial rates (v_0) on initial concentration of a 1:1 mixture of **1** and **2b** at [Et$_3$N]=0.1 [RSH]$_0$. The other conditions are as in Fig. 2.

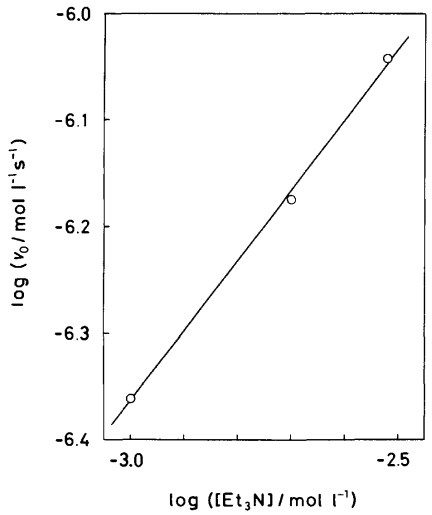

Fig. 4. Dependence of initial rates (v_0) on initial concentration of Et$_3$N at [RSH]$_0$=0.010 M. The other conditions are as in Fig. 2.

Discussion

Mechanism of the Oxidation. Base-catalyzed oxidation of thiols is known to proceed through the following reaction paths (Eqs. 6—10).[12-15]

$$RSH + Et_3N \underset{}{\overset{K_6}{\rightleftharpoons}} RS^- + Et_3NH^+ \quad k_{+6}, k_{-6} \qquad (6)$$

$$RS^- + O_2 \longrightarrow RS\cdot + O_2^{\cdot-} \quad k_7 \qquad (7)$$

$$RSH + O_2^{\cdot-} \longrightarrow RS\cdot + OOH^- \qquad (8)$$

$$OOH^- \longrightarrow OH^- + \frac{1}{2}O_2 \qquad (9)$$

$$2\,RS\cdot \longrightarrow RS\text{-}SR \qquad (10)$$

The equilibrium shown in Eq. 11 would contribute to the recovery of Et$_3$N.[13] These yield Eq. 12 as the overall stoichiometry of the oxidation.

$$Et_3N + H_2O \underset{}{\overset{K_{11}}{\rightleftharpoons}} Et_3NH^+ + OH^- \qquad (11)$$

$$2\,RSH + \frac{1}{2}O_2 \longrightarrow RS\text{-}SR + H_2O \qquad (12)$$

The rate-determining step of base-catalyzed oxidation of thiols is shown to be either the formation of thiolate anions (Eq. 6) or its oxidation to the corresponding thiyl radicals (Eq. 7).[12,13] This view appears to hold true for the oxidation presented here, considering that the oxidation is first-order with respect to thiols.[16] Uncertainty still remains about what causes the downward curvatures in kinetic profiles (Fig. 2).

An intriguing aspect of the kinetic results is the large negative activation entropies (Table 2). The activation entropies of −51 to −45 cal K^{-1} mol^{-1} for the present oxidation are more negative than those of about −20 to −10 cal K^{-1} mol^{-1} for ordinary bimolecular reactions[17]. Bimolecular reactions with highly ordered transition states generally have $\Delta S^{\neq}$ values of similar magnitude: −49 to −22 cal K^{-1} mol^{-1} for Diels-Alder reactions,[18] −43 to −22 cal K^{-1} mol^{-1} for 1,3-dipolar cycloadditions,[19] and −42 to −19 cal K^{-1} mol^{-1} for Menschutkin reactions between tertiary amines and alkyl iodides.[20] These observations suggest that the

oxidation presented in this paper would have a highly ordered transition state.

Factors Governing the Selectivity. Oxidation of thiol **1** proceeds more than 100 times faster than that of **2** (Table 1). The initial rates for oxidation of 1:1 mixtures of **1** and **2** decreased to about half (v_0= (1.8—2.1)×10^{-6} mol l^{-1} s^{-1}) of that for oxidation of **1** (v_0=4.4×10^{-6} mol l^{-1} s^{-1}), $[\mathbf{1}]_0$ for oxidation of 1:1 mixtures being half that for oxidation of **1** (Table 1). These results indicate that the thiolate anion which is formed predominantly from the 1:1 mixtures is that derived from **1**. Thus, the selective formation of symmetrical disulfide **3** might be expected at an early stage, though the oxidation gives the high selectivity (r) in most cases (Fig. 1). However, this is not the case, because the product ratio in this type of oxidation is kinetically controlled so that the selectivity does not vary with the reaction time.[2] This fact suggests the presence of fast exchange reaction between an anion and a thiol (Eq. 13) or between a radical and a thiol (Eq. 14).

$$\underset{\mathbf{2}}{XS^-} + \underset{\mathbf{1}}{YSH} \rightleftharpoons \underset{\mathbf{2}}{XSH} + \underset{\mathbf{1}}{YS^-} \quad (13)$$

$$\underset{\mathbf{2}}{XS\cdot} + \underset{\mathbf{1}}{YSH} \rightleftharpoons \underset{\mathbf{2}}{XSH} + \underset{\mathbf{1}}{YS\cdot} \quad (14)$$

The initial rates for oxidation of 1:1 mixtures of **1** and **2a—c** are expressed by a single rate equation (Eq. 5). Further, the rate constants for the oxidation do not change appreciably with the structures of R (Table 2); this makes a sharp contrast with our previous work[1] that the selectivity alters markedly with the structures of R (Fig. 1). Accordingly, the product ratio would not be controlled in the rate-determining step.[21]

We have reported that thiols **1** and **2** associate strongly in benzene *via* two NH···O intermolecular hydrogen bonds between the inner -NHC(=O)- units in the -CNHCNH- group to form tetramers (**9—13**, reaction intermediates) as well as dimers (**6—8**) (Fig. 5).[1,22,23] The S-S bonds would be formed between the two proximate HS groups in tetramers **9—13**.[22] Each of the tetramers gives the corresponding disulfide(s) selectively when treated with oxygen.[4] The relative concentration of the tetramers would vary with the structures of R and temperature,[4] thereby leading to the selectivity alterations (Fig. 1). These selectivity data appear to reflect weak interactions[5] specific for the shape of the recognition sites of **1** and **2**.

Conclusion

Triethylamine-catalyzed oxidation of 1:1 mixtures of **1** and **2a—c** in 80% (v/v) acetonitrile-20% water follows the rate equation $v=k_{1.7}$ [RSH][Et_3N]$^{0.7}$, although a detailed mechanism of the oxidation still remains to be elucidated. The $k_{1.7}$ values for the 1:1 mixtures are similar to one another, in sharp contrast to our previous work that the selectivity varies markedly with the structures of R and temperature. This indicates that the product ratio does not depend upon the $k_{1.7}$. The present results including the large negative activation entropies are consistent with our view that the formation of disulfides **3—5** occurs *via* tetrameric intermediates **9—13**.

Experimental

Materials. All the thiols **1** and **2** were prepared as described previously.[1,24] Acetonitrile was dried and purified by distillation from calcium hydride and phosphorus pentaoxide, and stored over molecular sieves. The reaction solvent was prepared by mixing 62.58 g of dry acetonitrile with 19.96 g of water [4:1 (v/v) at 20 °C], and allowed to stand overnight under an oxygen atmosphere. Triethylamine was distilled over potassium hydroxide through a fractionating column. The iodine solution (0.001 M) containing potassium iodide (0.005 M) was titrated with 1.00×10^{-3} M aqueous sodium arsenite standard solution before use.

Determination of Rates of the Oxidation. Samples of thiols were accurately weighed into a two-necked flask and dissolved in 10.00 ml of the reaction solvent. The solution was placed in a well-stirred water bath thermostated to

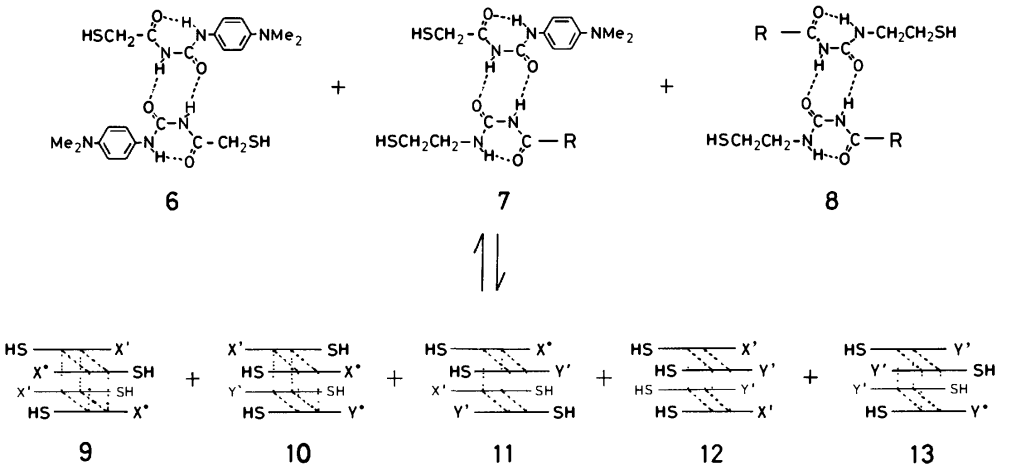

Fig. 5. Association patterns of three dimers **6—8** and association schemes of tetramers **9—13** formed by dimerization of the dimers. The hydrogen bonds (----) in the dimers and the noncovalent weak interactions (·····) responsible for the stabilization of the tetramers are shown. The symbols X′ and Y′ represent *p*-$Me_2NC_6H_4$ and R, respectively.

±0.1 °C for 5 h with stirring under an oxygen atmosphere. Oxidation of thiols was negligible in the absence of Et_3N. At time zero, an appropriate amount of Et_3N was added into the solution with a microsyringe, and time measurement was begun. At appropriate time intervals, a 0.50 ml portion of the reaction mixture was pipetted out and quenched in 5 ml of a 1:9 mixture of 3 M hydrochloric acid with acetonitrile. The amount of remaining thiols in the quenched solution was then determined by titration with the 0.001 M iodine solution.

Rate constants were determined by the method of initial rates.[17] Plots of concentration of thiols against time were constructed, and initial rates for 10% conversion were calculated. Initial rates presented in Tables 1 and 2 are average values of at least three, generally five, or more determinations. The reaction order and rate constants were evaluated from the initial rates measured at different initial concentrations of thiols and Et_3N (Figs. 3 and 4), through least square optimization.

Calculations of Activation Parameters. Activation energies were determined from the slopes of Arrhenius plots (ln k *vs.* $1/T$). Activation enthalpies and entropies were obtained from the plots of ln (k/T) against $1/T$ based on Eyring equation.[17]

We thank Mr. Kazuo Guro and Mr. Hideki Ueda for valuable assistance. We are also grateful to the referees for helpful suggestions.

8) In the presence of 2.0 equivalents of Et_3N, downward curvature was still observed.

9) No appreciable changes took place in kinetic profiles for the oxidation with O_2 whose pressure was slightly larger than 1 atm.

10) For a 1:1 mixture of **1** and **2d**, the overall order of the oxidation became 2.2 in the thiol concentration range similar to that for **1** and **2a—c**.

11) The fact that the oxidation is first-order with respect to thiols agrees with the results by Wallace *et al.* for base-catalyzed oxidation of simple aliphatic and aromatic thiols.[7]

13) A. A. Oswald and T. J. Wallace, "Anionic Oxidation of Thiols and Co-oxidation of Thiols with Olefins," in "Organic Sulfur Compounds," ed by N. Kharash, Pergamon Press, New York (1965), Vol. 2, Chap. 8.

14) The initial rate for oxidation of a 1:1 mixture of **1** and **2b** decreased by 33% on addition of hydroquinone (0.020 M). This suggests the participation of free radicals in the oxidation [W. A. Pryor, "Free Radicals," Mcgraw-Hill, New York (1966), Chap. 21].

15) Though O_2^- oxidizes thiols very readily [S. Oae, T. Takata, and Y. H. Kim, *Bull. Chem. Soc. Jpn.*, **54**, 2712 (1981)], it is uncertain whether or not the step in Eq. 8 contributes to the rate for the present oxidation, since O_2^- is known to be labile in aqueous media [J. Rabani and S. O. Nielsen, *J. Phys. Chem.*, **73**, 3736 (1969)].

16) If the formation of thiolate anions (Eq. 6) is rate-determining, the rate may be expressed as

$$v = 2\,k_{+6}[\mathrm{RSH}][\mathrm{Et_3N}]$$

Thus the oxidation will be first-order with respect to both thiols and Et_3N. In contrast, if the oxidation of RS^- (Eq. 7) is rate-determining, the rate may follow the expression

$$v = k_7' K_6[\mathrm{RSH}]\left(\frac{[\mathrm{Et_3N}]}{K_{11}+K_6[\mathrm{RSH}]}\right)^{0.5} \quad (k_7' = 2\,k_7[\mathrm{O_2}])$$

Provided that $K_{11} \gg K_6[\mathrm{RSH}]$, the oxidation will be first-order with respect to thiols and 0.5th-order with respect to Et_3N. Neither of the above equations completely agrees with the experimental results at an initial stage (0.7th-order with respect to Et_3N), suggesting the complex nature of the oxidation.

20) A. P. Harris and K. E. Weale, *J. Chem. Soc.*, **1961**, 146.

21) Some examples have been reported in which chemical selectivity is controlled prior to the rate-determining step: see, for example, H. Ozaki, A. Tai, and Y. Izumi, *Chem. Lett.*, **1974**, 935.

22) T. Endo, Y. Takeda, T. Orii, Y. Kaneko, and M. Kondo, *Chem. Lett.*, **1979**, 1455.

23) Thiolate anions would be formed from dimers (**6—8**) and tetramers (**9—13**) as well as monomers (Fig. 5). It is uncertain whether or not the dissociation constants for the thiols alter when the thiols associate. The rate equation shown in Ref. 16 is based on the assumption that $[RS^-]$ is practically unaffected by the association.

Reactions of Sodium Salts of Tosylhydrazone Compounds with Silver Chromate. Formation of Indazole, Pyrazole, and Benzonitrile Derivatives

Katsuhiro SAITO,*,† Takashi TODA, and Toshio MUKAI

†*Department of Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466*

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received July 19, 1983)

Tropone tosylhydrazone sodium salt was allowed to react with silver chromate to give 2-tosyl-2*H*-indazole. The reaction is thought to proceed through the cyclization of the hydrazyl radical intermediate. Under the same conditions, sodium salts of *m*-nitrobenzaldehyde tosylhydrazone (**5**), benzylideneacetone tosylhydrazone derivatives (**7a** and **7b**), and β-ionone tosylhydrazone (**9**) reacted to yield *m*-nitrobenzonitrile from **5** and pyrazole derivatives from **7a**, **b**, and **9**, respectively. *m*-Nitrobenzonitrile is formed by homolytic fission of nitrogen-nitrogen bond of **5**. Formation of the pyrazole derivatives can be explained by intramolecular 1,3-dipolar additions of the corresponding diazo intermediates.

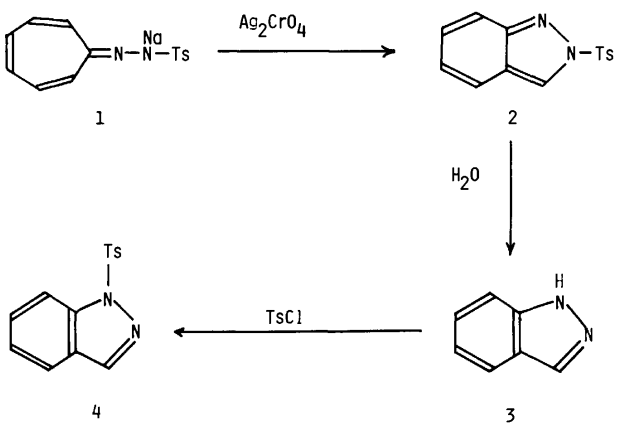
Considerable attention has been paid to the synthesis and chemistry of the heterocyclic compounds having two nitrogen atoms in the ring, *i.e.*, diaziridines, pyrazoles, and diazepines, from the viewpoint of electronic structures and the chemical reactivities of these compounds.[1]

Tosylhydrazone derivatives are readily available compounds which contain two nitrogen atoms in a molecule. It is known that one electron oxidation of amine derivatives affords amino radicals.[2] This fact suggested to us that one electron oxidation of tosylhydrazone derivatives may afford some of the above-mentioned heterocyclic compounds besides the products derived from 1,3-dipolar addition or carbenic reactions.[3] Actually, 2-phenyl-2*H*-indazole was obtained by lead tetraacetate oxidation of tropone phenyhydrazone although the yield was poor.[4]

We investigated an oxidation reaction of tropone tosylhydrazone sodium salt (**1**) with silver chromate as an oxidizing agent. The same type of reaction was carried out with sodium salts of tosylhydrazone derivatives **5**, **7**, and **9**. We wish to report the results of these investigations.

Results and Discussion

Tropone tosylhydrazone sodium salt (**1**) was allowed to react with silver chromate in anhydrous diglyme under a nitrogen stream at 125 °C for 10 min. Alumina chromatographic purification of the reaction mixture afforded 2-tosyl-2*H*-indazole (*2*) in 28% yield. The structure of **2** was deduced on the basis of the spectral properties and finally confirmed by the following experiments. Hydrolysis of **2** in basic aqueous media gave indazole (**3**) in 74% yield, implying that 2 was an indazole derivative. 1-Tosyl-1*H*-indazole (**4**) was synthesized from **3** and tosyl chloride which was isomeric to **2**.[5]



1 2 3 4

Fig. 1.

m-Nitrobenzaldehyde tosylhydrazone sodium salt (**5**) was allowed to react with silver chromate at 100 °C for 5 min to yield *m*-nitrobenzonitrile (**6**)[6] in 6% yield. Sodium salts of benzylideneacetone tosylhydrzaone derivatives (**7a** and **7b**) were also reacted under the analogous conditions to afford pyrazole derivatives (**8a** and **8b**) in yields of 70 and 44%, respectively. Similarly, β-ionone tosylhydrazone sodium salt (**9**) gave a pyrazole derivative (**10**) in 82% yield by the same reaction. The structures of **8a**, **8b**, and **10** were deduced from their spectral properties as follows. The electronic spectra are similar to those of the (aryl or arylalkyl) pyrazole derivatives.[7] Also, the chemical shift values of the pyrazole ring protons at δ 6.20 of **8a**, 6.23 of **8b**, and 5.73 of **10** correspond with those of the reported pyrazole derivatives.[8]

The mechanism for the formation of **2** is considered to be as follows. The hydrazyl radical (**11**) generated by oxidation of **1** by silver chromate cyclizes to form the 8,9-diazabicyclo[5.2.0]nonatriene intermediate (**12**). 2-Tosyl-2*H*-indazole (**2**) is formed by the loss of a hydrogen radical from the intermediate norcaradiene isomer (**13**). Bicyclo[5.2.0]nonatriene and 8,9-diazabicyclo-[5.2.0]nonatriene systems are known to rearrange to bicyclo[4.3.0]nonatriene systems *via* intermediate norcaradienes.[4,9]

The reaction of **5** was performed with the intention of synthesizing the 1-tosyl-1*H*-indazole derivative (**14**). However, a homolytic fission of the nitrogen-nitrogen bond occurred to form *m*-nitrobenzonitrile (**6**) *via* radical intermediates (**15** and **16**). This result corresponds with Binkley's finding that the benzylaminyl radical leads to benzonitrile.[10] 1,2-Benzodiazepine derivatives or pyrazole derivatives were expected to be formed in the reaction of **7**. The expected radical reaction *via* the hydrazyl radical (**19**) leading to **17**, however, did not occur, but the pyrazole derivatives (**8**) were obtained. The nitro group on the phenyl ring in **7b**, which is

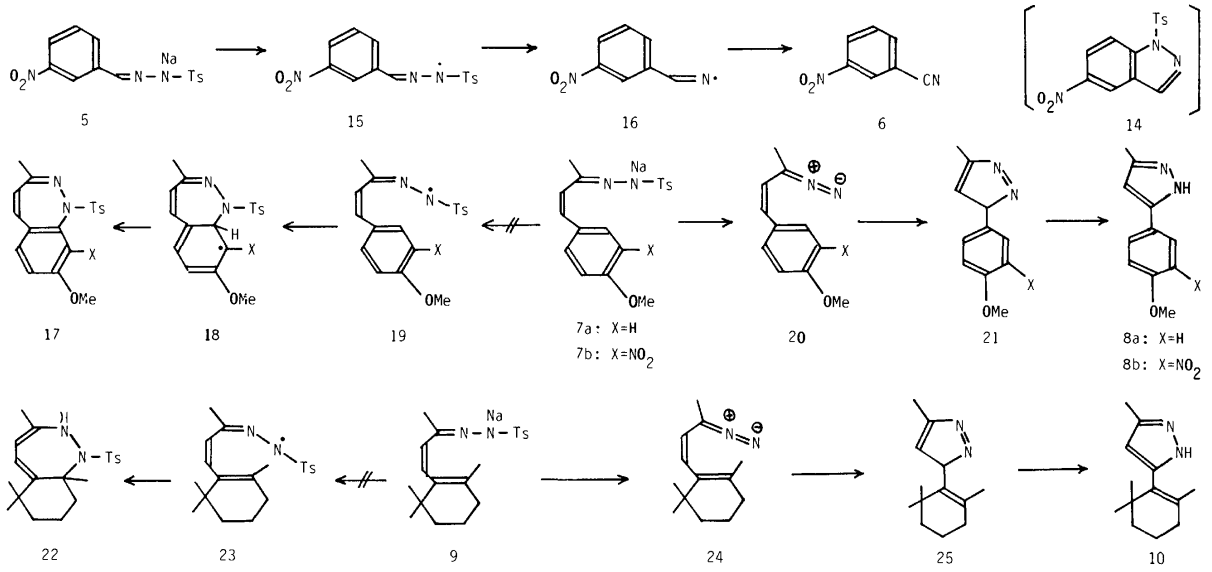


Fig. 2.

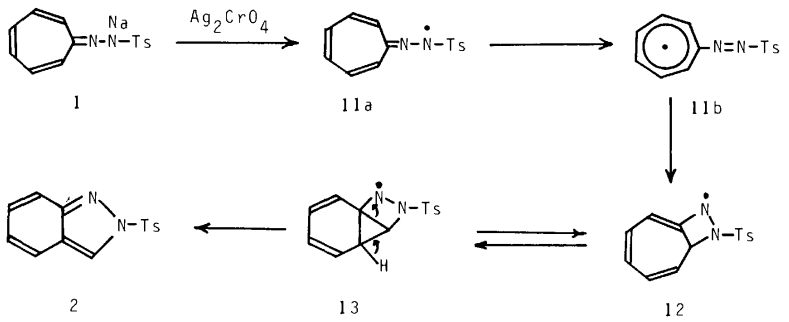

Fig. 3.

expected to stabilize the radical intermediate (**18**), did not promote the radical reaction. The reaction of **9** was performed to compare the reactivity of aliphatic double bond with that of aromatic skeleton. The cyclization reaction to form a seven-membered ring compound did not occur, but the experiment resulted in the formation of the pyrazole derivative (**10**).

The reactions of **7** and **9** are considered to proceed *via* diazo compounds **20** and **24**, respectively, because the pyrazole derivatives (**8** and **10**) did not contain any tosyl groups. The formation of pyrazoles from vinyldiazomethane derivatives is a well-documented reaction.[11]

The formation of the condensed ring indazole from **1** and the failure of phenyl substituted tosylhydrazones to form the condensed ring compounds may be explained as follows. Cycloheptatrienyl radical is readily formed from cycloheptatriene, so the hydrazyl radical (**11**) can be considered to be stabilized by the canonical formula **11b**.[12] No such stabilization effect is expected for the hydrazyl radicals **19** and **23**.

Experimental

All the melting and boiling points were uncorrected. NMR spectra were measured with a Varian HA-100 or a Hitachi R-20B spectrometer with deuteriochloroform as a solvent and tetramethylsilane as an internal standard. Benzylideneacetone derivatives were prepared according to a modification of the method of Drake and Allen.[13] All tosylhydrazones were prepared by ordinary methods from the corresponding ketones and tosylhydrazine.

Reaction of 1 with Silver Chromate. A mixtur of **1** (2.0 g, 6.8 mmol) and silver chromate (4.4 g, 13.3 mmol) in anhydrous diglyme (10 ml) was heated at 125 °C for 10 min under a nitrogen stream. After separation of the solid by filtration, the filtrate was extracted with ethyl acetate, washed with water and brine, and dried over anhydrous sodium sulfate. After filtration, the solvent was removed on a rotary evaporator to yield a tarry material, which was chromatographed on alumina using benzene as an eluent to give colorless crystals of **2** (562 mg). Recrystallization from ethyl acetate afforded pure crystals of **2** (510 mg, 28%); mp 139—140 °C; UV_{max} (MeOH) 244 nm (log ε 4.40), 276 (3.60), 288 (3.73), and 296 (3.68); IR (KBr) 3060, 1630, and 1596 cm^{-1}; NMR ($CDCl_3$) δ=2.33 (3H, s), 6.95—7.35 (4H, m), 7.5—7.7 (2H, m), 7.98 (2H, d), and 8.60 (1H, d); MS *m/z* (rel intensity) 272 (M^+, 34), 208 (29), 155 (26), and 91 (100). Found: C, 61.95; H, 4.36; N, 10.16%. Calcd for $C_{14}H_{12}O_2N_2S$: C, 61.76; H, 4.44; N, 10.29%.

Hydrolysis of 2. A solution of **2** (190 mg, 0.7 mmol) and 3 M† aqueous sodium hydroxide (10 ml) in methanol (5 ml) was heated at 90 °C for 2 h. After evaporation of methanol, the mixture was extracted with benzene, washed with water and brine, and dried over anhydrous sodium sulfate. After filtration, the solvent was removed on a rotary evaporator to yield colorless crystals of **3** (70 mg). Recrys-

† 1 M=1 mol dm^{-3}.

tallization from ethyl acetate gave pure crystals of **3** (60 mg, 74%); mp 145—146 °C (lit,[14] 146 °C).

Synthesis of 4. A solution of **3** (70 mg, 0.6 mmol) and tosyl chloride (230 mg, 1.2 mmol) in pyridine (5 ml) was heated at 110 °C for 2 h. The solution was poured into benzene (50 ml), washed with water, and dried over anhydrous sodium sulfate. After filtration the solvent was evaporated on a rotary evaporator to yield colorless crystals of **4** (160 mg). Recrystallization from ethanol gave pure crystals of **4** (140 mg, 79%); mp 111—112 °C; UV_{max} (MeOH) 237 nm (log ε 4.28) 241 (4.27), 269 (3.92), 277 (4.01), and 287 (4.00); IR (KBr) 3050, 1610, 1598, and 1360 cm^{-1}; NMR ($CDCl_3$) δ=2.33 (3H, s), 7.13—7.93 (8H, m), and 8.17 (1H, s); MS *m/z* (rel intensity) 272 (M^+, 36), 208 (34), 155 (15), 118 (100), and 91 (83). Found: C, 61.80; H, 4.20; N, 10.36%. Calcd for $C_{14}H_{12}O_2N_2S$: C, 61.76; H, 4.44; N, 10.29%.

Reaction of 5 with Silver Chromate. Sodium hydride (55%, 540 mg, 12.4 mmol) was added to a solution of *m*-nitrobenzaldehyde tosylhydrazone (3.2 g, 10.0 mmol) in anhydrous diglyme (30 ml). After evolution of hydrogen gas had ceased, silver chromate (5.2 g, 15.7 mmol) was added and the resulting mixture was heated at 100 °C for 5 min. The usual workup afforded a black tarry material, which was chromatographed on alumina using benzene as an eluent to give crystals of **6** (100 mg). Recrystallization from ethyl acetate gave pure crystals of **6** (85 mg, 6%); mp 117—118 °C (lit,[6] 117—118 °C).

Reaction of 7a with Silver Chromate. In the same way as above, a mixture of *p*-methoxybenzylideneacetone tosylhydrazone (1.7 g, 5.0 mmol), sodium hydride (55%, 300 mg, 6.9 mmol), and silver chromate (2.5 g, 7.5 mmol) in anhydrous diglyme (30 ml) was heated at 140 °C for 5 min. After the usual workup, the tarry material was chromatographed on alumina using benzene–ether (1:1) as an eluent to yield pale yellow crystals of **8a** (697 mg). Recrystallization from benzene gave pur crystals of **8a** (650 mg, 70%); mp 116—117 °C; UV_{max} (MeOH) 205 nm (log ε4.09) and 258 (4.16); IR (KBr) 3150, 2920, 1613, and 1570 cm^{-1}; NMR ($CDCl_3$) δ= 2.20 (3H, s), 3.73 (3H, s), 6.20 (1H, s), 6.76 (2H, d), 7.55 (2H, d), and 10.6 (1H, bs); MS *m/z* (rel intensity) 188 (M^+, 100), 173 (44), and 145 (13) Found: C, 70.12; H, 6.49; N, 14.73%. Calcd for $C_{11}H_{12}ON_2$: C, 70.18; H, 6.43 N, 14.88%.

Reaction of 7b with Silver Chromate. A mixture of 3-nitro-4-methoxybenzylideneacetone tosylhydrazone (2.0 g, 5.2 mmol), sodium hydride (55%, 300 mg, 6.9 mmol), and silver chromate (2.5 g, 7.5 mmol) in anhydrous diglyme (30 ml) was heated at 140 °C for 5 min. After the usual workup, the tarry material was chromatographed on alumina using benzene–ethyl acetate (1:1) as an eluent to give pale yellow crystals of **8b** (560 mg). Recrystallization from ethyl acetate gave pure crystals of **8b** (520 mg, 44%); mp 108—109 °C; UV_{max} (MeOH) 208 nm (log ε 4.10) and 252 (4.20); IR (KBr) 3150, 2950, and 1540 cm^{-1}; NMR ($CDCl_3$) δ=2.25 (3H, s), 3.90 (3H, s), 6.23 (1H, s), 7.0 (1H, d), 7.75 (1H, d), 8.05 (1H, d), and 10.6 (1H, bs); MS *m/z* (rel intensity) 233 (M^+, 100), 173 (7), 157 (19), and 130 (9). Found: C, 56.80; H, 4.77; N, 17.80%. Calcd for $C_{11}H_{11}O_3N_3$: C, 56.65; H, 4.75; N, 18.02%.

Reaction of 9 with Silver Chromate. A mixture of β-ionone tosylhydrazone (1.8 g, 5.2 mmol), sodium hydride (55%, 300 mg, 6.9 mmol), and silver chromate (2.5 g, 7.5 mmol) in anhydrous diglume (30 ml) was heated at 140 °C for 5 min. After the usual workup the oily material was chromatographed on alumina using benzene–ether (1:1) as an eluent to give a colorless oil of **10** (890 mg). Distillation under reduced pressure gave a pure oil of **10** (810 mg, 82%); bp 140 °C (bath temperature)/0.6 Torr (1 Torr ≈ 133.322 Pa); UV_{max} (MeOH) 205 nm (log ε 3.85) and 213 (sh, 3.83); IR (neat) 3100, 2960, and 1575 cm^{-1}; NMR ($CDCl_3$) δ=0.93 (6H, s), 1.40 (3H, s), 1.5—2.1 (6H, m), 2.23 (3H, s), 5.73 (1H, s), and 11.5 (1H, bs); MS *m/z* (rel intensity) 204 (M^+, 74), 189 (100), 147 (12), and 117 (21). Found: C, 76.29; H, 10.03; N, 13.68%. Calcd for $C_{13}H_{20}N_2$: C, 76.42; H, 9.87; N, 13.71%.

A Basic Study of the Amino Acid Residue in Protein. The Role of Hydrocarbon Groups in Enantiomer-differentiating Acylation

Yuji HIRAKI and Akira TAI*
Institute for Protein Research, Osaka University, Yamada-oka, Suita, Osaka, 565
(Received July 30, 1983)

The enantiomer-differentiating acylation (kinetic resolution) of 1-phenylalkylamines and their derivatives was carried out with (*S*)-2-phenylbutyric anhydride and its derivatives in aqueous and nonaqueous media. On the basis of the distributions of the two diastereomeric products, the molecular interactions between hydrocarbon residues responsible for the structural recognition of the reacting molecules were studied. In nonpolar media, the (*R*,*S*)-isomer was predominantly formed over the (*S*,*S*)-isomer. Moreover, the differentiation was mainly controlled by the size of the alkyl substituents of the substrates. In aqueous media, though, the (*S*,*S*)-isomer was predominantly formed. By a comparative study of the cyclohexyl analogs of the substrates and the reagents, it was shown that alkyl-phenyl and/or phenyl-phenyl interactions were important in the recognition process. A partitioning process of the substrate into the reagent phase was not effective in the differentiation of the enantiomer by the reaction in suspensions of optically active reagents in highly aqueous media.

Noncovalent molecular interactions as well as covalent interactions[1] play an important role in molecular recognition processes. However, only limited information is available for understanding the contributions of noncovalent interactions between small hydrocarbon residues of proteinous amino acids to a molecular recognition process.[2]

In previous reports[3,4] we have described the characterization of the function of small hydrocarbon residues in molecular recognition by analyzing the product distributions of the competitive acylation of two primary amines. Here, we wish to report the results of the enantiomer-differentiating acylation (kinetic resolution; Eq.1) of racemic primary amines with optically active acid anhydride in aqueous and nonaqueous media; we will also discuss the role of the hydrocarbon residues constituting a chiral center of substrates in the differentiation process. From the logarithmic molar ratio of the two diastereomeric products (ln r value: Eq.2), the differentiation efficiency of the reaction was evaluated. Since the nucleophilicities of amino groups in (*R*)-and (*S*)-substrates are identical with each other, the ln r value can be effected to reflect the interactions between hydrocarbon residues.

$$\left.\begin{matrix}(R)\text{-R-NH}_2\\(S)\text{-R-NH}_2\end{matrix}\right\} + (S)\text{-}(R^0\text{-CO})_2\text{O} \longrightarrow \left\{\begin{matrix}(R,S)\text{-R-NHCO-R}^0\\(S,S)\text{-R-NHCO-R}^0,\end{matrix}\right. \quad (1)$$

$$\ln r = \ln\left([(S,S)\text{-R-NHCO-R}^0]/[(R,S)\text{-R-NHCO-R}^0]\right). \quad (2)$$

Results and Discussion

The Reaction System. The enantiomer-differentiating acylation of primary amine with acid anhydride (Eq. 1) is one of the simplest systems for the study of a differentiation process, for it readily proceeds without any side reactions. Acid anhydrides react quantitatively with amines not only under homogeneously-dissolved conditions in the solvent (Phase I), but also in a suspension of acid anhydride in an aqueous solvent (Phase II); however, the modes of differentiation in these solvents are completely different from each other. By the estimation of the solubility of acid anhydride under the present reaction conditions (see Experimental), it was shown that (*S*)-2-phenylbutyric anhydride was homogeneously dissolved in a water-dioxane mixture with $\chi_{H_2O}<0.77$ (Phase I). In a water-dioxane mixture with $\chi_{H_2O}>0.77$, a large fraction of the reagent was insoluble, resulting in a heterogeneous solution containing oily droplets of the reagent (Phase II).[3]

For the evaluation of the differentiation efficiency by means of the ln r value, the reaction should be carried out in the presence of so large an excess of the substrates to the reagent as to eliminate the effects of the concentration changes in the substrates during the reaction. To establish the appropriate reaction conditions, the ln r values were determined in water-dioxane ($\chi_{H_2O}=0.76$) or dioxane under a variety of relative molar ratios of the substrates to a reagent ([(*R*)-R-NH_2+(*S*)-R-NH_2]/[((*S*)-R^0-CO)$_2$O]). The ln r value became constant when the relative molar ratio of the substrates to a reagent was over four. The four molar equivalents of the substrates were treated with one molar equivalent of a reagent in the following experiments. Using this ratio of substrates to a reagent, it was also confirmed that the same ln r value was obtained in the presence and in the absence of triethylamine, an acid quencher. The ln r value was not affected by the (*S*)-2-phenylbutyric acid liberated during the reaction.

Effects of Reaction Media on the Enantiomer-differentiation of 1-Phenylalkylamines. Four 1-phenylalkylamines, *i.e.* 1-phenylethylamine, 1-phenylpropylamine, 1-phenylbutylamine, and 1-phenyl-2-methylpropylamine, were treated with (*S*)-2-phenylbutyric anhydride in dioxane, benzene, or a water-dioxane mixture ($\chi_{H_2O}=0.76$). The resulting ln r values are listed in Table 1, together with the ν_x values of the alkyl group of the substrates.[5] In dioxane the ln r values were almost zero in the reaction of 1-phenylethylamine, which meant that no appreciable recognition of the substrate structure took place. The reaction of the other three amines resulted in negative ln r values, which meant that the (*S*)-reagent favored the reaction with (*R*)-substrates. The ln r value became negative with the increase in the size of the alkyl group (ν_x): The differentia-

Substrate (R'-CH(C_6H_5)-NH_2)	Size of R'	ln r values		
	ν_x[5] for R'	In dioxane	In benzene	In water-dioxane[a]
R'=CH_3-	0.52	0.027	0.009	0.332
R'=CH_3CH_2-	0.56	−0.066	−0.222	0.289
R'=$CH_3CH_2CH_2$-	0.68	−0.104	−0.286	0.229
R'=$(CH_3)_2CH$-	0.76	−0.356	−0.560	0.200

a) The mole fraction of water in the water-dioxane mixture (χ_{H_2O}) used in the experiments was 0.76.

tion efficiency was highest in the reaction of the substrate carrying the largest alkyl group. A similar effect of alkyl goups on the ln r value was also found in the reaction in benzene. These results suggest that enantiomer-differentiation in these solvents is mainly controlled by the size of the substituents. Since nonpolar media reduce polar interactions between reactants, the contribution of polar interactions to a differentiation process will be less in benzene than that in dioxane. Therefore, the low polarity of benzene explains why the effect of the size of the alkyl group on the ln r value was more pronounced in benzene than in dioxane.

In Phase I of a water-dioxane mixture (χ_{H_2O}=0.76), the ln r value was positive in every case. The ln r decreased in the order of the increase in the size of the alkyl group (R'-). However, the effect of the size on ln r was not so remarkable as that in benzene or dioxane. These results suggest that the effect of the size on the differentiation was overlaid with some intermolecular interaction between reagents to make the reagent select the other enantiomer in aqueous media. Thus, the modes of enantiomer-differentiation are quite different in the reactions in aqueous media and in nonaqueous media.

In order to obtain further information about the effects of the water in reaction media on enantiomer-differentiation, the enantiomer-differentiating acylation of racemic 1-phenylpropylamine with (*S*)-phenylbutyric anhydride was carried out in a water-dioxane mixture with various compositions of water. The ln r values are plotted against χ_{H_2O} in the plot (○) in Fig. 1. In Phase I, where the reaction proceeds in a homogeneous solution, ln r linearly increased with the increase in χ_{H_2O} in changing its sign from negative to positive and it reached its maximum at χ_{H_2O}=0.76. In Phase II, ln r sharply decreased with increase in χ_{H_2O}. Thus, no efficient enantiomer-differentiation is attainable by a phase-transfer process of substrates from the aqueous phase to the optically active organic phase. The reaction in Phase I will be discussed here, because we are chiefly concerned with differentiation and molecular interactions between a reagent and a substrate under homogeneous conditions.

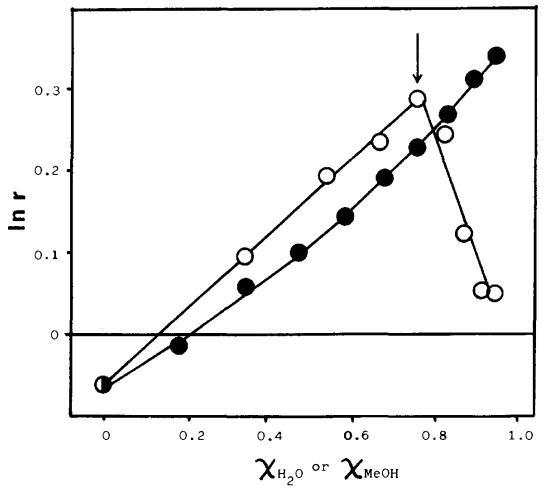

Fig. 1. The relationship between ln r value of the enantiomer-differentiating acylation with (*S*)-2-phenylbutyric anhydride and the mole fraction of water (χ_{H_2O}) or methanol (χ_{MeOH}). The ln r values were determined in the acylation of 1-phenylpropylamine in water-dioxane (○) or methanol-dioxane (●) mixed solvent.

As is shown by the (●) plot in Fig. 1, methanol had a similar effect on ln r to that of water in Phase I: ln r increased with the increase in χ_{MeOH} in changing its sign from negative to positive. Thus, the reaction in protic solvents, such as methanol and water, resulted in large positive ln r values.

The ln r values determined in various organic media are listed in Table 2, together with the solvent polarity parameters. The ln r value was very positive in polar media and almost zero or negative in nonpolar media. The dielectric constant or its related solvent parameters did not explain the increasing order of ln r values: the dielectric constants of DMF and acetonitrile are larger than that of methanol. However, it was in accordance with the increasing order of empirical solvent parameters, $E_T(30)$,[5] including the ln r values in water-dioxane (χ_{H_2O}=0.76, $E_T(30)$=52.4[7]) listed in Table 1. Thus, the remarkable changes in ln r must be a consequence of the elevation in polarity expressed by $E_T(30)$. These results suggest that the quite different molecular interactions from those caused by the bulkiness of hydrocarbon groups became important in the differentiaing process in highly polar reaction media, because bulkiness will not be affected so much by solvent polarity. In addition, water and methanol act as hydrogen-bond donors in the differentiation, since rather higher $E_T(30)$ values are assigned to hydrogen-bonded solvents than to those with high dielectric constants.[6]

Figure 2 shows the ln r *vs.* χ_{H_2O} plots in the enantiomer-differentiating acylation of 1-phenylethylamine in such aqueous media as water-dioxane, water-acetone, water-DMF and water-acetonitrile mixtures. In all cases, the ln r value increased linearly with an increase in χ_{H_2O} in Phase I, while it decreased in Phase II. The

Dioxane	36.0	0.03	−0.07
Benzene	34.5	0.01	−0.22

a) The empirical solvent polarity parameter $E_T(30)$-values are cited from "Solvent Effects in Organic Chemistry," by Christian Reichardt, Verlarg Chemie, New York (1979), pp. 270—272. b) *N*, *N* -Dimethylformamide is abbreviated as DMF. c) 1 cal=4.184 J.

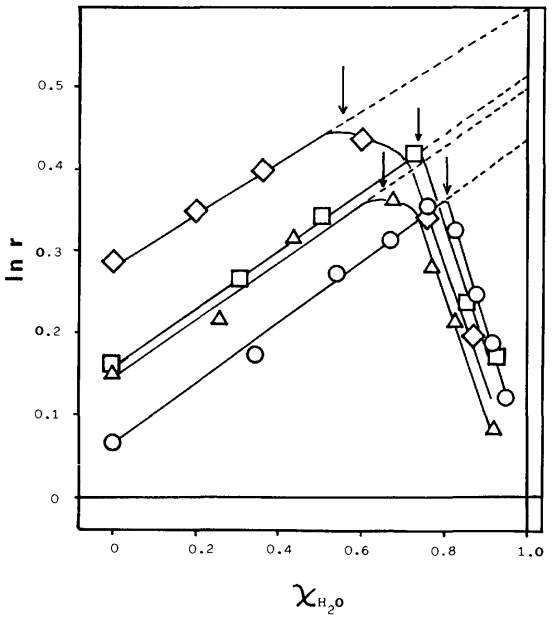

Fig. 2. The relationship between ln r value in enantiomer-differentiating acylation and the mole fraction of water (χ_{H_2O}) in several mixed solvents. (*S*)-2-Phenylbutyric anhydride and 1-phenylethylamine were employed as a reagent and a substrate respectively. The reaction was carried out in water-dioxane (○), water-acetone (△), water-DMF (□), or water-acetonitrile (◇) mixed solvent.

slopes in Phase I were similar with one another. In the water-acetonitrile mixture, the ln r value became as large as 0.44 at a maximum. The estimated ln r values in water obtained by extrapolation were not converged, as may be found in the figure. Without taking into account the solvophobic effect, the large ln r values in protic solvents cannot be explained.

The Role of Hydrocarbon Groups in Enantiomer-differentiating Acylation in Aqueous Media. As has been shown above (Table 1, Figs. 1 and 2), in the acylation of 1-phenylalkylamine derivatives with (*S*)-2-phenylbutyric anhydride the ln r value commonly exhibited a large change with an increase in the water content of the reaction media in Phase I. To ascertain the role of phenyl groups in the differentiation process, the reactions between reactants carrying no phenyl group were compared with those between reactants carrying a phenyl group.

Figure 3 shows the results of the enantiomer-differentiation of 1-phenylethylamine. In the reaction with (*S*)-2-phenylbutyric anhydride (plot (○)), no significant differentiation took place in dioxane (χ_{H_2O}=0), and the ln r value increased linearly with an increase in χ_{H_2O} in Phase I. In Phase II, the ln r value decreased to substantially zero in the very-high-water region. In the case of (*S*)-2-cyclohexylbutyric anhydride (plot (△)), the profile of the plot was the same as that of the (○) plot, though its gradient in Phase I was smaller than that of the (○) plot. In the case of (*S*)-2-ethylhexanoic anhydride (plot (□)), no appreciable differentiation took place in either Phase I or Phase II, even if a slight increase in the ln r value was detectable in Phase I.

Figure 4 shows the results of the enantiomer-differentiation of 1-cyclohexylethylamine and 1-methylbutyl-

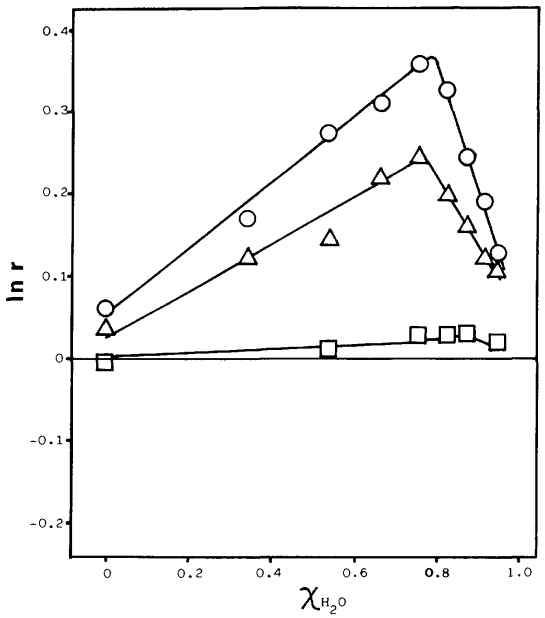

Fig. 3. The relationship between the ln r value in the acylation of racemic 1-phenylethylamine and χ_{H_2O} in water-dioxane mixed solvents. As a reagent, (*S*)-2-phenylbutyric anhydride (○), (*S*)-2-cyclohexylbutyric anhydride (△), and (*S*)-2-ethylhexanoic anhydride (□) were employed.

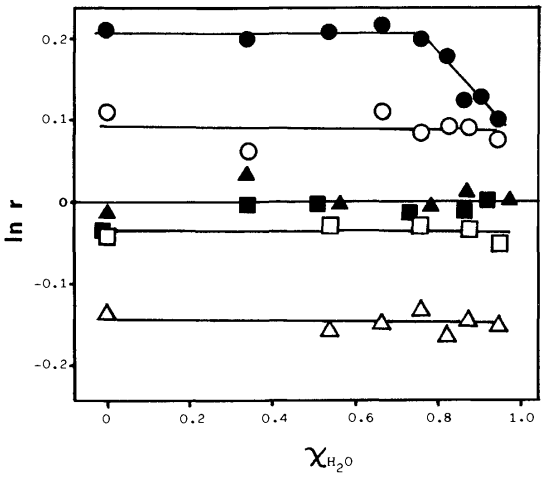

Fig. 4. The relationship between ln r value and χ_{H_2O} in water-dioxane mixed solvent. In the acylation of racemic 1-cyclohexylethylamine, (S)-2-phenylbutyric anhydride (●), (S)-2-cyclohexylbutyric anhydride (▲), and (S)-2-ethylhexanoic anhydride (■) were employes as a reagent. In the acylation of racemic 1-methylbutylamine, (S)-2-phenylbutyric anhydride (○), (S)-2-cyclohexylbutyric anhydride (△), and (S)-2-ethylhexanoic anhydride (□) were employed as a reagent.

amine. In no case, did any efficient differentiation take place, and the ln r value stayed constant in Phase I.

Thus, the large increase in the ln r value in Phase I was specific for the reaction where both reagent and substrate carry a phenyl group (Table 1, Figs. 1 and 3 plot (○)). In the reaction between a reagent and a substrate carrying only saturated hydrocarbon residues (plots (△), (□), (▲), and (■) in Fig. 4), the ln r value did not change at all in either Phase I or Phase II. These facts indicate that the existence of an alkyl-phenyl group in a reagent and the substrate is responsible for the interaction being evident in polar aqueous media. The plot (▲) in Fig. 4 suggests that the geometrical feature of a phenyl group are unimportant for the occurrence of this interaction.

The effect of a phenyl group in reactant molecules on enantiomer-differentiation in Phase I qualitatively parallels that found in the competitive acylation of two amines previously reported.[3] In that earlier report, we showed that the distinction of a phenyl group from alkyl groups easily took place due to the attractive alkyl-phenyl or phenyl-phenyl interaction, but that the distinction of alkyl groups with different chain lengths did not take place in polar aqueous media. The present results can be explained in terms of these attractive interactions. That is, enantiomer-differentiation results from a distinction between alkyl and phenyl groups in substrate molecules by means of alkyl and/or phenyl groups in a reagent molecule on the basis of alkyl-alkyl and alkyl-phenyl interactions and/or alkyl-phenyl and phenyl-phenyl interactions. On the other hand, in reaction between a reagent and a substrate carrying only saturated hydrocarbon groups, the enantiomer-differentiation does not take place, since neither alkyl-phenyl nor phenyl-phenyl interaction can be expected.

In the reaction where a phenyl group and a cyclohexyl group participated (the plot (△) in Fig. 3), the ln r value increased in Phase I, though the gradient of the plot was not large. This must be correlated with the fact that a phenyl group could slightly distinguish a branched alkyl group from an unbranched one.[8]

The results of the present study show that a phenyl group significantly influences the recognition of hydrocarbon groups by means of attractive alkyl-phenyl and/or phenyl-phenyl interactions[3] in aqueous media as well as by means of interaction based on its molecular size.

The attractive alkyl-phenyl and phenyl-phenyl interactions seem unlikely to be hydrophobic interactions between hydrocarbon groups, since no attractive interaction was found between alkyl groups (an alkyl-alkyl interaction). These attractive interactions might be a complex expression of noncovalent interactions induced in polar aqueous media. At this stage, weak solvophobic interaction and electron donor-acceptor interaction including CH···π[9] are probable candidates of the physicochemical entity of these attractive interactions.

In a biochemical field, a special aromatic character was postulated by Némethy[10] to characterize amino acid side chains. It was shown by the study of the structure-activity relationship that the aromatic character and the charge-transfer interactions were remarkably important in the expression of the biological activity of oligopeptides.[11] By the analysis of evolutionary changes in proteins, the relative mutabilities of Tyr or Phe can be said to be rather lower than those of Leu, Ile, and Val.[12] The probability of intermutation between Tyr and Phe was rather high, but probability of the mutation of Tyr or Phe to Leu, Ile, or Val was low.[12] These findings must be explained by the unique character of the phenyl groups that participate in the molecular recognition process through alkyl-phenyl or phenyl-phenyl interaction.

Experimental

Instruments. The ^{1}H-NMR and IR spectra were taken with a JEOL FX-100 spectrometer and a Shimadzu IR 27 G spectrometer respectively. The optical rotation was measured with a Perkin Elmer 241 polarimeter. The analytical GLC was carried out with a Shimadzu GC 6A gas chromatograph equipped with a Shimadzu Chromatopac C-R 1A apparatus, using a 3 m×5 mm o. d. glass column packed with 2% Silicone OV-17 on a Chromosorb W (OV-17) or Silicone OV-101 capillary column, 30 m×0.25 mm or 50 m×0.25 mm, at the stated temperature. The preparative GLC was carried out with a Shimadzu 3A instrument using a 3 m×6 mm o.d. stainless column packed with OV-17.

Materials. All the chemicals except those noted below were obtained from commercial sources and were used without further purification. The pure acetanilide used as an internal standard for the GLC analysis was obtained from Kishida Chemical, Inc., Osaka. Methyl stearate of a GLC analysis grade was obtained from Applied Science Laboratories, Inc., USA. (S)-2-Phenylbutyric acid was obtained by the preferential recrystallization of (R)-1-phenylethylamine salt from water; $[\alpha]_D^{20}$ +96.3° (*c* 10, benzene).[13] (S)-2-Phenylbutyric anhydride was prepared by the published method,[13] $[\alpha]_D^{20}$ +145° (*c* 5, benzene). (S)-2-Cyclohexylbutyric acid was prepared from optically pure (S)-2-phenylbutyric acid by hydrogenation with platinum oxide at a hydrogen pressure of 8.2 kg/cm^2 at 65 °C, $[\alpha]_D^{20}$ −1.32° (*c* 10, MeOH).[14] (S)-2-Cyclohexylbutyric anhydride was

a) Cyclohexyl and phenyl groups are denoted by cC_6H_{11} and C_6H_5 respectively. b) GLC analytical conditions are indicated by A, B, C, *etc.* A: A 3-m Silicone OV-17 column was used. The column temperature was elevated from 150°C to 250°C by 10°C/min. Methyl stearate was used as the internal standard. B: A Silicone OV-101 capillary column, 30 m×0.25 mm, was used. The column temperature was 240°C. Acetanilide was used as the internal standard. C: A Silicone OV-101 capillary column, 30 m×0.25 mm, was used. The column temperature was 170°C. Acetanilide was used as the internal standard. D: A Silicone OV-101 capillary column, 30 m×0.25 mm, was used. The column temperature was 220°C. Acetanilide was used as the internal standard. E: A Silicone OV-101 capillary column, 50 m×0.25 mm, was used. The column temperature was 175°C. Acetanilide was used as the internal standard. F: A Silicone OV-101 capillary column, 50 m×0.25 mm, was used. The column temperature was 170°C. Acetanilide was used as the internal standard.

prepared by the published method.[13] (*S*)-2-Ethylhexanoic acid was obtained by the recrystallization of (*R*)-1-phenylethylamine salt from acetonitrile, $[\alpha]_D^{20}$ +8.20° (neat).[15] (*S*)-2-Ethylhexanoic anhydride was prepared by the published method.[13] 1-Phenylpropylamine, 1-phenylbutylamine, and 1-phenyl-2-methylpropylamine were prepared from the appropriate oximes, which had themselves been prepared from propiophenone, butyrophenone, and isobutyrophenone respectively by hydrogenation with a Raney nickel catalyst in acetic anhydride at a hydrogen pressure of 90 kg cm^{-2} at 60°C and by succesive hydrolysis with 6 M HCl (1 M=1 mol dm^{-3}). The NMR and IR spectra were consistent with the desired structure; their boiling points were 98°C/20 mmHg (1 mmHg≈133.322 pa) (lit, 99—100°C/16 mmHg), 101—102°C/10 mmHg (lit, 107—109°C/16 mmHg), and 103—107°C/21 mmHg (lit, 214°C/760 mmHg) respectively. 1-Cyclohexylethylamine was prepared from *N*-acetyl-1-phenylethylamine by hydrogenation with platinum oxide in acetic acid at a hydrogen pressure of 8.2 kg cm^{-2} at 60°C and by successive hydrolysis with 6 M HCl. (*R*)-1-Cyclohexylethylamine was prepared from commercially available (*R*)-1-phenylethylamine; $[\alpha]_D^{20}$ +2.88° (*c* 5, MeOH).[16] (*R*)-1-Methylbutylamine was obtained by the preferential recrystallization of (+)-camphor-10-sulfonic acid salt from water; $[\alpha]_D^{20}$ −7.95° (*c* 5, MeOH).[17] The NMR spectra are consistent with the desired structures. The authentic samples of various amides for GLC analysis were prepared from an appropriate acid chloride and amine by a conventional method; they were then purified by preparative GLC. The NMR, IR spectra, and results of elemental analysis of each sample were consistent with the desired structures.

Reaction Procedure of Enantiomer-differentiating Acylation. In a flask, a 100-μl portion of a racemic mixture of a chiral amine (2 M dioxane solution) was dissolved in 3.8 ml of a reaction medium. To the resulting amine solution, a 100-μl portion of an optically active acid anhydride solution (0.5 M dioxane solution) was added all at once under vigorous stirring at room temperature; the mixture was then allowed to stand for 1 h. After a 100-μl portion of the internal standard (0.25 M dioxane solution), which will be specified in the following section, had been added for GLC analysis, the volume of the reaction mixture was made up to 5 ml with dioxane. GLC was used for the quantitative analysis of the products of the sample solution.

Assignment of Diastereomeric Reaction Products in GLC Analysis. The reaction shown in Eq. 1 affords two diastereomeric amides, *i.e.* the (*S,S*)-isomer and the (*R,S*)-isomer. These reaction products can be detected as two distinct peaks on a gas chromatogram. The amount of the products were determined by quantitative GLC using an internal-standard method. The analytical conditions and the retention times of the reaction products are listed in Table 3.

As far as the substrates and reagents employed in this study were concerned, the GLC peak with a shorter reten-

tion time was assigned to the (*S,S*)-isomer, while the peak with a longer retention time was assigned to the (*R,S*)-isomer, in the following manner.

In the acylation of racemic 1-phenylethylamine with (*S*)-2-phenylbutyric anhydride, the reaction product with a shorter retention time was identified with the authentic *N*-[(*S*)-1-phenylethyl]-(*S*)-2-phenylbutyramide, which had been prepared from (*S*)-2-phenylbutyric anhydride and (*S*)-1-phenylethylamine by GLC. Therefore, the reaction product with a longer retention time was identified as the (*R,S*)-isomer.

In the acylation of racemic 1-phenylpropylamine with (*S*)-2-phenylbutyric anhydride, the product with a longer retention time was identified as the (*R,S*)-isomer by a kinetic resolution of the amine. When an excess of racemic 1-phenylpropylamine was treated with (*S*)-2-phenylbutyric anhydride in benzene, the reaction product with a longer retention time was produced in excess. Moreover, the unreacted amine recovered showed a levorotatory power. Since (*S*)-1-phenylpropylamine is levorotatory,[17] the reaction product with a longer retention time was identified as the (*R,S*)-isomer.

The configurations of 1-phenylbutylamine and 1-phenyl-2-methylpropylamine have not yet been determined. Therefore, it is not possible to assign the configuration of the reaction products on the GLC. However, the results of the kinetic resolutions of both amines were the same as in the case of 1-phenylpropylamine. That is, the isomeric product with a longer retention time was obtained in excess, while levorotatory unreacted amine was recovered in either case. Since the levorotatory amine has the *S* configuration in other homologues, *i.e.*, 1-phenylethylamine and 1-phenylpropylamine, the configuration of (−)-1-phenylbutylamine and (−)-1-phenyl-2-methylpropoylamine was assumed to be also *S*. Thus, the product amide isomer with a shorter retention time in the GLC was identified as the (*S, S*)-isomer, and the other, is the (*R, S*)-isomer.

In all other cases, authentic (*R, S*)-isomers were prepared from the corresponding amine and acid anhydride. The diastereomeric products with longer retention times were identified with the authentic (*R, S*)-isomer.

Solubility of Acid Anhydride in Aqueous Media. The fraction of the acylating reagent dissolved in the water-dioxane mixture was determined by quenching it with a large excess of butylamine as follows: A 100-μl portion of (*S*)-2-phenylbutyric anhydride (0.5 M dioxane solution) was added to the solvent (0.9 ml), and the mixture was stirred vigorously. The resulting mixture was centrifuged at 2000 min^{-1} for 20 min to separate the undissolved portion of the anhydride from the solvent phase. A 50-μl portion of butylamine (2 M dioxane solution) was added to the 100-μl portion of the supernatant obtained under a vigorous stirring, after which the mixture was allowed to stand for 1 h to complete the reaction. By the quantitative GLC analysis of *N*-butylamide, the solubility of 2-phenylbutyric anhydride in aqueous media was estimated.

We wish to thank Professor Yoshiharu Izumi, Dr. Hiroshi Ozaki, and Dr. Tadao Harada of Osaka University for their helpful suggestions. Our thanks are also due to Mr. Motomasa Imaida, Mrs. Mihoko Yamamoto, and Miss Masako Yamashita for their technical assistance in preparing optically active compounds and in the GLC analyses.

Kinetics of the Ligand Exchange Reaction between Tetrakis(acetylacetonato)-thorium(IV) and Free Acetylacetone in CD_3CN and $CDCl_3$

Naoshi FUJIWARA, Hiroshi TOMIYASU, and Hiroshi FUKUTOMI*

Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, O-kayama, Meguro-ku, Tokyo 152

(Received November 14, 1983)

Kinetics of the ligand exchange reaction between tetrakis(acetylacetonato)thorium(IV) and free acetylacetone in CD_3CN and $CDCl_3$ was studied by ^1H NMR. The rate law was written as rate=k[Th(acac)$_4$][Hacac]$_{enol}$, where k=(1.0±0.1)×10^2 s^{-1} mol^{-1} kg at 0 °C in CD_3CN and (1.7±0.1)×10^2 s^{-1} mol^{-1} kg at −16 °C in $CDCl_3$. The rates were retarded by addition of bases and the retardation effect well correlated with the donor number of the bases. Under the conditions studied, the activation entropies gave large negative values. A ligand exchange mechanism passing through a nine-coordinate intermediate is proposed to interpret the kinetic law.

Thorium(IV) is one of the largest metal ions in size and gives complexes with high coordination numbers. Eight-coordination is usually common and even the existence of nine- and ten-coordinate complexes were reported.[1-6] Tetrakis(2,4-pentanedionato)thorium(IV), where hereafter the common name of the ligand, *i.e.* acetylacetonate (acac) will be used, has been known as one of the typical eight-coordinate complexes having a square antiprismatic structure. The same structure is established in such acac complexes as Zr(acac)$_4$, Hf(acac)$_4$, and U(acac)$_4$.[1]

Little has been known with respect to the kinetics of the ligand substitution in eight-coordinate complexes. Adams and Larsen[7] studied the ligand exchange in Zr(acac)$_4$ and Hf(acac)$_4$ and proposed the mechanism passing through a seven-coordinate intermediate which was formed by the partial breaking of one of the chelate rings. They also studied the ligand exchange in Th(acac)$_4$ but reported that the rate was too fast to be measured by ^1H NMR. On the other hand, the mechanism involving a nine-coordinate intermediate was proposed by Folcher *et al.*[8] in the ligand exchange of U(fod)$_4$ (fod=6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedionate).

In an earlier study,[9] it was found that the rate of the ligand exchange between Th(acac)$_4$ and Hacac was measurable in chloroform by ^1H NMR. In this paper, we report in detail the kinetic results of the acac exchange in Th(acac)$_4$ and propose a possible mechanism proceeding *via* a nine-coordinate intermediate.

Experimental

Materials. Th(acac)$_4$ was synthesized by the following procedure. The solution containing 0.01 mol of thorium nitrate was stirred with 5 g of acetylacetone; then aqueous ammonia was added slowly until the pH of the solution became 5. White precipitate obtained was dried *in vacuo* for 1 d. Recrystallization of the precipitate was carried out twice first from benzene and then Hacac. Found: C, 38.0; H, 4.3%, Calcd for $C_{20}H_{28}O_8Th$: C, 38.2; H, 4.5%.

Acetylacetone was dried over anhydrous calcium sulfate and distilled twice. Acetonitrile, dichloromethane, tetrahydrofuran (THF) and chloroform-*d* ($CDCl_3$) were distilled, and dimethyl sulfoxide (DMSO), *N,N*-dimethylformamide (DMF) and hexamethylphosphoric triamide (HMPT) were distilled under reduced pressure before use. Acetonitrile-d_3 (CD_3CN) was dried over Molecular Sieve 4A.

Water contents in CD_3CN and $CDCl_3$ were determined by the Karl-Fischer method.

Measurements of UV and ^1H NMR Spectra. The UV spectra of Th(acac)$_4$, Hacac and their mixture were measured by using a Shimadzu 210A spectrophotometer with a 0.1 mm quartz cell. A JEOL JNM-FX100 FT-NMR spectrometer equipped with a JNM-VT-3B temperature controller was used for ^1H NMR measurements. The preparation of NMR samples was carried out by dissolving a small amount of sample materials, which were weighed in 5 mmϕ NMR tubes with a microbalance, in appropriate solvents.

Determination of the Fraction of Keto- and Enol-forms in Hacac. Two forms, keto and enol, of Hacac are in tautomeric equilibrium and the concentration ratio, [enol]/[keto], was determined by area measurements of methyl proton signals for keto- and enol-isomers. In order to obtain the temperature dependence of the ratio, the area measurements were performed in the temperature range from −20 to 36 °C.

Rate Analysis. The first-order rate constants of the acac exchange in Th(acac)$_4$, k_{obsd}, were determined from the line shape analysis of the NMR signals by using the two site model.[10]

Results

The absorption spectrum of Th(acac)$_4$ shows a peak at 283 nm with molar extinction coefficients, ε, of 4.9×10^4 M^{-1} cm^{-1} (1 M=1 mol dm^{-3}) in acetonitrile and 4.8×10^4 M^{-1} cm^{-1} in dichloromethane. The spectra of the mixture containing Th(acac)$_4$ and Hacac coincided with the sum of those of each component in acetonitrile and dichloromethane, and remained unchanged for several hours.

The ^1H NMR spectra of the reaction mixture in CD_3CN are shown in Fig. 1. Three methyl proton

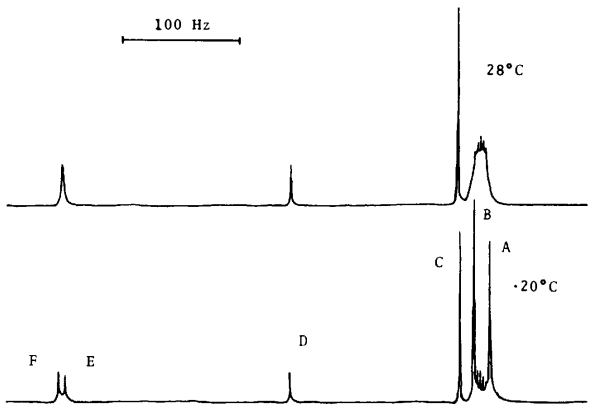

Fig. 1. ^1H NMR spectra of the reaction mixture in CD_3CN at −20 °C and 28 °C. [Th(acac)$_4$]=0.0707 mol kg^{-1} and [Hacac]$_{total}$=0.444 mol kg^{-1}.

signals and two methine proton signals were clearly observed at −20 °C. Two methyl proton signals of $Th(acac)_4$ (A) and Hacac in the enol-form (B) coalesced as the temperature was raised. Similar behavior was observed in methine proton signals of $Th(acac)_4$ (E) and Hacac in the enol-form (F). No line broadening was observed for the methyl proton signal (C) and methylene proton signal (D) of Hacac in the keto-form. Since signals A and B overlapped with the methyl proton signals of the solvent used, the rate analyses were carried out by using signals E and F.

The change of ^1H NMR signals in CD_3CN at various temperatures was very similar to that in $CDCl_3$ in the earlier work.[9] The ligand exchange reaction between $Th(acac)_4$ and Hacac in the enol-form can be described as follows.

$$Th(acac)_4 + Hacac^*_{enol} \rightleftharpoons Th(acac)_3(acac^*) + Hacac_{enol}, \quad (1)$$

where the asterisk denotes the exchanging species.

The life time of acac in the coordination site, τ_c, correlates directly with the first-order rate constant by the following equation.

$$k_{obsd} = 4\tau_c^{-1} \quad (2)$$

Plots of k_{obsd} *vs.* the concentration of $Th(acac)_4$ indicate that the values of k_{obsd} are independent of $[Th(acac)_4]$ (Fig. 2). On the other hand, plots of k_{obsd} *vs.* the concentration of Hacac in the enol-form, $[Hacac]_{enol}$, in CD_3CN and $CDCl_3$ show that the plots are linear passing through the origin (Figs. 3 and 4). These results lead to the following rate equation.

$$Rate = k_{obsd}[Th(acac)_4] = k[Th(acac)_4][Hacac]_{enol}, \quad (3)$$

where k is the second-order rate constant. The values of k and activation parameters are listed in Tables 1 and 2. These results indicate that the exchange rate is influenced by solvents, *i.e.* the rate in $CDCl_3$ is faster than that in CD_3CN. This is mainly due to the difference in activation entropy, ΔS^*, rather than the difference in activation enthalpy, ΔH^*.

Influence of the Addition of Bases. The kinetic parameters of the acac exchange in $Th(acac)_4$ were obtained also in the presence of various bases. The results are listed in Table 3. The addition of the bases retarded the exchange rate and this effect is remarkable in the case of strong bases. The order of the retardation effect is found to be as follows;

$$\underset{(38.8)}{HMPT} > \underset{(29.8)}{DMSO} > \underset{(26.6)}{DMF} > \underset{(20.0)}{THF}, \quad \underset{(18.0)}{H_2O}.$$

It is to be noted that this is the order of Gutmann's

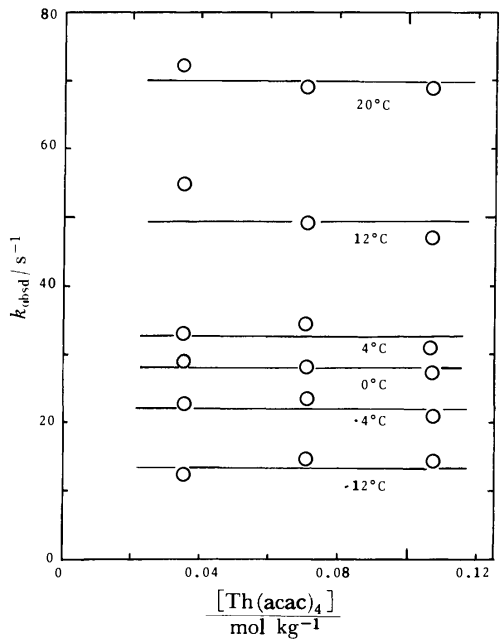

Fig. 2. Dependence of k_{obsd} on $[Th(acac)_4]$ in CD_3CN at various temperatures.

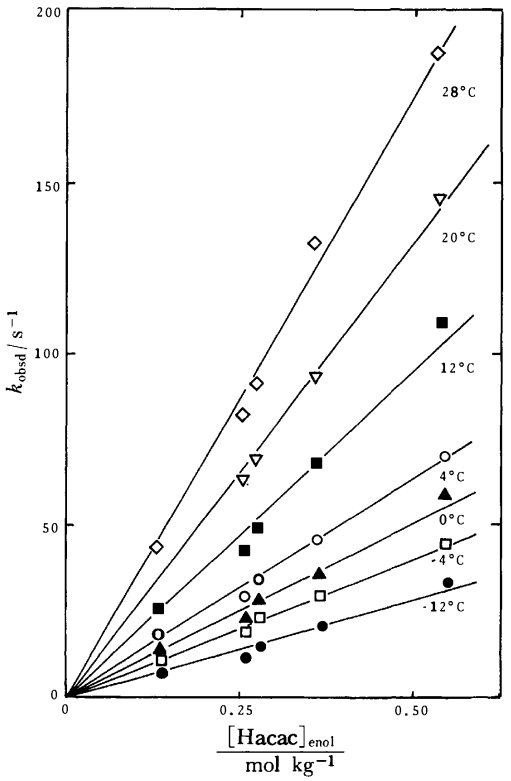

Fig. 3. Plots of k_{obsd} *vs.* $[Hacac]_{enol}$ in CD_3CN at various temperatures.

0.0812	0.275	0.272	0.672	21.2	31.8

The water content in the solvent ($CDCl_3$) is 0.008 mol kg^{-1}.

k^{-1}_{obsd} can be expressed by the following equation.

$$k^{-1}_{obsd} = a + b[H_2O \text{ or DMSO}], \quad (4)$$

where a and b are constants. The intercepts of these plots agree well with the values of k^{-1}_{obsd} in the absence of bases.

Discussion

It is generally considered that the ligand exchange processes in (acetylacetonato)metal complexes consist of several steps. Two types of initiation mechanism are presented for the acac exchange reactions: 1) bond breaking of one end of the chelate bond; 2) bond formation with free Hacac at the additional coordination site without a ring opening of the chelate.

Type (1) has been proposed for the acac exchanges in $Al(acac)_3$,[12] $Co(acac)_3$,[13] and type (2) has been proposed for those in $Cr(acac)_3$, $Rh(acac)_3$, $V(acac)_3$ and $Fe(acac)_3$.[13] In the case of the acac exchange in $Al(acac)_3$, a complete dissociation of one of the coordinated acac occurs prior to an attack of entering Hacac to the complex. For most of the other acac exchange reactions which belong to type (1) or type (2), a proton transfer from incoming Hacac to coordinated acac is involved in the acac exchange processes.

The ionic radius of Th^{4+} is large enough to make nine- or ten-coordinate complexes, *e.g.* $Th(tta)_4topo$ and $Th(tta)_4tbp$, where tta, topo and tbp are 2-thenoyltrifluoroacetonate, trioctylphosphine oxide and tributyl phosphate, respectively.[3] This fact suggests that type (2) seems to be probable for the acac exchange in $Th(acac)_4$.

As shown in Fig. 7, $Th(acac)_4$ (I) forms a nine-coordinate intermediate, $Th(acac)_4Hacac^*$ (II), by the attack of free acetylacetone, and the proton of entering Hacac* is transferred to one of the coordinated acac, followed by the Th-O bond breaking of the chelate ring. Then the protonated ligand (Hacac) leaves rapidly from the coordination sphere.

Since the rate of ligand exchange of unidentate ligands is generally much faster than that of bidentate ligands in the complexes of the same metal ion [10,14] it can be assumed that complexes (I) and (II) are in fast

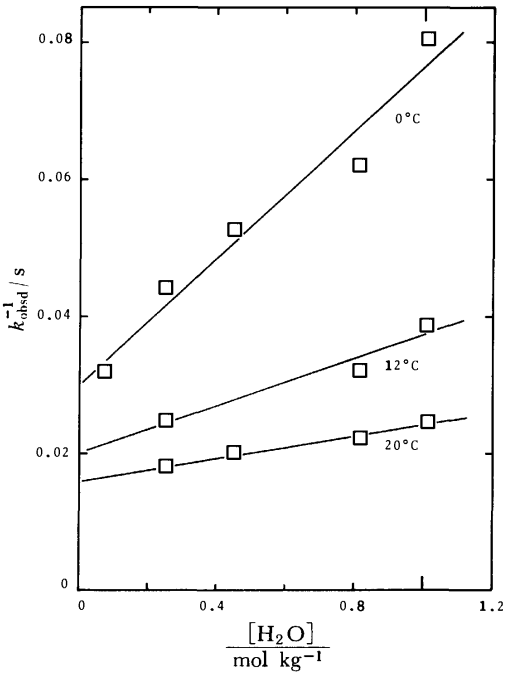

Fig. 5. Plots of k^{-1}_{obsd} against $[H_2O]$ in CD_3CN at various temperatures.

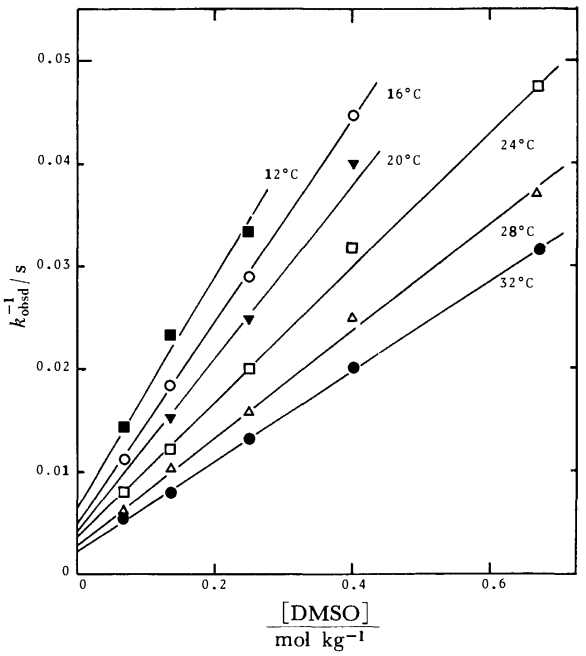

Fig. 6. Plots of k^{-1}_{obsd} against [DMSO] in $CDCl_3$ at various temperatures.

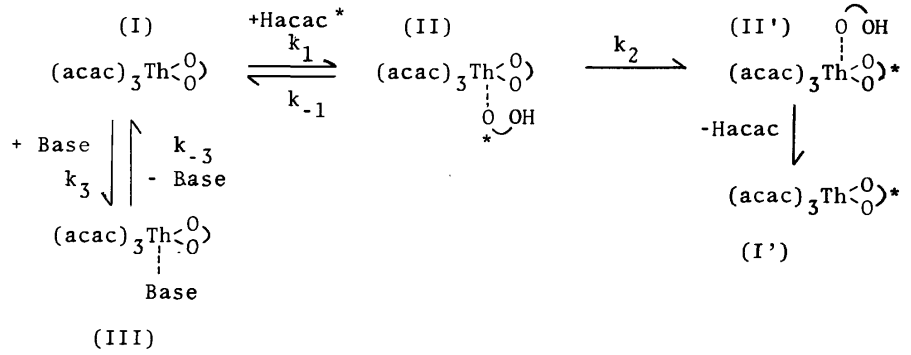

Fig. 7. Possible mechanism of the ligand exchange in $Th(acac)_4$. HOO represents Hacac in the enol-form.

equilibrium. Based on this assumption, the rate of exchange is expressed by Eq. (5).

$$\text{Rate} = \frac{k_1 k_2}{k_{-1}}[\text{I}][\text{Hacac}]_{\text{enol}} \quad (5)$$

If $[\text{I}] \gg [\text{II}]$ or $K_1[\text{Hacac}]_{\text{enol}} \ll 1$, where $K_1 = k_1/k_{-1}$, the first-order rate constant for the exchange of acac, k_{ex}, can be written by Eq. (6).

$$k_{\text{ex}} = k_2 K_1 [\text{Hacac}]_{\text{enol}} \quad (6)$$

Equation (6) is basically the same as Eq. (3), where k corresponds to k_2K_1 in the absence of water. The k_2 pathway involves two processes, *i.e.* the proton transfer from entering Hacac* to coordinated acac and the Th-O bond breaking in the chelate ring. It appears difficult to determine which process is the rate determining step from the above results.

In the case of tris(acetylacetonato) complexes,[12,13] it was often observed that the ligand exchange was accelerated in the presence of water. However, the retardation by the addition of bases including water was observed for the acac exchange in $Th(acac)_4$ as described above. A good correlation between $\ln k$ and DN as shown in Fig. 8 suggests that the donicity of bases might be important for the retardation effect. Strong donor bases may bind to $Th(acac)_4$ tightly forming adduct complex (III) and hence hinder the formation of (II).

On the assumption that complex (III) is in fast equilibrium with (I) and that the concentration of (II) is much low compared with that of (I) or (III), k_{ex} in the presence of bases is written by Eq. (7).

$$k_{\text{ex}} = \frac{k_2 K_1 [\text{Hacac}]_{\text{enol}}}{1 + K_3[\text{Base}]}, \quad (7)$$

or by Eq. (8).

$$k_{\text{ex}}^{-1} = \frac{1}{k_2 K_1 [\text{Hacac}]_{\text{enol}}} + \frac{K_3[\text{Base}]}{k_2 K_1 [\text{Hacac}]_{\text{enol}}}, \quad (8)$$

where $K_3 = k_3/k_{-3}$. Hence, when the concentration of Hacac is kept constant, the plots of k_{ex}^{-1} *vs.* [Base] should give a straight line. This relationship is the same as Eq. 4 which was determined experimentally.

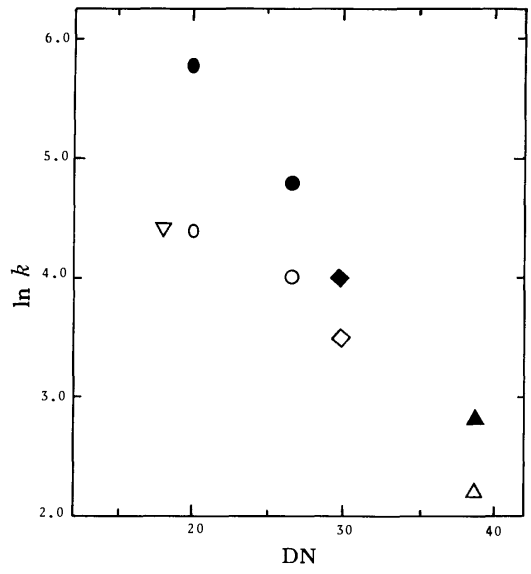

Fig. 8. Relationship between $\ln k$ and the donor number (DN) at 0°C. ▽: H_2O, ○: THF, ○: DMF, ◇: DMSO, △: HMPT in CD_3CN, and ●: THF, ●: DMF, ◆: DMSO, ▲: HMPT in $CDCl_3$.

Thus, the proposed mechanism can explain well the experimental results. The large negative values of activation entropies shown in Table 3 might support the formation of nine-coordinate intermediate.

