*Z-Ser-Ser-Asn-Tyr-Cys(MBzl)-Cys(MBzl)-Glu-Leu-Cys-(MBzl)-Cys(MBzl)-Asn-Pro-Ala-Cys(MBzl)-Thr-Gly-Cys-(MBzl)-Tyr-OBzl (**I**).* Compoud **V**[12] (1.18 g, 0.5 mmol) was dissolved with anisole (0.2 ml) in TFA (10 ml) at 0 °C and stirred at room temperature for 2 h. The solution was concentrated to a solid under reduced pressure. Meanwhile, compound **Id** (463 mg, 0.75 mmol) was suspended in DMF (5 ml) and cooled below −50 °C. The suspension was mixed with 6.72M HCl in dioxane (0.51 ml) and isopentyl nitrite (0.11 ml) and stirred at −20 °C for 30 min. The suspension became clear during this procedure, and was then mixed with *N*-methylmorpholine (1.0 ml) and a solution of the above solid in DMF. The mixture was stirred at 0 °C for 10 d and concentrated to dryness under reduced pressure. The residue was triturated in EtOH; wt 1.23 g (88.4%), mp 193 °C (dec), $[\alpha]_D^{20}$ −43.2° (*c* 1.0, DMSO). Amino acid ratio in the acid hydrolysate: Asp, 1.80 (2); Thr, 0.95 (1); Ser, 1.35 (2); Glu, 0.96 (1); Pro, 1.03 (1); Gly, 1.00 (1); Ala, 1.01 (1); 1/2Cys, not determined; Leu, 0.97 (1); Tyr, 1.68 (2).

Found: C, 57.87; H, 6.67; N, 9.66; S, 6.80%. Calcd for $C_{138}H_{172}O_{30}N_{20}S_6 \cdot 4H_2O$: C, 58.05; H, 6.35; N, 9.81; S, 6.74%.

*Z-Ser-Asn-Tyr-N_2H_3 (**IIa**).* Z-Ser-Asn-Tyr-OEt[12] (5.8 g, 10.7 mmol) was dissolved in DMF (30 ml) and mixed with 100% hydrazine hydrate (10.0 ml). The mixture was stirred at room temperature for 6 h and then concentrated to a solid under reduced pressure. The solid was recrystallized from DMF and EtOH; wt 5.8 g (100%), mp 241.5 °C (dec), $[\alpha]_D^{25}$ −11.5° (*c* 1.0, DMSO).

Found: C, 52.60; H, 5.72; N, 15.60%. Calcd for $C_{24}H_{30}O_8N_6 \cdot H_2O$: C, 52.55; H, 5.88; N, 15.32%.

*Z-Ser-Asn-Tyr-Cys(MBzl)-Cys(MBzl)-Glu-Leu-Cys(MBzl)-Cys(MBzl)-Asn-Pro-Ala-Cys(MBzl)-Thr-Gly-Cys(MBzl)-Tyr-OBzl (**II**).* Compound **V**[12] (1.18 g, 0.5 mmol) was dissolved with anisole (0.23 ml) in TFA (10 ml) at 0 °C and stirred at room temperature for 2 h. The solution was concentrated to a solid under reduced pressure. Meanwhile, compound **IIa** (318 mg, 0.6 mmol) was suspended in DMF (5 ml) and cooled below −50 °C. The suspension was mixed with 4.39M HCl in dioxane (0.41 ml) and isopentyl nitrite (0.09 ml) and stirred at −20 °C for 30 min. Then the resulting solution was mixed with *N*-methylmorpholine (1.0 ml) and a solution of the above solid in DMF (5 ml). The mixture was stirred at 0 °C for 2 d and concentrated to dryness under reduced pressure. The residue was triturated in 0.1 M HCl and collected. The material was boiled in hot EtOH and filtered after cooling to room temperature; wt 1.22 g (90.5%), mp 195 °C (dec), $[\alpha]_D^{16}$ −46.3° (c 1.0, DMSO). Amino acid ratio in the acid hydrolysate: Asp, 1.90 (2); Thr, 0.93 (1); Ser, 0.79 (1); Glu, 0.97 (1); Pro, 1.02 (1); Gly, 1.00 (1); Ala, 1.10 (1); 1/2Cys, not determined; Leu, 0.94 (1); Tyr, 1.81 (2).

Found: C, 58.82; H, 6.47; N, 9.52; S, 7.02%. Calcd for $C_{135}H_{167}O_{28}N_{19}S_6 \cdot 3H_2O$: C, 58.95; H, 6.34; N, 9.68; S, 7.00%.

*Z-Asn-Tyr-N_2H_3 (**IIIa**).* Z-Asn-Tyr-OEt[12] (4.57 g, 10.0 mmol) was dissolved in DMF (30 ml). The solution was mixed with 100% hydrazine hydrate (15 ml) and stirred at room temperature overnight. The gelatinous precipitate formed was collected with ether and reprecipitated from DMF and EtOH; wt 4.2 g (94.7%), mp 248 °C (dec), $[\alpha]_D^{20}$ −9.5° (*c* 0.5, DMSO).

Found: C, 54.91; H, 6.04; N, 15.58%. Calcd for $C_{21}H_{25}O_6N_5 \cdot H_2O$: C, 54.66; H, 5.90; N, 15.18%.

*Z-Asn-Tyr-Cys(MBzl)-Cys(MBzl)-Glu-Leu-Cys(MBzl)-Cys-(MBzl)-Asn-Pro-Ala-Cys(MBzl)-Thr-Gly-Cys(MBzl)-Tyr-OBzl (**III**).* Compound **V**[12] (1.18 g, 0.5 mmol) was dissolved with anisole (0.23 ml) in TFA (10 ml) at 0 °C and stirred at room temperature for 2 h. The solution was concentrated to a solid under reduced pressure. Meanwhile, compound **IIIa** (266 mg, 0.60 mmol) was dissolved in DMF (5 ml) and cooled below −50 °C. The solution was mixed with 4.39M HCl in dioxane (0.41 ml) and isopentyl nitrite (0.09 ml), stirred at −20 °C for 30 min and then mixed with *N*-methylmorpholine (1.0 ml) and a solution of the above solid in DMF (5 ml). The mixture was stirred at 0 °C for 3 d and then evaporated to a solid under reduced pressure. The solid was precipitated from DMF and EtOH; wt 1.16 g (88.9%), mp 203.5 °C (dec), $[\alpha]_D^{16}$ −46.9° (*c* 1.0, DMSO). Amino acid ratio in the acid hydrolysate: Asp, 1.92 (2); Thr, 0.92 (1); Glu, 0.98 (1); Pro, 1.00 (1); Gly, 1.00 (1); Ala, 1.03 (1); 1/2Cys, not determined; Leu, 0.99 (1); Tyr, 1.85 (2).

Found: C, 59.46; H, 6.56; N, 9.38; S, 7.36%. Calcd for $C_{132}H_{162}O_{26}N_{18}S_6 \cdot 3H_2O$: C, 59.53; H, 6.36; N, 9.47; S, 7.22%.

*Z-Tyr-Cys(MBzl)-Cys(MBzl)-Glu-Leu-OEt (**IVa**).* Boc-Cys(MBzl)-Cys(MBzl)-Glu(OBu^t)-Leu-OEt[12] (4.28 g, 5.0 mmol) was dissolved in CH_2Cl_2 (60 ml) and TFA (12.0 ml) was added to the solution. The solution was stirred at room temperature for 40 min and concentrated to a solid under reduced pressure. Meanwhile, Z-Tyr-N_2H_3 (1.98 g, 6.0 mmol) was dissolved in DMF (15.0 ml), cooled below −50 °C and mixed with 4.39M HCl in dioxane (4.1 ml) and isopentyl nitrite (0.88 ml). The solution was stirred at −20 °C for 30 min and then mixed with *N*-methylmorpholine (1.98 ml) and a solution of the above solid in DMF (10 ml). The mixture was stirred at 0—2 °C for 24 h and then concentrated to dryness under reduced pressure. The gelatinous residue was collected with AcOEt and reprecipitated from EtOH; wt 3.8 g (76.0%), mp 186.5—189.0 °C, $[\alpha]_D^{20}$ −14.3° (*c* 1.0, DMSO).

Found: C, 61.67; H, 6.48; N, 6.95; S, 6.27%. Calcd for $C_{52}H_{65}O_{11}N_5S_2 \cdot H_2O$: C, 61.33; H, 6.63; N, 6.88; S, 6.30%.

*Z-Tyr-Cys(MBzl)-Cys(MBzl)-Glu-Leu-N_2H_3 (**IVb**).* Compound **IVa** (3.8 g, 3.8 mmol) was dissolved in DMF (30 ml), mixed with 100% hydrazine hydrate (3.8 ml) and stirred at room temperature for 24 h. The precipitate formed was collected with EtOH, boiled in EtOH, cooled to room temperature and filtered; wt 3.0 g (80.0%), mp 212.5 °C (dec), $[\alpha]_D^{20}$ −14.7° (*c* 1.0, DMSO).

Found: C, 60.09; H, 6.69; N, 10.28 S, 6.51%. Calcd for $C_{50}H_{63}O_{10}N_7S_2 \cdot 1/2H_2O$: C, 60.34; H, 6.48; N, 9.85; S, 6.44%.

*Z-Tyr-Cys(MBzl)-Cys(MBzl)-Glu-Leu-Cys(MBzl)-Cys(MBzl)-Asn-Pro-Ala-Cys(MBzl)-Thr-Gly-Cys(MBzl)-Tyr-OBzl (**IV**).* Compound **V**[12] (1.64 g, 1.0 mmol) was dissolved with anisole (0.46 ml) in TFA (20 ml) at 0 °C and stirred at room temperature for 30 min. The solution was concentrated to a solid under reduced pressure. Meanwhile, compound **IVb** (1.18 g, 1.2 mmol) was dissolved in DMF (5 ml) and cooled below −50 °C. The solution was mixed with 4.39M HCl in dioxane (0.82 ml) and isopentyl nitrite (0.18 ml), stirred at −20 °C for 30 min, and was then mixed with TEA (1.2 ml)

and a solution of the above solid in DMF (7 ml). The mixture was stirred at 0 °C for 5 d and concentrated to dryness under reduced pressure. The residue was collected with EtOH, boiled in EtOH, and cooled to room temperature. The solid material was collected by filtration; wt 1.60 g (64.1%), mp 201.0 °C (dec), $[\alpha]_D^{16}$ −54.4° (*c* 1.0, DMSO). Amino acid ratio in the acid hydrolysate: Asp, 0.96 (1); Thr, 0.87 (1); Glu, 0.97 (1); Pro, 0.99 (1); Gly, 1.00 (1); Ala, 1.01 (1); 1/2Cys, not determined; Leu, 1.02 (1); Tyr, 2.09 (2).

Found: C, 60.93; H, 6.44; N, 8.88; S, 7.69%. Calcd for $C_{128}H_{156}O_{24}N_{10}S_6 \cdot 2H_2O$: C, 60.74; H, 6.37; N, 8.85; S, 7.60%.

Boc-Cys(MBzl)-Cys(MBzl)-Glu(OBu^t)-Leu-Cys(MBzl)-Cys(MBzl)-Asn-Pro-Ala-Cys(MBzl)-Thr-Gly-Cys(MBzl)-Tyr-OBzl (V). This compound was synthesized as described in the preceding paper.[12] Amino acid ratio in the acid hydrolysate: Asp, 0.95 (1); Thr, 0.89 (1); Glu, 0.96 (1); Pro, 0.93 (1); Gly, 1.00 (1); Ala, 1.03 (1); 1/2Cys, not determined; Leu, 0.99 (1); Tyr, 0.95 (1).

Deprotection, Air-oxidation and Purification of Toxic Peptides. Protected peptides **I**, **II**, **III**, **IV**, and **V** (100 μmol each) were treated with anhydrous liquid hydrogen fluoride (10 ml)[13] and spontaneously air-oxidized under similar conditions to those used for synthesis of ST_h. The air-oxidized materials were purified by ion-exchange chromatography on DEAE-Sephadex A-25 under the conditions described previously.[14] The peak fractions eluted were separated and assayed by the method described below. The toxic fractions were lyophilized and purified further by high-performance liquid chromatography (HPLC) under the conditions used for purification of ST_h, as described in the preceding paper.[12] The highly toxic fractions were isolated and lyophilized. The yields of purified peptides, ST_h[2-19], ST_h[3-19], ST_h[4-19], ST_h[5-19], and ST_h[6-19], were about 4.8, 5.8, 4.8, 5.3, and 27.4% on the basis of the amounts of the protected peptides **I**, **II**, **III**, **IV** and **V**, respectively.

Biological Assay. ST activity was assayed in suckling mice of 2—4 d old, as described previously.[1]

Aminopeptidase M Digestion of ST_h and its Analogs. Native and synthetic ST_h and synthetic analogs of ST_h (*ca.* 100 μg) were digested with aminopeptidase M (5 μg) in 0.1M Tris HCl buffer (100 μl) under the conditions described in the preceding paper.[12] The digested peptides were separated by HPLC as described in the preceding paper.[12]

Edman Degradation. A sample peptide (*ca.* 100μg) was allowed to react with phenyl isothiocyanate (40 μl) in 50% aq pyridine (0.3 ml) adjusted to pH 9.6 with *N*-methylmorpholine at 40 °C for 60 min. The reaction mixture was washed three times with benzene and then lyophilized. The lyophilized material was treated with a few drops of TFA at 40 °C for 20 min and dried under a stream of nitrogen. The residue was dissolved in 0.5M AcOH (0.2 ml) and washed with AcOEt. The aqueous layer was applied directly to a YMC-packed column ODS A-324 (10×300 mm) and the adsorbed material was eluted with a linear gradient of 10—40% acetonitrile in 0.05% TFA (pH 2.35) at a flow rate of 3 ml/min. The peak fractions were separated and lyophilized.

Heat-treatment. Synthetic peptides were each dissolved in 0.01M phosphate buffer (pH 7.2) at a concentration of 200 μg/ml. Sample solutions were sealed in capillary tubes and placed for given periods in an electric oven controlled at the required temperature. Then the tubes were rapidly cooled in an ice-bath and part of the solution (50 μl) was subjected to HPLC. HPLC was performed on a column of LiChrosorb RP-8 (4.6×250 mm). The column was developed with a linear qradient of 10—35% acetonitrile in 0.01M ammonium acetate (pH 5.7) with increase in acetonitrile of 1%/min at a flow rate of 0.5 ml/min.

Results and Discussion

Syntheses. First, protected linear peptides **I** to **V** lacking one to five N-terminal amino acid residues of ST_h, respectively, were synthesized, as shown in the

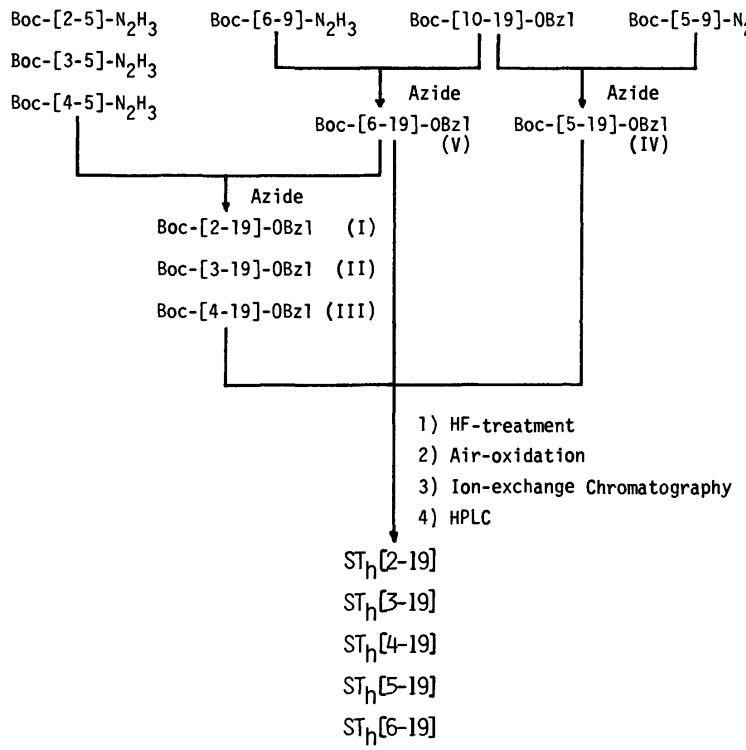

Fig. 2. Scheme for syntheses of shorter analogs of ST_h.

scheme in Fig. 2. Then these protected peptides **I** to **V** were treated with anhydrous liquid hydrogen fluoride[13] and spontaneously air-oxidized in dilute solution (5×10^{-5}M), as described for the synthesis of STh in the preceding paper.[12] The air-oxidized solutions of the deprotected peptides were subjected to HPLC, as shown in Fig. 3, and each fraction was separated and its toxicity was examined by the fluid accumulation test in suckling mice. The peak fractions shown by black bars had the highest toxicity. These fractions were purified by similar methods to those used for STh, as described in the preceding paper.[12] The fractions were confirmed to be pure by HPLC, as shown in Fig. 4, with a different buffer system as solvent from that used for the preparative purification. The amino acid compositions of the synthetic peptides are summarized in Table 1.

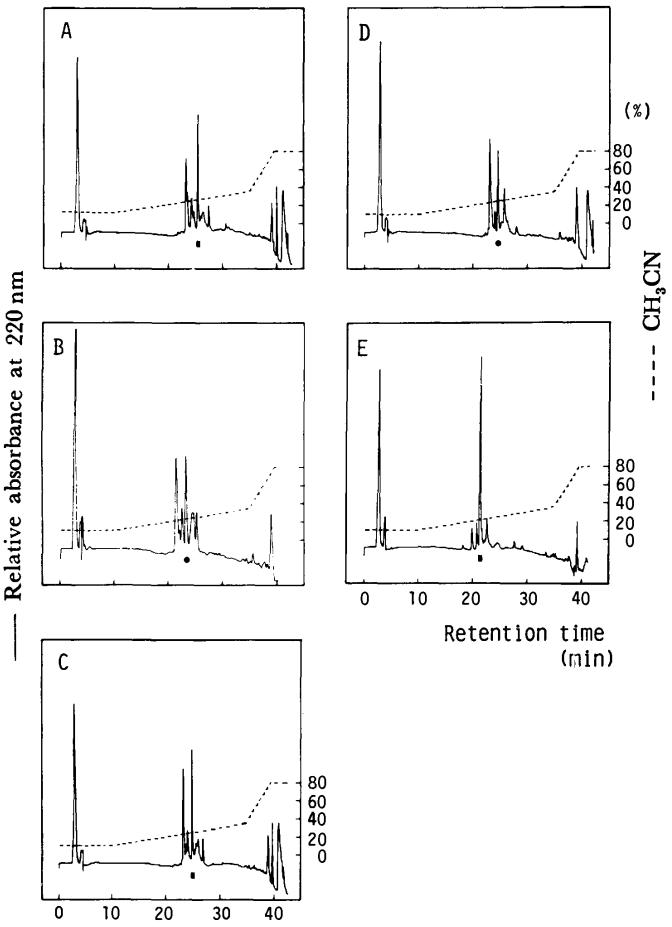

Fig. 3. HPLC profiles of deprotected and air-oxidized solutions of compounds **I**(A), **II**(B), **III**(C), **IV**(D), and **V**(E).
Column: LiChrosorb RP-8 (5 μm, 4×250 mm). The starting solvent was 10% CH_3CN in 0.01 M $AcONH_4$ (pH 5.7), and the flow rate was 1 ml/min.

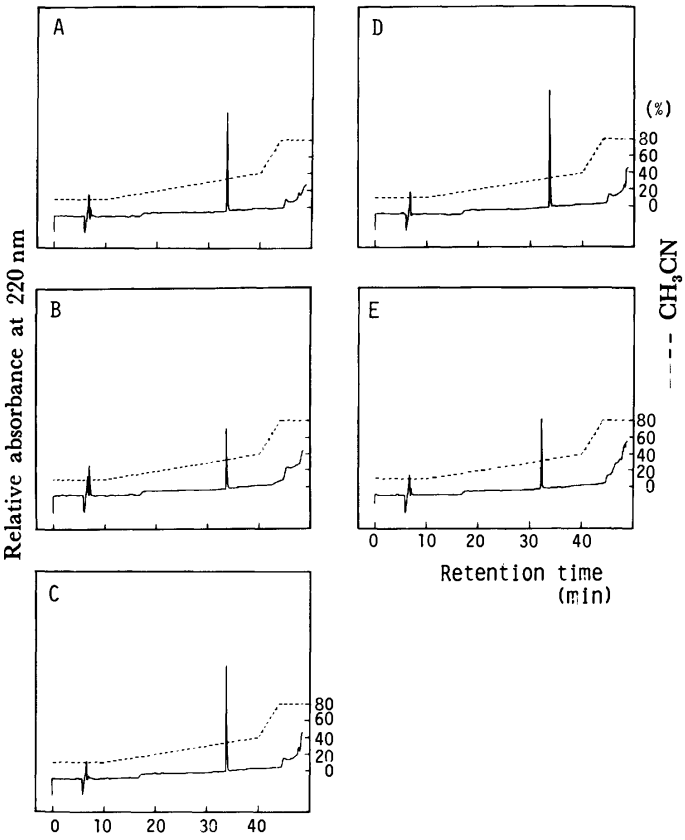

Fig. 4. HPLC profiles of synthetic STh[2-19] (A), STh[3-19] (B), STh[4-19] (C), STh[5-19] (D), and STh[6-19] (E) on a YMC-packed column ODS A-324 (5 μm, 10×300 mm). The starting solvent was 10 % CH_3CN in 0.05 % TFA (pH 2.35), and the flow rate was 2 ml/min.

Table 1. Amino acid compositions of shorter synthetic analogs of STh

	STh[2-19]	STh[3-19]	STh[4-19]	STh[5-19]	STh[6-19]
Asp	1.84(2)	2.02(2)	2.00(2)	1.07(1)	1.02(1)
Thr	0.92(1)	0.99(1)	1.00(1)	1.00(1)	1.01(1)
Ser	1.81(2)	0.96(1)	—	—	—
Glu	1.05(1)	1.02(1)	1.01(1)	1.02(1)	1.01(1)
Pro	0.99(1)	1.12(1)	1.10(1)	1.11(1)	0.99(1)
Gly	1.07(1)	1.03(1)	1.02(1)	1.04(1)	1.02(1)
Ala	1.00(1)	1.00(1)	1.00(1)	1.00(1)	1.00(1)
1/2Cys	4.82(6)	5.50(6)	5.47(6)	5.51(6)	5.39(6)
Leu	0.97(1)	1.03(1)	1.03(1)	1.03(1)	1.02(1)
Tyr	1.78(2)	1.98(2)	2.09(2)	1.98(2)	1.00(1)

Values were calculated as mol/mol of Ala; numbers in parentheses indicate nearest integer values.

High-performance Liquid Chromatography (HPLC) of ST_h Analogs. Shorter synthetic analogs of ST_h could be purified to homogeneity by HPLC under the conditions shown in Fig. 4. However, it was necessary to find conditions for elution of all or almost all the synthetic analogs of ST_h separately on HPLC, because all shorter synthetic analogs of ST_h except ST_h[6-19] had nearly the same retention times on HPLC under the conditions shown in Fig. 4. We tested several commercially available ODS columns and buffer solutions, and found that the following two procedures were satisfactory, although they did not separate all the ST_h analogs completely; i) A YMC-packed ODS column A-324 (10×300 mm) equilibrated with 0.05% heptafluorobutyric acid (pH 2.5) containing 10% CH_3CN and, after sample injection, developed with a gradient of 10% to 40% CH_3CN at a flow rate of

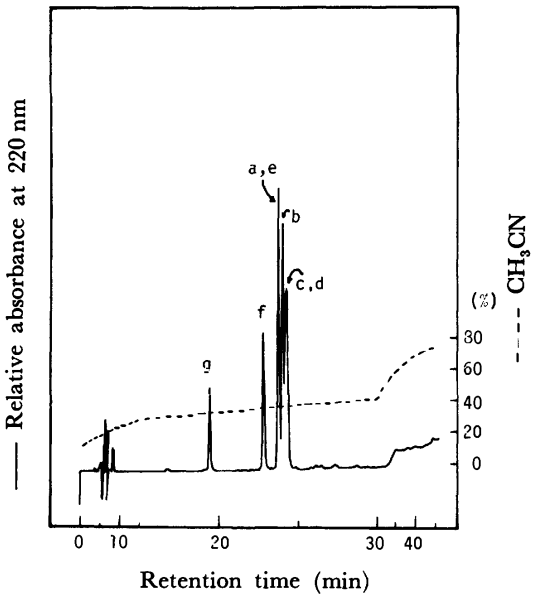

Fig. 5. HPLC profile of a mixture of synthetic ST_h [1-19] (a), ST_h[2-19] (b), ST_h[3-19] (c), ST_h [4-19] (d), ST_h[5-19] (e), and ST_h[6-19] (f) on a YMC-packed column ODS A-324 (5 μm, 10×300 mm). The starting solvent was 10% CH_3CN in 0.05% TFA (pH 2.35) and the flow rate was 3 ml/min. ST_h[6-18] (g) was added as an internal standard.

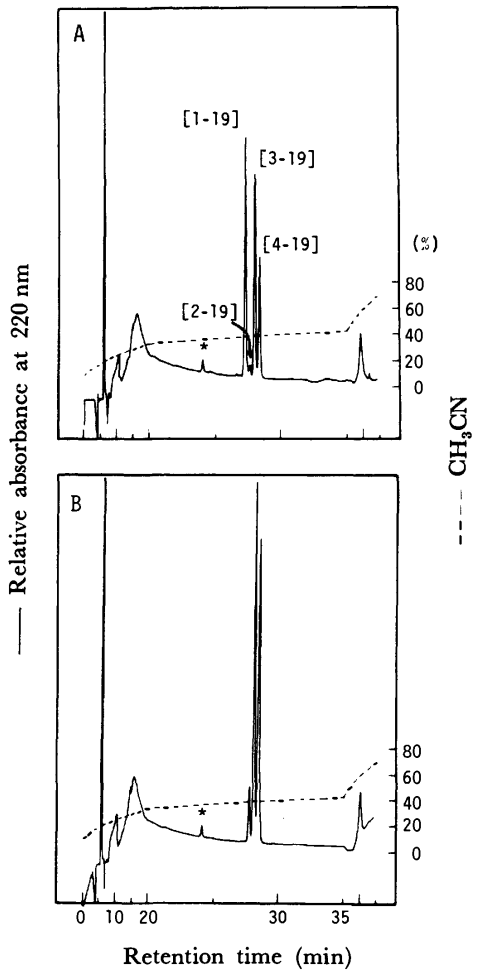

Fig. 6. HPLC profiles of digests of native ST_h (A) and synthetic ST_h[2-19] (B) with aminopeptidase M on a YMC-packed column ODS A-324 (5 μm, 10×300 mm). The starting solvent was 10% CH_3CN in 0.05 % heptafluorobutyric acid (pH 2.51) and the flow rate was 3 ml/min. ST_h[6-18] (peak denoted by*) was added to each digest as an internal standard.

TABLE 2. AMINO ACID COMPOSITIONS OF PEPTIDES OBTAINED BY ENZYMATIC AND EDMAN DEGRADATION OF NATIVE ST_h AND ITS SYNTHETIC ANALOGS

Starting peptide	Native ST_h		Synthetic ST_h[2-19]		Synthetic ST_h[4-19]	Synthetic ST_h[5-19]
Products	ST_h[3-19]	ST_h[4-19]	ST_h[3-19]	ST_h[4-19]	ST_h[5-19]	ST_h[6-19]
Asp	2.00(2)	2.01(2)	2.00(2)	1.98(2)	1.07(1)	1.08(1)
Thr	0.96(1)	1.00(1)	0.96(1)	1.00(1)	1.05(1)	1.03(1)
Ser	0.97(1)	—	0.96(1)	—	—	—
Glu	1.00(1)	1.04(1)	1.01(1)	1.00(1)	1.04(1)	1.02(1)
Pro	1.07(1)	1.11(1)	1.12(1)	1.02(1)	0.99(1)	1.11(1)
Gly	1.03(1)	1.04(1)	1.03(1)	1.04(1)	1.02(1)	1.00(1)
Ala	1.00(1)	1.00(1)	1.00(1)	1.00(1)	1.00(1)	1.00(1)
1/2Cys	5.34(6)	5.36(6)	5.48(6)	5.38(6)	5.58(6)	5.21(6)
Leu	1.05(1)	1.06(1)	1.05(1)	1.06(1)	1.05(1)	1.06(1)
Try	2.00(2)	1.99(2)	2.01(2)	2.00(2)	2.04(2)	1.00(1)

Values were calculated as mol/mol of Ala; numbers in parentheses indicate nearest integer values.

3 ml/min; ii) The same column developed under the same conditions as for i) but with 0.05% TFA instead of 0.05% heptafluorobutyric acid as the aqueous phase. The elution profile of a mixture of shorter synthetic analogs by the latter procedure is shown in Fig. 5. With this procedure, synthetic STh[1-19] and STh[3-19] could not be completely separated from STh[5-19] and STh[4-19], respectively.

Aminopeptidase M Digestion of Native STh and Identification of the Resulting Peptides with Synthetic Analogs. To confirm that shorter synthetic analogs of STh had intramolecular disulfide bonds at the same positions as those in native STh, we treated native STh with aminopeptidase M, isolated the resulting peptides and compared them with the synthetic analogs of STh by HPLC. The HPLC profile of the digest of native STh showed two major and one minor peak with a peak of undigested peptide, as illustrated in Fig. 6A. The materials in these fractions were separated and submitted to measurement of their molecular weights by fast atom bombardment mass spectrometry (data not shown) and amino acid analysis (Table 2). The two major fractions were identified as those of STh[3-19] and STh[4-19], which lacked two and three N-terminal amino acid residues, respectively, of STh. The minor peak fraction eluted between undigested STh and STh[3-19] was identified as that of a peptide STh[2-19] lacking the N-terminal Asn residue of STh, by comparison of its HPLC profile with that of native STh digested with aminopeptidase M (Fig. 6B). The shorter STh peptides lacking one to three amino acid residues (STh[2-19], STh[3-19], and STh[4-19]) thus prepared by digestion of native STh with aminopeptidase M were each mixed with an equal amount of the corresponding synthetic peptide and chromatographed on a reversed-phase column, as shown in Figs. 7A—7C. Each gave a single peak. Thus, synthetic STh[2-19], STh[3-19], and STh[4-19] were confirmed to have disulfide linkages in the same positions as those in native STh. The digestion of native STh with aminopeptidase M stopped with release of the three N-terminal amino acid residues and did not proceed further even when the ratio of the enzyme to STh was raised to 1/10 (w/w). Therefore, Edman degradation was carried out for further removal of the fourth and fifth amino acid residues of STh from the N-terminus, as described below.

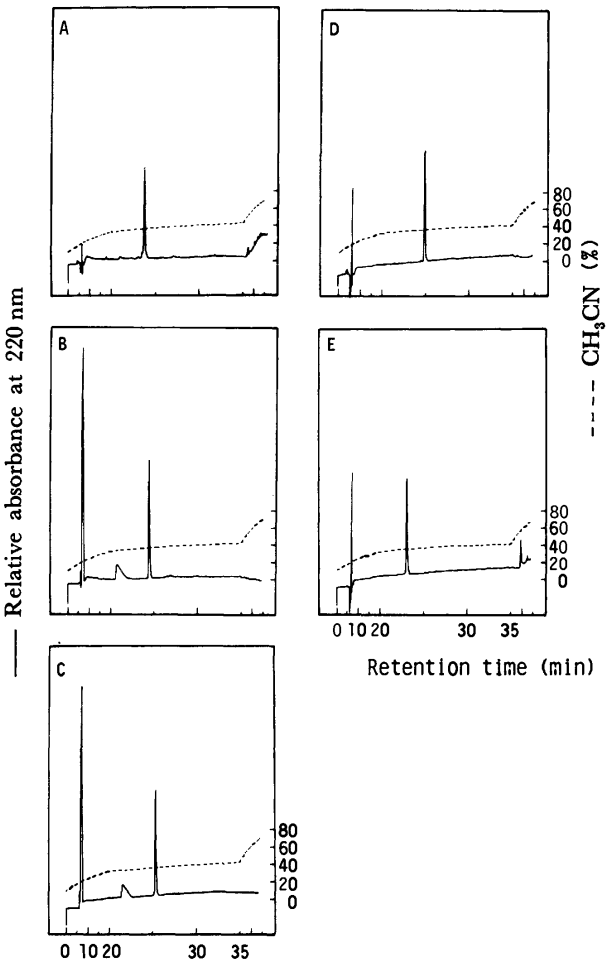

Fig. 7. HPLC profiles of mixtures of equal amounts of STh analogs on a YMC-packed column ODS A-324 (5 μm, 10×300 mm). The starting solvent was 10% CH_3CN in 0.05% TFA (pH 2.35), and the flow rate was 3 ml/min. (A) STh[2-19] enzymatically derived from native STh and synthetic STh[2-19]; (B) STh[3-19] enzymatically derived from native STh and synthetic STh[3-19]; (C) STh[4-19] enzymatically derived from native STh and synthetic STh[4-19]; (D) STh[5-19] prepared from synthetic STh[4-19] by Edman degradation and synthetic STh[5-19]; (E) STh[6-19] derived from synthetic STh[5-19] by Edman degradation and synthetic STh[6-19].

Edman Degradation and Comparison of the Degraded Peptides with Synthetic Peptides. Synthetic STh[4-19] was confirmed to have intramolecular disulfide linkages in the same positions as those in native STh, as described above. Then we subjected synthetic STh-[4-19] to Edman degradation[14] and obtained STh[5-19]. This shortened peptide of STh was purified by HPLC and its amino acid composition was analyzed (Table 2). A mixture of equal amounts of this peptide and synthetic STh[5-19] gave a single peak on HPLC, as shown in Fig. 7D, indicating that synthetic STh[5-19] was linked intramolecularly by disulfide bonds at the same positions as those in STh[4-19]. Then we degraded synthetic STh[5-19] by a similar method to that used for STh[4-19] and purified the degraded peptide by the same procedure as used for degraded STh[4-19]. The amino acid composition of the purified peptide is shown in Table 2. When this peptide was mixed with synthetic STh[6-19] and subjected to HPLC a single peak was obtained, as shown in Fig. 7E. Thus synthetic STh[6-19] had intramolecular disulfide linkages at the same positions as those in STh[5-19], and synthetic STh[5-19] and STh[6-19] were both intramolecularly linked by disulfide bonds in the same way as native STh.

Biological Activity. The toxicities of shorter synthetic analogs of STh were assayed as described previously.[1] The minimum effective doses of shorter synthetic analogs of STh were 1.0±0.4 ng, which were the same as that of native or synthetic STh within the limits of experimental error, as shown in Table 3.

These values were also almost the same as those for the corresponding peptides derived from native ST_h by digestion with aminopeptidase M or by Edman degradation. Furthermore, the toxicities of all the shorter synthetic analogs of ST_h were neutralized by anti-native ST_h antiserum. These results indicate that the active site of the toxicity of ST_h is located in the sequence between the Cys residue near the N-terminus and the C-terminal Tyr.

Heat-stability. Synthetic ST_h was found to have the same stability as that of native ST_h on boiling in phosphate buffer, as described in the preceding paper.[12] We examined the heat-stability of shorter synthetic analogs of ST_h by the method as described previously.[15] Synthetic ST_h[5-19] lacking four N-terminal amino acid residues of ST_h showed the same heat-stability as that of synthetic ST_h, as illustrated in Fig. 8. Furthermore, the toxicity of ST_h[5-19] was found to decrease with the duration of heat-treatment. Shorter synthetic analogs of ST_h lacking one to three the N-terminal amino acid residues of ST_h gave similar results (data not shown). On the other hand, synthetic ST_h[6-19] lacking five N-terminal amino acid residues of ST_h showed higher heat-stability than synthetic or native ST_h, as reported in a previous paper.[15] These results suggest that the sequence consisting of 13 amino acid residues from the Cys residue near the N-terminus to the C-terminal Tyr residue is essential for the heat-stability of the toxin. The enhanced structural stability of ST_h[6-19] may be due to decreased perturbation of the molecule on heating as a result of loss of the five N-terminal amino acid residues.

TABLE 3. BIOLOGICAL PROPERTIES OF SYNTHETIC ST_h ANALOGS

	Minimum effective dose (ng/100 μl)[a]	Neutralization by anti-native ST_h antiserum
Native ST_h	1.0 ng (0.5 pmol)[b]	+
Synthetic ST_h	0.8 ng (0.4 pmol)[b]	+
Synthetic ST_h[2-19]	0.8 ng (0.4 pmol)	+
Synthetic ST_h[3-19]	1.3 ng (0.7 pmol)	+
Synthetic ST_h[4-19]	1.1 ng (0.7 pmol)	+
Synthetic ST_h[5-19]	0.8 ng (0.5 pmol)	+
Synthetic ST_h[6-19]	0.6 ng (0.4 pmol)	+

Hydrogenation and Hydrogenolysis. XVII.[1] The Selectivities of Platinum Group Metals in Catalytic Hydrogenation of 2-Naphthol and Tetrahydro-2-naphthols

Shigeo NISHIMURA,* Shin-ichi OHBUCHI, Kiyoshi IKENO, and Yasuhiro OKADA
Department of Applied Chemistry for Resources, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184
(Received May 10, 1984)

Catalytic hydrogenation of 2-naphthol (NL) with the six platinum metals has been studied in *t*-BuOH at 80 °C and 4—5 MPa H_2 pressure. Selectivities for formation of 1,2,3,4- and 5,6,7,8-tetrahydro-2-naphthols (*ac*- and *ar*-TLs) have been determined by application of a kinetic equation. *ar*-TL was formed more predominantly than *ac*-TL over all the metals. The hydrogenation of *ac*- and *ar*-TLs has also been studied under the same conditions for comparison. The hydrogenation of NL and *ar*-TL was accompanied by extensive hydrogenolysis to give decalins over Os, Ir, and Pt, whereas the hydrogenolysis occurred only slightly over Ru, Rh, and Pd. In general the hydrogenolysis occurred to much lesser extents with *ac*-TL. The amounts of 2-decalone formed in hydrogenation of *ar*-TL have been determined by application of the kinetic equation. The 2-decalone was the *cis* isomer only except with Pd. For formation of the *cis* products at the ring juncture, hydrogenation of *ar*-TL was highly stereoselective with Ru, Rh, Os, and Ir, while hydrogenation of *ac*-TL was the most stereoselective with Os and Ir. The course of hydrogenolysis and the stereochemistry of hydrogenation are discussed from the comparative results on NL, *ar*-TL, and *ac*-TL.

The catalytic hydrogenation of aromatic compounds has been a subject of extensive studies not only as useful synthetic routes to alicyclic compounds but also from stereochemical and mechanistic viewpoints.[2] However, compared to a large number of studies on monocyclic aromatics, the catalytic hydrogenation of polycyclic aromatics has been investigated to rather limited extent.[3] One reason for this might be difficulties in the analysis of products that are often rather complicated. As the simplest polycyclic aromatics naphthalene and its derivatives have been hydrogenated with a variety of catalysts and conditions. Particular interests have been focused on the selectivity for formation of tetrahydro intermediates and the stereochemistry of hydrogenation in formation of decahydro derivatives.[2,3] The hydrogenation of naphthols has been interested as synthetic routes to 1,2,3,4- and 5,6,7,8-tetrahydronaphthols (abbreviated to *ac*- and *ar*-tetralols) that may be starting materials for further syntheses[4] or of therapeutic importance.[5,6] The selectivity for either *ac*- or *ar*-tetralol is known to be much influenced by the catalyst employed as well as by reaction conditions and additives.[2,7] The hydrogenation has also been studied for the stereochemistry of the resulting decahydronaphthols (abbreviated to decalols).[8—14] Among the platinum metals, platinum,[8—10] rhodium,[4,11] rhodium–platinum,[12] and ruthenium[13,14] have been used for complete hydrogenation to decalins and decalols, while palladium catalysts have been employed for selective transformation to the dihydro and tetrahydro derivatives.[6,7a,15] However, there appears to be few studies on the other platinum metals, and, to our knowledge, no comparative study on the six platinum metals with naphthols, although such a study has been reported by Weitkamp on the hydrogenation of naphthalene and its methyl derivatives.[3]

In this study the selectivities of the six platinum metals have been compared in the hydrogenation of 2-naphthol for formation of the two tetrahydro derivatives, *ac*- and *ar*-2-tetralols, for their trends towards hydrogenolysis, and for the stereochemistry in the formation of saturated compounds. The hydrogenation of *ac*- and *ar*-2-tetralols has also been studied under the same conditions for comparison.

Experimental

Materials. All the substrates hydrogenated are well documented compounds. Melting points are corrected. Their structures and purities were confirmed by NMR, IR, GC-MS, and GLC. 2-Naphthol (Wako Pure Chemical Industries) was purified by treating with Raney nickel in EtOH at 50—60 °C for 3 h to remove catalyst poisons. After removal of the catalyst, addition of water to the ethanol solution gave white crystals: mp 123 °C (lit,[16] mp 121—123 °C). *ac*- and *ar*-2-Tetralols were prepared from a mixture of them obtained by hydrogenation of 2-naphthol with Raney nickel in *i*-PrOH at 100 °C and 5—10 MPa. After removing the catalyst and solvent, the ethereal solution of the residue was extracted with 2% NaOH solution. Addition of hydrochloric acid to the extract gave crystals which were recrystallized from hexane: mp 61.5 °C (lit,[17] mp 61.5—62.5 °C). From the ethereal solution after removal of *ar*-2-tetralol, *ac*-2-tetralol was obtained by distillation at reduced pressure: bp 127 °C/6 mmHg (1 mmHg≈133.322 Pa); n_D^{25} 1.5620 (lit,[18] bp 120 °C/2 mmHg; n_D^{25} 1.5625). *trans*-Octahydro-2(1*H*)-naphthalenone (abbreviated to *trans*-2-decalone) was prepared by chromic acid oxidation of a trans-rich 2-decalol mixture obtained by isomerization of a 2-decalol mixture with Raney nickel at 160 °C and 0.2 MPa H_2. *cis*-Octahydro-2(1*H*)-naphthalenone (abbreviated to *cis*-2-decalone) was likewise obtained from a cis-rich mixture of 2-decalols. Both the *trans*- and *cis*-2-decalones were purified by a preparative GLC. *trans*-2-Decalone: n_D^{25} 1.4817 (lit,[19] n_D^{25} 1.4814); *cis*-2-decalone: n_D^{25} 1.4911 (lit,[19] n_D^{25} 1.4915). 3,4-Dihydro-2(1*H*)-naphthlenone (abbreviated to 2-tetralone) was obtained from Sigma Chemical Co. and used after distillation at reduced pressure: bp 93 °C/1 mmHg; n_D^{20} 1.5597 (lit,[20] bp 92—94 °C/1.8 mmHg; n_D^{20} 1.5594).

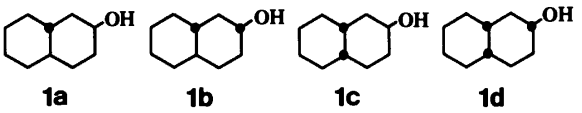
Catalysts. Unsupported metal catalysts were prepared by reducing the corresponding metal hydroxides (Ru, Rh, Ir) or oxides (Pt, Os) with hydrogen in water at atmospheric or elevated pressure.[21,22] Care was taken to remove

alkaline or acidic impurities with repeated reductions and washings. Pd-C catalyst (5% Pd) was obtained from Nippon Engelhard Co. and used throughout this study, since unsupported palladium was liable to deactivation during hydrogenation.

Solvent. *t*-Butyl alcohol (Wako Pure Chemical Industries) was distilled with addition of a small amount of sodium and stored in a refrigerator.

Hydrogenation. All hydrogenations were performed in a 40 ml stainless steel autoclave with a stirrer driven magnetically. The autoclave was immersed in an oil bath maintained at 80 °C during hydrogenation. The catalyst, the amount of which varied with metal, was pretreated with hydrogen at 80 °C and 5 MPa H_2 (15 min for Pd-C, 30 min for Rh, Ir, Os, and Pt, and 1 h for Ru). After the pretreatment the solvent was replaced by a new portion of *t*-butyl alcohol and then the substrate, dissolved in a small amount of the solvent, was added, the combined amount of the solvent being 16 ml. The mixture was hydrogenated at 80 °C and 4—5 MPa H_2 pressure.

Analysis of the Reaction Mixture. The reaction mixture was analyzed by GLC with 2-methoxynaphthalene as an internal standard. For the analysis of *cis*- and *trans*-decalins and tetralin, the reaction mixture was subjected directly to GLC, using a glass capillary column of OV-17 (0.3 mmϕ×30 m) at 70—130 °C programmed at 1 °C/min and with N_2 at 0.075 MPa. The retention times were 5.4 min (*trans*-decalin), 6.4 min (*cis*-decalin), 8.8 min (tetralin), and 33.9 min (2-methoxynaphthalene). For the analysis of four stereoisomeric 2-decalols, *ar*-2-tetralol, and 2-naphthol, the reaction mixture, after removal of the solvent, was trimethylsilylated and then subjected to GLC, using the same glass capillary column mentioned above under the same conditions. The retention times were 13.3 min (*trans,trans*-2-decalol (**1a**)), 16.9 min (*trans, cis*-2-decalol (**1b**)), 18.5 min (*cis,trans*-2-decalol (**1c**)), 19.3 min (*cis,cis*-2-decalol (**1d**)), 33.9 min (2-methoxynaphthalene), 35.5 min (*ar*-2-tetralol), and 38.8 min (2-naphthol). For the analysis of *ac*-2-tetralol, *trans*- and *cis*-2-decalones, and 2-tetralone, the trimethylsilylated products were subjected to GLC, using a DEGS column (3 mmϕ×3 m) at 170 °C and with N_2 at 0.09 MPa. The retention times were 13.2 min (*ac*-2-tetralol), 19.8 min (*trans*-2-decalone), 25.4 min (*cis*-2-decalone), 62.7 min (2-tetralone), and 65.3 min (2-methoxynaphthalene).



Results

Hydrogenation of 2-Naphthol to ar- *and* ac-*2-Tetralols.* Hydrogenation of 2-naphthol gives *ar*- and *ac*-2-tetralols as the intermediates leading to decalins and 2-decalols. In order to know the selectivities for the two tetralols, 2-naphthol was hydrogenated in *t*-butyl alcohol at 80 °C and 4—5 MPa of hydrogen pressure over the six platinum metals as catalysts. In

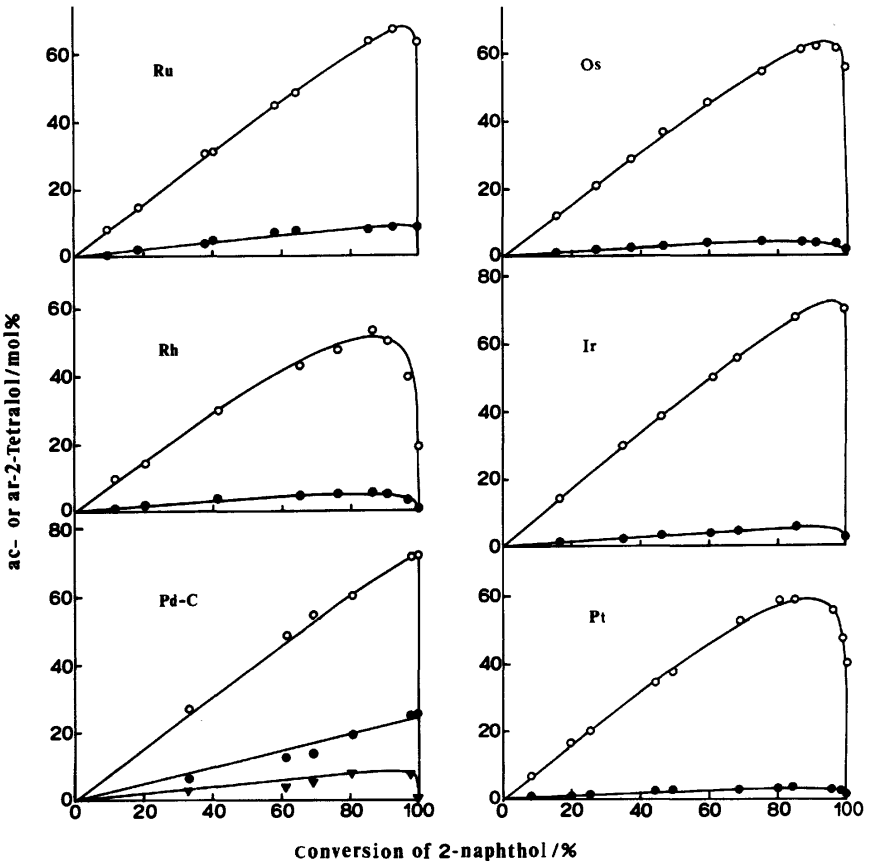


Fig. 1. Hydrogenation of 2-naphthol: formation of *ar*- and *ac*-2-tetralols. ○: *ar*-2-tetralol, ●: *ac*-2-tetralol (2-tetralone+*ac*-2-tetralol for Pd-C), ▼: 2-tetralone. The results show a set of separate experiments with varying conversions of 2-naphthol. The full lines show the theroretical curves given by Eq. 1. For the values of f and K, see Tables 1 and 8, respectively.

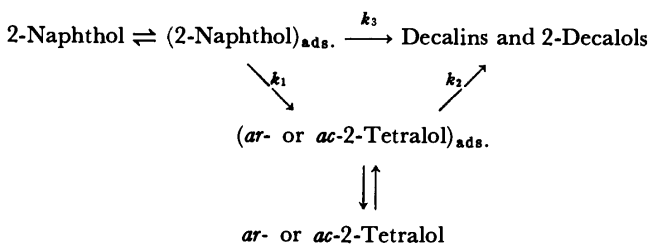
Fig. 1 are shown the variations in amount of the two tetralols during the course of hydrogenation as a function of 2-naphthol conversion. The selectivity for either *ar*- or *ac*-2-tetralol has been determined by application of Eq. 1 which is derived on the basis of the reaction pathways shown in Scheme 1.[23] C_{NL} and C_{TL} represent the concentrations of 2-naphthol and *ar*- or *ac*-2-tetralol, respectively, when the initial concentration of 2-naphthol is taken as unity. f is the fraction of 2-tetralol which leaves the catalyst surface and given by $k_1/(k_1+k_3)$ where k_1 and k_3 are the rate constants for the respective reaction pathways shown in Scheme 1. K is a constant which depends on the relative reactivity of 2-tetralol to 2-naphthol. The circles in Fig. 1 show the results of a set of experiments done separately for varying conversions of 2-naphthol. The full lines in Fig. 1 present the theoretical curves given by Eq. 1 when an appropriate set of values of f and K are selected to

$$C_{TL} = \frac{f}{K-1}(C_{NL} - C_{NL}^{K}) \quad (1)$$



Scheme 1. Hydrogenation pathways of 2-naphthol.

represent best the variations in concentration of *ar*- or *ac*-2-tetralol throughout the course of the hydrogenation. With palladium 2-tetralone was formed together with the tetralols (see Fig. 1). Since 2-tetralone has been converted nearly quantitatively to *ac*-2-tetralol over palladium,[24] the sum of *ac*-2-tetralol and 2-tetralone is plotted in Fig. 1. The selectivities for the products other than the tetralols were obtained by extrapolating the varying selectivities with the conversion of 2-naphthol to the initiation of hydrogenation. The composition of the products at the initial stage of hydrogenation thus obtained by application of Eq. 1 and the extrapolation method is summarized in Table 1.

Hydrogenation of ar-*2-Tetralol.* Since *ar*-2-tetralol has been the predominant intermediate in the hydrogenation of 2-naphthol over all the catalyst metals investigated, the hydrogenation of *ar*-2-tetralol has also been studied in detail. Table 2 summarizes the composition of the products obtained on complete hydrogenation. Analysis of the reaction mixture during hydrogenation indicated that 2-decalone is formed as an intermediate, the amount of which depended on the catalyst metal used, as shown in Fig. 2. Hydrogenation with osmium, however, gave no detectable amount of 2-decalone. The selectivity for 2-decalone has been determined by application of Eq. 1 to the varying concentrations of the ketone with the conversion of *ar*-2-tetralol. The selectivity for iridium was evaluated by extrapolation method since the amounts of 2-decalone found were too small to apply Eq. 1. It is noteworthy

a) 2-Naphthol (600 mg) was hydrogenated in *t*-BuOH (16 ml) at 80 °C and 4—5 MPa H_2 pressure. b) For the notations of compounds, see footnote b) in Table 2.

tetralol to *ar*-2-tetralol during hydrogenation was not found under the present conditions, although such an isomerization was observed by Weitkamp in the hydrogenation of methyltetrahydronaphthalenes.[3]

Hydrogenation of 2-Naphthol to Decalins and 2-Decalols. Table 6 summarizes the composition of the products obtained when 2-naphthol was hydrogenated completely to give decalins and 2-decalols.

Discussion

The Selectivity for Formation of ar- *and* ac-*2-Tetralols.* 2-Naphthol may be hydrogenated by way of either *ar*- or *ac*-2-tetralol as the intermediate leading to decalins and 2-decalols. The results in Table 1, however, indicate that, except over palladium, some 10—15% of 2-naphthol is hydrogenated apparently not through the tetralols and gives directly decalins and 2-decalols. Hydrogenation with palladium is an exception in that all naphthol is hydrogenated *via* either *ar*- or *ac*-2-naphthol and no other hydrogenation pathway was found on this metal. On the basis of the amounts of *ar*- and *ac*-2-tetralols determined, the selectivity ratios for hydrogenation of the unsubstituted ring (the benzene ring) to the substituted ring (the phenol ring) are shown in Table 7. The corresponding results on 2-methylnaphthalene obtained by Weitkamp[3] are also listed in the table for comparison. It is seen that the preferential hydrogenation of the unsubstituted ring is a common trend for both the compounds over all the catalysts. However, this trend is more pronounced in the hydrogenation of 2-naphthol than in 2-methylnaphthalene. Since the steric effect of the substituent against adsorption to catalyst is considered to be greater for the methyl group than for the hydroxyl group,[25] it would be difficult to explain the results by the steric effect of the substituent alone. Another explanation for the relative unreactivity of the phenol ring might be a great energy of resonance stabilization in the phenol ring that is estimated to be 22 kJ mol^{-1} greater than that in the benzene ring. A loss of the energy accompanying the activated adsorption would cause a difficulty in hydrogenation and this effect is considered to be greater in the phenol ring with a greater resonance energy.[2a] It is of interest that, in line with the results on methylnaphthalenes, the selectivity ratio is the smallest with palladium. As suggested by Weitkamp,[3] over palladium the product-controlling step may be different from those on the other metals, just as in the palladium-catalyzed hydrogenation of cycloolefins, where Siegel has proposed such a difference in product-controlling step between palladium and platinum.[27] The fact that with palladium no pathway other than the hydrogenations through the two tetralols was found indicates that an adsorption-desorption equilibrium has been established during hydrogenation with respect to 2-naphthol and the intermediate tetralols and gives a support for the suggestion made above. Such a complete establishment of adsorption-desorption equilibrium has also been observed in the palladium-catalyzed hydrogenation of isomeric cresols where the formation of methylcyclohexanones as intermediates has been shown to be quantitative.[28]

Table 7. Selectivity ratio for hydrogenation of the unsubstituted ring to the substituted ring

Catalyst	2-Naphthol	Catalyst	2-Methyl-naphthalene[a]
Ru	7.0	0.6% $Ru-Al_2O_3$	4.0
Rh	8.5	0.6% $Rh-Al_2O_3$	3.7
Pd-C	3.2	0.6% $Pd-Al_2O_3$	1.3
Os	9.3	5% Pd-C	3.0
Ir	9.8		
Pt	13.3		

a) Data based on the results in Fig. 11 by A. W. Weitkamp, *Adv. Catal.*, **18**, 1 (1968). 2-Methylnaphthalene was hydrogenated at 100 °C and *ca.* 7 MPa H_2 pressure.

The Rates of Hydrogenation of 2-Naphthol and 2-Tetralols. The relative rates of hydrogenation of *ar*- or *ac*-2-tetralol to 2-naphthol are given by the values of K in Eq. 1. The values were evaluated on the basis of the results shown in Fig. 1 and are summarized in Table 8. The rate constants in individual hydrogenation for 2-naphthol and *ar*-2-tetralol (k_{NL} and $k_{ar\text{-}TL}$) are also shown in Table 8. By assuming the relationship: K (*ar*-TL/NL)=($k_{ar\text{-}TL}/k_{NL}$)($b_{ar\text{-}TL}/b_{NL}$),[23] where K (*ar*-TL/NL) represents the relative reactivity of *ar*-2-tetralol to 2-naphthol and $b_{ar\text{-}TL}$ and b_{NL} are the adsorption coefficients for *ar*-2-tetralol and 2-naphthol, we can evaluate the relative ratio of the adsorption coefficients for *ar*-2-tetralol and 2-naphthol. These are also given in Table 8. The results in Table 8 clearly show that the low reactivities of *ar*-2-tetralol in the

Table 8. Rate data for the hydrogenation of 2-naphthol and 2-tetralols[a]

Catalyst	K(*ac*-TL/NL)	K(*ar*-TL/NL)	$10^3 k_{NL}$	$10^3 k_{ar\text{-}TL}$	$\frac{k_{ar\text{-}TL}}{k_{NL}}$	$\frac{b_{ar\text{-}TL}}{b_{NL}}$
			mol min^{-1} g $metal^{-1}$			
Ru	0.050	0.046	19.9	6.51	0.33	0.14
Rh	0.305	0.205	22.4	20.5	0.92	0.22
Pd-C	0	0.01	9.98	0.562	0.056	0.18

Pt	0.24	0.16	3.66	2.88	0.79	0.20

a) K is the relative reactivity of *ac*- or *ar*-2-tetralol to 2-naphthol (see Eq. 1); k is a rate constant in individual hydrogenation; b represents the adsorption coefficient for 2-naphthol or *ar*-2-tetralol.

presence of 2-naphthol, as expressed by the small values of K (*ar*-TL/NL), result from a strong adsorption of 2-naphthol over *ar*-2-tetralol. Although the values of K for *ac*-2-tetralol are larger than those for *ar*-2-tetralol except over palladium, the situation would be similar for *ac*-2-tetralol as well. Hydrogenation with palladium is noteworthy in that the values of K are extremely small for both *ar*- and *ac*-2-tetralols, and in contrast to the other metals, the value of $k_{ar\text{-TL}}/k_{\text{NL}}$ is also very small (0.056). Thus it is concluded that in the palladium-catalyzed hydrogenation of 2-naphthol the difference in the rates between 2-naphthol and *ar*-2-tetralol plays a more important role than the difference in the strengths of adsorption for the selective formation of *ar*-2-tetralol. It will be possible that this situation affects the product controlling step over palladium to be different from those on the other metals, as suggested in the preceding discussion. On the other hand, with rhodium catalyst the rate constants in individual hydrogenation are almost of the same magnitude for 2-naphthol and *ar*-2-tetralol and the selectivity is mostly controlled by a difference in strength of adsorption between the two compounds.

The Ketones as Intermediates. It is well documented that cyclohexanones are formed as intermediates in the hydrogenation of phenols.[2] With Raney nickel[29] and palladium[28] the formation of the ketone intermediates has been shown to be quantitative in hydrogenation of phenol and cresols, respectively. With ruthenium and rhodium some 50—70% of methylcyclohexanones are formed in hydrogenation of cresols, while the detectable amounts of the ketones are very small over the 3rd row platinum metals (Os, Ir, Pt).[28,30] In the hydrogenation of 2-naphthol, the formation of 2-tetralone was observed over palladium to the extent of 8.5% as an intermediate to *ac*-2-tetralol (see Table 1). However, the ketone was not formed in detectable amounts over the other metals. It will be possible that the ketone is also formed over the metals other than palladium, but is hydrogenated without leaving the catalysts, because it is presumed that the benzene ring in 2-tetralone may contribute to a strong adsorption and/or a high reactivity of the ketone. On the other hand, the formation of 2-decalone was observed over the metals except osmium with *ar*-2-tetralol (Fig. 2). It should be noted that, except with palladium, the 2-decalone found was the cis isomer only (see Table 3). It seems that this is related to the high stereoselectivities of ruthenium and rhodium for formation of the cis products at the ring juncture, as will be discussed later. In general, the amounts of 2-decalone given in Table 3 are considerably smaller than those of methylcyclohexanones reported in the hydrogenation of cresols.[28,30] Probably the use of *t*-butyl alcohol as solvent has decreased the detectable amounts of 2-decalone since hydrogenation of *m*-cresol in *t*-butyl alcohol has also decreased the amounts of 3-methylcyclohexanone formed during hydrogenation, compared to the hydrogenation without solvent.[31]

Hydrogenolysis. The proportion of hydrogenolysis obtained in hydrogenation of 2-naphthol and *ac*- and *ar*-2-tetralols is summarized in Table 9. It is clearly seen from the results in Table 9 that the hydrogenolysis occurs far more extensively over the 3rd row platinum metals (Os, Ir, Pt) than over the 2nd row metals (Ru, Rh, Pd). This characteristics is much pronounced in the hydrogenation of *ar*-2-tetralol and 2-naphthol. A similar trend of the platinum metals have also been observed in the hydrogenation of cresols.[30] The degree of the hydrogenolysis, however, is much higher with 2-naphthol and *ar*-2-tetralol than with cresols. Such an extensive hydrogenolysis in a phenol ring has also been reported in the hydrogenation of 2,5-dimethylphenol with an iridium catalyst.[32] Hydrogenolysis occurs to much lesser extents with *ac*-2-tetralol which is a homobenzyl-type alcohol. The proportion of hydrogenolysis which occurs in the pathway not *via ac*- and *ar*-2-tetralols is unusually high with ruthenium and rhodium, compared to the results with *ar*-2-tetralol and 2-naphthol. It is presumed that unsaturated alcohols, rather than unsaturated ketones, are concerned as intermediates with the high degree of hydrogenolysis in the pathway leading to direct formation of decalins and 2-decalols. This consideration comes from the fact that hydrogenation of *ar*-2-tetralol gives only slight hydrogenolysis with ruthenium and rhodium, where formation of the intermediates leading to 2-decalone may be significant and the hydrogenation through this pathway may be accompanied by little hydrogenolysis.

Table 9. Proportion of hydrogenolysis in the hydrogenation of 2-naphthol and *ac*- and *ar*-2-tetralols

Catalyst	Proportion of hydrogenolysis/mol%				
	ac-TL	*ar*-TL	Pathway not via *ac*- and *ar*-TL	NL	
				Calcd	Obsd
Ru	0.5	0.6	10.3	1.7	2.1

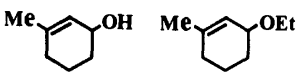
Pd-C	1.6	0.2	—	0.5	0.2
Os	5.3	28.5	27.6	26.6	35.0
Ir	3.2	36.0	35.5	33.6	33.0
Pt	7.2	41.6	46.4	40.5	36.9

From the amounts of hydrogenolysis for *ar*- and *ac*-2-tetralols, and for the pathway not *via* the tetralols, together with the selectivities for the respective pathways, we can calculate the amounts of hydrogenolysis that would occur in the hydrogenation of 2-naphthol. In Table 9 the amounts of hydrogenolysis thus calculated are compared with those obtained in the complete hydrogenation of 2-naphthol (see Table 6). It is seen that agreements between the calculated and observed values are generally satisfactory. With osmium, however, a considerably greater amount of hydrogenolysis was obtained with 2-naphthol, although the reason for that is not certain.

Possible intermediates that may lead to the extensive hydrogenolysis over the 3rd row metals are not clear from the knowledge now available. Both allyl- and enol-type intermediates must be taken into consideration. It seems that the extensive hydrogenolysis is difficult to explain by the allyl-type intermediates alone, because, as presumed from the results on an allyl alcohol

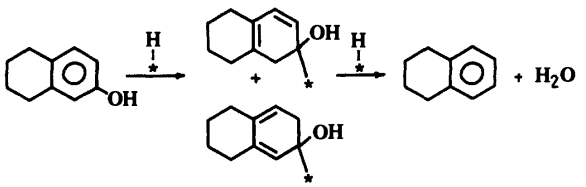


2 3

2 and its ethyl ether **3**,[1,30,33] allyl-type compounds are hydrogenolyzed not so extensively over the 3rd row metals as to be able to explain the present results. Rather, the high degree of hydrogenolysis over the 3rd row metals is a characteristics of an enol-type compounds towards hydrogenolysis as has been shown previously.[1,21] If this is the case, the intermediates leading to the extensive hydrogenolysis are presumed to be the adsorbed enols that are hydrogenated without being isomerized to the corresponding ketones, because 2-decalone, and possibly its precursors as well, should be hydrogenated with only slight hydrogenolysis even over the 3rd row metals, as shown in Table 4. The metals of low olefin isomerization activity such as the 3rd row metals may have a strong affinity for the olefinic bonds of the adsorbed enols and thus may activate the carbon–oxygen bond to be susceptible to hydrogenolysis, as has been discussed previously.[1,21]

The hydrogenolysis to give tetralin has also been observed at initial stages of the hydrogenation of 2-naphthol and *ar*-2-tetralol. The tetralin formation amounted to 7.2% with platinum in the hydrogenation of *ar*-2-tetralol. With the other metals, however, the amounts of tetralin detected were small and the route through tetralin will not be significant for the formation of decalins. The hydrogenolysis leading to tetralin is considered to occur through the half-hydrogenated states derived from *ar*-2-tetralol (an unsaturated enol), as shown in Scheme 2. This type of hydrogenolysis has previously been observed in the hydrogenation of *p*-ethoxytoluene in ethanol where toluene was formed to an extent of 8% over platinum.[33]

The Stereochemistry of Hydrogenation. In Table 10 are compared the amounts of the cis products at the ring juncture from hydrogenation of 2-naphthol and *ac*-and *ar*-2-tetralols. It is seen that, except with palladium and platinum, the selectivities for the cis products are very high for 2-naphthol and *ar*-2-tetralol. With *ac*-2-tetralol the selectivities decrease with ruthenium and rhodium to 88.0 and 87.1%, respectively. The high stereoselectivities of osmium and iridium are in accord with the results previously obtained with *o*-xylene and 1,2-dimethylcyclohexene.[34] However, the high stereoselectivities of ruthenium and rhodium as observed with 2-naphthol and *ar*-2-tetralol appear rather unusual, compared to the results on *ac*-2-tetralol as well as *o*-xylene and 1,2-dimethylcyclohexene.[2c] The unusually high selectivities of ruthenium and rhodium are probably related to the stereoselective formation of *cis*-2-decalone on the catalyst surface, because, as presumed from the results on cresols that the ketones are formed in the amounts of 50—70%, the hydrogenation through a ketone may be a significant pathway in hydrogenation of phenolic compounds over ruthenium and rhodium, although estimated amounts of 2-decalone were not so great (Table 3). The tendency of palladium to produce the trans products is in agreement with the results reported on aromatic hydrocarbons and related cycloolefins.[2c,3,27] A considerable amount of the trans isomer was also found in the 2-decalones formed from *ar*-2-tetralol over palladium. These results support the suggestion that the product controlling step over palladium differs from those on the other metals.



Scheme 2. Hydrogenolysis of *ar*-2-tetralol leading to the formation of tetralin.

TABLE 10. SELECTIVITY FOR THE CIS PRODUCTS AT RING JUNCTURE IN HYDROGENATION OF 2-NAPHTHOL AND *ac*- AND *ar*-2-TETRALOLS

Catalyst	Cis products/mol%		
	2-NL	*ac*-TL	*ar*-TL
Ru	97.5	88.0	98.9
Rh	95.1	87.1	96.1

Ir	97.6	95.2	97.8
Pt	87.3	86.2	87.2

Table 11 shows the selectivities for formation of *cis*-2-decalols (cis,cis and cis,trans isomers) and *cis,cis*-2-decalol in the decalol mixture. It is seen that the high selectivities for *cis*-2-decalols from 2-naphthol and *ar*-2-tetralol considerably decrease for *cis,cis*-2-decalol. The decrease is particularly pronounced in the case of ruthenium (from 99.0% to 70.6% with *ar*-2-tetralol). These results suggest that a stepwise hydrogenation is occurring in the course to saturated products even over those metals that give high yields of the cis products at the ring juncture. It is noted that the yields of *cis*-2-decalols and *cis,cis*-2-decalol in hydrogenation of 2-naphthol and *ar*-2-tetralol are much higher with ruthenium (95.6 and 69.5% for 2-naphthol; 98.4 and 70.2% for *ar*-2-tetralol) and with rhodium (92.4 and 70.8% for 2-naphthol; 95.1 and 77.7% for *ar*-2-tetralol)

TABLE 11. STEREOCHEMISTRY OF THE FORMATION OF 2-DECALOLS IN HYDROGENATION OF 2-NAPHTHOL AND *ac*- AND *ar*-2-TETRALOLS

Catalyst	Cis isomers[a] and cis,cis isomer in 2-decalols /mol%					
	NL		*ac*-TL		*ar*-TL

a) *cis,cis*- and *cis,trans*-2-Decalols.

than with the 3rd row metals because of the occurrence of extensive hydrogenolysis with the latter metals. In accord with the results in the literature,[4,11,12] the highest yield of the cis,cis isomer was obtained in the hydrogenation of *ar*-2-tetralol with rhodium catalyst. The yield further increased to 85.4% in the hydrogenation at 30 °C and 10 MPa of hydrogen pressure. The selectivities for the cis,cis isomer is generally much lower with *ac*-2-tetralol, as would be expected, because *ac*-2-tetralol can be adsorbed to the catalyst to afford the cis,trans isomer as equally as to give the cis,cis isomer. It is noteworthy that in the hydrogenation of *ar*-tetralol the proportion of *cis,cis*-2-decalol in *cis*-2-decalols is the greatest with palladium (84.6%) and the value is very close to that obtained in the hydrogenation of *cis*-2-decalone (84.9%) (see Table 4). This is in line with the findings that the hydrogenation through a ketone may be the exclusive pathway in the palladium-catalyzed hydrogenation of phenols.[28] The reason for the high stereoselectivity of palladium in the formation of the cis,cis isomer from *cis*-2-decalone is not certain. Since the conformation of *cis*-2-decalone is accepted not to be fixed, the stereochemistry of hydrogenation of *cis*-2-decalone would be not simply interpreted, as discussed by Hückel and coworkers.[35]

The Viscosity Coefficients of 18-Crown-6–Alkali Metal-ion Complexes

Fumio KAWAIZUMI,* Isao YAJIMA, Hiroyasu NOMURA, and Yutaka MIYAHARA
Department of Chemical Engineering, School of Engineering, Nagoya University, Chikusa-ku, Nagoya 464
(Received August 22, 1983)

The viscosities of LiCl, KCl, and CsCl have been measured in water and aqueous solutions containing 0.398 mol/dm^3 of 18-crown-6 (CR) at 25 °C. The *B*-coefficients of the alkali metal chlorides in water have been obtained using the theoretical values of the *A*-coefficients. The viscosity coefficients of 18-crown-6 itself have been determined in water and methanol. In systems containing crown ether, the viscosity increment due to the complex formed in solutions, $\Delta\eta_{[CR\text{-}M^+]Cl^-}$, has been evaluated by subtracting from the observed viscosity the increment attributed to non-coordinated crown ether and alkali metal chlorides in solutions. The two complex ions, [CR-K$^+$] and [CR-Cs$^+$], have nearly the same values of the *B*-coefficients, and these values are, in turn, approximately equal to that of 18-crown-6 in water. Measurements done on KCl in methanol containing 18-crown-6 have led to the finding that in methanol, 18-cown-6 and the [CR-K$^+$] ion take effectively the same *B*-value.

Macrocyclic polyether, crown ether, is known to form stable complexes with alkali or alkaline earth metal ions. The complex formation is characterized by the selectivity of certain crown ethers towards specific cations. A number of investigators[1–9] have endeavored to clarify the origin of the specificity observed in the interactions between crown ethers and metal ions in solutions. The metal ion is trapped in the central cavity of the crown ether by ion-dipole forces, and the ratio of the ionic radius of the cation to the dimension of the crown-ether cavity seems to be the most important factor governing the specificity of the complex formation, though an exception to the correlation of the cationic size with the hole size of crown ethers has been reported very recently.[8]

The effective volumes can presumably be expected to be different for the crown ether-cation complex and non-coordinated crown ether. When solute species flow in viscous media, the volume of solutes should affect the dragging resistance forces. Further, in spite of being a macroscopically measurable quantity, the viscosity of solutions has been found to give information on molecular interactions in solutions.

The purpose of this study is to determine the concentration dependence of the viscosity of solutions of three kinds of alkali chlorides (LiCl, KCl, and CsCl) in aqueous solutions containing 18-crown-6, and then to assess the contributions attributed to the crown ether-alkali metal-ion complexes. 18-Crown-6 has a very high solubility in water, which is an important factor in carrying out any viscometric study. The complex formation of an alkali metal ion with 18-crown-6 has been well confirmed for K$^+$ and Cs$^+$ ions in water, but this is not the case for Li$^+$. Therefore, as will be described in a later section, our experimental results for LiCl will be discussed from a standpoint different from that used for KCl and/or CsCl.

In order to compare the solvent effects, measurements have also been done for KCl in methanol and that containing 18-crown-6.

Experimental

Specimens and Solvents. The 18-crown-6 (abbreviated hereafter as CR) was purchased from the Nakarai Chemicals Co., Ltd. It was purified in a manner similar to the procedure proposed by Gokel and Cram;[10] about 50 g of CR were placed in an Erlenmeyer flask, into which 250 cm^3 of acetonitrile were then poured. The slurry was stirred and heated in a water bath held at 70 °C. A glass tube containing a drying agent was attached to the flask to prevent the penetration of humidity. The solution was then filtered. This process was repeated three times. After being stirred vigorously, the solution was allowed to cool to the ambient temperature. After the deposition of a fine white precipitate, the solution was kept in a refrigerator for 12 h. The precipitate was then collected by filtration. From the precipitate (CR-acetonitrile complex), acetonitrile was eliminated by heating at 35 °C under reduced pressure; then the product was kept in a vaccum for 48 h.

Guaranteed-grade chlorides were heated at 110—130 °C for more than 24 h; they were subsequently used without further purification.

Distilled and then deionized water was used as a solvent. The methanol was purified first by dehydrating it by means of a molecular sieve; then it was distilled by an ordinary procedure.

Apparatus and Measurements. In contrast to the case of the determination of the molecular weight of polymers, the use of an Ubbelohde viscometer of a conventional type is improper for the present purpose, since the degree of variation of the viscosity upon the addition of solutes with respect to the viscosity of pure solvent is relatively small. Therefore, an improved Ubbelohde viscometer with a sufficient efflux time at a low shear rate was designed and used. It has four successive bulbs, and the solution flows through a long capillary tube wound in a spiral form. The efflux times for water at 25 °C are 554, 887, and 1,377 s for the second, third, and fourth bulbs respectively. In addition, to determine the viscosity coefficient with a high degree of precision, measurements of the viscosity were carried out at approximately twenty different concentrations of salts in water as well as in aqueous solvents containing 18-crown-6 (the concentration of CR was 0.398 mol/dm^3), which have also served as solutions to determine the viscosity coefficients of non-coordinated 18-crown-6 in water. The concentration ranges of the salts investigated are much wider than in ordinary viscometric measurements.[11] On the other hand, in methanol, on account of the low solubility of KCl, experiments on KCl have been limited to concentrations far lower than in aqueous media (for KCl in methanol, up to *ca.* 0.03 mol/dm^3). The concentration of CR in methanol for KCl was 0.02085 mol/dm^3. Sample solutions were prepared by weight, and the concentrations of the solute were converted into volumetric concentration scales using the density data of solutions.

The densities were measured by means of a Digital Precision Density Meter, type DMA-02C, manufactured by the

Anton Paar Co., Ltd. The numerical values of density necessary were interpolated from the mathematical expression of the density-volumetric concentration relation obtained by the least-squares fitting of the experimental data.

All measurements were done at 25±0.05 °C.

Results and Discussion

Viscosity of LiCl, KCl, CsCl, and 18-Crown-6 in Water. The concentration dependence of the relative viscosity of dilute electrolyte solutions have been expressed in terms of the Jones-Dole equation:[12]

$$\eta_{rel} = 1 + Ac^{1/2} + Bc, \quad (1)$$

or:

$$\psi \equiv (\eta_{rel}-1)/c^{1/2} = A + Bc^{1/2}, \quad (2)$$

where c is the molarity. The B-coefficient has often been determined as a slope of the relation of Eq. 2 by plotting the data obtained in relatively dilute concentrations. However, our measurements, carried out up to rather high concentration ranges (for LiCl, to 0.65, and for KCl and CsCl, to 0.9—1 mol/dm^3), require a modified form of Eqs. 1 and 2:

$$\eta_{rel} = 1 + Ac^{1/2} + Bc + Dc^2, \quad (3)$$

or:

$$\psi = A + Bc^{1/2} + D(c^{1/2})^3. \quad (4)$$

The simultaneous determination of the parameters A, B, and D by means of simple least-squares fitting of the experimental data to the third-order equation of $c^{1/2}$ failed, for the analysis gave a negative value of A for the case of LiCl, a fact contradictory to the theory.[13,14] Therefore, the coefficients B and D have been determined in the following way: first, the A-coefficient was calculated according to the theory proposed by Falkenhagen.[13,14] Then, Eq. 4 was rearranged into the expression shown below:

$$(\eta_{rel}-1-Ac^{1/2})/c = B + Dc. \quad (5)$$

Using the calculated values of A-coefficients, the left-hand side of Eq. 5 was evaluated; meanwhile, the coefficients B and D have been obtained from the most suitable plot of the relation of Eq. 5. As an example, the case for CsCl is illustrated in Fig. 1. The unmerical values of the B- and D-coefficients thus obtained are summarized in Table 1, along with the values of the A-coefficient calculated and used. Our B-coefficients are in excellent agreement with the values given by Kaminsky[15] and Isono.[16] Differences exist, however, in the values of D. These differences seem to arise from the differences in the concentration ranges concerned in the measurements. Isono,[16] aiming to ascertain correlations between B- and D-coefficients, has carried out measurements in highly concentrated solutions (up to 3.5, 5.9, and 3.7 mol/dm^3 for KCl, CsCl, and LiCl respectively).

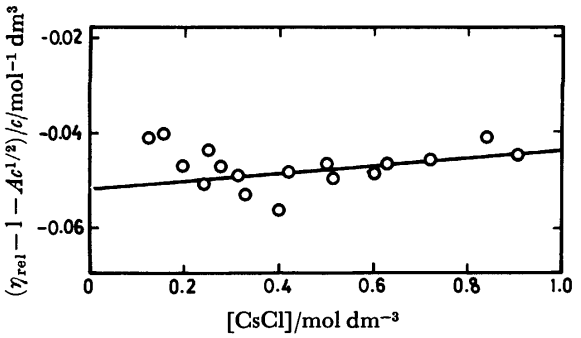

Fig. 1. Plot of $(\eta_{rel}-1-Ac^{1/2})/c$ against molar concentration c of CsCl in water at 25 °C.

The relative viscosities of aqueous solutions of 18-crown-6 measured in the concentrations less than 0.4 mol/dm^3 can be represented in terms of an equation similar to Eq. 3:

$$\eta_{rel} = 1 + B'c + D'c^2, \quad (6)$$

where the term corresponding to $Ac^{1/2}$ in Eq. 3 is dropped, for this term refers to interionic interaction and is unnecessary for non-electrolytic solute. The plot of $(\eta_{rel}-1)/c$ against c has led to the following values of the B'- and D'-coefficients:

$$B' = 0.846 \text{ dm}^3/\text{mol} \text{ and } D' = 0.559 \text{ (dm}^3/\text{mol)}^2.$$

Below, this B' value will be compared with the corresponding values of the [CR-M$^+$] ions.

Viscosity of LiCl, KCl, and CsCl in Aqueous Solutions Containing 18-Crown-6. The effects of an added solute on the relative viscosity should be expressed as:

$$\eta_{rel} = 1 + \Delta\eta_{solute}, \quad (7)$$

where $\Delta\eta_{solute}$ refers to the resultant variation in the relative viscosity of the solution due to the added solute. Aqueous solutions containing both 18-crown-6 and an electrolyte were prepared by introducing the electrolyte into the aqueous solutions containing 18-crown-6. First, the following relation has been considered as a starting equation for the data analysis:

$$\eta_{rel} = (1+\Delta\eta_{CR}) + \Delta\eta_{electrolyte}. \quad (8)$$

Mention should be made of the fact that the η_{rel} of the above equation is not related to the viscosity of the aqueous solutions containing 18-crown-6 to which the electrolyte is added, but to the viscosity of pure water.

Table 1. Viscosity coefficients of extended Jones-Dole equation for LiCl, KCl, and CsCl in water at 25 °C

	A[a]	B			D	
	[dm^3/mol]$^{1/2}$	[dm^3/mol]			[dm^3/mol]^2	
LiCl	0.0065	0.137	0.1425[b]	0.134[c]	0.0065	0.013[c]
KCl	0.0050	−0.0137	−0.0140[b]	−0.015[c]	0.0033	0.008[c]
CsCl	0.0049	−0.0517	−0.052[b]	−0.060[c]	0.0077	0.013[c]

a) Values calculated from theory. b) Values reported by M. Kaminsky.[15] c) Values reported by T. Isono.[16]

Equation 8 is equivalent to the assumption of a superposition of effects due to the crown ether and the electrolyte; in other words, there are no interactions between 18-crown-6 and electrolytic solutes in solutions. In actuality, however, such a crude assumption does not hold, and an attempt to represent experimental results in terms of Eq. 8 was unsuccessful for any kind of chloride investigated.

For KCl and CsCl, a complex formation with 18-crown-6 occurs.[1] We, therefore, have transformed Eq. (8) into the following form and analyzed the data related with KCl and CsCl:

$$\eta_{rel} = 1 + \Delta\eta_{CR} + \Delta\eta_{MCl} + \Delta\eta_{[CR-M^+]Cl^-}, \quad (9)$$

where $\Delta\eta_{[CR\cdot M^+]Cl^-}$ represents the variation in the solution viscosity due to the chloride of the crown ether-cation complex, $[CR\text{-}M^+]Cl^-$, formed in the solutions. Furthermore, considering the complex $[CR\text{-}M^+]Cl^-$ as an ordinary salt, we impose the following relation on $\Delta\eta_{[CR\cdot M^+]Cl^-}$:

$$\Delta\eta_{[CR\cdot M^+]Cl^-} = A(c_{[CR\cdot M^+]Cl^-})^{1/2} + Bc_{[CR\cdot M^+]Cl^-} \quad (10)$$

The actual contributions of $\Delta\eta_{CR}$, $\Delta\eta_{MCl}$, and $\Delta\eta_{[CR\cdot M^+]Cl^-}$ are dependent upon the amounts of the respective species present in the solutions. From the experimental concentrations and the stability constants, K, of the complex ions $[CR\text{-}M^+]$, the equilibrium concentrations of each solute species, $[M^+]$, $[CR]$, and $[CR\text{-}M^+]$, can be calculated. The stability constants of 18-crown-6-alkali metal ion complexes have been reported by Frensdorff[17] and by Izatt *et al.*[18] The values given by these authors are similar for the complex ion $[CR\text{-}K^+]$ ($\log K$=2.06[17] and 2.03[18]), while a certain difference exists for $[CR\text{-}Cs^+]$ ($\log K$=0.8[17] and 0.99[18]). We have used Frensdorff's values, which are concentration-equilibrium constants. After subtracting the amounts attributed to $\Delta\eta_{CR}$ and $\Delta\eta_{MCl}$, the resultant $\Delta\eta_{[CR\cdot M^+]Cl^-}$ has been found to be expressed in the form of the equation:

$$\frac{\Delta\eta_{[CR\cdot M^+]Cl^-}}{(c_{[CR\cdot M^+]Cl^-})^{1/2}} = A_{[CR\cdot M^+]Cl^-} + B_{[CR\cdot M^+]Cl^-}(c_{[CR\cdot M^+]Cl^-})^{1/2} \quad (11)$$

The results of the analysis of the data of CsCl carried out in this way are shown in Fig. 2. The straight line in Fig. 2 seems to support our approach. The final results of the $A_{[CR\cdot M^+]Cl^-}$ and $B_{[CR\cdot M^+]Cl^-}$ coefficients obtained, respectively, as the intercept and the slope of the relation of Eq. 11, are given in Table 2, which also includes the value of the B-coefficient of 18-crown-6.

As was mentioned in the last part of the introductory section of this paper, the stability constant of the complex ion $[CR\text{-}Li^+]$ has not been reported. Consequently, the analysis of our viscosity data for LiCl along the lines adopted for KCl and CsCl, namely, the analysis of the data using Eqs. 9 to 11, is impossible at present. However, as we have seen in the foregoing discussion, the simple additivity relation, as expressed in terms of Eq. 8, was unsuccessful in reproducing the experimental data for LiCl.

For the comparison of the B-coefficient of $[CR\text{-}M^+]Cl^-$ with that of 18-crown-6, the contribution from the

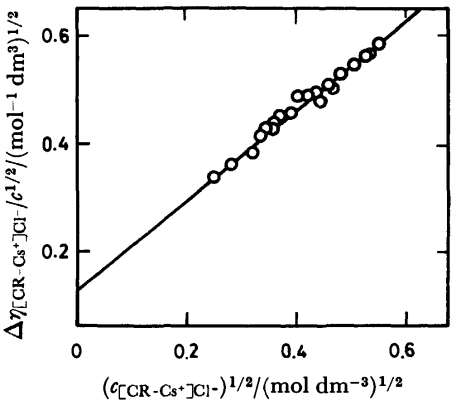

Fig. 2. Concentration dependence of $\Delta\eta_{[CR\text{-}Cs^+]Cl^-}/(c_{[CR\text{-}Cs^+]Cl^-})^{1/2}$ plotted against $(c_{[CR\text{-}Cs^+]Cl^-})^{1/2}$ for $[CR\text{-}Cs^+]Cl^-$ complex in water at 25 °C. The symbol c attached to the vertical axe means here $c_{[CR\text{-}Cs^+]Cl^-}$.

Table 2. Viscosity coefficients of 18-crown-6 and those assigned to 18-crown-6-alkali metal-ion complexes in aqueous solutions at 25 °C

	A $[dm^3/mol]^{1/2}$		B $[dm^3/mol]$
18-crown-6	—		0.846[b]
$[CR\text{-}K^+]Cl^-$	0.118	0.0082[a]	0.87
$[CR\text{-}Cs^+]Cl^-$	0.12		0.83

a) Theoretical value calculated using conductivity data reported in Ref. 9. b) B'-coefficient of Eq. 6.

Cl^- ion should be considered. Somewhat different values have been assigned to the values of the B-coefficient of the Cl^- ion on the basis of different criteria for the division: −0.007,[15] 0.014,[19] and −0.033.[20] In any case, the effect of the complex ion $[CR\text{-}M^+]$ is overwhelming. This fact enables us to compare the B values of Table 2. The complex ions $[CR\text{-}K^+]$ and $[CR\text{-}Cs^+]$ have similar values of the B-coefficients, and these values are near the B'-coefficient of the non-coordinated 18-crown-6 in water. Generally speaking, a direct comparison of the viscosity coefficient for an electrolyte with that for a nonelectrolyte is not free from disputation. This is because the concentration dependences of solution viscosities are expressed in different forms for electrolytes and nonelectrolytes. However, from the results given in Table 2, we can say that the dragging resistances of $[CR\text{-}K^+]$ and $[CR\text{-}Cs^+]$ complex ions are approximately the same as that of non-coordinated 18-crown-6 in water.

A theoretical evaluation of the A-coefficient is possible for the $[CR\text{-}K^+]Cl^-$ complex from the reported value of the limiting molar conductivity of the complex.[9] Our experimental A-coefficient of the $[CR\text{-}K^+]Cl^-$ complex is more larger than the theoretical one. A comparison of the experimental and theoretical A-coefficients for the $[CR\text{-}Cs^+]Cl^-$ complex is impossible because of the lack of conductivity data for this complex.

Viscosity Coefficients in Methanol Systems. As has already been mentioned in the Experimental section of this paper, viscosity measurements in methanol

Table 3. Viscosity coefficients of 18-crown-6, KCl, and [CR-K+]Cl complex in methanol at 25 °C

	A $[dm^3/mol]^{1/2}$	B $[dm^3/mol]$
18-crown-6	—	0.44[c]
KCl	0.024, 0.0173[a]	0.736, 0.7635[d]
$[CR\text{-}K^+]Cl^-$	0.039, 0.0208[b]	0.86

a) Theoretical value found in H. Falkenhagen, "Theorie der Electrolyte," S. Hirzel, Stuttgart (1971), Chap. 10. b) Theoretical value calculated using conductivity data reported by Y. Takeda.[9] c) B'-coefficient of Eq. 6. d) Value given by G. Jones and H. J. Fornwalt.[21]

systems have been carried out in relatively low concentration ranges. In such circumstances, the D- or D'-coefficient of Eq. 3 or Eq. 6 need not be taken into account. For KCl in methanol, the A- and B-coefficients have been determined simultaneously from the least-squares plotting of Eq. 2, without paying any attention to the theoretical values of A. On the contrary, the experimental data on 18-crown-6 in methanol and KCl in CR-methanol systems have been treated in a way analogous to that in the aqueous media described above. The numerical values of the viscosity coefficients in methanol systems obtained are shown in Table 3. Our B-coefficient for KCl in pure methanol is a little smaller than that in the literature,[21] while our experimental value of the A-coefficient is larger than the theoretical one. In our results, a small experimental B-coefficient is compensated for by a large experimental A-coefficient. The comparison of Tables 2 and 3 shows that the dragging resistance of 18-crown-6 is smaller in methanol than in water. For the discussion of B-coefficient of the complex ion $[CR\text{-}M^+]$, the contribution from the Cl^- ion, B_{Cl^-}, should be subtracted. The principle of the assignment of the B-coefficient of a salt into its constituent ionic B values has not been well established for the data in nonaqueous solvents. Criss and Mastroianni[22] evaluated the ionic B-coefficients in methanol on the assumption that $B_{K^+}=B_{Cl^-}$, as in water.[15] Following their results, we can obtain 0.48~0.49 dm^3/mol as the value of $B_{[CR\cdot K^+]}$. This value is approximately identical with that of non-coordinated 18-crown-6 in methanol. The results shown in Tables 2 and 3 lead to the conclusion that the hydrodynamic volume of the complex ion $[CR\text{-}K^+]$ remains effectively the same as that of the non-coordinated 18-crown-6, irrespective of the solvent media surrounding the complex ion. Further measurements will be required, however, to discuss whether or not the conclusion obtained in this work is applicable to other solvent systems.

The authors wish to express their thanks to Dr. Toshiaki Isono of the Institute of Physical and Chemical Research, who informed them of the numerical values of the viscosity coefficients of this study prior to publication.

The Structure of Liquid Alcohols by Neutron Diffraction. II. Molecular Structure of Ethyl Alcohol

Yukio TANAKA,† Norio OHTOMO,† and Kiyoshi ARAKAWA*

Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

†*Faculty of Engineering, Hokkaido University, Sapporo 060*

(Received September 21, 1983)

The structure factor $S_m(Q)$ for liquid ethyl alcohol (C_2D_5OD) at room temperature was obtained by means of the time-of-flight (TOF) neutron diffraction method using electron LINAC. An analysis of the diffraction data was carried out and the molecular structure in liquid phase was determined as follows: the O-D, C-O, and C-C bond lengths are 0.960±0.010 Å, 1.410±0.010 Å and 1.510±0.010 Å, respectively.

In the preceding papers,[1-3] the structure of liquid water (D_2O) and the molecular conformation of liquid methyl alcohol (CD_3OD) were determined successfully by means of the LINAC-TOF neutron diffraction method. Then, as a part of a series of studies for hydrogen-bonded liquids, we have investigated the molecular structure of ethyl alcohol C_2D_5OD in liquid phase.

Several authors have performed studies of gaseous ethyl alcohol. Concerning molecular geometries, the coexistence of two molecular conformations has been reported, which are the hydroxyl trans form and the gauche one.[4-8] The O-H groups in liquid ethyl alcohol are known to be concerned with hydrogen bond.[9-11] But, due to the lack of experimental techniques, there is very scarce information of the molecular structure of ethyl alcohol in liquid phase, which is fundamental to the consideration on the hydrogen-bonded liquid structure. Because the molecular conformation of ethyl alcohol in liquid phase may be subjected to the effect of its comparatively large alkyl group as well as to that of hydrogen bonding, its geometry in liquid phase is very interesting in comparison with the cases of water[1,2] and methyl alcohol.[3]

These circumstances add special interest to the investigation of molecular conformations in liquid ethyl alcohol. The objective of the present work is not only to determine the molecular structure of ethyl alcohol C_2D_5OD in liquid phase but also to examine that of a series of hydrogen-bonded liquids, D_2O, CD_3OD, and C_2D_5OD. Then, we have carried out a LINAC-TOF neutron diffraction measurement on liquid ethyl alcohol and have made an analysis of the data to determine its molecular structure.

Experimental

The experiment was performed by means of the TOF neutron diffraction method using electron LINAC at Hokkaido University. Neutron scattering intensities were measured for liquid ethyl alcohol C_2D_5OD (purity of deuteration 99%, Commissariat à l' Energie Atomique (CEA), France) at room temperature at five different scattering angles: 2θ=30.0°, 40.0°, and 65.0° at 24.0±0.5 °C, 2θ=90.0° at 20.0±0.5 °C, and, 2θ=120.0 at 22.0±0.5 °C. A thin-walled cylindrical quartz vessel was used to contain the sample. Detailed experimental apparatus and procedures were reported elsewhere.[3,12] After all corrections (background, absorption, multiple scattering, inelastic scattering and incoherent scattering), absolute normalizations and Q-scale calibrations, we obtained structure factors $S_m(Q)$ for five different scattering angles as shown in Fig. 1. The coincidence of the values from different angles in each overlapping region of Q is quite well as seen in the figure, and, combining these data set, we obtained the final $S_m(Q)$ curve of wide Q range. The statistical error for values of the $S_m(Q)$ is smaller than 1.0%, and the resolving power $\Delta Q/Q$ less than a few % in the whole range of Q.

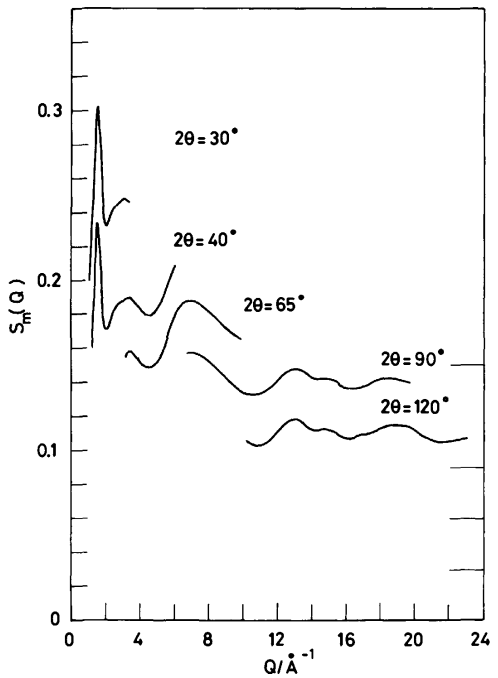

Fig. 1. Observed neutron structure factors $S_m(Q)$ for deutrated ethyl alcohol at various scattering angles.

Procedures of Analysis

Theoretical framework and procedures for determining the molecular structure from observed $S_m(Q)$ data have been stated previously,[3,13] and only a brief description is given here.

The intramolecular structure factor $f_1(Q)$, which is a dominant part of $S_m(Q)$ at higher Q, is written as,

$$f_1(Q) = \left(\sum_i b_i\right)^{-2} \sum_{ij} b_i b_j j_0(Qr_{ij}) \exp(-\gamma_{ij}Q^2), \quad (1)$$

where b_i is the coherent scattering length of i-th nucleus in the molecule, r_{ij} the distance between i-th and j-th nucleus, $2\gamma_{ij}$ the mean square variation to the distance r_{ij} and $j_0(x)=\sin x/x$ a zeroth order spherical Bessel function. $\sum$ is over all the nuclei in the molecule. With

respect to the mean square variation $2\gamma_{ij}$, we assume that $\gamma_{ij}=1/2D_{ij}^2r_{ij}$, where D_{ij} is estimated to be 0.03 Å$^{1/2}$ per Å for distances between carbon and oxygen atoms, 0.036 Å$^{1/2}$ for that between carbon atoms and 0.06 Å$^{1/2}$ for other distances in the molecule.[13]

The structure of ethyl alcohol molecule C_2D_5OD is shown in Fig. 2. The methyl group can rotate about the C-C axis in Fig. 2, and it is assumed that the three C-D bonds and the three DCD angles in the methyl group are all identical, respectively. It is also assumed that the deuterium atoms in the methylene group are located in plane symmetry about the CCO plane. The hydroxyl group can rotate about the C-O axis (Fig. 2). Then, we characterize the molecular structure by twelve structural parameters, *i.e.*, the bond lengths r_{OD}, r_{CO}, r_{CC}, r_{CD_M}, and r_{CD_N}, and, the angles COD, CCO, DCD_M, DCD_N, CCD_N, τ, and ϕ (Fig. 2). In order to determine these molecular parameters, $f_1(Q)$ were calculated for more than 15000 models by using Eq. 1 and the curves obtained were compared with the observed $S_m(Q)$ data in the higher Q region ($Q\gtrsim 6$ Å^{-1}).[3,13] The magnitudes of the parameters were varied in reference to the values given in Table 1.

Determination of the Molecular Structure

Observed Structure Factor Data. The structure factor data $S_m(Q)$ obtained for liquid ethyl alcohol C_2D_5OD is shown in Fig. 3. Comparing this $S_m(Q)$ data with those obtained for liquid water D_2O (Fig. 1 in Ref. 1 and Fig. 5 in Ref. 2), liquid methyl alcohol CD_3OD (Fig. 3 in Ref. 3) and liquid acetyl chloride CD_3COCl (Fig. 3 in Ref. 13) at room temperatures, we can point out several distinctive features as follows.

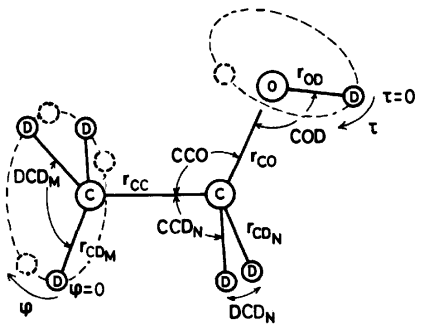

Fig. 2. The structure of deuterated ethyl alcohol (C_2D_5OD) molecule.

Table 1. Range of parameters

Parameter	Range	Interval of variation
r_{OD}/Å	0.930—1.010	0.010
r_{CO}/Å	1.380—1.445	0.005
r_{CC}/Å	1.480—1.540	0.010
r_{CD_M}/Å	1.070—1.100	0.005
r_{CD_N}/Å	1.070—1.100	0.005
COD/°	100.0—130.0	1.0
CCO/°	100.0—120.0	1.0
DCD_M/°	102.0—118.0	1.0
DCD_N/°	100.0—125.0	1.0
CCD_N/°	100.0—120.0	1.0
τ/°	0.0—360.0	5.0
ϕ/°	0.0—120.0	5.0
	free rotation	—

(1) With respect to the first peaks for the series of hydrogen-bonded systems, D_2O, CD_3OD, and C_2D_5OD, ratios of the heights to its $S_m(Q)$ values at $Q\to\infty$ decrease monotonously in the order of D_2O (≈2.0), CD_3OD (≈1.7), and C_2D_5OD (≈1.4). The same trend is seen for the peak positions (≈2.0 Å^{-1}, ≈1.8 Å^{-1}, and ≈1.5 Å^{-1} for D_2O, CD_3OD, and C_2D_5OD, respectively) as well as for their width as clearly seen.

(2) In the case of methyl alcohol CD_3OD, there is a doublet hump at *ca.* Q=4 Å^{-1}, and the similar but more subtle trend is observed for C_2D_5OD. On the other hand, for heavy water, there is a singlet hump at *ca.* Q=4 Å^{-1} of its $S_m(Q)$ curve. In the preceding paper of D_2O,[1,2] it is elucidated from the analysis of $S_m(Q)$ data that the hump is originated in the existence of the hydrogen-bonded liquid structure. Hydrogen-bonded structures are also expected in liquid CD_3OD and C_2D_5OD.[9-11] In addition to that, the calculated $f_1(Q)$ curves of these fluids have a peak at *ca.* Q=4 Å^{-1} (Ref. 3 for CD_3OD and Fig. 3 in this paper as seen in the next item), which is not seen in the case of water.[1,2] Then, these humps at *ca.* 4 Å^{-1} for CD_3OD and C_2D_5OD systems are due to the superposition of the two contributions: one of them is its intramolecular conformation and the other its intermolecular hydrogen-bonded structure.

(3) Concerning the second peaks at *ca.* Q=7 Å^{-1}, its intensity for CD_3OD and C_2D_5OD is distinctive, being in contrast to the broad second peak at *ca.* Q=8 Å^{-1} in the $S_m(Q)$ curve for D_2O. And, further, the position of each second peak is seen to shift to smaller Q side in the order of D_2O, CD_3OD, and C_2D_5OD (≈8.3 Å^{-1}, ≈7.1 Å^{-1}, and ≈6.8 Å^{-1}).

(4) Concerning the third peaks at *ca.* 13 Å^{-1}, the shoulder at *ca.* 14—15 Å^{-1} for C_2D_5OD is distinctive, being in contrast to the cases of D_2O and CD_3OD. It is noticeable that the nearly identical feature is seen in the data for liquid acetyl chloride.

(5) There are marked forth peaks at *ca.* Q=19 Å^{-1} of the data for CD_3OD and C_2D_5OD. These features are also seen in the case of liquid CD_3COCl.

Determination of Intramolecular Parameters for Liquid Ethyl Alcohol. By making the calculated $f_1(Q)$ curves fit with the observed $S_m(Q)$ data, we have determined the best structural parameters of liquid ethyl alcohol C_2D_5OD at room temperature as follows: r_{OD}=0.960±0.010 Å, r_{CO}=1.410±0.010 Å, r_{CC}=1.510±0.010 Å, r_{CD_M}=1.080±0.005 Å, r_{CD_N}=1.085±0.005 Å, COD=120.0±5.0°, CCO=105.0±1.0°, DCD_M=110.0±0.5DCD_N=112.0±3.0°, CCD_N=106.0±1.0°, and ϕ=12.0±5.0°.

Two structural models shown in Table 2, which differ only in the magnitudes of parameter τ determining the rotation angle of O-D bond, are found to give the best $f_1(Q)$ curves: τ=0.0°, the trans conformation and 160.0°, the gauche one. As seen in Fig. 3, the coincidence between the calculated $f_1(Q)$ curves for these models and the observed $S_m(Q)$ values is satisfactory

in the higher Q region ($Q \gtrsim 6$ Å^{-1}). The best structural parameters determined are tabulated in Table 3, together with those by other workers.[5,6,14]

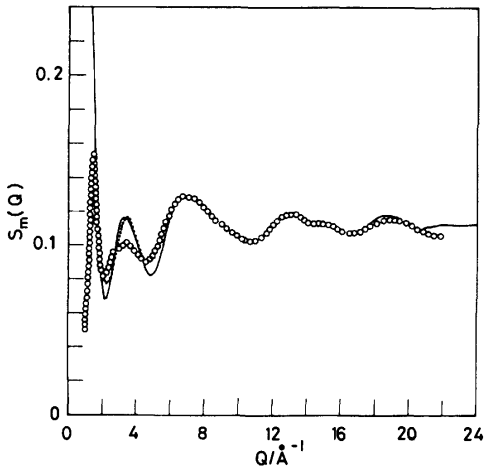

Fig. 3. Comparison between observed neutron structure factor $S_m(Q)$ and present $f_1(Q)$ curves calculated. ○: observed $S_m(Q)$, ——: calculated $f_1(Q)$ for the gauche conformation ($\tau=160.0°$, Table 2), ($\varepsilon=0.003327$), ·····: calculated $f_1(Q)$ for the trans conformation ($\tau=0.0°$, Table 2), ($\varepsilon=0.003328$).
ε is a measure for indicating the deviations of $f_1(Q)$ from the experimental data, and is expressed as,

$$\varepsilon=(\sum_i^N\{S_m(Q)_{obsd}-f_1(Q)_{calcd}\}^2)^{1/2}/\sum_i^N S_m(Q)_{obsd},$$

where N is the number of data points in the fitting range of Q, 6—18 Å^{-1}.

Structure of Molecules in Liquid State Compared with That in Gaseous One. By using microwave techniques, the geometrical parameters of ethyl alcohol molecules in gaseous phase were given by Sasada *et al.* for the trans and gauche conformations[5] and by Culot for the trans conformation[6] (Table 3). We have calculated the $f_1(Q)$ curves by using their parameters[5,6] and those are compared with the present $S_m(Q)$ curve in Fig. 4. Significant discrepancies between the present data and the $f_1(Q)$ curves calculated are seen on the whole range of Q. The disagreement at higher Q regions ($Q \gtrsim 6$ Å^{-1})[3,14] is ascribed to the variation of the intramolecular structure of molecules from gaseous to liquid states, as seen in Table 3.

One of the most interesting parameters of the molecule in liquid phase is the O-D distance, because a stretching of the bond length from gaseous to liquid phase gives a criterion for the strength of hydrogen bonds. As seen in Table 3, the present value of O-D distance obtained is 0.960±0.010 Å, and is nearly identical with that in gaseous state. It is distinguished from the cases of D_2O (0.98 Å)[1,2] and CD_3OD (0.99 Å),[3] and this trend suggests that the strength of hydrogen bonds for these fluid systems follows in the order of $C_2D_5OD \leq CD_3OD \leq D_2O$. The trend is also seen in the coordination numbers of these systems obtained by computer experiments.[11,15,16]

Concerning the C-O distance, we obtained the value of 1.410±0.010 Å. This is nearly identical with those obtained for gaseous dimethyl ether (1.410 Å)[17] and gaseous diethyl ether (1.408 Å),[18] and shorter than that obtained for gaseous ethyl alcohol by Culot (1.431 Å)[6]

and that by Sasada *et al.* (1.4247 Å, assumed value).[5] The Montague's value of the C-O bond, 1.571 Å in liquid phase is too large, as mentioned in their article.[14] The C-C distance obtained is 1.510±0.010 Å, being in good agreement with that by Culot (1.512 Å) in gaseous phase.[6] With respect to the methyl group, a slight shortening of the C-D distance and a slight increase of the DCDM angles are observed in comparison with those in gaseous state, and the same trend is also observed in the case of methyl alcohol.[3] The methyl rotation angle obtained is 12.0±5.0° and is nearly identical with that for liquid methyl alcohol.[3] Concerning the models with freely-rotating methyl group, the $f_1(Q)$ calculated is found to disagree with the observed $S_m(Q)$ ($Q\gtrsim6$ Å^{-1}) in contrast to the case of CD_3OD.[3] With respect to the angular parameters in the ethylene group, DCDN and CCDN angles are 112.0±3.0° and 106.0±1.0°, respectively, and is different from those in gaseous phase, about 108.0—110.7° for both angular parameters (Table 3). The C-D bonds in the ethylene group are 1.085±0.005 Å, and are shorter than those in gaseous phase, 1.094—1.098 Å (Table 3). With respect to the hydroxyl rotation angle τ for the gauche ethyl alcohol molecule, the present value is 160.0±10.0° and larger than that in gaseous state, 126.0±6.0°.[5]

Trans and Gauche Conformations with Respect to the Hydroxyl Internal Rotation. As stated in the preceding item, two conformations concerning the rotation of the OD radical, trans and gauche forms, are expected to exist in gaseous phase. With respect to the energy difference between the two conformations, Radom *et al.* gave the value of 0.63 kcal/mol by *ab initio* calculations.[19] In a recent microwave study on ethyl alcohol, Kakar and Quade showed that the energy difference is only 41.2 cm^{-1} (=0.12 kcal/mol).[8] The number ratio of trans to gauche molecules in the vapour phase at room temperature was estimated to be 2:1 by Barnes and Hallam.[4]

Jönssen reported the coexistence of the two conformers in solid phase by means of the X-ray diffraction.[20] According to the results the number ratio of the two conformers becomes 1:1. On the other hand there is no information concerning the rotational isomers in liquid phase. Considering the interaction between molecules within liquid, we can expect that the energy difference between the conformers of the trans and gauche types in liquid phase is small, and that the two types coexist in liquid phase as well as in gaseous and solid phases. Due to the small energy difference, the main frame of molecules won't be affected strongly by the hydroxyl rotation angle. Then, the present results that the two geometrical models of trans and gauche types fit with the observed $S_m(Q)$ data (Table 2 and Fig. 3) suggest the coexistence of the two conformers in liquid ethyl alcohol. The $f_1(Q)$ curves calculated for these two models are undiscriminated with each other at higher Q region ($Q\gtrsim6$ Å^{-1}, Fig. 3), and show a slight difference at the lower ($Q<6$ Å^{-1}), where intermolecular contributions appear as well as intermolecular ones. And, the number ratio of the two conformers in liquids is not determined in the present study.

On the Intermolecular Contribution to the Total Structure Factor $S_m(Q)$— the Effect of Debye-Waller Factors for Intermolecular Atomic Pairs.

In the present series of studies of liquid alcohols,[3] we have determined intramolecular structures within liquids by making calculated structure factors fit with observed diffraction data in the higher Q region ($Q\gtrsim6$ Å^{-1}), as described above. The procedure of analysis has been applied by several workers[1-3,13,21,22] including us for determining molecular structures from neutron diffraction data of liquids. For its successful application, the following fact is presupposed as the one established empirically for those molecular fluids treated (D_2O, CD_3OD, C_2D_5OD, CD_3COCl, C_3O_2, *etc.*): the $S_m(Q)$ is practically identical with $f_1(Q)$ (Eq. (1)) in the higher Q region ($Q\gtrsim6$ Å^{-1}) as the result of comparatively rapid decay of the intermolecular terms with increasing Q. We consider, here, why the intermolecular contributions decay so rapidly with increasing Q in these liquids. The most deterministic factor of that behavior of intermolecular terms at the high Q region may be tentatively considered to be the Debye-Waller factor of atomic pair between two molecules, and we concentrate our present concern to this problem.

Concerning the Debye-Waller factors for intermolecular atomic distances, which is expressed as exp ($-\gamma_{ij}Q^2$) ($2\gamma_{ij}$: the mean-square amplitude for the variation of the distance), a few discussions will be given below. The mean-square amplitude for the variation of the distance between atoms i and j in molecles p and

q ($p \neq q$) can be expressed as,

$$2\gamma_{ij} = \langle \Delta r_{cip}^2 \rangle + \langle \Delta r_{cpq}^2 \rangle + \langle \Delta r_{cjq}^2 \rangle. \quad (2)$$

$\langle \Delta r_{cip}^2 \rangle$ is the mean-square amplitude for the variation of the distance between the center of molecule p and its i-th atom, and $\langle \Delta r_{cpq}^2 \rangle$ is that for the distance between the centers of the p-th and q-th molecules. In the expression described above, the thermal vibration of atoms within a molecule and the thermal Brownian motion of the molecule on the whole are safely considered to be independent with each other, and the simple sum formula consists. The term $\langle \Delta r_{cpq}^2 \rangle$ is expressed as,

$$\langle \Delta r_{cpq}^2 \rangle = \langle \Delta r_{cp}^2 \rangle + \langle \Delta r_{cq}^2 \rangle = 2\langle \Delta r_{cp}^2 \rangle, \quad (3)$$

where $\langle \Delta r_{cp}^2 \rangle$ is the term due to the Brownian motion of the center of the molecule p. Then,

$$\gamma_{ij} = \langle \Delta r_{cp}^2 \rangle + \frac{1}{2}(\langle \Delta r_{cip}^2 \rangle + \langle \Delta r_{cjq}^2 \rangle). \quad (4)$$

The term $\langle \Delta r_{cp}^2 \rangle$ can be determined approximately from the effective free volume v_f (the statistical average of fluctuational void space[23,24]) and the effective hard-sphere diameter of molecules. The magnitude of the effective hard-sphere diameter is estimated from the first peak region of the $S_m(Q)_{obsd}$ by using the Percus-Yevick equation, that is, by making the theoretial $S(Q)$ fit with the observed first peak of $S_m(Q)$.[25-28] At the same time, we can obtain the packing fraction ξ, and can estimate the magnitude of v_f by the use of the Percus-Yevick equation.[23-24] Thus, for CD_3OD and C_2D_5OD, the magnitude of $\langle \Delta r_{cp}^2 \rangle^{1/2}$ becomes nearly equal at room temperature: 0.12 Å (the magnitudes of ξ also become nearly equal for these two alcohols, 0.36). The γ_{ij} for the intermolecular D···D pair in CD_3OD and C_2D_5OD becomes $(0.12)^2 + \langle \Delta r_{cD}^2 \rangle$, and $\langle \Delta r_{cD}^2 \rangle \gtrsim (0.06)^2$. Thus, for the intermolecular D···D pair, the term $\exp(-\gamma_{ij}Q^2)$ is found to decay to e^{-1} at about $Q \sim 7$ Å^{-1}. As clearly seen in the above rough estimation, the γ_{ij} for the intermolecular atomic pair is dominated by the contribution from the thermal Brownian motion of molecules, and this is expected to be the dominant factor for the rapid decay of the intermolecular contribution to the $S_m(Q)$ at about 6—7 Å^{-1} (Fig. 5) in sharp contrast to the case of the intramolecular terms. This is considered to be the main support of the adequacy of determining the intramolecular parameters from the observed $S_m(Q)$ in the higher Q region ($Q \gtrsim 6$ Å^{-1}).

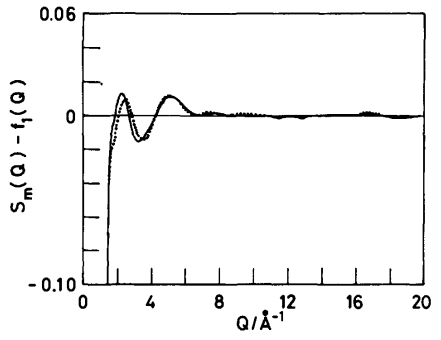

Fig. 5. Intermolecular contributions $S_m(Q)_{obsd} - f_1(Q)_{calcd}$ for the present two models.
——: intermolecular factor for the gauche conformation ($\tau = 160.0°$, Table 2), ·····: intermolecular factor for the trans conformation ($\tau = 0.0°$, Table 2).

Concluding Remarks

A neutron diffraction study of liquid ethyl alcohol (C_2D_5OD) by means of the LINAC-TOF method was performed and the structure of molecules within liquids was determined. The present result is primarilly due to the success in securing the structure factor data for wide Q range with sufficient accuracy. Then the result as well as the preceding one of CD_3OD[3] confirms the usefulness of the present LINAC-TOF neutron diffraction method to the structural study of polyatomic molecular fluids.

Sensitization of Polycrystalline $SrTiO_3$ Photoanodes by Lanthanum Doping

Byong-Tae CHANG,* Guy CAMPET,† Jean CLAVERIE,† and Paul HAGENMULLER†

Department of Chemistry, Faculty of Science, Korea University, Kodaira, Tokyo 187

†*Laboratoire de Chimie du Solide du C.N.R.S., Université de Bordeaux I, 351, cours de la Libération, 33405 Talence Cedex, France*

(Received January 30, 1984)

The behaviors of polycrystalline $La_xSr_{1-x}TiO_3$($x \leq 0.05$) electrodes in a photoelectrochemical cell for water decomposition have been investigated in aqueous NaOH electrolyte. The lanthanum substitution for strontium resulted in impressive visible photosensitization of the corresponding electrodes under anodic polarization. This visible photoresponse is based on the relatively deep subband gap states introduced into the forbidden band by lanthanum doping, in analogy with the polished undoped $SrTiO_3$ electrodes reported previously.

The practical realization of a photoelectrochemical system for the electrolysis of water will depend critically on the development of stable and efficient semiconductor electrodes. $SrTiO_3$ has received a great deal of attention as a semiconducting photoanode for the photodecomposition of water because it is chemically stable and requires no external biasing to generate H_2 and O_2.[1-12] However, it does not show visible light absorption due to its large band energy gap (3.2 ev). This is clearly insufficient for solar energy conversion applications. It is, therefore, very important to extend the $SrTiO_3$ spectral response in the visible region in realizing the efficient photodecomposition of water.

In our previous papers,[13,14] we have reported that mechanical polishing of undoped polycrystalline $SrTiO_3$ electrode surface results in an anomalous visible photoresponse extending to 600 nm with relatively negative onset potential of about −1V (*vs.* SCE, 1 M NaOH (1 M=1 mol dm^{-3})), and that the principal mechanism could be related to the introduction of subband states, $[Ti{:}3d(t_{2g})]_{sub}$ near the conduction band and $[O{:}2p]_{sub}$ near the valence band, by the mechanical polishing. These results suggests us the importance of controlling the formation of the subband states in the band gap by selected surface modifications or substitutions of Sr and/or Ti sites with appropriate dopants.

It is well-known that the reduced titnates such as n-TiO_2 and $SrTiO_3$ have a lot of defect energy levels in the forbidden band. The nature of these defects is largely dependent upon reduction temperature, oxygen activity, impurity additions, Sr/Ti ratio for $SrTiO_3$ and so on.[15-23] In general $SrTiO_3$ can be converted into n-type semiconductor by donor doping(*e.g.* niobium) and/or reduction in high vacuum or flowing hydrogen gas.[1,11,16,24] It is reasonable to think that lanthanum can be selected as a dopant of $SrTiO_3$ for three main reasons;

(i) stability in the trivalent state.

(ii) similarity of Sr^{2+} and La^{3+} ionic radii ($r_{Sr^{2+}}$= 0.140 nm, $r_{La^{3+}}$=0.132 nm) which insures a substitutional incorporation of lanthanum within the strontium sublattice.[25]

(iii) the compensation of extra charge resulting from partial $Sr^{2+} \rightarrow La^{3+}$ substitution may occur *via* electronic or lattice defects according to the reduction temperature and the oxygen partial pressure;[26,27]

$$Sr^{+2}_{1-x}La^{+3}_{x}Ti^{+4}O^{-2}_{3+x/2} \xrightarrow[\text{reduction}]{\text{Moderate}} Sr^{+2}_{1-x}La^{+3}_{x}Ti^{+4}_{1-y}Ti^{+3}_{y}O^{-2}_{3+x/2-y/2}, \quad (1)$$

$$\xrightarrow[\text{reduction}]{\text{Strong}} Sr^{+2}_{1-x}La^{+3}_{x}Ti^{+4}_{1-x}Ti^{+3}_{x}O^{-2}_{3}. \quad (2)$$

The presence of Ti^{+3} should confer n-character to $SrTiO_3$ and render the corresponding material performing as a photoanode, so La-doping can be expected to be a good method for controlling the formation of the subband states. Recently Odekirk and Blakemore have repored the enhancement of the photoactivity of lanthanum-doped, strongly reduced $SrTiO_3$ in microcrystalline ceramic form; La-doping ($x \leq 0.01$) provides an extention of the spectral response to longer wavelength and improves the quantum efficiency for all wavelengths.[28] Besides, Tsubomura *et al.* described briefly that lanthanum-doping showed week effect on the sensitization of $SrTiO_3$ photoanode at wavelengths longer than 400 nm.[29] The purpose of this paper is to study how lanthanum-doping changes the photoelectrochemical properties of polycrystalline $SrTiO_3$ electrodes and sensitizes it in more detail, in comparision with the mechanical polishing effects.

Experimental

The compounds synthesized in this work correspond to the compositions $Sr_{1-x}La_xTiO_{3+x/2}$ ($x \leq 0.05$). The polycrystalline samples have been prepared by heating the corresponding mixtures of $SrCO_3$, La_2O_3, and TiO_2 in air at 1350 °C for 16 h. The obtained powders were pelletized, sintered in air at 1400 °C for 16 h, and then reduced in flowing hydrogen gas at 1400 °C for 10—20 h to make them n-type. The conductivities of the samples after reduction were between 0.01—10 Ω^{-1} cm^{-1}.

Electrode preparation and electrochemical measurement procedures used to characterize the semiconductors have been described elsewhere.[13,14] 1 M NaOH solution was used as an electrolyte and all the potentials were referred to a saturated caromel electrode. To caluculate a quantum efficiency at each wavelength, the observed photocurrents were corrected for the spectral distribution of the light sourse(150W-Xe) and of the monochrometer. Impedance measurements have been performed a 10 kHz to get the flatband potential of the samples.

Results and Discussion

Figure 1 shows visible photocurrent (i_{vis})-potential curve of a La(0.5%)-doped sample (curve 1) under illumination of polychromatic visible light($\lambda \geq 400$ nm). For comparison, a similar curve of an polished undoped sample (curve 2) was also given in it. Dark currents were less than 10^{-6}A between -1.0 and 0.5 volts, and the visible photoreponses were very sharp. One can observed different behaviors of i_{vis}-potential curve for the above two; while the visible photocurrent of the polished undoped sample tends to be saturated as the potential becomes more positive, that of the lanthanum-doped sample increases almost linearly with a raising of the potential, at least below 1V. On the other hand, onset potential of i_{vis} for La-doped sample was found to be -0.8V, being more positive by 0.2V than that for the polished undoped sample. Such properties of the La-doped sample are very similar to those of Cr-doped $SrTiO_3$ photoanodes.[30]

As shown in Fig. 2, the effect of lanthanum-doping on the sensitization of $SrTiO_3$ becomes remarkable for [La]$\geq$0.5%. Too high concentration of the dopant ([La]$\geq$2%) leads to a decrease in the visible photocurrent as well as the full light photocurrent. Furthermore, mechanical polishing of the La-doped electrodes results in an enhancement of i_{vis} when [La]$\leq$1% as shown in curve 2.

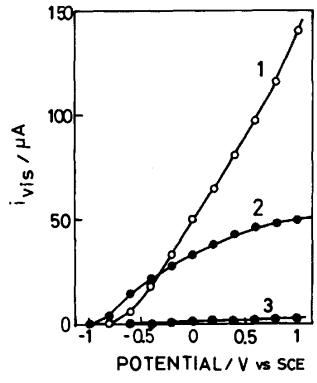

Fig. 1. Visible photocurrent-potential curves of La-(0.5 %)doped electrode(curve 1), the polished undoped electrode(curve 2), and the unpolished undoped electrode(curve 3) in 1 M NaOH ($\lambda \geq 400$ nm).

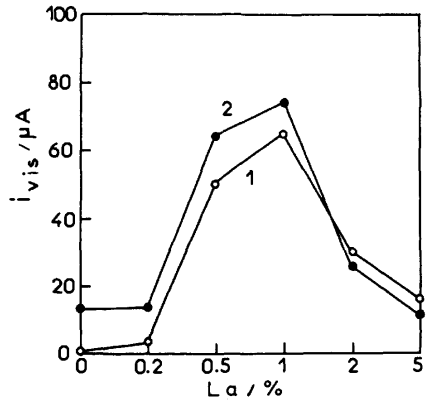

Fig. 2. Effect of the concentration of La-dopant on the sensitization of $SrTiO_3$ photoanode at 0 volt. curve 1; before polishing, 2; after polishing.

Mott-Schottky plots were constructed from capacitance *vs.* electrode potential measurements a 10 kHz and are shown in Fig. 3. The flatband potentials (V_{fb}), obtained from the intercepts of $1/C^2$ *vs.* potential, were found to be -1.35, -1.30, and -1.20 volts for [La]=0, 0.2 and 0.5%, respectively. This means that La-doping causes V_{fb} to shift to more positive direction. A striking feature of the Mott-Schottky plot is the break near -1V. This feature suggests us the existance of two kinds of donor levels, one very close to the conduction band and the other deep below it, as discussed on n-Fe_2O_3 electrodes.[31] According to Goodenough, counter-cation charge compensation of La^{+3} for Sr^{+2} introduces no anion vacancies to induce Ti^{+4} ion displacements, and the larger charge La^{+3} *vs.* Sr^{+2} ions stabilizes from the conduction band a shallow trap state which sharply reduces electron mobility, hindering electron-hole separation.[32] Typically it may be the case of heavily La^{+3}-doping; the full light photocurrent of La(0.5%)-doped sample at 0 volt was less than one tenth of the undoped sample. Lanthanum has a stronger affinity to oxygen than strontium because of its higher electron negativity. The covalent bond between titanium (mainly Ti^{+3}) and oxygen, neighboring La^{+3} on the opposite side, must be considerably weakened. Therefore, the formation of the above deep donor level could be associated with this lowering in the covalency between Ti^{+3} and O^{-2}. Analogous to the previously proposed mechanism of the sensitization of the polished undoped $SrTiO_3$,[14] it is reasonable to think that the appearance of the visible photoresponse by La-doping should result from the introduction of the deep subband gap states, $[Ti; 3d(t_{2g})]_{sub}$, accompanying the simultaneous introduction of the acceptor subband gap states, $[O; 2p]_{sub}$, above the valence band.

Figure 4 shows the effect of La-doping on wavelength dependences of the quantum efficiency(η) at 0 volt. It is obvious from comparison for curve 1 with curve 2 that La-doping results in a decrease of U.V. photocurrent, being inconsistent with Odekirk's results.[28] Thus the subband gap energy states introduced by La-doping act as intermediate centers for secondary recombination processes between the photogenerated conduction band

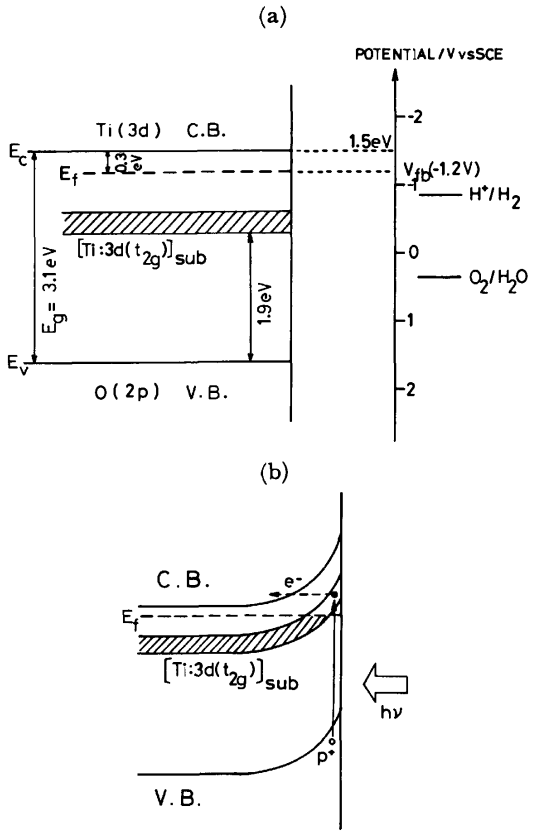

Fig. 5. Energy level diagram for La(0.5 %)-doped $SrTiO_3$ electrode at the flatband potential in 1 M NaOH (a) and a predominant mechanism giving rise to an anodic visible photoresponse (b).

electrons and valence band holes. At the same time, La-doping leads to a remarkable increase of the visible photoresponse down to 600 nm. Besides, one can see the appearance of shoulder near 370 nm in curve 2 for the La-doped sample. From $(\eta h\nu)^{1/2}$ *vs.* $h\nu$ plots by using Fig. 4, we can deduced a reduced value of E_g (3.10 eV) for the La(0.5%)-doped sample together with E_g=3.15 eV for the undoped sample. Furthermore, $(\eta h\nu)^{1/2}$ *vs.* $h\nu$ plots in the longer wavelengths can be extrapolated to E_g'=1.9 eV which probably corresponds to the energy gap between the top of the valence band and [Ti; $3d(t_{2g})]_{sub}$ or between the $[O; 2p]_{sub}$ and the bottom of the conduction band.

Based on the existence of the two subband gap energy states resulting from La-doping, two main mechanisms could be proposed to explain the production of the visible photocurrent. In mechanism I, the photocurrent is due to a direct electron excitation from the valence band to the empty [Ti; $3d(t_{2g})]_{sub}$ followed by a tunneling process of the excited electron to the conduction band. In mechanism II the electrons are photoexcited from the $[O; 2p]_{sub}$ to the conduction band by the visible light. The photogenerated holes must then tunnel into the valence band. Both processes I and II could take place simultaneously, especially under high anodic polarization.

Figure 5-(a) illustrates a schematic energy diagram at the flatband potential for the La(0.5%)-doped electrode in 1M NaOH solution when the mechanism I is assumed to be more predominant. From the observed value of V_{fb}=−1.20 volts and an assumption of $E_c-E_f\simeq$0.3 eV, the bottom of the conduction band, E_c, was set at −1.50 volts *vs.* SCE. The [Ti; $3d(t_{2g})]_{sub}$ states exist not only near the surface but also in the bulk of the electrode, differing from those in the polished undoped sample. As shown in Fig. 5-(b), anodic biasing is necessary for making the [Ti; $3d(t_{2g})]_{sub}$ states empty and for accelerating the tunneling process. The onset potential of the visible photocurrent must be much more positive than V_{fb}. As described above, the visible photocurrent of the polished undoped sample has a tendency to be saturated as the potential raises up. It appears to reflect the limited state density of the subband gap energy levels which decreases rapidly with the depth from the surface. On the other hand, in the La-doped sample the raising of anodic potential leads to a continuous increase in the empty state density by lowering E_f, and consequently results in the continuous increase of the visible photocurrent, at least below 1 volt.

(Received March 3, 1984)

The rate constants of the reactions of hydrogen and deuterium atoms with four ketenes have been measured using a pulse radiolysis-resonance absorption technique. For hydrogen atoms, the temperature dependence was also examined in the range of 240—440 K. The rate constants were well expressed by these Arrhenius equations: k(H+ketene)=$3.9\times10^{6}\exp(-975/T)$; k(H+methylketene)=$7.4\times10^{6}\exp(-881/T)$; k(H+ethylketene)=$4.4\times10^{6}\exp(-728/T)$; k(H+dimethylketene)=$6.0\times10^{6}\exp(-773/T)$, in units of $m^3\,mol^{-1}\,s^{-1}$. No isotope effect between H and D atoms could be observed except for the gas-kinetic-collision frequency.

In the reaction of oxygen atoms with simple olefins, it was found that the rate constants increase with the increase in the number of substituted alkyl radicals: ethylene<propene≃1-butene<2-methylpropene≃*cis*- and *trans*-2-butene<2-methyl-2-butene<2,3-dimethyl-2-butene.[1] On the other hand, in the reactions of hydrogen atoms, the order is quite different: ethylene≃*cis*- and *trans*-2-butene≃2,3-dimethyl-2-butene<propene≃1-butene≃2-methyl-2-butene<2-methyl-propene.[2,3] The rate constants for deuterium atoms were found to be always $1/\sqrt{2}$ of those for hydrogen atoms, suggesting that this isotope effect is due to the difference in collision frequency.[3,4]

Recently, we measured the rate constants of the reactions of oxygen atoms with four ketenes: ketene and methyl-, ethyl-, and dimethylketenes, and found that the rate constants increase with the increase in the number of substituted alkyl radicals, the order is similar to that obtained with olefins: ketene<methylketene≃ethylketene<dimethylketene. It was also found that the reactions of the last three ketenes have negative activation energies.[5]

For a comprehensive understanding of this type of reaction, we have measured the Arrhenius parameters for the reactions of hydrogen atoms with these four ketenes, since no previous work has shown these parameters except for the reaction of hydrogen atoms with the simplest ketene.

Experimental

The details of the preparation of ketenes were described in a previous paper.[5] The method of the rate-constant measurement was similar to that described previously,[4,5] except that a wave memory (NF Circuit Design Block Co., WM-852) and an X-Y recorder (Riken Denshi Co., F-35) were used to record the decay of the hydrogen and deuterium atoms. Briefly, about 80 kPa of $H_2(D_2)$ gas containing a small amount of a ketene (1—10 Pa) was irradiated with an electron pulse generated by a Febetron 706 apparatus (Hewlett Packard Co.). After the pulse, the decay in the H(D) atoms was measured by the absorption of Lymann-α. As has been discussed previously,[2] the H(D)-atom concentration is less than 1/100 that of the ketene present in the reaction chamber. Therefore, the pseudo-first-order reaction rate can be determined from this decay curve. The temperature of the reaction vessel was controlled by winding it with a heating tape or by introducing N_2 gas from boiling liquid nitrogen to the surrounding copper tubing. The reactant temperature was measured with a copper-constantan thermocouple at the center in the reaction chamber prior to pulse-irradiation.

Results

The experimental results for hydrogen atoms are summarized in Fig. 1 in the form of Arrhenius plots. All the data are well characterized by Arrhenius equa-

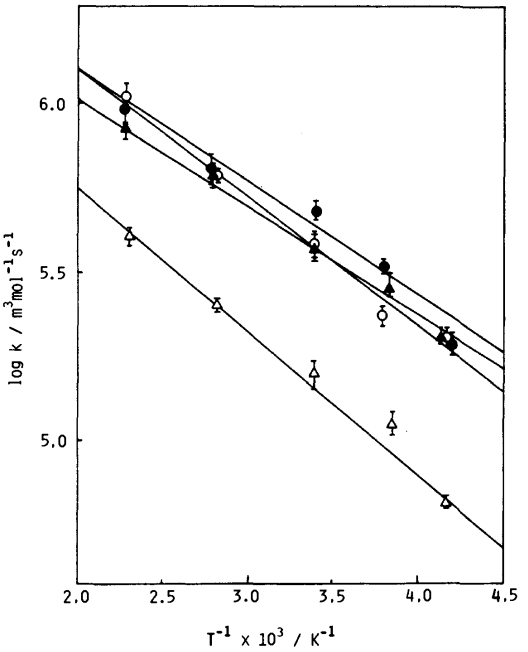

Fig. 1. Arrhenius plots for reactions H+CH_2CO (△), H+$CH_3(CH)CO$ (○), H+$C_2H_5(CH)CO$ (▲), and H+$(CH_3)_2CCO$ (●). The indicated error limits are 1σ diviations of the fit.

Table 1. Rate constants of H- or D-atom addition to ketenes at 295 K in units of $10^5\,m^3\,mol^{-1}\,s^{-1}$

	CH_2CO	$CH_3(CH)CO$	$C_2H_5(CH)CO$	$(CH_3)_2CCO$
H	1.6±0.2	3.8±0.3	3.7±0.4	4.8±0.3

tions. The results at room temperature are also shown in Table 1. The Arrhenius parameters, as determined by the least-squares method, are listed in Table 2.

Discussion

There have been previous measurements of the temperature dependence of the reaction between hydrogen atoms and the simplest ketene.[6,7] Figure 2 compares their data with ours. Unfortunately, no two of the three measurements are in good agreement with each other. In this figure, two other measurements carried out at room temperature are also included.[7,8]

Šlemr and Warneck used a discharge-flow method combined with a mass-spectrometer.[6] Hydrogen atoms were generated by microwave discharge in a low-pressure helium-gas flow containing hydrogen. Ketene was introduced into the flow behind the discharge. The sampling of the gas mixture for mass-spectroscopic analysis was carried out *via* a pin hole located at the bottom of the cylindrical reactor. The rate constant was estimated by measuring the decrease as the concentration of ketene as a function of the distance of the reaction zone, in which atomic hydrogen was present in excess. The concentration of hydrogen atoms was measured in different runs by titration with nitrogen dioxide. The authors stated that a large error could be expected to occur in the estimation of the concentration of hydrogen atoms. If their measured concentration is twice as large, the rate constants they obtained will be in good agreement with ours. In the present experiments, however, the absolute concentration of hydrogen atoms is not necessary to estimate the rate constants.

Michael *et al.* used two techniques, flash photolysis-resonance fluorescence and discharge flow-resonance fluorescence.[7] The temperature dependence was measured only by the former method. In this measurement, hydrogen atoms were produced by the flash photolysis of a mixture of methane, ketene, and diluent argon at λ>105 nm or by the flash photolysis of a two-component mixture of ketene and argon at λ>165 nm. The time-resolved detection of hydrogen atoms was accomplished by observing scattered resonance fluorescence at 121.6 nm. According to their paper, they had difficulty in creating appropriate conditions under which the rate measurment could be carried out, because ketene strongly absorbs the resonance fluorescence from excited hydrogen atoms.

The present authors also found that the absorption coefficient of ketene at 121.6 nm is larger than those of the olefins, but no difficulties were found in measuring the decay of hydrogen atoms. The discrepancy between the results of the discharge-flow method and the present one may be explained by the difference in the total pressures. Since the present results were obtained in the presence of 80 kPa of hydrogen, the rate constants may be regarded as the high-pressure limits.[2] On the other hand, under low-pressure conditions, such as in the case of the discharge flow, the measured rate constants may not be the limits. This explanation, however, is not applicable to the results of Michael *et al.*, who could observe no total pressure dependence of the rate constants between 2.7 and 13.3 kPa.

In the reactions of oxygen atoms with ketenes, the rate constants increase with the increase in the number of substituted alkyl radicals; the result is similar to that obtained with olefins.[1,5] On the other hand, in the reactions of hydrogen atoms, ketenes and olefins have different tendencies in their reaction rates; in the case of olefins, both activation energies and preexponential factors decrease with the increase in the number of the substituted alkyl radicals, while no systematic change could be observed in the case of ketenes.[3,9,11] Especially, there are no large differences among the rate constants of methyl-, ethyl-, and dimethylketene. This suggests that the reaction paths may be different in the reactions of hydrogen atoms with olefins and ketenes.

An oxygen atom adds to the C=C double bond, and the intermediate complex is believed to be formed either with olefins or with ketenes, although the detailed structure is not known. Cvetanović suggested a π-complex-type structure for the intermediate complex in the reactions of oxygen atoms with olefins.[11] If a similar structure can be assumed for the complex in the reactions with ketenes, the effect of the substituted alkyl radicals may well be similar to those of both olefins and ketenes.

On the other hand, in the hydrogen-atom reactions with olefins, it is believed that the hydrogen atom adds to the C=C double bond at the C-atom with less substituted alkyl radicals. The *ab initio* calculation showed that the geometry at the saddle point in the reaction between the H-atom and propene is:[10]

$$H_3C\text{-}\underset{\vdots\,H}{CH}\text{-}CH_2.$$

In the investigation of the reaction mechanism of the reaction between hydrogen atoms and ketene, the following primary step has been proposed:[8]

$$H + CH_2CO \longrightarrow CH_3 + CO.$$

If this mechanism is also applicable to other ketenes,

$$H + \begin{matrix}R_1\\R_2\end{matrix}CCO \longrightarrow \begin{matrix}R_1\\R_2\end{matrix}CH + CO,$$

and the intermediate complex can be illustrated as follows:

$$\begin{matrix}R_1\\R_2\end{matrix}\!\!\diagdown\!\!\diagup C\text{-}C{=}O,\quad \vdots\,H$$

then the order of the rate constants of ketenes may not necessarily agree with those obtained in the reaction of hydrogen atoms with olefins. Bennett and Mile have found that ketene is unique in the reaction with atomic hydrogen at 77 K.[12] They employed a rotating cryostat in conjunction with electron-spin-resonance spectroscopy. When water was used as the matrix, acetyl and methyl radicals were detected. This suggests that the initial step of the reaction is the addition of H atoms to the methylene group of ketene to give the CH_3-C=O radical, followed by decomposition into CH_3 and CO. This mechanism was further confirmed by the experiments with D atoms. On the other hand, in a matrix of benzene, the addition of H atoms occurred at the central carbon atom to give the CH_2-CH=O radical, while in a matrix of adamantane, both CH_3-C=O and CH_2-CH=O radicals were observed. They emphasized that no such dependence of the site of addition on the nature of the matrix could be observed in the cases of other unsaturated compounds. Further experiments to identify the initial radical products from H atoms and ketene and alkyl substituted ketenes are highly desirable.

The isotope effect observed in the present experiments between H- and D-atom reactions can be explained by taking into account the difference in collision frequency, as has been discussed in the case of olefin reactions.[4]

The Crystal and Molecular Structure of 3,4-Dimethyl-2,5-diphenyl-3,4-dihydro-3a-thia-1,3,4,6-tetraazapentalene

Fujiko Iwasaki* and Kin-ya Akiba†

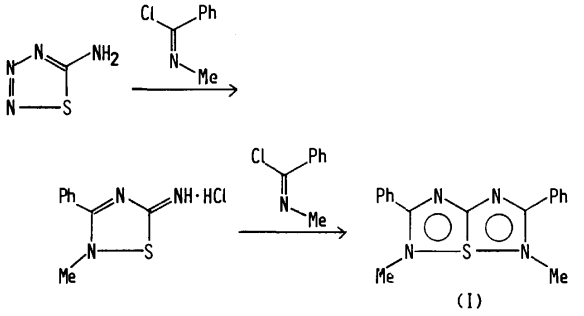
Department of Materials Science, The University of Electro-Communications, Chofu-shi, Tokyo 182

†*Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730*

(Received March 5, 1984)

The crystal structure of 3,4-dimethyl-2,5-diphenyl-3,4-dihydro-3a-thia-1,3,4,6-tetraazapentalene has been determined by the X-ray method. The crystals are orthorhombic, space group Pbcn, a=14.533(4), b=9.285(3), c=11.305(2) Å, V=1525.4(6) Å^3, Z=4, D_x=1.343 Mg m^{-3}. The final R value is 0.060 for 1107 reflections. The molecule has an exact C_2 symmetry, with the central S-C bond coincident with the 2-fold axis of the crystal symmetry. The length of 1.904 Å of the two equivalent S-N bonds indicates that the molecule is a tetraaza analogue of the thiathiophthenes. The length of this S-N bond is 9% longer than the N-S single bond and significantly less than the sum of the van der Waals radii.

In the course of the 1,3-dipolar addition to 4,5-dihydro-1,2,4-thiadiazole a bond switch has taken place at the π-hypervalent sulfur atom,[1,2] An intermediate state of the reaction should be of a thiathiophthene type; in fact, a molecule of such a type has been found in the crystalline state.[3] An addition of *N*-methylbenzimidoyl chloride to 5-amino-1,2,3,4-thiatriazole gave 2-methyl-3-phenyl-5-imino-2,5-dihydro-1,2,4-thiadiazole hydrochloride. Further addition gave the molecule **I**.[4] For such symmetric substituents it is interesting to investigate whether the molecule of **I** has a symmetric or unsymmetric structure. An X-ray structure analysis was undertaken to elucidate the structure of **I**.



Scheme 1.

Experimental

Crystal Data: $C_{17}H_{16}N_4S$, Mw=308.40, Orthorhombic, Pbcn, a=14.533(4), b=9.285(3), c=11.305(2) Å, V=1525.4(6) Å^3, Z=4, D_x=1.343 Mgm^{-3}.

Colorless crystals were grown from benzene-hexane solution. Intensities were collected on a Rigaku automatic diffractometer with graphite-monochromated Mo $K\alpha$ radiation, using the crystal with approximate dimensions 0.15×0.25×0.35 mm. Reflections in the range $2\theta \leq 55°$ were measured by the ω–2θ scan technique with a scan width of 1.2°+0.5° tan θ and a scanning rate of 4° min^{-1} in 2θ. At both ends of the scan range 10 s background counts were taken for each reflection. 1107 Reflections had $|F_o| \geq 3\sigma(F_o)$ and were considered observed. No absorption corrections were applied.

The structure was solved by the direct method with the program MULTAN 78.[5] Non-hydrogen atoms were refined by the block-diagonal least-squares with anisotropic temperature factors to an R value of 0.09. A difference map showed the all hydrogen atoms. A possibility of a disordered structure was clearly eliminated by the examination of the D-map and anisotropic temperature factors. Further refinement with anisotropic temperature factors for non-hydrogen atoms and isotropic ones for H gave the final R value of 0.060. The quantity minimized was $\sum w(|F_o|-k^{-1}|F_c|)^2$. w=0.3 if $|F_o|<4.0$, w=1.0 if $4.0 \leq |F_o| \leq 16.0$ and $w=(16.0/|F_o|)^2$ if $|F_o|>16.0$. Atomic scattering factors were taken from "International Tables for X-ray Crystallography".[6] All computations were performed on a HITAC M180 Computer of the Data Processing Center of the University of Electro-Communications with the programs UNICS III,[7] MULTAN 78,[5] and ORTEP II.[8] The final atomic parameters are given in Table 1.[9]

Discussion

Figure 1 shows the atomic numbering of the crystal-chemical unit. Bond lengths and angles are listed in Table 2. The molecule has an exact C_2 symmetry, with

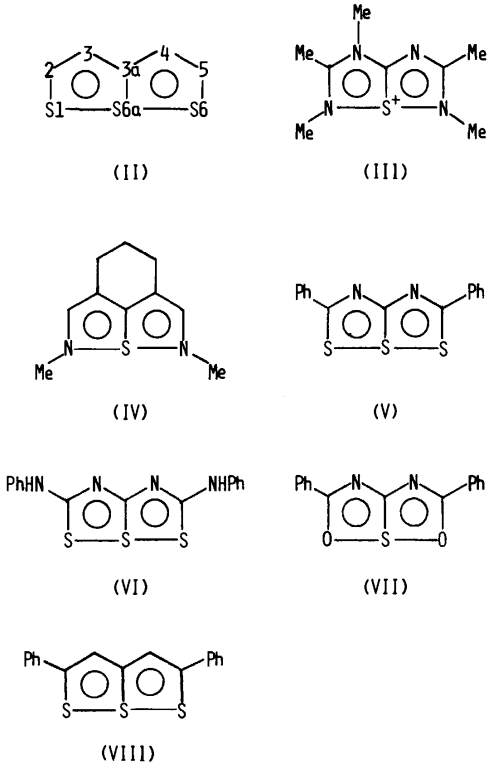
Superscript (i) $1-x$, y, $1/2-z$

the S(6)–C(3) bond coincident with the crystallographic 2-fold axis along the b axis. The S(6)–N(1) distance is 1.904 Å, 9% longer than the normal S–N single bond (1.74 Å).[10] Thus the molecule is found to be 3a-thia-1,3,4,6-tetraazapentalene, the tetraaza analogue of thiathiophthene (1,6,6a-trithiapentalene, **II**).[11] The corresponding lengths in **III**[3] are 1.983 and 1.833 Å, and in **IV**[12] 1.901 and 1.948 Å respectively. The average lengthening of the S–S bonds in the thiathiophthenes is



12%. The S–X (X=S, N, and O) bonds in the thiathiophthenes and in the related substances are weaker than other bonds in the molecule, and therefore are more affected by the substituents and/or by the crystalline field. The present molecule is the first example with the exactly equal S–N bonds among the N–S–N analogues of 1,6,6a-trithiapentalene. The CNDO/2 calculation based on the determined structure shows the net charges on the S and N atoms being +0.208 and −0.258 respectively. This suggests that there is an electrostatically attractive interaction between S and N. The existence of the molecule with the symmetrical N–S–N bond in the stable state is very interesting from the point of view of the 1,3-dipolar addition, where the bond-switch takes place at the π-hypervalent sulfur. Bürgi[13] pointed out that the correlation between the non-bonded and bonded S–S interactions of the thiathiophthenes corresponds to the reaction path of the linear exchange reac-

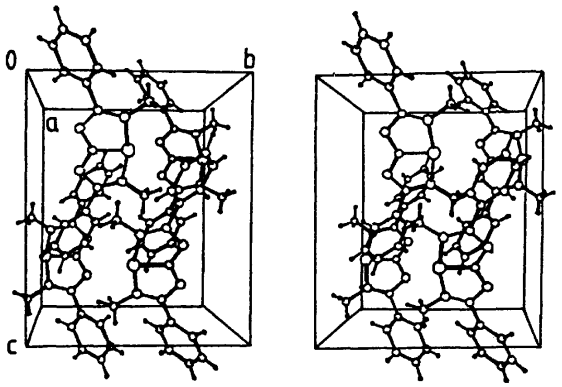


Fig. 2. Stereoscopic view of the crystal structure.

tion. The molecule of the symmetrical type should correspond to the intermediate model of the reaction such as 1,3-dipole additions.

Although the C(3)–S(6) length is longer than the corresponding ones in **III** (1.717 Å) and **IV** (1.742 Å), the longer values are also found in **V** (1.784 Å)[14] and in **VI** (1.789 Å).[15] The S(6a)–C(3a) lengths in the 1,6,6a-trithiapentalenes are remarkably constant within the range of 1.74—1.76 Å. The difference between the lengths of the S(6a)–C(3a) bonds in **I**, **V**, **VI**, and those of 1,6,6a-trithiapentalenes seems due to the presence of the two divalent N atoms in the rings of **I**, **V**, and **VI**. But for the dioxa derivative (**VII**) the short S–C bond (1.719 Å) was reported.[16] The length of the cyclic C(2)–N(3) bond is slightly longer than those in **V** (1.325 Å) and the length of the aromatic C–N bond in pyridine (1.340 Å), while the N(3)–C(3) distance is shorter than that of **V** (1.344 Å). In the 1,6,6a-trithiapentalenes the sum of the outer C(2)–C(3) and C(4)–C(5) lengths is always found to be smaller than the sum of the inner C(3a)–C(3) and C(3a)–C(4) lengths. This is the typical feature showing the resemblance between 1,6,6a-trithiapentalenes and naphthalene.[11] But in the case of 3,4-diaza derivatives such as **I**, **V**, **IV**, and **VII** no significant difference between the outer and inner N–C bonds is observed. The N(1)–C(2) bond is shorter than that of **IV** (1.388 Å) and the aromatic C–N bond. The C(2)–C(21) length is close to the average value of the corresponding C–C lengths in **V**. The N(1)–C(11) length is slightly shorter than the C–N single bond (1.47 Å). Such short C–N bonds are also found in **IV** (1.441 and 1.454 Å).

The equation for the least squares plane through the five membered ring is

$$-0.8152X+0.0375Y+0.5780Z=-4.163\ (\text{Å})$$

where X, Y, and Z in Å unit referred to the a, b, and c axes respectively. The deviations of S(6), N(1), C(2), N(3), C(3), C(11) and C(21) are 0.033, −0.039, 0.024, 0.012, −0.030, −0.028 and 0.198 Å respectively. The phenyl ring is planar with deviations within 0.007 Å. The dihedral angle between the planes of the central ring and the phenyl ring is 40.0°. The corresponding angles are 2.0 and 7.0° in **V**, 45.1 and 3.3° in **VIII**,[17] and nearly 0° in **VII**.

Figure 2 shows the stereoscopic view of the molecular packing. There are no significant intermolecular contacts shorter than the sum of the van der Waals radii.

(Received March 7, 1984)

The polarized Raman and infrared spectra of 2-chloro- and 2-bromopyrimidines were studied. Assignments of the normal vibrations for these molecules were made on the basis of polarization behaviors of the Raman and infrared bands and also through the normal coordinate calculation.

The infrared spectrum of 2-chloropyrimidine was first observed by Short and Thompson[1] and Lafaix and Lebas.[2] Sarma[3] remeasured the infrared spectrum of this molecule and gave assignment for the in-plane vibrations based on the normal coordinate calculation. Allenstein *et al.*[4] studied the infrared and Raman spectra of 2-fluoro-, 2-chloro-, 2-bromo-, and 2-iodopyrimidines and gave assignments for the normal vibrations of these molecules. Their assignments were not made on the basis of enough experimental evidences and no reasonable vibrational analysis of the phosphorescence spectrum of 2-chloropyrimidine, which shows the characteristic vibrational structure due to the Cl atom, can be made using their assignments.

In this paper, the assignments for the normal vibrations of 2-chloro- and 2-bromopyrimidines are reexamined through measurements of polarization behaviors of the Raman and infrared spectra.

Experimental

Material. 2-Chloro- and 2-bromopyrimidines were synthesized from 2-aminopyrimidine by means of the diazo reaction. The crude products were recrystallized from isopentane and then purified by repeated vacuum distillations. The final purification was made by zone-refining of about 100 passages.

Optical Measurement. Polarization measurement of the Raman spectrum was made in molten and single crystal phases with a JEOL 400 T Laser Raman Spectrophotometer. The sample was excited with the 514.5 nm line from an Ar^+ ion laser. A well grown single crystal of 2-chloropyrimidine was obtained by the Bridgman method. Then a cubic sample of about 5 mm^3 was cut off, where the cleavage plane was selected as one of the planes of the cube and each edge of the cube was cut along the crystallographic axis with a polarization microscope. A block of single crystal of 2-bromopyrimidine could not be obtained because this molecule was decomposed by heating over many hours in the Bridgman furnace. Thus a single crystal of this molecule was grown in a capillary glass tube of about 70 mm in length and 3 mm in diameter having a sharp conical end by heating for about three hours in the Bridgman furnace. The method of measurement of the polarized Raman spectrum was exactly the same as that described previously.[5]

The infrared spectrum was observed in molten and single crystal phases with a Hitachi Infrared Spectrophotometer Model 345. The preparation of the single crystal sample and the method of measurement of the polarized infrared spectrum are exactly the same as those described previously.[6,7]

Normal Coordinate Calculation

A normal coordinate calculation was performed through the standard ***GF*** matrix method with a FACOM M-200 computer at the Computer Center of Kyushu University. The geometrical parameters of the 2-chloropyrimidine molecule were taken from the data determined by Furberg *et al.*[8] The molecular structure of 2-bromopyrimidine was assumed to be identical with that of 2-chloropyrimidine except for the C–Br bond, whose distance was assumed to be 0.185 nm. The ***F*** matrix elements for the in-plane vibrations were evaluated with the potential fields of an improved modification of the Urey-Bradley force field.[5,6,7] The potential field is given by

$$V = V_{UB} + \rho\{\Sigma(\Delta R,\Delta R)_o - \Sigma(\Delta R,\Delta R)_m + \Sigma(\Delta R,\Delta R)_p\} + \Sigma k^o(\Delta r,\Delta r) + \Sigma k^m(\Delta r,\Delta r) + \Sigma k^m(\Delta R,\Delta R) + \Sigma h^m(\Delta R,\Delta\alpha) + \Sigma h^m(\Delta R,\Delta\beta) + \Sigma f^o(\Delta\alpha,\Delta\alpha),$$

where the symbols such as V_{UB} are the same as those used in the previous papers.[5,6,7] The symbols given for the atoms and internal coordinates and the molecular axes are illustrated in Fig. 1. For the out-of-plane vibrations the valence force field and the ϕ type torsional coordinates were used. The notations of the force constants Q, q, P, p, and t are the same as those given by Whiffen.[9]

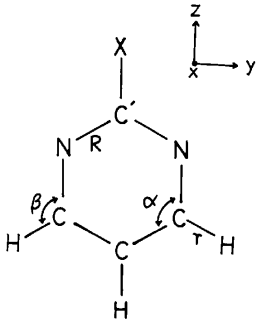

Fig. 1. Symbols given for the atoms and internal coordinates.

Results and Discussion

The force constants used for the in-plane and out-of-plane vibrations of 2-chloro- and 2-bromopyrimidines are listed in Tables 1 and 2, respectively. These values are consistent with the force constants given for pyrimidine.[10] The calculated frequencies and modes of the normal vibrations are given in Table 5.

Table 1. Force constants for in-plane vibrations

K_{C-N}	5.90	
K_{C-C}	4.65	
K_{C-H}	4.46	
K_{C-X}	2.07[a]	1.75[b]

p^{p}	0.02	
$t^{o}_{C'-N,X}$	−0.01	
$t^{o}_{C-N,H}$	−0.02	
$t^{o}_{C-C,H}$	−0.02	

Force constants are given in aJ/rad² (=mdyn Å/rad²) units. a) X is Cl atom. b) X is Br atom.

The polarized Raman and infrared spectra of 2-chloro- and 2-bromopyrimidines observed in single crystals are shown in Figs. 2, 3, 4, and 5, respectively. The infrared spectra measured with incident lights polarized parallel and perpendicular to the crystal growth direction, which was determined to be one of the crystallographic axes for both molecules, are referred to as // and ⊥ spectra and drawn with the solid and dotted lines, respectively. The polarized Raman spectrum of 2-chloropyrimidine single crystal was denoted by two characters such as uv. The first letter refers to the direction of polarization of the excitation light and the latter to that of the scattering light. Since the crystallographic analysis for the cleavage plane of 2-chloropyrimidine single crystal was not reported yet, the crystal growth direction was tentatively taken to the u axis and the direction perpendicular to it in the cleavage plane was taken to the v axis. The w axis was taken to the direction perpendicular to both the u and v axes. A single crystal of 2-bromopyrimidine grown in a capillary tube was held in a capillary cell system of JEOL Model RS-VTC41 in such a way that both the crystal growth direction and other one of the crystallographic axes make right angle to the excitation light beam polarized along the crystal growth direction. The scat-

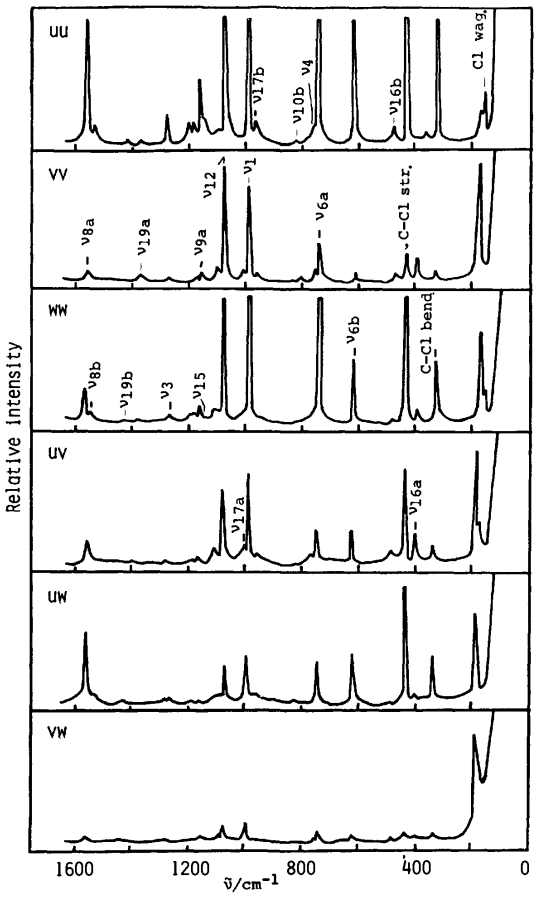

Fig. 2. Polarized Raman spectra of 2-chloropyrimidine single crystal.

tering light was observed from the direction perpendicular to the excitation light beam. The Raman spectra polarized parallel and perpendicular to the crystal growth direction are referred to as // and ⊥ spectra, respectively.

2-Chloropyrimidine. The non-totally symmetric Raman bands in the polarized single crystal Raman spectrum can be classified into three types based on their polarization behaviors as can be seen in Fig. 2. The relative intensity of each band belonging to the first type is strong in the uu spectrum and medium in the ww and uw spectra and weak in other spectra. The relative intensity of each second type band is weak in the uu, uv, and vv spectra and very weak in other spectra. The third type bands are observed with weak intensity in the uv and vv spectra and very weakly in other spectra. These three types of polarization behaviors are referred to as types A, B, and C, respectively.

The polarized infrared bands can be classified into three types I, II, and III based on their polarization behaviors as can be seen in Fig. 3. The bands belonging to the first type mainly constitute the // spectrum, that is, the bands are polarized nearly along the crystal growth direction. The intensity of each second type band in the // spectrum is nearly twice as strong as that in the ⊥ spectrum. The third type bands mainly constitute the ⊥ spectrum, that is, the bands are polarized exclusively perpendicular to the crystal growth direction.

Furberg *et al.*[8] analyzed the crystal structure of 2-chloropyrimidine and showed that the molecule crystallizes in the orthorhombic space group D_{2h}^{15}, where the molecular *x* axis orients nearly parallel to the crystal *b* axis and the *z* axis orients roughly parallel to the *c* axis although it leans somewhat toward the *a* axis. Therefore, the transition moments of the molecular vibrations belonging to the b_1 and a_1 symmetry species are expected to direct nearly along the crystal b and roughly along the *c* axes, respectively.

a_1 Species: Strongly polarized Raman bands observed at 437, 754, 990, 1078, 1163, 1380, 1561, 3010, and 3045 cm^{-1} in molten phase are straightforwardly assigned to the totally symmetric C–Cl stretching, ν_{6a}, ν_1, ν_{12}, ν_{9a}, ν_{19a}, ν_{8a}, ν_{13}, and ν_2 vibrations, respectively, on referring to the normal vibrations of pyrimidine[11–14] and other chlorinated pyrimidines,[6] and also based on the normal coordinate calculation. The corresponding single crystal infrared bands showed type I polarization behavior. This observation suggests that the crystal growth direction tends toward the crystal *c* axis.

b_2 Species: Infrared bands observed at 332, 626, 1154, 1277, 1384, 1425, 1540, and 3080 cm^{-1} in the single crystal spectrum showed type II polarization behavior and the corresponding single crystal Raman bands showed type A polarization behavior. These bands were assigned to the Cl bending, ν_{6b}, ν_{15}, ν_3, ν_{14}, ν_{19b}, ν_{8b}, and ν_{7b} vibrations, respectively, because higher frequencies of this band group are too much high to be assigned to the out-of-plane vibrations.

b_1 Species: Infrared bands observed at 477, 767, and 815 cm^{-1} in the single crystal spectrum showed type III polarization behavior and the corresponding crystal Raman bands showed type B polarization. These bands were assigned to the ν_{16b}, ν_4, and ν_{10b} vibrations, respectively. A Raman band observed at 960 cm^{-1} in single crystal showed type B polarization behavior and thus this band was assigned to the ν_{17b} vibration. A depolarized Raman band observed at 175 cm^{-1} in molten phase splits into two bands at 178 and 188 cm^{-1} in single crystal. The former band is clearly resolved in the uu, uv, and ww spectra while the latter is observed strongly in all spectra except for the uu. Therefore, the 178 cm^{-1} band was assigned to the Cl wagging vibration of b_1 species. The 188 cm^{-1} band may be ascribed to a lattice vibration.

a_2 Species: Raman bands observed at 405 and 1005 cm^{-1} showed type C polarization behavior in single crystal and no corresponding infrared bands could be observed. Therefore, these bands were assigned to the ν_{16a} and ν_{17a} vibrations, respectively.

The Raman bands observed at 330 and 437 cm^{-1} in molten phase, which were assigned to the Cl bending and C–Cl stretching vibrations, respectively, split into doublets separated by about 3 cm^{-1} in the Raman spec-

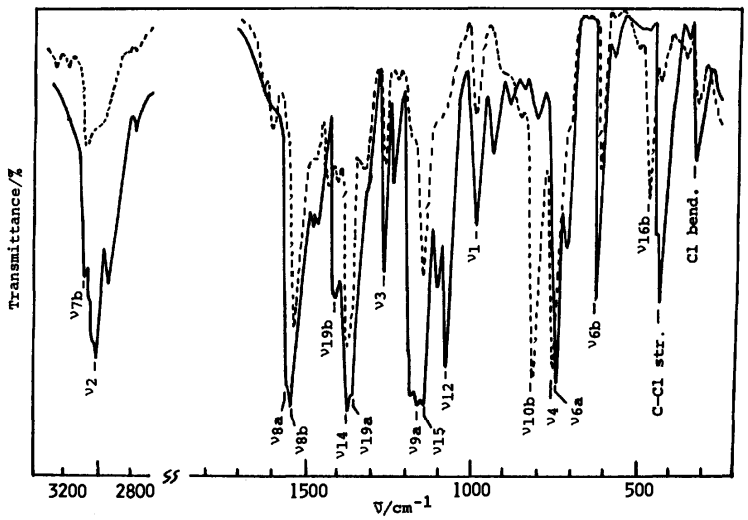

Fig. 3. Polarized infrared spectrum of 2-chloropyrimidine single crystal.

trum observed in solid phase under high resolution. The intensity ratio of the lower and higher frequency bands is about 1/3 for both bands. These splittings are ascribed to the isotopic shift, that is, the lower frequency band is due to the ^{37}Cl atom and the higher to the ^{35}Cl atom.

2-Bromopyrimidine. The depolarized Raman bands observed in molten phase show three different types of polarization behaviors in the single crystal Raman spectrum as can be seen in Fig. 4. The bands belonging to the first type can be observed clearly in the ⊥ spectrum. In the second type, the intensity of the // polarized band is slightly stronger than that of the ⊥ band. In the third type, the intensity of the ⊥ band is stronger than that of the // band. These three types of polarization behaviors are referred to as types A, B, and C, respectively. The polarized infrared bands of 2-bromopyrimidine were also classified into three types I, II, and III based on their polarization behaviors. In the first type, the intensities of the bands in the // and ⊥ spectra are nearly equal. In the second type, the intensity of the // band is stronger than that of the ⊥ band while in the third type, the intensity of the ⊥ band is much stronger than that of the // band.

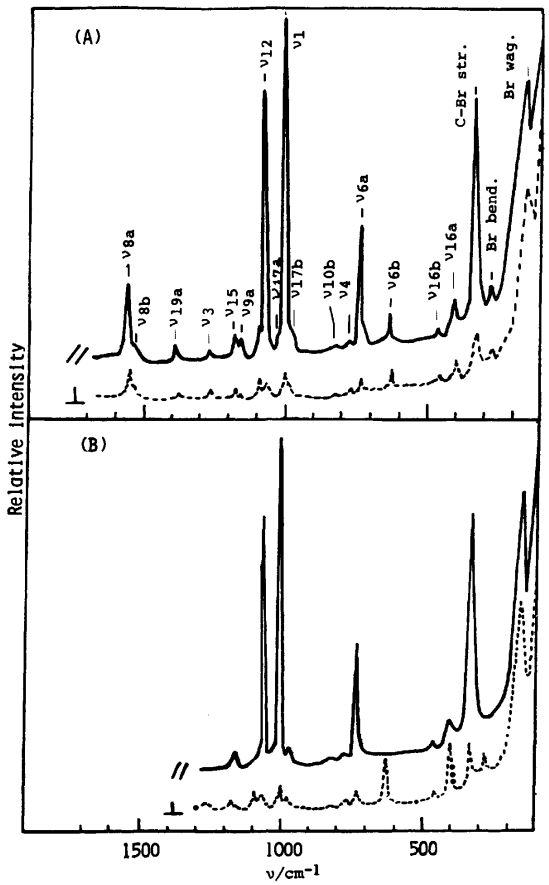

Fig. 4. Raman spectrum of 2-bromopyrimidine. (A): Depolarization behavior measured in moleten phase. (B): Polarization behavior measured in single crystal.

a_1 Species: Strongly polarized Raman bands observed at 330, 734, 998, 1074, 1157, 1381, 1559, 3013, and 3050 cm^{-1} in molten phase were straightforwardly assigned to the totally symmetric C–Br stretching, ν_{6a}, ν_1, ν_{12}, ν_{9a}, ν_{19a}, ν_{8a}, ν_{13}, and ν_2 vibrations, respectively on referring to the assignments given for pyrimidine and 2-chloropyrimidine, and also based on the calculation. The corresponding infrared bands showed type I polarization behavior in single crystal.

b_2 Species: Infrared bands observed at 276, 630, 1170, 1270, 1367, 1432, 1539, and 3080 cm^{-1} in single crystal showed type II polarization behavior and the corresponding Raman bands showed type A polarization behavior. These bands were assigned to the Br bending, ν_{6b}, ν_{15}, ν_3, ν_{14}, ν_{19b}, ν_{8b}, and ν_{7b} vibrations, respectively.

b_1 Species: Infrared bands observed at 465, 766, 826, and 960 cm^{-1} in single crystal showed type III polarization behavior and the corresponding Raman bands showed type B polarization. These bands were assigned to the ν_{16b}, ν_4, ν_{10b}, and ν_{17b} vibrations, respectively. A Raman band observed at 158 cm^{-1} showed type B polarization behavior and therefore this band was assigned to the Br wagging vibration of b_1 species.

a_2 Species: Raman bands observed at 400 and 1002 cm^{-1} showed type C polarization behavior and

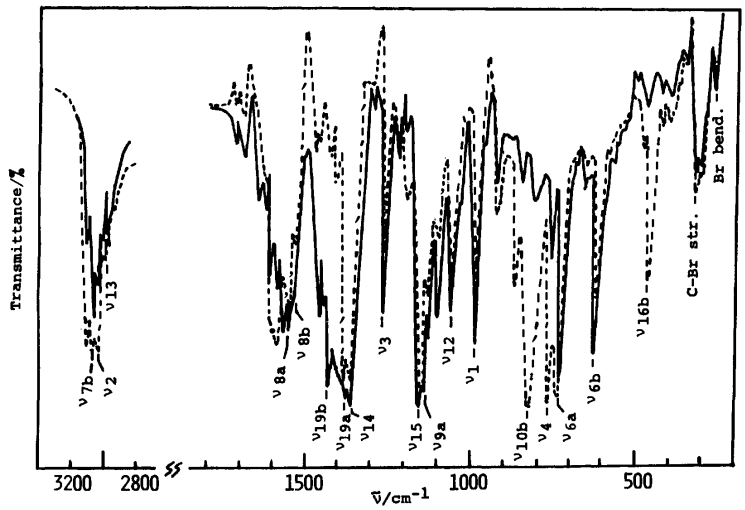

Fig. 5. Polarized infrared spectrum of 2-bromopyrimidine single crystal.

were assigned to the ν_{16a} and ν_{17a} vibrations, respectively. No corresponding infrared bands could be observed.

The isotopic splitting arising from the ^{79}Br and ^{81}Br atoms could not be observed because of small frequency differences due to the isotope. The single crystal infrared spectrum of 2-bromopyrimidine gave different polarization behavior from that of 2-chloropyrimidine. This may be due to different orientations of the two molecules in these single crystals. Detailed vibrational analyses of the Raman and infrared spectra of 2-chloro- and 2-bromopyrimidines are given in Tables 3 and 4, respectively. The normal vibrations are summarized in Table 5.

The assignments of the C–Cl stretching and ν_{6a} vibrations given by Sarma[3] are different from those given by Allenstein *et al.*[4] The normal coordinate calculation shows that the ν_{6a} vibration mixes with the C–X stretching vibration largely in 2-halopyrimidines, and this causes increase of the frequency of the ν_{6a} vibration and decrease of that of the C–X stretching vibration from their normal frequencies. Systematic vibrational analyses of the infrared and Raman spectra of 2-halopyrimidines given by Allenstein *et al.* support this mixing. These facts give the reasoning of assignments made by Allenstein *et al.* and us for the C–X stretching and ν_{6a} vibrations.

Sarma and Allenstein *et al.* assigned the 1169 cm^{-1} band of 2-chloropyrimidine to the ν_{15} vibration and 1158 cm^{-1} of 2-bromopyrimidine to the ν_3 vibration,

but these bands showed a_1 polarization behavior in the Raman and infrared spectra and hence these bands could not be assigned to the b_2 vibration. Frequencies of 1132 and 1165 cm^{-1} constitute the main progressions in the phosphorescence spectra of pyrimidine[15,16] and 2-chloropyrimidine,[15,17] respectively, and these frequencies are to be assigned to the ν_{9a} vibration. Hence the bands assigned to the ν_{15}, and ν_3 vibrations by Sarma and Allenstein *et al.* should be both assigned to the ν_{9a} vibrations of 2-chloro- and 2-bromopyrimidines.

Allenstein *et al.* assigned the 1270 and 1390 cm^{-1} bands of 2-chloropyrimidine and 1273 and 1385 cm^{-1} bands of 2-bromopyrimidine to the ν_{14} and ν_{19b} vibrations, respectively. These bands showed b_2 polarization behavior. On referring to the normal vibrations of pyrimidine, we assigned these bands to the ν_3 and ν_{14} vibrations, respectively. The normal coordinate calculation also supports these assignments.

Allenstein *et al.* observed a 760 cm^{-1} Raman band as a shoulder of the strong 754 cm^{-1} band and assigned it to the ν_{17a} vibration for 2-chloropyrimidine. We reexamined the observation of a Raman band showing a_2 polarization behavior around this region very carefully but no such a band could be observed. On the other hand, the polarized dark sublevel phosphorescence spectrum of pyrimidine indicates that a 1004 cm^{-1} band shows a_2 polarization behavior and thus this frequency should be assigned to the ν_{17a} vibration.[10] Therefore we assigned the 1005 cm^{-1} band showing a_2 polarization behavior in the Raman spectrum to the ν_{17a} vibration.

The normal coordinate calculation indicates that the ν_{16b} vibration mixes largely with the X wagging vibration. This mixing is supported by the observation that the frequencies of the ν_{16b} vibration for 2-chloro- and 2-bromopyrimidines increase from the frequency of 345 cm^{-1} for the ν_{16b} vibration of pyrimidine.

a) X is Cl or Br atom.

We believe that the assignments of the normal vibrations given for 2-chloro- and 2-bromopyrimidines are reliable and quite useful for the reasonable vibrational analysis of the phosphorescence spectrum of 2-chloropyrimidine, which will be reported soon.

Intramolecular Orbital Interactions in 6,6′-Bi(1,4-dithiafulvenyl) Studied by Photoelectron Spectroscopy

Tsunetoshi KOBAYASHI,* Zen-ichi YOSHIDA,† Hiroshi AWAJI,†
Tokuzo KAWASE,† and Shigeo YONEDA†
The Institute of Physical and Chemical Research, Wako, Saitama 351
†*Department of Synthetic Chemistry, Kyoto University, Yoshida, Kyoto 606*
(Received March 15, 1984)

Photoelectron spectra of tetrathiafulvalene (TTF) and 6,6′-bi(1,4-dithiafulvenyl) (BDTF) were measured and compared with each other. The first photoelectron spectral band of BDTF is only slightly shifted relative to that of TTF, though the BDTF molecule is lengthened compared with the TTF molecule by two sp^2 carbon atoms. From the LCGO model orbital interaction analysis, this apparent anomaly is ascribed to the near cancellation of the effects of two main factors, the energy and the terminal atomic orbital coefficient differences between the central olefinic group π orbitals. Orbital interaction analysis as demonstrated in this work may be useful for molecular design, especially for orbital energy control.

In 1973 a charge transfer complex between tetrathiafulvalene (TTF) and tetracyano-*p*-quinodimethane was found to show high electrical conductivity.[1] This finding triggered off present-day active researches on organic metals. Especially several cation radical salts of tetramethyltetraselenafulvalene closely related to TTF was recently found to show superconductivity at low temperature.[2]

During the course of the study to develop good electron donors, 6,6′-bi(1,4-dithiafulvenyl) (BDTF, 2,2′-ethanediylidenebis[1,3-dithiole]) structurally closely related to TTF was recently synthesized.[3] In this paper the photoelectron (PE) spectra of TTF and BDTF are measured and compared with each other in order to get informations useful for molecular design.

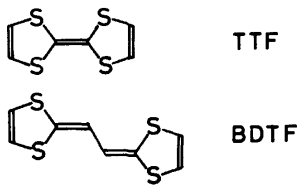

Fig. 1. Structural formulae of TTF and BDTF.

Experimental

Materials. Tetrathiafulvalene (TTF) purchased from the Aldrich Chemical Co. was recrystallized twice from hexane just before use. 6,6′-Bi(1,4-dithiafulvenyl) (BDTF) was synthesized as reported formerly[3] and purified by column chromatography (neutral alumina, benzene) and subsequent recrystallization from benzene.

Measurements. Vapor phase HeI PE spectra of TTF and BDTF were measured with the PE spectrometer described in Refs. 4 and 5. The sample inlet and target chamber systems were kept at 120 °C during the measurements. Xe gas was used as the internal reference standard for the calibrations of the energy scale.

Computational

Pariser-Parr-Pople (PPP) type SCF MO calculations of TTF and BDTF were carried out on a FACOM M-380 computer at the Institute of Physical and Chemical Research. The parameter set necessary in the calculations was taken from Ref. 6. The geometrical structural data for TTF were taken from Ref. 7. The bond angles and bond lengths of the central olefinic moiety of BDTF were assumed to be the same as those of *s-trans*-1,3-butadiene[8] and the dimensions of the two five-membered rings of BDTF were assumed to be the same as those in TTF.[7]

Results and Discussion

Photoelectron Spectral Band Assignments. The vapor phase HeI PE spectra of TTF and BDTF are shown in Fig. 2. The vertical ionization energies, E_{iv}, of TTF and BDTF obtained from the PE spectra are summarized in Table 1. The PE spectra of TTF were formerly reported,[9-11] but was remeasured this time for the sake of consistency. Our PE spectrum of TTF is consistent with those reported formerly.[9-11]

The first four PE spectral bands of TTF have already been assigned as $4b_{1u}\pi$, $3b_{3g}\pi$, $2a_u\pi$, and $2b_{2g}\pi$ from the top, respectively.[9b] Here in this paper the *z*-axes are taken perpendicular to the molecular planes for TTF and BDTF, and the *x*-axis is taken along the short molecular axis for TTF. The $2a_u$ and $2b_{2g}$ orbitals of TTF are completely localized on the two SCCS groups and are predicted degenerate within the simple zero-

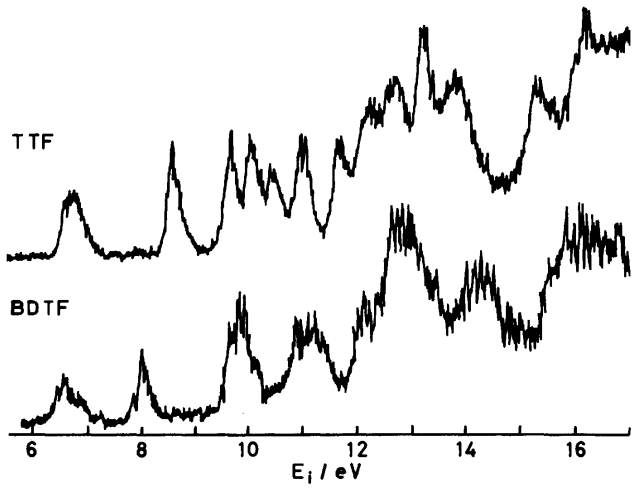

Fig. 2. Vapor phase HeI photoelectron spectra of TTF and BDTF.

a) Ref. 9b. b) Ref. 11. c) The Pariser-Parr-Pople type calculation, see the text. d) The linear combination of group orbitals calculation, see the text.

differential overlap approximation, but in reality, are split slightly because of the long range through-space interactions with the $2a_u$ orbital above the $2b_{2g}$ orbital.[9b] As for the fifth and sixth bands of TTF, Gleiter *et al.*[9b] suggested that these bands should be ascribed to $9b_{1g}n$ and $3b_{1u}\pi$ bands, respectively, based on the MINDO/3 calculations. However, afterwards, Schweig *et al.*[11] assigned those bands as the $3b_{1u}$ and $9b_{1g}$ bands, respectively, from the comparison among the PE spectra of TTF, diselenadithiafulvalene, and tetraselenafulvalene.

For the PE spectral band assignments of BDTF, we use two types of computational methods. One is the linear combination of group orbitals (LCGO) method and the other one is the PPP type method. As the PPP type calculation with Fabian *et al.*'s parameter set[6] reproduces well the observed E_{iv}'s for the first five bands of TTF[9b] (see Table 1 also) on the assumption of the Koopmans theorem,[12] let us apply this method to the case of BDTF. The calculated results are given in Table 1.

The calculated ionization energies reproduce rather well the observed E_{iv}'s for the first three bands of BDTF. The calculation suggests that the observed third band corresponds to the three ionizations, and this is reasonable from the band intensity relative to those of the first two bands. The $5b_g$ and $5a_u$ orbitals of BDTF calculated by the PPP method correspond almost to the $2b_{2g}$ and $2a_u$ orbitals of TTF which are completely localized on the two SCCS groups. The $5b_g$ and $5a_u$ bands of BDTF, therefore, are expected to appear in the same energy region as the $2b_{2g}$ and $2a_u$ bands of TTF, that is, around 9.7—10.0 eV. This is consistent with the assignment suggested above for the 9.70 eV band of BDTF. It is uncertain from the PPP calculation if the fourth 10.82 eV band should be assigned as the $4a_u$ band.

Now we use the LCGO model to make the band assignments more definite. This model has been used by Gleiter *et al.*[9b] in the PE spectral band assignments of TTF formerly. In the LCGO model calculations the TTF molecule is regarded to be composed of three CC double bond groups and four sulfur atoms. The BDTF molecule is regarded to be composed of two CC double bond groups, four sulfur atoms, and a *trans*-butadiene-like group. The interactions among the π and π^* orbitals of the CC double bond groups and the n orbitals of the sulfur atoms are considered in the case of TTF. As for BDTF the contributions from the $1a_u\pi_1$, $1b_g\pi_2$, $2a_u\pi_3^*$, and $2b_g\pi_4^*$ orbitals of the central *trans*-butadiene type group are also taken into account.

At first we reestimate the parameter values necessary in the LCGO model calculations. The newly reevaluated basis group orbital energy values are summarized in Table 2. Of the values in Table 2 the occupied π orbital energies of the CC double bond groups and the *trans*-butadiene-like group were estimated by using the E_{iv} values of ethylene[13] and *trans*-butadiene[14] obtained by PE spectroscopy. The vacant π basis orbital energies of those component groups were estimated by using the electron affinities of ethylene[15] and *trans*-butadiene[16] obtained by electron transmission spectroscopy. The resonance integral values for the CS π bonds, β_{CS}, and the basis orbital energy values of the sulfur atoms, A_S, were readjusted as −1.90 eV and −9.57 eV, respectively, to reproduce the first, third, and fourth E_{iv} values of TTF. The β_{CS} and A_S values suggested by Gleiter *et al.*[9b] formerly were −1.80 eV and −9.4 eV, respectively, and these values are close to those readjusted here. The

calculated results for the first five bands of TTF with the new parameter set are given in Table 1, and the overall agreement between theory and experiment is satisfactory with the band ordering assigned formerly.[11]

Now let us apply the simple LCGO method with our new parameter set to BDTF in question. The calculated results are shown in Table 1. The calculated band ordering by the simple LCGO model is the same as that suggested by the PPP method. The predicted E_{iv} values for BDTF by the LCGO method are closer to the observed ones as for the first three bands than those by the PPP method. Now the first two bands are unambiguously assigned as the $6b_g$ and $6a_u$ bands, respectively, and the apparent third band is ascribed to the three bands, $5b_g$, $5a_u$, and $4b_g$ bands highly overlapping with one another. The assignment of the 10.82 eV band is left unsettled for further detailed examinations.

Orbital Interaction Analysis. It is quite natural to expect that the first E_{iv} of BDTF is far smaller than that of TTF because the BDTF molecule is extended longer than the TTF molecule just by almost the same length as in the case of *trans*-butadiene compared with ethylene, the first E_{iv} values of these compounds being 9.03 eV[14] and 10.51 eV,[13] respectively. In reality, however, the first band of BDTF is only slightly (by 0.11 eV) shifted to the lower energy side compared with that of TTF, while the second band of BDTF is reasonably shifted to the lower energy side by 0.54 eV compared with that of TTF. This small shift of the first band of BDTF relative to that of TTF is interesting because of its contradiction to natural expectation. Theoretically both LCGO and PPP type methods predict well the point that the first E_{iv} value of BDTF is very close to that of TTF. For the second bands of these molecules, the LCGO model predicts quantitatively the reasonably large E_{iv} difference, 0.5 eV, and the PPP method predicts semiquantitatively this tendency.

Now let us analyze the PE spectral band shifts of BDTF relative to TTF by the LCGO model. At first we examine the case of the first bands. The highest occupied molecular orbital (HOMO) of TTF is of b_{1u} symmetry and is regarded to be formed mainly by the interaction among the following occupied π group orbitals: One is the central ethylene type group π orbital, and other two ones are those formed by the in-phase (b_{1u}) type combinations of the occupied π orbitals of the two SCCS groups of the TTF molecule. On the other hand the HOMO of BDTF is of b_g symmetry and is regarded to be formed mainly by the interactions among the following orbitals: One is the b_g symmetry π_2 orbital of the *trans*-butadiene type group and other two ones are the orbitals formed by the out-of-phase combinations of the occupied π orbitals of the two SCCS groups. It is noticed that the $4b_g$ MO in the LCGO model of BDTF is completely localized on the two SCCS groups just as the $2b_{2g}$ MO of TTF and is not taken into account in the above consideration. The energies of those out-of-phase type group orbitals described above are almost equal to those of the corresponding in-phase type group orbitals. In addition to those the π_4^* orbital of the *trans*-butadiene type group is also expected to contribute to the b_g HOMO of BDTF from the symmetry reason.

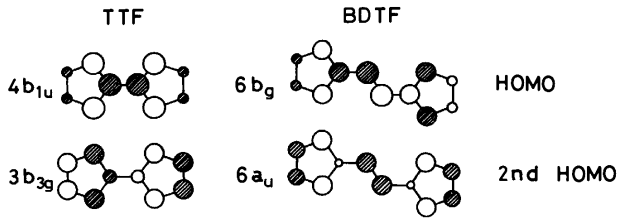

Fig. 3. Schematic representations of the first and second HOMO's of TTF and BDTF calculated by the PPP type method.

On the first stage we estimate the effect of the central olefinic group occupied π orbital energy change. In the case of TTF the central olefinic group π orbital energy is -10.51 eV, and the π_2 basis orbital energy of the *trans*-butadiene-like group is -9.03 eV. If we change the central olefinic group occupied π basis orbital energy from -10.51 eV to -9.03 eV, the effect of this change on the HOMO energy of TTF is evaluated to be -0.525 eV. Only 35% of the central olefinic group π orbital energy change is reflected on the HOMO energy change toward the destabilization.

In addition to the above effect, in the process of replacing the central ethylenic group of TTF by a *trans*-butadiene type group we must take into account the effect of the resonance integral change between the olefinic occupied π orbital and the group π orbital of the appropriate symmetry composed of the four sulfur atom 3p lone pair orbitals. The absolute values of the atomic orbital (AO) coefficients of the terminal carbon atoms of the central olefinic group HO-π-MO are 0.7071 in the case of the ethylene type group and 0.5727 in the case of the *trans*-butadiene type group. The latter values have been calculated by a modified CNDO method[17] for *trans*-butadiene. By using the latter values we can estimate the resonance integral value for the case of BDTF in question as -2.176 eV, that is, decrease in the absolute value by 0.5 eV from the corresponding one for TTF (-2.687 eV). By using this resonance integral value thus estimated we can estimate the additional HOMO energy change as -0.456 eV or stabilization of the HOMO by 0.456 eV. In this case the resonance integral value change influences almost directly on the HOMO energy change.

In order to estimate the effect of the π^* level on the HOMO energy, let us now introduce the π_4^* orbital of the *trans*-butadiene-like group into the above model with the appropriate symmetry. Thus, the effect is estimated to be 0.122 eV, or stabilization of the HOMO by 0.122 eV. From the above stepwise model calculations it is said that in replacing the central CC double bond in TTF by a longer *trans*-butadiene-like group, the central olefinic group HOMO energy change contributes considerably toward the stabilization of the HOMO by around 0.5 eV, while this effect is almost completely compensated by the decreases in the absolute values of the terminal AO coefficients of the central olefinic group HOMO. The HOMO stabilization effect of the π_4^* level of the central *trans*-butadiene-like group of BDTF is not so large (*ca.* 0.1 eV).

From the above model consideration it is concluded

that the anomalously small shift of the first band of BDTF compared with that of TTF can be explained by the almost perfect cancellation of the two main effects, the energy and the terminal AO coefficient changes of the central olefinic group π orbital.

Next let us compare the second E_{iv}'s of TTF and BDTF. The second E_{iv} of BDTF is smaller than that of TTF by *ca.* 0.5 eV, and this seems to be reasonable as stated before. Now we analyze the situation with the LCGO model. In the case of TTF the second HOMO is of b_{3g} symmetry and is contributed by the π^* orbital of the central ethylenic group toward stabilization. If we change only the energy of the central olefinic group vacant π basis orbital from 1.78 eV to 0.76 eV, the π_3^* basis orbital energy of the *trans*-butadiene type group, in TTF, the second HOMO stabilization by this change is only 0.04 eV and this effect is negligibly small.

Further let us change the absolute values of the terminal AO coefficients of the central olefinic group vacant π orbital from 0.7071 for the ethylene type group to 0.5595 for the *trans*-butadiene type π_3^* orbital. So the second HOMO of TTF is destabilized on this second step by 0.15 eV.

Introduction of the π_1 basis orbital of the *trans*-butadiene type group into this last model with the appropriate symmetry causes large destabilization of the second HOMO by 0.45 eV. From the above model calculations, it is concluded that the apparently reasonable decrease in the second E_{iv} energy of BDTF compared with that of TTF is ascribed mostly to the second HOMO destabilization caused by the contribution of the π_1 basis group orbital of the central *trans*-butadiene type group.

In the discussion so far we have been concerned with the apparent relative energy shifts of the first (second) bands of TTF and BDTF. However, from the standpoint of MO symmetry the HOMO and the second HOMO of TTF are to be correlated with the second HOMO and the HOMO of BDTF, respectively, that is, if we take the orbital symmetry into account, the original first band of TTF should be regarded to be shifted to the higher ionization energy side by 1.30 eV, while the second band of TTF is shifted to the lower ionization energy side by 1.95 eV, the ordering of the first and second bands being reversed, when the TTF molecule is stretched to BDTF.

Let us examine the HOMO energy shift of TTF in the above sence. The HOMO of TTF is of b_{1u} symmetry and contributed from the occupied group π orbital of the central CC double bond. In the LCGO model, if we change the basis orbital energy of this central CC double bond from -10.51 eV to -11.46 eV for the *trans*-butadiene type group π_1 orbital, the HOMO energy is only slightly stabilized by 0.24 eV. In this model if we change the terminal AO coefficients from 0.7071 for the ethylene π orbital to 0.4324 for the *trans*-butadiene π_1 orbital, the HOMO is additionally stabilized by 0.67 eV. In this model, if we introduce the π_3^* orbital of the *trans*-butadiene type group, the HOMO is further stabilized by 0.31 eV. The stabilization of the HOMO of TTF by the extension of TTF to BDTF is ascribed to the cumulative effect of the above three factors.

Next we discuss the second HOMO energy shift of TTF caused by the molecular lengthening to BDTF taking the orbital symmetries into account. The second HOMO of TTF is contributed from the π^* orbitals of the central olefinic group. If we change the π^* orbital energy of the central olefinic group in TTF from 1.78 eV for the ethylene type group to 2.8 eV for the *trans*-butadiene type group π_4^* orbital, the second HOMO of TTF is destabilized only by 0.03 eV. If we change in this model the absolute values of the terminal AO coefficients from 0.7071 for the ethylene π^* orbital to 0.4147 for the *trans*-butadiene π_4^* orbital, the second HOMO is further destabilized by 0.24 eV. If we introduce the π_2 basis orbital of the *trans*-butadiene type group into this model, the second HOMO is further considerably destabilized by 1.45 eV. The large destabilization of the second HOMO of TTF by the molecular lengthening to BDTF is mostly ascribed to the contribution of the π_2 orbital of the *trans*-butadiene type group.

Conclusion

Lengthening of a molecule toward its long molecular axis does not necessarily lead to the apparent efficient destabilization of the HOMO as seen in the case of TTF and BDTF treated in this paper. Anomalously small shift of the first PE spectral band of BDTF compared with that of TTF is ascribed to the near cancellation of the effects of two main factors, the energy and the terminal AO coefficient changes of the basis orbital of the central olefinic part. Orbital interaction analysis as demonstrated in this paper is expected to be useful for molecular design, especially for orbital energy control.

The Structure of the Cyclodextrin Complex. XVII. Crystal Structure of β-Cyclodextrin-Hexamethylenetetramine (1:1) Complex Hexahydrate

Kazuaki HARATA
Research Institute for Polymers and Textiles, 1-1-4 Yatabe-Higashi, Tsukuba, Ibaraki 305
(Received March 22, 1984)

The crystal structure of β-cyclodextrin-hexamethylenetetramine (1:1) complex hexahydrate was determined by the X-ray diffraction method. The crystal is monoclinic with the space group $P2_1$, $Z=2$, $a=15.285(3)$, $b=10.345(2)$, $c=20.118(2)$ Å, and $\beta=102.14(1)°$. The structure was solved by inspection of a Patterson map and the trial-and-error method combined with the rigid-body least-squares technique and refined by the block-diagonal least-squares method to the R-value of 0.056 for 4369 reflections ($\sin\theta/\lambda<0.55$). The β-cyclodextrin molecule is slightly distorted from the regular heptagonal structure. The orientation of two primary hydroxyl groups is statistically disordered. The secondary hydroxyl groups form intramolecular hydrogen bonds between adjacent glucose residues. The guest hexamethylenetetramine molecule, being located roughly at the center of the β-cyclodextrin ring, is in van der Waals contact with the interior surface of the host molecule. Two out of four nitrogen atoms of hexamethylenetetramine form N···H-O hydrogen bonds with water and adjacent β-cyclodextrin molecules. β-Cyclodextrin molecules are stacked along the crystallographic b axis, with which the plane through seven glycosidic oxygen atoms makes an angle of 46.7°, forming a "cage-type" packing. Water molecules occupy the intermolecular spaces between β-cyclodextrin molecules.

Cyclodextrins form inclusion complexes with a variety of guest molecules, of which shape and size are suitable to be accommodated within the cavity of the host macrocyclic ring.[1,2] Several β-cyclodextrin complexes with alcohol[3-5] and aromatic compounds[6-12] have been investigated by the X-ray method, and in these complexes the guest molecules have been found to be included within the host cavity. Compared with such linear or planar molecules, spherical molecules can be expected to be more favorably accommodated within the cylindrical cavity of β-cyclodextrin. Previously, we determined the crystal structure of the β-cyclodextrin-1,4-diazabicyclo[2.2.2]octane complex,[13] a complex with a spherically-shaped guest molecule. Hamilton and Sabesan have also reported the structure of the β-cyclodextrin complex with 1-adamantanecarboxylic acid[14] having a spherical adamantane moiety. In this paper, we present the crystal structure of β-cyclodextrin-hexamethylenetetramine complex in order to investigate how β-cyclodextrin includes the guest molecule with high symmetry ($\bar{4}3$ m).[15]

Experimental

β-Cyclodextrin and hexamethylenetetramine with *ca.* 1:1 molar ratio were dissolved in hot water. Colorless and prismatic crystals were obtained by standing the solution for a week at room temperature. Lattice parameters and diffraction intensities were measured on a Nicolet P3/F diffractometer with graphite-monochromated Cu $K\alpha$ radiation. The crystal was sealed in a quartz capillary with a drop of mother liquor to prevent from deterioration in air. The lattice parameters were refined by the least-squares method using 25 reflections in the 2θ range 35—40°. By using $\theta-2\theta$ scan mode, 4369 independent reflections with $|F_o|\geqq 3\sigma(F)$ were collected up to 115° in 2θ. No correction was made for absorption or extinction effect.

Crystal Data: $C_{42}H_{70}O_{35}\cdot C_6H_{12}N_4\cdot 6H_2O$, F.W.=1383.3, monoclinic, space group $P2_1$, $Z=2$, $a=15.285(3)$, $b=10.345(2)$, $c=20.118(2)$ Å, $\beta=102.14(1)°$, $V=3110.0(8)$ Å^3, $D_x=1.477$, $D_m=1.46$ g·cm^{-3}.

Determination and Refinement of the Structure

The orientation of the *pseudo* heptagonal axis of β-cyclodextrin was easily deduced by inspection of a Patterson map, and the translational parameters along the a and c axes were determined by the trial-and-error method. After the correction of the position and orientation of each glucose residue by the rigid-body least-squares method, atomic parameters were refined by the block-diagonal least-squares method. Successive Fourier and difference-Fourier syntheses revealed the positions of hexamethylenetetramine and water molecules. Occupancy factors of disordered hydroxyl groups were estimated from an electron-density map, but they were not refined. Further block-diagonal least-squares refinement of the structure, including 93 hydrogen atoms, achieved the R-value of 0.065. The quantity minimized was $\sum w(|F_o|-|F_c|)^2$ with $w=1.0$ for all the reflections. Atomic scattering factors were taken from the literature.[16] Final atomic coordinates and B_{eq} values are given in Table 1. Tables of observed and calculated structure factors, anisotropic temperature factors, atomic parameters of hydrogen atoms, bond distances, angles , and conformation angles of β-cyclodextrin, and the plane equation and atomic deviations from the plane of the seven glycosidic oxygen atoms are kept at The Chemical Society of Japan (Document No. 8440). The computation was carried out on a FACOM M-380 computer at the Center of Research Information Processing System, Agency of Industrial Science and Technology, Tsukuba.

Description and Discussion of the Structure

Outline of the Structure. A numbering scheme of the β-cyclodextrin-hexamethylenetetramine complex hexahydrate is shown in Fig. 1, and a stereo-view of the complex is given in Fig. 2. The β-cyclodextrin molecule is slightly distorted from the regular heptagonal symmetry. The guest hexamethylenetetramine

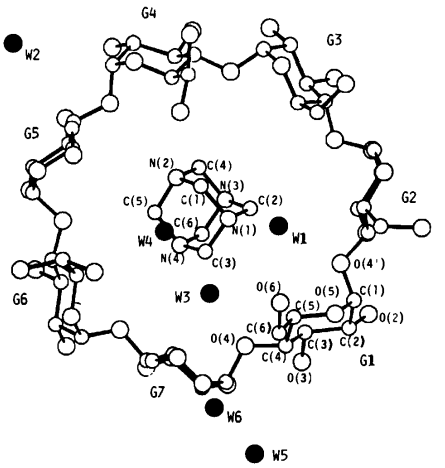

Fig. 1. Numbering scheme of the β-cyclodextrin–hexamethylenetetramine complex hexahydrate. Water molecules are shown by full circles.

molecule is located roughly at the center of the β-cyclodextrin ring, and is in van der Waals contact with the interior surface of the host molecule. β-

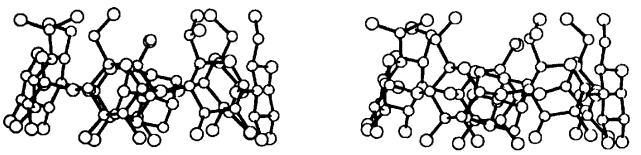

Fig. 2. Stereo-view of the β-cyclodextrin–hexamethylenetetramine complex.

Cyclodextrin molecules are stacked along the b axis, forming a "cage-type" packing. Water molecules occupy the intermolecular spaces between β-cyclodextrin molecules.

Conformation of β-Cyclodextrin. Average bond distances and angles for seven glucose residues (Fig. 3) are in good agreement with those of previously reported β-cyclodextrin complexes.[13] Two types of orientations are observed in the primary hydroxyl groups. The C(6)–O(6) bonds of the G1, G5, and G7 residues are in a *gauche-trans* conformation (to the C(5)–O(5) and C(5)–C(4) bonds, respectively), while the G2 and G3 residues have the C(6)–O(6) bonds with a *gauche-gauche* conformation. The orientation of the C(6)–O(6) bonds

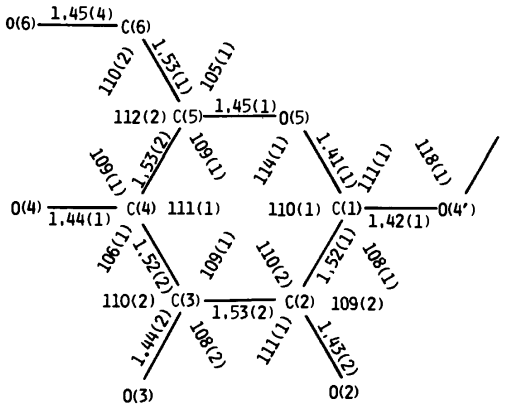

Fig. 3. Average bond distances and angles for seven glucose residues of β-cyclodextrin. Standard deviations in parentheses were estimated according to the equation:

$$\sigma = [\sum_{i=1}^{7} (x_i - \bar{x})^2/6]^{1/2}$$

where x_i refers to the bond distance or angle of the i-th residue and $\bar{x}$ is the average value.

in the G4 and G6 residues is statistically disordered, showing *gauche-trans* and *gauche-gauche* conformations.

The seven glycosidic oxygen atoms form a distorted heptagon. The radius of the heptagon, as shown in Table 2, is in the range 4.92—5.14 Å, and the O(4)···O(4′) distances between adjacent glucose residues being in the rage 4.31—4.45 Å. The average value of the radius is in good agreement with those found in the β-cyclodextrin complexes with 1,4-diazabicyclo[2.2.2]-octane (5.02 Å)[13] and 1-adamantanecarboxylic acid (5.03 and 5.08 Å).[14] The root-mean-square deviation, 0.077 Å, of O(4) atoms from the least-squares plane through the O(4) heptagon indicates the good planarity of the heptagon. As shown by the tilt-angles in Table 2, the G2, G5, and G7 residues are nearly perpendicular to the O(4) plane. The other residues incline by 14.7—17.3° with respect to the molecular axis of β-cyclodextrin, which is defined as the axis through the center of the O(4) heptagon and perpendicular to the heptagon. Distances between O(2) and O(3′) of the adjacent glucose residue are in the range 2.73—3.00 Å. These secondary hydroxyl groups are linked by the intramolecular hydrogen bonds; the O(2)-H···O(3) hydrogen bond is observed between the G1 and G2 residues, while the other hydrogen bonds are of the O(3)-H···O(2) type.

Structure of Hexamethylenetetramine. Hexamethylenetetramine has a high molecular symmetry ($\bar{4}3$ m) in the crystalline state.[15] In the cavity of β-cyclodextrin, the hexamethylenetetramine molecule shows no significant distortion from the $\bar{4}3$ m symmetry within the experimental error. The average values of C-N distance, N-C-N and C-N-C angles are 1.47(3) Å, 112(1)°, and 109(2)°, respectively. These values are in good agreement with those (1.464(4) Å, 113.3(9)°, and 107.5(5)°, respectively) found in the hexamethylenetetramine crystal at 298 K.[15]

Host-Guest Interaction. The hexamethylenetetramine molecule is roughly located at the center of the β-cyclodextrin cavity. The mirror plane through C(2,HT), C(5,HT), N(1,HT), and N(3,HT) is almost parallel to the molecular axis of β-cyclodextrin. The shortest intermolecular distance is 2.01 Å, which is found between hydrogen atoms of the C(5,HT)H_2 methylene group of the guest and the C(3,G5)H and C(5,G6)H methine groups of β-cyclodextrin. The shortest contact involving glycosidic oxygen atoms is 2.54 Å, which is found between O(4,G1) and a hydrogen atom of the C(3,HT)H_2 methylene group. The N(2) and N(4) nitrogen atoms of hexamethylenetetramine face to the interior surface of the β-cyclodextrin cavity, while the N(1) and N(3) atoms form N···H-O hydrogen bonds with the W2 water located at the primary hydroxyl side, and the O(2)-H hydroxyl group of the G3 residue in adjacent β-cyclodextrin at the secondary hydroxyl side, respectively. Therefore, the hexamethylenetetramine molecule is fixed within the β-cyclodextrin cavity by the hydrogen bonds and van der Waals force.

The position of hexamethylenetetramine in the β-cyclodextrin cavity is nearly the same as that of 1,4-

TABLE 2. GEOMETRICAL DATA FOR β-CYCLODEXTRIN

I. Radius of the O(4) heptagon

The radius is measured from the center of gravity of seven O(4) atoms to each O(4) atom.

Residue	Radius l/Å	Residue	Radius l/Å
G1	4.92	G5	5.05
G2	5.07	G6	5.07
G3	5.12	G7	5.14
G4	4.96	Average	5.05

II. O(4)···O(4) distance between adjacent glucose residues

Distance l/Å		Distance l/Å	
O(4, G1)···O(4, G2)	4.40	O(4. G4)···O(4, G5)	4.40
O(4, G1)···O(4, G7)	4.44	O(4, G5)···O(4, G6)	4.45
O(4, G2)···O(4, G3)	4.32	O(4, G6)···O(4, G7)	4.31
O(4, G3)···O(4, G4)	4.36	Average	4.38

III. Tilt-angle[a] and torsion-angle index[b]

Residue	Tilt-angle ϕ/°	Torsion-angle index ϕ/°
G1	17.3	123
G2	3.3	127
G3	16.8	120
G4	14.7	116
G5	5.3	120
G6	16.5	130
C7	6.0	119
Average	11.4	122

a) The tilt-angle is defined as an angle made by the O(4) plane and the plane through C(1), C(4), O(4), and O(4′) of each glucose residue. b) The torsion-angle index is defined as follows: $\phi = |\phi(C(1)\text{-}C(2))| + |\phi(C(2)\text{-}C(3))| - |\phi(C(3)\text{-}C(4))| - |\phi(C(4)\text{-}C(5))| + |\phi(C(5)\text{-}O(5))| + |\phi(O(5)\text{-}C(1))|$, where $\phi(C(1)\text{-}C(2))$ is the conformation angle of O(5)-C(1)-C(2)-C(3).

Table 3. Hydrogen-bond distances and angles

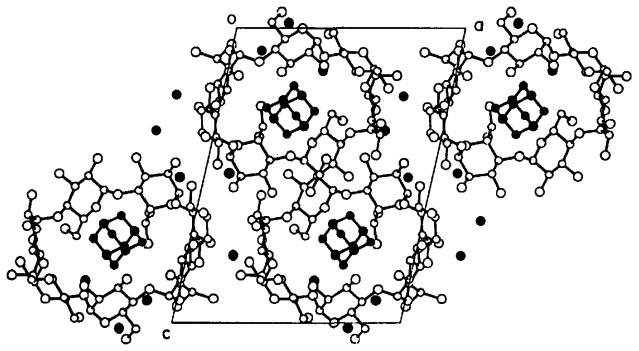

Fig. 4. Crystal structure viewed along the b axis.

diazabicyclo[2.2.2]octane,[13] but differs from that of the adamantane moiety of the 1-adamantane-carboxylic acid complex.[14] The adamantane moiety is found at the position near the primary or secondary hydroxyl side, and the carboxyl group forms hydrogen bonds with water molecules outside the cavity. Comparison of these structures suggests that the hydrogen-bond formation of the guest molecule is a more important factor to determine the host-guest geometry than van der Waals interaction.

Crystal Structure. The crystal structure is shown in Fig. 4 and 5. β-Cyclodextrin molecules are stacked along the b axis to form a "cage-type" structure similar to that found in the crystal of β-cyclodextrin.[17] The O(4) plane of β-cyclodextrin makes an angle of 46.7° with the b axis, as shown in Fig. 5. Both ends of the β-cyclodextrin cavity are blocked by adjacent β-cyclodextrin molecules. The spherical guest molecule is well accommodated within the "cage" of the β-cyclodextrin cavity. Water molecules are located in intermolecular spaces between β-cyclodextrin molecules, forming a hydrogen-bond network. W1, W3, and W4 are located near the primary hydroxyl side of the β-cyclodextrin ring, and are linked by the O(W1)-H···O(6, G1)···H-O(W3)-H···O(W4) hydrogen bonds (Table 3). W5 and W6 are also linked to each other by the O(W5)-H···O(W6) hydrogen bond, but the W2 water molecule is isolated, forming hydrogen bonds with β-cyclodextrin molecules.

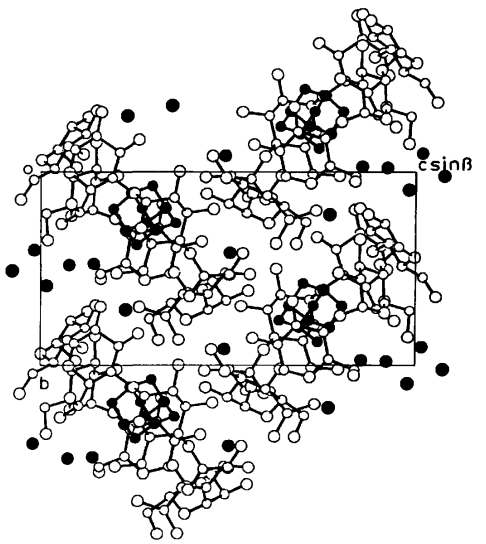

Fig. 5. Crystal structure viewed along the a axis.

(Received March 9, 1984)

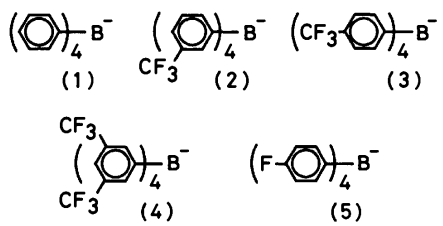
Tetrakis[3,5-bis(trifluoromethyl)phenyl]borate (TFPB) anion was highly lipophilic, practically insoluble in water, and durable against acid and oxidants. Partition equilibria of alkali TFPB between water and organic solvents and the stability in acid media are described and compared with the properties of the parent tetraphenylborate and of some fluorine-containing homologues.

Tetraphenylborate (TPB) (**1**) anion has a unique structure in which four phenyl groups are tetrahedrally bonded to the central boron atom of univalent negative charge.[1] The charged center is shielded by bulky lipophilic phenyl groups from the medium and no hydrophilic sites are present on the outside of the molecule. In this respect, the structure of TPB anion makes a strong contrast to those of ordinary organic anions such as conjugate bases of carboxylic and sulfonic acids, whose anionic oxygen atom is exposed into the surrounding medium and provides a strongly hydrophilic center. The relationship is just like that between a quarternary ammonium ion and less substituted ones, though the charge is opposite.

TPB anion forms hydrophobic ion pairs with various univalent cations, such as heavy alkali metals. By taking advantage of this property, TPB has been successfully applied as an ion-pairing agent to precipitation and solvent extraction of various organic and inorganic cations in aqueous solutions.[2]

One thing to be noticed is that TPB anion is chemically labile, especially in the presence of acids or oxidants.[3-8] This reagent must, therefore, be stored and used under strictly limited conditions. In the last two decades, several attempts have been made to overcome the drawback of chemical lability and at the same time to modify the physicochemical properties of TPB.[9-11]

Among them, tetrakis(*m*-trifluoromethylphenyl)borate (**2**) and the *p*-trifluoromethyl homologue (**3**) are worthy of attention. The strongly electron-withdrawing effect caused by the trifluoromethyl substituents would suppress the electrophilic attack by proton on to the phenyl-ring carbon ipso to the boron to increase the stability against acids.[5] And the hydrophobic fluorocarbon moieties would decrease the solubility of the ion pairs in an aqueous solution to promote the precipitate formation and the extraction into the organic solvent.[12]



On the basis of these presumptions, the structure of tetrakis[3,5-bis(trifluoromethyl)phenyl]borate (TFPB) (**4**) was designed. Convenient preparations of the fluorinated TPB derivatives including TFPB and their properties were roughly reported.[13] This paper describes detailed examinations of the chemical stability and lipophilicity of TFPB. Preparation of TFPB according to the scheme of Fig. 1 is briefly described in the experimental section. The alkali metal salts of TFPB were practically insoluble in cold water, while being slightly soluble in hot water and readily dissolved in ethanol, ether, and acetone, and to a less extent in chloroform, dichloromethane, and toluene.

Results and Discussion

Chemical Stability. The increased chemical stability of TFPB (**4**) is noteworthy. The acid-catalyzed degradations of TPB (**1**), TFPB (**4**), and related fluorinated derivatives, (**2**) and (**3**), were kinetically followed. The decrease of the parent borate in aqueous methanol was monitored by HPLC and ^{19}F-NMR in the presence of a large excess of sulfuric acid. Respective pseudo-first-order kinetic plots gave good linear relationships. The rate constants in 63% aq methanol are compared in Table 1. Provided the reaction rate is regarded as a first-order dependence on the acid concentration,[3] the stability in acid media can be compared in terms of the relative half-life period. The comparison shows that

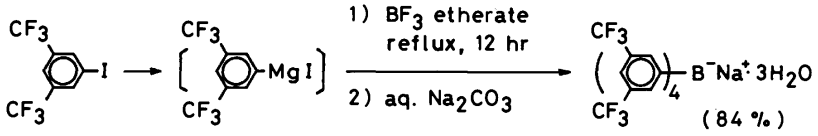


Fig. 1. Preparation scheme of TFPB.

Table 1. Comparisons of acid-catalyzed decomposition rates of tetraarylborates in aqueous methanol (methanol : water = 67 : 37)

Tetraaryl-borates	$\frac{[H^+]}{([H_2SO_4]\times 2)}$ / mol dm^{-3}	k_{obsd} / s^{-1}	$k_2=k_{obsd}/[H^+]$ / s^{-1} mol^{-1} dm^3	Relative half-life period
(1)	0.049	4.00×10^{-4}	8.00×10^{-3}	1
(2)	2.1	5.19×10^{-7}	2.47×10^{-7}	3.24×10^4
(3)	2.1	3.46×10^{-7}	1.65×10^{-7}	4.85×10^4
(4)	2.1	No decomp.	—	(Unmeasurable)
	8.2	No decomp.	—	

the trifluoromethylation on to the pendent phenyl rings increases the durability against acid to a striking extent. This extent was outstanding in TFPB; it showed no trace of decomposition after standing for one month in 4.1 mol dm^{-3} aq methanolic sulfuric acid at room temperature. The result was the same even when the sample was heated under reflux in 3.6 mol dm^{-3} methanolic sulfuric acid for 7 d.

If one assumes that electrophilic attacks by protons on to the phenyl-ring carbons ipso to the boron are correlated with the σ^+ value of trifluoromethyl groups,[5] the half-life period of TFPB can be estimated from an extrapolation of the log k_2–σ^+ plottings[14] of the upper three lines in Table 1, to be approximately 8000 d at 25 °C. This means that the reaction of TFPB takes 100 d to decompose 1% of the initial amount which might be an extent detectable by the present analytical method.

Under aerated conditions, oxidative degradation of TPB (**1**) and the trifluoromethylated derivatives (**2**), (**3**), and (**4**), were monitored by HPLC in a water–dichloromethane two-phase system. Decay curves are shown in Fig. 2. With the progress of oxidative degradation, two new peaks appeared in HPLC of the organic phase. These increased their peak areas as that of the parent borate peak decreased. One of the new peaks were assigned to the corresponding phenol and the other to the biphenyl. Although the stepwise degradation could not be differentiated, the *m*- and *p*-trifluoromethyl derivatives, (**2**) and (**3**), decomposed within 6 and 2.5 h, respectively, while TPB (**1**) took 10 h before the complete decomposition under our experimental conditions. The time when the borate peak disappeared corresponded to when those of the decomposition products ceased to increase. TFPB (**4**), on the other hand, indicated no trace of decomposition after being kept aerated for 21 h under the same conditions. If one takes account of the facts that TPB (**1**) was mostly partitioned into the aqueous phase, while the trifluromethylated derivatives, (**2**), (**3**), and (**4**), were partitioned into the dichloromethane phase during the air-oxidation in the present two-phase system, and that the solubility of oxygen in dichloromethane, though unavailable in the literature, might be estimated at about 10 times more than that in water based upon the data of homologous halomethanes at the same temperature,[15] it is obvious that the bis(trifluoromethyl)ation of the pendent phenyl groups enormously increased the durability of the TPB structure against the air-oxidation. TFPB was

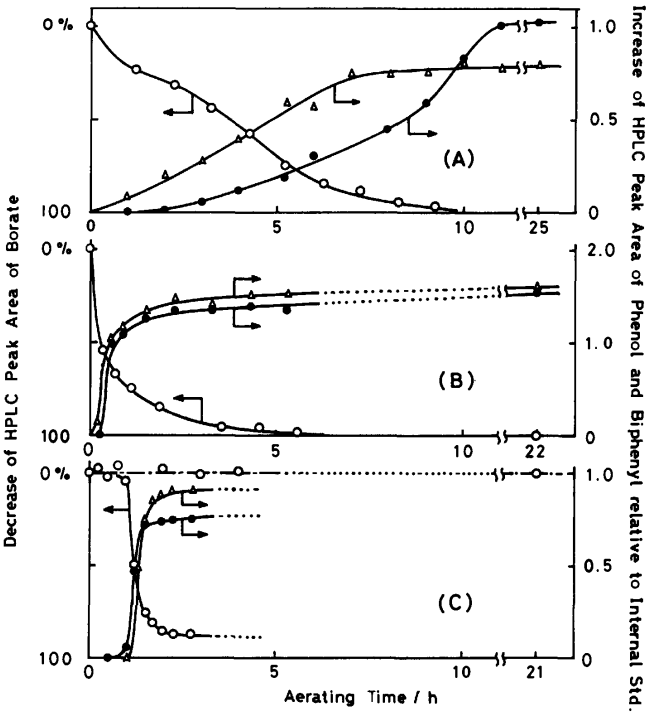

Fig. 2. Decay of the tetraarylborate (○) and occurrence of the corresponding phenol (△) and biphenyl (●) upon aeration.
(A): TPB (**1**), (B): *m*-trifluoromethyl deriv. (**2**), (C): *p*-trifluoromethyl deriv. (**3**) (——), and TFPB (**4**) (—·—).

also durable to a range of oxidants. It remained completely intact even after 22 h when its dichloromethane solution was stirred vigorously with 10% aqueous nitrous acid or 10% aqueous hypochlorite, and when treated with twice molar amounts of bromine in a chloroform solution at room temperature.[16]

Lipophilicity. Partition behaviors of the TFPB ion pairs with alkali metal ions were examined by HPLC in aqueous dichloromethane and aqueous toluene two-phase systems. The organic solvents might be regarded as the representatives of different polarities, and are frequently used as extractants.

Results are summarized in Tables 2 and 3, together with those of some related borates for comparisons.[13] The ion pairs were generally well extracted into a dichloromethane phase. One may readily notice that the saturated concentrations of alkali TFPB in the dichlo-

romethane phase are about 100 times higher than those of the others; these results indicated it to be highly lipophilic. Toluene was less efficient as an extractant of the ion pairs of such borates, as shown in Table 3. The borate was less soluble in this solvent, and so much remained in the aqueous phase.

Partitions between the two phases can be compared more clearly by their extraction coefficients, K_{ex}, which are given in Table 4. The values of TFPB salts are much higher than those of the others; especially the value of lithium salt was extremely increased. One may say that TFPB combined with toluene shows a somewhat different extraction behavior for alkali metal ions from the other homologues.

Unique behaviors of TFPB at the solvent extraction occurred not only in the partition equilibrium, but also in the phase-transfer rates, which were more than three times faster than that of tetrakis(*p*-fluorophenyl)borate (**5**), when compared by use of their lithium salts in both dichloromethane–water and toluene–water two-phase systems.[13]

As a conclusion, bis(trifluoromethyl)ation of the pendent phenyl rings of TPB was unexpectedly effective not only in the chemical stabilization of this ion-pairing agent, but also in the increase of solubility of its ion pairs in organic solvents and in the acceleration of the extraction rate. Also, the extraction coefficients varied depending upon the substituents on the pendent

phenyl rings and the kinds of organic extractants. This result suggested the possibility of selective solvent-extraction for certain organic and inorganic cations by use of a proper organic extractant combined with an ion-pairing agent.

Further studies along this line are now being undertaken in this laboratory.

Experimental

^{1}H- and ^{19}F-NMR spectra were obtained on a JEOL FX-100 and Hitachi R-24B-F instruments in reference to the internal TMS and trifluoroacetic acid, respectively, unless otherwise described. HPLC charts were recorded on a Hitachi 380-30 liquid chromatograph combined with a spectrophotometric detector and a Shimadzu recording integrator C-R1A Chromatopac. A separating column 500 mm long was packed with Hitachi gel 3010. Methanol was an efficient eluant unless otherwise stated. Sodium tetraphenylborate (**1**) (Dotite Kalibor®) and sodium tetrakis(*p*-fluorophenyl)borate (**5**) (Dotite Cesibor®) were commercially available reagents. Sodium tetrakis(*m*-trifluoromethylphenyl)borate (**2**)[9] and the *p*-trifluoromethyl homologue (**3**)[9] were prepared in this laboratory.[13]

Preparation of Sodium Tetrakis[3,5-bis(trifluoromethyl)-phenyl]borate (4). An ethereal solution of boron trifluoride (365 mg, 2.52 mmol) was added dropwise over 40 min into an ethereal solution of 3,5-bis(trifluoromethyl)phenylmagnesium iodide, which was prepared from 1-iodo-3,5-bis(trifluoromethyl)benzene (4.78 g, 14.06 mmol), magnesium turnings (0.42 g, 17.1 mmol) and anhydrous ether (13 cm^3). The mixture was, after being refluxed for 12 h, poured portionwise into aqueous sodium carbonate (24.0 g in 100 cm^3 of water) with vigorous stirring. The precipitated magnesium carbonate was filtered off and washed with ether. The aqueous layer of the filtrate was separated from the ethereal one, saturated with sodium chloride, and extracted repeatedly with ether. All the ethereal extracts were combined with the initial ethereal layer, and evaporated under reduced pressure. The residual solid was succesively eluted from a silica-gel column with hexane, dichloromethane, and methanol. The borate was isolated in the form of hydrated sodium salt from the dichloromethane and methanol fractions. The yield was 2.0 g (84%). IR (KBr): 3500, 1350, 1280, and 1200—1100 cm^{-1}. ^{19}F-NMR (CH_3OH): 13.52 ppm (s). ^{1}H-NMR ($CDCl_3$–DMSO-d_6): 7.50—7.70 (m) and 2.95 (s).

Hot aqueous tetraethylammonium iodide was added to a saturated hot aqueous solution of the sodium TFPB to yield colorless precipitates, which were successively eluted from a silica-gel column with hexane, benzene, ether, and methanol. The solid residue, which was obtained from the ether and methanol fractions by evaporation, was washed with cold chloroform to give the tetraethylammonium salt, mp 181—182 °C. IR (KBr): 1350, 1280, and 1200—1100 cm^{-1}. λ_{max} (ε): 269 (4100) and 278 nm (3200). ^{1}H-NMR ($CDCl_3$–DMSO-d_6): 1.25 (tt, J=2 and 7 Hz, $-CH_3$, 12H), 2.75 (s, H_2O), 3.20 (q, J=7 Hz, $-CH_2-$, 8H), and 7.50—7.70 (m, aromatic, 12H). Found: C, 48.25; H, 3.23; N, 1.33%. Calcd for $C_{40}H_{32}NF_{24}B$; C, 48.36; H, 3.27; N, 1.09%.

Kinetics of Acid Decomposition of the Trifluoromethylated Derivatives. A methanol solution (0.3 cm^3) of the trifluoromethylated compound (**2**, **3**, or **4**) (*ca.* 20 mg) and the required amount of aqueous sulfuric acid were combined in an NMR tube at a lowered temperature and then kept at 25 °C in a thermostat. The intensity change in ^{19}F-NMR signals of the parent borate and those of the decomposition products were followed at specified intervals.

The signal of the *m*-trifluoromethyl compound (**2**) at 14.2 ppm diminished with the increments of those of the corresponding decomposition products at 13.8, 13.7, and 13.4 ppm. The signal of the *p*-trifluoromethyl compound (**3**) at 14.7 ppm and those of the decomposition products at 14.0, 13.6, and 13.4 ppm changed in a similar manner.

On the condition that the total peak area of ^{19}F-NMR signals were unchanged throughout the reaction, the logarithm of relative peak area of the parent compound was plotted against the reaction time to give a good linear relationship with a correlation coefficient (γ) more than 0.99 at least over one half-life period. The gradient of the correlation line gave a pseudo-first-order rate constant, k_{obs}. The apparent second-order rate constant, k_2, was derived according to the equation, $k_2=k_{obs}/[H^+]$, where $[H^+]$ means the acid concentration.

Kinetics of Acid Decomposition of TPB. An aqueous solution of TPB (6.82×10^{-2} mol dm^{-3}, 8.5 cm^3), aqueous sulfuric acid (0.123 mol dm^{-3}, 10.0 cm^3) and methanol (31.5 cm^3) were combined in a stoppered flask, and the resulting solution was kept at 25 °C in a thermostat. An aliquot (0.50 cm^3) was taken out of the solution at 10 min intervals and neutralized with aqueous sodium hydroxide (0.0815 mol dm^{-3}, 0.35 cm^3). A sample of 40 mm^3 from the aliquot was analyzed by HPLC at 266 nm. Since the chromatographic peak of TPB and those of the degraded borates were not well resolved, the rate constant of the acid decomposition of TPB was derived from the initial rate measured in the linear region (the 50-min period since the beginning) of the pseudo-first-order plotting to be 4.00×10^{-4} sec^{-1} with γ of 0.998.

Air-oxidation of TPB. A two-phase mixture of an aqueous solution of TPB (5.62×10^{-4} mol dm^{-3}, buffered at pH 6.0, 25 cm^3) and dichloromethane (25 cm^3) was aerated. Every hour, 40 mm^3 samples were taken out of the organic and aqueous phases and analyzed by HPLC. TPB and degraded borates were found in the aqueous phase to give an overlapped HPLC peak. The decay curve, consequently, depicted the descending overall area of the overlapped peaks. The resulting phenol and biphenyl were found in the organic phase. Both were assigned by the comparison of their retention time in HPLC and GLC with those of the authentic specimen.

Air-oxidation of the Trifluoromethylated Derivatives. A two-phase mixture of an aqueous solution (20 cm^3, buffured at pH 6.0) of the *m*-trifluoromethyl compound (**2**) (6.05×10^{-4} mol dm^{-3}) and a dichloromethane solution (20 cm^3) of 4,4′-difluorobiphenyl (2.43×10^{-4} mol dm^{-3} as an internal standard) was aerated. At specified intervals a sample (40 mm^3) from the aqueous phase and one (10 mm^3) from the organic phase were analyzed by HPLC. The HPLC peak of the parent borate (t_R=1.3 min) in the aqueous phase was closely overlapped with those of degraded borates, which were also completely decomposed within 6 h under the experimental conditions, thereafter no HPLC peaks were observed by a photometric detector at 270 nm. The relative increase of the decomposition products (t_R=2.5 and 5.3 min) in the organic phase were also followed against the internal standard (t_R=8.5 min).

Structures of the decomposition products were assigned with those obtained in a separate air-oxidation experiment by use of 0.80 mmol of the borate. The fraction of t_R=2.5 min was assigned tentatively to be *m*-trifluoromethylphenol by GC-MS (m/z=162 (M^+)) and ^{19}F-NMR measurement (a singlet at δ=98.89 ppm downfield from C_6F_6) and ^{1}H-NMR spectral comparison with that in the literature.[18] The fraction of t_R=5.3 min was an unsymmetric bis(trifluoromethyl)biphenyl by GC-MS (m/z=290 (M^+)) and ^{19}F-NMR data (two equal signals of δ=99.55 and 99.42 ppm downfield from C_6F_6).

Air-oxidation of TFPB (**4**) and the *p*-trifluoromethyl com-

pound (**3**) were carried out in a similar manner by use of an aqueous buffer (25 cm^3, pH 6) and a dichloromethane solution (25 cm^3) of the borate and 4,4'-difluorobiphenyl as an internal standard. The remaining parent borate and decomposition products from the *p*-trifluoromethyl compound were found in the organic phase and were determined in a similar manner against the internal standard.

Partition of Alkali TFPB in Organic Solvent-water Two-phase Systems. Typical Procedure. Dichloromethane-water System: A mixture of sodium TFPB (*ca.* 2×10^{-5} mol), alkali acetate (0.1 mol dm^{-3})-acetic acid buffer (pH 6.0, 250 cm^3) and dichloromethane (10.0 cm^3) was shaken until equilibrated (2 h) at 30 °C in a thermostat. Added amounts of lithium, sodium, potassium, rubidium, and cesium acetates were each large enough so that sodium ions from sodium TFPB were negligible.

The resulting mixture settled and separated into two layers. TFPB in the organic layer was determined by HPLC at 270 nm with 40 mm^3 of sample in reference to an internal standard (toluene). The eluant was methanol containing 10 v% of water. TFPB in the aqueous layer was extracted from a 200-cm^3 portion with 10 cm^3 of dichloromethane so that the solute was concentrated 20-fold over the fraction in the aqueous layer, to be determined by HPLC in a similar manner.

Toluene-water System: A mixture of the aqueous buffer (pH 6.0, 800 cm^3) containing the acetate of alkali ion to be examined, toluene (25.0 cm^3), and sodium TFPB (*ca.* 5×10^{-6} mol) was equilibrated at 30 °C by 16-h shaking.

TFPB in the toluene phase was determined by HPLC in reference to the internal standard (*o*-cresol). TFPB in the aqueous phase was preconcentrated by extraction and determined by a standard-addition method: The first aliquot (250 cm^3) from the aqueous layer was extracted with dichloromethane (7.0 cm^3) by 30-min shaking, the 2nd 250 cm^3 was done with the same solvent (7.0 cm^3) containing 1.21×10^{-7} mol of sodium TFPB, and the 3rd one was done in a similar manner by use of 2.42×10^{-7} mol of sodium TFPB. Each extract was analyzed for TFPB by HPLC with 40 mm^3 of sample. Extrapolation of the linear plotting of TFPB peak area against the standard increment of TFPB afforded the analysis of TFPB in the first aliquot.

This study was supported by the Grant-in-Aid for Scientific Research from the Ministry of Education, Science, and Culture (Project No. 56470056), and in part from the Asahi Glass Foundation for Industrial Technology, to whom the authors are grateful. Thanks are also due to Mr. Kazutaka Onitsuka for his experimental assistance in this work.

An X-Ray Diffraction Study on the Structures of Mono(glycinato)copper(II) and Tris(glycinato)-cuprate(II) Complexes in Aqueous Solution

Kazuhiko OZUTSUMI and Hitoshi OHTAKI*

Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, 4259 Nagatsuta-cho, Midori-ku, Yokohama 227

(Received March 21, 1984)

The structures of mono(glycinato)copper(II) and tris(glycinato)cuprate(II) complexes in solution were determined by means of X-ray diffraction at 20 °C. The radial distribution curve obtained for solution A, in which comparable amounts of hexaaqua- and mono(glycinato)copper(II) complexes coexisted (the mole ratio $C_{gly}/C_{Cu}=0.700$, where C_i represents the total concentration of species i), showed that the mono(glycinato)copper(II) complex combined with four water molecules, two of which were at the distance of (1.98±0.01) Å at the equatorial position and the other two were of (2.27±0.01) Å at the axial one. The equatorial Cu–OH_2 bond length within the mono(glycinato)copper(II) was longer than that within the hexaaquacopper(II) ion (1.94 Å), whereas the axial Cu–OH_2 bond distance within the former complex was shorter than that within the latter (2.43 Å). Both lengths of the Cu–O and Cu–N bonds within the mono(glycinato)copper(II) ion were (1.99±0.02) Å. Thus the $[Cu(gly)(OH_2)_4]^+$ complex has an axially elongated octahedral structure. The X-ray scattering data of solution B with the C_{gly}/C_{Cu} mole ratio of 13.7, in which almost all Cu(II) ions formed the tris(glycinato)cuprate(II) complex were well explained in terms of a regular octahedral structure of the complex having the same Cu–O and Cu–N bond distances of (2.02±0.01) Å. The structure of the bis(glycinato)copper(II) complex was not determinable owing to its low solubility.