Nishizawa and Saito[14] studied the kinetics of acac exchange in $VO(acac)_2$ and found that the reaction was retarded by the addition of DMSO. They proposed that the retardation effect was attributed to the formation of an outer-sphere intermediate with DMSO, which prohibits an associative attack by free Hacac. Unlike their interpretation in $VO(acac)_2$, the retardation by bases in the present study arises from the competition between bases and Hacac in the enol-form at the ninth coordination site. From the slopes and intercept in Figs. 5 and 6, the formation constant of the nine-coordinate adduct complex (III) was determined to be *ca.* 0.9 $\text{mol}^{-1}\,\text{kg}$ at 12°C for $Th(acac)_4H_2O$ in CD_3CN, and *ca.* 20 $\text{mol}^{-1}\,\text{kg}$ at 32°C for $Th(acac)_4$dmso in $CDCl_3$. These values indicate that the presence of such strong bases as DMSO and HMPT in solution leads to the adduct formation with bases.

In this study, it was found that $Th(acac)_4$ was the most labile of acetylacetonato complexes of quadrivalent metal ions. The order of the lability for the ligand exchange reaction is as follows:[7,15,16]

$$\text{Th(acac)}_4 \geq \text{U(acac)}_4 > \text{Zr(acac)}_4 \simeq \text{Hf(acac)}_4 > \text{Ti(acac)}_3^{+}.$$

As the ionic size of Th^{4+} is much larger than the ionic radii of Zr^{4+} and Hf^{4+}, and the electronic configuration of Th^{4+} is $5f^0$ and $6d^0$, the electric repulsion between electrons of donor molecule and Th^{4+} might be weak. These facts also support the proposed mechanism in which the reaction proceeds through the nine-coordinate intermediate for the ligand exchange reaction between $Th(acac)_4$ and Hacac.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 57470035 from the Ministry of Education, Science and Culture.

Formation Process of Niobium Nitride by the Reaction of Niobium Pentachloride with Ammonia in the Vapor Phase and Properties of the Niobium Nitride Formed

Akimasa YAJIMA, Takashi ARAI, Ryoko MATSUZAKI, and Yuzo SAEKI*
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227
(Received January 25, 1984)

The reaction products of gaseous $NbCl_5$ with ammonia were $NbCl_5 \cdot 5NH_3$ at 200 °C, $NbCl_5 \cdot 5NH_3$, Nb_4N_5, and NH_4Cl at 250—500 °C, Nb_4N_5 and NH_4Cl at 550—950 °C, δ-NbN and NH_4Cl at 1000 °C, δ-NbN, Nb_2N, NH_4Cl, and HCl at 1100 °C, and δ-NbN, Nb_2N, Nb_4N_3, δ′-NbN, ε-NbN, NH_4Cl, and HCl at 1200—1300 °C. In the vapor-phase reaction of gaseous $NbCl_5$ with ammonia, the reaction of gaseous $NbCl_5$ with ammonia to form $NbCl_5 \cdot 5NH_3$ occurs first. Above *ca.* 235 °C, the $NbCl_5 \cdot 5NH_3$ reacts with ammonia to form Nb_4N_5. Above *ca.* 1000 °C, the Nb_4N_5 decomposes to δ-NbN. Above about 1100 °C, in addition to these reactions, the nitriding of niobium, formed by the reduction of gaseous $NbCl_5$ with the hydrogen resulting from the thermal dissociation of ammonia, also occurs to form Nb_2N at 1100 °C and Nb_2N, Nb_4N_3, δ′-NbN, and ε-NbN at 1200—1300 °C. When the Nb_4N_5, formed by the vapor-phase reaction, is heated in an argon atmosphere, it changes to δ-NbN at *ca.* 1000 °C, to δ-NbN and ε-NbN at 1100—1200 °C, and then to Nb_4N_3 and δ-NbN at 1300 °C. The niobium nitrides formed above 1200 °C are uniform, ultrafine powders with particle diameters of the order of 1/100 μm.

The vapor-phase reaction of transition-metal chlorides with ammonia has recently become important for the preparation of fine powders or thin films of transition-metal nitrides, which are aquiring importance as new industrial materials. However, no information has been available on the reaction process of transition-metal chloride with ammonia in the vapor phase. The present authors have previously reported the formation processes of some nitrides of transition metals of Groups IV and V by the reaction of the chloride with ammonia.[1,2]

Concerning the vapor-phase reaction of niobium pentachloride ($NbCl_5$) with ammonia, little information has been available apart from the work of Gavrilko and Kornilov.[3] They reported the preparation of fine niobium nitride powders by a vapor-phase reaction of the $NbCl_5$-NH_3-N_2 system at 5300—9200 K, with emphasis on the effect of the reaction temperature on the specific surface area and the particle size.

In this paper, the reaction products of gaseous $NbCl_5$ with ammonia at 200—1300 °C were examined in detail. The possible reactions which were considered to occur during the reaction process on the basis of the above experiments were examined. Further, the thermal stability of the niobium nitride formed was examined. The niobium nitride formed was also examined by electron microscopy.

Experimental

Materials. The $NbCl_5$ used was prepared by the reaction of niobium powder (Nb 99.8%, Hermann C. Starck Berlin) with chlorine at 300 °C.[4] Found: Nb, 34.3; Cl, 65.6%. Calcd for $NbCl_5$: Nb, 34.39; Cl, 65.61%. Ammonia was dried by passing it over sodium hydroxide granules and barium oxide powders.

Experimental Procedures. A transparent quartz or alumina reaction tube (1000 mm length) was used for examining the reaction products of gaseous $NbCl_5$ with ammonia. Gaseous $NbCl_5$ was formed by heating solid $NbCl_5$ (12 g) at 190 °C and was carried by a stream of argon (50 cm^3/min) into the reaction zone (28 mm i.d., 250 mm length), held at a specified temperature. The $NbCl_5$ inlet tube consisted of two concentric tubes. Gaseous $NbCl_5$ carried by argon was introduced through the inner tube, and the outer tube was utilized for introducing argon (50 cm^3/min) as a sheath gas to prevent the formation of product deposits in the chloride inlet tube. Ammonia was simultaneously introduced at a flow-rate of 100 cm^3/min into the reaction zone through a separate tube. The mean flow-rate of gaseous $NbCl_5$ was 6.0 cm^3/min. A quartz or alumina tube was inserted into the reaction tube to make the removal of the reaction product easier. The reaction was allowed to proceed for 2 h.

The by-product, ammonium chloride (NH_4Cl), which was deposited outside the reaction zone, together with the niobium nitride formed, was separated by heating the mixture in an argon stream at 400 °C for 10—15 h.

Analytical. The chemical analysis of the reaction product was performed as follows. The niobium content of the $NbCl_5$-NH_3 adduct was gravimetrically determined as Nb_2O_5 after hydrolyzing the sample in 3 M†-nitric acid. The chlorine and ammonia contents were determined by the gravimetric method as AgCl and by the Kjeldahl method, respectively, from the filtrate. In the case of a mixture of the adduct and niobium nitride, the niobium and chlorine contents were gravimetrically determined after the fusion of the sample with sodium carbonate. The NH_3 content was determined by the Kjeldahl method from the filtrate after hydrolyzing the sample in 3 M-nitric acid.

The X-ray analysis of the solid product was performed with an X-ray powder diffractometer equipped with a proportional counter and using Ni filtered Cu radiation. The sample chamber of the diffractometer was maintained under a dry nitrogen atmosphere, if necessary, to prevent any contamination of the sample by atmospheric moisture during the irradiation.

The sensitivity of the quartz helix used for thermogravimetry (TG) was approximately 113 mm/g. The sample (0.2 g) was heated at a rate of 2.5 °C/min, and the flow-rate of ammonia was maintained at 50 cm^3/min.

Throughout this work, the $NbCl_5$ and the reaction products were handled in an argon atmosphere to prevent any contamination by atmospheric moisture.

Results and Discussion

Reaction Products of Gaseous Niobium Pentachloride with Ammonia. The products formed by heating

† 1 M=1 mol dm^{-3}.

gaseous $NbCl_5$ in an ammonia stream at various temperatures were examined by both X-ray analysis[5-11] and chemical analysis. Reaction temperatures above 200 °C were employed, because gaseous $NbCl_5$ was generated at 190 °C.

The product formed at 200 °C showed no clear X-ray diffraction pattern. Found: Nb, 26.1; Cl, 49.8; NH_3, 24.0%. The ratio of Nb:Cl:NH_3 was calculated to be 1:5.00:5.02. This was considered to indicate that the product formed at 200 °C had a composition of $NbCl_5 \cdot 5NH_3$ (calcd for $NbCl_5 \cdot 5NH_3$:Nb, 26.15; Cl, 49.89; NH_3, 23.96%). The reaction products at various temperatures above 200 °C are shown in Table 1. Unreacted $NbCl_5$ was not observed throughout the temperature range of this work.

At 550—1000 °C, all the products were obtained outside the reaction zone. Above 1100 °C, in addition to the δ-NbN formed outside the reaction zone, Nb_2N was formed inside the reaction zone at 1100 °C, while Nb_2N, Nb_4N_3, δ'-NbN, ε-NbN, were formed both inside and outside the reaction zone at 1200—1300 °C. The products formed below 1000 °C and the products formed outside the reaction zone above 1100 °C were in the form of powder, while the products formed inside the reaction zone at 1100—1300 °C were in the form of film. The mole percentage of $NbCl_5$ converted to the nitrides formed inside the reaction zone was 16% at 1100 °C, 21% at 1200 °C, and 44% at 1300 °C. Also, it was observed that HCl was formed in addition to NH_4Cl above 1100 °C.

The presence of the following niobium nitrides has been reported: Nb_2N (hexagonal, a_0=3.055 Å, c_0=4.994 Å;[6] N/Nb 0.40—0.50[12]), Nb_4N_3 (tetragonal, a_0=4.382 Å, c_0=4.316 Å;[7] N/Nb 0.75—0.79[12]), δ-NbN (cubic, a_0=4.376—4.392 Å; N/Nb 0.86—1.06[10]), δ'-NbN (hexagonal, a_0=2.967 Å, c_0=5.538 Å;[5] metastable phase[13]), ε-NbN (hexagonal, a_0=2.960 Å, c_0=11.270 Å;[8] N/Nb 1.000—1.018[12]), Nb_4N_5 (tetragonal, a_0=6.873 Å, c_0=4.298 Å),[5] and Nb_5N_6 (hexagonal, a_0=5.193 Å, c_0=10.380 Å).[5] It was found that all the above nitrides except Nb_5N_6 were formed by the reaction of gaseous $NbCl_5$ with ammonia.

Reaction Process of Gaseous Niobium Pentachloride with Ammonia. To elucidate the reaction process of gaseous $NbCl_5$ with ammonia, the behavior of the $NbCl_5 \cdot 5NH_3$ and the Nb_4N_5, which had been formed during the reaction process, on heating in an ammonia stream were examined.

Behavior of $NbCl_5 \cdot 5NH_3$ on Heating in an Ammonia Stream: The TG curve of $NbCl_5 \cdot 5NH_3$ in an ammonia stream showed that the sample weight decreased continuously above about 235 °C and reached a constant value at about 460 °C. The sample after the heating to 500 °C was found by X-ray analysis to be Nb_4N_5.

In order to obtain more detailed information on the behavior of $NbCl_5 \cdot 5NH_3$ on heating in an ammonia stream, $NbCl_5 \cdot 5NH_3$ (1.0 g) in a quartz boat (70 mm length, 15 mm width, 7 mm depth) was placed in a straight reaction tube (28 mm i.d., 1000 mm length). Ammonia was introduced into the reaction tube at a flow-rate of 100 cm^3/min. The sample part was then placed in the centre of an electric furnace (300 mm heating length) maintained at a specified temperature for 1 h. The products obtained both inside and outside the boat were examined by X-ray analysis and chemical analysis. The results are shown in Table 2.

The results showed that $NbCl_5 \cdot 5NH_3$ reacted with ammonia to form Nb_4N_5 and NH_4Cl above about 235 °C and that a small part of the $NbCl_5 \cdot 5NH_3$ vaporized above about 350 °C. The formation of a small amount of Nb_4N_5 above 400 °C outside the boat was considered to indicate that the reaction of gaseous $NbCl_5 \cdot 5NH_3$ with ammonia to form Nb_4N_5 also occurred above about 400 °C.

Behavior of Nb_4N_5 on Heating in an Ammonia Stream: The samples obtained by heating Nb_4N_5 (0.1 g) in an ammonia stream (100 cm^3/min) at various temperatures of 900—1300 °C for 2 h were examined by X-ray analysis.[5,8,9] The Nb_4N_5 used was prepared by the reaction of gaseous $NbCl_5$ with ammonia at 900 °C, based on the experimental results shown in Table 1. The results are shown in Table 3. The results indicated that, on heating Nb_4N_5 in an ammonia stream above 1000 °C, Nb_4N_5 changed according to the following path: $Nb_4N_5 \rightarrow$ δ-NbN $\rightarrow$ ε-NbN $\rightarrow$ δ'-NbN.

Based on the above experimental results, the reac-

Temp/°C	Products
900	Nb > Nb_2N
1000	Nb > Nb_2N > δ′-NbN, ε-NbN > Nb_4N_3
1100	Nb_2N, ε-NbN > Nb, Nb_4N_3 > δ′-NbN
1200	Nb_4N_3 > Nb_2N, ε-NbN > δ′-NbN
1300	Nb_4N_3, ε-NbN

tion process of gaseous $NbCl_5$ with ammonia can be discussed. As shown in Table 1, $NbCl_5 \cdot 5NH_3$ alone was formed at 200 °C. This fact indicates that the reaction of $NbCl_5$ with ammonia to form $NbCl_5 \cdot 5NH_3$ occurs first. The Nb_4N_5 formed at 250—950 °C is considered to be due to the reaction of $NbCl_5 \cdot 5NH_3$ with ammonia, because the $NbCl_5 \cdot 5NH_3$ reacts with ammonia above about 235 °C to form Nb_4N_5, as described above. The δ-NbN formed above 1000 °C is considered to be due to the decomposition of the Nb_4N_5, because Nb_4N_5 decomposes above about 1000 °C to form δ-NbN, as described above.

As mentioned before, Nb_2N was formed in addition to δ-NbN at 1100 °C. At 1200—1300 °C, Nb_4N_3, δ′-NbN, and ε-NbN were formed in addition to δ-NbN and Nb_2N. Above 1100 °C, HCl was formed in addition to NH_4Cl. The percentage of HCl formed to the total amount of chlorine introduced as $NbCl_5$ was 18% at 1100 °C, 51% at 1200 °C, and 92% at 1300 °C. This amount of HCl formed is considerably higher than that of HCl formed by the thermal decomposition of NH_4Cl at each temperature under the experimental conditions in this work.[1] Also, it has been reported that the thermal dissociation of ammonia under the experimental conditions in this work proceeds markedly above about 1100 °C to form hydrogen and nitrogen[1] and that the reduction of gaseous $NbCl_5$ with hydrogen proceeds markedly above about 900 °C to form niobium.[14] Considering these facts, it was considered that the reduction of gaseous $NbCl_5$ with the hydrogen resulting from the thermal dissociation of ammonia also occurred to form niobium and HCl and that the niobium formed reacted with nitrogen or ammonia to form niobium nitrides.

Then, the products obtained by heating niobium (1.0 g) in a nitrogen stream and in an ammonia stream (100 cm^3/min) at various temperatures of 900—1300 °C for 2 h were examined by X-ray analysis.[5-8,15] The experimental results in a nitrogen stream are shown in Table 4. The results in an ammonia stream were similar to those in a nitrogen stream.

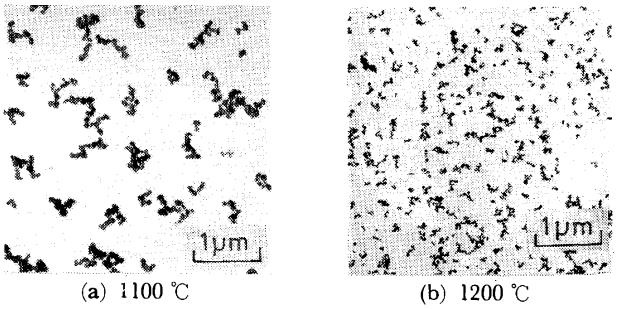
Based on the above experimental results, the formation processes of the Nb_2N, Nb_4N_3, δ′-NbN, and ε-NbN, which were formed above 1100 °C by the reaction of gaseous $NbCl_5$ with ammonia, can be discussed. As seen from the results shown in Tables 3 and 4, Nb_2N and Nb_4N_3 were not formed by the heating of Nb_4N_5 in an ammonia stream, but they were formed by the nitriding of niobium. This fact was considered to indicate that the formation of Nb_2N and Nb_4N_3 was due to the nitriding of the niobium resulting from the hydrogen reduction of $NbCl_5$. δ′-NbN and ε-NbN were considered to be formed by the heating of Nb_4N_5 in an ammonia stream or by the nitriding of niobium (Tables 3 and 4). However, as shown in Table 1, δ′-NbN and ε-NbN were always obtained, together with Nb_2N and Nb_4N_3, which were formed only by the nitriding of niobium. This fact was considered to indicate that δ′-NbN and ε-NbN were formed also by the nitriding of niobium.

From the above mentioned results, the formation process of niobium nitride by the vapor-phase reaction of $NbCl_5$ with ammonia can be represented as follows. The reaction of gaseous $NbCl_5$ with ammonia occurs first to form $NbCl_5 \cdot 5NH_3$. Above about 235 °C, the $NbCl_5 \cdot 5NH_3$ reacts with ammonia to form Nb_4N_5. Above about 1000 °C, the Nb_4N_5 decomposes to δ-NbN. Above about 1100 °C, in addition to these reactions, the nitriding of niobium, formed by the reduction of gaseous $NbCl_5$ with the hydrogen resulting from the thermal dissociation of ammonia, also occurs to form Nb_2N at 1100 °C and Nb_2N, Nb_4N_3, δ′-NbN, and ε-NbN at 1200—1300 °C.

Properties of the Niobium Nitride Formed. To obtain knowledge on the thermal stability of the niobium nitride formed by the reaction of gaseous $NbCl_5$ with ammonia, the Nb_4N_5 (0.1 g), formed at 900 °C, was heated in a argon atmosphere at various temperatures for 2 h. X-ray analysis of the samples obtained after the heating showed them to be unchanged Nb_4N_5 at 900 °C, δ-NbN at 1000 °C, δ-NbN ≫ ε-NbN at 1100—1200 °C, and Nb_4N_3 > δ-NbN at 1300 °C.

A comparison of the above results with the results on heating Nb_4N_5 in an ammonia stream (Table 3) showed that δ′-NbN was not formed by the heating of Nb_4N_5 in an argon atmosphere, and that in an argon atmosphere Nb_4N_5 decomposed to Nb_4N_3, while in an ammonia stream Nb_4N_5 did not give the nitride with a N/Nb atomic ratio of less than 1, Nb_4N_3.

Finally, the niobium nitrides obtained outside the reaction zone by the reaction of gaseous $NbCl_5$ with ammonia at various temperatures were examined by electron microscopy. Some typical micrographs of the niobium nitride are shown in Fig. 1.



(a) 1100 ℃ (b) 1200 ℃

Fig. 1. Electron micrographs of the niobium nitrides formed at various temperatures.

As seen from Fig. 1, the niobium nitrides formed above 1200 °C under the experimental conditions in this work were uniform, ultrafine powders with particle diameters of the order of 1/100 μm.

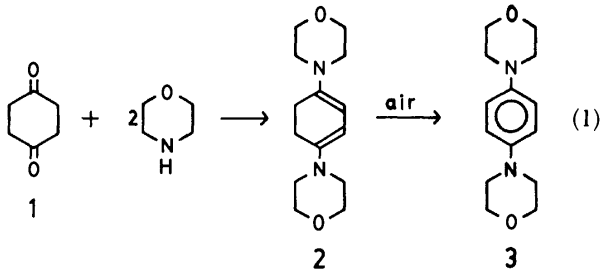
Condensations of 1,4-Cyclohexanediones and Secondary Aromatic Amines. The Formation of Alkyldiarylamines and Triarylamines

Kazuo HAGA,* Masayuki OOHASHI, and Ryohei KANEKO
Department of Industrial Chemistry, Faculty of Engineering, Utsunomiya Universty, Ishii-machi, Utsunomiya 321
(Received September 26, 1983)

Condensation of 1,4-cyclohexanedione with *N*-alkylarylamines gives *N*-alkyl-*N*-arylanilines, and that with diarylamines gives triarylamines. A mechanism involving dehydration of monoenamines of the 1,4-dione is proposed for the reaction. Relative rates of substituted *N*-ethylanilines on competitive reactions plotted *vs.* Hammet's σ values gave -2.0 as the ρ value. In separate reactions, however, a different tendency is noted for the yield, that is, the ease of reactions with *p*-chloro and *p*-nitro derivatives. This discrepancy is explained in terms of acidities of the conjugate acids of the amines used as the actual catalysts.

The condensations between ketones and secondary amines are known to produce enamines. Leonard and Sauers[1] reported that the condensation of 1,4-cyclohexanedione (**1**) with cycloalkylamines gave dienediamines, which converted by air oxidation to substituted *p*-phenylenediamines.



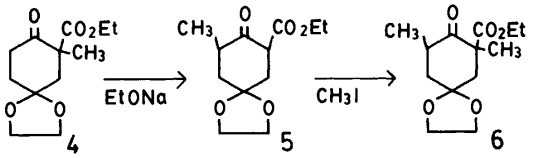
(1)

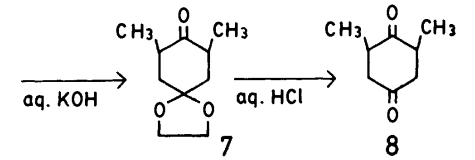
On the condensation of **1** with some secondary aromatic amines, we now have found that almost no dienediamines or phenylenediamines are obtained, but that tertiary monoamines are produced instead. In the present study, a mechanism for the reaction will be proposed and substituent effects will be discussed. This reaction is useful as a new procedure for the synthesis of tertiary aromatic amines. Preparation of 2,6-dimethyl-1,4-cyclohexanedione is also reported.

Results and Discussion

Preparation of 2,6-Dimethyl-1,4-cyclohexanedione. 2,6-Dimethyl-1,4-cyclohexanedione (**8**), one of the starting materials for the condensation reaction, was prepared as shown in Scheme 1. Ethyl 5,5-ethylenedioxy-3-methyl-2-oxocyclohexanecarboxylate (**5**) was obtained by isomerization of ethyl 5,5-ethylenedioxy-1-methyl-2-oxocyclohexanecarboxylate (**4**), and was methylated *in situ* in considerable yield. The alkaline hydrolysis of the product **6** yielded the monoacetal **7**, which on removal of the ethylenedioxy group gave 2,6-dimethyl-1,4-cyclohexanedione (**8**). This procedure was modified from the method of Mori and Matsui[2] for the methylation of ethyl 1-methyl-2-oxocyclohexanecarboxylate to afford ethyl 1,3-dimethyl-2-oxocyclohexanecarboxylate. This method for α,α'-dialkylation of cyclic ketones, exploiting the reversible cleavage of β-keto ester, was also useful for the formation of the 1,4-dione derivative.

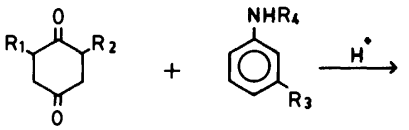
Condensation Reaction. When the condensation of **1** and *N*-methylaniline (**9**) was carried out in



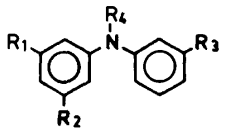


Scheme 1.

the presence of *p*-toluenesulfonic acid, *N*-methyl-*N*-phenylaniline (**10**) was obtained unexpectedly in 77% yield. The condensation of **1** with *N*-methyl-*m*-toluidine (**11**) in similar conditions gave *N*-methyl-*N*-phenyl-*m*-toluidine (**12**) which was produced also from 2-methyl-1,4-cyclohexanedione (**13**) on the reaction with *N*-methylaniline (**9**). Even diphenylamine (**14**) which is a very weak base ($pK_a=0.79$) reacted with **1** giving triphenylamine (**15**) in 72% yield, and with 2,6-dimethyl-1,4-cyclohexanedione (**8**) giving 3,5-dimethyltriphenylamine (**16**).



1: $R_1=R_2=H$ **9**: $R_3=H$, $R_4=CH_3$
13: $R_1=H$, $R_2=CH_3$ **11**: $R_3=R_4=CH_3$
8: $R_1=R_2=CH_3$ **14**: $R_3=H$, $R_4=C_6H_5$



(2)

10: $R_1=R_2=R_3=H$, $R_4=CH_3$
12: $R_1=R_2=H$, $R_3=R_4=CH_3$
15: $R_1=R_2=R_3=H$, $R_4=C_6H_5$
16: $R_1=R_2=CH_3$, $R_3=H$, $R_4=C_6H_5$

These reactions (Eq. 2) show that the 1,4-diones are converted into aniline derivatives, not the product in Eq. 1, and that the amines combine selectively to the carbonyl having no substituent at α-position.

Thus, the effect of the substituent on the starting aniline was examined in order to obtain insight into

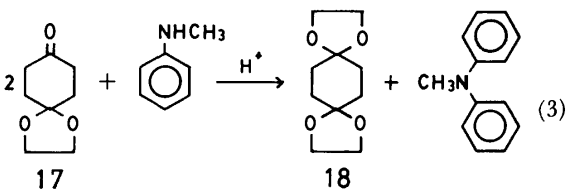
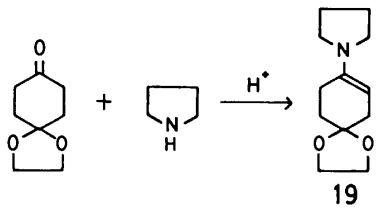
the reaction mechanism. Table 1 shows the results of the condensation of **1** with some substituted *N*-ethylanilines. No definite relationship can be found between the yields of the tertiary amines and the basicity of the starting amines. However, it is worth noting that *p*-nitro and *p*-chloro substitutions lead to good yield. Therefore, **1** was treated in a solution containing *N*-ethylaniline and another aniline, and the products were analyzed by means of gas chromatography. The relative rates on the competing reactions plotted *vs.* Hammet's σ values gave −2.0 as the ρ value, as shown in Fig. 1. The reactivities, hence, decrease with the decrease of the basic strengths of the amines. In addition to Fig. 1, *N*-ethyl-*p*-nitroaniline was found to react very slowly in the competitive reaction with *N*-ethylaniline.

The aromatization of cyclohexane ring was also found on condensation of 4,4-(ethylenedioxy)cyclohexanone (**17**) with secondary aromatic amines. The reaction of **17** with *N*-methylaniline produced *N*-methyl-*N*-phenylaniline and the diacetal **18** of the 1,4-dione.



(3)

The formation of **18** shows that an acetal exchange reaction occurred in these conditions. This may produce the 1,4-dione also, which could follow the reaction in Eq. 2, because no monoenamine was obtained even if the amine was used in large excess. On the other hand, the reaction of pyrrolidine with **17** has been reported[3] to produce the corresponding enamine **19**. In an effort to determine the effect of the catalyst, this reaction was further studied, but the same results were obtained regardless of the presence of the acid.



(4)

These results show that the conjugate acid of the aromatic amine is an active catalyst for the acetal-exchange reaction in these conditions but that the conjugate acid of the aliphatic amine has no or very little effect.

In spite of above results, an aromatic amine also produced a phenylenediamine derivative, as suggested in Eq. 1, if the reaction was carried out in the presence of $TiCl_4$. Under these conditions *N*-methylaniline gave *N,N'*-dimethyl-*N,N'*-diphenyl-*p*-phenylenediamine (**20**).

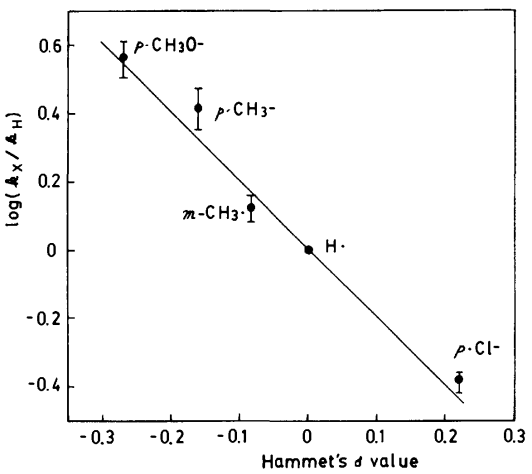


Fig. 1. Relative rates of substituted *N*-ethylanilines on the competitive reactions.

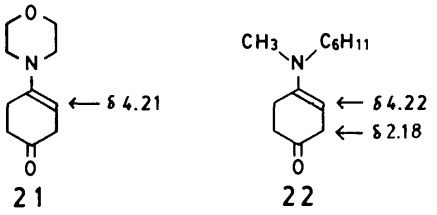
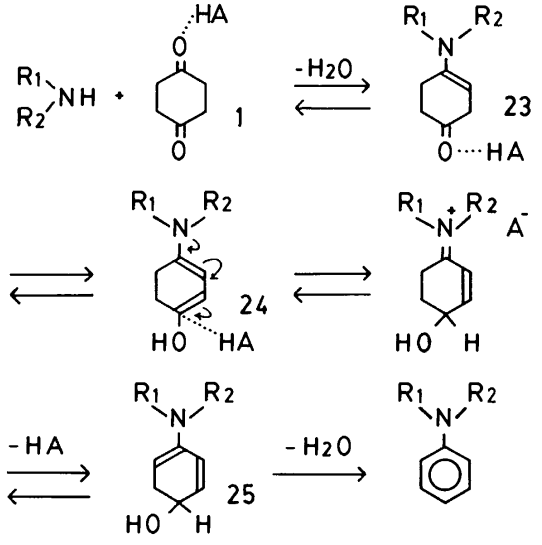
20

NMR Spectra of the Reaction Mixtures. In order to understand the differences between aromatic amine- and aliphatic amine-condensation processes, the reactions of **1** with some aliphatic or aromatic amine were followed by ^{1}H-NMR spectra of the reaction mixtures in sealed tubes under nitrogen. The spectra of the mixture of **1** and morpholine showed signals at δ 5.01 and at δ 2.13 due to the vinyl protons of the dienediamine **2** and its methylene protons and the vinyl proton of monoenamine **21** at δ 4.21. The signals due to **2** became progressively stronger as the reaction time, while those due to **21** disappeared after 4 h at 120 °C. When the sample was permitted to stand for 1 h in contact with air after the reaction, the signals due to **2** disappeared too and those due to aromatic protons of **3** appeared. ^{1}H-NMR spectra of the mixture of **1** with *N*-methylcyclohexylamime showed also signals due to the vinyl proton of monoenamine **22** at δ 4.22 along with those due to the corresponding dienediamine at δ 5.08.



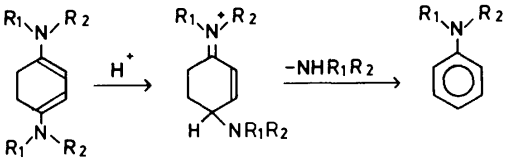
21 22

These facts show that the aliphatic amines reacted stepwise to the carbonyl groups of the 1,4-dione and that the intermediate monoenamines were produced in measurable amounts. On the contrary, ^{1}H-NMR spectra of the reaction mixture of *N*-methylaniline and **1** show the signals due to starting materials and those due to *N*-methyl-*N*-phenylaniline, but no signal ascribable to any intermediate.



Scheme 2.

Reaction Mechanism. On the basis of the above results, the mechanism shown in Scheme 2 is proposed for the reaction of aromatic amines with the 1,4-dione catalyzed by *p*-toluenesulfonic acid. The key steps in Scheme 2 are the enolization of monoenamine **23** and the protonation to γ-position of 24. These processes and the dehydration of **25** may be fast, because no intermediate was observed by ^{1}H-NMR spectroscopy. An alternate path which involves elimination of an amine from the dienediamine can also be considered (Eq. 6):



(6)

If the reaction proceeds *via* the dienediamine, the signals of the monoenamine should be observed at least in an early period of the reaction; this is because the reactivity of the residual carbonyl of the monoenamine **23** to the secondary aromatic amine should not be much greater than that of the starting ketone (**1**). Moreover, 2,6-dimethyl-1,4-cyclohexanedione (**8**) is very unlikely to produce any dienediamine because of its steric hindrance: therefore, the formation of **16** in Eq. 2 supports also Scheme 2. The discrepancy between the results of Fig. 1 and Table 1 is discussed below on the basis of the proposed mechanism.

Although there have been a number of examples of enamine formation, the mechanistic studies have been limited to the enamines derived from aliphatic amines. The addition step of aminoalcohol formation has been generally shown[3] to be noncatalytic. However, the addition reaction of weak bases such as semicarbazides or primary aromatic amines to carbonyl compounds is catalyzed by general acid catalysis. Since the addition step of the enamine formation is the same as that of the formation of the carbon nitrogen double bond, the addition of aromatic amines to **1** must occur by the general acid-catalysis. Consequently, essentially every step of the reaction in Scheme 2 is acid-catalyzed. Therefore, it is necessary to take into account not only the nucleophilicity of the amine, but also the acidity of the catalyst for discussion of the reactivity. In practice, the reactions with aromatic amines did not proceed without the acid catalyst. *p*-Toluenesulfonic acid was employed as the catalyst for the all experiments. HA in Scheme 2, then, is the conjugate acid of the amine in the mixture, and its acidity can be assumed to have a reverse tendency to the nucleophilicity of the amine. Therefore the ease of the reaction of the *N*-ethylaniline substituted with an electron-withdrawing group can be interpreted in terms of the increased acidity of its conjugate acid. The facility of the triphenylamine formation in Eq. 2 is also explained by the same reason. As seen in Fig. 1, two competitive reactions in a mixture were catalyzed by the same system, where the main acid was the conjugate acid of the more basic amine. Therefore, only nucleophilicity of the amine contributed to the relative reactivity on competitive reactions.

The fact that the condensation of **1** with aliphatic amines produced dienediamines but no tertiary monoamines is also explained by the same factor. The conjugate acids of aliphatic amines are so weak that the enolization of **23** and the protonation to 4-position of **24** are difficult. On the contrary, the formation of **23** and further addition of the aliphatic amine to the residual carbony of **23** must proceed smoothly, because the aliphatic amines react even without the acid catalyst.

On the other hand, the formation of the dienediamine derived from *N*-methylaniline in Eq. 5 may be due to the fast addition of the amine to the carbonyl activated by $TiCl_4$.

Finally we add a few comments on the present reactions from the viewpoint of organic synthesis. The formation of tertiary amines from secondary aromatic amines with halobenzene requires drastic conditions. Therefore, *N*-phenylation by use of 1,4-cyclohexanedione is worthwhile because of its mild conditions. The conditions in Table 1 are not always the most suitable. For example, increase of the catalyst concentration or of the reaction period lead to good yield of the products. As the solvent, aromatic hydrocarbonds are more favorable than polar ones such as dioxane. The reaction became slower in polar solvents.

Experimental

General. Melting points were uncorrected. ^{1}H-NMR spectra were recorded on a JNM-C-60HL spectrometer with $(CH_3)_4Si$ as an internal standard. IR spectra were taken on a JASCO Model IR-G spectrophotometer. Mass spectra were measured on a Hitachi M-80 mass spectrometer. GLPC analyses were carried out by a Hitachi 163 gas chromatograph using 1-decene or phenanthrene as an internal standard.

Materials. *N*-Ethyl-*p*-chloroaniline was prepared following a method given in "Organic Sytheses"[4]: Yield 60%; bp 89—90 °C / 2 Torr (1 Torr = 133.322 Pa). *N*-Ethyl-*p*-nitroaniline was obtained from *p*-nitroaniline in a similar manner: Yield 48%; mp 96—97 °C. *N*-Ethyl-*p*-anisidine was prepared in three steps involving acetylation of *p*-anisidine, alkylation by use of methyl iodide in the presence of sodium ethoxide, and successive hydration in basic coditions. The total yield was 28%. Found: C, 71.87; H, 8.96; N, 9.05%. Calcd for $C_9H_{13}NO$: C, 71.49; H, 8.67; N, 9.26%. The derivatives of 1,4-cyclohexanedione were all prepared from diethyl 4,4-(ethylenedioxy)pimelate (**26**). The compound **26** was obtained from furfural and malonic acid in three steps according to reported pocedures[5]: Bp 134—136 °C / 0.5 Torr (lit, 134 °C / 0.3 Torr). Ethyl 5,5-ethylenedioxy-2-oxocyclohexanecarboxylate (**27**) was prepared from **26** according to the direction of Gardner[5]: Bp 120 °C / 1 Torr (lit, 114 °C / 0.5 Torr). 4,4-(Ethylenedioxy)cyclohexanone (**17**) was obtained from **27** by hydration in 5% aq KOH for 6 h at room temperature: Yield 80%; mp 70—72 °C (lit,[6] 68—70 °C). Found: C, 61.77; H, 8.01%. Calcd for $C_8H_{12}O_3$: C, 61.52; H, 7.74%. Ethyl 5,5-ethylenedioxy-1-methyl-2-oxocyclohexanecarboxylate (**4**) and 2-methyl-1,4-cyclohexanedione (**13**) were prepared by the method of Narang.[7] Compound **4** was obtained from **26** in 59% yield: mp 71—72 °C (lit, 72 °C). Compound **13** was obtained from **4** in two steps: Yield 60%; mp 47—48 °C (lit, 47 °C). All other reagents were commercially available and were used after purification, if necessary.

2,6-Dimethyl-1,4-cyclohexanedione (8). A mixture of **4** (10 g, 4.13×10^{-2} mol) and sodium ethoxide prepared from 0.95 g (4.13×10^{-2} mol) of sodium was refluxed in ethanol (20 cm^3) for 10 h. Toluene (20 cm^3) was added to the reaction mixture, and then ethanol was gradually distilled off. An additional 20 cm^3 of toluene was added into the residue and the mixture was refluxed for 5 h. Methyl iodide (5.9 g, 4.15×10^{-2} mol) was then added at 0 °C and the mixture was allowed to stand overnight at room temperature. The mixture was refluxed for 2 h, and decomposed with 5% sodium carbonate solution (16 cm^3) and extracted with benzene. The extract was evaporated and the residue was distilled *in vacuo* to afford 6.3 g (60%) of ethyl 1,3-dimethyl-5,5-ethylenedioxy-2-oxocyclohexanecarboxylate (**6**): Bp 125 °C/1 Torr. The product (6.1 g, 2.4×10^{-2} mol) was refluxed with a mixture of 10% aqueous potassium hydroxide (30 cm^3) and ethanol (10 cm^3) for 10 h. The mixture was extracted with ether and evaporated *in vacuo*, giving 3.6 g (82%) of 2,6-dimethyl-4,4-(ethylenedioxy)cyclohexanone (**7**). The crude product (3.5 g, 1.9×10^{-2} mol) was warmed in 3 mol dm^{-3} hydrochloric acid (18 cm^3) at 80 °C for 1 h. Upon cooling to room temperature, a part of the product crystallized out of the solution, and was filtered. The filtrate was extracted with benzene and the extract was evaporated. The residue was combined with the above crystals and was recrystallized from hexane, affording 2.4 g (90%) of 2,6-dimethyl-1,4-cyclohexanedione: Total yield based on **4** is 44%; mp 84—86 °C; IR (KBr) 1707, 1142 and 2800—3000 cm^{-1}; NMR (CCl_4) δ=1.00—1.30 (6H, dd) and 1.80—3.00 (6H, m). Found: C, 68.75; H, 8.95%. Calcd for $C_8H_{12}O_2$: C, 68.55; H, 8.63%.

Condensation of 1,4-Cyclohexanediones and Secondary Aromatic Amines. The general procedure consists of a heating of 1,4-cyclohexanedione (0.5 g, 4.46×10^{-3} mol) with an equivalent of the amine and *p*-toluenesulfonic acid (20 mg) using toluene (30 cm^3) as the solvent in nitrogen atmosphere. The mixture was refluxed for 12 h under a Soxhlet extractor packed with $CaCl_2$ as desiccant, and the solution freed of the solvent *in vacuo*. The product was isolated by column chromatography on sillica gel eluted with hexane. The *N*-ethyl-*N*-phenylanilines obtained are summarized in Table 1. Some other tertiary amines obtained and their properties are presented below.

N-Methyl-*N*-phenylaniline (**10**) was obtained as a light yellow liquid from **1** and *N*-methylaniline in 77.2% yield: NMR (CCl_4) δ=3.25 (3H, s) and 6.63—7.28 (10H, m); MS, *m*/*z* 183 (M$^+$).

N-Methyl-*N*-phenyl-*m*-toluidine (**12**) was obtained as a light yellow liquid in 62.3% yield from **1** and *N*-methyl-*m*-toluidine, or in 61.6% yield from 2-methyl-1,4-cyclohexanedione and *N*-methylaniline: NMR (CCl_4) δ=2.28 (3H, s), 3.28 (3H, s) and 6.53—7.30 (9H, m); IR (neat) 1590, 1490, 750 and 690 cm^{-1}; MS, *m*/*z* 197 (M$^+$).

Triphenylamine (**15**) was obtained as crystals in 88.2% yield from **1** and diphenylamine: Mp 125—126 °C (from hexane).

3,5-Dimethyltriphenylamine (**16**) was obtained as crystals from 2,6-dimethyl-1,4-cyclohexanedione and diphenylamine in 28.9% yield: Mp 130—132 °C (from hexane); NMR (CCl_4) δ=2.20 (6H, s) and 6.45—7.35 (13H, m); IR (KBr disk) 1585, 1490, 755 and 690 cm^{-1}; MS, *m*/*z* 273 (M$^+$).

Competitive Reaction. A mixture of *N*-ethylaniline and another appropriate amine was used in the place of the amine component of the condensation described above. The competitive reaction was followed by gas chromatography every half hour until one of the amines gave 10% conversion. The relative rate (k_x/k_y) in Fig. 1 was determined from the ratios of the two products.

The Condensation of 4,4-(Ethylenedioxy)cyclohexanone (17) with N-Methylaniline. The method used here was virtually identical with that for 1,4-cyclohexanedione, but

the latter was replaced with **17**. *N*-Methylaniline (0.35 g, 3.3×10^{-3} mol) and 0.5 g (3.2×10^{-3} mol) of **17** were refluxed in toluene (30 cm^3) in presence of *p*-toluenesulfonic acid (20 mg). After 30 h, GLPC analysis showed that *N*-methyl-*N*-phenylaniline and diacetal **19** were produced in an approximately equal yield (9%).

Condensation of 17 and Pyrrolidine. The procedure was similar to that of Stork[3] except that 2×10^{-2} equivalent *p*-toluenesulfonic acid to pyrrolidine was added. The pyrrolidine enamine of **17** was produced in 82% yield: Bp 135—137 °C/3 Torr (lit, 110—120 °C/0.1—0.15 Torr); IR 1640, 1115, 1055, and 850 cm^{-1}.

Condensation of 1 and N-Methylaniline in Presence of $TiCl_4$. To a mixture of *N*-methylaniline (5.8 g, 5.42×10^{-3} mol) and **1** (1.0 g, 8.9×10^{-3} mol) in benzene (44 cm^3) a benzene solution (9 cm^3) containing $TiCl_4$ (1.88 g) was added during 20 min at below 10 °C in nitrogen atmosphere with stirring. Then the mixture was stirred for 12 h at room temperature, the precipitate was filtered, and the filtrate was evaporated. The residue was crystallized from ethanol, affording *N,N'*-dimethyl-*N,N'*-diphenyl-*p*-phenylenediamine (0.7 g, 27%) as crystals: Mp 149—150 °C; IR 1590, 1500, 860, and 840 cm^{-1}. Found: *m/z* 288.1614. Calcd for $C_{20}H_{20}N_2$: M, 288.1625.

The authors wish to thank Mr. Katsumasa Iwaya for obtaining some of the NMR spectra and Miss Machiko Nozawa for the preparation of the derivatives of 1,4-cyclohexanedione.

(Received October 25, 1983)

Kinetic study of the hydrolysis of silicon phosphate, $Si_3(PO_4)_4$ (hexagonal), was carried out in borax buffer solutions (pH 5—12, temperature 20—50 °C) to investigate how it acts as a hardener for alkali silicate adhesive. The silicon phosphate was found to be hydrolyzed with a resulting release of orthophosphate ion, soluble silicate ions, and colloidal silica under mild conditions; the decomposition rate increased with decreasing the particle size of the phosphate and with increasing the pH and temperature of the buffer solution. From the analysis of the decomposition rate on the basis of the shrinking core model, it was found that the decomposition rate could be adequately expressed by the rate equation based on the mixed control of diffusion through a residual layer and surface chemical reaction. This indicates that a part of the colloidal silica which resulted from the hydrolysis remains on the surface of the silicon phosphate particle and then partially limits the overall rate of the hydrolysis. The dependence of both rate-determining steps for the decomposition rate was quantitatively indicated according to the reaction conditions.

Because of the advantages of being heat-stable, incombustible, and solvent-resistant, inorganic adhesives are increasingly being used in many fields. A silicate adhesive using alkali silicate solution (generally referred to as "water glass") as a binder is most widely utilized.[2,3)] However, it still has some weak points; for instance, the hardened silicate materials at room temperature show water sensitivity. Since the adhesive properties of the hardened silicate materials are known to be predominantly dependent on the kind of hardeners used, a number of substances such as metal powders, oxides, hydroxides, mineral acids, borates, and phosphates are now being employed.[4,5)] However, no hardener having excellent properties, especially sufficient water resistance, has yet been obtained.

The present authors[1)] have prepared silicon phosphates such as $Si_3(PO_4)_4$ and SiP_2O_7 by calcination of silica gel impregnated with a small amount of phosphoric acid at temperatures up to 1000 °C and have shown that they can be used as a satisfactory hardener for silicate adhesives. The most important feature was that these phosphates with silicate adhesives showed excellent water resistance even without heat-treatment. Although the synthesis of silicon phosphates in a large excess of phosphoric acid has been done by earlier workers,[6,7)] no information is at present available on these chemical properties. Therefore, to investigate the mechanism of the enhancement in the water insensitivity by using silicon phosphates, an understanding of the hydrolysis behavior of silicon phosphates is desirable.

In this study, the kinetics of the hydrolysis of pure silicon phosphate ($Si_3(PO_4)_4$) in aqueous alkaline solutions was investigated in detail. As a model solution, borax buffer solution having the desired pH value was used here.

Experimental

Materials. In the preparation of $Si_3(PO_4)_4$, analytical reagent grade orthophosphoric acid (P_2O_5: 63%) and commercial silica gel for chromatography (200—300 mesh) were used. A buffer solution was prepared using analytical reagent grade sodium tetraborate decahydrate and sodium hydroxide. The pH of the buffer solution was adjusted to the desired value by mixing 0.2 mol dm^{-3} $Na_2B_4O_7$ with 1.0 mol dm^{-3} NaOH.

Preparation of $Si_3(PO_4)_4$.[6)] First, 17.5 g of orthophosphoric acid was transferred to a 30 cm^3 platinum crucible and heated for 30 min at 150 °C. Subsequently, 1.0 g of dried silica gel (P_2O_5/SiO_2 molar ratio: 5.0) was added to the crucible, which was then heated again for 5 h at 220—230 °C. After cooling, the suspension was centrifuged, and the resulting white powder was washed repeatedly with ethanol to remove adsorbed acid and then dried over P_2O_5 under reduced pressure. Since $Si_3(PO_4)_4$ is hygroscopic, it was well-dried before being used for the hydrolysis experiment. Although the spontaneous particle size of $Si_3(PO_4)_4$ was different in all runs, uniform-sized particles were obtained for each run. In this investigation, four different-sized $Si_3(PO_4)_4$ (hexagonal)[8)] were used without further pulverization. As

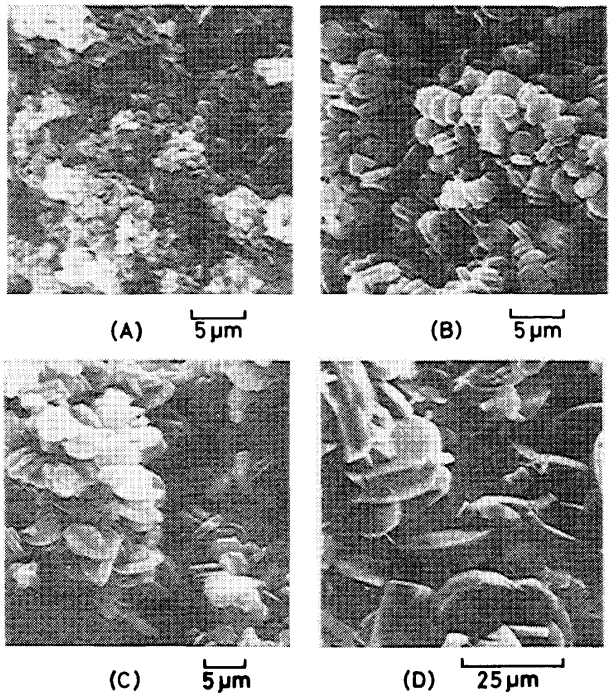

Fig. 1. Scanning electron micrographs of silicon phosphate ($Si_3(PO_4)_4$) used in this experiment.
Mean particle diameter (μm) —— A: 1.0, B: 2.2, C: 3.7, D: 22.6.

can be seen in Fig. 1, these phosphate particles were all disk-shaped. No differences in their crystal forms and chemical compositions were observed. The particle size was measured using a scanning electron microscope (Hitachi-Akashi MSM 4C-102) and the cylindrical shape equivalent diameter[9] was used as the mean particle size. The chemical composition was: Found: SiO_2, 36.6±3.2, P_2O_5, 59.5±1.9; Calcd for $Si_3(PO_4)_4$: SiO_2, 38.8, P_2O_5, 61.2%.

Measurement of Hydrolysis Rate. As the first step, 200 cm^3 of the buffer solution was transferred to a 300 cm^3 three-necked flask equipped with a mechanical stirrer (crescent shaped impeller, 60 mm×20 mm), a reflux condenser, and a thermometer and maintained at 20—50 °C. Then, a weighed amount of $Si_3(PO_4)_4$ was suspended in the buffer solution with vigorous agitation. The decomposition rate of $Si_3(PO_4)_4$ was determined by pipetting about 3 cm^3 of the suspension from the flask as regular time intervals, filtering out the insoluble residues, and chemically analyzing the supernatant solution for orthophosphate ion by colorimetric method.[10] In all experiments, no changes in the pH of the buffer solution were observed from before to after the hydrolysis.

Results and Discussion

Effect of Amount of $Si_3(PO_4)_4$ Added. Figure 2 shows the effect of changes in the amount of $Si_3(PO_4)_4$ on the decomposition rate of $Si_3(PO_4)_4$ conducted in the buffer solution of pH 11.0 at 30 °C with a stirring speed of 300 min^{-1}. The particle size of $Si_3(PO_4)_4$ used was 2.2 μm. Since the maximum difference in the percentage decomposition was only 4%, it cannot be said that there is any effect of amount of $Si_3(PO_4)_4$ under the conditions tested.

Effect of Stirring Speed. Figure 3 shows the effect of stirring speed on the decomposition rate of $Si_3(PO_4)_4$ under the same conditions as those conducted above. 0.2 g of $Si_3(PO_4)_4$ was used here. The decomposition rate was maximum at 300 min^{-1} and slightly decreased at 200 and 400 min^{-1}. When different-sized $Si_3(PO_4)_4$ were tested, the effect of stirring speed was also hardly observed under stirring speeds of 200—300 min^{-1}.

Effect of Particle Size. The decomposition rate was determined using 0.4 g of four different-sized $Si_3(PO_4)_4$, shown in Fig. 1, under the same conditions as those employed above. The result is given in Fig. 4. The decomposition rate obviously increased with de-

creasing particle size. The relationship between particle size and decomposition rate will be quantitatively discussed later.

On the basis of the data, subsequent experiments were carried out under the following conditions; particle diameter of $Si_3(PO_4)_4$, 2.2 μm; amount of $Si_3(PO_4)_4$, 0.2 g; stirring speed, 300 min^{-1}.

Effect of pH. Figure 5 shows the effect of pH on the decomposition rate of $Si_3(PO_4)_4$ at 30 °C (A) and 50 °C (B). At both temperatures, the decomposition rate increased with increasing the pH, although its effect was not so appreciable. In the experiments at 50 °C, more than 90% of the total quantity of $Si_3(PO_4)_4$ was hydrolyzed at all pH values tested.

Effect of Temperature. Fiure 6 shows the effect of temperature on the decomposition rate of $Si_3(PO_4)_4$ at pH 8.0 (A) and 11.0 (B). At both pH values, the temperature affected predominantly the decomposition rate, which increased significantly with increasing temperature.

Analysis of Hydrolysis Rate. The electron micrographs of the insoluble residues obtained from the suspensions after the decomposition of 30% and 70% of $Si_3(PO_4)_4$ are shown in Fig. 7. It was observed that the particles shrunk with progress of the hydrolysis. The profile of the residue was quite similar: the same percentage decomposition and independence of

the reaction conditions were found. The colloidal silica was gradually suspended in the buffer solution during the hydrolysis. According to Alexander *et al.*,[11] the solubility of the different forms of amorphous silica in water is 0.011—0.015 wt% at pH 6—9 and 25 °C, and increases to 0.2—0.4 wt% at pH 11. It also increases with a rise in temperature, but its effect is not appreciable compared to that of pH. Since the buffer solution used here contains a large amount of borate, the resulting silicate species should be present mainly as colloidal silica in it. Although the colorimetric determination of soluble silicate ion using ammonium molybdate was not so exact because of the coexistence of phosphate ion, the formation of the soluble silicate ion was identified in the buffer solution. From the results reported by Busey *et al.*,[12] the soluble silicate ions were thought to be $SiO(OH)_3^-$ and $Si(OH)_4$. Paper chromatography[13] also revealed that the phosphate ions in the buffer solution which originated from $Si_3(PO_4)_4$ were all orthophosphate ions, PO_4^{3-}. Thus $Si_3(PO_4)_4$ reacts with H_2O or OH^-, and decomposes in aqueous alkaline solution, which leads to the release of orthophosphate ion, soluble silicate ions, and colloidal silica.

Therefore, the hydrolysis reaction of $Si_3(PO_4)_4$ in aqueous alkaline solution is written as:

$$Si_3(PO_4)_4 + 6H_2O = 3SiO_2(\text{soluble and colloidal}) + 4PO_4^{3-} + 12H^+. \quad (1)$$

The decomposition rates of $Si_3(PO_4)_4$ were analyzed on the basis of the shrinking core model under the assumption that the phosphate particles form a homogeneous spherical solid phase.

The reaction in Eq. 1 can be represented simply as Eq. 2:

$$A(l) + \sigma S(s) \longrightarrow P(l). \quad (2)$$

When the reaction percentage of component P was represented as x and the steady state of the reaction was assumed, the following Eq. 3 was obtained as the rate equation:

$$\frac{dx}{dt} = \frac{3C_A V}{r_0} = \frac{1}{\frac{1}{k_L} + \frac{\sigma r_0}{D_e}\{(1-x)^{-1/3} - 1\} + \frac{1}{k_C}(1-x)^{-2/3}}. \quad (3)$$

Three rate-determining steps were studied: The diffusion in liquid film, the diffusion in residual layer, and the surface chemical reaction.[14] However, the diffusion in liquid film should not be the rate-determining step because the decomposition rate of $Si_3(PO_4)_4$ was not affected by the stirring speed but was significantly influenced by temperature, as described previously. Therefore, the following two equations were obtained for each rate-determining step by integration of Eq. 3:

i) For diffusion in residual layer (k_L, $k_C \gg D_e/r_o$)

$$1 - \frac{2}{3}x - (1-x)^{2/3} = \frac{2C_A D_e V}{\sigma r_0^2} t, \quad (4)$$

ii) For surface chemical reaction (k_L, $D_e/r_o \gg k_C$)

$$1 - (1-x)^{1/3} = \frac{C_A k_C V}{r_0} t, \quad (5)$$

In the first place, the results for the hydrolysis of $Si_3(PO_4)_4$ shown in Figs. 4 and 5 were replotted according to the rate equations shown in Eqs. 4 and 5. However, it was found that neither rate equation could express the decomposition rates satisfactorily. In general, the rate of heterogeneous reaction of a solid-liquid system is often dependent on both the rate of diffusion through residual layer and the surface chemical reaction. According to Habashi[15] and Sohn *et al.*,[16] a mixed control rate equation can be derived by combining the diffusion and chemically controlled expressions as shown in Eq. 6:

iii) For mixed control ($k_L \gg D_e/r_o$, k_C)

$$[1 - \frac{2}{3}x - (1-x)^{2/3}] + \beta[1-(1-x)^{1/3}] = kt, \quad (6)$$

where

$$\beta = \frac{2D_e}{k_C \sigma r_0},$$

$$k = \frac{2C_A D_e V}{\sigma r_0^2}.$$

The results for the hydrolysis of $Si_3(PO_4)_4$ shown in Figs. 4 and 5 are replotted according to Eq. 6 as Fig. 8. A good linear dependence of $[1-2/3x-(1-x)^{2/3}]+\beta[1-(1-x)^{1/3}]$ on time was obtained. The values of β and k used for replotting Fig. 8 were conveniently given by the slope and intercept of the straight line drawn between $[1-2/3x-(1-x)^{2/3}/t]$ and $[1-(1-x)^{1/3}/t]$ at constant temperature.[17] The values for the constants β and k for the four different-sized particles used are given in Table 1. If Eq. 6 describes the reaction conversion adequately, then the ratio of the values of k for two essentially monosized fractions should be equal to the square of the ratio of the radii. The comparison is shown as Table 2. Agreement between the expected results and those actually obtained is observed, and hence the suggestion that the hydrolysis of $Si_3(PO_4)_4$ is under mixed diffusion through residual layer and chemical reaction control is reasonable. A part of the resulting colloidal silica remains on the surface of $Si_3(PO_4)_4$ and the diffusion of the reactant through the silica layer partially controls the overall rate of the hydrolysis.

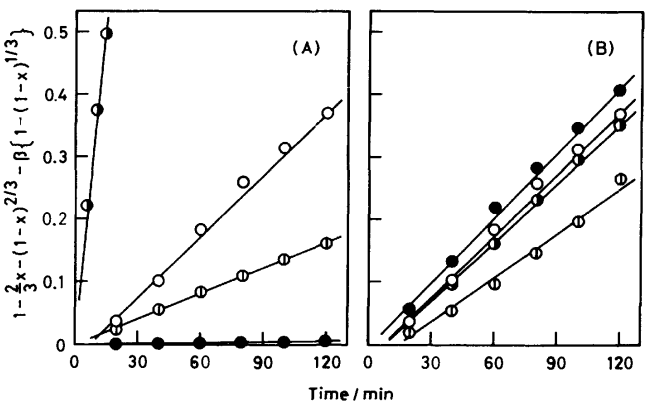

Fig. 8. Plots of decomposition data according to shrinking core model with mixed surface chemical and diffusional kinetics.
(A) Effect of phosphate particle diameter (Fig. 4), (B) Effect of pH (Fig. 5-A) (Symbols are the same as those in each Fig.).

The values for the constants β and k for various pH values and temperatures are summarized in Table 3. The value of k increased with increasing pH. On the other hand, at constant pH the value of β decreased

Table 1. Values of constants in Eq 6 for the decomposition of silicon phosphate in aqueous alkaline solution

Mean particle diameter[a] / μm	β	k / min^{-1}
1.0	0.9	1.6×10^{-2}
2.2	0.4	3.4×10^{-3}
3.7	0.2	1.4×10^{-3}
22.6	0.04	3.2×10^{-5}

a) Since the phosphate particle was disk-shaped, its diameter, d, could be calculated as follows: $d=(f\cdot h)^{1/3}$, where $f=\pi d'^2$.[9]

Table 3. Values of constants in Eq. 6 and Arrhenius activation energy

pH	Temperature / °C								E_a / kJ mol^{-1}
	20		30		40		50		
	β	k / min^{-1}	β	k / min^{-1}	β	k / min^{-1}	β	k / min^{-1}	
8.0	0.5	5.7×10^{-4}	0.4	2.5×10^{-3}	0.05	4.9×10^{-3}	0.01	7.9×10^{-3}	48.8
9.5	—	—	0.4	3.2×10^{-3}	—	—	0.01	7.9×10^{-3}	—
11.0	0.5	2.0×10^{-3}	0.4	3.4×10^{-3}	0.05	5.5×10^{-3}	0.01	1.1×10^{-2}	42.7
12.0	—	—	0.4	3.5×10^{-3}	—	—	—	—	—

with increasing temperature, whereas the value of k increased. The decrease in the value of β means that the contribution of the surface chemical reaction to the overall rate of the decomposition becomes smaller. The unusual behavior, that the value of β decreased with increasing temperature in spite of the increase in silica solubility, can be explained by the relative increase of the rate of the chemical reaction.

The Arrhenius plots for the data of pH 8.0 and 11.0 are given in Fig. 9. The dependence of ln k on temperature was approximately the same at both pHs. The apparent activation energies calculated from the Arrhenius plots were 48.8 and 42.7 kJ mol^{-1} at ph 8.0 and 11.0, respectively; these are reasonable values for the mixed control reaction.

The authors wish to thank Prof. Taijiro Okabe and Dr. Tsugio Sato of the Department of Applied Chemistry, Tohoku University, for their helpful discussions and Mr. Kazuhiro Sango of Mizusawa Industrial Chemicals, Ltd. for his experimental assistance.

Nomenclature

C_A=Bulk reactant concentration (mol cm^{-3}).
D_e=Effective diffusivity of reactant through the product layer (cm^2 min^{-1}).
d=Mean particle diameter (μm).
d'=Diameter of disk-shaped particle (μm).
h=Height of disk-shaped particle (μm).
k=Overall reaction rate constant (min^{-1}).
k_C=Surface chemical reaction rate constant (cm min^{-1}).
k_L=Mass transfer coefficient (cm min^{-1}).
r_o=Initial particle radius (cm).
t=Reaction time (min).
V=Molar volume of solid reactant (cm^3 mol^{-1}).
x=Fractional conversion (−).
β=Coefficient indicating surface chemical contribution to overall rate (−).
σ=Stoichiometry factor (−).

Stereoselective Formation of Rotaxanes Composed of Polymethylene-bridged Dinuclear Cobalt(III) Complexes and α-Cyclodextrin. II[1]

Kazuaki YAMANARI* and Yoichi SHIMURA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received December 5, 1983)

[2]-[[(en)$_2$Co{XCH$_2$S(CH$_2$)$_n$SCH$_2$Y}Co(en)$_2$]Cl$_m$]-[α-CDX]-rotaxanes (n=8, 10, and 12 for X=Y=CO$_2^-$ (m=4); n=10 for X=CO$_2^-$ and Y=CH$_2$NH$_2$(m=5); α-CDX=α-cyclodextrin) were prepared with partial stereoselectivity and characterized from their visible-UV absorption, circular dichroism(CD), and ^{13}C NMR spectra, and elemental analysis. The rotaxane formation could be identified by the down field shift of the chemical shift due to α-CDX in the ^{13}C NMR spectra and the increase of the CD intensity in the ligand-to-metal charge transfer band region in the CD spectra. The rotaxanes always showed apparently *ΔΔ*-rich CD spectra, the highest selectivity(10% *ΔΔ*-rich) being found in the case of n=10.

α-Cyclodextrin (CDX) has the hydrophobic cavity and is an excellent host molecule for a great variety of guest molecules.[2] Using this inclusion property of CDX, Ogino first prepared the novel cobalt(III) rotaxane complexes.[3] We recently prepared similar rotaxanes consisting of a dinuclear cobalt(III) complex [(en)$_2$Co{NH$_2$(CH$_2$)$_2$S(CH$_2$)$_n$S(CH$_2$)$_2$NH$_2$}Co(en)$_2$]$^{6+}$ (n=8, 10, and 12) and α- or β-CDX starting from a mononuclear thiolato complex [Co(aet)(en)$_2$]$^{2+}$ (Haet =2-aminoethanethiol, NH$_2$CH$_2$CH$_2$SH).[1] Interestingly, the rotaxanes showed the partial stereoselectivity, which led to the relatively higher yield of *ΔΔ*-rotaxanes as compared with that of *ΛΛ*-rotaxanes.

In this paper, another thiolato complex [Co(maa)-(en)$_2$]$^+$ (H$_2$maa=mercaptoacetic acid, HSCH$_2$CO$_2$H) was used as a starting material for the synthesis of [2]-[[(en)$_2$Co{XCH$_2$S(CH$_2$)$_n$SCH$_2$Y}Co(en)$_2$]Cl$_m$]-[α-CDX].[4] As shown in Fig. 1, the preparation was carried out for the two kinds of rotaxanes: X=Y=CO$_2^-$ (m=4), and X=CO$_2^-$ and Y=CH$_2$NH$_2$(m=5). The bridging quadridentate ligands are abbreviated to dtda for n=8 (X=Y=CO$_2^-$): 3,12-dithiatetradecanedioic acid; dhda for n=10 (X=Y=CO$_2^-$): 3,14-dithiahexadecanedioic acid; doda for n=12 (X=Y=CO$_2^-$): 3,16-dithiaoctadecanedioic acid; and adha for n=10 (X=CO$_2^-$ and Y=CH$_2$NH$_2$): 16-amino-3,14-dithiahexadecanoic acid. The cobalt(III) rotaxanes and the bridged complexes (=dinuclear complexes without α-CDX) were characterized from the elemental analysis, absorption, circular dichroism(CD) and ^{13}C NMR spectra. The optically active *ΔΔ*- and *ΛΛ*-rotaxanes were also prepared starting from the resolved mononuclear complexes.

Experimental

Preparation and Separation of Complexes. rac-, Δ'-, *and* Λ'-*[Co(aet)(en)$_2$]ClO$_4$*:[5] This complex was prepared and optically resolved according to the published procedure.[6]

rac-, Δ- *and* Λ-*[Co(maa)(en)$_2$]ClO$_4$*: The racemate was prepared according to the literature[6] and used as a starting material. The perchlorate salt was converted into the chloride by the use of QAE-Sephadex A-25 (Cl$^-$ form).

Optical resolution of this complex was attempted using resolving agents such as K$_2$[Sb$_2$(*d*-tart)$_2$]·3H$_2$O, Ag(*d*-H$_3$tart), NH$_4$(*d*-BCS), K[Co(edta)]·2H$_2$O, and Na(*d*-HDBT) (abbrev: *d*-H$_3$tart$^-$=hydrogen (*R*,*R*)-tartrate(1−), *d*-BCS$^-$=(1*R*,3*S*,-4*S*,7*R*)-3-bromocamphor-9-sulfonate, edta^{4-}=ethylenediaminetetraacetate (4−), and *d*-HDBT$^-$=hydrogen (*R*,*R*)-di-*O*-benzoyltartrate(1−)), only the last resolving agent leading to the successful result. The racemic complex [Co(maa)(en)$_2$]Cl (10.6 g, 35 mmol) was dissolved in 150 cm^3 of water. To this solution was added dropwise a solution of Na(*d*-HDBT) (19 mmol), which was previously prepared from 7.2 g of *d*-H$_2$DBT and 0.7 g of NaOH in 200 cm^3 of water at 50 °C. The mixture was allowed to stand at room temperature for overnight with stirring. The less soluble diastereomer $(-)^{CD}_{543}$-[Co(maa)(en)$_2$](*d*-HDBT) was filtered off and washed with water and then ethanol. The filtrate was later used for gaining $(+)^{CD}_{543}$-antipode. The excess of QAE-Sephadex A-25 (Cl$^-$ form) resin was added to a suspension of the diastereomer, and the mixture was stirred for 1 h. The resultant dark violet solution was collected by filtration and 6 g of NaClO$_4$ was added to it to yield the crystals of $(-)^{CD}_{543}$-[Co(maa)(en)$_2$]ClO$_4$. This was recrystallized by dissolving in a minimum amount of water, adding NaClO$_4$, and filtering. The yield was 3 g. $\Delta\varepsilon^{CD}_{543}$=−2.32. Found: C, 19.49; H, 4.93; N, 15.29%. Calcd for *Δ*-[Co(maa)(en)$_2$]ClO$_4$=C$_6$H$_{18}$N$_4$SO$_6$ClCo: C, 19.55; H, 4.92; N, 15.20%. The initial filtrate was condensed to *ca.* 130 cm^3 by rotaevaporation at 30 °C and 2 g of NaClO$_4$ was added to it. The first crystals deposited (2.5 g) were almost racemate and removed by filtration. Further addition of NaClO$_4$ (*ca.* 4 g) gave the desired $(+)^{CD}_{543}$-[Co(maa)(en)$_2$]ClO$_4$. The yield was 3.5 g. $\Delta\varepsilon^{CD}_{543}$=+2.32. Found: C, 19.55; H, 4.89; N, 15.19%. Calcd for *Δ*-[Co(maa)(en)$_2$]ClO$_4$=C$_6$H$_{18}$N$_4$SO$_6$ClCo: C, 19.55; H,4.92; N, 15.20%.

Δ- *and* Λ-*[Co{O$_2$CCH$_2$S(CH$_2$)$_{10}$Br}(en)$_2$]ClO$_4$)Br.* To 12 cm^3 of DMSO (dimethyl sulfoxide) solution containing *Δ*- or *Λ*-[Co(maa)(en)$_2$]ClO$_4$(2 g) was added 3.25 g of 1,10-dibromodecane, and then the mixture was kept at 30 °C for 2 d. The unreactive 1,10-dibromodecane was removed by extraction with diethyl ether for several times. To the resultant dark

red oil was added *ca.* 20 cm^3 of water. The precipitate of the desired product appeared immediately and then was filtered off and washed with water, ethanol, and diethyl ether. This complex was sparingly soluble in water but very soluble in DMSO, and used as a starting material for the preparation of adha rotaxanes described later. Found for the *Δ*-complex: C, 28.99; H, 5.85; N, 8.05%. Found for *Λ*-complex: C, 28.80; H, 5.85; N, 8.05%. Calcd for $[Co\{O_2CCH_2S(CH_2)_{10}Br\}(en)_2](ClO_4)Br=C_{16}H_{38}N_4SO_6ClBrCo$: C, 28.74; H, 5.73; N, 8.38%.

*[2]-[[(en)₂Co(dtda)Co(en)₂]Cl₄]-[α-CDX]-rotaxane (**R1**) and [(en)₂Co(dtda)Co(en)₂]Cl₄ (**B1**).* The starting materials of *rac*-$[Co(maa)(en)_2]ClO_4$ (1.4 mmol) and 1,8-dibromooctane (0.84 mmol, 20% excess) were dissolved in 4 cm^3 of DMSO containing 1.25 g of *α*-CDX. The mixture was kept at 30 °C for 7 d, leading to the red solution. The unreactive dibromooctane was extracted into diethyl ether. The resultant red oil was dissolved in water, adsorbed onto a cation exchange column (SP-Sephadex C-25, Na^+ form) and eluted with 0.3 mol dm^{-3} NaCl. Six colored bands, f1—f6, were eluted in this order. The species f2(dark violet), f4(red), f5(red), and f6(red) were assigned to $[Co(maa)(en)_2]^+$, $[Co\{O_2CCH_2S(CH_2)_8Br\}(en)_2]^{2+}$, [2]-$[(en)_2Co(dtda)Co(en)_2]^{4+}$-[*α*-CDX]-rotaxane, and $[(en)_2Co(dtda)Co(en)_2]^{4+}$, respectively. The other red bands f1 and f3 were remained unknown. The eluate from the red band f6 was evaporated to a small volume. After repeated removal of NaCl deposited out, a large amount of ethanol was added to it. The resultant solution was refrigerated for 2—3 d at −15 °C. The supernatant solution was discarded, and then the precipitate was washed with ethanol several times and filtered off. Found for **B1**; C, 29.41; H, 7.09; N, 12.39%. Calcd for $[(en)_2Co(dtda)Co(en)_2]Cl_4\cdot C_2H_5OH\cdot 3.5H_2O=C_{22}H_{65}N_8S_2O_{8.5}Cl_4Co_2$: C, 29.31; H, 7.27; N, 12.43%. The rotaxane **R1** was not isolated as a solid but the yield was 3.3±0.5% (the mean for 2 preparations). The band of the rotaxane showed apparently *ΔΔ*-rich CD spectra (*ca.* 2% rich).[6]

*[2]-[ΔΔ-[(en)₂Co(dtda)Co(en)₂]Cl₄]-[α-CDX]-rotaxane (**R2**) and ΔΔ-[(en)₂Co(dtda)Co(en)₂]Cl₄ (**B2**):* These complexes were prepared and chromatographed by the same procedure as **R1** and **B1** except for the use of *Δ*-$[Co(maa)(en)_2]ClO_4$ instead of the racemate. The yield was 2.5±0.5% for **R2** and 60±5% for **B2**. Found for **R2**; C, 34.07; H, 6.73; N, 5.76%. Calcd for [2]-[*ΔΔ*-$[(en)_2Co(dtda)Co(en)_2]Cl_4$]-[*α*-CDX]-rotaxane·$11H_2O=C_{56}H_{134}N_8S_2O_{45}Cl_4Co_2$: C, 34.26; H, 6.88; N, 5.71%. Found for **B2**; C, 26.90; H, 7.01; N, 12.32%. Calcd for *ΔΔ*-$[(en)_2Co(dtda)Co(en)_2]Cl_4\cdot 0.2C_2H_5OH\cdot 6H_2O=C_{20.4}H_{65.2}N_8S_2O_{10.2}Cl_4Co_2$: C, 26.93; H, 7.22; N, 12.32%.

[2]-[[(en)₂Co(dhda)Co(en)₂]Cl₄]-[α-CDX]-rotaxane (***R3***) *and [(en)₂Co(dhda)Co(en)₂]Cl₄ (**B3**):* These complexes were prepared and chromatographed in the same manner as **R1** and **B1** except for the use of 1,10-dibromodecane instead of 1,8-dibromooctane. In the separation seven bands f1′—f7′ were eluted in this order. The species f3′(dark violet), f5′(red), f6′(red), and f7′(red) were assigned to $[Co(maa)(en)_2]^+$, [2]-$[(en)_2Co(dhda)Co(en)_2]^{4+}$-[*α*-CDX]-rotaxane, $[Co\{O_2CCH_2S(CH_2)_{10}Br\}(en)_2]^{2+}$, and $[(en)_2Co(dhda)Co(en)_2]^{4+}$, respectively. Three species f1′(pink), f2′(red), and f4′(pink) were unassignable as yet. When the eluate f2′ was allowed to stand for several days at room temperature, white precipitate of *α*-CDX was deposited. Therefore, this species is inferred as an inclusion compound of $[Co\{O_2CCH_2S(CH_2)_{10}Br\}(en)_2]^{2+}$ and *α*-CDX from the analogy of $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_{10}Br\}]Cl_3\cdot 2$(*α*-CDX) reported previously.[1] The yield was 9.6±2% for **R3** and 47±4% for **B3** (3 preparations). In this system, pronounced selectivity was observed[7]: The band f5′ showed apparently *ΔΔ*-rich (*ca.* 10%) CD spectra and f7′ *ΛΛ*-rich (*ca.* 3%). Found for **R3**; C, 34.98; H, 6.80; N, 5.55%. Calcd for [2]-[$[(en)_2Co(dhda)Co(en)_2]Cl_4$]-[*α*-CDX]-rotaxane·$0.2C_2H_5OH\cdot 11H_2O=C_{58.4}H_{139.2}N_8S_2O_{45.2}Cl_4Co_2$: C, 35.06; H, 7.01; N, 5.60%. Found for **B3**; C, 29.83; H, 7.07; N, 12.36%. Calcd for $[(en)_2Co(dhda)Co(en)_2]Cl_4\cdot 0.2C_2H_5OH\cdot 4H_2O=C_{22.4}H_{65.2}N_8S_2O_{8.2}Cl_4Co_2$: C, 29.83; H, 7.29; N, 12.43%.

*[2]-[ΔΔ-[(en)₂Co(dhda)Co(en)₂]Cl₄]-[α-CDX]-rotaxane (**R4**), ΔΔ-[(en)₂Co(dhda)Co(en)₂]Cl₄ (**B4**), [2]-[ΛΛ-[(en)₂Co(dhda)Co(en)₂]Cl₄]-[α-CDX]-rotaxane (**R5**), and ΛΛ-[(en)₂Co(dhda)Co(en)₂]Cl₄ (**B5**):* These complexes were prepared and chromatographed in the same manner as **R3** and **B3** except for the use of *Δ*- or *Λ*-$[Co(maa)(en)_2]ClO_4$ instead of the racemate. The yield was 12% for **R4** and 52% for **B4** in the *Δ*-system (1 preparation), and 7% for **R5** and 49% for **B5** in the *Λ*-system (1 preparation). Found for **R4**; C, 36.14; H, 6.98; N, 5.38%. Calcd for [2]-[*ΔΔ*-$[(en)_2Co(dhda)Co(en)_2]Cl_4$]-[*α*-CDX]-rotaxane·$2C_2H_5OH\cdot 9.5H_2O=C_{62}H_{147}N_8S_2O_{45.5}Cl_4Co_2$: C, 36.21; H, 7.20; N, 5.45%. Found for **R5**; C, 32.55 H, 6.35; N, 5.01%. Calcd for [2]-[*ΔΔ*-$[(en)_2Co(dhda)Co(en)_2]Cl_4$]-[*α*-CDX]-rotaxane·$4NaCl\cdot 1.3C_2H_5OH\cdot 8H_2O=C_{60.6}H_{139.8}N_8S_2O_{43.3}Cl_8Na_4Co_2$: C, 32.62; H, 6.32; N, 5.02%. In the case of **B4** or **B5**, the addition of ethanol to the concentrated eluate yielded the gelatinous precipitate, which contained a large amount of NaCl. Therefore, no satisfactory analytical data were obtained for **B4** and **B5**. The concentrations of their CD spectra were calculated by reference to the molar absorption coefficient of the corresponding racemate **B3**.

*[2]-[ΔΛ-[(en)₂Co(dhda)Co(en)₂]Cl₄]-[α-CDX]-rotaxane (**R6**) and ΔΛ-[(en)₂Co(dhda)Co(en)₂]Cl₄ (**B6**):* These complexes were prepared from *Δ*-$[Co\{O_2CCH_2S(CH_2)_{10}Br\}(en)_2](ClO_4)Br$ (1.3 mmol), *Λ*-$[Co(maa)(en)_2]ClO_4$ (1.4 mmol), and *α*-CDX (2.5 g) in DMSO (8 cm^3). The reaction and separation conditions were the same as those for **R3** and **B3**. The yield was 8.8% for **R6** and 46% for **B6** (1 preparation). Found for **R6**; C, 35.13; H, 6.93; N, 5.43%. Calcd for [2]-[*ΔΛ*-$[(en)_2Co(dhda)Co(en)_2]Cl_4$]-[*α*-CDX]-rotaxane·$C_2H_5OH\cdot 12H_2O=C_{60}H_{146}N_8S_2O_{47}Cl_4Co_2$: C, 35.06; H, 7.16; N, 5.45%. corresponding bridged complexes. The ratios C/N in these complexes are somewhat higher than the ideal values because a large amount of ethanol was used for the isolation of them. It seems that the high ability of adduct formation with organic solvent is common in the present complexes with the hydrophobic polymethylene bridging atoms.

Table 1 collects the absorption and CD data of the present complexes. The representative absorption and CD spectra of the rotaxanes and the bridged complexes are shown in Figs. 2 and 3, respectively, together with those of dhdd complexes (n=10, X=Y=CH_2NH_2) for comparison. The starting thiolato complex [Co(maa)-

sorption, they contain only thioether donor atoms as sulfur atom. The first spin-allowed d-d absorption bands of the rotaxanes with the bridging methylene chain length $n=10$ gradually red-shift with the increase of oxygen atom, locating at 20440 cm^{-1} for the dhdd rotaxane with $2[Co(N)_5(S)]$ chromophore, at 20250 cm^{-1} for the adha one with $[Co(N)_5(S)]$ and $[Co(N)_4(S)(O)]$, and 20020 cm^{-1} for the dhda one with $2[Co(N)_4(S)(O)]$ (Fig. 2). The intense bands at *ca.* 35000 cm^{-1}, which can be assigned to the $Co(\sigma^*)\leftarrow S(\sigma)$ ligand-to-metal charge transfer (LMCT) band,[9] show apparently no such shift. The LMCT band intensity of the adha rotaxane is intermediate between those of the dhdd and dhda rotaxanes. Such a mean behavior of the adha rotaxane is also realized in the CD spectra. The absolute configurations of the present complexes can be assigned on the basis of the net CD sign in the first spin-allowed d-d absorption band region, that is, *Δ*-configuration for negative and *Λ*-one for positive.[1,6] The bridged complexes (Fig. 3) show the analogous absorption and CD spectral changes as the corresponding rotaxanes.

The rotaxanes prepared from *rac*-$[Co(maa)(en)_2]^+$ are each the mixture of four diastereomers, *ΔΔ*-, *ΛΛ*-, and two *ΔΛ*-forms (pseudo-*meso*) with respect to the bridged cobalt(III) moieties(neglecting the *R* and *S* chiralities of the donor sulfur atoms).[1] The optically active *ΔΔ* (or *ΛΛ*) rotaxane could be obtained in a pure form from the resolved starting material *Δ*(or *Λ*)-$[Co(maa)(en)_2]ClO_4$. The CD spectra of the dhda and adha rotaxanes are shown in Figs. 4(a) and 4(b), respectively. The CD spectra of the *ΔΔ*- and *ΛΛ*-rotaxanes are not completely enantiomeric to each other in each pair of diastereomers. The deviation is eminent by comparing the diastereomers in the CD intensity ratio,

$\Delta\varepsilon_{LMCT}/\Delta\varepsilon_{I}$, where $\Delta\varepsilon_{I}$ and $\Delta\varepsilon_{LMCT}$ denote the CD peak intensities in the first d-d absorption and LMCT band (*ca.* 35000 cm^{-1}) regions, respectively: The ratio is 3.25 for *ΛΛ*-dhda (**R5**) and 3.49 for *ΔΔ*-dhda (**R4**) rotaxanes, and 3.02 for *ΛΛ*-adha (**R11**) and 3.70 for *ΔΔ*-adha (**R10**) rotaxanes. It is noteworthy that all the ratios in the rotaxanes are higher than those of the corresponding bridged complexes, namely, 3.14 for dhda bridged complex (**B4**) and 2.85 for adha bridged one (**B10**). This is correlated with the sterically crowded structure of the rotaxane containing α-CDX as compared with the corresponding bridged complexes. The ratio becomes a measure to distinguish between the rotaxane and the bridged complex by the CD spectra.

^{13}C NMR Spectra. Figure 5 shows the ^{13}C NMR spectra of the bridged complexes with $n=10$. The dhdd and dhda complexes with C_2 symmetry clearly shows four resonances in the $-C(CH_2)_8C-$ region. The adha complex with C_1 symmetry exhibited the intermediate pattern. The ^{13}C NMR spectra of rotaxanes are quite different from the bridged complexes, giving the direct evidence of the rotaxane formation with α-CDX (Figs. 6—10). The rotaxane **R8** exhibited strong six signals in a low magnetic field (δ=60—105), which were assigned to α-CDX moiety[1] (Fig. 6). The other signals were assigned to $CH_2\underline{C}O_2^-$ (δ=*ca.* 182.7) and methylene carbons (δ=25—50) of $NH_2\underline{C}H_2-$, $-S\underline{C}H_2-$, and $-C(\underline{C}H_2)_{n-2}C-$ from the lower megnetic field side. The rotaxanes **R8** (Fig. 6) and **R9** (Fig. 7(a)) are composed of a single diastereomer, which has a C_1 symmetry because of the inequality of both openings of α-CDX. In the $-C(CH_2)_{10}C-$ region, they showed four strong (δ=31.75, 30.94, 29.32, and 28.72 for **R9**) and two weak (δ=32.13 and 30.45 for **R9**) resonances. Since it is reasonable to consider that each of the strong signals corresponds to two methylene carbons, the total number of the methylene resonances becomes ten in both the rotaxanes as expected. The results are consistent

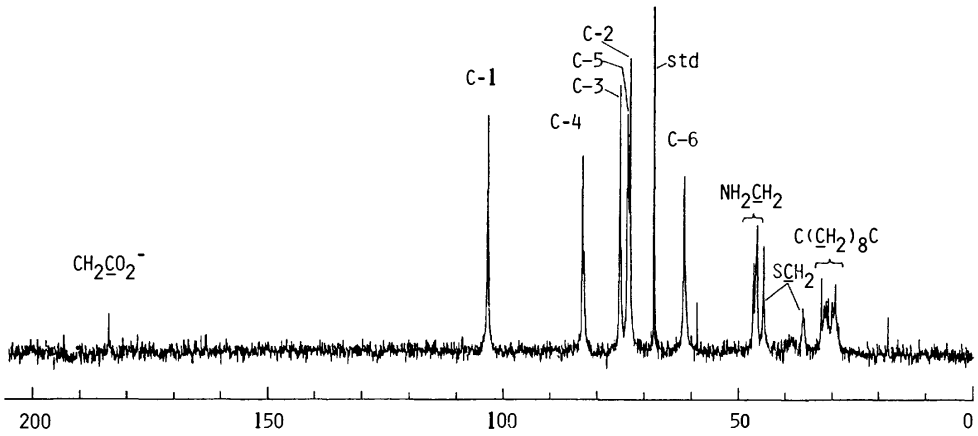

Fig. 8. ^{13}C NMR spectra of the rotaxane **R4**.

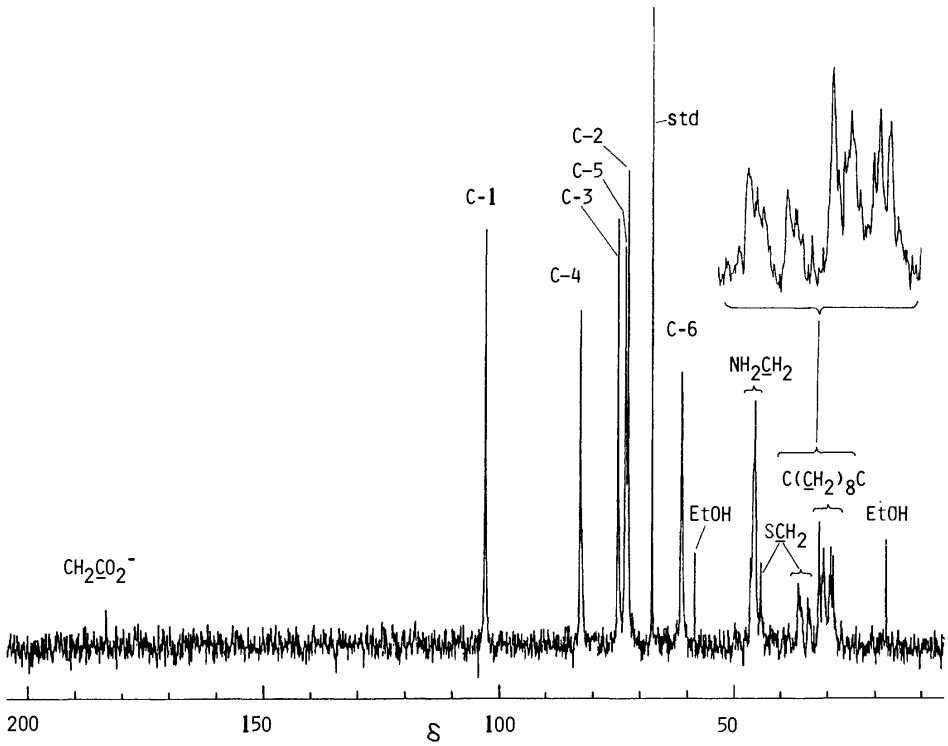

Fig. 9. ^{13}C NMR spectra of the rotaxane **R10**.

with the formation of the rotaxane with C_1 symmetry.

The characteristic features of ^{13}C NMR spectra are the same in the rotaxanes with $n=10$ (**R4** in Fig. 8 and **R10** in Fig. 9) and $n=8$ (**R2** in Fig. 10). However, a significant spectral change was observed in **R2**; two signals for each of C4, C5, and C6 in α-CDX appeared during the first several hours (Fig. 10(a)) and the higher field component in each pair became dominant with time (Fig. 10(b)). None of the final resonances corresponded to the chemical shifts of the free α-CDX. The absorption and CD spectra of the same sample after the ^{13}C NMR measurement were checked to elucidate the origin of such a change. The absorption spectrum was the same as the initial one except for the *ca.* 11% intensity decrease in the LMCT region. The pattern of the CD spectrum was the same but the CD intensity reduced to one-half its initial value. The results indicate that the decomposition reaction releasing free α-CDX does not occur and that the species with the uncoordinated thioether atoms, which will be formed by the Co-S cleavage, is also very low in concentration, if any, as judged by the absorption intensity in LMCT region. The most plausible explanation may be that the species with the uncoordinated carboxyl group in $-SCH_2CO_2$ moiety is partly produced owing to the steric crowding imposed by α-CDX. In fact, the ^{13}C-NMR change with time is most eminent only in **R2** with rather short chain length $n=8$. Such a splitting is observed only for C4 carbon in **R4** and **R10** with $n=10$ and the rotaxanes with $n=12$ had no splitting tendency.

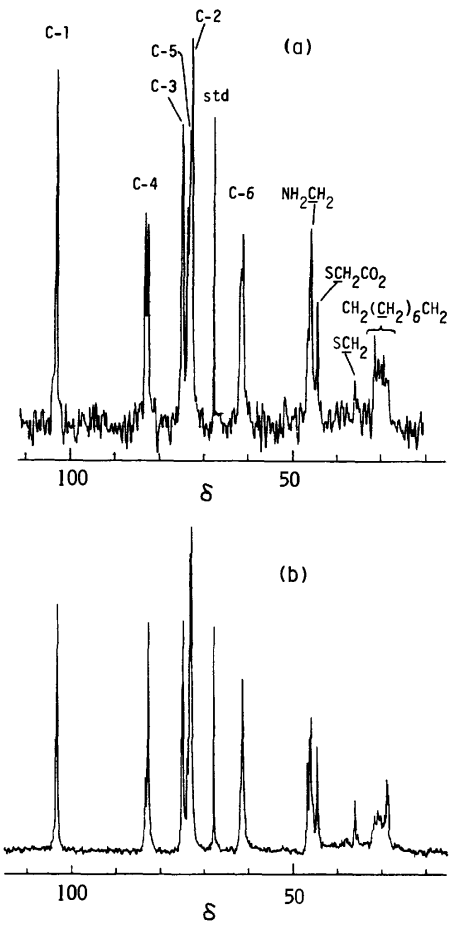

Fig. 10. ^{13}C NMR spectra of the rotaxane **R2**: (a) accumulated for *ca.* 6h after dissolution in D_2O; (b) accumulated for *ca.* 20h after dissolution in D_2O.

The chemical shifts due to α-CDX in the rotaxanes are summarized in Table 2. The assignment is after Colson *et al.*[10] and our results.[1] The chemical shifts of free α-CDX were significantly altered by the rotaxane formation, especially those of C1, C3, and C5 shifting to the down field. One of the substituent groups on each of the carbons undergoing such a large shift is directed toward the center part of the cavity of α-CDX and sterically interacted with the included polymethylene chain. This situation is responsible for the above shift. The values of the rotaxanes **R3**, **R4**, **R5**, and **R6** are very similar to one another irrespective of the absolute configurations of the cobalt(III) moieties, which is in good agreement with the earlier results.[1] The change of the bridging methylene length, however, affects the chemical shift. The resonances of C4, C5, and C6 were shifted regularly to the down field with the decrease of the methylene chain length from $n=ca.$ 17 to $n=7$,[11] whereas the chemical shifts of C1, C2, and C3 were hardly affected. The latter is relevant to the rigid hydrogen bonding network at the side of secondary hydroxyl groups on C2 and C3,[12] which makes the chemical shifts of C1, C2, and C3 insensitive to the

change of the bridging length. On the other hand, the hydroxyl group at C6 can rotate freely and is sensitive to the steric change. Such a steric change at C6 also influences the chemical shifts of C4 and C5. Thus, the rotaxan formation is explicitly identified by the ^{13}C NMR spectra.

Synthesis and Stereoselectivity. The yields of rotaxanes are summarized in Table 3, together with the earlier results for comparison. The yield is the highest in the doda rotaxanes with n=12 and decreases with the decrease of the chain length, namely, in the order 12>10>8. The $\Delta\Delta$-rotaxane was prepared in the highest yield among the rotaxanes with the identical chain length. This is attributable to the stereoselective inclusion by α-CDX.[13] The results are very similar to those for the earlier system (X=Y=CH$_2$NH$_2$) except for that the yields starting from the racemate are somewhat higher in the present system (X=Y=CO$_2^-$).

The highest selectivity was *ca.* 10% in the dhda rotaxane **R3**. The partial selectivity was also observed in the other rotaxanes **R1** and **R7**. It should be noted that the selectivity decreases in the order 10>12>8. This means that there is the optimum methylene length for the chiral discrimination. The rotaxanes of the present system (X=Y=CO$_2^-$, and X=CO$_2^-$ and Y=CH$_2$NH$_2$) are relatively unstable compared with those in the earlier system (X=Y=CH$_2$NH$_2$), because it was observed that the former underwent the partial racemization in the prolonged column chromatography. In conclusion, the yield and the selectivity of rotaxane are mainly dependent on the length of the bridging methylene chain and the absolute configuration of the starting cobalt(III) complex. The difference between the bidentate thiolate ligands aet and maa has a small influence on the yield and the selectivity of rotaxane.

Photochemical Reaction of Phenyl-substituted 1,3-Diketones

Michikazu YOSHIOKA,* Tsuneji SUZUKI, and Masashi OKA
Department of Chemistry, Faculty of Science, Saitama University, Shimo-okubo, Urawa, Saitama 338
(Received October 4, 1983)

Irradiation of 2,2-dimethyl-1-phenyl-1,3-diketones with 3-ethyl or 3-isopropyl substituents gave type II cyclization product, 3-hydroxy-2,2,4-trimethyl-3-phenylcyclobutanone or 3-hydroxy-2,2,4,4-tetramethyl-3-phenylcyclobutanone, along with type I cleavage products. The type II cyclization/type I cleavage ratio is greater with a 3-isopropyl group than with a 3-ethyl group. A similar irradiation of 2,2-dimethyl-1-phenyl-1,3-butanedione gave type I cleavage products and no type II cyclization product. Irradiation of 2,4-dimethyl-1-phenyl-1,3-pentanedione gave 3-hydroxy-2,2,4-trimethyl-3-phenylcyclobutanone and propiophenone. The geometry of 3-hydroxy-2,2,4-trimethyl-3-phenylcyclobutanone which arose from 2,2-dimethyl-1-phenyl-1,3-pentanedione was cis with respect to phenyl and 4-methyl groups and that which arose from 2,4-dimethyl-1-phenyl-1,3-pentanedione was trans.

Two major photochemical processes, Norrish type I and Norrish type II, have been widely studied.[1] The type II process is the most common photoreaction of monoketones with γ-hydrogens in the alkyl chain. However, in the case of 1,3-diketones, no example of type II photoreaction where an α-hydrogen to one carbonyl group undergoes 1,5-shift to another carbonyl oxygen has been found. Non- or difficultly-enolizable aliphatic 1,3-diketones have been found to undergo type I cleavage.[2] The photochemistry of aromatic 1,3-diketones has been studied for 3-aroylchromones[3] and 2-diaza-1-aryl-1,3-diketone compounds.[4] Little attention has been given to aromatic 1,3-diketones with an sp^3 carbon α to both carbonyl groups.[5] Since, for the same electronic and spin configuration, aryl alkyl ketones undergo type I cleavage more slowly than the analogous dialkyl ketones,[6] 1-aryl-3-alkyl-1,3-diketone compounds may undergo type II photoreaction where the aromatic carbonyl oxygen abstracts a hydrogen from the α-carbon on the 3-alkyl substituent, in competition with type I cleavage. In this paper, we report the photochemistry of 1-phenyl-3-alkyl-1,3-diketone compounds.

Results and Discussion

An acetonitrile solution of 2,2,4-trimethyl-1-phenyl-1,3-pentanedione (**1a**) was irradiated under nitrogen with a Pyrex filter. After removal of the solvent, 3-hydroxy-2,2,4,4-tetramethyl-3-phenylcyclobutanone (**2a**), isobutyrophenone (**3**), enol ester (**4a**), and 1,4-diketone (**5a**) were isolated by silica gel chromatography. A similar reaction was found to occur with 2,2-dimethyl-1-phenyl-1,3-pentanedione (**1b**). As shown in Table 1, the yield of **2** was higher with **1a** than with **1b**, and the yields of **4** and **5** were lower with **1a** than with **1b**. Irradiation of 2,2-dimethyl-1-phenyl-1,3-butanedione (**1c**) gave isobutyrophenone (**3**), enol ester (**4c**), and 1,4-diketone (**5c**), along with benzaldehyde and benzoic acid. In this case, no hydroxycyclobutanone was detected. Similar irradiation of 2,4-dimethyl-1-phenyl-1,3-pentanedione (**1d**) gave propiophenone (**3d**) and 3-hydroxy-2,2,4-trimethyl-3-phenylcyclobutanone (**2d**) which was a geometrical isomer of **2b**, along with several

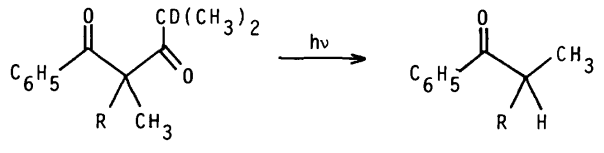
unidentified products. The structures of **2a**, **2b**, and **2d** were based on their spectroscopic and analytical properties and further supported by chemical evidence. The IR spectra showed a four-membered carbonyl band at 1770—1775 cm^{-1} and a hydroxyl band at 3600 cm^{-1}. The ^1H NMR spectrum of **2a** showed singlets at δ 1.38 and 1.40 due to four methyl groups, a singlet at δ 1.91 due to a hydroxyl group, and a singlet at δ 7.32 due to aromatic protons. This simple pattern is caused by the symmetry of the molecule. Compound **2a** underwent cycloreversion reaction to **1a** on heating at 150 °C or by treatment with aqueous sodium hydroxide. This chemical behavior strongly supports the proposed structure for **2a**. The ^1H NMR spectra of **2b** and **2d** resemble each other in their splitting patterns except for the aromatic protons, suggesting that they are geometrical isomers with respect to the phenyl and 4-methyl groups. In the spectrum of **2b**, the signal due to the aromatic protons appeared as a multiplet between δ 7.1—7.4, being consistent with the proposed structure in which the phenyl group was restricted to rotate by virtue of its cis-relationship to two methyl groups on C_2 and C_4. Whereas, in the spectrum of **2d**, the aromatic protons appeared as a singlet at δ 7.36. Compound **2b** underwent cycloreversion reaction to **1b** and **1d** in a ratio of 1:2 by heating at 150 °C, but **2d** converted mostly to **1d** under the same reaction conditions. The IR spectra of **4a—c** showed a strong band at 1730—1735 cm^{-1} due to ester carbonyl. The ^1H NMR spectra of **4a** and **4b** showed two singlets at the region between δ 1.5—1.8 due to two methyl groups attached to olefinic carbon atoms. The ^1H NMR spectrum of **4c** showed three singlets at δ 1.55, 1.75, and 1.95 due to three methyl groups attached to olefinic carbon atoms. These spectroscopic properties are consistent with the proposed structures for **4a—c**. The structures of **5a—c** were unambiguously assigned by their IR and NMR spectra.

The formation of **2** can best be explained by type II cyclization which involves 1,5-hydrogen shift from C_4 to the carbonyl oxygen on C_1. The product **3** may be formed by a type II elimination process or by a type I cleavage of the C_2-C_3 bond. It is known that α-diketones[7] and β,γ-unsaturated ketones[8] with γC-H bonds undergo type II cyclization and no type II elimination. The lack of elimination has been attributed to the perpendicular orientation of the p orbital on one radical site relative to the C_2-C_3 σ bond in the 1,4-biradical intermediate. In the 1,4-biradical formed from 1,3-diketone **1**, the C_4 radical site is allylic such that its π-system is completely perpendicular to the C_2-C_3 bond. This suggests that the 1,4-biradical will result in the formation of the cyclization product.



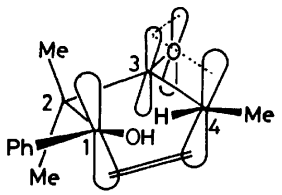
1d-d_1 R=H 3d R=H

1d-d_2 R=D 3d-d_1 R=D

Scheme 2.

Thus, **3** probably arises from a type I cleavage. In order to provide experimental information for the formation of **3**, photolysis of 2,4-dimethyl-1-phenyl-1,3-pentanedione-4-d_1 (**1d**-d_1) and 2,4-dimethyl-1-phenyl-1,3-pentanedione-2,4-d_2 (**1d**-d_2) was investigated. Photolysis of **1d**-d_1 in benzene gave propiophenone (**3d**) and not its deuterio derivative. Similar irradiation of **1d**-d_2 gave propiophenone-α-d_1 (**3d**-d_1) and no α,α-dideuterio derivative. These results suggest that **3** may arise from a type I cleavage.

It is noteworthy that **2b** and **2d** are geometrical isomers with respect to the phenyl and the 4-methyl groups. The ^1H NMR spectra of the irradiation mixtures showed no evidence for the formation of **2d** from **1b** and **2b** from **1d**. Lewis and Hilliard studied[9] the photochemistry of methyl-substituted 1-phenyl-1-butanones. They reported that both 2-methyl-1-phenyl-1-butanone and 1-phenyl-1-pentanone form 2-methyl-1-phenylcyclobutanol; however, only the trans isomer with respect to the phenyl and methyl groups is observed for 2-methyl-1-phenyl-1-butanone, whereas a 3.1:1 trans: cis ratio is observed for 1-phenyl-1-pentanone. They explained the specificity of 2-methyl-1-phenyl-1-butanone by a repulsive interaction of the phenyl and α-methyl groups in the 1,4-biradical. The interaction between the phenyl and γ-methyl groups in the 1,4-biradical was regarded as being small until the 1,4-bond is almost completely formed. The formation of *r*-3-hydroxy-2,2,*c*-4-trimethyl-3-phenylcyclobutanone **2d** from **1d** is consistent with their results. However, the preferential formation of *r*-3-hydroxy-2,2,*t*-4-trimethyl-3-phenylcyclobutanone **2b** rather than the corresponding 2,2,*c*-4-trimethyl isomer **2d** from **1b** is not expected. In the 1,4-biradical from **1b**, the methyl group on the C_4 radical site is probably trans to the C_2-C_3 bond owing to the steric effect,and the rotation of the C_1-C_2 bond is probably hindered by the interactions between the phenyl and α,α-dimethyl groups. Therefore, the transition state for cyclization of the 1,4-biradical from **1b** is pertinently depicted as **6** and results in the formation of **2b**.



6

Scheme 3.

The formation of **4** and **5** is explained by combination of radicals resulting from type I cleavage. Diketones **1a**, **1b**, and **1c** vary only at C_4. The photochemical results of **1a—c** indicate that as the C_4-H bond strength increases the type II cyclization decreases with increasing type I cleavage. Thus, as expected, appropriate 1-phenyl-1,3-diketones with 3-alkyl substituent undergo type II cyclization *via* 1,5-hydrogen shift from carbon atom α to aliphatic carbonyl group to the aromatic carbonyl oxygen, in competition with type I cleavage. Finally, both cyclization and α-

cleavage were completely quenched by 1,3-pentadiene suggesting a triplet state reaction.

Experimental

All melting points were uncorrected. ^{1}H NMR spectra were recorded on a Varian A-60D or a JEOL FX-90Q spectrometer with tetramethylsilane as an internal standard. ^{13}C NMR spectra were recorded on a JEOL FX-90Q spectrometer. IR spectra were recorded on a JASCO IRA-2 spectrometer. GLC analyses and preparative purification were performed on a Hitachi K-53 instrument using Silicone SE-30 as the stationary phase. Irradiations were carried out with an Ushio UM-452 high-pressure mercury lamp (450 W) or a Rikoh Kagaku UVL-100 high-pressure mercury lamp (100 W) with a water-cooled Pyrex jacket. For column chromatography, Wakogel C-300 or Merck Silica Gel 60 Art. 7734 was used.

Materials. Phenyl 1,3-diketones **1a—c** were prepared by condensation of isobutyrophenone with the corresponding aliphatic aldehydes using methylanilinomagnesium bromide as the condensing agent,[10] followed by chromium(VI) oxide oxidation. Similarly, **1d** was prepared from propiophenone and isobutyraldehyde. Compound **1a** was also prepared by a similar procedures from 2,4-dimethyl-3-pentanone and benzaldehyde. The deuterio derivatives (**1d**-d_1 and **1d**-d_2) of **1d** were prepared as follows. A mixture of 400 mg of **1d**, 100 mg of TsOH, 4 cm^3 of D_2O, and 4 cm^3 of dioxane was heated under reflux for 70 h. The solvent was evaporated, and the residue was extracted with ether. A usual work-up and purification by GLC gave 2,4-dimethyl-1-phenyl-1,3-pentanedione-2,4-d_2 (**1d**-d_2). A mixture of 100 mg of **1d**-d_2, a trace amount of TsOH, 2 cm^3 of H_2O, and 2 cm^3 of dioxane was heated at 80 °C for 40 h. The same procedures as described above gave 2,4-dimethyl-1-phenyl-1,3-pentanedione-4-d_1 (**1d**-d_1).

Photolysis of 1. A typical procedure is described. A solution of 20 mmol of **1** in 400 cm^3 of acetonitrile was irradiated. The progress of the reaction was monitored by TLC and GLC. After removal of the solvent, the residue was chromatographed on silica gel eluted with a hexane–ethyl acetate mixture as eluent to give **2—5**. Compounds **2a**, **2b**, and **2d** were recrystallized from a mixture of hexane and a small amount of benzene. Compounds **3—5** were purified by preparative GLC. Yields are given in Table 1 on the basis of **1** consumed. Physical properties of the isolated products are shown bellow.

*3-Hydroxy-2,2,4,4-tetramethyl-3-phenylcyclobutanone (**2a**).* Mp 135 °C. IR ($CHCl_3$) 1775 (C=O), 3600 (OH) cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=1.38 (s, 6H, Me), 1.40 (s, 6H, Me), 1 91 (s, 1H, OH), and 7.32 (s, 5H, Ph). ^{13}C NMR ($CDCl_3$) δ=18.643 (2q), 24.452 (2q), 63.538 (2s), 79.808 (s), 127.591 (d), 128.045 (2d), 128.374 (2d), 141.362 (s), and 221.386 (s). *1-Ethyl-2-methyl-1-propenyl Benzoate (**4b**).* IR (CCl_4) 1730 (C=O) cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=1.02 (t, *J*=7.0 Hz, 3H, Me), 1.56 (s, 3H, Me), 1.74 (s, 3H, Me), 2.36 (q, *J*=7.0 Hz, 2H, CH_2), 7.3—7.7 (m, 3H, aromatic), and 8.0—8.2 (m, 2H, aromatic). ^{13}C NMR ($CDCl_3$) δ=11.581 (q), 17.626 (q), 18.406 (q), 23.350 (t), 117.969 (s), 128.374 (2d), 129.870 (2d), 130.455 (s), 132.926 (d), 144.372 (s), and 164.791 (s). Found: C, 76.34; H, 8.01%. Calcd for $C_{13}H_{16}O_2$: C, 76.43; H, 7.89%.

*1,2-Dimethyl-1-propenyl benzoate (**4c**).*[11] IR (CCl_4) 1730 (C=O) cm^{-1}. ^{1}H NMR (CCl_4) δ=1.55 (s, 3H, Me), 1.75 (s, 3H, Me), 1.95 (s, 3H, Me), 7.2—7.6 (m, 3H, aromatic), and 8.0—8.2 (m, 2H, aromatic). Found: C, 75.55; H, 7.40%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%.

*2,4,4,5,5,7-Hexamethyl-3,6-octanedione (**5a**).*[12] IR (CCl_4) 1700 (C=O) cm^{-1}. ^{1}H NMR (CCl_4) δ=1.01 (d, *J*=7.0 Hz, 12H, Me), 1.21 (s, 12H, Me), and 3.03 (hep, *J*=7.0 Hz, 2H, CH). Found: C, 73.98; H. 11.59%. Calcd for $C_{14}H_{26}O_2$: C, 74.28, H, 11.57%.

*4,4,5,5-Tetramethyl-3,6-octanedione (**5b**).* IR (CCl_4) 1700 (C=O) cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=1.00 (t, *J*=7.0 Hz, 6H, Me), 1.16 (s, 12H, Me), and 2.50 (q, *J*=7.0 Hz, 4H, CH_2). ^{13}C NMR ($CDCl_3$) δ=8.135 (2q), 22.438 (4q), 32.165 (2t), 52.679 (2s), and 215.841 (2s).

*3,3,4,4-Tetramethyl-2,5-hexanedione (**5c**).*[12] IR (CCl_4) 1700 (C=O) cm^{-1}. ^{1}H NMR (CCl_4) δ=1.14 (s, 12H, Me) and 2.05 (s, 6H, Me).

Pyrolysis of 2. Pyrolysis was done at 150 °C in a sealed Pyrex tube for 3 h. The ^{1}H NMR analysis revealed that **2a** was quantitatively converted to **1a**, **2b** was converted to a 1:2 mixture of **1b** and **1d**, while **2d** was converted to **1d** along with a trace of **1b**.

*Treatment of **2a** with Aqueous Sodium Hydroxide.* To a solution of 50 mg of **2a** in 6 cm^3 of acetone was added one drop of 2 M (1 M=1 mol dm^{-3}) sodium hydroxide. The mixture was stirred at room temperature for 4 h, acidified with 3 M hydrochloric acid, and extracted with ether. A usual work-up gave **1a** in quantitative yield.

*Irradiation of **1d**-d_1 and **1d**-d_2.* A solution of 40 mg of **1d**-d_1 in 4 cm^3 of benzene was placed in a Pyrex tube, and irradiated with a 100 W high-pressure mercury lamp for 5 h. From the irradiation mixture, unlabelled propiophenone was isolated by preparative GLC. A similar irradiation of **1d**-d_2 gave propiophenone-α-d_1.

*Irradiation of **1a,d** in the Presence of 1,3-Pentadiene.* a): A solution of 10 mg of **1a,d** in 1 cm^3 of acetonitrile was placed in a Pyrex tube. b): A solution of 10 mg of **1a,d** in 1 cm^3 of a 1:1 mixture of acetonitrile and 1,3-pentadiene was placed in a Pyrex tube. Both solutions were irradiated under the same conditions with a 100 W high-pressure mercury lamp for 5 h. The ^{1}H NMR analysis showed that no reaction occurred in the case of *b*), while complete disappearance of **1a,d** was observed in the case of *a*).

(Received October 11, 1983)

The thermal behavior of head-to-head coumarin dimers and twelve lactone-opened derivatives was investigated. Though the lactone rings in coumarin dimers are very susceptible to nucleophilic ring-opening, heating these derivatives reformed six-membered lactone rings except for certain imide and diamide derivatives. The large neiboring group effect allowed the relactonization by the attack of hydroxyphenyl group to carbonyl carbon in preference to the scission of cyclobutane ring.

Our recent studies on coumarin dimers revealed that the lactone-openig reaction of coumarin dimers[1] and the photoreaction of their lactone-opened derivatives[2,3] are as attractive as their photochemical formation which have been extensively investigated.[4-16] The large strain of the six-four-six fused ring system in coumarin dimers markedly facilitates their lactone-opening reactions by nucleophiles, permitting the smooth reaction with diamines to give high-molecular-weight polyamides. The resulting polyamides show a characteristic photochemical behavior of the transformation of the main chain *via* the asymmetric scission of the cyclobutane rings.[17-19] On the other hand, the thermal degradation of these polyamides was proposed to proceed in quite a different manner to form five-membered imide ring or six-membered lactone ring by the scission of the main chain.[19]

In the previous communication,[20] we briefly reported the thermal behavior of some lactone-opened derivatives of *syn* head-to-head coumarin dimer. In this paper, we wish to present the anomalous thermal reaction of the lactone-opened derivatives of *syn* and *anti* head-to-head coumarin dimers in detail and to discuss these reaction behaviors mainly from the point of neighboring group effect.

Experimental

Materials. *Syn* and *anti* head-to-head coumarin dimers (*syn* dimer (**1**) and *anti* dimer (**2**)) were prepared by the methods of Krauch *et al.*[9] The lactone-opened derivatives were synthesized according to the methods described in the previous paper:[1] *N,N'*-Dibutyl-*c*-3,*c*-4-bis(2-hydroxyphenyl)-*r*-1,*c*-2-cyclobutanedicarboxamide (*syn* dibutyldiamide (**3**)), *N*-butyl-*c*-3,*c*-4-bis(2-hydroxyphenyl)-*r*-1,*c*-2-cyclobutanedicarboximide (*syn* butylimide (**4**)), *N*-phenyl-*c*-3,*c*-4-bis(2-hydroxyphenyl)-*r*-1,*c*-2-cyclobutanedicarboximide (*syn* phenylimide (**5**)), and *N,N,N',N'*-tetrabutyl-*c*-3,*c*-4-bis(2-hydroxyphenyl)-*r*-1,*c*-2-cyclobutanedicarboxamide (*neo* tetrabutyldiamide (**6**)) were prepared from *syn* dimer (**1**). *Anti* dimer (**2**) was converted to 2-ethoxycarbonyl-1-(2-hydroxyphenyl)-1α,2α,2aβ,8bβ-tetrahydro-3*H*-cyclobuta[*c*]chromen-3-one (*anti* monoethyl ester (**7**)), 1-(2-hydroxyphenyl)-2-phenylcarbamoyl-1α,2α,2aβ,8bβ-tetrahydro-3*H*-cyclobuta[*c*]chromen-3-one (*anti* monoanilide (**8**)), 2-butylcarbamoyl-1-(2-hydroxyphenyl)-1α,2α,2aβ,8bβ-tetrahydro-3*H*-cyclobuta[*c*]chromen-3-one (*anti* monobutylamide (**9**)), *t*-3,*c*-4-bis(2-hydroxyphenyl)-*r*-1,*t*-2-cyclobutanedicarboxylic acid (*anti* dicarboxylic acid (**10**)), diethyl *t*-3,*c*-4-bis(2-hydroxyphenyl)-*r*-1,*t*-2-cyclobutanedicarboxylate (*anti* diethyl ester (**11**)), *t*-3,*c*-4-bis(2-hydroxyphenyl)-*r*-1,*t*-2-cyclobutanedianilide (*anti* dianilide (**12**)), *N,N,N',N'*-tetrabutyl-*t*-3,*c*-4-bis(2-hydroxyphenyl)-*r*-1,*t*-2-cyclobutanedicarboxamide (*anti* tetrabutyldiamide (**13**)), and *N,N'*-dibutyl-*t*-3,*c*-4-bis(2-hydroxyphenyl)-*r*-1,*t*-2-cyclobutanedicarboxamide (*anti* dibutyldiamide (**14**)). 2,2'-Dihydroxystilbene was synthesized by the method reported in the literature.[3]

Measurements. TG-DSC curves were recorded on a Rigaku Denki THERMOFLEX TG-DSC with the heating rate of 5 °C/min in a nitrogen stream. IR spectra were recorded on a JASCO IRA-1 spectrophotometer. ^{1}H-NMR spectra were recorded on a HITACHI R-40 spectrophotometer. High performance liquid chromatography (HPLC) was carried out by detecting UV absorbance (at 280 nm) using a Merck LiChrosorb SI60 column (4ϕ×250 mm) with benzene-ethyl acetate (50:50 or 80:20 v/v%) as an eluent. Thin layer chromatography (TLC) was performed on Merck TLC plates Silica gel 60 F_{254} using the same eluents with HPLC.

Pyrolysis. *A) Pyrolysis in a TG-DSC Pan.* Sample (5—9 mg) was placed in an aluminium pan and heated in the furnace of the TG-DSC instrument under a nitrogen atmosphere. The pyrolyzed products were analyzed by ^{1}H-NMR and IR spectroscopy without purification.

B) Pyrolysis in a Sealed Tube. Sample (*ca.* 10 mg) was placed in a sealed tube under an argon atmosphere and heated in a salt bath. The pyrolyzed product was analyzed by HPLC.

C) Pyrolysis in a Sublimation Tube. Sample (*ca.* 0.2 g) was placed in a sublimation tube and heated in an oil bath under reduced pressure (0.5—1.0 Torr, 1 Torr=133.322 Pa). The product was analyzed by HPLC and IR spectroscopy without purification.

The identification of the pyrolyzed products were accomplished by the comparison of their spectroscopic and HPLC data with those of authentic samples.

Results and Discussion

Thermal Reaction of syn *Head-to-head Coumarin Dimer Derivatives.* The thermal reaction of *syn* dimer (**1**) and its derivatives was investigated on the

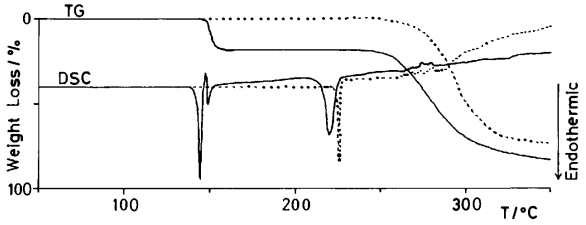

Fig. 1. TG-DSC curves of *syn* dibutyldiamide (**3**) [——] and *syn* butylimide (**4**) [----].

basis of their TG-DSC curves and the data of ^{1}H-NMR, IR, and HPLC analyses of the pyrolyzed products. Figure. 1 shows the TG-DSC curves of *syn* dibutyldiamide (**3**) and *syn* butylimide (**4**). In the TG-DSC curves of *syn* dibutyldiamide (**3**) there were sharp endo- and exothermic peaks at 144 and 147 °C, accompanying with the 16.4% weight loss. These two peaks and weight loss were attributed to melting and decomposition of *syn* dibutyldiamide (**3**) and crystallization of *syn* butylimide (**4**), formed from *syn* dibutyldiamide (**3**) with the elimination of one mole of butylamine (the calculated weight loss is 16.7%). The almost quantitative imide formation was confirmed by comparison of ^{1}H-NMR and IR spectra of the product, obtained by heating *syn* dibutyldiamide (**3**) at 200 °C in a TG-DSC pan, with those of *syn* butylimide (**4**). The thermal reaction in a solution was also carried out and monitored by ^{1}H-NMR spectroscopy. In a DMSO-d_6 solution, *syn* dibutyldiamide (**3**) remained unchanged on standing at 80 °C for 1 h. But the peaks of the cyclobutane ring protons changed completely into those of *syn* butylimide (**4**) on heating at 100 °C for 6.5 h. Moreover, HPLC analysis showed that heating *syn* butylimide (**4**) at 188 to 220 °C under reduced pressure resulted in the complete sublimation of *syn* butylimide (**4**) accompanying with the formation of a small amount of 2,2′-dihydroxystilbene. But, in the products obtained by heating at 270 °C for 3 min in a sealed tube, small amounts of coumarin and *syn* dimer (**1**) were detected along with 2,2′-dihydroxystilbene by HPLC analysis. These results indicate that under rather drastic conditions the symmetric cleavage of the cyclobutane ring *via* an anomalous relactonization occurred certainly in competition with the asymmetric scission of the cyclobutane ring, which would be the single pathway for the degradation at 220 °C.

On the other hand, a complete thermal conversion of *syn* phenylimide (**5**) into *syn* dimer (**1**) was achieved. In the TG-DSC curves of *syn* phenylimide (**5**), a broad endothermic peak in the temperature range of 181—223 °C with the weight loss of 21.4% and a sharp exothermic peak at 190 °C were observed, which correspond to the decomposition of *syn* phenylimide (**5**) with the vaporization of aniline eliminated (the calculated weight loss of aniline is 24.2%) and the crystallization of *syn* dimer (**1**)(Fig.2). Furtheremore, the decomposition mode of *syn* phenylimide (**5**) above 223 °C in TG-DSC curves was essentially the same as that of *syn* dimer (**1**). The product obtained by heating *syn* phenylimide (**5**) at 240 °C in a TG-DSC pan was identified as *syn* dimer (**1**) by ^{1}H-NMR and IR spectroscopy. This relactonization was also observed when a DMSO-d_6 solution of *syn* phenylimide (**4**) was heated at 185 °C for 1 h, giving a mixture of *syn* phenylimide (**4**) and *syn* dimer (**1**) (41:59, based on the peak areas of the cyclobutane ring protons in ^{1}H-NMR spectrum), and the finally decomposed product of *syn* dimer (**1**) was ascertained as coumarin on the basis of spectroscopic data. These thermal behaviors of the lactone-opened derivatives of *syn* dimer (**1**) are summarized in Scheme 1.

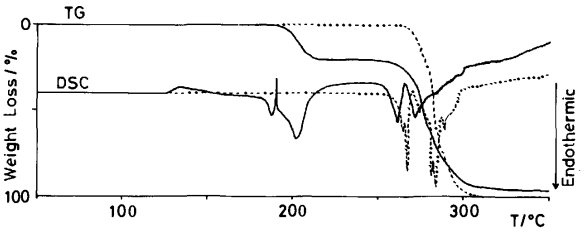

Fig. 2. TG-DSC curves of *syn* dimer (**1**) [----] and *syn* phenylimide (**5**) [——].

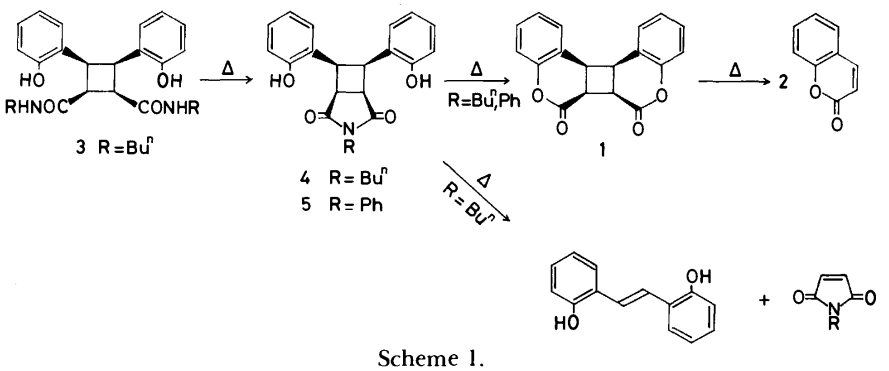
The difference in the thermal behaviors of *syn* butylimide (**4**) and *syn* phenylimide (**5**) is interpreted in terms of the electronic nature of their imide linkage. The less electron-donating character of the phenyl group than butyl group lowers the electron density of the imide carbonyl effectively enough to facilitate the nucleophilic attack of 2-hydroxyphenyl group in *syn* phenylimide (**5**).

In spite of the high reactivity of the lactone rings in *syn* dimer (**1**) to nucleophiles, the lactone of a phenolic acid reformed through the elimination of anilino group by the attack of *cis*-positioned 2-hydroxyphenyl group to regenerate *syn* dimer (**1**). It means that anomalously large neighboring group effect plays an important role in these thermal reactions, although phenoxyl group is a very effective leaving group in the lactone-opening reaction of *syn* dimer (**1**) as well as in general substitution reactions.

Thermal Reaction of anti *Head-to-head Coumarin Dimer Derivatives.* The thermal reaction of *anti* dimer (**2**) and its lactone-opened derivatives was investigated by analogous methods.

The thermal reaction of monolactone derivatives of *anti* dimer (**2**) such as *anti* monoethyl ester (**7**), *anti* monoanilide (**8**), and *anti* monobutylamide (**9**) was not clearly distinguished from the TG-DSC curves (Figs. 3—5), but the product sublimed on heating at 300 °C was



Scheme 1.

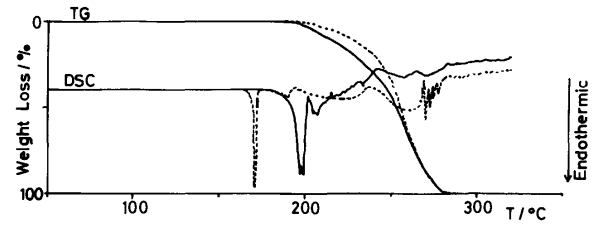


Fig. 3. TG-DSC curves of *anti* monoetyl ester (**7**) [----] and *anti* dietyl diester (**11**) [——].

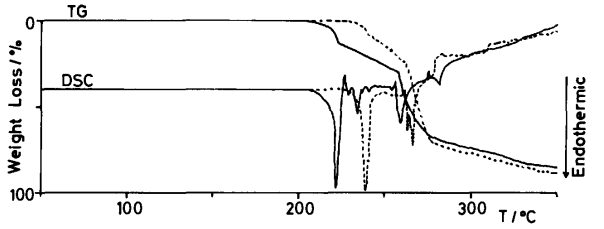

Fig. 4. TG-DSC curves of *anti* monoanilide (**8**) [----] and *anti* dianilide (**12**) [——].

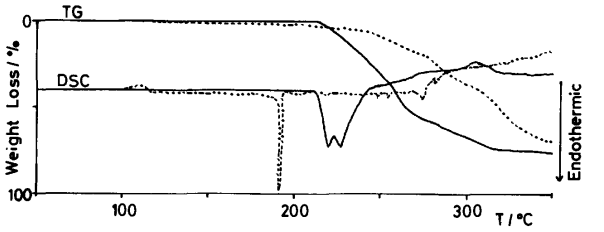

Fig. 5. TG-DSC curves of *anti* monobutylamide (**9**) [----] and *anti* dibutyldimide (**14**) [——].

solely coumarin. To clarify the reaction pathway from monolactone derivatives **7**, **8**, and **9** to coumarin, the heating in a TG-DSC pan was stopped when the weight loss corresponded to the release of one mole of alcohol or amine. The product was proved to be a mixture of the starting material and *anti* dimer (**2**) on the basis of IR and ^{1}H-NMR spectrometric data, indicating that coumarin was produced *via* anomalously relactonized *anti* dimer (**2**). The smooth relactonization was also supported by the following observation: In a DMSO-d_6 solution, *anti* monobutylamide (**9**) turned to a mixture of the starting compound **9**, *anti* dibutyldiamide (**14**), and *anti* dimer (**2**) (70:15:15, based on the peak areas of the cyclobutane ring protons in ^{1}H-NMR spectrum) on heating at 185 °C for 1 h, meaning that *anti* monobutylamide (**9**) slowly decomposed to *anti* dimer (**2**) with the elimination of butylamine, which attacked the residual lactone ring of *anti* monobutylamide (**9**) to give *anti* dibutyldiamide (**14**) (Scheme 2).

In the next stage, the thermal reactions of both lactone-opened derivatives of *anti* dimer (**2**) such as *anti* dicarboxylic acid (**10**), *anti* diethyl diester (**11**), *anti*

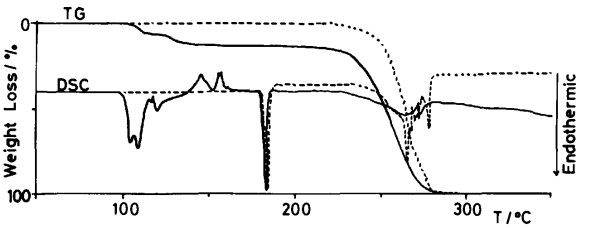

Fig. 6. TG-DSC curves of *anti* dimer (**2**) [----] and *anti* dicarboxylic acid (**10**) [——].

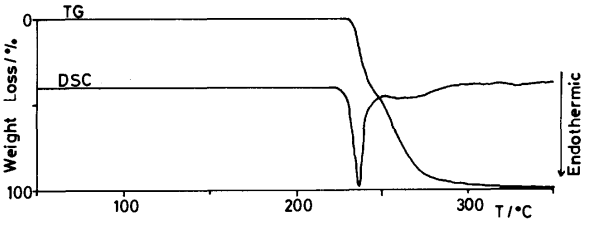

Fig. 7. TG-DSC curves of *anti* tetrabutyldiamide (**13**).

dianilide (**12**), *anti* tetrabutyldiamide (**13**), and *anti* dibutyldiamide (**14**) were carried out. The reactions except for *anti* dibutyldiamide (**14**) were made clear by comparison of their TG-DSC curves with those of the corresponding monolactone compounds **7**—**9** and *anti* dimer (**2**), suggesting that the reaction proceed *via* the monolactone compounds (Figs. 3, 4, 6, and 7). The product, obtained by heating in a TG-DSC pan up to the temperature at which the weight loss corresponded to the release of one mole of water, ethanol, aniline, or dibutylamine, was proved to be a mixture of starting material, the corresponding monolactone derivative, and *anti* dimer (**2**), and further heating was ascertained to give coumarin by TLC analysis and IR and ^{1}H-NMR spectroscopy. But, when *anti* dibutyldiamide (**14**) was heated at 216—217 °C for 30 min (corresponding to the weight loss of one mole of butylamine), the product showed IR absorptions at 1765, 1690, and 1650 cm^{-1} indicating the formation of five-membered imide. However, the thermal reaction of *anti* dibutyldiamide (**14**) in a sublimation tube *in vacuo* at 224—230 °C was found to give only *anti* monobutylamide (**9**) with starting compound **14** by TLC analysis. It is concluded that the both lactone-opened derivative of *anti* dimer (**2**) degradates successively into the corresponding monolactone derivative, *anti* dimer (**2**), and coumarin.

The thermal reactions of *anti* dimer derivatives are summarized in Scheme 3.

Thermal Reaction of neo *Tetrabutyldiamide.* The TG-DSC curves of *neo* tetrabutyldiamide (**6**) in Fig. 8 show gradual weight loss (20.3%) at 170 to 220 °C with an endothermic peak at 170 °C, which corresponds to the loss of one mole of dibutylamine (the calculated weight loss is 23.5%). Then, weight loss restarted at 239 °C and complete weight loss was achieved till

350°C. At the first stage of this reaction, *cis*-positioned carbonyl and 2-hydroxyphenyl groups were presumed to form six-membered lactone ring with the elimination of one mole of dibutylamine. But further heating did not cause the lactone formation between the *trans*-positioned residual carbonyl and 2-hydroxyphenyl groups but resulted in the scission of the cyclobutane ring (Scheme 4).

In conclusion, the imide formation is prior to other reactions when two carbonyl groups are situated in *cis* position. But, in the case of the imide formation being impossible, the relactonization between the *cis*-positioned 2-hydroxyphenyl and carbonyl groups occurs smoothly, and when both the reactions are impossible, the thermal treatment results in the scission of the cyclobutane ring.

In spite of being effective leaving groups in the nucleophilic lactone-opening reactions, 2-hydroxyphenyl groups attack carbonyl carbons of carboxyl, ester, and even amide to reproduce six-membered lactone rings as a common thermal reaction of these derivatives. This anomalous behavior clearly manifested the contribution of the large neighboring group effect in these reactions. In this point of view, the thermal behavior of coumarin dimer derivaitves is substantially influenced by the configuration of substituents on the cyclobutane ring in the similar manner with the observation in their photocleavage reaction.[3)]

Hydrophilicity and Complexing Ability of Alkyl Lariat Ethers

Isao IKEDA, Hiroshi EMURA, and Mitsuo OKAHARA*

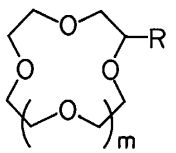
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka 2-1, Suita, Osaka 565

(Received October 17, 1983)

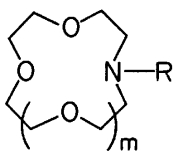
A series of long chain alkyl lariat ethers were synthesized and their aqueous properties in the absence and presence of alkali metal cations were investigated by measuring their cloud points and complex stability constants. In spite of the presence of ether oxygen(s) in the side chain, complexing abilities toward sodium and potassium cations did not significantly differ from those of the corresponding alkyl crown ethers. As the number of ether oxygens in the side chain of lariat ethers was increased, the water solubilities were much improved and showed high cloud points. However, the degree of salting-in effect decreased and the increment of cloud point caused by addition of salts decreased, probably due to the increase of acyclicity of the polyether molecule.

Since the crown ethers have strong interactions with metal cations and ammonium ions and show characteristic behaviors, many studies about their complexing ability, phase transfer catalysis, metal cation transport, and metal cation analysis have been reported. Various kinds of substituents have been introduced onto the crown ring to improve these functions.

As the crown ring acts as a hydrophile, some crown compounds having a suitable lipophilic substituent have been synthesized and declared to have interesting properties as nonionic surface active agents. LeMoigne,[1,2] Moroi,[3] and Kuwamura[4-7] reported the surface properties of some of these crown compounds. We also have synthesized long chain alkyl crown ethers (**1**)[8-11] and *N*-(long chain alkyl) monoaza crown ethers (**2**),[9,12] and investigated their surface properties[13,14] and clarified their behaviors toward metal cations in the aqueous solution.[8,15-17] Thus, alkyl crown ethers (**1**), unlike the usual acyclic poly(oxyethylene) type nonionic surfactants, show a salting-in effect in the presence of alkali metal cations based on the formation of metal-crown ring complex.[8,16]



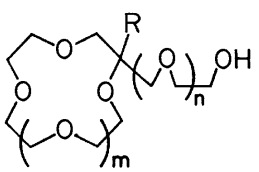
(1)



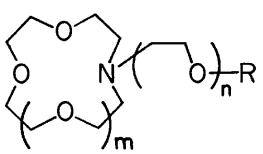
(2)

However, as the crown ring consists of a limited number of oxyethylene units and has no hydroxyl group, the hydrophilicity of this kind of surfactant is low compared with that of the usual nonionic surfactants.[15] Improvement of the hydrophilicity by enlarging the crown ring may affect the complexing ability with metal cations.

Recently, Gokel and his coworkers[18-23] and we[12,24] reported the synthesis and complexing ability of so-called "lariat ethers" (**3**, **4**) which have oxyethylene chain in the side arm. In the case of monoaza lariat ethers (**4**), not only the hydrophilicity but also the complexing ability of the molecule increased by the introduction of oligo-(oxyethylene) group.[12]



(3) R=H,CH3.



(4) R=H,alkyl.

In this paper, we report the syntheses of long alkyl chain lariat ethers (**5**) having one to three ether oxygens in the side chain and their properties affected by the side oxyethylene chain, especially the increase of hydrophilicity and the variation of salt effect by measuring the cloud point of aqueous solution in the presence of sodium or potassium chloride. The contribution of ether oxygens in the side chain to the complexation toward sodium and potassium cations was directly examined from the measurement of complex stability constants.

Experimental

Materials. The NaCl and KCl were commercial guaranteed-grade reagents, and were dried at 80 °C at reduced pressure [1 Torr(1 Torr=133.322 Pa), 6 h]. The water was deionized by passing through an ion-exchange resin column. Lariat ethers having one oxygen in the side chain (**5a—d**) were synthesized from alkyl glycidyl ethers and oligoethylene glycol according to the reported method (Scheme 1).[10] Lariat ethers having two or three oxygens in the side chain (**5e—l**) were synthesized by Williamson ether synthesis from hydroxymethyl crown ether (**7**)[10] and **8** which was prepared by chlorination of oligoethylene glycol monoalkyl ethers according to Scheme 2. As a typical procedure, preparation of 2-(dodecyloxy)ethoxymethyl-15-crown-5 (**5f**) is described. To 10 ml of *t*-butyl alcohol including 5 g (0.02 mol) of **7** (m=2), 0.35 g (0.015 mol) of sodium was dissolved and 7.5 g (0.03 mol) of 2-chloroethyl dodecyl ether (**8**, n=1) was added dropwise. After heating to reflux for 6 h, the *t*-butyl alcohol was evaporated off at reduced pressure. The residue was extracted with dichloromethane. After removal of the solvent, the oily

material which remained was distilled by Kugelrohr apparatus to give a colorless oil (**5f**) 6.2 g (yield 67%). In Table 1 are listed the boiling points (Kugelrohr distillation) and the yields of **5**. All the ethers (**5**) showed the almost the same IR and NMR spectra. IR (cm^{-1}); 2940(s), 2860(s), 1470(m), 1350(m), 1290(w), 1250(w), 1120(s), and 940(w). NMR; δ=0.89 (t, 3H), 1.28 (12 or 20H), 3.3—3.9 (m, [4*m*+4*n*+15]H). Elemental analyses showed the good agreement within 0.4% of deviation.

Measurement of Cloud Point. The cloud point (T_{cp}) of each aqueous solution of crown compound was determined by observation with naked eyes, using a solution of 10 mg of crown ether in 1 ml of water or the salt solution of specific concentration in a test tube of 10 mm of inner diameter under heating with a rate of *ca.* 0.5 °C/min.

Measurement of Stability Constant of Complexes. Stability constants were measured by Frensdroff's method.[25]

Results and Discussion

Lariat ethers having a long alkyl group were synthesized by two procedures: those having one oxygen in the side chain (**5a—d**) were synthesized by the cyclization of alkoxymethyl oligoethylene glycol (**6**) (Scheme 1),[10,11] and those having two or three ether oxygens in the side chain (**5e—l**) were synthesized from hydroxymethyl crown ethers (**7**)[10] and α-alkyl-ω-chlorooligo (oxyethylene) (**8**) by Williamson ether synthesis (Scheme 2) since the oligoethylene glycols having an excessively long side chain were not desirable as a precursor for cyclization, from the point of difficulty in purification due to their high boiling points.

Cloud points of twelve kinds of long chain alkyl lariat ethers are listed in Table 2, together with those of alkyl crown ethers (**1**) for comparison.

When the size of crown ring and the length of alkyl chain were the same, cloud points of the crown compounds rose almost linearly with increasing the number of ether oxygen atoms in the side chain. The slopes of four straight lines were almost equal. The degree of rise in cloud point with increase of the number of ether oxygen atom in the side chain was

about 50 to 70% of that with increase of the oxygen number in the crown ring.

Many studies about the effect of added inorganic electrolytes on the cloud points of open chain poly(oxyethylene) type nonionics have been reported.[26-29] In the presence of metal salts except for the salts having a counter anion of water-destructuring type, such as SCN^-, NO_3^-, and so on, the cloud points of these open chain poly(oxyethylene) type nonionics usually fall down, due to the salting-out effect. In the case of crown ethers, however, a salting-in effect based on the complexation of crown ring with metal cations causes the rise of cloud point compared with the cases in the absence of metal salts.[8,16,17] Figures 1 and 2 show the

correlations between the cloud points of aqueous solutions of octyl derivative series of lariat ethers and the concentrations of sodium and potassium chlorides as examples. In Figs. 3 and 4 are shown the correlations of the concentration of salt and the difference of cloud point (ΔT_{CP}) between the values in the absence and presence of sodium or potassium chloride, using dodecyl derivatives as examples.

15-Crown-5-NaCl System (Figs. 1 and 3). When the salts were added to the aqueous solutions of these crown ethers, the cloud points rose, since the salting-in effect is superior to the salting-out effect. However, as the salting-out effect works concurrently, the cloud points began to fall above a certain salt concentration.[16] In the case of octyl-15-crown-5, the ΔT_{cp} was the maximum at around the concentration of 4.5 m of NaCl. And the higher the number of ether oxygen atoms in the side chain, the lower the concentration of salts at which the ΔT_{cp} was maximum, though the cloud points themselves were higher (Fig. 1). As the cloud point of dodecyl-15-crown-5 in the absence of salts was below 0 °C, the maximum values of ΔT_{cp} could not be calculated, but the homologues having one and more than one ether oxygens in the side chain, showed the same tendency as the octyl derivatives showed. This can be explained by the following reasons: as the number of oxygen atoms in the side chain increased, the water-solubility of the whole molecule was enhanced, but it became easier to salt out the molecule, probably because the acyclicity of the molecule increased. Acyclicity causes the salting-out effect, and lariat ethers are apt to be salted-out even at a lower salt concentration. The higher the number of ether oxygens in the side chain, the larger the degree of fall of cloud point by the salting-out effect.

18-Crown-6-NaCl System (Figs. 2 and 3). In this system the salting-in effect works strongly in general and the T_{cp}s rise markedly. Upon the increase of number of oxygen in the side chain, the salting-out effect became also larger and the salt concentration showing the maximum ΔT_{cp} shifted to the lower region.

18-Crown-6-KCl System (Figs. 2 and 4). It is well known that the complexes of this combination are the most stable of all the crown ether-alkali metal cation systems. They showed the largest ΔT_{cp} values, 40—50 °C, showing that they are affected by the strong salting-in effect due to the strong complexation.

15-Crown-5-KCl System (Figs. 1 and 4). In this system, different from others, the complexing ability is small and the salting-in effect is so weak that ΔT_{cp} did not exceed 10 °C. The salting-out effect begins to overcome the salting-in effect even at as low as 2 m of salt concentration.

In all the systems, the changes of ΔT_{cp} caused by the difference of alkyl chain length were almost the same in both the octyl and dodecyl series and it is obvious that the additional methylene units in the side chain bring about only the increase of lipophilicity of the molecule. Considering from the changes of cloud point of a series of the lariat ethers which have the same alkyl chain and the same crown ring, it can be concluded that ether groups in the side chain are related to hydration, namely aqueous solubility, rather than the complexation with metal cations. To confirm directly the participation of ether oxygens in the side chain to the complexation, the stability constants of complexes with sodium and potassium cations in methanol were measured and are shown in Table 3. ΔT_{cp} of lariat ethers, especially in the low salt-concentration region where the neat effect of salting-in phenomenon was revealed, showed a good correlation with their complex stability constants, as was reported in the case of alkyl crown ethers[8,15,16] and alkyl aza crown ethers.[17]

Little differences of the stability constant were found within a series of the lariat ethers which had the same crown ring.

We already reported that, for the lariat ethers **3** (R=CH_3) and **4**, the higher the number of ether oxygen atoms in the side chain, the larger the stability constants. This fact was explained as due to the participation of the ether oxygens in the side chain. In the case of **3**, the geminal methyl group forces sterically oligo(oxyethylene) chain to take an advantageous position to complexation.[24,30] And in the case of **4**, the oligo-

a) in methanol. b) In water/methanol=10/90 (v/v). c) At 25 °C, values in 95% of confidence interval. d) Calculated by Frensdorff's equation. e) Values reported in Ref. 24. f) R=n-C_8H_{17}. g) Since values are dependent on the ratio of ligand and cation in the range of measured conditions, values at specific conditions (KCl=2.5 mmol·l^{-1}, 50 ml; ligand=12 mmol·l^{-1}, 20 ml) are shown.

(oxyethylene) chain can easily participate in the complexation because the junction (the nitrogen atom) of the crown ring and the side chain is flexible.[17] In the case of **5**, to the contrary, contribution of the side oligo(oxyethylene) chain to the complexation is found to be quite small. It is natural to consider that the oxygens in the side chain are apt to be located too far from the crown plane to induce-fit effectively the metal cation which complexes with the crown ring.

To determine the complexation of lariat ethers in the aqueous solution, the stability constants in methanol containing 10% of water were measured. Gokel measured the stability constants of complexes of 15-crown-5 and 18-crown-6 with sodium cation in the mixture of methanol and water and reported that the stability constants enhanced proportionally to the ratio of methanol in the mixture, and that no confusion in the order of stability constants was found between any two crown ethers.[31]

The results are shown in Table 3. The values were smaller than those in methanol, but the tendency was quite the same with that in methanol, showing that the ether oxygens in the side chain did not contribute to complexation in water either.

As a result, it can be concluded that the lariat ethers having desirable HLB and with complexing ability and selectivity of the parent alkyl crown ethers toward alkali metal cations could be designed by combining an alkyl group and a crown ring with a suitable length of oxyethylene chain.

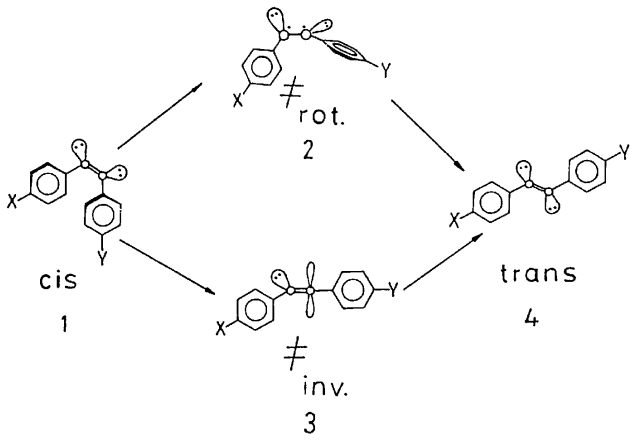
The Thermal Isomerization of Azobenzenes. III.[1] Substituent, Solvent, and Pressure Effects on the Thermal Isomerization of Push-pull Azobenzenes

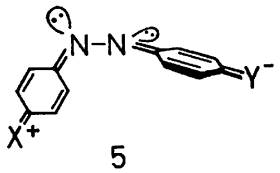
Norio NISHIMURA,* Shinya KOSAKO, and Yoshimi SUEISHI
Department of Chemistry, School of Science, Okayama University, Okayama 700
(Received July 18, 1983)

The substituent, solvent, and pressure effects on the rate of the thermal *cis*-to-*trans* isomerization of 4-dimethylamino-4′-nitroazobenzene(NDAAB) derivatives have been studied. 2-Methyl- and 2′-chloro-NDAAB isomerize faster than NDAAB, and 2′-methyl- and 2-chloro-NDAAB isomerize slower than NDAAB. For 2,2′-dimethyl- and 2,2′-dichloro-NDAAB, the rates are between those of the monosubstituted ones. These findings are very similar to those for 4-(dimethylamino)azobenzene (DAAB) derivatives, and no fundamental difference in the kinetic-substituent effects was observed between NDAAB and DAAB. The volume of activation, which is of a negative value, varies remarkably from solvent to solvent and from substituent to substituent; its magnitude increases generally with an increase in the solvent polarity. Even for DAAB and 4,4′-bis(diethylamino)azobenzene (BDEAAB), the rate is appreciably accelerated by external pressures in polar solvents. It is concluded that the observed results are more consistent with the inversion mechanism than with the rotational mechanism.

The mechanism of the thermal *cis*-to-*trans* isomerization of azobenzenes has attracted much attention for many years. Two mechanisms have been proposed. One involves rotation around the N=N double bond and includes the π-bond rupture. The other involves inversion on either or both of the azo-nitrogen atoms, the π-bond remaining intact.



Theoretical[2,3] and experimental[4-7] approaches favor the inversion mechanism for most cases. However, the rotational mechanism has been revived recently.[8-13] Nerbonne and Weiss[10] studied the isomerization of azobenzene in the cholesteric and isotropic phases and, observing that the Arrhenius plot in a liquid crystal did not yield a single straight-line slope, suggested the rotational mechanism. Whitten *et al.*[8,9] found a large solvent effect for push-pull-substituted azobenzenes and suggested a dipolar rotational transition state **5**.



5

Asano *et al.*[11-13] reported that the isomerization rate of 4-dimethylamino-4′-nitroazobenzene (NDAAB) is considerably accelerated by external pressures in benzene and in polar solvents, but is little affected in hexane. According to them, this can be regarded as evidence for a change in the mechanism with the solvents for such push-pull azobenzenes, *i.e.*, from inversion in hexane to rotation in benzene. Indeed, such large pressure and solvent effects are consistent with the change in mechanism from solvent to solvent. However, it would be unnatural to expect such a drastic change in mechanism in nonpolar solvents. Therefore, it seems necessary to examine whether or not the proposed mechanism also accommodates other factors influencing the isomerization rate.

Several years ago, we reported on the kinetic data for the thermal isomerization of 36 kinds of azobenzene derivatives.[1,14] We found that the introduction of substituents almost invariably accelerates the rate, irrespective of the nature of the substituents. The substituent effect is of an additive nature, and the following Hammett-type equation holds approximately:

$$\log k/k_0 = \sum\sigma_{c-t}, \quad (1)$$

where k_0 and k refer to the rate constant of a standard azobenzene derivative properly chosen and that of substituted derivatives with respect to the standard one respectively, and where σ_{c-t} denotes a substituent constant characteristic of the kind and the position of the substituent in question. We also found that the wavelength at the maximum absorption of the conjugation band of a *trans*-isomer is closely related to the rate constant. Another finding is that 2-methyl-4-(dimethylamino)azobenzene isomerizes about three times faster than 4-(dimethylamino)azobenzene (DAAB), whereas the 2′-methyl group rather retards the rate. We have interpreted these facts in terms of the resonance stabilization in the inversion-transition state. However, since the rotational mechanism has been newly proposed for NDAAB, we wish to examine which of the proposed mechanisms is more compatible with the experimental observations. Our views concerning the mechanistic implications will be described in some detail.

Experimental

Materials. The NDAAB derivatives were prepared by diazo coupling from the corresponding *N,N*-di-

methylanilines and *p*-nitroanilines. The crude products were purified by column chromatography on silica gel and recrystallized from ethanol. The melting points, IR, NMR, and UV spectra were utilized for identification. For 2-methyl-NDAAB: mp 183—184 °C (lit, [15] 179—180.5 °C). For 2'-methyl-NDAAB: mp 159.5—160.5 °C (lit, [16] 161—163 °C). For 2,6-dimethyl-NDAAB: mp 169—170 °C. Found: C, 64.34; H, 6.21; N, 18.95%. Calcd for $C_{16}H_{18}N_4O_2$: C, 64.41; H, 6.08; N, 18.78%. For 2,2',6-trimethyl-NDAAB: mp 198—199 °C. Found: C, 65.45; H, 6.34; N, 17.86%. Calcd for $C_{17}H_{20}N_4O_2$: C, 65.37; H, 6.45; N, 17.94%. For 2-chloro-NDAAB: sublimed *ca.* 209 °C. Found: C, 55.35; H, 4.57; N, 18.55%. Calcd for $C_{14}H_{13}ClN_4O_2$: C, 55.18; H, 4.30; N, 18.39%. For 2'-chloro-NDAAB: mp 198—199 °C (lit, [17] 198—199 °C). For 2,2'-dichloro-NDAAB: mp 226—227 °C. Found: C, 49.36; H, 3.65; 16.41%. Calcd for $C_{14}H_{12}Cl_2N_4O_2$: C, 49.58; H, 3.57; N, 16.52%. The preparation of the other materials has been described elsewhere.[1] The solvents were purified and distilled in the usual manner.

Measurements. The pressure vessel,[18] with four optical windows, was made of SNCM-8 stainless steel and equipped with a water-circulating jacket. In this work, we used only two of the windows. High pressures were generated by means of a plunger pump and measured by means of a Heise Bourdon gauge. A turn mirror was installed between the pressure vessel and a monochrometor in order to switch the excitation light and the monitoring light. A 650-watt projector lamp was used for excitation. The light was passed through a 20-mm water layer and introduced into an inner cell. The cell was made of Teflon and consists of two compartments connected by a capillary tube (ϕ=1 mm). This made the uniform irradiation of the solution in the upper compartment possible, avoiding the mixing of the irradiated and unirradiated solutions. In order to avoid the adventitious contamination of acid which may affect the isomerization rate, small amounts of piperidine (0.3%) were added to the reaction solution. The solution was charged in the inner cell, and a desired pressure was applied to the solution through a liquid-separation piston. After a constant temperature and pressure had been attained, the solution was irradiated for *ca.* 1 min. Then the mirror was turned by 45 °, the absorption maximum of the *trans*-isomers was monitored by means of a Hitachi 139 spectrophotometer, and the absorbance was recorded. Satisfactory and reproducible first-order plots were obtained. The values of the rate constants listed in the tables are the average of several runs, the errors being within 2% in most cases. For 2,6-dimethyl- and 3-methyl-NDAAB in hexane, 2,6-dimethyl-NDAAB in CCl_4, 2,2',6-trimethyl-NDAAB and 2'-chloro-NDAAB in toluene, and NDAAB in chloroform, the errors were within 5%.

Results

The wavelengths λ_{max} (nm) at the maximum absorption of the conjugation band of *trans*-NDAAB and other substances in various solvents are given in Table 1. It is noted that λ_{max} is quite sensitive to such solvent-polarity parameters as the E_T-values; *i.e.*, the band generally exhibits a bathochromic shift with an increase in the solvent polarity, with the exception of methanol, for which a specific solvent-solute interaction takes place, probably *via* hydrogen bonding. In Tables 2—4, the first-order rate constants in several

solvents are listed. The activation parameters were estimated by using the least-squares method; their representative sets are given in Table 5. The isomerization rate was also followed under various pressures up to 1200 bar (1 bar=10^5 Pa) in various solvents; the rate constants for representative species in representative solvents are given in Tables 6—8. Plots of $\ln k_p/k_1$ against the external pressure p for NDAAB in various solvents are shown in Fig. 1, where k_p and k_1 are the rate constants under the external pressure of p and 1 bar respectively. The solid lines in the figure represent the following quadratic regression equation:

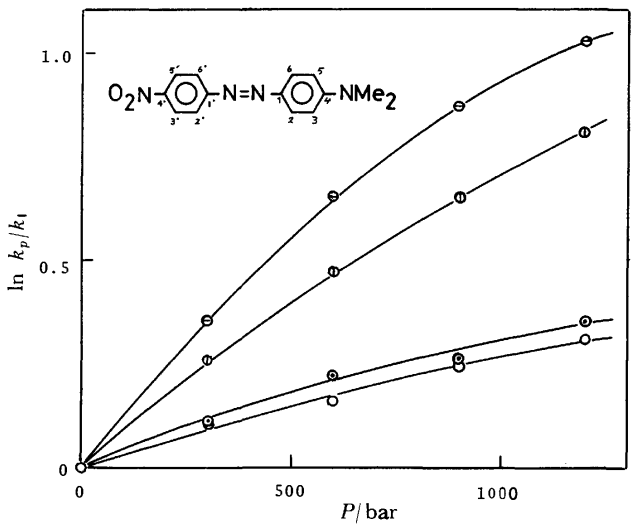

Fig. 1. Pressure effects on the first-order rate constants for the thermal *cis*-to-*trans* isomerization of 4-dimethylamino-4′-nitroazobenzene (NDAAB): (○) hexane; (⊙) CCl_4; (◑) toluene; (⊖) chloroform.

$$\ln k_p/k_1 = a + bp + cp^2. \quad (2)$$

The activation volumes at 1 bar were estimated according to Eq. 3; the values are given in Table 9:

$$\Delta V^* \approx -bRT. \quad (3)$$

Discussion

General Survey of Rate-controlling Factors. Large differences in the activation energy between azobenzenes and the corresponding iso-π-electronic stilbenes have been considered as indirect evidence of the inversion mechanism for azobenzenes.[5] Enthalpy considerations[19,20] and theoretical approaches[2,3] are compatible with this view. However, for 4-amino-4′-nitrostilbene, both the activation energy and the frequency factor drop a great deal compared with those of unsubstituted stilbene. According to Calvin and Alter,[21] the *cis*-isomer of this substance is thermally isomerized *via* a triplet state, as characterized by the very low frequency factor ($A \approx 10^5\ s^{-1}$). Hence, our data

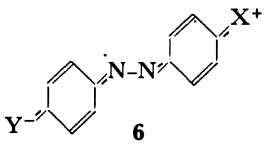
a) In chlorobenzene.

(Table 5) must preclude the intervention of the triplet state involving the rupture of the N=N π-bond.

Previously, we pointed out that the stabilization by means of the delocalization of the π-electrons in the transition state is an important rate-controlling factor. This inference has arisen from the following reasoning: if the conformation of the transition state of the species in question is similar to that of the *trans*-isomer in the sense that the phenyl rings are coplanar, the solvent and substituent effects on the isomerization rate would reflect the nature of the *trans*-isomer. As may be seen in Table 1, the conjugation band shifts to a longer wavelength almost invariably upon the introduction of the substituent, irrespective of their nature, and as the solvent polarity increases. It follows from an inspection of Tables 1—4 that, as the conjugation band of the *trans*-isomers of NDAAB derivatives shifts to a longer wavelength, the rate as a whole increases. This correlation has already been observed for DAAB derivatives.[1,14] The introduction of strong push-pull groups remarkably affects the rate and the position of the conjugation band. Because of the additive nature of the substituent effects on the rate, greatly accelerated rates are observed for NDAAB derivatives.

Very recently, Whitten and his co-workers[9,22] showed that the ΔG^{*} value for the isomerization of NDAAB is linearly related to Kosower's *Z*-values or other solvent polarity parameters, and suggested that **5** is responsible for the transition state. This conformation has also been supported by Asano *et al.* on the basis of the kinetic pressure effects.[11-13] However, we have a different idea of the conformation and the electronic structure of the activated complex, as will be discussed below.

Solvent Effects. The thermal isomerization of most azobenzenes exhibits few solvent effects. For push-pull azobenzenes such as NDAAB, however, a significant solvent effect has been observed. According to Whitten *et al*, [8,9] this favors a dipolar transition state **5**. Asano *et al.* also consider that **2** and **3** greatly differ in their polarities, and that in **2** (=**5**), the original π-electrons are transferred toward the pulling group and the newly formed positive charge center is stabilized by the pushing group. It should be noted that, in **5**, the N=N π-bond is completely ruptured. If such a charge-separated species is stabilized by solvation at the expense of the N=N π-bond rupture, the same logic must be admitted for the *cis*- and *trans*-isomers, too. Then the *trans*-isomer may have an electronic structure of the following type:



6

where the original N=N π-bond is completely broken and where charges are localized on the push and pull groups. If this were true, the dipole moment of the *trans*-isomer must be as large as 50 Debye, but this is not the case (see below). We admit that **6** is one of the canonical resonance forms, but it is not an *entity* (*cf.* **7**, **10**, and **11**).

The free energy of activation for the isomerization in the gas phase may be compensated for by solvation in a condensed medium. Laidler and Landskroener[23] gave expressions for the rate constant for reactions involving ions and dipoles. These are based on the treatment of Kirkwood, who gave general expressions for the free-energy change when a sphere with a radius *r* containing a distribution of charges is transferred from a medium of the unit dielectric constant to one of the dielectric constant ε. If azobenzenes are regarded as dipoles with no net charges, the rate constant for the thermal isomerization may be given by:

$$\ln k = \ln k_0 + \frac{3}{8kT}\left(\frac{\mu_{*}^2}{r_{*}^3} - \frac{\mu^2}{r^3}\right)\left(\frac{\varepsilon-1}{\varepsilon+1}\right), \qquad (4)$$

where k_0 is the hypothetical rate constant in a condensed medium of $\varepsilon=1$, and where μ and μ_{*} denote the dipole moments in the *cis* and transition states. We may expect that the plot of ln *k versus* $(\varepsilon-1)/(\varepsilon+1)$ makes a straight line.

In order to examine Eq. 4, the isomerization rate was followed for three representative azobenzenes in various solvents; the results are listed in Table 10. In Fig. 2, ln *k* is plotted against $(\varepsilon-1)/(\varepsilon+1)$. From the slope and assuming that $r \approx r_{*}=0.5$ nm, $T=300$ K, and $\mu=3$ D (1 Debye=3.3×10^{-30} m C), we tentatively estimated $\mu_{*} \approx 12$

Table 10. Rate constants for the thermal *cis*-to-*trans* isomerization of DAAB, NDAAB, and BDEAAB in various solvents at 25 °C

Solvent	ε	ln k/s^{-1}		
		DAAB	NDAAB	BDEAAB
Hexane	1.90	−10.3	−5.90	−7.47
Dioxane	2.21		−4.16	
CCl_4	2.23		−5.91	
Benzene	2.27	−10.16	−4.47	
Toluene	2.38		−4.50	
$CHCl_3$	4.70		−4.02	−4.71
Chlorobenzene	5.61	−9.54	−1.73	−5.40
1,2-Dichloroethane	10.37			−4.92
Acetone	20.5	−9.88	0.92[a]	−5.13
Methanol	32.6			−3.17
DMF	36.7		3.91[a]	
DMSO	48.9		4.79[a]

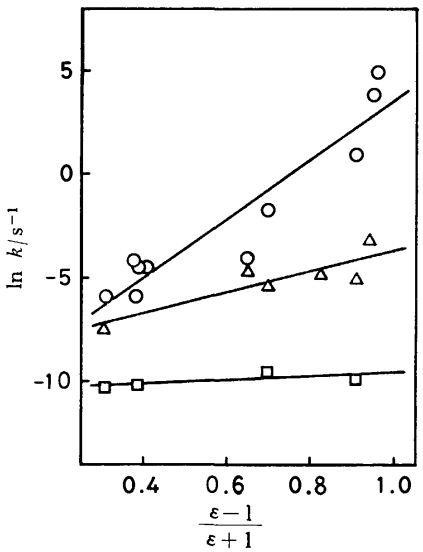

Fig. 2. Plots of ln k against $(\varepsilon-1)/(\varepsilon+1)$, according to Eq. 4: (○) NDAAB; (△) BDEAAB; (□) DAAB.

Debye for NDAAB. This may be an acceptable order of magnitude, since μ=7.91 D for *trans*-NDAAB.[24] There are very few solvent effects on DAAB, but it is notable that BDEAAB exhibits considerably greater solvent effects than DAAB, indicating a substantial polarity change upon activation. Therefore, we admit a polar *inversion* transition state for this kind of species, too (see **8** and **9** below), since a rotational dipolar structure such as **5** is quite unlikely. (Relevant discussion will be undertaken in the section on pressure effects.) The considerable scatter of the plots in Fig. 2 may indicate very complicated solvent effects on the rate, which has been often observed in Menschutkin reactions. The magnitude of the slope could then be regarded as a measure of the change in charge distribution upon activation.

Substituent Effects. As Talaty and Fargo[5] first pointed out, the introduction of substituents almost invariably accelerates the rate, regardless of the nature of the substituents. Therefore, the Hammett plot becomes V-shaped, with a mimimum near σ=0. Hall *et al.*,[25] and Herkstroeter[26] also reported similar observations for the isomerization of *N*-(hexafluoroisopropylidene)anilines and pyrazolone azomethines. They explained these observations in terms of a change in the mechanism. However, we question this and made a brief comment on it previously.[1] It has been found that the introduction of bulky substituents into *ortho* positions with respect to azomethine nitrogen always accelerates the rate. According to Kessler and his coworkers, the steric hindrance of bulky *ortho* substituents becomes less severe in the inversion-transition state than in the ground state, thus accounting for the acceleration in terms of the inversion mechanism.[27-30]

In this respect, we considered that, if we introduce substituents on *ortho* positions with respect to the azo group, and then examine the kinetic effects, it would shed light on the mechanism. Two sorts of substituents were chosen: Cl- and Me-groups. Let us regard NDAAB as the standard of the push-pull azobenzenes, since interest is focused on this species. When we examine the data in Tables 2—4, we notice some interesting points: (1) 2-Me- accelerates the rate, while 2′-Me- slightly retards it. (2) This effect tends to become more remarkable as the polarity of the solvent increases. (3) On the other hand, 2-Cl- retards the rate, while 2′-Cl- accelerates it. These kinetic substituent and solvent effects are more remarkable than those of the Me-group. (4) For 2,2′-disubstituted NDAAB, the rates fall between those of the 2- and 2′-groups. (5) The kinetic effect of 6-Me- is notable: 2-Me-$>$2,6-dimethyl, and 2,2′-dimethyl$<$2,2′,6-trimethyl in most solvents.