Many kinds of polyhedra appear in stereochemistry of copper(II) complexes, in which the coordination number of copper(II) ion is three, four, five or six. Of these a hexacoordinated copper(II) complex tends to have a distorted octahedral structure. A tetragonal distortion is frequently observed with the elongation of two bonds along the axis of the octahedron. Gažo *et al.*[1] collected crystal data for CuO_6, CuN_6, and CuN_4O_2 type complexes and discussed the correlation between equatorial and axial bond distances. The observation was that the equatorial and axial bond lengths correlated asymptotically with an increase of the interatomic distances within the equatorial plane, resulting in shortening the bond lengths along the axial direction.

Structures of copper(II) complexes have been extensively studied crystallographically. However, an axial bond distance in crystal may be significantly affected by an interaction between a ligand at the apex of a complex and counter ions around the complex ion, since an axial bond is essentially weak relative to an equatorial one. Thus, it seems to be desirable to investigate structures of copper(II) complexes without an effect of counter ions on copper(II)-ligand bonds along the axis.

Hexaaqua-,[2,3] some ammine-[4] and bis- and tris-(ethylenediamine)copper(II)[5] complexes in aqueous solution have been investigated so far by the X-ray diffraction method. All of the hexacoordinated complexes have an axially elongated octahedral structure. The equatorial bond distances are between 1.93 Å and 2.05 Å, whereas the axial bond lengths vary widely (2.3—2.9 Å). Recently the structures of tetraammine- and bis(ethylenediamine)copper(II) complexes in aqueous solution have been reported with a laboratory EXAFS apparatus.[6] Only four equatorial Cu–N bonds (≈2.03 Å) were detectable and the axial bond length was not determinable by the EXAFS measurement. The structure of a copper(II) chloride aqueous solution was studied by means of X-ray diffraction,[7] and it was reported that the equatorial sites of copper(II) ion were occupied by water molecules and chloride ions at 1.95 Å and 2.25 Å, respectively. However, the axial Cu–OH_2 and/or Cu–Cl bonds, which would appear at 2.2—2.3 Å for the former and at 2.8—3.0 Å for the latter, were not clearly observable because of overlapping of the peak owing to the axial bonds with that of the Cu–Cl (eq) bond within the complex and with the peak of the Cl–H_2O bond (≈3.1 Å) within the hydrated chloride ion. Distorted octahedral structures of copper(II)–chloro complexes were also found in methanol.[8]

Although there have been presented some structural data of copper(II) complexes in solution by the X-ray diffraction and EXAFS methods, no investigation has been carried out for structures of chelate complexes, except for ethylenediamine complexes, in solution. Therefore, in the present study we have attempted to determine the structures of glycinato copper(II) complexes in aqueous solution by the X-ray diffraction method.

In spite of a great importance of structural information of glycinato copper(II) complexes in the view point of coordination chemistry and biochemistry, the structure of only the bis(glycinato)copper(II) complex has been determined in crystal,[9] and structural data have been given for other complexes in neither solution nor the solid state. Therefore, we investigated the structures of the mono(glycinato)copper(II) and tris (glycinato)couprate(II) complexes in aqueous solution. The structure of the bis(glycinato)copper(II) complex in solution was not determinable by the present X-ray diffraction method due to its low solubility in water.

Experimental

Preparation and Analysis of Sample Solutions. All chemicals used were of reagent grade. Sample solutions were prepared by the similar way to that described in a previous

Table 1. The composition (mol dm^{-3}) and stoichiometric volume V per copper atom in solution A and per sodium atom in solutions B and C

paper.[10] *Solution A*, in which the mono(glycinato)copper(II) complex was mainly formed, was prepared by dissolving powder of the bis(glycinato)copper(II) complex to a copper(II) nitrate solution. *Solution B* was prepared by mixing the bis(glycinato)copper(II) and sodium glycinate in water. Almost all copper(II) ions formed the tris(glycinato)cuprate(II) complex in this solution. *Solution C* was an aqueous sodium glycinate solution.

Bis(glycinato)copper(II) was prepared by mixing an aqueous copper(II) sulfate solution with a glycine solution which had been neutralized with $NaHCO_3$ and then recrystallized from water. Sodium glycinate was obtained by the same manner previously reported.[10] Copper(II) nitrate and copper(II) sulfate of reagent grade were recrystallized from water.

The total concentration of copper(II) ions (C_{Cu}) in the test solutions was electrogravimetrically determined as metallic copper. The total glycine concentration (C_{gly}) in the solutions was determined by the Kjeldahl method. Concentrations of nitrate ions in solution A and of sodium ions in solutions B and C were evaluated from the material balance of ions in the solutions. Densities of the sample solutions were measured by using a pycnometer. The composition of the solutions is given in Table 1.

Method of Measurement and Treatment of X-Ray Scattering Data. The apparatus used and method of measurements were described previously.[2,10,11] Mo $K\alpha$ radiation (λ= 0.7107 Å) was used and the scattered intensities were measured at discrete points of θ over the range 1°—70° (2θ is the scattering angle). Times required to accumulate 120000 counts were recorded at each point. The scattered intensities were scaled to the absolute ones after corrections for absorption, polarization and multiple scatterings of X-rays by a usual manner.[11]

The reduced intensities $i(s)$ were extracted from the scaled intensities $I(s)$ by subtracting independent coherent scatterings according to Eq. 1:

$$i(s) = I(s) - \sum_i n_i[\{f_i(s)+\Delta f_i'\}^2 + (\Delta f_i'')^2]. \quad (1)$$

The reduced intensities multiplied by s ($=4\pi\lambda^{-1}\sin\theta$) of the sample solutions are shown in Fig. 1. The radial distribution function $D(r)$ was calculated by the Fourier transform of the reduced intensities as follows:

$$D(r) = 4\pi r^2\rho_o + \frac{2r}{\pi}\int_0^{s_{max}} s\cdot i(s)\cdot M(s)\cdot\sin(rs)ds, \quad (2)$$

where ρ_o ($=\{\sum_i n_i\cdot f_i(0)\}^2/V$) is the average scattering density in the stoichiometric volume V of the solution, and s_{max} represents the maximum s-value attained in the measurement. The modification function $M(s)$ had the form given in Eq. 3,

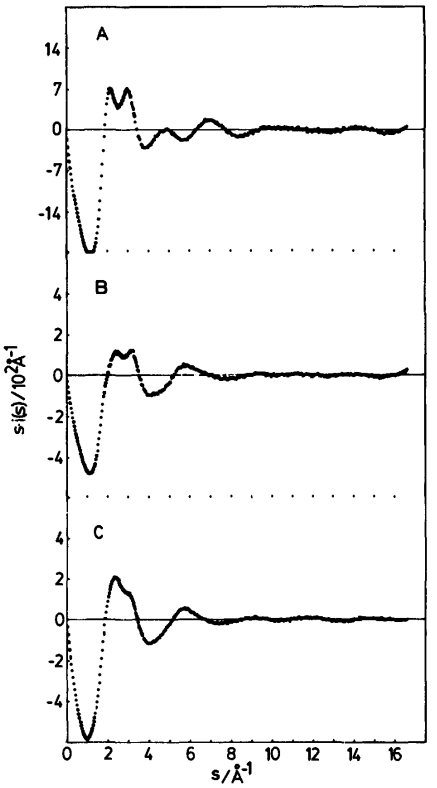

Fig. 1. The reduced intensities multiplied by s for solutions A, B, and C.

$$M(s) = \frac{[\sum_i n_i\cdot f_i(0)^2]}{[\sum_i n_i\cdot f_i(s)^2]}\cdot\exp(-k\cdot s^2). \quad (3)$$

The damping factor k was chosen as 0.01 Å^2 in the present case. In Eqs. 1—3 $f_i(0)$ and $f_i(s)$ denote the atomic scattering factors of atom i at s=0 and s, respectively. n_i is the number of atom i in the stoichiometric volume. $\Delta f_i'$ and $\Delta f_i''$ represent the real and imaginary parts of anomolous dispersion of atom i, respectively. The radial ($D(r)$) and differential radial ($D(r)-4\pi r^2\rho_o$) distribution curves of the test solutions are depicted in Figs. 2 and 3, respectively.

Calculations were performed by using by KURVLR[12] and NLPLSQ[13] programs with the computer at the Tokyo Institute of Technology and partly with the computer at the Institute for Molecular Science in Okazaki.

Results and Discussion

According to the formation constants of copper(II)-glycine complexes,[14] comparable amounts of the hexaaquacopper(II) and mono(glycinato)copper(II) complexes existed in solution A. The tris(glycinato)cuprate(II) complex is predominantly formed in solution B as a large excess of glycinate ions are contained. The coexistence of the bis(glycinato)copper(II) complex in both solutions needs not to be taken into consideration in the course of the analysis of the data, since the solubility of the bis(glycinato)copper(II) is low (about 0.025 mol dm^{-3}).

Structure of Mono(glycinato)copper(II) Complex. Figure 4 represents the radial distribution and differential radial distribution functions of solution A,

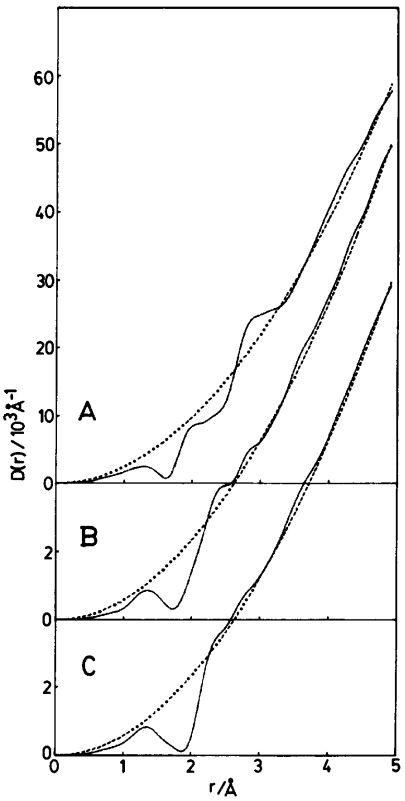

Fig. 2. The radial distribution curves, $D(r)$, for solutions A, B, and C. The curves of $4\pi r^2\rho_o$ are shown by dashed lines.

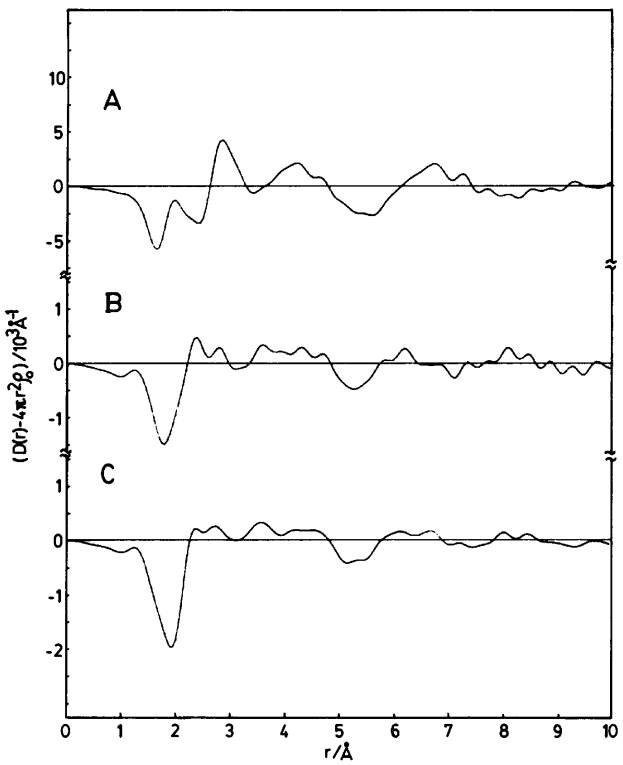

Fig. 3. The $(D(r)-4\pi r^2\rho_o)$ curves for solutions A, B, and C.

as well as the calculated peak shapes of each atom pair in the system which will be discussed in the later section. In the radial distribution curves (Figs. 4a and 4e) we see four peaks around 1.3, 2.0, 2.9, and 4.3 Å.

The small and broad peak appearing at 1.3 Å is due to the O-H bonds within water molecules, the N-O bonds within nitrate ions and N-H, C-H, C-C, C-N, and C...O bonds within glycinate ions. The second peak observed around 2.0 Å is attributable to the interactions of copper(II) ion with the ligand atoms in the first coordination shell. Nonbonding C···N, C···O, and O···O interactions within glycinate ions and O···O contacts within nitrate ions also contribute to the peak. The third peak at about 2.9 Å is ascribed to the nonbonding Cu···C interactions within the mono(glycinato)copper(II) ion, to the interactions between atoms within the ligands in the first coordination sphere of the complexes and to the O···O contacts of water mole-

(c) The theoretical peaks for Cu–OH_2(eq), Cu–OH_2(ax), and O···O pairs within the hexaaquacopper-(II) complex and O···O contacts of water molecules in the bulk. (d) The theoretical peaks calculated for Cu–OH_2(eq), Cu–O, Cu–N, Cu–OH_2(ax), Cu···C, N···O, and O···O pairs within the mono-complex. (e) The corresponding $(D(r)-4\pi r^2\rho_o)$ curve to the $D(r)$ in (a). The chain, dashed, and dotted lines indicate the residual curves after subtraction of the theoretical peaks in (b), (c), and (d), respectively.

cules in the bulk. The fourth peak is composed of peaks owing to longer intramolecular interactions as well as intermolecular interactions between ions in the solution, which will not be taken into account in the present analysis.

In the first step of the analysis of the radial distribution curve, we subtracted the calculated peak shapes owing to the intramolecular interactions of water molecules, glycinate and nitrate ions. The parameter values used were the same as those described in the previous paper.[10] The residual curve thus obtained is shown in Fig. 4 by the chain line. The broad peak at about 2.0 Å suggested that the mono(glycinato)copper(II) as well as the hexaaquacopper(II) complexes had a distorted octahedral structure.

In order to estimate the structural parameters for the mono(glycinato)copper(II) complex, the concentration ratio of the $[Cu(OH_2)_6]^{2+}$ to $[Cu(gly)]^+$ ions in the solution must be evaluated. In the second step of the analysis, we assumed the concentration ratio of the hexaaquacopper(II) to mono(glycinato)copper(II) complexes to be 40:60 according to the stability constants reported in dilute solutions,[14] and the theoretical peaks owing to the intramolecular interactions of $[Cu(OH_2)_6]^{2+}$ and the O···O contacts in the bulk water were subtracted. In the course of the calculation, the structure parameters for the $[Cu(OH_2)_6]^{2+}$ ion and the bulk water were quoted from the works by Ohtaki and Maeda[2] and by Narten,[15] respectively. The analysis of the residual curve (···) indicated that the broad peak around 2.0 Å consisted of two peaks centered at 2.0 and 2.3 Å. The peak area corresponded to four Cu-O and Cu-N bonds for the former and two Cu-O bonds for the latter,[16] and hence the mono(glycinato)copper(II) complex has a form of a distorted octahedron with one glycinate ion and four water molecules. Thus, the glycinate ion and two of the water molecules coordinated to the Cu(II) ion at the equatorial positions and additional two water molecules bound at the axial ones. The distances of the nonbonding Cu···C pairs and the interactions between the ligand atoms in the first coordination shell were evaluated by employing the above structure model.

The least-squares calculations were carried out by using $s \cdot i(s)$ values in the high angle region ($s>5$ Å^{-1}) (Fig. 5). In order to avoid errors introduced by neglecting long-range interactions, the lower limit of the s-value was varied from 5 to 7 Å^{-1}. The intramolecular interactions of water molecules, glycinate and nitrate ions and of hexaaquacopper(II) complex and the O···O contacts in the bulk water were fixed at the literature values during the refinements. The calculations were performed by inserting bond distances roughly estimated from the analysis of the radial distribution curve as initial value. Various sets of the initial values were examined in the course of the least-squares calculations: in one case the length of the Cu-OH_2 (eq), Cu-O, and Cu-N bonds were assumed to be 2.00 Å, while the length of the Cu-OH_2 (ax) within the $[Cu(gly)(OH_2)_4]^+$ complex was 2.30 Å. Another assumption was made for the initial bond lengths inserted to be 1.94 Å for the Cu-OH_2 (eq) in the $[Cu(gly)(OH_2)_4]^+$, which was the same as that of the Cu-OH_2 (eq) within the hexa-

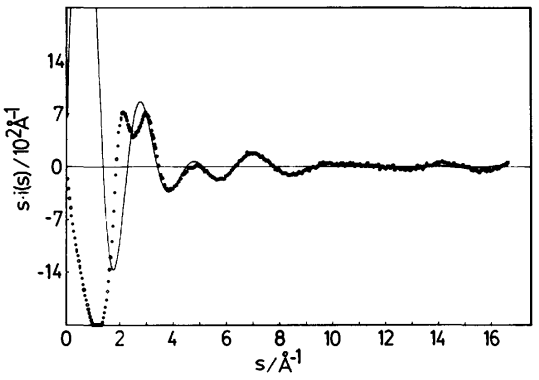

Fig. 5. The $s \cdot i(s)$ values for solution A. The observed curve is shown by circles and calculated one using parameter values listed in Table 2 by the solid line.

aquacopper(II) ion. Other bond lengths were assumed to be the same as those examined in the previous case.[10] Two additional assumptions were tested, in which the length of the Cu-OH_2 (eq) bond within $[Cu(gly)(OH_2)_4]^+$ was either 1.94 or 2.00 Å and the Cu-N and Cu-O bond distances were set to be a value between 1.95 to 2.05 Å. The different assumptions thus made, however, did not affect the result, and independent of the assumptions for the initial values inserted for the bond length within the $[Cu(gly)(OH_2)_4]^+$ complex, the values converged to those listed in Table 2.

In the course of the refinement described above, the concentration ratio of the hexaaquacopper(II) to mono(glycinato) copper(II) complexes was fixed at 40:60. At the next step of calculation, we changed the concentration ratio of the $[Cu(OH_2)_6]^{2+}$ to $[Cu(gly)(OH_2)_4]^+$ ions from 60:40 to 30:70 and performed the data refinement in the same way as described in the preceding section. The converged values coincided with those given in Table 2 within the standard deviations given in the previous calculations and were practically independent of the concentration ratio. The error square sum U,

$$U = \sum_{s_{min}}^{s_{max}} s^2(i(s)_{obsd} - i(s)_{calcd})^2 \quad (4)$$

for each set of the concentration ratios at different s-ranges examined are summarized in Table 3.

The minimum error square sum was obtained for the set in which the concentration ratio of the hexaaquacopper(II) to mono(glycinato)copper(II) complexes was 40:60, regardless of the s-ranges examined in the least-squares calculations.

From the result we concluded that the Cu-OH_2(eq), Cu-O and Cu-N bond lengths within the $[Cu(gly)(OH_2)_4]^+$ complex were approximately the same, and therefore, the complex has a distorted octahedral structure with a regular square plane. The concentration ratio of the $[Cu(OH_2)_6]^{2+}$ to $[Cu(gly)(OH_2)_4]^+$ complexes was 40:60 in the test solution.

Structure of Tris(glycinato)cuprate(II) Complex. The stability constant of the tris(glycinato)cuprate(II) complex has been reported to be small (log (K_3/mol^{-1} dm^3)$\simeq$0—1) and thus the solution in which the tris(glycinato)cuprate(II) complex is predominantly formed must contain a large excess of glycinate tions. In

solution B in which the C_{Gly}/C_{Cu} mole ratio was 13.7, almost all of the Cu(II) ions were expected to be present as the $[Cu(gly)_3]^-$ complex. However, the concentration of Cu(II) ions was much lower than that of sodium and glycinate ions in the solution (see Table 1).

Since the large contribution of the hydrated sodium and free glycinate ions to the measured intensities hid the structural information of the tris(glycinato)-cuprate(II) complex in this solution, it was difficult to obtain the structural parameters for the tris(glycinato)-cuprate(II) complex with a reasonable accuracy with a direct analysis of the reduced intensities for solution B. Therefore, we tried to determine the structure of the tris(glycinato)cuprate(II) complex by subtracting the contribution of sodium and free glycinate ions from the X-ray scattering data for solution B by taking into account the scattered intensities of solution C (an aqueous sodium glycinate solution).

The radial distribution and differential radial distribution curves of solutions B and C depicted in Figs. 2 and 3 showed simlar patterns over the whole r range. A slight different shape, however, was observed around 2 Å, which was attributable to the interaction of copper(II) ion with donor atoms in its first coordination sphere. A direct comparison of the data for solutions B and C could be made because the ρ_o value (the average scattering density in a stoichiometric volume of a solution) of solution B was approximately the same as that of solution C (see Table 1).

The radial distribution functions of solutions B and C could be compared provided that the Fourier transform (Eq. 2) of their intensities would be carried out by using the same modification function. Since the modification functions were different for these solutions because of different atomic compositions of the solutions, the direct comparison of the radial distribution curves of solutions B and C offered only qualitative information about the structural difference of these solutions. Therefore, the structural data for the tris-(glycinato)cuprate(II) complex in solution B was extracted by subtracting the reduced intensities of solution C from those of solution B. The difference of the reduced intensities of the two solutions, $i(s)_{diff}$, which includes any structural difference between the two solutions, is shown in Fig. 6. Since the stoichiometric volume of the solutions was normalized to that containing one sodium atom, the contribution of hydrated sodium ions to the reduced intensities of the solutions was entirely eliminated from the $i(s)_{diff}$ curve. The difference in the concentrations of glycinate ions in the two solutions could remain to some extent in the $i(s)_{diff}$ curve, but the number of glycinate ions in the stoichiometric volumes of solutions B and C was 1.17 and 1.0, respectively, and thus the difference was very small.

The $i(s)_{diff}$ curve, therefore, contained only intensities owing to interactions between copper(II) ions and ligand atoms within the coordination sphere and the nonbonding Cu···C interactions. Intensity difference due to different numbers of water molecules in the stoichiometric volumes of solutions B and C (which were 4.72 and 6.15, respectively) might appear as a part of the $i(s)_{diff}$ curve.

The Fourier transform of the $i(s)_{diff}$ data gave only one peak centered at about 2.02 Å, which should be ascribed to the Cu-O and Cu-N interactions within the tris-(glycinato)cuprate(II) complex (see Fig. 7). A small hump appearing at the right wing of the peak was thought to be a spurious one, because the shape of the hump changed when the s_{max} value of the Fourier transform of the $i(s)_{diff}$ data was changed. Since the $i(s)_{diff}$ data had large uncertainties in the high angle region, the s_{max} value did not exceed 13 Å^{-1}.

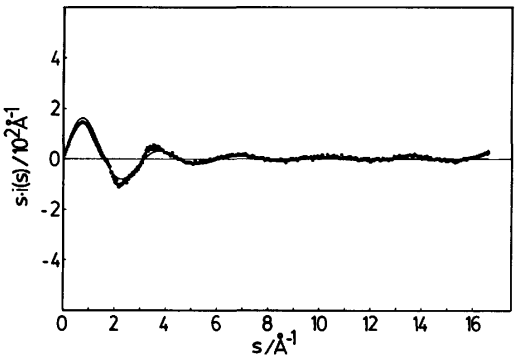

Fig. 6. The $s \cdot i(s)_{diff}$ curve (circles) obtained after subtracting reduced intensities of solution C from those of solution B. The solid line indicates the calculated values with the parameter values given in Table 4.

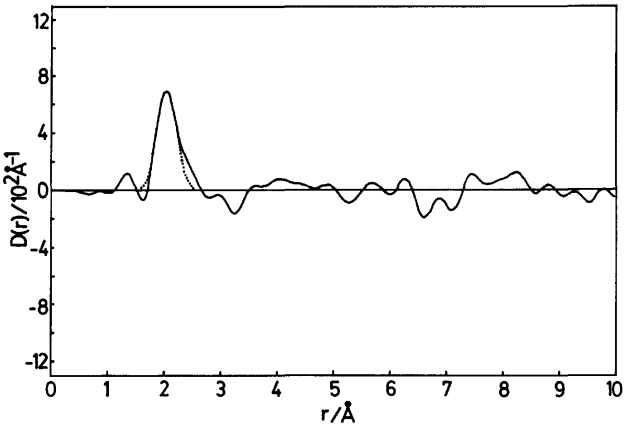

Fig. 7. The $D(r)$ curve obtained by the Fourier transform of the $s \cdot i(s)_{diff}$ values. Dotted line represents the theoretical peak shape for Cu-O and Cu-N bonds within the tris-complex.

Analysis of the peak shape (dotted line in Fig. 7) led to the Cu-O and Cu-N bond distances to be 2.02 Å and the temperature factors of the bonds to be 0.002 Å^2. The frequency factor of the sum of those of the Cu-O and Cu-N bonds was evaluated to be 6 from the area under the peak. The length of the nonbonding Cu···C interactions was estimated to be about 2.8 Å by using a suitable structure model of chelating glycinate ions within the tris(glycinato)cuprate(II) complex. However, no distinct peak corresponding to the Cu···C distance was observed in the curve in Fig. 7, probably the Cu···C peak having been cancelled by a part of the O···O peak due to the bulk water in solution C.

The structural parameters of the tris(glycinato)-cuprate(II) complex were determined by using a least-squares method for the $s \cdot i(s)_{diff}$ data over the range $s<13$ Å^{-1}. The lower limit of the s-values was changed from 0 to 2 Å^{-1}. In type-I refinement only two interactions, Cu-O and Cu-N, were taken into consideration. In type-II calculation contributions arising from intramolecular interactions within water molecules and glycinate ions were also taken into account, because the numbers of them in the stoichiometric volumes in solutions B and C were different. The frequency factors were kept constant to be 3 for both the Cu-O and Cu-N interactions in the course of the calculations. The results obtained by the two calculations were practically the same and were given in Table 4. When we inserted different lengths for the Cu-O and Cu-N bonds as initial values, they converged to indifferent values of the bond lengths through the least-squares calculations. Therefore, we concluded that the tris-(glycinato)cuprate(II) complex has a regular octahedral structure.

The lengths of Cu-OH_2(eq), Cu-O, Cu-N, and Cu-OH_2(ax) bonds within the $[Cu(OH_2)_6]^{2+}$,[2] $[Cu(gly)(OH_2)_4]^-$, and $[Cu(gly)_3]^-$ complexes in solution, together with those within the *cis*-$[Cu(gly)_2(OH_2)_2]$ in crystal, are tabulated in Table 5. In the *cis*-$[Cu(gly)_2(OH_2)_2]$ complex four sites in the square plane of the copper(II) ion were filled with two oxygen and two nitrogen atoms within the two glycinate ions coor-

dinated and one apex of the distorted octahedron of the copper(II) ions was occupied by a water molecule. The oxygen atom at the other apex of the octahedron was a carbonyl oxygen of a glycinate ion combined with an adjacent copper(II) ion in the crystal.

The tris(glycinato)cuprate(II) complex has a regular octahedral structure, although the structure of the other copper(II)-glycinato complexes distorted. Regular octahedral structures of copper(II) complexes have been found for the $[Cu(en)_3]SO_4$,[17] $K_2Pb[Cu(NO_2)_6]$[18] and $[Cu(OMPA)_3](ClO_4)_2$[19] (OMPA refers to octamethylpyrophosphoramide) complexes in crystal. The indifferent bond length within a copper(II) complex was often explained in terms of the dynamic Jahn-Teller effect. However, we found that the regular octahedral $[Cu(en)_3]^{2+}$ complex in crystal had different Cu-N(eq) and Cu-N(ax) bond lengths in solution,[5] and thus the dynamic Jahn-Teller effect was not observed in the complex in solution. Since the dynamic Jahn-Teller effect can hardly be observed in principle in the structural analysis of complexes in solution by the X-ray diffraction method, the regular octahedral structure of the $[Cu(gly)_3]^-$ complex found in the present study is not an averaged structure of a dynamically distorted octahedron, but a relatively rigid regular one. The small temperature factors of the Cu-O and Cu-N bonds within the complex support this conclusion.

The work has been financially supported, in part, by the Grant-in-Aid for Scientific Research No. 57470054 from the Ministry of Education, Science and Culture. The financial aid by the Asahi Glass Foundation for Industrial Technology is also acknowledged. A part of computer calculations carried out in the present work has been performed at the Institute for Molecular Science in Okazaki.

Structure and Properties of Thallium(I) Formate Solutions

Kazuhiko OZUTSUMI, Hitoshi OHTAKI,* and Asao KUSUMEGI†
Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227
†*National Laboratory for High Energy Physics, Oho-machi, Tsukuba-gun, Ibaraki 305*
(Received April 28, 1984)

The structure of thallium(I) formate aggregates in concentrated aqueous thallium(I) formate solutions was investigated by the X-ray diffraction method at 25 °C for solutions A (10.77 mol dm^{-3}) and B (3.493 mol dm^{-3}). The former solution had the density of 3.189 g cm^{-3} and the C_{H_2O}/C_{Tl} mole ratio of 2.59, where C_i represents the total concentration of species i, and was an almost saturated solution at room temperature. From the analysis of the X-ray diffraction data of solution A, thallium(I) formate was found to be present as a tetramer $Tl_4(O_2CH)_4$. The nearest interatomic distances between thallium(I) and atoms within the formate ions in the tetramer were determined as Tl-O: 2.79(1) Å and Tl···C: 3.33(2) Å. The nonbonding Tl···Tl distances within the aggregate were estimated to be 3.92(1) Å, 4.34(1) Å, and 4.79(1) Å. The Tl-OH_2 bond length was also determined to be 3.22(3) Å, which was much larger than the distance expected from the sum of the ionic radius of thallium(I) ion (≈1.4 Å) and size of a water molecule (≈1.4 Å). A comparison of the radial distribution function of solution A with that of solution B, which had the C_{H_2O}/C_{Tl} mole ratio of 13.5, indicated that the aggregate decomposed by dilution. Raman spectra of four different thallium(I) formate aqueous solutions of 3.493 to 10.77 mol dm^{-3} were measured and the frequencies of the C-O and C=O stretchings of formate ions in the solutions were compared with those of free formate ion. Band shifts of the two frequencies observed for concentrated thallium(I) formate solutions indicated the existence of bridge-type formate ions coordinated to thallium(I) ions, and the result agreed with that observed by the X-ray diffraction analysis. Densities, refractive indices, viscosities and conductivities were measured for thallium(I) formate aqueous solutions with varying concentrations.

It has been well known that some thallium(I) carboxylates are extremely soluble in water. Densities of concentrated solutions become 2—4 g cm^{-3} and thus the solutions can be used as heavy liquids for gravity concentrations of ores. The solutions also have large absorptivity for high energy beams and good transparency for visible light. Therefore, applications of the solutions to transparent shields for radiation instead of lead glasses have been examined.[1-3] Mixtures of thallium(I) carboxylates and organic scintillators may provide useful detectors of radiation beams. In this connection it is interesting to investigate structures and properties of thallium(I) carboxylate solutions.

Another interest of the structural study of concentrated solutions of thallium(I) carboxylates is concerned with an investigation in which structures of crystal hydrates are compared with those of hydrate melts. It has often been reported that a part of the structure of a crystal hydrate still remains in a concentrated solution of the salt. X-Ray diffraction data of hydrate melts of $CaCl_2 \cdot 6H_2O$[4] and $Ca(NO_3)_2 \cdot 3.5H_2O$[5] have been interpreted in terms of a quasi-lattice structure of the corresponding crystal hydrates. Structures of concentrated solutions of magnesium, aluminium and indium(III) with monovalent anions have been studied by means of X-ray diffraction and the liquid structure has been approximated to a quasi-close-packing lattice structure of hydrated cations.[6,7] Enderby and his coworkers' studies[8-10] on the structure of nickel(II) chloride solutions by the neutron diffraction method have suggested a quasi-lattice arrangement of hydrated nickel(II) ions in the solutions.

In the present investigation we focus our attension on the structure of thallium(I) formate aggregates formed in solution and changes in physicochemical properties of thallium(I) formate solutions with the concentration of the solute.

The crystal structure of thallium(I) formate has recently been determined by Oddon *et al.*[11] and has been found that a formate ion bridges two thallium atoms as a bidentate ligand through the two oxygen atoms and infinite -HCOO-Tl-HCOO-Tl- chains are formed in crystal. A thallium(I) ion is surrounded with four oxygen atoms within formate ions, the Tl-O distances being 2.559, 2.565, 2.736, and 3.047 Å. The coordination polyhedron of the thallium(I) ion is trigonal bipyramidal with the thallium(I) ion at one apex of the equatorial triangle plane.

The X-ray diffraction method is employed in the present work for the structural determination of thallium(I) formate complexes in solution. Raman spectroscopic measurements are also carried out as a supplement to the X-ray structural analysis. Densities, refractive indices, viscosities and conductivities of thallium(I) formate solutions with varying concentrations are measured.

Experimental

Preparation and Analysis of Sample Solutions. Two kinds of test solutions (A and B) were prepared for X-ray diffraction measurements by dissolving thallium(I) formate of reagent grade in water. Solution A was an almost saturated solution of thallium(I) formate at room temperature, while solution B was about three times more dilute than solution A. Concentrations of thallium(I) ions in the solutions were determined by gravimetry as TlI. Concentrations of formate ions were estimated from the stoichiometry of thallium(I) formate. The composition of the sample solutions is listed in Table 1. Solutions used for measurements of Raman spectra, densities, refractive indices, viscosities and conductivities were prepared by diluting a stock solution of thallium(I) formate with water.

X-Ray Scattering Measurements. X-Ray scattering data were obtained at 25 °C with a JEOL $\theta-\theta$ type diffractometer equipped with a Philips Mo X-ray tube (λ=0.7107 Å).

Table 1. The composition (mol dm^{-3}) and stoichiometric volume V per thallium atom in the solutions

	A	B
Tl	10.77	3.493
O	49.47	54.11
C	10.77	3.493
H	66.63	97.73
V/Å^3	154.2	475.4
C_{H_2O}/C_{Tl}	2.59	13.5
density/g cm^{-3}	3.189	1.720

The method of measurements and data treatments were described elsewhere.[12,13] The measured scattering angle (2θ) ranged from 2° to 140°. Times requiring to accumulate 80000 counts were recorded at each angle of 2θ. All calculations were carried out by using programs KURVLR[14] and NLPLSQ.[15]

Raman Spectroscopic Measurements. Raman spectroscopic measurements were performed by using a JEOL JPG-400D spectrometer with the use of the 5145 Å excited line of Ar^+ laser.

Measurements of Physicochemical Properties. Densities of thallium(I) formate solutions were measured pycnometrically. Two pycnometers were used for the measurements and the results agreed each other within 0.05%. Measurements of viscosities of solutions were carried out by using an Ubbelohde-type viscometer and water was employed as the standard. The efflux time was measured with a stop watch. Conductivities of solutions were measured by a direct current method. A conductivity cell and electrical circuits used for the measurements were essentially the same as those designed in the literature.[16] A current-supplying electrode was a platinum electrode and a TOA-type HC-205 calomel electrode was employed to measure voltage drops. The reproducibility of the conductivity measurements was within 0.3%. The temperature was kept at (25.00±0.03) °C in all the physicochemical measurements. An Atago NAR-3 Abbe-type refractometer was employed to refractive index measurements of solutions with the use of the NaD line (5893 Å). The temperature for the refractive index measurements was regulated at (25.0±0.1) °C by circulating thermostated water through the refractometer.

Results and Discussion

The observed $s \cdot i(s)$ and $(D(r)-4\pi r^2(\rho_o)$ curves, where ρ_o denotes the average scattering density in the stoichiometric volume V per thallium atom, of the test solutions are shown in Figs. 1 and 2, respectively.

The structure of formate ion in crystal has been determined for various formates with monovalent cations. The intramolecular bond distances of a formate ion in the thallium(I) salt[11] do not appreciably differ from those in lithium,[17] sodium,[18] potassium[19] and ammonium formates.[20] Therefore, in the course of the analysis of the radial distribution functions of solutions A and B, the intramolecular bond lengths of formate ion were assumed to be the same as those in the

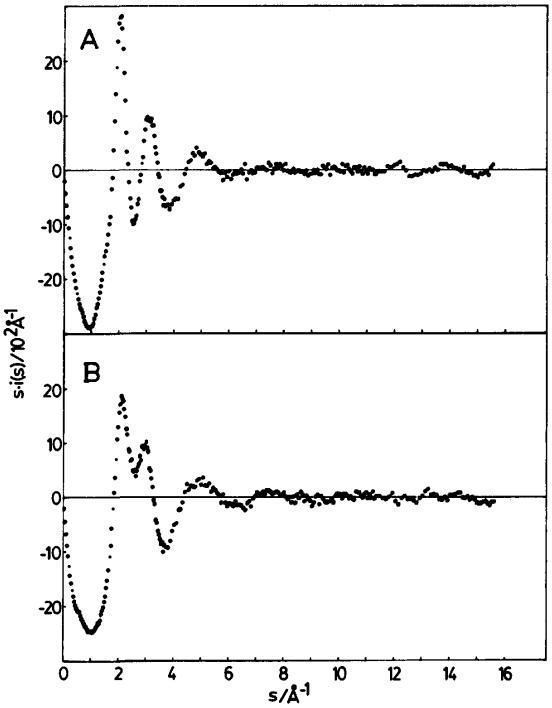

Fig. 1. The reduced intensities multiplied by s for solutions A and B.

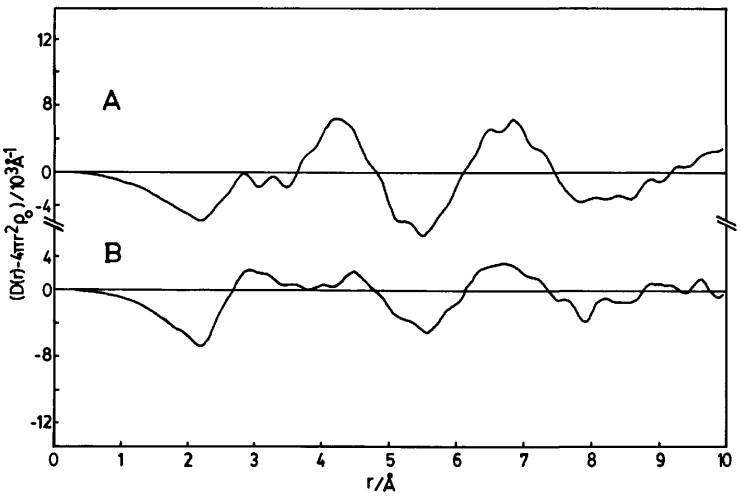

Fig. 2. The $(D(r)-4\pi r^2\rho_o)$ curves for solutions A and B.

thallium(I) formate crystal.[11] The temperature factors of atom-pairs within formate ion were taken from the electron diffraction data of the formic acid monomer in the gas phase.[21]

Structure of Thallium(I) Formate Aggregates in Solution A. The $s \cdot i(s)$ curve of solution A showed a sharper peak at 2.1 $Å^{-1}$ and a deeper minimum at 2.5 $Å^{-1}$ than the curve of solution B (see Fig. 1), and the radial distribution curve of solution A (Fig. 2) had a large and broad peak around 4.3 Å, which was not observed in the radial distribution curve of solution B.

The broad peak around 1.2 Å was composed of peaks owing to the O–H bonds within water molecules and the C–H and C⋯O bonds within formate ions. The second peak appearing at about 2.8 Å could be ascribed to the Tl–O bonds as was expected from the sum of their ionic radii. The hydrogen bonded O⋯O interactions within bulk water might contribute to the peak, but the contribution should be so small in such a concentrated thallium(I) formate solution that the O⋯O peak might be neglected in the course of the analysis of the radial distribution curve. The area of the peak gave the frequency factor of 3 for the Tl–O bond. If a thallium atom was combined with three formate ions, the nonbonding Tl⋯C distance should appear at about 3.2 Å. Therefore, the third peak observed at about 3.2 Å in Fig. 2 was attributed to be mainly due to the Tl⋯C distance within the thallium(I) formate aggregate.

The fourth peak around 4.3 Å was considered to be constructed by, at least, three peaks, because the broad peak had shoulders at both sides of the maximum. The large area of the peak could not well be explained in terms of the nonbonding Tl⋯O interactions and was only explainable by the existence of Tl⋯Tl interactions in the aggregate. By the trial-and-error method the peak could be divided into three peaks centered at 3.9, 4.4, and 4.8 Å, and the frequency factors of each peak corresponded to 0.5 (Tl⋯Tl) pairs, which indicated that each thallium(I) ion in the aggregate interacted with three thallium(I) ions with different distances (Fig. 3).

On the basis of the analysis of the radial distribution curve of solution A, calculated intensities and radial distribution curves drawn from model structures of various thallium(I) formate aggregates were compared with the experimental values. A dimer or a trimer structure was not acceptable because of their too small frequency factors for Tl⋯C and Tl⋯Tl interactions, and the area of the peak around 4.3 Å calculated by assuming a pentamer or a hexamer was too large compared with the peak area obtained by the experiment. The tetramer model depicted in Fig. 4 gave calculated intensities which satisfactorily agreed with observed ones over the s-range of 2—16 $Å^{-1}$ (see Fig. 5). The radial distribution curve drawn on the basis of the structural model thus proposed well explained the large peak found at 3.5—5 Å with two shoulders at the both side of the peak as seen in Fig. 3.

The least-squares method was applied to the $s \cdot i(s)$ curve for the refinement of the structural parameters of the tetramer by taking into account the formation of $Tl–OH_2$ bonds at each thallium(I) ion. The refinement was carried out over the range $s \geq 2.5$ $Å^{-1}$. All the

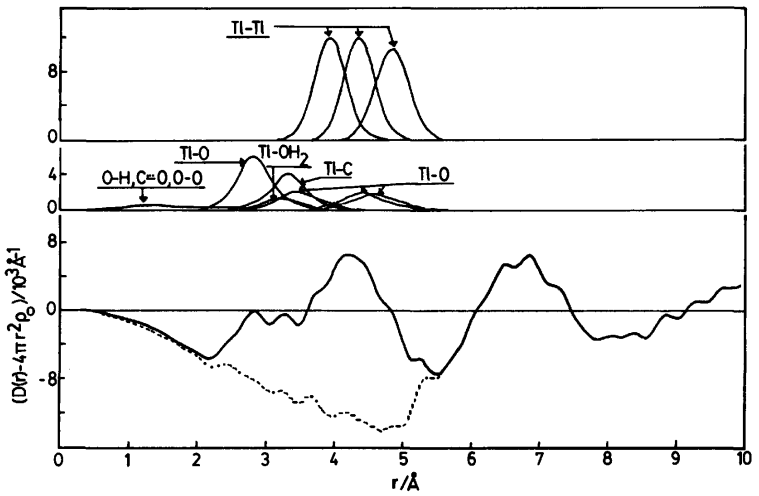

Fig. 3. The $(D(r)-4\pi r^2\rho_0)$ curve for solution A. The dashed line represents the residual curve after subtraction of the theoretical peaks calculated for the O–H bond within water molecule, C–H, C⋯O, and O⋯O pairs within formate ion and Tl–O, $Tl–OH_2$, Tl⋯C, Tl⋯O, and Tl⋯Tl interactions within $Tl_4(O_2CH)_4$.

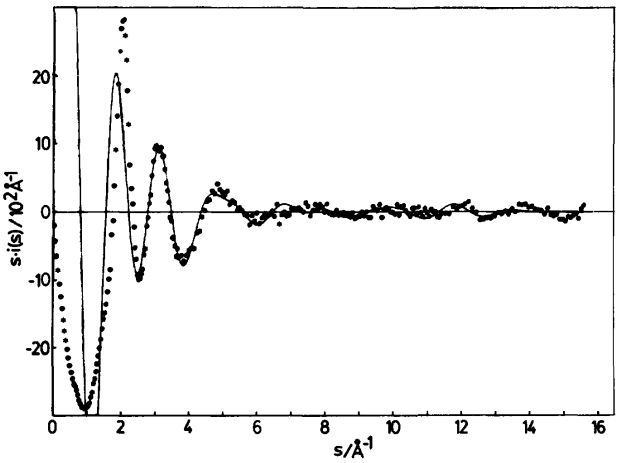

Fig. 5. The $s \cdot i(s)$ values for solution A. The observed curve is shown by circles and calculated one by the solid line.

interatomic distances and temperature factors were floated as independent variables. Frequency factors of atom-pairs within the model were fixed at values estimated from the model, except for the frequency factor for the Tl-OH_2 bonds. The agreement between calculated and experimental $s \cdot i(s)$ values was sufficient in the range $s \geq 2.5$ Å^{-1} (Fig. 5). The frequency factor for the Tl-OH_2 bond was estimated to be 0.7, which suggested that one water molecule combined with each thallium(I) ion in the tetramer, and therefore, the thallium(I) ion has the coordination number of 4. However, the Tl-OH_2 bond distance was much larger than the distance expected from the sum of the ionic radius of thallium(I) ion (≈1.4 Å) and the size of a water molecule (≈1.4 Å), the result suggesting a weak interaction between a thallium(I) ion and a water molecule.

In crystal of thallium(I) formate, the coordination number of the thallium(I) ion is four, and the thallium(I) ion is located at a corner of a triangle plane which is constructed with two oxygen and one thallium atoms, and other two oxygen atoms are situated above and below the plane. The model derived from the structure in the crystal did not give $s \cdot i(s)$ values which sufficiently fitted the experimental values.

The structural parameters finally obtained for the tetramer are listed in Table 2.

Structure of Solution B. The radial distribution curve of solution B did not give the large peak which had been observed in solution A, and therefore, the result showed that the thallium(I) formate tetramer did not exist as the predominant species in solution B and the aggregate decomposed by dilution. An asymmetrical peak at about 2.8 Å suggested the formation of bonds between thallium(I) and oxygen atoms in the solution, but the radial distribution curve was not explainable by assuming the formation of a simple 1:1 complex between thallium(I) and formate ions. In solution B there might be some complexes coexisting, but the radial distribution curve could not be analyzed without knowledge of formation constants for thallium(I) formate complexes, which had not been found in the literature. The conclusion which we can derive from the radial distribution curve is that the thallium(I) formate tetramer is not a predominant form in a relatively dilute solution, but can be the main species in a solution of extremely high concentration.

Raman Spectra. In Table 3 are summarized frequencies for vibrations found in Raman spectra of aqueous thallium(I) formate solutions of 3.493, 5.924, 8.528, and 10.77 mol dm^{-3}, as well as those observed in Raman and infrared spectra of thallium(I) formate crystal[11,22] and an aqueous potassium formate solution.[23]

Coordination types of carboxylato groups within complexes have been discussed on the basis of the change in the frequencies of the C-O ($\tilde{\nu}_2$) and C=O ($\tilde{\nu}_4$) stretching vibrations in the complexes by comparing with those in free carboxylate ions.[24] When a carboxylate ion coordinates to a metal ion as a unidentate ligand, $\tilde{\nu}$(C-O) and $\tilde{\nu}$(C=O) shift to lower and higher frequencies, respectively, than those in free ion. Thus the separation ($\Delta\tilde{\nu}$) between the two frequencies in the unidentate complexes becomes about 300—350 cm^{-1}, which is much larger than that in free ion (230—250 cm^{-1}). In the case of the formation of chelate complexes in which carboxylate ions coordinate to metal ions as a bidentate ligand, the $\tilde{\nu}$(C-O) band shifts toward the higher frequency side, while the $\tilde{\nu}$(C=O) band shifts toward the lower side, and

	Thallium(I) Formate						Potassium Formate Solution[e]
	Solution/mol dm^{-3}				Crystal		
	3.493	5.924	8.528	10.77	(I)[c]	(II)[d]	
$\tilde{\nu}_1$	2828	2821	2815	2810	2786	2775	2803
$\tilde{\nu}_2$	1356	1350	1350	1347	1351, 1333	1342	1351
$\tilde{\nu}_3$	768	769	772	765	758	759	760
$\tilde{\nu}_4$	1573	1567	1564	1562	1590	1572, 1606	1585
$\tilde{\nu}_5$	1388	1379	1382	1379	1387, 1406	1357	1383
$\tilde{\nu}_6$	1070	1067	1064	1064	—	—	1069
$\Delta\tilde{\nu}$[b]	217	217	214	215		(248)	234

a) $\tilde{\nu}_1$: C-H stretching, $\tilde{\nu}_2$: Symmetric OCO stretching, $\tilde{\nu}_3$: Symmetric OCO deformation, $\tilde{\nu}_4$: Asymmetric OCO stretching, $\tilde{\nu}_5$: Asymmetric OCO deformation, $\tilde{\nu}_6$: Out-of-Plane deformation. b) $\Delta\tilde{\nu}$ represents the separation between $\tilde{\nu}_2$ and $\tilde{\nu}_4$. c) Ref. 24. d) Ref. 11. e) Ref. 25.

therefore, the $\Delta\tilde{\nu}$ value becomes smaller by 70—100 cm^{-1} than that of free carboxylate ions. In the bridge-type coordination, on the other hand, the values of the $\tilde{\nu}$(C-O) and $\tilde{\nu}$(C=O) frequencies do not appreciably differ from those in free carboxylate ions and thus the $\Delta\tilde{\nu}$ value remains in the region 200—250 cm^{-1}.

As seen from Table 3, the frequencies of the C-O and C=O stretchings for the thallium(I) formate complex in the solutions are about 1350 and 1570 cm^{-1}, respectively, and the $\Delta\tilde{\nu}$ value is 214—217 cm^{-1}. Therefore, we concluded that the formate ions within the complex existing in the solutions coordinate to thallium(I) ion with the bridge-type. The conclusion derived from the Raman spectra supports the result obtained in the X-ray diffraction measurement.

Physicochemical Properties of Thallium(I) Formate Solutions. Densities ρ and refractive indices n_D measured in thallium(I) formate solutions with varying concentrations are plotted against the concentration (Fig. 6). The plots gave almost straight lines over a wide range of concentration, and no clear indication was obtained for the complex formation between thallium(I) and formate ions beginning at a specific concentration of the solute.

In Fig. 7 are shown absolute viscosities η, specific viscosities η_{SP}, and kinematic viscosities ν of thallium(I) formate solutions as a function of the concentration of the solute. The absolute and specific viscosities monotonously increased with the concentration of thallium(I) formate. However, the kinematic viscosity of the solution first decreased and then increased with the concentration. The kinematic viscosity of thallium(I) formate solution was lower than that of water even in 9 mol dm^{-3} thallium(I) formate solution.

The specific conductivity κ of thallium(I) formate solutions had a broad maximum around 7 mol dm^{-3}, although the molar conductivity Λ of the solutions monotonouly decreased with the concentration (Fig. 8). The Walden products $\Lambda\eta$ of thallium(I) formate solutions are plotted against the concentration in Fig. 9. Walden products of lithium nitrate[25] and chlorate[26] solutions, in which the cation is highly hydrated and thus no contact ion-pair formation is expected, decreased and then increased after passing through a minimum at about 8 mol dm^{-3}. Silver nitrate, which was known to form the contact ion-pair in concentrated solutions,[27] had the Walden product which had a minimum at about 4 mol dm^{-3}.[28] The values of the

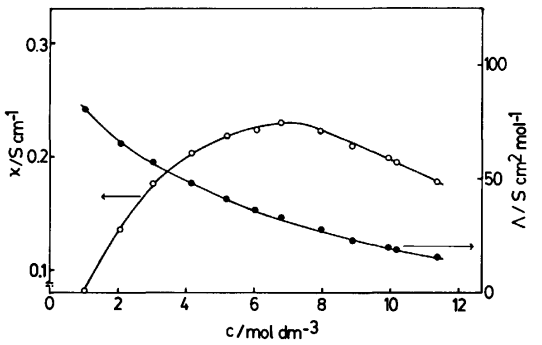

Fig. 8. Concentration dependence of conductivities.

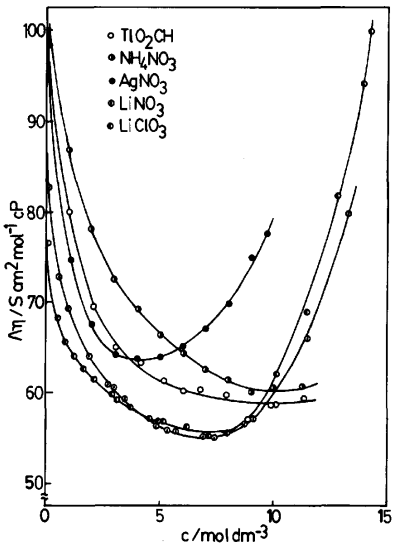

Fig. 9. Walden products of thalluim(I) formate, ammonium nitrate, silver nitrate, lithium nitrate, and lithium chlorate solutions.

Walden products of ammonium nitrate[28] and thallium(I) formate simply decreased with the concentration. It is still not clear what the minimum of the Walden product indicates, and no reliable theory has been proposed for explaining physicochemical properties in concentrated aqueous solutions. Therefore, it is not conclusive from the measurements of the physicochemical properties at which concentration thallium(I) formate begins to form the aggregates. Probably the aggregates gradually form with the increase in the concentration of the solute, and they may exist to some extent, besides mononucleic thallium(I) formate complex, even in a solution of relatively low concentration of the solute.

Extraction of Uranium(VI) by Emulsion Liquid Membrane Containing 5,8-Diethyl-7-hydroxy-6-dodecanone Oxime

Kenichi AKIBA,* Toshihiko TAKAHASHI, and Takuji KANNO
Research Institute of Mineral Dressing and Metallurgy, Tohoku University, Katahira-2, Sendai 980
(Received March 23, 1984)

Extraction of uranium(VI) by a liquid surfactant membrane has been studied. The stability of water-in-oil (w/o) emulsion dispersed in the continuous aqueous phase increased with an increase in surfactant concentrations and in the fraction of the organic phase in emulsion globules. Uranium(VI) in dilute acid solutions was extracted into (w/o) emulsions containing 5,8-diethyl-7-hydroxy-6-dodecanone oxime (LIX 63) as a mobile carrier and its concentration decreased according to $[U]_t=[U]_0 \exp(-k_{obsd}t)$. The apparent rate constants (k_{obsd}) increased with an increase in carrier concentrations and in external pH values, while they were slightly dependent on the stripping acid concentrations. Uranium was transported and concentrated into the internal aqueous droplets. The final concentration of uranium in the external aqueous phase dropped to about 10^{-3} of its initial value.

Separation of metal ions by liquid-liquid extraction can be achieved through the processes of extraction into the organic phase and stripping into the aqueous phase. Liquid membranes combining simultaneously both the extraction and the stripping processes have become of interest as a new technique of selective separation and concentration of metals from dilute aqueous solutions.[1,2] The extracting reagent plays a role as a mobile carrier in the membrane, and the metal ion can be concentrated by active transport against its concentration gradient across the liquid membrane.

Two types of liquid membranes, supported liquid membranes and emulsion liquid membranes, have been well known for separation of metal ions.[3,4] The effectiveness of liquid membrane method for the recovery of uranium from dilute solutions has been shown by means of supported liquid membranes containing various carriers,[5-7] and emulsion type liquid membranes of mixed carriers, bis(2-ethylhexyl) hydrogenphosphate and trioctylphosphine oxide, were also employed for uranium extraction from wet process phosphoric acid.[8] Emulsion liquid membranes consist of small droplets of the stripping aqueous phase stabilized by a surfactant and the extracting organic phase. They could give fast extraction owing to the large surface area of emulsion globules.

Previously, we revealed that a α-hydroxy ketone oxime, 5,8-diethyl-7-hydroxy-6-dodecanone oxime (LIX 63), is an excellent reagent for uranium extraction from weak acidic media[9] and also for a suitable ion carrier in the supported liquid membrane.[10] The present study deals with some of important factors affecting the stabilities of emulsions and the extraction of uranium(VI) by emulsion liquid membranes containing LIX 63 as a mobile carrier.

Experimental

Emulsion Liquid Membranes. The liquid membranes were composed of a nonionic surfactant, sorbitan monooleate (Span 80; Kao-Atlas) and 5,8-diethyl-7-hydroxy-6-dodecanone oxime (LIX 63; Henkel). The kerosene solutions of them were vigorously emulsified (20000 min^{-1} for 2 min) with stripping solutions of sulfuric acid (most commonly pH 1.5) by a high-speed homoginizer (Ultra-Disperser; Yamato Kagaku). No membrane strengthening agent such as liquid paraffin was added in the membrane solution, because there was little change in the stability of emulsion containing liquid paraffin up to 20 (w/v)%.

Emulsion Stability. The water-in-oil emulsion free from carriers was dispersed in ten times as much as the volume of water by stirring at 300 min^{-1}. To monitor the breaking of emulsions, stirring was stopped at time intervals so that the emulsion phase rose to the top of the beaker. After phase separation, samples of the aqueous phase were withdrawn and their pH values were measured with a pH meter (F-7ss; Horiba). When emulsions break down in the course of stirring, the internal stripping acid leaks out in the external aqueous phase. The emulsion breakdown was evaluated as percentage from the hydrogen ion concentrations as follows:

$$\varepsilon(\%) = \frac{([H^+]_{ext}-[H^+]_{ext,\,init.})V_{ext}}{[H^+]_{int}\times V_{int}} \times 100$$

where V refers to the volume and the subscripts ext and int represent the external and the internal aqueous phases, respectively.

Extraction of Uranium. The (w/o) emulsions containing LIX 63 were stirred with ten times as much as the volume of uranium solution (pH 3—4.5) containing ^{237}U as a tracer. The initial concentration of uranium was usually 10^{-5} mol dm^{-3}. After stirring at 300 min^{-1}, aliquots of the external aqueous solution were pipetted off for analysis at selected time intervals and their uranium concentrations were determined by measuring γ-radioactivities of ^{237}U with a NaI scintillation detector. The quantity of uranium moved into emulsion globules was evaluated from the difference between the concentrations in the external aqueous phase before and after stirring.

All experiments were carried out at 25 °C.

Results and Discussion

Emulsion Stability. When the (w/o) emulsion is dispersed by stirring in the continuous aqueous solution, the emulsion must be sufficiently stable in order to extract metal ions into the internal aqueous droplets. The emulsion breakdown will result in a lowering of extraction efficiency and loss of the extracted species. For the recovery of extracted metals, on the contrary, the emulsion must be readily broken by the use of demulsification techniques such as electrostatic means.[11]

The several factors governing the emulsion stability

have been examined in order to prepare the optimum emulsion liquid membranes suited for these conflicting requirements.

Figure 1 shows the effect of the surfactant concentration on the emulsion breakdown after stirring at 300 min^{-1}. The distilled water was stirred with emulsions consisting of equal volumes of the organic phase free from carriers and the sulfuric acid solution. The emulsion breakdown was less than 0.5% at Span 80 concentrations above 2 (w/v)%, indicating that the membrane was sufficiently stable, while the emulsion stability steeply decreased with a decrease in the surfactant concentrations less than 2%. No emulsion was formed at low Span 80 concentrations below 0.25% owing to a lack of the surfactant adsorbing the organic-aqueous interface. Though high concentrations of surfactant seem to be suitable for the stable emulsion, they would cause difficulties in demulsification. On the basis of the data, 2 (w/v)% of Span 80 was selected in the subsequent experiments.

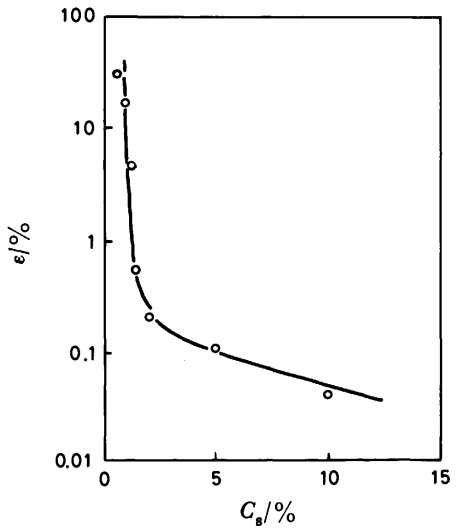

Fig. 1. Effect of Span 80 concentration on the emulsion breakdown after stirring at 300 min^{-1} for 40 min. V_{em}: 10 cm^3; V_{ext}: 100 cm^3.

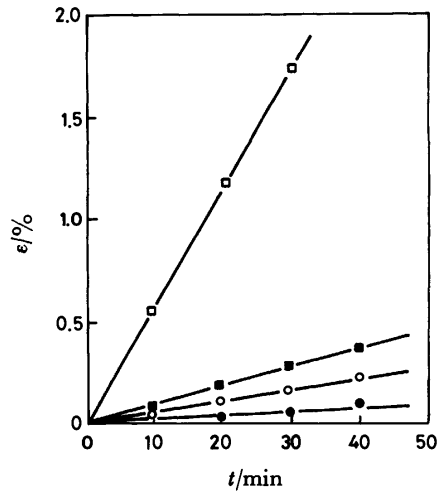

Fig. 2. Effect of stirring time on the emulsion breakdown. 2(w/v)% Span 80; V_{org}/V_{int}: □ 0.50, ■ 1.0, ○ 1.5, ● 2.0.

As shown in Fig. 2, the emulsion breakdown increased linearly with stirring time at 300 min^{-1}. This trend is marked with the emulsion of the low contents of the organic phase. The emulsion with the ratio (V_{org}/V_{int}) of 1 was found to be its optimum composition.

Equilibrium in Liquid-Liquid Extraction. Extraction equilibrium of uranium(VI) by LIX 63 (HR) can be expressed by,[9]

$$UO_2^{2+} + 2HR_{org} \overset{K_{ex}}{\rightleftharpoons} UO_2R_{2,org} + 2H^+. \quad (1)$$

The subscript org represents the organic phase, which corresponds to the membrane phase in the liquid membrane system. The extraction constants were obtained as $\log K_{ex}=-2.11$ and -3.32 for 0.1 mol dm^{-3} perchlorate and sulfate media, respectively. Based on these data, the hydrogen ion concentrations on both sides of the membrane can be adjusted so as to enhance the extraction in the external aqueous phase and the stripping in the internal aqueous phase. The overall processes promote the transport of the uranyl ion from the external to the internal aqueous phases through the liquid membrane and the transport of the hydrogen ion in the opposite direction.

Extraction by Emulsion Liquid Membrane. Effect of stirring on the extraction of uranium(VI) by the emulsion liquid membrane containing LIX 63 is shown in Fig. 3. The uranium solution at pH 4.2 was stirred with the emulsion having the volume ratio (V_{org}/V_{int}) of 1. The uranium concentrations in the external aqueous phase decreased with stirring time and then approached equilibrium. The rate of extraction increased with an increase in stirring speed, while the limiting value at equilibrium was approximately constant about 0.5% of the initial concentration irrespective of stirring speed under 500 min^{-1}, and little pH drop, *e.g.*, from 4.2 to 4.1, was observed at 500 min^{-1} for 1 h stirring. However, the external uranium concentration no longer decreased as above cases at higher speed of

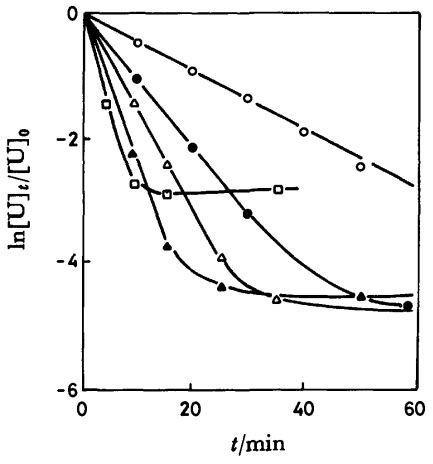

Fig. 3. Effect of stirring speed on the extraction of uranium(VI) by the emulsion liquid membrane. 5×10^{-3} mol dm^{-3} LIX 63; pH_{ext} 4.20; pH_{Int} 2.06; Stirring speed/min^{-1}: ○ 200, ● 300, △ 400, ▲ 500, □ 800.

stirring, and the pH drop became large, *e.g.*, from 4.2 to 3.7 at 800 min^{-1} for 40 min stirring. This anomalous behavior could be attributable to the high degree of emulsion breaking. Subsequent experiments were carried out at 300 min^{-1} where the emulsion breakdown during extraction was negligibly small.

Effect of Carrier Concentration. The rates of extraction were examined by varying carrier concentrations at 2 (w/v)% of Span 80 (Fig. 4). Plots of ln $[U]_t/[U]_0$ against time yielded a series of straight lines,

$$\ln\frac{[U]_t}{[U]_0} = -k_{obsd}t, \quad (2)$$

where $[U]_t$ and $[U]_0$ are the concentrations in the external aqueous phase at time t and initial one, respectively. The slope of the line gives the apparent rate constant, k_{obsd}. The plots of log (k_{obsd}/s^{-1}) *vs.* log ([LIX 63]/mol dm^{-3}) yielded the straight line with a slope of 0.61 (Fig. 5). Under these experimental conditions, about 99.5% of uranium in the external solution was extracted into the emulsion globules at equilibrium.

The high content of Span 80 resulted in a decrease in the extraction rate and further caused the extraction of small amounts of uranium by Span 80 alone. These findings together with the emulsion stability suggest that the optimum concentration of Span 80 lies in the 2% range. The uranium extraction by this 2% surfactant was negligibly small.

Effect of pH. It is important to maintain an appreciable pH gradient between the external and the internal aqueous phases, because this pH gradient provides an effective driving force of the active transport of uranium across the membrane.

Plots of log (k_{obsd}/s^{-1}) *vs.* pH_{ext} of the external aqueous phase gave the straight lines with slopes of about 1.3 at different concentrations of stripping acid (Fig. 6). As long as the internal acid concentrations were maintained high enough to strip uranium, the extraction rate increased with an increase in the external pH values.

The effect of stripping acid concentration on the extraction rate is illustrated in Fig. 7. Plots of log k_{obsd} *vs.* pH_{int} gave the linear lines with small negative slopes around −0.2 at different pH_{ext}. Varying the internal pH values over a fairly wide range has only a minor effect on the extraction rate.

From these findings, the extraction reaction into the membrane layers rather than the stripping reaction into

the internal aqueous phase probably contributes to the rate determining process. If the stripping reaction was the rate determining step, the content of the internal phase would also affect the extraction rate, but the k_{obsd} values at different compositions of emulsion, were nearly constant as seen in Fig. 8. This indicates that the stripping reaction is not of importance in the rate determining process.

The most significant factor for the carrier-mediated transport appears to control the external pH value maintaining the pH gradient against internal pH. The final concentration of external uranium was observed to decrease greatly under the large pH gradient; the uranium remaining in the external solution dropped to 10^{-3} of its initial concentration under the conditions of pH_{ext} 4.6 and pH_{int} 2.0.

Furthermore, wide variations in the initial uranium concentration ranging from 10^{-7} to 10^{-4} mol dm^{-3} gave no effect on the extraction efficiency and the extraction rate. The reagent LIX 63 in the membrane acts as an ion carrier from the outer to the inner solutions, rather than a metal storage phase in liquid-liquid extraction. Thus, uranium could be efficiently concentrated into small encapsulated droplets with the concentration factor of V_{ext}/V_{int} given by the volume ratio of the external to the internal aqueous phases.

Enthalpies of Transfer of Single Ions and Metal Complexes from Water to an Aqueous Dioxane Solution

Shin-ichi ISHIGURO and Hitoshi OHTAKI*

Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received March 24, 1984)

Enthalpies of solution of some 1:1 and 2:1 electrolytes were determined in water and in a dioxane-water mixture (the dioxane content; 0.2 mole fraction or 55.0% w/w) by calorimetry at 25 °C. Enthalpies of transfer (ΔH_t°) of single ions from water to the dioxane-water mixture were obtained by employing the extrathermodynamic tetraphenylarsonium tetraphenylborate (TATB) assumption. Enthalpies of transfer of nickel(II) and copper(II) complexes with glycinate (gly^-) and ethylenediamine (en) were also evaluated for $[Ni(gly)_n]^{(2-n)+}$ (n=1—3), $[Ni(en)_n]^{2+}$ (n=1—3), and $[Cu(en)_n]^{2+}$ (n=1—2) by combining enthalpies of transfer of the relevant single metal ions and ligands with enthalpies of complex formation reactions $M+nL=ML_n$ ($M=Ni^{2+}$ or Cu^{2+} and $L=gly^-$ or en) in water and in the mixture. The enthalpies of transfer of the metal complexes examined here increased almost linearly with an increase in the number of the ligands within the complexes. The values of ΔH_t° of the ethylenediamine complexes of nickel(II) and copper(II) ions were all negative, as well as those of free Ni^{2+} and Cu^{2+} ions. On the other hand, the enthalpies of transfer of the noncharged $[Ni(gly)_2]$ and anionic $[Ni(gly)_3]^-$ complexes were positive, while that of the $[Ni(gly)]^+$ complex was still negative. The result suggested that hydration of the ligands coordinating to the central metal ions plays an essential role in the enthalpies of transfer of the metal complexes from water to the dioxane-water mixture.

In previous papers we reported formation constants or Gibbs energies, enthalpies and entropies of formation of ethylenediamine complexes of nickel(II)[1] and copper(II)[2] ions in water and in dioxane-water mixtures containing 0.1 and 0.2 mole fractions (35.2 and 55.0% w/w, respectively) of dioxane and discussed about solvent effects on the complex formation reactions.

Although it was pointed out that the Gibbs energies of transfer of metal ions from water to the dioxane-water mixtures were negative[3-5] and thus the metal ions should be more stable in the mixtures than in water, the formation of the ethylenediamine complexes of nickel(II) and copper(II) ions was more favorable in the dioxane-water mixtures than in water. This result indicated that the ethylenediamine complexes of nickel(II) and copper(II) ions should be more stabilized than the respective free metal ions on transferring the species from water to the dioxane-water mixtures, provided that the instabilization of the neutral ligand in the mixtures was not too significant compared with that in water.

NMR studies[6,7] suggested that metal ions were preferentially solvated with water in their primary coordination sphere over a wide range of composition of dioxane-water mixtures. Thus, we concluded[1-3] that the aqua and ethylenediamine complexes of nickel(II) and copper(II) ions were hydrated even in aqueous mixture of dioxane because of weaker donor property of dioxane (the donor number (DN)=14.8) than water (DN=18.0)[8] and the hydration of the metal ions and complexes was more enhanced in the mixtures than in water.

The above conclusion was supported by evidence from calorimetric measurements. Enthalpies of solution of some 1:1 electrolytes so far reported indicated that hydration of metal ions was strengthened in dioxane-water mixtures due, probably, to breaking of the hydrogen-bonded structure of water in the bulk solvents.[9,10] The enthalpies of transfer of the $[Ni(en)_n]^{2+}$ (n=1—3) complexes estimated were all negative, which showed that solvation of the complexes was enhanced in the dioxane-water mixtures.[1]

In order to expand our studies to other metal-ligand systems, we first undertook to determine enthalpies of transfer of single metal ions and ligands involved in the metal-ligand complexes from water to a dioxane-water mixture. The mixture of the dioxane content of 0.2 mole fraction (55.0% w/w) was chosen as the mixed solvent in the present study, because complex formation reactions of various metal ions were studied in this mixture in our laboratory. Moreover, various solvent properties of dioxane-water mixture show a significant variation with changing solvent composition in the water-rich region of about 0.2 mole fraction dioxane content.[11]

In the present work the extrathermodynamic tetraphenylarsonium tetraphenylborate assumption $\Delta H_t^\circ(Ph_4As^+)=\Delta H_t^\circ(BPh_4^-)$, was adopted[12] for dividing enthalpies of transfer of salts from water to the dioxane-water mixture into those of individual ions, where ΔH_t° denotes the enthalpy of transfer of a species from water to the 0.2 mole fraction dioxane-water mixture, which is given by the difference between enthalpies of solution of the species in the two solvents.

Enthalpies of transfer of Ni^{2+}, Cu^{2+}, and glycinate (gly^-) ions and ethylenediamine (en) from water to the 0.2 mole fraction dioxane-water mixture thus evaluated were combined with enthalpies of formation of the $[Ni(gly)_n]^{(2-n)+}$ (n=1—3), $[Ni(en)_n]^{2+}$ (n=1—3), and $[Cu(en)_n]^{2+}$ (n=1—2) complexes in the solvents and thus enthalpies of transfer of the metal complexes were obtained. The enthalpy of transfer of proton was calculated by using ΔH_t°'s of glycinate ion and glycine, and enthalpies of formation of glycine in water and in the dioxane-water mixture. Enthalpies of transfer of the Hen^+, H_2en^{2+}, and H_2gly^+ species from water to the

0.2 mole fraction dioxane-water mixture were also estimated.

Experimental

Reagents. All chemicals used were of reagent grade. *Nickel(II) and copper(II) chlorides* were prepared by dissolving respective metal oxides into hydrochloric acid of super special grade. The metal oxides had been prepared as described elsewhere.[1] The hexahydrates of nickel(II) and copper(II) chlorides were prepared by drying the solutions in a vacuum evaporator, and then dried at 150 °C in a vacuum oven to obtain the anhydrous salts. *Bis(glycinato)nickel(II) dihydrate crystals* were prepared by dissolving freshly precipitated nickel(II) carbonate to an aqueous glycine solution, and then recrystallized from water. The dihydrate salt was dried at 150 °C in a vacuum oven to obtain the anhydrous one. *Sodium glycinate* was prepared by mixing equimolar amounts of glycine and sodium hydroxide in methanol and recrystallized three times from methanol. Purity of the sodium glycinate thus prepared was more than 99.8%. *Glycine* was recrystallized three times from water. *Sodium perchlorate* was prepared and purified as described previously.[13] *Sodium tetraphenylborate, tetraethylammonium chloride, and tetraethyl ammonium perchlorate* used were recrystallized from acetone and then washed with ester. *Tetraphenylarsonium chloride and sodium chloride* were used without further purification and dried at 180 °C. All chemicals thus prepared and purified were stored in a vacuum desiccator over P_2O_5. *Dioxane and ethylenediamine* were dried by using metallic sodium and then distilled.

Calorimetric Measurements. Enthalpies of solution were measured in a room thermostated at (25.0±0.2) °C by using an MPS-11 calorimeter (Tokyo Riko, Tokyo). A teflon vessel was placed in an aluminium block controlled at (25.000±0.003) °C in an air-bath. All parts inserted in the vessel were made of teflon. A standard heater and a thermal sensor were sandwiched between the bottom of the vessel and the aluminium block. Powder of a sample salt was placed in a glass ampoule in a dry box over P_2O_5, and the ampoule was weighed and then sealed. An ampoule containing a given amount of a sample salt was immersed in a solvent of 50 cm^3 in the teflon vessel.

The measurement of heat of solution of a sample consisted of two stages I and II. A typical chart for a heat measurement of a sample salt is shown in Fig. 1.

A vessel equipped with an ampoule in a solvent was installed in an aluminium block. At the beginning of measurement, the vessel was thermally equilibrated with the aluminium block (temperature: θ_0). Then the vessel was heated with a standard heater for a given period of time from $t=0$ to $t=t_h$. Thus temperature of the vessel rose during the heating period then spontaneously fell and became to the initial temperature (θ_0) within a few hours (stage I). Then the ampoule was mechanically broken and the temperature increased or decreased depending on the exothermic or endothermic dissolution of a salt. In Fig. 1 an example for the endothermic dissolution of a salt (NaCl in this case) is depicted (stage II). The temperature change detected by using a thermal sensor was recorded in a JEC 6 electronic computer (JEOL, Tokyo) every second through a 10-bit AD converter. Measurements were performed with the aid of the on-line system for calorimetry developed in our laboratory.

Determination of Heat of Solution. Under nonadiabatic conditions, the change in temperature $\theta(t)$ of a vessel in which heat is evolved or absorbed by dissolution of a sample salt is followed by the equation 1:

$$C_p\{d\theta(t)/dt\} = q(t) - \lambda\{\theta(t)-\theta_0\}, \quad (1)$$

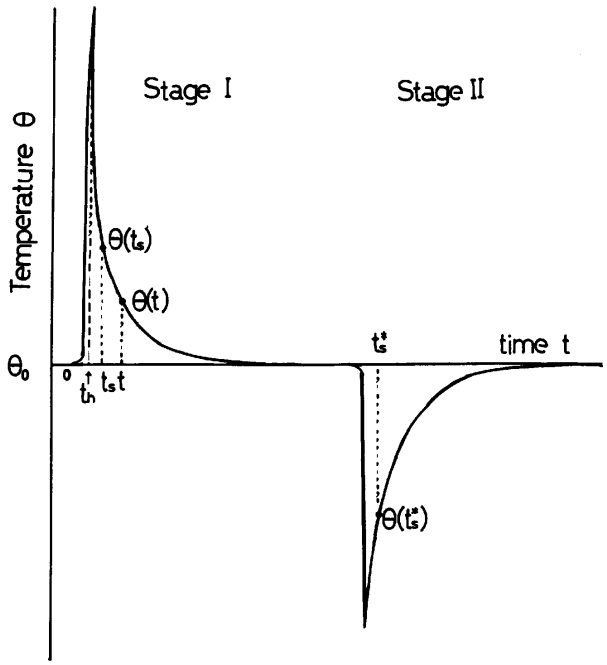

Fig. 1. A typical example for the calorimetric determination of heat of solution of a salt.

where C_p and λ stand for heat capacity and heat transfer coefficient of the vessel, respectively. $q(t)$ denotes heat evolved (or absorbed) per unit time at time t. Since $\theta(t)=\theta_0$ at $t=0$ and ∞, the total heat Q evolved (or absorbed) in the vessel is thus obtained by integrating measured temperatures from $t=0$ to $t=\infty$ as follows:

$$Q = \int_0^\infty q(t)dt = \lambda\int_0^\infty \{\theta(t)-\theta_0\}dt. \quad (2)$$

Therefore, in order to relate measured temperature changes to the total heat it is needed to know the values of C_p and λ. The values of C_p and λ were determined by heating the vessel with a standard heater at stage I in advance of dissolution of a salt at stage II.

At stage I, a standard heater was operated for a given period of time from $t=0$ to $t=t_h$ and a given amount of heat Q_{ev} was evolved. At $t>t_h$ where no more heat is evolved, temperature of the vessel spontaneously decreased. At a region of the spontaneous cooling of the vessel, a temperature at $t=t_s$, $\theta(t_s)$, ($t_s>t_h$) decreases according to Eq. 3:

$$\theta(t) - \theta_0 = \{\theta(t_s)-\theta_0\}\exp\{-\mu(t-t_s)\}, \quad (3)$$

where $\mu=\lambda/C_p$. The value of μ is obtained by plotting $\ln\{\theta(t)-\theta_0\}$ as a function of $(t-t_s)$, since $\ln\{\theta(t)-\theta_0\}=\ln\{\theta(t_s)-\theta_0\}-\mu(t-t_s)$.

The right hand side of Eq. 2 can be separated into two terms as follows:

$$\begin{aligned} Q_{ev} &= \lambda\left[\int_0^{t_s}\{\theta(t)-\theta_0\}dt + \int_{t_s}^\infty\{\theta(t)-\theta_0\}dt\right] \\ &= \lambda\left[\int_0^{t_s}\{\theta(t)-\theta_0\}dt \right. \\ &\quad \left. + \int_{t_s}^\infty\{\theta(t_s)-\theta_0\}\exp\{-\mu(t-t_s)\}dt\right]. \end{aligned} \quad (4)$$

At a given time t_s, $\theta(t_s)$ is a constant and thus the second term of Eq. 4 is given as $\{\theta(t_s)-\theta_0\}/\mu$.

Since Q_{ev} and μ are known and the first term of Eq. 4 is approximated by using the relation

$$\int_0^{t_s}\{\theta(t)-\theta_0\}dt = \sum_0^{t_s}\{\theta(t)-\theta_0\}\Delta t, \quad (5)$$

the constant λ and C_p are obtained as follows:

$$\lambda = Q_{ev}/[\sum_0^{t_s}\{\theta(t)-\theta_0\}\Delta t+\{\theta(t_s)-\theta\}/\mu], \quad (6)$$

$$C_p = \lambda/\mu. \quad (7)$$

In the course of the determination of μ, a certain time after 900 seconds beyond t_h (t_h=300 seconds) was taken as t_s and successive 70 points of $\theta(t)$ measured at every 30 seconds after t_s was subjected to the least-squares calculation for the ln-$\{\theta(t)-\theta_0\}$ plots *vs.* $(t-t_s)$. The value of Δt in Eq. 6 was one second, and all the t values employed in the course of the calculation of μ were used as t_s in the evaluation of λ by using Eq. 6. Thus the final λ value was obtained by averaging 70 λ's in each set of data with different t_s's.

Once we know the constants λ and C_p of the vessel, we can determine unknown heat evolved or absorbed by dissolution of a sample salt. An ampoule immersed in a solvent was mechanically broken and a salt in the ampoule dissolves exothermically or endothermically to yield a temperature change as is shown in Fig. 1, stage II, as an example (in the present example an endothermic dissolution process is given). The heat Q evolved or absorbed at dissolution of m moles of a salt is given, by using the constant λ and C_p obtained at stage I, as follows:

$$Q = \lambda[\sum_0^{t_s}\{\theta(t)-\theta_0\}\Delta t+(C_p/\lambda)\{\theta(t_s^*)-\theta_0\}]. \quad (8)$$

Q values were estimated at various t_s^* and the final Q value was determined by averaging the Q values estimated at various t_s^*. The uncertainty of the Q value was within ±0.5%. The enthalpy of solution of the salt (ΔH_s°) was thus given as $\Delta H_s^\circ = -Q/m$.

Results and Discussion

Enthalpies of Transfer of Single Ions. Enthalpies of solution of six salts were measured in water and in the 0.2 mole fraction dioxane-water mixture and the results are summarized in Table 1. Enthalpies of solution of the salts showed no appreciable dependence on the concentration except for NaCl and $(C_2H_5)_4NCl$ in the dioxane-water mixture. The values in Table 1 for NaCl and $(C_2H_5)_4NCl$ were obtained by extrapolating enthalpies of solution measured in the mixture with various concentrations of the salts to those at infinite dilution. The enthalpies of solution obtained in water for all the salts examined here agree with those in the literature within±1.2 kJ mol^{-1}.[14]

At infinite dilution all the salts in Table 1 were assumed to be fully dissociated both in water and in the dioxane-water mixture, and thus, the enthalpy of transfer of a salt i of 1:1 electrolyte (consisting of A^+ and B^-) from water to the mixture was represented as the sum of the enthalpies of transfer of each ionic component as follows:

$$\Delta H_t^\circ(A^+B^-) = \Delta H_t^\circ(A^+) + \Delta H_t^\circ(B^-). \quad (9)$$

Enthalpies of transfer of six single ions were thus evaluated from those of the salts in Table 1 by applying the extrathermodynamic TATB assumption $\Delta H_t^\circ(Ph_4As^+)=\Delta H_t^\circ(BPh_4^-)$ to the calculation and by minimizing the error-square sum $U=\sum\{\Delta H_{t,obsd}^\circ(i)-\Delta H_{t,calcd}^\circ(i)\}^2$.

Table 1. Enthalpies of solution (ΔH_s°) of some 1:1 electrolytes in water and in dioxane-water mixture (0.2 mole fraction of dioxane), and enthalpies of transfer (ΔH_t°) of the electrolytes from water to the mixture at 25 °C

Species	ΔH_s°(w) / kJ mol^{-1}	ΔH_s°(mix) / kJ mol^{-1}	ΔH_t° / kJ mol^{-1}
$NaBPh_4$	−20.0(−20.0)[a]	−39.4	−19.4
Ph_4AsCl	−10.2(−10.9)[a]	5.7	15.9
NaCl	4.4(3.8)[a]	0.2	−4.2
$NaClO_4$	15.0(13.8)[a]	−9.4	−24.4
$(C_2H_5)_4NClO_4$	32.2(31.0)[a]	23.2	−9.0
$(C_2H_5)_4NCl$	−12.4(−13.6)[a]	−1.4	−11.0

a) Values in parentheses are those quoted from Ref. 14.

Table 2. Enthalpies of transfer (ΔH_t°) of single ions from water to the dioxane-water (0.2 mole fraction of dioxane) at 25 °C.

Ion	ΔH_t°/kJ mol^{-1}
Ph_4As^+	0.4
BPh_4^-	0.4
Na^+	−19.8
Cl^-	15.5
$(C_2H_5)_4N^+$	−4.5
ClO_4^-	−4.6

The enthalpies of transfer of the single ions thus obtained are tabulated in Table 2. The enthalpies of transfer of all the salts in Table 1 were satisfactorily reproduced by those of the single ions in Table 2 within ±0.1 KJ mol^{-1}. The enthalpies of transfer of single ions in Table 2 are consistent with those calculated by interpolating the enthalpies of transfer from water to dioxane-water mixtures of different composition, which were obtained by employing the tetraphenylphosphonium tetraphenylborate assumption $\Delta H_t^\circ(Ph_4P^+)=\Delta H_t^\circ(BPh_4^-)$.[10]

Enthalpies of solution of $NiCl_2$, $CuCl_2$, sodium glycinate, glycine, and ethylenediamine were also measured in these solvents and the values are listed in Table 3. Sodium glycinate and ethylenediamine were dissolved in an alkaline solution to prevent protonation of the species. Glycine was dissolved in neutral solvents in which glycine form the zwitterion, Hgly. For all the species in Table 3, no appreciable change was found for the enthalpies of solution with the concentration of the salts over a range of 10^{-3} to 10^{-2} mol dm^{-3}. The enthalpy of solution of ethylenediamine obtained in water agreed well with the value reported by Nochols *et al.*[15]

It was also assumed that $NiCl_2$, $CuCl_2$, and sodium glycinate are completely dissociated in the solvents examined, and the enthalpies of transfer of nickel(II), copper(II) and glycinate ions from water to the dioxane-water mixture are thus estimated by subtracting the contribution of their counter ions which had been obtained in advance.

Table 3. Enthalpies of solution (ΔH_s°) of some compounds in water and in the dioxane-water mixture (0.2 mole fraction of dioxane), and their enthalpies of transfer (ΔH_t°) from water to the mixture at 25 °C

Species	ΔH_s°(w) / kJ mol^{-1}	ΔH_s°(mix) / kJ mol^{-1}	ΔH_t° / kJ mol^{-1}
$NiCl_2$	−79.9	−90.0	−10.1
$CuCl_2$	−56.3	−61.0	−4.7
Nagly[a]	−11.3	−2.4	8.9
Hgly	15.0	16.2	1.2
en[b]	−34.5(−32.0)	−34.8	−0.3

a) Dissolved in solutions containing 0.01 mol dm^{-3} NaOH. b) Dissolved in solutions containing 0.1 mol dm^{-3} LiOH and 3 mol dm^{-3} $LiClO_4$. The value in parentheses was obtained in the same alkaline solution without $LiClO_4$.

Enthalpies of Transfer of Proton, Protonated Glycine and Protonated Ethylenediamine. Glycinate ion (gly^-) reacts with proton to form the zwitterionic glycine (Hgly or $NH_3^+CH_2COO^-$) in solution. The enthalpy of the reaction, $H^+ + gly^- = Hgly$, was −57.9 and −62.7 kJ mol^{-1} in water (ΔH°_{Hgly}(w)) and in the dioxane-water mixture (ΔH°_{Hgly}(mix)), respectively.[16] The difference between the enthalpies of formation of Hgly in these solvents is related to the enthalpies of transfer of the species participating in the formation reaction as follows:

$$\Delta H^\circ_{Hgly}(mix) - \Delta H^\circ_{Hgly}(w) = \Delta H_t^\circ(Hgly) - \Delta H_t^\circ(H^+) - \Delta H_t^\circ(gly^-). \quad (10)$$

Since the ΔH_t° values of gly^- and Hgly were already determined as described in the previous section, the enthalpy of transfer of proton $\Delta H_t^\circ(H^+)$ from water to the mixture could be evaluated. By knowing ΔH_t°(en) and $\Delta H_t^\circ(H^+)$ thus obtained and the enthalpies of formation of Hen^+ in the two solvents,[1] the enthalpy of transfer of Hen^+ could also be estimated.

By the same procedure as described above the enthalpies of transfer of H_2gly^+ and H_2en^{2+} from water to the 0.2 mole fraction dioxane-water mixture were calculated, since the enthalpies of formation of these species in both solvents were known:

$$\Delta H_t^\circ(H_2L^{(q+2)+}) = \Delta H_t^\circ(HL^{(q+1)+}) + \Delta H_t^\circ(H^+) + \Delta H^\circ_{H_2L}(mix) - \Delta H^\circ_{H_2L}(w), \quad (11)$$

where L denotes gly ($q=-1$) or en ($q=0$), and $\Delta H^\circ_{H_2L}$(s) stands for the enthalpy of the second stepwise formation reaction, $H^+ + HL^{(q+1)+} = H_2L^{(q+2)+}$, in solvents. The value of $\Delta H^\circ_{H_2L}$ for glycine was determined to be −5.5 and −10.3 kJ mol^{-1} in water and in the dioxane-water mixture, respectively.[16] The values for ethylenediamine were reported previously.[1] The enthalpies of transfer of glycinate ion and ethylenediamine and their protonated species, as well as the value for proton, from water to the dioxane-water mixture thus evaluated are summarized in Table 4.

The enthalpy of transfer of proton was −22.7 kJ mol^{-1}, which was close to that of sodium ion (−19.8 kJ mol^{-1}).

Table 4. Enthalpies of transfer (ΔH_t°) of single species from water to the 0.2 mole fraction dioxane-water mixture at 25 °C

Species	ΔH_t° / kJ mol^{-1}	Species	ΔH_t° / kJ mol^{-1}
H^+	−22.7	$[Ni(gly)]^+$	−12.7
Ni^{2+}	−41.1	$[Ni(gly)_2]$	12.3
Cu^{2+}	−35.7	$[Ni(gly)_3]^-$	39.8
gly^-	28.7	$[Ni(en)]^{2+}$	−38.9
en	−0.3	$[Ni(en)_2]^{2+}$	−35.2
Hgly[a]	1.2	$[Ni(en)_3]^{2+}$	−30.2
H_2gly^+	−26.3	$[Cu(en)]^{2+}$	−35.0
Hen^+	−20.0	$[Cu(en)_2]^{2+}$	−33.1
H_2en^{2+}	−41.7		

a) Zwitterion, $NH_3^+CH_2COO^-$.

The ΔH_t° value of ethylenediamine was practically zero. The ΔH_t° values of Hen^+ and H_2en^{2+} were −20.0 and −41.7 kJ mol^{-1}, respectively, the latter value being almost double of the former. These results suggest that the enthalpies of transfer of the protonated ethylenediamine species are mostly influenced by the change in the enthalpies of solvation of charged ammonio groups within the species.

The enthalpy of transfer of protonated glycine H_2gly^+, which has a charged ammonio group and a noncharged carboxyl group, was −26.3 kJ mol^{-1}, the value being slightly more negative than that of Hen^+. Glycinate ion involving an anionic carboxylato group and a neutral amino group gave a positive ΔH_t° value (28.7 kJ mol^{-1}).

The enthalpy of transfer of zwitterionic glycine was small (1.2 kJ mol^{-1}), which might be compared with that of ethylenediamine (−0.3 kJ mol^{-1}). In fact, the enthalpy of hydration of glycine zwitterion in water was estimated to be −243 kJ mol^{-1},[17] which was considerably negative compared with those of noncharged molecules such as methylamine (−45.2 kJ mol^{-1}) and neutral acetic acid (−52.7 kJ mol^{-1}), although the value for the glycine zwitterion was less negative than those of H_2gly^+ (−365.4 kJ mol^{-1}) and gly^- (−379.5 kJ mol^{-1}).[17] The result suggests that the glycine zwitterion is strongly hydrated in water through both the ammonio and carboxylato groups. Two plausible interpretations for the small enthalpy of transfer of glycine from water to the dioxane-water mixture may be given: 1) hydration of a zwitterion is restricted to the vicinity of charged groups and is not appreciably changed when a part of water of the solvent is replaced with dioxane, 2) a large, negative enthalpy of transfer of an ammonio group is cancelled by a large, positive enthalpy of transfer of a carboxylato group within a zwitterionic glycine. Since the entropy of transfer of glycine between the two solvents is estimated to be −21 JK^{-1} mol^{-1},[16] which is rather largely negative, the latter interpretation is more acceptable.

Neutral Bis(glycinato)nickel(II) Complex. Enthalpy of transfer of the neutral bis(glycinato)nickel(II) complex can be determined without the extrathermody-

namic assumption. However, the solubility of the complex was too low in both water and the dioxane-water mixture to directly measure the heat of solution of the complex with a sufficient accuracy. Therefore, the complex salt was dissolved in each of the solvents containing sodium or lithium glycinate in which the neutral species was expected to be fully converted to the tris(glycinato)nickel(II) complex, and thus, the measured enthalpy at dissolution of the bis(glycinato)nickel(II) complex in the solvents was given as the sum of the enthalpy of solution (ΔH_{s1}°) of the complex and the enthalpy (ΔH_{3}°) of the reaction, $Ni(gly)_2+gly^-=Ni(gly)_3^-$, in the solvents. Since the latter was already known,[16] the former value was determinable.

The enthalpy of solution (ΔH_{s2}°) of the dihydrate salt $[Ni(gly)_2(H_2O)_2]$ was also determined by the same procedure as mentioned above in the two solvents. In a given solvent used, as is shown in Fig. 2, enthalpies of solution of the bis(glycinato)nickel(II) (ΔH_{s1}°) and diaquabis(glycinato)nickel(II) (ΔH_{s2}°) complexes are related to the enthalpy of reaction 12, ΔH_{h}°:

$$Ni(gly)_2(c) + 2H_2O(s) = Ni(gly)_2(H_2O)_2(c), \quad (12)$$

where (c) and (s) denote the crystalline and solution states, respectively. The enthalpy values of ΔH_{s1}°, ΔH_{s2}°, and ΔH_{h}° thus obtained in water and in 0.2 mole fraction dioxane-water mixture are summarized in Table 5, together with the values of ΔH_{3}° in the solvents.

The difference between the enthalpies of reaction 12 in water ($\Delta H_{h}^{\circ}(w)$) and in the 0.2 mole fraction dioxane-water mixture ($\Delta H_{h}^{\circ}(mix)$) is attributed to the enthalpy of transfer of two moles of water from water to the dioxane-water mixture:

$$\Delta H_{h}^{\circ}(w) - \Delta H_{h}^{\circ}(mix) = 2\Delta H_{t}^{\circ}(H_2O). \quad (13)$$

The values of ΔH_{h}° were −60.0 and −58.8 kJ mol^{-1} in water and in the dioxane-water mixture, respectively,

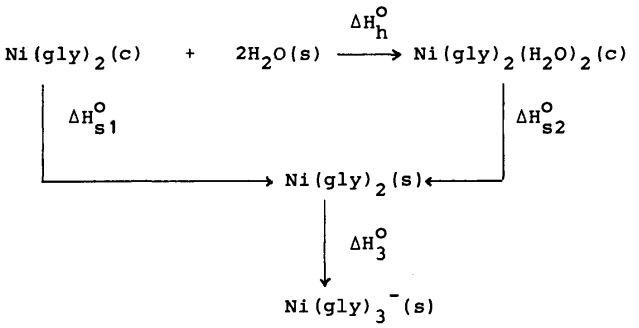

Fig. 2. Relationship between ΔH_{s1}°, ΔH_{s2}°, ΔH_{h}°, and ΔH_{3}°.

and thus, the $\Delta H_{t}^{\circ}(H_2O)$ value was estimated to be −0.6 kJ mol^{-1}. This result is consistent with the fact that the heat of mixing of water with dioxane is only slightly exothermic in a composition of water-rich.[18] The relatively small $\Delta H_{t}^{\circ}(H_2O)$ value suggested that the interaction energy between water molecues or between water and dioxane molecules in the dioxane-water mixture was not appreciably different from that between water molecules in water.

Since the interaction energies between solvent molecules in the two solvents are thus concluded to be similar, the difference in the enthalpies of transfer of ions and complexes in the two solvents should be ascribed to the different solvation energies of the species in the solvents.

Enthalpies of Transfer of Metal Complexes. By a similar way of evaluation of enthalpies of transfer of protonated glycine and ethylenediamine as described in the previous section, the enthalpies of transfer of glycinato and ethylenediamine complexes of nickel(II) ions and ethylenediamine complexes of copper(II) ions were determined. The enthalpies of formation of a complex ML_n (charge is omitted) pertaining to the reaction, $M+nL=ML_n$, in water ($\Delta H_{\beta n}^{\circ}(w)$) and in the 0.2 mole fraction dioxane-water mixture ($\Delta H_{\beta n}^{\circ}(mix)$) are related to the enthalpies of transfer of the free metal ion M, ligand L and the complex ML_n as follows:

$$\Delta H_{\beta n}^{\circ}(mix) - \Delta H_{\beta n}^{\circ}(w) = \Delta H_{t}^{\circ}(ML_n) - \Delta H_{t}^{\circ}(M) - n\Delta H_{t}^{\circ}(L). \quad (14)$$

The enthalpies of formation of the (glycinato)nickel(II) complexes[16] and ethylenediamine complexes of nickel(II) and copper(II) ions[1,2] have been measured in both solvents. Since the enthalpies of transfer of free nickel(II), copper(II), and glycinate ions and ethylenediamine have been determined in the previous sections, the enthalpies of transfer of the relevant metal complexes can be evaluated by using Eq. 14. The ΔH_{f}° value for the $[Ni(gly)_2]$ complex thus evaluated was in accord with that obtained by the difference $\Delta H_{s1}^{\circ}(mix)-\Delta H_{s1}^{\circ}(w)$ in enthalpies of solution of the anhydrous bis(glycinato)nickel(II) complex salt in water and in the dioxane-water mixture. Enthalpies of transfer of the metal complexes thus obtained are summarized in Table 4, together with the enthalpies of transfer of the free metal ions and ligands.

It has been known that metal ions are preferentially solvated by water molecules in the first coordination sphere in dioxane-water mixtures of water-rich,[6,7] and thus the difference in the enthalpies of solvation of ions, as well as complexes whose first coordination shells are

Table 5. Enthalpies of solution, ΔH_{s}°/kJ mol^{-1}, of anhydrous (ΔH_{s1}°) and dihydrate (ΔH_{s2}°) salts of bis(glycinato)nickel(II) complexes in water and in 0.2 mole fraction dioxane-water mixture and related enthalpies (definition of which is given in Fig. 2) at 25 °C

filled with ligands, in water and the dioxane–water mixture should be caused by the change in solvation in the second and further solvation shells.

Plots of the ΔH_t° values of the $[Ni(gly)_n]^{(2-n)+}$, $[Ni(en)_n]^{2+}$, and $[Cu(en)_n]^{2+}$ complexes against n are shown in Fig. 3. They linearly increased with n for all the complexes, although the changes in ΔH_t° of the latter two were rather insensitive to n.

The ethylenediamine complexes of nickel(II) and copper(II) ions gave relatively large negative values of ΔH_t°. Since the first coordination shell of the metal ions within the complexes were occupied by ethylenediamine and/or water molecules, the result showed that solvation of the second coordination shell of the species was enhanced in the mixture than in water, although the enhancement may be less pronounced in a complex with a larger number of ethylenediamine coordinated to the metal ion.

In the case of the glycinato complexes of nickel(II) ions in which the charge of the complexes change from +2 (for Ni^{2+}) to −1 (for $[Ni(gly)_3]^-$), the ΔH_t° values of the complexes much more steeply increased with n than those of $[Ni(en)_n]^{2+}$ and $[Cu(en)_n]^{2+}$ did, the charge of these complexes being independent of n. Although the ΔH_t° value of the $[Ni(gly)]^+$ complex was still negative, the value was much less negative than the values of H^+ and Na^+. The ΔH_t° values for $[Ni(gly)_2]$ and $[Ni(gly)_3]^-$ were positive, the latter being much larger than that of glycinate ion. The result indicated that the solvation structure of the second coordination shell of the $[Ni(gly)_2]$ and $[Ni(gly)_3]^-$ complexes was partly destroyd in the dioxane–water mixture compared with that in water.

The linear relationship between ΔH_t° and n for the $[Ni(gly)_n]^{(2-n)+}$ complexes suggests that solvation of glycinate ions coordinated to the central nickel(II) ion is most responsible for the stabilization of the solvation structure of the second coordination shell of the complexes. In the $[Ni(gly)_n]^{(2-n)+}$ complexes, one of oxygen atoms within each carboxylato group of glycinate ions combines with the central metal ions, while the other oxygen atom of the carboxylato group faces to solvent molecules in the second coordination shell to interact each other. Since free glycinate ion has a positive value of ΔH_t°, the interaction between the latter glycinato-oxygen atom and solvent molecules in the second coordination shell may have a contribution to the ΔH_t° values of the complexes to make them more positive. The linear change in the ΔH_t° of the $[Ni(gly)_n]^{(2-n)+}$ complexes with n suggests that the interaction between the glycinato-oxygen atom and solvent molecules in the second coordination shell may proportionally change with the number of the oxygen atoms. The same trend can be seen for the ΔH_t° values of $[Ni(en)_n]^{2+}$ and $[Cu(en)_n]^{2+}$, although the change in the ΔH_t° values with n is much less pronounced compared with those of $[Ni(gly)_n]^{(2-n)+}$, probably due to the invariable charge of the former complexes and a relatively small ΔH_t° value of ethylenediamine.

The work has partially been supported by the Grant-in-Aid for Scientific Research No. 57470054 from the Ministry of Education, Science and Culture and by the Asahi Glass Foundation for Industrial Technology.

Crystal Structures and Characterization of Cobalt(II), Manganese(II), and Zinc(II) Complexes of 2-[Bis-(2-benzimidazolylmethyl)amino]ethanol

Kazuhiro TAKAHASHI, Yuzo NISHIDA, and Sigeo KIDA*
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812
(Received March 26, 1984)

Cobalt(II), manganese(II), and zinc(II) complexes with the tripodal ligand, 2-[Bis(2-benzimidazolylmethyl)-amino]ethanol, bbt, were prepared and characterized by infrared and electronic spectra, magnetism, and conductivities. Their crystal structures were determined by X-ray diffraction method. Crystal data: [Co(bbt)(NCS)$_2$] (**1**), space group $P2_12_12_1$(orthorhombic), a=12.881(1), b=17.970(2), c=9.076(1) Å; [Mn(bbt)(NCS)$_2$](**2**), space group $P2_12_12_1$(orthorhombic), a=18.179(2), b=13.073(2), c=9.097(2) Å; [Zn(bbt)(NCS)$_2$](**3**), space group $P2_1/a$(monoclinic), a=15.421(4), b=14.803(4), c=10.589(3) Å, β=115.81(2)°. The final R values are 0.044 (**1**), 0.054 (**2**), and 0.079 (**3**), for non-hydrogen atoms. The coordination geometries of **1** and **2** can be described as a distorted octahedron. In **3**, the alcoholic oxygen of bbt is not in coordination, hence the zinc ion is five-coordinated forming a highly distorted trigonal bipyramid. In all the complexes, thiocyanate ions coordinate in *cis* form with the nitrogen atoms. The magnetic measurements revealed that **1** and **2** are high spin complexes.

In some metalloenzymes, imidazole nitrogen of histidine moiety coordinates to a metal ion in the active sites.[1] The X-ray crystallographic study of the zinc enzyme, carboxypeptidase A,[2] have revealed the active site structure where two imidazoles are bound to the zinc(II) ion. The metal-substituted carboxypeptidase A showed remarkable changes from the native enzyme in the peptidase and esterase activities.[3] One of the origins of the changes was ascribed to the structural rearrangement of the active site due to the change in coordination occured on the metal ion. Thus, it is interesting to examine for a series of metal complexes how the coordination structure changes depending on metal ions.

In a preceding paper,[4] we reported the crystal structures of [Cu(bbt)X]$ClO_4 \cdot CH_3OH$(X is Cl or Br), whose coordination geometry is a square pyramid. The ligand, bbt, is a benzimidazole-containing ligand with a 3NlO mixed donor set,[5] as shown in Fig. 1, and has a substantial flexibility in coordination structure.

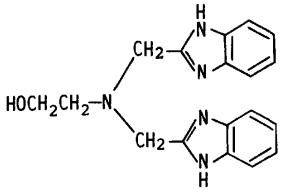

Fig. 1. Chemical structure of bbt.

In this study, we prepared the Co(II), Mn(II), and Zn(II) complexes with the general formula, [M^{II}(bbt)$(NCS)_2$], and determined their crystal structures by X-ray diffraction method in order to investigate the metal-dependent feature of coordination structure. Furher characterizations were carried out by infrared and electronic spectra, magnetism, and conductivities. A part of this work was reported as preliminary form.[6]

Experimental

Preparations. The ligand, bbt, was prepared as described previously.[5] [Co(bbt)(NCS)$_2$](**1**), [Mn(bbt)(NCS)$_2$](**2**), and [Zn(bbt)(NCS)$_2$](**3**) were prepared by the following method. A methanol solution (10 ml) of respective metal(II) nitrate hexahydrate (2 mmol) and a hot methanol solution (30 ml) of bbt·H_2O (2 mmol) were mixed. To this solution was added a methanol solution(10 ml) of NH_4NCS (5 mmol). The resulting solution was allowed to stand for several days, the crystals of **1**, **2**, and **3** were obtained as violet irregular prisms, pale pink prisms, and colorless columnar crystals, respectively. They were filtered and dried *in vacuo* on P_2O_5 for 2 d. **1** Found: C, 48.31; H, 3.86; N, 19.32%. Calcd for $C_{20}H_{19}N_7OS_2Co$: C, 48.39; H, 3.86; N, 19.75%. **2** Found: C, 48.83; H, 3.93; N, 19.87%. Calcd for $C_{20}H_{19}N_7OS_2Mn$: C, 48.78; H, 3.89; N, 19.91%. **3** Found: C, 47.81; H, 3.78; N, 19.19%. Calcd for $C_{20}H_{19}N_7OS_2Zn$: C, 47.77; H, 3.81; N, 19.50%.

Measurements. Infrared spectra were recorded by a Hitachi-Perkin Elmer Grating Infrared Spectrophotometer Model 225. Magnetic susceptibilities were measured by the Faraday method. Conductivities of solutions were measured at 25±1 °C, using a Yanaco Conductivity Outfit MY-8. Absorption spectra were recorded by the use of a Shimadzu UV-240 spectrophotometer for 200—850 nm and a Shimadzu MPS-5000 spectrophotometer for 650—1400 nm. Absorption spectra on nujol mull were obtained by the latter instrument for 250-1400 nm.

X-Ray Crystallographic Analyses. Reflection data of the complexes were measured on a Rigaku-Denki Automatic Four-circle Diffractometer AFC-5, using graphite monochromated Mo $K\alpha$ radiation (λ=0.71069 Å) at 294±1 K. Lattice constants were determined from least-squares fit of 25 strong reflections for **1**($18<2\theta<31°$), 20 reflections for **2**($21<2\theta<39°$), and **3**($18<2\theta<33°$). Intensity data were collected by the $\omega-2\theta$ scan technique in the range of $2.5<2\theta<50°$ with a scan rate of 6°/min for **1**, and 8°/min for **2** and **3**. For weak reflections, the intensity measurement was repeated up to three times depending on their intensities. Three standard reflections were monitored after every 97 reflections, and their intensities of each complex showed good stability during the data collection. The intensity data were corrected for Lorentz and polarization effects, but not for absorption. Independent reflections with $|F_o|>3\sigma(|F_o|)$ were considered as "observed" and used in the structure analyses.

The structure of each complex was solved by the heavy atom and successive Fourier and difference-Fourier methods, and refined by the block-diagonal least-squares procedures. The final refinements were performed using anisotropic ther-

mal parameters for non-hydrogen atoms. The final shifts in the atomic parameters were less than 53(**1**), 19(**2**), and 51%(**3**) of their estimated standard deviations. Final difference-Fourier map of each complex showed no significant electron density of non-hydrogen atom(>1 e Å^{-3}). The crystallographic data, some of the experimental details, and the R values of the complexes are given in Table 1.

All calculations were carried out on a FACOM M-200 computer at the Computer Center of Kyushu University by the use of local version[7] of the UNICS-II[8] and ORTEP programs.[9] The atomic scattering factors were adopted from the International Tables for X-ray Crystallography.[10] Lists of their structure factors and anisotropic thermal parameters have been deposited at the office of the Chemical Society of Japan as a Document No.8441.

The final positional and isotropic thermal parameters of **1**, **2**, and **3** are given in Table 2.

Results and Discussion

Molecular Structures. The ORTEP drawings of **1**, **2**, and **3** are shown in Figs. 2, 3, and 4, respectively. The atomic numberings are labelled in the same manner for all the complexes. Selected bond distances and angles of their coordination spheres are given in Table 3.

As shown in Fig. 2, coordination geometry of **1** is described as a distorted octahedron with the principal axis through N(A), Co, and O. The equatorial plane consists of N(1), N(3), N(5), and N(B). The molecular structure of **2** is similar to that of **1** in general aspect. Each coordination bond length of **2** is slightly longer than the corresponding bond length of **1**. The deviations of the equatorial atoms from the least-squares plane (see Table 4) are smaller for **1** than those for **2**. The bond length differences between **1** and **2** are similar to those between the Co(II) and Mn(II) complexes of [M^{II}(2,2′-bipyridine)$_2$(NCS)$_2$].[11]

The ligand arrangements of **1** and **2** are similar to that of the already reported [Cu(bbt)X]ClO$_4$·CH$_3$OH (X is Cl or Br).[4] In these complexes, the three donor nitrogens(N(1), N(3), N(5)) of bbt occupy three vertexes of the basal plane of a square pyramid and the alcoholic oxygen(O) the apical position. The two benzimidazolyl planes[12] are nearly parallel (dihedral angle of the two planes: 19.5° for **1**; 16.7° for **2**; 4.7° for [Cu(bbt)X]ClO$_4$·CH$_3$OH(X is Cl or Br)).

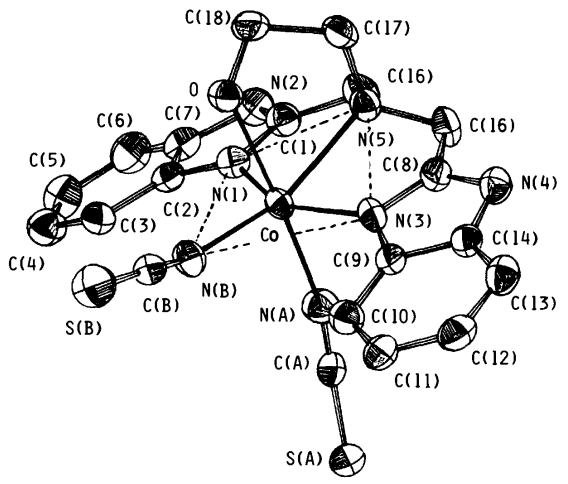

Fig. 2. ORTEP drawing of [Co(bbt)(NCS)$_2$](**1**) (thermal ellipsoids are drawn at 50% probability level).

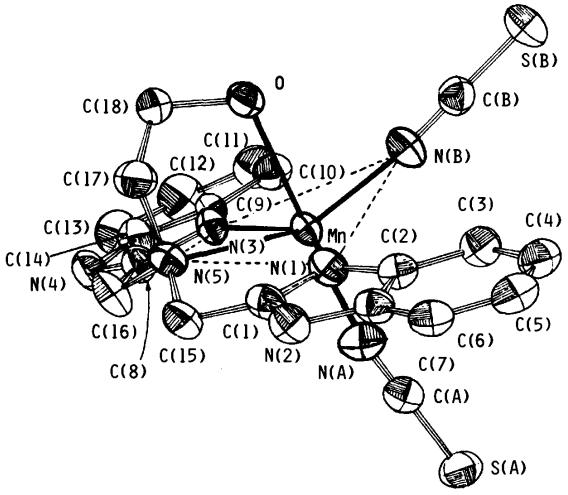

Fig. 3. ORTEP drawing of [Mn(bbt)(NCS)$_2$](**2**) (thermal ellipsoids are drawn at 50 % probability level).

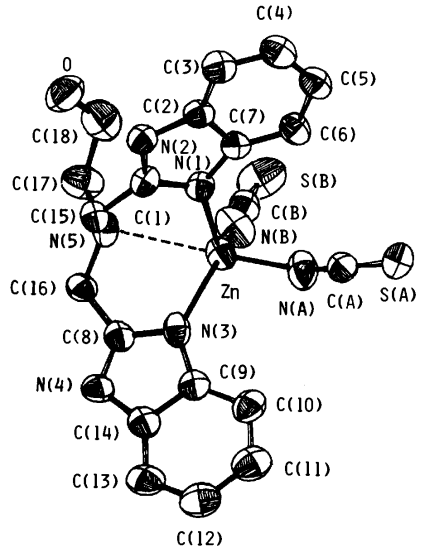

Fig. 4. ORTEP drawing of [Zn(bbt)(NCS)$_2$](**3**) (thermal ellipsoids are drawn at 50 % probability level).

The metal-dependent nature of bbt appears in the Zn(II) complex, **3**. As shown in Fig. 4, the alcoholic oxygen does not coordinate to Zn(II) ion. The coordination number of Zn(II) is five, and the geometry can be regarded as a highly distorted trigonal bipyramid with one weak coordination bond, Zn-N(5)(2.652(7) Å). The dihedral angle of the two benzimidazolyl planes(67.1°) is larger than those of **1**, **2**, and [Cu(bbt)X]ClO_4·CH_3OH(X is Cl or Br).

In all the present complexes, the two thiocyanate ions coordinate in *cis* form with their nitrogen atom. Each M-NCS bond is almost linear, the deviations of the M-N-C angles from 180° being in the range 6—28°.

Intermolecular Distances. Significant intermolecular distances less than 3.51 Å are listed in Table 5. The distances, N(4)-O in **1** and **3**, and N(2)-O in **2** are less than 3 Å, implying the presence of hydrogen bonds. The distances S(A)-O in **1** and **2**, and S(B)-O and S(A)-N(2) in **3** also suggest the presence of weak hydrogen bonds since their distances are less than or nearly equal to the sum of van der Waals radii of sulfur atom (1.8 Å) and oxygen(1.5 Å) or nitrogen atom(1.55 Å).[13]

In **1** and **2**, there seems to exist a contact between

Table 4. Equations of least-squares planes of the equatorial atoms of **1** and **2**, and deviations of the atoms in their coordination spheres

Complex	Equation of least-squares plane[a] [Deviations of atoms from the plane/Å]
1	Plane through N(1), N(3), N(5), and N(B) $0.7771x-0.1214y+0.6176z=0.6308$ [N(1) −0.226, N(3) −0.235, N(5) 0.273, N(B) 0.188, N(A) −2.237, O 2.096, Co −0.160]
2	$0.1210x-0.7897y+0.6015z=0.0266$ [N(1) −0.275, N(3) −0.263, N(5) 0.329, N(B) 0.209, N(A) −2.414, O 2.102, Mn −0.286]

a) The equation is expressed as $Ax+By+Cz=D$, where x,y,z are in Å units referred to the crystallographic axes.

Table 6. Electronic spectral, conductance, and magnetic data

Complex	$\tilde{\nu}_{max}/10^3$ cm^{-1} a) Solution	Mull	Λ_m Ω^{-1} mol^{-1} cm^2	μ_{eff}/B.M. (295 K)
1	17.7[206]	19.4	82b)	4.76
	13.0[≈16]	13.0sh		
2			75c)	5.99
3			80b)	

a) Band maxima in visible region; sh indicates a shoulder; molar extinction coefficient ε(mol^{-1} cm^2) is in brackets. b) Solvent methanol at 1×10^{-3} mol dm^{-3} (25 °C). c) Solvent DMF at 1×10^{-3} mol dm^{-3}(25 °C).

thiocyanate C≡N and S of adjacent complex entities, as shown in Fig. 5. In the case of **3**, no such contact was observed.

Characterization of the Complexes. The infrared spectra of **1**, **2**, and **3** in KBr disks are similar to each other in 400—4000 cm^{-1} region. Each spectrum showed two sharp peaks due to the N-coordinated thiocyanate ions,[14] *i.e.*, at 2108 and 2070 cm^{-1} for **1**, 2097 and 2063 cm^{-1} for **2**, and 2093 and 2070 cm^{-1} for **3**. The splitting of the ν(CN) band is compatible with the *cis*-coordination of the two thiocyanate ions which was verified by X-ray analyses.

Electronic spectra, conductance, and magnetic data are listed in Table 6. The effective magnetic moments of **1** and **2** indicate that both are high spin complexes.[15] The electronic spectra of **1** in methanol and nujol mull are shown in Fig. 6. Both spectra show two broad bands in the visible region (*cf.* Table 6), which are assignable to the $^4T_{1g}(F)\rightarrow{}^4T_{1g}(P)$ and $^4T_{1g}\rightarrow{}^4A_{2g}$ transitions on the assumption of octahedral symmetry.[16] The high intensity and broadening of these bands are implying a considerable distortion from the regular octahedron. The molar conductance value of **1** in methanol indicates a 1:1 electrolyte,[17] suggesting that one of the thiocyanate ions is replaced by a methanol molecule. This is compatible with the observed spectral differences in band position and shape between two phases. The conductivity measurements also showed that **2** and **3** are 1:1 electrolytes in the solutions.[17] No bands due to d-d transitions were observed for **2** and **3** in either nujol or solution.

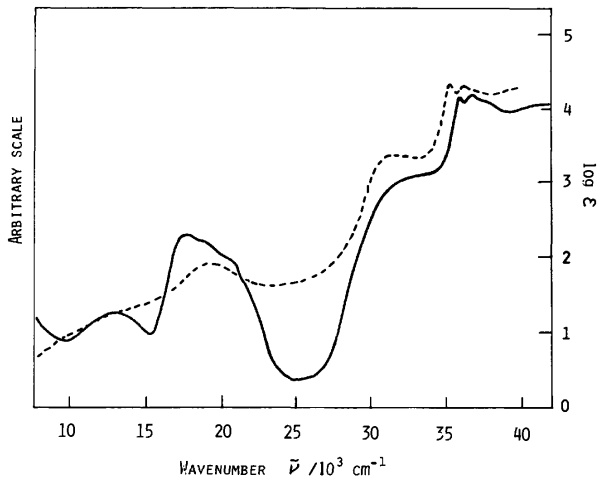

Fig. 6. Electronic spectra of **1**.

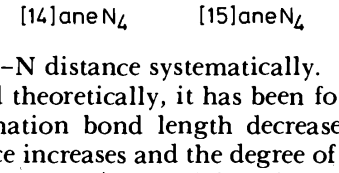
X-Ray Structural Study on Molecular Stereochemistries of Six-coordinate Zn(II) Complexes of *trans*-ZnX_2N_4 Type. Out-of-plane Displacement of Zn(II) from a Plane Formed by In-plane Four Nitrogens

Tasuku Ito,* Masako Kato, and Haruko Ito
Department of Applied Molecular Science, Institute for Molecular Science, Okazaki National Research Institutes, Okazaki 444
(Received March 30, 1984)

Molecular structures of *trans*-bis(isothiocyanato)(1,4,8,11-tetraazacyclotetradecane and 1,4,8,12-tetraazacyclopentadecane)zinc(II) complexes, $[Zn(NCS)_2(C_{10}H_{24}N_4)]$ (**1**) and $[Zn(NCS)_2(C_{11}H_{26}N_4)]$ (**2**), have been determined by X-ray analyses. Crystal data are: for **1**, orthorhombic, space group $P2_1nb$, a=14.502(2), b=18.163(2), c=6.552(1) Å, V=1718.0(4) Å^3, Z=4; for **2**, monoclinic, space group $P2_1/a$, a=14.453(2), b=14.436(1), c=9.213(1) Å, β=104.82(1)°, V=1858.3(4) Å^3, Z=4. Coordination geometries about Zn(II) in **1** and **2** are of the pseudo-octahedral type with two NCS groups at the trans positions, but the Zn(II) ion in each compound deviates from a plane defined by the four nitrogens of the macrocyclic ligand by 0.179 Å on the average in **1** and 0.193 Å in **2**. Structural features of **1** and **2** suggest, complemented with data reported previously for out-of-plane Zn(II) structures, that potential surface regarding the out-of-plane displacement is very flat. The Zn–NCS distance has been found to decrease as an in-plane Zn–N length (or cavity size of the ligand) increases. The observed negative correlation is substantially stronger than those for Ni(II) and Co(III) complexes and discloses the softness of a Zn(II) ion.

This paper is one of a series of investigations on metal ion characteristics viewed from the correlation between axial and in-plane coordination bond lengths of tetragonal six-coordinate complexes. The aim and method of the studies have been described elsewhere along with a historical review.[1] In order to visualize metal ion characteristics from this point of view, we have carried out *ab initio* MO calculations and X-ray analyses for a series of complexes which have the same or very similar coordination environments. In the theoretical approach, we have discussed the metal ion characteristics on the basis of potential energy surfaces of *trans*-$[MCl_2(NH_3)_4]$ ($M=Co^{3+}$, Fe^{2+}, Ni^{2+}, and Zn^{2+}) along the axial and in-plane coordination bonds.[1] In the experimental approach, we have determined the structures of a series of complexes of *trans*-MX_2N_4 type ($M=Ni^{2+}$, Zn^{2+}, and Co^{3+}). Tetraazacycloalkanes with different ring sizes, 1,4,8,11-tetraazacyclotetradecane ([14]aneN$_4$), 1,4,8,12-tetraazacyclopentadecane ([15]aneN$_4$), and 1,5,9,13-tetraazacyclohexadecane ([16]aneN$_4$), were used as in-plane ligands, so as



[14]aneN$_4$ [15]aneN$_4$

to vary an M–N distance systematically. Both experimentally and theoretically, it has been found that the axial coordination bond length decreases as the in-plane distance increases and the degree of the negative correlation is strongly metal ion dependent (Zn^{2+}> Ni^{2+}>Co^{3+}). A summary of the studies[1] and structural details of the Ni(II) complexes[2] have been described elsewhere.

The present paper reports structural details of the compounds, $[Zn(NCS)_2([14]aneN_4)]$ (**1**) and $[Zn(NCS)_2([15]aneN_4)]$ (**2**). We have tried to synthesize *trans*-dichloro- and *trans*-bis(isothiocyanato)zinc(II) complexes with the tetraazacycloalkanes. We succeeded in the isolation of single crystals suitable for X-ray work only for **1** and **2**. Other combinations of in-plane and axial ligands did not afford single crystals of the desired six-coordinate Zn(II) complexes, but gave mostly five-coordinate complexes.

As will be discussed later, the most characteristic feature in molecular stereochemistries of **1** and **2** is the out-of-plane displacement of Zn from the plane formed by four nitrogens of the in-plane ligand (hereafter abbreviated as the N_4 plane). It is well characterized that Zn(II) complexes with porphine or its analogs, $[Zn(H_2O)(tpp)]$ (tpp=5,10,15,20-tetraphenylporphine),[3a] [(Zn(py)(tpyp)] (tpyp=5,10,15,20-tetra(4-pyridyl)porphine),[3b] and Zn(hexylamine)(pc) (pc=phthalocyanine)[3c], are five-coordinate complex with the square pyramidal geometry. It had been suspected that the Zn(II) atom is too large to fit into the cavities of the porphinato or phthalocyanato ligands, though examples of the in-plane structure were recently found for [Zn(pc)][4] and $[Zn(tpp)]\cdot(toluene)_2$.[5] The results of X-ray analyses of **1** and **2** have shown that the cavity sizes of the present macrocyclic ligands are somewhat larger than those of the porphinato or phthalocyanato complexes. Therefore, it seems that whether Zn(II) in six-coordinate complexes of the *trans*-ZnX_2N_4 type takes an out-of-plane position or an in-plane position is not solely determined by the relative sizes of a hole of a macrocyclic ligand and a Zn(II) ion.

Experimental

Materials. The tetraazacycloalkanes, [14]aneN$_4$ and [15]aneN$_4$, were purchased from Strem Chemical Inc.

Preparation of [Zn(NCS)$_2$([14]aneN$_4$)] (1). $ZnCl_2$ was allowed to react with an equimolar amount of [14]aneN$_4$ in

H_2O at 50 °C for 1 h. To the filtered solution was added two equivalents of KSCN at room temperature. Immediate complexation occurred to yield a white precipitate. The product was dissolved in $CHCl_3$ and the filtered solution was evaporated to dryness. The residue was recrystallized from nitromethane. Anal. Calcd for $[Zn(NCS)_2([14]aneN_4)]=ZnS_2C_{12}H_{24}N_6$: C, 37.74; H, 6.34; N, 22.01%. Found: C, 37.65; H, 6.42; N, 21.94%. IR (Nujol mull): 3210(NH), 2025(CN) cm^{-1}.

Preparation of [Zn(NCS)$_2$([15]aneN$_4$)] (2). This compound was synthesized in a similar way using [15]aneN$_4$ in place of [14]aneN$_4$. The crude product was recrystallized from acetonitrile. Anal. Calcd for $[Zn(NCS)_2([15]aneN_4)]=ZnS_2N_6C_{13}H_{26}$: C, 39.44; H, 6.62; N, 21.23%. Found: C, 39.70; H, 6.71; N, 21.50%. IR (Nujol mull): 3180(NH), 2050(CN) cm^{-1}.

Measurements. IR spectra were recorded on a HITACHI 295 spectrophotometer.

Collection and Reduction of X-ray Diffraction Data. Diffraction data were obtained on a Rigaku AFC-5 four-circle diffractometer with use of graphite-monochromatized Mo $K\alpha$ radiation. The intensity data were corrected for Lorentz-polarization effects. Absorption corrections were applied with a numerical integration procedure with a Gaussian grid (6×6×6). The procedures used for data collection were standard and have been described previously.[6] Pertinent crystallographic data for the compounds are summarized in Table 1.

Solution and Refinement of the Structures. Both the structures were solved and refined by standard Patterson, Fourier, and block-diagonal least-squares techniques. The atomic scattering factors for non-hydrogen atoms were taken from Ref. 7 and those for hydrogen from Stewart, Davidson, and Simpson.[8] The effects of anomalous dispersion for non-hydrogen atoms were corrected in structure factor calculations. The weights (w) were taken as $w=[\sigma_c^2+(0.015|F_o|^2)]^{-1}$. Non-hydrogen and hydrogen atoms were refined anisotropically and isotropically, respectively.

Calculations of the refinements for both the compounds converged nicely. However, we noticed in the structure of compound **1** thus obtained that a thermal ellipsoid of the Zn atom is extraordinarily elongated along the normal to the N_4 plane of the [14]aneN$_4$ ligand. The Zn atom in **1** was found to take an out-of-plane position and thus the two axial coordination bond distances differed substantially from each other. Even the shorter axial coordination bond length [Zn–N(5)=2.247(6) Å] was somewhat longer than normal Zn(II)–NCS bond lengths.[9] Then we collected intensity data for another crystal of **1** grown from a chloroform–methanol mixture and solved the structure. The resultant structural features were essentially the same. The situation seemed to be similar to that reported in the erroneous structure analysis

on an aqua(tetraphenylporphinato)zinc(II) complex, [Zn(H_2O)(tpp)],[10] the structure of which was later redetermined by taking disorder in the Zn atom location into consideration.[3a] Then the structure of **1** was solved in a similar way with the Zn atom in two disordered positions.[11] The Zn atom was located at two positions, equidistantly above (Zn) and below (Zn') the N_4 plane. Full-matrix least squares calculations were carried out under the restricted condition that the sum of occupancy factors (P) of Zn and Zn' equals one. Final P_{Zn} and $P_{Zn'}$ values were 0.64 and 0.36. In the converged structure, geometries of [Zn(NCS)$_2$([14]aneN$_4$)] and [Zn'(NCS)$_2$([14]aneN$_4$)] are related approximately to each other by inversion at the center of the N_4 basal plane (Ct).

For **1**, all the hydrogen atoms were located by the difference syntheses and their positional and isotropic thermal parameters were refined. However, for **2**, 19 hydrogens out of 26 were found and included in the calculations.

The final R indices are listed in Table 1. Positional parameters for non-hydrogen atoms are given in Tables 2 and 3.[12] All the calculations were carried out on the HITAC M-200H computer at the Computer Center of the Institute for Molecular Science with the Universal Crystallographic Computation Program System UNICS III.[13]

Description of the Structure

Figure 1 shows perspective views of the complexes **1** and **2**. As shown in Fig. 1, the geometry about the Zn in each compound is of the pseudo octahedral type with NCS^- groups at the trans positions. Table 4 lists relevant bond lengths and angles. Deviations of atoms included in the first coordination sphere from the N_4 best plane are given in Table 5. Figure 2 represents perspective diagrams of the coordination environments of the Zn atoms in **1** and **2**.

[Zn(NCS)$_2$([14]aneN$_4$)] (1). The structure of this compound was solved assuming that the Zn atom is disordered above and below the N_4 plane. The Zn and Zn' atoms are displaced by 0.177(3) and 0.184(4) Å from the N_4 plane toward the N(5) and N(6) atoms of the NCS^- ligands, respectively. The overall stereochemistry of the macrocyclic ligand is essentially the same as that found for Ni(II),[2] Zn(II),[15,16] Pd(II),[16] Pd(IV),[16] and Ag(II)[16] complexes with [14]aneN$_4$. The alternating six- and five-membered chelate rings are in the stable chair and gauche conformations, respectively. Intermolecular hydrogen-bonds operate between sulfur atoms and secondary amine groups of the neighbouring complexes.[17] If the complex with the ring conformations assumes a structure with high symmetry such as C_{2h} or C_i, the occupancy factors of the Zn and Zn' atoms should be 0.5 each. However, intramolecular and packing interactions including the hydrogen

a) Atoms used in the calculation of the best plane.

bonds lower more or less the symmetry of the skeletal structure of the macrocyclic ligand to cause the difference in the occupancy factors.

$[Zn(NCS)_2([15]aneN_4)]$ (2). Three six-membered and one five-membered chelate rings adopt a chair-chair-skew-gauche conformational sequence. The ring conformation of this type has been found for $[Ni(NCS)_2([15]aneN_4)]$.[2] But the [15]aneN$_4$ ligand in $[NiCl_2([15]aneN_4)]$[2] and $[\{Zn([15]aneN_4)\}_3(O_2COCH_3)_2](ClO_4)_4$,[15] and that in $[CoCl_2([15]aneN_4)](ClO_4)$ (green form)[18] have been reported to take chair-skew-chair-gauche and skew-skew-skew-gauche conformations, respectively.

The Zn atom in this compound also takes an out-of-plane position and is displaced by 0.193(3) Å from the N$_4$ best plane toward the N(5) atom. The Zn-N(6)

distance lengthens to 2.479(6) Å, while the Zn–N(5) distance of 2.095(5) Å is within the normal range. Sulfur atoms are again involved in intermolecular hydrogen-bonds with secondary amine groups of the neighbouring complexes.[17]

It has been reported that, in metal complexes with the [15]aneN$_4$ ligand in the chair-chair-skew-gauche conformation, notable structural distortions arise at the periphery of the N(1) atom, which links a gauche five-membered and a skew six-membered chelate ring.[2] Typical distortions in such compounds are lengthening of an M–N(1) bond and deviation of the N(1) atom from the N$_4$ best plane. But, in compound **2**, such strains are relieved to some extent by the displacement of the Zn atom from the N$_4$ plane. This is evidenced by comparison of bond distances and angles associated with the N(1) atom of the present compound and those for [Ni(NCS)$_2$([15]aneN$_4$)].[2]

Discussion

There are two distinct features in the coordination geometries of compounds **1** and **2**: (i) the Zn atom is displaced *ca.* 0.2 Å from the mean plane formed by the four nitrogens of the macrocyclic ligand; (ii) there is a negative correlation between in-plane and axial coordination bond lengths. The out-of-plane displacement of the Zn causes, in each compound, rather large inequalities in two axial coordination bond lengths. The differences amount to 0.38 Å on the average for both **1** and **2**. The distances between the Zn atoms and the weakly bonded NCS$^-$ groups [Zn–N(6)=2.58(1) Å and Zn′–N(5)=2.53(1) Å for **1**, and Zn–N(6)=2.479(6) Å for **2**] appear to be rather long as coordination bond distances. However, the Zn atoms in these compounds should be described as six-coordinate, since deviations of Zn(II) from basal plane reported for the five-coordinate Zn(II) complexes with the square-pyramidal geometry are much larger. It is interesting to note that, in each compound, the nitrogens of the weakly bonded and the strongly bonded NCS$^-$ groups are nearly equidistant from the mean N$_4$ plane: for **1**, Ct–N(5)=2.35, Ct–N(6)=2.40 Å; for **2**, Ct–N(5)=2.29, Ct–N(6)=2.29 Å (see Fig. 2).

The hole sizes found for the present tetraazacycloalkane complexes (Ct–N distance) are 2.10 Å for **1** and 2.13 Å for **2**, and are larger than those of the Zn(II) porphinato or phthalocyanato complexes (1.98—2.07 Å). In spite of this, the Zn atoms in the present compounds take out-of-plane positions. Table 6 collates bond lengths and angles within the [M([14]aneN$_4$)] moieties of various metal complexes containing the [14]aneN$_4$ ligand. In all the compounds, the [14]aneN$_4$ ligand adopts the same overall stereochemistry with the most stable chelate ring conformations. The values in Table 6 are averaged assuming C_{2h} symmetry for the [M([14]aneN$_4$)] moiety. The compounds are listed in increasing order of the Ct–N distance. Some important facts are noted in Table 6 relative to the observed out-of-plane structures. Except for Zn(II) complexes, all the compounds in Table 6 take the in-plane structures. Interestingly, the largest cation, Ag(II), the ionic radius of which is much larger than a Zn(II) ion, sits precisely in the N$_4$ plane [Ag–N=2.158(2) Å].[19] Furthermore, half of Zn(II) atoms in the crystal structure of [Zn(O_2C-OCH_3)([14]aneN$_4$)](ClO_4) take the in-plane position.[15] These observations suggest that simple argument, such that Zn(II) is too large to be accomodated into the cavity in a planar fashion to result in the out-of-plane structure,[3a] must be changed. In Table 6, various bond lengths and angles increase or decrease smoothly, or remain unchanged on going from shorter to longer Ct–N structures, in general. However, it can be seen that some structural parameters such as bond angles of N–M–N(6*) and C–C–C (see footnotes of Table 6 for notations) deviate from the trend in the out-of-plane Zn structures and return to the original tendency in the Ag(II) complex. There is no doubt that cumulative bond length and angle strain is relieved by taking the out-of-plane structure in the Zn(II) complexes. It is also certain from Table 6 that sizes of Ag(II) and Zn(II) ions are larger than a natural cavity size of the [14]aneN$_4$ ligand. In the case of the Ag(II) complex, much larger electronic strain would be introduced if the Ag(II) took an out-of-plane position.

A Zn(II) ion has an electronic configuration of $(3d)^{10}$ and thus no ligand field stabilization due to 3d electrons takes place for a Zn(II) complex. *Ab initio* MO calculations for *trans*-[$ZnCl_2(NH_3)_4$] show that the potential surface along the direction of the out-of-plane displacement of Zn is very flat.[20] It is likely that very similar situations exist for the Zn(II) complexes with the out-of-plane structures. Since the potential surface along the direction in an isolated complex is very flat, it would be affected easily in its crystalline state by the potential from surrounding ions and packing forces. Subtle intra- or intermolecular forces including the intermolecular hydrogen bonds seem to be responsible for the out-of-plane structures. Conversely, it follows that a Zn(II) ion might take the in-plane position if the situation were otherwise. In fact, such examples have been found for [Zn(O_2COCH_3)([14]aneN$_4$)](ClO_4), and [{Zn([15]aneN$_4$)}$_3$(O_2COCH_3)$_2$](ClO_4)$_4$.[15] The out-of plane structures found for the present Zn(II) complexes are associated not only with the relative size between Zn(II) and the cavity but also with the flatness of the potential surface along the normal to the N$_4$ plane.

The $^{13}C\{^1H\}$ NMR spectrum of compound **1** in $CDCl_3$ shows only four signals, which are assignd to C–$\underline{C}H_2$–C (δ, 28.6), two N–$\underline{C}H_2$ carbons (δ, 47.9 and 49.4), and N$\underline{C}$S (δ, 133.9). The observed spectral pattern indicates that compound **1** has C_{2h} symmetry in solution. Such symmetry can be expected when the Zn atom sits precisely in the N$_4$ plane and the [14]aneN$_4$ ligand takes a chair-gauche-chair-gauche conformation, or when the Zn atom moves up and down passing through the N$_4$ hole at a faster rate than an NMR time scale. We failed to answer this question.[21] As for compound **2** in solution, whether the Zn takes the in-plane position or the out-of-plane position was not clear from the NMR study, because **2** has no symmetry element even if Zn were in the in-plane position.

On going from the fourteen-membered to the fifteen membered rings, average in-plane Zn–N or Ct–N distances increased by *ca.* 0.04 Å. The amount of the increase is slightly smaller than those in the Ni–N dis-

tances (0.05—0.06 Å) for one ring member added similarly in Ni(II) complexes with the same tetraazacycloalkanes.[2] The increases are not as large as expected from calculations of strain energy minimizations for free ligand molecules (0.10—0.15 Å).[22] The shorter axial coordination bond length (Zn–N(5)) in **1** is longer than the corresponding distance (Zn–N(5)) in **2**. The longer one (Zn–N(6)) in **1** is also longer than the corresponding distance (Zn–N(6)) in **2**. That is, the axial coordination bond length decreases as the in-plane distance increases. The same relationship also holds when the mean distance of Zn–N(5) and Zn–N(6) or an average Ct–NCS^- distance is taken as the "axial bond length".

It is most reasonable to consider the observed correlation to be a result of the electronically controlled cis effect, since the crystal structures of **1** and **2** show no significant steric effects that would cause the correlation. The degree of the correlation found for the Zn complexes is substantially stronger than those reported for a series of similar Ni(II) and Co(III) complexes.[1]

We have previously discussed the electronic origin that gives rise to the correlations between intramolecular coordination bond lengths from the viewpoint of the potential energy surface.[1] A section of the potential surface along the in-plane and axial coordination bond axes is an ellipse which is elongated in the M–X directon and has a tilt with respect to the coordination bond axes. Such features of the potential surface are primarily responsible for the experimentally observed correlations. Furthermore, the shape of the potential surface, *i.e.*, the degree of the correlation is closely related to softness or hardness in the HSAB concept[23] for metal ions.[1] The present result indicates that a Zn(II) ion is much softer than a Ni(II) ion, though Pearson classifies both of these ions into borderline between soft and hard metal ions.[23]

In structures containing the thiocyanate ion bonded to a metal atom through nitrogen, a wide range of metal-isothiocyanate bond angles have been obtained, though the majority of examples fall in the range 150—180°.[24] It has also been suggested that inter- and intra-molecular forces affect this angle though such effects are often difficult to prove.[24] The angles found for the present complexes are somewhat smaller than the normal values. The values for **1** range from 132.0(10)° to 137.8(9)°. For **2**, one of the angles [Zn–N(6)–C(13)] narrows down to 129.9(6)°, which is comparable to the smallest value so far reported, 129°, for bis(isothiocyanato)- bis(*N,N'*-dimethylethylenediamine)-copper(II).[24]

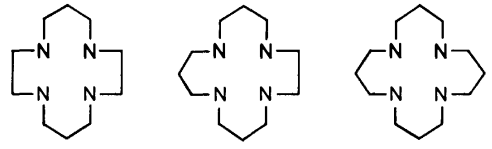
The Structures of *trans*-Dichloro- and *trans*-Bis(isothiocyanato)nickel(II) Complexes with 1,4,8,11-Tetraazacyclotetradecane, 1,4,8,12-Tetraazacyclopentadecane, and 1,5,9,13-Tetraazacyclohexadecane. The Negative Correlation between the Axial and In-plane Coordination Bond Lengths in Tetragonal Ni(II) Complexes of the *trans*-NiX_2N_4 Type

Tasuku Ito,* Masako Kato, and Haruko Ito
Department of Applied Molecular Science, Institute for Molecular Science, Okazaki National Research Institutes, Okazaki 444
(Received February 9, 1984)

The molecular structures of the six titled compounds, which contain 14-membered, 15-membered, or 16-membered tetraazamacrocyclic ligands, have been determined by single crystal X-ray analyses. On going from smaller to larger rings, the average in-plane Ni–N distance increased by 0.05—0.06 Å for each ring member added. For a series of complexes with given axial ligands (X), the mean axial coordination bond length (Ni–X) was found to decrease as the average in-plane distance (Ni–N) increased. The degree of the negative correlation was stronger for complexes with weaker axial ligands (Cl^-) than for those having stronger axial ligands (NCS^-). Similar negative interrelationships between the Ni–X and Ni–N distances have been found for complexes which have the same in-plane macrocyclic ligand, but different axial ligands. The molecular stereochemistries of the complexes have been discussed. For all the complexes with the 1,4,8,12-tetraazacyclopentadecane ligand, a structural disorder of the same type has been found: gauche five-membered and skew six-membered chelate rings are randomly interchanged in the crystal. This arises mainly from the similarity of the bite angles of the five- and six-membered chelate rings in the gauche and the skew conformations respectively.

This paper is one of a series of investigations of metal-ion characteristics viewed from the correlation between the axial and in-plane coordination bond lengths in tetragonal six-coordinate complexes of the *trans*-MX_2N_4 type ($M=Ni^{2+}$, Zn^{2+}, and Co^{3+}). The aim and method of the studies have been described in a previous paper along with a historical review.[1] In this series of investigations, we have carried out *ab initio* MO calculations and X-ray analyses for a series of complexes which have the same or very similar coordination environments. Both experimentally and theoretically, it has been found that the axial M-X distance decreases as the in-plane M–N distance increases. The degree of the negative correlation is strongly metal ion dependent and varies in the order: $Zn^{2+}>Ni^{2+}>Co^{3+}$. A summary of the studies[1] and the structures of the Zn complexes[2] have been described elsewhere. The present paper reports the structural details and the correlation observed for the titled Ni(II) complexes: [$NiCl_2$([14]aneN$_4$)] (**1**), [$NiCl_2$([15]aneN$_4$)] (**2**), [$NiCl_2$([16]aneN$_4$)] (**3**), [Ni(NCS)$_2$([14]aneN$_4$)] (**4**), [Ni(NCS)$_2$([15]aneN$_4$)] (**5**), and [Ni(NCS)$_2$([16]aneN$_4$)] (**6**).



[14]aneN$_4$ [15]aneN$_4$ [16]aneN$_4$

As in-plane ligands, the tetraazacycloalkanes shown above were employed. On going from smaller to larger rings, the average M–N bond lengths can be varied systematically.[3,4] As axial ligands (X), we chose Cl^- and NCS^-, which have a relatively weak and a strong ligand field strength respectively, so that it was possible to investigate the effect of the ligand field strength on the correlation.

The structure of **1** was reported previously by Bosnich *et al.*[5] We have now redetermined the structure, aiming at an improvement in the accuracy of the structure analysis, and also because the atomic parameters for this compound have not been reported.

In this study, we have also measured the far-infrared spectra of a series of complexes of this type in order to see if the electronic interaction between the in-plane and axial ligands is manifested in the stretching vibrations of the coordination bonds.

Experimental

Materials. All the compounds **1**—**6** were prepared according to the reported synthetic procedures.[3] Blue violet column crystals of **2**, violet block crystals of **5**, and blue block crystals of **6** were grown slowly from a methanol solution. Pink prismatic crystals of **1**, green polyhedral crystals of **3**, and red violet plates of **4** were obtained by recrystallization from a methanol–chloroform mixed solvent, nitromethane, and acetonitrile, respectively.

Measurement. The far-infrared spectra were recorded as nujol mull on polyethylene film with a Nicolet FT-IR 7199A spectrometer.

Collection and Reduction of X-ray Diffraction Data. The diffraction data were obtained on a Rigaku AFC-5 four-circle diffractometer by the use of graphite-monochromatized Mo $K\alpha$ radiation. The lattice parameters were obtained from the least-squares fit of 40—50 2θ values with $26°<2\theta<30°$. The $\theta-2\theta$ scan mode was used at a scan rate of 3° min^{-1} to record the intensities. The intensities of three standard reflections were monitored for each crystal at 100-

a) ($|F_o|>3\sigma(|F_o|)$)

reflection intervals. The fluctuations of their F_o values were within experimental error. The intensity data were corrected for the Lorentz-polarization effects and for the absorption. The pertinent crystallographic data for the compounds are summarized in Table 1.

Solution and Refinement of the Structures. All the structures were solved and refined by standard Patterson, Fourier, and block-diagonal least-squares techniques. The atomic scattering factors for non-hydrogen atoms were taken from Ref. 6, and those for hydrogen, from Stewart, Davidson, and Simpson.[7] The effect of anomalous dispersion for non-hydrogen atoms was corrected in the structure factor calculations. The weight (w) was taken as $w=[\sigma_c^2+(0.015|F_o|)^2]^{-1}$, where σ_c denotes a standard deviation of F_o as calculated from the counting statistics.

In the cases of Compounds **2** and **5**, each of which has the [15]aneN$_4$ ligand with a six-membered chelate ring and a five-membered chelate ring in the skew and gauche conformations respectively, significant disorder was found in the crystal structure. The disorder occurs in such a way that the gauche five-membered chelate ring and the skew six-membered chelate ring are randomly interchanged in the crystal. The general structural features found for the moiety are depicted in Fig. 1. For the disordered chelate rings, Fourier maps showed relatively sharp peaks for nitrogens, but very broad peaks for carbon atoms. The central carbon (C_b) was generally not found clearly in a Fourier map, and so it was located by a difference synthesis. The carbon atom adjacent to the nitrogen (C_a or C_c) appeared as a broad single peak, but was not observed as two peaks corresponding to the five- and six-membered chelate rings. Therefore, the structures were refined assuming occupancy factors of 1.0 for C_a and C_c, and 0.5 for C_b.

Except for Compounds **2** and **5** which involve disorder, the difference syntheses permitted the location of all the hydrogen atoms, and their positional and isotropic thermal parameters were refined. The final R indices are listed in Table 1, while the positional parameters for non-hydrogen atoms are given in Table 2.[8]

All the calculations were carried out on the HITAC M-200H computer at the Computer Center of the Institute for Molecular Science using the Universal Crystallographic Computation Program System UNICS III.[9]

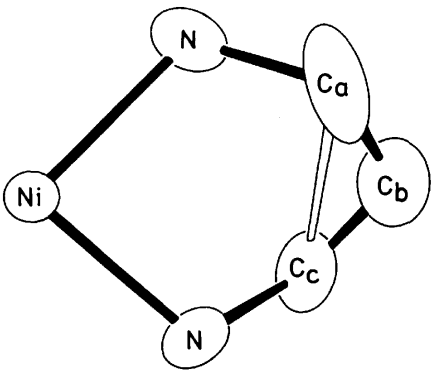

Fig. 1. Disorder of the gauche five-membered and skew six-membered chelate rings in [15]aneN$_4$ complexes.

Description of the Structures

Figure 2 shows the perspective views of Complexes **1**—**6**. As shown in Fig. 2, the geometries about Ni in all the compounds are of the *trans*-NiX_2N_4 type. The coordination bond distances and angles are given in Table 3. Table 4 lists the deviations of the atoms in a first coordination sphere from a NiN_4 best plane formed with Ni and the in-plane four nitrogens for Complexes **3**, **5**, and **6**. The data for **1**, **2**, and **4** are not given, since in these compounds the Ni atom lies at a center of symmetry.

trans-[NiCl$_2$([14]aneN$_4$)] (1). The total stereochemistry is the same as that reported previously.[5] The accuracy of the bond lengths and angles is raised approximately one order of magnitude, as evidenced by

their esd values. The alternating two six- and two five-membered chelate rings are in the stable chair and gauche conformations, respectively.

trans-*[NiCl₂([15]aneN₄)]* (**2**). The structure of this compound was solved under the crystallographic requirement that the Ni atom lies at a center of symmetry, even though the entire molecule cannot have such a symmetry element. This is because of the structural disorder described in the previous section. As is shown in Fig. 2(b), the three six-membered and one five-membered chelate rings are in a chair–skew–chair–gauche conformational sequence.

a) Parameters are multiplied by 10^5. b) Parameters are multiplied by 10^4.

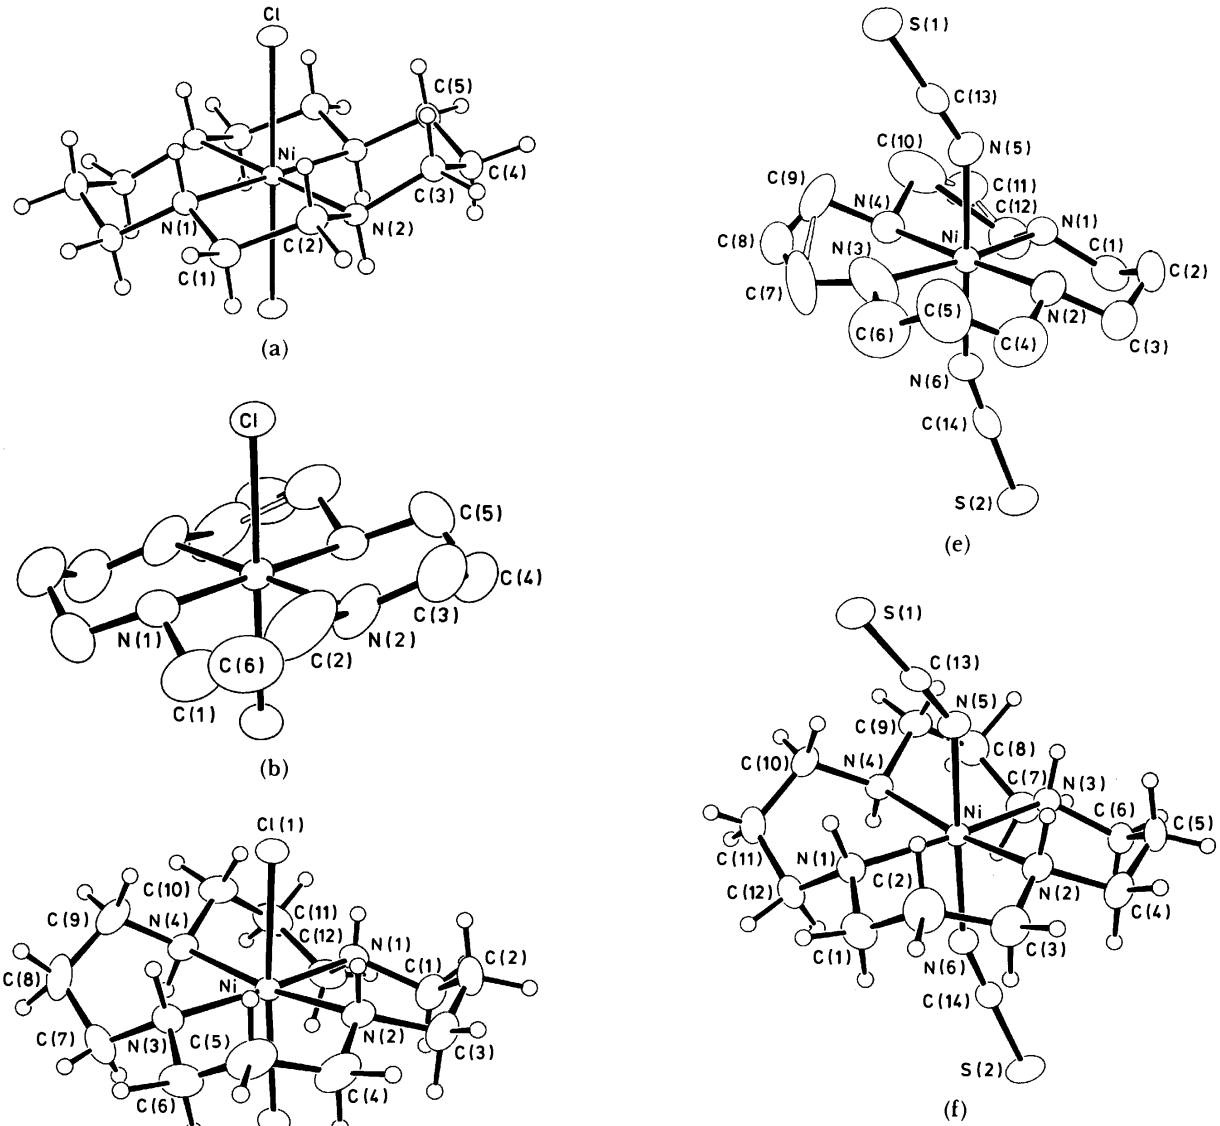

Fig. 2. Perspective views of the structures: (a) $[NiCl_2([14]aneN_4)]$(**1**); (b) $[NiCl_2([15]aneN_4)]$ (**2**); (c) $[NiCl_2([16]aneN_4)]$ (**3**); (d) $[Ni(NCS)_2([14]aneN_4)]$ (**4**); (e) $[Ni(NCS)_2([15]aneN_4)]$ (**5**); (f) $[Ni(NCS)_2$-$([16]aneN_4)]$ (**6**). In (b) and (e), which involve disorder, one linkage of the macrocyclic skeleton is shown with solid bonds, and the alternative with open bonds. The drawing (d) corresponds to the complex (b) in Fig. 4.

trans-[NiCl₂([16]aneN₄)] (3). The entire molecule constitutes a crystallographically asymmetric unit and thus has no rigorous symmetry. However, as Fig. 3 shows, there is an approximate symmetry plane, which lies perpendicular to the coordination plane of the [16]aneN$_4$ ligand, passing through Ni, N(2), and N(4) atoms. The four six-membered chelate rings adopt a chair-chair-skew-skew conformational sequence. The coordination bond lengths and angles show that the coordination geometry deviates appreciably from D_{4h} symmetry (Table 3). The Ni–N(4) distance [2.211(3) Å] is by far the longest among the Ni–N bonds, and the two Ni–Cl distances differ by 0.107 Å.

trans-[Ni(NCS)$_2$([14]aneN$_4$)] (4) There are four crystallographically independent [Ni(NCS)$_2$([14]-aneN$_4$)] complexes, in each of which Ni resides at a center of symmetry. The total stereochemistries of the [14]aneN$_4$ ligands in these complexes are essentially the same and are very similar to that found for **1**. The coordination bond lengths are slightly different in the four complexes. The in-plane Ni–N distances range from 2.064(2) to 2.082(2) Å, while the corresponding axial Ni–N (NCS) distances vary from 2.130 (2) to 2.075(6) Å. Though the ranges of the in-plane or axial bond lengths are very limited, a negative correlation is noted between them (*vide infra*).

Of particular interest is the wide variety of orientation modes of the NCS$^-$ groups (Fig. 4). The tilts of the Ni–N (NCS) bonds from the normal to the NiN$_4$ best planes range from 1.3° to 1.9°. The Ni–N–C and N–C–S angles within the NCS$^-$ groups range from 156.2(2) to

168.2(2)° and from 177.8(5) to 179.2(2)°, respectively. All the NCS^- groups are involved in intermolecular hydrogen-bonds between the sulfur atoms and the secondary amine groups of the neighboring complexes,[10] forming a linear chain along the a-axis. The orientations of the NCS^- groups are mainly determined by these hydrogen-bonds.

trans-[Ni(NCS)$_2$([15]aneN$_4$)] (5) In this compound, the three six-membered rings and one five-membered ring are in a chair–chair–skew-gauche conformational sequence. Although the total stereochemistry of the [15]aneN$_4$ ligand differs from that in **2**, a similar structural disorder was observed for the gauche five-membered and the skew six-membered chelate rings (Fig. 2(e)). The combination of the chiral configurations of the four nitrogen donors are the same

as those in **3**. The structural distortions characteristic of the nitrogen configurations will be discussed later.

trans-*[Ni(NCS)$_2$([16]aneN$_4$)] (**6**)* Four six-membered chelate rings adopt chair–chair–skew–skew conformations, as in the *trans*-dichloro analogue **3**. The nitrogen configurations are the same as those in **3** and **5**. The distortions arising from the nitrogen configuration will be discussed in a subsequent section. The orientation of the NCS^- ligands is, again, caused by intermolecular hydrogen-bonds between the sulfur atoms and the amine nitrogens of the neighboring complexes.[10]

Discussion

Stereochemistries of Coordinated Macrocyclic Ligands. It has been known that the cyclic nature of the tetraazacycloalkane ligand gives rise to isomerism as a result of the difference in the combination of the chiralities of the four coordinated secondary amine nitrogens.[11] In all the present complexes having the [14]aneN$_4$ ligand, the macrocyclic ligands adopt the same nitrogen configurations, and thereby have the same overall skeletal structure. Alternating two six- and two five-membered chelate rings are in the chair and gauche conformations, respectively. This ring conformation has been known to be the most strain free among the five possible isomers when the [14]aneN$_4$ ligand is coordinated in a planar fashion.[11] The same stereochemistry of the [14]aneN$_4$ ligand has been found in the crystal structures of [Ni([14]aneN$_4$)](PF$_6$)$_2$,[12a] [Ni([14]aneN$_4$)I]I,[12b] [NiCl$_2$([14]aneN$_4$)](ClO$_4$),[13] [Pd([14]aneN$_4$)](ClO$_4$)$_2$,[14] [PdCl$_2$([14]aneN$_4$)](NO$_3$)$_2$,[14] [Pd([14]aneN$_4$)][PdCl$_2$([14]aneN$_4$)](ClO$_4$)$_4$,[14] [Zn(O$_2$CCH$_3$)([14]aneN$_4$)](ClO$_4$),[15] and [Ag([14]aneN$_4$)](ClO$_4$)$_2$ (P$\bar{1}$-form)[16].

Busch and his associates separated two configurational isomers each for *trans*-[CoCl$_2$([15]aneN$_4$)]$^+$ and *trans*-[CoCl$_2$([16]aneN$_4$)]$^+$ and discussed the stereochemical stabilities of the isomers and other possible configurational isomers on the basis of strain energy calculations, the ^{13}C NMR spectra, and the chemical properties.[4] The overall stereochemistry of the macrocyclic skeleton found for **5** is the same as that reported for the most stable brown isomer of [CoCl$_2$([15]aneN$_4$)]$^+$ (Isomer I in their notation). However, the overall structure of **2** is the type of neither the Isomer I nor the Isomer II of [CoCl$_2$([15]aneN$_4$)]$^+$. The latter was found to be a skew-skew-skew-gauche form.[4,17] The calculations of strain-energy minimization for *trans*-[CoCl$_2$([15]aneN$_4$)]$^+$ show that the conformational structure of **2** is the second least strained among six possible configurational isomers.[4] We did not obtain in the synthetic and X-ray studies any indication of the presence of isomers for the trans-dichloro Ni(II) complex of [15]aneN$_4$. The skeletal structures of [16]aneN$_4$ found in **3** and **6** are the same as that reported for the green isomer of [CoCl$_2$([16]aneN$_4$)]$^+$ (Isomer II).[4]

It is known that the cyclic nature of tetraaza macrocyclic ligands in a planar coordination introduces strain in the metal-donor atom distance, the chelate (bite) angle subtended at the central metal atom, and so on.[11] Such strain is generally relieved by relaxing the coplanarity of the metal-donor atom set. Except for **1**, **2**, and **4**, in which Ni atoms reside at the inversion center, all the structures show a distortion of the NiN$_4$ set toward the tetrahedral character (Table 4).

The combinations of the nitrogen configurations in complexes **3**, **5**, and **6** are all of the same type : three NH protons are above, and the remaining one below, the NiN$_4$ plane. The former ones are bound to three nitrogens, N(1), N(2), and N(3), which are involved in two adjacent six-membered chelate rings in the chair form, while the latter is bound to N(4), which links two skew rings or a skew and a gauche ring. The following structural distortions are commonly noted in these compounds and are likely to be characteristic of the skeletal structure arising from the configuration : inequality in the in-plane Ni–N distances, inequality in the two axial bond lengths, distortion of the in-plane donor atom set of a tetrahedral character, and a fairly large deviation of the Ni atom from the mean NiN$_4$ plane. Among the complexes, the distortion of the in-plane donor atom set toward the tetrahedral character becomes larger in this order: **6**>**3**>**5**. This is ascribed to the suitability of size between the hole of the macrocycle and the high-spin octahedral Ni^{2+}: (i) the 16-membered macrocycle is less fit for Ni^{2+} than the 15-membered one, and (ii) the cavity size of the [16]aneN$_4$ ligand in **6** enlarges as compared with that of **3**, because of the cis effect (see below).

When the cavity size is larger than the natural or the best fit size for Ni^{2+}, the deviations of carbon atoms adjacent to donor nitrogens from the mean plane of the chelate ring generally become larger. As a result, in Complexes **3** and **6**, which have [16]aneN$_4$, C(9) and C(10) atoms are disposed so close to one of the axial coordination sites as to exert a steric effect, and the resulting steric hindrance causes the lengthening of the axial bond [Ni–Cl(1) in **3** and Ni–N(5) in **6**].

Correlation between Axial and In-plane Coordination Bond Lengths. As expected, the in-plane Ni–N distance increases with an increase in the number of ring members of the macrocyclic ligand. This increase in the Ni–N distance amounts to 0.05—0.06 Å for each ring member added. The increase is not, however, as large as expected from calculations of the strain energy minimization for free ligand molecules (0.10—0.15 Å).[18] The observed correlations between the average Ni–N and Ni–X distances are shown in Fig. 5. The data reported previously for the same types of complexes with similar tetraazamacrocyclic or diamine ligands are also included: *trans*-[NiCl$_2$(N$_4$7)],[20] *trans*-[NiCl$_2$(N$_4$9)],[20] *trans*-[Ni(NCS)$_2$(NH$_3$)$_4$],[21] and *trans*-[Ni(NCS)$_2$(en)$_2$].[22] As is seen in Fig. 5, there exists a negative correlation for each series of complexes with given axial ligands: the axial coordination bond length decreases as the in-plane distance increases. Similar observations have also been reported for some other systems.[23–25] The results in Fig. 5 were obtained assuming that each metal-donor atom set (*trans*-NiX$_2$N$_4$) has D$_{4h}$ symmetry. Although some Ni–X and Ni–N distances in Fig. 5 show quite a large standard deviation because of distortion from the D$_{4h}$ symmetry, there is no doubt that the negative

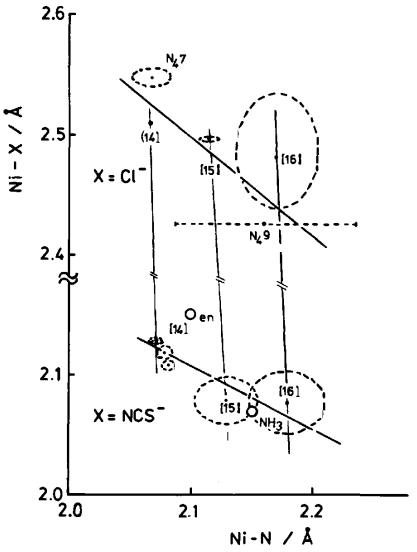

Fig. 5. Correlation between axial and in-plane coordination bond lengths in Ni(II) complexes of the *trans*-NiX_2N_4 type. Size of a dashed ellipse or line illustrate an esd obtained upon averaging chemically or crystallographically nonequivalent distances,[19] while that of a full-line figure within the dashed one shows an arithmetic mean of esd's for individual metal-ligand distances. Ligand abbreviations: [14]=[14]aneN$_4$, [15]=[15]aneN$_4$, [16]=[16]aneN$_4$, en=ethylenediamine, and N$_4$7 and N$_4$9 see Ref. 20. For NH_3 and en complexes, no esd values were reported.

interrelationship holds. The data points for Complexes **3** and **6** deviate from the smoothed lines in Fig. 5. In these complexes, there exists an obvious steric effect that causes a lengthening of the M-X bond, as described previously. Unless the steric constraint were present, the mean M-X bond distances in these complexes would be somewhat shorter and the data points would approach the smoothed lines.

It is interesting to note that the data for the four crystallographically inequivalent molecules of *trans*-[Ni(NCS)$_2$([14]aneN$_4$)] show a clear trend for the negative correlation within a very limited range of metal-ligand distances (see Fig. 5).

When the $NiCl_2N_4$ and $Ni(NCS)_2N_4$ systems are compared, the slope for the chloro complexes is steeper than that for the isothiocyanato complexes. This indicates that the weaker the axial ligand field is, the stronger the correlation. The effect of the ligand field strength of the axial ligand upon the correlation has been explained theoretically on the basis of the features of the potential energy surface.[1]

From the data given in Fig. 5, it is possible to see changes in the M-N distances of complexes with the same in-plane ligand upon alterations in the axial ligand. Although the number of data for such comparisons are very limited and the changes in the M-N distances are very small, the thin lines in Fig. 5 likely show the presence of a negative dependence of the in-plane Ni-N lengths on the axial Ni-X bond distances.

Coordination geometries found for Ni(II) complexes with 1,4,7,10-tetraazacyclotetradecane (N$_4$7) may provide further evidence for the occurrence of such an electronic interaction between the axial and in-plane ligands. Interestingly, the structural analyses reveal that coordination geometries of $[NiCl_2(N_47)]$[25] and $[Ni(NCS)_2(N_47)]$[26] are of the trans-type and of the cis-type with the macrocycle folded, respectively. It is most reasonable to consider the observed cis and trans stereochemistries to be a result of the electronically controlled cis effect. If strong axial ligands such as NCS^- are to coordinate at the axial positions, the Ni-N (in-plane) distance must be elongated. However, it is impossible with this macrocycle, since the hole size of this particular macrocycle is equal to or slightly smaller than necessary to accommodate a high-spin octahedral Ni^{2+}.[27]

Busch and his coworkers observed a very similar phenomenon in a ligand field electronic spectral study of a series of the same type of Ni(II) complexes.[3] They found that the ligand field strength of an axial ligand (Dq^z) decreases as the in-plane ligand field strength (Dq^{xy}) increases, and they termed this the "*electronic cis effect*". The correlation found in the electronic spectral study and that observed in the present study seem to have the same electronic origin.

We have previously discussed the electronic origin that brings about the correlations in Fig. 5 from the standpoint of the potential energy surface.[1] A section of the potential surface along the in-plane and axial coordination bond axes is an ellipse which has a tilt with respect to the coordination bond axes. When the ligand field strength of the axial ligand is weaker than the in-plane ligand field, the ellipse is elongated in the Ni-X direction. Such features of the potential surface are primarily responsible for the observed correlation of the coordination bond lengths.[1] It has also been shown that the slope of the line showing the interrelationship in Fig. 5 discloses the degree of softness[28] of a Ni(II) ion semiquantitatively.[1]

Figure 6 shows plots of the Ni-Cl stretching frequencies [ν(Ni-Cl)] *vs.* the Ni-Cl and Ni-N bond distances. Band assignments to the Ni-Cl stretching vibrations were made by a comparison of the spectra of *trans*-dichloro, *trans*-dibromo, and *trans*-bis(isothiocyanato) complexes with a series of macrocyclic ligands. It was impossible from only such simple comparisons to assign bands due to Ni-N stretching vibrations. As a result, we failed to figure a plot of ν(Ni-Cl) *vs.* ν(Ni-N), but the following discussion is possible on the basis of the IR data in Fig. 6. Under rigorous D_{4h} symmetry, a single band due to the antisymmetric Ni-Cl stretching vibration (ν_a) is expected to appear. When the complex has lower symmetry, two bands due to antisymmetric and symmetric vibrations (ν_a and ν_s) will appear. Single bands were observed at 198 cm^{-1} for **1**, at 223 cm^{-1} (very broad) for **2**, at 225 cm^{-1} for $[NiCl_2(N_49)]$, and at 187 cm^{-1} for $[NiCl_2(N_47)]$. On the other hand, Compound **3** showed two clearly separated sharp bands at 216 (ν_a) and 178 cm^{-1} (ν_s). This result corresponds to the relatively large difference in the two Ni-Cl distances in **3**. As shown in Fig. 6(a), the antisymmetric band ν_a(Ni-Cl) shifts to higher frequencies as the Ni-Cl distance decreases. When the ν_a(Ni-Cl) band posi-

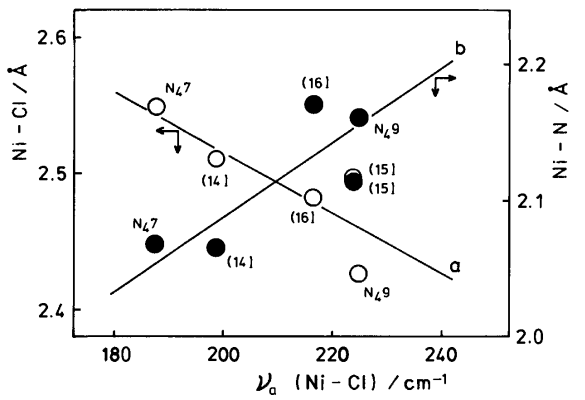

Fig. 6. Plots of antisymmetric Ni–Cl stretching frequencies (ν_a(Ni–Cl))/cm^{-1}) *vs.* mean Ni–Cl distances (a) and *vs.* average Ni–N distances (b). See the caption of Fig. 5 for the ligand abbreviations.

tions are plotted against the Ni–N distance, a reversed relationship is obtained (Fig. 6(b)). This result suggests, though indirectly, that the electronic cis effect is manifested in the far infrared spectra due to coordination bond stretching vibrations.

Structural Disorder Characteristic of [15]aneN$_4$ Complexes. We have thus far determined five structures of metal complexes containing the [15]aneN$_4$ ligand : the present two complexes, **2** and **5**, *trans*-[CoCl$_2$([15]aneN$_4$)](ClO$_4$) (green form),[17] [Zn(NCS)$_2$([15]aneN$_4$)],[2] and [{Zn([15]aneN$_4$)}$_3$(O$_2$COCH$_3$)$_2$](ClO$_4$)$_4$.[29] All the compounds have a gauche five-membered and a skew six-membered chelate ring in a pair. We found the same type of disorder common to all these structures. The general features are shown in Fig. 1. Because of this disorder, the bond distances of C$_a$–C$_b$ and C$_b$–C$_c$ appear somewhat shorter, whereas the C$_a$–C$_c$ distance is longer, than the normal value. It is worth noting that, in spite of the presence of the significant disorder, the positional parameters of the nitrogens involved in the disordered chelate rings were refined to have reasonably small esd values. This indicates that the nitrogens for the five- and six-membered rings are at nearly the same position in the crystal structure; therefore, the bite angles of the gauche five- and skew six-membered chelate rings must be very similar. In fact, the bite angles found for the skew six-membered rings which are not involved in the disorder (87.3(1)° and 87.1(1)° for **3**, and 87.1(1)° and 85.9(1)° for **6**) are close to the normal value of the gauche chelate rings (~86°).[11] Concomitantly, the bite angles found for the disordered ring average 87.2(1)° for **2** and 86.7(3)° for **5**. The disorder in the crystals of the [15]aneN$_4$ complexes is considered to arise mainly from such a situation.

Cobalt(III) Complexes with $[N_{6-n}X_n]$ type Ligands. IV.[1] The Preparation and Properties of Tetraammine(salicylideneaminato)cobalt(III) and Diamminebis(salicylideneaminato)cobalt(III) Complexes

Yoshihisa YAMAMOTO* and Eiko TOYOTA
Faculty of Pharmaceutical Sciences, Higashi Nippon Gakuen University, Ishikari-Tobetsu, Hokkaido 061-02
(Received Febuary 14, 1984)

Tetraammine(salicylideneaminato)cobalt(III) complexes, $\left[Co\left(\begin{smallmatrix}HN{=}HC\\ \\ O\end{smallmatrix}\right)(NH_3)_4\right]X_2\cdot nH_2O$ (X: Cl, NO_3, ClO_4, and picrate) and diamminebis(salicylideneaminato)cobalt(III) complexes, $\left[Co\left(\begin{smallmatrix}HN{=}HC\\ \\ O\end{smallmatrix}\right)_2(NH_3)_2\right]X\cdot nH_2O$ (X: Cl, NO_3, ClO_4, and picrate), have been isolated from a reaction mixture of $CoCl_2\cdot 6H_2O$, 25% aqueous ammonia, 30% H_2O_2 and salicylaldehyde, and characterized. In the latter complexes, the three isomers of green, orange and brown color have been isolated by column chromatography on alumina and their configurations have been established by their NMR spectra, *i.e.*, the configuration of the green complex is in the *trans-trans-trans* positions for two ammine ligands, and two phenoxyl groups and two CH=NH groups of the coordinated salicylideneaminato ligands, respectively, while those of the orange and brown complexes are in the *trans-cis-cis* and *cis-cis-trans* positions, respectively.

Previously, we have been concerned with the preparation, properties and isomers of the mixed ligand complexes of the $[CoN_{6-n}O_n]$ type, *e·g*, salicylato(amine)cobalt(III) complexes,[2-7] $[Co(sal\text{-}R)L]X\cdot nH_2O$, and amine(8-quinolinolato)cobalt(III) complexes,[8-12] $[Co(oxine\text{-}R)_lL]X_m\cdot nH_2O$, (L: NH_3, en, bpy, trien, 2,3,2-tet, 3,2,3-tet, and 3,3,3-tet; R: H, Me; *l*: 1 or 2; *m*: 1 or 2). The *cis*-β_1 and β_2 isomers of salicylato(quadridentate amine)cobalt(III) complexes have been isolated and the ^1H and ^{13}C chemical shifts of their amine protons, methylene protons and methylene carbons have been assigned. In addition, the configurations of the coordinated two (2-methyl-)8-quinolinolato ligands in ethylenediaminebis(2-methyl-8-quinolinolato)cobalt(III) complexes[8] and diamminebis(8-quinolinolato)cobalt(III) complexes[10,11] have been reported. The former of these complexes has a *cis-trans* configuration for the two oxygen and two nitrogen atoms, and the latter has a *trans-cis* configuration for the two oxygen and two nitrogen atoms.

Many investigations of bis- or tris(*N*-substituted salicylideneaminato)metal complexes have been reported especially concerning the preparation,[13-28] geometrical isomerism,[28-30] IR spectra,[14-16] absorption spectra,[14-23] NMR spectra,[14,29] and magnetic susceptibilities.[15-19,24,25] However the isolation and stereochemistry of the mixed ligand metal complexes with salicylideneaminato ligand and the derivatives in an octahedral configuration have not previously been described except for dichlorobis(*N*-substituted salicylideneaminato) metal,

$$\left[M\left(\begin{smallmatrix}R\\ |\\ N{=}HC\\ \\ O\end{smallmatrix}\right)_2Cl_2\right]$$

(M: Ti,[31] Mo,[32] Sn,[33] and Th[34]), and tetraammine(salicylideneaminato)cobalt(III) complexes,

$$\left[Co\left(\begin{smallmatrix}HN{=}HC\\ \\ O\end{smallmatrix}\right)(NH_3)_4\right]Cl_2\cdot H_2O.$$[35]

In the stereochemistry of

$$\left[M\left(\begin{smallmatrix}R\\ |\\ N{=}HC\\ \\ O\end{smallmatrix}\right)_2Cl_2\right],$$

the configuration of the coordinated *N*-substituted salicylideneaminato ligands is *trans-trans* for the two phenoxyl and two CH=NR groups. However, other isomers with *cis-trans* configurations and *cis-cis* configurations for the two phenoxyl and two CH=NR groups of the coordinated salicylideneaminato ligand and the *N*-substituted derivatives have not yet been reported. The present paper deals with the preparation and properties of the mixed ligand complexes with salicylideneaminato and ammine ligands of tetraammine(salicylideneaminato)cobalt(III) complexes,

$$\left[Co\left(\begin{smallmatrix}HN{=}HC\\ \\ O\end{smallmatrix}\right)(NH_3)_4\right]X_2\cdot nH_2O$$

and diamminebis(salicylideneaminato)cobalt(III) complexes,

$$\left[Co\left(\begin{smallmatrix}HN{=}HC\\ \\ O\end{smallmatrix}\right)_2(NH_3)_2\right]X\cdot nH_2O$$

(X: Cl, NO_3, ClO_4, pic), and deals with the assignment of the configuration of the latter complexes.

Results and Discussion

The abbreviations of the ammine(salicylideneaminato)cobalt(III) complexes studied in this research are listed in Table 1. Russet tetraammine(salicylideneaminato)cobalt(III) chloride hydrate,

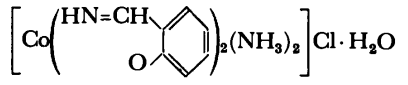
(**1a**), and green and orange diamminebis(salicylideneaminato)cobalt(III) chloride hydrate,



(green: **2a**; orange: **3a**), have been isolated by column chromatography on alumina from a reaction mixture of $CoCl_2 \cdot 6H_2O$, 25% aqueous ammonia, 30% H_2O_2 and salicylaldehyde. Brown diamminebis(salicylideneaminato)cobalt(III) nitrate hydrate (**4b**) has been isolated by chromatography on alumina from a reaction mixture of **2a** and silver nitrate, while the corresponding chloride (**4a**) could not be isolated on the solid state (*cf.* Experimental section). The corresponding nitrates (**1b**, **2b**, **3b**), perchlorates (**1c**, **2c**, **3c**, **4c**) and picrates (**1d**, **2d**, **3d**, **4d**) have been prepared from a reaction mixture of **1a**, **2a**, **3a**, or **4b** and silver nitrate, sodium perchlorate, or picric acid, respectively. The diamminebis(salicylideneaminato)cobalt(III) complex has five possible isomers of A, B, C, D, and E as is shown in Fig. 1. The configurations of isomers A, B, C, and E have C_2 symmetry, while isomer D has C_1 symmetry.

The electric conductivities of **1a—c** in aqueous solutions were 190—220 S cm^2 equiv^{-1} and those of **2a—c**, **3a—c** and **4b—c** were 100—110 S cm^2 equiv^{-1} as is shown in the experimental section. In the IR spectra, bands due to the C=N streching vibrations[14-16,31,33,34] and rocking deformation vibrations[36-38] of all complexes were observed at 1625 cm^{-1} and in the 810—830 cm^{-1} regions, respectively (*cf.* Experimental section). These complexes are diamagnetic complexes of low spin type from their magnetic susceptibilities. In the absorption spectra of **1a—c**, **2a—c**, **3a—c**, and **4b—c** in methanol, the absorption bands at about 380 nm are assigned to the charge transfer band[10,11] and those at about 540 nm or 610 nm are the first absorption bands as shown in Table 2. The ε values at about 380 nm of **2a—c**, **3a—c**, and **4b—c** are larger than those of **1a—c** as shown in Table 2.

The ^{1}H NMR spectra of all complexes were measured in DMSO-d_6 and the ^{13}C NMR spectra of **1a**, **2a**, **3a**, and **4b** were measured in D_2O and 14% ammonia-D_2O solution as shown in Fig. 2. The ^{1}H and ^{13}C NMR spectra of **2a—d**, **3a—d**, and **4b—d** are consistent with C_2 symmetry.[8,11,39,40] In the ^{1}H NMR spectra, the signals at 2.6—4.1 ppm of these complexes are assigned to the protons of the coordinated ammine ligands. The multiplet signals at 6.4—7.3 ppm are assigned to the ring protons of the coordinated salicylideneaminato ligand (abbreviation: the

Solvent and standard: 1) DMSO-d_6, internal TMS ($\delta=0$). a): Experimental section.

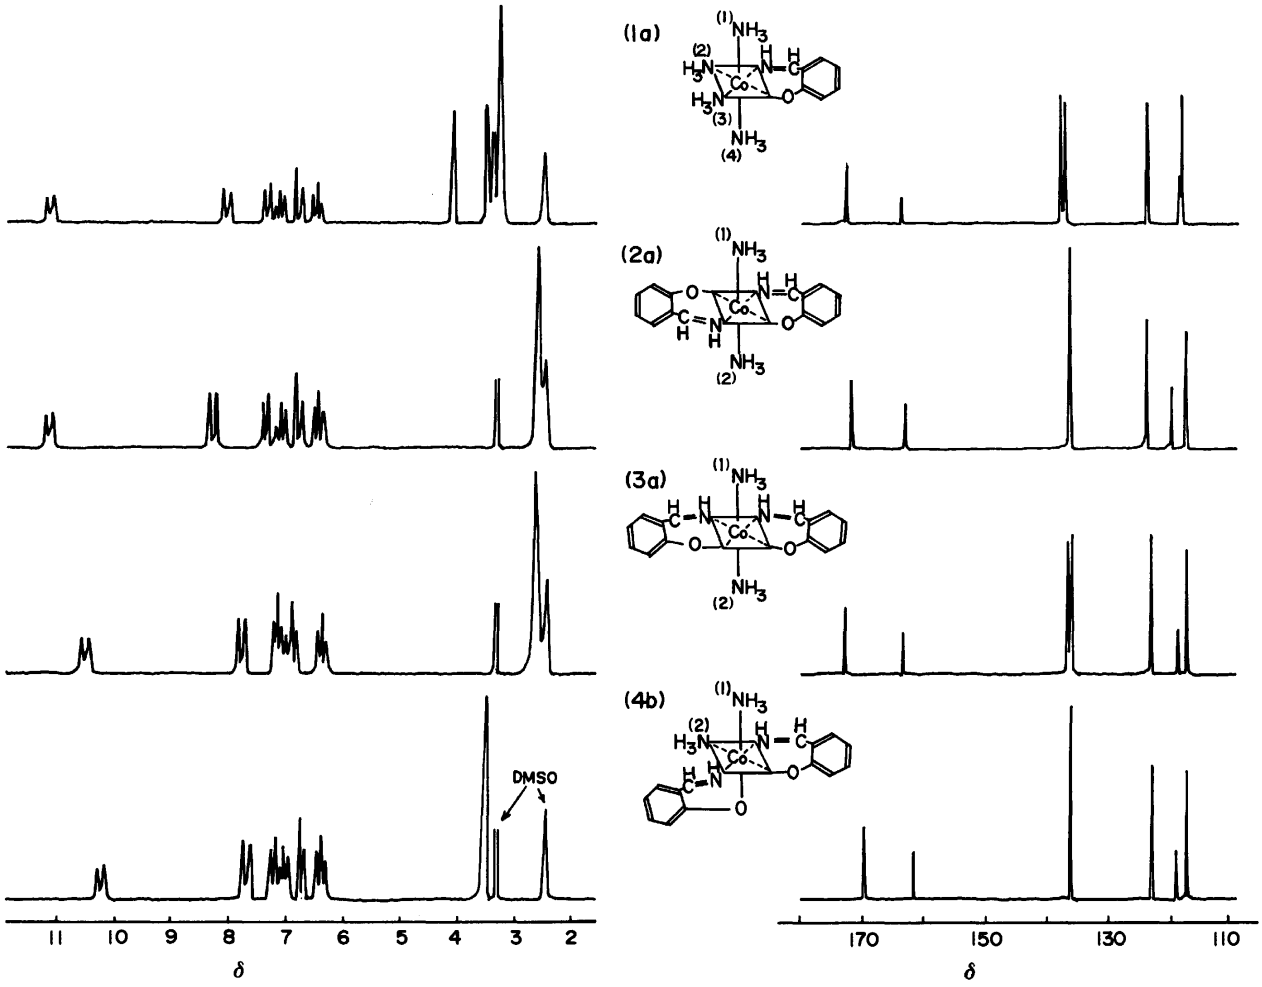

Fig. 2. The ^1H and ^{13}C NMR spectra of **1a**, **2a**, **3a**, and **4b** complexes.

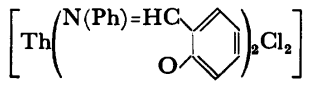
1a: $\left[Co\left(HN{=}HC\text{-}C_6H_3(O)\text{-}O\right)(NH_3)_4\right]Cl_2\cdot H_2O$, **2a**: *trans-trans-trans*-$\left[Co\left(HN{=}HC\text{-}C_6H_3(O)\text{-}O\right)_2(NH_3)_2\right]Cl\cdot H_2O$,

3a: *trans-cis-cis*-$\left[Co\left(HN{=}HC\text{-}C_6H_3(O)\text{-}O\right)_2(NH_3)_2\right]Cl\cdot H_2O$, **4b**: *cis-cis-trans*-$\left[Co\left(HN{=}HC\text{-}C_6H_3(O)\text{-}O\right)_2(NH_3)_2\right]NO_3\cdot H_2O$.

chelate ligand). The doublet signal at about 8 ppm can be assigned to the CH=N proton.[29,33,34] The doublet signal at 10—11 ppm can be assigned to the C=NH proton of the chelate ligand. Their coupling constants (J_{HCNH}) are 10.5 or 11.2 Hz as shown in Table 2. The ^1H NMR spectrum of **1a** showed three singlet signals in the intensity ratios of 2:1:1 for the coordinated ammine ligands. The signal at 3.26 ppm (6H) is assigned to the protons of the two ammine ligands of N(1)H_3 and N(4)H_3 in the positions *cis* to the coordinated chelate ligand, because the two ammine ligands should be equivalent.[11] The singlets at 3.46 ppm (3H) and at 4.07 ppm (3H) are assigned to the protons of the ammine ligands of N(2)H_3 and N(3)H_3 in the position trans[6,11,41] of the phenoxyl and CH=NH group of the coordinated chelate ligand, respectively. The signals of the ammine protons and the C=NH proton of **1a** are at a lower field than those of **1b—d**.

The signal at 3.49 ppm of **4b** is similar to that (3.46 ppm, 3H) of N(2)H_3 of **1a**, and thus the signal of **4b** can be assigned to the ammine protons in the *trans* positions of the phenoxyl groups of the coordinated chelate ligands. Thus, the configuration of complexes **4a—d** can be assigned to isomer E, in *cis-cis-trans* positions as shown in Fig. 1. On the other hand, the chemical shifts of the coordinated ammine ligands of **2a** and **3a** are very different from that of the coordinated ammine ligands of **4b**, and are close to that of N(1)H_3 and N(4)H_3 in the *trans* positions of **1a**. Accordingly the ammine proton signals of **2a** and **3a** can be assigned to those in the *trans* position to each other. A clear distinction between complexes **2a** and **3a** was found in the CH=NH proton signals of their ^1H NMR spectra as shown in Fig. 2. The CH=NH proton signals of **2a** are at a lower field than those of **3a**. Thus, the configuration of the two CH=NH groups of the coordinated chelate ligands of **2a** is *trans*[6,10,41] because the nitrogen atom of CH=NH group is less electronegative than the oxygen atom of the phenoxyl

group. In addition, the chemical shift (8.27 ppm) of the CH=N proton signal of **2a** is similar to that[34] (8.5 ppm) of the CH=N proton signal of dichlorobis-(*N*-phenyl salicylideneaminato)thorium complex,



(**5**). This is *trans-trans-trans* for the two chloro ligands, the two phenoxyl groups and the two CH=N(Ph) groups of the coordinated chelate ligands, respectively. Accordingly the configuration of **2a** has been assigned to isomer A, which is *trans-trans-trans* and that of **3a** has been assigned to isomer B which is *trans-cis-cis* as shown in Fig. 1.

The ^{13}C NMR spectra of **1a**, **2a**, 3a, and **4b** showed seven signals for the chelated ligand as shown in Fig. 2. Their chemical shifts were assigned on the basis of the results of those of salicylaldehyde[42] and tetraammine(salicylato)cobalt(III) chloride hydrate.[6] The ^{13}C NMR results, color, decomposition temperature of the complexes are collected in the experimental section.

Experimental

Measurements. The NMR spectra were recorded with an FX-60 apparatus (JEOL) for ^{13}C NMR and with an R-40 apparatus (Hitachi) for ^{1}H NMR. The IR spectra were recorded as potassium bromide disks with an IR-27G apparatus (Shimadzu). The visible absorption spectra were recorded with a Shimadzu MPS-5000 recording spectrophotometer. The electric conductivities of the aqueous solutions were determined by the use of a conductometric meter CM-30 (Shimadzu) at room temperature. The magnetic susceptibilities were measured by the Faraday method using a magnetic balance (Shimadzu) at room temperature.

Preparation of Complexes. Tetraammine(salicylideneaminato)cobalt(III) Chloride Hydrate (1a), Diamminebis(salicylideneaminato)cobalt(III) Chloride Hydrate (2a and 3a) and Hexaamminecobalt(III) Chloride (6): A 25% aqueous ammonia (40 cm^3) was added to an aqueous solution (20 cm^3) of $CoCl_2 \cdot 6H_2O$ (10.0 g, 42.0 mmol), and about 5 cm^3 of 30% H_2O_2 solution was added slowly to the solution at 0 °C. The color of the solution changed from brown to red. A methanol solution (50 cm^3) of salicylaldehyde (5.13 g, 42.0 mmol) was added dropwise to the solution during 2 h at 50 °C. The solution was stirred for 1 d at 50 °C, concentrated with a rotary evaporator at 50 °C, and dried over silica gel. Complexes **1a**, **2a**, and **3a** were extracted with 200 cm^3 of dry methanol from the dried reaction mixture. The methanol solution was concentrated to about 50 cm^3 with a rotary evaporator at 50 °C, the complex **1a** precipitated was filtered and recrystallized twice from water-ethanol. The separation of complexes **2a** and **3a** from the filtrate was achieved by column chromatography on alumina. On elution with methanol, the effluent of the first green band (complex **2a**) was collected, concentrated and recrystallized from 10% aqueous ammonia twice. The effluent of the second orange band (complex **3a**) was collected, concentrated and recrystallized twice from water. The russet band of complex **1a** in the filtrate moved only slightly on alumina. Complex **6** which remained was not soluble in dry methanol. Complex **2a** isomerizes to **4a** at 20 °C in DMSO, methanol and water, but the isomerization is very slow in 10% aqueous ammonia at 20 °C. Yields: 3.6 g (25.5%) for **1a**; 2.8 g (17.2%) for **2a**; 0.65 g (4.0%) for **3a**; 3.59 g (32%) for **6**. Found **1a**: C, 25.26; H, 6.34; N, 20.66; Cl, 21.57%. **2a**: C, 43.98; H, 5.17; N, 14.16; Cl, 9.77%. **3a**: C, 43.55; H, 5.66; N, 14.12; Cl, 9.57%. Calcd for **1a**: $CoC_7H_{20}N_5O_2Cl_2$ (MW 336.11) C, 25.01; H, 6.00; N, 20.84; Cl, 21.10%. **2a** and **3a**: $CoC_{14}H_{20}N_4O_3Cl$ (MW 386.73) C, 43.48; H, 5.21; N, 14.49; Cl, 9.17%. Color **1a**: russet; **2a**: green; **3a**: orange. Dp: 161—163 °C for **1a**; 195—197 °C for **2a**; 163—165 °C for **3a**. Λ=220 for **1a**, 104 for **2a**, and 102 S cm^2 equiv^{-1} for **3a** in water. IR spectra: 1625 cm^{-1} (C=N), 810 cm^{-1} ($\rho_r(NH_3)_r$) for **1a** and **2a**: 1625 cm^{-1} (C=N), 825 cm^{-1} ($\rho_r(NH_3)_r$) for **3a**. ^{13}C NMR spectra: δ 117.9(c-1)*, 163.2(c-2), 117.5(c-3), 137.0(c-4), 123.1(c-5), 136.3 (c-6), 173.0(c-7) in D_2O. **2a**: δ 119.3(c-1), 163.5(c-2), 117.1 (c-3), 136.2(c-4), 123.4(c-5), 136.2(c-6), 172.6(c-7) in 14% ammonia-D_2O. **3a**: δ 118.6(c-1), 163.0(c-2), 117.0(c-3), 137.0 (c-4), 123.1(c-5), 136.2(c-6), 174.2(c-7) in D_2O.

Brown Diamminebis(salicylideneaminato)cobalt(III) Chloride (4a): Complex **4a** was identified by the isomerization of **2a** in DMSO, methanol and water. A brown band of **4a** and a green band of **2a** are separated by column chromatography on alumina from a methanol solution of **2a**. From a brown solution, complex **2a** was obtained, complex **4a** could not be obtained in the solid state. The ^{1}H NMR spectrum of **4a** was observed in DMSO solution of **2a** at room temperature.

Tetraammine(salicylideneaminato)cobalt(III) Nitrate (1b): An aqueous solution of silver nitrate (4.04 g, 23.8 mmol) was added to an aqueous solution of **1a** (4.0 g, 11.9 mmol), the mixture was stirred, and the precipitated silver chloride was filtered. The filtrate was concentrated and recrystallized from water twice. Yield: 3.6 g (81.5%). Found: C, 22.24; H, 4.74; N, 26.09%. Calcd for $CoC_7H_{18}N_7O_7$ (MW 371.20) C, 22.65; H, 4.89; N, 26.41%. Color: reddish brown. Dp: 147—148 °C. Λ=215 S cm^2 equiv^{-1} in water. IR spectrum: 1625 cm^{-1} (C=N), 810 cm^{-1} ($\rho_r(NH_3)_r$).

Tetraammine(salicylideneaminato)cobalt(III) Perchlorate (1c): An aqueous solution of sodium perchlorate (2.2 g, 18.0 mmol) was added to an aqueous solution of **1a** (3.0 g, 8.9 mmol), the mixture was stirred for 1 h at 40 °C, and was concentrated with a rotary evaporator and dried. Complex **1c** was extracted with 15 cm^3 of acetone from the dried reaction mixture. The acetone solution was concentrated and recrystallized from water twice. Yield: 3.0 g (75.6%). Found: C, 19.04; H, 4.50; N, 15.78; Cl, 16.13%. Calcd for $CoC_7H_{18}N_5O_9Cl_2$ (MW 446.09) C, 18.85; H, 4.07; N, 15.70; Cl, 15.89%. Color: reddish brown. Dp: 212—215 °C. Λ=191 S cm^2 equiv^{-1} in water. IR spectrum: 1625 cm^{-1} (C=N), 810 cm^{-1} ($\rho_r(NH_3)_r$).

Tetraammine(salicylideneaminato)cobalt(III) Picrate (1d): An aqueous solution of **1a** (0.5 g, 1.49 mmol) was added to an aqueous solution of picric acid (0.68 g, 2.97 mmol), the mixture was stirred. The complex **1d** was precipitated, filtered, washed with water and dried. Yield: 0.18 g (77.3%). Found: C, 32.67; H, 3.06; N, 21.73%. Calcd for $CoC_{19}H_{22}N_{11}O_{15}$ (MW 703.39) C, 32.44; H, 3.15; N, 21.90%. Color: yellowish brown. Dp: 185—187 °C. IR spectrum: 1625 cm^{-1} (C=N), 810 cm^{-1} ($\rho_r(NH_3)_r$).

trans-trans-trans *and* cis-cis-trans-*Diamminebis(salicylideneaminato)cobalt(III) Nitrate Hydrate (2b and 4b)*: An aqueous solution of silver nitrate (1.1 g, 6.48 mmol) was added to a methanol-water (1:1) solution of **2a** (2.5 g, 6.46 mmol), the mixture was stirred, and the precipitated silver chloride was filtered. The filtrate was concentrated and the complexes **2b** and **4b** were separated by column chromatography on alumina. On elution with methanol, the effluent of the first green band (**2b**) was collected and concentrated and recrystallized from methanol-ether twice. The effluent of the second brown band (**4b**) was collected, concentrated and recrystallized from methanol-ether twice. Yields: 0.85 g

*: position: Table 2.

(31.8%) for **2b** and 0.96 g (36.0%) for **4b**. Found **2b**: C, 40.94; H, 4.56; N, 17.25%. **4b**: C, 40.24; H, 4.49; N, 17.10%. Calcd for $CoC_{14}H_{20}N_5O_6$ (MW 413.28) C, 40.69; H, 4.88; N, 16.95%. Color **2b**: greenish brown; **4b**: brown. Dp: 186—188 °C for **2b**; 183—185 °C for **4b**. Λ=108 for **2b**, 105 S cm^2 equiv^{-1} for **4b** in water. IR spectra: 1625 cm^{-1} (C=N), 820 cm^{-1} (ρ_r-$(NH_3)_r$) for **2b**; 1625 cm^{-1} (C=N), 830 cm^{-1} ($\rho_r(NH_3)_r$) for **4b**. ^{13}C NMR spectrum **4b**: δ 119.0(c-1), 162.8(c-2), 117.2 (c-3), 136.2(c-4), 122.7(c-5), 136.2(c-6), 170.8(c-7) in D_2O.

trans-cis-cis-*Diamminebis(salicylideneaminato)cobalt(III) Nitrate Dihydrate (3b)*: This complex was prepared from the reaction mixture of silver nitrate (0.22 g, 1.30 mmol) and **3a** (0.5 g, 1.29 mmol). The mixture was stirred, and the silver chloride precipitate filtered. The filtrate was concentrated on a rotary evaporator. A small amount of silver complex in the filtrate was excluded by column chromatography on alumina. Complex **3b** was recrystallized from methanol-ether twice. Yield: 0.37 g (66.5%). Found: C, 38.77; H, 5.30; N, 16.55%. Calcd for $CoC_{14}H_{22}N_5O_7$ (NW 431.30) C, 38.99; H, 5.14; N, 16.24%. Color: orange. Dp: 180-182 °C. Λ=107 S cm^2 equiv^{-1} in water. IR spectrum: 1625 cm^{-1} (C=N), 830 cm^{-1} ($\rho_r(NH_3)_r$).

trans-trans-trans *and* trans-cis-cis-*Diamminebis(salicylideneaminato)cobalt(III) Perchlorate (2c and 3c)*: An aqueous solution of sodium perchlorate (0.16 g, 1.31 mmol) was added to a methanol-water (1:1) solution of **2a** or **3a** (0.5 g, 1.29 mmol), and the precipitated complex **2c** or **3c** was filtered, and washed with ethanol-ether. Yields: 0.53 g (94.9%) for **2c**, 0.51 g (91.4%) for **3c**. Found **2c**: C, 38.90; H, 4.17; N, 12.76; Cl, 8.65%. **3c**: C, 38.61; H, 4.22; N, 12.43; Cl, 7.90%. Calcd for $CoC_{14}H_{18}N_4O_6Cl$ (MW 432.71) C, 38.86; H, 4.19; N, 12.95; Cl, 8.19%. Color **2c**: green; **3c**: orange. Dp: 225—226 °C for **2c**; 225—227 °C for **3c**. Λ=112 for **2c**, 106 S cm^2 equiv^{-1} for **3c** in water. IR spectra: 1625 cm^{-1} (C=N), 810 cm^{-1} ($\rho_r(NH_3)_r$) for **2c**; 1625 cm^{-1} (C=N), 830 cm^{-1} ($\rho_r(NH_3)_r$) for **3c**.

cis-cis-trans-*Diamminebis(salicylideneaminato)cobalt(III) Perchlorate (4c)*: This complex was prepared from the reaction mixture of sodium perchlorate (0.1 g, 0.82 mmol) and **4b** (0.34 g, 0.82 mmol) according to the method of **1c**, and recrystallized from methanol-ether. Yield: 0.15 g (42.3%). Found: C, 38.73; H, 4.16; N, 12.76; Cl, 8.76%. Calcd for $CoC_{14}H_{18}N_4O_6Cl$ (MW 432.71) C, 38.86; H, 4.19; N, 12.95; Cl, 8.19%. Color: brown. Dp: 197—199 °C. Λ=103 S cm^2 equiv^{-1} in water. IR spectrum: 1625 cm^{-1} (C=N), 830 cm^{-1} ($\rho_r(NH_3)_r$).

trans-trans-trans, trans-cis-cis *and* cis-cis-trans-*Diamminebis(salicylideneaminato)cobalt(III) Picrate (2d, 3d, and 4d)*: These complexes were prepared from the reaction mixture of picraic acid (0.3 g, 1.31 mmol) and **2a** or **3a** (0.5 g, 1.29 mmol) or **4b** (0.54 g, 1.31 mmol) according to the method of **1d** Yields: 0.69 g (95.3%) for **2d**, 0.63 g (87.0%) for **3d**, 0.57 g (77.6%) for **4d**. Found **2d**: C, 42.10; H, 4.08; N, 17.15%. **3d**: C, 42.39; H, 3.81; N, 17.11%. **4d**: C, 42.51; H, 3.55; N, 17.11%. Calcd for $CoC_{20}H_{20}N_7O_9$ (MW 561.36) C, 42.79; H, 3.59; N, 17.47%. Color **2d** and **3d**: yellowish brown, **4d**: orange. Dp: 184—185 °C or **2d**, 193—194 °C for **3d**, 171—172 °C for **4d**. IR spectra: 1625 cm^{-1} (C=N), 820 cm^{-1} ($\rho_r(NH_3)_r$) for **2d**, 1625 cm^{-1} (C=N), 830 cm^{-1} ($\rho_r(NH_3)_r$) for **3d**; 1625 cm^{-1} (C=N), 825 cm^{-1} ($\rho_r(NH_3)_r$) for **4d**.

Solubility: Complexes **1a—c** are readily soluble in water and DMSO, and soluble in methanol and DMF, though insoluble in the other common organic solvents. Complex **1c** is soluble in acetone. Complex **1d** is soluble in DMSO, DMF and acetone, and somewhat soluble in methanol, and insoluble in water. Complexes **2a—d**, **3a—d**, and **4b—d** are soluble in DMSO. Complexes **2c—d**, **3c—d**, and **4c—d** are soluble in acetone. Complexes **2a—b**, **3a**, and **4b** are soluble in water, though **2c**, **3b—c**, and **4c** are slightly soluble, and **2d**, **3d**, and **4d** are insoluble in water. Complexes **2a—c**, **3b—c**, and **4b—c** are soluble in methanol, though **2d** and **3a** are somewhat soluble in methanol.

Intramolecular Photocycloaddition of Noncyclic Polyether Compounds Containing α,ω-Dicinnamates End Groups and Uptake of Alkali Metal Thiocyanates with Them[1)]

Kazuhisa HIRATANI* and Sei-ichi AIBA

Industrial Products Research Institute, Higashi 1-chome, Yatabe-machi, Tsukuba-gun, Ibaraki 305

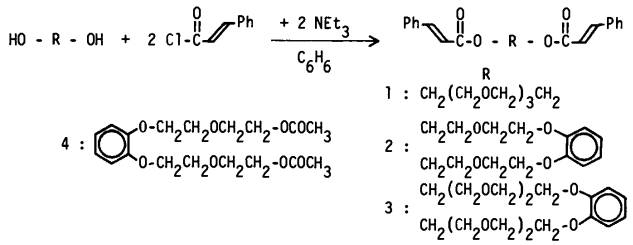
(Received December 26, 1983)

Synopsis. Noncyclic polyethers containing two cinnamoyl end groups have been prepared, they were cyclized by photosensitized intramolecular addition. The uptake of alkali metal (sodium and potassium) thiocyanates with these compounds and their ability to extract has been investigated before and after the cyclization.

Intramolecular photocycloaddition in α,ω-dicinnamates to construct macrocycles has been studied by several groups,[2)] but there are few applications of them to prepare cyclic polyethers which exhibit, for example, the extracting ability for cations.[3)] Conversion of the noncyclic polyethers to the cyclic ones will bring about a change of the ability in the cation-uptake. In this paper we wish to report the photo-induced intramolecular cyclization of noncyclic oligoethylene glycol derivatives containing cinnamoyl group at both ends of the molecule and the ability of uptake for alkali thiocyanate with them.

Results and Discussion

As shown in Scheme 1, three noncyclic polyether compounds having two cinnamoyl end groups were prepared by the reaction of an oligoethylene glycol with two mole equivalents of cinnamoyl chloride in the presence of triethylamine. By this procedure, tetraethylene glycol dicinnamate (**1**), 1,2-bis[2-[2-(cinnamoyl)ethoxy]ethoxy]benzene (**2**), and 1,2-bis[2-[2-[2-(cinnamoyl)ethoxy]ethoxy]ethoxy]benzene (**3**) were obtained. 1,2-Bis[2-(2-acetoxyethoxy)ethoxy]benzene (**4**) was also prepared to allow comparison of the abilities of uptake. In Table 1, the analytical data are summarized.



Scheme 1. Preparation of polyethers with two cinnamoyl end groups.

Intramolecular photocycloaddition of biscinnamates (**1**)—(**3**) was carried out by high dilution technique in acetone using a 400-W high pressure mercury lump under bubbling of gaseous nitrogen in the presence of a catalytic amount of benzophenone as a sensitizer (Scheme 2): **5**; yield 27%, NMR ($CDCl_3$) δ=3.4—4.7 (12H, m, cyclobutane ring+oligo(oxyethylene)), 3.67 (8H, s, oligo(oxyethylene)), 7.33 (10H, s, C_6H_5) ppm; and **6**; yield 21%, NMR ($CDCl_3$) δ=3.0—4.5 (24H, m, cyclobutane ring+oligo(oxyethylene)), 6.89 (4H, s, *o*-phenylene), and 7.32 (10H, s, C_6H_5) ppm. But an attempt to prepare the corresponding cycloadduct from **2** was unsuccessful. In the IR spectra, the absorption band based on cinnamoyl C=C double bond (at 1635 cm^{-1} for **1** and **3**) disappeared completely after the photoirradiation. In the proton NMR, the signal

Table 2. Solubilization of thiocyanate salts into CH_2Cl_2

Polyether	Amount of solubilized thiocyanates (mol of MSCN/mole of polyether)[a]	
	NaSCN	KSCN
1	0.12	≈0
2	0.22	≈0
3	0.48	0.53
4	0.21	≈0
5	0.21	0.03
6	0.45	0.34

a) The values were calculated from elemental analysis.

of the olefin proton of **1** disappeared in **5** and the signal for the cyclobutane ring protons appeared at around 4 ppm. The stereochemistry at the point of closure could not be elucidated from the cyclobutane protons since these were obscured by other oxyethylene protons. But it is presumed that such macrocyclic ring-closure in solution phase may be δ-addition(anti, head to head) according to the literature.[2b] In addition, the mass spectroscopic data confirmed that the molecular weights of **5** and **6** are exactly the same as those of **1** and **3**, respectively.

Thus, the ability of uptake for sodium and potassium thiocyanates with these compounds was examined. After we mixed the polyether and powdered alkali thiocyanate in dichloromethane at room temperature, we determined the amount of alkali thiocyanates solubilized into the solvent by elemental analysis (see Experimental). The results are shown in Table 2. The 17-membered ring compound (**5**) can uptake NaSCN two times better than **1**, whereas both **1** and **5** can uptake very little KSCN. Noncyclic polyether (**3**), which has a longer oxyethylene moiety compared with **1**, exhibits better uptake for K^+ salt than that for Na^+ salt. On the other hand, the 26-membered ring compound (**6**) can solubilize Na^+ salt a little more than K^+ salt.

Contrary to our expectation, the difference in the selectivity and ability of uptake between cyclic and noncyclic compounds was not so large. It could be considered that the cyclobutane structure bearing two ester groups largely distorts the cyclic polyether structure and therefore their ability of uptake can not be improved distinctly compared with that of noncyclic ones. Furthermore, it has been reported that the metal ion complexing properties of crown ethers containing ester groups are generally different from the corresponding ones which are formed from ethylene glycol units.[4] Our failure may be attributed to the introduction of both cyclobutane ring and two ester groups into a macrocyclic system.

In the extraction of alkali salts by noncyclic polyethers, (**1**)—(**4**), the longer the oxyethylene chain is, the better the ability of uptake is. It means that in this case the structure of end groups of these noncyclic polyethers has little effect on their ability of uptake.

Experimental

The 2-(2-chloroethoxy)ethanol and 2-[2-(2-chloroethoxy)-ethoxy]ethanol were commercially available (Aldrich Chem. Co.) and were used without further purification. The NMR and IR spectra were recorded on a Varian EM-360 (60 MHz) using TMS as the internal standard and on a JASCO IRA-1 infrared spectrometers, respectively. The mass spectrum was measured with a Hitachi M-52 mass spectrometer.

General Procedure for the Preparation of Noncyclic Polyethers. 1,2-Bis[2-(2-hydroxyethoxy)ethoxy]benzene and 1,2-bis[2-[2-(2-hydroxyethoxy)ethoxy]ethoxy]benzene were prepared by the reaction of catechol with 2 mole equivalents of 2-(2-chloroethoxy)ethanol and 2-[2-(2-chloroethoxy)ethoxy]ethanol, respectively, in the presence of powdered potassium carbonate in DMF. Then, to the benzene of the mixture of 1 mole equivalent of the oligoethylene glycol and 2 mole equivalents of triethylamine was added dropwise 2 mole equivalents of cinnamoyl chloride at room temperature. After the solution was stirred for 12 h at room temperature, the solution was washed with water and dried with magnesium sulfate. After removal of benzene by evaporation, the residue was submitted to column chromatography(chloroform) on silica gel.

General Procedure of Irradiation. Irradiations on a preparative scale were performed with Pyrex-filtered light from a 400-W high pressure mercury lamp (Riko) under bubbling of gaseous nitrogen in an immersion apparatus.

Preparation of 5. An acetone (250 ml) solution of 1.3 g of **1** and 0.01 g of benzophenone was irradiated in the Pyrex cell described above at 40 °C for 7 h. After solvent was removed, the remaining reaction products were isolated by column chromatography on alumina. The first elution with chloroform gave a colorless oily product, **5**, which was identified with IR, NMR, and mass spectroscopic method and elementary analysis. The other product were also oily and seemed to be intermolecular adducts(oligomeric products) because of their high viscosity. Further identification was not done.

In a similar manner, a cyclic product, **6**, was isolated.

Extraction Procedure. In a typical experiment, to the solution (0.1 g of the polyether prepared in 5 ml of dichloromethane) 0.5 g of alkali thiocyanate powder was added, and then the mixture was stirred for 12 h at room temperature. The insoluble salt was filtered off and the solvent was evaporated from the filtrate. The amounts of alkali thiocyanate solubilized into dichloromethane was determined by elementary analysis. The results are summarized in Table 2. Under these conditions, thiocyanate salts in the absence of the polyether did not dissolve in dichloromethane at all.

Zeta Potentials of Metal Oxides in Aqueous Solution of Water-soluble Titanate Coupling Agents

Kunio ESUMI* and Kenjiro MEGURO

Department of Applied Chemistry and Institute of Colloid and Interface Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received January 13, 1984)

Synopsis. The zeta potentials of γ-Fe_3O_4 and TiO_2 were measured as a function of the amount of water-soluble titanate coupling agents added in aqueous solution. Compared with untreated samples, the zeta potential of γ-Fe_3O_4 increased negatively with an increase of the amount of water-soluble titanate coupling agents, while that of TiO_2 changed little. Furthermore, after a washing process, it was confirmed by ESCA measurement that a certain amount of water-soluble titanate coupling agent still remained on the surface of the γ-Fe_3O_4.

Silane and titanate coupling agents for modifying many fillers have been employed[1-3] to improve the bonding between reinforcements and polymer matrices. When coupling treatments are applied to a dispersion system containing porous material in solution, electrokinetic measurement[4] is a useful method to detect changes in the surface properties. Esumi *et al.*[5,6] studied the change in the zeta potential of metal oxides coated with coupling agents and they found that the zero point of the charge of the metal oxides coated with (3-aminopropyl)triethoxysilane and tris[2-(2-aminoethylamino)ethoxy]isopropoxytitanium(IV) is shifted to a higher value.

It is known that chelated titanate coupling agents can be made water-soluble *via* a quaternization technique which converts water-insoluble chelated titanates to water-soluble, ionic quadrivalent nitrogen salt complexes. Such water-soluble titanate coupling agents seem very interesting materials because they can be applied to aqueous dispersion system.

In this work the influence of water-soluble titanate coupling agents on the surface properties of γ-Fe_3O_4 and TiO_2 was investigated by measuring their zeta potential and ESCA spectra.

Experimental

Materials. The titanate coupling agents used in this study were bis{*O'*,*O'*-dioctyl pyrophosphato(1-)}(1-oxoethylenedioxy)titanium(KR-238S) and bis{*O'*,*O'*-dioctyl pyrophosphato(1-)}(ethylenedioxy)titanium(KR-138S), kindly supplied by Ajinomoto Co. As metal oxides, γ-Fe_3O_4 and TiO_2 (rutile) were obtained from BASF and Teikoku Kako, respectively. The specific surface areas of γ-Fe_3O_4 and TiO_2 determined by nitrogen adsorption at its liquid temperature were 6.1 and 49 m^2/g. The zero point of charge for sample was 7.5 for γ-Fe_3O_4, 4.2 for TiO_2.

Procedure. Quaternization of titanate coupling agents was made by the addition of triethylamine(TEA) into the coupling agents. The mixing ratios were 1:1 bg weight for KR-138S-TEA and 1:0.5 for KR-238S-TEA. The water-soluble titanate coupling agent obtained was then added to deionized water and the metal oxide added to the solution, dispersed in an ultrasonic cleaning bath.

Measurements of the zeta potential for the dispersed system were conducted using a Pen Kem Laser 500 Zeta Potential. The pH of the suspension was measured with a Corning pH meter.

ESCA spectra of γ-Fe_3O_4 treated with water-soluble titanate coupling agents were obtained using a Kokusaidenki VK-5B photoelectron spectrometer equipped with an aluminium $K\alpha$ X-ray source.

Results and Discussion

Figure 1 shows the zeta potentials of γ-Fe_3O_4 and the pH values of the suspensions as a function of the amount of water-soluble titanate coupling agents added. The zeta potential value of γ-Fe_3O_4 increased negatively with increase of the amount of KR-238S-TEA added and reached about −40 mV, while the pH of the suspension was in the range between 7—7.8. Since

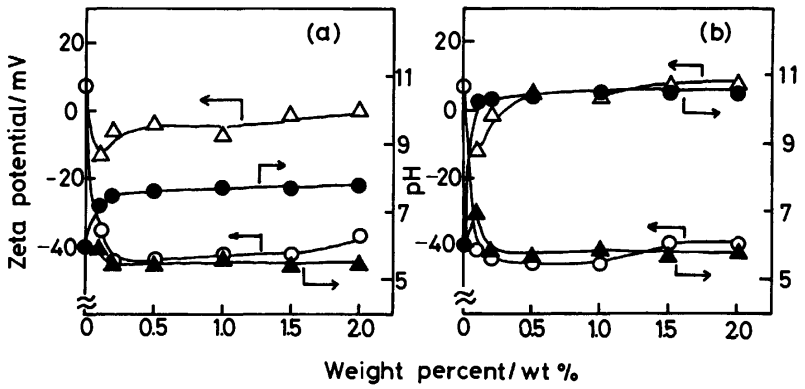

Fig. 1. Zeta potential of γ-Fe_3O_4 and the pH value of the suspension as a function of amount added of water-soluble titanate coupling agents: (a) KR-238S-TEA, (b) KR-138S-TEA; (○,●) immediate measurement, (△,▲) measurement after washing process.

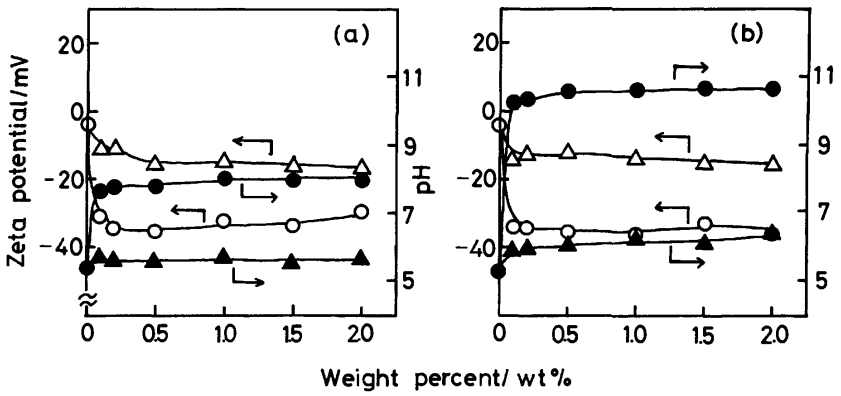

Fig. 2. Zeta potential of TiO_2 and the pH value of the suspension as a function of amount added of water-soluble titanate coupling agents: (a) KR-238S-TEA, (b) KR-138S-TEA, (○,●) immediate measurement, (△,▲) measurement after washing process.

the zero point of the charge (ZPC) for untreated γ-Fe_3O_4 was about 7.5, it seems that the complexes of KR-238S-TEA are adsorbed on the surface of γ-Fe_3O_4, resulting in a negative zeta potential. The change in the zeta potential of γ-Fe_3O_4 by addition of KR-138S-TEA was analogous to that for KR-238S-TEA. Further, from the measurement of the ESCA spectra for the samples treated with KR-238S-TEA and KR-138S-TEA, a Ti 2P photopeak due to water-soluble titanate coupling agents was detected. This result indicates that these water-soluble titanate coupling agents are adsorbed on γ-Fe_3O_4.

The attachment strength of the water-soluble titanate coupling agents was estimated by measuring the zeta potential of γ-Fe_3O_4 treated after a washing process. The γ-Fe_3O_4 particles in the presence of the water-soluble titanate coupling agent were collected and washed five times with a 10 ml of deionized water, then dispersed in deionized water. After such a washing process, the zeta potential of γ-Fe_3O_4 for KR-238S-TEA showed a negative value, while the sample for KR-138S-TEA provided a positive zeta potential with a value of +12 mV which is almost the same as for the untreated sample at pH=5.5. These results suggest that after washing, for KR-238S-TEA some titanate molecules still remain on the surface of γ-Fe_3O_4, but not for KR-138S-TEA. To confirm that some titanate molecules exist on the surface of γ-Fe_3O_4 after the washing process, ESCA spectra were measured. It was observed that the Ti 2P photopeak for KR-238S-TEA was detected, but not for KR-138S-TEA. Thus, it is found that the attachment of KR-238S-TEA on the surface of γ-Fe_3O_4 is much stronger than that of KR-138S-TEA.

Figure 2 gives the zeta potential of TiO_2 and the pH of the suspension for addition of various amounts of water-soluble titanate coupling agents. In both KR-138S-TEA and KR-238S-TEA, the zeta potential values by addition of the water-soluble titanate coupling agents were close to those of the untreated samples, indicating that adsorption of these titanate coupling agents scarcely occurs on TiO_2 or may occur by ion exchange. Also, after the washing process, the zeta potential of TiO_2 was −20 mV which is almost identical to that of the untreated sample at about pH=6. Thus, the zeta potential of TiO_2 by addition of various amounts of water-soluble titanate coupling agents and after the washing process changed little compared with that of an untreated sample.

The Thermal Decomposition of CF_3I in Ar

Ko SAITO,* Yuji YONEDA, Hiroyuki TAHARA,
Sadao KIDOGUCHI, and Ichiro MURAKAMI
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received February 24, 1984)

Synopsis. The thermal decomposition of CF_3I behind reflected shock waves was studied by means of the UV absorption over the temperature range of 935—1235 K and in the density range of 6.3×10^{-6}—3.8×10^{-5} mol cm^{-3}. The decomposition rate was in the fall-off region, and the main process was the C-I bond fission. The rate constants corresponding to the limiting high- and low-pressure regions were determined to be;

$$k_\infty = 10^{14.67}\exp(-27200/T)\ \mathrm{s}^{-1}$$

and;

$$k_0/[\mathrm{Ar}] = 10^{14.71}\exp(-15000/T)\ \mathrm{cm}^3\ \mathrm{mol}^{-1}\ \mathrm{s}^{-1}.$$

In connection with the other halogenated methanes, the thermal unimolecular rate constant of the CF_3I decomposition is interesting from such points of view as the contribution of the internal vibrational modes to the bond rupture and the energy transfer in collisions between the reactant and the heat bath. In the past, the high-pressure rate constant for the primary process, $CF_3I \rightarrow CF_3+I$, was determined by Danidov *et al.*[1] in the temperature range between 608—723 K. Skorobogatov[2] evaluated an Arrhenius expression for the rate constant over the temperature range between 400—1400 K on the basis of the equilibrium constant and the rate data for the reverse reaction. In their study of the kinetics of the CF_3 radical, Modica and Sillers[3] used a low-pressure rate constant evaluated from the classical collision theory, not from experiments.

The main purpose of the present study is to determine the high- and low-pressure rate constants for the primary reaction in order to ascertain the unimolecular behavior in Ar.

Experimental

A 9.4-cm-i.d. shock tube was used for this experiment. The optical system to follow the UV absorption was essentially the same as in previous works;[4,5] that is, a deuterium lamp, a 25-cm monochromator, a photomultiplier, and a digital memory were the basic line-up of the time-resolved absorption system. The disappearance rate of the shock-heated CF_3I was measured by observing the absorption at 290 nm with FWHM=1.65 nm. The absorption coefficient (base e) was determined to be $(1.8\pm0.5)\times10^5$ cm^2 mol^{-1} over the temperature range of 900—1250 K.

CF_3I (PCR Research Chemicals) was used after trap-to-trap distillations. Mixtures (0.67—2.0 mol% CF_3I in Ar) were prepared in 25-l cylindrical glass reservoirs and then allowed to stand for more than 12h before use.

Results and Discussion

Figure 1 shows some typical absorption records at different temperatures. The apparent first-order rate constant, k_a, was determined by means of this definition: $k_a=-\mathrm{d}(\ln[CF_3I])/\mathrm{d}t$. The k_a's observed varied with the total density, suggesting that the decomposition was in the fall-off region. Table 1 lists the Arrhenius parameters for k_a determined at three different total densities.

In order to evaluate the high- and low-pressure rate constants, k_∞ and $k_0/[\mathrm{Ar}]$, the fall-off data were extrapolated to high and low pressures along with the fall-off curves, which were themselves calculated by the reduced form of the Kassel theory.[6] This was performed in the usual manner described in a previous paper.[7] By fitting the fall-off curves to the data points, the two Arrehnius expressions for the limiting pressures were evaluated as;

$$k_\infty = 10^{14.67}\exp(-27200/T)\ \mathrm{s}^{-1}$$

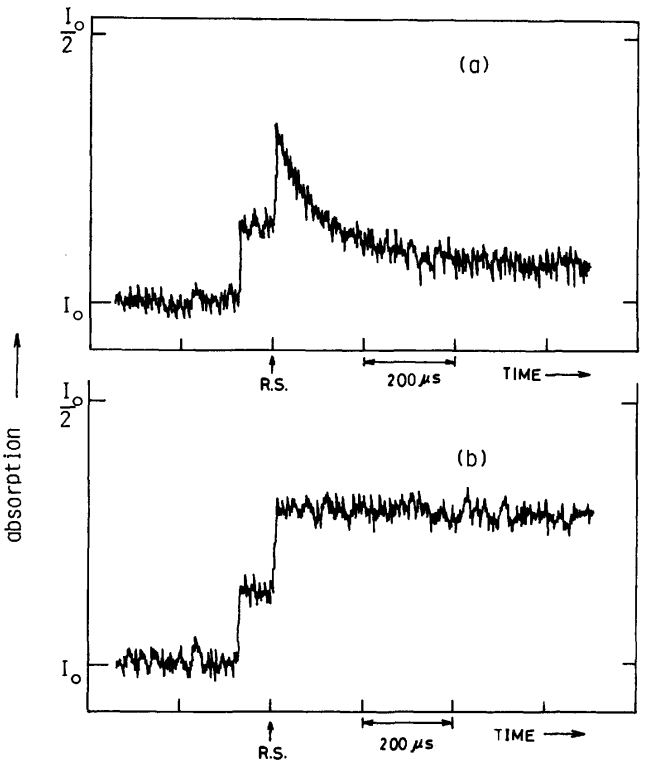

Fig. 1. Typical absorption records at 290 nm. a: [M] $=2.20\times10^{-5}$ mol cm^{-3}, Temp=1200 K, 1.0 mol% CF_3I in Ar; b: [M] $=2.05\times10^{-5}$ mol cm^{-3}, Temp= 930 K, 1.0 mol% CF_3I in Ar.

TABLE 1. ARRHENIUS PARAMETERS FOR k_a

Total density / mol cm^{-3}	A / cm^3 mol^{-1} s^{-1}	E_a / kJ mol^{-1}
6.3×10^{-6}	5.8×10^8	130
1.0×10^{-5}	1.6×10^9	134
$(3.5\pm0.3)\times10^{-5}$	9.6×10^9	146

and;

$$k_0/[\mathrm{Ar}] = 10^{14.71}\exp(-15000/T)\ \mathrm{cm^3\ mol^{-1}\ s^{-1}},$$

with an error limit of about 50% in the temperature range of 950—1235 K.

The initial decay of CF_3I diluted in Ar is considered to proceed *via* the following reactions;

$$(1)\quad CF_3I\ (+Ar) \longrightarrow CF_3 + I\ (+Ar),$$

$$(2)\quad CF_3I + I \longrightarrow CF_3 + I_2,$$

$$(3)\quad CF_3I + CF_3 \longrightarrow CF_2I + CF_4,$$

$$(4)\quad CF_3I + CF_3 \longrightarrow C_2F_6 + I.$$

The effects of Reactions (2)—(4) on the decay rate were examined by using a series of reactions with appropriate rate constants. As a result, the participation of these secondary reactions was found to be negligibly small at the early stage, where the decay rates were measured. Thus, it was ascertained that the evaluated values for k_∞ and $k_0/[\mathrm{Ar}]$ corresponded to Reaction (1).

The Arrhenius parameters for k_∞ obtained in the present work are comparable to the values estimated by Skorobogatov,[2] $k_\infty = 10^{14}\exp(-26500/T)\ \mathrm{s^{-1}}$. The present rate constant exceeds this by a factor of 2.6 at 1000 K; it is thus in good agreement. However, the value obtained by Danidov *et al*,[1] $k_\infty = 10^{15.40}\exp(-23750/T)\ \mathrm{s^{-1}}$, exceeds the present value by about two orders at 1000 K. For the low-pressure-rate constant, on the other hand, there are no experimental data to be compared. An estimation by Modica and Sillers[3] using the classical collision theory is too low (less than two orders) compared with the present results. The cause of this large discrepancy is perhaps the high bond-dissociation energy (240.1 kJ $\mathrm{mol^{-1}}$) used in their calculation.

The weak collision parameters were calculated by the use of a relation between observed and strong collision rate constants,[8] as has been performed for some similar molecules.[5,7] Table 2 lists the calculated results for the collision efficiency, β_c, and the average energy transferred per collision, $\langle\Delta E\rangle$, together with the data for CH_3I.[5]

It is of interest to compare the rate data between CF_3I and CH_3I in the same temperature range, because the molecular constants of these molecules differ substantially from each other, although the dissociation energies of the C-I bonds are very close. We can see from Table 2 there is no serious difference in the weak collision parameters between the two systems. However, the dissociation of CH_3I in Ar was in the low-pressure region; this was in contrast to that of CF_3I under the same conditions.[5] The fall-off pressures at 1100 K were estimated to be 130 and 2270 atm for CF_3I and CH_3I respectively.[9] This apparently low fall-off pressure of the CF_3I decomposition seems to show that this molecule acts as if its internal degrees of freedom were larger than that of CH_3I. In fact, the effective numbers of the internal freedom, S_{eff}, are 5.76 and 3.06 for CF_3I and CH_3I respectively, where $S_{eff} = -T^{-1}[d\ln Q_{vib}/d(1/T)]$.[6] The fall-off pressure of the CF_3I decomposition is rather close to that of the CF_3CN decomposition in Ar at the same temperature.[10]

Table 2. Comparison of weak collision parameters between CF_3I and CH_3I

System	T/K	β_c	$-\langle\Delta E\rangle$/J $\mathrm{mol^{-1}}$
CF_3I-Ar[a]	1100	0.032	490
	1200	0.021	347

Tokiwadai, Hodogaya-ku, Yokohama 240
(Received February 24, 1984)

Synopsis. The amount of methyl or ethyl alcohol existing in a hydrate solid deposited from ternary mixtures of methyl (or ethyl) alcohol-tetrahydrofuran-water has been determined using ^{14}C-labeled alcohols. It was found that these alcohols could be enclathrated within the water lattice of tetrahydrofuran clathrate hydrate.

In a previous paper[1] a phase-diagrammatic method for examining the ability of an alcohol to form a clathrate-like hydrate in the presence of a reference substance, ethylene oxide or tetrahydrofuran, has been proposed and it has been concluded that both methyl and ethyl alcohols can be enclathrated within the water lattice of tetrahydrofuran(THF) hydrate (Type II). However, this method may lead to a wrong conclusion in some cases, especially when (1) a peak position in a phase diagram is obscured because of the flatness of the peak and (2) the peak position does not apparently shift owing to a complicated change of activity coefficients of the components concerned with their concentrations.[2] In fact, some other measurements have concluded that methyl alcohol cannot be enclathrated within the water lattice of such hydrates as ethylene oxide and THF.[2]

The purpose of this paper is, therefore, to carry out a direct measurement of the amount of either methyl or ethyl alcohol present in the solid carefully formed from a ternary mixture of the alcohol-THF-water by using radioactive alcohols.

Experimental

Procedure and Measurements. A mixture (about 10 g) containing given amount of either methyl or ethyl alcohol (^{14}C-labeled, 0.1—0.3 μCi), tetrahydrofuran(THF), and water was prepared. The mixture was inserted into one portion of a forked glass vessel, and cooled until the solid phase appeared. It was then gradually warmed until only a small amount of the solid remained undissolved. Then the mixture was kept standing for more than 12 h at an appropriate temperature mentioned below in order to grow the solid as slowly as possible.

A known amount (0.5—3 g) of the solid sample, which was separated from its supernatant solution by filtration, was dissolved in a given amount of scintillator, Insta-gel (Packard Instrument Co., Inc.). The radio activity of the sample was measured using the TRI-CARB 460C Automatic Liquid Scintillation System (Packard Instrument Co., Inc.).

Determination of the Experimental Conditions. In Fig. 1, the solid-liquid phase diagrams[1] for the ethyl alcohol-THF-water systems are shown, in which the dissolution temperature is plotted against the sum of the mole fractions, $X=X_{THF}+X_{alc}$, where X_{THF}, and X_{alc} are the mole

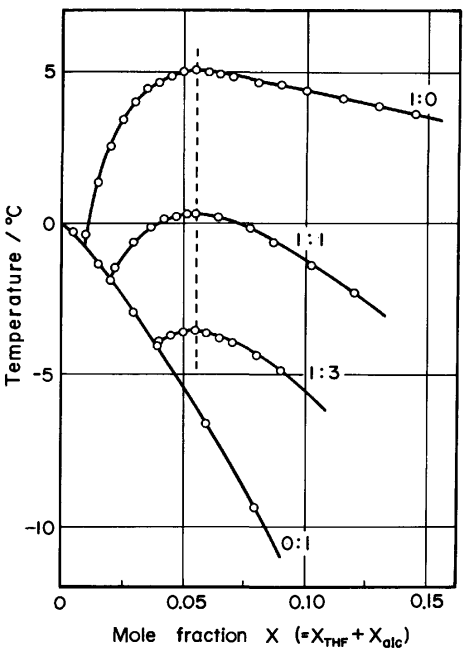

Fig. 1. The solid-liquid phase diagrams for THF–ethyl alcohol–water systems. Explanations are given in the text.

fractions of THF and ethyl alcohol, respectively. Each curve corresponds to the system in which the ratio $X_{THF}:X_{alc}$ is kept constant. The curve marked 1:0 is for the THF-water binary system and the congruent melting point at 5.1 °C and X=0.056 indicates the formation of the clathrate hydrate of THF (Type II). Similarly the curve marked 0:1 is for the ethyl alcohol-water binary system. This curve indicates no formation of a clathrate hydrate in the temperature range examined in agreement with several other experiments.[3-5] However, the other two curves (marked with 1:1 and 1:3) in Fig. 1 give no information about the composition of the solid phase since, in these ternary systems, the abscissa of Fig. 1 does not indicate a solid phase composition even at a peak position.[1] A direct determination of the composition of the solid phase is the object of this study as mentioned above. Preliminary experiments showed that, (1) for the systems containing ethyl alcohol with $X_{THF}+X_{alc}$=0.056 and $X_{THF}:X_{alc}$=1:1—1:3, solid phases formed at temperatures higher than −10 °C were morphologically different from those formed below −10 °C and the latter were identified with ice, and (2) the solid formed from the mixture containing much ethyl alcohol than $X_{THF}:X_{alc}$=1:4 was found to be ice. Systems containing methyl alcohol also showed similar behavior except that the limit of the ratio $X_{THF}:X_{alc}$ was 1:6 instead of 1:4. From these facts, appropriate experimental conditions were determined as follows: temperature=−6 °C, the molar ratio $X_{THF}:X_{alc}$=1:1—1:3 for ethyl alcohol and

1:0.5—1:4 for methyl alcohol. The mole fraction X was kept constant at 0.056 in all cases.

Results and Discussion

Estimation of the Amount of the Liquid Phase Adhering to the Solid Phase. In order to know the composition of the solid phase exactly, we must first estimate the weight fraction, y, of the liquid phase coexisting with the wet solid sample separated from a supernatant solution. Since, if alcohol can form a mixed clathrate hydrate with THF expressed by a formula $(\text{alcohol})_x(\text{THF})_{1-x}\cdot 17H_2O$, x should decrease with increasing temperature, as exemplified by other systems,[6] we tentatively assumed that x was equal to zero for the solid formed at a temperature as high as possible. Based upon this assumption the value of y was estimated to be 0.46 for the systems containing ethyl alcohol from the radioactivity measurements for the solid formed from the mixtures of $X_{THF}:X_{alc}=1:1$ at −2.5 °C and −3.7 °C, and 0.35 for the systems containing methyl alcohol from the data corresponding to $X_{THF}:X_{alc}=1:0.5$ at −0.5 °C. We further assumed that the same y values could be used in analyzing the experimental results since (1) the appearance of the solid phase (formed at −6 °C) was closely the same as when values above y were estimated, and (2) the temperature dependence of y was proved to be negligible.

Enclathration of Alcohols within the Water Lattice of the Clathrate Hydrate of THF. Using the y values evaluated above, the observed x's in an assumed formula $(\text{alcohol})_x(\text{THF})_{1-x}\cdot 17H_2O$ are summarized in Table 1. Each value is an average of 5—10 measurements.

Table 1 shows that x's for the systems containing ethyl alcohol are relatively small, around 0.05, and almost constant irrespective of the molar ratio $X_{THF}:X_{alc}$, indicating that ethyl alcohol can be enclathrated within the lattice of the THF clathrate hydrate from the following reasons: (1) if ethyl alcohol cannot form a mixed clathrate hydrate with THF, x should likewise be zero as assumed in the estimation of y; and (2) a solid-liquid phase diagram of the system which forms a mixed clathrate hydrate requires that x should be constant at a given temperature regardless of the composition of the system,[6] in fair agreement with the above experimental results.

Table 1. The observed x values in the assumed formula $(\text{alcohol})_x(\text{THF})_{1-x}\cdot 17H_2O$ for the solid formed at −6 °C in ternary mixtures of alcohol–THF–water with $X_{THF}+X_{alc}=0.056$

Alcohol	X_{THF} : X_{alc}	x
Ethyl alcohol	1 : 2	0.055
	1 : 3	0.044
Methyl alcohol	1 : 2	0.024
	1 : 3	0.16
	1 : 4	0.29

It can also be concluded that methyl alcohol is included within the THF clathrate hydrate lattice since the x values in Table 1 are larger than zero. However, in contrast to the systems containing ethyl alcohol, x increases with increasing methyl alcohol content. Although a precise explanation for this phenomenon cannot be given because of the lack of any other information, one possibility would be that methyl alcohol can also be accommodated within such vacant water cages as 12-hedron or 14-hedron as well as 16-hedron as its concentration increases. This phenomenon will be, in a sense, a typical one for an inclusion compound as exemplified by the fact that, in a gas hydrate, the degree of occupancy of a guest molecule increases with increasing its partial pressure.

Primary Structure and Molecular Evolution of Protein. Internal Homology and Intramolecular Evolutionary Tree of Calmodulin

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received March 7, 1984)

Synopsis. One notable feature of the primary structure of calmodulin is its internal homology. It can be subdivided into four domains having a similar amino acid sequence. In the present paper, an intramolecular evolutionary tree was constructed with the four domains. The origin and evolution of calmodulin was discussed on the basis of these results.

Origin and evolution of protein is one of the most important problems in biology and biochemistry. Evolutionary trees of typical proteins, such as cytochrome c and globins, have been constructed with a number of biological species.[1] In previous papers,[2,3] we studied molecular evolution of calmodulin (CaM), one of the calcium-binding proteins. It has four calcium-binding sites, and interacts reversibly with Ca^{2+} to form a calmodulin-Ca^{2+} complex.[4] CaM plays an important role in regulating other enzymatic reactions or cellular processes. The complete amino acid sequence of bovine brain CaM was first determined by Watterson *et al.*[5] and by Kasai *et al.*[6] It contains 148 amino acids and has a trimethylated lysin at position 115.

One notable feature of CaM is that it is widely distributed throughout eukaryotes and that the primary structure of CaM is highly conservative against evolution.[2] Another interesting feature is that the primary structure of CaM has internal homology, that is, it can be subdivided into four domains having a similar amino acid sequence. This is shown, for example, in Fig. 1 with bovine brain CaM, where the first domain (residues 8 to 40), the second (residues 44 to 76), the third (residues 81 to 113) and the fourth (residues 117 to 148) are aligned for purposes of comparison. The amino acids which do not belong to the four domains are residues 1 to 7, 41 to 43, 77 to 80 and 114 to 116. These are the linking sequences between the domains. In the following, we only discuss the amino acids belonging to the four domains. In the previous paper,[3] we found by visual inspection that the amino acid sequence homology is greatest when the first domain is aligned with the third, and the second domain with the fourth . In order to explain this fact, a two-step intragenic duplication model (refer to Fig. 4 of Ref. 3) was proposed to the primary amino acid sequence of CaM. In this model, it is assumed that an ancestral one-domain quarter-calmodulin (AQ) underwent an elongation by the first intragenic duplication, which resulted in an ancestral two-domain half-calmodulin (AH). In the period from the birth of AH to the next intragenic duplication (stage 1 in Fig. 4 of Ref. 3), AH underwent evolutionary changes and some replacements of amino acids occurred in it. At the end of stage 1, the second intragenic duplication took place, resulting in an ancestral four-domain calmodulin (AC). In the period from the birth of AC to the present time (stage 2 in Fig. 4 of Ref. 3), AC underwent further evolution and some replacements of amino acids took place.

Fig. 1. Comparison and homology of the amino acid sequences of the four domains in bovine brain calmodulin. The first domain (residues 8 to 40), the second (residues 44 to 76), the third (residues 81 to 113) and the fourth (residues 117 to 148) are aligned for purposes of comparison.

Clearly, this model is based on the finding that relations between the first and third domains and between the second and fourth domains are closest. However, these two relations do not necessarily support the above two-step intragenic duplication model. In order to support this model definitely, we should construct intramolecular phylogenetic tree of the four domains. If such a tree is once constructed, we can clearly show how the four domains are related with one another.

There have been known two approaches to construct such an evolutionary tree;[1] one is common ancestor method and the other, matrix method. If the evolutionary rate of protein is slow enough, the two methods reach the same conclusion. In the present paper, we construct intramolecular evolutionary tree of the four domains of bovine brain CaM by the use of the common ancenstor method. "Maximum parsimony method" is used for this purpose. It is generally known that codons of m RNA are translated into amino acids of protein. Any codon is composed of a series of three nucleotides and is expressed by "the genetic code". Therefore, the observed difference of amino acid residues of CaM between the domains (see Fig. 1) is attributable to the difference of nucleotides between the corresponding codons. Referring to the

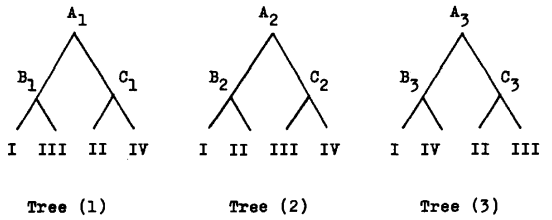

Fig. 2. Three possible intramolecular evolutionary trees (1), (2), and (3) for the four domains of bovine brain calmodulin. The first domain, the second, the third and the fourth are indicated by I, II, III, and IV, respectively. See Fig. 1 for the amino acid sequences of those domains. In each tree, we assume amino acid sequences of common ancestral domains (A_i), (B_i), and (C_i), (i=1, 2 or 3), so that the total number of nucleotide substitutions within the tree can be minimized (the maximum parsimony method). For further details, see the text.

genetic code, we assume that the difference of amino acids is given by the least number of nucleotide substitutions of the codons. In order to examine the above intragenic duplication model, we assume three evolutionary trees, as shown in Fig. 2. The tree (1) represents the evolutionary change, where the first and third domains were diverged from the common ancestral domain (B_1), while the second and fourth domains, from the common ancestor (C_1). The common ancestors (B_1) and (C_1) had been diverged from the common ancestral domain (A_1). Clearly, the tree (1) represents faithfully the evolutionary change of the above-mentioned intragenic duplication model. That is, the common ancestor (A_1) corresponds to the former or latter half of AH, since at the birth of AH it was formed by duplication of AQ. In a similar way, the common ancestor (B_1) corresponds to the first or third domain of AC, while the common ancestor (C_1), to the second or fourth domain of AC (see Fig. 4 of Ref. 3).

In addition to the tree (1), we further consider two possible evolutionary trees (2) and (3). The tree (2) assumes that the first and second domains were diverged from the common ancestral domain (B_2), while the third and fourth domains, from the common ancestor (C_2). These two common ancestors had been diverged from the common ancestral domain (A_2). In this tree, the relations between the first and second domains and between the third and fourth domains are closest. In a similar way, the tree (3) assumes that the first and fourth domains came from the common ancestral domain (B_3), while the second and third domains, from the common ancestor (C_3). Both (B_3) and (C_3) had come from the common ancestral domain (A_3). In order to determine which tree is most probable, we use the maximum parsimony method. In each tree, we assume amino acid sequences of common ancestral domains (A_i), (B_i), and (C_i), (i=1, 2 or 3), so that the total number of nucleotide substitutions within the tree can be minimized. In order to do this, we note a lack of one amino acid of the fourth domain at position 149 (see Fig. 1). The corresponding amino acid residues of the first, second and third domains are Gly at position 40, Met at position 76 and Gly at position 113, respectively. These three amino acid residues are excluded from our counting, because we cannot compare the amino acid residues in all four domains. Taking into account the remaining amino acid residues in the four domains, we calculated the minimum number of nucleotide substitutions of the trees (1), (2), and (3) as 65, 72, and 72, respectively. Therefore, the maximum parsimony method rejects the evolutionary trees (2) and (3) and suggests that the evolutionary tree (1) is most probable. This conclusion confirms that the homologies between the first and third domains and between the second and fourth domains are greatest, and supports strongly our previous two-step intragenic duplication model for the primary amino acid sequence of CaM.

cDNA Sequences and Molecular Evolution of Calmodulin Genes of Chicken and Eel

Yôichi IIDA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received April 18, 1984)

Synopsis. c DNA sequences of calmodulin genes taken from chicken and eel were compared to investigate the molecular evolution of its protein. One notable feature of the amino acid coding region of the gene is that the second positions of codons are more conservative than the first positions, while the third positions are highly diverged to exhibit almost saturation. This kind of behaviour is reminiscent of that of the histone gene.

Origin and evolution of protein is one of the most important problems in biology and biochemistry. Recently, primary nucleotide sequences have been determined with a number of genes which code for proteins. Studies on molecular evolution of proteins in terms of such DNA sequences are very interesting. Calmodulin (CaM) is one of the calcium-binding proteins.[1-3] It has four calcium-binding sites, and interacts reversibly with Ca^{2+} to form a calmodulin-Ca^{2+} complex. It contains 148 amino acids and has a trimethylated lysine at position 115. One notable feature of CaM is that it is widely distributed throughout eukaryotes and that the primary amino acid sequence is highly conservative against evolution. In previous papers,[4,5] we examined the origin and evolution of CaMs in terms of their primary amino acid sequences. So for, their amino acid sequences have been determined with a number of representative species.[1-5] However, little information was known with the m RNAs that code for CaM. Recently, Lagacé *et al.* and Putkey *et al.* isolated m RNAs of CaM from the electroplax of electric eel (Electrophorus electricus) and from chicken brain, respectively,[6,7] and their c DNAs (DNA complementary to m RNA) have been cloned and sequenced. Therefore, it is very interesting to compare the DNA sequences between both biological species. We pay attention to how the highly conservative amino acid sequence of CaM is related to the coding region of c DNA.

Figure 1 shows the amino acid coding regions of the nucleotide sequences of CaM c DNAs for chicken and eel. The numbers indicate amino acid positions. The initiation (ATG) and termination (TGA) codons are common to the two species. If we exclude these two codons, the coding region of the c DNA is composed of 148 codons. For the two species, the corresponding codons are aligned and compared in Fig. 1. Those nucleotides which are different between the two species are indicated by asterisk (*). The other nucleotides are found to be identical between the two. As is expected from the highly conservative amino acid sequences of CaM, the primary nucleotide sequences in the amino acid-coding regions of the respective c DNA are highly homologous, with an overall homology of 79%. Particularly, the first and second positions (replacement sites) of codons show markedly higher degree of homology than does the overall homology. In contrast to these, the third positions (silent sites) of codons are very much diverged.

In order to treat these situations more quantitatively, we consider one-parameter and two-parameter models for evaluating the degree of nucleotide changes proposed by Kimura *et al.*[8] In estimating the evolutionary distances between homologous sequences in terms of the number of nucleotide substitutions, corrections for multiple and revertant changes at homologous sites are important. The total number of nucleotide substitutions per site, K, which separate two sequences and therefore involve two branches each with time length T, is expressed by $K=2Tk$, where k is the total rate of substitutions per site per year. In the one-parameter model where probability of every nucleotide substitution is assumed to be common, K is given by[8]

$$K = -\frac{3}{4}\ln\left(1-\frac{4\lambda}{3}\right), \tag{1}$$

where λ is the fraction of sites for which two sequences differ from each other. From the data of Fig. 1 of the chicken and eel CaM genes, the λ value for the first positions of codons was calculated as 7/148=0.0473, while the values for the second and third positions, as 1/148=0.00676 and 84/148=0.568, respectively. As can be seen from the highly conservative amino acid sequences of CaM, the magnitudes of λ for the replacement sites are extremely small, while that for the silent site is found to be larger than 1/2. If nucleotide substitutions occur randomly, the λ value will show a saturated value of 3/4=0.75. In view of this, the value for the third position appears to approach such a saturated value. Using Eq. 1, the K values for the first, second and third positions of codons were calculated as 0.049 (±0.019), 0.0068 (±0.0068) and 1.06 (±0.17), respectively, where the figures in parentheses show standard error.[8]

In the two-parameter model, the probabilities of transition type nucleotide substitutions and transversion type substitutions are discriminated. The transitions are substitutions of purines by purines (A↔G), and pyrimidines by pyrimidines (T↔C), while the transversions are substitutions in which a purine is replaced by a pyrimidine, or a pyrimidine is replaced by a purine (A or G↔T or C). In this model, the K value is expressed by[9]

$$K = -\frac{1}{2}\ln\{(1-2P-Q)\sqrt{1-2Q}\}. \tag{2}$$

Here, P and Q are given by the fraction of sites for which two sequences differ from each other with respect to transition type and transversion type substitutions, respectively. In the chicken and eel CaM genes, P and Q for the first positions of codons were calculated as 4/148=0.0270 and 3/148=0.0203, respectively. These values lead to K=0.049 (±0.019) for the first positions, where the figure in parentheses shows stan-

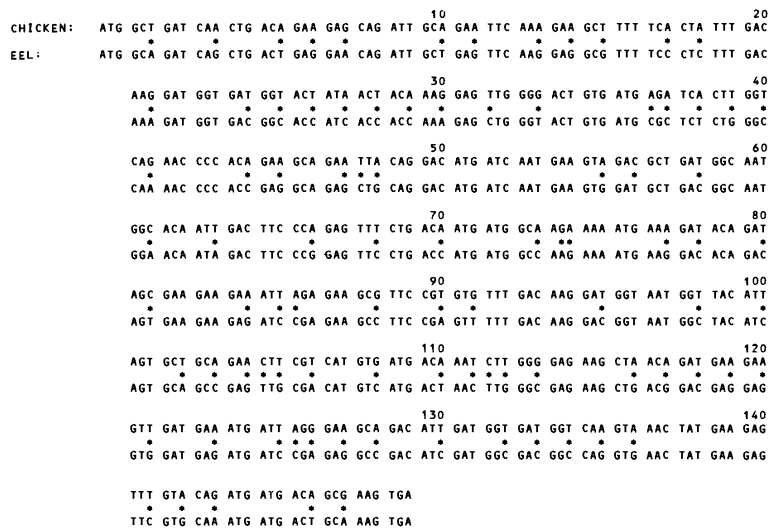

Fig. 1. Comparison and homology of the amino acid coding regions of the c DNA sequences taken from chicken and electric eel (Electrophorus electricus).[6,7] The initiation (ATG) and termination (TGA) codons are common between the two species. The numbers indicate amino acid positions. Those nucleotides which are different between the two species are shown by asterisk (*).

dard error.[9] Similarly, for the second positions, $P=1/148=0.00676$, $Q=0.00000$ and $K=0.0068$ (± 0.0068), and for the third positions, $P=53/148=0.358$, $Q=31/148=0.209$ and $K=1.44$ (± 0.49). In all three positions, P is greater than $(1/2)Q$, indicating that the transitions have occurred more frequently than have the transversions. In this respect, the two-parameter model is more realistic than the one-parameter model, and the following discussion will be made with the two-parameter model.

The most notable feature of the CaM genes is that the K value of the third positions (K_3) is much greater than those of the first (K_1) and second (K_2) positions. This means that the pressure by natural selection has been strongly applied to amino acid sequences of CaM, while the third positions of codons are almost neutral against evolution; most of the third positions are synonymous with respect to changes of amino acid residues. It is also found that the magnitude of K_2 is less than that of K_1. The order of $K_2<K_1<K_3$ holds generally with various protein genes, such as β-globin gene.[10]

Using the equation of $K=2Tk$, we estimate the values of k, the rate of nucleotide substitutions per site per year. We assume that the common ancestor of eel and chicken CaMs diverged $T=3.5\times10^8$ years ago (the time of divergence into osteichthyes and amphibians).[11] Then, the values of k for the first, second and third positions of codons of CaM are calculated as $k_1=0.070\times10^{-9}$, $k_2=0.0097\times10^{-9}$ and $k_3=2.1\times10^{-9}$, respectively. These results may be compared with histone H4 which is known to be the most highly conservative protein against evolution. The rate of amino acid substitutions per site per year of histone H4 is known as $k_{aa}=0.006\times10^{-9}$.[12] The value of k_2 of CaM is of comparable order with that of k_{aa}, while the value of k_1 of CaM is about ten times larger than that of k_{aa}. Therefore, although the first positions of codons of CaM are less conservative than those of histone H4, the conservative properties of these two proteins are comparable with each other. In contrast to these, the rate of $k_3=2.1\times10^{-9}$ of the third positions of CaM is as high as 2.3×10^{-9} of fibrinopeptide or $(3.7\pm1.4)\times10^{-9}$ of the third nucleotide positions of histone H4 gene.[12] The latter two values are known as the highest rate of nucleotide substitutions. It is remarkable that, in CaM gene, synonymous mutant substitutions have occurred with the highest rate, while the amino acid substitutions have occurred with as low rate as that of histone H4.

Preparation of Sodium Bis(L-aspartato)rhodate(III)

Masatoshi WATABE,* Kenji FURIHATA, and Yoshio ODAKA
General Education Department, Kogakuin University Nakano-cho, Hachioji-shi, Tokyo 192
(Received November 11, 1983)

Synopsis Bis(L-aspartato) rhodate(III) complex was prepared and separated into three isomers, and their absorption, CD curves and ^{1}H NMR spectra are presented. The geometrical configurations of three isomers are assigned mainly on the basis of the spectral analogy between this complex and the $[Co(L\text{-}asp)_2]^-$ complex.

Numerous studies of cobalt(III) complexes containing amino carboxylate ion have been reported,[1-3] but only a few rhodium(III) complexes with amino carboxylate ion have been studied.[4] As both cobalt(III) and rhodium(III) have the same low spin d^6 electronic configuration, the spectral features of the rhodium(III) complexes should resemble those of the cobalt(III) complexes having the same ligands. Smith and Sawyer[4] have reported on the preparation and the characterization by ^{1}H-NMR spectra of rhodium(III) complexes having iminodiacetate ion (=ida) and *N*-methyliminodiacetate ion (=mida), in which UV and ^{1}H-NMR spectra of these complexes resemble those of the cobalt(III) complexes having the same ligand. The present paper deals with the preparation and the assignment of Bis(L-aspartato) rhodate(III).

Experimental

To a hot solution (20 cm^3) containing 2g of $Rh(NO_3)_3$ (0.007 mol) 4 mol dm^{-3} KOH solution was added untill the pH of the solution reached 7. The precipitate was centrifuged and suspended in 80 cm^3 of water containing 1.84 g of aspartic acid (0.0138 mol) in a pyrex tube and heated at 120—130 °C for five hours. After cooling, the tube was opened carefully and a small quantity of metallic rhodium removed by filtration. This solution was loaded on a QEA-Sephadex A-25 anion exchanger column (50×300 mm). After the elution of the cation and non charged complexes with water, the column was eluted with 0.1 mol dm^{-3} NaCl solution. Five bands descended and showed yellow or yellow brown color (R1, R2, R3, R4, and R5; those are named in the order of elution). The bands R1, R2, and R3 were the desired isomers as established below. The separation of R2 and R3 was not good. The complexes corrsponding to bands R4 and R5 did not possess one minus charge because these bands gradually spread with 0.1 mol dm^{-3} NaCl solution. Each eluate was concentrateed by using a rotary evaporator at room temperature. Calcd for $Na[Rh(L\text{-}asp)_2]\ 2H_2O$ C, 21.80; H, 4.12; N, 6.36%. Found (R1): C, 21.75; H, 4.01; N, 6.55%. Found (R2): C, 21.86; H, 4.36; N, 6.37. Found (R3): C, 22.00; H, 4.05; N, 6.45%.

Spectral Measurements. Visible absorption and circular dichroism spectra were measured with JASCO-UV505 and JASCO-J20 spectrometers in aqueous solution. ^{1}H NMR spectra were measured with a Varian FT-80A spectrometer in D_2O solution with TSP (sodium 3-(trimethylsilyl) propionate) as an internal standard.

Results and Discussion

Figure 1 shows the possible isomers of $[Rh(L\text{-}asp)_2]^-$. These complexes are composed of one

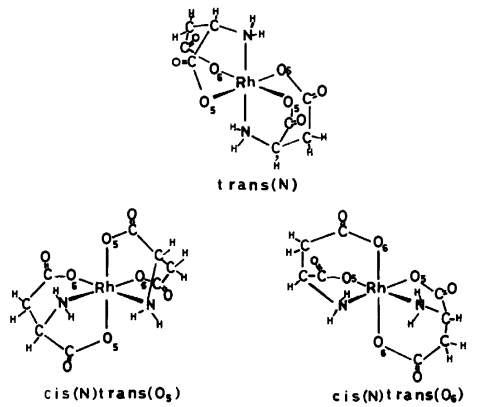

Fig. 1. The three possible isomers of $[Rh(L\text{-}asp)_2]^-$.

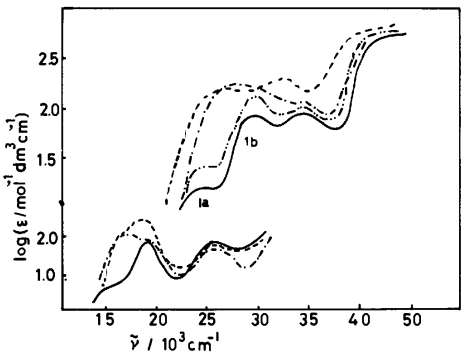

Fig. 2. Visible absorption spectra of $[Rh(L\text{-}asp)_2]^-$· (upper) R1 ——, R2 ----, R3 —·—, *trans*(N)-$[Rh(ida)_2]^-$, —··—, and $[Co(L\text{-}asp)_2]^-$· (lower) F ——, S ---- and T —·—.

trans(N) and two *cis*(N) isomers. The two *cis*(N) isomers are designated *cis*(N) *trans*(O_5) and *cis*(N) *trans*(O_6) as in the case of bis(L-aspartato) cobaltate(III) complexes.[5] Figure 2. shows the UV spectra of $[Rh(L\text{-}asp)_2]^-$ along with those of $[Co(L\text{-}asp)_2]^-$ and *trans*(N)-$[Rh(ida)_2]^-$. The lowest energy band of the R1 isomer split into well-separated components (24300 and 29400 cm^{-1}) and the splitting pattern in the first and the second absorption band regions agree with those of *trans*(N)-$[Rh(ida)_2]^-$. The isomer R1, therefore, is assigned as the *trans*(N) isomer (Fig. 1). It should be noted that the peak maximum of this isomer in the second absorption band region lies *ca.* 8000 cm^{-1} higher than that of the F isomer of $[Co(L\text{-}asp)_2]^-$[1] while the peak maximum of 1b (29400 cm^{-1}) in the first absorption band region lies *ca.* 10000 cm^{-1} higher than that of the F isomer of $[Co(L\text{-}asp)_2]^-$ (Table 1). This larger shift of the first absorption band causes the smaller seperation between the peak maxima of the first and the second absorption band than the corresponding separation for *trans*(N)-$[Co(L\text{-}asp)_2]^-$. This relation also prevails between *trans*(N)-$[Rh(ida)_2]^-$ and *trans*(N)-$[Co(ida)_2]^-$.

TABLE 1. AB AND CD DATA FOR $[Rh(L\text{-}asp)_2]^-$ AND ITS RELATED COMPLEXES

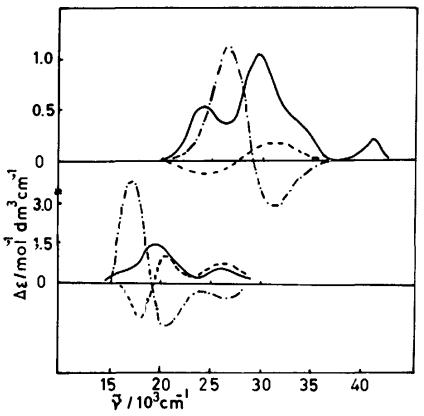

Fig. 3. CD spectra of $[Rh(L\text{-}asp)_2]^-$ (upper); R1 ——, R2 ----, and R3 —·—, and $[Co(L\text{-}asp)_2]^-$ (lower); F ——, S ----, and T —·—.

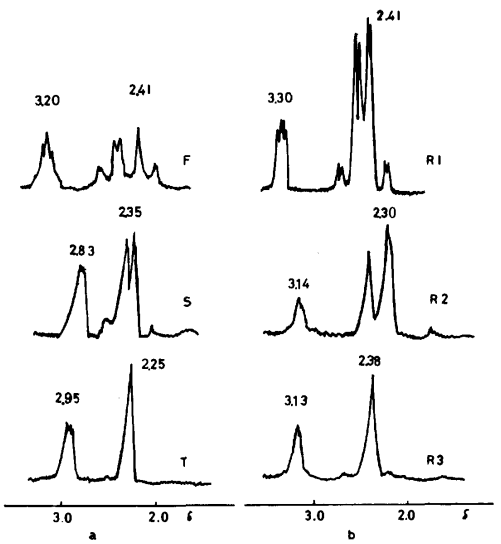

Fig. 4. ^{1}H-NMR spectra of $[Co(L\text{-}asp)_2]^-$ (left side); F, S, and T and $[Rh(L\text{-}asp)_2]^-$ (right side); R1, R2, and R3. ppm from TSP.

The three CD spectra are shown in Fig. 3 along with those of $[Co(L\text{-}asp)_2]^-$. From the crystal-structural analysis,[2] the geometry of the T isomer has been determined as a *cis*(N) *trans*(O_6) configuration. These three CD spectra of the $[Rh(L\text{-}asp)_2]^-$ complexes closely resemble those of $[Co(L\text{-}asp)_2]^-$ except that the peak maxima shift to higher energies. We assigned the R2 and the R3 isomers as *cis*(N) *trans*(O_5) and *cis*(N) *trans*(O_6).

^{1}H NMR spectra of the $[Rh(L\text{-}asp)_2]^-$ complex are shown in Fig. 4 along with those of the $[Co(L\text{-}asp)_2]^-$. The resemblance of the ^{1}H NMR spectra (80 MHz) between $[Rh(L\text{-}asp)_2]^-$ and $[Co(L\text{-}asp)_2]^-$ is notable. We have reported that when X is an oxygen atom in the moiety -CH-NH_2-Co-X (X is trans to NH_2), the methine proton signals appear at a slightly higher magnetic field than is the case where X is a nitrogen atom.[3] This trend holds for most cobalt(III) complexes. The chemical shifts of the methine proton of $[Rh(L\text{-}asp)_2]^-$ are 3.30 ppm for R1, 3.14 ppm for R2 and 3.13 ppm for R3. These values suggest that the chemical shift trend holds good in the rhodium(III) complex. However the two *cis*(N) isomers can not be distinguished only from this terend of the ^{1}H NMR data. On the basis of the elemental analysis data and the resemblance of the spectra between the $[Rh(L\text{-}asp)_2]^-$ and the $[Co(L\text{-}asp)_2]^-$ complexes, we assigned the isomers R1,R2, and R3 as *trans*(N), *cis*(N) *trans*(O_5), and *cis*(N) *trans*(O_6).

The Preparation of Pyridinium μ-Oxo-bis[nitrilotriacetatodioxomolybdate(VI)] and Pyridinium Di-μ-oxo-bis[nitrilotriacetatooxomolybdate(V)] Monohydrate and the X-ray Structure of the Molybdenum(VI) Complex

Keiji MATSUMOTO,* Yoshiaki MARUTANI, and Shun-ichiro OOI
Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received December 7, 1983)

Synopsis. Nitrilotriacetato complexes of Mo^{VI} and Mo^{V} were prepared and the X-ray structure of the former complex is described. On the basis of the UV-visible and IR spectra and elemental analyses, the latter complex is formulated as $(pyH)_2[Mo_2O_4(ntaH)_2]\cdot H_2O$.

As a part of studies on the structure of molybdenum complexes,[1-3] we describe here the preparation of nitrilotriacetato complexes of Mo^{VI} and Mo^{V}, and the X-ray structure of the molybdenum(VI) complex.

Experimental

Preparation of $(pyH)_2[Mo_2O_5(ntaH)_2]$ (1). Pyridine(py) was added to nitrilotriacetic acid($ntaH_3$) (2 m mol) in 20 ml of water and the solution was adjusted to pH 7—8. To this solution was added 2 m mol of MoO_3 and the suspension was warmed on a water bath with stirring for 0.5 h at 60 °C. During the reaction pyridine was added in order to keep pH 7—8. The resulting solution was filtered, evaporated to 4 ml, and methanol (5 ml) and acetone (8 ml) added. Colorless crystals were obtained after standing a couple of days. Yield, 270 mg. Found: C, 32.50; H, 3.36; N, 6.87%. Calcd for $(pyH)_2[Mo_2O_5(ntaH)_2]$; C, 32.60; H, 3.24; N, 6.92%.

Preparation of $(pyH)_2[Mo_2O_4(ntaH)_2]\cdot H_2O$ (2). $(pyH)_2[MoOCl_5]$ (2 m mol) and $ntaH_3$ (2 m mol) were added to 20 ml of water. The solution was warmed at 60 °C with stirring for 0.5 h and was adjusted to pH 7—8 with pyridine. The solution was filtered, evaporated to 7 ml, and methanol (5 ml) and acetone (5 ml) were added. Brown crystals were obtained after standing for 24 h. Yield, 520 mg. Found: C, 32.47; H, 3.58; N, 6.83%. Calcd for $(pyH)_2[Mo_2O_4(ntaH)_2]\cdot H_2O$: C, 32.52; H, 3.48; N, 6.90%.

Crystal Data of 1: $C_{22}H_{26}O_{17}N_4Mo_2$, F. W.=810.4, triclinic, space group $P\bar{1}$, a=17.244(8) Å, b=12.161(4) Å, c=7.558(2) Å, α=104.99(3)°, β=83.36(3)°, γ=74.88(3)°, Z=2, D_m=1.84 g cm^{-3}, D_c=1.86 g cm^{-3}, μ(Mo $K\alpha$)=9.42 cm^{-1}, λ(Mo $K\alpha$)=0.7107 Å, U=1449.3(8) Å^3.

The intensities were measured on a Philips PW1100 diffractometer. Crystal size: 0.23×0.32×0.39 mm^3; scan speed: 0.033° s^{-1}; scan range: 1.0°; backgroung measurement at each side of the scan range: half of the scan time; maximum 2θ value: 50°; number of reflections with $F_o^2 \geq 3\sigma(F_o^2)$: 4338.

The refinement of the structure was performed by the block-diagonal least-squares method. The function minimized was $\sum w(F_o-|F_c|)^2$, where $w=1/\sigma^2(F_o)$ was used. The R value was 0.031 ($R_w=[\sum w\Delta F^2/\sum wF_o^2]^{1/2}$=0.047). In the final cycles of the refinement hydrogen atoms were included but their parameters were not refined. Hydrogen atoms defined by the geometry of the complex were located at calculated positions and those bonded to OA5 and OB5 atoms were found in the difference Fourier map. All the parameter shifts were less than 0.3σ. The maximum peak in the final difference Fourier map was 0.6 eÅ^{-3}. The atomic scattering factors, with corrections for anomalous scattering of Mo were taken from Ref. 4. The F_o-F_c Tables, anisotropic temperature factors, and coordinates of hydrogen atoms are preserved by the Chemical Society of Japan (Document No. 8429). The atomic coordinates are listed in Table 1. Computations were performed on a FACOM 230-60 computer at Osaka City University and on an ACOS 900 computer at the Crystallographic Research Center. Institute for Protein Research, Osaka University. The programs in the UNICS were used.[5]

The absorption spectrum was recorded on a Hitachi 330 spectrophotometer and infrared spectra were obtained in KBr disks with a JASCO IRA-1 spectrophotometer.

Results and Discussion

Figure 1 gives a perspective view of the complex in **1**. The complex has an approximate two fold axis. The complex consists of two octahedra sharing a single non-linear oxo bridge (MoA-OB-MoB=167.0(2)°). The two terminal oxo ligands on each Mo are mutually cis and cis to the bridging oxo. The $Mo(O_t)_2$ (O_t=terminal oxo) groups lie on the same side of the complex. The distorted octahedral coordination of each Mo is formed by two terminal and one bridging oxo (O_b), and two carboxylato oxygen atoms and one amino nitrogen atom of ntaH. One carboxylate group in ntaH is free from the coordination. The Mo-O_t distances (1.683(3)—1.700(3) Å) are comparable to those in cis dioxo complexes (Table 2).[6] The average Mo-O_b distance is 1.876(6) Å. The two Mo-O distances to the ntaH ligand in each Mo at 2.072(2) (trans to O_b) and 2.151(6) Å (trans to O_t) indicate that O_t has a larger trans bond weakening effect. The Mo-N bond (trans to O_t) is longer than

the Mo–O bond (trans to O_t).

The IR spectrum of **2** gives the stretching vibrations of the Mo=O groups at 920 and 945 cm^{-1} and that of the Mo_2O_2 group at 783 cm^{-1}.[7] The IR spectra of the symmetric and assymmetric stretching vibrations of the carboxylato groups are similar in **1** and **2**. The UV-visible spectrum of **2** in pH 4 sodium acetate/acetic acid buffer solution gives two absorption peaks at 380 nm (shoulder, ε=162 l mol^{-1}cm^{-1}) and 297 nm (ε=5080 l mol^{-1} cm^{-1}). The spectrum is similar to that of $[Mo_2O_4(edta)]^{2-}$.[8] On the basis of the UV-visible and IR spectra and elemental analyses we formulate **2** as pyridinium di-μ-oxo-bis[nitrilotriacetatooxomolybdate(V)] monohydrate, $(pyH)_2[Mo_2O_4(ntaH)_2]\cdot H_2O$.

We wish to thank Dr. Takashi Shibahara for the sample of $(pyH)_2[MoOCl_5]$ and Mr. Junichi Gohda for elemental analyses.

Formation Process of Aluminium Nitride by the Vapor-phase Reaction of Aluminium Trichloride with Ammonia

Yuzo SAEKI,* Suh Ho PARK, Akimasa YAJIMA, and Masayo AKIYAMA
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227
(Received March 21, 1984)

Synopsis. The reaction products of gaseous $AlCl_3$ with ammonia were $AlCl_3 \cdot 3NH_3$ at 200—500 °C, AlN, $AlCl_3 \cdot 3NH_3$, NH_4Cl at 550—900 °C, and AlN, NH_4Cl at 1000 °C. AlN is considered to be formed by the reaction of gaseous $AlCl_3 \cdot 3NH_3$, formed by the reaction of gaseous $AlCl_3$ with ammonia, with ammonia above *ca.* 550 °C.

The properties of aluminium nitride (AlN) suggest that AlN has potential applications in electronic devices for high-temperature operations. AlN has become of interest as a piezoelectric film material. Concerning the deposition of AlN from aluminium trichloride ($AlCl_3$) by the vapor-phase reaction, Chu *et al.*[1] have reported the epitaxial growth of AlN by the reaction of gaseous $AlCl_3$ with ammonia. Bauer *et al.*[2] have studied the dependence of the AlN deposition rate on the conditions of the vapor-phase reaction of $AlCl_3$ with ammonia and the properties of the AlN films formed. Arnold *et al.*[3] have examined the yields of AlN films by the vapor-phase reaction of $AlCl_3$ with ammonia under various reaction conditions and estimated that the decomposition of $AlCl_3$–NH_3 adduct, formed in the reaction process, significantly contributes for the formation of AlN. However, the formation process of AlN by the vapor-phase reaction of $AlCl_3$ with ammonia has not been revealed. In this paper, the reaction products of gaseous $AlCl_3$ with ammonia at 200—1000 °C were examined. Also, the possible reactions which were considered to occur during the reaction process were examined. From these results, the formation process of AlN by the vapor-phase reaction of $AlCl_3$ with ammonia is discussed.

Experimental

The $AlCl_3$ used was prepared by the reaction of pure aluminium (Al 99.99%) with chlorine at 400 °C.[4] The chemical analysis gave Al, 20.2; Cl, 79.8% (calcd for $AlCl_3$: Al, 20.24; Cl, 79.76%). The ammonia was dried by passing it over sodium hydroxide granules and barium oxide powders.

Experimental apparatus and procedures for examining the reaction products of gaseous $AlCl_3$ with ammonia are the same as those described in the previous paper.[5] Gaseous $AlCl_3$ was formed by heating solid $AlCl_3$ (10 g) at 165 °C and was carried by a stream of argon (50 cm^3/min) into the reaction zone. The mean flow-rate of gaseous $AlCl_3$ was 6.0 cm^3 Al_2Cl_6(g)/min. Ammonia was simultaneously introduced at a flow-rate of 100 cm^3/min into the reaction zone through a separate tube. The reaction was allowed to proceed for 2 h.

The aluminium, chlorine and ammonia contents of the $AlCl_3$–NH_3 adduct formed were determined by chelatometric titration,[6] gravimetric method as AgCl, and the Kjeldahl method, respectively, after dissolving the sample in 3M-nitric acid. Thermogravimetry (TG) of the $AlCl_3$–NH_3 adduct was performed by using a thermal balance with a quartz helix (the sensitivity: approximately 113 mm/g). The sample (0.2 g) was heated at a rate of 2.5 °C/min and the flow-rate of ammonia or argon was maintained at 50 cm^3/min.

Results and Discussion

The products formed by heating gaseous $AlCl_3$ in an ammonia stream at various temperatures were examined by both X-ray analysis[7,8] and chemical analysis.

The products formed at 200—500 °C showed the same X-ray diffraction pattern, which was clearly different from those of known aluminium compounds. From the chemical analysis of the products at 200—500 °C, the ratios of Al:Cl:NH_3 of the products were calculated to be 1:3.00:3.06—3.35. As will be described later, it was found that the products absorbed ammonia. From these results, the removal of the ammonia absorbed by heating the product in an argon stream was examined by using the thermal balance. The result showed that the ammonia absorbed into the products was removed by heating the products in an argon stream at 150 °C for 3 h. A typical chemical analysis of the products formed at 200—500 °C after the removal of the ammonia absorbed gave Al, 14.6; Cl, 57.6; NH_3, 27.6%. The ratio of Al:Cl:NH_3 was calculated to be 1:3.00:3.00. From the results, it was considered that the products formed at 200—500 °C had a composition of $AlCl_3 \cdot 3NH_3$ (calcd for $AlCl_3 \cdot 3NH_3$: Al, 14.63; Cl, 57.67; NH_3, 27.70%).

The reaction products of gaseous $AlCl_3$ with ammonia at various temperatures above 200 °C are summarized in Table 1. Unreacted $AlCl_3$ was not observed throughout the temperature range of this work.

To elucidate the reaction process of gaseous $AlCl_3$ with ammonia, the behavior of the $AlCl_3 \cdot 3NH_3$, which had been formed during the reaction process, on heating in an ammonia stream was examined.

Table 1. Reaction products of gaseous $AlCl_3$ with ammonia at various temperatures

Temp/°C	Products	
	In the reaction zone	Outside the reaction zone
200—300	$AlCl_3 \cdot 3NH_3$	$AlCl_3 \cdot 3NH_3$
350—500	—	$AlCl_3 \cdot 3NH_3$
550—650	AlN (6—28)	$AlCl_3 \cdot 3NH_3$; NH_4Cl
700—900	AlN (42—82)	AlN, $AlCl_3 \cdot 3NH_3$; NH_4Cl
1000	AlN (86)	AlN; NH_4Cl

Note: the values in parentheses are mole percentages of gaseous $AlCl_3$ converted to AlN.

Table 2. Reaction products of gaseous $AlCl_3 \cdot 3NH_3$ with ammonia at various temperatures

Temp/°C	Products	
	In the reaction zone	Outside the reaction zone
500	—	$AlCl_3 \cdot 3NH_3$
550—650	AlN (6—33)	$AlCl_3 \cdot 3NH_3$; NH_4Cl
700—800	AlN (58—82)	AlN, $AlCl_3 \cdot 3NH_3$; NH_4Cl
900	AlN (85)	AlN; NH_4Cl

Note: the values in parentheses are mole percentages of gaseous $AlCl_3 \cdot 3NH_3$ converted to AlN.

The result of TG of $AlCl_3 \cdot 3NH_3$ in an ammonia stream showed that $AlCl_3 \cdot 3NH_3$ gradually absorbed ammonia at room temperature. The weight gain due to the absorption of ammonia reached a constant value after about 5 h. By heating the sample after the absorption, it lost weight gradually above about 60 °C, and the weight decreased markedly above about 230 °C. The weight loss reached 100% above about 370 °C. Vaporization of $AlCl_3 \cdot 3NH_3$ was observed during the weight loss above 230 °C. To obtain more detailed information on the behavior of $AlCl_3 \cdot 3NH_3$ on heating in an ammonia stream, $AlCl_3 \cdot 3NH_3$ (1.0 g) in a quartz boat was placed in a straight reaction tube. Ammonia was introduced into the reaction tube at a flow-rate of 100 cm^3/min. The sample part was then placed in the centre of an electric furnace maintained at a specified temperature for 1 h. The products obtained inside and outside the boat were examined. The results indicated that $AlCl_3 \cdot 3NH_3$ vaporized in an ammonia stream and that the percentage of the vaporized $AlCl_3 \cdot 3NH_3$ was 0% at 200 °C, <1% at 230 °C, 1% at 250 °C, 9% at 280 °C, 48% at 300 °C, and 100% at 320 and 350°C.

The reaction of gaseous $AlCl_3 \cdot 3NH_3$ with ammonia was then examined under similar experimental conditions for examining the reaction products of gaseous $AlCl_3$ with ammonia, described before. Gaseous $AlCl_3 \cdot 3NH_3$ was formed by heating solid $AlCl_3 \cdot 3NH_3$ in a stream of ammonia (50 cm^3/min) at 330 °C and was introduced into the reaction zone. The mean flow-rate of $AlCl_3 \cdot 3NH_3$ was 9.0 cm^3/min. The reaction products of gaseous $AlCl_3 \cdot 3NH_3$ with ammonia at various temperatures are shown in Table 2.

The results showed that the reaction of gaseous $AlCl_3 \cdot 3NH_3$ with ammonia occurred above about 550 °C to form AlN and NH_4Cl.

From the above-mentioned experimental results, the formation process of AlN by the vapor-phase reaction of $AlCl_3$ with ammonia can be represented as follows: The reaction of gaseous $AlCl_3$ with ammonia to form $AlCl_3 \cdot 3NH_3$ occurs first. Above about 550 °C, the gaseous $AlCl_3 \cdot 3NH_3$ reacts with ammonia to form AlN.

Conversion of Alcohols into Haloalkanes in Tertiary Phosphine/Methyl Halide/4-Methyl-1,2,4-triazolidine-3,5-dione (MTAD) System

Tatsuo OSHIKAWA* and Mitsuji YAMASHITA

Department of Applied Chemistry, Faculty of Engineering, Shizuoka Usniversity, Hamamatsu 432

(Received November 28, 1983)

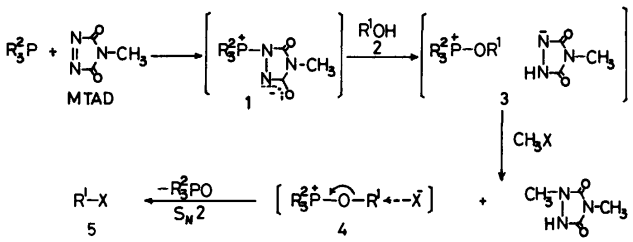
Synopsis. Alcohols were succesfully converted to the corresponding alkyl halides using the betaine provided by tertiary phosphine/4-methyl-1,2,4-triazolidine-3,5-dione (MTAD) system. Stereospecific reaction involving inversion of configuration on the carbon atom (S_N2 reaction) was clarified.

In a series of studies on 4-methyl-1,2,4-triazolidine-3,5-dione (MTAD), reaction of diene and ene components were examined. These are known to act as a dienophile or enophile[1] towards MTAD.[2] The previous studies on MTAD were mainly limited to the addition reaction.

This report describes the transformation of alcohols **2** such as benzyl alcohol (**2a**), cyclohexanol (**2b**), (−)-menthol (**2c**), (−)-borneol (**2d**), and (−)-2-octanol (**2e**) to the haloalkanes **5** using tertiary phosphine and MTAD system. Stereospecific conversion of alcohols into haloalkanes with inversion of configuration by using the conventional method with well known reagents such as dihalophosphine[3,4] afforded the inverted products. However, conversion of alcohols into haloalkanes using a betaine formed from reaction of triphenylphosphine with MTAD has not previously been reported. Reaction of triphenylphosphine with diethyl azodicarboxylate is known to form a betaine-like intermediate **1**.[5]

Results and Discussion

In the present reaction, the yields of **5** were extremely high and they did not depend on the choice of the tertiary phosphine used *i.e.*, triphenylphosphine or tributylphosphine (Table 1). The reaction can be explained by assuming the successive formation of a betaine **1** and an alkoxyphosphonium salt **3**. Methyl halide methylate intermediates **3** liberate a halide anion which, in turn, attacks the carbon atom of the alkoxide group in the Arbzov type intermediate, *i.e.*, alkoxyphosphonium salt **4**.[6,7] By using this procedure, alcohols **2c** and **2e** were successfully converted into the corresponding halides with inversion of configuration (S_N2 type reaction)[6] at the carbon atom (Table 2).



Attempted reaction of compound **2b** with methyltriphenylphosphonium bromide to promote the dissociation of the halogen in the presence of an equimolar amount of MTAD was unsuccessful. These results show that the tertiary phosphine/methyl halide/MTAD system does not proceed *via* a formation of methyltriphenylphosphonium halide, that the system is effective for halogenation of alcohols in the yield and stereospecificity, and that the intermediate of first formed key betaine **1** as well as the last Arbzov type one

a) DEADC=Diethyl azodicarboxylate (EtO-C(=O)-N=N-C(=O)-OEt). b) Isolated yield by distillation.

play an important role in the stereospecific halogenation. Comparison of the yield and stereospecificity of the present method with that using the triphenylphosphine/diethyl azodicarboxylate/methyl iodide system[5] in conversion of alcohols **2** into iodoalkanes **5** (Table 3) shows that this method is an exellent alternative for preparation of haloalkanes. No large difference in the purity of haloalkanes was recognized in the tow methods.

This new procedure has some advantages in preparing haloalkanes, *i.e.*, mild reaction conditions, high product yield, and facile work up to remove tertiary phosphine oxide and 2,4-dimethyl-1,2,4-triazolidine-3,5-dione.

Identification of the products **5** was established by comparison with authentic samples by IR and ^1H NMR spectra, optical rotation, and/or retention time of G. L. C.

Experimental

Measurements. Melting points were measured on a Yanagimoto Seisakusho micro melting point apparatus. ^1H NMR spectra were recorded on a Hitachi R-24 (60 MHz) spectrometer with TMS as an internal standard, IR spectra on a JASCO A-3 infrared spectrophotometer, G. L. C. on a Yanagimoto Gas Chromatograph GCG-550T, and optical rotations were determined with JASCO DIP-4 digital and Atago Polax photometers.

Preparation of Neomenthyl Iodide (5c); Typical Procedure: A solution of MTAD (2.4 g, 21 mmol) in tetrahydrofuran (20 ml) was added to a tetrahydrofuran (30 ml) solution of (−)-menthol (**2c**) (3.0 g, 19 mmol) and triphenylphosphine (5.5 g, 21 mmol) at a temperature of 0 °C. After 10—15 min, methyl iodide (2.7 g, 19 mmol) in tetrahydrofuran (5 ml) was added to the solution (excess methyl halide caused the yield of haloalkanes to be decreased). The mixture was stirred for 6 h at room temperature, then, the solvent was evaporated under reduced pressure. The product was taken up into ether, the insoluble material filtered off and washed with ether to removed triphenylphosphine oxide and 2,4-dimethyl-1,2,4-triazolidine-3,5-dione.

The filtrate was evaporated under reduced pressure, and the residue separated by thin-layer chromatography (silica gel, 1:1 ether/benzene) or distilled under reduced pressure (bp 120—121 °C/15 mmHg, 1 mmHg=133.322 Pa) to give pure neomenthyl iodide (**5c**) in 88% yield, ^1H NMR ($CDCl_3$), δ=0.86 (d, J=7.1 Hz, 3H, CH_3), 0.96 (d, J=7.1 Hz, 6H, $CH(C\underline{H}_3)_2$), 0.63—2.43 (m, 9H, $C\underline{H}(CH_3)_2$ and ring protons other than CHI), and 4.63 (m, 1H, CHI); IR ν_{max}^{neat}, 1170 cm^{-1} (C-I); $[\alpha]_D^{17.0}$ +39.6° (c=1.01, C_2H_5OH) (lit,[8] neomenthyl iodide $[\alpha]_D$ +41.2°); G. L. C. retention time 2 min (column: Versamide 20%, 900 on Neopack 1A, 60/80 mesh; carrier gas; H_2 (1 Kg/cm^2); column temperature: 141 °C; column length: 2 m).

The authers wish to express their thanks to Professor M. Suzuki's laboratory of Shizuoka University for providing facility for measurement of the optical rotation.

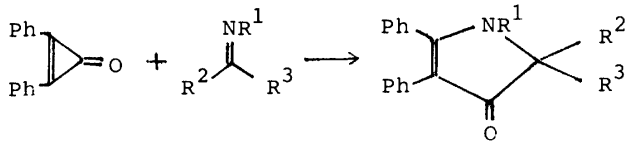
Preparation of 5-Substituted-2-pyrrolin-4-ones from *N*-(4-Oxo-2-pyrrolin-5-yl)sulfoximines

Hiroshi YOSHIDA,* Shoichi BANDO, Shosuke NAKAJIMA,
Tsuyoshi OGATA, and Kiyoshi MATSUMOTO†
Department of Applied Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu 432
†*College of Liberal Arts and Sciences, Kyoto University, Kyoto 606*
(Received December 13, 1983)

Synopsis. In trifluoroacetic acid, immonium cations were generated from *S,S*-dimethylsulfoximines in which the pyrrolinone ring was substituted. Nucleophiles such as alcohols, thiocyanic acid, thiols, or acetylacetone reacted with the immonium salts to yield 5-substituted 2-pyrrolin-4-ones.

In previous papers[1,2] we have reported the reaction of diphenylcyclopropenone with compounds in which C=N groups such as imidate, amidine, imidothioate, or *N*-imidoyl sulfoximine were substituted, giving pyrrolinone derivative as the major product:



R^1,R^2=Alkyl, Aryl: R^3=RO, R_2N, RS, $Me_2\overset{\oplus}{S}(O)\overset{\ominus}{N}$

In the continuation of our studies on the chemical and physical properties of imines and ylides, we have been much interested in the chemical nature of the pyrrolinone-substituted sulfoximines (**1a—d**) which posess high thermostability.

a) Phenyl ring protons appeared at δ 6.4—8.0 as multiplets. b) Trifluoroacetic acid (10% v/v) was added.

The sulfoximines **1a—d** were stable in ethanolic sodium hydroxide. In acidic ethanol (hydrochloric or trifluoroacetic acid). However, **1a—d** decomposed easily within one day to **2a—d** (X=EtO) in good yields. In trifluoroacetic acid **1a—d** gave dark brown solutions within 5 min. Treatment of these with nucleophiles such as alcohols, thiols, thiocyanic acid, or acetylacetone yielded 2-pyrrolin-4-one derivatives **2a—d** (X) as listed in Table 1, while, treatment of the acid solution of **1a** with primary or secondary amine gave no amino-substituted products, with only resinous mass being formed. The products **2a** (X=EtO), **2b** (X=EtO), **2c** (X=EtO, EtS), and **2d** (X=EtO) were identical to the compounds obtained from the reaction of diphenylcyclopropenone with the corresponding imidates or imidothioate. The structure of the other compounds listed in Table 1 was elucidated on the basis of their ^{1}H-NMR, MS, and elemental analyses (Table 2).

The structure of the product obtained by the reaction with thiocyanic acid was found to be not thiocyanate but isothiocyanate, since **2c** (X=NCS) reacted with dimethylamine to yield **2c** (X=Me_2NCSNH) in a good yield.

A plausible mechanism for the formation of **2a—d** was shown in Scheme 1. The initial step involves the protonation of the imino nitrogen of **1a—d** followed by the elimination of sulfoximine to give iminium cations **3a—d**. The eliminated sulfoximine yielded S-aminosulfoxonium salt in trifluoroacetic acid.[3] The formation of the cations has been supported as follows. The color of the solution of **1a—d** in $CDCl_3$ changed from yellow to dark brown immediately on addition of trifluoroacetic acid. ^{1}H-NMR spectra of the brown solutions showed the signals of the substituents of **3a—c** shifted to lower field compared with those of the parent sulfoximines **1a—c** (Table 3) together with aminodimethylsulfoxonium ion **4** (δ=3.49). The down field shift of the alkylsubstituents of carbonium ions has been well documented.[4] The cations **3a—d** in trifluoroacetic acid were stable at room temperature for a day when they were kept from the atmospheric moisture. Addition of a nucleophile to the solutions, the color of which turned yellow within a minute, gave 5-substituted pyrrolinones **2a—d(X)**; none of the starting **1a—d** was recovered.

Experimental

General. Melting points are uncorrected. ^{1}H-NMR spectra were recorded on a Hitachi-Perkin Elmer R-24 (60 MHz) spectrometer using TMS as an internal standard, and mass spectra on a Hitachi RMU-7M mass spectrometer.

*Preparation of Pyrrolinone-substituted Sulfoximines **1a—d**.* Sulfoximines **1a—d** were prepared according to the previously reported method.[1]

*The Reaction of the Sulfoximines **1a—d** with Nucleophiles.* In a stoppered flask, sulfoximine **1** (1 mmol) in trifluoroacetic acid (3 cm^3) was stirred for 5 min to give a dark brown solution. To the solution was added a nucleophile [alcohol, sodium thiocyanate, acetylacetone (3 mmol) or thiol (1 mmol)]. We stirred the mixture until the color of the solution changed to yellow. To the mixture, water (15 cm^3) was added and the product was extracted with chloroform. The extract was dried over sodium sulfate and evaporated under reduced pressure. The crude product was either recrystallized from an appropriate solvent or purified by chromatography over silica gel. The results are collected in Table 1 and physical properties of new compounds are shown in Table 2.

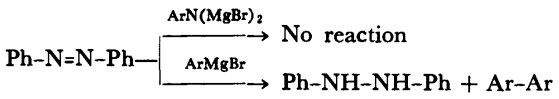
(Received December 16, 1983)

Synopsis. Oxidation peak potentials of *p*-$RC_6H_4N(MgBr)_2$ and *p*-RC_6H_4MgBr (R=CH_3O, CH_3, F) were determined by cyclic voltammetry with a platinum disk electrode in tetrahydrofuran. The potentials obtained proved to be a semiquantitative measure of electron-donating abilities of organomagnesium reagents.

It was proposed very recently that aryliminodimagnesium reagent ($ArN(MgBr)_2$, aryl-IDMg) was less reactive—less "electron-donating"—than arylmagnesium reagent (ArMgBr): The proposal remained entirely qualitative because it was based on comparison of the distribution of major and minor products formed in the reactions with carbonyl and nitro compounds.[1] Even the clearly different behavior of azobenzene toward $ArN(MgBr)_2$ and ArMgBr (Scheme 1)[2] suggests



Scheme 1.

strongly but still qualitatively that the latter reagent is much more electron-donating than the former, and determination of oxidation potentials as a quantitative measure of electron-donating abilities is needed. The electrochemical reduction of a wide variety of electron-accepting organic compounds were studied extensively: The correlation of reduction potentials with Hammett's substituent constants were reviewed.[3] The study of electrochemical oxidation potentials of carbanions[4,5] and amide anions[6] as well as their correlation with substituent constants[7] are now in progress. In the field of electrochemistry of organomagnesium reagents, an important result was provided by the measurement of anodic overvoltages of some alkyl Grignard reagent at constant current density.[8] In this paper, the result of a voltammetric study for estimating semiquantitatively the oxidation potentials of *p*-$RC_6H_4N(MgBr)_2$ and *p*-RC_6H_4MgBr (R=CH_3O, CH_3, F) will be described.

Procedures. Cyclic voltammograms were recorded on a Yanaco P-1000 Voltammetric Analyzer having electrolysis cell equipped with three electrodes: working electrode (Pt-disk), reference electrode (Ag-wire), and counter electrode (Pt-wire). Tetrahydrofuran, which has been used as the reaction solvent, was used also for electrolysis: Tetrabutylammonium perchlorate (TBAP, 0.2M) was used as the supporting electrolyte. The concentration of organomagnesium reagents was 1.0—2.0×10^{-3}M (1 M=1 mol dm^{-3}), and all the measurements were carried out under nitrogen atmosphere. Contamination of the surface of working electrode was unavoidable, and the surface was polished by use of alumina powder prior to the individual measurements.

The typical voltammogram with a scan rate of 50 mV/s is shown in Fig. 1. Two oxidation peaks were observed in every case, the first peak(I) being assigned to the initial oxidation of the magnesium reagent and the second peak(II) to the further oxidation of the initially formed radical species. Even when the faster scan rate(500 mV/s) was applied, a very small reduction peak was observed only in two cases: The electrode process is almost completely irreversible and the redox potential was not determined by this method. For comparison of the values of oxidation peak potentials[9] with each other, the observed potentials of I were normalized by use of the redox potential of ferrocenium/ferrocene couple added as internal standard: 0.400 V *vs.* NHE.[10]

ArN(MgBr)₂ and ArMgBr. The normalized oxidation peak potentials of individual reagents were plot-

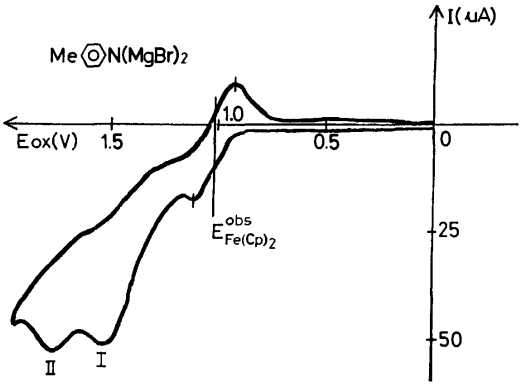


Fig. 1. Cyclic voltammogram of *p*-methylphenyl-IDMg reagent using Ag-wire as reference electrode.

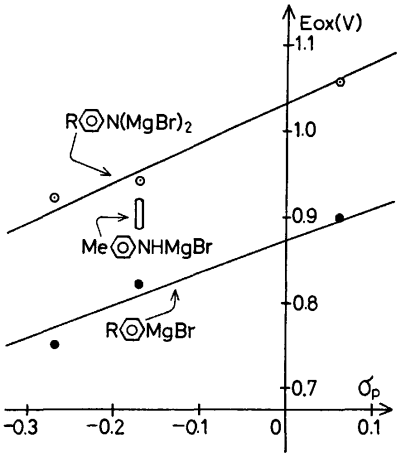

Fig. 2. Plot of oxidation peak potentials *vs.* substituent constants σ_p. The values of potentials are normalized using the redox potential of ferrocenium/ferrocene couple as internal standard.

ted against substituent constants (σ_p, Fig. 2): The difference between the potentials of two kinds of reagent was 120—170 mV. The higher oxidation peak potentials of IDMg in comparison with those of ArMgBr support the previous suggestion of the lower electron-donating ability of the former reagent than that of the latter.[1,2,11] The substituent effect on the oxidation peak potentials ($CH_3O<CH_3<F$) of the respective kinds of reagent is in accord with the effect on the electron-donating ability suggested previously.[2] The reaction constants(ρ) were not determined since the potentials obtained are not the redox potentials but the oxidation peak potentials which, however, proved to be at least a semiquantitative measure of electron-donating abilities of organomagnesium reagents.

ArNHMgBr and ArN(MgBr)$_2$. The oxidation peak potentials of *p*-CH_3-substituted PhNHMgBr, PhN(MgBr)$_2$, and PhMgBr were also compared (Fig. 2). The potential of the anilinomagnesium reagent was difficult to be determined precisely, however, the medium potential compared with those of ArMgBr and IDMg was established.

The higher ability of ArNHMgBr than that of ArN(MgBr)$_2$ as electron donors is suggested from the result of an experiment, which, however, is performed in an unadvisable manner. When the IDMg reagent[12] containing a small amount (*ca.* 5%) of anilinomagnesium species was allowed to react with a nitroarene, a large amount of unidentifiable dark brown materials was formed with a heavy loss of the expected azoxyarene:[13] The result is due to the preferential electron-transfer from the anilinomagnesium species, the process being followed by decomposition and/or polymerization of nitroarene anion radical.[14] The reactivity of different types of magnesium reagents, *i.e.*, ArMgBr, ArSMgBr, ArNHMgBr, ArN(MgBr)$_2$, and ArOMgBr, in the replacement reaction of β-methoxy α,β-enones is discussed elsewhere.[15]

The lower electron-donating ability of ArN(MgBr)$_2$ than that of ArNHMgBr is ascribable to the presence of two positive Mg atoms attached to the anionic nitrogen atom.

Temperature and Isotope Effects in the Reactions of Phenylcarbene with Acetone

Hideo TOMIOKA,* Yasuji OZAKI, Hiroyuki NAKAMURA, and Yasuji IZAWA
Department of Industrial Chemistry, Faculty of Engineering, Mie University, Tsu, Mie 514
(Received January 5, 1984)

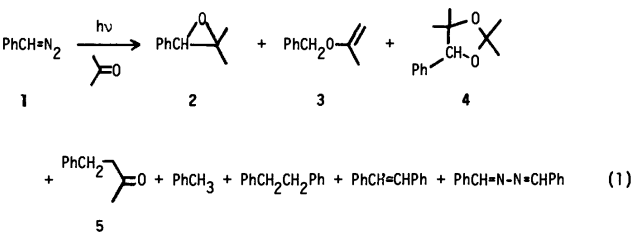
Synopsis. Phenylcarbene generated in acetone solution gives oxirane, vinyl ether and 1,3-dioxolane presumably *via* initial attack of the singlet state on the lone pair electrons of carbonyl oxygen leading to a carbonyl ylide, whereas a C-H insertion product arising from the triplet markedly increases in matrix environments.

In the past few years several research groups have studied the chemistry of carbenes in rigid matrices at low temperature.[1-4] In the case of carbenes with triplet ground states there are profound differences between the chemistry observed in fluid solution at ambient temperature and that obtaining in a matrix at −196 °C. For example, arylcarbene generated in olefinic solution at ambient temperature gives cyclopropanes almost exclusively which are mostly derived from the singlet state, whereas arylcarbene generated in olefinic matrices at −196 °C result in a dramatic increase in C-H insertion products at the expense of the cyclopropanes.[2] It has been proposed[1-4] that these C-H insertion products are formed *via* an abstraction-recombination of the triplet carbene on the basis of extensive spectroscopic and chemical evidence for the presence of the ground-state triplet carbene in the low temperature matrix photolysis of most aryldiazomethanes at −196 °C. Similar dependence of the product distribution upon the temperature at which the arylcarbene is generated has been observed in its reactions with alcohol,[1a] ether,[1f] amine,[1f] and halide,[1e] and pertinent information as to the relationship between the multiplicity and reaction pattern of the carbene is available from these studies.

In this work we have extended the matrix study of carbene reactions by investigating the mechanism of its reaction with ketone. In contrast to the intensive study lavished upon the reaction of carbenes with carbon-carbon double bonds,[5] only scant information is available concerning the reactions with the carbon-oxygen double bond. Interest in this reaction has intensified and a number of papers have appeared on the subject in the last few years.[6]

Results and Discussion

A solution of phenyldiazomethane (**1**) in degassed acetone was irradiated in a Pyrex tube at different temperatures. GLC analysis of the product mixture revealed the presence of oxirane (**2**), vinyl ether (**3**), 1,3-dioxolane (**4**) and 4-phenyl-2-butanone (**5**), along with toluene, bibenzyl, *cis*- and *trans*-stilbenes, and aldehyde azine as indicated in equation (1). The product distributions at different temperatures were determined by GLC analysis as summarized in Table 1. It is evident from the Table that the product distributions are highly dependent on the temperature at which the irradiation was carried out. Photolysis of **1** in acetone at 0 °C, for example, gave **4** as the main product along with **2** and **3**. When the photolysis was carried out below −150 °C, however, **5** became the main reaction product at the expense of 1,3-dioxolane.



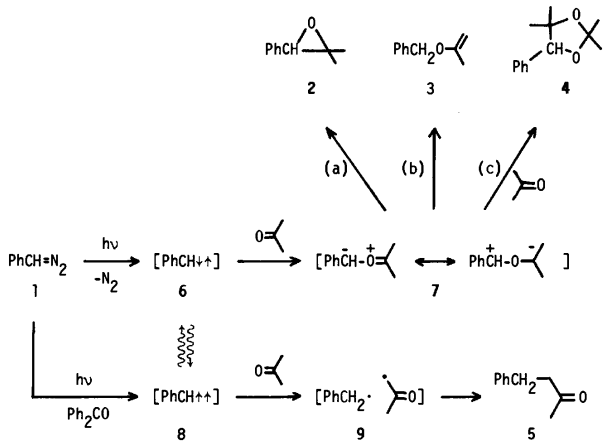
(1)

The phenomena are similar to those observed[1-4] in the reaction of phenylcarbene with other substrates, *e.g.*, alcohol,[1a] and can be explained as follows. Phenylcarbene (**6**) is expected to react with acetone in its singlet state to form carbonyl ylide (**7**) as a result of electrophilic attack on the nonbonding electrons of the carbonyl oxygen, since it is well known[5] that most singlet carbenes can react as Lewis acids by sharing a pair of nonbonding electrons. The formation of a carbonyl ylide by reaction of carbene with acetone has been demonstrated recently by Wong, Griller, and Scaiano.[7] They generated singlet fluorenylidene, which was identified spectrophotometrically, and followed its capture by acetone to from a carbonyl ylide. The carbonyl ylide (**7**) thus formed collapses *via* three competing reaction pathways:[8] (a) ring-closure to give oxirane (**2**), (b) intramolecular proton shift to yield vinyl ether (**3**), and (c) reaction with a second acetone molecule leading to dioxolane (**4**). A sharp decrease in the yield of **4** in the solid phase reaction is then expected on the basis of the above scheme since mobility of a molecule in a matrix is limited and the intermolecular pathway becomes unfavorable.

Table 1. Product distribution as a function of temperature in photolysis of **1** in acetone-H_6 (D_6)

T/°C	Yield/%[a]			
	2	**3**	**4**	**5**
0[b]	4.6 (5.9)	10.8(5.7)	20.9(41.6)	0(0)
−78[b]	4.5 (2.2)	6.9(3.6)	16.2(33.5)	0(0)
−110[c]	10.5 (2.3)	8.2(4.7)	12.3(31.2)	<1(0)
−150[c]	6.0 (2.6)	9.8(3.8)	5.5 (0.7)	20.0(4.7)
−196[c]	1.9(11.4)	1.8(4.3)	1.3 (1.3)	21.1(0.7)

a) Determined by GC. Yields in parentheses are for irradiations in acetone-d_6. Other products detected in each experimental condition were toluene, bibenzyl, stilbenes and aldehyde azine. b) Liquid phase. c) Solid phase.



4-Phenyl-2-butanone on the other hand, should presumably arise from insertion of phenylcarbene into the C–H bonds of acetone. Since this compound is only formed in a matrix environment, we propose that the triplet state is responsible for its formation. Thus, triplet phenylcarbene (**8**) generated in the matrix abstracts hydrogen from the host acetone to give the radical pair (**9**), which recombines with high efficiency to afford **5** due to the limited diffusibility of the radical pair.

The reason why triplet reactivity appears at low temperature has been a key question. A reasonable explanation has been advanced recently by Senthilnathan and Platz.[3] Their kinetic analysis of the decay of triplet arylcarbenes in a rigid matrix has demonstrated that a predominant decay path of triplet carbene is by hydrogen atom tunneling. The availability of this tunneling pathway at low temperature leads to the hydrogen abstraction products. One of the characteristic phenomena of the tunneling reaction is a large kinetic isotope effect. For example, Wong and Williams[9] have observed that k_H/k_D is larger than 1.3×10^3 for intermolecular hydrogen atom abstraction by $CH_3\cdot$ from a CH_3NC matrix at −150 °C. Measured isotope effects with triplet arylcarbenes are much more modest. Thus, k_H/k_D is 23 for hydrogen atom abstraction by diphenylcarbene from toluene at −196 °C.[3a] The kinetic results are consistent with the isotope effects on the product distribution. For example, product analyses of the reaction of phenylcarbene in deuterated alcoholic matrices at −196 °C revealed that a substantial isotope effect was observed for C–H (D) insertion while the isotope effect on O–H (D) insertion was small.[1h,3c] With these precedents in mind we irradiated **1** in acetone-d_6 at various temperatures. The results summarized in the Table clearly indicate that there is a substantial isotope effect in the C–H insertion process at −196 °C; the yield of 4-phenyl-2-butanone is reduced by almost a factor of 20 in acetone-d_6. In the light of the lack of an isotope effect on the O–H (D) insertion process of singlet phenylcarbene compared with a substantial isotope effect in C–H insertion in deuterated alcoholic matrices at −196 °C, the considerable isotope effect on C-H insertion leading to **5** supports the view that **5** arises from a triplet carbene, presumably *via* hydrogen atom tunneling followed by recombination of the resulting radical pairs (**9**).

Experimental

Materials. Phenyldiazomethane **1** was prepared immediately before use as described in the literature. Acetone-d_6 was purchased from E. Merck and used without purification. Authentic samples of the phenylcarbene adducts with acetone (**2**—**5**) were prepared as follows. Oxirane **2** was obtained by the oxidation of 2-methyl-1-phenyl-1-propene with *m*-chloroperbenzoic acid. Vinyl ether **3** was prepared by the reaction of benzyl alcohol with propylene in the presence of iodine and mercuric oxide followed by treatment of the resulting 2-benzyloxypropyl iodide with ethanolic KOH. 1,3-Dioxolane **4** was isolated from the reaction mixture by column chromatography on silica-gel. Satisfactory spectroscopic and mass spectral data have been obtained on all compounds.

Product Analyses. All irradiations for product analyses were conducted with use of a water-cooled Halos 300-W high-pressure mercury lamp. In a typical procedure, 0.005 mmol of **1** was added to 2.0 cm^3 of acetone in Pyrex tubes. The sample was then degassed by three freeze-thaw cycles, and the sample tube sealed under vacuum. The tube was suspended in a transparent Pyrex Dewar flask filled with coolant and irradiated until all **1** was destroyed.[1c] The product identification and yields were conveniently determined by GC (Silicone OV-17 on Diasolid L) and GC-MS (Shimadzu GC-MS 1000 spectrometer) techniques.

Oxidation of 2,6-Bis(hydroxymethyl)phenols to 2-Hydroxyisophthalaldehydes by MnO_2

Shozo TANIGUCHI

Department of Industrial Chemistry, Ibaraki Technical College, Nakanefukayatsu, Katsuta, Ibaraki 312

(Received January 20, 1984)

Synopsis. A facile and direct preparative method of 2-hydroxyisophthalaldehydes from 2,6-bis(hydroxymethyl) phenols using activated manganese(IV) oxide is described. The aldehydes are obtained in good yields.

2-Hydroxyisophthalaldehyde derivatives (**2**) are useful compounds for the investigation of binuclear metal complexes,[1-4] and macrocyclic binuclear metal complexes.[5,6] Since binuclear copper(II) complexes have been prepared from Schiff bases of **2a** by Robson[1a] and Okawa[2a], the investigatons have been directed toward the study of their molecular structures,[5,6b] affinity[3b,6c] for carbon monoxide and ethylene, intermolecular electron transfer process,[6a] and redox behavior.[4,6] All of these investigations adopted the Ullmann's method[7] for the preparation of **2**, but the reaction is achieved through the following three-steps: conversion of 2,6-bis(hydroxymethyl)-4-methylphenol (**1a**) to the tosylated diol, its oxidation to the tosylated diformyl compound by sodium dichromate, and final formation of **2a** by treatment in sulfuric acid. This method is cumbersome and the yield of the compound is low. Once the aldehydes are synthesized, the route to the final ligand compounds is fairly straightfoward. Therefore, a facile and direct preparation of the aldehydes is an important factor for the synthesis of the binuclear metal complexes.

Recently, the reaction of **1b** with vanadyltriisopropylate was found to afford 3,3′-[oxybis(methylene)] bis[5-*t*-butyl-2-hydroxybenzaldehyde] (**3**) as the major product and **2b** as the by-product.[8] Since manganese(IV) oxide prepared by heating a manganese(II) salt such as carbonate or oxalate at 220—280 °C, is known to oxidize salicyl alcohol to salicylaldehyde in good yield,[9] the activated MnO_2 can be used for oxidation of **1** to **2**. In this paper, the author reports the results of the present procedure, and the desired products were obtained in 67—70% yields in a sufficiently pure state for most purposes.

Experimental

All melting points are uncorrected. The IR spectra were recorded on a Hitachi EPI-G3 spectrometer in KBr disks. The ^1H NMR spectra and mass spectra were recorded on a Hitachi R-24B spectrometer with TMS as the internal standard in $CDCl_3$ solution, and a Hitachi M-70 mass spectrometer, respectively.

Reagents. Compounds **1** were prepared by a modification of the literature method.[7] Activated manganese(IV) oxide[10] was prepared by heating manganese(II) carbonate at 250 °C for 5 h.

General Procedure. Compound **1** (10 g) was added to manganese(IV) oxide (80 g) suspended in 300 ml of $CHCl_3$ in a 500 ml Erlenmeyer flask, and the mixture was stirred by a magnetic stirrer at room temperature. The phenol which was slightly soluble in the solvent dissolved within about 3 h. After 2 d, the solution was filtered. The solid was washed twice thoroughly with 200 ml each of $CHCl_3$, and the washings were added to the original filtrate.[11] The combined solution was evaporated to yield a pale yellow solid (6.5—6.9 g). The yields and analytical data of the products are described below.

2a: 67% yield, mp 130 °C (lit, mp 133.5 °C,[7] mp 129—130 °C[4]); IR (cm^{-1}) 2880 (formyl CH), 1682 (formyl C=O), 1668 (formyl C=O associated with OH), 1216 (phenolic C-O); ^1H NMR δ=2.83 (3H, s, methyl), 7.73 (2H, s, aromatic), 10.15 (2H, s, CHO), 11.35 (1H, s, OH); MS *m/z* 164 (M^+).

2b: 70% yield, mp 105 °C; IR (cm^{-1}) 2880 (formyl CH), 1692 (formyl C=O), 1662 (formyl C=O associated with OH), 1224 (phenolic C-O); ^1H NMR δ=1.24 (9H, s, methyl), 7.83 (2H, s, aromatic), 10.17 (2H, s, CHO), 11.28 (1H, s, OH); MS *m/z* 206 (M^+); Calcd for $C_{12}H_{14}O_3$: C, 69.89; H, 6.84. Found: C, 69.79; H, 6.84.

10) Compounds **2** were obtained in low yields by heating with commercial manganese(IV) oxide at 250 °C for 5 h.

11) After filtration the remaining solid consisting mainly of manganese(IV) oxide was dried and treated in aq NaOH solution. The color of the solution changed to fluorescent greenish-yellow. By acidifying the solution, a small amount of compounds **2** was generally obtained.

Characteristic Transport Properties of Diaza-crown Ethers for Primary and Secondary Ammonium Cations

Hiroshi TSUKUBE

Department of Chemistry, College of Liberal Arts and Science, Okayama University, Okayama 700

(Received February 13, 1984)

Synopsis. Simple lipophilic diaza-crown ethers show unique transport properties for primary and secondary ammonium salts, which are markedly different from those observed with common crown ether systems.

An important advantage of aza-crown ethers over oxa-crown ethers is the presence of soft nitrogen donor atoms which can offer characteristic complexing and transporting abilities.[1] Recently, pyrido-crown ethers and their analogues have received much attention as specific ligand and/or carrier for primary ammonium cations and some metal ions.[2] Here we report that simple diaza-crown ethers show new and unique cation transport properties, especially for a series of amino acid ester salts. They were demonstrated to transport both primary and secondary ammonium cations with high efficiency and unique selectivity, which were not attained in the oxa-crown ether systems.

Three kinds of lipophilic diaza-crown ethers having 15- to 21-membered rings, **1**—**3**, were employed as cation carriers (Fig.). They were easily prepared from benzyl chloride and corresponding diaza-crown ethers (see Experimental), and have limited solubilities in water. In the liquid membrane system employed,[3] the crown ether carrier dissolved in the chloroform membrane phase mediates the transport of guest cation and co-transported anion from the source aqueous phase through the membrane phase into the receiving aqueous phase by complexing and solubilizing guest salt into the membrane phase.

The diaza-crown ethers **1**—**3** showed high transport abilities for various ammonium cations of amino acid esters, while they offered low transport rates for K^+ and other metal ions (Table). It is of particular importance that they transport "secondary" ammonium cation of proline ester with efficiency comparable to those observed for primary ammonium cations. Although many kinds of oxa-crown ethers are known to transport primary ammonium cations effectively like the carrier **4**, such an effective transport of secondary ammonium cation has not been achieved in these oxa-crown ether systems. Since the employed diaza-crown ethers have various cavity sizes (diameter: *ca.* 2.0—4.0 Å), our results strongly suggest that nitrogen donor atoms in the macrocycles play an important role in complexation and transportation of ammonium cations. Probably, guest ammonium cation would be tightly attached by "two" hydrogen bonds to two diametrical nitrogen donor atoms in the diaza-crown ether. Similar complex structures have been proposed in the diazametacyclophane and related systems.[4]

Table also indicates that diaza-crown ethers **1**—**3** have largely different transport selectivities from those observed in the oxa-crown ether **4** system. When the crown ether **4** was employed, hydrophobic primary ammonium salts such as phenylalanine and tryptophan esters were much more effectively transported than the hydrophilic glycine and alanine esters. On the other hand, diaza-crown ethers **1**—**3** offered high transport rates for a variety of ammonium salts including glycine, alanine, and proline esters. Recently we demonstrated that lipophilic macrocyclic polyamine-type carriers showed parallel transport trend for a series of amino acid esters.[5] Hence, introduction of the nitrogen donor atoms into the macrocycles would offer not only

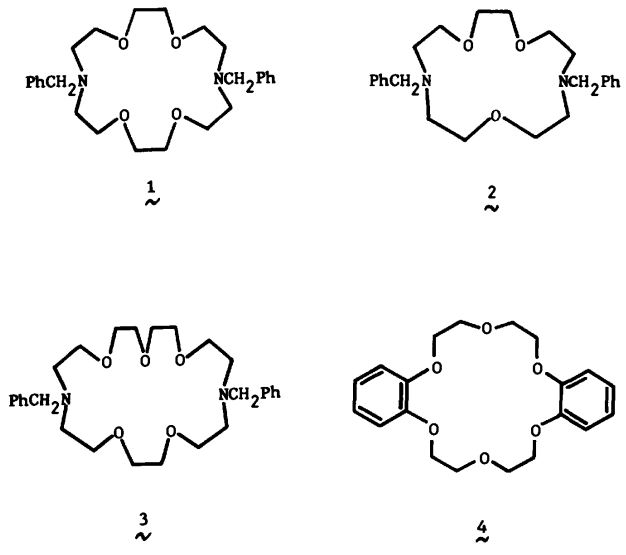

Fig. Macrocyclic carriers examined.

TABLE. CATION TRANSPORT PROPERTIES OF DIAZA-CROWN ETHER CARRIERS

Guest	Additive	Transport rate ×10⁶ mol/h			
		1	**2**	**3**	**4**
NaCl	$NaClO_4$	0.5	0.5	0.7	0.2

Transport conditions: Source aqueous phase; guest salt, 0.5 mmol. Additive, 1.0 mmol/H_2O, 5 ml. Membrane; carrier, 0.0372 mmol/$CHCl_3$, 12 ml. Receiving aqueous phase; H_2O, 5 ml.

high efficiency but also unique selectivity in the transport process.

The nature of co-transported anion has a pronounced effect on the cation-transport rate. As frequently reported in the crown ether-type carrier systems,[6] ClO_4^-, SCN^-, and other hydrophobic anions were required to promote this cation-transport process. Since we confirmed that diaza-crown ethers having 15- to 21-membered ring sizes showed potential transport properties for ammonium salts, they may provide wide applications in the cation-transport and in the related biomimetic systems.

Experimental

Materials. Diaza-crown ethers **1**—**3** were prepared in a two-phase reaction system (chloroform/water). Typically, a chloroform solution (15 ml) of benzyl chloride (3.48 g) was added dropwise to an aqueous solution (15 ml) of "Kryptofix 22" (Merck Japan, 3.00 g) and NaOH (2.00 g). After vigorous stirring at room temperature overnight, the organic layer was washed with aqueous HCl solution and water, and dried over Na_2SO_4. The solvent was removed, and recrystallization from ether gave colorless crystals **1**: Mp 82 °C (lit, 80 °C).[1b] Yield, 80%. IR (Nujol) 1602, 1498, 1125, 755, and 705 cm^{-1}. ^1H NMR (60 MHz, $CDCl_3$) δ=2.83 (8H, t, $NC\underline{H}_2CH_2$), 3.50—3.73 (20H, m, $OC\underline{H}_2CH_2$, $NC\underline{H}_2C_6H_5$), 7.23—7.40 (10H, m, $CH_2C_6\underline{H}_5$).

The carriers **2** and **3** were similarly prepared and purified by column chromatography on alumina (elute, $CHCl_3$). **2**: yellowish oil, 65%. IR (neat) 1600, 1495, 1450, 1125, 735, and 700 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.67—2.95 (8H, t+t, $NC\underline{H}_2CH_2$), 3.52—3.73 (16H, m, $OC\underline{H}_2CH_2$, $NC\underline{H}_2C_6H_5$), 7,17—7.45 (10H, m, $CH_2C_6\underline{H}_5$). **3**: yellowish oil, 58%. IR (neat) 1600, 1495, 1455, 1100, 740, and 700 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.83 (8H, t, $NC\underline{H}_2CH_2$), 3.53—3.77 (24H, m, $OC\underline{H}_2CH_2$, $NC\underline{H}_2C_6H_5$), 7.20—7.47 (10H, m, $CH_2C_6\underline{H}_5$). Satisfactory elemental analyses were obtained for these carriers.

Phenylalanine ethyl ester, leucine ethyl ester, alanine ethyl ester, and glycine ethyl ester were obtained from Nakarai Chem. Ltd., and other employed esters were purchased from Tokyo Chem. Ind. Ltd.

Transport Procedure. The transport experiments were carried out at room temperature in a U-tube glass cell (2.0 cm, i.d.) as reported before.[3] The carrier in chloroform (12 ml) was placed in the base of the U-tube, and two aqueous phases (5 ml, each) were placed in the arms of the U-tube, floating on the chloroform phase. The membrane phase was stirred with a magnetic stirrer. The transport rates were calculated from the initial rates of appearance of co-transported anion, ClO_4^-, into the receiving aqueous phase, which were determined by means of ion-selective electrode (Orion Model 93-81). Phenylalanine and tryptophan esters were also monitored spectroscopically. Reproducibility was confirmed as ±15% or better.

This research was supported in part by a Grant-in-Aid for Scientific Research No.58740230 from the Ministry of Education, Science, and Culture, Japan.

(Received February 18, 1984)

Synopsis. The structure of D-glucono-lactam (5-amino-5-deoxy-D-glucono-lactam) has been established by means of X-ray crystal structure analysis. The stereochemistry of D-glucono-lactam in crystal was determined to be a half-chair conformation.

In earlier papers,[2] we reported on the lactam rule in relation to the sign of the n-π^* carbonyl Cotton effect for the stereochemistry of the lactam ring. There are, however, difficulties to decide the ring conformation of six-membered lactams from the sign of the n-π^* Cotton effect, because the ring chiralities of δ-lactams are known to take both half-chair and half-boat conformations.[3,4] In this paper, we report the conformation of D-glucono-lactam in crystal determined by X-ray analysis.

Experimental

The crystals are colorless prisms. A specimen of D-glucono-lactam with the dimensions of 0.30×0.25×0.25 mm was used for the intensity measurements. The density was measured by the flotation method in a mixture of petroleum ether and carbon tetrachloride. The cell constants were determined by the least-squares procedure from the 2θ values of 24 reflections measured on a diffractometer using monochromated Cu $K\alpha$ radiation. Three dimensional intensity data were collected on a Rigaku automatic four-circle diffractometer with graphite monochromated Cu $K\alpha$ radiation. Background was counted for 10s at both sides of each peaks. Three standard reflections were measured every 50 reflections during the course of collection. A total of 1120 of independent reflections were collected. Reflections having an intensity exceeding the corresponding standard deviations by a factor of five were treated as observed. 912 reflections with $2\theta<140°$ were retained and corrected for Lorentz and polarization factors but not for absorption factor.

Crystal Data. $C_6H_{11}O_5N$, MW 177.16, mp 207 (dec), $[\alpha]_D$ −42° (c=1, water), crystal system orthorhombic, space group $P2_12_12_1$ a=11.721(1) Å, b=13.471(2), c=4.926(1), V=777.8(1) Å^3, Z=4, $F(000)$=376, D_c=1.514 g·cm^{-3}, D_o=1.51.

Determination and Refinement of the Structure. The crystal structure was solved by the multi-solution method (MULTAN),[5] using 108 normalized structure factors with $E\geqq1.3$. Origin and enantiomorph fixings were carried out automatically by the program. Two of the eight possible solutions gave high combined figures of merit and the E map from one of these showed sensible positions and bond relations for all the non-hydrogen atoms. Refinement of the positional parameters of the twenty atoms was carried out by the block-diagonal matrix least-squares method, in which the other non-hydrogen atoms were assumed to be carbon atoms, the quantity minimized being $\sum w(|F_o|-|F_c|)^2$ with w=1.0 for all the reflections used. Five cycles of calculation gave an R-value of 0.17. The oxygen and nitrogen atoms were deduced from chemical considerations, the bond lengths and the unusually low values of the parameters due to assuming those atoms as carbon. Further refinement carried out with anisotropic thermal parameters gave an R-value of 0.07.

All the hydrogen atoms of the molecule were found from difference maps, and they were refined with isotropic thermal parameters. Five cycles of the refinement by the block-diagonal least-squares method gave the final R value of 0.043 for 912 reflections. The final atomic parameters and the atomic scattering factors for C, O, N were given by Cromer and Mann.[6] The final atomic parameters are given in Table 1. Anisotropic thermal parameters of non-hydrogen atoms and complete F_o-F_c data are deposited as Document No.8430 at the Office of the Editor of the Bull. Chem. Soc. Jpn.

Results and Discussion

The bond lengths and angles are given in Tables 2 and 3. No abnormal lengths and angles were found in the structure. The molecular framework with numbering of the atoms is shown in Fig. 1. From this perspective view of the molecule, the conformation of the compound clearly takes the half-chair form. As shown in Table 4, the torsional angle of C(2)-C(1)-N-C(5) is −4.8°, which means that atoms C(2), C(1), N, and C(5)

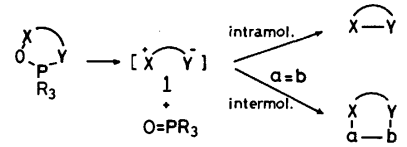
A Novel Route to *N*-Phenyl-*C*-(trifluoromethyl)nitrilimine from 3-Phenyl-5-trifluoromethyl-2,3-dihydro-1,3,4,2-oxadiazaphosphole

Kiyoshi TANAKA,* Toh-ru IGARASHI, Seiji MAENO, and Keiryo MITSUHASHI
Department of Industrial Chemistry, Seikei University Musashino-shi, Tokyo 180
(Received February 28, 1984)

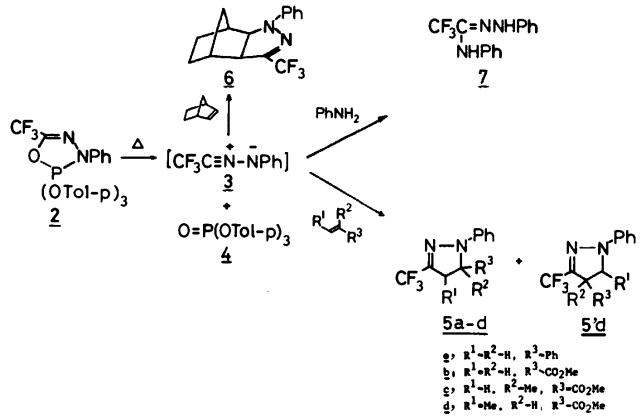
Synopsis. Thermolysis of 3-phenyl-5-trifluoromethyl-2,2,2-tris-(*p*-tolyloxy)-2,3-dihydro-1,3,4,2-oxadiazaphosphole in the presence of various olefins gave the 1,3-dipolar cycloadducts of *N*-phenyl-*C*-(trifluoromethyl)nitrilimine *in situ* formed. The similar decomposition in aniline afforded *N*-phenyltrifluoroacetamide phenylhydrazone.

Pentacovalent phosphorus compounds (phosphoranes) have high potential as synthetic reagents[1] but only a little information is available.[2] A cyclic oxyphosphorane is known to decompose with the formation of phosphine oxide and a polar intermediate (**1**) which cyclizes inter- or intramolecularly as shown below. Such a reaction mode could be utilized as a general method for the synthesis of heterocyclic compounds:[3] for example, Burger and his co-workers have been exploring the reactions of benzonitrile bis(trifluoromethyl)ylide generated from 5,5,5-trialkoxy-2-phenyl-4,4-bis(trifluoromethyl)-4,5-dihydro-1,3,5-oxazaphosphole.[4] We have previously described the preparation of 3-phenyl-5-trifluoromethyl-2,2,2-tris(*p*-tolyloxy)-2,3-dihydro-1,3,4,2-oxadiazaphosphole (**2**) and its possibile use as a precursor of *N*-phenyl-*C*-(trifluoromethyl)nitrilimine (**3**).[5]



In the present paper, we wish to report that thermolysis of the phosphole **2** in the presence of various olefins or nucleophiles like aniline affords the corresponding 1,3-dipolar cycloadducts or 1,3-adducts, respectively, of the nitrilimine **3** formed *in situ*. Such results must indicate the phosphole **2** to be the novel effective source of the nitrilimine **3**.[6]

The thermal decomposition of **2** in the presence of excess styrene was carried out at 140 °C for 24 h to give 1,5-diphenyl-3-trifluoromethyl-2-pyrazoline (**5a**) in 73% yield along with 65% of tris(*p*-tolyl) phosphate (**4**). A similar cleavage did not take place at 110 °C, the greater part of **2** being recovered unchanged. In the presence of methyl acrylate and methacrylate, thermolysis of **2** provided the corresponding pyrazolines **5b** and **5c** in 98 and 73% yields, respectively. On the other hand, in the case of methyl crotonate, the formation of both the pyrazoline **5d** and its regioisomer **5'd** in the ratio of 80/20 was found. The structure of these pyrazolines was determined by their elemental analyses and spectral data or by comparison with our authentic samples. The regioselectivity of these cycloadditions of **3** derived from **2** was analogous to that from *N*-phenyltrifluoroacetohydrazonoyl chloride which, for example, with methyl crotonate, gives a 90/10 mixture



of **5d** and **5'd**.[7]

Cycloaddition was also found to occur when **2** was decomposed in the strained olefin like norbornene, where the syn-adduct **6** was exclusively obtained in 48% yield. The exo-configuration of **6** is supported by the absence of coupling between the bridgehead protons and the corresponding vicinal pyrazoline protons in ^{1}H NMR.[8] Similarly, on the cleavage of **2** in aniline, the 1,3-addition product, *N*-phenyltrifluoroacetamide phenylhydrazone (**7**), was produced in 61% yield.

The present alternative route to **3** has the advantage that the thermal decomposition of **2** is carried out at a relatively low temperature and under neutral conditions.[9]

Experimental

All melting and boiling points are uncorrected. The IR spectra were recorded on a JASCO IRA-1 spectrometer. The ^{1}H and ^{31}P NMR spectra were measured with JEOL JNM-PMX 60 and FX 90Q spectrometers using tetramethylsilane and 85% phosphoric acid as internal and external standards, respectively; the chemical shifts are given in δppm downfield. The MS spectra were obtained with a Finnigan 4023 GC-MS DS spectrometer.

Preparation of **2**. Phosphorus pentachloride 5.20 g (24.9 mmol) was added to a stirred suspension of 4.74 g (23.2 mmol) of *N*-phenyltrifluoroacetohydrazide in 40 ml of toluene. The mixture was stirred at room temperature for an additional 2 h with evolution of hydrogen chloride. The solvent was evaporated under reduced pressure to leave oily matter which was distilled to give 7.33 g (93%) of 2,2,2-trichloro-3-phenyl-5-trifluoromethyl-2,3-dihydro-1,3,4,2-oxadiazaphosphole, bp 124—126 °C/12 mmHg (1 mmHg= 133.322Pa), IR(film) 1650 cm^{-1} (C=N), ^{1}H NMR ($CDCl_3$) δ=7.3 (br. s). A mixture of 2.00 g (5.9 mmol) of trichlorophosphole thus obtained and 3.19 g (17.7 mmol) of *O*-trimethylsilyl-*p*-cresol in 20 ml of toluene was refluxed for 4.5 h. The solvent was removed to leave a residue which was recrystallized from hexane to give the colorless crystals **2**, 1.78 g (54%), mp 96—97 °C, IR (KBr) 1648 cm^{-1} (C=N),

^{1}H NMR (CCl_4) δ=2.3 (s, 9H), 6.8 (A_2X_2, 12H), and 7.4 (br. s, 5H), ^{31}P NMR ($CDCl_3$) δ=−69.0, MS (CI, *m/z*) 583 ($M+C_2H_5$)$^+$ and 555 $(M+H)^+$.

Found: C, 62.82; H, 4.62; N, 4.78. Calcd for $C_{29}H_{26}F_3N_2O_4P$: C, 62.82; H, 4.73; N, 5.05.

Thermolysis of **2** *in Styrene.* A mixture of 0.55 g (1.0 mmol) of **2** and 0.52 g (5.0 mmol) of styrene in 20 ml of xylene was refluxed for 24 h and the solvent was removed. The resulting oily matter was placed on a column (silica gel) and eluted with hexane–chloroform (1:1) to give 0.21 g (72%) of **5a** and 0.24 g (65%) of **4**. The pyrazoline **5a** was further purified by recrystallization from hexane. **5a**; mp 87.5—88.5 °C, IR (KBr) 1610 cm^{-1} (C=N), ^{1}H NMR (CCl_4) δ=2.88 (ddq, *J*=8, 18, 2 Hz, 1H), 3.60 (ddq, *J*=12, 18, 2 Hz, 1H), 5.25 (dd, *J*=8, 12 Hz, 1H), and 6.5—7.5 (m, 10H).

Found: C, 66.25; H, 4.52; N, 9.75. Calcd for $C_{16}H_{13}F_3N_2$: C, 66.20; H, 4.51; N, 9.65.

In a similar manner, **6** was isolated in 47% yield. **6**; mp 78.5—79.5 °C (recrystallized from methanol), IR (KBr) 1595 cm^{-1} (C=N and Ph), ^{1}H NMR ($CDCl_3$) δ=1.1—1.7 (m, 6H), 2.5—2.8 (m, 2H), 3.33 (dm, *J*=10 Hz, 1H), 4.20 (d, *J*=10 Hz, 1H), and 6.8—7.4 (m, 5H).

Found: C, 64.44; H, 5.34; N, 10.03. Calcd for $C_{15}H_{15}F_3N_2$: C, 64.28; H, 5.39; N, 9.99.

Thermolysis of **2** *in Methyl Crotonate.* A mixture of 1.50 g (2.7 mmol) of 2 and 3.0 ml of methyl crotonate in a sealed tube was stirred at 140—145 °C for 24 h. The product ratio was determined by GLC analysis of the reaction mixture; **5d**/**5'd** ratio of 80/20. After excess methyl crotonate was removed, 0.73 g (94%) of a mixture of **5d** and **5'd** was obtained by column chromatography (silica gel, hexane–chloroform, 3:2). Each pyrazoline was isolated by preparative GLC. **5d**; IR (film) 1750 cm^{-1} (C=O), ^{1}H NMR (CCl_4) δ=1.43 (d, *J*=7 Hz, 3H), 3.51 (dqm, *J*=7, 7 Hz, 1H), 3.70 (s, 3H), 4.35 (d, *J*=7 Hz, 1H), and 6.7—7.4 (m, 5H). **5'd**; IR (film) 1750 cm^{-1} (C=O), ^{1}H NMR (CCl_4) δ=1.37 (d, *J*=7 Hz, 3H), 3.63 (dm, 1H), 3.72 (s, 3H), 4.77 (dq, *J*=7, 7 Hz, 1H), and 6.6—7.3 (m, 5H).

Found: C, 54.43; H, 4.57; N, 9.75 (for a mixture of **5d** and **5'd**). Calcd for $C_{13}H_{13}F_3N_2O_2$: C, 54.55; H, 4.58; N, 9.79.

Similarly, **5b** and **5c** were isolated in 98 and 73% yields, respectively. **5b**; mp 58—60 °C (lit,[7] 60—61.5 °C), IR (KBr) 1745 (C=O) and 1620 cm^{-1} (C=N), ^{1}H NMR ($CDCl_3$) δ=2.8—3.5 (m, 2H), 3.71 (s, 3H), 4.87 (dd, *J*=11, 9 Hz, 1H), and 6.8—7.4 (m, 5H). **5c**; colorless oil, IR (film) 1745 cm^{-1} (C=O), ^{1}H NMR (CCl_4) δ=1.59 (s, 3H), 3.00 (dm, *J*=17 Hz 1H), 3.53 (dm, *J*=17 Hz, 1H), 3.73 (s, 3H), and 6.7—7.4 (m, 5H).

Found: C, 54.40; H, 4.57; N, 9.73. Calcd for $C_{13}H_{13}F_3N_2O_2$: C, 54.55; H, 4.58; N, 9.79.

Thermolysis of **2** *in Aniline.* A mixture of 1.50 g (2.7 mmol) of **2** and 5.04 g (54.2 mmol) of aniline in 30 ml of xylene was refluxed for 15 h and the solvent was removed. To the residual oil was added diethyl ether and the mixture was washed twice with water, dried over magnesium sulfate, and evaporated. The resulting oily matter was submitted to column chromatography (silica gel, hexane–chloroform, 1:1) to give 0.46 g (61%) of **7** which was further purified by recrystallization. **7**; mp 66.5—67.5 °C (hexane), IR (KBr) 3360 cm^{-1} (NH), ^{1}H NMR ($CDCl_3$) δ=5.5 (br. s, 1H) and 6.8—7.4 (m, 11H).

Found: C, 60.07: H, 4.28; N, 15.10. Calcd for $C_{14}H_{12}F_3N_3$: C, 60.21; H, 4.33; N, 15.05.

A Convenient Procedure for Iodination of Electron-rich Aromatic Compounds using Iodine-Copper(II) Acetate

C. Akira HORIUCHI* and J. Yasuo SATOH
Department of Chemistry, Rikkyo (St. Paul's) University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171
(Received March 28, 1984)

Synopsis. The iodination of some electron-rich aromatic compounds, namely, three polymethylbenzenes, aniline, phenol, anisole, and phenetole, using iodine-copper(II) acetate in acetic acid, afforded the corresponding iodo compound in high yield.

Much work has been reported on the bromination and chlorination of aromatic compounds. However, since it is known that iodination is usually difficult accomplish due to the reducing effect of the hydrogen iodide produced, the iodination of aromatic compounds has been carried out in the presence of an oxidizing reagent such as nitric acid, iodic acid, sulfur trioxide, or hydrogen peroxide.[1] Many procedures are available for the iodination of activated aryl compounds by iodine-thallium(I) acetate,[2] iodine-mercury(II) acetate,[3] iodine-silver(I) acetate,[4] iodine-ammonium hexanitratocerate(IV),[5] and alkali metal iodide-ammonium hexanitratocerate(IV).[5] Moreover, Bird and Surridge recently reported[6] that the iodination of aromatic compounds with iodine and copper(II) halide gave the aryl iodides. Still more recently, it was reported the iodination of the less reactive substrates with iodine-aluminum(III) and copper(II) chloride[7] gave the corresponding aryl halide.

We have been investigating a novel iodination using iodine-copper(II) acetate; and as a first step in this research project, we reported earlier the α-iodination of ketones,[8] and the regioselective iodination of estradiol, estriol, and estrone.[9] In the work described in these reports, we demonstrated that iodine-copper(II) acetate in acetic acid is a useful reagent for the syntheses of some iodo compounds.

In the present paper, we report the iodination of some activated aryl compounds, namely, three polymethylbenzenes, aniline, phenol, anisole, and phenetole.

The reactions of the polymethylbenzenes, mesitylene (**1**), durene (**2**), and pentamethylbenzene (**3**) with iodine and copper(II) acetate in acetic acid under refluxing for 5—9 h yielded in all cases the iodo compound (**8**—**10**) (70—89%). All products were characterized by comparisons of their NMR and IR spectra and their melting points with those of authentic samples. Similarly, the reaction of aniline (**4**) afforded 4-iodoaniline (**11**) in a good yield. In the cases of anisole (**5**) and phenetole (**6**), *para*-substituted products (**12** and **13**) were obtained. This result is in agreement with the fact that the iodination of anisole using thallium(I) acetate[2] or copper(II) chloride[6] occurs at the *para*-position. The method used in the present work gave a better yield than Cambie's one. In the case of phenol (**7**), it was found that *ortho*-attacked products, namely, 2-iodo- (**15**) (64%) and 2,6-diiodo-phenol (**14**) (11%), and 4-iodo derivative (**16**) (5%) were obtained. This agrees with the result of the iodination using thallium(I) acetate or silver(I) acetate; and both of these results are also supported by our earlier finding that the iodination using the iodine-copper(II) acetate of the 3-hydroxy-estrogen derivative occurred at the *ortho*-position,[9] while the reaction of 3-methoxyestrogen derivative resulted in the recovery of the starting material. Thus, it was found that the iodine and copper(II) acetate used in these reactions were efficient and selective iodinating agents for electron-rich aromatic compounds.

Experimental

All the melting points are uncorrected. The IR and NMR spectra were measured using a Hitachi model 215 grating infrared spectrometer and a nuclear magnetic resonance spectrometer, Hitachi-Perkin Elmer R-20A, in carbon tetrachloride with TMS as an internal standard.

General Procedure. A mixture of a substrate (1.1×10^{-2} M), iodine (1.0 mol. equiv), and copper(II) acetate (1.0 mol. equiv) in acetic acid (50 ml) was stirred under refluxing for 6—9 h. The precipitated copper(I) iodide was removed by filtration, and the filtrate was poured into water and extracted with ether. The ethereal solution was washed with sodium hydrogencarbonate solution and with water, then

TABLE 1. PRODUCTS AND ISOLATED YIELDS (%) IN THE IODINATION OF ELECTRON-RICH AROMATIC COMPOUNDS (**1**—**7**)

Materials	Time/h	Products	Isolated yield/%	Mp θ_m/°C	Lit. Mp θ_m/°C
Mesitylene (**1**)	5	Iodomesitylene (**8**)	80	30—31	32—34[10]
Durene (**2**)	6	Iododurene (**9**)	89	79—80	80—81[11]
Pentamethylbenzene (**3**)	9	Iodopentamethylbenzene (**10**)	70	139—140	141—142[11]
Aniline (**4**)	2	4-Iodoaniline (**11**)	90	61—62	59—62[2]
Anisole (**5**)	10	4-Iodoanisole (**12**)	69	48—49	48—50.5[2]
Phenetole (**6**)	10	4-Iodophenetole (**13**)	80	29—30	29[12]

		2-Iodophenol (**15**)	64	43—44	42—43[2]
		4-Iodophenol (**16**)	5	92—93	92—94[10]

dried with anhydrous sodium sulfate. After removal of the desiccant, evaporation of the solvent left a solid, which was recrystallized from hexane to give the corresponding aryl iodide.

Iodination of Phenol (**7**). A mixture of phenol (**7**) (1.021 g), iodine (2.753 g), and copper(II) acetate (2.167 g) in acetic acid was treated according to the general procedure. After the usual work-up, the resultant oil was chromatographed on silica gel (50 g). Elution with hexane (50 ml) and benzene (70 ml) gave plates of **14** (420 mg) from hexane, mp 66—67 °C. The next fraction, eluted by the same solvent (70 ml), on crystallization from hexane gave plates of **15** (1.529 g), mp 43—44 °C, while the last fraction, eluted with the same solvent (30 ml), on crystallization from hexane gave plates of **16** (115 mg), mp 92—93 °C.

The Reaction of Diethyl Acyl Phosphites with α,β-Unsaturated Carbonyl Compounds

Yoshiki OKAMOTO* and Toshio AZUHATA
The Institute of Scientific and Industrial Research, Osaka University, Mihogaoka 8-1, Ibaragi, Osaka 567
(Received April 9, 1984)

Synopsis. Diethyl acetyl and diethyl benzoyl phosphites reacted with propenal and 3-buten-2-one to give 1,4-addition products respectively. While the reaction of diethyl acetyl phosphite with 2-butenal and 2-methyl- and 3-phenylpropenals gave 1,2-addition products exclusively.

Trialkyl phosphites are known to react sluggishly with aldehyde. The reaction requires rather drastic conditions or much long reaction time and give several addition compounds such as 1:1, 1:2 or 1:3 in relatively low yield.[1] Dialkyl trimethylsilyl phosphite reacts smoothly with aldehyde and ketone to produce [α-(trimethylsiloxy) alkyl] phosphonate.[2] In the case of the reaction with α,β-unsaturated carbonyl compounds, the adducts resulting from 1,2 and 1,4 modes of addition have been obtained.[2] Diethyl acetyl phosphite (**1a**) reacted in diethyl ether exothermically with chloroacetaldehyde to give diethyl (1-acetoxy-2-chloroethyl)-phosphonate (56—95%).[3] Chloral, benzaldehyde, and 3-methylbutanal reacted also in same manner. The unchlorinated aldehyde required higher temperature.[4]

In this report, the reaction of diethyl acyl phosphite (**1**) with α,β-unsaturated carbonyl compounds is reported.

The reaction of diethyl acyl phosphite (**1**) with propenal (**2a**) proceeded exothermically at room temperature, while the reaction with α- or β-substituted α,β-unsaturated aldehyde (**2**) required heating to the refluxing temperature of benzene for several hours.

Propenal (**2a**) reacted with diethyl acetyl phosphite (**1a**) to give a mixture of 1,4-addition product (**3a**) and several unidentified products. In the case of the reaction of **2a** with diethyl benzoyl phosphite (**1b**), only 1,4-addition product (**3b**) was isolated in 69% yield. Diethyl 2,2-dimethylpropionyl phosphite (**1c**) did not reacted with **2a**. 3-Buten-2-one (**2b**) reacted also smoothly with **1a** and **1b** to afford only 1,4-addition products (**3c** and **3d**) respectively. On the other hand, when α- or β-substituted α,β-unsaturated aldehyde (**2c**, **2d**, and **2e**) was allowed to react with **1a**, only 1,2-addition products (**4a**, **4b**, and **4c**) were obtained exclusively. But 4-methyl-3-penten-2-one did not react with **1a**. Diethyl benzoyl phosphite (**1b**) did not react with these substituted aldehydes (**2c**, **2d**, and **2e**). Such a restricted limitation of the reaction may be caused by the high sensitivity of the dialkyl acyl phosphite (**1**) to steric hindrance. ^{1}H-NMR spectroscopy and GLC analysis of these products showed them to be in pure states, but assignment of olefin geometries could not be done.

Experimental

Dialkyl acyl phosphites were prepared from diethyl phosphorochloridite and sodium carboxylates.[5] Benzene was distilled under nitrogen from calcium hydride. Aldehydes and ketones were freshly distilled. All reactions were carried out under an atmosphere of nitrogen with the rigid exclusion of moisture from reagent and glasswares. ^{1}H NMR spectra were recorded on a JNM FX-100 spectrometer. Analytical gas chromatography were performed on a Shimadzu GC-7A gas chromatograph using a 2 m glass column of 2% OV-17 on a 60-80 mesh DMCS Chromosorb W support.

General Procedure. To a flask equipped with a reflux condenser, a magnetic stirrer, and an addition funnel were added 10 ml of benzene and 20 mmol of carbonyl compound. While the mixture was stirred at room temperature, 20 mmol of dialkyl acyl phosphite was added dropwise. After completion of addition, the solution was refluxed for 3 h. Distillation at atmospheric pressure removed the solvent. Susequent vacuum distillation afforded the product. The purity was checked by GLC analysis and ^{1}H NMR spectroscopy. The results are summarized in Table 1.

Preliminary Work on Orientation of Nematic Liquid-Crystalline Molecule by Electronic Spectra

Michio KOBAYASHI, Toshiyuki KASAHARA,† Keihachiro NAKAJIMA††
Kazunori MARUYAMA, and Yoshie TANIZAKI*
Department of Materials Science and Technology, Technological University of Nagaoka, Nagaoka 949-54
(Received December 23, 1983)

Absorption spectra of a nematic liquid-crystalline molecule (4-butyl-4′-ethoxyazobenzene) were measured in sandwich-type cells with very thin gaps which ranged from 0.2 to 1.0 μm when the cells were empty. The intensity ratio of the first (354 nm) to second (240 nm) band in the liquid state (86 °C) decreases as the state changes into liquid-crystalline (LC) states (70 and 48 °C). According to results of dichroism analysis and MO calculation, the 354 nm and 240 nm bands are due to π-π^* transitions polarized along the molecular long and short axes, respectively (with an angle of about 66°to each other). This finding coupled with an assumption that the molecular orientation of the liquid state is isotropic, allows a qualitative discussion on the orientation of molecule in the LC state, leading to a conclusion that the molecular long axis against the cell surface takes two kinds of orientation with respective tendencies to be parallel in the interface region and perpendicular in the bulk region.

Descriptions[1] have been given for a problem concerning the orientation of liquid-crystalline (LC) molecules, *i.e.*, the problem of the orientational order parameter.[2] Many approaches to this problem seem to be limited to optical phenomena associated with the refractive index or, indirectly, to dichroic and anisotropic magnetic properties of guest dye molecules, which are induced by orientation of host LC molecules. No direct approaches by means of analyzing anisotropic absorption spectra of oriented LC molecules from the viewpoint of electronic structure, have been attempted except few cases,[3,4] where linear dichroisms of LC molecules oriented by rubbing were measured but no interpretation of spectra was given.[4]

Since the electronic transition moment of a molecule has to be correlated closely with the molecular structure if the absolute transition direction of LC molecule itself is known or determined beforehand, knowledge of the molecular orientation of LC state should be obtained *via* analysis of anisotropic electronic spectra. Thus, for instance, the relative intensity of two absorption bands of a molecule in the isotropic (liquid) state, whose transition moment vectors cross each other, must change depending on its orientation in the LC state.

With a view to investigating the molecular orientation in the LC state from the viewpoint of molecular structure, we conducted an experiment as the first step to make sure the above consideration. As a result, we observed the fact that the relative intensity of the first and second bands of an LC molecule which is considered to take the nematic phase[5] changes with transition from the liquid (isotropic) to LC state. The present communication will report the cause for anisotropic absorption spectra and results obtained through qualitative discussion on the state of molecular orientation induced by that cause.

Experimental

Commercially available 4-butyl-4′-ethoxyazobenzen (BEAB) was purified by repeated recrystallization from aqueous ethanol. Polarized absorption spectrum of BEAB in a stretched poly(vinyl alcohol) (PVA) film was measured with a Shimadzu UV-360 spectrophotometer equipped with a rotatable Rochon-type polarizer. The polarization of electronic absorption bands of BEAB was determined by the stretched PVA film method.[6,7]

The sandwich-type cell used comprised two polished quartz glass plates of 3×23×23 mm size. We did not apply intentionally to the glass plates any surface treatments such as rubbing or coating. The two glass plates were held tight with adhesive except the cell entrance of appropriate size through which melted BEAB was introduced. The gaps of the empty cells were estimated to be in the range 0.2—1.0 μm from interference spectra recorded on the UV-360. In a vacuum vessel, the sample was melted and was introduced into the cell through the entrance by being sucked up under atmospheric pressure.

The cell was set in a cell holder which was specially designed to fit the sample compartment of UV-360. The temperature in the cell holder could be controlled within about ±1 °C with a handmade temperature controller. In the liquid-crystalline (nematic) state, however, all sample cells prepared as above exhibited a slight positive dichroism such that the direction of sucking up provides an optical axis, though the liquid (isotropic) state did not show any dichroism. The dichroism reappeared whenever the sample cell was cooled to the LC state after it had been heated to the isotropic state.

Results

The absorption spectrum of BEAB in ethanol indicates that the absorbance of the first band (A_1) is larger than that of the second (A_2) (see Table 1). The intensity ratio $R_{12}=A_1/A_2$ is about 1.71, which is considered as the value when BEAB is free from the molecular interaction.

Figure 1 shows the polarized absorption spectra of BEAB in a stretched PVA film, where $A_\parallel$ and $A_\perp$ are the absorbances for the polarized lights whose electric vectors are parallel to and perpendicular to the stretching direction of the film, respectively. R_d is the ratio of the absorbances (optical densities), $R_d=A_\parallel/A_\perp$.

It is known that a long molecule in a polymer film under uniaxial stretching inclines its long axis preferentially to the stretching direction of film. Thus it

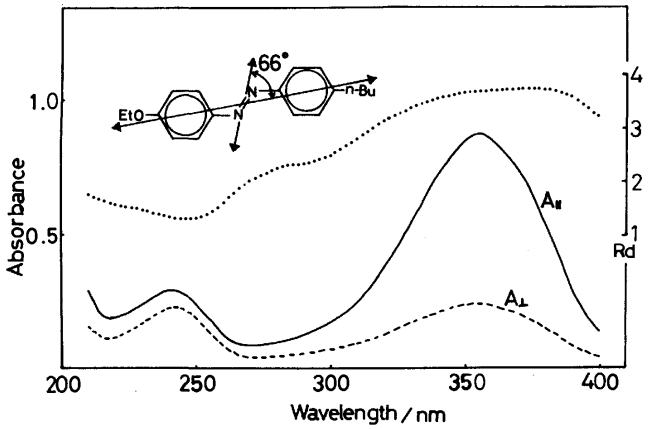

Fig. 1. Polarized absorption spectra of BEAB in a stretched PVA film. R_s=3.86 is the stretch ratio of the film (Ref. 6). The angle between the transition moments of the first (354 nm) and second (240 nm) bands is obtained from the values of R_d and R_s by the dichroism analysis (Ref. 7).

TABLE 1. EXPERIMENTAL AND CALCULATED RESULTS FOR THE ABSORPTION SPECTRUM OF BEAB

Band	λ_{max} /nm[a,d]	$\varepsilon[f]$[a,d]	Polarization[b]	Angle[c,d]
1	345[362]	21400[1.24]	17.5° (log axis)	66°[76°]
2	237[235]	13100[0.33]	48.5° (short axis)	

a) Observed in ethanol. ε is the extinction coefficient and f is the oscillator strength. b) The angle of the transition moment to the orientation axis of molecule (Ref. 7). c) The angle between the two transition moments as determined by the dichroism analysis (Ref. 7). d) [ ]: Results calculated by the semiempirical MO (PPP) method.

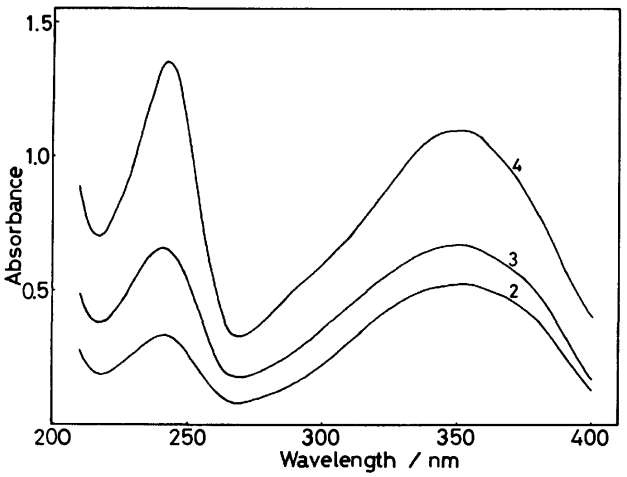

Fig. 2. Absorption spectra of BEAB in the LC state at the lower temperature (48 °C). The number indicated along the curve is the measurement number in Table 2.

follows that the R_d value for a long axis-polarized band is high, whereas for a short axis-polarized band is low. According to Fig. 1, the R_d value is high for the first band (354 nm) and is low for the second (240 nm), implying that the first and second bands are polarized along the long and short molecular axes, respectively. The transition moments corresponding to the two bands cross each other, as shown in Fig. 1, with an angle of about 66° as determined from the R_d values by the dichroism analysis.[7]

In Table 1, the observed results for the absorption spectra of BEAB are compared with the results calculated by the semiempirical MO (PPP) method.[8] The calculated results reproduce the observed ones fairly well.

Absorption spectra of BEAB in sandwich-type cells with various gaps have been measured with natural light for the liquid state (at 86 °C) and for the LC states at higher (70 °C) and lower (48 °C) temperatures. The spectra at the lower temperature are shown in Fig. 2 as an example. Spectra observed with different cells having different gaps, *i.e.*, different optical path lengths in the range 0.2—1.0 μm, indicate that the absorption intensity for the isotropic state is directly proportional to the path length, whereas for the LC state, as is evident from Fig. 2, the relative intensity of A_1 and A_2 changes with path length (compare the R_{12} values in Table 2).

Discussion

The intensity ratios R_{12} ($=A_1/A_2$) for different path lengths estimated for the isotropic state are almost constant as given by $R_{12}=1.69\pm0.04$ (see R_{12} of Liq. (86 °C) in Table 2), which can be compared with $R_{12}^0=1.71$ for the free BEAB molecule. The former is nearly equal to the latter. Let us assume, therefore, that the molecular structure of BEAB in the isotropic state is similar to that in ethanol solution, and that the angle between the transition moments of A_1 and A_2 of the molecule itself is kept constant even in the LC state.

The fact that the R_{12} values for the isotropic state are almost constant irrespective of the cell gap, refers to two useful facts: First, Lambert's law is regarded as being realized. Therefore, the absorbance can be substituted for the optical path length of cell of which the absolute value is difficult to be determined, in such a concrete way that different cell gaps for the LC state can be graduated by referring to the absorbances for the corresponding cells in the isotropic state. Second, the R_{12} value of 1.69 is considered as the value of isotropic distribution of the BEAB molecules. The extent of anisotropy of the LC state, therefore, can be determined from the deviation of R_{12} from $R_{12}=1.69$.

The absorption spectrum of BEAB changes as follows: As the condition goes from the isotropic to LC state at the higher temperature and then to the lower temperature, the absorbance of the first band decreases considerably, while the second band increases slightly. This means that the dimension of the projection of the molecular long axis onto the plane of cell becomes smaller with the change from the liquid to LC state. In other words, the BEAB molecule tends to incline its long axis to the direction of light propagation, *i.e.*, to the direction perpendicular to the plane of the cell.

Now, let us examine the relation between R_{12} of LC state and the cell gap. The data of R_{12} are summarized in Table 2, where, in place of cell gaps, the absorbances

TABLE 2. ABSORPTION DATA FOR NATURAL LIGHT OF BEAB IN VARIOUS CELL GAPS

Cell No.	Meas. No.	Cell gap[a] (Abs.)	Intensity ratio R_{12} Liq.(86°C)	LC(70°C)	LC(48°C)
I[b]	1	0.40	1.69	1.75	1.67
	2	0.51	1.68	1.68	1.58
II	3	0.96	1.67	1.24	1.02
III[b]	4	1.93	1.71	1.07	0.808
	5	2.37	1.73	1.01	0.765
IV	6	2.92	1.68	0.987	0.723

a) The absorbance (Abs.) of the first band in the isotropic state is used instead of cell gap. b) The data of the two measurements of cell Nos. I and III are those obtained for different spots of the same cells.

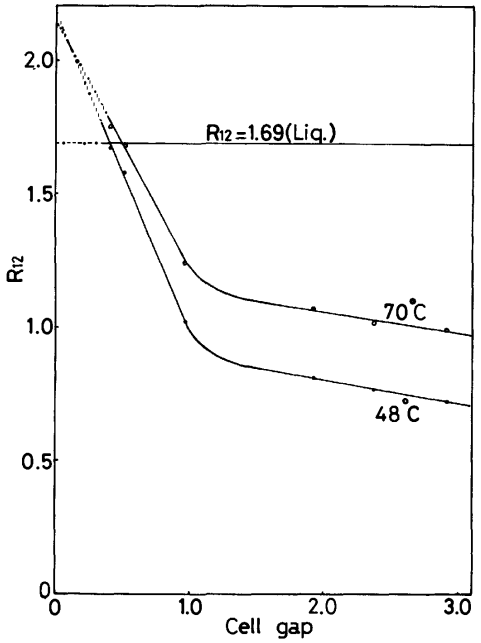

Fig. 3. The R_{12}-cell gap relations for BEAB in the isotropic state (86°C) and in the LC states at higher (70°C) and lower (48°C) temperatures. R_{12} is the absorbance ratio of the first and second bands. The cell gap is graduated by the absorbance for the first band in the isotropic state.

of the first band measured in the liquid state are used. From the data in Table 2, the relationship between R_{12} and cell gap (in absorbance scale) is obtained as shown in Fig. 3. According to the figure, the R_{12} values for the LC state are smaller than 1.69 for the liquid state except for very small cell gaps.

Figure 3 shows that the R_{12} value decreases steeply in the range of smaller cell gaps and slowly in that of larger cell gaps. Figure 3 shows also that the two slopes of R_{12} at the lower (48°C) and the higher temperature (70°C) are nearly equal to each other in the range of cell gaps larger than 1.0, and moreover that the difference of R_{12} in this range is larger than that in the smaller range of cell gaps.

The above-mentioned facts about the behavior of R_{12} indicate that the thinner the cell gap, the greater the emphasis of the characteristic of R_{12} in the interface region and that the thicker the greater that of R_{12} in the bulk region. In order to discuss the above characteristics, we have considered that the molecular orientation in a cell can be divided into two kinds of orientation states with respective characteristics in the interface and bulk regions.

Taking into account that the two interfaces are common to all cells, the difference between the thick and thin cells is attributable to the part of bulk. For this reason, we can get absorption spectra for the bulk itself from difference spectra for various cell thicknesses. In this way, difference spectra have been obtained for the LC state at the higher and lower temperatures. The difference spectra at the lower temperature are shown in Fig. 4 as an example. As is evident from this figure, all of the difference spectra in the respective temperatures are quite similar in shape to one another. This indicates that the oriented state in the bulk region is kept constant independently of the thickness. Moreover, the relative intensity of the first band is apparently larger for the higher temperature than for the lower. This implies that the inclination of the molecular long axis is prevented and is caused to shift to an isotropic state by elevation of temperature. Incidentally, though not observed apparently in the difference spectra at the higher temperature, a new band appears

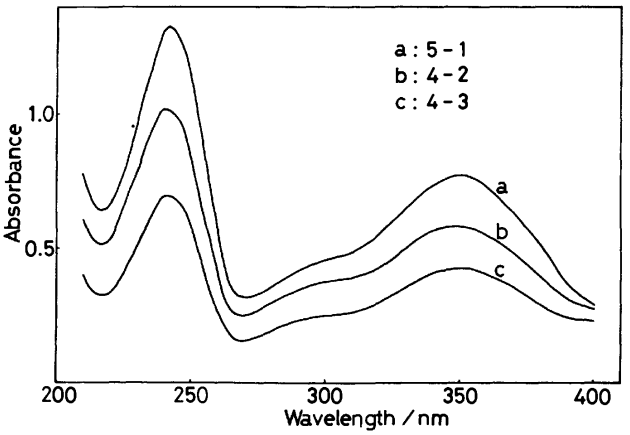

Fig. 4. The difference spectra of BEAB in the LC state at the lower temperature (48°C). The numbers given for a, b, and c are the measurement numbers (Table 2) used for subtruction.

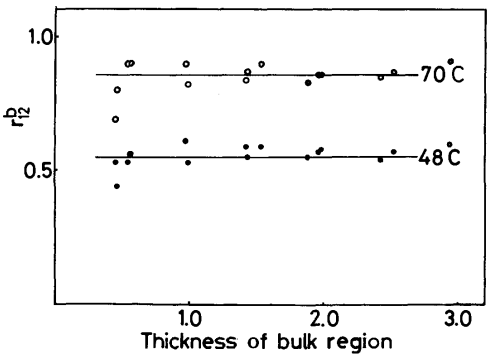

Fig. 5. The relation of r_{12}^b and thickness of bulk region in the LC state. The r_{12}^b value is the ratio of the first and second bands of difference spectrum. The thickness is graduated by absorbance of the first band in the isotropic state.

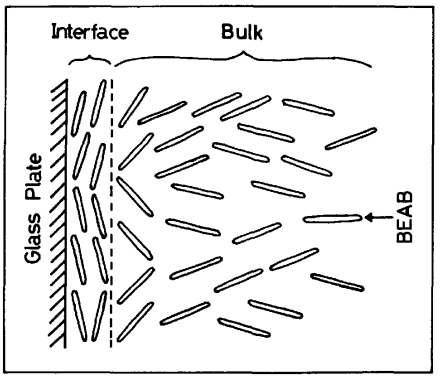

Fig. 6. A model for the molecular orientation of BEAB in the LC state in a thin glass cell.

at around 290 nm in Fig. 4, but at present its cause remains unexplained.

Defining r_{12}^{b} for difference spectra in the same sense as R_{12} and plotting r_{12}^{b} against the thickness of bulk, we obtain Fig. 5. For each temperature, r_{12}^{b} is regarded as nearly constant, the average values being about 0.6 (48 °C) and 0.9 (70 °C). These values are smaller than those corresponding to R_{12} (Fig. 3), which suggests that the intensity ratio (r_{12}^{f}) of the first and second bands for the interface region is larger than $R_{12}=1.69$. In fact, the R_{12} value larger than 1.69 is observed for the thinnest cell in the LC state (see Table 2 and Fig. 3).

If this is true, it is concluded that the LC state consists of two kinds of orientation states such that the molecular long axis inclines to the direction parallel to the cell plane in the interface region or perpendicular to the cell plane in the bulk region. Figure 6 shows schematically a model for the orientation of BEAB molecules in the cell. This model gives explanations for the findings already pointed out in Fig. 3 as follows: According to the model in Fig. 6, the following expression for R_{12} is obtained:

$$R_{12}=\frac{A_1}{A_2}=\frac{\varepsilon_1^{f}p^{f}+\varepsilon_1^{b}p^{b}}{\varepsilon_2^{f}p^{f}+\varepsilon_2^{b}p^{b}},$$

where ε and p are the molecular extinction coefficient and path length (cell gap), respectively, the superscripts f and b indicate the interface and bulk regions, respectively, and the subscripts 1 and 2 stand for the first and second bands, respectively. In the above expression, only p^{b} is a variable, which increases with increasing cell gap. R_{12} is, therefore, a hyperbolic function of p^{b}. $R_{12}\simeq\varepsilon_1^{b}/\varepsilon_2^{b}=r_{12}^{b}$ for $p^{b}\gg p^{f}$, and $R_{12}=\varepsilon_1^{f}/\varepsilon_2^{f}=r_{12}^{f}$ for $p^{b}=0$. Since $r_{12}^{b}<r_{12}^{f}$, the first derivative of R_{12} with respect to p^{b} is negative. Thus, the R_{12} value decreases along the hyperbolic curve with increasing cell gap (p^{b}), *i.e.*, the R_{12} value decreases steeply in the range of smaller cell gaps and gradually in that of larger cell gaps, which tendency is responsible for approximately two straight lines of different slopes to have been observed as shown in Fig. 3. When the temperature (T) is raised in the LC state, the molecular orientations in the interface and bulk regions approach each other through thermal motion, resulting in the same orientation ($r_{12}^{f}=r_{12}^{b}=1.69$) in the isotropic state. In other words, if $T<T'$, $r_{12}^{f}(T)>r_{12}^{f}(T')>1.69$ and $r_{12}^{b}(T)<r_{12}^{b}(T')<1.69$. The model predicts, therefore, that the two curves for the higher and lower temperatures in Fig. 3 must cross each other, which seems indeed to have been realized as the dotted lines at the small cell gaps. Strictly speaking, the model does not, however, explain the finding that the slopes of the two lines for 70 and 48 °C in Fig. 3 are nearly equal for larger cell gaps, because the model claims that the slopes of the two hyperbolic curves for different temperatures are the same only when they are both zero (horizontal). Therefore, the model in Fig. 6 is applicable fairly well to smaller cell gaps, but finds some difficulty in being applied to larger cell gaps.

To tell the truth, we expected at first that the orientation state in LC is only one kind. But actually, as shown in Fig. 6, it has become clear that the two kinds of orientation states exist in a cell. The orientation state in the bulk region, in this case, is thought to be the orientation in the LC state itself. (The reason why the molecules in the bulk region are arranged altogether perpendicularly to the cell plane is not clear.) If so, what makes the orientation in the interface induced? As pointed out in the Experimental section, the dichroism always reappears in the LC state even after it has disappeared in the isotropic state. This means that the orientation in the interface does not originate from the so-called flow alignment.[9] Therefore, the motive force for the orientation in the interface must remain on the cell wall. As the motive force concerned, a kind of rubbing effect in the interface region is considered which is generated by the friction when the melted sample is sucked up into the cell.

Knowledge of the rubbing effect on the cell wall *via* the fluid just mentioned may be obtained, provided that an absorption spectrum for the interface region has been determined and then, from analysis of the spectrum, details of the molecular arrangement relative to the cell wall have been clarified.

In principle, an absorption spectrum may be determined for the interface region as well as for the bulk region and accordingly the molecular orientations in both the regions may be analyzed in a three dimensional space. However, in this preliminary work, we could not do so because of the involvement of considerably large experimental errors as manifested in Fig. 5. But qualitatively, the above-mentioned conclusions concerning the orientation of BEAB molecules in the cell can be derived.

We wish to thank Professor Shunsuke Kobayashi, Department of Electronic Eng., Tokyo University of Agriculture and Technology, for his helpful suggestion about the experimental technique for cell preparation. The present work was partially supported by a Grant-in-Aid (to Y. T.) from Nippon Seiki Co., Ltd., Nagaoka, Niigata, to which we wish to express our thanks.

Internal Heavy Atom Effects on the Exciplex Fluorescence: Anthracene-*N,N*-Dimethylaniline System

Sanyo HAMAI
Department of Physics, Miyazaki Medical College, Kiyotake, Miyazaki 889-16
(Received February 6, 1984)

Intrinsic fluorescence yields of exciplexes, ϕ_f^0, have been determined for halogenated systems of anthracene (A)-*N,N*-dimethylaniline (DMA) in cyclohexane. By the substitution of a chlorine atom for a hydrogen atom in either A or DMA, ϕ_f^0 is reduced to about 1/5, whereas by the bromine substitution it is reduced to about 1/80. When more than one halogen atom of the same kind are substituted in the A-DMA exciplex, the first substitution causes more prominent reduction in ϕ_f^0 than the subsequent substitution does. Although there is a remarkable irregularity in the fluorescence quantum yields of halogenated anthracenes which were used as the electron acceptors in the exciplexes, ϕ_f^0 varies regularly according to the kind and the number of the halogen substitutions. The internal heavy atom effect on ϕ_f^0 is explained by the enhancement of the intersystem crossing rate to the triplet state.

It has been well established that heavy atoms such as halogens affect many relaxation processes in excited molecules.[1] The fluorescence yields of benzene[2], naphthalene,[3,4] and phenanthrene[5] are reduced by the substitution of a halogen atom, demonstrating the internal heavy atom effect. On the other hand, fluorescence yields of halogen-substituted anthracenes are known not to exhibit such normal heavy atom effects. The fluorescence yields of anthracene, 9,10-dichloroanthracene, 9-bromoanthracene, and 9,10-dibromoanthracene have been reported to be 0.36 (in cyclohexane),[6] 0.55 (in cyclohexane),[6] 0.018 (in 2,2-dimethylbutane/pentane (8:3)),[7] and 0.094 (in cyclohexane).[8] The anomalous photophysical properties including "inverse heavy atom quenching" of halogenated anthracenes are explained by the small energy gap between the first excited singlet state (S_1) and the second excited triplet state (T_2) through which the nonradiative crossing occurs, and by the energy level inversion caused by the substitution between these two states.[9-11] In anthracene derivatives, which of the S_1 and T_2 states is higher than the other is governed critically by the kind(s) and position(s) of the substituent group(s).

Only a few studies have been made on the fluorescence of the halogen-substituted exciplex systems. For the exciplexes of benzo[*ghi*]perylene and dibenzo[*def*, *mno*]chrysene with *p*-chloro-*N,N*-dimethylaniline, Watkins has reported the reduction in the fluorescence yields of these exciplexes.[12,13] No exciplex fluorescence has been observed for the systems of some 9- or 9,10-substituted anthracene-bromobenzene derivatives.[14] In the case of the intramolecular charge-transfer states of 6-(arylamino)-2-naphthalenesulfonate derivatives, the fluorescence yields have been found not to be influenced by the halogen substitution.[15]

The aim of this work is to investigate systematically how the halogen substitution on the individual component constituting the exciplex affects the fluorescence yield of the exciplex. Anthracene-*N,N*-dimethylaniline, which is a typical exciplex,[16] was chosen as an unsubstituted parent exciplex.

Experimental

Anthracene (A) was obtained from Wako, 1-chloroanthracene (CA) from Aldrich, 9,10-dichloroanthracene (DCA) from Tokyo Kasei, 9-bromoanthracene (BA) from Aldrich, and 9,10-dibromoanthracene (DBA) from Tokyo Kasei. Anthracene and its halogen derivatives were purified by column chromatography. *N,N*-Dimethylaniline (DMA) purchased from Tokyo Kasei was distilled under reduced pressure. *p*-Chloro-*N,N*-dimethylaniline (CDMA) was synthesized from *N,N*-dimethyl-*p*-phenylenediamine by the Sandmeyer reaction,[17] and recrystallized twice from ethanol. *p*-Bromo-*N,N*-dimethylaniline (BDMA) obtained from Fluka AG was recrystallized twice from cyclohexane. Cyclohexane, used as the solvent, was percolated through a silica-gel column.

Absorption spectra were measured with a Hitachi 124 spectrophotometer, and fluorescence spectra were recorded on a Shimadzu RF-501 spectrofluorophotometer equipped with a cooled EMI 9789 QA photomultiplier. Fluorescence was viewed at right angles to the direction of excitation. Fluorescence spectra were corrected for the spectral response of the detection system. The correction factor was obtained by the previously described method[18] employing a Rhodamine B quantum counter (below 600 nm) and a standard solution method[19] using 4-(dimethylamino)-4'-nitrostilbene (above 600 nm). Measurements were made on cyclohexane solutions of a fixed concentration of anthracene (2×10^{-5} mol dm^{-3}) or halogenated anthracene (1×10^{-5} mol dm^{-3}) and the varying concentrations of DMA derivatives. Samples for fluorescence measurements were nitrogen bubbled. 9.10-Diphenylanthracene in deaerated cyclohexane was used as a standard (ϕ_f= 0.90) for the fluorescence yield determinations.[20] All the measurements were made at 25±0.1 °C.

Results and Discussion

For every combination of the electron donor (DMA or its derivative) and the electron acceptor (A or its derivative) used in this work, the exciplex fluorescence was observed. As is usually the case the exciplex fluorescence is structureless and red-shifted from the monomer fluorescence of A or its derivative.[21] The positions of the fluorescence maxima of the exciplexes involving the same acceptor have been found to be independent of the kind of the donor to within ≈5 nm. In addition, the energy differences between the acceptor and its exciplex fluorescence have been found to be nearly constant, irrespective of the kind of acceptor. These results suggest that the geometrical structure and the potential energy curve of the halogen-substituted exciplex are similar to those of the unsubstituted

exciplex A-DMA. The exciplex formation can be described by the following scheme:[22]

$$M^* + Q \underset{k_2}{\overset{k_1}{\rightleftharpoons}} (MQ)^*$$

$$M + h\nu_f \quad M \quad M + Q + h\nu_f' \quad M + Q$$

Here M* is anthracene (or its halogen derivative) in the excited singlet state, Q is DMA (or its halogen derivative), and (MQ)* is the exciplex formed between M* and Q. k_1, k_2, k_f, k_n, k_f', and k_n' are the rate constants for exciplex formation, exciplex dissociation, radiative transition of M*, nonradiative transition of M*, radiative transition of (MQ)*, and nonradiative transition of (MQ)*, respectively.

Under photostationary conditions, the relation between the intrinsic fluorescence yield of the exciplex, ϕ_f^0 $(=k_f'/(k_f'+k_n'))$, and the fluorescence yield of the exciplex, ϕ_f, at a given donor concentration [Q] is expressed by

$$\frac{1}{\phi_f} = \frac{1}{\phi_f^0} + \frac{(k_f+k_n)(k_2+k_f'+k_n')}{k_1 k_f'} \frac{1}{[Q]}.$$

The intrinsic fluorescence yield ϕ_f^0 can be evaluated from a plot of $1/\phi_f$ *vs.* $1/[Q]$. As typical examples, plots for A-DMA, A-CDMA, and A-BDMA are displayed in Fig. 1. From the intercepts of the straight lines as shown in Fig. 1, the intrinsic fluorescence yields ϕ_f^0 for all

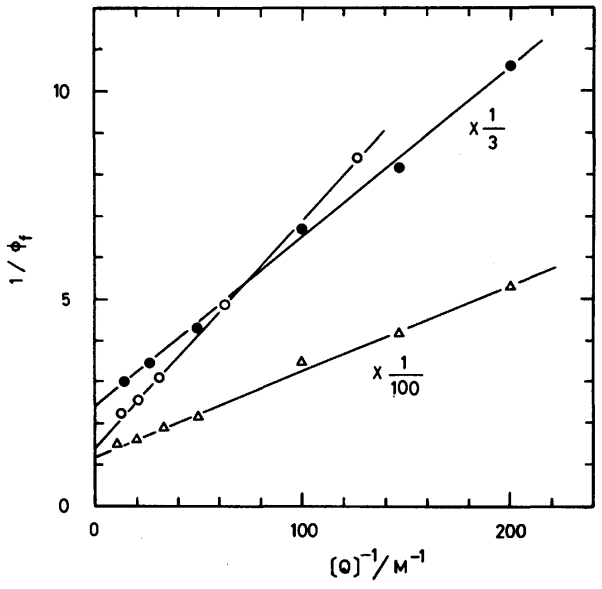

Fig. 1. Plots of $1/\phi_f$ *vs.* $1/[Q]$.
○: A-DMA, ●: A-CDMA, △: A-BDMA.

TABLE 1. INTRINSIC FLUORESCENCE YIELDS OF EXCIPLEXES (ϕ_f^0) AND FLUORESCENCE YIELDS OF THEIR COMPONENT ACCEPTORS (ϕ_f(monomer)) IN CYCLOHEXANE

	ϕ_f(monomer)	ϕ_f^0		
		DMA	CDMA	BDMA
A	0.32	0.72	0.14	0.0083
CA	0.11	0.14	0.071	0.0053
DCA	0.60	0.087	0.080	0.0056
BA	0.013	0.0086	0.0075	0.0041
DBA	0.13	0.0047	0.0049	0.0038

the combinations of the donor and acceptor have been determined. They are listed in Table 1.[23] Also included in Table 1 are the fluorescence yields, ϕ_f(monomer), of anthracene and of its halogen derivatives.

It can be seen from Table 1 that the value of ϕ_f^0 in every row drops in going from left to right (with the increase in the atomic number of the heavy atom in the electron donor). The only exception for this trend is ϕ_f^0 of DBA-CDMA, which is the same as that of DBA-DMA within experimental uncertainties. The substitution of the chlorine atom in A-DMA decreases ϕ_f^0 to about 1/5, whereas the bromine substitution decreases ϕ_f^0 to about 1/80. Such regularity in ϕ_f^0 is further confirmed by looking at ϕ_f^0 in the columns of Table 1 (the exciplexes consisting of the same electron donor). As in the case of the rows (the exciplexes consisting of the same electron acceptor), ϕ_f^0 decreases in going from top to bottom. Table 1 also shows that the values of ϕ_f^0 do not depend on whether the halogen atom is substituted in the donor or acceptor component (*e.g.*, for the case of A-CDMA and CA-DMA *etc.*). When two halogen atoms of the same kind are introduced in the exciplex, ϕ_f^0 is further reduced by the second substitution of the halogen atom. However, the effect of the second substitution on ϕ_f^0 is much less than that of the first one.

The ratio of the exciplex fluorescence yield of the monosubstituted exciplex to that of the unsubstituted exciplex, R, is 0.19 for the chlorine-atom substitution (both for CA-DMA and A-CDMA), whereas R is 0.012 for the bromine-atom substitution (both for BA-DMA and A-BDMA). The ratio of the fluorescence yield of the halogenated aromatic monomer to that of the unsubstituted parent monomer has been reported to be 0.081 for chlorobenzene and <0.002 for bromobenzene at room temperature.[2] Moreover, these ratios have been found to be 0.080 and 0.017 for 1-chloronaphthalene and 1-bromonaphthalene, respectively.[4] Thus, both for chlorine and bromine substitution, the values of R for the A-DMA exciplex system are comparable with the reported values for benzene and naphthalene monomers, except for bromobenzene. It appears, therefore, that the internal heavy atom effect on the exciplex fluorescence is caused by a similar mechanism to that in the case of the aromatic monomer fluorescence, that is, by a normal heavy atom effect enhancing the rate of the intersystem crossing to the triplet state as the deactivation process.

The first excited singlet state of anthracene is lowered by 4200 cm^{-1} by virtue of the exciplex formation with DMA.[16] For the halogen-substituted exciplexes, almost the same stabilization energy is expected from their similar spectroscopic characteristics. On the other hand, laser photolysis studies on the systems of A-DMA and A-*N*,*N*-diethylaniline have revealed that the triplet state produced from the singlet exciplex is the triplet state of not the exciplex but of anthracene itself.[24,25] Although the energy level of the triplet exciplex is unknown, this fact indicates that the triplet state of the exciplex, to which the singlet exciplex decays, is dissociative.

On the basis of these facts, the result that ϕ_f^0 is regularly and stepwisely reduced by the halogen

substitution in the A–DMA exciplex system may be explained as follows. In contrast to halogenated anthracene, no inversion of the energy level between the first excited singlet state and the second triplet state occurs in the halogenated exciplexes of the A–DMA systems. Therefore, the intersystem crossing rate to the triplet state, which immediately dissociates to the triplet state of the halogenated anthracene, is accelerated by the substitution of halogen.

With respect to the heavy atom effect for the triplet exciplex, detailed studies of Steiner and Winter were performed by flash spectroscopy.[26,27] They have determined the radical yields and rate constants in the quenching reaction of thionine triplet with the series of monohalogen substituted anilines.[26] The radical yield decreases with increasing the spin-orbit coupling constant of the halogen substituent. This result is explained in terms of the internal heavy atom effect on the $T \rightarrow S_0$ intersystem crossing rate in the triplet exciplex.[26,27] The internal heavy atom effects in the singlet exciplexes of the A–DMA systems found in this study are thus qualitatively similar to those observed for the triplet exciplexes.

The author wishes to thank Professor Fumio Hirayama for his valuable discussion.

Reversing-Pulse Electric Birefringence of Poly(γ-methyl L-glutamate) in Hexafluoro-2-propanol

Kazuyoshi UEDA
Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received March 8, 1984)

Reversing-pulse electric birefringence (RPEB) signals of poly(γ-methyl L-glutamate) (PMLG) were measured, for the first time, in hexafluoro-2-propanol at 25 °C and at 535 nm. Quantitative analyses were carried out on the steady-state birefringence and the field-free decay time ($<\tau>_{EB}$) in the wide field strength region and also on the rise, reverse, and decay portions in the low field strength region by taking into account the continuous molecular length distribution of a fractionated PMLG sample. The weight-average length (l_w), permanent dipole moment (μ_w), polarizability anisotropy ($\Delta\alpha_w$), and the degree of polydispersity (l_w/l_n) were evaluated by two procedures: one from the analysis of the reverse-transient portion and the other from the field-free decay portion of RPEB signals. These two sets of the parameters should be identical with each other, if the electrooptical and hydrodynamic properties of PMLG do not change during the field-on and field-off processes. However, the length of the PMLG helix is shorter by about 18% in the presence of an electric field than that in the absence of the field. In order to explain this discrepancy, a new concept of reversible conformational transition under the external electric field is introduced.

Poly(γ-methyl L-glutamate) (PMLG) in solution has been studied by the methods of spectroscopy, circular dichroism, linear dichroism,[1-3] in order to resolve an important optical problem, that is, the strong-coupling exciton theory of the helical polypeptide.[4-6] For this purpose the PMLG molecule has been regarded as a suitable model, because it has no strongly absorbing chromophore in the side chain in the far ultraviolet region and exists as a helix in some organic solvents. In order to clarify the optical properties, the exact solution conformation of PMLG must be confirmed. However, few reports have appeared on this subject.[7,8] Although the electric birefringence (EB) is very useful for such studies,[9-11] only one study was reported, in which the Kerr constant of PMLG was measured in a mixed organic solvent.[7]

In this work, the reversing-pulse electric birefringence (RPEB) of PMLG in hexafluoro-2-propanol (HF2P) has been measured to determine the hydrodynamic and electrooptical properties in detail. Recently, some analytical procedures have been developed for the experimental data of polydisperse systems which were obtained by the rectangular pulse EB[12-16] and electric dichroism[17] methods. These enable one to estimate the weight-average molecular length and the breadth of the distribution from the decay signals. As compared with those methods, the RPEB method has a special feature that the parameters, which characterize the molecular weight distribution, can be determined independently from the two portions of a transient signal; one from the field-free decay and the other from the field-on reverse portion.[18,19] Therefore, the two sets of the molecular parameters obtained respectively in the presence and the absence of an external electric field may be compared. The results indicate that the transient processes in these two portions differ from each other.

The purposes of this work are (1) to evaluate quantitatively the discrepancy between the reverse and the decay processes involved in the RPEB signals of PMLG in HF2P by taking into account the molecular length distribution, (2) to clarify the electrooptical properties and solution conformation, and (3) to ascertain the effect of the applied electric field. The results are discussed by assuming some possible causes, such as molecular association, flexibility, partial destruction of helix, and electric field-induced conformational transition. By simulating the rise, reverse, and decay processes of the RPEB signal, a possible conformational change under the electric field is proposed on the basis of the change of the molecular length of the PMLG helix.

Experimental

Materials and Viscometric Characterization. Poly(γ-methyl L-glutamate), (PMLG), was purchased from Pilot Chemicals, Inc. (Watertown, Mass., USA). It was prepared by polymerizing the corresponding *N*-carboxyanhydride with sodium methoxide in dioxane. The specific viscosity, η_{sp}/c, [c=0.2% in dichloroacetic acid (DCA)] was 3.40, as supplied by the manufacturer. This sample was dissolved in chloroform and the solution was filtered to remove insoluble lumps. The PMLG sample in the clear solution was fractionated into five fractions with ethanol as precipitant by the successive precipitation method.[11] The third fraction was used in the present work. 1,1,1,3,3,3-Hexafluoro-2-propanol (HF2P) for spectroscopy (Merck) was used without further purification. Reagent-grade DCA (Tokyo Kasei Kogyo Co.) was shaken with P_2O_5 and then kept overnight in the dark. The supernatant was distilled under reduced pressure at 6 mmHg (1 mmHg=133.3 Pa) in a nitrogen gas atmosphere.[20] PMLG was dissolved in HF2P and in DCA after drying under reduced pressure at 78.3 °C for 10 h. The viscosity of all samples was measured in a Ubbelohde-type dilution viscometer at 25 °C. The intrinsic viscosity of PMLG in DCA, $[\eta]_{DCA}$, was 267 cm³/g in the concentration range 1.0—11.0 mM (1 mM=10^{-3} mol dm^{-3}). The concentration of PMLG was expressed in terms of monomer units throughout this work. From the value of $[\eta]_{DCA}$, the weight-average molecular weight (M_w) was estimated to be 13.5×10^4 (the degree of polymerization, DP_w, is 943) by using the relationship between $[\eta]_{DCA}$ and M_w which was obtained by Okamoto and Sakamoto.[7] The intrinsic viscosity of PMLG in HF2P, $[\eta]_{HF2P}$, was found to be 931 cm³/g in the concentration range 1.7—10.6 mM). The viscosity of HF2P was also obtained to be 1.595 cP (1 cP=10^{-3} Pa s).

RPEB Measurements. All RPEB signals were measured at 25 °C and at 535 nm on an apparatus which was designed

and constructed in this laboratory.[18,21] The data acquisition and processing were achieved with a system consisting of a two channel transient wave memory (Riken Denshi Model TCH-4000(s), whose maximum sampling time is 50 ns/word, 8 bit, 4 kw) and of a microcomputer (Oki Denki IF-800 Model 10).[22] The signals were accumulated in arbitrary numbers, averaged, and then stored on a floppy disk. A quarter-wave plate was inserted in the optical path. The electric birefringence, Δn, was expressed as $\Delta n=\lambda\delta/2\pi d$, where δ is the phase retardation, λ is the wavelength *in vacuo*, and d is the optical path length of a Kerr cell, which was made of Kel-F.[23] The electrode gaps are 0.207 cm (d=1.0 cm) and 0.33 cm (d=2.0 cm), respectively. The Kerr constant of HF2P, B_{HF2P}, was found to be positive and 5.6×10^{-13} cm V^{-2}. This value is very small compared with the Kerr constant of PMLG solution, but cannot be ignored for a dilute PMLG solution ($c\leq0.49$ mM); hence, the phase retardation, δ_{HF2P} ($=2\pi dBE^2$), was subtracted from the δ values observed for dilute solutions.

Analysis of Data. For a polydisperse polymer solution, in which rigid rodlike solutes show a continuous distribution of molecular weights, *i. e.*, lengths, the steady-state electric birefringence at an arbitrary electric field strength E is expressed with the weight-average orientation function, $\langle\Phi\rangle_w$, as[15,24]

$$\Delta n(\infty)=\frac{2\pi\bar{C}_v}{n}(g_3-g_1)\langle\Phi(\beta(l),\gamma(l))\rangle_w, \quad (1)$$

where n is the refractive index of the solution, $\bar{C}_v$ is the volume fraction of the solute, and (g_3-g_1) is the optical anisotropy factor. $\beta(l)=\mu(l)E/kT$ and $\gamma(l)=\Delta\alpha(l)E^2/kT$, where $\mu(l)$ is the permanent dipole moment and $\Delta\alpha(l)$ is the polarizability anisotropy of the molecule with length l.

In the low electric field region where the Kerr law holds, the reverse portion of a normalized RPEB signal is expressed as[18,25]

$$\frac{\Delta n(t)}{\Delta n(\infty)}=\frac{\int_a^b\Delta n(\infty,l)\left\{1-\frac{3\beta(l)^2}{\beta(l)^2+2\gamma(l)}(e^{-2\theta_{11}(l)t}-e^{-6\theta_{11}(l)t})\right\}dl}{\int_a^b\Delta n(\infty,l)dl}, \quad (2)$$

where θ_{11} is the rotary diffusion coefficient of the cylindrical molecule with a diameter of $2b$. In this work, θ_{11} is calculated by using Broersma's equation.[26] $\Delta n(\infty,l)=(2\pi\bar{C}_v/15n)\times(g_3-g_1)\,\phi(l)\,[\beta(l)^2+2\gamma(l)]$, where $\phi(l)$ is the fraction of solute molecules with length l. $\phi(l)$ is proportional to $lf_n(l)$, where $f_n(l)$ is the probability density function, which is defined on the basis of the number of solute molecules.[13,15] The length distribution of PMLG molecules in a soluion is assumed to be logarithmic-normal (the Lansing-Kraemer distribution).[27] Then, $f_n(l)$ was given by[28]

$$f_n(l)=\frac{1}{\omega l\sqrt{\pi}}\exp\left[-\frac{1}{\omega^2}\left(\ln\frac{l}{l_L}\right)^2\right], \quad (3)$$

where ω and l_L are parameters with which the weight-average molecular length, l_w, may be defined as $l_w=l_L(l_w/l_n)^{3/2}$ and the degree of polydispersity, expressed in terms of the ratio of weight- to number-average lengths, l_w/l_n, as $l_w/l_n=\exp(\omega^2/2)$. Similarly, the rise portion of the same RPEB signal is given as[29]

$$\frac{\Delta n(t)}{\Delta n(\infty)}=1-\frac{\int_a^b\Delta n(\infty,l)\left\{\frac{3\beta(l)^2e^{-2\theta_{11}(l)t}-[\beta(l)^2-4\gamma(l)]e^{-6\theta_{11}(l)t}}{2[\beta(l)^2+2\gamma(l)]}\right\}dl}{\int_a^b\Delta n(\infty,l)dl}. \quad (4)$$

The decay portion is written as

$$\frac{\Delta n(t)}{\Delta n(0)}=\frac{\int_a^b\Delta n(0,l)e^{-6\theta_{11}(l)t}dl}{\int_a^b\Delta n(0,l)dl}, \quad (5)$$

where $\Delta n(0,l)\equiv\Delta n(\infty,l)$. In all calculations, the upper and lower integral limits a and b were set as 50 and 6450 Å instead of (0, ∞).

The intrinsic viscosity for thin rods can also be calculated by taking into account the polydispersity of molecular lengths. By using Simha's equation,[30] it can be expressed as follows:

$$\frac{\langle[\eta]\rangle}{\bar{v}}=\frac{\int_a^b lf_n(l)\left\{\left(\frac{l}{2b}\right)^2\left[\frac{1}{15(\ln l-\ln b-1.8)}+\frac{1}{5(\ln l-\ln b-0.8)}\right]+\frac{14}{15}\right\}dl}{\int_a^b lf_n(l)dl}, \quad (6)$$

where $\bar{v}$ is the average partial specific volume of solutes and $\langle[\eta]\rangle$ is the weight-average intrinsic viscosity.[29,31] Once the $f_n(l)$ is determined from Eq. 3 with the parameters l_w and l_w/l_n which are obtained from the reverse-transient analysis by assuming an appropriate value of b, $\langle[\eta]\rangle$ can be calculated from Eq. 6. By comparing the calculated $\langle[\eta]\rangle$ with the experimentally obtained $[\eta]$, the selection can be made for the most probable value of b that reproduces both the observed $[\eta]$ and the reverse-transient signal from several likely values of b by an iteration procedure.[29]

Results and Discussion

Steady-state Birefringence of PMLG. Figure 1 shows a typical RPEB signal of PMLG in HF2P with an applied pulse field. In this case, twenty signals were accumulated and then averaged to improve the signal-to-noise ratio. After an electric pulse is applied, the signal rises, reaches a steady-state, then decays to the baseline after the pulse is terminated. The sign of the signal is positive. Similarly to the previous cases of poly(α-L-glutamic acid), (PGA),[18] and poly(γ-benzyl L-glutamate), (PBLG),[29] the RPEB signal of PMLG

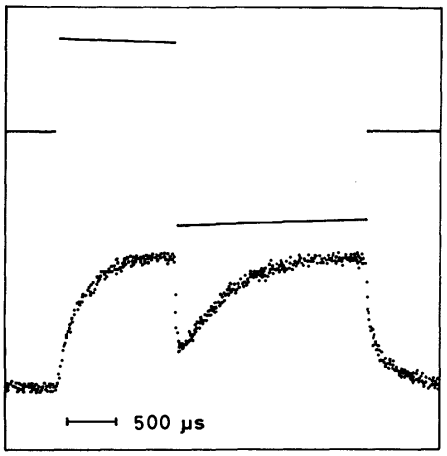

Fig. 1. A typical RPEB signal of PMLG in HF2P and an applied electric pulse field. The signal was digitized with a transient wave memory and averaged twenty-fold in real time with a microcomputer. The sampling time is 1 μs/word. The concentration: 7.82 mM. The field strength: 3.39 kV/cm.

shows a large dip in the reverse portion. This result immediately indicates that the permanent dipole moment contributes to the electric field orientation of PMLG.[25] Figure 2 shows the dependence of the steady-state phase retardation δ on field strength. Values of δ tend to saturate at higher fields, but are proportional to the square of field strength in the low field region ($E<3.5$ kV/cm), that is, the Kerr law holds (insert).

The Kerr constant, B, is defined as

$$B = \frac{1}{\lambda}\left[\frac{\Delta n}{E^2}\right]_{E\to 0} = \frac{1}{2\pi d}\left[\frac{\delta}{E^2}\right]_{E\to 0}. \quad (7)$$

Figure 3 shows plots of δ/E^2 against the square of electric field strength. Values of δ/E^2 are nearly constant below 3.5 kV/cm. By extrapolating these values to zero field strength, the Kerr constant was calculated. The specific Kerr constant, B/c, is given in Table 1, and also shown in Fig. 4(a). The values of B/c are independent of the concentration of PMLG. The intrinsic Kerr constant, $(B/c)_{c\to 0}$, was found to be 6.2×10^{-7} cm^4 g^{-1} V^{-2}. This value is rather small: about one half of the intrinsic Kerr constant obtained for PBLG[19] and about one-third for PGA[18] of almost the same molecular size.

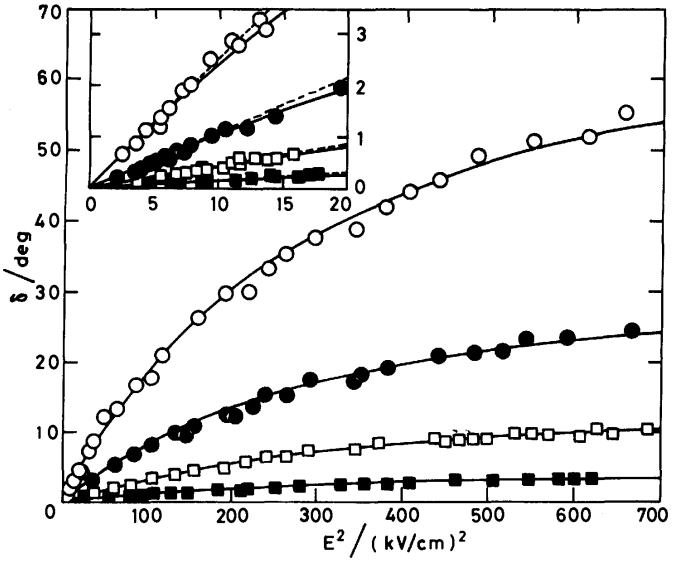

Fig. 2. The field-strength dependence of the steady-state electric birefringence, δ, of PMLG in HF2P. Insert: the low field strength region. The concentrations of PMLG are 7.82 mM (○), 3.52 mM (●), 1.41 mM (□), and 0.49 mM (■). The solid lines represent the theoretical curves with parameters in Table 2. The dotted lines represent the Kerr law.

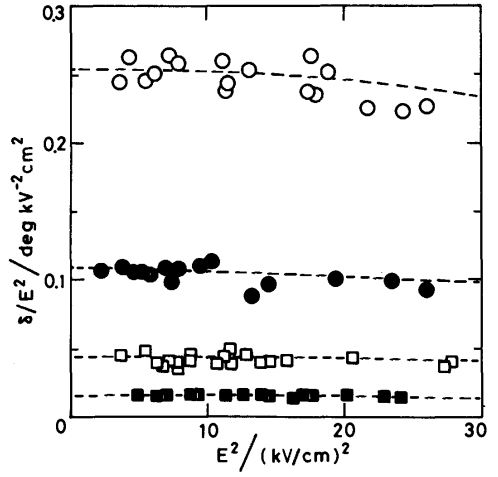

Fig. 3. The phase retardation per square of field strength, δ/E^2, in the low field strength region. Symbols are the same as in Fig. 2.

In order to investigate the aggregation of PMLG helices, values of δ at four electric field strengths were measured in detail over a wide range of concentrations. For example, the values of δ/c were still almost constant at a fifty-fold dilution (0.15 mM), as plotted in Fig. 4(b). Since they would change with molecular association,[32-34] no intermolecular association of PMLG seems to occur below 8 mM. This conclusion is also confirmed in the later section, where the relation between the molecular weight and molecular length is discussed.

Reverse-transient Process of PMLG. The minimum in the reverse portion of an RPEB signal can be specified by t_m, the time required for the signal to reach the minimum after the pulse reversal, and Δ_m, the height from the baseline at t_m. Both t_m and Δ_m are

Table 1. Specific Kerr constant B/c, reverse-transient minimum position, $(t_m)_{E\to 0}$ and $(\Delta_m)_{E\to 0}$, and weight-average relaxation time, $\langle\tau\rangle_w$, of PMLG in HF2P at various concentrations c.

c	B/c	$(t_m)_{E\to 0}$	$(\Delta_m)_{E\to 0}$	$\langle\tau\rangle_w$
mM	10^{-7}cm^{4}g^{-1}V^{-2}	μs		μs

In (b) the symbols are the same as in Fig. 2; moreover, two lower concentrations, 0.3 mM (△), 0.15 mM (▲), are also added.

plotted against the square of field strength in Fig. 5. The limiting values at zero field strength, $(t_m)_{E\to 0}$ and $(\Delta_m)_{E\to 0}$, are given in Table 1. From these values, the reverse portion of the RPEB signal can be analyzed with the aid of Eq. 2 to determine the values of l_w, l_w/l_n, and $(\beta_w)^2/2\gamma_w$. (This procedure was shown in detail in Figs. 7 and 8 in Ref. 18.) The theoretical orientation function $\langle\Phi\rangle_w$ can then be calculated with those parameters [l_w, l_w/l_n, $(\beta_w)^2/2\gamma_w$] which are given in Table 2. By comparing $\langle\Phi\rangle_w$ with experimentally obtained δ values in a wide range of field strengths, on a double logarithmic plot, the values of μ_w, $\Delta\alpha_w$, and the optical anisotropy factor (g_3-g_1) can be obtained separately (the matching procedure).[11,35] These values are also given in Table 2. The best-fitted theoretical curve of δ was calculated by using these values with the aid of Eq. 1, and is shown in Fig. 2 by a solid line at each concentration of PMLG. The curves agree well with experimental points in all cases over the entire field strength region.

By using a weight-average degree of polymerization of 943, the permanent dipole moment per residue was calculated to be 2.2—2.4 D (1 D=3.336×10^{-30} C m). Such values are about half of the known values of the polypeptide main chain residue moment (4.8—5.0 D/res).[36] In fact, previously obtained values are 5.3 D/res for PGA and 3.5—4.0 D/res for PBLG.[18,19] This may be due to the side chain conformation of PMLG, which differs from that of PGA and PBLG, that is, the side chain of PMLG may be oriented so as to cancel the main chain moment more effectively. Wada[36] has discussed some possible conformations of the side chain of polypeptides and the values of dipole moments associated with these conformations. He pointed out that a side chain moment of about 2.5 D/res, at maximum, may direct in opposition to the permanent dipole moment of the main chain. Thus, the small value of the permanent dipole moment of PMLG in HF2P, as revealed in the present work, can be explained by the side chain conformation.

Decay Process of PMLG. The decay portion of a RPEB signal is related to the rotational relaxation time of a solute molecule. From the decay curve, the electric birefringence-average relaxation time, $\langle\tau\rangle_{EB}$, may be obtained by the area method.[37] Figure 6 shows plots of $\langle\tau\rangle_{EB}$ for PMLG solutions at four concentrations against the square of the steady-state field strength applied prior to the decay. A slight dependence of $\langle\tau\rangle_{EB}$ on concentration was observed, probably because of the solute-solute interaction of PMLG molecules. Values of $\langle\tau\rangle_{EB}$ also depend on field strength, indicating that this PMLG sample is polydisperse

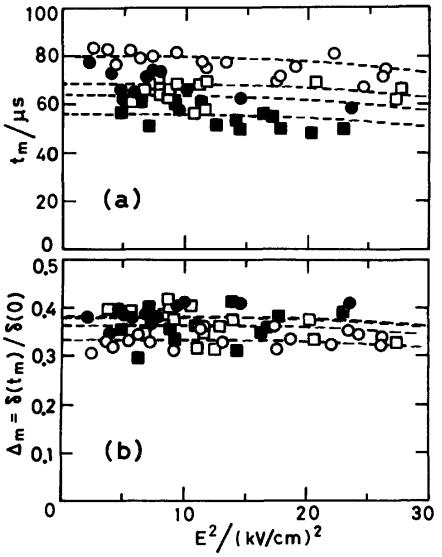

Fig. 5. The field strength dependence of the minimum position in the reverse-transient signal of PMLG in HF2P. (a) The time required for the signal to reach the minimum, t_m, and (b) the normalized phase retardation at t_m, $\Delta_m=\delta(t_m)/\delta(0)$. Symbols are the same as in Fig. 2. The limiting values of $(t_m)_{E\to 0}$ and $(\Delta_m)_{E\to 0}$ are given in Table 1.

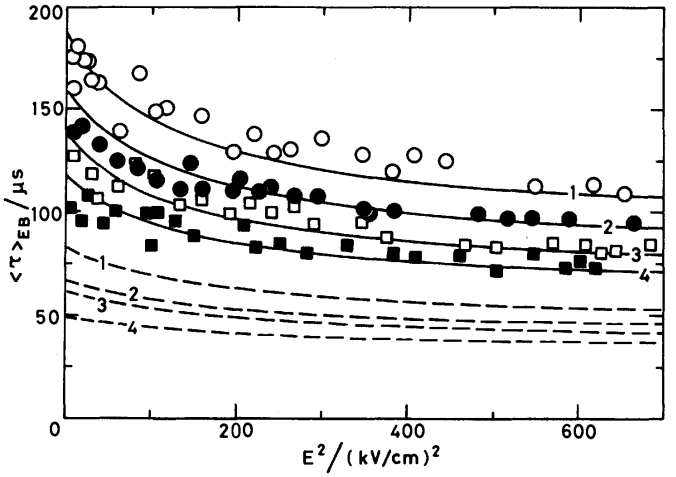

Fig. 6. The electric birefringence-average relaxation time, $\langle\tau\rangle_{EB}$, versus the square of the field strength before the start of decay. Symbols are the same as in Fig. 2. The solid lines were calculated with the decay parameters, while the dashed lines were calculated with the reverse-transient parameters. Numerals indicate the concentrations: (1) 7.82 mM, (2) 3.52 mM, (3) 1.41 mM, and (4) 0.49 mM.

with respect to molecular length.[17]

The field strength dependence of $\langle\tau\rangle_{EB}$ can be expressed by the following equation, which takes into account the molecular length distribution:[17]

$$\langle\tau\rangle_{EB} = \frac{\int_a^b \tau(l)\Phi(\beta(l), \gamma(l))lf_n(l)dl}{\int_a^b \Phi(\beta(l), \gamma(l))lf_n(l)dl}. \quad (8)$$

With the aid of Eq. 8, the parameters (l_w, l_w/l_n) can be obtained from decay signals quite independently without relying on the result of the reverse-transient signals given in the preceding section. At infinitely high fields, Φ approaches unity, and the $\langle\tau\rangle_{EB}$ becomes the weight-average relaxation time $\langle\tau\rangle_w$,[17] which does not depend on the electric parameters $\beta(l)$ and $\gamma(l)$, but only on the parameters (l_w, l_w/l_n). The theoretical relationships between $\langle\tau\rangle_w$ and the parameters (l_w, l_w/l_n) were calculated from Eq. 4 in Ref. 17. The results are shown in Fig. 7, where the dashed lines are experimental values of $\langle\tau\rangle_w$. These were obtained by extrapolating observed values of $\langle\tau\rangle_{EB}$,

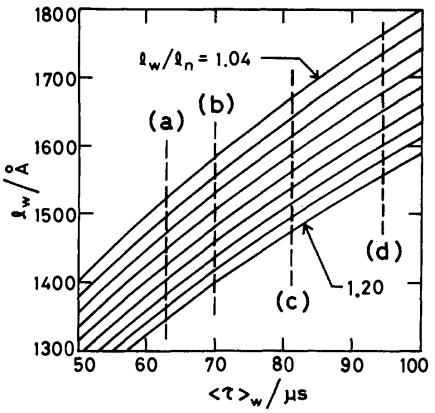

Fig. 7. Theoretical relationship between the weight-average relaxation time, $\langle\tau\rangle_w$, and the weight-average length, l_w, with the degree of polydispersity, l_w/l_n, as parameter. Values of l_w/l_n range between 1.04 and 1.20 at intervals of 0.02. The logarithmic-normal distribution was used. The relaxation time $\tau(l)$ was calculated by using Broersma's equation with a diameter 2b of 10.5 Å. Dashed lines indicate the experimental values of $\langle\tau\rangle_w$, for concentrations of (a) 0.49 mM, (b) 1.41 mM, (c) 3.52 mM, and (d) 7.82 mM.

which were plotted either against E^{-1} or against E^{-2}, to infinitely high field strength.[17] Several sets of paired values (l_w, l_w/l_n) can be obtained from the intersections between the theoretical curves and each dashed line. With each pair (l_w, l_w/l_n) thus evaluated, the theoretical curves of Δn *vs.* E^2 and of $\langle\tau\rangle_{EB}$ *vs.* E^2 can be computed from Eqs. 1 and 8 at various values of [$(\beta_w)^2/2\gamma_w$, β_w] as parameters. By matching these theoretical curves with experimentally observed plots of δ *vs.* E^2 (Fig. 2) and of $\langle\tau\rangle_{EB}$ *vs.* E^2 (Fig. 6), the best set of values can be searched for [l_w, l_w/l_n, $(\beta_w)^2/2\gamma_w$, β_w] by the trial-and-error method (this procedure is referred to as "procedure I"), and then μ_w, $\Delta\alpha_w$, and (g_3-g_1) may be separately evaluated. These values are all given in Table 3. The solid curves in Fig. 6 represent the theoretical $\langle\tau\rangle_{EB}$ *vs.* E^2 curves, which were calculated from Eq. 8. They are all in good agreement with experimental values, thus indicating that the parameters [l_w, l_w/l_n, $(\beta_w)^2/2\gamma_w$, β_w] were evaluated correctly.

Similarly to the above, the $\langle\tau\rangle_{EB}$ *vs.* E^2 curves can also be calculated by using the parameters obtained from the reverse-transient signals (Table 2). These theoretical curves are shown in Fig. 6 by dashed curves, but surprisingly they differ from the observed points of $\langle\tau\rangle_{EB}$ far beyond experimental errors. This unexpected result indicates that the reverse process for an RPEB signal is different from the decay. Some possible explanations will be considered in the following sections.

Simulation of RPEB Signal. With the two sets of parameters [l_w, l_w/l_n, $(\beta_w)^2/2\gamma_w$], one from the reverse-transient process and the other from the decay process, the theoretical curves of the rise, reverse, and decay portions of RPEB signals of PMLG at various concentrations were calculated from Eqs. 2, 4, and 5, in order to justify the correctness of the estimated parameters. The RPEB signal at 3.52 mM was calculated as an example and is shown in Fig. 8. The rise (Fig. 8(a)) and reverse (Fig. 8(b)) portions of the observed data (dots) under an applied external field are well reproduced by the curve (solid line) calculated with the reverse-transient parameters [l_w=1260 Å, l_w/l_n=1.10, $(\beta_w)^2/2\gamma_w$=2.0], but definitely deviate from the curve (dash-dot line) calculated with the decay parameters [l_w=1530 Å, l_w/l_n=1.15, $(\beta_w)^2/2\gamma_w$=3.0]. On the other hand, the observed decay data (Fig. 8(c)) transfer, upon removal of the pulse field, from the theoretical curve with the reverse-transient parameters

Table 3. Electrooptical and hydrodynamic properties of PMLG in HF2P, obtained from the analysis of the decay portions of RPEB signals

a) The lengths l_w in the upper row were obtained by "procedure I" and those in the lower row by "procedure II". b) Values in parentheses are obtained from the reverse-transient portions (Table 2).

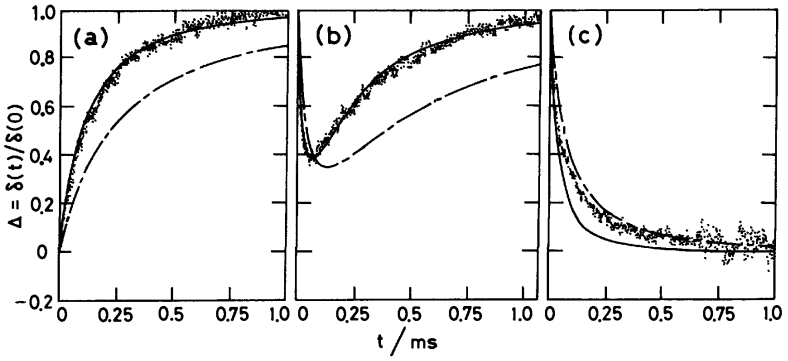

Fig. 8. Comparison of the rise (a), reverse (b), and decay (c) portions of a normalized RPEB signal of PMLG at 3.52 mM with theoretical curves. The observed data were average of 150 signals taken below 3.5 kV/cm in the Kerr law region. The solid curves represent the simulated RPEB signal which was calculated with the reverse-transient parameters (l_w=1260 Å, l_w/l_n=1.10, $(\beta_w)^2/2\gamma_w$=2.0), while the dash-dot-dashed curves represent the signal calculated with the decay parameters (l_w=1530 Å, l_w/l_n=1.15, $(\beta_w)^2/2\gamma_w$=3.0). The logarithmic-normal distribution (2b=10.5 Å) was assumed.

to the one with the decay parameters in the time course between 20—200 μs. The same results have been obtained for many RPEB signals at other concentrations and field strengths. Any RPEB signal of PMLG in HF2P must therefore contain two processes with different sets of molecular parameters during the application and removal of an external electric field.

Since the steady-state and the reverse-transient are observed under the presence of an electric field, a combination of these data should give consistent results. On the other hand, the decay parameters obtained with the steady-state data by "procedure I" should only be apparent. It is now clear, therefore, that the decay portion of the RPEB signal must be analyzed without recourse to the steady-state value. By assuming that the PMLG molecules change identically regardless of their lengths under an electric field, the degree of polydispersity l_w/l_n may be considered to be constant in the presence and absence of the field. Then, with the value of l_w/l_n in Table 2, which was obtained from the reverse portion, the weight-average molecular length l_w can be determined from $<\tau>_w$ (this is referred to as "procedure II"), as was shown in Fig. 7. The values of l_w thus obtained are given in the second row at each concentration in Table 3. The difference in l_w estimated from two procedures (I and II) is no more than 60 Å or 4%, being comparable with experimental errors. Therefore, the difference in the molecular lengths obtained from the reverse (Table 2) and the decay (Table 3) should be attributed to the direct effect of an applied electric field and not to the analytical procedures.

The reverse-transient portion is a process under the influence of an applied field (Fig. 8(b)): an observed value of t_m at the minimum position is 69 μs, while the one calculated with the reverse-transient parameters is also 69 μs, clearly differing from the one calculated with the decay parameters, 136 μs. It has been shown that t_m does not depend on the electric properties, such as $(\beta_w)^2/2\gamma_w$ and μ_w, but depends only on l_w and l_w/l_n, even if a sample is polydisperse.[18] Therefore, the discrepancy resulting from the application and removal of a pulse field can clearly be attributed to the difference in molecular lengths of PMLG helices. Four possible explanations for this discrepancy may be considered. (1) The PMLG helices are flexible enough to be bent under an electric field. (2) They associate to form molecular aggregates in HF2P which transform from one type to another, when the electric pulse is applied. (3) In HF2P they are partly broken to have, *e.g.*, a coiled tail by the electric field. (4) They are subjected to field-induced conformational transition.

In the case of (1), the slightly bending PMLG helices in solution may be stretched under an electric field. The RPEB signal would rise fast at the initial stage, then slow down due to a rotational relaxation of straightened longer molecules. This idea is not supported by the experimental signals in the rise portion. Conversely, the originally straight PMLG helices may be bent momentarily due to an abrupt rotation caused by the applied field. Here, they must return to the original form, when the RPEB signal reaches the steady-state. They should then behave like a straight rod in the subsequent decay process, but the actual decay curve contains a transfer (Fig. 8(c)). Moreover, we have studied the RPEB of a PBLG sample with an average molecular length of 2450 Å.[19,29] This PBLG helix may be fairly flexible, considering the persistence length of PBLG (about 1200 Å);[38,39] yet the $<\tau>_{EB}$ *vs.* E^2 curve was well reproduced by the parameters which were obtained from the reverse portion. The difference between reverse-transient and decay processes can not be attributed to the flexibility of PMLG molecules.

The second case (2) may be ruled out immediately because intermolecular association does not occur in this solution, as shown in Fig. 4. This notion is additionally supported by the degree of polymerization obtained from the intrinsic viscosity in DCA (DP=943). If the conformation of PMLG is the α-helix,[40,41] the length should be about 1400 Å (1.5 Å×943), which agrees well with the value of l_w, as obtained from the analysis of the decay portion of RPEB signals (Table 3).

Therefore, the PMLG helices undoubtedly remain molecularly dispersed at low concentration. The third case (3) may be excluded on the basis that, if a PMLG helix is partially broken by the electric field, the helix should be steadily unwound with an increase in field strengths. In such a case, the field strength dependence of the steady-state value could no longer be simulated by a single set of parameters [l_w, l_w/l_n, $(\beta_w)^2/2\gamma_w$, β_w] in Table 2, which would change continuously and considerably by the destruction of helices with increasing field strength. Figure 2 shows clearly that this is contrary to the experimental results. The last case (4) remains as the most probable and more precise discussions will be given in the following sections.

Intrinsic Viscosity and Molecular Conformation. Once taken under the same conditions, both the intrinsic viscosity and the RPEB data in HF2P may be combined to obtain the hydrodynamical diameter of a PMLG molecule in the following way.[29] Since the intrinsic viscosity was determined in the absence of electric field, the parameters (l_w, l_w/l_n) evaluated from the decay signal must be used. These values were first calculated for three diameters (10, 10.5, and 11 Å) by "procedure II"; hence, three sets of (l_w, l_w/l_n). Three intrinsic viscosity values, $<[\eta]>$, at each concentration were calculated with the aid of Eq. 6 for the three parameter sets. The results are shown with open symbols in Fig. 9(a). A value of 0.763 was used for the partial specific volume of PMLG.[7,8] By comparing the values of $<[\eta]>$ extrapolated to zero concentration with the observed value of $[\eta]_{HF2P}$, a diameter of 10.5 Å was selected for 2*b*. For comparison, the values of $<[\eta]>$ were also calculated by using the parameters (l_w, l_w/l_n) evaluated from the decay signal by "procedure I," and are plotted with closed symbols in Fig. 9(a). The result clearly indicates that the diameter is not affected by two analytical methods, and that the value of 10.5 Å is adequate for the diameter of a PMLG helix. It must be stated that, for all analyses in the preceding sections, the value of 10.5 Å was used as the best hydrodynamic diameter of PMLG.

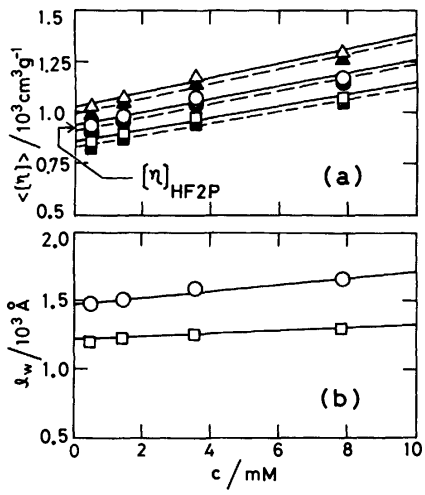

Fig. 9. (a) The dependence of the calculated intrinsic viscosities, $<[\eta]>$, and (b) the dependence of the length l_w on concentration of PMLG in HF2P. The diameters are 2b=10 Å (△, ▲), 10.5 Å (○, ●), and 11 Å (□, ■). The theoretical values were calculated from the parameters of "procedure I" (open symbols and solid lines), and of "procedure II" (closed symbols and dashed lines). Arrow indicates the observed $[\eta]_{HF2P}$. The values of l_w (○) were obtained from the decay portion (lower rows in Table 3) and (□) from the reverse portion (Table 2).

Molecular Length of PMLG. Figure 9(b) shows two plots of the weight-average molecular length l_w against concentration; one from the reverse-transient (squares) and the other from the decay (circles). Being dependent on concentration, probably due to solute-solute interaction, values of l_w should be extrapolated to zero concentration, in order to obtain the molecular length free from such interaction. The limiting values are: $(l_w)_{R,c\to0}$=1210 Å from the reverse-transient process and $(l_w)_{D,c\to0}$=1470 Å from the decay process. Thus, the length of PMLG helix is shorter by about 18% under an electric field than that in the absence of the field. From the degree of polymerization of this PMLG sample, the length per residue is determined to be 1.56 Å/res from $(l_w)_{D,c\to0}$ and is 1.29 Å/res from $(l_w)_{R,c\to0}$. It should be pointed out that these values nearly correspond to the α-helix (1.5 Å/res)[40,41] and the ω-helix (1.3 Å/res),[42-44] respectively.

A Possible Model of Conformational Transition. Finally, a plausible mechanism of the conformational transition induced by the electric field will be discussed on the basis of reversible helix-to-helix alteration. A helical segment is illustrated on the left-hand side in Fig. 10, where an α-helix structure is used as a model. A peptide residue of the main chain is inclined at 64.5° relative to the helix axis, and the length per residue, $h_D \equiv (l_w)_{D,c\to0}/DP_w$, is taken to be 1.56 Å. The plane of the peptide unit is assumed to be parallel to the axis. Although the direction of the permanent dipole moment has not been fully established as yet, it is generally assumed to make an angle of 56.2° relative to the

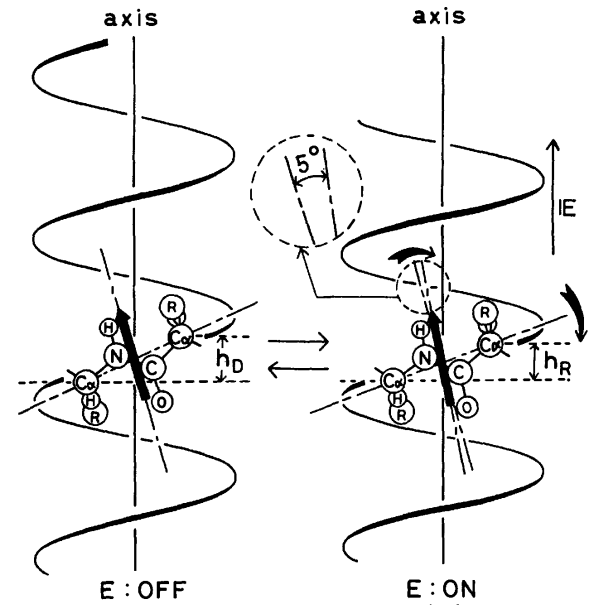

Fig. 10. A possible mechanism for electric field-induced conformational transition of PMLG in HF2P. (a) Electric field is off, and (b) electric field is on. See text for details.

C–N bond.[36,45] A probable direction is indicated with an arrow.

When an electric pulse field is applied, the dipole moment in each peptide group would be oriented toward the helix axis because of the interaction between the field strength and the dipole moment. As a result, the axial translation per residue may be shortened, as shown on the right-hand side of Fig. 10. The PMLG helix would be distorted in such a way that a shorter helix appears. In order to lower the axial translation by about 18% ($h_R \equiv (l_w)_{R,c\to 0}/DP_w = 1.29$ Å), the direction of the permanent dipole moment would have to be rotated clockwise around the normal to the helix axis by no more than 5 degrees, as indicated on the right-hand side of Fig. 10. It is reasonable to believe that this conformational transition occurs in the low field strength region (the lowest field strength in this study is about 1 kV/cm), for the change of the moment direction could possibly be less than 5° being associated with no drastic alteration of the helix backbone or hydrogen-bond breaking. The change in axial translation per residue from 1.56 Å to 1.29 Å is in the same order as that of the α- to ω-helices. Both helices belong to the same intramolecular hydrogen-bond-forming class and their stability is energetically comparable.[43,46] The PMLG helix in HF2P probably transforms from an α-helix to an ω-helix in the presence of an electric field. Matsumoto *et al.*[47] measured the electric birefringence of poly(α-L-glutamic acid) in a dimethyl sulfoxide–methanol mixtures. They discussed the possibility that the PGA helix (presumably the α-helix) is induced to be the ω-helix by solvent composition.

In the present work, the electric field-induced conformational transition of PMLG in HF2P was discovered in the course of an extensive analysis of RPEB signals. The usefulness of the RPEB method is evident in investigating the molecular properties of polypeptides in solutions subjected to electric fields.

Conclusion

By analyzing the reverse and decay portions of the RPEB signal of PMLG independently, two sets of the same molecular parameters (l_w, l_w/l_n, μ_w, $\Delta\alpha_w$) were obtained. The length l_w from the reverse portion differs from the decay portion, the former being shorter about 18% than the latter. The dipole moment per residue of PMLG (2.2—2.4D) is only about one half that of PGA or PBLG.[18,19] The side chain moment of PMLG must considerably cancel the contribution from the main chain moment. A plausible mechanism was proposed to explain the reversible shortening of the helical length upon application of an external electric field. With due considerations of the parameters evaluated in this work, it was concluded that the PMLG molecule probably forms an α-helix in the absence of an electric field, but transforms to another helix, possibly an ω-helix, by the electric field.

The author wishes to thank Associate Professor Kiwamu Yamaoka for his continuous support and encouragement in the course of this study. The author also wishes to thank Mr. Shinobu Yamamoto for his skilled assistance in computer programming.

Stopped-flow Kinetic Studies of Cu^{2+} Ion Binding to Bovine Serum Albumin

Naohisa KURE, Hitoshi NAKATSUJI, Takayuki SANO, and Tatsuya YASUNAGA*
Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received March 17, 1984)

The interaction of Cu^{2+} ion with bovine serum albumin (BSA) was studied statically by equilibrium dialysis and ultraviolet spectrophotometric titration techniques, and kinetically by the stopped-flow method with transmittance detection at 255 nm. The static measurements showed the presence of one primary binding site and a number of weaker binding sites at pH 5.2. Stopped-flow measurements were undertaken in the pH region of 4—6.4 where a single reaction process was observed on the order of several seconds following the rapid absorbance change within the dead-time of the apparatus. This single reaction process was attributed to reaction of Cu^{2+} ion with the primary BSA site. The analyses of pH and concentration dependences of both the relaxation time and absorbance change confirmed the presence of two types of bound Cu^{2+} species to the primary binding site. One type formed during the dead-time of the apparatus is postulated as a square-planar complex formed between Cu^{2+} and the three N-terminal peptides of BSA. This reaction occurs with Cu^{2+} being exchanged for hydrogen ions on the N-terminal peptides. The second type of bound Cu^{2+}, observed by stopped-flow method is thought to result from a bimolecular binding of Cu^{2+} ion a deprotonated imidazolyl group in the third position of the histidyl residue; the value of the molar extinction coefficient for this species, determined kinetically, suggests a further coordination of the β-carboxyl group to the bound Cu^{2+}.

Various studies on the binding of Cu^{2+} ions to bovine serum albumin (BSA),[1-3] the 1—24 N-terminal peptide unit of BSA,[4-6] and the 1—4 N-terminal peptide unit of BSA[5] have confirmed the presence of at least two types of bound species in neutral and low pH regions. A chelated complex, predominant above pH 6, between Cu^{2+} ion and the three N-terminal peptides (Asp-Thr-His-) of BSA shows a square-planar configuration made by coordinations by α-amino, imidazolyl, and two peptide nitrogen atoms to the central Cu^{2+} ion.[3,4] Another type of species has been identified in the low pH range below 5.5. Iyer *et al.*[7] have reported the presence of two types of complexes between Cu^{2+} and N-terminal site of a synthetic peptide of human serum albumin (HSA) and have pointed out the necessity of kinetic studies for elucidation of the mechanism in forming of these complexes.

In the present study, the binding nature of Cu^{2+} ion to BSA was investigated both statically by equilibrium dialysis and ultraviolet (UV) spectrophotometric titration techniques and kinetically by stopped-flow measurements in the pH range where the two types of bound Cu^{2+} species coexist. A plausible mechanism of Cu^{2+} binding to the peptide sites is proposed; the molecular structure of the complexes is also discussed.

Experimental

Materials. Bovine serum albumin (prepared from Fraction V and essentially fatty acid-free) was purchased from Sigma Chem. Co. and used without further purification. The concentration of BSA was determined spectrophotometrically.[8] Solutions of Cu^{2+} ion were made by direct weighing of $CuSO_4$ anhydrous. The pH values of the solutions were adjusted by H_2SO_4 and/or KOH. No pH buffers were added. All measurements were made in 1 mM† solutions of K_2SO_4. Analytical grade reagents were used throughout.

Equilibrium Dialysis. The extent of binding was measured by the equilibrium dialysis technique at pH 5.2 with a dialysis cell (Sanko Plastics Co. type 5044-05) having ten separate chambers. After 72 to 84 hours of dialysis at 25±1 °C, concentrations of Cu^{2+} in the dialysed solutions were determined with a Perkin-Elmer Model 5000 atomic absorption spectrophotometer. The detection limit of this method for Cu^{2+} concentration was 1.5×10^{-7} M. The pH values of the dialysed solutions were 5.2±0.08.

Spectrophotometry. The difference spectra of BSA solutions in the presence and absence of Cu^{2+} ions were measured in the ultraviolet region using a Union Giken SM 401 spectrophotometer at 25±0.2 °C.

Stopped-flow Experiments. The kinetic measurements were carried out using a Union Giken Stopped-flow spectrophotometer RA 401. The dead-time of this apparatus is 5 ms. For the case of very small amplitudes, an accurate relaxation time was obtained by signal averaging 2—10 measurements using the averaging capabilities of the wave memory apparatus. All kinetic measurements were made at 25±0.2 °C.

Results and Discussion

Binding Parameters. Klotz and Curne[9] reported that at most there are sixteen sites on BSA for binding Cu^{2+} ions at pH 4.83, but data obtained in their study were limited to high binding conditions, *i.e.*, at a binding ratio, r, (moles of bound Cu^{2+}/moles of protein) >1.5. Naik *et al.*[10] determined the binding isotherm of Cu^{2+} with BSA at low binding conditions with the Cu^{2+} titration technique using a Cu^{2+} ion-specific electrode. However, in our investigations using the Cu^{2+} ion-specific electrode, we found that BSA ions significantly lower the voltage of the Cu^{2+} ion-specific electrode which results in serious errors in the binding data. Consequently, the binding data were obtained at low binding conditions using an equilibrium dialysis technique, measuring Cu^{2+} in dialysed solutions with atomic absorption.

Figure 1 illustrates a Scatchard plot of the binding of Cu^{2+} ion to BSA at pH 5.2±0.08. The shape of the isotherm reveals the existence of at least two classes of binding sites. The analysis of this plot, using the maximum number of Cu^{2+} sites per BSA molecule of 16,[9] yields the binding parameters: n_p=0.8—1.3, K_p=(5.5—8.8)$\times10^5$ M^{-1}, n_s=14.7—15.2, K_s=(5.4—5.8)×

† 1 M=1 mol dm^{-3}.

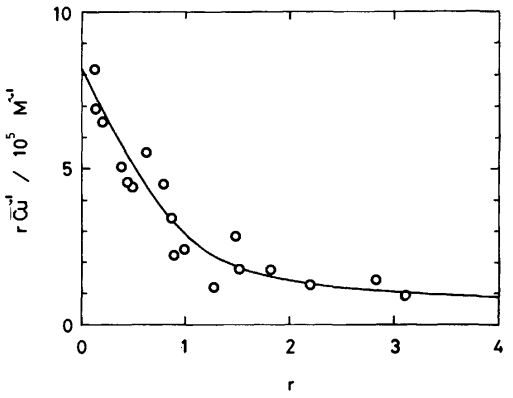

Fig. 1. Scatchard plot of the binding of Cu^{2+} ion to BSA in 1 mM K_2SO_4 solution at pH 5.2±0.08 and 25±1 °C. The circle represents the observed data, and the solid line shows the theoretical curve calculated using n_p=1, K_p=7.2×10^5 M^{-1}, n_s=15 and K_s= 5.6×10^3 M^{-1}.

10^3 M^{-1} where the n and K are the number of binding sites and the binding constants, respectively; the subscripts p and s refer to the primary and secondary binding sites, respectively. As can be seen in Fig. 1, the observed data fall on the theoretical curve calculated using these values. These results are consistent with the assignment of one primary binding site and fifteen secondary ones to the BSA molecule under the present pH conditions.

Ultraviolet Spectrophotometric Titration. The Cu^{2+}–BSA complex exhibits a strong ultraviolet (UV) absorption maximum around 250 mn in addition to two maxima at 525 nm and 650—700 nm in the visible region.[3,4] The absorption band around 250 nm, characteristic of Cu^{2+} complexes with amino acids[11,12] and peptides,[12–17] has been assigned to a charge transfer transition from amino, carboxylato, imidazolyl groups and ionized peptide nitrogen to Cu^{2+} ions. The absorbance increased linearly for this charge transfer absorption band up to a metal to protein ratio (M/P) of about unity at pH 5.2±0.02 as shown in Fig. 2(a). Since the absorbance of free Cu^{2+} ion is negligibly small at the present wavelength, the observed change in absorbance (ΔA^{255}) may be written as

$$\Delta A^{255}/\text{cm} = (\varepsilon^{255}_{c,app} - \varepsilon^{255}_{BSA}) \cdot \bar{C}, \quad (1)$$

where and ε^{255}_{BSA}, $\varepsilon^{255}_{c,app}$ and $\bar{C}$ denote the molar extinction coefficient of BSA, the apparent molar extinction coefficient of Cu^{2+}-BSA complex and its equilibrium concentration, respectively; the superscript 255 refers to the wavelength. The variation of $\varepsilon^{255}_{c,app}-\varepsilon^{255}_{BSA}$, which is given by calculating $\Delta A^{255}/\bar{C}$ using the binding parameters obtained above, was represented as a function of binding ratio r in Fig. 2 (b). Reasonable constancy of $\varepsilon^{255}_{c,app}-\varepsilon^{255}_{BSA}$ up to an r value of unity further confirms the presence of one primary binding site. The molar extinction coefficient $\varepsilon^{255}_{c,app}$ of the complex formed on the primary site was estimated to be 24500 M^{-1} cm^{-1} by using a value of 21400 M^{-1} cm^{-1} for ε^{255}_{BSA}.

Experimental Results in Stopped-flow Measurements. In order to elucidate the dynamic mechanism of the complex formation on the primary site, stopped-flow measurements were undertaken at a fixed and small

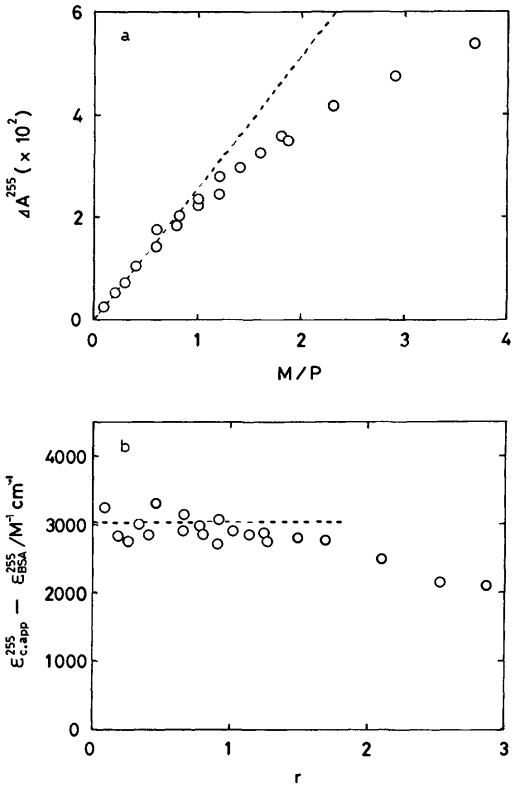

Fig. 2. (a) M/P dependence of the absorbance change (per 1 cm path-length) at 255 nm measured by titrating BSA (1.0×10^{-5} M) solutions with various amounts of Cu^{2+} ions, at pH 5.2±0.02 and 25± 0.2 °C. (b) A plot of $\varepsilon^{255}_{c,app}-\varepsilon^{255}_{BSA}$ *vs.* binding ratio r.

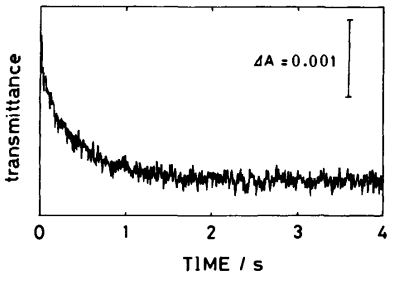

Fig. 3. A typical oscillographic trace of the stopped-flow experiment of the reaction between Cu^{2+} ion (2.0×10^{-6} M) and BSA (1.0×10^{-5} M) monitored by the change in the transmittance intensity (increasing upward) at 255 nm, pH 4.6 and 25±0.2 °C in 1 mM K_2SO_4 solution. The magnitude of the absorbance change is indicated by the bar in the upper right-hand corner.

M/P ratio of 0.2. The reaction between Cu^{2+} ion and BSA was followed by monitoring the change in transmittance at 255 nm. As shown in Fig. 3, a definite decrease in transmittance intensity was observed within several seconds at every pH value and concentration examined. Other reactions were not discernible within the time resolution of the apparatus (5 ms—100 s). The spectra of the solutions after mixing were quite stable over a period of two days.

The relaxation time of the reaction was determined by the semilogarithmic plot of the reaction curve near the equilibrium point. The variation of the reciprocal relaxation time (τ^{-1}) with pH, and with concentration

at pH 4.6 and 5.2 are represented in Figs. 4, 5, and 6, respectively.

The absorbance change (ΔA_{SF}^{255}) estimated from the reaction trace observed by the stopped-flow measurements, the total absorbance change (ΔA_{total}^{255}) due to reaction measured statically with a spectrophotometer at 255 nm, and the difference between ΔA_{total}^{255} and ΔA_{SF}^{255}, which corresponds to the absorbance change (ΔA_{DT}^{255}) within the dead-time of the stopped-flow apparatus are represented in Fig. 7 as a function of pH.

pH Dependence of Absorbance Changes. As can be seen in Fig. 7, the changes in the magnitude of ΔA_{SF}^{255} and ΔA_{total}^{255} as a function of pH reveal the presence of at least one rapid reaction process within the dead-time of the apparatus in addition to the one actually observed (see, *e.g.*, the change in ΔA_{DT}^{255}). The pH dependence of ΔA_{DT}^{255} implies that this rapid reaction involves the exchange of Cu^{2+} ions with hydrogen ions bound to BSA and that the complex formed from this process predominates above pH 6. These observed properties are characteristic of chelation complex formation between Cu^{2+} and the N-terminal three peptides (Asp-Thr-His-) of BSA, as has been reported in various studies on the binding of Cu^{2+} ions to BSA[3,4] and the model peptides of BSA.[4-6] Accordingly, the absorbance change within the dead-time is attributed to the formation of the chelation complex. On the other hand, ΔA_{SF}^{255} shows a quite different pH dependence, exhibiting a maximum around pH 4.8. This reveals that the reaction observed by the stopped-flow measurements results in a different kind of bound species from the chelated one. The bound species may correspond to the type of complex observed at low pH region in visible spectroscopic studies by others.[3,4]

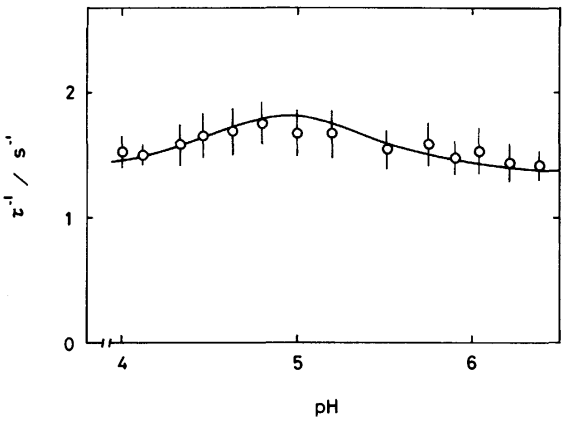

Fig. 4. The pH dependence of τ^{-1} at the fixed concentrations of Cu^{2+} ion (2.0×10^{-6} M) and BSA (1.0×10^{-5} M).

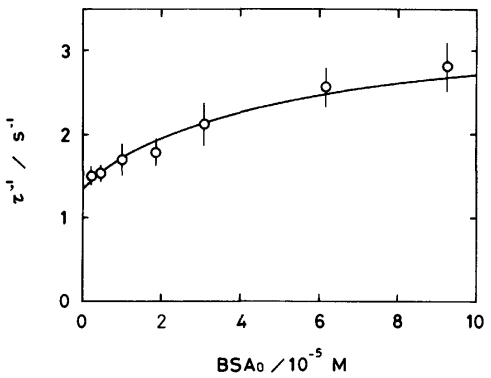

Fig. 5. The variation of τ^{-1} with the total concentration of BSA (BSA_0) at a fixed M/P of 0.2 and pH 4.6.

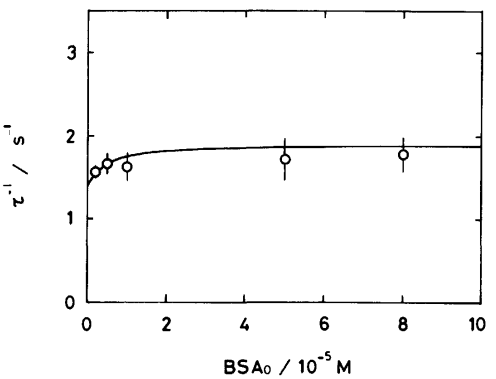

Fig. 6. The variation of τ^{-1} with the total concentration of BSA (BSA_0) at a fixed M/P of 0.2 and pH 5.2.

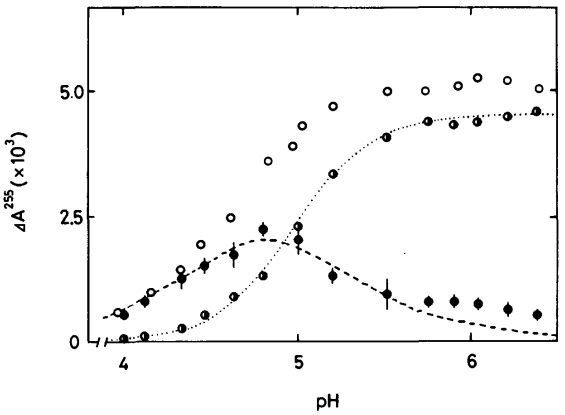

Fig. 7. The pH dependence of absorbance changes at 255 nm due to the reaction between Cu^{2+} (2.0×10^{-6} M) and BSA (1.0×10^{-5} M): ○, the total absorbance change (ΔA_{total}^{255}) measured spectrophotometrically; ●, the absorbance change (ΔA_{SF}^{255}) observed by stopped-flow method; ◑, the absorbance change within the dead-time of the stopped-flow apparatus (ΔA_{DT}^{255}) determined from $\Delta A_{total}^{255} - \Delta A_{SF}^{255}$ at each pH value.

Rapid Reaction within Dead-time of Apparatus. A reaction scheme of the chelation complex, formed rapidly within the dead-time of the apparatus, was examined on the basis of the pH dependence of ΔA_{DT}^{255}. In the neutral pH region, the three N-terminal peptides (Asp-Thr-His-) have three titratable hydrogen ions from the β-carboxyl and α-amino groups in the first terminal aspartly residue and from the imidazolyl group in the third possition of histidly residue. The pK_a values of these function groups, obtained from a titration study of the N-terminal 1—4 peptide of BSA by Bradshow *et al.*,[6] were 3.4, 7.7, and 6.7, respectively. As judged from these values, only the two deprotonation equilibria of the β-carboxyl and imidazolyl groups are important under the present pH range of 4—6.4. Therefore, the three N-terminal peptides of BSA may be represented by the following equilibria,

$$S_1 \overset{K_{\beta c}}{\underset{H}{\rightleftharpoons}} S_2 \overset{K_{im}}{\underset{H}{\rightleftharpoons}} S_3 \qquad \text{(I)}$$

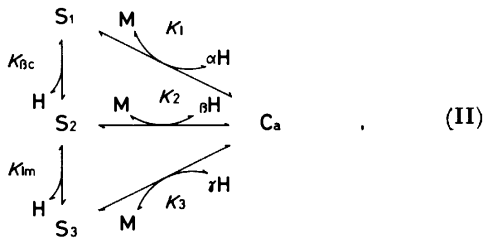
H, $K_{\beta c}$, and K_{im} are the hydrogen ion and the deprotonation constants of β-carboxyl and imidazolyl groups, respectively; the S_i (i=1, 2, and 3) refer to the possible protonation and/or deprotonation states of the titratable groups on the three N-terminal peptides, defined as

S_1: Asp(protonated β-carboxyl)-Thr-His(protonated imidazolyl);

S_2: Asp(deprotonated β-carboxyl)-Thr-His(protonated imidazolyl);

S_3: Asp(deprotonated β-carboxyl)-Thr-His(deprotonated imidazolyl),

where α-amino group in the terminal aspartyl residue is protonated in every states. Since it is common for a transition metal ion to bind to a ligand in the protonated state by exchanging itself with a hydrogen ion,[18-20] every S_1, S_2, and S_3 are assumed to be available in the binding of Cu^{2+} ion. Under this assumption, by considering the competition of Cu^{2+} ion with the variously available hydrogen ions, the following reaction scheme was examined:



(II)

where M, C_a, and K_i (i= 1, 2, and 3) denote the free Cu^{2+} ion, the chelated complex and the binding constant of each step, respectively; and where α, β, and γ are the number of hydrogen ions released from each binding reaction step, respectively. The cyclic nature of the reaction requires

$$K_1 = K_{\beta c}K_2 = K_{\beta c}K_{1m}K_3, \qquad (2)$$

$$\alpha = \beta + 1 = \gamma + 2. \qquad (3)$$

By use of the molar extinction coefficient ($\varepsilon^{255}_{C_a}$) of C_a and that of BSA, the equation of a net absorbance change resulting from the formation of C_a is given by

$$\Delta A^{255}_{DT}/\text{cm} = (\varepsilon^{255}_{C_a} - \varepsilon^{255}_{BSA})\cdot \bar{C}_{a,r}, \qquad (4)$$

with

$$\bar{C}_{a,r} = \frac{1}{2A}\{A(M_0+S_0) + B - \sqrt{A^2(M_0-S_0)+2AB(M_0+S_0)+B^2}\}, \qquad (5)$$

$$A = K_1/\bar{H}_r^3, \qquad (6)$$

$$B = 1 + K_{\beta c}/\bar{H}_r + K_{\beta c}K_{1m}/\bar{H}_r^2, \qquad (7)$$

where a bar with a subscript r and a subscript 0 refer to the equilibrium concentration after the rapid equilibria and the total concentration of each species, respectively. In the present analyses, the values of 4×10^{-4} M for $K_{\beta c}$ and 2×10^{-7} for K_{im} reported by Bradshow *et al.*,[6] were adopted. The equilibrium hydrogen ion concentration was approximated by the final concentration of hydrogen ion since the pH changes in solution after mixing were within ±0.03 of the initial pH. The observed ΔA^{255}_{DT}, plotted *vs.* $\bar{C}_{a,r}$ calculated for various values of α and K_1, is shown in Fig. 8. As can be seen in the figure, an excellent linear correlation passing through the origin was found for α=3 demonstrating the plausibility of reaction Scheme II. The values of K_1, K_2, and K_3 obtained using α=3 are listed in Table 1. From the slope of the straight line in Fig. 8, the value of $\varepsilon^{255}_{C_a}$ was estimated to be 23700 $M^{-1}cm^{-1}$. As can be seen in Fig. 7, the data of ΔA^{255}_{DT} fall on the theoretical curve (dotted line) calculated from Eqs. 4—7 using this value.

Reaction Process Observed by Stopped-flow Method. Since the reaction was observed under the conditions where complex formation at the primary site predominates, the following three types of reactions at the N-terminal site were considered: (a) Reactions succeeding the rapid formation of the chelation complex, (b) intermediate reactions occurring during the formation of chelation complex, and (c) reactions

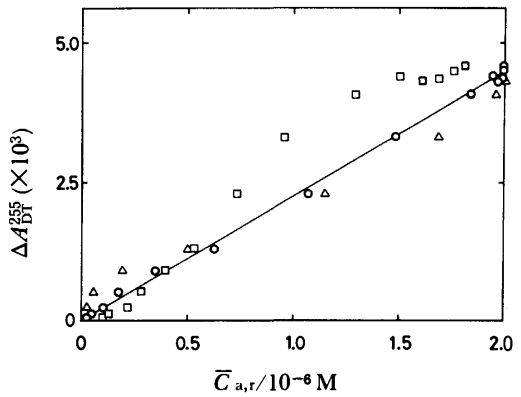


Fig. 8. Plots of ΔA^{255}_{DT} *vs.* $\bar{C}_{a,r}$ calculated for various values of α and K_1: □, α=2 and $K_1=2.4\times10^{-4}$ M; ○, α=3 and $K_1=4.8\times10^{-9}M^2$; △, α=4 and $K_1=5.6\times10^{-14}M^3$.

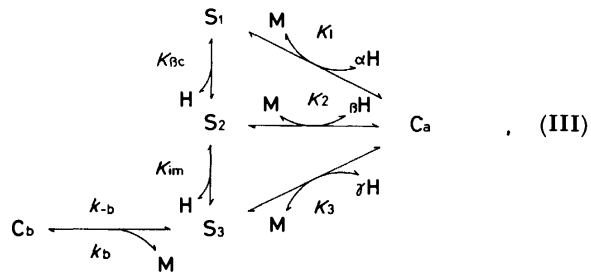
$M^{-1}cm^{-1}$	$M^{-1}cm^{-1}$	$M^{-1}cm^{-1}$	$M^{-1}cm^{-1}$
24500	23700	26200	24400

a) Statically obtained for the primary binding site at pH 5.2. b) Calculated from Eqs. 12 and 13 for pH 5.2 using equilibrium constants and molar extinction coefficients obtained kinetically.

essentially independent of the formation of the chelation complex. Among these, reactions in group (a) expected only at higher pH, were eliminated from consideration. Furthermore, since the present reaction takes place after the establishment of the chelation complex, reaction in group (b) could also be excluded. Therefore, only reactions in group (c) needed further investigation. As can be seen in Figs. 5 and 6, the difference in the concentration dependences of τ^{-1} obtained at different pH values implies the contribution of a specific protonation/deprotonation state of the N-terminal peptides to the present reaction, and the increase of τ^{-1} at pH 4.6 with increasing concentration suggests a bimolecular reaction. In addition, the approximate constancy in τ^{-1} obtained at various pH values as shown in Fig. 4 implies that hydrogen ions do not participate directly in the present reaction. These observations suggest a simple binding reaction of Cu^{2+} ion with the N-terminal peptides at a given pH-dependent state. Thus, bimolecular binding mechanisms between Cu^{2+} ion and the N-terminal site in each of three different states, designated with S_1, S_2, and S_3, were examined in detail. Among these, binding reactions with S_1 and S_2 were discounted due to poor agreement between the data and theoretical τ^{-1} calculated at the corresponding pH and concentration conditions. Subsequently, the binding reaction between Cu^{2+} ion and S_3 was examined. By combining the rapid equilibria (Scheme II) with the binding reaction, the mechanism is rewritten as



(III)

(present reaction) (rapid equilibria)

with

$$K_b = k_b/k_{-b}, \tag{8}$$

where k_b, k_{-b}, and K_b are the forward and backward rate constants and the equilibrium constant, respectively. Under the conditions of constant hydrogen ion concentration, the equation of τ^{-1} for the present reaction is given by

$$\tau^{-1} = k_{-b}\left[K_b\frac{\bar{S}_3(F-K_3\bar{M}/\bar{H})}{F(1+K_3\bar{S}_3/\bar{H})}+\frac{\bar{M}}{F}+1\right], \tag{9}$$

with

$$F = (1+\bar{H}/K_{\beta c})(\bar{H}+K_3\bar{S}_3)/K_{1m}+K_3(\bar{M}+\bar{S}_3)/\bar{H}+1, \tag{10}$$

where the overbar refers to the equilibrium concentration of each reacting species. The concentration term in the bracket in Eq. 9 was calculated for various values of K_b. A plot of τ^{-1} measured at various pH values and concentrations *vs.* the concentration term obtained for $K_b=3.9\times10^6\,M^{-1}$ gave a good correlation passing through the origin. From the slope of this line, the value of k_{-b} was determined to be $1.3\,s^{-1}$ and that of k_b calculated to be $5.2\times10^6\,M^{-1}s^{-1}$. Theoretical

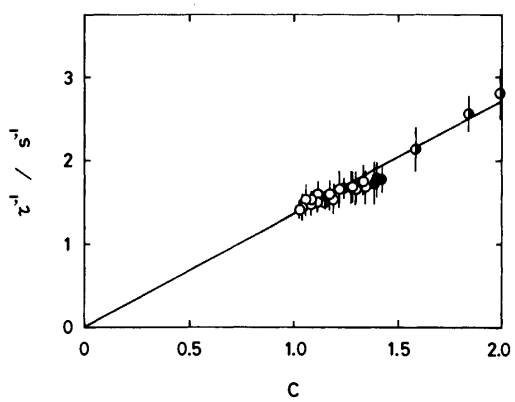


Fig. 9. A plot of τ^{-1} obtained at each pH value and concentration *vs.* the concentration term in Eq. 9, designated by C in this figure and calculated for $K_b=3.9\times10^6\,M^{-1}$.

curves of τ^{-1} obtained for these values are drawn in Figs. 4, 5, and 6, respectively. Good agreement between the theoretical curves and the data as shown in the figures confirms the plausibility of reaction mechanism III.

The absorbance change ΔA^{255}_{SF}, accompanying the present reaction is related linearly to the equilibrium concentration of the complexes as follows:

$$\Delta A^{255}_{SF}/cm = (\varepsilon^{255}_{C_a}-\varepsilon^{255}_{BSA})(\bar{C}_a-\bar{C}_{a,r}) + (\varepsilon^{255}_{C_b}-\varepsilon^{255}_{BSA})\bar{C}_b, \tag{11}$$

where $\varepsilon^{255}_{C_b}$ denotes the molar extinction coefficient of the complex C_b. As shown in Fig. 7, the variation of ΔA^{255}_{SF} with pH (drawn with the dashed line), calculated from Eq. 9 by use of the K_b value obtained above, for $\varepsilon^{255}_{C_b}=26200\,M^{-1}cm^{-1}$ gives good fit with data at each pH value. This fact further supports the validity of mechanism III.

The equilibrium and rate constants and the molar extinction coefficients (at 255 nm) of the complexes determined in the present analyses are summarized in Table 1. Using these values, the apparent association constant K_{app}, defined as $(\bar{C}_a+\bar{C}_b)/(\bar{S}_1+\bar{S}_2+\bar{S}_3)\cdot\bar{M}$, and the apparent molar extinction coefficient $\varepsilon^{255}_{c,app}$, can be calculated from the following relations:

$$K_{app} = \frac{K_1/\bar{H}+K_{\beta c}K_{1m}K_b/\bar{H}^2}{1+K_{\beta c}/\bar{H}+K_{\beta c}K_{1m}/\bar{H}^2}, \tag{12}$$

and

$$\varepsilon^{255}_{c,app} = \frac{\varepsilon^{255}_{C_a}\bar{C}_a+\varepsilon^{255}_{C_b}\bar{C}_b}{\bar{C}_a+\bar{C}_b}. \tag{13}$$

The values calculated for pH 5.2 are also listed in Table 1 together with those of K_p and $\varepsilon^{255}_{c,app}$ obtained from the equilibrium dialysis and UV spectrophotometric titration studies performed at pH 5.2, for the primary complex on BSA. The agreement between the values obtained kinetically and statically strongly support mechanism III as well as the assumptions adopted.

The presence of a Cu^{2+}–BSA complex at low pH, appearing below pH 5.5 and exhibiting a broad maximum around 650—700 nm, was confirmed by Breslow,[3] and Peters and Blumenstock.[4] However, the specific binding site on BSA of this complex has not yet been clarified. The present static and kinetic studies reveal that the low pH complex, detected directly by stopped-flow method, is formed in competition with

the chelation complex on the N-terminal site of BSA. This consists with the results of the potentiometric titration study[7] of the binding between Cu^{2+} and a derivative of the native-sequence tripeptide (Asp-Ala-His-NHMe)[21] of the N-terminal site of human serum albumin (HSA). Some useful information regarding the structure of the low pH complex can be derived from the present kinetic results. As shown in Scheme III, the selective formation of the low pH complex in the specific state, S_3, reveals the coordination of a deprotonated nitrogen atom of imidazolyl group with the Cu^{2+} ion. Furthermore, the absence of the proton release in this process supports further the suggestion, by Breslow based on the visible spectroscopy,[3] that the coordination of peptide nitrogen atoms may not be involved in the structure of low pH complex. In addition, the larger value in the molar extinction coefficient of the low pH complex ($\varepsilon_{C_b}^{255}=26200$) compared to that of chelated one ($\varepsilon_{C_a}^{255}=23700$) suggests a charge transfer from the oxygen atom rather than nitrogen atom; hence, the low pH complex likely involves the β-carboxylato group of the terminal aspartyl residue. From these observations, the most likely configuration for the low pH complex is a *di*-coordinated structure involving a nitrogen atom of imidazolyl group and an oxygen atom of β-carboxylato group. The rate-determining step for the coordination of the small ligands to Cu^{2+} ion has been assigned to the metal-water exchange process (10^7—10^9 $M^{-1}s^{-1}$).[22-26] However, the value of 5.2×10^6 $M^{-1}s^{-1}$ for the second-order formation rate constant k_b is small compared to those values. This implies a higher activation energy is involved in the formation process of the low pH Cu^{2+}-BSA complex. One possible explanation is that a conformational change is the rate-determining process which is required to allow the β-carboxylato group to coordinate to the bound Cu^{2+}.

On the other hand, the chelation complex is formed faster than the time resolution of the present stopped-flow apparatus. As shown by Scheme III and the pK_a values of each N-terminal site group, at most two hydrogen ions are expelled by the formation of the chelation complex in the range of pH 5—6. In contrast with the present result, the square-planar structure of the chelation complex, originally proposed by Peters and Blumenstock[4] and further supported by Shearer *et al.*,[5] requires four released hydrogen ions in the corresponding pH region. This inconsistency in the number of released hydrogen ions may imply that only two hydrogen ions of the four possible compete with Cu^{2+} ion in the formation of the chelation complex. Further elucidation requires application of a rapid relaxation technique to the present system.

The X-Ray Fluorescence Spectroscopy of Inorganic Solids. VII. The Fe $K\beta_{1,3}$ Energy Shifts in Oxide Glasses

Michiko YOSHIOKA, Takashi MAEKAWA,* and Toshio YOKOKAWA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received January 27, 1984)

The Fe $K\beta_{1,3}$ energy shifts in the binary sodium borate, silicate, and phosphate glasses containing small amounts of the iron ion were examined. The Fe $K\beta_{1,3}$ energy decreases with an increase in the sodium oxide content in the borate and silicate glasses. The data are in accordance with those of previous studies that the coordination number of the Fe(III) ion is four in the borate and silicate glasses and six in the phosphate glasses. The structure of the coordination sphere around the Fe(III) ion in the borate glasses was also discussed.

Many studies have been reported about the chemical state of the transition metal ions in oxide glasses and melts. Especially, the optical and magnetic studies have provided much information about the valency state and the coordination number of these ions in the various host glasses.[1] Recently the coordination number of the Fe(III) ion in the binary glasses was estimated by means of Mössbauer spectroscopy; thus, it can be said the coordination number of the Fe(III) ion is six in Na_2O–P_2O_5 glasses and nearly four in Na_2O–SiO_2 and K_2O–B_2O_3 glasses.[2-4] The X-ray energy of the constituents of the oxide glasses varies slightly depending on their chemical surroundings (coordination number, bond polarity, and so on), as the previous studies of Al, Si, K have revealed.[5-7] In the present work, a two-crystal spectrometer was used for the measurement of the X-ray energy of the iron ion in the binary sodium borate, silicate, and phosphate glasses. The results were discussed in terms of the effective positive charge and the coordination number of the Fe(III) ion in these glasses.

Experimental

Apparatus. The iron fluorescence spectra were obtained by means of a two-crystal spectrometer as has been described in a previous paper.[8] The analyzing crystals were Ge ($2d$=0.6533 nm). The chromium X-ray tube (50 kV, 30 mA) was used for the primary excitation. The energy shifts were obtained by the "standard spectra method" developed in our laboratory.[9] The reference material was α-Fe_2O_3. The measurements were repeated at least ten times, and the limit of error was estimated, assuming the t-distribution, with a 95% certainty.

Samples. The glassy samples were prepared by melting weighed quantities of SiO_2, $NaH_2PO_4 \cdot 2H_2O$, H_3BO_3, and Na_2CO_3 of a guaranteed reagent grade in a platinum crucible for 10—12 h at around 1000 °C (at around 1200 °C for silicates). The iron ion was added in the form of Fe_2O_3 or sometimes $Fe(COO)_2$. No appreciable difference was observed between the chosen starting materials.

Valency Change by X-ray Irradiation. High-energy irradiation generates the various defect centers in the glasses. When the transition metal ions are present in the glasses, they may react with defect centers to change their valency state. Bishay and Makar reported that a part of the Fe(II) ions change to Fe(III) ions when γ-ray irradiation in $CaO \cdot P_2O_5$ glass.[10] However, no differences were observed in the energy shifts of the same sample with different durations of the irradiation time. This means that the degree of the valency change is negligibly small under the present experimental conditions.

Results and Discussion

The $K\beta_{1,3}$ energy shifts in the binary glasses are summarized in Table 1 and are plotted in Fig. 1. The energy shifts depend on the composition and on the

kind of glass in which the iron ion was doped. In each system, the characteristic behavior is as follows.

i) Fe ion in sodium borate glasses: The Fe $K\beta_{1,3}$ energy gets smaller with an increase in the sodium oxide content, and the energy drops abruptly at the particular mole fraction of the sodium oxide.

ii) Fe ion in sodium silicate glasses: The Fe $K\beta_{1,3}$ energy also decreases with an increase in the sodium oxide content. However, there seems to be no such sharp change in the shift with the composition as is seen in the sodium borate glasses.

iii) Fe ion in sodium phosphate glasses: The energy shifts are more positive than those in the above two systems. The composition dependence of the energy shifts could not be detected because of the narrow composition range covered in this work.

In the preliminary experiments, the X-ray energy shifts of Fe $K\beta_{1,3}$ in various crystalline iron compounds were measured. The results were in quantitative agreement with that of the previous author[11] and so will not be presented here. However, the data suggest that the energy depends primarily on the effective positive charge on the Fe atom rather than on its formal charge, and that it changes with the coordination number. Thus, CN^-, S^{2-}, O^{2-}, and SO_4^{2-} as the counter anion in compounds gives rise to a negative shift of Fe $K\beta_{1,3}$ in that descending order nearly irrespective of the formal charge of the Fe atom. When O^{2-} is the common counter ion (*i.e.*, Fe_2O_3, FeO, FeO(OH), Fe_3O_4), the structure of the coordination polyhedron affects the shift. On the other hand, iron is substantially in the trivalent state in the glasses examined in the present study.[12] Therefore, the data of the energy shift will be discussed from the viewpoint of the effects of the bulk basicity of host glasses and of the coordination number upon the iron(III) ion.

In our laboratory, the basicities of oxide melts have been measured in terms of the thermodynamic activity of Na_2O in Na_2O–P_2O_5, –B_2O_3, –SiO_2, and other binary systems. P_2O_5 was found to be a quite acidic oxide. The Na_2O activity in borate melts changes drastically (by an order of 10^4) at around 20 mol% Na_2O.[13] These observations are in good agreement with the present results. Thus, the Fe(III) ion is the most positively charged in phosphate glasses, and becomes firmly coordinated with oxygen atoms with an increase in the basicity.

Kurkjian and Sigety concluded that the Fe(III) ion is tetrahedrally coordinated in silicate and octahedrally coordinated in phosphate glasses.[2] Park and Chen, from their EXAFS measurements, showed that the Fe(III) ion coordinates six oxygens in sodium disilicate glass.[14] Morinaga *et al.* also found the same Fe(III) ion in the acidic range of the system.[3] Nishida and Takashima showed that the Fe(III) ion coordinated with four oxygen atoms is predominant in potassium borate glasses.[4] These results, taken together, enable us to conclude that the Fe(III) ion coordinates six oxygen atoms in such an acidic range as in phosphate glass and four oxygens in a less acidic range. The boundary seems to be somewhere around a $K\beta_{1,3}$ energy of 0.25 eV referred to that of α-Fe_2O_3. Koster and Rieck's work[15] on the Fe $K\beta_{1,3}$ energy shift in crystalline compounds in relation to the coordination number are in qualititative agreement with the present results for the glassy materials, although the absolute values differ between the two systems.

B_2O_3 is more acidic than SiO_2 as long as the Na_2O activity is compared at the same composition on a molar basis. Considering the number of atoms of B and Si in one mole of the oxide, however, the order of their acidity becomes nearly the same. This partly accounts for the sequential difference between the basicity, (silicate>borate>phosphate), and the Fe $K\beta_{1,3}$ shifts (borate>silicate>phosphate).

It is worthwhile to consider further the energy shift as a function of the composition in the borate glasses. In the low concentration range of the alkali metal oxide, the borate network consists mainly of a tetrahedral unit, accompanied by the alkali ions as charge compensators, in addition to the trigonal unit without the non-bridging oxygen ions. The further addition of the alkali oxide produces in the network a non-bridging oxygen ($-BO^-$). In the latter composition range, the Fe(III) ion can coordinate with the $-BO^-$ end group and make a coordination sphere with four bridging oxygens and one sodium ion ($[FeO_4]Na$). In the former range, however, some discussion is needed. The Fe(III) ion in this range is forced to accommodate itself to poor O^{2-} or O^- circumstances. Thus, the Fe(III) ions dissolve in the borate network without joining the sodium ions. Lacy proposed a tricluster model about the structure of the aluminium ions, a model in which the aluminium ion coordinates the bridging oxygen in the acidic glasses.[16] From the similarity in the atomic dimensions between the Al(III) and Fe(III) ions, one possible explanation of the structure of the coordination sphere around the Fe(III) ion can be made by means of the above picture. On the other hand, Kawazoe *et al.* introduced a π-electron concept to aid in understanding the borate anomaly.[17] In the low alkali content glasses, the p_π electrons of the oxygens delocalize among the network composed of the trigonal unit (for example, the boroxol ring). The appearance of a tetrahedral unit in the network (tetraborate, diborate, and so on) reduces the degree of resonance and causes an abrupt change in the basicity. Thus, either a tricluster type or an interstitial dissolution among boroxol groups may explain the existence of the Fe(III) ion in the network of the low alkali content glasses. The abrupt change in the $K\beta_{1,3}$ energy at 20 mol% Na_2O may correspond to the structural change in the coordination sphere around the Fe(III) ion in conjunction with the large structural change in the glass matrices.

Molybdenum Peroxo Complex. Structure and Thermal Behavior

Koichi SEGAWA,* Katsumi OOGA, and Yasuhiko KURUSU
Department of Chemistry, Faculty of Science and Technology, Sophia University, 7-1 Kioicho, Chiyoda-ku, Tokyo 102
(Received February 23, 1984)

The molybdenum peroxide (Mo-y) prepared by oxidation of molybdenum metal with hydrogen peroxide has been studied to determine its structure and thermal behavior. Temperature programmed decomposition has been used to study the thermal stability of Mo-y. Two distinct peaks, I and II, of decomposition processes are discernible in Mo-y. Peak I corresponds to the elimination of water of crystallization and peak II to the decomposition of a peroxide ion of Mo-y. IR and UV examinations support the results of the thermal analysis. The IR band at 931 cm^{-1} and the UV band at 381 nm show the same thermal behavior. Both bands are attributable to the peroxide ion of Mo-y. Spectroscopic studies show that Mo-y has the tetrahedral coordination derived from the single molybdenum complex, which has double bond oxygens attached to Mo atom and has a symmetric type of peroxide ion with one water of crystallization.