We previously reported that Eq. 1 approximately holds for DAAB derivatives for a specified solvent. The above findings indicate that Eq. 1 is valid for NDAAB derivatives and in other solvents, too. However, the rule is not valid for the 6-Me-group. A plausible reason for this may be the additional steric hindrance: 2-Me-$<$2,6-dimethyl in the transition state and 2,2′-dimethyl$<$2,2′,6-trimethyl in the *cis* ground state.

As is shown in Table 1, λ_{max} is sensitive to substituents: 2-Me- and 2′-Cl- shift the conjugation band to a longer wavelength, while 2′-Me- and 2-Cl- shift it to a shorter one. Fig. 3 shows the relationship between the ln k/k_0 and $\bar{\nu}_{max}$ values of the *trans*-isomers. In benzene as well as in hexane, good parallelograms can be observed. These observations suggest that the delo-

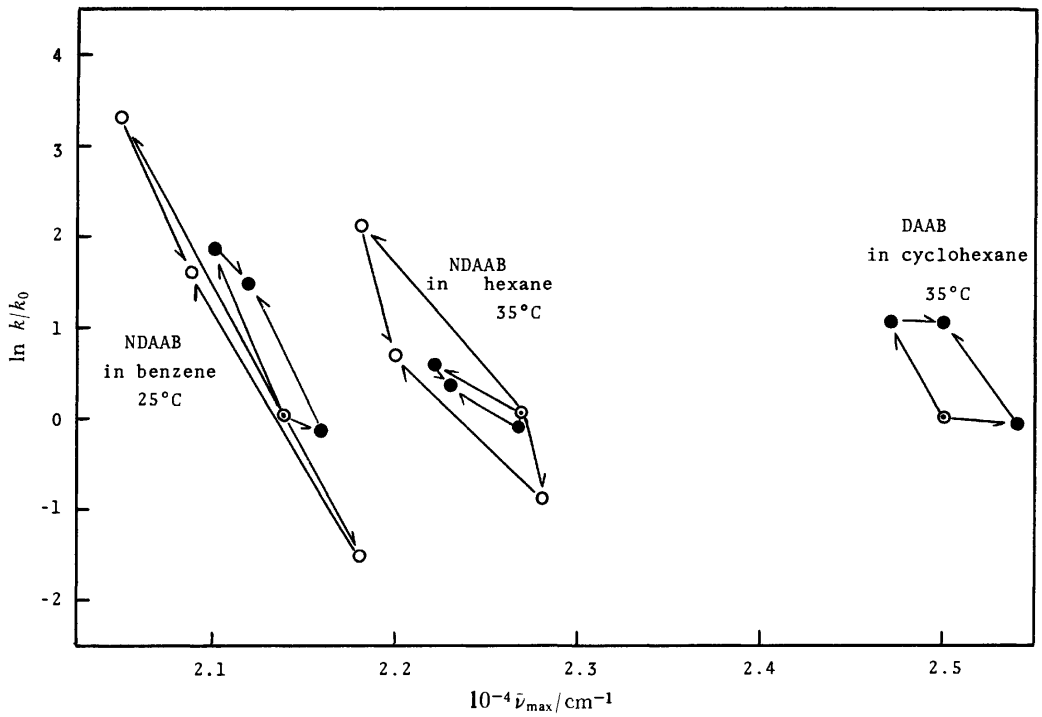

Fig. 3. Correlation between ln k/k_0 and $\bar{\nu}_{max}$ for Me-substituted (●), and Cl-substituted (○) azobenzene derivatives. Data for DAAB are cited from Ref 1.

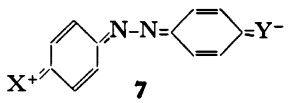
calization of the π-electrons, and hence the mesomeric effect, are important rate-controlling factors. Therefore, the two phenyl rings must be coplanar; this supports the inversion mechanism. If **5** is assumed, the correlation shown in Fig. 3 could not be expected, since the benzene rings are twisted in relation to each other.

From the above observations, one could say that there is no indication of the mechanism change for any kind of azobenzene in any solvent. The idea that NDAAB and its homologues isomerize *via* a route to rotation in solvents other than hexane, while other azobenzenes do so *via* a route to inversion or inversion-rotation competition paths, is thus questionable.

The substantial contribution of the canonical resonance form **7**:



7

which is possible for push-pull azobenzenes alone, may be responsible for the enhanced rate, especially in polar solvents. This resonance contribution must be strongly forbidden in the *cis*-isomer, for which two phenyl rings are twisted by 56° out of the C-N-N-C plane,[31] as well as in the rotational transition state (compare **7** with **5**). Therefore, we can reasoably assume that, for push-pull azobenzenes, a remarkable polarity change occurs on going from the *cis* to the inversion transition state, a change which accommodates the substantial substituent and solvent effects. From the theoretical approaches,[2,3] it is known that the energy required for the hybrid change from sp^2 to sp is much less than the energy needed for the π-bond rupture. Even if the latter energy were compensated for partially by solvation in the rotational dipolar transition state, it is unlikely that *cis* push-pull azobenzene prefers a route *via* rotation to a route *via* inversion in benzene, and *vice versa* in hexane.

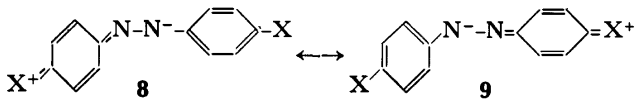
Linear Free-energy Relationship. According to Leffler and others,[32-36] a linear enthalpy-entropy relationship should hold for the simple interaction mechanism. If the ΔH^* *versus* ΔS^* plot is scattered, more than two interactions must be involved. Shinkai and his co-workers[7,12] have shown that the ΔH^* *versus* ΔS^* plots for various kinds of azobenzenes, but not NDAAB, constitute a straight line, while the same plots for NDAAB in various solvents, including hexane, give other straight line shifted downward, thus accounting for the change in the mechanism. Nevertheless, they opined that the mechanism change for NDAAB depends on the solvents, on the basis of the kinetic pressure effect; this is inconsistent.

If the data in Table 5 are inspected, it may be seen that ΔH^* tends to increase with the increase in ΔS^*. It may also be noted that the sets of ΔH^* and ΔS^* in hexane for NDAAB derivatives fall in the region in which other sets are involved, and we cannot see any indication of special behavior in hexane. We consider that the downward shift is not due to the mechanism change, but to the remarkable free-energy depression attributable to the extra mesomeric contribution **7** and the accompanying solvation.

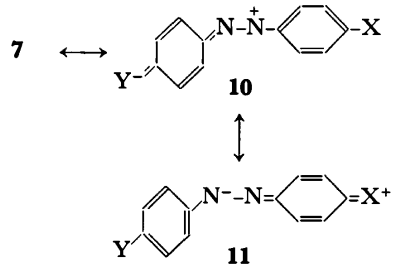
Pressure Effects. We now wish to examine the pressure effects on the isomerization of various kinds of azobenzenes in various solvents with different polarities. From an inspection of Tables 6—9, we see some interesting points: (1) First of all, an appreciable acceleration in the rate by external pressures for NDAAB and its homologues can be observed, even in hexane. The values of ΔV^* are similar to those reported

by Asano *et al.*, except for that of NDAAB in hexane. (2) The pressure effect and, hence the activation volume $|\Delta V^{*}|$, tend to increase as the solvent polarity increases, but there is a distinction between CCl_4 and toluene. (3) When ln k_p is plotted against p for substituted NDAAB, we can see that the patterns of the kinetic pressure effect for 2-Me- and 2′-Cl- , 2′-Me- and 2-Cl-, and 2,2′-dimethyl and 2,2′-dichloro-NDAAB are very similar to each other. We have already pointed out that these sets of substituents exert similar effects on the rate as well as the position of $\bar{\nu}_{max}$. (4) Astonishingly, BDEAAB and DAAB also exhibit appreciable pressure effects in toluene, chloroform, and methanol (Table 9).

The above findings indicate very complex kenetic pressure effects, and it is very difficult to give a clear-cut explanation of them. It is well known, though, that if a reaction starts from a nonpolar ground state and proceeds *via* a polar transition state, a more negative activation volume is to be expected for a less polar solvent, as observed in Menschutkin reactions.[37-40] The above findings are just the reverse; therefore, they could be explained in terms of two competing reaction paths for push-pull azobenzenes for which $|\Delta V^{*}|$(inversion)≈0, and $|\Delta V^{*}|$(rotation)=20—30 cm^3 mol^{-1}.[13] However, the (4) observation excludes this, since a dipolar structure for the rotational transition state is least likely for a bis-substituted azobenzene such as BDEAAB. At the same time, it is possible to write the dipolar inversion transition state for push-push azobenzenes as follows:



The partial charge on the molecule would cause the polarization of the surrounding solvent molecules, thus accounting for the substantial pressure and solvent effects for these kinds of azobenzenes. The red shift of the conjugation band of *trans*-BDEAAB, which is nominally a nonpolar molecule, could thus be explained (Table 1). For push-pull azobenzenes, there must be a substantial contribution of the following dipolar canonical resonance forms to the stabilization of the inversion transition state:



The solvent dependencies of ΔV^{*} for reactions in which a polarity change between a reactant and the activated complex takes place have hitherto been interpreted as follows: if Eq. 4 is differentiated with respect to the pressure, it follows that:

$$\left(\frac{\partial \ln k}{\partial p}\right)_T = -\frac{\Delta V^{*}}{RT} = \frac{3}{4kT}\left(\frac{\mu_{*}^2}{r_{*}^3} - \frac{\mu^2}{r^3}\right)\frac{(\partial\varepsilon/\partial p)_T}{(\varepsilon+1)^2}. \quad (5)$$

The $(\partial\varepsilon/\partial p)_T/(\varepsilon+1)^2$ term generally decreases as the polarity of a solvent increases, in agreement with the trend observed in Menschutkin reactions. However, this is nothing but a qualitative explanation. For example, ΔV^{*}(benzene)/ΔV^{*}(nitrobenzene)≈1.6(obsd) and 10(calcd) for a reaction between pyridine and methyl iodide. This large discrepancy, together with the considerable scatter in Fig. 2, may be ascribed to the neglect of specific solute-solvent interactions in the Kirkwood model. Such interactions will give rise to a polarization enhanced by polar solvents. In our case, the dipole moment in the transition state may be more susceptible to the solvent polarity, compared with the case of the Menschutkin reactions, since the transition state of substituted azobenzenes are *soft* in the sense that the π-electrons are labile(see **7**—**11**). Thus, if the effect of solvent polarity on the μ-term overwhelms the effect on the ε-term in Eq. 5, ΔV^{*} will increase with the increase in solvent polarity, and *vice versa*, the preference depending on the type of reactions. It seems that the investigation and the interpretation along these lines have not yet been well-established, and so we must suspend a straightforward conclusion.

The above assumption requires that the plot of Fig. 2 be curved concavely upward. Probably, a quadratic regression equation for NDAAB will support it, but the plots are too scattered, and therefore more sophisticated investigations are necessary. Further, the freedom to rotate around the C-N bond in the *cis* and transition states may be deeply related to the nature of the solvents as well as to the bulkiness and positions of substituents. The above findings (1)—(4), together with the solvent and substituent effects, show very complicated aspects of the isomerization of azobenzenes.

Conclusion

We have compared the kinetic substituent, solvent, and pressure effects for the thermal *cis*-to-*trans* isomerization of push-pull azobenzenes with those for other kinds of azobenzenes for which the inversion mechanism has been accepted, and have seen that there are no essential differences in kinetic behavior between them. Rather, we have observed very similar *ortho* effects between NDAAB and DAAB derivatives. Further, we have found substantial kinetic-pressure and solvent effects for symmetrically substituted azobenzene. The above findings argue in favor of the inversion mechanism and against the rotational one.

We wish to express our gratitude to Emeritus Professor Jiro Osugi and Dr. Kimihiko Hara of Kyoto University for their technical advice on the high-pressure experiments and also for their encouragement.

Extrinsic Carrier-photogeneration in Poly(*N*-vinylcarbazole)

Ken-ichi OKAMOTO* and Akira ITAYA

Department of Chemical Engineering, Faculty of Engineering, Yamaguchi University, Ube, Yamaguchi 755

(Received September 5, 1983)

The carrier-photogeneration efficiency of holes in poly(*N*-vinylcarbazole) (PVCz) films was investigated by means of the time-of-flight method as a function of applied electric field, temperature, and excitation band. The extrinsic effects on the efficiency were examined; these included photooxidation of film surface and doping with a weak electron-acceptor, dimethyl terephthalate (DMTP). The experimental results were analyzed according to the Onsager theory of geminate recombination of a bound electron-hole pair with an interionic separation of r_0. The primary yield of the electron-hole pair, ϕ_0, increased from 0.02 to 0.059 with decreasing excitation wavelength. By photooxidation, it increased up to 0.09 for all the excitation bands. The r_0 was independent of the excitation band, and was identical between fresh and photooxidized films. In DMTP(1.8 mol%)-doped films, both ϕ_0 and r_0 were independent of the excitation band, although their values were different from those of undoped films. These results indicate that the extrinsic carrier-photogeneration *via* nonrelaxed exciplexes formed between singlet excitons and acceptor-like impurities or photooxidation products is predominant in PVCz films for all the excitation bands.

A number of papers have appeared in the literature concerned with the carrier-photogeneration process in poly(*N*-vinylcarbazole) (PVCz), one of the typical photoconducting polymers.[1-10] Taking account of the ionization potential (6.1 eV)[11] and the electron affinity (1.5 eV)[12] of PVCz in a solid film, the intrinsic carrier-photogeneration due to the autoionization mechanism, which has been observed for anthracene single crystals,[13] is considered only for the π-π^* excitation higher than 4.6 eV (^1B_b and ^1B_a transitions). For the lower π-π^* excitation (^1L_b and ^1L_a transitions), the extrinsic carrier-photogeneration expressed by Scheme 1 is the most probable mechanism at the present stage.[10] Photooxidation products of PVCz produced within the surface layer of a film seem to be the most probable as the acceptor-like impurity A in Scheme 1.[9]

$$^1D^* + A \longrightarrow \underset{\text{encounter complex}}{(^1D^* \cdots A)} \longrightarrow \underset{\text{nonrelaxed exciplex}}{^1(D^+A^-)^{**}} \xrightarrow{\text{thermalization}}$$

$$\underset{\text{bound electron-hole pair}}{^1(D^+ \overset{r_0}{\cdots} A^-)} \xrightarrow[P(E)]{\text{field-assisted dissociation}} \underset{\text{carriers}}{D^+ + A^-}$$

$$\downarrow \text{ geminate recombination } 1-P(E)$$

$$\underset{\text{relaxed exciplex}}{^1(D^+A^-)^*}$$

Scheme 1.

The overall carrier-photogeneration efficiency, ϕ, is given as the product of the primary quantum yield, ϕ_0, of a bound electron-hole pair with an interionic separation of r_0 and the dissociation probability, $P(E)$:

$$\phi = \phi_0 P(E). \quad (1)$$

The ϕ_0 is considered to be independent of the electric field, E. The field-dependent probability of $P(E)$, which is given by the Onsager theory,[14] is a function of r_0.

The field dependence of the photogeneration efficiency in PVCz films has been analyzed according to the Onsager theory by two groups of investigators.[4,8] They have reported that ϕ_0 is independent of the excitation wavelength and that r_0 increases in steps with decreasing excitation wavelength. However, there has been no explanation of their results. These results are quite opposite to the predictions based on the extrinsic carrier-photogeneration process expressed by Scheme 1.

The above results were obtained by means of the xerographic discharge technique. Although it is convenient and practical, especially for high fields, this technique seems inferior to the time-of-flight method because it is difficult to avoid two effects: trapped space charge due to preexposures and photodegradation of film surface caused by exposing it to corona-charge. Unfortunately, to our knowledge, there have been few reports in which the field dependence of the photogeneration efficiency has been measured in detail by means of the time-of-flight method, taking cautions to prevent any photooxidation of the films, and has been analyzed according to the Onsager theory.

In the present paper, in order to make clearer the carrier-photogeneration process, we investigate effects of the excitation wavelength and temperature on the photogeneration efficiency in PVCz over a wide range of fields by means of time-of-flight method. We also investigated the photogeneration efficiency in PVCz films which were slightly-photooxidized or doped with dimethyl terephthalate (DMTP), a weak electron acceptor, by comparing the results with that obtained for the fresh films.

Experimentals

The PVCz was prepared by free-radical polymerization (initiator: AIBN) of the highly-purified monomer and was purified by reprecipitation from a benzene solution with methanol several times. The polymer sample was stored in tubes with an argon atmosphere in the dark. Gel permeation chromatography analysis showed $M_n = 1.95 \times 10^5$ and $M_w/M_n = 2.3$. Films were cast on NESA-coated quartz plates from a benzene solution and were dried *in vacuo*. Photooxidized films were prepared by irradiating the free surface of fresh films in air for 1—18 min through a water filter (10 cm) with the full spectrum of a 500 W high pressure mercury lamp at a distance of 40 cm from the lamp. A semitransparent gold electrode with a typical area of 1 cm^2 was evaporated on a film to prepare a sandwich-type cell. Caution

was taken in all procedures of the experiment to keep the sample from being exposed to the room light. Film thickness was determined from the weight and density (1.188 g/cm^3) of a film with a known area (*ca.* 1.5 cm^2) and/or by a capacitive method.

A 3 μs light pulse from an air-gap flash was irradiated on a cell set in a cryostat with a high vacuum, better than 1.3 mPa, through appropriate narrow band pass filters. An induced transient photocurrent was observed through a series load resistor in the current or differential mode by means of a storage oscilloscope. In order to avoid the space charge effect due to previous exposures and to get reproducible results, the cell was irradiated by visible light (λ>450 nm) while short-circuited for several minutes prior to each measurement. The intensity of each light pulse was monitored by a Si photodiode equipped with a peak-hold circuit, the output of which was calibrated by means of a potassium ferrioxalate actinometer.

The dielectric constant ε of films was determined from capacitance measurements. The value of 3.38, which was determined at the frequency of 1 kHz at 23 °C, was used in the calculation of $P(E)$, neglecting the temperature dependence of ε.

The $P(E)$ was calculated according to the method developed by Geacintov and Pope.[15]

Results and Discussion

Effects of Excitation Band and Temperature on ϕ_0 and r_0 in Fresh Films. As shown in Fig. 1, three kinds of band bass filters were used in order to excite the ^1L_b, ^1L_a, and ^1B_a absorption bands. 90% of the incident light of 340, 280, and 240 nm was absorbed within layers of less than 0.51, 0.23, and 0.065 μm in depth, respectively. A typical set of transient photocurrent signals for positive gold-electrode illumination is shown in Fig. 2. The observed photocurrent signal generally had an initial spike-like signal superimposed on a longer-duration signal. This spike-like signal cannot be attributed to loss of holes by bimolecular volume-recombination in the excitation layer, as for the case of anthracene,[17] but to fast hole transport in a short duration immediately after carrier generation.[18] The number of collected carriers (holes) per unit area, N_p, was obtained from the integral of the photocurrent over the entire drift times using a set of transient signals such as shown in Fig. 2. The N_p was proportional to the light intensity, ranging from 1×10^{12} to 1×10^{14} photons/cm^2 pulse, and was independent of the film thickness, which ranged from 3 to 12 μm. These results indicate that the observed values of N_p are not affected by space-charge effects, bulk recombination, or range limitation of hole carriers. The ϕ was obtained by dividing N_p by the light intensity.

Figure 3 shows the field dependence of ϕ in fresh films for the different excitation bands. The measurements were done at 65 °C in order to avoid the complicating effects due to bulk carrier trapping in the low-field region.[2] The ϕ increased in the order of the

^1L_b, ^1L_a, and ^1B_a bands. The solid lines were calculated from Eq. 1, with r_0 of 26 Å and with ϕ_0 of 0.020, 0.035, and 0.059 for the ^1L_b, ^1L_a, and ^1B_a bands, respectively. They are in good agreement with the experimental data. The results indicate that the increase in ϕ with decreasing excitation wavelength is due only to a change in ϕ_0. Although being quite opposite to the results reported in the literature,[4,8] these results are explained by the extrinsic carrier-photogeneration process (Scheme 1) mentioned below.

The singlet excitons, which migrate in a film to encounter molecules A, are the lowest excited singlet state, irrespective of the excitation wavelength, because the internal conversion from any higher excited singlet state to the lowest excited one precedes excitation energy migration. Therefore, r_0 is independent of the excitation wavelength. Taking account of the singlet exciton migration efficiency,[16] ϕ_0 is considered to increase with increasing concentration of A in the concentration range less than the order of 10^{-3} mol/mol-basic-unit (expressed by mol% hereafter). As the photooxidation proceeds preferentially near the surface of a film, the concentration of photooxidation products acting as A in Scheme 1 becomes higher on going from the bulk to the surface. Because of this concentration profile, ϕ_0 has a tendency to be higher for the excitation wavelength having higher absorption coefficient; that is, ϕ_0 increases in the order of the ^1L_b, ^1L_a, ^1B_b, and ^1B_a transitions.

Figure 4 shows the temperature dependence of ϕ in fresh films for the 340 nm excitation. The solid lines were calculated from Eq. 1 with r_0=26 Å and ϕ_0=0.020, assuming that both r_0 and ϕ_0 were independent of temperature. They are in fairly good agreement with the experimental data, indicating that both r_0 and ϕ_0 do not depend on temperature in the relatively narrow range. The result for ϕ_0 seems to be due to the fact that the singlet exciton migration length is insensitive to temperature in this range.[16]

Effects of DMTP-doping on ϕ_0 and r_0. Figure 5 shows the field dependence of ϕ in films doped with DMTP (1.8 mol%). The ϕ in these films is much larger

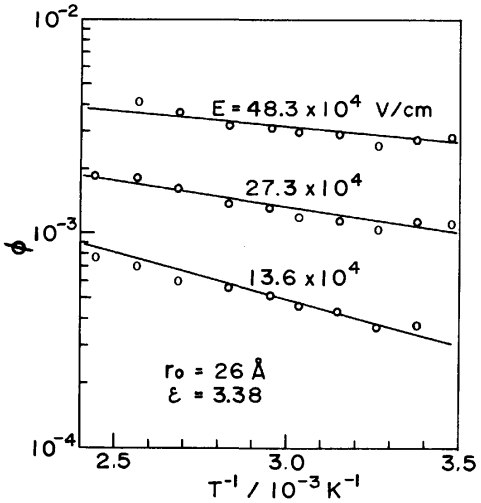

Fig. 4. Temperature dependence of ϕ in fresh films for the 340 nm excitation. The solid lines were calculated from Eq. 1 with r_0=26 Å and ϕ_0=0.020.

than that in undoped films and is independent of the excitation bands. The data are in fairly good agreement with the solid line calculated from Eq. 1 with r_0= 22 Å and ϕ_0=0.9. In the DMTP-doped films, the host excimer fluorescence was almost completely replaced by the exciplex fluorescence,[16] indicating that most of the singlet excitons encounter DMTP molecules to form encounter complexes. Furthermore, the probability of triplet exciton formation from a singlet exciton by intersystem crossing is in the order of 10^{-2}.[19] It is, therefore, reasonable that the DMTP-doped films

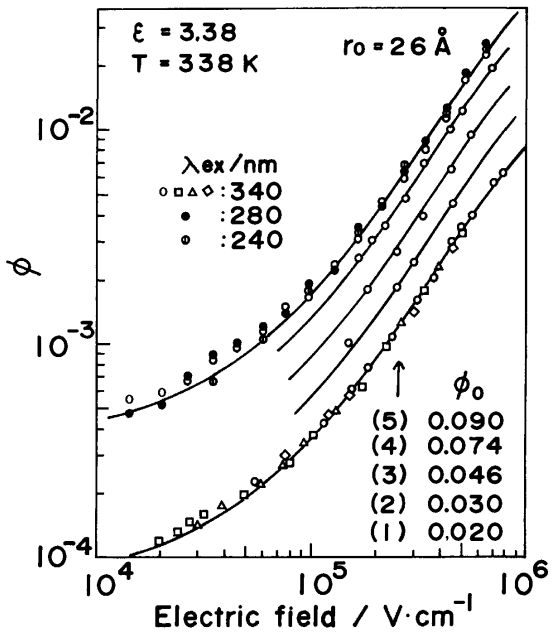

Fig. 6. Field dependence of ϕ in photooxidized films for different irradiation times. The solid lines were calculated from Eq. 1 with r_0 and ϕ_0 values presented in the figure. The irradiation time: (1) 0, (2) 0.9, (3) 3.3, (4) 9, and (5) 18 min. See the text concerning the irradiation conditions.

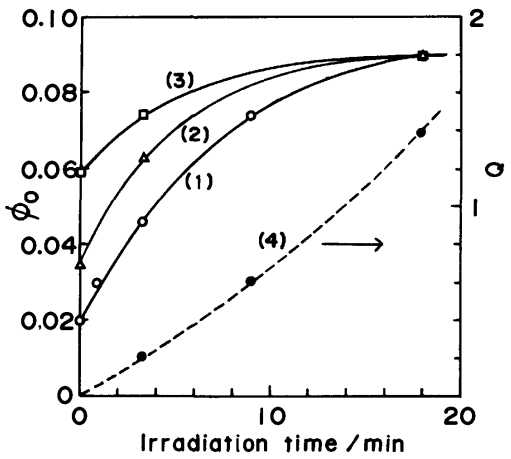

Fig. 7. Irradiation-time dependence of ϕ_0 and the quenching factor, Q, of the excimer fluorescence. ϕ_0: (1) 340 nm, (2) 280 nm, and (3) 240 nm excitation. Q: (4) 340 nm excitation.

have the ϕ_0 value of 0.9 for all the excitation bands. This high value of ϕ_0 is comparable to the value of 0.8 for PVCz films doped with 1,2,4,5-tetracyanobenzene (2 mol%) on excitation of the charge transfer band,[20] and is much larger than the value of 0.23 for films doped with 2,4,7-trinitro-9-fluorenone (6 mol%).[21] The r_0 value of 22 Å is the same as that observed from the quenching experiment of the exciplex fluorescence by electric field.[10]

Effects of Photooxidation on ϕ_0 and r_0. Figure 6 shows the field dependence of ϕ in photooxidized films for different irradiation times. The data are in good agreement with the solid lines calculated from Eq. 1 with r_0=26 Å, the same value as in fresh films, irrespective of both the excitation bands and the irradiation time. The ϕ_0 values thus determined are shown in Fig.7 as a function of irradiation time. The ϕ_0 increased rapidly with increasing irradiation time and soon leveled off to a value of 0.09 for all the excitation bands. The increase in ϕ with increasing irradiation time within the present level of photooxidation is thus explained by the increase in ϕ_0 only, which was caused by an increase in the concentration of acceptor-like photooxidation products acting as molecule A in Scheme 1.

The films irradiated in air showed remarkable changes in the fluorescence spectra, while such changes were not observed for the films irradiated in a high vacuum of 1.3×10^{-3} Pa. With irradiation time, the excimer fluorescence of PVCz films decreased and a new fluorescence band, which has been attributed to the exciplex formed between an excited carbazole chromophore and an acceptor-like photooxidation product,[9] appeared around 515 nm. The decrease in the excimer fluorescence in films is shown in Fig. 7, using a quenching factor Q. In each film, the value of Q for the 280 nm excitation was roughly twice as large as that for the 340 nm excitation. According to the random hopping model of singlet exciton migration, Q is expressed by Eq. 2:

$$Q=([A])+[T_s])/[E], \quad (2)$$

where [A] is the concentration of acceptor-like photooxidation products acting as molecule A in Scheme 1; $[T_s]$ is the concentration of non-acceptor-like photooxidation products acting as singlet exciton traps; and [E] is the concentration of the excimer-forming sites. According to Scheme 1, ϕ_0 is expressed by Eq. 3:

$$\phi_0=\phi_s^*[A]/([E]+[A]+[T_s]), \quad (3)$$

where ϕ_s^* is the quantum yield of the singlet exciton formation. The $[T_s]$ and [A] were evaluated from the Q and ϕ_0 values, taking [E] and ϕ_s^* as 0.27 mol%[16] and 0.9,[19] respectively, irrespective of the irradiation time. The $[T_s]$ and [A] thus obtained are listed in Table 1. They are the effective concentrations in the surface layer through *ca.* 0.5, 0.2, and 0.07 μm in depth for the 340, 280, and 240 nm excitations, respectively. Both $[T_s]$ and [A] were higher for the shorter-wavelength excitation, because the photooxidation proceeds preferentially near the surface of a film. With increasing irradiation time, both [A] and $[T_s]$ increased, but their ratio, $[A]/[T_s]$, decreased. This is reasonable, judging from the facts that the acceptor-like photooxidation products are intermediates and undergo further photooxidation and that the exciplex fluorescence around 515 nm was observed most strongly for the films with the Q value of 1—3.[9] The small value (0.09) of ϕ_0 observed for all the excitation bands is thus explained by a small value of the ratio, $[A]/([E]+[A]+[T_s])$, and is independent of the excitation layer.

The ϕ_0 values of 0.11[8] and 0.14[4] determined by the xerographic discharge technique are comparable to the value of 0.09 in the photooxidized films and are much larger than the value of 0.02 for the 340 nm excitation in fresh films. This suggests that the surface of films exposed to xerographic photo-discharge even in a nitrogen atmosphere is subjected to the photooxidation at a fairly high level.

The r_0 is considered to depend on the properties of acceptor-like molecules,[10] while both the fresh and photooxidized films had the identical value (26 Å) of r_0. This suggests that the main acceptor-like molecules are identical for these films. The r_0 is considered to depend on the excess energy to be dissipated. It was,

18	0.065	0.10	—	0.315	0.67

a) 340, 280, and 240 nm are the excitation wavelengths. See the text.

nevertheless, independent of the excitation bands, as mentioned above. This indicates that the direct carrier-photogeneration from the higher excited singlet states is negligible for films investigated in this paper.

Based on the energetical considerations,[10,11] intrinsic carrier-photogeneration due to the autoionization mechanism is expected to be possible for the ^1B_b and ^1B_a excitations. Yokoyama *et al.* have proposed this mechanism for the photocurrent in copolymers of *N*-vinylcarbazole with 1-vinylnaphthalene.[22] However, the comparison of r_o and ϕ_o between the 240 nm excitation and the 280 or 340 nm excitation clearly indicates that the extrinsic carrier-photogeneration in Scheme 1 rather than the intrinsic autoionization mechanism is predominant even for the 240 nm excitation. This is reasonable, judging from both the relatively high concentration of acceptor-like impurities ([A]=0.018 mol%) in the surface layer through 0.07μm in depth of fresh PVCz films and the relatively low value of the primary quantum yield ($\phi_o<10^{-2}$) for the autoionization process in anthracene single crystals.[23] The intrinsic autoionization mechanism is considered to become important when the higher singlet excited states are formed in a bulk sample which has a low concentration of acceptor-like impurities, as is the case of the triplet-triplet annihilation in the copolymers.[22]

Conclusion. As mentioned above, the excitation wavelength dependences of r_o and ϕ_o in fresh, photooxidized and DMTP-doped films lead to the conclusion that the extrinsic carrier-photogeneration process expressed by Scheme 1 and Eq.1 is predominant in every film for all the excitation bands.

Electrophilic Substitution Reactions on Methine Carbon of the Unsymmetrical Tetradentate Schiff Base and its Complexes with Nickel(II) and Copper(II)

Kuninobu KASUGA,* Takeo NAGAHARA, Teruaki MASUDA, Shunji KIYOTA, and Yasuo YAMAMOTO
Department of Chemistry, Faculty of Science, Shimane University, Matsue 690
(Received July 1, 1983)

A number of unsymmetrical tetradentate Schiff base complexes of nickel(II) and copper(II) having only one methine carbon in the ligand were synthesized and characterized by means of UV and ^{1}H NMR spectra. The kinetic studies of the electrophilic substitution reactions on the methine carbon with *N*-halogenosuccinimide gave no support to an aromatic character of the chelate ring, being consistent with the results of ^{1}H NMR studies for the nickel(II) complexes.

Nature of the bonding in β-diketone metal complexes has been the subject of considerable controversy. A π-bonding between ligands and metal ion in the complexes was once proposed.[1-3] However, an aromaticity of the chelate ring has been suspected on the basis of electronic spectral and ^{1}H NMR data.[4] Collman and his coworkers subsequently reported various replacements of methine protons of these complexes by electrophiles such as bromine, iodine, *N*-halogenosuccinimide, nitro derivatives, acyl derivatives, and sulfur, suggesting the aromatic character of the chelate ring.[5] Furthermore electrophilic substitution reactions on the chelate ring have been reported for mixed ligand β-diketone complexes of cobalt(III),[6] and tetradentate Schiff base complexes of nickel(II) and copper(II).[7-9] Further replacement of the halogen-substituted methine carbon of the β-diketone and tetradentate Schiff base complexes were also carried out using benzenethiol and its derivatives as a nucleophile.[8,10,11]

Although the reactions of coordinated ligands were considerably studied from the synthetic aspects, only a few studies have been reported on the reaction mechanism.[6,9,12] One of the reasons is the presence of two or more methine carbons in the chelate rings, which makes it difficult to study the reaction kinetics. In the present paper, a series of nickel(II) and copper(II) complexes with only one methine carbon in their chelate ring was prepared and the aromaticity of the chelate ring was studied by means of the ^{1}H NMR spectra and reaction kinetics of the electrophilic substitution on the methine carbon. The complexes used in the present study are shown in Fig. 1.

Experimental

Complexes. [*N*-(1-Methyl-3-oxobutylidene)-*N'*-salicylideneethylenediaminato]copper(II), Cu(L-H, Me, H), was prepared by the method described before.[13] Other derivatives of copper(II) were prepared according to the similar procedure to that for Cu(L-H, Me, H). However, the method was inapplicable to the preparation of the nickel(II) complex because of a great difficulty in separating the product from the by-products such as [*N*,*N'*-bis(1-methyl-3-oxobutylidene)ethylenediaminato]nickel(II) and (*N*,*N'*-disalicylideneethylenediaminato)nickel(II). Therefore, the nickel(II) complex, Ni(L-H, Me, H), was prepared by the reaction of nickel(II) acetate and a free ligand which was previously liberated from the copper(II) complex, Cu(L-H, Me, H). Hydrogen sulfide was bubbled through a chloroform solution(50 ml) of 1.0 g (3.2 mmol) Cu(L-H, Me, H) at room temperature for 20 min. After filtering off copper(II) sulfide, active charcoal was added to the filtrate, and the mixture was stirred for several min. After filtering off charcoal, tarry crude precipitates of the free ligand were obtained by concentrating the filtrate under a reduced pressure. The pale yellowish white crystals of the free ligand were subsequently recrystallized from cyclohexane. The nickel(II) complex was precipitated after standing a methanol solution(30 ml) of 0.74 g (3.0 mmol) free ligand and 0.75 g (3.0 mmol) nickel(II) acetate tetrahydrate at room temperature for 30 min. Then, the bright brown crystals of the nickel(II) complex were recrystallized from dichloromethane added with a small amount of methanol. The other nickel(II) complexes were prepared by the reactions of nickel(II) acetate tetrahydrate and the free ligands which were liberated from the corresponding copper(II) complexes.

Halogen Derivatives. *N*-Chlorosuccinimide (CSI) (0.44 g, 3.3 mmol) was added to 30 ml of the dichloromethane solution of 0.91 g (3.0 mmol) Ni(L-H, Me, H), which was stirred at room temperature for 20 min. After concentrating the solution under a reduced pressure, [*N*-(2-chloro-1-methyl-3-oxobutylidene)-*N'*-salicylideneethylenediaminato]nickel(II), Ni (L-Cl, Me, H), was precipitated by the addition of an adequate amount of methanol. The brown crystals were subsequently recrystallized from acetone. The other chloro derivatives were also prepared according to the similar method described above. Bromo derivatives of the nickel(II) complexes were prepared using *N*-bromosuccinimide (BSI) instead of CSI (the reaction temperature was maintained below −5 °C). The halogen derivatives of the copper(II) complexes were prepared

using a similar method to the nickel(II) complexes. The chlorination of the free ligand was performed by adding 0.88 g (6.6 mmol) CSI to the 50 ml dichloromethane solution of 1.5 g (6.0 mmol) (L-H, Me, H), and was left at room temperature for 20 min. After evaporation of the solvent, the precipitates remained were dissolved in 30 ml methanol, and an adequate amount of water was added to the solution. Then, the pale yellowish white precipitates were obtained, and subsequently recrystallized from cyclohexane.

Kinetic Measurements. *N*-Chlorosuccinimide and *N*-bromosuccinimide were recrystallized from ethanol, and dried under a reduced pressure. The solvents used for kinetic measurements were dehydrated on anhydrous calcium chloride and distilled under a reduced pressure. The reaction rate was measured by the absorbance change with time on a Hitachi 215 spectrophotometer. The temperature was kept at 20.0±0.1 °C.

Other Measurements. The ^{1}H NMR spectra were recorded with a JEOL-MH 100 spectrophotometer at a frequency of 100 MHz. The chemical shifts were determined in ppm, using TMS as the internal standard. The electronic spectra in solution were measured on a Hitachi 215 spectrophotometer.

Results and Discussion

Electronic and ^{1}H NMR Spectra of the Complexes. The results of elemental analyses and yields of the complexes are listed in Table 1.

In Table 2, the electronic spectral data in benzene solutions are given. Nickel(II) complexes (**1**—**20**) show the d-d absorption bands at 550—570 nm which are characteristic of a square planar nickel(II) complex. The Ni(L-X, Ph, Z) complexes (**5**—**8** and **13**—**16**) show the d-d bands at longer wavelengths than Ni(L-X, Me, Z) (**1**—**4** and **9**—**12**). This lower-energy shift may be attributed to an electron-withdrawing effect of a phenyl group which weakens the in-plane crystal field. The 5-chloro and 5-bromo derivatives show little shift of the d-d bands, whereas the 3-methoxy derivatives (**4**, **8**, **12**, and **20**) shift the bands somewhat to longer wavelengths compared with the unsubstituted complexes (**1**, **5**, **9**, **13**, and **17**). The lower-energy shift in the methoxy derivatives may also be attributed to the electron-withdrawing effect of the methoxyl group. On the other hand, the d-d bands (560 nm) of the copper(II) complexes (**21**—**26**) show little shift. The π-π^* absorption bands in 310 to 350 nm have the following characteristic points; 1) the X substituents such as chlorine and bromine of the nickel(II) complexes (**9** and **17**) shift the bands to shorter wavelengths than Ni(L-H, Me, H) (**1**), whereas the Z substituents (**2**—**4**) to longer wavelengths. 2) In the copper(II) complexes, on the contrary, the X substituents (**24** and **25**) shift the bands to longer wavelengths, and the Z substituents scarcely shift the bands (**22** and **23**) compared with Cu(L-H, Me, H) (**21**). That is, the effect of copper(II) on the π-system of the chelate ring is different from that of nickel(II). Further studies will be performed on the effect of other metal ions on the π-π^* absorption bands.

The ^{1}H NMR data are listed in Table 3. The ^{1}H NMR signals arising from the methine proton disappear in the halogen derivatives, indicating the replacement of the methine proton with the substituents. The ^{1}H

a) Yields are in molar percentages.

NMR signals of the methyl groups are largely shifted to lower magnetic fields in the order of X=H, Cl, and Br derivatives of nickel(II). This tendency is attributable to the magnetic anisotropic effect of halogen rather than to its inductive effect.

Aromaticity of the Chelate Rings. Nature of the chelate-ring bonding of β-diketone complexes has called considerable attention for a long time. In 1945, Calvin *et al.* proposed the conjugated system of type II for the chelate-ring bonding of the complexes.[1)]

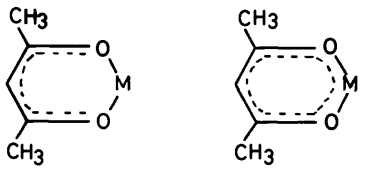
Confidence limits are ±0.02 ppm. a) in 1, 1, 2, 2-tetrachloroethane-d_2. s=singlet, d=doublet, t=triplet, m =multiplet, and br=broad. The ^1H NMR spectra of Ni(L-Cl, Ph, Cl) and Ni(L-Cl, Ph, Br) were not obtained because of their poor solubilities.



Barnum also suggested the significant π-bonding between the ligands and the metal ion on the basis of electronic spectra.[2] Further, Nakamoto suggested from the results of IR spectra that acetylacetone complexes of nickel(II), copper(II), and palladium(II) have the structure of type (II), although those of zinc(II) and cobalt(II) have that of type (I).[3] However, Cotton *et al.* pointed out that the aromaticity was unreasonable on the basis of the symmetry and energy of the metal orbitals available for the π-bonding.[4] On the other hand, Collman and his coworkers have studied the numerous electrophilic substitution reactions on the chelate rings, which support the conjugate system of type (II).[5] They also reported the quasiaromatic character of the chelate ring from the ^1H NMR spectra of diamagnetic cobalt(III) and rhodium(III) complexes with the mixed ligands of acethylacetone and its derivatives.[14]

To examine the quasiaromatic character of the chelate ring of Ni(L-H, Y, Z), we investigated the effect of the Z groups on the ^1H NMR signals of the methine proton (Table 3). If the chelate ring had the quasiaromaticity, the electron density of the methine proton is expected to change with the Z groups. In a series of the complexes with the methyl substituents at position Y, Ni(L-H, Me, Z), the methine signals are observed at 5.51 (Z=H), 5.51 (Cl), 5.50 (Br), and 5.51 ppm (OCH_3), respectively. For Ni(L-H, Ph, Z), the signals appear at 6.22 (Z=H), 6.24 (Cl), 6.23 (Br), and 6.24 ppm (OCH_3). These facts show that the effect of the Z substituents is little on the ^1H NMR signals of the methine proton, and this agrees with the ^1H NMR data investigated for a broad range of diamagnetic metal complexes of acetylacetone; the metal ions do not significantly affect the shift of the methine-proton signals.[4] Therefore, the ^1H NMR data seem to give no support for an aromaticity of the nickel(II) chelate-ring of the Schiff base complexes such as shown in aromatic compounds.

Kinetics of Electrophilic Ring-substitution Reactions. By the addition of *N*-chlorosuccinimide, the spectrum

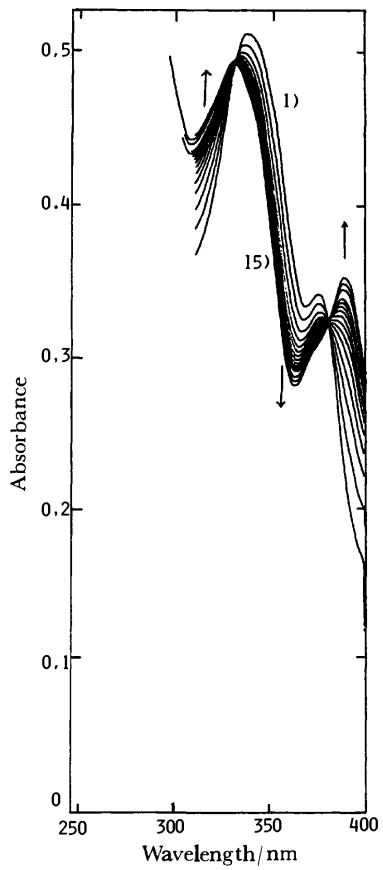


Fig. 2. Spectra changes during the reaction of Ni(L-H, Me, H) with CSI in the benzene solution at 20°C; $[Ni(L\text{-}H, Me, H)]_0=7.48\times10^{-5}$ mol dm^{-3}, $[CSI]_0=1.05\times10^{-4}$ mol dm^{-3}: 1) 40 s, 2) 1 min 40 s, 3) 2 min 40 s, 7) 6 min 40 s, 11) 10 min 40 s, 13) 15 min 40 s, 14) 20 min 40 s, and 15) 30 min 40 s, after the reaction.

TABLE 4. THE RATE CONSTANTS OF THE REACTIONS OF THE COMPLEXES WITH CSI IN A BENZENE SOLUTION

Run	$k/10^2$ mol^{-1} dm^3 s^{-1}	Conditions
1	0.53±0.03	Ni(L-H, Me, H) + CSI
2	0.51±0.04	same reactants with a few mg of the scavenger
3	0.30±0.02	Ni(L-H, Ph, H) + CSI
4	0.21±0.05	Ni(L-H, Me, Cl) + CSI
5	0.25±0.03	Ni(L-H, Me, Br) + CSI
6	0.55±0.04	Ni(L-H, Me, OCH_3) + CSI
7	8.0 ±1.2	Cu(L-H, Me, H) + CSI
8	1.1 ±0.2	(L-H, Me, H) + CSI

Isosbestic points for the reactions of the copper(II) complex and the free ligand with CSI are at 337 and 324 nm, respectively. [complex]$_0$=4.4×10^{-5}—7.5×10^{-5} mol dm^{-3}; [CSI]$_0$=1.05×10^{-4} mol dm^{-3}; temp= 20.0±0.1 °C.

of Ni(L-H, Me, H) in the benzene solution changed to that of Ni(L-Cl, Me, H) with isosbestic points at 334 and 380 nm (Fig. 2). The existence of the isosbestic points clearly indicates that only the following reaction occurs:

Ni(L-H, Me, H)+CSI→Ni(L-Cl, Me, H)+succinimide. (1)

Thus, the rate of reaction (1) is determined by an absorbance change at 393 nm. The second-order plot of $(a-b)^{-1}\ln[b(A_t-A_\infty)/\{b(A_0-A_\infty)-a(A_0-A_t)\}]$ *versus* time is linear for at least 90% completion, a and b being intial concentrations of Ni(L-H, Me, H) and CSI. A_0, A_t, and A_∞ represent the absorbances at the beginning, time t, and infinity, respectively. From the slope, the rate constant was estimated to be (5.3±0.3)×10/mol^{-1} dm^3 s^{-1}. The rate was also measured at 340 nm. The rate constant, (5.1±0.4)×10/mol^{-1} dm^3 s^{-1}, agreed with that obtained at 393 nm within an error, showing no wavelength dependence of the rate. The other rate constants were also obtained in a similar manner to that described above.

Further experiments were performed to elucidate the reaction mechanism (Table 4, Figs. 3 and 4), and the results are as follows: 1) A few mg of 2,6-di-*t*-butylphenol were added into the CSI solution and the solution was subsequently mixed with the Ni(L-H, Me, H) solution. The rate constant of the reaction (Run 2) was the same as that without scavenger (Run 1), which excludes a radical mechanism consistent with the result of the chlorination of [*N*,*N*′-bis(4,4,4-trifluoro-1-methyl-3-oxobutylidene)ethylenediaminato]nickel(II), Ni(tfac$_2$en), with CSI.[9] As shown in Fig. 3, the rate constant increased with the amount of dichloromethane added to the benzene solution. It is known that the reaction of CSI involves the radical mechanism in crystals or in solvents such as carbon tetrachloride and cyclohexane, but involves an ionic mechanism in solvents such as 1,1,2,2-tetrachloroethane and acetonitrile.[15,16] Thus, the above solvent effect observed supports the ionic mechanism. On the other hand, the rate constant decreased slightly by the addition of acetone and remarkably by ethyl ether. It has been reported that acetone and ethyl ether react with BSI to exchange α-hydrogen with bromine.[16] Thus, the addition of the solvents must decrease the concentration of CSI, resulting in the decrease of the rate constant; 2) The rate constant of the chlorination of Ni(L-H, Me, H) (Run 1) was almost the same as those of Ni(L-H, Me, Cl), and Ni(L-H, Me, Br) (Runs 3—5); 3) The rate constant of bromination with *N*-bromosuccinimide was larger than that of chlorination (the rate of bromination was so fast that the rate constant could not be determined). The smaller electron negativity of bromine may produce the cationic bromine more easily from BSI than the cationic chlorine from CSI; 4) The addition of triethylamine (3.0×10^{-5}/mol dm^{-3}) inhibited extreamly the reaction presumably because of the reaction with CSI;[16] 5) As is shown in Fig. 4, the addition of alcohols remarkably increased the

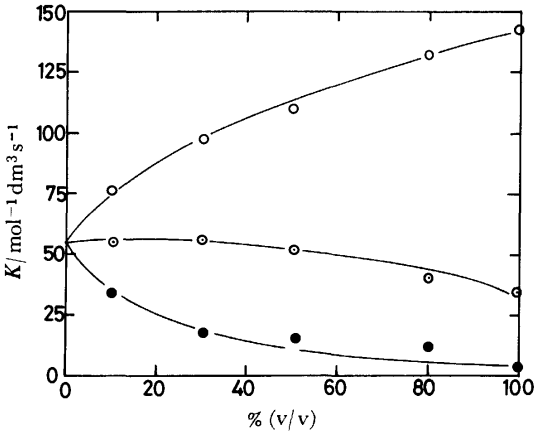

Fig. 3. The effect of solvents on the rate constant of the chlorination reaction: O, dichloromethane; ⊙, acetone; ●, diethyl ether.

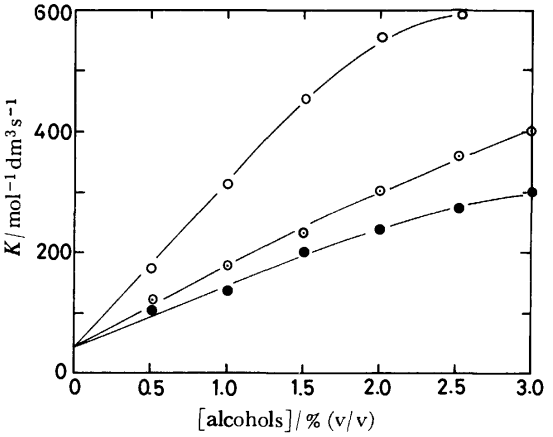

Fig. 4. The effect of alcohols on the rate constant of the chlorination: O, methyl alcohol; ⊙, ethyl alcohol; ●, butyl alcohol.

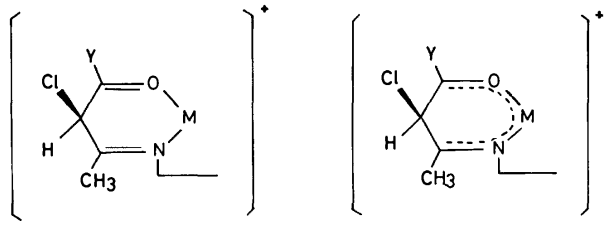
rate constant. It is reported that molecular chlorine is liberated from CSI by the addition of alcohols.[17] Thus, chlorine liberated by alcohols may accelerate the reaction rate; 6) The rate constants of the chlorination of Cu(L-H, Me, H) and (L-H, Me, H) are $(8.0\pm 1.2)\times10^2$ and $(1.1\pm0.2)\times10^2$ / mol^{-1} dm^3 s^{-1}, respectively (Runs 7 and 8).

On the basis of the above results and discussion, the chlorination of M(L-H, Y, Z) can be assumed to proceed *via* an intermediate (A)[9] or (B) in which a π-system is extended through the central metal ion. However, for the free ligand, in which an extended π-system like (B) is impossible, also proceeds the chlorination, and the order of the rate constant is Ni(II)-complex< free ligand<Cu(II)-complex. Therefore, these results indicate that the chlorination of M(L-H, Y, Z) proceeds *via* the intermediate (A) which is consistent with the result for Ni($tfac_2en$).[9]



(A) (B)

That is, the electrophilic ring-substitution reaction on the chelate ring of metal complexes does not necessarily support the existence of the benzenoid resonance as shown for the β-diketone metal complexes by Collman *et al.*[5] The results agree with those obtained by the ^1H NMR studies.

The copper(II) complex shows an extremely large rate constant as compared with the nickel(II) complex and the free ligand. At present, there is no satisfactory explanation for the behavior of the copper(II) complex. The copper(II) complex may catalyze the reaction presumably *via* the formation of a CSI adduct. Further studies on the effect of the central metal ions will be performed.

A Versatile Synthesis of Four-, Five-, and Six-membered Cyclic Ketones Using Methyl Methylthiomethyl Sulfoxide

Katsuyuki OGURA,*,† Mitsuo YAMASHITA, Michiyo SUZUKI, Shigeko FURUKAWA, and Gen-ichi TSUCHIHASHI*,††

Sagami Chemical Research Center, Nishi-Ohnuma 4-4-1, Sagamihara, Kanagawa 229

(Received October 14, 1983)

Cyclization of 1,*n*-dihalo[or bis(tosyloxy)]alkanes with methyl methylthiomethyl sulfoxide in the presence of a base (*n*-BuLi or KH) gave three-, four-, five-, and six-membered 1-methylsulfinyl-1-methylthiocycloalkanes. These cyclization products were easily converted to the corresponding ketones by acid hydrolysis except 1-methylsulfinyl-1-methylthiocyclopropane which afforded a complicated mixture. The combination of the cyclization with the acid hydrolysis thus provides a new method for synthesizing four-, five-, and six-membered cycloalkanones. Several representative preparations, such as those of substituted cyclobutanones, 3-cyclopentenone, and tetrahydro-4-pyrone, are described.

Cyclic ketones, especially five- and six-membered cycloalkanones, are widely spreaded skeletons in naturally occurring organic compounds, and development of a new methodology for constructing these skeletons is one of the most important problems in organic synthesis. Further, exploitation of various methods for ring expansion of cyclobutanones to cyclopentanones[1] is looking forward to an efficient way to make four-membered cyclic ketones. In this paper, we report a novel synthetic method of cyclobutanones, cyclopentanones, and cyclohexanones using methyl methylthiomethyl sulfoxide (**1**).[2] A previous paper[3] revealed that **1** undergoes monoalkylation on treatment with an alkyl halide (RX) in the presence of NaH and the acid hydrolysis of the resultant alkylated product gives an aldehyde (RCHO).[4] The present method for synthesis of cycloalkanones (**4**) comprizes the reaction of 1,*n*-dihalo[or bis(tosyloxy)]alkanes (**2**) with **1** to give 1-methylsulfinyl-1-methylthiocycloalkanes (**3**) and the subsequent acid-hydrolysis of **3** leading to **4**, as shown in Scheme 1.[11] The characteristic features of this cycloalkanone synthesis are as follows: i) one-step cyclization of **1** with **2** is achieved; ii) ring-strained cyclobutanone is conveniently made in a high yield, and (iii) cycloalkanones having many kinds of substituents can be easily synthesized.

Results and Discussion

For the reaction of 1,*n*-dihalo[or bis(tosyloxy)]-alkanes (**2**) with methyl methylthiomethyl sulfoxide (**1**), two types of procedures were employed: (a) with 2.2—2.8 equiv of KH in tetrahydrofuran (THF) (−10 °C—room temperature; "Method A") and (b) with 2.0—2.5 equiv of the lithio derivative (**1'**; M=Li) of **1** in THF (−70 °C—room temperature; "Method B"). The results are summarized in Table 1, showing that both Method A and Method B gave the dithioacetal *S*-oxides (**3**; *n*=3, 4, 5) of cyclobutanone, cyclopentanone, and cyclohexanone in fair to good yields starting from either the corresponding 1,*n*-dibromoalkanes (**2**; X=Br) or 1,*n*-bis(tosyloxy)alkanes (**2**; X=TolSO$_3$). However, 1-methylsulfinyl-1-methylthiocyclopropane (**3**; *n*=2) could be produced in 78% yield only by applying Method B to 1,2-bis(tosyloxy)ethane (**2**; *n*=2, X=TolSO$_3$). For the reaction of **1** with **2**, NaH could be employed as a base in place of KH, but heating the reaction mixture at 50 °C was required and the yields of **3** were relatively low [*n*=5 42%; *n*=4 46%]. The reaction of **1** with 1,3-dibromopropane (**2**; *n*=3, X=Br) in the presence of NaH in THF (50 °C/6 h) was

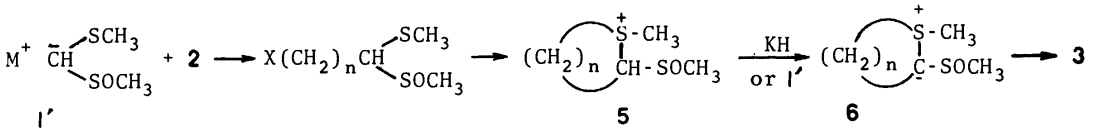
a) With 2.2—2.8 equiv of KH in THF. b) With 2.0—2.5 equiv of the lithio derivative (**1'**, M=Li) in THF. c) When Method A was employed, the yield of **3** (*n*=4) was 31%. d) 1,8-Bis(methylsulfinyl)-1,8-bis(methylthio) octane (**19**) and 1-methylsulfinyl-1-methylthio-7-bromoheptane (**20**) were obtained in 24 and 11% yields, respectively. e) The yields of **19** and **20** were 20 and 22%, respectively. f) The yield of **19** was 23%.



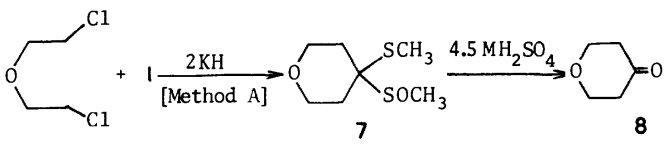
Scheme 2

accompanied with dehydrobromination to give 4-methylsulfinyl-4-methylthio-1-butene in 38% yield (82% yield based on the unrecovered **1**).

It should be noted that 1,6-dibromo [or bis(tosyloxy)]-hexane (**2**; n=6, X=Br or $TolSO_3$) did not produce the corresponding **3** (n=6) by ether Method A or Method B, in a contrast to the base-assisted cyclization of diethyl malonate with 1,n-dihaloalkanes, where a seven-membered cycloalkane derivative is favorably produced.[12] Furthermore, in the present cyclization reaction, **2** afforded the cyclic compounds (**3**) in high yields by the reaction with 2 equiv of the lithio derivative (**1′**; M=Li), indicating the involvement of a more acidic intermediate than **1**. The ring-strained **3** (n=3) is produced at a comparable rate to that of **3** (n=4 or 5). These facts seem to be in accord with the hypothesis that the cyclization may pass through an intermediary sulfonium salt (**5**), followed by the Stevens-type rearrangement to form **3**.

When **3** (n=4 or 5) was treated with a small amount of 4.5 M† sulfuric acid in diethyl ether or ethanol, an acid hydrolysis took place smoothly at room temperature to give cyclopentanone (92%) or cyclohexanone (88%), respectively. These yields were obtained by their derivation into the corresponding 2,4-dinitrophenylhydrazones. When the acid-catalyzed hydrolysis of **3** (n=5) was performed in the presence of trietyl orthoformate in ethanol, the corresponding diethyl acetal of **4** (n=5) was obtained in 83% yield. In the case of 1-methylsulfinyl-1-methylthiocyclobutane (**3**; n=3), an elevated temperature (45 °C) was required for completing the conversion to cyclobutanone. 1-Methylsulfinyl-1-methylthiocyclopropane (**3**; n=2) resisted the acid hydrolysis. Prolonged heating **3** (n=2) with sulfuric acid in ethanol resulted in complicated decomposition. Thus, the present method was shown to be suitable to the synthesis of four-, five-, and six-membered cycloalkanones. Versatility of this method is demonstrated by making certain cycloalkanone derivatives described in the following sections.

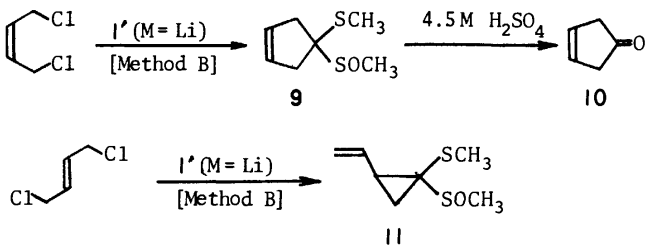
Synthesis of Tetrahydro-4-pyrone (8). The reaction of **1** with bis(2-chloroethyl) ether in the presence of KH (2.4 equiv) in THF at 0 °C—room temperature [Method A] afforded the dithioacetal *S*-oxide (**7**) which was subjected to the acid hydrolysis with 4.5 M sulfuric acid in diethyl ether (room temperature/2 h) to give **8** in an overall yield of 66%.



Scheme 3

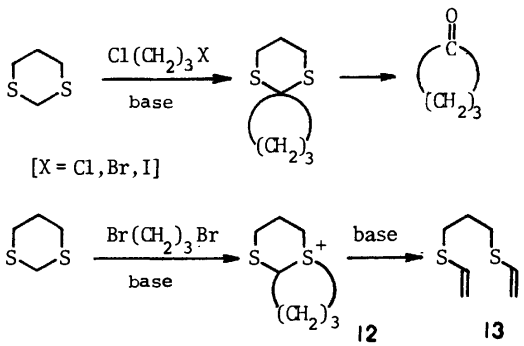
†1 M=1 mol dm^{-3}.

Synthesis of 3-Cyclopentenone (10). When *cis*-1,4-dichloro-2-butene was allowed to react with 2.5 equiv of **1′** (M=Li) in THF at −78 °C—room temperature, 4-methylsulfinyl-4-methylthio-1-cyclopentene (**9**) was obtained in 78% yield. On the other hand, *trans*-1,4-dichloro-2-butene gave 1-methylsulfinyl-1-methylthio-2-vinylcyclopropane (**11**) in 76% yield under the similar reaction conditions.[13] On treatment of **9** with 4.5 M sulfuric acid in acetone-water (9:1) at room temperature, the expected 3-cyclopentenone was formed in 60% yield along with 2-cyclopentenone (6%) (by a GLC analysis). The ratio of 3-cyclopentenone/2-cyclopentenone decreased with the increase of the reaction time and reached to 2.5 after 24 h.



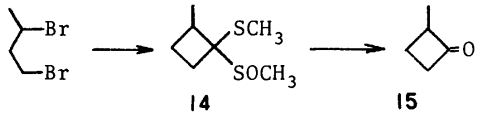
Scheme 4

Synthesis of 2- or 3-Substituted Cyclobutanones. Seebach and Corey reported an elegant synthesis of cyclobutanone by the reaction of 1,3-dithiane with 1,3-dihalopropane.[14] To practice this synthesis, a somewhat complicated procedure is necessitated to avoid the formation of the undesirable disubstituted product: After 2-(3-chloro-1-propyl)-1,3-dithiane is once produced by the reaction of the lithiated 1,3-dithiane with 1-bromo-3-chloropropane, 1-chloro-3-iodopropane, or 1,3-dichloropropane (an excessive amount), this product is again treated with n-BuLi. The use of 1,3-dibromopropane appeared to be impractical because of the formation of a cyclic sulfonium salt (**12**), which gave 1,3-bis(vinylthio)propane (**13**) on treatment with a base.[14]



Scheme 5

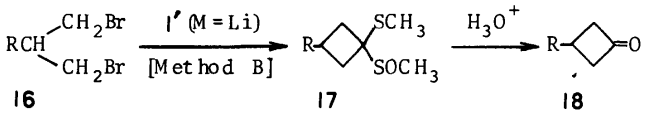
In contrast, 1,3-dibromo[or bis(tosyloxy)]propane can be preferably employed for conversion of **1** to 1-methylsulfinyl-1-methylthiocyclobutane (**3**; $n=3$), a synthetic precursor of cyclobutanone as above mentioned. Furthermore, the reaction of 1,3-dibromobutane with 2.4 equiv of **1'** (M=Li) at room temperature for 46.5 h in THF furnished 1-methylsulfinyl-1-methylthio-2-methylcyclobutane (**14**) (80% yield), which consisted mainly of two diastereomer in the ratio of 1:2.[15] The acid hydrolysis of cyclization product (**14**) afforded 2-methylcyclobutanone (**15**) which was isolated as its 2,4-dinitrophenylhydrazone (77% yield).



14 15

Scheme 6

By the present method, 3-substituted cyclobutanones (**18**) are simply and conveniently synthesized. Treatment of 2-benzyl-1,3-dibromopropane (**16a**) with 2.3 equiv of **1'** (M=Li) in THF [Method B] resulted in the formation of 3-benzyl-1-methylsulfinyl-1-methylthiocyclobutane (**17a**) (77% yield) as a 2:1 mixture of two diastereomers.[15] The acid hydrolysis of **17a** was effected with 4.5 M sulfuric acid in refluxing diethyl ether to yield 3-benzylcyclobutanone (**18a**) in 78% yield.



16 17 18

[a: R = $PhCH_2$ b: R = $PhCH_2O$]

Scheme 7

When 2-benzyloxy-1,3-dibromopropane (**16b**) was allowed to react with **1** according to Method B, a cyclization product (**17b**) was formed in 77% yield as a mixture of two diastereomers (1.1:1). The product (**17b**) gave 3-benzyloxycyclobutannone (**18b**) (60% yield) on treatment with perchloric acid in diethyl ether at room temperature for 24 h.

In conclusion, methyl methylthiomethyl sulfoxide (**1**) is a novel reagent for the synthesis of four-, five-, and six-membered cycloalkanones. By the use of **1**, many kinds of their derivatives can be simply and conveniently prepared.

Experimental

Melting points were determined on a hot-stage microscope apparatus (Yanagimoto) and were uncorrected. ^1H NMR spectra were obtained on Varian HA-100 and Varian EM-390 spectrometers. IR spectra were measured with a Hitachi EPI-G3 infrared spectrometer.

Reaction of 1,3-Dibromopropane with 1. A Typical Procedure: *(a) Method A;* To a suspension containing KH (1.01 g: 25.3 mmol) in THF (15 ml), was added to **1** (1.04 g: 8.39 mmol) under an argon atmosphere and the resulting mixture was stirred for 1 h under ice-cooling. After dropwise addition of 1,3-dibromopropane (2.07 g: 10.3 mmol) over 10 min, the mixture was further stirred for 1 h under ice-cooling and then at room temperatre for 17 h. CH_2Cl_2 (100 ml) was added and the deposited insoluble matter was filtered off. The filtrate was concentrated *in vacuo* and the residue was subjected to column chromatography on silica gel using CH_2Cl_2 and Et_2O as eluents to give **3** ($n=3$) as a pale yellow oil (1.08 g: 78%) along with **1** (199 mg). **3** ($n=3$): IR (neat) 1052 cm^{-1}; ^1H NMR ($CDCl_3$) $\delta=1.5$—3.1 (6H, m), 2.13 (3H, s), and 2.47 (3H, s).

This compound was transformed into the corresponding disulfone: To a solution of **3** ($n=3$) (261 mg: 1.59 mmol) in MeOH (5 ml), were added Na_2WO_4-$2H_2O$ (10 mg) and 30% aq solution (1 ml) of H_2O_2 and the resulting mixture was stirred at room temperature for 2 d. Addition of water (10 ml) deposited the disulfone as colorless crystals: mp 141.5—142 °C (from CH_2Cl_2-CCl_4); IR (KBr) 1295, 1140, 1110, 945, 771, and 505 cm^{-1}; ^1H NMR ($CDCl_3$) $\delta=2.0$—2.6 (2H, m), 2.7—3.1 (4H, m), and 3.15 (6H, s). Calcd for $C_6H_{12}O_4S_2$: C, 33.94; H, 5.70; S, 30.21%. Found: C, 33.99; H, 5.66; S, 30.27%.

(b) Method B; To a solution containing **1** (657 mg: 5.30 mmol) in THF (10 ml), was added a 1.44 mol/l hexane solution (4.0 ml) of *n*-BuLi (5.8 mmol) at −10 °C, and the mixture was stirred for 2 h. After addition of 1,3-dibromopropane (530 mg: 2.63 mmol) together with THF (3 ml), the resulting mixture was stirred under ice-cooling for 0.5 h and then at room temperature for 2 h. CH_2Cl_2 (100 ml) was added and the mixture was washed with water (30 ml). The aqueous layer was extracted with four 50-ml portions of CH_2Cl_2. The organic layer and the extracts were combined and dried (Na_2SO_4). The solvents were evaporated, and the residue was column-chromatographed on silica gel [elution with CH_2Cl_2 and CH_2Cl_2-Et_2O (4:1)] to give **3** ($n=3$) as a pale yellow oil (300 mg: 70% yield based on 1,3-dibromopropane). Employment of 1,3-bis(tosyloxy)propane in place of 1,3-dibromopropane gave **3** ($n=3$) in 91% yield as shown in Table 1.

Similarly, the following compounds were prepared. **3** ($n=2$): an oil; IR (neat) 1055 cm^{-1}; ^1H NMR ($CDCl_3$) $\delta=0.89$—1.60 (4H, m), 2.23 (3H, s), and 2.56 (3H, s). The disulfone of **3**($n=2$): mp 140—140.5 °C (from methanol); IR (KBr) 1332, 1318, 1300, and 1125 cm^{-1}; ^1H NMR ($CDCl_3$) $\delta=1.83$ (4H, s) and 3.27 (6H, s). Calcd for $C_5H_{10}O_4S_2$: C, 30.29; H, 5.08; S, 32.35%. Found: C, 30.13; H, 5.04; S, 32.34%.

3 ($n=4$): an oil; IR (neat) 1045 cm^{-1}; ^1H NMR ($CDCl_3$) $\delta=1.6$—2.3 (8H, m), 2.18 (3H, s), and 2.64 (3H, s). The disulfone of **3** ($n=4$): mp 173—173.5 °C (from CH_2Cl_2-CCl_4-hexane); IR (KBr) 1315, 1305, 1288, and 1132 cm^{-1}; ^1H NMR ($CDCl_3$) $\delta=1.7$—2.2 (4H, m), 2.2—2.7 (4H, m), and 3.17 (6H, s). Calcd for $C_7H_{14}O_4S_2$: C, 37.15; H, 6.24; S, 28.34%. Found: C, 37.29; H, 6.22; S, 28.31%. **3** ($n=5$): mp 57.5—58.5 °C (from benzene-hexane); IR (KBr) 1045 cm^{-1}; ^1H NMR ($CDCl_3$) $\delta=1.5$—2.1 (10H, m), 2.08 (3H, s), and 2.60 (3H, s). Calcd for $C_8H_{16}OS_2$: C, 49.95; H, 8.39; S, 33.34%. Found: C, 50.18; H, 8.22; S, 33.26%.

Reaction of 1,6-Dibromohexane with 1. A Typical Procedure: To a solution containing **1** (1.32 g: 10.6 mmol) in THF (10 ml), was added to 1.30 mol/l hexane solution (8.2 ml) of *n*-BuLi (10.7 mmol) and the reaction mixture was stirred at −15 °C for 2 h. After addition of 1,6-dibromohexane (1.01 g: 4.14 mmol), the resulting mixture was further stirred at −15 °C for 3 h and then at room temperature for 18 h. CH_2Cl_2 (15 ml) was added and the deposited solid was filtered off. The filtrate was concentrated, and the residue was subjected to column chromatography on Florisil using CH_2Cl_2 and AcOEt as eluents to give 1,8-bis(methylsulfinyl)-1,8-bis(methylthio)octane (**19**) as a pale brown oil (273 mg: 20% yield) and 1-methylsulfinyl-1-methylthio-7-bromoheptane (**20**) as a pale brown oil (256

mg: 22% yield). The compound **19** was identified by its derivation to 1,1,8,8-tetrakis(methylsulfonyl)octane: mp 163.5—165.5 °C; IR (KBr) 1310, 1150, and 1120 cm^{-1}; ^1H NMR (DMSO-d_6) δ=1.39 (4H, broad s), 1.59 (4H, broad s) 2.07 (4H, broad s), 3.19 (12H, s), and 5.08 (t, 2H, J=5.8 Hz). Calcd for $C_{12}H_{26}O_8S_4$: C, 33.78; H, 6.14; S, 30.07%. Found: C, 33.69; H, 6.11; S, 30.31%. The compound **20** was also converted to its disulfone derivative: mp 56—58 °C; IR (KBr) 1335, 1315, 1310, 1140, 1125, 1120, and 755 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.3—1.6 (4H, m), 1.6—2.0 (4H, m), 2.0—2.3 (2H, m), 3.15 (6H, s), and 3.93 (1H, t, J=5.5 Hz). Calcd for $C_9H_{19}O_4S_2Br$: C, 32.24; H, 5.71; S. 19.13%. Found: C, 32.64; H, 5.73; S, 19.13%.

Acid-catalyzed Hydrolysis of **3** *(n=3).* To a solution of **3** (n=3) (432 mg: 2.63 mmol) in EtOH (3 ml), was added 8 drops of 4.5 M sulfuric acid, and the resulting solution was stirred at room temperature for 18 h and then at 45 °C for 5 h. This solution was shown not to contain **3** (n=3) by a TLC analysis. A 2,4-dinitrophenylhydrazine solution (25 ml) [3.0 g/sulfuric acid (30 ml)+H_2O (20 ml)+EtOH (70 ml)] was added and the mixture was allowed to stand overnight at room temperature. Addition of water (20 ml) deposited cyclobutanone 2,4-dinitrophenylhydrazone (518 mg: 79%) as orange crystals: mp 146.5—148 °C (from EtOH and CCl_4-hexane) (lit,[16] mp 146 °C); IR (KBr) 3280, 3080, 1615, 1587, 1510, 1338, 1310, and 1270 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.9—2.5 (2H, m), 2.8—3.4 (4H, m), 7.87 (1H, d, J=10 Hz), 8.27 (1H, dd, J=2.5 and 10 Hz), 9.12 (1H, d, J=2.5 Hz), and 10.73 (1H, broad, NH). Calcd for $C_{10}H_{10}N_4O_4$: C,48.00; H, 4.02; N, 22.39%. Found: C, 47.97; H, 4.02; N, 22.17%.

Acid Hydrolysis of **3** *(n=4).* To a solution of **3** (n=4) (211 mg: 1.19 mmol) in EtOH (5 ml), was added 5 drops of 4.5 M sulfuric acid and the resulting solution was stirred at room temperature for 15 h. By the above-mentioned procedure, the resulting ketone was converted to the corresponding 2,4-dinitrophenylhydrazone (290 mg: 92%) which was identified as cyclopentanone 2,4-dinitrophenylhydrazone by comparison of its IR spectrum with that of the authentic sample.

Acid Hydrolysis of **3** *(n=5).* *a)*: To a solution of **3** (n=5) (293 mg: 1.53 mmol) in EtOH (3 ml), was added 3 drops of 4.5 M sulfuric acid and the resulting solution was stirred at room temperature for 4 h. The above-mentioned work-up gave yellow crystals (375 mg: 88%) which were identified as cyclohexanone 2,4-dinitrophenylhydrazone by comparison of their IR spectrum with that of the authentic sample.

b): To a mixture containing **3** (n=5) (10.79 g: 56.2 mmol) in Et_2O (50 ml), was added 4.5 M sulfuric acid (0.5 ml), and the resulting mixture was stirred at room temperature. Then $NaHCO_3$ (800 mg) and Na_2SO_4 were added. After the insoluble solid was filtered off, the filtrate was evaporated under atmospheric pressure. The residue was subjected to fractional distillation to afford three fractions: (i) bp 56—75 °C/80 Torr (1 Torr=133.322 pa) which was shown by an NMR analysis to consist of dimethyl disulfide (765 mg) and cyclohexanone (655 mg); (ii) bp 75—84 °C/80 Torr which consisted of dimethyl disulfide (258 mg) and cyclohexanone (1.64 g); and (iii) 50—56 °C/20—14 Torr which consisted of dimethyl disulfide (50 mg) and cyclohexanone (2.03 g). The last fraction showed the same IR spectrum to that of cyclohexanone. The yield of cyclohexanone was calculated to be 79%.

c): A mixture containing **3** (n=5) (9.18 g: 47.8 mmol), EtOH (14 ml), triethyl orthoformate (12 ml), and sulfuric acid (0.2 ml) was stirred at room temperature for 14 h. K_2CO_3 (1.5 g) was added and the mixture was further stirred for 30 min. After addition of 0.5 M aq solution (50 ml) of K_2CO_3 and extraction with three 70-ml portions of Et_2O, the extracts were combined and dried (K_2CO_3). The solvents were evaporated, and the residue was subjected to fractional distillation to give cyclohexanone diethyl acetal (6.84 g: 83% yield) as a colorless liquid having bp 100—105 °C/57 Torr (lit,[17] bp 78—85 °C/18 Torr): IR (near) 2890—2830 and 1090—1045 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.16 (6H, t, J=7 Hz), 1.2—1.8 (10H, broad), and 3.45 (4H, q, J=7 Hz). Calcd for $C_{10}H_{20}O_2$: C, 69,72; H, 11.70%. Found: C, 69.62; H, 11.43%.

Synthesis of Tetrahydro-4-pyrone (8). To a suspension containing KH (3.81 g: 95.3 mmol) in THF (30 ml), was dropwise added to **1** (4.98 g: 40.2 mmol) under ice-cooling over 30 min. After the resulting mixture was stirred for 45 min at the same temperature, bis(2-chloroethyl) ether (5.82 g: 40.7 mmol) was dropwise added over 30 min and the reaction mixture was further stirred under ice-cooling for 1 h and then at room temperature for 4 h. CH_2Cl_2 (100 ml) was added and the deposited solid was filtered off. The filtrate was evaporated and the residue was subjected to column chromatography on silica gel using Et_2O as an eluent to give 4-methylsulfinyl-4-methylthiotetrahydro-4-pyrane (**7**) contaminated with a small amount of **1** as a pale yellow oil (6.17 g).

This oil was dissolved in Et_2O (100 ml) and 4.5 M sulfuric acid (1 ml) was added. After the reaction mixture was stirred at room temperature for 2 h, $NaHCO_3$ (1.5 g) was added to neutralize the acid and then anhydrous Na_2SO_4 was added. After the mixture was allowed to stand overnight, the insoluble solid was filtered off and the filtrate was concentrated *in vacuo*. Distillation of the residue gave two fractions, a colorless liquid (384 mg) having bp 86—88 °C/59 Torr and a colorless oil (2.40 g) having bp 88—91 °C/59 Torr. The former was shown by an NMR analysis to consist of dimethyl dislfide (92 mg) and 8 (292 mg) and latter was pure **8**: IR (neat) 1720, 1217, 1088, and 990 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.50 (4H, t, J=6 Hz) and 3.98 (4H, t, J=6 Hz). Its 2,4-dinitrophenylhydrazone: mp 191.5—192.5 °C (from water-EtOH) (lit,[18] mp 186.5—187 °C). Calcd for $C_{11}H_{12}N_4O_5$: C, 47.14; H, 4.32; N, 19.99%. Found: C, 47.24; H, 4.36; N, 19.74%.

Reaction of cis-1,4-Dichloro-2-butene with **1**. To a solution of lithio derivative **1'** (M=Li) in THF (150 ml) which was prepared from 1 (24.9 g: 0.200 mol) and n-BuLi (0.200 mol), was added *cis*-1,4-dichloro-2-butene (10.0 g: 0.08 mol). The mixture was further stirred at −70 °C for 3.5 h and then at room temperature for 16.5 h, and then CH_2Cl_2 (400 ml) was added. The mixture was washed with water (100 ml) and the aqueous layer was extracted with five 100 ml-portions of CH_2Cl_2. The organic layers were combined and dried ($MgSO_4$). The solvents were evaporated, and the residue was subjected to column chromatography on Florisil using AcOEt as an eluent to give 4-methylsulfinyl-4-methylthio-1-cyclopentene (**9**) as a pale yellow oil (11.1 g: 78% yield): IR (neat) 1617 and 1050 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.24 (3H, s), 2.60 (3H, s), 2.35—3.4 (4H, m), and 5.68 (2H, s). The *S,S,S',S'*-tetraoxide derivative: mp 168—169 °C (from CCl_4); IR (KBr) 1630, 1320—1305, 1295, and 1140 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.20 (6H, s), 3.23 (4H, s), and 5.69 (2H, s). Calcd for $C_7H_{12}O_4S_2$: C, 37.48; H, 5.39; S, 28.59%. Found: C, 37.48; H, 5.38; S, 28.58%.

Acid Hydrolysis of **9** *Leading to 3-Cyclopentenone (10).* The authentic sample of **10** was synthesized by pyrolysis of tricyclo[5.2.1.$0^{2,6}$]deca-3,8-dien-5-ol according to a literature.[19] To a solution of **9** (105 mg: 0.597 mmol) in 10 ml of acetone-water (8:1) was added 2 drops of 4.5 M sulfuric acid, and the mixture was stirred at room temperature for 5 h. By a GLC analysis (20% XF1150 column, 1 m, 130 °C; nitrogen, 1 kg/cm^2; internal standard, cyclopentanone), the yields of 3-cyclopentenone and 2-cyclopentenone were shown to be 60% and 6%, espectively.