Molybdenum peroxide is obtained by oxidation of molybdenum metal powder or molybdenum trioxide with hydrogen peroxide; it has one more oxygen than molybdenum oxide and shows other distinctive features. This molybdenum peroxide (yellow crystallites, abbrreviated as Mo-y) exhibits catalytic activities or acts as an oxygen carrier for a wide variety of organic reactions. For example, Mo-y is active for catalytic dehydration and stoichiometric oxidation of various alcohols and for catalytic epoxidation of various olefinic compounds with *t*-butyl hydroperoxide.[1,2] According to the results derived from these reactions, Mo-y shows dual-function properties: acid properties and oxidation properties as an oxygen carrier.

In the present paper, we describe a neat conclusion about the structure of Mo-y reached by comparing spectral data and thermal behavior.

Experimental

Preparation of Molybdenum Peroxide (Mo-y). The preparation procedure of Mo-y for the work reported here was described in detail previously.[3] In brief, 6.3 g of molybdenum metal powder (Mo: 99.9%, Wako Chemical Co.) was reacted with ice-cooled 50 cm^3 of hydrogen peroxide (30%, Mitsubishi Gas Chemical Co. Ltd.). The solution was maintained below 310 K for 1 h and was allowed to stand for several days at room temperature. A yellow precipitate formed from the solution. The precipitate was collected by filtration and dried under vacuum at room temperature.

Thermal Analysis. Both thermal gravimetrical analysis (TGA) and temperature programmed decomposition (TPDE) experiments were performed under vacuum conditions. About 100 mg of a sample was charged in a quartz basket attached to a standard vacuum system (1×10^{-4} Pa). A McBain type of quartz spiral spring was hung down to the sample basket. The weight change during the TGA experiment was determined by the change in length of the quartz spring (sensitivity: 0.02 mm mg^{-1}), which was equipped with a displacement meter (type 2U, Shinko Electronic Co.).

For TPDE examination, the pressure change of the decomposed gas of the sample was monitored by a vacuum gauge which recorded automatically. Both experiments were operated simultaneously.

Infrared Spectroscopy. A vacuum tight IR cell having KBr windows was designed to fit an infrared spectrometer (260-50, Hitachi Co.) and to be attachable to a vacuum system. Samples (3—5 mg) were dispersed on a thin silicone plate (1×2 cm). The cell was arranged such that a sample plate could be lowered into slots between the optical windows for the spectroscopic examination and withdrawn upward by a magnet into a heated portion (self-contained furnace) for various treatments described below.

UV-Diffuse Reflectance Spectroscopy. A photomultiplexer (R446U, Shimadzu Co.) was attached in the sample cavity of a spectrometer (UV-240, Shimadzu Co.). Each sample of Mo-y (about 50 mg), after a specified heat treatment, was charged into a cell which was covered by a quartz glass plate. $BaSO_4$ was used as a reference.

X-Ray Powder Diffractometry. X-Ray powder diffraction patterns were obtained by a RAD-2A (Rigaku Electronic Co.) diffractometer. The sample of X-ray analysis were the same samples as used for the UV measurements mentioned above.

Results and Discussion

Thermal Analysis. A Mo-y sample which had been previously dried under vacuum at room temperature was evacuated at 323 K for 2 h in the system. A small amount of physically adsorbed water was desorbed during this treatment. TGA and TPDE were carried out from 323 K up to 600 K, and the temperature was raised at various constant rates (4—10 K min^{-1}). Figure 1 shows the TGA curve which was obtained under vacuum conditions. The weight de-

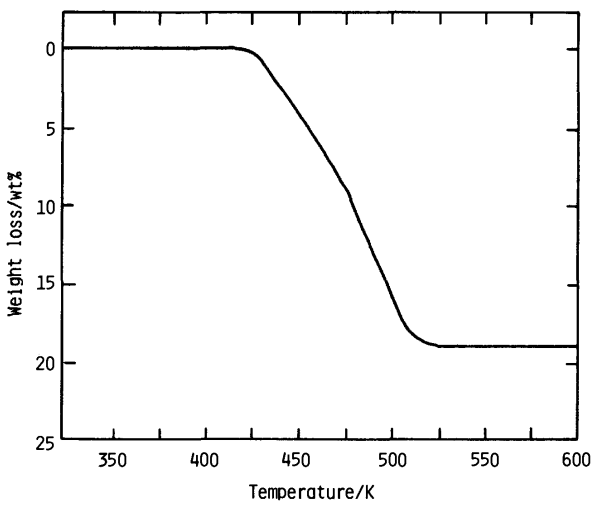

Fig. 1. TGA curve of Mo-y. Heating rate: 5 K min^{-1}.

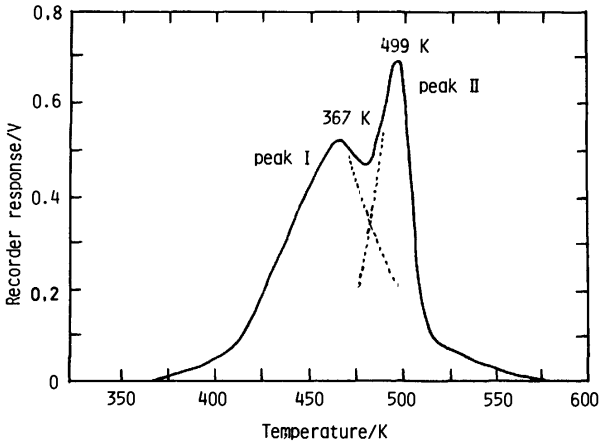

Fig. 2. TPDE spectrum of Mo-y. Heating rate: 5 K min^{-1}.

crease started about 420 K and completed at around 530 K. A well-reproduced weight decrease was observed, based on the weight of the starting Mo-y: it amounted to 19.1±0.1 wt%. The TGA curve represents a one-stage decomposition of Mo-y. However, the curve at around 470 K (10—13 wt% decrease) shows a slight *S* shape.

It is clear that the TPDE spectrum in Fig. 2 represents a two-stage decomposition of Mo-y. When the contributions of these peaks are estimated, the area ratio of peak I at 367 K to peak II at 499 K is about 2 to 1. This result suggests that the thermal decomposition of Mo-y has two kinds of decomposition species. Theoretical derivations[4] give Eq. (1) for the TPDE experiments:

$$\frac{\mathrm{d}\ln(T_m^2/\beta)}{\mathrm{d}\ln(1/T_m)} = \frac{E_d}{R} \qquad (1)$$

where T_m is the temperature which corresponds to the maximum rate of decomposition for a sample, β is the heating rate, and E_d is the activation energy for the decomposition. Figure 3 shows the Arrhenius plots for the decomposition of Mo-y; these were derived from Eq. (1) at various heating rates (4—10 K min^{-1}). The slopes for peaks I and II in Fig. 3 yield activation energies of 41.6 kJ mol^{-1} and 106.0 kJ mol^{-1}, respectively. A result for peak I shows elimination of some relatively weaker chemical species, which could be related to the water molecules generated from Mo-y. On the other hand, the activation energies for peak II represent the decomposition of Mo-y; this peak has rather higher thermal stabilities than peak I. Thus peak II must be correlated to the decomposition of peroxide ion of Mo-y.

Infrared Spectroscopy. Figure 4 (A) shows the IR spectrum of Mo-y evacuated at room temperature in the vacuum cell. After 1 h, the vacuum conditions inside the cell reached 1×10^{-4} Pa. The OH asymmetrical and symmetrical stretching frequencies were observed at 3517 cm^{-1} and 3450 cm^{-1}, together with OH bending vibration of water molecules at 1615 cm^{-1}, respectivery. It can be seen that water molecules of Mo-y are rather easily replaced by D_2O molecules at room temperature (P_{D_2O}=0.7 kPa). OD stretching bands in spectrum (B) were observed at 2620 cm^{-1} and 2540 cm^{-1}, while the bending modes for HDO and D_2O were also observed

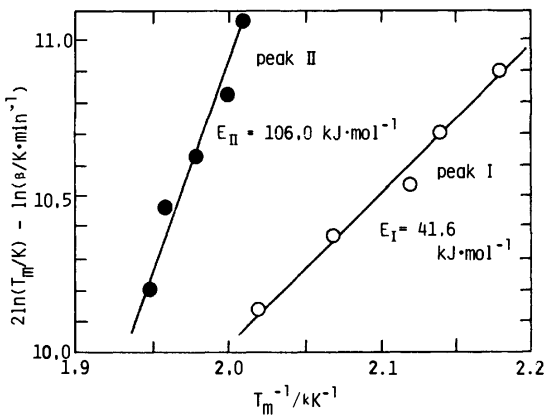

Fig. 3. Arrhenius plots for decomposition of Mo-y. T_m: Temperature of the maximum rate of decomposition for peaks I and II, β: heating rate (K min^{-1}).

at 1420 cm^{-1} and 1195 cm^{-1}. The IR sample was evacuated at various temperatures, which were chosen from the characteristics of the results of TGA and TPDE experiments. The relationship between the normalized integrated intensities of OH stretching and bending bands at various evacuation temperatures gives a straight line going through the origin, as shown in Fig. 5. These results suggest that the water molecule is attached to the molybdenum peroxide molecule with a hydrogen bond. There is no evidence of Mo–OH bonding because the stretching frequencies are relatively lower (3517 and 3450 cm^{-1}) than that of water molecules at 3652 cm^{-1}.[5]

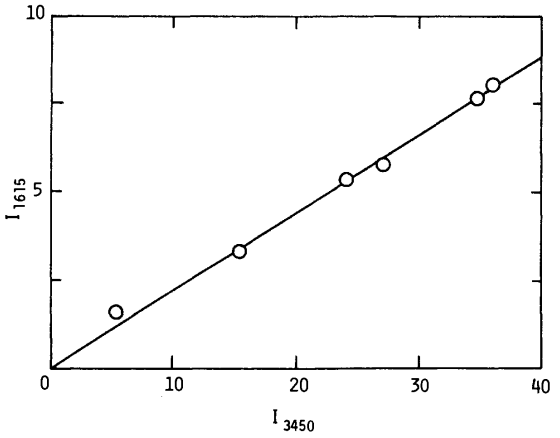

Fig. 5. Integrated intensities of OH stretching and bending vibrations of Mo-y for various evacuation temperatures.

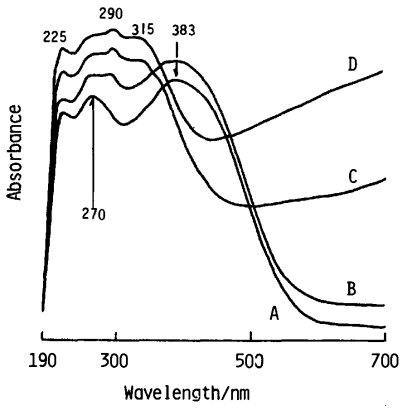

Fig. 6. UV-diffuse reflectance spectra of Mo-y after various treatments. A: Evacuated at room temperature, B: evacuated at 423 K, C: evacuated at 503 K, D: evacuated at 583 K.

At the lattice vibration region of oxides, spectrum (A) shows the stretching vibration of Mo=O,[6] which gives a band at 980 cm^{-1}; this band was also observed in spectrum (C), for the sample evacuated at 673 K. Asymmetric and symmetric stretching of Mo-O were observed at 635 cm^{-1} and 530 cm^{-1}, respectively. No bands of bridging oxygen for Mo-O-Mo[7] were obserbed in spectrum (A). However, after evacuation at 673 K, spectrum (C) shows the bands of Mo-O-Mo at 867 cm^{-1} and 618 cm^{-1}. Furthermore, the band at 931 cm^{-1} in spectrum (A) also disappeared in spectrum (C); this band could be attributed to the O-O stretching vibration of the peroxy structure of Mo-y. In general, the O-O vibration of superoxide ion (O_2^-) and peroxide ion (O_2^{2-}) appears at *ca.* 1140 cm^{-1} and *ca.* 800 cm^{-1}, respectively.[8] However, the O-O stretching frequencies of the symmetric type of peoxide ion appear lower between 932 cm^{-1} to 742 cm^{-1};[9] their location seems to depend on the electronegativities of each transition metal. Mimoun *et al.*[10] ascribed the band of vanadium peroxo complex ranging from 940 cm^{-1} to 935 cm^{-1} to the O-O stretching vibration. As was stated previously, the O-O stretching can be observed in a broad region. But the assignment of the O-O stretching of Mo-y is supported by the results of the thermal

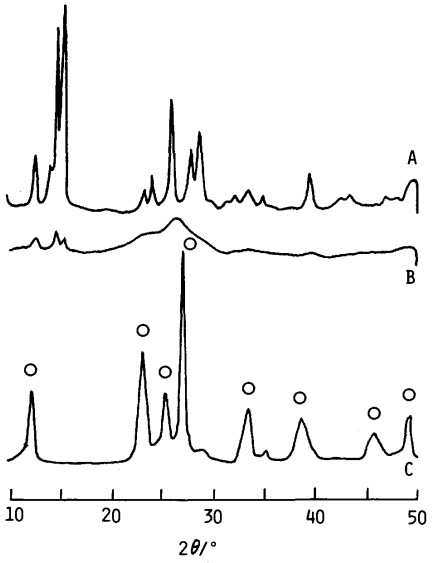

Fig. 7. XRD patterns of Mo-y evacuated at various temperatures. A: Room temperature, B: 473 K, C: 623 K.

analysis. According to the TPDE spectrum in Fig. 2, the thermal decomposition corresponding to peak II seems to coincide with the properties of the band at 931 cm^{-1}, which can be attributed to the decomposition of the peroxide ion of Mo-y.

UV-Diffuse Reflectance Spectroscopy. The UV-diffuse reflectance spectra of Mo-y after various treatments are shown in Fig. 6. Spectrum (A) showed a $2t_2$ to $3t_2$ transition at 225 nm and a t_1 to $3t_2$ adsorption at 270 nm; these are associated with the charge transfer bands of a $Mo^{6+}=O^{2-}$ for the tetrahedral coordination derived from the single molybdenum complex.[11] The additional band at 383 nm in spectra (A) and (B) disappeared after evacuation at temperatures 505 K to 583 K in spectra (C) and (D). The spectra (C) and (D) are quite similar to the authentic spectrum of molybdenum trioxide. These are not characteristic of the tetrahedral coordination: in comparison with spectrum (A), both (C) and (D) have an additional band (290 nm or 315 nm) which corresponds to the octahedral coordination of Mo^{6+}.[12]

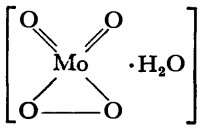
X-Ray Diffractometry. Figure 7 shows the XRD patterns of Mo-y. (A) is freshly prepared Mo-y; this was the same sample as used for the UV examinations. The finely crystallized particles of Mo-y became amorphous after evacuation at 473 K; this pattern is shown in (B). (C) shows the sample after evacuation at 623 K. Almost all the lines obtained here in (C) are superimposed on the lines of authentic crystallites of molybdenum trioxide which is marked as open circle. The results shows the rearrangements of the lattice structure of Mo-y from tetrahedral to another that might be octahedral in configuration.

The results of the TGA and TPDE measurements suggest that the 19.1 wt% weight decrease is equivalent to the loss of one molecule of water of crystallization and half a molecule of oxygen gas from Mo-y, as shown in Eq.(2):

$$[MoO_4 \cdot H_2O] \xrightarrow{\Delta} MoO_3 + H_2O + 1/2O_2. \quad (2)$$

The elimination of water of crystallization occurred

at a somewhat lower temperature (peak I in Fig. 2) than that of peroxide ion (peak II) of Mo-y. Spectroscopic investigations show that Mo-y consists of the tetrahedral coordination derived from a single molybdenum complex, which has double bond oxygens attached to the Mo atom and has a symmetric type of peroxide ion with one water of crystallization. The idealized structure of Mo-y can be shown as Scheme 1.



Scheme 1.

Vanadium (V) peroxo complexes which homolytically cleave to give V^{4+}–OO· species are different from the known molybdenum or tungsten peroxo complexes which heterolytically cleave to M^{+}–O–O^{-} species.[10] The O–O vibration of Mo-y appears at higher wave number region. This result is similar to that of vanadium peroxo complexes reported by Mimoun *et al.*,[10] and it may be ascribable to Mo-y having a different reactivity from other peroxo complexes which react heterolytically.

Syntheses, and Crystal and Molecular Structures of Tris(benzamide)-bis(*O,O'*-diisopropyl dithiophosphato)lanthanoid(III) *O,O'*-Diisopropyl Dithiophosphate (M=Gd, Tb, Dy, Er, and Yb)

Kiyofumi NAGAI,* Reiko NAKAMURA, Mamoru SHIMOI, and Akira OUCHI
Department of Chemistry, College of Arts and Sciences, The University of Tokyo, Komaba 3-8-1, Meguro-ku, Tokyo 153
(Received March 9, 1984)

Five isomorphous lanthanoid(III) complexes were synthesized, and the structure of the terbium (**1**) and erbium (**2**) complexes were determined by the use of the single-crystal X-ray diffraction method. Crystals of **1** and **2** are monoclinic, with the space group $P2_1/n$, and the cell constants are: (**1**) a=25.076(8), b=15.446(3), c=14.579(8) Å, β=100.77(4)°; (**2**) a=25.036(20), b=15.228(4), c=14.805(19) Å, β=99.50(12)°. The structures were solved by the heavy-atom method and refined by the block-diagonal least-squares method. The final R values of **1** and **2** are 0.061 and 0.055 respectively. They consist of discrete complex cations and dithiophosphate anions. The central metal atom of the cationic complex is hepta-coordinated, and it is in a pentagonal bipyramidal geometry, where four sulfur atoms of two dithiophosphate ions and one oxygen atom of a benzamide ligand take the equatorial positions, while two benzamide oxygen atoms are in the axial positions.

Although lanthanoid elements are "hard" acid according to the HSAB theory,[1] their complexes of *O,O'*-dialkyl dithiophosphate (R_2dtp),[2-4] *N,N*-dialkyldithiocarbamates,[5] and dialkyl dithiophosphinates[6] have already been reported. Pinkerton obtained two kinds of *O,O'*-diethyl dithiophosphate-triphenylphosphine oxide lanthanoid(III) mixed complexes, $[M(Et_2dtp)_3\{(C_6H_5)_3PO\}_2]$ (where M=La—Pr, and Et=C_2H_5) and $[M(Et_2dtp)_2\{(C_6H_5)_3PO\}_3](Et_2dtp)$ (where M=Nd—Lu), and established their structures by means of the X-ray diffraction technique.[3] The present authors previously tried to obtain such types of mixed complexes of the *O,O'*-diisopropyl dithiophosphate, using *N,N*-dimethylacetamide (dma) as the additional ligand, but only $[M(iPr_2dtp)_3(dma)_2]$[where M=La or Nd; iPr=$(CH_3)_2CH$}-type complexes of light lanthanoids were obtained, as was reported in a previous paper.[7] Furthermore, we obtained a series of mixed complexes of the heavy lanthanoid elements with the formula $[M(iPr_2dtp)_2(bza)_3](iPr_2dtp)$ (where M=Gd, Tb, Dy, Er, and Yb; bza=benzamide). The present paper reports on the structures of the terbium(III) (**1**) and erbium(III) (**2**) complexes as determined by the X-ray diffraction technique.

Experimental

Preparation of $[Er(iPr_2dtp)_2(bza)_3](iPr_2dtp)$, and the Tb, Dy, and Yb Complexes. Erbium (III) chloride hexahydrate ($ErCl_3\cdot6H_2O$)(0.61 g, 1.6 mmol) and sodium *O,O'*-diisopropyl dithiophosphate (2.0 g, 8.6 mmol) were dissolved in 25 cm³ of 2-propanol, and the solution was refluxed for 20 min at about 80 °C. After the residue had then been filtered off, 0.57 g (4.7 mmol) of benzamide was added to the filtrate and the mixture was allowed to stand for 5 min at about 65 °C to terminate the reaction. The solution was then evaporated to dryness using the vacuum rotary evaporator at about 65 °C. The residue was dissolved in 5 cm³ of 2-propanol, the insoluble matter was filtered off, and the filtrate was left in a silica-gel desiccator for several days. The crystalline product was then filtered off, washed with diisopropyl ether, and dried in a vacuum desiccator at the ambient temperature. The yield was about 0.83 g (0.71 mmol, 45%). The Tb, Dy, and Yb complexes were obtained in almost the same way.

Preparation of $[Gd(iPr_2dtp)_2(bza)_3](iPr_2dtp)$. The added benzamide should be more than three times the metal salt in mole units. After the 2-propanol solution of the crude product has been concentrated by a vacuum rotary evaporator, it was left in diisopropyl ether vapor at the ambient temperature for several days. The $[Gd(iPr_2dtp)_2(bza)_3](iPr_2dtp)$ complex was thus precipitated. The yield of the complex was 0.80 g (0.69 mmol, 31%) from 0.83 g of $GdCl_3\cdot6H_2O$ (2.2 mmol).

$[Gd(iPr_2dtp)_3(bza)_2]$ was obtained if the added benzamide was less than 2.1 times the starting metal salt in mole units.

All the complexes thus obtained are stable in air for several months. The elemental analyses and their magnetic moments, as measured by means of a Gouy balance at the ambient temperature, are shown in Table 1.

a) The equivalent isotropic temperature factors for non-hydrogen atoms were computed using the following expression: $B_{eq}=4/3(B_{11}a^2+B_{22}b^2+B_{33}c^2+B_{13}ac\cos\beta)$. The B_{ij}'s are defined by: $\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2klB_{23}+2hlB_{13}+2hkB_{12})]$.

Single-crystal X-ray Analysis. **1** and **2** are isomorphous and monoclinic, the space group being $P2_1/n$. Their crystallographic data are as follows:

1. $TbC_{39}H_{63}N_3O_9P_3S_6$, F. W.=1162.3, a=25.076(8), b=15.446(3), c=14.579(8) Å, β=100.77(4)°, U=5547(3) Å^3, D_m=1.41(3), D_x=1.39 Mg m^{-3}, μ(Mo$K\alpha$)=1.67 mm^{-1}, Z=4.

2. $ErC_{39}H_{63}N_3O_9P_3S_6$, F. W.=1170.4, a=25.036(20), b=15.228(4), c=14.805(19) Å, β=99.50(12)°, U=5567(8) Å^3, D_m=1.41(3), D_x=1.39 Mg m^{-3}, μ(Mo$K\alpha$)=1.94 mm^{-1}, Z=4.

The crystals of **1** and **2** used for the structure determination were about 0.3×0.3×0.4 mm^3 in size. All their edges were ground off, but they were not shaped into spheres.

The reflections in the range of $3°<2\theta<50°$ were collected on a Rigaku AFC-6A automated four-circle diffractometer, with graphite monochromated Mo$K\alpha$ radiation (the scan speed and scan width for **1** and **2** were 2° min^{-1} and 1.40+0.5tanθ°, and 4° min^{-1} and 1.50+0.5tanθ°, respectively), the ω-scan technique being employed. The intensities were corrected for Lorentz and polarization factors, but no correction was made for absorption and extinction. Among the 10196 and 10222 independent reflections collected for **1** and **2**, 6538 and 5220 with $|F_o|>3\sigma(|F_o|)$ were respectively used for the structure determination.

Structure Determination. The structure of **2** was solved by the heavy-atom method. The positional and thermal parameters were refined by the block-diagonal least-squares method. Although all the non-hydrogen atoms were found, we could not determine the positions of any hydrogen atoms from the Fourier map.[8] At the first stage of the refinement of **1**, the positional and thermal parameters of **2** were tentatively applied; they were then refined by the block-diagonal least-squares method in the same way as that of **2**.

The final R values obtained for **1** and **2** are 0.061 and 0.055 respectively,[9] applying the anisotropic temperature factors for non-hydrogen atoms. In each calculation, twenty-one hydrogen atoms obtained by the calculation[8] were included, with their positional and thermal parameters fixed and assuming B_{iso}=10.0.

There is a large void near a isopropyl group (C(22), C(23)) and a phenyl group (C(106), C(107)), and the thermal parameters of these four atoms are abnormally large, although no significant peaks remained in the difference Fourier synthesis map.

All the calculations were carried out on a HITAC M-200H computer at the Computer Center of the University of Tokyo, using the local version of the UNICS program.[10] The atomic-scattering factors were taken from Ref. 11.

Other Measurements. The visible absorption spectra were measured with a Hitachi 124 spectrophotometer. The X-ray powder patterns of these complexes were obtained by the use of Model DX-GO-F JEOL, using Cu$K\alpha$ radiation in the range from 4° to 40° in 2θ.

Results and Discussion

The final atomic parameters of **1** and **2** are listed in Table 2, while the bond lengths and angles and short intermolecular distances are tabulated in Table 3.[12] The perspective drawing of **1** around the central

Keys to the symmetric opertions: i: $-0.5+x$, $0.5-y$, $0.5+z$; ii: $1.5-x$, $-0.5+y$, $0.5-z$.

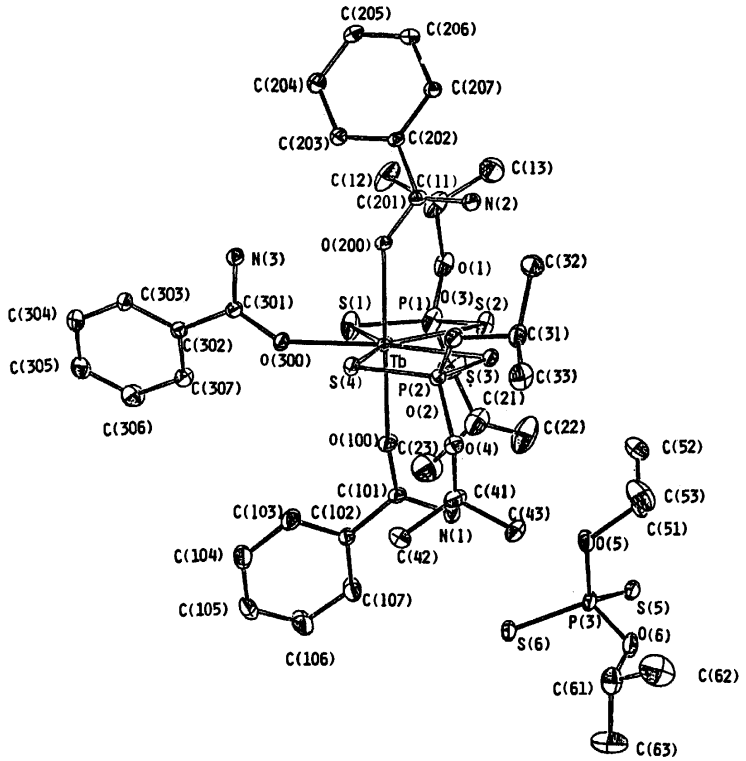

Fig. 1. A perspective drawing of the terbium(III) complex with the numbering scheme.

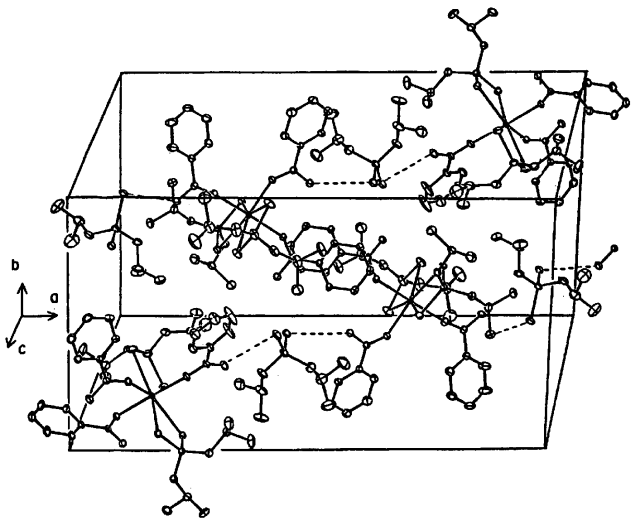

Fig. 2. Crystal packing diagram of the terbium(III) complex.

metal atom, together with the numbering scheme, is shown in Fig. 1, and the crystal packing diagram, in Fig. 2. The general features of **2** are the same as those of **1**, and the numbering scheme of **2** is the same as that of **1**. The metal atoms in the crystals have no mutual magnetic interaction with each other, judging from the magnetic-moment data shown in Table 1. The complex molecule is mono-cationic, and its electric charge is balanced by the $(iPr_2dtp)^-$ anion existing separately. Some interatomic distances, such as S(6)···N(1), N(3)···S(5^{i}), S(5)···N(2^{ii}) (where the keys to the symmetry operations are: i: $-0.5+x$, $0.5-y$, $0.5+z$; ii: $1.5-x$, $-0.5+y$, $0.5-z$), are shorter than 3.5 Å; they may be hydrogen bonds, since the S···H–N hydrogen bond has been reported to be about 3.42 Å in length between S and N.[13]

The central metal atom of the complex is heptacoordinated and is in a pentagonal-bipyramidal geometry, where four sulfur atoms of two iPr_2dtp ligands and one oxygen atom of a bza ligand take the equatorial position, while two bza oxygen atoms from the two ends of the axis. The positional deviations of the coordinated sulfur and oxygen atoms, as well as of the central metal atom, from the average pentagon plane are: **1**. 0.095 Å at the maximum (0.055 Å in the average); **2**. 0.070 Å at the maximum (0.041 Å in average).

As is shown in Table 3, the bond lengths of the M–S pair of each coordinated ligand are approximately the same; however, M–S(1) and M–S(2) are significantly shorter than M–S(3) and M–S(4). The difference in the average M–S bond lengths of Complexes **1** and **2** is 0.029 Å, which is comparable with the difference in their ionic radii, Tb=1.040 and Er=1.004 Å.[14]

The bond lengths of the P–S pair of each ligand are approximately the same, too. Therefore, it is likely that the P=S double bonds of the ligands in both complexes are delocalized. Each Er–O bond length is shorter than that of the corresponding Tb–O by about 0.035 Å; this is also approximately the same as the difference in the ionic radii. The metal–oxygen bond length of the equatorial ligand (Er of Tb–O(300)) is slightly longer than those of the axial ligands in each complex, probably because of the steric effect of the vicinal sulfur atoms on the plane. The other bond lengths, as well as the bond angles of **2** are in good agreement with the corresponding values of **1**. The unit-cell volume of **2** is

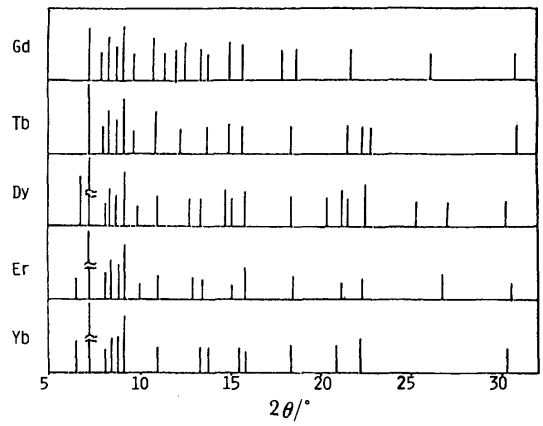

Fig. 3. X-Ray powder patterns of the five lanthanoid(III) complexes.

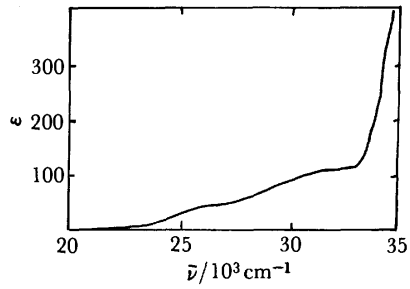

Fig. 4. Absorption spectra of the Yb(III) complex in an acetonitrile solution. (1.88 mmol dm^{-3})

larger than that of **1**, although the unit-cell volume of the series of isomorphous lanthanoid(III) complexes commonly decreases when the metal atomic number increases.[15–18]

The X-ray powder patterns of the gadolinium(III), terbium(III), dysprosium(III), erbium(III), and ytterbium(III) complexes, which have the same chemical formula, judging from the results of elemental analysis, are shown in Fig. 3. They can likely be divided into two groups on the base of their features; Gd(III) and Tb(III) make one group, and the others, another one. This is why we have analysed the two isomorphous structures of **1** and **2**.

In some lanthanoid complexes, extraordinary charge-transfer bands in the near-ultraviolet region have been reported.[2,5,19] The absorption spectra of the Yb complex in an acetonitrile solution are shown in Fig. 4. Although the solid is colorless, the solution is yellow in color, and a charge-transfer band is found at about 33000 cm^{-1}.

The authors wish to thank the Shin-Etsu Chemical Co., Ltd., for presenting the highly pure lanthanoid oxides. This work is partially supported by a Grant-in-Aid for Scientific Research (No. 57430011) from the Ministry of Education, Science, and Culture.

(Received April 9, 1984)

The M–O bond lengths and some bond angles of the acetato ligands in the title compounds were compared with each other using their structural data as obtained by the single-crystal X-ray diffraction method. With the increase in the atomic number of the central metal atom, the length of the weakest M–O bond in the bridge increases, even though all the other M–O bonds are shortened. This fact can be explained as follows: as the number of ligating oxygen atoms around the central metal atom is almost at a maximum in these complexes, the sharing space of the tenth coordinating atom on the coordination sphere decreases when the radius of the central metal atom is shortened as a result of the lanthanoid contraction effect.

It has already been reported by some authors that the light and heavy lanthanoid complexes of the same ligand are often in different geometries around the central metal atom, where the coordination number of the former is higher than that of the latter.[1,2,3] Therefore, it is expected that, even in a series of isomorphous lanthanoid complexes, some bond lengths change systematically in the order of the atomic number of the central metal. For example, if the number of the coordinating atoms around the central metal atom is large, some ligating atom can be expected to leave farther from the center when the atomic number of the metal increases and its space on the coordination sphere decreases; however, no investigations of such a phenomenon yet been reported. Exact data about the problem are hard to obtain by the comparison of the structural data of only a few discrete members of the isomorphous complexes, especially those measured by different authors.

On the other hand, the structure of the carboxylato complexes is an interesting theme of research because of their complicated structures. As has been shown by Catterick, the ligands are in many types of coordination modes in the complexes.[4] They are classified as follows (some types of bonding are shown schematically in Fig. 1; the numbering scheme in the figure is also used in Table 4 and in its explanations); i) One metal atom is coordinated to one of the carboxyl oxygen atoms. ii) One metal atom is coordinated to each of the carboxyl oxygen atoms, thus forming four-membered chelate ring. iii) Two metal atoms are coordinated to each oxygen atom of a carboxyl group, bridged by the ligand. In this paper, the *Z*, *E* expression is used to show their conformation; if the other carboxyl oxygen and ligating metal atoms are bonded on the same side of a C–O bond of a carboxyl group, it is named *Z*, and if they are on different sides, it is shown by *E*. Therefore, the bridges are classified into these three groups; a) *Z*, *E*, b) *E*, *E*, and c) *Z*, *Z*, conformations, which correspond with the *syn-anti*, *anti-anti* and *syn-syn* classifications of Catterick respectively.[4] iv) One oxygen atom (O(1)) of a carboxylato chelate around a metal atom (M) is also bonded to another metal atom (M′), and, as a whole, the ligand acts as a tridentate. There are many examples of this iv type bridges in lanthanoid carboxylates.[5,6,7,9–18] Moreover, such bridging has also been reported in some manganese[19] and copper complexes,[20,21] as well as in calcium acetate.[22] In many cases, bridges of this type are deformed, and usually the O(1)–M bond is longer than O(2)–M or O(1)–M′; sometimes it is the longest M–O bond in the complex. Therefore, this bond may be removed first when the area of the coordination sphere decreases.

The change in some bond lengths and bond angles of the bridging carboxylato ligands can be expected to be affected not only by the change in the radius of the central metal atom, but also by the mutual steric interactions of the ligands. Therefore, in order to study the effect of the size of the central metal atom

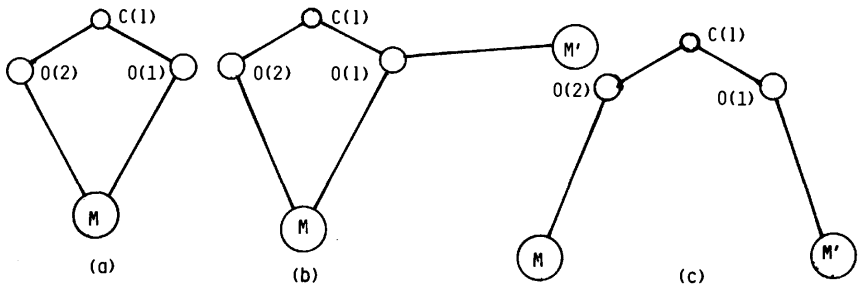

Fig. 1. Schematic presentation of ligands: a) chelating (type ii); b) tridentate type bridging (type iv); c) (*Z*,*Z*) type bridging (type iiic) carboxylate ligand.

on the coordination mode, avoiding the other steric influences, we have made a comparative structural study of the bridging acetato ligand, using the series of isomorphous complexes indicated in the title. Although Porai-Koshits has reported the structure of the cerium complex,[23] the data were not refined enough (R=0.177). Therefore, we have reinvestigated its structure, too.

Experimental

Synthesis of Guanidinium Di(μ-acetato)bis(triacetatoaqualanthanoidates(III)). The complexes in the title, where the metal is La, Ce, Pr, Nd, or Sm, were obtained by means of Canneri's method.[24] The crude product thus obtained was dissolved into water containing a little guanidinium acetate and then recrystallized by being left standing in a sillca-gel desiccator for several days. Although this synthetic method was also used in an attempt to obtain the same type of complexes of heavier lanthanoids, these attempts were not successful even when a large excess of guanidinium acetate was added; in these cases, only the guanidinium acetate and lanthanoid acetate (in their hydrated form) were precipitated separately. Anal. ($M_2C_{18}H_{40}O_{18}N_6$) M, C, H, N. (where M= La, Ce, Pr, Nd, or Sm).

Single-crystal X-ray Analysis. Crystals with dimensions of 0.3×0.3×0.4 mm³ of the lanthanum(III), cerium(III), and praseodymium(III), 0.4×0.4×0.3 mm³ of neodymium(III), and 0.3×0.3×0.3 mm³ of the samarium(III) complexes, were used for the measurement. All edges were ground off, but they were not shaped into spheres. They are isomorphous, and monoclinlc, with the space group $P2_1/n$; Z=2 for the formula $[(NH_2)_3C]_2[M_2(CH_3CO_2)_8(H_2O)_2]$. Other crystallographic data, some experimental conditions, and the final R values obtained by applying the anisotropic temperature factors,[25] are tabulated in Table 1.

The reflections were collected on a Rigaku AFC-6A automated four-circle diffractometer with graphite monochromated Mo $K\alpha$ radiation (0.7107 Å), at the scan speed 4° min⁻¹, by means of the θ-2θ scan technique. From the measured independent reflections, those with $(|F_o|)>3\sigma(|F_o|)$ were selected and were used for the calculations. The intensities were corrected for Lorentz and polarization factors, but no correction was made for absorption and extinction. All the calculations were carried out on a HITAC M-200H computer of the Computer Center of the University of Tokyo, using a local version of the UNICS program.[26] The atomic-scattering factors were taken from the table.[27]

Structure Determination. The structure of the lanthanum(III) complex was solved by the heavy-atom method. The positions of the central metal and some oxygen atoms were deduced from three-dimensional Patterson map, while all the other non-hydrogen atoms were found successively by repeated Fourier syntheses and by the block-diagonal least-squares method.

The structure of the other tetraacetato complexes were solved by assuming that their atomic coordinates were almost the same as those of the isomorphous lanthanum(III) complex. Therefore, at the first step, the final parameters for the lanthanum(III) complex were tentatively applied to them, and then they were refined as usual.

Results and Discussion

The final atomic parameters and their equivalent isotropic temperature factors are shown in Table 2, while some interatomic distances as well as bond angles are tabulated in Table 3. The perspective drawing of the complex around the central lanthanum atom, with the numbering scheme used in Tables 2 and 3, is shown in Fig. 2,[28] and the schematic bonding mode of the lanthanum(III) complex around a metal atom in Fig. 3.

The complex is in a dimer form. Each central-metal atom of the title complexes is deca-coordinated, being coordinated to ten oxygen atoms, and is in a distorted *cis*-bicapped cube (tetradecahedron) geometry including the weak M-O bonding from the bridging ligand. Each metal atom has three chelating acetato ligands, and each is bridged to the next metal atom by two "tridentate" acetato ligands.

In the titled complexes, as shown in Table 3, all the C-O bond lengths, as well as the O(n1)-C(n1)-O(n2) bond angles (where n=1, 2, 3, or 4), are not much different from each other, and they are almost the same as those of the other lanthanoid carboxylates.[5,6,11,12,15,18] All the M-O bond lengths of the same metal complex are about the same except for the long M-O(41), and the corresponding bond length of M-O(nn') (where n=1, 2, 3, or 4; n'=1 or 2) decreases depending on the order of the atomic number of the respective central metal, while that of M-O(41) increases in the same order.

Table 4 shows the selected bond lengths and bond angles of the coordinated carboxyl groups in the title complex as well as in some related lanthanoid carbox-

ylates. The numbering scheme of the atoms used in the table as well as in its explanation presented below is shown in Fig. 1.

Typical examples of some bond lengths and bond angles of the four membered chelate ring of the lanthanoid carboxylates are shown in Table 4 as the "ch" group. In many cases, the two M-O-C bond angles are not the same; they are about 90 and 95° respectively, where the M-O, which is about 3% longer than the other one, has the larger M-O-C angle. Usually the planarity of the chelate ring is good, although there are some exceptions.

As shown in Table 4, the bridging ligands in lanthanoid formates (Complexes 4 and 5 in Table 4) have forms a little different from those of the other carboxylates. A special *Z,E*-type bridge is found in them, where the M-O(2)-C(1) (*Z*-side) and M'-O(1)-C(1) (*E*-side) bond angles are about 140 and 145° respectively, and where both the M and M' atoms are almost on the carboxyl COO plane. The interatomic distance, M···O(1), from the *Z*-side metal to the *E*-side oxygen atom is about 3.8 Å, about 63% longer than the average of M-O(2) and M'-O(1), while the M···M' distance is about 6.0 Å. Typical *E,E*-type bridges are found in the same formates. They are about symmetric, and the M-O(2)-C(1) and M'-O(2)-C(1) bond

angles as well as the interatomic distances, M···O(1) and M′···O(2), are about the same; 129—132° and 4.51—4.53 Å respectively. The M···M′ distance is about 6.7 Å.

Typical examples of *Z,Z*-type bridge are shown as the *Z,Z* group in Table 4. As is shown in the table, this type of bridging is about symmetric in terms of bond lengths and bond angles: M–O(2) and M′–O(1); M···O(1) and M′···O(2); M–O(2)–C(1) and M′–O(1)–C(1), and M–O(1)–C(1) and M′–O(2)–C(1) are almost the same. However, in their real forms, M and M′ atoms are not strictly on the C(1), O(1), O(2) plane. The M···M′ distance is about 4.2···4.5 Å. As the M···O(1) distance is about 62% longer than the average of M–O(2) and M′–O(1), an effective bonding between them is not probable.

An idealized figure of the tridentate-type bridge, deduced from those of calcium acetate[22] and others, is shown in Fig. 1b; the ligand forms a chelate around the M atom, while another metal atom, M′, approaches the O(1) atom from the direction of the extension of O(2)···O(1); the M–O(2) and M′–O(1) bond lengths, as well as that of M–O(1) are not very different from each other; both of the metal atoms are almost on the carboxyl C(1), O(1), O(2) plane, and the expected C(1)–O(1)–M′ angle is about 150° (*E*-side). However, in many of the "tri"-type ligands shown in Table 4, M–O(2)–C(1) and M–O(1)–C(1) are each about 93—99°, the former commonly larger than the latter. The M–O(1) bond length is longer than M–O(2) or M′–O(1) by several per cent, the latter two being approximately the same, although M′–O(2) is much longer (more than 4 Å).

In the cases of more deformed tridentate-type bridges, they are classified separately in Table 4 as the "int"-group. They range from the one resembling a tridentate bridge to the one having almost the structure of the *Z,Z*-type bridge. In the "tri"-type bridge, the M′ atom is on the *E*-side, and in the *Z,Z*-type one, on the *Z*-side, although the C(1)–O(1)–M′ angle is about the same in both cases (140—150°). In the series of "int"-group members, the angle seems not to change in definite way, for the shift of the M′-atom position from the C(1), O(1), O(2) plane is irregular in them. On the other hand, the elongation of the M–O(1) length compared with the mean of the M–O(2) and M′–O(1) lengths increasing from 15 to 66%, the C(1)–O(2)–M bond angle increasing from 110 to 140°, and the C(1)–O(1)–M bond angle decreasing from 86 to 60°, they change in about the same order, while the position of the M′ atom moves from the *E* side to *Z* side, at least at the early stage of the series; their values of the typical tridentate- and the *Z,Z*-type bridges are 0 and 63%, 97 and 140°, and 92 and 60° respectively. Of course, there are some irregularities in some examples, especially when the positional deviations of the M and M′ atoms from the carboxyl C(1), O(1), O(2) plane are large. In the cases of the last four members of the "int"-group series, the elongation of the M–O(1) length is very large, almost the same as that of the *Z,Z*-type bridges, and no interaction between them can be expected; however, its symmetry in shape is not so good as in the *Z,Z*-type bridges.

The corresponding data from the ligands in the titled complexes are shown in the GL—GS column in Table 4. The bond lengths and bond angles of these complexes resemble those of the "int"-group ones. The deviations of their bond lengths and bond angles from the typical tridentate-type bridge are in the order of the increase on the atomic number of the central metal. Therefore, the bridge in the lanthanum complex has the most resemblance, and that of the samarium, the least similarity, to the tridentate bridge. However, even in the samarium complex, the elongation percentage of M–O(1) is about 26%, and the M–O(2)–C(1) and M–O(1)–C(1) angles are 111.9 and 82.3° respectively; these values correspond with those of some early members in the "int"-group series shown in the table. Therefore, the M–O(1) bonding of the titled complexes is expected to be effective, although such bond may be weaker than those of the typical tridentate ones and the bonds are weakened in the order of the atomic number of the central metal. As the geometrical environments of the bridge, except for the size of the central metal atom, are about the same in all these isomorphous complexes, this change in the M–O(1) length can be expected to be concerned mainly with the contraction of the central-metal atomic radius.

Although this is only one example, the authors have recognized that, in a series of lanthanoid complexes where the coordination number of the central metal atom is large, the weakest bonding is continuously weakened depending on the decrease in the coordination sphere; this fact can also be expressed by saying that the coordination number of the central metal atom of such complexes decreases continuously depending on the increase in the atomic number of the central metal.

The authors wish to thank The Shin-Etsu Chemical Co., Ltd., for aiding this study by presenting us with the highly pure lanthanoid oxides. The helpful discussions about this research with Mr. Kiyofumi Nagai and Miss Reiko Nakamura are also gratefully acknowledged. The present work was partially supported by a Grant-in-Aid for Scientific Research (No. 57430011) from the Ministry of Education, Science and Culture.

Ion Exchange from a Nonaqueous Solution. Zinc (II) Bromide and Iodide in Ethylene Glycol

Tetsu KUMAGAI
Himeji Institute of Technology, Shosha, Himeji, Hyogo 671-22
(Received March 14, 1984)

The distribution behavior of the zinc ion in sodium bromide and iodide solutions between the cation-exchange resin for forced-flow liquid chromatography and the absolute or aqueous ethylene-glycol phase was investigated radiometrically. From the experimental data, consecutive complex formation constants for zinc bromide and iodide in the glycol have been calculated by the nonlinear least-squares method. The results are as follows: in absolute glycol $\beta_1^{Br}=2.60$ and $\beta_2^{Br}=3.91$ for zinc bromide, $\beta_1^{I}=2.36$ and $\beta_2^{I}=3.04$ for zinc iodide; in 5 wt% aqueous glycol $\beta_1^{Br}=2.30$, $\beta_2^{Br}=3.32$, and in 10 wt% aqueous glycol, $\beta_1^{Br}=1.87$, $\beta_2^{Br}=2.78$, respectively.

There have been many investigations of the complex formation of metal ions in a pure or aqueous organic solvent, especially using such electrochemical methods as the emf, electric conductivity, and ion-selective electrode techniques. However only a little work seems to have been done on complex formation in a nonaqueous solution using a distribution method between the two phases, for example, the solvent-extraction and ion-exchange techniques. Previously, the solvent-extraction method between the polar organic and nonpolar organic phases has been studied in order to gain knowledge that the metal-ion equilibrium in a nonaqueous system.[1-6] However there are not many polar solvents immiscible with the nonpolar solvents. In contrast to the solvent extraction, the ion-exchange method seems to be hopeful because some of the exchange resins for the forced-flow liquid chromatography can resist many of the organic solvents and so the distribution equilibrium can be easily reached between the resin and the metal ions.

In previous papers,[7,8] the present author and his co-workers have reported data on the formation constants of zinc chloride in pure and aqueous ethylene glycol, and in aqueous methanol, obtained using the ion-exchange method. The aim of the present work is to extend our research to bromide and iodide complexes of zinc in pure and aqueous ethylene glycol using the ion-exchange method.

Experimental

Materials and Apparatus. Zinc-65 was supplied as the chloride in hydrochloric acid by New England Nuclear, Boston, Mass., U. S. A. The radioactive tracer was converted into perchlorate by the addition of perchloric acid, followed by repeated evaporation. It was dissolved with ethylene glycol. Reagent-grade ethylene glycol was dried on zeolite and distilled under reduced pressure.

The cation-exchange resin, Hitachi custom ion-exchange resin 2611, for the liquid chromatograph was washed with 1 mol dm^{-3} hydrochloric acid and converted into the Na^+ form by the use of a 0.2 mol dm^{-3} sodium-chloride solution. After having been washed with pure water and dried in a vacuum, the resin was stored over phosphorus pentaoxide in a desiccator. The stock zinc solution was prepared by dissolving dry zinc oxide with perchloric acid, evaporating to near dryness, and diluting it with ethylene glycol.

The procedure of ion-exchange was essentially the same as that described in a previous paper.[8] Sixteen milliliters of an ethylene-glycol solution of sodium halide containing sodium perchlorate, zinc perchlorate (1×10^{-6} mol dm^{-3}) with radioactivities, and perchloric acid (1×10^{-5} mol dm^{-3}) were stirred together with portions (10—50 mg) of the dry resin, in a 30-cm^3 centrifugal tube equipped with a grass stopper by using a magnetic stirrer for 12 h in a thermostat at 25°C. After the equilibrium had been attained, the solution and the resin phase were separated by centrifugation. Two milliliters of the solution phase were pipetted out, and the γ-activities were counted with a well-type scintillation counter, Metro Electronics Model PBW-6.

Results and Discussion

The distribution of zinc in present system was practically independent of the range of zinc perchlorate (5×10^{-7}—1×10^{-4} mol dm^{-3}). Therefore in subsequent studies, 1×10^{-6} mol dm^{-3} of zinc perchlorate in an ethylene-glycol solution was used.

Even stirring for 30 min was found to be enough for the attainment of the distribution equilibrium. In the present studies, however stirring for 12 h was adopted, because ethylene glycol has a somewhat high viscosity and the resin was a little difficult to disperse in the glycolic solution. The influence of the cation-exchange resin on the distribution of zinc was examined with regard to resin amounts of 1.25, 2.5, and 5.0 g dm^{-3}, while keeping the other variables constant. As is to be expected from Eq. 10, a linear relationship between log D^* and the resin amount was observed, with a slope of about 1, in various bromide concentrations (Fig. 1).

The equilibria in the ethylene glycol phase are expressed as follows:

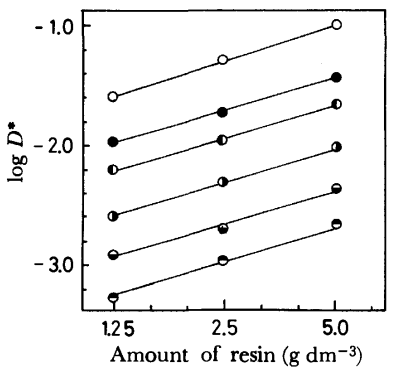

Fig. 1. Influence of resin amount in sodium bromide system (pure ethylene glycol).
Concentration of sodium bromide; ○: 0.03 mol dm^{-3}, ●: 0.05 mol dm^{-3}, ◐: 0.07 mol dm^{-3}, ◑: 0.10 mol dm^{-3}, ◒: 0.15 mol dm^{-3}, ◓: 0.20 mol dm^{-3},

$$Zn^{2+} + 2X^- = ZnX_2 \quad (\beta_n^X), \quad (1)$$

$$Zn^{2+} + 2Y^- = ZnY_2 \quad (\beta_n^Y), \quad (2)$$

$$ZnX^+ + Y^- = ZnXY \quad (K_m^Y), \quad (3)$$

$$ZnY^+ + X^- = ZnXY \quad (K_m^X), \quad (4)$$

$$Zn^{2+} + Na_2R = ZnR + 2Na^+ \quad (\beta_n^R), \quad (5)$$

$$ZnX^+ + Na_2R = ZnXNaR + Na^+ \quad (K_m^{RX}), \quad (6)$$

$$ZnY^+ + Na_2R = ZnYNaR + Na^+ \quad (K_m^{RY}). \quad (7)$$

Here, X^- denotes the halide ion, Y^- shows ClO_4^-, and R stands for the two functional groups in the resin.

The total concentration of zinc in the resin phase, $(C_{Zn})_R$, is defined as follows:

$$(C_{Zn})_R = m_{ZnR} + m_{ZnXNaR} + m_{ZnYNaR}. \quad (8)$$

Here m stands for the weight molarity.

The total zinc concentration in the glycol phase at equilibrium, $(C_{Zn})_E$, is given by:

$$(C_{Zn})_E = C_{Zn} + C_{ZnX} + C_{ZnX_2} + C_{ZnY} + C_{ZnY_2} + C_{ZnXY}$$
$$= (m_{Zn} + m_{ZnX} + m_{ZnX_2} + m_{ZnY} + m_{ZnY_2} + m_{ZnXY})/\rho. \quad (9)$$

Here ρ is the density of the glycolic solution.

The distribution coefficient, D, is defined as:

$$D = (C_{Zn})_R/(C_{Zn})_E. \quad (10)$$

Equations 8—10 are rewritten using Eqs. 1—7 as follows:

$$(C_{Zn})_R = \left(\frac{\gamma_{Zn}\cdot\gamma_{Na_2R}\cdot m_{Zn}}{\gamma_{ZnR}\cdot\gamma_{Na}^2\cdot m_{Na}^2}\cdot\beta_2^R + \frac{\gamma_{Zn}\cdot\gamma_X\cdot\gamma_{Na_2R}\cdot m_{Zn}\cdot m_X}{\gamma_{Na}\cdot\gamma_{ZnXNaR}\cdot m_{Na}}\cdot K_m^{RX}\cdot\beta_1^X + \frac{\gamma_{Zn}\cdot\gamma_Y\cdot\gamma_{Na_2R}\cdot m_{Zn}\cdot m_Y}{\gamma_{Na}\cdot\gamma_{ZnYNaR}\cdot m_{Na}}\cdot K_m^{RY}\cdot\beta_1^Y\right)\cdot m_{Na_2R}, \quad (8')$$

$$(C_{Zn})_R = \left(\gamma_{Zn}\cdot m_{Zn} + \frac{\gamma_{Zn}\cdot\gamma_X\cdot m_{Zn}\cdot m_X}{\gamma_{ZnX}}\cdot\beta_1^X + \frac{\gamma_{Zn}\cdot\gamma_X\cdot m_{Zn}^2\cdot m_X^2}{\gamma_{ZnX_2}}\cdot\beta_2^X + \frac{\gamma_{Zn}\cdot\gamma_Y\cdot m_{Zn}\cdot m_Y}{\gamma_{ZnY}}\cdot\beta_1^Y + \frac{\gamma_{Zn}\cdot\gamma_Y^2\cdot m_{Zn}\cdot m_Y^2}{\gamma_{ZnY_2}}\cdot\beta_2^Y + \frac{\gamma_{Zn}\cdot\gamma_X\cdot\gamma_Y\cdot m_{Zn}\cdot m_X\cdot m_Y}{\gamma_{ZnXY}}\cdot\beta_1^X\cdot K_m^Y\right)\Big/\rho, \quad (9')$$

$$D = m_{Na_2R}\cdot\rho\cdot\left(\frac{\beta_2^R}{\gamma_{Na}^2\cdot m_{Na}^2} + \frac{\gamma_X\cdot m_X}{\gamma_{Na}\cdot m_{Na}}\cdot K_m^{RX}\cdot\beta_1^X + \frac{\gamma_Y\cdot m_Y}{\gamma_{Na}\cdot m_{Na}}\cdot K_m^{RY}\cdot\beta_1^Y\right)\Big/(1 + \sum\gamma_X^n\cdot m_X^n\cdot\beta_n^X/\gamma_{ZnX_n} + \sum\gamma_Y^n\cdot m_Y^n\cdot\beta_n^Y/\gamma_{ZnY_n} + \gamma_X\cdot\gamma_Y\cdot m_X\cdot m_Y\cdot\beta_1^X\cdot K_m^Y/\gamma_{ZnXY}). \quad (10')$$

Here, γ stands for the activity coefficient of each ion, γ_{Na_2R}, γ_{ZnR}, γ_{ZnXR}, and γ_{ZnYR} can be regarded as 1, and $\gamma_{ZnX}=\gamma_{ZnY}$, $\gamma_{ZnX_2}=\gamma_{ZnY_2}=\gamma_{ZnXY}$. γ_X, γ_Y, γ_{Zn}, and γ_{Na} are calculated, on the basis of Debye-Hückel's theory, as;

$$\ln\gamma_X = \ln\gamma_\pm^{1/2} = -\left(\frac{A|Z^+Z^-|I^{1/2}}{1+BdI^{1/2}}\right)^{1/2}, \quad (11)$$

$$A = 8.1622\times\frac{\rho}{\varepsilon^{3/2}}\times10^2 \quad B = 2.9127\times\left(\frac{\rho}{\varepsilon}\right) \text{ at } 25\,^\circ\text{C}. \quad (12)$$

Here, d denotes the parameter of the ionic radius (Å unit), I represents the ionic strength; m_{Na_2R} is expressed as g resin (Na-form)/dm^3 ethylene glycol, and ε is the dielectric constant of ethylene glycol. The dielectric constant of 5% aqueous ethylene glycol was obtained by the interpolation of the constants of 100, 90, and 80% ethylene glycol.[9] In the Zn^{2+}–X–Y system, the sum of m_X and m_Y was kept constant, and sodium halide and sodium perchlorate are assumed to dissociate perfectly into ions in the glycolic solution. Therefore, the $m_{Na}=m_X+m_Y$ holds good. Hence, Eq. 10′ can be transformed as a function of the halide-ion weigth molarity, m_X. As it is assumed that β_2^R is much greater than β_1^R, β_1^R can be disregarded.

In the zinc halide system, Eq. 10′ can be converted into the following fractional functions:

$$D^* = \frac{P_{(1)}+P_{(2)}L^2}{1+P_{(3)}L+P_{(4)}L^2}. \quad (13)$$

Here, $L=\gamma_X\cdot m_X$, $D^*=D\cdot\gamma_{Na}^2\cdot m_{Na}^2/\rho$, $P_{(1)}=\beta_2^R\cdot m_{Na_2R}$, $P_{(2)}=\beta_1^X\cdot K_m^{RX}\cdot m_{Na_2R}$, $P_{(3)}=\beta_1^X/\gamma_{ZnX}$ and $P_{(4)}=\beta_2^R$.

In the zinc halide perchlorate system, Eq. 10′ can be reduced to:

$$D^* = \frac{(P_{(1)}+P_{(2)}m_X+P_{(3)}m_Y)}{1+P_{(4)}m_X+P_{(5)}m_X^2+P_{(6)}m_Y+P_{(7)}m_Y^2+P_{(8)}m_X\cdot m_Y}. \quad (14)$$

Here $D^*=D\cdot\gamma_{Na}^2\cdot m_{Na}^2/\rho$, $P_{(1)}=m_{Na_2R}\cdot\beta_2^R$, $P_{(2)}=m_{Na_2R}\cdot\beta_1^X\cdot K_m^{RY}\cdot\gamma_X\cdot\gamma_{Na}\cdot m_X\cdot m_{Na}$, $P_{(3)}=m_{Na_2R}\cdot\beta_1^Y\cdot K_m^{RY}\cdot\gamma_{Na}\cdot\gamma_Y\cdot m_{Na}\cdot m_Y$, $P_{(4)}=\gamma_X\cdot\beta_1^X/\gamma_{ZnX}$, $P_{(5)}=\gamma_X^2\cdot\beta_2^X$, $P_{(6)}=\gamma_Y\cdot\beta_1^Y/\gamma_{ZnY}$, $P_{(7)}=\gamma_Y^2\cdot\beta_2^Y$, and $P_{(8)}=\gamma_X\cdot\gamma_Y\cdot m_X\cdot m_Y\cdot\beta_1^X\cdot K_m^Y$.

Each activity coefficient, γ, was calculated from Eqs. 11 and 12 as a function of the ionic strength. These coefficients have a constant ionic strength.

To obtain the parameters, $P_{(i)}$, of Eqs. 13 and 14, we used the computer program of the nonlinear least-squares method, a modified Gauss-Newton method; the valuses obtained by this procedure were then tested by the aid of the curve-fitting method using computer graphics.

The dependence of log D^* on the bromide activity calculated using Eq. 11 in pure and aqueous ethylene glycol is shown in Figs. 2—4. The figures show that the distribution of zinc decreases precipitiously in the lower activity range of bromide and gradually in the higher range. The stability constants obtained by using the program described above are listed in Table 1.

Figure 5 indicates the dependence of the zinc distribution on the iodide activity in pure ethylene glycol in 1.25, 2.5, and 3.75 g resin per 1 dm^3 glycol. Though the zinc distribution decreases abruptly with the increase in the iodide activity, much as in the case of the bromide system, the magnitude of the decrease in the iodide system is somewhat less than that in the bromide one. This means that zinc-iodide complexes are less stable than the corresponding bromide complexes. This results are listed in Table 1. The blending of water for pure ethylene glycol leads to considerably large errors in the calculations of the stability constants of zinc iodide because of a lowering of the stability.

The variation in the zinc distribution in the presence of both bromide and perchlorate ions was examined in order to make the ionic strength in the glycol solution constant. The distribution coefficient of zinc is plotted

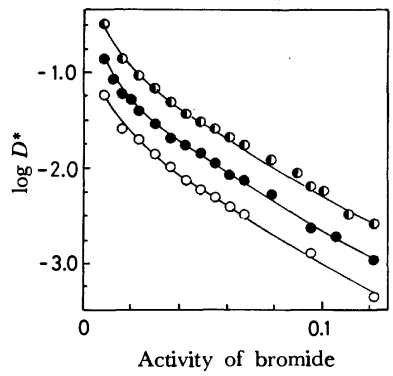

Fig. 2. Distribution coefficients of zinc bromide system in the pure glycolic solution.
amount of resin; O: 1.25 g dm^{-3}, ●: 2.50 g dm^{-3}, ◐: 5.00 g dm^{-3}.

amount of resin; O: 1.0 g dm^{-3}, ●: 2.0 g dm^{-3}.

in Fig. 6 as a function of the concentration of bromide and perchlorate ions. As there exist 8 parameters in Eq. 14 in the present system, it is very difficult to obtain exact values. Only the value of K_m can be calculated; it is listed in Table 1. Similally, in the zinc iodide-perchlorate system, exact results were not obtained.

The decreasing order of stability of zinc halide complexes in ethylene glycol is as follows; Cl>Br>I≃ ClO_4. Also the stability constants in ethylene glycol are somewhat smaller than those in methanol.

Preparation of Ni- or Pt-Containing Cyclic Esters by Oxidative Addition of Cyclic Carboxylic Anhydrides and Their Properties

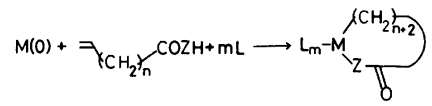
Kenji SANO, Takakazu YAMAMOTO,* and Akio YAMAMOTO

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227

(Received March 21, 1984)

Metal containing cyclic ester complexes, $L\overline{NiCHR^1CHR^2COO}$ (L=1,2-bis(diphenylphosphino)ethane (dpe) or 2,2′-bipyridine (bpy); R^1, R^2=H or CH_3) and $L_n\overline{PtCOCH_2CH_2COO}$ (L=tricyclohexylphosphine (PCy_3) or dpe; n=1 or 2), have been prepared by oxidative addition of cyclic carboxylic anhydrides to zero-valent metal complexes. These complexes have been characterized by elemental analysis and spectroscopies (IR as well as ^{1}H-, ^{13}C{^{1}H}-, and ^{31}P{^{1}H}-NMR) and chemical reactivities. Rate of the oxidative addition of succinic anhydride to Ni(bpy)(cod) (cod=1,5-cyclooctadiene) is expressed by a second order rate equation, $R=k$[Ni(bpy)(cod)][succinic anhydride], and temperature dependence of k gives the activation energy of 68 kJ mol^{-1}. The reaction of methylsuccinic anhydride with $Ni(cod)_2$ in the presence of tertiary phosphine or bpy affords two isomers, $L_n\overline{NiCH_2CH(CH_3)COO}$ and $L_n\overline{NiCH(CH_3)CH_2COO}$, corresponding to two modes of C–O bond cleavage in methylsuccinic anhydride promoted by Ni; dependence of the ratio between the two isomers on the kind of ligand added and reaction conditions has been examined.

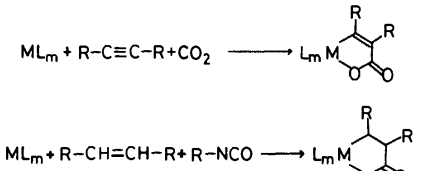
Metallacycles are regarded as key intermediates in numerous metal-catalyzed reactions.[1] Especially, much attention has been paid to the role of the metallacycles in metathesis[2] and cycloaddition[3] of olefins and isolation of several metallacycles consisting of transition metal and hydrocarbons has been reported. However, there have been only few reports concerning with the metallacycles containing functional groups, which have potential value in synthetic chemistry. Our research group has reported preparation of metal-containing cyclic amide and ester type complexes by the reaction of zero-valent metal complexes with unsaturated amides and acids.[4,5a]



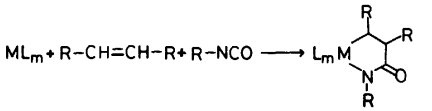
(1)

n=1,0 M=Ni, Pd; Z=NH, O
m=1, 2

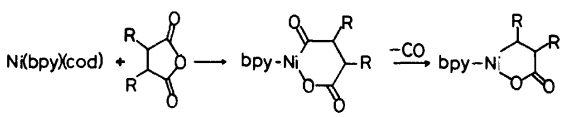
Other research groups also, independently from our work described above, reported preparation of similar metallacycles through two different synthetic routes: (i) Cycloaddition of olefin or acetylene with carbon dioxide or isocyanate (Eq. 2)[6] and (ii) oxidative addition of cyclic carboxylic anhydrides.[7]



(2a)



(2b)



(3)

bpy: 2,2′-bipyridine, cod: 1,5-cyclooctadiene

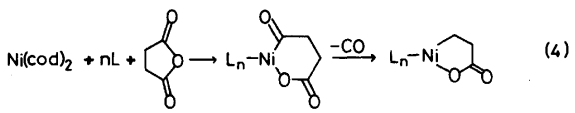
However, as for the latter preparative method (Eq. 3) characterization of the complexes obtained is based only on their rough elemental analysis and IR spectra, and more unequivocal characterization of the complexes by other instrumental analysis and chemical reactivities is required.

In order to develop the chemistry of the transition metal-containing cyclic ester type complexes and to establish the mechanism of the oxidative addition of cyclic carboxylic anhydrides to transition metal complexes, we have expanded this oxidative addition reaction by using other transition metal complexes as well as other cyclic carboxylic anhydrides and characterized the isolated complexes by elemental analysis, spectroscopy (IR and NMR), and chemical reactivities. Upon confirmation of the structures of these complexes, we examined kinetics of oxidative addition of cyclic carboxylic anhydrides to the Ni(0) complexes.

Oxidative addition of acyclic carboxylic anhydrides to Ni(0) and Pd(0) complexes has been already reported from our research group,[5c] and some of the data described in this paper have been reported in communication form.[5b]

Results and Discussion

Oxidative Addition of Cyclic Carboxylic Anhydride to Zero-valent Nickel Complexes. Succinic Anhydride: The reaction of Ni(0) with succinic anhydride in the presence of appropriate ligands such as bpy and PCy_3 gives five membered nickel-containing cyclic esters, **2**.



(4)

1 **2**

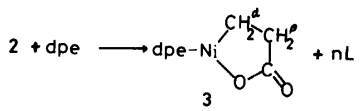
1a: bpy 2a: bpy

1b: PR_3 2b: PR_3

Complex **2** is considered to be formed through oxidative addition of succinic anhydride to Ni giving six-membered 2-oxo-nickel-containing cyclic ester **1** first followed by its decarbonylation. Carbon monoxide thus released is trapped by Ni(0) complexes to afford $Ni(CO)_2L_n$, (see Experimental); therefore stoichiometry of the formation of **2** seems to be expressed by the following equation,

$$3Ni(cod)_2 + (2n+n')L + \text{succinic anhydride} \longrightarrow \mathbf{2}\,\mathbf{2} + Ni(CO)_2L_{n'} \quad (5)$$

Uhlig and his coworkers reported the isolation of **1**a,[7b] however our attempts to isolate the intermediate complex **1**a have not been successful. High sensitivity to air and/or low solubility of **2** prevented its full characterization, and thus **2** has been converted into a stable and soluble dpe complex by ligand exchange reaction,



(6)

dpe : 1,2 -bis(diphenylphosphino)ethane

Use of dpe-d_4, $Ph_2PCD_2CD_2PPh_2$, affords **3**-d_4. In our previous work we observed that Ni-containing cyclic ester type complexes having dpe ligand have high stability and solubility in solvents,[4] and dpe has much higher coordinating ability than bpy and monodentate phosphine toward divalent organonickel complexes.[8] Attempts to prepare **3** directly according to Eq. 4 was not successful presumably due to formation of inert $Ni(dpe)_2$.

Table 1 summarizes the analytical data, yields, and color of **3** and related complexes. Figure 1 shows the ^{1}H-NMR spectrum of **3**. Its NMR data, together with those of other related complexes are summarized in Table 2. The coupling patterns of H^α and H^β have been analyzed by homodecouplings. Magnitudes of the

coupling constants between protons as well as proton and ^{31}P are reasonable for the metallacyclic structure shown above. Figure 1 shows magnetic equivalence of the two H^{α}'s and H^{β}'s due to planarity of Ni-containing 5-membered ring or rapid steric interconversion of 5-membered ring. Figure 2 shows the ^{13}C{^{1}H}-NMR spectrum of **3**. The signals of the CH_2 carbons of dpe ligand are assigned unequivocally by comparing the ^{13}C{^{1}H}-NMR spectrum of **3** with that of **3**-d_4. The other signals are assigned on the basis of their chemical shifts and magnitudes of the ^{13}C-^{31}P coupling constants. The appearance of the H^{α} and $\underline{C}H_2^{\alpha}$ signals at considerably high magnetic fields in the ^{1}H- and ^{13}C{^{1}H}-NMR spectra, respectively, indicates the presence of the CH_2 group directly bonded to nickel. IR spectrum of the complex **3** shows a strong $\nu_{(C=O)}$ band at 1640 cm^{-1}.

The reaction of complex **3** with CO gives succinic anhydride and nickel carbonyl complex. The result not only supports the structure shown above but also

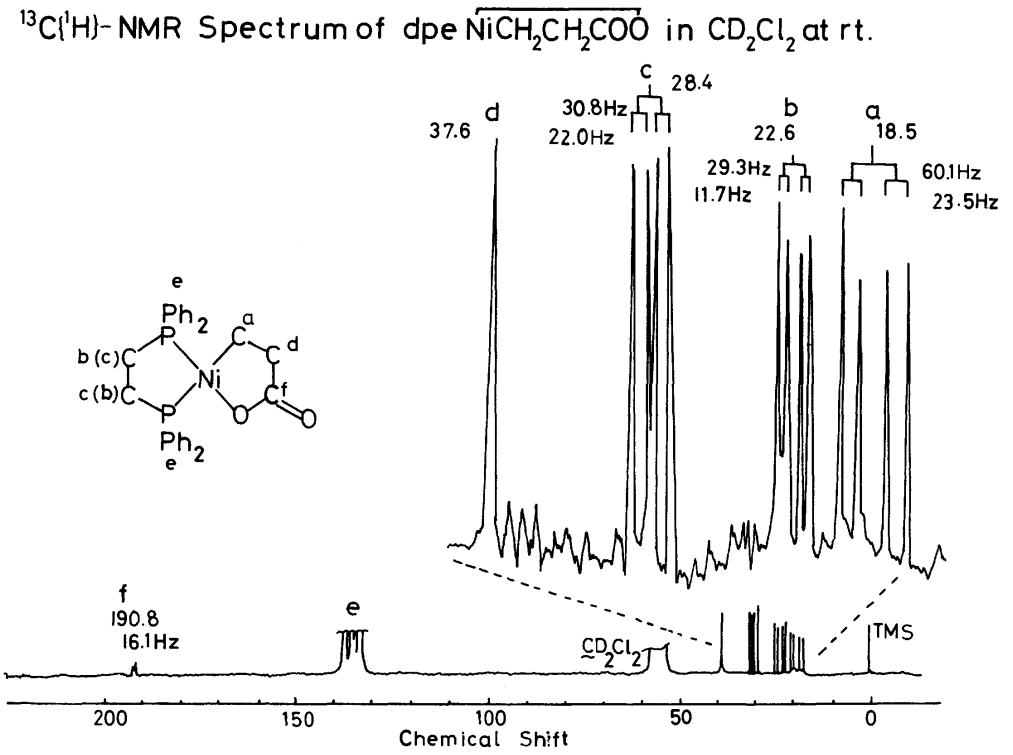

Fig. 2. $^{13}C\{^1H\}$-NMR spectrum of **3** in CD_2Cl_2.

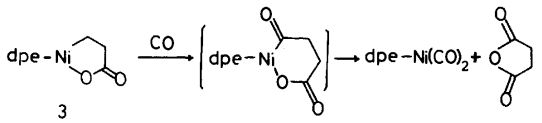
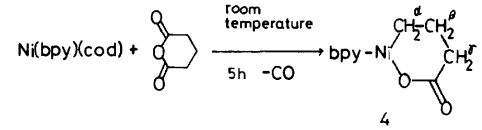
reveals reversibility of the decarbonylation reaction and the oxidative addition.



(7)

Results of reaction of metal-containing cyclic complexes with CO are summarized in Table 3.

Glutaric Anhydride: Reaction of glutaric anhydride with Ni(bpy)(cod) in THF gives a new six-membered ring complex, **4**.



(8)

CO released is trapped as $Ni(bpy)(CO)_2$ similarly to the case of reaction with succinic anhydride. Complex **4** is very air sensitive but has a moderate solubility in organic solvents. ^1H-NMR spectrum of **4** shows three groups of signals of the methylene groups of **4** with the same intensity at 0.8, 1.3, and 2.2 ppm in CD_2Cl_2. The NMR signals are somewhat broadened possibly by a paramagnetic character of **4**, contamination with paramagnetic decomposition product(s) of **4** or rapid conformational change of the six-membered ring of **4**. Reaction of **4** with CO affords glutaric anhydride in 29% yield. On treatment with maleic anhydride in CH_2Cl_2 **4** gives a β-elimination product, 3-butenoic acid, in quantitative yield. These observations support the above six-membered structure of **4**.

Thermal decomposition of complex **4** in solid state or in a CH_2Ph_2 solution above 160 °C releases CO_2 and propylene in 20—30% yield, demonstrating occurrence

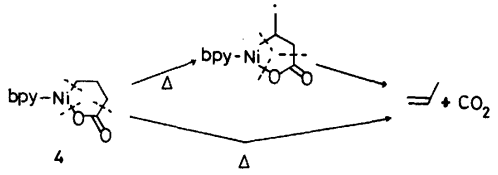
11	No reaction

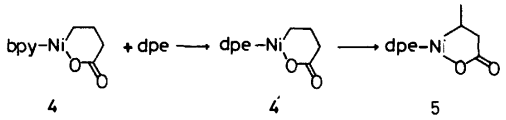
a) Identified by IR.

of the following bond cleavage in six-membered ring or ring contracted five-membered ring.



(9)

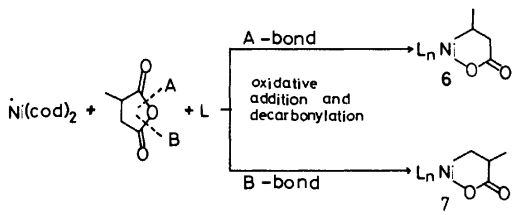
Addition of dpe to the solution of complex **4** gives a five-membered complex **5** in a high yield, demonstrating that complex **4'** has been completely isomerized to the five membered complex **5** under the experimental conditions.[5a]



(10)

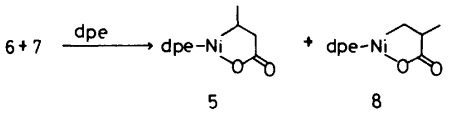
Factors controlling the ring contraction will be reported elsewhere.

Methylsuccinic Anhydride: Oxidative addition of methylsuccinic anhydride to Ni(bpy)(cod) gives two isomeric complexes, **6** and **7**, corresponding to two modes (A or B) of the oxidative addition.



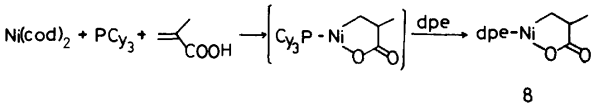
(11)

The ratio of **6** to **7** was determined by measuring intensity of $^{31}P\{^1H\}$-NMR signals of complexes **5** and **8** after ligand exchange reaction with dpe. The **6**/**7** ratio varies depending on the ligand employed and the reaction temperature. The results are given in Table 4.



(12)

Complex **8** was independently prepared according to the following reaction.



(13)

PCy_3 : tricyclohexylphosphine

The new complex **8** is characterized by elemental analysis, IR- and NMR (^1H-, $^{13}C\{^1H\}$-, and $^{31}P\{^1H\}$-) spectroscopy, and chemical reactivities. Coupling patterns observed in ^1H- and $^{31}P\{^1H\}$-NMR spectra are similar to those observed in ^1H- and $^{31}P\{^1H\}$-NMR spectra of the previously reported nickel-containing cyclic amides complex (dpe-$\overline{NiCH_2CH(CH_3)CONH}$) prepared from methacrylamide.[4] The NMR data are included in Table 2. Reaction of complex **8** with CO gives methylsuccinic anhydride in a quantitative yield as shown in Table 3. Table 4 summarizes effect of ligand added and reaction conditions on the distribution of products, **6** and **7**, which are formed by cleavage of A- and B-bonds, respectively. Examination of Table 4 clearly indicates that the oxidative addition involving the B-bond cleavage proceeds preferentially to the oxidative addition with the A-bond cleavage. This seems to be attributable to steric influence of the methyl substituent rather than electronic influence of the methyl substituent. When bpy or 4,4′-dimethyl-2,2′-bipyridine is used as ligand, the ratio of **7** against **6** increases with lowering of the reaction temperature, indicating that activation energy for the oxidative addition of the B-bond is smaller than that of the A-Bond.

Kinetics of the Oxidative Addition: Oxidative addition of succinic anhydride to Ni(bpy)(cod) is followed by observing change of visible spectrum which shows clear isosbestic points. The reaction obeys first order kinetics concerning the concentration of Ni(bpy)(cod) as shown in Fig. 3.

$$-\frac{d[Ni(bpy)(cod)]}{dt} = k'[Ni(bpy)(cod)]. \quad (14)$$

The dependence of the pseudo-first-order rate constant k' on the concentration of succinic anhydride is shown in Fig. 4, which demonstrates that k' is proportional

a) 4, 4′-dimethyl-2,2′-bipyridine.

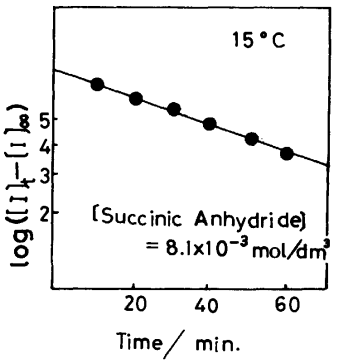

Fig. 3. First-order plot for the reaction of Ni(bpy)-(cod) with succinic anhydride.

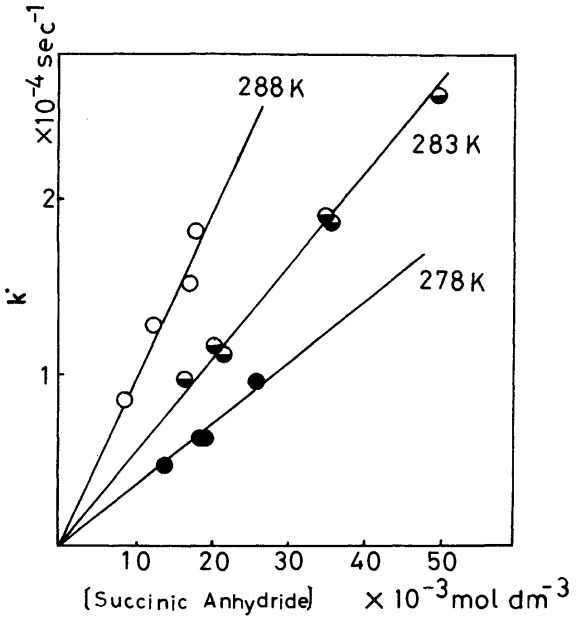

Fig. 4. Dependence of k' on concentration of succinic anhydride.

to [succinic anhydride]. Thus, the rate of reaction is expressed by second-order rate equation,

$$-\frac{d[Ni(bpy)(cod)]}{dt} = k[Ni(bpy)(cod)][\text{succinic anhydride}]. \quad (15)$$

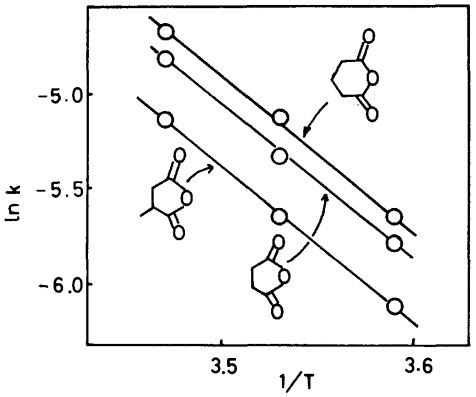

Fig. 5. Arrhenius plot of the rate constant.

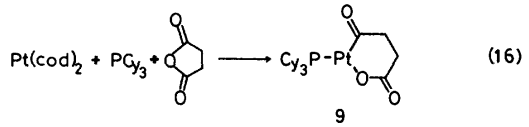
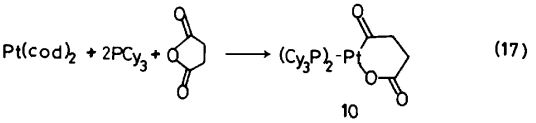
Similar second-order rate equations are also obtained for other cyclic carboxylic anhydrides. From the Arrhenius plot of k against $1/T$, the activation energy for the oxidative addition of cyclic carboxylic anhydride to Ni(bpy)(cod) is estimated as shown in Table 5. The $\Delta H^{\ddagger}$ values obtained for the present oxidative addition of cyclic carboxylic anhydrides are considerably smaller than the $\Delta H^{\ddagger}$ value (88 kJ mol^{-1})[8] obtained for the oxidative addition of phenyl propionate to Ni(0) complex, indicating that the oxidative addition of cyclic carboxylic anhydride to Ni(0) is an energetically easier process than the oxidative addition of ester to Ni(0).

Oxidative Addition to Zero-valent Platinum. A reaction of $Pt(cod)_2$ with a mixture of PCy_3 (1 mol/$Pt(cod)_2$) and succinicanhydride (1 mol/$Pt(cod)_2$) in THF at room temperature affords a white insoluble complex, which is considered to have the following platinum-containing cyclic structure as judged from its IR spectrum and analytical data (Table 1). When 2 mol of PCy_3 per mol of $Pt(cod)_2$ is added, the reaction affords a similar platinum cyclic complex **10** having two PCy_3 ligands.

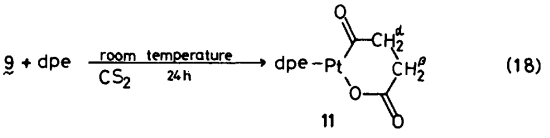


(16)



(17)

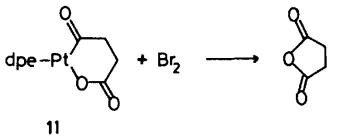
Low solubility of these complexes presumably due to its polymeric structure prevented analyzing their structures by NMR spectroscopy. However, a ligand exchange reaction with dpe in CS_2 gives a soluble dpe-coordinated complex **11**.



(18)

By using dpe-d_4, **11**-d_4 is prepared.

IR spectrum of complex **9** shows two strong bands at 1650 cm^{-1} and 1560 cm^{-1} assignable to $\nu_{(C=O)}$ of the acyl group and $\nu_{(C=O)}$ of the carboxylato group. These two peaks overlap in IR spectra of **10** and **11**. NMR data of **11** are included in Table 2, and consistent with the above structure. Appearance of the peak of the acyl carbon at 240.3 ppm in $^{13}C\{^1H\}$-NMR spectrum as well as the appearance of all H and $\underline{C}H_2$ signals at relatively low magnetic fields in the ^1H- and $^{13}C\{^1H\}$-NMR spectra, respectively, indicates that the decarbonylation has not taken place, in contrast to the analogous nickel complex **1** which undergoes the ready decarbonylation. Reaction of **11** with Br_2 affords the reductive elimination product, succinic anhydride, in 27% yield.



(19)

These observations support the non-decarbonylated 2-oxo-platinum-containing cyclic structure shown above.

When other ligands (bpy, PPh_3, $P(CH_2Ph)_3$, $PMePh_2$, dpe) are added to the mixture of $Pt(cod)_2$ and succinic anhydride, oxidative addition did not take place even at elevated temperatures. Blake and his coworkers[7] reported oxidative addition of perfluorinated succinic anhydride to $Pt(PPh_3)_2(C_2H_4)$.

In contrast to the Ni(0) and Pt(0) complexes, Pd(0) complexes ($Pd(PCy_3)_2$ and bis(1,5-diphenyl-1,4-pentadien-3-one) palladium (0))[9] did not show any apparent change on interaction with the cyclic carboxylic anhydrides at room temperature. A coordinatively unsaturated Rh(I) complex, $RhCl(PPh_3)_3$, showed no apparent change on the interaction with the cyclic carboxylic anhydrides, either.

TABLE 5. ACTIVATION PARAMETERS FOR OXIDATIVE ADDITION OF CYCLIC CARBOXYLIC ANHYDRIDES TO ZERO-VALENT NICKEL [a]

Glutaric anhydride	67.7	−46.8	65.2	78.6

a) Ni(bpy)(cod).

Experimental

General, Materials, Analysis, and Spectroscopic Measurement. Reactions were carried out under N_2 or Ar as reported in papers from our research group.[4] $Pt(cod)_2$ was prepared according to the literature.[11] Commercially available $Ni(cod)_2$ was recrystallized from hot toluene. Microanalysis of C and H was performed by Mr. Saito of our laboratory with Yanagimoto CHN Autocorder MT-2. Ni content of **4** was determined by titration method.[12] IR spectra were recorded on a Hitachi Model 295 spectrometer, ^1H-NMR spectra on a JEOL Model JNM-PS-100 spectrometer, and ^{13}C- and ^{31}P-NMR spectra on JEOL Model JNM-PFT-PS-100 Fourier transform spectrometer. GLC analysis of organic products was performed with Shimadzu GC-3BT gas chromatograph.

Preparation of Complexes. **2**: Complex **2a** was pre-

pared according to literature.[7] From the reaction system we obtained $Ni(CO)_2(bpy)$ (confirmed by IR[13]) besides **2a**. Other complexes of type **2** were prepared analogously by using monodentate tertiary phosphines, but isolation of the complexes was not feasible and the crude complexes were used in further reaction with dpe (see text).

3: A THF (10 cm^3) solution containing 340 mg (1.2 mmol) of $Ni(cod)_2$, 190 mg (1.2 mmol) of bpy, and 120 mg (1.2 mmol) of succinic anhydride was stirred for 3 h at 25 °C to obtain a red precipitate from the homogeneous solution. The precipitate was separated by filtration and washed with hexane repeatedly, and then dissolved in CH_2Cl_2 (10 cm^3) containing 490 mg (1.2 mmol) of dpe at room temperature. The solution was filtered, and the filtrate was dried under reduced pressure. The residual solid was washed with THF repeatedly and dried under vacuum to obtain yellow **3**. yield=221 mg (33%).

4: A THF solution (40 cm^3) containing 3.0 g (11 mmol) of $Ni(cod)_2$, 1.7 g (11 mmol) of bpy, and 1.3 g (11 mmol) of glutaric anhydride was stirred for 6 h at 25 °C to obtain a red precipitate. The complex was filtered, washed with hexane repeatedly and dried to yield 2.0 g (60%) of a red complex **4**.

5: A CH_2Cl_2 solution (40 cm^3) containing 53 mg (0.18 mmol) of complex **4** and 70 mg (0.18 mmol) of dpe was stirred at room temperature. After change of color from red to yellow, the solution was filtered. The filtrate was dried under reduced pressure to obtain a yellow solid, which was washed with Et_2O repeatedly and dried to yield 41 mg (43%) of **5**.

8: A THF solution (5 cm^3) containing 510 mg (1.9 mmol) of $Ni(cod)_2$ and 520 mg (1.9 mmol) of PCy_3 and 0.16 cm^3 (1.9 mmol) of methacrylic acid was stirred for 24 h at 0 °C. Then, 740 mg (1.9 mmol) of dpe was added to the solution to obtain a yellow precipitate, which was separated by filtration, washed with THF and hexane repeatedly, and dried under vacuum to yield 580 mg (57%) of **8**.

9 and **10**: A THF (4 cm^3) solution containing 170 mg (0.4 mmol) of $Pt(cod)_2$ and 41 mg (0.4 mmol) of PCy_3 was stirred for 1 h at room temperature to obtain a white precipitate, which was separated by filtration, washed with hexane repeatedly, and dried under vacuum to obtain 81 mg (31%) of **9**. Complex **10** was prepared analogously using 2 mol of PCy_3 per mol of $Pt(cod)_2$ (yield=37%).

11: A CS_2 (10 cm^3) solution containing 440 mg (0.80 mmol) of **9** and 320 mg (0.80 mmol) of dpe was stirred for 24 h. CS_2 was removed by evaporation and the residue was washed with benzene repeatedly. Extraction with acetone (10 cm^3), and removing acetone by evaporation gave a white solid from which **11** was extracted by CH_2Cl_2. This extract was dried to obtain a white residue which was washed with hexane and dried to yield 245 mg (46%) of **11**.

Reaction of Methylsuccinic Anhydride: A Schlenk tube containing a THF solution of $Ni(cod)_2$ (0.1 mol/cm^3) and methylsuccinic anhydride (0.1 mmol/cm^3) was placed in a thermostated water bath. Ligand (see text) was added to the solution to start the reaction. After 1 h, dpe was added to the solution and solvent was removed under reduced pressure. The residue was washed with hexane to remove dpe-$Ni(CO)_2$ and free ligands.

Reaction of the Complex with CO: A 20 cm^3-Schlenk tube containing a CH_2Cl_2 (3—4 cm^3) solution of the complex (0.1—0.2 g) was evacuated and 1 atm of CO was introduced. The products were analyzed by GLC, GC-mass, and IR.

Kinetics: Dry THF was introduced into a quartz Schlenk tube connected to a UV cell by trap to trap distillation. 1,5-Cyclooctadiene was added to stabilize Ni(bpy)(cod). Then, THF solutions containing cyclic carboxylic anhydride and Ni(bpy)(cod) were added to the reaction vessel, and the change of visible spectrum with time was measured.

Liquid-Liquid Distribution Study of the Dissociation of Perchloric, Nitric, and Picric Acids in Polar Organic Solvents

Tatsuya SEKINE,* Tohru YOSHIKATA, and Takashi SAITOU
Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received March 28, 1984)

The liquid-liquid distribution equilibria of perchioric, nitric, and picric acids between water and 4-methyl-2-pentanone or 4-methyl-2-pentanol have been determined at 298 K by measuring the concentrations of the anions in the two phases by spectrophotometry. The distribution ratio always increased on increase of the acid concentration; this was explained in terms of an increase in the degree of association of the acids in the organic phase. It was concluded from the analysis of the distribution data that the dissociation constant of perchloric acid was the highest and the value of picric acid was higher than that of nitric acid in 4-methyl-2-pentanone. The dissociation constant of picric acid was also higher in 4-methyl-2-pentanol than that of nitric acid; it was similar to that of perchloric acid. The differences of the dissociation constants were larger in 4-methyl-2-pentanone than in 4-methyl-2-pentanol.

In a previous study of solvent extraction of several mineral acids into 4-methyl-2-pentanone (MIBK), it was found that the shape of the extraction curve as a function of the acid concentration was appreciably different for different acids.[1] Several factors in the liquid-liquid system could be responsible for this and the difference in the dissociation of the acid in the organic phase might be one of the reasons. In order to learn further details of this problem, the liquid-liquid distribution ratio of perchloric, nitric, and picric acids between water and 4-methyl-2-pentanone or 4-methyl-2-pentanol has been measured as a function of the acid concentration and the extraction constant. The dissociation constant in the organic solvents were also calculated for these acids.

Experimental

The solvents and the acids were of reagent grade. The solvents were washed first with 0.5 mol dm^{-3} perchloric acid and then twice with water. They were then washed twice with 0.5 mol dm^{-3} sodium hydroxide solution and water. The solvent was finally washed several times with water. The concentrations of the stock solutions of the acids were determined by titration with standard sodium hydroxide solution. A 6 cm^3 portion of an aqueous acid solution and the same volume of the solvent were placed in a stoppered glass tube (capacity 20 cm^3). The two phases were vigorously agitated by a mechanical shaker for 15 min and centrifuged. A portion was pipetted from each phase and each was transferred separately into another tube.

The distribution ratio of picric acid was determined as follows. A 5 cm^3 portion of an aqueous 0.01 mol dm^{-3} solution of tetrabutylammonium chloride was added to the tube containing the equilibrated organic phase and the two phases were agitated for about 5 min in order to exchange the proton of the extracted picric acid with the tetrabutylammonium ion and thus all the picrate in the organic phase was in the anionic form whose optical density was higher than that of the acid form. Since the acid concentration in the aqueous phase was always lower than 1×10^{-4} mol dm^{-3} (its pK_a is 0.3[2]), this acid should be completely in the dissociated form. The amount of picrate was determined from the optical absorption of the organic phase thus obtained at 364 nm ($\varepsilon=1.50\times10^4$ in 4-methyl-2-pentanol) or 375 nm ($\varepsilon=1.80\times10^4$ in 4-methyl-2-pentanone). The amount of picrate ions in the equilibrated aqueous phase was also determined from the absorption at 355 nm ($\varepsilon=1.45\times10^4$ in aqueous solutions).

The distribution ratio of perchloric and nitric acid was determined as follows. A 5 cm^3 portion of water was added to the tube containing the equilibrated organic phase. The two phases were agitated in order to back-extract the acid and then centrifuged. A 4 cm^3 portion of the aqueous phase was transferred to another tube and a 1 cm^3 portion of 1×10^{-3} mol dm^{-3} solution of Crystal Violet and a 5 cm^3 portion of chlorobenzene were added. The two phases were vigorously agitated for 5 min and centrifuged. When the acid concentration was high, the amount extracted was large. In such a case, the washed solution was diluted with water before the dye and the solvent were added and a 4 cm^3 portion of the resulted solution was treated in the same manner as above. The optical absorption of the organic phase was measured at 596 nm. The apparent molar absorption coefficient after this treatment was 1.06×10^5 for perchloric acid and 3.35×10^4 for nitric acid. When the distribution ratio was low, the acid in the aqueous phase at equilibrium was calculated from the amount initially present in the aqueous phase and that extracted into the organic phase. In other cases, the aqueous phase was treated in the manner described above in order to determine the acid concentration. When the acid concentration was higher than 0.1 mol dm^{-3}, however, titration with a standard barium hydroxide was also employed for the determination of the acid in both phases. The water content in the organic phase was determined by a Karl-Fischer titration.

Statistical

In the present paper any species in the organic phase is denoted by a subscript "org" and that in the aqueous phase by lack of any subscript. Solvent extraction of an acid which dissociates in the aqueous phase may be written as;

$$H^+ + A^- \rightleftharpoons HA_{(org)}$$

$$K_{ex} = \{HA\}_{org}\{H^+\}^{-1}\{A^-\}^{-1}$$

$$= (\gamma_{HA}^{org})(\gamma_{\pm HA})^{-2}[HA]_{org}[H^+]^{-1}[A^-]^{-1}, \quad (1)$$

where $(\gamma_{\pm HA})$ is the mean activity coefficient of the acid in the aqueous phase and (γ_{HA}^{org}) is the activity coefficient of the acid in the associated form in the organic phase. When the extracted acid also dissociates in the organic phase, the equilibrium may be written as;

$$HA_{(org)} \rightleftharpoons H^+_{(org)} + A^-_{(org)}$$

$$K_{a(org)} = \{H^+\}_{org}\{A^-\}_{org}^{-1}\{HA\}_{org}^{-1}$$

$$= (\gamma_{\pm HA}^{org})^2(\gamma_{HA}^{org})^{-1}[H^+]_{org}[A^-]_{org}[HA]_{org}^{-1}, \quad (2)$$

where $(\gamma^{org}_{\pm HA})$ is the mean activity coefficient of the acid in the dissociated form in the organic phase. The distribution ratio of the acid in the absence of any other acids and salts of A^- may be written as;

$$D = [HA]_{org,\,total}/[HA]_{total}$$
$$= ([HA]_{org}+[H^+]_{org})/([HA]+[H^+])$$
$$= ([HA]_{org}+[A^-]_{org})/([HA]+[A^-]) \quad (3)$$
$$= (K_{ex}(\gamma_{\pm HA})^2(\gamma^{org}_{HA})^{-1}[A^-]^2 + \sqrt{K_{a(org)}K_{ex}}(\gamma_{\pm HA})(\gamma^{org}_{\pm HA})^{-1}[A^-])/([HA]+[A^-]). \quad (4)$$

When the acid dissociation in the aqueous phase is complete, the distribution ratio may be given as;

$$D = (\gamma_{\pm HA})^2(\gamma^{org}_{HA})^{-1}K_{ex}[A^-] + (\gamma_{\pm HA})(\gamma^{org}_{\pm HA})^{-1}\sqrt{K_{ex}K_{a(org)}}. \quad (5)$$

The values of $(\gamma_{\pm HA})$ were taken from the literature.[3] When the material concentration in the organic phase is low, both of the activity coefficients (γ^{org}_{HA}) and $(\gamma^{org}_{\pm HA})$ can be taken as unity, Eq. 5 can then be rewritten as;

$$D = (\gamma_{\pm HA})^2K_{ex}[H^+] + (\gamma_{\pm HA})K_{ex}K_{a(org)}. \quad (6)$$

From the values of D determined against $[H^+]$, the values of K_{ex} and $K_{a(org)}$ may be calculated on the basis of Eq. 6 by a successive approximation method using a least squares computer program.

Results and Discussion

Figures 1 and 2 give the log D *vs.* log $[H^+]$ plots of the acids. By the least squares calculation of these data, the extraction constant in Eq. 2 and the acid dissociation constant in the organic phase in Eq. 3 were obtained as listed in Table 1. The solid curves in Figs. 1 and 2 were calculated by Eq. 6 using the values of these constants.

As seen from Table 1, extraction constants of perchloric and nitric acid into 4-methyl-2-pentanol are higher than into 4-methyl-2-pentanone but that of picric acid is one order higher into the ketone. The increase in the slope of the plot on increasing the acid concentration can be explained in terms of the higher degree of association of the acid at higher concentration in the organic phase as seen from Eq. 5.

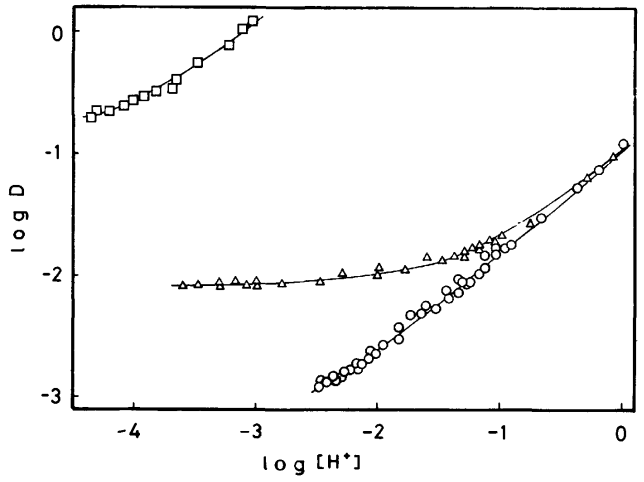

Fig. 1. The distribution ratio of acids as a function of their concentration in the equilibrated aqueous phase when solvent is 4-methyl-2-pentanone. Acids: perchloric acid (△), nitric acid (○), and picric acid (□). The solid curves were calculated by Eq. 6 using the value in Table 1.

In aqueous solutions, the acid strengths are in the order of perchloric acid>nitric acid>picric acid. The two mineral acids dissociate completely in their aqueous solutions. Picric acid is not a weak acid and its dissociation in aqueous solution is nearly complete over the concentration range of the present study. However, all of the acids are weak in these two organic solvents. Perchloric acid is always the strongest in both of the solvents but picric acid in 4-methyl-2-pentanol is as strong as perchloric acid. The difference in the strength of the acid is greater in 4-methyl-2-pentanone than in 4-methyl-2-pentanol and perchloric acid is weaker in the alcohol than in the ketone but the other two acids show an opposite tendency.

Several properties, such as the dielectric constant, solvation of the proton and anion, and interactions among the solvent molecules should affect the dissociation of the acid in these solvents. Furthermore, the solvents are saturated with water. It was found that the water content determined by Karl-Fischer titration was nearly constant except when the acid concentration in the aqueous phase was higher than 0.1 mol dm^{-3}. Above this an increase of water content was observed but the calculated values of K_{ex} and $K_{a(org)}$ were not affected whether or not the data obtained in this higher acid concentration range were included in the calculation.

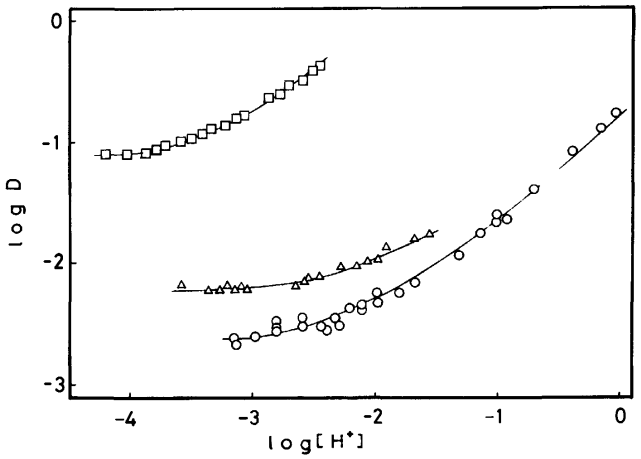

Fig. 2. The distribution ratio of acids as a function of their concentration in the equilibrated aqueous phase when solvent is 4-methyl-2-pentanol. Acids: perchloric acid (△), nitric acid (○), and picric acid (□). The solid curves were calculated by Eq. 6 using the value in Table 1.

Table 1. Extraction constant (Eq. 1) and acid dissociation constant (Eq. 2) in organic solvents

	4-methyl-2-pentanone		4-methyl-2-pentanol	
	$pK_{a(org)}$	$\log K_{ex}$	$pK_{a(org)}$	$\log K_{ex}$
Perchloric acid	3.5	−0.6	4.3	−0.2
Nitric acid	6	−0.6	4.8	−0.4
Picric acid	4.7	3.1	4.4	2.1

The association of strong acids in organic solvents have been extensively studied by conductimetry and potentiometry (for example Ref. 2 and Refs. 4 to 7 and also the references cited therein). Another approach to this problem is spectrophotometry which is however, applicable only when the optical absorption changes on acid dissociation as for picric acid.[5-6] The previous papers[5-7] observe that the strong acids which dissociated completely or nearly completely in aqueous solutions dissociated only partially in polar organic solvents. Furthermore the order of the dissociation in the solvents could be different from that in aqueous solutions and it could also be different in different organic solvents. For example, it was pointed out that the dissociation of picric acid was higher in dimethyl sulfoxide than of perchloric acid. This was explained in terms of the solvation of the former being stronger than that of the latter.[2]

In the present study, the solvents were saturated with water whereas in most of these previous studies, the solvents had been distillated and the water content should be much below saturation level. However, the tendency of the acid dissociation found in the present study is similar to that found previously. It can be pointed out that although the water content was different at different acid concentrations, a set of values of the two equilibrium constants could explain the results reasonably over a wide range of acid concentration.

There have been few quantitative studies of acid dissociation in organic solvents by liquid-liquid distribution methods. The present results indicate that this method is favorable for because even though the determination is done spectrophotometrically it can also be applied to those acids which have no strong optical absorption. If a dye of high molar extinction is used, it is possible to determine the equilibrium even when the acid concentration is low. However, it should also be noted that control of the water content in the solvent is not possible and several coexisting anions may interfere with the determination. Furthermore, the solvent should be water-immiscible and the anion should at least to some extent be extractable with a cationic dye.

The authors are very grateful for Dr. Satoshi Kusakabe for his valuable discussions during this study.

Preparation and Characterization of [S-(2-Aminoethyl)-L-homocysteinato]-cobalt(III) Complexes with Bidentate Ligands

Masutaro SUZUKI, Osamu ARISATO, Ken-ichi OKAMOTO,* Hisahiko EINAGA,† and Jinsai HIDAKA
Department of Chemistry, University of Tsukuba, Sakura, Ibaraki 305
†*Institute of Materials Science, University of Tsukuba, Sakura, Ibaraki 305*
(Received April 4, 1984)

Three kinds of cobalt(III) complexes with S-(2-aminoethyl)-L-homocysteinate (L-aehc) and a bidentate ligand (glycinate, oxalate, and ethylenediamine) were prepared and chromatographically separated into the quasi-enantiomeric isomers: *Δ*L-*trans(O)·mer(N)-R(S)*, *Δ*L-*cis(O)·mer(N)-R(S)*, *Λ*L-*cis(O)·mer(N)-S(S)*, and *Λ*L-*cis(O)·fac(N)-S(S)* for the glycinato complex, *Δ*L-*trans(N)-R(S)* and *Λ*L-*cis(N)-S(S)* for the oxalato one, and *Δ*L-*R(S)* and *Λ*L-*S(S)* for the ethylenediamine one. These isomers were characterized from their electronic absorption, CD, and ^{13}C NMR spectra. The conformations of the six-membered N-S chelate ring in the L-aehc, of the chair for *Δ*L-*R(S)* and of the chair or skew-boat for *Λ*L-*S(S)*, were suggested on the basis of the ^{13}C NMR spectra. The CD spectra of the isomers are discussed in relation to their geometrical and absolute configurations.

CD spectra of the cobalt(III) complexes with a thioether-type terdentate ligand such as L-methioninate, S-methyl-L-cysteinate and their derivatives have been investigated in relation to the stereochemical properties of the coordinated sulfur donor atom.[1-8] In these works, however, the chiral sulfur atom, *R(S)* or *S(S)*[9] configuration, has been suggested to be configurationally labile.[6,10] S-(2-Aminoethyl)-L-homocysteinate (L-aehc) functions as a quadridentate ligand to a cobalt(III) ion and forms two five-membered (N-S and N-O) chelate rings and a six-membered (N-S) one (Fig. 1). Accordingly, the L-aehc cobalt(III) complex gives a fixed chiral sulfur atom as well as the cobalt(III) complexes with (2-aminoethylthio)acetate[11] or (2*R*)-2-(carboxymethylthio) propionate.[12] The L-aehc ligand can take two kinds of coordination modes which are mutually quasi-enantiomeric, as shown in Fig. 1. The sulfur donor atom in (a) or (c) of Fig. 1 takes only *S(S)* configuration, while two configurations, *R(S)* and *S(S)*, are possible for the sulfur donor atom in (b) or (d), depending on the possible conformations, chair and skew-boat, of the six-membered N-S ring. Of the four isomers for [Co(L-aehc)(gly)]$^+$, two isomers were determined to be the *Δ*L-*trans(O)·mer(N)-R(S)* and *Δ*L-*cis(O)·mer(N)-R(S)* ones by the X-ray crystal structure analysis.[13-15]

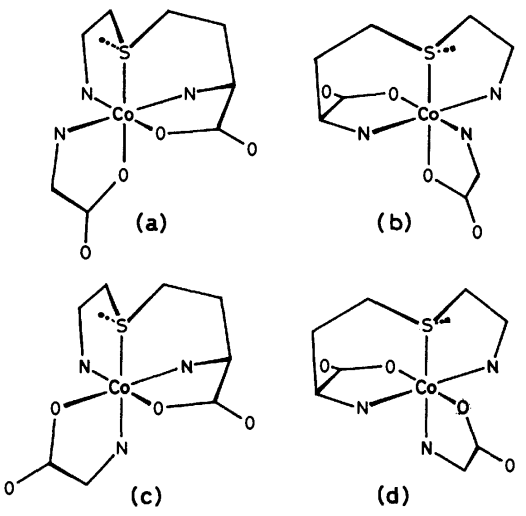

Fig. 1. Possible isomers of [Co(L-aehc)(gly)]$^+$: (a) *Δ*L-*cis(O)·mer(N)-S(S)*, (b) *Δ*L-*cis(O)·mer(N)-R(S)*, (c) *Λ*L-*cis(O)·fac(N)-S(S)*, and (d) *Δ*L-*trans(O)·mer(N)-R(S)*. *Δ*L-*cis(O)·mer(N)-S(S)* and *Δ*L-*trans(O)·mer(N)-S(S)* are omitted.

In this work, the [Co(L-aehc)(bidentate)]-type complexes were prepared and chromatographically separated into their possible isomers, namely, four isomers for the glycinato complex, two for the oxalato one, and two for the ethylenediamine one. The [Co(L-aehc)$(NH_3)_2]^{2+}$ and [Co(L-met)$(NH_3)_3]^{2+}$ complexes were also prepared in order to compare the CD spectra with the isomers of [Co(L-aehc)(en)]$^{2+}$. The coordination modes of L-aehc, *Λ*L-*S(S)*, *Δ*L-*R(S)*, and *Δ*L-*S(S)*, were suggested from comparisons of the CD and ^{13}C NMR spectra of the *Δ*L-*trans(O)·mer(N)-R(S)*- and *Δ*L-*cis(O)·mer(N)-R(S)*-[Co(L-aehc)(gly)]$^+$ isomers with those of the remaining isomers of the gly complex and of the isomers of the ox and en complexes.

Experimental

Preparation of Ligand. S-(2-Aminoethyl)-L-homocysteine was prepared by a procedure similar to that used for the preparation of S-(carboxymethyl)-L-homocysteine,[16] using 2-bromoethanamine hydrobromide instead of chloroacetic acid. The reaction mixture was neutralized with a 1 mol dm^{-3} aqueous solution of sodium hydroxide and the deposited sodium chloride was filtered off. The filtrate was poured onto a column of Dowex 50W-X8 (H^+ form, 5 cm×40 cm). After unreacted L-methionine had been swept with a 0.2 mol dm^{-3} sodium citrate buffer solution (pH 4.25), the desired product was eluted with a 1.0 mol dm^{-3} aqueous ammonia. The eluate was concentrated with a rotary evaporator until it became sirupy. It was neutralized with concd hydrobromic acid and to the solution was added a large amount of acetone. The crystals were collected by filtration and then washed well with acetone. Found: C, 27.59; H, 5.89; N, 10.53%. Calcd for L-Haehc·HBr=$C_6H_{14}N_2O_2S$·HBr: C, 27.57; H, 5.83; N, 10.80%.

Preparation and Separation of Complexes. 1) (S-(2-Aminoethyl)-L-homocysteinato)(glycinato)cobalt(III) Perchlorate: [Co(L-*aehc*)(*gly*)]ClO_4. A solution containing 4.0 g of L-Haehc·HBr and 2.0 g of glycine in 40 cm^3 of water was adjusted to pH 7 with a 1 mol dm^{-3} aqueous solution of sodium hydroxide. To this solution was added a solution containing 4.8 g of $CoCl_2·6H_2O$ in 40 cm^3 of water, 0.5 g of activated charcoal, and 8.0 g of PbO_2. The mixture was stirred at *ca.* 65 °C for 15 min and then filtered. The filtrate was poured onto a column of Dowex 50W-X8 (200—400 mesh, Na^+ form, 3 cm×40 cm). After the column had been swept with water, the adsorbed band was eluted with a 0.1 mol dm^{-3} aqueous

solution of NaCl. Four colored bands; red-violet (A-1), violet (A-2), red-violet (A-3), and red (A-4), were eluted in this order. It was found from the absorption and CD spectral measurements that A-1, A-2, A-3, and A-4 eluates contained *Δ*L-*trans(O)*·*mer(N)*, *Δ*L-*cis(O)*·*mer(N)*, *Δ*L-*cis(O)*·*mer(N)*, and *Λ*L-*cis(O)*·*fac(N)* isomers, respectively. Each eluate was concentrated to a small volume with a rotary evaporator below 25 °C and the deposited NaCl was filtered off. The filtrate was passed through a column of Sephadex G-10 (3.5 cm×100 cm) by elution with water. By use of an anion-exchange column (QAE-Sephadex A-25, ClO_4^- form, 3 cm×20 cm), the chloride salt in the eluate was converted into the perchlorate one. The eluate was concentrated to a small volume again. After adding a small amount of ethanol, the solution was kept in a refrigerator for several days. The crystals which appeared were collected by filtration and recrystallized from water by addition of ethanol. Found for A-1: C, 23.44; H, 4.14; N, 10.13%. Found for A-4: C, 23.36; H, 4.16; N, 10.13%. Calcd for [Co(L-aehc)(gly)]ClO_4= $CoC_8H_{17}N_3O_8SCl$: C, 23.45; H, 4.18; N, 10.25%. Found for A-2: C, 23.30; H, 4.57; N, 9.83%. Found for A-3: C, 22.48; H, 4.41; N, 9.80%. Calcd for [Co(L-aehc)(gly)]$ClO_4\cdot H_2O$: C, 22.46; H, 4.49; N, 9.82%.

2) (S-(2-Aminoethyl)-L-homocysteinato)(oxalato)cobalt(III): [Co(L-aehc)(ox)]. This complex was prepared by the same procedure as in *1)*, using oxalic acid dihydrate instead of glycine. The reaction mixture was filtered and the filtrate was passed through columns of Dowex 1-X8 (Cl^- form, 4 cm×25 cm) and Dowex 50W-X8 (Na^+ form, 4 cm×25 cm) in order to remove charged compounds. The concentrated eluate was poured onto a column of QAE-Sephadex A-25 (Cl^- form, 3.0 cm×150 cm) and eluted with water. The adsorbed band was separated into two bands, dark-violet (B-1) and purple (B-2), in this order. It was found from the absorption and CD spectral measurements that B-1 and B-2 eluates contained *Δ*L-*trans(N)* and *Λ*L-*cis(N)* isomers, respectively. Each eluate was concentrated to a small volume with a rotary evaporator below 25 °C and kept in a refrigerator overnight. The complex which precipitated was collected by filtration, then washed with ethanol and ether. B-1 isomer was obtained as violet needle crystals and B-2 isomer as light purple powder. Found for B-1: C, 29.42; H, 4.02; N, 8.60%. Found for B-2: C, 29.27; H, 3.98; N, 8.57%. Calcd for [Co(L-aehc)-(ox)]=$CoC_8H_{13}N_2O_6S$: C, 29.63; H, 4.04; N, 8.64%.

3) (S-(2-Aminoethyl)-L-homocysteinato)(ethylenediamine)cobalt-(III) Perchlorate: [Co(L-aehc)(en)]$(ClO_4)_2$. A solution containing 2.0 g of L-Haehc·HBr in 40 cm^3 of water was adjusted to pH 7 with a 1 mol dm^{-3} aqueous solution of sodium hydroxide. To this solution were added 2.0 g of *trans*-[$CoCl_2(en)_2$]Cl[17] and 0.5 g of activated charcoal. The resulting mixture was stirred at *ca.* 75 °C for 15 min. The color of the solution changed from green to violet and finally to orange-red. The mixture was filtered and the filtrate was poured onto a column of Dowex 50W-X8 (200—400 mesh, Na^+ form, 3.5 cm×30 cm). After the column had been swept with water, the adsorbed band was eluted with a 0.5 mol dm^{-3} aqueous solution of NaCl. Four colored bands: a red-violet, another red-violet, orange-red (C-1), and orange (C-2), were eluted in this order. It was found from the absorption and CD spectral measurements that C-1 and C-2 eluates contained the desired isomers, but the earlier two red-violet eluates contained a by-product; the absorption spectra of the two eluates did not show any sulfur-to-metal charge transfer band in the region of 30—35×10^3 cm^{-1}.[1-4,6-8,10-12] Each of the C-1 and C-2 eluates was concentrated to a small volume with a rotary evaporator below 25 °C. The solution was passed through columns of Sephadex G-10 (3.5 cm×100 cm) and QAE-Sephadex A-25 (ClO_4^- form, 3 cm×20 cm), by elution with water as in *1)*. To the eluate concentrated again was added a small amount of methanol; this mixture was kept in a refrigerator for several days. The complex which precipitated was collected by filtration, then washed with methanol and ether. C-1 isomer was obtained as orange-red needle crystals and C-2 isomer as orange-red powder. Found for C-1: C, 18.91; H, 4.55; N, 10.88%. Calcd for [Co(L-aehc)(en)]$(ClO_4)_2\cdot H_2O$=$CoC_8H_{21}N_4O_{10}SCl_2\cdot H_2O$: C, 18.72; H, 4.53; N, 10.92%. Found for C-2: C, 18.89; H, 4.12; N, 11.12%. Calcd for [Co-(L-aehc)(en)]$(ClO_4)_2\cdot 0.5H_2O$: C, 19.05; H, 4.20; N, 11.11%.

4) (S-(2-Aminoethyl)-L-homocysteinato)diamminecobalt(III) Chloride: [Co(L-aehc)$(NH_3)_2$]Cl_2. To a solution containing 2.0 g of L-Haehc·HBr in 200 cm^3 of water was added 3.5 g of *cis*-K[$Co(CO_3)_2(NH_3)_2$]·H_2O.[18] To this solution was gradually added 3 mol dm^{-3} hydrochloric acid with stirring at *ca.* 45 °C until the evolution of carbon dioxide ceased. The color of the solution changed from blue-violet to dark red. The mixture was filtered and the filtrate was poured onto a column of SP-Sephadex C-25 (Na^+ form, 3 cm×90 cm). After the column had been swept with water and 0.02 mol dm^{-3} acetic acid (pH 4.5), the adsorbed band was eluted with a 0.2 mol dm^{-3} aqueous solution of NaCl. Only the red band was eluted; it was concentrated to a small volume with a rotary evaporator below 20 °C. The solution was passed through a column of Sephadex G-10 (4 cm×45 cm) and then poured onto a column of SP-Sephadex C-25 (Na^+ form, 3 cm×90 cm) again. The adsorbed band was eluted by the same conditions as described above. Four colored bands: red, red-violet, red (D-1), and another red (D-2), were eluted in this order. It was found from the comparison with the absorption and CD spectra of [Co(L-aehc)(en)]$^{2+}$ isomers that D-1 and D-2 eluates contained the desired isomers. Since the yield was very poor, the desired isomers could not be isolated. The concentration of the complex cation in each eluate was evaluated by the plasma emission spectral analysis.

5) Triammine(L-methioninato)cobalt(III) Perchlorate: [Co-(L-met)$(NH_3)_3$]$(ClO_4)_2$. A solution containing 4.8 g of ammonium chloride and 7.2 cm^3 of 25% aqueous ammonia in 40 cm^3 of water were added to a solution containing 4.0 g of L-methionine in 12 cm^3 of water. To this solution was added a solution containing 1.7 g of $Co(CH_3COO)_2\cdot 4H_2O$ in 40 cm^3 of water and 10 g of PbO_2. The molar ratio, Co^{2+}: L-methionine: NH_3: NH_4^+, was 1:1:3:3.5. This solution was stirred at *ca.* 60 °C for 18 min, cooled to room temperature, and then filtered. The filtrate was poured onto a column of SP-Sephadex C-25 (Na^+ form, 4 cm×120 cm). After the column had been swept with water and then with a 0.03 mol dm^{-3} aqueous solution of NaCl, the adsorbed band was eluted with a 0.18 mol dm^{-3} aqueous solution of NaCl. Three colored bands: pink, orange-pink, and orange, were eluted in this order. It was found from the absorption and CD spectral measurements that the second eluate contained the desired complex. The second eluate was concentrated to a small volume with a rotary evaporator and the deposited NaCl was filtered off. The filtrate was passed through a column of QAE-Sephadex A-25 (ClO_4^- form, 3 cm×20 cm) by elution with water. The eluate was concentrated to a small volume. The crystals which appeared were collected by filtration, then washed with ethanol and ether. Found: C, 12.25; H, 4.05; N, 11.89%. Calcd for [Co(L-met)$(NH_3)_3$]$(ClO_4)_2\cdot 0.5H_2O$=CoC_5H_{19}-$N_4O_{10}SCl_2\cdot 0.5H_2O$: C, 12.88; H, 4.32; N, 12.02%.

Measurements. The electronic absorption spectra were recorded with a JASCO UVIDEC-1 spectrophotometer and the CD spectra with a JASCO J-20 spectropolarimeter. The concentration of D-1 or D-2 isomer for [Co(L-aehc)$(NH_3)_2$]$^{2+}$ was measured with a Jarrell-Ash model 96—975 plasma Atom Comp. The ^1H and ^{13}C NMR spectra were recorded on a JEOL JNM-FX-100 NMR spectrometer at the probe temperature in D_2O or 70% $DClO_4$ solvent. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as an internal

reference.

Results and Discussion

Structural Assignment. Two pairs of quasi-enantiomeric geometrical isomers, *Λ*L-*cis(O)·mer(N)* and *Δ*L-*cis(O)·mer(N)*, and *Λ*L-*cis(O)·fac(N)* and *Δ*L-*trans(O)·mer(N)*, are expected for [Co(L-aehc)(gly)]$^+$, regardless of the chiral sulfur atom, *R*(*S*) or *S*(*S*), in L-aehc (Fig. 1).[15] In the first absorption band region, A-1

a) sh denotes a shoulder.

isomer of [Co(L-aehc)(gly)]$^+$ exhibits well separated two absorption components, A-2 and A-3 isomers exhibit a broad band, and A-4 isomer exhibits a sharp band (Figs. 2 and 3, and Table 1). These splittings of the first absorption bands agree well with the splitting patterns which can be expected from the semiempirical calculation[19] on the basis of the ligand field strength, N>S>O.[1-4,6-8,10-13] Of these isomers, A-1 and A-3 isomers were determined to be Λ_L-*trans(O)·mer(N)*[13] and Λ_L-*cis(O)·mer(N)*,[14] respectively, by the X-ray crystal structure analysis and then A-2 isomer was assigned to Λ_L-*cis(O)·mer(N)* from a comparison of the absorption and CD spectra with those of A-3 one.[14] Thus A-4 isomer is Λ_L-*cis(O)·fac(N)*. For the [Co(L-aehc)(ox)] complex, the isomers are regulated to a pair of quasi-enantiomeric isomers, Λ_L-*trans(N)* and Λ_L-*cis(N)* (Fig. 1). In the first absorption band region, B-1 isomer of [Co(L-aehc)(ox)] exhibits a band with an explicit shoulder on the lower energy side and B-2 isomer exhibits a sharp band (Fig. 4 and Table 1). These spectral patterns suggest that B-1 isomer is Λ_L-*trans(N)* and B-2 one Λ_L-*cis(N)*. Similarly, the two isomers, Λ_L and Λ_L, are possible for the ethylenediamine complex, [Co(L-aehc)(en)]$^{2+}$. In this case, however, it is

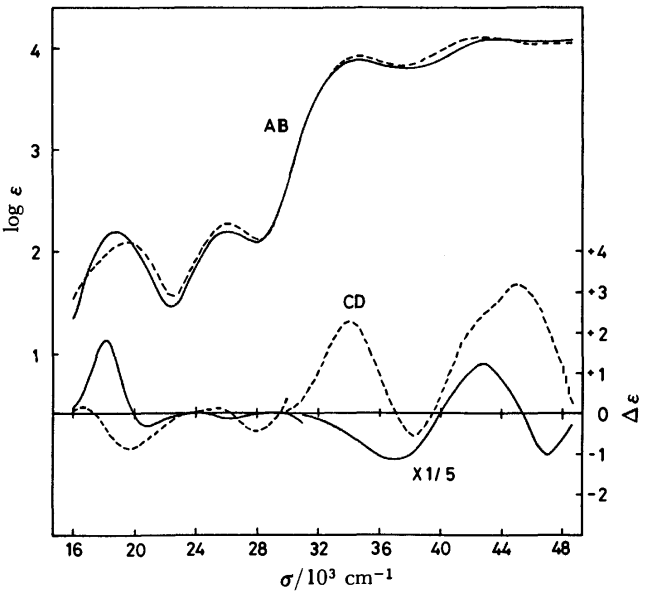

Fig. 4. Absorption and CD spectra of [Co(L-aehc)(ox)]: Λ_L-*cis(N)* (——) and Λ_L-*trans(N)* (------).

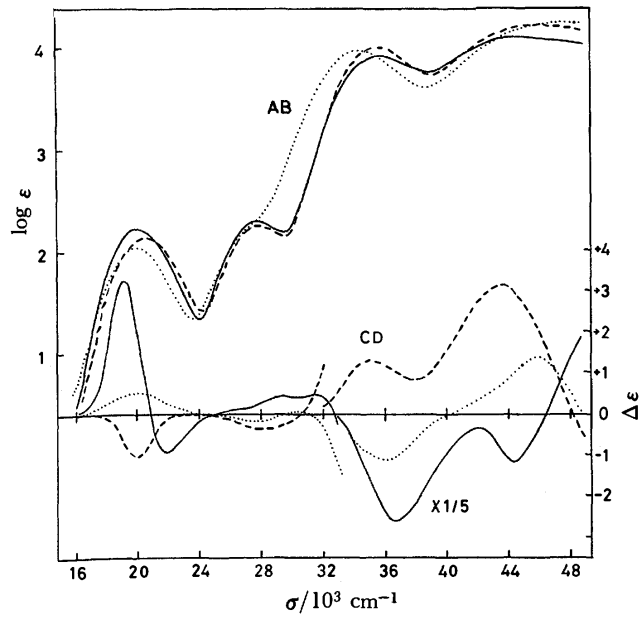

Fig. 5. Absorption and CD spectra of [Co(L-aehc)(en)]$^{2+}$: Λ_L (——) and Δ_L (------), and [Co(L-met)$(NH_3)_3$]$^{2+}$ (……).

difficult to assign the structure of the two isomers on the basis of their first absorption bands (Fig. 5), so their ^{13}C NMR spectra were measured.

The ^{13}C NMR spectra of the six isomers of the gly and ox complexes can be classified into two groups according to the distribution of the chemical shifts due to the β-methylene carbon atom of L-aehc (Fig. 6). One group, the Δ_L isomers, exhibits the resonance line in the range of 40—43 ppm (A-1, A-3, and B-1 isomers), while the other, the Λ_L isomers, exhibits the line in the range of 34—37 ppm (A-2, A-4, and B-2 isomers). The same trend was observed for the ^{13}C NMR spectra of the two isomers of [Co(L-aehc)(en)]$^{2+}$, namely, the resonance line for the β-methylene carbon atom of C-1 isomer (34.51 ppm) appears at a higher field than that of C-2 one (40.25 ppm) (Fig. 6). Stereomodel examination reveals that the interligand interaction between the six-membered N-S chelate ring containing the β-methylene and the five-membered N-S chelate ring of L-aehc is more remarkable for the Λ_L isomer than for the Δ_L one. Taking the classification based on the ^{13}C NMR spectral behavior of the β-methylene carbon and the steric effects of the chemical shift of carbon[19,20] into consideration, the C-1 isomer of [Co(L-aehc)(en)]$^{2+}$ is tentatively assigned to Λ_L and the C-2 isomer to Δ_L. This assignment is consistent with that from their CD spectra (*vide infra*).

According to the model constructions, the coordinated sulfur atom of the Λ_L isomer is limited to *S*(*S*) configuration, whereas that of the Δ_L isomer is able to take *R*(*S*) and *S*(*S*) configurations which depend on the conformation of the six-membered N-S chelate ring in L-aehc, namely, the *R*(*S*) coordination takes with a chair-formed N-S chelate ring and the *S*(*S*) coordination with a skew-boat one. In fact, Δ_L-*trans(O)*·*mer(N)*-[Co(L-aehc)(gly)]$^+$ (A-1) has the *R*(*S*) configuration and the six-membered N-S chelate ring in the chair form,[13] and the Δ_L-*cis(O)*·*mer(N)* isomer

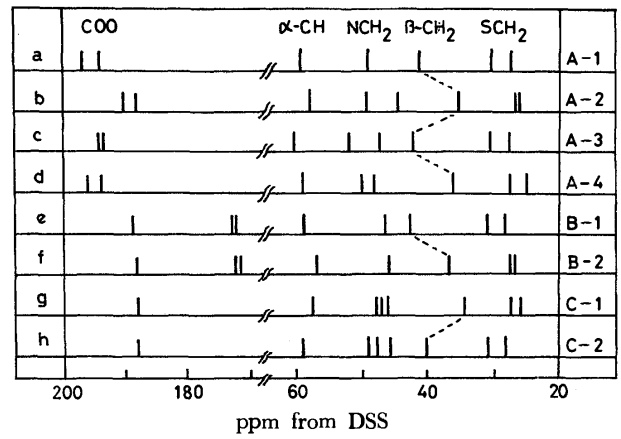

Fig. 6. The distribution of ^{13}C NMR chemical shifts of [Co(L-aehc)(L)].
a—d: L=gly; e and f: L=ox; g and h; L=en.

(A-3) also has *R*(*S*) with the chair-formed N-S chelate ring.[14] These two glycinato isomers show similar ^{13}C NMR spectral behavior on the carbon atoms of L-aehc to those of the Δ_L-*trans(N)*-[Co(L-aehc)(ox)] and Δ_L-[Co(L-aehc)(en)]$^{2+}$ ones (Fig. 6). The distribution of the chemical shifts for each carbon atom of L-aehc seems to be related with the interligand interaction between the six-membered N-S chelate ring and the five-membered N-S chelate ring, as in the case of the chemical shift for the β-methylene carbon mentioned above. Thus it is suggested that the six-membered N-S chelate ring for the ox and en complexes takes a chair conformation (simultaneously *R*(*S*) configuration) in the Δ_L isomers.

Two isomers, Δ_L and Λ_L, are possible for [Co(L-aehc)$(NH_3)_2$]$^{2+}$ as well as the ethylenediamine complex. The absorption spectra of D-1 and D-2 isomers of the diammine complex are quite similar to those of the [Co(L-aehc)(en)]$^{2+}$ and [Co(L-met)$(NH_3)_3$]$^{2+}$ complexes over the whole region (Figs. 5 and 7). Furthermore, the CD spectral patterns of D-1 and D-2 isomers also agree well with those of [Co(L-aehc)(en)]$^{2+}$ isomers (*vide infra*).

CD Spectra. The CD spectra of the L-aehc complexes are shown in Figs. 2—5 and 7, and their data are summarized in Table 1. Three pairs of quasi-enantiomeric geometrical isomers for the gly and ox complexes exhibit approximately enantiomeric CD patterns, respectively, though some deviations are observed in the first absorption band region (Figs. 2—4). This enantiomeric CD spectral relationship can be applied for the assignment of the two isomers of [Co(L-aehc)(en)]$^{2+}$, namely, Λ_L for C-1 isomer and Δ_L for C-2 one (Fig. 5). This assignment agrees with that based on their ^{13}C NMR spectra mentioned above. Similarly, D-1 and D-2 isomers of [Co(L-aehc)$(NH_3)_2$]$^{2+}$ correspond to Δ_L- and Λ_L-[Co(L-aehc)(en)]$^{2+}$, respectively, as shown in Fig. 7. Here, it should be noted that Δ_L-[Co(L-aehc)$(NH_3)_2$]$^{2+}$ (D-1) isomerized gradually to Λ_L one (D-2) in aqueous solution, while Λ_L isomer did not. This trend in isomerization agrees with the suggestion from the stereomodel examination that L-aehc prefers Λ_L coordination to Δ_L one, because of more strained *R*(*S*) caused by the Δ_L coordination of L-aehc. Further study is being undertaken to investigate the isomerization

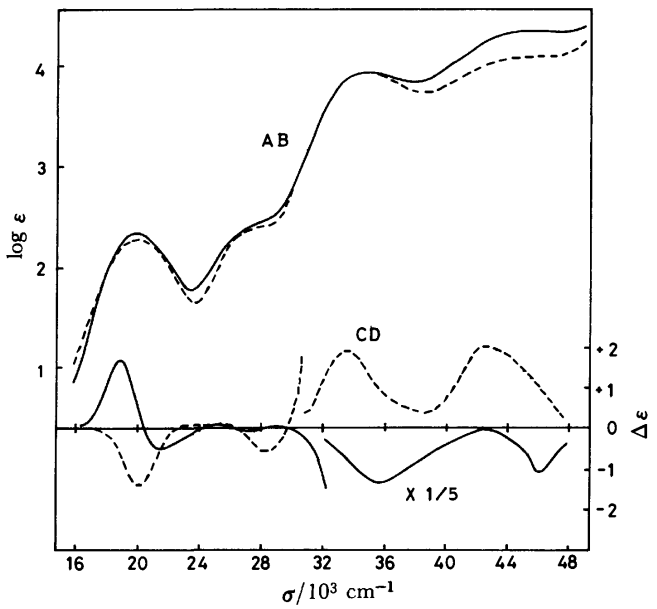

Fig. 7. Absorption and CD spectra of [Co(L-aehc)-$(NH_3)_2]^{2+}$: Δ_L (——) and Δ_L (------).

in detail.

In order to estimate the CD contribution due to the L-methionine moiety of L-aehc, the triammine(L-methioninato)cobalt(III) complex, $[Co(L\text{-met})(NH_3)_3]^{2+}$, was prepared. The ^1H NMR spectrum of the triammine complex exhibits a peak (2.34 ppm) with a shoulder at lower field due to the *S*-methyl protons, suggesting the coexistence of *R*(*S*) and *S*(*S*) isomers. This result suggests that the CD spectrum of $[Co(L\text{-met})(NH_3)_3]^{2+}$ is mainly due to *S*(*C*) of the L-met (Fig. 5). In contrast to the triammine complex, $[Co(L\text{-aehc})(NH_3)_2]^{2+}$ and $[Co(L\text{-aehc})(en)]^{2+}$ have two additional CD contributions besides that due to *S*(*C*) of L-aehc, namely, one from the configurational chirality due to the skew pair of chelate rings of L-aehc and the other the chirality due to the sulfur donor atom, though the two contributions can not be separated. As shown in Fig. 5, the CD curves of $[Co(L\text{-aehc})(en)]^{2+}$ isomers in the region of $24—48\times10^3\,cm^{-1}$ are almost enantiomeric, taking into account that the CD curve of $[Co(L\text{-met})(NH_3)_3]^{2+}$ is subtracted from that of Δ_L- or Λ_L-$[Co(L\text{-aehc})(en)]^{2+}$, while their CD patterns in the first absorption band region deviate significantly from the enantiomeric relation. The same situation holds for each of the quasi-enantiomeric pairs of the other L-aehc complexes (Figs. 2—4). The Λ_L isomers of all the L-aehc complexes exhibit a similar CD pattern ((+) and (−) from lower energy) in the first absorption band region, regardless of the geometrical configurations with respect to the coordinated atoms, while the patterns of Δ_L isomers depend remarkably on their geometrical configurations. These CD spectral behaviors of Δ_L and Λ_L isomers in the first absorption band region are also observed for the CD spectra of the *S*-(carboxymethyl)-L-homocysteinato and *S*-(2-carboxyethyl)-L-homocysteinato complexes.[22] These deviations in the first absorption band region seem to be attributed to the difference of configurational chiralities due to the coordinated L-aehc, Δ_L-*R*(*S*) and Λ_L-*S*(*S*), rather than the chiral sulfur atom, taking account of the fact that the CD patterns of *R*(*S*)- and *S*(*S*)-[Co(*R*-cmtp or *R*-cetp)$(NH_3)_3]^+$, which are mainly contributed to the chirality due to the sulfur donor atom, are almost enantiomeric in the first absorption band region (where *R*-cmtp and *R*-cetp denote (2*R*)-2-(carboxymethylthio)propionate and (2*R*)-2-(2-carboxyethylthio)propionate).[12]

Development of a Laboratory EXAFS System and Its Application to Aqueous Nickel(II) Ammine Solutions

Mitsuru SANO,* Tetsuya MARUO,† and Hideo YAMATERA†

Laboratory of Inorganic Chemistry, College of General Education, Nagoya University, Nagoya 464

†*Department of Chemistry, Faculty of Science, Nagoya University, Nagoya 464*

(Recieved May 1, 1984)

A laboratory EXAFS system with a curved crystal has been developed. This apparatus consists of a usual X-ray tube, a spectrometer with a Johan-type curved crystal, and two proportional counters detecting the X-rays. The resolution and performance tests have been carried out and excellent spectra have been obtained for NiO. With this system, aqueous solutions of ammine and ethylenediamine nickel(II) salts have been studied. The spectra were analyzed by the curve-fitting method by reference to the spectra of appropriate crystals containing the corresponding complexes. The values obtained for the Ni–N distances are 2.12±0.01 Å. These values are very close to those of the corresponding complexes in crystals.

The extended X-ray absorption fine structure (EXAFS) technique for the study of the molecular structure has made a rapid development and has been applied to a variety of problems.[1] Synchrotron orbital radiation (SOR) is evidently of great value in EXAFS spectroscopy; however, the use of an SOR facility is inevitably accompanied by various restrictions as to place and time.

In previous papers, we reported EXAFS studies of aqueous cyanocuprate(I)[2] and copper(II) ammine[3] solutions with a laboratory system equipped with a position-sensitive photodiode array. The system has advantages of high efficiency in the data collection and of little dependence on the X-ray flux fluctuation with time. This detector has an excellent position resolution (28μ/channel) which may be applied for SOR facilities[4] and for a small angle scattering apparatus[5] as a highly efficient X-ray detector. However, continuous X-rays generated by the tube contain many characteristic lines from the target as well as contaminants. When the photodiodes detect all the X-rays without energy resolution, the voltage applied to the anode of the X-ray tube is restricted in order to avoid the contamination of the higher-order reflections; then the brightness of the continuous X-rays is kept at low. Thus the application of our system with a photodiode array is limited to particular kinds of chemical elements.

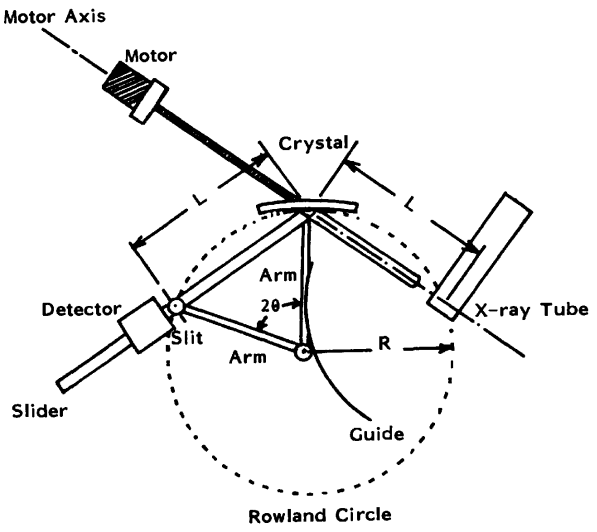

Fig. 1. Schematic diagram of the X-ray monochromator with a Johan-type curved crystal.

In order to extend the EXAFS study of solution systems, we have developed a new laboratory EXAFS system with a Johan-type curved crystal. We have carried out its performance test and then applied the method to the structural study of aqueous solutions of ammine and ethylenediamine nickel(II) salts.

Ammine complexes of metal ions are the most fundamental and important species in coordination chemistry. Fujita and Ohtaki[6] studied the structure of the aqueous ethylenediamine nickel(II) solutions by the X-ray diffraction technique. They reported Ni–N distances of 2.10 Å for the bis-complex and 2.20 Å for the tris-complex. X-ray studies of the solid tris-ethylenediamine complex salts[7–10] gave about 2.1 Å for the Ni–N bond distances; the results on solutions are not consistent with those on crystals. Our EXAFS results will be given below.

System Configuration

The laboratory EXAFS system consists of three parts; a usual X-ray generator, a spectrometer with a curved crystal, and an X-ray detector system. The X-ray spectrometers with a bent crystal have been reported by Knapp *et al.*,[11] Williams,[12] Thulke *et al.*,[13] and Tohji *et al.*[14] The present system is basically of the same configuration as theirs, but has two features, the spectrometer with a Johan crystal and one stepping motor and the counter system with energy resolution activity.

A. X-ray Source. The X-rays are generated by a Rigaku 2kW X-ray generator equipped with a Philips fine focus X-ray tube with a Mo anode. The X-rays are emitted from a vertical square (8-mm high) on the anode. Its effective width at a take-off angle of 6° is about 0.04 mm.

B. Spectrometer. The basic geometrical arrangement for the EXAFS spectrometer is schematically shown in Fig. 1. The essential features of this instrument are the same as the Applied Research Laboratories design.[15] The anode of the X-ray generator, the LiF crystal ($2d$=4.027 Å) and the receiving slit are held on a Rowland circle. The guide, arms, and wires (not shown in Fig. 1) were provided to effect the following movements as a function of θ:

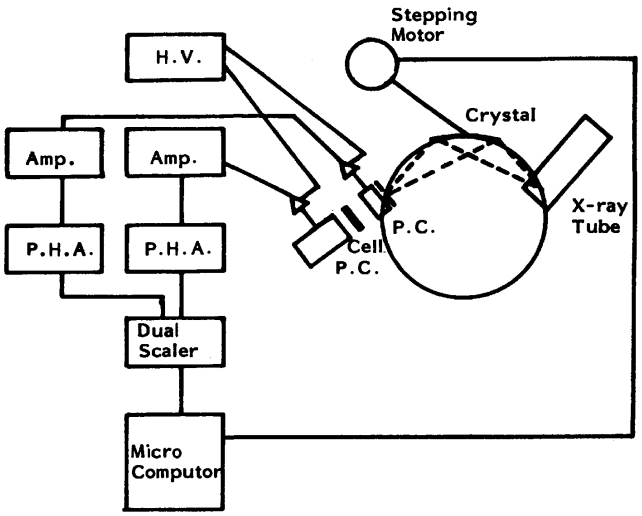

Fig. 2. Schematic diagram of the laboratory EXAFS system.

(1) The crystal moves on the motor-axis in a straight line away from the source aperture, thereby increasing the crystal-source distance, L, in accordance with $L=2R\sin\theta$. (2) The detector moves keeping the relation $r=2R\sin 2\theta$, where r is the distance between the source and the detector. (3) The detector slit is always directed toward the center of the crystal. Above conditions have been accomplished by one stepping motor. As the Rowland geometry is satisfied, the radiation with $n\lambda=2d\sin\theta$ is Bragg-diffracted from the LiF crystal and subsequently focused at the receiving slit on the Rowland circle. The focusing by the Johan crystal is less satisfactory than that by the crystal of the Johansson type. However, the monochromator can be more easily adjusted.

C. Detection System. The block diagram of the detection system is shown in Fig. 2. Monochromatized X-ray coming through the receiving slit passes first through a proportional counter which monitors the intensity of the radiation incident on the sample(I_0). The intensity of the X-ray which is transmitted by the sample is then measured by the second proportional counter. The photon received by each counter is converted to an electric pulse, which is amplified, pulse-hight-analyzed and counted. Both signals from the first and the second proportional counters are counted until the number of signals detected by the first (I_0) counter reaches the preset-number of the dual scaler. After reading-out, the spectrometer is set to the next Bragg angle, and both counters are started again. The spectra are stored on a magnetic disk of a microcomputer (SORD M223-Mark V) which also controls the stepping motor. A high voltage supply (1.6 kV) operates the two proportional counters (90% Ar–10% CH_4 gas flow at 1 atm).

Performance

The resolution of an X-ray spectrometer based on the Johan crystal optics is lower than that based on the Johansson's. The experimental resolution was obtained from the measured intensity profile of the characteristic emission lines of the impurity copper

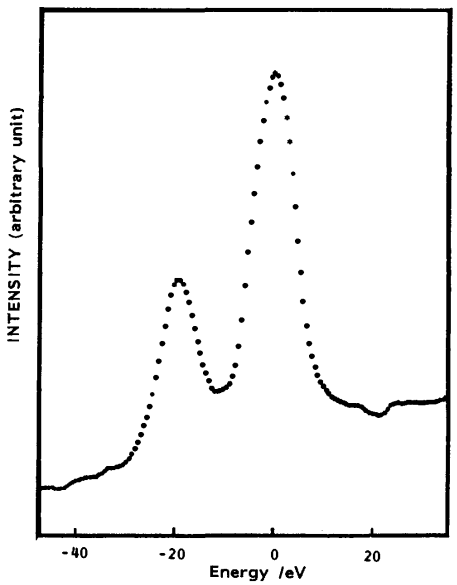

Fig. 3. Cu $K\alpha$ doublet obtained with a LiF(220) Johan-type crystal.

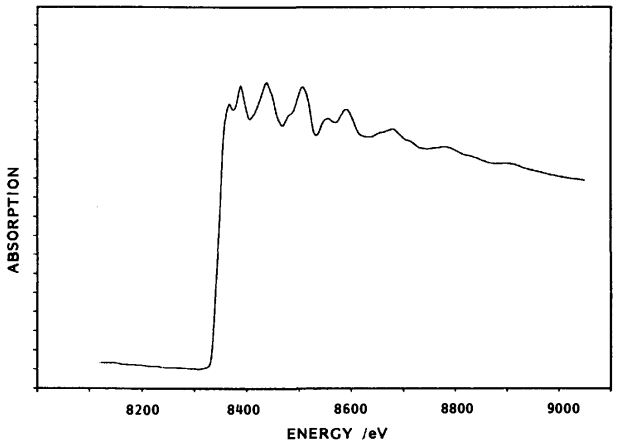

Fig. 4. X-ray absorption spectrum of 5-μm thick Ni foil.

contained in the anode of the X-ray tube. Figure 3 shows the $K\alpha$ doublet of Cu. A resolution satisfactory for measuring EXAFS was obtained when the receiving slit was set to 0.1 mm. In these conditions, the X-ray source operating at 16 kV and 5 mA gave an X-ray flux of 5×10^4 cps.

Since metal foil shows a pronounced EXAFS and is easily available, it has widely been used as a standard sample in EXAFS measurements. Figure 4 shows the absorption spectrum of Ni foil obtained from a run of 4-h measurement at 16 kV and 5 mA. The feature is almost identical with that obtained with SOR.

As an example of the results obtained for substances of chemical interest, the subtracted EXAFS oscillation $\chi(k)$ and the Fourier transform of $k^3\chi(k)$ of NiO powder are shown in Fig. 5(a) and (b). EXAFS up to 14 $Å^{-1}$ in the k range above the edge is clearly seen. The Fourier transform indicates the existence of some atoms, all in accordance with the known crystal structure when the phase shift is taken into account.

It is often quoted that characteristic lines from contaminated anode materials seriously impair the

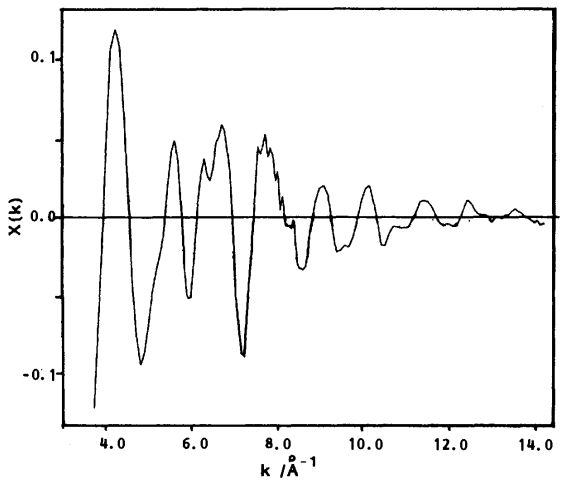

Fig. 5a. EXAFS spectrum of NiO.

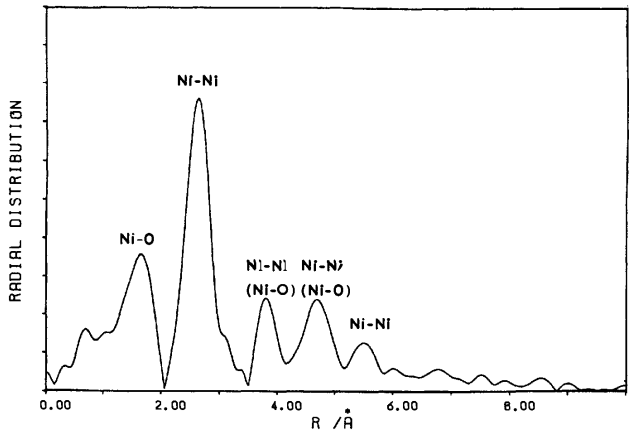

Fig. 5b. Fourier transformation of Fig. 5a.

quality of EXAFS spectra. For example, the L_α and L_η lines of W from the filament overlap the absoption spectrum of Ni. However, this difficulty can be avoided with a proper electronic circuits employed here. Measurements on two examples evidenced that the present system can give spectra good enough for a practical EXAFS analysis.

It is worth to discuss the advantage of the use of the proportional counter system over an ion-chamber system for the X-ray flux of our laboratory apparatus. The leak current of the ion chamber may be of the order of 10^{-16} A, which corresponds to *ca.* 10^3 photons. When the X-ray flux is high, for example 10^{10} photons/s, as in SOR, this leak current causes no trouble. But it is serious matter in a laboratory spectrometer operating with 10^6—10^5 photons/s. Although the photon counting systems with proportional (and scintillation) counters need the correction for the dead time in a higher X-ray flux, a proportional counter with a proper electronic circuit is preferred in this case.

Experimental

Aqueous solutions of ammine and ethylenediamine nickel(II) salts were prepared by dissolving $Ni(NO_3)_26H_2O$ in aqueous solutions of ammonia and ethylenediamine. The concentrations were determined by standard methods; Ni (0.300 M (1 M=1 mol dm^{-3})) and NH_3 (6.58 M) for ammine solution and Ni (0.292 M) and en (1.05 M) for ethylenediamine solution. The known stability constants show that the main species contained in these solutions are $[Ni(NH_3)_6]^{2+}$ for the ammine and $[Ni(en)_3]^{2+}$ for the ethylenediamine solutions. A plastic cell contained a small volume of the sample solution between windows spaced 1.0 mm apart. The solid sample was well grounded and deposited on to a piece of scotch-tape.

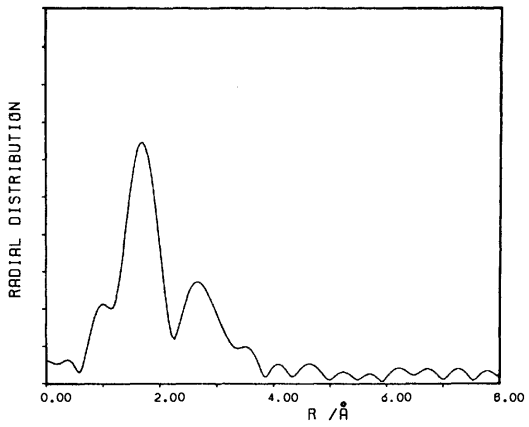

Fig. 6. Fourier transformation of the EXAFS spectrum of aqueous $[Ni(en)_3]^{2+}$ solution.

Data Analysis

The EXAFS spectra have been analyzed by following the standard procedure. The absorption background before the edge has been substracted from the experimental absorption spectrum, and the resulting spectrum $\mu(k)$ was normalized by using the atomic absorption coefficient $\mu_0(k)$, in order to give the χ(k) fine structure defined by $\chi(k)=[\mu(k)-\mu_0(k)]/\mu_0(k)$. The photoelectron wave vector is given by $k=[(E-E_0)2m/\hbar^2]^{1/2}$, where E is the photon energy and E_0, some reference energy which may not coincide with the energy of the absorption edge.

Result for the Solutions of the Ammine and Ethylenediamine Complexes

Figure 6 shows the results of Fourier transformation from the k space to the r space for aqueous $[Ni(en)_3]^{2+}$ solution. The radial distribution curve shows two peaks, of which the main one should correspond to the N atoms of the coordinated ethylenediamine ligands and the smaller one may be due to the C atoms of the ligands.

The curve-fitting analysis was performed according to the method of Cramer *et al.*[16] using the following formula.

$$k^2\chi(k) = c_0Nr^{-2}\exp(-c_1k^2)k^{-c_2}\sin[a_0+(a_1+2r)k+a_2k^2],$$

N and r represent the coordination number and the interatomic distance, respectively, and c_0—c_2 are the parameters for the amplitude functions and a_0—a_2 the phase shift parameters. To determine the parameter values, we first examined the spectra of the cryslalline $[Ni(en)_3]SO_4$ and $[Ni(en)_3](NO_3)_2$ of which the structures are known ($r_{Ni\text{-}N}$=2.124 Å for sulfate,[7] $r_{Ni\text{-}N}$= 2.120 Å for nitrate,[8] and N=6 for both complexes).

TABLE 1. CROSS-CHECK OF THE RESULTS OF LEAST-SQUARES FITS TO EXAFS DATA FOR CRYSTALLINE $[Ni(en)_3](NO_3)_2$ AND $[Ni(en)_3]SO_4$

	Coordination number	Ni–N distance/Å
$[Ni(en)_3](NO_3)_2$	5.7±0.8(6.0)	2.11±0.01(2.120)[a]
$[Ni(en)_2]SO_4$	6.2±0.8(6.0)	2.13±0.01(2.124)[b]

a) Obtained with parameters derived from the EXAFS of $[Ni(en)_3]SO_4$. (The values in parentheses are the results of an X-ray diffraction study.[8]) b) Obtained with parameters derived from the EXAFS of $[Ni(en)_3](NO_3)_2$. (The values in parentheses are the results of an X-ray diffraction study.[7])

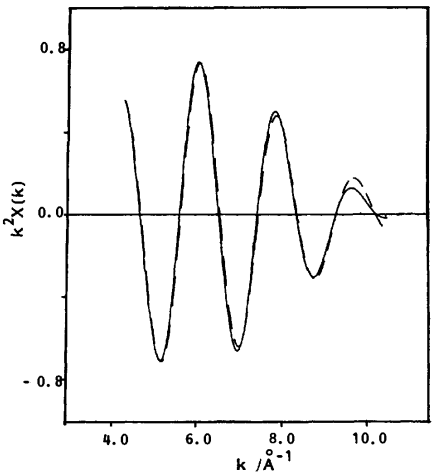

Fig. 7. First-shell fit for determining the structure of $[Ni(en)_3]^{2+}$ in solution by use of a set of parameters derived from the spectrum of solid $[Ni(en)_3]SO_4$. The solid line is the filtered EXAFS spectrum and dashed line is the least-squares fit.

With the fixed N and r, we obtained two sets of six parameters by curve-fitting the Fourier-filtered spectra for the isolated Ni–N interaction. For checking the accuracy of the results from analyses with these parameters, the least-squares fit to the filtered spectrum of each compound was carried out with the set of parameters obtained above for the other compound. The values obtained for N and r are shown in Table 1, which demonstrates that the analysis adopted here gives a reliable structural information.

Then we determined the N and r values for the ammine and the ethylenediamine complexes of nickel(II) in aqueous solutions with both sets of parameters. The Fourier-filtered and the least-squares fit curves are shwon in Fig. 7 for a solution of ethylenediamine nickel(II) nitrate; a set of parameters obtained from the spectrum of solid $[Ni(en)_3](NO_3)_2$ was used in the analysis. The numerical results are summarized in Table 2. Analyses with two different sets of parameters gave results in good agreement with each other. The measured coordination numbers are about six and the measured Ni–N distances are about 2.12 Å for both complexes in solutions. The values for the ethylenediamine complex are close to those for the same complex in the crystals, but are significantly different from that obtained by Fujita *et al.*[6] from their diffraction study on a solution. This inconsistency needs further investigation. Generally speaking, the EXAFS method as applied to solutions has the advantage that it detects only the interatomic interactions in which the nickel atom (or any other atom concerned) is involved, whereas the X-ray diffraction method gives a diffraction pattern which is the superposition of various diffractions by different pairs of atoms at different distances.

TABLE 2. RESULTS OF THE CURVE FITTING ANALYSIS OF THE EXAFS SPECTRA OF AQUEOUS $[Ni(NH_3)_6]^{2+}$ AND $[Ni(en)_3]^{2+}$ SOLUTIONS

	Set of parameters	Coordination number	Ni–N distance/Å
$[Ni(NH_3)_6]^{2+}$	A	6.0±0.8	2.13±0.01
	B	5.7±0.8	2.12±0.01
$[Ni(en)_3]^{2+}$	A	6.1±0.8	2.13±0.01
	B	5.8±0.8	2.12±0.01

A: Parameters derived from the spectrum of solid $[Ni(en)_3](NO_3)_2$. B: Parameters derived from the spectrum of solid $[Ni(en)_3]SO_4$.

The authors (especially M. S.) would like to thank Prof. K. Taniguchi of Osaka Electrocommunication University for his encouraging suggestions and useful discussions.

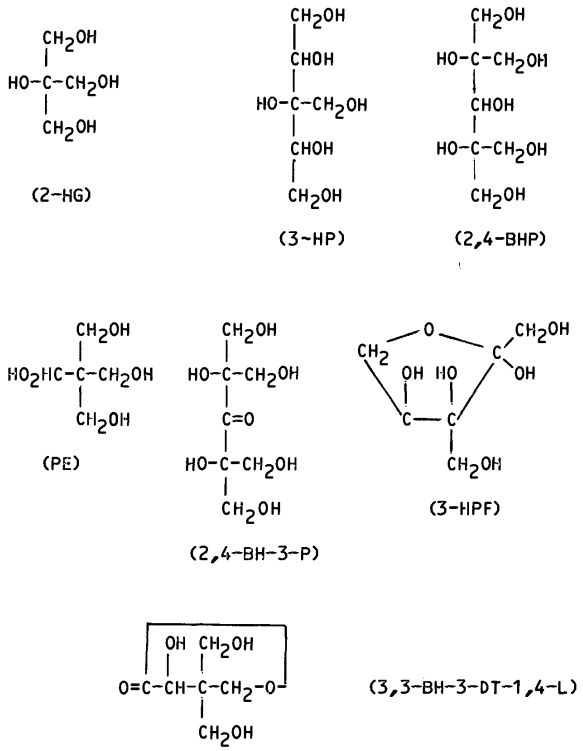
Formose Reactions. XXI. A Selective Formation of Dihydroxyacetone in the Formose Reaction in *N,N*-Dimethylformamide

Yoshihiro SHIGEMASA,* Yoshihiro SASAKI, Nasuo UEDA, and Ruka NAKASHIMA
Department of Industrial Chemistry, Faculty of Engineering, Tottori University, Tottori 680
(Received November 11, 1983)

Dihydroxyacetone (DHA) was obtained in good yield from the selective formose reaction which was conducted with 2-(dimethylamino)ethanol and vitamin B_1 in *N,N*-dimethylformamide (DMF). The major products were isolated from the formose and identified as dihydroxyacetone and 2-(1,2-dihydroxyethyl)-5-(2-hydroxyethyl)-4-methylthiazole by spectral data. Vitamin B_1 suppressed the vaporization of formaldehyde from the reaction solution. Irrespective of the 2-(dimethylamino)ethanol concentration (above 0.1 M (1M=1 mol dm^{-3})), the maximum yield of DHA was 80—90 glc% at 1.0 M formaldehyde concentration, when the formaldehyde consumption was above 90%. Above 3.0 M formaldehyde concentration, selective formation of DHA (above 80 glc%) was obtained at the early stage of the reaction. The scheme for the formation of DHA in the formose reaction in the presence of vitamin B_1 was also proposed.

Dihydroxyacetone, a fermentation product of glycerol,[1] has been used as a building block for pharmaceuticals, dyes, foodgrade emulsifiers, plasticizers, fungicides, and alkyd-type resins. It is, furthermore, noted as a key intermediate in a novel pathway for formaldehyde fixation in methanol-utilizing yeasts.[2] Several methods of preparation of DHA by chemical means were studied.[3] It is also formed in the formose reaction catalyzed by aq-alc $Ca(OH)_2$.[4] Recently, Inoue *et al.*[5] reported that dihydroxyacetone was obtained in a good yield (80%) when the formose reaction was carried out in dioxane in the presence of 3-ethylbenzothiazolium bromide and triethylamine at 100 °C. The formose reaction[6] catalyzed by triethylamine and a derivative of thiazole in DMF solution at 100 °C was found to give no branched sugars such as glucose, galactose, xylose, and glyceraldehyde dimer. Furthermore at the early stage of the reaction glyceraldehyde dimer was the major products. It is important that three carbon carbohydrates such as dihydroxyacetone and glyceraldehyde are obtained in high selectivity.

We have studied the effects of various reaction conditions on the product distribution, such as catalysts, the concentration of formaldehyde and catalyst, the reaction temperature, the kind of solvent and so on. In our studies,[7-12] it has been found that some formose reactions in H_2O or methanol give selectively 2-(hydroxymethyl)glycerol (2-HG), 3-(hydroxymethyl)pentitol (3-HP), 2,4-bis(hydroxymethyl)pentitol (2,4-BHP), pentaerythritol (PE), 2,4-bis(hydroxymethyl)-3-pentulose (2,4-BH-3-P), 3-(hydroxymethyl)pentofuranose (3-HPF), or 3,3-bis(hydroxymethyl)-3-deoxy-tetrono-1,4-lactone (3,3-BH-3-DT-1,4-L), and these products have been isolated in a pure form. All of these products are branched sugars and sugar alcohols. It is interesting to study the formose reaction, using dipolar aprotic solvents such as DMF and dimethyl sulfoxide (DMSO) instead of protic solvents such as H_2O and methanol. We have searched for the catalysts which give the simple product-distribution in the gas chromatogram of trimethylsilyl derivatives, using DMF and DMSO as a solvent and have already reported that dihydroxyacetone (DHA) is formed selectively in the presence of 2-(dimethylamino)ethanol and vitamin B_1.[13] The role of vitamin B_1 was also observed: in the absence of vitamin B_1, formaldehyde vaporized and a self-condensation of



vaporized formaldehyde to paraformaldehyde took place very readily under the given reaction conditions; in the presence of vitamin B_1, however, such reactions were sufficiently suppressed for the formose reaction in DMF to occur smoothly. A product derived from vitamin B_1 was also isolated and assigned to be 2-(1,2-dihydroxyethyl)-5-(2-hydroxyethyl)-4-methylthiazole (**I**) on the basis of spectroscopic data.

The purpose of this paper is to report the effects of various inorganic and organic catalysts on the formose reaction in DMF and to reveal the effects of vitamin B_1, the reaction temperature, and the concentration of 2-(dimethylamino)ethanol and formaldehyde on the formation of DHA and (**I**).

Experimental

Materials. Two types of paraformaldehyde were used. Paraformaldehyde produced by Merck Co. (95%) had a smaller particle size and gave a faster HCHO consumption

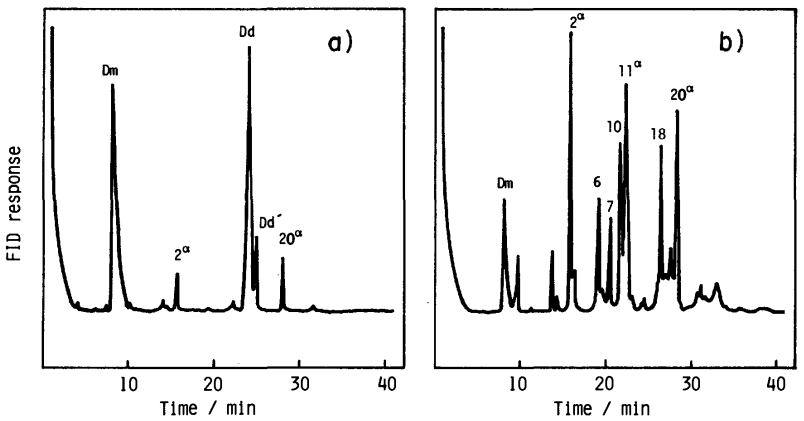


Fig. 1. The glc patterns of trimethylsilylated products from: (a) the selective formose reaction for 180 min starting from [HCHO]= 1.1 M, [2-(Dimethylamino)ethanol]=0.11 M, [Vitamin B_1-HCl]= 0.028 M and DMF=180 ml at 60°C, and (b) non-selective formose reaction for 5 min starting from [HCHO]=1.1 M, [$Ca(OH)_2$]=0.11 M, [Vitamin B_1-HCl]=0.028 M and DMF=180 ml at 100°C.

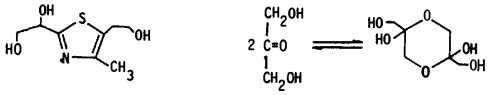
than that of Mitsubishi Gas Chem. (86%), but the differences in the product-distribution and the formose yield between the two were small. All the inorganic and organic bases used as catalysts were of analytical grade. DMF was purified in the usual way.[14]

Procedure. A representative example of the reaction is as follows. A five-necked flask (200 ml), which contained 180 ml of DMF, was preequilibrated at 60°C in a thermostat under nitrogen; the reaction was then initiated, followed by the addition of 2-(dimethylamino)ethanol (1.8 g, 0.11 M), paraformaldehyde (Merck Co., 6.3 g, 1.1 M), and vitamin B_1-HCl (1.7 g, 0.028 M) in this order. At suitable intervals, 5 ml aliquots were withdrawn into a 10 ml flask, and the reaction was quenched immediately by acidification with 9M HCl. The aliquots were analyzed for formaldehyde following the method of Bricker *et al.*,[15] except that the optical density was measured at 579 nm. Then, the reaction mixture was concentrated under reduced pressure (25—30°C/2 mmHg†) to yield a brownish syrup (6.5 g). The product yield and distribution were determined as the pertrimethylsilylated products by gas-liquid chromatography. The yield (mg/ml) was measured by the internal standard (pentaerythritol) method. The glc pattern (Fig. 1a) clearly indicates the selective formation (90%) of the product corresponding to the peaks Dm, Dd, and Dd', the retention times of which are the same as those of pertrimethylsilylated dihydroxyacetone. Furthermore, the glc analysis of peracetylated products indicated one major peak in the same manner as that of authentic DHA.

Separation and Identification of Products. The product corresponding to glc peaks Dm, Dd, and Dd' was isolated as follows: The formose syrup (6.5 g) obtained by the above reaction was acetylated with acetic anhydride in pyridine, and the reaction mixture was extracted with chloroform, the extract was concentrated to 4 ml and re-extracted with 400 ml of water. Then, the water layer was concentrated to 25 ml and 4 g of active carbon was added to the concentrated solution. Acetylated dihydroxyacetone (2.5 g, hydroscopic) was obtained as a yellow crystalline form by eluting the active carbon with methanol, followed by concentrating the methanol solution. ^{1}H NMR ($CDCl_3$) δ=2.15 (6H, s, 2×O-$COCH_3$) and 4.8 (4H, s, 2×C-CH_2). The molecular ion was observed at *m/z* 174 in the electron impact mass spectrum. IR (KBr) 1745 (C=O), 1418, 1373, 1239 (OAc), and 1052 cm^{-1}. The IR spectrum was in agreement with that of an authentic sample of acetylated dihydroxyacetone.

Deacetylation of the peracetylated products with barium hydroxide gave the original product, and the trimethylsilyl derivative showed exactly the same glc behaviour as that for the directly trimethylsilylated product. The product corresponding to peaks Dm, Dd, and Dd', therefore, was assigned as a mixture of dihydroxyacetone monomer and its diastereomeric dimers (**II**).



(I) (II)

The product (**I**) (40 mg, colorless syrup) corresponding to the glc peak 20$^\alpha$ was also isolated by chromatography on an active carbon column with water and methanol as eluent, followed by purification of the acetyl derivative of 20$^\alpha$ with thin-layer chromatography (benzene/EtOAc=1/1). IR (KBr) 1750 (C=0), 1640 (C=N-C), 1370, 1240 (OAc), and 1050 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=2.07 (6H, s, 2×O-CO-CH_3), 2.16 (3H, s, O-CO-CH_3), 2.36 (3H, s, C-CH_3), 3.06, 4.23 (each 2H, t, -CH_2), 4.47 and 4.64 (each 1H, dd, J_{AX}=7.08 Hz, J_{BX}=3.62 Hz, **H**-A, B), and 6.24 (1H, dd, J_{AX}=7.08 Hz, J_{BX}=3.62 Hz, **H**-X). ^{13}C NMR ($CDCl_3$) δ=170.7 (s, **C**OCH_3), 170.4 (s, **C**OCH_3), 169.7 (s, **C**OCH_3), 161.6 (s, C-2), 149.6 (s, C-4), 128.2 (s, C-5), 70.6 (d, C-2'), 64.6 (s, C-2''), 63.9 (t, C-5''), 25.9 (t, C-5'), 20.9 (q, **C**OCH_3), 20.7 (q, **C**OCH_3), and 14.9 (q, CH_3). The chemical ionization mass spectra using *i*-C_4H_{10}, NH_3, or ND_3 as a reagent gas[16] showed a quasi-molecular ion at *m/z* 330 (MH^+), 347 ($M \cdot NH_4^+$), or 351 ($M \cdot ND_4^+$), respectively, which precisely indicated a molecular weight of 329. These results suggested that the acetate of the product (**I**) had no active hydrogen in the molecule. Deacetylation of the acetate with barium hydroxide gave product (**I**) as a colorless syrup. IR (KBr) 3350 (br., OH), 1630 (C=N-C), 1550, 1440, 1320, 1190, and 1050 cm^{-1}. ^{1}H NMR(CD_3OD) δ=2.29 (3H, s, C-CH_3), 2.90 and 3.69 (each 2H, t, -CH_2-), 3.74 (2H, d, -CH_2OH), and 3.83 (^{1}H, t, >CHOH). ^{13}C NMR (CD_3OD) δ=171.8 (s, C-2), 148.9 (s, C-4), 129.8 (s, C-5), 73.5 (d, C-2') 67.4 (t, C-2''), 63.1 (t, C-5''), 30.5 (t, C-5'), and 14.7 (q, CH_3). The chemical ionization mass spectra using *i*-C_4H_{10}, NH_3, or ND_3 as a reagent gas showed a quasi-molecular ion at *m/z* 204 (MH^+), 221 ($M \cdot NH_4^+$), or 228 ($d_3M \cdot ND_4^+$), respectively, which precisely indicated a molecular weight of 203 and the presence of three active hydrogens in the molecule. These results led us to assign 20$^\alpha$ to be 2-(1,2-dihydroxyethyl)-5-(2-hydroxyethyl)-

† 1 mmHg≈133.322 Pa.

4-methylthiazole as the product derived from vitamin B_1.

Results and Discussion

Formose Reactions in DMF in the Presence of Inorganic and Organic Bases. The formose reactions were carried out with various inorganic bases (Table 1). In the case of LiOH and $Pb(CH_3COO)_2 \cdot Pb(OH)_2$, formaldehyde was consumed smoothly, but after 2 h of reaction time, NaOH, $Mg(OH)_2$, $Ba(OH)_2$, and $Pb_2O(OH)_2$ gave little formose. LiOH, $Ca(OH)_2$, and $Sr(OH)_2$ were found to give the product of GP-11 selectively which had the same retention time as 3,3-BH-3-DT-1,4-L.[7] Under these reaction conditions, the formose yield was low and considerable paraformaldehyde adhered to the upper part of the reaction flask as described previously.[13]

The results of the formose reactions catalyzed by various inorganic bases and organic bases in the presence of vitamin B_1 are summarized in Tables 2 and 3, respectively. In Table 2, product (**I**) corresponding to glc peak 20$^{\alpha}$ which was derived from vitamin B_1 was

a) DMF=180 ml, [HCHO]=1.1 M, [Base]=0.11 M, [Vitamin B_1-HCl]=0.028 M, Stirring rate=240 min^{-1}., pH: not adjusted, Temp=100°C. b) The amount of paraformaldehyde adhering to the flask was small. c) Parentheses indicate yield(mg/ml) measured by the internal standard(pentaerythritol) method. d) A lot of paraformaldehyde adhered to the flask. e) Solid paraformaldehyde remained in the reaction solution. f) GLC was below 1%. g) Total yield(mg/ml) is the summation of the yield of each product measured by the internal standard(pentaerythritol) method.

formed. LiOH, KOH, and $Ba(OH)_2$ were found to give DHA selectively. Compared with the cases in the absence of vitamin B_1, formaldehyde was consumed smoothly, the yield of formose increased, and the amount of formaldehyde adhering to the reaction vessel was small. In the absence of base, the formose reaction did not proceed and the added formaldehyde was recovered entirely over 120 min. Hence, it can be concluded that by itself vitamin B_1 has no catalytic action for the formose reaction in DMF. As shown in Table 3, (**I**) was also formed except in the case of dimethylamine and morpholine. Dimethylamine, morpholine, *N,N*-dimethylaniline, and β-picoline were found to give gas chromatogram peak number 1^{β} (GP-1^{β}) as a major product which was formed easily when vitamin B_1 was heated in DMF; 2-(dimethylamino)ethanol, trimethylamine, *N*-methylpiperidine, and triethylamine were found to give the good yield of DHA.

Effects of Vitamin B_1. As described above, the formose reactions in the presence of vitamin B_1 gave smoother formaldehyde consumption, better yield of formose, and less formaldehyde adhering to the reaction vessel. The solubility of formaldehyde in DMF at 60 or 100°C was measured in the presence or absence of vitamin B_1 with the results shown in Fig. 2. The amount of dissolved formaldehyde in DMF and the solution rate increased with an increase in temperature. At 60°C, formaldehyde scarcely vaporized and remained in the solution, but at 100°C, the vaporization of formaldehyde proceeded smoothly and the formaldehyde concentration in the solution decreased rapidly. In the presence of vitamin B_1, however, the vaporization of formaldehyde was suppressed. Furthermore, solid paraformaldehyde remained in the solution.

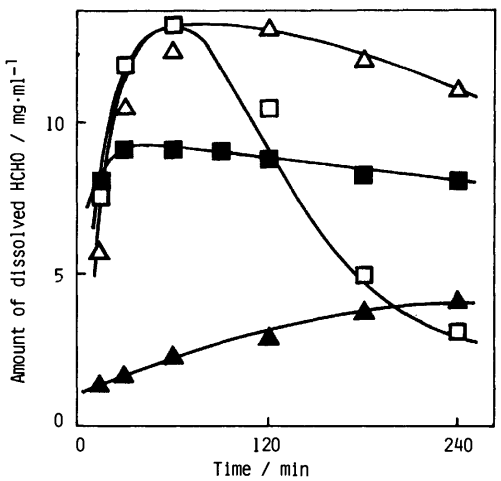

Fig. 2. Solubility of HCHO in DMF.
DMF=180 ml, [HCHO]=1.1 M, Stirring rate=240 min^{-1}. □, Temp=100°C; ▲, Temp=60°C; ■, Temp=100°C; up to 15 min and 60°C after 15 min; △, Temp=100°C; [Vitamin B_1-HCl]=0.028 M.

In all cases studied, the total amount of adhering, dissolved, and residual formaldehyde at 240 min was nearly equal to the amount of formaldehyde added. These results suggest that the interaction between vitamin B_1 and formaldehyde yields the Lapworth intermediate (**III**)[6,17] which is well known as "active aldehyde" in the transketolase reaction.[18]

Figure 3 shows the relationship between the vitamin B_1 concentration and the yield of DHA in the presence of 2-(dimethylamino)ethanol at 100°C. As the reaction proceeded, the yield of DHA increased and reached a constant value. The yield of DHA increased with increasing vitamin B_1 concentration up to a concentration

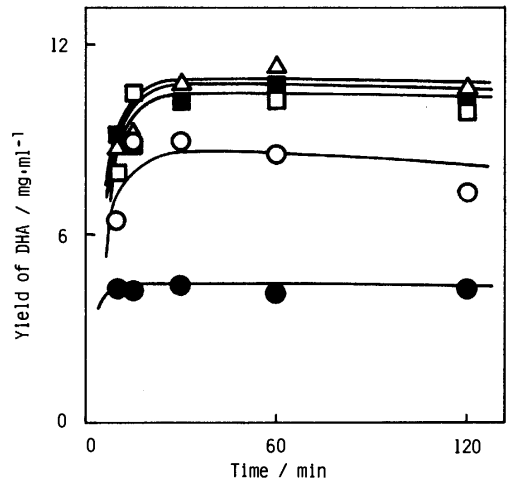

Fig. 3. Effect of vitamin B_1 concentration on the yield of DHA.

○, Max. percentage of DHA (glc%); ●, The time(min) when DHA showed max. percentage.

of 0.028 M. In the absence of vitamin B_1, 4.4 g of paraformaldehyde adhered to the upper part of the reaction vessel after 120 min of reaction time, when the formaldehyde consumption was 11% and DHA no longer formed. GP-2$^{\alpha}$ formed in *ca.* 20 glc% yield at 0.007 M of vitamin B_1 and, with an increase in vitamin B_1 concentration, decreased to less than 1 glc% at 0.028 M. The yield of product (**I**), furthermore, increased with increasing concentration of vitamin B_1.

Effects of the Reaction Temperature. The influence of the reaction temperature on the formose reaction was studied. This included the yield of DHA, the product distribution, the formaldehyde consumption *etc.* The results are shown in Fig. 4. By raising the reaction temperature, the formaldehyde consumption

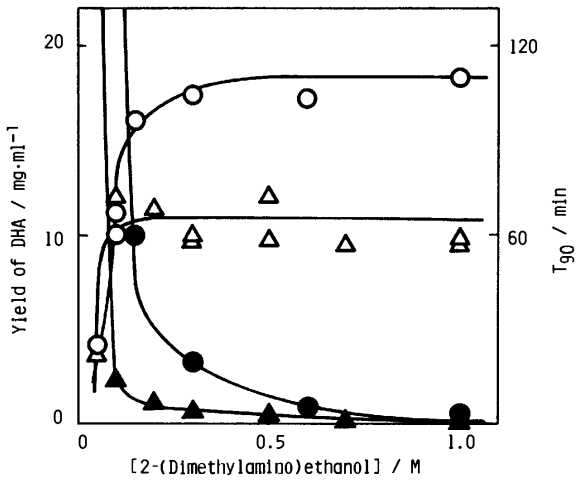

Fig. 5. Effect of the concentration of 2-(dimethylamino)ethanol on the yield of DHA and T_{90}.
DMF=180 ml, [Vitamin B_1-HCl]=0.028 M, Temp.=100°C, Stirring rate=240 min^{-1}. Yield of DHA, [HCHO] (M): △, 1.1; ○, 3.0. T_{90}, [HCHO] (M): ▲, 1.1; ●, 3.0.

rate increased, the yield of DHA decreased, and the side-products (**I**) and GP-2$^{\alpha}$ formed appreciably. The time at which DHA showed maximum percentage in the gas chromatogram decreased rapidly with an increase in the reaction temperature and at that time the formaldehyde consumption was above 90%. Irrespective of the reaction temperature, the amount of DHA hardly changed after reaching the maximum value. It can therefore be presumed from these results that even at the high reaction temperature of 100 or 120°C, DHA is stable under these reaction conditions.

Effects of the 2-(Dimethylamino)ethanol Concentration. Figure 5 shows the relationship between the yield of DHA, the formaldehyde consumption, and the 2-(dimethylamino)ethanol concentration. With an increase in the 2-(dimethylamino)ethanol concentration, the yield of DHA and the decreasing rates of the total sugar and DHA increased, however, above 0.1 and 0.15 M of the base concentration at the formaldehyde concentration of 1.0 and 3.0 M, respectively, the maximum yield of DHA had a constant value regardless of the base concentration. The maximum total sugar yield were 10—13 and 30—35 mg/ml, respectively. The maximum percentage of DHA, furthermore, was 80—90 and 60—80 glc% at 1.0 and 3.0 M of the formaldehyde concentration, when the formaldehyde consumption was above 90 and 60—80%, respectively. At a formaldehyde concentration of 3.0 M the formation of other products which might be derived from DHA reduced the selectively for DHA formation. The time (T_{90}) when the formaldehyde consumption reached 90% shortened with increasing base concentration. This suggests that 2-(dimethylamino)-ethanol not only catalyzes the formose reaction, but also decomposes the products formed. It is also considered that DHA is the principal in the formose reaction. Product (**I**) was detected only below 0.1 M of the base concentration at 1.0 M of the formaldehyde concentration, however, at 3.0 M of formaldehyde, the yield of product (**I**) was 1—2 mg/ml, regardless of the base concentration.

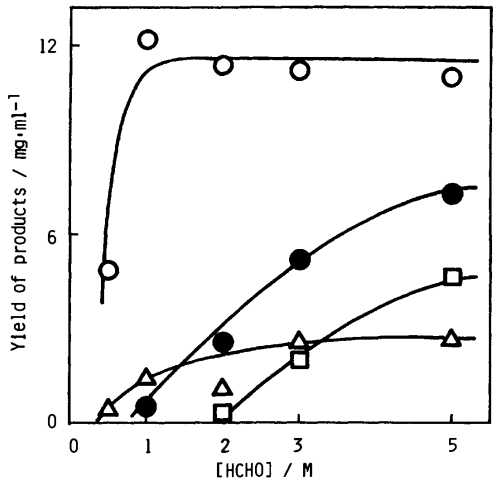

Fig. 6. Effect of HCHO concentration on the yield of products.

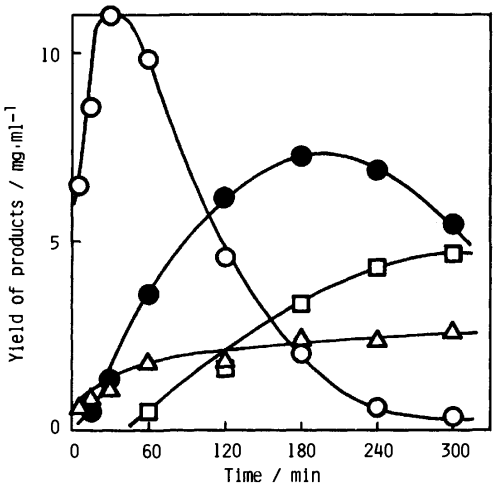

Fig. 7. Time-courses of the yield of products.
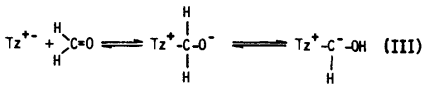
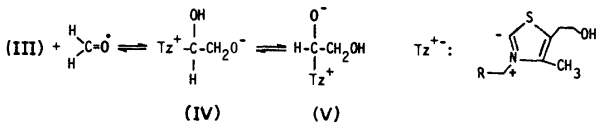
DMF=180 ml, [HCHO]=5.0 M, [2-(Dimethylamino)-ethanol]=0.11 M, [Vitamin B_1-HCl]=0.028 M, Stirring rate=240 min^{-1}, Temp=100°C.
○, DHA; ●, 2$^{\alpha}$; □, 10; △, 20$^{\alpha}$.

Effects of the Formaldehyde Concentration on the Product Distribution. The relationship between the formaldehyde concentration and the product distribution is shown in Fig. 6. Irrespective of the formaldehyde concentration (above 1.0 M), the maximum amounts of DHA and product (**I**) showed constant values of *ca.* 12 and 2 mg/ml, respectively. However, by raising the formaldehyde concentration, the yields of GP-2$^{\alpha}$ and GP-10 increased; the isolation and structure elucidation of these products are now under investigation. The proportion of DHA in the total products decreased. Above 3.0 M formaldehyde concentration, the selective formation of DHA (above 80 glc%) occurs during the early stage of the reaction. Concerning the formation of glyceraldehyde, the same phenomenon was observed by J. Castells *et al.*[6]: Paraformaldehyde (1.33 mol) was added, with continuous stirring, to a solution of triethylamine (186 mmol) and 3-benzyl-5-(2-hydroxyethyl)-4-methylthiazolium chloride (185 mmol) in DMF (250 ml) at 100°C. The amount of DHA formed, furthermore, decreased rapidly with in increase in the formaldehyde concentration. Figure 7 shows the typical time-courses of the products. In these experiments, the formaldehyde consumption at 300 min was 85%. GP-2$^{\alpha}$ and GP-10 increased instead of DHA decreasing. These results suggest that DHA is a precursor of GP-2$^{\alpha}$ and GP-10 and play an important role in the formose reaction.

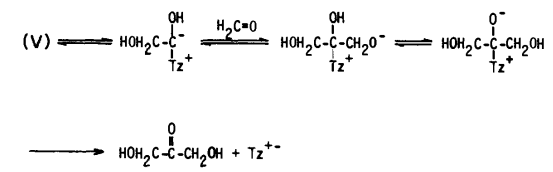
Scheme for DHA Formation. J. Castells *et al.*[6] suggested the following scheme concerning the formation of glycolaldehyde, glyceraldehyde, and DHA in the formose reaction carried out under the similar reaction conditions to ours. In the scheme they made two assumptions: (1) The Lapworth intermediate (**III**) did not attack ketone carbonyl groups. This assumption was based on the fact that no branched-chain products were isolated in any benzoin condensation.; (2) The Lapworth intermediate (**III**) did not react, or reacted slowly, with aldohexoses, due to the predominance of hemiacetal forms (masked aldehyde carbonyl groups).



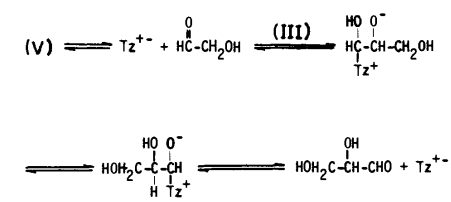


In penetrating studies on benzoin and acetoin formation in the presence of thiamine and other thiazolium compounds pursued by Breslow and others,[18,19] the hydrogen atoms at position 2 of the thiazolium ring was found to exchange rapidly in a deuterated solvent. The product (**I**), furthermore, was detected in the products of the formose reaction in the presence of vitamin B_1. These results suggest the presence of the intermediate (**IV**) which would give the intermediate (**V**). Then, the two following paths may be considered: Further addition of formaldehyde and formation of DHA (Path 1); formation of glycolaldehyde and glyceraldehyde (Path 2).

Path 1



Path 2



The formation of glycolaldehyde and glyceraldehyde as minor products and of dihydroxyacetone (DHA) as a major product suggests that Path 1 would be predominant under the reaction conditions investigated in this report. The above formulation of the reaction mechanism, however, can not explain why Path 1 proceeds in preference to Path 2, and how the substituent group on the nitrogen atom of the thiazolium ring affects the formation of DHA.

Conclusions. From these observations, one can draw the following conclusions. First, vitamin B_1 has no catalytic action for the formose reaction in DMF by itself, but gives more smooth formaldehyde consumption, better yield of formose, and the formation of 2-(1,2-dihydroxyethyl)-5-(2-hydroxyethyl)-4-methylthiazole and some complexes with formaldehyde. Second, by raising the reaction temperature, the side-reactions also proceed easily, however, even at such high reaction temperatures as 100 or 120°C, DHA is stable under these reaction conditions. Third, DHA is the principal intermediate in the formose reaction and is decomposed by the excess of base.

Finally, the present investigation provides the following guide-lines for obtaining high DHA yield in batch-reaction systems. Further addition of formaldehyde to DHA and the decomposition of DHA must be minimized. This may be done at low formaldehyde concentrations, at relatively low reaction temperature (60°C), and at high [base]/[HCHO] ratios with low base concentrations, or by stopping the reaction at an early stage in the case of high formaldehyde concentrations.

Regio- and Stereocontrolled Synthesis of Allenic and Acetylenic Derivatives. Organotitanium and Boron Reagents

Kyoji FURUTA, Masaharu ISHIGURO, Ryuichi HARUTA, Nobuo IKEDA, and Hisashi YAMAMOTO*
Department of Applied Chemistry, Nagoya University, Chikusa, Nagoya 464
(Received December 26, 1983)

The propargyltitanium reagents derived from 1-alkylpropyne condensed with aldehydes to give α-allenyl alcohol regioselectively, while the allenyltitanium reagents generated from 1-alkyl-1-butyne derivatives gave *threo*-β-acetylenic alcohols with high regio- and stereoselectivities. The course of the reaction was determined by the substitution pattern of starting alkynes. The similar reactions of metallated 1,3-bis(trialkylsilyl)propyne or (trialkylsilyl)acetonitrile with aldehydes were also investigated.

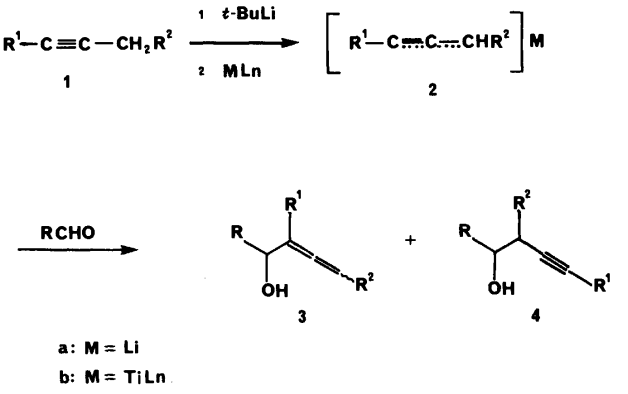
The importance of the propargylic anions in synthetic chemistry emerged from the recognitions of their utility for the extension of the carbon chain and facility in the interconversion of the functionality.[1] Their applicability in organic synthesis, however, has been limited because of the difficulties in controlling the regio- and stereoselectivities of the reaction. As it is often pointed out, the propargylic anion may be in equilibrium with allenic anion.[2] Thus, in the condensation with carbonyl compounds, two products, acetylenic and allenic alcohols, can be formed. Furthermore, each product may consist of two stereoisomers, *i. e.*, *erythro* and *threo* isomers.[3] Under the ordinary reaction conditions, therefore, these four isomers should be produced. Thus, to achieve the selective reaction, it is necessary to solve the regiochemical (allenic and acetylenic) and stereochemical (*erythro* and *threo*) problems at the same time. The similar ambiguity should be observed in the reaction of allylic anions.[4]

In general, the structure and reactivities of the ambident anion are highly dependent on the nature of the countercations and solvents.[5] In our continuative studies on the organometallic reagents, we found the propargylic titanium reagents partially solved the aforementioned problems. We also investigated the reaction of nitrile anion,[6] which had an analogous structure with propargylic anion, and observed that the boron as a countercation gave the best result in this particular case.

We report here a regio- and stereocontrolled synthesis of allenic and acetylenic alcohols using propargyltitanium reagents. The application of the methodology for the synthesis of enynes and α,β-unsaturated nitriles were also described herein.[7]

Results and Discussion

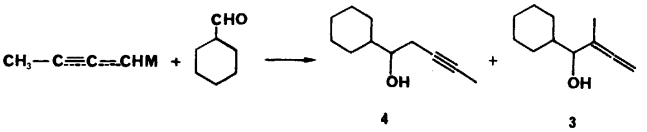
Synthesis of Allenic and Acetylenic Alcohols. The lithio propargylic derivatives, which were easily generated from substituted propyne derivatives and *t*-butyllithium, were subject to condensation with aldehydes as such or after the exchange of the lithium ion by subsequent treatment with appropriate metal salts (Scheme 1).



Scheme 1.

The lithio reagent **2a** (R^1=Me, R^2=H) derived from 2-butyne reacted with cyclohexanecarbaldehyde in tetrahydrofuran (THF) solvent to give a mixture of α-allenic and β-acetylenic alcohol **3** and **4**, respectively, in the ratio of 42:58. On the other hand, the titanium derivative **2b** (R^1=Me, R^2=H) gave the α-allenic alcohol **3** without contamination of any β-acetylenic alcohol **4**. The slight alteration in product distribution was observed by changing the solvent from THF to ether. The effects caused by changing the metal cation and solvent were studied in detail and the results are summarized in Table 1.

TABLE 1. THE REGIOSELECTIVITY OF THE REACTION OF METALLATED 2-BUTYNE WITH CYCLOHEXANECARBALDEHYDE[a]



4 3

Entry	Metal[b]	Solvent	4	3[c]

9	Phenyl	CH_3	Phenyl	>99: 1 (98: 2)	92

a) Determined by GLC analysis. b) Values in parenthesis refer to ratios of **4**/**3** obtained in the reactions with lithium reagents. c) 56:44 using Mg ion; 75:25 using Zn ion.

The regioselectivity is heavily dependent on the kind of metal ion. Thus, the titanium reagent showed the highest regioselectivity (entry 4) in a variety of metal ions investigated.[8] In most cases, THF was a superior solvent to ether.

Since the unusual selectivities of the titanium reagents became apparent from the above results, their reactivities were examined in detail. The results were summarized in Table 2.

The titanium reagent generated from 1-substituted propyne (**2b**, R^1=alkyl or trialkylsilyl, R^2=H) condensed with an aldehyde to give the α-allenic alcohol **3** exclusively, similar to that observed in the reaction of 2-butyne (entries 1—4). However, a dramatic alteration in the product distribution occurred when the reactions of the homologous titanium reagents derived from 1,3-disubstituted propyne (**2b**, R^1=alkyl or trialkylsilyl, R^2=Me) were conducted with the same aldehydes. Thus, none of the corresponding α-allenic alcohols were detected, and instead the β-acetylenic alcohols **4** were obtained (entries 5—9). The high regioselectivity appears to be general for a range of acetylenes and aldehydes. Although the corresponding lithio derivatives generally gave the less selective results, in the case of 1,3-disubstituted propyne, even the lithio derivatives showed moderate to fairly high selectivities (entries 7—9).

From the above results, the characteristic features of the reaction may be summarized as follows. The substitution pattern of the starting alkynes plays a dominant role in determining the regioselectivity of the reaction: The alkynes having a substituent on propargylic carbon (**1**, $R^2 \neq H$) produced β-acetylenic alcohols exclusively, while allenic alcohols were obtained from the alkynes not substituted at propargylic carbon (**1**, R^2=H).

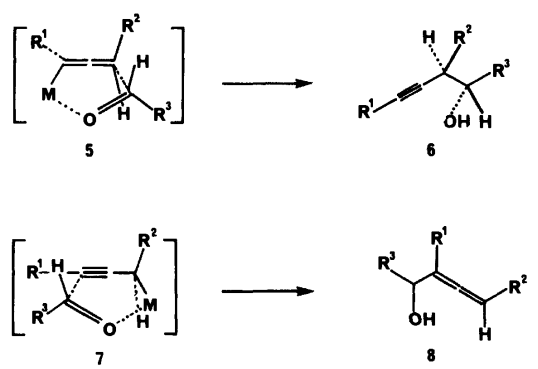

Fig. 1. S_Ei' process.

It is currently assumed that the addition of the allenic and acetylenic organometallics to the carbonyl takes place through an allylic rearrangement of the organometallic by a chelate transition state depicted in Fig. 1.[9]

That is to say, an allenic organometallic produced the β-acetylenic alcohol, while the α-allenic alcohol was derived from an acetylenic reagent. On the basis of these mechanistic considerations, the highly regioselective reaction of the titanium reagents could be explainable as follows. The titanation of the propargylic anion took place with extremely high regioselectivity to produce either allenic or acetylenic titanium derivatives depending on the substitution pattern of the original alkynes. Indeed, the IR spectrum of the titanium reagent in THF derived from 1-(trimethylsilyl)-1-butyne showed a strong absorption at 1898 cm^{-1} characteristic for allenic structure,[10] while that of the reagent derived from 1-(trimethylsilyl)propyne revealed only acetylenic absorption at 2092 cm^{-1},[10] in accord with the above speculation. In contrast to the highly selective formation of either allenic or acetylenic structure with titanium reagent, other metal cations, Li^+, MgX^+, *etc.*, furnished a mixture of the allenic and the acetylenic reagent in a variable ratio depending on the metal cations used. Siteselectivity was assumed to be determind primarily by steric requirements, and the steric repulsion between R^2 and metal centre (Fig. 2) provided conclusive factor of selectivity.

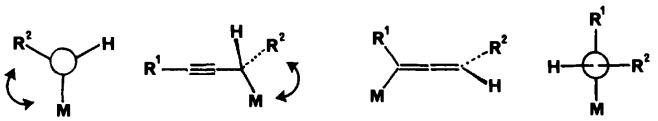

Fig. 2. Steric repulsion.

While the general trend of the regioselectivity of the titanium reagents has become apparent, it was of considerable interest to us to determine whether the tita-

nium reagents would exhibit an extraordinary diastereoselection for the β-acetylenic alcohol synthesis. Accordingly, we have carefully examined the diastereomeric ratios of the β-acetylenic alcohols (Table 3).

As summarized in Table 3, diastereomeric ratio is influenced significantly by the nature of the counter cation. Thus, the lithium, magnesium, and zinc reagents afforded the mixture of *erythro* and *threo* alcohols with low to moderate stereoselectivities. The enhanced selectivity was now observed with titanium reagents. The titanium reagents afforded predominantly the *threo*-β-acetylenic alcohols (entries 3, 6, and 7) and *erythro*-α,β-acetylenic diols[11] (entries 9—17) with synthetically useful levels of stereoselectivities. The alkoxyl group served as a bulky substituents and did not give a special influence on the regio- and stereoselectivities of the reaction. Such stereoregulation may be understandable simply by considering the same chelate type transition state (Fig. 3).

The titanium reagent which was present as the allenic form with a tight metal-carbon bond, forms the two six-membered ring chelate transition states, T_1 and T_2, according to the direction of the carbonyl approach. As is apparent from the Fig. 3, the steric repulsion between R and R_2 controls the course of the carbonyl approach to the reaction centre. Therefore, the transition state T_1 is more favorable than T_2 and the predominant production of the *threo* adduct *via* T_1 was observed.

Examination of the other data in Table 3 reveals several other trends: (1) Most remarkable is the reaction with benzaldehyde exhibiting an opposite stereoselection,[12] that is, *erythro*-β-acetylenic alcohol was obtained albeit in a lower level of selectivity(entry 4); (2) a trimethylsilyl group at R^1 of the reagents gave

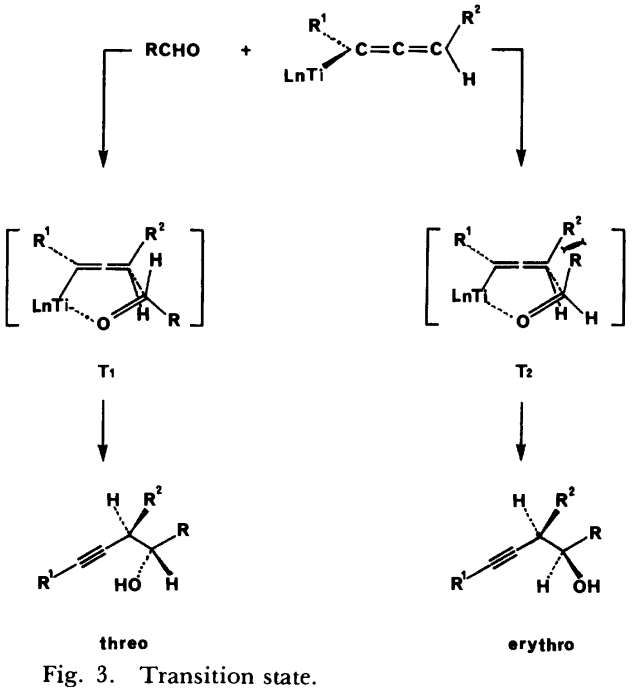

Fig. 3. Transition state.

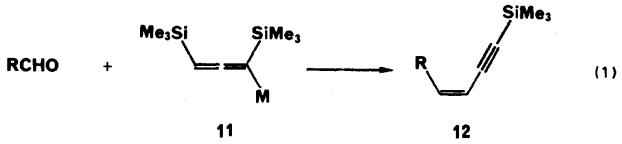
slightly lower selectivities for the reaction (entries 9 and 10); (3) a lower reaction temperature leads to higher selectivities (entries 3 and 7). The reverse change in stereoselectivity observed in the reaction with benzaldehyde can not be fully explicable at present, but a similar anomaly has been observed elsewhere.[13]

It should be noted that the condensations of the titanium reagent with ketones were unsuccessful, and starting ketones were recovered. Similar chemoselectivities for the titanium reagents were reported.[8]

Synthesis of Enyne and α,β-Unsaturated Nitrile. The regio- and stereoselective behaviours of the propargyltitanium reagents in carbonyl addition have now become apparent in detail. Thus the additional applications of the similar reagents were examined for synthetic purposes.

We[1h] have already reported an efficient silicon-mediated (*Z*)-enyne synthesis using metallated 1,3-bis(trialkylsilyl)propyne as exemplified in Eq. 1.[11,14]



11 12 (1)

It was demonstrated that the alkyl groups on silicon provide powerful steric screening effect which plays an important role for the stereochemical course of the reaction. It was also pointed out that the tightness of the bond with counterion has a similar potential as a control element in stereochemistry: In order to maximize the stereoselectivity of the reaction, "a tight chelate transition state" should be achieved. For example, a magnesium chelate may be tighter than that for lithium, thus maximizing the steric effect. Unfortunately, however, the elimination step of Peterson olefination seems to proceed smoothly when lithium, sodium or potassium derivatives are used, the magnesium derivatives being comparatively slow to undergo elimination.[15] Taking these requirements and aforementioned results into account, we have tested the titanium reagents for the enyne synthesis.

1,3-Bis(trialkylsilyl)propyne[16] was treated with *t*-butyllithium and then with titanium tetraisopropoxide. The condensation with aldehydes was then conducted (Table 4). As seen from the Table 4, (*Z*)-enynes were obtained exclusively except for the reaction with benzaldehyde. The anomalous behaviour of benzaldehyde was described previously.[13]

Since the syn elimination mechanism of the β-oxide trialkylsilyl derivatives in Peterson reaction has been accepted,[17] the stereoselectivity of the reaction should be determined by the direction of the initial attack of carbanion to carbonyl.[18] For the diastereoselective addition of the titanium reagents, the similar explanation employed previously may be given again (Fig. 3): With this substituted pattern, the allenic (not acetylenic) titanium reagent was predominantly produced. Therefore, in Fig. 3, one might anticipate that the transition state T_2 might be destabilized relative to T_1 due to the R↔R^2 (R^2=R_3Si) steric repulsion. As a result, (*Z*)-enyne was produced selectively *via* transition

state T_1.

Next we called our attention to the nitrile anion which has analogous structure to the propargyl anion except that it has no substituents at a terminal nitrogen atom. Thus we investigated the reaction of α-silyl-substituted acetonitrile anion which condensed with aldehyde to give α,β-unsaturated nitriles through addition-elimination sequences.[19] Judging from the similarity of the reaction system to the α-silylated propyne, a (*Z*)-olefin may result from this reaction. The α,β-unsaturated nitrile is a useful synthetic intermediate since it is easily converted to the synthetically useful α,β-unsaturated carbonyl compound.[20]

The metallated derivatives of (trialkylsilyl)acetonitrile[21] was condensed with various aldehydes and the results were summarized in Table 5.

Surprisingly, the reaction of simple lithio reagent with aldehyde produced the *Z*-isomer with moderate stereoselectivity (entry 1).[22] The titanium reagents showed a little improvements, but the boron reagents are much superior.[23] In contrast to the previous observations of propargyl anions, the stereochemical course of the reaction showed little dependence on the steric screening effect of the silyl group, but the effects of the reaction temperature and the solvent were crucial. Thus the longer reaction period at room temperature tends to decrease the stereoselectivity of the reaction (entries 3 and 4). Since the presence of excess base (LDA) also decreases the selectivity, secondary isomerization of the produced olefin may be caused by the base particularly at higher temperature.[24] Consequently the quenching of the reaction at low temperature is essential to accomplish the selective reaction.[25]

It should be notable that the addition of HMPA to the reaction mixture remarkably raised the proportion of *Z*-isomer (entry 5). The role of HMPA is not clear, but the rate of the desilylation is clearly accelerated by the addition of HMPA. The lack of the selectivity in the condensation with benzaldehyde was observed as previously, which may be due to the intervention of a competing electron-transfer pathway, or an acyclic transition state.[13]

The regioisomer, ketenimine, which corresponded to the allenyl alcohol for the reaction of propargylic anion, was not detected in a series of this reaction.[26] Since the transition state for this reaction could be regarded as similar to that of propargyl anion, the *Z*-selectivity could be readily understandable. For nitrile anion, however, the site of metallation could be recognized as occurred predominantly at nitrogen atom for all metals studied.[27] This is presumably due to the steric requirement along with the strong affinity of metal-nitrogen bond.

Experimental

General. ^{1}H NMR spectra were taken on a JNM-PMX 60 spectrometer. The chemical shifts are reported in parts per million relative to TMS. The infrared spectra were recorded on a Hitachi 260-10 spectrometer in CCl_4 solution unless otherwise stated. The isomeric ratio of the products was determined by gas-liquid chromatography (GLC) using a Hitachi Model 163 and 164 instruments equipped with a flame ionization detector using nitrogen as carrier gas. For TLC analysis throughout this work, Merck precoated TLC plates (silica gel 60 GF_{254}, 0.25 mm, or silica gel 60 HF_{254} silanized, 0.25 mm) were used. The products were purified by preparative column chromatography on silica gel E. Merck Art. 9385, or silanized silica gel E. Merck Art. 7719. Microanalyses were accomplished at the Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University. Unless otherwise specified, all reactions were carried out under an atmosphere of dry argon. In experiments requiring dry solvents, ether and tetrahydrofuran (THF) were distilled from sodium-benzophenone. Benzene, hexane, and toluene were dried over sodium metal. Dichloromethane was dried over 4A Molecular Sieve. Pyridine and triethylamine were stored over potassium hydroxide pellets. Hexamethylphosphoric triamide (HMPA) was used after distillation from CaH_2. Other commercially supplied materials were used as received.

Preparation of 1-(Trimethylsilyl)propyne.[16] To a solution of propyne (20 g, 0.50 mol) in ether (600 ml) was added butyllithium in hexane (1.6 mol dm^{-3} solution, 312 ml, 0.50 mol) at −78 °C under argon. After stirring for 1 h at the same temperature, chlorotrimethylsilane (63 ml, 0.50 mol) was added to this solution. The resulting mixture was stirred at 25 °C for 12 h and then poured into 2 mol dm^{-3} hydrochloric acid. The organic layer was separated and the aqueous layer was extracted with ether. The combined extracts were dried and evaporated. The residue was distilled under atmospheric pressure to give 1-(trimethylsilyl)propyne (34 g, 60%). Bp 94—98 °C; ^{1}H NMR (CCl_4) δ=0.15 (s, 9H), 1.93 (s, 3H).

Preparation of 1-Trimethylsilyl-1-butyne.[28] To a solution of 1-butyne (15 g, 0.28 mol) in ether (500 ml) was added butyllithium in hexane (1.6 mol dm^{-3} solution, 160 ml, 0.26 mol) at −78 °C under argon. After stirring for 1 h at the same temperature, chlorotrimethylsilane (33 ml, 0.26 mol) was added to the reaction mixture. The mixture was stirred at 25 °C for 12 h and then poured into 2 mol dm^{-3} hydrochloric acid. The organic layer was separated and the aqueous layer was extracted with ether. The combined extracts were dried and evaporated. The residue was distilled under atmospheric pressure to give 1-trimethylsilyl-1-butyne (23 g, 70%). Bp 115—116 °C; ^{1}H NMR (CCl_4) δ=0.13 (s, 9H), 1.16 (t, *J*=7 Hz, 3H), 2.21 (q, *J*=7 Hz, 2H).

Preparation of 3-(Tetrahydro-2-pyranyloxy)-1-trimethylsilyl propyne. To a solution of 2-propyn-1-ol (11 g, 0.20 mol) and 3,4-dihydro-2*H*-pyran (22 ml, 0.24 mol) in ether (300 ml) was added *p*-toluenesulfonic acid monohydrate (4 g, 21 mmol) at 0 °C. The mixture was stirred for 0.5 h at 0 °C and 1 h at 25 °C. Then, the reaction mixture was poured into water and the product was extracted with ether. The ether layer was washed with brine, dried over sodium sulfate, and evaporated. Chromatography of the residual crude oil on a silica-gel column (2:1, hexane-ether) afforded 3-(tetrahydro-2-pyranyloxy)propyne (24 g, 86%). ^{1}H NMR (CCl_4) δ=1.3—2.0 (m, 6H), 2.40 (t, *J*=2.5 Hz, 1H), 3.3—4.0 (m, 2H), 4.23 (d, *J*=2.5 Hz, 2H), 4.80 (m, 1H); IR (neat) 3300 cm^{-1}.

To a solution of 3-(tetrahydro-2-pyranyloxy)propyne (5.6 g, 40 mmol) in ether (100 ml) was added butyllithium in hexane (1.6 mol dm^{-3} solution, 25 ml, 40 mmol) at −78 °C. After stirring for 1 h at −78 °C, chlorotrimethylsilane (5.0 ml, 40 mmol) was added to this mixture. The resulting mixture was stirred at 25 °C for 12 h and then poured into 2 mol dm^{-3} hydrochloric acid and extracted with ether. The combined extracts were dried and evaporated. Chromatography of the crude product on a silica-gel column (15:1 hexane-ether) afforded 3-(tetrahydro-2-pyranyloxy)-1-(trimethylsilyl)propyne (6.9 g, 81%). ^{1}H NMR (CCl_4) δ=0.13 (s, 9H), 1.1—2.0 (m, 6H), 3.4—3.9 (m, 2H), 4.03 (s, 2H), 4.63 (t, *J*=2 Hz, 1H); IR (neat) 2190 cm^{-1}. Found: C, 62.38; H, 9.22%. Calcd for $C_{11}H_{20}O_2Si$: C, 62.21; H, 9.49%.

Preparation of 1-(Tetrahydro-2-pyranyloxy)-2-butyne.[29] To a solution of 2-butyn-1-ol (5 ml, 66 mmol) and 3,4-dihydro-2*H*-pyran (9.0 ml, 99 mmol) in ether (130 ml) was added *p*-toluenesulfonic acid monohydrate (1.9 g, 10 mmol) at 0 °C. After stirring for 0.5 h at 0 °C and then 1 h at 25 °C, the reaction mixture was poured into water and extracted with ether. The ether layer was washed with brine, dried, and evaporated. Chromatography of the residual oil on a silica-gel column (10:1 hexane–ether) afforded 1-(tetrahydro-2-pyranyloxy)-2-butyne (10 g, 98%). R_f=0.7 (10:1 hexane–ether); ^{1}H NMR (CCl_4) δ=1.3—1.9 (m, 6H), 1.75 (t, J=2.5 Hz, 3H), 3.2—3.8 (m, 2H), 4.0 (q, J=2.5 Hz, 2H), 4.65 (m, 1H); IR (neat) 2250 cm^{-1}.

Preparation of 1-(1-Methoxy-1-methylethoxy)-2-butyne. To a solution of 2-butyn-1-ol (2.0 ml, 26 mmol) and 2-methoxypropene (3.6 g, 50 mmol) in dichloromethane (30 ml) was added *p*-toluenesulfonic acid monohydrate (0.75 g, 3.9 mmol) at 0 °C. The resulting mixture was stirred at 0 °C for 20 min and treated with triethylamine (1.4 ml, 10 mmol) at 0 °C. The mixture was poured into water and the product was extracted with ether. The organic layer was dried and concentrated. Chromatography of the resulting oil on a silica-gel column (4:1 hexane–ether) afforded 1-(1-methoxy-1-methylethoxy)-2-butyne (2.77 g, 75%). R_f=0.8 (4:1 hexane–ether); ^{1}H NMR (CCl_4) δ=1.33 (s, 6H), 1.83 (t, J=2.5 Hz, 3H), 3.20 (s, 3H), 4.05 (q, J=2.5 Hz, 2H); IR (neat) 2250 cm^{-1}.

Preparation of 1-(Tetrahydro-2-furyloxy)-2-butyne. To a solution of 2-butyn-1-ol (2.0 ml, 26 mmol) and 2,3-dihydrofuran (2.8 g, 40 mmol) in ether (30 ml) was added *p*-toluenesulfonic acid monohydrate (0.75 g, 3.9 mmol) at 0 °C. After stirring for 0.5 h at 0 °C and 1 h at 25 °C, the mixture was poured into water and the product was extracted with ether. The organic layer was dried and concentrated. Chromatography of the crude product on a silica-gel column (10:1 hexane–ether) afforded 1-(tetrahydro-2-furyloxy)-2-butyne (2.8 g, 77%). ^{1}H NMR (CCl_4) δ=1.83 (m, 7H), 3.7—4.0 (m, 2H), 4.15 (m, 2H), 5.27 (m, 1H); IR (neat) 2230 cm^{-1}.

Metallation of Acetylenic Compounds. To a solution of acetylenic compounds (2.0 mmol) dissolved in dry THF (5 ml) was added *t*-butyllithium in pentane (1.8 mol dm^{-3} solution, 1.11 ml, 2.0 mmol) at −78 °C with stirring, and the resulted slightly yellow solution was stirred at 0 °C for 1 h leading to complete lithiation. Corresponding titanium derivatives were prepared by adding titanium tetraisopropoxide (0.60 ml, 2.0 mmol) to a solution of the lithio salt obtained as above at −78 °C. The boron derivatives were similarly prepared with use of one equivalent of boron triisopropoxide. Magnesium, zinc, and tin(II) derivatives were generated by adding one equivalent of magnesium iodide,[30] zinc bromide, or tin(II) chloride, respectively. For the preparation of aluminium reagents, two equivalents of diethylaluminium chloride (hexane solution) were used.

IR Analysis of Metallated Alkyne Derivatives. The lithio derivative of a 1-(trimethylsilyl)propyne solution in THF obtained as above was transferred into IR cell under nitrogen, and the spectrum was measured. IR 1880 cm^{-1} (m, allenic), 2020 cm^{-1} (m, acetylenic). The IR spectra of the other metallated reagents: Titanated 1-(trimethylsilyl)propyne: 2092 cm^{-1}. Titanated 1-trimethylsilyl-1-butyne: 1898 cm^{-1}.

*Reaction of **2b** with Cyclohexanecarbaldehyde.* To a cooled solution (−78 °C) of **2b** (2.0 mmol) in THF was added freshly distilled cyclohexanecarbaldehyde (0.22 ml, 1.8 mmol) over a period of 5 min at −78 °C, and the mixture was stirred at −78 °C for 1 h. The resulting mixture was poured into ice-cooled 1 mol dm^{-3} hydrochloric acid, and the product was extracted with ether repeatedly. The combined ethereal layer was dried and concentrated *in vacuo*. The crude product was purified by silica-gel column chromatography (1:2 ether–heaxne) to give 1-cyclohexyl-3-pentyn-1-ol and 1-cyclohexyl-2-methyl-2,3-butadien-1-ol (269 mg, 90% total yield). GLC analysis of the product revealed the ratio of 1:99.

1-Cyclohexyl-3-pentyn-1-ol: R_f=0.35 (2:1 hexane–ether); ^{1}H NMR (CCl_4) δ=0.7—2.0 (m, 11H), 1.78 (t, J=2.4 Hz, 3H), 2.25 (m, 2H), 3.30 (m, 1H), 4.62 (br s, 1H); IR 2275 cm^{-1}.

1-Cyclohexyl-2-methyl-2,3-butadien-1-ol: R_f=0.43 (2:1 ether–hexane); ^{1}H NMR (CCl_4) δ=0.72—2.22 (m, 11H), 1.62 (t, J=3 Hz, 3H), 2.02 (s, 1H), 3.67 (br d, 1H), 4,63 (m, 2H); IR 1970 cm^{-1}. Found: C, 79.31; H, 10.73%. Calcd for $C_{11}H_{18}O$: C, 79.46; H, 10.91%.

1-Cyclohexyl-4-trimethylsilyl-3-butyn-1-ol:[1g] ^{1}H NMR (CCl_4) δ=0.14 (s. 9H), 0.92—2.0 (m, 12H), 2.32 (d, J=5.4 Hz, 2H), 3.37 (br s, 1H); IR 2180 cm^{-1}.

1-Cyclohexyl-2-trimethylsilyl-2,3-butadien-1-ol:[1g] ^{1}H NMR (CCl_4) δ=0.12 (s, 9H), 0.86—2.03 (m, 12H), 3.81 (br s, 1H), 4.38 (d, J=2 Hz, 2H); IR 1930 cm^{-1}. Found: C, 69.49; H, 10.60%; Calcd for $C_{13}H_{24}OSi$: C, 69.58; H, 10.78%.

1-Phenyl-4-trimethylsilyl-3-butyn-1-ol:[1f,g] ^{1}H NMR (CCl_4) δ=0.08 (s, 9H), 2.47 (d, J=6.2 Hz, 2H), 3.23 (br d, J=3 Hz, 1H), 4.60 (dt, J=3 and 6.2 Hz, 1H), 7.17 (s, 5H); IR 2180 cm^{-1}.

1-Phenyl-2-trimethylsilyl-2,3-butadien-1-ol:[1f,g] ^{1}H NMR (CCl_4) δ=0.02 (s, 9H), 3.33 (br s, 1H), 4.45 (d, J=3 Hz, 2H), 5.17 (t, J=3 Hz, 1H), 7.19 (s, 5H); IR 1930 cm^{-1}; MS m/z: 218 (M^+).

1-Phenyl-3-pentyn-1-ol:[1f] ^{1}H NMR (CCl_4) δ=1.70(t, J=2.5 Hz, 3H), 2.42 (dq, J=2.5 and 6 Hz, 2H), 2.77 (br s, 1H), 4.60 (t, J=6 Hz, 1H), 7.18 (s, 5H).

2-Methyl-1-phenyl-2,3-butadien-1-ol:[1f,31] ^{1}H NMR (CCl_4) δ= 1.47 (t, J=3 Hz, 3H), 3.04 (br s, 1H), 4.68 (m, 2H), 4.98 (br s, 1H), 7.16 (s, 5H); IR 1960 cm^{-1}; MS m/z: 160 (M^+).

1,4-Diphenyl-2-methyl-3-butyn-1-ol (Mixture of erythro *and* threo *Isomers)*: ^{1}H NMR (CCl_4) δ=1.06 and 1.14 (2d, J=7 Hz each, 3H), 2.85 (quintet, J=7 Hz, 1H), 3.08 (br s, 1H), 4.45 (m, 1H), 7.17 (m, 10H); IR 2250 cm^{-1}. Found: C, 86.16; H, 7.07%; Calcd for $C_{17}H_{16}O$: C, 86.41; H, 6.82%.

erythro-*1-Cyclohexyl-2-methyl-4-trimethylsilyl-3-butyn-1-ol*:[32] ^{1}H NMR (CCl_4) δ=0.13 (s, 9H), 0.78—2.03 (m, 12H), 1.13 (d, J=6.5 Hz, 3H), 2.52 (quintet, J=6.5 Hz, 1H), 3.20 (t, J=5 Hz, 1H); IR 2170 cm^{-1}.

threo-*1-Cyclohexyl-2-methyl-4-trimethylsilyl-3-butyn-1-ol*:[32] ^{1}H NMR (CCl_4) δ=0.15 (s, 9H), 0.87—2.08 (m, 12H), 1.18 (d, J= 7 Hz, 3H), 2.60 (dq, J=2 and 7 Hz, 1H), 2.95 (m, 1H); IR 2160 cm^{-1}. Found: C, 70.70; H, 10.81%; Calcd for $C_{14}H_{26}OSi$: C, 70.52; H, 10.99%.

erythro-*2-Methyl-1-phenyl-4-trimethylsilyl-3-butyn-1-ol*:[33] ^{1}H NMR (CCl_4) δ=0.07 (s, 9H), 1.07 (d, J=7 Hz, 3H), 2.28 (br s, 1H), 2.67 (quintet, J=7 Hz, 1H), 4.51 (d, J=6.2 Hz, 1H), 7.21 (s, 5H); IR 2180 cm^{-1}.

erythro-*1-Cyclohexyl-2-methyl-4-phenyl-3-butyn-1-ol*:[32] ^{1}H NMR (CCl_4) δ=0.69—2.35 (m, 12H), 1.24 (d, J=6.4 Hz, 3H), 2.74 (quintet, J=6.4 Hz, 1H), 3.32 (t, J=6.4 Hz, 1H), 7.22 (br s, 5H); IR 2250 cm^{-1}.

threo-*1-Cyclohexyl-2-methyl-4-phenyl-3-butyn-1-ol*:[32] ^{1}H NMR (CCl_4) δ=0.67—2.34 (m, 12H), 1.27 (d, J=6.8 Hz, 3H), 2.80 (dq, J=4 and 6.8 Hz, 1H), 3.03 (br s, 1H), 7.20 (m, 5H); IR 2240 cm^{-1}. Found: C, 84.16; H, 9.23%. Calcd for $C_{17}H_{22}O$: C, 84.25; H, 9.15%.

Reaction of Metallated Alkoxyalkyne Reagents with Aldehydes. The following procedure is representative for these type

of reagents (entries 8—17 in Table 3). *t*-Butyllithium in pentane (1.8 mol dm^{-3} solution, 0.83 ml, 1.5 mmol) was added dropwise to a solution of 1-(tetrahydro-2-pyranyloxy)-2-butyne (231 mg, 1.5 mmol) in dry THF (4 ml) with stirring under argon at −78 °C. After 40 min at −78 °C, titanium tetraisopropoxide (0.45 ml, 1.5 mmol) was added dropwise to the resulting orange solution of the anion, and the slightly darkened solution was stirred there for 10 min. Freshly distilled hexanal (0.155 ml, 1.3 mmol) was added over a period of 5 min at −78 °C, and the mixture was stirred at −78 °C for 30 min and then at 20 °C for 30 min. The reaction mixture was poured into ice-cooled 1 mol dm^{-3} hydrochloric acid, and the product was extracted with ether repeatedly. The combined ethereal layer was concentrated *in vacuo* to give a crude hydroxy ether, which was dissolved in dry methanol (5 ml) at 0 °C. *p*-Toluenesulfonic acid monohydrate (5 mg) was added, and the mixture was stirred at 20 °C for 30 min. After the consumption of all tetrahydropyranyl ether by TLC assay, the reaction was terminated by the addition of excess sodium hydrogencarbonate (10 mg). The suspension was concentrated *in vacuo*, and the slurry was directly subjected to column chromatography on silica gel (2:1 ether–hexane) to afford 2-decyne-4,5-diol (168 mg, 76%). The diol was acetylated by Ac_2O–pyridine, and the GLC analysis of the diacetate revealed the isomeric ratio of 95:5 (*erythro*:*threo*).[34]

2-Decyn-4,5-diol: ^{1}H NMR (CCl_4) δ=0.5—1.67 (m, 11H), 1.87 (d, J=3 Hz, 3H), 2.97 (br s, 2H), 3.63 (m, 1H), 4.28 (dq, J=3 and 3 Hz, 1H); IR 3400, 2260 cm^{-1}. Found: C, 70.32; H, 10.68%. Calcd for $C_{10}H_{18}O_2$: C, 70.55; H, 10.65%.

1-Cyclohexyl-4-trimethylsilyl-3-butyn-1,2-diol:[35] ^{1}H NMR (CCl_4) δ=0.16 (s, 9H), 0.75—2.17 (m, 11H), 2.78 (br s, 2H), 3.17 (dd, J=4 and 6 Hz, 1H), 4.22 (d, J=4 Hz, 1H); IR 3400, 2200 cm^{-1}.

1-Trimethylsilyl-1-nonyn-3,4-diol:[35] ^{1}H NMR (CCl_4) δ=0.16 (s, 9H), 0.66—1.58 (m, 11H), 2.14 (br m, 1H), 2.69 (m, 1H), 3.48 (m, 1H), 4.13 (m, 1H); IR 3400, 2230cm^{-1}.

1-Cyclohexyl-3-pentyn-1,2-diol: ^{1}H NMR (CCl_4) δ=0.67—2.33 (m, 11H), 1.88 (d, J=2 Hz, 3H), 2.83 (br s, 2H), 3.32 (dd, J=3 and 7 Hz, 1H), 4.41 (dq, J=3 and 4 Hz, 1H); IR (neat) 3400, 2280 cm^{-1}. Found: C, 72.34; H, 10.10%. Calcd for $C_{11}H_{18}O_2$: C, 72.49; H, 9.95%.

Preparation of 1,3-Bis(trimethylsilyl)propyne.[16] To a solution of 1-(trimethylsilyl)propyne (13.5 g, 120 mmol) in ether (200 ml) were added *N,N,N′,N′*-tetramethylethylenediamine (21.1 ml, 140 mmol) and butyllithium in hexane (1.6 mol dm^{-3} solution, 87.5 ml, 140 mmol) at −5 °C under argon. After stirring for 30 min, chlorotrimethylsilane (17 ml, 134 mmol) was added and the mixture was stirred at 25 °C for 12 h. The resulting mixture was poured into ice-cooled water and the product was extracted with ether. The combined extracts were dried and evaporated. The residue was distilled under reduced pressure to give 1,3-bis(trimethylsilyl)propyne (16.6 g 75%). Bp 75—76 °C (34 mmHg†): ^{1}H NMR ($CDCl_3$) δ=0.17 and 0.24 (2s, 9H each), 1.61 (s, 2H).[16]

Preparation of 3-(t-Butyldimethylsilyl)-1-(trimethylsilyl)propyne. To a solution of 1-(trimethylsilyl)propyne (22.4 g, 200 mmol) in ether (300 ml) was added *t*-butyllithium[36] in pentane (1.8 mol dm^{-3} solution, 111 ml, 200 mmol) at −5 °C. After stirring for 30 min, *t*-butyldimethylsilyl chloride (30.1 g, 200 mmol) was added and the mixture was stirred for 12 h. The resulting mixture was poured into ice-cooled water and the product was extracted with ether. The combined extracts were dried and concentrated. The residue was distilled under reduced pressure to give 3-(*t*-butyldimethylsilyl)-1-(trimethylsilyl)propyne (24.4 g, 54%). Bp 106—107 °C (31 mmHg); ^{1}H NMR ($CDCl_3$) δ=0.14 and 0.19 (2s, 15H), 0.98 (s, 9H), 1.63 (s, 2H); MS *m/z*: 226 (M^+).

† 1 mmHg≈133.322 Pa.

Reaction of Metallated 1,3-Bis(trialkylsilyl)propyne with Aldehydes.[37] The following experimental procedure is representative. To a solution of 1,3-bis(trimethylsilyl)propyne (368 mg, 2.0 mmol), in THF (4 ml) was added *t*-butyllithium in pentane (1.8 mol dm^{-3} solution, 1.1 ml, 2.0 mmol) at −78 °C. After 1 h at −78 °C, titanium tetraisopropoxide (0.60 ml, 2.0 mmol) was added to the mixture and the solution was stirred for 10 min at −78 °C. Cyclohexanecarbaldehyde (0.22 ml, 1.8 mmol) was added to the solution and the resulting mixture was stirred at −78 °C for 30 min and then at 25 °C for 1 h. The reaction mixture was poured into 1 mol dm^{-3} hydrochloric acid, and the product was extracted with ether repeatedly. The combined ethereal layer was concentrated *in vacuo* to give a crude oil, which was subjected to column chromatography on silica gel (hexane) to afford 4-cyclohexyl-1-trimethylsilyl-3-buten-1-yne (323 mg, 87%). GLC analysis of the product revealed the isomeric ratio of 17:1 (*Z*:*E*).[38]

(Z)-4-Cyclohexyl-1-trimethylsilyl-3-buten-1-yne:[37] ^{1}H NMR (CCl_4) δ=0.17 (s, 9H), 0.77—1.95 (m, 10H), 2.57 (br m, 1H), 5.27 (d, J=11 Hz, 1H), 5.72 (dd, J=8.5 and 11 Hz, 1H); IR 2150, 1450, 1255, 1015, 700 cm^{-1}.

(E)-4-Cyclohexyl-1-trimethylsilyl-3-buten-1-yne:[37] ^{1}H NMR (CCl_4) δ=0.13 (s, 9H), 5.28 (d, J=16 Hz, 1H), 6.02 (dd, J=7 and 16 Hz, 1H), 0.65—2.0 (m, 11H); IR 2150, 1450, 1250, 960 cm^{-1}.

(Z)-1-Trimethylsilyl-3-nonen-1 yne:[39] ^{1}H NMR (CCl_4) δ=0.17 (s, 9H), 0.8—1.5 (m, 9H), 2.27 (m, 2H), 5.33 (d, J=11 Hz, 1H), 5.80 (dt, J=7 and 11 Hz, 1H); IR 2150, 1250, 1050, 700 cm^{-1}.

(E)-1-Trimethylsilyl-3-nonen-1-yne:[39] ^{1}H NMR(CCl_4) δ=0.13 (s, 9H), 0.76—1.58 (m, 9H), 2.10 (m, 2H), 5.32 (d, J=16 Hz, 1H), 6.08 (dt, J=7 and 16 Hz, 1H); IR 2150, 1260, 1095, 960 cm^{-1}.

(Z)-4-Phenyl-1-trimethylsilyl-3-buten-1-yne:[37] ^{1}H NMR(CCl_4) δ=0.22 (s, 9H), 5.56 (d, J=11 Hz, 1H), 6.53 (d, J=11 Hz, 1H), 7.18 (m, 3H), 7.72 (m, 2H).

(E)-4-Phenyl-1-trimethylsilyl-3-buten-1-yne:[37] ^{1}H NMR (CCl_4) δ=0.20 (s, 9H), 6.05 (d, J=16 Hz, 1H), 6.93 (d, J=16 Hz, 1H), 7.27 (s, 5H).

Preparation of (Trimethylsilyl)acetonitrile.[19b] To a mixture of chlorotrimethylsilane (36 g, 0.33 mol) and activated granular zinc (38 g, 0.58 mol), in THF–benzene (1:1, 400 ml) was added a solution of chloroacetonitrile (22 g, 0.29 mol) in benzene (20 ml). The resulting mixture was heated under reflux for 30 h and then poured into a buffer solution (AcONa–AcOH, 300 ml). The organic layer was separated and the aqueous layer was extracted with benzene. The combined extracts were dried and concentrated. The residue was distilled under reduced pressure to give (trimethylsilyl)acetonitrile (13.5 g, 41%). Bp 65 °C (20 mmHg); ^{1}H NMR (CCl_4) δ=0.23 (s, 9H), 1.53 (s, 2H); IR (neat) 2215 cm^{-1}. This compound was also prepared from bromoacetonitrile in the similar manner.[19b]

Preparation of (Triphenylsilyl)acetonitrile. To a solution of acetonitrile (4.1 g, 0.10 mol) in THF (200 ml) was added butyllithium in hexane (1.6 mol dm^{-3}, 62.5 ml, 0.10 mol) at −78 °C. After stirring for 20 min, chlorotriphenylsilane (29.5 g, 0.10 mol) in THF (50 ml) was added at −78 °C and the mixture was stirred at −78 °C for 30 min and then 25 °C for 5 h. The resulting mixture was poured into water and the product was extracted with ether. The combined extracts were dried and concentrated to give a crude product. Recrystallization from acetone–methanol gave colourless crystals of (triphenylsilyl)acetonitrile (16.7 g, 56%). Mp 135.5—136 °C (acetone); ^{1}H NMR ($CDCl_3$) δ=2.30 (s, 2H), 7.45 (br s, 15H); IR 2250 cm ; MS *m/z*: 299 (M^+).

Preparation of (t-Butyldimethylsilyl)acetonitrile. To a solution of acetonitrile (4.1 g, 0.10 mol) in THF (200 ml) was added butyllithium in hexane (1.6 mol dm^{-3}, 62.5 ml, 0.10 mol) at −78 °C. After stirring for 20 min, *t*-butyldimethylsilyl chloride (15.1 g, 0.10 mol) in THF (50 ml) was

added at −78 °C and the mixture was stirred at −78 °C for 30 min and 25 °C for 5 h. The resulting mixture was poured into water and the product was extracted with ether. The combined extracts were dried and concentrated. The residue was distilled under reduced pressure to give (*t*-butyldimethylsilyl) acetonitrile (7.75 g, 50%). Bp 102 °C (30 mmHg); ^{1}H NMR ($CDCl_3$) δ=0.19 (s, 6H), 0.95 (s, 9H), 1.54 (s, 2H); IR 2250 cm^{-1}; Mp 71—72 °C; MS *m/z*: 155 (M^+).

Reaction of Metallated (Trialkylsilyl)acetonitrile with Aldehydes.[19b] The following experimental procedure provides details of the typical preparation of (*Z*)-unsaturated nitriles: To a solution of (trimethylsilyl)acetonitrile (113 mg, 1.0 mmol) in THF (2 ml) was added dropwise butyllithium in hexane (1.6 mol dm^{-3} solution, 0.63 ml, 1.0 mmol) at −78 °C. After 10 min, boron triisopropoxide (0.231 ml, 1.0 mmol) was added at −78 °C and the solution was stirred there for an additional 10 min. Cyclohexanecarbaldehyde (0.121 ml, 1.0 mmol) in THF (0.5 ml) was added slowly and after 2 min, dry HMPA (0.4 ml) was added to the reaction mixture and stirring was continued for 1 h. Addition of water to the mixture at −78 °C, then the product was extracted with ether. The combined organic layer was dried and concentrated. Chromatography of the crude product on silica-gel column (1:6 ether-hexane) gave 3-cyclohexylacrylonitrile (105 mg, 78%). GLC analysis of the product revealed 23:1 (*Z*)-isomer.[38]

(Z)-3-Cyclohexylacrylonitrile (Contains ca. 4% of the (E)-Isomer):[19c] R_f=0.46 (1:6 ether-hexane); ^{1}H NMR (CCl_4) δ= 0.72—3.0 (m, 11H), 5.15 (d, *J*=11 Hz, 1H), 6.23 (dd, *J*=10 and 11 Hz, 1H); IR 2910, 2840, 2210, 1625, 740 cm^{-1}. Found: C, 80.08; H, 9.73; N, 10.18%. Calcd for $C_9H_{13}N$: C, 79.95; H, 9.69; N, 10.36%.

(Z)-2-Octenenitrile (Contains ca. 7% of the (E)-Isomer):[19c] R_f=0.44 (1:5 ether-hexane); ^{1}H NMR (CCl_4) δ=0.63—2.0 (m, 9H), 2.0—2.67 (m, 2H), 5.22 (d, *J*=11 Hz, 1H), 6.37 (dt, *J*=7 and 11 Hz, 1H); IR 2960, 2940, 2860, 2230, 1630, 740 cm^{-1}; Found: C, 78.17; H, 10.56; N, 10.92%. Calcd for $C_8H_{13}N$: C, 78.00; H, 10.63; N, 11.37%.

(2Z,4E)-2,4-Octadienenitrile (Contains ca. 11% of the (E,E)-Isomer):[40] R_f=0.35 (1:5 ether-hexane); ^{1}H NMR (CCl_4) δ=0.94 (t, *J*=7 Hz, 3H), 1.17—1.83 (m, 2H), 1.92—2.5 (m, 2H), 5.00 (d, *J*=10 Hz, (*Z*)-isomer), 5.20 (d, *J*=15 Hz, (*E*)-isomer), 5.83—7.0 (m, 3H); IR 2975, 2940, 2875, 2225, 1645, 740 cm^{-1}.

(Z)-3-Phenylacrylonitrile (Contains ca. 25% of the (E)-Isomer):[19b,c] R_f=0.31 (1:5 ether-hexane); ^{1}H NMR (CCl_4) δ= 5.33 (d, *J*=12 Hz, (*Z*)-isomer), 5.76 (d, *J*=17 Hz, (*E*)-isomer), 7.00 (d, *J*=12 Hz, 1H), 7.33 and 7.72 (m, 5H); IR 3050, 3030, 2220, 1615, 970, 775, 750, 685 cm^{-1}.

We thank the Asahi Glass Foundation for financial support of this work.

32) The stereochemical assignment of the acetylenic alcohols was based on the NMR analyses and GLC behaviour in comparison with the authentic sample prepared independently. *threo*-1-Cyclohexyl-2-methyl-4-trimethylsilyl-3-butyn-1-ol was prepared as follows. Wittig reaction of cyclohexanecarbaldehyde with triphenylphosphonium ethylide gave (*Z*)-1-cyclohexylpropene as a major product.[41] Oxidation of the olefin with *m*-CPBA followed by ring opening with diethyl(trimethylsilylethynyl)aluminium[42] afforded the mixture of *threo*-1-cyclohexyl-2-methyl-4-trimethylsilyl-3-butyn-1-ol and 3-cyclohexyl-5-trimethylsilyl-4-pentyn-2-ol (regioisomer). GLC behaviour of the former product was in complete coincidence with the major product of the reaction of titanium reagents. *erythro*-1-Cyclohexyl-2-methyl-4-trimethylsilyl-3-butyn-1-ol was prepared as follows.

Treatment of the (*E*)-1-cyclohexylpropene, which was prepared by the established procedure[43] from the reaction of cyclohexanecarbaldehyde and triphenylphosphonium ethylide, with *m*-CPBA followed by ring opening with the above aluminium reagent gave the *erythro*-1- cyclohexyl-2-methyl-4-trimethylsilyl-3-butyn-1-ol and its regioisomer, 3-cyclohexyl-5-trimethylsilyl-4-pentyn-2-ol. Both isomers of 1-cyclohexyl-2-methyl-4-phenyl-3-butyn-1-ol and 1-cyclohexyl-2-methyl-3-hexyn-1-ol were prepared in a similar manner.

33) The stereochemistry of this compound was determined by the NMR analysis after the conversion to the corresponding aldol product:[44] Treatment of this acetylenic alcohol with mercury(II) sulfate and sulfuric acid gave 4-hydroxy-3-methyl-4-phenyl-2-butanone. ^{1}H NMR spectrum of this product (CCl_4) revealed absorptions at 4.5 (d, J= 8 Hz, weak) and 4.9 ppm (d, J=4 Hz, strong) arising from the benzyl protons. The smaller coupling constant may be expected to belong to *erythro*-isomer.[45]

34) The stereochemistry of this compound was determined as follows. Epoxidation of 1-hexen-3-ol with *t*-BuOOH-VO(acac)$_2$ followed by ring opening with lithium dibutylcuprate-(I) reagent (excess) gave the *erythro*-4,5-decanediol.[46] The NMR analysis and GLC behaviour were identical with the hydrogenation product from entries 14, 15, and 17.

35) The stereochemical assignment of this compound was based on the NMR analysis and GLC behaviour in comparison with the authentic sample prepared independently. Treatment of (*Z*)-4-cyclohexyl-1-trimethylsilyl-3-buten-1-yne, which was prepared by the reported procedure,[1h] with osmium tetraoxide[47] gave *erythro*-1-cyclohexyl-4-trimethylsilyl-3-butyn-1,2-diol. The acetylated product (acetic anhydride-pyridine) of this diol was identical with the major isomer from entries 8 and 9. *erythro*-1-Trimethylsilyl-1-nonyn-3,4-diol was prepared in a similar manner.

36) The butyllithium-*N*,*N*,*N*′,*N*′-tetramethylethylenediamine method may cause the rearrangement of acetylenic bond.

38) The *Z*-isomer was characterized by an infrared absorption at ≈700 cm^{-1} and coupling constant between the vicinal olefinic hydrogens of ≈11 Hz observed in the ^{1}H NMR spectrum. On the other hand, the *E*-isomer was characterized by an infrared absorption at 960—970 cm^{-1} and a coupling constant of ≈16 Hz.

Stereocontrolled Synthesis of (±)-Asperlin and Related Stereoisomers Using Organotitanium Reagent

Hiroaki HIRAOKA, Kyoji FURUTA, Nobuo IKEDA, and Hisashi YAMAMOTO*
Department of Applied Chemistry, Nagoya University, Chikusa, Nagoya 464
(Received December 26, 1983)

The naturally occurring antibiotics asperlin and related fungal metabolites containing a 5,6-dihydro-2-pyrone moiety have been synthesized stereoselectively. The propargyltitanium reagent derived from 1-trimethylsilyl-3-(tetrahydropyranyloxy)propyne condensed with crotonaldehyde affords the corresponding *erythro* alcohol as the major product, which is converted to (±)-asperlin and the related three stereoisomers in seven steps.

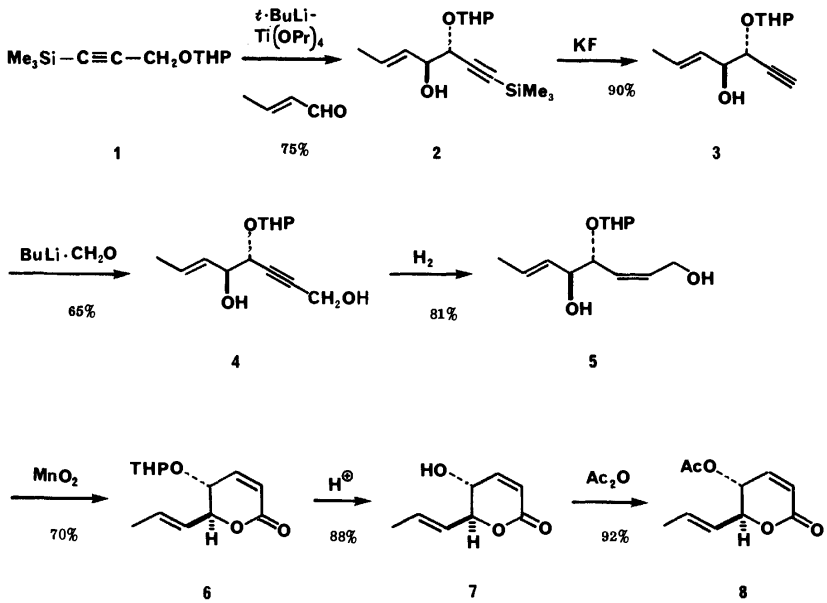
The recent discovery of the regio- and stereoselective synthesis of β-acetylenic alcohols[1] using titanium reagents[2] has substantially simplified the task of stereoselective construction of 3-alkene-1,2-diols and the related structures. We now report the use of this process as a key step in a simple, stereoselective synthesis of (±)-asperlin and related fungal metabolites containing a 5,6-dihydro-2-pyrone moiety, isolated from growing cultures of *Aspergillus nidulans*.[3]

The acetylenic tetrahydropyranyl ether **1** was prepared from propargyl alcohol by reaction with 3,4-dihydro-2*H*-pyran in ether containing a catalytic amount of *p*-toluenesulfonic acid (94%), and then with butyllithium–chlorotrimethylsilane in ether at ambient temperature for 1 h (98%). Successive treatment of acetylene **1** at −78°C with *t*-butyllithium, titanium tetraisopropoxide, and finally crotonaldehyde effected smooth, stereoselective alkylation to the alcohol **2** in 75% yield (*erythro*: *threo*=95:5). The similar high degree of stereoselectivity has been found previously when the carbon α to acetylene is functionalized, for example, the tetrahydropyranyl ether of propargyl alcohol.[1,2] Exposure of the resulting trimethylsilylacetylene to potassium fluoride in methanol at room temperature for an overnight produced **3** in 90% yield.

The construction of the structure of δ-lactone was carried out by three steps. The acetylene **3** was converted to the dilithio derivative by reaction with butyllithium in dry tetrahydrofuran and then allowed to react with excess paraformaldehyde at room temperature. The resulting propargylic alcohol **4** was reduced with hydrogen using Pd–$CaCO_3$ as catalyst in benzene to afford the (*Z*)-allylic alcohol **5** (81%). Oxidation with activated manganese dioxide in dichloromethane gave the δ-lactone **6** directly.[4]

Tetrahydropyranyl group in **6** was cleaved using *p*-toluenesulfonic acid in methanol at room temperature for 30 min to afford the corresponding alcohol **7** (88%). Acetylation of **7** with acetic anhydride–pyridine produced the acetate **8** which was treated with *m*-chloroperbenzoic acid in dichloromethane at room temperature to give *erythro*-5,6-dihydro-5-acetoxy-6-(*trans*-1,2-epoxypropyl)-2*H*-pyran-2-one (**9**) in 83% yield. Chromatographic separation of **9A** and **9B**, using silica gel and ether–hexane (1:1) as the eluent, gave the pure **9A** and **9B** (3:5).[3f,5]

The *threo*-isomer **11** was obtained by Mitsunobu reaction.[6] Thus, the alcohol **7** was treated with diethyl azodicarboxylate and triphenylphosphine in acetic acid and tetrahydrofuran at room temperature for 30 min to give the isomerically pure 5β-acetate **10**.[3f] Exposure of **10** to *m*-chloroperbenzoic acid in dichloromethane at room temperature yielded after chromatography on silica gel (±)-asperlin and its stereoisomer (47% from **7**). The less polar epoxide **11A** was shown to be spectroscopically identical with naturally derived asperlin.[3]



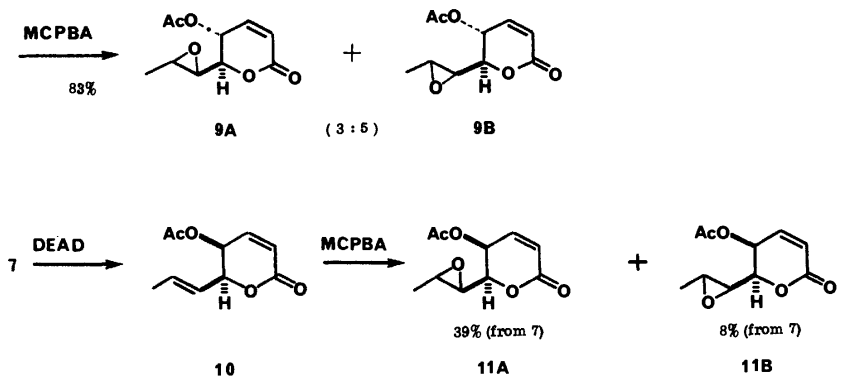


TABLE 1. INHIBITORY EFFECTS OF (±)-ASPERLIN AND STEREOISOMERS ON THE GROWTH OF KB-CELLS *in vitro*

Compound	IC_{50}(μg/ml)
9A	>10
9B	6.1
11A((±)-Asperlin)	6.2
11B	7.2

Preliminary inhibitory test of **9A**, **9B**, **11A**, and **11B** on the growth of KB-cells *in vitro* was shown in Table 1.[7]

Experimental

General. ^{1}H NMR spectra were taken on a JNM-PMX 60 spectrometer. The chemical shifts are reported as parts per million relative to TMS as the internal standard. The infrared spectra were recorded on a Hitachi 260—10 spectrometer in CCl_4 solution unless otherwise stated. The isomeric ratio of the products was determined by gas-liquid phase chromatography (GLC) using Hitachi Model 163 and 164 instruments equipped with a flame ionization detector using nitrogen as carrier gas. For TLC analysis throughout this work, Merck precoated TLC plates (silica gel 60 GF_{254}, 0.25 mm, or silica gel 60 HF_{254} silanized, 0.25 mm) were used. The products were purified by preparative column chromatography on silica gel E. Merck Art. 9385, or silanized silica gel E. Merck Art. 7719. Microanalyses were accomplished at the Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University. Unless otherwise specified, all reactions were carried out under an atmosphere of dry argon. In experiments requiring dry solvents, ether and tetrahydrofuran (THF) were distilled from sodium-benzophenone. Benzene was dried over sodium metal. Dichloromethane was dried over **4A** molecular sieves. Pyridine was stored over potassium hydroxide pellets. Other commercially supplied materials were used as received.

3-(Tetrahydro-2-pyranyloxy)-1-(trimethylsilyl)propyne (1). To a mixture of propargyl alcohol (5.82 ml, 100 mmol) and 3,4-dihydro-2*H*-pyran(11.0 ml, 120 mmol) in dry ether (100 ml) was added a catalytic amount of *p*-toluenesulfonic acid (0.2 g) at 0 °C. After the mixture was stirred for 30 min at room temperature, the solution was poured into aqueous sodium hydrogencarbonate and the product was extracted with ether. The combined extracts were washed with water, dried over magnesium sulfate, and concentrated *in vacuo*. Purification of the residue by chromatography on silica gel using ether-hexane (1:12) as eluent to give the propargyl ether as a colorless oil (13.2 g, 94%). A solution of the resulting acetylene (12.6 g, 90 mmol) in dry ether (100 ml) was treated with butyllithium in hexane (1.6 mol dm^{-3} solution, 61.8 ml, 98.9 mmol) dropwise at 0 °C. After the resulting white suspension was stirred for 30 min at 0 °C, chlorotrimethylsilane (12.6 ml, 98.9 mmol) was added at 0 °C. After being stirred for 1 h, the solution was poured into diluted hydrochloric acid and the product was extracted with ether repeatedly. The combined ether layers were washed with water, dried over magnesium sulfate and concentrated *in vacuo*. Purification of the residue by chromatography on silica gel using ether-hexane (1:30) as eluent to afford the ether **1** as a colorless liquid (18.9 g, 99%). ^{1}H NMR (CCl_4) δ=0.17 (s, 9H, Me_3Si), 1.63 (m, 6H, CH_2), 3.21—3.88 (m, 2H, C(6')H_2), 4.10 (s, 2H, ≡C-CH_2), 4.69 (m, 1H, C(2')H); IR 2970, 2205, 1260, 1135, 1040, 860 cm^{-1}; Found: C, 62.38; H, 9.22%. Calcd for $C_{11}H_{20}O_2Si$: C, 62.21, H, 9.49%. TLC analysis showed a single spot (R_f=0.61; 1:2, ether-hexane).

(5E)-erythro-*3-(Tetrahydro-2-pyranyloxy)-1-trimethylsilyl-5-hepten-1-yn-4-ol (2).* To a solution of the acetylene **1** (3.18 g, 15 mmol) in dry tetrahydrofuran (15 ml) at −78 °C was added *t*-butyllithium in pentane (1.96 mol dm^{-3} solution, 7.65 ml, 15.0 mmol) dropwise over 5 min. The resulting red solution was stirred for 1 h at −78 °C and treated with titanium tetraisopropoxide (4.47 ml, 15.0 mmol). After stirring 10 min at −78 °C, the orange solution was treated with crotonaldehyde (1.14 ml, 14.0 mmol), and was then stirred 10 min at −78 °C, allowed to reach room temperature over 1 h. The yellow solution was diluted with ether and washed with diluted hydrochloric acid. The dried (magnesium sulfate) ether layers were concentrated and the residue was subjected to chromatography on silica gel using ether-hexane (1:7) as eluent to give the alcohol **2** as a colorless oil (2.96 g, 75%). ^{1}H NMR (CCl_4) δ=0.15 (s, 9H, Me_3Si), 1.4—2.0 (m, 9H), 2.6 (s, 1H, OH), 3.27—4.30 (m, 4H), 4.78 (m, 1H), 5.33—5.77 (m, 2H, CH=CH); IR 3600, 3450, 2960, 2880, 2200, 1685, 1260, 1025, 850 cm^{-1}; Found: C, 63.59; H, 9.41%. Calcd for $C_{15}H_{26}O_3Si$: C, 63.78; H, 9.28%. TLC analysis showed a single spot (R_f=0.30; 1:2, ether-hexane). GLC analysis of the hydrolized diol showed that the product was 95% pure *erythro* isomer and contained 5% of *threo* isomer.

(5E)-erythro-*3-(Tetrahydro-2-pyranyloxy)-5-hepten-1-yn-4-ol (3).* A mixture of **2** (2.91 g, 10.3 mmol), potassium fluoride (2.99 g, 51.5 mmol), and methanol (20 ml) was stirred overnight at ambient temperature, then diluted with ether, washed with water, dried (magnesium sulfate), and concentrated to a light yellow oil which was subjected to chromatography on silica gel using ether-hexane (2:5) as eluent to give the acetylene **3** as an oil (1.95 g, 90%). ^{1}H NMR (CCl_4) δ=1.7 (m, 9H), 2.33 (t, J=2 Hz, 1H, ≡CH), 2.62 (m, 1H), 3.27—4.40 (m, 4H), 4.87 (m, 1H), 5.52—5.77 (m, 2H, CH=CH); IR 3600, 3450, 3320, 2950, 1685, 1130, 1030, 970 cm^{-1}; Found: C, 68.51; H, 8.69%. Calcd for $C_{12}H_{18}O_3$: C, 68.54; H, 8.63%. TLC analysis showed a single spot (R_f=0.32; 1:2, ether-hexane).

(6E)-erythro-*4-(Tetrahydro-2-pyranyloxy)-6-octen-2-yn-1,5-diol (4).* A solution of the acetylene **3** (8.60 g, 41.0 mmol) in dry tetrahydrofuran (90 ml) at 0 °C was treated with

butyllithium in hexane (1.60 mol dm^{-3} solution, 51.2 ml, 82.0 mmol). The pale yellow solution was stirred 1 h at 0 °C and treated with paraformaldehyde (6.14 g, 205 mmol). After stirring 10 min at 0 °C and 30 min at room temperature, the mixture was poured into diluted hydrochloric acid and the product was extracted with ether. The combined extracts were washed with water, dried (magnesium sulfate), and concentrated. Purification of the residue by chromatography on silica gel using ethyl acetate–hexane (1:1) as eluent to furnish the alcohol **4** as a colorless liquid (6.36 g, 65%). ^{1}H NMR (CCl_4) δ=1.7 (m, 9H), 3.61 (m, 4H), 4.12 (m, 2H), 4.20 (br s, 2H, CH_2OH), 4.90 (m, 1H), 5.47—5.77 (m, 2H, CH=CH); IR 3410, 2970, 1260, 1130, 1030, 870 cm^{-1}; Found: C, 64.77; H, 8.53%. Calcd for $C_{13}H_{20}O_4$: C, 64.98; H, 8.39%. TLC analysis showed a single spot (R_f=0.28; ether).

(2Z,6E)-erythro-4-(Tetrahydro-2-pyranyloxy)-2,6-octadien-1,5-diol (5). A mixture of the alcohol **4** (4.94 g, 20.6 mmol), Lindlar catalyst (5 g) and quinoline (0.655 ml) in benzene (80 ml) was stirred 12 h at room temperature under hydrogen (1 atm). The mixture was filtered, and the filter cake was washed with ether repeatedly. The filtrates were combined and concentrated *in vacuo*. The residue was subjected to chromatography on silica gel using ethyl acetate–hexane (2:3) as eluent to yield the (*Z*)-allylic alcohol **5** as a colorless oil (4.05 g, 81%). ^{1}H NMR (CCl_4) δ=1.7 (br s, 6H), 1.73 (d, *J*=6 Hz, 3H, CH_3), 3.50 (m, 2H), 3.83—4.47 (m, 6H), 4.60 (m, 1H), 5.13—6.13 (m, 4H, olefinic protons); IR 3410, 2955, 1250, 865 cm^{-1}; Found: C, 64.73; H, 8.87%. Calcd for $C_{13}H_{22}O_4$: C, 64.43; H, 9.15%; R_f=0.23 (ether).

5,6-Dihydro-6-[(E)-1-propenyl]-5-(Tetrahydro-2-pyranyloxy) 2H-pyran-2-one (6). Activated manganese (IV) oxide (25.7 g, 296 mmol) was added portionwise to a stirred solution of the diol **5** (3.89 g, 16.1 mmol) in dichloromethane (120 ml) at room temperature. After stirring 12 h at room temperature, the reaction mixture was filtered, and the filter cake was washed well with ether. The solvent was removed *in vacuo*, leaving a pale yellow oil which was submitted to chromatography on silica gel using ethyl acetate–hexane (1:5) as eluent to afford the lactone **6** as a colorless liquid (2.67 g, 70%). ^{1}H NMR (CCl_4) δ=1.63 (br m, 6H), 1.76 (d, *J*=7 Hz, 3H, =CCH_3), 3.27—4.33 (m, 4H), 4.77 (m, 1H), 5.57—6.10 (m, 3H), 6.73 (dd, *J*=9 and 3 Hz, C(4)H); IR 2955, 1740, 1125, 1030 cm^{-1}; Found: C, 65.33; H, 7.77%. Calcd for $C_{13}H_{18}O_4$: C, 65.53; H, 7.61%. TLC analysis showed a single spot (R_f=0.64; ether).

5,6-Dihydro-5-hydroxy-6-[(E)-1-propenyl]-2H-pyran-2-one (7). The lactone **6** (1.72 g, 7.20 mmol) was dissolved in dry methanol (20 ml) and treated with a catalytic amount of *p*-toluenesulfonic acid (150 mg) at room temperature. After stirring 30 min at room temperature, the reaction mixture was poured into aqueous sodium hydrogencarbonate and the product was extracted with ethyl acetate three times. The combined organic layers were washed with water, dried over magnesium sulfate, and concentrated. The residue was submitted to chromatography on silica gel using ether–hexane (3:1) as eluent to give the alcohol **7** as a colorless liquid (978 mg, 88%). ^{1}H NMR ($CDCl_3$) δ=1.75 (d, *J*=6 Hz, 3H, CH_3), 3.1 (s, 1H, OH), 4.03—4.82 (m, 2H), 5.43—6.07 (m, 3H), 6.83 (dd, *J*=2 and 10 Hz); IR 3410, 2960, 2930, 2860, 1720, 1260, 1080, 1020 cm^{-1}; Found: C, 62.06; H, 6.74%. Calcd for $C_8H_{10}O_3$: C, 62.32; H, 6.54%. TLC analysis showed a single spot (R_f=0.46; ether).

5,6-Dihydro-5-acetoxy-6-[(E)-1-propenyl]-2H-pyran-2-one (8). A mixture of the alcohol **7** (154 mg, 1.00 mmol), pyridine (1 ml) and acetic anhydride (1 ml) was allowed to stand at room temperature for 1 h. The resulting solution was poured into aqueous sodium hydrogencarbonate and the product was extracted with ethyl acetate repeatedly. The combined organic layers were washed with brine and dried over magnesium sulfate. Concentration yielded the acetate **8** as an oil (181 mg, 92%). ^{1}H NMR (CCl_4) δ=1.73 (d, *J*=6 Hz, 3H, CH_3), 2.05 (s, 3H, Ac), 4.77 (t, *J*=6 Hz, 1H, C(6)H), 5.23 (m, 1H, C(5)H), 5.4—5.9 (m, 2H, propenyl), 6.03 (br d, *J*=10 Hz, 1H, C(3)H), 6.68 (dd, *J*=4 and 10 Hz); IR 1745, 1375, 1225, 1025 cm^{-1}. TLC analysis showed a single spot (R_f=0.62; ether). This product was used for the next reaction without further purification.

(±)-Asperlin (11A) and Related Stereoisomers (9A, 9B, and 11B). The crude acetate **8** (165 mg, 0.842 mmol) was dissolved in dichloromethane (3 ml) at 0 °C and the solution was treated with *m*-chloroperbenzoic acid (415 mg, 1.68 mmol). After stirring overnight at ambient temperature, the mixture was poured into aqueous sodium sulfite and the product was extracted with ethyl acetate several times. The combined organic layers were washed with water, dried over magnesium sulfate and concentrated *in vacuo*. The residue was subjected on silica-gel chromatography using ether–hexane (1:1) as eluent to afford two isomeric epoxides **9A** (less polar fraction, 57 mg, 32%) and **9B** (more polar fraction, 91 mg, 51%).

9A: ^{1}H NMR (CCl_4) δ=1.33 (d, *J*=5 Hz, 3H, CH_3), 2.07 (s, 3H, Ac), 2.63—3.13 (m, 2H, epoxide), 4.07 (t, *J*=6 Hz, 1H, C(6)H), 5.35 (t, *J*=4 Hz, 1H, C(5)H), 6.03 (d, *J*=10 Hz, 1H, C(3)H), 6.77 (dd, *J*=4 and 10 Hz, 1H, C(4)H); IR 3000, 2940, 1750, 1375, 1230 cm^{-1}; Found: C, 56.88; H, 5.86%. Calcd for $C_{10}H_{12}O_5$: C, 56.60; H, 5.70%. TLC analysis showed a single spot (R_f=0.60; ether).

9B: ^{1}H NMR (CCl_4) δ=1.30 (d, *J*=5 Hz, 3H, CH_3), 2.10 (s, 3H, Ac), 2.73—3.15 (m, 2H), 4.47 (t, *J*=4 Hz, 1H, C(6)H), 5.37 (t, *J*=4 Hz, 1H, C(5)H), 6.00 (d, *J*=10 Hz, 1H, C(3)H), 6.67 (dd, *J*=4 and 10 Hz, 1H, C(4)H); IR 2990, 2950, 1750, 1380, 1230, 1120, 1030 cm^{-1}; Found: C, 56.47; H, 5.83%. Calcd for $C_{10}H_{12}O_5$: C, 56.60; H, 5.70%. TLC analysis showed a single spot (R_f=0.46; ether).

A solution of the alcohol **7** (0.33 g, 2.14 mmol), triphenylphosphine (2.81 g, 10.7 mmol), and acetic acid (0.613 ml, 10.7 mmol) in dry tetrahydrofuran (10 ml) was combined with a solution of diethyl azodicarboxylate (1.68 ml, 10.7 mmol) in tetrahydrofuran (4.3 ml) at room temperature. After 30 min, the reaction mixture was poured into aqueous sodium hydrogencarbonate and the product was extracted with ethyl acetate several times. The combined extracts was washed with water, dried over magnesium sulfate, and concentrated *in vacuo*. The residual oil was subjected to simple short-path chromatography (ether–hexane, 2:1) and the crude product was used for the next reaction without further purification.

The oxidation was carried out in an analogous manner from the above acetate to produce the two isomeric epoxides **11A** (less polar fraction, 177 mg, 39% from the alcohol **7**) and **11B** (more polar fraction, 37 mg, 8% from the alcohol **7**).

(±)-Asperlin (11A):[3] ^{1}H NMR ($CDCl_3$) δ=1.37 (d, *J*=5 Hz, 3H, CH_3), 2.13 (s, 3H, Ac), 2.90—3.28 (m, 2H, epoxide), 4.17 (dd, *J*=3 and 7 Hz, 1H, C(6)H), 5.32 (dd, *J*=3 and 6 Hz, 1H, C(5)H), 6.17 (d, *J*=10 Hz, 1H, C(3)H), 7.03 (dd, *J*=6 and 10 Hz, 1H, C(4)H); IR 3000, 2960, 1750, 1380, 1230, 1040, 760 cm^{-1}; Found: C, 56.76; H, 6.04%. Calcd for $C_{10}H_{12}O_5$: C, 56.60; H, 5.70%. TLC analysis showed a single spot (R_f=0.51; ether).

11B: ^{1}H NMR (CCl_4) δ=1.32 (d, *J*=5 Hz, 3H, CH_3), 2.12 (s, 3H, Ac), 2.75—3.15 (m, 2H, epoxide), 4.28 (t, *J*=4 Hz, 1H, C(6)H), 5.47 (dt, *J*=4 and 6 Hz, 1H, C(5)H), 6.07 (d, *J*=10 Hz, C(3)H), 6.73 (dd, *J*=6 and 10 Hz, 1H, C(4)H); IR 2990, 2950, 1750, 1380, 1230, 1050 cm^{-1}; Found: C, 56.77; H, 6.20%. Calcd for $C_{10}H_{12}O_5$: C, 56.60; H, 5.70%. TLC analysis showed a single spot (R_f= 0.37; ether).

We acknowledge Professor T. Nishiguchi for helpful discussions.

Selective Condensation of [3-(Alkylthio)allyl]titanium Reagent with Carbonyl Compounds

Kyoji FURUTA, Yoshihiko IKEDA, Noriyuki MEGURIYA, Nobuo IKEDA, and Hisashi YAMAMOTO*
Department of Applied Chemistry, Nagoya University, Chikusa, Nagoya 464
(Received December 26, 1983)

[3-(Ethylthio)allyl]titanium reagent generated easily from allyl ethyl sulfides condensed with aldehydes to give *erythro*-β-hydroxy sulfides in highly regio- and stereoselective manner. In contrast, crotyl ethyl sulfide reacted with aldehydes affording δ-hydroxy vinyl sulfide exclusively. The substitution pattern of the starting sulfide can have a pronounced effect on the selectivity in this condensation reaction. *erythro*-β-Hydroxy sulfide obtained was transformed stereoselectively to the *trans*-vinyloxirane or 1,3-alkadiene.

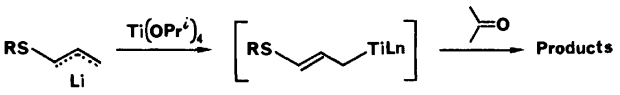
The role of the sulfur function in synthetic chemistry has become increasingly extensive.[1] In particular, the α-carbanion stabilized by sulfur contributed to the many important developments in sulfur utilizing synthetic chemistry.[2] Especially noteworthy is a large body of data relating to the reaction of sulfur-stabilized allylic carbanions.[2] The alkylthioallyl anion generated easily by treating the alkyl allyl sulfide with strong base can react with a variety of electrophiles to give synthetically useful intermediates. Efficient and useful methods for the extension of carbon chain by means of such reagents have recently been described.[3] Unsaturated β-hydroxy sulfide, which can be obtained in the reaction of alkylthioallyl anion with carbonyl compounds, has a potential utility as it can be easily converted to the alkenyloxiranes or 1,3-alkadienes. If it can be possible to obtain this olefinic β-hydroxy sulfide regio- and stereoselectively, the general route to stereochemically pure alkenyloxiranes or 1,3-alkadienes may be established. Previous investigators have attempted to optimize the stereoselectivity of the reaction. Consequently, the available methods afford only one substitution type of pure olefinic β-hydroxy sulfides after a rather tedious sequence in high yields.[2,3]

The major problem encountered in the reaction of allylic carbanions with carbonyl compounds is the one concerning the regio- (α/γ) and stereoselectivities (*erythro/threo*) of the reaction. Generally, it has been thought that the reactivity and the structure of the metallated carbanions are highly dependent on the countercation and solvents.[4] For example, it has been often observed that the lithio derivatives have shown little selectivity in some reactions, but the use of some other metals gave excellent results in the same reactions. In our continuous studies on the reaction of anionic species, we have confirmed the important role of metal countercation in the reaction. Among others, the organotitanium reagents have shown unusual results over a wide range of reactions.[5] This particular reactivity of the titanium reagents has not been fully understood,but it might be suggested that the rather tight nature of carbon–titanium bond and susceptibility to the steric demand are the origin of the selectivity. From this point of view, it may be meaningful to examine the ability of the [3-(alkylthio)allyl]titanium reagents for the selective reaction.

This paper deals with the reaction between a wide variety of [3-(alkylthio)allyl]titanium reagents and carbonyl compounds as a promising versatile synthetic method. Application of this methodology to the stereoselective syntheses of alkenyloxiranes and 1,3-alkadienes were also described.[6]

Results and Discussion

Regio- and Stereoselectivity. Easily prepared [3-(alkylthio)allyl]titanium reagent of type **1** from alkyl lithioallyl sulfide and titanium tetraisopropoxide was subjected to the reaction with carbonyl compounds. The major results of our findings are illustrated in Table 1. Several trends emerge from these data. First,



1

the substitution pattern of the starting sulfide can have a pronounced effect on α/γ ratio in the final condensation products. With unsubstituted allyl sulfides (R^1=R^2=R^3=R^4=H, entries 1—10), α-adducts were produced selectively with most of the aldehydes studied (the α % was about 95—99%). Even the aromatic aldehydes and ketones gave α-adduct with high regioselectivities.[7] On the other hand, a dramatic change in product distribution occurs when the condensation with aldehyde was carried out by using γ-substituted allyl sulfides (R^3 and/or R^4=Me, entries, 15, 16, and 19). In these cases, excellent γ-selectivity was observed. α- or β-Mono- and α,β-disubstituted allyl sulfides (R^1 and/or R^2=Me) were, however, showed a very high α-selectivities again. Furthermore, it is highly interesting that α,γ-disubstituted allyl sulfide (R^1=R^3=Me) gave the α-adduct almost exclusively (entry 18).

The second important trend that may be seen from the data in Table 1 is the exceedingly high *erythro* selectivity of the reaction. For example, [3-(phenylthio)allyl]titanium reagent generated from allyl phenyl sulfide reacted with cyclohexanecarbaldehyde at α-position to give *erythro*-β-hydroxy sulfide exclusively (entry 1). For the reaction with aromatic aldehyde and α,β-unsaturated aldehyde, the *erythro* selectivity was relatively low (entries 4, 5, and 10) compared with other saturated systems. This anomalous trend of unsaturated system was often observed in other similar type of reactions,[7] and may be due to an acyclic transition state or other electronic factors.[8] One electron transfer mechanism in the reaction of aromatic carbonyl compounds with some carbanion species was confirmed experimentally by Ashby.[8a] If such was

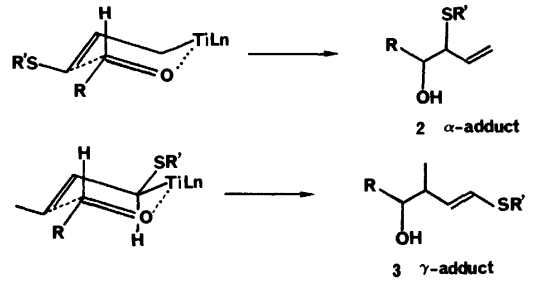
a) All reactions were performed on a 2—3 mmol scale with the same experimental procedure as described in the text. b) Freshly distilled prior to use. A: Cyclohexanecarbaldehyde; B: Hexanal; C: 2-Hexenal; D: Benzaldehyde; E: 4-*t*-Butylcyclohexanone; F: Acetophenone. c) Isolated pure product. d) Unless otherwise specified, stereochemical assignments were based on conversion to the corresponding oxiranes. *erythro/threo* Ratio was determined by GLC analyses of the α adduct and/or the corresponding oxirane. e) The major product (97%) was found to be the structure having an axial hydroxyl group. f) Structure determination was not unambiguous but was based on (1) extrapolation from the other examples and (2) the characteristic features of NMR spectrum which were almost identical with those of entry 11 and different from those of the *threo* isomer.

the case, it was surprising that aromatic ketone revealed an exceedingly high *erythro* selectivity (entry 7).

It should be noted that the *erythro* stereoselectivity was not affected by the α and/or β branching of the starting sulfides. In addition, these regio- and stereoselectivities were not affected by the difference in another groups (R^5) on the sulfides. The corresponding [3-(alkylthio)allyl]lithium or other similar organometallic species are totally unsatisfactory reagents[3] for such rigorously regio- and stereoselective transformations. For example, [1-methyl-1-(phenylthio)allyl]lithium (see entry 11 of Table 1) gave 33% yield of the α-adduct (*erythro/threo*=61:39) and 62% yield of the γ-adduct. Analogously, [2-methyl-1-(phenylthio)allyl]lithium (see entry 13 of Table 1) produced 26% yield of the α-adduct (*erythro/threo*=52:48) and 73% yield of the γ-adduct.



2 α-adduct

3 γ-adduct

The possible explanation of these observation is as follows. It is generally assumed that the addition of the allylic organometallics to the carbonyl takes place through an allylic rearrangement of the organometallics by a chelate transition state (Fig. 1).[9] From this point of view, the structural feature of organometallic species may considerably influence on the regioselectivity of the reaction. Thus, the metal site in the organometallic reagents may be the cotrolling factor of the regioselectivity. It is very useful to know the structure of the organometallic reagents for the estimation of the course of the reactions, but it is, of course, not an easy task. In this case, our efforts to confirm the structure (metal site) of the anionic species by a physical technics gave, hitherto, unsuccessful results. Consequently, the only method for an understanding of the selectivity of this reaction is to examine the product distributions. If one can accept the assumption of the allylic rearrangement mechanism, the alkylthioallyl anion which has a countercation at the γ-position should give the α-adduct, and in contrast, that with cation at α-position to sulfur affords γ-adduct (see Fig. 1). In conclusion, the metal site of the alkylthioallyl anion can be rationalized as follows; (1) for unsubstituted allyl sulfide (entries 1—10), titanium moiety is attached at γ-position to sulfur; (2) γ-substituted allyl sulfide (entries 15, 16, and 19) has, in contrast, the titanium

metal at its α-position; (3) α- or β-mono- and α,β-disubstituted allyl sulfides are metallated at γ-position again; (4) α,γ-disubstituted allyl sulfide (entry 18) is metallated at γ-position with remarkably high selectivity. Thus, the metallation (titanation) of the alkyl allyl sulfide is very sensitive to the substitution pattern of the starting allyl sulfide. If these trends are owing to the steric factor between the titanium metal and geminal substituent, the complete selectivity for the crotyl sulfide metallation is very surprising.

Next noticeable results is the high *erythro* selectivity of the reaction. The predominant formation of *erythro*-β-hydroxy sulfide (α-adduct) was explicable by considering the transition state structure for an allylic rearrangement mechanism stated above (see Fig. 1). As shown in Fig. 1, a six-membered ring transition state in which both R'S and R groups are equatorial is more favorable, and *erythro* product is thus formed. Apparently, it should be expected that the large substituents at α-position of the allyl sulfide reduce the stereoselectivity as a result of the disordering of the sulfide stereochemistry in the transition state (axial-equatorial).

The Synthesis of Alkenyl Oxiranes and Dienes. As the general trends of the reaction of [3-(alkylthio)allyl]-titanium reagents with carbonyl compounds became clear, our attention turned to the synthetic applications of this reaction. Thus, the well-known procedure to desulfurize β-hydroxy sulfides *via* sulfonium salt formation followed by base-catalyzed cyclization[10] converts this reaction into a new stereoselective entry to alkenyloxirane synthesis.[11]

A few examples of this transformation were summarized in Table 2.

Table 2. Stereoselective synthesis of alkenyloxiranes[a]

Entry	Hydroxy Sulfide	Oxirane	*cis*:*trans*[b]	Yield/%	^{1}H NMR δ[i]
1		 11g)	c)	96	2.95 (dd, *J*=2, 5.5 Hz, 1H), 2.43 (br, 1H)[j]
2			96:4	86	2.88 (dd, *J*=2, 5.5 Hz, 1H), 2.61 (br, 1H)[k]
3			88:12[d]	97	3.2 (d, *J*=6.2 Hz, 2H)[l]
4		 11c, j)	86:14	94	3.15 (dd, *J*=2, 6 Hz, 1H), 3.55 (d, *J*=2 Hz, 1H)[m]
5			c)	83

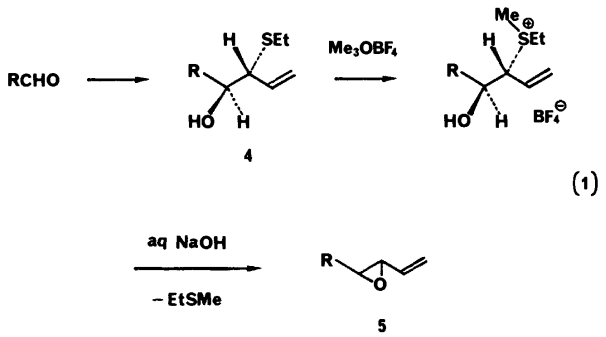
9			c), g)	82[h]	1.33 (s, 3H, Me), 2.17 (br, 1H)
10			93:7[d]	94	2.98 (d, *J*=2 Hz, 1H), 2.5 (br, 1H)[n]

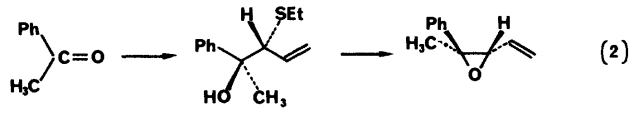
a) All reaction were performed on a 0.5 mmol scale. b) Unless otherwise specified, stereochemical assignments were based on the NMR analyses of the oxiranes. *cis*/*trans* Ratio was determined by GLC and/or NMR analyses. c) Not determined. Two isomers were not separated on GLC, but pure *trans* isomer was confirmed by NMR analysis. d) Determined by NMR analysis. e) This product was transformed to the saturated oxirane, and spectrally identified by comparison with an authentic specimen prepared independently. f) The stereochemical assignment was based on the method of Trost. The equatorial/axial ratio was 96:4 (GLC). The major isomer was the one depicted in Table. g) Stereochemical assignment was based on NMR analysis of the saturated oxirane derived from the corresponding saturated hydroxy sulfide. The saturated oxirane was >95% pure *trans* by GLC analysis (trace amount of *cis* isomer was detected). h) It should be noted that the usual reaction conditions gave none of the desired product in this case (see text). The same reaction proceeds but in very low yield with use of the corresponding phenylthio derivatives. i) Measured in $CDCl_3$. j) *cis*-Isomer: ^{1}H NMR δ=3.20 (dd, *J*=5, 6 Hz, 1H), 2.58 (br, 1H). k) *cis*-Isomer: ^{1}H δ=3.19 (dd, *J*=5, 6 Hz, 1H). l) *cis*-Isomer: ^{1}H NMR δ=3.47 (m, 2H). m) *cis*-Isomer: ^{1}H NMR δ=4.03 (d, *J*=4 Hz, 1H). n) *cis*-Isomer: ^{1}H NMR δ=3.18 (d, *J*=4 Hz, 1H).

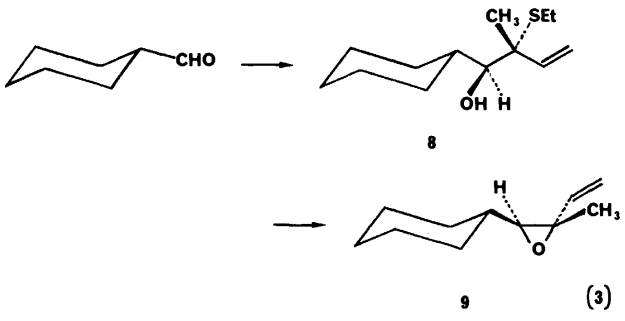


This desulfurization reaction is known to proceed *via* anti attack of oxide ion to sulfonium carbon in complete stereospecific manner. Thus, the *erythro*-β-hydroxy sulfides should be converted to *trans*-oxiranes. Actually, *trans*-oxirane was obtained as a major isomer and the isomer ratios (*trans/cis*) were parallel to those of the β-hydroxy sulfide (*erythro/threo*).

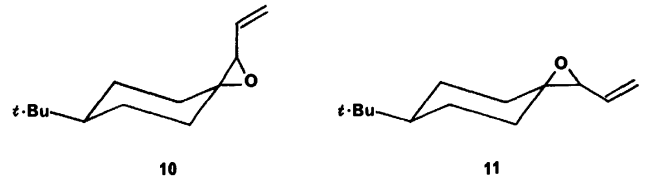
It should be noted that the efficiency of this transformation highly depends on steric factors, especially on the size of alkyl substituents on sulfur atom. Thus, the phenylthio and *t*-butylthio derivatives resulted in lower yield of oxirane than the corresponding ethylthio compound (see entries 1 and 5, 4 and 6 in Table 2). The same reaction in entry 10 but with the use of the phenylthio derivatives proceeds with fairly low yield.

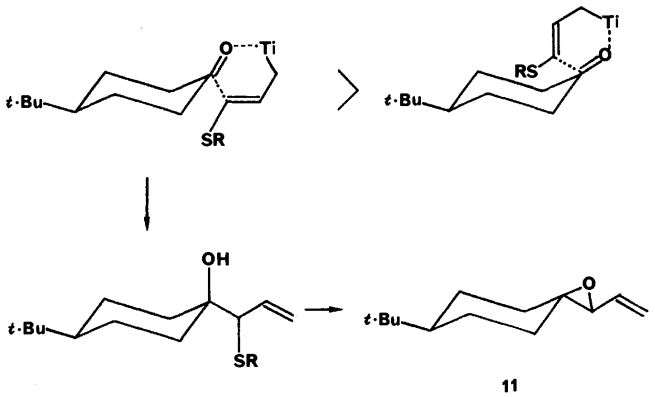
The significant feature of this method can be seen for the preparation of trisubstituted oxiranes, for which there exists no stereoselective methodology (entries 7—9). Thus, two types of trisubstituted oxiranes can be prepared stereoselectively by this method in compliance with the appropriate choice of the starting materials (Eqs. 2 and 3).





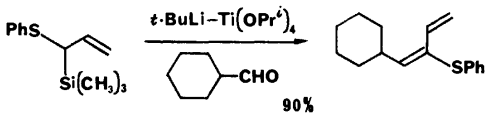
Another type of stereoselection is also observed in entry 8 of Table 2. It was known that the diphenylsulfonium allylide reacted with 4-*t*-butylcyclohexanone to give two isomeric vinyloxiranes **10** and **11** in a ratio of 1:4.[11b] In comparison with this data, it can be stated that the equatorial attack selectivity of the [3-(alkylthio)ally]titanium reagent is exceedingly high (96%).





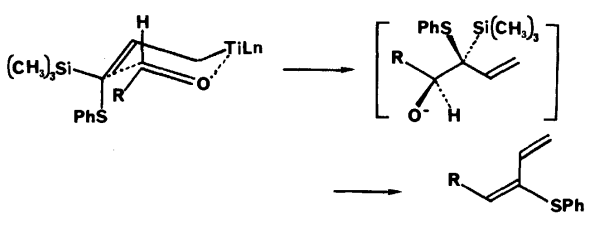
11

We next chose to examine the related reaction system in which the alkyl substituent was replaced by the silyl group. As mentioned in the preceeding section, the α-substituent of the starting allyl sulfides induce the α regioselectivity of the product and may give the significant influence on the *erythro* selectivity of the reaction. The silyl substituent in place of alkyl group may be expected to function in the same way. The silyl group when positioned at α to sulfur has the potential of Peterson elimination[12] following α-selective addition to carbonyl compounds so as to produce 2-(alkylthio)-1,3-alkadiene, an intriguing structure as a Diels-Alder component. Thus the metallation of **12**,[3g,13] metal exchange with titanium tetraisopropoxide as usual manner, and condensation with cyclohexanecarbaldehyde followed by elimination of Me_3SiO^- afforded the (*E*)-sulfide **13** (*E*/*Z*=10:1).[14]



12 13

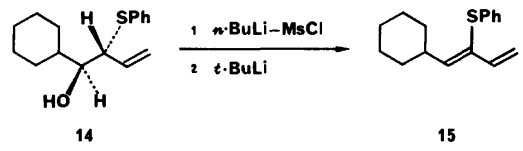
The formation of the elimination product is indicative of the α-selective addition of this reagent to carbonyl. As the syn elimination of the Me_3SiO^- in Peterson reaction gains general acceptance,[12] the product (*E*)-dienyl sulfide **13** must result from the α-*erythro*-selective carbonyl addition of the reagent. Although the other possible explanation is the α-*threo*-selective carbonyl addition followed by anti elimination, the α-*erythro*-selective reaction mechanism seems to be more likely since the similar syn elimination of Me_3SiO^- using titanium tetraisopropoxide was observed previously[15] and since allyltrimethylsilane on treatment with *t*-BuLi-Ti(OPr^i)$_4$ followed by cyclohexanecarbaldehyde gave the (*Z*)-diene selectively.[16]



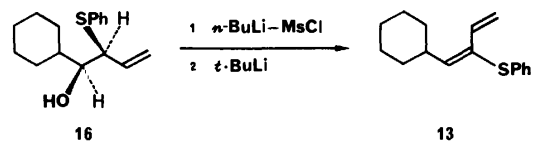
13

It should be noted that the reverse positioning (equatorial→axial) of the sulfur group in transition state is essential for the *erythro* selective addition of this reagent (Fig. 2). The direction of two substituents, phenylthio and trimethylsilyl group, in transition state may be determined by the thermodynamic requirement (relative stability between the possible transition states). Thus, the large trimethylsilyl group should have the equatorial position.

Further interesting results were obtained from the direct dehydration from the sulfide **14** (entry 1 of Table 1). Sequential treatment of the *erythro*-β-hydroxy sulfide **14** in THF first with butyllithium, then methanesulfonyl chloride and finally two equivalents of *t*-butyllithium produced the (*Z*)-sulfide **15** stereospectifically. This reaction is highly stereospecific. Thus,



14 **15**

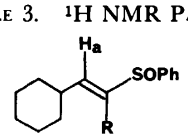


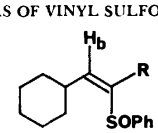
16 **13**

the corresponding *threo* isomer **16**, obtained from the [3-(phenylthio)allyl]lithium and aldehyde followed by chromatographic separation, gave the (*E*)-isomer **13** exclusively under the same reaction conditions. Thus the remarkable syn elimination of MsOH should be concluded. The mechanistic details of this reaction will be published elsewhere.

For the confirmation of the stereochemistry of the dienes, the sulfides **13** and **15** were converted to the corresponding sulfoxides through $NaIO_4$ oxidation. The large downfield shift (ΔH_1 shift=6.38 ppm) of the resonances of HC=CS(O)Ph of the product derived from **13** in the presence of Eu(fod)$_3$ (0.4 equiv) is expected from its *E* configuration. On the other hand, the (*Z*)-isomer revealed a small downfield shift (1.29 ppm) under the same conditions. The model experiment of (*E*)- and (*Z*)-2-cyclohexylvinyl phenyl sulfoxides gave a supporting result for this characteristic shift of absorption spectra (Table 3).

Table 3. ^{1}H NMR Parameters of vinyl sulfoxides[a]

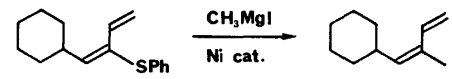




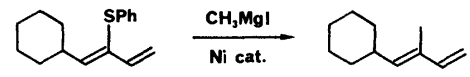
R	δH_a	δH_b	δH_c[b]	ΔH[c]
H	6.42		11.02	4.60
CH=CH$_2$	6.22		12.60	6.38
H		~5.8	7.13	~1.3
CH=CH$_2$		5.98	7.27	1.29

a) Chemical shifts are reported in parts per million downfield from the internal TMS reference. b) δH_E shows the chemical shift of H_a or H_b in the presence of 0.4 equiv of Eu(fod)$_3$. c) $\Delta H=\delta H_E-\delta H_a$ (or δH_b).

Exposure of these sulfides **13** and **15** to methylation conditions with MeMgI under Ni catalyst[17] led to dienes **17** and **18**, respectively with rigorous stereospecificities.



13 **17**



15 **18**

Experimental

General. ^{1}H NMR spectra were taken on a JNM-PMX 60 spectrometer. The chemical shifts are reported as parts per million relative to TMS as the internal standard. The infrared spectra were recorded on a Hitachi 260-10 spectrometer in CCl_4 solution unless otherwise stated. The isomeric ratio of the products was determined by gas-liquid phase chromatography (GLC) using a Hitachi Model 163 and 164 instruments equipped with a flame ionization detector using nitrogen as carrier gas. For TLC analysis throughout this work, Merck precoated TLC plates (silica gel 60 GF_{254}, 0.25 mm, or silica gel 60 HF_{254} silanized, 0.25 mm) were used. The products were purified by preparative column chromatography on silica gel E. Merck Art. 9385, or silanized silica gel E. Merck Art. 7719. Microanalyses were accomplished at the Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University. Unless otherwise specified, all reactions were carried out under an atmosphere of dry argon. In experiments requiring dry solvents, ether and tetrahydrofuran (THF) were distilled from sodium-benzophenone. Benzene, hexane, and toluene were dried over sodium metal. Dichloromethane was dried over 4A molecular sieves. Other commercially supplied materials were used as received.

Preparation of Allyl Sulfides. Method A:[18] To a mixture of thiol (0.15 mol) and sodium methoxide (0.17 mol) in methanol (200 ml) was added allyl bromide (0.15 mol) at 0 °C, and the mixture was stirred at 0 °C for 1 h and 25 °C overnight. The resulting mixture was poured into 2 mol dm^{-3} sodium hydroxide and the product was extracted with ether. The organic layer was washed with brine, dried, and freed of solvent. Distillation of the residue gave desired allyl sulfide. Method B: To a solution of alkyl allyl sulfide (48 mmol) dissolved in THF (50 ml) was added *t*-butyllithium in pentane (48 mmol) dropwise at −78 °C, and the resulted solution was stirred for 10 min at the same temperature and 30 min at 0 °C leading to complete lithiation. Then, the mixture was cooled to −78 °C again and methyl iodide (60 mmol) was added to this solution. After stirring for 10 min at −78 °C and 10 min at 0 °C, and further 20 min at 25 °C, the resulting mixture was poured into 2 mol dm^{-3} hydrochloric acid. The product was extracted with ether, and the combined organic layer was dried and freed of solvent. Distillation of the residue gave desired allyl sulfide.

Preparation of Phenyl 1-(Trimethylsilyl)allyl Sulfide.[19] To a solution of allyl phenyl sulfide (15 g, 100 mmol) in THF

TABLE 4. PREPARATION OF ALLYL SULFIDES[a]

Sulfides	Method[b]	Yield(%)	Bp(°C)/mmHg	^{1}H NMR δ[c]
	A	72	110—115/760	1.20(t, 7Hz, 3H), 2.41(q, 7Hz, 2H), 3.06(d, 6.5Hz, 2H), 4.8—5.3(m, 2H), 5.75(ddt, 6.5, 9, and 18Hz, 1H).[3b,19a]
	A	84	110—111/23	3.43(d, 6.5Hz, 2H), 4.98(dd, 1 and 10Hz, 1H), 5.02(dd, 1 and 18Hz, 1H), 5.83(ddt, 6.5, 10, and 18Hz, 1H).[18]

	B	79	e)	1.35(d, 7Hz, 3H), 3.68(dt, 7 and 7Hz, 1H), 4.87(dd, 1 and 16Hz, 1H), 4.88(dd, 1 and 10Hz, 1H), 5.4—6.07(m, 1H), 7.20(m, 5H).[18]
	A	83	36—37/19	1.18(t, 7Hz, 3H), 1.78(s, 3H), 2.34(q, 7Hz, 2H), 3.0(s, 2H), 4.72(s, 2H).[19b]
	A	89	113—115/18	1.83(s, 3H), 3.42(s, 2H), 4.74(s, 2H), 7.17(m, 5H).[2a,21]
	A	87[f]	42—47/19	1.19(t, 7Hz, 3H), 1.70(m, 3H), 2.38(q, 7Hz, 2H), 2.99(m, 2H), 5.42(m, 2H).[19b]
	A	96[g]	119—122/20	1.64(d, 3.5Hz, 3H), 3.41(m, 2H), 5.46(m, 2H), 7.14(s, 5H).[18,21]
	B	78	118—122/19	1.38(d, 7Hz, 3H), 1.82(s, 3H), 3.68(q, 7Hz, 1H), 4.62(s, 2H), 7.18(m, 5H).[22]
	B	72[h]	130—132/26	1.32(d, 7Hz, 3H), 1.58(d, 5Hz, 3H), 3.59(dt, 7 and 7Hz, 1H), 5.31(m, 2H), 7.17(m, 5H).[21]
	A	90	133—139/23	1.56(s, 3H), 1.69(s, 3H), 3.42(d, 7.5Hz, 2H), 5.24(t, 7.5Hz, 1H), 4.16(m, 5H).[23]

a) The reactions were performed on 50—250 mmol scale. b) Method A: Thiol-sodium methoxide-allyl bromide; Method B: Allyl sulfide-*t*-butyllithium-methyl iodide. c) ^{1}H NMR spectrum were measured in CCl_4 solution. d) This product was contaminated with *ca.* 15% of diallyl sulfide, which could not be separated. The mixture was used for the reaction. e) Purified by silica-gel column chromatography (hexane, R_f=0.24). A small amount of the regioismer, 1-butenyl phenyl sulfide, was also produced as a side product, but it could be separated out by column chromatography (hexane, R_f=0.35). f) This contains *ca.* 8% of the *Z*-isomer. g) This contains *ca.* 4% of the *Z*-isomer and 5% of the regioisomer, 1-methylallyl phenyl sulfide. They could be separated out by repeated fractional distillation. h) This contains *ca.* 10% of *Z*-isomer.

(200 ml) was added *t*-butyllithium in pentane (2.0 mol dm^{-3} solution, 50 ml, 100 mmol) at −78 °C. The solution was stirred at 0 °C for 30 min, and then cooled to −78 °C again. Titanium tetraisopropoxide[24] (32.7 ml, 110 mmol) was added to the mixture and the resulting solution was stirred for 10 min at the same temperature. To this solution was added chlorotrimethylsilane (12.7 ml, 100 mmol) at −78 °C, and stirring was continued for 10 min at −78 °C and 1 h at 0 °C. The reaction mixture was poured into 2 mol dm^{-3} hydrochloric acid and the product was extracted with ether. The combined organic layer was dried and concentrated.[25] Fractional distillation of the residue gave phenyl 1-(trimethylsilyl)-allyl sulfide (14.6 g, 66%). Bp 73—74 °C (0.9 mmHg†); ^{1}H NMR (CCl_4) δ=0.13 (s, 9H), 3.12 (d, *J*=8.5 Hz, 1H), 4.86 (dd, *J*=1 and 8.5 Hz, 1H), 4.88 (dd, *J*=1 and 17 Hz, 1H), 5.72 (dt, *J*=8.5 and 17 Hz, 1H).

Reaction of [3-(Alkylthio)allyl]titanium Reagents with Carbonyl Compounds. The following experimental procedure provides details of typical reaction conditions. To a solution of allyl phenyl sulfide (0.36 g, 2.4 mmol) in THF (8 ml) was added butyllithium[26] in hexane (1.6 mol dm^{-3} solution, 1.5 ml, 2.4 mmol) dropwise at −78 °C, and the orange mixture was stirred at 0 °C for 30 min. Titanium tetraisopropoxide (0.71 ml, 2.4 mmol) was added to the solution at −78 °C, and the resulting solution was stirred for 10 min. Cyclohexanecarbaldehyde (0.24 ml, 2.0 mmol) was added over a period of 5 min at −78 °C, and the mixture was stirred at −78 °C for 10 min and then at 0 °C for 1 h. Then the mixture was poured into 2 mol dm^{-3} hydrochrolic acid and the product was extracted with ether. The organic layer was dried and concentrated. Chromatography of the residue on silica-gel column[27] (4:1 hexane-ether) gave *erythro*-1-cyclohexyl-2-phenylthio-3-buten-1-ol (0.52 g, 99%).[28] GLC analysis of the product revealed the isomeric ratio of >30:1 (*erythro*: *threo*). Stereochemical assignments of the sulfide-carbonyl adducts were based on conversion to the corresponding oxiranes.

erythro-*1-Cyclohexyl-2-phenylthio-3-buten-1-ol*: R_f=0.30 (4:1 hexane-ether); ^{1}H NMR (CCl_4) δ=0.55—2.3 (m, 11H), 2.17 (d, *J*=3 Hz, 1H), 3.30 (m, 1H), 3.73 (dd, *J*=4 and 8.5 Hz, 1H), 4.96 (dd, *J*=2 and 16.5 Hz, 1H), 5.04 (dd, *J*=2 and 10 Hz, 1H), 5.83 (ddd, *J*=8.5, 10, and 16.5 Hz, 1H), 7.2 (m, 5H); IR 3550, 3090, 2930, 2860, 1645, 1450 cm^{-1}; Found: C, 73.20; H, 8.47%. Calcd for $C_{16}H_{22}OS$: C, 73.23; H, 8.45%.

erythro-*1-Cyclohexyl-2-ethylthio-3-buten-1-ol*: R_f=0.38 (2:1 hexane-ether); ^{1}H NMR (CCl_4) δ=1.22 (t, *J*=7 Hz, 3H), 0.83—2.17 (m, 12H), 2.42 (q, *J*=7 Hz, 2H), 3.33 (m, 2H), 5.00 (dd, *J*=2 and 18 Hz, 1H), 5.10 (dd, *J*=2 and 8 Hz, 1H), 5.42—6.08 (m, 1H); IR 3550, 3090, 2920, 2850, 1640, 1450 cm^{-1}; Found: C, 66.95; H, 10.30%. Calcd for $C_{12}H_{22}OS$: C, 67.23; H, 10.35%.

erythro-*3-Ethylthio-1-nonen-4-ol*: R_f=0.31 (2:1 hexane-ether); ^{1}H NMR (CCl_4) δ=0.73—1.73 (m, 14H), 1.85 (m, 1H), 2.41 (q, *J*=7 Hz, 2H), 3.15 (dd, *J*=4.2 and 8 Hz, 1H), 3.50 (m, 1H), 4.98 (dd, *J*=2 and 16 Hz, 1H), 5.05 (dd, *J*=2 and 9 Hz, 1H), 5.37—

erythro-*1-Cyclohexyl-3-methyl-2-phenylthio-3-buten-1-ol*: R_f=0.23 (8:1 hexane-ether); ^{1}H NMR (CCl_4) δ=0.87—2.2 (m, 12H), 1.82 (s, 3H), 3.2—3.53 (m, 1H), 3.62 (d, J=7 Hz, 1H), 4.75 (m, 2H), 7.17 (m, 5H); IR 3600, 3090, 2940, 2860, 1650, 1600, 1450 cm^{-1}; Found: C, 73.95; H, 8.78%. Calcd for $C_{17}H_{24}OS$: C, 73.86; H, 8.75%.

erythro-*1-Cyclohexyl-2-ethylthio-3-methyl-3-buten-1-ol*: R_f=0.35 (8:1 hexane-ethyl acetate); ^{1}H NMR (CCl_4) δ=1.20 (t, J=7 Hz, 3H), 1.80 (s, 3H), 1.0—2.0 (m, 12H), 2.33 (q, J=7 Hz, 2H), 3.27 (br s, 2H), 4.83 (m, 2H); IR 3500, 3080, 2940, 2860, 1650, 1450 cm^{-1}; Found: C, 68.47; H, 10.67%. Calcd for $C_{13}H_{24}OS$: C, 68.37; H, 10.59%.

1-Cyclohexyl-2-methyl-4-phenylthio-3-buten-1-ol: R_f=0.20 (8:1 hexane-ether); ^{1}H NMR (CCl_4) δ=1.06 (d, J=7 Hz, 3H), 0.67—2.0 (m, 12H), 2.45 (m, 1H), 3.03 (br s, 1H), 5.63—6.33 (m, 2H), 7.18 (br s, 5H); IR 3500, 3080, 2930, 2850, 1590, 1450 cm^{-1}; Found: C, 73.91; H, 8.76%. Calcd for $C_{17}H_{24}OS$: C, 73.86; H, 8.75%.

1-Cyclohexyl-4-ethylthio-2-methyl-3-buten-1-ol: R_f=0.22 (8:1 hexane-ethyl acetate); ^{1}H NMR (CCl_4) δ=1.07 (t, J=7 Hz, 3H), 1.34 (d, J=7 Hz, 3H), 0.83—2.11 (m, 12H), 2.44 (m, 1H), 2.63 (q, J=7 Hz, 2H), 3.00 (m, 1H), 5.38 (dd, J=8 and 15 Hz, 1H), 5.92 (d, J=15 Hz, 1H); IR 3550, 2920, 2840, 1440, 980, 970 cm^{-1}; Found: C, 68.54; H, 10.65%. Calcd for $C_{13}H_{24}OS$: C, 68.37; H, 10.59%.

erythro-*1-Cyclohexyl-2,3-dimethyl-2-phenylthio-3-buten-1-ol*: R_f=0.36 (4:1 hexane-ether); ^{1}H NMR (CCl_4) δ=1.25 (s, 3H), 0.75—2.0 (m, 11H), 2.03 (s, 3H), 2.12 (s, 1H), 3.41 (br m, 1H), 4.80 (br s, 1H), 4.90 (br s, 1H), 7.25 (m, 5H); IR 3600, 3500, 3080, 2920, 2850, 1635, 1450 cm^{-1}; Found: C, 74.45; H, 9.06%. Calcd for $C_{18}H_{26}OS$: C, 74.43; H, 9.02%.

erythro-*1-Cyclohexyl-2-methyl-2-phenylthio-3-penten-1-ol*: R_f=0.39 (4:1 hexane-ether); ^{1}H NMR (CCl_4) δ=1.28, (s, 3H), 1.65 (d, J=6 Hz, 3H), 0.75—1.83 (m, 11H), 2.52 (d, J=2 Hz, 1H), 3.17 (d, J=2 Hz, 1H), 5.23 (dq, J=6 and 16 Hz, 1H), 5.83 (d, J=16 Hz, 1H), 7.27 (m, 5H); IR 3540, 3080, 2930, 2850, 1450, 975 cm^{-1}; Found: C, 74.23; H, 8.98%. Calcd for $C_{18}H_{26}OS$: C, 74.43; H, 9.02%.

1-Cyclohexyl-2,2-dimethyl-4-phenylthio-3-buten-1-ol: R_f=0.25 (4:1 hexane-ether); ^{1}H NMR (CCl_4) δ=1.08 (s, 6H), 0.86—1.94 (m, 12H), 3.01 (s, 1H), 5.97 (s, 2H), 7.14 (s, 5H); IR 3650, 3080, 2930, 2850, 1590, 1480, 1450, 1100, 970 cm^{-1}; Found: C, 74.63; H, 9.07%. Calcd for $C_{18}H_{26}OS$: C, 74.43; H, 9.02%.

Synthesis of Vinyloxiranes.[10] *The following experimental procedure is typical for the conversion of β-hydroxy sulfides to oxiranes*: To a suspension of trimethyloxonium tetrafluoroborate (0.54 mmol) in dichloromethane (2 ml) was added β-hydroxy sulfide (0.50 mmol) dissolved in dichloromethane (2 ml) at 0 °C, and the mixture was stirred at 0—25 °C until all the sulfide had been consumed (TLC assay). Then, 0.5 mol dm^{-3} sodium hydroxide solution (5 ml) was added to the mixture at 0 °C, and the resulting two phases mixture was efficiently stirred for 1—12 h at 25 °C. The reaction mixture was poured into water and the product was extracted with ether. The combined organic layer was dried and concentrated. Chromatography of the residual oil on silica-gel column (20:1 hexane-ether) gave the pure vinyloxirane.[29] 4-Cyclohexyl-3,4-epoxy-3-methyl-1-butene (entry 9 in Table 2) could not be prepared by this typical procedure, but was efficiently formed by treating the sulfonium salt obtained as above with butyllithium (1 equiv) at −78 °C.

The *trans*-oxirane was generally characterized by a coupling constant between the vicinal oxirane hydrogenes of ≈2 Hz[11] observed in the ^{1}H NMR spectrum. On the other hand, the *cis*-oxirane was characterized by a coupling constant of ≈4 Hz.[11]

The stereochemistry of 3,4-epoxy-4-phenyl-1-pentene was determined as follows. To a solution of propyltriphenylphosphonium bromide (1.55 g, 4 mmol) in THF (10 ml) was added butyllithium in hexane (1.6 mol dm^{-3}, 2.5 ml, 4 mmol) at 0 °C, and the mixture was stirred for 30 min at the same temperature. Acetophenone (0.47 ml, 4 mmol) dissolved in THF (1 ml) was added to the solution and the resulting mixture was stirred for 2 h at 0 °C and 0.5 h at 25 °C. Then, the reaction mixture was poured into water and the product was extracted with ether. The combined organic layer was dried and evaporated. Chromatography of the residual oil on silica-gel column (hexane) gave 2-phenyl-2-pentene (530 mg, 91%). NMR analysis of this product revealed an isomeric ratio of *ca.* 7:3 (*Z*:*E*).[30] ^{1}H NMR (CCl_4) δ=0.57—1.41 (m), 1.98 (s, 3H), 1.67—2.44 (m, 2H), 5.31 (br t, J=6.5 Hz, *Z*-isomer), 5.61 (br

t, J=7 Hz, *E*-isomer), 7.04 (m, 5H). To a solution of *m*-chloroperbenzoic acid (271 mg, 1.1 mmol) in dichloromethane (4 ml) was added 2-phenyl-2-pentene (150 mg, 1.0 mmol) dissolved in dichloromethane (2 ml) at 0 °C. The mixture was stirred for 1 h at 0 °C, and then poured into aqueous sodium sulfite solution. The product was extracted with ether and washed with aqueous sodium hydrogencarbonate. The combined organic layer was dried and concentrated. Chromatography of the residue on silica-gel column gave the isomeric mixture of 2,3-epoxy-2-phenylpentane (156 mg, 96%). GLC analysis of this product revealed the isomeric ratio of 28:72 (*trans*:*cis*). ^{1}H NMR CCl_4 δ=0.67—1.35 (m, 5H), 1.56 (s, 3H), 2.58 (t, J=6 Hz, *trans* isomer), 2.80 (t, J=5.8 Hz, *cis* isomer), 7.13 (s, 5H). NMR spectrum and GLC behaviour of the major isomer of this product was in complete agreement with the product derived from the sulfide-carbonyl adduct by the following sequence: (1) Reduction of double bond by H_2NNH_2–H_2O_2–$CuSO_4$ in aquous ethanol at 0—25 °C (60%); (2) Epoxidation by the general method described in text (90%).

3-Ethylthio-2-phenyl-2-pentanol: ^{1}H NMR (CCl_4) δ=0.77—1.43 (m, 8H), 1.58 (s, 3H), 2.1—2.77 (m, 4H), 7.22 (m, 5H).

trans-*2,3-Epoxy-2-phenylpentane*: ^{1}H NMR (CCl_4) δ=0.83—1.33 (m, 5H), 1.56 (s, 3H), 2.58 (t, J=6 Hz, 1H), 7.12 (s, 5H); MS m/z: 162 (M^+).

The stereochemistry of 4-cyclohexyl-3,4-epoxy-3-methyl-1-butene was determined as follows. To a solution of propyltriphenylphosphonium bromide (1.93 g, 5.0 mmol) in THF (15 ml) was added butyllithium in hexane (1.6 mol dm^{-3} solution, 3.13 ml, 5.0 mmol) at 0 °C, and the mixture was stirred for 1 h at the same temperature. Methyl iodide (0.31 ml, 5.0 mmol) was added to the mixture and the solution was stirred for 1 h at 0 °C. To the resulting dark brown solution was added butyllithium in hexane (3.13 ml, 5.0 mmol) at 0 °C. After stirring for 1 h, cyclohexanecarbaldehyde (0.61 ml, 5.0 mmol) was added to the solution at 0 °C and stirring was continued for 1 h. The reaction mixture was poured into water and the product was extracted with ether. The combined organic layer was dried and concentrated. Chromatography of the residual oil on silica-gel column (pentane) gave 1-cyclohexyl-2-methyl-1-butene (0.52 g, 69%). GLC analysis of this product revealed an isomeric ratio of *ca.* 1.3:1 (*E*:*Z*). ^{1}H NMR ($CDCl_3$) δ=1.00 (t, J=7 Hz), 1.60 (d, J=1.5 Hz, *E*-isomer), 1.67 (d, J=1.8 Hz, *Z*-isomer), 0.67—2.33 (m), 4.95 (br d, J=8 Hz, 1H). To a solution of *m*-chloroperbenzoic acid (271 mg, 1.1 mmol) in dichloromethane (4 ml) was added 1-cyclohexyl-2-methyl-1-butene (152 mg, 1.0 mmol) dissolved in dichloromethane (2 ml) at 0 °C. The mixture was stirred for 1 h at 0 °C, and then poured into aqueous sodium sulfite solution. The product was extracted with ether and washed with aqueous sodium hydrogencarbonate. The combined organic layer was dried and concentrated. Chromatography of the residue on silica-gel column gave the isomeric mixture of 1-cyclohexyl-1,2-epoxy-2-methylbutane (162 mg, 96%). ^{1}H NMR ($CDCl_3$) δ=1.27 (s, *trans*-isomer), 1.29 (s, *cis*-isomer), 0.67—2.11 (m), 2.41 (br, 1H). GLC analysis of this product showed an isomeric ratio of *ca.* 1.4:1 (*trans*:*cis*).[31] The major isomer (*trans*) was spectrally and chromatographically in complete agreement with the product derived from the sulfide-carbonyl adduct by the following sequence: (1) Reduction of the double bond by H_2NNH_2–H_2O_2–$CuSO_4$ in aqueous ethanol at 0—25 °C (44%); (2) Epoxidation by usual manner (89%).

1-Cyclohexyl-2-ethylthio-2-methyl-1-butanol: ^{1}H NMR ($CDCl_3$) δ=1.08 (t, J=7 Hz), 1.24 (s, 3H), 0.67—2.02 (m), 2.32 (m, 1H), 2.43 (q, J=7 Hz, 2H), 3.09 (br d, J=4 Hz, 1H).

1-Cyclohexyl-1,2-epoxy-2-methylbutane: ^{1}H NMR (CCl_4) δ=1.17 (s, 3H),[32] 0.67—2.08 (m, 16H), 2.18 (br, 1H); ($CDCl_3$) δ=1.26 (s, 3H), 0.67—2.08 (m, 16H), 2.39 (br, 1H); MS m/z: 168 (M^+). GLC analysis of this product showed a >95% purity of *trans* isomer.

Reaction of Metallated 4 with Cyclohexanecarbaldehyde. To a solution of phenyl 1-(trimethylsilyl)allyl sulfide (445 mg, 2.0 mmol) in THF (5 ml) was added *t*-butyllithium in pentane (2.0 mol dm^{-3} solution, 1.0 ml, 2.0 mmol) at −78 °C, and the mixture was stirred at 0 °C for 1 h. Titanium tetraisopropoxide (0.65 ml, 2.2 mmol) was added to the solution at −78 °C, and the resulting mixture was stirred for 10 min. Cyclohexanecarbaldehyde (0.24 ml, 2.0 mmol) was added at −78 °C and the solution was stirred for 10 min at −78 °C and 1 h at 0 °C, and further 1 h at 25 °C. Then the mixture was poured into 2 mol dm^{-3} hydrochloric acid and the product was extracted with ether. The organic layer was dried and concentrated. Chromatography of the residue on silanized silica-gel column (hexane) gave (*E*)-1-cyclohexyl-2-phenylthio-1,3-butadiene (440 mg, 90%). GLC analysis of the product revealed the *E*/*Z* ratio of 10:1. R_f=0.59 (hexane, silanized silica gel); ^{1}H NMR (CCl_4) δ=0.41—1.91 (m, 10 H), 2.57 (br, 1H), 5.11 (ddd, J=1, 1, and 10.4 Hz, 1H), 5.61 (dd, J=1 and 17 Hz, 1H), 5.99 (br d, J=9.6 Hz, 1H), 6.64 (dd, J=10.4 and 17 Hz, 1H), 7.03 (br s, 5H); IR 3080, 3020, 2940, 2870, 1633, 1590, 1485, 1460, 1450, 1040, 986, 928, 910 cm^{-1}; MS m/z: 244 (M^+).

Dehydration of 1-Cyclohexyl-2-phenylthio-3-buten-1-ol. To a solution of *erythro*-1-cyclohexyl-2-phenylthio-3-buten-1-ol (525 mg, 2.0 mmol) in THF (8 ml) was added butyllithium in hexane (1.6 mol dm^{-3} solution, 1.25 ml, 2.0 mmol) at 0 °C. Methanesulfonyl chloride (0.155 ml, 2.0 mmol) was added to the mixture and stirring was continued for 1 h at 0 °C. Then, the resulting mixture was cooled to −78 °C and treated with *t*-butyllithium in pentane (2.0 mol dm^{-3} solution, 2.0 ml, 4.0 mmol). After stirring for 2 h at 0 °C, the mixture was poured into ice-cooled 2 mol dm^{-3} hydrochloric acid and the product was extracted with ether. The organic layer was dried and concentrated to give oily product. Chromatography of the crude product on silica-gel column (hexane) gave(*Z*)-1-cyclohexyl-2-phenylthio-1,3-butadiene (318 mg, 65%). R_f=0.31 (hexane); ^{1}H NMR (CCl_4) δ=0.72—1.97 (m, 10H), 2.82 (br m, 1H), 4.94 (dd, J=1 and 10 Hz, 1H), 5.42 (dd, J=1 and 16.4 Hz, 1H), 6.01 (d, J=9 Hz, 1H), 6.28 (dd, J=10 and 16.4 Hz, 1H); IR 3080, 3020, 2940, 2870, 1635, 1595, 1482, 1455, 1450, 1035, 990, 918, 908 cm^{-1}; MS m/z: 244 (M^+).

The corresponding *E*-isomer was prepared by this method from the *threo*-1-cyclohexyl-2-phenylthio-3-buten-1-ol. The NMR spectrum and GLC behaviour of this compound were complete agreement with the product from the reaction of metallated **4** with aldehyde.

NMR Analysis of Vinyl Sulfoxides. (*E*)- and (*Z*)-1-cyclohexyl-2-phenylsulfinyl-1,3-butadiene were prepared by the oxidation of the corresponding sulfides with sodium periodate (excess, in MeOH–H_2O, 2:1).

(E)-1-Cyclohexyl-2-phenylsulfinyl-1,3-butadiene: ^{1}H NMR (CCl_4) δ=0.9—2.07 (m, 10H), 2.42 (br m, 1H), 5.17 (dd, J=1.5 and 11 Hz, 1H), 5.36 (dd, J=1.5 and 17.5 Hz, 1H), 6.22 (d, J=9.5 Hz, 1H), 6.25 (dd, J=11 and 17.5 Hz, 1H), 7.34 (m, 5H).

(Z)-1-cyclohexyl-2-phenylsulfinyl-1,3-butadiene: ^{1}H NMR (CCl_4) δ=0.82—2.08 (m, 10H), 3.07 (br m, 1H), 4.99 (dd, J=2 and 10.4 Hz, 1H), 5.37 (dd, J=2 and 18 Hz, 1H), 5.98 (d, J=10 Hz, 1H), 6.14 (dd, J=10.4 and 18 Hz, 1H), 7.41 (br s, 5H).

(*E*)- and (*Z*)-2-cyclohexylvinyl phenyl sulfoxide were prepared by the following sequence: (1) Condensation of cyclohexanecarbaldehyde with phenyl lithio(trimethylsilyl)-methyl sulfide (1 equiv) in THF; (2) Separation of (*E*) and (*Z*)-2-cyclohexylvinyl phenyl sulfide by silica-gel column chromatography (hexane); (3) Oxidation with sodium periodate (5 equiv, in MeOH–H_2O, 2:1).

(E)-2-Cyclohexylvinyl Phenyl Sulfoxide: ^{1}H NMR (CCl_4) δ=0.78—2.36 (m, 11H), 6.00 (d, J=15.5 Hz, 1H), 6.42 (dd, J=5.5 and 15.5 Hz, 1H), 7.41 (m, 5H).

(Z)-2-Cyclohexylvinyl Phenyl Sulfoxide: ^{1}H NMR (CCl_4) δ= 0.72—2.13 (m, 10H), 2.97 (br, 1H), 5.8 (m, 2H), 7.43 (m, 5H).

NMR spectra of the mixture of vinyl sulfoxides (0.50 mmol) and shift reagent, tris(6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedionato)europium (0.20 mmol), in carbon tetrachloride (0.70 ml) were taken (see Table 3).

Synthesis of 1-Cyclohexyl-2-methyl-1,3-butadiene. To a mixture of 1-cyclohexyl-2-phenylthio-1,3-butadiene (244 mg, 1.0 mmol) and [$NiCl_2(PPh_3)_2$] (65 mg, 0.1 mmol) in benzene (10 ml) was added methylmagnesium iodide in ether (5.0 mmol) which was prepared from magnesium (300 mg, 12 mmol) and methyl iodide (0.25 ml, 4 mmol) in ether (10 ml). After the removal of ether from the reaction system, the mixture was heated for 2 h under reflux. The resulting mixture was poured into 2 mol dm^{-3} hydrochloric acid and the product was extracted with ether. The organic layer was washed with 1 mol dm^{-3} sodium hydroxide, and then brine. The combined organic layer was dried and concentrated. Chromatography of the residue on silica-gel column (hexane) gave 1-cyclohexyl-2-methyl-1,3-butadiene. *(E)*-1-Cyclohexyl-2-methyl-1,3-butadiene: 70% yield; R_f=0.6 (hexane); ^{1}H NMR (CCl_4) δ=1.71 (d, J=1.5 Hz, 3H), 0.64—1.98 (m, 10H), 2.29 (br m, 1H), 4.72—5.39 (m, 3H), 6.24 (dd, J=10.8 and 17.6 Hz, 1H); IR 2920, 1780, 1640, 1610, 1440, 990, 890 cm^{-1}; MS m/z: 150 (M^+).

(Z)-1-Cyclohexyl-2-methyl-1,3-butadiene: 78% yield; R_f=0.58 (hexane); ^{1}H NMR (CCl_4) δ=1.76 (s, 3H), 0.6—2.02 (m, 10H) 2.33 (br m, 1H), 4.76—5.37 (m, 3H), 6.65 (dd, J=10.4 and 17.6 Hz, 1H); IR 2920, 1800, 1645, 1595, 1440, 990, 900 cm^{-1}; MS m/z: 150 (M^+).

24) Lithio reagent gave a mixture of regioisomers, which were difficult to separate.

25) This compounds may undergo thioallylic rearrangement

to give phenyl 3-(trimethylsilyl)allyl sulfide. Addition of 2,6-di-*t*-butyl-4-methylphenol can effectively prevent the rearrangement.

26) Deprotonation of allyl phenyl sulfide could be accomplished with butyllithium without any difficulties. In contrast, *s*- or *t*-butyllithium was required for alkyl allyl sulfide. *t*-Butyllithium recommended for the generation of 1-alkylallyl phenyl sulfide anion.

27) For prevention of thioallylic rearrangement of the produced phenyl sulfides, small amount of hydroquinone or 2,6-di-*t*-butyl-4-methylphenol was added during the workup and chromatographic operations.

28) Trace amount of regioisomer, 1-cyclohexyl-4-phenylthio-3-buten-1-ol, was also formed. This was isolated by column chromatography (R_f=0.15, 4:1 hexane–ether).

29) This reaction is highly stereospecific. Thus, the corresponding *cis*-isomers were prepared under the same reaction conditions from the *threo*-β-hydroxy sulfides, which were obtained from the reaction of [3-(alkylthio)allyl]lithium reagents followed by separation by column chromatography.

Ab Initio Self-consistent Field MO Calculations of Ethanethiol and Ethanol

Masaru OHSAKU,* Takehiro ICHIISHI, Akira IMAMURA, and Michiro HAYASHI
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received February 23, 1984)

Ab initio self-consistent field MO calculations were performed on EtSH and EtOH, and the optimized geometries were obtained by the use of the STO-3G and STO-3G* basis sets. It was found that *ab initio* MO calculations reproduced the observed geometries of these molecules sufficiently well. The variation in the observed bond angle, α(CCX) (X=S and O), from the *trans* to the *gauche* rotamers, which was observed by means of microwave spectroscopy, was very reasonably reproduced from the results of these calculations. The total energy calculated gives a reasonable explanation of the stability between the rotational isomers.

Ethanethiol is well known as one of the simplest molecules to exhibit *trans-gauche* isomerism around the CC–SH bond. Ethanol is its oxygen analog. However, up to the present time, there have appeared no reports which have successfully determined independently the molecular structures of the *trans* and *gauche* forms of ethanol; this has been because of the very large spectral splitting due to the internal rotation of the OH group. A very large number of experimental works in the geometrical mode have been published during the last decade: For EtSH, *e.g.*, by microwave[1–4] and far-IR[5,6] spectroscopies, and for EtOH, by microwave studies.[7,8] Among these publications, the main interests of spectroscopists have been on the experimental result that the bond angle α(CCS) of EtSH widens sharply from the *trans* form (T-form) to the *gauche* form (G-form).[3,4] The same trend is also seen in the structurally analogous molecules, *e.g.*, ethyl methyl sulfide.[9,10] A part of these experimental results has already been explained by *ab initio* calculations.[11] Theoretical works on the basis of the LCAO SCF molecular orbital calculations had also been performed with various methods; that is, semiempirical calculations on EtSH[12–14] and *ab initio* calculations on EtOH[15,16] and related molecules[17–19] have been carried out. However, as far as we know, no *ab initio* conformational study of ethanethiol has been published; although an *ab initio* calculation was performed on MeSH very early in the *ab initio* age.[20] Some other thiols have also been treated by semiempirical and *ab initio* MO procedures.[13,21]

In the present article, the geometry of EtSH was optimized by means of the *ab initio* energy-gradient method, and the difference in α(CCS) between *trans* and *gauche* forms was explained in terms of the through-space interaction. Similar calculations were performed on EtOH for comparison.

Method of Calculations

Calculations were performed by the use of the Gaussian 80 program package.[22] Geometry optimization was made by the gradient method,[23] which is included in the Gaussian 80 package. The basis sets used were STO-3G and STO-3G*. The 3-21G basis was also partly used for EtSH, and the 4-31G* basis, was for EtOH.

First, in order to confirm the observed geometrical parameters of EtSH, a full geometrical optimization was performed by the use of the STO-3G and STO-3G* basis sets.

For further analysis, in order to save computer cpu time, only the α(CCS) angle was then optimized, while the other geometries were transferred from the observed *trans* ones and were fixed during the optimization;[2] that is, in the calculations for the T- and G- forms, the geometry of the observed *trans* form was commonly used.

Nonbonded atomic interactions which correspond to the through-space interaction were then quantitatively analyzed by means of the following procedure. The SCF equation can be expressed as in Eq. (1);[24]

$$FC = SCE. \tag{1}$$

Elements of Fock matrix and overlap integrals were written as in Eqs. (2) and (3) respectively:

$$F_{rs} = I_{rs} + \sum_{t=1}^{m}\sum_{u=1}^{m} P_{tu}[(rs|tu) - (1/2)(rt|su)] \tag{2}$$

$$S_{rs} = \int x_r(1)x_s(1)d\tau, \tag{3}$$

where I_{rs}, P_{tu}, and $(rs|tu)$ or $(rt|su)$ indicate the one-electron integral, the density matrix, and the two-electron integral respectively. When the Fock matrix elements, F_{rs}, and the overlap integral, S_{rs}, between certain atomic orbitals, *e.g.*, r and s, are set equal to zero, the SCF equation, in which the interaction between those pairs is not taken into account, can be obtained as in Eq. (4);

$$F'C' = S'C'E'. \tag{4}$$

When all of the interactions between the AOs which belong to, *e.g.*, the A atom and those belonging to the B atom are cut off, the interaction between the A and B atoms can be considered to be dropped. The difference in the total energy obtained between Eqs. (1) and (4) shows the interaction energy between the certain atomic pair, A and B, in question. Using these equations, the interaction energy between nonbonded atoms (the through-space interaction) can be obtained quantitatively. For this purpose, a part of the Gaussian 80 program package was modified, and during these calculations the geometry was fixed. It should be mentioned that a more sophisticated procedure of analysis might be possible by using the localized orbitals as the basis sets in Eq. (2). The programming for this purpose is not so easy. In the present paper, there-

fore, the rough procedure presented above was employed for the analysis as a first approximation.

Results and Discussion

Ethanethiol. The optimized geometries are shown in Tables 1-a and -b.

There is an excellent agreement between the theoretically calculated and the observed geometries, and it can be seen that there is no remarkable difference between the geometries obtained by the STO-3G and STO-3G* basis sets. However, the STO-3G* basis set, which has a polarization function on the sulfur atom, gives a geometry different from that obtained by the use of STO-3G. As for the bond lengths, the r(C–H) and r(C–C) values do not depend greatly on the difference in the basis set. However, r(C–S) and r(S–H) vary with the change of the set. That is, the STO-3G basis set gives

longer bond lengths of r(C–S) and r(S–H) than those of the STO-3G*. A similar tendency was found in ethyl methyl sulfide;[11] *i.e.*, the bond length, r(C–S), calculated by the use of the STO-3G* set is *ca.* 0.015 A shorter than that obtained by the use of the STO-3G set. With these bond angles, we cannot see any clear differences between the geometries calculated by the STO-3G and STO-3G* sets except for the ones including the sulfur atom. The STO-3G basis reproduced poorly the α(CCS) of the protonated species $EtSH_2^+$. It is well known that the d-functions on the sulfur atom are also necessary to produce a proper geometry in the ionized sulfur compounds.[25] Therefore, most of the calculations to be discussed hereafter were those based on the STO-3G*.

We then optimized the α(CCS) angle of EtSH using the observed geometrical parameters[2] in order to save computer cpu time and simplify the problem. The geometry of the *gauche* form was transferred from the *trans* form except for the dihedral angle about the CC–SH bond; 60° was used for this angle. The results of the optimization are 109.10° and 113.50°, obtained by means of the STO-3G* basis set for the *trans* and *gauche* forms respectively. There is a very good agreement with the experimental values:

108°34′ (*trans*) and 113°37′ (*gauche*),[2,3]

108°33′ (*trans*) and 113°16′ (*gauche*).[4]

With ethyl methyl sulfide, the same tendency of the α(CCS) angle has previously been found in experimentation between the *trans* and *gauche* forms[9,10] and this has been reproduced by calculations.[11] The difference in the total energy ($E_{trans}-E_{gauche}$) between the *trans* and *gauche* forms obtained is 369 cal/mol, (1 cal=4.184 J) a value obtained by using the STO-3G* basis set under the optimized α(CCS), while that observed is 406±43 cal/mol.[4] Between the observed and calculated values, an excellent agreement is obtained.

In order to analyze the effect of the lone pairs on the sulfur atom or of some other interactions on the variation of the α(CCS) angle, some model calculations were performed on the $EtSH_2^+$ species, in which a proton is attached to a lone pair orbital of the sulfur atom in the EtSH molecule. Here, in the case of the *trans* form, there is only one possibile way to attach a proton onto one of the lone pair orbitals, as one can easily understand from Fig. 1. However in the case of the *gauche* form, there are two possibilities, as is shown in Fig. 2, and these two forms can be distinguished from each other. These two forms are named *gauche*-1 and *gauche*-2 in the present article. By calculating the total energies for these structures, we can estimate the effect of the lone pair orbitals on the sulfur atom or of some other interactions which govern the geometry.

In order to evaluate the result for $EtSH_2^+$, a negative ionic species, EtS^-, was also calculated. The calculated bond populations between methyl carbon and thiol hydrogen are listed in Table 2, together with the optimized α(CCS) values for EtSH, $EtSH_2^+$, and EtS^-. By examining the variation in the bond population between the $C_1\cdots H$(SH) shown in this table, the population was found to change little from the EtSH to the $EtSH_2^+$ species in the case of the *trans* form. The value of the *gauche*-1 form varies considerably from the EtSH to the $EtSH_2^+$ species, but it varies little in

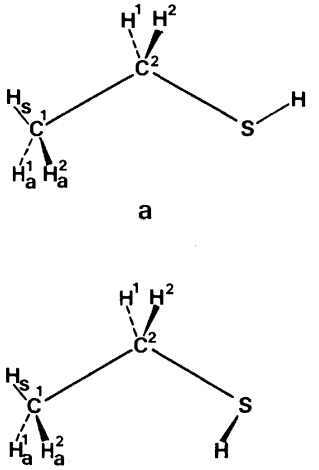

Fig. 1. Schematic structure and atom numberings for the *trans* and *gauche* isomers of EtSH. In the case of EtOH, S atom is substituted by O atom.

the case of the *gauche*-2. Here in this table, the positive figure indicates the attractive interaction, while the negative one, the repulsive one. In the case of the *gauche*-1 form, whose geometrical situation after protonation is very analogous to the *trans* form of $EtSH_2^+$, the quantity of the variation is the largest of all. In the case of the T-form, the interaction between the nonbonded pair $C_1\cdots H$(SH) is attractive. On the other hand, in the case of the G-form, the interaction between them is repulsive. As a result, it can be understood, that in the case of the *gauche*-1 form, the repulsive interaction could be weakened by the addition of a proton to the sulfur atom. This is reflected in the variation in the α(CCS) angle, 113.50° → 104.27°, as will be discussed in the following section.

Let us now discuss the variation in the α(CCS) bond angle. The α(CCS) angle of the T-form narrows about four degrees from the EtSH to the $EtSH_2^+$ species. That of the *gauche*-1, though, decreases dramatically upon the proton addition and stays around nearly the same value as the *trans* form. However, in the case of the *gauche*-2 form, it does not vary any more on the variation from the EtSH to the $EtSH_2^+$ species. This implies that one of the lone pair orbitals, the one which lies on the C–C–S plane, plays an important role in governing the α(CCS) angle of the EtSH. This is one of the most important findings of the present article. It is also very interesting that the angle α(CCS) of the EtS^- species becomes nearly the average value of the *trans* and *gauche* forms.

In order to analyze the interaction between the nonbonded atomic pairs, we have carried out SCF calculations by cutting off the Fock matrix elements, F_{rs}, and, at the same time, the overlap integrals, S_{rs}, between certain atomic pairs according to the procedure described above. The calculations were performed with two geometrical sets, the optimized ones at the T- and G-forms. The pairs contributing greatly to governing the energy are summarized in Table 3.

By cutting off the interactions between the $C_1\cdots H$(SH) pair, the *trans* form raises the energy, while the *gauche* form lowers it. The positive value of the energy difference shows that the cut interaction in question is repulsive, while negative value is attactive.

Here, two types of interactions were taken into consideration: a) $C_1\cdots H$(SH) and b) $H_a^2\cdots H$(SH), because in these pairs the difference in the bond population between the *trans* and *gauche* forms is the largest of all.

From Table 3, it is found, for the *trans* form, that the total energy including the $C_1\cdots H$ interaction is lower than that without this interaction; that is, the $C_1\cdots H$ interaction stabilizes the molecule in the *trans* form. Upon a variation in α(CCS), the interaction energy is larger in the case of a smaller α(CCS) angle. This implies that a smaller α(CCS) angle is more favorable than a larger one in the *trans* case. On the other hand, in the case of the *gauche* form, the state without this interaction is more stable than the state with it. When this interaction is included, the repulsive force becomes smaller in a wider α(CCS) angle than in a narrower angle. As a result, the *gauche* form has a wider angle of α(CCS) than that of the T-form.

With the $H_a^2\cdots H$ interaction, in the case of the *trans* form, the magnitude of the interaction energy is rela-

Table 6. Total energy and energy diffrence of EtOH with or without interaction between certain bonds (STO-3G)[a]

a) Unit: kcal/mol b) See also Fig. 1. c) In (a), the α(CCO) angle used was 108.52°, and in (b), that used was 113.42°.

tively small, and it does not depend greatly on the α(CCS) angle. However, in the case of the *gauche* form, it seems that a wider α(CCS) is more favorable.

The calculated results indicate a reasonable explanation of the observed geometry. As a result, it can be concluded that, in addition to the lone pair orbital, such nonbonded interactions as those between $C_1 \cdots$ H(SH) and between $H_a^2 \cdots$H(SH) are also responsible for the determination of the α(CCS) angle. This is another interesting finding of the present work.

Ethanol. In order to confirm the result obtained for EtSH, the present analysis was extended to test the oxygen analog, EtOH. With this molecule, the geometry optimization by using the 4-21G set had already been performed by Schäfer *et al.*[15,16] Therefore in the present article, the α(CCO) angle alone was optimized for the analysis. The geometry used for the calculation is summarized in Table 4. Geometrical parameters were commonly both used for the *trans* and *gauche* forms except for the dihedral angle τ(CC–OH), whose value, 60.0°, was used for the G-form. The STO-3G set was used for the computations, while the 4-31G* set was partly used for the sake of comparison. The total energy of the T-form obtained is smaller than that of the G-form: $E_{gauche} - E_{trans} = ca.$ 0.2 kcal/mol. This agrees well with the previous calculations.[15,16] The bond population and α(CCO) are shown in Table 5. The angle of α(CCO) obtained for the *gauche* form is wider by *ca.* 5 degrees than that for the *trans* form, although the geometrical parameters for the *gauche* form has not yet been experimentally determined. The bond population decreases in the *trans* form from EtOH to $EtOH_2^+$, while it increases in the *gauche*-1 and *gauche*-2 forms. In the case of EtSH, the population of the *trans* form varies very slightly. However, in the case of EtOH, it changes remarkably. The tendency of the population in the G-form of EtOH is also different from that of EtSH. That is, in the case of EtSH, the populations of *gauche*-1 and *gauche*-2 are considerably different from each other. However, in EtOH, the bond populations of the *gauche*-1 and *gauche*-2 forms show nearly the same trend.

Now let us discuss the variation in the α(CCO) angle. The angle of the *trans* form widens by *ca.* three degrees from the parent to the protonated species. An inverse tendency has already been seen in the sulfur analog. In the case of the G-form, the angle decreases in the *gauche*-1 and increases in the *gauche*-2 for $EtOH_2^+$, in comparison with EtOH. The same tendency was also seen in EtSH. In EtO^-, the angle of α(CCO) obtained is nearly the average of those of the *trans* and *gauche* forms.

Table 7. Dipole moment (Debye)

I) EtSH

	Obsd		Calcd		
			STO-3G*	STO-3G	3-21G
Trans	1.56[a]	1.58[c]	0.472	1.016	2.043
Gauche	1.77[b]	1.61[c]	0.472	1.038	2.150

a) From Ref. 2. b) From Ref. 3. c) From Ref. 4.

II) EtOH

	Obsd	Calcd	
		STO-3G	4-31G*
Trans	1.441[d]	1.442	1.857
Gauche		1.533	1.955

d) From Ref. 27.

The change in the total energy by cutting off a certain Fock element and the overlap integral is given in Table 6. The tendency obtained on EtOH is, in general, analogous to that of EtSH. An examination of the absolute value shows that the interaction energy between $H_a^2 \cdots$H(OH) in EtOH is nearly the same as in EtSH. However, in the case of $C_1 \cdots$H(OH), the variations in the interaction energy in EtOH are much larger than those in EtSH. This means that the interaction between C_1 and H(OH) in EtOH is much stronger than the corresponding one in EtSH. This type of interaction may stabilize the *trans* form more, and may destabilize the *gauche* form more in EtOH than in EtSH.

Dipole Moments. It is very difficult to obtain an agreement between the experimental and calculated values in the dipole moments. We have summarized in Table 7 the observed and calculated dipole moments of EtSH. An examination of the observed moments[2–4] shows that the value of the *gauche* form is a bit larger than the *trans* one. From the estimation of the dielectric constant, however, a rather smaller value (1.39 Debye) was proposed.[26] The tendency between the *gauche* and *trans* forms is also seen in the calculations by using the STO-3G and 3-21G basis sets. The absolute values did not, however, perfectly reproduce the observed values when any of these basis sets was used. The STO-3G* basis set reproduces a fairly smaller value than those of the observed. On the other hand, the 3-21G reproduces values a bit larger. The value of the STO-3G lies between those calculated by STO-3G* and 3-21G.

The dipole moment of EtOH has been reported,[27] and the present STO-3G basis set reproduces the observed values well.

Conclusions

The relative conformational stability of EtSH and EtOH was very well reproduced by *ab initio* MO calculations. The interesting changes in α(CCX) (X=S or O) with the variation in the rotational isomers could also be explained by the present analysis. That is, the main factors governing the α(CCX) angle (X=S or O) are: (a) one of the lone pair orbitals on the sulfur or oxygen atom, (b) the interaction between the non-bonded $C_1 \cdots H(XH)$ (X=S or O), and (c) that between $H_a^2 \cdots H(XH)$ (X=S or O).

We are very grateful to the Computer Center of the Institute for Molecular Science and the Information Processing Center of Hiroshima University for their generous permission to use their HITAC M-200H systems.

(Received March 26, 1984)

This paper proposes a method by means of which the heat of solution at an infinite dilution of an organic compound in water, directly measured by means of calorimetry at a given temperature, is extended over a wide range of temperatures by the use of a phase diagram with water. The heat of solution at an infinite dilution in water over a temperature range from 290 to 350 K, which is estimated by this method for some alkanols and alkanoic acids, increases with a rise in the temperature and has a transition temperature from the exothermic region to the endothermic region which is close to the minimum dissolution temperature in the solubility curve in water for each substance. The increase in the heat of solution might be due to the breakdown of the iceberg formed around the alkyl group. The difference between the partial molar heat capacity at an infinite dilution and the molar heat capacity at the pure state, $\Delta_s c_p^{\circ}$, has its maximum at a certain temperature. The higher homolog shows a sharper curve with a lower maximum temperature. The curve of $\Delta_s c_p^{\circ}$ *vs.* the temperature for 2- or 3-alkanol corresponds to that for the lower 1-alkanol. These facts reveal that a polar group, such as OH and COOH, would preferentially break the weaker structure of the iceberg within its breaking sphere, which structure should break down at a lower temperature.

In previous papers,[1,2] the present authors have constructed phase diagrams for binary systems of water and normal alkane derivatives, such as alkanols, alkylamines, and alkanoic acids, in which each aqueous-phase line commonly has a minimum point at a temperature, but in which the corresponding organic-phase line is monotonical. Such phenomena suggest that the state of the aqueous phase changes with the temperature, while those of the organic phases do not change so much. It is now believed that an ice-like structure of water, referred to as an "iceberg," is formed around a dissolved nonpolar alkyl group, but gradually breaks down with a rise in the temperature.[3] If this is true, the partial molar enthalpy of such a solute in water should increase with a rise in the temperature. The change in the partial molar enthalpy of a solute with the temperature must be reflected by the change in the heat of solution, since the heat of evaporation is almost independent of the temperature for such substances.[1] It has been shown that the heat of solution at an infinite dilution, $\Delta_s h_2^{\circ}$ can be evaluated correctly from the phase diagram and the activity coefficient of the organic substance in its own phase, γ_2^{or}, according to the following equation, when the solubility of the organic substance in water is so small that the aqueous phase may be regarded as an ideal dilute solution:[2]

$$\Delta_s h_2^{\circ} = R\left[\frac{\partial \ln (x_2^{or}\gamma_2^{or}/x_2^{aq})}{\partial T^{-1}}\right]_{p.sat}, \qquad (1)$$

where x_2^{or} and x_2^{aq} are the mole fractions of an organic substance in organic and aqueous phases at mutual saturation respectively; T, the absolute temperature, p, the pressure, and R, the gas constant, and where "sat" designates mutual saturation. Unfortunately, γ_2^{or} is available for only a few substances in the literature.[4,5]

The following approach, however, can be used instead of measurements of γ_2^{or} to evaluate $\Delta_s h_2^{\circ}$ over a wide range of temperatures. When mutual saturation is maintained under a constant pressure, the differential of ln γ_2^{or} with respect to the reciprocal of the absolute temperature, T^{-1}, can be expressed by:

$$\left[\frac{\partial \ln \gamma_2^{or}}{\partial T^{-1}}\right]_{p.sat} = \left[\frac{\partial \ln \gamma_2^{or}}{\partial \ln x_2^{or}}\right]_{T,p}\left[\frac{\partial \ln x_2^{or}}{\partial T^{-1}}\right]_{p.sat} + \left[\frac{\partial \ln \gamma_2^{or}}{\partial T^{-1}}\right]_{p,x_2^{or}}, \qquad (2)$$

because γ_2^{or} is, in general, a function of T, p, and x_2^{or}. The partial pressures of 1-propanol over its mixtures with water at several temperatures are available in the literature;[4] the literature shows that the estimated activity coefficients of 1-propanol are not so dependent on the temperature as on the composition, as is shown in Fig. 1. If $[\partial \ln \gamma_2^{or}/\partial T^{-1}]_{p,x_2^{or}}$, therefore, is assumed to be negligible in comparison with the first term, Eq. 2 is reduced to:

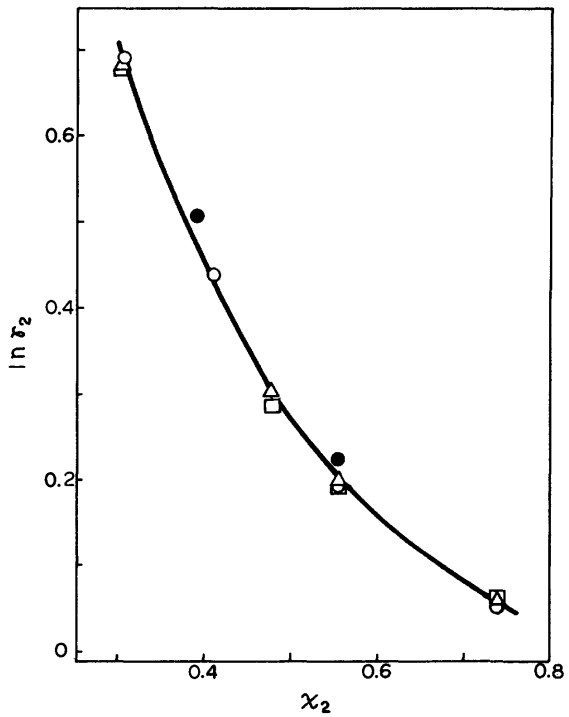

Fig. 1. Plots of the activity coefficient of 1-propanol in the mixture with water *vs.* the mole fraction of 1-propanol calculated from the vapor pressures.[4]
●: 303.50 K, ○: 323.07 K, △: 339.09 K, □: 353.95 K.

$$\left[\frac{\partial \ln \gamma_2^{or}}{\partial T^{-1}}\right]_{p,sat} = \left[\frac{\partial \ln \gamma_2^{or}}{\partial \ln x_2^{or}}\right]_{T,p}\left[\frac{\partial \ln x_2^{or}}{\partial T^{-1}}\right]_{p,sat}. \quad (3)$$

The substitution of Eq. 3 into Eq. 1 gives:

$$\Delta_s h_2^{\circ} = R\left[\frac{\partial \ln \gamma_2^{or}}{\partial \ln x_2^{or}}\right]_{T,p}\left[\frac{\partial \ln x_2^{or}}{\partial T^{-1}}\right]_{p,sat} + R\left[\frac{\partial \ln (x_2^{or}/x_2^{aq})}{\partial T^{-1}}\right]_{p,sat}. \quad (4)$$

If $\Delta_s h_2^{\circ}$ is actually determined at a certain temperature besides the phase diagram, then $[\partial \ln \gamma_2^{or}/\partial \ln x_2^{or}]_{T,p}$ at that temperature can be obtained by the aid of Eq. 4. The values for $\Delta_s h_2^{\circ}$ at other temperatures may now be estimated, if $[\partial \ln \gamma_2^{or}/\partial \ln x_2^{or}]_{T,p}$ is assumed to be independent of the temperature. The solubility of water in an organic phase, $(1-x_2^{or})$, does not change very markedly between 290 and 350 K.[2] The heats of solution at an infinite dilution, $\Delta_s h_2^{\circ}$, have been measured calorimetrically at 298 or 303 K for several compounds.[6-12] The purpose of the present paper is to determine the dependence of $\Delta_s h_2^{\circ}$ on the temperature as exactly as possible, in order to elucidate the dissolution states of normal alkane derivatives with a polar group in water over a wide range of temperatures, including the change in the iceberg formed around the alkyl groups.

Experimental

The alkanols and alkanoice acids used were the same as those described in a previous paper.[1] They were used after having been dried over calcium hydride and were above 99.9% in purity, as verified by gas chromatography using a Shimadzu GC-4CM PF apparatus.

Measurements were made of the heats of mixing various amounts of a solute with a constant amount of water, 5.55 mol, at 298 K by using a 8721-1 solution calorimeter of the precision calorimetry system (LKB Produkter AB), according to a procedure described elsewhere.[13]

Results and Discussion

Temperature Dependence of the Heat of Solution at an Infinite Dilution. Figure 2 shows that the heats of mixing, ΔH, of normal alkane derivatives with water, measured at 298 K, are proportional to the number of moles of the normal alkane derivative added, n_2, while the amount of water is always constant, 5.55 mol. This means that the solutions are dilute enough to be regarded as ideal dilute solutions; therefore, the slope of each straight line is equal to the heat of solution at an infinite dilution, $\Delta_s h_2^{\circ}$ for each substance.[14] The values for $\Delta_s h_2^{\circ}$ obtained are summarized in Table 1, together with the values from the literature.[7,11] The value of -8.24 ± 0.08 kJ mol^{-1} for 1-pentanol can be compared with that of -8.08 ± 0.42 kJ mol^{-1} measured by Aveyard and Mitchell,[7] which is closer than those obtained by other authors.[6,8,9] The values of $[\partial \ln \gamma_2^{or}/\partial \ln x_2^{or}]_{T,p}$ are also listed in Table 1; they were estimated from the $\Delta_s h_2^{\circ}$ values in Table 1 and the phase diagrams with water,[2] according to Eq. 4. The value for 1-butanol, -1.09, is comparable to that of -1.01 estimated from

Table 1. Heats of solution at infinite dilution and $[\partial \ln \gamma_2^{or}/\partial \ln x_2^{or}]_{T,p}$ of normal alkane derivatives in water at 298 K

O and Δ are directly measured by calorimetry (O: obtained here, Δ: from the literature.) Dotted line is obtained by substituting γ_2^{or} of 1-butanol[5] into Eq. 4.

the partial vapor pressures at 298 K.[5] The heats of solution at an infinite dilution, $\Delta_s h_2^\circ$ at other temperatures were estimated from the value of $[\partial \ln \gamma_2^{or}/\partial \ln x_2^{or}]_{T,p}$ in Table 1 and the phase diagram,[2] again by the aid of Eq. 4, assuming $[\partial \ln \gamma_2^{or}/\partial \ln x_2^{or}]_{T,p}$ to be constant over the range of temperatures in which the phase diagram was measured. The values of $\Delta_s h_2^\circ$ thus obtained are plotted against the temperature in Figs. 3 and 4, in which O and Δ are directly measured by means of calorimetry. Butler *et al.* have obtained the activity coefficient of 1-butanol, γ_2^{or}, over a wide range of compositions with water at 298 K by the determination of the partial vapor pressure.[5] The values of $\Delta_s h_2^\circ$ obtained from γ_2^{or} and the phase diagram by the use of Eq. 4, superimposed as a dotted line in Fig. 3, are substantially coincident with the line, A_1, estimated by the present method over the whole range of temperatures.

The heat of solution at an infinite dilution, $\Delta_s h_2^\circ$ increases with a rise in the temperature, from negative to positive, for each substance. Thus, there is a transition temperature, T_t, from the exothermic region to the endothermic region, *i.e.*, the temperature at which $\Delta_s h_2^\circ = 0$. The transition temperature, T_t, is close to the minimum dissolution temperature, T_m, on the solubility curve of the substance in water,[1] within the difference between 0.5 and 6.3 K.

The Breakdown of the Iceberg with the Temperature. The increase in the heat of solution at an infinite dilution, $\Delta_s h_2^\circ$, with the temperature, as shown in Figs. 3 and 4, may be attributed mainly to the increase in the partial molar enthalpy of the solute at an infinite dilution in the aqueous solution, since the heat of evaporation is almost independent of the temperature.[1] When an organic molecule with a hydrophobic group, such as an alkyl group, is introduced in water, the water molecules in the vicinity of the dissolved hydrophobic group form a so-called iceberg, which gradually breaks down with the subsequent rise in the temperature.[3] Such phenomena should make the partial molar enthalpy of the solute higher with the temperature.

The tangent of the curve in Figs. 3 and 4 is equal to the difference between the partial molar heat capacity of the solute at an infinite dilution and its molar heat capacity at the pure state, $\Delta_s c_{p2}^\circ$. The relations between $\Delta_s c_{p2}^\circ$ and the temperature are shown in Figs. 5, 6, 7, and 8 for each homologous series; all the curves are characterized as having a maximum at a certain temperature, T_x. The curves reveal that most of the water molecules in the iceberg break down around T_x and reinforce the concept that the iceberg structure disappears at a higher temperature.[15,16] The higher homolog shows a sharper curve with a lower T_x in any series. The curve for 2- or 3-alkanol in Figs. 6 and 7 corresponds to that for the lower 1-alkanol in Fig. 5. These facts suggest that there are structures different in strength in an iceberg around an alkyl group; the weaker one breaks down at the lower temperature, and a polar group, such as OH or COOH, acts as a breaker against the iceberg,[17] preferentially the weaker structure, which should break down at the lower temperature. If a polar group is assumed to have a certain breaking sphere, the number of water molecules in an iceberg within the sphere would be more for 2- or 3-alkanol than for 1-alkanol. Thus, it may

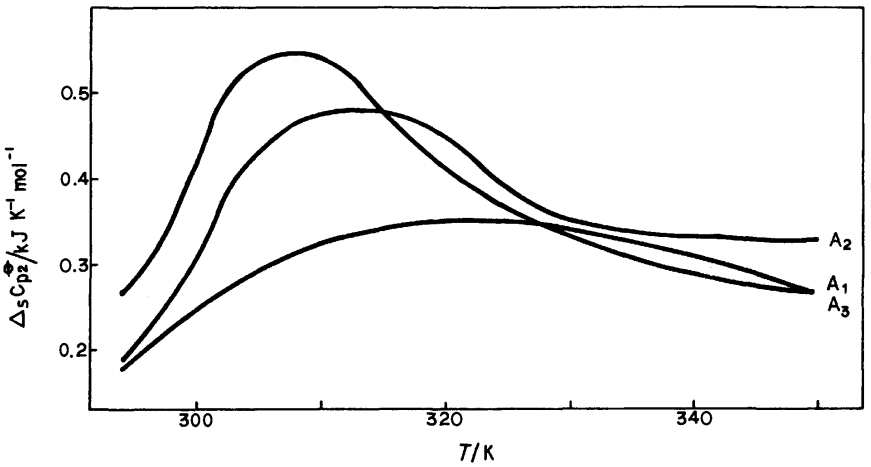

Fig. 5. The difference between the partial molar heat capacity at an infinite dilution in water and the molar heat capacity at the pure state for 1-alkanols.

be concluded that a polar group breaks the weaker structure of the iceberg within its breaking sphere. In addition, the COOH group must be a stronger breaker than the OH group, because the curves for alkanoic acids in Fig. 8 are broader curves, with higher T_x values, than the corresponding curves for 1-alkanols in Fig. 5.

^{1}H NMR and Differential Scanning Calorimetry Studies on Molecular Motions and Phase Transitions in Butylammonium Bromide

Shin-ichi FUKADA, Ryuichi IKEDA, and Daiyu NAKAMURA*
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464
(Received March 29, 1984)

The temperature dependences of the ^{1}H NMR spin-lattice relaxation time and of the second moment of ^{1}H NMR absorptions in the temperature ranges of 90—400 K and 77—456 K, respectively, were studied for butylammonium bromide and its *N*-deuterated analog. There are three known crystalline phases in butylammonium bromide as a result of two phase transitions which are confirmed by the present differential thermal analysis (DTA) experiments. The transition temperatures determined in this study are 200 and 249 K for butylammonium bromide. In the low temperature phase of this salt, CH_3 groups perform the C_3 reorientation with a relatively low activation energy of 11.0 kJ mol^{-1}. The asymmetric T_1 curves observed suggest the existence of some kind of disorder in the crystal structure of this phase. In the intermediate phase, the C_3 reorientation of NH_3^+ groups and the 180° flip motion of butylammonium chains are activated with the activation energies of 23 and 14 kJ mol^{-1}, respectively. The present NMR results for the high temperature phase indicate the occurrence of the conformational melting of the cation chains. The mechanism of the phase transitions is discussed.

It is known that alkylammonium halides involving rather short carbon chains up to C_{10} usually form tetragonal crystals at room temperature.[1-4] In the series of these crystals, the long axis of the carbon chain is located along the crystallographic fourfold axis. Therefore, the presence of dynamical disorder is expected in the arrangement of alkylammonium chains about their long axes.[4] With decreasing temperature, the motion of linear alkylammonium chains should become slow and finally be frozen. This suggests that the tetragonal crystals of these compounds lose their fourfold axis at lower temperatures and are transformed into less symmetric ones. In fact, many of the higher members of the series undergo solid-state phase transitions around or below room temperature,[5] and propyl- and pentylammonium chloride are known to form less symmetric monoclinic crystals at low temperatures.[6,7] Accordingly, it is thought that the molecular motions of alkylammonium chains play an important role in the mechanism of these phase transitions.

Tsau and Gilson[8] studied the wide-line ^{1}H NMR of various alkylammonium chlorides from C_3 to C_{10}, and discussed mainly on the molecular motions of the cations in solid. Recently, the motion of cations in methylammonium halides[9-11] and propylammonium chloride[12] was studied in more detail by use of pulsed and wide-line ^{1}H NMR techniques.

The present investigation of butylammonium bromide by ^{1}H NMR, differential scanning calorimetry (DSC), and differential thermal analysis (DTA) has been undertaken in order to obtain detailed information on the molecular motion of butylammonium cations in solid and also on the mechanism of the successive phase transitions taking place below room temperature.[5]

Experimental

Butylammonium bromide (baBr) was prepared by neutralizing an ethanol solution of butylamine with hydrobromic acid. Colorless crystals separated were purified by recrystallization which was performed twice from a nearly saturated solution of the salt dissolved in a mixed solvent of ethanol and diethyl ether by cooling it very gradually. Vacuum sublimation at *ca.* 80 °C was also employed as another purification method. A partially deuterated analog $C_4H_9ND_3Br$, which is hereafter abbreviated as baBr-d_3, was obtained from the normal salt by repeated recrystallization from heavy water. The deuterated analog thus prepared was finally recrystallized from deuterated ethanol (C_2H_5OD) solution by slowly evaporating the solvent. Since the purified samples were highly hygroscopic, they were carefully dried in vacuum desiccators and sealed in aluminium sample holders for DSC or glass ampouls for NMR and DTA measurements.

The second moment (M_2) of ^{1}H NMR absorptions recorded at 40 MHz were determined at various temperatures between 77 and 456 K by means of a JEOL JNM-MW-40S wide-line NMR spectrometer. The measurements of ^{1}H spin-lattice relaxation time T_1 at the resonance frequency of 20 MHz were carried out by use of a homemade spectrometer[13] and those at 12.6 and 32 MHz were made by another pulsed spectrometer constructed using a transmitter and a receiver from MATEC, Inc.[14] A conventional 180°-τ-90° pulse sequence was used to determine T_1.

A Parkin-Elmer DSC-1B differential scanning calorimeter was employed to determine enthalpy changes at the solid-solid phase transitions and at the melting of the samples. The temperature of the samples was scanned at a rate of 5 K min^{-1}. The values of the transition enthalpies observed at lower temperatures were calibrated against that of succinonitrile observed at 233 K. The melting of indium was also used as a calibration standard for the melting enthalpy. A homemade DTA apparatus was used to determine the phase transition and the melting temperatures.

Results

DTA curves recorded for baBr are shown in Fig. 1. When the sample was cooled from room temperature, two exothermic anomalies appeared at 246 and 195 (±1) K. When it was warmed from *ca.* 80 K, three endothermic ones were observed at 200, 249, and 478 (±1) K. The last one was due to the melting of the sample. The two solid-solid phase transitions showed thermal hysteresis. The samples purified by the two different methods described in the experimental section yielded DTA curves analogous to each other giving the same transition temperatures, T_{tr} as well as the same melting point. Accordingly, it is concluded that baBr undergoes two first-order solid-solid phase transitions at 200 and 249 K. The temperatures of the former transition (200 K) and of the melting agree well with those determined by Tsau and Gilson[5] in their DSC study (198 and 479 K), while the transition temperature

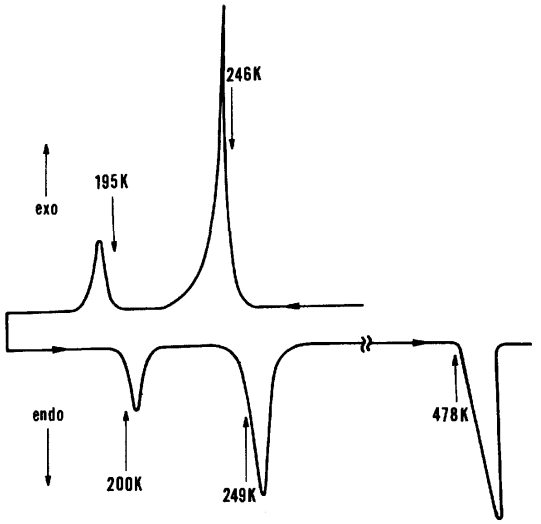

Fig. 1. DTA curves of baBr.

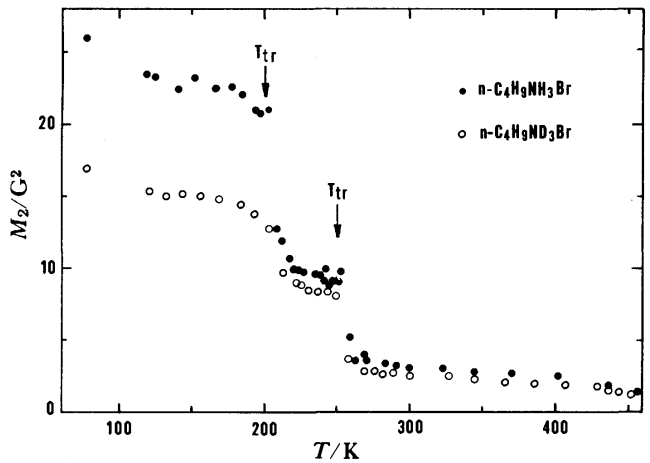

Fig. 2. Temperature dependences of the second moment M_2 of ^{1}H NMR absorptions.

of 249 K is considerably lower than that of 257 K reported by the same authors. For baBr-d_3, two heat anomalies showing quite similar DTA curves to those of baBr were observed at 198 and 249 ($\pm$1) K on heating.

The enthalpy changes (ΔH_{tr}) of the phase transitions determined by the DSC measurements of baBr on heating were 1.5$_3$ and 5.7$_4$ kJ mol^{-1} for the phase transitions at 200 and 249 K, respectively, and 8.3$_0$ kJ mol^{-1} for the melting at 478 K. These transition enthalpies in the present study are much larger than the corresponding ones (0.93 and 5.18 kJ mol^{-1} for the low and high transition temperatures, respectively) reported by Tsau and Gilson.[5]

The temperature dependence of M_2 values observed for baBr and baBr-d_3 is indicated in Fig. 2. These values were obtained with increasing the temperature of the sample. From *ca.* 100 K to *ca.* 170 K, baBr yielded an almost constant M_2 value of 23 G^2. In a rather narrow temperature range of 180—200 K, the M_2 value decreased gradually, whereas it decreased discontinuously to 13 G^2 at *ca.* 200 K. This temperature agrees well with the lowest T_{tr} determined by DTA. With increasing temperature above 200 K, the M_2 value gradually decreased until it became 9 G^2 at 250 K.

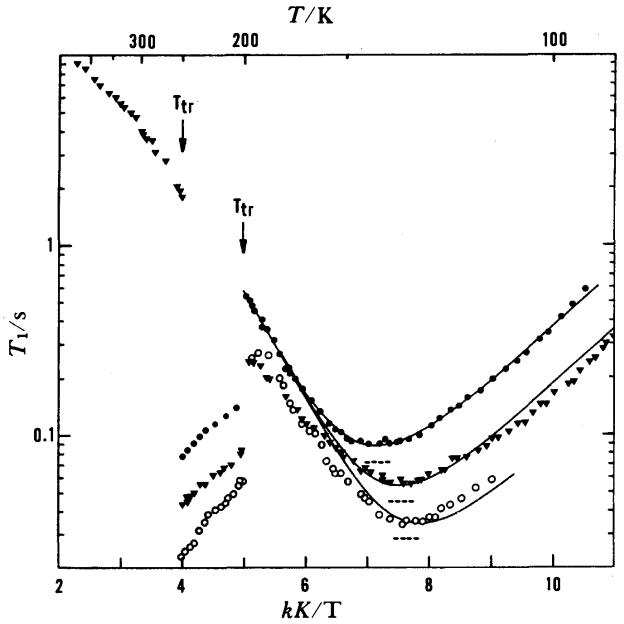

Fig. 3. Temperature dependences of the proton T_1 at 32 (●), 20 (▼), and 12.6 (○) MHz observed for baBr. The solid lines show the theoretical curves fitted by the method of least-squares. The broken lines show the T_1 minima predicted by the BPP theory.

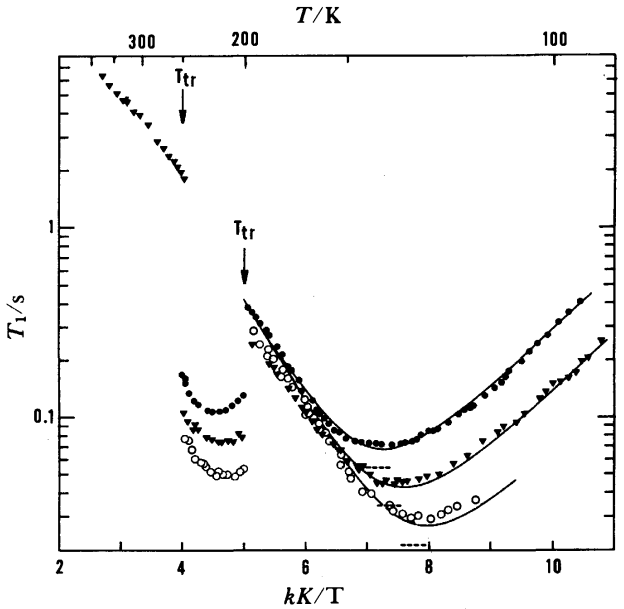

Fig. 4. Temperature dependences of the proton T_1 at 32 (●), 20 (▼), and 12.6 (○) MHz for baBr-d_3. The solid lines show the theoretical curves fitted by the method of least-squares. The broken lines show the T_1 minima predicted by the BPP theory.

Immediately above this temperature, the M_2 value dropped again discontinuously to 4 G^2 in agreement with the occurrence of the phase transition at 249 K. Between 260 and 320 K, the almost constant M_2 value of 3 G^2 was observed. With increasing temperature further, M_2 gradually decreased to *ca.* 1.5 G^2 at *ca.* 460 K. The partially deuterated analog yielded a temperature dependence curve of M_2 similar to that of baBr although the M_2 value of the latter was expectedly larger than that of the former at the same temperature.

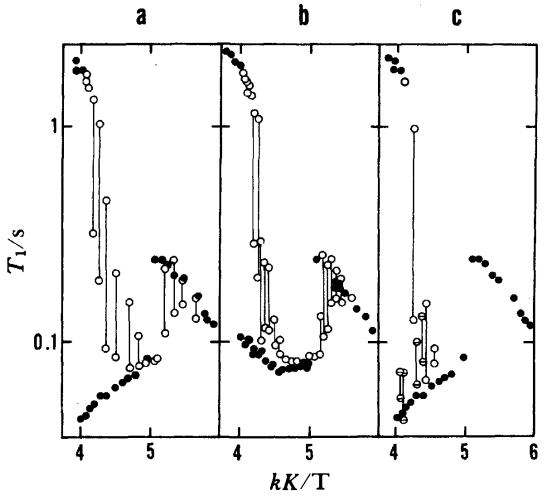

Fig. 5. Proton T_1 values (at 20 MHz) determined for baBr (a, c) and baBr-d_3 (b). Dots indicate the T_1 data obtained with increasing temperature, while open circles are those observed with decreasing temperature. The T_1 interval determined at a given temperature on the cooling run is shown by a vertical line connecting two open circles indicating the longest and shortest T_1 values. The symbols (⊖) indicate the T_1 values obtained with increasing temperature for the sample which had been cooled down to 215 K in advance.

The T_1 values measured at 12.6, 20, and 32 MHz are plotted in Figs. 3 and 4 for baBr and baBr-d_3, respectively. These values were determined at various temperatures between 90 and 400 K. The measurements were made with increasing the temperature of the sample. Each salt yielded a T_1 curve having discontinuities at 200 and 249 K in agreement with the T_{tr}'s determined by DTA. With decreasing temperature, on the other hand, the temperature dependence curve of T_1, which was different from that obtained on the heating run, was observed below each T_{tr} for both salts. In a rather narrow temperature range below each T_{tr}, nonexponential decay of ^{1}H magnetization could be observed for both salts, even though the sample temperature was kept constant for more than half an hour. In these ranges of temperature the longest and shortest T_1 could be approximately determined from the magnetization recovery curve. The results are indicated in Figs. 5a and 5b for the measurements at 20 MHz. It should be noted, here, that the T_1 interval between the longest and shortest values determined at a given temperature varies to some extent at every cooling run of the T_1 measurements.

In the above temperature ranges, another type of anomalous behavior of T_1 was observed. When the sample cooled somewhat below each T_{tr} in advance was warmed, the T_1 values did not reversibly follow those obtained on the cooling run, but decreased roughly along those of the heating run as shown in Fig. 5c. This anomalous behavior is understandable by considering that crystal domains of lower temperature phases newly produced through each phase transition develop gradually with decreasing temperature. Namely, the sample in these temperature ranges is thought to be a mixture of at least two different crystalline phases, the mixing ratio of which is changed with decreasing temperature. The above explanation is compatible with the DTA results that each heat anomaly is accompanied by a long tail only on the low temperature side of the cooling run.

In the low temperature phase, both baBr and baBr-d_3 showed a broad T_1 minimum on the T_1 curve observed at each resonance frequency.

In the intermediate phase, the T_1 value of baBr decreased steadly with increasing temperature to the higher T_{tr}, whereas each of three T_1 curves observed for baBr-d_3 with increasing temperature yielded a shallow minimum. At the T_{tr}, the T_1 values of baBr increased suddenly by about two orders of magnitude. A similar T_1 jump was also observed for baBr-d_3.

In the high temperature phase, long T_1 values were obtained for both salts and they increased monotonously with increasing temperature. No frequency dependence of T_1 was observed in this phase for both baBr and baBr-d_3.

Discussion

The theoretical values of M_2 for four motional states of the cation in solid baBr can be calculated by use of the Van Vleck formula.[15] The results are given in Table 1 along with the total M_2 values of baBr-d_3 calculated in the same way.

In the calculation, all bond angles in the cation were assumed to be tetrahedral and the C-H, N-H, C-C, and C-N bond distances were taken as 1.096, 1.045, 1.540, and 1.470 Å respectively, in accordance with Tsau and Gilson.[8] A trans-zigzag conformation was also assumed for the cation chain.

According to Hendricks,[1] baBr forms tetragonal crys-

tals at room temperature with $a=5.02$ Å, $c=15.23$ Å, and $Z=2$. In the crystal, the cations are packed together between the layers consisting of bromide ions and form a thick layer perpendicular to the c-axis, where the axes of the cationic chains are situated parallel to the c-axis. As to the accurate arrangement of the cations in the layer, no information is available up to date. This is probably because there is a good possibility for the cations in the layer to take highly disordered orientation about their chain axes even at room temperature. Therefore, we estimated the interionic contribution to M_2 by assuming the probable arrangement of the cations in the unit cell as depicted in Fig. 6. The reduction factors of M_2 arising from the averaging of the magnetic dipolar interactions through the molecular motions were evaluated with reference to the methods described in the literature.[16-18]

The ^{1}H spin-lattice relaxation study also furnishes valuable information concerning the molecular motion of the cation. If magnetic dipolar relaxation is governed by the molecular motion such as the reorientation of CH_3 or NH_3^+ groups in a ba$^+$ cation, T_1 can be written as,[19]

$$T_1^{-1} = Cf(\tau) = C\{\tau/(1+\omega^2\tau^2) + 4\tau/(1+4\omega^2\tau^2)\}. \quad (1)$$

Here, C, τ, and ω denote the motional constant, the correlation time of the motion responsible for the relaxation in question, and the angular resonance frequency, respectively. Assuming an Arrhenius-type relation between τ and the activation energy, E_a of the motional process, one obtains

$$\tau = \tau_\infty \exp(E_a/RT), \quad (2)$$

where τ_∞ is the correlation time at the limit of infinite temperature.

Low-Temperature Phase. Below 170 K, the nearly constant M_2 values of 23 and 15 ($\pm$2) G^2 were obtained for baBr and baBr-d_3, respectively. These values agree fairly well with those calculated under the assumption of the motional model that only the CH_3 group of the cation reorients about its C_3 axis. This means that the CH_3 groups of the cations in this phase reorient more frequently than 10^5 Hz.

The analysis of T_1 gives an analogous conclusion. The broad T_1 minimum($T_{1\,min}$) observed for each salt is attributable to the C_3 reorientation of the CH_3 groups because of its short minimum value. This indicates that the correlation time of the CH_3 reorientation is *ca.* 10^{-9} s even at about 130 K in agreement with the foregoing discussion of the second moment.

It is noteworthy that the T_1 data observed for both compounds are unexplainable by the BPP theory (Eq. (1)) in the following three respects. First, the $T_{1\,min}$ values observed for baBr which are 90, 56, and 34 ms at the resonance frequencies of 32, 20, and 12.6 MHz, respectively, and also those for baBr-d_3 which are 72, 45, and 19 ms in the same order of the resonance frequencies are all considerably longer than the theoretical values estimated from Eq. (1). For example, the calculated $T_{1\,min}$'s at 32 MHz are 72 and 54 ms for baBr and baBr-d_3, respectively, if an isolated CH_3 group with the H···H distance of 1.79 Å is assumed. Secondly, the observed T_1 curves are all highly asymmetric. Namely, the slopes of the T_1 curve on the low and high temperature sides of each minimum are considerably different from each other. Finally, the frequency dependence of T_1 values on the low temperature side of the minimum disagrees with the relationship ($T_1 \propto \omega^2$) derived from Eq. 1.

Conner[20] showed that shallow and asymmetric T_1 curves similar to those of the present compounds can be explained by introducing continuously distributed correlation times into Eq. 1. We assume a Cole-Davidson type distribution of τ given by [21]

$$\left.\begin{aligned} g(\tau) &= \frac{\sin\beta\pi}{\pi}\left(\frac{\tau}{\tau_0-\tau}\right)^\beta & \tau \leqq \tau_0 \\ &= 0 & \tau > \tau_0 \end{aligned}\right\}, \quad (3)$$

where β represents a width of the distribution and τ_0 is a limit of τ. The value of $\beta(0<\beta\leqq 1)$ is a measure of the relative weight of the shorter correlation times than τ_0 and in the limit of $\beta=1$, a single correlation time as used in the BPP theory is obtained. Using Eq. 3, T_1 becomes

$$T_1^{-1} = C\left[\frac{\tau_0 \sin(\beta \tan^{-1}\omega\tau_0)}{\omega\tau_0(1+\omega^2\tau_0^2)^{\beta/2}} + \frac{2\tau_0 \sin(\beta \tan^{-1} 2\omega\tau_0)}{\omega\tau_0(1+4\omega^2\tau^2)^{\beta/2}}\right]. \quad (4)$$

The theoretical T_1 curves expressed by Eqs. 2—4 were fitted to the values observed at 32 MHz for baBr and baBr-d_3 by use of a least mean squares method. The fitted curves (at 32 MHz) are shown in Figs. 3 and 4. The values of the unknown parameters determined from this fitting calculation are given in Table 2. By use of these values of the parameters, the theoretical T_1 curves at 20 and 12.6 MHz are also calculated and exhibited in Figs. 3 and 4. The observed T_1 values agree well with the corresponding calculated curves. The obtained motional constants (see Table 2) also agree well with the values calculated using the geometry of the CH_3 group employed in the calculation of M_2. The values of E_a thus obtained are very close to the average value of E_a for the end CH_3 groups in various kinds of crystalline paraffines,[22] which is *ca.* 11 kJ mol^{-1}, and also to the potential barrier to the internal rotation of the CH_3 group in gaseous $CH_3CH_2CH_2F$ (12.4 kJ mol^{-1}).[23] This indicates that the crystal field hindering the CH_3 rotation is quite small in the low temperature phase of the present compounds.

From the β values obtained, we can expect the existence of some kind of disorder in the low temperature phase. As a possible reason for the existence of

Table 2. Activation energies (E_a), motional constants (C), parameters representing width of τ distribution (β), and pre-exponential factor (τ_∞) obtained from observed T_1 curves at 32 MHz for the CH_3 reorientations in baBr and baBr-d_3

baBr-d_3	10.0	2.6(2.60)	0.60	7.6

*The values in parentheses are theoretical ones obtained by use of the BPP equation without distribution of τ.

this disorder, we can presume the following. The disordered structure of the crystal existing in the higher temperature phases, for which we will discuss below may be partly supercooled down to the low temperature phase. To obtain information about this disorder, we measured T_1 of the samples which had been annealed in the following manner; the samples were first cooled gradually from the room temperature phase to the intermediate one and kept at *ca.* 200 K for from several hours to two weeks. After that, they were again cooled slowly to the low temperature phase and, then, one sample was kept at *ca.* 180 K for several hours, and the other was at 77 K for half a day. The observed values of T_1 for the two samples agreed with each other. The values coincide also with those of the normally cooled samples within experimental errors. Accordingly, this disordered structure of the low temperature phase seems to have a very long relaxation time.

At various temperatures between *ca.* 160 and 200 K, the T_1 values of baBr observed at 12.6 and 20 MHz disagree with those at 32 MHz, whereas no such marked disagreement can be observed for baBr-d_3 in the same temperature range. To obtain information about this disagreement, we measured the frequency dependence of T_1 values between 10 and 32 MHz at a fixed temperature of 189 K which is immediately below the low T_{tr}, and obtained a broad T_1 minimum of 19 ms at 18 ± 4 MHz. Since the T_1 of the quadrupolar bromine nuclei in baBr crystals can be expected to decrease near the T_{tr}, the broad T_1 minimum of baBr is considered as resulting from Zeeman-quadrupolar cross relaxation between protons and bromine nuclei,[24] both of which interact through N-H···Br type hydrogen bonds. The above disagreement of the T_1 values may be also explained by the same relaxation mechanism. Although no NQR frequency data are available for baBr, the value of *ca.* 18 MHz seems to be reasonable as an NQR frequency of bromine in baBr crystals because similar frequencies (12—18 MHz) have been reported for analogous alkylammonium bromides.[25]

Intermediate Phase. The shallow T_1 minimum observed for baBr-d_3 clearly indicates the existence of a new relaxation process in the intermediate phase. On the other hand, the sharp decrease of T_1 with increasing temperature obtained for baBr can be attributed to another more effective relaxation process. The shallow T_1 minimum which is also expected to exist in baBr can be thought to be masked by the sharp decrease of T_1 in the case of baBr.

When the T_1 curve of baBr-d_3 was subtracted from that of baBr after a correction for the difference of the number of protons in these two compounds was made, the resultant $\log T_1$ of baBr showed an almost linear decrease against T^{-1} in the nearly whole temperature range of this phase. Although no minimum was observed on the corrected T_1 curve, this linear T_1 decrease can be assigned to the C_3 reorientation of the NH_3^+ groups because this T_1 decrease disappears by *N*-deuteration. From the linear portion of the corrected T_1 curve of baBr, the activation energy for the NH_3^+ reorientation was evaluated as 23 kJ mol^{-1}. It is interesting to note that this E_a value is considerably larger than that for the CH_3 reorientation evaluated above. This means that the NH_3^+ groups are tightly fixed on the layer formed by bromide anions through weak hydrogen bonding, although the CH_3 groups are situated in a weak crystal field produced by the surrounding alkyl chains.

Other alkylammonium bromides having similar crystal structures to that of baBr, such as methylammonium bromide[10] and propylammonium bromide,[26] have fairly close E_a values for the reorientations of the NH_3^+ and CH_3 groups. For propylammonium chloride, strong interactions between the NH_3^+ groups and the Cl^- ions are expected. However, the reorientations of the CH_3 and NH_3^+ groups give rise to their T_1 minima at nearly the same temperature and have the activation energies of 10.0 and 15.5 kJ mol^{-1}, respectively.[12]

From the analysis of the second moment, a conclusion similar to that derived above for the intermediate phase of baBr-d_3 can be obtained. When baBr-d_3 having no NH_3^+ groups was warmed, a marked decrease in M_2 was observed around the low T_{tr}. This clearly indicates that some new motional processes other than the NH_3^+ reorientation are responsible for the reduction of M_2.

Although the M_2 values of baBr and baBr-d_3 obtained for this phase decrease rather sharply at first with increasing temperature, they yield almost the constant values of 9.5 and 8.5 (±1) G^2, respectively, at the higher temperatures. Referring to the calculated values of M_2 listed in Table 1, these plateau values observed are too small to be attributed to the motional state of the cations performing only the CH_3 and NH_3^+ reorientations. Furthermore, these values are too large, if one assigns them to the motional model in which the cation rotates as a whole about its long axis while it keeps the rigid conformation of the chain with the end CH_3 and NH_3^+ groups rotating. Therefore, some new motional modes other than the above ones should be adopted in the interpretation of the M_2 values obtained in this phase.

As a possible relaxation process, we take up the 180° flip motion (C_2 reorientation) of the cation about its long axis. This motion is acceptable for the cations shown in Fig. 6, because each NH_3^+ group can form the same type hydrogen bonds with the surrounding Br^- ions even after the 180° flipping. Although the crystal structure of the intermediate phase is necessarily different from that of the high temperature phase, local atomic arrangements around the NH_3^+ groups are expected to be similar for both phases.

As another analogous motional process, the 90° flip motion of the cation about its long axis can be proposed. This type of motion was found to exist in $(n\text{-}C_3H_7NH_3)_2CdCl_4$[27] and $(n\text{-}C_{10}H_{21}NH_3)_2CdCl_4$.[28] The calculated values of M_2 for this motional model, however, are 6.8 and 5.8 G^2 for baBr and baBr-d_3, respectively, these values are too small as compared with the experimental ones. The model of the 180° flip process of the cation together with the independent reorientations of the CH_3 and NH_3^+ groups yielded the M_2 values given in Table 1. These are in good agreement with the observed plateau values of *ca.* 9.5

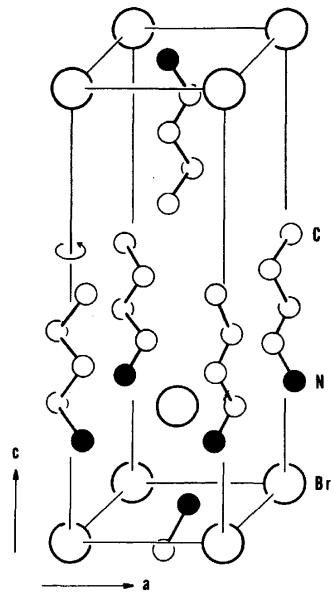

Fig. 6. Predicted crystal structure of baBr at room temperature. The orientations of the cation chains are statistically distributed along the *c* axis.

and 8.5 G^2 for baBr and baBr-d_3, respectively. Accordingly, it can be concluded that there exists the 180° flip motion of butylammonium chains activated in the intermediate phase of baBr. The E_a value for this motion roughly estimated from the T_1 curves of baBr-d_3 is listed in Table 3.

The entropy change, ΔS_{tr} ($=\Delta H_{tr}/T_{tr}$) at the phase transition of 200 K was determined as 7.6 J mol^{-1} K^{-1} from the present DSC experiments. If we assume that the observed ΔS_{tr} is due only to the orientational freedom obtained by butylammonium ions during the transition, this entropy change can be expressed by $R\ln\Omega$ where R and Ω are the gas constant and the number of the orientations permissible to the cation above T_{tr}, respectively. By use of the observed ΔS_{tr}, we obtain Ω=2.5, which is reasonably explained by our model of the 180° flip process.

Reorientations of the ethyl or the propyl group of the cation, *i.e.*, dynamic *trans-gauche* isomerization can be taken as a new motional process alternative to the 180° flip. Although this isomerization is found to exist in the crystalline paraffine ($C_{19}H_{40}$) by ^{1}H NMR studies,[22] the concentration of the gauche conformation is low (less than 1%). From ^{2}H NMR measurements, a similar result is obtained even for the high temperature rotator phase of the paraffine.[29] Accordingly, it is expected that the gauche isomers generated in this phase of baBr or baBr-d_3 are few and give only a minor contribution to the reduction of M_2 and also to the relaxation time.

High-Temperature Phase. At the high T_{tr}, each salt of baBr and baBr-d_3 showed a sudden change of M_2. Above the T_{tr}, the M_2 value of the high temperature phase decreased gradually with increasing temperature, suggesting that some motional process governing the M_2 is gradually growing. The M_2 values observed for baBr and baBr-d_3, respectively, at 300 K are 3.2 and 2.3 (±0.5) G^2, and at 435 K, 1.9 and 1.7 (±0.2) G^2. These M_2 values of baBr and baBr-d_3, respectively, are smaller than those of 4.3 and 3.6 G^2 calculated on the basis of a

High temp phase		
baBr	10.0±0.5(250—300 K)	Whole cationic rotation
	5.8±0.5(310—430 K)	Whole cationic rotation
baBr-d_3	8.2±0.5(250—280 K)	Whole cationic rotation
	6.7±0.5(290—400 K)	Whole cationic rotation

motional model where the cation having its rotating CH_3 and NH_3^+ groups rotates as a whole about its chain axis. This result indicates the existence of some motional processes other than the chain rotation. One of the motions that we can expect to take place in the high temperature phase is the rotation of the cations accompanied by the conformational disorder of the alkyl chain. The observed gradual decrease of M_2 suggests that crystal domains where the cations perform such a motion grow gradually in the crystal with increasing temperature.

The presence of the ba$^+$ cations having such a high degree of movability in the crystal can be proved from the large entropy change (23 J mol^{-1} K^{-1}) observed at the transition to the high temperature phase. This is much larger than that of fusion (17 J mol^{-1} K^{-1}) and is comparable to those reported for various crystals at their transition to a plastic phase.[30] On the other hand, the melting entropy observed is fairly small even though the cation has many allowable conformations in the alkyl chain. Even compounds with no conformational freedom of ions such as NaSCN, KSCN, and KN_3 have the melting entropies of 30—40 J mol^{-1} K^{-1}.[31] These results support our explanation of the second moments and, therefore, it can be concluded that the conformational melting of the cation chains occurs in the high temperature phase.

With increasing temperature, the T_1 value of both salts showed a remarkable increase at the high T_{tr}. This means that the motional time constant of the cations decrease so much at the T_{tr}. In other words, the cations in this phase can move quite freely as compared with those of the intermediate phase. With increasing temperature furthermore the T_1 value increased fairly steeply, although a somewhat nonlinear relation was observed between $\log T_1$ and T^{-1}. The E_a values of baBr determined from the slopes of the T_1 curves are 10.0 and 5.8 kJ mol^{-1} at *ca.* 280 and 380 K, respectively, while those of baBr-d_3 are 8.2 and 6.7 kJ mol^{-1} at the respective temperatures as above. These results suggest that the random chain rotation of the cations mainly contributes to the ^{1}H relaxation at lower temperature in this phase, while contribution from other relaxation process, the dynamic *trans-gauche* isomerization for example, gradually increases with increasing temperature.

Conclusion

From the present study of NMR the low temperature phase can be considered to have a disordered structure, probably of static nature, about the environment of the CH_3 groups. The only motion detected by NMR in this phase was the C_3 reorientation of the CH_3 groups. In the intermediate phase, the 180° flip motion of the cation about its long axis as well as the C_3 reorientation of the NH_3^+ groups are expected to take place. From these motional processes, the intermediate phase is characterized to be a dynamically disordered phase about the orientation of the cations. Above the high temperature transition, the cations obtain much more motional freedom than those in the intermediate phase. The conformational disorder of the cations is considered to develop in the crystals with increasing temperature.

When baBr was cooled through the high T_{tr}, marked nonexponential behavior of T_1 indicating the coexistence of at least two crystalline phases was observed in a fairly wide temperature range. This can be explained by considering that the random axial orientation of the ba^+ chains in the high temperature phase is partially frozen below the T_{tr} and the disordered chains are gradually settled in the stable arrangement with decreasing temperature.

Tsau and Gilson[8] studied the wide-line NMR of butylammonium chloride which is known to show two phase transitions, and assigned the decrease of M_2 at the low T_{tr} to the reorientation of butyl chains with rotating CH_3 and rigid NH_3^+ groups. However, the present study reveals that the NH_3^+ groups of baBr reorient very rapidly even in the intermediate phase. This may be due to the N-H···Br type hydrogen bonds which are weaker than those of the N-H···Cl type.

The authors are particularly indebed to Mr. K. Kawase and Dr. K. Toriyama in the Government Industrial Research Institute of Nagoya for carrying out DSC experiments.

(Received May 21, 1984)

Hydrogen evolution reaction on a series of hydrogen absorbing Ni-V alloys, *viz.* Ni_2V, NiV, and NiV_3, before and after pretreatments with aq HF was studied in 1 M NaOH (1 M=1 mol dm^{-3}) at 288—333 K by a galvanostatic overpotential transient technique. Results are related with the surface characteristics revealed by XPS techniques. It is concluded that the Ni in the Ni-V alloys is mainly responsible for their electrochemical properties and that the reaction proceeds *via* the Volmer-Tafel reaction route with mixed rate-determining characteristics: The activation heats are 7.7, 6.8, and 6.8 kcal mol^{-1} (1 cal=4.184 J) for two elementary steps, Volmer and Tafel, and the overall reaction, respectively. The electrocatalytic activity of the Ni-V alloys, particularly NiV_3, is drastically enhanced through the treatment with aq HF, and this is in parallel with the formation of porous Ni layers on their surface, namely the increase of the effective surface area. Potentiality of the alloys for water electrolysis cathode materials is indicated by a higher electrocatalytic activities of the Ni-V alloys over ordinary Raney nickel electrodes. Hydrogen absorbability of the alloys was also investigated: NiV_3 stored hydrogen up to [H]/[M]=$\leq$0.3 after a cathodic polarization at about −400 mV hydrogen overpotential, but that in Ni_2V or NiV was far smaller.

Overpotential is one of the major factors which decrease efficiency of electrochemical processes and, accordingly, the electrode is often made to possess a large surface area.[1] We have reported recently that a series of amorphous Ni-Ti and Ni-Zr alloys after a brief treatment with aq HF attain a high electrocatalytic activity for the hydrogen electrode reaction (HER). Surface characterizations including XPS observations indicated that this is due to formation of a porous layer rich in nickel on their surface during the acid treatment, similar to usual Raney nickel electrodes.[2]

The Raney nickel materials are usually prepared from Ni-Al or Ni-Zn alloys by leaching Al or Zn out with alkaline solutions. Further, we have shown in a previous paper[3] that essentially the same electrocatalytic activity is obtained by the use of aq HF as the developer instead of aq NaOH. Since V is rapidly soluble in aq HF as compared with Ni, similar to Ti or Zr, we may apply it in developing a series of Ni-V alloys.

Various elements including those of Va group such as V are known to form hydrides,[4] and thus noted as hydrogen storage materials, similar to a series of alloys containing rare earth elements.[5] The element V itself has a high hydrogen absorbability and forms nonstoichiometric hydrides up to [H]/[V]=2.0 at ambient pressure and temperature.[6] Further, effects of Ti, Cr, Fe, and Co as alloying elements on the hydrogen solubility of V-based alloys have been reported by Eguchi and Morozumi[7] or Lynch *et al.*[8]

In the Ni-V system, there are four types of intermetallic compounds (Ni_3V, Ni_2V, NiV, and NiV_3) which crystallize with tetragonal (I4/mmm),[9a] orthorhombic (Immm),[9b] tetragonal ($P4_2/mmm$),[9c] and cubic ($Pm3n$)[9d] systems, respectively. However, no systematic study has so far been reported on their hydrogen storage property.

The HER on many electrocatalytically active metals in aqueous solutions consists of two elementary steps, *viz.* the discharge of proton (in acidic solutions) or water (in alkaline solutions), the Volmer step, and the recombination of hydrogen adatoms H(a), the Tafel step.

Volmer step:

$$H^+B + e \rightleftharpoons H(a) + B \quad (B=H_2O, OH^-), \qquad (1)$$

Tafel step:

$$2H(a) \rightleftharpoons H_2. \qquad (2)$$

Use of thin foils of hydrogen permeating metals or alloys as hydrogen electrodes has a particular advantage in the mechanistic studies: The kinetics of the individual elementary steps of the HER can be obtained by analyzing transient rise and decay characteristics of the overpotential. The overpotential components shared by the constituent steps can individually be evaluated because of a large difference in the relaxation time constant between the Volmer step, which is very fast, and the Tafel step, which is extremely slow because of slow rate of variation in the activity of H(a) on the electrode surface.[10] The same technique may be applied to the Ni-V alloys to derive kinetics of the individual elementary steps and determine the mechanism of the HER.

Experimental

Preparation of Electrodes. The alloy ingots (about 5 g) with compositions of Ni_2V, NiV, and NiV_3 were synthesized from Ni (99.9%) and V (99.9%) by arc-melting as described elsewhere.[11] Their weight loss during the fabrication was negligible, or the composition of the product was essentially equal to the starting one. The alloys obtained were annealed at 1300 K for 10—15 h *in vacuo* (*ca.* 5×10^{-4} Pa), spark-cut into slices (0.5—1.0 mm in thickness), and then the surface was polished with emery papers (no. 170—200). Powder X-ray diffraction patterns of Ni_2V and NiV agreed with those in the literatures,[9b,c] but not for NiV_3 [the powder data (d_{obsd}/Å and I/I_0) observed within $(\sin\theta)/\lambda<0.50$ Å^{-1} were as follows: 2.33, 60; 2.19, 60; 2.13, 55; 2.08, 45; 2.02. 100; 1.99, 85; 1.94, 45]. The acid treatment of a series of Ni-V alloys was made with 1 M HF solution at room temperature, the period being 10 h for Ni_2V or NiV and 10—30 min for NiV_3, respectively.

Electrochemical Measurements. The electrodic properties of the Ni-V alloys were investigated in 1 M NaOH at

288—333 K according to the technique described previously.[2] The electrolytic solution was prepared from special grade NaOH (Merck Japan, Ltd.) with water obtained from a Millipore pure water system. A platinized Pt was used for a hydrogen reference electrode. Roughness factor (*RF*) of the test electrode was evaluated from double layer capacitance data assuming *a* value of 18 $\mu F\,cm^{-2}$ (true), usually observed on Hg electrode.

XPS Measurements. Surface analysis of the Ni–V alloys was performed using an ESCA apparatus (VG-III) with Al $K\alpha$ X-ray radiation. The binding energy values recorded were calibrated using the $4f_{7/2}$ signal (83.8 eV) from a gold plate which was employed as an internal standard. Surface sputtering by Ar^+ ion bombardment was carried out under the condition of 1—2 keV and 4—10 $\mu A\,cm^{-2}$. The depth D_s sputtered by the bombardment was estimated from the following equations,[12]

$$D_s = \frac{N_{Ar} \cdot Y \cdot M}{N_A \cdot \rho} \times 10^8\ \text{Å}, \quad (3)$$

$$N_{Ar} = \frac{I \cdot T}{1.6 \times 10^{-9}}, \quad (4)$$

where N_{Ar} is the Ar^+ ion flux density in ions per second, Y is the sputtering yield, M is the atomic weight, N_A is Avogadro's number, ρ is the density of the alloys, I is the ion current density in amperes and T is the duration of the bombardment in seconds. The Y value was deduced by averaging the sputtering yields for each pure component of the alloy, which were in turn evaluated by interpolation of the values determined by Kanaya *et al.*[12] at given Ar^+ ion energy values (1.0, 1.5, and 2.0 keV). An average atomic weight corresponding to the alloy composition was used for M.

Results and Discussion

Electrochemical Properties. The electrocatalytic activity of the nontreated (as-obtained) Ni_2V and NiV alloys for the HER was relatively high, so that the reversible HER potential was realized soon after introduction of the electrode into the electrochemical cell. The electrode of NiV_3, without the pretreatment which was performed later, did not give the potential because of its very low activity.

On metal and alloy electrodes which have high solubility as well as mobility of hydrogen in the bulk, a plateau region should appear on the short time (several seconds) galvanostatic overpotential rise and decay transient curves before the attainment of the steady-state polarization or equilibrium potential, respectively.[2,13] Such overpotential plateaus were indeed seen clearly on both the nontreated Ni_2V and NiV alloy electrodes. Typical rise and decay transient curves observed on the NiV alloy electrode are shown in Fig. 1. As discussed previously,[10] we can estimate two overpotential components, η_1 and η_2', for the step of discharge of water and the step of recombination of hydrogen adatoms, respectively.

Tafel plots of η_1 on the nontreated Ni_2V and NiV alloy electrodes both in the cathodic and anodic regions are shown in Fig. 2. The approximate symmetry of these curves about the abscissa and the slope (about 120 mV/decade) of the linear portions of the "Tafel lines" indicate that η_1 should represent the component overpotential for a one-electron transfer reaction, namely, the Volmer step. The symmetry factor (for the cathodic unidirectional current) is 0.5—0.6 near the reversible potential, as same as that observed earlier on $LaNi_5$ and Ni–Ti alloy electrodes.[2,13c] Likewise,

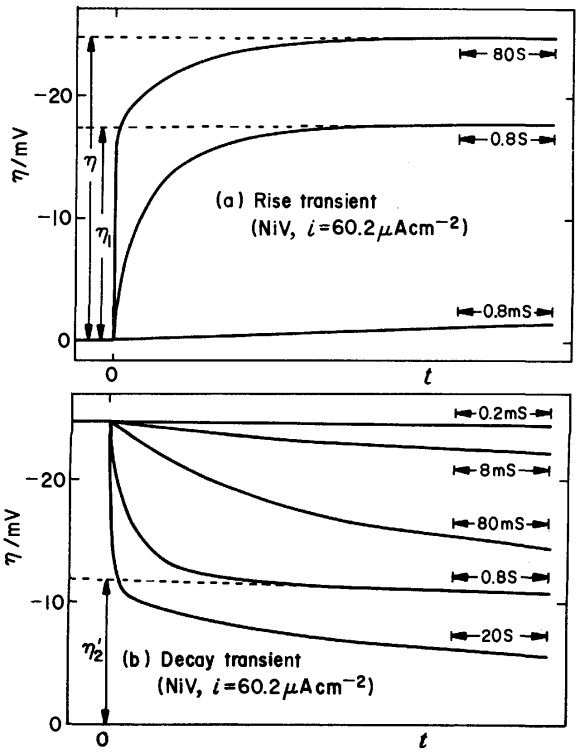

Fig. 1. Typical galvanostatic overpotential (a) rise and (b) decay transients with various time scales on a nontreated NiV alloy electrode. 1 M NaOH, 303 K. $-i$=60.2 $\mu A\,cm^{-2}$ (apparent).

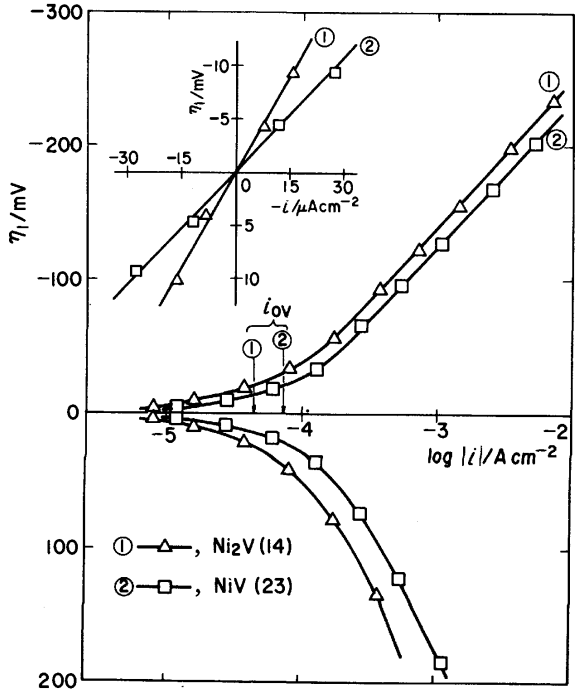

Fig. 2. Cathodic and anodic polarization behaviours of the rapidly rising overpotential component η_1 on both nontreated Ni_2V and NiV alloy electrodes. The arrows on the abscissa indicate i_{ov} as evaluated from the linear plots (the inset figure) of η_1 *vs.* i near the reversible potential. The numerals in the parentheses indicate the *RF* values. 1 M NaOH, 303 K.

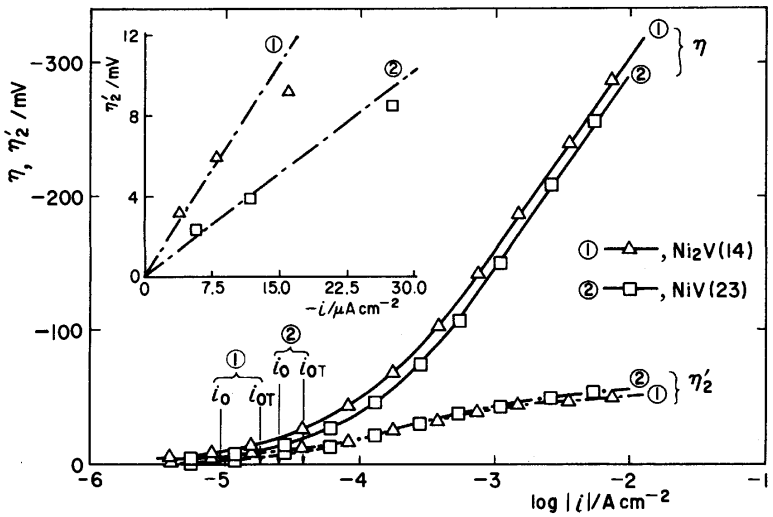

Fig. 3. Cathodic polarization behaviours of the total overpotential η and the slowly decaying overpotential component η_2' on both nontreated Ni_2V and NiV alloy electrodes. The arrows on the abscissa indicate i_o and i_{oT} obtained at low overpotentials (the inset figure). The numerals in the parentheses indicate the *RF* values. 1 M NaOH, 303 K.

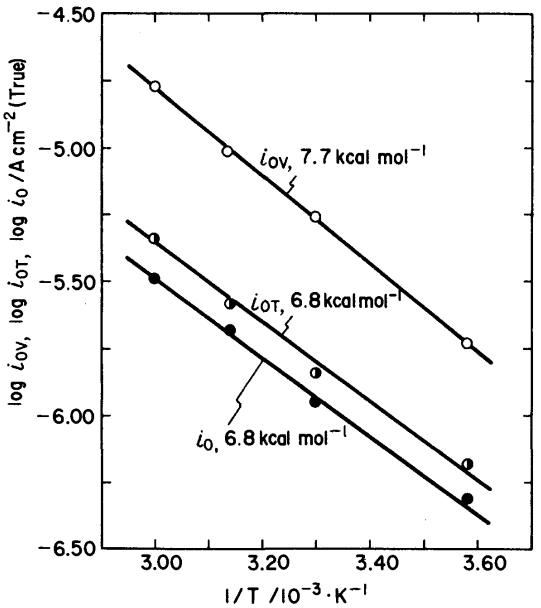

Fig. 4. Arrhenius plots of the exchange current densities for the Volmer and Tafel elementary steps and the overall reaction on the nontreated NiV alloy electrode with *RF*=29. The numerals give their corresponding activation heats. 1 M NaOH.

the approximate linearity of the cathodic η_2' *vs.* log i behaviours with the slope of about 30 mV/decade, as shown in Fig. 3, indicates that η_2' should be attributed to the Tafel step, as same as the case of the Pd electrode reported previolusly.[13a]

The exchange current densities of the Volmer and Tafel elementary steps, i_{oV} and i_{oT}, were obtained from the polarization resistance at low overpotentials (see the inset figures in Figs. 2 and 3) in a similar manner as the cases of other hydrogen absorbing electrodes.[13c] These values are both around the same order of magnitude, 10^{-4} A cm^{-2} (apparent) and hence, the reaction is of the mixed rate-determining type. The characteristics are similar to those of ordinary Ni electrodes. The exchange current density, i_o, of the overall reaction is readily evaluated by the relationship, $1/i_o=1/i_{oV}+1/i_{oT}$. In Figs. 2 and 3, the values of i_{oV}, i_{oT}, and i_o are respectively indicated by arrows on the abscissa.

The activation heats of the reaction steps are determined from the temperature dependences of the exchange current densities. Typical Arrhenius plots obtained on the NiV alloy electrode (*RF*=29) are shown in Fig. 4. The activation heats observed are 7.7, 6.8, and 6.8 kcal mol^{-1} for the Volmer and Tafel elementary steps and the overall reaction, respectively. These values practically agree with those determined on some Ni-based alloy electrodes, of which the reaction is also catalyzed by the nickel in the alloy matrix.[2,13c] It is noted that the heat values as well as rate data of the Tafel step and the overall reaction are close to each other. This means that the overall reaction around the reversible hydrogen electrode potential must be more intimately controlled by the Tafel step than by the Volmer step. On the other hand, the slope of the linear portion of the Tafel lines at high cathodic overpotentials is around 120 mV/decade and this is attributable to the one-electron transfer step. Necessity of variation of the overall kinetics as such in the case of the mixed rate-determining reaction has been discussed elsewhere.[10]

It is seen that the electrocatalytic activity of the specimens of the Ni-V alloys, particularly NiV_3, is drastically improved by the treatment with aq HF, along with increase in the *RF* values. Another tendency observed is that the higher the Ni content in the alloy matrix is, the higher the *RF* values attained are. Presumably, the specimen containing a larger amount of V is attacked more readily by aq HF than those of lower V content, and thus gives rise to the surface more effectively roughened.

Typical galvanostatic rise and decay behaviours on the HF-treated NiV_3 electrode are given in Fig. 5. These are similar to those of the nontreated specimens, but

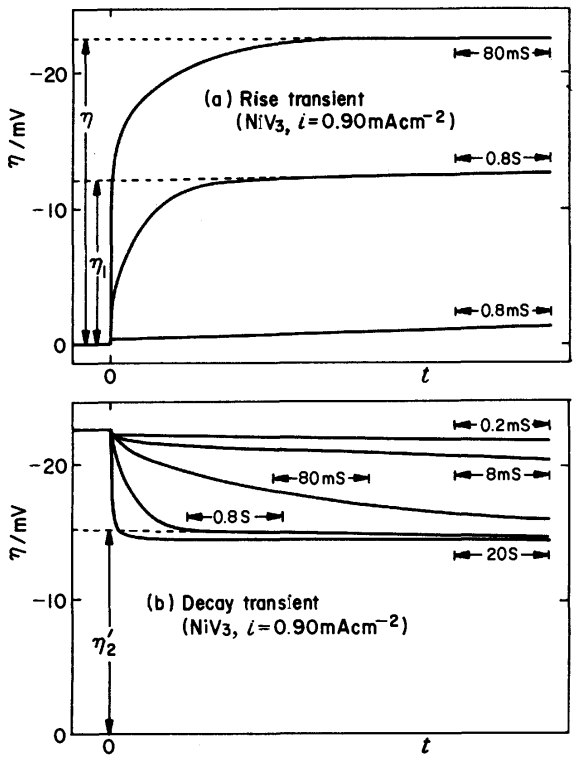

Fig. 5. Typical galvanostatic overpotential (a) rise and (b) decay transients with various time scales on a HF-treated NiV_3 alloy electrode. 1 M NaOH, 303 K. i=0.90 mA cm^{-2}.

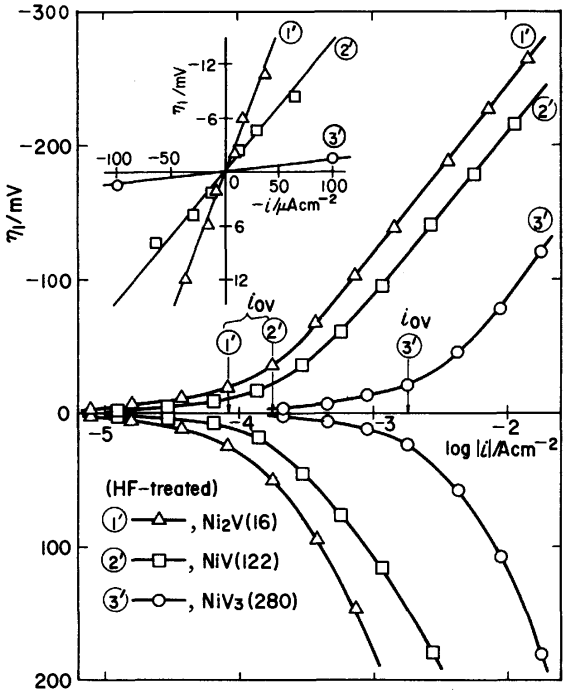

Fig. 6. Cathodic and anodic polarization behaviours of the rapidly rising overpotential component η_1 on a series of HF-treated Ni-V alloy electrodes. The arrows on the abscissa indicate i_{oV} as evaluated from the linear plots (the inset figure) of η_1 *vs.* i near the reversible potential. The numerals in the parentheses indicate the *RF* values. 1 M NaOH, 303 K.

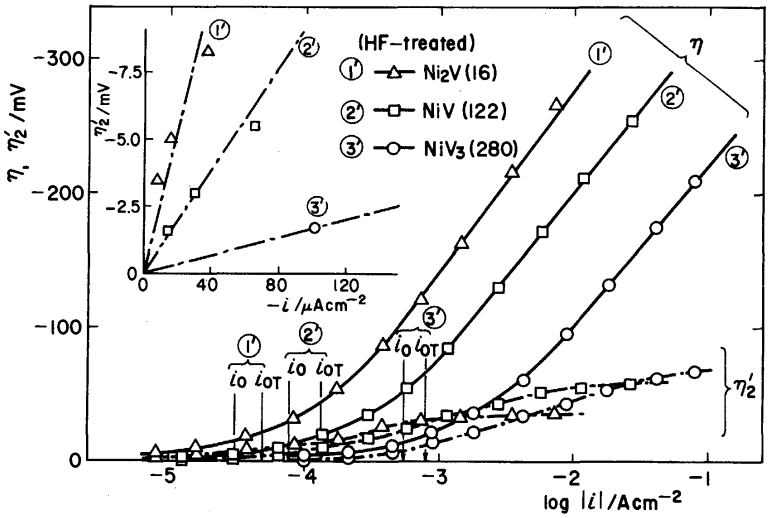

Fig. 7. Cathodic polarization behaviours of the total overpotential η and the slowly decaying overpotential component η'_2 on a series of HF-treated Ni-V alloy electrodes. The arrows on the abscissa indicate i_{oT} obtained at low overpotentials (the inset figure) and i_o evaluated by the relation of $1/i_o=1/i_{oV}+1/i_{oT}$. The numerals in the parentheses indicate the *RF* values. 1 M NaOH, 303 K.

the ratio η'_2/η of the HF-treated NiV_3 specimens is somewhat larger than those of the nontreated or HF-treated Ni_2V and NiV electrodes. This might indicate, on NiV_3, that the rate of diffusion in the solution phase begings to play a role in controlling the overall rate because these electrodes are highly active.

The polarization behaviours with respect to η_1, η'_2, and η on a series of HF-treated Ni-V alloys are given in Figs. 6 and 7. These characteristics are altogether essentially the same with those observed above on the nontreated electrodes.

The numerals in the parentheses in Figs. 6 and 7 represent the *RF* values of the electrodes. It is seen that the exchange current densities of the Volmer and Tafel steps, i_{oV} and i_{oT}, are almost in parallel with the *RF* values. Thus, the NiV_3 alloy electrodes which have *RF*

values of several hundreds give the i_{oV} and i_{oT} values around 10^{-3} A cm^{-2} (apparent). Yet, as the limiting current of the H_2 diffusion in solution is of the same order of magnitude with this value, the value of i_{oT} is likely to be somewhat under-estimated from the real value.

The exchange current density (i_o) of the overall reaction, evaluated by the relation $1/i_o=1/i_{oV}+1/i_{oT}$, is naturally also enhanced by the increase of the roughness. The electrocatalytic activity of the HF-treated alloys, particularly NiV_3, is as high as that of smooth of electrodes ($i_o=\leq 10^{-3}$ A cm^{-2}) on apparent surface area basis.

The HF-treated NiV_3 alloys could store hydrogen up to [H]/[M]$=\leq 0.3$ by cathodic polarization for 10—20 h at $\eta=\leq -400$ mV. (The amount absorbed in the Ni_2V and NiV specimens was negligible even after polarization for several days.) The condition with respect to hydrogen pressure P_{H_2}, to which the cathode is effectively exposed, can be obtained from the over-potential component η_2', as discussed in previous work,[14] as

$$-\eta_2' = \frac{RT}{2F} \ln P_{H_2} \qquad (5)$$

In Fig. 8, the relation between η_2' (or log P_{H_2}) and [H]/[M] ratios observed on the HF-treated NiV_3 alloy electrode (RF=530) is shown: The [H]/[M] ratios are evaluated by collecting the H_2 gas liberated from the alloy after termination of the polarization current. Also shown in this figure are typical absorption isotherms of Cr–V alloys (and not data for the Ni–V alloys, which are not available) reported by Lynch *et al.*[8] It is generally seen that the hydrogen absorbability of the V-based alloys containing Cr, Fe, or Co[7,8] is lowered with increase of the content of the added element (see Fig. 8).

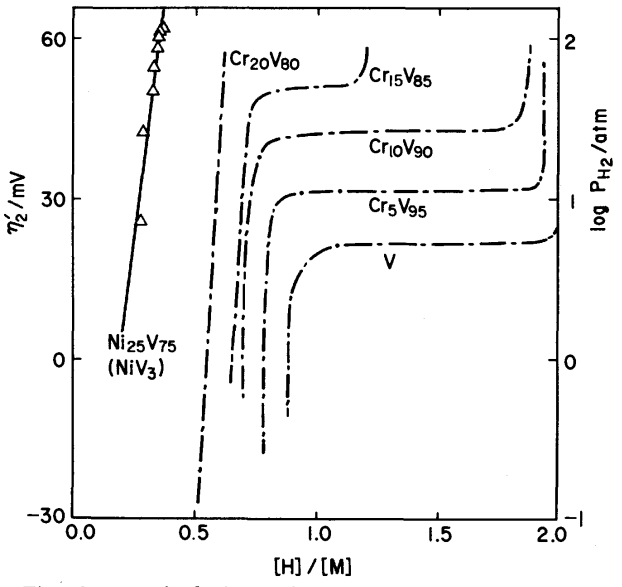

Fig. 8. Typical absorption isotherms (η_2' or log P_{H_2} *vs.* [H]/[M]) obtained on the NiV_3 alloy electrode with RF=530 after a cathodic polarization at η= 50—400 mV at 303 K for 10—20 h. The absorption isotherms of Cr–V alloys at 313 K reported by Lynch *et al.*[7] are shown for comparison.

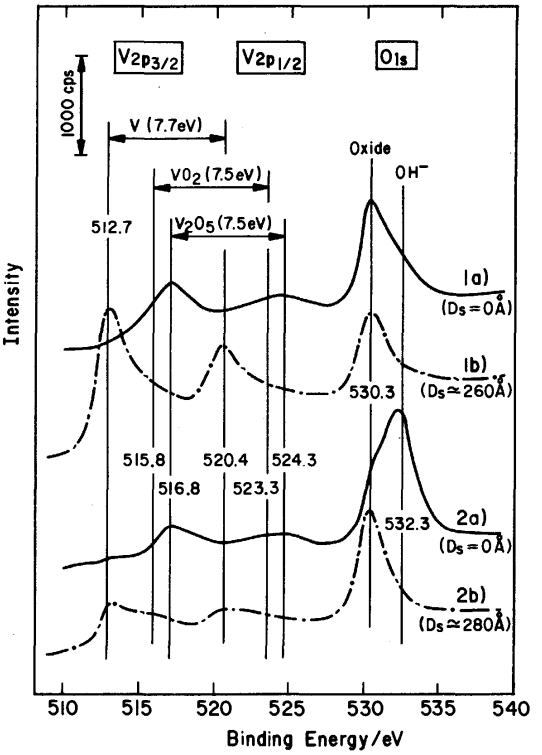

Fig. 9. XPS patterns of the V_{2p} and O_{1s} electrons on the NiV_3 alloys before (solid-lines) and after (broken-lines) Ar^+ ion bombardments up to D_s=250—300 Å, respectively. Spectra: 1a) and 1b), nontreated specimens; 2a) and 2b), HF-treated specimens.

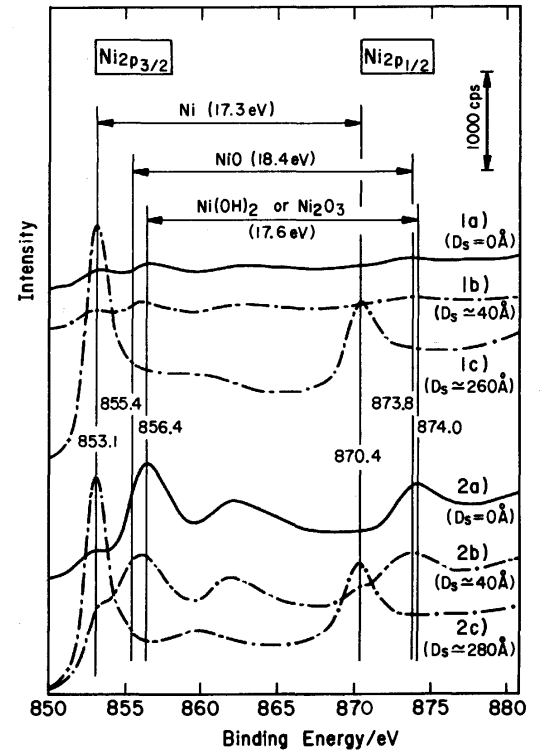

Fig. 10. XPS patterns of the Ni_{2p} electrons on the NiV_3 alloys before (solid-lines) and after (broken-lines) Ar^+ ion bombardments up to D_s=40—300 Å, respectively. Spectra: 1a), 1b), and 1c), nontreated specimens; 2a), 2b), and 2c), HF-treated specimens.

The same tendency might be expected with the Ni–V alloys, namely the larger the amount of Ni was, the smaller the amount of the stored hydrogen would be. Thus, in Fig. 8, the position of the isotherms of the NiV_3 alloy ($Ni_{25}V_{75}$) which appear at left-hand side of the line for $Cr_{20}V_{80}$ seems reasonable. The Ni–V alloys containing still smaller concentration of Ni may have a possibility as cathode materials if those of higher hydrogen absorbability are desired.

Surface Characterization. A series of XPS patterns of the Ni–V alloys have been observed before and after the treatment with aq HF. On the nontreated specimens, the signals from V are very strong compared with those from Ni. However, the spectrum intensity of Ni is drastically increased on the HF-treated Ni–V alloys, particularly NiV_3, while that of V is decreased. Typical X-ray photoelectron spectra derived from the V_{2p}, O_{1s}, and Ni_{2p} electrons on the NiV_3 alloys are given in Figs. 9 and 10, together with assignments given according to XPS data listed in a handbook.[15] (Practically the same spectra have been observed on other Ni–V alloys, *viz.* Ni_2V and NiV.)

The $V_{2p3/2}$ or $V_{2p1/2}$ signals on the nontreated and HF-treated Ni–V alloys consists mainly of two spectrum bands; The peak positions are *ca.* 515.8 and 516.8 eV for $V_{2p3/2}$ and *ca.* 523.3 and 524.3 eV for $V_{2p1/2}$, respectively. The V_{2p} spectra around 515.8 and 523.3 eV are assigned to the vanadium of VO_2 while the signals at the other peak positions are attributable to the V_{2p} electrons of V_2O_5. Signals of the metallic V become observable only after the Ar^+ ion bombardments up to the D_s of 100—200 Å. Therefore, most of the vanadium on the alloy surface exists as oxides which are probably electrocatalytically inert. This would explain the low activity of the nontreated NiV_3 alloys towards the HER.

The O_{1s} spectra on the Ni–V alloys have peaks at 530.3 and 532.3 eV, which are assigned to the oxygens of anhydrous oxides (V_2O_5, NiO, *etc*) and hydroxides (hydroxyl groups), respectively, but the latter spectrum band is significantly decreased after the Ar^+ ion bombardments ($D_s = \leq 50$ Å). This observation indicates that the hydroxides exist only near the surface.

The signals of Ni_{2p} electrons on the nonbombarded specimens appear at *ca.* 853.1, 855.4, and 856.4 eV for $Ni_{2p3/2}$ (and at *ca.* 870.4, 873.8, and 874.0 eV for $Ni_{2p1/2}$). Among them, the nickels of metal and NiO are responsible for two $Ni_{2p3/2}$ spectra (853.1 and 855.4 eV), but the remaining spectrum band is not precisely assigned to that of $Ni(OH)_2$ which is expected to exist near the surface according to the observations of the O_{1s} signal from hydroxyl groups: The same spectra have been observed on the specimens of which the hydroxyl groups are completely removed by the Ar^+ ion bombardments (see spectra 1b) and 2b) in Fig. 10). Perhaps, the Ni_{2p} spectrum bands at 856.4 and 874.0 eV may be due to the nickels of $Ni(OH)_2$ or Ni_2O_3. Signals from NiF_2 which have been observed previously on the HF-treated Ni–Al alloys[3] were not detected on a series of the HF-treated Ni–V alloys preparaed in this work.

The surface concentration ratios $C^S_{Ni/V}$ of the component metals on the nontreated and HF-treated Ni–V alloys are estimated from the integral peak intensity I of Ni_{2p} and $V_{2p3/2}$ using the following equation:

$$C^S_{Ni/V} = \frac{I_{Ni}/S_{Ni}}{I_V/S_V}, \quad (6)$$

where S is the atomic sensitivity factor for X-ray. In this work, $S_{Ni}=5.4$ and $S_V=1.4$ listed in the literature[15] are employed.

The relationships between $C^S_{Ni/V}$ and the nominal bulk compositions, $C^B_{Ni/V}$, of the Ni–V alloys before and after the acid treatments are shown in Fig. 11(a). For all the nontreated specimens, the surface Ni concentration is lower than the bulk one (below the broken-line), or the surface is enriched in V. On the other hand, the $C^S_{Ni/V}$ value of the Ni–V alloys containing a large amount of V, particular NiV_3, is significantly increased by the acid treatment. This means that the vanadium near the surface of the V-rich alloys is effectively dissolved out with aq HF and a Ni-rich layer is formed.

In Fig. 11(b), the in-depth profiles of the $C^S_{Ni/V}$ of the nontreated and HF-treated NiV_3 alloys are given. It is clearly seen that the $C^S_{Ni/V}$ value of the HF-treated specimen differs considerably from that of the nontreated one. The electrochemical capacitance data also indicate that the layer is very porous, and hence it may be considered as a kind of Raney nickel material. Consequently, the high electrocatalytic activity of the HF-treated NiV_3 alloy is concluded to be brought about by the porous Ni-rich layer formed on the surface, after leaching V out with aq HF.

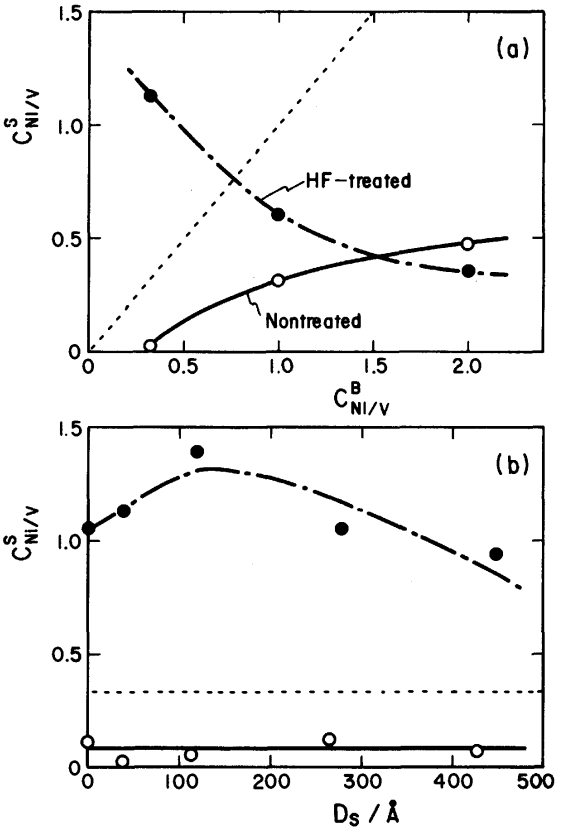

Fig. 11. (a) Relationship between the surface and bulk atomic ratios ($C^S_{Ni/V}$ and $C^B_{Ni/V}$) in a series of Ni–V alloys before and after the acid treatment. The broken line represents the case that $C^S_{Ni/V}$ equals $C^B_{Ni/V}$. (b) In-depth profiles of the surface atomic ratios $C^S_{Ni/V}$ for NiV_3 alloys before and after the acid treatment. The broken line indicates $C^S_{Ni/V}$.

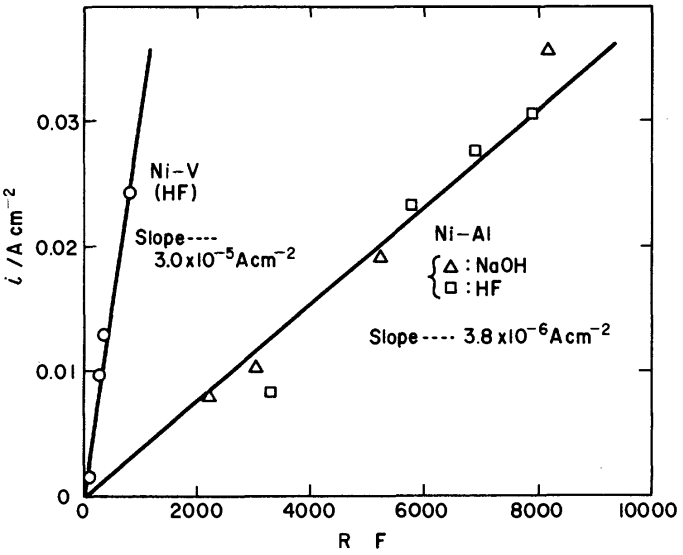

Fig. 12. Relationships between the current density (at η=−100 mV) and *RF* values on the HF-treated Ni-V alloy electrodes (○), together with those[3] on the Raney nickel electrodes treated with aq NaOH (△) and HF (□).

Synergistic Effect. It is noteworthy that a synergistic effect between Ni and V is suggested in the electrocatalytic activity on true unit surface area basis. In Fig. 12, the relation between the current density at η arbitrarily chosen at −100 mV and *RF* values on the HF-treated Ni-V alloys is shown, together with that on ordinary Raney nickel electrodes.[3] The current density on the Ni-V alloys as well as Raney nickel alloys increases linearly with the *RF* values but the slopes are clearly different. The slope (which gives the average current density per true unit surface area) is about 3.0×10^{-5} A cm^{-2} on the Ni-V alloy electrodes and this is about one order of magnitude higher than that of ordinary Raney nickel electrodes (3.8×10^{-6} A cm^{-2}). As reported elsewhere,[3] the difference in the electrocatalytic activity caused by the use of different developer, *viz.* aq NaOH or aq HF, is practically negligible. The difference in the slopes, therefore, indicates existence of a synergistic effect between Ni and V.

Conclusion

The HER on a series of the Ni-V alloy electrodes, *viz.* Ni_2V, NiV, and NiV_3, in 1 M NaOH is mainly catalyzed by nickel on the surface. The reaction proceeds *via* the Volmer-Tafel route with mixed rate-determining characteristics. The electrocatalytic activity as well as the *RF* values is drastically improved after the treatments with aq HF. On the NiV_3 alloy, in particular, the electrocatalytic activity attained is very high, being comparable with that of smooth Pt electrodes. A synergistic effect of about one order of magnitude is indicated. In view of this effect as well as their ability to produce porous Ni layers, the Ni-V alloys can be a potential candidate as a cathode material for water electrolysis.

The Influence of Culture Conditions on the Fibrillation of Cellulose Gel Produced by *Acetobacter xylinum*

Akira KAI

Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received February 27, 1984)

The influence of the culture conditions, such as the temperature of incubation and the pH of the culture medium, on the fibrillation of cellulose gels produced by *Acetobacter xylinum* was studied by means of electron microscopy. The incubation temperature did not show any influence on the fibrillation of cellulose gels as long as it was in the range between 10 to 28 °C. However, in the incubation at 5 °C the fibrillation occurred very slowly. When incubation was carried out at 5 °C, the fibril produced by the 5 °C incubation maintained an amorphous state for about 3 h, and the microscopic fibrils appeared in the fibril only after incubation for 12 h. However, the width of the microscopic fibril was not influenced by the temperature of incubation. The pH of the medium influenced the linear growth rate of a fibril. The rate increased with an increase in the pH, reached the maximum at pH 6.8, and decreased at higher pHs. The fibrillation occurred more rapidly at a constant temperature as the linear growth rate was lowered, but the width of a microscopic fibril was not influenced by the pH of the medium, just as it was not influenced by the temperature.

The fibril just after production by *Acetobacter xylinum* (*A. xylinum*) seems to be in a homogeneous, amorphous state.[1,2] However, When the amorphous fibril is extruded from the cell, it becomes clearer that its cellulose chains are already arranged as sheets of monomolecular layers corresponding to the ($1\bar{1}0$) plane of Cellulose I.[3,4] In the amorphous fibril regarded as an assembly of the cellulose sheets, microscopic fibrils with almost the same width (about 40 Å) were always developed in the course of time.[5,6] It is interesting to study whether the width of a microscopic fibril is dependent on the culture conditions, that is, the crystallization conditions, or whether it is dependent on the fact that, when cellulose is extruded from the synthesizing sites in the envelope of a bacterial cell,as reported by Brown *et al.*[7] and Zaar,[8] the precursors of microscopic fibrils are already included in it.

In this paper the influence of the culture conditions, such as the incubation temperature and the pH of the medium, on the fibrillation of cellulose gels produced by *A. xylinum* was studied by means of electron microscopy.

Experimental

Culture of Cells and Preparation of the Samples for Electron Microscopy. The methods described previously[3] were employed.

Preparation of Cellulose-free Cell Suspension: An amount of 10 ml of an *A. xylinum*-preserved culture medium (IFO 13693) was added to 100 ml of an complex medium, and the mixture was incubated at 28 °C for 72 h. An amount of 10 ml of the liquid phase of the starter culture was added to 100 ml of the fresh complex medium, and the mixture was incubated at 28 °C for 48 h. The cells collected from the incubated medium according to the method of previous papers[1,3] were suspended in 60 ml of a buffer solution with a pH value of 6.8.

Samples for the Study of the Influence of the Temperature of Incubation: A 4-ml quantity of a 0.2 wt% glucose medium with 2 wt% sodium tungstophosphate (pH 6.8) was added to 36 ml of a cell suspension. A drop of the culture medium was immediately placed on a sheet mesh covered with a collodion membrane and incubated in a 100% RH atmosphere at a given temperature for a given time. After the fibrils thus produced had been allowed to settle on the sheet mesh by removing the medium, they were dried over P_2O_5 for more than 24 h at room temperature and then observed through an electron microscope.

Samples for the Study of the Influence of the pH of a Medium: After the cell suspension and the 0.2 wt% glucose medium with 2 wt% sodium tungstophosphate had been adjusted to a given pH with 1 M† HCl or NaOHaq respectively, a 4-ml quantity of the glucose medium was added to 36 ml of the cell suspension. A drop of the culture medium was placed on a sheet mesh and incubated in a 100% RH atmosphere at 28 °C for a given time. After this incubation, samples for electron microscopy were prepared as has been described above.

Measurement of the Linear Growth Rate of a Fibril. The linear growth rate of a fibril under a given pH was obtained from the relation between the time of incubation and the mean length of ten fibrils after glucose incubation. The linear growth rate was constant within the range of the measureable length of a fibril.

For electron microscopy, all the preparations were examined with a JEOL JEM-100U electron microscope operating at 80 kV.

Results and Discussion

Brown *et al.*[9] suggested that the rate of crystallization

of the amorphous cellulose produced by *A. xylinum* influences the linear growth rate of a fibril. The linear growth rate is basically influenced by the conditions of culture, mostly by the temperature of incubation and the pH of the medium.[3,6] The temperature of incubation greatly influences the linear growth rate. The growth rate is at its maximum (2.6 μm/min) at 28°C and lowers with a lowering of the temperature: 1.3 at 20°C, 0.39 at 10°C, and 0.27 at 5°C. The pH of the medium also much influences the linear growth rate. Under a constant temperature, the rate is at its maximum at pH 6.8 and is lowered to about 1/4 of the maximum at pH 5.5 and 7.7 respectively (see Fig. 1). This trend does not change even if the temperature of incubation is changed.

It is considered that the temperature of incubation influences not only the linear growth rate of a fibril but also the rate of crystallization of an amorphous fibril. The fibril made by the incubation under the most suitable culture conditions (28°C, pH 6.8) maintained an amorphous state for about 30 min after production. The uneven staining behavior of the fibrils could be observed about 1 h later, striations were found to run parallel to the long axis of the fibril about 3 h later, and microscopic fibrils were developed about 5 h after.[6] The microscopic fibril was already in a crystalline state.[10] The resistance to alkali of a fibril with uneven staining behavior showed Cellulose I crystalline.[10]

The fibrils made by incubation at 5°C could be stained homogeneously with sodium tungstophosphate over a long period (Fig. 2a). An uneven staining behavior of the fibril was found only after the 6-h incubation (Fig. 2b), and the microscopic fibrils were found in the fibril from the 12-h incubation (Fig. 2c). It became clear that the linear growth rate of a fibril became lower under the 5°C incubation and that the fibrillation of an amorphous cellulose also occurred more slowly than under the 28°C incubation.

Although the linear growth rate of a fibril is close to that of the 5°C incubation under the 10°C incubation, the rate of the fibrillation of an amorphous cellulose was close to that of the 28°C incubation. Striations were parallel to the long axis of a fibril in the fibril from the 3-h incubation at 10°C (Fig. 3a). The microscopic fibrils were found in the fibril from the 6-h incubation as is the 28°C incubation (Fig. 3b, c).

The influence of the temperature of incubation on the fibrillation is remarkable at 5°C. However, there was no difference in the influence at temperatures between 10°C and 28°C. Moreover, it is very interesting that the width of a microscopic fibril does not change with the temperature of incubation.

The linear growth rate could be lowered by changing the pH of the medium from pH 6.8, however, the rate of fibrillation was increased accordingly. In the case of the medium with a pH of 5.5, striations were distinctly found in the fibril from the 1-h incubation (Fig. 4a), and the microscopic fibrils were already found in the fibril from the 3-h incubation (Fig. 4b).

In the case of pH 7.7, the linear growth rate is near to that in the case of pH 5.5. Striations were also clearly found in the fibril from the 1-h incubated medium with a pH of 7.7 (Fig. 5a). The microscopic fibrils were found in the fibril from the 3-h incubation (Fig. 5b).

It became clear that the fibrillation became faster with a lowering of the linear growth rate by changing the pH at a constant temperature. The width of a microscopic fibril, however, was not influenced by the pH as it was in the case of the temperature.

The temperature of incubation and the pH of the medium influence the rate of fibrillation of an amorphous cellulose fibril, but they do not influence the width of a microscopic fibril developed in it later. These facts suggest that an amorphous fibril, when extruded from the cell, consists of the precursors of microscopic fibrils independent of each other. If an amorphous fibril after production is a mere assembly of cellulose sheets, the width of the microscopic fibril thus developed may differ from each other. However, the fact that the width of a microscopic fibril hardly changes suggests that the precursors of microscopic fibrils have structures which are able to join with each

other at its surface, but which can not gather to form a crystalline. The structure of the precursor of a microscopic fibril must be hereafter examined in more detail.

The relation between the crystallization of an amorphous fibril and its linear growth rate suggested by Brown *et al.*[9] could not found in this study. This problem must, therefore, be also studied hereafter in more detail.

Cadmium(II)-, Magnesium(II)-, and Zinc(II)-bearing Ferrites Formed from γ-FeOOH at Various Reaction pH's

Kazuo Ito,*,† Yutaka Tamaura, and Takashi Katsura
Department of Chemistry, Tokyo Institute of Technology Ookayama, Meguro-ku, Tokyo 152
(Received November 21, 1983)

The reaction of γ-FeOOH with the metal (Cd(II), Mg(II), or Zn(II)) and Fe(II) ions in solution gave the metal ion-bearing ferrites without oxidation. The ferrites obtained were the stoichiometric Mg(II)- and Zn(II)-bearing ferrites [$Mg_{0.27}Fe_{2.73}O_{4.00}$ (pH 10.6), $Zn_{0.38}Fe_{2.61}O_{4.00}$ (pH 10.5)] at pH 7.5—11.4, and the nonstoichiometric Cd(II)-bearing ferrites [$Cd_{0.19}Fe_{2.68}O_{4.00}$ (pH 10.2)] at pH 7.5—10.5 (25 °C). The Cd(II)- and Mg(II)-ion content in the ferrites increases with an increase in the reaction pH, but the Zn(II)-ion content is almost constant at pH 7.5—10.5. This pH dependence of the metal-ion content in the ferrites agrees with that of the fractional adsorption of these metals on γ-FeOOH. This suggests that only the adsorbed metal ions are incorporated into the ferrites. The pH dependence of these metal-ion contents in the air-oxidation reaction is also similar to that in the transformation reaction from γ-FeOOH. This transformation reaction seems to be one process in the air-oxidation reaction.

The formation of metal ion-bearing ferrites in solution by the air-oxidation of a $Fe(OH)_2$ suspension in the presence of other metal ions at temperatures above 60 °C has previously been studied.[1-11] The reaction pH affects the amount of metal ions incorporated into the ferrites.[5-7] Recently, we found that γ-FeOOH is transformed to Fe_3O_4 in the presence of the Fe(II) ion.[12,13] This transformation reaction is triggered by the adsorption of the Fe(II) ion on γ-FeOOH.[13] In the presence of Fe(II) and Zn(II) ions, γ-FeOOH is transformed to Zn(II)-bearing ferrites.[14] We proposed that the Zn(II) ions were adsorbed on γ-FeOOH and subsequently incorporated to form the Zn(II)-bearing ferrites.[14,15] It seems likely that any ferrite would be formed from γ-FeOOH in the presence of Fe(II) and other metal ions. In the present experiment, we have investigated the formation of Cd(II)-, Mg(II)-, and Zn(II)-bearing ferrites from γ-FeOOH at various reaction pH's; we will also discuss briefly the pH effect of the metal-ion contents in the ferrites, in relation to the adsorption of the metals on γ-FeOOH.

Experimental

Chemicals. All the chemicals used in the present work were of an analytical grade, and the chemical solutions were prepared by the use of distilled water. The NaOH solution was prepared by the use of distilled water through which nitrogen gas had been passed to remove any dissolved oxygen. The γ-FeOOH was prepared according to a method described previously.[13]

Apparatus. The reaction vessel which had been used in a previous paper was adopted.[1]

Procedure. After adding a M(II) (M=Cd, Mg, or Zn)-ion solution (0.02 dm^3, 0.27 mol/dm^3, pH 3.0) to the γ-FeOOH suspension (0.75 dm^3, pH 4.0), nitrogen gas was passed through for 2 h to remove any dissolved oxygen and carbon dioxide. $FeCl_2$ solution (0.02 dm^3, 0.54 mol/dm^3. pH 3.0) was then added to the suspension, and the pH was raised to the desired value. When the pH became the desired value (7.5—11.4), the reaction was initiated and the reaction pH became lower. The reaction pH was kept constant by adding an alkaline solution. During the reaction, nitrogen gas was passed through the suspension to prevent any oxidation reaction. After the reaction has continued for 60 h (25 °C), the reaction suspension was centrifuged at 4000 rpm under a nitrogen atmosphere. The precipitate was then washed with an acetate buffer solution (pH 4.1, 0.05 mol/dm^3) to isolate the products by dissolving the unreacted Fe(II) and M(II) ions. The precipitate was washed further with distilled water and then with acetone to remove the water as completely as possible. The washing water and acetone had been deaerated by passing nitrogen gas through to prevent oxidation. Finally, the precipitate was dried under a nitrogen atmosphere (room temperature). The products thus obtained were examined by means of X-ray diffractometry, IR spectroscopy, and Mössbauer spectroscopy.

Metal-ion Adsorption on γ-FeOOH. Into a 1.0-dm^3 polyethylene beaker, 0.8 dm^3 of a γ-FeOOH suspension containing the M(II) ion (iron of γ-FeOOH: 10 mmol, M(II)-ion concentration: 5×10^{-5} mol/dm^3, NaCl concentration: 6×10^{-5} mol/dm^3) was transferred. The suspension temperature was maintained at 25±0.2 °C, and nitrogen gas was passed through the suspension to remove the carbon dioxide and to stir the suspension. When the suspension pH became constant after adding an alkaline solution, 0.01 dm^3 of the suspension was taken out by means of a syringe and immediately filtered using a Millipore filter (pore size; 220 nm). The M(II)-ion concentration in the filtrate was measured by means of an atomic-absorption method (Varian Techtron, AA 875 type).

Chemical Analysis. The Fe(II) and Fe_{total} concentrations were determined by the 2,2'-bipyridyl method.[16] When the Fe_{total} was determined, the Fe(III) ion was reduced to the Fe(II) ion with hydroxylamine.

Results and Discussion

X-Ray Diffraction Patterns, IR and Mössbauer Spectra, Chemical Compositions and Lattice Constants. In the present study, the mole ratio among the Fe(II) ion, the M(II) ion (M=Cd, Mg, or Zn), and γ-FeOOH (as Fe) in the initial suspension was fixed at 1:2:2. This reaction was initiated by adding the Fe(II) ion. However, the reaction rate was extremely slow at pH values below 7, and no reaction at all occurred at pH values below 6.5. Therefore, in the present paper, no data will be given for pH values below 6. As has been reported previously,[13] the Fe(II) ion is adsorbed on γ-FeOOH at pH values above around 6.8, and the γ-FeOOH is transformed to Fe_3O_4 by the adsorption of the Fe(II) ion on γ-FeOOH. These results suggest that

†Present address: Toshiba Corporation, R & D Center, 1 Komukai, Saiwai-ku, Kawasaki 210

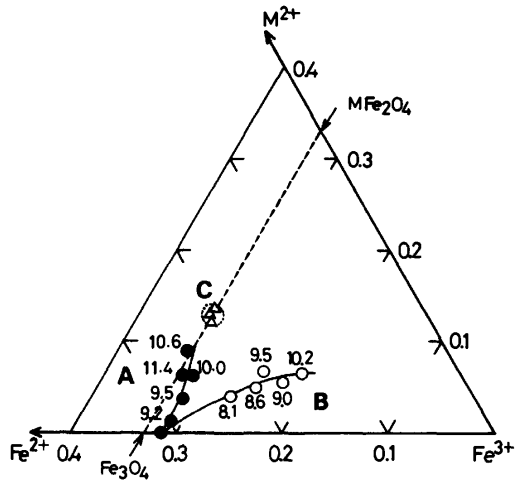

Fig. 1. Ternary diagram showing the chemical compositions of Mg(II)-bearing ferrites(A), Cd(II)-bearing ferrites(B), and Zn(II)-bearing ferrites(C). The values given at the points indicate the reaction pH. M^{2+} means the metal ions of Mg(II), Cd(II), or Zn(II).

the reaction in the present work also proseeds by means of the adsorption of the Fe(II) ion on γ-FeOOH. In the X-ray diffraction patterns of the products, only the peaks of the spinel-type compound appeared. In the IR spectra, no bands of γ-FeOOH or other iron (III) oxides were observed, but bands of ferrites were observed. These results indicate that the γ-FeOOH was completely transformed to ferrites. All the lines of the Mössbauer spectra were assigned to ferrites, as will be described below.

Figure 1 shows the chemical compositions of the ferrites formed at various reaction pH's. The values given at the points for Curves A and B are the reaction pH values. The small region denoted by C represents the chemical compositions of the Zn(II)-bearing ferrites. The Zn(II) ion contents in the ferrites remain nearly constant at various reaction pH values, and their compositions are included in the small region. The straight line (broken line) connecting Fe_3O_4 and MFe_2O_4 corresponds to the stoichiometric chemical compositions of M(II)-bearing ferrites ($M_{1-x}Fe_{2+x}O_4$). As can be seen from Fig. 1, the chemical compositions of the Zn(II)- and Mg(II)-bearing ferrites (A and C) are nearly stoichiometric, but those of the Cd(II)-bearing ferrites (B) deviate fairly much from stoichiometry [$Cd_{0.19}Fe_{2.68}O_{4.00}$ (pH 10.2)]. The deviation increases with an increase in the Cd(II)-ion content in the ferrite. This suggests that vacant sites of the Cd(II)-bearing ferrites increase with an increase in the Cd(II) content in the ferrites. The nonstoichiometric Cd(II)-bearing ferrites were also formed in the air-oxidation reaction,[6] so the Cd(II)-bearing ferrites seem to be oxidized easily. These may cause the nonstoichiometry of the Cd(II)-bearing ferrites. The relationship between the M(II)-ion content in the ferrites and the reaction pH will be described later.

Figure 2 gives the room-temperature Mössbauer spectra of the M(II)-bearing ferrites with the highest M(II)-ion content. Spectrum a corresponds to the Fe_3O_4 formed from γ-FeOOH. The spectra of the Fe_3O_4 and

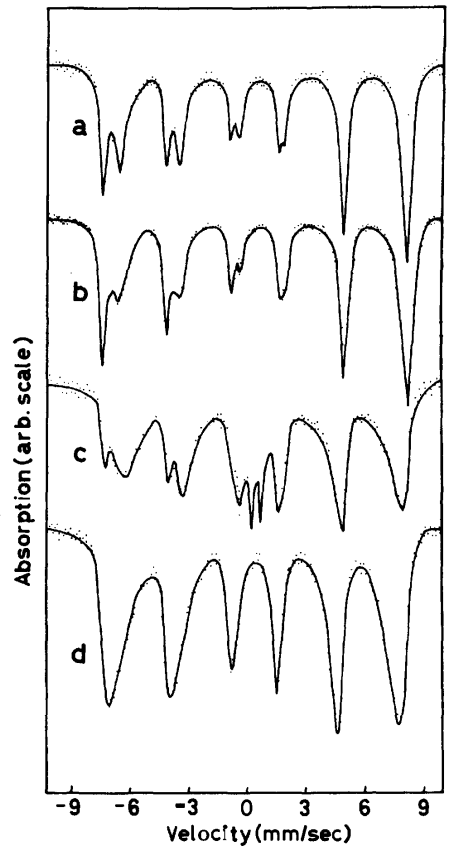

Fig. 2. Room temperature Mössbauer spectra of magnetite formed from γ-FeOOH(a), Mg(II)-bearing ferrite (b), Zn(II)-bearing ferrite (c), and Cd(II)-bearing ferrite (d). The chemical compositions of the ferrites are $Fe_{2.93}O_{4.00}$ (a), $Mg_{0.27}Fe_{2.73}O_{4.00}$ (b), $Zn_{0.38}Fe_{2.61}O_{4.00}$ (c), and $Cd_{0.19}Fe_{2.68}O_{4.00}$ (d) respectively.

the Mg(II)-bearing ferrites show two distinct hyperfine patterns; one is due to the tetrahedral Fe(III) ions (A site), and the other, to the octahedral Fe(III) and Fe(II) ions (B site). The line intensities at the B site for the Mg(II)-bearing ferrites are lower than those for the Fe_3O_4. This indicates that the Mg(II) ion is incorporated into the B site of the ferrites. The spectrum of the Zn(II)-bearing ferrite (Spectrum c) shows two broadened Zeeman patterns and a quadrupole doublet. Dobson *et al.*[17] reported that the Zn(II)-bearing ferrite ($Zn_{0.6}Fe_{2.4}O_{4.0}$) formed by a solid-state reaction had a similar pattern in its spectrum. The Zn(II)-bearing ferrites from γ-FeOOH seem to have the same ionic distribution as those produced by the soild-state reaction. The spectra of the Cd(II)-bearing ferrites (Spectrum d) show six broadened absorption lines. This broadening may come from the nonstoichiometry and/or the Cd(II)-ion incorporation into the spinel structure.

The lattice constant of the Zn(II)-bearing ferrite with the highest Zn(II) content in Fig. 1 ($Zn_{0.38}Fe_{2.61}O_{4.00}$) was 0.8416 nm. This higher value of the lattice constant than that of Fe_3O_4 (0.8397 nm)[18] confirms the incorporation of the Zn(II) ion into the lattice point by replacing the Fe(II) ion in Fe_3O_4 with the Zn(II) ion. The lattice constant of the Mg(II)-bearing ferrite with the highest Mg(II)-ion content in Fig. 1 ($Mg_{0.27}Fe_{2.73}O_{4.00}$)

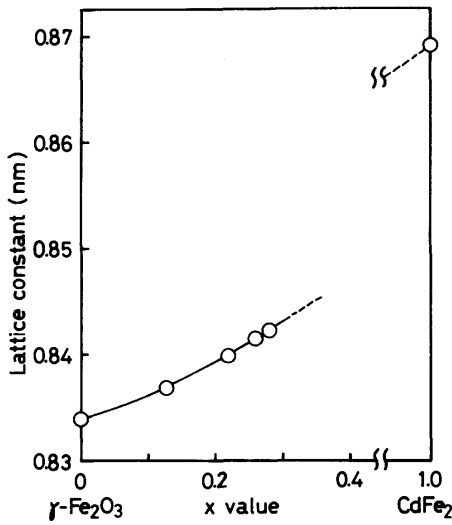

Fig. 3. The relationship between the lattice constants and the x values of the completely oxidized Cd(II)-bearing ferrites. The x values represent the mole ratio of $CdFe_2O_4$ to ($CdFe_2O_4$+γ-Fe_2O_3).

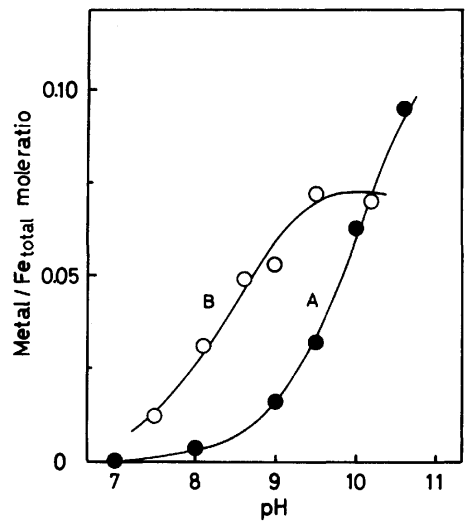

Fig. 4. pH dependence on the metal ion contents incorporated into Mg(II)-bearing ferrites (A) and Cd(II)-bearing ferrites (B).

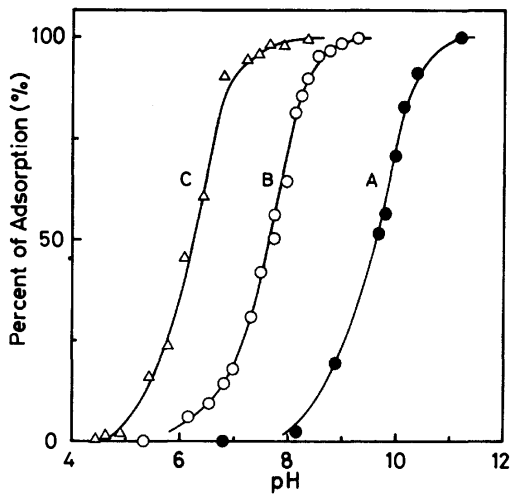

Fig. 5. Fractional adsorption of Mg(II) (A), Cd(II) (B), and Zn(II) (C) on γ-FeOOH as a function of pH.

was 0.8388 nm, slightly lower than that of Fe_3O_4. The lattice constant of $MgFe_2O_4$ (0.8387 nm)[19] is near to that of Fe_3O_4; therefore, the lattice constant probably is not so greatly changed by replacing the Fe(II) ion in Fe_3O_4 with the Mg(II) ion. The Cd(II)-bearing ferrites were nonstoichiometric; they formed a solid solution among Fe_3O_4, γ-Fe_2O_3, and $CdFe_2O_4$, so the lattice constant is determined by means of these three components. To simplify the analysis of the lattice constants, the component number of the nonstoichiometric Cd(II)-bearing ferrites in Fig. 1 was reduced to two (a solid solution between γ-Fe_2O_3 and $CdFe_2O_4$) by oxidizing the ferrites. The Cd(II)-bearing ferrites are readily oxidized at 150 °C for 2 d, since their particle size is small (100—200 nm). Figure 3 shows the relationship between the lattice constant and the mole fraction x of the $CdFe_2O_4$ component in the solid solution between γ-Fe_2O_4 and $CdFe_2O_4$. The lattice constant of γ-Fe_2O_3 and $CdFe_2O_4$ were determined by Schrader and Büttner[20] and by Roberts and Merwin[21] respectively. The lattice constants of the oxidized Cd(II)-bearing ferrites fall between those of γ-Fe_2O_3 and $CdFe_2O_4$. This confirms the incorporation of the Cd(II) ion into the lattice structure of the ferrites.

pH Effect of M(II)-ion Contents in Ferrites. Figure 4 shows the relationship between the Mg(II) and Cd(II) ion contents in the ferrites, and the reaction pH. As may be seen in Fig. 4, the Mg(II) (Curve A)- and Cd(II) (Curve B)-ion contents increase with an increase in the reaction pH. The Zn(II)-ion content remained almost constant, as has been mentioned above. Next, we compared this result (Fig. 4) with the adsorption of M(II) on γ-FeOOH at various pHs. Figure 5 shows the relationship between the fractional adsorption of M(II) and the solution pH. Curves A, B, and C are fractional adsorptions of Mg(II), Cd(II), and Zn(II) respectively. All of them increase from near nil to near 100% with an increase in the pH. The pH regions of the pH-adsorption edges (the sharp rise of the curves) for Zn(II), Cd(II), and Mg(II) increase in this order. Over the pH values from pH 7 to 11, where the ferrites are formed from γ-FeOOH, this adsorption behavior is quite similar to the incorporation profiles against the pH. The pH regions of the pH-adsorption edges fit those of the pH-incorporation edges for the Cd(II) and Mg(II) ions (Fig. 4). Measures, the adsorbed amount and the incorporated amount of Zn(II) both remain constant in this pH region. This strongly suggests that the metals are adsorbed on γ-FeOOH, and then subsequently incorporated to form the metal ion-bearing ferrites. The air oxidation of an $Fe(OH)_2$ suspension containing metal ions brings about the formation of the metal ion-bearing ferrites.[1-11] In previous reports,[12-15] we have suggested that the air-oxidation reaction involves a process in which the γ-FeOOH-layer is formed on the Fe_3O_4 by the oxidation of the adsorbed Fe(II) ion. The Fe_3O_4 particles will grow by the repetition of these processes during the air oxidation. When the other metal ion is present in the reaction suspension, the metal ion will be adsorbed along with the Fe(II) ion on the γ-FeOOH-layer, and the γ-FeOOH will be transformed into the metal

ion-bearing ferrites on the surface. For Cd(II), Mg(II), and Zn(II) ions, the pH dependence of their contents, as incorporated into the ferrites in the air-oxidation reaction[5-7], is very similar to the results in the present study (Fig. 4 and 5). These results suggest the validity of the above discussion.

Nitrogen-14 Magnetic Resonance Studies of the Exchange of Solvent Pyridine on Bis(β-diketonato)bis(pyridine)nickel(II) and -cobalt(II) Complexes

Seiko Ito[††] and Yoshiko Yano*,[†]

Institute of Chemistry, The University of Tsukuba, Sakuramura, Ibaraki 305

[†]*Laboratory of Chemistry, Wayo Women's University, Kohnodai Ichikawa, Chiba 272*

(Received December 26, 1983)

The analysis of linewidth and shift data of the nitrogen-14 magnetic resonance gave the following activation parameters for the exchange reaction of pyridine (py) on $CoA_2(py)_2$ (A=acac, tfa, and tta) and $Ni(acac)_2(py)_2$ with a pyridine molecule as bulk solvent: $\Delta H^{\neq}$=41.4, 51.1, 48.3, and 47.2 kJ mol^{-1}, $\Delta S^{\neq}$=18, 17, 3, and 10 JK^{-1} mol^{-1}, and k_1(298K)=2.9×10^6, 5.3×10^4, 2.9×10^4, and 1.3×10^5 s^{-1}. Here acac=acetylacetonate, tfa=trifluoroacetylacetonate and tta=thenoyltrifluoroacetonate. The electron-withdrawing power of substituent groups on the β-diketonate rings was correlated with more favorable activation of the exchange, that is, the stronger electron withdrawal causes less dissociative activation. This explains qualitatively even the negative $\Delta S^{\neq}$ values observed for similar pyridine exchange in the cases of $Co(hfa)_2(py)_2$ (hfa=hexafluoroacetylacetonate) and $Ni(tta)_2(py)_2$.

Exchange reactions of a coordinated solvent molecule (S) on bis(β-diketonato) complexes of Ni^{II} and Co^{II}(M), represented by Eq. 1, have been kinetically studied by several authors[1-7] using NMR techniques.

$$MA_2S_2 + S^* \longrightarrow MA_2SS^* + S. \quad (1)$$

In most of the cases, the exchange rates were discussed in terms of the nature of β-diketone rings; that is, electron-withdrawing substituents on the rings were shown to be a major factor retarding the exchange and the trend was described quantitatively by the Hammet equation. On the other hand, only a few attempts have been made[4-7] to clarify the reaction mechanism, mainly because observed activation parameters contained rather large uncertainties. The FT-NMR systems enables us to reduce the uncertainties originated from previous instrumental problems and ^{14}N NMR is more favorable; its advantage has already been pointed out.[8] In the present work, we first focus our attention on a series of bis(β-diketonato)cobalt(II) complexes in pyridine solvent, since ^{14}N NMR studies of an analogous series of Ni^{II} were already reported by Lincoln *et al.* using CW wideline spectrometer.[6] Nickel(II) complexes with acac and tta are also examined; the former is considered as a standard complex for comparison to other works. The tta complexes of both Co^{II} and Ni^{II} appear in similar solvent exchange studies.

Experimental

Materials. Anhydrous $M(acac)_2$ and $M(tta)_2$ were prepared by the method of Cotton *et al.*[9] or by a slightly modified version of it. $Co(tfa)_2(py)_2$ and $Co(hfa)_2(py)_2$ were obtained by repeated recrystalization of the corresponding diaqua complexes from pyridine solution. The values of chemical analysis of all products were in good agreement with the theoretical values. Pyridine used as a solvent was dried over pottasium hydroxide for several days and then doubly distilled in the presence of a small amount of suspended barium oxide. Deuterated pyridine was obtained in ampules from CEA France and an ampule was freshly opened just before each use,without any purification.

Solutions for NMR experiments were prepared under a nitrogen atmosphere by dissolution of complexes into pyridine which contained 13 v.% of pyridine-d_5. The concentration range of the paramagnetic ions was 0.01—0.15 mol dm^{-3}; this was quantitatively determined by EDTA titration. The water content of the solutions was found by the GC method[10] to be less than 2ppm, which means the content was negligible.

The electronic absorption spectra of the solution were recorded and the molecular weight measurements were carried out for the preliminary characterization of the solvated complexes in pyridine: a JASCO UVDEC-1 spectrometer and a Corona-117 apparatus for vapor pressure depression method were used.

NMR Measurements. A JEOL FX-90Q FT-NMR spectrometer operated at 6.42 MHz for ^{14}N was used in the ^{2}H lock mode. Typically,the free induction decay(FID) spectrum was accumulated over 1000 to 4000 pulses of 20 μs with a spectral width of 6 kHz. Since a WIND function was applied, linewidths of plotted spectra were necessarily corrected with subtraction by the corresponding broadening factors in Hz. The temperatures(−18—113 °C) were measured by using a copper-constantan thermocouple in a 10φ o.d. NMR tube with silicone oil before and after pulsing; while accumulation was being performed, temperature drift was monitored by a thermocouple installed inside JEOL temperature control unit; correspondence between temperature readings from two thermocouples had been investigated before accumulation. The accumulated FID's were used for data analysis only when the temperature deviation during the accumulations had been less than ±0.3 °C.

Results

Relaxation Data. The ^{14}N transverse relaxation time due to the interaction between pyridine solvent and a paramagnetic β-diketonato complex (T_{2p}) is defined as Eq. 2:

$$T_{2p} = (1/T_2 - 1/T_{2A})^{-1} P_m (1-P_m)^{-1}. \quad (2)$$

Here T_2 is the observed relaxation time of paramagnetic solution and T_{2A} is that of the pure solvent, both derived from the observed half-height widths in Hz, $W(=\pi^{-1}T_2^{-1})$ and $W_A(=\pi^{-1}T_{2A}^{-1})$. P_m is the mole fraction of the solvent in the first coordination sphere, assuming an additional coordination number of 2. The values of it were small enough in the present work to treat $(1-P_m)$ in Eq. 2 as 1. According to Swift and Connick,[11] T_{2p} can be represented in a reduced form as follows:

$$T_{2p}^{-1} = [\tau_m + \{\tau_m(\Delta\omega_m)^2\}^{-1}]^{-1} + (T_2^*)^{-1}. \quad (3)$$

[††]Present address: Seiko Nomura, Utsunomiya Kaisei Joshigakuin High-school, Utsunomiya, Tochigi 321-32

Here τ_m is the mean lifetime of coordinated pyridine and $\Delta\omega_m$ is the chemical shift in radian/s of ^{14}N of complexed solvent relative to free solvent.

$$\tau_m = h(k_B T)^{-1} \exp\{\Delta H^{\neq}(RT)^{-1} - \Delta S^{\neq} R^{-1}\} \quad (4)$$

$$\Delta\omega_m = (2\pi)^2 (A/h)\omega\mu_{eff}\mu_B\{S(S+1)\}^{1/2} T^{-1}(3k_B\gamma_N). \quad (5)$$

Here A/h is the scalar coupling constant, μ_{eff} the effective magnetic moment (3.13 and 4.82 BM for Ni and Co complexes), S the net electron spin of the paramagnetic ions, ω the radio frequency(Hz) of operation, k_B the Boltzman constant and γ_N the gyromagnetic ratio of ^{14}N; other symbols have their usual meanings. The first term of Eq. 3 is a reduced form of the full equation of Swift and Connick assuming that $\Delta\omega_m^2 \gg T_{2m}^{-2}$, τ_m^{-2}, in the relatively lower temperature range and that $\tau_m^{-2} \gg \Delta\omega_m^2 \gg (T_{2m}\tau_m)^{-1}$, in the higher temperature range, where T_{2m} is the relaxation time of ^{14}N in pyridine coordinated to M in the absence of chemical exchange. The former condition was experimentally confirmed by the constant chemical shift of the bulk pyridine peak. The latter was not sure since the pyridine peak was not recognized while coordinated to the paramagnetic ion, even at the lowest temperature, because of the small P_m and the broadening of the line. It seemed reasonable, however, that T_{2m} in pyridine case could be replaced by that in acetonitrile, which had been already found to meet the latter condition.[8] The T_2^* term of Eq. 3 is the additional contribution from the outer coordination sphere or the fast exchange region.

The circles in Figs. 1 to 6 are the observed T_{2p}'s and they are shown along with full lines of the computed best fits. The full lines in Figs. 2 and 3 were obtained by use of the SALS (Statistical Analysis with Least-Squares Fittings)[17] program applied to Eq. 3 in which $\Delta H^{\neq}$, $\Delta S^{\neq}$, and A/h were treated as parameters and the T_2^* term was ignored. In Figs. 1 and 5, SALS computation was first performed about the temperature range in which the T_2^* was negligible. The term was treated as an additional parameter which caused the deviation of the observed points; it affected the first term in brackets at the lowest temperature and/or $\tau_m(\Delta\omega_m)^2$ in the highest temperature range. In Figs. 4 and 6, only the τ_m term in brackets of Eq. 3 was used for the computation. The activation parameters and the A/h values obtained

from the computation are summarized in Table 1.

Shift Data. The chemical shift of the paramagnetic solutions is represented also in terms of τ_m, $\Delta\omega_m$, and T_{2m} by Swift and Connick.[11] Assuming the same two conditions as in the case of the T_{2p} data analysis, Eq. 6 can be derived:

$$S_p = (S-S_0)P_m^{-1} = -(\Delta\omega_m/2\pi)\{1+(\Delta\omega_m\tau_m)^2\}^{-1}. \quad (6)$$

Here S(in Hz) is the observed chemical shift of the paramagnetic solution and S_0(in Hz) is that of the pure solvent. The observed shift data of the present systems are illustrated in Figs. 7 and 8 along with the calculated one(full lines in the Figs.). The latter were obtained from Eq. 6 by using the results of the relaxation data analysis already mentioned. The agreement between them indicated the validity of the relaxation data analysis again. The dashed lines denote cases in which the prediction by Eq. 6 was impossible, since the relaxation data lacked any contribution from the $\tau_m(\Delta\omega_m)^2$ term. (See Figs. 4 and 6.)

It should be noted that A/h values could be also obtained, roughly but absolutely independently from the relaxation data, from the observed S_p values. In the Figs. 7 and 8, the values of S_pT on the ordinate become constant as the temperature approaches the highest values, except in Co(hfa)$_2$(py)$_2$ and Ni(tta)$_2$(py)$_2$ cases. The constant values must be $-\Delta\omega_m T/2\pi$. That is because the $(\Delta\omega_m\tau_m)^2$ term in the Eq. 6 was negligible at temperature high enough for τ_m to be very small. A/h values were, therfore, derived from Eq. 5; they are shown in parentheses in Table 1.

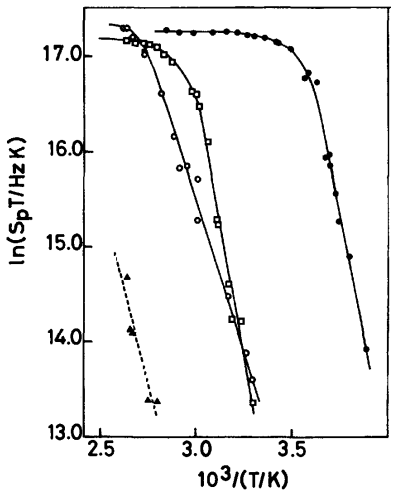

Fig. 7. Temperature dependence of the shift for the pyridine solutions containing Co(II) complexes.