Reaction of trans-*1,4-Dichloro-2-butene with 1.* To a solution of **1'** (M=Li) in THF (30 ml) which was prepared from **1** (2.91 g: 23.5 mmol) and *n*-BuLi (23.0 mmol), was added to *trans*-1,4-dichloro-2-butene (1.32 g: 10.6 mmol) at −70 °C, and then the reaction mixture was stirred at room temperature for 2.5 h. Water (30 ml) was added and the mixture was extracted with four 50 ml-portions of CH_2Cl_2. The extracts were combined and dried (Na_2SO_4). The solvents were evaporated, and the residue was subjected to column chromatography on silica gel using CH_2Cl_2-Et_2O (4:1) as an eluent to afford 1-methylsulfinyl-1-methylthio-2-vinylcyclopropane (**11**) as a pale yellow oil (1.41 g: 76% yield):[13] IR (neat) 1632 and 1060 cm^{-1}. The corresponding *S,S,S',S'*-tetraoxide: mp 102—102.5 °C (from CCl_4 and MeOH-water); IR (KBr) 1640, 1625, 1335, 1325, 1305, 1290, of CH_2Cl_2. The extracts were combined and dried (Na_2SO_4). The solvents were evaporated, and the residue was subjected to column chromatography on silica gel using CH_2Cl_2-Et_2O (4:1) as an eluent to afford 1-methylsulfinyl-1-methylthio-2-vinylcyclopropane (**11**) as a pale yellow oil (1.41 g: 76% yield):[13] IR (neat) 1632 and 1060 cm^{-1}. The corresponding *S,S,S',S'*-tetraoxide: mp 102—102.5 °C (from CCl_4 and MeOH-water); IR (KBr) 1640, 1625, 1335, 1325, 1305, 1290, 1160, and 1130 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.80 (1H, dd, J=6.5 and 10 Hz), 2.18 (1H, dd, J=6.5 and 8 Hz), 2.96—3.22 (1H, m), 3.14 (3H, s), 3.20 (3H, s), 5.22—6.02 (3H, m). Calcd for $C_7H_{12}O_4S_2$: C, 37.48; H, 5.39; S, 28.59%. Found: C, 37.22; H, 5.23; S, 28.37%.

Synthesis of 2-Methylcyclobutanone (14) Using 1. To a solution of **1'** (M=Li) in THF (15 ml) which was prepared from **1** (1.57 g: 12.6 mmol) and *n*-BuLi (12.6 mmol), was added to 1,3-dibromobutane (1.13 g: 5.2 mmol) at −70 °C, and the reaction mixture was stirred at room temperature for 46.5 h. Water (20 ml) was added and the mixture was extracted with one 100 ml-portion and four 20 ml-portions of CH_2Cl_2. The extracts were combined, washed with brine (20 ml), and dried ($MgSO_4$). The solvents were evaporated, and the residue was subjected to colum chromatography on Florisil using CH_2Cl_2 as an eluent to afford 1-methylsulfinyl-1-methylthio-2-methylcyclobutane as a pale yellow oil (746 mg: 80% yield), which consisted mainly of two diastereomers in the ratio of 1:2; IR (neat) 1050 cm^{-1}; ^1H NMR of the major isomer ($CDCl_3$): δ=1.18 (3H, d, J=7 Hz), 1.6—4.0 (5H, m), 2.33 (3H, s), and 2.67 (3H, s); ^1H NMR of the minor isomer ($CDCl_3$): δ=1.39 (3H, d, J=7 Hz), 1.6—4.0 (5H, m), 2.18 (3H, s), and 2.47 (3H, s).

This *S*-oxide (212 mg) was dissolved in EtOH (3 ml) and 8 drops of 4.5 M sulfuric acid were added. The resulting mixture was stirred at room temperature for 15 h and then at 43—47 °C for 24 h. The thus-formed 2-methylcyclobutanone was trapped as its 2,4-dinitrophenylhydrazone (241 mg: 77%): orange crystals; mp 119.5—122 °C (from CCl_4-Et_2O); IR (KBr) 3260, 3075 2935, 2895, 1667, 1615, 1588, 1515, 1500, 1420, 1335, 1310, and 1268 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.33 (3H, d, J=7 Hz), 1.72 (1H, m), 2.33 (1H, m), 2.97 (2H, m), 3.40 (1H, m), 7.81 (1H, d, J=10 Hz), 8.22 (1H, dd, J=2.6 and 10 Hz), 9.04 (1H, d, J=2.6 Hz), and 10.67 (1H, broad, NH). Calcd for $C_{11}H_{12}N_4O_4$: C, 50.00; H, 4.58; N, 21.20%. Found: C, 50.07; H, 4.49; N, 20.99%.

Synthesis of 3-Benzylcyclobutanone (18a). The starting material 2-benzyl-1,3-dibromopropane (**16a**) was synthesized by reduction of diethyl benzylmalonate with $LiAlH_4$ in Et_2O leading to 2-benzyl-1,3-propanediol and the subsequent treatment of this diol with CBr_4 and PPh_3 in CH_3CN.[20] To a solution of 1' (M=Li) in THF (15 ml) which was prepared from **1** (1.01 g: 8.15 mmol) and *n*-BuLi (8.64 mmol), was added **16a** (1.03 g: 3.53 mmol) at −10 °C and the mixture was further stirred at −10 °C for 100 min and then at room temperature for 3 h. CH_2Cl_2 (100 ml) was added and washed with water (30 ml). The aqueous layer was extracted with two 50 ml-portions of CH_2Cl_2. The organic layers were combined, washed with brine (20 ml), and dried (Na_2SO_4). The solvenrs were evaporated, and the residue was subjected to column chromatography on silica gel using CH_2Cl_2-AcOEt (9:1) as an eluent to give 1-methylsulfinyl-1-methylthio-3-benzylcyclobutane (**17a**) as a pale yellow oil (686 mg: 77% yield): IR (neat) 1055 and 1035 (sh) cm^{-1}. ^1H-NMR ($CDCl_3$) showed that this oil consisted of two diastereomers (2:1). The methyl signals of the major isomer appeared at δ=2.12 and 2.49, while the minor isomer exhibited the methyl signals at δ=2.08 and 2.42.

The *S*-oxide (2.70 g: 10.6 mmol) was dissolved in Et_2O (140 ml), and 4.5 M sulfuric acid (2.8 ml) was added. The resulting mixture was stirred at room temperature for 2 d and then heated under a reflux for 2 d. After addition of $NaHCO_3$ and $MgSO_4$, the mixture was further stirred for a while and the insoluble solid was filterd off. The filtrate was concentrated, and the residue was subjected to column chromatography on silica gel using CH_2Cl_2 and hexane as eluents to give 3-benzylcyclobutanone (**18a**) as a colorless oil (1.13 g: 66% yield) IR (neat) 1785 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.43—3.49 (7H, m) and 7.21 (5H, s). Its 2,4-dinitrophenylhydrazone derivative: mp 138—139.5 °C (from CCl_4-hexane). Calcd for $C_{17}H_{16}N_4O_4$: C, 59.99; H, 4.74; N, 16.46%. Found: C, 60.02; H, 4.70; N, 16.46%.

The *S*-oxide (398 mg) was dissolved in Et_2O (20 ml). Then 4.5 M sulfuric acid (0.4 ml) was added and the resulting mixture was stirred at room temperature for 1 d and then heated under a reflux for 7 h. After addition of $NaHCO_3$ and $MgSO_4$, the mixture was stirred for a while and the insoluble solid was filterd off. The filtrate was subjected to the reaction with 2,4-dinitrophenylhydrazine to give the 2,4-dinitrophenylhydrazone of **18a** (417 mg: 78% yield).

Synthesis of 3-Benzyloxycyclobutanone (18b) Using 1. To a solution of **1'** (M=Li) in THF (40 ml) which was preparted from **1** (4.81 g: 38.7 mmol) and *n*-BuLi (38.5 mmol), was dropwise added to 2-benzyloxy-1,3-dibromopropane[21] (4.95 g: 16.1 mmol) at −70 °C over 15 min, and the reaction mixture was stirred at −70 °C for 2 h and then at room temperature for 15.5 h. After addition of CH_2Cl_2 (200 ml), the mixture was washed with water (30 ml). The washings were extracted with four 50 ml-portions of CH_2Cl_2. The organic layers were combined, washed with brine (30 ml), and dried ($MgSO_4$). The solvents were evaporated, and the residue was subjected to column chromatography on Florisil using AcOEt to afford 1-methylsulfinyl-1-methylthio-3-benzyloxycyclobutane (**17b**) as a pale yellow oil (3.35 g: 77% yield), which was shown by its ^1H NMR spectrum to consist of two diastereomers (1.1: 1). In the ^1H NMR spectrum, the sulfinylmethyl protons appeared at δ 2.38 (s) and 2.48 (s) in the relative intensity of 1.1:1.

After this *S*-oxide (593 mg) was dissolved in Et_2O (10 ml), 35% perchloric acid (0.45 ml) was added. The resulting mixture was stirred at room temperature for 25 h. After addition of $NaHCO_3$ and $MgSO_4$, the mixture was stirred for a while and the insoluble solid was filterred off. The filtrate was concetrated and the residue was subjected to column chromatography on silica gel using $CHCl_3$ as an eluent to give **18b** (233 mg: 60% yield) as a colorless oil; IR (neat) 1795 (sh) and 1787 cm^{-1}; ^1H NMR ($CDCl_3$) 3.10 (4H, d, J=6 Hz), 4.28 (1H, quintet, J=6 Hz), 4.45 (2H, s), and 7.28 (5H, s). Its semicarbazone: mp 164—166.5 °C (from acetone-water); IR (KBr) 3445, 3260, 3145, 2895, 2850, 1667, 1593, 1485, and 1088 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.00 (4H, m), 4.16 (1H, m), 4.42 (2H, S), 5.50 (2H, broad s), 7.29 (5H, s), and 8.70 (1H, broad s). Calcd for $C_{12}H_{15}N_3O_2$: C, 61.79; H, 6.48; N, 18.01%. Found: C, 61.80; H, 6.45; N, 17.89%.

An Account of the Site- and Regio-selectivity in the Reaction of Nitrile Oxides with Substituted *p*-Benzoquinones by Frontier Molecular Orbital Theory

Tohru HAYAKAWA, Koji ARAKI, and Shinsaku SHIRAISHI*
Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106
(Received October 27, 1983)

The 1,3-dipolar cycloaddition reactions of nitrile oxides with substituted *p*-benzoquinones are discussed in terms of Frontier Molecular Orbital (FMO) theory. The calculation is carried out by *ab initio* Self Consistent Field (SCF) method with STO-3G basis set. The site- and regio-selectivities in the reactions are correlated with two types of FMO interactions. Some predictions have been confirmed by experimental results.

Frontier Molecular Orbital (FMO) theory is widely used to explain or predict the reactivities and the selectivities in the organic reactions. In the field of cycloaddition reactions, such as Diels-Alder and 1,3-dipolar cycloaddition reactions, it is a powerful tool to study and account for the reactions.[1-6] By applying FMO theory to cycloaddition reactions, Sustmann has classified them into three groups.[7]

We reported before[8-11] the 1,3-dipolar cycloaddition reactions of nitrile oxides with various *p*-benzoquinones, which have two kinds of potentially reactive sites, one is the carbon-oxygen double bond and the other the carbon-carbon double bond. Depending on the number, pattern, combination and kind of the substituents of the quinones, two different types of the adducts were obtained in the reactions. One is the C=O addition product, *i.e.* spiro[1, 4, 2]dioxazole derivative and the other is the C=C addition product, *i.e.* isoxazoline derivative. We tried to account for the site-selectivity and reactivity of the quinones, and also the regio-selectivity in the C=C addition reactions in terms of FMO theory. This paper describes the calculation of the energy levels of FMO's and the coefficients of FMO's on the atoms of nitrile oxides and substituted *p*-benzoquinones, and correlates the experimental results with the calculation.

Results and Discussion

The following were studied: nitrile oxides: 2,4,6-trimethylbenzonitrile oxide (**1a**) and 2,6-dichlorobenzonitrile oxide (**1b**); quinones: 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (**2a**), tetrafluoro-*p*-benzoquinone (**2b**), tetrachloro-*p*-benzoquinone (**2c**), tetramethyl-*p*-benzoquinone (**2d**), tetramethoxy-*p*-benzoquinone (**2e**), 2,6-dichloro-*p*-benzoquinone (**2f**), 2-methyl-*p*-benzoquinone (**2g**), 2,5-dimethyl-*p*-benzoquinone (**2h**), and 2,6-dimethyl-*p*-benzoquinone (**2i**), 2,5,6-trimethyl-*p*-benzoquinone (**2j**). The structures are shown in Fig. 1. The reactions of **1a** with **2a**—f has been known to give 1,4,2-dioxazole derivatives through C=O addition and those with **2g**—**i** isoxazoline derivatives through C=C addition. The reactions of **1b** gave similar results, except with **2d**—f as will be discussed later. This kind of site-selectivity and the orientation of the addition (regio-selectivity in C=C addition) are to be accounted for and predicted.

Ab Initio *SCF Calculation.* The FMO calculations on nitrile oxides, not only fulminic acid but also aromatic nitrile oxides, by semiempirical methods have been reported.[1,5] The calculation by nonempirical method has been reported only for fulminic acid[12] and no calculations for aromatic nitrile oxides have been reported as far as we know.

On the other hand, the calculations for several *p*-benzoquinones by *ab initio* method have been reported by Rozemboom *et al.*,[13] though only the one for 2-methyl-*p*-benzoquinone is available for our study. We calculated the FMO's of nitrile oxides and substituted *p*-benzoquinones by *ab initio* SCF method with STO-3G basis set.[14]

The calculation for nitrile oxides were carried out using the bond lengths (in nm) 0.1436 for C-C, 0.1147 for C-N, and 0.1243 for N-O, which are the averaged values of the X-ray results for 4-methoxy-2,6-dimethyl- and 4-bromo-2,6-dimethylbenzonitrile oxides.[15] Other geometries used are standard ones given by Pople and Gordon.[16] The methyl substituents of **1a** can have various conformations. We computed the energies for several representative conformations of the methyl groups and selected and used the most stable one for the FMO calculation. When one hydrogen of the methyl group is placed in the same plane as the aromatic nucleus of the nitrile oxides, the energy of FMO's does not exceed that of the most stable conformation by more than 0.1 eV.

The energy values and coefficient magnitudes of FMO's of nitrile oxides are given in Table 1, together with the negative values of the ionization potential (experimentally estimated HOMO energies).[12,17,18] The orderings of the calculated HOMO energy and the experimentally estimated ones are the same. Our calculation on fulminic acid gave nearly the same energy values as the one (HOMO −7.69 eV) reported by *ab initio* method. From fulminic acid to **1b**, the

Table 1. Energy levels and coefficients of FMO of nitrile oxides

Nitrile oxide	FMO	ε/eV		Cα[b]	C	N	O
		Calcd	Exptl[a]				
HCNO	LUMO	8.66		—	0.82	−0.80	0.43
	HOMO	−7.61	−10.83	—	0.54	0.14	−0.84
phCNO	LUMO	5.33		0.53	0.27	−0.42	0.29
	HOMO	−6.42	−8.96	−0.26	0.44	0.20	−0.72
1a	LUMO	5.58		0.50	0.27	−0.42	0.28
	HOMO	−6.12	−8.35	−0.32	0.41	0.21	−0.69
1b	LUMO	4.43		0.55	0.22	−0.40	0.29
	HOMO	−6.89	—	−0.24	0.46	0.18	−0.73

a) These are the negative values of the ionization potentials. b) This carbon connects with the dipole moiety.

calculated values well reflect the substituent effect. The phenyl group of benzonitrile oxide, which is a conjugative group, raises HOMO energy and lowers LUMO energy. Substitution on benzonitrile oxide with methyl groups, which are electron-releasing groups, raise both HOMO and LUMO energies; the increase in HOMO is larger than that of LUMO (**1a**). Chlorine atoms lower both HOMO and LUMO energies. The decrease in LUMO is larger than that of HOMO as a result of mixing of electron-withdrawing and -releasing natures (**1b**). Furthermore, inspection of Table 1 reveals that the nodal positions and the ordering of the magnitudes of the atomic orbital coefficients are preserved in all four calculated nitrile oxides.

The results of the calculations of the substituted *p*-benzoquinones are listed in Table 2. The geometries of quinones, *p*-benzoquinone, **2a**, **2b**, **2c**, and **2f** are those of X-ray results.[19] In the cases of methyl- and methoxy-substituted quinones, such as **2d**, **2e**, **2g**, **2h**, **2i**, and **2j**, the methyl group can take various conformations. The conformation of methyl group of **2g** used for the calculation is the same one as reported by Rozemboom *et al.*[13] and those for **2d**, **2e**, **2h**, **2i**, and **2j** are the most stable ones estimated by computation in the same way as in the case of **1a**. The geometries of quinone moieties of **2g**, **2h**, **2i**, and **2j** are derived from that of *p*-benzoquinone,[19] and those of **2d** and **2e** are X-ray results.[20] The electron affinities of these quinones[21] are also listed in Table 2. The tendency is in good accordance with that of the calculated values. The substituent effects to FMO's energies are also reasonable.

Our calculation values and those reported by Rozemboom *et al.*[13] for *p*-benzoquinone and 2-methyl-

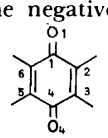
a) The values are the negatives of the average of the EA's determined from reduction potentials and charge-transfer spectra except **2b** and **2j**. b) The values are the negatives of EA's determined from reduction potentials. c) The numbering of the atoms is the following:



p-benzoquinone are nearly the same, the difference is due to the difference in the geometry of the quinone moiety which was employed.

C=O Addition. Figure 2 shows the FMO energy levels of the nitrile oxides and the quinones. The quinones **2a—f**, which have been found to undergo C=O addition with **1a**, have very low LUMO energy values, except for **2d** and **2e**. The energy difference between the HOMO of **1a** and the LUMO of the quinones is smaller than that between the LUMO of **1a** and the HOMO of the quinones by more than about 5 eV, except in the cases of **2d** and **2e**. This energetical analysis clearly suggests that the HOMO (nitrile oxide)-LUMO (quinone) interaction is the governing factor of C=O addition. This suggests that the reactions of **1b** with **2a—c** give C=O adducts; this is indeed the case. The reactions of **1b** with **2d—f** will be discussed later.

The kinetic data of these reactions also supports this suggestion. Reaction rate constants measured by a UV method at 20 °C[10] (Table 3) show that quinone **2a**, which has the lowest LUMO energy value, reacts most rapidly, and also that the rate in the reactions of **1b** with **2a—c** is always slower than that of **1a** with the corresponding quinones. This is reflecting the fact that **1b** has a lower HOMO energy value than **1a** by 0.65 eV.

C=C Addition. The quinones **2g—j** have been known to undergo C=C addition with **1a**, and their FMO energy levels are higher than those of quinones **2a—f**, except **2d** and **2e**, as shown in Fig 1. In addition, *p*-benzoquinone, which has been reported to undergo C=C addition with benzonitrile oxide,[22] has nearly the same FMO levels as the quinones **2g—j** and was confirmed to undergo C=C addition with **1a** and **1b** as described in the Experimental section. The energy differences between the two possible interactions are far smaller than those in the cases mentioned in the preceding section and are less than 3.9 eV with **1a** and less than 2.0 eV with **1b**. The participation of LUMO(nitrile oxide)-HOMO(quinone) interaction is considered to become important to some extent in these reactions.

The reaction rate constants were also measured as shown in Table 3. Contrary to the C=O addition, the reaction rate of the C=C addition of **1b** with **2h—j** is shown to be always faster than the corresponding one of **1a**. This indicates that the orbital interactions exerted different effects from those in C=O addition. We should take note of not only the decrease of the HOMO level of **1b** but also that of the LUMO level. As mentioned above, the decrease of the HOMO level of **1b** is only 0.65 eV, but that of the LUMO level is 1.09 eV. Because of this large decrease in LUMO of **1b**, the ener-

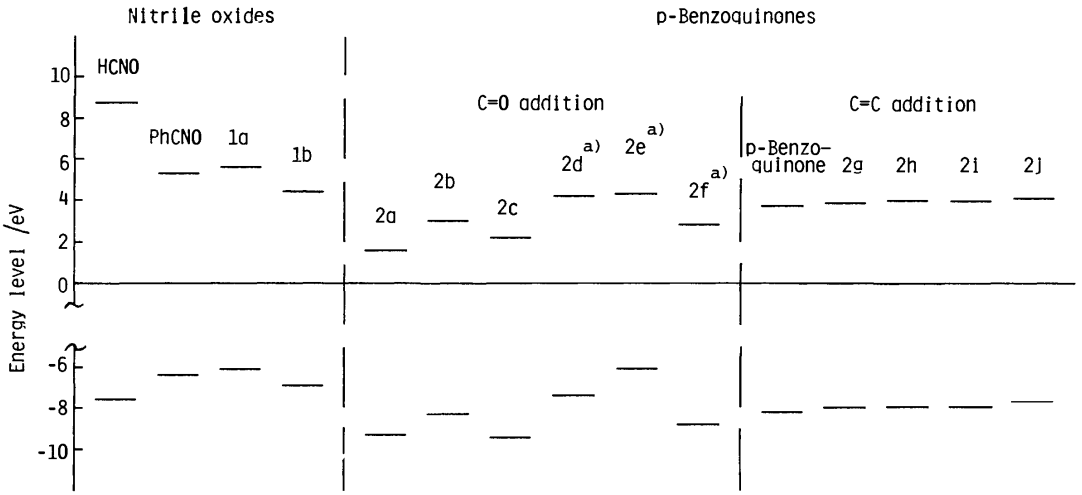


Fig. 2. Energy levles of HOMO and LUMO of nitrile oxides and substituted *p*-benzoquinones calculated by *ab initio* SCF method with STO-3G basis set.
a) The reaction with Ia gives C=O adduct.

TABLE 3. RATE CONSTANTS FOR THE REACTIONS OF NITRILE OXIDES WITH QUINONES

Quinone	Solvent	k/l mol^{-1} s^{-1} With **1a**[a]	With **1b**	Mode
2a	$CHCl_3$	3.52	5.98×10^{-2}	C=O
	C_6H_6	5.60×10^{-1}	3.60×10^{-3}	
2b	$CHCl_3$	5.18×10^{-2}	1.15×10^{-3}	C=O
2c	$CHCl_3$	1.59×10^{-2}	7.09×10^{-4}	C=O
2h	$CHCl_3$	4.77×10^{-4}	2.36×10^{-3}	C=C
	C_6H_6	9.30×10^{-4}	4.94×10^{-3}	
2i	$CHCl_3$	1.33×10^{-3}	4.50×10^{-3}	C=C
	C_6H_6	1.50×10^{-3}	5.26×10^{-3}	
2j	C_6H_6	4.35×10^{-4}	2.60×10^{-3}	C=C

a) The values for **2a—c** measured in $CHCl_3$ are reported ones.[10]

Table 4. The energy difference between LUMO(nitrile oxides)-HOMO(quinones) and HOMO(nitrile oxides)-LUMO(quinones) interaction

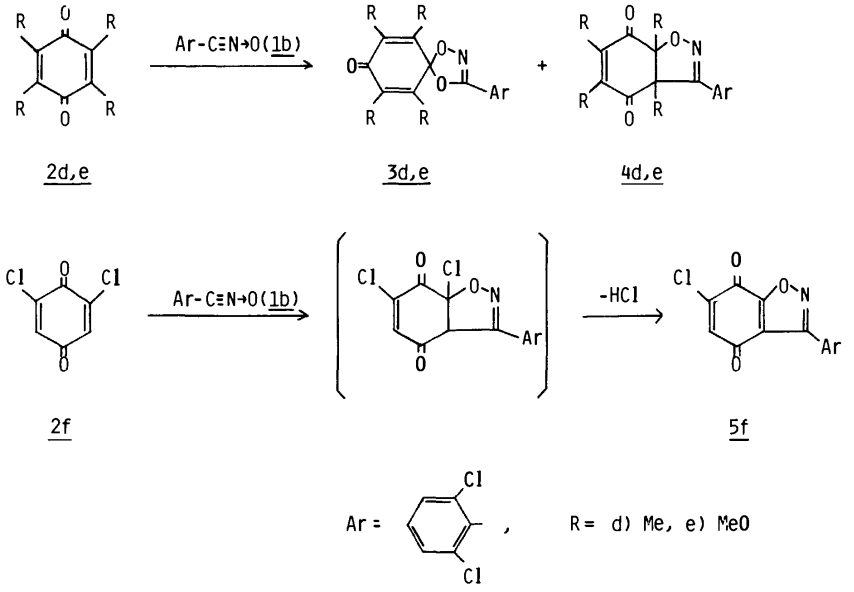


Scheme 1.

gy gain by LUMO (**1b**)-HOMO (quinone) interaction overcomes the energy loss by the HOMO (**1b**)-LUMO (quinone) interaction. This result suggests that in the reactions giving C=C adducts LUMO (nitrile oxide)-HOMO (quinone) interaction is more significant than the opposite interaction. Usually *p*-benzoquinones are thought to be electron acceptor and known to form CT complexes with many electron donors. The reactivity and selectivity of the reactions involving *p*-benzoquinones are known to be dominated by the interaction of LUMO of quinones and HOMO of nucleophiles or dienes. But in the reactions discussed here, HOMO of quinones participates in the reactions to some extent, and quinones appear to behave as if electron donors.

We show in Table 4 the energy difference between LUMO (nitrile oxide)-HOMO (quinone) and HOMO (nitrile oxide)-LUMO (quinone) interaction. The results with **1a** shows that, if the energy difference is larger than 5 eV, C=O addition will occur, and if the energy difference is less than 4 eV, C=C addition will occur, except for the cases of **2d** and **2e**. This energetical analysis predicts that the reaction of **1b** with **2f** will give C=C adduct because the energy difference is less than 4 eV. Moreover it is expected that the reaction pattern of **1b** with **2d** and **2e** will be different from that of **1a**.

In fact, **1b** underwent C=C addition with **2f** and not C=O addition. As shown in Scheme 1, isoxazoloquinone **5f** was formed in the reaction *via* C=C addition and subsequent dehydrochlorination. The structure of the product **5f** was determined by spectral data; the characterization is described in the Experimental section.

The reactions of **1b** with **2d** and **2e** were also found to proceed in a different mode from those of **1a**. Compound **1b** underwent both C=C and C=O additions with **2d** and **2e**. The results are shown in Scheme 2. The characterization of the adducts is also described in the Experimental section. Though the yields were low, the reactions were clean and no other products were detected. This is the first case of the isolation of C=C adducts in the reactions of nitrile oxides with tetrasubstituted *p*-benzoquinones and of the competitive reactions of C=C and C=O additions. Compound **2d** has FMO levels very close to those of the quinones **2g—j**, while **2e** has very close LUMO to those of **2g—j**, but a much higher HOMO level. The energy difference between the two possible interactions of **1b** with **2d** is less than 1 eV. For tetrasubstituted *p*-benzoquinones, the steric hindrance cannot be neglected. Actually, tetrafluoro-*p*-benzoquinone (**2b**) underwent only C=O addition with **1b** despite the energy difference being smaller than 4 eV. The reaction of tetramethoxy-*p*-benzoquinone (**2e**) is not clearly understood by considering the steric effect only. The higher orbital interactions involving methoxy groups may have to be considered in the interpretation of the experimental result, for which further study is needed.

Accounts for the Selectivity. In the 1,3-dipolar cycloaddition reactions, the square of the products of the coefficients of the interacting atoms and resonance integral ($C_aC_b\beta_{ab}$) should be taken into consideration, as discussed by Houk.[1] But such an approach to rationalize the site-selectivity may be applicable only for the specific addition to a bond among the same kinds of unsaturated bonds, and not among the dif-

ferent kinds of unsaturated bonds. Furthermore there are many factors which cannot be neglected: for example, Coulombic repulsion, and we cannot exactly estimate the extent of the importance of the factors.

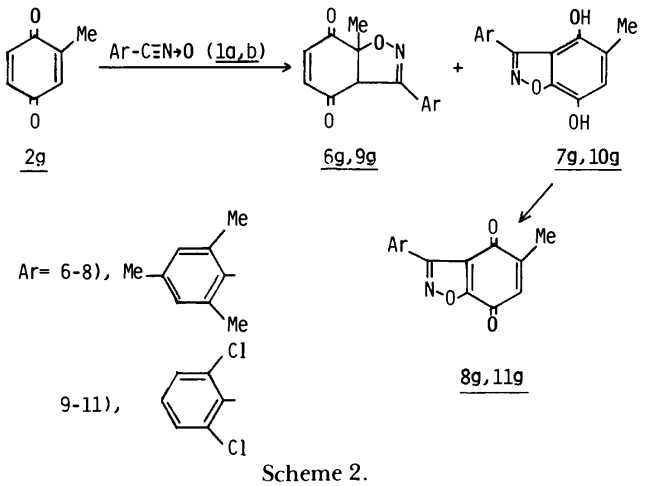
In the reactions giving C=O adducts, which is considered to be chiefly governed by the HOMO (nitrile oxide)-LUMO (quinone) interaction, Coulombic repulsion is thought to play a significant role. The regio-selectivity of the C=O addition is clearly influenced by Coulombic repulsion but not by the overlap of the orbitals.

2,6-Dichloro-*p*-benzoquinone (**2f**) has two different C=O sites and undergoes C=O addition onto the carbonyl group of chlorine-substituted side exclusively.[9] This site-selectivity among the two C=O addition sites has been interpreted in terms of LFER theory.[10] This can also be treated by considering the primary interactions in FMO theory, *i.e.* comparison in the sum of the square of the product of the coefficients of interacting atoms and resonance integral ($Cc Co\beta co$)[1] for two possible interaction shows that the value for the addition to the substituted side (2.41) is larger than that to the unsubstituted side (2.20).

The reactions giving C=C adducts are thought to be governed chiefly by the LUMO(nitrile oxide)-HOMO (quinone) interaction. Considering this interaction, one notes that the coefficients on the carbon atom are nearly equal in **1a** or less in **1b** than those on the terminal oxygen atom. But by taking into consideration the secondary orbital interaction with the α-carbon connecting with the nitrile oxide moiety,[5,23] regio-selectivity can be explained.

For the purpose of the study of the selectivities of the reactions, we tried the reactions of nitrile oxides with 2-methyl-*p*-benzoquinone (**2g**), which has two types of carbon-carbon double bond. The C=C adduct added on the methyl-substituted side was isolated in the reactions and the formation of the adduct added on the other side was only suggested.[11] Here we could confirm the formation of the two C=C adducts by derivating the latter to the corresponding isoxazoloquinone (**8g** or **11g**) by oxidation, as shown in Scheme 2. The characterization of the adducts will be described in the Experimental section.

The quinone **2g** has a larger coefficient magnitude on the carbon atoms of the methyl-substituted C=C



Scheme 2.

bond. The most efficient overlap of the orbitals of interacting atoms leads to the products **6g** or **9g**. The interaction leading to products **7g** or **10g** has not so efficient an overlap, and the yields of **6g** and **9g** are thought to become much larger than those of **7g** and **10g**. In fact, the yield of **6g** or **9g** is larger but not so much, which is thought to be due to the steric effect of the methyl group. In the reactions with 2,5,6-trimethyl-*p*-benzoquinone (**2j**), the cycloaddition occurred onto only the less hindered side,[11] though the coefficients of HOMOs' of the carbon atoms at the hindered side are larger than those at the less hindered side.

The orientation of the C=C addition with quinones **2f—j**[11] is in accordance with the theory that the most efficient overlap of the interacting orbitals includes secondary orbital interaction of LUMO of nitrile oxides with HOMO of quinones, as mentioned before.

In conclusion we can classify the substituted *p*-benzoquinones into two groups: One is a group giving C=O adducts, the reaction of which is chiefly governed by HOMO (nitrile oxide)-LUMO (quinone) interaction, and the other is that giving C=C adducts, the reaction of which is chiefly governed by LUMO (nitrile oxide)-HOMO (quinone) interaction. The borderline-energy-difference between two interactions may be about 4 eV, having some exceptions. Some quinones such as **2d** and **2e** gave both C=C and C=O adducts competitively in the reactions with **1b**.

Experimental

Melting points were measured using a micro-melting-point-measuring apparatus (Yazawa Co., Ltd.) and are uncorrected. Column chromatography was conducted on silica gel (Wako gel C-200) with benzene as an eluent. IR spectra were recorded with a JASCO IRA-1 spectrophotometer. UV spectra were recorded with a JASCO UVIDEC-505 spectrophotometer. ^{1}H NMR spectra were measured in $CDCl_3$ with a JEOL JMN-MH 100 spectrometer, and chemical shifts are reported in ppm from internal tetramethylsilane. Mass spectra were recorded with a Hitachi RMU-7L high resolution mass spectrometer.

Materials. 2,4,6-Trimethylbenzonitrile oxide (**1a**) and 2,6-dichlorobenzonitrile oxide (**1b**) were prepared by the method of Grundmann.[24] *p*-Benzoquinone, 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (**2a**), tetrafluoro-*p*-benzoquinone (**2b**), tetrachloro-*p*-benzoquinone (**2c**), tetramethyl-*p*-benzoquinone (**2d**), and 2-methyl-*p*-benzoquinone (**2g**) were commercially obtained and were used after recrystallization. Tetramethoxy-*p*-benzoquinone (**2e**) was prepared by the method of Robinson and Vasey.[25] 2,5-Dimethyl-*p*-benzoquinone (**2h**), 2,6-dimethyl-*p*-benzoquinone (**2i**), and 2,5,6-trimethyl-*p*-benzoquinone (**2j**) were prepared by the method described in the previous paper.[11]

*Reactions of 2,4,6-Trimethylbenzonitrile Oxide (**1a**) and 2,6-Dichlorobenzonitrile Oxide (**1b**) with* p*-Benzoquinone.* A solution of 0.806 g (5 mmol) of **1a** and 1.081 g (10 mmol) of *p*-benzoquinone in 100 ml benzene was stirred for 3 d at room temperature. Solvent was then evaporated under reduced pressure, and the residue was subjected to column chromatography. 3-(2,4,6-Trimethylphenyl)-1,2-benzisoxazole-4,7-dione (0.853 g 64%) was obtained and the recrystallization was carried out from benzene-hexane. Mp 130—132 °C. IR (KBr) 1670 and 1680 cm^{-1} ($\nu_{C=O}$). ^{1}H NMR ($CDCl_3$) δ=2.07 (s, 6H, mesityl *o*-methyl), 2.35 (s, 3H, mesityl *p*-methyl), 6.74 (d, 1H, olefinic), 6.89 (d, 1H, olefinic), and 6.96 (s, 2H, aromatic).

Found: C, 71.79; H, 4.80; N, 5.49%. Calcd for $C_{16}H_{13}N_1O_3$: C, 71.65; H, 4.89; N, 5.22%.

The reaction of 2,6-dichlorobenzonitrile oxide (**1b**) with *p*-benzoquinone was conducted and worked up in a similar manner. 3-(2,6-dichlorophenyl)-1,2-benzisoxazole-4,7-dione (73%). Mp 178—180 °C. IR (KBr) 1670 and 1680 cm^{-1} ($\nu_{C=O}$) ^1H NMR ($CDCl_3$) δ=6.78 (d, 1H, olefinic), 6.87 (d, 1H, olefinic), and 7.42 (s, 3H, aromatic).

Found: C, 52.89; H, 1.53; N, 4.70%. Calcd for $C_{13}H_5N_1O_3Cl_2$: C, 53.09; H, 1.71; N, 4.76%.

*Reaction of 2,6-Dichlorobenzonitrile Oxide (1b) with Tetramethyl-*p*-benzoquinone (2d).* A solution of 0.503 g (3 mmol) of **1b** and 0.574 g (3 mmol) of **2d** in 60 ml of benzene was stirred for about one month at room temperature. The solvent was evaporated under reduced pressure, and the residue was worked up with column chromatography. The first fraction gave a mixture of starting materials and **3d**. The residue was recrystallized from benzene-hexane to give 3-(2,6-dichlorophenyl)-6,7,9,10-tetramethyl-2-aza-1,4-dioxaspiro[4.5]-deca-2,6,9-trien-8-one (**3d**), (0.14 g 13%). Mp 204—205 °C. IR (KBr) 1665 cm^{-1} ($\nu_{C=O}$) ^1H NMR ($CDCl_3$) δ=1.97 (s, 6H, methyl), 2.24 (s, 6H, methyl), and 7.47 (s, 3H, aromatic). M^+ (351.0361) was observed as a very weak signal, and fragment ion peaks at *m/z* 186.9574 and 164.0841 arising from the starting component (*i. e.* the nitrile oxide and the quinone) were very intensive in the mass spectrum. The fragmentation pattern is characteristic of C=O adducts.

Found: C, 58.03; H, 4.31; N, 3.92%; M^+, 351.0361. Calcd for $C_{17}H_{15}N_1O_3Cl_2$: C, 57.97; H, 4.29; N, 3.98%; M^+, 351.0431.

The second fraction gave yellow needles of 3-(2,6-dichlorophenyl)-3a,5,6,7a-tetramethyl-3a,7a-dihydro-1,2-benzisoxazole-4,7-dione (**4d**), (0.14 g 13%), which was recrystallized from benzene-hexane. Mp 135—136 °C. IR (KBr) 1670 and 1710 cm^{-1} ($\nu_{C=O}$) ^1H NMR ($CDCl_3$) δ=1.53 (s, 3H, methyl), 1.59 (s, 3H, methyl), 1.97 (s, 3H, methyl), 2.07 (s, 3H, methyl), and 7.31 (s, 3H, aromatic). M^+ was not observed but characteristic fragmentation of the C=C adducts, which was the elimination of angular methyl and CO, was observed in the mass spectrum.

Found: C, 57.84; H, 4.38; N, 3.91%. Calcd for $C_{17}H_{15}N_1O_3Cl_2$: C, 57.97; H, 4.29; N, 3.98%.

*Reaction of 2,6-Dichlorobenzonitrile Oxide (1b) with Tetramethoxy-*p*-benzoquinone (2e).* The reaction was conducted and worked up in the same manner as the above. The second fraction gave 3-(2,6-dichlorophenyl)-3a,5,6,7a-tetramethoxy-3a,7a-dihydro-1,2-benzisoxazole-4,7-dione (**4e**), (27%). Mp 174—176 °C. IR (KBr) 1685 and 1700 cm^{-1} ($\nu_{C=O}$) ^1H NMR ($CDCl_3$) δ=3.27 (s, 3H, methoxyl methyl), 3.84 (s, 3H, methoxyl methyl), 4.04 (s, 3H, methoxyl methyl), 4.06 (s, 3H, methoxyl methyl), and 7.31 (s, 3H, aromatic).

Found: C, 48.85; H, 3.65; N, 3.34%; M^+, 415.0302. Calcd for $C_{17}H_{15}N_1O_7Cl_2$: C, 49.06; H, 3.63; N, 3.37%; M^+, 415.0227.

The third fraction gave 3-(2,6-dichlorophenyl)-6,7,9,10-tetramethoxy-2-aza-1,4-dioxaspiro[4.5]deca-2,6,9-trien-8-one (**3e**), (13%). Mp 163—164 °C. IR (KBr) 1650 cm^{-1} ($\nu_{C=O}$) ^1H NMR ($CDCl_3$) δ=3.70 (s, 6H, methoxyl methyl), 4.12 (s, 6H, methoxyl methyl), and 7.38 (s, 3H, aromatic). M^+ was not observed, but fragment ion peaks at *m/z* 186.9576 and 288.0625 arising from the starting component (*i.e.* the nitrile oxide and the quinone) were very intense in the mass spectrum.

Found: C, 49.12; H, 3.62; N, 3.42%. Calcd for $C_{17}H_{15}N_1O_7Cl_2$: C, 49.06; H, 3.63; N, 3.37%.

*Reaction of 2,6-Dichlorobenzonitrile Oxide (1b) with 2,6-Dichloro-*p*-benzoquinone (2f).* A solution of 0.94 g (5 mmol) of **1b** and 0.885 g (5 mmol) of **2f** in 100 ml benzene was stirred for 3d at room temperature. Then the solvent was evaporated under reduced pressure. The residue was worked up with column chromatography. The first fraction gave 3-(2,3-dichlorophenyl)-6-chloro-1,2-benzisoxazole-4,7-dione (**5f**), (1.14 g 63%), which was recrystallized from hexane. Mp 142—145 °C. IR (KBr) 1680 and 1700 cm^{-1} ($\nu_{C=O}$) ^1H NMR ($CDCl_3$) δ=7.05 (s,1H, olefinic), and 7.46 (s, 3H, aromatic). The mass spectrum shows the elimination of CO from the parent ion, which is a characteristic pattern of C=C adduct.

Found: C, 47.48; H, 1.19; N, 4.53%. Calcd for $C_{13}H_4N_1O_3Cl_3$: C, 47.53; H, 1.22; N, 4.26%.

*Reaction of 2,4,6-Trimethylbenzonitrile Oxide (1a) with 2-Methyl-*p*-benzoquinone (2g).* A solution of **1a** 0.805 g (5 mmol) and **2g** 0.61 g (5 mmol) in 100 ml of benzene was stirred for about one week at room temperature. The solvent was evaporated under reduced pressure, and the residue was subjected to column chromatography. The first fraction gave the mixture of **1a** and **2g**. The second fraction gave the yellow crystals of 3-mesityl-7a-methyl-3a,7a-dihydro-1,2-benzisoxazole-4,7-dione (**6g**), (0.48 g 34%), which was recrystallized from benzene-hexane. Mp 137—139 °C. IR (KBr) 1680 and 1700 cm^{-1} ($\nu_{C=O}$) ^1H NMR ($CDCl_3$) δ=1.62 (s, 3H, angular methyl), 2.16—2.43 (m, 9H, mesityl methyl), 4.30 (s, 1H, angular methine), 6.72 (d, 1H, olefinic), 6.94 (d, 1H, olefinic), and 6.84 (s, 2H, aromatic).

Found: C, 72.02; H, 6.15; N, 5.17%. Calcd for $C_{17}H_{17}N_1O_3$: C, 72.07; H, 6.04; N, 4.94%.

The third fraction gave a glassy mass which was assumed to be 3-mesityl-5-methyl-1,2-benzoisoxazole-4,7-diol (**7g**), which can not be isolated as a pure state, from its IR spectrum (ν_{OH} at about 3200 cm^{-1}). Oxidation of **7g** was conducted with sodium dichromate in the presence of sulfuric acid in benzene-water mixture with vigorous stirring. The reaction mixture was extracted from benzene. The extract was dried over anhydrous sodium sulfate. Evaporation of the solvent gave 3-mesityl-5-methyl-1,2-benzisoxazole-4,7-dione (**8g**), (0.28 g 20%). The recrystallization was carried out from benzene-hexane. Mp 139—141 °C. IR (KBr) 1670 and 1680 cm^{-1} ($\nu_{C=O}$) ^1H NMR ($CDCl_3$) δ=2.12 (s, 6H, mesityl *o*-methyl), 2.24 (s, 3H, methyl), 2.37 (s, 3H, mesityl *p*-methyl), 6.65 (s, 1H, olefinic), and 7.00 (s, 2H, aromatic).

Found: C, 72.96; H, 5.55; N, 4.55%. M^+, 281.1084. Calcd for $C_{17}H_{15}N_1O_3$: C, 72.58; H, 5.37; N, 4.98%. M^+, 281.1053.

*The Reaction of 2,6-Dichlorobenzonitrile Oxide (1b) with 2-Methyl-*p*-benzoquinone (2g).* The reaction was conducted and worked up in the same manner as the above.

3-(2,6-Dichlorophenyl)-7a-methyl-3a,7a-dihydro-1,2-benzisoxazole-4,7-dione (**9g**), (47%). Mp 175—177 °C. IR (KBr) 1680 and 1700 cm^{-1} ($\nu_{C=O}$) ^1H NMR ($CDCl_3$) δ=1.77 (s, 3H, angular methyl), 4.51 (s, 1H, angular methine), 6.89 (d, 1H, olefinic), 7.06 (d, 1H, olefinic), and 7.42 (s, 3H, aromatic).

Fonud: C, 54.41; H, 2.87; N, 4.90%. Calcd for $C_{14}H_9N_1O_3Cl_2$: C, 54.22; H, 2.92; N, 4.52%.

3-(2,6-dichlorophenyl)-5-methyl-1,2-benzisoxazole-4,7-dione (**11g**), (31%). Mp 215—217 °C. IR (KBr) 1680 and 1685 cm^{-3} ($\nu_{C=O}$). ^1H NMR ($CDCl_3$) δ=2.14 (s, 3H, methyl), 6.71 (s, 1H, olefinic), and 7.43 (s, 3H, aromatic).

Found: C, 54.98; H, 2.13; N, 4.63%; M^+, 306.9720. Calcd for $C_{14}H_7N_1O_3Cl_2$: C, 54.54; H, 2.29; N, 4.55%; M^+, 306.9804.

The Reactions of 1b with 2a—c: The reaction was carried out using 2.5 mmol of each reactant in chloroform at room temperature for 1 d and worked up in the same manner as the above. The product of each reaction follows. The reaction gave exclusively spiro[1,4,2]dioxazole derivatives.

6,7-Dichloro-9,10-dicyano-3-(2,6-dichlorophenyl)-2-aza-1,4-dioxaspiro[4.5]deca-2,6,9-trien-8-one. Yield 77%. Mp 172—174 °C. IR (KBr) 1700 cm^{-1} ($\nu_{C=O}$). Found: C, 43.61; H, 0.79; N, 9.86%. Calcd for $C_{15}H_3N_3O_3Cl_4$: C, 43.41; H, 0.73; N, 10.12%.

6,7,9,10-Tetrafluoro-3-(2,6-dichlorophenyl)-2-aza-1,4-dioxaspiro[4.5]deca-2,6,9-trien-8-one. Yield 92%. Mp 148—150 °C. IR (KBr) 1700 cm^{-1} ($\nu_{C=O}$). Found: C, 42.70; H, 0.71; N, 3.96%. Calcd for $C_{13}H_3N_1O_3Cl_2F_4$: C, 42.42; H, 0.82; N, 3.81%.

6,7,9,10-Tetrachloro-3-(2,6-dichlorophenyl)-2-aza-1,4-dioxaspiro-[4.5]deca-2,6,9-trien-8-one. Yield 88%. Mp 165—167 °C. IR (KBr) 1695 cm^{-1} ($\nu_{C=O}$). Found: C, 36.34; H, 0.57; N, 3.34%. Cacld for $C_{13}H_3N_1O_3Cl_6$: C, 35.99; H, 0.70; N, 3.23%.

Kinetic Study. The reaction rate constants were measured by UV method at 20 °C.[10] As the solvent, benzene and chloroform were used. Equimolar portions of the solutions of a nitrile oxide and a quinone were placed in a quartz cell for UV measurement and the progress of the reaction was followed by the spectral change at the absorption maximum of the quinone or of the adduct formed. The concentration of the reactants was about $(2—4)\times10^{-3}$ mol l^{-1} in C=O addition reactions and about $(1—3)\times10^{-2}$ mol l^{-1} in C=C addition reactions.

The authors indebted to Dr. Kosugi, Department of Chemistry, Faculty of Science, University of Tokyo, for helpful advice in the *ab initio* calculation.

Synthesis of Several New Pyrazolo[5,1-*c*][1,2,4]triazoles, Imidazo[1,2-*b*]-pyrazoles, and Pyrazolo[3,4-*b*]pyrazines. Reaction of Nitrilimines with Amino- and Oxo-substituted Azoles. II

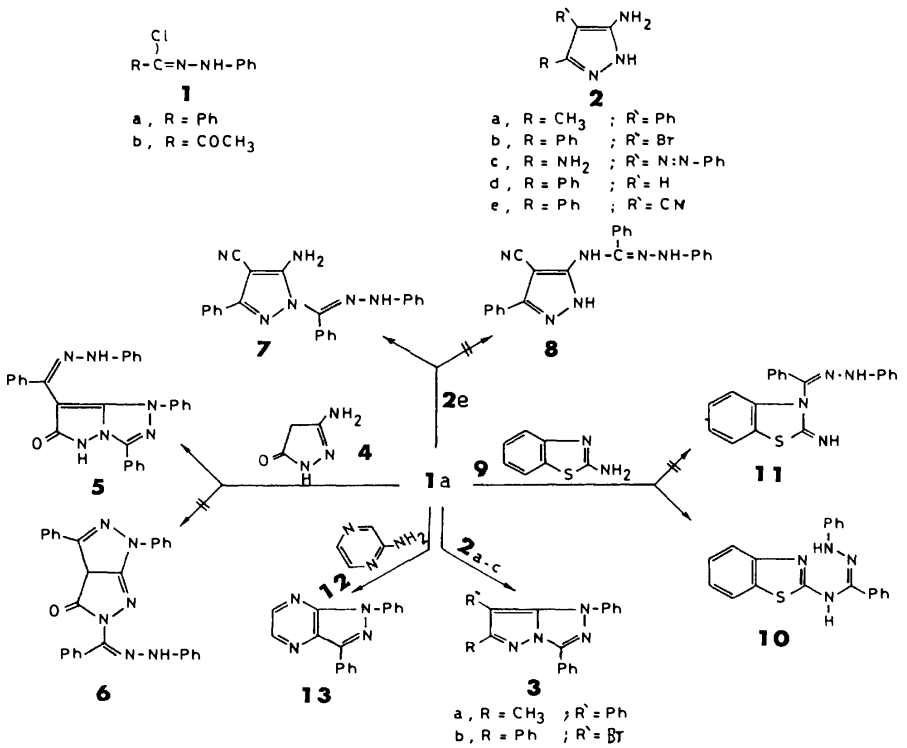
(Received July 4, 1983)

The reactivity of amino and hydroxy azoles toward nitrilimines and hydrazonoyl halides was investigated. Several novel rotes for synthesis of derivatives of known heterocyclic systems are reported.

Nitrilimines, usually synthesised *in situ* by base-catalysed elimination of halogeno acid from hydrazonoyl halides, are reactive intermediates that have found extensive use in heterocyclic syntheses.[1] Recently we reported that these reactive intermediates react readily with amino and oxo diazoles, thus, enabling preparation of a variety of new, otherwise difficult to obtain, fused azole derivatives.[2,3] We have been interested to see if reactions of this type can be utilized to constitute a general route to fused azoles. In the present paper we reported the results of our investigation on the reactivity of *N*-phenylbenzohydrazonoyl chloride (**1a**) and *N*-phenylpyruvohydrazonoyl chloride (**1b**) toward a variety of amino and oxo azoles in order to define the exact behaviour of **1a,b** toward this class of compounds.

Thus, it has been found that **1a** reacts with the aminopyrazole derivatives **2a—c** in the presence of triethylamine to yield the pyrazolo[5,1-*c*][1,2,4]triazole derivatives **3a—c**. The formation of **3a—c** is assumed to proceed *via* 2+3 dipolar cycloaddition mechanism. Similar mechanism was suggested to account for the formation of pyrazolo[5,1-*c*][1,2,4]triazole derivative from the reaction of **1a** with **2d**.[3] The 3-amino-2-pyrazolin-5-one (**4**) reacted with **1a** to yield a product with the molecular formula $C_{29}H_{22}N_6O$ (M^+=470). Two theoretically possible isomeric structure **5** and **6** were considered for the product. Structure **6** was readily ruled out based on IR and ^{1}H-NMR spectrum of the product as well as its chemical behaviour. The IR spectrum revealed absorption at 1690 cm^{-1} for ring CO group. Whereas the ^{1}H-NMR spectrum showed no pyrazole C(4)-H signal at δ_H *ca.* 6.0. Furthermore the reaction product proved to be stable under conditions reported to effect decomposition of *N*-substituted pyrazoles of structure similar to that of **6**.[3] The formation of **5** is assumed to proceed *via* reaction of **4** with two molecules of **1a** and elimination of ammonia.

In contrast to the behaviour of **2a—c**, reaction of aminopyrazole derivative **2e** with **1a** afforded *N*-alkylated product (M^+=378) which may be formulated as **7** or **8**. The isomeric structure **7** was established for the reaction product showed a signal for NH_2 at δ 5.9. Attempts to effect cyclization of this product were unsuccessful. The formation of **7** in this case is assumed to proceed *via* alkylation sequence. Alkylation of aminoazoles with hydrazonoyl halides has been previously observed.[3]



Similar to the behaviour of **2e**, 2-aminobenzthiazole (**9**) reacted with compound **1a** under the same experimental condition to yield an alkylated product, although structures **10** and **11** seemed possible, structure **11** was readily ruled out based on IR spectrum which revealed the absence of absorption at 1670—1630 cm^{-1} for exocyclic C=N.

2-Aminopyrazine (**12**) reacted with **1a** to yield the pyrazolo[3,4-*b*]pyrazine derivative **13**. The structure of **13** was established based on analytical and spectral data. The formation of **13** in this reaction represents the first observed 2+3 cycloaddition of nitrilimine to diazine derivative.

Whereas compound **1b** reacted with **2a** to yield the imidazo[1,2-*b*]pyrazole derivative **14** ($M^+=315$), it reacted with compounds **2b, c, e** to yield only the acyclic *N*-alkylated products **15a—c**. The formation of **14** may be assumed to proceed either *via* the stepwise sequence

18	3500—3200 (NH); 1690 (CO);1610(C=N)	
20	3500—2500 (chelated NH); 1680—1650 (acetyl and ring CO); 1610 (C=N)	

(route A) or dipolar addition mechanism (route B). We believed that **14** is formed mainly *via* a cycloaddition mechanism as acyclic intermediate for the reaction of **1b** and **2a** could not be traced. Moreover compounds **15a—c** were found resistant to cyclization under the reaction conditions or even more drastic conditions.

Reactivity of **1b** toward **4**, **9** and **12** was also investigated. Only in the case of **4** the cyclic product **16** was obtained (M^+=241). With other aminoazoles only the alkylated products **17** and **18** were obtained. Similarly **1b** reacted with 3-methyl-2-pyrazolin-5-one (**19**) to yield the acyclic *N*-alkylated product **20**.

It may thus concluded that nitrilimines would react with aminoazoles either *via* a 2+3 dipolar cycloaddition or by alkylation sequence. The exact course of the reaction seems to depend on the nature of the aminoazole and the nitrilimine. Fused azoles can only be readily obtained from a cycloadditions, trials to cyclise products of alkylation has failed in our hands.

Experimental

All melting points are uncorrected. IR spectra were recorded (KBr) on a Pye Unicam SP-1000 spectrophotometer. ^{1}H-NMR spectra were obtained in an EM-390 spectrometer at 90 MHz with DMSO-d_6 as solvent and TMS as internal reference. Analytical data were obtained from the Analytical Data Unit at Cairo University.

Reaction of the Hydrazonoyl Chlorides 1a, b with Amino and/or Oxo-substituted Azoles. General Procedure: A suspension of compound **1a** or **1b** (20 mmol) and the appropriate amino or oxo-substituted azoles (20 mmol) in ethanol (30 ml) was refluxed with triethylamine (20 mmol) for 3 h and then evaporated to dryness under reduced pressure. The residue was washed with petroleum ether, triturated with ethanol, and the resulting solid product was filtered off and crystallized from the appropriate solvent (Table 1). Analytical and spectroscopic data are given in Table 1 and 2.

Synthesis and Reactions of Quinoxaline Derivatives

Mahmoud Zarif Amin BADR,* Galal Moustafa EL-NAGGAR,
Hassan Ahmad Hassan EL-SHERIEF, and Safar Ahmed MAHGOUB
Chemistry Department, Faculty of Science, Assiut University, Assiut, Egypt

(Received April 6, 1983)

Reaction of 3-methyl-2(1*H*)quinoxalinone (**1**) with alkyl, benzyl, and arenesulfonyl halides in the presence of K_2CO_3 in dry acetone gave 1-substituted 3-methyl-2(1*H*)-quinoxalinones (**2a—g**). However **1** reacts with benzoyl chloride under the same conditions to give 3-methyl-2-quinoxalinyl benzoate, while it reacts with P_2S_5 in dry pyridine to give 3-methyl-2(1*H*)quinoxalinethione (**4**). Treatment of **4** with methy iodide in the presence of K_2CO_3 in dry acetone gave 2-methyl-3-(methylthio)quinoxaline but not 1,3-dimethyl-2(1*H*)-quinoxalinethione which has been obtained from **2a** and P_2S_5 in dry pyridine. Treatment of **4** with benzyl bromide and/or *p*-nitrobenzyl bromide in the presence of K_2CO_3 in dry acetone gave 2-benzylthio and 2-(*p*-nitrobenzylthio)-3-methylquinoxalines. Syntheses of 1-methyl-3-(substituted styryl)-2(1*H*)-quinoxalinone (**8a—m**) were achieved by condensation of **2a** with aromatic aldehydes. Addition of thiophenols and mercaptoacetic acid to **8** gives 1-methyl-3-[2-(substituted phenylthio)ethyl]-2(1*H*)-quinoxalinones and 1-methyl-3-[2-(substituted phenyl)-2-(carboxymethylthio)ethyl]-2(1*H*)-quinoxalinones respectively. 1,3-Dimethyl-2(1*H*)-quinoxalinone (**2a**) condensed with ketones in the presence of $ZnCl_2$ to give 1-methyl-3-[2-(substituted phenyl)-1-alkenyl]-2(1*H*)-quinoxalinones. 1-Methyl-3-(substituted styryl)-2(1*H*)-quinoxalinethiones were produced by refluxing a mixture of **8** with P_2S_5 in dry pyridine.

Quinoxaline derivatives are important as insecticides,[1] fungicides,[2,3] antibacterials,[4] and they show important biological effects.[5,6] In continuation of our earlier work[7] on quinoxaline derivatives, the present investigation deals with the synthesis of a series of new quinoxaline and quinoxalone compounds applying new procedures which are easier and afford better yields.

It has been observed in the present study that 3-methyl-2(1*H*)-quinoxalinone[8] (**1**) reacts with alkyl, benzyl, and arenesulfonyl halides in the presence of K_2CO_3 in dry acetone to give the corresponding 1-substituted 3-methyl-2(1*H*)-quinoxalinone (**2a—g**). These compounds showed IR absorption bands between 1665—1710 cm^{-1} for C=O group and between 1600—1610 cm^{-1} for C=N group but they did not show absorption band at 3350 cm^{-1} for NH group. The UV spectra of **2b,c** in ethanol were similar to that of **1** and showed three characteristic absorption bands as shown in Table 1.

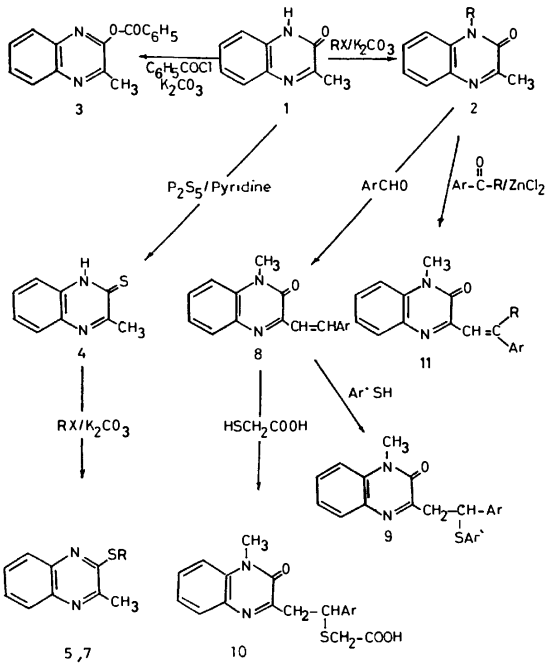
The ^{1}H-NMR spectra of compounds **2a—f** in $CDCl_3$ as a solvent were in agreement with the suggested structures and showed the signals given in Table 2.

However, when **1** was allowed to react with benzoyl chloride in the presence of anhydrous K_2CO_3 in dry acetone, the *O*-benzoylation was observed to give 3-methyl-2-quinoxalinyl benzoate (**3**).

The IR spectrum of **3** showed absorption band at 1740 cm^{-1} for C=O of the ester group. The NMR spectrum determined in $CDCl_3$ showed a singlet at δ 2.71 (3H, $-CH_3$), a symmetrical multiplet centered at δ 7.65 (5H, $-C_6H_5$) and a symmetrical multiplet centered at δ 8.2 (4H, aromatic protons of quinoxalinone nucleus).

Reaction of **1** with P_2S_5 in dry pyridine gave 3-methyl-2(1*H*)-quinoxalinethione (**4**), whose structure was confirmed by its IR spectrum which showed bands at 3350 cm^{-1} (NH) and at 1550 cm^{-1} (C=S).

Treatment of 3-methyl-2(1*H*)quinoxalinethione (**4**) with methyl iodide in the presence of K_2CO_3 in dry acetone gave 2-methyl-3-(methylthio) quinoxaline[9] (**5**). However, 1,3-dimethyl-2(1*H*)-quinoxalinethione (**6**) was not detected among the products. Compound **6** was prepared by reaction of 1,3-dimethyl-2(1*H*)-quinoxalinone (**2a**) with P_2S_5 in pyridine. However this observation does not exclude the possibility that 3-methyl-2(1*H*)-quinoxalinethione (**4**) exists in solution as 2-mercaptoquinoxaline rather than as cyclic thioamide tautomer. This was further confirmed by the similarity of the UV spectra of **6** together with that of compound **4** and their subsequent difference from that corresponding to 2-methyl-3-(methylthio)quinoxaline (**5**) (Table 3). The structures of **5** and **6** were further confirmed by NMR spectra in $CDCl_3$. Compound **5** showed a singlet at δ 2.68 (6H, $-S-CH_3$ and $-C-CH_3$) and a symmetrical multiplet centered at δ 7.8 (4H, aromatic protons), where compound **6** showed a singlet at δ 2.82 (3H, $-C-CH_3$), a singlet at δ 4.2 (3H, $N-CH_3$) and a multiplet at δ 7.4—7.9 (4H, aromatic protons).



Scheme 1.

Treatment of 3-methyl-2(1*H*)-quinoxalinethione (**4**)

Table 1. UV spectral data of some 1-substituted 3-methyl-2(1*H*)-quinoxalinones

with benzyl bromide and/or *p*-nitrobenzyl bromide in the presence of K_2CO_3 in dry acetone gave 2-benzylthio and 2-(*p*-nitrobenzylthio)-3-methylquinoxalines (**7a**,**b**) respectively. Their electronic absorption spectra were similar with that of **5** (Table 3).

The ^{1}H-NMR spectrum of **7b** in CF_3 COOH showed a singlet at δ 2.55 (3H, -C-CH_3), a singlet at δ 4.35 (2H, -S-CH_2-) and a multiplet at δ 7.2—7.8 (8H, aromatic protons).

The reactivity of the 3-methyl group towards condensation reaction into the corresponding styryl compounds **8** was demonstrated either by: (A) Fusion of 1,3-dimethyl-2(1*H*)-quinoxalinone (**2a**) with the corresponding aldehyde in the presence of few drops of piperidine or (B) refluxing **2a** with the corresponding aldehyde in dry pyridine using few drops of piperidine and (C) refluxing **2a** with the corresponding aldehyde in acetic anhydride. The IR spectra of compounds **8a—m** showed bands at 1665—1650 cm^{-1} for C=O group, at 1630—1610 cm^{-1} for C=C group and at 1580 cm^{-1} C=N. It is suggested that compounds **8** are of trans configuration since a strong absorption band appeared in the region 990—980 cm^{-1} characteristic of trans olefinic configuration. The coupling constants of the styryl protons in the NMR spectra are 15—16 Hz, confirming its trans configuration.

The UV spectra of the styryl compounds (**8a**,**b**,**d**,**e**) showed a bathochromic shift of the K-band as compared with that of the parent compound (**2a**). This shift has been attributed to the difference in auxochromic character of the styryl residue at position-3 of the quinoxalinone ring in conjugation with -C=N- group. *o*-Nitrostyryl derivative (**8j**) showed less bathochromic shift than its *p*-isomer (**8i**) due to the steric hindrance at ortho-position distorting the coplanarity and conjugation (Table 4).

Table 4. UV spectral data of 1-methyl-3-styryl-2(1*H*)-quinoxalinones (**8**)

No.	Ar	λ_{max}/nm	ε/$dm^3\ mol^{-1}\ cm^{-1}$
8a	$-C_6H_5$	384	7350
8b	$-C_6H_4OCH_3(p)$	404	8800
8d	$-C_6H_4N(CH_3)_2(p)$	452	9400
8e	$-C_6H_4OH(p)$	402	6950
8i	$-C_6H_4NO_2(p)$	402	9250
8j	$-C_6H_4NO_2(o)$	394	6000

Thiophenols were added to 1-methyl-3-(substituted styryl)-2(1*H*)-quinoxalinones (**8**) to produce 1-methyl-3-[2-(substituted phenyl)-2-(substituted phenylthio)-ethyl]-2(1*H*)-qunoxalinones (**9a—e**) whose IR spectra showed band at 1670 cm^{-1} for C=O group and revealed the disappearance of C=C band at 1620—1610 cm^{-1}. The UV spectrum of **9b** in ethanol showed absorption band at λ_{max} 340 nm (ε 1800) which is close to that of **2a** λ_{max} 340 nm (ε 5500) confirming the saturation of the styryl side chain. The ^{1}H-NMR spectrum of **9b** in

Compounds are colorless crystals except **2e—g** are brownish crystals. a) Not changed by admixture with the reference sample.[10)]

$CDCl_3$ showed a singlet at δ 3.38 (3H, *N*-CH_3), a doublet at δ 3.58 (2H, -CH_2-side chain), a singlet at δ 3.7 (3H, -OCH_3), a triplet at δ 4.35 (1H, -CH-side chain). J_{vic} 6—7 Hz and a multiplet at δ 6.7—7.85 (13H, aromatic protons). Mercaptoacetic acid underwent addition to 1-methyl-3-styryl-2(1*H*)-quinoxalinones (**8a—c, i**) giving the products, 1-methyl-3-[2-(carboxymethylthio)-2-(substituted phenyl)ethyl]-2(1*H*)-quinoxalinones (**10a—d**). The IR spectra of **10a,c** showed bands at 1650 cm^{-1} (C=O) of quinoxalinone nucleus, at 1720 cm^{-1} (C=O) of carboxylic acid and a broad band at 2700—2500 cm^{-1} (assoc. OH). The UV spectrum of **10a** in ethanol showed a band at λ_{max} 343 nm (ε 2000) which is close to λ_{max} 340 nm (ε 5500) of the compound **2a**. The NMR spectrum of **10a** in $CDCl_3$ showed a singlet at δ 3.15 (2H, -CH_2-carboxyl); a doublet at δ 3.6 (2H-CH_2- to quinoxalinone nucleus), a singlet at δ 3.85 (3H, *N*-CH_3), a triplet at δ 4.80 (1H, -CH-side-chain), J_{vic} 6—7 Hz and a multiplet at δ 7.2—8 (9H, aromatic protons).

1,3-Dimethyl-2(1*H*)-quinoxalinone (**2a**) condensed with ketones, such as, acetophenone, *p*-bromo-, *p*-methyl-, *p*-methoxy acetophenones, and benzophenone, in the presence of zinc chloride gave 1-methyl-3-[2-(substituted phenyl)-1-alkenyl]-2(1*H*)-quinoxalinones (**11a—e**). The NMR spectrum of compound **11e** in $CDCl_3$ showed a singlet at δ 3.7 (3H, *N*-CH_3), a singlet at δ 6.85 (1H, -CH=) and a multiplet at δ 7.35—7.65 (14H, aromatic protons).

Syntheses of 1-methyl-3-(substituted styryl)-2(1*H*)-quinoxalinethiones (**12a—e**) were achieved by refluxing a mixture of **8** with P_2S_5 in dry pyridine for 5 h. In the IR spectrum of compound **12d** C=O Stretching disappeared, while two new bands at 1515, 1240 cm^{-1} for C=S group and also a band at 1610 cm^{-1} for C=C group was observed. The UV spectrum of compound **12d** in $CHCl_3$ showed a bathochromic shift for the K-band at λ_{max} 442 nm (ε 135×10^2) in comparison with its precursor 1,3-dimethyl-2(1*H*)-quinoxalinethione (**6**), λ_{max} 390 nm (ε 86×10^2), which proves the extended conjugation between the styryl residue and -C=N- group of 2(1*H*)-quinoxalinethione nucleus.

Experimental

Melting points reported are uncorrected. IR spectra were recorded on a Beckman 20 infrared spectrophotometer using KBr Wafer technique. UV spectra in ethanol on a Pye-Unicam SP 8000 Spectrophotometer and NMR spectra were recorded on a 90 MHz Bruker spectrospin and a Varian EM-390 spectrometer.

*3-Methyl-2(1H)-quinoxalinone (**1**).*[8)] Colorless crystals from ethanol, mp 245 °C (sublim). NMR exhibit a singlet at δ 2.9 (3H, -CH_3), a multiplet at δ 7.4—8.15 (4H, aromatic protons), while the NH proton at δ 7.1 disappeared by adding D_2O.

*Reactions of 3-Methyl-2(1H)-quinoxalinone (**1**) with Alkyl, Benzyl, and Arenesulfonyl Halides. General Procedure*: A mixture of 3-methyl-2(1*H*)-quinoxalinone (**1**) (0.01 mol), alkyl, benzyl, or arenesulfonyl halides (0.012 mol), and anhydrous K_2CO_3 were refluxed together for several hours in dry acetone (30 ml). The resultant *N*-substituted derivatives (**2a—g**) were crystallized from the proper solvent (Table 5).

*Synthesis of 3-Methyl-2-quinoxalinyl Benzoate (**3**).* A mixture of 3-methyl-2(1*H*)-quinoxalinone (**1**) (0.01 mol) in dry acetone, anhydrous K_2CO_3 (0.012 mol), and benzoyl chloride (0.012 mol) was heated for several hours. Acetone solution was filtered and evaporated. The product was crystallized from petroleum ether (60—80 °C) to give **3** as yellowish crystals, mp 110—111 °C, yield 2.3 g (90%). Found: C, 72.69; H, 4.68; N, 10.49%. Calcd for $C_{16}H_{12}N_2O_2$ C, 72.71; H, 4.58; N, 10.60%.

*Synthesis of 3-Methyl-2(1H)-quinoxalinethione (**4**).* A mixture of 3-methyl-2(1*H*)-quinoxalinone (**1**) (0.01 mol) and P_2S_5 (0.01 mol) was refluxed in dry pyridine (20 ml) for 5 h. The solvent was evaporated and the residue was treated with dil acetic acid. The solid product was filtered and crystallized from absolute ethanol to give **4** as orange-brown crystals, mp 250—251 °C (sublim), yield 1.4 g (85%). Found: C, 61.56; H, 4.59; N, 15.95%. Calcd for $C_9H_8N_2S$: C, 61.36; H, 4.58; N, 15.90%.

*Reaction of 3-Methyl-2(1H)-quinoxalinethione (**4**) with Alkyl and Benzyl Halides. General Procedure*: A mixture of 3-methyl-2(1*H*)-quinoxalinethione (**4**) (0.01 mol) in dry acetone, anhydrous K_2CO_3 (0.012 mol) and the corresponding alkyl or benzyl halide was heated on a steam bath for 4 h. Acetone solution was filtered and evaporated and the product was crystallized from suitable solvent.

*2-Methyl-3-(methylthio)quinoxaline (**5**)*: Colorless crystals from pet. ether (40—60 °C), mp 55—56 °C, yield 1.8 g

All compounds are yellowish crystals from pet. ether (40—60 °C).

(95%). Found: C, 63.19; H, 5.35; N, 14.90%. Calcd for $C_{10}H_{10}N_2S$: C, 63.15; H, 5.30; N, 14.74%.

*2-Benzylthio-3-methylquinoxaline (**7a**)*: Colorless crystals from acetone, mp 84—85 °C, yield 2.4 g (90%). Found: C, 72.25;H, 5.34; N, 10.56; S, 12.00%. Calcd for $C_{16}H_{14}N_2S$: C, 72.16; H, 5.30; N, 10.52; S, 12.02%.

*Synthesis of 1,3-Dimethyl-2(1H)-quinoxalinone (**6**)*: From 1,3-dimethyl-2(1*H*)-quinoxalinone (**2a**) and P_2S_5 following the same procedure for the synthesis of **4**. Brown crystals from ethanol, mp 146—147 °C, yield 85%. Found: C, 63.20; H, 5.40; S, 16.90%. Calcd for $C_{10}H_{10}N_2S$: C, 63.15; H, 5.30; S, 16.82%.

*Synthesis of 1-Methyl-3-substituted Styryl-2(1H)-quinoxalinone (**8**). Procedure (A)*: In the presence of piperidine; 1,3-Dimethyl-2(1*H*)-quinoxalinone (**2a**) (0.01 mol) was fused with the corresponding aromatic aldehyde (0.012 mol) for 10 min in the presence of few drops of piperidine. The product was isolated from the reaction mixture by adding ethanol, filtered and crystallized from the proper solvent (Table 6).

Procedure (B): In the presence of pyridine solvent and piperidine; 1,3-Dimethyl-2(1*H*)-quinoxalinone (**2a**) (0.01 mol) and the appropriate aromatic aldehyde (0.012 mol) were refluxed together in dry pyridine as solvent in the presence of few drops of piperidine for 3 h after which the excess solvent was removed and the product was crystallied from suitable solvent.

Procedure (C): In acetic anhydride solvent; 1,3-Dimethyl-2(1*H*)-quinoxalinone (**2a**) (0.01 mol) and the appropriate aromatic aldehyde (0.012 mol) were refluxed together in acetic anhydride as solvent for 20 h after which the excess solvent was removed and the reaction mixture was treated as usual.

*Addition of Substituted Thiophenol to 1-Methyl-3-(substituted styryl)-2(1H)-quinoxalinone (**8**). General Procedure*: A mixture of 1-methyl-3-(substituted styryl)-2(1*H*)-quinoxalinone (**8**) (0.002 mol) and substituted thiophenol (0.004 mol) was heated at 100 °C for 2 h. The yellow-brown oil formed was triturated with pet. ether (40—60 °C) and the products obtained were crystallized from the proper solvent.

*1-Methyl-3-[2-phenyl-2-(phenylthio)ethyl]-2(1H)-quinoxalinone (**9a**)*: Colorless crystals from pet. ether (60—80 °C), mp 129—130 °C, yield 0.5 g (65%). Found: C, 74.09; H, 5.50; N, 7.45%. Calcd for $C_{23}H_{20}N_2S$: C, 74.17; H, 5.41; N, 7.52%.

Asymmetric Reduction of Schiff's Bases with Lithium Aluminium Hydride–Monosaccharide Complexes to Give Optically Active Secondary Amines

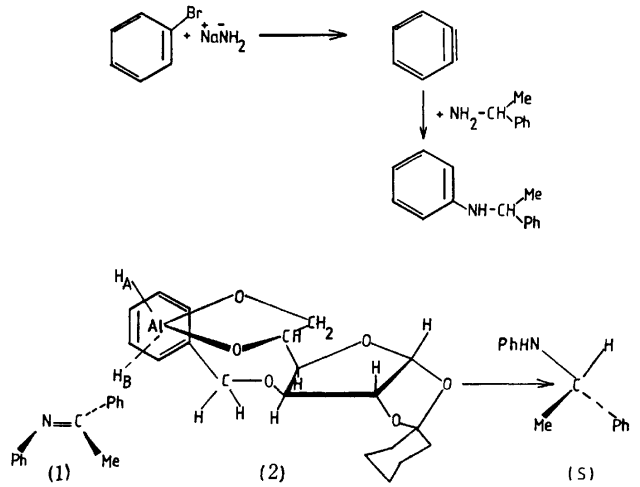
(Received May 10, 1983)

The asymmetric reduction of selected Schiff's bases (ketimines) with the lithium aluminium hydride–monosaccharide complexes derived from 3-*O*-benzyl-1,2-*O*-cyclohexylidene-α-D-glucofuranose gives optically active secondary amines. The absolute configuration of *N*-(1-phenylethyl)aniline was assigned as *S* by *N*-phenylation of *S*-(−)-1-phenylethylamine and hence all the levo-rotatory secondary amines obtained by this asymmetric reduction are assigned the *S*-configuration.

The asymmetric reduction of ketoximes and their *O*-substituted ether derivatives with the lithium aluminium hydride–monosaccharide complexes has been reported by us to give optically active primary amines.[1] We have now extended these investigations to the reduction of structurally related Schiff's bases (ketimines) to give optically active secondary amines. Prior to this investigation, an asymmetric reduction of ketimines was briefly reported by Cervinka and Suchan[2] who obtained "partially optically active primary amine". The primary amines so obtained were of low optical yields and have known configurations. More recently, Solladie and his coworker[3] described the introduction of a new chiral site on an *N*-chirally substituted imine by stereoselective reduction followed by subsequent hydrogenolysis of the chiral substituent on the nitrogen to give an optically active primary amine.



(1) (2) (S)

The reduction of ketimines with lithium aluminium hydride–3-*O*-benzyl-1,2-*O*-cyclohexylidene-α-D-glucofuranose complex (**2**) follows the same pattern as that of the oxime and oxime ethers.[1] A similar mechanism is therefore postulated for the reduction of ketimines and this is shown in **1** and **2**. A preferential hydride transfer of the less shielded H_B to the carbon of the imino group with the phenyl pointing away from the shielding 3-*O*-benzyl group of the monosaccharide derivative is predicted to give optically active secondary amines of the *S*-configuration. The *N*-phenyl group is as remote from the carbohydrate moiety as the tetrahydropyranyloxy group is in the reduction of ketone oxime ethers and, therefore, not likely to play any part in the stereoselective process. The stereoselectivity of the reduction process would thus be determined by the steric and electronic interactions between the *C*-phenyl and alkyl substituents on the ketimines and the 3-*O*-benzyl group of the carbohydrate residue.

Four examples of a homologous series of ketimines were reduced with the lithium aluminium hydride complex **2** (Table 1) and gave optically active secondary amines, all levo-rotatory, which were characterised by IR, NMR, and elemental analysis (Table 2).

The absolute configuration of *N*-(1-phenylethyl)aniline was previously reported by Wittig and Thiele.[4] A confirmation of this configuration was obtained for *N*-(1-phenylethyl)aniline by phenylation *via* the benzyne of (+)- and (−)-1-phenylethylamine and comparison of the products with that obtained from the reduction of the amine. Benzyne, generated by the action of sodamide on bromobenzene in liquid ammonia,[5] reacted with *S*-(−)-1-phenylethylamine[6,7] to give (−)-*N*-(1-phenylethyl)aniline which therefore has the *S*-configuration. This method should give minimum racemisation of the optically active amine and the optical purity of the *N*-(1-phenylethyl)aniline is estimated to be >95%. This value is much greater than the 40% ee reported by Kagan *et al.*[8] The maximum specific rotation obtained was −6.2° which was used to calculate the stereoselectivity of the asymmetric reduction and gave a maximum of excess enantiomer of 23.6% (Table 3).

The three other amines for which the configuration has not been determined previously are now assigned the *S*-configuration on the basis that in our laboratory, the asymmetric reduction with this reagent of 40 compounds comprising ketones, oximes, oxime ethers, and now ketimines has without exception given products with the *S*-configuration.[1,9]

Several methods for the synthesis of ketimines have been reported in the literature.[10] Recently, the condensation of a ketone with a primary aromatic amine in the presence of hydrogen cyanide was briefly reported to give α-amino nitriles in good yields, and these were coverted into the ketimines with methanolic potassium

hydroxide at room temperature.[11]

$$R'COR + PhNH_2 + KCN \xrightarrow{HOAC} RR'C(CN)NHPh \xrightarrow{KOH\text{-}MeOH} RR'C{=}NPh$$

In our laboratory, the elimination of hydrogen cyanide from the α-amino nitrile did not proceed in reasonable yield at room temperature, but excellent yields were obtained when the reaction was carried out under reflux for 1 h. The four examples of homologous series of ketimines used for these asymmetric reductions were synthesized by this method, and their structures confirmed by IR, UV, and NMR spectroscopy and their elemental analyses.

Experimental

Thin layer chromatography of carbohydrate derivates was performed on silica gel with benzene-methanol (98:2) as solvent system and a 1,3-naphthalenediol-phosphoric acid spray for detection. The ester used in the reductions was repeatedly dried over sodium. The purity of the amines was established by GLC on a 5 ft glass column of Carbowax 20 M on Chromosorb W (for the liquid amines), and by several recrystallizations with constant melting points were obtained (in the case of the solid amines). Optical rotations (0.01°) were determined for neat samples unless otherwise stated, with a Stanley photoelectric polarimeter and/or with a Perkin-Elmer 141 polarimeter at 20 °C. NMR spectra were obtained for solutions in deuteriochloroform with Varian A60 and T60 spectrometers, tetramethylsilane being used as internal reference.

Preparation of α-Amino Nitrile. The ketone (0.66 mol) and aniline (6.12 g, 0.06 mol) were dissolved in glacial acetic acid (25 ml). The mixture was gently stirred at 0 °C while portions of solid potassium cyanide (4.3 g, 0.66 mol) were cautiously added. Stirring was continued until a solid crystallized (*ca.* 1 h). The mixture was then cooled and filtered; the solid residue was washed with water (4×100 ml) and light petroleum (bp 40—60 °C; 4×50 ml) and then crystallized from methanol, yields 80—90% ν_{max} 2230 (CN) and 3400 cm^{-1} (NH).

Preparation of Ketimines. The α-amino nitrile (0.03 mol) was dissolved in hot methanol (40 ml). To this a solution of potassium hydroxide (6.7 g, 0.12 mol) in methanol (50 ml) was carefully added and the reaction mixture heated under reflux for 1 h. Water (100 ml) was added to the cooled mixture and the organic material removed by extraction with light petroleum (bp 40—60 °C; 4×50 ml). The combined light petroleum extracts were washed with water (2×100 ml), dried ($MgSO_4$) and the solvent evaporated to give a light yellow oil which was refrigerated. The crude solid material was recrystallized from light petroleum (bp 40—60 °C) to give the pure ketimine; ν_{max} 1640—1650 cm^{-1} (C=N).

Reduction of Ketimines with the Lithium Aluminium Hydride-3-O-benzyl-1,2-O-cyclohexylidene-α-D-glucofuranose Complex. A solution of the glucofuranose (8.8 g, 0.025 mol) in dty ether (50 ml) was added to a measured volume of a standardized ethereal solution of lithium aluminium hydride (*ca.* 18—20 g l^{-1}). The mixture was heated under reflux for 90 min, after which a solution of the ketimine (0.025 mol) in dry ether (20 ml) was added. Heating under reflux was continued for 2.5 h, after which the mixture was cooled, the complex decomposed with water (15 ml) and the precipitated hydroxide filtered off and washed with ether (2×30 ml). The combined filtrate and washings were extracted with dilute hydrochloric acid (3×20 ml) to separate all basic components. The aqueous acid layer was strongly basified (6 M† NaOH) and extracted with ether (3×50 ml) and the extract washed with water (2×30 ml) and dried ($MgSO_4$). Evaporation gave an oily porduct. The optically active secondary amine was isolated by fractional distillation under reduced pressure and characterized by IR, NMR spectroscopy, and elemental analysis; its purity was checked by GLC or by recrystallization in the case of a solid product (Table 2).

Determination of the Absolute Configuration of N-*(1-phenylethyl)-aniline.* Metallic sodium (0.58 g, 0.025 mol) and an excess of liquid ammonia (20 ml) were stirred for 1 h, after which bromobenzene (4 g, 0.025 mol) was added. The resultant dark violet product was further stirred for 1 h, after which 1-phenylethylamine (3.0 g, 0.025 mol) was added dropwise with stirring. Stirring was continued for another 3 h, the reaction mixture was neutralized with dilute hydrochloric acid (3×10 ml) and the aqueous layer strongly basified (6 M NaOH). Work-up gave an oily product which was distilled under reduced pressure and then characterized by IR and NMR spectroscopy; the optical rotation

Cyclic Carbonates Obtained by Reactions of Alkali Metal Carbonates with Epihalohydrins

Gabriel Rokicki* and Witold Kuran

Faculty of Chemistry, Technical University (Politechnika), Koszykowa 75, 00-662 Warsaw, Poland

(Received July 11, 1983)

A study has been carried out on the reaction of alkali metal carbonates with epihalohydrins in the presence of cation complexing agents *e.g.* crown ethers. 3-Glycidyloxypropylene carbonate was found to be formed as the main product of the reaction of epichlorohydrin with potassium carbonate promoted by 18-crown-6. The effect of various epihalohydrins and alkali metal carbonates on the reaction course was examined. It was found that the reaction of potassium hydrogencarbonate with epichlorohydrin gives 4-hydroxymethyl-1,3-dioxolan-2-one. When the reaction of epihalohydrins with potassium carbonates was carried out in the atmosphere of carbon dioxide the products contained linear carbonate linkage apart from cyclic one. From these results, a plausible mechanism was proposed for the reaction of alkali metal carbonates with epihalohydrins in the presence of crown ethers.

The polycondensation reaction of alkali metal carbonates with α,ω-dihalo compounds in the presence of crown ethers, leading to polycarbonates,[1] prompted to develop studies on the application of alkali metal carbonates for the synthesis of high polymers.

Recently we have shown the possibility of using alkali metal carbonates as substrates for the synthesis of dialkyl carbonates, which when having been subjected to transesterification yielded high-molecular-weight polycarbonates.[2]

From the literature data[3] it results that alkali metal carbonates promoted by crown ethers initiate an anionic polymerization of oxiranes. The presence of carbon dioxide in the polymerization system with propylene oxide was found to stop the polymerization. In this system cyclic propylene carbonate was formed,[3] but in rather low yield.[4]

Recently, we have shown that cyclic carbonates could be obtained in nearly quantitative yield in the reaction of carbon dioxide with oxiranes in the presence of alkali metal halides, *e.g.* potassium iodide and anion-activating agents. Potassium carbonate, however, appeared also to be an efficient catalyst for the above reaction in the case of (halomethyl) oxiranes.[4] On the other hand, the reaction of potassium carbonate with α,ω-dibromo derivatives was reported to produce cyclic carbonates.[5]

In the course of investigations on the polymerization of epihalohydrins by the potassium carbonate–crown ether system, instead of a polymeric product, we found the formation of products containing a 1,3-dioxolan-2-one ring. Thus, in this paper we decided to study the synthesis of cyclic carbonates by the reaction of alkali metal carbonates with epihalohydrins in the presence of cation complexing agents.

Cyclic carbonates were found recently[6] as rather useful monomers for a number of new polymer syntheses.

Results and Discussion

It was found that the reaction of potassium carbonate (**1a**) with epihalohydrin (1-chloro-2,3-epoxypropane (**2a**)) carried out in the presence of 18-crown-6 or benzyltriethylammonium chloride (TEBA) yielded 3-glycidyloxypropylene carbonate [4-(oxiranylmethoxymethyl)-1,3-dioxolan-2-one (**3a**)]. The IR spectrum of the post-reaction mixture did not exhibit any absorption bands characteristic for a linear carbonate linkage.

The reactions of sodium and lithium carbonates in the presence of 15-crown-5 were found also to give **3a** but in lower yield than when **1a** was used (Table 1).

Considering the structure of cyclic carbonate **3a** the following scheme of the reaction of **1a** with **2a** can be proposed.

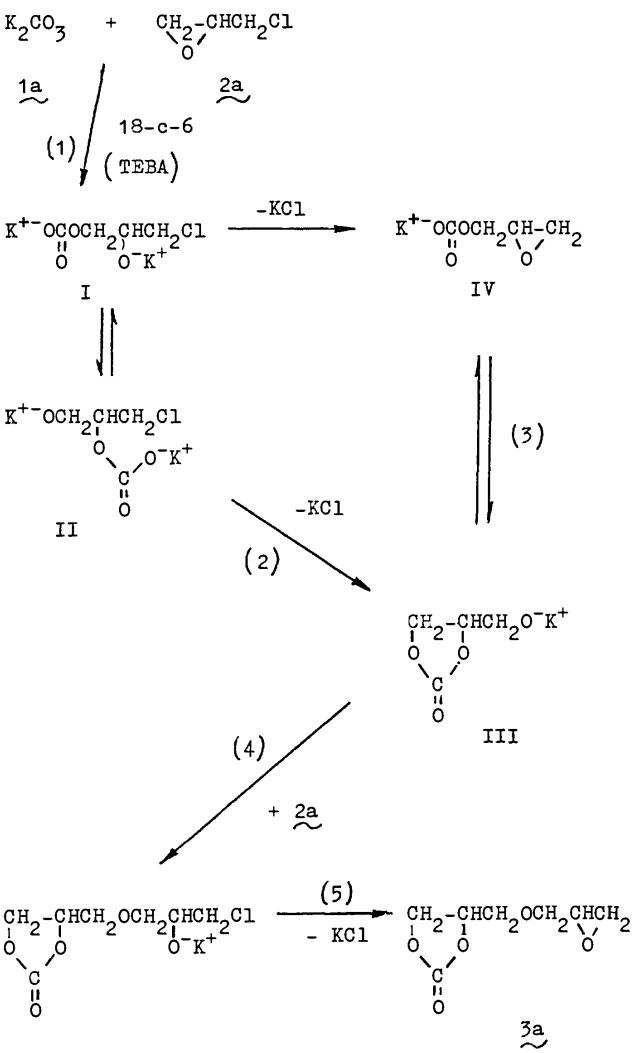

Table 1. The yield of **3a** in reaction of **2a** with alkali metal carbonates[a)]

Alkali metal carbonate	Anion activating agent	Reaction conditions: Molar ratio Carbonate/**2a**	Temp °C	Time h	Yield of **3a** %
K_2CO_3	18-c-6	1 : 4	85	24	53

$CaCO_3$	18-c-6	1 : 10	90	24	—

a) See Exptl part.

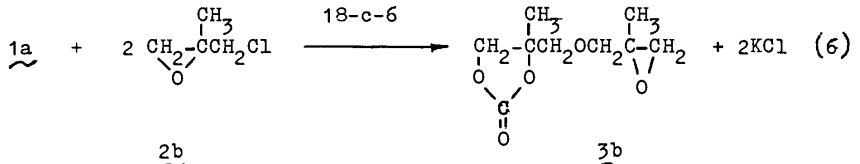
The carbonate ion, as an active nucleophilic agent when **1a** is complexed by a crown ether, can attack the C_α atom of the oxirane ring according to Eq. 1. The resulting **I** should undergo an intramolecular ester-exchange reaction leading to **II**, which can be followed by a cyclization reaction (Eq. 2) yielding **III**. The intermediate **III** can be also formed according to Eq. 3 involving an intramolecular nucleophilic attack of the carbonate ion on the oxirane ring in **IV**. The alcoholate ion in **III** can undergo reaction with **2a**, being in excess with respect to **1a** in the reaction system, and **3a** is formed as the final product (Eqs. 4 and 5).

When 1-chloro-2-methyl-2,3-epoxypropane (**2b**) was used instead of **2a** to the reaction with **1a**, a cyclic carbonate **3b** of a structure analogous to **3a** was formed (Eq. 6). This indicates that the reactions of substituted epihalohydrins with **1a** give also derivatives with oxirane and 1,3-dioxolan-2-one rings as the main reaction products.

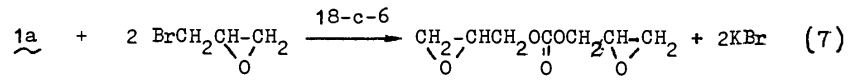
However, in the case of the reaction of **1a** with 1-bromo-2,3-epoxypropane (**2c**) it appeared that this reaction leads to products with linear carbonate linkages besides those with 1,3-dioxolan-2-one ring as it is indicated by the appearance of an infrared absorption band at 1750 cm^{-1} (C=O in a linear carbonate linkage). This absorption band was twice less intense than that at 1803 cm^{-1}, characteristic for carbonyl of 1,3-dioxolan-2-one ring. Taking into account our previous results[7)] of studies on the reaction of **2c** with phenolates, one may consider that in the system studied a nucleophilic attack of a carbonate ion on the carbon atom bonded to a bromine atom is plausible and a linear carbonate linkage can be formed (Eq. 7).

In the course of our studies on the reaction of 4-bromomethyl-1,3-dioxolan-2-one with **1a** also a nucleophilic attack of the carbonate ion on the carbon atom bonded to bromine was shown to occur. As a result the product containing both cyclic and linear carbonate linkages was formed (Eq. 8).

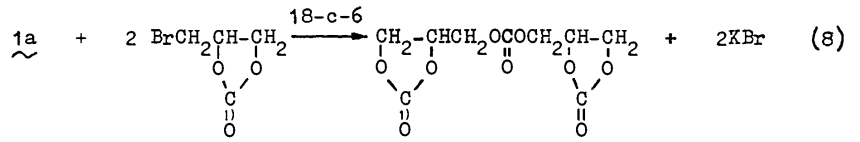
When the reaction of **2a** with **1a**, promoted by a crown ether, was carried out in the presence of small amount of water, the post-reaction mixture was found to contain 4-hydroxymethyl-1,3-dioxolan-2-one (**4a**). The formation of **4a** probably results from the presence of potassium hydrogencarbonate (**1b**) in the above water-containing reaction mixture. **1b** should be formed by basic hydrolysis of carbonate groups (Eqs. 9 and 10).



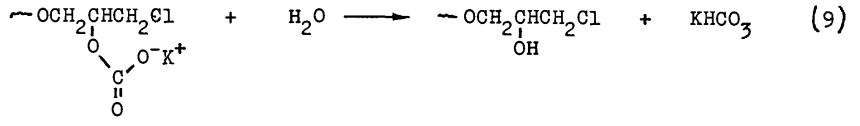
(6)



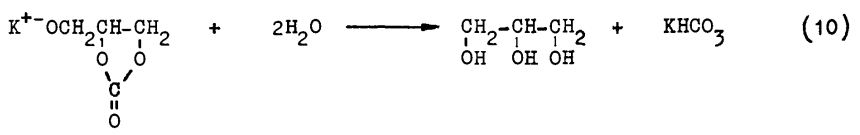
(7)



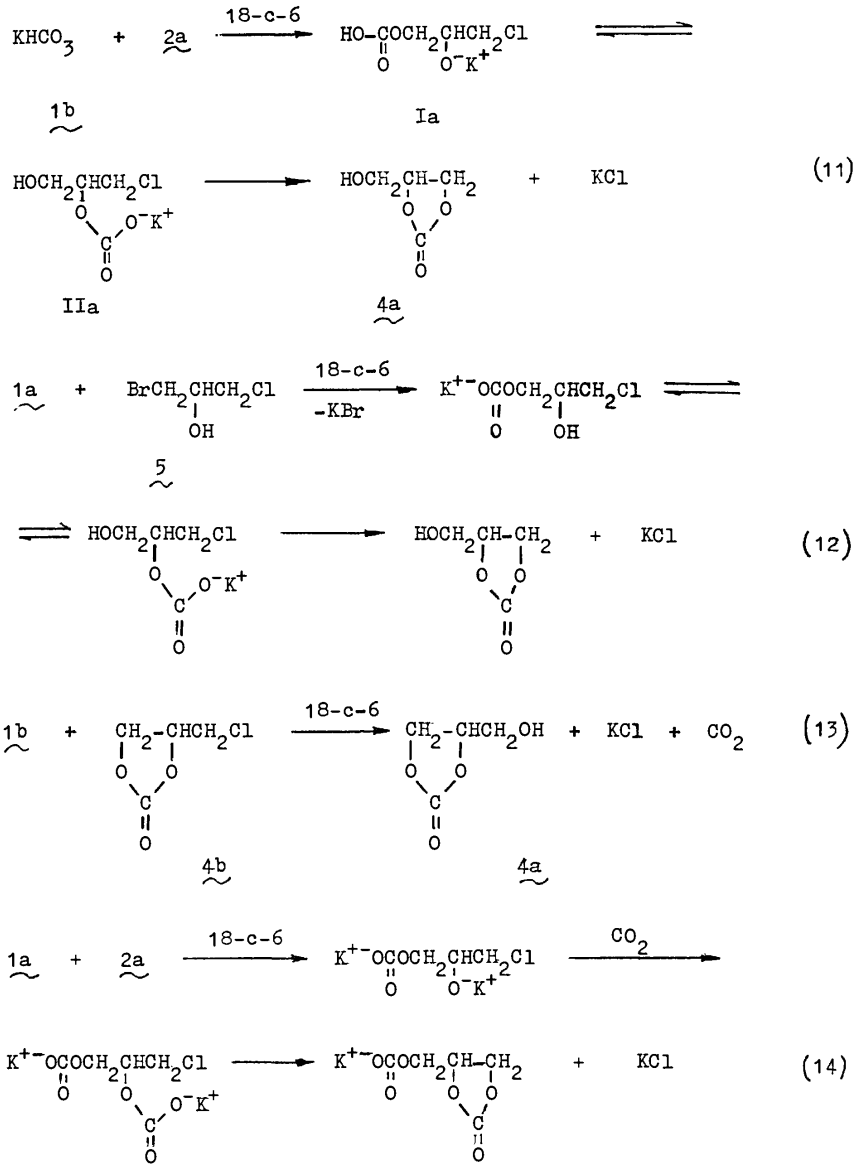
(8)



(9)



(10)



In order to confirm the above suggestion, the reaction of **1b** with **2a** in the presence of a crown ether was studied and it appeared to produce **4a** as the main product. The course of this reaction may be represented by Eq. 11.

Also in this case a nucleophilic attack of the hydrogencarbonate ion on the C_α atom of the oxirane ring of **2a** takes place, analogously as in the reaction of **1a** with **2a**. The resulting **Ia** exists in an equilibrium with the corresponding product of the intramolecular ester exchange **IIa**, which undergoes cyclization to **4a**.

Another reaction between **1a** and 1-bromo-3-chloro-2-propanol with 18-crown-6 was carried out to confirm the proposed pathway of **4a** formation (Eq. 12). Also in this case the product formed appeared to be **4a** but not 5-hydroxy-1,3-dioxan-2-one.

4a was shown to be formed also by heating of **1b** with 4-chloromethyl-1,3-dioxolan-2-one (**4b**) in the presence of a crown ether. Carbon dioxide was found to evolve during this reaction (Eq. 13).

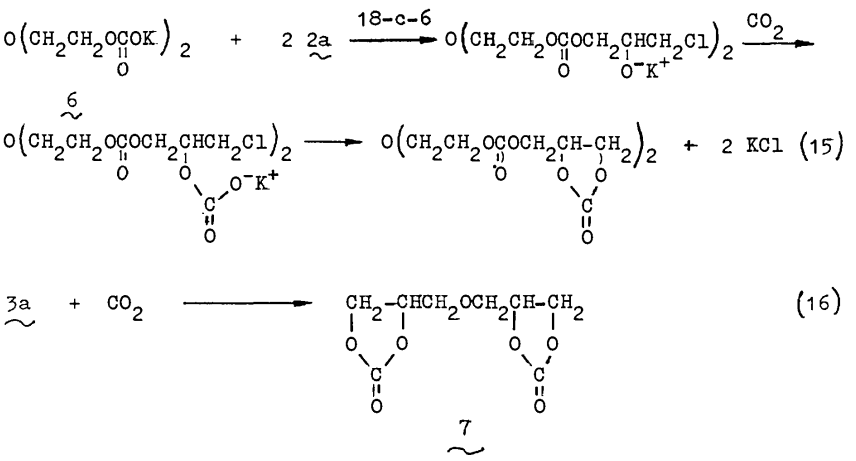
The above data obtained are consistent with the proposed mechanism of the **4a** formation involving **1b** in the system containing **2a**, **1a**, crown ether and slight amount of water (Eqs. 9 and 10).

The reaction of **1a** with **2a** in the presence of a crown ether carried out under carbon dioxide atmosphere was found to yield products containing linear carbonate linkages (IR absorption band 1740 cm^{-1}) apart from the cyclic ones (IR absorption band 1805 cm^{-1}). Thus, this reaction occurs most probably involving the carbon dioxide addition to the secondary alcoholate ion and relatively stable carbonate ion formation followed by the cyclization to the 1,3-dioxolan-2-one ring (Eq. 14).

Such a reaction mechanism could be supported by the course of the reaction of potassium alkyl carbonate **6** with **2a** under the carbon dioxide atmosphere (Eq. 15).

The reactions run according to Eqs. 14 and 15 were accompanied by the addition of carbon dioxide to **2a** yielding **4b**. The mechanism of this addition is discussed elsewhere.[4]

3a, which is the main product of the **1a** with **2a** reaction, was subjected to the reaction with carbon



dioxide using the potassium iodide–crown ether catalyst. The product appeared to be bis(2,3-dihydroxypropyl) ether dicarbonate (**7**) (Eq. 16). **7** was obtained also in the reaction of diglycidyl ether with carbon dioxide under analogous reaction conditions.

It seems noteworthy to mention that **3a** appeared to be very well soluble in water in contrast to **7** and **4a**.

Preliminary studies on the reactions of bis(cyclic carbonate) monomers, such as **7**, showed them to be useful for the synthesis of high-molecular-weight polymers like poly(hydroxy ether)s and poly(hydroxy urethane)s.[6]

Experimental

IR spectra were recorded on a Perkin-Elmer 521 spectrometer. The ^{1}H-NMR spectra were recorded with a 100 MHz JEOL NMR spectrometer using TMS as a standard. Elemental analyses of the products were carried out with a Perkin-Elmer model 240 microanalyzer.

The content of epoxy groups in products was determined by titration with a HCl solution in dioxane.

*Reaction of Potassium Carbonate (**1a**) with 1-Chloro-2,3-epoxy propane (**2a**).* A mixture of 13.8 g (0.1 mol) of **1a**, 0.2 g (0.76 mmol) of 18-crown-6 and 55.2 g (0.6 mol) of **2a** was heated at 85 °C within 24 h. After cooling the post-reaction mixture to room temperature KCl precipitate containing unreacted **1a** was filtered off. The filtrate was distilled to give **3a**. Bp 160—166 °C/0.4 mmHg (1 mmHg≈133.322 pa). Yield 10.6 g (60%). $d^{20}=1.2793$ g/cm^3; $n^{20}=1.4605$. Found: C, 48.02; H, 5.73%. Calcd for $C_7H_{10}O_5$: C, 48.27; H, 5.80%. IR: 1805 (C=O of 1,3-dioxolan-2-one ring), 1120 (H_2C-O-CH_2), 910 cm^{-1} (HC—CH_2). Epoxide content—0.57. Molecular weight of **3a** found from epoxide content was 176 (Calcd 174.1).

*Reaction of Potassium Carbonate (**1a**) with 1-Chloro-2-methyl-2,3-epoxypropane (**2b**).* A mixture of 13.8 g (0.1 mol) of **1a**, 0.2 g (0.76 mmol) of 18-crown-6 and 63.6 g (0.6 mol) of **2b** was heated at 90 °C within 24 h. The resultant mixture was cooled and potassium salt precipitate was filtered off. 3-(β-Methylglycidyloxy)-2-methylpropylene carbonate (**3b**) was distilled at 170—174 °C/0.8 mmHg. Yield 10.5 g (52%). Found: C, 52.85; H, 6.78%. Calcd for $C_9H_{14}O_5$: C, 53.45; H, 6.99%. IR: 1800 (C=O of 1,3-dioxolan-2-one ring), 1120 (H_2C-O-CH_2), 955 cm^{-1} (C—CH_2). ^{1}H-NMR: $\delta=1.42$ (3H, CH_3C—C), 1.56 (3H, CH_3C-C-OC-O), 4.28 and 4.68 (2H, CH_2-C-OC-O).

*Reaction of Potassium Carbonate (**1a**) with 1-Bromo-2,3-epoxypropane (**2c**).* A mixture of 7.9 g (0.05 mol) of **1a**, 0.1 g (0.38 mmol) of 18-crown-6 and 34.2 g (0.25 mol) of **2c** was heated at 70 °C within 15 h. After filtration of precipitate the filtrate contained products with linear carbonate linkages beside cyclic carbonate ones. IR: 1803 (C=O of 1,3-dioxolan-2-one ring) and 1750 cm^{-1} (C=O of linear carbonate linkages). Yield 2.8 g (32%) of **3a**.

*Reaction of Potassium Hydrogencarbonate (**1b**) with 1-Chloro-2,3-epoxypropane (**2a**).* A mixture of 10.0 g (0.1 mol) of **1b**, 0.2 g (0.76 mmol) of 18-crown-6 and 27.6 g (0.3 mol) of **1a** was heated at 80 °C under stirring within 36 h. After cooling and filtration of the potassium salt an organic layer was washed with water and **4a** was distilled at 152—160 °C/0.6—0.8 mmHg. Yield 4.83 g (41%). Found: C, 40.57; H, 5.21%. Calcd for $C_4H_6O_4$: C, 40.68; H, 5.03%. IR: 1800 (C=O of 1,3-dioxolan-2-one ring), 3500 cm^{-1} (OH).

*Reaction of Potassium Carbonate (**1a**) with 1-Bromo-3-chloro-2-propanol (**5**).* A mixture of 13.8 g (0.1 mol) of **1a**, 0.2 g (0.76 mmol) of 18-crown-6 and 51.9 g (0.3 mol) of **5** was heated at 80 °C within 24 h. After cooling and filtration of potassium salt precipitate, an organic layer was washed with water and **4a** was distilled at 150—160 °C/0.8 mmHg. Yield 8.8 g (75%). Found: C, 40.52; H, 5.23%. Calcd for $C_4H_6O_4$: C, 40.68; H, 5.13%.

*Reaction of **6** with 1-Chloro-2,3-epoxypropane (**2a**) in the Carbon Dioxide Atmosphere.* In a 50 cm^3 pressure autoclave 1.3 g (7.0 mmol) of the dipotassium salt of diethylene glycol, 10 cm^3 of dioxane, 0.3 g (1.14 mmol) of 18-crown-6 were added under nitrogen. Gaseous carbon dioxide was than introduced to the system under a pressure of 30 atm during 20 min. The carbon dioxide was released and 1.65 g (17.5 mmol) of **2a** was added to the autoclave containing resulting **6** and carbon dioxide introduction under pressure was repeated. The autoclave was then heated at 80 °C within 26 h. After cooling, carbon dioxide was released and the post-reaction mixture was extracted with benzene to remove **4b**. The residue contained a product with linear and cyclic carbonate linkages. IR: 1805 (C=O of 1,3-dioxolan-2-one ring), 1740 cm^{-1} (C=O of linear carbonate linkage).

*Reaction of 3-Glycidyloxypropylene Carbonate (**3a**) with Carbon Dioxide.* In a autoclave 17.4 g (0.1 mol) of **3a**, 0.2 g (1.2 mmol) of KI and 0.1 g (0.38 mmol) of 18-crown-6 were

placed. Carbon dioxide was then introduced to the system under a pressure of 30 atm. The autoclave was heated at 120 °C within 12 h. The post-reaction mixture was washed with water. 20.2 g (93% yield) of **7** was obtained. Mp 62—64 °C. Found: C, 44.84; H, 4.74%. Calcd for $C_8H_{10}O_7$: C, 44.04; H, 4.63%.

Addition Reaction of Carbon Dioxide to Diglycidyl Ether (8) In a autoclave 13.0 g (0.1 mol) of **8**, 0.2 g (1.2 mmol) of KI and 0.1 g (0.38 mmol) of 18-crown-6 were placed.Carbon dioxide was then introduced to the system under a pressure of 30 atm and the autoclave was heated at 120 °C within 14 h. After cooling, carbon dioxide was released and the reaction product was washed with water. 21.1 g (97% yield) of **7** was obtained. Mp 62—63 °C. Found: C, 43.97; H, 4.71%. Calcd for $C_8H_{10}O_7$: C, 44.04; H, 4.63%.

Reactions of 2-Diazo-1,2-Diphenylethanone and Diphenyldiazomethane with Ketohydrazones

Girija Shankar Singh, Surendra Bahadur Singh, and Kailash Nath Mehrotra*

Department of Chemistry, Banaras Hindu University, Varanasi-221 005, India

(Received August 30, 1983)

The reactions of 2-diazo-1,2-diphenylethanone (**1**) with ketohydrazones (**3a—c**) in equimolecular ratio yield (diphenylacetyl)hydrazones (**4a—c**) of the corresponding benzophenones which on further treatment with **1** in equimolecular ratio leads to 1-diphenylacetylazo-1,1,3,3-tetraaryl-2-propanones (**5a—c**). The product **5a** is also obtained in the reaction of **1** with benzophenone hydrazone (**3a**) in 2 : 1 molecular ratio. The bis(acetylacetonato)copper(II)-catalyzed reaction of **1** and also of diphenyldiazomethane (**2**) with ketohydrazones (**3**) affords ketazines (**6**). The mechanistic route for the formation of products is discussed.

The thermal decomposition of 2-diazo-1,2-diphenylethanone (**1**) in the presence of amines has been observed to yield diphenylacetamides.[1] Using bis(acetylacetonato)copper(II) as a catalyst in the above reaction the products formed are benzilmonoimines.[1] Copper powder,[2] salts,[3] and complexes[4] have been employed earlier as these are known to prevent Wolff rearrangement of carbenes to ketenes in the decomposition of α-diazo ketones. Bis(acetylacetonato)copper(II)-catalyzed decomposition of diphenyldiazomethane (**2**) in the presence of primary amines gives benzophenone (*N*-substituted imines).[5] The reaction of **1** with *N*-substituted imines has been reported to yield 2-azetidinones[6] which are also formed in the reaction of diphenylketene with fluorenone acetyl (or benzoyl) hydrazones.[7] The thermal decomposition of **1** in the presence of monoanils of benzil has been observed to yield spiro-2-azetidinones.[8] The reaction of **1** with 1,1-diphenylmethanimine has been reported to form a 2-azetidinone derivative.[9] We now report the thermal decomposition of 2-diazo-1,2-diphenylethanone (**1**) in the presence of ketohydrazones (**3a—c**) to give (diphenylacetyl) hydrazones (**4a—c**) of the corresponding benzophenones, these on further reaction with **1** yield 1-diphenylacetylazo-1,1,3,3-tetraaryl-2-propanones (**5a—c**). In each step the reacting species is diphenylketene. The reaction between **1** and **3a** in 2 : 1 molecular ratio also gives the product **5a**. The bis(acetylacetonato)copper(II)-catalyzed decomposition of **1** and also of diphenyldiazomethane (**2**) in the presence of ketohydrazones **3** form ketazines **6a—g** in which benzoylphenylcarbene and diphenylcarbene, respectively, are the reacting species.

Results and Discussion

An equimolecular mixture of 2-diazo-1,2-diphenylethanone (**1**) and benzophenone hydrazone (**3a**) was heated to reflux in dry benzene for 8 h under a stream of nitrogen. The reaction product was separated by fractional crystallization from ethanol; it consisted of benzophenone(diphenylacetyl)hydrazone (**4a**). The structural assignment of **4a** was made on the basis of its analytical and spectral data.

Similar treatment of hydrazones **3b** and **3c** gave (diphenylacetyl)hydrazones **4b** and **4c**, respectively, (identified on the basis of their analytical and spectral data).

Treatment of compounds **4a—c** with **1** in equimolecular ratio gave 1-diphenylacetylazo-1,1,3,3-tetraaryl-2-propanones (**5a—c**) characterized on the basis of their analytical and spectral data. The product 1-diphenylacetylazo-1,1,3,3-tetraphenyl-2-propanone(**5a**) was also obtained in the reaction of **1** with **3a** in 2 : 1 molecular ratio. In the above reaction, benzophenone (diphenylacetyl)hydrazone (**4a**) seems to be an intermediate as shown in Scheme 1.

The product mixture, obtained from the bis(acetylacetonato)copper(II)-catalyzed reaction of **1** with **3a** in dry benzene, was separated by elution chromatography and crystallized from ethanol; it gave 2-diphenylmethylenehydrazono-1,2-diphenylethanone (**6a**). The structure of **6a** was assigned on the basis of analytical and spectral data.

Similar treatment of **1** with hydrazones **3b—f** gave 2-diarylmethylenehydrazono-1,2-diphenylethanones(**6b—f**) identified on the basis of their analytical and spectral data. Authentic samples of the products **6a—f** were prepared following the reported method[10] for comparison (analytical and spectral data).

When diphenyldiazomethane (**2**) was allowed to react with benzophenone hydrazone (**3a**), in an analogous manner, a yellow solid was obtained which was identified as benzophenone azine (**6g**) on the basis of its analytical and spectral data and also comparison (IR, NMR, and mp) with an authentic sample, prepared according to the method reported.[11]

Similar treatment of **2** with benzil monohydrazone (**3d**) afforded yellow crystalline product, characterized as ketazine **6a** on the basis of its analytical and spectral data.

Thermal decomposition of **1** may lead to benzoylphenylcarbene which has been known to undergo Wolff rearrangement to give diphenylketene[12] (Scheme 1). The products **4a—c** arise through a proton transfer from the zwitterionic intermediate **A**, formed by the addition of diphenylketene to hydrazones **3a—c**. A similar zwitterionic intermediate has been proposed earlier in the reaction of diphenylketene with *N*-benzylideneaniline to give *N*-phenylimidate.[13] Addition of a second molecule of diphenylketene to compounds **4a—c** gives rise to products **5a—c** through a proton transfer from an intermediate **B**. A similar intermediate has been proposed earlier in the reaction of benzenediazonium ion with aldehyde arylhydrazones to give bis(arylazo)methanes.[14]

The proton shift in **B** appears to be more feasible than the cyclization to β-lactams due to steric factors (pre-

sence of four bulky aryl groups on the terminal carbon atoms in **B**). However, in the presence of bis(acetylacetonato)copper(II), the Wolff rearrangement of the carbene is prevented[4] (Scheme 2) and in this case a carbene-copper complex is formed.[15] The respective carbenes from the complexes react with ketohydrazones to give ketazines **6a—g** through an intermediate **C**, formed by the interaction of carbenes with N–H bond of hydrazones.

Experimental

Melting points have been determined on a Büchi apparatus (capillary method) and are uncorrected. The ultraviolet spectra were obtained in 95% ethanol on a Carry-14 spectrophotometer. The infrared spectra were recorded in nujol mull on a Perkin-Elmer 720 spectrophotometer. The PMR spectral data were obtained on a Varian A-60D spectrometer in $CDCl_3$ using TMS as internal standard.

Materials. Benzil, 4,4-dimethoxybenzil, 4,4'-dimethylbenzil, and bis(acetylacetonato)copper(II) were obtained from EGA chemicals, West Germany; benzophenones and hydrazine hydrate from BDH, India; 2-diazo-1,2-diphenylethanone,[16] diphenyldiazomethane,[17] benzophenone hydrazones,[18] and benzil monohydrazones[19] were prepared according to reported methods and characterised on the basis of their analyses and spectral data.

*Preparation of Benzophenone (Diphenylacetyl)hydrazones **4a—c**. General Procedure*: A mixture containing 2-diazo-1,2-diphenylethanone (**1**) (0.01 mol) and hydrazones **3a—c** (0.01 mol) in 80 ml of dry benzene (thiophene free) in a 250 ml three necked round bottomed flask equipped with a condenser and a mercury trap was heated to reflux for 8 h under a stream of nitrogen and kept overnight at room temperature. The solvent was removed on a rotatory evaporator and residual material was triturated with ethanol. The solid obtained was recrystallized from ethanol to afford the products.

*Benzophenone (Diphenylacetyl)hydrazone (**4a**).* A yield of 80% was obtained, mp 149 °C. UV (EtOH): 290 nm; IR (Nujol): 3325 (N–H); 1690 (C=O) and 1605 cm^{-1} (C=N); NMR ($CDCl_3$) δ=8.85 (s, 1H, NH, D_2O exchangeable), 7.33 (m, 20H, aromatic protons) and 6.17 (s, 1H, CH). Found: C, 82.82; H, 5.84; N, 6.85%. Calcd for $C_{27}H_{22}N_2O$: C, 83.08; H, 5.64; N, 7.18%.

*4,4'-Dimethoxybenzophenone (Diphenylacetyl)hydrazone (**4b**).* A yield of 53% was obtained, mp 119 °C. UV (EtOH): 298 nm; IR (Nujol): 3280 (N–H); 1660 (C=O) and 1605 cm^{-1} (C=N); NMR ($CDCl_3$) δ=9.38 (s, 1H, NH, D_2O exchangeable), 7.33 (m, 18H, aromatic protons), 6.25 (s, 1H, CH) and 3.83 and 3.78 (a pair of singlet, 6H, two OCH_3 protons). Found: C, 77.27; H, 5.91; N, 6.36%. Calcd for $C_{29}H_{26}N_2O_3$: C, 77.31; H, 5.77; N, 6.22%.

*4-Chlorobenzophenone (Diphenylacetyl)hydrazone (**4c**).* A yield of 52% was obtained, mp 99 °C. UV (EtOH): 290 nm; IR (Nujol): 3280 (N–H): 1660 (C=O) and 1600 cm^{-1} (C=N); NMR ($CDCl_3$) δ=8.08 (s, 1H, NH, D_2O exchangeable), 7.20 (m, 19H, aromatic protons) and 6.00 (s, 1H, CH). Found: C, 76.10; H, 5.07; N, 6.66%. Calcd for $C_{27}H_{21}N_2OCl$: C, 76.32; H, 4.94; N, 6.59%.

*Preparation of 1-Diphenylacetylazo-1,1-diaryl-3,3-diphenylpropanones **5a—c**. General Procedure*: A similar procedure was used as described above for the preparation of **4a—c** taking 0.01 mol of **1** and 0.01 mol of **4a—c**.

*1-Diphenylacetylazo-1,1,3,3-teraphenyl-2-propanone (**5a**).* A yield of 71% was obtained, mp 177 °C. UV (EtOH): 250 nm; IR (Nujol): 1670 (C=O) and 1600 cm^{-1} (N=N); NMR ($CDCl_3$) δ=7.40 (m, 30H, aromatic protons), 5.83 (s, 1H, -CHCON=N) and 5.12 (s, 1H, CHCOC). Found: C, 83.87; H, 5.31; N, 5.02%. Calcd for $C_{41}H_{32}N_2O_2$: C, 84.25; H, 5.48; N, 4.79%.

*1-Diphenylacetylazo-1,1-bis(4-methoxyphenyl)-3,3-diphenyl-2-propanone (**5b**).* A yield of 50% was obtained, mp 140 °C. UV (EtOH): 238 nm; IR (Nujol): 1665 (C=O) and 1600 cm^{-1} (N=N); NMR ($CDCl_3$) δ=6.70 (m, 28H, aromatic protons), 5.53 (s, 1H, CHCON=N-), 4.83 (s, 1H, CHCOC) and 3.66 (s, 6H, two OCH_3 protons). Found: C, 80.45; H, 5.90; N, 4.29%. Calcd for $C_{43}H_{36}N_2O_4$: C, 80.12; H, 5.59; N, 4.34%.

*1-Diphenylacetylazo-1-(4-chlorophenyl)-1,3,3-triphenyl-2-propanone (**5c**).* A yield of 51% was obtained, mp 148 °C. UV (EtOH); 248 nm; IR (Nujol): 1670 (C=O) and 1600 cm^{-1} (N=N); NMR ($CDCl_3$) δ=7.20 (m, 29H, aromatic protons), 5.76 (s, 1H, $CHCON_2$) and 5.01 (s, 1H, CHCOC). Found: C, 79.58; H, 5.04; N, 4.26%. Calcd for $C_{41}H_{31}N_2O_2Cl$: C, 79.54; H, 5.01; N, 4.52%.

*Preparation of 1-Diphenylacetylazo-1,1,3,3-tetraphenyl-2-propanone (**5a**) from **1** and **3a**.* A yield of 52% was obtained by using a similar procedure as described above by taking **1** and **3a** in 2:1 molecular ratio.

*Preparation of Ketazines **6a—g**. General Procedure*: To a suspension containing 1 m mol of bis(acetylacetonato) copper(II) in 30 ml of dry benzene(thiophene free), heated under reflux with stirring in a 250 ml three necked round bottom flask equipped with a condenser and a mercury trap, a solution containing 0.01 mol of **1** and 0.01 mol of the hydrazones **3a—f** in 80 ml of dry benzene (thiophene free) was slowly added over a period of 3 h from a pressure equalizing funnel under a stream of nitrogen. The contents were heated to reflux for additional 4—6 h and kept overnight at room temperature. The reaction mixture was passed through a neutral alumina (10g, 1.2 cm × 10 cm^2) column and the products were eluted with benzene leaving the copper salt in column. The solvent was evaporated under reduced pressure and the residual material was triturated with ethanol to afford the products.

Similar procedure was adopted for the preparation of ketazines **6g** and **6a** by the reaction of diphenyldiazomethane (**2**) with keto hydrazones **3a** and **3d** respectively.

*2-Diphenylmethylene hydrazono-1,2-diphenylethanone (**6a**).* A yield of 88% was obtained, mp 129 °C. UV (EtOH) : 255, 315 nm; IR (Nujol): 1670 (C=O) and 1600 cm^{-1} (C=N-N=C); NMR ($CDCl_3$) δ=8.00 (m, H, aromatic protons) and 7.38 (m, H, aromatic protons). Found: C, 83.62; H, 4.92; N, 7.39%. Calcd for $C_{27}H_{20}N_2O$: C, 83.48; H, 5.19; N, 7.21%.

*2-[Bis(4-methoxyphenyl)methylenehydrazono]-1,2-diphenylethanone (**6b**).* A yield of 52% was obtained, mp 95 °C. UV (EtOH): 252, 295 nm; IR (Nujol): 1670 (C=O) and 1600 cm^{-1} (C=N-N=C); NMR ($CDCl_3$) δ=8.10 (m, 2H, aromatic protons), 7.30 (m, 16H, aromatic protons) and 3.96 and 3.81 (two s, 6H, two OCH_3 protons). Found: C, 77.60; H, 4.97; N, 6.14%. Calcd for $C_{29}H_{24}N_2O_3$: C, 77.67; H, 5.34; N, 6.25%.

*2-(4-Chloro-α-phenylbenzylidenehydrazono)-1,2-diphenylethanone (**6c**).* A yield of 55% was obtained, mp 114 °C. UV (EtOH): 255, 315 nm; IR (Nujol): 1670 (C=O) and 1600 cm^{-1} (C=N-N=C); NMR ($CDCl_3$) δ=7.66 (m, H, aromatic protons) and 7.13 (m, H, aromatic protons). Found: C, 76.80; H, 4.75; N, 6.79%. Calcd for $C_{27}H_{19}N_2OCl$: C, 76.68; H, 4.49; N, 6.62%.

*2-(α-Benzoylbenzylidenehydrazono)-1,2-diphenylethanone (**6d**).* A yield of 92% was obtained, mp 201 °C. UV (EtOH): 255, 315 nm; IR (Nujol): 1680 (C=O) and 1601 cm^{-1} (C=

N-N=C); NMR ($CDCl_3$) δ=7.99 (m, H, aromatic protons) and 7.45 (m, H, aromatic protons). Found: C, 80.76; H, 4.86; N, 6.79%. Calcd for $C_{28}H_{20}N_2O_2$: C, 80.76; H, 4.80; N, 6.73%.

*2-[4-Methoxy-α-(4-methoxybenzoyl)benzylidene hydrazono]-1,2-diphenyl-ethanone (**6e**).* A yield of 71% was obtained, mp 131 °C. UV (EtOH): 255, 320 nm; IR (Nujol): 1660 (C=O) and 1601 cm^{-1} (C=N-N=C); NMR ($CDCl_3$) δ=7.92 (m, 4H, aromatic protons), 7.13 (m, 14H, aromatic protons) and 3.83 and 3.72 (two s, 6H, two OCH_3 protons) Found: C, 75.54; H, 5.10; N, 6.03%. Calcd for $C_{30}H_{24}N_2O_4$: C, 75.62; H, 5.08; N, 5.88%.

*2-[4-Methyl-α-(4-methylbenzoyl)benzylidenehydrazone]-1,2-diphenylethanone (**6f**).* A yield of 85% was obtained, mp 151 °C. UV (EtOH): 255, 320 nm; IR (Nujol): 1670 (C=O) and 1601 cm^{-1} (C=N-N=C): NMR ($CDCl_3$) δ=7.90 (m, 4H, aromatic protons), 7.25 (m, 14H, aromatic protons), and 2.33 and 2.20 (two s, 6H, two CH_3 protons). Found: C, 81.10; H, 5.46; N, 6.22%. Calcd for $C_{30}H_{24}N_2O_2$: C, 81.06; H, 5.44; N, 6.30%.

*Benzophenone azine (**6g**).* A yield of 60% was obtained, mp 161 °C. UV (EtOH): 275, 310 nm; IR (Nujol): 1600 cm^{-1} (C=N-N=C); NMR ($CDCl_3$) δ=7.33 (m, H, aromatic protons). Found: C, 86.58; H, 5.49; N, 7.75%. Calcd for $C_{26}H_{20}N_2$: C, 86.66; H, 5.56; N, 7.78%.

*2-Diphenylmethylene hydrazono-1,2-diphenylethanone (**6a**).* A yield of 75% was obtained in the reaction of **2** with ketohydrazone **3d**, mp 129 °C, mmp 129 °C. The IR spectrum was superimposable to that of the product described above.

We are thankful to Professor B. M. Shukla for providing the facilities and to C. S. I. R., New Delhi, for grant of a fellowship to G. S. S.

Equilibria in the Aqueous Ternary System Containing Na^+, $CH_3CO_2^-$, and $P_2O_7^{4-}$ between 38 and 85°C

Takahiro WADA,* Fumiko YOKOTANI, and Yoshihiro MATSUO
Central Research Laboratory, Matsushita Electric Industrial Co. Ltd., 1006 Kadoma, Osaka, 571
(Received August 29, 1983)

Synopsis. The ternary system CH_3CO_2Na-$Na_4P_2O_7$-H_2O was investigated between 38 and 85 °C. No double salt occurs in this temperature range. The saturated CH_3CO_2Na solutions can contain only small amount of $Na_4P_2O_7$. The CH_3CO_2Na solutions have a very strong dehydrating influence on $Na_4P_2O_7 \cdot 10H_2O$. So, the lowest formation temperature of anhydrous $Na_4P_2O_7$ is about 47 °C.

In an earlier paper,[1] we have reported that the addition of a small amount of sodium pyrophosphate decahydrate to sodium acetate solutions is very effective for the crystal nucleation of sodium acetate trihydrate from the solutions. Subsequently, we studied the influence of preheating on crystallization of sodium acetate trihydrate from the aqueous solution with addition of a small amount of sodium pyrophosphate decahydrate and proposed an adsorption model to account for the crystal nucleation catalytic effect.[2] To complete the investigation, knowledge is required of the ternary system sodium acetate-sodium pyrophosphate-water.

The phase diagrams of the binary systems sodium acetate-water and sodium pyrophosphate-water, based on the data from Seidell's compilation[3] are shown in Fig. 1. In this figure, W_a and W_b are the mass fraction of sodium acetate and sodium pyrophosphate respectively.

This paper reports the results from the investigation of sodium pyrophosphate together with sodium acetate aqueous solution.

Experimental

Sodium acetate trihydrate, anhydrous sodium acetate, and sodium pyrophosphate decahydrate were guaranteed grade reagents. Weighed quantities of reagents and water were placed in a glass vessel equipped with a stirrer bar. The glass vessel was sealed and immersed in a water bath, whose temperature was controlled within ±0.5 °C. After the sample was stirred at a determined temperature for 6 h, the supernatant solution was pipetted off through the filter.

The pyrophosphate ion concentration was measured colorimetrically. Concentrated nitric acid was added in the dilute supernatant solution, and heated at 80 °C for about 1 h in order to decompose a pyrophosphate ion into two orthophosphate ions. Dilute sulfuric acid was further added. When ammonium molybdate aqueous solution was introduced into the solution, a yellow ammonium molybdophosphate precipitate was deposited. The precipitate was extracted with isobutyl methyl ketone. The extract was dried over anhydrous sodium sulfate. The absorbance of the extract was measured at 400 nm.

The supernatant solution was also dried at 120 °C in an oven and the total salt concentration was determined. The sodium acetate concentration was caluculated from the difference in concentration between the total salts and sodium pyrophosphate. The residual solid, which was in equilibrium with the saturated solution was separated and identified by X-ray diffraction. The solution in equilibrium with two solid phases was confirmed by analyzing the solution added by these solids.

Results

In the ternary system sodium acetate-sodium pyrophosphate-water, five isotherms between 38 and 85 °C are shown in Table 1. The solubilities of the binary systems, sodium acetate-water and sodium pyrophosphate-water, which are determined in the present ex-

a) W_a is the mass fraction of CH_3CO_2Na in the system. b) W_b is the mass fraction of $Na_4P_2O_7$ in the system. c) Symbols: C=CH_3CO_2Na, C·3=$CH_3CO_2Na·3H_2O$, P=$Na_4P_2O_7$, P·10=$Na_4P_2O_7·10H_2O$.

periments are plotted in Fig. 1. From these figures, it is clear that the solubilities determined here are in good agreement with the reported data.

The solids which exist in equilibrium with the solution of the system include no double salt in the temperature range investigated. The principal interest is therefore connected with the changes in the isothermally invariant equilibria and the lowest formation temperature of the anhydrous sodium pyrophosphate. The saturated sodium acetate solutions contain only a small amount of sodium pyrophosphate and they have a very strong dehydrating influence on the sodium pyrophosphate decahydrate. Accordingly anhydrous sodium pyrophosphate must be formed at temperatures which are low compared with the corresponding one in the pure aqueous system (79.5 °C). A synopsis of the isothermally invariant equilibria below 85 °C is given in Fig. 2. There it is presumed that the solubility of sodium pyrophosphate in the sodium acetate solutions is insignificant below 0 °C. This figure gives a survey of the formation of the solid.

Isothermally invariant points were plotted, with temperature as ordinate and sodium pyrophosphate concentration as abscissa. The lowest formation temperature of anhydrous sodium pyrophosphate is determined from the point of intersection of the curves on which the solution is equilibrium with two solid phases and it is about 47 °C.

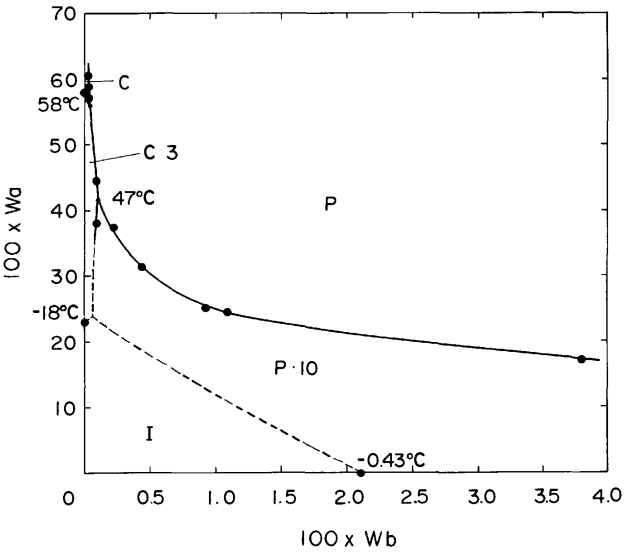

Fig. 2. Synopsis of the composition of the solutions at the invariant and univariant equlibria of the ternary system CH_3CO_2Na–$Na_4P_2O_7$–H_2O. The symbols in this figure indicate the same phases as those in Fig. 1.

The authors wish to express their thanks to Dr. Ryoichi Kiriyama for his useful discussions and to Drs. Tsuneharu Nitta, Eiichi Hirota, and Masanari Mikoda for their continuous encouragements. The authors are grateful to Miss Akiko Ueno for the colorimetric analyses. They are also grateful to Dr. Ryoichi Yamamoto for his discussions throughout this work.

A Direct Evidence for the Overestimation of Acidity Incidental to the Benesi Method

Shozi MISHIMA* and Tsuyoshi NAKAJIMA
Department of Synthetic Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380
(Received September 16, 1983)

Synopsis. Acid strength distributions of silica-alumina, silica-magnesia, and their mixtures were measured by the Benesi method. Overestimation of acidity has been demonstrated by the measurement that the acidity in the range $H_0 \leqq -3.0$ for the mixtures is larger than the value expected from additivity.

The amine titration method (the Johnson[1] and the Benesi[2] method), consisting essentially of titration of a solid acid by using butylamine and a series of Hammett indicators, has widely been employed[3] for determining the acid strength distribution of solid acids, which is in close connection with their catalytic activity.

The reliability of this method has not sufficiently been discussed. Matsuzaki *et al.*[4] initially pointed out that overestimation of acidity is to be involved in the Johnson method due to slow migration of the butylamine once adsorbed on weak acid sites to strong acid sites. Take *et al.*[5] experienced a difficulty in establishing adsorption equilibrium between butylamine and a thin wafer of silica-alumina even at 100 °C. From this phenomenon, they suggested the possibility that overestimation of acidity would be involved in the Benesi method for strong acid sites. The same suggestion was presented by Deeba and Hall[6] from their result obtained by column chromatography. However, such overestimation has not yet been given any experimental proof, especially for the Benesi method.

In this study, aiming at a direct demonstration of occurrence of the overestimation, mixtures of silica-alumina and silica-magnesia which possess strong and medium acid sites, respectively, were titrated by the Benesi method; the acidity for strong sites in the range $H_0 \leqq -3.0$ for the mixed samples has been found larger than that expected from additivity.

Experimental

Silica-alumina (Nikki Chem. Co., N631-L) was powdered to below 250 mesh and activated at 450 °C for 3 h in an electric furnace. Silica-magnesia was coprecipitated from an aqueous solution of sodium silicate and magnesium chloride by a similar way as reported by Ikebe;[7] the recipitate was dried at 105—110 °C and powdered to below 250 mesh, and the powder was calcined at 500 °C for 3 h befor use. Silica-alumina and silica-magnesia will be abbreviated as SA and SM, respectively. Mixtures of SA and SM were prepared simply by mixing the component powders. Benzene dried with silica gel was used as solvent. 4-Phenylazo-1-naphthylamine ($pK_a=+4.0$), *p*-dimethylaminoazobenzene ($pK_a=+3.3$), 4-(phenylazo)diphenylamine ($pK_a=+1.5$), dicinnamylideneacetone ($pK_a=-3.0$), benzylideneacetophenone ($pK_a=-5.6$), and anthraquinone ($pK_a=-8.2$) were used as indicators in the form of 4×10^{-3} mol dm^{-3} benzene solution. Butylamine solution in benzene of 0.1 mol dm^{-3} was used as titrant.

SA, SM, and their mixtures (1:1 and 1:2 in weight) were titrated by the Benesi method in the following procedure: A mixture of 0.4 g powder and 5 ml solvent was taken in each of several 50 ml Erlenmeyer's flasks and known amounts of amine were added to each flask. In this way, a series of samples was prepared in which each sample had a different amount of base added. The samples were tightly stoppered and shaken at 30 °C for 1—2 d, and then a portion of each slurry (*ca.* 1 ml) was transferred into each of several test tubes. A small amount of indicator (20—50 μl) was added to each sample and the color was observed. The acid strength distribution was determined from the amount of amine required to discolor the acid color of each indicator substantially. The transfer of slurry and addition of indicators were repeated after 1 d shaking to confirm the duplication of the preceding measurement. All the above procedure was performed in dry air to avoid moisture contamination.

Results and Discussion

The acid strength distributions obtained for SA and SM are shown in Fig. 1. SA has a 0.2 mmol g^{-1} acidity in the range $H_0 \leqq -3.0$ for strong acid sites and a 0.075 mmol g^{-1} acidity in $-3.0 < H_0 \leqq +4.0$ for medium ones. SM has a 0.35 mmol g^{-1} acidity in $-3.0 < H_0 \leqq +4.0$ but none in $H_0 \leqq -3.0$. These results are in qualitative agreement with the results obtained by Benesi.[1]

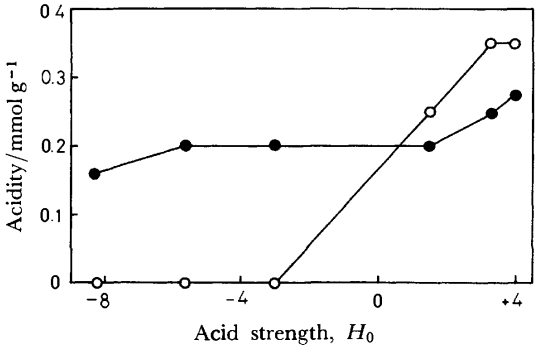

Fig. 1. Acid strength distributions of silica-alumina and silica-magnesia.
●: silica-alumina, ○: silica-magnesia.

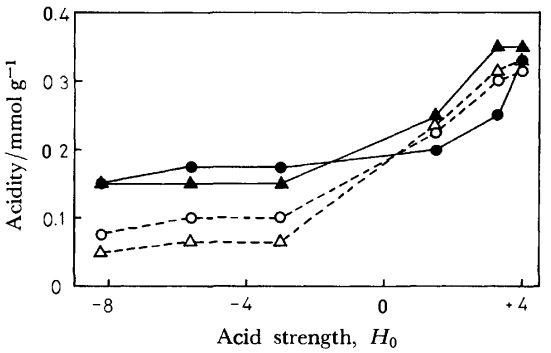

Fig. 2. Acid strength distribution of the mixtures.
● and ▲: Experimentally obtained, ○ and △: calculated from distribution of each solid for SA: SM=1:1 and 1:2, respectively.

Figure 2 shows the acid strength distributions for the mixtures of SA and SM (solid lines) in weight ratios 1:1 and 1:2. The distributions expected on the basis of additivity from the distributions of each solid are also shown in Fig. 2 (broken lines). If there is no overestimation in operation, the solid and the broken line should coincide with each other and the acidities in $H_0 \leqq -3.0$ for the 1:1 and 1:2 mixtures should be 1/2 and 1/3, respectively, of the acidity for SA given in Fig. 1. The observed acidity in $H_0 \leqq -3.0$ is, however, about two or three times larger than that expected from the distributions of each solid on the basis of the mixing ratios. Thus, these results have demonstrated the occurrence of overestimation. The degree of overestimation corresponds to 86% of the medium acid sites in SM for both the cases. Matsuzaki *et al.*,[4] Take *et al.*,[5] and Deeba and Hall[6] pointed out that butylamine adsorbs on acid sites substantially irreversibly. With the irreversibility taken into account, the observed overestimation is attributable to the irreversible adsorption of amine not only on strong sites but also on relatively weak sites. Thus, when the acid color of dicinnamylideneacetone has disappeared, the whole acid sites in $H_0 \leqq -3.0$ and the greater part of the acid sites in $-3.0 < H_0 \leqq +4.0$ will be taking part in the adsorption of amine.

For the range $-3.0 < H_0 \leqq +4.0$, the acidities of the mixtures are in agreement with those expected from the acidities of each solid within experimental errors. However, this agreement does not necessarily conclude the absence of overestimation in the medium and weak ranges $-3.0 < H_0$ since if overestimation should be operative in these ranges, weak acid sites in $+4.0 < H_0$ would be included in the estimate for the range $-3.0 < H_0 \leqq +4.0$ and since the present study made no measurement on the presence of any acid sites in the range $+4.0 < H_0$; thus, it is left to future experimental check whether or not these medium and weak ranges are free from overestimation.

Recently, it has been observed that some portions of butylamine or Hammett indicators adsorbed on strong acid sites of silica-alumina can migrate,[8] and that no overestimation occurs when a mixture of silica-alumina and nickel sulfate containing medium acid sites ($-3.0 < H_0 \leqq +1.5$) is subjected to a measurement by the Benesi method.[9] These results are different from the present findings. The difference cannot be explained reasonably at this stage for lack of detailed knowledge about the behavior of amine and indicators adsorbed on the surface of solid acid.

Optical Resolution of DL-Alanine by Formation of Ternary Copper(II) Complexes with L-Isoleucine

Tadashi SHIRAIWA,* Hirofumi FUKUOKA, Masahiro YOSHIDA, and Hidemoto KUROKAWA
Faculty of Engineering, Kansai University, Yamate-cho, Suita, Osaka 564
(Received October 11, 1983)

Synopsis. A ternary complex, (D-alaninato)(L-isoleucinato)copper(II) (abbreviated as [Cu(D-ala)(L-ile)]), was crystallized selectively at 0 °C from an aqueous solution containing DL-alanine (DL-Ala), L-isoleucine (L-Ile), and copper(II) acetate monohydrate ($Cu(OAc)_2 \cdot H_2O$) in the molar ratio of 1:1:1.

Many studies have been reported on optical resolution of DL-amino acids through formation of ternary copper(II) complexes.[1-4] Most of such optical resolutions have taken advantage of electrostatic ligand-ligand interaction or stereoselective ligand exchange, and little work has been reported on resolution of DL-amino acids having an aliphatic side chain through formation of ternary complexes composed of two kinds of such amino acids. This note describes the possibility of optical resolution of DL-Ala by formation of ternary copper(II) complexes with L-Ile. [Cu(D-ala)(L-ile)] was crystallized selectively at 0 °C from an aqueous solution containing DL-Ala, L-Ile, and $Cu(OAc)_2 \cdot H_2O$ in the molar ratio of 1:1:1. This was confirmed by preparation of [Cu(D-ala)(L-ile)] and [Cu(L-ala)(L-ile)]. The cis-trans isomers for the two nitrogen or two oxygen donor atoms exist in these complexes. Such geometrical isomerism was also investigated from infrared spectra.

Experimental

Amino Acids. DL-Ala and L-Ile ($[\alpha]_{436}^{20}$+78.8° (*c* 1.00, 1 mol dm^{-3} HCl)) were purchased from Wako Pure Chemical Ind., Ltd., L-Ala ($[\alpha]_{436}^{20}$+34.6° (*c* 1.00, 1 mol dm^{-3} HCl)) from Kanto Chemical Co., Ltd., and D-Ala ($[\alpha]_{436}^{20}$−34.6° (*c* 1.00, 1 mol dm^{-3} HCl)) from Sigma Chemical Co. These amino acids were recrystallized from water–ethanol.[5]

Optical Resolution. DL-Ala (0.01 mol) and L-Ile (0.01 mol) were dissolved in 70 cm^3 of water and the solution was kept at 0 °C. To the solution was added a solution containing 0.01 mol of $Cu(OAc)_2 \cdot H_2O$ in 30 cm^3 of water at 0 °C. A ternary complex [Cu(D-ala)(L-ile)] was crystallized on standing at 0 °C overnight or by adding ethanol (100, 200, 300, or 400 cm^3) to the reaction mixture. The ternary complex was filtered and dissolved in 300 cm^3 of water by being heated at a temperature below 50 °C. An acetone solution of 8-quinolinol was added to precipitate the copper(II) in the aqueous solution as bis(8-quinolinolato)-copper (II). After filtration, a mixture of Ala and L-Ile was obtained by evaporating the filtrate to dryness under reduced pressure, and thoroughly washed with acetone. On the other hand, the filtrate from the reaction mixture was treated with 8-quinolinol in a similar manner. The amounts[6] and optical purities[7] of Ala in these mixtures were determined on the basis of specific rotation and ^{1}H NMR data.

Preparation of Ternary Complexes. Ternary complexes were prepared in a similar manner to the procedure for optical resolution. An aqueous solution containing D- or L-Ala, L-Ile, and $Cu(OAc)_2 \cdot H_2O$ in the molar ratio of 1:1:1 gave crystalline ternary copper(II) complexes at 0 °C. The complexes were recrystallized from water. Elemental analysis and specific rotation of [Cu(D-ala)(L-ile)]: C, 38.28; H, 6.43; N, 10.08%; ($[\alpha]_{436}^{20}$+24.3° (*c* 0.50, 1 mol dm^{-3} HCl). [Cu(L-ala)(L-ile)]: C, 38.52; H, 6.57; N, 10.09%; ($[\alpha]_{436}^{20}$+48.3° (*c* 0.50, 1 mol dm^{-3} HCl). Calcd for $C_9H_{18}N_2O_4Cu$: C, 38.36; H, 6.44; N, 9.94%.

Measurements. Specific rotations were measured with a Union Giken high sensitivity PM-101 digital polarimeter in 1 mol dm^{-3} hydrochloric acid using a 0.5 dm path length quartz cell. ^{1}H NMR spectra were recorded on a JEOL JNM-PMX 60 NMR spectrometer in deuterium oxide. Infrared spectra were obtained in the range 4000—400 cm^{-1} with a JASCO A-102 infrared spectrophotometer by the KBr disk method.

Results and Discussion

Results of Optical Resolution. The bluish violet complex, crystallized at 20 °C from an aqueous solution containing DL-Ala, L-Ile, and $Cu(OAc)_2 \cdot H_2O$ in the molar raio of 1:1:1, was bis(L-isoleucinato)copper(II) monohydrate with a specific rotation of +62°.[8] The precipitation of this binary complex could be avoided by keeping the reacting solution at 0 °C and the ternary complex [Cu(D-ala)(L-ile)] was crysallized. The ternary complex had an optical purity of 93.4%. The specific rotation of the complex increased with an increase in the amount of added ethanol, since more soluble [Cu(L-ala)(L-ile)] was also precipitated by adding ethanol. [Cu(D-ala)(L-ile)] was almost completely precipitated by adding 400 cm^3 of ethanol, and [Cu(L-ala)(L-ile)] with an optical purity of 96.1% was obtained from the filtrate. The copper(II) within these complexes was removed with 8-quinolinol. ^{1}H NMR spectra of the mixtures obtained showed that the mixtures were composed of equimolar amounts of Ala and L-Ile. Ala in the mixture obtained from the precipitate had an abundance of D-isomer, whereas Ala from the filtrate an abundance of L-isomer. The results of optical resolution are summarized in Table 1.

These results indicate that DL-Ala was resolved into optical isomers with high optical purity by formation of the ternary copper(II) complexes with L-Ile, though the mixtures were not separated into D- or L-Ala and L-Ile.

Infrared Spectra. The geometrical isomerism existing in [Cu(D-ala)(L-ile)] and [Cu(L-ala)(L-ile)] was investigated on the basis of infrared spectra. Subtle spectral differences in 4000—1000 cm^{-1} are observed between these ternary complexes. In the range 1000—400 cm^{-1}, however, the spectral patterns are considerably different from each other as shown in Fig. 1. The differences may come from the presence of cis-trans isomers for the two nitrogen or two oxygen atoms.[9,10] The geometrical isomerism will give rise to differences in the absorption wave number of infrared active copper-ligand bands; the cis isomer should exhibit two ν_{Cu-N} and two ν_{Cu-O}, whereas the trans

Table 1. Results of optical resolutions

Amount of added ethanol	[Cu(D-ala)(L-ile)]		Ala in mixture			
	Yield	Optical purity[a]	Configuration[b]	Yield	Optical purity	Degree of resolution[c]
cm^3	g	%		g	%	%
0	0.336	93.4	D	0.10	98.5	22
			L	0.76	15.2	26
100	1.311	72.3	D	0.40	69.2	62
			L	0.44	62.2	61
200	1.547	58.4	D	0.46	62.3	64
			L	0.40	77.5	70
300	1.590	49.6	D	0.52	49.0	57
			L	0.33	81.7	61
400	1.922	39.5	D	0.58	41.8	54
			L	0.28	93.4	59

a) The optical purities were determined on the basis of the specific rotation of an equivalent mixture of [Cu(D-ala)(L-ile)] and [Cu(L-ala)(L-ile)] ($[\alpha]_{436}^{20}$ +38.0° (1 mol dm^{-3} HCl)). b) D-Isomer was obtained from the precipitate and L-isomer from the filtrate. c) Degree of resolution (%)=[Yield of Ala (g)×Optical purity (%)]/0.445 (g).

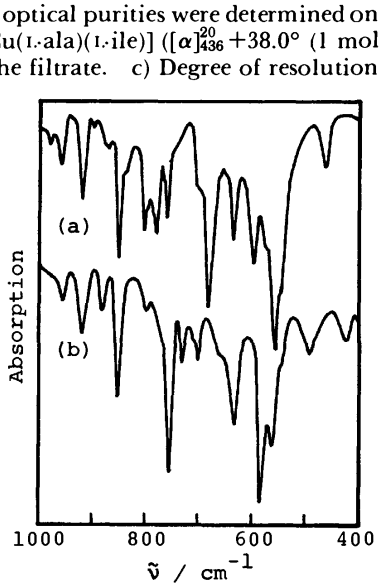

Fig. 1. Infrared spectra of the ternary copper(II) complexes.
(a): Cu[(L-ala)(L-ile)], (b): Cu[(D-ala)(L-ile)].

isomer only one for each of these modes.[10,11] In the range 500—400 cm^{-1}, [Cu(D-ala)(L-ile)] exhibits two bands at 494 and 422 cm^{-1} and [Cu(L-ala)(L-ile)] only one band at 466 cm^{-1}. These bands can be assigned to the ν_{Cu-N}, since in copper(II) complexes of amino acids, ν_{Cu-N} appears in 500—400 cm^{-1} and ν_{Cu-O} in the range below 350 cm^{-1}.[10,11] These results suggeste that [Cu(D-ala)(L-ile)] has a cis structure and that [Cu(L-ala)(L-ile)] has a trans one.

(Received December 23, 1983)

Synopsis. The crystal and molecular structure of the title complex has been determined by the use of the single-crystal X-ray diffraction method. The crystal of $CeC_{21}H_{17}O_{10}$, F. W. 569.48, was monoclinic; space group $P2_1/c$, a=13.401(2), b=19.173(5), c=8.079(1) Å, β=98.94(1)°, U=2050.6(8) Å^3, Z=4, D_m=1.84(3), D_x=1.84 Mg m^{-3}, and μ(Mo $K\alpha$)=2.31 mm^{-1}. Each cerium(III) atom is ennea-coordinated and is in a tri-capped trigonal-prism geometry. They are in a linear polymer, and each cerium(III) atom is bridged to the next metal atom by three carboxylate ligands.

The structures of lanthanoid(III) carboxylates, are actively being investigated.[1-5] The present authors showed in previous paper the structure of the lanthanoid(III) complexes of *m*-hydroxybenzoic acid with the formula of $[LnL_3(H_2O)_2]\cdot HL\cdot 2H_2O$, where Ln= La, Ce, Pr, and Nd, and HL=*m*-hydroxybenzoic acid.[6] Although the type of the complex of cerium(III) was obtained from aqueous solution containing an excess of the free acid, the titled complex was crystallized from the aqueous solution containing cerium(III) and the carboxylate ions in a stoichiometric ratio (pH≈5). Therefore, its crystal and molecular structure was determined by the single-crystal X-ray-diffraction method.

Experimental

*Synthesis of [Aquatris(*m*-hydroxybenzoato)cerium(III)] Polymer.* The cerium(III) hydroxide obtained by mixing aqueous solutions of about 1.5 g (4 mmol) of cerium(III) chloride heptahydrate and an excess of sodium hydroxide was dissolved into a hot aqueous solution of *m*-hydroxybenzoic acid (1.7 g (12 mmol) in 20 cm^3 of water). The insoluble matter was filtered off, and the filtrate was kept in a silica-gel desiccator several days, until the volume of the solution was reduced to about 10 cm^3. The precipitated crystals were filtered off and washed with water and acetone, in that order. The yield was about 1.1 g (48%).

Single-crystal X-Ray Analysis. A crystal with dimensions of 0.4×0.4×0.2 mm^3 was used for the measurement. All its edges were ground off. The reflections within the range of 3°<2θ<46° were collected on a Rigaku AFC-6A four-circle automated X-ray diffractometer with Mo $K\alpha$ radiation, where the ω-scan (3—30°) or θ-2θ-scan (30—46°) technique was employed. From the 2978 independent reflections observed, 2479|F_o|>3σ(|F_o|) were selected and used for the refinement. The intensities were corrected for the Lorentz and polarization factors, but no correction was made for the absorption or extinction.

All the calculations were carried out on a HITAC M-200H computer at the Computer Center of the University of Tokyo, using the local version of the UNICS.[7] The scattering factors were taken from the tables.[8]

Structure Determination. The structure was solved by the heavy-atom method and refined by the block-diagonal least-squares method. All non-hydrogen atoms were found, and the final R value was 0.032, with anisotropic temperature factors for all atoms.[9]

Results and Discussion

The selected final atomic coordinates and equivalent isotropic temperature factors are shown in Table 1, while the bond lengths and bond angles, in Table 2.[10] A perspective drawing of the complex, with the numbering scheme, is shown in Fig. 1; its crystal packing diagram, in Fig. 2, and a schematic presentation of the bonding modes of the ligands, in Fig. 3.

As is shown in the figures, this complex has a structure different from those of the tetracarboxylates $[ML_3(H_2O)_2]\cdot HL\cdot 2H_2O$ (M=La—Nd) or of the tricarboxylates $[ML_3(H_2O)_3]_2\cdot 2H_2O$ (M=Sm—Yb) (HL= *m*-hydroxybenzoic acid), where the complex molecules are lined parallel to the c-axis.[6] In this complex, the central cerium(III) atom is ennea-coordinated and is in a deformed tri-capped trigonal-prism geometry. One of the oxygen atoms of each ligand, O(11), O(21), and O(31), takes each cap position, while O(22) or O(32)

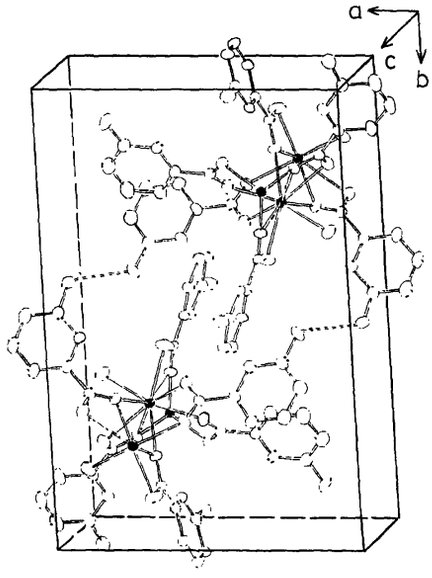

Fig. 2. The crystal packing diagram of the title complex.

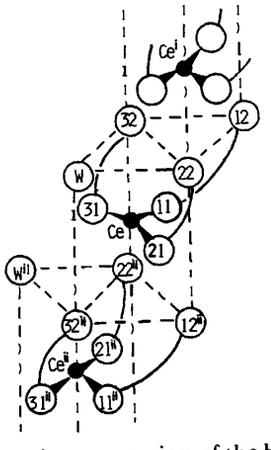

Fig. 3. Schematic presentation of the bonding modes of ligands.
(●: cerium(III), O: oxygen atoms)

take the tips of the upper triangle of the prism. The water oxygen atom, O(W), occupies the other tip of the triangle. All of the three ligands form bridges to the next cerium(III) atom, Ce^{i},[11] and O(12), O(22), and O(32) atoms are at the three tips of the bottom triangle of the prism around the Ce^{i} atom. Thus, the O(22)–O(32) edge is common to both of the triangles, as is shown in Fig. 3. The three oxygen atoms at the bottom triangle of the prism around the Ce atom are $O(12^{ii})$, $O(22^{ii})$, and $O(32^{ii})$,[11] which are parts of the bridging ligands between Ce and Ce^{ii} atoms.[11] Thus, Ce and Ce^{i}, as well as Ce and Ce^{ii}, are each bridged with three carboxylate ligands. One of the three ligands bond to each cerium(III) atom with one each oxygen atom of its carboxyl group. Each one of the other two ligands bridges two metal atoms by one carboxyl oxygen atom, and, at the same time, the other carboxyl oxygen atom of the ligand is coordinated to one of the bridged metal atoms. One of the Ce–O bondings of each latter type of ligand, Ce–O(22) or Ce–O(32), is a little longer than the other Ce–O bondings, as is shown in Table 2. The bond length of Ce–O(W) is also a little longer than the others. The difference in the C–O bond lengths of each carboxyl group of the ligands is not large: 0.019, 0.004, and 0.024 Å respectively, and the oxygen atom of the shorter C–O bond occupies the cap position.

It is found that some O···O interatomic distances are shorter than about 2.9 Å, and hydrogen bondings between the phenol oxygen atoms and the oxygen atoms of the other ligands are expected to exist; the $O(33)\cdots O(13^{iii})$, $O(12)\cdots O(23^{ii})$, $O(W)\cdots O(33^{iv})$, and $O(W)\cdots O(31^{i})$, shown in Fig. 2, are examples (2.723(7), 2.820(7), and 2.910(6) Å respectively).[11] Thus, the linear complex chains weakly bond with other chains.

The authors are greatly obliged to the Shin-Etsu Chemical Co., Ltd., for aiding the study by presenting the highly pure lanthanoid(III) oxides. The present work was partly supported by a Grant-in-Aid for Scientific Research (No. 57430011) from the Ministry of Education, Science and Culture.

Syntheses and Circular Dichroism Studies of Oligopeptides Having Tri- or Tetra-L-prolyl Sequences

Kazuki SATO,* Masato TANAKA, and Tetsuo HAYASE†
Mitsubishi-Kasei Institute of Life Sciences, 11 Minamiooya, Machida, Tokyo 194
†*Research Center, Mitsubishi Chemical Industries Ltd., Kamoshida, Midori-ku, Yokohama 227*
(Received May 23, 1983)

Synopsis. CD spectra of many oligopeptides having tri- or tetra-L-prolyl sequences showed that a penta- or hexapeptide having a tetra-L-prolyl sequence took poly(L-proline) II helix irrespective of amino acid residues at N- or C-terminal of a L-prolyl cluster and that as to a size of the cluster, tri-L-prolyl sequence was enough to form the helix, when glycine was used as substituent.

It has been reported that oligo(L-proline)s begin to form poly(L-proline) II (PPII) helix at the tetramer, and that the pentamer or the greater has higher population of the helix.[1-4] However, there has been no report in detail on the PPII helix of oligopeptides containing a variety of amino acids other than L-proline. This paper describes syntheses and CD measurements of many oligopeptides having tri- or tetra-L-prolyl sequences (**1b—19b**, **12c**, and **14c**; see Table 1) to study effects of amino acid residues bound to the L-prolyl cluster on the formation of PPII helix.[5]

First, we synthesized sequential peptides **1b—6b**. Compound **1b** showed a negative CD band at 201 nm. Both **3b** and **5b** showed larger CD bands at longer wavelength of 203 nm (Table 1). Marked difference was not observed between **3b** and **5b**. Okabayashi *et al.* reported that Aoc-oligo(L-proline)s having some populations of PPII helix showed a CD minimum at longer wavelength than 203 nm.[2] So, the CD spectra suggests that both **3b** and **5b** have ordered conformation such as PPII helix and that **1b** has unordered one. All of Boc-[(Pro)$_4$-Gly]$_m$-OH showed large negative CD bands at 203.5 nm suggesting that all these peptides took also PPII helix. Therefore, prolyl peptides with more than five amino acid residues and at least one tri-L-prolyl sequence seem to take PPII helix. CD spectra of **7b** and **8b** support this consideration; **8b** showed a negative CD band at 203 nm similar to those of **3b** and **5b**, whereas **7b** showed a weak CD band at shorter wavelength of 200.5 nm.

TABLE 1. CD SPECTRAL DATA OF SYNTHETIC PEPTIDES[a]

Peptides	$[\theta]^{min}_{\sim 200nm}$	$[\theta]^{max}_{\sim 225nm}$
	10^3 degree cm^2 dmol^{-1}	
Boc-(Pro)$_3$-Gly-OH (**1b**)	−23.3 (201.0)	0.9 (223.0)

Boc-(Pro)$_4$-Ser-OH (**17b**)	−25.2 (203.0)	1.1 (226.0)
Boc-(Pro)$_4$-Val-OH (**18b**)	−29.8 (203.5)	0.4 (227.0)
Boc-Ser-(Pro)$_4$-Gly-OH (**19b**)	−25.7 (203.0)	1.1 (227.5)
Boc-Ser-(Pro)$_4$-NH$_2$ (**12c**)	−25.9 (204.0)	1.0 (227.0)
Boc-Tyr-(Pro)$_4$-NH$_2$ (**14c**)	−22.7 (206.0)	4.2 (228.0)

a) Figures in parentheses are wavelength at $[\theta]^{extrema}$

To study the relation between amino acid sequences and CD spectra, many peptides having a variety of amino acids at either or both of N- and C-termini of tetra-L-prolyl sequence (**9b—19b**, **12c**, and **14c**) were synthesized. N-terminal substitution caused various patterns of CD spectra (**9b—15b**), however, all these peptides showed CD bands at longer wavelength than 203 nm suggesting that they took PPII helix. A tendency was observed; the longer wavelength a CD band shifted the weaker its intensity decreased. Close similarity of CD spectra between Boc-Gly-(Pro)$_4$-OH (**9b**) and Boc-(Pro)$_5$-OH (which showed a CD minimum of -31.0×10^3 degree cm^{2}dmol^{-1} at 203.5 nm)[6] suggested that Gly residue was suitable for PPII helix. As to a C-terminal substitution, clear-cut tendency was not observed in the range of this experiment (**2b**, **17b**, and **18b**). Compounds **12b**, **16b**, and **19b**, which had the same Ser-(Pro)$_4$ sequence, showed similar CD spectra to each other suggesting that chain elongation from pentapeptide (**12b**) to hexapeptides (**16b** and **19b**) did not affect significantly to PPII helix. Amide derivatives (**12c** and **14c**) showed a little larger CD bands than the corresponding peptides with free carboxyl groups (**12b** and **14b**). It seems that charged group near L-prolyl cluster is not suitable for the helix.

From CD spectra of various prolyl peptides mentioned above, we concluded that a penta- or hexapeptide having a tetra-L-prolyl sequence took PPII helix irrespective of the amino acid residues at N- or C-terminal of a L-prolyl cluster, and that as to a size of the cluster tri-L-prolyl sequence was enough to form PPII helix, when glycine is used as substituent.

Experimental

Melting points were uncorrected. Optical rotations were measured on an Union automatic polarimeter PM-201. Yields and analytical data of synthetic peptides except for some oily products are summarized in Table 2; compounds **1a—19a** with benzyl ester group at C-termini are precursors of **1b—19b**.

Boc-(Pro)$_3$-Gly-OBzl (1a). To a chilled solution of Boc-Pro-OH (4.30 g, 20 mmol), H-(Pro)$_2$-Gly-OBzl·HCl (7.92 g, 20 mmol), and TEA (2.8 ml, 20 mmol) in $CHCl_3$ (80 ml) was added EDC·HCl (3.83 g, 20 mmol), and the reaction mixture was stirred for 1 h at 0 °C and overnight at room temperature and evaporated. The residue was dissolved in EtOAc (120 ml), and the solution was washed successively with 10% citric acid, 4% $NaHCO_3$, and water, and then evaporated to a small volume after being dried over anhydrous Na_2SO_4. Addition of petroleum ether to the solution gave amorphous solid which was reprecipitated from EtOAc-petroleum ether; yield, 8.46 g (76%).

Compounds **2a—19a** were prepared as described for **1a**; in such cases that a product was soluble in water, column chromatographies with silica gel or Sephadex LH-20 were used instead of acid and alkali washings.

a) *c* 1, MeOH. b) $0.5H_2O$. c) $1.5H_2O$. d) $2H_2O$. e) $3H_2O$. f) H_2O. g) $0.25H_2O$. h) $2.5H_2O$.

Boc-(Pro)$_3$-Gly-OH (1b). Compound **1a** (5.57 g, 10 mmol) dissolved in MeOH (20 ml) was hydrogenated in the presence of 5% paradium carbon (*ca.* 2 g) for 4 h at room temperature. The product was recrystallized from EtOAc-petroleum ether; yield, 4.33 g (93%).

Compounds **2b—19b** were prepared as describe for **1b**.