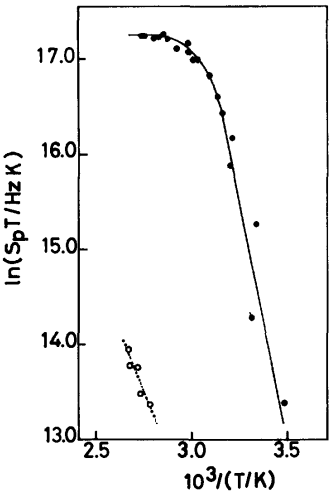

Fig. 8. Temperature dependence of the shift for the pyridine solutions of Ni(II) complexes.

In the case of either $Co(hfa)_2(py)_2$ or $Ni(tta)_2(py)_2$, A/h was only estimated from the observed S_p and the τ_m value derived from the relaxation data, by the use of Eq. 6. The results are shown in brackets in Table 1.

Discussion

Table 1 reveals that the pyridine exchange is retarded by electron-withdrawing substituents of chelate rings, which can be described by the Hammett equation:[1] $\log(k/k_0)=\rho\sigma$, where σ is the sum of the Taft σ^* parameters for the substituents of β-diketons. The trend is consistent with other authors' observations.[1,2,6] The σ^* values of tta was obtained by interpolation of the present observations, resulting in the value of 0.9 for σ^* of thienyl group. This seems quite suitable,in comparison with the value of 0.6 of the phenyl group.

The $\Delta S^{\neq}$ values listed in Table 1 suggest that, among a series of β-diketonato complexes of the metals, the electron-withdrawing power of the substituents have an effect also on the activation mechanism of the pyridine exchange. The stronger electron withdrawal causes the lower electron density within a chelate ring and the larger effective oxidation number of a central metal. It is reasonable in an activated state that the central metal with a larger effective oxidation number would interact with both leaving and entering pyridine molecules to form virtually two bonds. This case might be called an "associatively" activated mechanism. When the effective oxidation number is much smaller, the interaction between the central metal and any leaving or entering solvent is weak enough to lead all the present complexes, except $Co(hfa)_2(py)_2$ and $Ni(tta)_2(py)_2$, to dissociative activation. It should be noted here that actual activated states cannot be clearly visualized as either associative(ly) or dissociative. There might be possibilities of β-diketonates as unidentate ligands at an activated state and/or of a *trans-cis* equiliblium with their mutual conversion. A straight comparison, therefore, between the cases of simply solvated ions by six solvent molecules[13,14] and the present case is of little significance.

Taking into account the fact that the $\Delta H^{\neq}$ values reflect the crystal field theory activation energies (C.F.A.E),[15,16] the $\Delta H^{\neq}$ values in Table 1 support partly the trend of the activation mechanism already suggested by the $\Delta S^{\neq}$ values. The smaller effective oxidation number of a central ion causes the smaller C.F.A.E., assuming a dissociatively activated state. Assuming an associatively activated one, the circumstances are exactly the reverse. (The smaller C.F.A.E. must be the reflection of either the easier bond rupture or the more difficult bond formation.) In the actual series of Co complexes, the acac complex has a smaller $\Delta H^{\neq}$ compare to the tfa analogue, which has a larger effective oxidation number. This behavior is consistent with their dissociative activations predicted by $\Delta S^{\neq}$ values. That the $\Delta H^{\neq}$ value of the hfa analogue is smaller than the tta one can be explained as follows: The activation mechanism of the former complex is associative and that of the latter has a transient feature. They are consistent with what the $\Delta S^{\neq}$ values suggested. Furthermore, the differences in the $\Delta H^{\neq}$ values between $Co(acac)_2(py)_2$ and the Ni analogue and between $Co(tta)_2(py)_2$ and its Ni analogue are roughly parallel to C.F.A.E. calculated by Basolo and Pearson,[15] assuming a trigonal bipyramidal five coordinate and an octahedral wedge seven coordinate transition state.

Since it proved significant that solvent molecules interact with the effective charge of a central metal ion, not only the nature of the ligand but also the basicity of the solvents should be one of the alternate factors to predict the nature of activation. Trimethyl phosphate seems suitable as a solvent with small basicity and enough affinity to solvate to bis(β-diketonato) complexes in the present work. In any case, even a strong electron-withdrawing substituent induces an effective charge on a central ion which is not large enough to cause "associative" activation. A precise report will be submitted soon.

The authors wish to thank Prof. Kozo Nagashima of Institute of Chemistry, The University of Tsukuba, for his continuing support and encouragement during the course of this work. Thanks are also due to Mr. Hideto Suzuki and Dr. Shigeo Tanuma for their assist-

ance in instrumental problems and in computing.

Thermal Square Planar-to-octahedral Transformation of Nickel(II) Complexes Containing 1,2-Diphenyl-1,2-ethanediamine in the Solid Phase

Yoshinori IHARA* and Ryokichi TSUCHIYA†

Laboratory of Chemistry, Faculty of Education, Kanazawa University, Kanazawa 920

†*Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920*

(Received January 5, 1984)

The following ten nickel(II) complexes with *meso*- or *dl*-1,2-diphenyl-1,2-ethanediamine (abbreviated as *meso*-stien and *dl*-stien, respectively) were prepared, and their thermal behavior was investigated in the solid phase: $[Ni(meso\text{-stien})_2]X_2$ (X=Cl, Br, I, NO_3, or ClO_4), $[Ni(dl\text{-stien})_2]X_2$ (X=I or ClO_4), and $[Ni(H_2O)_2(dl\text{-stien})_2]X_2$ (X=Cl, Br, or NO_3). The square planar bis(*dl*-stien) complex chloride, bromide, and nitrate obtained by thermal dehydration of their respective octahedral diaqua complexes were found by various techniques to be transformed, upon further heating, to the octahedral diacido bis(*dl*-stien) complexes. The complexes containing *dl*-stien have a stronger tendency to show such structural transformations than those containing *meso*-stien. The reason for this difference is discussed.

Nickel(II) ion forms complexes with various structures, *e.g.* octahedral, tetrahedral, and square planar, depending upon the nature of the ligands, and mutual transformation among these structures often occurs in solution.[1,2] Up to the present, however, a few studies[3-5] have dealt with the thermal reaction of octahedral diaqua complexes, $[Ni(H_2O)_2(diamine)_2]X_2$, in the solid phase. These complexes were found to lose $2H_2O$ upon heating to form either square planar bis-diamine complexes by mere deformation or octahedral diacido complexes by anation of counter ions.

An interesting example of thermal transformation from the square planar to the octahedral geometry was found in the anation of $[Ni(bimd)_4](NO_3)_2 \cdot 2.5C_2H_5OH$, where bimd denotes benzimidazole.[6] Similar transformations were also reported for the nickel(II) complexes with 2-aminobenzimidazole[7] and 2,3-butanediamines.[8] The purpose of the present study is to find whether or not the nickel(II) complexes with stien undergo the thermal square planar-to-octahedral transformation in the solid phase depending upon the structure of stiens and counter anions. Another purpose is to confirm the stronger tendency toward the transformation of the complexes with *dl*-stien than those with *meso*-stien, which was found for the complexes of *dl*- and *meso*-2,3-butanediamine.[8]

Experimental

Preparation. The ligands, *meso*-stien and *dl*-stien, were obtained by the methods described in the literature.[9,10] Aqueous solutions of nickel(II) chloride, bromide, iodide, nitrate, or perchlorate were added to ethanolic solutions of the ligands in the molar ratio of 1:2 to prepare the desired bis-type complexes. The resulting yellow or violet crystals were collected by filtration and washed with ethanol and diethyl ether. The formulas determined by elemental analyses and also by spectral and magnetic measurements (Table 1) are as follows: $[Ni(meso\text{-stien})_2]X_2$ (X=Cl, Br, I, NO_3, or ClO_4), $[Ni(dl\text{-stien})_2]X_2$ (X=I or ClO_4), and $[Ni(H_2O)_2(dl\text{-stien})_2]X_2$ (X=Cl, Br, or NO_3).

Measurements. Simultaneous TG and DSC measurements were carried out with a Rigaku Denki standard TG-DSC apparatus under a constant flow of nitrogen. The heating rates and amounts of samples used are given in Fig. 1. The complexes shown in Table 2 were obtained by isothermal heating at the temperatures corresponding to the respective DSC peaks.

The electronic spectra in the solid phase were measured by the diffuse reflectance method on a JASCO UNIDEC-410 spectrophotometer. The effective magnetic moments were evaluated from the susceptibilities measured by Gouy's method at room temperature.

Results and Discussion

Thermal Analyses. Of the ten complexes studied, all the yellow *meso*-stien complexes, and *dl*-stien iodide and perchlorate, did not show expected color changes. Heating of the remaining three diaqua complexes, however, led to an irreversible thermochromism consisting of two steps from violet to blue through yellow before decomposition.

The results of the simultaneous TG-DSC measure-

a) Calculated values are in parentheses.

ments are shown in Fig. 1. The weight losses in TG curves correspond to two moles of coordinated water (obsd 6.06%, calcd 6.10% for chloride; 4.11%, 5.31% for bromide; and 5.85%, 5.60% for nitrate). The dehydration proceeds endothermically; thereafter, a small endothermic peak appears at 145 °C, 150 °C, and 170 °C for the chloride, bromide, and nitrate, respectively, without any change in TG curves. The yellow complexes obtained by the loss of the coordinated water were converted to blue after the second endothermic peaks, which indicated the thermochromism from violet to blue through yellow.

Cooling of the blue products did not cause the reverse color change. However, the yellow products absorbed water molecules relatively easily in the coordination sphere, and after cooling and standing in the air for several hours, they changed completely to the original octahedral complexes. This change was confirmed by the data of elemental analyses, electronic spectra, and magnetic moments.

The exothermic peak observed only for the chloride at 172 °C did not seem to correspond to a fundamental structural change, because the complex did scarcely show any color change, and the IR spectra measured at 165 °C and 180 °C, *i.e.* before and after the peak, were

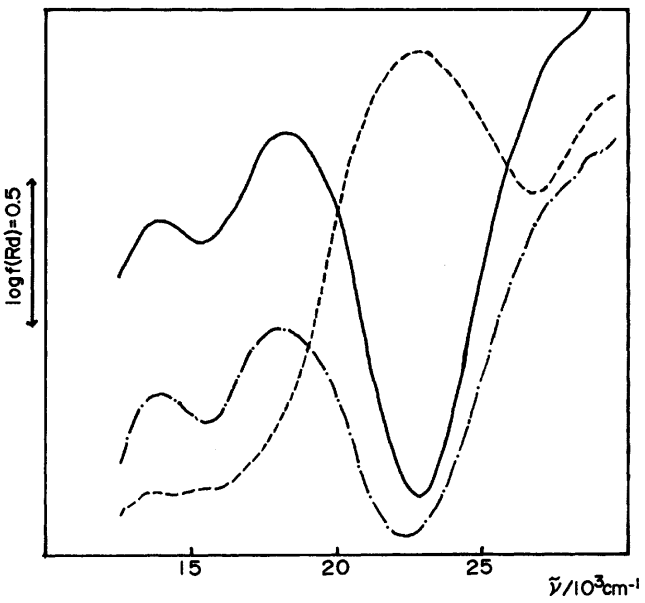

Fig. 2. Electronic spectra of $[Ni(H_2O)_2(dl\text{-stien})_2]Br_2$ before heating (——) and after heating at 120 °C (------) and at 170 °C (—·—).

TABLE 3. THE ENTHALPY CHANGES AND INITIATION TEMPERATURES OF THE SQUARE PLANAR-TO-OCTAHEDRAL TRANSFORMATION

X\NN	*dl*-stien	*meso*-bn[8]	*dl*-bn[8]
Cl	4.1 kJ/mol 145 °C		17.6 kJ/mol 159 °C
Br	2.4 kJ/mol 150 °C		16.0 kJ/mol 175 °C
NO_3	10.0 kJ/mol 170 °C	9.7 kJ/mol 188 °C	

nearly the same.

Electronic Spectra. The electronic spectra corresponding to the color change of the solid bromide upon heating are shown in Fig. 2. The spectral data are summarized in Table 2, together with the magnetic moments and analytical data.

The blue product has a spectral pattern identical with that of the original octahedral structure. On the other hand, the pattern of the yellow product, which is completely different from others, coincides with that of characteristic square planar nickel(II) complexes which have usually a broad and strong absorption band in the same frequency region. The chloride and nitrate show similar changes in the absorption spectra (Table 2).

Magnetic Moments. The yellow products are diamagnetic, whereas the blue products paramagnetic (3.22—3.33 BM). These facts, together with the above absorption spectral data, suggest that the yellow and blue products are the square planar and octahedral complexes, respectively. The stepwise thermochemical changes observed for the three diaqua *dl*-stien complexes are represented by the following scheme:

$$[Ni(H_2O)_2(dl\text{-stien})_2]X_2 \xrightarrow[\Delta]{-2H_2O} [Ni(dl\text{-stien})_2]X_2 \xrightarrow[\Delta]{}$$

$$[NiX_2(dl\text{-stien})_2] \quad (X=Cl, Br, \text{or } NO_3)$$

Comparison with the Butanediamine Complexes. In Table 3 the enthalpy changes and the initiation temperatures of the square planar-to-octahedral transformation estimated from the DSC peaks are compared with those of the corresponding 2,3-butanediamine (bn) complexes. The blank space in the Table means the absence of the transformation. The data show that the heat required to cause the transformation is smaller for the stien complexes than for the bn complexes.

In conclusion, the present study confirmed the stronger tendency of the complexes containing the *dl*-form toward the square planar-to-octahedral transformation than those of the *meso*-form. It was also found that the smaller anion is more advantageous for the configurational change, *i. e.* the order, $Cl^->Br^->I^-$ holds for the complex halides.

The nitrate complexes seem to have a somewhat higher inclination to cause the transformation irrespective of the ligand configuration (*meso*- or *dl*-), as was recognized for benzimidazole[6] and 2-aminobenzimidazole.[7] Additional stabilization due to the formation of hydrogen bonding between nitrate ion and diamines during the thermal structural change seems to be a plausible reason for the special property of the nitrate complex.

The discussion developed in the preceding paper[8] can be applied similarly to the difference in reactivity between the *meso*- and *dl*-stien complexes. In the *dl*-stien complexes containing two moles of stien with a square planar structure, four phenyl groups are able to occupy the equatorial positions, whereas for the *meso*-stien complexes at least two of four phenyl groups are forced to occupy the axial positions. The latter conformation will make the apical approach of the counter ion to the central metal ion difficult because of the steric hindrance.

Recovery of Heavy Metals with Calcium Silicon Alloy. III. Stoichiometric Discussion on the Reduction of Copper(II) Ions

Shuzo TOKUNAGA
National Chemical Laboratory for Industry, Yatabe, Ibaraki 305
(Received February 10, 1984)

For the reduction of Cu^{2+} ions with Ca-Si alloy in aqueous solutions, the following elementary reactions were postulated:

$$Ca^0+Cu^{2+}=Ca^{2+}+Cu^0, \quad (1)$$
$$Ca^0+2H_2O=Ca^{2+}+H_2+2OH^-, \quad (2)$$
$$Si^0+2Cu^{2+}+3H_2O=H_2SiO_3+2Cu^0+4H^+, \quad (3)$$
$$Si^0+3H_2O=H_2SiO_3+2H_2. \quad (4)$$

From these reactions, amounts of Si^{IV} species were estimated by using those of H_2 and increments of H^+ ions. Total equivalents of the reduction products showed good agreement with those of the oxidation products, indicating the validity of the elementary reactions. The remained problems of the stoichiometric disagreement and the phenomenon of pH decrease indicated in Part II could be solved by using these elementary reactions. At the beginning of the reaction, a small amount of Cu^+ ions formed. Decomposition of water occurred subsequently to the Cu^{2+} reduction. A contribution of Si^0 to the reaction became greater than that of Ca^0 at higher Cu^{2+} concentrations than *ca.* 10 matom dm^{-3}. Thus, it proved that Si^0 in the alloy exhibits a great reducing effect.

Various metal ions having high standard electrode potentials are reduced effectively with Ca-Si alloy.[1-3] In Part II,[3] discussions were made on the reduction of Cu^{2+} ions about the reaction rate and the effects of acids, salts, and other metal ions. The following phenomena have remained uninterpreted. At lower Cu^{2+} concentrations than 5 matom dm^{-3}, equivalents of Cu^{2+} ions reduced well accounted for total equivalents of Ca^{II} and Si^{IV} species dissolved in the solution, and the pH tended to increase as the reaction proceeded. On the other hand, at higher Cu^{2+} concentrations, the equivalents of Cu^{2+} ions reduced became considerably greater than the total equivalents of Ca^{II} and Si^{IV} species dissolved in the solution, and the pH decreased from 4 to 2 or lower. The objectives of the present study are to solve these problems and, at the same time, to elucidate the mechanism of the whole reaction inclusive of decomposition of water as a side reaction. To this end, potential elementary reactions were postulated basing on the observed phenomena, and stoichiometric discussions were made on the reaction products.

Experimental

One dm^3 of *ca.* 2.5—40-matom dm^{-3} Cu^{2+} solutions was prepared and the pH was adjusted to 4.0 with HCl or NaOH. The sample solution was placed in a 25 °C thermostat. Prior to a run, nitrogen was bubbled thoroughly to purge dissolved oxygen. To the solution was added 3.0 g of Ca-Si alloy powder, and nitrogen bubbling and magnetic stirring were continued. An aliquot of the solution was taken at intervals and filtered quickly under reduced pressure through a membrane filter 0.30 μm in pore size. Then, analyses were made on the filtrate. The increment of H^+ or OH^- ions was determined by titration with either *ca.* 0.01-mol dm^{-3} standard NaOH or HCl solution, respectively. Cu^+ ions were determined by colorimetry with Bathocuproinesulfonate (disodium 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline-disulfonate).[4] Cu^{2+} and Ca^{2+} ions and dissolved silicate were determined in the same way as reported previously.[3] Separately, similar runs were made in a closed system to determine the volume of H_2 being collected in a graduated cylinder. The same materials were used as those in the previous report.

Results and Discussion

Postulation of Elementary Reactions. On adding Ca-Si alloy, Cu^{2+} ions are reduced effectively and recovered entirely from the solid phase as Cu^0. At the beginning of the reaction, a small amount of Cu^+ ions form. At the same time, decomposition of water occurs generating H_2. On the other hand, the alloy is oxidized to form Ca^{II}, Si^{IV} species, H^+, and OH^- ions in the solution.

It was indicated previously that, at high Cu^{2+} concentrations, equivalents of Cu^0 were greater than the total equivalents of Ca^{II} and Si^{IV} species dissolved in solution. The main causes of such disagreement are considered to be the neglect of effects of water decomposition and the possibility of existence of oxidation products (Ca^{II} and/or Si^{IV} species) also in the solid phase. For the former cause, H_2 and the increment of H^+ or OH^- ions were determined in the present study. As for the latter, their existence was not recognized in the X-ray diffraction pattern of the solid product. There is little possibility of formation of insoluble amorphous calcium silicate under the present experimental conditions of low pH (4—2 or lower). Consequently, Ca^{II} species exists entirely in the dissolved form, Ca^{2+} ions. The IR absorption spectrum of the solid products showed a broad and strong absorption band in the wave number range from *ca.* 900 to 1350 cm^{-1}. It is characteristic of amorphous silica, and was not found in the spectrum of the original alloy. It is, therefore, necessary to take into account the amount of silica present in the solid phase for the stoichiometric discussion. However, it was practically impossible to determine its amount at the time of interruption of the reaction by solid-liquid separation, since oxidation of unreacted alloy by water proceeded under the wet condition even after the separation.

Then potential elementary reactions were postulated on the basis of the observed phenomena, and are shown in Fig. 1. The elementary reactions are composed of reduction of Cu^{2+} ions and decomposition of water

$$Ca^0 + Cu^{2+} = Ca^{2+} + Cu^0 \quad (1)$$
$$a \qquad\qquad a \quad a$$
$$Ca^0 + 2H_2O = Ca^{2+} + H_2 + 2OH^- \quad (2)$$
$$b \qquad\qquad b \quad b \quad 2b$$
$$Si^0 + 2Cu^{2+} + 3H_2O = H_2SiO_3 + 2Cu^0 + 4H^+ \quad (3)$$
$$c \qquad\qquad\qquad\qquad c \quad 2c \quad 4c$$
$$Si^0 + 3H_2O = H_2SiO_3 + 2H_2 \quad (4)$$
$$d \qquad\qquad d \quad 2d$$

Fig. 1. Elementary reactions and stoichiometric relations for the reduction of Cu^{2+} ions with Ca-Si alloy in aqueous solution.

by Ca^0, reactions 1 and 2 respectively, and of Cu^{2+} reduction and water decomposition by Si^0, reactions 3 and 4 respectively. In reaction 3, Si^0 is oxidized to form silicic acid, when decomposition of water occurs inevitably to form H^+ ions. This can interpret the unsolved phenomenon of decrease in pH accompanying the reduction of Cu^{2+} ions. Silicic acid may exist in other forms, which can be ignored in the stoichiometric discussion. Reduction of one atom of Si^0 always results in formation of four H^+ ions. Part of silicic acid forming in reactions 3 and 4 exists in the form of amorphous silica in the solid phase. In addition, there exist consecutive reactions $Cu^{2+}+e=Cu^+$ and $Cu^++e=Cu^0$ in the initial stage of the reaction. For the sake of simplification, these elementary reactions were discussed stoichiometrically at the time when the reduction of Cu^{2+} ions to Cu^0 had been complete.

In these elementary reactions, Ca^{2+} and H_2 can be determined directly. The increment of either H^+ or OH^- ions can be determined by neutralization titration. The amount of Cu^0 can be estimated from residual Cu^{2+} concentration. Then the total amount of Si^{IV} species forming in both liquid and solid phases at the time of the interruption of the reaction was estimated by using amounts of other determinable components dissolved in the solution as follows: Let a and b be numbers of atoms of Ca^0 oxidized in reactions 1 and 2, respectively. And let c and d be those of Si^0 in reactions 3 and 4, respectively. Then, we get

$$a + b = Ca^{2+},$$
$$a + 2c = Cu^0,$$
$$b + 2d = H_2,$$
$$4c - 2b = \Delta H^+ \text{ (or } -\Delta OH^-).$$

Solving these equations for Si^{IV}, we get

$$Si^{IV} = c + d = 1/2H_2 + 1/4\Delta H^+ \text{ (or } -1/4\Delta OH^-).$$

Unfortunately, a, b, c, and d cannot be determined individually by this method. But it became possible to discuss the whole reaction only with the reaction products in the solution and H_2.

Stoichiometric Discussion. The validity of these deductions was examined by comparing the total equivalents of the reduction and oxidation products of *ca.* 2.5—40-matom dm^{-3} Cu^{2+} solutions. Values at the time when the Cu^{2+} reduction was almost complete (*ca.* 3—8 min after the alloy addition) were used in order to minimize the effects of water decomposition and to exclude those of Cu^+ formation. Equivalents of Ca^{2+} and Si^{IV} as the oxidation products and the total of both values are plotted against total equivalents of Cu^0 and H_2 as the reduction products in Fig. 2. In addition, equivalents of H_2 are plotted to show the degree of water decomposition. The results show that the total of the found Ca^{2+} and the calculated Si^{IV} values are approximately on a straight line with a slope of 1.0 passing the origin 0. This indicates the validity of postulated elementary reactions 1—4, and consequently that of estimation of the amount of Si^{IV}. Thus, the remained problems of stoichiometric disagreement and pH decrease phenomenon are solved. The stoichiometric agreement at low Cu^{2+} concentrations in the previous study may be due to entire dissolution of Si^{IV} species and little water decomposition. It has been considered that Cu^{2+} ions are reduced mainly by Ca^0. But, as a matter of fact, the contribution of Si^0 to the reduction was greater than that of Ca^0 at high Cu^{2+} concentrations. It was very small at 2.5 matom dm^{-3} but increased linearly with the amounts of reduction. On the other hand, the contribution of Ca^0 became small relatively at high reduction values, where Ca^0 in the alloy was mostly consumed. Thus, it proved that Si^0, practically an inactive element due to passivation by silica film on the surface, exhibits its original strong reducing power in Ca-Si alloy when the fresh surface appears after dissolution of Ca^0. Proportion of H_2 in the reduction values became smaller at higher values, indicating that the alloy was used more effectively for the reduction of Cu^{2+} ions.

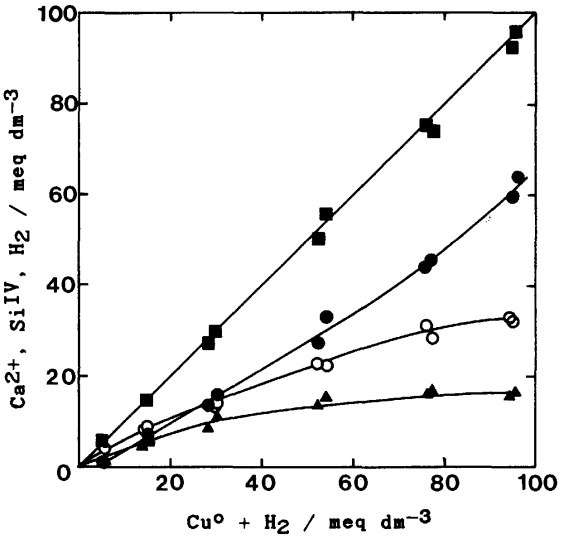

Fig. 2. Relation between equivalents of reduction products (Cu^0 and H_2) and oxidation products (Ca^{2+} and Si^{IV}).
O: Ca^{2+}, ●: Si^{IV}, ■: $Ca^{2+}+Si^{IV}$, ▲: H_2.

Behavior of Reaction Products. In order to know the whole aspect of the reaction, behavior of all the products was studied with the 10.0-matom dm^{-3} Cu^{2+} solution. Concentrations of the products in meq dm^{-3} are plotted in Fig. 3 against the time after addition of the alloy. At the beginning of the reaction (after *ca.* 1.5 min), pH decreased from 4.0 to 2.2 because of formation of H^+ ions in the reduction of Cu^{2+} ions

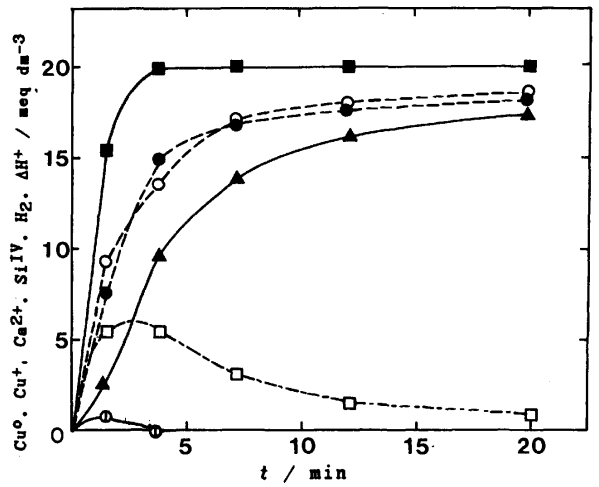

Fig. 3. Behavior of the reaction products in the reduction of 10.0-matom dm^{-3} Cu^{2+} solution.
■: Cu^0, Φ: Cu^+, ○: Ca^{2+}, ●: Si^{IV}, ▲: H_2, □: ΔH^+.

by Si^0. Then, *ca.* 0.8 and 2.3 matom dm^{-3} of Cu^+ and Cu^{2+} ions, respectively, were found in the solution. The remainder of copper species was recovered from the solid phase as Cu^0. According to Charlot,[5] the reduction process of Cu^{2+} to Cu^0, potentially including formation of Cu^+ species, is subject to pH value and the concentration of Cl^- ion. Therefore, the details of the reduction process of Cu^{2+} through Cu^+ are unknown with the present data. After *ca.* 4 min, the Cu^{2+} reduction was almost complete when Cu^+ and Cu^{2+} ions were undetectable in the solution. The reduced Cu^{2+} was entirely recovered from the solid phase.

Decomposition of water proceeded almost simultaneously with the Cu^{2+} reduction, and became slow in rate after completion of the Cu^{2+} reduction. A considerable amount of alloy was consumed in the decomposition of water. Calculated values of Si^{IV} species were much greater than those found in the solution. Ca^0 and Si^0 exhibited almost similar contribution to the entire reaction. After *ca.* 4 min, the increment of H^+ ions decreased because of completion of Cu^{2+} reduction by Si^0 and because of formation of OH^- ions in the decomposition of water by Ca^0.

(Received February 13, 1984)

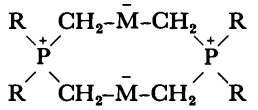
The reactions of methylenetriphenylarsorane, $(C_6H_5)_3As{=}CH_2$ (**L**), with $ZnCl_2$ or $HgCl_2$ in the mole ratio 2:1 yield new monomeric compounds of bis(methylenetriphenylarsorane)metal dichloride, $[(C_6H_5)_3AsCH_2\text{-}M\text{-}CH_2As(C_6H_5)_3]Cl_2$. The reactions of **L** with $BeCl_2$ or $MgCl_2$ in the mole ratio 2:2 yield dimeric trigonal compounds of di-μ-chloro-bis[(methylenetriphenylarsorane)metal] dichloride, $[(C_6H_5)_3AsCH_2\text{-}M\langle^{Cl}_{Cl}\rangle M\text{-}CH_2As(C_6H_5)_3]Cl_2$. The reactions of **L** with $AlCl_3$ or $InCl_3$ in the mole ratio 4:2 yield dimeric tetrahedral compounds of di-μ-chloro-bis[bis(methylenetriphenylarsorane)metal] tetrachloride, $[\{(C_6H_5)_3AsCH_2\}_2\text{-}M\langle^{Cl}_{Cl}\rangle M\text{-}\{CH_2As(C_6H_5)_3\}_2]Cl_4$. The reactions of **L** with $(C_6H_5)_3MCl$ (M: Sn and Pb) in the mole ratio 1:1 yield new monomeric compounds of (methylenetriphenylarsorane)triphenyl-metal chloride, $[(C_6H_5)_3AsCH_2\text{-}M(C_6H_5)_3]Cl$. They are thermally stable complexes and their properties are compared with those of the methylenetriphenylphosphorane metal compounds.

A previous paper,[1] in this series, was concerned with the preparation and properties of Cu, Ag, Au, Zn, Cd, Hg, Ge, Sn, Pb, Pd, and Pt complexes with methylenetris(dimethylamino)phosphorane, $(Me_2N)_3P{=}CH_2$.

Many investigations of organometallic compounds between unstable phosphonium ylides and metals have been reported concerning their preparation, structure, general properties, stability and NMR spectra. The metal compounds with methylenetriphenylphosphorane, $(C_6H_5)_3P{=}CH_2$, have a linear structure,[2-7] *e.g.*,

$$[(C_6H_5)_3\overset{+}{P}CH_2\text{–}\overset{-}{M}\text{–}CH_2\overset{+}{P}(C_6H_5)_3]Cl^- \quad (M: Cu, Ag, Au).$$

On the other hand, the metal compounds with methylenetrimethylphosphorane, $(CH_3)_3P{=}CH_2$, and the related phosphoranes, $R_2(CH_3)P{=}CH_2$ (R: C_2H_5, C_6H_5), are cyclic[8-21] such as



(M: Cu, Ag, Au).

The cyclic structure compound is formed by a rapid intermolecular proton exchange[22] of the phosphoranes.

In the arsenic ylide series, many researchers tried to isolate methylenetriphenylarsorane, $(C_6H_5)_3As{=}CH_2$.[22-25] However, it was not isolated until 1975,[26] because of its sensitivity to air, water, and temperature. Even now, the investigation of organometallic compounds with methylenetriphenyl(or trimethyl)arsorane is limited to the Cu, Ag, Au compounds.[3,28-30] Very little is known of the physical properties and general chemistry of the arsorane metal compounds, in contrast to the information on phosphorane metal compounds. The present paper deals with the preparation and properties of bis(methylenetriphenylarsorane)metal dichloride, $[(C_6H_5)_3AsCH_2\text{-}M\text{-}CH_2As(C_6H_5)_3]Cl_2$ (M: Zn, Cd, Hg), di-μ-chloro-bis[(methylenetriphenylarsorane)metal] dichloride, $[(C_6H_5)_3AsCH_2\text{-}M\langle^{Cl}_{Cl}\rangle M\text{-}CH_2As(C_6H_5)_3]Cl_2$ (M: Be, Mg), di-μ-chloro-bis[bis(methylenetriphenylarsorane)-metal] tetrachloride, $[\{(C_6H_5)_3AsCH_2\}_2\text{-}M\langle^{Cl}_{Cl}\rangle M\text{-}\{CH_2As(C_6H_5)_3\}_2]Cl_4$ (M: Al, In), and (methylenetriphenylarsorane)triphenylmetal chloride, $[(C_6H_5)_3AsCH_2M(C_6H_5)_3]Cl$ (M: Sn, Pb).

Results and Discussion

Zinc, Cadmium, and Mercury Complexes. Bis(methylenetriphenylarsorane)zinc dichloride (**1**) and the corresponding mercury(II) chloride (**3**) have been isolated from a reaction mixture of arsorane, $(C_6H_5)_3As{=}CH_2$ (**L**), and $ZnCl_2$ or $HgCl_2$ in the mole ratio of 2:1. The corresponding cadmium complex (**2**) was not isolated (*cf.* Experimental section). Complexes **1** and **3** are soluble in chloroform, dichloromethane, *N*,*N*-dimethylformamide (DMF), dimethyl sulfoxide(DMSO) and methanol but insoluble in acetone, ether, pentane, tetrahydrofuran (THF), ethyl acetate, acetic acid, hydrochloric acid and water.

$$2(C_6H_5)_3As{=}CH_2 + MCl_2 \longrightarrow [(C_6H_5)_3AsCH_2\text{-}M\text{-}CH_2As(C_6H_5)_3]Cl_2$$

1, 3

1: M=Zn, **3**: M=Hg

Complex **3** is unstable in dichloromethane at room temperature, but stable at −80 °C. On the other hand, complex **1** was slowly changed to methyltriphenylarsonium chloride $[(C_6H_5)_3AsCH_3]Cl$ (**4**) in dichloromethane at −80 °C. They are highly hygroscopic. The ^1H NMR spectrum of **3** showed a singlet signal for the CH_2As at δ 2.9 and the multiplet signal for the phenyl groups at δ 7.1—9.2 in a ratio of 2:15 in dichloromethane-d_2 at −80 °C as is shown in Table 1. The chemical shift of the methylene protons of **3** is at a lower field than that[26] (δ 0.93) of arsorane (**L**). This property is similar to those of bis(methylenetriphenylarsorane)gold(I) chloride[3] $[(C_6H_5)_3AsCH_2\text{-}Au\text{-}CH_2As(C_6H_5)_3]Cl$ (**5**) and bis(methylenetriphenylphosphorane)metal(II) dichloride,[4] $[(C_6H_5)_3PCH_2\text{-}M\text{-}CH_2P(C_6H_5)_3]Cl_2$ M: Zn, Cd,

Hg (**6**). The arsorane (**L**) is bonded to the metal atom through the carbanionic donor atom. Complexes **1** and **3** have free anion from the equivalent conductance, and the chloride is precipitated by silver nitrate in methanol–water solution. Thus, we suggest that the structures of **1** and **3** are linear similar to those of complexes **5** and **6**.

Beryllium and Magnesium Complexes. Di-μ-chloro-bis(methylenetriphenylarsorane)beryllium dichloride (**7**) and the corresponding magnesium dichloride (**8**) have been isolated from a reaction mixture of arsorane (**L**) with $BeCl_2$ or $MgCl_2$ in the mole ratio of 2:2. Complex **7** is somewhat soluble in nitric acid and hydrochloric acid, and very slightly soluble in chloroform and dichloromethane. Complex **8** is soluble in DMF, DMSO, methanol, and water, and very slightly soluble in chloroform and dichloromethane, though insoluble in acetic acid, benzene,

$$2(C_6H_5)_3As{=}CH_2 + 2MCl_2 \longrightarrow [(C_6H_5)_3AsCH_2\text{-}M(\mu\text{-}Cl)_2M\text{-}CH_2As(C_6H_5)_3]Cl_2$$

7, 8

7: M=Be, **8**: M=Mg

ether, ethyl acetate and THF. They are highly hygroscopic. Complexes **7** and **8** were slowly changed to the corresponding arsonium salt (**4**) in dichloromethane at −80°C, showing signals of both **4** and **7** or **8** in the NMR spectra. The NMR spectra of **7** and **8** showed a singlet signal for the CH_2As at δ 2.79 and 2.84, respectively and the multiplet signal for phenyl groups at δ 7.2—8.7 as is shown in Table 1. The chemical shifts of the methylene protons of **7** and **8** are at a lower field than that of **L**. The arsorane is bonded to the metal atom. Two structures for the beryllium compounds have been considered possible: either a tetrahedral (monomeric,[30] dimeric,[31] and polymeric[32,33]) or trigonal (monomeric,[34] dimeric,[35] and trimeric[36,37]) structure. Complexes **7** and **8** are not polymeric, because they are soluble in methanol. They have free anion from the equivalent conductance. Their solubility in chloroform and dichloromethane is different from that of **1**, **3**, **5**, and **6** (linear structure) and di-μ-chloro-bis[bis(methylenetriphenylphosphorane)-metal] tetrachloride,[7] $[\{(C_6H_5)_3PCH_2\}_2\text{-}M(\mu\text{-}Cl)_2M\text{-}\{CH_2P(C_6H_5)_3\}_2]Cl_4$ M:Al, Ga, In (**9**), and the corresponding arsorane complexes (**11**, **12**) (tetrahedral structure). Their elemental analyses agreed with that of $[LMCl_2]_2$. These properties resemble those of di-μ-chloro-bis(methylenetriphenylphosphorane)metal dichloride, $[(C_6H_5)_3PCH_2\text{-}M(\mu\text{-}Cl)_2M\text{-}CH_2P(C_6H_5)_3]Cl_2$ M:Be and Mg (**10**), of dimeric trigonal structure,[7] reported previously. Thus, we suggest that their structure can be neither linear nor tetrahedral but a dimeric trigonal structure bridged by chloride.

Aluminium and Indium Complexes. Di-μ-chloro-bis[bis(methylenetriphenylarsorane)aluminium] tetrachloride (**11**) and the corresponding indium tetrachloride (**12**) have been isolated from a reaction mixture of arsorane (**L**) and $AlCl_3$ or $InCl_3$ in the mole ratio of 4:2. Complexes **11** and **12** are soluble in chloroform, dichloromethane, DMF, DMSO, methanol and water, though insoluble in acetone, benzene, acetic acid, and THF. They are highly hygroscopic. The ^1H NMR

$$4(C_6H_5)_3As{=}CH_2 + 2MCl_3 \longrightarrow [(C_6H_5)_3AsCH_2(\mu\text{-}Cl)_2M(\mu\text{-}CH_2As(C_6H_5)_3)_2]Cl_4$$

11, 12

11: M=Al, **12**: M=In

spectra of complexes **11** and **12** showed a singlet signal for the CH_2As at about δ 2.9 and a multiplet signal for the phenyl groups at δ 7.3—8.3, though both complexes were slowly changed to salt **4** in dichloromethane at −80°C. Complexes **11** and **12** are not polymeric, because they are soluble in dichloromethane and methanol. The elemental analyses of **11** and **12** agreed with that of $[L_2MCl_3]_2$. Their colors are white. They have free anions from the equivalent conductance. Their properties resemble those of complex **9**.[7] The structure of $AlCl_3$, $InCl_3$ and related compounds are of a dimeric, tetrahedral structure bridged by chloride.[38–42] Then, we suggest that their structure is dimeric bridged by chloride and tetrahedral.

Tin and Lead Complexes. (Methylenetriphenylarsorane)triphenyltin chloride (**13**) and the corresponding lead chloride (**14**) have been isolated from a reaction mixture of the arsorane (**L**) and triphenyltin chloride or triphenyllead chloride in the mole ratio of 1:1. Complexes **13** and **14** are soluble in alcohols,

$$(C_6H_5)_3As{=}CH_2 + (C_6H_5)_3MCl \longrightarrow [(C_6H_5)_3AsCH_2\text{-}M(C_6H_5)_3]Cl$$

13, 14

13: M=Sn, **14**: M=Pb

chloroform, dichloromethane, DMF, DMSO, and THF, but insoluble in benzene, ether, and water. They are hygroscopic. Complex **14** is soluble in chloroform and dichloromethane, though complex **13** is slightly soluble in both solvents. The ^1H NMR spectra of **13** and **14** showed a singlet signal for the methylene group

TABLE 1. ^1H NMR DATA OF COMPLEXES

No	CH_2As δ	C_6H_5 δ	Temp °C	Solvent and Standard
1	2.88 s	7.1—8.7 m	−80	1)
3	2.90 s (4H)	7.1—9.2 m (30H)	−80	1)
7	2.79 s	7.3—8.1 m	−80	1)
8	2.84 s	7.2—8.7 m	−80	1)
11	2.90 s	7.3—8.3 m	−80	1)
12	2.88 s	7.3—8.3 m	−80	1)
13	2.32 s (2H)	6.9—8.0 m (30H)	r.t.	1)
14	2.45 s (2H)	6.8—8.0 m (30H)	r.t.	1)
L[a]	0.93 s (2H)	7.1—8.2 m (15H)	r.t.	2)
4	3.2 s (3H)	7.7 m (15H)	r.t.	1)

Solvents: 1) CD_2Cl_2, 2) $C_6D_5CD_3$. Standard: internal TMS (δ=0). a) Ref. 26.

(CH_2As) at δ 2.32 for **13** (δ 2.45 for **14**) and a multiplet signal for the phenyl group at δ 6.9—8.0 in a ratio of 2:30 in dichloromethane at room temperature as is shown in Table 1. The chemical shifts of their methylene protons are at a lower field than that of **L**. Complexes **13** and **14** have free anion from the equivalent conductance, and the chloride is precipitated by silver nitrate in ethanol–water solution. Thus, their structure is monomeric tetrahedral. The chemical shift of methylene protons of **14** is different from that (δ 2.68)[5] of the corresponding phosphorane lead complex, $[(C_6H_5)_3PCH_2Pb(C_6H_5)_3]Cl$ (**15**), and complex **13** is stable in dichloromethane at room temperature, though the corresponding phosphorane tin complex[5] (**16**) is unstable at −80°C. This can be ascribed to a property of the As or P in the complexes. The configuration (sp^3-sp^3) of the CH_2–M bonds of **13** and **14** is similar to those of **11** and **12** but complexes **11** and **12** are not so stable as complexes **13** and **14** in dichloromethane.

The monomeric complexes have a linear and tetrahedral structure. The structure of the dimeric complexes is trigonal and tetrahedral. All complexes are thermally stable. The Ag, Au, Hg, Sn, and Pb arsorane complexes are stable but the Cu, Be, Mg, Zn, Al, and In complexes are unstable. In the other hand, the Cu, Ag, Au, Mg, Zn, Cd, Al, Ga, In, and Pb phosphorane complexes are stable in dichloromethane, but the Be, Hg, and Sn complexes are not. The stable and unstable metal complexes with arsorane are the unstable and stable metal complexes of phosphorane, respectively, except for Ag, Au, Pb, and Be complexes. This difference is ascribed to both ylides, *i.e.*, the carbanionic carbon of the arsorane can be tetrahedral[26] and that of the phosphorane is trigonal.[43,44]

Experimental

Measurements. The NMR spectra were recorded with an R-40 spectrometer (Hitachi), Varian XL-200 spectrometer for ^1H NMR. The electric conductivities of solutions were determined by the use of a conductometric meter, CM-30 (Shimadzu) in dichloromethane at −80°C for **1**, **3**, **7**, **8**, **11**, **12** and room temperature for **13**, **14**.

Starting Materials. Methylenetriphenylarsorane (**L**) was prepared from a reaction mixture of methyltriphenylarsonium bromide[45] and sodium amide in dry THF by the method of the previous paper.[26,28]

Ylide-metal Complexes. Bis(methylenetriphenylarsorane)-zinc Dichloride (1): Zinc dichloride (0.15 g, 1.10 mmol) was added to a dry THF solution (15 cm^3) of arsorane (0.71 g, 2.22 mmol). The mixture was stirred for 1 d at room temperature. The color of the ylide changed to colorless from yellow. The white complex which formed was filtered, washed with pentane and dried. Yield: 0.54 g (62.3%). Found: C, 58.78; H, 4.50%. Calcd for $C_{38}H_{34}As_2ZnCl_2$ (MW 776.82) C, 58.76; H, 4.41%. Mp 117—120°C.

Bis(methylenetriphenylarsorane)cadmium Dichloride (2): Cadmium dichloride (0.22 g, 1.20 mmol) was added to a dry THF solution (10 cm^3) of arsorane (0.78 g, 2.44 mmol). The mixture was stirred for 1—24 h at room temperature. Complex **2** was not isolated from the reaction mixture, because the precipitate was a gum.

Bis(methylenetriphenylarsorane)mercury Dichloride (3): Mercury(II) chloride (0.33 g, 1.22 mmol) was added to a dry THF solution (11 cm^3) of arsorane (0.78 g, 2.44 mmol). The mixture was stirred for 12 h at room temperature. The color of the ylide changed to colorless from yellow. The white complex precipitate was filtered, washed with pentane and dried. Yield: 0.7 g (62.9%). Found: C, 49.81; H, 4.03%. Calcd for $C_{38}H_{34}As_2HgCl_2$ (MW 912.03) C, 50.04; H, 3.76%. Mp 196—198°C.

Di-μ-chloro-bis[(methylenetriphenylarsorane)beryllium] Dichloride (7): The arsorane **L** (0.44 g, 1.37 mmol) was added to dry THF (14 cm^3), and beryllium dichloride (0.11 g, 1.38 mmol) was added to the solution. The mixture was stirred for 20 h at room temperature, the white complex which precipitated was filtered, washed with pentane and dried. Yield: 0.28 g (51.1%). Found: C, 57.28; H, 4.62%. Calcd for $C_{38}H_{34}As_2Be_2Cl_4$ (MW 800.37) C, 57.03; H, 4.28%. Mp 133—135°C.

Di-μ-chloro-bis[(methylenetriphenylarsorane)magnesium] Dichloride (8): To a dry THF (10 cm^3) solution of arsorane (0.35 g, 1.09 mmol), magnesium dichloride (0.1 g, 1.05 mmol) was added and the mixture was stirred for 1 d at room temperature. The white complex which formed was filtered, washed with pentane and dried. Yield: 0.4 g (88.3%). Found: C, 54.85; H, 4.50; Cl, 16.14%. Calcd for $C_{38}H_{34}As_2Mg_2Cl_4$ (MW 830.96) C, 54.93; H, 4.12; Cl, 17.06%. Dp 190°C.

Di-μ-chloro-bis[bis(methylenetriphenylarsorane)aluminium] Tetrachloride (11): Aluminium trichloride (0.18 g, 1.35 mmol) was added to a dry THF (10 cm^3) solution of arsorane (0.87 g, 2.72 mmol) and the mixture stirred for 2 h at room temperature. The white complex precipitate was filtered and washed with pentane and dried. Yield: 0.56 g (53.2%). Found: C, 58.98; H, 4.40; Cl, 13.48%. Calcd for $C_{76}H_{68}As_4Al_2Cl_6$ (MW 1547.74) C, 58.98; H, 4.43; Cl, 13.74%. Mp 157—160°C.

Di-μ-chloro-bis[bis(methylenetriphenylarsorane)indium] Tetrachloride (12): Indium trichloride (0.20 g, 0.904 mmol) was added to a dry THF (10 cm^3) solution of arsorane (0.58 g, 1.81 mmol) and the mixture stirred for 3 h at room temperature. The white complex which formed was filtered, washed with pentane and dried. Yield: 0.55 g (70.5%). Found: C, 52.61; H, 4.11; Cl, 11.89%. Calcd for $C_{76}H_{68}As_4In_2Cl_6$ (MW 1723.42) C, 52.97; H, 3.98; Cl, 12.34%. Mp 122—125°C.

Methylenetriphenylarsorane(triphenyl)tin Chloride (13): The arsorane **L** (0.67 g, 2.09 mmol) was added to dry THF (12 cm^3) under nitrogen, and triphenyltin chloride (0.80 g, 2.08 mmol) was added to the solution. The mixture was stirred for 2 h at −40°C. The color of the ylide changed from yellow to colorless. Dry ether was then added to the solution at −40°C. The white complex precipitate was filtered at −40°C, washed with dry ether and dried under vacuum. Yield: 0.56 g (38.0%). Found: C, 62.80; H, 4.45%. Calcd for $C_{37}H_{32}AsSnCl$ (MW 705.73) C, 62.97; H, 4.57%. Dp 120°C.

Methylenetriphenylarsorane(triphenyl)lead Chloride (14): The arsorane **L** (0.74 g, 2.31 mmol) was added to dry THF (12 cm^3) under nitrogen, and triphenyllead chloride (1.1 g, 2.32 mmol) was added to the solution. The mixture was stirred 1 h at room temperature. The color of the ylide changed to colorless from yellow. Dry pentane was added to the solution, and the white complex precipitate was filtered, washed with pentane and dried under vacuum. Yield: 0.51 g (27.8%). Found: C, 55.69; H, 4.04%. Calcd for $C_{37}H_{32}AsPbCl$ (MW 794.16) C, 55.96; H, 4.06%. Mp 157°C.

(Received March 31, 1984)

Seven chelating agents were synthesized. The complexation properties of these reagents with divalent metals (Cu^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+}) were investigated in dioxane-water (75% dioxane, 25% water), and the complex formation constants were compared with those of 8-quinolinol as a reference chelating agent. These sulfonamidoquinoline reagents formed ML and ML_2 type complexes, and the order of complex stabilities followed Irving-Williams' order except for 2-methyl substituted derivatives. With 2-methyl derivatives, Ni^{2+} complexes were less stable than Co^{2+} complexes. Structural characteristics of sulfonamides as chelating agent were discussed in detail.

We have synthesized a series of new sulfonamide reagents, and studied their properties as regards the complexation and the solvent extraction of metal ions.[1-4] The acidity of an amide proton of sulfonamide is comparable to that of phenol, and in this respect sulfonamide-type chelating agents are expected to show a similar complex-forming ability to ordinary phenol-based chelating agents. Experimental studies showed that this is in fact the case.[1-7]

8-Sulfonamidoquinoline derivatives extract transition metal ions as 8-quinolinol do, but they strongly prefer the extraction of copper(II) and do not extract iron(III).[1,3,8,9] To understand somewhat unusual metal extraction behavior of 8-sulfonamidoquinoline as compared with phenolic or β-diketone-type extractants, a measurement of complex formation constants of this series of chelating agents is highly desirable.

In this study, the complex formation constants with divalent metals of sulfonamidoquinolines, 8-(methanesulfonamido)quinoline (**MQ**), 8-(2,4,6-trimethylbenzenesulfonamido)quinoline (8-(mesitylenesulfonamido)quinoline; **MsQ**), 8-(trifluoromethanesulfonamido)-quinoline (**FQ**), 8-(*p*-toluenesulfonamido)quinoline (*p*-**TQ**), 2-methyl-8-(methanesulfonamido)quinoline (**MMQ**), 2-methyl-8-(mesitylenesulfonamido)quinoline (**MMsQ**), and 2-methyl-8-(trifluoromethanesulfonamido)-quinoline (**MFQ**), were investigated by potentiometric method.

Experimental

*Syntheses of Sulfonamide Reagents. 2-Methyl-8-methanesulfonamidoquinoline (**MMQ**).* To a pyridine solution (15 ml) of 8-amino-2-methylquinoline (1.0 g, 6.32 mmol) was added dropwise a benzene solution of methanesulfonyl chloride (0.793 g, 6.92 mmol) in an ice bath during 1 h. The reaction mixture was gradually warmed to 60°C, and 1 ml of water was added. After stirring for 30 min, the reaction mixture was evaporated under reduced pressure. The residue was dissolved in chloroform, and was washed with diluted sulfuric acid, water, 5% sodium carbonate solution and water, successively. The chloroform solution was dried with sodium sulfate, concentrated, and was chromatographed on a silica-gel column (WAKOGEL C-200, 17×40 mm) with chloroform as an eluent. The main band was collected, and the product was recrystallized from methanol. Yield, 0.83 g (55%). Pale yellow needles. Mp 142.5—143.5°C. IR (KBr disk) 3300 (NH), 1328, 1147 cm^{-1} (SO_2). ^1H NMR (δ ppm from TMS; $CDCl_3$); δ=2.70 (3H, s, CH_3-2), 3.00 (3H, s, CH_3SO_2-), 7.35—8.12 (5H, m, Ar-H). Found: C, 55.90; H, 5.16; N, 11.77%. Calcd for $C_{11}H_{12}N_2O_2S$: C, 55.91; H, 5.12; N, 11.86%.

*8-(Trifluoromethanesulfonamido)quinoline (**FQ**).* To a dichloromethane solution (70 ml) of 8-aminoquinoline (7.2 g, 50 mmol) was slowly added a dichloromethane solution (10 ml) of freshly distilled trifluoromethanesulfonic anhydride (15.3 g, 54 mmol) in the period of 30 min. The mixture was stirred for 1.5 h in an ice bath, and then gradually warmed to 60°C (1h). After the removal of solvent under reduced pressure, the reaction mixture was dissolved in chloroform, and was washed with water. The chloroform solution was dried with sodium sulfate, concentrated, and was chromatographed on a silica-gel column (WAKOGEL C-200, 20×40 mm) with chloroform as an eluent. The main band was collected and the product was recrystallized from chloroform. Yield, 10.8 g (78%). Yellow prisms. Mp 146—147°C. IR (KBr disk) 3140 (NH), 1295, 1145 cm^{-1} (SO_2). ^1H NMR ($CDCl_3$); δ= 7.30—7.75 (3H, m, H-3, -5, and -6), 7.90 (1H, dd, H-7, J=2.6, 6.0 Hz), 8.23 (1H, dd, H-4, J=1.6, 7.8 Hz), 8.81 (1H, dd, H-2, J=4.1, 1.6 Hz). Found: C, 43.35; H, 2.60; N, 10.17%. Calcd for $C_{10}H_7F_3N_2O_2S$: C, 43.38; H, 2.55; N, 10.14%.

*2-Methyl-8-(trifluoromethanesulfonamido)quinoline (**MFQ**).* This compound was prepared in a similar manner to **FQ**. Recrystallized from methanol-chloroform. Yield, 80%. Yellow needles. Mp 137.0—137.5°C. IR (KBr disk) 3165 (NH), 1290, 1154 cm^{-1} (SO_2). ^1H NMR ($CDCl_3$); δ=2.75 (3H, s, CH_3-), 7.37 (1H, d, H-3, J=8.0 Hz), 7.40—7.70 (2H, m, H-5 and -6), 7.85 (1H, dd, H-7, J=6.5, 2.5 Hz), 8.10 (1H, d, H-4, J=8.0 Hz). Found: C, 45.54; H, 3.21; N, 9.65%. Calcd for $C_{11}H_9F_3N_2O_2S$: C, 45.52; H, 3.13; N, 9.65%.

*8-Mesitylenesulfonamidoquinoline (**MsQ**) and 2-Methyl-8-mesitylenesulfonamidoquinoline (**MMsQ**).* These compounds were prepared in a similar manner to **MMQ**. Recrystallized from methanol-chloroform.

MsQ: Yield, 90%. Colorless prisms. Mp 178—179°C. IR (KBr disk) 3305 (NH), 1359, 1150 cm^{-1} (SO_2). ^1H NMR ($CDCl_3$); δ=2.15 (3H, s, CH_3-4'), 2.74 (6H, s, CH_3-2' and -6'),

6.81 (2H, s, H-3′ and -5′), 7.25—7.70 (4H, m, H-3, -5, -6, and -7), 8.11 (1H, dd, H-4, J=2.0, 8.5 Hz), 8.80 (1H, dd, H-2, J=5.0, 2.0 Hz). Found: C, 65.67; H, 5.67; N, 8.48%. Calcd for $C_{12}H_{18}N_2O_2S$: C, 66.23; H, 5.56; N, 8.58%.

MMsQ: Yield 71%. Pale yellow needles. Mp 169—170.5 °C. IR (KBr disk) 3295 (NH), 1157 cm^{-1} (SO_2). ^1H NMR ($CDCl_3$); δ=2.16 (3H, s, CH_3-4′), 2.67 (6H, s, CH_3-2′ and -6′), 2.74 (3H, s, CH_3-2), 6.79 (2H, s, H-3′ and -5′), 7.17—7.68 (4H, m, H-3, -5, -6, and -7), 7.92 (1H, d, H-4, J=8.2 Hz). Found: C, 66.84; H, 6.03; N, 8.22%. Calcd for $C_{19}H_{20}N_2O_2S$: C, 67.03; H, 5.92; N, 8.23%.

*8-(Methanesulfonamido)quinoline (**MQ**) and 8-(p-Toluenesulfonamido)quinoline (p-**TQ**).* These compounds were prepared according to the reported procedure.[7]

Measurement of Acid Dissociation Constants and Complex Formation Constants. Reagent: Dioxane was used immediately after purification. Standard potassium hydroxide (0.1 M (1 M=1 mol dm^{-3})) solution was prepared by the Albert's method.[10] Metal nitrate solutions (0.01 M) were prepared by dissolving the metal nitrate (guaranteed reagents) in distilled water. The concentration was determined by chelatometric titration.[11] Other reagents were of guaranteed grade.

Measurement. Two milliliters of 0.01 M perchloric acid, 2 ml of 0.1 M potassium nitrate, 1 ml of 0.01 M metal nitrate aqueous solution, 2 ml of 0.01 M ligand solution in dioxane, and 13 ml of dioxane were taken in a titration vessel (75% dioxane solution). When acid dissociation constants were determined, 1 ml of water was taken instead of 1 ml of 0.01 M metal nitrate solution. The titration vessel was maintained at 30±0.1 °C. Nitrogen gas which was pre-passed through 75% dioxane-water was slowly passed over the solution throughout the titration. The standard potassium hydroxide solution was added to the stirred solution with small portions together with three times volume of pure dioxane in order to keep the solvent composition constant. All pH measurements were made with GC-195C combined pH electrode (TOA Elect. Ltd.) on HM-15A digital pH meter (TOA Elect. Ltd.).

Evaluation of Acid Dissociation Constants. Since the sulfonamide ligand has one dissociable amide proton and one quinolinic nitrogen, two proton dissociation constants are defined as in Eqs. 1 and 2. Ka_1 and Ka_2 correspond to the dissociation of quinolinium and amide protons, respectively.

$$H_2L^+ \rightleftarrows HL + H^+ : \quad Ka_1 = \frac{[HL][H^+]}{[H_2L^+]}, \tag{1}$$

$$HL \rightleftarrows L^- + H^+ : \quad Ka_2 = \frac{[L^-][H^+]}{[HL]}. \tag{2}$$

First, the pH meter was calibrated in a usual manner against phthalate and phosphate buffers. Then, a standard solution of perchloric acid in 75% dioxane was titrated by standard potassium hydroxide solution while keeping the composition of the solvent constant. A certain constant value (0.55) was found to be added in order to convert the measured (apparent) pH values to $-\log [H^+]$ values, *i.e.*,

$$-\log [H^+] = pH_{app} + 0.55. \tag{3}$$

A titration of standard perchloric acid solution beyond an equivalence point or of pure mixed solvent (with added potassium perchlorate) by standard potassium hydroxide gave an estimation of "conditional" ionic product Kw for the dissociation of water. Thus, for known concentrations of OH^- ion, $-\log [H^+]$ values were obtained according to Eq. 3 from the measured pH_{app} values for the solution. The relationship between $[OH^-]$ and $[H^+]$ was found to be

$$Kw = [H^+][OH^-] = 10^{-17.4}. \tag{4}$$

The conditional Kw value is close to the value of $10^{-17.70}$ reported for the similar solvent (30% water −70% dioxane (v/v)) without added salt.[12]

A conventional treatment of mass balance and equilibrium in solution leads to the following expressions (under conditions, $Ka_1 \gg Ka_2$) which relate proton dissociation constants to the experimentally observable variables. When $0<a<1$,

$$T_{OH} = \frac{-[H^+]^3 - Ka_1[H^+]^2 + (Kw + Ka_1 \cdot T_L)[H^+] + Ka_1 \cdot Kw}{[H^+](Ka_1 + [H^+])}, \tag{5}$$

and when $1<a<2$,

$$T_{OH} = \frac{-[H^+]^3 - Ka_2[H^+]^2 + (Kw + Ka_2 \cdot T_L)[H^+] + Ka_2 \cdot Kw}{[H^+](Ka_2 + [H^+])} + T_L, \tag{6}$$

where T_{OH} is a total concentration of added potassium hydroxide, T_L is a total concentration of ligand, and a is equal to T_{OH}/T_L.

Ka_1 and Ka_2 values were calculated from titration data of ligands in the absence of metal ions (Figs. 1a—1h) by using Marquardt nonlinear least squares method[14] according to Eqs. 5 and 6.

Evaluation of Complex Formation Constants. The complex formation equilibria of sulfonamide reagents in this study with divalent metal ion are generally formulated as follows:

$$M^{2+} + L^- \rightleftarrows ML^+ : \quad K_1 = \frac{[ML^+]}{[M^{2+}][L^-]}, \tag{7}$$

$$ML^+ + L^- \rightleftarrows ML_2 : \quad K_2 = \frac{[ML_2]}{[ML^+][L^-]}. \tag{8}$$

In this study, however, the second proton dissociation constant Ka_2 was sometimes too low to be measured accurately, and it is generally inconvenient to treat the complex formation in terms of the concentration of L^- species. Thus, the equilibria were described in a different way as follows:

$$M^{2+} + HL \rightleftarrows ML^+ + H^+ : \quad K_1' = \frac{[ML^+][H^+]}{[M^{2+}][HL]}, \tag{9}$$

$$ML^+ + HL \rightleftarrows ML_2 + H^+ : \quad K_2' = \frac{[ML_2][H^+]}{[ML^+][HL]}. \tag{10}$$

Then, K_1 and K_2 are related to K_1' and K_2', respectively, as follows:

$$K_1 = K_1'/Ka_2, \tag{11}$$

$$K_2 = K_2'/Ka_2. \tag{12}$$

A treatment of complex formation equilibria leads to Eq. 13, and K_1' and K_2' were calculated from the titration data by nonlinear least squares method in a usual manner.

$$T_{OH} = T_L - A - [H^+] + Kw/[H^+], \quad (13)$$

where,

$$A = \frac{-C+\sqrt{C^2-4BD}}{2B}, \quad (14)$$

$$B = K_1' \cdot K_2'(Kw - T_{OH}[H^+] - [H^+]^2 + 2T_M[H^+]), \quad (15)$$

$$C = K_1'[H^+](Kw - T_{OH}[H^+] - [H^+]^2 + T_M[H^+]), \quad (16)$$

$$D = [H^+]^2(Kw - T_{OH}[H^+] - [H^+]^2). \quad (17)$$

Results and Discussion

Acid Dissociation Constants. Titration curves of sulfonamide ligands in 75% dioxane–water are illustrated in Figs. 1a—1h including 8-quinolinol (**HQ**) as a reference ligand. The ligand concentration could not be increased over 10^{-3} M because of the solubility limitation of the ligand itself or metal complexes derived. At such relatively low concentrations, the proton dissociation constants (p*K*a) lower than 3 or higher than 14 can not be accurately determined by pH measurement; a computer simulation study indicated that pH measurement error of 0.02 pH unit can result in artificial proton dissociation constants of that order of acid strength. Thus, such low or high p*K*a values numerically obtained were not adopted as real constants.

Few equilibrium data have been reported on the complex formation in 75% dioxane–water medium. 8-Quinolinol (**HQ**) and 2-methyl-8-quinolinol (**MHQ**)

were studied in 50% dioxane-water,[9] and the reported constants are listed in Table 1 for comparison. In the case of 8-quinolinol, the change of 50 to 75% for the volume fraction of dioxane in the medium caused a decrease of 0.56 in pKa_1 and an increase of 1.8 in pKa_2. This is explained that charged species, H_2L^+ and L^- are less stable in organic-rich medium than in water rich solvent.

Complex Formation Constants. Titration curves of the chelating agents in the presence of divalent metal ions are illustrated in Figs. 1a—1h. It is evident from these curves that most ligands including 8-quinolinol form ML and ML_2 type, stable complexes with divalent metal cations. The complex formation constants calculated from these data are summarized in Table 1, K_1 and K_2 values rather than K_1' and K_2' are shown. As mentioned before, the latter values are experimentally more reliable for ligands with high pKa_2 values (log K_2 values for proton association)(>13) since they are free from the ambiguity in the determination of Ka_2. K_1 and K_2 values are obtained by using Eqs. 11 and 12.

The formation constants suffer a considerable medium effect (composition of solvent). Thus, except for Cu^{2+} all of log K_1, log K_2, and log β value are greater in 75% dioxane-water than in 50% dioxane-water. This may be explained in a usual manner that the complex state M-L is more stable than the free metal cation plus L^- state which is more stabilized by hydration in water-rich medium. The increased stability of the complexes in 75% dioxane-water probably holds in sulfonamide ligands.

The orders of stabilities, log K_1, log K_2, log β of 8-sulfonamidoquinolines which do not carry 2-methyl group all follow Irving-Williams' order (*i.e.* $Cu^{2+}>Ni^{2+}>Co^{2+}$). Since **FQ** and Cu^{2+} formed a complex insoluble in 75% dioxane, the stability constants could not be obtained.

The order of metal complex stabilities of 2-methylquinoline derivatives (including 2-methy-8-quinolinol) are $Cu^{2+}>Co^{2+}>Ni^{2+}$, the order of Ni^{2+} and Co^{2+} being reversed from that of Irving-Williams. The difference of log K_1 between Ni^{2+} and Co^{2+} is smaller than that of log K_2. This may be considered that the ML_2 type Co^{2+} complex can assume either tetrahedral or octahedral configuration (chelating ligands of square planar configuration, with coordinated water molecules in axial position), while Ni^{2+} complex takes (distorted) octahedral configuration.[15]

If two 8-sulfonamidoquinoline chelating ligands take square planar configuration around a metal ion, a steric interaction between 2-methyl group of one ligand and 8-sulfonamide group of the other is expected from a molecular model consideration. 2-Methyl group may interact with a coordinated water in the same plane even when a single chelating ligand is bound to the metal. The complex formation constants (log β) for Cu^{2+} and Ni^{2+} are unanimously lowered on introduction of 2-methyl group in 8-sulfonamidoquinoline or 8-quinolinol, inspite of the increased basicity of L^- associated with the methyl substitution. For **MMsQ** where an extremely bulky mesitylenesulfonyl group comes close to the ligand on the opposite side of the plane, nickel complex is expected to become especially unstable. The titration curve (Fig. 1d), however, indicates a considerable pH depression at *a* value above 1. Around this pH region, however, proton dissociation from coodinated water is also expected to take place as a side reaction. In accordance with this, the titration data did not give well-defined K_1 and K_2 values.

a) The value could not be calculated. b) Precipiated. c) Data in 50% dioxane-water (v/v), μ= 0.1 (Ref. 13).

The plots of log K_1 or log K_2 against pKa_2 are shown in Fig. 2. The points are classified in two groups, trifluoromethane-sulfonamides and the rest of the sulfonamides. Both log K_1 and log K_2 decrease as pKa_2 decreases when the two groups are compared, indicating that a large decrease in basicity of the ligand inevitably leads to a decrease in nucleophilicity toward metal cations. However, there is no obvious correlation between the complex formation constants and the second proton dissociation constants within the individual group. Similar trends were observed for other metal ions when log K_1 and log K_2 values were plotted against pKa_2.

It is more convenient to consider the structural factors of complex formation in terms of the ion exchange-type equilibria formulated in Eqs. 9 and 10, the equilibrium constants of which do not involve the contribution from the second proton dissociation constants, *i.e.*,

$$\log K_1' = \log K_1 - \mathrm{p}Ka_2, \quad (18)$$

$$\log K_2' = \log K_2 - \mathrm{p}Ka_2, \quad (19)$$

$$\log \beta' = \log K_1 + \log K_2 - 2\mathrm{p}Ka_2. \quad (20)$$

In other words, log K_1' (or log K_2') is expected to reflect the contribution of (i) nucleophilicity of quinoline nitrogen and (ii) steric factors to the free energy of 1:1 (or 1:2) complex formation. In addition, log K_1' and log K_2' can be an indirect measure of an ease of solvent extraction, since the reagents with higher K_1' and K_2' values can extract metal ions under lower pH conditions. Table 2 summarizes these constants.

One first can compare the simplest sulfonamide homologue **MQ** with **HQ**. For clarity, log K_1' and log K_2' values for **MQ** and **HQ** are shown in Fig. 3. The constants K_1' almost parallel in the two chelating agents (for the four metal ions studied). The magnitude of the constants are also quite close to each other. This suggests the chelating behavior of the agents **MQ** and **HQ** toward the four metal ions are similar in nature toward the four metal ions in spite of the difference in the coordinating atoms.

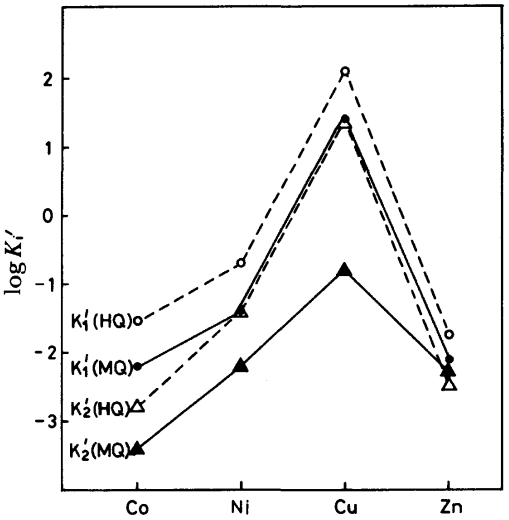

Fig. 3. Comparison of complex formation equilibrium constants K_i' between 8-(methanesulfonamido)quinoline (**MQ**) and 8-quinolinol (**HQ**).

One now looks in Fig. 3 at the log K_2' values of **HQ**, and finds that they almost parallel with the log K_1' values. On the other hand, however, there is no such parallelism in **MQ** metal chelates, *i.e.*, for Cu^{2+} the K_2' value is too low and for Zn^{2+} the value is too high. This suggests that there are some structural factors which lower the formation constant of 1:2 copper(II)-**MQ** chelate. Such structural factors are not easily foreseeable from the analogy between **MQ** and **HQ** mentioned just above. In the same notion, there seems to be some stabilizing factor for the 1:2 zinc(II)-**MQ** chelate as compared with the corresponding **HQ** chelate. A destabilizing effect in 1:2 copper(II) chelate has already been noticed for the sulfonamide chelating agents derived from 2-(aminomethyl)pyridine,[2] and a steric bulkiness of sulfonamido group may be the reason of the destabilization. As to the stabilizing effect in 1:2 zinc(II) chelate (as compared with the corre-

a) Calculated from the data in Table 2. b) Data in 50% dioxane-water.

sponding 8-quinolinol chelate), there is no reasonable explanation at present.

Table 3 summarizes the effect of substituent (mainly 2-methyl substitution on quinoline ring) on the stability of metal complexes. The positive values indicate destabilization of the complex on methyl-substitution, and the negative values, stabilization. The major effect of substitution shown in the table may be assumed to be those of steric interaction and not those of electronic effect, since, as discussed before, K' value does not include a contribution from the basicity of sulfonamide anion or the proton dissociation constant Ka_2. Electron-donating effect of methyl group which increases the basicity of quinoline nitrogen (see Table 1 for pKa_1 values of **HQ** and **MHQ**) should not be treated lightly, but the net effect of the increase in basicity is to increase the stability of the metal complex in rather a uniform manner irrespective of the nature of metal ion.

It is seen in Table 3 that 2-methyl group on quinoline ring causes a strong overall destabilizing effect (large positive value for β' row in Table 3) on copper(II) and nickel(II) chelates of both 8-sulfonamidoquinoline and 8-quinolinol. A moderate to none destabilizing effect is observed with cobalt(II) chelates, while a stabilizing effect is noticed for zinc(II) chelates of sulfonamides. The increase of stability in zinc(II) chelates of 2-methyl-substituted sulfonamide reagents is at least partially due to the increase in basicity (nucleophilicity) of quinoline nitrogen, since no steric constraints due to methyl substitution are expected in tetrahedral configuration of zinc(II) chelates. However, **HQ** and **MHQ** chelates in Table 3 indicate that the introduction of methyl group causes a decrease in stability even for zinc(II) chelate (though small as compared with copper(II) and nickel(II)). A stabilization of zinc(II) complex with 8-sulfonamide chelating agent as compared with 8-quinolinol has been pointed out earlier. It may deserve further study.

It is important to note that the destabilization by 2-methyl substitution is already pronounced at the formation of *1:1* complex for some metal-ligand combination (Cu-**MMsQ** and Ni-**MFQ** in Table 3). This means that the effect of methyl substitution —whether it can be purely steric or not— is operating not only between the coordinated chelating ligands but also between the chelating ligand and the water both coordinated on the metal.

A change from *p*-toluenesulfonyl to mesitylenesulfonyl group causes a moderate over-all destabilization of the complex except for copper(II) (see β' row in Table 3). In this case, a steric interaction between the chelating ligands seems to be an important factor, since contributions from K_2' term (the value of K_2' row, Table 3) are positive for all the metal ions.

In summary, it is concluded that (i) the coordination behavior toward Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+} of 8-sulfonamidoquinoline chelating agents quite resemble 8-quinolinol, but (ii) a steric bulkiness of sulfonamido group exerts a destabilizing effect when the configuration of the complex is not tetrahedral. An introduction of methyl group on 2-position of quinoline ring further amplifies the latter effect through a chelating ligand-ligand interaction and through a chelating ligand-coordinated water interaction, leading to destabilization in zinc(II) chelates. The point (ii) above seems to be the most notable feature of sulfonamide reagents, but it is likely that the effect did not work in full for the metal ions herein studied. For metal cations of smaller ionic radius such as Fe^{3+}, a destabilizing effect is expected to be more pronounced. Unfortunately, rather unusual medium used in the present work (75% dioxane) hampered a detailed study on iron(III) chelates.

Solvent Effects on Dimerization of Copper(II) Decanoate in Ketone Solvents

Hiromichi YAMADA,* Kaoru TAKAHASHI, Yukio FUJII, and Masateru MIZUTA
Faculty of Engineering, Gifu University, 1-1, Yanagido, Gifu 501-11
(Received April 9, 1984)

The extraction of copper(II) with decanoic acid in some ketone solvents was carried out at 25 °C and at 0.1 mol/dm^3 ($NaClO_4$) aqueous ionic strength. Organic solvents used are 2-pentanone, 3-pentanone, 2-hexanone, 4-methyl-2-pentanone, 5-methyl-2-hexanone, and 2-octanone. For all solvents, the extracted species are CuA_2, CuA_2HA, Cu_2A_4, and $Cu_2A_4(HA)_2$ (HA: decanoic acid). The dimerization and adduct formation of copper(II) decanoates in each organic phase can be formulated as:

$$CuA_2 + HA \overset{K_{ad,monomer}}{\rightleftharpoons} CuA_2HA,$$

$$Cu_2A_4 + 2HA \overset{\beta_{ad,dimer}}{\rightleftharpoons} Cu_2A_4(HA)_2,$$

$$2CuA_2 \overset{K_{dim-1}}{\rightleftharpoons} Cu_2A_4,$$

$$2CuA_2HA \overset{K_{dim-2}}{\rightleftharpoons} Cu_2A_4(HA)_2.$$

The solvent effects on the dimerization of copper(II) decanoate can be interpreted in terms of the regular solution theory. It was proved that the number of solvent molecules liberated in the formation of the dimeric copper(II) decanoate in ketones was less than that in alcohols.

In a series of investigations[1–7] on the extraction of copper(II) with aliphatic carboxylic acids in various inert solvents, the extracted species has been established to be the dimeric copper(II) carboxylates. On the other hand, by using 1-octanol as solvating solvent, the monomeric copper(II) decanoates were extracted together with the dimeric ones.[8] In the previous work,[9] it has been shown that the monomeric (CuA_2) and dimeric copper(II) decanoates (Cu_2A_4, and $Cu_2A_4(HA)_2$) are responsible for the extraction with decanoic acid in some alcohol solvents and the solvent effects on the dimerization of copper(II) decanoate in the alcohol phase can be interpreted by means of the regular solution theory.

The present paper describes the results of the extraction of copper(II) with decanoic acid in some ketone solvents. Through the comparison of the present results with those obtained for alcohol solvents, it was found that the dimerization constants of copper(II) decanoates in ketones was much larger than those in alcohols and the number of solvent molecules set free in the dimerization of copper(II) decanoate in ketones was less than that in alcohols.

Experimental

Reagents. *Solvents*: 2-Pentanone, 3-pentanone, 2-hexanone, 4-methyl-2-pentanone, 5-methyl-2-hexanone, and 2-octanone of reagent grade were purified by distillation and saturated with distilled water at 25 °C.

Reagent grade 8-quinolinol was used for the spectrophotometric determination of lower concentration of copper in the organic phase.

Copper(II) perchlorate was prepared in the same manner as presented previously.[8]

Sodium perchlorate and decanoic acid were purified by the method described previously.[8]

All other reagents were reagent grade and used without further purification.

Procedure. Experiments were carried out in the same manner as was stated in the previous work.[8]

Apparatus. For mechanical shaking in a thermostat, Taiyo Incubator M-100^N (Taiyokagaku-Kogyo Co., Tokyo) was used. A Orion Research Microprocessor Ionalyzer 901 (Orion Research Inc., USA) and Horiba pH Analyzer F-80 (Horiba Seisakusho Ltd., Kyoto) were used for the determination of hydrogen ion concentration in the aqueous phase. Spectrophotometric determination was carried out on a Shimadzu double-beam type UV-210A Spectrophotometer (Shimadzu Seisakusho Ltd., Kyoto).

Results and Discussion

Distribution of Decanoic Acid. Distribution ratio of decanoic acid between water and the organic solvent is written as follows:

$$D = \frac{C_{HA,o}}{C_{HA,w}} = \frac{K_{D,HA}(1+2K_{dim,HA}K_{D,HA}[HA])}{1+\frac{K_a}{[H^+]}}, \quad (1)$$

where K_a, $K_{dim,HA}$, and $K_{D,HA}$ denote the dissociation constant in the aqueous phase, the dimerization constant in the organic phase, and the partition constant of decanoic acid, respectively. At lower pH where the dissociation of decanoic acid in the aqueous phase is negligible, Eq. 1 is rewritten as:

$$\log D = \log K_{D,HA} + \log (1+2K_{dim,HA}K_{D,HA}[HA]). \quad (2)$$

Distribution ratio of decanoic acid between water and 4-methyl-2-pentanone was illustrated in Fig. 1 as a function of the concentration of decanoic acid in the aqueous phase. In Fig. 1, the concentration of hydrogen ion in the aqueous phase is 10^{-3} mol/dm^3 and the ionic strength in the aqueous phase is 0.1 mol/

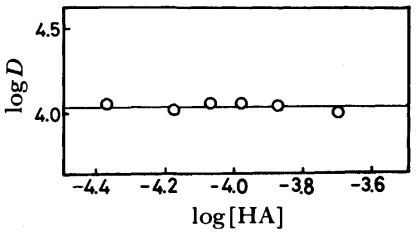

Fig. 1. Distribution of decanoic acid between water and 4-methyl-2-pentanone.
The ionic strength and $[H^+]$ in the aqueous phase are 0.1 mol/dm^3 and 10^{-3} mol/dm^3, respectively.

dm^3 ($NaClO_4$). Under the present experimental conditions the distribution ratio of decanoic acid can be approximated by Eq. 2. As demonstrated in Fig. 1, the distribution ratio of decanoic acid seems to be constant, independent of the concentration of decanoic acid in the aqueous phase. This suggests that the dimerization of decanoic acid in the organic phase (4-methyl-2-pentanone) does not occur to any appreciable extent. Then, the distribution ratio of decanoic acid is equal to the partition constant: $D=K_{D,HA}$. From Fig. 1, the value of log $K_{D,HA}$ obtained was to be 4.04. G. K. Schweitzer and D. K. Morris[10] have reported that the partition constant of octanoic acid between water and 4-methyl-2-pentanone is about 10^3. In addition, it is evident that the increment of the partition constant of carboxylic acid for each methylene group is nearly constant irrespective of solvent, that is, $\Delta\log K_{D,HA}/-CH_2-=0.56$—$0.60$.[11] Then, from these results, the partition constant of decanoic acid between water and 4-methyl-2-pentanone can be expected to be $10^{4.12-4.20}$. This is in fairly good agreement with the present value.

Consequently, under the present experimental conditions, the concentration of the monomeric decanoic acid in the 4-methyl-2-pentanone phase can be adequately approximated by the total concentration of decanoic acid: $[HA]_o=C_{HA}$. For the other ketones used the similar relations are expected to hold.

Distribution of Sodium Perchlorate. In the present work, the ionic strength in the aqueous phase was kept constant by sodium perchlorate. Then, the distribution ratio of sodium perchlorate between water and some ketones were determined under the following experimental conditions: $C_{NaClO_4}=0.1$ mol/dm^3 and $-\log[H^+]=3.5$. The results are summarized in Table 1. The distribution ratio of sodium perchlorate between water and 4-methyl-2-pentanone is reported[12] to be $10^{-2.60}$. The value for 4-methyl-2-pentanone in Table 1 is in fair agreement with this. As shown in Table 1, the distribution ratio of sodium perchlorate for any ketone is extremely small. Thus, the effect of perchlorate ion on the present extraction systems was proved to be negligible.

TABLE 1. DISTRIBUTION RATIO OF SODIUM PERCHLORATE BETWEEN WATER AND SOME KETONES

4-Methyl-2-pentanone	−2.82
5-Methyl-2-hexanone	−3.06
2-Octanone	−3.27

a) $C_{NaClO_4}=0.1$ mol/dm^3 and $-\log[H^+]=3.5$.

Extraction of Copper(II) with Decanoic Acid. The extraction equilibrium in the present systems was elucidated according to the previously described manner.[9]

As previously reported, if a j-merized copper(II) decanoate, $Cu_jA_{2j}(HA)_a$ is responsible for the extraction, the extraction equilibrium can be expressed as follows:

$$jCu^{2+} + (2j+a)(HA)_o \rightleftharpoons (Cu_jA_{2j}(HA)_a)_o + 2jH^+,$$

with the extraction constant:

$$K_{ex(ja)} = \frac{[Cu_jA_{2j}(HA)_a]_o[H^+]^{2j}}{[Cu^{2+}]^j[HA]_o^{(2j+a)}}, \quad (3)$$

where the subscript o refers to the organic phase.

From the results obtained for alcohols,[9] it is expected that the monomeric and dimeric copper(II) decanoates are responsible for the extraction of copper(II) with decanoic acid in ketones. Then, the following equation can be expected to hold for the present extraction systems:

$$\log C_{Cu,o} - (\log C_{Cu,w} - 2\log[H^+]) = (2+a)\log[HA]_o + \log K_{ex(1a)} + \log\left(1+\frac{2K_{ex(2p)}}{K_{ex(1a)}}[HA]_o^{(2+p-a)} \cdot C_{Cu,w}[H^+]^{-2}\right), \quad (4)$$

where the subscript w refers to the aqueous phase, and $K_{ex(1a)}$ and $K_{ex(2p)}$ represent the extraction constants of the monomer $CuA_2(HA)_a$ and the dimer $Cu_2A_4(HA)_p$, respectively. By comparing the plot of the values of the left-hand side of Eq. 4 against $(\log C_{Cu,w}-2\log[H^+])$ at constant $[HA]_o$ with the normalized curve, $\log(1+X)$ *vs.* $\log X$, it is confirmed that the monomeric and dimeric copper(II) decanoates are responsible for the extraction. The results obtained for 2-hexanone are shown in Fig. 2. As expected, it was proved that the monomer $CuA_2(HA)_a$ and the dimer $Cu_2A_4(HA)_p$ were extracted into the 2-hexanone phase. The same results were obtained for the other ketones.

In the region where the monomer prevails, it was found by the same approach as in the previous work[9] that the two monomeric copper(II) decanoates were responsible for the extraction and they were CuA_2 and $CuA_2(HA)_a$ ($a \geqq 1$). Then, we have the following expression in the similar manner described in the previous report:[9]

$$\log C_{Cu,o} - (\log C_{Cu,w} - 2\log[H^+]) - 2\log[HA]_o = \log K_{ex(10)} + \log\left(1+\frac{K_{ex(1a)}}{K_{ex(10)}}[HA]_o^a\right), \quad (5)$$

where $K_{ex(10)}$ and $K_{ex(1a)}$ represent the extraction constants of the monomeric species, CuA_2 and $CuA_2(HA)_a$, respectively. By comparing the plot of the values of

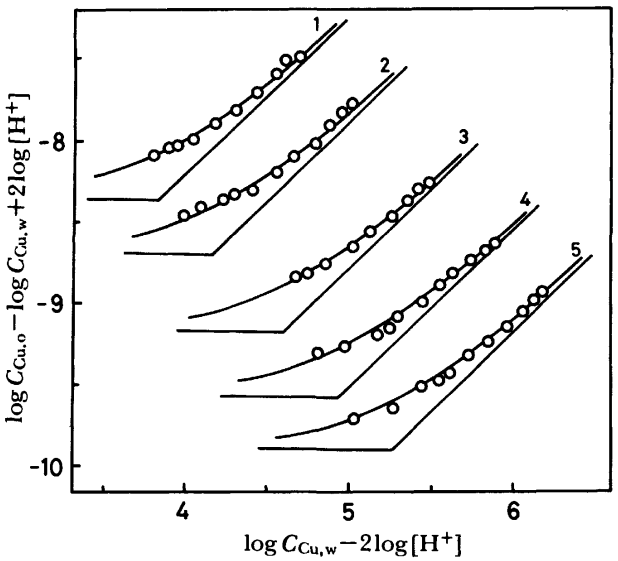

Fig. 2. The identification of the degree of polymerization of Cu(II) decanoates.
C_{HA}; No. 1: 2.0, No. 2: 1.5, No. 3: 1.0, No. 4: 0.7, No. 5: 0.5 mol/dm³. Solvent: 2-hexanone.

the left-hand side of Eq. 5 against log[HA]$_o$ with the following normslized curves: log(1+X^n) *vs.* log$X$, we can find the number of decanoic acid molecules involved in another monomeric copper(II) decanoate. The results are shown in Figs. 3a and 3b. As can be seen in Figs. 3a and 3b, for all the solvents the plots fit well the normalized curve with n=1, that is, a=n=1. Thus, CuA_2 and CuA_2HA are found to be responsible for the extraction. From Figs. 3a and 3b, we can also obtain the respective extraction constants $K_{ex(10)}$ and $K_{ex(11)}$ by fitting the normalized curve to the observed values. The results obtained for each solvent are listed in Table 2 together with the other constants.

Subsequently, the composition of the dimeric copper(II) decanoates was determined by the same manner as in the previous paper.[9] It was proved that the dimeric species in each ketone phase were Cu_2A_4 and $Cu_2A_4(HA)_p$($p \geqq 1$). Then, we can obtain the following expression:

$$\log C_{Cu,o} - 2(\log C_{Cu,w} - 2\log[H^+]) - 4\log[HA]_o = \log\left(1+\frac{K_{ex(2p)}}{K_{ex(20)}}[HA]_o^p\right) + \log K_{ex(20)} + \log 2, \quad (6)$$

where $K_{ex(20)}$ and $K_{ex(2p)}$ refer to the extraction constants of Cu_2A_4 and $Cu_2A_4(HA)_p$, respectively. The values of the left-hand side of Eq. 6 were plotted against $\log[HA]_o$. As shown in Figs. 4a and 4b, for all the solvents the plots fit well the normalized curve, $\log(1+X^2)$ *vs.* $\log X$, that is, $p=n=2$. As expected, the dimeric species were Cu_2A_4 and $Cu_2A_4(HA)_2$ irrespective of the solvent. From Figs. 4a and 4b we can also obtain the respective extraction constants, $K_{ex(20)}$ and $K_{ex(22)}$ by fitting the normalized curve to the observed values. The results are summarized in Table 2 together with the other constants.

Consequently, we conclude that the extraction equilibria for the present extraction systems are written as follows:

$$Cu^{2+} + 2(HA)_o \overset{K_{ex(10)}}{\rightleftharpoons} (CuA_2)_o + 2H^+,$$

$$Cu^{2+} + 3(HA)_o \overset{K_{ex(11)}}{\rightleftharpoons} (CuA_2HA)_o + 2H^+,$$

$$2Cu^{2+} + 4(HA)_o \overset{K_{ex(20)}}{\rightleftharpoons} (Cu_2A_4)_o + 4H^+,$$

$$2Cu^{2+} + 6(HA)_o \overset{K_{ex(22)}}{\rightleftharpoons} (Cu_2A_4(HA_2)_o) + 4H^+.$$

Then, the adduct formation and dimerization of copper(II) decanoates in the present ketone solutions can be formulated as:

$$CuA_2 + HA \overset{K_{ad,monomer}}{\rightleftharpoons} CuA_2HA,$$

$$Cu_2A_4 + 2HA \overset{\beta_{ad,dimer}}{\rightleftharpoons} Cu_2A_4(HA)_2,$$

$$2CuA_2 \overset{K_{dim-1}}{\rightleftharpoons} Cu_2A_4,$$

$$2CuA_2HA \overset{K_{dim-2}}{\rightleftharpoons} Cu_2A_4(HA)_2.$$

We can readily calculate the corresponding adduct formation and dimerization constants from the respective extraction constants for each solvent. The values obtained are listed in Table 2 together with the extraction constants. In addition, the dimerization constants of copper(II) decanoate in alcohols[9] are shown in Table 3 for comparison.

Solvent Effects on the Dimerization of Copper(II) Decanoate in the Ketone Solutions. According to the regular solution theory,[13,14] the dimerization constant of copper(II) decanoate, K_{dim-1} is given as follows by the same approach as in the previous work:[9]

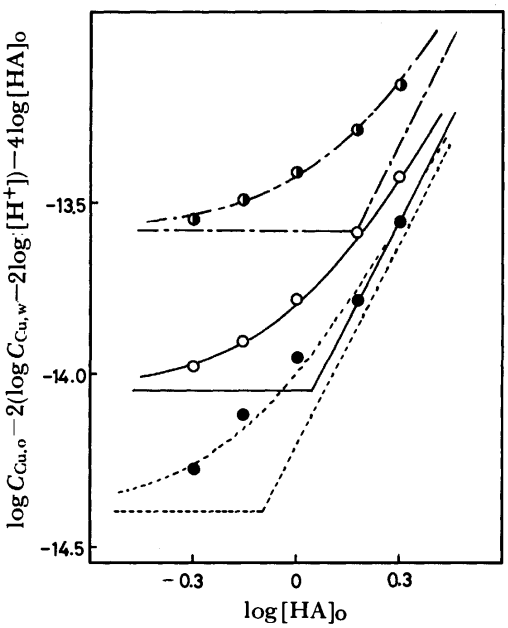

Fig. 4a. Determination of the number of decanoic acid molecules involved in the dimeric Cu(II) decanoates.
Curves and straight lines are the normalized curves, $\log(1+X^2)$ *vs.* $\log X$ and their asymptotes, respectively. Solvent; ◑: 2-octanone, ○: 2-hexanone, ●: 3-pentanone.

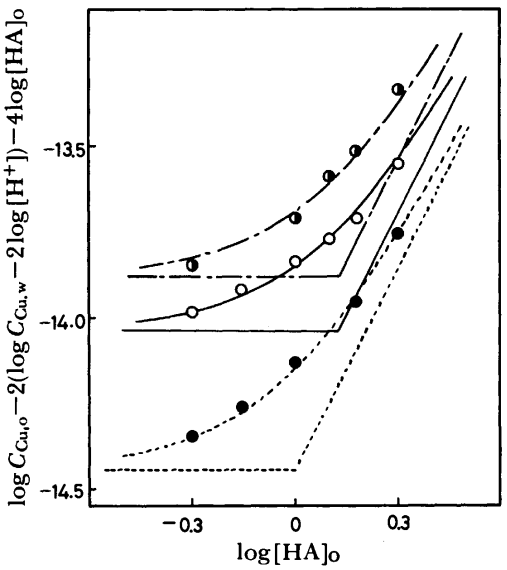

Fig. 4b. Determination of the number of decanoic acid molecules involved in the dimeric Cu(II) decanoates.
Curves and straight lines are the same as in Fig. 4a. Solvent; ◑: 5-methyl-2-hexanone, ○: 4-methyl-2-pentanone, ●: 2-pentanone.

TABLE 3. DIMERIZATION CONSTANTS OF COPPER(II) DECANOATE IN ALCOHOLS[9]

	Cyclohexanol	1-Pentanol	1-Hexanol	1-Heptanol	1-Octanol[8]
$\delta^{a)}/J^{1/2}cm^{-3/2}$	23.3	22.7	22.0	21.5	21.1
$V^{b)}/cm^3$	103	108	125	142	158
$\log K_{dim-1}$	2.23	2.26	2.77	3.04	3.46

a) : Solubility parameter. b) : Molar volume.

$$\log K_{\text{dim}-1} - \log V_s = 0.43nV_s(\delta_s-\delta')^2/RT + \log K_{\text{dim}-1}^\circ - 3, \quad (7)$$

where V_s and δ_s represent the molar volume and the solubility parameter of the solvent, δ' refers to the solubility parameter of copper(II) decanoate, $K_{\text{dim}-1}^\circ$ denotes the dimerization constant of copper(II) decanoate in an ideal solution, and n denotes the number of solvent molecules set free in the dimerization of copper(II) decanoate, that is, $nV_s=2V_{CuA_2}-V_{Cu_2A_4}$, where V_{CuA_2} and $V_{Cu_2A_4}$ represent the molar volume of the monomeric and dimeric copper(II) decanoates, respectively. The optimum δ' value based on the assumption, that the monomeric and dimeric copper(II) decanoates have the same solubility parameter, was found to be 24.1 ($J^{1/2}cm^{-3/2}$) from the previous work.[9] According to Eq. 7, the plot of ($\log K_{\text{dim}-1} - \log V_s$) against $0.43V_s(\delta_s-\delta')^2/RT$ should result in a straight line with a slope of n. The straight line shown in Fig. 5 leads to the validity of Eq. 7. The previous results for alcohol solvents are also implied in Fig. 5 for comparison. The values of n and $\log K_{\text{dim}-1}^\circ$ were calculated to be 2.8 and 3.19, respectively, by the least squares method. The value of n for alcohols was revealed to be 4.5 in the previous paper.[9] Thus, it was proved that the number of solvent molecules liberated in the formation of the dimeric copper(II) decanoate in ketones was less than that in alcohols. This suggests that the solvation of copper(II) decanoates in these two kinds of solvents differs from each other. Taking into account the hydrogen bonding abilities of the two types of solvents, it can be expected that in alcohols the copper(II) decanoates are much more solvated than in ketones. Further, judging from the difference in the n value between alcohols and ketones, the monomeric copper(II) species in alcohols seems to be more extensively solvated compared to the dimeric species. This is consistent with the view that the lower dimerization constant of copper(II) decanoate in alcohols is attributable to the more favorable solvation of the monomeric copper(II) decanoate by alcohol molecules.

On the other hand, as seen in Fig. 5, the intercept of the respective straight lines for alcohols and ketones agreed closely with one another. Then, the dimerization constant of copper(II) decanoate in an ideal solution, which was estimated by the extrapolation of the respective linear plots for alcohols and ketones, were found to be practically equal: $\log K_{\text{dim}-1}^\circ$=3.14 and 3.19, respectively.

Thus, the dimerization of copper(II) decanoate in the organic solvent seems to be strongly influenced by the solvation. The difference between the solvation of copper(II) decanoates in alcohols and ketones can be primarily attributable to the hydrogen bonding abilities of these two types of solvents.

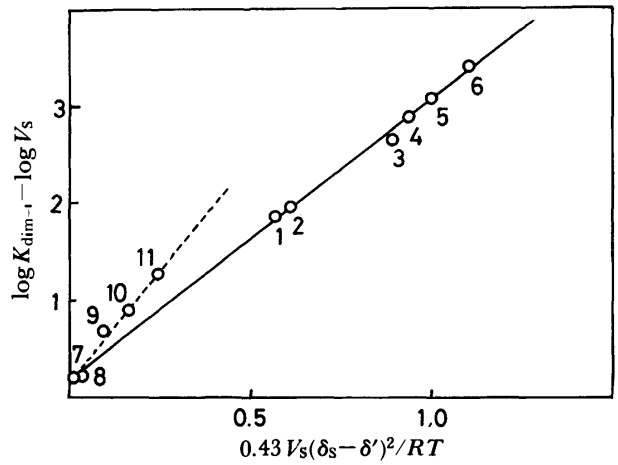

Fig. 5. Correlation of the dimerization constant of Cu(II) decanoate with the solubility parameter of solvents. Solid and dotted lines are the straight lines with a slope of 2.8 and 4.5, and with a intercept of 0.19 and 0.14, respectively. δ'=24.1 ($J^{1/2}cm^{-3/2}$). Ketones; No. 1: 3-pentanone, No. 2: 2-pentanone, No. 3: 2-hexanone, No. 4: 4-methyl-2-pentanone, No. 5: 5-methyl-2-hexanone, No. 6: 2-octanone, Alcohols; No. 7: cyclohexanol, No. 8: 1-pentanol, No. 9: 1-hexanol, No. 10: 1-heptanol, No. 11: 1-octanol.

The authors wish to thank Professor Motoharu Tanaka of Nagoya University for his valuable discussion.

Synthesis and Stereochemistry of (Diamine)(2,9-dimethyl-4,7-diazadecane-2,9-dithiolato)cobalt(III) Complexes and Their Derivatives

Kazuaki YAMANARI,* Norimatsu TAKESHITA, and Yoichi SHIMURA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received April 24, 1984)

Several (diamine)(2,9-dimethyl-4,7-diazadecane-2,9-dithiolato)cobalt(III) complexes, $[Co(SNNS)(diamine)]^+$ (diamine=1,2-ethanediamine and (*R,R*)-1,2-cyclohexanediamine), were prepared and characterized by the visible-UV absorption, circular dichroism(CD), and ^{13}C NMR spectra. The above SNNS quadridentate ligand gave only the *cis-β* geometrical isomer, which was chromatographically separated into two diastereomers owing to the configurations of chiral nitrogen atoms. All the thiolato and the corresponding sulfinato complexes exhibited two CD bands of opposite signs in the $Co(\sigma^*)\leftarrow S(\sigma)$ ligand-to-metal charge transfer band region. The sign pattern was found to be in connection with the absolute configurations of these complexes.

For the complex $[Co(SNNS)(diamine)]^+$ where SNNS denotes a quadridentate ligand having SNNS donor set, three geometrical isomers, *cis-α*-(R^NR^N/S^NS^N), *cis-β*-(R^NR^N/S^NS^N), and *cis-β*-(R^NS^N/S^NR^N), are possible as shown in Fig. 1. One of such quadridentate ligands 3,6-dimethyl-3,6-diazaoctane-1,8-dithiol (H_2endet) gave *cis-α* and *cis-β*-(R^NS^N/S^NR^N) isomers together and the other (*R*)-3,4,6-trimethyl-3,6-diazaoctane-1,8-dithiol(*R*-H_2pndet) gave *Δ-cis-α*-(R^NR^N) and *Δ-cis-β*-(S^NR^N) isomers only.[1] However, the complexes containing these ligands were generally prepared in low yield and unstable in aqueous solutions owing to the air-oxidation. This may be mainly due to the high reactivity of the thiolato group bonded to the primary carbon.

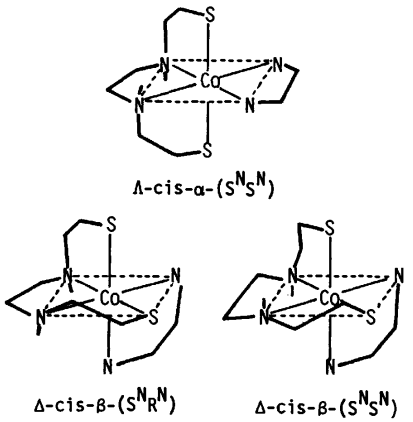

Fig. 1. Three geometrical isomers of [Co(SNNS)-(diamine)]$^+$.

In this paper, a new SNNS quadridentate ligand 2,9-dimethyl-4,7-diazadecane-2,9-dithiol (H_2dddt), where the thiols are attached to the tertiary carbon, was used to prepare several cobalt(III) complexes [Co(SNNS)-(diamine)]$^+$ (diamine=en, *R*-pn, *RR*-chxn, tn, *NN'*-Me_2en, meso-bn, and phen)[2] and their oxidation derivatives. The geometrical and optical isomers were chromatographically separated and characterized by the visible-UV absorption, circular dichroism(CD), and ^{13}C NMR spectra. In this system, only two kinds of *cis-β* isomers, *cis-β*-(R^NR^N/S^NS^N) and *cis-β*-(R^NS^N/S^NR^N), were found. The absolute configurations of the optical isomers were discussed in relation to the CD signs in the first d-d and the $Co(\sigma^*)\leftarrow S(\sigma)$ ligand-to-metal charge transfer (LMCT) band regions.

Experimental

Preparation of 2,9-Dimethyl-4,7-diazadecane-2,9-dithiol (H_2dddt), [$HSC(CH_3)_2CH_2NHCH_2-]_2$: This ligand was prepared according to the reference.[3] ^{13}C NMR (benzene): δ 31.03 (-C(CH_3)$_2$SH), 45.82 (-C(CH_3)$_2$SH), 50.04 (-NHCH_2C-(CH_3)$_2$SH), and 63.80 (-NHCH_2CH_2NH-). Found: C, 51.84; H, 10.21; N, 11.65%. Calcd for H_2dddt·0.07 C_6H_6=$C_{10.42}H_{24.42}N_2S_2$: C, 51.74; H, 10.08; N, 11.56%.

Preparation of cis-β-*[Co(dddt)(diamine)]ClO_4 (Diamine=en,* R-*pn,* RR-*chxn, tn,* NN'-*Me_2en, meso-bn, and phen)*: To a solution of 0.5 g of $[Co(NH_3)_6]Cl_3$ in 30 cm^3 of water was added a mixture of 0.46 g of H_2dddt and 0.24 g of en in 10 cm^3 of water and then a small amount of activated charcoal. The mixed solution was stirred at 70°C for 1 h. After removing the precipitate the filtrate was poured onto a column of SP-Sephadex C-25 (Na^+ form) and eluted with water and then 0.1 mol dm^{-3} $NaClO_4$ to give a dark violet band, which was assigned to *cis-β* isomer by the absorption spectrum. The eluate was concentrated on a rotary evaporator and cooled to give the perchlorate salt. The presence of *cis-α* isomer was undetectable in spite of the repeated experiments. Found for en complex: C, 32.09; H, 6.65; N, 12.30%. Calcd for *cis-β*-[Co(dddt)(en)]ClO_4=$C_{12}H_{30}N_4S_2O_4ClCo$: C, 31.82; H, 6.68; N, 12.37%.

The other complexes of *R*-pn, *RR*-chxn, tn, *NN'*-Me_2en, and meso-bn were prepared according to the same method as that of *cis-β*-[Co(dddt)(en)]ClO_4 except for the use of an appropriate diamine instead of en. Found for *R*-pn complex: C, 33.61; H, 6.91; N, 12.01%. Calcd for *cis-β*-[Co(dddt)(*R*-pn)]ClO_4=$C_{13}H_{32}N_4S_2O_4ClCo$: C, 33.44; H, 6.91: N, 12.00%. Found for *RR*-chxn complex: C, 38.01; H, 7.18; N, 11.03%. Calcd for *cis-β*-[Co(dddt)(*RR*-chxn)]ClO_4=$C_{16}H_{36}N_4S_2O_4$-ClCo: C, 37.91; H, 7.16; N, 11.05%. Found for tn complex: C, 33.65; H, 6.92; N, 12.06%. Calcd for *cis-β*-[Co(dddt)(tn)]ClO_4=$C_{13}H_{32}N_4S_2C_4ClCo$: C, 33.44; H, 6.91; N, 12.00%. Found for meso-bn complex: C, 35.04; H, 7.09; N, 11.68%. Calcd for *cis-β*-[Co(dddt)(meso-bn)]ClO_4=$C_{14}H_{34}N_4S_2O_4ClCo$: C, 34.96; H, 7.13; N, 11.65%. Found for *NN'*-Me_2en complex: C, 35.00; H, 7.16; N, 11.56%. Calcd for *cis-β*-[Co(dddt)(*NN'*-Me_2en)]ClO_4=$C_{14}H_{34}N_4S_2O_4ClCo$: C, 34.96; H, 7.13; N, 11.65%.

The complex *cis-β*-[Co(dddt)(phen)]ClO_4 was prepared as follows: to a solution of 0.5 g of $[Co(CO_3)(phen)_2]Cl$ in 15 cm^3 of water was added a mixture of 0.23 g of H_2dddt and 0.2 g of $(C_2H_5)_3N$ in 5 cm^3 of water. The mixed solution was stirred at 40°C for 1 h and filtered. The filtrate was poured onto a column of SP-Sephadex C-25(Na^+ form) and eluted with 0.1 mol dm^{-3} $NaClO_4$. The brown band was evaporated on a rotary evaporator and cooled to give the desired perchlorate. Found: C, 45.47; H, 5.25; N, 9.64%. Calcd for *cis-β*-[Co-(dddt)(phen)]ClO_4·0.5H_2O=$C_{22}H_{31}N_4S_2O_{4.5}ClCo$: C, 45.40; H, 5.37; N, 9.63%.

Diastereomer Separation of cis-β-*[Co(dddt)(diamine)]$^+$ (Diamine=en and* RR-*chxn)*: An aqueous solution of *cis*-β-[Co(dddt)(en)]ClO_4 was poured onto a column of Dowex 50W×2 (Na^+ from, φ4×5 cm) and eluted with 0.2 mol dm^{-3} Na_2SO_4. Two bands, dark violet (**A1**) and brown (**A2**), were eluted in this order. Each eluate was concentrated by a vacuum evaporator. After repeated removal of Na_2SO_4 deposited, a small amount of NaCl was added to the filtrate to yield the desired crystals. The formation ratio **A1**/**A2** was *ca.* 8, which was almost identical to that determined by the column chromatography of the reaction solution. Found for **A1** isomer: C, 36.74; H, 7.78; N, 14.13%. Calcd for *cis*-β-[Co(dddt)(en)]Cl: $0.25H_2O$=$C_{12}H_{30.5}N_4S_2O_{0.25}ClCo$: C, 36.64; H, 7.81; N, 14.24%. Found for **A2** isomer: C, 36.41; H, 7.70; N, 14.03%. Calcd for *cis*-β-[Co(dddt)(en)]Cl·$0.5H_2O$=$C_{12}H_{31}N_4S_2O_{0.5}ClCo$: C, 36.22; H, 7.85; N, 14.08%.

The column separation using SP-Sephadex C-25 (Na^+ form, φ4×60 cm) was ineffective. The use of $NaClO_4$ or NaCl as an eluent was troublesome because in the former case the desired perchlorate salt crystallized in the column and in the latter case evaporation of the eluate caused coprecipitation of the complex chloride and NaCl. Acidic eluent has been usually used to prevent the racemization *via* proton exchange at secondary nitrogen centers. However, it is well known that the thiolato cobalt(III) complexes give the protonated species in an acid media.[4] In this system, the protonated species caused the band broadening and the significant decrease of the elution rate. Therefore, the column chromatography was achieved under neutral conditions.

In *cis*-β-[Co(dddt)(*RR*-chxn)]$^+$, the Dowex chromatography of the reaction mixture gave two bands, dark violet (**B1**) and brown (**B2**), in this order. The absorption and CD spectral measurements confirmed that the former band contains two species (**B1-I** and **B1-II**) and the latter single one. No solid complex **B1-I** or **B1-II** was isolated because the less soluble pseudo racemate composed of **B1-I** and **B1-II** tended to deposit. The CD spectra of **B1-I** and **B1-II** were measured with the fractionated solutions, whose concentrations were calculated from the measured absorbance using the absorption coefficient of **B1** complex. The formation ratio **B1**/**B2** was 2.8. Found for **B1** complex: C, 37.84; H, 7.17; N, 11.06%. Found for **B2** complex: C, 37.86; H, 7.13; N, 10.97%. Calcd for *cis*-β-[Co(dddt)(*RR*-chxn)]ClO_4=$C_{16}H_{36}N_4S_2O_4ClCo$: C, 37.90; H, 7.16; N, 11.05%.

Preparation and Diastereomer Separation of cis-β-*[Co(dddsi)(diamine)]$^+$ (H_2dddsi=2,9-dimethyl-4,7-diazadecane-2,9-disulfinic Acid, $[HO_2SC(CH_3)_2CH_2NHCH_2-]_2$ and Diamine=en and* R,R-*chxn)*: In general, sulfinato complexes can be prepared *via* H_2O_2 oxidation of the corresponding thiolato complexes. To the reaction mixture of *cis*-β-[Co(dddt)(en)]$^+$ was added an excess H_2O_2 and the resulting solution was kept standing for 3 d. The resulting yellow solution was poured onto a column of SP-Sephadex C-25 (Na^+ form, φ4×60 cm) and eluted with 0.1 mol dm^{-3} Na_2SO_4 to give two yellow bands (**C1** and **C2** in this order). The formation ratio **C1**/**C2** was about 8. Both isomers showed twelve ^{13}C NMR signals and therefore have the *cis*-β geometry. The oxidation of the pure isomer **A1**-*cis*-β-[Co(dddt)(en)]$^+$ yielded only **C1** sulfinato complex. These facts indicate that no isomerization occurs during the oxidation reaction. The solid complexes were isolated by the same way as described above. Found for **C1** isomer: C, 27.04; H, 6.02; N, 10.57%. Found for **C2** isomer: C, 26.85; H, 6.03; N, 10.40%. Calcd for *cis*-β-[Co(dddsi)(en)]ClO_4·H_2O=$C_{12}H_{32}N_4S_2O_9ClCo$: C, 26.94; H, 6.03; N, 10.47%.

The oxidized solution of **B1**-*cis*-β-[Co(dddt)(*RR*-chxn)]$^+$ was separated by a column of Dowex 50W×2 (Na^+ form, φ4×8 cm; 0.15 mol dm^{-3} Na_2SO_4). The earlier eluted fractions (**D1-I**) showed a positive CD band in the spin-allowed first d-d absorption band region and the latter fractions (**D1-II**) a negative and a positive band from the lower energy in the same region. Found for **D1-I** isomer: C, 32.01; H, 6.59; N, 9.21%. Calcd for *cis*-β-[Co(dddsi)(*R*,*R*-chxn)]ClO_4·$1.5H_2O$=$C_{16}H_{39}N_4S_2O_{9.5}ClCo$: C, 32.14; H, 6.57; N, 9.37%. The concentration of **D1-II** was calculated from the measured absorbance by assuming that the absorption coefficient of **D1-II** is the same as that of **D1-I**. The complex **D2**-*cis*-β-[Co(dddsi)(*R*,*R*-chxn)]ClO_4 was obtained by the oxidation reaction of the corresponding **B2** complex. Found: C, 32.74; H, 6.24; N, 9.56%. Calcd for *cis*-β-[Co(dddsi)(*RR*-chxn)]ClO_4·H_2O=$C_{16}H_{38}N_4S_2O_9ClCo$: C, 32.63; H, 6.50; N, 9.51%.

Measurement. The visible and ultraviolet absorption spectra were measured on a Hitachi 330 spectrophotometer and CD spectra with a JASCO MOE-1 spectropolarimeter in

aqueous solutions. The ^{13}C NMR spectra were recorded with a JEOL FX-90Q NMR spectrometer.

Results and Discussion

Characterization of Geometrical Isomers. The absorption spectra and data of [Co(N)$_4$(thiolato)$_2$] type complexes are shown in Figs. 2 and 3 and Table 1. Both isomers **A1**- and **A2**-[Co(dddt)(en)]$^+$ showed very similar absorption spectra. The intense band in 30000—40000 cm^{-1} region, which is assigned to the Co(σ^*)←S(σ) LMCT transition,[5] is composed of two components at 34400 and *ca.* 37000 cm^{-1} for each isomer. Such a spectral pattern is characteristic of *cis(S)* geometry.[1] Therefore, both isomers can be assigned to the *cis*-β geometry. This assignment was confirmed by the ^{13}C NMR spectra (Table 2): each isomer showed twelve or eleven signals, which is consistent with the *cis*-β geometry of C_1 symmetry. The thiolato complexes containing the other diamines were also assigned to *cis*-β isomer on the basis of the absorption spectra.

The yield of the first eluted isomer is considerably higher than that of the second one in either *cis*-β-[Co(dddt)(en)]$^+$ or *cis*-β-[Co(dddt)(*RR*-chxn)]$^+$. For the complexes containing triethylenetetramine (trien) as a quadridentate ligand, the strain minimization cal-

a) All complexes were converted into the soluble sulfate salts for measurement. b) The intensity is *ca.* twice those of others.

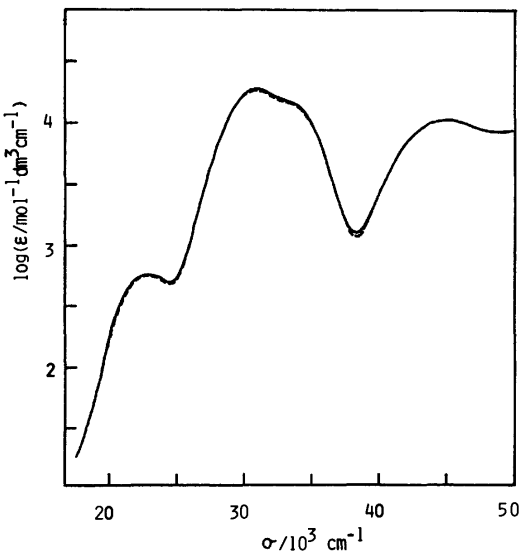

Fig. 4. Absorption spectra of *cis*-β-[Co(dddsi)(en)]$^+$: **C1** isomer (——) and **C2** isomer (----).

culations were carried out by several groups.[6] These calculations indicated that *cis*-β-(R^NR^N/S^NS^N) isomer is more stable than *cis*-β-(R^NS^N/S^NR^N) one. This was experimentally confirmed by the higher yield of *cis*-β-(R^NR^N/S^NS^N) isomer in $[CoX_2(trien)]^{n+}$ (X_2=$NH_2CH_2CO_2^-$,[6b] $2NH_3$,[6c] $2NCS^-$,[7] and $2CN^-$[8]). Therefore, it is reasonable to consider that **A1** isomer has the *cis*-β-(R^NR^N/S^NS^N) structure and **A2** isomer the *cis*-β-(R^NS^N/S^NR^N) one. Similarly **B1** isomer was assigned to a pair of the diastereomers of *Λ-cis*-β-(R^NR^N)(R^CR^C) and *Δ-cis*-β-(S^NS^N)(R^CR^C), but **B2** isomer was found to be stereoselectively composed of *Δ-cis*-β-(S^NR^N)(R^CR^C) as described later. Another empirical criterion of the geometry assignment may be derived from ^{13}C NMR spectra. The chemical shift of *cis*-β-(R^NR^N/S^NS^N) isomer always locates at the higher magnetic field than that of the corresponding *cis*-β-(R^NS^N/S^NR^N) one in all $[CoX_2(trien)]^{n+}$ complexes so far isolated (X_2=$2NH_3$,[6c] $2NCS^-$,[7] $2CN^-$,[8] and en[9]). In the present system, **A1** isomer exhibited the ^{13}C NMR resonances at somewhat higher magnetic field than **A2** one, which leads to the assignment that **A1** and **A2** isomers are *cis*-β-(R^NR^N/S^NS^N) and *cis*-β-(R^NS^N/S^NR^N), respectively. Thus, the same assignment was derived from the formation ratio and the relative position of ^{13}C NMR chemical shift.

The absorption spectra of sulfinato complexes are shown in Figs. 4 and 5 and Table 1. All sulfinato complexes showed the intense LMCT band of two components at 27000—37000 cm^{-1}, which is characteristic for the S-bonded sulfinato complex.[10] Both isomers **C1**- and **C2**-[Co(dddsi)(en)]$^+$ could be assigned to the *cis*-β geometry based on the ^{13}C NMR spectra (Table 2) and the absorption spectral resemblance to *cis*-β-[Co(endesi)(diamine)]$^+$.[1] The formation ratio **C1**/**C2** in the sulfinato complex was almost identical to the ratio **A1**/**A2** in the starting thiolato complex and the oxidation of *cis*-β-(R^NR^N/S^NS^N)-[Co(dddt)(en)]$^+$ (**A1** isomer) gave only **C1** isomer. Therefore, **C1** isomer is assignable to *cis*-β-(R^NR^N/S^NS^N) and **C2** one to *cis*-β-(R^NS^N/S^NR^N). From a similar argument, **D1** isomer was attributed to a pair of diastereomers of *Λ-cis*-β-

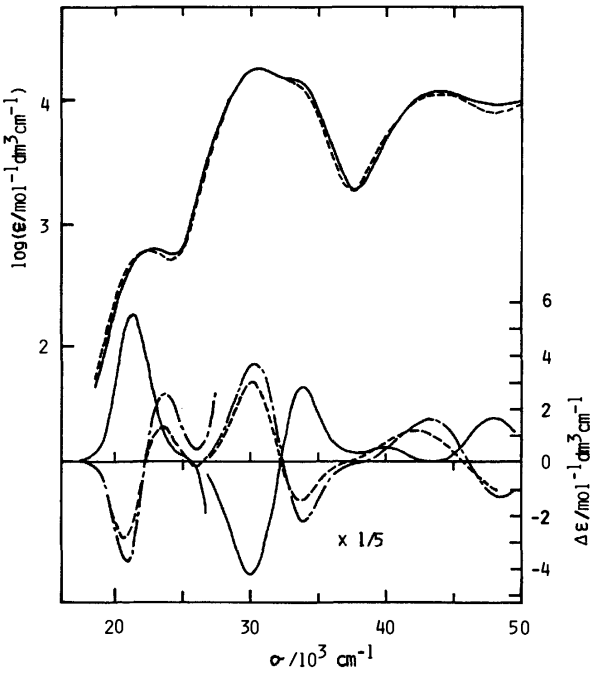

Fig. 5. Absorption and CD spectra of *cis*-β-[Co(dddsi)(*RR*-chxn)]$^+$: **D1-I** isomer (——), **D1-II** isomer (— — —), and **D2** isomer (----).

(S^NS^N)(R^CR^C) and *Λ-cis*-β-(R^NR^N)(R^CR^C), and **D2** isomer to *Λ-cis*-β-(S^NR^N)(R^CR^C).

Synthesis and Property of Cobalt(III) Complexes with SNNS Ligand. Several cobalt(III) complexes of [Co(SNNS)(diamine)]$^+$ type could be prepared using the dddt quadridentate ligand $^-SC(CH_3)_2CH_2NHCH_2CH_2NHCH_2C(CH_3)_2S^-$. This ligand did not react directly with the tris(diamine)cobalt(III) complexes such as $[Co(en)_3]^{3+}$ and $[Co(RR\text{-chxn})_3]^{3+}$, though the endet (R=H) and *R*-pndet ($R=CH_3$) ligands having general skeleton $^-SCH_2CH_2N(CH_3)CH_2CHRN(CH_3)CH_2CH_2S^-$ reacted immediately with these complexes.[1] In the latter ligands, it was found that the mononuclear complex formation is possible only when the remaining two coordination sites are occupied by such tightly bound ligands as diamine, $2CN^-$, and $NH_2CH_2CH_2S^-$. However, in the present dddt ligand, the formation of $[Co(dddt)ox]^-$ ($ox=^-O_2CCO_2^-$) was confirmed by the absorption spectrum. The thiolato complexes with endet or *R*-pndet were liable to oxidation by air in aqueous solutions but the dddt complexes were not. The complete oxidation of the thiolato complex to the sulfinato one with an excess of H_2O_2 necessitated *ca.* 3 d at room temperature in the dddt complex. Such long time was not needed for the endet complexes.[1] These facts indicate that the dddt ligand has not so higher reactivity as the endet or *R*-pndet. This is attributable to the structure of dddt where the thiolate are bonded to the tertiary carbon. A similar situation is encountered between cysteinate(cyst) $NH_2CH(CO_2^-)CH_2S^-$ and penicillaminate(pen) $NH_2CH(CO_2^-)C(CH_3)_2S^-$: The former ligand and its analog $NH_2CH_2CH_2S^-$, where the thiolate is bonded to the primary carbon, tend to form polymeric complexes with μ-thiolato structure because of residual reactivity after coordination.[11] Bis(terdentato)cobalt(III) complex has been

reported only for the penicillaminate.[12]

The endet and *R*-pndet ligands gave both *cis*-α and *cis*-β isomers[1] but the dddt only *cis*-β one. In general, cobalt(III) complexes containing two or three thiolato groups prefer the *cis(S)* geometry as found in *trans(N)*- and *trans(O)*-[Co(D-pen)$_2$]$^-$,[12b] *fac(S)*-[Co($NH_2CH_2CH_2S$)$_3$],[5] and *fac(S)*-[Co(L-cyst)$_3$]$^{3-}$,[5] because of the strong structural trans effect of the thiolato sulfur atom.[13] The fact that only *cis*-β isomers with the *cis(S)* geometry were found in the dddt ligand agrees well with the above general tendency of the thiolato complexes. The endet and *R*-pndet ligands have the methyl group on the nitrogen atoms. The steric repulsion between the two methyl groups may be weakened in the *cis*-α structure rather than in the *cis*-β one, which is responsible for the formation of *cis*-α isomer in the endet and *R*-pndet complexes. A similar substituent effect has been observed for the edda complexes [Co(edda)X_2]$^+$ (edda= ethylenediamine-*N*,*N*′-diacetate and X_2=en or $2NH_3$):[14] A trace of *cis*-β isomer was found for the edda complexes but no *cis*-β isomers for the *N*,*N*′-dimethyl- and *N*,*N*′-diethyl-edda complexes.

A linear flexible edda-type ONNO ligand apparently resembles the present SNNS ligand. In the edda complexes, *cis*-α isomer is dominantly formed[14] and the formation of *cis*-β isomer depends mainly on the properties of the bidentate ligands[15] and the reaction temperature.[16] No couple of *cis*-β isomers, *cis*-β-(R^NR^N/S^NS^N) and *cis*-β-(R^NS^N/S^NR^N), has been known so far,[17] though the possible existence of two *cis*-β isomers in [Co(edda)(H_2O)$_2$]$^+$ and [Co(edda)CO_3]$^-$ was suggested by a ^{1}H NMR study.[15c] The X-ray structural study showed that *cis*-β-[Co(edda)(H_2O)$_2$]ClO_4 is the racemate consisting of Λ-*cis*-β-(R^NS^N) and Δ-*cis*-β-(S^NR^N)[15c] and Δ-*cis*-β-[Co(edda)(*R*-pn)]Cl takes the (S^NR^N) configuration[18] in the crystalline state. Thus, it has been concluded that the (S^NR^N) configuration represents the thermodynamically stable isomer in solution as well as in the solid state.[18] Such conclusion is in good agreement with that for the endet and *R*-pndet complexes where *cis*-α and only *cis*-β-(R^NS^N/S^NR^N) isomers were found. However, two *cis*-β isomers have been found for the present dddt complexes, the *cis*-β-(R^NR^N/S^NS^N) configuration being predominant. The stereochemistry of the dddt complexes resembles that of the trien complexes rather than the edda complexes.

Absolute Configurations of Thiolato and Sulfinato Complexes. The CD spectra are shown in Figs. 3 and 5. **B1-I** isomer showed three positive CD components in the first d-d absorption band region and therefore is assigned to the Λ-*cis*-β-(R^NR^N)(R^CR^C) configuration.[1] Since **B1-II** isomer showed main two negative CD components in the same region, it can be assigned to the Δ-*cis*-β-(S^NS^N)(R^CR^C) configuration. The CD spectrum of less soluble **B1** isomer is the same as that calculated from equimolecular amount of **B1-I** and **B1-II**, which means that **B1** isomer is a pseudoracemate composed of **B1-I** and **B1-II**. Only one diastereomer **B2** was found for the later eluted band. On the basis of the two negative CD bands in the first d-d absorption band region, the Δ-*cis*-β-(S^NR^N)(R^CR^C) configuration is assigned to it. It is noteworthy that such complete stereoselectivity was found in other sys-

tem of Λ-*cis*-β-(S^NR^N)-[Co(endet)(*R*-pn or *RR*-chxn)]$^+$ and Λ-*cis*-β-(S^NR^N)-[Co(*R*-pndet)(en or *RR*-chxn)]$^+$.[1] The corresponding Λ-*cis*-β-(R^NS^N) structure has been considered to be less stable in these complexes because of a steric repulsion between the two amine protons on bidentate diamine and the two methylene protons adjacent to the tertiary amine of the quadridentate. The same discussion is effective for the present complex *cis*-β-[Co(dddt)(*RR*-chxn)]$^+$. The configurations of the sulfinato complexes were determined by the CD sign in the first absorption band region, being in agreement with those based on the oxidation reaction of the corresponding thiolato complexes: **D1-I** and **D1-II** isomers are Λ-*cis*-β-(R^NR^N)(R^CR^C) and Δ-*cis*-β-(S^NS^N)-(R^CR^C), respectively, and **D2** isomer Δ-*cis*-β-(S^NR^N)-(R^CR^C).

A clear relationship between absolute configuration and CD sign could be found in the LMCT band region. All the present complexes showed two intense CD bands of opposite signs at 30000—40000 cm^{-1} for the thiolato complexes and at 27000—37000 cm^{-1} for the sulfinato complexes. The sign pattern in this region always relates to that in the first d-d band region, that is, (+)(−)CT from the lower energy corresponds to (−)d-d, and (−)(+)CT to (+)d-d. Therefore, the complexes with (+)(−) and (−)(+) patterns from the lower energy in the LMCT band region can be assigned to the Δ and Λ configurations, respectively.

Table 4 collects the thiolato and sulfinato complexes with two or more sulfur donor atoms. All complexes

have the *cis(S)* geometry and showed two intense CD bands of opposite signs as well as characteristic LMCT absorption band with two components. It is very interesting that the above empirical relationship about absolute configuration is applicable to all thiolato and sulfinato complexes with two or more sulfur donor atoms no matter what the ligands may be. This is exemplified in the system containing monodentate ligand $[Co(SO_3)_2(en)_2]^-$.[19] The thiolato and sulfinato complexes in Table 4 have only CD contribution owing to the skew pairs of chelate rings and their LMCT transitions overlap neither with two d-d transitions nor with the other LMCT transitions such as Co(σ^*)←N(σ), the situations being responsible for the above result. The empirical relationship does not hold for the *trans(S)* complexes such as *cis*-α-[Co(endet)(diamine)]$^+$,[20] *cis*-α-[Co(*R*-pndet)(diamine)]$^+$,[1] and *trans(S)*-$[Co(mp)_2(en)]^+$ (mp=2-pyridinethiolate), because they show the single LMCT band at relatively lower energy. In the complexes containing sulfenato and/or thioether groups, there is also no simple relationship because another CD contribution owing to the chiral sulfur donor atoms adds to that owing to the skew pairs of chelate rings.

Selective Adsorption of Molybdenum(VI) and/or Vanadium(V) Using Cross-linked Polystyrene Resins with Bis(2-hydroxyethyl)-amino, Bis(carboxymethyl)amino, and Bis-(phosphonomethyl)amino Groups

Masato NISHIZAWA,* Toshiro YOKOYAMA, Tetsuo KIMURA, and Toshishige M. SUZUKI*
Government Industrial Research Institute, Tohoku. 4-2-1, Nigatake, Sendai 983
(Received April 27, 1984)

Styrene–divinylbenzene copolymers containing $-N(CH_2CH_2OH)_2$, $-N(CH_2CO_2H)_2$, and $-N(CH_2PO(OH)_2)_2$ moieties have been synthesized and applied to the selective adsorption of molybdenum and/or vanadium from aqueous solution. The equilibrium adsorption capacity *vs.* pH correlation and exchange kinetics of the resins for Mo^{VI} and V^{V} have been studied. The resin containing bis(2-hydroxyethyl)amino group is particularly effective for the selective recovery of Mo^{VI} and/or V^{V} by column operation due to its high adsorption capacity and faster exchange rate, whereas other resins required much longer time to attain adsorption equilibrium. The bis(2-hydroxyethyl)amino resin was used for the selective recovery of molybdenum from an acid-leaching solution of waste desulfurization catalyst.

In all industrialized countries a significant proportion of the metals consumed by industry should be provided by recycling of used metals. Therefore it is important to achieve a process to recover metals from scrap and industrial wastes. Waste catalysts used in the desulfurization of petroleum contain appreciable amounts of molybdenum and vanadium.[1] We have been searching for highly selective chelating resins in order to recover these metals from acid-leaching solution. Multidentate ligands containing bis(carboxymethyl)amino group(s) are known to form stable complexes with oxomolybdenum(VI) and oxovanadium(V) ions.[2,3] The selective adsorption of these metal ions has been demonstrated by polymer-immobilized iminodiacetic acid[4,5] and *N*-[2-(2-pyridyl)ethyl]ethylenediamine-*N*,*N*′-diacetic acid.[5]

We have recently prepared cross-linked polystyrene resins containing a series of multidentate ligands as discrete units to attain a high adsorption capacity and selectivity.[6,7] In our preliminary work we found that those resins which contain bis(2-hydroxyethyl)amino and bis(phosphonomethyl)amino moieties have a potential utility for selective adsorption of oxometal ions.[8] In the present paper we deal with a detailed study on the adsorption of Mo^{VI} and/or V^{V} using chelating resins having bis(2-hydroxyethyl)amino (HEA), bis(carboxymethyl)amino (CMA), and bis(phosphonomethyl)amino (PMA) moieties as depicted in Fig. 1 to elucidate the correlation of the adsorption characteristics with the properties of the functional groups. The application of the resins for the selective recovery of molybdenum from the acid-leaching solution of waste catalyst has been studied.

Experimental

Materials. Reagent grade $Na_2MoO_4 \cdot 2H_2O$, $K_2MoO_4 \cdot 5H_2O$, NH_4VO_3, and ethylenediamine-*N*,*N*,*N*′,*N*′-tetraacetic acid (EDTA) were used without further purification. *N*,*N*,*N*′,*N*′-Tetrakis(2-hydroxyethyl)ethylenediammonium bis(perchlorate) (THEED·$2HClO_4$)[9] and *N*,*N*,*N*′,*N*′-tetrakis-(phosphonomethyl)ethylenediamine (EDTPO)[10] were prepared by the reported methods and identified by ^{1}H-NMR and ^{13}C-NMR spectroscopy. Gel-type of polystyrene-2%-divinylbenzene copolymer beads (200—400 mesh, Kanto Chemical Co.) were used as the polymer matrix of the chelating resins.

Leaching Solution of Desulfurization Catalyst. Metal ions were leached from waste desulfurization catalyst by treatment with 4 M HCl (1 M = 1 mol dm^{-3}) as described previously.[5] The main components in the leaching solution were molybdenum, vanadium, and aluminium, of which the latter two metals originated from crude oil and catalyst support (Al_2O_3), respectively.

Preparation of the Chelating Resins. Polystyrene beads were chloromethylated followed by functionalization with diethylenetriamine (*dien*) to give a *dien*-resin in which *dien* is linked to the polymer uniquely through the imino group.[6,7] The *dien*-resin was used as the starting material for the preparation of *N*-substituted derivatives.

HEA Resin: The *dien*-resin (11 g) was stirred with aqueous ethylene oxide (9.6 g in 100 cm^3) for 3 h under ice-cooling. After standing overnight at room temperature, the resin beads were filtered, washed throughly with water, ethanol, and diethyl ether, and then dried *in vacuo* at 50°C. Yield: 19.5 g. Nitrogen analysis: 7.3%.

CMA and PMA resins were prepared by carboxymethylation and phosphonomethylation of the *dien*-resin as described previously.[7] Nitrogen analyses of CMA and PMA resins were 7.7 and 6.5%, respectively.

Determination of Adsorption Capacity. A batchwise technique was used to determine the equilibrium adsorption capacity (amount of metal adsorbed on one gram of dry resin) with metal ion always being excess over the resin capacity.

Typically, 100 mg of dry resin was added to 100 cm^3 of metal

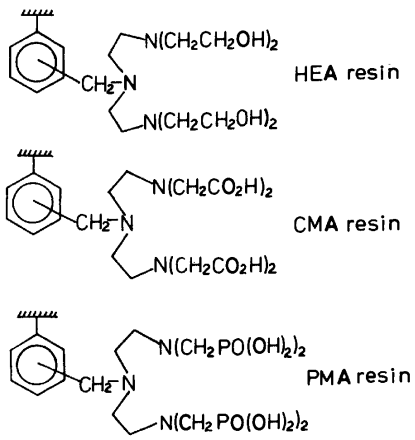

Fig. 1. Polymer-immobilized multidentate ligands.

ion solution of various pH and the mixture was shaken at room temperature. After equilibrium was attained, the concentration of the remaining metal ion in the supernatant was analyzed by atomic absorption spectrometry. The capacity of the resins was calculated by the change in the metal concentration observed.

Adsorption Rate. Time-course experiments for the adsorption of metal ion were carried out under a batchwise procedure: To a buffered metal solution (2—4 mM) was added 500 mg of resin which was swollen with water in advance. While stirring, small portions of the samples were withdrawn at appropriate intervals and analyzed as described above.

Kinetic Runs. Complex formation kinetics of THEED, EDTPO, and EDTA with Mo^{VI} was studied at 25 °C in the pH regions 3.9—5.6, 3.7—6.1, and 4.5—6.8, respectively. The reaction was followed spectrophotometrically at 270 nm by a stopped-flow technique. The kinetic runs were carried out under pseudo-first-order conditions, ligand concentration being in excess (3×10^{-3} M) over Mo^{VI} (1×10^{-4} M). The pH was adjusted with perchloric acid and sodium hydroxide solution at an ionic strength of 0.5 ($NaClO_4$). Plots of log $(A_\infty-A_t)$ against time gave straight lines until the reaction reached 85% completion.

Column-breakthrough Experiments. A 5 g sample of chelating resin was swollen with water and poured onto a glass column (ϕ 1.3 cm). The column was conditioned with dilute HCl (pH 1) in advance, then the metal ion solution was passed through the column continuously at a rate of 1.5 $cm^3\,min^{-1}$. The effluent was fractionated into 10 cm^3 portions and the amount of metal ion was determined. The adsorbed molybdenum and/or vanadium was liberated from the column by elution with 1 M sodium hydroxide solution. The resin was regenerated by this procedure and used in the successive operation.

A similar column operation was applied to the actual leaching solution of waste catalyst in which various foreign metal ions other than molybdenum and vanadium were also present. The concentration of the components in the feed solution were 360, 220, 53, 15, 4, and 3 ppm for Mo, V, Al, Co, Ni, and Fe, respectively.

Measurements. The ^1H-NMR and ^{13}C-NMR were obtained with a JEOL FX-100 spectrometer with sodium 3-(trimethylsilyl)-1-propanesulfonate as the internal standard. UV spectra were recorded with a Hitachi 100-60 spectrophotometer. The metal ion concentration was determined with a Shimadzu atomic absorption/flame photometer Model AA-610S. The complexation reaction was followed by a stopped-flow method using a Union Giken RA 601 with a data processor and an X-Y recorder.

Results

Preparation of the Chelating Resins. The chelating resins used in the present study were derived from diethylenetriamine which was immobilized on polystyrene through the imino nitrogen.[6,7] The HEA resin was prepared by treatment of the *dien*-resin with aqueous ethylene oxide solution. *N*-Carboxymethylation and *N*-phosphonomethylation of the *dien*-resin yielded the CMA resin and PMA resin, respectively. Nitrogen analyses indicated that the HEA, CMA, and PMA resins formally contain 1.7, 1.8, and 1.6 mmol of the functional group per gram resin, respectively. All the resins have a satisfactory stability over a wide pH range.

Equilibrium Adsorption. The adsorption capacity *vs.* pH profiles of the resins are given in Figs. 2, 3. The amount of Mo^{VI} adsorbed on one gram of resin are approximately 3 mmol over pH 1—6 irrespective of the functional group. Thus, the ratios of Mo^{VI} capacity to the content of functional group are in the range 1.8—2.0. Previously we reported the capacity of the CMA resin for Mo^{VI} to be 1—1.5 mmol g^{-1} by allowing the resin for 3 h in a metal solution.[5] However a slower adsorption step took place subsequently and the equilibrium was attained after seven days. In any case, the capacities for Mo^{VI} and V^V are markedly decrease in alkaline solution (pH 10) in which pH region the functional groups coordinate to the metal species with difficulty.[11] Therefore adsorbed Mo^{VI} and V^V were readily liberated from the resin on treatment with dilute sodium hydroxide solution. The adsorption capacities

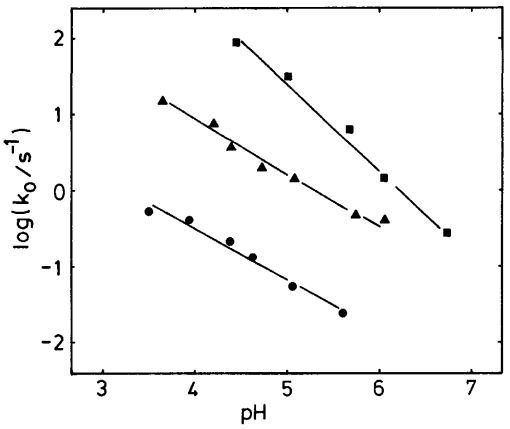

Fig. 5. Conditional first-order rate constant of Mo^{VI} complex formation as a function of pH.
-●-: THEED, -▲-: EDTPO, -■-: EDTA.

of the present resins were reproducible over several adsorption-regeneration cycles. Apparent selectivity was observed for all the resins, the capacities for vanadium at pH below 2.0 is remarkably lower than those for molybdenum. In addition, these resins revealed very little affinity for the common metal cations including Al^{3+}, Cu^{2+}, Co^{2+}, Ni^{2+}, Fe^{2+}, at pH lower than 3.0.

Complexation Kinetics. The time-course of Mo^{VI} adsorption on the present resins was followed by monitoring the concentration in the aqueous phase at pH 4 and the results are shown in Fig. 4. The HEA resin can adsorb the metal ion rapidly and equilibrium was attained within 3 min, while the CMA and PMA resins required much longer time for equilibration under identical conditions. A similar trend was observed at pH 1 for Mo^{VI} uptake and at pH 4 for V^{V}. As mentioned above, the adsorption of Mo^{VI} by CMA resin involves two steps, *i.e.*, rapid adsorption took place in the initial 1 or 2 h followed by a second slower step which required extremely long time for equilibration.

The rate of complexation between functional groups and Mo^{VI} was estimated by model reactions employing ethylenediamine derivatives, THEED, EDTA, and EDTPO. The absorption intensity of aqueous Mo^{VI} solution at 300—200 nm region increases on addition of the ligands and was monitored spectrophotometrically. Figure 5 shows the profile of the pseudo-first-order rate constants against pH. EDTA coordinates to Mo^{VI} in one order of magnitude faster than EDTPO and two orders of magnitude than THEED. In every case the rate was enhanced as the concentration of proton increased, however the spectral change became complicated at pH lower than 3.5 due to side reactions.

Column Breakthrough. In the batch experiments present resins showed an apparent selectivity toward Mo^{VI} at pH lower than 1.5 suggesting the possibility of selective recovery of the metal ion. When a model solution containing equimolar Mo^{VI} and V^{V} (4 mM each, pH 1.0) was passed continuously through the column of HEA resin, Mo^{VI} was quantitatively adsorbed on the resin while V^{V} was found in the eluate. The amount of Mo^{VI} adsorbed on one gram of the resin at breakthrough point (breakthrough capacity) is approximately 90% of the equilibrium capacity obtained by batch experiment. Vanadium was then quantitatively

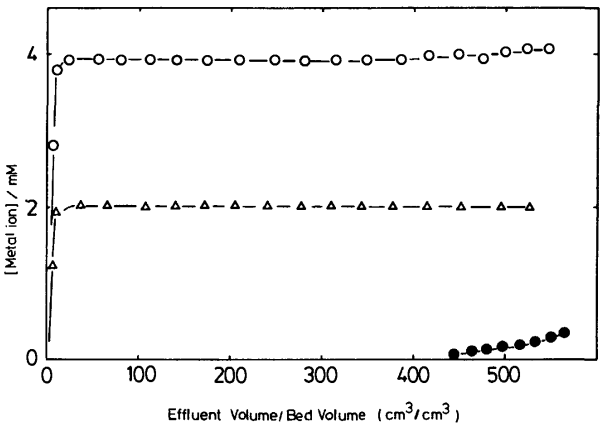

Fig. 6. Breakthrough profile of the acid-leaching solution of waste catalyst.
-●-: Mo, -Δ-: Al, -○-: V.
Bed resin: HEA resin, 5 g (wet volume 13 cm^3), pH of the feed: 1.0, Flow rate: 1.5 $cm^3\,min^{-1}$.

collected from the eluate upon subsequent column operation at pH 2—3. Using the column with CMA and PMA resins, on the other hand, both Mo^{VI} and V^{V} leaked through the column in the early stage regardless of the pH of the feed solution.

Based on the column experiments we chose HEA resin for selective recovery of molybdenum and/or vanadium from the acid-leaching solution of desulfurization catalyst. Using the column operation described above, molybdenum was quantitatively adsorbed on the resin, while other metals leaked through the column. The breakthrough curves are given in Fig. 6. Small amount of vanadium was cosorbed in a molar ratio Mo/V *ca.* 5/1. The adsorbed ion was liberated in concentrated form, 60-fold over the feed solution, on elution with 1 M sodium hydroxide. Repeated column operation for the eluate greatly improved the Mo/V ratio to be 50/1.

Discussion

EDTA is known to form 1:2 (ligand:metal) complex with oxomolybdenum(VI) ion in the presence of excess metal ion. The facial tridentate coordination of each iminodiacetate arm to the trioxomolybdenum-

(VI) was suggested by ^{1}H- and ^{13}C-NMR studies[12-14] and confirmed in the solid state for $Na_4(MoO_3)_2$-EDTA·$8H_2O$.[15] The HEA, CMA, and PMA resins formally contain two sets of tridentate ligand, bis(2-hydroxyethyl)amino, bis(carboxymethyl)amino, and bis(phosphonomethyl)amino moieties, respectively. It appears that each of the tridentate ligand units forms a 1:1 complex with Mo^{VI} in a similar fashion to that for the EDTA-Mo^{VI} complex since the metal capacity values in equilibrium are approximately twice the value of the ligand capacity.

The coordination of the hydroxyl arm onto the Mo^{VI} center has been demonstrated by Freeman *et al.*, using *N*-methyl-*N*-hydroxyglycine (MHEG) and *N*-(2-hydroxyethyl)ethylenediaminetriacetic acid (HEDTA).[14] They reported that ^{13}C peaks of 2-hydroxyethyl carbons shift *ca.* δ=13 (hydroxyl carbon) and δ=5 (carbon adjacent to N) down field upon coordination to Mo^{VI}. The ^{13}C-signals of THEED appear at δ 50.5, 57.9, and 58.4 in which the latter two peaks correspond to the 2-hydroxyethyl carbons. On addition of Mo^{VI} (Mo:L=2:1) at pH 5.0 seven peaks are observed in which two peaks at δ 63.0 and 73.9 can be assigned to the coordinated 2-hydroxyethyl carbons. Therefore Mo^{VI} seems to be retained on HEA resin *via* chelate formation with the bis(2-hydroxyethyl)amino moiety.

Although equilibrium capacity is of fundamental importance in characterizing the resin, the rate at which equilibrium is achieved is extremely important from a practical point of view. If the adsorption rate is not sufficiently rapid, the concentration of a metal on the resin is unlikely owing to the short contact time between the resin and the solution. In fact effective column separation of Mo^{VI}/V^{V} was realized only by use of the HEA resin which is superior to other resins with respect to the adsorption rate. On the other hand, CMA and PMA resins were not applicable for column separation due to their slow adsorption rates. In those cases, a batch extraction with a large excess of resin could be conducted over an extended period.

The metal adsorption process of a chelating resin may include the following steps, i) diffusion of the metal ion into the polymer matrix, ii) complex formation with the functional group. The rate for the latter step was estimated by measuring the conditional rate constant of Mo^{VI} complex formation using model ligands. The observed pH dependence of the rates could be accounted for by a mechanism involving protonation to the oxo groups in the activated complexes.[16] The complexation rates are, in any extent, appreciably rapid, especially in the low pH region. Moreover the order of the complexation rate in a homogeneous solution was not in accord with the order of the adsorption rate of the respective resins. Thus, this step is unlikely to play a rate-determining role in the adsorption process.

Since Mo^{VI} was adsorbed on an anion exchange resin at pH 1—2, Mo^{VI} must, principally, exist as anionic form(s) in this pH region. Under acidic conditions, HEA resin is expected to be positively charged due to protonation of the amine nitrogen. The local charge density must be highly concentrated inside the polymer beads where the functional groups are fixed closely, and hence the migration of oxoanion into polymer matrix may be facilitated. On the other hand, the functional group in the PMA resin holds a negative charge on the phosphonomethyl group.[17] Then, the migration of anionic species into the polymer would be retarded due to charge repulsion. Our view is consistent with the observation that PMA resin readily adsorb a wide range of metal cations.[7] Although bis(carboxymethyl)amino moiety itself has a strong affinity toward Mo^{VI},[18] an efficient adsorption of the ion was not achieved by CMA resin. Currently we have no clear explanation for the stepwise adsorption of Mo^{VI} by the CMA resin.

In addition to the high selectivity and rapid adsorption rate toward oxometal ions, HEA resin has little or no affinity for the common cations which are usually contained in the acid-leaching solution. Therefore HEA resin is the most promising agent for practical recovery of oxometal ions from industrial wastes.

The authors thank Professor K. Saito for his permission to use the stopped-flow apparatus at Tohoku University.

Fragmentation of Human Erythrocyte Ghosts and Their Application as a Carrier of Heme Complex

Noriko SEKI, Hiroyuki OHNO, Eishun TSUCHIDA,* and Shigeru SASAKAWA†
Department of Polymer Chemistry, Waseda University, Tokyo 160
†*Department of Research, Central Blood Center, Japanese Red Cross, Tokyo 150*
(Received December 27, 1983)

Human erythrocyte ghosts were taken into fragments by sonication. The average radius of the fragmented ghosts gradually decreased with the sonication time. The fragmented ghosts were obtained as spheres and reached to about 0.1 μm. In spite of the change in radius, their membrane fluidity was the same as that of the unsonicated ghost membrane. The [*meso*-α,α,α,α-tetrakis(*o*-pivalamidophenyl)porphinato]iron(III)-*mono* (1-dodecyl-2-methylimidazole) complex was incorporated into the hydrophobic region of the fragmented ghost membrane. This hybrid showed a semistable oxygen adduct in pH 7.0 phosphate buffer solution.

Human erythrocyte ghost membranes have been widely used in many fields due to their interesting character and brief preparation method.[1] The purified ghosts could be obtained easily in large quantities by direct hemolysis. They have also been studied extensively as a typical model for cell membranes. Ghost membranes are turned into liposomes by treating them in hypotonic buffer solution. These liposomes become inside-out when they were prepared in hypotonic alkaline buffer solution, but right side out liposomes were generally obtained by treating them in hypotonic Tris buffer solution.[2,3]

It is known that bilayer membranes can be used as vehicles for biological-active materials. The authors succeeded in oxygen-binding by incorporating the [*meso*-α,α,α,α-tetrakis(*o*-pivalamidophenyl)porphinato]-iron(III)-*mono*(1-dodecyl-2-methylimidazole) complex (abbreviated as "heme") into phosphatidylcholine liposomes.[4] Human erythrocyte ghost membranes were expected to carry the heme complex instead of synthetic lipid liposomes, because the fluidity of ghost membranes was relatively low. This paper describes the fragmentation of human erythrocyte ghost and the oxygen-binding ability of the heme embedded in the fragmented ghost membrane.

Experimental

Preparation of Ghost Membranes. Human erythrocytes were isolated from whole blood of healthy donors. Erythrocytes were centrifuged (3000 min^{-1} for 5 min at 4 °C) three times with 10 volumes of 0.9% NaCl solution to remove buff coating. The erythrocytes were lysed with hypotonic Tris buffer solution (pH 7.4).[1] Erythrocyte white ghosts were collected by centrifugation (13000 min^{-1} for 20 min at 4 °C). Then this pellet was dispersed in isotonic Tris buffer solution and was incubated at 37 °C for 1 h before use.

Incorporation of Glycoprotein in Liposome. Bovine glycoprotein (fraction IV) and dimyristoyl phosphatidylcholine (DMPC) were purchased from Sigma. The phospholipid liposomes with glycoprotein incorporated could be prepared by the dialysis with cholic acid.[5] A suitable amount of purified glycoprotein was added to 50 mg DMPC in isotonic Tris buffer solution (pH 7.0). The detergent solution containing the glycoprotein and phospholipid was then extensively dialyzed against a Tris buffer solution at 37 °C for 48 h. The final concentration of DMPC was set to 0.1 wt% in the buffer solution. Glycoprotein was set to 1—25% (wt/wt DMPC).

Sonication. Fragmented white ghosts were prepared by sonication (Tomy Seiko Co., Ltd., UR-200P) with different sonication times from 0 to 30 min at 25 W in an ice bath.

Scanning Electron Microscopy. Fragmented ghosts were fixed with 1% glutaraldehyde. Radius of each of the fragmented ghosts was measured directly by Hitachi S-800 scanning electron microscope without spattering.

Fluorescence Depolarization Measurement. Fluorescence probes sodium 8-anilino-1-naphthalenesulfonate (ANS) and 1,6-diphenyl-1,3,5-hexatriene (DPH) were purchased from Tokyo Kasei Co., Ltd. Erythrocyte ghosts were labeled with ANS or DPH by incubation with gentle shaking at 37 °C for 12 h. The stained erythrocyte ghosts were washed once with isotonic Tris buffer solution. The ghosts were centrifuged at 10000 min^{-1} for 30 min at 4 °C, and then were resuspended in the same buffer. The labeled ghosts were sonicated for a suitable period of time and the molecular motion of component lipids were measured by means of fluorescence depolarization measurements (JASCO FP-550 fluorescence spectrophotometer). Lights with wavelengths of 375 nm and 366 nm were used for excitation of membrane-incorporated ANS and DPH respectively. The emission intensities from ANS and DPH were detected at 480 nm and 432 nm. The fluorescence polarization was evaluated from averaging the fluorescence intensities polarized parallel ($I_{\parallel}$) and perpendicular ($I_{\perp}$) to the direction of the polarized excitation beam. The degree of polarization (P) is defined in the following equation:

$$P = (I_{\parallel} - I_{\perp})/(I_{\parallel} + I_{\perp})$$

The $1/P$-value represents the membrane fluidity.

Incorporation of Heme. Dichloromethane solution of the iron(III) derivative of heme ([Fe]=0.05 mM (1 M=1 mol dm^{-3}), [1-dodecyl-2-methylimidazole]=2.25 mM) was evaporated to prepare a thin film on a glass flask under nitrogen gas flow. A phosphate buffer solution containing 10 vol% of the white ghost (pH 7.0) was mixed with the thin film, then it was sonicated for a suitable period of time under nitrogen atmosphere. In degassed solution, the incorporated iron(III) derivative of heme was reduced by L-ascorbic acid. The resulting solution was incubated at 37 °C for 1 h. Oxygen gas was bubbled through the solution for 15 s to induce the oxygen-binding of heme. The reduction and oxygen-binding were detected by visible absorption spectrometry (Hitachi-320 UV. *vis.* spectrophotometer).

Results and Discussion

Fragmentation of Human Erythrocyte Ghosts. Human erythrocyte ghosts turned into fragments by the sonication, and they formed smaller liposomes than the initial ghosts. The shape and radius of fragmented

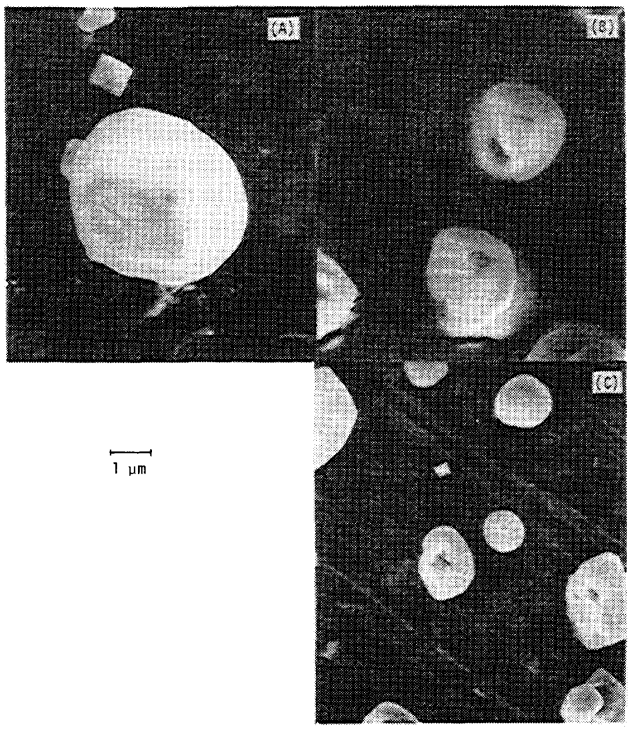

Fig. 1. Scanning electron micrographs of fragmented ghost.
Sonication time was 10 s (A), 60 s (B), 5 min (C) respectively.

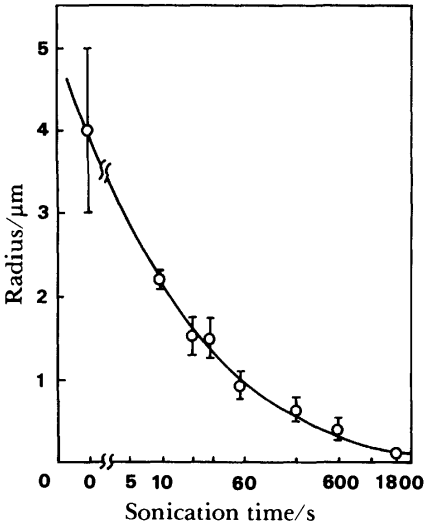

Fig. 2. Effect of sonication time on the average radius of fragmented ghost.
Average radius was directly measured by SEM. Sonication (25 W, in ice bath)

ghosts were detected directly by means of high resolution scanning electron microscopy. The fragmented ghost was generally observed as a sphere, as shown in Fig. 1. The average radius greatly depended on the sonication time. Figure 2 shows the effect of sonication time on the radius of the fragmented ghosts. The average radius of the intact white ghost was about 4 μm, which decreased with increasing sonication time and turned about 1 μm after 60 s sonication. Finally it reached to about 0.1 μm by 30 min sonication.

The motion of membrane-constituted molecules

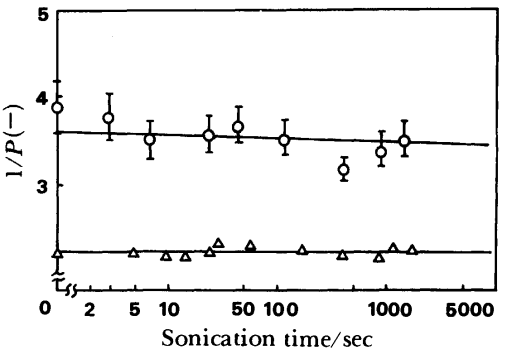

Fig. 3. Effect of sonication time on the membrane fluidity of fragmented ghosts.
Sonication (25 W, in ice bath), ○: ANS, △: DPH, [ANS]=[DPH]=10^{-6} M.

Table 1. Membrane fluidity of fragmented ghost and DMPC liposome with or without glycoprotein

Liposome	Membrane fluidity (1/P)	
	ANS	DPH
DMPC	8.24	3.75
Glycoprotein incorporated	2.85	2.11
Fragmented ghost	3.68	2.20

[DMPC]=0.1 wt%; [Glycoprotein]=10% (wt/wt DMPC); [ghost]=1 vol%; [DPH]=1.0×10^{-6} M; at 37°C

could be detected by the fluorescence depolarization measurements.[6,7] Fluorescence measurements with different types of probe molecules gave us important information for membrane fluidity at molecular level, because the location of the incorporated probe molecules depends on their molecular structure.[6] As an ANS molecule dissociates to give an anion, ANS can be incorporated into the hydrophobic region closest to the surface of the membrane.[8] On the other hand, as DPH is a conjugated aromatic hydrocarbon, it is located at the center of the hydrophobic hydrocarbon of cell membranes.[9] It was observed that the membrane fluidity of the fragmented ghosts was independent of their radius and was almost the same as that of unsonicated ghost membrane, as shown in Fig. 3. This shows that the network structure of the ghost membrane was taken off by sonication but the composition of membrane-constituted molecules was almost unchanged.

The membrane fluidity of the fragmented ghosts was compared with that of the DMPC liposome and DMPC liposome with glycoprotein incorporated. Results are summarized in Table 1. When the liposomes are labeled with ANS, the membrane fluidity of the fragmented ghost was higher than that of DMPC liposome with glycoprotein incorporated. But it was suppressed more strongly than that of DMPC liposome only. On the other hand, the membrane fluidity of fragmented ghost was almost the same as that of DMPC liposome with 10% (wt/wt DMPC) of glycoprotein when labeled by DPH. These results show that the effect of sonication in fragmented ghost membrane was more remarkable in the surface region than in the hydro-

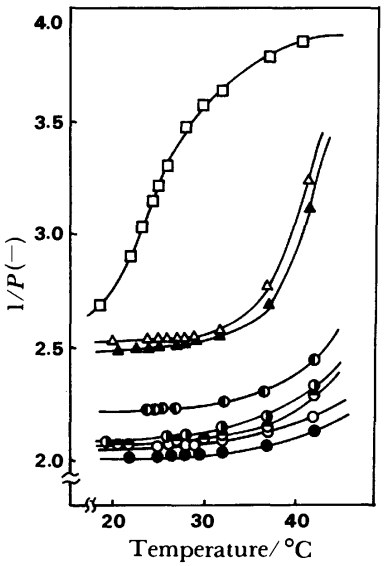

Fig. 4. Temperature dependence of the membrane fluidity of the DMPC liposome with the glycoprotein incorporated.
[DMPC]=0.1 wt%, [DPH]=10^{-6} M, Sonication (25 W, for 30 sec), [glycoprotein]=0.0 (□), 1.0 (△), 2.5 (▲), 5.0 (◐), 10 (◑), 15 (◓), 20 (○), 25 (●) % (wt/wt DMPC)

phobic region. The membrane fluidity of the initial ghost membranes was considered to be higher than that of human erythrocytes. The membrane fluidity of erythrocytes was reduced by the existence of the network structure. Though the network structure of spectrin in the fragmented ghost was destroyed by the sonication, the membrane fluidity in the hydrophobic region was kept lower because of the existence of the membrane proteins. Figure 4 shows the temperature dependence of the fluidity of the DMPC liposome with or without glycoprotein. The membrane fluidity of the DMPC liposome increased remarkably at 24°C. This temperature corresponded to the gel to liquid-crystalline phase transition temperature (T_c). On the other hand, the membrane fluidity of DMPC liposome with glycoprotein incorporated was gradually increased at temperature higher than T_c, and the transition point became unclear with increasing concentration of the incorporated glycoprotein, as shown in Fig. 4. So, it is clear that the membrane fluidity of DMPC liposome with glycoprotein incorporated remarkably depended on the concentration of the incorporated glycoprotein. The effect of the concentration was particularly, dramatic when the concentration of incorporated glycoprotein was less than 5.0% (wt/wt DMPC). The molecular motion of lipids was considered to be suppressed through the interaction with the incorporated glycoprotein. When 10% (wt/wt DMPC) of glycoprotein was incorporated to DMPC liposome, the membrane fluidity in the hydrophobic region was almost the same as that of fragmented ghost membrane, as shown in Table 1. It is expected that these fragmented ghosts could be applicable as a membrane model when synthetic pospholipid hybrid liposomes are prepared. This is because fragmented ghost liposomes could be prepared easily and their membrane fluidity was adequately suppressed, in almost the same

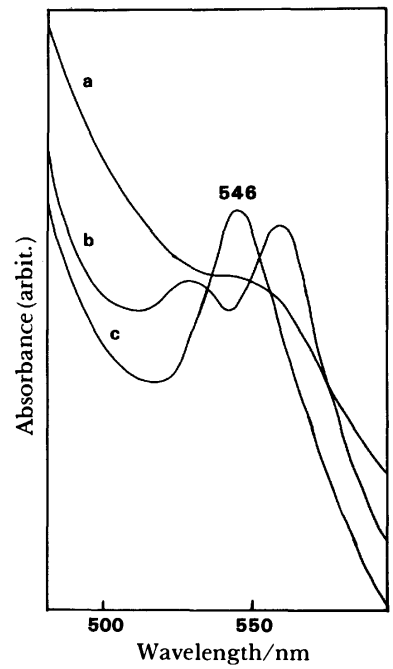

Fig. 5. Visible absorption spectra of ghost-embedded heme in fragmented ghost.

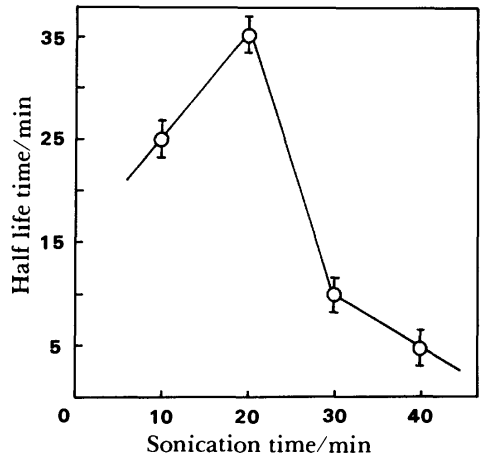

Fig. 6. Relation between the dispersion state and the life time of oxygen adduct on ghost-embedded heme. Sonication (25 W, in ice bath)

way as that of ghost membranes or phospholipid liposomes containing glycoprotein.

Application as a Carrier of Heme Complex. The fragmented ghost containing heme in the hydrophobic region (ghost-embedded heme) was prepared by a sonication method. The stability and oxygen-binding ability of the ghost-embedded heme suspension was measured by means of visible absorption spectrometry, as shown in Fig. 5. Fig. 5 (a) shows the visible spectra of the ghost-embedded heme before reduction. They were incubated at 37°C for 1 h after adding a reducing agent. The absorption bands of the ghost-embedded heme were observed at 535 nm and 555 nm, corresponding to the penta-coordinated heme, as shown in Fig. 5 (b). The oxygen adducts were obtained after bubbling oxygen gas for 15 sec through that solution. The formation of oxygen adducts was

detected by the appearance of a single peak at 546 nm, as shown in Fig. 5 (c). This peak coincided with that of semistable oxygen adducts of the liposome-embedded heme.[4] In this system, it is important to analyze the effect of sonication time of the dispersion state of ghost-embedded heme and of the life time of its oxygen adduct. These results are summarized in Fig. 6. It was found that ghost-embedded heme could be dispersed relatively homogeneously by a suitable period of sonication time. The life time of the semistable oxygen adducts turns longer (35 min) when they were sonicated for 20 min at 25 W. But most of ghost-embedded heme phase-separated (aggregated) when incubated overnight. Contrary to this, the life time of the semistable oxygen adducts was only for 20 min when ghosts were fragmented by 30 min sonication. But, they were quite stable and the dispersion state was maintained over several days. As the fluidity was completely independent of the sonication time, it was better for the vehicle size to be as small as possible. The reason of the effect of sonication time on the life time of oxygen adducts has not been clarified yet. It is expected that more stable oxygen adducts with longer life time should be obtained by the improvement of the composition of iron heme/complex/the membrane-constituted molecules as well as the physicochemical conditions.

This work was partially supported by the Grant-in-Aid for Special Project Reserch (No. 58211018) from the Ministry of Education, Science and Culture, Japan. Grateful acknowledgement is also made to Dr. H. Shii and Dr. H. Koyama, Central Research Laboratory, Furukawa Electric Co., for taking the electron micrographs.

The Platinum Catalyzed Reduction of Nitroarenes to Aminoarenes with Carbon Monoxide and Water

Yoshihisa WATANABE,* Yasushi TSUJI, Tatsuya OHSUMI, and Ryo TAKEUCHI
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received January 27, 1984)

Nitroarenes were transformed into the corresponding aminoarenes in high yields at 80 °C with carbon monoxide (an initial pressure 30—60 kg cm^{-2}) and water in the presence of a catalytic amount of a platinum catalyst. The platinum catalyst was combined with tin(IV) chloride, triphenylphosphine and triethylamine. This combination was essential for the high catalytic activity.

The homogeneous water gas shift reaction (WGSR) with transition metal catalysts is of current interest[1] (Eq.1).

$$CO + H_2O \xrightarrow{[cat]} H_2 + CO_2 \quad (1)$$

The application of WGSR to the reduction of organic compounds such as nitroarenes,[2-7] aldehydes[8,9] and olefins[10] has been widely attempted. In these reductions, iron,[2,8] rhodium[2-5,8,9] and ruthenium[2,6-8] clusters have been mostly employed as effective catalysts. With these catalyst systems, however, reaction temperatures are rather high[2,4,8] or a large amount of the catalyst is required under the mild conditions.[4-6]

Concerning the related platinum-catalyzed reaction, Yoshida *et al.* have reported that WGSR can be catalyzed by platinum(0) phosphine complexes.[11] Eisenberg and co-workers described the reduction of olefins with carbon monoxide and HCl aq in the presence of a platinum complex.[10] They also have reported the platinum-catalyzed WGSR and discussed the mechanism of hydrogen and carbon monoxide evolution.[12] The activities of these platinum catalysts, however, were rather low.

In this paper, we describe the platinum-catalyzed reduction of nitroarenes with carbon monoxide and water.[13] The nitroarenes were converted into the corresponding aminoarenes under mild reaction conditions (Eq. 2).

$$Ar\text{-}NO_2 + 3CO + H_2O \longrightarrow Ar\text{-}NH_2 + 3CO_2 \quad (2)$$

Results and Discussion

The results of nitrobenzene are listed in Table 1. Nitrobenzene was converted into aniline almost quantitatively with dichlorobis(triphenylphosphine)-platinum(II) combined with triethylamine and tin(IV) chloride (Runs 1, 2).

When triethylamine was removed from the catalyst system, the reduction did not take place at all (Run 3). The conversion of nitrobenzene was considerably decreased without tin(IV) chloride or triphenylphosphine (Runs 5, 6). In the absence of water or platinum complex, reduction did not proceed (Runs 7, 8). Thus, for the high activity by the present catalyst system, the presence of triethylamine, tin(IV) chloride, and triphenylphosphine is essential.

The effect of the reaction temperature and the initial carbon monoxide pressure are summarized in Table 2. Nitrobenzene was reduced to aniline almost

a) Nitrobenzene 20 mmol, $[PtCl_2(PPh_3)_2]$ 0.10 mmol, Lewis acid 2.0 mmol, Et_3N 1.0 mmol, dioxane 10 ml, carbon monoxide 60 kg cm^{-2} at 80 °C for 4h. b) Without Et_3N. c) Reaction time 8h.

quantitatively at 80 °C (Run 2). Lower temperatures, 50 °C and 20 °C, gave only low conversions of nitrobenzene and low selectivities to aniline (Runs 9, 10). The reaction temperature over 80 °C is desired for the high conversion and the high selectivity. The activity of the catalyst system was also affected by the initial carbon monoxide pressure. A higher pressure (60 kg cm^{-2}) of the initial carbon monoxide was more favorable for the reaction (Run 2). The selectivity to aniline slightly reduced to 91% under 30 kg cm^{-2} of the initial carbon monoxide pressure (Run 11). Under 15 kg cm^{-2} of the initial pressure, the conversion of nitrobenzene was not improved even by prolonging the reaction time to 20 h (Runs 12,13). The reduction was also sluggish with bubbling carbon monoxide and expelling the resultant carbon dioxide from the reaction system (Run 14).

Tin(IV) chloride played an important role in the present catalyst system. Effects of the presence of Lewis acids as co-catalysts with or without triethylamine are summarized in Table. 3. In the presence of triethylamine, tin(IV) chloride was the most favorable. Tin(II) chloride and iron(III) chloride were less effective (Runs 15,16). On the other hand, the reaction without triethylamine showed an interesting contrast. Employing tin(IV) chloride, aniline was not obtained at all, as mentioned above. However, employing tin(II) chloride, aniline was produced with 100% selectivity and 78% conversion even without the amine (Run 17), although the conversion was not improved by prolonging the reaction time (Run 18). Other Lewis acids, such as iron(III) chloride, aluminum chloride, and zinc chloride were less effective and the conversion was decreased considerably (Runs 19—21).

Various nitroarenes could be converted to the corresponding aminoarenes by this procedure (Table 4). 4-Methylaniline was obtained from 1-methyl-4-nitrobenzene in 71% yield (80% selectivity and 89% conversion) (Run 22). The yield of the product was improved to 100% in the presence of less water (Run 23). 1-Chloro-4-nitrobenzene was converted to 4-chloroaniline in 89% yield (94% selectivity and 95% conversion) at 80 °C (Run 24). The yield increased to 95% (99% selectivity and 96% conversion) by elevating the reaction temperature to 100 °C (Run 25). 3-Methoxyaniline was reduced to 3-methoxyaniline in high yield (Run 26). However, for ortho-substituted nitroarenes, the

TABLE 4. REDUCTION OF VARIOUS NITROARENES WITH CARBON MONOXIDE AND WATER[a]

Run	Nitroarene	Conv./%[b]	Selectivity to[b] aminoarene

28	2-Methoxynitrobenzene	100	32

a) Nitroarene (20 mmol), $[PtCl_2(PPh_3)_2]$ (0.10 mmol), $SnCl_4$ (2.0 mmol), Et_3N (1.0 mmol), H_2O (1.0 ml), Dioxane (10 mmol), CO(initial 60 kg cm^{-2} at r.t.)for 4h. b) By GLC, figures in parentheses were determined based on the isolated products. c) H_2O (0.5 ml). d) at 100 °C.

selectivities to the corresponding aminoarenes were low (Runs 27, 28). The steric effect of the ortho-substituents would cause these low selectivities.

After the reaction, analysis of the gas phase by gas chromatography revealed that only carbon dioxide was produced. Furthermore, a control experiment showed that the present catalyst system could not catalyze the WGSR.[14] These observations clearly indicated that the nitroarenes were not reduced to aminoarenes by the hydrogen produced by the WGSR (Eq. 1). In fact, aniline was obtained from nitrobenzene only in 34% yield with the same catalyst system under 60 kg cm^{-2} of hydrogen pressure in place of carbon monoxide and water. This result indicates that carbon monoxide and water is a more effective reductant than hydrogen with the present catalyst system.

Other substrates such as 1-nitropropane, 2-ethyl-2-hexenal, phenylacetylene and diphenylacetylene were not reduced by this procedure. The competitive reduction of nitrobenzene and diphenylacetylene by this procedure[15] gave only aniline as the reaction product in 88% selectivity and 80% conversion, while diphenylacetylene was recovered quantitatively. Thus, by the present reaction, the nitroarenes appeared to be reduced chemoselectively. This chemoselectivity is an outstanding feature which was not seen in the previous studies.[2-9]

A possible route for the present reaction is as follows. The nitroarenes is deoxygenated with carbon monoxide to an arylnitrene intermediate (Eq. 3). The carbonylation of the nitrene intermediate successively occurs and generates the phenyl isocyanate intermediate (Eq. 4). Iqbal[16] has reported the transition metal catalyzed deoxygenation of nitroarenes with carbon monoxide and proposed the nitrene intermediate for the reaction. Bennett *et al.*[17] and Collman *et al.*[18] have reported the formation of phenyl isocyanate from phenyl azide under carbon monoxide pressure and Bennett *et al.* have suggested that arylnitrene was the reaction intermediate. Furthermore, we have recently reported that the present platinum catalyst system catalyzed the reductive carbonylation of nitroarenes in ethanol and the corresponding ethyl phenylcarbamates were obtained in high yield[19] (Eq. 6). We have proposed the arylnitrene and phenyl

isocyanate as key intermediates in that reaction. Although that reaction required the elevated reaction temperature (at 180°C), we recently found that the reaction temperature can be lowered to 150°C by employing 1 equiv ethanol in benzene.[20] In the

$$Ar\text{-}NO_2 + 2CO \longrightarrow Ar\text{-}N: + 2CO_2 \quad (3)$$

$$Ar\text{-}N: + CO \longrightarrow Ar\text{-}NCO \quad (4)$$

$$Ar\text{-}NCO + H_2O \longrightarrow [Ar\text{-}NHCOOH] \xrightarrow{-CO_2} Ar\text{-}NH_2 \quad (5)$$

$$Ar\text{-}NO_2 \xrightarrow{[Pt]} [Ar\text{-}NCO] \xrightarrow{ROH} Ar\text{-}NHCOOR \quad (6)$$

present reduction of nitroarenes, we propose the phenyl isocyanate as a key intermediate as mentioned above (Eq. 4). The phenyl isocyanate can react with water to give phenylcarbamic acid which easily decarboxylates to aminoarene (Eq. 5). Tarakanov *et al.* have reported a phenylcarbamic acid intermediate in the reaction of phenyl isocyanate and water.[21] In this reaction, nitroarenes were chemoselectively reduced to aminoarene. This chemoselectivity must be originated in the reaction pathway including the phenylcarbamic acid intermediate.

There is another possible route, in which the nitrene intermediate abstracts hydrogen from the solvent or other hydrogen source.[22] As indicated by Run 7 (Table 1), the aminoarene was not obtained at all in the absence of water. This result clearly shows that water is the only possible hydrogen source. However, there is no example that nitrene intermediate abstract hydrogen from water, although it is well known that hydrocarbon solvents are good hydrogen donors.[22] Therefore, it is rather hard to accept that the aminoarenes were generated *via* the nitrene intermediate by hydrogen abstraction from water.

In this reaction, characterization of the active catalyst species was not done. Several studies have indicated that Lewis acid promotes migratory insertion of coordinated carbon monoxide to a carbon-metal bond.[23] In the present reaction, tin(IV) chloride may be operative in promoting the insertion of carbon monoxide into a nitrogen-metal bond to generate the phenyl isocyanate intermediate (Eq. 4).

Experimental

Materials. The reagents employed in this study were purified by distillation or recrystallization before use. Carbon monoxide (>99.9%) was used without further purification. Platinum complexes were prepared by the methods in the literature.[24,25]

General Procedure. A 100 ml stainless steel autoclave (Nitto Koatsu SUS 316) equipped with a magnetically driven stirrer was used. A glass liner was set in the autoclave. The reagents were charged in the glass liner in the following order: dioxane (10 ml), water (1 ml), nitroarene (20 mmol), triethylamine (0.14 ml, 1.0 mmol), $PtCl_2(PPh_3)_2$ (79 mg, 0.10 mmol) and $SnCl_4$ (0.24 ml, 2.0 mmol). After sealing and flushing with carbon monoxide, the reactor was pressurized with carbon monoxide to 60 kg cm^{-2} at r.t. The autoclave was heated to 80°C in 10 min and then held at this temperature for 4 h. The reaction was terminated by rapid cooling and the autoclave was discharged. The resultant clear brown solution was analyzed with GLC.

Product Isolation. The solvent, dioxane, was evaporated off from the reaction mixture and benzene (20 ml) was added. The benzene solution was shaken with 10% HCl aq and the benzene layer was discarded. Then the aqueous layer was neutralized with 20% NaOH aq and extracted with benzene (20 ml). After filtering the whole mixture, the oil layer was separated and dried. Evaporation of benzene from the solution give a pure aminoarene.

Analytical Procedure. The GLC analyses were performed on Shimadzu GC-3BT (with thermal conductivity detector) or GC-4CM (with flame ionization detector) with columns (3 mmϕ×3 m) packed with Versamide 900 (10% on Neopak 1A 60—80 mesh), PEG 20 M TPA (10% on Chromosorb W AW 60—80 mesh) or Apieson Grease L (5% on Neopak 1A). The conversion of the substrate and the selectivity to the product were determined by the internal standard method with naphthalene according to the calibration curve obtained for each sample. The analysis of gas phase was performed on Shimadzu GC-3BT with a column (3 mm ϕ×3 m) packed with Active Carbon 60—80 mesh.

The identification of the products was confirmed by comparing the spectral data (^{13}C-, ^{1}H-NMR and IR spectra) with those of the authentic samples.

The ^{13}C- and ^{1}H-NMR spectra were recorded 25.05 MHz and 100 MHz with a JEOL JNM FX 100 spectrometer. The IR spectra were measured on a Hitachi model 215 grating spectrometer.

Reduction under Hydrogen Pressure. Nitrobenzene (20 mmol) was reduced in the presence of the platinum catalyst system ($PtCl_2(PPh_3)_2$ 0.10 mmol; Et_3N 1.0 mmol; $SnCl_4$ 2.0 mmol) in dioxane (10 ml) under hydrogen pressure (initial pressure 60 kg cm^{-2} at r.t.) at 80°C for 4 h. After the reaction, GLC analysis indicated that the conversion of nitrobenzene was 39% and the selectivity to aniline was 87% (yield 34%).

Synthesis of Ethyl Phenylcarbamate. A mixture of nitrobenzene (20 mmol), ethanol (20 mmol), $PtCl_2(PPh_3)_2$ (0.20 mmol), $SnCl_4$ (2.0 mmol), Et_3N (3.6 mmol) and benzene (18.5 ml) was stirred under carbon monoxide pressure (initial 60 kg cm^{-2}) at 150°C for 4 h. The GLC analysis of the reaction mixture showed that ethyl phenylcarbamate was obtained in 70% yield (100% conversion).

Gas Chromatography-Mass Spectrometry of Trimethylsilyl Derivatives of Some Iminodicarboxylic Acids

Katsuhiro KAWASHIRO,* Shiro MORIMOTO, and Hideyuki YOSHIDA

Department of Chemical Engineering, Faculty of Engineering, Tokushima University, Minamijosanjima, Tokushima 770

(Received February 20, 1984)

Trimethylsilylation of eight iminodicarboxylic acids (IDCAs) with *N,O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA) or *N,O*-bis(trimethylsilyl)acetamide was studied under various reaction conditions. The IDCAs include iminodiacetic acid (**1**), 2- and 3-(carboxymethylamino)propionic acids (**2** and **3**), 2,2′-, 2,3′-, and 3,3′-iminodipropionic acids (**4—6**), *N*-methyliminodiacetic acid (**7**), and nitrilotriacetic acid (**8**). For **1—6**, both bis- and tris(trimethylsilyl) (TMS) derivatives were formed under usual silylating conditions, although the proportion of amounts of the two derivatives varied depending on reaction conditions. This double derivatization was due to the steric hindrance of *N*-substituent group. However, under mild silylating conditions (BSTFA alone, 120 °C, 30 min), **1—6** yielded only the di-TMS derivatives. Upon electron impact at 20 eV, both the di- and tri-TMS derivatives showed simple spectra with a molecular (M^+) ion and M −15 (loss of CH_3). The α,α'-IDCAs (**1**, **2**, **4**, **7**, and **8**) are characterized by fragments M −43 (loss of CH_3 and CO) and M −117 (loss of COOTMS) (base peak). On the other hand, the β,β'-IDCA (**6**) is characterized by fragments M −57 (loss of CH_3, CH_2, and CO) and prominent M −131 (loss of $CH_2COOTMS$). The α,β'-IDCAs (**3** and **5**) exhibit both the fragments characteristic of α,α'- and β,β'-IDCAs, M −43, M −57, M −117, and M −131. However, base beaks are usually the fragment M −117 and not M −131.

In recent years, gas chromatography-mass spectrometry (GC-MS) has become an important method for unequivocal identification of amino acids and related compounds. Amino acids themselves are nonvolatile and cannot be analyzed by GC without their prior conversion into suitable volatile derivatives. Preparations of a number of such volatile derivatives have been reported by many investigators, which have been reviewed by Hušek and Macek.[1] Of these volatile derivatives for GC, *N*-trifluoroacetyl (TFA) alkyl ester and trimethylsilyl (TMS) derivatives are used most widely at present.

In our previous paper,[2] we reported on mass spectra (electron impact at 20 eV) of both butyl and *N*-TFA butyl esters of some iminodicarboxylic acids (IDCAs) as shown in Fig. 1. The mass spectra of the butyl ester derivatives are rather simple, but those of the *N*-TFA butyl ester derivatives are very complicated due to the presence of rearrangement peaks. For this reason, we undertook a GC-MS study of TMS derivatives of IDCAs, which are expected to give much simpler spectra than the *N*-TFA butyl ester derivatives.

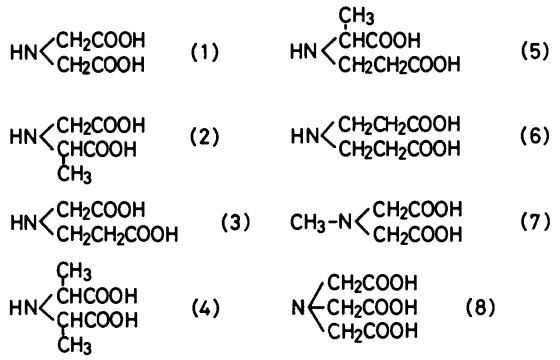

Fig. 1. Iminodicarboxylic acids.

TMS derivatives of amino acids have received great interest since Rühlmann and Giesecke[3] first reported on the preparation of some of them and their resolution by GC in 1961, because of the thermal stability and simplicity of preparation. In general, the TMS derivative can be prepared by use of a silylating reagent with heating (one-step derivatization), whereas multiple procedures are necessary for many other volatile derivatives such as the *N*-TFA butyl ester derivative. At present, many silylating reagents are easily available. Of these reagents, *N,O*-bis(trimethylsilyl)acetamide (BSA)[4] and *N,O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA)[5] are known to be strong TMS donors and have been used most frequently by many investigators. Gehrke *et al.*[6,7] reported on derivatization conditions using BSTFA and single-column resolution of protein amino acids for rapid and quantitative analysis of protein hydrolyzates.

The GC-MS of TMS derivatives of protein amino acids has been studied by several investigators[8–13] for unequivocal identification of amino acids present in biological samples. In most instances, mass spectra exhibited easily recognizable molecular (M^+) and M−15 ions, which are useful for molecular weight determination. However, double derivatization[8,12,13] due to steric hindrance has been found to take place for certain amino acids such as glycine and lysine.

The GC-MS of TMS derivatives of nonprotein amino acids[14–17] has far less been studied. Mařik *et al.*[16] studied silylation of some ω-amino acids with BSA in the presence of catalyst such as HCl. In most instances, both di- and tri-TMS derivatives were formed. However, they established the derivatization conditions under which only the tri-TMS derivative can be prepared.

This investigation reports on silylation of some IDCAs as shown in Fig. 1, with BSA or BSTFA under various conditions, and on mass spectra of the TMS derivatives obtained upon electron impact at 20 eV. The IDCAs include iminodiacetic acid (**1**), 2- and 3-(carboxymethylamino)propionic acids (**2** and **3**), 2,2′-2,3′-, and 3,3′-iminodipropionic acids (**4—6**), *N*-methyliminodiacetic acid (**7**), and nitrilotriacetic acid (**8**).

Results and Discussion

Trimethylsilylation. The silylation of the IDCAs was carried out under various conditions with or without solvent. In general, hydrogen atoms attached to heteroatoms (active hydrogens) can be replaced by TMS groups. In most instances, a suspended IDCA was dissolved into a reagent solution completely during silylation. This fact suggests that free IDCA remaining in the reaction mixture was of a negligible amount. For **1—6**, both di- and tri-TMS derivatives were found to be present by means of GC–MS, although the proportion of their amounts varied depending on silylating conditions. However, any GC peaks corresponding to a mono-TMS derivative could not be detected. These findings indicate that the silylation takes place in two steps, the first formation of di-TMS derivative and its successive conversion into tri-TMS derivative (*N*-TMS di-TMS ester). In the di-TMS derivative, the two TMS groups are considered to be present as silyl esters (di-TMS ester), because it is known that silylation of amines is more difficult than carboxyl groups.

Table 1 gives retention times of the two derivatives of the IDCAs on GC. As expected, the di-TMS derivative has a consistently shorter retention time than the corresponding tri-TMS derivative. Both the two derivatives gave sharp and symmetrical GC peaks on a glass column (1 m) packed with 1.5% OV-101 on Chromosorb G HP. Of these TMS derivatives, the tri-TMS derivative of **4** was found to give two GC peaks, which were evidenced on the basis of mass spectral data. This is ascribable to the separation between diastereomers, as **4** has two asymmetric carbons. However, such separation was not observed for the di-TMS derivative of **4**.

Table 1. Retention times of the TMS derivatives of **1—8** on GC[a]

Parent IDCA	Retention time/min	
	Di-TMS	Tri-TMS
1	10.2	12.5
2	10.0	13.3
3	12.1	15.2
4	9.6	14.2, 15.1
5	11.8	16.1
6	14.2	17.9
7	10.2	—
8	20.0[b]	—

a) Initial temp: 100°C. Initial hold: 5 min. Program rate: 5°C/min. Final temp: 230°C. Injector: 230°C. Column: 3 mmϕ×1 m(glass). Packing: OV-101 1.5% on Chromosorb G HP (100/120 mesh). Retention time of phenanthrene: 17.0 min. b) A tri-TMS ester.

Table 2. Silylation of **1—6** in BSTFA-CH_3CN[a,b]

Parent IDCA	Immediately after silylation		After 1 d	
	Di-TMS/%	Tri-TMS/%	Di-TMS/%	Tri-TMS/%
1	2	98	2	98
2	10	90	7	93
3	11	89	10	90
4	79	21	78	22
5	82	18	56	44
6	12	88	8	92

a) Silylation was carried out at 140°C for 30 min (IDCA, 50 μmol; BSTFA, 0.25 ml; CH_3CN, 0.25 ml) and then the reaction mixture was allowed to stand at room temperature. b) Values indicate peak area ratios.

Table 2 gives the results of silylation of **1—6** in BSTFA-acetonitrile (1:1, v/v), which has been recommended by Gehrke *et al.*[5-7] for silylation of amino acids. Although the reaction conditions (140°C, 30 min) are rather severe, both the di- and tri-TMS derivatives were formed for **1—6**. It is well known that the proportion of the amounts of TMS derivatives varies with the standing time after silylation[8,16] when double derivatization occurs. Therefore, aliquots of the reaction mixture were analyzed by GC immediately after silylation and subsequently after standing for about 1 d at room temperature. A small amount of the di-TMS derivative (2%) still remains even for **1**, the imino group of which is least hindered of the IDCAs. The amounts of the tri-TMS derivatives are much smaller than those of the corresponding di-TMS derivatives for **4** and **5**, the imino groups of which are much more hindered than **1**. Under mild conditions (120°C, 30 min), **4** and **5** gave only the di-TMS derivatives immediately after silylation. These findings indicate that the conversion of the di-TMS derivatives into the corresponding tri-TMS derivatives is governed by the steric hindrance of *N*-substituted groups.

Gehrke and Leimer[18] studied the effect of different solvents on silylation of glycine with BSTFA. They found that polar solvents such as acetonitrile, *N,N*-dimethylformamide (DMF), and pyridine, gave both *N,O*-di-TMS and *N,N,O*-tri-TMS derivatives, whereas nonpolar solvents (dichloromethane, 1,2-dichloroethane, hexane, *etc.*) gave consistently only the di-TMS derivative, under the conditions studied. Table 3 presents the solvents used and their effects on silylation of **1** with BSA. Of these solvents, pyridine gives the highest yield of tri-TMS derivative. The amount of the derivative is 97% immediately after silylation and increases up to 98% after subsequent standing at room temperature for 1 d. It is interesting to note that tetrahydrofuran (THF) gives an extraordinarily high yield of tri-TMS derivative (93%) immediately after silylation, of the nonpolar solvents. In instances of nonpolar solvents such as 1,2-dichloroethane and hexane, as expected, the amount of tri-TMS derivative formed is rather small immediately after silylation, but it increases up to 95—97% on standing at room temperature for 1 d. The amount of tri-TMS derivative after 1 d is somewhat larger than that formed under comparable conditions in polar solvents such as acetonitrile and DMF, which have been used as preferable solvents most frequently. This complicated solvent effect cannot be explained in terms of the polarity of a solvent used, and other factors controlling silylation must be considered.

Figure 2 shows the catalytic effect of HCl on silylation of **1** using BSA or BSTFA in the absence of solvent. It is evident that the silylation is greatly enhanced by the presence of HCl as demonstrated by

Mařik *et al.*[16] for ω-amino acids. In the instance of the HCl salt of **1** and BSA (A), the amount of tri-TMS derivative is 96% immediately after silylation and then gradually increases up to 98% on standing for 3 d at room temperature. Further changes in composition were not observed over the next 4 d at room temperature. This finding indicates that the silylation reaches an equilibrium. As shown in Fig. 2, silylation in other three instances (B, C, and D) also has a tendency to proceed to an equilibrium slowly. These facts are consistent with results obtained by Bergström *et al.*,[8] that silylation of certain amino acids (glycine and lysine) proceeds to an equilibrium in which a few percent of a less silylated derivative still remains. Although Mařik *et al.*[16] have reported that only a tri-TMS derivative was obtained reproducibly in silylation of certain ω-amino acids under comparable conditions (*i.e.*, in silylation by BSA alone in the presence of HCl at 90 °C for 0.5—1 h followed by standing for 1 d at room temperature), we failed to find such conditions under which only the tri-TMS derivative can be formed for **1—6**. A comparison of A with C and of B with D in Fig. 2, indicates obviously that BSA is a stronger TMS donor than BSTFA.

The solvent effect on the silylation of **1**·HCl with BSA was also studied. The addition of pyridine accelerated the silylation to a slight extent. On the other hand, the addition of acetonitrile resulted in a decrease in the amount of the tri-TMS derivative ; this is consistent with results obtained by Mařik *et al.*[16] for the silylation of ω-amino acids. These findings suggest that pyridine is an effective solvent for silylation of hydrochlorides of IDCAs with BSA.

As described above, it seemed impossible to prepare only the tri-TMS derivative for **1—6** under the present conditions. Therefore, silylating conditions under which only the di-TMS derivative can be prepared selectively, were studied. When silylation was carried out with BSTFA alone at 120 °C for 30 min, only the di-TMS derivative was detected for **1—6** immediately after silylation. For **4—6**, the conversion into the tri-TMS derivative did not take place during subsequent standing at room temperature for several days. On the other hand, for **1—3** which have less bulky *N*-substituted groups, the formation of the tri-TMS derivative was observed as shown in Table 4. Therefore, when these IDCAs are analyzed as their di-TMS derivatives, the derivatized solution should be injected into a GC column as soon as possible after silylation. Under the same conditions, BSA was found to give both the

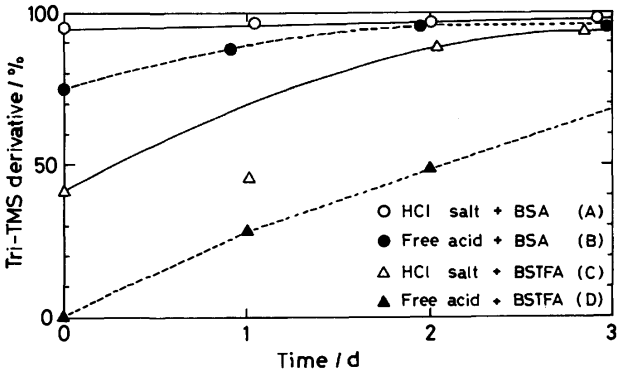

Fig. 2. Catalytic effect of HCl on silylation of **1**. Silylation was carried out at 120 °C for 30 min (**1** or **1**·HCl, 25 μmol; BSA or BSTFA, 0.25 ml) and then the reaction mixture was allowed to stand at room temperature.

Table 3. Solvent effect on silylation of **1** with BSA[a]

Solvent	Dielectric constant (20 °C)[b]	Immediately after silylation		After 1 d	
		Di-TMS/%	Tri-TMS/%	Di-TMS/%	Tri-TMS/%
CH_3CN	37.5	20	80	8	92

a) Silylation was carried out at 120 °C for 30 min (**1**, 50 μmol; solvent, 0.25 ml; BSA, 0.25 ml) and then the reaction mixture was allowed to stand at room temperature. b) Cited from Ref. 19. c) At 25 °C.

Table 4. Silylation of **1—6** with BSTFA alone[a]

Parent IDCA	Immediately after silylation		After 1 d		After 2 d	
	Di-TMS/%	Tri-TMS/%	Di-TMS/%	Tri-TMS/%	Di-TMS/%	Tri-TMS/%
1	100	—	72	28	52	48
2	100	—	99	1	96	4
3	100	—	91	9	72	28
4	100	—	100	—	100	—
5	100	—	100	—	100	—
6	100	—	100	—	100	—

a) Silylation was carried out at 120 °C for 30 min (IDCA, 25 μmol; BSTFA, 0.25 ml) and then the reaction mixture was allowed to stand at room temperature. In the instances of **4** and **5**, 0.5 ml of BSTFA was used.

di- and tri-TMS derivatives for **1**—**3**, even immediately after silylation. This fact also indicates that BSA is a stronger silylating reagent than BSTFA.

Figure 3 shows the time course of the silylation of **2** with BSTFA alone at 120 °C, as a typical example. The peak area ratio of the di-TMS derivative to an internal standard (phenanthrene) becomes almost constant after reaction time of 20 min, and its conversion into the tri-TMS derivative was not observed. This fact indicates that **2** can be converted quantitatively into the di-TMS derivative under the silylating conditions (BSTFA alone, 120 °C, and 30 min) described above, and also that the amounts of free **2** and the mono-TMS derivative remaining in the reaction mixture are negligible.

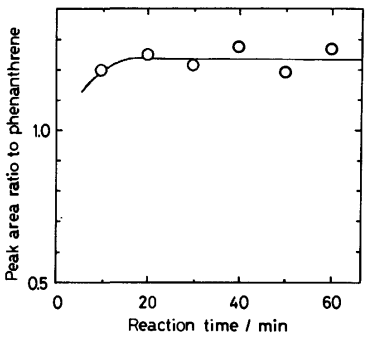

Fig. 3. Time course of the silylation of **2** with BSTFA alone at 120 °C (**2**, 25 mmol; BSTFA, 0.5 ml; phenanthrene, 1.8 mg).

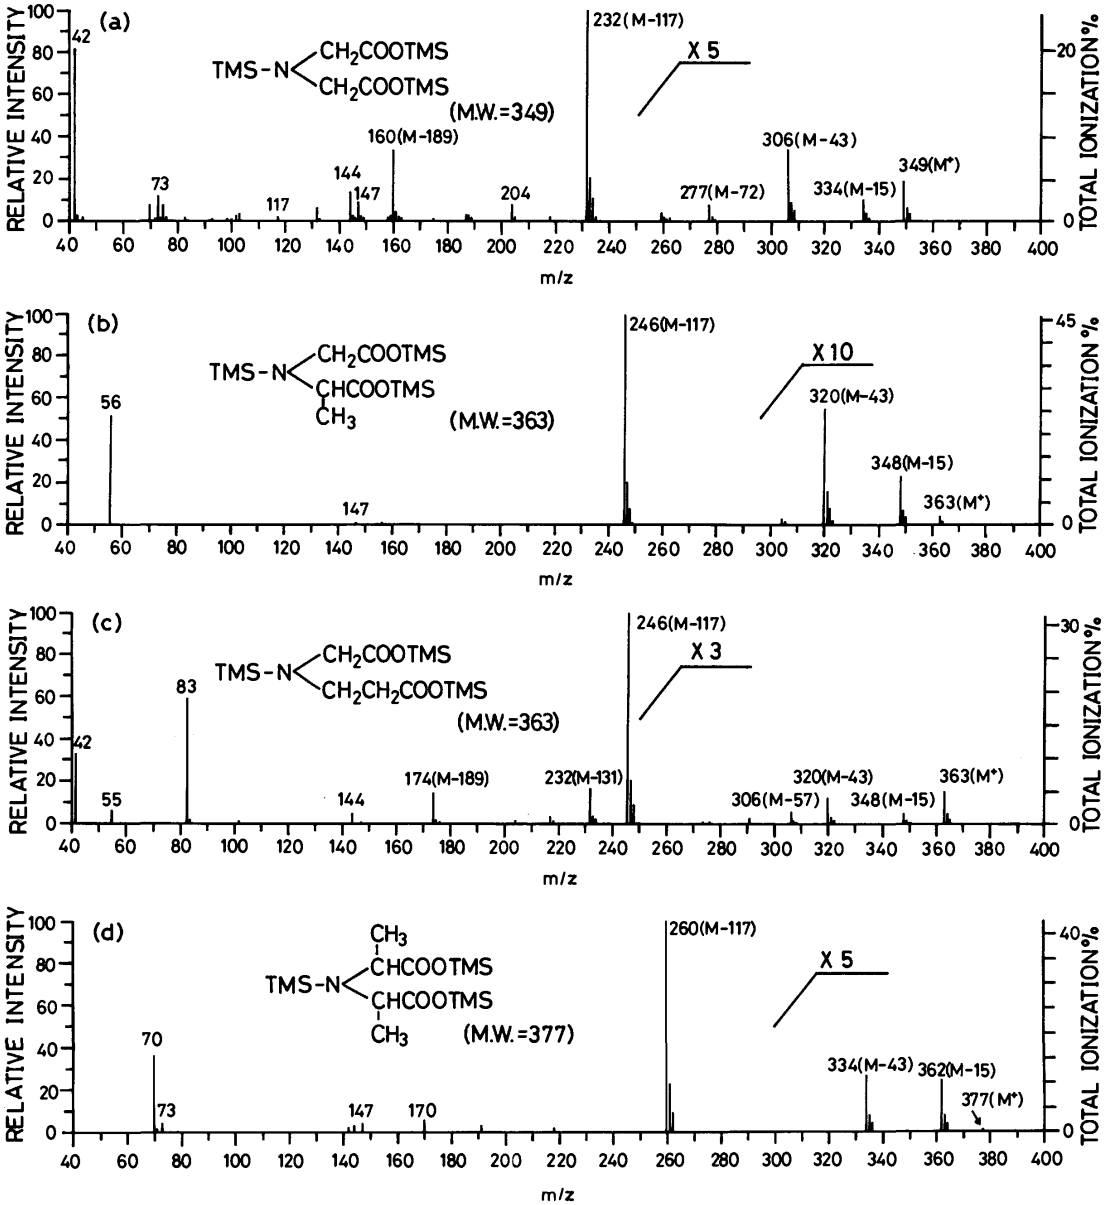
As shown in Table 1, the GC separation of the di-TMS derivatives of the IDCAs is rather poor on the 1 m column. A longer column (2 m), however, showed an indication of partial decomposition of the TMS derivatives of **6** and **8** having longer retention times.

Mass Spectra. Since the IDCAs (**1**—**8**) are regarded as α- or β-amino acids, their TMS derivatives are expected to behave in the same manner as those of α- or β-amino acids upon electron impact. Compounds **7** and **8** are *N*-substituted IDCAs, so that only one derivative, a silyl ester, was formed for each compound.

A) Tri-TMS Derivatives (N-TMS TMS Esters): Figures 4a—f show the mass spectra of the tri-TMS deriv-



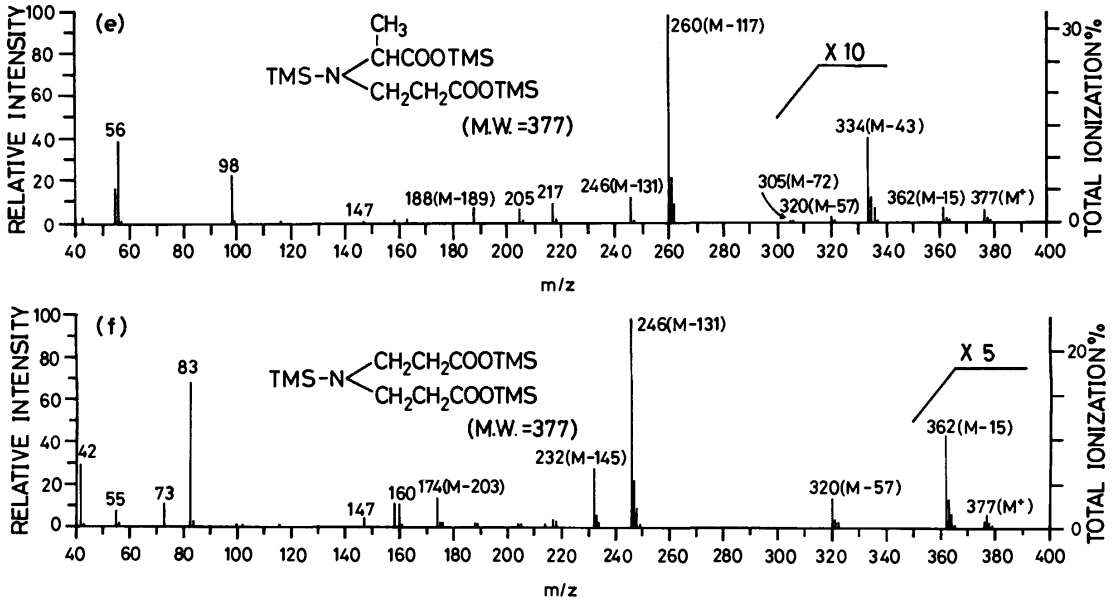


Fig. 4. Mass spectra of the tri-TMS derivatives of IDCAs.
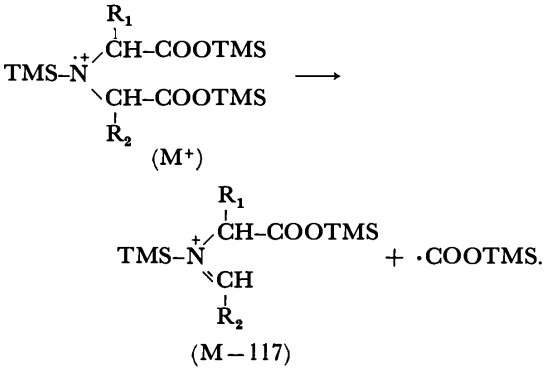
a: **1**, b: **2**, c: **3**, d: **4**, e: **5**, and f: **6**.

atives of **1**—**6**. Both the M^+ and M−15 (CH_3) ions characteristic of TMS derivatives are present in all the spectra. These spectra are much simpler than those of the corresponding *N*-TFA butyl ester derivatives previously reported.[2]

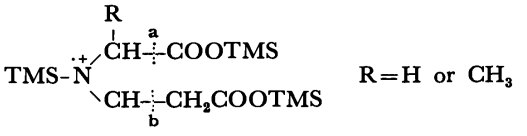
The α,α'-IDCAs (**1**, **2**, and **4**) exhibit characteristic ions such as M^+, M−15, M−43 (CH_3+CO), and M−117 (COOTMS). The M−117 ion constitutes a base peak, which results from the M^+ ion by the loss of a COOTMS group with charge retention on the imino nitrogen as follows:



This fragment is very prominent due to the resonance stabilization of the resultant ion. An analogous fragmentation has been described for α-amino acids.[8,13,14] The M−43 ion is difficult to be explained in terms of simple cleavage of the M^+ ion and may be a result of a certain rearrangement process.[14,17] This ion appears for the α,α'- and α,β'-IDCAs but not for the β,β'-IDCA (**6**), indicating the presence of an $\geq NCH_2COOTMS$ group in the molecule. Additional characteristic ions are observed at *m/z* 277 (M−72) and 160 (M−189) for **1**. The M−72 and M−189 ions may result from the M^+ and M−117 ions, respectively, by the loss of a neutral molecule, $CH_2{=}Si(CH_3)_2$, from the ester portion.[14]

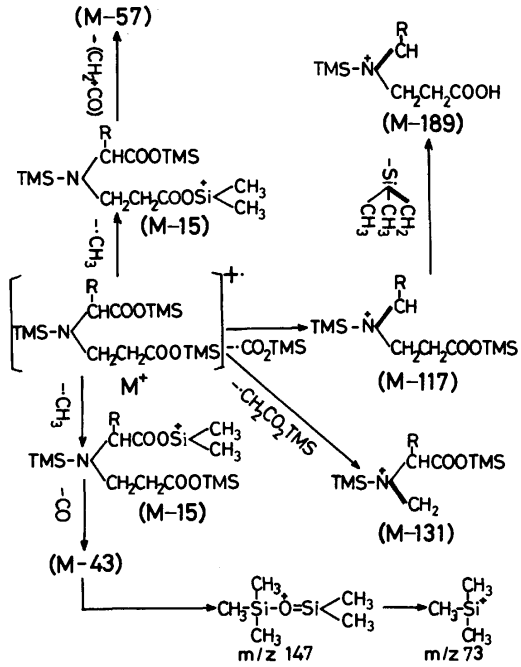
On the other hand, the β,β'-IDCA is characterized by the M^+, M−15, M−57 (CH_3+CH_2+CO), and M−131 ($CH_2COOTMS$) ions. The M−131 fragment at *m/z* 246 constitutes a base peak, which arises from the M^+ ion by the loss of a $CH_2COOTMS$ group due to the alpha-beta bond cleavage (α-cleavage) to the imino nitrogen. Because of the stability of this ion due to resonance, the fragmentation losing a COOTMS group which is typical of α,α'-IDCAs does not take place to any appreciable extent. This fragment then gives an M−203 ion at *m/z* 174 by loss of a neutral molecule, $CH_2{=}Si(CH_3)_2$, from the residual ester portion. The elementary composition of the M−57 ion was confirmed by a high-resolution mass measurement. This ion is observed for β,β'- and α,β'-IDCAs, but not for α,α'-IDCAs, indicating the presence of an $\geq NCH_2$-$CH_2COOTMS$ group in the molecule. The M−57 ion also is difficult to be explained in terms of simple cleavage of the M^+ ion as with the M−43 ion described for α,α'-IDCAs. It can therefore be presumed that a rearranged M−15 ion may break down to this ion by the loss of CH_2 and CO.

It is interesting to note that α,β'-IDCAs (**3** and **5**) are characterized by both the ions typical of α,α'- and β,β'-IDCAs. However, the M−117 ion constitutes a base peak as with α,α'-IDCAs. The M−131 ion which is a base peak for **6**, is much less intense than the M−117 ion. This fact indicates that a silylated carboxyl group (a), defined below, is more preferentially split off than



an *O*-silylated methylcarboxyl one (b), also defined above, due to α-cleavage to the imino nitrogen. Additional characteristic ions, the M−72 ($CH_2{=}Si(CH_3)_2$) and M−189 (COOTMS+$CH_2{=}Si(CH_3)_2$), appear for both **3** and **5**. The M−203 ($CH_2COOTMS$+$CH_2{=}Si(CH_3)_2$) ion

typical of **6**, however, is not observed in these instances. Scheme 1 presents the fragmentation pathways for α,β'-IDCAs as an illustrative example, which also involves the characteristics of both α,α'- and β,β'-IDCAs.



Scheme 1. Fragmentation pathways for the tri-TMS derivatives of α,β'-IDCAs.

B) Di-TMS Derivatives (TMS Esters): Figures 5a—c show the mass spectra of the di-TMS derivatives of 2,2′-, 2,3′-, and 3,3′-iminodipropionic acids (**4**—**6**). In general, the mass spectra of the di-TMS derivatives of **1**—**6** are more complex than those of the corresponding tri-TMS derivatives. For **1**—**6**, the absence of M−45 (COOH) ion indicates that the two TMS groups exist as silyl esters in the molecule, and therefore that the imino nitrogen is not silylated. Characteristic ions for **1**—**8** are listed in Table 5.

α,α'-IDCAs (**1**, **2**, **4**, **7**, and **8**) are characterized by the M^+, M−15, M−43, and M−117 (base peak) ions. On the other hand, β,β'-IDCA (**6**) exhibits a more complex spectrum with characteristic ions such as M^+, M−15, M−57, and M−131. The M−131 ion is very prominent but not a base peak. $\alpha;\beta'$-IDCAs (**3** and **5**) exhibit both the ions characteristic of α,α'- and β,β'-IDCAs. The M−117 ion constitutes a base peak in these instances. These facts indicate that the fragmentation pathways for the di-TMS derivatives are similar to those for the corresponding tri-TMS derivatives.

However, some differences are noted between these two TMS derivatives. The M+1 ion appears only for the di-TMS derivatives, the intensity of which is higher than the corresponding M^+ ion in certain instances (**4** and **5**). An ion *m/z* 172 observed for **4** (Fig. 5a), was confirmed to be M−133 (CH_3+CO+$(CH_3)_3SiOH$) by a high-resolution mass measurement. This fact suggests that this ion results from the M−43 ion by the loss of a $(CH_3)_3SiOH$ group. The M−133 ion is characteristic of α,α'-IDCAs, indicating the presence of an

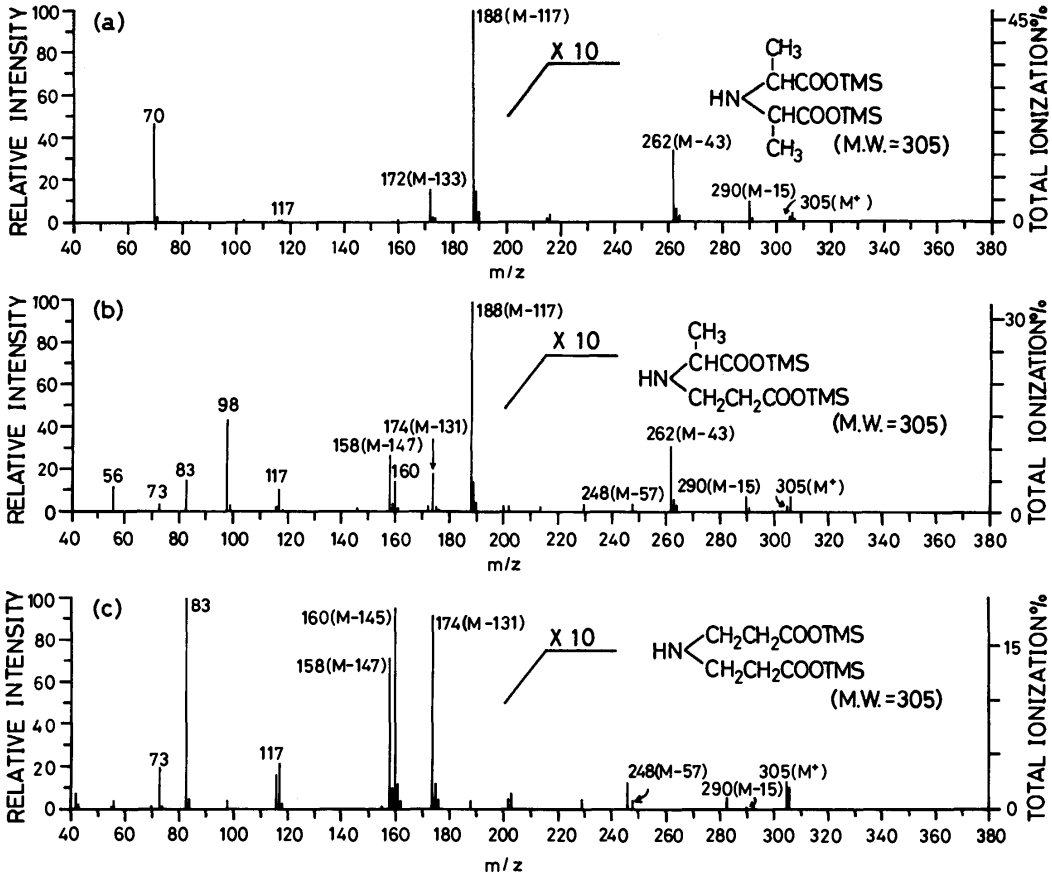


Fig. 5. Mass spectra of the di-TMS derivatives of IDCAs.
a: **4**, b: **5**, and c: **6**.

$\geq NCH_2COOTMS$ group in the molecule. This fragmentation has been described for TMS derivatives of amino acids and peptides.[13,20] On the other hand, two prominent unusual ions are observed at *m/z* 160 and 158 for **6** (Fig. 5c). The elementary composition of the latter ion was determined as $C_6H_{12}NO_2Si$ by a high-resolution mass measurement, which corresponds to M−147 (CH_3+CH_2+CO+$(CH_3)_3SiOH$). This fact suggests that the M−147 ion results from the M−57 ion by the loss of a $(CH_3)_3SiOH$ group as with the M−133 ion described for α,α'-IDCAs. The M−147 ion characteristic of β,β'-IDCA indicates the presence of an $\geq NCH_2CH_2COOTMS$ group in the molecule. Another prominent ion at *m/z* 160 was determined as $C_6H_{14}NO_2Si$ also by a high-resolution mass measurement, which corresponds to M−145 ($2CH_2$+COOTMS). This observation suggests that the M−145 ion results from the M^+ ion by the loss of a $CH_2CH_2COOTMS$ group *via* the N-C bond cleavage. The M−145 ion is characteristic of β,β'-IDCA and also observed at *m/z* 232 with a relative intensity of 29% for the tri-TMS derivative of **6** (Fig. 4f). As expected, α,β'-IDCAs (**3** and **5**) are characterized by the M−133, M−145, and M−147 ions.

Other characteristic ions such as M−89, M−90, M−102, M−103, M−104, and M−105 appear with a low intensity for the di-TMS derivatives. In the instance of **1**, however, the M−89 ion at *m/z* 188 is very prominent (Table 5). Of them, the M−89 and M−90 ions were determined to correspond to fragments M−$(CH_3)_3SiO$ and M−$(CH_3)_3SiOH$, respectively, by a high-resolution mass measurement. The characteristic ions described above have been observed for TMS derivatives of amino acids and peptides[13,20] except the M−103 ion. The disiloxynium ion ($(CH_3)_2Si{=}\dot{O}{-}Si(CH_3)_3$)[8,14,16] at *m/z* 147 indicating the presence of an -OTMS group, appears for all the tri-TMS derivatives, though as a minor peak. This ion is not observed for all the di-TMS derivatives. On the other hand, the ion *m/z* 117 with the structure $\dot{O}{\equiv}CO$-TMS[8,16] is observed for all the di-TMS derivatives but not for the tri-TMS derivatives except **1**. The ion at *m/z* 83 appears for most of the di-TMS derivatives with different intensities, which is a base peak for **6**. This ion is observed also for certain tri-TMS derivatives (**1**, **3**, and **6**).

As shown in Table 6, the total ionization of the base peak (M−117) for α,α'- and α,β'-IDCAs, generally depends on the structure of IDCA. The IDCAs with a methyl group on an α-carbon or an imino nitrogen atom have larger total ionization. Since **7** is an isomer of **2**, the mass spectra of their di-TMS derivatives resemble each other. However, **7** carrying a methyl group on its imino nitrogen is characterized not only by a more intense M^+ ion but also by a larger total ionization of the base peak (M−117) (Tables 5 and 6).

Previous investigators[13,16] have found that, for amino acids which do form double derivatives, the relative intensity of the M^+ ion was higher than that of more highly silylated derivatives, but this is not true for the TMS derivatives of **1**—**6**.

In the present study, the TMS derivatives of the IDCAs are shown to have advantages over the *N*-TFA butyl ester derivatives[2] in both the simplicity of preparation and the simple mass spectra containing the M^+, M−15, and additional characteristic ions. However, double derivatization was found to occur for **1**—**6**, which is often observed for TMS derivatives. This is possibly because of the bulkiness of TMS group. This double derivatization may be overcome by introducing TFA to the imino nitrogen instead of TMS group, which is less bulky and also known to be a good *N*-masking group for amino acids for GC

Table 6. Total ionization of base peaks of the di-TMS derivatives of **1**—**8**

a) Values in parentheses indicate relative intensity. b) Relative intensity of this ion is less than 0.1%. c) A tri-TMS ester.

analysis. However, one-step derivatization of such *N*-TFA TMS esters of amino acids[21] is not established at present. Further study must be undertaken along this line.

Experimental

Materials. BSA and BSTFA were obtained from Wako Pure Chemical Industries, Ltd. and Nakarai Chemicals, Ltd., respectively. Acetonitrile, DMF, pyridine, dichloromethane, 1,2-dichloroethane, and hexane were obtained from Wako Pure Chemical Industries, Ltd. as S grade reagents and used as silylation solvents without further purification. Compounds **1**—**8** were the same as previously reported.[2]

Silylation. About 50 μmol of each IDCA was weighed into a 1 ml screw vial. Then, 0.25 ml of a silylating reagent and 0.25 ml of a solvent were added to the vial. It was closed tight with a silicone cap and then heated at different temperatures for different durations in a constant-temperature air bath (Yamato Drying-Oven, DX-58). When silylation was performed with a silylating reagent alone in the absence of solvent, about 25 μmol of each IDCA was heated with 0.25 or 0.50 ml of a silylating reagent. The hydrochloride of **1** was prepared by treating **1** with distilled 6 M HCl (1 M=1 mol dm^{-3}). After reaction, the solution was evaporated completely to dryness under reduced pressure. The hydrochloride obtained was purified by recrystallization. Usually, 1 μl portions of silylated solutions were injected into a GC column.

GC. GC was carried out with a Hitachi gas chromatograph 163 equipped with a flame ionization detector. The conditions were the same as previously reported.[2]

GC-MS. GC-MS was carried out with a JEOL JMS-D 300 mass spectrometer connected with a JGC-20 KP gas chromatograph and mass spectra upon electron impact at 20 eV were obtained. The GC-MS conditions were the same as previously reported.[2]

Note added in proof

Better GC separation of the di-TMS derivatives of the IDCAs was obtained when a fused silica capillary column (OV-101 FS-WCOT, 0.35 mmϕ×25 m, Gasukuro Kogyo Co., Ltd.) was used instead of the packed column. In this instance, the separation between diastereomers was observed for **4**. Decomposition of the di-TMS derivatives did not take place on the capillary column because of the absence of solid support.

Photoresponsive Crown Ethers. 13. Synthesis of Photoresponsive NS_2O Crown Ethers and Application of the Cu(I) Complexes to O_2-Binding

Seiji SHINKAI,* Kazuyoshi SHIGEMATSU, Yoshihiro HONDA, and Osamu MANABE*
Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852
(Received March 10, 1984)

Photoresponsive crown ethers with heavy metal affinity were synthesized: They are the NS_2O crowns bound to photofunctional azobenzene at 4,4′-positions *via* X(CH_2 or CO) (**1**(X=CH_2) and **1**(X CO), respectively). They efficiently extracted heavy metal ions from aqueous phase to organic(dichloromethane) phase. The continuous variation method established that both *trans*-**1** and photoisomerized *cis*-**1** bind two Cu(II) ions forming 1:1 metal/NS_2O crown complexes. The *trans*-**1**(X=CH_2)·$Cu(I)_2$ complex was irreversibly oxidized by O_2 to the $Cu(II)_2$ complex, whereas the *cis*-**1**(X=CH_2)·$Cu(I)_2$ complex bound O_2 in a partly reversible manner like Osborn's complex. Thus, a photoinduced change in the Cu(I)·····Cu(I) interatomic distance is responsible for the stability of the O_2 complex. These results show that the extraction of heavy metal ions and the O_2-complexation can be controlled by light with the mediation of photoresponsive NS_2O crown ethers.

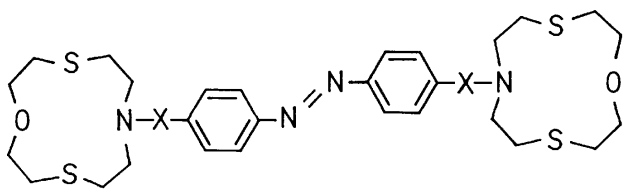
Chemical substances which exhibit photoinduced structural changes are potential candidates not only for the storage of light energy but also as mediators for the conversion of light into other forms of energy. Further, if the structural changes occurring in the photoresponsive chromophores can be transmitted to functional molecules, the fundamental functions of photoresponsive systems in nature may be mimicked in artificial systems. Azobenzene derivatives which exhibit photoinduced reversible cis-trans isomerism have frequently been employed as photoantennae which trigger subsequent events of a number of functional molecules.[1-6]

The purpose of our investigation has been to control the functions of a crown ether family by an on-off light switch, which would lead to photoregulated ion-extraction and membrane transport.[7-12] It was shown that in these photoresponsive crown ethers, not only the binding ability but also the ion selectivity was markedly changed by photoirradiation.[7-16] Two different techniques have been developed to change the binding ability of crown ethers by light. One method is to induce a conformational change in the crown ether moiety in conjugation with a photoinduced configurational change in the azobenzene moiety. The other method is associated with a change in the spatial position between two crown rings which leads to interconversion between 1:1 and 2:1 crown/cation complexes. It is known that a thiacrown family exhibits a significant affinity toward heavy metal cations.[17,18] Thus, if one can extend the above concept to the thiacrown family, it would lead to photocontrol of the ion-binding ability toward heavy metal cations. As a related system, Blank *et al.*[19] recently reported the photoresponsive binding of Zn(II) to 4,4′-bis(α-iminodiacetic acid) azotoluene. We considered that in photoresponsive thiacrown ethers, the heavy metal complexes would have affinity toward small molecules such as O_2 and CO, and thus the affinity might be also photocontrolled. With these objects in view, we synthesized **1**—**3** and evaluated the reversible O_2 binding to the Cu(I) complexes.

Experimental

Materials. 1-Oxa-4,10-dithia-7-azacyclododecane (NS_2O crown) was prepared from equimolar amounts of 3-oxapentane-1,5-dithiol and 1,5-dibromo-3-azapentane hydrobromide in absolute ethanol in the presence of sodium ethoxide: Mp 64—67 °C (lit,[20] 64 °C), yield 31.5%. $M^+(m/z)$: 207. IR (Nujol): ν_{NH} 3255, 3230 cm^{-1}, ν_{C-O-C} 1280, 1115 cm^{-1}. Found: C, 46.05; H, 8.36; N, 6.67; S, 30.70%. Calcd for $C_8H_{17}NOS_2$: C, 46.33; H, 8.26; N, 6.75; S, 30.92%.

4,4′-Bis(1-oxa-4,10-dithia-7-azacyclododec-7-ylmethyl)azobenzene **1**(X=CH_2)) was synthesized from the NS_2O crown and 4,4′-bis(chloromethyl) azobenzene in acetonitrile in the presence of excess powdered K_2CO_3. The detailed procedure is essentially similar to that described for the synthesis of the crown ether analogue.[9] The product was isolated by a TLC method (silica gel and chloroform-ethanol (10:1 by volume)) and finally recrystallized from benzen-ligroin: Mp 117—118 °C, yield 43%. $M^+(m/z)$: 620. ^{1}H-NMR ($CDCl_3$, δ): SCH_2 and NCH_2 in the rings, 2.63—3.10, 24H; OCH_2 and $ArCH_2N$, 3.70—3.90, 12H; 3,3′-ArH, 7.44, 4H; 2,2′-ArH, 7.82, 4H.



trans-1(X=CH_2 or CO)

3

Found: C, 57.83; H, 7.12; N, 8.87; S, 20.50%. Calcd for $C_{30}H_{44}N_4O_2S_4$: C, 58.03; H, 7.14; N, 9.02; S, 20.65%.

4,4'-Bis(1-oxa-4,10-dithia-7-azacyclododec-7-ylcarbonyl)azobenzene (**1**(X=CO)) was synthesiszed from the NS_2O crown and 4,4'-*bis*(*chloroformyl*)*azobenzene* in benzene in the presence of excess triethylamine. A similar procedure was described previously for the synthesis of the crown ether analogue.[9] The product was isolated by a TLC method(silica gel and chloroform–ethanol (10:1 by volume)) and recrystallized from benzene–ether: Mp 246—247 °C, yield 54%. $M^+(m/z)$: 648. ^{1}H-NMR($CDCl_3$, δ): SCH_2, 2.5—3.2, 16H; OCH_2 and NCH_2 in the rings, 3.5—4.2, 16H; 3,3'-ArH, 7.52, 4H; 2,2'-ArH, 7.97, 4H. Found: C, 55.12; H, 6.21; N, 8.66; S, 19.56%. Calcd for $C_{30}H_{40}N_4O_4S_4 \cdot 0.25\ H_2O$: C, 55.15; H, 6.25; N, 8.57; S, 19.63%.

1,4-Bis(1-oxa-4,10-dithia-7-azacyclododec-7-ylmethyl)benzene (**2**)was prepared from the NS_2O crown and α,α'-dibromo-*p*-xylene in acetonitrile in the presence of excess powdered K_2CO_3. The method is analogous to that employed for the synthesis of **1**(X=CH_2). The product was isolated by a TLC method (silica gel and chloroform–ethanol (10:1 by volume)) and recrystallized from benzene–petroleum ether: Mp 109—110 °C, yield 34%. $M^+(m/z)$: 516. ^{1}H-NMR($CDCl_3$, δ): SCH_2 and NCH_2 in the rings, 2.65—3.05, 24H; $ArCH_2N$, 3.64, 4H; OCH_2, 3.78, 8H; ArH, 7.26, 4H. Found: C, 55.84; H, 7.92; N, 5.35; S, 24.65%. Calcd for $C_{24}H_{40}N_2O_2S_4$: C, 55.78; H, 7.80; N, 5.42; S, 24.81%.

N-(*p*-Nitrobenzyl)-1-oxa-4,10-dithia-7-azacyclododecane (**3**-(X=NO_2)) was synthesized from the NS_2O crown and *p*-nitrobenzyl chloride in acetonitrile in the presence of excess powdered K_2CO_3 in a manner similar to that described previously.[9] After TLC separation (silica gel and chloroform–ethanol (10:1 by volume)), the product was recrystallized from benzen–ligroin: Mp 133—134 °C, yield 60%. $M^+(m/z)$: 342. ^{1}H-NMR($CDCl_3$, δ): SCH_2 and NCH_2 in the ring, 2.61—3.00, 12H; OCH_2 and $ArCH_2N$, 3.72, 6H; *o*-ArH, 7.44, 2H; *m*-ArH, 8.08, 2H. Found: C, 52.51; H, 6.54; N, 8.19; S, 18.84%. Calcd for $C_{15}H_{22}N_2O_3S_2$: C, 52.61; H, 6.47; N, 8.18; S, 18.72%.

N-Benzyl-1-oxa-4,10-dithia-7-azacyclodedecane (**3**(X=H)) was similarly synthesized from the NS_2O crown and benzyl chloride: Mp 108—110 °C, yield 65%. Found: C, 60.66; H, 7.80; N, 4.77%. Calcd for $C_{15}H_{23}NOS_2$: C, 60.56; H, 7.79; N, 4.71%.

Miscellaneous. The methods of solvent extraction and the rate determination of thermal cis-to-trans isomerization were described previously.[7-12] As a UV-light source for the trans-to-cis isomerization, a 500 W high-pressure Hg-lamp with a colour glass filter (330 nm<λ<380 nm) was used. In the solvent extraction of Cu(II) with **1**(X=CH_2), we measured the concentrations of picrate ion (by absorption spectroscopy) as well as Cu(II) (by atomic absorption spectroscopy) extracted into the dichloromethane phase. It was found that the concentration of Cu(II) is very close to that of picrate ion, indicationg that Cu(II) is extracted as Cu·picrate·Cl.

The O_2-absorption experiments of **1**—**3** were carried out by using a Thunberg cuvette. The thiacrown ether dissolved in propylene carbonate (PC) was placed in the bottom cell of the Thunberg cuvette and $[Cu(CH_3CN)_4]BF_4$ in PC was deposited in the side arm. After N_2-substitution by repeating a freezing-and-thawing, two solutions were mixed and subjected to spectral measurement at 30 °C. At this time, there was no absorption maximum at around 700 nm. An O_2 stream was introduced into the cell for 5 min at 40—50 °C, and the spectrum was recorded at 30 °C. Then, the mixture was evacuated at 1.0 mmHg for 1h at 70 °C (for *cis*-**1**, for 20 min at 40 °C in order to suppress the cis-to-trans thermal isomerization). The fraction of the oxygenation product was estimated from the decrease in the absorption band at around 700 nm.

Results and Discussion

Spectral Examination of Metal-crown Interactions. The spectroscopic properties of *trans*-**1** are summarized in Table 1. Since the π-π^* band of *trans*-**1** and the n-π^* band of *cis*-**1** are clearly separated, one may expect that trans-to-cis and cis-to-trans isomerizations are controlled by irradiation of UV and visible light, respectively. Under UV-light irradiation, the absorbance of the π-π^* band decreased and that of the n-π^* band increased gradually with tight isosbestic points and finally reached a photostationary state. The cis concentration at the photostationary state was estimated (Table 1) by the decrease in the OD of the absorption maxima, assuming that the OD of *cis*-**1** at these wavelengths is negligible in comparison with that of *trans*-**1**. The cis-forms of **1**(X=CH_2) and **1**(X=CO) isomerized thermally to the trans-forms with k(first-order rate constant)=0.0347 and 0.0958 h^{-1}, respectivery, at 30 °C in dichloromethane. Under visible light irradiation (200 W tungsten-lamp, 15 s at intervals of 10 min), the isomerization reaction was speeded up to 1.24 and 4.90 h^{-1}, respectively.

The addition of $CuCl_2$ to a dichloromethane solution of **1**(X=CH_2) gave rise to a new shoulder at 390—420 nm region as well as to an absorption maximum at around 700 nm. Since a similar spectral change was observed for **2**[18] and **3**, these absorption bands are attributed to the $CuCl_2$–NS_2O crown interaction. On the other hand, the spectral change of **1**(X=CO) occurred to a relatively smaller extent. We chose 390 nm to conduct the continuous variation method of *trans*- and *cis*-**1**(X=CH_2), because this band is relatively stronger than the 700 nm band and corresponds to an isosbestic point of the cis-trans isomerism. Thus, one may estimate the extent of the Cu(II)-crown association directly from the observed OD without regard to the cis percentage. Figure 1 shows that the maxima appear at $[CuCl_2]/[\mathbf{1}(X=CH_2)]=2$, indicating that both *trans*- and *cis*-**1**(X=CH_2) form the 2:1 copper/**1** complexes. This means that each NS_2O crown binds one Cu(II) and the composition is not changed by the photoisomerization.