H-(Pro)$_3$-Gly-OBzl·HCl. Compound **1a** (2.78 g, 5 mmol) dissolved in 0.1 mol dm^{-3} hydrogen chloride in formic acid (60 ml) was allowed to stand for 30 min at room temperature and evaporated. Addition of ether to the residue gave highly hygroscopic crystals, which were used for the next reaction without further treatment.

Boc groups in other peptides (**2a—4a**, and **12a**) were removed as described above.

Boc-Ser-(Pro)$_4$-NH$_2$ (12c). Compound **12a** (137 mg, 0.2 mmol) dissolved in MeOH (3 ml) saturated with NH_3 was allowed to stand at room temperature for 3 d. After the evaporation of solvent, the residue was purified by silica gel ($CHCl_3$-MeOH; 10:1, v/v) and Sephadex LH-20 (MeOH) column chromatographies; yield, 91 mg (77%).

Compound **14c** was prepared as described for **12c**.

CD Measurements. CD spectra were measured on a JASCO J-40A spectropolarimeter at 23 °C in H_2O solution with quartz cells of 1-mm path length. The ellipticity was expressed as mean residual molar ellipticity [θ] in degree cm^2 dmol^{-1}.

We thank Drs. Tsuneko Uchida and Ukon Nagai of this institute for helpful discussion, and the members of Analysis Center, Mitsubishi Chemical Industries Ltd. for elemental analysis.

(Received December 15, 1983)

Synopsis. Racemic compounds containing a phosphorus or a sulfur atom as a chiral center were resolved by high-performance liquid chromatography on optically active (+)-poly(triphenylmethyl methacrylate). The resolved compounds include insecticides such as *O*-ethyl *O*-(4-nitrophenyl) phenylphosphonothionate (EPN), *O*-(4-cyanophenyl)-*O*-ethyl phenylphosphonothionate (cyanofenfos), and 2-methoxy-4*H*-1,3,2-benzo-dioxaphosphorin 2-sulfide (salithion).

Optically active poly(triphenylmethyl methacrylate) (PTrMA)[1] has been used as an effective chiral packing material for liquid chromatographic resolution of various racemic compounds,[2-9] most of which possess an asymmetric carbon. Here, we wish to report the resolution of racemic compounds containing a phosphorus or a sulfur atom as the asymmetric center using high-performance liquid chromatography (HPLC) with a (+)-PTrMA column.

Recently, Pirkle and coworkers successfully resolved racemic sulfoxides on their chiral HPLC column.[10] However, liquid chromatographic resolution of racemic phosphoric compounds has not so far been reported.

Experimental

The synthesis of compounds **1**—**5** in Table 1 has been carried out in the following manner. **1**: Preparation procedures were similar to those in a literature.[11] Methyl methyl(phenyl)phosphinate was reacted with benzylmagnesium chloride in diethyl ether to give a crude product which was purified by chromatography (silica gel) to give white solid **1**; ^{31}P NMR ($CDCl_3$ with external standard of 85% H_3PO_4) δ= 35.2 (single peak). ^{1}H NMR ($CDCl_3$) δ=1.60 (d, J=12 Hz, 3H), 3.20 (d, J=15 Hz, 2H), 6.83—7.75 (m, 10H). IR (Nujol) 1297, 1175, 1115, 920, 897, 770, 740 cm^{-1}. TLC (acetone) R_f= 0.5. **2**: Similarly, methyl methyl(phenyl)phosphinate was allowed to react with 1-naphthylmagnesium bromide, giving rise to a solid product **2** after purification by chromatography. **3**: The hydrolysis of a spirophosphonane, 5-phenyl-1,4,6-trioxa-5-phosphaspiro[4.4]nonan-7-one, gave 2-hydroxyethyl (2-carboxyethyl)phenylphosphinate (mp 75—76 °C) whose esterification with diazomethane produced **3**. **4**: Phenylphosphonic dichloride was treated with an equimolar amount of ethanol in the presence of triethylamine in benzene followed by a further reaction with an equimolar amount of methanol in the presence of triethylamine in benzene to give **4**, bp 69—72 °C/0.2 mmHg**. **5**: Phenylphosphonic dichloride was subjected to reaction with an equimolar amount of cyclohexanol and then with methanol (equimol.) in the presence of pyridine in benzene to give **5**, bp, 105—110 °C/0.2 mmHg. ^{31}P NMR ($CDCl_3$) δ=19.1 (single peak). ^{1}H NMR ($CDCl_3$) δ=1.00—2.05 (m, 10H), 3.60(d, J=11 Hz, 3H), 4.33 (br, 1H), 7.28—7.95 (m, 5H). IR (neat) 2930, 2850, 1440, 1245, 1130, 1050, 990, 800, 557 cm^{-1}. TLC (diethyl ether) R_f=0.6.

Compounds **6**—**9** were commercially obtained.

The preparations of (+)-PTrMA[12] and the packing material[4] for HPLC were described previously. The resolution was accomplished with a JASCO TRIROTOR II chromatograph equipped with a UV detector at 15 °C, methanol (0.5 ml/min) being used as eluent.

Results and Discussion

Figure 1 shows the chromatograms of the resolution of 2-hydroxyethyl [2-(methoxycarbonyl)ethyl] phenylphosphinate (**3**), *O*-ethyl *O*-(4-nitrophenyl) phenylphosphonothionate (EPN, **6**), and 2-methoxy-4*H*-1,3,2-benzo-dioxaphosphorin 2-sulfide (salithion, **8**) on (+)-PTrMA columns; the results are summarized in Table 1 together with the data for the resolution of other racemic compounds. Most compounds in Table 1 were resolved on (+)-PTrMA. The separation factor α was increased by the addition of water to the eluent, suggesting that the chiral recognition ability of (+)-PTrMA is enhanced in a polar medium, probably due to the stronger hydrophobic interaction between the polymer and enantiomers. Phosphinate **3** was resolved most effectively. Insecticides, **6**, *O*-(4-cyanophenyl) *O*-ethyl phenylphosphonothionate (cyanofenfos, **7**), and **8** were also resolved. Although optically active isomers of **6** and **7** have already been prepared and the difference of the biological activities between the optical an-

a) Column: 25 cm×0.46(id)cm. b) k' (capacity factor to less retained enantiomer)=(retention time of less retained enantiomer−dead time)/dead time; the sign in parenthesis is that of the optical rotation at 365 nm. c) α (separation factor)=(capacity factor to more retained enantiomer)/k_1'. d) Resolution factor=2×(difference of retention times of more and less retained enantiomers)/(sum of the band width of the two enantiomer peaks). e) Eluent: CH_3OH-H_2O(80:20). f) Eluent: CH_3OH-H_2O(60:40). g) Elipticity of the CD spectrum at 263 nm. h) Column (50 cm× 0.72(id)cm).

tipodes has been studied,[13,14] optical isomers of **8** and their activity have not yet been reported.*** These isomers are expected to show different biological activity.

Phenyl vinyl sulfoxide (**9**) was not separated with methanol as eluent but was resolved with methanol-water (80:20).

These results suggest that the (+)-PTrMA column is useful for the resolution of racemic compounds having heteroatoms.

The authors thank to Dr. Yukitoshi Narukawa for the help in preparation of the phosphorus compounds. A part of this work was supported by a Grant-in-Aid for Developmental Scientific Research No.58850188 from the Ministry of Education, Science and Culture.

The Study of Metal Colloids Produced by Means of Gas Evaporation Technique. II. Reaction of Metal Sols in Organic Solvents

Keisaku KIMURA

Instrument Center, Institute for Molecular Science, Myodaiji, Okazaki 444

(Received September 19, 1983)

Synopsis. The reaction of copper colloid in ethanol was studied. In the beginning of the reaction, very small particles reacted with ethanol producing ethoxide. With the proceeding of the reaction, the 577-nm characteristic copper band showed a red shift together with the broadening of the line width. This was explaind by the size dependence of the particles on the spectrum. Lead colloid was also examined.

We have recently proposed a new technique to prepare metal colloids in organic solvents.[1] It was found that the colloid stability was dependent on the kinds of metal; In, Al, Ag, and Au were stable and Pb, Sn, Ca, and Cu were unstable. In the latter case, the color of the metal colloid solution changed with time. An absorption peak was found at 213 nm, irrespective of the metal species which suggested a formation of alkoxide anion.[2] The color change was particularly prominent in copper colloid, the color of which changed from wine red to yellow within 30 min under aerobic conditions while within one day under anaerobic conditions. In the present paper, we have studied this reaction in order to clarify the cause of the time dependence of the spectrum and the origin of the 213-nm peak.

Experimental

The metal colloids were prepared by the method described in the previous report.[1] Ethanol (99.5%) was used without further purification. Hexane was distilled *in vacuo* from CaH_2 to completely exclude traces of oxygen and water. An authentic sample of ethoxide was prepared by dissolving a small grain of sodium metal in ethanol.

The time development of the spectra (room temperature) was recorded by a Hitachi 556 spectrophotometer just after the preparation of the sol in an Ar atmosphere.

Results and Discussion

Figure 1 shows the time course of the spectra of copper-ethanol colloid. The existence of an isosbestic point at 296 nm shows that the reacting system contains two components. In this system, the metal fine particles change to a single unknown product, because the 577-nm peak, which is characteristic in fine copper particles,[3] gradually decreased as time passed. The increase of the peak height of the 213-nm absorption band is suggestive of the formation of the ethoxide ion.

In the previous paper, we postulated a formation of metal ethoxide. In order to confirm this conjecture, we measured the optical absorption spectrum of the colloid in hexane solution in which no alkoxide can form. Although the fine metal particles have a tendency to coagulate in alkanes, it is possible to measure the absorption spectrum if it is immediately after the preparation of the sample. In Fig.2 is shown the absorption spectra of copper colloid in ethanol (a), and in hexane (b) together with that of ethoxide ion (c). It is clear that there is no 213-nm peak in hexane. Therefore, the 213-nm peak in ethanol is concluded as coming from ethoxide ion.

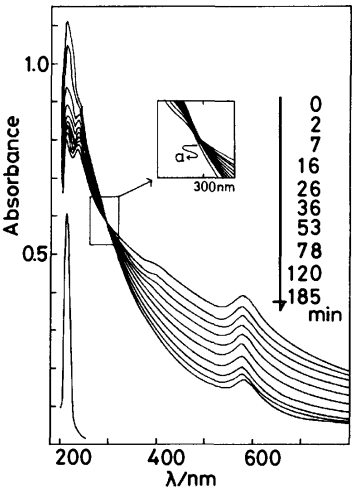

Fig. 1. Optical absorption spectra of copper colloid as a function of time. The number in the figure are the time after the preparation of the sample. The spectrum of sodium ethoxide in ethanol is also shown in the same figure. The insertion is the expansion of the region of isosbestic point. The deviation from the isosbestic point at 10 h after the preparation is shown by a.

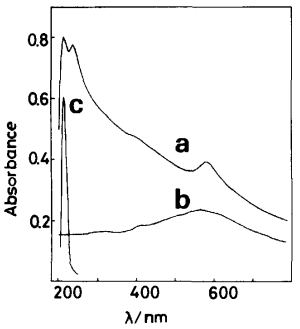

Fig. 2. Absorption spectra of copper colloid in ethanol (a) and in hexane (b). The spectrum of sodium ethoxide in ethanol is shown in c.

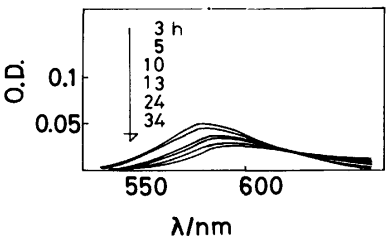

Fig. 3. Optical absorption spectra of copper colloid in the visible region as a function of time later than 3 h. Spectra are drawn after subtraction of the background slope.

Returning now to Fig.1, we notice that the 577-nm peak shifts to longer wavelength at 185 min and that the spectrum does not pass through the isosbestic point at 185 min and at 10 h after the preparation of the sample (see the expanded spectra in the insert). This peak shift is more noticeable after longer periods of time as seen in Fig. 3. After such a long reaction time, all spectra did not pass through the isosbestic point at 296 nm. These findings show that a new reaction phase has progressed. In this stage, the color of the solution gradually changed to yellow from wine red. It should also be noted in the same figure that the band width is broadened with the peak shift. The time dependences of the peak shift, of the band width at the half maxima, and of the absorption intensity are shown in Fig. 4 after correction for background absorption.

As mentioned before, the position of the absorption band of the copper colloid does not vary for the first couple of hours. When it is over 180 min, the peak gradually shifts to longer wavelength. Initially the band width decreases with time, but then it increases later than 180 min with the concurrent shifting of the peak as seen in Fig. 4. As for the intensity, it monotonously decreases with time, corresponding to the decrease of particle size. These findings show that the

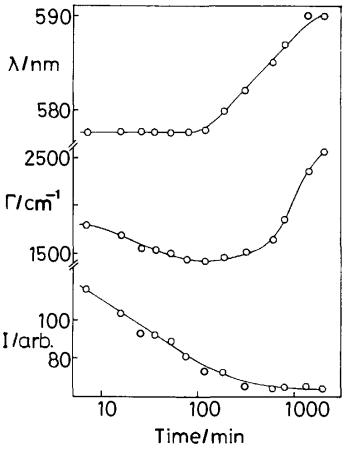

Fig. 4. The absorption peak, the band width and the absorption intensity as a function of time. These were calculated from the spectra in Fig. 3. Solid lines are for eye guide.

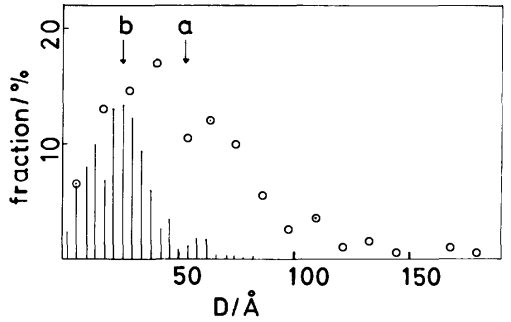

Fig. 5. The distribution of the particle size of colloids. The diameter distribution of the sample, 7 min after the preparation, is shown by circles. The average diameter is indicated by the arrow a. The histogram shows the distribution of the sample at 3 hr after the preparation. The average diameter of this sample is shown by b.

colloid system changes in the size distribution and in the average diameter and that this change becomes prominent at 180 min. The electron micrographs of the colloids were taken at 7 min and at 180 min after the preparation. The size distributions of the colloids at the different time are shown in Fig.5. Just after the preparation, the average diameter of the colloids was 53 Å and the width at the half maxima of the distribution was 60 Å. These values changed to 26 Å and 30 Å respectively at 180 min after. This finding shows that the size distribution becomes narrower and the average diameter also decreases after longer periods.

Based on these observations, we can explain the time dependence of the band width and the position of the absorption peak shown in Fig.4. In the first stage, ultrafine particles diminish rapidly because very small particles easily react with ethanol forming ethoxide. Therefore, the distribution of particle size becomes narrower, resulting in the decrement of the band width, because the absorption band is a superposition of many bands of the particles with different sizes. In the second stage, many particles reduce their radii, resulting in the reduction of the average particle size which may cause the change in the peak position and the band width.

It is well known that the spectrum of fine particles depends on the particle size. Quantum mechanical calculation shows that the band width of the surface plasmon is broadened and the peak shifts to higher energy with a decrease in the radius.[4,5] These results conflict with the present observations, if we explain the peak shift and broadening as a size dependence of a plasmon band. On the other hand, Abe *et al.* reported that the 577-nm band should not be regarded to a pure plasmon band but to interband transitions mixed with plasmon band.[3] Kreibig reported the size dependence of the interband transition edge in gold particles in which the band edge shifts toward lower energy with a decrease in size.[6] If this tendency also holds for the peak position, the peak shift is explaind by the size dependence of the interband transition of copper colloid. The 214-nm peak found in the lead-ethanol system also disappeared in the lead-hexane system. This finding is also consistent with the results of copper described above.

The author wishes to express his thanks to Messrs. S. Bandow and M. Yamakawa in technical assistance. His thanks are due to Prof. S. Sako of Mie University in obtaining the size distribution of the colloids.

The Solubilization Site of Methylferrocene in Cationic Micelles

Katsuyoshi HOSHINO, Tetsuo SAJI, Yasuhiko OHSAWA, and Shigeru AOYAGUI*
Department of Chemical Engineering, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152
(Received November 7, 1983)

Synopsis. The voltammetry of methylferrocene (MeFC) in a dodecyltrimethylammonium bromide micellar solution leads to the conclusion that most MeFC molecules reside in the micelle phase. They are located within the hydrophobic core where water cannot reach, judging from our finding that oxygen decomposes MeFC in the presence of water, but otherwise does not.

The most important function of aqueous micelles is to solubilize water-insoluble substances. A number of investigations have been devoted to determining the partition of such substances between the water phase and the micelle phase. Further interest has been taken in the problem of the location of the solubilizate in the micelle, *i.e.*, either the hydrophobic site in the micelle core or the hydrophilic site near the head group.[1]

This paper will deal with the solubilization site of methylferrocene (MeFC) in cationic micelles of dodecyltrimethylammonium bromide (DTMAB). In an earlier paper dealing with the cyclic voltammetry and potentiometry of ferrocene (FC) in nonionic micellar solutions, Yeh and Kuwana suggested that the environment of FC in the micelles was quite similar to that in the hydrophobic liquid membrane, but they gave no direct evidence for it.[2] Unfortunately, the generally applicable method of site determination, which is based on the different absorption maximum frequencies (λ_{max}) of the solubilizate in polar and nonpolar media, cannot be used in our case, because the λ_{max} values of MeFC in both media are very close to each other and MeFC is only poorly soluble in water. Instead, we make use of our finding that oxygen decomposes MeFC in the presence of water, but does not do so in its absence. Though this is a kind of the probe technique which has been extensively used for studying the microenvironment of the micelle, the chemical reactions of the guest substances have rarely been used for this purpose, except for quenching reactions[1] and chemical equilibria.[3-6] The redox potential of the $MeFC^{+/0}$ couple in DTMAB micellar solution is also measured to determine the partition of MeFC between the micelle phase and the water phase.

TABLE 1. SOLUBILITY AND PARTITION PARAMETER (K_R) OF FERROCENE (FC), METHYLFERROCENE (MeFC) AND BUTHYLFERROCENE (n-BuFC) IN 0.2 M Li_2SO_4 WITH AND WITHOUT 0.1 M DODECYLTRIMETHYLAMMONIUM BROMIDE AT 25 °C

MeFC	0.15	11.1	1.4
n-BuFC	0.14	8.32	1.7

a, b) Solubility of complex (C) in a) water and b) a micellar solution respectively. c) Ratio of the concentration of the complex in the water phase to that in the micelle phase. d) Data in Ref. 8.

Experimental

MeFC was prepared by the literature method.[7] The molar absorptivity values of MeFC at 250 nm, $1.8\times10^3\ M^{-1}\ cm^{-1}$ ($1\ M=1\ mol\ dm^{-3}$) in the water phase and $4.0\times10^3\ M^{-1}\ cm^{-1}$ in the micelle phase, were determined by the method described in a previous paper.[8] The other experimental procedures used in this work were also described in that paper.

Results and Discussion

According to our previous paper,[8] we can determine the partition parameter, K_R *i.e.*, the ratio of the concentration in moles of MeFC in water to that in micelles, per liter of the micellar solution, under the specific conditions of $MeFC^+$ residing only in the water phase. To see if these conditions are fulfilled, the obserbed value for the reversible half-wave potential of the $MeFC^{+/0}$ in the micellar solution ($E^r_{1/2}$) was compared with the value calculated by using the following equation:[8]

$$E^r_{1/2}=E^0_W+(RT/F)\ln(1+K_R)/K_R-(RT/F)\ln(D_0/D_R)^{1/2}, \quad (1)$$

with:

$$D_R=(D_{RM}+K_RD_{RW})/(1+K_R) \quad (2)$$

and:

$$K_R=[MeFC_W]/[MeFC_M]=[MeFC_W]_{sat}/([MeFC]_{sat}-[MeFC_W]_{sat}). \quad (3)$$

The abbreviations used are the same as have been described in a previous paper.[8]

Tables 1 and 2 summarize, respectively, the results of the spectroscopic determination of the solubility and

TABLE 2. VOLTAMMETRIC DATA OF METHYLFERROCENE (MeFC) AND METHYLFERROCENIUM ($MeFC^+$) IN 0.2 M Li_2SO_4 WITH AND WITHOUT 0.1 M DODECYLTRIMETHYLAMMONIUM BROMIDE (DTMAB) AT 25 °C[a]

MeFC	0.1	0.82×10^{-6}	—	0.185	—
$MeFC^+$	0.1	—	7.1×10^{-6}	0.185	—
MeFC	0	—	—	—	0.114

a) All the voltammograms are diffusion-controlled, as is indicated by the linear plot of the peak current *vs.* the square root of the potential-scan rate. b, c) Apparent diffusion coefficients of b) $MeFC^+$ in a micellar solution respectively. d, e) Reversible halfwave potentials of the $MeFC^{+/0}$ redox system in d) a micellar solution and e) water respectively. The latter value was estimated from the peak potential in the reduction of $MeFC^+$ plus 0.029 V.

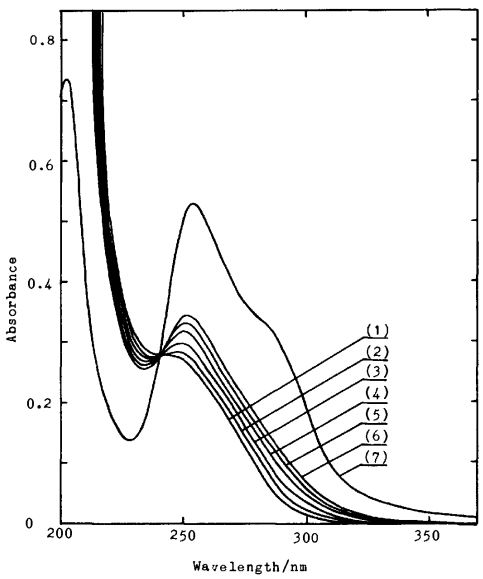

Fig. 1. UV absorption spectra of methylferrocene saturated in aqueous 0.2 M Li_2SO_4 at 25°C recorded at time t after oxygen introduction into the solution: t=(1) 0, (2) 40, (3) 87, (4) 150, (5) 203, (6) 258 min, and (7) 7 d.

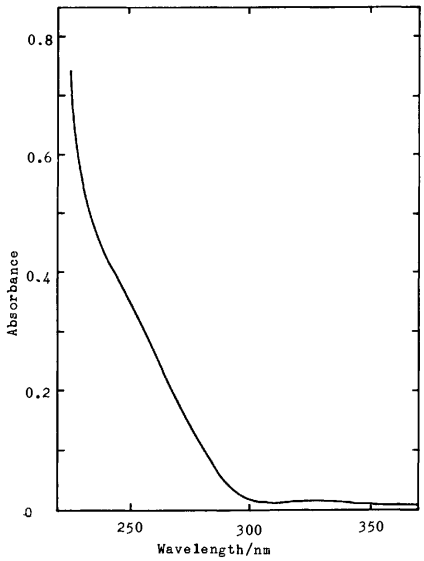

Fig. 2. UV absorption spectrum of 0.088 mM methylferrocene in an aqueous solution of 0.2 M Li_2SO_4 and 0.1 M dodecyltrimethylammonium bromide.

the voltammetric determination of the diffusion coefficient and the reversible half-wave potential. Table 1 also lists the data for FC and butylferrocene (*n*-BuFC). The ($E^r_{1/2W}$), value for the redox couple $MeFC^{+/0}$ calculated from Eqs. 1 and 3 with these data was 0.186 V *vs.* SCE. It is in excellent agreement with the experimental value of 0.185 V. Consequently, Eq. 1 applies to this redox system; hence, it can be concluded that the $MeFC^+$ ions are located only in the water phase and that most of the MeFC molecules reside in the micelle phase, as is indicated by the small K_R value of 1.4×10^{-2}.

Figure 1 shows the absorption spectra of a saturated solution of MeFC (0.15 mM) in 0.2 M Li_2SO_4, which were recorded (1) before and (2—7) after the introduction of oxygen gas into the solution. In the absence of oxygen, the 1 spectrum was kept unchanged for more than a day, but in its presence a new peak appeared at about 250 nm and grew linearly in height with the time, while the peak at 200 nm got lower. The isosbestic point at 240 nm indicates that this reaction gives only one product. The reaction scheme of the oxidation of MeFC will be discussed in a separate paper. Contrary to aqueous solutions, the spectra of MeFC in nonaqueous solvents, such as hexane, ethanol, and acetonitrile, were kept unchanged for more than 100 d in the presence of oxygen. These findings show that MeFC reacts with oxygen only in the coexistence of water.

Figure 2 shows an absorption spectrum of MeFC in a micellar solution. According to the above voltammetric results, the spectroactive species is the MeFC located in and/or on the micelle. The fact that the shape of this spectrum did not change for more than 4 h after introducing oxygen gas into the solution strongly suggests that the microenvironment of the solubilized MeFC molecules is highly hydrophobic for the following reasons: the decomposition of MeFC requires both water and oxygen; the solubilities of ferrocene and oxygen are higher in aliphatic solvents than in water; we have evidence for oxygen residing in micelles.[9] Considering the NMR experimental finding of Menger *et al.* that water molecules can penetrate into the micelle core as far as seven carbon atoms away from the head group,[10] we can conclude that the MeFC molecules reside deep in the interior of the micelle core where water molecules cannot reach. However, another finding of the same authors, that the CH≡ group substituted for the terminal methyl protons of $DTMA^+$ is located in a wet environment[11], seems incompatible with our findings, if no specific conformation of this surfactant molecule is assumed.

The authors wish to thank Dr. Masamichi Fujihira for his helpful suggestions.

Translational Energy Distribution of the Excited Hydrogen Atom (n=4) Produced in Electron-Benzene Collisions

Hirofumi KAWAZUMI, Junichi KURAWAKI, and Teiichiro OGAWA*
Department of Molecular Science and Technology, Kyushu University, Kasuga, Fukuoka 816
(Received December 26, 1983)

Synopsis. Line shapes of the Balmer-β line of H* produced in dissociative excitation of C_6H_6 were precisely measured. The translational energy distributions of H* (n=4) have two peaks at about 1 and 4 eV, and their relative intensity depends on incident electron energy.

Benzene is a basic organic molecule with a high symmetry. All six hydrogen atoms are equivalent. The dissociation mechanism of benzene for the formation of the excited hydrogen atoms should be a key process for dissociation dynamics of the organic molecule.

Benzene gives photoemissions of both its own excited states and fragment species such as H* and CH* upon collision with electrons.[1-4] Balmer series are intense, and the analysis of the Doppler line shape can give the translational energy distribution of the excited hydrogen atom.[5] The translational energy distribution is useful not only for an elucidation of dissociation mechanism of highly excited molecule but also for a correction of optical signal losses due to the high velocity of the fragments in the determination of the absolute emission cross section.

This note presents the translational energy distributions of H* (n=4) and D* (n=4) produced by controlled electron impact on C_6H_6 and C_6D_6 and their incident electron energy dependence.

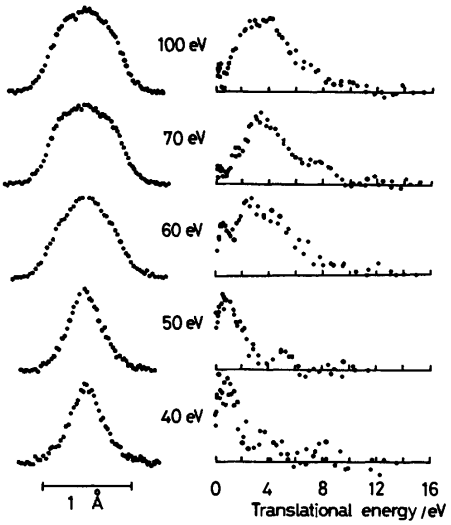

Fig. 1. High resolution spectra and translational energy distribution of H*(n=4) produced in e-C_6H_6 collisions. Electron energy: 40—100 eV, optical resolution: 0.0031—0.0042 nm.

Experimental

The apparatus has been described in detail previously.[6] The Balmer lines were measured at optical resolution of 0.0031—0.0042 nm with a Fabry-Perot interferometer; this resolution is sufficient for the analysis of the Doppler profile. Excitation function was measured with an interference filter (band width 2 nm). Benzene (research grade) was deaerated before use.

Results and Discussion

The line shapes of the Balmer-β emissions produced in e-C_6H_6 collisions were measured precisely at 90° with respect to the electron beam and the results taken at various incident electron energies are shown in the left of Fig. 1. The translational energy distributions calculated from them are shown in the right of Fig. 1.

The line shapes of H* (n=4) from C_6H_6 taken a 90° and at 55° (magic angle) and D* (n=4) from C_6D_6 taken at 90° were also recorded for comparison at an electron energy of 100 eV, as shown in Fig. 2; their translational energy distributions have been obtained. The line shapes and the translational energy distributions at 90° and at 55° agreed with each other within the experimental uncertainty; thus, effect of anisotropy seems to be small.

The translational energy distribution has a peak at 1 eV when excited at electron energies of 40—50 eV. With increasing the incident electron energy, a new peak appears at about 4 eV; the distribution shifts toward higher energy. There seems to be an additional shoulder at 6—8 eV at an electron energy of 100 eV. The translational energy distribution of H* (n=4) measured at 100 eV looks similar to those from CH_4[7]

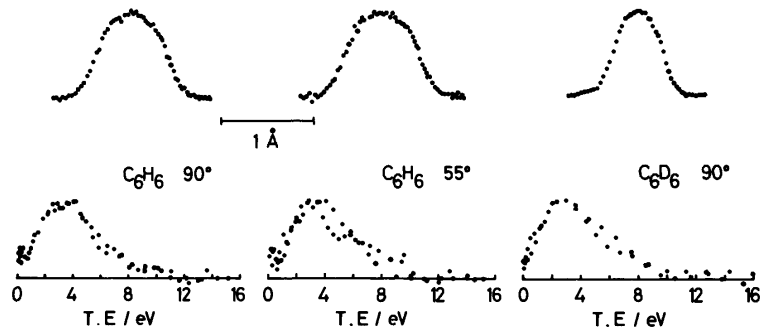

Fig. 2. High resolution spectra and translational energy distribution of H*(D*) produced in e-C_6H_6(C_6D_6) collisions at 100 eV.

and $CHCl_3$.[8] These results indicate that a few electronic excited states and a few dissociation processes take part in the production of the excited hydrogen atoms. The dissociation process, which has the peak of the translational energy distribution at 4 eV, is the major process at higher excitation energy and should proceed through repulsive potential surfaces. This process should also be symmetry forbidden, since the slope of the Fano plot for the Balmer-β emission is zero.[4]

The excited hydrogen atom with 4 eV of the translational energy has a velocity of 28000 $m \cdot s^{-1}$ and about 3 mm in 119 ns (average lifetime of H* (n=4)). A correction for the loss of the excited species is necessary for the determination of the absolute emission cross section and this correction should be estimated from the translational energy distribution. Furthermore, the fly-out rate of H* from the collision volume and the correction for the absolute emission cross section depend on the incident electron energy.

The dissociation processes are expected to be identical for isotope molecules such as H_2 and D_2,[9] and H_2O and D_2O,[10] however, the relative importance of coexisting processes are often different. In the case of benzene there is no clear quantitative difference in the translational energy distributions of H* and D* (Fig. 2).

The measured excitation function for the Balmer-β emission (0—100 eV) is similar to that reported by Beenakker and de Heer.[4] The threshold energy are 19.6±0.6 eV for C_6H_6, which agrees well with previous papers,[4,11] and 19.5±1.3 eV for C_6D_6; no obvious onset was observed except the first threshold.

The observed translational energy distributions and threshold energy indicate that a major route for the formation of the excited hydrogen atoms as lower incident electron energies is as follows:

$$C_6H_6(19.6\,eV) \rightarrow C_6H_5(\tilde{X}\,^2A_1) + H^*(n=4) + E_{excess}(2.0\,eV)$$
$$E_{excess}(2.0\,eV) = E_{trans}(\approx 1\,eV) + E_{int}(\approx 1\,eV),$$

where (19.6 eV) represents the excitation energy, E_{excess} the energy equal to the difference between the excitation energy and the calculated dissociation limit, E_{trans} the translational energy of H* and E_{int} the internal energy.

At higher incident electron energies, an enormous number of direct and multistep fragmentation paths can be estimated from thermochemical data. Doubly excited Rydberg states converging to excited ion states or doubly ionized states, which are optically forbidden and generally repulsive, should play important roles.

Determination of Solubility Products of Rare Earth Fluorides by Fluoride Ion-selective Electrode

Hisako ITOH, Hiromitsu HACHIYA, Masashi TSUCHIYA, Yasuo SUZUKI,* and Yasukazu ASANO†

Department of Industrial Chemistry, Faculty of Engineering, Meiji University, Higashimita, Tama-ku, Kawasaki 214

†*Denki Kagaku Keiki Co., Ltd. Kichijoji-kitamachi, Musashino, Tokyo 180*

(Received August 26, 1983)

Synopsis. Solubility product values of the rare earth fluorides were determined potentiometrically by using fluoride ion-selective electrodes at 25.0 °C. The pK_{sp} values of the lanthanoid fluorides decreased gradually from 20.0 to 16.9, while the value for yttrium fluoride was locate in between those of terbium and dysprosium fluorides. The value for scandium fluoride was appreciably smaller than any of the lanthanoid fluorides, as expected from the cationic radii. The solubility product value of lanthanum fluoride single crystal could not be determined, since the saturated solution was not obtained through measurements of over three months.

Generally, the solubilities of lanthanoid salts increase with increasing atomic number when the anion of the salt arises from a strong acid and decreases with increasing atomic number when the anion originates from a weak acid. For example, solubility of the sulfates increases with increasing atomic number, while that of the hydroxides or dimethylphosphates decreases with increasing atomic number.[1)]

The solubility product values of lighter and heavier rare earth fluorides were determined titrimetrically by Nikolaev *et al.*[2)] and Ikurami *et al*,.[3)] respectively. Fraustro da Silva and Queimado[4)] also determined the solubility product values of the fluorides throughout the rare earth elements in mixed solutions of sodium fluoride and rare earth nitrates by using a fluoride ion-selective electrode. They showed that the solubility of the lanthanoid fluorides increased with increasing atomic number. In this study, the solubility product values of the rare earth fluorides, including yttrium and scandium fluorides, were determined in solution containing the respective fluorides only by using a fluoride ion-selective electrode.

Experimental

Reagents. Fifteen rare earth fluorides of 99.99% purity were obtained from Shin-etsu Chem. Ind. Co., Ltd. Single crystals of lanthanum fluoride prepared for the fluoride ion-selective electrode membrane were supplied from Denki Kagaku Keiki Co., Ltd. One of the single crystals was an europium-doped lanthanum fluoride. All the other chemicals were of reagent grade.

Apparatus and Procedure. Denki Kagaku Keiki model 7200 fluoride ion-selective electrode and model 4083 double junction Ag-AgCl reference electrode were used with Denki Kagaku Keiki model IOC-10 pH/mV meter.

A portion of a fluoride powder was taken into a covered polyethylene beaker together with water, and stirred continuously at 25.0 °C until a constant millivolt reading was obtained with the fluoride ion-selective electrode. After keeping the mixture for another day without stirring at 25.0 °C, an aliquot portion of the supernatant was brought to a pH of 5 with a portion of the Denki Kagaku Keiki pH5-AB buffer solution. To prevent the formation of hydrogen fluoride in acidic solutions, the sample solution has to be kept at pH 5 by using the buffer solution, as described above.

Calculations. In a solution, a rare earth fluoride should be dissociated as described in Eq. 1:

$$LnF_3 \longrightarrow Ln^{3+} + 3F^-, \quad (1)$$

where Ln means a rare earth element. The solubility product values can be calculated by Eq. 2, if no common ions are originally present in the solution:

$$K_{sp} = [Ln^{3+}][F^-]^3 = \frac{[F^-]^4}{3}. \quad (2)$$

Since the activity coefficient of fluoride ion may be considered unity in solution of such a low concentration, the activity of fluoride ion would be equal to the concentration.

Results and Discussion

The solubility product values obtained for the powder of the rare earth fluorides are shown in Table 1. The pK_{sp} values apparently decrease with increasing atomic number of lanthanoids. This tendency agrees with the assumption that the solubility of the slightly soluble salts of lanthanoids derived from the anions of strong acids increases with increasing atomic number. On the other hand, one would expect that solubility decreases with increasing atomic number, since the size of the lanthanoid ion decreases and the lattice energy is inversely proportional to the sum of the anion and the cation radii. Fraustro da Silva and Queimado[4)] showed that the solubility product values would be affected by the lattice and hydration energies, and thus the order of the pK_{sp} values was correct.

The comparison of the solubility product values of this study with the values of Fraustro da Silva and

TABLE 1. SOLUBILITY PRODUCT VALUES OF RARE EARTH FLUORIDES

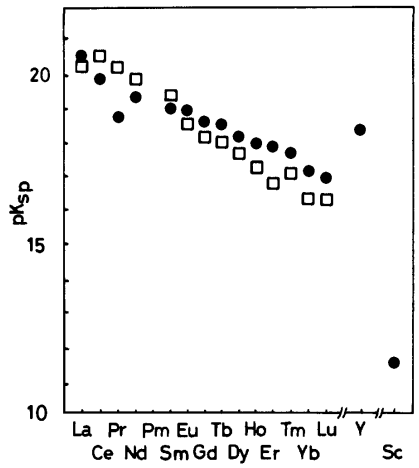

Fig. 1. A comparison of the pK_{sp} values of the rare earth fluorides at 25.0°C.
●: This work, □: Fraustro da Silva and Queimado.[4]

Queimado is given in Fig. 1. Their report were made in mixed solutions of sodium fluoride and rare earth nitrate; thus the fluoride solutions contained nitrate, sodium, and rare earth ions. In this study, the solubility product values were determined by using the rare earth fluoride powder, and the sample solutions contained only rare earth and fluoride ions. As shown in Fig. 1, the present values are in fairly good agreement with those of Fraustro da Silva and Queimado, though the present pK_{sp} slope is apparently smaller than theirs. The rather unusual pK_{sp} location of praseodymium fluoride was not corrected even after the repeated measurements. The difference of the pK_{sp} values would be attributed to the origin of the rare earth fluorides present in the solutions.

The solubility product value of lanthanum fluoride single crystal was determined by the same experimental procedures as used for the powder fluorides; however, no saturated solutions of fluoride ion were obtained even after more than three months of continuous stirring. The previously reported solubility product values[5-8] of lanthanum fluoride single crystal were widely scattered and remarkably smaller than those of the powder fluorides, possibly because of the difference in crystal size or surface. Single crystals could be dissolved at considerably slower rates than the powder fluorides. This means that lanthanum fluoride single crystal is preferable to the fluoride powder as the fluoride ion-selective electrode membranes.

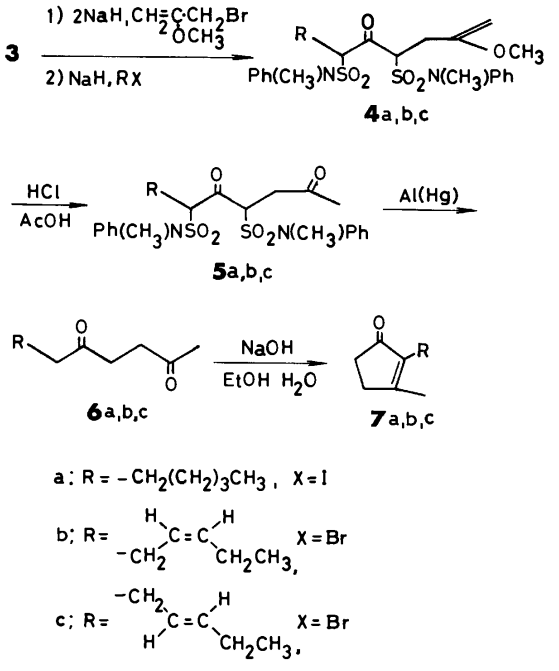
Synopsis. The titled jasmones were synthesized from *N,N'*-dimethyl-2-oxo-1,3-propanedisulfonanilide, a new three carbon building block for organic preparation.

2-Oxo-1,3-propanedisulfonic acid (**1**), which is easily accessible from acetone, has three kinds of reactive groups (sulfonic acid, carbonyl, and methylene groups) and seems to be a promissing intermediate for routine synthesis. But little is known about its synthetic utilization. Recently we have reported an application of the dialkyl sulfonates as practical alkylating reagents.[1] To show the utility of **1**, we now report a new synthesis of dihydrojasmone, *cis*- and *trans*-jasmones from *N,N'*-dimethyl-2-oxo-1,3-propanedisulfonanilide (**3**) through undecane- and 8-undecene-2,5-diones. The sulfonanilide can be prepared easily from the corresponding sulfonyl chloride (**2**)[1] and *N*-methylaniline and it behaves as an acetone with highly activated methylenes.

$O{=}C(CH_2X)_2$ **1**, X=SO_3H; **2**, X=SO_2Cl; **3**, X=$SO_2N(CH_3)Ph$

The process of synthesis was outlined in Scheme 1. In the case of dihydrojasmone, introduction of two necessary carbon fragments, pentyl and acetonyl groups, into **3** was conducted in one pot reaction with a high yield. Thus, the dianion generated from **3** with two equivalents of sodium hydride was allowed to react first with 3-bromo-2-methoxypropene[2] and the resulting reaction mixture was treated with one more equivalent of NaH. The unsymmetrical dianion formed was then alkylated with 1-iodopentane. The product enol ether (**4a**) was easily hydrolysed with HCl in acetic acid to the diketone (**5a**), which was desulfonated with aluminum amalgum in THF to afford 2,5-undecanedione (**6a**). The aldol cyclization of **6a** with NaOH in aq ethanol yielded dihydrojasmone (**7a**).[3] By the essentially same procedure, using *cis*- and *trans*-1-bromo-2-pentenes in place of 1-iodopentane, *cis*- and *trans*-jasmone were synthesized, respectively.



Scheme 1.

As illustrated above, the sulfonanilide (**3**) seems to be a good synthetic part for nucleophilic introduction of acetone unit. Particularly it is noteworthy that the smooth introduction of two electrophiles into the both methylene carbons of **3** is possible in one pot reaction, involving the successive generation of dianions.[4]

Experimental

The melting points were not corrected. The solvents were of a reagent grade. All the known compounds were confirmed by a comparison of the melting points and spectroscopic data with those of the authentic samples or the reported data. The reaction products were fractionated with a JAI LC-08 gel permeation liquid chromatograph (GPLC) using chloroform as eluent. The ^1H NMR spectra were recorded on a JEOL PMX-60 spectrometer in $CDCl_3$ and the shifts were given in δ unit from internal TMS. The IR spectra were measured on a Hitachi 260-30 spectrometer. The boiling points shown were bath temp.

N,N'-Dimethyl-2-oxo-1,3-propanedisulfonanilide (3). *N*-Methylaniline (149.7 g, 1.397 mol) was added dropwise to a benzene (60 cm^3) suspension of 2-oxo-1,3-propanedisulfonyl chloride (**2**, 118.9 g, 0.466 mol)[1] at 13—15 °C with stirring. After stirring was continued for 4 h at the same temperature, benzene was removed under reduced pressure and the residue was poured into aq MeOH (500 cm^3, 1:1 v/v). The mixture was made acidic with HCl and the precipitated crystals were collected by suction filtration, washed with water, and dried. Recrystallization from methanol yielded colorless crystals (122.6 g, 71%, mp 77—78 °C).[5] IR: 1725 ($\nu_{C=O}$) cm^{-1}. ^1H NMR: 3.30 (s, 6H, CH_3), 4.27 (s, 4H, CH_2), 7.35 (s, 10H, Ph). Found: C, 51.76; H, 4.96; N, 7.04%. Calcd for $C_{17}H_{20}N_2O_5S_2$: C, 51.50; H, 5.08; N, 7.07%.

N,N'-Dimethyl-2,5-dioxo-4,6-undecanedisulfonanilide (5a). Sodium hydride (60% in mineral oil, 1.20 g, net 30.0 mmol) was washed twice with hexane and suspended in DMSO 30 cm^3) under N_2. The sulfonanilide (**3**) was added to the mixture with stirring at the room temp and stirring was continued for 1 h. 3-Bromo-2-methoxypropene[2] (3.0 g, 45 mmol) was added dropwise with stirring and the mixture was stirred for 3 h at the ambient temp. Sodium hydride (60% in mineral oil, 0.60 g, net 15 mmol) was added and the mixture was stirred for 0.5 h. 1-Iodopentane (2.37 g, 12.0 mmol) was added to the mixture and stirring was continued for further 3 h at the room temp. The reaction mixture was decomposed with water (10 cm^3) and made acidic with HCl. The mixture was extracted with $CHCl_3$ and the combined extracts were washed with water and dried ($MgSO_4$). The crude product obtained on concentration under reduced pressure was subjected to GLPC fractionation. The enol ether (**5a**) was effectively separated by means of the recycle tech-

nique and hydrolyzed with AcOH (20 cm³) containing 1 M† HCl (10 cm³). The diketone (**5a**) was extracted with ether and the combined extracts were washed with 5% aq $NaHCO_3$ and water, successively, and dried (Na_2SO_4). On the vacuum concentration, **5a** was obtained as a colorless viscous oil (4.47 g, 85.5%). IR (neat): 1726 (sh, $\nu_{C=O}$), 1720 ($\nu_{C=O}$) cm^{-1}. ^1H NMR: 0.55—1.57 (m, 11H, pentyl), 2.0 (s, 3H, CH_3 of acetyl), 2.87 (d, J=6 Hz, 2H, CH_2 of acetonyl), 3.27 (s, 6H, CH_3-N), 4.76 (dd, J=10 and 4 Hz, 1H, pentyl side methine), 5.8 (t, J=6 Hz, 1H, acetonyl side methine), 7.32 (s, 10H, Ph). Found: C, 57.62; H, 6.62; N, 4.58%. Calcd for $C_{25}H_{24}N_2O_6S_2$: C, 57.45; H, 6.56; N, 4.36%.

*2, 5-Undecanedione (**6a**).* The sulfonanilide (**5a**, 2.66 g, 5.09 mmol) was dissolved in the mixture of THF (170 cm³) and water (10 cm³). Aluminum amalgum prepared from Al foil (4.12 g, 0.15 mol) was added to the solution and heated to reflux[6] for 3 h. After cooling down, the reaction mixture was digested with cold dil HCl and THF was removed under reduced pressure. The residue was extracted with ether and the combined extracts were washed with brine, dried (Na_2SO_4), and concentrated under reduced pressure. The crude diketone was purified by GPLC and bulb to bulb distillatin (bp 99—101 °C/1 Torr, 1 Torr=133.322 Pa) to yield a faintly yellow oil (0.45 g, 47.9%). IR (neat): 1703 ($\nu_{C=O}$) cm^{-1}. ^1H NMR: 0.87 (deformed t, J=5 Hz, 3H, CH_3 of hexyl), 1.07—1.85 (m, 8H, internal tetramethylenes of hexyl), 2.17 (s, 3H, CH_3 of acetyl), 2.27 (t, J=7 Hz, 2H, terminal methylene of hexyl), 2.67 (s, 4H, methylenes between carbonyls). Found: C, 70.70 H, 10.94%. Calcd for $C_{12}H_{20}O_2$: C, 70.90; H, 10.77%. Desulfonation could also be done by 6% Na(Hg) in MeOH containing Na_2HPO_4 (21% yield).

*3-Methyl-2-pentyl-2-cyclopentenone (Dihydrojasmone, **7a**).* The diketone (**6a**, 0.560 g, 3.04 mmol) was submitted to the aldol cyclization according to the reported method[3] to yield dihydrojasmone as a colorless oil (bp 110—112 °C/10 Torr, 0.39 g, 77.3%). IR (neat): 1700 ($\nu_{C=O}$), 1645 ($\nu_{C=C}$) cm^{-1}. ^1H NMR: 0.55—1.85 (m, 9H, methyl and internal trimethylenes of pentyl), 1.95—2.90 (m including s at 2.07 for CH_3 at C_3, 9H, CH_3, ring methylenes, and the terminal methylene of pentyl). Found: C, 79.53; H, 10.69%. Calcd for $C_{11}H_{18}O$: C, 79.46; H, 10.91%. 2,4-Dinitrophenylhydrazone melted at 120—121 °C.[7] Found: C, 58.92; H, 6.17; N, 16.12%. Calcd for $C_{17}H_{22}O_4N_4$: C, 58.95; H, 6.40; N, 16.17%.

*cis- and trans-N,N'-Dimethyl-2,5-dioxo-8-undecene-4,6-disulfonanilides (**5b and 5c**).* By the essentially same procedure, **3** was allowed to react first with 3-bromo-2-methoxypropene[2] and then with *cis-* or *trans-*1-bromo-2-pentene[8] in place of 1-iodopentane. Working up in the same way as in the case of **5a** yielded **5b** or **5c** as a faintly yellow viscous oil (both 86%).

*cis- and trans-8-Undecene-2,5-diones (**6b and 6c**).* The dioxodisulfonanilide (**5b**, 2.42 g, 4.65 mmol or **5c**, 1.99 g, 3.82 mmol) was refluxed in the mixture of THF and water (200 cm³, 9:1 v/v for **5b** or 130 cm³, 15:1 v/v for **5c**) with aluminum amalgum, prepared from Al foil (6.27 g, 0.23 mol for **5b** or 3.24 g, 0.12 mol for **5c**) for 3 h under stirring. Working up the reaction mixture in the same way as in the case of **6a** afforded **6b** or **6c** as a colorless oil (**6b**: bp 140 °C/2 Torr, 0.40 g, 47.3%; **6c**: bp 137 °C/4 Torr, 0.11 g, 15.8%). IR: **6b** (neat), 1710 ($\nu_{C=O}$); **6c** (neat), 1712 ($\nu_{C=O}$) cm^{-1}. ^1H NMR: **6b**, 0.95 (t, J=7 Hz, 3H, CH_3 of heptenoyl), 1.27—*ca.* 2.5 (m, 4H, allylic methylenes), 2.18 (s, 3H, CH_3 of acetyl), 2.43 (t, J=4 Hz, 2H, heptenoyl methylene neighboring to the carbonyl), 2.7 (s, 4H, methylenes between carbonyls), 5.2—5.6 (m, 2H, olefinic); **6c**, 0.95 (t, J=7 Hz, 3H, CH_3 of heptenoyl), 1.1—2.6 (m, 6H, methylenes of heptenoyl), 2.18 (s, 3H, CH_3 of acetyl), 2.68 (s, 4H, methylenes between carbonyls), 5.3—5.6 (m, 2H, olefinic). Found: **6b**, C, 71.98; H, 9.58%; **6c**, C, 72.75; 9.94%. Calcd for $C_{11}H_{18}O_2$: C, 72.49; H, 9.95%.

*2-(cis-2-Pentenyl)-3-methyl-2-cyclopentenone (cis-Jasmone, **7b**).* The diketone (**6b**, 0.303 g, 1.66 mmol) was refluxed in 0.5 M aq NaOH (5 cm³) containing ethanol (2 cm³) for 5 h. The reaction mixture was extracted with ether. The combined extracts were washed with brine, dried (Na_2SO_4), and concentrated under reduced pressure. The crude product was purified by GPLC and vacuum distillation to yield a colorless oil (bp 82—85 °C/1 Torr, 0.13 g, 50%). IR (neat): 1700 ($\nu_{C=O}$), 1650 ($\nu_{C=C}$) cm^{-1}. ^1H NMR: 0.98 (t, J=7 Hz, 3H, CH_3 of pentenyl), 1.7—2.7 (m, 6H, methylenes), 2.07 (s, 3H, CH_3 at C_3), 2.94 (d, J=5 Hz, 2H, CH_2 between double bonds), 5.1—5.7 (m, 2H, olefinic). Found: C, 79.91; H, 9.71%. Calcd for $C_{11}H_{16}O$: C, 80.44; H, 9.82%. 2,4-Dinitrophenylhydrazone melted at 115—116 °C.[9] Found: 59.05; H, 5.96; N, 15.91%. Cacld for $C_{17}H_{20}O_4N_4$: C, 59.29; H, 5.85; N, 16.27%.

*2-(trans-2-Pentenyl)-3-methyl-2-cyclopentenone (trans-Jasmone, **7c**).* The diketone (**6c**, 0.240 g, 1.32 mmol) was heated to reflux for 6 h in the mixture of ethanol (2 cm³) and 0.5 M aq NaOH (3 cm³). The reaction mixture was worked up and purified in the same way as in the case of **7b** to obtain **7c** as a colorless oil (bp 87—90 °C/1 Torr, 0.136 g, 63%). IR (neat): 1700 ($\nu_{C=O}$), 1650 ($\nu_{C=C}$) cm^{-1}. ^1H NMR: 0.94 (t, J=7 Hz, 3H, CH_3 of pentenyl), 1.6—2.7 (m, 6H, methylenes), 2.07 (s, 3H, CH_3 at C_3), 2.88 (d, J=4 Hz, 2H, CH_2 between double bonds), 5.3—5.6 (m, 2H, olefinic). Found: C, 79.88; H 9.72%. Calcd for $C_{11}H_{16}O$: C, 80.44; H, 9.82%. 2,4-Dinitrophenylhydrazone melted at 127—128 °C.[9] Found: C 59.15; H, 5 62; N, 16.16%. Calcd for $C_{17}H_{20}O_4N_4$: C, 59.29; H, 5.85; N, 16 27%.

The authors wish to express their thanks to the Asahi Glass Foundation for Industrial Technology for the generous financial aid.

Selective Mono- and Dibromination of Thymol by Electrolysis in Acetonitrile and Methanol

Isao TANIGUCHI,* Kouzou TAKADA, Hiroko YAMAGUCHI, and Kazuo YASUKOUCHI
Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860
(Received November 21, 1983)

Synopsis. For anodic bromination of thymol, MeCN and MeOH were suitable solvents for mono- and dibromination respectively. In MeCN, no dibrominated product was observed even when four Faradays per mole of thymol were passed.

Regioselective halogenation is one of the attractive subjects in electroorganic synthesis. Electrochemical chlorination of benzene derivatives in aqueous solutions was developed by Osa *et al.*[1] by using an α-cyclodextrin immobilized electrode. Gileadi *et al.*[2] have shown that the product ratio of bromophenols for anodic bromination of phenol depended on the charge consumed in aqueous solutions. In nonaqueous solvents, regioselective halogenation takes place at ordinary anodes. Matsuda *et al.*[3] have recently reported that para-preferential chlorination of alkoxybenzenes proceeded at a Pt electrode in *N,N*-dimethylacetamide and *N,N*-dimethylformamide, whereas in methanol, 2,4-dichlorophenetole was the product.[4] We have also reported[5] that anisole was easily brominated in high para-selectivity in acetonitrile. Recentrly, Becker[6] and Torii[7] reviewed studies of anodic halogenation. However, information on selective halogenation in nonaqueous solvents is still limited.[8]

Hence we have examined anodic bromination of thymol (*p*-cymene-3-ol) in acetonitrile (MeCN) and methanol (MeOH), because thymol derivatives are useful for medicinal materials.

Experimental

Controlled-potential electrolysis (CPE) was carried out at 25 °C by using a two-compartment cell. The amount of charge consumed was measured by a Hokuto Denko HF-201 coulometer. The working (5×8 cm^2) and the counter electrodes were Pt plates. The anolyte was 50 cm^3 in volume.

An Ag/0.01 M $AgClO_4$ in MeCN or MeOH was used as a reference electrode. Anode potentials for CPE were determined from the cyclic voltammograms of the test solutions. The products were analyzed gas chromatographically. The column used was 2 m×3 mmφ SUS packed with 5% polyethylene glycol 20 M on Uniport HP. Authentic samples of bromothymols donated from Kohjin Co., were identified by mass spectrometry. No significant difference in product distribution was observed when CPE was undertaken at temperatures between 0 and 40 °C. Throughout this paper 1 M=1 mol dm^{-3}.

Results and Discussion

Figure 1 shows the change in the yield of product as a function of the amount of charge passed for anodic bromination of thymol. In MeCN, thymol was brominated to 6-bromothymol at a current efficiency of more than 90% when up to one equivalent charge (two Faradays per mole of thymol) was passed. Further electrolysis caused a slight decrease in the amount

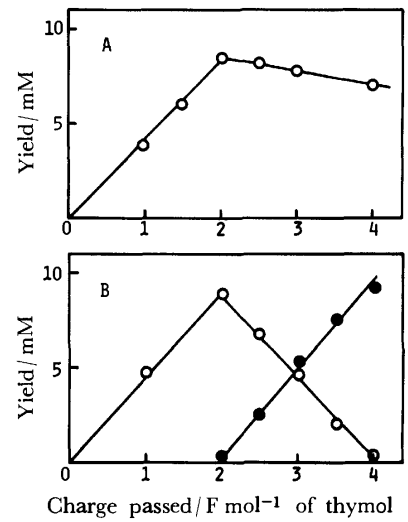

Fig. 1. Change in the yields of products as a function of the amount of charge passed for anodic bromination of thymol in MeCN (A) and MeOH (B). ○; 6-bromothymol and ●; 2,6-dibromothymol. Electrolyses were carried out in solutions consisted of 10 mM thymol, 20 mM bromide and 0.1 M perchlorate.

of 6-bromothymol, but no dibrominated product was obtained. On the other hand, in MeOH, the initial product was 6-bromothymol, as in MeCN, and was further brominated to 2,6-dibromothymol with high selectivity in a yield of *ca.* 90% at two equivalent charges. Typical results of CPE are summarized in Table 1. In MeCN, neither the anode potential nor the concentration ratio of thymol to bromide ion affected the selective monobromination (runs 1—10).

In MeOH, the total yield and the selectivity of brominated products decreased at potentials more positive than 0.55 V (*vs.* Ag/Ag^+ in MeOH). This is because oxidation of thymol itself and of the solvent both occurred (runs 11—18). No significant influence of the counter ion of the bromide ion source on the bromination behavior was observed (runs 11, 12, and 19—24). Thus, clearly, selective mono- and dibromination of thymol can be performed in MeCN and MeOH, respectively; an excess amount of bromide with respect to thymol is preferable for effective bromination in high selectivity (runs 7—10, 13, and 14).

A possible explanation for the difference in regioselectivity in MeCN and MeOH can be given as follows: (i) Since MeOH is a strong electron-acceptor (acceptor number, AN=41.3[9]), anodically generated bromine would be more polarized, $Br\overset{\delta+}{-}Br\overset{\delta-}{-}S$ where S is the solvent, in MeOH than in MeCN (AN=19.3[9]), and bromine molecules in MeOH become much more active than in MeCN. (ii) In MeCN, Br_3^- which is not active for bromination[5,10] is stable and the equilibrium of $Br_2+Br^-=Br_3^-$ lies to the right (pK=−7[11]), while unstability of Br_3^- in an amphiprotic solvent such as

Table 1. Anodic bromination of thymol

a) 50 cm^3 of solution consisted of 10 mM thymol, 20 mM bromide and 0.1 M perchlorate as a supporting electrolyte, except runs 7—10, 13, and 14. b) V *vs.* Ag/0.01 M $AgClO_4$ in MeCN or in MeOH. Potentials for CPE were chosen at which bromine was produced. c) One equivalent charge is 96.5 C (=2 F/mol of thymol). d) Based on 10 mM thymol. The yields were calculated from gas chromatographic data. The values also indicate the current efficiencies for the bromination. e) Oxidation of 6-bromothymol also occurred. f) 10 mM thymol and 50 mM bromide. g) 10 mM thymol and 100 mM bromide. h) Oxidation products of thymol itself were also detected.

MeOH shifts the equilibrium far to the left ($pK = -2.2$[11]). Thus, the actual concentration of Br_2 during electrolysis is larger in MeOH than in MeCN. (iii) Moreover, bulky bromine molecules may be solvated in MeCN through the dispersion force between solvent and bromine molecules, but the solvation would be unlikely in MeOH because of low acceptability of hydrogen-bond of Br_2; thus the active bromine would be larger in size in MeCN than in MeOH. Accordingly, these kinetic and steric factors make dibromination (the second bromination at 2-position) of thymol favorable in MeOH, but not in MeCN.

The following results also support the difference in regio-selectivity in MeCN and MeOH. Chlorination of anisole in MeCN gave monochlorinated products,[8] whereas in MeOH, 2,4-dichloroanisole was obtained as well, as reported by Matsuda *et al.*[4] For bromination of phenol, di- and tribromophenols were obtained in MeOH, but only in small amounts in MeCN.

On the other hand, exceptions were also observed. Bromination and iodination of anisole gave *p*-halogenoanisole in high para-selectivity and no dihalogenation took place at all, even in MeOH. This can be explained in terms of the steric hindrance at the ortho position by the methoxyl group for larger halogen molecules.

Finally, MeCN and MeOH are, rather generally, promising solvents for mono- and di- (and/or multi) halogenation of aromatic compounds, respectively.

(Received December 20, 1983)

Synopsis. The 1- or 4-hydroxyl group in cis isomers of 3-alkoxycarbonyl-1-tetralols and 2-ethoxycarbonyl-4-thiochromanols are predominantly quasi-equatorial and those of the trans isomers quasi-axial. *cis*-2-Ethoxycarbonyl-4-chromanol prefers the quasi-axial OH conformation.

Intramolecular OH···π interaction has been used as a means of configurational and conformational studies on unsaturated alcohols.[1,2] This paper deals with the conformations of the alcohols having an alkoxycarbonyl group γ to the OH group.

The ν_{OH} absorption maxima of the alcohols examined are summarized in Table 1. Basing upon that the tetralin, chroman, and thiochroman skeletons exist preferentially as a half-chair from,[2-6] the previous studies elucidated that 1-tetralol and 4-chromanol epimers with quasi-axial OH group show each only a band around 3618 cm^{-1} and the quasi-equatorial one a doublet at 3622 and 3600 cm^{-1}, as represented by **4a**—**6a** and **4b**—**6b**, respectively, in Table 1. It is therefore readily assigned that the OH groups in **1a** and **3a** prefer the quasi-equatorial orientation and those of **1b** and **3b** the quasi-axial one. In contrast with these, **2a** showed two ν_{OH} bands at 3610 and 3596 cm^{-1}, the former band being stronger. Referring to the previous results,[3] an appearance of the two bands is ascribed to the coexistence of two conformers with quasi-axial and -equatorial OH groups, the former being predominant. This means that the conformation A with both axial OH and ester groups is more predominant than the conformation B.

A B

To clarify the conformational equilibrium, temperature dependence of the OH absorption was examined for **2a** and **3a** in the range 10—50 °C. The result indicated that the intensity of the lower frequency band increased with a rise in temperature for both **2a** and **3a**: the intensity ratio A_{3592}/A_{3619} of the two ν_{OH} bands at 3592 and 3619 cm^{-1} for **3a** changed from 1.3 at 10 °C to 2.2 at 50 °C. Accordingly, the quasi-axial OH conformer is more stable than the quasi-equatorial one in the equilibrium. Generally speaking, 3-hydroxycyclohexanecarboxylic acid ester do not form an intramolecular hydrogen bond.[7] If the two substituents in the cis isomer are fixed in a diaxial conformation, however, both carbonyl and alkoxyl oxygen-bonded OH species should be observed.[8] Although authors can not give a decisive explanation, the band at 3610 cm^{-1} of **2a** presumably arose from the diaxial conformation which is possible to form a hydrogen bond. Examination of the $\nu_{C=O}$ bands for **1a**, **2a**, and **3a**, however, afforded no clear sign of hydrogen-bond formation.

The above interpretation is supported by the ^{1}H-NMR measurements for **1**—**6** (Table 2). The coupling constants in Table 2 can be used to deduce the relative configurations and substituent conformations by making use of the Karplus relationship between vicinal HC-CH coupling constants and dihedral angles. A simplified method[5,6,9] can be adapted to the present cases. If the 2-substituent is in the equatorial position on half-chair dihydropyran ring and all the vicinal J's have the same sign, the value of $J_{3a\text{-}4}+J_{3e\text{-}4}$ would be significantly smaller for 2,4-*trans* than for 2,4-*cis* isomers.

TABLE 2. NMR PROTON COUPLING CONSTANTS FOR 1-TETRALOLS, 4-CHROMANOLS, AND 4-THIOCHROMANOLS

Compound	HC-CH coupling in $CDCl_3$ $J_{3a,4}+J_{3e,4}$/Hz		HC-OH coupling in DMSO J_{HC-OH}/Hz	
	cis	trans	Quasi-equatorial OH	Quasi-axial OH
1a	15.4(d.d)		6.3	
1b		6.8(t)[a]		5.0
2a	10.0(t)			5.0
3a	12.5(d.d)[a]		5.8

4a	17.0(d.d)[b]		7.1	
4b		6.0(t)[b]		5.3
5a	15.5—16.0(d.d)[c]		6.7	
5b		6.0—6.5(t)[c]		5.0
6a	15.3(d.d)[d]		6.3	
6b		5.9(t)[d]		5.4

a) Coupling constant of the acetate. b) Ref. 4. c) Refs. 5 and 6. d) Ref. 3b.

This explanation is assured with the data for **4—6** in Table 2. It is thus considered that the OH groups in **1a** and **3a** prefer the quasi-equatorial orientation and those of **1b** and **3b** the quasi-axial one. The value of $J_{3a,4}+J_{3e,4}$ (10.0 Hz) observed for **2a** is smaller than those of **1a** and **3a**, supporting the existence of the conformational equilibrium of **2a** in solution. The equilibrium is also supported by the hydroxyl ^{1}H-NMR measurements for **1—6** in dimethyl sulfoxide (DMSO) (Table 2).[10] The J_{HC-OH} of **2a** is significantly smaller than those of **1a** and **3a** and similar to those of the compounds with a quasi-axial OH group (**4b**, **5b**, and **6b**), rather than a quasi-equatorial OH group (**4a**, **5a**, and **6a**).

Experimental

3-Alkoxycarbonyl-1-tetralol (**1**),[11] 2-ethoxycarbonyl-4-chromanol (**2**),[12] and 2-ethoxycarbonyl-4-thiochromanol (**3**)[12] were prepared by reducing the corresponding ketones as reported. Since the pure *cis*-2-ethoxycarbonyl-4-thiochromanol (**3a**) was not readily isolated due to its instability, the mixture (1:1) of **3a** and **3b** was used for measurements. Then the infrared and NMR spectra of **3a** were obtained by subtracting the spectra of pure **3b** from those of the mixture.

Infrared spectra were measured using a KCl cell of 30 mm in optical length; the concentration of the CCl_4 solution was ca. 4×10^{-3} mol/dm^3. NMR spectra were measured at a probe temperature of 30 °C, using TMS as the internal standard.

π-Electron Distribution in Benz[*a*]indeno[1,2,3-*cd*]azulene and the Corresponding Azepinium Ion

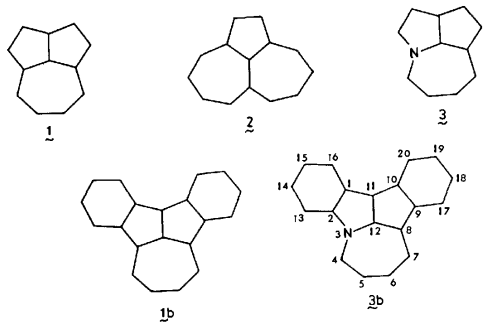
Shigeru MURATA and Hiizu IWAMURA*
Institute for Molecular Science, Myodaiji, Okazaki 444
(Received December 21, 1983)

Synopsis. The π-electron density distribution in benz[*a*]indeno[1,2,3-*cd*]azulene and the corresponding azepinium ion has been calculated by the PPP MO method. The effects of the hetero atom and the benzo annellation on the π-electron density and bond order of the cyclopent[*cd*]azulene are discussed.

Since Hafner *et al.* synthesized the dimetyl derivatives of cyclopent[*cd*]azulene (**1**) and cyclohept[*cd*]azulene (**2**) (Hafner's hydrocarbon),[1] their electronic structures have attracted the interest of many organic and theoretical chemists.[2,3] Parent molecules **1** and **2** were treated by the self-consistent field molecular orbital theory on π-conjugated systems developed by Pariser, Parr, and Pople.[4] The essence of these theoretical calculations[5] is summarized as follows. Thermodynamically, **1** is more stable than **2** as shown by their Dewar's resonance energy of 0.018 and 0.016$|\beta|$, respectively. However there is higher olefinic character in the 5-membered rings of **1**, and therefore **1** should be kinetically less stable of the two.

Some more derivatives of **1** and **2** were synthesized, and in 1969 and 1970 crystallographic studies on 5,7-dimethyl-2-phenylcyclopentazulene[6] and 3,5,8,10-tetramethylcycloheptazulene[7] showed almost planar structure of these molecules. More recently we found a facile access to the dibenzo derivative (**1b**) of **1** *via* the photorearrangement of 1-alkoxytriptycenes.[8] The corresponding azepinium salt (**3b**) was also obtained by the hydride abstraction reaction of the similar photoproduct of 1-azatriptycene.[9]

Since the benzoannellation is so located as to block the reactive olefinic bonds in **1**, **1b** proved to be a very stable compound. These experimental work encouraged us to study the electronic structure of **1b** and **3b**.



Method and Parameters

The self-consistent-field method used here is the Pariser-Parr-Pople method within the zero-differential-overlap approximation. The matrix elements of the closed shell Hartree-Fock operator are written as follows,

$$F_{rr} = -I_r + \frac{1}{2}q_r\gamma_{rr} + \sum_{s\neq r}(q_s-1)\gamma_{rs},$$

$$F_{rs} = \beta_{rs} - \frac{1}{2}p_{rs}\gamma_{rs},$$

where q_r and p_{rs} are π-electron density and bond order, respectively, and I_r is the ionization potential of atom r in its valence state, and γ_{rr} is one-center repulsion integral which is estimated as the difference between valence state ionization energy and electron affinity.

As the resonance integral, β_{rs}, a constant value was used for neighboring atoms, and for non-neighboring atoms β_{rs} was assumed to be zero. The two-center repulsion integral, γ_{rs}, was calculated by the Mataga-Nishimoto formula[10] using the standard geometries.

The parameters used in this calculation are shown in Table 1, with the Hückel parameters h and k in $\alpha_N = \alpha_C + h\beta_{CC}$, and $\beta_{CN} = k\beta_{CC}$ for initial guess.[11] These vaules were determined in reference to the DasGupta's work on nonbenzenoid hydrocarbons[5] and the study of methyleneammonium ion by Brown.[12]

The molecules discussed here are all assumed to have planar geometries, with all the carbon-carbon and carbon-nitrogen bonds being 1.39 Å and 1.36 Å, respectively. The bond angles of the cyclopent[*cd*]azulene moiety are close to those of the crystal structure[6] of related compounds and collected in Table 2. The bond angles of the annulated benzene rings are assumed to be equal to 120°.

Calculations were carried out on a Hitachi M-200H computer, using "SCF-CI-PI-MO Program with PPP Approximation" programmed by Mueller-Westrhoff and filed in the program library of the Computer Center of Institute for Molecular Science.

Results and Discussion

In Table 3 are given the calculated π-electron densities and π-bond orders of cyclopent[*cd*]azulene (**1**) and its dibenzo derivative (**1b**) together with their azepinium derivatives (**3** and **3b**). The present results for cyclopent[*cd*]azulene agree with those of the previous calculations,[2,3,5,6] confirming the validity of our parametrization. Although the π-electron density is somewhat sensitive to choice of parameters,[5] the data in Table 3 indicate some trends which do not depend on the parameters. Firstly, we note that the charge density at the positive nitrogen center (position 3) is more effectively neutralized in **3b** than in **3**. As a result, π-electron densities are slightly reduced not only at the neighboring carbons (position 2, 4, 12) but also the remote carbon atoms (position 6, 8, 10). Secondly, the π-electron density on the benzene rings is little influenced by the change of atoms at position 3. For a third, when the dibenzo derivatives are compared with the parent compounds, it is noted that the extent of the separation of charge densities is smaller in the dibenzo derivatives. Thus **1b** and **3b** are expected to be less polar and therefore less reactive than the corresponding parent compounds.

An operational test for the validity of the calculated charge distributions is provided by the ^{1}H NMR data for **1b** and **3b**. Plots of the chemical shifts of the nonbenzenoid hydrogens 4—7 *vs.* the calculated π-electron densities gave a line as shown in Fig. 1. The slope is close to the well-known 10 ppm/π-electron. The reason why the proton at position 5 of **3** deviated from the line is not clear for the moment.

Turning now to π-bond orders (Table 3), we note that the bond alternation in the 7-membered ring is more evident in the dibenzo derivatives than in their parent compounds in which the bond orders in the 7-membered rings are more uniform and suggest the reasonably high aromatic character. Whereas the 3-12 and 8-12 bonds, which are shared by two rings of different type, have a single bond character with bond order 0.38—0.44, the 11-12 bond between the same ring types has an aromatic character with bond order 0.68—0.69 in the dibenzo derivatives. Bonds 1-2 and 9—10 on the 5-membered rings of **1** and **3** have very high bond order 0.73—0.77 which is supported by the short bond length (1.359 and 1.386 Å) found in the crystal structure of the related compounds.[6] The benzo annellation reduced the latter bond orders to 0.55—0.57 by sharing the bonds as a part of the benzene ring. Whereas the double bond character of these bonds is reduced, the bond alternation in the rest of the molecules is found to be enhanced by the benzo annellation in these systems. The trend is interpreted in terms of an increased contribution of canonical structure A over B and B′ which require the quinonoid structure of one of the benzene rings. In the aza-analogs, the extent of the bond alternation is somewhat enlarged as compared to the hydrocarbons.

(Received December 22, 1983)

Synopsis. The induced circular dichroism (CD) spectra of the sequential histidine polypeptide-azo dye complexes were measured. The induced CD arose from the dye bound to the polypeptide in the random coil conformation. The intensity of the induced CD decreased with increasing distance between the intramolecular histidine residues.

The induced optical activities of complexes of anionic poly(L-glutamic acid) (PLG) with cationic dyes were first reported by Stryer and Blout.[1,2] Induced optical activities have been reported mostly for the PLG complexes. Lately, however, the complexes of cationic poly(L-lysine)-,[3,4] poly(alkyl-L-lysine)s-,[5,6] and poly(L-arginine)-azo dyes[7,8] have been reported to exhibit optical activity. In the course of our study of the induced CD of biopolymers,[4-8] we wish to report here on the induced CD due to the interaction between the cationic poly(L-histidine) (PLH) and an azo dye.

Experimental

The four histidine polypeptides, PLH (I, $[\eta]^{25}_{DCA}$=0.18), poly(His-Gly) (II, $[\eta]^{25}_{DCA}$=0.19), poly(His-βAla-Gly) (III, $[\eta]^{25}_{DCA}$=0.20), and poly(His-Gly$_3$) (IV, $[\eta]^{25}_{DCA}$=0.17) were synthesized according to the racemization-free diphenyl phosphoryl azide method (dichloroacetic acid was abbreviated as DCA).[9,10] 4-(4-dimethylaminophenylazo)benzenesulfonic acid sodium salt (Methyl Orange, MO) was guaranteed reagents (Wako). The mixtures were prepared by adding the dye solution to the polypeptide solutions; the pH values of the solutions were then brought up to the desired pH by the addition of NaOH or HCl. The final concentrations of histidine residue in polypeptides and MO were 10^{-4} mol residue dm^{-3} and 2×10^{-5} mol dm^{-3}, respectively. The absorption and CD spectra were measured with JASCO UVIDEC-1 and CD J-40A spectrometers, respectively. The molar ellipticity [θ] (degree cm^2 dmol^{-1}) and molar extinction coefficient ε (dm^3 mol^{-1} cm^{-1}) were expressed on the basis of the dye concentration.

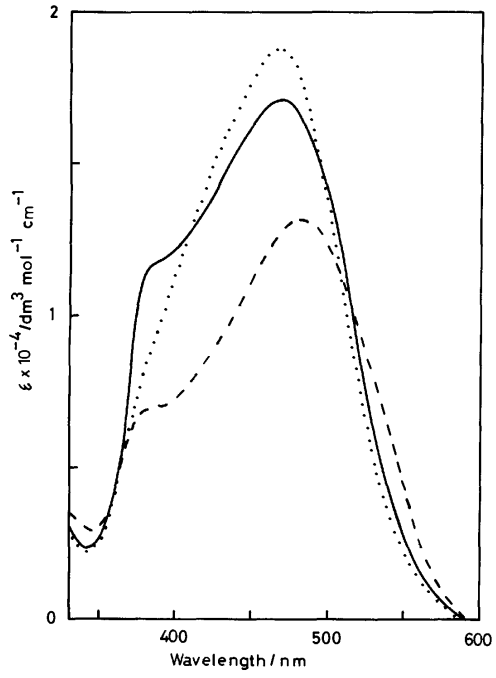

Fig. 1. Absorption spectra of the PLH (I)-MO complex in water at R/D=5: (·····) at pH 4.4, (——) at pH 4.1, and (------) at pH 3.7.

Results and Discussion

Since PLH is not soluble in water above pH 6,[11-13] the absorption and CD spectra of MO with and without polypeptides were measured over the pH range 3 to 6. Upon adding PLH (I), the position of the peak and the band shape of MO in the visible absorption spectrum were changed and the PLH (I)-dye complex exhibited the induced CD. Figure 1 shows the absorption spectra of the PLH (I)-MO complex in water as a function of pH at residue/dye (R/D)=5. At pH 4.6, the visible absorption spectrum showed a peak at 467 nm. As the pH of the solution was lowered from 4.6 to 3.1, the peak at 467 nm shifted to 506 nm. Between pH 4.3 and 3.2 an additional shoulder was observed at around 370 nm. The blue-shifted shoulder (or peak) suggests a nearly parallel orientation of the MO molecules.[3,14] At low PLH (I) concentration, R/D<2, the shoulder at 370 nm was not clear. Figure 2 shows the induced CD spectra of the PLH (I)-MO complex in

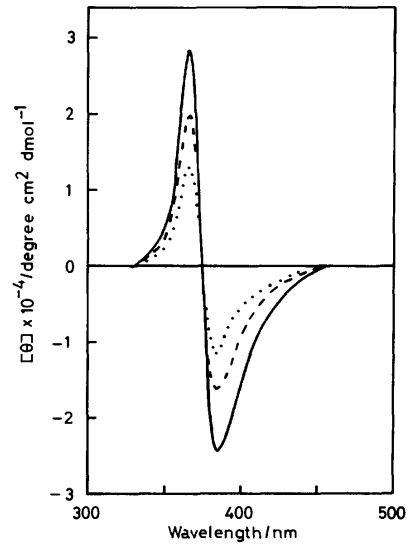

Fig. 2. Induced CD spectra of the PLH (I)-MO complex in water at R/D=5: (·····) at pH 4.4, (——) at pH 4.1, and (------) at pH 3.7.

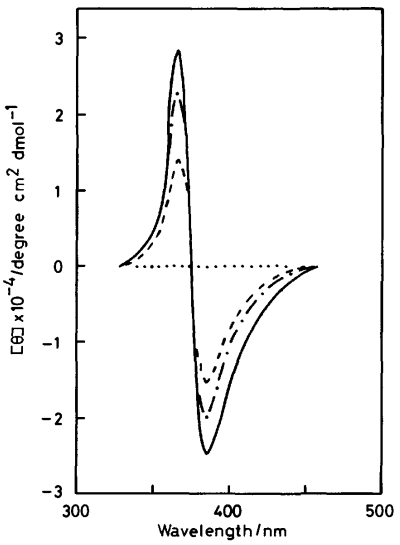

Fig. 3. Induced CD spectra of the PLH (I)-MO complex at various NaCl concentrations (at pH 4.1 and R/D=5): (——) 0 mM, (-·-·-) 0.5 mM, (------) 2 mM, and (·····) 5 mM.

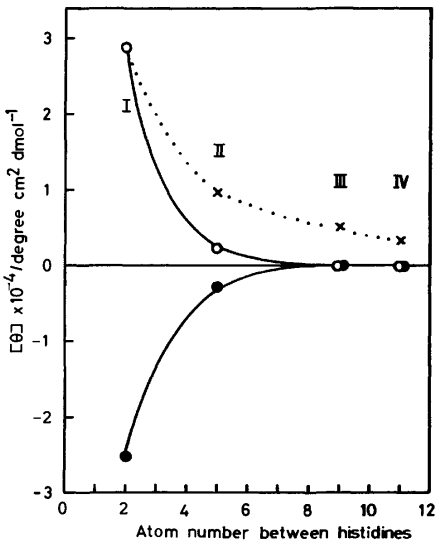

Fig. 4. Induced CD values at the extrema of the sequential polypeptide MO-complexes as a function of distance between histidine residues in water at pH 4.1 and R/D=5: ○ at 366 nm and ● at 385 nm. Samples I—IV, see text. The estimated induced CD values (× and dotted line) were calculated from the CPK model examinations, assuming the stretched backbone conformation and the nearest distances between histidine residues.

water as a function of pH at R/D=5. pH 4.1 was optimal for the induced CD of the PLH (I)-MO system, and the spectra at pH 3.7 and 4.4 showed smaller CD values. Two induced CD extrema were observed at 385 nm with $[\theta]=-25200$ and at 366 nm with $[\theta]=28800$ at pH 4.1. The PLH (I)-MO complex at pH 4.1 showed the characteristic CD bands at 222 nm with $[\theta]=2000$ and at 203 nm with $[\theta]=-4200$ (based on the histidine residue). These ellipticity values suggest that the degree of ionization of the imidazole side chains is about 50% and the conformation of the complex is a random coil.[13]

Figure 3 shows the change in the induced CD spectra of the PLH (I)-MO complex in an aqueous solution with various sodium chloride concentrations at pH 4.1 and R/D=5. With increasing concentration of sodium chloride from 0 to 0.005 mol dm^{-3}, the intensity of the induced CD became weaker. No induced CD was observed in 0.005 mol dm^{-3} sodium chloride.