Metal Ion Catalyses in the Thermal Cis-to-Trans Isomerization. We have described that the photoinduced cis-trans interconversion of **1** occurs reversibly. It is known that some heavy metal ions can catalyze the thermal isomerization of azo-linkages[12,21,22] probably because of the stabilization of the transition state through metal ion coordination to the azo linkages. In Table 2, typical first-order rate constants in the presence of metal ions are summarized. From Table 2, most of the heavy metal ions used are capable of catalyzing the thermal isomerization and, in particular, Cu(II) provides the greatest catalytic effect. We thus carried out further detailed investigation on the Cu(II) catalysis. In Fig. 2, the first-order rate constants for **1** are plotted against the Cu(II) concentration. The plots for **1** give a biphasic dependence which consists of no rate increase at $[CuCl_2]/[\mathbf{1}]<2$ and marked rate increase at $[CuCl_2]/[\mathbf{1}]>2$. The result suggests that Cu(II) is selectively bound to the two NS_2O crown ethers in the first phase and the interaction with the azo

Table 1. λ_{max} and ε_{max} of *trans*-**1**, cis/trans ratio at the photostationary state, and first-order rate constants(k) for theramal isomerization[a]

a) Solvent: dichloromethane: ethanol=96.9: 3.1 by volume, [metal salt]=1.00×10^{-4} M. [**1**]=2.50×10^{-5} M.

linkage which is associated with the rate enhancement begins at $[CuCl_2]/[1]>2$. This is second evidence that each NS_2O crown binds one Cu(II).

Solvent Extraction of Heavy Metal Ions. In Table 3, the influence of photoirradiation on the extractability of **1** and related compounds **2** and **3**(X=NO_2) is summarized. **3**(X=NO_2) was mainly used because of the analogy between NO_2 and azobenzene as electron-withdrawing substituents. It is seen from extractabilities (Ex%) of **2** and **3**(X=NO_2) that Hg(II) has a contrasting characteristic to other metal ions: Cu(II), Co(II), Ni(II), and Pb(II) give the smaller Ex% in **3**(X=NO_2) than in **2**, while the Ex% for Hg(II) is slightly enhanced in **3**(X=NO_2). The result means that the basicity of the nitrogen in the NS_2O crown ring plays a decisive role in the complexation with the four metal ions, while the affinity with the sulfur atoms is

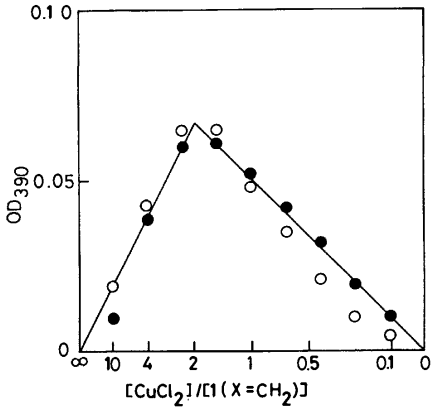

Fig. 1. Continuous variation plots of OD_{390}. 30°C, CH_2Cl_2 (containing 3.1 vol% ethanol), [**1**(X=CH_2)]+[$CuCl_2$]=2.50×10^{-5} M.

most important in the Hg(II)-binding. Most important in Table 3 is the fact that the Ex% for **1** is scarcely affected by photoirradiation. This means that two NS_2O crown rings act rather independently. We previously examined the photoresponsive behaviors of 4,4′-bis(1,4,7,10-tetraoxa-13-azacyclopentadec-13-ylmethyl)-azobenzene and 4,4′-bis(1,4,7,10-tetraoxa-13-azacyclopentadec-13-ylmethyl)azobenzene and 4,4′-bis(1,4,7,10-tetraoxa-13-azacyclopentadec-13-ylcarbonyl)azobenzene (monoaza-15-crown-5 analogues of **1**(X=CH_2) and **1**(X=CO)).[9] The photoisomerized cis-forms of these

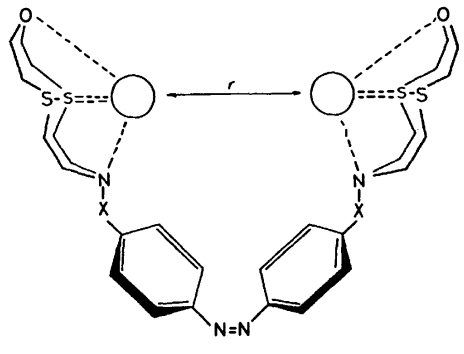

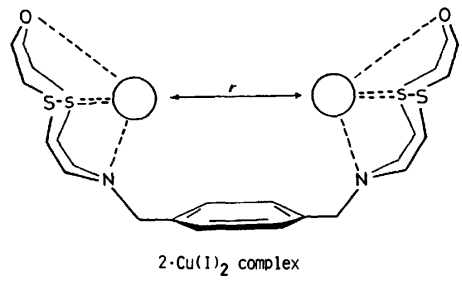

Fig. 3. Ear-muff conformation of the Cu(I) complexes of **2** and *cis*-**1**(X=CH_2).

crown ethers bound Rb^+ and Cs^+ with relatively large ion radii more efficiently than the trans-forms, but no significant difference could be seen for Na^+. One may presume, therefore, that the caity constructed by two intramolecular crown rings is pretty large. The ion radius of Cu(II) (0.76—0.87 Å) is much smaller than that of Na^+ (1.13—1.16 Å). Provided that the cis-forms of **1**(X=CH_2) and **1**(X=CO) construct the cavity similar to these crown ethers, it is very likely that two NS_2O crown rings in *cis*-**1** cannot coordinate to one Cu(II) ion cooperatively.

The results indicate, together with the result of the continuous variation experiment (Fig. 1), that both *trans*- and *cis*-**1** form the 2:1 (*i.e.*, 1:1 metal/crown) complexes with metal ions. Based on the foregoing informations, we conducted photocontrol studies of reversible O_2 adsorption to the **1**(X=CH_2)·$Cu(I)_2$ complex.

Oxygen Adsorption to the Cu(I)-complexes of 1, 2, and 3. The preparation of complexes which contain two transition metal ions separated by distances of 3.5—6 Å has been of much concern in recent years. Interest in such complexes stems from their potential for the functionality to flank small molecules in a sandwich manner as a so-called cascade complex.[23] In particular, the systems which are capable of binding O_2 or N_2 are of special interest because of their relevance to biological systems, such as haemocyanin, hemerythrin, and perhaps nitrogenase. There are several precedents for bi-metallic copper complexes which bind O_2 or CO, although the revesibility is not satisfactory yet.[18,24-26] Osborn *et al.*[18] reported **2**·$Cu(I)_2$ complex, in which the oxygenation-deoxygenation sequence in the solid state can be repeated several times although the reversibility in solution is not as complete as in the solid state.

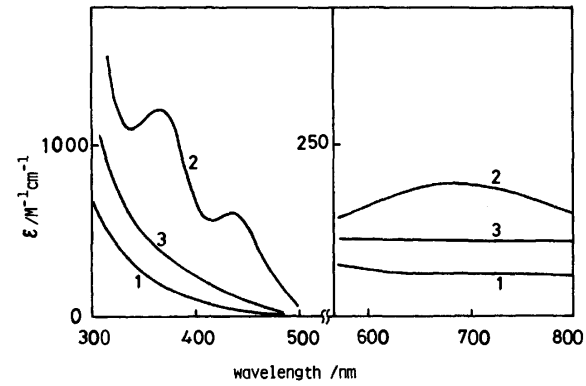

Fig. 4. Spectral change for the reaction of **2**·$Cu(I)_2$ (1.00×10^{-3} M) and O_2 in propylene carbonate. **2**·$Cu(I)_2$; was prepared from 1.00 mM of **2** and 4.00 mM of $[Cu(CH_3CN)_4]BF_4$. 1, **2**·$Cu(I)_2$; 2, after introduction of O_2; 3, after evacuation.

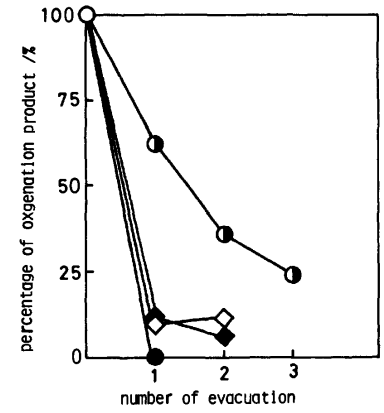

Fig. 5. Reversibility in O_2-binding in propylene carbonate.
◑ [**2**]=1.00×10^{-3} M, [$Cu(CH_3CN)_4\cdot BF_4$]=4.00×10^{-3} M; ◇ [**3**(X=NO_2)] and ◆ [**3**(X=H)]=1.00×10^{-3} M, [$Cu(CH_3CN)_4\cdot BF_4$]=3.83×10^{-3} M; ● [*trans*-**1**(X=CH_2)]=2.50×10^{-4} M, [$Cu(CH_3CN)_4\cdot BF_4$]=2.66×10^{-3} M.

It occurred to us that as the ability of the bi-metallic complexes to bind O_2 is largely governed by the distance between two metal ions, a change in this would directly induce a change in the stability of the O_2-complex. Molecular models show that for preferred ear-muff conformation of **2** (Fig. 3) the two Cu(I) ions are separated by 3.5—5 Å: the later X-ray study of the **2**·$Cu(I)_2$·OH complex gave a distance of 3.384 Å.[27] We estimated on the basis of the CPK model building that the Cu(I)···Cu(I) interatomic distance in the *cis*-**1**(X=CH_2)·$Cu(I)_2$ complex is in the range 3.0—9.0 Å. The wide distance range is due to the conformational freedom of the thiacrowns. The ear-muff conformation of **1**(X=CH_2) and **2** may not be the stable one, but one may expect for the O_2-complexes the "lock-in" effect[8,16] of O_2 that enforces the ear-muff conformation. Therefore, the Cu(I) complex of **1**(X=CH_2) and **2** may allow the reversible binding of O_2 only when it is photoisomerized to cis and adopts the preferred ear-muff conformation (Fig. 3). On the other hand, such favorable distance between the two intramolecular Cu(I) ions is not expected for the complex with *trans*-**1**(X=CH_2).

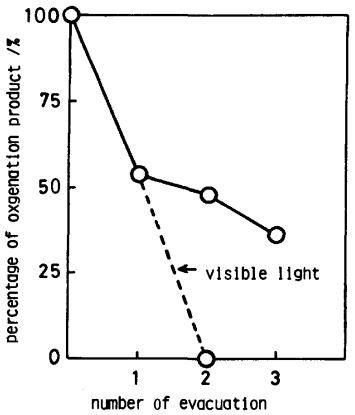

Fig. 6. Reversibility in O_2-binding to *cis*-**1**(X=CH_2) in propylene carbonate. [photoirradiated **1**(X=CH_2) (*cis* 72%)]=2.50×10^{-4} M, [$Cu(CH_3CN)_4\cdot BF_4$]=2.66×10^{-3} M. Photoirradiation was carried out before mixing with the Cu(I) solution.

In an optical cell, the appropriate amount of thiacrown ethers (*trans*-**1**, **2**, and **3**) was mixed with $[Cu(CH_3CN)_4]BF_4$ in propylene carbonate (PC) under anaerobic conditions. An oxygen stream was introduced into the optical cell at 40—50°C for 5 min and the mixture was subjected to spectral measurement at 30°C. A new broad absorption maximum appeared at around 700 nm (Fig. 4), which was scarcely affected by further introduction of oxygen. This band is attributable either to a reversible oxygenation product (Cu(I)·····O_2·····Cu(I)) or to an irreversible oxidation product (Cu(II)).[18,24-26] The fraction of the reversible oxygenation product was evaluated from the disappearance of the absorption maximum on evacuation[18] (1.0 mmHg, 70°C, 1 h). The results are illustrated in Fig. 5. When the treatment was repeated several times, oxygen was newly introduced after evacuation. It is seen from Fig. 5 that the Osborn's complex **2**·$Cu(I)_2$(λ_{max} of the O_2-complex 686 nm) is capable of binding O_2 in a reversible manner for several times: the fractions of the oxygenated product are 62 (1st evacuation), 36 (2nd evacuation), and 23% (3rd evacuation). Thus, the reversibility becomes inferior as the repeated number of evacuation and the irreversible oxidation product is accumulated. The reversibility of the mononuclear complexes **3**·Cu(I) (λ_{max} of the O_2-complex 694 nm for **3**(X=NO_2) and 684 nm for **3**(X=H)) was found to be much inferior: 9 (1st evacuation) and 11% (2nd evacuation) for **3**(X=NO_2) and 12 (1st evacuation) and 6% (2nd evacuation) for **3**(X=H). As expected, no decrease in the absorbance was observed for the *trans*-**1**(X=CH_2)·$Cu(I)_2$ complex ((λ_{max} 710 nm), indicating that the irreversible oxidation to Cu(II) is the sole reaction path.

In contrast, we found that *cis*-**1**·$Cu(I)_2$ complex ((λ_{max} 708 nm) is capable of forming the significant fraction of the reversible oxygenation product. The evacuation was carricd out under milder conditions (1.0 mmHg, 40°C, 20 min) where the progress of the thermal cis-to-trans isomerization is almost negligible (k=0.12 h^{-1} at 40°C: for the conditions see the figure caption to Fig. 5). We used photoisomerized **1**(X=CH_2) containing 72% of *cis*-**1**(X=CH_2) at the beginning. We observed 54% decrease in the absorbance after first evacuation. This value indicates that 75% of *cis*-**1**(X=CH_2) form the oxygenation product (Fig. 6). Second and third evacuations gave 48 and 36% decrease, respectively. In a separate study, we irradiated the sample by visible light for 5 min after first evacuation. The spectral measurement showed that by this treatment the remaining cis-form has been isomerized to the trans-form. Then, O_2 was introduced. As shown in Fig. 6, no oxygenated product was detected on second evacuation. The marked difference in the reversibility between the the *trans*- and *cis*-**1**(X=CH_2)·$Cu(I)_2$ complexes suggests that this process may be controlled by a light switch through the photoinduced cis-trans interconversion of **1**(X=CH_2).

Conclusions. In this article we have indicated that the concept to photocontrol the chemical and physical functions of a crown ether family can be extended to a thiacrown ether family which acts as receptors for heavy metal ions. Being different from "inactive" alkali metal ions, some kinds of heavy metal ions are "active" for small molecules and others as seen in metalloproteins. We thus consider that the activities of heavy metal ions could be photocontrolled by use of thiacrown ethers or azacrown ethers linked to photofunctional groups. One example is the reversible O_2-binding reported here. Although the frameworks of the photoresponsive thiacrown ethers are still to be improved, the results indicate that the affinity of heavy metal ions with O_2 can be controlled, in principle, by switching the light source on and off. Further investigation is currently in progress in this laboratory.

This research was supported by a grant from the Ministry of Education of Japan. We thank Professor H. L. Ammon and Professor K. T. Douglas for helpful discussions. Appreciation is also expressed to Professor J. A. Osborn for teaching the experimental conditions.

(Received May 25, 1984)

Four new quassinoids, shinjulactones F, I, J, and K were isolated from *Ailanthus altissima* Swingle. The structure of shinjulactone F was established to be 1α,11-epoxy-1β,20-dihydroxy-5β*H*-picrasa-3,9(11)-diene-2,12,16-trione by X-ray diffraction analysis. The structures of shinjulactones I, J, and K were determined to be 11α-acetoxy-2α,12α-dihydroxypicrasane-1,16-dione, 1β,12β-dihydroxypicrasane-2,11,16-trione, and 12α-acetoxy-2α,11α-dihydroxypicrasane-1,16-dione, respectively, by spectral and chemical means.

Bitter principles of Simaroubaceous plants have been extensively investigated from the interest in structure determination and their useful biological activities. In previous papers we have reported the isolation and structure elucidation of several quassinoids from *Ailanthus altissima* Swingle (Japanese name: Shinju or Niwaurushi).[2-5)] Recently quassinoid glycosides have been isolated from seeds of this plant.[6)] This paper describes structure determination of four new bitter principles, shinjulactones F, I, J, and K (**1**, **2**, **3**, and **4**), isolated from the same plant.

Aqueous extract of the root bark of *A. altissima* was continuously extracted with dichloromethane. The organic layer was subjected to separation by a silica-gel column chromatography and then further purified by a partition column chromatography on silicic acid to afford four minor bitter quassinoids, shinjulactones F (**1**, *ca.* 0.003% yield), I (**2**, *ca.* 0.0002% yield), J (**3**, *ca.* 0.0001% yield), and K (**4**, *ca.* 0.0005% yield) together with other known quassinoids.[2-5)]

Shinjulactone F (**1**), mp 201—203 °C, was shown to have a molecular formula, $C_{20}H_{22}O_7$, by elemental analysis and high-resolution mass spectrum. IR and UV spectra indicated the presence of hydroxyl(s) (ν_{max} 3450 cm^{-1}), δ-lactone (ν_{max} 1735 cm^{-1}), and two α,β-unsaturated carbonyls (ν_{max} 1685 cm^{-1}; λ_{max} 244 nm and 291 nm). Investigation on ^1H and ^{13}C NMR spectra of **1** revealed that shinjulactone F (**1**) possesses a vinyl methyl, a tertiary methyl, a secondary methyl, and a hydroxymethyl group.

Spectral comparison with known quassinoids such as ailanthone (**5**)[3)] and shinjulactone B (**6**)[5)] suggested the presence of partial structures **A** and **B** for shinjulactone F (**1**). The A ring of shinjulactone F (**1**) was shown to resemble that of ailanthone (**5**) except for the facts described below. ^{13}C NMR of **1** showed a signal assignable to a hemiacetal carbon (δ 120.6 s) instead of a signal (δ 84.4 d) due to C-1 for **5**. In ^1H NMR spectrum of **1** a signal due to a proton attached to C-1 was not observed. Thus the partial structure **A** was proposed for the A ring of shinjulactone F (**1**). In the part of the C ring the presence of the partial structure **B** was inferred from the following evidence. In ^{13}C NMR spectrum of **1** signals ascribable to the partial structure **B** were observed at δ 135.9 s, 149.9 s, and 194.3 s. These signals are similar to those assignable to a diosphenol part (δ 138.5 s; C-9, δ 145.1 s; C-11, and δ 195.9 s; C-12) of shinjulactone B (**6**) in its

Acetylation of **1** gave a diacetate (**7**), which did not show the IR absorption band due to hydroxyl groups, indicating the presence of two hydroxyl groups for **1**. Assuming the picrasane skeleton, the presence of a 1,11-epoxide structure would be proposed for **1**, because the nature of all the seven oxygen atoms including the hemiacetal one at C-1 and nine of the ten unsaturation degrees have been clarified. Polonsky *et al.*[7] isolated karinolide from *Simaba multiflora*, for which 1α,11α-epoxypicrasane structure has been proposed. Treatment of **1** with hydrogen chloride in methanol afforded a reaction mixture, from which a dimethoxy derivative (**8**) and a monomethoxy derivative (**9**) were obtained by preparative TLC separation. The presence of a dienone moiety in the A ring of both **8** and **9** was indicated by UV (λ_{max} 325 nm) and MS (*m/z* 165; fragment ion **C**) spectra. In the UV spectra **8** exhibited an absorption maximum at 252 nm, while **9** showed it at 276 nm. These absorption maxima were reminiscent of quassin (**10**; 255 nm) and the diosphenol (**11**; 270 nm), respectively.[8] These observations indicated the presence of an enone moiety in the C ring for **8** and **9**. On methylation with diazomethane shinjulactone F (**1**) afforded 1-*O*-methyl derivative (**12**) and 11-*O*-methyl derivative (**13**), which were acetylated to give the corresponding acetates, **14** and **15**, respectively. Formation of these compounds adequately demonstrates the presence of the hemiacetal functionality at C-1 position for shinjulactone F (**1**).

The ^1H NMR spectrum of shinjulactone F (**1**) showed a multiplet signal at δ 2.71 due to a methine proton

at C-5, which is coupled with methylene protons at C-6 with coupling constants, $J_{5,6\alpha}$=3 Hz and $J_{5,6\beta}$=5.5 Hz (see Table 1). These coupling patterns have never been observed in ^{1}H NMR of any known quassinoids. However this observation could be reasonably explained if an inversion of a chiral center at C-5 occurs so as to form the 1,11-epoxide ring with a less strain. Configurations of the hydroxyl group at C-1 and the hydrogen at C-5 could be determined by NOE measurement of 1-*O*-methyl monoacetate (**14**). On saturation of the signal due to $C_{(10)}$-CH_3, the signals due to $C_{(1)}$-OCH_3 and $C_{(5)}$-H showed increase in area by 3 and 9%, respectively. This observation implies the $C_{(1\beta)}$-OCH_3 and $C_{(5\beta)}$-H orientations.

Unambiguous proof for the structure of shinjulactone F (**1**) was provided by X-ray diffraction analysis. The crystal of **1** obtained from benzene–acetone solution belongs to a monoclinic space group $P2_1$ with the cell parameters of a=8.392(2), b=14.920(4), c=7.581(2) Å, and β=105.3(2)°. Two molecules of **1** and two water molecules are contained in the unit cell to give D_c=1.42 g·cm^{-3}. Intensity data were measured on a Philips PW1100 automatic four-circle diffractometer using monochromated Cu $K\alpha$ radiation. A total of 1883 independent structure factors with $F_o \geq 2.5\sigma(F_o)$ within 2θ=156° were obtained by the 2θ–θ scanning mode. The structure was solved by the direct method using MULTAN 80 program. An E-map revealed the positions of all the non-hydrogen atoms, and the hydrogen atoms except those of water molecule were located in a difference electron density map. The structure was refined by the block-diagonal least-squares calculations assuming anisotropic thermal motions for non-hydrogen atoms and isotropic ones for hydrogen atoms. The final R-factor was 0.036. The final atomic coordinates are listed in Table 2 and bond lengths and bond angles are listed in Tables 3 and 4[9]. The hemiacetal structure and the $C_{(5\beta)}$-H configuration were clearly established as shown in Fig. 1. Thus the structure of shinjulactone F (**1**) was established to be 1α,11-epoxy-1β,20-dihydroxy-5βH-picrasa-3,9(11)-diene-2,12,16-trione.

Shinjulactone F (**1**) contains several interesting structural features. 1,11-Epoxypicrasanes are rarely found and only two types have been reported; artificial bisnorquassin and its derivatives[10] and karinolide.[7] It is noteworthy that shinjulactone F (**1**) is the first example of 5β-H picrasane skeleton with all-*cis* configurations at A/B, B/D, and C/D ring junctures to form a unique folded-shape molecule.

Shinjulactone I (**2**) crystallized from acetone as colorless prisms, mp 220—223 °C. High-resolution mass spectrum indicated the molecular formula $C_{22}H_{32}O_7$. IR spectrum showed the presence of hydroxyl(s) (3430 cm^{-1}), a δ-lactone (1725 cm^{-1}), and an isolated carbonyl group (1705 cm^{-1}). ^{1}H (Table 1) and ^{13}C NMR spectra revealed that shinjulactone I (**2**) possesses two

tertiary methyls, two secondary methyls, and an acetoxyl group. Since five oxygen atoms were characterized by a lactone, an isolated carbonyl, and an acetoxyl group, the remaining two oxygen atoms were shown to be those of hydroxyl groups. Spectral comparison with amarolide (**16**)[11] suggests that

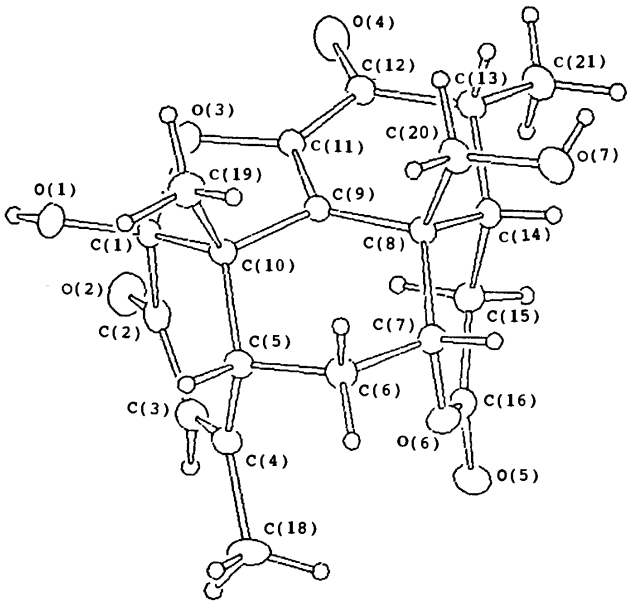

Fig. 1. Perspective view of shinjulactone F (**1**).[a]
a) For clarity hydrogen atoms are represented by spheres of arbitrary radius.

shinjulactone I (**2**) possesses the same structure as **16** in respect of A ring. In the part of C ring the presence of a partial structure **D** was proposed by ^{1}H NMR double resonance experiment for **2** at 90 MHz. Irradiation on a double doublet signal at δ 5.15 (11-H) caused a collapse of a triplet at δ 3.97 (12-H) into a doublet and changed a doublet at δ 3.35 (9-H) into a singlet. Irradiation on a multiplet at δ 2.15 (13-H) changed a doublet methyl-signal at δ 1.10 (13-CH_3) into a singlet and the triplet at δ 3.97 (12-H) into a doublet. The configurations of the four adjacent protons were, therefore, deduced to be 9α-axial, 11β-axial, 12β-equatorial, and 13β-axial orientations from the coupling constants, $J_{9,11}$=11.9, $J_{11,12}$=2.7, and $J_{12,13}$=2.7 Hz, respectively. A low magnetic field resonance due to $C_{(11)}$-H implies that the acetoxyl group is attached to C-11 position. From these observations the structure **2** might be formulated for shinjulactone I. The structure of shinjulactone I (**2**) was firmly established by a conversion into known amarolide diacetate (**17**).[11] Acetylation of shinjulactone I (**2**) at 0°C for 6h afforded its monoacetate (**18**). A signal at δ 4.72 due to $C_{(2)}$-H in ^{1}H NMR spectrum of **2** was shifted to a lower magnetic field at δ 5.56 in that of **18**. Protons at C-12 of **2** and **18** resonated at nearly the same magnetic fields (δ 3.97 and δ 3.90, respectively). This fact shows that the hydroxyl group at C-12 position remained intact. Jones oxidation of the monoacetylated derivative (**18**) afforded amarolide diacetate (**17**), which was completely identical with an authentic sample. Thus the structure of shinjulactone I (**2**) was determined to be 11α-acetoxy-2α,12α-dihydroxypicrasane-1,16-dione.

The molecular formula, $C_{20}H_{28}O_6$, of shinjulactone J (**3**), mp 127—130°C, was determined by high-resolution mass spectrum. IR spectrum revealed characteristic absorptions for hydroxyl(s) (3510 cm^{-1}),

isolated carbonyl(s) (1715 cm^{-1}), and a δ-lactone (1725 cm^{-1}). ^1H (Table 1) and ^{13}C NMR spectra showed the presence of two secondary methyls, two tertiary methyls, two isolated carbonyls, and a lactone grouping. Four of six oxygen atoms were thus explained and the presence of two hydroxyl groups was indicated by two broad singlet signals at δ 3.49 and δ 3.53 due to hydroxyl protons, which disappeared on addition of D_2O. Signals due to protons attached to carbons with hydroxyl groups were observed as a singlet at δ 3.82 and a doublet at δ 3.95, respectively, the both signals being coupled with hydroxyl protons with small coupling constants. A signal assignable to $C_{(9)}$-H was observed at δ 2.80 as a singlet. These findings suggest that hydroxyl groups exist at C-1 and C-12 positions and isolated carbonyl groups are located at C-2 and C-11 positons. This is also supported by comparison with other quassinoids. Most of quassinoids with six oxygen atoms possess oxygenated functionalities at C-1, C-2, C-11, and C-12 positions other than a δ-lactone moiety. Configurations of hydroxyl groups of shinjulactone J (**3**) was determined by NOE experiment at 400 MHz. On saturation of the proton singlet due to $C_{(9)}$-H, the signals due to $C_{(1)}$-H and $C_{(12)}$-H showed increase in area by 14 and 7%, respectively. This observation indicates the $C_{(1\beta)}$-OH and $C_{(12\beta)}$-OH orientations. From these results the structure **3** was proposed for shinjulactone J.

In order to confirm the proposed structure **3**, a preparation of shinjulactone J (**3**) from known chaparrolide (**19**)[12] was carried out as follows. Treatment of chaparrolide (**19**) with *t*-butyldimethylsilyl chloride in the presence of imidazole in *N*,*N*-dimethylformamide afforded a monosilyl derivative (**20**; yield 40%) and a disilyl derivative (**21**; yield 17%). The monosilyl derivative (**20**) was acetylated at room temperature for 4 d to give 2-siloxy monoacetate (**22**; yield 96%), which was further acetylated at 110 °C for 40 h to afford 2-siloxy triacetate (**23**; yield 51%). The ^1H NMR spectrum of **23** showed a signal due to an olefinic proton (δ 5.51 br s; 15-H) and three singlet methyl-signals due to acetyl groups (δ 2.14, 2.16, and 2.30). The ^{13}C NMR of **23** showed a signal at δ 202.9 assignable to a carbonyl carbon atom at C-11 position and a signal at δ 110.6 due to sp^2 carbon atom at C-15. The IR spectrum of **23** revealed no absorption band due to hydroxyl groups, while an absorption at 1670 cm^{-1} with a middle intensity ascribable to $\Delta^{15(16)}$-double bond with two oxygen functions was observed. Since the dihedral angle between $C_{(14)}$-H and $C_{(15)}$-H was estimated to be *ca.* 90° from the Drieding model, the fact that the olefinic proton at C-15 appeared as a singlet signal was well explained. From these observations the structure of 2-siloxy triacetate (**23**) was firmly established. Treatment of **23** with AcOH–H_2O–THF afforded 2-hydroxy triacetate (**24**; yield 64% based on consumed **23**), which was subjected to Jones oxidation to give 2-keto triacetate (**25**; yield *ca.* 80%). Finally this compound (**25**) was hydrolyzed under acidic conditions to afford shinjulactone J (**3**; yield *ca.* 50%), whose spectral data showed good agreements with those of a natural specimen. The structure of shinjulactone J (**3**) was, therefore, concluded to be 1β,12β-dihydoxypicrasane-2,11,16-trione.

Shinjulactone K (**4**), mp 135—139 °C, crystallized from chloroform–hexane as colorless prisms. The molecular formula, $C_{22}H_{32}O_7$, was determined by high-resolution mass spectrum. ^1H (Table 1) and ^{13}C NMR spectra showed that shinjulactone K (**4**) possesses two secondary methyls, two tertiary methyls, an isolated carbonyl, a lactone, and an acetoxyl group. The IR absorption band at 3430 cm^{-1} suggested that the remaining two oxygen atoms are ascribed to hydroxyl groups. These spectral features were very similar to those of shinjulactone I (**2**). The ^1H NMR spectral comparison between shinjulactones I (**2**) and K (**4**) is indicative of a difference in the relative position of hydroxyl and acetoxyl groups in C ring. Shinjulactone K (**4**) showed a double doublet at δ 3.88 and a triplet at δ 5.37, which were assignable to protons attached to carbons with hydroxyl and acetoxyl groups, respectively. The shapes of these signals were quite parallel to those of the signals due to $C_{(11)}$-H and $C_{(12)}$-H of shinjulactone I (**2**), respectively, and their chemical shifts seemed to be just reversed. Double resonance experiment on shinjulactone K (**4**) was carried out in the same way as developed in the case of shinjulactone I (**2**). Irradiation on the double doublet at δ 3.88 (11-H) changed the triplet at δ 5.37 (12-H) into a doublet and a doublet at δ 2.83 (9-H) into a singlet. Irradiation on a multiplet at δ 2.27 (13-H) changed a doublet methyl-signal at δ 0.95 (13-CH_3) into a singlet and the triplet at δ 5.37 (12-H) into a doublet. These observations could propose the structure **4** for shinjulactone K.

Finally shinjulactones I (**2**) and K (**4**) were chemically correlated to each other. Acetylation of shinjulactone I (**2**) with acetic anhydride in pyridine in the presence of 4-dimethylaminopyridine at room temperature for 6 d gave its diacetate (**26**) together with the monoacetylated product (**18**). Shinjulactone K (**4**) was also acetylated under similar conditions to afford a diacetyl derivative

(**26**), which was completely identical with the diacetyl derivative (**26**) derived from shinjulactone I (**2**). Thus the structure of shinjulactone K (**4**) was established to be 12α-acetoxy-2α,11α-dihydroxypicrasane-1,16-dione.

Experimental

General Procedure. All melting points were measured on a Mel-temp capillary melting apparatus (Laboratory devices) and uncorrected. Optical rotations were determined on a JASCO polarimeter DIP-181. Ultraviolet absorption (UV) spectra and infrared (IR) spectra were measured on a Hitachi 340 and a Hitachi 260-30 spectrometer, respectively. Mass (MS) spectra were run on a JEOL JMS D-300 mass spectrometer operating at 70 eV. Proton nuclear magnetic resonance (^{1}H NMR) spectra (90 MHz) were taken using a Varian EM 390 or a JEOL FX 90Q and carbon-13 nuclear magnetic resonance (^{13}C NMR) spectra (22.5 MHz) were measured on a JEOL FX 90Q unless otherwise stated. Measurement of ^{1}H NMR spectra at 400 MHz and ^{13}C NMR at 100 MHz was carried out on a JEOL JMN GX 400 spectrometer. Chemical shifts were expressed in ppm downfield from tetramethylsilane as an internal standard (δ value) and coupling constants in Hz. Thin-layer chromatography (TLC) was carried out on Kieselgel 60 GF_{254} coated in 0.25 mm- or 0.5 mm-thickness. Wakogel C-200 (Wako) or Silicic acid AR (Mallinckrodt) was used for column chromatography.

Plant Material. Roots of *Ailanthus altissima* Swingle were collected at the Botanical Gardens, Faculty of Science, the University of Tokyo in August 1982. Bark was stripped off from the root, air-dried, and chipped to afford 6.2 kg of materials.

Extraction and Separation. The root bark (6.2 kg) was extracted with hot water overnight. The aqueous layer was concentrated and continuously extracted with dichloromethane. The organic layer was evaporated to give a residue (40 g), which was separated by a silica-gel column chromatography. Gradient elution with 7 and 13% methanol-chloroform gave fractions A and B, respectively.

Fraction A was subjected to a partition column chromatography of silicic acid (250 g) on which water (150 ml) was adsorbed. Gradient elution with 1—2 and 4—8% 1-butanol-benzene afforded fractions C and D, respectively. Fraction C was further purified by a silica-gel column chromatography eluted with benzene-acetone (3:1) to afford shinjulactone K (**4**; *ca.* 20 mg). Fraction D was also purified by a silica-gel column chromatography eluted with benzene-acetone (3:1) to give shinjulactone I (**2**; *ca.* 10 mg) and shinjulactone J (**3**; *ca.* 6 mg) together with shinjulactone H.[4]

Fraction B was separated by a partition column chromatography eluted with 0—16% ethanol-chloroform. The fraction eluted with 8% ethanol-chloroform was further purified by a silica-gel column chromatography eluted with 3% methanol-ethyl acetate to give shinjulactone F (**1**; *ca.* 170 mg) together with shinjulactone G.[4]

Shinjulactone F (1). Colorless prisms cryltallized from ethanol-chloroform or benzene-acetone, mp 201—203 °C, $[\alpha]_D^{20}$ −148° (*c* 2.1, pyridine); IR (KBr) 3450, 1735, 1685, 1220, and 1040 cm^{-1}; UV(ethanol) 244 nm (ε 7400) and 291 nm (ε 3400); ^{1}H NMR (Table 1); ^{13}C NMR (C_5D_5N) δ=11.4q, 20.3q, 23.2q, 27.2t, 27.6t, 30.1d, 38.8d, 40.8s, 41.9d, 47.8s, 63.0t, 78.1d, 120.6s, 126.8d, 135.9s, 149.9s, 164.3s, 168.0s, 190.4s, and 194.3s; MS *m/z* (%) 374 (M^+; 1.5), 356 (7), 340 (5), 282 (100), 266 (25), 253 (35), 236 (50), 189 (50), and 177 (45); Found: *m/z* 374.1364. Calcd for $C_{20}H_{22}O_7$: M 374.1366. Found: C, 62.03; H, 5.93%. Calcd for $C_{20}H_{22}O_7 \cdot 2/3H_2O$: C, 62.17; H, 6.09%.

1,20-Di-O-acetylshinjulactone F (7). Shnjulactone F (**1**; 12 mg) was acetylated with acetic anhydride (0.5 ml) in pyridine (2 ml) at room temperature for 40 h. Addition of methanol and the usual work-up afforded a reaction mixture, which was purified by preparative TLC developed with *ca.* 2% methanol-ethyl acetate to give 1,20-di-*O*-acetylshinjulactone F (**7**; 4 mg), mp 128—132 °C (acetone); IR (Nujol) 1740, 1685, 1675, and 1220 cm^{-1}; UV (ethanol) 245 nm (ε 8000) and 285 nm (ε 2900); ^{1}H NMR ($CDCl_3$) δ=1.11 (3H, d, *J*= 7 Hz), 1.40 (3H, s), 2.19 (9H, br s), 4.36 (2H, s), 4.63 (1H, t, *J*= 2.5 Hz), and 6.21 (1H, br s); MS *m/z* (%) 458 (M^+; 30), 416 (100), 398 (45), 356 (50), 193 (55), and 151 (75); Found *m/z* 458.1554. Calcd for $C_{24}H_{26}O_9$: M 458.1576.

Reaction of 1 with Hydrogen Chloride. To a solution of shinjulactone F (**1**; 31 mg) in dry methanol (6 ml), acetyl chloride (0.3 ml) was added and the mixture was stirred at room temperature for 3 h to give a complex mixture, from which a dimethoxy derivative (**8**; *ca.* 1.5 mg) and a monomethoxy derivative (**9**; *ca.* 1.5 mg) were obtained by preparative TLC developed with 2% methanol-ethyl acetate. **8**: Mp 166—169 °C (acetone); UV(ethanol) 252 nm and 325 nm; ^{1}H NMR ($CDCl_3$) δ=1.45 (3H, s), 1.81 (3H, s), 1.93 (3H, br s), 3.64 (3H, s), 3.75 (3H, s), 4.63 (1H, m), and 5.96 (1H, br s); MS *m/z* (%) 402 (M^+; 75), 388 (20), 370 (18), and 165 (100); Found: *m/z* 402.1682. Calcd for $C_{22}H_{26}O_7$: M 402.1677. **9**: Mp 157—160 °C (acetone); UV(ethanol) 276 nm and 325 m; ^{1}H NMR ($CDCl_3$) δ=1.45 (3H, s), 1.80 (3H, s), 1.93 (3H, br s), 3.34 (1H, s), 3.73 (3H, s), 3.78 (2H, br s), 4.81 (1H, m), and 5.94 (2H, br s); MS *m/z* (%) 388 (M^+; 100), 370 (10), 356 (18), 280 (45), and 165 (80); Found: *m/z* 388.1515. Calcd for $C_{21}H_{24}O_7$: M 388.1520.

Methylation of 1 with Diazomethane. Shinjulactone F (**1**; 38 mg) in THF (10 ml) was treated with diazomethane in ether and the reaction mixture was allowed to stand at room temperature for 12 h. Usual work-up and separation by preparative TLC (7% methanol-chloroform) afforded 1-*O*-methyl derivative (**12**; 9.5 mg) and 11-*O*-methyl derivative (**13**; 11 mg). **12**: Mp 200—201 °C (chloroform); IR(KBr) 3450, 1720, 1710, 1680, and 1225 cm^{-1}; UV(ethanol) 245 nm (ε 8200) and 295 nm (ε 3000); ^{1}H NMR ($CDCl_3$) δ=1.09 (3H, d, *J*=7 Hz), 1.40 (3H, s), 2.10 (3H, br s), 3.53 (3H, s), 3.90 (2H, br s), 4.84 (1H, m), and 6.02 (1H, br s); MS *m/z* (%) 388 (M^+; 20), 358 (100), 343 (15), 329 (20), and 314 (45); Found: *m/z* 388.1472. Calcd for $C_{21}H_{24}O_7$: M 388.1520. **13**: Mp 118—122 °C (ethanol-ethyl acetate); IR (KBr) 3450, 1720, 1680, 1275, and 1040 cm^{-1}; UV (ethanol) 256 nm (ε 7200); ^{1}H NMR ($CDCl_3$) δ=1.11 (3H, d, *J*=7 Hz), 1.55 (3H, s), 2.19 (3H, br s), 3.65 (3H, s), 3.77 and 3.98 (each 1H, d, *J*=10 Hz), 4.85 (1H, m), and 6.08 (1H, br s); ^{13}C NMR ($CDCl_3$) δ=12.2, 21.2, 23.6, 27.6, 29.3, 36.9, 40.5, 42.1, 48.3, 51.8, 60.1, 66.3, 77.5, 128.9, 135.8, 151.4, 166.7, 167.9, 188.9, 193.9, and 198.8; MS *m/z* (%) 388 (M^+; 70), 358 (100), 329 (75), and 283 (50); Found: *m/z* 388.1540. Calcd for $C_{21}H_{24}O_7$: M 388.1520.

Acetylation of 12 and 13. A crude mixture (*ca.* 60 mg) of 1-*O*-methyl derivative (**12**) and 11-*O*-methyl derivative (**13**) was acetylated with acetic anhydride (2 ml) in pyridine (5 ml) at room temperature for 16 h. Addition of methanol and the usual work-up afforded a reaction mixture, which was separated by preparative TLC developed with chloroform-ethyl acetate (9:1) to afford 1-*O*-methyl monoacetate (**14**; 15 mg) and 11-*O*-methyl monoacetate (**15**; *ca.* 6 mg). **14**: Mp 193—195 °C (acetone-ether); IR(KBr) 1740, 1685, 1380, and 1220 cm^{-1}; UV(ethanol) 243 nm (ε 12000) and 291 nm (ε 4500); ^{1}H NMR ($CDCl_3$, 400 MHz) δ=1.12 (3H, d, *J*= 7 Hz; 13-CH_3), 1.42 (3H, s; 10-CH_3), 1.85 (1H, dd, *J*=18, 12.5 Hz; 15α-H), 2.09 (3H, br s; 4-CH_3), 2.15 (3H, s; CH_3CO-), 2.34 (1H, ddd, *J*=16, 6, 2.5 Hz; 6β-H), 2.52 (1H, dd, *J*=18, 6 Hz; 15β-H), 2.59 (1H, m; 5-H), 2.66 (1H, ddd, *J*=16, 3.5, 2.5 Hz; 6α-H), 2.69 (1H, ddd, *J*=12.5, 6, 3.5 Hz; 14-H), 3.06 (1H, dq, *J*=3.5, 7 Hz; 13-H), 3.53 (3H, s; CH_3O-), 4.32 and 4.36 (each 1H, d, *J*=12 Hz; 20-H), 4.62 (1H, t, *J*=2.5 Hz; 7-H), and 6.05 (1H, br s; 3-H); ^{13}C NMR ($CDCl_3$) δ=11.3q, 20.1q,

20.7q, 22.9q, 26.7t, 26.9t, 38.4s, 39.2d, 41.0d, 41.8d, 47.5s, 54.7q, 62.7t, 76.6d, 108.2s, 126.6d, 133.1s, 148.5s, 162.4s, 167.0s, 170.1s, 188.5s, and 191.0s; MS *m/z* (%) 430 (M^+; 72), 402 (75), 361 (70), 329 (100), and 301 (80); Found: *m/z* 430.1622. Calcd for $C_{23}H_{26}O_8$: M 430.1627. **15**: amorphous solid from ether, mp *ca.* 80—85 °C; IR(film) 1740, 1680, and 1220 cm^{-1}; UV (ethanol) 258 nm (ε 9200); ^1H NMR ($CDCl_3$) δ=1.16 (3H, d, *J*=7 Hz), 1.58 (3H, s), 2.13 (6H, s), 3.70 (3H, s), 4.13 and 4.51 (each 1H, d, *J*=12 Hz), 4.63 (1H, m), and 6.13 (1H, br s); MS *m/z* (%) 430 (M^+; 60), 402 (100), 387 (45), 371 (40), and 329 (93); Found: *m/z* 430.1611. Calcd for $C_{23}H_{26}O_8$: M 430.1627.

Shinjulactone I (2). Colorless prisms crystallized from acetone, mp 220—223 °C; $[\alpha]_D^{16}$+33° (*c* 0.67, $CHCl_3$); IR(KBr) 3430, 1725, 1705, and 1245 cm^{-1}; ^1H NMR (Table 1); ^{13}C NMR ($CDCl_3$) δ=13.4q, 13.9q, 18.3q, 21.1q, 21.7q, 26.4t, 28.8d, 29.4t, 30.5d, 32.1d, 35.9s, 44.8d, 48.0d, 48.6s, 49.0t, 70.1d, 72.8d, 73.4d, 82.3d, 170.0s, 171.1s, and 214.3s; MS *m/z* (%) 408 (M^+; 1.3), 390 (4.5), 380 (7), 352 (8), 348 (12), 330 (10), 320 (15), 302 (29), 258 (76), 242 (62), and 171(100); Found: *m/z* 408.2162. Calcd for $C_{22}H_{32}O_7$: M 408.2146.

2-O-Acetylshinjulactone I (18). Shinjulactone I (**2**; 6 mg) was treated with acetic anhydride (1 ml) in pyridine (2 ml) at 0 °C for 6 h. After addition of methanol and the usual work-up, the reaction mixture was separated by silica-gel column chromatography eluted with benzene–acetone (9:1) to afford the starting shinjulactone I (**2**; 1 mg) and 2-*O*-acetylshinjulactone I (**18**; 4.5 mg), mp 285—288 °C (benzene–acetone); IR (film) 3480, 1720, and 1250 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.95 (3H, d, *J*=5.5 Hz), 1.07 (3H, d, *J*=7 Hz), 1.24 (3H, s), 1.28 (3H, s), 2.04 (3H, s), 2.14 (3H, s), 3.26 (1H, d, *J*=12 Hz), 3.90 (1H, m), 4.10 (1H, t, *J*=2.5 Hz), 5.14 (1H, dd, *J*=12, 3 Hz), and 5.56 (1H, dd, *J*=12, 7 Hz); MS *m/z* (%) 450 (M^+; 11), 406 (10), 390 (65), 330 (100), and 274 (54); Found: *m/z* 450.2228. Calcd for $C_{24}H_{34}O_8$: M 450.2253.

Oxidation of 18 with Jones Reagent. 2-*O*-Acetylshinjulactone I (**18**; 3 mg) was treated with Jones reagent (in excess) in acetone (5 ml) at 0 °C for 1 h. After addition of 2-propanol (*ca.* 3 ml) and sodium hydrogencarbonate (*ca.* 1 g), the reaction mixture was filtered through Florisil (Wako, 100—200 mesh; *ca.* 5 g). After evaporation, brine and dichloromethane were added. Extraction with dichloromethane, evaporation, and purification by silica-gel column chromatography eluted with benzene–acetone (4:1) afforded amarolide diacetate (**17**), which was identified with an authentic sample by TLC, ^1H NMR, IR and mass spectra.

Shinjulactone J (3). White powder from benzene, mp 127—130 °C; $[\alpha]_D^{13}$−41° (*c* 0.4, $CHCl_3$); IR (film) 3510, 1725 (shoulder), 1715, and 1120 cm^{-1}; ^1H NMR (Table 1); ^{13}C NMR ($CDCl_3$, 100 MHz) δ=11.0q, 15.0q, 19.7q, 22.2q, 25.9t, 27.8t, 31.4d, 40.7s, 41.5d, 42.1d, 44.5d, 45.0s, 46.9t, 51.3d, 77.0d, 82.3d, 85.5d, 169.6s, 208.2s, and 208.7s; MS *m/z* (%) 364 (M^+; 23), 346 (19), 320 (66), 292 (17), and 206 (100); Found: *m/z* 364.1859. Calcd for $C_{20}H_{28}O_6$: M 364.1884.

t-Butyldimethylsilylation of Chaparrolide (19). Chaparrolide (**19**; 71 mg) was treated with *t*-butyldimethylsilyl chloride (53 mg; 1.8 equiv) in the presence of imidazole (63 mg; 4.7 equiv) in DMF (3 ml) at room temperature for 17 h. After addition of water (2 ml), evaporation under reduced pressure, dichloromethane and 2 M (1 M=1 mol dm^{-3}) hydrochloric acid were added. After extraction with dichloromethane, the organic layer was washed with a saturated solution of sodium hydrogencarbonate, dried over magnesium sulfate, and subjected to separation by a silica-gel column chromatography eluted with benzene–acetone (3:1) to give a monosilyl derivative (**20**; 37 mg) and a disilyl derivative (**21**; 20 mg). 2-*O*-(*t*-Butyldimethylsilyl)chaparrolide (**20**): Mp 178—179 °C (acetone–hexane); IR(KBr) 3460, 1720, 1250, and 1065 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.06 (6H, s), 0.87 (9H, s), 0.90 (3H, d, *J*=*ca.* 6 Hz), 1.09 (3H, s), 1.14 (3H, d, *J*=6 Hz), 1.34 (3H, s), 2.46 (1H, br s), 2.53 (1H, s), 2.92 (1H, br d, *J*=9 Hz), 3.52 (1H, d, *J*=5 Hz), 3.65 (1H, m), 3.88 (1H, dd, *J*=10.5, 5 Hz), and 4.31 (1H, t, *J*=3 Hz); MS *m/z* (%) 465 (M^+-CH_3; 0.8), 423 (63), 331 (100), 313 (70), and 75 (66); Found: *m/z* 465.2695. Calcd for $C_{25}H_{41}O_6Si$ ($M-CH_3$): 465.2672. 2,12-Bis(*O-t*-butyldimethylsilyl)chaparrolide (**21**): Mp 247 °C (chloroform–hexane); IR(film) 3550, 1730, and 1255 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.01 (3H, s), 0.05 (6H, s), 0.12 (3H, s), 0.86 (9H, s), 0.90 (9H, s), 1.05 (3H, d, *J*=7 Hz), 1.10 (3H, s), 1.33 (3H, s), 2.35 (1H, d, *J*=2.5 Hz), 2.38 (1H, s), 2.89 (1H, dd, *J*=9, 2.5 Hz), 3.65 (1H, m). 3.91 (1H, d, *J*=11 Hz), and 4.26 (1H, t, *J*=2.5 Hz); MS *m/z* (%) 579 (M^+-CH_3; 2), 561 (1) 537 (90), 519 (30), and 75 (100); Found: *m/z* 579.3548. Calcd for $C_{31}H_{55}O_6Si_2$ ($M-CH_3$): 579.3537.

Acetylation of 2-O-(t-Butyldimethylsilyl)chaparrolide (20). 2-*O*-(*t*-Butyldimethylsilyl)chaparrolide (**20**; 49 mg) was acetylated with acetic anhydride (1 ml) in pyridine (2 ml) in the presence of a catalytic amount of 4-dimethylaminopyridine at room temperature for 4 d. After the usual work-up, purification by a silica-gel column chromatography eluted with benzene–acetone (9:1) afforded 2-*O*-(*t*-butyldimethylsilyl)-12-*O*-acetylchaparrolide (**22**; 51 mg) as an amorphous solid, IR (film) 3580, 1730, and 1235 cm^{-1}, ^1H NMR ($CDCl_3$) δ=0.05 (6H, s), 0.87 (9H, s), 0.87 (3H, d, *J*=*ca.* 7 Hz), 1.02 (3H, d, *J*=7 Hz), 1.13 (3H, s), 1.31 (3H, s), 2.15 (3H, s), 2.96 (1H, d, *J*=9 Hz), 3.63 (1H, m), 4.30 (1H, t, *J*=3 Hz), and 4.90 (1H, d, *J*=12 Hz); MS *m/z* (%) 507 (M^+-CH_3; 1.2), 465 (32), 373 (42), 331 (13), 313 (66), and 75 (100); Found: *m/z* 507.2742. Calcd for $C_{27}H_{43}O_7Si$ ($M-CH_3$): 507.2777. 2-*O*-(*t*-Butyldimethylsilyl)-12-*O*-acetylchaparrolide (**22**; 51 mg) was further acetylated with acetic anhydride (2 ml) in pyridine (2 ml) in the presence of a catalytic amount of 4-dimethylaminopyridine at 110 °C for 40 h. After the same work-up as above, the reaction mixture was purified by a silica-gel column chromatography eluted with chloroform–ethyl acetate (4:1) to give 2-siloxy triacetate (**23**; 30 mg) as an amorphous solid, IR (film) 1735, 1670, and 1230 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.04 (6H, s), 0.84 (9H, s), 0.93 (3H, d, *J*=6 Hz), 0.98 (3H, d, *J*=6 Hz), 1.14 (3H, s), 1.42 (3H, s), 2.14 (3H, s), 2.16 (3H, s), 2.30 (3H, s), 3.75 (1H, m), 4.30 (1H, t, *J*=3 Hz), 4.60 (1H, d, *J*=9 Hz), 5.11 (1H, d, *J*=12 Hz), and 5.51 (1H, br s); ^{13}C NMR ($CDCl_3$) δ=−4.8, −4.3, 12.0, 14.7, 17.8, 18.1, 19.5, 20.3, 21.0, 23.2, 25.6, 25.6, 25.6, 27.6, 27.7, 37.1, 39.9, 41.8, 43.0, 43.5, 45.1, 52.9, 68.9, *ca.* 77.0(overlapped with the signal of $CDCl_3$), 82.6, 84.2, 110.6, 164.1, 166.0, 167.6, 169.1, and 202.9; MS *m/z* (%) 591 (M^+-CH_3; 12), 549 (3), 507 (10), 465 (17), 447 (14), 405 (6), 387 (21), 373 (30), 313 (50), 159 (100), and 75 (44); Found: *m/z* 591.3031. Calcd for $C_{31}H_{47}O_9Si$ ($M-CH_3$): 591.2989.

Desilylation of 2-Siloxy Triacetate (23). 2-Siloxy triacetate (**23**; 17 mg) was treated with AcOH (4 ml), H_2O (2 ml), and THF (2 ml) at room temperature for 6 d. The reaction mixture was evaporated and separated by a silica-gel column chromatography to afford the starting 2-siloxy triacetate (**23**; 4.5 mg) and 2-hydroxy triacetate (**24**; 6.5 mg), mp 94—98 °C (chloroform–hexane); IR(film) 3460, 1750, 1735, 1670, and 1235 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.92 (3H, d, *J*=7 Hz), 0.96 (3H, d, *J*=6.5 Hz), 1.12 (3H, s), 1.39 (3H, s), 2.13 (3H, s), 2.15 (3H, s), 2.33 (3H, s), 3.80 (1H, m), 4.26 (1H, br s), 4.50 (1H, d, *J*=10 Hz), 5.01 (1H, d, *J*=12 Hz), and 5.54 (1H, s); MS *m/z* (%) 492 (M^+; 1.1), 451 (1.7), 433 (4), 390 (32), 373 (46), 330 (74), 313 (78), and 55 (100); Found: *m/z* 492.2353. Calcd for $C_{26}H_{36}O_9$: M 492.2358.

Oxidation of 24 with Jones Reagent. 2-Hydroxy triacetate (**24**; 6 mg) was treated with Jones reagent (in excess) in acetone (3 ml) at 0 °C for 30 min. The usual work-up afforded 2-keto triacetate (**25**; 5 mg), mp 131—135 °C, IR (film) 1730, 1670, and 1225 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.00 (3H, d, *J*=7 Hz), 1.03 (3H, d, *J*=5.5 Hz), 1.13 (3H, s), 1.34 (3H, s), 2.13 (3H, s), 2.15 (3H, s), 2.33 (3H, s), 4.35 (1H, br s), 4.80

(1H, d, J=12.5 Hz), 4.95 (1H, s), and 5.60 (1H, s); MS m/z (%) 490 (M^+; 72), 406 (82), 362 (74), 206 (64), and 85 (100); Found: m/z 490.2214. Calcd for $C_{26}H_{34}O_9$: M 490.2203.

Acidic Hydrolysis of ***25***. A solution of 2-keto triacetate (**25**; 2 mg) in 1.5 M sulfuric acid–THF (each 1.5 ml) was refluxed for 5.5 h. After evaporation and addition of dichloromethane and brine, the mixture was extracted with dichloromethane. The organic layer was dried over magnesium sulfate, and evaporated to give a residue. Purification by silica-gel column chromatography eluted with benzene–acetone (7:3) afforded shinjulactone J (**3**; *ca.* 1 mg), which was identified with a natural specimen by TLC, ^{1}H NMR, IR, and mass spectra.

*Shinjulactone K (****4****).* Colorless prisms from chloroform-hexane, mp 135—139°C, $[\alpha]_D^{24}$+33° (c 1.0, $CHCl_3$); IR (KBr) 3430, 1730, and 1230 cm^{-1}; ^{1}H NMR (Table 1); ^{13}C NMR ($CDCl_3$) δ=13.4q, 13.9q, 18.5q, 21.0q, 21.8q, 26.4t, 28.7d, 28.9t, 31.9d, 33.8d, 35.9s, 44.9d, 47.2d, 47.9t, 49.7s, 69.1d, 70.6d, 77.1d, 82.5d, 170.3s, 170.7s, and 221.9s; MS m/z (%) 408 (M^+; 1.1), 390 (12), 380 (8), 362 (7), 348 (20), 302 (15), 258 (32), 222 (58), and 198 (100); Found: m/z 408.2139. Calcd for $C_{22}H_{32}O_7$: M 408.2146.

*2,12-Di-O-acetylshinjulactone I (****26****).* Shinjulactone I (**2**; 2 mg) was treated with acetic anhydride (1 ml) in pyridine (2 ml) in the presence of a catalytic amount of 4-dimethylaminopyridine at room temperature for 6 d. After addition of methanol and evaporation under a reduced pressure, the reaction mixture was separated by a silica-gel column chromatography to give 2-*O*-acetylshinjulactone I (**18**; *ca.* 1 mg) and 2,12-di-*O*-acetylshinjulactone I (**26**; *ca.* 1 mg), mp 258—260°C (chloroform–hexane); IR (film) 1735 and 1250 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.97 (6H, d, J=7 Hz), 1.30 (6H, s), 1.90 (3H, s), 2.15 (3H, s), 2.24 (3H, s), 3.18 (1H, d, J=12 Hz), 4.14 (1H, t, J=3 Hz), 5.18 (1H, dd, J=12, 3 Hz), 5.29 (1H, t, J=3 Hz), and 5.57 (1H, dd, J=12, 7 Hz); MS m/z (%) 492 (M^+; 18), 450 (5), 432 (29), 407 (32), 390 (100), 330 (68), and 258 (69); Found: m/z 492.2378. Calcd for $C_{26}H_{36}O_9$: M 492.2358.

*2,11-Di-O-acetylshinjulactone K (****26****).* Shinjulactone K (**4**; 10 mg) was acetylated with acetic anhydride (1 ml) in pyridine (2 ml) in the presence of a catalytic amount of 4-dimethylaminopyridine at room temperature for a week. The usual work-up and purification by a silica-gel column chromatography eluted with 0—10% acetone–benzene afforded 2,11-di-*O*-acetylshinjulactone K (**26**; 7 mg), which was identified with 2,12-di-*O*-acetylshinjulactone I (**26**) by TLC, ^{1}H NMR, IR, and mass spectra.

The authors wish to thank Mr. Kazuhiro Matsushita of JEOL Co. Ltd. for measurement of NMR spectra and Mr. Eiichi Ishii of the Botanical Gardens, Faculty of Science, the University of Tokyo, for collecting *Ailanthus altissima* Swingle.

Structure and Synthesis of Miyaginin, a *p*-Allylphenyl Glycoside from *Lespedeza thunbergii* forma *macrantha*

Makoto OJIKA, Hiroki KUYAMA, Haruki NIWA, and Kiyoyuki YAMADA*
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received May 14, 1984)

The structure of miyaginin previously reported as *p*-vinylphenyl *O*-D-xylosyl-(1→6)-D-glucoside without stereochemical assignment of two glycosidic linkages was reinvestigated by spectral and chemical means and shown to be revised as *p*-allylphenyl *O*-β-D-xylopyranosyl-(1→6)-β-D-glucopyranoside (*p*-allylphenyl β-primeveroside). In order to confirm the revised structure, an unambiguous synthesis of miyaginin was performed.

Miyaginin was first isolated from *Lespedeza thunbergii* (Miyaginohagi in Japanese) and its structure was reported to be *p*-vinylphenyl *O*-D-xylosyl-(1→6)-D-glucoside (**1**) without configurational assignment of two glycosidic linkages.[1] In connection with the carcinogenicity of bracken, *Pteridium aquilinum* var. *latiusculum*, we have examined the constituents of a carcinogenic fraction obtained from the aqueous extract of bracken and isolated a new *p*-hydroxystyrene glycoside, ptelatoside-A (**4**).[2] While the planar structure of ptelatoside-A (**4**) was the same as the previously assigned structure[1] of miyaginin (structure **1**), both compounds were found to be different by comparison of the spectral and physical properties.

In order to establish the complete structure of miyaginin we have isolated miyaginin from *Lespedeza thunbergii* forma *macrantha* [Kehagi in Japanese, a wild type of Miyaginohagi (*L. thunbergii*)] and reinvestigated the structure by chemical and spectral means. As the result the structure of miyaginin previously reported as **1** was shown to be revised to *p*-allylphenyl *O*-β-D-xylopyranosyl-(1→6)-β-D-glucopyranoside (*p*-allylphenyl β-primeveroside) (**2**). We describe the details of structural determination of miyaginin (**2**) and its unambiguous synthesis.

Results and Discussion

Isolation of Miyaginin (2). The ethanolic extract of *L. thunbergii* forma *macrantha* dissolved in water was washed successively with hexane, ether, and ethyl acetate. The aqueous layer was then extracted repeatedly with 1-butanol. The 1-butanol extract was chromatographed on silica gel and then alumina to give crude miyaginin (**2**). Further purification with preparative HPLC afforded pure miyaginin (**2**) (0.07% yield based on dried plant material), mp 215—216°C, $[\alpha]_D^{21}$ −81.0°. Spectral (UV, IR, and ^{1}H NMR) and physical (mp and $[\alpha]_D$) properties of miyaginin (**2**) were identical with those of the authentic sample[1] isolated previously from *L. thunbergii*. Although, in search for miyaginin (**2**), we have examined the constituents of the ethanolic extract of *L. thunbergii* collected in the botanical garden of Tohoku University, **2** was not detected.

Structure of Miyaginin (2). The molecular formula of miyaginin (**2**) was determined to be $C_{20}H_{28}O_{10}$ based on the elemental analysis of **2** and the hexaacetate **3** coupled with FAB-MS of **2**. The spectral data of miyaginin (**2**) suggested the presence of a *p*-(substituted oxy)allylbenzene moiety in **2**: ^{1}H NMR δ=5.00 (2H, m, H-9), 5.96 (1H, ddt, *J*=17.6, 9.5, and 6.4 Hz, H-8), and 7.07 (4H, m, aromatic protons); ^{13}C NMR δ=156.0 (s, C-1), 117.9 (d, C-2 and 6), 130.6 (d, C-3 and 5), 135.7 (s, C-4), 39.6 (t, C-7), 138.8 (d, C-8), and 116.4 (t, C-9); UV 221 (ε 9900), 272 (1200), and 279 nm (1000).

On acidic methanolysis miyaginin (**2**) afforded an aglycone, *p*-allylphenol (chavicol)(**5**)[3,13] and a mixture of methyl glycosides of D-xylose and D-glucose. After acetylation followed by chromatographic separation the methyl glycosides were identified as methyl 2,3,4-tri-*O*-acetyl-α-D-xylopyranoside and methyl 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranoside, respectively by comparison with authentic specimens. The aglycone, *p*-allylphenol (**5**) was identified by comparison of the spectral data with those of the authentic sample, the synthesis of which is described later and also by conversion into the known 3,5-dinitrobenzoate **6**.[4] Acetylation of miyaginin (**2**) gave the corresponding hexaacetate **3** as colorless needles, mp 163—164°C, spectral and physical properties of which were identical with those of the authentic sample.[1] The signals at δ=68.9 (t, C-6′), 101.6 (d, $^1J_{CH}$=164 Hz, C-1′), and 104.2 (d, $^1J_{CH}$=163 Hz, C-1″) in the ^{13}C NMR spectrum of miyaginin (**2**) and the signals at δ=4.89 (1H, d, *J*=7.9 Hz, H-1′), 4.38 (1H, d, *J*=6.8 Hz, H-1″), and 3.50—3.80 (2H, m, H-6′) in the ^{1}H NMR spectrum of the hexaacetate **3** suggested the sugar moiety of miyaginin to be represented as β-D-xylopyranosyl-(1→6)-β-D-glucopyranosyl (β-primeverosyl). The structure of miyaginin was therefore determined to be *p*-allylphenyl β-primeveroside (**2**). In order to confirm the structure of miyaginin, the unambiguous synthesis of **2** was performed as described below.

Synthesis of Miyaginin (2). *p*-Allylphenol (**5**) was previously reported to be synthesized from allylbenzene in very low yield.[13] In the present study we have executed a new synthesis of **5** in 80% overall yield starting from commercially available 3-(4-hydroxyphenyl)-1-propanol (**7**). The alcohol **7** was converted by the procedure developed by Sharpless[5] into the selenide **8** in quantitative yield. Oxidation of **8** with hydrogen peroxide and subsequent elimination of *o*-nitrobenzeneselenenic acid from the resulting selenoxide gave *p*-allylphenol (**5**) in 80% yield. Glycosylation of **5** with penta-*O*-acetyl-β-D-glucopyranose under the Helferich's conditions[6] gave *p*-allylphenyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside-(**9**)[7] in 56% yield. Methanolysis of **9** with sodium methoxide in

methanol afforded *p*-allylphenyl β-D-glucopyranoside (**10**), a natural glucoside previously isolated from *Pinus contorta*,[7] in 84% yield. The glucoside **10** was then converted to *p*-allylphenyl 2,3,4-tri-*O*-acetyl-β-D-glucopyranoside (**11**) in 40% overall yield by the following three-step sequence;[8] (i) tritylation with trityl chloride–pyridine, (ii) acetylation with acetic anhydride–pyridine, (iii) detritylation with aqueous acetic acid. Glycosylation of **11** with 2,3,4-tri-*O*-acetyl-α-D-xylopyranosyl bromide under the Helferich's conditions[9] gave miyaginin hexaacetate (**3**) in 88% yield. The physical and spectral properties of synthetic **3** were identical with those of the authentic sample derived from natural miyaginin (**2**) in all respects. Finally, methanolysis of **3** with sodium methoxide in methanol afforded *p*-allylphenyl β-primeveroside (**2**), colorless needles, mp 211.5—213 °C, $[\alpha]_D^{14}$ −81.6° in 89% yield. The physical and spectral properties as well as chromatographic mobilities of synthetic **2** were completely identical with those of natural miyaginin in all respects. Thus, the structure of miyaginin was unambiguously established to be *p*-allylphenyl *O*-β-D-xylopyranosyl-(1→6)-β-D-glucopyranoside (*p*-allylphenyl β-primeveroside) (**2**).

So far, there have been known a few *p*-allylphenyl glycosides in nature: *p*-allylphenyl rutinoside,[10] *p*-allylphenyl *O*-α-L-arabinofuranosyl-(1→6)-β-D-glucopyranoside,[11] *p*-allylphenyl *O*-[3-*C*-(hydroxymethyl)-β-D-erythrofuranosyl]-(1→6)-β-D-glucopyranoside (furcatin),[12] and *p*-allylphenyl β-D-glucopyranoside (**10**).[7] *p*-Allylphenol (**5**) itself was also isolated from the plant, *Viburnum japonicum*.[3]

Experimental

Boiling point and melting points were uncorrected. Optical rotations were measured with a JASCO DIP-4 or a JASCO DIP-181 digital polarimeter. IR and UV spectra were recorded on a JASCO model IR-S spectrophotometer and a JASCO UVIDEC-510 spectrophotometer, respectively. ^1H and ^{13}C NMR spectra were measured at 90 MHz and 22.5 MHz, respectively with a JEOL FX-90QE spectrometer: the chemical shifts are given in δ using Me_4Si as internal standard except for the ^{13}C-chemical shifts measured in D_2O, which are reported in ppm downfield from Me_4Si by assigning the resonance from internal dioxane to 67.4 ppm. Mass spectra and the fast atom bombardment mass spectrum (FAB-MS) were taken on a Hitachi RMU-6C mass spectrometer and a JEOL JMS-DX300 mass spectrometer, respectively. For column chromatography Fuji-Davison silica gel (BW-820 MH) and Merck neutral alumina (Aluminiumoxid 90, activity II-III) were used. Preparative thin layer chromatography (TLC) was carried out using Merck silica gel PF_{254}. A high performance liquid chromatography (HPLC) was performed with a JASCO TRI ROTAR-II apparatus equipped with a UV detector (JASCO UVIDEC-100-II) set at 221 nm.

Isolation of Miyaginin (2). The air-dried and chopped leaves and stems (278 g) of *L. thunbergii* forma *macrantha* collected in the Higashiyama botanical garden (Nagoya city) in June, 1983, were immersed in ethanol (2.4 L) at room temperature for 10 d. The ethanol extract was concentrated to dryness under reduced pressure. The residue (20 g) was diluted with water (200 mL) and the mixture was washed successively with hexane (10×200 mL), ether (7×200 mL), and ethyl acetate saturated with water (19×100 mL). The aqueous layer was then extracted with 1-butanol saturated with water (5×100 mL). The 1-butanol layer was concentrated to dryness under reduced pressure. The residue (2.6 g) was chromatographed on silica gel (55 g). Elution with chloroform–methanol (4:1) gave a fraction (0.5 g) containing **2**, which was subsequently chromatographed on alumina (20 g) with methanol–water (9:1) to afford crude **2** (320 mg). Further purification by preparative HPLC on Develosil ODS-5 (250×10 mm I.D.) using ethanol–water (30:70) (flow rate, 3 mL/min) afforded **2** (retention time, 12.4 min) as an amorphous powder (208 mg, 0.07% based on dried plant material). Recrystallization from aqueous acetone gave **2** as colorless needles, mp 215—216 °C (lit,[1] mp 212—214 °C); $[\alpha]_D^{21}$ −81.0° (*c* 1.0, H_2O) [lit,[1] $[\alpha]_D^{20}$ −86.25° (*c* 2.0, H_2O)]; UV (MeOH) 221 (ε 9900), 272 (1200), and 279 nm (1000); IR (KBr) 3440, 1636, 1610, 1511, 1231, 1100, 1075, 1038, and 908 cm^{-1}; ^1H NMR (CD_3OD) δ=4.32 (1H, d, *J*=7.3 Hz, H-1″), 5.00 (2H, m, H-9), 5.96 (1H, ddt, *J*=17.6, 9.5, and 6.4 Hz, H-8), and 7.07 (4H, m, aromatic protons); ^{13}C NMR (D_2O) δ=39.6 (t, C-7), 65.9 (t, C-5″), 68.9 (t, C-6′), 69.9 (d), 70.1 (d), 73.8 (d), 75.8 (d), 76.5 (d), 101.6 (d, $^1J_{CH}$=164 Hz, C-1′), 104.2 (d, $^1J_{CH}$=163 Hz, C-1″), 116.4 (t, C-9), 117.9 (d, C-2 and 6), 130.6 (d, C-3 and 5), 135.7 (s, C-4), 138.8 (d, C-8), and 156.0 (s, C-1); FAB-MS *m/z* 451 (M^++Na), 429 (M^++1), 427 (M^+−1). Found: C, 55.18; H, 6.74%. Calcd for $C_{20}H_{28}O_{10}\cdot 1/2H_2O$: C, 54.91; H, 6.68%.

Acetylation of 2. A solution of **2** (40 mg) in acetic anhydride (2 mL) and pyridine (2 mL) was stirred at room temperature for 2 h. The mixture was evaporated under reduced pressure and the residue was purified by column chromatography on silica gel (30 g) with benzene–ether (3:1)

to give miyaginin hexaacetate (**3**). Recrystallization from methanol gave pure **3** (30 mg) as colorless needles, mp 163—164 °C (lit,[1] mp 164—165 °C); $[\alpha]_D^{21}$ −46.4° (*c* 0.41, $CHCl_3$); UV (MeOH) 220 (ε 10800), 272 (1000), and 278 nm (800); IR ($CHCl_3$) 3050, 1760, 1635, 1604, 1508, 1220, 1052, 986, and 907 cm^{-1}; ^1H NMR (C_6D_6) δ=1.58 (3H, s, $COCH_3$), 1.65 (3H, s, $COCH_3$), 1.72 (6H, s, 2×$COCH_3$), 1.74 (6H, s, 2×$COCH_3$), 2.89 (1H, dd, *J*=11.7 and 8.8 Hz, H-5″), 3.26 (2H, d, *J*=6.6 Hz, H-7), 3.50 (2H, m, H-5′ and 6′), 3.80 (1H, m, H-6′), 3.87 (1H, dd, *J*=11.7 and 5.1 Hz, H-5″), 4.38 (1H, d, *J*=6.8 Hz, H-1″), 4.89 (1H, d, *J*=7.9 Hz, H-1′), 5.00—5.60 (complex pattern), 5.94 (1H, ddt, *J*=17.2, 9.3, and 6.6 Hz, H-8), 7.00 and 7.17 (2H each, AA′BB′ system, aromatic protons); ^{13}C NMR ($CDCl_3$) δ=20.5 (q, 6×$CO\underline{C}H_3$), 39.3 (t, C-7), 62.0 (t, C-5″), 67.5 (t, C-6′), 68.9 (d, 2C), 70.7 (d), 71.3 (d), 71.5 (d), 72.8 (d), 73.8 (d), 99.3 (d, $^1J_{CH}$=163 Hz, C-1′), 100.4 (d, $^1J_{CH}$=161 Hz, C-1″), 115.6 (t, C-9), 116.8 (d, C-2 and 6), 129.8 (d, C-3 and 5), 135.0 (s, C-4), 137.5 (d, C-8), 155.4 (s, C-1), 169.2, 169.3, 169.4, 169.7, 169.8, and 170.0 (s each, 6×$COCH_3$). Found: C, 56.35; H, 6.05%. Calcd for $C_{32}H_{40}O_{16}$: C, 56.46; H, 5.92%.

Methanolysis of Miyaginin (2). To a solution of **2** (41 mg) in methanol (3 mL) was added concd H_2SO_4 (0.09 mL) and the mixture was refluxed for 14 h. After cooling, the mixture was neutralized with a saturated aqueous $NaHCO_3$ solution and concentrated. The residue was diluted with water (2 mL) and the mixture was extracted with chloroform (3×20 mL); the aqueous layer was saved for further experiment. The chloroform layer was dried (Na_2SO_4) and concentrated under reduced pressure to give an oily residue, which was purified by preparative TLC ($CHCl_3$–MeOH, 4:1), affording *p*-allylphenol (**5**) as colorless oil (9 mg). The ^1H NMR spectrum of **5** (see the experimental section of synthesis of **5**) was identical with that of the authentic sample. For identification **5** was converted with 3,5-dinitrobenzoyl chloride in pyridine to the corresponding *p*-allylphenyl 3,5-dinitrobenzoate **6**, mp 102.5—103 °C (benzene–hexane) (lit,[4] mp 103.5—104.5 °C). The aqueous layer obtained after extraction of the aglycone **5** described above was concentrated under reduced pressure and the residue (*ca.* 200 mg) was treated with acetic anhydride (2 mL) and pyridine (2 mL) at room temperature for 14 h. The mixture was concentrated under reduced pressure to dryness. The residue was diluted with chloroform and the insoluble materials were removed by filtration and washed with chloroform. The filtrate and washings were combined and concentrated under reduced pressure to afford a syrup, which was purified by preparative TLC (hexane–EtOAc, 1:1) to give methyl 2,3,4-tri-*O*-acetyl-α-D-xylopyranoside (9.3 mg) and methyl 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranoside (13 mg). Methyl 2,3,4-tri-*O*-acetyl-α-D-xylopyranoside (ether–hexane): mp 82—83 °C; $[\alpha]_D^{24}$ +122° (*c* 0.26, $CHCl_3$); ^1H NMR (C_6D_6) δ=1.70, 1.74, 1.78, and 3.06 (3H each, s), 3.41 (1H, dd, *J*=10.9 and 10.8 Hz), 3.66 (1H, dd, *J*=10.9 and 6.5 Hz), 4.79 (1H, d, *J*=3.6 Hz), 4.89 (1H, dd, *J*=10.2 and 3.6 Hz), 5.00 (1H, ddd, *J*=10.8, 10.1, and 6.5 Hz), and 5.65 (1H, dd, *J*=10.2 and 10.1 Hz). Methyl 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranoside (ether–hexane): mp 63.5—64.5 °C; $[\alpha]_D^{24}$ +129° (*c* 0.24, $CHCl_3$); ^1H NMR (C_6D_6) δ= 1.70, 1.75, 1.76, 1.79, and 3.04 (3H each, s), 3.80 (1H, ddd, *J*=9.9, 4.3, and 2.7 Hz), 4.00 (1H, dd, *J*=11.9 and 2.7 Hz), 4.24 (1H, dd, *J*=11.9 and 4.3 Hz), 4.86 (1H, d, *J*=3.7 Hz), 4.96 (1H, dd, *J*=9.9 and 3.7 Hz), 5.18 (1H, dd, *J*=9.9 and 9.0 Hz), and 5.70 (1H, dd, *J*=9.9 and 9.0 Hz); these data were identical with those of the authentic samples derived from D-xylose and D-glucose, respectively.

Preparation of p-*Allylphenol (5).* To a stirred solution of 3-(4-hydroxyphenyl)-1-propanol (**7**) (1.0 g, 6.6 mmol) and *o*-nitrophenyl selenocyanate (1.93 g, 8.46 mmol) in anhydrous tetrahydrofuran (50 mL) was added tributylphosphine (3.2 mL, 12.8 mmol) at room temperature under nitrogen. After stirring for 5 h, the mixture was diluted with ether and the insoluble materials were removed by filtration and washed with ether. The filtrate and washings were combined and concentrated under reduced pressure to afford a brown syrup, which was purified by column chromatography on silica gel (150 g) using cyclohexane–ether (2:1) to give a crystalline selenide **8** (2.4 g, quantitative yield), mp 45—47 °C (without recrystallization); UV (MeOH) 226 (ε 13900), 255 (13600), 275 (sh, 7600), and 389 nm (3600); IR ($CHCl_3$) 3630, 3380, 1613, 1594, 1570, 1514, and 1334 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.08 (2H, quintet, *J*=7.2 Hz, H-8), 2.72 and 2.88 (2H each, t, *J*=7.2 Hz, H-7 and 9), 6.74 and 7.04 (2H each, AA′BB′ system, H-2, 3, 5, and 6), 7.36 (3H, m, H-4′, 5′, and 6′), and 8.24 (1H, br d, *J*=7.2 Hz, H-3′); MS (70 eV) *m/z* (rel intensity) 337 (M^+, $C_{15}H_{15}NO_3{}^{80}Se$; 26), 202 (13), 186 (18), 133 (97), and 107 (100). Found: *m/z* 337.0195. Calcd for $C_{15}H_{15}NO_3{}^{80}Se$: M, 337.0217.

To a stirred solution of **8** (2.2 g, 6.5 mmol) in tetrahydrofuran (50 mL) was added dropwise a 30% hydrogen peroxide solution (6.8 mL, 65 mmol) at room temperature. After stirring at 40 °C for 3.5 h, the mixture was extracted with ether (4×30 mL). The ethereal extracts were washed with 1 M (1 M=1 mol dm^{-3}) $Na_2S_2O_3$ (5×15 mL) and a saturated NaCl solution, dried (Na_2SO_4), and evaporated. The residue was purified by column chromatography on silica gel (40 g) with ether–hexane (1:3) to give a crude oil (863 mg) of **5**. By the same procedure described above 937 mg of oily **5** was obtained from 2.20 g of the selenide **8**. The combined crude oil (1800 mg) was distilled to afford pure **5** (1.40 g, 80%) as a colorless liquid, bp 100.5—101.5 °C/7.5 mmHg (1 mmHg≈ 133.322 Pa) (lit,[13] bp 105—110 °C/11 mmHg); ^1H NMR ($CDCl_3$) δ=3.31 (2H, br d, *J*=6.8 Hz, H-7), 4.84 (1H, br s, OH), 5.02 (2H, m, H-9), 5.95 (1H, ddt, *J*=17.3, 9.4, and 6.8 Hz, H-8), 6.75 and 7.05 (2H each, AA′BB′ system, aromatic protons).

p-*Allylphenyl 2,3,4,6-Tetra-O-acetyl-β-D-glucopyranoside (9).* A mixture of penta-*O*-acetyl-β-D-glucopyranose (512 mg, 1.31 mmol), *p*-allylphenol (**5**) (370 mg, 2.76 mmol), acetic anhydride (0.12 mL, 1.3 mmol), and anhydrous *p*-toluenesulfonic acid (12 mg, 0.07 mmol) was stirred at 100—110 °C for 50 min under reduced pressure (20 mmHg). After cooling, the mixture was diluted with benzene (20 mL) and washed successively with water (3 mL), 0.25 M NaOH (15 mL), and water (10 mL). The benzene layer was dried (Na_2SO_4) and evaporated under reduced pressure to give a residue, which was chromatographed on silica gel (20 g) with benzene–ether (5:1), affording crude crystals of **9**. Recrystallization from methanol afforded **9** (337 mg, 56%) as colorless needles, mp 141—142 °C (lit,[7] mp 136—138 °C); $[\alpha]_D^{16}$ −21.1° (*c* 0.78, $CHCl_3$); IR (Nujol) 1756, 1640, 1610, 1590, 1514, 1230, 1043, 990, and 910 cm^{-1}; ^1H NMR (C_6D_6) δ=1.68, 1.69, 1.72, and 1.73 (3H each, s, 4×$COCH_3$), 3.15 (2H, d, *J*=6.5 Hz, H-7), 3.20 (1H, m, H-5′), 3.94 (1H, dd, *J*=12.3 and 2.6 Hz, H-6′), 4.18 (1H, dd, *J*=12.3 and 4.8 Hz, H-6′), 4.82 (1H, d, *J*=7.7 Hz, H-1′), 4.97 (2H, m, H-9), 5.00—5.60 (3H, complex pattern), 5.82 (1H, ddt, *J*=17.6, 9.0, and 6.5 Hz, H-8), and 6.95 (4H, s, aromatic protons).

p-*Allylphenyl β-D-Glucopyranoside (10).* To a stirred solution of **9** (100 mg, 0.22 mmol) in anhydrous methanol (2 mL) was added a solution of 1 M sodium methoxide in methanol (0.04 mL) at room temperature under nitrogen. After stirring for 2 h, the mixture was neutralized by adding ion-exchange resin, Amberlite IRC-50 (260 mg). The resin was removed by filtration and washed with methanol. The filtrate and washings were combined and concentrated to afford an amorphous powder. Purification by column chromatography on silica gel (20 g) with chloroform–methanol (6:1) gave **10** (54 mg, 84%) as a colorless solid, which was recrystallized from water to give crystalline **10**, mp 149—150 °C (lit,[12] mp 148—149 °C); $[\alpha]_D^{15}$ −56.3° (*c* 0.39, MeOH)

[lit,[12] $[\alpha]_D^{20}$ −61.8° (*c* 0.275, MeOH)]; UV (MeOH) 222 (ε 6800), 273 (900), and 279 nm (700); IR (KBr) 3350, 1633, 1610, 1590, 1507, 1230, and 910 cm^{-1}; ^1H NMR (CD_3COCD_3) δ=3.32 (2H, d, *J*=6.6 Hz, H-7), 4.91 (1H, d, *J*=7.0 Hz, H-1′), 5.00 (2H, m, H-9), 5.96 (1H, ddt, *J*=16.9, 10.1, and 6.6 Hz, H-8), 6.97 and 7.12 (2H each, AA′BB′ system, aromatic protons).

p-Allylphenyl 2,3,4-Tri-O-acetyl-β-D-glucopyranoside (11). A solution of **10** (51 mg, 0.17 mmol) and trityl chloride (147 mg, 0.527 mmol) in anhydrous pyridine (1 mL) was stirred at 100°C for 7 h. After cooling, acetic anhydride (0.5 mL) was added to the mixture. The mixture was stirred for additional 4.5 h at room temperature and concentrated under reduced pressure. The residue was diluted with 80% acetic acid (3 mL) and the mixture was stirred at 100°C for 30 min and then at room temperature for several hours. The crystalline precipitates in the mixture were removed by filtration and washed with 75% methanol (20 mL). The combined filtrate and washings were concentrated under reduced pressure to leave a solid, which was purified by column chromatography on silica gel (20 g) with benzene–ether (2:1) to give crude **11**. Recrystallization from ether–hexane afforded **11** (29 mg, 40% overall yield) as colorless needles, mp 79—80°C; $[\alpha]_D^{12}$ −9.40° (*c* 0.24, $CHCl_3$); UV (MeOH) 221 (ε 10400), 272 (1300), and 278 nm (1000); IR ($CHCl_3$) 3400, 3040, 1760, 1638, 1607, 1510, 1220, 993, and 910 cm^{-1}; ^1H NMR (C_6D_6) δ=1.57, 1.61, and 1.73 (3H each, s, 3×$COCH_3$), 3.15 (2H, br d, *J*=6.4 Hz, H-7), 3.15 (1H, m, H-5′), 3.40 (2H, m, H-6′), 4.80—5.60 (6H, complex pattern), 5.86 (1H, ddt, *J*=17.8, 9.2, and 6.4 Hz, H-8), 6.94 (4H, s, aromatic protons); ^{13}C NMR ($CDCl_3$) δ=20.5 (q, 3×$CO\underline{C}H_3$), 39.3 (t, C-7), 61.3 (t, C-6′), 68.7 (d), 71.4 (d), 72.8 (d), 74.4 (d), 99.2 (d, $^1J_{CH}$=162 Hz, C-1′), 115.7 (t, C-9), 116.8 (d, C-2 and 6), 129.7 (d, C-3 and 5), 135.0 (s, C-4), 137.3 (d, C-8), 155.2 (s, C-1), 169.2, 169.8, and 170.2 (s each, 3×$\underline{C}OCH_3$); MS (70 eV) *m/z* (rel intensity) 422 (M^+, 1), 331 (14), 289 (91), 229 (100), 187 (35), 169 (72), 134 (84), 127 (98), and 109 (71). Found: C, 59.12; H, 6.29%. Calcd for $C_{21}H_{26}O_9$: C, 59.71; H, 6.20%.

Miyaginin Hexaacetate (3). A solution of **11** (43 mg, 0.10 mmol), 2,3,4-tri-*O*-acetyl-α-D-xylopyranosyl bromide (100 mg, 0.29 mmol), mercury(II) bromide (91 mg, 0.25 mmol), and mercury(II) cyanide (64 mg, 0.25 mmol) in dry acetonitrile (3 mL) was stirred at room temperature under nitrogen in the dark. After stirring for 5 h, the mixture was concentrated under reduced pressure. The residue was dissolved in chloroform (20 mL) and the insoluble materials were removed by filtration and washed with chloroform. The filtrate and washings were combined and washed with a saturated KBr solution, until washings showed no coloration with an aqueous ammonium sulfide solution. The chloroform layer was dried (Na_2SO_4) and concentrated under reduced pressure to leave a syrup. Purification by column chromatography on silica gel (25 g) with benzene–ether (3:1) gave **3** (60 mg, 88%) as a colorless solid. Recrystallization from methanol gave **3** as colorless needles, mp 163—164°C; $[\alpha]_D^{21}$ −44.9° (*c* 0.55, $CHCl_3$). The physical (mp and $[\alpha]_D$) and spectral (IR, UV, ^1H NMR, and ^{13}C NMR) properties of synthetic **3** were identical with those of **3** derived from natural miyaginin (**2**).

Miyaginin (2). Methanolysis of **3** (23 mg, 0.034 mmol) was performed by essentially the same procedure as described in the preparation of **10**. The crude product was purified by column chromatography on silica gel (20 g) with chloroform–methanol (4:1) to give **2** (13 mg, 89%) as an amorphous solid. Recrystallization from aqueous acetone afforded crystalline **1** as colorless needles, mp 211.5—213°C; $[\alpha]_D^{14}$ −81.6° (*c* 0.36, H_2O). The physical (mp and $[\alpha]_D$) and spectral (UV, IR, ^1H NMR, and ^{13}C NMR) properties and chromatographic mobilities of synthetic **2** were completely identical with those of natural **2** in all respects.

We are grateful to Dr. Hiroaki Matsuda, the University of Tokyo for providing us with authentic samples of miyaginin and the hexaacetate, and to Emeritus Prof. Arika Kimura, Tohoku University and Prof. Hiroyoshi Ohashi, Tohoku University for their kind assistance in the collection and the identification of the plant materials.

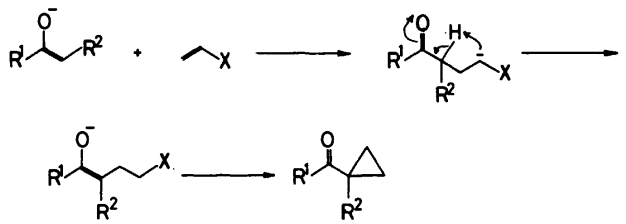
Reactions of Enolates with Vinyl Selenoxides and Vinyl Selenones. One-step Synthesis of Cyclopropylcarbonyl Compounds

Ryoichi ANDO, Tomoo SUGAWARA, Makoto SHIMIZU,† and Isao KUWAJIMA*
Department of Chemistry, Tokyo Institute of Technology, Meguro, Tokyo 152
(Received May 22, 1984)

In the reactions with enolate anions, organoselenium moieties of aryl vinyl selenoxides and selenones have exhibited two important roles, *e.g.*, activation of C=C bonds for conjugate addition reaction and behaviors as excellent leaving groups. Owing to such characteristic features, ketone enolates react with *p*-chlorophenyl vinyl selenoxide to afford the corresponding cyclopropyl ketones through an initial conjugate addition followed by substitution processes. On the other hand, use of vinyl selenones usually gives much better results with anionic species of active methylene compounds. Vinyl selenones bearing hydroxyl, ketone, and ester groups can also be employed equally well for this type of transformation.

Cyclopropylcarbonyl compounds have recently received much attention because of their versatility in synthetic organic reactions.[1,2] Reactive conjugate receptors in which electron-withdrawing activator **X** also acts as a good leaving group may be used as versatile ethylene transfer reagents for enolates (dibasic nucleophiles) to yield the corresponding cyclopropyl ketones as shown in Scheme 1. Relatively few examples of reactions of this type are known. Gosselck and his collaborators reported the formation of cyclopropanes in the reaction of active methylene compounds with substituted dimethylvinylsulfonium salts.[3] Johnson and Lockard observed the cyclopropane ring formation in the reaction between [(dimethylamino)phenyl](2-phenylvinyl)oxosulfonium tetrafluoroborate and active methylene compounds.[4] More recently it was reported that the reaction of lithium enolate of acetophenone with dimethylvinylsulfonium perchlorate gave the corresponding cyclopropyl ketones.[5]



Scheme 1.

However, these procedures have only limited applicability due to the difficulty encountered for the preparation of vinylsulfonium salts and to the fact that only active methylene compounds are employable for the former two examples. In the latter case only acetophenone meets with success. It is, therefore, desirable to develop an easy and reliable ethylene transfer methodology to a variety of carbonyl compounds.

A few years ago, we began to study on use of vinyl selenoxide or vinyl selenones for such kind of organic transformations. In contrast to studies on the reactivities of vinyl sulfoxides,[6] those on vinyl selenoxides have limited numbers of investigation,[7] because alkyl aryl selenoxides are in usual quite unstable if they bear β-hydrogens. A well-documented *syn*-elimination of selenoxides always takes place at low temperature in such case, leading to the formation of olefins.[8,9] Selenoxides become relatively stable when there is no β-hydrogen available or areneseleninyl groups are attached to sp^2 or sp hybridized carbons.[7a,10] Further it has been reported that selenoxides are more polar and more basic than sulfoxides are.[11] In this regard, vinyl selenoxides appear to be more reactive than vinyl sulfoxides toward nucleophiles.

In this paper, we describe our results for the preparation of cyclopropylcarbonyl compound in full details by using organoselenium compounds.[12,13]

Results and Discussion

Although to date no reports deal with S_N2 type substitution of areneseleninyl groups, the weak C–Se bonds appear to make this type transformation feasible, which will lead to an introduction of a new functional group to the carbon bearing areneseleninyl group. In light of polar character of selenoxides[11] coupled with weak C–Se bonds, it is then expected that when **X** in Scheme 1 is displaced with areneseleninyl group, a cyclopropane ring may be formed through conjugate addition followed by substitution in the reaction between ketone enolates and aryl vinyl selenoxides.

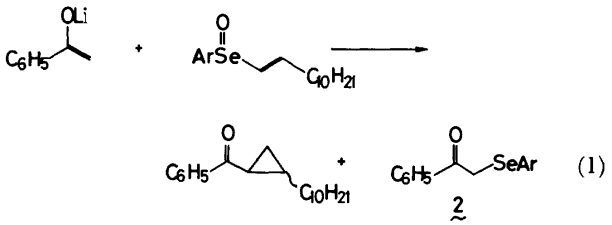
Aryl vinyl selenoxides are readily prepared by oxidation of the corresponding aryl vinyl selenides with either 1 equiv of *m*-CPBA or sodium periodate.[7a] For the preparation of the starting materials, aryl vinyl selenides, two methods are now available[7a,14,15]: One involves an addition of an areneselenenyl halide to olefins followed by elimination of hydrogen halide with an appropriate base, and the other is the transformation from selenoacetals obtained from aldehydes and areneselenol.

Treatment of 1-dodecenyl phenyl selenoxide thus obtained with sodium diethyl malonate indeed gave rise to the 1,1-cyclopropanedicarboxylic ester in 47% yield.

It has been reported that the reaction of sodium diethyl malonate to tolyl vinyl sulfoxide proceeds in refluxing tetrahydrofuran (THF) to afford the addition product (not the cyclopropane derivative).[6] In strong contrast to the sulfoxide, vinyl selenoxides seem to be much more reactive toward this nucleophile, and the reaction proceeds at as low as −20°C.

†Present address: The Institute of Physical and Chemical Research, Wako, Saitama 351-01.

The reaction of the selenoxide with lithium enolate of acetophenone gave the cyclopropyl ketone **1** in much higher yield than the case with diethyl malonate. This conversion, however, is not free from side-reactions: Major by-product formed during the reaction is α-

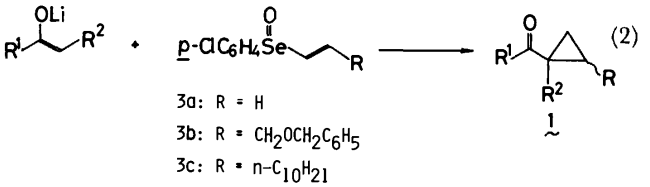


(1)

phenylselenoacetophenone **2** arising from selenenylation of the enolate. To improve the procedure more precisely, effects of substituents on the benzene ring of areneseleninyl group as well as the reaction solvent were examined on the reaction of aryl 1-dodecenyl selenoxide with lithium enolate of acetophenone. Results are shown in Table 1.

As shown in the Table 1, significant effects of substituents on aryl selenoxides together with those of solvents were observed. An electron-withdrawing substituent such as *m*-trifluoromethyl or *p*-chloro group facilitates the reaction remarkably (runs 6 and 9), whereas electron-donating *o*-methyl group decreased the product yield (run 5). In the *syn*-elimination reaction of selenoxides, *o*-nitro group has been known to facilitate the reaction.[16] In the present case, however, no detectable amount of the desired product was obtained (run 7). The use of ether as solvent proved to be most suitable because the undesired selenenylation of the enolate could be practically excluded. When THF is employed as the solvent, areneselenenylation of acetophenone usually accompanies up to 15% yield. It is likely that in ether the eliminated selenium species has poor solubility, which seems to make this species incapable of selenenylation.

A variety of lithium enolates were subjected to the reaction with three types of *p*-chlorophenyl vinyl selenoxides **3a**, **3b**, and **3c**. Table 2 lists the results.



(2)

Relatively hard nucleophiles such as ketone or α-phenylthio ester enolates gave better results, whereas the yields of cyclopropylcarbonyl compounds were decreased with soft nucleophiles such as α-phenylsulfinyl or α-phenylsulfonyl ester enolates and lithium diethyl malonate (runs 25, 26, 27, and 28).

The present reaction proceeds most probably *via* conjugate addition of enolates to vinyl selenoxides followed by proton transfer from **4** to **5** and displacement of areneseleninyl group as outlined in Scheme 2.

The first conjugate addition step appears to be favored with relatively hard nucleophiles. With soft

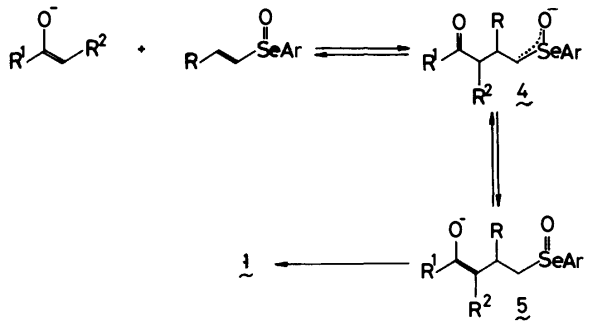


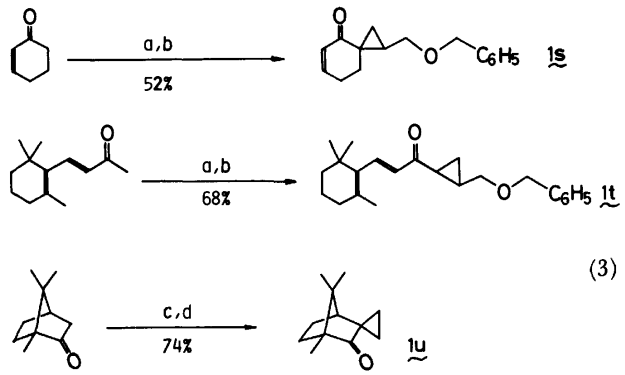
Scheme 2.

nucleophiles, the conjugate addition seems to proceed under equilibrium conditions. The equilibrium is usually favored on the left side (Scheme 2) and the other side reactions, *e.g.*, attack of enolates to areneseleninyl moiety or proton abstraction from vinyl selenoxide, may cause the low yield of the desired product.

As the third step, the displacement of areneseleninyl group, this type of intramolecular substitution has closely related precedents in sulfone chemistry, where an approach to chrysanthemic acid represents an outstanding example.[17]

Although the formation of a cyclopentanone derivative might also be conceivable when the parent ketone is enolizable on both sides, such products were not obtained in any cases.

Further application to cyclohexenone, β-ionone, and camphor shows the utility of the present method.



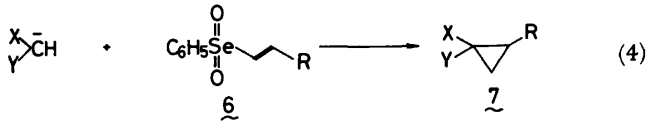
(3)

a) LDA (1.5 eq), ether. b) 3b (1.2 eq)
c) LDA (1.5 eq), DME. d) 3a (1.2 eq)

Cyclopropanation of camphor in THF gave rise to the desired ketone in only 38% yield along with concomitant formation of α-selenenylated ketone (18%). 1,2-Dimethoxyethane (DME) was proved to be a solvent of choice in that case.

Cory and his collaborators have reported the reaction of bicycloannulation of cyclohexenone derivatives with vinyltriphenylphosphonium salts[18] or vinyl sulfones.[19] In the present system, enolates of α,β-unsaturated ketones underwent cyclopropanation solely as indicated in the case with cyclohexenone. Relatively low efficacy of active methylene compounds as dibasic nucleophiles for this type of transformation may be attributable to insufficient activation of the neighboring C=C bonds with areneseleninyl group as well as its less efficient character as the leaving group.

Recently, we described preparation of vinyl selenones **6**: They can be easily prepared by oxidation of the corresponding vinyl selenides with 2—2.2 equiv of *m*-CPBA in an alcoholic media.[20] Further, in their reactions with alkoxides, *e.g.*, oxetane formation[20a] and fragmentation reactions,[20b] the selenonyl group has exhibited such similar characters as the seleninyl group described above, *e.g.*, activation of C=C bonds and as excellent leaving groups. By using such features of vinyl selenones, we have also examined the cyclopropanation reaction of enolate anions. Various examinations revealed that reactivity of a C=C bond to active methylene compounds has been greatly improved to form a cyclopropane ring on that linkage efficiently. For example, 1-hexenyl phenyl selenone was treated with an equimolar amount of sodium dimethyl malonate in THF at room temperature for 4 h, which gave the corresponding cyclopropanedicarboxylic ester in 92% yield. Various kinds of active methylene compounds can also be used equally well to give the corresponding cyclopropane **7** in good yields (see Table 3).



(4)

A transition metal-catalyzed reaction of olefins with diazo compounds has also been widely employed for

a) A reactant ratio, ketone:selenone=1.2:1.0. b) Lithium enolate was used.

this type of transformation,[20] but there exist serious drawbacks on the following two points; (i) use of an excess amount of olefin is usually required for moderate success, and (ii) a range of its application suffers from severe limitation because oxygen-containing functional groups prevent the cyclopropanation reaction.[21a]

Both of them have been overcome efficiently by the present method using vinyl selenones. First, olefins can be converted to the corresponding vinyl selenones effectively *via* vinyl selenides, and active methylene compounds undergo cyclopropanation with a stoichiometric amount of the vinyl selenones. In the second, various oxygen-containing functionalities do not disturb this olefin unit transfer to active methylene sites to give the corresponding cyclopropane in excellent yields as exemplified in formation of **7h—m**.

Further, the following example has demonstrated site-selective activation of terminal olefins. When started from a diene, selenenylation takes place selectively on the terminal C=C bond.[14,22] Although an internal one also undergoes oxidation to the oxirane during conversion of a selenide to the selenone, selective formation of cyclopropane ring has been executed on the parent terminal C=C bond under the reaction conditions where the oxirane survives as shown in Eq. 5.

Conclusion

As shown above, various kinds of enolate anions behave as dibasic nucleophiles toward vinyl selenoxides and vinyl selenones due to characteristic features of seleninyl and selenonyl groups. Difference between vinyl selenoxides and vinyl selenones should be noted here. As described earlier, the formers in general give much better results with usual enolates than with anionic species of active methylene compounds. On the contrary, vinyl selenones has exhibited slight different behavior toward enolate nucleophiles. Thus, in addition to activation of a neighboring C=C bond to nucleophiles, a selenonyl group appears to enhance the acidity of vinyl proton, which sometimes results in undesired side-reactions such as decomposition to the corresponding acetylene[23] when anionic species of less acidic substrates are used as nucleophiles. For example, treatment of 1-dodecenyl phenyl selenone with lithium enolate of acetophenone led to the formation of the cyclopropane in 41% yield together with 1-dodecyne (19%). Such a feature clearly disfavors use of vinyl selenones for the preparation of cyclopropyl ketones, and use of vinyl selenoxides should be recommended.

There have been developed several types of procedures for cyclopropanation of olefins, *e.g.*, use of oxosulfonium,[24] phosphonium[25] selenium ylides,[26] or Simmons-Smith reagent.[27] In regard to the accessibility of the starting material, the present procedure, complementary to these methods, offers a simple and useful approach to cyclopropylcarbonyl compounds.

Experimental

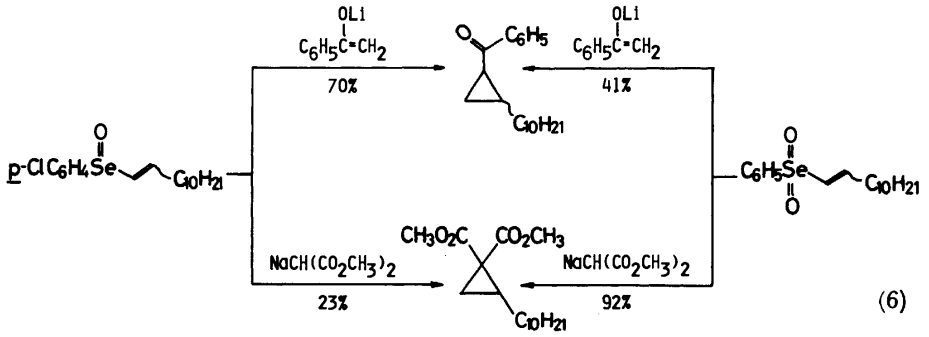
General Methods. Boiling points and melting points are uncorrected. Infrared (IR) spectra were recorded on a Hitachi EPI-G3 spectrometer; absorptions are given in reciprocal centimeters. Proton nuclear magnetic resonance spectra (^1H NMR) were obtained on a Hitachi R-24B spectrometer; chemical shifts (δ) are expressed in parts per million downfield from internal tetramethylsilane. Mass spectra (70 eV) were determined on a Hitachi RMU-6C or RMU-7M spectrometer. Microanalysis were performed with a Perkin Elmer 240 at the Microanalysis Laboratory, Tokyo Institute of Technology.

Reactions involving air- or moisture-sensitive compounds were carried out in appropriate round-bottomed flasks with magnetic stirring bars under nitrogen or argon. Bulb-to-bulb distillation was performed with a Büchi Kügelrohr apparatus.

Preparative thin-layer chromatography (TLC) was carried out on glass plates (20×20 cm) coated with Merck silica gel PF 254 (1 mm thick). Column chromatography was performed on Merck Kieselgel or Wakogel C-200.

Ether, tetrahydrofuran (THF), and 1,2-dimethoxyethane were distilled from sodium-benzophenone ketyl in a recycling still immediately before use. *m*-Chloroperbenzoic acid (*m*-CPBA, 85% pure), purchased from Aldrich Chemical Co., was used directly without purification.

Preparation of Aryl Vinyl Selenides. The preparation



(6)

of 1-dodecenyl *p*-chlorophenyl selenide, which was prepared by a similar method developed by Raucher *et al*,[14a] represents a typical procedure. To a solution of *p*-chlorobenzeneselenenyl bromide prepared from bis(*p*-chlorophenyl) diselenide (2.29 g, 6.0 mmol) and bromine (6 mL of 1 M (1 M=1 mol dm^{-3}) carbon tetrachloride solution, 6.0 mmol) in 5 mL of acetonitrile was added a solution of 1-dodecene (2.02 g, 12 mmol) in 35 mL of acetonitrile, and the reaction mixture was stirred for 2.5 h at room temperature. After all the solvent was removed, potassium *t*-butoxide (2.7 g, 24 mmol) and THF (50 mL) were added to the crude mixture, and the resulting brown-colored mixture was stirred for 1 h at room temperature. Then, it was washed with satd aq NaCl, and the aqueous layer was extracted with ethyl acetate. The combined extracts were dried and concentrated to give an oil, which was distilled to afford a mixture of (*E*)- and (*Z*)-1-dodecenyl *p*-chlorophenyl selenide (2.98 g, 69%); bp 105 °C/0.08 mmHg**; IR (neat) 2900, 1600, 1470, 1380, 1090, 1010, 950, 810, 725; NMR (CCl_4) 0.80—1.70 (m, 19H), 1.90—2.33 (m, 2H), 5.73—6.50 (m, 2H), 7.03—7.60 (m, 4H). Calcd for $C_{18}H_{27}SeCl$: C, 64.42; H, 7.61%. Found: C, 64.72; H, 7.79%.

1-Dodecenyl Phenyl Selenide. IR (neat) 2919, 1580, 1480, 1440, 1075, 1025, 1000, 955, 740, 690; NMR (CCl_4) 0.70—1.60 (m, 19H), 1.90—2.63 (m, 2H), 5.70—6.50 (m, 2H), 7.00—7.50 (m, 5H). Calcd for $C_{18}H_{28}Se$: C, 66.86; H, 8.73%. Found: C, 66.82; H, 8.67%.

1-Dodecenyl o-Tolyl Selenide. IR (neat) 2900, 1605, 1585, 1565, 1460, 1375, 1050, 1035, 950, 740; NMR (CCl_4) 0.70—1.70 (m, 19H), 1.57—2.50 (m, 2H), 2.37 (s, 3H), 5.73—6.50 (m, 2H), 6.83—7.50 (m, 4H). Calcd for $C_{19}H_{30}Se$: C, 67.63; H, 8.96%. Found: C, 67.72; H, 9.04%.

1-Dodecenyl o-Nitrophenyl Selenide. IR (neat) 2890, 1580, 1465, 1445, 1330, 1300, 1100, 1040, 970, 860, 790, 735; NMR (CCl_4) 0.70—1.70 (m, 19H), 2.00—2.50 (m, 2H), 6.20—6.50 (m, 2H), 7.00—7.57 (m, 3H), 8.03—8.90 (m, 1H). Calcd for $C_{18}H_{27}NO_2Se$: C, 58.69; H, 7.39; N, 3.80%. Found: C, 58.99; H, 7.55; N, 3.95%.

1-Decenyl m-Trifluoromethylphenyl Selenide. IR (neat) 2905, 1575, 1465, 1420, 1315, 1270, 1160, 1125, 1095, 1080, 1065, 995, 960, 890, 790, 690; NMR (CCl_4) 0.50—1.70 (19H), 2.00—2.67 (m, 2H), 6.13—6.23 (m, 1H), 6.50—6.70 (m, 1H), 7.50—8.10 (m, 4H). Calcd for $C_{19}H_{27}F_3Se$: C, 58.31; H, 6.95%. Found: C, 58.59; H, 7.29%.

3-Benzyloxy-1-propenyl p-Chlorophenyl Selenide. To a solution of sodium *p*-chlorobenzeneselenolate prepared by reduction of bis(*p*-chlorophenyl) diselenide (7.6 g, 20 mmol) with sodium borohydride (1.5 g, 40 mmol) in ethanol (100 mL) was added a solution of epichlorohydrin (11.1 g, 120 mmol) in ethanol (20 mL) at −78 °C and the reaction mixture was allowed to stand at room temperature for 20 h. Then all the solvent was removed *in vacuo*. The resulting residue was washed with satd aq NaCl, and the aqueous layer was extracted with ethyl acetate. The combined extracts were dried and concentrated to give an oil. To a suspension of sodium hydride (45 mmol) in THF (10 mL) was added a solution of the crude oil obtained above in 40 mL of THF, and the mixture was stirred under refluxing for 1.5 h. Then a solution of benzyl bromide (6.7 g, 39.2 mmol) in THF (20 mL) was added to the ice-cooled mixture. After allowed to stand for 16 h at room temperature, the reaction mixture was washed with satd aq NaCl and dried. Removal of the solvent gave an oil, which was distilled to yield the title compound (8.8 g, 67%) as a mixture of (*E*)- and (*Z*)-isomers: bp 122 °C (bath temp)/0.08 mmHg; IR (neat) 3000, 2900, 2830, 1605, 1475, 1450, 1390, 1360, 1305, 1210, 1095, 1015, 950, 820, 740, 700; NMR (CCl_4) 3.93, 3.96 (unresolved dd, *J*=5 and 6 Hz, 2H), 4.47 (unresolved, s, 2H), 5.70—6.80 (m, 2H), 7.00—7.60 (m, 4H). Calcd for $C_{16}H_{15}OSeCl$: C, 56.91; H, 4.48%. Found: C, 56.67; H, 4.32%.

p-Chlorophenyl Vinyl Selenide. To a solution of sodium *p*-chlorobenzeneselenolate prepared from bis(*p*-chlorophenyl) diselenide (3.81 g, 10 mmol) and sodium borohydride (758 mg, 20 mmol) in ethanol (29 mL) was added 1,2-dichloroethane (78 mL) at room temperature, and the mixture was allowed to stand for 24 h at that temperature. After usual work-up, potassium *t*-butoxide (3.36 g, 30 mmol) was added to a THF (50 mL) solution of the crude oil obtained above, and it was stirred for 1 h at room temperature. Usual work-up of the reaction mixture followed by distillation gave the title compound (2.6 g, 60%) as a colorless oil: bp 115 °C (bath temp)/0.2 mmHg; IR(neat) 2910, 1585, 1475, 1390, 1250, 1100, 1020, 965, 895, 870, 820, 795, 770; NMR (CCl_4) 5.12 (dd, *J*=16 and 2Hz, 1H), 5.40 (dd, *J*=10 and 2 Hz, 1H), 6.30 (dd, *J*=16 and 10 Hz, 1H), 6.87—7.10 (m, 4H). Calcd for C_8H_7SeCl; C, 44.17; H, 3.24%. Found: C, 43.95; H, 3.18%.

Preparation of 1-Dodecenyl p-Chlorophenyl Selenoxide 3c. General Procedure for the Preparation of Vinyl Selenoxide. A solution of 1-dodecenyl *p*-chlorophenyl selenide (179 mg, 0.5 mmol) in dichloromethane (4 mL) was added to a solution of *m*-CPBA (152 mg of 85% pure material, 0.75 mmol) in 1 mL of dichloromethane. After allowed to stand for 30 min at room temperature, the reaction mixture was washed with satd aq $NaHCO_3$ and dried. Removal of the solvent from organic layer gave the title compound as a colorless oil (176 mg, 94%) which was homogeneous in tlc; IR (neat) 2905, 1980, 1470, 1090, 1015, 820, 730; NMR (CCl_4) 0.70—1.70 (m, 19H), 2.23—2.56 (m, 2H), 6.17—6.30 (m, 1H), 6.33—6.80 (m, 1H), 7.10—7.70 (m, 4H).

p-Chlorophenyl Vinyl Selenoxide 3a. IR (neat) 2890, 2830, 1590, 1570, 1470, 1390, 1360, 1175, 1090, 1020, 970, 940, 890, 830, 735; NMR(CCl_4) 6.03 (dd, *J*=9 and 1 Hz, 1H), 6.27 (dd, *J*=17 and 1 Hz, 1H), 6.93 (dd, *J*=17 and 9 Hz, 1H), 7.30—7.67 (m, 4H).

3-Benzyloxy-1-propenyl p-Chlorophenyl Selenoxide 3b. IR (neat) 2880, 1465, 1380, 1085, 1010, 820, 730, 695; NMR (CCl_4) 4.00 (unresolved s, $CH_2C_6H_5$), 4.13 (unresolved s, $CH_2C_6H_5$), 4.36—4.57 (m, 2H), 6.20 (unresolved s, 1H), 6.70 (unresolved s, 1H), 6.80—7.70 (m, 4H).

2-Decylcyclopropyl Phenyl Ketone 1c. General Procedure for the Reactions in Tables 1 and 2. A solution of acetophenone (66 mg, 0.55 mmol) in ether (3 mL) was added to a solution of lithium diisopropylamide (LDA) (0.75 mmol) in ether (2 mL) at −30 °C, and the mixture was stirred for 30 min at that temperature. An ethereal solution (5 mL) of 1-dodecenyl *p*-chlorophenyl selenoxide (164 mg, 0.44 mmol) was added to the solution of enolate, and it was stirred for 1 h at the same temperature. Then, after allowed to stand at room temperature for 5 h, the reaction mixture was washed with satd aq NaCl and dried. Removal of the solvent from organic layer followed by purification by preparative tlc gave the title compound (102 mg, 81%) as a colorless oil; bp 114 °C (bath temp)/0.04 mmHg; IR (neat) 1655; NMR (CCl_4) 0.60—1.80 (m, 24H), 2.10—2.50 (m, 1H), 7.25—7.50 (m, 3H), 7.65—8.00 (m, 2H). Calcd for $C_{20}H_{30}O$: C, 83.86; H, 10.56%. Found: C, 83.57; H, 10.47%.

Cyclopropyl Phenyl Ketone 1a. IR (neat) 1660; NMR (CCl_4) 0.50—1.70 (m, 4H), 2.35—2.85 (m, 1H), 7.00—7.60 (m, 5H). These spectroscopic properties were identical with those of the commercially available sample from Aldrich Chemical Co.

2-Benzyloxymethylcyclopropyl Phenyl Ketone 1b. IR (neat) 1660; NMR (CCl_4) 0.70—2.00 (m, 3H), 2.35—2.70 (m, 1H), 3.20—3.50 (m, 2H), 4.43 (s, 2H), 6.90—7.60 (m, 8H), 7.60—8.10 (m, 2H); mass spectrum *m/z* (relative %) 266 (M^+, 1), 234 (1), 160 (10), 145 (9), 115 (5), 105 (100), 91 (93), 77 (64), 65 (29), 51 (36).

** 1 mmHg=133.322 Pa

1-Methylcyclopropyl Phenyl Ketone **1d.** Bp 55 °C (bath temp)/0.2 mmHg; IR (neat) 1670; NMR (CCl_4) 0.50—1.70 (m, 7H including a singlet (3H) at 1.40), 7.10—7.55 (m, 3H), 7.55—7.90 (m, 2H). Calcd for $C_{11}H_{12}O$: C, 82.46; H, 7.54%. Found: C, 82.84; H, 7.55%.

2-Benzyloxymethyl-1-methylcyclopropyl Phenyl Ketone **1e.** IR (neat) 1670; NMR (CCl_4) 0.70—2.00 (m, 6H including a singlet (3H) at 1.40), 3.10—3.55 (m, 1H), 3.70—4.00 (m, 1H), 4.50 (s, 2H), 7.00—7.50 (m, 8H), 7.70—8.50 (m, 2H).

2-Decyl-1-methylcyclopropyl Phenyl Ketone **1f.** IR (neat) 1670; NMR (CCl_4) 0.70—1.80 (m, 27H), 7.20—7.50 (m, 3H), 7.50—7.80 (m, 2H); mass spectrum *m/z* (relative %) 300 (M^+, 12), 285 (2), 215 (2), 201 (9), 173 (14), 145 (4), 134 (12), 105 (100), 91 (9), 77 (27).

Ethyl 1-(Phenylthio)cyclopropanecarboxylate **1g.** Bp 85 °C (bath temp)/0.1 mmHg; IR (neat) 1705; NMR (CCl_4) 0.70—2.00 (m, 7H), 4.03 (q, J=9 Hz, 2H), 6.85—7.50 (m, 5H); Anal. Calcd for $C_{12}H_{14}O_2S$: C, 64.85; H, 6.35; S, 14.43%. Found: C, 65.18; H, 6.21; S, 14.43%.

Ethyl 2-Benzyloxymethyl-1-(phenylthio)cyclopropanecarboxylate. **1h.** Bp 135 °C (bath temp)/0.04 mmHg; IR (neat) 1705; NMR (CCl_4) 0.75—1.30 (m, 4H including a triplet (J=7 Hz, 3H) at 1.33), 1.55—2.50 (m, 2H), 3.40—3.80 (m, 2H), 4.00 (q, J=7 Hz, 2H), 4.30 (s, 2H), 6.70—7.40 (m, 10H). Calcd for $C_{20}H_{22}O_3S$: C, 70.16; H, 6.48; S, 9.37%. Found: C, 70.20; H, 6.43; S, 9.39%.

Ethyl 2-Decyl-1-(phenylthio)cyclopropanecarboxylate **1i.** IR (neat) 1705; NMR (CCl_4) 0.70—2.00 (m, 27H), 4.05 (q, J= 7 Hz, 2H), 7.13 (s, 5H).

1-(Benzyloxymethyl)spiro[2.11]pentadecan-4-one **1j.** IR (neat) 1670; NMR (CCl_4) 0.70—2.70 (m, 13H), 3.15—3.75 (m, 2H), 4.43 (unresolved s, 2H), 7.23 (unresolved s, 5H).

1-Decylspiro[2.4]octan-4-one **1k.** IR (neat) 1675; NMR (CCl_4) 0.70—2.10 (m, 32H).

t-*Butyl 2-Decylcyclopropyl Ketone* **1l.** Bp 87 °C (bath temp)/0.08 mmHg; IR (neat) 1680; NMR (CCl_4) 0.70—2.00 (m, 34H including a singlet (9H) at 1.10). Calcd for $C_{18}H_{34}O$: C, 81.13; H, 12.86%. Found: C, 81.10; H, 12.72%.

t-*Butyl 2-Decylcyclopropanecarboxylate* **1m.** Bp 86 °C (bath temp)/0.01 mmHg; IR (neat) 1715; NMR (CCl_4) 0.50—1.90 (m, 34H including a singlet (9H) at 1.30). Calcd for $C_{18}H_{34}O_2$: C, 76.54; H, 12.13%. Found: C, 76.29; H, 12.09%.

2-Decylcyclopropyl Isopropyl Ketone **1n.** IR (neat) 1680; NMR (CCl_4) 0.50—1.85 (m, 30H), 1.85—2.30 (m, 1H), 2.30—3.00 (m, 1H).

2-Decyl-1-(phenylthio)cyclopropyl Hexyl Ketone **1o.** IR (neat) 1680; NMR (CCl_4) 0.50—2.10 (m, 33H), 2.80 (t, J= 6 Hz, 2H), 7.10 (s, 5H); mass spectrum *m/z* (relative %) 388 (M^+, 15), 217 (12), 208 (6), 154 (18), 148 (12), 110 (65), 109 (41), 105 (29), 91 (59), 85 (32), 77 (35), 71 (53), 69 (53), 57 (100), 55 (82).

Ethyl 2-Decyl-1-(phenylsulfinyl)cyclopropanecarboxylate **1p.** IR (neat) 1725, 1710; NMR (CCl_4) 0.50—2.00 (m, 27H), 4.03 (q, J=6 Hz, 2H), 7.00—7.83 (m, 5H).

Ethyl 2-Decyl-1-(phenylsulfonyl)cyclopropanecarboxylate **1q.** IR (neat) 1720; NMR (CCl_4) 0.50—2.20 (m, 27H), 4.07 (q, J= 6 Hz, 2H), 7.17—8.00 (m, 5H).

Diethyl 2-Decyl-1,1-cyclopropanedicarboxylate **1r.** Bp 110 ° C (bath temp)/0.03 mmHg; IR (neat) 1720; NMR (CCl_4) 0.67—1.83 (m, 30H), 4.13 (q, J=6 Hz, 4H); mass spectrum *m/z* (relative %) 281 (M^+−45, 13), 253 (17), 235 (7), 173 (73), 160 (100), 127 (93), 108 (27), 99 (33), 95 (27), 81 (23), 74 (40), 59 (73), 55 (53). Calcd for $C_{19}H_{34}O_4$: C, 69.90; H, 10.50%. Found: C, 69.67; H, 10.41%.

1-(Benzyloxymethyl)spiro[2.5]oct-5-en-4-one **1s.** IR (neat) 1665; NMR (CCl_4) 0.70—2.70 (m, 7H), 3.15—3.80 (m, 2H), 4.35—4.70 (m, 2H), 5.80—6.25 (m, 1H), 6.70—7.60 (m, 6H).

1-(2-Benzyloxymethylcyclopropyl)-3-(2,6,6-trimethyl-1-cyclohexenyl)-2-propen-1-one **1t.** IR (neat) 1670; NMR (CCl_4) 0.70—2.25 (m, 19H including singlets at 1.03 and 1.76), 3.35 (m, 2H), 4.17 (s, 2H), 4.13 (d, J=16 Hz, 1H), 7.17 (s, 5H), 7.23 (d, J=16 Hz, 1H).

4,7,7-Trimethylspiro[bicyclo[2.2.1]heptan-2,1'-cyclopropan]-3-one **1u.** IR (neat) 1720; NMR (CCl_4) 0.50—2.33 (m, 18H including three methyl singlets at 0.83, 0.87, and 0.97); mass spectrum *m/z* (relative %) 178 (M^+, 13), 162 (17), 135 (25), 109 (29), 95 (100), 83 (33), 74 (33), 69 (42), 59 (54), 55 (42).

1-Hexenyl Phenyl Selenone. General Procedure for the Preparation of Vinyl Selenones **6.** To a solution of 1-phenylseleno-1-hexene (1.50 g, 6.3 mmol) in methanol (20 mL) was added *m*-CPBA (2.8 g, 14 mmol) at 0 °C, and it was stirred overnight at room temperature. After the solvent was removed *in vacuo*, satd aq $NaHCO_3$ was added and it was extracted with chloroform. The combined extracts were dried and concentrated to give an oil, which was purified by column chromatography (hexane:ethyl acetate=1:1) to afford the title compound (1.30 g, 76%); IR (neat) 935, 885; NMR (CCl_4) 0.60—1.85 (m, 7H), 2.05—3.00 (m, 2H), 6.30—7.30 (m, 2H), 7.35—8.15 (m, 5H).

Dimethyl 2-Butyl-1,1-cyclopropanedicarboxylate **7a.** *General Procedure for an Olefin Unit Transfer to Active Methylene Compounds in Table 3.* To a suspension of NaH (0.33 mmol) in THF (0.5 mL) was added dimethyl malonate (48 mg, 0.37 mmol) at 0 °C and it was stirred for 10 min at that temperature. Then, a THF (1.0 mL) solution of 1-hexenyl phenyl selenone (83 mg, 0.30 mmol) was added to the resulting mixture, and it kept stirring 4 h at room temperature. The reaction mixture was quenched with water and the aqueous layer was extracted with ether. The combined extracts were washed with satd aq NaCl, dried over anhyd $MgSO_4$, and then concentrated to give an oil, which was purified by column chromatography to afford the title compound (60.0 mg, 92%); bp 62—64 °C (bath temp)/0.012 mmHg; IR (neat) 1710; NMR (CCl_4) 0.65—2.10 (m, 12H), 3.62 (s, 6H). Calcd for $C_{11}H_{18}O_4$: C, 61.66; H, 8.47%. Found: C, 61.40; H, 8.54%.

Methyl 1-Acetyl-2-butylcyclopropanecarboxylate **7b.** Bp 85 °C (bath temp)/9 mmHg; IR (neat) 1710; NMR (CCl_4) 0.60—2.15 (m, 12H), 2.26 (s, 3H), 3.69 (s, 3H). Calcd for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15%. Found: C, 66.57; H, 9.11%.

N-t-*Butyl-1-acetyl-2-butyl-1-cyclopropanecarboxamide* **7c.** Two stereoisomers (**A** and **B**) were isolated. **A**; IR (neat) 3280, 1650; NMR (CCl_4) 0.65—1.65 (m, 12H), 1.30 (s, 9H), 2.14 (s, 3H), 6.70 (br s, 1H); Anal. Calcd for $C_{14}H_{25}NO_2$: C, 70.25; H, 10.53; N, 5.85. Found: C, 70.17; H, 10.43; N, 6.03. **B**; IR (neat) 3280, 1650; NMR (CCl_4) 0.60—1.70 (m, 12H), 1.33 (s, 9H), 2.01 (s, 3H), 7.38 (br s, 1H).

Methyl 2-Butyl-1-cyanocyclopropanecarboxylate **7d.** Bp 53—57 °C (bath temp)/0.012 mmHg; IR (neat) 2230, 1730; NMR (CCl_4) 0.70—2.10 (m, 12H), 3.74 (s, 3H). Calcd for $C_{10}H_{15}NO_2$: C, 66.27; H, 8.34; N, 7.73%. Found: C, 65.94; H, 8.31; N, 7.52%.

1-Butyl-2-nitrocyclopropane **7e.** Bp 80 °C (bath temp)/9 mmHg; IR (neat) 1530; NMR (CCl_4) 0.60—2.05 (m, 12H), 3.87 (m, 1H). Calcd for $C_7H_{13}O_2N$: C, 58.72; H, 9.15; N, 9.78%. Found: C, 58.94; H, 9.34; N, 9.72%.

2-Butyl-1-(phenylthio)cyclopropyl Methyl Ketone **7f.** Bp 110 °C (bath temp)/3 mmHg; IR (neat) 1685; NMR (CCl_4) 0.65—2.15 (m, 12H), 2.31 (s, 3H), 6.85—7.20 (m, 5H). Calcd for $C_{15}H_{20}OS$: C, 72.54; H, 8.12; S, 12.91%. Found: C, 72.45; H, 7.88; S, 12.96%.

Ethyl 2-Butyl-1-(phenylthio)cyclopropanecarboxylate **7g.** Bp 140 °C (bath temp)/3 mmHg; IR (neat) 1708; NMR (CCl_4) 0.68—2.10 (m, 15H), 4.06 (q, J=7 Hz, 2H), 6.87—7.50 (m, 5H). Calcd for $C_{16}H_{22}O_2S$: C, 69.03; H, 7.96; S, 11.52%. Found: C, 68.80; H, 7.92; S, 11.07%.

Diethyl 2-[(1-Hydroxycyclohexyl)methyl]-1,1-cyclopropanedicarboxylate **7h.** To a THF (0.3 mL) solution of lithio

diethyl malonate prepared from diethyl malonate (26.4 mg, 0.17 mmol) and butyllithium (0.11 mL of 1.57 M hexane solution, 0.17 mmol) was added a THF (0.3 mL) solution of 1-(3-phenylselenonyl-1-propenyl)-1-cyclohexanol (45.1 mg, 0.14 mmol), and it was stirred for 4 h at room temperature. Then, the reaction mixture was quenched with water, and the aqueous layer was extracted with ethyl acetate. The combined extracts were washed with satd aq NaCl and were dried over anhyd $MgSO_4$. Removal of the solvent followed by purification with column chromatography afforded the title compound (29.6 mg, 72%); bp 114 °C (bath temp)/0.08 mmHg; IR (neat) 3475, 1724; NMR (CCl_4) 1.0—2.2 (m, 22H), 4.07 (q, J=7.0 Hz, 4H). Calcd for $C_{16}H_{26}O_5$: C, 64.40; H, 8.76%. Found: C, 64.23; H, 8.81%.

Dimethyl 2-(4-Hydroxynonyl)-1,1-cyclopropanedicarboxylate **7i**. Bp 120 °C (bath temp)/0.019 mmHg; IR (neat) 3350, 1710; NMR (CCl_4) 0.65—1.95 (m, 21H), 3.20—3.55 (br s, 1H), 3.59 (s, 6H). Calcd for $C_{16}H_{28}O_5$: C, 63.97; H, 9.39%. Found: C, 63.90; H, 9.47%.

Dimethyl 2-(4-Oxononyl)-1,1-cyclopropanedicarboxylate **7j**. Bp 114 °C (bath temp)/0.013 mmHg; IR (neat) 1705; NMR (CCl_4) 0.65—1.90 (m, 16H), 2.10—2.50 (m, 4H), 3.58 (s, 3H), 3.61 (s, 3H). Calcd for $C_{16}H_{26}O_5$: C, 64.41; H, 8.78%. Found: C, 64.28; H, 8.75%.

Dimethyl 2-(9-Oxotridecyl)-1,1-cyclopropanedicarboxylate **7k**. Bp 134 °C (bath temp)/0.024 mmHg; IR (neat) 1720, 1705; NMR (CCl_4) 0.70—1.85 (m, 24H), 2.10—2.45 (m, 4H), 3.60 (s, 6H). Calcd for $C_{20}H_{34}O_5$: C, 67.77; H, 9.67%. Found: C, 67.83; H, 9.96%.

Dimethyl 2-(8-Methoxycarbonyloctyl)-1,1-cyclopropanedicarboxylate **7l**. Bp 116 °C/0.015 mmHg; IR (neat) 1725; NMR (CCl_4) 1.05—2.35 (18H), 2.83 (s, 3H), 2.93 (s, 6H). Calcd for $C_{17}H_{28}O_6$: C, 62.18; H, 8.59%. Found: C, 62.36; H, 8.45%.

Dimethyl 2-(4-Methoxycarbonyloctyl)-1,1-cyclopropanedicarboxylate **7m**. Bp 138 °C/0.14 mmHg; IR (neat) 1725; NMR (CCl_4) 0.70—2.30 (m, 22H), 3.62 (s, 6H), 3.98 (q, J=7.0 Hz, 2H). Calcd for $C_{18}H_{30}O_6$: C, 63.14; H, 8.83%. Found: C, 63.00; H, 8.75%.

Dimethyl 2-(5,6-Epoxy-2,6-dimethylheptyl)-1,1-cyclopropanedicarboxylate **7n**. Bp 96 °C (bath temp)/0.02 mmHg; IR (neat) 1735; NMR (CCl_4) 0.75—1.95 (m, 18H), 2.30—2.50 (m, 1H), 3.58 (s, 6H). Calcd for $C_{16}H_{26}O_5$: C, 64.41; H, 8.78%. Found: C, 64.63; H, 8.84%.

(Received January 30, 1984)

The electronic absorption spectrum of diphenylhexatriyne has been divided into two components polarized along the long and the short molecular axes by means of dichroism analysis using the stretched-polymer-film technique; *i.e.*, a reduced polarization spectrum has been obtained. This reduced polarization spectrum can be explained by a modified PPP calculation including the interaction between mutually perpendicular π and π′ systems in the conjugated system. It has been clarified that the relative intensities of the first and second bands of diphenylhexatriyne reflect the magnitude of interaction between mutually perpendicular π and π′ systems, which is quite great. The magnitude of the electron-repulsion integral between π and π′ electrons is estimated to be about 20—30 per cent of that between ordinary π (or π′) electrons.

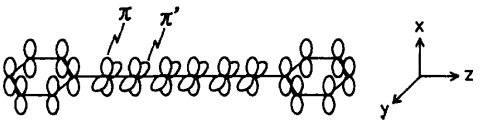
Armitage *et al.* synthesized a series of diphenylpolyynes (Ph-(C≡C)$_n$-Ph) and determined the electronic and vibrational absorption spectra.[1] They have shown that the Lewis-Calvin equation,[2] $\lambda^2=kn$, should be kept for the wavelength (λ) of the first band and the number (n) of polyynes, as in the case of polyenes, and, moreover, that the second bands increase in intensity as n increases, while the first bands become less intense. On the other hand, for the case of polyynes with terminal groups other than phenyl, Akiyama *et al.* found relationships different from the above equation between λ and n, depending on the kinds of terminal groups.[3] As has been mentioned above, studies of the electronic spectra of the polyynes have been concerned merely with phenomenological interpretations. In order to obtain more detailed information on the electronic structures and spectra of the conjugated polyynes, we measured a polarized absorption spectrum of diphenylhexatriyne using the stretched-polymer-film technique[4,5] and performed a modified PPP calculation which includes the interaction between mutually perpendicular π and π′ systems in the conjugated system including conjugated triple bonds.

Experimental

Diphenylhexatriyne was synthesized by the method described previously.[3] The polarized absorption spectrum in a stretched poly(vinyl alcohol)(PVA) film was measured in a way described elsewhere.[6] In the figure of the polarized absorption spectrum, $D_{\parallel}$ and $D_{\perp}$ denote the optical densities for the polarized-light beams, whose electric vectors are parallel to and perpendicular to the stretched direction of the PVA film respectively. The dichroic ratio (R_d) is defined as $R_d=D_{\parallel}/D_{\perp}$. R_s is the stretching ratio of the film.

Theoretical

In a PPP approximation,[7,8] each atom is considered to offer only one atomic p orbital for conjugation. It is, therefore, impossible to treat simultaneously the $\pi(2p_x)$ and $\pi'(2p_y)$ conjugated systems, which are contained, for example, in diphenylhexatriyne, by the conventional PPP method. This is because the π and π′ systems are mutually perpendicular, as is shown below, where both terminal phenyl rings are on the same plane. π means an ordinary conjugated system delocalized over the whole molecule, and π′, another conjugated system localized on the conjugated triple bonds of the hexatriyne moiety.



Thus, a modified PPP calculation which includes both π and π′ systems should be performed.[9] In this calculation, the interaction of π and π′ systems is taken into account in terms of the electron-repulsion integrals $(\pi_{2p}(r)\pi_{2p}(r)|\pi'_{2p}(s)\pi'_{2p}(s))$ between π and π′ electrons, the magnitudes of which are estimated by means of this equation;

$$(\pi_{2p}(r)\pi_{2p}(r)\,|\,\pi'_{2p}(s)\pi'_{2p}(s))=(\pi_{2p}(r)\pi_{2p}(r)\,|\,\pi'_{2p}(s)\pi'_{2p}(s))_0\times F.$$

Here, F is a parameter to be evaluated semiempirically, and $\pi_{2p}(r)$ and $\pi'_{2p}(s)$ stand for 2p atomic orbitals on the r and s atoms respectively. The values of the atomic integrals $(\pi_{2p}(r)\pi_{2p}(r)\,|\,\pi'_{2p}(s)\pi'_{2p}(s))_0$ are evaluated by assuming, after the manner of the CNDO/2 method,[15] that $(\pi_{2p}(r)\pi_{2p}(r)\,|\,\pi'_{2p}(s)\pi'_{2p}(s))_0=(\pi_{2p}(r)\pi_{2p}(r)\,|\,\pi_{2p}(s)\pi_{2p}(s))_0$. Here, the values of the atomic integrals $(\pi_{2p}(r)\pi_{2p}(r)\,|\,\pi_{2p}(s)\pi_{2p}(s))_0$ are obtained by the semiempirical method ordinarily used.[8,10] The resonance integrals between π_{2p} and π'_{2p} are all neglected, while those between 2p atomic orbitals within the π or π′ system are estimated using the variable β method.[11]

Results and Discussion

Figures 1 and 2 show the absorption spectra of diphe-

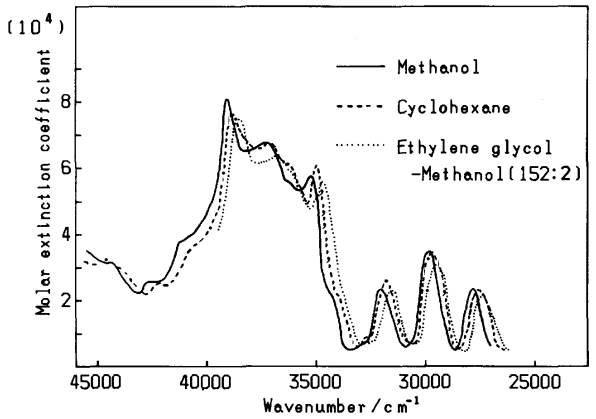


Fig. 1. Absorption spectra of diphenylhexatriyne in various solvents.

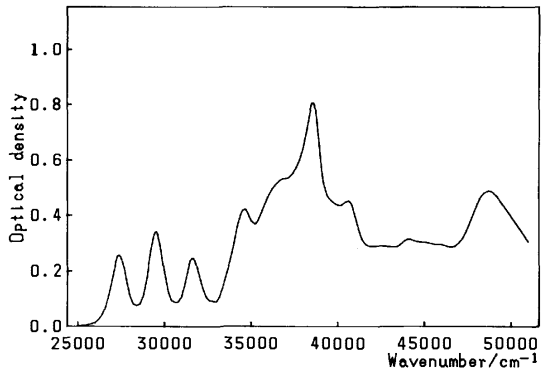

Fig. 2. Absorption spectrum of diphenylhexatriyne in the unstretched PVA film.

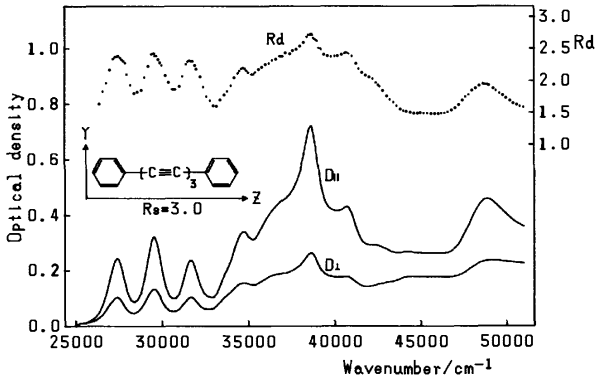

Fig. 3. The polarized absorption spectrum of diphenylhexatriyne in the stretched PVA film at room temperature.

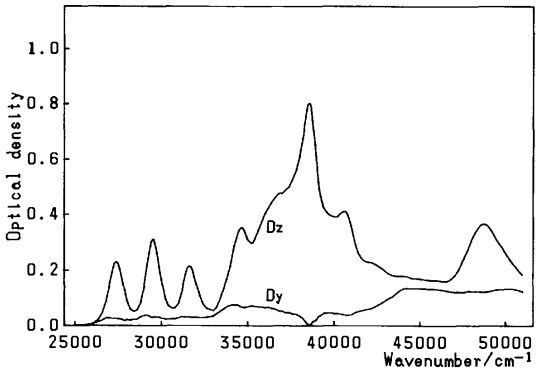

Fig. 4. The reduced polarization spectrum of diphenylhexatriyne.

nylhexatriyne in various solvents and in the unstretched PVA film respectively. The comparison of these two figures reveals that the peculiar band contour of the intense peaks in the range of 34000—41000 cm^{-1} in the PVA film is significantly different from that of the corresponding band peaks in the other solvents. This may be due to something like the Shpol'skii effect,[12,13] which is usually observed in *n*-paraffine matrices and which gives rise to very fine vibrational structures. The band peaks concerned are, therefore, considered to be members of a vibrational progression of the purely single electronic absorption band, whose 0-0 transition is at 34600 cm^{-1}. The first three peaks in the range of 27000—33000 cm^{-1} are, judging from the regularities in their shapes and positions, also considered to be members of a vibrational progression of the 27400-cm^{-1} electronic transition. These considerations are supported by the results of the modified PPP calculation discussed below; *i.e.*, there are only two allowed electronic transitions that can be assigned to the band peaks in the range of 27000—41000 cm^{-1}.

Figure 3 shows the polarized $S_n \leftarrow S_0$ absorption spectrum of diphenylhexatriyne in the stretched PVA film. In the spectrum of this compound, as has been discussed above, there are two electronic band systems whose 0-0 transitions are at 27400 and 34600 cm^{-1}. In Fig. 3, an additional electronic band is obvious at 48800 cm^{-1}. It is known that molecules adsorbed in the PVA film have a tendency that the molecular long axis inclines, on uniaxial stretching of the film, preferentially to the stretching direction of the film. Thereby, R_d values for a long-axis-polarized band are high, while those for a short-axis-polarized one are low. The R_d curve is high and takes a peak at the position of each 0-0 transition, indicating that the transitions at 27400, 34600, and 48800 cm^{-1} are polarized along the long axis (Z) of the molecule. The R_d value is highest for the most intense peak at 38600 cm^{-1}, which indicates that the intense peak at 38600 cm^{-1} may be regarded as being due purely to a longer-molecular-axis-polarized transition. Thus, taking this R_d value as a standard, the absorption spectrum of diphenylhexatriyne measured in the unstretched PVA film (Fig. 2) has been divided into two components polarized along the long (Z) and short (Y) axes by means of dichroism analysis.[4] That is, a reduced polarization spectrum has been obtained (Fig. 4). It is evident from this figure that the vibrational progressions of the two band systems, the one in the range of 27000—33000 cm^{-1}, and the other, in that of 34000—41000 cm^{-1}, and the band at 48800 cm^{-1} are all indeed polarized along the long axis of the molecule. This figure also shows that the short-axis-polarized bands are at 44000 cm^{-1} and at around 50000 cm^{-1}. Besides, a long-axis-polarized band might exist around 45000 cm^{-1}. These observations are summarized in the right column of Table 1.

In order to explain the above experimental results,

a standard PPP calculation, in which only the π system is included, has been carried out. The calculated results can not, however, explain the above experimental results; *i.e.*, the observed 34600 cm^{-1} band can not be reproduced by this calculation (Table 1, Calc. 1). Thus, we performed a modified PPP calculation, including both π and π′ systems. The calculated results are shown in Table 1 (Calc. 2—4). The calculated transition energies and polarizations of Calc. 2, in which 0.0 is used for the value of the parameter F, well explain the observed results. However, the calculated intensity of the first-band transition is too large compared to the observation. As a result, the relative intensity of the second-band transition with respect to that of the first one can not be explained by this calculation; *i.e.*, the calculated intensity for the second transition is smaller than that for the first one, while the observed intensity for the second band is three or four times greater than that for the first one. This may be due to the fact that the interaction between π and π′ systems is neglected in Calc. 2. That is, if there is no interaction between the π system (diphenylhexatriene) and the π′ system (hexatriene), their first transitions should remain unchanged to give the first and second transitions of the united (π+π′) system (diphenylhexatriyne). If this is the case, since the conjugation of the π system is longer than that of the π′ system, and since the first transitions of both systems are polarized along the long axis, the transition energy and the transition moment for the first transition of the π system are, respectively, smaller and larger than those of the π′ system. These values are represented diagrammatically in Fig. 5 as the positions and magnitudes of the transition moment. It is, therefore, a natural result in the case of Calc. 2 that the calculated intensity for the second band of the (π+π′) system, which stems from the π′ system, is smaller than that for the first band of the (π+π′), from the π system.

However, the interaction of π and π′ systems changes the intensities (transition moments) of the first and second transitions of the (π+π′) system, as is shown in Fig. 5. In this figure, the first transition moment of the π system (diphenylhexatriene) has been made to interact with that of π′ (hexatriene) to give the combined first and second transition moments of the (π+π′) system (diphenylhexatriyne). This type of interaction between the transition moments affects only the energy levels of the excited states; the result is that the lower lying $\psi_1^0(\pi\pi^*)$ energy level is stabilized, while the upper lying $\psi_1^0(\pi'\pi'^*)$ one is destabilized. In other words, in the transition-energy scale in Fig. 5, the location of the large transition-moment vector of the π system is lowered *via* the interaction with the upper-lying, moderately large transition-moment vector of the π′ system, with their vectors being opposite in direction. As a result, the two vectors are cancelled in part, resulting in a small transition moment, *i.e.*, a weak electronic transition for the first transition of the (π+π′) system. On the other hand, the moderately large transition-moment vector of the π′ system is heightened *via* the interaction with the lower-lying large transition-moment vector of the π system, with the two vectors being the same in direction. This destabilization is small, since the transition moment concerned is also interacting with the upper-lying transition moment of π. The sum of the two vectors results, therefore, in a very large transition moment, *i.e.*, a very strong electronic transition for the second transition of the (π+π′) system.

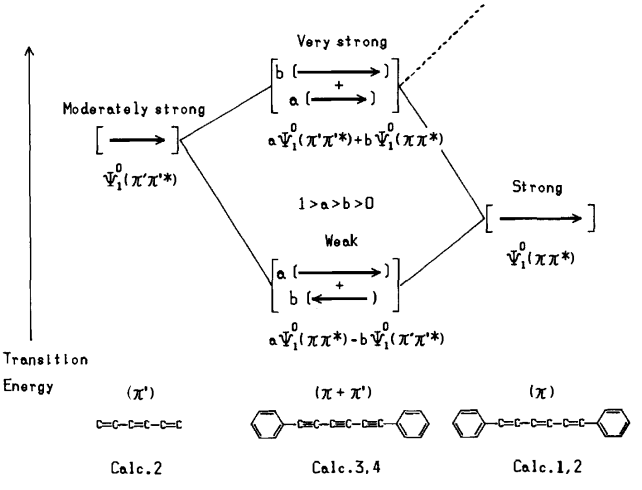

Fig. 5. The interaction of the first transition-moment vectors of the π and π′ systems, which gives the first and second transition-moment vectors of the united (π+π′) system.

*: The observed transition energy in wave number.

Thus, the relative intensities of the first and second bands of diphenylhexatriyne reflect the magnitude of the interaction between the π and π' systems. That is, the fact that the intensity of the second-band system is larger than that of the first-band system implies that there is a considerable interaction between the π and π' systems. The magnitude of the interaction between the two π systems is controlled by the magnitude of the parameter F used in the equation to obtain the electron-repulsion integral between π and π' electrons, and it is manifested by the mixing coefficients a and b given in Fig. 5. For zero interaction (F=0.0), a=1 and b=0. For non-zero interaction (F>0.0), the relation $1>a>b>0$ holds ($a^2+b^2=1$).

The calculated results for a large interaction (Calc. 3, F=1.0) deviate greatly from the observed results as to the location and intensity of the first transition. That is, the first transition moment of diphenylhexatriyne is stabilized too much and cancelled to an excessive degree. The appropriate value of the parameter F is 0.2—0.3 (Calc. 4), which yields reasonable intensities for the first and second transitions. The evaluation of the parameter F has already been discussed elsewhere.[9] In the CNDO/2 method, F is regarded as 1.0.[15] The results of Calc. 4 reproduce the observed spectrum fairly well. That is, the long-axis (Z) polarized bands observed at 27400, 34600, 45000, and 48800 cm^{-1} correspond to the calculated transitions ($^1B_{1u} \leftarrow {}^1A_g$, D_{2h}) from S_0 to S_1, S_4, S_{10}, and S_{18} respectively, while the short-axis (Y) polarized bands at 44000 and 50000 cm^{-1} correspond to the transitions ($^1B_{2u} \leftarrow {}^1A_g$) to S_8 and S_{22} respectively.

Incidentally, the interaction scheme given in Fig. 5 also gives an explanation of the finding made by Armitage *et al.* that, in a series of diphenylpolyynes (Ph-(C≡C)$_n$-Ph), the second bands increase in intensity as n increases, while the first bands become less intense. As n increases, the magnitudes of the transition moments of both the π and π' systems become larger, which results in a larger value (an increase in intensity) for the plus combination (the second bands) of the two vectors, but their difference may, though not easy to predict *a priori*, become smaller, which results in a smaller value (a decrease in intensity) for the minus combination (the first bands). F and the mixing coefficients (a and b) are now assumed to be constant, irrespective of n.

In order to ascertain the nature of each electronic transition of diphenylhexatriyne, configuration analysis[14] has been performed for the wavefunctions of Calc. 4 whose results are in good agreement with the observations as has been discussed above; some interesting results have thus been obtained (see Table 2). The main contributors to the S_1 and S_4 states are, respectively, the π-π^* and π'-π'^* configurations; *i.e.*, the $S_1 \leftarrow S_0$ observed at 27400 cm^{-1} is regarded as a typical π-π^* transition, and the $S_4 \leftarrow S_0$ at 34600 cm^{-1}, as a π'-π'^* within the π' framework perpendicular to the π system. The eighth excited state (S_8) corresponding to the short-axis polarized 44000 cm^{-1} band consists of the π-π^* configuration ($\psi_{7th}^0(\pi\pi^*)$=100%), in which the electronic transition occurs from the MO delocalized over the π system to the MO localized on the two phenyl rings, or *vice versa*.

It should, moreover, be noted that a mixing between mutually perpendicular π and π' electron systems results from a considerable degree of configuration interaction. That is, the S_1 ($\psi_{1st}^0(\pi\pi^*) \simeq 92\%$) state con-

tains about 8% of the π'–π'^* character ($\psi^0_{1st}(\pi'\pi'^*) \simeq 8\%$), and the S_4 ($\psi^0_{1st}(\pi'\pi'^*) \simeq 86\%$) state, about 12% of the π–π^* character ($\psi^0_{1st}(\pi\pi^*) \simeq 8\%$, $\psi^0_{5th}(\pi\pi^*) \simeq 4\%$).

The Radiopolarography of Gadolinium, Ytterbium, and Californium

Yoshinobu SHIOKAWA* and Shin SUZUKI
The Research Institute for Iron, Steel, and Other Metals, Tohoku University, Katahira, Sendai 980
(Received February 29, 1984)

The polarographic reduction of Gd, Yb, and Cf was investigated. It was found that the M(III)→Hg(M) reduction process in an aqueous solution, that cannot be detected by dc polarography, can be detected by radiopolarography. The polarographic behavior of Gd, Eu, Yb, and Cf in the presence of 1,4,7,10,13,16-hexaoxacyclooctadecane(18-crown-6) suggests that Cf(III) is reduced in two steps to Hg(Cf) in an aqueous solution.

The existence of divalent californium has been confirmed by the hydrogen reduction of CfI_3,[1] the polarographic reduction in an acetonitrile,[2] and the distribution between molten salts and liquid Bi.[3] However, concerning its existence in an aqueous solution there are conflicting observations. Musikas *et al.* observed through dc polarography and cyclic voltammetry that Cf(III) in 0.1 M $(CH_3)_4NI$ (1 M=1 mol dm^{-3}) was reduced in two steps.[4] On the other hand, David and Samhoun observed through radiopolarography Cf(III) in 0.1 M LiCl or 0.1 M $(CH_3)_4NClO_4$ was reduced in a single step.[5,6]

In the present work we wish to clarify the reduction process of Cf(III) in an aqueous solution. First, we performed the polarographic reduction of Gd(III) and Yb(III) in order to examine how the M(III)→Hg(M) process was observed by means of radiopolarography. Next, the reduction behavior of Gd, Eu, Yb, and Cf in the presence of 18-crown-6 was investigated.

Experimental

The ^{153}Gd, ^{169}Yd, and $^{250,252}Cf$ were purified by the standard ion exchange technique.[7,8] The tetramethylammonium iodide was used as a supporting electrolyte; in it Musikas *et al.* had observed the existence of Cf(II).[4] Aliquots of the gadolinium, ytterbium, or californium solution were evaporated to dryness and the residue was dissolved in 1 ml of 0.01 M H_2SO_4 and 5 ml of 0.2 M $(CH_3)_4NI$, and then the mixture was diluted to 10 ml. The pH value of the solution was adjusted by the use of 0.1 M H_2SO_4 or 0.1 M $(CH_3)_4NOH$.

In a conventional radiopolarographic cell, the aqueous solution examined is directly in contact with the insulating phase(CCl_4), in which the radioactive amalgam is accumulated. In such a cell, because of the direct contact with the organic solvent, the radiopolarographic reduction in an organic solvent or an aqueous solution which contains some soluble substance such as 18-crown-6 in the CCl_4, is difficult. In this experiment, however, we used a new radiopolarographic cell, shown in Fig. 1, in which the solution examined was not directly in contact with the CCl_4 phase. In this cell, the inner surface of the part of capillary E(inner diameter, 3 mm) below the stopcock F was treated with the vapor of dimethyldichlorosilane. The increased surface tension between the solution and the glass makes the solution hold above the argon phase.

The deoxidized CCl_4 and then the solution examined were introduced into the cell, and the tube connected to the needle valve I was filled with argon. A constant potential was imposed at the DME during 10 min, while the mercury drops were passed through the capillary E and the argon phase and then accumulated in the compartment on the stopcock G. Then, the stopcock F was closed and the needle valves I and J, and the stopcock G were opened. By the flow of CCl_4(J→G→I), the amalgam was rinsed in order to remove the radioactive solution adhered to it and falled into the compartment on the stopcock H. After the stopcock G was closed, the amalgam was taken out from cell with a small quantity of CCl_4. The dried amalgam was weighed, and then the amalgamated metal was extracted by shaking it with 1 ml of 0.5 M HCl or 0.5 M HNO_3 for 10 min. For the Gd and Yb runs, an aliquot of the extraction solution was determined by means of γ-ray spectrometry. For Cf, the sample, prepared by evaporating an aliquot of the solution on a dish of stainless steel, was determined by means of α-ray spectrometry.

There was no difference of more than 0.1 of the pH value between before and after experiments. The radiopolarographic cell was placed in a constant-temperature box with 25±1 °C. The polarograph and the DME knocker for obtaining a constant lifetime of a mercury drop were manufactured by ourselves. The DME knocker was used only in the dc polarography. The 18-crown-6 was a product of the Nippon Soda Co.,Ltd., and was dried by use of P_2O_5 in a vacuum desiccator with a liquid-nitrogen trap.

Results and Discussion

The dc polarogram of lanthanoid(III), except for

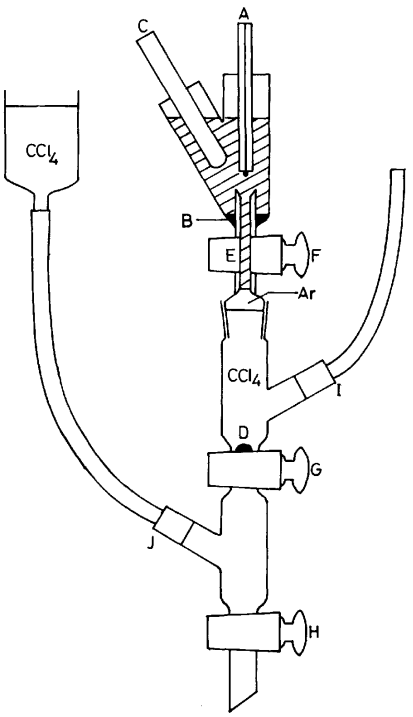

Fig. 1. Radiopolarographic cell.

Eu(III) and Yb(III) in an aqueous solution, exhibits two waves, whose processes are not limited by the rate of diffusion, beyond the hydrogen discharge. According to Large and Timnick,[9] the first wave is attributed to the reduction of the hydrogen ions produced by the protolytic dissociation of the hydrated lanthanoid(III) at the electrode surface, while the second is due to the adsorption of the hydrolytic species of lanthanoid(III). Therefore, the reduction process of lanthanoid(III) cannot be detected by dc polarography.

In radiopolarography, the measured quantity is not the flux of electrons(current), but the amount of the amalgamated radioactive nuclide. That is, this quantity corresponds to the mass transfer associated by the electrode reaction and not to the electron transfer. Also, the concentration of the metal ions is much lower than that used in the dc polarography. It can, therefore, be expected that the reduction process of lanthanoid(III) in an aqueous solution can be detected by means of the radiopolarography.

Figure 2 shows the radio and dc polarograms of Yb(III). In the dc radiopolarogram, two waves due to the hydrogen discharge and reduction of Yb(III) to Yb(II) at about −1.5 V,[10] which, naturally, cannot be detected by the radiopolarography, are overlapped, while the wave at about −2.0 V is attributed to the reduction of Yb(II) to Hg(Yb). Its reciprocal of the slope of logarithmic analysis for the wave is 29—34 mV. On the other hand, the radiopolarographic wave is detected at about −2.0 V, and its reciprocal of the slope is 27—31 mv. Moreover, as is shown in Fig. 3, the limiting activity A_d, one at the plateaus of the radiopolarogram, is controlled by the rate of diffusion. Therefore, the radiopolarographic results are almost the same as the dc polarographic ones; nevertheless, the concentration of ytterbium on each solution examined differs by an order of four. The diffusion coefficient calculated from the limiting activity is 3—4×10^{-6} cm^2s^{-1}, which is lower than that calculated from the limiting current. This may be attributed to desamalgamation in CCl_4.[5]

However, there is a little difference in the half-wave potentials, $E_{1/2}$, obtained by the two methods. The potentials obtained by the dc polarography are more negative and dependent on the pH values; $E_{1/2}$=−2.033 V at pH=2.9, $E_{1/2}$=−2.059 V at pH=3.5. A similar dependence is observed by the dc polarographic reduction of Eu(II) to Hg(Eu).[11] On the other hand, the half-wave potentials obtained by the radiopolarography are independent of the pH values; $E_{1/2}$=−2.016 V at pH=2.8, $E_{1/2}$=−2.015 V at pH=3.5. The dependency of the potentials on the pH observed by the dc polarography have been explained by the formation of hydroxo complexes.[11] This explanation is not correctly but we ourselves cannot at present explain these differences in pH dependency.

Figure 4 shows the radio and dc polarograms of Gd(III). In the dc polarogram, except for the hydrogen discharge at about −1.5 V, two waves are observed, as has been mentioned above: One at about −1.80 V and another at about −2.07 V. In the radiopolarogram, the wave is found at about −2.15 V, and the half-wave potentials are independent of the pH; $E_{1/2}$=−2.154 V at pH=2.8, $E_{1/2}$=−2.149 V at pH=3.5. As is shown in Fig. 3, this process is limited by the rate of diffusion, while the reciprocal of the slope of logarithmic analysis for the wave is about 35 mV. Therefore, the radiopolarographic wave must be due to the reduction of Gd(III) to Hg(Gd) being irreversible.

By means of radiopolarography, in an aqueous

solution the reduction wave of not only lanthanoid(II) but also lanthanoid(III) can be detected, as has been mentioned above. Thus radiopolarography can be expected to elucidate the reduction process of Cf(III) in an aqueous solution.

Figure 5 shows the radiopolarogram and logarithmic analysis of Cf(III). The half-wave potential and the reciprocal of the slope are −1.750 V and 19 mv respectively, and this process is limited by the rate of diffusion, as is shown in Fig. 3. The half-wave potential obtained is almost in agreement with that obtained by David and Shahoun through radiopolarography,[5,6] but not with that obtained by Musikas *et al.* through dc polarography.[4] According to Musikas *et al.*, the half-wave potential is −1.71 V for Cf(III)/Cf(II) and −1.93 V for Cf(II)/Hg(Cf). At this amalgamated potential, as is shown in Run 2 of Fig. 5, no appreciable change in the radiopolarogram is observed. The disagreement is not due to the difference in the concentration of Cf(III), because, as is shown in Fig. 2, the potentials obtained by radio and dc polarography are almost in agreement. The disagreement may be attributed to the difference in the specfic activity of a solution. In this work, the specific activity of $^{250,252}Cf$ was about 0.3 μCi/ml (the concentration of Cf: 4×10^{-9} M), while Musikas *et al.* carried out at about 0.5 mCi/ml (10^{-4}—10^{-3} M). The difference in the potentials, $E_{1/2}$, may be attributed to the influence of the α activity in the electrical double layer at the electrode.

From the logarithmic analysis of the radiopolarographic wave, David and Samhoun have drawn the conclusion that Cf(III) is reduced by a single step to Hg(Cf). Our reciprocal of the slope, as is shown in Fig. 5, supports their conclusion. However, as the reduction wave of Cf(III) to Cf(II), even if the reduction can occur, cannot be detected by radiopolarography, it is desirable to investigate the electrode reaction from a different viewpoint. In the present work, therefore, the shift of half-wave potentials in the presence of

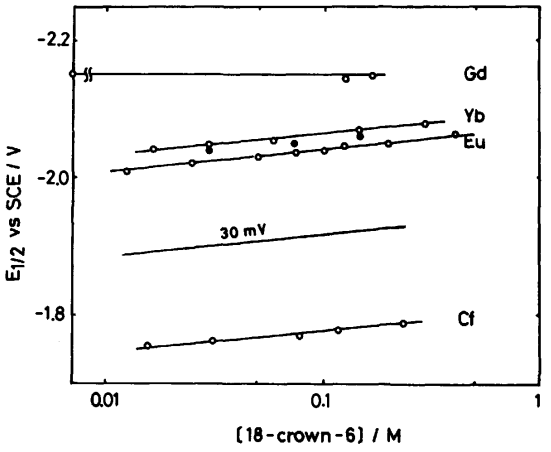

Fig. 6. $E_{1/2}$ of Eu, Gd, Yb, and Cf as a function of 18-crown-6 concentration.

18-crown-6 was investigated.

It is well known that 18-crown-6 forms stable complexes with cations whose ionic diameters are very close to the cavity diameter of 18-crown-6. Izatt *et al.* showed that, in an aqueous solution, 18-crown-6 with a cavity diameter of 280 pm[12] does not form complexes with La(III) with an ionic radius $r_{La^{3+}}$=103 pm[13] upon the calorimetry.[14] Therefore, it cannot form complexes with Cf(III) with a smaller radius $r_{Cf^{3+}}$=95 pm[13] than La(III). On the other hand, 18-crown-6 is expected to form complexes with Cf(II) because of two adavantages, its radius, $r_{Cf^{2+}}$=107 pm[13], is larger than that of Cf(III), and its hydration energy is lower than that of La(III).

Figure 6 shows the dependence of the half-wave potentials of the reduction to the amalgam on the concentration of 18-crown-6. The potentials $E_{1/2}$ of Gd, Cf, and a part of Yb (blackened circles in Fig. 6) were obtained by radiopolarography, and the others, by dc polarography.

For the case of Gd, the potentials $E_{1/2}$ shown in Fig. 6 are due to the reduction of Gd(III) to Hg(Gd); the potential $E_{1/2}$ in the absence of 18-crown-6 is also shown in this figure. No shift of potentials $E_{1/2}$ and no appreciable change in the irreversibility are observed, even in the presence of 18-crown-6.

For Eu and Yb, the potentials $E_{1/2}$ shown are due to the reversible reduction of M(II) to Hg(M). The observed slope of the half-wave potentials *vs.* the logarithmic concentration of 18-crown-6 is 30 mV, as is shown in Fig. 6. As is well known, if the reduction is reversible, such a plot has a slope of $P(RT/nF)$, where P is the coordination number of 18-crown-6. Figure 6 suggests that 18-crown-6 forms 1:1 complexes with Eu(II) and Yb(II). Their stability constants are estimated to be $\log K_{Eu^{2+}}$=2.7 and $\log K_{Yb^{2+}}$=2.4.

The observed shift of the half-wave potentials of Cf indicates that 18-crown-6 forms complexes with Cf(II), as has been mentioned above, and that Cf(II) reduces to Hg(Cf). However, the mean reciprocal of the slope of logarithmic analysis in the presence of 18-crown-6 is 23 mV, which is nealy equal to that in the absence of 18-crown-6, as is shown in Fig. 5, and corresponds to a Cf(III)→Hg(Cf) process, not a Cf(II)→Hg(Cf) process. We cannot interpret these conflicting results. Miranda *et al.* have pointed out, in their critical survey of radio-

polarography, that the logarithmic analysis of the radiopolarogram cannot always be taken at its face value.[15] Therefore, at the present time the results of the logarithmic analysis of Cf remain as the question to be solved later.

It is of interest that the observed dependence of the half-wave potentials of Cf on the concentration of 18-crown-6 has the same slope as that of Eu(II) to Hg(Eu) and that of Yb(II) to Hg(Yb). Therefore, we may suppose that the reduction of Cf is reversible. Figure 6 shows that 18-crown-6 forms 1:1 complexes with Cf-(II) and its stability constant is estimated to be log $K_{Cf^{2+}}$=2.0. The estimated stability constants of 18-crown-6 with Eu(II), Yb(II), and Cf(II) satisfy the relationship between the stability constants of alkaline-earth elements and their ionic radii.[12]

The Synthesis and Thermal Decomposition of Calcium Phosphoramidate

Makoto WATANABE,* Yoshio MORII, and Shoji SATO
Department of Industrial Chemistry, Chubu University, Matsumoto-cho, Kasugai, Aichi 487
(Received March 5, 1984)

Calcium phosphoramidate monohydrate was made by adding an aqueous calcium chloride solution to an aqueous potassium hydrogenphosphoramidate solution at pH 9.0—9.5 below 5 °C. The product was stable at room temperature, but it was decomposed by heating. When the product was heated at 150 °C in air, the phosphoramidate decomposed to produce anhydrous calcium phosphoramide and also ortho- and diphosphates. The elimination of ammonia from amino groups to form a P-N(H)-P linkage was not observed at this temperature. The phosphoramidate decomposed in air to form ortho-, imidodi-, di-, and a small amount of higher polyphosphates at a temperature higher than 150 °C. Imidodiphosphate was decomposed to diphosphate by moisture in air. β-Calcium diphosphate was formed by heating the phosphoramidate at a temperature higher than 750 °C in air. When the phosphoramidate was heated in dried N_2, it showed the same thermal reaction as that in air below 250 °C, while the amount of imidodiphosphate in the thermal product was larger than that in air at a temperature higher than 400 °C

There are so many phosphorus-nitrogen compounds which have a P-N covalent bond. In the compounds, the phosphazens are maybe the best known and most intensively investigated compounds. There are a series of phosphorus-nitrogen compounds which have amino groups on a P atom. These compounds have potential for use as a new type of chemical fertilizer with a P-N covalent bond and as flameproof materials because they produce polyphosphates containing imino and amino groups when they are heated. They can also be used as starting materials for the preparation of many organic and inorganic phosphorus compounds.[1] In our previous paper,[2,3] the thermal decomposition of calcium or magnesium bis(hydrogenphosphoramidate) was studied. The two hydrogenphosphoramidates were unstable even at room temperature and were decomposed to polyphosphates at that temperature or at higher temperatures. This unstability was concluded to be due to the presence of an OH group in the phosphoramidates. This paper will describe the synthesis and the thermal decomposition of calcium phosphoramidate in order to ascertain the difference in thermal properties between the phosphoramidate and the hydrogenphosphoramidates.

Experimental

Preparation. The potassium hydrogenphosphoramidate was made by the method described in a previous paper;[4] 0.12 mol of the phosphoramidate was dissolved in 1.2 dm^3 of water. The aqueous solution of calcium chloride, which was made by dissolving 0.12 mol of calcium chloride dihydrate in 360 cm^3 of water, was added to the phosphoramidate solution below 5 °C to prevent the hydrolysis of the phosphoramidate. The resulting solution was stirred for 15 min. During the treatment, the pH of the solution was kept at 9.0—9.5 with 2.7% aqueous ammonia. The white precipitate thus produced was filtered off and washed with 50-V% aqueous ethanol, ethanol, and then acetone. The product was dried under 5330 Pa at 25 °C for 2 d.

Chemical Analysis. About 0.2 g of the product was dissolved in 20 cm^3 of 6-mol nitric acid, and the solution was heated on a water bath for 1 h. The orthophosphate in the solution was determined by the gravimetric method.[5] The nitrogen and calcium were estimated by, respectively, the Kjeldahl method and the EDTA (disodium dihydrogen ethylenediaminetetraacetate dihydrate) substitution-titration method with a BT indicator.

Paper Chromatography and Colorimetry of Phosphates. The paper-chromatographic separation of phosphate species in a sample and the determination of the phosphates on the chromatogram were run by the method described in our previous paper.[2]

X-Ray Diffractometry. An X-ray diffraction diagram of a powder sample was taken with nickel-filtered Cu $K\alpha$ radiation by using a Toshiba X-ray diffractometer, ADG-102.

IR Spectrophotometry. An IR spectrum of a sample was recorded on a JASCO IR spectrophotometer, A-3, by means of the KBr disc method.

DTA and TG. A sample was heated at a rate of 5 °C min^{-1} in air and dried N_2 by means of a Cho Balance TRDA$_1$-H apparatus.

^{31}P NMR Measurement. About 50 mg of a powder sample was put in 1.2 cm^3 of a 6% EDTA deuterated-water solution and stirred for 1—20 min, depending on the solubility of the sample, below 5 °C. The ^{31}P NMR spectrum of the solution was then measured by means of a JEOL JNM-FX-60-FT-NMR instrument.

Determination of Bound Water. The bound water in a sample was estimated by means of the Karl Fisher method with an MK-AII apparatus made by Kyoto Denshi.

Results and Discussion

Composition of the Product. The yield of the product was about 15 g. The ^{31}P NMR spectrum of the product gave only one peak of phosphoramidate at 3.4 ppm. (To get a single peak, the measuring time had to be as short as possible because the phosphoramidate was easily hydrolyzed to orthophosphate and the spectrum of the phosphoramidate solution also showed a peak of orthophosphate, depending on the experimental conditions.) Found: P, 19.9; N, 8.9; Ca, 27.1; H_2O, 12.1%. Calcd for $CaPO_3NH_2 \cdot H_2O$: P, 20.2; N, 9.2; Ca, 26.2; H_2O, 11.8%. Accordingly, it was found that the product was calcium phosphoramidate monohydrate, $CaPO_3NH_2 \cdot H_2O$. The product was stable at room temperature.

Thermal Reaction in Air. *(1) DTA and TG*: The DTA and TG curves of the product in air are presented in Fig. 1. The samples, numbered as in Fig. 1, were removed from the furnace, cooled in a silica-gel desiccator, and subjected to further analysis. The results are shown in Table 1 and Fig. 2. According to Table 1, the first large endothermic peak accompanying a rapid weight loss seemed to be mainly

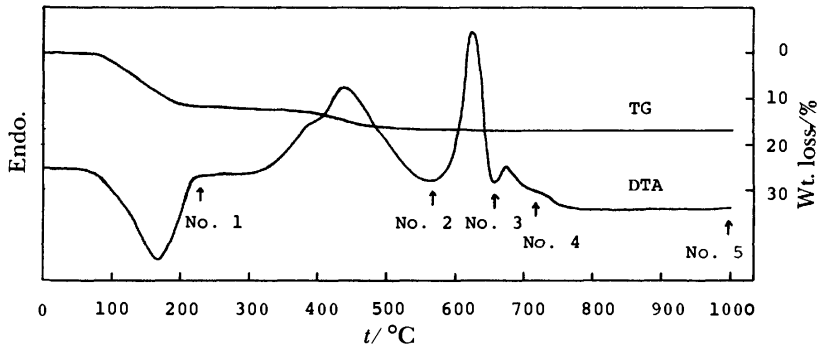

Fig. 1. DTA and TG curves of $CaPO_3NH_2 \cdot H_2O$ in air.

TABLE 1. WEIGHT LOSS OF THE PRODUCT, AND NITROGEN AND WATER CONTENT OF THE THERMAL DECOMPOSITION PRODUCTS IN AIR

Sample	Total N/%	Water/%	Wt. loss/%
Product	8.9	12.1	—
No. 1	9.1	1.4	11.3
No. 2	4.0	0	16.9
No. 3	1.6	0	17.1
No. 4	1.2	0	17.2
No. 5	0	0	17.2

caused by the elimination of bound water. The weight loss of the product at this stage was very close to the one calculated according to the following reaction:

$$CaPO_3NH_2 \cdot H_2O \longrightarrow CaPO_3NH_2 + H_2O, \quad (1)$$

but the thermal product, No. 1, still had 1.4% of water and its nitrogen content was a little less than that of $CaPO_3NH_2$. The IR spectrum of No. 1 showed a peak at 930 cm^{-1} which is considered to be due to a P-N(H)-P or a P-O-P linkage, and it was found that the endothermic reaction included condensation. The following condensation reaction is acceptable for the formation of a P-N(H)-P linkage:

$$2CaO_3P\text{-}NH_2 \longrightarrow CaO_3P\text{-}N(H)\text{-}PO_3Ca + NH_3. \quad (2)$$

There are two ways for the formation of a P-O-P linkage. One is:

$$2CaO_3P\text{-}NH_2 + 2H_2O \longrightarrow 2CaO_3P\text{-}ONH_4 \longrightarrow CaO_3P\text{-}O\text{-}PO_3Ca + 2NH_3 + H_2O; \quad (3)$$

the other is:

$$\left.\begin{aligned} &CaO_3P\text{-}N(H)\text{-}PO_3Ca + 2H_2O \longrightarrow 2CaO_3P\text{-}OH + NH_3 \\ &2CaO_3P\text{-}OH \longrightarrow CaO_3P\text{-}O\text{-}PO_3Ca + H_2O. \end{aligned}\right\} \quad (4)$$

It was, however, impossible to distinguish between the P-N(H)-P and the the P-O-P linkages according to the IR spectrum. There appeared a broad exothermic peak accompanying weight loss at 320—560 °C. After the reaction, the nitrogen content in the product decreased from 9.1 to 4.0, so the reaction includes the elimination of ammonia. As has been mentioned above, Reactions 2, 3, and 4 can be presented for the elimination of ammonia. As Fig. 2 shows, the No. 1 thermal product has a very weak peak of NH_4^+ at 1400 cm^{-1}. It is still

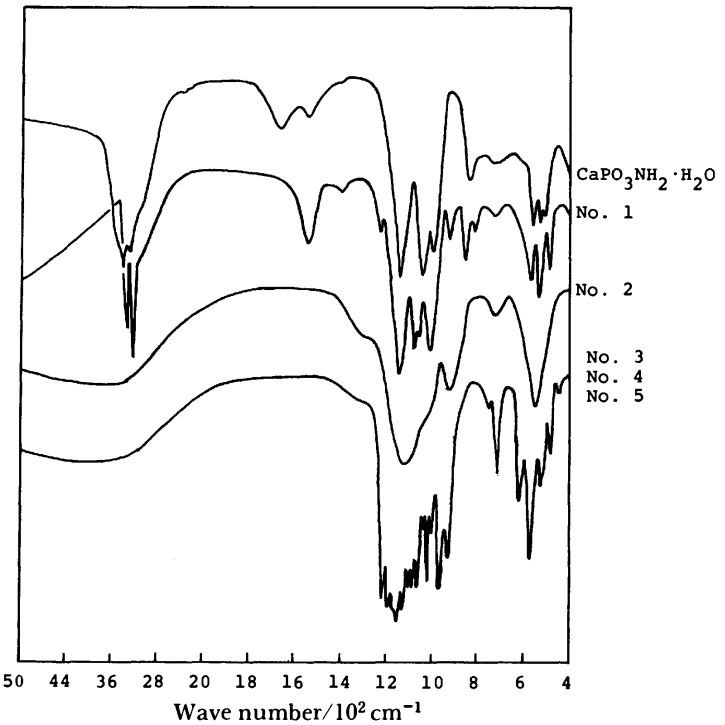

Fig. 2. IR spectra of the thermal decomposition products of $CaPO_3NH_2 \cdot H_2O$ in air.

difficult to say that Reaction 3 does not take place much, because the overall-reaction rate of Reaction 3 in that temperature range is obscure in these data. No detailed information about Reaction 4 could be obtained by the above data, either. The exothermic reaction may, however, be thought to include all these reactions at this stage. The formation of an ammonium ion in the thermal product will be discussed in the next section. The No. 1 sample showed an unkown X-ray diffraction pattern, while No. 2 was X-ray diffractometrically amorphous. The unknown pattern may be thought to be due to $CaPO_3NH_2$, because Reaction 1 may be predominant at this step. The IR spectrum of No. 2 showed a weak absorption of a $(PO_2)^-$ group at 1300 cm^{-1}, a strong absorption of a $(PO_3)^{2-}$ group at 1150 cm^{-1}, and absorptions of a P-N(H)-P or a P-O-P linkage at 930 and 730 cm^{-1}. The sample did not show any absorptions of an amino group in its spectrum. Accordingly, the main thermal product involved in No. 2 may be calcium diphosphate, $CaO_3P\text{-}O\text{-}PO_3Ca$, or calcium imidodi-

phosphate, $CaO_3P-N(H)-PO_3Ca$. If the sample is the imidodiphosphate, its nitrogen content should be 5.5%. Therefore, the sample No. 2 may be a mixture of the two diphosphates. To obtain proof of this, the ^{31}P NMR spectrum of No. 2 was taken; it is shown in Fig. 3. The peaks at about 0.9 and 10—11 ppm may be due to imidodiphosphate and diphosphate respectively. As has been described above, the sample No. 2 showed a weak IR absorption of a $(PO_2)^-$ group at 1300 cm^{-1}. This means that the thermal product contains polyphosphates or imidopolyphosphates with chain lengths longer than that of the dimer (diphosphate and imidodiphosphate). According to Reactions 2—4, the formation of such polyphosphates with a $(PO_2)^-$ group seems to be impossible at a relatively low-temperature range. The problem can be solved by assuming that the following disproportionation is taking place in the amorphous thermal decomposition products:

$$2\,Ca\text{-}O\text{-}P(=O)(O)\text{-}ONH_4 \longrightarrow Ca_{1/2}O\text{-}P(=O)(O)\text{-}ONH_4 + O\text{-}P(=O)(Ca\text{-}O)\text{-}OCa_{1/2}. \quad (5)$$

The $Ca_{1/2}(NH_4)_2PO_4$ species is bifunctional for thermal condensation in this temperature range and can produce tri- and higher polyphosphates. The sample No. 2 did not show any ^{31}P NMR peak of a $(PO_2)^-$ group. The sample contained an insoluble part, and so it could be concluded that the polyphosphates with a $(PO_2)^-$ group has a very low solubility. The NMR spectrum of No. 2 also exhibited a peak of phosphoramidate. It is found that the thermal product No. 2 is composed of these compounds. After the sharp large exothermic peak at around 630 °C, the sample showed an X-ray diffraction diagram of β-$Ca_2P_2O_7$ (ASTM cards, Nos. 9—346 and 20—24). It is clear that the thermal reaction is caused by the crystallization of amorphous calcium diphosphate to the β-form. It was difficult to understand the next small exothermic peak at about 670 °C because no definitive change in the IR spectrum or in the X-ray diffraction diagram of the sample after the exothermic peak was observed. As Table 1 shows, however, nitrogen was released from the sample during the crystallization, so it might be said that the amorphous calcium diphosphate produced according to Reactions 3 and/or 4 in this temperature range crystallizes at around 670 °C. The weight loss of the product was observed until about 620 °C; this seems to support the above discussion. The samples Nos. 3—5 did not indicate any IR absorption of a $(PO_2)^-$ group. The disappearance of the absorption may be explained by the following reorganization or degradation of amorphous phosphates to β-$Ca_2P_2O_7$;

$$Ca\text{-}O\text{-}P(=O)(O)\text{-}O\text{-}(P(=O)(O)\text{-}O)_n\text{-}P(=O)(O\text{-}Ca)\text{-}O\text{-}P(=O)(Ca\text{-}O)\text{-}O\text{-}Ca + n\,O\text{-}P(=O)(Ca\text{-}O)\text{-}OCa_{1/2}$$

$$\longrightarrow (n+1)\,O\text{-}P(=O)(Ca\text{-}O)\text{-}O\text{-}P(=O)(O\text{-}Ca)\text{-}O. \quad (6)$$

$(n \geqq 1)$

The sample No. 5 did not contain nitrogen. The nitrogen as an imino group in the thermal product may be converted to oxygen according to Reaction 4. Since the weight change associated with the reaction is very small, no increase in the weigh of the thermal product could be observed by the TG.

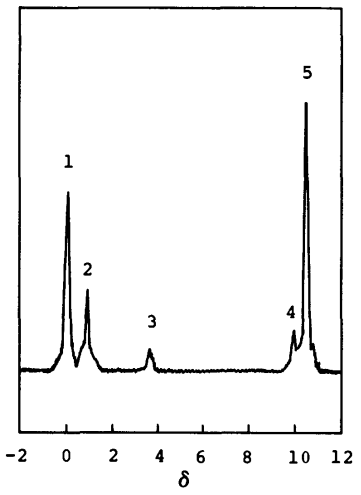

Fig. 3. ^{31}P NMR spectrum of the thermal product, No. 2.
1: Orthophosphate, 2: imidodiphosphate, 3: phosphoramidate, 4: and 5: diphosphate.[6]

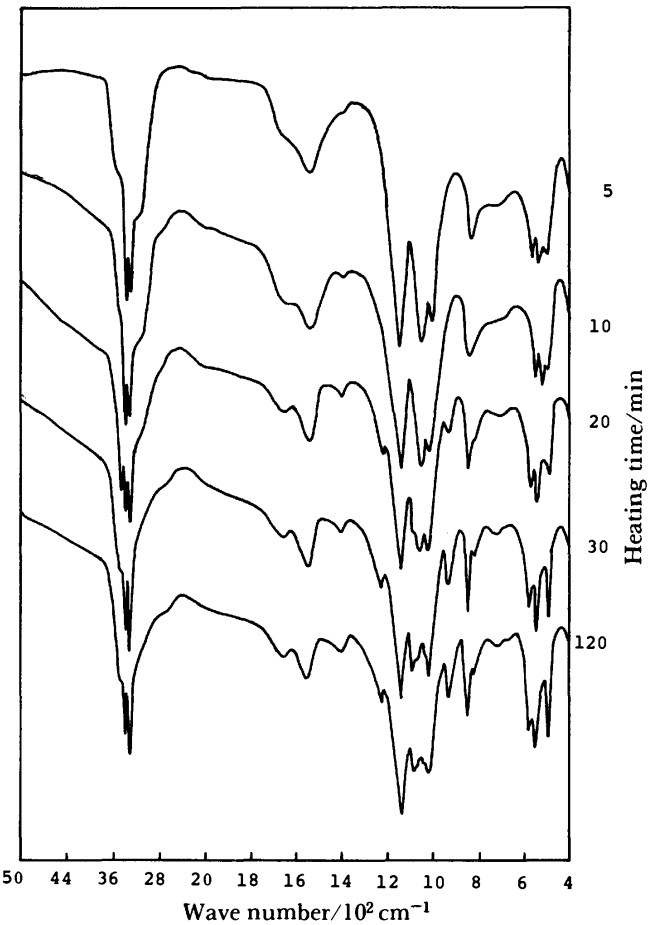

Fig. 4. IR spectra of the isothermal decomposition products in air at 150 °C.

(2) Isothermal Reaction at 150°C: As has been mentioned above, it was difficult to get clear information about the formation of an ammonium ion according to Reaction 3 by means of the DTA-TG instrument. Therefore, $CaPO_3NH_2 \cdot H_2O$ was isothermally heated at 150°C. This temperature seemed to be suitable for the analysis, because the thermal reaction was active and the elimination of ammonia from the product was very slow at this temperature. The IR spectra of the isothermal decomposition products in Fig. 4 indicate a very small peak due to NH_4^+ at 1400 cm^{-1}. This means that the amount of nitrogen present as NH_4^+ is very small. If only the dehydration of bound water from the product is taking place at this temperature according to Reaction 1, the nitrogen content in the thermal product should be 10.4%. As Table 2 shows, however, the nitrogen content was less than 10.4%. Therefore, ammonia must be released from the product. The ^{31}P NMR spectrum shows that the thermal product is composed of orthophosphate, phosphoramidate, and diphosphate. Reactions 2—4 can be responsible for the reaction. Imidophosphates were not made at all at this temperature. Therefore, Reactions 1 and 3 occur at 150°C. By the way, the thermal product heated at 150°C showed very small IR absorption of NH_4^+, while it had a large ^{31}P NMR peak of orthophosphate. The orthophosphate without NH_4^+ can be made by the elimination of ammonia as follows:

$$CaO_3PONH_4 \longrightarrow CaO_3POH + NH_3. \quad (7)$$

As has been mentioned above, phosphoramidate is hydrolyzed easily to orthophosphate in water. It is difficult to ascertain which reaction is responsible for the appearance of the large NMR peak of orthophosphate, but it seems reasonable that both reactions contribute to it. The other reactions do not occur at this temperature; they may take place at a temperature higher than 150°C.

Thermal Reaction in Dried N_2. According to Reactions 3 and 4, the presence of water causes the decomposition of the $P-NH_2$ and P-N(H)-P linkages. The water which brings about the decomposition comes from bound water and from moisture in the air. After the release of the bound water, the moisture in the air may give an important effect on the decomposition. To avoid its influence, the DTA and TG measurements of $CaPO_3NH_2 \cdot H_2O$ were made in dried N_2; the results are shown in Fig. 5. According to the results shown in Table 3, the first endothermic reaction, accompanied by a rapid weight loss, seemed to be mainly caused by the release of bound water. The weight loss of the product exhibited a value very close to the one calculated with Reaction 1, but the sample No. 6 still contained 1.5% of water and its nitrogen content was less than that of $CaPO_3NH_2$. Therefore, the elimination of ammonia seemed to take place at the same time. The IR spectrum of No. 6 had absorptions at 930 and 720 cm^{-1}. These absorptions were considered to be due to a P-N(H)-P or a P-O-P linkage. The ^{31}P NMR spectrum of No. 6 in Fig. 6 shows that the thermal product contains ortho- and diphosphates other than phosphoramidate. The sample also indicated a small IR peak of NH_4^+ at 1400 cm^{-1}. Accordingly, the thermal reactions taking place here are Reactions 1, 3, and 7. The other reactions may not occur at this stage. The X-ray diffraction pattern of No. 6 was the same as that of No. 1 and is concluded to be the pattern of $CaPO_3NH_2$. The sample No. 7 had the same X-ray diffraction diagram and IR spectrum as those of No. 6, while No. 7 indicated the loss of nitrogen and a ^{31}P NMR peak at 0.9 ppm which seemed to be due to imidodiphosphate. Therefore, reaction 2 may be taking place at this stage. The sample showed a small endothermic peak, accompanied by a fast weight loss, at around 450°C. The sample No. 8 was X-ray diffractometrically amorphous and had a small NMR peak of phosphoramidate and a large

Table 2. Weight loss of the product, and nitrogen and water content of the isothermal decomposition products at 150°C in air

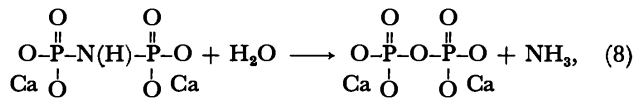
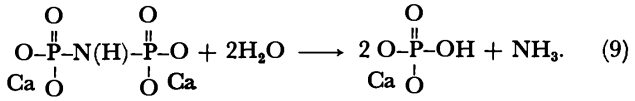
1: Orthophosphate, 2: imidodiphosphate, 3: phosphoramidate, 4: diphosphate.

NMR peak of imidodiphosphate. The sample No.7 had a very small peak of NH_4^+. Therefore, reaction 2 may be taking place rapidly at this stage. According to the above discussion and the result that the DTA curve did not show any exothermic peak of the crystallization of calcium diphosphate at around 630°C, the main thermal decomposition product in No. 8 is concluded to be calcium imidodiphosphate, but the sample also indicated large NMR peaks of ortho- and diphosphates. The appearance of the two large ^{31}P NMR peaks can be explained by the hydrolysis of imidodiphosphate to ortho- and diphosphates as follows:





The samples Nos. 7 and 8 also had a weak IR absorption at 1300 cm^{-1} which seemed to be the absorption of a $(PO_2)^-$ group. The small amount of ammonium calcium orthophosphate which was produced by Reaction 3 may disproportionate according to Reaction 5 and then produce polyphosphates with chain lengths longer than that of diphosphate in this temperature range. As has been discussed above, the calcium polyphosphates seemed to have a very low solubility, for samples Nos. 7 and 8 did not exhibit any NMR peak of a $(PO_2)^-$ group. After the small endothermic peak at about 450°C, the weight loss of the product lasted until about 650°C. During the reaction, the nitrogen content of the thermal product decreased from 6.1 to 4.0. The sample No. 9 did not have any ^{31}P NMR peak of phosphoramidate at all. Therefore, the loss of nitrogen content at this stage may be mainly caused by Reaction 2. The sample No. 9 did not show any IR absorption of a $(PO_2)^-$ group. The reorganization of Reaction 6 may also be taking place at this stage. The sample No. 9 showed several complex exothermic reactions in the temperature range of 700—1000°C. The sample No. 9 was X-ray diffractometrically amorphous, while No. 10 showed an X-ray diffraction diagram of β-$Ca_2P_2O_7$ and the nitrogen content decreased a little after the exothermic reaction. It could be concluded, from the presence of slight amounts of water in the DTA-TG instrument, that the conversion of an imino group to oxygen seems to occur according to Reaction 4 at this stage. It was difficult to prevent such decomposition in the instrument used here.

Difference of Thermal Reaction Between Phosphoramidate and Hydrogenphosphoramidate. The calcium and magnesium bis (hydrogenphosphoramidate)[2,3] were unstable and decomposed to polyphosphates at room temperature. They also decomposed to polyphosphates and did not form a P-N(H)-P linkage at all upon the elimination of ammonia at a temperature higher than room temperature. On the other hand, the calcium phosphoramidate made in this study was stable at room temperature, and quite a bit of the phosphoramidate, especially in dried N_2, produced a P-N(H)-P linkage upon thermal condensation at a temperature higher than 150°C.

The Syntheses, Properties, and Crystal and Molecular Structures of Bis(benzamide)tris(*O,O'*-diisopropyl dithiophosphato)neodymium(III), $[Nd\{(C_3H_7O)_2PS_2\}_3(C_6H_5CONH_2)_2]$, and Its Isomorphous Complexes of La, Ce, Pr, Sm, Eu, and Gd

Reiko NAKAMURA, Kiyofumi NAGAI,* Mamoru SHIMOI, and Akira OUCHI

Department of Chemistry, College of Arts and Sciences, The University of Tokyo, Komaba 3-8-1, Meguro-ku, Tokyo 153

(Received March 15, 1984)

The new complexes indicated in the title have been synthesized, and the crystal and molecular structure of the neodymium(III) complex has been determined by the X-ray diffraction method. The crystal is monoclinic, with the space group C2/c, $Z=16$, $a=28.887(4)$, $b=28.913(5)$, $c=24.814(5)$ Å, $\beta=106.72(1)°$. The final R value for 7761 reflections is 0.066. The central neodymium(III) atom of the complex is octa-coordinated and is in a dodecahedron geometry; three *O,O'*-diisopropyl dithiophosphato ligands, chelating by both of the sulfur atoms, span the two *m* edges of a trapezium as well as one *a* edge of the other trapezium, and two oxygen atoms of both the benzamide ligate at both tips of the base edge of the latter trapezium. The solid and the acetonitrile solution of the europium(III) complex are orange in color, and they show a charge-transfer band in their near-ultraviolet absorption spectra.

The lanthanoid metal complexes of sulfur-ligating ligands, such as *O,O'*-dialkyl dithiophosphate,[1-3] dialkyl dithiophosphinates,[4] and dialkyldithiocarbamates,[5] are very interesting compounds, because they are stable enough in spite of the fact that lanthanoid elements are known as "hard acids" according to the HSAB theory.[6] The structure of some complexes of the type have already been determined by means of X-ray analysis.[1,2,4,5,7]

Our group has already reported about the mixed complexes of lanthanoid(III) containing the *O,O'*-diisopropyl dithiophosphato (iPr_2dtp) ligand, as well as *N,N*-dimethylacetamide (dma).[1] Although we could obtain La, Ce, and Nd complexes of the type, all of which are isomorphous with each other, those of Sm and of the heavier members of lanthanoid were not synthesized in a stable crystalline state. Therefore, we tried to find more stable mixed complexes of the type. The adducts obtained this time, which are isomorphous with each other, were those of all members from La to Gd, except for Pm. All of them are stable, and all can be kept in air for several months at room temperature without decomposition.

Another interesting problem about the type of complexes is the coordination position of the oxygen atoms. As has been shown in the previous paper,[1] the two oxygen atoms take side-by-side positions in $[La(iPr_2dtp)_3(dma)_2]$, while in the case of $[La(Et_2dtp)_3\{(C_6H_5)_3PO\}_2]$ the two oxygen atoms are apart.[2c] We assumed that the difference is due mainly to the size of the ligand molecule;[1] consequently, the titled complexes, where the benzamide (bza) ligand is larger than dma, are expected to have different oxygen-atom positions around the central metal atom.

Among the series of titled complexes, the best crystals were obtained for Nd(III) complex. Therefore, its structure was determined by the single-crystal X-ray diffraction method.

Attempts to obtain similar complexes of lanthanoid heavier than gadolinium has not been successful until now; in these cases, other isomorphous complexes with the formula of $[M(iPr_2dtp)_2(bza)_3]^+(iPr_2dtp)^-$ (where M=Gd, Tb, Dy, Er, and Yb) were obtained. The details about them will be shown in a separate paper.[8]

Experimental

Synthesis of Bis(benzamide)tris(O,O'-diisopropyl dithiophosphato)neodymium(III). Neodymium(III) chloride hexahydrate (0.5 g, 1.4 mmol) and sodium *O,O'*-diisopropyl dithiophosphate (1.5 g, 6.3 mmol)[1] were dissolved in 25 cm^3 of 2-propanol, and the mixture was refluxed for about 20 min at 80 °C to complete the reaction. The solution was then filtered off, and about 0.5 g (4.1 mmol) of benzamide was added to the filtrate. It was warmed and kept at about 65 °C for 5 min to terminate the reaction. The solution was then evaporated almost to dryness by the use of a rotary vacuum evaporator at 65 °C. The residue was dissolved in 5 cm^3 of 2-propanol, the turbid materials were filtered off, and the clear filtrate was kept in a silica-gel desiccator for several days. The deposited crystals were filtered off, washed with small portions of 2-propanol and diisopropyl ether, in that order, and dried in a vacuum desiccator. The yield was about 0.7 g (0.7 mmol, 49%).

The isomorphous complexes of La, Ce, and Pr(III) were obtained in almost the same way. In the cases of the Sm and Eu(III) complexes, the crude product was obtained by adding 10 cm^3 of diisopropyl ether to the evaporating residue. Their crystals were obtained when they were dissolved in 5 cm^3 of 2-propanol; then were subsequently kept in the diisopropyl ether-vapor moiety. In all cases, the yield was about 50% calculated from the starting metal salt.

In the case of the Gd(III) complex, 0.49 g (1.3 mmol) of gadolinium chloride hexahydrate and 1.29 g (5.5 mmol) of sodium *O,O'*-diisopropyl dithiophosphate were used as the starting materials. The added benzamide should be less than 0.33 g (2.7 mmol). About 10 cm^3 of diisopropyl ether was added to the solution before it was placed in a desiccator to obtain the crystals. The yield was 0.63 g (0.6 mmol, 47%). (If the mol ratio of benzamide to the metal salt was higher, the $[Gd(iPr_2dtp)_2(bza)_3]^+(iPr_2dtp)^-$-type complex was mainly deposited).

The results of the elemental analyses, their average yields, and their magnetic moments as measured by a Gouy balance at the ambient temperature are shown in Table 1.

Intensity-data Collection. A crystal with dimensions of 0.4×0.4×0.25 mm^3 was used for the measurement without shaping. The crystallographic data are $NdC_{32}H_{56}N_2O_8P_3S_6$, $F.W.=1026.36$, monoclinic, space group C2/c, $Z=16$, $a=28.887(4)$, $b=28.913(5)$, $c=24.814(5)$ Å $\beta=106.72(1)°$, $U=$

a) 1 BM=$9.274078(36)\times10^{-24}$ J T^{-1}

19, 848(6) Å^3, D_x=1.37, D_m=1.36(3) Mg m^{-3}, μ(Mo $K\alpha$)=1.47 mm^{-1}. The reflections whithin the range of $3°<2\theta<48°$ were collected on a Rigaku AFC-6A automated four-circle diffractometer with graphite monochromated Mo $K\alpha$ radiation, the ω-scan technique being employed (scan speed: 4° min^{-1}; scan width: $1.40+0.5\tan\theta°$). The crystal was stable during the exposure to X-rays. From the 10017 independent reflections thus measured, 7761 with $|F_o|>3\sigma(|F_o|)$ were selected and used for the structure determination. The intensities were corrected for the Lorentz and polarization factors, but no correction was made for absorption and extinction.

Structure Determination. The structure was solved by the heavy-atom method. The positions of the Nd, P, and S atoms were deduced from a three-dimensional Patterson map; the other non-hydrogen atoms were located by means of successive Fourier syntheses. Their positional, isotropic, and then anisotropic thermal parameters were refined by the block-diagonal least-squares method. All the calculations were carried out on a HITAC M-200H computer at the Computer Center of the University of Tokyo, using the local version of the UNICS program system.[9] The atomic-scattering factors were taken from the tables.[10]

Although the positional and thermal parameters of the central Nd(III) atoms, as well as those of the other atoms near them, were exactly determined, those of some isopropyl groups and of some phenyl rings were found to have relatively large standard deviations; this may be due to the fact that they are not fixed tightly in the crystal. As is shown in Table 2, the thermal parameters of some isopropyl carbon atoms are very large; therefore, we can know only the probable domains, not the exact positions, of some atoms, even after the repeated-refinement process, although they converged to the respective values. The position of C(226) was not decided. The seven carbon atoms of the phenyl groups, C(11C), C(11D), C(11E), C(11F), C(31D), C(31E), and C(31F), were fixed at the positions calculated from those of the vicinal atoms; their isotropic temperature factors were assumed to be 16.0 Å^2. In the final cycle of the refinement, the parameter shifts of the atoms were less than one-third of the corresponding standard deviations.

The final R value was 0.066.[11]

Other Measurements. The X-ray powder patterns of these complexes were obtained by the use of a diffractometer, Model DX-GO-F JEOL, using Cu Kα radiation, in the range from 6° to 40° in 2θ. The infrared spectra of the samples were obtained by means of a JASCO A202 grating infrared spectrophotometer, using Nujol and hexachloro-1,3-butadiene mull. The near-ultraviolet absorption spectra of the complexes were measured with a Hitachi 124 spectrophotometer.

Results and Discussion

The final atomic parameters of the title complex are listed in Table 2.[12] The sixteen neodymium(III) atoms in one unit cell are divided into three groups. The Nd(1) atom is at a general equivalent position, while the Nd(2) as well as Nd(3) atoms and P(21) as well as P(31) atoms take special equivalent positions on the two-fold axes (Wyckoff notation: e). Some bond lengths and bond angles of the complex are shown in Table 3.[13] The general features of the three types of complex molecules are almost the same; their corresponding bond lengths and bond angles are compared in the table.

A perspective drawing of the complex around the central metal Nd(1) atom is shown in Fig. 1. The numbering scheme of the ligand atoms is shown in Fig. 2, and the configuration of the ligating atoms around the Nd(1) atom, in Fig. 3.

Each complex molecule is isolated, and no bridgings are found between them. However, as is shown in Table 2, some interatomic distances between S and N atoms are shorter than 3.5 Å; these may be the hydrogen bonds, since the S···H–N hydrogen bond length has been reported to be about 3.42 Å between S and N atoms.[14] As is shown in Fig. 3, the central Nd(III) atom is octa-coordinated and is in a distorted dodecahedron geometry, where three iPr_2dtp ligands span at two m edges of a trapezium and one a edge of the other trapezium, chelating by both of the sulfur atoms. Two oxygen atoms of bza ligands take the two tip positions of the base edge of the latter trapezium. Five atoms, including the central metal atom, of each trapezium of each complex are almost on one plane (the deviation of each atom's position from the plane was 0.267 Å in the maximum and 0.12 Å on the average), and the dihedral angle between the two planes of each complex is almost right-angled (88.7—90.2°).[13]

a) The equivalent isotropic temperature factors were computed using the following expression; $B_{eq}=4/3(B_{11}a^2+B_{22}b^2+B_{33}c^2+B_{13}ac\cos\beta)$. The B_{ij}'s are defined by; $\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2klB_{23}+2hlB_{13}+2hkB_{12})]$.

As is shown in Table 3, all the Nd-S bond lengths are in the range from 2.888(6) to 2.988(5) Å; they are almost equal. Taking the difference in the ionic radii of La^{III} and Nd^{III} (1.160 and 1.109 Å respectively)[15] into consideration, they are comparable with the La-S bond lengths of $La(iPr_2dtp)_3(bza)_2$, which range from 2.998(3) to 3.046(7) Å.[1] All the P-S bond lengths are not very different, either; they are in the range of 1.943(8)—1.961(7) Å, except for S(122)-P(12) (1.982(8) Å); it is likely that the P=S double bond of the ligand is almost completely delocalized. Although in some cases the respective lengths of the pair of Nd-S and of P-S of each ligand are different from each other, there is probably no general rule such as that the sulfur

a) $n=1$, 2 or 3 means the numbering of the central metal atom. Keys to the symmetry operations: i $-x$, y, $0.5-z$; ii $1.0-x$, y, $0.5-z$; iii $0.5-x$, $-0.5+y$, $0.5-z$. The symmetry operations for the atoms around Nd(n) ($n=2$ or 3) in the bond-angle columns are: b) i for $n=2$, and original for $n=3$; c) original for $n=2$, and ii for $n=3$; d) i for $n=2$, and ii for $n=3$.

atom of a longer P-S has the shorter Nd-S bond. The nitrogen atoms of bza ligands are not ligated to the central metal atom; the average Nd···N distance is 4.040 Å. The Nd-O bond lengths of this complex are about 0.047 Å shorter than those of the La(iPr$_2$dtp)$_3$-(dma)$_2$; this difference is also comparable to the difference in the ionic radii of Nd^{III} and La^{III}.[15] Therefore, the Nd-O bond lengths are shorter than those of the common oxygen-atom-ligating lanthanoid complexes (2.5 Å),[16,17,18] as in the case of the dma adduct of lanthanum.[1]

The positions of the coordinating oxygen atoms

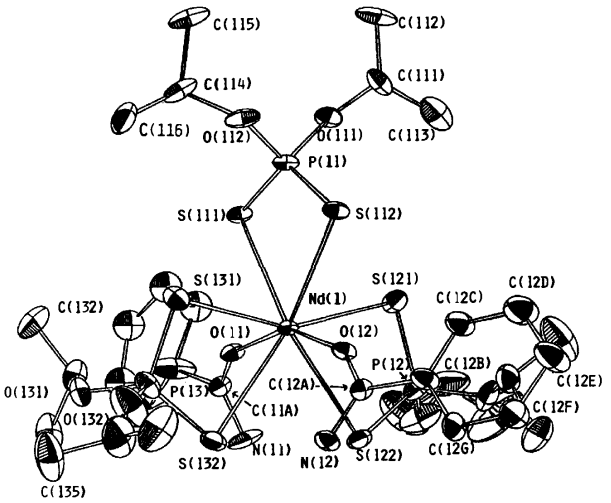

Fig. 1. A perspective drawing of the neodymium-(III) complex around Nd(1) atom with numbering scheme.

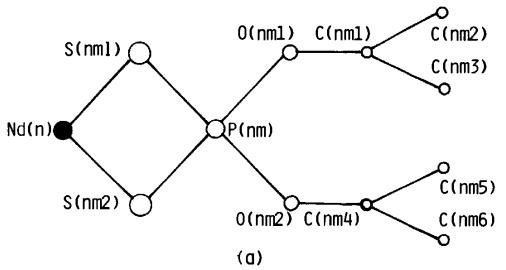

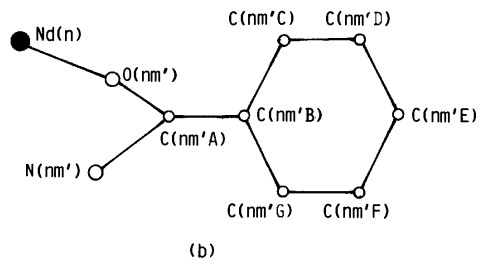

Fig. 2. Numbering scheme of the ligand atoms. a) iPr2dtp (where *n*: numbering of the central Nd(III) atom, 1—3; *m*: numbering of each iPr2dtp ligand, 1—3). b) bza (where *n*: numbering of the central Nd(III) atom, 1—3; *m'*: numbering of each bza ligand, 1—2).

of the title complex are different from those of the La(iPr2dtp)3(dma)2. This discrepancy is probably due to the bulkiness of the bza molecule. Although Pinkerton wrote that La(Et2dtp)3{(C6H5)3PO}2 is in a deformed square-antiprism geometry,[2c] it can also be regarded as in the deformed dodecahedron geometry. According to the latter aspect, two coordinating oxygen atoms of the complex take positions of the two tips of the base edge of a trapezium, like the titled complex.

The powder X-ray diffraction patterns of the M-(iPr2dtp)3(bza)2 (where M=La, Ce, Pr, Nd, Sm, Eu, and Gd) complexes show that they are all isomorphous.

The infrared-absorption spectral pattern of the title complex, benzamide, Na[Nd(iPr2dtp)4], and Na-

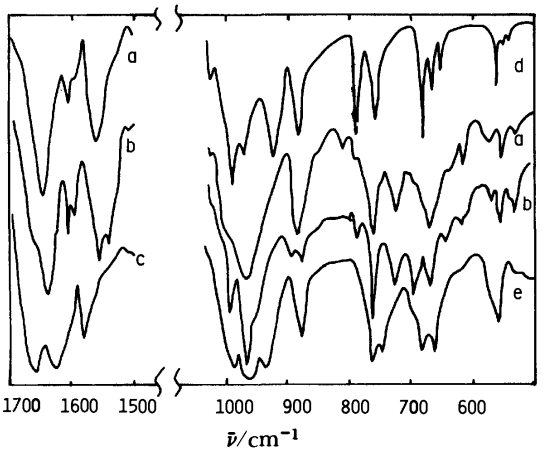

Fig. 4. Infrared spectra of the complex and some related compounds. a: [Nd(iPr2dtp)3(bza)2], b: [Er-(iPr2dtp)2(bza)3](iPr2dtp), c: bza, d: Na[Nd(iPr2dtp)4], e: Na(iPr2dtp).

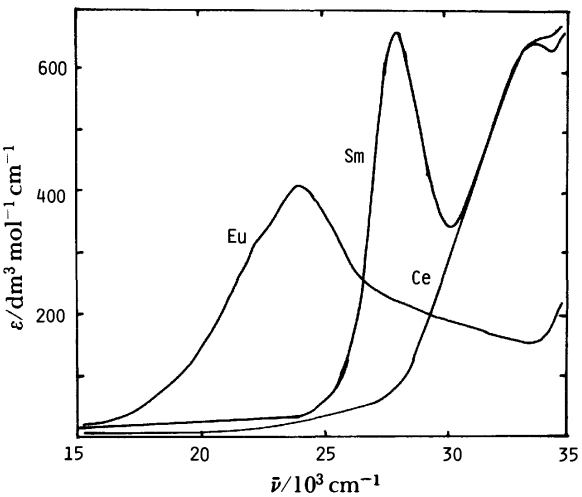

Fig. 5. Electronic spectra of [M(iPr2dtp)3(bza)2] type complexes (M=Ce, Sm, and Eu).

(iPr2dtp) are shown in Fig. 4. As all of the isomorphous complexes show almost the same spectral pattern, only the spectra of the neodymium(III) complex are shown. The amide I and II bands of bza appear at about 1660, 1623, and 1578 cm^{-1}, the former one seeming to split into two peaks. In the spectra of the neodymium complex, the corresponding peaks appear in a wave-number region about 20 cm^{-1} lower. The bands characteristic of the iPr2dtp ligand, ν_s(P–S)+ν_s(P–O), ν_{as}(P–O), and ν_{as}(P–S), which were expected to be found near the

700-cm^{-1} region, appeared at 783, 748, and 676 cm^{-1} in the spectra of the title complex. Their wave numbers are a little lower than those of the corresponding peaks of $Na[Nd(iPr_2dtp)_4]$.

The ultraviolet absorption spectra of the type of the cerium, samarium, and europium complexes in acetonitrile solutions (about 0.4—1.0×10^{-2} mol dm^{-3} in concentration) are shown in Fig. 5. The samarium and europium complexes show a very strong absorption in this region (Sm complex: ν_{max}=3.39×10^4 cm^{-1}, ε_{max}=6.4×10^2 dm^3 mol^{-1} cm^{-1}; Eu complex: ν_{max}= 4.27×10^4 cm^{-1}, ε_{max}=4.2×10^2 dm^3 mol^{-1} cm^{-1}). This kind of band has already been found in the spectra of the lanthanoid complexes where sulfur atoms ligate the central metal atom, and it has been assigned as a charge-transfer band.[3,5,19] However, these iPr_2dtp–bza mixed complexes are found to be more stable than any other compounds ever reported which show the absorption band.

The authors are greatly obliged to the Shin-Etsu Chemical Co., Ltd., for aiding this study by presenting the highly pure lanthanoid oxides. They also wish to thank Professor Yoichi Iitaka, The Faculty of Pharmaceutical Sciences, The University of Tokyo, for aiding in the calculations of this study. The present work was partially supported by a Grant-in-Aid for Scientific Research (No. 57430011) from the Ministry of Education, Science, and Culture.

A Nuclear Magnetic Resonance Study of the Kinetics of Ligand Exchange Reactions in Uranyl Complexes. VI. *N,N*-Dimethylformamide Exchange in Bis(acetylacetonato) (*N,N*-dimethylformamide)dioxouranium(VI)

Yasuhisa IKEDA, Hiroshi TOMIYASU, and Hiroshi FUKUTOMI*

Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received May 4, 1984)

The exchange reaction of *N,N*-dimethylformamide(dmf) in $[UO_2(acac)_2dmf]$(acac=acetylacetonato) has been studied by the NMR line-broadening method in CD_3COCD_3 and CD_2Cl_2. In CD_3COCD_3, the rate of dmf exchange is independent of the free DMF concentration. The rate constant(s^{-1}) at 25 °C and activation parameters $\Delta H^{\ddagger}$(kJ mol^{-1}) and $\Delta S^{\ddagger}$(JK^{-1} mol^{-1}) are 1.19×10^3, 42.0±1.3, and −45.8±5.5, respectively. In CD_2Cl_2, the exchange rate depends on the free DMF concentration. The exchange rate constant (k_{ex}) is expressed by $k_{ex}=k_1+k_2$[DMF], where k_1(25 °C)$=1.90\times10^2$ s^{-1}, $\Delta H^{\ddagger}=32.8\pm1.7$ kJ mol^{-1}, and $\Delta S^{\ddagger}=-92.0\pm5.9$ JK^{-1} mol^{-1}, and k_2 (25 °C)$=5.66\times10^3$ M^{-1} s^{-1}(1M=1 mol dm^{-3}), $\Delta H^{\ddagger}=37.0\pm2.1$ kJ mol^{-1}, and $\Delta S^{\ddagger}=-49.6\pm8.8$ JK^{-1} mol^{-1}. The D and I mechanisms are proposed for the dmf exchange in $[UO_2(acac)_2$ dmf].

The uranyl β-diketonato complexes, $[UO_2(\beta$-diketonato$)_2L]$ (L=adduct ligand) have been studied extensively in view of the extraction of uranyl ions[1] and the IR laser separation of uranium isotopes.[2] In particular, the synergistic effect on the extraction[1] and the relationship between the bond-strength and basicity[3] have been studied for the adduct ligands. However, only limited kinetic data are available with respect to the reactivity of adduct ligands.[4,5]

Recently, we studied exchange reactions of dimethyl sulfoxide(dmso) in $[UO_2(acac)_2$dmso] and $[UO_2(dbm)_2$ dmso] (dbm=dibenzoylmethanate) by using NMR[6] and proposed the exchange mechanism to be either D or I.[7] The dmso exchange rates in these complexes are much slower than that in $[UO_2(dmso)_5]^{2+}$.[8] This result suggests that the steric hindrance is regarded as significant for the ligand exchange reactions in uranyl complexes. In order to examine the steric effect on the ligand exchange reaction in uranyl complexes and the relationship between the reactivity and basicity of adduct ligands, the exchange reaction of dmf in $[UO_2(acac)_2\cdot$dmf] was studied and compared with the dmso exchange in $[UO_2(acac)_2$dmso] and the dmf exchange in $[UO_2(dmf)_5]^{2+}$.[9]

Experimental

The $[UO_2(acac)_2$dmf] complex was prepared by the same method as described in a previous paper.[5] Calcd for $[UO_2(acac)_2$dmf]: C, 28.84; H, 4.28; N, 2.59. Found: C, 28.79; H, 3.89; N, 2.55. Acetone-d_6 (CD_3COCD_3, Merck 99.8%) and dichloromethane-d_2 (CD_2Cl_2, Merck 99%), which were used as solvents, were dried over 3A and 4A molecular sieves (Wako Pure Chemical Ind. Ltd.), respectively. *N,N*-Dimethylformamide (Wako) was distilled over barium oxide *in vacuo*, followed by distillation with molecular sieves, and stored over 3A molecular sieves. Sample solutions for NMR measurements were prepared by weighing the complex, DMF and solvents in a 1 cm^3 volumetric flask and some of each solution was placed in an NMR sample tube and sealed. All samples were prepared in a glove box filled with dried nitrogen. The measurement of the ^1H NMR spectra was carried out at 100 MHz on a JEOL JNM FX-100 FT-NMR spectrometer equipped with a JNM-VT-3B temperature controller. The infrared spectra of $[UO_2(acac)_2\cdot$dmf] in CD_2Cl_2 were recorded in the 200—4000 cm^{-1} range by using a JASCO DS-701G IR spectrophotometer. The dmf exchange reaction in $[UO_2(acac)_2$dmf] was measured by the NMR linebroadening method. The kinetic parameters were calculated by using a computer program on the assumption of a two-site exchange process as described in the previous paper.[5]

Results and Discussion

The Structure of $[UO_2(acac)_2dmf]$ in Solutions. Figure 1 shows the ^1H NMR spectrum of a solution containing $[UO_2(acac)_2\cdot$dmf], DMF, and CD_3COCD_3 at −75 °C. In the spectrum, signals (a) and (d) are assigned to the methyl protons and the 3-H protons of coordinated acac, respectively, and signals (b) and (c), and signals (e) and (f) are the methyl protons, and the formyl protons of free and coordinated DMF, respectively. The area ratio of (f) to (d) to (c) to (a) was 1:2:6:12, and this ratio remained constant in solutions i, ii, and iii listed in Table 1. This fact indicates

TABLE 1. SOLUTION COMPOSITION AND KINETIC PARAMETERS FOR THE EXCHANGE OF dmf IN $[UO_2(acac)_2$dmf]

Solution	$[UO_2(acac)_2dmf]$	[DMF][a]	$[CD_3COCD_3]$	$[CD_2Cl_2]$	$\Delta H^{\ddagger}$	$\Delta S^{\ddagger}$	k_{ex}(25 °C)[b]

a) Added as DMF. b) Calculated values from $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ at 25 °C.

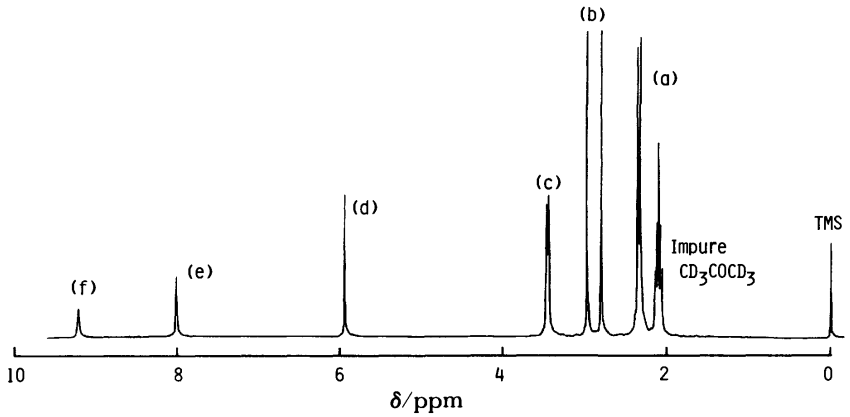

Fig. 1. The ^1H NMR spectrum of a solution containing of $[UO_2(acac)_2dmf]$ (0.0661 M), DMF (0.112 M), and CD_3COCD_3 (13.3 M) at −75°C.

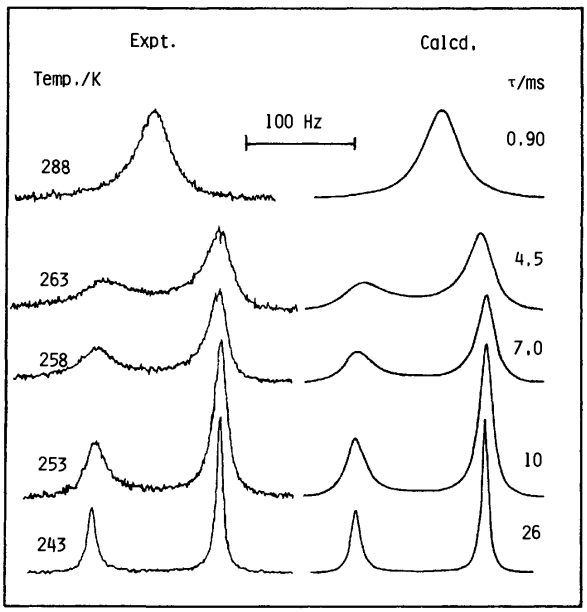

Fig. 2. Experimental (left side) and best-fit calculated lineshapes of a solution containing $[UO_2(acac)_2dmf]$ (0.0661 M), DMF (0.112 M), and CD_3COCD_3 (13.3 M). Temperatures and best-fit t values are shown at left and right sides of the figure, respectively.

that two acac ions and one DMF molecule coordinate to a uranyl ion. The singlet signal of the 3-H protons means that two coordinated acac ions are bidentate ligands. Therefore, the structure of $[UO_2(acac)_2dmf]$ is presumed to be pentagonal bipyramidal, which is the same as those of $[UO_2(acac)_2dmso]$ and $[UO_2(acac)_2\cdot H_2O]$.[6,10] This structure is supported by the separation of the methyl protons of the coordinated acac, because in such a structure the two methyl groups of the coordinated acac are in different magnetic environments, *i.e.* the nearest group to and the farthest group from the coordinated dmf.

In CD_2Cl_2, similar phenomena were also observed in the ^1H NMR spectra. The IR spectra of $[UO_2(acac)_2dmf]$ measured in CD_2Cl_2 showed that the C–O stretching for the coordinated dmf was observed at 1652 cm^{-1}, which was 27 cm^{-1} lower than that observed in pure DMF (1675 cm^{-1}). It has been known that the C–O stretching, so-called Amide I, will shift to a lower side when DMF coordinated through oxygen.[11,12] Hence, the observed band of C–O stretching indicates that dmf in $[UO_2(acac)_2dmf]$ is coordinated through oxygen. In addition, only one band corresponding to the carbonyl vibration of coordinated acac was observed at 1574 cm^{-1}. This result indicates that acac ions in $[UO_2(acac)_2dmf]$ are coordinated as the bidentate, since the frequency less than 1600 cm^{-1} is characteristic of the carbonyl vibration of chelated metal β-diketonato complexes.[13] On the basis of these results, it is concluded that $[UO_2(acac)_2dmf]$ has a pentagonal bipyramidal structure in CD_3COCD_3 and CD_2Cl_2.

dmf Exchange in $[UO_2(acac)_2dmf]$. The formyl proton signals of the coordinated and free DMF were measured at various temperatures. Results are shown in Fig. 2. This figure shows that DMF molecule exchanges between the coordinated and free sites. The best-fit life times (τ values) were determined by using a computer program for the two-site exchange[14] and are shown at the right side in Fig. 2 together with the corresponding line shapes. From these τ values, the first-order rate constants, k_{ex}, were calculated by the following equations, where τ and P with the subscripts f and c are the life times and mole fractions of the free and coordinated sites, respectively.

$$\tau = P_f\tau_c = P_c\tau_f \quad (1)$$

$$k_{ex} = 1/\tau_c = \text{rate}/[UO_2(acac)_2dmf] = (kT/h)\exp(-\Delta H^*/RT)\exp(\Delta S^*/R), \quad (2)$$

The same measurements were carried out for the solutions with different compositions listed in Table 1. In Fig. 3, the values of k_{ex} are plotted semi-logarithmically against the reciprocal temperature. The activation parameters obtained from Fig. 3 are listed in Table 1. As can be seen in Fig. 3 and Table 1, the exchange rate of dmf in CD_3COCD_3 is independent of [DMF], while that in CD_2Cl_2 is dependent on [DMF]. Plots of k_{ex} values against [DMF] are linear in CD_2Cl_2(Fig. 4) and result in the following equation.

$$k_{ex} = k_1 + k_2[DMF] \quad (3)$$

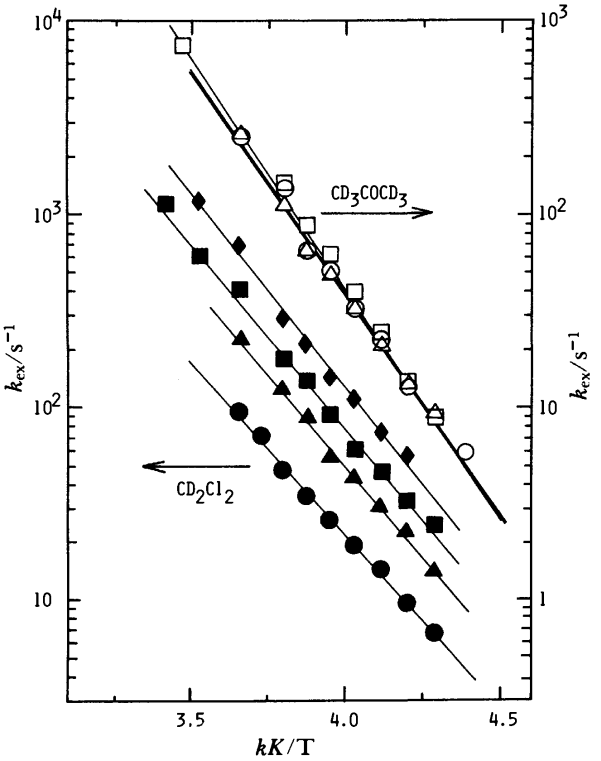

Fig. 3. Semilogarithmic plots of k_{ex} against the reciprocal temperature for the exchange of dmf in $[UO_2(acac)_2dmf]$ in CD_3COCD_3 and CD_2Cl_2. The symbols of ○, △, □, ●, ▲, ■, and ◆, correspond to i, ii, iii, iv, v, vi, and vii solutions in Table 1.

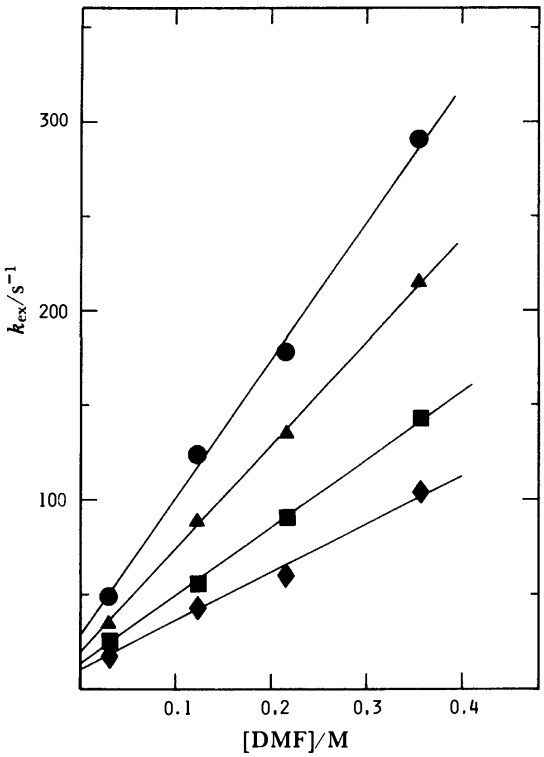

Fig. 4. plots of k_{ex} *vs.* [DMF] for the exchange of dmf in $[UO_2(acac)_2dmf]$ in CD_2Cl_2. ●: −10°C; ▲: −15°C; ■: −20°C; ◆: −25°C.

The values of k_1 and k_2 were obtained from the intercepts and the slopes of the plots in Fig. 4 by means of the least-squares method, and are listed in Table 2. The activation parameters for these pathways are given in Table 1.

Exchange Mechanism. The exchange rate of dmf in $[UO_2(acac)_2\cdot dmf]$ in CD_3COCD_3 is independent of the free DMF concentration. This result suggests that the dmf exchange in CD_3COCD_3 proceeds through either the D or I mechanism.[7] In the D mechanism, the exchange processes are expressed as

$$UO_2(acac)_2dmf + DMF^* \xrightarrow[\text{slow}]{k_d} UO_2(acac)_2 + DMF + DMF^* \xrightarrow[\text{fast}]{} UO_2(acac)_2dmf^* + DMF, \quad (4)$$

where an asterisk is used to denote the exchanging species. In this mechanism, the rate-determining step is the dissociation of the coordinated dmf from $[UO_2(acac)_2dmf]$. Thus, k_{ex} is given by

$$k_{ex} = k_d \quad (5)$$

In the I mechanism, the exchange processes are represented as follows.

$$UO_2(acac)_2dmf + DMF^* \underset{\text{fast}}{\overset{K_{os}}{\rightleftharpoons}} UO_2(acac)_2dmf\cdots DMF^* \xrightarrow[\text{slow}]{k_I} UO_2(acac)_2dmf^*\cdots DMF \longrightarrow UO_2(acac)_2dmf^* + DMF, \quad (6)$$

where K_{os} is the formation constant of the outer-sphere complex, $UO_2(acac)_2dmf\cdots DMF^*$, and k_I is the rate constant for the interchange of dmf molecule between the first and second coordination spheres. In this mechanism, k_{ex} is given by Eq. (7).

$$k_{ex} = k_I K_{os}[DMF]/(1+K_{os}[DMF]) \quad (7)$$

If $K_{os}[DMF] \gg 1$, Eq. (7) can be simplified as

$$k_{ex} = k_I. \quad (8)$$

Equations (5) and (8) are compatible with the experimental results. However, the I mechanism seems to be unlikely for the following reasons. In the I mechanism, the condition of $K_{os}[DMF] \gg 1$ must be satisfied over the DMF concentration range (0.0383—

Table 2. The values of k_1 and k_2 at various temperatures for the exchange of dmf in $[UO_2(acac)_2dmf]$ in CD_2Cl_2

Temp	k_1	k_2
°C	$10\,s^{-1}$	$10^2\,M^{-1}\,s^{-1}$
−10	2.82±0.72	7.26±0.33
−15	2.01±0.24	5.45±0.11
−20	1.44±0.13	3.56±0.58
−25	1.08±0.38	2.54±0.18

0.112 M) employed in this study. This indicates that K_{os} should be at least larger than 50 M^{-1}. However, such a value of K_{os} is too large considering that the reactants $[UO_2(acac)_2dmf]$ and DMF are both uncharged. On the other hand, the four-coordinated intermediate in the equatorial plane should be formed in the D mechanism. This is supported by the fact that some uranyl complexes, *e.g.* $[UO_2(H_2O)_4]^{2+}$,[15,16] $[UO_2(hmpa)_4]^{2+}$[17] (hmpa=hexamethylphosphoric triamide), exist in solution as a tetragonal bipyramidal structure.

In CD_2Cl_2, the dmf exchange occurs through two pathways as seen in Fig. 4. The k_1 pathway, where the exchange rate is independent of the free DMF concentration, is considered to be the same D mechanism as the dmf exchange in CD_3COCD_3. The k_2 pathway exhibits a first-order dependence with respect to the free DMF concentration and seems to proceed through either the I or A mechanism.[7] In the A mechanism, the dmf exchange processes are expressed as

$$UO_2(acac)_2dmf + DMF^* \xrightarrow[slow]{k_a} UO_2(acac)_2dmf\cdot dmf^* \xrightarrow[fast]{} UO_2(acac)_2dmf^* + DMF, \quad (9)$$

where the rate-determining step is the coordination of DMF to $[UO_2(acac)_2dmf]$, followed by the formation of six-coordinated intermediate in the equatorial plane. Hence, if the dmf exchange in CD_2Cl_2 proceeds through the D and A mechanisms, k_{ex} is given by Eq. (10).

$$k_{ex} = k_d + k_a[DMF] \quad (10)$$

On the other hand, if the dmf exchange proceeds through the D and I mechanisms, k_{ex} is given by Eq. (11).

$$k_{ex} = \frac{k_d + k_I K_{os}[DMF]}{1 + K_{os}[DMF]} \quad (11)$$

When $K_{os}[DMF] \ll 1$, Eq. (11) becomes Eq. (12).

$$k_{ex} = k_d + k_I K_{os}[DMF] \quad (12)$$

Both of Eqs. (10) and (12) are compatible with Eq. (3). Although it has been known that the uranyl ion forms six-coordinated complexes in the equatorial plane with small ligands,[18] the A mechanism for the k_2 pathway seems to be unlikely, because the coordinated acac is a bulky chelating ligand and may make it difficult to form a six-coordinated intermediate in the equatorial plane of $[UO_2(acac)_2dmf]$. On the other hand, if the k_2 pathway proceeds through the I mechanism, the condition of $K_{os}[DMF] \ll 1$ has to be satisfied. This condition seems to be fulfilled in the present exchange reaction, since both of $[UO_2(acac)_2dmf]$ and DMF are uncharged and hence the K_{os} vlaue is expected to be relatively small. In fact, the corresponding K_{os} value to the dmso exchange in$[UO_2(acac)_2dmso]$ in CD_2Cl_2 is *ca.* 5 M^{-1}.[6] Taking into account Gutmann's donor number[19] that the basicity of DMF is smaller than that of DMSO, the K_{os} value for tbe present exchange reaction is supposed to be smaller than 5 M^{-1} and satisfies the condition mentioned above in the DMF concentration range 0.0287 to 0.357 M (Table 1). Therefore, it is suggested that the dmf exchange in $[UO_2(acac)_2dmf]$ in CD_2Cl_2 proceeds through both the D and I mechanisms.