The main features of the optical activities arise from the dipole-dipole couplings of the chromophores with each another. The intensity of the split Cotton effect is inversely proportional to the square of the interchromophoric distance and is changed by the dihedral angle between the transition moments.[15] In an electrostatic interaction systems, the dihedral angle between the transition moments is difficult to examine but the interchromophoric distance can be changed by sequential polypeptides. Figure 4 shows the induced CD values at the extrema of four sequential polypeptide-MO complexes as a function of distance between C_α of the histidine residues. Since the random coil conformations of the four sequential polypeptide-MO complexes do not allow the exact estimation of the distance between chromophores, we tentatively used the numbers of backbone atoms between histidine residues as abscissa. Clearly, an increased distance decreased the intensity of the induced CD. Beyond the bold approximation of the distances between the nearest intramolecular histidine residues by the CPK model examinations, the observed values of the induced CD of sequential polypeptides decreased sharply.

These results are the first observed induced CD of PLH-MO complexes and demonstrate that the intensity of the induced CD of the polypeptide-dye complex is dependent on the distance between the intramolecularly interacting chromophores.

(Received May 8, 1982)

Synopsis. A new inorganic ion exchanger, cerium(IV) selenite has been synthesized with a cation exchange capacity of 0.98 mequiv g^{-1}. It is fairly stable in water and in dilute solutions of acids, bases and salts. The K_d values for number of metal ions were determined in different solvent systems. The exchanger possesses a high affinity for Hg(II) and hence its separation from certain metal ions have been made.

Selenites of tin,[1] titanium,[2] and tantalum[3] have been synthesized and used for various separations. However, no such studies have so far been reported on cerium(IV) selenite. Our studies on this material reveal that it is highly selective for Hg(II). As mercury is a toxic substance, its determination and separation should be of great importance. In the present report the synthesis and the ion exchange properties of cerium (IV) selenite are described as well as its possible application to separation of Hg(II) from other metal ions.

Experimental

Synthesis. Cerium(IV) selenite was prepared by mixing solutions of sodium selenite (Riedel, Germany) and ammonium cerium(IV) sulfate (British Drug House,England). The solution of 0.05 mol dm^{-3} sodium selenite was added to a solution of 0.05 mol dm^{-3} ammonium cerium(IV) sulfate in the volume ratio of 1:1 at pH 1. The pH was adjusted by adding either nitric acid or aqueous ammonia. The precipitate so obtained was kept standing for 24 h to ensure complete precipitation. It was then filtered, washed with deionized water and dried at 40 °C. The dried product was then converted to H^+ form by treatment with 1 mol dm^{-3} HNO_3.

The ion exchange capacity, which in fact is the capacity to decompose neutral salts, was determined by column operation. A solution of 1.0 mol dm^{-3} of Na^+, K^+, Mg^{2+}, Ca^{2+}, Sr^{2+}, and Ba^{2+} was passed through a column containing 1 g of exchanger. The eluted hydrogen ion concentration was then determined titrimetrically.

To determine the chemical stability, 0.5 g cerium(IV) selenite was shaken with an appropriate solution for six hours in a conical flask. The cerium[4] and selenium[5] released into the supernatant solution were determined by standard methods.

The pH titrations of cerium(IV) selenite were performed with LiOH, NaOH, KOH and aqueous ammonia in the presence of Li^+, Na^+, K^+ and NH_4^+ chlorides, respectively, by the method of Topp and Pepper.[6]

For equilibrium studies 0.5 g of exchanger in H^+ form was shaken with 50 cm^3 solution of 1.0 mol dm^{-3} sodium nitrate. The amount of released H^+ ions in the supernatant solution was determined after appropriate intervals.

The distribution coefficient (K_d values) were determined by shaking 50 cm^3 of 0.001 mol dm^{-3} solution of different metal ions with 0.5 g of the exchanger for six hours at room temperature.[3]

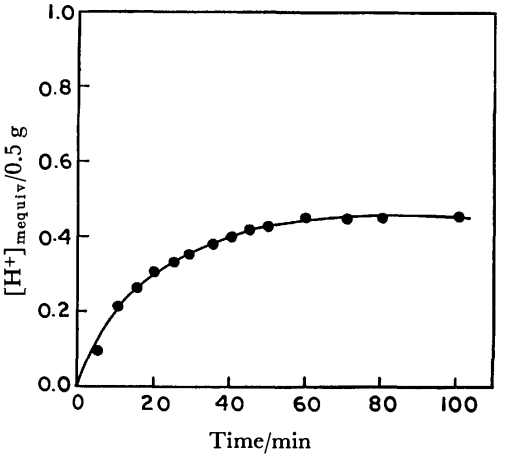

Fig. 1. Attainment of equilibrium of Na^+-H^+ exchange on cerium(IV) selenite.

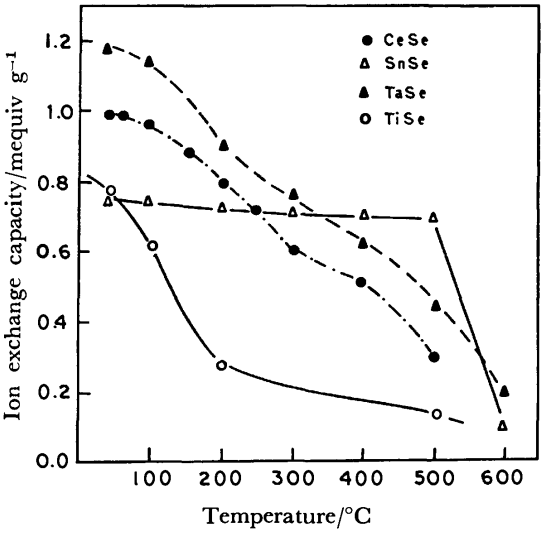

Fig. 2. Ion exchange capacity of various selenites as a function of drying temperature.

Results and Discussion

The hydrogen ion liberation capacity of cerium(IV) selenite for some uni and bivalent metal ions such as Na^+, K^+, Mg^{2+}, Ca^{2+}, Sr^{2+}, and Ba^{2+} were found to be 0.98, 0.86, 0.90, 0.80, 0.82, and 0.85 mequiv g^{-1} respectively.

The equilibrium studies (Fig. 1) show that the equilibrium is attained in 60 min. The effect of drying temperatures of cerium(IV) selenite on the ion exchange capacity (Fig. 2) indicates that the selenite also shows deterioration after 100 °C as in the case of tantalum selenite. The reason for the decrease in capacity with the increase in drying temperature upto 500 °C may be attributed to the loss of structural

Table 1. Some separations on cerium(IV) selenite columns

Separation	Eluent	Elution volume/ml	Amount of cation	
			Loaded mg	Recovered mg
Cd(II)-Hg(II)	Cd(II)-0.01 mol dm^{-3} HNO_3	0.0—80	0.74	0.74
	Hg(II)-0.1 mol dm^{-3} (HNO_3+NaNO_3)	90—160	1.6	1.6
Ni(II)-Hg(II)	Ni (II)-0.1 mol dm^{-3} HNO_3	0.0—70	0.48	0.49
	Hg(II)-0.1 mol dm^{-3} (HNO_3+NaNO_3)	80—160	1.6	1.6
Pb(II)-Hg(II)	Pb (II)-0.01 mol dm^{-3} HNO_3	0.0—90	1.6	1.6
	Hg(II)-0.1 mol dm^{-3} (HNO_3+NaNO_3)	100—170	1.6	1.5

water, selenium and attached replaceable hydrogen ion.

The results of chemical stability test of cerium(IV) selenite revealed that the material is fairly stable (less than 1.2 mg of Se and 0.28 mg of Ce were lost) in demineralized water, 2.0 mol dm^{-3} solution of each of $NaNO_3$, NH_4NO_3, HNO_3, CH_3COOH, HCOOH, and CH_3OH but less stable (3.24 mg of Se and 2.8 mg of Ce were lost) in sulphuric acid of over 2.0 mol dm^{-3}. The pH titration curves (Fig. 3) of the exchanger in H^+ form show bifunctional behaviour.

The chemical analysis revealed that Ce : Se ratio as 1 : 1.1. TGA curve showed the loss of water molecules, 11% at 200 °C. Therefore, the material possibly possesses the empirical formula $CeO_2 \cdot Se(OH)_2O \cdot nH_2O$ with a formula weight of 301 for the anhydride. The value of '*n*' the external water molecule per mole of oxide was 2.07.

The analytical importance of cerium(IV) selenite can be deduced from the K_d values of various metal ions in water, 0.1 mol dm^{-3} $NaNO_3$ and in different concentrations of HNO_3. The ion exchanger showed a selective trend in various solution as may be predicted by the K_d values, which are in parentheses *e.g.* in water: Hg^{2+} (total adsorption), Al^{3+} (1160), Pr^{3+} (700), Ho^{3+} (585), Zr^{4+} (470), Y^{3+} (440), Th^{4+} (340), La^{3+} (390), Sm^{3+} (240), Fe^{3+} (240), Ca^{2+} (200), Ba^{2+} (200), Cu^{2+} (170), Mn^{2+} (160), Sr^{2+} (110), Mg^{2+} (100), Zn^{2+} (100), Ni^{2+} (80), Cd^{2+} (68), and Pb^{2+} (55) and in 0.01 mol dm^{-3} HNO_3: Hg^{2+} (2020), Al^{3+} (640), Pr^{3+} (580), Ho^{3+} (400), Y^{3+} (340), Th^{4+} (170), La^{3+} (140), Sm^{3+} (120), Fe^{3+} (180), Ca^{2+} (70), Ba^{2+} (60), Cu^{2+} (120), Mn^{2+} (90), Sr^{2+} (40), Mg^{2+} (50), Zn^{2+} (60), Ni^{2+} (40), Cd^{2+} (20), and Pb^{2+} (10). These indicate that the exchanger shows greatest preference for Hg(II) in solvent media like H_2O and 0.01 mol dm^{-3} HNO_3, where total absorption of Hg(II) was observed. Its elution was possible only when a mixture of 0.1 mol dm^{-3} solution each of HNO_3 and $NaNO_3$ was used. The high affinity of cerium(IV) selenite for Hg(II) paved the way for its separation from most of the metal ions. For separations a glass column of 30 cm in height and of internal diameter 0.69 cm was loaded with 2 g of the exchanger. A solution was then poured into the column. The flow rate was kept 0.5 ml/min. After repeated recyclization the metal ions were eluted with an appropriate solution in which the K_d value was lowest. The separation was practically complete and the order of elution of different metals are shown in Table 1. The separations were quantitative and the errors were within admissible range.

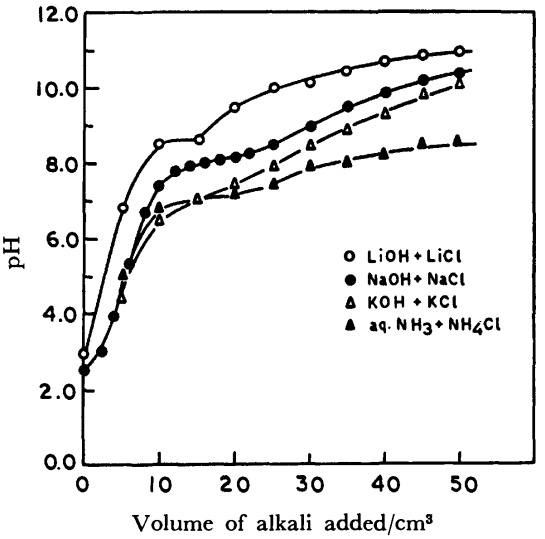

Fig. 3. pH titration curves of cerium(IV) selenite (H^+ form).

Amperometric Determination of Silver(I) with Hydrazine Sulfide and Its Estimation in Presence of Lead(II)

Govind S. Deshmukh, Arun G. Kulkarni,* and Shashikant N. Joshi†
Department of Chemistry, Ramnarain Ruia College Matunga, Bombay 400 019, India

(Received May 30, 1983)

Synopsis. Silver(I) has been estimated by an amperometric method using hydrazine sulfide as titrant. The titration is carried out in ammonium tartrate–ammonia supporting electrolyte (pH≈9). Further, this method is extended to determine silver(I) in presence of lead(II). Under these conditions lead(II) reacts only after all silver(I) has been precipitated. The accuracy of the procedure is comparable with that obtained in classical method.

One of the oldest procedure for the determination of silver was carried out by Lamber and Walker[1] using dead stop end point method. Potassium hexacyanoferrate(II)[2] has been used for the determination of silver at an applied potential of +0.4 V. Songina[3] titrated silver with potassium iodide at rotating platinum electrode. Thiourea[4,5] has been successfully used for estimation of silver. Deshmukh and Garde[6] determined silver using potassium thiocarbonate. Ethyl xanthate[7] was used to determine silver alone and in presence of lead. Many complexing agents like diphosphorus pentasulfide,[8] thiosemicarbazide,[9] and 8 quinolinethiol[10] have been successfully used to determine silver. Recently ethyltrithiocarbonate[11] has been reported as titrant for silver.

In the present investigation a new amperometric method for determination of silver(I) has been developed using hydrazine sulfide as titrant. The procedure is further applied for quantitative estimation of silver(I) in presence of lead(II). Preliminary studies of the polarogram characteristics of hydrazine sulfide at dropping mercury electrode revealed a well developed anodic wave in pH range 8 to 9.5 in ammonium tartrate–ammonia buffer. It was considered useful for titration of metals giving precipitates. Furthermore the anodic current of hydrazine sulfide and cathodic current of metal ions can be employed for simultaneous determination of binary mixture of silver and lead.

Experimental and Results

Solutions. Stock solutions of silver(I) and lead (II) were prepared from AnalaR grade samples. These stock solutions were standardized by classical methods.[12] The lower concentrations were then obtained by successive dilution of these stock solutions. The standard solution of hydrazine sulfide was prepared by dissolving an accurately weighed quantity of pure recrystallised sulfur in hydrazine hydrate and was protected from atmospheric contact with a layer of petroleum ether. The solution was found to be quite stable under these conditions.[13]

Ammonium tartrate solution (0.1 M (1 M=1 mol dm^{-3})) was prepared from pure sample and its pH was adjusted to 9 by concentrated ammonia.

† Present address: Forchungsinstitut, Meinsberg, 7305 Waldheim DDR.

6	2.157	2.165	+0.37

A simple form of an amperometric titration unit with rotating platinum micro electrode described by Kolthoff[14] was used.

Determination of Silver(I). Preliminary experiments were carried out to study appropriate conditions for quantitative precipitation of silver in base solution of ammonium tartrate–ammonia in pH range 8 to 9.5 and following procedure was followed.

An aliquots of silver(I) solution was placed in Pyrex beaker containing 25 ml of ammonium tartrate–ammonia buffer (pH≈9). The titration was carried out at an applied potential of +0.2 V *versus* SCE. The calibrated 2 ml microburette was used for delivery of titrant. The galvanometer reading was noted initially and after each addition of titrant. The diffusion current remained constant till the whole of silver was precipitated. After the end point hydrazine sulfide gave the diffusion current of its own, resulting the regular rise in the current. The plot of volume of hydrazine sulfide added against galvanometer reading gave reverse 'L' shaped curve. The results are given in Table 1.

Determination of Silver(I) and Lead(II). Earlier results from this laboratory reported determination of lead with hydrazine sulfide.[13] Since the half wave potential of lead(II) (−0.54 V) is more negative than that of silver(I) (>O) at pH 9, the latter can be determined cathodically while lead(II) end point can be determined anodically. An attempt was, therefore, made to estimate silver(I) and lead(II) in mixed solution. The applied potential, which was chosen, was such that lead(II) was not reduced at this potential but reagent has anodic diffusion current.

Aliquots of silver(I) and lead(II) were taken in 100 ml Pyrex beaker containing 25 ml ammonium tartrate – ammonia buffer (pH≈9). The titration was performed with hydrazine sulfide. The current was noted at −0.2 V *versus* SCE. With the addition of hydrazine sulfide to mixture, diffusion current of silver (I) reduced gradually and became steady. When all

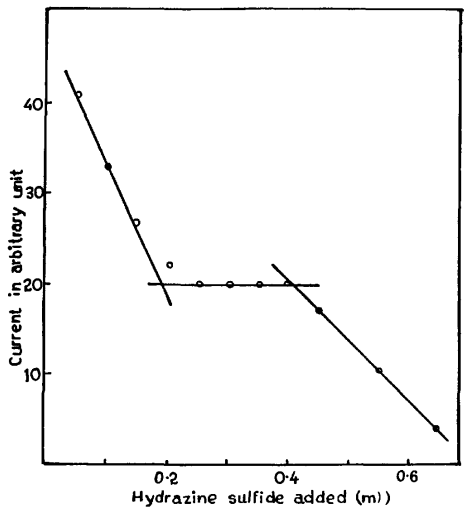

Fig. 1. A typical amperometric titration curve for mixture of Ag^{+} and Pb^{II} in tartrate buffer at −0.2 V *versus* SCE.

silver was precipitated with further addition of titrant, lead started getting precipitated. After all lead(II) was precipitated excess of reagent gave anodic diffusion current of its own. A typical titration curve is shown in Fig. 1. The first intersection gives the amount of silver(I) while second intersection gives the amount of lead(II). The results are returned in Table 2.

Besides simplicity, accuracy and time economy a significant advantage offered by the present method is the use of pure elemental sulfur directly as primary standard for preparing the solution of the titrant.

Preparation and Characterization of Dinitrosylmolybdenum Chelate Complexes

K. S. NAGARAJA and M. R. UDUPA*

Department of Chemistry, Indian Institute of Technology, Madras-600 036, India

(Received August 11, 1983)

Synopsis. Nitrosyl complexes of molybdenum with the composition $Mo(NO)_2L_2$ (HL=8-quinolinol, 2-mercaptobenzothiazole, 2-pyridinethiol, or ethylmercaptoacetate) have been prepared. The infrared spectral absorptions at 1740 and 1625 cm^{-1} indicate that the nitrogen monoxide groups are coordinated as NO^+ and are cis to each other. The ^1H-NMR spectral studies are also presented. The analytical, magnetic and spectral data suggest that molybdenum is in formal zero oxidation state with octahedral coordination completed by univalent bidentate ligands.

Nitrogen monoxide is a potent inhibitor for *nitrogenase*[1], a molybdoenzyme, and further nitrosyl complexes of molybdenum have been found by Zeuch[2,3] to be active disproportionatoin catalysts. With this view, the preparation and characterization of nitrosyl complexes of molybdenum with 8-quinolinol (Hoxine), 2-mercaptobenzothiazole (Hmbt), 2-pyridinethiol (Hmp), and ethylmercaptoacetate (Hetg) have been reported in the present note.

Experimental

The chemicals employed such as ammonium heptamolybdate, hydroxylammonium chloride, and ligands are pure and of Laboratory grade.

Preparation of Dinitrosylbis(8-quinolinato)molybdenum, Mo(NO)$_2$(oxine)$_2$. The interaction of ammonium heptamolybdate (0.5 g) with hydroxylammonium chloride (2.0 g) in *N,N*-dimethylformamide (20 ml) yielded green solution. 8-quinolinol (2.0 g) in ethanol (60 ml) was added to the above solution and refluxed for 1 h. The fine precipitate separated out was filtered, washed with ethanol and dried. Yield: 60%

The other complexes were also prepared by following the similar procedure as described above. The complexes are red in colour and the analytical data are listed in Table 1. The infrared, far infrared, UV-visible and ^1H-NMR spectra were recorded on Perkin-Elmer 257, Polytech IR 12, Carl Zeiss DMR 21 and Varian XL-100 spectrometers, respectively.

Results and Discussion

The complexes are found to be diamagnetic from the magnetic susceptibility measurements. The electronic transitions at 470 nm (Table 2) is attributed to charge transer transition involving $t_{2g}\rightarrow\pi^*$ (NO) or may be represented as $e(\pi^b)[d_{xz},d_{yz}]\rightarrow e(\pi^*)$ charge transfer, which has been identified[4] in a number of metal nitrosyl complexes. The other higher energy and intense absorptions are assigned[5] to internal ligand transitions. The strong absorptions observed at 1730 and 1625 cm^{-1} in the IR spectra (Fig.1) of the complexes are assigned to sym and asym stretching of NO groups. The bands suggest[6] that the NO groups are coordinated as NO^+ and further two NO groups are cis to each other. For trans configuration there will be only one mode of vibration. The strong absorption

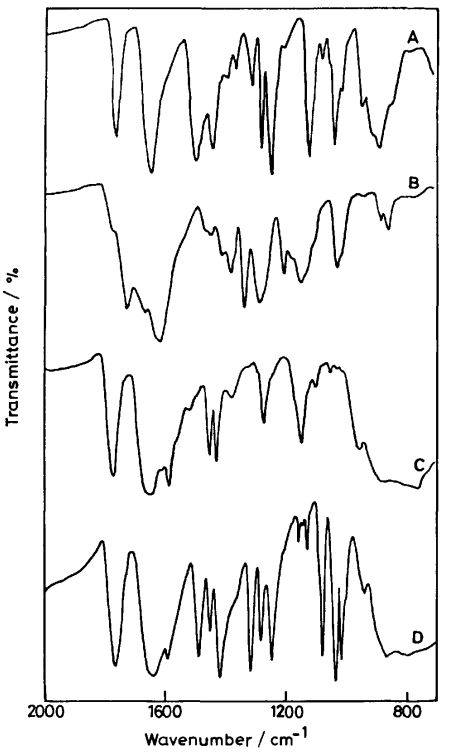

Fig. 1. Infrared spectra of (A) $Mo(NO)_2(oxine)_2$, (B) $Mo(NO)_2(etg)_2$, (C) $Mo(NO)_2(mp)_2$, and (D) $Mo(NO)_2(mbt)_2$.

in the IR spectrum of $Mo(NO)_2(oxine)_2$ at 1120 cm^{-1} (C–O) is the characteristic of the coordinated 8-quinolinol.[7] The bands at 540 and 315 cm^{-1} are due to Mo–O and Mo–N. The IR spectra of $Mo(NO)_2(mbt)_2$ and $Mo(NO)_2(mp)_2$ showed absorption at 1595 cm^{-1} (C=N) of heterocyclic ring. The absorptions in the far IR spectra at 390 and 235 cm^{-1} are due to Mo–S and Mo–N. $Mo(NO)_2(etg)_2$ has a shoulder peak at 1650 cm^{-1} (C=O). The lower value when compared with aliphatic ester (1730 cm^{-1}) indicates that the carbonyl oxygen is involved in coordination. Mo–O and Mo–S absorptions are found at 500 and 375 cm^{-1}. The absence of peak due to S–H in the last three complexes indicate deprotonation of the mercapto group. The IR spectral studies suggest that NO is coordinated as NO^+ and the complexes are of cis configuration. The univalent and bidentate nature of the ligands are also suggested by IR spectral studies.

^1H-NMR spectra of $Mo(NO)_2(mbt)_2$, $Mo(NO)_2(mp)_2$ and $Mo(NO)_2(etg)_2$ were recorded (Table 3) in $CDCl_3$ using TMS as reference. The spectrum of $Mo(NO)_2(oxine)_2$ is not recorded due to poor solubility. The NMR spectrum of $Mo(NO)_2(mbt)_2$ has a doublet of multiplet in the range δ 7.4—7.8 which is attributed to aromatic protons. The signals of the aromatic

Table 2. UV-visible[a] and IR[b] spectral data

Compound	λ_{max}^{c}/min (ε/dm^3 mol^{-1} cm^{-1})		$\nu_{(N-O)}$/ cm^{-1}
	$t_{2g}\rightarrow\pi^*$(NO)	Internal ligand transitions	
$Mo(NO)_2(oxine)_2$	460(200)	310(19980), 250(23450)	1700 s, 1640 s
$Mo(NO)_2(mbt)_2$	450(98)	340(15000), 285(19900)	1740 s, 1620 s
$Mo(NO)_2(mp)_2$	465(120)	275(14800), 240(20100)	1755 s, 1620 s
$Mo(NO)_2(etg)_2$	425(106)	305(12100), 250(17750)	1715 s, 1620 s

a) In methanol, b) KBr pellet.

Table 3. ^{1}H NMR spectral data

Compound	δ	Assignment
$Mo(NO)_2(mbt)_2$	7.40, 7.50, 7.54, 7.68, 7.80, 7.82, 7.84, 7.86	Aryl protons
$Mo(NO)_2(mp)_2$	7.78, 7.80, 7.82, 7.84, 7.88	Aryl protons
$Mo(NO)_2(etg)_2$	4.10, 4.14, 4.20, 4.22, 4.26	$-SCH_2-$ and $-OCH_2$
	1.14, 1.24, 1.28, 1.30, 1.32	$-COCH_2$ and $-CH_3$

protons in the spectrum of $Mo(NO)_2(mp)_2$ are observed at δ 7.82 as complex multiplet. $Mo(NO)_2(etg)_2$ has two sets of multiplet resonances in the range δ 4.2—4.8 (4H) and δ 1.40—1.80 (5H). The integrated ratio and the δ values suggest that the first set of peaks are due to $-SCH_2-$ and $-OCH_2-$ and second are due to $-COCH_2-$ and $-CH_3$ protons. In fact even the simple compound $Mo(NO)_2(Me_2dtc)_2$, which was prepared similarly, exhibited complex multiplet resonances in its ^{1}H and ^{13}C-NMR spectra, indicating cis configuration of the complex.[8]

The nitrosyls formulated as NO^+, the complexes contain $4d^6$ configuration with molybdenum in formal zero oxidation state. The presumed octahedral structure is consistent with low-spin molybdenum complex thus explaining diamagnetic behaviour.

The authors thank Council of Scientific and Industrial Research, India for the financial assistance.

A Model for Interactions of Amino Acid Side Chains with Watson-Crick Base Pair of Guanine and Cytosine. Crystal Structures of 9-(2-Carboxyethyl)guanine and Its Crystalline Complex with 1-Methylcytosine

Sigeo FUJITA, Akio TAKENAKA, and Yoshio SASADA*
Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokokama 227
(Received September 12, 1983)

A new compound, 9-(2-carboxyethyl)guanine, was successfully synthesized and its crystalline complex with 1-methylcytosine was prepared, in order to investigate the protein-nucleic acid interactions involving guanine base. The crystal structures of 9-(2-carboxyethyl)guanine (cx^{9}G) and of the complex of cx^{9}G with 1-methylcytosine (cx^{9}G:m^{1}C) were determined by the X-ray analysis. Crystal data: cx^{9}G, $P2_1/c$, a=12.221(3), b=11.022(2), c=6.961(2) Å, β=100.22(2)°; cx^{9}G:m^{1}C, $P\bar{1}$, a=8.932(1), b=12.370(1), c=7.139(1) Å, α=85.01(1), β=99.21(1), γ=86.64(1)°. In cx^{9}G, the carboxyl group is doubly hydrogen-bonded with N(2) and N(3) of the guanine moiety of the adjacent molecule, N(2)-H···O distance being 2.939(5) Å and N(3)···H-O 2.660(5) Å for N···O. In cx^{9}G:m^{1}C, the guanine moiety and 1-methylcytosine form a Watson-Crick base pair. The carboxyl group takes an O=C-OH antiperiplanar conformation and is hydrogen-bonded with N(7) of guanine in the adjacent base pair. This hydrogen bond distance is very short, 2.634(2) Å, though the unfavorable conformation of the carboxyl group. This may suggest the marked preference of the carboxyl group for N(7) of guanine in the Watson-Crick base pair. On the basis of the geometrical data found in the present crystals, some possible models of interactions were constructed and examined, for example, aspartic or glutamic acid residue in the major groove of double stranded DNA.

In order to understand the mechanism of the specific interactions between nucleic acid and protein, we have been engaged in studying on the elementary binding patterns between their components by X-ray analyses of the model crystals.[1-9] But most of them are concerned with binary systems.[1-7] As the structural basis of the interactions between protein and double stranded region of nucleic acid, the systems containing amino acid side chains and Watson-Crick base pairs are important. Two model crystals for the ternary systems of adenine-thymine-carbamoyl group[8] and of adenine-uracil-carboxyl group[9] have been reported, but no Watson-Crick base pair has been obtained.

On the other hand, model systems containing guanine base have been little studied because guanine derivatives are poorly soluble for any organic solvent and in addition appropriate guanine derivatives with amino acid side chains are not known. We have succeeded in synthesizing a new compound, 9-(2-carboxyethyl)guanine (cx^{9}G), which is a starting material to prepare model crystals covalently linked with amino acid and enables us to examine the interactions involving guanine base.

This paper describes the interaction modes between the Watson-Crick base pair of guanine-cytosine and amino acid side chains of glutamic acid and aspartic acid.

Experimental and Structure Determination

Materials. The reaction of 2-*N*-acetylguanine with β-propiolactone in the presence of 4-dimethylaminopyridine resulted in 2-carboxyethylation of the former. After purification on a silica gel column, the product was deacetylated with 6.0 equivalent of NaOH to give 9-(2-carboxyethyl)guanine (cx^{9}G). Colorless needle-like crystals of cx^{9}G were obtained from a water-acetic acid (1:1) solution. Complex of cx^{9}G and 1-methylcytosine was prepared in the dimethyl sulfoxide solution containing equimolar amounts of both components. Colorless plate-like crystals were deposited from the solution by the vapor diffusion method with ethyl acetate.

pKa Measurement. A mixture solution of 20.0 cm^3 of cx^{9}G (0.0050 mol dm^{-3}) and 2.0 cm^3 of NaOH (0.10 mol dm^{-3}) was titrated with HCl (0.10 mol dm^{-3}) and at each step the value of pH was recorded using Toshiba-Beckman pH meter. The pKa values were evaluated to be 4.1 for the carboxyl group and 2.5 for the guanine moiety from least-squares fitting.

X-Ray Work. Oscillation and Weissenberg photographs showed that the cx^{9}G crystals were twin in which the c axes of the twin components coincided but their b axes were antiparallel to each other and almost equal quantities of the components were included. Densities of the crystals were measure by the flotation method in a hexane and tetrachloromethane solution. Crystal data are listed in Table 1.

Data collection was carried out for both crystals on a Rigaku four-circle diffractometer with graphite-monochromated Cu $K\alpha$ radiation (λ=1.54184 Å). Five reference reflections monitored showed no significant intensity deterioration during the data collection. For the crystal of cx^{9}G, intensities of only one of the twin components were carefully measured; reflections with abnormally high background or unresolved reflections were excluded. Corrections were made for the Lorentz and polarization factors, but not for absorption effects. The standard deviations were estimated by the equation of $\sigma^2(F_o)=\sigma_p^2(F_o)+qF_o^2$, where q was derived from the variation of the monitored reflections and $\sigma_p(F_o)$ was due to counting statistics.[10] The experimental conditions are summarized in Table 1.

Structure Determination. The structures were solved by the direct method with the program of MULTAN 78[11] and the atomic parameters were refined by the full-matrix least-squares method. The quantity minimized in the refinement was $\sum\omega(|F_o|-|F_c|)^2$ with $\omega=1/\sigma^2(F_o)$. In the refinement, the zero-reflections with $|F_c|>F_{lim}$ were included by assuming $F_o=F_{lim}$ and $\omega=\omega(F_{lim})$, F_{lim} being the observed threshold value (Table 1). All the hydrogen atoms found on difference maps were included in the refinement. Since the $hk0$ reflections of

the crystal of cx^{9}G consist of the contributions from the both twin components, the layer scale of $hk0$ reflections was also refined. Initial value of $1/\sqrt{2}$ was evaluated by assuming 1 : 1 twin and it converged to be 0.6062 in the last some cycles of the refinement.

The space group of the complex was assumed to be $P\bar{1}$, as the normalized structure factor indicated the centrosymmetric distribution. The R value and the maximum shift of the parameters are given in Table 1. The final atomic parameters are given in Tables 2 and 3.[12] The atomic scattering factors were taken from Ref. 13.

Results and Discussion

Molecular and Crystal Structure of 9-(2-Carboxyethyl)-guanine. The bond distances and angles are shown in Fig. 1. The guanine moiety is not protonated by the carboxyl group, as expected from the lower dissociation constant of guanine moiety (pKa= 2.5). The dimensions of the carboxyl group are typical of the non-dissociated form, and the hydrogen atom of the carboxyl group appears on a difference map. The guanine moiety is planar within 0.020 Å, and its bond distances and angles are similar to those of the guanine derivatives such as 9-ethylguanine[14] and

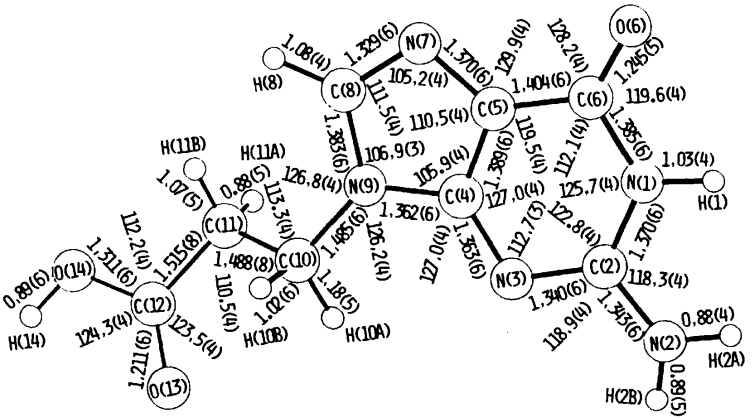

Fig. 1. Bond distances (l/Å) and angles (ϕ/°) in 9-(2-carboxyethyl) guanine. E.s.d.'s are shown in parentheses.

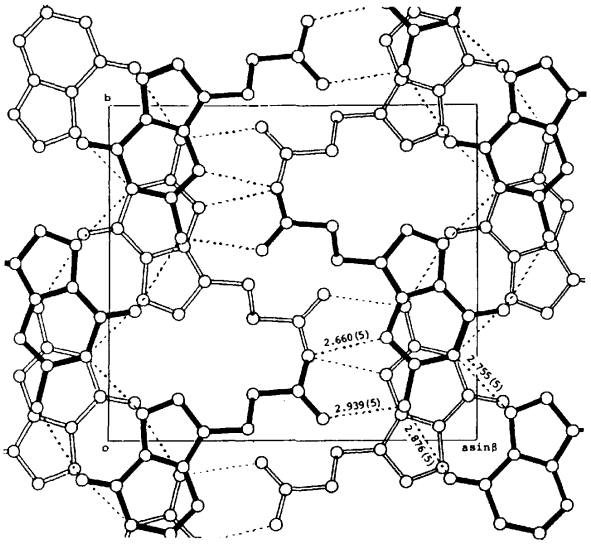

Fig. 2. Crystal structure of 9-(2-carboxyethyl) guanine, projected along the c axis. The broken lines indicate the hydrogen bonds, distances (l/Å) being added.

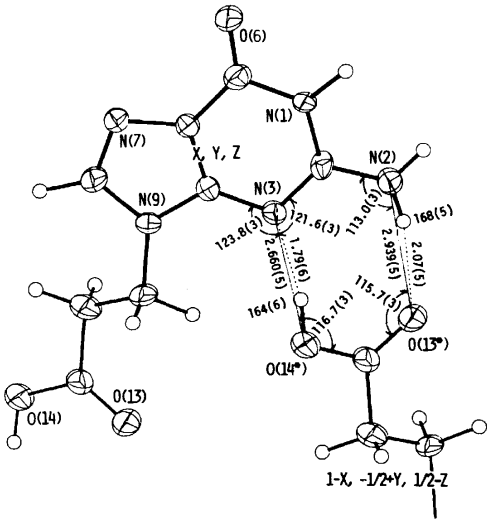

Fig. 3. A projective view of binding mode of the carboxyl group to the guanine moiety. Hydrogen bond distances (l/Å) and angles (ϕ/°) are shown with e.s.d.'s in parentheses. Thermal ellipsoids are drawn at 50% probability level.

guanosine.[15] As in guanine hemihydrate crystal,[16] the C(5)-N(7)-C(8) angle is slightly expanded due to the hydrogen bond to N(7). The torsion angles are 184.2(4)° for C(5)-C(4)-N(9)-C(10), 215.2(5)° for C(4)-N(9)-C(10)-C(11), 184.1(4)° for N(9)-C(10)-C(11)-C(12), and 162.4(4)° for C(10)-C(11)-C(12)-O(14).

The crystal structure and the hydrogen bond geometry are shown in Figs. 2 and 3. The carboxyl group of the adjacent molecule interacts with N(2) and N(3) of the guanine moiety through O···H-N and O-H···N hydrogen bonds. The dihedral angle between the least-squares planes of the purine ring and carboxyl group is 24.6(2)°. The guanine ring related by the 2_1 screw symmetry are linked by hydrogen bonds between N(1) and N(7) and between N(2) and O(6). These hydrogen bonds form a sheet parallel to the ab plane. There is no hydrogen bonds between the sheets.

Molecular and Crystal Structure of the Complex of 9-(2-Carboxyethyl)guanine and 1-Methylcytosine. The bond distances and angles are shown in Fig. 4. The carboxyl group takes an antiperiplanar O=C-O-H conformation.[17] This conformation is less stable by 2—4 kcal mol^{-1} than the synperiplanar form[18] and is usually found when the hydroxyl group participates in the intramolecular hydrogen bond.[19] The present crystal is a rare case where the hydroxyl group is hydrogen-bonded to the adjacent molecule. The bond distances of C=O and C-O of the carboxyl group are significantly different. The O=C-O angle is slightly contracted and the C-C-O angle is slightly expanded, in contrast to the synperiplanar O=C-O-H form. The geometry may be typical of the antiperiplanar carboxyl group without constrain of intramolecular hydrogen bonding.

The purine ring is planar within 0.030 Å. The bond distances and angles of the guanine moiety are similar to those of cx^{9}G in the preceding section. The torsion angles are 185.2(2)° for C(5)-C(4)-N(9)-C(10), 60.4(3)° for C(4)-N(9)-C(10)-C(11), 59.4(2)° for N(9)-C(10)-C(11)-C(12) and 12.7(3)° for C(10)-C(11)-C(12)-O(14).

1 cal=4.186 J

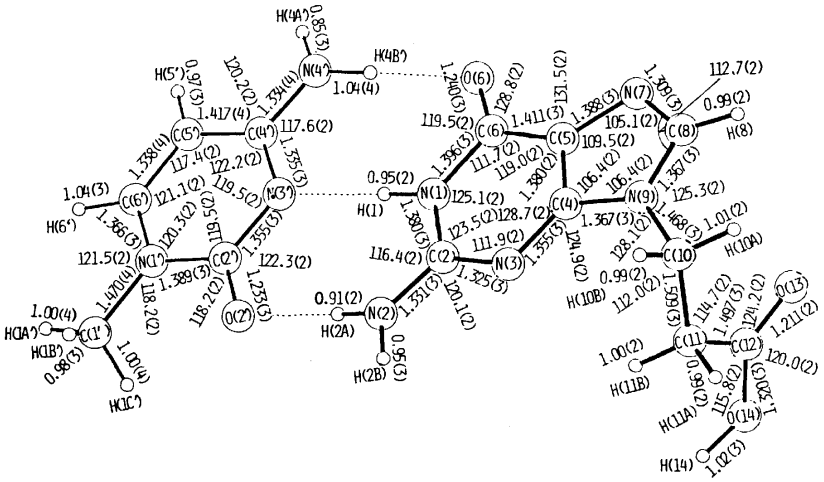

Fig. 4. Bond distances (l/Å) and angles (ϕ/°) in 9-(2-carboxyethyl)guanine : 1-methylcytosine complex. E.s.d.'s are shown in parentheses.

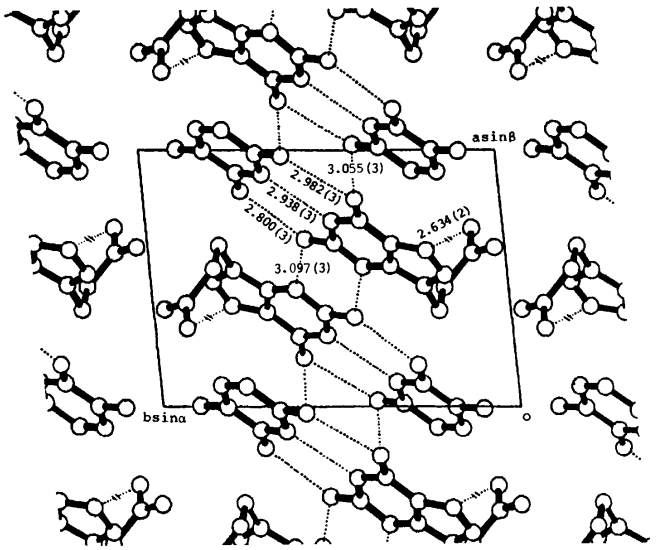

Fig. 5. Crystal structure of 9-(2-carboxyethyl) guanine: 1-methylcytosine complex projected along the c axis. Hydrogen bond distances (l/Å) are indicated.

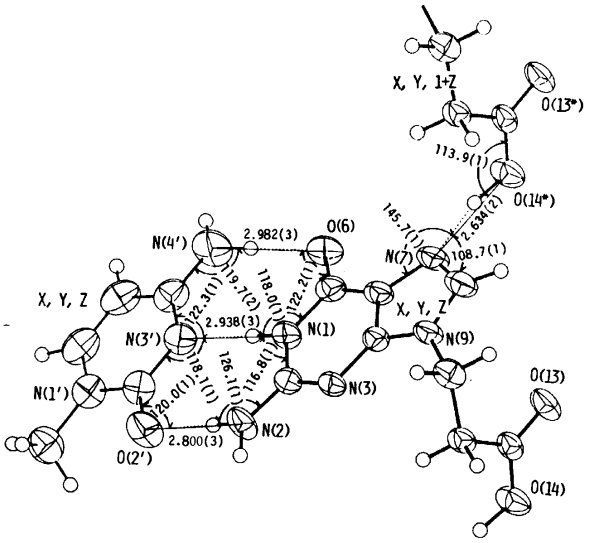

Fig. 6. A projective view of binding mode of the carboxyl group to the guanine-cytosine Watson-Crick base pair. Hydrogen bond distances (l/Å) and angles (ϕ/°) are shown with e.s.d.'s in parentheses. Thermal ellipsoids are drawn at 50% probability level.

The methylene chain is folded in contrast to that of cx^{9}G.

The bond distances and angles of 1-methylcytosine in the present complex are in good agreement with those of 1-methylcytosine[20] and cytidine.[21] The pyrimidine ring is essentially planar.

The crystal structure and hydrogen bond geometry are shown in Figs. 5 and 6. The guanine moiety and 1-methylcytosine form a Watson-Crick base pair through N(2)-H···O(2'), N(1)-H···N(3'), and O(6)···H-N(4') hydrogen bonds. The hydrogen bond distances are similar to those found in the complexes of 9-ethylguanine: 1-methylcytosine,[22] 9-ethylguanine: 1-methyl-5-fluorocytosine,[22] 9-ethylguanine: 1-methyl-5-bromocytosine,[23] deoxyguanosine: 5-bromocytidine,[24] and some salts of guaninyl-3',5'-cytidine.[25] The carboxyl group of the adjacent molecule interacts with N(7) of guanine in the Watson-Crick pair by O-H···N hydrogen bond. The hydrogen bond distance is very short, although the carboxyl group takes an unfavorable conformaion. This suggests that there is a marked preference between the carboxyl group and N(7) of guanine.

The carbonyl oxygen O(13) does not participate in any hydrogen bond; the closest contact 2.23(3) Å is observed with H(8) of the guanine moiety at ($-x$, $-y$, $1-z$). The base pairs form a ribbon extending along the [102] axis by the hydrogen bonds N(2)-H···N(3) and N(4')-H···O(6) around inversion centers at (1/2, 1/2, 0) and (1, 1/2, 1). The O(2') atom of 1-methylcytosine points to C(11) at ($1-x$, $1-y$, $-z$), the distance being 3.147(4) Å.

Hydrogen Bonding between the Watson-Crick Base Pair and Acidic Side Chain of Amino Acid. The present X-ray analyses of the model crystals are the first study on the interaction of amino acid side chain with guanine base, especially with guanine-cytosine Watson-

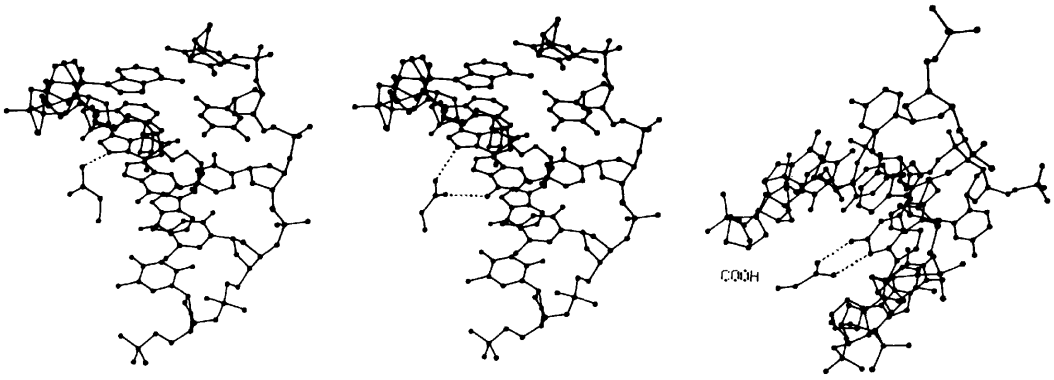

Fig. 7. Possible model fitting for the binding of the carboxyl group with guanine in the major and minor grooves of B-DNA. a) The carboxyl group takes an antiperiplanar conformation in the major groove, b) it is hydrogen-bonded with two adjacent base pairs in the major groove, and c) it is doubly hydrogen-bonded with guanine in the minor groove.

Crick pair. The model compound cx^{9}G contains the guanine moiety (p*K*a=2.5) and propionic acid moiety (p*K*a=4.1), the dissociation constants of which are comparable to those of guanosine nucleotide derivatives[26] and acidic side chains in the derivatives of amino acid or peptide,[27] respectively. So, the chemical behavior of each part of the present model compound is similar to that of the corresponding derivatives. Thus, the interaction found in this study may be realized in the protein-nucleic acid interactions.

The specificity in protein-nucleic acid interactions would arise from suitable combination of preferred hydrogen bonds between their components which are supported by the three-dimensional structure of macromolecules. It is important to examine if the hydrogen bonding found in the model crystals could be permitted for the bases in the particular secondary or tertiary structure of nucleic acids.

The carboxyl group was inserted in the major groove of B-DNA using the interaction geometry found here. Model fitting has been done successfully with the antiperiplanar O=C-O-H conformation (Fig. 7a). By the rotation of the carboxyl group around the O-C bond followed by slight translation, the other oxygen atom can form a hydrogen bond with the adjacent base in the same strand, as shown in Fig. 7b where adenine amino group is a binding site. Thus, the present hydrogen bond geometry may be an interaction model of guanine-cytosine base pair in the major groove with acidic side chain of proteins.

As the model for binding of the carboxyl group in the minor groove, the double hydrogen bonds with N(2) and N(3) of guanine, found in the crystal of cx^{9}G, might be useful, because the formation energy of this type is greater than any other double hydrogen bonds (ΔH_f= -15.0 kcal mol^{-1} calculated by the CNDO/2 method[28] while that for the Watson-Crick pairing is -18.2 kcal mol^{-1}). Although this groove is rather tight, the model fitting was also successful with slight changes of the binding geometry, as shown in Fig. 7c. As any double hydrogen bonds of carboxyl group in the minor groove can not be set up for the other nucleic acid bases, the present model could take a part in recognition of particular base sequences.

Solvent Effects on Optical and ESR Spectra of One-Electron Reduced Species of Cobalt(III) and Manganese(III) Tetraphenylporphyrins Produced by γ-Radiolysis at 77 K

Mikio Hoshino,* Shiro Konishi, and Masashi Imamura
Solar Energy Research Group, The Institute of Physical and Chemical Research, Wako, Saitama 351
(Received October 31, 1983)

One-electron reduction by γ-ray irradiation of cobalt(III) and manganese(III) tetraphenylporphyrins (ClCo(III)TPP, ClMn(III)TPP, and IMn(III)TPP) in ethanol and MTHF(2-methyltetrahydrofuran) solutions at 77 K results in the reduction of the central metals of these porphyrins. From the optical and ESR measurements, the reduced species are found to retain the axial anion, Cl^- or I^-, in MTHF but not in ethanol. The absorption spectroscopic studies of these porphyrins in ethanol solutions indicate that the axial halide ion is displaced by an ethanol molecule prior to γ-ray irradiation.

Reduced and oxidized porphyrins generated chemically and electrochemically have been subjected to numerous spectroscopic studies because of their importance as key intermediates in biological reactions.[1] In particular, optical absorption and ESR spectroscopic studies provide useful information on thir electronic structures and chemical properties. However, chemical reduction and oxidation and electrolysis techniques are unable to be applied to observation of unstable reduced and oxidized species in fluid solutions.

Radiation chemical techniques have been successfully applied to the detection of one-electron oxidation and reduction products of inorganic compounds,[2-7] metalloporphyrins,[8,9] and biologically important substances.[10,11] Recently we have systematically carried out optical and ESR measurements of one-electron reduced and oxidized products of metalloporphyrins and cobaloximes formed by γ-radiolysis of rigid solutions at 77 K.[12-19] Since molecules are immobilized in the low-temperature rigid solutions, the reduced or oxidized species are trapped as stable products and are subjected to the conventional spectroscopic measuremens.

In previous papers[12,16] we have shown that ClCo(III)TPP and ClMn(III)TPP in a less-polar solvent, MTHF, are reduced upon γ-ray irradiation at 77 K to from $Cl^-\cdots$Co(II)TPP and $Cl^-\cdots$Mn(II)TPP in which the anion Cl^- is confined in the axial position. These results imply that ClCo(III)TPP and ClMn(III)TPP hardly undergo ionic dissociation in MTHF.

In a preliminary experiment, we found that the absorption spectra of ClCo(III)TPP, ClMn(III)TPP, and IMn(III)TPP in ethanol solutions distinctly differ from those in MTHF solutions. The purpose of the present study is to investigate the one-electron reduced species of ClCo(III)TPP, ClMn(III)TPP, and IMn(III)TPP, produced by γ-ray irradiation at 77 K in a polar solvent, ethanol. The optical absorption and ESR spectra of the reduced species in ethanol are presented for the comparison with those in MTHF.

Experimental

Metalloporphyrins, ClCo(III)TPP, ClMn(III)TPP, and IMn(III)TPP, were prepared according to literature[20,21] and purified by column chromatography on Sephadex LH 20. 2-Methyltetrahydrofuran was purified by fractional distillation and stored on Na-K alloy to remove traces of water. Ethanol was used as supplied.

Optical absorption and ESR spectra were recorded on a Cary 14 spectrophotometer and a JEOL JES FE-3AX X-band spectrometer, respectively.

High-purity quartz cells having an optical pathlength of 0.1 mm were used for optical measurements. Two Kinds of ESR tubes were used: one is made of high-purity quartz and the other, specially prepared glass in which no hydrogen atoms are formed upon γ-ray irradiation at 77 K. A 1.2 kCi ^{60}Co source was used for γ-ray irradiation at a dose rate of *ca.* 53 kr min^{-1}.

Sample solutions containing 10^{-3} M (1 M=1 mol dm^{-3}) porphyrins were degassed and frozen in a Dewar vessel before γ-ray irradiation. A broad absorption due to trapped electrons formed by irradiation was eliminated by photobleaching before optical measurements of the reduced species. For the study of chemical reactions occurring in the irradiated solutions at elevated temperatures, the sample cells and tubes were warmed slightly by withdrawing them from liquid nitrogen for suitable time.

Results

Absorption Spectra. Figure 1 shows the absorption spectra of ClCo(III)TPP in ethanol solution before and after γ-ray irradiation at 77 K. The absorption

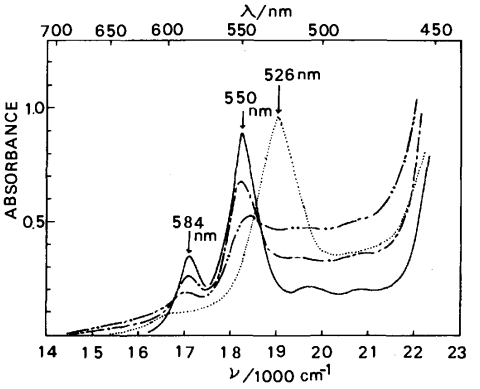

Fig. 1. Absorption spectra of ClCo(III)TPP in ethanol solution at 77K before γ-ray irradiation (——), after γ-ray irradiation for 60 min (— — —) and 150 min (— · —), and after once warming the irradiated solution for 2.0 min (·····).

peaks of ClCo(III)TPP are located at 550 and 584 nm. Except for band narrowing, the spectrum at 77 K is in good accord with that measured at room temperature. Upon γ-ray irradiation the intensities of these peaks decrease and a broad absorption appears over the wavelength region from 450 to 700 nm; the spectral change shows isosbestic points at 595 and 537 nm. The spectrum measured after irradiation for 150 min still indicates the presence of ClCo(III)TPP. Warming of the irradiated solution for 2 min gives the spectrum at 77 K shown by a dotted line in Fig. 1. Since the spectrum is the same as that of authentic Co(II)TPP in ethanol solution at 77 K, the broad absorption in 450—700 nm observed after irradiation is considered to be due to the one-electron reduced species of ClCo(III)TPP, which is transformed to Co(II)TPP at elevated temperatures. The absorption spectrum of the warmed solution shows the absence of ClCo(III)TPP, indicating that the remaining ClCo(III)TPP is reduced by solvent radicals formed upon γ-ray irradiation at 77 K.

An MTHF solution of ClCo(III)TPP at 77 K gives absorption peaks at 557 and 598 nm. The spectrum measured after γ-ray irradiation for 50 min shows the formation of a reduced species having an absorption peak at 513 nm. The reduced species changed to Co(III)TPP after warming the irradiated solution to room temperature.[12] It is noted that the reduced species of ClCo(III)TPP in MTHF exhibits a clear absorption peak at 513 nm, while that in ethanol, a broad band in the Q band region.

Figure 2 shows the absorption spectra of IMn(III)-TPP in MTHF measured before and after γ-ray irradiation at 77 K. The spectrum of IMn(III)TPP at 77 K closely resembles that at room temperature; the peak maxima are located at 550, 568, 602, and 646 nm in the Q band region. After γ-ray irradiation for 30 min the solution gives a new spectrum at 77 K. Since the spectrum measured at 77 K after once warming the irradiated solution for 1.0 min was identical with that of Mn(II)TPP prepared chemically, the new band is ascribed to the one-electron reduced species of IMn-(III)TPP, which is transformend to Mn(II)TPP at elevated temperatures.

Figure 3 shows the absorption spectra of IMn(III)-

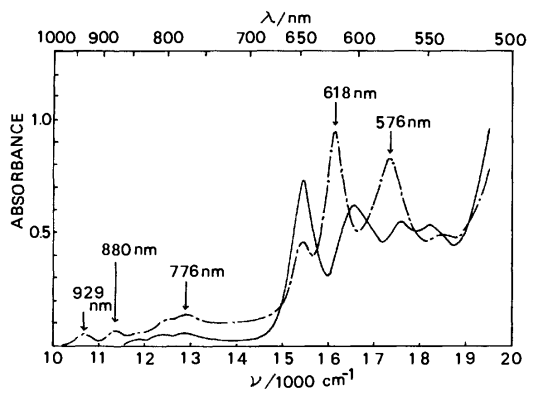

Fig. 2. Absorption spectra of IMn(III)TPP in MTHF solution at 77 K before (——) and after γ-ray irradiation for 30 min (— - —).

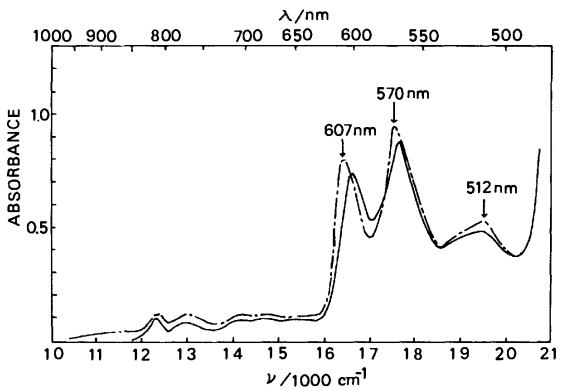

Fig. 3. Absorption spectra of IMn (III)TPP in ethanol solution at 77K before (——) and after γ-ray irradiation for 30 min (— - —).

TPP in ethanol solution before and after γ-ray irradiation at 77 K. No marked differences were observed between the two spectra of IMn(III)TPP at room temperature and 77 K. The location of the major absorption peaks in ethanol solution is fairly different from that in MTHF solution. γ-Ray irradiation of the solution gives rise to a new spectrum having major absorption peaks at 570 and 607 nm. The spectrum measured after once warming the irradiated solution shows the absorption maxima at 568 and 606 nm at 77 K, indicating the formation of Mn(II)TPP.

The absorption spectrum of ClMn(III)TPP in MTHF solution markedly differs from that of IMn-(III)TPP in MTHF, probably due to the effects of the different axial ions, Cl^- and I^-. Contrary to the MTHF solutions, ethanol solutions of ClMn(III)TPP and IMn(III)TPP give the same absorption spectrum. This result is interpreted by assuming that both ClMn-(III)TPP and IMn(III)TPP undergo ionic dissociation in ethanol solutions to from a common species, $Mn(III)TPP^+(EtOH)_2$, in which the axial positions are occupied by two ethanol molecules.[22,23]

ESR Spectra of γ-Irradiated Solutions. Figure 4A shows the ESR spectrum observed for ethanol solution of ClCo(III)TPP γ-irradiated at 77 K. The hyperfine structure of a cobalt atom (I=7/2) appearing in the parallel component reveals that the central metal, Co(III), in ClCo(III)TPP is reduced to Co(II). The ESR parameters determined for the reduced species are $g_{/\!/}=2.010\pm0.005$, $A_{/\!/}=105\pm5\times10^{-4}$ cm^{-1}, $g_\perp\simeq2.45$, and $A_\perp\simeq57\times10^{-4}$ cm^{-1}. Figure 4B shows the ESR spectrum measured at 77 K after warming the irradiated solution for 1.0 min. This spectrum is identical with that of authentic Co(II)TPP which is expected to have a structure of $Co(II)TPP(EtOH)_2$ in ethanol solution at 77 K. The ESR parameters are $g_{/\!/}=2.024\pm0.005$, $A_{/\!/}=99\pm5\times10^{-4}$ cm^{-1}, $g_\perp\simeq2.45$, and $A_\perp\simeq57\times10^{-4}$ cm^{-1}.

Figure 5A shows the ESR spectrum observed for the γ-irradiated MTHF solution of IMn(III)TPP at 77 K. The spectrum shows well-resolved six hyperfine lines due to ^{55}Mn (I=5/2) at the g=6 region in addition to an intense signal from solvent radicals at g=2.0. The absence of the hyperfine coupling due to the iodine

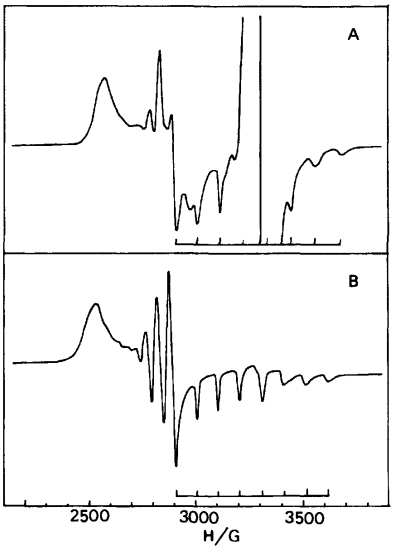

Fig. 4. ESR spectra of ClCo(III)TPP solution in ethanol measured at 77K after 20 min γ-irradiation (A), followed by 2.0 min warming of the irradiated solution (B).

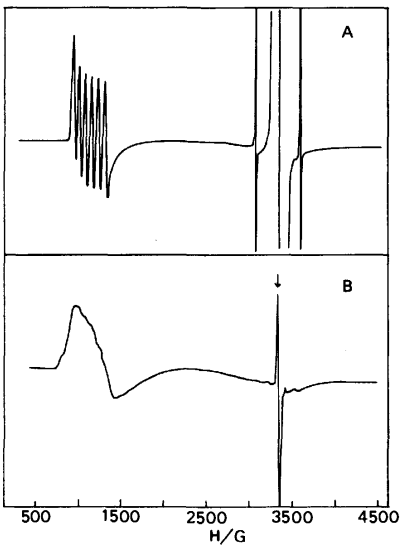

Fig. 5. ESR spectra IMn(III)TPP solution in MTHF measured at 77K after 20 min γ-irradiation (A), followed by 2.0 min warming of the irradiated solution (B). An arrow in B indicates the signal from color centers in quartz tube.

atom implies that the I-Mn bond in IMnTPP is dissociated by the dissociative electron attachment. Figure 5B shows the ESR spectrum measured for the γ-irradiated solution at 77 K after once warming it to remove signals due to solvent radicals. The low-field signal at g=6 becomes broad and the high field signals becomes observable by warming the irradiated sample. The ESR spectrum is the same as that of authentic Mn(II)TPP in MTHF solution at 77 K.

Figure 6A shows the ESR spectrum of a γ-irradiated ethanol solution of IMn(III)TPP at 77 K. The spectrum shows less-resolved six hyperfine lines at g=6. When the irradiated solution is warmed for 1.0 min

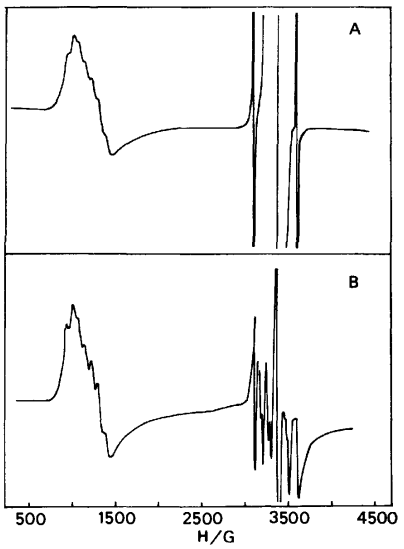

Fig. 6. ESR spectra of IMn(III)TPP solution in ethanol measured at 77K after 20 min γ-irradiation (A), followed by 2.0 min warming of the irradiated solution.

and recooled to 77 K, the signal intensity at g=6 slightly decreases and a new signal due to unidentified manganese(II) species appears at $g\simeq2$. The line shape of the low-field signals is invariant even after warming the irradiated solution. These results are in good accord with those obtained for the γ-irradiated Mn(III)TPP solution in deuterated methanol at 77 K.[9]

A γ-irradiated ethanol solution of ClMn(III)TPP gives the same ESR spectra, both before and after warming, as those shown in Fig. 6A and 6B. This result implies that the common species is produced from the ethanol solutions of ClMn(III)TPP and IMn(III)TPP upon γ-ray irradiation. Taking account of the optical measurements, $Mn(III)TPP^+(EtOH)_2$ is considered to be a precursor of the reduced species in the ethanol solutions.

Discussion

Formation of One-electron Reduced Species by γ-Ray Irradiation. Solid ethanol solutions exposed to γ-rays at 77 K release mobile electrons (e_m^-) according to:

$$CH_3CH_2OH \longrightarrow CH_3CH_2OH^+ + e_m^-$$

The ethanol cation radical, $CH_3CH_2OH^+$, undergoes ion-molecular reaction with a parent ethanol molecule to form a 2-hydroxyethyl or ethoxyl radical and a protonated ethanol.[13] The mobile electrons are either trapped in the solution or captured by solute molecules (S) if any to form trapped electrons (e_t) or solute anions (S^-), respectively:

$$e_m^- \longrightarrow e_t^-$$

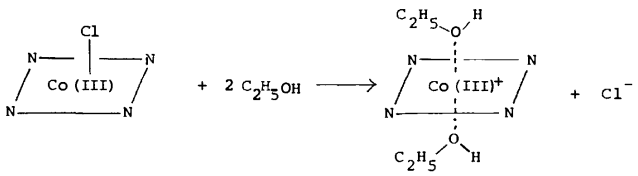
$$e_m^- + S \longrightarrow S^-.$$

The similar processes take place in MTHF solution, too. γ-Irradiation of metalloporphyrin solutions in ethanol or MTHF at 77 K, therefore, produces one-electron reduced metalloporphyrins along with e_t^- and radicals originated from ethanol or MTHF molecules. The absorption spectra of one-electron reduced

metalloporhyrins in ethanol are measured after photobleaching of e_t which has a broad absorption band centered around 530 nm.[25,26]

Identification of One-electron Reduced Species at 77 K. The one-electron reduced product of ClCo(III)TPP in MTHF at 77 K has a structure of a constrained complex in which the anion, Cl^-, is confined in the axial position of Co(II)TPP.[12] The ESR spectrum of the constrained complex is characteristically different from that of authentic Co(II)TPP in MTHF solution at 77 K. The ESR parameters of the constrained complex are qualitatively interpreted by assuming that A_1^2 state of Co(II)TPP is mixed with the higher excited states[27] such as E^4 by electrostatic interaction due to the axial anion.

The one-electron reduced species of ClCo(III)TPP in ethanol solution at 77 K, on the other hand, does not form the constrained complex. The fact that the ESR parameters of the one-electron reduced species in ethanol considerably resemble those of authentic Co(II)TPP suggests that Cl^- is located far from the cobalt atom in Co(II)TPP. The paperelectrophoresis studies revealed that ClCo(III)TPP in alcohol solution is dissociated as[28]



Consequently ClCo(III)TPP in ethanol solution at 77 K is regarded as having a form of $Co(III)TPP^+(EtOH)_2$. When the ethanol solution is exposed to γ-rays, $Co(III)TPP^+(EtOH)_2$ is reduced by a mobile electron to form $Co(II)TPP(EtOH)_2'$ which is transformed to $Co(II)TPP(EtOH)_2$ by warming the irradiated solution. Since $Co(III)TPP^+(EtOH)_2$ may accept a mobile electon without accompanying displacement of axial ethanol molecules owing to high viscosity of the solvent at 77 K, the distance, $Co-O\begin{smallmatrix}H\\ \diagdown C_2H_5\end{smallmatrix}$, in $Co(III)TPP^+(EtOH)_2'$ is expected to be almost the same as that in $Co(III)TPP^+(EtOH)_2$. Taking account of the electrostatic interaction between a positively charged Co(III) atom and an oxygen atom of axial ethanol, the Co-O distance in $Co(III)TPP^+(EtOH)_2$ is reasonably assumed to be shorter than that in $Co(II)TPP(EtOH)_2$. We therefore conclude that the Co-O distance in $Co(II)TPP(EtOH)_2'$ is shorter than that in $Co(II)TPP(EtOH)_2$. The transformation of $CO(II)TPP(EtOH)_2'$ to $Co(II)TPP(EtOH)_2$ by warming presumably results in a small displacement of axial ethanol molecules and, therefore, in the absorption and ESR spectral change of the one-electron reduced product of ClCo(III)TPP in ethanol at elevated temperatures.

The ESR spectrum observed for the γ-irradiated ethanol solutions of IMn(III)TPP at 77 K shows six hyperfine lines due to ^{55}Mn at $g=6$, indicating the formation of high-spin Mn(II)TPP which has a d^5-electron configuration. For MTHF solution, the structure of the reduced species is concluded to be $I^-\cdots Mn(II)TPP$ on the basis of the previous ESR studies on one-electron reduced species of ClMn(II)-TPP and BrMn(III)TPP; the two species give well-resolved ESR spectrum at $g=6$ owing to the effects of the axial anions.[16] Warmig the irradiated IMn(III)-TPP solution gives the same ESR spectrum at 77 K as that for chemically prepared Mn(II)TPP. This result indicates that liberation of I^- from $I^-\cdots$ Mn(II)TPP occurs by warming. The one-electron reduced species of IMn(III)TPP in ethanol solution, on the other hand, gives less resolved ESR spectrum at $g=6$, which is in good accord with that of chemically prepared Mn(II)TPP. We concluded that axial anion I^- is located far from the central Mn atom in the ethanol solution.

Conclusion

The absorpion spectra of ClCo(III)TPP and IMn(III)TPP in ethanol solutions are essentially different from those in MTHF solutions. The optical and ESR studies on their one-electron reduced species produced by γ-ray irradiation at 77 K show that these species retain axial anions in MTHF whereas not in ethanol. This fact leads to the conclusion that ClCo(III)TPP or IMn(III)TPP has already been dissociated in ethanol solutions into $Co(III)TPP^+(EtOH)_2$ and Cl^- or $Mn(III)TPP^+(EtOH)_2$ and I^- prior to acceptance of an electron ejected from solvent molecules by γ-ray irradiation.

The Crystal Structure of a New Thiosilicate of Thallium, $TlInSiS_4$

Yuji NAKAMURA,* Atsushi ARUGA, Izumi NAKAI, and Kozo NAGASHIMA
Department of Chemistry, The University of Tsukuba, Ibaraki, 305
(Received November 1, 1983)

The crystal structure of a new synthetic compound with the composition of $TlInSiS_4$ has been determined. The crystal is orthorhombic, and the space group is *Pbnm* with $Z=8$. The cell dimensions are $a=11.74(1)$, $b=17.038(7)$, and $c=7.285(3)$ Å. The structure was solved by the Patterson method and refined to a final R-value of 0.074 for all the observed reflections. The structure is characterized by a sheet structure built up from alternating infinite $(InS_3)_n$ chains and dimeric Si_2S_6 groups. The Si_2S_6 groups consist of two SiS_4 tetrahedra sharing an edge. The thallium atoms are situated between the sheets and are surrounded by nine sulfur atoms at distances between 3.293 and 3.957 Å.

Studies of ternary and quaternary chalcogenides containing 4B elements in the periodic table have been extensively carried out during the last two decades. Numerous phases have been found, and the determinations of their crystal structures have provided evidence for the existence of various anionic groups formed by arrangements of thioanions. For example, it is well known that there are SiS_4^{4-},[1] GeS_4^{4-}[1-3], and SnS_4^{4-}[4] (isolated tetrahedral anions), $Ge_2S_7^{6-}$[5] and $Sn_2S_7^{6-}$[5] (dimeric anions consisting of two tetrahedra sharing one corner), $Ge_2S_6^{4-}$[6,7], and $Sn_2S_6^{4-}$[7] (dimeric isolated anions consisting of edge-sharing tetrahedra), $Si_4S_{10}^{4-}$[8] and $Ge_4S_{10}^{4-}$[8-10] (adamantane-like anions), and $(GeS_3)_n^{2n-}$[11,12] (infinite chains).

In order to elucidate systematically the crystal chemistry of those chalcogenides, we have undertaken the preparation of Tl-III-IV-S_4 type compounds with III=Al, Ga, In; IV=Si, Ge by the conventional evacuated-silica-tube method. This study produced single crystals of five new compounds with a quaternary composition.[13] The crystal structure of $TlInSiS_4$ is described in the present paper.

Experimental

A tabular crystal with approximate dimensions of 0.050×0.175×0.125 mm was used for the X-ray investigations. The rotation and Weissenberg photographs with Cu $K\alpha$ radiation showed an orthorhombic symmetry with systematic absences of $h+l=2n+1$ for $(h0l)$ reflections and of $k=2n+1$ for $(0kl)$ reflections, so that possible space groups are non-centrosymmetric $Pbn2_1$ and centrosymmetric *Pbnm*; the latter was subsequently established by the crystal-structure analysis.

The lattice parameters were determined by a least-squares refinement using the 2θ values of 22 reflections in the range of 21—34° centered automatically on a Rigaku AFC-5 four-circle diffractometer with Mo $K\alpha$ radiation ($\lambda=0.71068$ Å); they led to these orthorhombic cell constants: $a=11.74(1)$, $b=17.038(6)$, and $c=7.285(3)$ Å.

The chemical composition was determined by means of electron-probe X-ray microanalysis (JEOL JXA-50A X-ray microanalyzer automated by the ELIONIX ACPS-XR control system at the Chemical Analysis Center of the University of Tsukuba). The result of analysis gave the following values: Tl=41.1(42.98), In=25.1(24.15), Si=5.7(5.90), S=27.1(26.97), $\sum$ 99.0(100.00) wt%, The theoretical values for $TlInSiS_4$ are given in brackets. The density calculated for $TlInSiS_4$, $D_x=4.34\,g\cdot cm^{-3}$ for eight formula units in the unit cell, agrees well with the measured density of $4.37\,g\cdot cm^{-3}$. Table 1 summarizes the crystallographic data of $TlInSiS_4$.

Table 1. Crystallographic data

Formula	$TlInSiS_4$
Formula weight	475.52
Decomposition point	300 °C
Crystal system	Orthorhombic
Space group	*Pbnm*
a	11.74(1) Å
b	17.038(7) Å
c	7.285(3) Å
V	1457(2) Å^3
Z	8
D_m	$4.37\,g\cdot cm^{-3}$
D_x	$4.34\,g\cdot cm^{-3}$
μ(Mo $K\alpha$)	$266.72\,cm^{-1}$

The intensity data were collected on a Rigaku Rotaflex four-circle diffractometer operated at 50 kV and 160 mA with graphite monochromated Mo $K\alpha$ radiation, 2θ-ω scan technique, and a scan speed of 2° per minute. The scanning widths and offset values were determined by the following formulae; $\Delta\omega=1.0+0.5\times tan\theta$ and $\delta=0.5\times\Delta\omega$ respectively. The intensity measurements were repeated up to two times for each reflection until $\sigma(|Fo|)/|Fo|$ became less than 0.05. The intensities of three standard reflections, (122), (0, 10, 0) and (004), were measured every 50 reflections. No significant fluctuation in the intensities could be observed during the data collection. A total of 2383 independent reflections below $2\theta=61°$ were measured, of which 940 reflections with $|Fo|\geqq 3\sigma(|Fo|)$ were considered as observed and used for the structure determination. The intensity data were corrected for Lorentz, polarization, and absorption factors (μ(Mo $K\alpha$)=266.72 cm^{-1}). The absorption corrections were made by the use of the computer program ACACA.[14] The transmission factors varied from 0.079 to 0.278.

Determination and Refinement of the Structure

The positions of one independent thallium atom and the indium atom were determined from the Patterson maps. The positions of the other thallium atom, six sulfur atoms, and two silicon atoms were determined by successive Fourier and difference Fourier syntheses. The full-matrix least-squares refinements, including all atoms with isotropic temperature factors using RFINE-2,[15] yielded the $R(=\sum||Fo|-|Fc||/\sum|Fo|)$ value of 0.234 and $R_w(=\{\sum w(|Fo|-|Fc|)^2/\sum w|Fo|^2\}^{1/2}$,

where $w=1/\sigma^2(|Fo|)$) of 0.241 for all observed reflections. The difference Fourier synthesis at this stage indicated that the assumed silicon sites with high positive residual peaks seemed to be partly occupied by indium atoms. In a similar way, the indium site showed a negative residual peak, suggesting that the site is partly replaced by the silicon atoms. Then, the site occupancies were refined with the program RFINE-2 on the basis of the assumption that the total occupancy of the site is 1. The occupancies of the silicon atoms at the Si(1) and Si(2) sites were 0.42 and 0.91 respectively, and the partial occupancy of the indium atom at the In site could be determined to be 0.67. Further refinement with anisotropic temperature factors and anomalous dispersion correction reduced the R-value to 0.074 and the R_w-value to 0.059 for all the observed reflections. The maximum shift of the atomic parameters in the last cycle was less than 0.01 times the corresponding standard deviations. A difference Fourier synthesis using the final atomic parameters showed no significant residual peaks. The scattering factors for neutral atoms tabulated by Cromer and Mann[16] were used in the calculations. The anomalous dispersion correction factors were taken from the International Tables for X-ray Crystallography.[17] The computations were performed on a FACOM M-200 computer at the Information Center of the University of Tsukuba.

The final atomic coordinates and thermal parameters are given in Table 2, while Table 3 shows the site occupancies of the indium and silicon atoms. Lists of the anisotropic temperature factors and the observed and calculated structure factors are deposited as Document No. 8419 at the Chemical Society of Japan.

Description and Discussion of the Structure

The crystal structure of $TlInSiS_4$ is presented in Fig. 1-(a) (projected along the c axis) and Fig. 1-(b) (projected on to the (100) plane). In the structure, In, S(1), and S(2) are located in the general positions at nearly $z=0$, while all the remaining atoms are in the special positions at $z=0.25$.

Table 3. Site occupancies of indium and silicon atoms

Site	In	Si	Position
In	0.67	0.33	8 *d*
Si(1)	0.58	0.42	4 *c*
Si(2)	0.09	0.91	4 *c*

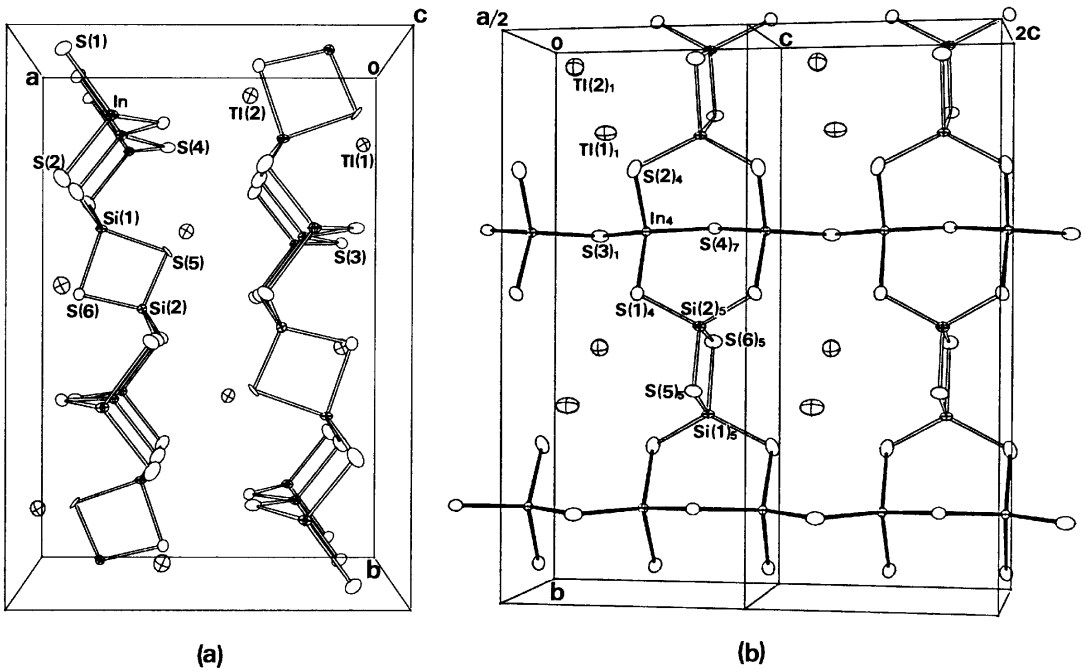

Fig. 1. Structure of $TlInSiS_4$ with the numbering scheme of atoms. (a) Projection along the c axis. (b) Projection along the a axis.

The two silicon atoms, Si(1) and Si(2), are essentially four-coordinated by sulfur atoms forming the SiS_4 tetrahedra. The two tetrahedra share an edge to form dimeric Si_2S_6 groups. Similarly, the indium atom is tetrahedrally coordinated by four sulfur atoms. The InS_4 tetrahedra are linked together to form an infinite chain by sharing one vertex along the *c* axis, as is shown in Fig. 1-(b). The chains are connected with the dimeric Si_2S_6 groups by sharing two sulfur atoms at the apexes to form an infinite two-dimensional sheet. The sheet extends parallel to the (100) plane. Individual layers are held together by the electrostatic forces of the thallium ions lying between them. It may be worth mentioning that the temperature factors of all the atoms in the structure have unusually large values in comparison with those of any compound including these atoms.

The interatomic distances and bond angles are listed in Tables 4 and 5 respectively. The atomic configuration of the Si_2S_6 group is illustrated in Fig. 2, along with the calculated bond lengths. The Si_2S_6 groups consist of two tetrahedra joined by a common edge, where two silicon atoms, Si(1) and Si(2), and two sulfur atoms, S(5) and S(6), in the four-membered ring lie on the same plane. The S(1) and S(2) atoms in the Si_2S_6 group seem to imply some terminal character due to comparatively weak bonding with indium atoms. Such atoms will be called "terminal" in the present paper. The terminal Si-S bond distances are shorter than the bridging Si-S bond distances. This feature is especially remarkable in the configuration of sulfur atoms bonded with Si(1). In the dimer, the mean Si(1)-S bond distance is longer than the mean Si(2)-S bond distance. This difference can be ascribed to the partial substitution of indium atoms for silicon atoms. The Si(1)-S distances for distorted $Si(1)S_4$ tetrahedron range from 2.230 to 2.365 Å, with an average of 2.297 Å, which is close to the value for the sum of the covalent radii, 2.30 Å, estimated by considering the occupancies of silicon and indium atoms at the Si(1) site. The terminal bonds have a definite π-content, while the bridging Si(1)-S bonds correspond approximately to single bonds. On the other