The difference in mechanisms observed in two solvents CD_3COCD_3 and CD_2Cl_2, which was also observed in the dmso exchange in $[UO_2(acac)_2dmso]$ and $[UO_2(dbm)_2dmso]$ in the same two solvents,[6] may primarily be due to the difference in basicity and dielectric constant of these solvents. Acetone has a relatively large basicity compared with dichloromethane and tends to preferentially solvate to the second coordination sphere of $[UO_2(acac)_2dmf]$ under the present experimental conditions. This preferential solvation may block the access of DMF molecule to the outer-sphere of $[UO_2(acac)_2dmf]$. Moreover, the dielectric constant of acetone (20.7) is fairly larger than that of dichloromethane(8.93). These factors may lead to the smaller K_{os} value in CD_3COCD_3 than that in CD_2Cl_2. This is consistent with the results that the dmf exchange in CD_3COCD_3 proceeds through only the D mechanism, while that in CD_2Cl_2 proceeds through both the D and I mechanisms. In spite of the result that the dmf exchange in $[UO_2(acac)_2dmf]$ proceeds through the D and I mechanisms, activation entropies have large negative values. This may be attributed to the contribution of solvent rearrangement around the complex as proposed by Benneto and Caldin.[20]

It is of interest to compare the dmf exchange in $[UO_2(acac)_2dmf]$ with that in $[UO_2(dmf)_5]^{2+}$ and the dmso exchange in $[UO_2(acac)_2dmso]$, whose kinetic parameters are summarized in Table 3. It was not clear which mechanism (I_d or I_a) is reasonable for the dmf exchange in $[UO_2(dmf)_5]^{2+}$. The fact that the dmf ex-

TABLE 3. KINETIC PARAMETERS FOR THIS WORK AND RELATED REACTIONS[a]

change rate in $[UO_2(acac)_2dmf]$ becomes slower than that in $[UO_2(dmf)_5]^{2+}$ suggests that the dmf exchange in $[UO_2(dmf)_5]^{2+}$ proceeds through the I_a mechanism, since if the exchange occurs associatively, the exchange rate is expected to be reduced with crowding at the reaction site. In the ligand(L) exchange in $[UO_2(acac)_2L]$ (L=dmso or dmf) proceeding through the D mechanism, the rate constant for the dmf exchange is larger than that for the dmso exchange. This may be due to the fact that the basicity of DMF is smaller than that of DMSO, and hence the bond-strength between UO_2^{2+} and dmf in $[UO_2(acac)_2dmf]$ is expected to be weaker than that between UO_2^{2+} and dmso in $[UO_2(acac)_2dmso]$, because the rate-determining step is the dissociation of dmf or dmso in the D mechanism. This is supported by the result that the ΔH^* value for the dmf exchange is smaller than that for the dmso exchange. Since the kinetic parameters in the I mechanism for the dmf exchange in $[UO_2(acac)_2dmf]$ are obtained for k_1K_{os}, it is difficult to compare directly with the kinetic parameters for the dmso exchange in $[UO_2(acac)_2dmso]$. The K_{os} value is considered to be smaller than that for the dmso exchange in $[UO_2(acac)_2dmso]$ (*ca.* $5\,M^{-1}$). Therefore,the k_1 value for the dmf exchange in $[UO_2(acac)_2dmf]$ should be larger than $1.01\times10^3\,s^{-1}$ (Table 3) for the dmso exchange in $[UO_2(acac)_2\cdot dmso]$. This suggests that the I mechanism for the exchange of L in $[UO_2(acac)_2L]$ (L=dmso or dmf) is not I_a but I_d on the basis of the same reasons as described above. It might be concluded that the D mechanism is the major process for the exchange of L in $[UO_2(\beta\text{-diketonato})_2L]$ complexes because of the steric hindrance.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 57470035 from the Ministry of Education, Science and Culture, and by the International Joint Research Program sponsored by the Japan Society for the Promotion of Science.

Magnetic Circular Dichroism and Electronic Absorption Spectra of Mixed (Amine)(carboxylato) Complexes with the $[Pd(N)_n(O)_{4-n}]$-type (n=0—4)

Kazuhiko NAKAYAMA,* Takashi KOMORITA, and Yoichi SHIMURA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received March 29, 1984)

Mixed-ligand $[Pd(N)_n(O)_{4-n}]$-type complexes constituting a long systematic series (n=0—4) were synthesized. Ammonia, ethylenediamine, *rac*-propylenediamine, trimethylenediamine, glycinate, β-alaninate, acetate, oxalate, and malonate were employed as ligands. Their magnetic circular dichroism (MCD) and electronic absorption spectra were discussed together with the CD spectra of the corresponding optically active complexes. The results strongly suggest that the dispersion of MCD observed in the spin-allowed d-d region is primarily a composite of B terms. Moreover, the MCD in the charge transfer region was found to be qualitatively additive with respect to contributions by the constituent ligands. From a detailed examination of the spin-allowed d-d absorption bands, it is noted that the substitution of an *N,O*-ligand for an *N,N*-ligand largely affects neither the band area nor band width whereas that of an *O,O*-ligand for an *N,O*-ligand does.

The concurrent examination of absorption, magnetic circular dichroism(MCD), and CD spectra furnished useful information on the electronic structures of *cis*- and *trans*- $[Pd(Cl)_2(N)_2]$-type complexes.[1] In the preceding paper,[2] we reported the synthesis of a large number of mixed-ligand $[Pd(N)_n(O)_{4-n}]$-type complexes with at least one optically active ligand and the detailed investigation of the CD spectra.

In the present work, optically inactive $[Pd(N)_n(O)_{4-n}]$-type complexes were synthesized corresponding to the previous optically active comlexes,[2] and their MCD spectra were examined. Although most of the former complexes were found to be more labile than the latter, the systematized synthetic methods developed previously[2] were effective. Ammonia, ethylenediamine(en), *rac*-propylenediamine(*rac*-pn), and trimethylenediamine(tn) were employed as *N*- or *N,N*-ligands; glycinate(gly) and β-alaninate(β-ala) were as *N,O*-ligands; and acetate, oxalate(ox), and malonate(mal) were as *O*- or *O,O*-ligands. Di-μ-hydroxodipalladium complexes were also obtained. Although these complexes, if approximated by a D_{4h} symmetry, are expected to exhibit A-term MCD based on $^1E_g \leftarrow {}^1A_{1g}$ in the d-d transition region, our spectral examination indicates that the contribution of the A term is minor and that inherent B terms generally predominate irrespective of the symmetries of the complexes, unlike in the case of $[MCl_4]^{2-}$ (M=Pt and Pd)[3] and *cis*-$[Pd(Cl)_2(N)_2]$-type complexes.[1] Although three or four spin-allowed d-d transitions should occur in a D_{4h} or lower symmetries, the spin-allowed d-d absorption bands of the series of complexes appear only as a single broad unsymmetrical band. These bands are analyzed in terms of band area and the band shape parameters,[1] and the influence of ligands on the band shape and band area is discussed.

Experimental

$[Pd(N)_4]$-type Complexes. *1) $[Pd(NH_3)_4](ClO_4)_2$*: This complex was obtained by metathesis of the corresponding chloride with the calculated amount of silver perchlorate. Found: H, 3.33; N, 14.97%. Calcd for $H_{12}N_4Cl_2O_8Pd$: H, 3.24; N, 15.00%.

2) $[Pd(en)(NH_3)_2]Cl_2$: This complex was prepared in the same manner as for $[Pd(S\text{-pn})(NH_3)_2]Cl_2$,[2] but ethanol was used for crystallization in place of ether. Yield: 70%. Found: C, 8.99; H, 5.20; N, 20.52%. Calcd for $C_2H_{14}N_4Cl_2Pd$: C, 8.85; H, 5.20; N, 20.64%.

3) $[Pd(en)(tn)]Cl_2$: This was prepared from $[PdCl_2(en)]$ in the same way as for $[Pd(S\text{-pn})(tn)]Cl_2$[2] but crystallized from a methanol–ethanol medium instead of an ethanol–ether one. Yield: 80%. Found: C, 19.23; H, 5.79; N, 17.94%. Calcd for $C_5H_{18}N_4Cl_2Pd$: C, 19.28; H, 5.82; N, 17.98%.

4) $[PdL(N,N\text{-}Et_2en)]Cl_2$ (L=en and tn): These complexes were prepared by methods similar to those for the corresponding (2*S*)-N^1,N^1-diethyl-1,2-propanediamine(N^1,N^1-Et_2-(*S*)-pn) complexes.[2] Yield: 75—85%. Found: C, 24.79; H, 7.20; N, 14.32%. Calcd for $[Pd(en)(N,N\text{-}Et_2en)]Cl_2\cdot 2H_2O$=$C_8H_{28}N_4Cl_2O_2Pd$: C, 24.66; H, 7.24; N, 14.38%. Found: C, 28.20; H, 7.31; N, 14.55%. Calcd for $[Pd(tn)(N,N\text{-}Et_2en)]Cl_2\cdot H_2O$=$C_9H_{28}N_4Cl_2OPd$: C, 28.03; H, 7.32; N, 14.53%.

5) $[PdL_2]Cl_2$ (L=N,N-Et₂en and N,N,C,C-Me₄en):[4] These were obtained in a way similar to that for $[Pd(N^1,N^1\text{-}Et_2\text{-}(S)\text{-pn})_2]Cl_2$.[5] Found: C, 35.15; H, 7.92; N, 13.63%. Calcd for $[Pd(N,N\text{-}Et_2en)_2]Cl_2$=$C_{12}H_{32}N_4Cl_2Pd$: C, 35.18; H, 7.87; N, 13.67%. Found: C, 32.40; H, 8.14; N, 12.61%. Calcd for $[Pd(N,N,C,C\text{-}Me_4en)_2]Cl_2\cdot 2H_2O$=$C_{12}H_{36}N_4Cl_2O_2Pd$: C, 32.33; H, 8.14; N, 12.57%.

6) Other Complexes: The complexes $[Pd(en)_2]Cl_2$ and $[Pd(tn)_2]Cl_2$ were obtained according to the method described in the literature[6] or the one similar to it. Found: C, 16.18; H, 5.43; N, 18.83%. Calcd for $[Pd(en)_2]Cl_2$=$C_4H_{16}N_4Cl_2Pd$: C, 16.15; H, 5.42; N, 18.83%. Found: C, 22.20; H, 6.24; N, 17.14%. Calcd for $[Pd(tn)_2]Cl_2$=$C_6H_{20}N_4Cl_2Pd$: C, 22.13; H, 6.19; N, 17.21%.

$[Pd(N)_3(O)]$-type Complexes. *1) $[Pd(gly)(NH_3)_2]ClO_4$*: Silver perchlorate (246 mg) and freshly prepared silver oxide (140 mg) were successively added to a suspension of 250 mg of *cis*-$[PdCl_2(NH_3)_2]$[7] in 10 cm^3 of water and the mixture was stirred at room temperature for 10 min in the dark. Immediately after removal of the silver chloride the filtrate was mixed with an aqueous solution (1 cm^3) of 89 mg of glycine, evaporated to *ca.* 4 cm^3 under reduced pressure, and chilled in an ice-bath. After 2 h lemon yellow crystals were collected, washed with cold water, and dried in air. Yield: 200 mg. Found: C, 7.73; H, 3.27; N, 13.34%. Calcd for $C_2H_{10}N_3ClO_6Pd$: C, 7.65; H, 3.21; N, 13.38%.

2) $[Pd(gly)L]ClO_4$ (L=en and tn): Each of these complexes was prepared by the method adopted for $[Pd(S\text{-ala})(S\text{-pn})]ClO_4$[2] but crystallized from a water–methanol medium. The crude product was recrystallized from warm water (*ca.* 60 °C). Yield: 55 (en) and 75% (tn complex). Found: C, 14.31; H, 3.60; N, 12.36%. Calcd for $[Pd(gly)(en)]ClO_4$=$C_4H_{12}N_3ClO_6Pd$: C, 14.13; H, 3.56; N, 12.36%. Found: C, 17.09; H, 4.03; N, 11.92%. Calcd for $[Pd(gly)(tn)]ClO_4$=$C_5H_{14}N_3ClO_6Pd$: C, 16.96; H, 3.99; N, 11.87%.

3) $[Pd(\beta\text{-ala})L]ClO_4$ (L=en and tn) and [Pd(N-Megly)(en)]-

ClO$_4$: These complexes were prepared and crystallized in the same way as for [Pd(*S*-ala)(*S*-pn)]ClO$_4$.[2] The β-ala complexes were recrystallized from warm water, by adding acetone if necessary. Yield: 50 (en) and 70% (tn) for the β-ala complexes; and 90% for the *N*-Megly (=sarcosinato) complex. Found: C, 17.15; H, 4.06; N, 11.76%. Calcd for [Pd(β-ala)(en)]ClO$_4$=$C_5H_{14}N_3ClO_6Pd$: C, 16.96; H, 3.99; N, 11.87%. Found: C, 19.68; H, 4.40; N, 11.37%. Calcd for [Pd(β-ala)(tn)]ClO$_4$=$C_6H_{16}N_3ClO_6Pd$: C, 19.58; H, 4.38; N, 11.42%. Found: C, 17.09; H, 4.05; N, 11.85%. Calcd for [Pd(*N*-Megly)(en)]ClO$_4$=$C_5H_{14}N_3ClO_6Pd$: C, 16.96; H, 3.99; N, 11.87%.

cis-[Pd(N)$_2$(O)$_2$]-type Complexes. *1) [Pd(CH$_3$CO$_2$)$_2$L] (L= en and tn)*: Each of these complexes was prepared by the same method as for [Pd(CH$_3$CO$_2$)$_2$(*S*-pn)][2] but crystallized from a water-acetone medium. Yield: 75—80%. Found: C, 24.19; H, 5.21; N, 9.37%. Calcd for [Pd(CH$_3$CO$_2$)$_2$(en)]·0.75H$_2$O= $C_6H_{15.5}N_2O_{4.75}Pd$: C, 24.17; H, 5.24; N, 9.40%. Found: C, 26.57; H, 5.74; N, 8.55%. Calcd for [Pd(CH$_3$CO$_2$)$_2$(tn)]·H$_2$O=$C_7H_{18}N_2O_5Pd$: C, 26.55; H, 5.73; N, 8.85%.

*2) [Pd(ox)L] (L=*rac-*pn and tn)*: These complexes were obtained by the reaction of [PdCl$_2$L] with silver oxalate,[2] in an 85—90% yield. Found: C, 22.36; H, 3.75; N, 10.44%. Calcd for [Pd(ox)(*rac*-pn)]=$C_5H_{10}N_2O_4Pd$: C, 22.36; H, 3.75; N, 10.43%. Found: C, 22.37; H, 3.76; N, 10.46%. Calcd for [Pd(ox)(tn)]=$C_5H_{10}N_2O_4Pd$: C, 22.36; H, 3.75; N, 10.43%.

3) [Pd(ox)(en)] and [Pd(mal)L] (L=cn, rac-*pn, and tn)*: These complexes were prepared by the method adopted for [Pd(mal)(*S*-pn)][2]. Yield: 70—85%. Found: C, 18.84; H, 3.21; N, 10.97%. Calcd for [Pd(ox)(en)]=$C_4H_8N_2O_4Pd$: C, 18.87; H, 3.17; N, 11.01%. Found: C, 22.29; H, 3.78; N, 10.31%. Calcd for [Pd(mal)(en)]=$C_5H_{10}N_2O_4Pd$: C, 22.36% H, 3.75; N, 10.43%. Found: C, 25.56; H, 4.28; N, 9.90%. Calcd for [Pd(mal)(*rac*-pn)]=$C_6H_{12}N_2O_4Pd$: C, 25.50; H, 4.28; N, 9.91%. Found: C, 24.96; H, 4.44; N, 9.72%. Calcd for [Pd(mal)(tn)]·0.33H$_2$O=$C_6H_{12.66}N_2O_{4.33}Pd$: C, 24.98; H, 4.42; N, 9.71%. The complexes [Pd(ox)(en)] and [Pd(mal)(en)] are almost insoluble in water.

4) [Pd(mal)(NH$_3$)$_2$]: A suspension of 200 mg of *cis*-[PdCl$_2$(NH$_3$)$_2$] in 6 cm^3 of water was stirred with 225 mg of freshly prepared silver oxide for 10 min at room temperature. After removal of the silver chloride the filtrate was evaporated to *ca.* 4 cm^3 under reduced pressure and mixed with an aqueous solution (1.5 cm^3) of 98 mg of malonic acid. The reaction mixture was allowed to stand at room temperature to give light orange crystals, which were washed with cold water and methanol and dried *in vacuo*. Yield: 180 mg. Found: C, 14.56; H, 3.47; N, 11.02%. Calcd for [Pd(mal)(NH$_3$)$_2$]·0.5H$_2$O= $C_3H_9N_2O_{4.5}Pd$: C, 14.33; H, 3.61; N, 11.14%. This complex is insoluble in water without decomposition.

5) [Pd(ox)L$_2$] (L=NH$_3$, CH$_3$NH$_2$, and (CH$_3$)$_2$NH): These complexes were prepared from *cis*- or *trans*-[PdCl$_2$L$_2$][1] in the same manner as in 4). Yield: 75—85%. Found: C, 10.20; H, 2.82; N, 11.64%. Calcd for [Pd(ox)(NH$_3$)$_2$]·0.5H$_2$O=$C_2H_7N_2O_{4.5}Pd$: C, 10.11; H, 2.97; N, 11.79%. Found: C, 17.44; H, 4.25; N, 9.95%. Calcd for [Pd(ox)(CH$_3$NH$_2$)$_2$]·H$_2$O= $C_4H_{12}N_2O_5Pd$: C, 17.50; H, 4.41; N, 10.20%. Found: C, 22.22; H, 5.57; N, 8.59%. Calcd for [Pd(ox){(CH$_3$)$_2$NH}$_2$]·2H$_2$O= $C_6H_{18}N_2O_6Pd$: C, 22.48; H, 5.66; N, 8.74%. Every complex is insoluble in water.

6) [Pd$_2$(μ-OH)$_2$L$_2$](ClO$_4$)$_2$ (L=en and tn): An aqueous solution containing each of these complexes was prepared in the same way as for [Pd$_2$(μ-OH)$_2$(*S*-pn)$_2$](ClO$_4$)$_2$.[2] The en complex was crystallized by mixing the concentrated solution with methanol-free acetone (because alcohols reduce the complex to deposit palladium metal), and the tn complex by evaporating and cooling the solution. Yield: 65% for both complexes. Found: C, 8.73; H, 3.29; N, 9.52%. Calcd for [Pd$_2$(μ-OH)$_2$(en)$_2$](ClO$_4$)$_2$=$C_4H_{18}N_4Cl_2O_{10}Pd_2$: C, 8.49; H, 3.21; N, 9.90%. Found: C, 12.28; H, 3.75; N, 9.38%. Calcd for [Pd$_2$(μ-OH)$_2$(tn)$_2$](ClO$_4$)$_2$=$C_6H_{22}N_4Cl_2O_{10}Pd_2$: C, 12.13; H, 3.73; N, 9.43%. The en complex is less stable than the corresponding *S*-pn one and decomposes in a basic aqueous solution, whereas the tn complex is more stable than the latter.

[Pd(N)(O)$_3$]-type Complexes. *1) K[Pd(CH$_3$CO$_2$)$_2$(gly)]*: The starting material K[PdCl$_2$(gly)] was prepared in the same way as for the corresponding *S*-ala complex.[8] Found: C, 7.88; H, 1.95; N, 4.58%. Calcd for K[PdCl$_2$(gly)]·H$_2$O=$C_2H_6NCl_2O_3KPd$: C, 7.79; H, 1.96; N, 4.54%. The electronic absorption (AB) and MCD data in a 0.20 M KCl aqueous solution (1 M=1 mol dm^{-3}) are as follows in $\sigma_{max}/10^3$ cm^{-1}(ε/mol^{-1} dm^3 cm^{-1}) and $\sigma_{ext}/10^3$ cm^{-1} ($\Delta\varepsilon_M$/mol^{-1} dm^3 cm^{-1} T^{-1}), respectively; AB: 19.6sh (13), 25.28 (312) [$\Delta\sigma^-$=2.56 and $\Delta\sigma^+$=2.63],[9] 37.8sh (1900), and 46.23 (19900) and MCD: 23.6 (+0.023), 26.8 (−0.027), 37.1 (+0.23), and 44.0 (−0.6).

The crude product which was obtained by the same method as for K[Pd(CH$_3$CO$_2$)$_2$(*S*-ala)][2] was considerably contaminated with bis(glycinato)palladium(II), and could not be purified by repeated recrystallizations from water-acetone. Orange-brown crystals deposited in the second recrystallization were mechanically separated from faint yellow needles [Pd(gly)$_2$]. Yield: 15%. Found: C, 21.45; H, 3.00; N, 4.17%. Calcd for $C_6H_{10}NO_6KPd$: C, 21.34; H, 2.98; N, 4.15%.

2) K[Pd(mal)(gly)]: This complex was prepared and separated in a manner similar to that in 1). Yield: 30%. Found: C, 18.52; H, 1.94; N, 4.32%. Calcd for $C_5H_6NO_6KPd$: C, 18.67; H, 1.88; N, 4.35%.

3) K[Pd(ox)(β-ala)]: The calculated quantity of a 1 M KOH aqueous solution was added drop by drop to an aqueous suspension containing equimolar amounts of palladium chloride and β-alanine, with stirring at *ca.* 45 °C. After continuous stirring a small amount of undissolved material was filtered off, and the filtrate was concentrated and mixed with acetone. The crude product K[PdCl$_2$(β-ala)] was recrystallized from water-acetone below 50 °C.[10] Found: C, 12.02; H, 2.04; N, 4.66%. Calcd for K[PdCl$_2$(β-ala)]= $C_3H_6NCl_2O_2KPd$: C, 11.83; H, 1.99; N, 4.60%. The AB and MCD data in 0.20 M KCl are as follows in the same format as in 1); AB: 20.0sh (12), 25.66 (360) [$\Delta\sigma^-$=2.23 and $\Delta\sigma^+$= 2.50], 38.4sh (2800), and 46.60 (17300) and MCD: 20 (+0.0008), 24.1 (+0.015), 27.3 (−0.027), 38.3 (+0.26), and 45.8 (−0.41).

An aqueous solution (20 cm^3) containing K[PdCl$_2$(β-ala)] (600 mg) and oxalic acid dihydrate (250 mg) was stirred with freshly prepared silver oxide (460 mg) for 10 min at room temperature. After removal of the silver chloride the filtrate was evaporated to *ca.* 4 cm^3. The product separated was dissolved again in the mother liquor at 50 °C and the resulting solution was allowed to stand at room temperature. Orange crystals were collected after 4 h, washed with a cold mixture of water-acetone, and dried *in vacuo*. Yield: 120 mg. Found: C, 18.59; H, 1.91; N, 4.27%. Calcd for $C_5H_6NO_6KPd$: C, 18.67; H, 1.88; N, 4.35%. Further crops obtained from the mother liquor were contaminated with bis(oxalato)palladium(II) and could not be purified perfectly by recrystallization.

4) K[Pd(mal)(β-ala)]: This complex was prepared in the same manner as in 3), but crystallized from a more concentrated solution. Although the crude product was contaminated with a small amount of [Pd(β-ala)$_2$], it was purified twice by recrystallization from warm water-acetone. Yield: 40%. Found: C, 20.23; H, 2.94; N, 3.94%. Calcd for K[Pd(mal)(β-ala)]·H$_2$O=$C_6H_{10}NO_7KPd$: C, 20.38; H, 2.85; N, 3.96%.

[Pd(O)$_4$]-type Complexes. The complexes K$_2$[Pd(ox)$_2$] and K$_2$[Pd(mal)$_2$] were prepared by a method similar to that reported for K$_2$[Pd(ox)$_2$],[11] but the number of water of crystallization was different from the literature values.[11-13]

Found: C, 12.09; H, 1.00%. Calcd for $K_2[Pd(ox)_2]\cdot 2H_2O$= $C_4H_4O_{10}K_2Pd$: C, 12.11; H, 1.02%. Found: C, 16.20; H, 2.29%. Calcd for $K_2[Pd(mal)_2]\cdot 3H_2O$=$C_6H_{10}O_{11}K_2Pd$: C, 16.28; H, 2.28%. The corresponding platinum(II) complexes, which were prepared for the purpose of comparison, turned out to have analogous compositions (Found: C, 9.99; H, 0.85%. Calcd for $K_2[Pt(ox)_2]\cdot 2H_2O$=$C_4H_4O_{10}K_2Pt$: C, 9.90; H, 0.83%. Found: C, 13.63; H, 1.95%. Calcd for $K_2[Pt(mal)_2]\cdot 3H_2O$= $C_6H_{10}O_{11}K_2Pt$: C, 13.56; H, 1.90%).

Measurements. Electronic absorption and MCD spectra were recorded with the same apparatus and in the same manner as described elsewhere.[3] Unless otherwise noted, all the measurements were made in aqueous solutions at room temperature. CD spectra were measured in our previous work.[2]

Results and Discussion

Synthesis. All the mixed-ligand palladium(II) complexes isolated in the present work were synthesized on the basis of the principle that a ligand with higher affinity for palladium(II) ion is made to coordinate in preference to a ligand with lower affinity.[2] However, disproportionation reactions were observed in the course of the synthesis of $[Pd(N)_3(O)]$- and $[Pd(N)(O)_3]$-type complexes, particularly in the latter. These complexes were usually contaminated with the corresponding bis(amino carboxylato) complexes, but $K[Pd(ox)(\beta\text{-ala})]$ was with the bis(oxalato) complex. The $[Pd(N)_3(O)]$-type complexes can be purified by recrystallization, whereas the $[Pd(N)(O)_3]$-type ones generally can not because a disproportionation reaction further proceeds during the course of recrystallization. The pure products of the latter type could be obtained only by careful crystallization under a mild condition followed by a mechanical separation. Although most of the complexes with every combination of the ligands were successfully isolated, the complexes $[Pd(tn)(NH_3)_2]Cl_2$, $[Pd(\beta\text{-ala})(NH_3)_2]ClO_4$, $K[Pd(ox)(gly)]$, and $K[Pd(CH_3CO_2)_2(\beta\text{-ala})]$ as well as mixed-ligand $[Pd(O)_4]$-type complexes could not be obtained.[14] As noticed easily, three of these complexes contain one six-membered chelate ring and two unidentate ligands. On the contrary, similar but neutral complexes, $[Pd(mal)(NH_3)_2]$ and $[Pd(CH_3CO_2)_2(tn)]$, could be isolated. This seems to be ascribed to the low solubilities of the mixed-ligand complexes relative to those of the disproportionation products.

The mixed-ligand complexes with en or gly are more labile than the corresponding complexes with *S*-pn or *S*-ala, judging from the degree of the disproportionation observed in the synthesis or recrystallization. This may be attributable to high flexibility of an en or gly chelate ring over an *S*-pn or *S*-ala one, but the following observations can not be explained so easily. The mixed-ligand complexes with tn or β-ala are also more labile than those with *S*-pn or *S*-ala when the remaining coordination sites are occupied by an *N,N*- or *N,O*-ligand, whereas they are comparable or more stable when the sites are occupied by an *O,O*- or two *O*-ligands.

MCD Spectra. *1) [Pd(N)$_4$]-type Complexes*: Figure 1 shows the absorption and MCD spectra of typical $[Pd(N)_4]$-type complexes together with the CD spectra of the corresponding optically active complexes. For convenience these spectra are divided into three regions: spin-forbidden d-d, spin-allowed d-d, and charge transfer (CT) regions (Tables 1 and 2). Each of the MCD spectra shows a positive band and a dispersion comprising a positive and a negative lobe in the spin-forbidden and -allowed d-d regions, respectively. The dispersion changes sign at $2\text{—}3\times10^3\,cm^{-1}$ lower energy than the peak position of the main negative CD band (*ca.* $35\times10^3\,cm^{-1}$), originating primarily from the $^1E_g\leftarrow{}^1A_{1g}$ transition (D_{4h}),[2] of the corresponding optically active complexes. The negative lobe lies at energies only by $0.2\text{—}0.5\times10^3\,cm^{-1}$ higher than the main CD band; and the positive lobe occurs at almost the same energy as the positive CD maximum of $[Pd(S\text{-pn})(tn)]^{2+}$ ($31.4\times10^3\,cm^{-1}$), which has been assigned to the $^1A_{2g}\leftarrow{}^1A_{1g}$ transition (D_{4h}).[2] These facts suggest that the possible A term based on the $^1E_g\leftarrow{}^1A_{1g}$ transition does not contribute so significantly to the dispersion. Therefore, it is reasonable to consider, in combination with the information from the CD spectra,[2] that the positive lobe of the dispersion is mainly composed of a negative B term assigned to the $^1A_{2g}\leftarrow{}^1A_{1g}$ transition and that the large negative lobe is a composite of two positive B terms ascribed to the ^1E_g and $^1B_{1g}\leftarrow{}^1A_{1g}$ transitions (D_{4h}). The same assignment is appropriate for the *N,N*-Et$_2$en complexes (Fig. 2).

The MCD spectra have various features in the CT region, depending on the kind of the ligands. Namely, the complexes $[Pd(NH_3)_4]^{2+}$, $[Pd(tn)_2]^{2+}$, and $[Pd(en)_2]^{2+}$ exhibit a weak positive, an intense positive, and a medium negative band, respectively; however, an additivity holds qualitatively for the MCD spectra of

the mixed-ligand complexes (Fig. 1). An analogous situation is also observed for the mixed-ligand *N*,*N*-Et_2en complexes. A positive and a negative A term are correlated with the CT absorption bands around $50\times10^3\,cm^{-1}$ in the complexes of en and tn, respectively (Fig. 2). We previously found that the complexes having two *N*,*N*-dialkylamino groups in positions trans to each other exhibited a splitting both in the absorption and CD bands which were assigned to $Pd\leftarrow N(\sigma)$ transitions.[2] The spectra of such complexes show a negative and a positive band corresponding to the two split components (Fig. 2). These two B terms may be considered as a pseudo A term.[15] The MCD spectrum of $[Pd(en)(NH_3)_2]^{2+}$ shows a weak positive band on the lower edge of the CT absorption band, and it is presumably attributed to an orbitally-forbidden CT transition.

2) [Pd(N)$_3$(O)]-type Complexes: The spectra of the complexes containing gly or β-ala are shown in Fig. 3 or 4, respectively, and the numerical data in Tables 3 and 4. The MCD spectra showed a single positive or a couple of + and − bands in the spin-forbidden d-d region. Taking into account the overlapping of the neighboring intense positive band, all the complexes are expected to have the two (+ and −) bands in the region. The minimum around $26\times10^3\,cm^{-1}$ is considered to be formed by such an undetectable negative band, and included in Table 4; the main CD band of spin-forbidden nature occurs at almost the same energy as the minimum (Figs. 3 and 4). Such a correspondance is also found in the $[Pd(N)_4]$-type complexes (Figs. 1 and 2; Table 2).

The MCD spectra in the spin-allowed d-d region of the $[Pd(gly)(N)_2]$-type complexes are very similar to those of the corresponding $[Pd(en)(N)_2]$-type complexes (Figs. 3 and 1). The MCD spectra of the

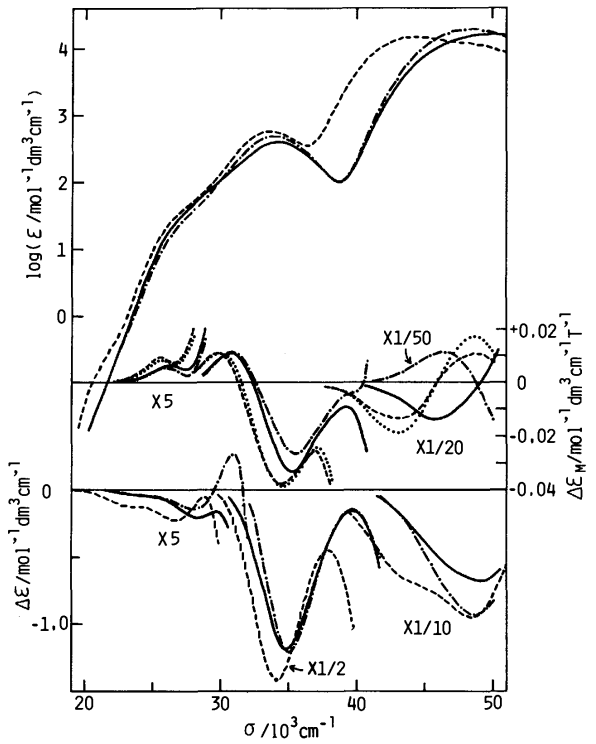

Fig. 2. Absorption and MCD spectra of [Pd(*N*,*N*-Et$_2$en)(en)]Cl$_2$ (——), [Pd(*N*,*N*-Et$_2$en)(tn)]Cl$_2$ (—·—), and [Pd(*N*,*N*-Et$_2$en)$_2$]Cl$_2$ (------); MCD spectrum of [Pd(*N*,*N*,*C*,*C*-Me$_4$en)$_2$]Cl$_2$ (·····) (the absorption spectrum is almost identical with that of [Pd(*N*,*N*-Et$_2$en)$_2$]Cl$_2$); and CD spectra of [Pd(*N*^{1},*N*^{1}-Et$_2$-(*S*)-pn)(en)]Cl$_2$ (——), [Pd(*N*^{1},*N*^{1}-Et$_2$-(*S*)-pn)(tn)]Cl$_2$ (—·—), and [Pd(*N*^{1},*N*^{1}-Et$_2$-(*S*)-pn)$_2$]Cl$_2$ (------).

[Pd(β-ala)(N)$_2$]-type complexes in the same region do not largely differ from those of the corresponding gly complexes (Figs. 4 and 3). Thus, these MCD spectra can be interpreted in analogy with those of the [Pd(N)$_4$]-type complexes. The complexes containing tn exhibit larger intensity ratios of the positive to the negative lobe of the dispersion, $|\Delta\varepsilon_M(+)/\Delta\varepsilon_M(-)|$, than the corresponding en complexes. Moreover it is noteworthy that the ratio is closely related to the sign and intensity of the MCD band in $45—50\times10^3$ cm^{-1}: the complexes which exhibit an intense positive MCD in the CT region do also an intense positive MCD band in the spin-allowed d-d region, and the complexes with a negative band in the former region exhibit a weak positive band in the latter region (Figs. 2 and 3). This fact is proved to hold likewise for the complexes of the other types, implying the mixing of a CT excited state with a d-d vibronic excited state.

Again in the CT region, the [Pd(gly)(N)$_2$]-type complexes generally exhibit MCD features similar to those of the corresponding en complexes, except for the positive band at 43.3×10^3 cm^{-1} in [Pd(en)(NH$_3$)$_2$]$^{2+}$. On the other hand, [Pd(β-ala)(en)]$^+$ exhibits a unique pattern of −, +, and −, and [Pd(β-ala)(tn)]$^+$ a pattern characteristic of the complexes containing tn. These observations indicate that gly and en ligands make an almost equivalent contribution to the MCD in the region but that a β-ala has a greater influence on the MCD than an en but smaller than a tn.

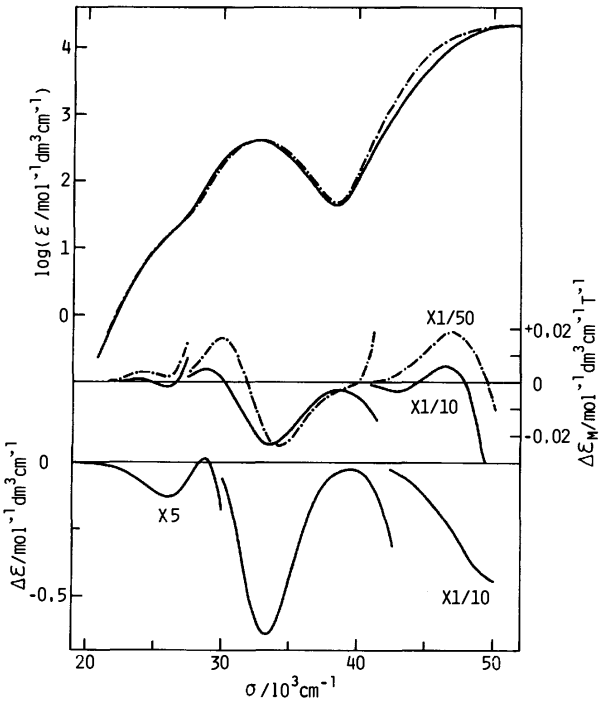

Fig. 4. Absorption and MCD spectra of [Pd(β-ala)L]ClO$_4$: L=en (——) and L=tn (—·—), and CD spectrum of [Pd(β-ala)(*S*-pn)]ClO$_4$ (——).

3) cis-[Pd(N)$_2$(O)$_2$]-type Complexes: The spectra of the complexes with this type are shown in Figs. 5—7, and the numerical data in Tables 5 and 6. The situation in the spin-forbidden d-d region is substantially the same as for the [Pd(N)$_3$(O)]- and [Pd(N)$_4$]-type complexes, but the negative MCD band in the higher energy side appears more explicitly. A comparison of the MCD spectrum of [Pd(ox)(*rac*-pn)] with the CD

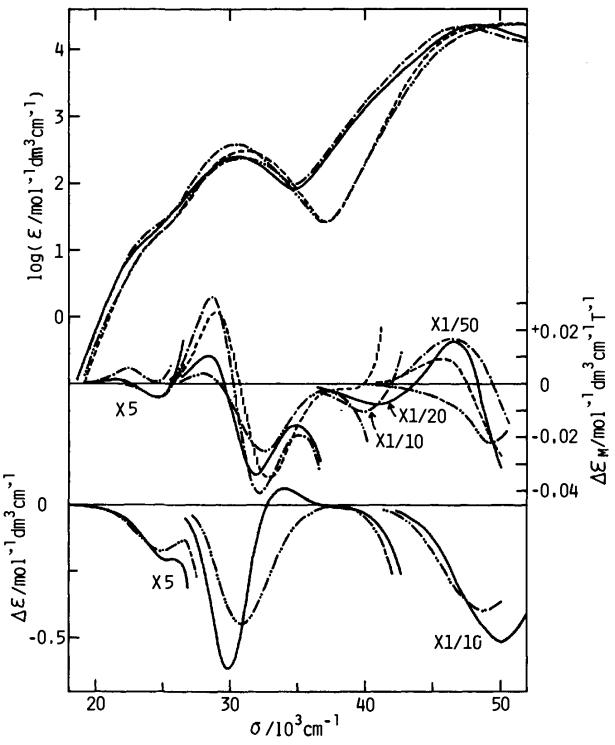

Fig. 5. Absorption and MCD spectra of [Pd(ox)(*rac*-pn)] (——), [Pd(ox)(tn)] (—·—), [Pd(mal)(*rac*-pn)] (—· ·—), and [Pd(mal)(tn)] (------); and CD spectra of [Pd(ox)(*S*-pn)] (——) and [Pd(mal)(*S*-pn)] (—· ·—).

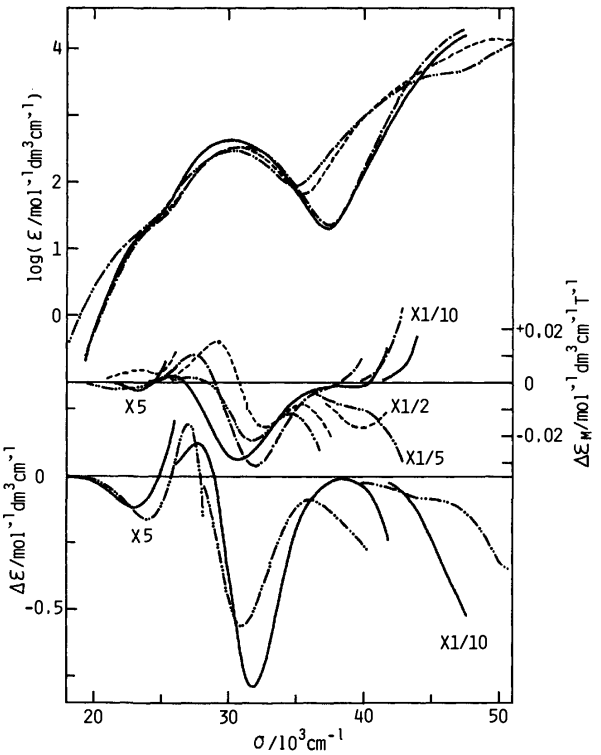

Fig. 6. Absorption and MCD spectra of $[Pd(CH_3CO_2)_2L]$ in 0.50 M CH_3CO_2Na: L=en (——) and L=tn (—·—), and $[Pd_2(\mu\text{-}OH)_2L_2](ClO_4)_2$ in H_2O: L=en (—· ·—) and L=tn (------); and CD spectra of $[Pd(CH_3CO_2)_2(S\text{-pn})]$ in 0.50 M CH_3CO_2Na (——) and $[Pd_2(\mu\text{-}OH)_2(S\text{-pn})_2](ClO_4)_2$ in H_2O (—· ·—).

one of [Pd(ox)(*S*-pn)] in the spin-allowed d-d region leads to the expectation that the A term based on the $^1E_g \leftarrow {}^1A_{1g}$ transition (D_{4h}) contributes to the dispersion of MCD more substantially than in the case of the $[Pd(N)_4]$- and $[Pd(N)_3(O)]$-type complexes (Fig. 5). The CD band at *ca.* $34\times10^3\,cm^{-1}$, which was assigned to the $^1B_{1g} \leftarrow {}^1A_{1g}$ transition (D_{4h}),[2] is correlated to a positive B term included in the negative lobe of the dispersion. The intensity ratio, $|\Delta\varepsilon_M(+)/\Delta\varepsilon_M(-)|$, is determined primarily by the kind of the *N*-ligand as seen in the previous section and secondarily by that of the *O*-ligand: it decreases in the order of the ox, mal, and CH_3CO_2 complexes when compared within the complexes with the same *N*-ligand. No such regularity is found for the complexes with μ-hydroxo or aqua ligands. The complex $[Pd(OH_2)_2(en)]^{2+}$ is so unique among the series of the complexes studied here as to exhibit only a negative band in the MCD of the spin-allowed d-d region (Fig. 7). The MCD band lies at the lower energy side of the main CD band of $[Pd(OH_2)_2(S\text{-pn})]^{2+}$; accordingly, a positive B term is expected for the $^1A_{2g} \leftarrow {}^1A_{1g}$ transition (D_{4h}) in this complex. The diacetato complex $[Pd(CH_3CO_2)_2(en)]$ is similarly situated, although it exhibits a weak positive MCD band. The weak band is considered to be the remainder of the positive lobe of the minor negative A term based on the $^1E_g \leftarrow {}^1A_{1g}$ transition canceled by the positive B term on the $^1A_{2g} \leftarrow {}^1A_{1g}$ one.

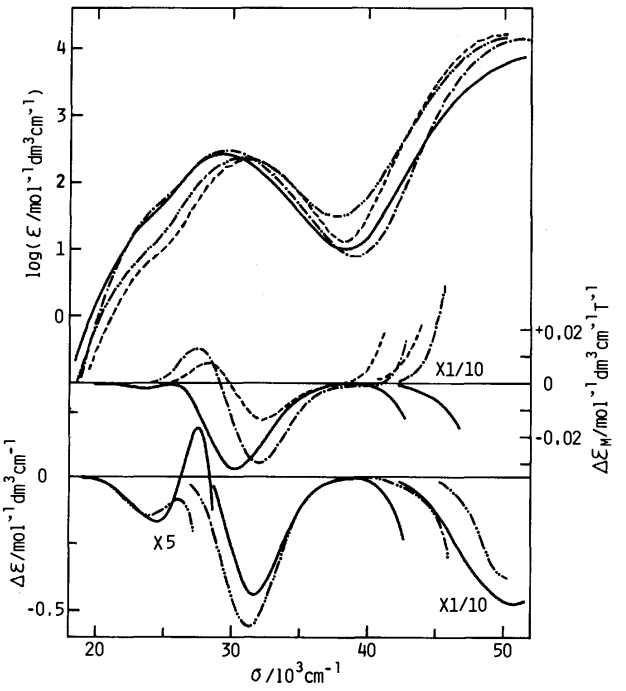

Fig. 7. Absorption and MCD spectra of $[Pd_2(\mu\text{-}OH)_2L_2](ClO_4)_2$ in 0.01 M $HClO_4$ (=2[$Pd(OH_2)_2L$]$(ClO_4)_2$): L=en (——) and L=tn (— · —), and in 0.01 M NaOH (=2[$Pd(OH)_2L$]): L=tn (------); absorption and CD spectra (— · · —) of $[Pd_2(\mu\text{-}OH)_2(S\text{-pn})_2](ClO_4)_2$ in 0.01 M NaOH (=2[$Pd(OH)_2(S\text{-pn})$]); and CD spectrum (——) of $[Pd_2(\mu\text{-}OH)_2(S\text{-pn})_2](ClO_4)_2$ in 0.01 M $HClO_4$ (=2[$Pd(OH_2)_2(S\text{-pn})$]$(ClO_4)_2$).

The MCD spectra in the CT region of the complexes with ox or mal are qualitatively additive with respect to the constituent ligands as noted in the $[Pd(N)_4]$-type complexes (Figs. 5, 1, and 9). This fact agrees with the expectation that two kinds of CT transitions, namely Pd←N(σ) and O(n, π, and/or σ), are present with small energy gaps. The absorption band which was observed as a shoulder around 42×10^3 cm^{-1} in the complexes with ox is readily assigned to the latter CT transitions, to which a positive B term corresponds. On the other hand, the CD spectra show no remarkable band in $35\text{—}45\times10^3\,cm^{-1}$; this can be explained by the fact that an asymmetric center is present only in the *N*-ligand, if such a chirality is more effective in Pd←N than in Pd←O CT transitions. A similar spectral behavior has been observed also for $[Pd(Cl)_2(N)_2]$-type complexes.[1] Therefore, the CD bands at *ca.* $50\times10^3\,cm^{-1}$ are attributable primarily to Pd←N(σ) transitions (Fig. 5).

4) [Pd(N)(O)$_3$]-type Complexes: The absorption and MCD spectra of the complexes of this type are shown in Fig. 8 together with the CD spectra of the relating complexes with *S*-ala, and the numerical data in Tables 7 and 8. The MCD spectra of the complexes with gly are very similar to those of the corresponding en (or *rac*-pn) complexes of *cis*-$[Pd(N)_2(O)_2]$-type over the range $20\text{—}50\times10^3\,cm^{-1}$ (Figs. 8, 5, and 6). Thus, the MCD spectra of the former complexes can be interpreted in analogy with those of the latter. The MCD spectrum of $[Pd(CH_3CO_2)_2(gly)]^-$ supports the idea proposed be-

a) sh: shoulder ($\Delta\varepsilon_M$ is for the value σ given); m: minimum of $|\Delta\varepsilon_M|$. b) $\Delta\varepsilon_M$ is based on palladium.

fore that the vicinal CD contribution by *S*-ala exhibits a dispersion pattern of + and − for the $^1E_g \leftarrow {}^1A_{1g}$ transition (D_{4h}).[2] The MCD spectra of the two complexes with β-ala are similar to that of [Pd(β-ala)(en)]$^+$ in the d-d region, particularly in the intensity ratio $|\Delta\varepsilon_M(+)/\Delta\varepsilon_M(-)|$, and showed a composite of the patterns characteristic of the constituent ligands in the CT region (Figs. 8 and 4).

5) [Pd(O)$_4$]-type Complexes: The absorption and MCD spectra are shown in Fig. 9 and the numerical data in Tables 7 and 8. The MCD curves in the d-d region of [Pd(ox)$_2$]$^{2-}$ and [Pd(mal)$_2$]$^{2-}$ are very similar to each other, although the intensity for the former complex is about a half of that for the latter. Considering only coordinating atoms, the complexes of this type can be approximated by a D_{4h} symmetry; nevertheless the contribution of the A term based on the $^1E_g \leftarrow {}^1A_{1g}$ transition is considered to be small from the MCD features. This situation is similar to that in the [Pd(N)$_4$]-type complexes.

The MCD spectrum of [Pd(ox)$_2$]$^{2-}$ showed four bands in the CT region. The lowest-energy band, which was observed only as a shoulder, corresponds to the absorption band (shoulder) at 32.8×10^3 cm^{-1}. Neither the MCD nor the absorption band corresponding to the above respective band was observable in the complexes containing only one ox ligand because of the relatively high intensities of the neighboring bands. The three higher-energy bands are familiar in the complexes with ox (See also Figs. 5 and 8). The MCD spectrum of [Pd(mal)$_2$]$^{2-}$ showed two bands in the CT region; a positive B term and a positive A term correspond to

composed of an unsymmetrical broad band and a lower-lying shoulder in the d-d transition region, and these bands are roughly assigned to a spin-allowed and a spin-forbidden band, respectively. The former band will be described in detail and discussed briefly hereafter. We previously demonstrated that such an unsymmetrical band could be characterized by the half-value-width parameters and the unsymmetry parameter.[1] The parameters are listed in Table 9 for the complexes studied here.

Figure 10 represents the complexes together with the relating optically active complexes[2] as a function of the molar absorption coefficient of the absorption peak and the half-value width $\Delta\sigma_{1/2}$; moreover it shows the approximate band area, which is proportional to the oscillator strength. The [Pd(N)$_4$]-type complexes composed of ammine, en (or *S*-pn) and/or tn are classified into four groups, *i.e.*, a tetraammine complex, diammine(five-membered chelate) complexes, bis(five-membered chelate) complexes, and tn-containing complexes; the half-value width decreases and the band area increases in this order. A similar behavior is also found among the [Pd(N)$_4$]-type complexes containing *N*,*N*-diethylethylene(or propylene)diamine. The [Pd(N)$_3$(O)]-type complexes can be classified into three groups: complexes containing no six-membered chelates, complexes composed of a five-membered N–O and a six-membered N–N chelate, and complexes containing a six-membered N–O chelate. Thus the complexes with β-ala form a single group in Fig. 10 irrespective of the sizes of the accompanying diamines, and this situation is very similar to that found for the [Pd(N)$_4$]-type complexes with tn.

a) $\varepsilon=\varepsilon_{max}/2$ at $\sigma=\sigma_{max}-\Delta\sigma^{-}$ and $\sigma_{max}+\Delta\sigma^{+}$; $\Delta\sigma_{1/2}=\Delta\sigma^{-}+\Delta\sigma^{+}$. b) unsymmetry parameter= $\{(\Delta\sigma^{+}-\Delta\sigma^{-})/\Delta\sigma_{1/2}\}\times100$. c) In acetonitrile. d) In 0.50 M CH_3CO_2Na. e) $[Pd_2(\mu\text{-}OH)_2(en\text{ or }tn)_2](ClO_4)_2$ in 0.01 M $HClO_4$. f) $[Pd_2(\mu\text{-}OH)_2(tn)_2](ClO_4)_2$ in 0.01 M NaOH.

The substitution of β-ala for tn largely affect neither the band area nor the band width, but that of mal for β-ala does. An analogous behavior is also found in the series of en(or pn)–gly(or *S*-ala)–ox complexes except a pair of [Pd(ox)(pn)] and [Pd(gly)(en)] (Fig. 10).

The complexes containing tn, β-ala, or CH_3CO_2 generally possess oscillator strengths higher than the corresponding en(or pn), gly, or mal(or ox) complexes, respectively (Fig. 10). The exceptions are limited to the complexes with one tn and two unidentate ligands: $[Pd(CH_3CO_2)_2(tn)]$, $[Pd(OH)_2(tn)]$, and $[PdCl_2(tn)]$.[16] These complexes are expected to be less distorted than the corresponding en or *S*-pn complexes mainly in terms of bond angle. In other complexes, ligand-ligand interactions are presumed to be predominant. The complex $K_2[Pd(ox)_2]$ has the lowest oscillator strength among the palladium(II) complexes which we have so far investigated $[(\Delta\sigma_{1/2}\times\varepsilon)/10^5\ mol^{-1}\ dm^3\ cm^{-2}=6.57$; *cf.* $K_2[PdCl_4]$ (6.66)]. This may be attributable to the high planarity of the complex ion.

Figure 11 displays the unsymmetrical shape of the spin-allowed d-d absorption band. The complexes which exhibit an absorption band with a swelling in the higher or lower energy side are located on the lower right or upper left of the line $\Delta\sigma^{+}=\Delta\sigma^{-}$ (See the footnote of Table 9), respectively; the farther the complexes are located away from the line, the more unsymmetrical their band shapes are. The introduction of *N*,*N*-Et_2en(or N^1,N^1-Et_2-(*S*)-pn) in place of en(or *S*-pn) increases the band width mainly through the increase in $\Delta\sigma^{-}$. This behavior can be explained by supposing an increased transition energy difference between $^1A_{2g}$ and $^1E_g\leftarrow{}^1A_{1g}$ and/or the enhanced oscillator strength of $^1A_{2g}\leftarrow{}^1A_{1g}$. The location of the di-μ-hydroxo complex of en or S-pn in Fig. 11 may be also attributable to the relative lowering of the transition energy of $^1A_{2g}\leftarrow{}^1A_{1g}$.

The en or pn complexes of μ-OH, OH, mal, and ox are correlated with the corresponding tn complexes in a similar fashion (Fig. 11): the substitution of tn for en or pn decreases the band width with the decrease of $\Delta\sigma^{-}$ which is more substantial than that of $\Delta\sigma^{+}$.

The band shapes of the diaqua complexes are similar to each other irrespective of the kind of diamine ligands, whereas the diacetato complex with tn exhibits a band shape largely different from that of the corresponding complex with en or pn; thus, aqua and the diamine ligands have a predominant influence on the band shape in the former and the latter case, respectively. Similarly, tn and β-ala ligands seem to have a overwhelming influence on the band shape

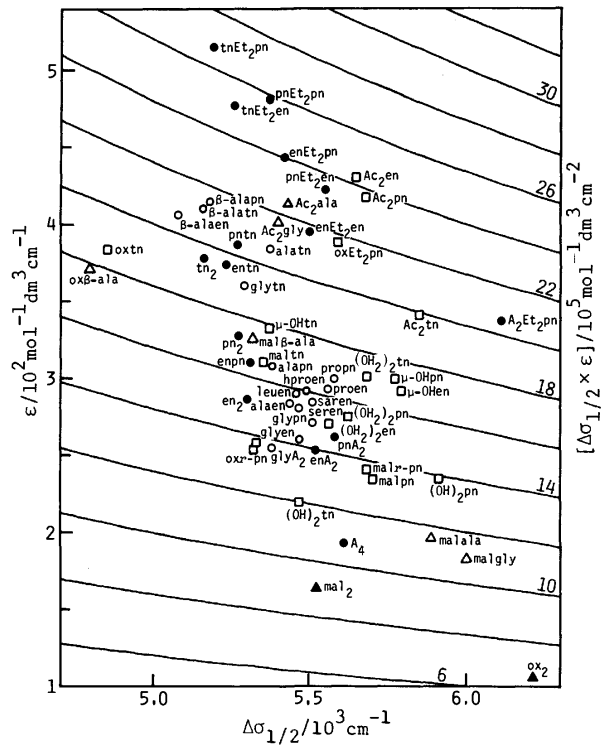

Fig. 10. Area intensity of the spin-allowed d-d absorption band represented as a function of the molar absorption coefficient of the absorption peak and the half-value width $\Delta\sigma_{1/2}$; ●: $[Pd(N)_4]$-, ○: $[Pd(N)_3(O)]$-, □: *cis*-$[Pd(N)_2(O)_2]$-, △: $[Pd(N)(O)_3]$-, and ▲: $[Pd(O)_4]$-type complexes; A=NH_3, pn=S-pn, *r*-pn=*rac*-pn, Et_2en=*N*,*N*-Et_2en, Et_2pn=N^1,N^1-Et_2-(*S*)-pn, ala=(*S*)-alaninato, ser=(*S*)-serinato, leu=(*S*)-leucinato, pro=(*S*)-prolinato, hpro=(*S*)-hydroxyprolinato, sar=sarcosinato, and Ac=acetato.

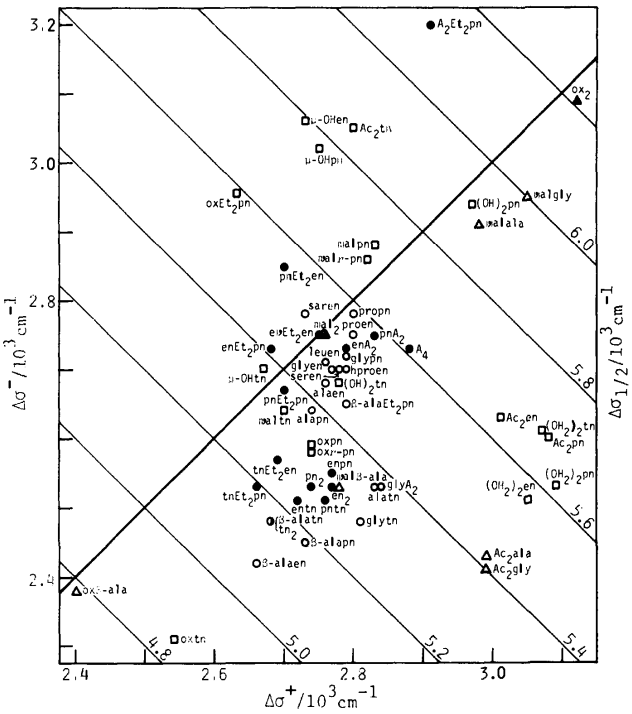

Fig. 11. Half-value width $\Delta\sigma_{1/2}$ (thin lines) represented as a function of $\Delta\sigma^+$ and $\Delta\sigma^-$; the thick line denotes $\Delta\sigma^+=\Delta\sigma^-$. See the footnote of Table 9 and the figure caption of Fig. 10 as to the marks and abbreviations.

in the $[Pd(N)_4]$- and $[Pd(N)_3(O)]$-type complexes, respectively.

The complexes containing tn, β-ala, or ox possess a band width narrower than the corresponding en(or pn), gly, or mal complexes, respectively, except $[Pd(OH_2)_2(tn)]^{2+}$, $[Pd(CH_3CO_2)_2(tn)]$, $[Pd(\beta\text{-ala})(tn)]^+$, and $[Pd(ox)_2]^{2-}$.

The relationship between the absorption band width $\Delta\sigma_{1/2}$ and the MCD intensity ratio $|\Delta\varepsilon_M(+)/\Delta\varepsilon_M(-)|$ is visualized in Fig. 12; which includes the data for $[Pd(Cl)_n(N)_{4-n}]$(n=1,2, and 4) and *cis*-$[Pd(Cl)_2(N)(O)]$-type complexes in addition to those for the $[Pd(N)_n(O)_{4-n}]$-type ones and reveals two facts. Firstly, the complexes with tn have a larger value of $|\Delta\varepsilon_M(+)/\Delta\varepsilon_M(-)|$ than the corresponding en or pn complexes without exception. Secondly, the complexes which possess a smaller $\Delta\sigma_{1/2}$ value exhibit a larger $|\Delta\varepsilon_M(+)/\Delta\varepsilon_M(-)|$ value and *vice versa*. This relationship implies a possibility of the mixing between d-d vibronic excited states by applied magnetic field; and such a mixing is presumed to give a negative B term for the $^1A_{2g}\leftarrow{}^1A_{1g}$ transition depending upon the magnitude of the mixing, which should be inversely proportional to the energy gap involved.[17] Thus, the MCD features predominated by B terms can be qualitatively explained by the mixing of this kind and by the mixing between a d-d vibronic excited state and a CT excited state as proposed in the previous section.

Photoelectrochemical Behavior of the $Fe(CN)_5^{2-}$ Complexes Coordinated to the Poly(4-vinylpyridine) Film on Graphite Surfaces

Noboru OYAMA,* Hisao YAMAMOTO, Takeo OHSAKA, and Masao KANEKO†

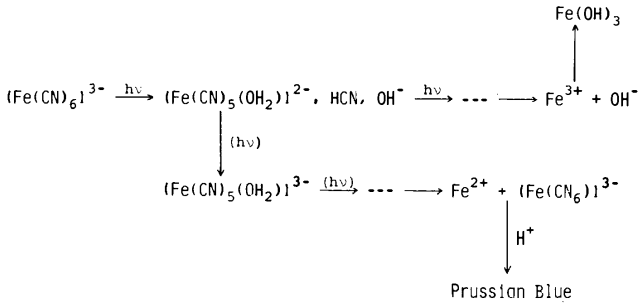
Department of Applied Chemistry for Resources, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184

†*The Institute of Physical and Chemical Research, Wako-shi, Saitama 351*

(Received April 19, 1984)

Photoelectrochemical reaction of the $Fe(CN)_5^{2-}$ complex ($PVP[Fe(CN)_5^{2-}]_n$) coordinated to the unprotonated poly(4-vinylpyridine) (PVP) film on a graphite electrode was examined in an aqueous solution. It was found that the carbon electrode coated with the $PVP[Fe(CN)_5^{2-}]_n$ generates the long-time responses of the photocurrents under irradiation of visible light and that the mechanism of its photochemical reaction is different from that for the photochemical reaction of $[Fe(CN)_6]^{3-}$ in a bulk solution, where the dissociation reaction of $[Fe(CN)_6]^{3-}$ to its aqua ion occurs.

Recently, the present authors have reported that the carbon surfaces coated with a couple of tris (2,2′-bipyridine)ruthenium(II) and methylviologen can generate the photocurrent.[1-3] As a series of papers regarding photoresponsive electrode prepared by coating of the photochemically active polymer, the present paper reports the photoelectrochemical investigation of the $Fe(CN)_5^{2-}$ complex (abbreviated as $PVP[Fe(CN)_5^{2-}]_n$) which is coordinated to the unprotonated poly(4-vinylpyridine) film coated on a basal plane pyrolytic graphite electrode in an aqueous solution. The photosensitivity of $[Fe(CN)_6]^{3-}$ and $[Fe(CN)_6]^{4-}$ was already known in 19th century and since then, a number of reports dealing with the photochemistry of $[Fe(CN)_6]^{3-}$ and $[Fe(CN)_6]^{4-}$ in aqueous solutions have appeared.[4] Moggi *et al.*[5] have studied the photochemical behavior of some cyanide complexes at various wavelengths in the ligand field spectral region and proposed a reaction mechanism involving a primary photoaquation reaction for the photolysis of the $[Fe(CN)_6]^{3-}$ ion both in neutral and in acidic solutions (see Scheme 1). Recently, Bowen and Hurlen[6] have studied the effect of irradiation on the electrode reactions of the $[Fe(CN)_6]^{4-}/[Fe(CN)_6]^{3-}$ couple at passive iron electrodes in borate solution and suggested that the rate of oxidation of $[FeCN)_6]^{4-}$ is markedly increased on irradiation, whereas the reduction of $[Fe(CN)_6]^{3-}$ is not affected. The overall photochemical reactions of $[Fe(CN)_6]^{3-}$ and $[Fe(CN)_6]^{4-}$ in aqueous solutions are composed of photoaquation, photooxidation-reduction and photosubstitution processes which sometimes occur simultaneously or successively. The photochemical reactions of these complexes are thus complicated, so that their photolysis has not been completely understood yet.



Scheme 1. $[Fe(CN)_6]^{3-}$ photolysis schematized by Ref. 5

The electrode reaction of $Fe(CN)_5^{2-/3-}$ redox couple, which is coordinated to the unprotonated PVP film coated on a graphite electrode, at the electrode/PVP film interfaces and the electron transfer reaction within the PVP film have been examined in previous papers,[7,8] where the special effect of the domain of the polymer film upon the electron transfer reactions has been demonstrated. Therefore, it is of interest to examine whether the polymeric domains influence upon the photochemical reaction of the $Fe(CN)_5^{2-/3-}$ complexes which are coordinated to the unprotonated PVP film or not.

Experimental

Electrochemical measurements were performed with a voltammetric analyzer (Model P-1000, Yanaco Co.). A 500 W Xenon lamp power supply (Model UI-501C, Ushio Electric Co.) was used as an irradiation source. The irradiation on the graphite electrode was performed with visible light (400—800 nm) through UV (Toshiba VY-42) and IR (Toshiba IRQ-80) cut-off filters. The intensity of the light could be varied by means of neutral density filters, and the wavelength could be varied using interference filters of bandpass 10 nm. IR spectra of $PVP[Fe(CN)_5^{2-}]_n$ film coated on electrode surface was measured by infrared spectrophotometer (A-302, Japan Spectroscopic Co., LTD.).

Poly(4-vinylpyridine) (PVP) (Bordon Inc., Philadelphia, PA) which was used in the present experiment unless otherwise described was reprecipitated twice from methanol-diethyl ether and its average molecular weight was 7.4×10^5.[9] Solutions containing PVP to which various quantities of $Fe(CN)_5^{3-}$ groups were coordinated were prepared, as described previously,[7] by mixing methanolic solutions of PVP having appropriate concentrations and aqueous solutions of $[Fe(CN)_5(OH_2)]^{3-}$ which were prepared by dissolving $Na_3[Fe(CN)_5(NH_3)]\cdot3H_2O$ (Tokyo Kasei Kogyo Co., Ltd.) in aqueous solutions under conditions where substitution of the NH_3 ligand by H_2O proceeds rapidly. Aliquots of the resulting solution of the polymer were transferred to the surface of a freshly cleaved basal plane graphite electrode (BPG, Union Carbide Corp.) and then the evaporation of the solvent was carried out at room temperature. The resulting coatings were swelled in an aqueous solution but remained insoluble. The thickness of the coating was calculated from the polymer densities (0.65 g cm^{-3}) estimated from the solvent-swelling measurements. The quantities of $Fe(CN)_5^{3-}$ moiety present in the coatings were measured by integrating the current from cyclic voltammograms which were observed at a low scan rate of 1—4 mV s^{-1}.[10] The exposed area of each electrode was 0.17 cm^2.

The test solution was made of a distilled water and a supporting electrolyte (0.2 M (1 M=1 mol dm^{-3}) CF_3COONa) and its pH was adjusted to desired pH value with NaOH and CF_3COOH solutions. Solutions were deaerated with prepurified argon and experiments were conducted at 25 °C under an atmosphere of argon. All potentials are reported with respect to a sodium chloride saturated calomel electrode (SSCE).

Results and Discussion

In previous papers,[7,8] we have succeeded in evaluation of the kinetic parameters of the electron-transfer reactions within the $PVP[Fe(CN)_5^{3-/2-}]_n$ film coated on a BPG and at the BPG/film interface in a solution containing only supporting electrolyte. Such a success depended upon the insolubility of the $PVP[Fe(CN)_5^{3-/2-}]_n$ film coated on electrodes in an aqueous solution. Figure 1 shows typical voltammetric response which is obtained with a pyrolytic graphite electrode coated with $PVP[Fe(CN)_5^{3-/2-}]_n$ film in a 0.2 M

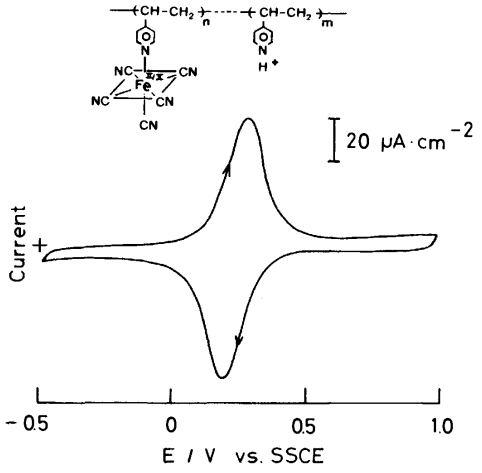


Fig. 1. Cyclic voltammogram for the $PVP[Fe(CN)_5^{2-}]_n$-coated BPG electrode in 0.2 M CF_3COONa aqueous solution adjusted to pH 3.0 at scan rate of 100 mV s^{-1}. $\Gamma_{PVP}=5.6\times10^{-7}$ mol cm^{-2} of pyridine units as PVP and $\Gamma_{Fe(CN)_5}=1.4\times10^{-9}$ mol cm^{-2} of electroactive $[Fe(CN)_5(pyridine)]$ moieties.

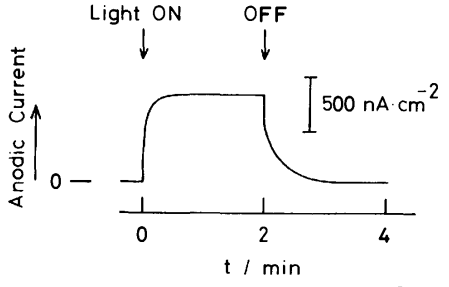

Fig. 2. Photocurrent responses to ON and OFF of irradiation on the $PVP[Fe(CN)_5^{2-}]_n$-coated BPG electrode in 0.2 M CF_3COONa solution adjusted to pH 3.0 at the electrode potential of +0.80 V *vs.* SSCE. $\Gamma_{PVP}=5.6\times10^{-7}$ mol cm^{-2} and $\Gamma_{Fe(CN)_5}=6.8\times10^{-9}$ mol cm^{-2}. Photocurrents were measured as the difference between the total current and its residual current measured with an uncoated BPG electrode at the same potential. Intensity of the visible light (400—800 nm) through UV and IR cut-off filters is 140 mW cm^{-2}.

CF_3COONa solution adjusted to pH 3.0 in dark or under irradiation. The anodic and cathodic peak potentials under irradiation were the same as those in dark. The voltammograms remained unchanged for several hours of continued cycling of the electrode potential in an acidic solution (pH 3.0) under the usual diffuse light, although the peak currents decreased gradually with increasing the irradiation time of visible light as mentioned below.

Figure 2 demonstrates the photoresponses induced by ON and OFF of the irradiation of visible light (400—800 nm) on the $PVP[Fe(CN)_5]_n$ coated BPG electrode in a 0.2 M CF_3COONa solution (pH 3.0) at +0.80 V *vs.* SSCE. The same photocurrent response to ON and OFF of irradiation was obtained repeatedly. The anodic photocurrent responses were observed at the positive-side potential more than *ca.* 0.3 V and the values increased as the applied potential shifts to the positive side. The photocurrent was also influenced by pH of the solution in which the electrode is soaked, and its maximum was observed in the solution of pH 3.0. In the case of the electrode coated with PVP film ($\Gamma_{PVP}=5.6\times10^{-7}$ mol cm^{-2}) to which the $Fe(CN)_5^{3-}$ moieties of $\Gamma_{Fe(CN)_5}=6.8\times10^{-9}$ mol cm^{-2} were coordinated, the anodic photocurrent of 0.9 μA cm^{-2} was obtained at the potential of 0.80 V under the irradiation with the intensity of 140 mW cm^{-2} in a 0.2 M CF_3COONa solution (pH=3.0). No photocurrent response under irradiation were observed with a bare BPG electrode and the BPG electrode coated with PVP coordinating no $Fe(CN)_5^{2-}$ complexes. The cathodic photocurrents were also observed at the negative-side potential more than about 0.2 V, although their values were smaller than the values of the anodic ones.

Figure 3 shows the action spectrum of the anodic photocurrent obtained with the coated electrode, coverages of which are $\Gamma_{PVP}=1.1\times10^{-6}$ mol cm^{-2} and $\Gamma_{Fe(CN)_5}=3.6\times10^{-8}$ mol cm^{-2}, at the electrode potential of 0.80 V under irradiation of monochromatic light. The shift (about 20 nm) of the action spectrum to longer wavelengths than the absorption spectrum in water

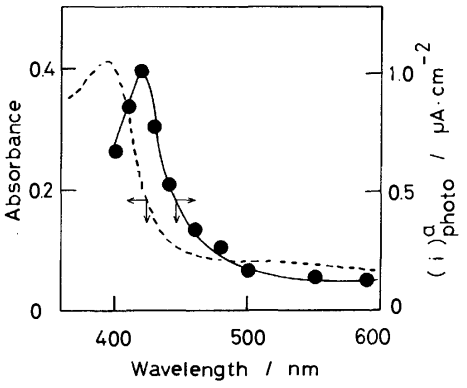

Fig. 3. Action spectrum for the anodic photocurrent observed with the $PVP[Fe(CN)_5^{2-}]_n$-coated electrode, coverages of which are $\Gamma_{PVP}=1.1\times10^{-6}$ mol cm^{-2} and $\Gamma_{Fe(CN)_5}=3.6\times10^{-8}$ mol cm^{-2}. (●) experimental; (----) absorption spectrum of 0.46 mM $[Fe(CN)_5^{2-}]_n$ coordinated to PVP of the average molecular weight 1980 in 0.2 M CF_3COONa aqueous solution adjusted to pH 3.0.

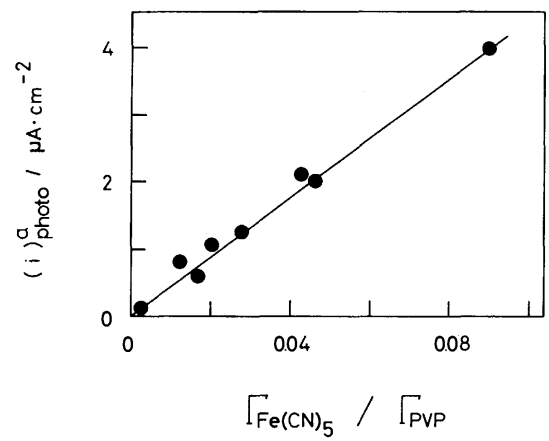

Fig. 4. Anodic photocurrent *vs.* $\Gamma_{Fe(CN)_5}/\Gamma_{PVP}$. Γ_{PVP} is constant (5.6×10^{-7} mol cm^{-2}). Other experimental conditions are the same as in Fig. 2.

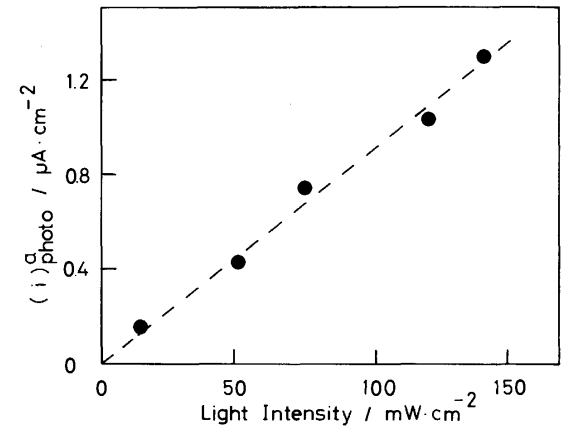

Fig. 5. Anodic photocurrent *vs.* light intensity. $\Gamma_{PVP}=5.6\times10^{-7}$ mol cm^{-2} and $\Gamma_{Fe(CN)_5}=1.6\times10^{-8}$ mol cm^{-2} at electrode potential +0.80 V *vs.* SSCE. Other experimental conditions are the same as in Fig. 2.

suggests some strong interaction[11] between the metal complex and PVP. Its shape almost agrees with that of the spectrum of the $PVP[Fe(CN)_5^{2-}]_n$ complexes formed with PVP of the average molecular weight 1980 in aqueous solutions, indicating that the excitation of the $Fe(CN)_5^{2-}$ complexes coordinated to the unprotonated PVP film is responsible for their photoelectrochemical behaviors.

Figure 4 shows the dependence of the anodic photocurrent, $(i)^a_{photo}$, upon the ratio $\Gamma_{Fe(CN)_5}/\Gamma_{PVP}$ at the constant concentration of pyridine ligand as PVP ($\Gamma_{PVP}=5.6\times10^{-7}$ mol cm^{-2}). The measurements were made in a 0.2 M CF_3COONa (pH 3.0) at the electrode potential of 0.80 V *vs.* SSCE under the irradiation of visible light with the intensity of 140 mW cm^{-2}. $(i)^a_{photo}$ was proportional to $\Gamma_{Fe(CN)_5}/\Gamma_{PVP}$. The dependence of the anodic photocurrent on the light intensity at the electrode potential of 0.80 V *vs.* SSCE was also measured and is shown in Fig. 5. $(i)^a_{photo}$ exhibits essentially linear dependence on the light intensity. The similar dependence of photocurrent on the light intensity has been reported in the photochemistry of an aqueous solution of $[Fe(CN)_6]^{4-}$.[6] At constant values of $\Gamma_{Fe(CN)_5}/\Gamma_{PVP}$, $(i)^a_{photo}$ increased with an increase in Γ_{PVP}.

Moggi *et al.*[5] have suggested that $[Fe(CN)_5(OH_2)]^{2-}$ is the main primary product of the photoreaction of $[Fe(CN)_6]^{3-}$ and the photochemical aquosubstitution reaction of $[Fe(CN)_5(OH_2)]^{2-}$ occurs simultaneously with the oxidation-reduction reaction which yields $[Fe(CN)_5(OH_2)]^{3-}$. They have confirmed that the products formed by a series of these reactions under long irradiation periods are $Fe(OH)_3$ (in neutral solution), prussian blue (in acidic solution), $[Fe(CN)_5(OH_2)]^{3-}$, Fe^{2+} and Fe^{3+}, and further that the pH of aqueous solutions slowly increases during irradiation in neutral solution and after some time tends to reach a constant value. On the basis of the mechanism (Scheme 1) proposed previously for photochemical reaction of the aqueous solution of $[Fe(CN)_6]^{3-}$, the mechanism of the photoelectrochemical reaction of $PVP[Fe(CN)_5]_n$ coated on the BPG can be expressed as follows:

$$PVP[Fe(CN)_5^{3-}]_n - e \rightleftharpoons PVP[Fe(CN)_5^{2-}]_n, \quad (1)$$

$$PVP[Fe(CN)_5^{2-}]_n \xrightarrow{h\nu} PVP[Fe(CN)_5^{2-}]^*_n, \quad (2)$$

$$PVP[Fe(CN)_5^{2-}]^*_n \longrightarrow PVP[Fe(CN)_{5-x}(OH_2)_x^{(2-x)-}]_n, \quad (3)$$

$$PVP[Fe(CN)_{5-x}(OH_2)_x^{(2-x)-}]_n \xrightarrow{OH^-} PVP, Fe(OH)_3, CN^-, \quad (4)$$

$$PVP[Fe(CN)_{5-x}(OH_2)_x^{(2-x)-}]_n \xrightarrow{H^+} PVPH^+, Fe^{2+}, HCN, \quad (5)$$

$$PVP[Fe(CN)_{5-x}(OH_2)_x^{(2-x)-}]_n \longrightarrow PVP[Fe(CN)_{5-x}(OH_2)_x^{(3-x)-}]_n, \quad (6)$$

where, Eq. 1 shows the electrode reaction of $PVP[Fe(CN)_5^{3-/2-}]_n$ couple, $PVP[Fe(CN)_5^{2-}]^*_n$ is the excited species formed from $PVP[Fe(CN)_5^{2-}]_n$ by the irradiation of visible light, $PVPH^+$ is the protonated PVP, Eqs. 3 and 6 denote aqua-substitution and thermal reduction reactions, respectively, and Eqs. 4 and 5 show the decomposition reactions in neutral and acidic solutions, respectively. If this series of the reaction mechanism is applicable to the present system, anodic photocurrent could not be observed for the longer irradiation time than that which is enough for the reaction expressed by Eq. 2 to be terminated. However, when the $PVP[Fe(CN)_5^{2-}]_n$ coated on electrode, the coverages of which were $\Gamma_{PVP}=2.8\times10^{-7}$ mol cm^{-2} and $\Gamma_{Fe(CN)_5}=1.9\times10^{-9}$ mol cm^{-2}, was irradiated with visible light for 30 h in a 0.2 M CF_3COONa solution (pH 3.0) at the electrode potential of 0.80 V *vs.* SSCE, total amount of electricity, Q_p, that flowed during irradiation was estimated to be 1.8×10^{-3} coulomb cm^{-2}, which corresponds to 1.9×10^{-8} mol cm^{-2}. After 30 h, $PVP[Fe(CN)_5^{2-}]_n$ of $\Gamma_{Fe(CN)_5}=2.0\times10^{-10}$ mol cm^{-2} remained still confined in the PVP film on electrode surface. The concentration of $Fe(CN)_5^{2-}$ moiety decreased to about 10% of its initial value, nevertheless the value of Q_p corresponded to about ten times the initial concentration of $Fe(CN)_5^{2-}$ moiety. The anodic photocurrent after 30 h was also about 10% of its initial value, although about 80% of its initial value was lost

within 1 h of irradiation. The decays in the current and in the concentration of the $Fe(CN)_5$ complex are rapid and almost exponential. Judging from the fact that the redox potentials of $[Fe(CN)_6]^{4-/3-}$ and $[Fe(CN)_5(py)]^{3-/2-}$ (where py=pyridine) couples were 0.20 V *vs.* SSCE and that of $[Fe(CN)_5(OH_2)]^{3-/2-}$ was 0.09 V *vs.* SSCE at a bare BPG in aqueous solutions, if the aquoated complex, *i.e.*, $[Fe(CN)_{5-x}(OH_2)_x]^{(2-x)-}$ formed during the photochemical reaction of $Fe(CN)_5^{2-}$ remains in the PVP film without any dissociation, the peak potentials of voltammograms would be different from those for $Fe(CN)_5^{3-/2-}$ couple coordinated to the unprotonated PVP film. However, the redox potential estimated from cyclic voltammogram obtained with the $PVP[Fe(CN)_5]_n$-coated electrode which was irradiated with visible light for 30 h was the same as that (0.2 V *vs.* SSCE) obtained with the same electrode before irradiation (see Fig. 1). Further, Fe^{2+} aqua ion as Prussian blue was undetected.

From these results, it seems unlikely that the similar mechanism (Eqs. 1—6) to the photochemical reaction of $[Fe(CN)_6]^{3-}$ in aqueous solution is applicable to the photoelectrochemical reaction of $PVP[Fe(CN)_5]_n$ coated on the BPG. In the place of reactions expressed by Eqs. 3—6, we can consider the following reaction mechanisms for the photochemical reaction under consideration:

$$PVP[Fe(CN)_5^{2-}]_n^* + H_2O \longrightarrow PVP[Fe(CN)_5^{3-}]_n + 1/2O_2 + 2H^+, \quad (7)$$

$$PVP[Fe(CN)_5^{2-}]_n^* \longrightarrow PVP^+[Fe(CN)_5^{3-}]_n, \quad (8)$$

$$PVP[Fe(CN)_5^{2-}]_n^* + (BPG) \longrightarrow PVP[Fe(CN)_5^{3-}]_n + (BPG)^+, \quad (9)$$

where, $PVP^+[Fe(CN)_5^{3-}]_n$ denotes the species resulting from oxidation of pyridine ring and/or vinyl group of PVP, $(BPG)^+$ denotes the product obtained from oxidation of the BPG material itself by the $PVP[Fe(CN)_5^{2-}]_n^*$. IR absorption spectra of the $PVP[Fe(CN)_5]_n$ coated on the BPG after long-time irradiation (30 h) demonstrated the new absorption peak which seems to be characteristic of carbonyl group at 1670 cm^{-1}. This suggests the formation of carbonyl group which is caused by Eq. 8 during the irradiation of visible light, although the details of this reaction mechanism are not clear. From the reaction expressed by Eq. 7, the evolution of oxygen is expected under long-time irradiation but has not been detected by gas chromatography. Figure 6 demonstrates the decay in the anodic photocurrent under the irradiation. As seen from this figure, the electricity, Q_p, that flows as a photocurrent during 35 h irradiation is estimated to be 9.4×10^{-3} coulomb cm^{-2}, which corresponds to 9.7×10^{-8} mol cm^{-2}. This value of Q_p corresponded to fifty times the initial concentration of the $Fe(CN)_5^{2-}$ complexes and about five times the initial concentration of pyridine ligand as PVP. Therefore, the process expressed by Eq. 9 (*i.e.*, the oxidation of the BPG electrode used as an anode) seems to be mainly responsible for the photochemical responses, since vinylpyridine moiety of PVP, not oxidized, is still on the BPG surfaces.

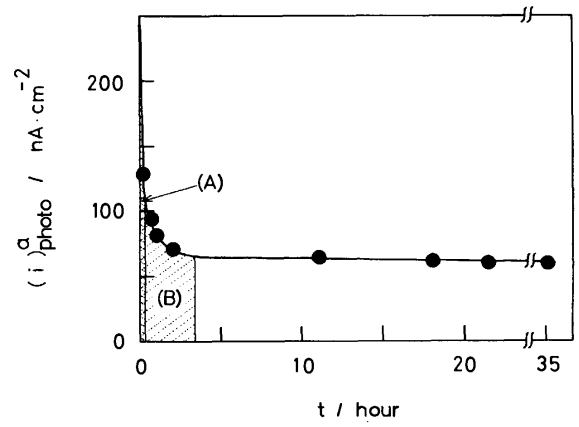

Fig. 6. Anodic photocurrent *vs.* irradiation time. Initial value of $\Gamma_{PVP}=1.8\times10^{-8}$ mol cm^{-2} and initial value of $\Gamma_{Fe(CN)_5}=1.9\times10^{-9}$ mol cm^{-2}. Other experimental conditions are the same as in Fig. 2. Area (A) corresponds to the initial value of $\Gamma_{Fe(CN)_5}$; area (B) corresponds to the initial value of Γ_{PVP}.

The present results conclude that the mechanism of the photochemical reaction following the oxidation of $PVP[Fe(CN)_5^{3-}]_n$ coated on the BPG surfaces is different from that of an aqueous solution of $[Fe(CN)_6]^{3-}$ [5] and photochemical processes are oxidation-reduction reactions expressed by Eqs. 8 and 9. Further, it became to be clear that the photoaquation and the subsequent dissociation reactions, which are very familiar in the photochemistry of aqueous solutions of $[Fe(CN)_6]^{3-}$ and $[Fe(CN)_6]^{4-}$, [4,5] seem to be suppressed in the polymer domains. However, some unsolved problems still remain: (1) A rapid, almost exponential decay in the anodic photocurrent occurred during the short-time (less than 1 h) irradiation. We have no idea to explain such a behavior at present. (2) Anodic photocurrents were influenced by pH of the solution in which the $PVP[Fe(CN)_5^{2-}]_n$-coated electrode was soaked, and their maxima were observed for the solution of pH 3.0. It seems to be considered that the change of morphology of the $Fe(CN)_5^{2-}$ complex polymer with pH results in the pH-dependence of the photocurrent. (3) The cathodic photocurrents were also observed at the negative-side potential more than about 0.20 V and their values were smaller than the anodic ones at the same coating electrode. The reduction of the BPG electrode by the $PVP[Fe(CN)_5^{3-}]_n^*$ may result in the cathodic photocurrents but we have no direct evidence to support this interpretation.

In conclusion, we emphasize that modification of the carbon electrode by coating the photosensitive species on it can generate the photocurrent.

The present work was partially supported by the Grant of the Nissan Science Foundation.

Theory of Time-resolved Photon Absorption by Molecules after Radiationless Transition. Application to Benzene after $S_2 \rightsquigarrow S_0$.

Yuichi FUJIMURA,* Minoru ARAI, Nobuaki NAKASHIMA,† and Keitaro YOSHIHARA†

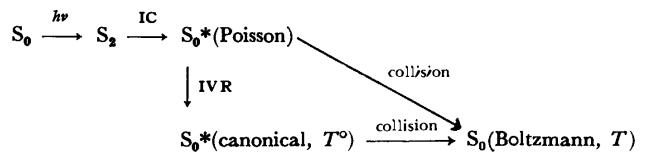
(Received May 18, 1984)

Expressions for the intensity of the time-resolved absorption (TRA) by molecules after radiationless transition have been derived. It is assumed that a non-equilibrium vibronic distribution is realized after the radiationless transition and relaxes to the equilibrium one. Two types of non-equilibrium distributions, Poisson distribution and canonical distribution with temperature higher than that of the heat bath are taken into account. The theory developed is applied to the TRA spectra ($S_3 \leftarrow S_0$) of benzene after the internal conversion $S_2 \rightsquigarrow S_0$ (N. Nakashima and K. Yoshihara, *J. Chem. Phys.* **79**, 2727, (1983)). It is shown that the expression for the intensity in the Sulzer-Wieland model is involved in the expression derived using the canonical distribution.

Recently Nakashima and Yoshihara[1] have observed the time-resolved absorption (TRA) spectra of gaseous benzenes after excitation to the $S_2(^1B_{1u})$ state. It has been shown that the transient spectra consist of the $S_3(^1E_{1u}) \leftarrow S_0(^1A_{1g})$ transition at high temperatures. The spectra reflect the vibronic energy distribution after the internal conversion from the S_2 state to the ground state. The spectral changes with time are mainly brought about by collisional deactivation processes of the hot benzene by inert gas and unexcited benzene. The transient spectrum at $t=0$ was explained by using the Sulzer-Wieland model[2] originally applied to absorption spectra of diatomic molecules with a large potential displacement at high temperatures. This model has been applied to analysis of the high temperature ultraviolet absorption spectra of polyatomic molecules in shock waves by Astholz *et al.*[3] and by Hippler *et al.*[4] as well. To our knowledge, however, there exists no any sufficient theoretical explanation for the applicability of the Sulzer-Wieland model to the polyatomic molecules in the highly excited vibronic states. The purpose of this paper is to develop a theory of the time-resolved absorption spectra of hot molecules produced by radiationless transition, and to apply the theory to the time-resolved absorption spectra of benzene observed previously.[1]

The TRA spectra of molecules strongly depend on the initial non-equilibrium vibronic energy distribution which is realized in a time scale of observation. The following scheme can account for the observed TRA spectra.



Two types of the vibronic energy distributions different from the thermal equilibrium distribution can be expected after radiationless transitions. One is a Poisson (intramolecular) vibronic energy distribution,[5,6] and the other is a canonical distribution characterized by a higher temperature $T°$ than that of the heat bath T. The former distribution is formed just after internal conversion (IC) following laser excitation. One of the evidences for the intramolecular vibronic energy distribution is seen in the TRA spectra ($^3B_{1g} \leftarrow {}^3B_{2u}$) after excitation to the S_1 state of naphthalene in vapor.[7] A vibronic structure associated with the triplet-triplet absorption appears in the TRA spectra just after the intersystem crossing takes place. A canonical vibronic energy distribution with $T°>T$, on the other hand, is expected to be realized when an intramolecular vibrational redistribution takes place following the radiationless transition. Taking into account the two types of the initial distributions we derive expressions for the absorption intensity of the TRA spectra of polyatomic molecules. In deriving the expressions for the intensity, it is assumed that the initial distributions relax to the Boltzmann distribution due to collisional deactivations and that the collision rates vary linearly with respect to the vibrational quantum number.[8] It is shown that the expression for the time-resolved absorption intensity of the molecular system with a canonical distribution as the initial distribution involves the expression derived by Sulzer and Wieland as a special case. A model calculation of the TRA spectra using the derived expressions supports the conclusion given in the previous paper:[1] the initial vibronic distribution is of the canonical one with a high temperature.

Theory

Let us consider a time-resolved absorption process from the vibrationally hot ground electronic state a to an electronically excited state b. The initial, vibrational state in the non-equilibrium condition is produced by internal conversion $S_2 \rightsquigarrow S_0^*$. The intensity per unit length, $D_{ab}(\omega_R, t)$, as a function of time, t, and the laser frequency, ω_R is expressed in the form,[5]

$$D_{ab}(\omega_R, t) = \sum_{\{v\}} k_{a\{v\}}(\omega_R)\chi_{\{v\}}(t), \qquad (1)$$

where $k_{a\{v\}}(\omega_R)$ represents the absorption coefficient from a single vibronic level $\{v\}$ in the ground state a, and $\chi_{\{v\}}(t)=\prod_j^N \chi_{vj}(t)$ in which $\chi_{vj}(t)$ denotes the vibronic energy distribution of the optical vibrational mode j

per unit volume at time t, and N is the number of the optical modes whose potential forms between a and b states are different. The distribution $\chi_{\{v\}}(t)$ depends on the dynamical behavior and the initial distribution. In this paper we consider Poisson and canonical distributions. First we treat the time-evolution of molecules characterized by a Poisson distribution which relaxes to the equilibrium distribution with T. In a previous paper,[6] a theoretical treatment of the TRA spectroscopy was presented in the case of the relaxation of the Poisson distribution to the lowest vibronic state in the low temperature limit.

Poisson Vibronic Energy Distribution. We assume that at $t=0$ a non-equilibrium state originating from an intramolecular radiationless transition has been prepared. It has been shown that the distribution of the vibrational mode j with frequency ω_j after the radiationless transition from the lowest vibronic level is expressed as[5,6]

$$\chi_{v_j}(0) = S_{0_j'v_j} \exp\left[-v_j\bar{\beta}\hbar\omega_j + \frac{\bar{\Delta}_j^2}{2}\{1-\exp(-\bar{\beta}\hbar\omega_j)\}\right], \quad (2)$$

where the displaced harmonic oscillator model has been used. $S_{0_j'v_j}$ is the optical Franck-Condon factor between $0_j'$ and v_j states, and given by $S_{0_j'v_j}=(\bar{\Delta}_j/\sqrt{2})^{2v_j}$ $\exp(-\bar{\Delta}_j^2/2)/v_j!$. $\bar{\Delta}_j$ is the displacement of the mode j in the equilibrium points between the relevant two electronic states. $\bar{\beta}$ in Eq. (2) is a parameter which is determined from the condition of the energy conservation for the radiationless transition. Equation (2) satisfies $\sum_{v_j}\chi_{v_j}(0)=1$. Equation (2) can be rewritten in the form of a Poisson distribution,

$$\chi_{v_j}(0) = \frac{\alpha_j^{v_j}}{v_j!}\exp(-\alpha_j), \quad (3)$$

with the average vibrational quantum number[5] given by

$$\alpha_j = \frac{\bar{\Delta}_j^2}{2}\exp(-\bar{\beta}_j\hbar\omega_j). \quad (4)$$

In the case of the radiationless transition from v_j' level, the expression for the distribution can approximately be represented by Eq. (2) in which $S_{0_jv_j}$ is replaced by $S_{v_j'v_j}$.

If we assume that the molecular system undergoes only a collisional vibrational energy exchange between the system and the heat bath, and interactions between the vibrational modes of the system are neglected, *i.e.* each vibrational mode relaxes to its equilibrium distribution, then the time-dependent distribution χ_{v_j} satisfies the master equation,[8]

$$\begin{aligned}\frac{d\chi_{v_j}(t)}{dt} = {} & \kappa_j\{1-\exp(-\theta_j)\}^{-1}[v_j\exp(-\theta_j)\chi_{v_j-1}(t) \\ & - \{v_j+(v_j+1)\exp(-\theta_j)\}\chi_{v_j}(t) \\ & + (v_j+1)\chi_{v_j+1}(t)], \end{aligned} \quad (5)$$

where κ_j is the transition probability per unit time between levels $v_j=1$ and 0 of mode j, and $\theta_j=\hbar\omega_j/kT$. T denotes temperature of the heat bath consisting of unexcited benzenes. The master equation with the initial condition as given by Eq. (3) is solved as[8]

$$\begin{aligned}\chi_{v_j}(\tau_j) = {} & \left\{\frac{1-\exp(\theta_j)}{\exp(-\tau_j)-\exp(\theta_j)}\right\} \\ & \times \exp\left[\frac{\alpha_j\exp(-\tau_j)\{\exp(\theta_j)-1\}}{\exp(-\tau_j)-\exp(\theta_j)}\right] \\ & \times \left\{\frac{1-\exp(-\tau_j)}{\exp(\theta_j)-\exp(-\tau_j)}\right\}^{v_j} L_{v_j}(y_j), \end{aligned} \quad (6)$$

in which $L_{v_j}(y_j)$ is the Laguerre polynomials,

$$y_j = \frac{\alpha_j\exp(-\tau_j)\{\exp(\theta_j)-1\}^2}{\{1-\exp(-\tau_j)\}\{\exp(-\tau_j)-\exp(\theta_j)\}}, \quad (7)$$

and

$$\tau_j = \kappa_j t\{1-\exp(-\theta_j)\}. \quad (8)$$

In the case in which the vibronic band is characterized by a Lorentzian envelope, the absorption coefficient $k_{a\{v\}}$ in Eq. (1) is given by

$$k_{a\{v\}}(\omega_R) = \frac{4\pi\omega_R}{3\hbar c}\mathrm{Re}\sum_{\{v''\}}\frac{|R_{bv'',av}|^2}{i(\omega_{bv'',av}-\omega_R)+\Gamma_{ba}}, \quad (9)$$

where $\omega_{bv'',av}$ is the frequency difference between two vibronic levels, bv'' and av, $R_{bv'',av}$, the matrix element of the electric transition dipole moment, and Γ_{ba}, the damping constant associated with the interactions between the optical and other vibrational modes. We invoke the adiabatic and Condon approximations since we are interested in the allowed electronic transition $S_3(E_{1u})\leftarrow S_0(A_{1g})$ of benzene. In these approximations, Eq. (9) can be expressed as

$$k_{a\{v\}}(\omega_R) = C\sum_{\{v''\}}\frac{\Gamma_{ba}|\langle\eta_{bv''}|\eta_{av}\rangle|^2}{(\omega_{bv'',av}-\omega_R)^2+\Gamma_{ba}^2}, \quad (10)$$

where $C=4\pi\omega_R|R_{ab}^0|^2/(3\hbar c)$, and η denote the vibrational wavefunctions. We adopt a displaced harmonic oscillator model for the optical modes.

Carrying out the summation over the vibronic states in Eq. (1), we express the absorption coefficient, Eq. (10), as:

$$\begin{aligned}k_{a\{v\}}(\omega_R) = {} & \frac{C}{2}\exp(-S)\int_{-\infty}^{\infty}d\xi\exp[i\xi(\omega_{ba}-\omega_R)-\Gamma_{ba}|\xi| \\ & + \sum_{j=1}^{N}\frac{\Delta_j^2}{2}\exp(i\omega_j\xi)]\sum_{n_1=0}^{v_1}\cdots\sum_{n_j=0}^{v_j}\cdots\sum_{n_N=0}^{v_N}\prod_j \\ & \times\frac{v_j!\Delta_j^{2n_j}}{(v_j-n_j)!(n_j!)^2}(\cos\omega_j\xi-1)^{n_j}, \end{aligned} \quad (11)$$

where S $(=\sum_{j=1}^{N}\bar{\Delta}_j^2/2)$ is the coupling strength in the low temperature limit. Substituting Eqs. (6) and (11) into Eq. (1), we can derive an analytical expression for the time-dependent intensity:

$$\begin{aligned}D_{ab}(\omega_R,\tau) = {} & C\exp[-S-\sum_{j=1}^{N}a(\tau_j)]\sum_{n_1=0}^{\infty}\cdots\sum_{n_j=0}^{\infty}\cdots\sum_{n_N=0}^{\infty} \\ & \times\sum_{l_1=0}^{\infty}\cdots\sum_{l_j=0}^{\infty}\cdots\sum_{l_N=0}^{\infty}\sum_{m_1=0}^{l_1}\cdots\sum_{m_j=0}^{l_j}\cdots\sum_{m_N=0}^{l_N}\sum_{k_1=0}^{l_1-m_1}\cdots\sum_{k_j=0}^{l_j-m_j}\cdots\sum_{k_N=0}^{l_N-m_N}\end{aligned}$$

$$\times \sum_{p_1=0}^{2(m_1+k_1)} \cdots \sum_{p_j=0}^{2(m_j+k_j)} \cdots \sum_{p_N=0}^{2(m_N+k_N)} \left[\prod_{j=1}^{N} \binom{l_j}{m_j} \binom{l_j-m_j}{k_j} \binom{2m_j+2k_j}{p_j} \right.$$
$$\times \frac{(-1)^{p_j}}{n_j!\,(m_j+k_j)!\,(l_j-m_j)!} \left(\frac{\Delta_j^2}{2}\right)^{n_j+m_j+k_j}$$
$$\left. \times a(\tau_j)^{l_j-m_j} \left\{ \frac{1-\exp(-\tau_j)}{\exp(\theta_j)-1} \right\}^{m_j} \right]$$
$$\times \frac{\Gamma_{ba}}{\{\omega_{ba}+\sum_{j=1}^{N} \omega_j(n_j+k_j+m_j-p_j)-\omega_R\}^2+\Gamma_{ba}^2}, \quad (12)$$

where $\tau \equiv \{\tau_j\}$, $j=1, 2, \cdots, N$, and

$$a(\tau_j) = \frac{\alpha_j \exp(-\tau_j)\{\exp(\theta_j)-1\}}{\exp(\theta_j)-\exp(-\tau_j)}. \quad (13)$$

A detailed derivation of Eq. (12) is presented in Appendix A.

In the case in which $a(\tau_j)>1$ is satisfied, it is appropriate to use the following approximate expression for the intensity:

$$D_{ab}(\omega_R, \tau) = C \exp[-S] \sum_{n_1=0}^{\infty} \cdots \sum_{n_j=0}^{\infty} \cdots \sum_{n_N=0}^{\infty} \sum_{l_1=0}^{\infty} \cdots \sum_{l_j=0}^{\infty} \cdots \sum_{l_N=0}^{\infty}$$
$$\times \sum_{m_1=0}^{l_1} \cdots \sum_{m_j=0}^{l_j} \cdots \sum_{m_N=0}^{l_N} \sum_{k_1=0}^{l_1-m_1} \cdots \sum_{k_j=0}^{l_j-m_j} \cdots \sum_{k_N=0}^{l_N-m_N} \sum_{p_1=0}^{m_1+k_1} \cdots \sum_{p_j=0}^{m_j+k_j} \cdots \sum_{p_N=0}^{m_N+k_N}$$
$$\times \sum_{q_1=0}^{p_1} \cdots \sum_{q_j=0}^{p_j} \cdots \sum_{q_N=0}^{p_N} \sum_{r_1=0}^{m_1+k_1-p_1} \cdots \sum_{r_j=0}^{m_j+k_j-p_j} \cdots \sum_{r_N=0}^{m_N+k_N-p_N}$$
$$\times \left\{ \prod_{j=1}^{N} \frac{(-1)^{p_j-q_j+r_j}}{n_j!\,(m_j+k_j)!} \left(\frac{\Delta_j^2}{2}\right)^{n_j+m_j+k_j} \right.$$
$$\times \binom{l_j}{m_j} \binom{l_j-m_j}{k_j} \binom{m_j+k_j}{p_j} \binom{p_j}{q_j} \binom{m_j+k_j-p_j}{r_j}$$
$$\times \left[\frac{1-\exp(-\tau_j)}{\exp(\tau_j)-1} \right]^{m_j} \exp\left[-\frac{\{l_j-m_j-a(\tau_j)\}^2}{2a(\tau_j)} \right] \Bigg\}$$
$$\times \frac{\Gamma_{ba}}{\{\omega_{ba}+\sum_{j=1}^{N} \omega_j(n_j+k_j+m_j-p_j)-\omega_R\}^2+\Gamma_{ba}^2}. \quad (14)$$

Canonical Vibronic Energy Distribution. It is assumed that at $t=0$, a local equilibrium characterized by a canonical distribution with T° ($>T$) has been prepared. The solution of the master equation Eq. (5) in this case is given[8] by

$$\chi_{v_j}(\tau_j) = \{1-\exp[-u(\tau_j)]\} \exp[-v_j u(\tau_j)], \quad (15)$$

with

$$u(\tau_j) = \log\left[\frac{\exp(-\tau_j)\{1-\exp(\theta_j-\theta_j^0)\}-\exp(\theta_j)\{1-\exp(-\theta_j^0)\}}{\exp(-\tau_j)\{1-\exp(\theta_j-\theta_j^0)\}-\{1-\exp(-\theta_j^0)\}} \right]. \quad (16)$$

The expression for the intensity of the TRA spectra can be written as

$$D_{ab}(\omega_R, \tau) = \frac{C}{2} \exp[-S(\tau)] \int_{-\infty}^{\infty} d\xi \exp[i\xi(\omega_{ba}-\omega_R)-\Gamma_{ba}|\xi|$$
$$+ \sum_{j=1}^{N} \frac{\Delta_j^2\{n(\tau_j)+1\}}{2} \exp(i\omega_j\xi)$$
$$+ \sum_{j=1}^{N} \frac{\Delta_j^2 n(\tau_j)}{2} \exp(-i\omega_j\xi)], \quad (17)$$

where $S(\tau)$, time dependent coupling strength, is defined as

$$S(\tau) = \sum_{j=1}^{N} \{2n(\tau_j)+1\} \frac{\Delta_j^2}{2}. \quad (18)$$

Equation (17) has the same structure as that of the absorption band shape in the equilibrium condition. In Eq. (17), $n(\tau_j)$, the time-dependent occupation number of the optical mode j, is given as

$$n(\tau_j) = [\exp\{u(\tau_j)\}-1]^{-1}. \quad (19)$$

From Eqs. (16) and (19), we obtain $n(0)=[\exp(\theta^0)-1]^{-1}$ and $n(\infty)=[\exp(\theta)-1]^{-1}$ which are the occupation numbers at the initial time and in the equilibrium state, respectively.

Applying the Tayler expansions to Eq. (17), and carrying out the integration of the resulting expression over ξ, we can derive an analytical expression for the intensity as

$$D_{ab}(\omega_R, \tau) = C \exp[-S(\tau)] \sum_{k_1=0}^{\infty} \cdots \sum_{k_j=0}^{\infty} \cdots \sum_{k_N=0}^{\infty} \sum_{l_1=0}^{\infty} \cdots \sum_{l_j=0}^{\infty} \cdots \sum_{l_N=0}^{\infty}$$
$$\times \left[\prod_{j=1}^{N} \frac{\left[\{n(\tau_j)+1\}\frac{\Delta_j^2}{2}\right]^{k_j} \left\{n(\tau_j)\frac{\Delta_j^2}{2}\right\}^{l_j}}{k_j!\,l_j!} \right]$$
$$\times \frac{\Gamma_{ba}}{\{\omega_{ba}+\sum_{j=1}^{N} \omega_j(k_j-l_j)-\omega_R\}^2+\Gamma_{ba}^2}. \quad (20)$$

Equation (20) can be applied to both weak and strong coupling cases in principle. A fast convergence for the summations over k_j and l_j in Eq. (20) can be expected for the weak coupling case in which $S(\tau)\leq 1$. In the strong coupling case in which $S(\tau)>1$, on the other hand, we cannot expect the fast convergence. The classification for these coupling cases depend on time, as well as temperature, the frequency of the mode and the potential displacement. In the time domain in which the strong coupling case is satisfied and further $\Gamma_{ba}^2 < \sum_j \omega_j^2 \Delta_j^2 \{2n(\tau_j)+1\}$, it is better to use an approximate expression for the absorbance rather than Eq. (20). Neglecting Γ_{ba}, expanding $\exp(\pm i\omega_j\xi)$ to the second order of ξ in Eq. (17), and carrying out the integration of the equation over ξ we obtain

$$D_{ab}(\omega_R, \tau) = \frac{\sqrt{2\pi}C}{\sigma(\tau)} \exp\left[-\frac{\left(\omega_{ba}+\sum_{j=1}^{N} \frac{\omega_j\Delta_j^2}{2}-\omega_R\right)^2}{2\sigma^2(\tau)} \right], \quad (21)$$

where $\sigma(\tau)$, the time-dependent half-width of the TRA spectrum, is given as

$$\sigma(\tau) = \left[\sum_{j=1}^{N} \frac{\omega_j^2\Delta_j^2}{2} \{2n(\tau_j)+1\} \right]^{1/2}, \quad (22)$$

or

$$\sigma(\tau) = \left[\sum_{j=1}^{N} \frac{\omega_j^2\Delta_j^2}{2} \coth\frac{u(\tau_j)}{2} \right]^{1/2}. \quad (23)$$

It should be noted that the expression for the intensity in the Sulzer-Wieland model is involved in Eq. (21), that is, by setting $\tau=0$ in Eq. (21) we can obtain the expression given by Sulzer and Wieland[2] for one vibrational mode case:

$$D_{ab}(\omega_R, 0) \propto \left\{\tanh\frac{\hbar\omega}{2kT}\right\}^{1/2} \times \exp\left[-\tanh\frac{\hbar\omega}{2kT}\left\{\frac{\omega_{ba}+\omega\Delta^2/2-\omega_R}{\omega\Delta}\right\}^2\right]. \quad (24)$$

For the multimode case we can obtain the intensity expression simillar to that given by Asholz *et al.*[3]

Discussion

In order to clarify the initial vibronic distribution reflected in the TRA spectra we apply the derived expressions for the absorbance to benzene S_0* produced by internal conversion after the $S_2 \leftarrow S_0$ excitation.[1] We shall first calculate the TRA spectra assuming that Poisson distribution is realized and relaxes to the equilibrium one. It is necessary to estimate the parameter set for constructing vibronic distribution given by Eq. (3) after the internal conversion ($^1B_{1u} \rightsquigarrow {}^1A_{1g}$). Though it is recognized that benzene in the $^1B_{1u}$ state is subjected to the pseudo Jahn-Teller effect and the geometry of the $^1B_{1u}$ state may belong to D_{2h} symmetry, we neglect the geometry reduction. We simply adopt a model in which there are two displaced optical modes, one is a carbon-carbon stretching mode with frequency $\omega_{C\text{-}C}=1000\,cm^{-1}$, and the other is a carbon-hydrogen stretching mode with $\omega_{C\text{-}H}=3000\,cm^{-1}$. It was tentatively assumed that $\Delta_{C\text{-}C}=1.5$ and $\Delta_{C\text{-}H}=0.3$ for the dimensionless displacements.[9,10] Using these parameters we obtained $\alpha_{C\text{-}C}=6.8$ and $\alpha_{C\text{-}H}=12.5$ in Eq. (3) from the constraint of the energy conservation of the internal conversion with the electronic energy gap of 6.43 eV. Figure 1 shows the TRA spectra ($S_3 \leftarrow S_0$) calculated by using Eq. (12). Here the same molecular parameters of the S_3 state as those of the S_2 state were assumed.[11] The TRA spectra for the case of $\tau=0$, 0.5 (which corresponds to $t\simeq 0.5\times10^{-6}$ s) and 1 are indicated by solid, broken and dotted-broken lines, respectively. The remaining parameters have been assumed as follows: $\kappa_{C\text{-}C}=10^6\,s^{-1}$, $\kappa_{C\text{-}H}=2\times10^4\,s^{-1}$, $\Gamma_{ba}=500\,cm^{-1}$, and $T=300$ K. In Fig. 1 we can see the vibronic structure originating from the C-C stretching mode in the wavelength region of 180~200 nm even at early times. The carbon-hydrogen mode is, on the other hand, almost inactive in the TRA spectra because of its small magnitude of the displacement though this mode acts as the effective accepting mode for the internal conversion.[12] The TRA spectrum calculated at $\tau=0$ is different from the structureless spectrum which has been observed by Nakashima and Yoshihara.[1]

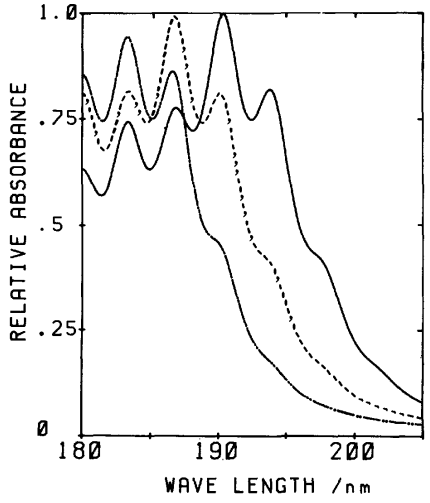


Fig. 1. The calculated TRA spectra ($S_3 \leftarrow S_0$) of benzene. Poisson distribution is adopted as the initial vibronic distribution. The calculation has been carried out by using Eq. (12). The solid, broken and dotted-broken lines denote TRA spectra at $\tau=0$, 0.5 and 1, respectively. See text for the parameter set.

Assuming that the canonical distribution with temperature higher than that of the heat bath is produced and relaxes to the equilibrium one, we now calculate the TRA spectra of benzene by using Eq. (21). Figure 2 shows the calculated spectra. The solid, broken and dotted-broken lines denote the TRA spectra at $\tau=0$, 0.5 ($t\simeq 0.14\times10^{-6}$ s) and 1, respectively. Here we, for simplicity, adopt an approximate expression for the half-width given by Eq. (23): $\sigma(0)\approx\overline{(\omega\Delta)^2}kT^\circ/\hbar\bar{\omega}$ at $\tau=0$, where the bars indicate magnitudes of the quantities averaged over the vibrational modes: we use $\overline{\omega\Delta}=2600\,cm^{-1}$, $\bar{\omega}=200\,cm^{-1}$, $T^\circ=3400$ K and $T=300$ K which were estimated in a previous paper.[1] The collisional vibrational transition probability κ is taken as $6\times10^6\,s^{-1}$. The closed circles in Fig. 2 denote experimental values for 2 Torr benzene at $\tau=0$.[1] In order to compare the experimental values with the calculated ones at $\tau=0$ the calculated molar extinction coefficient at 230 nm was taken to be equal to the experimental one. From Fig. 2 we can see that the initial vibronic distribution is of the canonical one rather than the Poisson one. In other words, lifetime of the vibronic states just after the internal conversion

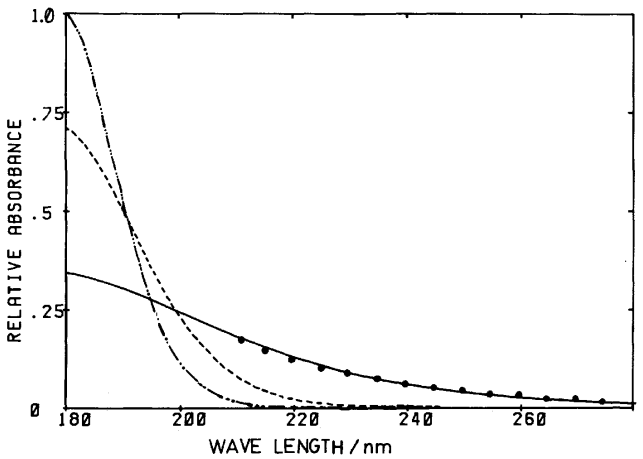

Fig. 2. The calculated TRA spectra of benzene when a canonical distribution is adopted as the initial distribution. The calculation has been carried out by using Eq. (21). The solid, broken and dotted-broken lines denote TRA spectra at $\tau=0$, 0.5, and 1, respectively. The closed circles represent experimental values for 2 Torr benzene at $\tau=0$.

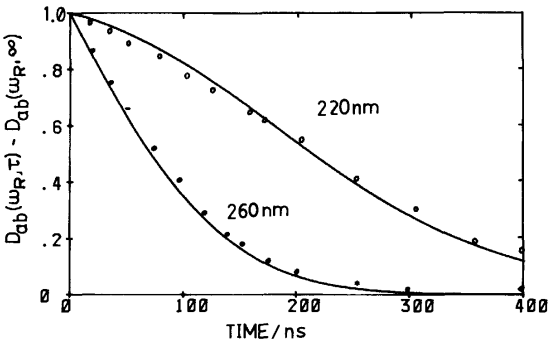

Fig. 3. The calculated decay curves, $D_{ab}(\omega_R, \tau)-D_{ab}(\omega_R, \infty)$ at 220 and 260 nm. The measured values of the absorbances of the 2 Torr (1 Torr≈133.322 Pa) benzene and 10 Torr propane are denoted at 220 nm (○) and 260 nm (●). See text for detail.

$S_2 \rightsquigarrow S_0$ is too short to observe the Poisson distribution because of a fast vibrational redistribution in the high vibronic state of S_0. The vibrational redistribution is caused by intramolecular couplings such as the ones caused by anharmonicities and mode mixings. This explains why the low vibrational frequency and the large potential displacement within the harmonic approximation has to be included in simulating the TRA spectra of benzene with the canonical distribution.

In Fig. 3 are shown decay curves, $D_{ab}(\omega_R,\tau)-D_{ab}(\omega_R,\infty)$ at 220 and 260 nm calculated by using Eq. (21). The same parameters as those in Fig. 2 are adopted except for $\kappa=9\times10^6\,s^{-1}$. The measured absorbances of the 2 Torr benzene and 10 Torr propane are plotted at 220 nm (○) and 260 nm (●).[13] The calculated decay curves are in fairly good agreement with the observed values. This suggests the validity of the linear collisional deactivation mechanism for the vibrationally hot benzene. In the previous paper, an energy-dependent energy transfer model has been adopted in order to explain the decay curves.

In summary we have developed a theory of the TRA spectra of molecules after radiationless transition. Two types of the initial vibronic distribution, Poisson and canonical ones are taken into account. The theory developed has been applied to the TRA spectra ($S_3 \leftarrow S_0$) of benzene produced by the internal conversion $S_2 \rightsquigarrow S_0$. It has been shown that the canonical distribution can explain the transient behavior of benzene after the internal conversion. Finally it should be noted that we can semi-quantitatively explain both time-resolved spectra and decay curves of benzenes in a foreign gas by using the derived expressions for the time-dependent absorption intensity. These expressions can be applied to the investigation of the relaxation processes in hot molecules, such as hexafluorobenzene[14] and other polyatomic molecules as well.

Appendix

A. Time-resolved absorption intensity for a Poisson distribution.

In this appendix, analytical expressions for the intensity $D_{ab}(\omega_R,\tau)$ are derived for the molecular system characterized by a Poisson distribution. Two cases depending on the magnitudes of the coupling strength $\sum_j \Delta_j^2/2 \gtrless 1$ will be considered.

Substituting Eqs. (6) and (11) into Eq. (1) yields

$$D_{ab}(\omega_R, \tau) = \frac{C}{2}\sum_{v_1=0}^{\infty}\cdots\sum_{v_j=0}^{\infty}\cdots\sum_{v_N=0}^{\infty} \times \exp(-S)\int_{-\infty}^{\infty} d\xi \exp[i\xi(\omega_{ba}-\omega_R)-\Gamma_{ba}|\xi| + \sum_{j=1}^{N}\frac{\Delta_j^2}{2}\exp(i\omega_j\xi)]\Big[\prod_{j=1}^{N} L_{v_j}\{\Delta_j^2(1-\cos\omega_j\xi)\} \times \frac{1-\exp(\theta_j)}{\exp(-\tau_j)-\exp(\theta_j)}\exp\left[-\frac{\alpha_j\exp(-\tau_j)\{\exp(\theta_j)-1\}}{\exp(\theta_j)-\exp(-\tau_j)}\right] \times \left\{\frac{1-\exp(-\tau_j)}{\exp(\theta_j)-\exp(-\tau_j)}\right\}^{v_j} L_{v_j}(y_j)\Big], \quad (A.1)$$

or

$$D_{ab}(\omega_R, \tau) = \frac{C}{2}\exp(-S) \times \left\{\prod_{j=1}^{N}\exp\left[-\frac{\alpha_j\exp(-\tau_j)\{\exp(\theta_j)-1\}}{\exp(\theta_j)-\exp(-\tau_j)}\right]\right\} \times \int_{-\infty}^{\infty} d\xi \exp[i\xi(\omega_{ba}-\omega_R)-\Gamma_{ba}|\xi| + \prod_{j=1}^{N}\frac{\Delta_j^2}{2}\exp(i\omega_j\xi)] \times \prod_{j=1}^{N}\frac{1-\exp(\theta_j)}{\exp(-\tau_j)-\exp(\theta_j)}\sum_{v_j=0}^{\infty}\sum_{n_j=0}^{v_j}\frac{v_j!\,x_j^{n_j}(\xi)}{(v_j-n_j)!\,(n_j!)^2} \times \sum_{m_j=0}^{v_j}\frac{v_j!\,(-y_j)^{m_j}}{(v_j-m_j)!\,(m_j!)^2}\left\{\frac{1-\exp(-\tau_j)}{\exp(\theta_j)-\exp(-\tau_j)}\right\}^{v_j}, \quad (A.2)$$

where $x_j(\xi)=\Delta_j^2(\cos\omega_j\xi-1)$, $y_j=\alpha_j\exp(-\tau_j)\{\exp(\theta_j)-1\}^2/[\{1-\exp(-\tau_j)\}\{\exp(-\tau_j)-\exp(\theta_j)\}]$, and the following expression for the Laguerre polynomials has been used,

$$L_v(y) = \sum_{m=0}^{v}\frac{v!\,(-y)^m}{(v-m)!\,(m!)^2}. \quad (A.3)$$

Applying the identity

$$\frac{1}{n!} = \frac{1}{2\pi i}\oint\frac{\exp(z)}{\cdot\, z^{n+1}}dz \quad (A.4)$$

to Eq. (A. 2) and after taking summations over m_j and n_j, one obtains

$$D_{ab}(\omega_R, \tau) = \frac{C}{2}\exp(-S) \times \left\{\prod_{j=1}^{N}\exp\left[-\frac{\alpha_j\exp(-\tau_j)\{\exp(\theta_j)-1\}}{\exp(\theta_j)-\exp(-\tau_j)}\right]\right\} \times \int_{-\infty}^{\infty} d\xi \exp[it(\omega_{ba}-\omega_R)-\Gamma_{ba}|\xi| + \prod_{j=1}^{N}\frac{\Delta_j^2}{2}\exp(i\omega_j\xi)] \times \prod_{j=1}^{N}\frac{1-\exp(\theta_j)}{\exp(-\tau_j)-\exp(\theta_j)}\Lambda_j(\xi), \quad (A.5)$$

where

$$\Lambda_j(\xi) = \left(\frac{1}{2\pi i}\right)^2\oint dz_1\oint dz_2\frac{\exp(z_1+z_2)}{z_1z_2}\sum_{v_j=0}^{\infty}\left\{1+\frac{x_j(\xi)}{z_1}\right\}^{v_j} \times \left(1-\frac{y_j}{z_2}\right)^{v_j}\left\{\frac{1-\exp(-\tau_j)}{\exp(\theta_j)-\exp(-\tau_j)}\right\}^{v_j}. \quad (A.6)$$

Assuming convergence of the summation over v_j in Eq. (A. 6), one can express Eq. (A. 6) as

$$\Lambda_j(\xi) = \left(\frac{1}{2\pi i}\right)^2 \oint dz_1 \oint dz_2 \frac{\exp(z_1+z_2)}{z_1 z_2 (1-A_j)} \times \left\{1 - \frac{A_j x_j(\xi)}{(1-A_j)z_1} + \frac{A_j y_j}{(1-A_j)z_2} + \frac{A_j x_j(\xi) y_j}{(1-A_j)z_1 z_2}\right\}^{-1}, \quad (A.7)$$

where

$$A_j = \{1-\exp(-\tau_j)\}/\{\exp(\theta_j)-\exp(-\tau_j)\}. \quad (A.8)$$

Equation (A. 7) can be expanded as

$$\Lambda_j(\xi) = \left(\frac{1}{2\pi i}\right)^2 \oint dz_1 \oint dz_2 \frac{\exp(z_1+z_2)}{z_1 z_2 (1-A_j)} \times \sum_{l_j=0}^{\infty} \left\{\frac{A_j x_j(\xi)}{(1-A_j)z_1} - \frac{A_j y_j}{(1-A_j)z_2} - \frac{A_j x_j(\xi) y_j}{(1-A_j)z_1 z_2}\right\}^{l_j}. \quad (A.9)$$

In order to obtain the correct values of the intensity for the limiting cases, $\tau \to 0$ and $\tau \to \infty$, it is necessary to define

$$B_j = -A_j y_j = \frac{\alpha_j \exp(-\tau_j)\{\exp(\theta_j)-1\}^2}{\{\exp(\theta_j)-\exp(-\tau_j)\}^2}. \quad (A.10)$$

Utilizing the binomial expansion and Eq. (A. 4) one can rewrite Eq. (A. 9) as

$$\Lambda_j(\xi) = \frac{\exp(-\tau_j)-\exp(\theta_j)}{1-\exp(\theta_j)} \sum_{l_j=0}^{\infty} \sum_{m_j=0}^{l_j} \sum_{k_j=0}^{l_j-m_j} \binom{l_j}{m_j} \binom{l_j-m_j}{k_j} \times \left(\frac{A_j}{1-A_j}\right)^{m_j} \left(\frac{B_j}{1-A_j}\right)^{l_j-m_j} \frac{\{x_j(\xi)\}^{m_j+k_j}}{(m_j+k_j)!\,(l_j-m_j)!}. \quad (A.11)$$

Here it should be noted that one has $m_j=0$ for $\tau_j \to 0$ that is, $A_j=0$, and $k_j=0$ and $l_j=m_j$ for $\tau_j \to \infty$, that is, $B_j=0$.

One uses the following expansions,

$$\{x_j(\xi)\}^{m_j+k_j} = \left(\frac{\Delta_j^2}{2}\right)^{m_j+k_j} \sum_{p_j=0}^{m_j+k_j} \sum_{q_j=0}^{p_j} \sum_{r_j=0}^{m_j+k_j-p_j} \binom{m_j+k_j}{p_j} \binom{p_j}{q_j} \times \binom{m_j+k_j-p_j}{r_j} (-1)^{m_j+k_j-q_j-r_j} \exp[i\omega_j(q_j-r_j)\xi], \quad (A.12a)$$

or

$$\{x_j(\xi)\}^{m_j+k_j} = \left(\frac{\Delta_j^2}{2}\right)^{m_j+k_j} \sum_{p_j=0}^{2(m_j+k_j)} (-1)^{p_j} \binom{2(m_j+k_j)}{p_j} \times \exp\{i\omega_j(k_j+m_j-p_j)\xi\}, \quad (A.12b)$$

Substituting Eq. (A. 11) with Eq. (A. 12b) into Eq. (A. 5) yields

$$D_{ab}(\omega_R, \tau) = \frac{C}{2} \exp\left[-S - \sum_{j=1}^{N} \frac{\alpha_j \exp(-\tau_j)\{\exp(\theta_j)-1\}}{\exp(\theta_j)-\exp(-\tau_j)}\right] \times \sum_{l_1=0}^{\infty} \cdots \sum_{l_j=0}^{\infty} \cdots \sum_{l_N=0}^{\infty} \sum_{m_1=0}^{l_1} \cdots \sum_{m_j=0}^{l_j} \cdots \sum_{m_N=0}^{l_N} \sum_{k_1=0}^{l_1-m_1} \cdots \sum_{k_j=0}^{l_j-m_j} \cdots \sum_{k_N=0}^{l_N-m_N} \times \sum_{p_1=0}^{2(m_1+k_1)} \cdots \sum_{p_j=0}^{2(m_j+k_j)} \cdots \sum_{p_N=0}^{2(m_N+k_N)} \left[\prod_{j=1}^{N} \left(\frac{\Delta_j^2}{2}\right)^{m_j+k_j} \binom{l_j}{m_j} \binom{l_j-m_j}{k_j} \times \left\{\frac{1-\exp(-\tau_j)}{\exp(\theta_j)-1}\right\}^{m_j} \left\{\frac{\alpha_j \exp(-\tau_j)[\exp(\theta_j)-1]}{\exp(\theta_j)-\exp(-\tau_j)}\right\}^{l_j-m_j} \times \frac{(-1)^{p_j}\binom{2m_j+2k_j}{p_j}}{(m_j+k_j)!\,(l_j-m_j)!}\right] \int_{-\infty}^{\infty} d\xi \exp\left[i\xi\{\omega_{ba} + \sum_{j=1}^{N} \omega_j(k_j+m_j-p_j) - \omega_R\} + \sum_{j=1}^{N} \frac{\Delta_j^2}{2} \exp(i\omega_j\xi) - \Gamma_{ba}|\xi|\right]. \quad (A.13)$$

Integration over ξ in Eq. (A. 13) will be carried out in the weak coupling case, $S \leq 1$ and the strong coupling case, $S > 1$, separately.

i. Weak Coupling Case. In this case, utilizing the Tayler expansion and integrating the expression over ξ, one can obtain the analytical expression for the absorption intensity,

$$D_{ab}(\omega_R, \tau) = C \exp\left[-S - \sum_{j=1}^{N} \frac{\alpha_j \exp(-\tau_j)\{\exp(\theta_j)-1\}}{\exp(\theta_j)-\exp(-\tau_j)}\right] \times \sum_{n_1=0}^{\infty} \cdots \sum_{n_j=0}^{\infty} \cdots \sum_{n_N=0}^{\infty} \sum_{l_1=0}^{\infty} \cdots \sum_{l_j=0}^{\infty} \cdots \sum_{l_N=0}^{\infty} \sum_{m_1=0}^{l_1} \cdots \sum_{m_j=0}^{l_j} \cdots \sum_{m_N=0}^{l_N} \times \sum_{k_1=0}^{l_1-m_1} \cdots \sum_{k_j=0}^{l_j-m_j} \cdots \sum_{k_N=0}^{l_N-m_N} \sum_{p_1=0}^{2(m_1+k_1)} \cdots \sum_{p_j=0}^{2(m_j+k_j)} \cdots \sum_{p_N=0}^{2(m_N+k_N)} \times \left[\prod_{j=1}^{N} \left(\frac{\Delta_j^2}{2}\right)^{n_j+m_j+k_j} \binom{l_j}{m_j} \binom{l_j-m_j}{k_j} \frac{(-1)^{p_j}\binom{2m_j+2k_j}{p_j}}{n_j!\,(m_j+k_j)!\,(l_j-m_j)!} \times \left\{\frac{\alpha_j \exp(-\tau_j)[\exp(\theta_j)-1]}{\exp(\theta_j)-\exp(-\tau_j)}\right\}^{l_j-m_j} \left\{\frac{1-\exp(-\tau_j)}{\exp(\theta_j)-1}\right\}^{m_j}\right] \times \frac{\Gamma_{ba}}{\{\omega_{ba} + \sum_{j=1}^{N} \omega_j(n_j+k_j+m_j-p_j) - \omega_R\}^2 + \Gamma_{ba}^2}. \quad (A.14)$$

ii. Strong Coupling Case. In this case, one can use the expansion of $\exp(i\omega_j\xi)$ to the second order,

$$\exp(i\omega_j\xi) \fallingdotseq 1 + i\omega_j\xi - \frac{\omega_j^2\xi^2}{2}. \quad (A.15)$$

In the strong coupling case the following relation is satisfied for the optical transition between two electronic states of molecules,

$$\sum_{j=1}^{N} \frac{\omega_j^2 \Delta_j^2}{4} > \Gamma_{ba}^2, \quad (A.16)$$

that is, effect of the damping on the spectrum can be neglected.

Substituting Eq. (A. 15) into Eq. (A. 13) and integrating the expression over ξ yield

$$D_{ab}(\omega_R, \tau) = D_{ab}(\omega_{max}, \infty)_{T=0} \times \exp\left[-\sum_{j=1}^{N} \frac{\alpha_j \exp(-\tau_j)\{\exp(\theta_j)-1\}}{\exp(\theta_j)-\exp(-\tau_j)}\right] \sum_{l_1=0}^{\infty} \cdots \sum_{l_j=0}^{\infty} \cdots \sum_{l_N=0}^{\infty} \times \sum_{m_1=0}^{l_1} \cdots \sum_{m_j=0}^{l_j} \cdots \sum_{m_N=0}^{l_N} \sum_{k_1=0}^{l_1-m_1} \cdots \sum_{k_j=0}^{l_j-m_j} \cdots \sum_{k_N=0}^{l_N-m_N} \sum_{p_1=0}^{2(m_1+k_1)} \cdots \sum_{p_j=0}^{2(m_j+k_j)} \cdots \sum_{p_N=0}^{2(m_N+k_N)} \times \left[\prod_{j=1}^{N} \left(\frac{\Delta_j^2}{2}\right)^{m_j+k_j} \binom{l_j}{m_j} \binom{l_j-m_j}{k_j} \frac{(-1)^{p_j}\binom{2m_j+2k_j}{p_j}}{(m_j+k_j)!\,(l_j-m_j)!} \times \left\{\frac{\alpha_j \exp(-\tau_j)[\exp(\theta_j)-1]}{\exp(\theta_j)-\exp(-\tau_j)}\right\}^{l_j-m_j} \left\{\frac{1-\exp(-\tau_j)}{\exp(\theta_j)-1}\right\}^{m_j}\right] \times \exp\left[-\frac{\left\{\omega_{ba} + \sum_{j=1}^{N} \omega_j\left(\frac{\Delta_j^2}{2}+k_j+m_j-p_j\right) - \omega_R\right\}^2}{2\sum_{j=1}^{N} \frac{\omega_j^2\Delta_j^2}{2}}\right] \quad (A.17)$$

where $D_{ab}(\omega_{max}, \infty)_{T=0} = \sqrt{2\pi}C/\{\sum_{j=1}^{N} \omega_j^2\Delta_j^2/2\}^{1/2}$ is the maximum absorption intensity at 0 K in the equilibrium state.

13) The vibrational energy of the hot benzene in the presence of foreign molecules can be exchanged with the translational degree of freedom of the foreign molecule. In this case within the linear interaction model the collision-induced vibrational relaxation can be explained by using the master equation given by Eq. (5) in which $\kappa_j(1-e^{-\theta})^{-1}$ is replaced by $\kappa_j(1-e^{-\theta})^{-1}+\kappa_j'$ where κ_j' is the transition probability between levels $v_j=1$ and $v_j=0$ of mode j of the hot benzene for the vibration-translation energy exchange.[8)]

Synthesis of Pharmaceutically Important Heteroaromatics from Methyl Phenyl Sulfone

Masataka YOKOYAMA,* Kouichi TSUJI, and Tsuneo IMAMOTO
Department of Chemistry, Faculty of Science, Chiba University, Yayoi-cho, Chiba 260
(Received April 26, 1984)

Some 5-substituted pyrazoles and pyrimethamine were prepared from 3-methylthio-1-phenyl-4-phenylsulfonyl-2-buten-1-one (**5a**) or (*E*)-1-*p*-chlorophenyl-1-cyano-2-methylthio-3-phenylsulfonylpropene (**6b**) which could be easily synthesized from methyl phenyl sulfone.

Pyrazole derivatives are found in several febrifuges, weed killers, and insecticides. And pyrimethamine is a useful antimalarial agent, which is about 1000 times as active as quinine.[1] Thus, improvement of the synthetic method for these compounds is important. We found that 1,1-bis(methylthio)-2-phenylsulfonylethene (**1**), derived easily from methyl phenyl sulfone, was a useful starting material for the synthesis of these pharmaceutical heteroaromatics. In this paper we describe an efficient method for the synthesis of 5-[(*Z*)-1,3-butadienyl]-3-phenylpyrazole (**2**), 5-methyl-3-phenylpyrazole (**3**), and pyrimethamine (**4**) from methyl phenyl sulfone.

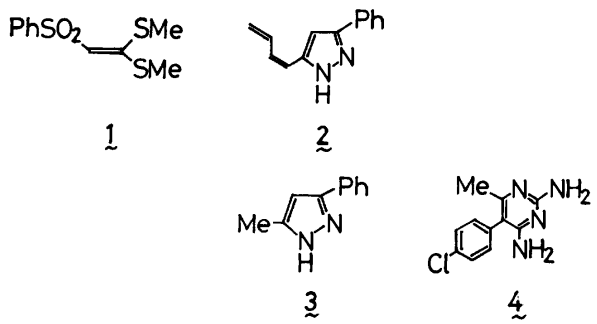

Fig. 1.

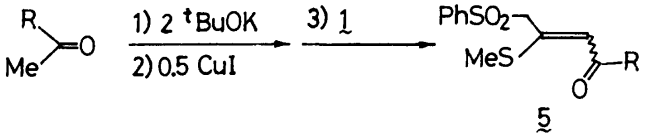
Results and Discussion

Reaction of (1) with α-Metalated Ketones or Nitriles. Compound (**1**) was prepared by means of the condensation between methyl phenyl sulfone and methyl trithiocarbonate, followed by methylation in 50% yield. Although Vialle *et al.* have already prepared this compound,[2] our method has a better yield.

Fig. 2.

When treated with α-metalated ketones[3] or nitriles, **1** was converted to 3-(methylthio)vinyl ketones (**5**) or nitriles (**6**) in moderate yields. The results are summarized in Table 1.



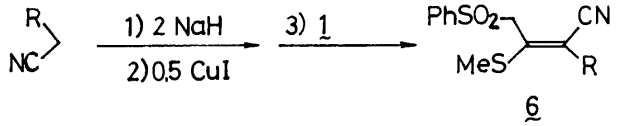


Fig. 3.

TABLE 1. PREPARATION OF **5** AND **6**

Product	R	Yield/%
5a	Phenyl	72
5b	2-Thienyl	64
5c	2-Pyridyl	38
5d	2-Naphthyl	78
5e	Methyl	57
6a	Phenyl	61
6b	*p*-Chlorophenyl	71

In this reaction, copper(I) iodide acted as an inhibitor of the formation of 1,1,2-tris(methylthio)ethene[4] which was generated in the side reaction.[5] But in the case of the reaction with methyl 2-pyridyl ketone, product **5c** could not be obtained in the presence of copper(I) iodide, probably due to the reduced reactivity of the carbanion by chelation of the pyridine nitrogen toward the copper. Compounds (**5**) were obtained as *E,Z* mixtures, while compounds (**6**) were given almost stereoselectively owing to the steric hindrance.

Preparation of Pyrazole Derivatives. Compound (**5a**) reacted with hydrazine hydrate in ethanol at refluxing temperature in the presence of a catalytic amount of sulfuric acid to give 3-phenyl-5-(phenylsulfonylmethyl)-pyrazole (**7**)[6] in 98% yield. When **7** was treated with 2 equivalents of *n*-BuLi, followed by addition of allyl bromide, **8** was obtained in 81% yield. Then **8** could easily be converted to 5-[(*Z*)-1,3-butadienyl]-3-phenylpyrazole (**2**) in 89% yield by treatment with 2 equivalents of *t*-BuOK. By the reaction of dianion of **7** with *p*-chlorobenzaldehyde, 5-[2-(*p*-chlorophenyl)-2-hydroxy-1-(phenylsulfonyl)ethyl]-3-phenylpyrazole (**9**) was afforded in 71% yield. Furthermore **7** could also give 5-methyl-3-phenylpyrazole (**3**) in 78% yield on treatment with 5% sodium-amalgam (Na/Hg).[7] In this way, **7** could be converted into various pyrazoles which have an alkadienyl, alkyl, or other functional group at 5-position. This is the principal advantage of the present method over known preparative methods for pyrazoles.[8]

Preparation of Pyrimethamine. When **6b** was treated with 2 equivalents of guanidine, 5-(*p*-chlorophenyl)-2,4-diamino-6-(phenylsulfonylmethyl)pyrimidine (**10**) was obtained in 92% yield. And **10** could be converted to pyrimethamine (**4**) on treatment with

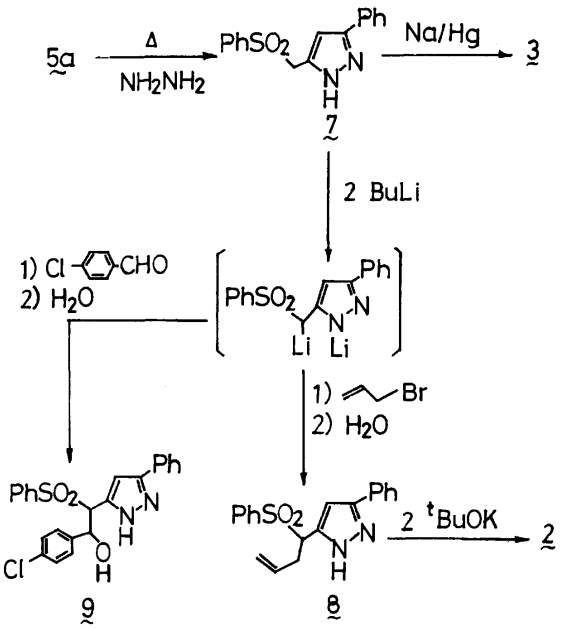

Fig. 4.

Na/Hg quantitatively. The attempts to introduce electrophiles into 6-position failed, owing to low reactivity of the corresponding carbanaion and the presence of free amino groups. However our preparative method for **4** can compete in terms of simple preparation and yield with hitherto known ones.[1]

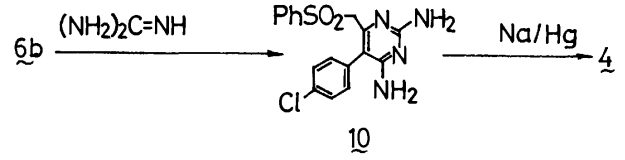

Fig. 5.

Experimental

Microanalyses were performed with Perkin-Elmer 240 elemental analyser at the Chemical Analysis Center of Chiba University. IR, UV, Mass, and ^{1}H-NMR spectra were measured with Japan Spectroscopic Co. DS 403G, Hitachi EPS-3T, RMU 6MC instruments, and Japan Electron Optics Lab. Co. C-60HL instruments, respectively. The silica gel used for TLC was Wakogel B-5F.

Preparation of 1,1-Bis(methylthio)-2-phenylsulfonylethene (1). A solution of methyl phenyl sulfone (9.4 g, 0.06 mol) in 60 ml of THF was added to 60% NaH (5.3 g, 0.13 mol) under nitrogen. After reflux for 1 h and then cooling to 0 °C, methyl trithiocarbonate (8.3 g, 0.06 mol) in 20 ml of THF was added to the mixture. It was stirred for 30 min at 0 °C and at room temperature for an additional 12 h. After addition of methyl iodide (0.12 mol), the resulting mixture was stirred for 3 h, quenched with water, and extracted with chloroform. The chloroform extract was dried over sodium sulfate and evaporated. The yellow powder was obtained and recrystallized from ethanol to give 7.8 g (50% yield) of **1** as white needles, mp 122—123 °C (lit,[2] 119 °C).

Reaction of 1 with α-Metalated Ketones. To a suspension of ketone (1.0 mmol), *t*-BuOK (274 mg, 2.2 mmol), and copper (I) iodide (100 mg, 0.5 mmol) in 5 ml of THF was added a solution of **1** (260 mg, 1.0 mmol) in 5 ml of THF. After stirring for 15 h, water and chloroform were added to the mixture, and acidified with 2M HCl(1 M=1 mol dm^{-3}). The resulting mixture was filtered through Celite, and the organic layer was dried over sodium sulfate and rotary-evaporated. The resulting brown oil was purified by TLC on silica gel using AcOEt–hexane (2:3) as a developing solvent to afford **5**. In the case of methyl 2-pyridyl ketone, copper (I) iodide was not used in the reaction.

3-Methylthio-1-phenyl-4-phenylsulfonyl-2-buten-1-one (5a): Yellow needles (from EtOH); 239 mg (72%); a 1:4 mixture of two stereoisomers; IR (KBr): 3050 (arom CH), 2960, 2900 (CH), 1640 (C=O), 1320 and 1150 cm^{-1} (SO_2); NMR ($CDCl_3$): δ=7.85 (2H, m, $PhSO_2$), 7.63 (2H, m, Ph), 7.40 (6H, m, 2Ph), 6.70, 6.58 (1H, s, CH), 5.00, 4.30 (2H, s, CH_2), 2.43, 2.38 (3H, s, CH_3); MS: *m/z* 332 (M^+). Found: C, 61.39; H, 4.86%. Calcd for $C_{17}H_{16}O_3S_2$: C, 61.42; H, 4.85%.

3-Methylthio-4-phenylsulfonyl-1-(2-thienyl)-2-buten-1-one (5b): White prisms (from $CHCl_3$); 217 mg (64%); a 1:4 mixture of two stereoisomers; IR (KBr): 3080 (arom CH), 2950, 2900 (CH), 1620 (C=O), 1320 and 1140 cm^{-1}(SO_2); NMR ($CDCl_3$): δ=7.88 (2H, m, C_6H_5), 7.48 (5H, m, C_6H_5, C_4H_3S), 7.02 (1H, m, C_4H_3S), 6.45 (1H, s, CH), 5.01, 4.25 (2H, s, CH_2), 2.48, 2.38 (3H, s, CH_3); MS: *m/z* 338 (M^+). Found: C, 53.02; H, 4.15%. Calcd for $C_{15}H_{14}O_3S_3$: C, 53.23; H, 4.17%.

3-Methylthio-4-phenylsulfonyl-1-(2-pyridyl)-2-buten-1-one (5c): Greenish brown needles (from acetone); 127 mg (38%); a 1:5 mixture of two stereoisomers; IR (KBr): 3050 (arom CH), 2970, 2890 (CH), 1650 (C=O), 1310 and 1140 cm^{-1}(SO_2); NMR ($CDCl_3$): δ=8.63 (1H, m, C_5H_4N), 7.93 (4H, m, C_6H_5, C_5H_5N), 7.63 (1H, s, CH), 7.47 (4H, m, C_6H_5, C_5H_4N), 5.08, 4.38 (2H, s, CH_2), 2.52, 2.48 (3H, s, CH_3); MS: *m/z* 286 ($M-47$)$^+$. Found: C, 57.61; H, 4.51; N, 4.13%. Calcd for $C_{16}H_{15}NO_3S_2$: C, 57.64; H, 4.53; N, 4.20%.

3-Methylthio-1-(2-naphtyl)-4-phenylsulfonyl-2-buten-1-one (5d): Yellow needles (from EtOH); 298 mg (78%); a 2:5 mixture of two stereoisomers; IR (KBr): 3050 (arom CH), 2990, 2900 (CH), 1640 (C=O), 1310 and 1150 cm^{-1}(SO_2); NMR ($CDCl_3$): δ=8.30—7.20 (12H, m, C_6H_5, $C_{10}H_7$), 6.78, 6.72 (1H, s, CH), 5.05, 4.33 (2H, s, CH_2), 2.45, 2.38 (3H, s, CH_3); MS: *m/z* 382 (M^+). Found: C, 65.90; H, 4.82%. Calcd for $C_{21}H_{18}O_3S_2$: C, 65.94; H, 4.74%.

4-Methylthio-5-phenylsulfonyl-3-penten-2-one (5e): White plates (from EtOH); 154 mg (57%); a 3:5 mixture of two stereoisomers; IR (KBr): 3050 (arom CH), 2970, 2900 (CH), 1660 (C=O), 1300 and 1150 cm^{-1} (SO_2); NMR ($CDCl_3$): δ=7.88 (2H, m, Ph), 7.23 (3H, m, Ph), 5.93 (1H, s, CH), 4.85, 4.18 (2H, s, CH_2), 2.35 (3H, s, SCH_3), 2.00 (3H, s, CH_3); MS: *m/z* 270 (M^+). Found: C, 53.35; H, 5.18%. Calcd for $C_{12}H_{14}O_3S_2$: C, 53.31; H, 5.22%.

Reaction of 1 with α-Metalated Nitriles. To a solution of nitrile (1.0 mmol) and **1** (260 mg, 1.0 mmol) in 10 ml of THF was added 60% NaH (88 mg, 2.2 mmol) and copper (I) iodide (100 mg, 0.5 mmol). The treatment described above gave **6**.

(E)-3-Methylthio-2-phenyl-4-phenylsulfonyl-2-butenenitrile (6a): Colorless plates; mp 116—118 °C (from EtOH); IR (KBr): 3050 (arom CH), 2900 (CH), 2200 (CN) 1330 and 1160 cm^{-1} (SO_2); NMR ($CDCl_3$): δ=8.03 (2H, m, $PhSO_2$), 7.57 (3H, m, $PhSO_2$), 7.33 (5H, s, Ph), 4.61 (2H, s, CH_2), 2.48 (3H, s, CH_3); MS: *m/z* 329 (M^+). Found: C, 61.94; H, 4.62; N, 4.22%. Calcd for $C_{17}H_{15}NO_2S_2$: C, 61.98; H, 4.59; N, 4.25%.

(E)-2-(p-Chlorophenyl)-3-methylthio-4-phenylsulfonyl-2-butenenitrile (6b): White plates; mp 131—132 °C (from $CHCl_3$); IR (KBr): 3040 (arom CH), 2900 (CH), 2200 (CN), 1330 and 1160 cm^{-1} (SO_2); NMR ($CDCl_3$): δ=8.03 (2H, m, Ph), 7.60 (3H, m, Ph), 7.30 (4H, s, *p*-ClC_6H_4), 4.58 (2H, s, CH_2), 2.50 (3H, s, CH_3); MS: *m/z* 363 (M^+). Found: C, 55.84; H, 3.87; N, 3.79%. Calcd for $C_{17}H_{14}ClNO_2S_2$: C, 56.11; H, 3.88; N, 3.85%.

Preparation of 3-Phenyl-5-(phenylsulfonylmethyl)pyrazole (7). To a solution of **5a** (500 mg, 1.5 mmol) in 40 ml of EtOH was added hydrazine hydrate (150 mg, 3.0 mmol) in 10 ml of

EtOH and a few drops of 5% sulfuric acid. When stirred at refluxing temperature for about 2 h, the yellow solution turned colorless. After being quenched with water, the mixture was extracted with chloroform. The chloroform extract was dried over sodium sulfate and evaporated. A white powder was obtained (439 mg, 98%) and recrystallized from chloroform to give **7** as white plates, mp 170—171 °C (lit, [6] 173 °C).

Preparation of 3-Phenyl-5-(1'-phenylsulfonyl-3'-butenyl)-pyrazole (8). To a solution of **7** (388 mg, 1.3 mmol) in 10 ml of THF was added 1.4 M solution of *n*-BuLi in hexane (2.0 ml, 2.86 mmol) at −70 °C under nitrogen. After stirring for 30 min, allyl bromide (0.12 ml, 1.43 mmol) was added to the mixture and it was stirred for 10 min at −70 °C, and then for 1 h at room temperature. After being quenched with saturated solution of ammonium chloride, the mixture was extracted with ethyl acetate. The ethyl acetate extract was dried over sodium sulfate and rotary-evaporated. The resulting colorless oil was purified by TLC on silica gel using AcOEt–hexane (1:1) as a developing solvent to give 356 mg (81%) of **8** as a colorless oil; bp 130 °C/13.3 Pa; IR (KBr): 3300 (NH), 1300 and 1150 cm^{-1} (SO_2); NMR ($CDCl_3$): δ= 11.68 (1H, br, NH), 7.55 (10H, m, 2Ph), 6.60 (1H, s, CH), 6.20—5.37 (1H, m, CH_2=C<u>H</u>CH_2), 5.10 (1H, dd, J_{trans}=18 Hz, J_{gem}=1 Hz, C<u>H</u>$_2$=CH), 5.02 (1H, dd, J_{cis}=10 Hz, J_{gem}=1 Hz, C<u>H</u>$_2$=CH), 4.59 (1H, t, J=8 Hz, $PhSO_2CH$), 3.07 (2H, m, CH_2=CH-C<u>H</u>$_2$); MS: *m/z* 338 (M^+).

Preparation of 5-[(Z)-1,3-Butadienyl]-3-phenylpyrazole (2). To a solution of **8** (203 mg, 0.6 mmol) in 5 ml of THF was added *t*-BuOK (165 mg, 1.32 mmol), the mixture was stirred for 3 h. The treatment described above gave white powder. It was purified by TLC on silica gel using AcOEt–hexane (2:3) as a developing solvent to give 105 mg (89%) of **2** as white needles; mp 50 °C (decomp.); IR (KBr): 3200 cm^{-1} (NH); NMR ($CDCl_3$): δ=12.15 (1H, br, NH), 7.61 (2H, m, Ph), 7.26 (3H, m, Ph), 6.57 (1H, s, CH), 6.55 (1H, m, CH_2=C<u>H</u>), 6.54 (1H, d, J_{cis}=8 Hz, CH_2=CHC<u>H</u>=CH), 6.20 (1H, dd, J_{cis}=8 Hz, J=10 Hz, CH_2=CHC<u>H</u>=CH), 5.29 (1H, dd, J_{cis}=10 Hz, J_{gem}= 1 Hz, C<u>H</u>$_2$=CH), 5.20 (1H, dd, J_{trans}=17 Hz, J_{gem}=1 Hz, C<u>H</u>$_2$=CH); MS: *m/z* 196 (M^+). Found: C, 79.35; H, 6.21; N, 14.20%. Calcd for $C_{13}H_{12}N_2$: C, 79.56; H, 6.16; N, 14.27%.

Preparation of 5-[2-(p-Chlorophenyl)-2-hydroxy-1-(phenylsulfonyl)ethyl]-3-phenylpyrazole (9). The compound was prepared from **7** (149 mg, 0.5 mmol) in 2 ml of THF by the same method as described in the preparation of **8**; white prisms; mp 164—165 °C (from acetone); IR (KBr): 3650—3010 (NH, OH), 1310 and 1130 cm^{-1}(SO_2); NMR (CD_3CO-CD_3): δ=8.00—6.88 (15H, m, $2C_6H_5$, *p*-ClC_6H_4, NH), 6.72 (1H, s, CH), 6.01 (1H, d, J=2 Hz, C<u>H</u>(OH)), 5.45 (1H, br, OH), 4.78 (1H, d, J=2 Hz, $PhSO_2CH$); MS: *m/z* 421 $(M-17)^+$. Found: C, 62.97; H, 4.39; N, 6.44%. Calcd for $C_{23}H_{19}$-ClN_2O_3S: C, 62.94; H, 4.36; N, 6.38%.

Preparation of 5-Methyl-3-phenylpyrazole (3). To a solution of **7** (89.1 mg, 0.3 mmol) and anhydrous disodium hydrogenphosphate (170 mg, 1.2 mmol) in 10 ml of dry MeOH was added 5% sodium amalgam (1 g). After stirring for 2 h, water and ether were added to the reaction mixture. The resulting mixture was filtered through Celite, and the organic layer was dried over sodium sulfate and rotary-evaporated. The resulting white powder was purified by TLC on silica gel using AcOEt–hexane (1:1) as a developing solvent to afford 37 mg (78%) of **3** as white crystals, mp 123—124 °C (lit,[9] 127 °C).

Preparation of 5-(p-Chlorophenyl)-2,4-diamino-6-(phenylsulfonylmethyl)pyrimidine (10). NaOEt (74.9 mg, 1.1 mmol) was added to the solution of **6b** (182 mg, 0.5 mmol) and guanidine hydrochloride (105 mg, 1.1 mmol) in 10 ml of absolute EtOH. The resulting mixture was refluxed for 24 h. The reaction was quenched with 10% sodium hydroxide solution. An organic substance was extracted with chloroform, and the extract was dried over sodium sulfate. After removal of the solvent under reduced pressure, the red powder was purified by TLC on silica gel using AcOEt–MeOH (9:1) as a developing solvent to afford 172 mg (92%) of **10** as white needles; mp 206—207 °C (from $CHCl_3$); IR (KBr): 3340, 3150 (NH), 1300 and 1160 cm^{-1}(SO_2); NMR ($CDCl_3$): δ=7.70 (5H, m, Ph), 7.48 (2H, B part of AB quartet, J=8 Hz), 7.12 (2H, A part of AB quartet, J=8 Hz), 5.75, 5.38 (4H, br, $2NH_2$), 4.17 (2H, s, CH_2); MS: *m/z* 374 (M^+). Found: C, 54.40; H, 4.06; N, 15.14%. Calcd for $C_{17}H_{15}ClN_4O_2S$: C, 54.47; H, 4.03; N, 14.95%.

Preparation of 5-(p-Chlorophenyl)-2,4-diamino-6-methylpyrimidine (4). 5% Sodium amalgam (3g) was added to the solution of **10** (150 mg, 0.4 mmol) and anhydrous disodium hydrogenphosphate (227 mg, 1.6 mmol) in 10 ml of dry MeOH. After stirring for 2 h, the reaction was quenched with water and filtered through Celite. The resulting mixture was acidified with 2 M HCl, and washed with ether three times. After neutralization, the solvent was evaporated, and the residue was washed with hot MeOH three times. Removal of MeOH from the washings gave 93.9 mg (100%) of **4** as white needles, mp 269—271 °C (from MeOH) (lit,[1] 264—265 °C).

Synthesis of Fluorescent Peptides and Their Phosphorylation by the Catalytic Subunit of cyclicAMP-dependent Protein Kinase†

Hiroki KONDO,* Katsunori TAKAKI, Ryoichi KUROKI, Akihiro TADA, Kunihiro FUKUMOTO, and Junzo SUNAMOTO

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852

(Received May 1, 1984)

The following two fluorescent peptides were prepared as substrates of the cyclicAMP-dependent protein kinase reaction: Leu-Arg-Arg-Ala-Ser-Leu-X; **1** (X= 2-(dansylamino)ethylamino or DAE) and **2** (X=4-methyl-2-oxo-7-chromenylamino or MCA). Both peptides were phosphorylated by ATP and the catalytic subunit of cyclicAMP-dependent protein kinase from bovine heart in a stoichiometric manner. Phosphorylation of peptide **1** is accompanied by a 10% increase in the fluorescence intensity at 550 nm. This enables one to assay peptide phosphorylation by fluorescence spectroscopy. The kinetic parameters obtained by this and the conventional phosphocellulose paper method for this phosphorylation were the following: K_m 7.8 μM and V_{max} 35 μmol·min^{-1}·mg^{-1} for **1**, and K_m 7.4 μM and V_{max} 16 μmol·min^{-1}·mg^{-1} for **2**.

Phosphorylation and dephosphorylation of proteins are one of the major mechanisms by which functions of proteins are regulated in biological systems.[1,2] A number of protein kinases, which mediate protein phosphorylation by ATP, are now known, but despite their importance in cellular regulation the detailed mechanism of enzymatic phosphoryl transfer reactions remains largely obscure. cAMP-dependent protein kinase is one of the most ubiquitous protein kinases[3] and is the only protein kinase whose primary structure has been reported.[4-6] This enzyme recognizes the two successive basic amino acid residues placed N-terminal to the phosphorylatable Ser or Thr of a protein.[7-9] Model peptides such as **3** that bears this feature of the amino acid sequence serve as good a substrate as do the natural protein substrates.[8] This fact as well as

Leu-Arg-Arg-Ala-Ser-Leu-Gly

3

the known primary sequence of the protein makes this enzyme system suitable for mechanistic studies. We have undertaken a study of enzyme-substrate interaction by use of fluorescent peptides and fluorescence spectroscopy. Besides mechanistic studies, such peptides are useful for assaying peptide phosphorylation spectroscopically and continuously. To date a few peptides bearing a fluorophore or chromophore at the N-terminus or in the middle of the sequence of **3** have been reported.[10-12] Unfortunately, however, a large spectral change was not observed before and after phosphorylation of the peptide and in the presence or absence of enzyme. In this aritcle we have attempted a C-terminal modification of peptide **3** with a fluorophore to examine if the resulting peptide is a sensitive probe of phosphorylation and/or the polarity of the enzyme active site.

† Abbreviations: cAMP, adenosine 3′,5′-cyclic monophosphate; DCC, dicyclohexylcarbodiimide; HOBt, 1-hydroxybenzotriazole; EEDQ, *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline; TFA, trifluoroacetic acid; Boc, *t*-butoxycarbonyl; Bzl, benzyl (ester); DCUrea, dicyclohexylurea; NEM, *N*-ethylmorpholine; Mops, 4-morpholinepropanesulfonic acid; EGTA, ethyene glycol bis (β-aminoethyl ether)-*N,N,N′,N′*,-tetraacetic acid; BSA, bovine serum albumin; SDS-PAGE, sodium dodecyl sulfate-polyacrylamide gel electrophoresis. The abbreviations used for amino acids follow the nomenclature recommended by the IUPAC-IUB Joint Commission on Biochemical Nomenclature (*Eur. J. Biochem.*, **138**, 9 (1984)).

Results and Discussion

Synthesis. The synthesis of peptides **1** and **2** has been accomplished by the route illustrated in Fig. 1. The peptides were bisected between Ala and Ser. The resulting two fragments were prepared separately and then combined at the late stage of the synthesis. The C-terminal fragment which contains the fluorophore was assembled by a stepwise elongation of the sequence from the C terminus. The N-terminal fragment was further divided into two dipeptides mainly for synthetic reasons. It was first attempted to synthesize the tetrapeptide also by the stepwise elongation method, but a difficulty was encountered at the synthesis of tripeptide Boc-Arg(NO_2)-Arg(NO_2)-Ala-OMe(**4**). A coupling of Boc-Arg(NO_2)-OH with H-Arg(NO_2)-Ala-OMe by the DCC method or the mixed anhydride method with ethyl chloroformate gave impure **4** in a low yield (<30%, depending on the coupling method). The poor solubility of **4** in most common solvents except MeOH hampered purification by recrystallization or chromatograpy. In one case, tetrapeptide

2	0.47	0.40	0.88

a) For solvents see text. b) Mobility relative to Arg.

Boc-Leu-Arg(NO_2)-Arg(NO_2)-Ala-OMe was prepared by coupling of Boc-Leu-OH with H-Arg(NO_2)-Arg-(NO_2)-Ala-OMe, derived from partially purified **4**, by the DCC-HOBt method. The product purified by recrystallization from CH_3CN-ether was analytically pure and identical within experimental error in optical rotations with the peptide obtained by the fragment condensation of Boc-Leu-Arg(NO_2)-OH and H-Arg-(NO_2)-Ala-OMe; the former product, $[\alpha]_D^{26}$ −26.8° (*c* 1.0, MeOH); the latter peptide, $[\alpha]_D^{27}$ −27.7° (*c* 1.0, MeOH). This suggests that racemization of Arg has been suppressed in the DCC fragment condensation of dipeptides in the presence of HOBt.

A final condensation of the N-terminal tetrapeptide with the C-terminal fragment by either EEDQ or DCC-HOBt method afforded fully protected hexapeptides with the fluorophore at their C-termini in moderate yields (50—70%). The peptides were subjected to HF cleavage followed by chromatography on Sephadex G-10 and CM-cellulose. The purified peptides were characterized by various analytical techniques such as TLC and ^1H NMR. The data obtained were consistent with the proposed structure for the peptides (Table 1). Peptides **1** and **2** exhibit absorption maxima at 333 and 327 nm, respectively, and when excited at their respective absorption maximum wavelength, they emit strong fluorescence with maxima at 550 and 393 nm. This observation and the ready phosphorylation by the enzyme provide final proof of the identity of both peptides.

Fluorescence Assay of Phosphorylation. Both peptides **1** and **2** are phosphorylated by ATP and the catalytic subunit of cAMP-dependent protein kinase from bovine heart. Phosphorylation of peptide **1** gives rise to a slight blue shift (4 nm) of the emission maximum and a 10% increase in the fluorescence intensity (Fig. 2), while no discernible change was observed in the fluorescence spectrum of **2** before and after phosphorylation (data not shown). The magnitude of intensity change in **1** is half of that observed for the peptide bearing a Trp residue just N-terminal to the phosphorylatable Ser.[12] Peptide phosphorylation can be assayed by taking advantage of the spectral change in **1** as well as by the conventional phosphocellulose paper method.[13] As the time course experiment given in Fig. 3 demonstrates, phosphorylation of **1** in the presence of a saturating concentration of ATP, *i.e.*, about fifty times the $K_{m,ATP}$,[14] is rapid and stoichiometric; 0.96±0.03 mol of phosphate is incorporated to **1** and **2** in ≈10 min. For identification of the phosphorylated peptides, the reaction mixture was subjected to high voltage paper electrophoresis at pH 3.6. As the reaction progresses, a spot migrating toward the cathode more slowly than

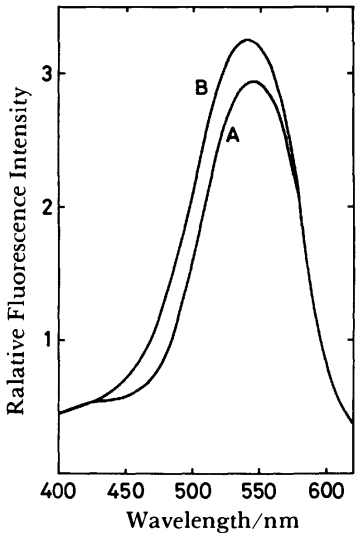

Fig. 2. Fluorescence spectra of peptide **1** in 50 mM Mops, pH 7.0, before (A) and after phosphorylation (B).

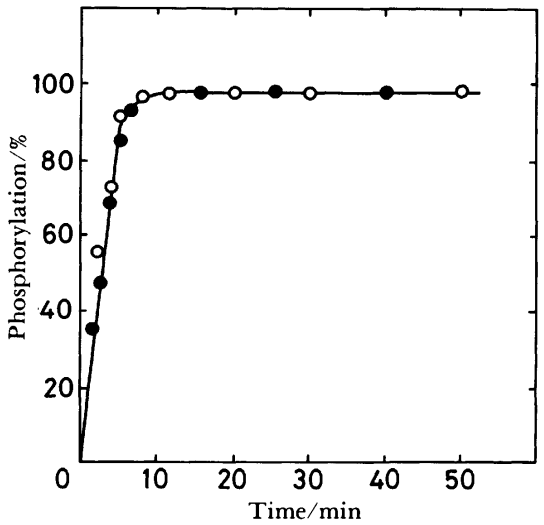

Fig. 3. Time course of peptide **1** phosphorylation at 30°C.
The extent of reaction was determined by the fluorescence (○) or phosphocellulose paper method (●). The assay mixture consisted of 250 μM [γ-^{32}P]ATP, 12.5 mM magnesium acetate, 0.25 mM EGTA, 140 μM **1**, 0.1 mg/ml BSA, and 1.8 μg/ml enzyme in 50 mM Mops, pH 7.0.

the unphosphorylated peptide becomes visible (data not shown). This is as expected, since phosphorylation introduces 1—2 negative charges into substrate.

Initial rate data of peptide phosphorylation at a low enzyme concentration were analyzed in terms of Henri-Michaelis-Menten formulation.[15] The results are summarized in Table 2. The kinetic parameters for **1** obtained by the fluorescence assay are identical within experimental error with those determined by the phosphocellulose paper method; *e.g.*, K_m was 7.5 μM for the former and 7.8 μM for the latter. The K_m values for **1** and **2** are smaller than that of peptide **3**. This result is consistent with the previous observation that a hydrophobic substituent placed C-terminal to the

Table 2. Kinetic parameters for phosphorylation of peptides **1** and **2** by ATP and the catalytic subunit of cAMP-dependent protein kinase at pH 7.0 and 30 °C

Peptide	K_m/μM	V_{max}/μmol·min^{-1}·mg^{-1}	Reference

phosphorylatable Ser increases the binding ability of peptide substrate to the enzyme.[16] In addition to K_m, the catalytic rates (V_{max}) are high and comparable with those of peptide **3** and protein substrates. This excellent substrate activity of peptides **1** and **2** makes them useful in mechanistic studies of enzyme-substrate interaction by, for example, fluorescence spectroscopy.

Experimental

Materials. L-Amino acids were obtained from Protein Research Foundation or Wako Pure Chemical Ind. Co., both Osaka. DCC, HOBt, and EEDQ were purchased from the former source, while TFA and dansyl chloride were from the latter. Sephadex G-10 and CM-cellulose were obtained from Pharmacia and Brown, respectively. Carrier-free [^{32}P] inorganic phosphate was the product of Japan Atomic Energy Research Institute. Scintillation reagents 2,5-diphenyloxazole (PPO) and 2,2′-(*p*-phenylene)bis[5-phenyloxazole] (POPOP) were obtained from Nakarai Chemical Ltd., Kyoto. 4-Methyl-7-aminocoumarin was prepared according to the literature,[17] whereas 2-(dansylamino)ethylamine was synthesized by the route illustrated in the Scheme. [γ-^{32}P]ATP of specific radioactivity 20—200 cpm/pmol was prepared by the method of Glynn and Chappell.[18]

Apparatus. Electronic absorption and fluorescence spectra were taken on a Shimadzu UV-150 and Hitachi 650-10S spectrophotometer, respectively. ^{1}H NMR spectra were recorded on a Jeol JNM-MH-100 spectrometer. Optical rotations were read on a Jasco DIP-4. Paper electrophoresis was run with a Toyo HPE-406 apparatus. Radioactivity was determined on an Aloka liquid scintillation counter LSC-703.

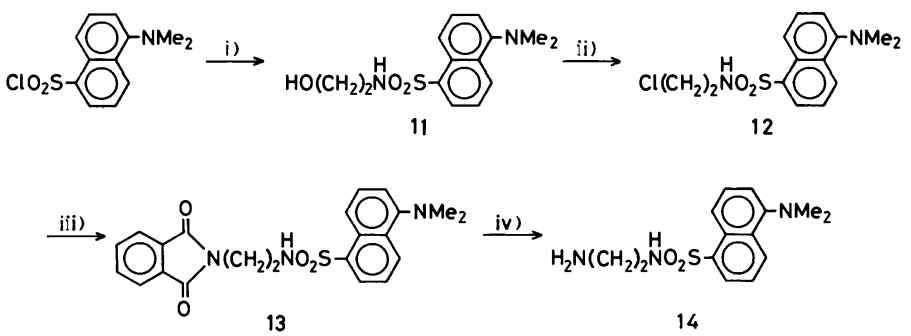
Miscellaneous. TLC was run on a silica-gel plate in the following solvent systems: (A) AcOH: Pyridine: *n*-BuOH: H_2O=1:1:4:2 (B) AcOH:*n*-BuOH:H_2O=4:2:1 (C) MeOH (D) $CHCl_3$:MeOH=5:1 (E) $CHCl_3$:MeOH:benzene=5:1:1. Paper chromatography was carried out on a Toyo Roshi filter paper No.51 in one of the solvents described above. High-voltage paper electrophoresis was run on the same filter paper in AcOH:Pyridine:H_2O=10:1:99 (solvent F) at pH 3.6 and 2,500 V for ≈2 h. Peptide concentrations were determined spectroscopically by using ε_{329} 4780 of *N*-ethyl-5-dimethylamino-1-naphthalenesulfonamide[19] for **1** and ε_{324} 26800 of Leu-MCA·HCl[20] for **2**.

Enzyme Preparation and Assay. The catalytic subunit of bovine heart cAMP-dependent protein kinase was prepared by the method of Demaille *et al.*[16] The preparation gave a single band on SDS-PAGE that corresponds to a molecular weight of ≈41000.[4] The enzyme concentration was determined on the basis of $A_{280}^{1\%}$14.9.[16] The enzyme activity was assayed by the phosphocellulose paper method of Witt and Roskoski[13] with a slight modification.[21,22] The components of an assay solution and the assay conditions are given in the caption of Fig. 3. The radioactivity associated with the peptide was counted with 5 ml of a toluene solution of 4 g/l PPO and 0.1 g/l POPOP.

Boc-Arg(NO$_2$)-Ala-OMe (5). A mixture of Boc-Arg(NO$_2$)-OH (9.6 g, 30 mmol), HOBt (4.1 g, 30 mmol), and DCC (6.2 g, 30 mmol) in CH_3CN (50 ml)-DMF (20 ml) was stirred at −5 °C for 20 min. A pre-cooled solution of H-Ala-OMe·HCl (4.2 g, 30 mmol) and NEM (3.8 ml, 30 mmol) in CH_2Cl_2 (50 ml) was added and the whole mixture was stirred at −5 °C for 1 h and then at room temperature overnight. The precipitate formed (DCUrea) was removed by filtration. The filtrate was kept in a refrigerator for 4 h and DCUrea was filtered off again. Evaporation of the solvent *in vacuo* gave a semi-solid. It was taken up in AcOEt (300 ml) and the insoluble material was removed by filtration. The filtrate was washed with 70 ml each of the following ice-cold solutions three times; 4% $NaHCO_3$, aq saturated NaCl, 10% citric acid, aq saturated NaCl. After drying over Na_2SO_4, the solvent was evaporated *in vacuo* to yield a solid. It was recrystallized from CH_3CN-Et_2O (7.0 g, 58%), mp. 149.5—151 °C. Found: C, 44.66; H, 7.11; N, 20.63%. Calcd for $C_{15}H_{28}N_6O_7$: C, 44.55; H, 6.98; N, 20.78%. Use of 1.5-equiv DCC and HOBt increased the yield to 62%.

Boc-Leu-Arg (NO$_2$)-OMe (6). To a stirred solution of Boc-Leu-OH·H_2O (7.5 g, 30 mmol) and NEM (3.8 ml, 30 mmol) in THF (40 ml) chilled at −15 °C was added isobutyl chloroformate (4.0 ml, 30 mmol). Ten min later, a pre-cooled solution of H-Arg(NO$_2$)-OMe·HCl (8.1 g, 30 mmol) and NEM (3.8 ml, 30 mmol) in CH_2Cl_2 (40 ml)-DMF (50 ml) was added. The mixture was stirred at −15 °C for 2 h and then at room temperature overnight. The precipitate formed was filtered off and washed with CH_2Cl_2. The solvents were evaporated *in vacuo*. The resulting syrup was taken up in 500 ml of AcOEt. The solution was washed and worked up essentially as described above. The crude product was recrystallized from aqueous ethanol (12.1 g, 90%), mp 146—148 °C. Found: C, 48.36; H, 7.82; N, 18.95%. Calcd for $C_{18}H_{34}N_6O_7$: C, 48.42; H, 7.67; N, 18.82%.

Boc-Leu-Arg(NO$_2$)-Arg(NO$_2$)-Ala-OMe(7). A sample of **6** (4.2 g, 10 mmol) was treated with 20 g of TFA (175 mmol) in 35 ml of CH_2Cl_2 at room temperature for 40 min. The solvent and excess TFA were evaporated *in vacuo*. The residual syrup was taken up in CH_2Cl_2 and the solvent was



Scheme. Reagents: i, $HO(CH_2)_2NH_2$; ii, $SOCl_2$; iii, potassium phthalimide; iv, H_2NNH_2.

evaporated *in vacuo*. This procedure was repeated until constant weight was reached for H-Arg(NO_2)-Ala-OMe (**8**)·2TFA. Boc-Leu-Arg(NO_2)-OH (**9**) was preapred by saponification of **6** in the way identical with that described for **10** below. A mixture of **8**·2TFA (1.5 g, 2.8 mmol), **9** (1.2 g, 2.8 mmol), NEM (0.65 g, 5.6 mmol), HOBt (0.38 g, 2.8 mmol), and DCC (0.58 g, 2.8 mmol) in 30 ml of THF was allowed to react at 0°C for 2 h and then at room temperature overnight. The precipitate formed was filtered off. The filtrate was concentrated to dryness. The residue was taken up as much as possible in 1 l each of AcOEt. The insoluble material was extracted three more times with 1 l each of AcOEt. The extract was washed and worked up as described above for **5**. The product was recrystallized from CH_3CN-Et_2O (1.9 g, 93%), mp 140—142°C. TLC R_f 0.69 (C).

Boc-Leu-Arg(NO_2)-Arg(NO_2)-Ala-OH (10). A sample of **7** (0.72 g, 1.0 mmol) in 20 ml of MeOH was allowed to react with 1.7 ml of 1 M NaOH at room temperature for 7 h. The solution was diluted with 20 ml of water and MeOH was evaporated *in vacuo*. After washing with Et_2O, the aqueous solution was chilled in ice and the pH was brought to 3—4 with ice-cold 10% citric acid. The precipitate formed was collected by filtration and recrystallized from MeOH-Et_2O (0.69 g, 98%), mp 205—208°C. TLC R_f 0.53 (C). Found: C, 43.31; H, 6.90; N, 23.01%. Calcd for $C_{26}H_{48}N_{21}O_{11}\cdot H_2O$: C, 43.21; H, 6.97; N, 23.26%.

2-(5-Dimethylamino-1-naphthalenesulfonamido)ethanol (11) Dansyl chloride (2.0 g, 7.4 mmol) was added dropwise to a 33% aqueous 2-aminoethanol solution (2 ml). The mixture was heated at 80°C until the dansyl chloride disappeared as inspected by TLC. The solution was made weakly acidic (pH 3—4) and the product was extracted with AcOEt. The extract was dried over Na_2SO_4 and then concentrated to dryness. The crude product obtained was recrystallized from ether-petroleum ether (2.10 g, 96%), mp 102.5—104°C. TLC R_f 0.71 (D), 0.55 (E). Found: C, 56.66; H, 6.21; N, 9.23%. Calcd for $C_{14}H_{18}N_2O_3S$: C, 57.12; H, 6.16; N, 9.52%.

1-Chloro-2-(5-dimethylamino-1-naphthalenesulfonamido)ethane (12). To a solution of **11** (0.42 g, 1.4 mmol) in chloroform (30 ml) was added dropwise 1.7 g (14 mmol) of thionyl chloride in chloroform (25 ml). The mixture was refluxed for 4 h. The excess reagent and solvent were evaporated *in vacuo* to leave a solid, which was taken up in water. The solution was made weakly alkaline and the precipitate formed was extracted with AcOEt and treated as above for **11** (yield 95%), mp 87—90°C. TLC R_f 0.75 (E).

N-[(5-Dimethylamino-1-naphthalenesulfonamido)ethyl]phthalimide (13). A mixture of **12** (0.42 g, 1.3 mmol) and potassium phthalimide (0.29 g, 1.5 mmol) in 30 ml of DMF was stirred at 100°C for 3 h. The solution was mixed with 200 ml of 0.1 M NaOH (1 M=1 mol dm^{-3}) and extracted with 50 ml each of chloroform four times. The extract was washed with 0.2 M NaOH and water, and dried over Na_2SO_4. The following work-up procedures were the same as that for **11**. The product was obtained in 76% yield, mp 160—165°C. TLC R_f 0.81 (D).

2-(5-Dimethylamino-1-naphthalenesulfonamido)ethylamine (14). A methanolic solution (25 ml) of **13** (0.43 g, 1.0 mmol) and hydrazine hydrate (0.10 g, 2.0 mmol) was refluxed for 2 h. The mixture was diluted with water (25 ml) and methanol was removed *in vacuo*. The turbid solution left was heated with conc. HCl for 2 h. The solution was made alkaline and the precipitate formed was extracted with AcOEt. The product was obtained in 72% yield by the usual work-up described above, mp 155—157°C. TLC R_f 0.10 (E). Found: C, 57.24; H, 6.53; N, 13.71%. Calcd for $C_{14}H_{19}N_3O_2S$: C, 57.32; H, 6.53; N, 14.32%.

Boc-Leu-DAE (15). A mixture of **14** (0.58 g, 2.0 mmol), Boc-Leu-OH·H_2O (0.55 g, 2.2 mmol), HOBt (0.30 g, 2.2 mmol), NEM (2.2 mmol), and DCC (0.45 g, 2.2 mmol) in 25 ml of CH_2Cl_2 was stirred at 0°C for 2 h and then at room temperature overnight. The precipitated DCUrea was filtered off. The filtrate was concentrated, diluted with 200 ml of AcOEt and washed as described earlier for **5**. After drying over Na_2SO_4, the solution was concentrated to dryness, 0.94 g (94%), mp 63—64.5°C. TLC R_f 0.53 (E). Found: C, 59.11; H, 7.63; N, 10.47%. Calcd for $C_{25}H_{38}N_4O_5S$: C, 59.26; H, 7.56; N, 11.06%.

Boc-Ser(Bzl)-Leu-DAE (17). H-Leu-DAE (**16**)·3TFA was prepared from **15** as described for **8**. The reaction of **16**·3TFA (1.25 g, 1.7 mmol) with Boc-Ser(Bzl)-OH (0.54 g, 1.8 mmol) in the presence of NEM (0.58 g, 5.0 mmol), HOBt (0.25 g, 1.8 mmol), and DCC (0.38 g, 1.8 mmol) in CH_2Cl_2 (5 ml) and AcOEt (25 ml) and the usual work-up of the reaction mixture gave 1.1 g (94%) of **17** (AcOEt-petroleum ether), mp 68—70°C. TLC R_f 0.63 (E). Found: C, 60.94; H, 7.25; N, 10.22%. Calcd for $C_{35}H_{49}N_5O_7S$: C, 61.47; H, 7.22; N, 10.24%.

Boc-Leu-Arg(NO_2)-Arg(NO_2)-Ala-Ser(Bzl)-Leu-DAE (19). H-Ser(Bzl)-Leu-DAE (**18**)·3TFA was prepared from **17** as described for **8**. A mixture of **18**·3TFA (1.3 g, 1.4 mmol), **10** (1.1 g, 1.5 mmol), NEM (0.49 g, 4.2 mmol), DCC (0.31 g, 1.5 mmol), and HOBt (0.21 g, 1.5 mmol) was allowed to react at 2°C for 2 h and then at room temperature overnight. The precipitate formed was filtered off. The filtrate was kept in a refrigerator for 4 h to ensure precipitation of DCUrea, which was again removed by filtration. The filtrate was concentrated to a small volume and the product was precipitated with 100 ml of AcOEt in 52% yield (0.93 g), mp 211—212°C. TLC R_f 0.31 (E).

Boc-Ser(Bzl)-Leu-MCA (21). H-Leu-MCA (**20**) was prepared by the deprotection of Boc-Leu-MCA[20] with TFA in CH_2Cl_2. A mixture of **20**·TFA (1.37 g, 3.4 mmol), Boc-Ser(Bzl)-OH (1.0 g, 3.4 mmol), NEM (0.43 ml, 3.4 mmol), and EEDQ (0.84 g, 3.4 mmol) in DMF (5.5 ml) was stirred at room temperature for 12 h. Following evaporation of the solvent, the residue was taken up in AcOEt and washed with acid and alkaline solutions as above to give 1.5 g of the product in 78% yield. Recrystallized from MeOH-ether, mp 152—154°C. Found: C, 65.25; H, 7.25; N, 7.30%. Calcd for $C_{31}H_{39}N_3O_7\cdot 0.5\ H_2O$: C, 64.79; H, 7.02; N, 7.31%.

Boc-Leu-Arg(NO_2)-Arg(NO_2)-Ala-Ser(Bzl)-Leu-MCA (23). H-Ser(Bzl)-Leu-MCA (**22**)·TFA was prepared from **21** as above. An equimolar mixture (1.9 mmol) of **10**, **22**·TFA, and NEM was allowed to react with EEDQ in DMF at room temperature for 12 h. The solvent was evaporated *in vacuo* and the product was precipitated with EtOAc in 70% yield. Recrystallized from MeOH-ether, mp 176—178°C. TLC R_f 0.36 (E).

Peptide 2. A sample of **23** (550 mg) was treated with 20 ml of HF and 8 ml of anisole at 0°C for 50 min. The HF was removed *in vacuo* and the residue was taken up in 10% AcOH. Anisole was removed by extraction with 10 ml each of AcOEt three times. The aqueous phase was concentrated to *ca.* 5 ml and then applied to a column of Sephadex G-10 (3.2×56 cm). The column was eluted with 1% AcOH and the peak fractions were pooled and lyophilized. The peptide was further purified by chromatography on a column of CM-cellulose (1.8×24 cm) with a linear gradient elution with 25 mM ammonium acetate, pH 5.0, and 700 mM ammonium acetate, pH 6.0. The desired fractions were combined, concentrated to *ca.* 10 ml, and then applied to the same Sephadex G-10 column. The column was first washed with water for desalting and the peptide was eluted with 1% AcOH.

Peptide **1** was obtained also by an analogous treatment of **19**.

The authors are grateful to Professor E. T. Kaiser

for helpful advice in initiating this project. They are also indebted to Mr. H. Maruta for expert technical assistance. They also thank Professors M. Sugii and M. Koida, Nagasaki University, for making them accessible to a scintillation counter. This work was supported by the Naito Foundation Subsidy for Inter-Institute Researches and in part by the Eighteenth Bank Fund for Community Development and Promotion.

Reaction of Trifluoronitrosomethane with Arenesulfonohydrazides. Synthesis of *N*-Trifluoromethyl-*N*-hydroxyarenesulfonamides

Akira SEKIYA and Teruo UMEMOTO*

Sagami Chemical Research Center, Nishi-Ohnuma 4-4-1, Sagamihara, Kanagawa 229

(Received May 10, 1984)

The reaction of trifluoronitrosomethane **1** with arenesulfonohydrazides resulted in the formation of *N*-trifluoromethyl-*N*-hydroxyarenesulfonamides **3** which were characterized by spectral and elemental analyses. It showed a sharp contrast to the reaction of **1** with acyl- or carbamoylhydrazines, which afforded the corresponding trifluoromethylazo compounds. As an alternative route, **3** could be synthesized by the reaction of **1** with arenesulfinic acids or their salts. The sulfonamides **3** were converted to the corresponding methyl ethers or tosylates.

Trifluoronitrosomethane[1] **1** is an interesting blue gas, which is expected to have high reactivity because of a combination of a reactive nitroso group and a highly electronegative trifluoromethyl group. It has been known that **1** condensed with amino compounds such as aromatic amines,[2] alkylamines,[3] amino acids,[4] and other amines[5] to give the corresponding trifluoromethylazo compounds. Recently, we reported that electron-deficient amino compounds, arenesulfonamides, condensed with **1** only in the presence of a base to give trifluoromethylazosulfonylarenes in high yields.[6] This paper described that the reaction of arenesulfonohydrazides **2** with **1** led to unexpected compounds, *N*-trifluoromethyl-*N*-hydroxyarenesulfonamides **3.**

Results and Discussion

Benzenesulfonohydrazide **2a** in *N*,*N*-dimethylformamide (DMF) reacted with two molar equivalent amount of **1** at room temperature. After the solvent was removed under vacuum, the residue was column-chromatographed on silica gel using ether as an eluent to give a stable colorless compound. The ^{19}F NMR spectrum showed a singlet at 65.00 ppm which could be assigned to trifluoromethyl group bonding to a nitrogen atom. The ^{1}H NMR showed a AB_2X_2 pattern in the region of aromatic protons, characteristic of benzenesulfonyl group, and a broad peak at 7.88 ppm which was assigned to a hydroxyl group by deuterium oxide exchange experiment. The infrared spectrum showed strong absorption bands at 3410 and 1370 cm^{-1} due to OH and SO_2 stretching vibration, respectively. It was found that the compound contains a nitrogen atom in the molecule from the elemental analysis. From the above results, the structure of the product was assigned to be entirely unexpected *N*-trifluoromethyl-*N*-hydroxybenzenesulfonamide **3a**.

$$2\,CF_3NO + ArSO_2NHNH_2 \longrightarrow CF_3\text{-}\overset{OH}{\overset{|}{N}}\text{-}SO_2Ar$$

1 **2a—f** **3a—f**

The reaction proceeded smoothly in several kinds of solvents (Table 1). As a result, methanol was the best solvent because of its low boiling point and shorter reaction time. Several *N*-trifluoromethyl-*N*-hydroxyarenesulfonamides **3a—f** were synthesized under the conditions in high yields (Table 1).

p-Toluenesulfonohydrazide **2b** was allowed to react with **1** in DMF, and the same post-treatment gave 61% yield of **3b** and 28% yield of a 2:1 complex of **3b** with DMF. The complex was characterized by IR, NMR, and elemental analyses.

From the fact that two molar equivalent amount of **1**

TABLE 1. SYNTHESIS OF **3a—f** FROM **1** AND **2a—f**

Run	Ar		Solv.	Time / min	Yield of **3a—f**[a]/%
1	Ph-	**3a**	DMF	50	96
2	Ph-	**3a**	CH_3CN	540	92
3	Ph-	**3a**	THF	90	99
4	Ph-	**3a**	CH_3COOH	90	94
5	Ph-	**3a**	CH_3OH	15	96
6		**3b**	CH_3OH	40	97
7		**3c**	CH_3OH	35	88
8		**3d**	CH_3OH	35	87
9		**3e**	CH_3OH	35	74
10		**3f**	CH_3OH	35	91

a) Based on the amount of **2a—f**.

to **2** was consumed in the reaction, it is clear that the reaction consists of at least two steps. In order to isolate the intermediate, the reaction of **1** with an equimolar amount of **2** was carried out. The reaction solution contained no intermediate but a 1:1 mixture of **3** and **2**, which indicated that the second reaction with **1** should be faster than the first one.

Interestingly, these results showed a sharp contrast to the reaction of **1** with acyl- or carbamoylhydrazines.

$$\underset{\mathbf{4}}{PhCONHNH_2} \xrightarrow{1} \underset{\mathbf{5}}{CF_3N{=}NNHCOPh} \quad 97\%$$

$$\underset{\mathbf{6}}{CH_3CONHNH_2} \xrightarrow{1} \underset{\mathbf{7}}{CF_3N{=}NNHCOCH_3}^{5a)} \quad 50\%$$

$$\underset{\mathbf{8}}{PhNHCONHNH_2} \xrightarrow{1} \underset{\mathbf{9}}{CF_3N{=}NNHCONHPh} \quad 98\%$$

Hydrazines **4**, **6**, and **8** were treated with two molar equivalent of **1** in methanol at room temperature for 3 d to produce normal condensation products **5**, **7**, and **9** with recovery of one molar equivalent of **1**.

From a different point of view, **3** can be regarded as the combination of **1** and arenesulfinic acid. As an alternative route, we tried the reaction of **1** with arenesulfinic acid. Benzene- and toluenesulfinic acids

$$\mathbf{1} + ArSO_2H \longrightarrow \underset{\mathbf{3a}\ (95\%)\\ \mathbf{3b}\ (91\%)}{CF_3\text{-}\overset{OH}{\overset{|}{N}}\text{-}SO_2Ar}$$

absorbed smoothly an equivalent amount of **1** at room temperature to produce **3a** and **3b** in high yields. This experimental result afforded another proof of the structural assignment of **3** and suggested the following reaction mechanism for the formation of **3** in the reaction of **1** with hydrazides **2**. Probably, the intermediate resulting from the first step decomposes so as to produce arenesulfinic acid, which reacts with **1** to afford **3**. Unfortunately, an attempt to isolate the other part of decomposition products from the intermediate was failed. This result demonstrates the quite difference in the reactions between **2** and other hydrazines **4**, **6**, and **8**. This may be because acyl or carbamoyl groups cannot act as leaving groups, while arenesulfonyl groups are relatively strong leaving groups.[7]

On the other hand, sodium benzenesulfinate gave **3a** in a low yield in its reaction with **1** in methanol. The salt absorbed **1** very smoothly, but several undetermined by-products were produced in addition to **3a**. It indicates that high nucleophilicity of the salt compared to the sulfinic acid causes side reactions.

$$\mathbf{1} + PhSO_2Na \longrightarrow \mathbf{3a} \quad 40\%$$

Since **3** have free hydroxyl groups, it is possible to derive some ethers or esters as follows. Treatment of **3** with methyl iodide afforded the methyl ethers **10a—c** in 33—85% yields. Tosyl chloride gave the esters **11a** and **11b** in 20 and 55% yields, respectively.

$$\mathbf{3} \xrightarrow{CH_3I} \underset{33\text{—}85\%}{CF_3\text{-}\overset{OCH_3}{\overset{|}{N}}\text{-}SO_2Ar} \quad \begin{matrix}\mathbf{10a}\ (Ar{=}Ph)\\ \mathbf{10b}\ (Ar{=}p\text{-Tolyl})\\ \mathbf{10c}\ (Ar{=}o\text{-Tolyl})\end{matrix}$$

$$\mathbf{3} \xrightarrow{TsCl} \underset{20\text{—}55\%}{CF_3\text{-}\overset{OTs}{\overset{|}{N}}\text{-}SO_2Ar} \quad \begin{matrix}\mathbf{11a}\ (Ar{=}Ph)\\ \mathbf{11b}\ (Ar{=}p\text{-Tolyl})\end{matrix}$$

Experimental

General. Melting and boiling points were uncorrected. ^1H NMR spectra were determined with a Varian HA-100 NMR spectrometer or a Varian EM 390 NMR spectrometer. ^{19}F NMR spectra were determined with a Varian XL-100A NMR spectrometer or a Hitachi R-20B NMR spectrometer. ^{19}F chemical shifts are given in ppm upfield from trichlorofluoromethane as an internal standard. IR spectra were measured on a Jasco A-202 diffraction grating infrared spectrophotometer.

Materials. Trifluoronitrosomethane **1** was prepared as previously.[8] Arenesulfonohydrazides, *p*-toluenesulfinic acid, and sodium benzenesulfinate used were commercial products and used without further purification.

N-Trifluoromethyl-N-hydroxyarenesulfonamides 3a—f. The reactions were carried out in 200 ml glass vessels fitted with valves. Arenesulfonohydrazide **2** (5.5 mmol) was dissolved in a solvent (10 ml) in the reactor and the vessel was cooled to −196 °C and then evacuated. The amount of **1** (11.1 mmol) was determined by PVT measurements assuming ideal gas behavior and it was condensed into the reactor. The vessel was warmed to room temperature with a water bath and the solution was stirred by magnetic stirrer. After the blue color of **1** disappeared, the solvent was removed under vacuum. The residue was column-chromatographed on silica gel eluted with ether to give **3**. The results are summarized in Table 1.

3a: Bp 146—148 °C/800 Pa, mp 42—43 °C; IR (KBr, cm^{-1}) 3410 (OH), 1370 (SO_2); ^{19}F NMR ($CDCl_3$) 65.00 (s); ^1H NMR ($CDCl_2$); δ=7.4—7.8 (3H, m, ArH), 7.88 (1H, bs, OH), 7.98 (2H, m, ArH). Found: C, 34.78; H, 2.46; N, 5.83%. Calcd for $C_7H_6F_3NO_3S$: C, 34.86; H, 2.51; N, 5.81%.

3b: Mp 65—71 °C; IR (KBr, cm^{-1}) 3370 (OH), 1370 (SO_2); ^{19}F NMR ($CDCl_3$) 65.74 (s); ^1H NMR ($CDCl_3$); δ=2.44 (3H, s, CH_3), 7.35 (2H, d, J=8.0 Hz, ArH), 7.68 (1H, bs, OH), 7.86 (2H, d, J=8.0 Hz, ArH). Found: C, 37.71; H, 3.18; N, 5.48%. Calcd for $C_8H_8F_3NO_3S$: C, 37.65; H, 3.17; N, 5.49%.

3c: Mp 79.5—80 °C; IR (KBr, cm^{-1}) 3320 (OH), 1355 (SO_2); ^{19}F NMR (CD_3CN) 63.25 (s); ^1H NMR (CD_3CN); δ=2.70 (3H, s, CH_3), 7.2—8.1 (4H, m, ArH), 8.56 (1H, s, OH). Found: C, 37.48; H, 3.21; N, 5.46%. Calcd for $C_8H_8F_3NO_3S$: C, 37.65; H, 3.16; N, 5.49%.

DMF Complex of 3b. *p*-Toluenesulfonohydrazide **2b**

in DMF was treated with **1** in a similar manner as described above. After removing the solvent under vacuum, the residue was washed with water, extracted with benzene, and the benzene solution was dried with magnesium sulfate. The compound **3b** and the complex **3b**·1/2DMF were isolated by column chromatography on silica gel eluted with benzene in 61 and 28% yields, respectively. **3b**·1/2DMF: Mp 55—56 °C (hexane); IR (KBr, cm^{-1}) 3390 (OH, sh), 3160 (OH), 2890 (CH), 1645 (C=O), 1380 (SO_2); ^{19}F NMR ($CDCl_3$) 64.75 (s); ^1H NMR ($CDCl_3$); δ=2.45 (3H, s, CH_3), 2.90 (1.5H, s, 1/2CH_3), 3.00 (1.5H, s, 1/2CH_3), 7.35 (2H, d, J=9.0 Hz, ArH), 7.85 (2H, d, J=9.0 Hz, ArH), 8.02 (0.5H, s, 1/2CHO), 9.65 (1H, bs, OH). Found: C, 39.01; H, 3.87; N, 7.23%. Calcd for $C_{9.5}H_{11.5}F_3N_{1.5}O_{3.5}S$: C, 39.11; H, 3.97; N, 7.20%.

Trifluoromethylazo Compounds **5**, **7**, *and* **9**. The reaction between 5.5 mmol of hydrazides **4**, **6**, or **8** and 11.1 mmol of **1** in 11 ml of methanol was carried out in a similar way as described above. The blue color of **1** didn't disappear even after stirring for 3 days at room temperature and 4 mmol of **1** was recovered by trap to trap separation. After removing methanol under vacuum, the residue was column-chromatographed on silica gel eluted with ether to give the normal condensation products **5**, **7**, and **9** in the yields of 97, 50, and 98%, respectively.

5: Mp 110—111 °C; IR (KBr cm^{-1}) 3150 (NH), 1680 (C=O); ^{19}F NMR (CCl_4) 67.5 (s); ^1H NMR (CCl_4); δ=7.4—8.1 (5H, m, ArH), 11.1 (1H, bs, NH). Found: C, 44.18; H, 2.83; N, 19.60%. Calcd for $C_8H_6F_3N_3O$: C, 44.25; H, 2.79; N, 19.35%

7: Mp 42—43 °C (lit,[5a] 51 °C); IR (KBr, cm^{-1}) 3110 (NH), 1715 (C=O); ^{19}F NMR (CCl_4) 67.5 (s); ^1H NMR (CCl_4) δ=2.40 (3H, s, CH_3), 11.30 (1H, bs, NH). Found: C, 23.48; H, 2.73; N, 26.80%. Calcd for $C_3H_4F_3N_3O$: C, 23.24; H, 2.60; N, 27.10%.

9: Mp 136—136.5 °C; IR (KBr, cm^{-1}) 3310 (NH), 3165 (NH), 1680 (C=O); ^{19}F NMR (CCl_4) 67.5 (s); ^1H NMR (CCl_4) δ=7.1—7.6 (5H, m, ArH), 7.8 (1H, bs, NH), 11.5 (1H, bs, NH). Found: C, 41.68; H, 3.13; N, 24.43%. Calcd for $C_8H_7F_3N_4O$: C, 41.39; H, 3.04; N, 24.13%.

The Reaction of **1** *with* p-*Toluenesulfinic Acid*. Into a flask containing a solution of 0.50 g (3.2 mmol) of *p*-toluenesulfinic acid in 6 ml of methanol, **1** was gradually introduced at room temperature till the absorption of **1** stopped. The methane **1** (0.3 g, 3 mmol) was absorbed and 20 min was needed as the reaction time. After evaporation of the solvent, the residue was column-chromatographed on silica gel using a mixture of ethyl acetate and pentane (15:85) as an eluent, giving 0.74 g (91%) of **3b**.

The Reaction of **1** *with Benzenesulfinic Acid*. Benzenesulfinic acid derived from sodium benzenesulfinate (2 hydrates) by treatment with hydrochloric acid was treated with **1** in a similar manner as described above, except that THF was used as a solvent instead of methanol. The yield of **3a** was 95%.

The Reaction of **1** *with Sodium Benzenesulfinate*. Sodium benzenesulfinate (2 hydrates) (11.1 mmol) in 10 ml of methanol was treated with **1** (11.1 mmol) in a similar manner as the case of the reaction of **1** with arenesulfonohydrazides **2**. After 3 min at room temperature, the absorption of **1** was completed. The solvent was then evaporated under vacuum. The residue was extracted with ether, washed with water, and dried with magnesium sulfate. Evaporation of ether gave an oily product, of which TLC analysis indicated that it contained at least six components. Distillation gave 1.07 g (40%) of pure **3a**. Bp 141—142 °C/1600 Pa.

N-*Trifluoromethyl*-N-*methoxyarenesulfonamides* ***10a—c***. Into a solution of **3** (4 mmol) in methyl iodide (1 ml) and DMF (7 ml), sodium carbonate (10 mmol) was added, and the mixture was stirred for 5 days at room temperature. The reaction mixture was poured into water and extracted with ether. The ether layer was dried over magnesium sulfate. Methyl ethers **10** were obtained by column chromatography on silica gel eluted with benzene. **10a**: Ar=phenyl 52%; **10c**: Ar=*o*-tolyl 33%; **10b**: Ar=*p*-tolyl 85% yield (in this case, 4.5 mmol of calcium oxide was employed instead of sodium carbonate).

10a: Liquid; IR (neat, cm^{-1}) 1392 (SO_2); ^{19}F NMR (CCl_4) 65.00 (s); ^1H NMR (CCl_4); δ=3.98 (3H, s, CH_3), 7.60 (3H, m, ArH), 7.93 (2H, d, J=8.0 Hz, ArH). Found: C, 37.62; H, 3.04; N, 5.41%. Calcd for $C_8H_8F_3NO_3S$: C, 37.65; H, 3.16; N, 5.49%.

10b: Mp 30—30.5 °C; IR (KBr, cm^{-1}) 1392 (SO_2); ^{19}F NMR (CCl_4) 65.25 (s); ^1H NMR (CCl_4); δ=2.45 (3H, s, CH_3), 3.98 (3H, s, OCH_3), 7.27 (2H, d, J=9.0 Hz, ArH), 7.75 (2H, d, J=9.0 Hz, ArH). Found: C, 39.90; H, 3.62; N, 5.12%. Calcd for $C_9H_{10}F_3NO_3S$: C, 40.15; H, 3.74; N, 5.20%.

10c: Liquid; IR (neat, cm^{-1}) 1380 (SO_2); ^{19}F NMR (CCl_4) 64.88 (s); ^1H NMR (CCl_4); δ=2.69 (3H, s, CH_3), 3.87 (3H, s, OCH_3), 7.2—7.65 (3H, m, ArH), 8.0 (1H, m, ArH). Found: C, 40.00; H, 3.61; N, 5.01%. Calcd for $C_9H_{10}F_3NO_3S$: C, 40.15; H, 3.74; N, 5.20%.

N-*Trifluoromethyl*-N-*(p-tolylsulfonyloxy)arenesulfonamides* ***11a—b***. The reaction of **3** (5 mmol) with *p*-toluenesulfonyl chloride (5 mmol) in pyridine (15 ml) were carried out for 23 h at 5 °C. The reaction mixture was treated in a similar manner as described in the preparation of **10**. Tosylates **11a** and **11b** were obtained from **3a** and **3b** in 20 and 55% yields, respectively.

11a: Mp 60—62 °C; IR (KBr, cm^{-1}) 1400 (SO_2); ^{19}F NMR ($CDCl_3$) 62.63 (s); ^1H NMR ($CDCl_3$); δ=2.47 (3H, s, CH_3), 7.3—8.0 (9H, m, ArH). Found: C, 42.14; H, 3.06; N, 3.41%. Calcd for $C_{14}H_{12}F_3NO_5S_2$: C, 42.53; H, 3.06; N, 3.54%.

11b: Mp 110—111 °C; IR (KBr, cm^{-1}) 1400 (SO_2); ^{19}F NMR ($CDCl_3$) 62.50 (s); ^1H NMR ($CDCl_3$); δ=2.45 (6H, s, 2×CH_3), 7.2—8.0 (8H, m, ArH). Found: C, 44.16; H, 3.54, N, 3.42%. Calcd for $C_{15}H_{14}F_3NO_5S_2$: C, 44.01; H, 3.45; N, 3.42%.

(Received May 18, 1984)

Steady state and presteady state kinetic analyses were performed for thermolysin-catalyzed hydrolysis of chromophoric tripeptide substrates with free carboxyl terminal. The pH dependence of k_{cat} showed fairly higher pK_a (≃7) than that of the second-order rate parameter(k_{cat}/K_m)(≃5) and the pH-dependence of K_m resembled that of K_i for *N*-blocked dipeptidyl inhibitor observed before (S. Kunugi *et al.*, *Eur. J. Biochem.* **124**, 157 (1982)). These findings indicated that the reaction with this type of substrate involves a nonproductive binding mode. In a presteady state kinetic study by stopped-flow method, a burst process of 10—20 ms order was observed before the linear steady state at a relatively low pH and temperature. This process showed moderate pH dependence. Considering these experimental results coupled with those accumulated so far on this enzyme, a unified mechanism including a nonproductive binding and an isomerization process in prior to the cleavage of the peptide bond was proposed for the dipeptidyl carboxypeptidase activity of this enzyme.

Thermolysin is a microbial thermostable zinc-containing protease.[1] This enzyme shows no exo-activity. Dipeptides or *N*-blocked amino acids act as inhibitors.[2] It shows, however, dipeptidyl carboxypeptidase activity towards certain *N*-blocked peptides with free carboxyl terminal, such as *N*-(benzyloxycarbonyl)glycyl-L-leucyl-L-leucine (ZGlyLeuLeu), *N*-benzyloxycarbonyl-L-phenylalanylglycyl-L-leucyl-L-alanine (ZPheGlyLeuAla)[3] and 3-(2-furyl)acrylolglycyl-L-leucyl-L-alanine (FuaGlyLeuAla).[4] The K_m values of thermolysin against several synthetic peptides are relatively high: that for 3-(2-furyl)acryloylglycyl-L-leucinamide (FuaGlyLeuNH_2) or 3-(2-furyl)acryloylglycyl-L-phenylalaninamide (FuaGlyPheNH_2), widely used for the assay of the activity of this enzyme, is around 0.5 mM (1M=1 mol dm^{-3}) at acidic pH and 5 mM at neutral pH.[5] These low affinities limited detailed kinetic analysis of the catalytic reactions. Analysis of the presteady state in this enzyme reaction was performed only for special tripeptide or pentapeptide substrates having fluorescent acyl group[6,7] and thorough discussions of the reaction processes have not been given as yet.

In the research on the interaction of various substrate analogues with several zinc-containing proteases[5,8,9] we noticed that the C-free amino acid or dipeptide inhibited these enzymes very strongly at acidic pH and showed very steep pH dependences. An X-ray crystallographic study by Kester *et al.*[10] showed that an anionic inhibitors of this type binds on the active site of thermolysin in an inversed manner with the carboxylate directly coordinating on the active site zinc, which is to have strong relation with the peculiar pH dependence of the inhibition. Such a binding mode could be common in the case of the substrates having free carboxyl end, such as *N*-acylated tripeptides. Thus we report here results of detailed steady-state kinetic analysis of the hydrolysis of 3-(2-furyl)acryloyl tripeptide substrates catalyzed by thermolysin, as well as the observation of the presteady state process of the reaction and discuss the mechanisms of the dipeptidyl carboxypeptidase activity of this enzyme.

Experimental

Materials. Thermolysin was obtained from Daiwa Kasei (Osaka), (lot. T8CA81), and its active concentration was determined as described previously.[5] Four chromophoric substrates, 3-(2-furyl)acryloylglycyl-L-phenylalanyl-L-alanine (FuaGlyPheAla), FuaGlyLeuAla, FuaGlyPheNH_2 and FuaGlyLeuNH_2 were the same samples as used in the previous studies.[5,9] Good's buffers (Mes and Hepes) were purchased from Dojindo Laboratories (Kumamoto). Other chemicals were of reagent grade and used without further purifications. Deionized and distilled water was used in the present work.

Methods. The steady-state kinetics were followed by an ultraviolet/visible spectrophotometer (Union SM401, Union Giken, Hirakata). The difference spectrum between the chromophoric substrate(FuaGlyPheAla) and the products (FuaGly and PheAla) was referred to in the previous paper.[9]

The second-order rate constant (k_{cat}/K_m) was obtained from the initial velocity of the pseudo-first order rate at a low substrate concentration. The k_{cat} and K_m values were evaluated from Eadie-type plot of the velocities at various substrate concentrations. At lower pH the K_m for FuaGlyPheAla was so low that its concentration could not be reduced enough to evaluate K_m and k_{cat}/K_m. In such a case, the velocity devided by initial enzyme concentration at saturated substrate condition ([S]>0.3 mM) was considered as the k_{cat} (for details see result). The reactions were studied in 0.1 M buffer solution containing 0.01 M $CaCl_2$ unless otherwise mentioned.

The presteady state of the reaction was measured on a stopped-flow spectrophotometer (Union RA1100, Union Giken, Hirakata). The dead-time of this apparatus attached with a 10 mm cell has been determined as 3.0 ms.[11] The strong back ground absorbance of the substrate at high concentration limited observation at wavelengths higher than 330 nm. The temperature of the solution was controlled by circulating thermostated water (Neslab RTE-8) through the cell compartments of the spectrophotometers and occasionally checked with a thermister(±0.1 °C).

Results and Discussion

Steady State Kinetics. In Fig. 1, the pH dependences of k_{cat}/K_m, k_{cat}, and K_m[12] for FuaGlyPheAla are shown. At pH lower than 6, where the K_m becomes very low, we show only the apparent second-order rate constant at $[S]_0$=10 μM (which is the lowest concentration to get a reliable rate) in Fig. 1-a, the rate constant at $[S]_0$>0.3 mM in Fig. 1-b and the ratio of the above two quantities in Fig. 1-c. In Fig. 1-a the left half of

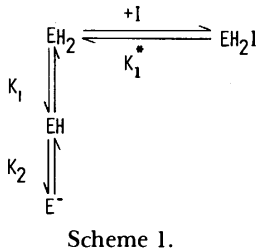
a) k_{cat}/K_m (○, ◑) FuaGlyPheAla; (●) FuaGlyLeuAla. ○, obtained from Eadie plot; ◑, ● rate at [substrate]=10 μM. b) k_{cat} for FuaGlyPheAla. (○) obtained from Eadie-plot with [substrate]=20 μM–2 mM; (◑) velocity at [substrate]>0.3 mM. c) K_m for FuaGlyPheAla. (○) from Eadie-plot; (◑) ratio of velocity at [substrate]=10 μM to that at [substrate]>0.3 mM. Due to the insufficiently low concentration of the substrate for the determination of k_{cat}/K_m, K_m data deviated downward from the curve calculated on the pK_1 obtained from FuaGlyLeuAla especially at low pH. d) pH dependence of two inhibitors for comparison. (○) ZPhe; (●) ZLeuGly. Both are taken from Ref. 5.

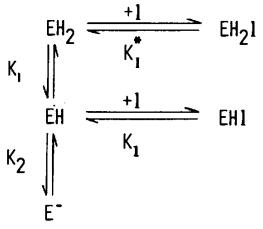
the pH profile of the second-order rate for FuaGly-LeuAla at $[S]_0=10\,\mu M$, which satisfies the condition of $[S] \ll K_m$ for this substrate, was also given. The pH dependence is apparently explained by assuming two pK_a's (pK_{a1} for the lower side and pK_{a2} for the higher side) and one limiting rate constant. The pK_{a1} was evaluated from the data of FuaGlyLeuAla to be 5.00 ± 0.03 and pK_{a2} was from those of FuaGlyPheAla as 8.18 ± 0.02, both of which are consistent to the values obtained for the neutral dipeptide substrates, FuaGly-PheNH$_2$ and FuaGlyLeuNH$_2$.[5] Compared with this pK_{a1}, the pH profile of k_{cat} value gave a high apparent pK_a. Accordingly K_m showed a very characteristic pH dependence, the value being approximately proportional to the 1/2 power of $[H^+]$. This resembles the pH dependence of the K_i of dipeptide substrate analogue[5] (Fig. 1-d, ●).

In the study of the pH dependence of K_i of *C-free N-benzyloxycarbonyl amino acids*, such as ZPhe and ZLeu,[5] it was made clear that these inhibitors are bound only to the enzyme form which is protonated at catalytic site with the carboxylato group coordinating on the active site zinc and they show a very strong pH dependence of K_i as an example given in Fig. 1-d, (○ for ZPhe). This result was formally represented by Scheme 1, where the cationic form of the enzyme is written as EH_2. K_n's and K_I^* denote the proton dissociation constants and the dissociation constant for the inhibitor(I)-enzyme complex, respectively. The pH profile for *dipeptide inhibitor* (● for ZLeuGly) is, as well, explained by Scheme 2, where two binding modes are assumed. A K_I/K_I^* ratio of 22 gave a satisfactory curve as fitted to the data in Fig. 1-d.

Based on these schemes, the presently observed pH dependence of K_m of the *tripeptide substrates* can be explained by Scheme 3, where S written in the left-hand side of E (SEH_2) indicates that the substrate is bound on the active site in a different manner. That is, this type of substrate can be bound on the enzyme



Scheme 1.



Scheme 2.

active site in two different manners. The one is a normal (productive) mode (K_s) in which the carbonyl carbon of the scissile bond is located on the zinc and the amino acid side residues are located in their respective subsites.[10] The other (K_S^*) is considered similar to that seen in C-free *N*-blocked amino acids and the terminal carboxylate is coordinating on the zinc. In the kinetic formula, however, this scheme is identical with the one given for Scheme 4, where $1/K_3^* = 1/K_3 + K_S/K_S^*/K_1$. A nonlinear regression of the data in Fig. 1 gave the parameters for Scheme 4 as: $pK_1 = 5.3 \pm 0.1$, $pK_2 = 8.2 \pm 0.02$, $pK_3^* = 6.9 \pm 0.05$, $pK_4 = 10.0 \pm 0.1$. Insufficiently low concentration of FuaGlyPheAla gave slightly higher pK_1 for this substrate than the intrinsic value(5.0).[5] The solid curves in Fig. 1 are reconstituted on these parameters. When we *a priori* assume that the pK_a for the protonation of the productive enzyme-susbtrate complex is not so much different from that of the free enzyme, then we get the K_S/K_S^* ratio around $10-10^2$, which is not inconsistent to the value evaluated in Fig. 1-d.

Presteady State Kinetics. Mixing FuaGlyPheAla with the enzyme in a stopped-flow apparatus, we observed the reaction traces as shown in Fig. 2. A presteady state relaxation process was observed before the steady state linear decrease in absorbance. To get clearer traces the temperature was lowered. The relevant parameters under some experimental conditions are summarized in Table 1. The inverse of the observed relaxation time of the presteady part is k_{burst} and the difference in the optical density during this burst process, which is obtained by an extrapolation of the steady state linear portion to time zero with consideration of the dead time of the apparatus, is the burst amplitude (ΔOD_{burst}). The steady state parameters obtained under this stopped-flow conditions ($v_{steady}/[E]_0$) were consistent with those measured by the conventional method. The strong background absorbance due to the substrate of higher concentrations, the small absorbance change accompanied by the large change of the steady state, and the rapidness of the process, all of these unfortunately limited the conditions and the accuracy of the observation of the presteady state process, but we can point the following features for the process detected here.

1) The apparent rate slowly increased with an increase in the substrate concentration,

2) it increased only 2.5 times by an increase in the pH from 5.3 to 6.75, and,

3) the burst amplitude did not strongly depend on the substrate concentration or pH of the solution, at least within the range studied here.

By this observation of the presteady process we must modify the reaction Scheme of 4 or 3 into what allows the existence of a certain burst process. Morgan and Frouton observed a presteady process in thermolysin catalysis of the hydrolyis of fluorescent tripeptide or pentapeptide substrate[6] and explained the process as the binding of the substrate, having k_{bind} of 3×10^6 $M^{-1}s^{-1}$ and $k_{dissociate}$ of $55\,s^{-1}$ at 25 °C and pH 8.5. Lobb

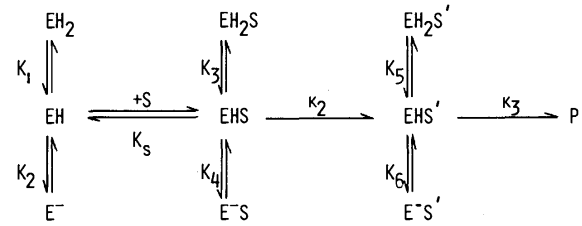
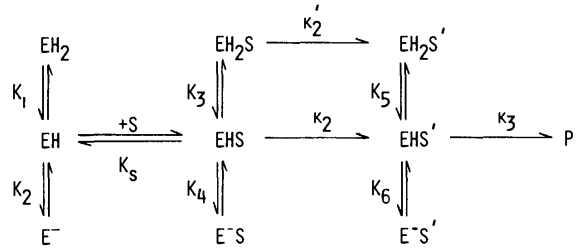
and Auld also observed a similar presteady state process for a *N*-dansylated tripeptide and an apparent rate constant was $50\,s^{-1}$ at 15 °C, pH 6.0 and [substrate] $=0.045\,mM$.[7] If the presently observed burst process was the binding of the substrate, then k_{bind} would be calculated as around $2\times10^5\,M^{-1}s^{-1}$ and $k_{dissociate}$ around $30\,s^{-1}$. The former one is considerably small for a molecular complex formation process, even at a reduced temperature.[14] Furthermore in the case of chromophoric substrate such as the present one, binding on the enzyme active site generally results in a far smaller difference spectrum than the fluorescent one, as was exemplified for the Fua-substituted amino acid ester bound on α-chymotrypsin, where the difference extinction coefficient was less than a few hundreds.[14] The positive concentration dependence of the inverse of the relaxation time will discourage the possibility that the observed process is the conformational change of the enzyme protein prior to the binding of the substrate on it. Therefore we would like to conclude that the presently observed burst process is an isomerisation subsequent to the substrate binding. Since the observed process is clearly an upward change in the absorbance, it is neither due to a mere time lag of the final product appearance (see Appendix).

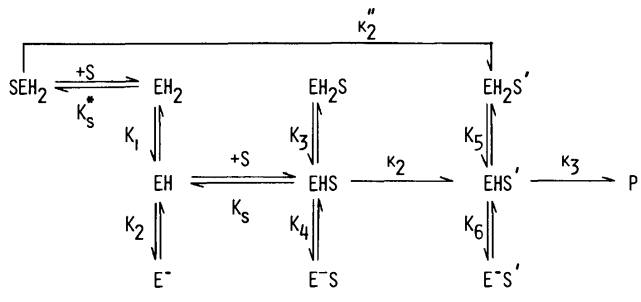
Possible Reaction Mechanism. The first possible and simplest mechanism we can postulate is such as Scheme 5. This scheme qualitatively explains the pH independence of the burst amplitude, by assuming that both EHS′ and EH_2S' have (positive) difference extinction coefficients against free substrate, and also the pH dependences of steady state parameters. It cannot, however, explain the moderate pH dependence of the burst rate in the measured pH range. There could be, of course, a number of possible reaction schemes, which explain all of these quantities, when several reaction processes and kinetic parameters are assumed. The simplest and most reasonable one which is consistent to the present data is that given in Scheme 6, containing the second pathway from EH_2S to EH_2S'.



Scheme 5.



Scheme 6.



Scheme 7.

In contrast to the precise data regression for the steady state result in the former section, the limited number and rather high deviations of the presteady state data provided us only a semi-quantitative parametrization of the Scheme, and the calculated pH dependences of the several quantities from Scheme 6 are given in Fig. 3 for a plausible set of the parameters. In analogy to the relation of Scheme 3 and 4, Scheme 6 is formally equivalent to the reaction mechanism of Scheme 7, where the nonproductively bound substrate, as postulated in the steady state analysis, has a route to be converted to the productive mode and the actual reaction is likely to occur by such a mechanism. At relatively low pH the second route becomes important.

Then the problem is the molecular description of the EHS′ intermediate. Regarding several discussions so far given on the mechanism of zinc-containing proteases, at least three possibilities are to be considered;

1) conversion of the noncovalently bound substrate-enzyme complex to an intermediate covalently attached to the enzyme (such as acid anhydride acylenzyme),[15-17] 2) formation of the tetrahedral intermediate on the carbonyl carbon of the scissile bond, and 3) a conformational transition of the enzyme

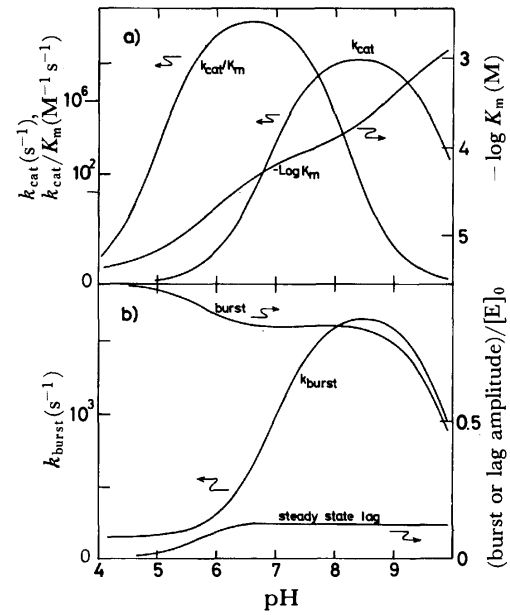


Fig. 3. Simulation of the pH dependences of several quantities at saturated substrate level calculated on the basis of the reaction Scheme 6 with following parameters, which are considered most plausible for the hydrolysis of FuaGlyPheAla at 25 °C.
$pK_1=5$, $pK_2=8.2$, $pK_3=7$, $pK_4=10$, $pK_5=6.8$, $pK_6=10$, $K_s=0.001$ M, $k_2=1500\,s^{-1}$, $k_{2'}=150\,s^{-1}$, $k_3=250\,s^{-1}$. (a) k_{cat}/K_m, k_{cat}, and K_m (b) k_{burst}, burst and the steady state lag.
Burst amplitude and lag are normalized to $[E]_0$ value.

protein or 3') that of the substrate.

The positive absorbance change due to the burst process will discourage reduction of the process to a purely conformational change of the protein. A change in the absorbance of the Fua-modified substrate due to the formation of an acyl intermediate have been observed in the case of serine proteases such as α-chymotrypsin[18] and trypsin[19] and have provided fruitful analyses of the presteady state kinetics for these enzymes. In those instances the difference extinction coefficients($\Delta\varepsilon$) of the acyl intermediate against the free substrate were around 3000—3500($M^{-1}cm^{-1}$) at 330nm and ≈3000 ($M^{-1}cm^{-1}$) at 335nm.[14] When we apply the reaction scheme 6 or 7 to the presently observed burst amplitude, the expected $\Delta\varepsilon_{335}$ values is calculated as only around 1000 ($M^{-1}cm^{-1}$) at saturated substrate concentration (see Appendix). Furthermore the k_{burst} expected at very large substrate concentration would be around $200\,s^{-1}$ at pH 6.75 and 7.5 °C and $>100\,s^{-1}$ at pH 5.15 and 25 °C. That at optimum conditions would be near $1000\,s^{-1}$, which is considerably large for an acyl transfer step from a peptide substrate. Even the rate constant for the acyl transfer from the ester to Glu270 of carboxypeptidase A under similar conditions[16] was estimated in the order of $10^1\,s^{-1}$ and the highest $k_{acylation}$ value observed for the acylation of Ser-195 of α-chymotrypsin[13] by normal alkyl ester of amino acid was no more than $10^3\,s^{-1}$.

On the basis of the temperature dependence of the pK_a values controlling the second-order rate constant of thermolysin catalysis and several experimental data given by other investigators,[10,20] we proposed the general-base mechanism including the zinc-coordinated water molecule for this enzyme. Recent X-ray studies on inhibitor or interaction with thermolysin also ruled out the anhydride mechanism.[21] Considering all these, the observed burst process is to be related to the possibility 2) or 3'). As for the hydrolysis of Fua-TrpNH$_2$ by α-chymotrypsin, Hess's group observed some presteady state process by using a temperature jump and stopped flow apparatus.[22] The k_{burst} was $31\,s^{-1}$ at pH 6.7 and 15 °C and the authors speculated that the observed intermediate is the tetrahedral intermdiate accumulated during the acylation reaction, since the acylation step is the rate limiting in the overall hydrolytic reaction of amide substrate catalyzed by this enzyme. Also in the cases of thermolysin and carboxypeptidase A, the general-base reaction can proceed *via* such an intermediate and for the specific substrates the accumulated amount of the intermediate could be significant.

On the other hand, Lipscomb[23] and Clealand[13] have postulated that in the carboxypeptidase A catalyzed hydrolysis of peptide the entry of the C-terminal residue into its subsite which places the carboxylato group on Arg145 and causes a strain in the peptide bond of the substrate, is rate-limiting. Though there is no evidently working electrostatic interaction in the case of thermolysin and the substrate binding force is mainly hydrophobic, the reactivity of the enzyme-bound substrate may also be raised by forcing the peptide bond to have a strained structure and to increase proton-acceptability of the imino group;[24] geometric destabilization, just we have seen in the α-chymotrypsin-catalyzed hydrolysis of activated peptide-model compounds.[25] In the case of thermolysin the destablization process might not be so slow to limit the overall reaction but it might limit the presteady process. The absorbance of the bound substrate could be altered with breakage of the resonance structure along the peptide bond to provide an observable burst process.

Though we cannot conclusively discriminate the two possibilities[26] given above, an isomerization process of the enzyme-bound substrate was observed as a presteady state process in the hydrolysis of tripeptide substrate and especially at lower pH, the conversion from the nonproductively (inversely) bound substrate to a productive one might be significant to this burst process.

Appendix

When we assume the reaction mechanism of Scheme 6, the time dependences of EHS'+EH$_2$S' and P are given as follows;

$$[EHS'+EH_2S'] = (C_1/C_2)(1-\exp(-C_2t))(1+[H^+]/K_6), \quad (1)$$

$$[P] = k_3(C_1/C_2)t + k_3(C_1/C_2^2)(\exp(-C_2t)-1), \quad (2)$$

where

$$C_1 = (k_2+k_2'[H^+]/K_4)[E]_o/(A(1+[H^+]/K_6))$$

$$C_2 = (k_2+k_2'[H^+]/K_4)(1+[H^+]/K_6+K_5/[H^+])/(A(1+[H^+]/K_6))+k_3/(1+[H^+]/K_6)$$

$$A = 1+[H^+]/K_4+K_3/[H^+]+(1+[H^+]/K_2+K_1/[H^+])K_5/[S]_o.$$

The first term of Eq. 2 corresponds to the steady state change and the second term is the burst process. Assuming that the amount of ES is very small and stationary, the observed change in optical density is written

$$\Delta OD(t) = \Delta\varepsilon_{EHS'}[EHS'] + \Delta\varepsilon_{EH_2S}[EH_2S'] + \Delta\varepsilon_P[P]. \quad (3)$$

If the extinction coefficients of EHS' and EH$_2$S' can be considered equal($\Delta\varepsilon_x$), then Eq. 3 is reduced to

$$\Delta OD(t) = \Delta\varepsilon_x[EHS'](1+[H^+]/K_6) + \Delta\varepsilon_P[P]. \quad (4)$$

The change in the optical density as given in Fig. 2 means $\Delta\varepsilon_x>0$ and $\Delta\varepsilon_P<0$. $\Delta\varepsilon_P$ at 335 nm was evaluated as −1540 at 25 °C pH 5.35. The burst amplitude(ΔOD_{burst}), which is obtained experimentally by an extrapolation of the steady-state part to time zero, is derived from Eqs. 1, 2, and 4 as

$$\Delta OD_{burst} = \Delta\varepsilon_x(1+[H^+]/K_6)C_1/C_2 - \Delta\varepsilon_P k_3 C_1/C_2^2, \quad (5)$$

where the first term is from the formation of the intermediate(s) and the second term is due to the lag period of the product formation. According to Scheme 6, the amount of the intermediates formed at saturated substrate concentration becomes 90% of the total enzyme at acidic to neutral pH (Fig. 3) and therefore the fact that the burst amplitude(in O.D.) observed at saturated substrate concentration was the order of 0.01 at the present enzyme concentration means that the difference extinction coefficient of the intermediate is around 1000($M^{-1}cm^{-1}$).

We gratefully acknowledge Professor Norio Ise, Kyoto University, for his advice and encouragement throughout the work.

26) In either case of tetrahedral intermediate or strained peptide bond, an apparent difficulty of the mechanism of Scheme 6 or scheme 7 is in the observed similarity in the pH dependence and the magnitude of K_i of the several inhibitors with those of K_m of the substrate. However, in many substrate-analogues, inhibition of the hydrolysis of the chromophoric substrate is as the result of the very slow reaction of the nonchromophoric substrate (considered as inhibitor) and therefore the evaluation of the K_i values always include the contribution from the (small fraction of) further reacting intermediate such as EHS'. Furthermore the significant contribution of inversely bound substrate is limited at lower pH. Therefore the discussion on the binding step of this enzyme in the previous paper[9] based on the pressure dependence of K_m is not influenced by the present finding of the presteady state process.

(Received May 18, 1984)

A detailed analysis of the 400 MHz ^{1}H-NMR spectrum of magydardienediol (**1**), a diterpene isolated from *Magydaris panacifolia* (Vahl) Lange, has been performed by use of a combination of proton homonuclear spin decoupling, COSY, NOE difference, and NOESY techniques. This ^{1}H-NMR spectral analysis, in conjunction with the mass spectral analysis of some derivatives of **1**, revealed that the structure of **1** should be revised to *t*-6-hydroxymethyl-1,*t*-3-dimethyl-*t*-2-(3-methyl-2-butenyl)-3-(4-methyl-3-pentenyl)-*r*-1-cyclohexanol.

Magydardienediol, magydartrienol, and magydartrienyl acetate[1] are diterpenes isolated from *Magydaris panacifolia* (Vahl) Lange (Umbelliferae) and have been formulated as **2**, **3**, and **4**, respectively.[2] Recently, it was found that the ^{1}H-NMR spectral data of the diastereomers with structure **3** prepared from α-santonin were different from those reported for magydartrienol.[3] This finding prompted us to reinvestigate the structures of these natural diterpenes.[4]

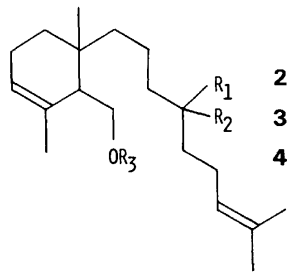
1′



2 $R_1 = CH_3$ $R_2 = OH$ $R_3 = H$
3 $R_1, R_2 = CH_2$ $R_3 = H$
4 $R_1, R_2 = CH_2$ $R_3 = COCH_3$

We now wish to present a detailed analysis of the 400 MHz ^{1}H-NMR spectrum of magydardienediol (**1**) (Fig. 1) by use of a combination of ^{1}H-NMR spectroscopic techniques, *i.e.* proton homonuclear spin decoupling, two-dimensional proton-proton correlation (COSY)[5] (Fig. 3), NOE difference (Figs. 5 and 6), and two-dimensional NOE (NOESY)[6] (Fig. 7) spectroscopies, together with the mass spectral fragmentations of some derivatives of **1**. This spectral analysis showed unequivocally that the structure of magydardienediol should be revised to *t*-6-hydroxymethyl-1,*t*-3-dimethyl-*t*-2-(3-methyl-2-butenyl)-3-(4-methyl-3-pentenyl)-*r*-1-cyclohexanol (**1**),[7] and corroborated the structural revision of this diterpene preliminarily reported very recently by one of us and his associates.[8]

Magydardienediol (**1**), mp 55—56 °C (from hexane); $[\alpha]_D^{24}$ +24.0° (*c* 1.2, $CHCl_3$); EI-MS (*m/z* 308.2705. Calcd for $C_{20}H_{36}O_2$: M^+, *m/z* 308.2714); ^{13}C-NMR (see Experimental), is a monocyclic diterpene posessing two trisubstituted double bonds and two hydroxyl groups (one primary and one tertiary).[2] Its ^{1}H-NMR spectrum at 400 MHz (Fig. 1) showed distinctly four olefinic methyl peaks at δ 1.71, 1.70, 1.68, and 1.60; this indicated that the structure of **1** was quite different from that reported previously.[2]

It was found firstly that **1** had partial structures **A**, **B**, and **C**, along with two tertiary methyls (partial structures **D** and **E**), by the proton homonuclear spin decoupling experiments in conjunction with the COSY analysis (Fig. 2).

Partial structure **A**. The resonances at δ 2.30 (H_e) and δ 2.05 (H_f) were assigned to the two nonequivalent allylic methylene protons spin-coupled to the olefinic proton observed at δ 5.30 (H_a). Although the methine proton H_j signal at δ 1.59 (dd, J=8.5 and 3 Hz) was partially (one of the four-lines) overlapped by the olefinic methyl peak (δ 1.60), the cross peaks, H_e—H_j, in the COSY spectrum (Fig. 3) indicated unambiguously the vicinal spin couplings between these protons. The methine group (CH_j) had two quaternary carbon neighbors, because the irradiation at δ 1.59 (H_j) changed only the signals at δ 2.30 (H_e) and 2.05 (H_f).[9] Long-range spin couplings were observed between H_a and the olefinic methyls (δ 1.71 and 1.70) in both the decoupling and the COSY experiments. The broader peak at δ 1.70 was assigned to the olefinic methyl *cis* to H_a by analogy with the preceding examples[10] and also by the NOESY spectrum.
